IMPROVED APPROXIMATION ALGORITHMS FOR THE UNCAPACITATED FACILITY LOCATION PROBLEM*

FABIÁN A. CHUDAK† AND DAVID B. SHMOYS‡

Abstract. We consider the uncapacitated facility location problem. In this problem, there is a set of locations at which facilities can be built; a fixed cost f_i is incurred if a facility is opened at location i. Furthermore, there is a set of demand locations to be serviced by the opened facilities; if the demand location j is assigned to a facility at location i, then there is an associated service cost proportional to the distance between i and j, c_{ij}. The objective is to determine which facilities to open and an assignment of demand points to the opened facilities, so as to minimize the total cost. We assume that the distance function c is symmetric and satisfies the triangle inequality. For this problem we obtain a $(1+2/e)$-approximation algorithm, where $1+2/e \approx 1.736$, which is a significant improvement on the previously known approximation guarantees.

The algorithm works by rounding an optimal fractional solution to a linear programming relaxation. Our techniques use properties of optimal solutions to the linear program, randomized rounding, as well as a generalization of the decomposition techniques of Shmoys, Tardos, and Aardal [*Proceedings of the 29th ACM Symposium on Theory of Computing*, El Paso, TX, 1997, pp. 265–274].

1. Introduction.

The study of the location of facilities to serve clients at minimum cost has been one of the most studied themes in the field of operations research (see, e.g., the textbook edited by Mirchandani and Francis [MF90]). In this paper, we focus on one of its simplest variants, *the uncapacitated facility location problem*, also known as *the simple plant location problem*, which has been extensively treated in the literature (see, e.g., the survey by Cornuéjols, Nemhauser, and Wolsey [CNW90]). This problem can be described as follows. There is a set of potential facility locations $\mathcal{F}$; building a facility at location $i \in \mathcal{F}$ has an associated nonnegative fixed cost f_i, and any open facility can provide an unlimited amount of a certain commodity. There also is a set of clients or demand points $\mathcal{D}$ that require service; client $j \in \mathcal{D}$ has a positive demand of commodity d_j that must be shipped from one of the open facilities. If a facility at location $i \in \mathcal{F}$ is used to satisfy the demand of client $j \in \mathcal{D}$, the service or transportation cost incurred per unit is proportional to the distance from i to j, c_{ij}. The goal is to determine a subset of the set of potential facility locations at which to open facilities and an assignment of clients to these facilities so as to minimize the overall total cost, that is, the fixed costs of opening the facilities plus the total service cost. We will consider only the *metric*

variant of the problem in which the distance function c is nonnegative, symmetric, and satisfies the triangle inequality. Throughout this paper, a *ρ-approximation algorithm* is a polynomial-time algorithm that delivers a feasible solution within a factor of ρ of optimum. Our main result is a 1.736-approximation algorithm for the metric uncapacitated facility location problem.

In contrast to the uncapacitated facility location problem, Cornuéjols, Fisher, and Nemhauser [CFN77] studied the problem in which the objective is to maximize the difference between assignment and facility costs. They showed that with this objective, the problem can be thought of as a bank account location problem as follows. A company seeks to maximize its available funds by paying bills using checks drawn on banks at different locations. More precisely, if a bill is incurred in location j and is paid with a check from location i, there is delay in the clearing time that generates a profit, such as interest, c_{ij}. On the other hand, maintaining an account at location i has a fixed cost f_i. Thus the company would like to choose a subset of locations at which to open accounts so as to maximize the difference between the total profit from clearing times minus the total fixed cost of maintaining the accounts. Notice that even though the maximization and minimization problems are equivalent from the point of view of optimization, they are not equivalent from the point of view of approximation: the maximization problem can be approximated within a constant factor, whereas the minimization problem with an arbitrary distance function is as hard as the set cover problem, and thus a c-approximation algorithm with $c = o(\log |\mathcal{D}|)$ is unlikely to exist (see [Fei98] for details). Interestingly, Cornuéjols, Fisher, and Nemhauser showed that for the maximization problem, the greedy procedure that iteratively tries to open the facility that most improves the objective function yields a solution of value within a constant factor of optimum. In contrast, Hochbaum [Hoc82] showed that the greedy algorithm is an $\Theta(\log |\mathcal{D}|)$-approximation algorithm for the minimization problem with an arbitrary distance function.

By filtering a linear programming relaxation, Lin and Vitter [LV92b] also obtained an $O(\log |\mathcal{D}|)$-approximation algorithm for the uncapacitated facility location problem when the distance function c is arbitrary. In addition, they also considered the *k-median problem*, in which only k facilities can be opened, but there are no fixed costs in the objective function. They showed how to find a solution with objective function value within $(1+\epsilon)$ of optimum, but that opens $(1+1/\epsilon)O(\log |\mathcal{D}|)\, k$ facilities. Under the assumption that the distance function is a metric, they have also shown (see [LV92a]) how to find a solution of cost no more than $2(1+\epsilon)$ of optimum, opening at most $(1 + 1/\epsilon)k$ facilities. This latter result was the starting point of most recent work on metric facility location problems; although limited to the k-median problem, it essentially contains the core ideas needed to obtain a constant approximation algorithm for the metric uncapacitated facility location problem.

The metric uncapacitated facility location problem is known to be *NP*-hard (see [CNW90]). Very recently, Guha and Khuller [GK99] and Sviridenko [Svi98] have shown that it is *MAX-SNP*-hard. In fact, Guha and Khuller have also shown that the existence of a ρ-approximation algorithm for $\rho < 1.463$ implies that $NP \subseteq TIME(n^{O(\log \log n)})$ (see also Feige [Fei98]), and combined with an observation of Sviridenko [Svi98] such an algorithm would also imply that *P=NP*.

We briefly review previous work on approximation algorithms for the metric uncapacitated facility location problem. The first constant-factor approximation algorithm was given by Shmoys, Tardos, and Aardal [STA97], who presented a 3.16-approximation algorithm, based on rounding an optimal solution of a classical linear programming relaxation for the problem, due to Balinski [Bal65]. This bound

was subsequently improved by Guha and Khuller [GK99], who provided a 2.408-approximation algorithm. Guha and Khuller's algorithm requires a stronger linear programming relaxation, in which they add to the relaxation a facility budget constraint that separately bounds the total facility cost incurred. After running the algorithms of [STA97], they use a greedy procedure (as in [CFN77] and [Hoc82]) to improve the quality of the solution: iteratively, open one facility at a time if it improves the cost of the solution. However, since the optimal facility cost is unknown, they instead consider all reasonable values of the form $(1+\epsilon)^k$ for some integer k and $\epsilon > 0$. As a consequence, they must solve a weakly polynomial number of linear programs, round the optimal solution to each, and then select the best solution found. In contrast, the 1.736-approximation algorithm presented in this paper requires the solution of just one linear program, the one introduced by Balinski [Bal65], providing as a by-product further evidence of the strength of this linear programming relaxation.

In a different line of work, Korupolu, Plaxton, and Rajaraman [KPR00] showed that a simple local improvement heuristic produces a solution within a constant factor of optimum, though the best constant they obtain is 5. Very recently, Arora, Raghavan, and Rao [ARR98] have presented a quasi-polynomial approximation scheme for the case in which demand and facility points are in $\mathbb{R}^d$, where the dimension d is fixed, and the distance function is the usual Euclidean distance. If $d = 2$, then they obtain a polynomial approximation scheme. Their method is similar to the one used by Arora [Aro98] to produce approximation schemes for the traveling salesman problem. Thus, in contrast with the algorithm presented here, it appears to have only theoretical relevance due to the inefficiency of this approach.

Without loss of generality we shall assume that the set of potential facility locations $\mathcal{F}$ and the set of demand points $\mathcal{D}$ are disjoint; let $\mathcal{N} = \mathcal{F} \cup \mathcal{D}$, $n = |\mathcal{N}|$. Even though all our results hold for the case of arbitrary nonnegative demands, for the sake of simplicity of the exposition we will assume that each demand d_j is 1 ($j \in \mathcal{D}$); thus, the cost of assigning a client j to an open facility at location i is c_{ij}. The distance between any two points $k, \ell \in \mathcal{N}$ is $c_{k\ell}$. We assume that the $n \times n$ distance matrix $(c_{k\ell})$ is nonnegative, symmetric (that is, $c_{k\ell} = c_{\ell k}$ for all $k, \ell \in \mathcal{N}$), and satisfies the triangle inequality (that is, $c_{ij} \le c_{ik} + c_{kj}$ for all $i, j, k \in \mathcal{N}$). The simplest linear programming relaxation (from [Bal65]), which we will refer to as P, is as follows:

$$\text{Minimize} \quad \sum_{j\in\mathcal{D}} \sum_{i\in\mathcal{F}} c_{ij}x_{ij} + \sum_{i\in\mathcal{F}} f_i y_i$$

$$(\mathsf{P}) \qquad \text{subject to} \qquad \sum_{i\in\mathcal{F}} x_{ij} = 1 \qquad \text{for each } j \in \mathcal{D}\ , \tag{1}$$

$$x_{ij} \le y_i \qquad \text{for each } i \in \mathcal{F},\ j \in \mathcal{D}\ , \tag{2}$$

$$x_{ij} \ge 0 \qquad \text{for each } i \in \mathcal{F},\ j \in \mathcal{D}. \tag{3}$$

Any 0-1 feasible solution corresponds to a feasible solution to the uncapacitated facility location problem: $y_i = 1$ indicates that a facility at location $i \in \mathcal{F}$ is open, whereas $x_{ij} = 1$ means that client $j \in \mathcal{D}$ is serviced by the facility built at location $i \in \mathcal{F}$. Inequalities (1) state that each demand point $j \in \mathcal{D}$ must be assigned to some facility, whereas inequalities (2) say that clients can be assigned only to open facilities. Thus the linear program P is indeed a relaxation of the problem. Given a feasible fractional solution $(\overline{x}, \overline{y})$, we will say that $\sum_{i\in\mathcal{F}} f_i \overline{y}_i$ and $\sum_{j\in\mathcal{D}} \sum_{i\in\mathcal{F}} c_{ij}\overline{x}_{ij}$ are, respectively, its fractional facility and service cost.

Given a feasible solution to the linear programming relaxation P, the algorithm of Shmoys, Tardos, and Aardal first partitions the demand points into clusters and

then for each cluster opens exactly one facility, which services all of the points in it. In their analysis, they show that the resulting solution has the property that the total facility cost is within a constant factor of the fractional facility cost, and the total service cost is within a constant factor of the fractional service cost. The main drawback of this approach is that *most of the time* the solution is *unbalanced*, in the sense that the first constant is approximately three times smaller than the second.

One of the simplest ways to round an optimal solution (x^*, y^*) to the linear program P is to use the randomized rounding technique of Raghavan and Thompson [RT87] as proposed by Sviridenko [Svi97] for the special case in which all of the distances are 1 or 2. The 1.2785-approximation algorithm of [Svi97] essentially opens a facility at location $i \in \mathcal{F}$ with probability y_i^* and then assigns each demand point to its nearest facility. Guha and Khuller [GK99] also considered this special case and proved a matching lower bound; that is, no better guarantee is possible unless $P = NP$. Ageev and Sviridenko [AS97] have recently shown that the randomized rounding analysis for the maximum satisfiability problem of Goemans and Williamson [GW94] can be adapted to obtain improved bounds for the maximization version of the problem studied by [CFN77].

The following simple ideas enable us to develop a rounding procedure for the linear programming relaxation P with an improved performance guarantee. We explicitly exploit optimality conditions of the linear program, and, in particular, we use properties of the optimal dual solution and complementary slackness. A key element to our improvement is the use of randomized rounding in conjunction with the approach of Shmoys, Tardos, and Aardal. To understand the essence of our approach, suppose that for each location $i \in \mathcal{F}$, independently, we open a facility at i with probability y_i^*. The difficulty arises when attempting to estimate the expected service cost: the distance from a given demand point to the closest open facility might be too large. However, we could always use the routing of the algorithm of Shmoys, Tardos, and Aardal if we knew that each cluster has a facility open. Rather than opening each facility independently with probability y_i^*, we instead open *one* facility in each cluster with probability y_i^*. The precise algorithm is not much more complicated, but the most refined analysis of it is not quite so simple. Our algorithms are randomized and can be easily derandomized using the method of conditional expectations. Our main result is the following.

THEOREM 1.1. *There is a polynomial-time algorithm that rounds an optimal solution to the linear programming relaxation* P *to a feasible integer solution whose value is within* $(1 + 2/e) \approx 1.736$ *of the optimal value of the linear programming relaxation* P.

Since the optimal linear programming value is a lower bound on the integer optimal value, the theorem yields a 1.736-approximation algorithm. The running time of the algorithm is dominated by the time required to solve the linear programming relaxation P.

Since the appearance of the preliminary version of this paper [Chu98], there have been significant strides forward on research on approximation algorithms for this problem. Most notably, Jain and Vazirani [JV01] gave a primal-dual 3-approximation algorithm for this problem, which, by virtue of no longer needing to solve the linear programming relaxation, yields a substantially more efficient algorithm. The starting point of our algorithm is the graph defined by positive fractional primal assignment variables for which complementary slackness conditions are then invoked to yield tight dual constraints; the method of Jain and Vazirani first constructs a dual solution, and this serves to define an analogous graph in which the edges have the corresponding

dual constraints hold with equality.

Subsequent algorithmic results have touched on several different paradigms. Sviridenko [Svi02] has provided a more sophisticated analysis of the approach used here, also incorporating a more clever use of the so-called pipeage rounding technique. Another significant contribution of this paper is a much simpler technique for proving one of the crucial probabilistic lemmas of our paper (as well as a generalization needed for this subsequent improvement).

A number of papers have given analyses that are primal-dual in flavor. Results of Jain, Mahdian, and Saberi [JMS02] and Mahdian, Markakis, Saberi, and Vazirani [MMSV01] gave a primal-dual based analysis of greedy-style algorithms. Mettu and Plaxton [MP00] gave an algorithm that, at first consideration, does not appear to be a primal-dual algorithm at all, but, by defining "radii" for amortizing the fixed cost needed to open a facility at a particular location, is merely doing so implicitly. At this writing, the best known performance guarantee follows from an analysis of this type: Mahdian, Ye, and Zhang have given a 1.52-approximation algorithm [MYZ02].

Further work has also been done on local search algorithms; most notably, Charikar and Guha [CG99] have given a more sophisticated neighborhood structure that is amenable to analysis to yield stronger bounds than those obtained by Korupolu, Plaxton, and Rajaraman. Kolliopoulos and Rao [KR99] have also improved on the state of the art in constructing polynomial approximation schemes for these problems; most notably, they showed that a polynomial approximation scheme could be obtained in Euclidean metric spaces of constant dimension.

2. A simple 4-approximation algorithm. In this section we present a new simple 4-approximation algorithm. Even though the guarantees we will prove in the next section are substantially better, we will use most of the ideas presented here. After stating a few definitions and simple facts, we review the work of Shmoys, Tardos, and Aardal [STA97] and introduce the dual of the linear programming relaxation P and properties of primal and dual solutions that will be useful throughout the paper. First we define the *neighborhood* of a demand point $k \in \mathcal{D}$.

DEFINITION 2.1. *If $(\overline{x}, \overline{y})$ is a feasible solution to the linear programming relaxation P and $j \in \mathcal{D}$ is any demand point, the* neighborhood *of j, $\mathsf{N}(j)$, is the set of facilities that fractionally service j, that is, $\mathsf{N}(j) = \{i \in \mathcal{F} : \overline{x}_{ij} > 0\}$.*

The following fact is a simple consequence of the previous definition and inequality (1).

FACT 1. *For each demand point $j \in \mathcal{D}$, $\sum_{i \in \mathsf{N}(j)} \overline{x}_{ij} = 1$.*

The following definition was crucial for the algorithm of Shmoys, Tardos, and Aardal [STA97].

DEFINITION 2.2. *Suppose that $(\overline{x}, \overline{y})$ is a feasible solution to the linear programming relaxation P, and let $g_j \geq 0$ for each $j \in \mathcal{D}$. Then $(\overline{x}, \overline{y})$ is* g-close *if $\overline{x}_{ij} > 0$ implies that $c_{ij} \leq g_j$ $(j \in \mathcal{D}, i \in \mathcal{F})$.*

Notice that if $(\overline{x}, \overline{y})$ is g-close and $j \in \mathcal{D}$ is any demand point, all the neighbors of j, that is, the facilities that fractionally service j, are inside the ball of radius g_j centered at j. The following lemma is from [STA97].

LEMMA 2.3. *Given a feasible g-close solution $(\overline{x}, \overline{y})$, we can find, in polynomial time, a feasible integer $3g$-close solution $(\widehat{x}, \widehat{y})$ such that*

$$\sum_{i \in \mathcal{F}} f_i \widehat{y}_i \leq \sum_{i \in \mathcal{F}} f_i \overline{y}_i.$$

We briefly sketch the proof below. The algorithm can be divided into two steps:

a clustering step and a facility opening step. The clustering step works as follows (see Table 1). Let $\mathcal{S}$ be the set of demand points that have not yet been assigned to any cluster; initially, $\mathcal{S} = \mathcal{D}$. Find the unassigned demand point $j_\circ$ with smallest g_j-value and create a new cluster *centered* at $j_\circ$. Then all of the unassigned demand points that are fractionally serviced by facilities in the neighborhood of $j_\circ$ (that is, all of the demand points $k \in \mathcal{S}$ with $\mathsf{N}(k) \cap \mathsf{N}(j_\circ) \neq \varnothing$) are assigned to the cluster centered at $j_\circ$; the set $\mathcal{S}$ is updated accordingly. Repeat the procedure until all of the demand points are assigned to some cluster (i.e., $\mathcal{S} = \varnothing$). We will use $\mathcal{C}$ to denote the set of centers of the clusters.

TABLE 1
The clustering construction of Shmoys, Tardos, and Aardal.

1.	$\mathcal{S} \leftarrow \mathcal{D}, \quad \mathcal{C} \leftarrow \varnothing$
2.	while $\mathcal{S} \neq \varnothing$
3.	choose $j_\circ \in \mathcal{S}$ with smallest g_j value ($j \in \mathcal{S}$)
4.	create a new cluster $\mathcal{Q}$ centered at $j_\circ$, $\mathcal{C} \leftarrow \mathcal{C} \cup \{j_\circ\}$
5.	$\mathcal{Q} \leftarrow \{k \in \mathcal{S} : \mathsf{N}(k) \cap \mathsf{N}(j_\circ) \neq \varnothing\}$
6.	$\mathcal{S} \leftarrow \mathcal{S} - \mathcal{Q}$

The following fact follows easily from the clustering construction and the definition of neighborhood, and is essential for the success of the algorithm.

FACT 2. *Suppose that we run the clustering algorithm of Table* 1*, using any g-close solution $(\overline{x}, \overline{y})$. Then the neighborhoods of distinct centers are disjoint; that is, if j and k are centers, $j \neq k \in \mathcal{C}$, then $\mathsf{N}(j) \cap \mathsf{N}(k) = \varnothing$.*

After the clustering step, the algorithm of [STA97] opens exactly one facility per cluster. For each center $j \in \mathcal{C}$ we open the facility $i_\circ$ in the neighborhood of j, $\mathsf{N}(j)$, with smallest fixed cost f_i and assign all the demand points in the cluster of j to facility $i_\circ$. Observe that by inequalities (2) and Fact 1, $\sum_{i \in \mathsf{N}(j)} \overline{y}_i \geq 1$; thus $f_{i_\circ} \leq \sum_{i \in \mathsf{N}(j)} f_i \overline{y}_i$. Using Fact 2, the total facility cost incurred by the algorithm is never more than the total fractional facility cost $\sum_{i \in \mathcal{F}} f_i \overline{y}_i$.

Next consider any demand point $k \in \mathcal{D}$, and suppose it belongs to the cluster centered at $j_\circ$; let $\ell \in \mathsf{N}(k) \cap \mathsf{N}(j_\circ)$ be a common neighbor, and let $i_\circ$ be the open facility in the neighborhood of $j_\circ$ (see Figure 1). Then the distance from k to $i_\circ$ can be bounded by the distance from k to ℓ (which is at most g_k) plus the distance from ℓ to $j_\circ$ (which is at most $g_{j_\circ}$) plus the distance from $j_\circ$ to $i_\circ$ (which is at most $g_{j_\circ}$). Thus, the distance from k to an opened facility is at most $2g_{j_\circ} + g_k$, which is at most $3g_k$, since $j_\circ$ was the remaining demand point with minimum g-value. Hence the total service cost can be bounded by $3 \sum_{k \in \mathcal{D}} g_k$.

Shmoys, Tardos, and Aardal used the filtering technique of Lin and Vitter [LV92b] to obtain g-close solutions (as we will describe in section 5) and then applied Lemma 2.3 to obtain the first constant factor approximation algorithm for the problem. However, a simpler g-close solution is directly obtained by using the optimal solution to the dual linear program of P. More precisely, the dual of the linear program P is given by

$$\begin{aligned}
&&&\text{Maximize} && \sum_{j \in \mathcal{D}} v_j && \\
(4) \qquad &(\mathsf{D}) \qquad &&\text{subject to} && \sum_{j \in \mathcal{D}} w_{ij} \leq f_i && \text{for each } i \in \mathcal{F}, \\
(5) \qquad &&&&& v_j - w_{ij} \leq c_{ij} && \text{for each } i \in \mathcal{F},\ j \in \mathcal{D}, \\
(6) \qquad &&&&& w_{ij} \geq 0 && \text{for each } i \in \mathcal{F},\ j \in \mathcal{D}.
\end{aligned}$$

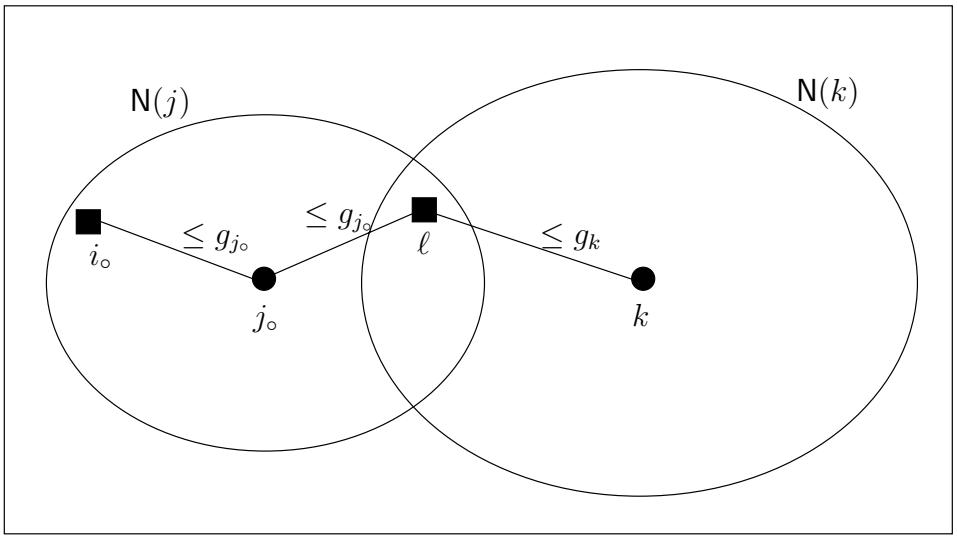

FIG. 1. *Bounding the service cost of k (4-approximation algorithm). The circles (●) are demand points, whereas the squares (■) are facility locations.*

Fix an optimal primal solution (x^*, y^*) and an optimal dual solution (v^*, w^*), and let LP^* be the optimal linear programming value. Complementary slackness gives that $x^*_{ij} > 0$ implies $v^*_j - w^*_{ij} = c_{ij}$; since $w^*_{ij} \geq 0$, we get the following lemma.

LEMMA 2.4. *If (x^*, y^*) is an optimal solution to the primal linear program P and (v^*, w^*) is an optimal solution to the dual linear program D, then (x^*, y^*) is v^*-close.*

By applying Lemma 2.3 to the optimal v^*-close solution (x^*, y^*), we obtain a feasible solution for the problem with total facility cost at most $\sum_{i\in\mathcal{F}} f_i y^*_i$ and with total service cost bounded by $3\sum_{j\in\mathcal{D}} v^*_j = 3\,\mathsf{LP}^*$. We can bound the sum of these by $4\,\mathsf{LP}^*$; thus we have a 4-approximation algorithm. Note the imbalance in bounding facility and service costs.

3. A randomized algorithm. After solving the linear program P, a very simple randomized algorithm is the following: open a facility at location $i \in \mathcal{F}$ with probability y^*_i *independently* for every $i \in \mathcal{F}$ and then assign each demand point to its closest open facility. Notice that the expected facility cost is just $\sum_{i\in\mathcal{F}} f_i y^*_i$, the same bound as in the algorithm of section 2. Focus on a demand point $k \in \mathcal{D}$. If it happens that one of its neighbors has been opened, then the service cost of k would be bounded by the optimal dual variable v^*_k. However, if we are unlucky and this is not the case (an event that, as we will see, can easily be shown to occur with probability at most $1/e \approx 0.368$, where the bound is tight), the service cost of k could be very large. On the other hand, suppose that we knew, for instance, that, for the clustering computed in section 2, k belongs to a cluster centered at j and that one of the facilities in $\mathsf{N}(j)$ has been opened. Then in this unlucky case we could bound the service cost of k using the routing cost of the 4-approximation algorithm.

Our algorithm is also based on randomized rounding, and the expected facility cost is $\sum_{i\in\mathcal{F}} f_i y^*$. However, we weaken the randomized rounding step and do *not* open facilities *independently* with probability y^*_i, but rather in a dependent way, to ensure that each cluster center has *one* of its neighboring facilities opened.

Even though the algorithms presented in this section work for any g-close feasible

solution, for the sake of simplicity of the exposition we will assume as in the end of section 2 that we have a fixed optimal primal solution (x^*, y^*) and a fixed optimal dual solution (v^*, w^*), so that (x^*, y^*) is v^*-close. It is easy to see that we can assume that $y_i^* \leq 1$ for each potential facility location $i \in \mathcal{F}$.

To motivate the following definition, fix a demand location $j \in \mathcal{D}$, and suppose without loss of generality that the neighborhood of j (that is, the facilities i for which $x_{ij}^* > 0$) is $\{1, \ldots, d\}$, with $c_{1j} \leq c_{2j} \leq \cdots \leq c_{dj}$. Then it is clear that we can assume that j is assigned "as much as possible" to facility 1, then to facility 2, and so on; that is, $x_{1j}^* = y_1^*$, $x_{2j}^* = y_2^*$, $\ldots$, $x_{d-1,j}^* = y_{d-1}^*$ (but maybe $x_{dj}^* < y_d^*$).

DEFINITION 3.1. *A feasible solution $(\overline{x}, \overline{y})$ to the linear programming relaxation* P *is* complete *if $\overline{x}_{ij} > 0$ implies that $\overline{x}_{ij} = \overline{y}_i$ for every $i \in \mathcal{F}$, $j \in \mathcal{D}$.*

Thus the optimal solution (x^*, y^*) is "almost" complete, in the sense that for every $j \in \mathcal{D}$ there is at most one $i \in \mathcal{F}$ with $0 < x_{ij}^* < y_i^*$. We point out that the notion of completeness will be helpful to highlight the main ideas of the proofs and simplify the derandomization of the algorithm, although it is not essential. Next we show that any feasible solution to P can be made complete for an equivalent instance of the problem. Recall that for a feasible solution $(\overline{x}, \overline{y})$, its fractional facility and service costs are given by, respectively, $\sum_{i \in \mathcal{F}} f_i \overline{y}_i$ and $\sum_{j \in \mathcal{D}} \sum_{i \in \mathcal{F}} c_{ij} \overline{x}_{ij}$.

LEMMA 3.2. *Suppose that $(\overline{x}, \overline{y})$ is a feasible solution to the linear program* P *for a given instance of the uncapacitated facility location problem $\mathcal{I}$. Then we can find, in polynomial time, an equivalent instance $\widetilde{\mathcal{I}}$ and a complete feasible solution $(\widetilde{x}, \widetilde{y})$ to its linear programming relaxation with the same fractional facility and service costs as $(\overline{x}, \overline{y})$. The new instance $\widetilde{\mathcal{I}}$ differs only by replacing each facility location by at most $|\mathcal{D}| + 1$ copies of the same location; furthermore, if $(\overline{x}, \overline{y})$ is g-close, then so is $(\widetilde{x}, \widetilde{y})$.*

Proof. Pick any facility $i \in \mathcal{F}$ for which there is a demand point $j \in \mathcal{D}$ with $0 < \overline{x}_{ij} < \overline{y}_i$ (if there is no such facility, the original solution $(\overline{x}, \overline{y})$ is complete, and we are done). Among the demand points $j \in \mathcal{D}$ for which $\overline{x}_{ij} > 0$, let $j_\circ$ be the one with smallest $\overline{x}_{ij}$ value. Next create a new facility location i' which is an exact copy of i (i.e., the same fixed cost and in the same location), and set $\widetilde{y}_{i'} = \overline{y}_i - \overline{x}_{ij_\circ}$ and set $\widetilde{y}_i$ equal to $\overline{x}_{ij_\circ}$. Next for every $j \in \mathcal{D}$ with $\overline{x}_{ij} > 0$, set $\widetilde{x}_{ij} = \overline{x}_{ij_\circ} = \widetilde{y}_i$, and set $\widetilde{x}_{i'j} = \overline{x}_{ij} - \overline{x}_{ij_\circ}$ (which is nonnegative by the choice of $j_\circ$). All of the other components of $\overline{x}$ and $\overline{y}$ remain unchanged. Clearly, $(\widetilde{x}, \widetilde{y})$ is a feasible solution to the linear programming relaxation of the new instance; if $(\overline{x}, \overline{y})$ is g-close, so is $(\widetilde{x}, \widetilde{y})$. It is straightforward to verify that the new instance is equivalent to the old one and that the fractional facility and service costs of the solutions $(\overline{x}, \overline{y})$ and $(\widetilde{x}, \widetilde{y})$ are the same. Since the number of pairs (k, j) for which $0 < \overline{x}_{kj} < \overline{y}_k$ has decreased at least by one, and initially there can be at most $|\mathcal{D}||\mathcal{F}| \leq n^2$ such pairs, n^2 iterations suffice to construct a new instance with the desired complete solution. ∎

By Lemma 3.2, we can assume that (x^*, y^*) is complete. To understand some of the crucial points of our improved algorithm we will first consider the following RANDOMIZED ROUNDING WITH CLUSTERING. Suppose that we run the clustering procedure exactly as in Table 1, and let $\mathcal{C}$ be the set of cluster centers. We partition the facility locations into two classes, according to whether they are in the neighborhood of a cluster center or not.

DEFINITION 3.3. *The set of* central facility locations $\mathcal{L}$ *is the set of facility locations that are in the neighborhood of some cluster center, that is, $\mathcal{L} = \cup_{j \in \mathcal{C}} \mathsf{N}(j)$; the remaining set of facility locations $\mathcal{R} = \mathcal{F} - \mathcal{L}$ are* noncentral facility locations.

The algorithm opens facilities in a slightly more complicated way than the simplest randomized rounding algorithm described in the beginning of the section. First we

open exactly one central facility per cluster as follows: independently for each center $j \in \mathcal{C}$, open neighboring facility $i \in \mathsf{N}(j)$ at random with probability x^*_{ij} (recall Fact 1). Next, we independently open each noncentral facility $i \in \mathcal{R}$ with probability y^*_i. The algorithm then simply assigns each demand point to its closest open facility.

LEMMA 3.4. *For each facility location $i \in \mathcal{F}$, the probability that a facility at location i is open is y^*_i.*

Proof. If i is a noncentral facility ($i \in \mathcal{R}$), we open a facility at i with probability y^*_i. Suppose next that i is a central facility ($i \in \mathcal{L}$), and assume that $i \in \mathsf{N}(j)$ for a center $j \in \mathcal{C}$. A facility will be opened at location i only if the center j chooses it with probability x^*_{ij}; but $x^*_{ij} = y^*_i$, since (x^*, y^*) is complete. □

COROLLARY 3.5. *The expected total facility cost is $\sum_{i\in\mathcal{F}} f_i y^*_i$.*

For each demand point $k \in \mathcal{D}$, let $\overline{C}_k$ denote the fractional service cost of k, that is, $\overline{C}_k = \sum_{i\in\mathcal{F}} c_{ik} x^*_{ik}$. The expected service cost of $k \in \mathcal{D}$ is bounded in the following lemma whose proof is presented below.

LEMMA 3.6. *For each demand point $k \in \mathcal{D}$, the expected service cost of k is at most $\overline{C}_k + (3/e)v^*_k$.*

Overall, since $\sum_{k\in\mathcal{D}} v^*_k = \mathsf{LP}^*$, the expected total service cost can be bounded as follows.

COROLLARY 3.7. *The expected total service cost is at most $\sum_{k\in\mathcal{D}} \overline{C}_k + (3/e)\,\mathsf{LP}^*$.*

By combining Corollaries 3.5 and 3.7, and noting that $\sum_{k\in\mathcal{D}} \overline{C}_k + \sum_{i\in\mathcal{F}} f_i y^*_i = \mathsf{LP}^*$, we obtain the following.

THEOREM 3.8. *The expected total cost incurred by* RANDOMIZED ROUNDING WITH CLUSTERING *is at most $(1 + 3/e)\mathsf{LP}^*$.*

Proof of Lemma 3.6. Fix a demand point $k \in \mathcal{D}$. For future reference, let $j_\circ$ be the center of the cluster to which k belongs; notice that $j_\circ$ always has a neighboring facility $i_\circ$ opened (i.e., $i_\circ \in \mathsf{N}(j_\circ)$), and hence its service cost is never greater than $v^*_{j_\circ}$. To gain some intuition behind the analysis, suppose first that each center in $\mathcal{C}$ shares at most one neighbor with k; that is, $|\mathsf{N}(j) \cap \mathsf{N}(k)| \le 1$ for each center $j \in \mathcal{C}$. Each neighbor $i \in \mathsf{N}(k)$ is opened with probability $y^*_i = x^*_{ik}$ *independently* in this special case. For notational simplicity suppose that $\mathsf{N}(k) = \{1, \ldots, d\}$, with $c_{1k} \le \cdots \le c_{dk}$. Let q be the probability that none of the facilities in $\mathsf{N}(k)$ is open. Note that $q = \prod_{i=1}^{d}(1 - y^*_i) = \prod_{i=1}^{d}(1 - x^*_{ik})$. One key observation is that q is "not too big": Fact 1 combined with $1 - x \le e^{-x}$ $(x > 0)$ implies that

$$q = \prod_{i=1}^{d}(1 - x^*_{ik}) \le \prod_{i=1}^{d} e^{-x^*_{ik}} = e^{-\sum_{i=1}^{d} x^*_{ik}} = \frac{1}{e}.$$

We will bound the expected service cost of k by considering a provably worse algorithm: assign k to its closest open neighbor; if none of the neighbors of k is open, assign k to the open facility $i_\circ \in \mathsf{N}(j_\circ)$ (exactly as in section 2). If facility 1 is open, an event which occurs with probability y^*_1, the service cost of k is c_{1k}. If, on the other hand, facility 1 is closed, but facility 2 is open, an event which occurs with probability $(1 - y^*_1)y^*_2$, the service cost of k is c_{2k}, and so on. If all of the facilities in the neighborhood of k are closed, which occurs with probability q, then k is assigned to the open facility $i_\circ \in \mathsf{N}(j_\circ)$. But in this case, k is serviced by $i_\circ$, so the service cost of k is at most $2v^*_{j_\circ} + v^*_k \le 3v^*_k$ exactly as in Figure 1 (section 2); in fact, this *backup routing* gives a deterministic bound: the service cost of k is *always* no more than $3v^*_k$.

Thus the expected service cost of k is at most

$$c_{1k}\, y_1^* + c_{2k}\, y_2^*(1-y_1^*) + \cdots + c_{dk}\, y_d^*(1-y_1^*)\ldots(1-y_{d-1}^*) + 3v_k^*\, q$$
$$\leq \sum_{i=1}^{d} c_{ik} x_{ik}^* + \frac{1}{e}\, 3v_k^* = \overline{C}_k + \frac{3}{e}\, v_k^*,$$

which concludes the proof of the lemma in this special case.

Now we return to the more general case in which there are centers in $\mathcal{C}$ that can share more than one neighbor with k. We assumed that this was not the case in order to ensure that the events of opening facilities in $\mathsf{N}(k)$ were independent, but now this is no longer true for facilities $i, i' \in \mathsf{N}(k)$ that are neighbors of the same center. However, if one of i or i' is closed, the probability that the other is open increases; thus the dependencies are favorable for the analysis. The key idea of the proof is to group together those facilities that are neighbors of the same cluster center, so that the independence is retained and the proof of the special case above still works. A more rigorous analysis follows.

Let $\widehat{\mathcal{C}}$ be the subset of centers that share neighbors with k. For each center $j \in \mathcal{C}$, let $S_j = \mathsf{N}(j) \cap \mathsf{N}(k)$, and so $\widehat{\mathcal{C}} = \{j \in \mathcal{C} : S_j \neq \varnothing\}$. We have already proved the lemma when $|S_j| \leq 1$ for each center $j \in \mathcal{C}$. For each center $j \in \widehat{\mathcal{C}}$, let E_j be the event that at least one common neighbor of j and k is open (see Figure 2). To follow the proof, for each $j \in \widehat{\mathcal{C}}$, it will be convenient to think of the event of choosing facility i in S_j as a sequence of two events: first j chooses to "open" S_j with probability $p_j = \sum_{i \in S_j} x_{ik}^*$ (i.e., event E_j occurs); and then if S_j is open, j chooses facility $i \in S_j$ with probability x_{ij}^*/p_j (which is the conditional probability of opening i, given event E_j). Now let $\overline{c}_j = \sum_{i \in S_j} c_{ik} x_{ik}^*/p_j$; that is, $\overline{c}_j$ is the conditional expected distance from k to S_j, given the event E_j. For example, if $S_j = \{r, s, t\}$ are the common neighbors of j and k, the event E_j occurs when one of r, s, or t is open, $p_j = x_{rk}^* + x_{sk}^* + x_{tk}^*$, and $\overline{c}_j = c_{rk} x_{rk}^*/p_j + c_{sk} x_{sk}^*/p_j + c_{tk} x_{tk}^*/p_j$. Notice that by Fact 2, the events E_j ($j \in \widehat{\mathcal{C}}$) are independent. This completes the facility central grouping. Consider the neighbors of k that are noncentral facility locations; that is, locations $i \in \mathsf{N}(k) \cap \mathcal{R}$. For each noncentral neighbor $i \in \mathsf{N}(k) \cap \mathcal{R}$, let E_i be the event in which facility i is open, let $\overline{c}_i$ be the distance c_{ik}, and let $p_i = x_{ik}^*$. Next notice that *all* of the events E_ℓ are independent. It follows easily from the definitions that $\sum_\ell p_\ell = \sum_{i \in \mathcal{F}} \overline{x}_{ik} = 1$ and $\sum_\ell \overline{c}_\ell p_\ell = \overline{C}_k$.

Now we can argue essentially as in the simple case when $|S_j| \leq 1$ for each center $j \in \mathcal{C}$. Assume that there are d events E_ℓ, and, for notational simplicity, that they are indexed by $\ell \in \{1, \ldots, d\}$, with $\overline{c}_1 \leq \cdots \leq \overline{c}_d$. Let D be the event that none of $E_1, \ldots, E_d$ occurs; that is, D is precisely the event in which all the facilities in the neighborhood of k, $\mathsf{N}(k)$, are closed; let q be the probability of event D. Note that, as in the simple case, the service cost of k is never greater than its backup routing cost $3v_k^*$; in particular, this bound holds even conditioned on D. As before, we will analyze the expected service cost of a worse algorithm: k is assigned to the open neighboring facility with smallest $\overline{c}_\ell$; and if all the neighbors are closed, k is assigned through its backup routing to the open facility $i_\circ \in \mathsf{N}(j_\circ)$. If the event E_1 occurs (with probability p_1), the expected service cost of k is $\overline{c}_1$. If event E_1 does not occur, but event E_2 occurs (which happens with probability $(1-p_1)p_2$), the expected service cost of k is $\overline{c}_2$, and so on. If we are in the complementary space D, which occurs with probability $q = \prod_{\ell=1}^{d}(1-p_\ell)$, the service cost of k is never greater than its backup

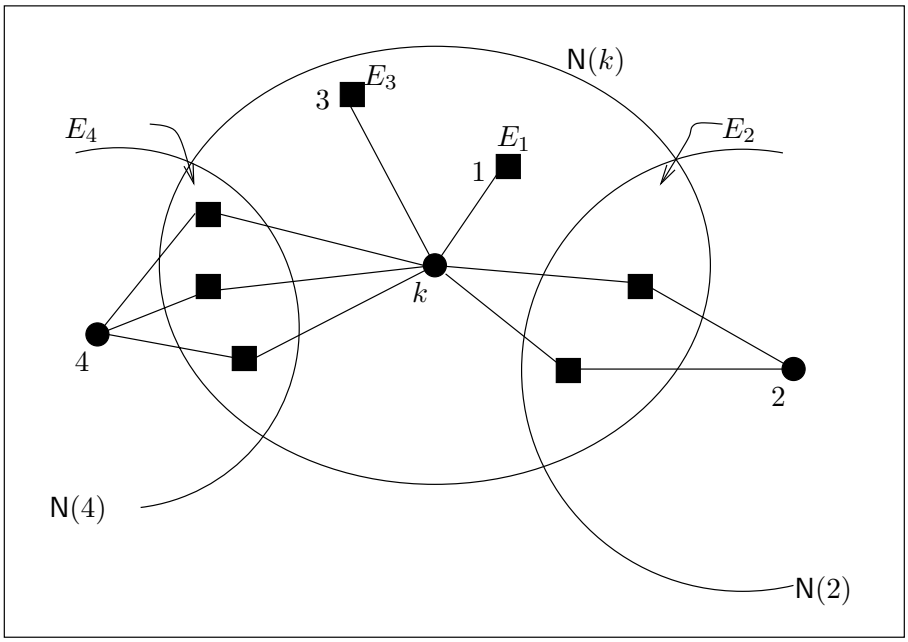

FIG. 2. *Estimating the expected service cost of k. Here the centers that share a neighbor with k are demand locations 2 and 4 ($\widehat{\mathcal{C}} = \{2, 4\}$). The neighbors of k that are noncentral locations are 1 and 3. Event E_2 (respectively, E_4) occurs when a facility in $\mathsf{N}(k) \cap \mathsf{N}(2)$ (respectively, $\mathsf{N}(k) \cap \mathsf{N}(4)$) is open, while event E_1 (respectively, E_3) occurs when facility 1 (respectively, 3) is open. Though there are dependencies among the neighbors of a fixed center, the events E_1, E_2, E_3, and E_4 are independent.*

service cost $3v_k^*$. Thus the expected service cost of k can be bounded by

$$\overline{c}_1\, p_1 + \overline{c}_2\, (1 - p_1)p_2 + \cdots + \overline{c}_d\, (1 - p_1) \ldots (1 - p_{d-1})p_d + 3v_k^*\, q. \tag{7}$$

To prove the lemma we bound the first d terms of (7) by $\overline{C}_k$, and q by $1/e$. □

Notice than even though the clustering construction is deterministic, the backup service cost of k (that is, the distance between k and the facility open in $\mathsf{N}(j_\circ)$) is a random variable B. In the proof above, we used the upper bound $B \leq 3v_k^*$. In fact, the proof of Lemma 3.6 shows that the expected service cost of k is no more than $\overline{C}_k + q\,\mathsf{E}[B|D]$, where D is the event in which no neighbor k is open, as in the proof of the lemma. As can be easily seen, the upper bound used for (7) is not tight. In fact, we can get an upper bound of $(1 - q)\,\overline{C}_k + q\,\mathsf{E}[B|D]$ as follows. First note the following simple probabilistic interpretation of the first d terms of (7). Let Z_ℓ ($\ell = 1, \ldots, d$) be independent 0-1 random variables, with $\mathsf{Prob}\{Z_\ell = 1\} = p_\ell$. Consider the set of indices for which Z_ℓ is 1, and let Z be the minimum $\overline{c}_\ell$ value in this set of indices; if all of the Z_ℓ are 0, Z is defined to be 0. Then the expected value of Z is exactly equal to the first d terms of (7). Given a set of numbers S, we will use $\min_\circ(S)$ to denote the smallest element of S if S is nonempty, and 0 if S is empty, so that $Z = \min_\circ \{\overline{c}_\ell Z_\ell : \ell = 1, \ldots, d \text{ and } Z_\ell = 1\}$. The following intuitive probability lemma, whose proof is given in section 6, provides a bound on the first d terms of (7). (A much simpler proof of this lemma, based on the Chebyshev integral inequality, was observed by Sviridenko [Svi02].)

LEMMA 3.9. *Suppose that* $0 \le \bar{c}_1 \le \cdots \le \bar{c}_d$, $p_1, \ldots, p_d > 0$, *with* $\sum_{\ell=1}^{d} p_\ell = 1$. *Let* $Z_1, \ldots, Z_d$ *be* 0-1 *independent random variables, with* $\mathsf{Prob}\{Z_\ell = 1\} = p_\ell$; *let* $\overline{C} = \sum \bar{c}_\ell p_\ell$. *Then*

$$\mathsf{E}\left[\min_{\{\ell: Z_\ell = 1\}}{}_{\circ}\ \bar{c}_\ell Z_\ell + \overline{C}\prod_{\ell=1}^{d}(1 - Z_\ell)\right] \le \overline{C}.$$

Applying the lemma to the first d terms of (7), since $\mathsf{E}[\prod_{\ell=1}^{d}(1-Z_\ell)] = \prod_{\ell=1}^{d}(1-p_\ell) = q$, we have that

$$\bar{c}_1 p_1 + \bar{c}_2(1-p_1)p_2 + \cdots + \bar{c}_d(1-p_1)\ldots(1-p_{d-1})p_d \le \overline{C}_k(1-q). \tag{8}$$

Thus we have proved the following.

LEMMA 3.10. *For each demand point* $k \in \mathcal{D}$, *the expected service cost of* k *is at most* $(1-q)\,\overline{C}_k + q\,\mathsf{E}[B|D]$.

Finally, we introduce the last idea that leads to the $(1 + 2/e)$-approximation algorithm. In Figure 1, we have bounded the distance from the center $j_\circ$ to the open facility $i_\circ$, $c_{i_\circ j_\circ}$, by $v^*_{j_\circ}$. However, $i_\circ$ is selected (by the center $j_\circ$) with probability $x^*_{i_\circ j_\circ}$, and, thus, the expected length of this leg of the routing is $\sum_{i\in\mathcal{F}} c_{ij_\circ} x^*_{ij_\circ} = \overline{C}_{j_\circ}$, which in general is smaller than the estimate $v^*_{j_\circ}$ used in the proof of Lemma 3.6. Thus, to improve our bounds, we slightly modify the clustering procedure by changing line 3 of Table 1 to

3'.	choose $j_\circ \in \mathcal{S}$ with smallest $v^*_j + \overline{C}_j$ value $(j \in \mathcal{S})$

We will call the modified algorithm RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING. Notice that Lemmas 3.4 and 3.10 are unaffected by this change. We will show that the modified rule 3' leads to the bound $\mathsf{E}[B|D] \le 2v^*_k + \overline{C}_k$, improving on the bound of $3v^*_k$ we used in the proof of Lemma 3.6.

LEMMA 3.11. *If we run* RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING, *the conditional expected backup service cost of* k, $\mathsf{E}[B|D]$, *is at most* $2v^*_k + \overline{C}_k$.

Proof. Suppose that the clustering partition assigned k to the cluster with center $j_\circ$. Deterministically, we divide the proof into two cases.

Case 1. Suppose that there is a facility $\ell \in \mathsf{N}(k) \cap \mathsf{N}(j_\circ)$ such that $c_{\ell j_\circ} \le \overline{C}_{j_\circ}$ (see Figure 3(a)). Let i be the facility in $\mathsf{N}(j_\circ)$ that was opened by $j_\circ$; notice that $c_{ij_\circ} \le v^*_{j_\circ}$ (because $(\overline{x}, \overline{y})$ is v^*-close). Then the service cost of k is at most $c_{ik} \le c_{k\ell} + c_{\ell j_\circ} + c_{j_\circ i}$, which, using again that (x^*, y^*) is v^*-close, is at most $v^*_k + c_{\ell j_\circ} + v^*_{j_\circ} \le v^*_k + \overline{C}_{j_\circ} + v^*_{j_\circ} \le \overline{C}_k + 2v^*_k$, where the last inequality follows from the fact that the center has the minimum $(\overline{C}_j + v^*_j)$ value. In this case, we have a (deterministic) bound, $B \le \overline{C}_k + 2v^*_k$.

Case 2. Assume that $c_{\ell j_\circ} > \overline{C}_{j_\circ}$ for every $\ell \in \mathsf{N}(k) \cap \mathsf{N}(j_\circ)$ (see Figure 3(b)). First note that when we do not condition on D (i.e., that no facility in $\mathsf{N}(k)$ is open), then the expected length of the edge from $j_\circ$ to the facility that $j_\circ$ has selected is $\overline{C}_{j_\circ}$. However, we are given that all of the facilities in the neighborhood of k are closed, but, in this case, all of these facilities that contribute to the expected service cost of $j_\circ$ (the facilities in $\mathsf{N}(k) \cap \mathsf{N}(j_\circ)$) are at a distance greater than the average $\overline{C}_{j_\circ}$. Thus the conditional expected service cost of $j_\circ$ is at most the unconditional expected service cost of $j_\circ$, $\overline{C}_{j_\circ}$. It follows then that if $\ell \in \mathsf{N}(k) \cap \mathsf{N}(j_\circ)$, the conditional expected service cost of k is at most $\overline{C}_{j_\circ} + c_{j_\circ \ell} + c_{\ell k} \le \overline{C}_{j_\circ} + v^*_{j_\circ} + v^*_k \le \overline{C}_k + 2v^*_k$, where again the last inequality follows from the fact that $\overline{C}_{j_\circ} + v^*_{j_\circ} \le \overline{C}_k + v^*_k$. Hence, $\mathsf{E}[B|D] \le \overline{C}_k + 2v^*_k$ in this case too. □

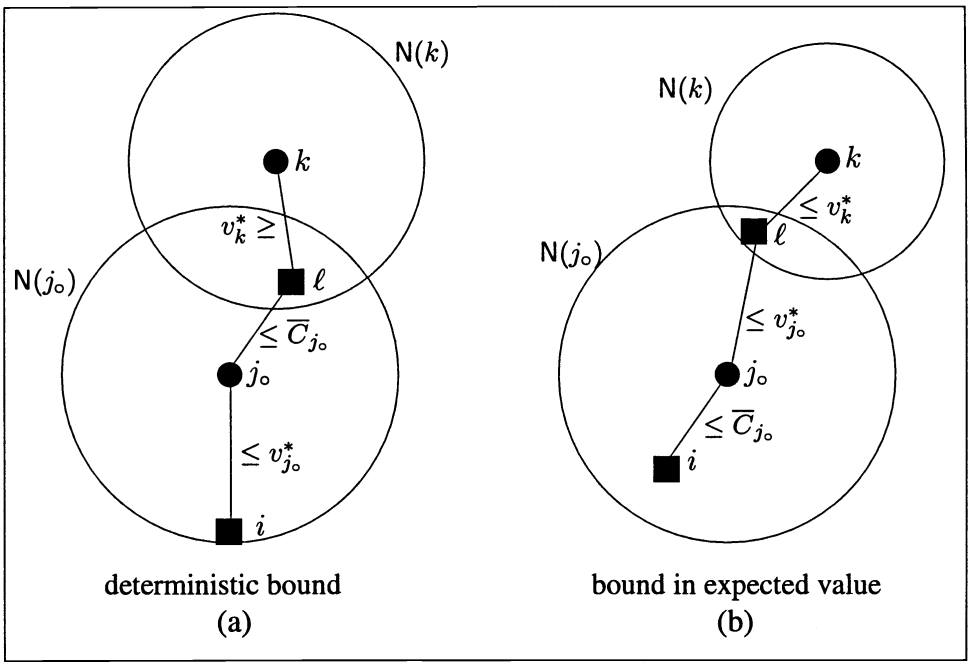

FIG. 3. *Bounding the backup service cost of k.*

Thus, using Lemmas 3.10 and 3.11, the expected service cost of k can be bounded by

$$\overline{C}_k(1-q) + q\,(2v_k^* + \overline{C}_k) = \overline{C}_k + 2q\,v_k^* \leq \overline{C}_k + \frac{2}{e}v_k^*,$$

where once again we bound q by $1/e$.

COROLLARY 3.12. *The expected total service cost of* RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING *is at most* $\sum_{k\in\mathcal{D}} \overline{C}_k + (2/e)\sum_{k\in\mathcal{D}} v_k^*$.

Combining Corollaries 3.5 and 3.12, RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING produces a feasible solution with expected cost no greater than

$$\sum_{i\in\mathcal{F}} f_i y_i^* + \sum_{k\in\mathcal{D}} \overline{C}_k + \frac{2}{e}\sum_{k\in\mathcal{D}} v_k^* = \left(1 + \frac{2}{e}\right)\mathsf{LP}^* \approx 1.736\ \mathsf{LP}^*.$$

Thus we have proved the following theorem.

THEOREM 3.13. *There is a polynomial-time randomized algorithm that finds a feasible solution to the uncapacitated facility location problem with expected cost at most* $(1 + 2/e)\ \mathsf{LP}^*$.

As a consequence of the theorem, we obtain the following corollary on the quality of the value of the linear programming relaxation of [Bal65].

COROLLARY 3.14. *The optimal value of the linear programming relaxation* P *is within a factor of* 1.736 *of the optimal cost.*

This improves on the previously best known factor of 3.16 presented in [STA97].

To finish the proof of Theorem 1.1 we will show in the next section that the algorithm of Theorem 3.13 can be derandomized using standard methods.

4. Derandomization. In this section we show how to derandomize the algorithm of Theorem 3.13. To this end, we will use the method of conditional expectations due to Erdös and Selfridge [ES73] (see also Spencer [Spe87]) that works as follows. Suppose that we have m 0-1 random variables $U_1, \ldots, U_m$ and know that $\mathsf{E}[F] = G$, where $F = g(U_1, \ldots, U_m)$ for a nonnegative real-valued function g of m variables. Our task is to determine a set of values $\overline{u}_1, \ldots, \overline{u}_m$ for the random variables $U_1, \ldots, U_m$ such that $g(\overline{u}_1, \ldots, \overline{u}_m) \leq G$. We wish to decide whether to set U_1 to 0 or 1. The expected value $\mathsf{E}[F]$ is a convex combination of the conditional expectations $\mathsf{E}[F|U_1 = 0]$ and $\mathsf{E}[F|U_1 = 1]$; more precisely,

$$\mathsf{E}[F] = \mathsf{Prob}\{U_1 = 0\}\,\mathsf{E}[F|U_1 = 0] + \mathsf{Prob}\{U_1 = 1\}\,\mathsf{E}[F|U_1 = 1].$$

We would have certainly made the right decision if the conditional expectation decreases. Thus we set $\overline{u}_1$ to 1 if $\mathsf{E}[F|U_1 = 1] \leq \mathsf{E}[F|U_1 = 0]$, and 0 otherwise. Note that $\mathsf{E}[F|U_1 = \overline{u}_1] \leq \mathsf{E}[F] = G$. The process continues inductively. Suppose that we have already decided on the values $\overline{u}_1, \ldots, \overline{u}_t \in \{0, 1\}$ so that the conditional expected value $\mathsf{E}[F|U_1 = \overline{u}_1, \ldots, U_t = \overline{u}_t]$ is at most G. Now $\mathsf{E}[F|U_1 = \overline{u}_1, \ldots, U_t = \overline{u}_t]$ is a convex combination of $\mathsf{E}[F|U_1 = \overline{u}_1, \ldots, U_t = \overline{u}_t, U_{t+1} = 0]$ and $\mathsf{E}[F|U_1 = \overline{u}_1, \ldots, U_t = \overline{u}_t, U_{t+1} = 1]$. Again we choose to set $\overline{u}_{t+1}$ to 1 if the expected value decreases, that is, if $\mathsf{E}[F|U_1 = \overline{u}_1, \ldots, U_t = \overline{u}_t, U_{t+1} = 1] \leq \mathsf{E}[F|U_1 = \overline{u}_1, \ldots, U_t = \overline{u}_t, U_{t+1} = 0]$, and 0 otherwise. Clearly, at termination, we obtain a set of 0-1 values $\overline{u}_1, \ldots, \overline{u}_m$ such that $g(\overline{u}_1, \ldots, \overline{u}_m) \leq G$ as desired. Notice that we need only to compute $2m$ conditional expected values. However, for this process to work we have to be able to compute all the intermediary conditional expectations efficiently (i.e., in polynomial time).

We first show that the analysis of RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING also provides a random variable W, a *pessimistic estimator* [Rag88], such that the cost of the solution delivered by the algorithm is at most W, and the bounds we obtained can be read off as a bound on the expected value of W, that is, $\mathsf{E}[W] \leq (1 + 2/e)\mathsf{LP}^*$. Furthermore, the expected value of W can be computed exactly. The upper bound W will let us use the method of conditional expectations to derandomize the algorithm.

The random variable W is precisely the cost of the worse algorithm we used to prove Theorem 3.13; this algorithm either assigns each demand k to the closest open neighbor (in the $\overline{c}$ sense as in the proof of Lemma 3.6) or, if none of its neighbors is open, it assigns k to the backup facility of the cluster to which k belongs. More concretely, for each potential facility location $i \in \mathcal{F}$ let U_i be the 0-1 random variable that is 1 exactly when a facility at location i is open. Notice that the random variables U_i are not independent in general, and that, since we assumed that the feasible solution $(\overline{x}, \overline{y})$ was complete, the expected value of U_i is $\overline{y}_i$. It follows immediately that the facility cost of the randomized algorithm is $\sum_{i \in \mathcal{F}} f_i U_i$.

Next we need to find an upper bound for the service costs expressed in terms of the U_i's. We fix a demand location $k \in \mathcal{D}$ and carefully revise the bounds on the expected service cost of k given in the previous section. Recall the notation used in the proof of Lemma 3.6. For each $\ell \in \{1, \ldots, d\}$, we extend the definition of S_ℓ when ℓ is a neighbor of k by just setting S_ℓ equal to $\{\ell\}$. Note that in any case $\overline{c}_\ell p_\ell = \sum_{i \in S_\ell} c_{ik} \overline{y}_i = \mathsf{E}[\sum_{i \in S_\ell} c_{ik} U_i]$. Now let $P_\ell = \sum_{i \in S_\ell} U_i$ and $T_\ell = \sum_{i \in S_\ell} c_{ik} U_i$ for $\ell = 1, \ldots, d$; and let $Q = \prod_{\ell=1}^{d} (1 - P_\ell)$. Observe that because of the dependencies, the random variables P_ℓ are 0-1 with $p_\ell = \mathsf{E}[P_\ell] = \sum_{i \in S_\ell} x^*_{ik}$. Now suppose that according to Lemma 3.11 we are in Case 1. Then the arguments given to bound the

expected service cost of k in effect say that the service cost of k is at most

$$T_1 + T_2(1-P_1) + \cdots + T_d(1-P_1)\ldots(1-P_{d-1}) + Q(v_k^* + v_{j_\circ}^* + \overline{C}_{j_\circ}); \tag{9}$$

let Z_k denote this upper bound. Since the factors of the products in each term are independent, it is straightforward to verify that the bound on the service cost of k of Theorem 3.13 implies $\mathsf{E}[Z_k] \le \overline{C}_k + (2/e)v_k^*$.

For Case 2, the service cost of k is at most

$$T_1 + T_2(1-P_1) + \cdots + T_d(1-P_1)\ldots(1-P_{d-1}) + Q\Big(v_k^* + v_{j_\circ}^* + \sum_{i\in\mathsf{N}(j_\circ)-\mathsf{N}(k)} c_{ij}U_i\Big), \tag{10}$$

which as before will be denoted by Z_k. This case is slightly more complicated than Case 1, since before we used the fact that our upper bound was deterministic. Now dependencies have to be taken into account. As in Case 1, the expected value of the first d terms can be upper bounded, exactly as in the proof of Theorem 3.13, by $(1-q)\overline{C}_k$. For the last term, notice first that the dependencies imply that $P_{j_\circ}U_i = 0$ (and thus $(1-P_{j_\circ})U_i = U_i$) for each $i \in \mathsf{N}(j_\circ) - \mathsf{N}(k)$; hence, if $Q' = \prod_{j\neq j_\circ}(1-P_j)$,

$$Q \sum_{i\in\mathsf{N}(j_\circ)-\mathsf{N}(k)} c_{ij}U_i = Q'\,(1-P_{j_\circ}) \sum_{i\in\mathsf{N}(j_\circ)-\mathsf{N}(k)} c_{ij}U_i = Q' \sum_{i\in\mathsf{N}(j_\circ)-\mathsf{N}(k)} c_{ij}U_i.$$

Now the two factors on the rightmost expression are independent, and

$$\mathsf{E}\left[\sum_{i\in\mathsf{N}(j_\circ)-\mathsf{N}(k)} c_{ij}U_i\right] \le (1-p_{j_\circ})\overline{C}_{j_\circ},$$

since, by Case 2, $c_{ij_\circ} > \overline{C}_{j_\circ}$ for all $i \in S_{j_\circ}$. Thus the expected value of the last term of (10) can be bounded by $q(v_k^* + v_{j_\circ}^* + \overline{C}_{j_\circ})$. Putting the pieces together, we have again that $\mathsf{E}[Z_k] \le \overline{C}_k + (2/e)v_k^*$ as needed. Notice also that, as in Case 1, Z_k can be written as a sum in which each term is the product of independent random variables.

Clearly, if $W = \sum_{i\in\mathcal{F}} f_iU_i + \sum_{k\in\mathcal{D}} Z_k$, the cost of the randomized algorithm can be bounded by W, and $\mathsf{E}[W] \le (1+2/e)\mathsf{LP}^*$. Since W is the cost of a worse algorithm, if we were able to find 0-1 values for the U_i's so that the corresponding value of W is at most its expected value $\mathsf{E}[W]$, we would have a feasible solution to the problem whose cost is at most $(1+2/e)\mathsf{LP}^*$, thus proving Theorem 1.1. As mentioned earlier, to find such values for the U_i's we apply the method of conditional expectations.

We need to explain how to compute the conditional expected values of W. To understand how to apply the method of conditional expectations suppose first that *all* of the U_i's are independent random variables. Now the conditional expected value $\mathsf{E}[W|U_i = 0]$ (respectively, $\mathsf{E}[W|U_i = 1]$) is easy to compute: simply replace U_i by 0 (respectively, by 1) in the expression of W and compute the expected value directly. It is also easy to see that we can substitute each U_i by $u_i \in \{0,1\}$ for $i \in \mathcal{E}$, for any subset $\mathcal{E} \subseteq \mathcal{F}$, and compute $\mathsf{E}[W|U_i = u_i \ (i \in \mathcal{E})]$. Thus, if we did not have dependencies, the derandomization of the algorithm is quite simple. However, if, for instance, U_s and U_t ($s,t \in \mathcal{F}$, $s \neq t$) are dependent, when conditioning on the event $\{U_s = 1\}$, we cannot just replace U_s by 1 in the expression of W, since the value of U_t might also be affected. This apparent difficulty can be easily overcome in our case,

since the dependencies imply that $U_t = 0$ whenever $U_s = 1$. Next we describe the derandomization process with more detail.

We first consider the noncentral facilities. If i is a noncentral facility location, $i \in \mathcal{R}$, it is easy to compute the conditional expected value of W, given that $U_i = u$ $(u = 0, 1)$: simply substitute U_i by u in the expression of W and take expected values. In the same way, we can also compute $\mathsf{E}[W|U_i = u_i \ (i \in \mathcal{E})]$, for any subset $\mathcal{E} \subseteq \mathcal{R}$, where $u_i \in \{0, 1\}$ $(i \in \mathcal{E})$. Now we can determine the values of $\overline{u}_i$ for $i \in \mathcal{R}$ applying the method of conditional expectations as described earlier. For notational simplicity, we will assume that $\mathcal{R} = \{1, \ldots, r\}$. In the first step, we set $\overline{u}_1$ equal to 1 (or, equivalently, open facility 1) only if $\mathsf{E}[W|U_1 = 1] \leq \mathsf{E}[W|U_1 = 0]$; otherwise, we set $\overline{u}_1$ equal to 0. Inductively, if we already know $\overline{u}_1, \ldots, \overline{u}_{h-1}$, in step h we set U_h to 1 if $\mathsf{E}[W|U_1 = \overline{u}_1, \ldots, U_{h-1} = \overline{u}_{h-1}, U_h = 1] \leq \mathsf{E}[W|U_1 = \overline{u}_1, \ldots, U_{h-1} = \overline{u}_{h-1}, U_h = 0]$, and to 0 otherwise. When $h = r$, we have values $\overline{u}_1, \ldots, \overline{u}_r$ such that if $\overline{W}$ is the conditional random variable $W|U_1 = \overline{u}_1, \ldots, U_r = \overline{u}_r$, then $\mathsf{E}[\overline{W}] \leq \mathsf{E}[W]$.

In what follows we find values for the remaining variables U_i, that is, decide which central facilities to open, in such a way that at termination the cost of the solution is at most $\mathsf{E}[\overline{W}]$. Fix a center $j \in \mathcal{C}$. We wish to decide which neighboring facility to open. For each neighbor $i \in \mathsf{N}(j)$ we can compute the conditional expectation of $\overline{W}$, given that U_i is 1 as follows. Since $U_i = 1$, for all the other neighbors i' of j it must be that $U_{i'} = 0$. Hence we just replace these values in the formula of $\overline{W}$ and compute the corresponding expectation. The key observation is that, since we open exactly one facility in the neighborhood of j, $\mathsf{E}[\overline{W}]$ is a convex combination of the conditional expected values $\mathsf{E}[\overline{W}|U_i = 1]$ for $i \in \mathsf{N}(j)$, that is,

$$\mathsf{E}[\overline{W}] = \sum_{i \in \mathsf{N}(j)} \mathsf{Prob}\{U_i = 1\}\, \mathsf{E}[\overline{W}|U_i = 1].$$

Thus we open the neighboring facility $i_\circ \in \mathsf{N}(j)$ for which the conditional expected value is smallest; more precisely, we set $\overline{u}_{i_\circ}$ equal to 1 and set $\overline{u}_i$ equal to 0 for $i \in \mathsf{N}(j), i \neq i_\circ$. Using now that the neighborhoods of distinct centers are disjoint, we can essentially argue as in the simple case when all the variables were independent. We repeat the process inductively; at each step we treat a new center and decide which neighboring facility to open so that the conditional expected value never increases.

Finally, notice that there are $|\mathcal{R}| + |\mathcal{C}|$ steps, and overall we need only to compute $1 + 2|\mathcal{R}| + |\mathcal{L}|$ expected values. The most expensive computation that dominates the whole derandomization process is to find, initially, the expected value of W, which takes $O(|\mathcal{D}||\mathcal{F}| \log |\mathcal{F}|)$ arithmetic operations.

5. Extensions. To motivate the results of this section, suppose that the contribution of the fractional facility cost to the optimal fractional cost is very small. If we run RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING and focus on the analysis, we would have an imbalance between the facility and service cost upper bounds. Hence, it is intuitively clear that we could afford to open facilities with higher probability to balance out the bounds. In this section, we will show how to do this in general, providing a more refined performance guarantee that depends on information related to the cost distribution of the optimal fractional solution.

A standard technique to improve the performance of randomized rounding consists of using a nontrivial mapping of the optimal fractional solution into probabilities. One of the most common approaches boosts all the probabilities by a factor of γ for a fixed parameter $\gamma > 0$. For instance, the simplest randomized rounding algorithm

would open facility $i \in \mathcal{F}$ with probability $\min\{\gamma y_i^*, 1\}$. These ideas can also be applied to our randomized algorithm in a simple fashion that we describe below.

First of all, as mentioned in section 3, the proof of Theorem 3.13 is valid for any g-close solution; that is, if $(\overline{x}, \overline{y})$ is g-close, RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING produces a feasible solution with expected cost at most

$$\sum_{i \in \mathcal{F}} f_i \overline{y}_i + \sum_{j \in \mathcal{D}} \sum_{i \in \mathcal{F}} c_{ij} \overline{x}_{ij} + \frac{2}{e} \sum_{j \in \mathcal{D}} g_j.$$

In fact, it is also easy to see that the derandomization of section 4 also carries over to this more general setting.

Now suppose again that $(\overline{x}, \overline{y})$ is g-close and complete, and let $\gamma \geq 1$. We next describe the algorithm γ-RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING, which is a variant of RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING. The only difference is that now we open facilities with higher probabilities. Each noncentral facility $i \in \mathcal{R}$ is opened independently with probability $\min\{\gamma \overline{y}_i, 1\}$. As in RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING, each center $j \in \mathcal{C}$ opens one facility in its neighborhood $i \in \mathsf{N}(j)$, with probability $\overline{x}_{ij}$, in a *first phase*. Additionally, if a facility $i \in \mathsf{N}(j)$ has not been opened, it is now opened in a *second phase* with probability $\min\{\gamma \overline{y}_i - \overline{x}_{ij}, 1\} = \min\{\gamma \overline{y}_i - \overline{y}_i, 1\}$. The new algorithm has a guarantee given by the following theorem, whose proof is a minor variation of the proof of Theorem 3.13.

THEOREM 5.1. *For each $\gamma \geq 1$, the expected cost of the solution produced by* γ-RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING *is at most*

$$\gamma \sum_{i \in \mathcal{F}} f_i \overline{y}_i + \sum_{j \in \mathcal{D}} \sum_{i \in \mathcal{F}} c_{ij} \overline{x}_{ij} + \frac{2}{e^\gamma} \sum_{j \in \mathcal{D}} g_j.$$

Proof. For simplicity, we will analyze a worse algorithm in which we are allowed to open more than one facility at each location $i \in \mathcal{F}$. More precisely, for each facility $i \in \mathcal{L}$, if i is in the neighborhood of center j, we open a facility at location i in the second phase with probability $\min\{\gamma \overline{y}_i - \overline{y}_i, 1\}$ independently of whether there is already an open facility at i (from the first phase); in this case, we of course take into account the extra facility cost.

First we estimate the expected total facility cost as in Lemma 3.4. If $i \in \mathcal{R}$ is a noncentral facility, i is open with probability $\min\{\gamma \overline{y}_i, 1\}$, giving a contribution to the expected total facility cost of $f_i \min\{\gamma \overline{y}_i, 1\} \leq \gamma f_i \overline{y}_i$. Now if $i \in \mathcal{L}$ is a central facility location, $i \in \mathsf{N}(j)$ for $j \in \mathcal{C}$, a facility is open at i first with probability $\overline{y}_i = \overline{x}_{ij}$, contributing $f_i \overline{y}_i$. In addition, another facility is open at i with probability $\min\{\gamma \overline{y}_i - \overline{y}_i, 1\}$, contributing an additional $f_i \min\{\gamma \overline{y}_i - \overline{y}_i, 1\}$ to the expected total facility cost. Overall, the contribution of i is $f_i \overline{y}_i + f_i \min\{\gamma \overline{y}_i - \overline{y}_i, 1\} \leq \gamma f_i \overline{y}_i$, once again. Thus, the expected total facility cost is at most $\gamma \sum_{i \in \mathcal{F}} f_i \overline{y}_i$.

Next focus on a demand point $k \in \mathcal{D}$. As in the proof of Lemma 3.6, for each center $j \in \mathcal{C}$, $S_j = \mathsf{N}(j) \cap \mathsf{N}(k)$ and $\widehat{\mathcal{C}} = \{j \in \mathcal{C} : S_j \neq \varnothing\}$. Now, for each $j \in \widehat{\mathcal{C}}$, the event E_j occurs when a facility in S_j is open in the first phase; the probability of event E_j is then $p_j = \sum_{i \in S_j} \overline{x}_{ik}$. In addition, for each central neighbor $i \in \mathsf{N}(k) \cap \mathcal{L}$, define the event E_i in which a facility is open at location i in the second phase; hence the probability of event E_i is $p_i = \min\{\gamma \overline{y}_i - \overline{y}_i, 1\}$. For each noncentral neighbor $i \in \mathsf{N}(k) \cap \mathcal{R}$, the event E_i occurs when a facility at location i is open, and the probability of event E_i is $p_i = \min\{\gamma \overline{y}_i, 1\}$. As in the proof of Lemma 3.6 and by the assumption at the beginning of the proof, all the events E_ℓ are *independent*. For each

$j \in \widehat{\mathcal{C}}$, $\overline{c}_j$ is the expected distance from k to S_j, given the event E_j and considering only the first phase. For each neighbor $i \in \mathsf{N}(k)$, $\overline{c}_i$ is simply the distance c_{ik}. Without loss of generality, we assume that there are d events E_ℓ and that they are indexed by $\ell \in \{1, \ldots, d\}$ with $\overline{c}_1 \leq \cdots \leq \overline{c}_d$. Let D be the event in which none of the events $E_1, \ldots, E_d$ occurs, and let $q = \prod_{\ell=1}^{d}(1-p_\ell)$ be the probability of event D. If B is the backup service cost of k, that is, the distance from k to the facility open during the first phase in the cluster to which k belongs (as in the proof of Lemma 3.10), following the proofs of Lemmas 3.6 and 3.10, the expected service cost of k is at most

$$\overline{c}_1\, p_1 + \overline{c}_2\, (1-p_1)p_2 + \cdots + \overline{c}_d\, (1-p_1)\ldots(1-p_{d-1})p_d + \mathsf{E}[B|D]\, q. \tag{11}$$

It is easy to see that the proof of Lemma 3.11 remains valid, so that $\mathsf{E}[B|D] \leq 2g_k + \sum_{i\in\mathcal{F}} c_{ik}\overline{x}_{ik}$. Following the proof of Theorem 3.13, we need only to show that the first d terms of (11) are at most $(1-q)\sum_{i\in\mathcal{F}} c_{ik}\overline{x}_{ik}$ and that $q \leq 1/e^\gamma$. We will use the following generalization of Lemma 3.9, whose proof is postponed until section 6. (A much simpler proof of this lemma, based on the Chebyshev integral inequality, was observed by Sviridenko [Svi02].)

LEMMA 5.2. *Let $0 \leq \overline{c}_1 \leq \cdots \leq \overline{c}_d$, and $z_1, \ldots, z_d > 0$, with $\sum_{\ell=1}^{d} z_\ell = 1$, and let $\gamma \geq 0$. Suppose that $Z_1, \ldots, Z_d$ are* 0-1 *independent random variables, with* $\mathsf{Prob}\{Z_\ell = 1\} = \min\{\gamma z_\ell, 1\}$*; let $\overline{C} = \sum \overline{c}_\ell z_\ell$. Then*

$$\mathsf{E}\left[\min_{Z_\ell=1}{}_{\circ}\, \overline{c}_\ell Z_\ell + \prod_{\ell=1}^{d}(1-Z_\ell)\overline{C}\right] \leq \overline{C}.$$

If $j \in \widehat{\mathcal{C}}$, let $z_j = p_j/\gamma$ so that $p_j = \gamma z_j = \min\{\gamma z_j, 1\}$. If $i \in \mathsf{N}(k) \cap \mathcal{R}$, let $z_i = \overline{y}_i = \overline{x}_{ik}$ so that $p_i = \min\{\gamma z_i, 1\}$. Finally, if $i \in \mathsf{N}(k) \cap \mathcal{L}$, with $i \in \mathsf{N}(j)$, $j \in \widehat{\mathcal{C}}$, let $z_i = \overline{x}_{ik} - \overline{x}_{ik}/\gamma$ so that $p_i = \min\{\gamma z_i, 1\}$. Now we have that $\sum_\ell z_\ell = 1$, and $\sum_\ell \overline{c}_\ell z_\ell = \sum_{i\in\mathcal{F}} c_{ik}\overline{x}_{ik}$. As in the proof of Lemma 3.10, using now Lemma 5.2, the first d terms of (11) can be bounded by $(1-q)\sum_{i\in\mathcal{F}} c_{ik}\overline{x}_{ik}$.

To finish the proof of the theorem notice that if p_ℓ is 1 for some ℓ, q is 0; otherwise,

$$q = \prod_{\ell=1}^{d}(1-p_\ell) = \prod_{\ell=1}^{d}(1-\gamma z_\ell) \leq \prod_{\ell=1}^{d} e^{-\gamma z_\ell} = e^{-\sum_{\ell=1}^{d}\gamma z_\ell} = \frac{1}{e^\gamma}. \qquad \square$$

Using similar arguments to those given in section 4, the algorithm of the theorem can be derandomized.

For the rest of the section let $\rho \in [0,1]$ be defined by $\rho\,\mathsf{LP}^* = \sum_{i\in\mathcal{F}} f_i y_i^*$. If ρ is either 0 or 1, there is an optimal solution to P which is integral; that is, all the y_i's are 0 or 1. When $\rho = 0$, the optimal solution sets y_i to 1 exactly for those facilities $i \in \mathcal{F}$ for which $f_i = 0$. The case when $\rho = 1$ is slightly more complicated and requires that the distance function be symmetric and satisfy the triangle inequality. First, for each facility location $i \in \mathcal{F}$, define D_i as the set of demand points that are at distance 0 from i. If $i, \ell \in \mathcal{F}$ and $j, k \in \mathcal{D}$, the inequality $c_{ij} \leq c_{ik} + c_{\ell k} + c_{\ell j}$ implies that for $i \neq i'$, either $D_i = D_{i'}$ or $D_i \cap D_{i'} = \varnothing$. Hence, we can partition the set of facilities into classes such that if i and i' belong to the same class, $D_i = D_{i'}$, and $D_i \cap D_{i'} = \varnothing$ otherwise. Now, since $\rho = 1$, the sets D_i ($i \in \mathcal{F}$) cover all the demand points. Finally, the optimal solution simply opens the cheapest facility in each class. (Notice that the fact that $D_i \cap D_{i'} = \varnothing$ for i and i' in different classes is crucial to argue optimality.) Thus we will assume that $0 < \rho < 1$. For each fixed ρ, we want to apply Theorem 5.1

to a g-close feasible solution to P with a conveniently chosen γ so as to improve the performance guarantee of γ-RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING.

First we consider the optimal solution (x^*, y^*), which is v^*-close. By Theorem 5.1, the expected cost of the solution produced by γ-RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING is at most

$$\gamma \sum_{i \in \mathcal{F}} f_i y_i^* + \sum_{j \in \mathcal{D}} \sum_{i \in \mathcal{F}} c_{ij} x_{ij}^* + \frac{2}{e^\gamma} \sum_{j \in \mathcal{D}} v_j^*.$$

Since $\sum_{j \in \mathcal{D}} v_j^* = \mathsf{LP}^*$, and $\sum_{j \in \mathcal{D}} \sum_{i \in \mathcal{F}} c_{ij} x_{ij}^* = (1-\rho)\,\mathsf{LP}^*$, the expected performance guarantee is at most

$$\gamma\,\rho + (1-\rho) + \frac{2}{e^\gamma}. \tag{12}$$

Now we choose $\gamma \geq 1$ so as to minimize (12), which gives

$$\gamma = \begin{cases} \ln(2/\rho) & \text{if } \rho \leq 2/e, \\ 1 & \text{if } \rho > 2/e. \end{cases}$$

In this case, we obtain a performance guarantee of

$$\begin{cases} 1 + \rho \ln(2/\rho) & \text{if } \rho \leq 2/e, \\ 1 + 2/e & \text{if } \rho > 2/e. \end{cases}$$

Figure 4 shows the performance of the new algorithm for each value of ρ. Notice that the performance improves when ρ gets closer to 0, but then there is no improvement, for instance, when ρ is close to 1. To improve the guarantees for this range of values of ρ, we will use a different g-close solution, the one proposed by Shmoys, Tardos, and Aardal [STA97], which provides better guarantees when ρ is close to 1.

In what follows, we apply Theorem 5.1 to the g-close solutions given in [STA97], which were obtained using the filtering technique of Lin and Vitter [LV92b] applied to the optimal solution (x^*, y^*). Fix $\alpha \in (0, 1]$. For a demand point $j \in \mathcal{D}$, suppose that $\mathsf{N}(j) = \{1, \ldots, d\}$, with $c_{1j} \leq \cdots \leq c_{dj}$. Let $\ell^* = \min\{\ell : 1 \leq \ell \leq d, \sum_{i=1}^{\ell} x_{ij}^* \geq \alpha\}$; then the *$\alpha$-point* of j, $c_j(\alpha)$ is $c_{\ell^* j}$. For each demand point $j \in \mathcal{D}$, let

$$\beta_j^\alpha = \sum_{i : c_{ij} \leq c_j(\alpha)} x_{ij}^*.$$

The filtered solution (x^α, y^α) is defined in a simple way to ensure g-closeness, for $g_j = c_j(\alpha)$ $(j \in \mathcal{D})$, as follows: if $j \in \mathcal{D}$, $i \in \mathcal{F}$,

$$x_{ij}^\alpha = \begin{cases} \dfrac{x_{ij}^*}{\beta_j^\alpha} & \text{if } c_{ij} \leq c_j(\alpha), \\ 0 & \text{otherwise,} \end{cases}$$

and $y_i^\alpha = \min\{1, y_i^*/\alpha\}$ for $i \in \mathcal{F}$. It is easy to verify that (x^α, y^α) is a feasible primal solution (because $\beta_j^\alpha \geq \alpha$) and that (x^α, y^α) is $(c_j(\alpha))$-close. The total fractional facility cost of the filtered solution is $\sum_{i \in F} f_i y_i^\alpha$, and it is clearly bounded by $\sum_{i \in F} f_i y_i^*/\alpha$. Next define $\tau(\alpha) = \sum_{j \in \mathcal{D}} c_j(\alpha) / \sum_{j \in \mathcal{D}} \sum_{i \in \mathcal{F}} c_{ij} x_{ij}^*$. The following lemma follows from Lemma 10 of [STA97] and was observed in [GK99].

LEMMA 5.3. *The function $\tau(\alpha)$ satisfies the following expression:*

$$\int_0^1 \tau(\alpha)\ \mathrm{d}\alpha = 1.$$

Proof. It was shown in [STA97] that $\int_0^1 c_j(\alpha)\ \mathrm{d}\alpha = \sum_{i\in\mathcal{F}} c_{ij}x^*_{ij}$, from which the lemma follows at once according to our definitions. □

Also note that $\tau(\alpha)$ is a left continuous step function that has at most $O(|\mathcal{D}||\mathcal{F}|)$ break points. Since for each demand point $k \in \mathcal{D}$, the fractional service cost of the filtered solution is bounded by the fractional transportation cost, that is,

$$\sum_{i\in\mathcal{F}} c_{ik}x^\alpha_{ik} = \sum_{\{i:c_{ik}\le c_k(\alpha)\}} c_{ik}\frac{x^*_{ik}}{\beta^\alpha_j} \le \sum_{i\in\mathcal{F}} c_{ik}x^*_{ik},$$

the previous theorem implies that the expected total cost of the solution of γ-RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING when applied to the $(c_j(\alpha))$-close solution (x^α, y^α) is at most

$$\gamma\sum_{i\in F} f_i\frac{y^*_i}{\alpha} + \sum_{j\in\mathcal{D}}\sum_{i\in\mathcal{F}} c_{ij}x^*_{ij} + \frac{2}{e^\gamma}\sum_{j\in D} c_j(\alpha),$$

or an expected performance guarantee of

$$\gamma\frac{\rho}{\alpha} + 1 - \rho + \frac{2}{e^\gamma}(1-\rho)\tau(\alpha). \tag{13}$$

To find the best possible guarantee we will use binary search on a target guarantee and Lemma 5.3 in a way similar to that used in [GK99] as follows. Fix $c > 1$, and suppose that γ-RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING does not produce a c-approximation algorithm for every $\alpha \in (0,1)$, $\gamma \ge 1$. Then

$$\tau(\alpha) > \frac{e^\gamma}{2}\frac{(c-1+\rho)\alpha - \gamma\rho}{(1-\rho)\alpha}. \tag{14}$$

We are interested only in values of α for which the expression on the right is nonnegative; hence we will assume that $\alpha \ge \gamma\rho/(c-1+\rho)$. For fixed α, the value of $\gamma \ge 1$ that makes the right-hand side of (14) greatest is given by

$$\gamma(\alpha) = \begin{cases} \dfrac{(c-1+\rho)\alpha - \rho}{\rho} & \text{if } 2\rho/(c-1+\rho) \le \alpha \le 1, \\ 1 & \text{if } \rho/(c-1+\rho) \le \alpha \le 2\rho/(c-1+\rho). \end{cases}$$

Thus, from (14), we obtain a lower bound for $\tau(\alpha)$, $LB_c(\alpha)$, given by

$$LB_c(\alpha) = \begin{cases} \dfrac{\rho}{2}\dfrac{\exp\{[(c-1+\rho)\alpha-\rho]/\rho\}}{(1-\rho)\alpha} & \text{if } 2\rho/(c-1+\rho) \le \alpha \le 1, \\ \dfrac{e}{2}\dfrac{(c-1+\rho)\alpha-\rho}{(1-\rho)\alpha} & \text{if } \rho/(c-1+\rho) \le \alpha \le 2\rho/(c-1+\rho), \\ 0 & \text{if } 0 \le \alpha \le \rho/(c-1+\rho). \end{cases}$$

Note that $LB_c(\alpha)$ is a continuous and increasing function of α (since c and ρ are fixed). Now since $\int_0^1 \tau(\alpha)\ \mathrm{d}\alpha = 1$, and $\tau(\alpha) > LB_c(\alpha)$, if we can show that $\int_0^1 LB_c(\alpha)\ \mathrm{d}\alpha > 1$,

we have a contradiction, and, thus, the performance guarantee of the algorithm is no greater than c. Using bisection search we can find the smallest c, say $c_\circ$, within a small error tolerance (say 0.0001) for which $\int_0^1 LB_{c_\circ}(\alpha)\ \mathrm{d}\alpha > 1$, and hence show that the algorithm has a performance guarantee $c_\circ$. It is clear that the bisection search takes constant time. We finally address the issue of how to find the parameters α and γ to obtain a $c_\circ$-approximation algorithm. We know that

$$\int_0^1 \tau(\alpha)\ \mathrm{d}\alpha = 1 < \int_0^1 LB_{c_\circ}(\alpha)\ \mathrm{d}\alpha; \tag{15}$$

hence there must be a value of α, say $\alpha_\circ$, such that

$$\tau(\alpha_\circ) \le LB_{c_\circ}(\alpha_\circ). \tag{16}$$

This implies that when $\gamma = \gamma(\alpha_\circ)$, γ-RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING produces a solution with expected cost within a factor of $c_\circ$ of optimum. Thus we need only to argue how to find such an $\alpha_\circ$ in polynomial time.

Now we know that $\tau(\alpha)$ is a left continuous step function with at most $O(|\mathcal{D}|^2)$ break points. Hence we can find a partition of the interval $(0,1] = (0,s_1] \cup (s_1,s_2] \cup \cdots \cup (s_k,1]$, with $k = O(|\mathcal{D}|^2)$, such that $\tau(\alpha)$ is constant in each subinterval. Suppose that $\tau(\alpha) = z$ in the subinterval $(s_i, s_{i+1}]$. If $z > LB_{c_\circ}(s_{i+1})$, since $LB_{c_\circ}$ is increasing, the inequality must hold for the whole subinterval. Thus if for all the right endpoints of the subintervals inequality (16) does not hold, $\tau(\alpha) > LB_{c_\circ}(\alpha)$ for each $\alpha \in (0,1]$, contradicting (15). This gives a simple way to find a $c_\circ$-approximation algorithm. Figure 4 shows the performance guarantees obtained using this algorithm.

We conclude the section by pointing out that there is a minor improvement on the best guarantee we can achieve using the algorithms γ-RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING. Indeed, a careful computation gives a slightly improved overall performance guarantee of $1.73352 < 1.73576 \approx 1 + 2/e$.

6. Proof of Lemmas 3.9 and 5.2. Notice that Lemma 3.9 follows from Lemma 5.2 by simply taking $\gamma = 1$. Thus we need only to prove Lemma 5.2. As noted above, Sviridenko [Svi02] (in the proof and discussion around his Lemmas 4 and 5) observed that a much simpler version of this proof can be derived from the Chebyshev integral inequality, and he cited particular variants in the text of Hardy, Littlewood, and Pólya [HLP52].

The key idea of the proof is to observe that the expected value decreases as a function of γ; thus, since when γ is 0 the expected value is exactly $\overline{C}$, we are done.

For $\gamma \ge 0$, let $p(\gamma) := \mathsf{E}[\min_{\circ\{i:Z_i=1\}} \overline{c}_i Z_i + \prod_{i=1}^d (1-Z_i)\overline{C}]$. Let $\overline{\gamma} = \min_i(1/z_i)$. We first prove the lemma for $\gamma \le \overline{\gamma}$, so that $\gamma z_i < 1$, if $\gamma < \overline{\gamma}$. In this case, $p(\gamma)$ can be computed as

$$\overline{c}_1\gamma z_1 + \overline{c}_2\gamma z_2(1-\gamma z_1) + \cdots + \overline{c}_d\gamma z_d(1-\gamma z_1)\cdots(1-\gamma z_{d-1}) + \overline{C}\prod_{\ell=1}^{d}(1-\gamma z_\ell).$$

Notice that $p(\gamma)$ is a polynomial on γ and that $p(0) = \overline{C}$. Hence, to prove the lemma in this case it is enough to show that $p'(\gamma) \le 0$ for $\gamma \in (0, \overline{\gamma})$.

Next define for each $\ell = 0, 1, \ldots, d$

$$F_\ell(\gamma) = \begin{cases} 1 & \text{if } \ell = 0, \\ (1-\gamma z_\ell)F_{\ell-1}(\gamma) & \text{if } \ell \ge 1. \end{cases}$$

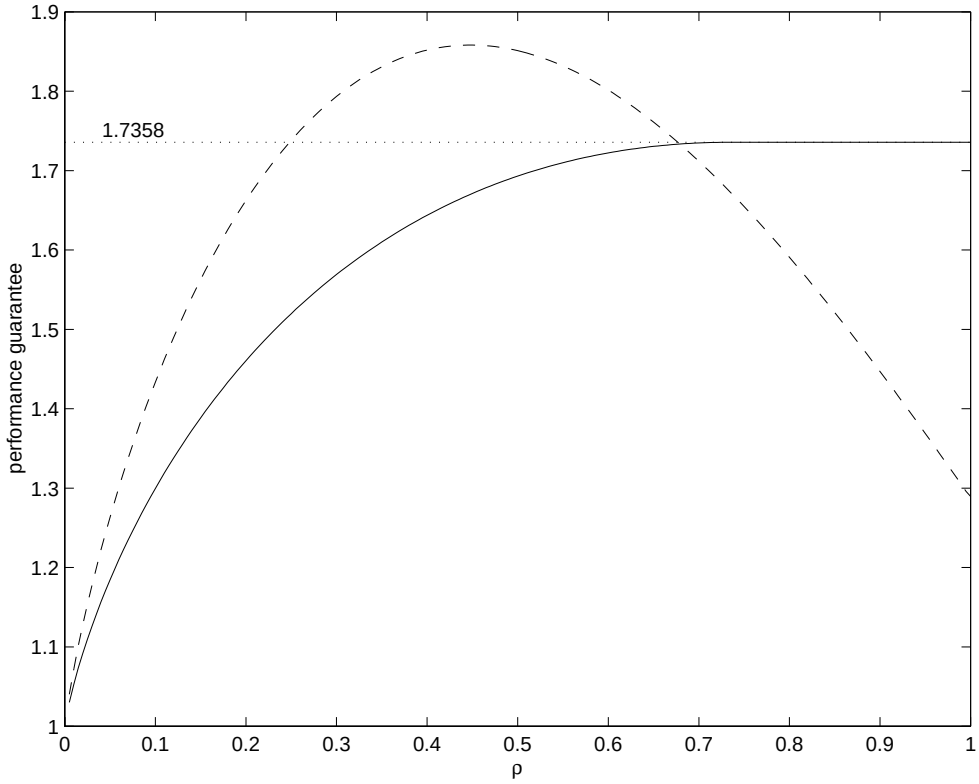

FIG. 4. *Performance guarantees of* γ-RANDOMIZED ROUNDING WITH IMPROVED CLUSTERING *as a function of* ρ. *The solid line corresponds to the algorithm that uses the optimal* v^**-close solution* (x^*, y^*), *while the dashed line corresponds to the algorithm run with the filtered solution of* [STA97].

Thus we can write

$$\begin{aligned} p(\gamma) &= \overline{c}_1\gamma z_1 F_0(\gamma) + \overline{c}_2\gamma z_2 F_1(\gamma) + \cdots + \overline{c}_d\gamma z_d F_{d-1}(\gamma) + \overline{C}F_d(\gamma) \\ &= \sum_{\ell=1}^{d} \overline{c}_\ell\gamma z_\ell F_{\ell-1}(\gamma) + F_d(\gamma)\sum_{\ell=1}^{d}\overline{c}_\ell z_\ell \\ &= \sum_{\ell=1}^{d} \overline{c}_\ell z_\ell \left[\gamma F_{\ell-1}(\gamma) + F_d(\gamma)\right]. \end{aligned}$$

Then

$$p'(\gamma) = \sum_{\ell=1}^{d} \overline{c}_\ell z_\ell \left[F_{\ell-1}(\gamma) + \gamma F'_{\ell-1}(\gamma) + F'_d(\gamma)\right].$$

For $\ell = 1, \ldots, d$, let $\lambda_\ell = F_{\ell-1}(\gamma) + \gamma F'_{\ell-1}(\gamma) + F'_d(\gamma)$ so that $p'(\gamma) = \sum_{\ell=1}^{d} \overline{c}_\ell z_\ell \lambda_\ell$. Next note that

$$F'_\ell(\gamma) = \begin{cases} 0 & \text{if } \ell = 0, \\ -z_\ell F_{\ell-1}(\gamma) + (1-\gamma z_\ell)F'_{\ell-1}(\gamma) & \text{if } \ell \geq 1. \end{cases}$$

It is easy to check by induction that $F'_\ell(\gamma) \le 0$, $\ell = 0, \dots, d$. To prove the lemma in this case, we will use the following two claims.

CLAIM 1. *The following equality holds:* $\sum_{\ell=1}^{d} z_\ell \lambda_\ell = 0$.

CLAIM 2. *There is an index* $\ell_\circ$, $0 \le \ell_\circ \le d$, *such that* $\lambda_1, \dots, \lambda_{\ell_\circ - 1} \ge 0$, *and* $\lambda_{\ell_\circ}, \dots, \lambda_d \le 0$.

To prove that $p'(\gamma) \le 0$, take $\ell_\circ$ as in Claim 2; then use Claim 1 and the order of the $\overline{c}_\ell$'s:

$$\begin{aligned} p'(\gamma) &= \sum_{\ell=1}^{\ell_\circ - 1} \overline{c}_\ell \lambda_\ell z_\ell + \sum_{\ell=\ell_\circ}^{d} \overline{c}_\ell \lambda_\ell z_\ell \\ &\le \overline{c}_{\ell_\circ} \left(\sum_{\ell=1}^{\ell_\circ - 1} \lambda_\ell z_\ell \right) + \overline{c}_{\ell_\circ} \left(\sum_{\ell=\ell_\circ}^{d} \lambda_\ell z_\ell \right) \\ &= \overline{c}_{\ell_\circ} \sum_{\ell=1}^{d} \lambda_\ell z_\ell \\ &= 0. \end{aligned}$$

We complete the proof of the lemma for $\gamma \in [0, \overline{\gamma}]$ by proving the claims.

Proof of Claim 1. Note first that for $\ell = 1, \dots, d$

$$-z_\ell F_{\ell-1}(\gamma) - \gamma z_\ell F'_{\ell-1}(\gamma) = F'_\ell(\gamma) - F'_{\ell-1}(\gamma).$$

Thus

$$\sum_{\ell=1}^{d} [-z_\ell F_{\ell-1}(\gamma) - \gamma z_\ell F'_{\ell-1}(\gamma)] = F'_d(\gamma) - F'_0(\gamma) = F'_d(\gamma),$$

which implies that $\sum_\ell z_\ell \lambda_\ell = 0$, since $\sum_\ell z_\ell = 1$. □

Proof of Claim 2. If $\lambda_\ell \ge 0$ (or $\lambda_\ell \le 0$) for all ℓ, using Claim 1, $\lambda_\ell = 0$ for all ℓ, and any index works. Hence we can assume that at least one $\lambda_\ell < 0$ and at least one $\lambda_\ell > 0$. Suppose the claim does not hold. Then there must exist an index ℓ, $1 \le \ell \le d$, such that $\lambda_\ell \le 0$, but $\lambda_{\ell+1} > 0$. In particular,

$$\lambda_{\ell+1} = F_\ell(\gamma) + \gamma F'_\ell(\gamma) + F'_d(\gamma) > 0.$$

Thus,

$$\begin{aligned} \lambda_{\ell+1} - F'_d(\gamma) &= F_\ell(\gamma) + \gamma F'_\ell(\gamma) \\ &= (1 - \gamma z_\ell) F_{\ell-1}(\gamma) + (1 - \gamma z_\ell) \gamma F'_{\ell-1}(\gamma) - \gamma z_\ell F_{\ell-1}(\gamma) \\ &= (1 - \gamma z_\ell)[F_{\ell-1}(\gamma) + \gamma F'_{\ell-1}(\gamma)] - \gamma z_\ell F_{\ell-1}(\gamma) \\ &> -F'_d(\gamma) \\ &\ge 0. \end{aligned}$$

Let $t := F_{\ell-1}(\gamma) + \gamma F'_{\ell-1}(\gamma)$. Since $(1 - \gamma z_\ell) > 0$ and $-\gamma z_\ell F_{\ell-1}(\gamma) < 0$, it must be the case that $t > 0$. Since $\lambda_\ell \le 0$, $t \le -F'_d(\gamma)$. Thus,

$$0 < t \le -F'_d(\gamma) < \lambda_{\ell+1} - F'_d(\gamma) = (1 - \gamma z_\ell) t - \gamma z_\ell F_{\ell-1}(\gamma) < (1 - \gamma z_\ell) t,$$

which is impossible since $(1 - \gamma z_\ell) < 1$. □

Next suppose that $\gamma \geq \overline{\gamma}$, and let $\ell_\circ$ be the smallest index for which $\min\{\gamma z_\ell, 1\}$ is 1. Now we have that

$$p(\gamma) = \overline{c}_1\gamma z_1 + \overline{c}_2\gamma z_2(1-\gamma z_1) + \cdots + \overline{c}_{\ell_\circ}(1-\gamma z_1)\ldots(1-\gamma z_{\ell_\circ-1}).$$

We reduce this case to the previous one as follows. Let $\alpha = \sum_{\ell=1}^{\ell_\circ-1} z_\ell$, $\gamma' = \gamma\alpha$, and let $z'_\ell = z_\ell/\alpha$ for $\ell = 1, \ldots, \ell_\circ - 1$; note that $\sum_{\ell=1}^{\ell_\circ-1} z'_\ell = 1$. We have then that

$$p(\gamma) = \overline{c}_1\gamma' z'_1 + \overline{c}_2\gamma' z'_2(1-\gamma' z'_1) + \cdots + \overline{c}_{\ell_\circ}(1-\gamma' z'_1)\ldots(1-\gamma' z'_{\ell_\circ-1}). \tag{17}$$

Notice that $\gamma' z'_\ell < 1$ for each $\ell = 1, \ldots, \ell_\circ - 1$. If $\overline{C}' = \sum_{\ell=1}^{\ell_\circ-1} \overline{c}_\ell z'_\ell$, and $q = \prod_{\ell=1}^{\ell_\circ-1}(1-\gamma' z'_\ell)$, we can apply the previous case to conclude that the first $\ell_\circ - 1$ terms of (17) can be bounded by $(1-q)\overline{C}'$. Thus,

$$p(\gamma) \leq (1-q)\overline{C}' + \overline{c}_{\ell_\circ} q. \tag{18}$$

Suppose that $q \leq 1-\alpha$. Then, since $\overline{C}' \leq \overline{c}_{\ell_\circ}$ by the ordering of the $\overline{c}$'s, from (18)

$$p(\gamma) \leq \alpha\overline{C}' + (1-\alpha)\overline{c}_{\ell_\circ} = \sum_{\ell=1}^{\ell_\circ-1} \overline{c}_\ell z_\ell + (1-\alpha)\overline{c}_{\ell_\circ} \leq \sum_{\ell=1}^{d} \overline{c}_\ell z_\ell = \overline{C},$$

and the lemma follows. Hence, to conclude the proof, we need only to argue that $q \leq 1-\alpha$. First note that since $1 - x \leq e^{-x}$ $(x \geq 0)$,

$$q = \prod_{\ell=1}^{\ell_\circ-1}(1-\gamma' z'_\ell) \leq \prod_{\ell=1}^{\ell_\circ-1} e^{-\gamma' z'_\ell} = e^{-\gamma'\sum_{\ell=1}^{\ell_\circ-1} z'_\ell} = e^{-\gamma'} = e^{-\gamma\alpha}.$$

Now, since $\gamma z_{\ell_\circ} \geq 1$, it must be that $\gamma \geq 1/(1-\alpha)$. Finally,

$$q \leq e^{-\gamma\alpha} \leq e^{-\alpha/(1-\alpha)} \leq 1-\alpha,$$

where the last inequality follows from $1 - \ln(y) \leq 1/y$ for $y \in (0,1)$ by setting $y = 1-\alpha$.

FASTER SUFFIX TREE CONSTRUCTION WITH MISSING SUFFIX LINKS*

RICHARD COLE† AND RAMESH HARIHARAN‡

Abstract. We consider suffix tree construction for situations with missing suffix links. Two examples of such situations are suffix trees for parameterized strings and suffix trees for two-dimensional arrays. These trees also have the property that the node degrees may be large. We add a new back-propagation component to McCreight's algorithm and also give a high probability hashing scheme for large degrees. We show that these two features enable construction of suffix trees for general situations with missing suffix links in $O(n)$ time, with high probability. This gives the first randomized linear time algorithm for constructing suffix trees for parameterized strings.

Key words. suffix tree, parameterized strings, two-dimensional suffix trees, dynamic perfect hashing

1. Introduction.

The *suffix tree* of a given string of length n is the compacted trie of all its suffixes. This tree has size $O(n)$ and can be constructed in $O(n)$ time [12, 16, 15]. Suffix trees have several applications (see [8]). One of the main applications of suffix trees is to preprocess a text in linear time so as to answer pattern occurrence queries in time proportional to the length of the query and independent of the length of the preprocessed text. The preprocessing involves building the suffix tree for the text. Next, given a query pattern, the unique path down the suffix tree traced by this pattern is determined; each leaf of the tree which lies further down from this path corresponds to an occurrence of the pattern.

Parameterized suffix trees. Baker [1] generalized the definition of suffix trees to *parameterized* strings, i.e., strings having variable characters or *parameters* in addition to the usual fixed *symbols*. The set of parameters and the set of symbols are disjoint. Two parameterized strings are said to *match* each other if the parameters in one can be *consistently* replaced with the parameters in the other to make the two strings identical. Here, consistency demands that all occurrences of a particular parameter are replaced by the same parameter and distinct parameters are replaced by distinct parameters. Baker [1] gave a definition of suffix trees for parameterized text strings t so as to facilitate answering pattern occurrence queries in time independent of the text length $|t|$.

Two-dimensional suffix trees. Giancarlo [7] generalized suffix trees to two-dimensional (2D) texts t in order to answer pattern occurrence queries (i.e., find all occurrences of a given square array p in the square text t) in time independent of $|t|$.

Suffix tree construction. There are several algorithms for constructing the suffix tree of a string drawn from a constant-sized alphabet set in $O(n)$ time. These include the algorithms by McCreight [12], Weiner [16], and Ukkonen [15]. All these algorithms exploit an important property of suffix trees; namely, each node has an outgoing suffix link.

Farach [5] showed how to construct suffix trees in $O(n)$ time even when the alphabet size was not constant but some polynomial in n. This algorithm differs from the others above in that it is not sweep-based and seems to be less critically dependent on the existence of outgoing suffix links. However, it requires renaming pairs of adjacent characters to get a string of size half that of the original string. The suffix tree for this smaller string is built recursively; Farach shows how the suffix tree of the original string can be obtained from the suffix tree of this smaller string in $O(n)$ time.

In contrast to suffix trees for strings, suffix trees for both parameterized strings and 2D arrays lack the suffix link property; i.e., there could be nodes in the tree without an outgoing suffix link defined. In addition, the node degrees in these suffix trees need not be bounded by a constant. Due to these two problems, the best constructions known until recently for suffix trees for parameterized strings [1, 11] and 2D arrays [7] took $O(n \log n)$ time in the worst case, where n is the size of the input string/array. In each case (i.e., in [1] and [7]; [11] uses a different data structure), the problem of missing suffix links was handled by using a dynamic tree data structure [14]; this data structure is used to find the insertion site of the next suffix in $O(\log n)$ time. Further, the problem of large node degrees was handled by the standard approach of maintaining a binary search tree, which also gave a $\Theta(\log n)$ overhead.

We mention here that Baker [1] gives two algorithms for constructing suffix trees for parameterized strings, one with time complexity $O(n \log n)$, as mentioned above, and another with time complexity $O(n(|\Pi|+\log|\Sigma|))$, where Π is the set of parameters and Σ is the set of symbols. Kosaraju [11] gave a faster algorithm with time complexity $O(n(\log|\Pi| + \log|\Sigma|))$, which is $O(n \log n)$ when $|\Pi| = \Theta(n)$.

Recently, Kim and Park [10] used the paradigm of Farach [5] to give an $O(n)$ time algorithm for 2D suffix tree construction (for polynomially bounded alphabet size). However, it is not clear how to apply this paradigm to the case of parameterized strings. In particular, it is not clear how the renaming of pairs of adjacent characters mentioned above can be accomplished in such a way that the suffix tree of the given string can be obtained from the suffix tree of the renamed string in $O(n)$ time.

Our contribution. We present two new tools in this paper.

(i) The first tool is aimed at tackling the problem of missing suffix links. We augment McCreight's algorithm with a new feature which copies nodes backwards (imagine suffix links as going forwards), thus adding additional nodes and suffix links to the suffix tree. Using a nontrivial accounting procedure, we show that this back-propagation adds only $O(n)$ extra nodes and accomplishes the construction of the suffix tree in $O(n)$ time even with missing suffix links. The back-propagation is similar to fractional cascading, as used in many pointer-based data structures of bounded degree (when viewed as graphs); the difficulty here is that the degrees are potentially unbounded, which appears to necessitate quite a different analysis.

(ii) The time analysis in (i) assumes that given a node x and a character a, the unique edge from x to a child of x starting with the character a is com-

putable in $O(1)$ time. To enable this for high degree nodes x, we give an extension of the dynamic version of the Fredman–Komlos–Szemerédi (FKS) perfect hashing scheme [6] which supports insertion of n items from a polynomial sized range in amortized constant time and linear space, with close to inverse exponential, i.e., $\frac{O(\log n)}{2^{\Theta(n^{1-\epsilon}/\log n)}}$, failure probability. This is in contrast to the previous expected time result of Dietzfelbinger et al. [3] and the previous result of Dietzfelbinger and Meyer auf der Heide [4], which achieves inverse polynomial failure probability. Searching for an item requires worst-case constant time. In fact, the items being in a polynomial sized range is not necessary for our hashing scheme; it suffices if they can be hashed into a polynomial sized range in linear time.

The above two tools provide a unified framework from which randomized $O(n)$ time algorithms for constructing suffix trees for regular strings, parameterized strings, and 2D arrays are easily derived. These algorithms work with high probability (for 2D arrays, the failure probability is only inverse polynomial and not close to inverse exponential as in the case of regular and parameterized strings; this higher failure probability arises in the process of casting the 2D array problem in the above unified framework). This is the first $O(n)$ time randomized algorithm for parameterized suffix tree construction; the previous best algorithms [1, 11] took $O(n \log n)$ deterministic time. The suffix trees we construct also have the property that the unique path in the tree corresponding to a given pattern string p can be found in $O(p)$ time, regardless of the degrees of the nodes.

2. The general setting. Before describing our algorithm, we describe the general setting for which our algorithm works. We need the following definitions.

Compacted trie. A compacted trie is a tree data structure defined on a collection of strings. This tree has one leaf per string in this collection, and each internal node has at least two children. Therefore, the number of nodes is linear in the number of strings in the given collection. Each edge of the tree is associated with (or labeled with) some substring of one of the strings in the given collection. The key property is that for every pair of leaves, the string formed by concatenating the edge labels on the path from the root to the least common ancestor of these two leaves is the longest common prefix of the strings associated with the two leaves.

In this paper, we are interested in compacted tries for certain kinds of string collections.

Quasi-suffix collections. An ordered collection of strings $s_1, s_2, \ldots, s_n$ is called a quasi-suffix collection if and only if the following conditions hold. Let $|s|$ denote the length of string s.

1. $|s_1| = n$ and $|s_i| = |s_{i-1}| - 1$. Therefore, $|s_n| = 1$.
2. No s_i is a prefix of another s_j.
3. Suppose strings s_i and s_j have a common prefix of length $l > 0$. Then s_{i+1} and s_{j+1} have a common prefix of length at least $l - 1$.

We will assume that all the strings are drawn from an alphabet of size polynomial in n.

Character oracles. Note that the total length of the strings in a quasi-suffix collection of n strings is $O(n^2)$, while our aim is to achieve $O(n)$ time construction for the compacted trie. Therefore, we cannot afford to read the collections explicitly. Instead, we will assume an oracle which supplies the ith character of the jth string of the collection on demand in $O(1)$ time.

Multiple quasi-suffix collections. Consider several distinct quasi-suffix collections

having l strings in all. These quasi-suffix collections constitute a multiple quasi-suffix collection if conditions 2 and 3 above hold for any pair of strings s_i, s_j over all the collections (in other words, these conditions hold for pairs within each collection and for pairs drawn from distinct collections as well).

Our main result will be the following.

THEOREM 1. *Let ϵ be any positive constant. The compacted trie of a quasi-suffix collection of n strings can be constructed in $O(n)$ time and space with failure probability at most $\frac{O(\log n)}{2^{\Theta(n^{1-\epsilon}/\log n)}}$, given the above character oracle. Further, the compacted trie of a multiple quasi-suffix collection comprising l strings in all can be constructed in $O(l)$ time and space with failure probability at most $\frac{O(\log l)}{2^{\Theta(l^{1-\epsilon}/\log l)}}$,*

2.1. Examples of quasi-suffix collections. The significance of the above theorem comes from the following examples of quasi-suffix collections. The simplest example is the collection of all suffixes of a string s with a special end-of-string symbol. This is a quasi-suffix collection but with a stronger property; namely, condition 3 in the definition of quasi-suffix collections is satisfied with equality. The compacted trie of these suffixes is the well-known suffix tree of the string s. Next, we give two more significant examples for which equality need not hold in condition 3.

2.1.1. Suffix trees for parameterized strings. Recall from the introduction that a parameterized string s has *parameters* and *symbols*. The alphabet from which parameters are derived is disjoint from the alphabet from which symbols are derived. Further, both alphabet sizes are polynomial in n, the length of s. As is standard, assume that s ends in a symbol \$ which does not occur elsewhere in s. From s, Baker [1] defined the following collection of strings.

Each suffix s' of s is mapped to a string $num(s')$ with parameters replaced by numbers and symbols retained as such (assume that symbols are not numbers). The replacement of parameters is done as follows. The first occurrence of each parameter in s' gets value 0 in $num(s')$. Subsequent occurrences of a parameter get values equal to the distance from the previous occurrence of the same parameter. Consider the collection of strings $\{num(s')|s' \text{ suffix of } s\}$ in decreasing length order. Baker [1] defined the suffix tree of parameterized string s to be the compacted trie of this collection. That this collection of strings is indeed a quasi-suffix collection can be seen as follows.

Condition 1 clearly holds, and condition 2 follows from the occurrence of the special symbol \$ at the end of s. Condition 3 is shown to hold next. Note that if s'_i and s'_{i+1} are two consecutive suffixes of s, then $num(s'_{i+1})$ can be obtained from $num(s'_i)$ as follows: for each well-defined index $k > 0$, set $num(s'_{i+1})[k]$ to $num(s'_i)[k+1]$ if $num(s'_i)[k+1] \neq k$, and set $num(s'_{i+1})[k]$ to 0 otherwise. Next, consider two suffixes s'_i and s'_j of s. From the above observation, it follows that if $num(s'_i)$ and $num(s'_j)$ have a common prefix of length $k+1$, then $num(s'_{i+1})$ and $num(s'_{j+1})$ have a common prefix of length k. Further, if $num(s'_i)$ and $num(s'_j)$ differ at location $k+1$, then $num(s'_{i+1})$ and $num(s'_{j+1})$ could be identical at location k if one of $num(s'_i)[k+1], num(s'_j)[k+1]$ equals k and the other equals 0. Condition 3 is now easily seen to hold.

The character oracle for the above quasi-suffix collection is easily implemented in $O(1)$ time after the following precomputation: for each occurrence of a parameter in s, determine the previous occurrence, if any, of this parameter in s. This precomputation is easily done in $O(n)$ time.

2.1.2. Suffix trees for 2D arrays. Consider a 2D array s having size $m \times n$, $m \geq n$ and characters drawn from some polynomial range. For each square subarray s' of s which is *maximal* (i.e., touches either the right boundary or the bottom boundary or both boundaries of s), Giancarlo [7] defined a string $num(s')$ as follows.

Defining $num(s')$. Partition s' into L's as in [7] (an L is formed by taking a prefix of a row and a prefix of a column, with the common point being at the bottom-right; both prefixes have equal lengths; the resulting shape is actually the image of the character L reflected about a vertical axis). $num(s')$ will be a sequence of numbers, with one number for each such L; these numbers are arranged in increasing order of L sizes. The number for a particular L is obtained by reading this L as a string and then mapping strings to integers in such a way that distinct strings map to distinct integers (by using, for example, the Karp–Rabin fingerprinting scheme [9], which ensures this property with inverse polynomial failure probability). Finally, a special end-of-string symbol \$ is appended to $num(s')$, as was done for parameterized strings.

The quasi-suffix collections. Consider a particular top-left to bottom-right diagonal and consider all maximal square subarrays of s with top-left point on this diagonal. The $num()$ strings corresponding to these subarrays are easily seen to form a quasi-suffix collection. Thus each top-left to bottom-right diagonal gives a quasi-suffix collection of strings. Since there are $m+n-1$ diagonals, we have $m+n-1 = O(m)$ distinct quasi-suffix collections in all. It is easy to check that these $m+n-1$ quasi-suffix collections together constitute a multiple quasi-suffix collection (we will use distinct end-of-string symbols for each diagonal to satisfy condition 2 for pairs of strings drawn from distinct collections). Note that the number of strings in each collection is at most n. Giancarlo [7] defined the common compacted trie of these $m+n-1$ collections to be the suffix tree of s.

The character oracle. A character oracle which works with inverse polynomial failure probability in $O(1)$ time after $O(mn)$ preprocessing is easy to implement using the Karp–Rabin fingerprinting scheme. The preprocessing involves computing prefix sums for each row and column.

2.2. Proving Theorem 1. The rest of the paper is devoted to proving Theorem 1. First, we will describe how to construct the compacted trie of a *single* quasi-suffix collection of n strings in $O(n)$ time with high probability. This algorithm can easily be extended to multiple quasi-suffix collections (such as those resulting from 2D arrays). This extension is sketched briefly in section 6.

Our algorithm for a single quasi-suffix collection will have two components. The first component is a modification of McCreight's algorithm and is described in section 4 and section 5. In these sections, we will assume that the unique child of any given node with edge label beginning with a given character can be determined in $O(1)$ time. The second component, i.e., a dynamic perfect hashing scheme described below, will handle this problem.

Note that in all the above examples of quasi-suffix collections, the alphabet size is a polynomial in n (while a radix sort followed by relabeling could reduce this to size at most n, the difficulty would be to subsequently process searches in the suffix tree, as the search string would be written using the "old" alphabet). Thus to access the unique edge with a particular starting character from a node, we need to perfectly hash $O(n)$ pairs, where the first entry in the pair is a node number and the second entry is a character from the alphabet. Each such pair can be treated as a number from a range polynomial in n. In section 7, we give a dynamic hashing scheme which will perfectly hash items from a polynomial in n range with close to inverse exponential

failure probability.

Before giving our algorithms, we need an outline of McCreight's algorithm for constructing the suffix tree of a string.

3. McCreight's algorithm. The use of *suffix links* is crucial to this algorithm. Suffix links are defined as follows.

Definitions. For a node x, let $str(x)$ denote the substring associated with the path from the root of the tree to x. A suffix link points from a node x to a node y such that $str(y)$ is just $str(x)$ with the first character removed. Let $link(x)$ denote this node y. Let $par(x)$ denote the parent of x. For a string u, define $node(u)$ to be that node x, if any, for which $str(x) = u$.

Since condition 3 in the definition of quasi-suffix collections is satisfied with equality for the collection of suffixes of a string, suffix links are defined for each node x in the suffix tree; i.e., for each node x, a node $y = link(x)$ with the above description exists.

McCreight's construction inserts suffixes into the suffix tree one by one in order of decreasing length. For each suffix i, one new leaf and possibly one new internal node are inserted. The algorithm for inserting suffix $i+1$, given that suffix i inserted leaf y as a child of an existing or new internal node x, is as follows.

The search for the insertion site of suffix $i+1$ begins from $link(par(x))$. It involves two stages: a *rescanning* stage and, possibly, a *scanning* stage.

In the rescanning stage, the tree is *rescanned* downwards from $link(par(x))$ until the right position for $link(x)$ is found. Rescanning requires determining that path down the tree from $link(par(x))$ whose edge labels form the same substring as the label on the edge between $par(x)$ and x. Such a path is guaranteed to exist by condition 3 in the definition of quasi-suffix collections. By virtue of this guarantee, it suffices to examine just the first character on each edge to determine this path, as opposed to examining all the characters comprising the edge label; thus we have the term rescanning (as opposed to *scanning*, which involves examining all the characters in the labels at each edge encountered).

Next, there are two cases depending on whether or not a node is already present at the position for $link(x)$ identified above. If no node is currently present, then equality in condition 3 in the definition of quasi-suffix collections demands that a new internal node be inserted at this location and a new leaf corresponding to suffix $i+1$ be inserted as its child; there is no scanning stage in this case. On the other hand, if a node is indeed present at the above position, then the algorithm involves scanning downwards from this position. In either case, note that $link(x)$ is now well defined.

The two key facts used to show $O(n)$ time performance over all suffixes are as follows. Consider the portions of the suffix tree traversed in the scanning stages for the various suffixes (we will call them *scanned* portions). These scanned portions correspond to disjoint portions of the input string, and, therefore, they sum up to $O(n)$ in length (the length of a scanned portion is the number of characters, not nodes, encountered in the path scanned). Further, the total time taken in rescan stages between any two consecutive scanning stages is bounded by the time taken in the first of these two scanning stages.

Two problems. Two related problems arise in generalizing the above algorithm to quasi-suffix collections. The first is that $link(par(x))$ may not be defined. The second is that the lack of a node at the right position for $link(x)$ (as located in the rescanning stage) no longer requires a new node to be inserted at this location (this is due to the lack of equality in condition 3 in the definition of quasi-suffix collections);

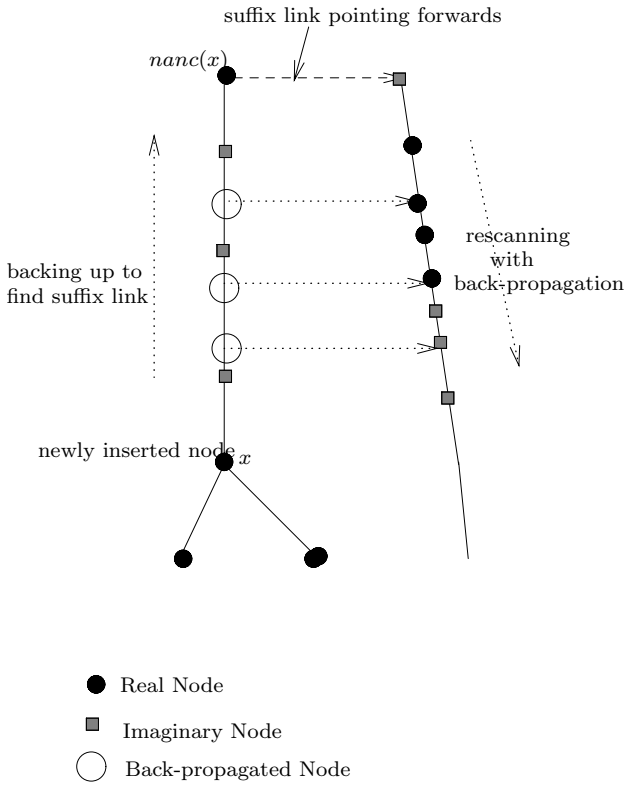

FIG. 1. *Backing up and back-propagation.*

we note that if a new node is not inserted, then a scanning stage will begin from this position.

4. Our algorithm. As in McCreight's algorithm, we will insert the strings in the given collection $s_1, \ldots, s_n$ in the compacted trie in decreasing order of length. Much of the algorithm remains the same; however, we make two key modifications. The first involves traversing the path up the tree from a newly inserted node to find an ancestor with a suffix link. The second involves copying nodes backwards while rescanning down the tree from the destination of the above suffix link. These changes affect only the rescanning algorithm; the scanning part remains unchanged. We describe these changes in detail next.

Defining suffix links. For a node x, $link(x)$ is now defined to be that node y such that if $str(x)$ is the longest common prefix of some s_i and s_j, then $str(y)$ is a common prefix of s_{i+1} and s_{j+1}; further, $|str(y)| = |str(x)| - 1$. Note that since condition 3 in the definition of quasi-suffix collections need not be satisfied with equality, $link(x)$ need not be defined for every node x. Also note that if $link(x)$ exists, then it is unique.

Backing up. Recall McCreight's algorithm above. Now, since $link(par(x))$ need not exist, we must traverse up the tree from x until a node with a suffix link is found. We call this node $nanc(x)$ (*nanc* stands for nearest ancestor). It may be that $nanc(x) = x$. Next, the tree is rescanned downwards from $link(nanc(x))$, as before, but with one modification to be described shortly. See Figure 1.

Real and imaginary nodes. Recall our description of McCreight's algorithm above. If a new scanning stage begins from the position identified for $link(x)$ in the rescanning stage, and there is no node at this position, we introduce an *imaginary node* at this position. Note that this imaginary node has only one child. Internal nodes which are not imaginary will be called *real*. Real nodes will have at least two children each; in addition, they will also have outgoing suffix links pointing, possibly, to imaginary nodes.

Note that there are just $O(n)$ real nodes and $O(n)$ imaginary nodes (at most one real internal node, one leaf, and one imaginary node are inserted per suffix). Since real nodes have at least two children each, imaginary nodes have just one child each, and the number of leaves is n, the total number of children over all real and imaginary nodes is $O(n)$. Also note that the total length of the scanned portions of the tree in McCreight's algorithm is $O(n)$, and this remains the same for our algorithm. We state these facts below for future reference.

FACT 1.

(i) *The number of real and imaginary nodes together is* $O(n)$.
(ii) *The total number of children of real and imaginary nodes together is* $O(n)$.
(iii) *The total length of the scanned portions of the tree is* $O(n)$ *(the length of a single scanned portion is the number of characters, not nodes, encountered in the path scanned).*

We need to add one more feature to McCreight's algorithm to get linear time complexity for quasi-suffix collections.

Back-propagated nodes. Other than real and imaginary nodes, our construction will involve internal nodes of a third kind, called *back-propagated nodes*. Back-propagated nodes will always have suffix links and only one child each. They are defined as follows. In the following, think of suffix links as pointing forwards (i.e., to the right; see Figure 1).

When the appropriate path starting at $link(nanc(x))$ is rescanned in order to determine the position for $link(x)$, several nodes could be encountered in the process. If more than two nodes are encountered, then alternate nodes are propagated back to the path $(nanc(x), x)$ (i.e., new nodes with suffix links pointing to the traversed nodes are set up on this path), taking care that the first and the last nodes traversed are not propagated back. The new nodes are called back-propagated nodes.

Direction of back-propagation. Note that a node could be back-propagated in several different directions; i.e., several back-propagated nodes could have their suffix links pointing to this node. Further, a back-propagated node could be propagated backwards further, forming a chain of back-propagated nodes.

Definitions. For a node x, let $prev(x)$ be a set of strings defined as follows. For each s_i in the given quasi-suffix collection having prefix $str(x)$, $prev(x)$ contains the prefix of s_{i-1} of length $|str(x)| + 1$. Note that $prev(x)$ is a set and not a multiset; therefore all strings in it are distinct. *Direction* u is said to be *valid* for node x if string u appears in $prev(x)$. Node x is said to be *back-propagated in direction* u if there exists a string u in $prev(x)$ such that $node(u)$ exists and is a back-propagated node (see Figure 2). Note that the suffix link of $node(u)$ points to x under these conditions, i.e., $link(node(u)) = x$.

The following invariant is maintained by our algorithm by virtue of the fact that only alternate nodes encountered are back-propagated and the first and last nodes encountered are not back-propagated.

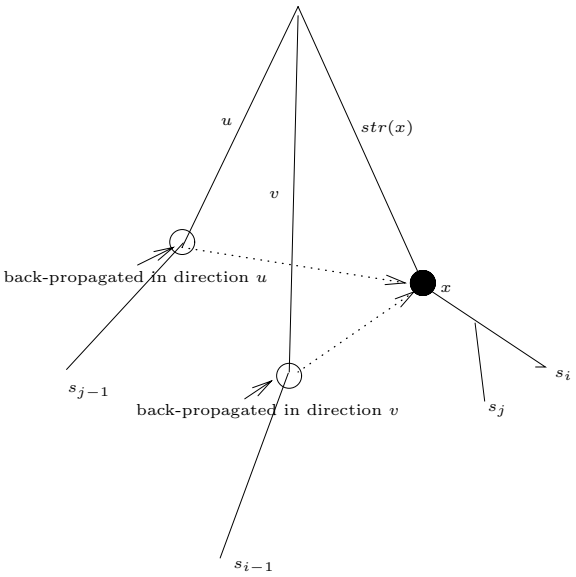

FIG. 2. *Direction of back-propagation.*

INVARIANT 1. *If a node x is back-propagated in direction u, then its parent is not back-propagated in direction u', where u' is a prefix of u. The algorithm is presented in pseudocode below.*

The algorithm is presented in pseudocode in Figure 3.

5. Time complexity. There are two aspects to the time taken to insert a particular string s_i from the given quasi-suffix collection. The first involves backing up from x to $nanc(x)$, subsequent to the insertion of x. The second involves rescanning the appropriate path down from $link(nanc(x))$ until the position for $link(x)$ is located. We account for these two aspects of the time separately.

We make a few remarks on the second aspect here. Each step taken here involves one of the following:

1. Creating a new back-propagated node.
2. Adding a suffix link to an already existing node. This happens when one seeks to back-propagate a node but the site of this back-propagation is already occupied by some other node. For this to happen, the latter node must not have a suffix link; i.e., it must be an imaginary node. A suffix link is now added to this imaginary node.
3. Creating a new real or imaginary node. This is the node $link(x)$.

Since only one real or imaginary node is added when rescanning from $link(nanc(x))$ to $link(x)$, the time taken in this rescanning is proportional to $O(1)$ plus the number of nodes back-propagated in this process plus the number of imaginary nodes for which suffix links are set up in this process. Since each imaginary node can get only one suffix link during the course of the entire algorithm, bounding the above time boils down to bounding the number of back-propagated nodes by $O(n)$.

5.1. Bounding back-propagated nodes. This will use a charging argument, where each back-propagated node will be charged to either some real/imaginary node or to some character in the string s_1. Each real/imaginary node and each character

//Insert suffix s_1
  Create a single edge (x_1, y_1) with x_1 as the root, labeled s_1.
for $i = 2$ to n **do**
  //Insert suffix s_i
    Let y_{i-1} be the leaf inserted for s_{i-1}, and let x_{i-1} be its parent.
    Find $nanc(x_{i-1})$, the nearest ancestor of x_{i-1} with a suffix link, if any; $nanc(x_{i-1})$ is the root node otherwise.
    Rescan the path starting at link $(nanc(x_{i-1}))$ until the location for link (x_{i-1}) is reached.
    If link (x_{i-1}) is a new node, split the label on the edge previously containing link (x_{i-1})'s location so that $|string(link(x_{i-1}))| = |string(x_{i-1})| - 1$.
    As the rescan proceeds, back propagate every second node encountered, starting two nodes after $link(nanc(x_{i-1}))$ and stopping two nodes before $link(x_{i-1})$.
    If node b is the back propagation of node c, split the label on the edge previously containing b's location so that $|string(b)| = |string(c)| + 1$.
    If $link(x_{i-1})$ was already present, scan from $link(x_{i-1})$ to find the location for y_i.
    Add a label for the edge to node y_i so that $string(y_i) = s_i$.
od

FIG. 3. *Algorithm for quasi-suffix tree construction.*

in s_1 will be charged $O(1)$ in the process. The $O(n)$ bound will follow from Fact 1. It may be that a node created by back-propagation subsequently becomes real or imaginary. These nodes are not counted; only nodes that are not real or imaginary when the full tree is built are counted.

Note that a back-propagation chain always starts at a real or an imaginary node. We will define a tree for each real or imaginary node x as follows.

Defining $BP - tree(x)$. All nodes in this tree other than the root x are back-propagated nodes. Those back-propagated nodes which are back-propagated from x (i.e., have suffix links pointing to x) are children of x in this tree. Trees rooted at these children are defined recursively; i.e., children of a node are those which are back-propagated from that node. The leaves of this tree are those nodes from which no further back-propagation occurs.

Consider the forest of $BP - trees(*)$ rooted at the various real/imaginary nodes that are back-propagated. Each back-propagated node appears in exactly one tree in this forest.

Decomposing $BP - tree(x)$ *into paths.* We partition the nodes of this tree into paths. The first path is the minimal path starting from the root x and ending on a node y with the following property: either there exists a valid direction u such that y has not been back-propagated in this direction or there is no valid direction for y. Clearly, such a node y must exist. But for the termination restriction, the path starting at the root is chosen arbitrarily. Once nodes in this path are removed, the subtrees hanging off this path are decomposed recursively.

Clearly, each back-propagated node will belong to exactly one of the various paths formed above. Think of each path as going backwards from its start node.

Accounting for long paths. We show that the sum of the lengths of all the paths obtained above is proportional to the number of such paths plus $O(n)$. It will then

suffice to bound the number of such paths.

Consider any path obtained above. Let x be any node on this path other than its start node. $link(x)$ is the node from which x was back-propagated, say in direction u. Note that $link(x)$ will precede x in the path being considered (as paths go backwards).

By Invariant 1, the parent $par(link(x))$ of $link(x)$ in the compacted trie has not been back-propagated in the direction u', where u' is the prefix of u such that $|u'|$ equals $|str(par(link(x)))| + 1$; u', of course, is a valid direction for $par(link(x))$ (because u is valid for $link(x)$ itself). It follows that either $par(link(x))$ is a real/imaginary node or $par(link(x))$ is a back-propagated node and the last node in its path (for if there is a direction in which a node is not back-propagated, then by construction that node is the last node on its path). In either case, we charge $par(link(x))$ for x.

Clearly, in this process each real/imaginary node and each back-propagated node which is the last node in its respective path will be charged an amount bounded by the number of its children. From Fact 1(ii), this charge sums to $O(n)$ for real/imaginary nodes. Note that back-propagated nodes have only one child each. Thus, it now suffices to bound the total number of paths.

Bounding the total number of paths. We will extend the above paths backwards to form a collection of *extended paths*, as below.

Consider any one path, and let x be the last node on this path. The extension to this path is performed as follows. Start at x and follow that direction backwards along which x was not back-propagated (there is at least one such direction, unless there are no valid directions for x). Next, repeatedly follow any arbitrarily chosen valid direction backwards. This extension need not always encounter a node (in fact we will stop when we hit a node); it is allowed to cut through edges.[1] So if a particular step of this extension leads to the middle of an edge e, take an arbitrary valid direction back from that point on e. Continue this extension until either a node is reached or there is no valid direction along which to continue.

Thus an extended path consists of an initial prefix of nodes (i.e., the path itself), followed by a walk which cuts through edges, and possibly terminates on a node. Again, note that we think of a path as going backwards. We have the following claims.

LEMMA 5.1. *Two distinct extended paths cannot intersect (i.e., they cannot cut through the same point on some edge or have a node in common), except that the last node of one can be the first node of the other.*

Proof. Since forward directions are always unique, two extended paths can intersect otherwise only if the start node of one path is contained in the other path and is not the last node on that path. This is a contradiction since all the unextended paths begin at nodes, the unextended paths are node disjoint, and the extension of a path terminates as soon as a node is reached. □

LEMMA 5.2. *If an extended path terminates by reaching a node y (and not by running out of valid directions), then y cannot be a back-propagated node.*

Proof. Let x be the last node of the path whose extension is under consideration. Suppose y is a back-propagated node. As forward links are unique, clearly x must have been back-propagated in the direction implied by y. But we started the extension of this path by choosing a direction along which x was not back-propagated, a contradiction. □

[1] We have defined valid directions only for nodes in the compacted trie. However, this definition can be extended for points in the middle of an edge in the obvious way, i.e., by imagining a node to be present at that point.

LEMMA 5.3. *The total number of paths is $O(n)$, and hence the total number of back-propagated nodes is $O(n)$.*

Proof. Consider a particular extended path. If it ends at a node without running out of valid directions, this node must be real/imaginary by Lemma 5.2; the current path is then charged to this node. By Lemma 5.1, each real/imaginary node is just charged once.

On the other hand, if this extended path ends because all further valid directions backwards are exhausted, then the substring associated with the termination point is a prefix of s_1. Further, by Lemma 5.1, different extended paths which end in this way are associated with distinct prefixes of s_1. Thus the number of paths is $O(n)$.

The lemma follows from the argument given earlier that the number of back-propagated nodes is proportional to the number of paths plus $O(n)$. ∎

5.2. Backing-up time. It remains to account for the time taken to determine $nanc(x)$ after the insertion of a leaf as a child of x. Note that all such nodes x for which $nanc(x)$ will be determined are real nodes (because x has at least two children).

This computation requires traversing upwards from x until the nearest node with a suffix link is found. All nodes encountered on the way must be imaginary (real and back-propagated nodes have suffix links), and we need to account for the time taken to traverse these nodes.

The key claim is the following. Note that an imaginary node y signals the beginning of a new scanning phase in McCreight's algorithm, in which the tree is scanned downwards starting at y, until a new leaf is inserted as a child of a new or existing internal node z.

LEMMA 5.4. *The total number of times imaginary node y can be encountered while determining $nanc(*)$ over the entire algorithm is at most $|str(z)| - |str(y)|$.*

Proof. Note that z is a real node after the above scanning phase starting at y finishes. y could be encountered once while setting up $link(z)$. Subsequently, since $link(z)$ is in place, y will be encountered only when finding $nanc(z')$, where z' is real and on the path from y to z. There can be at most $|str(z)| - |str(y)|$ such distinct real nodes z'. ∎

COROLLARY 5.5. *The total time taken in traversing imaginary nodes while determining $nanc(*)$ is $O(n)$.*

Proof. $|str(z)| - |str(y)|$ equals the number of characters scanned in the scanning phase following the insertion of imaginary node y. By Fact 1(iii), summed over all y, this is $O(n)$ characters. But by Lemma 5.4, summed over all y, this is also the number of imaginary nodes encountered while determining $nanc(*)$. ∎

Theorem 1 now follows for quasi-suffix collections, assuming that the correct child of a particular node can be found in $O(1)$ time. The extension to quasi-suffix collections is sketched next.

6. Algorithm for multiple quasi-suffix collections. We sketch how to extend the above algorithm to a multiple quasi-suffix collection having l strings in all. The time taken will be $O(l)$.

Suffix links and back-propagation directions need to be redefined appropriately as follows. Let s_i^k denote the ith string in the kth quasi-suffix collection under consideration (assume an arbitrary ordering on the various quasi-suffix collections).

Suffix links. For a node x, $link(x)$ is now defined to be that node y such that if $str(x)$ is the longest common prefix of some s_i^k and s_j^l, then $str(y)$ is a common prefix of s_{i+1}^k and s_{j+1}^l; further, $|str(y)| = |str(x)| - 1$. Note that since condition 3 in the

definition of quasi-suffix collections need not be satisfied with equality, $link(x)$ need not be defined for every node x. Also note that if $link(x)$ exists, then it is unique; this follows because if $str(x)$ is a prefix of s_i^k and of $s_j^{k'}$, then s_{i+1}^k and $s_{j+1}^{k'}$ agree in the first $|str(x)| - 1$ characters.

Back-propagation directions. For a node x, let $prev(x)$ be a set of strings defined as follows. For each s_i^k having prefix $str(x)$, $prev(x)$ contains the prefix of s_{i-1}^k of length $|str(x)| + 1$. Note that $prev(x)$ is a set and not a multiset; therefore all strings in it are distinct. *Direction* u is said to be *valid* for node x if string u appears in $prev(x)$.

The algorithm. The algorithm inserts each collection in turn into the current compacted trie. The first string of each quasi-suffix collection starts a new scanning stage beginning at the root of the compacted trie. The subsequent strings in the collection are inserted as in the previous algorithm. Note that the size of the compacted trie will now be $\Theta(l)$. Fact 1 continues to hold with $O(n)$ replaced by $O(l)$. The analysis is as before with the following two changes. All $O(n)$ terms are replaced by $O(l)$. Further, in Lemma 5.3, if an extended path ends because all further valid directions backwards are exhausted, then the substring associated with the termination point is a prefix of the first string in one of the several quasi-suffix collections being considered.

7. The hashing scheme. Recall from section 2.2 that we need to perfectly hash $O(n)$ pairs, where the first entry in each pair is a node number and the second entry is a character from the alphabet. Each such pair can be treated as a number from a range polynomial in n. We give a dynamic hashing scheme which will perfectly hash an item from a polynomial in n range in amortized $O(1)$ time, with close to inverse exponential failure probability. The time taken to access a particular item will be $O(1)$, and the total space is $O(n)$.

Fredman, Komlos, and Szemerédi [6] showed how n items from the range $[0 \ldots poly(n)]$ can be hashed into the range $[0 \ldots s]$ without any collisions, where $s = \Theta(n)$. Their algorithm takes $O(n)$ time and space and works by choosing randomly from a family of almost-universal hash functions (assuming constant time arithmetic on $O(\log n)$ bits). It ensures no collisions with probability at least $1/2$.

This was generalized by Dietzfelbinger et al. [3] to the dynamic setting. The expected amortized insertion/deletion time for their algorithm is $O(1)$; searching takes $O(1)$ worst-case time. Subsequently, Dietzfelbinger and Meyer auf der Heide [4] achieved $O(1)$ worst-case insertion/deletion/search time with inverse polynomial failure probability. We achieve close to inverse exponential failure probability but with $O(1)$ amortized insertion/deletion times and $O(1)$ worst-case search time. This is done by modifying the FKS perfect hashing scheme to make it work with high probability, first in the static setting and then in the dynamic setting.

First, we present the static algorithm. The key idea is to create several perfect hashing subproblems and to apply the FKS scheme on each independently to obtain a high success probability.

7.1. The static hashing scheme. The following steps are performed. Let ϵ be any positive constant. The time and space taken by our data structure will be linear but with a $\frac{1}{\epsilon}$ constant factor. The failure probability will decrease as ϵ gets closer to 0.

Step 1. Start with an imaginary array A of size n^c, where the n items to be hashed come from the range $1 \ldots n^c$. Each item indexes into a unique element in this array. Next, repeatedly partition this array as in Step 2.

Step 2. Construct a *partition tree* as described below. Each node in this tree will have a subarray of A associated with it. The depth of this tree will be a constant, and the number of nodes will be $O(n)$. The root of this tree is A itself. It has n^ϵ children, each associated with a distinct subarray of A of size $n^{c-\epsilon}$ obtained by partitioning A into n^ϵ disjoint pieces. Each subarray with more than n^ϵ items is recursively partitioned; the remaining subarrays become leaves. Each leaf has at most n^ϵ items. Clearly, the number of levels in this tree is $O(\frac{c}{\epsilon}) = O(1)$, and the total size in $O(n)$. The total time taken to set up the tree is easily seen to be $O(n)$.

Step 3. Next, we consider each leaf of the above tree in turn and the items in the subarray associated with this leaf. We perfect-hash these items using the FKS perfect hashing scheme. Since this scheme succeeds only with probability 1/2, several trials may be required before these items are perfectly hashed. We show that with high probability, the total time taken in this process over all leaves is $O(n)$.

7.2. Time complexity. We need to bound the time taken to perform several FKS perfect hashings, where the total sizes of all subproblems is n, each subproblem has size at most n^ϵ, and a subproblem is performed successfully in linear time with probability 1/2.

Size categories. Divide the leaves into $O(\log n)$ categories quadrupling by size (i.e., the number of items associated with the leaf). Consider just leaves in any one size category, namely, the category in which leaf sizes are in the range $\frac{n^\epsilon}{4^{i+1}} \cdots \frac{n^\epsilon}{4^i}$, $i \geq 0$. We will show that the time taken for this category is proportional to the sum of the sizes of leaves in this category plus $O(\frac{n}{2^i})$, with failure probability $\frac{O(\log n)}{2^{\Theta(\frac{2^i n^{1-\epsilon}}{\log n})}}$. It follows that the total time taken over all categories is $O(n)$, with failure probability $\frac{O(\log n)}{2^{\Theta(\frac{n^{1-\epsilon}}{\log n})}}$.

A leaf is said to *succeed* when the items in it are perfectly hashed. A *round* refers to one trial for each of the relevant leaves. The trials for the various leaves can be imagined to have proceeded in rounds, with leaves succeeding in one round dropping out of the subsequent rounds. We organize the rounds into groups.

Grouping rounds. The 0th group comprises rounds performed before the number of unsuccessful leaves in this size category drops below $\frac{n^{1-\epsilon}2^i}{\log n}$. For $j \geq 1$, the jth group comprises rounds performed after the number of unsuccessful leaves in this size category drops below $\frac{n^{1-\epsilon}2^i}{2^{j-1}\log n}$ but before this number drops below $\frac{n^{1-\epsilon}2^i}{2^j \log n}$.

We show that group 0 has $O(i + \log\log n)$ rounds and that each group $j \geq 1$ has $O(2^j)$ rounds, with failure probability $\frac{O(\log n)}{2^{\Theta(\frac{n^{1-\epsilon}2^i}{\log n})}}$ (over all groups). Further, we show that with the same failure probability, every two consecutive rounds in group 0 reduce the number of unsuccessful leaves by half. The total time taken for rounds in group 0 is then proportional to the sum of leaf sizes in this category. The time taken for rounds in the other groups is

$$O\left(\sum_{j=1}^{\Theta(\log n)} [2^j \frac{n^{1-\epsilon}2^i}{2^{j-1}\log n}\frac{n^\epsilon}{4^i}]\right) = O\left(\frac{n}{2^i}\right),$$

as required.

The key property. To show the above claims on the number of rounds in each group, we will need the following property, obtained using the Chernoff bound [2]. If there are $\#u$ unsuccessful leaves at some instant of time, then half these leaves succeed in the next $2k$ rounds, with failure probability $\frac{1}{2^{\Theta(\#uk)}}$.

Group 0. First, consider group 0. If the number of unsuccessful leaves at some instant is at least $\frac{n^{1-\epsilon}2^i}{\log n}$, then two rounds will halve the number of unsuccessful leaves, with failure probability at most $\frac{1}{2^{\Theta(\frac{n^{1-\epsilon}2^i}{\log n})}}$ (apply the above property with $k = 1$ and $\#u \geq \frac{n^{1-\epsilon}2^i}{\log n}$). Note that the number of leaves in the size category being considered is at most $\frac{n}{n^\epsilon/4^{i+1}} = n^{1-\epsilon}4^{i+1}$ to begin with. It follows that group 0 has $2(i+2+\log\log n)$ rounds, and halving occurs in each pair of consecutive rounds, with failure probability at most $\frac{(i+2+\log\log n)}{2^{\Theta(\frac{n^{1-\epsilon}2^i}{\log n})}} = \frac{O(\log n)}{2^{\Theta(\frac{n^{1-\epsilon}2^i}{\log n})}}$.

Other groups. Next, consider group j, $j \geq 1$. Applying the above property with $k = 2^j$ and $\#u \geq \frac{n^{1-\epsilon}2^i}{2^j \log n}$, we get that group j has $2\cdot 2^j$ rounds, with failure probability $\frac{1}{2^{\Theta(\frac{n^{1-\epsilon}2^i 2^j}{2^j \log n})}} = \frac{1}{2^{\Theta(\frac{n^{1-\epsilon}2^i}{\log n})}}$. Finally, adding up the failure probability over all $O(\log n)$ groups gives $\frac{O(\log n)}{2^{\Theta(\frac{n^{1-\epsilon}2^i}{\log n})}}$, as required.

The total time and space taken above is thus $O(n)$, with high probability. Searching for an element requires following the unique path down the partition tree to reach the relevant perfect-hash table. These operations are easily seen to take $O(1)$ worst-case time.

Comment. This analysis can also be applied to the second stage of the standard FKS scheme, assuming the first stage has succeeded (i.e., the initial hash has partitioned the items so that the expected number of pairwise collisions is $O(n)$, and so every bucket holds $O(n^{1/2})$ items). We then conclude that the second stage fails with close to exponentially small probability.

This might lead one to consider a high probability 3-stage FKS-like scheme. The first stage will be the standard FKS first stage, but it will be decreed to succeed if the number of pairwise collisions is at most $n^{3/2}$. This happens with probability $1 - O(1/n^{1/2})$ by Markov's inequality. This step can be repeated up to $2d$ times to obtain a failure probability of $O(1/n^d)$. The sets resulting from the first stage are then hashed using a standard 2-stage FKS scheme, but as each of these sets has size $O(n^{3/4})$, by an analysis similar to the one of this section one obtains a close to exponentially small failure probability. Thus the overall failure probability is $O(1/n^d)$. Note that as the first stage is repeated only if necessary, this appears to entail fewer arithmetic steps than using a $2d$-independent hash function.

7.3. The dynamic hashing scheme. The dynamic version of the above static scheme maintains the partition tree described in Step 2 above at each instant (with the same parameters; i.e., A has size n^c and the branching factor is n^ϵ; here n is the total number of items which will ever be inserted).

Initially, the partition tree will have just an empty root node. This tree will build up as insertions are made. The size of the partition tree at any instant will be proportional to the number of items in it. Further, at each instant, the perfect-hash structure at any leaf will have an associated *capacity*. This capacity will be at least the number of items at that leaf but no more than twice this quantity. It follows that the total space required at any instant will be proportional to the number of items present.

The algorithm for an insertion is described next. Note that our compacted tree application involves only insertions and no deletions.

Insertions. On an insertion x, the path down this partition tree to the appropriate leaf v is traced in $O(1)$ time. Subsequently, there are two cases depending upon how many items are already present in this leaf v.

First, suppose v has more than n^ϵ items, including x. Then the subarray associated with v is subdivided as in Step 2 of the static algorithm, and the subtree rooted at v is developed. Each leaf in this tree will have at most n^ϵ elements in it. The elements in each of these leaves are then perfect-hashed.

Next, suppose v has at most n^ϵ items, including x. Then the items already in v would have been perfect-hashed; further, this perfect-hash structure will have a certain capacity. If this capacity is equaled by the insertion of x, then all the items in v (including x) are rehashed into a perfect-hash structure of twice the capacity. Otherwise, if this capacity is not equaled, then v is perfect-hashed. If there is no collision, then v's insertion is complete. Otherwise, if there is a collision, then all the items in v along with x are perfect-hashed again.

Time analysis. We will show that the total time taken to perform n insertions is $O(n)$, with failure probability at most $\frac{O(\log n)}{2^{\Theta(n^{1-\epsilon}/\log n)}}$. To show the above, the following facts need to be noted.

1. The height of the partition tree is $O(1)$; therefore, the time spent in developing leaves into subtrees on insertion is just $O(n)$ over all n insertions.
2. The perfect-hash structure at any leaf in the partition tree begins with capacity which is twice the number of items currently in the structure. Future insertions increase this number until it equals the capacity. Until this happens, this perfect-hash structure stays in place, though it may have to be rebuilt as many times as collisions are caused by insertions. Once the number of items matches the capacity, this perfect-hash structure is abandoned, and a new perfect-hash structure with twice the capacity is put in place.
3. The total capacities of all perfect-hash structures which were ever in existence at any time during the n insertions is $O(n)$ (note that when a perfect-hash structure at a leaf is replaced by a new structure with twice the capacity, each structure is counted separately in the above sum). This follows from the doubling of capacities at a leaf and from the constant depth of the partition tree.
4. When the capacity of a perfect-hash structure at a leaf is doubled, the probability that this structure needs rebuilding before the number of items in it equals the new capacity is at most $1/2$. Further, the time taken for rebuilding a particular perfect-hash structure is proportional to its capacity.
   Note the difference from the static case, where a perfect-hash trial succeeds on the items currently present with probability $1/2$. Now, this is replaced by the fact that a perfect-hash trial succeeds with probability $1/2$ even on future insertions as long as the capacity is not equaled.

Thus, to establish the total time bound above, it suffices to bound the total time taken for rebuilding the perfect-hash structures at the various leaves. This in turn boils down to the following question: What is the total time taken to perform several FKS perfect hashings, where the total sizes of all subproblems is $\Theta(n)$, each subproblem has size at most n^ϵ, and a subproblem is performed successfully in linear time with probability $1/2$? The analysis is now identical to the static case.

We conclude with two remarks on generalizing the above scheme when the number of items is unknown and deletions need to be performed as well. Neither of these is relevant to our application of constructing suffix trees.

Unknown number of items. Suppose the number of items to be hashed is an unknown quantity m, with each item coming from the range $1 \ldots n^c$. Then we start with an initial estimate of 1 and double the estimate each time it is equaled by

insertions. Suppose the current estimate is $2e$, and the number of items inserted is e. We first hash these items into an imaginary array A of size $(2e)^c$. No collisions occur, with inverse polynomial (in e) failure probability (using families of almost-universal hash functions). We repeatedly try new hash functions until no collisions occur. Subsequently, we build the partition tree with degree $(2e)^\epsilon$. When the number of insertions equals $2e$, we double our estimate to $4e$ and rebuild the entire structure. If the total number of insertions is m, then the total time and space required is $O(m)$, with probability 1 minus an inverse polynomial in m. This failure probability can be reduced to $\frac{1}{m^{\Theta(\log m)}}$ by using a family of hash functions defined by Siegel [13], instead of a family of almost-universal hash functions.

Deletions. Deletions can be easily handled as follows. A deleted item is just marked as deleted, without causing any other change to the data structure. Whenever the number of items marked as deleted becomes a constant fraction of the number of items currently in the data structure the entire structure is rebuilt on the undeleted items. The running time remains $O(m)$ for m insertions and deletions, with the same failure probability as above. The space at any instant is proportional to the number of undeleted items.

NONDETERMINISTIC COMMUNICATION WITH A LIMITED NUMBER OF ADVICE BITS*

JURAJ HROMKOVIČ† AND GEORG SCHNITGER‡

Abstract. We present a new technique for differentiating deterministic from nondeterministic communication complexity. As a consequence we give almost tight lower bounds for the nondeterministic communication complexity with a restricted number of advice bits. In particular, for any function $t : \mathbb{N} \to \mathbb{N}$ with $t(n) \leq n/2$ we construct a family $(L_{n,t(n)} : n \in \mathbb{N})$ of languages such that

- $L_{n,t(n)} \subseteq \{0,1\}^{2n}$,
- $\mathrm{nc}(L_{n,t(n)}) = O(t(n) \cdot \log_2 \frac{n}{t(n)})$ and $\mathrm{nc}(\overline{L_{n,t(n)}}) = O\big(\frac{n}{t(n)\cdot \log_2 \frac{n}{t(n)}} + \log_2 t(n)\big)$,
- but $\mathrm{nc}_{o(t(n))}(L_{n,t(n)}) = \Omega\big(\frac{n}{\log_2 \frac{n}{t(n)}}\big)$.

Here $\mathrm{nc}_r(L)$ is the nondeterministic communication complexity of L, assuming that at most r advice bits are utilized. Thus, in contrast to probabilistic communication complexity, a small reduction in the number of advice bits results in almost maximal communication. As a special case we obtain a family $L_n \subseteq \{0,1\}^{2n}$ of languages with

$$\mathrm{nc}_{o(\sqrt{n}/\log_2 n)}(L_n) = \Omega\left(\frac{n}{\log_2 n}\right),$$
$$\mathrm{nc}(L_n) + \mathrm{nc}(\overline{L_n}) = O(\sqrt{n}),$$

and hence nondeterministic communication with slightly restricted access to advice bits is almost quadratically weaker than nondeterminism that always gives correct answers (from the set {yes, no, ?}). As a consequence we obtain an almost optimal separation between Monte-Carlo communication and "correct" nondeterminism and answer a question of Beame and Lawry.

Key words. communication complexity, nondeterminism

1. Introduction.

Communication complexity for two-party protocols [1, 21] is one of the most thoroughly investigated complexity measures (see, for instance, the textbooks [9, 15]). Communication complexity is closely related to fundamental complexity measures of several parallel and sequential computational models, i.e., Boolean circuits [19], VLSI circuits [16], Turing machines [14], branching programs and pseudorandomness [4], and combinatorial optimization [20].

An additional reason to investigate communication complexity is to determine exact relationships between the computation modes determinism, nondeterminism, and probabilism [2, 3, 11, 17]. In this paper we consider the number of advice bits for nondeterministic two-party communication as a computational resource. The related problem, namely, restricting the number of random bits for probabilistic two-party communication, has been considered in [6, 7, 18]. In [18] it was shown that a logarithmic number of random bits suffices for optimal probabilistic (i.e., Las Vegas, Monte-Carlo and bounded-error) protocols. We show that the situation for nondeterministic communication is completely different.

Let $L \subseteq \{0,1\}^{2n}$ be a given language. We assume the fixed-partition model of communication complexity; i.e., processor A (resp., B) receives an input $x \in \{0,1\}^n$ (resp., $y \in \{0,1\}^n$), and both processors try to determine whether $(x,y) \in L$. We assume that an advice bit is given to a processor that requests it; hence we work within the model of *private* nondeterministic communication as opposed to the public model, in which both processors know the advice bits. For a natural number $r \in N$, let

$$\mathrm{nc}_r(L)$$

be the nondeterministic communication complexity of L restricted to protocols that do not require more than r advice bits. $\mathrm{nc}(L) = \mathrm{nc}_n(L)$ denotes the conventional nondeterministic communication complexity, whereas $\mathrm{c}(L) = \mathrm{nc}_0(L)$ is the deterministic communication complexity of L. We can now state our main result.

THEOREM 1.1. *Let $t : \mathbb{N} \to \mathbb{N}$ be an arbitrary function with $t(n) \leq n/2$. Then there is a family $L_{n,t(n)} \subseteq \{0,1\}^{2n}$ of languages with*

$$\begin{aligned}
\mathrm{nc}(L_{n,t(n)}) &= O\left(t(n) \cdot \log_2 \frac{n}{t(n)}\right), \\
\mathrm{nc}(\overline{L_{n,t(n)}}) &= O\left(\frac{n}{t(n) \cdot \log_2 \frac{n}{t(n)}} + \log_2 t(n)\right), \quad \textit{or alternatively} \\
\mathrm{nc}_{\log_2 t(n)}(\overline{L_{n,t(n)}}) &= O\left(\frac{n}{t(n)} + \log_2 t(n)\right), \quad \textit{but} \\
\mathrm{nc}_{o(t(n))}(L_{n,t(n)}) &= \Omega\left(\frac{n}{\log_2 \frac{n}{t(n)}}\right).
\end{aligned}$$

Observe that $\mathrm{nc}_r(L) = \mathrm{nc}(L)$, provided $\mathrm{nc}(L) \leq r$. Thus the nondeterministic communication of $L_{n,t(n)}$ remains bounded by $s = O(t(n) \cdot \log_2 \frac{n}{t(n)})$, even if at most s advice bits are available, and Theorem 1.1 describes an almost maximal blow-up in communication, when the number of advice bits is reduced by a logarithmic factor.

Nondeterministic communication can be restricted to being one-way without increasing communication costs. Klauck [13], however, shows a round hierarchy for nondeterministic communication with slightly restricted access to advice bits.

The crucial dependence on the number of advice bits is not just limited to nondeterministic communication, but applies to *self-verifying nondeterminism* as well, where three types of answers may be given: *yes*, *no*, and *I do not know*. Whenever the answer is "yes" or "no," then the answer has to be correct, and for each input one of these answers has to be given by at least one computation.

It is not difficult to see that svnc(L), the communication complexity of self-verifying protocols for a language L, satisfies the inequality

$$\max\{\mathrm{nc}(L), \mathrm{nc}(\overline{L})\} \leq \mathrm{svnc(L)} \leq \max\{\mathrm{nc(L)}, \mathrm{nc}(\overline{\mathrm{L}})\} + 1,$$

and we get $\mathrm{c}(L) = O(\mathrm{svnc(L)}^2)$ [2]. Our next result shows that this quadratic gap also appears between self-verifying nondeterminism and nondeterminism with slightly restricted access to advice bits. If we impose the restriction $t(n) \leq \sqrt{n}/\log_2 n$ in Theorem 1.1, then the nondeterministic communication complexity of $\overline{L_{n,t(n)}}$ dominates the nondeterministic communication complexity of $L_{n,t(n)}$, and hence $\mathrm{svnc}(L_{n,t(n)}) = O(\frac{n}{t(n) \cdot \log_2 n})$. Moreover, we can reduce the consumption of advice bits for $\overline{L_{n,t(n)}}$ by choosing the alternative version, and we get the following.

COROLLARY 1.2. *Let $t : \mathbb{N} \to \mathbb{N}$ be an arbitrary function with $t(n) \leq \sqrt{n}/\log_2 n$. Then there is a family $L_{n,t(n)} \subseteq \{0,1\}^{2n}$ of languages with*

$$\begin{aligned} \operatorname{svnc}(L_{n,t(n)}) &= O\left(\frac{n}{t(n)\cdot \log_2 n}\right), \quad \textit{or alternatively} \\ \operatorname{svnc}_{t(n)\cdot\log_2 n}(L_{n,t(n)}) &= O\left(\frac{n}{t(n)}\right), \quad \textit{but} \\ \operatorname{nc}_{o(t(n))}(L_{n,t(n)}) &= \Omega\left(\frac{n}{\log_2 n}\right). \end{aligned}$$

If we set $t(n) = \sqrt{n}/\log_2 n$ and $L_n = L_{n,t(n)}$, then the almost quadratic and thus almost maximal blow-up between slightly restricted nondeterministic communication and self-verifying nondeterminism becomes apparent.

COROLLARY 1.3. *There is a family $L_n \subseteq \{0,1\}^{2n}$ of languages with*

$$\begin{aligned} \operatorname{svnc}(L_n) &= O(\sqrt{n}), \quad \textit{but} \\ \operatorname{nc}_{o(\sqrt{n}/\log_2 n)}(L_n) &= \Omega\left(\frac{n}{\log_2 n}\right). \end{aligned}$$

Thus nondeterministic and self-verifying nondeterministic protocols show a completely different behavior compared with their probabilistic counterparts, Monte-Carlo and Las Vegas protocols, which require at most $O(\log_2 n)$ random bits [18].

Beame and Lawry ([5]; see also problem 3.11 in [15]) ask whether the communication complexity of self-verifying nondeterministic protocols is an asymptotic upper bound for the Las Vegas communication complexity. We show that Corollary 1.3 implies a negative answer even for Monte-Carlo communication. Let $\operatorname{mcc}(L)$ be the Monte-Carlo communication complexity of L, where we assume error probability $\frac{1}{2}$. By [18] we have $\operatorname{mcc}(L) \geq \operatorname{nc}_{O(log_2 n)}(L) - O(\log_2 n)$, and hence Corollary 1.3 implies

$$\operatorname{mcc}(L_n) = \Omega\left(\frac{\operatorname{svnc}(L_n)^2}{\log_2 n}\right).$$

Thus there is an almost quadratic gap (and hence almost maximal gap) between Monte-Carlo communication and self-verifying nondeterminism. This consequence of Theorem 1.1, however, is superseded by a recent result of [12], which constructed a family of languages $L_n \subseteq \{0,1\}^n$ with two-sided error randomized communication complexity $\Theta(n)$ and self-verifying nondeterministic communication complexity $\Theta(\sqrt{n})$.

The proof of Theorem 1.1 utilizes the fact that a nondeterministic protocol with r advice bits is a collection of at most 2^r deterministic protocols. Hence one such deterministic protocol exists that accepts at least $\frac{|L_{n,t(n)}|}{2^r}$ entries of $L_{n,t(n)}$ and rejects all elements of the complement. Let us call such a protocol an r-protocol.

Proof techniques are required that give good results for the communication complexity of r-protocols but weak results for nondeterministic protocols. We briefly discuss the most prominent general techniques, i.e., the rank method, fooling sets, and upper-bounding the size of monochromatic submatrices.

The rank method does not seem to be adequate, since it does not apply to nondeterminism, even when limiting the number of advice bits. Moreover, the following observation shows that each language $L \subseteq \{0,1\}^n$ can be decomposed into $O(\log_2 n)$

languages L_i such that the rank of each L_i over $\mathbb{Z}_2$ is bounded by the nondeterministic communication complexity of L. The argument, however, does not apply to the rank over the reals. (For a language $K \subseteq \{0,1\}^{2n}$ let $\text{rank}_F(K)$ be the rank of the communication matrix of K over the field F.)

PROPOSITION 1.4. *Let $L \subseteq \{0,1\}^{2n}$ be an arbitrary language with $\text{nc}(L) = c$. Then languages $L_1, \ldots, L_{2n+1} \subseteq \{0,1\}^{2n}$ exist such that*

$$L = \bigcup_{i=1}^{2n+1} L_i \quad \textit{and} \quad \log_2(\text{rank}_{\mathbb{Z}_2}(L_i)) \leq \text{nc}(L) \quad \textit{for all } i.$$

In other words, $\log_2(2n+1)$ advice bits suffice to recognize L if we are allowed to replace deterministic protocols by "small-rank" protocols.

Proof. Let $\text{nc}(L) = k$. Then we obtain the representation $M = \bigcup_{i=1}^{2^k} M_i$ for the communication matrix M of L: An optimal nondeterministic protocol consists of at most 2^k accepting messages, which each contribute a rank-1 matrix M_i. For a vector α of 2^k zeroes and ones we define the matrix

$$M(\alpha) = \sum_{i=1}^{2^k} \alpha_i \cdot M_i$$

over $\mathbb{Z}_2$. Observe that $\text{rank}(M(\alpha)) \leq 2^k$ and that

$$M[i,j] = 0 \Rightarrow M(\alpha)[i,j] = 0.$$

On the other hand, if we choose the vector α at random, then

$$\text{prob}[M(\alpha)[i,j] = 0] = \frac{1}{2}$$

for any *positive* entry (i,j) (i.e., $M[i,j] = 1$).

Hence if we choose $2n+1$ vectors $\alpha^{(1)}, \ldots, \alpha^{(2n+1)}$ at random, we get

$$\text{prob}[M(\alpha^{(1)})[i,j] = 0 \wedge \cdots \wedge M(\alpha^{(2n+1)})[i,j] = 0] = \frac{1}{2^{2n+1}}$$

for any positive entry (i,j). Thus $\alpha^{(1)}, \ldots, \alpha^{(2n+1)}$ exist with

$$M(\alpha) = \bigcup_{i=1}^{2n+1} M(\alpha_i),$$

and the claim follows if we define L_i as the language with communication matrix $M(\alpha^{(i)})$. □

The methods of 1-*fooling sets* [9, 15] (i.e., determining large sets of 1-entries of the communication matrix with the fooling set property) and 1-*chromatic submatrices* [9, 15] (i.e., upper-bounding the size of the largest 1-chromatic submatrix) have to fail since they yield lower bounds for nondeterministic communication as well. The corresponding methods of 0-*fooling sets* and 0-*chromatic submatrices* cannot be applied without change, since elements of the language may be rejected. Thus, in order to prove lower bounds for protocols with a restricted degree of nondeterminism, we have to develop new proof techniques.

The situation is far easier if we consider a sublogarithmic number of advice bits. The language $\text{NID}_n = \{(x,y) : x, y \in \{0,1\}^n \text{ and } x \neq y\}$ benefits the most if many advice bits are available.

PROPOSITION 1.5.
(a) *For each language* $L \subseteq \{0,1\}^{2n}$ *and any* $r \in N$,

$$\mathrm{nc}_r(L) \geq \frac{\mathrm{c}(L)}{2^r}.$$

(b) $\frac{n}{2^r} \leq \mathrm{nc}_{r+1}(\mathrm{NID}_n) \leq \frac{n}{2^r} + r + 1$.

Proof. (a) A nondeterministic protocol with r advice bits and c exchanged bits can be simulated by a deterministic protocol with $2^r \cdot c$ exchanged bits.

(b) We describe a nondeterministic protocol for NID_n. The protocol partitions the n bits of processor A into at most $2^r + 1$ intervals of length $\lfloor \frac{n}{2^r} \rfloor$. Processor A guesses an interval (with at most $r+1$ advice bits) and communicates the interval and its bits. □

The paper is organized as follows. The next section introduces a disjointness language that will be hard for restricted nondeterminism. Section 3 introduces the crucial concept of simple and double witnesses and shows some basic properties. A proof sketch and a description of a new approach for distinguishing deterministic and nondeterministic communication complexity make up section 4. The argument is completed in sections 5 through 7. Conclusions and open problems are given in section 8.

2. A disjointness language. From now on we fix nonnegative integers m, n, and s (with $n \leq m$). We begin with a construction of the language family mentioned in Theorem 1.1.

DEFINITION 2.1.
(a) $\mathcal{P}_{m,n}$ *denotes the collection of all* n*-element subsets of* $\{1, \ldots, m\}$, *and*

$$\mathcal{P}_{m,n}^{(s)} = \times_{i=1}^{s} \mathcal{P}_{m,n}.$$

(b) *Let* L *be a subset of* $\{0,1\}^{2n}$. *The set*

$$L^{(s)} = \{(x_1, \ldots, x_s; y_1, \ldots, y_s) : \forall\, i,\ x_i, y_i \in \{0,1\}^n \text{ and } (x_i, y_i) \in L\}$$

is called the s*-fold direct sum of* L.
(c) $D_{m,n}$ *denotes the complement of the language of* set disjointness *when inputs are subsets of* $\{1, \ldots, m\}$ *of size* n, *i.e.,*

$$D_{m,n} = \{(x, y)\ :\ x, y \in \mathcal{P}_{m,n} \text{ and } x \cap y \neq \emptyset\}.$$

Theorem 1.1 is an immediate consequence of the following reformulation.

THEOREM 2.2. *Assume that* m *and* n *are sufficiently large with* $m \geq n^{32}$.
(a) $\mathrm{nc}(D_{m,n}^{(s)}) = O(s \cdot \log_2 m)$ *and* $\mathrm{nc}(\overline{D_{m,n}^{(s)}}) = O(n + \log_2(s \cdot \log_2 m))$.
(b) $\mathrm{nc}_{o(s)}(D_{m,n}^{(s)}) = \Omega(s \cdot n)$.

Obviously $\mathrm{nc}(D_{m,n}^{(s)}) = O(s \cdot \log_2 m)$ follows by having a nondeterministic protocol guess a common element s times. We exploit the following surprising result, which provides an efficient nondeterministic protocol to verify disjointness.

PROPOSITION 2.3 (Example 2.12 in [15]). *Assume that processors* A *and* B *receive* k*-element subsets* $x, y \subseteq \{1, \ldots, N\}$, *respectively. Then there is a nondeterministic protocol that verifies whether* x *and* y *are disjoint by exchanging at most* $O(k + \log\log N)$ *bits.*

As a consequence of Proposition 2.3 we obtain $\mathrm{nc}(\overline{D^{(s)}_{m,n}}) = O(n+\log_2(s\cdot\log_2 m))$, since guessing a pair of disjoint sets requires just $\log_2 s$ bits. Thus it remains to show part (b), and this is the topic of subsequent sections. Next we show that Theorem 1.1 is a consequence of Theorem 2.2.

Proof of Theorem 1.1. Input size k and the upper bound $t(k)$ on the number of advice bits are given. Choose n such that

$$k = \Theta\left(t(k)\cdot\log_2\binom{n^{32}}{n}\right).$$

Thus $k = \Theta(t(k)\cdot n\cdot\log_2 n)$ (resp., $n\cdot\log_2 n = \Theta(\frac{k}{t(k)})$), and hence $\log_2 n = \Theta(\log_2(n\cdot\log_2 n)) = \Theta(\log_2\frac{k}{t(k)})$. We set

$$L_{k,t(k)} = D^{t(k)}_{n^{32},n}.$$

We observe first that a nondeterministic protocol can recognize $L_{k,t(k)}$ by guessing common elements for each of the $t(k)$ sets. Hence $\mathrm{nc}(L_{k,t(k)}) = O(t(k)\cdot\log_2 n) = O(t(k)\cdot\log_2\frac{k}{t(k)})$.

To recognize the complement we guess one of the $t(k)$ sets and apply Proposition 2.3 to verify disjointness. Thus

$$\begin{aligned}\mathrm{nc}(\overline{L_{k,t(k)}}) &= O(n+\log_2\log_2 m+\log_2 t(k))\\ &= O\left(\frac{k}{t(k)\cdot\log_2 n}+\log_2 t(k)\right)\\ &= O\left(\frac{k}{t(k)\cdot\log_2\frac{k}{t(k)}}+\log_2 t(k)\right).\end{aligned}$$

Alternatively, we guess one of the $t(k)$ sets and then communicate this set completely. This gives

$$\begin{aligned}\mathrm{nc}_{\log_2 t(k)}(\overline{L_{k,t(k)}}) &= O(n\cdot\log_2 n+\log_2 t(k))\\ &= O\left(\frac{k}{t(k)}+\log_2 t(k)\right).\end{aligned}$$

We now use Theorem 2.2(b) for the lower bound on $L_{k,t(k)}$:

$$\begin{aligned}\mathrm{nc}_{o(t(k))}(L_{k,t(k)}) &= \mathrm{nc}_{o(t(k))}(D^{t(k)}_{n^{32},n})\\ &= \Omega(t(k)\cdot n) = \Omega\left(\frac{k}{\log_2 n}\right)\\ &= \Omega\left(\frac{k}{\log_2\frac{k}{t(k)}}\right),\end{aligned}$$

and the claim follows. □

3. Simple and double witnesses. Our argument is tailor-made for $D^{(s)}_{m,n}$ and more generally for direct sums of languages with small nondeterministic communication complexity. We utilize the properties of such languages through the crucial concepts of simple and double witnesses.

DEFINITION 3.1. *Let I be a subset of $\{1,\dots,s\}$.*
(a) *An element*

$$w \in \times_{i=1}^{s}(\mathcal{P}_{m,0} \cup \mathcal{P}_{m,1} \cup \mathcal{P}_{m,2})$$

is called a witness. If $|w_i| \le 1$ for all components i and $I = \{i : |w_i| = 1\}$, then w is called a simple *witness with core I. If $1 \le |w_i| \le 2$ for all components i and $I = \{i : |w_i| = 2\}$, then w is called a* double *witness with core I. Finally, we say that a witness w with core I is a witness for $x \in \mathcal{P}_{m,n}^{(s)}$, provided $w_i \subseteq x_i$ for all $i \in I$.*
(b) *$\mathrm{Witness}_{I,1}$ is the set of simple witnesses with core I, and $\mathrm{Witness}_{I,2}$ is the set of double witnesses with core I. We define for $r \in \{1,2\}$ and $x \in \mathcal{P}_{m,n}^{(s)}$*

$$\mathrm{Witness}_{I,r}(x) = \{w \ : \ w \in \mathrm{Witness}_{I,r} \text{ and for all } i \in I,\ w_i \subseteq x_i \ \}.$$

(c) *Let w be a witness, and let X be a subset of $\mathcal{P}_{m,n}^{(s)}$. Then*

$$p_X(w) = \frac{|\{x \in X \ : \ \text{for all } i,\ w_i \subseteq x_i \ \}|}{|X|}$$

is the probability that a random element of X possesses w as a witness.

If two elements $x, y \in \mathcal{P}_{m,n}^{(s)}$ possess a common simple witness w (with core I), then this witness guarantees an intersection of x_i and y_i for every component $i \in I$. Thus any common witness w with core $\{1,\dots,s\}$ testifies that (x,y) belongs to $D_{m,n}^{(s)}$.

We show in the next lemma that there is a *small* set of witnesses that is able to testify for a *large* number of entries of a 1-chromatic submatrix. Hence, on an intuitive level, the canonical nondeterministic protocol that guesses one witness *should* not be too far away from an optimal protocol.

LEMMA 3.2. *Let X and Y be subsets of $\mathcal{P}_{m,n}^{(s)}$ with $M = X \times Y$ as the induced submatrix of the communication matrix for $D_{m,n}^{(s)}$. Let I be a subset of $\{1,\dots,s\}$ of size k.*
(a) *$\sum_{w \in \mathrm{Witness}_{I,1}} p_X(w) = n^k$ and $\sum_{w \in \mathrm{Witness}_{I,1}} p_Y(w) = n^k$.*
(b) *Assume that M is 1-chromatic. Then*

$$\sum_{w \in \mathrm{Witness}_{I,1}} p_X(w) \cdot p_Y(w) \ge 1.$$

(c) *For $0 \le \rho \le 1$ set $W_I(\rho) = \{w \in \mathrm{Witness}_{I,1} : p_X(w) \ge \rho \text{ and } p_Y(w) \ge \rho\}$. Assume that M is 1-chromatic. Then, for every $\alpha > 0$,*

$$|W_I(\alpha \cdot n^{-k})| \le \frac{n^{2k}}{\alpha}$$

and

$$\sum_{w \in W_I(\alpha \cdot n^{-k})} p_X(w) \cdot p_Y(w) \ge 1 - 2\alpha.$$

Remark 3.1. Fix the core I of size k. Observe that there are exactly m^k simple witnesses with core I. Therefore, as a consequence of part (a), $(\frac{n}{m})^k$ is the average probability for a random element in X having a given witness. Hence the set $W_I(\alpha \cdot n^{-k})$ consists of highly likely witnesses, since $m \ge n^{32}$.

For $\alpha = \frac{1}{4}$ we get relatively few, namely $4 \cdot n^{2k} \ll m^k$, simple witnesses that already contribute $\frac{1}{2}$ towards the sum $\sum_{w \in \text{Witness}_{I,1}} p_X(w) \cdot p_Y(w)$.

Proof. (a) We first observe that $|\text{Witness}_{I,1}(x)| = n^k$ and hence obtain

$$\begin{aligned}\sum_{w \in \text{Witness}_{I,1}} p_X(w) &= \sum_{w \in \text{Witness}_{I,1}} \sum_{x \in X, w \in \text{Witness}_{I,1}(x)} \frac{1}{|X|} \\ &= \sum_{x \in X} \sum_{w \in \text{Witness}_{I,1}(x)} \frac{1}{|X|} \\ &= \sum_{x \in X} \frac{|\text{Witness}_{I,1}(x)|}{|X|} = \sum_{x \in X} \frac{n^k}{|X|} = n^k.\end{aligned}$$

(b) Assume that M is 1-chromatic. Then for each entry (x, y) of M there exists a simple witness w with core I and $w_i \subseteq x_i \cap y_i$ for all $i \in I$. Hence, since $p_X(w) \cdot |X|$ (resp., $p_Y(w) \cdot |Y|$) is the number of rows (resp., columns) with witness w,

$$|X| \cdot |Y| \leq \sum_{w \in \text{Witness}_{I,1}} p_X(w)|X| \cdot p_Y(w)|Y|,$$

and the claim follows.

(c) The upper bound on $|W_I(\alpha \cdot n^{-k})|$ is an immediate consequence of part (a). Moreover, we obtain again with part (a) that

$$\begin{aligned}&\sum_{w \in \text{Witness}_{I,1},\ w \notin W_I(\alpha \cdot n^{-k})} p_X(w) \cdot p_Y(w) \\ &\quad \leq \sum_{w \in \text{Witness}_{I,1}} p_X(w) \cdot \alpha \cdot n^{-k} + \sum_{w \in \text{Witness}_{I,1}} \alpha \cdot n^{-k} \cdot p_Y(w) \leq 2\alpha,\end{aligned}$$

and the remaining part of the claim follows. □

Next, we determine the size of $D^{(s)}_{m,n}$ and the expected number of entries with a double witness. It should not come as a surprise that this expected number is small when compared to the size of $D^{(s)}_{m,n}$, since double intersections are rare.

LEMMA 3.3.

(a) *If m and n are sufficiently large with $m \geq n^{32}$, then*

$$|D^{(s)}_{m,n}| \geq e^{-s/n} \cdot \left(\frac{n^2}{m}\right)^s \cdot \binom{m}{n}^{2s}.$$

(b) *Let $X = \mathcal{P}^{(s)}_{m,n}$. Then for any integer k $(1 \leq k \leq s)$*

$$\sum_{I \subseteq \{1,\ldots,s\}, |I|=k} \sum_{w \in \text{Witness}_{I,2}} p_X(w) \cdot p_X(w) \leq 2^{-k} \cdot \binom{s}{k} \cdot \left(\frac{n^2}{m}\right)^{s+k}.$$

Proof. (a) Fix an element $x \in \mathcal{P}^{(1)}_{m,n}$. If a set $y \in \mathcal{P}^{(1)}_{m,n}$ is randomly chosen, then

$$\text{prob}[x \text{ and } y \text{ intersect}] \geq n \cdot \frac{\binom{m-n}{n-1}}{\binom{m}{n}},$$

since the right-hand side counts intersections in exactly one element. Hence, provided that m and n are sufficiently large with $m \geq n^{32}$,

$$\begin{aligned}
\text{prob}[x \text{ and } y \text{ intersect}] &\geq \frac{n^2}{m} \cdot \frac{\binom{m-n}{n-1}}{\binom{m-1}{n-1}} \\
&= \frac{n^2}{m} \cdot \frac{m-n}{m-1} \cdots \frac{m-2n+2}{m-n+1} \\
&= \frac{n^2}{m} \cdot \left(1 - \frac{n-1}{m-1}\right) \cdots \left(1 - \frac{n-1}{m-n+1}\right) \\
&\geq \frac{n^2}{m} \cdot \left(1 - \frac{n-1}{m-n+1}\right)^{n-1} \\
&\geq \frac{n^2}{m} \cdot e^{-(n-1)\cdot\frac{n-1}{m-2n+2}} \qquad \text{since } (1-x) \geq e^{\frac{-x}{1-x}} \\
&\geq \frac{n^2}{m} \cdot e^{-1/n}.
\end{aligned}$$

Thus $|D^{(1)}_{m,n}| \geq e^{-1/n} \cdot (\frac{n^2}{m}) \cdot \binom{m}{n}^2$, and the claim follows since $|D^{(s)}_{m,n}| = |D^{(1)}_{m,n}|^s$.

(b) Let w be a double witness with core I and $|I| = k$. Remember that $X = \mathcal{P}^{(s)}_{m,n}$. Then

$$\begin{aligned}
p_X(w) &= \frac{\binom{m-2}{n-2}^k}{\binom{m}{n}^k} \cdot \frac{\binom{m-1}{n-1}^{s-k}}{\binom{m}{n}^{s-k}} \\
&= \left(\frac{n \cdot (n-1)}{m \cdot (m-1)}\right)^k \cdot \left(\frac{n}{m}\right)^{s-k} \\
&\leq \left(\frac{n}{m}\right)^{2k} \cdot \left(\frac{n}{m}\right)^{s-k} = \left(\frac{n}{m}\right)^{s+k}.
\end{aligned}$$

Hence

$$\begin{aligned}
\sum_{w \in \text{Witness}_{I,2}} p_X(w) \cdot p_X(w) &\leq \binom{m}{2}^k \cdot m^{s-k} \cdot \left(\frac{n}{m}\right)^{s+k} \cdot \left(\frac{n}{m}\right)^{s+k} \\
&\leq 2^{-k} \cdot m^{2k} \cdot m^{s-k} \cdot \left(\frac{n}{m}\right)^{s+k} \cdot \left(\frac{n}{m}\right)^{s+k} \\
&= 2^{-k} \cdot \left(\frac{n^2}{m}\right)^{s+k},
\end{aligned}$$

and the claim follows. □

4. A proof sketch. We first give a rough proof outline of Theorem 2.2(b). Assume that P_N is a nondeterministic protocol, which accepts $D^{(s)}_{m,n}$ with r advice bits and communicates $o(s \cdot n)$ bits. Then P_N consists of a collection of at most 2^r deterministic protocols $P_1, \ldots, P_{2^r}$, where each P_i accepts only inputs that belong to $D^{(s)}_{m,n}$ and communicates at most $o(s \cdot n)$ bits.

In order to show that r advice bits are also necessary it suffices to show that any *deterministic* protocol Q, which accepts only inputs from $D^{(s)}_{m,n}$ and exchanges at

most $o(s \cdot n)$ bits, accepts fewer than $|D^{(s)}_{m,n}|/2^r$ elements from $D^{(s)}_{m,n}$. Assume to the contrary that Q accepts at least the fraction

$$2 \cdot \frac{|D^{(s)}_{m,n}|}{2^{\varepsilon \cdot s}}$$

of elements from $D^{(s)}_{m,n}$. Then at least half of the entries that are accepted by Q belong to large 1-chromatic matrices $M_1, \ldots, M_x$, each with at least $\binom{m}{n}^s / 2^{o(s \cdot n)}$ rows and columns. Assume that M_i has X_i (resp., Y_i) as its set of rows (resp., columns) and let $X_0 = Y_0 = \mathcal{P}^{(s)}_{m,n}$ be the set of rows and columns of the communication matrix. Since Q is a deterministic protocol we get

$$\sum_{I,|I|=k} \sum_{w \in \mathrm{Witness}_{I,2}} p_{X_0}(w) \cdot p_{Y_0}(w) \geq \sum_{i=1}^{x} \frac{|X_i| \cdot |Y_i|}{|X_0| \cdot |Y_0|} \cdot \sum_{I,|I|=k} \sum_{w \in \mathrm{Witness}_{I,2}} p_{X_i}(w) \cdot p_{Y_i}(w). \tag{4.1}$$

Now, according to Lemma 3.2, there is a small set W^* of simple witnesses (with core $\{1, \ldots, s\}$) which testify for most nonempty intersections of $M = M_i$. For such a witness $w \in W^*$ let $M(w)$ be the large submatrix of M consisting of all rows and columns of M with simple witness w.

Imagine that we remove w from the row and column vectors of $M(w)$. (In other words, if x is the label of a row or column of $M(w)$, then we replace x by x' with $x'_i = x_i - \{w_i\}$.) We obtain a large submatrix, which will, however, in general not be 1-chromatic. Now assume that *any* large, not necessarily 1-chromatic, matrix has a considerable number of simple witnesses that are quite likely for both rows and columns. Then, provided that M is large, $M(w)$ has a large number of simple witnesses, and these witnesses turn into double witnesses after merging with w. (In general we will not obtain many simple witnesses with core $I = \{1, \ldots, s\}$, since even a large submatrix may possess components i with $x_i \cap y_i = \emptyset$ for all of its rows x and all of its columns y. Hence we have to work with large core sets.)

The following lemma expresses that M will indeed have many double witnesses.

LEMMA 4.1. *Let $\varepsilon \in]0,1[$ be sufficiently small. Assume that m and n are sufficiently large with $m \geq n^{32}$. Let $M = X \times Y$ be a 1-chromatic submatrix with*

$$|X| \geq 4 \cdot n^s \cdot \alpha_1^{s \cdot n} \cdot \binom{m}{n}^s \quad \text{and} \quad |Y| \geq 4 \cdot n^s \cdot \alpha_2^{s \cdot n} \cdot \binom{m}{n}^s,$$

where $\alpha_1, \alpha_2 \in [0,1[$ are sufficiently large. Then, for $k = (1 - 2\varepsilon) \cdot s$,

$$\sum_{I,|I|=k} \sum_{w \in \mathrm{Witness}_{I,2}} p_X(w) \cdot p_Y(w) \geq 2^{-15k/16} \cdot \binom{s}{k} \cdot \left(\frac{n^2}{m}\right)^k.$$

Our goal is to show that Q produces, through its large disjoint 1-chromatic submatrices M_i, far too many double witnesses. We apply Lemma 4.1 and get with (4.1)

$$\begin{aligned} \sum_{I,|I|=k} \sum_{w \in \mathrm{Witness}_{I,2}} p_{X_0}(w) \cdot p_{Y_0}(w) &\geq \sum_{i=1}^{x} \frac{|X_i| \cdot |Y_i|}{|X_0| \cdot |Y_0|} \cdot 2^{-15k/16} \cdot \binom{s}{k} \cdot \left(\frac{n^2}{m}\right)^k \\ &\geq \frac{|D^{(s)}_{m,n}|}{2^{\varepsilon \cdot s} \cdot \binom{m}{n}^{2s}} \cdot 2^{-15k/16} \cdot \binom{s}{k} \cdot \left(\frac{n^2}{m}\right)^k. \end{aligned}$$

However,

$$\frac{|D^{(s)}_{m,n}|}{\binom{m}{n}^{2s}} \geq e^{-s/n} \cdot \left(\frac{n^2}{m}\right)^s$$

and therefore

$$\sum_{I,|I|=k} \sum_{w \in \mathrm{Witness}_{I,2}} p_{X_0}(w) \cdot p_{Y_0}(w) \geq e^{-s/n} \cdot 2^{-15k/16-\varepsilon \cdot s} \cdot \binom{s}{k} \cdot \left(\frac{n^2}{m}\right)^{s+k}$$

for $X_0 = Y_0 = \mathcal{P}^{(s)}_{m,n}$. This contradicts assertion (b) of Lemma 3.3, and Theorem 2.2 follows.

Thus Lemma 4.1 is the technical core of our argument. To obtain the rather precise bounds, we follow a qualitative approach; namely, we show that it suffices to consider monotone submatrices M. The next section treats the problem of multiple counting when determining the number of double witnesses. Monotone submatrices will be investigated in section 6. Finally we conclude the argument in section 7, where we show that *any* large, not necessarily 1-chromatic matrix has a considerable number of simple witnesses which are quite likely for both rows and columns.

5. 1-chromatic submatrices and double witnesses. Our goal is to show Lemma 4.1. In a first step we reduce the problem of counting double witnesses in large 1-chromatic submatrices to the problem of counting simple witnesses in large but otherwise arbitrary submatrices.

We fix a 1-chromatic matrix $M = X \times Y$ with the properties described in Lemma 4.1. With Lemma 3.2(c) we obtain (for $\alpha = \frac{1}{4}$) a set W^* of simple witnesses with core $\{1, \ldots, s\}$ such that

$$p_X(w), p_Y(w) \geq \frac{1}{4 \cdot n^s} \quad \text{for all } w \in W^*, \tag{5.1}$$

$$|W^*| \leq 4 \cdot n^{2s}, \quad \text{and} \tag{5.2}$$

$$\sum_{w \in W^*} p_X(w) \cdot p_Y(w) \geq \frac{1}{2}. \tag{5.3}$$

Let ε be a positive real number to be determined later. For the moment we fix a subset $I \subseteq \{1, \ldots, s\}$ of size $k = (1 - 2\varepsilon) \cdot s \geq s/2$. For each $w^* \in W^*$ let $M(w^*) = X(w^*) \times Y(w^*)$ be the submatrix of $M = X \times Y$ consisting of exactly those entries (x, y) of M with w^* as a common witness (i.e., $w^*_i \subseteq x_i \cap y_i$ for all i). We obtain for each simple witness $w \in \mathrm{Witness}_{I,1}$ (with $w_i \neq w^*_i$ for all elements $i \in I$) the double witness $u = w^* \cup w$ for $M(w^*)$; i.e., $u_i = w^*_i \cup w_i$ for all i. However, we cannot immediately infer that the matrix M has a correspondingly large number of double witnesses with core I, since the double witness u may be induced by too many simple witnesses. Observe that this can happen only if u contains too many witnesses from the set W^*.

Let $u \in \mathrm{Witness}_{I,2}$ be a double witness. The set

$$W^*(u) := \{ w^* \in W^* \ : \ w^*_i \subseteq u_i \text{ for all } i \in I \}$$

contains all witnesses from W^* that "generate" u. We say that the simple witness $w \in \mathrm{Witness}_{I,1}$ *counts* if there is no double witness $u \in \mathrm{Witness}_{I,2}$ with $w_i \subseteq u_i$ for

all $i \in I$ and $|W^*(u)| \geq 2^{7k/8}$. If a witness counts, then none of its generated double witnesses contains more than $2^{7k/8}$ witnesses from W^*, and consequently multiple counting will be "modest." How many simple witnesses do not count?

Assume that w does not count and that the double witness u is the reason. If all elements of $W^*(u)$ agree on at most $k/4$ components from I with w, then they agree with $u - w$ on the remaining components, and hence

$$\begin{aligned}
|W^*(u)| &\leq \sum_{i=0}^{k/4} \binom{k}{i} \leq k \cdot \binom{k}{k/4} \\
&\leq k \cdot 4^{k/4} \cdot \left(\frac{4}{3}\right)^{3k/4} \qquad \text{since } \binom{t}{\alpha \cdot t} \leq \left(\frac{1}{\alpha}\right)^{\alpha \cdot t} \cdot \left(\frac{1}{1-\alpha}\right)^{(1-\alpha)\cdot t} \\
&= k \cdot \left(4 \cdot \frac{4^3}{3^3}\right)^{k/4} = k \cdot \left(\frac{4}{3^{3/4}}\right)^k \\
&< 2^{7k/8}.
\end{aligned}$$

The last inequality holds for sufficiently large k, since $\frac{4}{3^{3/4}} < 2^{7/8}$. In other words, if w does not count, then some element $w^* \in W^*$ agrees with w on at least $k/4$ components in I. But then, for $n \leq m^{1/32}$ and m sufficiently large, at most

$$\begin{aligned}
|W^*| \cdot \binom{k}{k/4} \cdot m^{3k/4} &\leq 4 \cdot n^{2s} \cdot \binom{k}{k/4} \cdot m^{3k/4} \qquad \text{because of (5.2)} \\
&\leq 2^{s+2} \cdot \left(\frac{n^{2s}}{m^{k/4}}\right) \cdot m^k \qquad \text{since } \binom{k}{k/4} \leq 2^s \\
&\leq 2^{s+2} \cdot \frac{m^k}{m^{k/8}} \qquad \text{since } n^2 \leq m^{1/16} \leq m^{k/(8\cdot s)} \\
&\leq (\varepsilon_2 \cdot m)^{(1-11\varepsilon_2)k}, \quad \text{where } \varepsilon_2 = \frac{1}{99}, \qquad (5.4)
\end{aligned}$$

witnesses in $\text{Witness}_{I,1}$ do not count.

The following lemma provides the promised reduction to counting simple witnesses. Before presenting the lemma, we set up a number of constants. Let w^* be an element of W^*. We decrement m and n by one to reflect that only restrictions of witnesses $w \in \times_{i=1}^{s}\{1,\ldots,m\} - \{w_i^*\}$ are considered. Remember that $|X| = 4n^s \cdot \alpha_1^{sn} \cdot \binom{m}{n}^s$, by assumption on the matrix M. Since $p_X(w^*) \geq \frac{1}{4\cdot n^s}$ (with (5.1)), we get

$$|X(w^*)| \geq \alpha_1^{s\cdot n} \cdot \binom{m}{n}^s \geq \alpha_1^{s\cdot(n-1)} \cdot \binom{m-1}{n-1}^s,$$

where the last inequality holds for sufficiently large m and n. The analogous statement holds of course for $|Y(w^*)|$ as well. Moreover, we choose $\alpha_1, \alpha_2 < 1$ so large that the following hold, with $\varepsilon_1 = \varepsilon$ and $\varepsilon_2 = \frac{1}{80}$:

$$\begin{aligned}
\alpha_1, \alpha_2 &> 4^{1/n-1} \cdot e^{-\varepsilon_1^4/2} \quad \text{and} \quad \varepsilon_1^2 \geq \frac{2(n-1)}{m-1}, \\
\alpha_1, \alpha_2 &> 4^{1/(n-1)} \cdot e^{-\varepsilon_2^3\cdot(1-\varepsilon_2)/4} \quad \text{and} \quad \varepsilon_2 \geq \frac{n-1}{(1-\varepsilon_2)\cdot(m-1)}, \\
\frac{1}{32} \cdot \frac{(1-\varepsilon_1)^{3s}}{\binom{s}{\varepsilon_1 \cdot s}} &\geq e^{-\varepsilon_2^2 \cdot s/2}.
\end{aligned}$$

This is clearly possible for the first four inequalities, provided m and n are sufficiently

large and $n^{32} \le m$. The fifth inequality follows if $\varepsilon_1 = \varepsilon$ is sufficiently small.

LEMMA 5.1. *$\alpha_1, \alpha_2 \in [0,1]$ as well as $\varepsilon_1, \varepsilon_2 \in [0, 1/6]$ satisfy the inequalities*

$$\alpha_1, \alpha_2 > 4^{1/n} \cdot e^{-\varepsilon_1^4/2} \quad \text{and} \quad \varepsilon_1^2 \ge \frac{2n}{m}, \tag{5.5}$$

$$\alpha_1, \alpha_2 > 4^{1/n} \cdot e^{-\varepsilon_2^3 \cdot (1-\varepsilon_2)/4} \quad \text{and} \quad \varepsilon_2 \ge \frac{n}{(1-\varepsilon_2)\cdot m}, \tag{5.6}$$

$$\frac{1}{32} \cdot \frac{(1-\varepsilon_1)^{3s}}{\binom{s}{\varepsilon_1 \cdot s}} \ge e^{-3 \cdot \varepsilon_2 \cdot s/2}. \tag{5.7}$$

Assume that X and Y are subsets of $\mathcal{P}^{(s)}_{m,n}$, with $|X| = \alpha_1^{s\cdot n} \cdot \binom{m}{n}^s$ and $|Y| = \alpha_2^{s\cdot n} \cdot \binom{m}{n}^s$. Then there is a subset $I \subseteq \{1, \ldots, s\}$ of size at least $k = (1-2\varepsilon_1)\cdot s$ such that, for any set W of simple witnesses with core I,

$$\sum_{w \in \mathrm{Witness}_{I,1} - W} p_X(w) \cdot p_Y(w) \ge \frac{1}{32} \cdot \frac{(1-\varepsilon_1)^{5k}}{\binom{s}{\varepsilon_1 \cdot s}^2} \cdot \left(\frac{n^2}{m}\right)^k,$$

provided $|W| \le (\varepsilon_2 \cdot m)^{(1-11\cdot\varepsilon_2)\cdot s}$.

In what follows we show that Lemma 5.1 implies Lemma 4.1. The proof of Lemma 5.1 is given in the subsequent sections.

We apply Lemma 5.1 to the submatrix $X(w^*) \times Y(w^*)$ and obtain a subset $I(w^*) \subseteq \{1, \ldots, s\}$ of size $k = (1-2\varepsilon)\cdot s$. Observe that at most $(\varepsilon_2 \cdot m)^{(1-11\varepsilon_2)k}$ simple witnesses from $\mathrm{Witness}_{I(w^*),1}$ do not count (because of (5.4)), and hence

$$\begin{aligned}\sum_{w \in \mathrm{Witness}_{I(w^*)} \text{ and } w \text{ counts}} p_{X(w^*)}(w) \cdot p_{Y(w^*)}(w) &\ge \frac{1}{32} \cdot \frac{(1-\varepsilon)^{5k}}{\binom{s}{\varepsilon\cdot s}^2} \cdot \left(\frac{(n-1)^2}{m-1}\right)^k \\ &\ge \frac{1}{64} \cdot \frac{(1-\varepsilon)^{5k}}{\binom{s}{\varepsilon\cdot s}^2} \cdot \left(\frac{n^2}{m}\right)^k.\end{aligned}$$

The last inequality holds for $n \ge 4$. We set

$$\mathrm{simple}(w^*, I) := \sum_{w \in \mathrm{Witness}_{I,1} \text{ and } w \text{ counts}} p_{X(w^*)}(w) \cdot p_{Y(w^*)}(w).$$

If a witness counts, then none of its generated double witnesses contains more than $2^{7k/8}$ witnesses from W^*. Hence

$$\begin{aligned}&\sum_{|I|=k} \sum_{w \in \mathrm{Witness}_{I,2}} p_X(w) \cdot p_Y(w) \\ &\quad\ge 2^{-7k/8} \cdot \sum_{|I|=k} \sum_{w^* \in W^*} p_X(w^*) \cdot p_Y(w^*) \cdot \mathrm{simple}(w^*, I) \\ &\quad\ge 2^{-7k/8} \cdot \sum_{w^* \in W^*} p_X(w^*) \cdot p_Y(w^*) \cdot \mathrm{simple}(w^*, I(w^*)) \\ &\quad\ge 2^{-7k/8} \cdot \sum_{w^* \in W^*} p_X(w^*) \cdot p_Y(w^*) \cdot \frac{1}{64} \cdot \frac{(1-\varepsilon)^{5k}}{\binom{s}{\varepsilon\cdot s}^2} \cdot \left(\frac{n^2}{m}\right)^k \\ &\quad\ge 2^{-7k/8} \cdot \frac{1}{128} \cdot \frac{(1-\varepsilon)^{5k}}{\binom{s}{\varepsilon\cdot s}^2} \cdot \left(\frac{n^2}{m}\right)^k \qquad \text{with (5.3)} \\ &\quad\ge 2^{-15k/16} \cdot \binom{s}{k} \cdot \left(\frac{n^2}{m}\right)^k,\end{aligned}$$

provided that the positive real number ε is chosen sufficiently small (and hence k is sufficiently large).

This concludes the proof of Lemma 4.1. We still have to deal with the problem of counting simple witnesses when disregarding a small witness-set. We start to tackle this problem in the next section, where we show that it suffices to investigate monotone submatrices.

6. Monotone submatrices. We have to give rather precise estimates of the number of entries with a double witness for large 1-chromatic submatrices. As already outlined above, we start by estimating the number of entries with a simple witness for large (not necessarily 1-chromatic) submatrices. To obtain tight bounds we follow a qualitative approach; namely, we show that it suffices to consider monotone submatrices.

DEFINITION 6.1.

(a) *Let* $x = (x_1, \ldots, x_s)$ *and* $y = (y_1, \ldots, y_s)$ *be elements of* $\mathcal{P}^{(s)}_{m,n}$ *with* $x_i = \{x_{i,1} < \cdots < x_{i,n}\}$ *and* $y_i = \{y_{i,1} < \cdots < y_{i,n}\}$. *Then*

$$x \leq y \quad \Leftrightarrow \quad x_{i,j} \leq y_{i,j} \quad \text{for all } i, j.$$

(b) *A subset* $X \subseteq \mathcal{P}^{(s)}_{m,n}$ *is called monotone decreasing (resp., monotone increasing) if for all* $x \in X$ *and for all* $y \in \mathcal{P}^{(s)}_{m,n}$

$$y \in X \text{ whenever } y \leq x \text{ (resp., } y \in X \text{ whenever } x \leq y).$$

(c) *A matrix* $M = X \times Y$ *is monotone provided* X *is monotone decreasing and* Y *is monotone increasing.*

Our first goal is to show that monotone submatrices minimize the sum

$$\sum_{w \in \mathrm{Witness}_{I,1}} p_X(w) \cdot p_Y(w).$$

This can be verified along the lines of Frankl and Füredi [8] (establishing Harper's isoperimetric inequality for the hypercube). In particular, they show that the minimal distance between two sets of vertices of the n-dimensional hypercube is minimized by choosing (generalized) Hamming balls centered at 0 (resp., 1). Since a Hamming ball around 0 (resp., 1) is in our terminology monotone decreasing (resp., increasing), this result supports the intuition that monotone submatrices "minimize intersections."

However, the situation gets involved since we also have to deal with a set W of forbidden witnesses and the transformation from an arbitrary matrix to a monotone matrix loses track of those witnesses. Therefore we introduce the concept of a *system*, consisting of a submatrix $M = X \times Y$ and assignments f, g of sets of forbidden witnesses to elements of X and Y, respectively.

DEFINITION 6.2. *Let* I *be a subset of* $\{1, \ldots, s\}$. *A* system (X, f, Y, g, I) *consists of subsets* $X, Y \subseteq \mathcal{P}^{(s)}_{m,n}$ *and assignments* $f : X \to \mathcal{P}(\mathrm{Witness}_{I,1})$ *and* $g : Y \to \mathcal{P}(\mathrm{Witness}_{I,1})$. *We define*

$$\mathrm{legal}_I(X, f, Y, g) = \{(x, w, y) \,:\, x \in X, y \in Y, \\ w \in (\mathrm{Witness}_{I,1}(x) - f(x)) \cap (\mathrm{Witness}_{I,1}(y) - g(y))\}.$$

Moreover, we demand that $f(x) \subseteq \mathrm{Witness}_{I,1}(x)$ *and* $g(y) \subseteq \mathrm{Witness}_{I,1}(y)$ *for all* $x, y \in Y$.

The next lemma allows us to restrict attention to monotone submatrices only.

LEMMA 6.3. *The sets $X, Y \subseteq \mathcal{P}^{(s)}_{m,n}$ are given. Then there is a monotone decreasing subset X' and a monotone increasing subset Y' with*

$$|X| = |X'| \quad \textit{and} \quad |Y| = |Y'|.$$

Moreover, for any subset $I \subseteq \{1, \ldots, s\}$ and any system (X, f, Y, g, I), a system (X', f', Y', g', I) exists such that

$$\sum_{x \in X} |f(x)| = \sum_{x' \in X'} |f'(x')| \quad \textit{and} \quad \sum_{y \in Y} |g(y)| = \sum_{y' \in Y'} |g'(y')|, \tag{6.1}$$

as well as

$$|\operatorname{legal}_I(X, f, Y, g)| \geq |\operatorname{legal}_I(X', f', Y', g')|. \tag{6.2}$$

Remark 6.1. Observe that the transformation from the sets X and Y to the sets X' and Y' is independent of the assignments f, g and the core I.

Let $p^*_X(w)$ be the probability that w occurs as a *legal* witness for a row of X, and define $p^*_Y(w)$, $p^*_{X'}(w)$, and $p^*_{Y'}(w)$ analogously. The last inequality of Lemma 6.3 now implies that

$$\sum_{w \in \operatorname{Witness}_{I,1}} p^*_X(w) \cdot p^*_Y(w) \geq \sum_{w \in \operatorname{Witness}_{I,1}} p^*_{X'}(w) \cdot p^*_{Y'}(w),$$

and we have reached our goal. However, now a witness may be legal for some rows and columns and forbidden for others. However, the number of pairs (x, w)—with w forbidden for x—remains unchanged.

Proof. We initially follow the construction in the argument of Frankl and Füredi [8]. In particular, set

$$[z] = \sum_{i=1}^{s} \sum_{j=1}^{n} z_{i,j}$$

for $z \in \mathcal{P}^{(s)}_{m,n}$, and introduce the weight-function

$$\operatorname{weight}(Z) = \sum_{z \in Z} [z]$$

for a subset $Z \subseteq \mathcal{P}^{(s)}_{m,n}$. If X is not monotone decreasing or if Y is not monotone increasing, then we construct subsets X' and Y' of $\mathcal{P}^{(s)}_{m,n}$ such that properties (6.1), (6.2) of the lemma are satisfied and

$$\operatorname{weight}(Y') - \operatorname{weight}(X') > \operatorname{weight}(Y) - \operatorname{weight}(X).$$

Obviously the lemma follows after repeating this procedure until monotonicity is reached.

We assume without loss of generality that X is not monotone decreasing and, in particular, that there is $x = (x_1, x_2, \ldots, x_s) \in X$ with $\xi \in x_1$, $\xi - 1 \notin x_1$ such that

$$(x_1 - \{\xi\} \cup \{\xi - 1\}, x_2, \ldots, x_s) \notin X.$$

For $x \in X$ set $\hat{x} = (x_1 - \{\xi\} \cup \{\xi - 1\}, x_2, \ldots, x_s)$ and define

$$\text{decrease}_\xi(x) = \begin{cases} \hat{x} & \text{if } x_1 \cap \{\xi - 1, \xi\} = \{\xi\} \text{ and } \hat{x} \notin X, \\ x & \text{otherwise.} \end{cases}$$

For $y \in Y$ set $\hat{y} = (y_1 - \{\xi - 1\} \cup \{\xi\}, y_2, \ldots, y_s)$ and define

$$\text{increase}_\xi(y) = \begin{cases} \hat{y} & \text{if } y_1 \cap \{\xi - 1, \xi\} = \{\xi - 1\} \text{ and } \hat{y} \notin Y, \\ y & \text{otherwise.} \end{cases}$$

We replace X and Y by

$$X' = \{\text{decrease}_\xi(x) \mid x \in X\} \quad \text{and} \quad Y' = \{\text{increase}_\xi(y) \in Y \mid y \in Y\}.$$

Thus we move x "down" (resp., y "up") whenever possible. We say that $x^* \in X$ is a *twin* of $x \in X$ if x^* and x differ only in their first component and one obtains x_1^* from x_1 by replacing ξ by $\xi - 1$ or vice versa. If $\{\xi - 1, \xi\} \subseteq x_1$, then x is called its own twin. Observe that a twin prevents x from moving down.

We get $|X| = |X'|$, $|Y| = |Y'|$, and moreover $\text{weight}(Y') - \text{weight}(X') > \text{weight}(Y) - \text{weight}(X)$, since $\text{weight}(Y') \geq \text{weight}(Y)$ and $\text{weight}(X') < \text{weight}(X)$.

Assume that $x' \in X'$ and $y' \in Y'$ are given with $\text{decrease}_\xi(x) = x'$ and $\text{increase}_\xi(y) = y'$ for $x \in X$ and $y \in Y$. We first consider the easy case $1 \notin I$ and define $f'(x') = f(x)$ and $g'(y') = g(y)$. Obviously property (6.1) holds as well as property (6.2): If $w \in \text{Witness}_{I,1}(x) - f(x)$, then $w \in \text{Witness}_{I,1}(x') - f'(x')$ since $1 \notin I$.

The case $1 \in I$ has to be treated more carefully. In particular, we move up forbidden witnesses for x' whenever possible. Why? Property (6.2) requires that the new system have no more legal triples (x', w, y') than the old system. The decrease-operation for X moves sets down, whereas the increase-operation for Y moves sets up, and thus the sets in X and Y are moved away from each other. Legal witnesses for the new sets x' and y' should also move away from each other and hence should be moved down (resp., up). To create space for these movements we move forbidden witnesses in the opposite direction whenever possible; these movements are harmless, since the intersections created by forbidden witnesses are not counted.

We now define $f'(x')$ and $g'(y')$ with the help of the decrease and increase operations relative to $f(x)$ as opposed to X (resp., relative to $g(y)$ as opposed to Y).

Case 1. $x' \notin X$ (resp., $y' \notin Y$). Remember that we obtain x' (resp., y') by moving x down (resp., by moving y up). We set

$$f'(x') = \{\text{decrease}_\xi(w) \ : \ w \in f(x)\} \quad \text{and} \quad g'(y') = \{\text{increase}_\xi(w) \ : \ w \in g(y)\}.$$

Hence $f(x)$ (resp., $g(y)$) is moved down (resp., up) as well. From now on we omit the definition of g', since it will be completely analogous to the definition of f'.

Case 2. $x' \in X$. Observe that $x' = x$.

Case 2.1. x has no twin in X. We set $f'(x) = f(x)$.

Case 2.2. x has a twin in X. We assume without loss of generality that $\xi - 1 \in x_1$. This time f' will move up witnesses whenever possible. In particular, if $x \neq \text{twin}(x)$, then we redistribute forbidden witnesses within $f(x) \cup f(\text{twin}(x))$. The witnesses in $f(x)$ all have $\xi - 1$ as their element. We remove such a witness w from $f(x)$ and insert its twin w^* into $f(\text{twin}(x))$ iff w^* is not already an element of $f(\text{twin}(x))$. Hence we set

$$f'(x) = \{w \in f(x) : w_1 \neq \xi - 1\} \cup \{w \in f(x) : w_1 = \xi - 1 \text{ and } \text{twin}(w) \in f(\text{twin}(x))\}.$$

The remaining forbidden witnesses from the union $f(x) \cup f(\text{twin}(x))$ are placed into $f'(\text{twin}(x))$. We can move up forbidden witnesses also if $x = \text{twin}(x)$, i.e., if $\{\xi - 1, \xi\} \subseteq x_1$. We set

$$f'(x) = \{\text{increase}_\xi(w) \ : \ w \in f(x)\}.$$

Observe that our construction of f' and g' satisfies property (6.1) of Lemma 6.3: We have either $|f'(x')| = |f(x)|$ or $|f'(x')| + |f'(x^*)| = |f(x')| + |f(x^*)|$ for twins x' and x^*.

In order to verify property (6.2) we define an injection

$$\text{count} \ : \ \text{legal}_I(X', f', Y', g') \ \rightarrow \ \text{legal}_I(X, f, Y, g).$$

Let $(x', u', y') \in \text{legal}_I(X', f', Y', g')$ be given. We assume that $x' = \text{decrease}_\xi(x)$ and $y' = \text{increase}_\xi(y)$ for $x \in X$ and $y \in Y$. We set $u = u' - \{\xi\} \cup \{\xi - 1\}$.

Case 1. $u'_1 \notin \{\xi - 1, \xi\}$. Then $(x, u', y) \in \text{legal}_I(X, f, Y, g)$, and we set count$(x', u', y') = (x, u', y)$. Obviously count is injective when restricted to arguments satisfying the case assumption.

Case 2. $u'_1 = \xi$. Since $\xi \in x'_1$, we obtain $x' = x$, and x was not moved down due to the twin $x^* \in X$. Let y^* be the twin of y if y has a twin in Y. We first make a few easy observations.

(A) If $x = x^*$, then $f'(x')$ was obtained by applying the increase-operation to $f(x)$. But $u' \notin f'(x')$, since u' is legal and hence $u, u' \notin f(x)$.

(B) If $y = y^*$, then $g'(y')$ was obtained by applying the decrease-operation to $g(y)$. It is not possible that both u and u' belong to $g(y)$, since otherwise $u' \in g'(y)$.

(C) If $x \neq x^*$, then $f'(x')$ keeps all forbidden witnesses from $f(x)$ and receives increased witnesses from $f(x^*)$. Since $u' \notin f'(x)$, we have $u \notin f(x^*)$ and $u' \notin f(x)$.

(D) If $y \neq y^*$, then $g'(y')$ is the subset of $g(y)$ obtained by removing all witnesses w, whose decreased version does not belong to $g(y^*)$. But $u' \notin g'(y)$, and thus if $u' \in g(y)$, then $u \notin g(y^*)$.

Case 2.1. $y' \neq y$. Hence y was moved up and obviously $u_1 \in y_1$. If $x = x^*$, then $u \notin f(x) = f(x^*)$ with (A). If $x \neq x^*$, then $u \notin f(x^*)$ with (C). In either case $u \notin f(x^*)$ and $u_1 = \xi - 1 \in x^*_1$. We set count$(x', u', y') = (x^*, u, y)$.

We can assume $y' = y$ from now on.

Case 2.2. $y = y^*$ and $x = x^*$. With (B) one of u or u' does not belong to $g(y)$ and with (A) $u, u' \notin f(x)$. Thus, if $u \notin g(y)$, set count$(x', u', y') = (x, u, y)$, and otherwise set count$(x', u', y') = (x, u', y)$.

Case 2.3. $y \neq y^*$ and $x = x^*$. We have $u, u' \notin f(x)$ with (A). If $u \notin g(y^*)$, we set count$(x', u', y') = (x, u, y^*)$. Otherwise $u' \notin g(y)$ with (D) and we set count(x', u', y') $= (x, u', y)$.

Case 2.4. $y = y^*$ and $x \neq x^*$. We have $u \notin f(x^*)$ and $u' \notin f(x)$ with (C). Moreover, it is not possible that both u and u' belong to $f(y)$ with (B). If $u \notin f(y)$, then set count$(x', u', y') = (x^*, u, y)$. Otherwise $u' \notin g(y)$ and we set count$(x', u', y') =$ (x, u', y).

Case 2.5. $y \neq y^*$ and $x \neq x^*$. Again we have $u \notin f(x^*)$ and $u' \notin f(x)$ with (C). If $u \notin g(y^*)$, then we set count$(x', u', y') = (x^*, u, y^*)$. Otherwise $u' \notin g(y)$ with (D) and we set count$(x', u', y') = (x, u', y)$.

Case 3. $u'_1 = \xi - 1$. This case is analogous to Case 2.

Why is "count" injective? Assume that $\text{count}^{-1}(x,w,y)$ is nonempty. If $w_1 \notin \{\xi-1,\xi\}$, then (x,w,y) is generated through Case 1, but count, when restricted to Case 1, is injective.

Now assume that (x,w,y) is generated through Case 2. We observe by inspection that if (x,w,y) is generated by one subcase, then no other subcase can generate (x,w,y): If $y \neq y'$, then Case 2.1 is responsible and all other subcases can be uniquely identified when checking which of x and y is its own twin.

By symmetry, injectivity within Case 3 is guaranteed as well. Thus injectivity can only be violated if (x,w,y) is generated through Case 2 *and* Case 3. By checking for $x \neq x'$, $y \neq y'$, and which of x and y are its own twin, one finds that a collision is possible only if Case 2.i collides with 3.i for $i \geq 2$. Each Case 2.i attempts first to assign the witness u with $u_1 = \xi - 1$ and assigns u' with $u'_1 = \xi$ only when this is impossible. Case 3 follows this approach symmetrically by trying first to assign the witness v with $v_1 = \xi$ and assigns v' with $v'_1 = \xi - 1$ only when this is impossible.

Now it suffices to observe that a failure in the first attempt in Case 2.i makes a generation by Case 3.i impossible. □

The next proposition states a basic property of monotone sets, namely, that the probability of a witness increases if we reduce one or several of its components.

PROPOSITION 6.4. *Let X be a monotone decreasing subset of $\mathcal{P}^{(s)}_{m,n}$. Then for any subset $I \subseteq \{1,\ldots,s\}$ and for any simple witnesses $u,v \in \text{Witness}_{I,1}$ with $u_i \leq v_i$ for all $i \in I$,*

$$p_X(u) \geq p_X(v).$$

Proof. Let $I \subseteq \{1,\ldots,s\}$ be given. Assume that a row $x \in X$ possesses v as a simple witness (i.e., $v_i \in x_i$ for all $i \in I$). We set $y_i = x_i$ whenever $i \notin I$, and otherwise

$$y_i = \begin{cases} x_i & \text{if } \{u_i,v_i\} \subseteq x_i, \\ x_i - \{v_i\} \cup \{u_i\} & \text{otherwise.} \end{cases}$$

The function f, with $f(x) = (y_1,\ldots,y_s)$, is an injection mapping elements of X with witness v to elements of X with witness u. The claim follows. □

The next lemma exhibits the crucial advantage of monotone sets, namely, that a large monotone set X possesses a witness w_X (with a large core set I) such that w_X

- has only large components and
- is nevertheless still quite likely.

In particular we describe the relationship between the size of X (expressed by α) on one side and the component size of w_X (expressed by β), the probability of w_X (expressed by ε), and the size of the core (expressed by δ) on the other side.

LEMMA 6.5. *$\alpha \in [0,1]$ and $\beta,\delta,\varepsilon \in [0,1/2]$ are nonnegative real numbers with*

$$\alpha > 4^{1/n} \cdot e^{-\varepsilon^2 \cdot \beta \cdot \delta/4} \quad \text{and} \quad \varepsilon \geq \frac{n}{\beta \cdot m}. \tag{6.3}$$

Let $X \subseteq \mathcal{P}^{(s)}_{m,n}$ be monotone decreasing with $|X| = \alpha^{n \cdot s} \cdot \binom{m}{n}^s$.

(a) *With probability at least $1-2^{-s}$, an element $(x_1,\ldots,x_s) \in X$ has the property that*

$$|\{(1-\beta)\cdot m+1,\ldots,m\} \cap x_i| \geq (1-\varepsilon)^2 \cdot \beta \cdot n$$

for at least $(1-\delta)\cdot s$ components i.

(b) *There is a subset* $I \subseteq \{1,\dots,s\}$ *with* $|I| = (1-\delta)\cdot s$ *such that for any subset* $J \subseteq I$ *of size* k *the simple witness* w^J*, with core* J *and* $w^J_j = (1-\beta)\cdot m$ *for* $j \in J$*, satisfies*

$$p_X(w^J) \geq \frac{(1-\varepsilon)^{2k}}{2\cdot\binom{s}{\delta\cdot s}}\cdot\left(\frac{n}{m}\right)^k.$$

Proof. (a) We first determine an upper bound for the probability

$$p_E = \mathrm{prob}[|y \cap \{(1-\beta)\cdot m+1,\dots,m\}| \leq E],$$

where y is a random subset of $\{1,\dots,m\}$ of size n. We claim that

$$p_E \leq \mathrm{prob}\left[\sum_{i=1}^{n} Y_i \leq E\right], \tag{6.4}$$

where

$$Y_i = \begin{cases} 1 & \text{with probability } \beta - \frac{n}{m}, \\ 0 & \text{with probability } 1-\beta+\frac{n}{m}. \end{cases}$$

Assume that we pick n elements from $\{1,\dots,m\}$ without replacement and call the selection of an element from $\{(1-\beta)\cdot m+1,\dots,m\}$ a success. Then the success probability in the $n+1$st attempt will be minimal if all previous attempts have been successful, and hence the success probability is always at least $\frac{\beta\cdot m-n}{m} = \beta - \frac{n}{m}$. Hence (6.4) follows, since the probability of staying below the threshold E is higher when we assume a smaller success probability.

We have $\varepsilon \geq \frac{n}{\beta\cdot m}$ (with (6.3)) and therefore $1-\frac{n}{\beta\cdot m} \geq 1-\varepsilon$. Thus,

$$\beta - \frac{n}{m} \geq (1-\varepsilon)\cdot\beta \ \text{ and } \ \beta-\frac{n}{m} \geq \frac{\beta}{2} \ \left(\text{since } \varepsilon \leq \frac{1}{2}\right). \tag{6.5}$$

Observe that $E^* = (\beta - \frac{n}{m})\cdot n$ is the expected value of $\sum_{i=1}^{n} Y_i$. We set $E = (1-\varepsilon)\cdot E^*$ and obtain as a consequence of Chernoff's bound

$$\begin{aligned} p_E &\leq \mathrm{prob}\left[\sum_{i=1}^{n} Y_i \leq (1-\varepsilon)\cdot E^*\right] \\ &\leq e^{-\varepsilon^2\cdot E^*/2}. \end{aligned}$$

Let J be a subset of $\{1,\dots,s\}$, and let $p_E(J)$ be the probability that a randomly chosen element $x = (x_1,\dots,x_s)$ of $\mathcal{P}^{(s)}_{m,n}$ has the property that x_j, for all $j \in J$, intersects $\{(1-\beta)\cdot m+1,\dots,m\}$ in at most E elements. Then we get

$$p_E(J) \leq e^{-\varepsilon^2\cdot E^*\cdot|J|/2}$$

and, as a consequence,

$$\sum_{J\subseteq\{1,\dots,s\},|J|=\delta\cdot s} p_E(J) \leq 2^s\cdot e^{-\varepsilon^2\cdot E^*\cdot\delta\cdot s/2}.$$

In other words, the probability that a randomly chosen element x intersects $\{(1-\beta)\cdot m+1,\ldots,m\}$ in at most E elements for $\delta\cdot s$ components is small. On the other hand, $|X|=\alpha^{s\cdot n}\cdot\binom{m}{n}^s$ with

$$\begin{aligned}\alpha^{s\cdot n} &\geq 2^{2s}\cdot e^{-\varepsilon^2\cdot\beta\cdot\delta\cdot s\cdot n/4} \qquad \text{because of (6.3)}\\ &\geq 2^{2s}\cdot e^{-\varepsilon^2\cdot(\beta-\frac{n}{m})\cdot n\cdot\delta\cdot s/2} \qquad \text{because of (6.5)}\\ &= 2^s\cdot 2^s\cdot e^{-\varepsilon^2\cdot E^*\cdot\delta\cdot s/2},\end{aligned}$$

and hence

$$\sum_{J\subseteq\{1,\ldots,s\},|J|=\delta\cdot s} p_E(J)\leq 2^{-s}\cdot\frac{|X|}{\binom{m}{n}^s}.$$

Therefore all but $|X|/2^s$ elements $(x_1,\ldots,x_s)$ of X have the property that $|\{(1-\beta)\cdot m+1,\ldots,m\}\cap x_i|>E$ for at least $(1-\delta)\cdot s$ components i. The claim follows, since $E=(1-\varepsilon)\cdot E^*=(1-\varepsilon)\cdot(\beta-\frac{n}{m})\cdot n\geq(1-\varepsilon)^2\cdot\beta\cdot n$ (with (6.5)).

(b) According to (a) there is a set $I\subseteq\{1,\ldots,s\}$ with $|I|=(1-\delta)\cdot s$ and a subset $X_0\subseteq X$ such that

- $|X_0|\geq\frac{|X|}{2\cdot\binom{s}{\delta\cdot s}}$ and
- for all $i\in I$ and for all $x\in X_0$, $|\{(1-\beta)\cdot m+1,\ldots,m\}\cap x_i|>E$.

Hence for every subset $J\subseteq I$ with $|J|=k$,

$$\begin{aligned}&\sum_{u\in\text{Witness}_{J,1},u_j>(1-\beta)\cdot m\text{ for all }j\in J} p_X(u)\\ &\quad=\sum_{u\in\text{Witness}_{J,1},u_j>(1-\beta)\cdot m\text{ for all }j\in J}\frac{|\{x\in X\ :\ u\in\text{Witness}_{J,1}(x)\}|}{|X|}\\ &\quad=\sum_{x\in X}\frac{|\{u\in\text{Witness}_{J,1}(x)\ :\ u_j>(1-\beta)\cdot m\text{ for all }j\in J\}|}{|X|}\\ &\quad=\sum_{x\in X}\frac{\prod_{j\in J}|\{(1-\beta)\cdot m+1,\ldots,m\}\cap x_j|}{|X|}.\end{aligned}$$

We can now bring X_0 into play and get

$$\sum_{x\in X}\frac{\prod_{j\in J}|\{(1-\beta)\cdot m+1,\ldots,m\}\cap x_j|}{|X|}\geq\sum_{x\in X_0}\frac{E^k}{|X|}\geq\frac{|X|}{2\cdot\binom{s}{\delta\cdot s}}\cdot\frac{E^k}{|X|}=\frac{E^k}{2\cdot\binom{s}{\delta\cdot s}}.$$

As a consequence of Proposition 6.4, the witness w^J (with core J and $w^J_j=(1-\beta)\cdot m$ for all $j\in J$) has the highest probability of all simple witnesses u with core J and $u_j>(1-\beta)\cdot m$ for all $j\in J$ and hence

$$\begin{aligned}p_X(w^J)&\geq\frac{E^k}{2\cdot\binom{s}{\delta\cdot s}\cdot(\beta\cdot m)^k}\\ &\geq\frac{(1-\varepsilon)^k\cdot(\beta-\frac{n}{m})^k n^k}{2\cdot\binom{s}{\delta\cdot s}\cdot(\beta\cdot m)^k}\cdot\\ &\geq\frac{(1-\varepsilon)^k}{2\cdot\binom{s}{\delta\cdot s}}\cdot\frac{(\beta-\frac{n}{m})^k}{\beta^k}\cdot\left(\frac{n}{m}\right)^k\\ &\geq\frac{(1-\varepsilon)^{2k}}{2\cdot\binom{s}{\delta\cdot s}}\cdot\left(\frac{n}{m}\right)^k \qquad \text{because of (6.5)},\end{aligned}$$

and this was to be shown. □

The results of this section are crucial for proving Lemma 5.1. This will be done in the next section.

7. Large submatrices and simple witnesses. As a first step in the proof of Lemma 5.1, we show that witnesses from a relatively small set W of witnesses will constitute a correspondingly small minority among simple witnesses for the rows of a relatively large matrix. The next lemma makes the size dependencies explicit and will be used to show that small sets of forbidden witnesses have only little impact.

LEMMA 7.1. *$\alpha \in [0,1]$ and $\varepsilon \in [0,1/6]$ are nonnegative real numbers with*

$$\alpha > 4^{1/n} \cdot e^{-\varepsilon^3 \cdot (1-\varepsilon)/4} \quad \text{and} \quad \varepsilon \geq \frac{n}{(1-\varepsilon)\cdot m}.$$

Assume that X is a subset of $\mathcal{P}^{(s)}_{m,n}$ of size $\alpha^{s\cdot n} \cdot \binom{m}{n}^s$. For a subset $I \subseteq \{1,\ldots,s\}$ of size $k \geq s/2$ let W be a subset of $\mathrm{Witness}_{I,1}$ *with $|W| \leq (\varepsilon \cdot m)^{(1-11\varepsilon)\cdot k}$. Then*

$$\sum_{w \in W} p_X(w) \leq 2 \cdot e^{-3\varepsilon \cdot k} \cdot n^k.$$

Proof. We first show, using the methods in the proof of Lemma 6.3, that one can assume that W is monotone decreasing, i.e., if $u \leq v$ componentwise and $v \in W$, then also $u \in W$. If W is not monotone decreasing, then there will be an element $w \in W$ such that, without loss of generality, $w_1 = \{\xi\}$ and $w' = (\{\xi - 1\}, w_2, \ldots, w_s) \notin W$.

For $x \in X$ set $x' = (x_1 - \{\xi\} \cup \{\xi - 1\}, x_2, \ldots, x_s)$ and define

$$\mathrm{decrease}_\xi(x) = \begin{cases} x' & \text{if } x_1 \cap \{\xi - 1, \xi\} = \{\xi\} \text{ and } x' \notin X, \\ x & \text{otherwise.} \end{cases}$$

Analogously define the function $\mathrm{decrease}_\xi(u)$ for $u \in W$. We replace X and W by

$$X' = \{\mathrm{decrease}_\xi(x) \mid x \in X\} \text{ and } W' = \{\mathrm{decrease}_\xi(u) \in W \mid u \in W\},$$

and observe first that $|X| = |X'|$ and $|W| = |W'|$. Finally we claim that

$$\sum_{w \in W} p_X(w) \leq \sum_{w' \in W'} p_{X'}(w').$$

Let u be an element of W. If $\{\xi - 1, \xi\} \cap u_1 = \emptyset$, then $u \in W'$ and $p_X(u) = p_{X'}(u)$. Otherwise u has a twin u', i.e., $u \neq u'$ and one of u and u' results from the other by an application of decrease. If $u' \in W$, then both belong to W' and $p_X(u) + p_X(u') = p_{X'}(u) + p_{X'}(u')$. Otherwise $u' \in W' - W$ and therefore $u'_1 = \{\xi - 1\}$. Hence $p_X(u) \leq p_{X'}(u')$.

Thus, after repeating the above procedure suitably often, we obtain a subset $X^* \subseteq \mathcal{P}^{(s)}_{m,n}$ (with $|X^*| = |X|$) and a monotone decreasing subset W^* (with $|W^*| = |W|$), such that

$$\sum_{w \in W} p_X(w) \leq \sum_{w^* \in W^*} p_{X^*}(w^*).$$

Let I be a subset of $\{1,\ldots,s\}$ of size $k \geq s/2$. Since $|W^*| = |W|$ and $|W| \leq (\varepsilon \cdot m)^{(1-11\varepsilon)\cdot k}$ and since W^* is monotone decreasing, *each* element of W^* has at least $11\varepsilon \cdot k$ components of value at most $\varepsilon \cdot m$, since otherwise

$$|W^*| > (\varepsilon \cdot m)^{(1-11\varepsilon)\cdot k}.$$

Thus all elements of W^* have a large number of small components. We say that a component i is *regular* for $(x_1, \ldots, x_s)$ provided

$$|\{\varepsilon \cdot m + 1, \ldots, m\} \cap x_i| \geq (1-\varepsilon)^3 \cdot n.$$

Finally we call x *conventional* if x has at least $(1-\varepsilon) \cdot s$ regular components. We apply Lemma 6.5(a) (with $\beta = 1-\varepsilon$ and $\delta = \varepsilon$) and obtain, with probability at least $1 - 2^{-s}$, that an element $x^* \in X^*$ is conventional. Fix an arbitrary conventional element x^* and distinguish exactly $(1-\varepsilon) \cdot s$ of its regular components. We claim that

$$|\{w \in W^* \mid w \in \text{Witness}_{I,1}(x^*)\}| \leq e^{-3\varepsilon \cdot k} \cdot n^k. \tag{7.1}$$

Let E be the expected number of small components (i.e., of value at most $\varepsilon \cdot m$) of a witness $w \in \text{Witness}_{I,1}(x^*)$, where we consider only the distinguished regular components of x^*. Then $E \leq (k - \varepsilon \cdot s) \cdot (1 - (1-\varepsilon)^3) \leq (k - \varepsilon \cdot s) \cdot 3\varepsilon \leq 3\varepsilon \cdot k$. We choose β, with $\beta \cdot E = 9\varepsilon \cdot k$, and obtain

$$\text{prob}[w \text{ has at least } 9\varepsilon \cdot k \text{ small components} \mid w \in \text{Witness}_{I,1}(x^*)] \leq e^{-E \cdot (\beta-1)^2/3}$$

with the Chernoff bound. We have $E \cdot (\beta - 1) = E \cdot \beta - E \geq 6\varepsilon \cdot k$ and hence $\beta - 1 \geq 2$ as well as $E \cdot (\beta-1)^2 \geq 12\varepsilon \cdot k$. Thus the probability of having at least $9\varepsilon \cdot k$ small components is bounded by $e^{-12\varepsilon \cdot k/3} \leq e^{-3\varepsilon \cdot k}$.

If we also consider the at most $\varepsilon \cdot s$ irregular components of I, we obtain, with probability at most $e^{-3\varepsilon \cdot k}$, at least $9\varepsilon \cdot k + \varepsilon \cdot s \leq 11\varepsilon \cdot k$ components with value at most $\varepsilon \cdot m$. Claim (7.1) follows, since elements of W^* have at least $11\varepsilon \cdot k$ components with value at most $\varepsilon \cdot m$.

We conclude by also considering (the few) unconventional elements of X^* and obtain

$$\begin{aligned}
\sum_{w \in W^*} p_{X^*}(w) &= \sum_{x \in X^*} \frac{|\{w \in W^* \mid w \in \text{Witness}_{I,1}(x^*)\}|}{|X^*|} \\
&\leq \frac{|X^*|}{2^s} \cdot \frac{n^k}{|X^*|} + \sum_{x \in X^*,\ x \text{ is conventional}} e^{-3\varepsilon \cdot k} \cdot \frac{n^k}{|X^*|} \\
&\leq \frac{n^k}{2^s} + e^{-3\varepsilon \cdot k} \cdot n^k = \left(\frac{1}{2^s} + e^{-3\varepsilon \cdot k}\right) \cdot n^k \leq 2 \cdot e^{-3\varepsilon \cdot k} \cdot n^k,
\end{aligned}$$

where the last inequality follows, since $\varepsilon \leq \frac{1}{4}$. □

Proof of Lemma 5.1. We have to show that a large subset $I \subseteq \{1, \ldots, s\}$ (of size k) exists, such that many quite likely (simple) witnesses w (with core I) are common to X and Y even if witnesses in a small set W are not counted. We may assume that X and Y are large ($|X| = \alpha_1^{s \cdot n} \cdot \binom{m}{n}^s$ and $|Y| = \alpha_2^{s \cdot n} \cdot \binom{m}{n}^s$) and that W is small ($|W| \leq (\varepsilon_2 \cdot m)^{(1-11 \cdot \varepsilon_2) \cdot s}$).

We start by making the transition to monotone sets X' and Y' according to Lemma 6.3 (with $|X| = |X'|$ and $|Y| = |Y'|$). Next, Lemma 6.5, applied for $\varepsilon = 2\beta = \delta = \varepsilon_1$, provides a subset $I_{X'} \subseteq \{1, \ldots, s\}$ of size $(1-\varepsilon_1) \cdot s$ such that

$$p_{X'}(u^J) \geq \frac{(1-\varepsilon_1)^{2l}}{2 \cdot \binom{s}{\varepsilon_1 \cdot s}} \cdot \left(\frac{n}{m}\right)^l$$

for any subset $J \subseteq I_{X'}$ of size l, where $u_j^J = (1-\varepsilon_1/2)\cdot m$ for all $j \in J$. The situation for Y' is analogous, and we obtain a subset $I_{Y'} \subseteq \{1,\ldots,s\}$ of size $(1-\varepsilon_1)\cdot s$ such that

$$p_{Y'}(v^J) \geq \frac{(1-\varepsilon_1)^{2l}}{2\cdot\binom{s}{\varepsilon_1\cdot s}}\cdot\left(\frac{n}{m}\right)^l$$

for any subset $J \subseteq I_{Y'}$ of size l, where $v_j^J = (1-\varepsilon_1/2)\cdot m$ for all $j \in J$. We set $I = I_{X'} \cap I_{Y'}$ and obviously $k := |I| \geq (1-2\cdot\varepsilon_1)\cdot s$.

We go back to Lemma 6.3 and apply it for the system (X, f, Y, g, I), where

$$f(x) = W \cap \mathrm{Witness}_{I,1}(x),$$
$$g(y) = W \cap \mathrm{Witness}_{I,1}(y).$$

With Lemma 6.3 we obtain functions $f' : X' \to \mathcal{P}(\mathrm{Witness}_{I,1})$ and $g' : Y' \to \mathcal{P}(\mathrm{Witness}_{I,1})$ defining the new sets of forbidden witnesses such that

$$\sum_{x\in X}|f(x)| = \sum_{x'\in X'}|f'(x')| \text{ and } \sum_{y\in Y}|g(y)| = \sum_{y'\in Y'}|g'(y')|. \tag{7.2}$$

Finally we set

$$p_X^*(u) = |\{x \in X \ : \ u \in \mathrm{Witness}_{I,1}(x) - f(x)\ \}|/|X|,$$
$$p_Y^*(u) = |\{y \in Y \ : \ u \in \mathrm{Witness}_{I,1}(y) - g(y)\ \}|/|Y|$$

and introduce $p_{X'}^*(u), p_{Y'}^*(u)$ analogously. Then we get

$$\sum_{w\in\mathrm{Witness}_{I,1}} p_X^*(w)\cdot p_Y^*(w) \geq \sum_{w\in\mathrm{Witness}_{I,1}} p_{X'}^*(w)\cdot p_{Y'}^*(w)$$

as a consequence of Remark 6.1. We apply Lemma 7.1 (with $\varepsilon = \varepsilon_2$) and utilize (7.2) to get

$$\sum_{x'\in X'}|f'(x')| = \sum_{x\in X}|f(x)| = |X|\cdot\sum_{w\in W}p_X(w) \leq 2|X|\cdot e^{-3\varepsilon_2\cdot k}\cdot n^k \text{ and}$$
$$\sum_{y'\in Y'}|g'(y')| = \sum_{y\in Y}|f(y)| = |Y|\cdot\sum_{w\in W}p_Y(w,) \leq 2|Y|\cdot e^{-3\varepsilon_2\cdot k}\cdot n^k.$$

Call a simple witness $u \in \mathrm{Witness}_{I,1}$ *crucial* if $\varepsilon_1\cdot m/2+1 \leq u_i \leq (1-\varepsilon_1/2)\cdot m$ for all $i \in I$. Observe that there are $(1-\varepsilon_1)^k\cdot m^k$ crucial witnesses. Let

$$U = \{u \ : \ u \in \mathrm{Witness}_{I,1} \text{ is crucial and } p_{X'}^*(u) < p_{X'}(u)/2\}.$$

We claim that $|U| \leq \frac{1}{4}\cdot(1-\varepsilon_1)^k\cdot m^k$. The difference between $p_{X'}^*$ and $p_{X'}$ is due to forbidden witnesses and, since

$$\sum_{u\in U}|\{x' \in X' \ : \ u \in \mathrm{Witness}_{I,1}(x') - f'(x')\ \}|$$
$$\geq \sum_{u\in U}|\{x' \in X' \ : \ u \in \mathrm{Witness}_{I,1}(x')\ \}| - \sum_{x'\in X'}|f'(x')|,$$

we obtain

$$\begin{aligned}|X'| \cdot \sum_{u \in U} p^*_{X'}(u) &\geq |X'| \cdot \sum_{u \in U} p_{X'}(u) - \sum_{x' \in X'} |f'(x')| \\ &\geq |X'| \cdot \sum_{u \in U} p_{X'}(u) - 2|X| \cdot e^{-3\varepsilon_2 \cdot k} \cdot n^k.\end{aligned}$$

As a consequence, since $|X| = |X'|$,

$$\sum_{u \in U} p^*_{X'}(u) \geq \sum_{u \in U} p_{X'}(u) - 2 \cdot e^{-3\varepsilon_2 \cdot k} \cdot n^k. \tag{7.3}$$

Let u be a crucial witness. Then with Proposition 6.4 and Lemma 6.5,

$$p_{X'}(u) \geq p_{X'}(u^I) \geq \frac{(1-\varepsilon_1)^{2k}}{2 \cdot \binom{s}{\varepsilon_1 \cdot s}} \cdot \left(\frac{n}{m}\right)^k,$$

and therefore, assuming $|U| > \frac{1}{4} \cdot (1-\varepsilon_1)^k \cdot m^k$,

$$\begin{aligned}\sum_{u \in U} p_{X'}(u) &\geq |U| \cdot \frac{(1-\varepsilon_1)^{2k}}{2 \cdot \binom{s}{\varepsilon_1 \cdot s}} \cdot \left(\frac{n}{m}\right)^k = \frac{|U|}{m^k} \cdot \frac{(1-\varepsilon_1)^{2k}}{2 \cdot \binom{s}{\varepsilon_1 \cdot s}} \cdot n^k \\ &> \frac{1}{4} \cdot (1-\varepsilon_1)^k \cdot \frac{(1-\varepsilon_1)^{2k}}{2 \cdot \binom{s}{\varepsilon_1 \cdot s}} \cdot n^k = \frac{1}{8} \cdot \frac{(1-\varepsilon_1)^{3k}}{\binom{s}{\varepsilon_1 \cdot s}} \cdot n^k \\ &\geq 4 \cdot e^{-3\varepsilon_2 \cdot k} \cdot n^k \qquad \text{because of (5.7).}\end{aligned}$$

Thus, if $|U| > \frac{1}{4} \cdot (1-\varepsilon_1)^k \cdot m^k$, then with (7.3),

$$\sum_{u \in U} p^*_{X'}(u) \geq \sum_{u \in U} p_{X'}(u) - 2 \cdot e^{-3\varepsilon_2 \cdot k} \cdot n^k \geq \sum_{u \in U} p_{X'}(u)/2,$$

and $p^*_{X'}(u) \geq p_{X'}(u)/2$ for at least one witness $u \in U$. This contradicts the definition of U, and therefore $|U| \leq \frac{1}{4} \cdot (1-\varepsilon_1)^k \cdot m^k$.

We carry out the same argument for the set Y of columns and obtain that for at least one half of all crucial witnesses u,

$$p^*_{X'}(u) \geq \frac{p_{X'}(u)}{2} \geq \frac{(1-\varepsilon_1)^{2k}}{4 \cdot \binom{s}{\varepsilon_1 \cdot s}} \cdot \left(\frac{n}{m}\right)^k \quad \text{and}$$

$$p^*_{Y'}(u) \geq \frac{p_{Y'}(u)}{2} \geq \frac{(1-\varepsilon_1)^{2k}}{4 \cdot \binom{s}{\varepsilon_1 \cdot s}} \cdot \left(\frac{n}{m}\right)^k.$$

Since

$$\begin{aligned}\sum_{u \in \text{Witness}_{I,1} - W} p_X(u) \cdot p_Y(u) &= \sum_{u \in \text{Witness}_{I,1}} p^*_X(u) \cdot p^*_Y(u) \\ &\geq \sum_{u \in \text{Witness}_{I,1}} p^*_{X'}(u) \cdot p^*_{Y'}(u) \\ &\geq \sum_{u \text{ is crucial}} p^*_{X'}(u) \cdot p^*_{Y'}(u) \\ &\geq \frac{1}{2} \cdot (1-\varepsilon_1)^k \cdot m^k \cdot \frac{(1-\varepsilon_1)^{4k}}{16 \cdot \binom{s}{\varepsilon_1 \cdot s}^2} \cdot \left(\frac{n}{m}\right)^{2k} \\ &\geq \frac{1}{32} \cdot \frac{(1-\varepsilon_1)^{5k}}{\binom{s}{\varepsilon_1 \cdot s}^2} \cdot \left(\frac{n^2}{m}\right)^k,\end{aligned}$$

the claim follows. □

8. Conclusion. We have shown that a reduction in the number of advice bits by a logarithmic factor may result in an almost optimal increase for nondeterministic communication. This result was obtained for the language $D^{(s)}_{m,n}$, a direct sum version of the disjointness language, by

1. first showing that any 1-chromatic submatrix of the communication matrix has few *simple* witnesses testifying for most entries and
2. then utilizing this property by showing that a large 1-chromatic submatrix has a large number of quite likely *double* witnesses.

A deterministic protocol partitions the communication matrix into submatrices, and hence the number of double witnesses is at least as large as the sum, over all 1-chromatic submatrices M, of the number of double witnesses of M. Thus a deterministic protocol that exchanges few bits and accepts many inputs cannot be correct, since it generates too many double witnesses. Step 2 is verified by showing that monotone submatrices will have the smallest number of entries with a common simple witness and hence follows a qualitative approach.

Consequently we obtained a family $L_n \subseteq \{0,1\}^{2n}$ of languages with

$$\mathrm{nc}_{o(\sqrt{n}/\log_2 n)}(L_n) = \Omega\left(\frac{\mathrm{svnc}(L_n)^2}{\log_2 n}\right) = \Omega\left(\frac{n}{\log_2 n}\right), \tag{8.1}$$

and hence an almost quadratic gap between self-verifying nondeterministic communication and advice-restricted nondeterminism. As an immediate consequence of this gap we also obtained an almost quadratic gap between self-verifying nondeterministic communication and Monte-Carlo communication, namely,

$$\mathrm{mcc}(L_n) \geq \mathrm{nc}_{o(\sqrt{n}/\log_2 n)}(L_n) = \Omega\left(\frac{\mathrm{svnc}(L_n)^2}{\log_2 n}\right) = \Omega\left(\frac{n}{\log_2 n}\right).$$

We close with two questions. Can the logarithmic gap in (8.1) be removed? Are there further application areas for the new lower bound method?

Acknowledgment. Paul Beame observed that Theorem 1.1 separates Monte-Carlo communication from self-verifying nondeterministic communication.

QUALITY MESHING WITH WEIGHTED DELAUNAY REFINEMENT*

SIU-WING CHENG† AND TAMAL K. DEY‡

Abstract. Delaunay meshes with bounded circumradius to shortest edge length ratio have been proposed in the past for quality meshing. The only poor quality tetrahedra, called *slivers*, that can occur in such a mesh can be eliminated by the *sliver exudation* method. This method has been shown to work for periodic point sets, but not with boundaries. Recently a randomized point-placement strategy has been proposed to remove slivers while conforming to a given boundary. In this paper we present a deterministic algorithm for generating a weighted Delaunay mesh which respects the input boundary and has no poor quality tetrahedron including slivers. As in previous work, we assume that no input angle is acute. Our result is achieved by combining the weight pumping method for sliver exudation and the Delaunay refinement method for boundary conformation.

Key words. tetrahedral mesh generation, mesh quality, algorithms, computational geometry, Delaunay triangulation, weighted Delaunay refinement, sliver

1. Introduction.

In finite element methods a three-dimensional domain is often partitioned with tetrahedra. The quality of their shapes influences the quality of the finite element solution [21]. This motivated the decade-long research on generating meshes with guaranteed aspect ratio called *quality meshes* [1, 3, 5, 6, 7, 18, 19, 20]. A considerable literature has built up on the subject; see the surveys and books [2, 11, 14, 22]. We review only a few of them in the context of the work in this paper.

Bern, Eppstein, and Gilbert [3] pioneered a quadtree-based triangulation approach for producing quality meshes with close to optimal size in two dimensions. Mitchell and Vavasis [18] extended this technique to triangulate polyhedra with guaranteed aspect ratio in higher dimensions. This line of work provided many crucial insights into the problem, though the elements produced by this method have a biased alignment because of the axis-parallel boxes used in quadtree/octtree subdivisions. Delaunay-based triangulations do not have this problem, and they are widely used in mesh generation for their uniqueness and many other nice properties; see [14, 11]. As a result, researchers have also concentrated on computing meshes as a subcomplex of a Delaunay mesh with guaranteed quality. Chew proposed a simple circumcenter insertion method for the problem in two dimensions [5] which produces a uniform mesh of quality triangles. Ruppert [19], in a pioneering work called Delaunay refinement, showed how circumcenter insertion can be used to produce a quality graded mesh with optimal size.

Many of the concepts, including the analysis of the *local feature size*, introduced by Ruppert are the basis of the further developments in this area. Shewchuk made an important contribution in extending the Delaunay refinement to three-dimensional

domains with boundaries [20]. This refinement eliminates any tetrahedron that has a large ratio of its circumradius to the shortest edge length. Consequently the resulting mesh satisfies the *radius-edge ratio property*; i.e., all tetrahedra have radius-edge ratios below a threshold. Although most of the poor quality tetrahedra are removed by the radius-edge ratio property, one type of bad tetrahedra called *slivers* are not eliminated; see [8]. Slivers are formed by four points placed almost uniformly around the equator of a sphere. Slivers have bounded radius-edge ratio, but they have negligible volume, which makes them poor quality. Cheng et al. [7] proposed the *sliver exudation* method to get rid of the slivers from a Delaunay mesh that already have the radius-edge ratio property. They introduced the *pumping* technique, which assigns a weight to each vertex, which prohibits any sliver to be incident on them in the weighted Delaunay triangulation. Subsequently, Edelsbrunner et al. [12] developed a method for perturbing the points so that the unweighted Delaunay tetrahedralization has the radius-edge ratio property and is sliver-free.

Unfortunately, the algorithms of [7, 12] could not handle boundaries and were applied to periodic point sets. In a recent work, Edelsbrunner and Guoy [13] experimented with the sliver exudation method, which reveals that the technique is very effective in eliminating slivers. After sliver exudation, almost all tetrahedra have angles greater than 5° (except that some tetrahedra with angles less than 5° survive near the boundary). Thus, boundary handling remains a challenge. Recently, Li and Teng [15] showed that it is possible to construct a sliver-free Delaunay mesh, in the presence of boundaries, with a randomized point-placement strategy extended from that of Chew [6]. A sliver is destroyed by inserting a random point near its circumcenter. The analysis of this algorithm is a nice example of the confluence of the results developed over the years by Chew [6], Ruppert [19], Shewchuk [20], and Cheng et al. [7].

In this paper we present the first *deterministic* algorithm to construct a Delaunay mesh, with the radius-edge ratio property and without any sliver, of a three-dimensional domain with boundaries. We combine Delaunay refinement with sliver exudation and obtain what we call the *weighted Delaunay refinement*. We show that this technique produces a graded mesh with asymptotically optimal size. Our work can be viewed as an advance along the line of research initiated by Chew and Ruppert [5, 19] and carried forward by Dey, Bajaj, and Sugihara [8], Shewchuk [20], Cheng et al. [7], Edelsbrunner et al. [12], and Li and Teng [15]. Encouraged by the experimental results of Edelsbrunner and Guoy [13], we believe that weighted Delaunay refinement is eminently practical. Their experiments show that, after sliver exudation, relatively few slivers near the domain boundary survive. Thus, we expect that most slivers can be destroyed without adding extra points.

The rest of the paper is organized as follows. Section 2 describes the basic definitions. Section 3 presents our algorithm, and its behavior is analyzed in sections 4, 5, and 6. Section 7 proves the guarantees achieved by our algorithm. We conclude in section 8.

2. Definitions. We need the following definitions, most of which have been introduced in earlier works.

Quality of tetrahedra. The volumes of tetrahedra in a normalized sense capture their quality. Poor quality tetrahedra have small normalized volume. Let R, L, and V be the circumradius, shortest edge length, and volume, respectively, of a tetrahedron τ. We characterize τ by two ratios $\rho(\tau) = R/L$ and $\sigma(\tau) = V/L^3$. If $\rho(\tau)$ exceeds a threshold ρ_0, then we call it *skinny*. If $\rho(\tau) \leq \rho_0$ and $\sigma(\tau)$ does not exceed a threshold

σ_0, then we call τ a sliver. As in previous work [7, 15], we will show that there exist ρ_0 and σ_0 independent of the domain such that our algorithm does not produce any skinny tetrahedron or sliver with respect to ρ_0 and σ_0.

Piecewise linear complex. The domain to be meshed is a bounded volume, and its boundary is presented using a *piecewise linear complex* (PLC). A collection $\mathcal{P}$ of vertices, segments, and facets in $\mathbb{R}^3$ is called a PLC (i) if all elements on the boundary of an element in $\mathcal{P}$ also belong to $\mathcal{P}$ and (ii) if any two elements intersect, their intersection is a lower-dimensional element in $\mathcal{P}$.

Input. We assume that the domain to be meshed is a convex bounded volume containing a collection of vertices, segments, and facets represented as a PLC. An input angle is the angle between two segments sharing a vertex, a segment and a facet sharing one vertex, or two facets sharing a vertex or a segment. We assume that no input angle is acute. If the input PLC does not bound a convex volume, we enclose it in a large box, mesh the inside of the box, and keep only the tetrahedra covering the original domain. This technique has been used before [11, 19]. We use $\mathcal{P}$ to denote the (possibly extended) input PLC.

Incidence. Two elements in $\mathcal{P}$ are incident if one is in the boundary of the other.

Adjacent elements. We call two elements of $\mathcal{P}$ *adjacent* if either they are incident or they are nonincident but their closure intersect. For example, two segments sharing an endpoint are adjacent, and two facets sharing a segment are adjacent. As another example, if a segment does not lie on the boundary of a facet but they share a vertex, then they are adjacent. A vertex of $\mathcal{P}$ is not adjacent to any other element that is not incident to it.

Local feature size. The local feature size for $\mathcal{P}$ is a function $f : \mathbb{R}^3 \to \mathbb{R}$, where $f(x)$ is the radius of the smallest ball centered at x intersecting two nonadjacent elements of $\mathcal{P}$.

Weighted Delaunay triangulation. We use $\widehat{x}$ to denote a *weighted point* at x with weight X^2. The weighted point $\widehat{x}$ can be interpreted as a sphere centered at x with radius X. Notice that any point can be thought of as a weighted point with weight zero. The *weighted distance* $\pi(\widehat{x}, \widehat{y})$ between two weighted points $\widehat{x}$ and $\widehat{y}$ is given by

$$\pi(\widehat{x}, \widehat{y}) = \|x - y\|^2 - X^2 - Y^2.$$

If $\pi(\widehat{x}, \widehat{y}) = 0$, then for any point $z \in \widehat{x} \cap \widehat{y}$, $\|x-z\|^2 + \|y-z\|^2 = X^2 + Y^2 = \|x-y\|^2$. That is, $\angle xzy = \pi/2$. Thus we say that $\widehat{x}$ and $\widehat{y}$ are *orthogonal.* If $\pi(\widehat{x}, \widehat{y})$ is greater (resp., smaller) than 0, then for any point $z \in \widehat{x} \cap \widehat{y}$, $\angle xzy > \pi/2$ (resp., $\angle xzy < \pi/2$), and we say that $\widehat{x}$ and $\widehat{y}$ are *further than (resp., closer to) orthogonal* from each other. The *bisector plane* of $\widehat{x}$ and $\widehat{y}$ is the locus of points at equal weighted distances from $\widehat{x}$ and $\widehat{y}$.

Let τ be a simplex of dimension one or more in $\mathbb{R}^3$; i.e., τ is an edge, a triangle, or a tetrahedron. The *smallest orthosphere* of τ is the smallest sphere, say $\widehat{x}$, so that $\widehat{x}$ is orthogonal to each weighted vertex of τ. The smallest orthosphere is the counterpart of the *smallest circumspheres* for simplices with unweighted vertices; see Figure 2.1. Notice that for a tetrahedron there is only a single sphere orthogonal to all of its four weighted vertices, which is its smallest orthosphere. The center and radius of the smallest orthosphere of any simplex are called its *orthocenter* and *orthoradius*, respectively.

For a weighted point set $\mathcal{V}$, a tetrahedron spanning four points of $\mathcal{V}$ is *weighted Delaunay* if its orthosphere is further than orthogonal away from any other weighted point in $\mathcal{V}$. A *weighted Delaunay triangulation* of $\mathcal{V}$ is the collection of all weighted Delaunay tetrahedra along with their triangles, edges, and vertices.

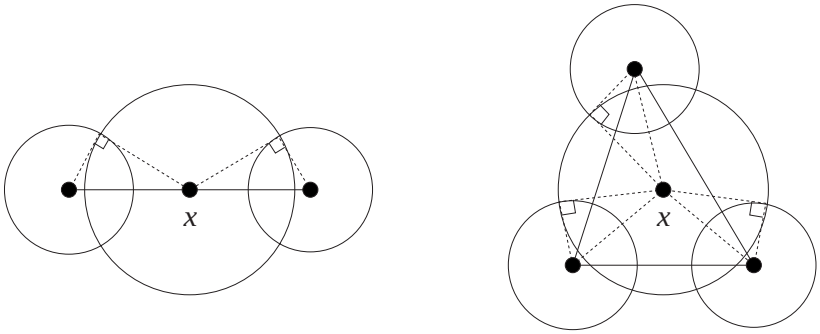

FIG. 2.1. *Smallest orthospheres of an edge and a triangle with orthocenter x.*

3. Weighted Delaunay refinement.

3.1. Overview. The Delaunay refinement algorithm as originally proposed by Ruppert [19] and later extended to three dimensions by Shewchuk [20] iteratively inserts circumcenters of tetrahedra that have radius-edge ratio above a threshold. Whenever a circumcenter x lies so close to an element F in the input PLC that some of its subsets cannot appear in the current Delaunay triangulation, x is rejected and F is subdivided instead. It can be proved that a new vertex x is inserted at least $c \cdot f(x)$ distance away from all other vertices and input elements for some constant $c > 0$. This lower bound on distances guarantees the termination because only a finite number of points can be accommodated in a bounded domain with a lower bound on the interpoint distances.

Delaunay refinement achieves bounded radius-edge ratio but fails to remove slivers. This motivated the sliver exudation method of Cheng et al. [7], which eliminates slivers from a Delaunay mesh that already have bounded radius-edge ratio. The key algorithmic tool in sliver exudation is the assignment of weights to unweighted vertices. The weight assignment can be viewed as *pumping* the unweighted vertex to grow it to a sphere (weighted vertex). When an unweighted vertex v is pumped, there is a restriction on the weight to be assigned to v. The weight must be selected from the interval $[0, \omega^2 N(v)^2]$, where $N(v)$ is the Euclidean distance to its nearest vertex and $\omega \in (0, 1/2)$ is a constant. It is shown that there exists a weight in the mentioned interval for each vertex v so that if v is assigned that weight, all slivers incident to v are removed from the weighted Delaunay triangulation of the vertex set (see [7]). This is stated precisely in the following sliver theorem.

THEOREM 3.1 (sliver theorem; see [7]). *Given a periodic point set $\mathcal{V}$ and a Delaunay triangulation of $\mathcal{V}$ with radius-edge ratio $\leq \rho$, there exist $\rho_0 > 0$, $\sigma_0 > 0$, and a weight assignment in $[0, \omega^2 N(v)^2]$ for each vertex v in $\mathcal{V}$ such that $\rho(\tau) \leq \rho_0$ and $\sigma(\tau) > \sigma_0$ for each tetrahedron τ in the weighted Delaunay triangulation of $\mathcal{V}$.*

The required weights can be assigned in a deterministic manner for periodic point sets as defined by Cheng et al. [7]. Periodic point sets are infinite points sets without boundaries. So Theorem 3.1 does not give an algorithm for meshing bounded domains. For a bounded domain, the weight assignment may challenge the boundary. We solve this problem by combining the Delaunay refinement with pumping while redefining the encroachment with respect to weighted points.

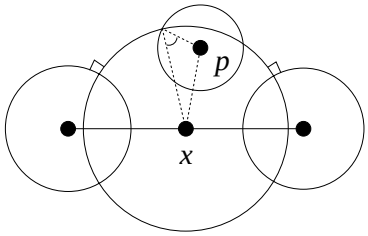

FIG. 3.1. *A subsegment is encroached by $\widehat{p}$. Note that the angle shown between $\widehat{p}$ and the smallest orthosphere of the subsegment is less than $\pi/2$. The subsegment is split by its orthocenter x.*

Our algorithm refines a Delaunay triangulation until it determines that it is safe to pump vertices to remove slivers. In the refinement process it attempts to insert circumcenters of skinny tetrahedra. However, these centers may come close to or challenge some boundary elements, which are then subdivided. The subdivision process may trigger further subdivision with new vertices. This refinement process is exactly the same as that of Ruppert [19] and Shewchuck [20]. We introduce another stimulus for refinement in preparation for pumping the vertices to remove slivers in a final stage. If a vertex v has a sliver incident to it, we check whether the vertex with maximum allowed weight challenges any boundary element. If so, a refinement process is triggered. We will see that even if v does not challenge any boundary element, $\widehat{v}$, the weighted vertex, may. At these stages, we maintain only the unweighted Delaunay triangulation of the current vertex set. At the end of the refinement process, when no further boundary element is challenged by weighted or unweighted vertices, we safely pump the vertices to eliminate slivers.

3.2. Subsegments and subfacets. Our algorithm maintains a set of vertices $\mathcal{V}$ which consists of the input vertices initially, and it grows as we refine boundary elements and insert circumcenters of skinny tetrahedra.

The vertices in $\mathcal{V}$ on a segment of $\mathcal{P}$ subdivide it into *subsegments*. Let ab be a subsegment. A point p *encroaches* upon ab if p lies inside the smallest circumsphere of ab. Suppose that there is no encroached subsegment. Consider the vertices in $\mathcal{V}$ on a facet of $\mathcal{P}$ in isolation. The two-dimensional Delaunay triangulation of these vertices conforms to the boundary of the facet. Each triangle on the facet is called a *subfacet*. A point p *encroaches* upon a subfacet abc if p lies inside the smallest circumsphere of abc.

Eventually, we will assign weights to vertices in $\mathcal{V}$. This will require us to deal with the weighted versions of subsegments, subfacets, and encroachment. The *weighted-subsegments* are exactly the same as subsegments but possibly with weighted endpoints. A weighted point $\widehat{p}$ encroaches upon a weighted-subsegment ab if $\widehat{p}$ is closer than orthogonal to the smallest orthosphere of ab. See Figure 3.1 for an illustration. Suppose that there is no encroached weighted-subsegment. Consider the weighted vertices on a facet of $\mathcal{P}$ in isolation. The two-dimensional weighted Delaunay triangulation of these vertices conforms to the boundary of the facet. Each triangle on the facet is called a *weighted-subfacet*. A weighted point $\widehat{p}$ encroaches upon a weighted-subfacet abc if $\widehat{p}$ is closer than orthogonal to the smallest orthosphere of abc.

We will prove several properties for the weighted Delaunay triangulation (Lemmas 3.2–3.6) later. As the weighted case is more general than the unweighted case, these results are applicable for the unweighted Delaunay triangulation as well as when only some of the vertices are weighted.

3.3. Weight assignment. For a vertex u, there are at most two assigned weights, one to check whether $\widehat{u}$ encroaches upon a boundary element, and possibly another if u participates in an actual pumping in the final stage. Let $\omega_0 < 1$ be a constant chosen in advance. The value of ω_0 will be determined in section 5. We use the weight $\omega_0^2 f(u)^2$ for an encroachment check and the interval $[0, \omega_0^2 f(u)^2]$ to assign weights during pumping. It is important that there be enough space around u when it is pumped. Recall that the vertex $\widehat{u}$ with weight U^2 is equivalent to a sphere centered at u with radius U. The assigned weights also impose a requirement that no other vertex be allowed within an Euclidean distance of $2\omega_0 f(u)$ from u. Consequently, after pumping, $\widehat{u}$ can reach up to half of the Euclidean distance to its nearest neighbor. Thus no two weighted vertices intersect after pumping. We provide an exact statement of this property below.

Vertex gap property. For each vertex u in $\mathcal{V}$, the weight of u used for encroachment checking or pumping is at most $\omega_0^2 f(u)^2$, and the Euclidean nearest neighbor distance of u in $\mathcal{V}$ is at least $2\omega_0 f(u)$.

Note that we need to maintain the vertex gap property throughout the algorithm as new vertices are inserted (added to $\mathcal{V}$). As the weights assigned to the vertices are not large compared with interpoint distances, the resulting weighted Delaunay triangulation satisfies many properties of the unweighted one, and many results of the Delaunay refinement carry over to the weighted Delaunay refinement (Lemmas 3.2–3.6). We will prove the vertex gap property in section 5.

3.4. Locations of centers. Whenever a subsegment is encroached, we split it by inserting its midpoint. Whenever a subfacet is encroached, we split it by inserting its circumcenter. This requires the circumcenter to lie on the facet of $\mathcal{P}$ containing that subfacet. Whenever there is a skinny tetrahedron, we insert its circumcenter. This requires the circumcenter to lie inside the input domain to prevent perpetual growth of the mesh. Although at this point we need these results for Delaunay triangulations, we prove them for weighted Delaunay triangulations that we will need in section 7 for pumping.

LEMMA 3.2. *Suppose that the vertex gap property holds. If there is no encroached weighted-subsegment or weighted-subfacet, no weighted vertex $\widehat{p}$ intersects a segment or a facet that does not contain p.*

Proof. Assume to the contrary that the lemma does not hold. First of all, $\widehat{p}$ cannot enclose any vertex other than p because of the vertex gap property. Let F be a segment intersected by $\widehat{p}$ if there is any. Otherwise, let F be a facet intersected by $\widehat{p}$. Let q be the projection of p on F. Observe that any point on F lies inside the smallest orthosphere of some weighted-subsegment or weighted-subfacet, or inside some weighted vertex on F (viewed as a sphere). Suppose that q lies inside the smallest orthosphere $\widehat{x}$ of a weighted-subsegment or weighted-subfacet τ. We have $\|p - x\|^2 = \|q - x\|^2 + \|p - q\|^2 < X^2 + P^2$ as $\|q - x\| < X$ and $\|p - q\| < P$. This implies that $\widehat{p}$ encroaches upon τ, a contradiction. Suppose that q lies inside a weighted vertex $\widehat{v}$. Similarly, we get $\|p - v\|^2 = \|q - v\|^2 + \|p - q\|^2 < V^2 + P^2$. This implies that $\widehat{p}$ and $\widehat{v}$ intersect, which contradicts the vertex gap property. ∎

LEMMA 3.3. *Suppose that the vertex gap property holds.*

(i) *A weighted-subsegment contains its orthocenter.*
(ii) *If no weighted-subsegment is encroached, a facet contains the orthocenter of any weighted-subfacet on it.*
(iii) *If no weighted-subsegment or weighted-subfacet is encroached, the input domain contains the orthocenter of any weighted Delaunay tetrahedron inside the input domain.*

Proof. Because of the vertex gap property, (i) is obvious. We present a proof that works for both (ii) and (iii). Let Ω be a facet or the input domain. Let τ be a weighted-subfacet on Ω or a weighted Delaunay tetrahedron inside Ω correspondingly. Let $\widehat{s}$ be the smallest orthosphere of τ. Assume to the contrary that s lies outside Ω.

Let p be a vertex of τ such that ps crosses $\partial\Omega$. By Lemma 3.2, $\widehat{p}$ does not cross $\partial\Omega$, so $\widehat{s}$ must cross $\partial\Omega$ in order to be orthogonal to $\widehat{p}$. Let E be the element in $\partial\Omega$ closest to s. As $\widehat{s}$ is empty of vertices, E is either a segment or facet. Let L_E be the affine hull of E. Let $\widehat{y}$ be the diametral/equatorial sphere of $\widehat{s} \cap L_E$. We make four observations (see Figure 3.2).

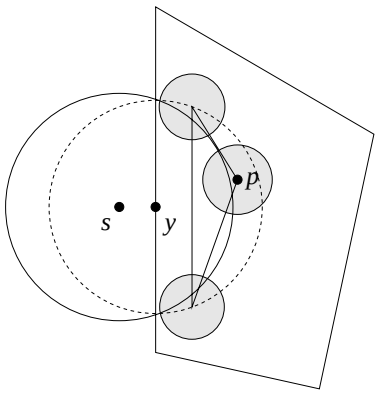

FIG. 3.2. *Illustration for Lemma* 3.3 *when* Ω *is a facet. The shaded disks are the vertices of the weighted-subfacet whose orthocenter is* s*. The solid circle is* $\widehat{s}$*, and the dashed one is* $\widehat{y}$*.*

First, y lies in the interior of E.

Second, the bisector plane of $\widehat{s}$ and $\widehat{y}$ contains E. Note that p and s lie on opposite sides of this bisector plane. So $\pi(\widehat{p}, \widehat{y}) < \pi(\widehat{p}, \widehat{s}) = 0$.

Third, for any vertex v on E, we have $\pi(\widehat{v}, \widehat{y}) \geq 0$ because $\pi(\widehat{v}, \widehat{s}) = \pi(\widehat{v}, \widehat{y})$ and $\widehat{s}$ is not closer than orthogonal to $\widehat{v}$.

Fourth, we claim that the projection q of p onto L_E lies in the interior of E. Assume to the contrary that q does not lie in the interior of E. By the first observation, y lies in the interior of E. So qy intersects an endpoint of E if L_E is a line or qy intersects a weighted-subsegment in ∂E if L_E is a plane. Let γ denote the endpoint/weighted-subsegment that qy intersects. Let $\widehat{x}$ denote $\widehat{\gamma}$ if γ is a vertex, or the smallest orthosphere of γ if γ is a weighted-subsegment. Let H be the bisector plane of $\widehat{x}$ and $\widehat{y}$. Consider $\pi(\widehat{v}, \widehat{x})$ for each vertex v of γ. If γ is a vertex, then $\pi(\widehat{v}, \widehat{x}) = \pi(\widehat{x}, \widehat{x}) = -2X^2 \leq 0$; otherwise, γ is a weighted-subsegment and $\pi(\widehat{v}, \widehat{x}) = 0$. On the other hand, by the third observation, $\pi(\widehat{v}, \widehat{y}) \geq 0$ for each vertex v of γ. We conclude that for each vertex v of γ, $\pi(v, \widehat{y}) \geq \pi(v, \widehat{x})$. Thus γ lies in the halfspace H^+ bounded by H, where $\pi(a, \widehat{x}) \leq \pi(a, \widehat{y})$ for each point $a \in H^+$. The ray emitting from x through y must shoot outside H^+ because a point sufficiently far in this direction is closer to $\widehat{y}$ than $\widehat{x}$. Coupling this with the fact that qy intersects γ, we conclude that $q \in H^+$. Note that pq is parallel to H. Thus $p \in H^+$, which implies that $\pi(\widehat{p}, \widehat{x}) \leq \pi(\widehat{p}, \widehat{y})$. By the second observation, $\pi(\widehat{p}, \widehat{y}) < 0$ and so $\pi(\widehat{p}, \widehat{x}) < 0$. If γ is a vertex, this contradicts the vertex gap property; otherwise, it contradicts the assumption that no weighted-subsegment is encroached. This proves the claim.

Let τ be the weighted-subsegment or weighted-subfacet in the interior of E that contains q. Let $\widehat{z}$ be the smallest orthosphere of τ. Let H_1 be the bisector plane of $\widehat{y}$

and $\widehat{z}$. By the third observation, for each vertex v of τ, $\pi(\widehat{v},\widehat{y}) \geq 0 = \pi(\widehat{v},\widehat{z})$. Thus τ lies inside the halfspace H_1^+ bounded by H_1, where $\pi(a,\widehat{z}) \leq \pi(a,\widehat{y})$ for each point $a \in H_1^+$. As $q \in \tau$ and pq is parallel to H_1, we have $p \in H^+$. Thus $\pi(\widehat{p},\widehat{z}) \leq \pi(\widehat{p},\widehat{y})$, which is negative by the second observation. However, $\widehat{p}$ encroaches upon τ then, a contradiction. □

3.5. Adjacent elements and encroachment. A key property in ordinary Delaunay refinement (without weight assignment) is that vertices on one element of $\mathcal{P}$ cannot encroach upon subsegments and subfacets on an adjacent element of $\mathcal{P}$, provided that no input angle is less than $\pi/2$. This property is needed for the algorithm to terminate. We show that this property also holds for the weighted case.

LEMMA 3.4. *If the vertex gap property holds, then for any weighted-subsegment ab on an edge e of $\mathcal{P}$, ab cannot be encroached upon by any vertex that lies on an edge adjacent to e or a facet adjacent but nonincident to e.*

Proof. Let $\widehat{x}$ be the smallest orthosphere of ab. By Lemma 3.3(i), x lies on ab. Let E be an edge adjacent to e or a facet adjacent but nonincident to e. Let u be a vertex on E. Let v be the common vertex of E and e. By the vertex gap property, $\widehat{u}$ does not contain v. Clearly, $\widehat{x}$ does not contain v. $\pi(\widehat{x},\widehat{u}) = \|u-x\|^2 - X^2 - U^2 > \|u-x\|^2 - \|v-x\|^2 - \|u-v\|^2$. Because all input angles are at least $\pi/2$, $\|u-x\|^2 \geq \|v-x\|^2 + \|u-v\|^2$. Thus $\pi(\widehat{x},\widehat{u}) > 0$ and $\widehat{u}$ does not encroach upon ab. □

LEMMA 3.5. *Let abc be a weighted-subfacet on a facet F of $\mathcal{P}$. If there is no encroached weighted-subsegment, then abc cannot be encroached by any vertex that lies on a facet adjacent to F or an edge adjacent but non-incident to F.*

Proof. Let H be the plane containing F. Let T denote the two-dimensional weighted Delaunay triangulation of the vertices on F. Let V_T denote the subdivision of H induced by T. Let Σ be the set of the smallest orthospheres of the triangles in T, the smallest orthospheres of weighted-subsegments in ∂F, and a sphere centered at infinity in H with infinite radius. By duality, V_T is the intersection of H and the weighted Voronoi diagram of Σ. Let u be a vertex that lies on a facet adjacent to F or an edge adjacent but nonincident to F. Because no input angle is less than $\pi/2$, the orthogonal projection of u onto H falls outside F or on ∂F. Consider any weighted-subfacet abc on F. The directed segment from the projection of u to a intersects a sequence of cells of V_T, including some weighted-subsegment vw in ∂F. This yields a corresponding sequence of spheres in Σ owning the cells intersected. The weighted distances from $\widehat{u}$ to the spheres in the sequence increase along the sequence. It follows that if $\widehat{u}$ encroaches upon abc, $\widehat{u}$ also encroaches upon vw, a contradiction. □

3.6. Projection. Instead of finding any encroached subfacet, we will focus on one that contains the projection of its encroaching vertex. Such a result has been proved by Shewchuk [20] for encroachments by unweighted points in the unweighted Delaunay triangulations. We will need a weighted version of this result.

LEMMA 3.6. *If no weighted-subsegment is encroached and $\widehat{p}$ encroaches upon some weighted-subfacet on a facet F, then there exists a weighted-subfacet h on F which is encroached upon by $\widehat{p}$, and h contains the orthogonal projection of p on F.*

Proof. Let H be the plane containing F. Let T denote the two-dimensional weighted Delaunay triangulation of the vertices on F. Let V_T denote the subdivision of H induced by T. Let Σ be the set of the smallest orthospheres of the triangles of T, the smallest orthospheres of the subsegments in ∂F, and a sphere centered at infinity in H with infinite radius. V_T is the intersection of H and the weighted Voronoi diagram of Σ. Let t_1 be a weighted-subfacet of F that is encroached upon by $\widehat{p}$. Suppose that p projects to a cell t_2 in V_T. When we walk along the directed segment

from the projection of p (inside t_2) to an interior point of t_1, we encounter a sequence of cells in V_T. This yields a corresponding sequence of spheres in Σ owning the cells encountered. The weighted distances from $\widehat{p}$ to the spheres in this sequence increase along the sequence. If t_2 is outside F, then the walk will exit a triangle t outside F and enter a triangle t' inside F at some point; i.e., $t \cap t'$ is a weighted-subsegment in ∂F. Because $\widehat{p}$ encroaches upon t_1, we have $\pi(\widehat{p}, \widehat{x}) \leq \pi(\widehat{p}, \widehat{y}) < 0$, where $\widehat{x}$ is the smallest orthosphere of $t \cap t'$ and $\widehat{y}$ is the smallest orthosphere of t_1. It follows that $\widehat{p}$ encroaches upon $t \cap t'$, which is a contradiction. □

3.7. Algorithm. The input to our algorithm QualMesh is a PLC. The PLC bounds a convex domain and may contain vertices, segments, and facets within the domain. We also assume that no input angle is less than $\pi/2$. This includes all angles between two segments sharing a vertex, a segment and a facet sharing one vertex, or two facets sharing a vertex or a segment. The assumption of a convex bounded domain is not a serious restriction because any PLC can be enclosed within a large enough box whose elements are included in the extended PLC. After the meshing is finished, one can choose to retain the desired tetrahedra. This standard technique has been used before [11, 19].

In the algorithm below we have a refinement step which is done in the unweighted Delaunay triangulation though some of the refinements may be triggered by a weighted point. Subsequent to this refinement, the vertices are pumped to eliminate slivers. Obviously, this is carried out in the weighted Delaunay triangulation. The results proved so far for the weighted Delaunay triangulation also remain valid for the unweighted case (where all weights are assumed to be zero) as well as when only some vertices are weighted.

QualMesh($\mathcal{P}$).

1. Compute the Delaunay triangulation of the input vertices of $\mathcal{P}$.
2. Repeatedly apply a rule from the following list until no rule is applicable. Rule i is applied only if it is applicable and no Rule j with $j < i$ is applicable. The parameters ρ_0, σ_0, and ω_0 will be determined later.

   Rule 1 (subsegment refinement). If there is an encroached subsegment, insert its midpoint.

   Rule 2 (subfacet refinement). If there is an encroached subfacet, there exists an encroached subfacet h that contains the projection of its encroaching vertex on the facet containing h. Insert the circumcenter of h, provided that it does not encroach upon any subsegment. Otherwise, reject the circumcenter and apply Rule 1 to split an encroached subsegment.

   Rule 3 (tetrahedron refinement). Assume that there is a tetrahedron with radius-edge ratio exceeding ρ_0 and circumcenter z. If z does not encroach upon any subsegment or subfacet, insert z. Otherwise, reject z and perform one of the following actions:
   - If z encroaches upon some subsegment(s), use Rule 1 to split one such subsegment.
   - Otherwise, z encroaches upon some subfacet(s) and use Rule 2 to split one such subfacet that contains the projection of z.

   Rule 4 (weighted encroachment). Let $\operatorname{Del}\mathcal{V}$ be the Delaunay triangulation of the current vertex set $\mathcal{V}$. Take a vertex v that is incident on a sliver τ (i.e., $\sigma(\tau) \leq \sigma_0$). Let $\widehat{v}$ be the weighted vertex v with weight $\omega_0^2 f(v)^2$.
   - If $\widehat{v}$ encroaches upon some subsegment in $\operatorname{Del}\mathcal{V}$ that does not lie on

the same segment as v, use Rule 1 to split one such subsegment.
- If $\widehat{v}$ encroaches upon some subfacet in $\mathrm{Del}\,\mathcal{V}$ that does not lie on the same facet as v, use Rule 2 to split one such subfacet that contains the projection of v.

Notice that we always maintain an unweighted Delaunay triangulation in step 2, and $\widehat{v}$ is used only for checking encroachments.

3. For each vertex v incident on a sliver τ (i.e., $\sigma(\tau) \leq \sigma_0$), pump v with weight in $[0, \omega_0^2 f(v)^2]$ until no sliver is incident to v. Maintain the weighted Delaunay triangulation during the pumping. We claim that no pumped vertex encroaches upon any weighted-subsegment and weighted-subfacet.

3.8. Time analysis. We analyze the time complexity of the algorithm in terms of n, the number of input vertices, and N, the number of output vertices. We will prove in section 7.4 that N is no more than a constant factor of the minimum number of vertices possible.

Consider the lifting map $\mu : \mathbb{R}^3 \to \mathbb{R}^4$, which maps a point $x = (x_1, x_2, x_3) \in \mathbb{R}^3$ to a point $\mu(x) = (x_1, x_2, x_3, x_1^2 + x_2^2 + x_3^2) \in \mathbb{R}^4$. For a point set $\mathcal{V}$ in three dimensions, let $\mu(\mathcal{V}) = \{\mu(v),\ v \in \mathcal{V}\}$. The Delaunay triangulation of $\mathcal{V}$ is the projection of the convex hull of $\mu(\mathcal{V})$ (see [10]). The first step can be done in $O(n^2)$ time using Chazelle's convex hull algorithm [4]. The second step is a loop, and a new vertex is added in each iteration. Thus there are fewer than N iterations. After each vertex insertion in Rule 1, 2, 3, or 4, we have to update the Delaunay triangulation. An inserted point p is the center of a circumsphere, circumcircle, or a segment. In each case we get a tetrahedron that is destroyed after inserting p. We explore in the Delaunay data structure in a depth-first manner to collect all tetrahedra that are destroyed with the insertion of p. Once these tetrahedra are identified, p is connected to the boundary of the union of them to update the Delaunay triangulation. If D_p is the number of deleted tetrahedra, the complexity of this update is $O(D_p)$. Thus the total time of all updates over the entire algorithm is upper bounded by the number of deleted tetrahedra. We argue that this number is $O(N^2)$.

In the lifted diagram in four dimensions, the insertion of p can be viewed as follows. The point $\mu(p)$ is below the convex hull of $\mu(\mathcal{V})$, and let T be the set of tetrahedra on this convex hull visible to $\mu(p)$. Insertion of $\mu(p)$ destroys all tetrahedra in T and creates new tetrahedra on the updated convex hull by connecting $\mu(p)$ to the boundary of the union of tetrahedra in T. Let us call the union of new tetrahedra incident to $\mu(p)$ its *cap*. The space between the cap of $\mu(p)$ and T can be triangulated by connecting $\mu(p)$ to each tetrahedron in T. Thus, assuming that the convex hull of the initial point set is triangulated, one can maintain a triangulation in the lifted diagram after each insertion, which contains the lifted deleted tetrahedra. Therefore, all tetrahedra deleted by QualMesh can be mapped to tetrahedra in the triangulation of N points in four dimensions. Since the size of any triangulation of N points in four dimensions is only $O(N^2)$ (see Theorem 1.2 of [9]), the same bound applies to the number of deleted tetrahedra.

Each insertion is preceded by a search of an encroached subsegment, subfacet, or skinny tetrahedron. We argue that this search can also be done in $O(N^2)$ total time. We maintain a stack of all skinny tetrahedra. Whenever an update is performed in the triangulation, we update the stack and mark any tetrahedron deleted through pointers. Thus, a skinny tetrahedron can be obtained by popping the stack until the popped tetrahedron is not marked. The time to create the initial stack is $O(n^2)$, the complexity of the initial Delaunay triangulation. The time to update the stack can be

absorbed in the triangulation update time, which is $O(N^2)$ in total. Next, we need to account for searching the encroached subsegments and subfacets. This encroachment may occur by an inserted or rejected point. Since each rejected point leads to an insertion, the total number of inserted and rejected points is $O(N)$. For each such point we can scan all subfacets and subsegments to determine the encroachments. At any time of the algorithm, the total number of subsegments and subfacets is $O(N)$. This is because the subfacets and subsegments on a planar facet create a plane graph whose complexity is linear in terms of the number of vertices, and each input edge can be incident to only a constant number of facets due to the input angle constraint. Therefore, counting over all points, all encroachments can be determined in $O(N^2)$ time.

Other than vertex insertion, we also need to compute $f(v)$ for some vertex v in each application of Rule 4. This can be done in $O(n)$ time by checking all the input elements. Thus the total time spent in computing local feature sizes is $O(Nn)$. Hence, the total time taken by the second step is $O(N^2 + Nn + n^2) = O(N^2)$. The third step pumps at most N vertices. Each pumping requires updating the mesh connectivity. The complexity of these updates again can be counted through the lifted diagram to be $O(N^2)$. Thus, the third step takes $O(N^2)$ time. In all, we have the following theorem.

THEOREM 3.7. *The time complexity of* QUALMESH *is* $O(N^2)$*, where* N *is the minimum number of points required to mesh the input domain with tetrahedra that have bounded aspect ratio.*

4. Insertion radii. We define a notion of *insertion radius* for each vertex inserted or rejected by QUALMESH. The main result in this section is a relation among insertion radii and local feature sizes which allows us to prove a lower bound on intervertex distances in section 5. For any vertex x in the input PLC, the insertion radius r_x is the Euclidean distance from the nearest input vertex. For any vertex x that QUALMESH inserts or rejects, the insertion radius r_x is the distance of x from the nearest vertex in the current $\mathcal{V}$. In section 5, we will see that a lower bound on the insertion radii of vertices implies a lower bound on the intervertex distances. Thus a packing argument shows that QUALMESH must terminate as the domain has bounded volume.

The analysis uses a parent-child relation among all vertices that are input vertices or inserted/rejected by QUALMESH. This is similar to the parent-child relation defined by Shewchuk [20] for the three-dimensional Delaunay refinement, but we need some modifications because of refinement triggered by weighted points. Parents of input vertices are undefined. If QUALMESH inserts or rejects a vertex x using Rule i, $1 \le i \le 3$, then x has type i. The parent of x is defined as follows.

1. x has type 3. Among the two endpoints of the shortest edge of the tetrahedron split by x, the vertex p that appeared in the latest $\mathcal{V}$ is the parent of x.
2. x has type 1 or 2. Then x is the circumcenter of a subsegment or subfacet τ. There are two cases.
   (a) If τ is encroached by a weighted vertex $\widehat{p}$ in Rule 4, the parent of x is p.
   (b) If τ is encroached by an unweighted vertex, we choose the parent of x to be the encroaching vertex p nearest to x. If p was not rejected, then $r_x = \|p - x\|$; otherwise, $r_x = X \ge \|p - x\|$.

Our goal is to lower bound r_x in terms of $f(x)$ and r_p, where p is the parent of x. (This recurrence will be useful in an inductive proof to lower bound r_x in terms of $f(x)$ only.) To this end, we prove two technical lemmas. Lemma 4.1 lower bounds

$\|p-x\|$ in terms of $f(x)$, $f(p)$, and r_p. Lemma 4.2 lower bounds r_x in terms of $\|p-x\|$. Both apply under some special conditions. Then we employ these two lemmas and analyze the remaining cases to obtain the lower bound on r_x in terms of $f(x)$ and r_p.

LEMMA 4.1. *Suppose that the vertex gap property holds. Let x be a vertex of type 1 or 2. Let p be the parent of x. Let $\widehat{x}$ be the smallest circumsphere of the subsegment or subfacet centered at x.*

(i) *If p is an input vertex, p has type 1, or p has type 2 and x has type 2, then $\|p-x\| \geq \max\{f(x), f(p)\}$.*

(ii) *Suppose that p has type 2 and x has type 1, or that p has type 3. If p does not lie inside $\widehat{x}$, then $\|p-x\| \geq r_p/\sqrt{2}$.*

Proof. Let F be the segment containing x if x has type 1; otherwise let F be the facet containing x. We first claim that p does not lie on F. If the insertion/rejection of x is induced in Rule 4, the claim is enforced by the algorithm. Otherwise, because the unweighted Delaunay triangulation of vertices on a segment or facet gives the subsegments and subfacets, an unweighted vertex on a segment (facet) cannot encroach upon subsegments (subfacets) on the same segment (facet).

Case 1: p is an input vertex. The two balls centered at p and x with radius $\|p-x\|$ intersect two nonadjacent input elements (F and p). Thus $\|p-x\| \geq f(p)$ and $\|p-x\| \geq f(x)$.

Case 2: p has type 1, or p has type 2 and x has type 2. Let F' be the segment/facet containing p. We already know that $F' \neq F$. We argue that F and F' are nonadjacent. If x has type 1 and p has type 1, then Lemma 3.4 implies that F' is nonadjacent to F. Suppose that x has type 2. The insertion/rejection of x could be induced in an application of Rule 4, or it could be induced in a direct application of Rule 2. In any case, there is no encroached subsegment; otherwise Rule 1 would have been invoked instead. Thus Lemma 3.5 implies that F' and F are nonadjacent. As F and F' are nonadjacent, $\|p-x\| \geq f(x)$ and $\|p-x\| \geq f(p)$.

Case 3: p has type 2 and x has type 1, or p has type 3. (When p has type 2 and x has type 1, p and x may lie on the same facet.) By assumption, p does not lie inside $\widehat{x}$. This implies that the insertion/rejection of x is induced in Rule 4. Also, QUALMESH enforces two conditions. First, p was inserted by QUALMESH. Second, if x has type 1 (resp., type 2) and lies on a segment (resp., facet), p does not lie on the same segment (resp., facet). It suffices to lower bound the distance from p to F. Go back to the time when p was inserted by QUALMESH.

Case 3.1: x has type 1. Then F is a segment. Let ab be the subsegment on F that contains x at that time. Observe that p lies outside the smallest circumsphere of ab; otherwise, p would have been rejected for encroaching upon a subsegment because p has type 2 or 3. If the nearest point of ab to p is a or b, then $\|p-x\| \geq \min\{\|p-a\|, \|p-b\|\} \geq r_p$ because a and b exist when p is inserted. Otherwise, the nearest point lies in the interior of ab. Assume that the orthogonal projection of p onto ab lies on ay, where y is the midpoint of ab. Then $\sin\angle pay \geq 1/\sqrt{2}$. Thus $\|p-x\| \geq \|a-p\| \cdot \sin\angle pay \geq r_p/\sqrt{2}$.

Case 3.2: x has type 2. Then p has type 3 and F is a facet. Observe that p lies outside the smallest circumsphere of any subsegment in ∂F or any subfacet on F. Otherwise, p would have been rejected for encroaching upon a subsegment or subfacet because p has type 3.

If the nearest point of F to p lies on a segment F' in ∂F, by apply-

ing the analysis in Case 3.1 to F', we conclude that $\|p-x\| \geq r_p/\sqrt{2}$. Otherwise, the nearest point q on F to p lies inside some subfacet abc on F. Note that q is the orthogonal projection of p onto abc. The Voronoi diagram of a, b, and c divides abc into three regions, each containing a vertex of abc. Assume that q lies inside the region containing a. Let $\widehat{z}$ be the smallest circumsphere of abc. Let H be the plane that is perpendicular to F and passes through a and p. $H \cap \widehat{z}$ is a circle and p lies outside it. Let y be the center of $H \cap \widehat{z}$. Observe that q lies on ay and so $\sin \angle pay \geq 1/\sqrt{2}$. The Euclidean distance from p to F is $\|a-p\| \cdot \sin \angle pay \geq r_p/\sqrt{2}$. □

LEMMA 4.2. *Suppose that the vertex gap property holds. Let x be a vertex of type 1 or 2. Let p be the parent of x. Then $r_x \geq \|p-x\|/\sqrt{2}$.*

Proof. Let $\widehat{x}$ be the circumsphere of which x is the center. If p lies inside $\widehat{x}$, p is unweighted, and it follows from the definition of parent that $r_x \geq \|p-x\|$. Assume that p does not lie inside $\widehat{x}$. For p to be the parent of x, the insertion/rejection of x must be induced in Rule 4 by the weighted vertex $\widehat{p}$ with weight $\omega_0^2 f(p)^2$. This also implies that $p \in \mathcal{V}$ at that time. By Lemma 4.1, $\|p-x\| \geq f(p)$ or $\|p-x\| \geq r_p/\sqrt{2}$. If $\|p-x\| \geq f(p)$, then $\|p-x\|/\sqrt{2} \geq \omega_0 f(p)$ as $\omega_0 \leq 1/2$. If $\|p-x\| \geq r_p/\sqrt{2}$, as $r_p \geq 2\omega_0 f(p)$ by the vertex gap property, we also get $\|p-x\|/\sqrt{2} \geq \omega_0 f(p)$. Because $\widehat{p}$ was closer than orthogonal to $\widehat{x}$, we have $X^2 + \omega_0^2 f(p)^2 > \|p-x\|^2$. Substituting $\omega_0^2 f(p)^2$ by $\|p-x\|^2/2$ and rearranging terms, we get $r_x = X > \|p-x\|/\sqrt{2}$. □

We are ready to lower bound r_x in terms of $f(x)$ and the insertion radius of the parent of x. This is the main result of this subsection.

LEMMA 4.3. *Suppose that the vertex gap property holds. Let x be an input vertex or a vertex inserted or rejected. Let p be the parent of x, if it exists.*

(i) *If x is an input vertex or p is an input vertex, then $r_x \geq f(x)/\sqrt{2}$.*
(ii) *Otherwise, $r_x \geq f(x)/\sqrt{2}$ or $r_x \geq c \cdot r_p$, where $c = 1/2$ if x has type 1 or 2 and $c = \rho_0$ if x has type 3.*

Proof. If x is an input vertex, then $r_x \geq f(x)$ by the definition of local feature size. Suppose that QUALMESH inserts x or rejects x by Rule 1, 2, or 3. Recall that x is the center of the smallest circumsphere of a subsegment, subfacet, or tetrahedron. Let $\widehat{x}$ denote this circumsphere.

Consider the case where p is an input vertex. If x has type 1 or 2, then $\|p-x\| \geq f(x)$ by Lemma 4.1. Note that $r_x \geq \|p-x\|/\sqrt{2}$ by Lemma 4.2. Thus we get $r_x \geq f(x)/\sqrt{2}$. Suppose that x has type 3. Let τ be the skinny tetrahedron split by x. One endpoint of the shortest edge of τ is p. Let q denote the other endpoint. Because p is an input vertex, q is also an input vertex. This is because p did not appear in $\mathcal{V}$ earlier than q by the definition of parent-child relation, which can only happen if q is also an input vertex. This means that the empty ball centered at x with radius r_x has two input vertices, namely p and q, on its boundary. Therefore, $r_x = \|p-x\| \geq f(x)$.

Consider the case where p is not an input vertex. If x has type 3, then r_p is at most the shortest edge length of the tetrahedron split by x. Then $r_x = X \geq \rho_0 r_p$. Suppose that x has type 1 or 2. If p has type 1, or p has type 2 and x has type 2, then $\|p-x\| \geq f(x)$ by Lemma 4.1 and $r_x \geq \|p-x\|/\sqrt{2}$ by Lemma 4.2. Then $r_x \geq f(x)/\sqrt{2}$. The remaining cases are that p has type 2 and x has type 1, or p has type 3.

Case 1: p lies inside $\widehat{x}$. Thus p was rejected by QUALMESH and $r_x = X$. Let τ be the subsegment or subfacet of which $\widehat{x}$ is the smallest circumsphere.

Case 1.1: τ is a subsegment ab. Let a be the vertex of τ nearest to p. Then $\angle pxa \leq \pi/2$. It follows that $\|p-a\| \leq \sqrt{2}X = \sqrt{2}r_x$. The vertex a was in $\mathcal{V}$ when p was rejected. Thus $r_p \leq \|p-a\|$. Hence, $r_x \geq r_p/\sqrt{2}$.

Case 1.2: τ is a subfacet abc. The Voronoi diagram of a, b, and c divides abc into three regions, each owned by a vertex of abc. Rule 2 enforces that τ contain the orthogonal projection of p. Thus we can assume that the projection of p lies in the region, say, owned by a. Let H be the plane that is perpendicular to abc and passes through a and p. Let y be the center of the circle $H \cap \widehat{x}$. As the projection of p lies inside the region owned by a, $\angle pya \leq \pi/2$. This implies that $\|p-a\|^2 \leq \|y-p\|^2 + \|y-a\|^2 \leq \|y-p\|^2 + X^2$. As p lies inside $\widehat{x} \cap H$, $\|y-p\| < \text{radius}(H \cap \widehat{x}) \leq X$. It follows that $\|p-a\| \leq \sqrt{2}X = \sqrt{2}r_x$. The vertex a was in $\mathcal{V}$ when p was rejected. Thus $r_p \leq \|p-a\|$. Hence, $r_x \geq r_p/\sqrt{2}$.

Case 2: p does not lie inside $\widehat{x}$. We have $\|p-x\| \geq r_p/\sqrt{2}$ by Lemma 4.1(ii) and $r_x \geq \|p-x\|/\sqrt{2}$ by Lemma 4.2. Thus $r_x \geq r_p/2$. □

5. Vertex-to-vertex distances. In this section, we apply Lemma 4.3 to prove lower bounds on the insertion radii and intervertex distances. In the process, we also prove that the vertex gap property holds throughout the algorithm. We will use these results in section 7 to prove several guarantees provided by weighted Delaunay refinement. We need the following relation involving local feature sizes and insertion radii.

LEMMA 5.1. *Let x be a vertex with parent p. If $r_x \geq c \cdot r_p$, then $f(x)/r_x \leq f(p)/(c \cdot r_p) + \sqrt{2}$.*

Proof. Recall that when x is inserted, x is the center of the smallest circumsphere of a subsegment, subfacet, or tetrahedron. Let $\widehat{x}$ denote this circumsphere. If x has type 3, then $r_x = \|p-x\|$. If x has type 1 or type 2, then $r_x \geq \|p-x\|/\sqrt{2}$ by Lemma 4.2. Starting with the Lipschitz condition, we get

$$\begin{aligned} f(x) &\leq f(p) + \|p-x\| \\ &\leq \frac{f(p)}{c \cdot r_p} \cdot r_x + \sqrt{2}r_x, \end{aligned}$$

which implies that $f(x)/r_x \leq f(p)/(c \cdot r_p) + \sqrt{2}$. □

The following are the constants of proportionality in Lemma 5.2, the main result in this subsection:

$$C_1 = \frac{7\sqrt{2}\rho_0}{\rho_0 - 4}, \qquad C_2 = \frac{3\sqrt{2}\rho_0 + 2\sqrt{2}}{\rho_0 - 4}, \qquad C_3 = \frac{\sqrt{2}\rho_0 + 3\sqrt{2}}{\rho_0 - 4}, \qquad \omega_0 = \frac{1}{2(1+C_1)}.$$

Note that whenever $\rho_0 > 4$, we have $C_1 > C_2 > C_3 > \sqrt{2}$.

LEMMA 5.2. *Let x be a vertex of $\mathcal{P}$ or a vertex inserted or rejected by* QUALMESH. *We have the following invariants for $\rho_0 > 4$:*

(i) *If x is a vertex of $\mathcal{P}$ or the parent of x is a vertex of $\mathcal{P}$, then $r_x \geq f(x)/\sqrt{2} > f(x)/C_3$. Otherwise, if x has type i for $1 \leq i \leq 3$, then $r_x \geq f(x)/C_i$.*

(ii) *For any other vertex y that appears in $\mathcal{V}$ currently, $\|x-y\|$ is greater than or equal to $\max\{f(x)/C_1, f(y)/(1+C_1)\}$.*

(iii) *If x is inserted by* QUALMESH, *the vertex gap property holds afterwards.*

Proof. We prove by induction. Invariant (i) holds before QUALMESH starts (the basis case). Clearly, invariant (i) is not affected by pumping a vertex. Thus it suffices to prove invariant (i) where x is inserted or rejected by QUALMESH. Let p be the

parent of x. If p is an input vertex, Lemma 4.3 implies that $r_x \geq f(x)/\sqrt{2}$. Suppose that p is not an input vertex. We assume inductively that invariant (i) holds for p and we conduct a case analysis. If x has type 3, then $r_x \geq \rho_0 \cdot r_p$ by Lemma 4.3. By induction, we get $f(p) \leq C_1 r_p$ regardless of the type of p. By Lemma 5.1, we get

$$\frac{f(x)}{r_x} \leq \frac{C_1}{\rho_0} + \sqrt{2} = C_3.$$

If x has type 2, the proof of Lemma 4.3 reveals that $r_x \geq f(x)/\sqrt{2} > f(x)/C_2$ when p has type 1 or 2. When p has type 3, Cases 1 and 2 in the proof of Lemma 4.3 reveal that $r_x \geq r_p/2$. By the induction assumption, $f(p) \leq C_3 r_p$. Then, by Lemma 5.1, we get

$$\frac{f(x)}{r_x} \leq 2C_3 + \sqrt{2} = C_2.$$

If x has type 1, then the proof of Lemma 4.3 reveals that $r_x \geq f(x)/\sqrt{2} > f(x)/C_1$ when p has type 1. When p has type 2 or 3, Cases 1 and 2 in the proof of Lemma 4.3 reveal that $r_x \geq r_p/2$. By the induction assumption, $f(p) \leq C_2 r_p$. Then, by Lemma 5.1, we get

$$\frac{f(x)}{r_x} \leq 2C_2 + \sqrt{2} = C_1.$$

This proves that invariant (i) holds in general.

Consider invariant (ii). For any vertex y that appears in $\mathcal{V}$ currently, $\|x - y\| \geq r_x \geq f(x)/C_1$. Because of $f(x) \geq f(y) - \|x - y\|$, we also get $\|x - y\| \geq f(x)/C_1 \geq f(y)/C_1 - \|x - y\|/C_1$. It follows that $\|x - y\| \geq f(y)/(1 + C_1)$.

Consider invariant (iii). It follows from invariant (ii) that for any vertices u and v in $\mathcal{V}$, $\|u - v\| \geq f(u)/(1 + C_1)$. By our choice of values of C_1 and ω_0, $f(u)/(1 + C_1) = 2\omega_0 f(u)$. This proves that the vertex gap property still holds. □

6. Effect of pumping. Let $\mathcal{V}$ denote a set of unweighted points. Let $\operatorname{Conv}\mathcal{V}$ denote the convex hull of $\mathcal{V}$. Let $\widehat{\mathcal{V}}$ be the weighted points obtained after some weight assignment to points in $\mathcal{V}$. We have already defined $N(x)$ to be the distance to the nearest neighbor in $\mathcal{V}$ for any $x \in \mathcal{V}$. We extend the definition for any $x \in \mathbb{R}^3$ by letting $N(x)$ denote the Euclidean distance from x to its *second* nearest neighbor in $\mathcal{V}$ for any point $x \in \mathbb{R}^3$. If $x \in \mathcal{V}$, then $N(x)$ still denotes the nearest neighbor distance of x. We say $\widehat{\mathcal{V}}$ has *weight property* $[\omega]$ for some $\omega \in (0, 1/2)$ if $U \leq \omega N(u)$ for each $\widehat{u} \in \widehat{\mathcal{V}}$. Let $\operatorname{Del}\widehat{\mathcal{V}}$ denote the weighted Delaunay triangulation of $\widehat{\mathcal{V}}$. $\operatorname{Del}\widehat{\mathcal{V}}$ has *ratio property* $[\rho]$ if the orthoradius-edge ratio of every tetrahedron in $\operatorname{Del}\widehat{\mathcal{V}}$ is at most ρ.

The work of Cheng et al. [7] suggests that $\operatorname{Del}\mathcal{V}$ and $\operatorname{Del}\widehat{\mathcal{V}}$ behave similarly given the ratio and weight properties, as follows.

LEMMA 6.1 (Claim 7 in [7]). *Let $\mathcal{V}$ be a periodic point set. If $\operatorname{Del}\mathcal{V}$ has ratio property $[\rho]$ and $\widehat{\mathcal{V}}$ has weight property $[\omega]$, then $\operatorname{Del}\widehat{\mathcal{V}}$ has ratio property $[\rho']$ for some ρ' depending on ρ and ω.*

In this section, we prove a version of the Lemma 6.1 for dealing with a finite point set (see Lemma 6.6). There are two differences from Lemma 6.1. First, $\mathcal{V}$ is a finite point set instead of a periodic point set. Second, we need an extra condition that the orthocenter of each tetrahedron in $\operatorname{Del}\widehat{\mathcal{V}}$ lie inside $\operatorname{Conv}\mathcal{V}$. Then the rest of Lemma 6.1 carries over.

We need three results from Talmor's thesis [16]. We state them below and include the proof of Lemma 6.3, as we need an inequality in the proof later. For a point $p \in \mathcal{V}$, let $V_p(\mathcal{V})$ denote the Voronoi cell owned by p in the Voronoi diagram of $\mathcal{V}$. Let b_p and B_p be balls centered at p such that $\text{radius}(b_p) = N(p)/2$ and $\text{radius}(B_p) = \rho L \cdot N(p)$, where L is a constant used in the next lemma.

LEMMA 6.2 (Lemma 3.4.3 in [16]). *If* $\text{Del}\,\mathcal{V}$ *has ratio property* $[\rho]$*, the lengths of two adjacent edges of* $\text{Del}\,\mathcal{V}$ *differ by at most some constant factor* L *depending on* ρ*.*

LEMMA 6.3 (Lemma 3.5.1 in [16]). *Assume that* $\text{Del}\,\mathcal{V}$ *has ratio property* $[\rho]$*. For each* $p \in \mathcal{V}$*,* $V_p(\mathcal{V})$ *contains* b_p*, and* B_p *contains all vertices of* $V_p(\mathcal{V})$*.*

Proof. It is obvious that $b_p \subseteq V_p(\mathcal{V})$ as $\text{radius}(b_p) = N(p)/2$. Let $v \in \mathcal{V}$ such that $\|p - v\| = N(p)$. Then pv is an edge of $\text{Del}\,\mathcal{V}$. Let τ be some tetrahedron in $\text{Del}\,\mathcal{V}$ incident to p. Let pq be an edge of τ. Using Lemma 6.2, we get

$$\|p - q\| \leq L \cdot \|p - v\| = L \cdot N(p). \tag{6.1}$$

Let z be the circumcenter of τ; i.e., z is a vertex of $V_p(\mathcal{V})$. The ratio property implies that

$$\|p - z\| \leq \rho \cdot \|p - q\| \leq \rho L \cdot N(p) = \text{radius}(B_p).$$

Thus, B_p contains all vertices of $V_p(\mathcal{V})$. □

LEMMA 6.4 (Theorem 3.6.2 in [16]). *Assume that* $\text{Del}\,\mathcal{V}$ *has ratio property* $[\rho]$*. Let* xz *be a line segment lying inside* $\bigcup_{p\in\mathcal{V}} V_p(\mathcal{V}) \cap B_p$*. Let* $\widehat{z}$ *be the sphere centered at* z *with radius* $\|x - z\|$*. Then there is a constant* $C > 0$ *such that if* $\widehat{z}$ *is empty, then* $N(z) \leq C \cdot N(x)$*.*

Next, we apply Lemma 6.3 to show that B_p is so large that $V_p(\mathcal{V}) \cap B_p$ contains $V_p(\mathcal{V}) \cap \text{Conv}\,\mathcal{V}$. The implication is that $\bigcup_{p\in\mathcal{V}} V_p(\mathcal{V}) \cap B_p$ contains the Voronoi diagram of $\mathcal{V}$ clipped within $\text{Conv}\,\mathcal{V}$.

LEMMA 6.5. *Assume that* $\text{Del}\,\mathcal{V}$ *has ratio property* $[\rho]$*. For each* $p \in \mathcal{V}$*,* $V_p(\mathcal{V}) \cap \text{Conv}\,\mathcal{V} \subseteq V_p(\mathcal{V}) \cap B_p$*.*

Proof. We first prove that $V_p(\mathcal{V}) \cap \text{Conv}\,\mathcal{V} \subseteq B_p$. If $V_p(\mathcal{V})$ is bounded, then $V_p(\mathcal{V}) \subseteq B_p$ by Lemma 6.3. It follows that $V_p(\mathcal{V}) \cap \text{Conv}\,\mathcal{V} \subseteq B_p$. Suppose that $V_p(\mathcal{V})$ is unbounded. Then p is an extreme vertex of $\text{Conv}\,\mathcal{V}$. Let T be the set of boundary triangles of $\text{Conv}\,\mathcal{V}$ incident to p. For each triangle $t \in T$, let H_t denote the supporting plane of t, and let H_t^+ denote the halfspace bounded by H_t that contains $\text{Conv}\,\mathcal{V}$. By convexity, $V_p(\mathcal{V}) \cap \text{Conv}\,\mathcal{V} \subseteq V_p(\mathcal{V}) \cap \bigcap_{t\in T} H_t^+$. We show that B_p contains the vertices of $V_p(\mathcal{V}) \cap \bigcap_{t\in T} H_t^+$. A vertex z of $V_p(\mathcal{V}) \cap \bigcap_{t\in T} H_t^+$ has one of three types:

1. z is a vertex of $V_p(\mathcal{V})$. By Lemma 6.3, $z \in B_p$.
2. z is the intersection of some edge pq in $\text{Del}\,\mathcal{V}$ with a facet of $V_p(\mathcal{V})$. By (6.1), $\|p - q\| \leq L \cdot N(p) \leq \text{radius}(B_p)$, and so $z \in B_p$.
3. z is the intersection of H_t for some $t \in T$ and some edge of $V_p(\mathcal{V})$. Let q and r be the other two vertices of t. Let $\mathcal{Q}$ be the convex quadrilateral on H_t bounded by the bisector plane of p and q, the bisector plane of p and r, pq, and pr. See Figure 6.1.

   Let u be the vertex of $\mathcal{Q}$ diagonally opposite p. Observe that z lies inside $\mathcal{Q}$. Thus we are done if we can show that $\mathcal{Q} \subseteq B_p$. By (6.1), $\|p-q\| \leq \text{radius}(B_p)$ and $\|p - r\| \leq \text{radius}(B_p)$. It follows that p, q, and r lie inside B_p. Let $\theta = \angle pqr$ and $\beta = \angle prq$. The angle of $\mathcal{Q}$ at u is $\theta + \beta$. After splitting this

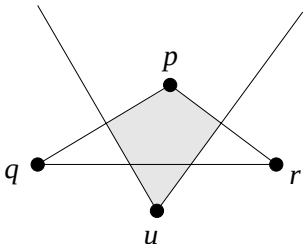

FIG. 6.1. *The shaded convex quadrilateral is* $\mathcal{Q}$.

angle into two with the diagonal pu, let γ denote the one on the same side as pq. Without loss of generality, assume that $\gamma \geq (\theta + \beta)/2$, which is at least $\min\{\theta, \beta\}$. By the ratio property, $\rho \geq \min\{1/(2\sin\theta), 1/(2\sin\beta)\}$. It follows that $\rho \geq 1/(2\sin\gamma)$. We have

$$\begin{aligned} \|p-u\| &= \frac{\|p-q\|}{2\cdot\sin\gamma} \\ &\leq \rho\cdot\|p-q\| \\ &\overset{(6.1)}{\leq} \rho L\cdot N(p) \\ &= \text{radius}(B_p). \end{aligned}$$

Therefore, $\mathcal{Q} \subseteq B_p$, and hence z lies inside B_p.

Note that $V_p(\mathcal{V}) \cap \bigcap_{t\in T} H_t^+$ is bounded. We conclude that $V_p(\mathcal{V}) \cap \operatorname{Conv}\mathcal{V} \subseteq V_p(\mathcal{V}) \cap \bigcap_{t\in T} H_t^+ \subseteq B_p$. Finally, $V_p(\mathcal{V}) \cap \operatorname{Conv}\mathcal{V} = V_p(\mathcal{V}) \cap V_p(\mathcal{V}) \cap \operatorname{Conv}\mathcal{V} \subseteq V_p(\mathcal{V}) \cap B_p$. ∎

Finally, we apply Lemmas 6.4 and 6.5 to prove the main result of this subsection.

LEMMA 6.6. *Let* $\mathcal{V}$ *be a finite point set. Assume that* $\operatorname{Del}\mathcal{V}$ *has ratio property* $[\rho]$, $\widehat{\mathcal{V}}$ *has weight property* $[\omega]$, *and the orthocenter of each tetrahedron in* $\operatorname{Del}\widehat{\mathcal{V}}$ *lies inside* $\operatorname{Conv}\mathcal{V}$. *Then* $\operatorname{Del}\widehat{\mathcal{V}}$ *has ratio property* $[\rho']$ *for some constant* ρ' *depending on* ρ *and* ω.

Proof. Let $\widehat{z}$ be the orthosphere of a tetrahedron τ in $\operatorname{Del}\widehat{\mathcal{V}}$. That is, z is the orthocenter of τ. Let qr be the shortest edge of τ. Let x be the intersection point $qz \cap \widehat{z}$.

By assumption, z lies inside $\operatorname{Conv}\mathcal{V}$. Thus we have $xz \subseteq \operatorname{Conv}\mathcal{V}$ by convexity. Using the fact that $\bigcup_{p\in\mathcal{V}} V_p(\mathcal{V}) = \mathbb{R}^3$, we get $xz \subseteq \operatorname{Conv}\mathcal{V} \cap \bigcup_{p\in\mathcal{V}} V_p(\mathcal{V}) = \bigcup_{p\in\mathcal{V}} V_p(\mathcal{V}) \cap \operatorname{Conv}\mathcal{V}$. Lemma 6.5 further implies that $xz \subseteq \bigcup_{p\in\mathcal{V}} V_p(\mathcal{V}) \cap B_p$. As $\widehat{z}$ is empty, we can apply Lemma 6.4 to xz and $\mathcal{V}$. We get

$$Z \leq N(z) \leq C\cdot N(x). \tag{6.2}$$

By the Lipschitz property, $N(x) \leq N(q) + \|q-x\|$. Because $\widehat{q}$ and $\widehat{z}$ intersect and $x = qz \cap \widehat{z}$, x lies inside $\widehat{q}$. By the weight property, the radius of $\widehat{q}$ is at most $\omega N(q)$, and so $\|q-x\| \leq \omega N(q)$. Thus, we have $N(x) \leq (1+\omega)N(q)$. As q and r are vertices in $\mathcal{V}$, $N(q) \leq \|q-r\|$. It follows that

$$N(x) \leq (1+\omega)\cdot\|q-r\|. \tag{6.3}$$

Substituting (6.3) into (6.2), we get $Z \leq C\cdot(1+\omega)\cdot\|q-r\|$. Recall that qr is the shortest edge of τ. Hence, ρ' can be set to be $C\cdot(1+\omega)$. ∎

7. Guarantees. We establish four guarantees for QualMesh. The first two guarantees, termination and gradedness, follow from Lemma 5.2. The absence of sliver and the size optimality are guaranteed using Lemma 5.2, Lemma 6.6, and some other results to be proved.

7.1. Termination and gradedness.

Theorem 7.1. QualMesh *terminates with a graded mesh.*

Proof. It follows from Lemma 5.2(ii) that any two vertices u and v at any stage of the algorithm must satisfy $\|u - v\| \geq f(u)/(1 + C_1) \geq f_{min}/(1 + C_1)$, where f_{min} is the minimum local feature size in the domain. If we center disjoint balls of radii $f_{min}/(2 + 2C_1)$ at the mesh vertices, then we can pack at most $24(1 + C_1)^3 \text{volume}(D)/(4\pi f_{min}^3)$ such balls inside a bounded domain D. Thus the algorithm must terminate. Gradedness follows from the vertex gap property. □

7.2. Conformity. After pumping in step 3, is $\text{Del}\,\widehat{\mathcal{V}}$ conforming? The vertices in $\widehat{\mathcal{V}}$ partition the input segments into weighted-subsegments. For any input facet F, the two-dimensional weighted Delaunay triangulation of vertices on F partition F into weighted-subfacets. We show that $\text{Del}\,\widehat{\mathcal{V}}$ is conforming by showing that no weighted-subsegment or weighted-subfacet is encroached.

Theorem 7.2. *No weighted-subsegment or weighted-subfacet is encroached upon during the completion of* QualMesh.

Proof. Assume to the contrary that a vertex $\widehat{v}$ in $\text{Del}\,\widehat{\mathcal{V}}$ encroaches upon a weighted-subsegment or weighted-subfacet τ.

Consider the case in which τ is a weighted-subsegment. Observe that the smallest circumsphere C of τ encloses the smallest orthosphere O of τ. Thus, the bisector H of C and O avoids C, and so H avoids τ too. τ lies in the halfspace H^+ bounded by H such that $\pi(p, C) \leq \pi(p, O)$ for all points $p \in H^+$. Observe that in order that $\widehat{v}$ encroach upon τ, τ contains the orthogonal projection of v onto the segment containing τ. Thus, $v \in H^+$, and so $\pi(\widehat{v}, C) \leq \pi(\widehat{v}, O) < 0$. The weight of $\widehat{v}$ is at most the weight used for v in Rule 4. However, this contradicts the fact that v, with that weight, did not encroach upon τ.

Consider the case in which τ is a weighted-subfacet on a facet F. By Lemma 3.6, we can assume that τ contains the projection of v. Let O be the smallest orthosphere of τ. The two-dimensional unweighted Delaunay triangulation of vertices in $\mathcal{V}$ on F partitions F into subfacets. Let τ' be the subfacet that contains the projection of v on τ. Let C be the smallest circumsphere of τ'. We claim that the bisector plane H of C and O avoids τ'. Otherwise, H intersects C, which implies that C and O intersect (H passes through their intersection). Because τ' has vertices on both sides of H, a vertex of τ' must lie inside O, a contradiction. Observe that τ' lies in the halfspace H^+ bounded by H such that $\pi(p, C) \leq \pi(p, O)$ for all point $p \in H^+$. Thus, $\pi(\widehat{v}, C) \leq \pi(\widehat{v}, O) < 0$. The weight of $\widehat{v}$ is at most the weight used for v in Rule 4. However, this contradicts the fact that v, with that weight, did not encroach upon τ'. □

7.3. No sliver. Slivers incident to an unweighted vertex p are eliminated by pumping p. In sliver exudation, p is pumped within the weight interval $[0, \omega_0^2 N(p)^2]$. During the pumping, tetrahedra incident to p change at discrete instances. For pumping to work, two conditions (Lemmas 7.3 and 7.4) must hold over the entire interval of pumping. First, the lengths of edges incident to p are within a constant factor. Second, only a constant number of tetrahedra can be incident to p. These two conditions are proved by Cheng et al. [7] for periodic point set using Lemma 6.1. Lemma 6.6 is

the analogue of Lemma 6.1 for finite point set. By Theorem 7.2 and Lemma 3.3(iii), the conditions of Lemma 6.6 are satisfied. Thus we can prove the two conditions for finite point set using exactly the same proofs as those used in [7]. For completeness, we sketch the proofs below. Let $K(\mathcal{V})$ be the graph consisting of edges in $\operatorname{Del}\widehat{\mathcal{V}}$ for all $\widehat{\mathcal{V}}$ with weight property $[\omega_0]$.

LEMMA 7.3 (Claim 10 in [7]). *Assume that* $\operatorname{Del}\mathcal{V}$ *has ratio property* $[\rho_0]$. *The lengths of any two adjacent edges in* $K(\mathcal{V})$ *are within a constant factor* $\nu_0 \geq 1$ *depending on* ρ_0 *and* ω_0.

Proof (sketch). Let p be a vertex in $\mathcal{V}$. First, consider a triangle $pqu \in \operatorname{Del}\widehat{\mathcal{V}}$ for some $\widehat{\mathcal{V}}$ with weight property $[\omega_0]$. Let Z be the radius of the smallest orthosphere of pqu. By Lemma 6.6, $Z \leq \rho' \cdot \|p-q\|$ and $Z \leq \rho' \cdot \|p-u\|$. On other hand, by the weight property, a constant fraction of pq lies outside $\widehat{p}$ and $\widehat{q}$. This fraction of pq lies inside the smallest orthosphere of pqu, and so $Z = \Omega(\|p-q\|)$. Similarly, $Z = \Omega(\|p-u\|)$. It follows that $\|p-q\|$ and $\|p-u\|$ differ by at most some constant factor k_1.

Second, consider the case in which pq and pu are two edges in $K(\mathcal{V})$ such that $\angle qpu$ is less than some constant angle bound η. Assume that $\widehat{\mathcal{V}_1}$ and $\widehat{\mathcal{V}_2}$ denote the two weighted versions of $\mathcal{V}$ such that $pq \in \operatorname{Del}\widehat{\mathcal{V}_1}$ and $pu \in \operatorname{Del}\widehat{\mathcal{V}_2}$. Let H be the plane passing through pqu. We pick the orthosphere $\widehat{z}$ of a tetrahedron τ in $\operatorname{Del}\widehat{\mathcal{V}_1}$ that is incident on pq. We intersect $\widehat{z}$ with H to obtain a circle $\widehat{y}$ centered at y with radius Y. Note that $\widehat{y}$ is orthogonal to the circles $\widehat{p} \cap H$ and $\widehat{q} \cap H$. By Lemma 6.6, the radius of $\widehat{z}$ is at most $\rho' \cdot \|p-q\|$. Clearly, Y is at most the radius of $\widehat{z}$. So $Y \leq \rho' \cdot \|p-q\|$. This implies that pq cuts deeply into $\widehat{y}$. As u lies outside $\widehat{y}$, for sufficiently small η (dependent on ρ' and ω_0), pu cannot be much shorter than pq. By symmetry, pq cannot be much shorter than pu. Thus, $\|p-q\|$ and $\|p-u\|$ differ by at most some constant factor k_2.

Next, we deal with all incident edges of p. Let S be a unit sphere centered at p. We take a maximal packing of disjoint spherical caps with angular radii $\eta/4$ on S. The number of such caps is a constant m dependent on η. Then we expand the angular radius of each cap to $\eta/2$. The expanded caps cover S. Each incident edge pq projects radially to a vertex q' on S. Each triangle pqr in $\operatorname{Del}\widehat{\mathcal{V}}$ for some $\widehat{V}$ with weight property $[\omega_0]$ projects radially to an arc $q'r'$ on S. This yields a connected graph embedded on S. Suppose that we walk from q' to an arbitrary vertex u' within the graph. If the walk stays within a cap, by our second observation, the edge length increases by at most a factor of k_2. If the walk enters a new cap, by our first observation, the edge length increases by at most a factor of k_1. If the walk returns to a cap visited before, the whole detour increases the edge length by at most a factor of k_2. As there are m caps, we conclude that $\|p-q\|$ and $\|p-u\|$ differ by at most a factor of $k_2^m k_1^{m-1}$. □

LEMMA 7.4 (Claim 11 in [7]). *Assume that* $\operatorname{Del}\mathcal{V}$ *has ratio property* $[\rho_0]$. *The degree of every vertex in* $K(\mathcal{V})$ *is bounded by some constant* δ_0 *depending on* ρ_0 *and* ω_0.

Proof (sketch). Let p be a vertex in $\mathcal{V}$. Let L be the length of the longest incident edge of p in $K(\mathcal{V})$. Let r be a neighbor of p in $K(\mathcal{V})$. By Lemma 7.3, $\|p-r\| \geq L/\nu_0$. The nearest neighbor of r is a Delaunay neighbor of r. Thus, by Lemma 7.3 again, the nearest neighbor distance of r is at least L/ν_0^2. It follows that, at the neighbors of p, we can center disjoint balls of radius $L/(2\nu_0^2)$. Observe that all these balls lie inside the ball centered at p with radius $L + L/(2\nu_0^2)$. Thus, a packing argument shows that p has $O(1)$ neighbors. □

Cheng et al. [7] proved that a sliver incident to p can remain weighted Delaunay only within a subinterval of width $O(\sigma_0 N(p)^2)$ during pumping. As the number of

tetrahedra in $K(\mathcal{V})$ incident to p is bounded by a constant, if we choose σ_0 properly, the intervals over which slivers remain incident to a vertex p can be made small enough so that there is a subinterval over which no sliver is incident to p. This is the key idea in [7] in the proof that pumping can eliminate slivers for periodic point sets. The freedom in choosing σ_0 reveals that it is unnecessary to use exactly the weight interval $[0, \omega_0^2 N(p)^2]$. It is equally good that the weight interval contains $[0, \overline{\omega}_0^2 N(p)^2]$ for some constant $\overline{\omega}_0 \leq \omega_0$.

We would like to employ Lemmas 7.3 and 7.4 with $\mathcal{V}$ being a finite point set. To this end, we first need to guarantee that the pumping in step 3 of QualMesh uses a weight interval $[0, \overline{\omega}_0^2 N(p)^2]$ and that the resulting weighted point set $\widehat{\mathcal{V}}$ has weight property $[\omega_0]$ for some constants $\overline{\omega}_0 \leq \omega_0$. The weight property $[\omega_0]$ follows from the vertex gap property. Lemma 7.5 tells us how to set $\overline{\omega}_0$.

Lemma 7.5. *Let $\mathcal{M}$ be the mesh obtained at the end of step 2 of* QualMesh. *For any vertex v in $\mathcal{M}$, its nearest neighbor distance is at most $2\sqrt{2}f(v)$.*

Proof. Let B_v denote the ball centered at v of radius $N(v)/2$. Assume to the contrary that $2\sqrt{2}f(v) < N(v)$. Then B_v intersects two disjoint elements of $\mathcal{P}$. B_v cannot contain any vertex in $\mathcal{V}$. So B_v intersects the interior of subsegments or subfacets. Let E be the nearest subsegment or subfacet to v that B_v intersects. Let $\tilde{v}$ be the orthogonal projection of v onto the affine hull of E. Note that $\tilde{v}$ lies on E. The Voronoi diagram of the vertices of E partitions E into regions, each owned by one vertex of E. Assume that $\tilde{v}$ lies in the region owned by the vertex w of E. Because $\|v - w\| \geq \text{radius}(B_v) > \sqrt{2}f(v)$ and $\|v - \tilde{v}\| \leq f(v)$, we have

$$\|v - \tilde{v}\| < \|v - w\|/\sqrt{2}. \tag{7.1}$$

Let $\widehat{x}$ be the smallest circumsphere of E. We have $\|v - x\|^2 = \|\tilde{v} - x\|^2 + \|v - \tilde{v}\|^2$. Because $\tilde{v}$ lies in the region owned by w, $\angle x\tilde{v}w \geq \pi/2$, which implies that $\|\tilde{v} - x\|^2 \leq \|w - x\|^2 - \|\tilde{v} - w\|^2$. Therefore,

$$\begin{aligned} \|v - x\|^2 &\leq \|w - x\|^2 - \|\tilde{v} - w\|^2 + \|v - \tilde{v}\|^2 \\ &= \|w - x\|^2 - \|v - w\|^2 + 2\|v - \tilde{v}\|^2 \\ &\overset{(7.1)}{<} \|w - x\|^2. \end{aligned}$$

However, v lies inside $\widehat{x}$ then, and so v encroaches upon E, a contradiction. □

In step 3 of QualMesh, we pump p using the weight interval $[0, \omega_0^2 f(p)^2]$. This interval contains $[0, \omega_0^2 N(p)^2/8]$ by Lemma 7.5. Using Lemmas 7.3 and 7.4, the same proof in [7] shows that pumping eliminates slivers for the finite point set $\mathcal{V}$. For completeness, we sketch the proof below. Algorithmically, we can use flips to generate new tetrahedra as pumping progresses and stop when no sliver is incident to p.

Theorem 7.6. *There is a constant $\sigma_0 > 0$ such that $\sigma(\tau) > \sigma_0$ for every tetrahedron τ in the output mesh of* QualMesh.

Proof (sketch). Let $pqrs$ be a sliver in some $\widehat{\mathcal{V}}$ with weight property $[\omega_0]$. We are to analyze what happens to $pqrs$ when p is pumped with weight from the interval $[0, \omega_0^2 f(p)^2]$. Let W_{qrs} be the subinterval such that $pqrs$ may remain weighted Delaunay when $P^2 \in W_{qrs}$.

We claim that $|W_{qrs}| = O(\sigma_0 N(p)^2)$. Let L be the shortest edge length of $pqrs$. Let $\widehat{z}$ be the orthosphere of $pqrs$. Let $H(P)$ be the signed distance of z from the plane passing through qrs when p has weight P^2. $H(P)$ is positive if p and z lie on the same side and $H(P)$ is negative otherwise. Observe that $Z^2 = H(P)^2 + Y^2$, where Y is the radius of smallest orthosphere of qrs. By Lemma 6.6, $Z \leq \rho' L$. The

circumradius of qrs is at least $L/2$. Also, by Claim 4 in [7], the circumradius of qrs is at most $Y/\sqrt{1-4\omega_0^2}$. It follows that $H(P)^2 = Z^2 - Y^2 = O(L^2)$ or $H(P) \in [-kL, kL]$ for some constant k. By Claim 13 in [7], $H(P) = H(0) - P^2/(2D)$, where D is the distance of p from the plane passing through qrs. Substituting into $H(P) \in [-kL, kL]$ and rearranging terms, we get $2D \cdot H(0) - 2kDL \le P^2 \le 2D \cdot H(0) + 2kDL$. Thus, $|W_{qrs}| \le 4kDL$. Note that volume$(pqrs) = \Theta(L^2 D)$ and volume$(pqrs)/L^3 \le \sigma_0$ as $pqrs$ is a sliver. This implies that $D = O(\sigma_0 L)$ and so $|W_{qrs}| = O(\sigma_0 L^2)$. The nearest neighbor of p is the Delaunay neighbor of p. Thus by applying Lemma 7.3 to p and then to q, r, and s, we conclude that $L = \Theta(N(p))$. Hence, $|W_{qrs}| = O(\sigma_0 N(p)^2)$.

Finally, by Lemma 7.4, there are at most δ_0^3 slivers incident to p throughout the entire pumping. Hence there are at most δ_0^3 forbidden subintervals. Their total length is at most $k'\sigma_0\delta_0^3 N(p)^2$ for some constant k'. By Lemma 7.5, the weight interval $[0, \omega_0^2 f(p)^2]$ contains $[0, \omega_0^2 N(p)^2/8]$. It follows that if $\sigma_0 < \omega_0^2/(8k'\delta_0^3)$, p can be assigned a weight within $[0, \omega_0^2 f(p)^2]$ such that p is not incident to any sliver. □

7.4. Size optimality. We prove that the size of our Delaunay mesh is within a constant factor of the size of any mesh that has bounded aspect ratio. Our proof is a combination of ideas in Ruppert's proof for the two-dimensional case [19] and ideas in Mitchell and Vavasis's proof for their octtree algorithm in higher dimensions [18].

Let T be a triangulation of the input domain that conforms to $\mathcal{P}$ and has bounded aspect ratio. Let τ be a tetrahedron in T. Denote the minimum height of τ from a vertex by $h(\tau)$. Let v_0, v_1, v_2, and v_3 be the vertices of τ. Each v_i is to be viewed as a column vector consisting of the coordinates of the vertex. Define M_τ to be the 3×3 matrix $(v_1 - v_0, v_2 - v_0, v_3 - v_0)$. Although M_τ depends on the numbering of the vertices of τ, the numbering does not affect the properties of M_τ that will be used. For a vector x, we use $\|x\|$ to denote its L_2-norm. For a square matrix A, we use $\|A\|$ to denote its spectral norm, i.e., the square root of the maximum eigenvalue of $A^t A$.

LEMMA 7.7 (Lemma 2 in [18]). *For any tetrahedron τ in T, $\|(M_\tau^{-1})^t\| = \|M_\tau^{-1}\| \le k_1/h(\tau)$ for some constant $k_1 \ge 1$.*

Proof. It is proved in [18] that $\|M_\tau^{-1}\| \le k_1/h(\tau)$ for some constant k_1. $\|A\| = \|A^t\|$ for any square matrix A. □

Between two points on two disjoint elements of T (vertices, edges, triangles, or tetrahedra), we show in the following lemma that one can always find a tetrahedron that is relatively small compared with the distance between the two points. The result is analogous to Theorem 2 in [18].

LEMMA 7.8. *Let p and q be two points in the interior of T. Let τ_p and τ_q be the tetrahedra of T containing p and q, respectively. If τ_p and τ_q do not share any vertex, then there is a tetrahedron τ in T intersecting pq such that*

(i) *$h(\tau) \le k_2\|p - q\|$ for some constant $k_2 \ge 1$;*
(ii) *τ shares a vertex with τ_q. (τ can be forced to share a vertex with τ_p instead, but τ cannot be guaranteed to share vertices with both τ_p and τ_q.)*

Proof. Define a simplicial map $\psi : T \to \mathbb{R}$ by setting $\psi(v) = 1$ for each vertex v of τ_q, and $\psi(w) = 0$ for all other vertices w. It follows that $\psi(x) = 1$ for all points $x \in \tau_q$, and $\psi(x) = 0$ for all points $x \in \tau_p$. As ψ is continuous, there exists a point u on pq such that the directional derivative of ψ at u has magnitude at least $1/\|p - q\|$. By convexity, there is a tetrahedron τ in T containing u. By the linearity of ψ on τ, $\bigtriangledown\psi$ is constant on τ. Therefore,

$$\|\bigtriangledown\psi\| \ge \frac{1}{\|p - q\|} \tag{7.2}$$

on τ. This implies that τ shares a vertex with τ_q; otherwise ψ and $\bigtriangledown\psi$ would be identically zero on τ, which is a contradiction. This proves (ii). We express $\bigtriangledown\psi$ on τ using M_τ as follows. Let v_0, v_1, v_2, v_3 be the vertices of τ. Define $r_i = \psi(v_i) - \psi(v_0)$ for $i = 1, 2, 3$. Observe that $0 \leq |r_i| \leq 1$.

CLAIM 7.1. *For any point z in τ, $\psi(z) - \psi(v_0) = (r_1, r_2, r_3)M_\tau^{-1}(z - v_0)$.*

Proof. The point z can be written as a convex combination of the vertices of τ: $z = \sum_{i=0}^{3} \lambda_i v_i$. This implies that

$$z - v_0 = \sum_{i=1}^{3} \lambda_i (v_i - v_0).$$

We view M_τ^{-1} as three row vectors $\alpha_1, \alpha_2, \alpha_3$ ordered from top to bottom. Recall that $M_\tau = (v_1 - v_0, v_2 - v_0, v_3 - v_0)$. As $M_\tau^{-1} M_\tau = I$, $\alpha_k \cdot (v_k - v_0) = 1$ and $\alpha_k \cdot (v_j - v_0) = 0$ for all $j \neq k$. It follows that

$$M_\tau^{-1}(z - v_0) = (\lambda_1, \lambda_2, \lambda_3)^t.$$

We conclude that $(r_1, r_2, r_3)M_\tau^{-1}(z - v_0) = \sum_{i=1}^{3} \lambda_i(\psi(v_i) - \psi(v_0)) = (\sum_{i=0}^{3} \lambda_i \psi(v_i)) - \psi(v_0) = \psi(z) - \psi(v_0)$. □

The claim implies that $\bigtriangledown\psi = (M_\tau^{-1})^t (r_1, r_2, r_3)^t$ on τ and so

$$\begin{aligned} \|\bigtriangledown\psi\| &\leq \|(M_\tau^{-1})^t\| \cdot \|(r_1, r_2, r_3)^t\| \\ &\leq \sqrt{3} \cdot \|(M_\tau^{-1})^t\|, \quad \text{as } 0 \leq |r_i| \leq 1 \\ &\overset{\text{Lemma 7.7}}{\leq} \sqrt{3} k_1 / h(\tau). \end{aligned}$$

Combining the above with (7.2), we obtain $h(\tau) \leq \sqrt{3} k_1 \|p - q\|$. This proves (i). □

As T has a bounded aspect ratio, it enjoys properties similar to those stated in Lemma 6.2. In particular, two tetrahedra sharing a vertex have similar minimum heights.

LEMMA 7.9 (see [17, 18]). *If two tetrahedra τ_1 and τ_2 in T share a vertex, then $h(\tau_1) \leq k_3 h(\tau_2)$ for some constant $k_3 \geq 1$.*

Next, we prove that the minimum heights of tetrahedra in T change smoothly. The result is analogous to Lemma 11 in [18].

LEMMA 7.10. *Let p and q be two points, and let τ_p and τ_q, respectively, be the two tetrahedra in T that contain them. Then $h(\tau_q) \leq k_4 \max\{h(\tau_p), \|p - q\|\}$ for some constant $k_4 \geq 1$.*

Proof. If τ_q shares a vertex with τ_p, then $h(\tau_q) \leq k_3 h(\tau_p)$, by Lemma 7.9. Consider the case where τ_q does not share a vertex with τ_p. By Lemma 7.8, there is a tetrahedron τ in T intersecting pq such that $h(\tau) \leq k_2 \|p - q\|$ and τ shares a vertex with τ_q. Starting with Lemma 7.9, we get $h(\tau_q) \leq k_3 h(\tau) \leq k_2 k_3 \|p - q\|$. □

The following lemma shows that the minimum heights of tetrahedra in T are also related to the local feature sizes. The result is analogous to Lemma 5 in [19].

LEMMA 7.11. *Let x be a point, and let τ be a tetrahedron in T containing x. Then $h(\tau) \leq k_5 f(x)$ for some constant $k_5 \geq 1$.*

Proof. Let B be the ball centered at x of radius $f(x)$. B contains two points p and q on two disjoint elements of $\mathcal{P}$. By Lemma 7.8, there is a tetrahedron τ' in T intersecting pq such that $h(\tau') \leq k_2 \|p - q\|$. Let u be a point in the intersection of τ'

and pq. By applying Lemma 7.10 to u and x, we have

$$\begin{aligned} h(\tau) &\le k_4 \max\{h(\tau'), \|u-x\|\} \\ &\le k_4 \max\{k_2\|p-q\|, \|u-x\|\} \\ &\le k_4 \max\{k_2 \cdot 2f(x), f(x)\} \\ &\le 2k_2k_4 f(x). \qquad \square \end{aligned}$$

We are now ready to prove the main theorem of this section.

THEOREM 7.12. *The output size of* QUALMESH *is within a constant factor of the size of any mesh of bounded aspect ratio for the same domain.*

Proof. Let $\mathcal{D}$ denote the domain to be meshed. Let n be the number of vertices in the Delaunay mesh output by QUALMESH. First, we show that n is at most some constant times $\int_{\mathcal{D}} \frac{dx}{f(x)^3}$. As $N(v) \ge f(v)/(1+C_1)$, we can center a ball B_v of radius $d_v = f(v)/(2+2C_1)$ at each vertex v so that all balls are disjoint. Observe that $f(x) \le f(v) + d_v$ for all $x \in B_v$. Therefore,

$$\begin{aligned} \int_{\mathcal{D}} \frac{dx}{f(x)^3} &\ge \sum_v \int_{B_v} \frac{dx}{f(x)^3} \\ &\ge \sum_v \frac{4\pi d_v^3}{3(f(v)+d_v)^3} \\ &\ge \sum_v \frac{4\pi}{3(3+2C_1)^3}. \end{aligned}$$

Therefore, we have

$$n = \sum_v 1 \le \frac{3(3+2C_1)^3}{4\pi} \int_{\mathcal{D}} \frac{dx}{f(x)^3}.$$

By Lemma 7.4, the number of tetrahedra in the Delaunay mesh is within a constant factor of n. More formally, let m be the number of tetrahedra; we have

$$m \le k_6 \int_{\mathcal{D}} \frac{dx}{f(x)^3}$$

for some constant k_6.

Next, consider a mesh T of $\mathcal{D}$ of bounded aspect ratio. For each point x in $\mathcal{D}$, define $\ell(x)$ to be the minimum height of the tetrahedra in T containing x. By Lemma 7.11, $\ell(x) \le k_5 f(x)$ and so

$$\begin{aligned} \int_{\mathcal{D}} \frac{dx}{f(x)^3} &\le k_5^3 \int_{\mathcal{D}} \frac{dx}{\ell(x)^3} \\ &\le k_5^3 \sum_{\tau \in T} \int_{\tau} \frac{dx}{h(\tau)^3} \\ &= k_5^3 \sum_{\tau \in T} \frac{\text{volume}(\tau)}{h(\tau)^3} \\ &\le k_5^3 k_7 \sum_{\tau \in T} 1, \end{aligned}$$

as $\text{volume}(\tau) \le k_7 h(\tau)^3$ for some constant k_7. Combining the above with the upper bound on m, we conclude that m is within a constant factor of the size of T. $\square$

8. Conclusions. A series of developments starting with Chew [5] and Ruppert [19] and continuing with Shewchuk [20] and Cheng et al. [7] brought the difficult problem of quality three-dimensional Delaunay meshing of bounded domains close to the solution. Li and Teng [15] recently developed a randomized point-placement strategy to generate a provably good three-dimensional Delaunay mesh of bounded domains. This paper introduces a new paradigm, weighted Delaunay refinement, which gives the first deterministic algorithm for the problem. We believe that we will add fewer points in practice because weighted Delaunay refinement uses pumping to eliminate slivers instead of point-placement.

Of course, as with previous algorithms the constants derived for the theory are miserably unsatisfactory for all practical purposes. For example, the constant $\rho_0 > 4$ is large for any practical purpose, and the constant σ_0 is extremely small. Experiments show that these constants need not be that bad in practice when sliver exudation and Delaunay refinement are used separately [13]. Will the same remain true when we combine the two into our weighted Delaunay refinement algorithm?

In QualMesh we need to compute the local feature size $f(v)$ while assigning weight to a vertex v. Although the computation of $f(v)$ is feasible, it is better if we can avoid computing it in practice. Toward this end, one can gradually increase the weight to v and check the quality of tetrahedra incident to v as they change at discrete moments. Experiments should be performed to see what bound on angles we get in practice with this strategy. We plan future work to answer these questions.

CONFLICT-FREE COLORINGS OF SIMPLE GEOMETRIC REGIONS WITH APPLICATIONS TO FREQUENCY ASSIGNMENT IN CELLULAR NETWORKS*

GUY EVEN†, ZVI LOTKER†, DANA RON†, AND SHAKHAR SMORODINSKY‡

Abstract. Motivated by a frequency assignment problem in cellular networks, we introduce and study a new coloring problem that we call *minimum conflict-free coloring* (min-CF-coloring). In its general form, the input of the min-CF-coloring problem is a set system $(X, \mathcal{S})$, where each $S \in \mathcal{S}$ is a subset of X. The output is a coloring χ of the sets in $\mathcal{S}$ that satisfies the following constraint: for every $x \in X$ there exists a color i and a unique set $S \in \mathcal{S}$ such that $x \in S$ and $\chi(S) = i$. The goal is to minimize the number of colors used by the coloring χ.

Min-CF-coloring of general set systems is not easier than the classic graph coloring problem. However, in view of our motivation, we consider set systems induced by simple geometric regions in the plane.

In particular, we study disks (both congruent and noncongruent), axis-parallel rectangles (with a constant ratio between the smallest and largest rectangle), regular hexagons (with a constant ratio between the smallest and largest hexagon), and general congruent centrally symmetric convex regions in the plane. In all cases we have coloring algorithms that use $O(\log n)$ colors (where n is the number of regions). Tightness is demonstrated by showing that even in the case of unit disks, $\Theta(\log n)$ colors may be necessary. For rectangles and hexagons we also obtain a constant-ratio approximation algorithm when the ratio between the largest and smallest rectangle (hexagon) is a constant.

We also consider a dual problem of CF-coloring points with respect to sets. Given a set system $(X, \mathcal{S})$, the goal in the dual problem is to color the elements in X with a minimum number of colors so that every set $S \in \mathcal{S}$ contains a point whose color appears only once in S. We show that $O(\log |X|)$ colors suffice for set systems in which X is a set of points in the plane and the sets are intersections of X with scaled translations of a convex region. This result is used in proving that $O(\log n)$ colors suffice in the primal version.

Key words. conflict-free coloring, frequency assignment, approximation algorithms, computational geometry

1. Introduction.

Cellular networks are heterogeneous networks with two different types of nodes: base-stations (that act as servers) and clients. The base-stations are interconnected by an external fixed backbone network. Clients are connected only to base-stations; links between clients and base-stations are implemented by radio links. Fixed frequencies are assigned to base-stations to enable links to clients. Clients, on the other hand, continuously scan frequencies in search of a base-station with good reception. This scanning takes place automatically and enables smooth transitions between links when a client is mobile. Consider a client that is within the reception range of two base-stations. If these two base-stations are assigned the same frequency, then mutual interference occurs, and the links between the client and each

of these conflicting base-stations are rendered too noisy to be used. A base-station may serve a client, provided that the reception is strong enough and interference from other base-stations is weak enough. The fundamental problem of frequency assignment in a cellular network is to assign frequencies to base-stations so that every client is served by some base-station. The goal is to minimize the number of assigned frequencies since spectrum is limited and costly.

We consider the following abstraction of the above problem, which we refer to as the *minimum conflict-free coloring problem (min-CF-coloring).*

DEFINITION 1.1. *Let X be a fixed domain (e.g., the plane), and let $\mathcal{S}$ be a collection of subsets of X (e.g., disks whose centers correspond to base-stations). A function $\chi : \mathcal{S} \to \mathbb{N}$ is a* CF-coloring *of $\mathcal{S}$ if, for every $x \in \bigcup_{S\in\mathcal{S}} S$, there exists a color $i \in \mathbb{N}$ such that $\{S \in \mathcal{S} : x \in S$ and $\chi(S) = i\}$ contains a single subset $S \in \mathcal{S}$.*

The goal in the min-CF-coloring problem is to find a CF-coloring that uses as few colors as possible. It is not hard to verify that, in its most general form defined above, this problem is not easier than vertex coloring in graphs and is even equally hard to approximate. An adaptation of the NP-completeness proof of minimum coloring of intersection graphs of unit disks by [CCJ90] proves that even CF-coloring of unit disks (or unit squares) in the plane is NP-complete. Since this proof is based on a reduction from coloring planar graphs, it follows that approximating the minimum number of colors required in a CF-coloring of unit disks is NP-hard for an approximation ratio of $\frac{4}{3} - \varepsilon$, for every $\varepsilon > 0$.

1.1. Our results. We restrict our attention to set systems $(X, \mathcal{R})$, where X is a set of points in the plane and $\mathcal{R}$ is a family of subsets of X that are defined by the intersections of X with closed geometric regions in the plane (e.g., disks). We refer to the members of $\mathcal{R}$ as *ranges*, and to $(X, \mathcal{R})$ as a *range-space.*

1.1.1. CF-coloring of disks. Given a finite set of disks $\mathcal{S}$, the *size-ratio* of $\mathcal{S}$ is the ratio between the largest and the smallest radiuses of disks in $\mathcal{S}$. For simplicity we assume that the smallest radius is 1. For each $i \geq 1$, let $\mathcal{S}^i$ denote the subset of disks in $\mathcal{S}$ whose radius is in the range $[2^{i-1}, 2^i)$. Let $\phi_{2^i}(\mathcal{S}^i)$ denote the maximum number of centers of disks in $\mathcal{S}^i$ that are contained in a $2^i \times 2^i$ square. We refer to $\phi_{2^i}(\mathcal{S}^i)$ as the *local density* of $\mathcal{S}^i$ (with respect to $2^i \times 2^i$ square). For a set of centers $X \subset \mathbb{R}^2$, and for any given radius r, let $\mathcal{S}_r(X)$ denote the set of (congruent) disks having radius r whose centers are the points in X.

Our main results for coloring disks are stated in the following theorem.

THEOREM 1.2.

1. *Given a finite set $\mathcal{S}$ of disks with size-ratio ρ, there exists a polynomial-time algorithm that computes a CF-coloring of $\mathcal{S}$ using $O\left(\min\left\{\sum_{i=1}^{\log(\rho)+1}(1+\log\phi_{2^i}(\mathcal{S}^i)), \log|\mathcal{S}|\right\}\right) = O\left(\min\left\{\log(\rho)\cdot\max_i\{\log\phi_{2^i}(\mathcal{S}^i)\}, \log|\mathcal{S}|\right\}\right)$ colors.*[1]
2. *Given a finite set of centers $X \subset \mathbb{R}^2$, there exists a polynomial-time algorithm that computes a coloring χ of X using $O(\log|X|)$ colors such that if we color $\mathcal{S}_r(X)$ by assigning each disk $D \in \mathcal{S}_r(X)$ the color of its center, then this is a valid CF-coloring of $\mathcal{S}_r(X)$ for every radius r.*

Tightness of Theorem 1.2 is shown by presenting, for any given integer n, a set $\mathcal{S}$ of n unit disks with $\phi_1(\mathcal{S}) = n$ for which $\Omega(\log n)$ colors are necessary in every CF-coloring of $\mathcal{S}$.

[1]For simplicity of notation, we avoid writing $\log(x+1)$ throughout the paper, even when x may equal 1, and consider $O(0)$ to be $O(1)$.

In the first part of Theorem 1.2, the disks are not necessarily congruent; that is, the size-ratio ρ may be bigger than 1. In the second part of Theorem 1.2, the disks are congruent (i.e., the size-ratio equals 1). However, the common radius is not determined in advance. Namely, the order of quantifiers in the second part of the theorem is as follows: Given the locations of the disk centers, the algorithm computes a coloring of the centers (of the disks) such that this coloring is conflict-free *for every* radius r. We refer to such a coloring as a *uniform* CF-coloring.

Uniform CF-coloring has an interesting interpretation in the context of cellular networks. Assume that base-stations are located in the disk centers X. Assume that a client located at point P has a reception range r. The client is served, provided that the disk centered at P with radius r contains a base-station that transmits in a distinct frequency among the base-stations within that disk.

Thus, uniform CF-coloring models frequency assignment in the setting of isotropic base-stations that transmit with the same power and clients with different reception ranges. Moreover, the coloring of the base-stations in a uniform CF-coloring is independent of the reception ranges of the clients.

Building on Theorem 1.2, we also obtain two bicriteria CF-coloring algorithms for disks having the same (unit) radius. In both cases we obtain colorings that use very few colors. In the first case this comes at a cost of not serving a small area that is covered by the disks (i.e., an area close to the boundary of the union of the disks). In the second case we serve the entire area, but we allow the disks to have a slightly larger radius. A formal statement of these bicriteria results follows.

THEOREM 1.3. *For every $0 < \varepsilon < 1$ and every finite set of centers $X \subset \mathbb{R}^2$, there exist polynomial-time algorithms that compute colorings as follows:*

1. *A coloring χ of $\mathcal{S}_1(X)$ using $O\left(\log \frac{1}{\varepsilon}\right)$ colors for which the following holds: The area of the set of points in $\bigcup \mathcal{S}_1(X)$ that are not served with respect to χ is at most an ε-fraction of the total area of $\mathcal{S}_1(X)$.*
2. *A coloring of $\mathcal{S}_{1+\varepsilon}(X)$ that uses $O\left(\log \frac{1}{\varepsilon}\right)$ colors such that every point in $\bigcup \mathcal{S}_1(X)$ is served.*

In other words, in the first case, the portion of the total area that is not served is an exponentially small fraction as a function of the number of colors. In the second case, the increase in the radius of the disks is exponentially small as a function of the number of colors.

1.1.2. CF-coloring of rectangles and regular hexagons. Let $\mathcal{R}$ denote a set of axis-parallel rectangles. Given a rectangle $R \in \mathcal{R}$, let $w(R)$ (respectively, $h(R)$) denote the width (respectively, height) of R. The *size-ratio* of $\mathcal{R}$ is defined by $\max\left\{\frac{w(R_1)}{w(R_2)}, \frac{h(R_1)}{h(R_2)}\right\}_{R_1,R_2\in\mathcal{R}}$.

The size-ratio of a collection of regular hexagons is simply the ratio of the longest side length to the shortest side length.

THEOREM 1.4. *Let $\mathcal{R}$ denote either a set of axis-parallel rectangles or a set of axis-parallel regular hexagons. Let ρ denote the size-ratio of $\mathcal{R}$, and let $\chi_{\mathrm{opt}}(\mathcal{R})$ denote an optimal CF-coloring of $\mathcal{R}$.*

1. *If $\mathcal{R}$ is a set of rectangles, then there exists a polynomial-time algorithm that computes a CF-coloring χ of $\mathcal{R}$ such that $|\chi(\mathcal{R})| = O((\log \rho)^2) \cdot |\chi_{\mathrm{opt}}(\mathcal{R})|$.*
2. *If $\mathcal{R}$ is a set of regular hexagons, then there exists a polynomial-time algorithm that computes a CF-coloring χ of $\mathcal{R}$ such that $|\chi(\mathcal{R})| = O(\log \rho) \cdot |\chi_{\mathrm{opt}}(\mathcal{R})|$.*

For a constant size-ratio ρ, Theorem 1.4 implies a constant-ratio approximation algorithm.

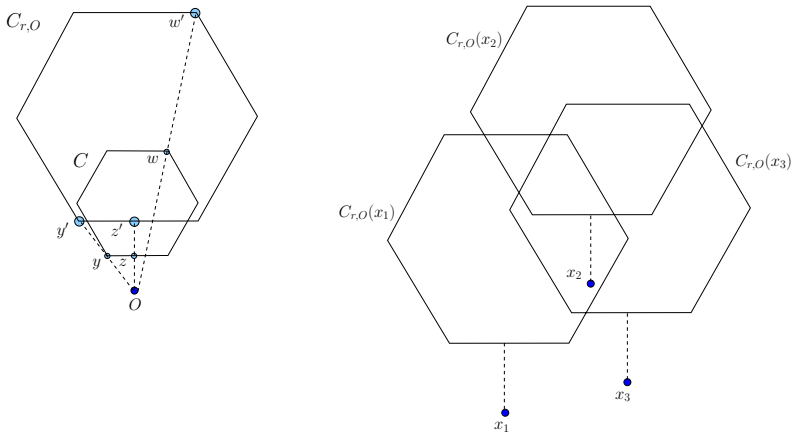

FIG. 1.1. *On the left is an example of a scaled translation $C_{r,O}$ of a regular hexagon C with respect to the point O, where the scaling factor is $r = 2$. The points y, z, and w on the small hexagon C are mapped to the points y', z', and w', respectively, on the larger hexagon $C_{r,O}$. The dashed lines correspond to the rays emanating from O toward the points y, z, and w. On the right is an additional set $X = \{x_1, x_2, x_3\}$ of three points and the corresponding set $\mathcal{C}_{r,O}(X) = \{\mathcal{C}_{r,O}(x_1), \mathcal{C}_{r,O}(x_2), \mathcal{C}_{r,O}(x_3)\}$.*

1.1.3. Uniform CF-coloring of congruent centrally symmetric convex regions. Consider a convex region C and a point O. *Scaling* by a factor $r > 0$ with respect to a center O is the transformation that maps every point $P \neq O$ to the point P' along the ray emanating from O toward P such that $|P'O| = r \cdot |PO|$. The center point O is a fixed point of the transformation of the scaling. We denote the image of C with respect to such a scaling by $C_{r,O}$. Given a point x and a scaling factor $r > 0$, we denote by $C_{r,O}(x)$ the image of $C_{r,O}$ obtained by the translation that maps O to x (see Figure 1.1). We refer to C' as a *scaled translation* of C if there exist points x, O and a scaling factor $r > 0$ such that $C' = C_{r,O}(x)$. Given a set of centers X and a scaling factor $r > 0$, the set $\mathcal{C}_{r,O}(X)$ denotes the set of scaled translations $\{C_{r,O}(x)\}_{x \in X}$.

A region $C \in \mathbb{R}^2$ is *centrally symmetric* if there exists a point O (called the *center*) such that the transformation of reflection about O is a bijection of C onto C. Note that disks, rectangles, and regular hexagons are all convex centrally symmetric regions.

The following theorem generalizes the uniform coloring result presented in part 2 of Theorem 1.2 to sets of centrally symmetric convex regions that are congruent via translations.

THEOREM 1.5. *Let C denote a centrally symmetric convex region with a center point O. Given a finite set of centers $X \subset \mathbb{R}^2$, there exists a coloring χ of X that uses $O(\log |X|)$ colors such that if we color each $c \in \mathcal{C}_{r,O}(X)$ with the color of its center, then this is a valid CF-coloring of $\mathcal{C}_{r,O}(X)$ for every scaling factor r.*

A polynomial-time constructive version of Theorem 1.5 holds when the region C is "well behaved," e.g., a disk, an ellipsoid, or a polygon. (More formally, a polynomial-time algorithm for computing Delaunay graphs of arrangements of regions $\mathcal{C}_{r,O}(X)$ is needed.)

1.2. Techniques.

1.2.1. A dual coloring problem: CF-coloring of points with respect to ranges. In order to prove Theorem 1.2, we consider the following coloring problem,

which is dual to our original coloring problem described in Definition 1.1.

DEFINITION 1.6. *Let $(X, \mathcal{R})$ denote a range-space. A function $\chi : X \to \mathbb{N}$ is a* CF-coloring *of X with respect to $\mathcal{R}$ if, for every $R \in \mathcal{R}$, there exists a color $i \in \mathbb{N}$ such that the set $\{x \in R : \chi(x) = i\}$ contains a single point.*

Note that in the original definition of CF-coloring (Definition 1.1) we were interested in coloring ranges (regions) in order to serve points contained in the ranges, while in Definition 1.6 we are interested in coloring points in order to "serve" ranges containing the points.

We give a general framework for CF-coloring points with respect to sets of ranges $\mathcal{R}$ and provide a sufficient condition under which a coloring using $O(\log |X|)$ colors can be achieved. This condition is stated in terms of a special graph constructed from $(X, \mathcal{R})$. When X is a set of points in the plane and $\mathcal{R}$ is the set of ranges obtained by intersections with disks, this graph is the standard Delaunay graph. We then study several cases in which the condition is satisfied. Theorems 1.2 and 1.5 follow by reduction to these cases. We believe that Theorem 1.7 stated below (from which Theorem 1.5 is easily derived) is of independent interest.

THEOREM 1.7. *Let C be a compact convex region in the plane, and let X be a finite set of points in the plane. Let $\mathcal{R} \subseteq 2^X$ denote the set of ranges obtained by intersecting X with all scaled translations of C. Then there exists a CF-coloring of X with respect to $\mathcal{R}$ using $O(\log |X|)$ colors.*

Recently, Pach and Tóth [PT03] proved that $\Omega(\log |X|)$ colors are required for CF-coloring *every* set X of points in the plane with respect to disks.

1.2.2. CF-coloring of chains. A *chain* $\mathcal{S}$ is a collection of subsets, each assigned a unique index in $\{1, \ldots, |\mathcal{S}|\}$, for which the following holds. For every (discrete) interval $[i, j]$, $1 \le i \le j \le |\mathcal{S}|$, there exists a point $x \in \bigcup_{S \in \mathcal{S}} S$ such that the subcollection of subsets that contains the point x equals the subcollection of subsets indexed from i to j. Moreover, for every point $x \in \bigcup_{S \in \mathcal{S}} S$, the set of indexes of subsets that contain the point x is an interval. (For an illustration, see Figure 6.2.) We show that chains of unit disks (respectively, unit squares and hexagons) are tight examples of Theorem 1.2 (respectively, Theorem 1.4); namely, every CF-coloring of a chain must use $\Omega(\log |\mathcal{S}|)$ colors, and it is possible to CF-color every chain using $O(\log |\mathcal{S}|)$ colors.

Chains also play an important role in our approximation algorithm for CF-coloring rectangles and hexagons. Loosely speaking, our coloring algorithm works by decomposing the set of rectangles into chains. An important component in our analysis is understanding and exploiting the intersections between pairs of different chains. Specifically, we show how different types of pairs of chains (see Figures 7.5 and 7.9) can "help" each other so as to go below the upper bound on the number of colors required to color chains, which is logarithmic in their size.

1.3. Related problems. As noted above, min-CF-coloring of general set systems is not easier (even to approximate) than vertex-coloring in graphs. The latter problem is of course known to be NP-hard, and is hard even to approximate [FK98]. The problem remains hard for the special case of unit disks (and squares), and it is even NP-hard to achieve an approximation ratio of $\frac{4}{3} - \varepsilon$ for every $\varepsilon > 0$ (by an adaptation of [CCJ90]).

Marathe et al. [MBH+95] studied the problem of vertex-coloring of intersection graphs of unit disks. They presented an approximation algorithm with an approximation ratio of 3. Motivated by channel assignment problems in radio networks, Krumke, Marathe, and Ravi [KMR01] presented a 2-approximation algorithm for the

distance-2 coloring problem in families of graphs that generalize intersection graphs of disks.

A natural variant of min-CF-coloring is min-CF-multicoloring. Given a collection $\mathcal{S}$ of sets, a CF-multicoloring of $\mathcal{S}$ is a mapping χ from $\mathcal{S}$ to *subsets* of colors. The requirement is that for every point $x \in \bigcup_{S\in\mathcal{S}} S$ there exists a color i such that $\{S : x \in S,\, i \in \chi(S)\}$ contains a single subset. The min-CF-multicoloring problem is related to the problem of minimizing the number of time slots required to broadcast information in a single-hop radio network. In view of this relation, it has been observed by Bar-Yehuda ([B01], based on [BGI92]) that every set system $(X, \mathcal{S})$ can be CF-multicolored using $O(\log|X| \cdot \log|\mathcal{S}|)$ colors.

Mathematical optimization techniques have been used to solve a family of frequency assignment problems that arise in wireless communication (for a comprehensive survey, see [AHK+01]). We elaborate why these frequency assignment problems do not capture min-CF-coloring. Basically, such frequency assignment problems are modeled using *interference* or *constraint* graphs. The vertices correspond to base-stations, and edges correspond to interference between pairs of base-stations. Each edge (v, w) is associated with a *penalty function* $p_{v,w} : \mathbb{N} \times \mathbb{N} \to \mathbb{R}$, so that if v is assigned frequency $i \in \mathbb{N}$ and w is assigned frequency $j \in \mathbb{N}$, then a penalty of $p_{v,w}(i, j)$ is incurred. A typical constraint is to bound the maximum penalty on every edge. A typical cost function is the number of frequencies used. CF-coloring cannot be modeled in this fashion because CF-coloring allows for conflicts between base-stations, provided that another base-station serves the "area of conflict." Even models that use nonbinary constraints (see [DBJC98]) do not capture CF-coloring. We note that the above models take into account interferences between close frequencies, while we have ignored this issue for the sake of simplicity. We can, however, incorporate some variants of such constraints. For example, in the case of unit disks we can easily impose the constraint that, for every point x, the frequency assigned to the disk that serves x differs by at least $\delta_{\min}$ from the frequency assigned to every other disk covering x. By applying Theorem 1.2 and multiplying each color by $\delta_{\min}$, we can satisfy the above constraint while using $O\left(\min\left\{\sum_{i=1}^{\log(\rho)+1} \log \phi_{2^i}(\mathcal{S}^i), \log|\mathcal{S}|\right\} \cdot \delta_{\min}\right)$ colors (and there is an example that exhibits tightness).

Frequency assignment problems in cellular networks as well as the positioning problem of base-stations have been studied extensively; see [AKM+01, GGRV00, H01] for other models and many references. Finally, we refer to [HS03, SM03] for further work on CF-coloring problems.

Further research. Among the open problems related to our results are the following: (1) Is there a constant approximation algorithm for min-CF-coloring of unit disks and disks in general? (2) Is it possible to extend our results to min-CF-coloring with capacity constraints defined as "every base-station is given a capacity that bounds the number of clients that it can serve"?

Organization. In section 2, preliminary notions and notations are presented. In section 3 we describe our results for CF-coloring points with respect to range-spaces: We describe a general framework and several applications. In section 4 we prove our results for CF-coloring of disks (Theorems 1.2 and 1.3), which build on results from section 3. Theorem 1.5 is proved in section 5, and tightness of Theorem 1.2 is established in section 6. Our $O(1)$-approximation algorithm for rectangles is provided in section 7. In section 8 we discuss how a very similar algorithm can be applied to color regular hexagons. Finally, in section 9 we derive a couple of additional related results.

2. Preliminaries.

2.1. Combinatorial arrangements. A finite set $\mathcal{R}$ of regions (in the plane) induces the following *equivalence relation*. Every two points x, y in the plane belong to the same class if and only if they reside in exactly the same subset of regions in $\mathcal{R}$. That is, x and y are in the same equivalence class if $\{R \in \mathcal{R} : x \in R\} = \{R \in \mathcal{R} : y \in R\}$. We refer to each such equivalence class as a *cell*. The set of all cells induced by $\mathcal{R}$ is denoted by $cells(\mathcal{R})$. With a slight abuse of notation, we view the pair $(cells(\mathcal{R}), \mathcal{R})$ as a range-space. To be precise, $(cells(\mathcal{R}), \mathcal{R})$ is the following range-space: (a) the ground set is equal to a representative from every cell, and (b) the ranges are the intersections of sets in $\mathcal{R}$ with the ground set. We henceforth refer to the range-space $(cells(\mathcal{R}), \mathcal{R})$ as the *combinatorial arrangement* induced by $\mathcal{R}$; we denote this combinatorial arrangement by $\mathcal{A}(\mathcal{R})$.

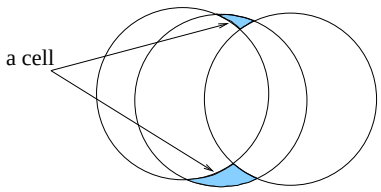

FIG. 2.1. *An arrangement of disks. The marked cell corresponds to the regions that are contained in the middle disk and only in that disk.*

The definition of a combinatorial arrangement differs from that of a topological arrangement (where one considers the subdivision into connected components induced by the ranges). For example, Figure 2.1 depicts a collection of disks. The two shadowed regions constitute a single cell in the combinatorial arrangement induced by the disk. In the definition of a topological arrangement these regions are considered as two separate cells. We often consider combinatorial arrangements of the form $(V, \mathcal{R})$, where $V \subset cells(\mathcal{R})$. We refer, in short, to combinatorial arrangements as arrangements.

2.2. Primal and dual range-spaces. Consider a range-space $(X, \mathcal{R})$. The dual set system is $(\mathcal{R}, X^*)$, where $X^* = \{N(x)\}_{x \in X} \subseteq 2^{\mathcal{R}}$ and $N(x) = \{R \in \mathcal{R} : x \in R\}$. One may represent a set system by a bipartite graph $(X \cup \mathcal{R}, E)$, with an edge (x, R) if $x \in R$. Under this representation, the dual set system corresponds to the bipartite graph in which the roles of the two sides of the vertex set are interchanged. Isomorphism of set systems is equivalent to the isomorphism between the bipartite graph representations of the corresponding set systems.

Let $\mathcal{T}$ denote a set of regions in the plane. We use $\mathcal{T}$ to denote a set of regions with some common property, for example, the set of all unit disks or the set of axis-parallel unit squares. Given a set of points X and a region R (such as a disk), when referring to R as a range (namely, a subset of X) we actually mean $R \cap X$.

A range-space $(X, \mathcal{R})$ is a $\mathcal{T}$-type range-space if $\mathcal{R} \subseteq \mathcal{T}$. We are interested in situations in which the dual of a $\mathcal{T}$-type range-space is isomorphic to a $\mathcal{T}$-type range-space.

DEFINITION 2.1. *A set of regions $\mathcal{T}$ is* self dual *if the dual range-space of every $\mathcal{T}$-type range-space is isomorphic to a $\mathcal{T}$-type range-space.*

For example, it is not hard to verify that the set of all unit disks is self dual. On the other hand, the set of all disks (or even disks of different radius) is not self dual.

The following claim states a condition on $\mathcal{T}$ that is sufficient for $\mathcal{T}$ to be self dual when X is a set of points in the plane.

CLAIM 2.2. *Let C be a fixed centrally symmetric region in the plane, and let $\mathcal{T}$ be the set of all regions congruent (via translation, not rotation) to C. Then $\mathcal{T}$ is self dual.*

Proof. Given a $\mathcal{T}$-type range-space $(X, \mathcal{R})$, let Y denote the set of centers of the ranges in $\mathcal{R}$. For a point x in the plane, let $C(x)$ denote the region congruent to C that is centered at x. For a set X of points in the plane, let $\mathcal{C}(X) \triangleq \{C(x) : x \in X\}$ denote the set of regions congruent to C centered at points of X. The range-space $(Y, \mathcal{C}(X))$ is obviously a $\mathcal{T}$-type range-space. To see that this system is isomorphic to the dual range-space $(\mathcal{R}, X^*)$, we identify every range $R \in \mathcal{R}$ with its center. Since C is centrally symmetric, it follows that $y \in C(x)$ if and only if $x \in C(y)$ for every two points x, y. This means that a center $y \in Y$ is in $C(x)$ if and only if the range $C(y)$ contains the point $x \in X$. Hence, for every point $x \in X$, the set $C(x) \cap Y$ equals the set of centers of ranges in $N(x)$, and the claim follows. □

As a corollary of Claim 2.2 we obtain the following.

COROLLARY 2.3. *Let C be a fixed centrally symmetric region in the plane, and let $\mathcal{T}$ be the set of all regions congruent (via translation, not rotation) to C. Then the CF-coloring arrangement of $\mathcal{T}$-type regions is equivalent to CF-coloring points with respect to a $\mathcal{T}$-type set of ranges.*

We rely on Corollary 2.3 in the proof of part 2 of Theorem 1.2 and in the proof of Theorem 1.5.

3. CF-coloring points with respect to ranges. In this section we present CF-coloring algorithms for points with respect to ranges. The colorings require $O(\log n)$ colors, where n denotes the number of points.

3.1. Intuition. We begin this subsection by presenting a high level description of our algorithm. We then briefly discuss how it can be applied to the special case where X is a set of n points in the plane and the ranges in $\mathcal{R}$ are intersections of X with disks.

The algorithm works in an iterative manner, where in iteration i it selects the subset of points that are colored by color number i. Let X_i denote the set of points that are colored by the color i, and let $X_{<i}$ (respectively, $X_{\leq i}$) denote the set $\bigcup_{j<i} X_j$ (respectively, $\bigcup_{j\leq i} X_j$). When determining X_i, the algorithm ensures that the following condition holds:

> For every range $S \in \mathcal{R}$, either (i) S can be served by a point colored $j < i$ (i.e., there exists $j < i : |S \cap X_j| = 1$), or (ii) $S \cap X_i$ contains at most one point, or (iii) S contains a point that is not colored yet (i.e., $S \not\subseteq X_{\leq i}$).

Correctness follows because if either (i) or (ii) holds, then S can be served by a point colored $j \leq i$, while if neither (i) nor (ii) holds, then there will be a point colored by a color greater than i that can serve S. In fact, a coloring that obeys the above condition has the following property: For every range $S \in \mathcal{R}$, the highest color of a point contained in S has multiplicity 1.

Observe that we can trivially obey the above condition by selecting X_i to consist of a single point in $X \setminus X_{<i}$, so that each point is colored by a different color. However, the total number of colors in this case is $|X| = n$, while we are interested in using only $O(\log n)$ colors. To obtain $O(\log n)$ colors, we show that (for the sets of ranges we consider), in each stage it is possible to select at least a constant fraction of the

remaining points (i.e., $|X_i| \geq \frac{1}{4} \cdot |X \setminus X_{<i}|$).

To make the above more concrete, consider the special case of coloring a set of points X with respect to disks. First assume that the points all lie on a straight line. In such a case, the choice of X_i involves simply picking every other point of $X \setminus X_{<i}$ (see Figure 3.1). By convexity, if a disk D contains two (or more) points from X_i, then it must contain all the points in between these two points. Between every two points in X_i there must exist at least one point not in $X_{\leq i}$. It follows that the condition required from X_i holds. Since $|X_i| = \lceil \frac{|X \setminus X_{<i}|}{2} \rceil$, the number of colors used is $O(\log n)$, as desired.

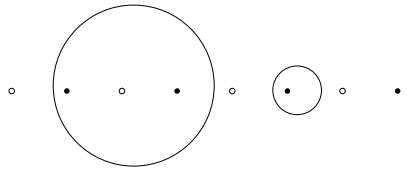

FIG. 3.1. *Selection of X_i when the points lie on a straight line. The points drawn are those in $X \setminus X_{<i}$. The points of X_i are denoted by filled dots. The unfilled dots denote points in $X \setminus X_{\leq i}$. The disk on the left contains two points in X_i and hence also an unfilled dot. The disk on the right contains only a single point in X_i.*

The choice of X_i when the points are in general position in the plane is more involved. In this case, we construct the Delaunay graph G_i of the set $X \setminus X_{<i}$: Two points p_i and p_j form an edge in G_i if and only if there is a closed disk D that contains p_i and p_j on its boundary and does not contain any other point in $X \setminus X_{<i}$. The graph G_i is planar and hence is 4-colorable. The largest color class contains at least $\frac{1}{4}$ of the remaining points and is an independent set in G_i. In Claim 3.4 below we prove that the largest color class is a good candidate for X_i.

3.2. A general framework. We start by presenting a general framework for CF-coloring a set X of points with respect to a set $\mathcal{R} \subseteq 2^X$ of ranges, and describe sufficient conditions under which the resulting coloring uses $O(\log n)$ colors. Since every range $R \in 2^X$ that contains a single point from X is trivially served by that point, we assume that every range in $\mathcal{R}$ contains at least two points from X.

DEFINITION 3.1. *Let X be a set of points and $\mathcal{R} \subseteq 2^X$ a set of ranges. A partition (X_1, X_2) of X is* $\mathcal{R}$-useful *if $X_1 \neq \emptyset$ and*

$$\forall S \in \mathcal{R} \ : \ |S \cap X_1| = 1 \quad \textit{or} \quad S \cap X_2 \neq \emptyset.$$

ALGORITHM 1. CF-COLOR$(X, \mathcal{R})$—CF-color a set X with respect to a set of ranges $\mathcal{R}$.

1: **Initialization:** $i \leftarrow 1$, $X^1 \leftarrow X$, $\mathcal{R}^1 \leftarrow \mathcal{R}$. ($i$ denotes an unused color, X^i is the set of points not yet colored, and $\mathcal{R}^i$ is the set of ranges that contain more than one point in X^i and cannot be served by points colored j, for $j < i$.)
2: **while** $X^i \neq \emptyset$**, do**
3: **Find an $\mathcal{R}^i$-useful partition** (X_1, X_2) of X^i. (See Claim 3.4 below.)
4: **Color:** $\forall x \in X_1 \ : \ \chi(x) \leftarrow i$.
5: **Project:** $X^{i+1} \leftarrow X_2$ and $\mathcal{R}^{i+1} \leftarrow \{S \cap X_2 : S \in \mathcal{R}^i, \ |S \cap X_1| \neq 1, \text{ and } |S \cap X_2| \geq 2\}$.
6: **Increment:** $i \leftarrow i + 1$.
7: **end while**

CLAIM 3.2. *The coloring of X computed by* CF-COLOR$(X, \mathcal{R})$ *is a CF-coloring of X with respect to $\mathcal{R}$.*

Proof. Consider a range $S \in \mathcal{R}$. Let i denote the last iteration in which $X^i \cap S \in \mathcal{R}^i$. In other words, in the ith iteration, the $\mathcal{R}^i$-useful partition (X_1, X_2) of X^i satisfies either $|X_1 \cap S| = 1$ or $|X_2 \cap S| = 1$. In the first case, S can be served by the single element $x \in X_1 \cap S$ (which is colored i). In the second case, S can be served by the single element $x \in X_2 \cap S$ (which is colored j, for $j > i$). Observe that if at the end of iteration i the range-space $\mathcal{R}^{i+1}$ becomes empty while X^{i+1} is not empty, then the partition $(X^{i+1}, \emptyset)$ is trivially $\mathcal{R}^{i+1}$-useful, and all the points in X^{i+1} can be colored with the color $i + 1$. □

Note that Algorithm CF-COLOR computes a CF-coloring in which every range $S \in \mathcal{R}$ is served by the point with the highest color among the points in S.

3.2.1. Sufficient conditions for using $O(\log |X|)$ colors. If in every iteration i we have $|X_1| = \Omega(|X^i|)$, then Algorithm CF-COLOR uses $O(\log |X|)$ colors. We formalize a condition guaranteeing that $|X_1|$ is a constant fraction of $|X^i|$. The condition is phrased in terms of a special graph that is attached to the range-space $(X^i, \mathcal{R}^i)$.

We refer to ranges $S \in \mathcal{R}^i$ as *minimal* if they are minimal with respect to inclusion. Recall that we initially assume that for every $S \in \mathcal{R}$, $|S| \geq 2$ (since ranges of size one are served trivially). The algorithm ensures that, in each iteration, every range in $\mathcal{R}^i$ contains at least two points. Hence, minimal ranges contain at least two points.

DEFINITION 3.3. *A* Delaunay graph *of a set system $(X, \mathcal{R})$ is a graph $DG_{\mathcal{R}}(X, E)$, defined as follows. For every minimal $S \in \mathcal{R}$, pick a pair $u, v \in S$ and define $e(S) = (u, v)$. The edge set E is defined by $E = \{e(S) : S \in \mathcal{R}$ and S is minimal$\}$.*

A Delaunay graph of a set system is not uniquely defined if there exist minimal ranges that contain more than two points. To simplify the presentation, we abuse notation and refer to the Delaunay graph of a set system as if it were unique.

We now discuss how Definition 3.3 is an extension of the standard definition of the Delaunay graph of a set of points in the plane. The Delaunay graph of a set of points X in the plane is defined as the dual graph of the Voronoi diagram of X [BKOS97]. Theorem 9.6 in [BKOS97] suggests an equivalent definition: Two points p_i and p_j form an edge in the Delaunay graph of X if and only if there is a closed disk D that contains p_i and p_j on its boundary and does not contain any other point in X. This equivalent definition implies that the edge set of a Delaunay graph corresponding to X equals the set of minimal ranges containing two points induced by disks. We leave it as an exercise to prove that every minimal range induced by a disk contains exactly two points. Hence, in the case of points in the plane and disks, $DG_{\mathcal{R}}(X, E)$ is the standard Delaunay graph of X.

The next claim shows how an $\mathcal{R}$-useful partition can be found by Algorithm CF-COLOR.

CLAIM 3.4. *If $X_1 \subseteq X$ is an independent set in $DG_{\mathcal{R}}$, then the partition $(X_1, X \setminus X_1)$ is $\mathcal{R}$-useful.*

Proof. Assume for the sake of contradiction that there exists an independent set X_1 such that $(X_1, X \setminus X_1)$ is not an $\mathcal{R}$-useful partition of X. That is, there exists a range $S \in \mathcal{R}$ such that $|S \cap X_1| \neq 1$ and $S \cap (X \setminus X_1) = \emptyset$. Note that assuming that $S \cap (X \setminus X_1) = \emptyset$ necessarily implies that $S \subseteq X_1$, and so we may replace the first condition (i.e., $|S \cap X_1| \neq 1$) by $|S \cap X_1| \geq 2$.

Let S' denote a minimal range that is a subset of S (hence $S' \subseteq X_1$). By the

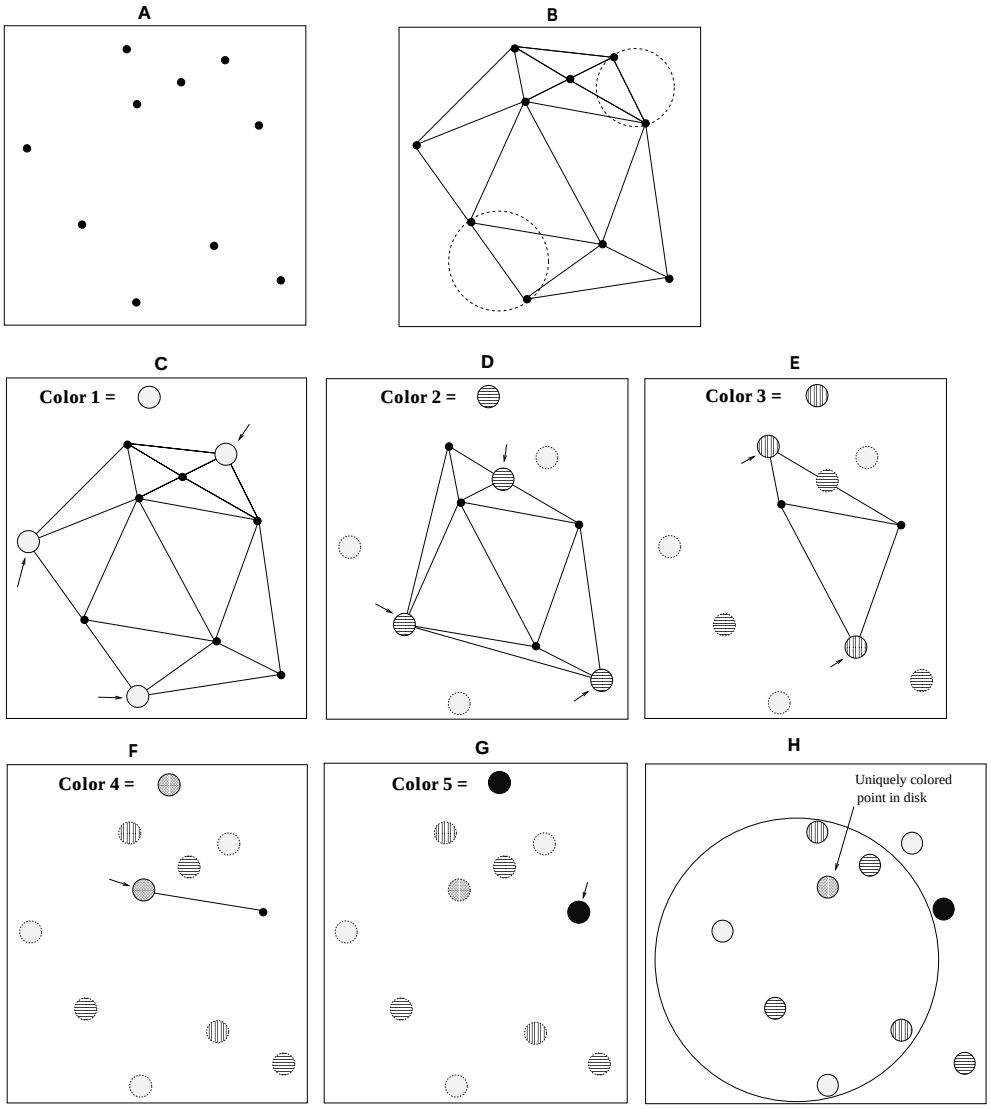

FIG. 3.2. *An illustration of the execution of Algorithm* 1 *in the case of disks in the plane. In panel A we see the given set of points. In panel B, the Delaunay graph is depicted. Recall that there is an edge between every pair of points* p, q *that are separated from the rest of the points by a disk. Two such disks are depicted for this graph. C–G depict five steps of the algorithm. In each step we see the Delaunay graph over the remaining uncolored points, where the newly colored points are marked by arrows. (The previously colored points also appear in the figure, but they are not part of the Delaunay graph.) In H we see the final coloring of all points, and an example of a disk and the point that can serve it. (In general, there may be more than one such point.)*

definition of the set of edges E in the Delaunay graph $DG_{\mathcal{R}}$ of $(X, \mathcal{R})$, it follows that there is an edge $e(S')$ between two points in S'. But this contradicts the assumption that X_1 is an independent set, and the claim follows. □

The method we use to show that Delaunay graphs have large independent sets is to show that Delaunay graphs are planar. Another easy way to show that there exists a large independent set is, for example, to show that the number of edges is linear.

CLAIM 3.5. *If in each iteration of the algorithm the Delaunay graph of* $(X^i, \mathcal{R}^i)$ *is planar, then Algorithm* 1 *uses* $O(\log |X|)$ *colors.*

Proof. By Claim 3.4, it suffices to show that, in every iteration of Algorithm CF-COLOR, the Delaunay graph has an independent set X_1 that satisfies $|X_1| = \Omega(|X^i|)$. The existence of a large independent set X_1 in the Delaunay graph $DG_{\mathcal{R}^i}(X^i, E)$ follows from the planarity of $DG_{\mathcal{R}^i}$. Planarity implies that the graph is 4-colorable [AH77a, AH77b], and therefore, the largest color-class is an independent set of size at least $|X^i|/4$. (Recall that planar graphs can be 4-colored in polynomial time [AH77a, AH77b, RSST96]. For our purposes, a coloring using six colors suffices. One could easily color planar graphs using six colors, since the minimum degree is at most 5. This means that a greedy algorithm could be used to find an independent set of size at least $|X^i|/6$.) □

In the rest of this section we apply Algorithm CF-COLOR to three types of range-spaces: disks in the plane, half-spaces in $\mathbb{R}^3$, and homothetic centrally symmetric convex regions in the plane. For each of these cases we prove that the premise of Claim 3.5 is satisfied—that is, that the Delaunay graph of the corresponding range-space is planar. Moreover, for disks, half-spaces in $\mathbb{R}^3$, and scaled translations of a convex polygon, the corresponding Delaunay graphs are computable in polynomial time, which implies that Algorithm CF-COLOR is polynomial.

3.3. Disks in the plane. Recall that, in the case of disks in the plane, the Delaunay graph that we attach to the set system $(X, \mathcal{R})$ is the standard Delaunay graph. Hence, the Delaunay graph is planar [BKOS97, Theorem 9.5]. We may now apply Claim 3.5 to obtain the following lemma.

LEMMA 3.6. *Let* X *denote a set of* n *points in the plane. Let* $\mathcal{R}$ *denote the collection of all subsets of* X *of size at least* 2 *obtained by intersecting* X *with a (closed) disk. Then it is possible to color* X *with respect to* $\mathcal{R}$ *using* $O(\log n)$ *colors.*

3.4. Half-spaces in $\mathbb{R}^3$. Given a hyperplane H (not parallel to the z-axis), the positive half-space H^+ is the set of all points that either lie on or are above H. We denote by $\mathcal{H}^+$ the set of all positive half-spaces in $\mathbb{R}^3$.

LEMMA 3.7. *Let* X *be a set of* n *points in* $\mathbb{R}^3$. *Let* $\mathcal{R}$ *denote the collection of all subsets of* X *of size at least two obtained by intersecting* X *with a half-space in* $\mathcal{H}^+$. *Then there exists a CF-coloring of* X *with respect to* $\mathcal{R}$ *that uses* $O(\log n)$ *colors.*

Let $CH(X)$ denote the convex hull of X. We make the following simplifying assumption: Every point in X is an extreme point of $CH(X)$. If not, then all the points of X that are not extreme points of $CH(X)$ may be colored by a unique "passive" color. The coloring of nonextreme points by a passive color means, in effect, that these points are removed. This reduction is justified by the fact that every half-space H^+ that intersects the convex hull of X must contain an extreme point of X. The coloring will be a CF-coloring of the extreme points of $CH(X)$ with respect to positive half-spaces, and hence $X \cap H^+$ will be served as well.

CLAIM 3.8. *Every minimal range in the range-space* $(X, \mathcal{R})$ *is a pair of points.*

Proof. Consider a range $R \in \mathcal{R}$ defined by half-space H^+. Translate H upward as much as possible so that every further translation upward reduces the range defined by the positive half-space to less than two points. Let H_1 denote the plane parallel to H obtained by this translation. Let R_1 denote the range corresponding to the positive half-space H_1^+. If R_1 contains more than two points, then either R_1 is contained in the plane H_1 or all but one of the points in R_1 are in the plane H_1. Assume that $R_1 \subset H_1$. Consider a line ℓ in H_1 that passes through two adjacent vertices u, v (i.e., an edge) in the polygon corresponding to the (two-dimensional) convex hull of R_1

relative to the plane H_1. Tilt the plane H_1 slightly, where the line ℓ serves as the axis of rotation. It is possible to rotate H_1 so that the resulting plane H_2 satisfies $X \cap H_2^+ = \{u, v\}$. A similar argument applies if there is a single point in $R_1 \setminus H_1$, and the claim follows. □

Proof of Lemma 3.7. Claim 3.8 implies that the Delaunay graph $DG_{\mathcal{R}} = (X, E)$ of the range-space $(X, \mathcal{R})$ is defined by $(u, v) \in E$ if and only if there exists a positive half-space H^+ such that $X \cap H^+ = \{u, v\}$. Recall that we assumed that every point in X is an extreme point of $CH(X)$. Two points $x, y \in X$ are *adjacent* if there exists a supporting plane H of $CH(X)$ such that $H \cap X = \{u, v\}$. The *skeleton graph* $G' = (X, E')$ of $CH(X)$ is the graph over the points in X with edges between adjacent points. The skeleton graph is drawn on the boundary of $CH(X)$ using straight lines without crossings. Since the boundary of $CH(X)$ is homeomorphic to a sphere, it follows that the skeleton graph is planar.

By definition, the edge set of the Delaunay graph is contained in the edge set of the skeleton graph. Hence the Delaunay graph is planar and, by Claim 3.5, X can be CF-colored with respect to $\mathcal{R}$ using $O(\log |X|)$ colors. □

3.5. Scaled translations of a convex region in the plane. In this subsection we prove Theorem 1.7. We first introduce some definitions and notation.

For a closed region C let ∂C denote the boundary of C, and let $\mathring{C}$ denote the interior of C. We next recall the definition of homothecy (cf. [C69, p. 68]).

DEFINITION 3.9. *A transformation $\tau : \mathbb{R}^2 \to \mathbb{R}^2$ is a* homothecy *if there exist a point O (called the* homothetic center*) and a nonzero real number λ (called the* similitude ratio*) such that*

1. *O is a fixed point of τ (namely, $O = \tau(O)$);*
2. *every point $P \neq O$ is mapped to a point $\tau(P)$ where* (i) *$\tau(P)$ is on the line OP, and* (ii) *the length of the segment $O\tau(P)$ satisfies $|O\tau(P)| = \lambda \cdot |OP|$.*

We use the notation $C' \sim C$ to denote that C' is a scaled translation of C. For a homothetic transformation $\tau : \mathbb{R}^2 \to \mathbb{R}^2$, we denote the image of a set $S \subseteq \mathbb{R}^2$ under τ by $\tau(S)$. Note that if the similitude ratio of a homothecy τ is positive, then $\tau(C) \sim C$.

DEFINITION 3.10. *A range $S \in \mathcal{R}$ is* induced *by a region C if $S = C \cap X$. A range $S \in \mathcal{R}$ is* boundary-induced *by a closed region C if $S = \partial C \cap X$ and $\mathring{C} \cap X = \emptyset$.*

Recall that, for the purpose of CF-coloring, ranges that contain one point as well as the empty range are trivial. Hence, we do not consider the empty set and subsets that contain a single point to be ranges. Therefore, we define the range-space $\mathcal{R}$ induced by a collection of regions $\mathcal{C}$ by

$$\mathcal{R} = \{C \cap X : C \in \mathcal{C} \text{ and } |C \cap X| \geq 2\}.$$

It follows that minimal ranges contain at least two points.

Let C denote a compact convex region in the plane. Let $X \subset \mathbb{R}^2$ denote a finite set of points in the plane. Let $(X, \mathcal{R})$ denote the range-space induced by the set of all scaled translations of C. By Claim 3.5, in order to prove Theorem 1.7, it suffices to prove that the Delaunay graph of $(X, \mathcal{R})$ is planar. To this end we first show the following.

CLAIM 3.11. *Every minimal range $S \in \mathcal{R}$ is boundary-induced by a region $C' \sim C$.*

Proof. Since S is a range, there exists a scaled translation $C_S \sim C$ such that $X \cap C_S = S$. By contracting C_S, if necessary, we may guarantee that the boundary of C_S contains a point from S. The interior of C_S contains at most one point of

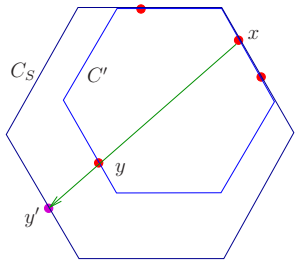

FIG. 3.3. *An illustration for the proof of Claim* 3.11.

S. Otherwise, by an infinitesimal contraction, we are left with a range $S' \subsetneqq S$ that contains at least two points, thus contradicting the minimality of S.

We now show how to find a region $C' \sim C$ such that all of S lies on the boundary of C'. Let $x \in S$ denote a point on the boundary of C_S. If S is not boundary-induced by C_S, then there is a unique point $y \in S \cap \mathring{C}_S$. The region C' is the image of C with respect to the homothecy τ that is defined as follows. Let y' denote the intersection point of the boundary of C_S with the half-open ray emanating from x toward y. Set x to be the homothetic center, and set the similitude ratio to be the ratio $|xy|/|xy'|$. By definition of τ, both x and y are on the boundary of C'. By minimality of S, it follows that $C' \cap X = S$. By definition of τ and convexity of C, it follows that $C' \subseteq C_S$. If a point $z \in S$ is in the interior of C', then it is in the interior of C_S; hence $z = y$, which contradicts $y \in \partial C'$. It follows that every point in S is in the boundary of C', and the claim follows. For an illustration, see Figure 3.3. □

We now show that a planar drawing of the Delaunay graph $DG_{\mathcal{R}} = (X, E)$ is obtained if its edges are drawn as straight line segments. Consider two edges $(x_0, y_0), (x_1, y_1) \in E$. For $i = 0, 1$, assume that $x_i, y_i \in S_i$ for a minimal range $S_i \in \mathcal{R}$, where $S_0 \neq S_1$. Let $C_i \sim C$ denote scaled translations of C such that S_i is boundary-induced by C_i. If $C_0 \cap C_1 = \emptyset$, then the segments x_0y_0 and x_1y_1 do not cross each other. If $C_0 \cap C_1 \neq \emptyset$, then the boundaries ∂C_0 and ∂C_1 intersect.

We first consider the case in which ∂C does not contain a straight side. Namely, no three points on ∂C are colinear. Under this assumption, since C_i is a scaled translation of C for $i = 0, 1$, it follows that $\partial C_0 \cap \partial C_1$ contains at most two points.

If $\partial C_0 \cap \partial C_1$ contains a single point p, then one can separate the convex regions C_0 and C_1 using a straight line passing through p. This separating line implies that the segments x_0y_0 and x_1y_1 cannot cross each other.

If $\partial C_0 \cap \partial C_1$ contains two points, denote these points by p and q. The boundary ∂C_i is partitioned into two simple curves, each delimited by the points p and q; one curve is contained in $\partial C_i \setminus \mathring{C}_{1-i}$, and the second curve is $\partial C_i \cap C_{1-i}$. We denote the curve $\partial C_i \setminus \mathring{C}_{1-i}$ by γ_i, and we denote the curve $\partial C_i \cap C_{1-i}$ by γ_i'. Since the interior $\mathring{C}_{1-i}$ lacks points of X, it follows that x_i and y_i are in γ_i.

In order to prove that the segments x_0y_0 and x_1y_1 do not cross each other, it suffices to show that the line pq separates $\gamma_0 \setminus \{p, q\}$ and $\gamma_1 \setminus \{p, q\}$. (Intersection of two edges means that the edges share an interior point, which cannot be p or q.) Assume, for the sake of contradiction, that $\gamma_0 \setminus \{p, q\}$ and $\gamma_1 \setminus \{p, q\}$ are on the same side of the line pq. These curves do not intersect, and together with the segment pq, one must contain the other, contradicting their definition.

The case in which ∂C contains a straight side (and so $\partial C_0 \cap \partial C_1$ may contain a subsegment of such a straight side) is dealt with similarly to the case in which ∂C

does not contain a straight side. It is not hard to verify that in such a case $\partial C_0 \cap \partial C_1$ consists of at most two connected components (each either straight line or a single point). By picking p to be any point from one component and q to be any point from the other component, we can apply essentially the same argument used above.

This concludes the proof of Theorem 1.7.

4. CF-colorings of arrangements of disks. In this section we prove Theorems 1.2 and 1.3 stated in the introduction.

4.1. Proof of Theorem 1.2. Part 2 of Theorem 1.2 is proved as follows. The disk centers $X \subset \mathbb{R}^2$ are given. Consider a radius r (which is not given to the algorithm!), and apply Corollary 2.3 to the arrangement $\mathcal{A}(\mathcal{S}_r(X))$. Let Y denote the set consisting of representatives from every cell in $cells(\mathcal{S}_r(X))$. The dual range-space is isomorphic to a range-space with (i) a ground set X and (ii) ranges induced by $\mathcal{S}_r(Y)$. We extend the range-space to ranges induced by all the disks (of all radiuses). A CF-coloring of the points in X with respect to the set of all disks is also a CF-coloring of every arrangement $\mathcal{A}(\mathcal{S}_r(X))$. Part 2 of Theorem 1.2 now follows directly from Lemma 3.6.

We now turn to proving part 1 of Theorem 1.2.

A transformation to points and half-spaces. In what follows, we show that the problem of CF-coloring n arbitrary disks in the plane reduces to CF-coloring of a set of points X in $\mathbb{R}^3$ with respect to the set of ranges $\mathcal{H}^+(X)$ determined by all positive half-spaces containing at least two points from X.

We use a fairly standard dual transformation that transforms a point $p = (a, b)$ in $\mathbb{R}^2$ to a plane p^* in $\mathbb{R}^3$, with the parameterization $z = -2ax - 2by + a^2 + b^2$, and transforms a disk S in $\mathbb{R}^2$, with center (x, y) and radius $r \geq 0$, to a point S^* in $\mathbb{R}^3$, with coordinates $(x, y, r^2 - x^2 - y^2)$.

It is easily seen that, in this transformation, a point $p \in \mathbb{R}^2$ lies inside (respectively, on the boundary of, outside) a disk S if and only if the point $S^* \in \mathbb{R}^3$ lies above (respectively, on, below) the plane p^*. Indeed, a point (a, b) lies inside a disk with center (x, y) and radius r if and only if $(a - x)^2 + (b - y)^2 < r^2$. After rearrangement, this is equivalent to $-2ax - 2by + a^2 + b^2 < r^2 - x^2 - y^2$. Now this inequality is equivalent to the condition that the point $(x, y, r^2 - x^2 - y^2) = S^*$ lies above the plane $z = -2ax - 2by + a^2 + b^2$, as asserted. The cases of a point lying on the boundary of a disk or outside a disk are treated analogously.

Given a collection $\mathcal{S} = \{S_1, \ldots, S_n\}$ of n distinct disks in the plane, one can use the above transformation to obtain a collection $\mathcal{S}^* = \{S_1^*, \ldots, S_n^*\}$ of n points in $\mathbb{R}^3$ such that any CF-coloring of $\mathcal{S}^*$ with respect to $\mathcal{H}^+(\mathcal{S}^*)$, with k colors, induces a CF-coloring of the disks of $\mathcal{S}$ with the same set of k colors.

As shown in subsection 3.4 (Lemma 3.7), it is possible to apply Algorithm 1 to obtain a CF-coloring of the points in $\mathcal{S}^*$ with respect to $\mathcal{H}^+(\mathcal{S}^*)$ using $O(\log n)$ colors. Recall that part 1 of Theorem 1.2 states that the number of colors is of the order of the minimum between $\log n$ and $\sum_{i=1}^{\log(\rho)+1} \log \phi_{2^i}(\mathcal{S}^i)$. Recall that ρ is the size-ratio of $\mathcal{S}$, $\mathcal{S}^i$ is the subset of disks in $\mathcal{S}$ whose radius is in the range $[2^{i-1}, 2^i)$, and $\phi_{2^i}(\mathcal{S}^i)$ is the maximum number of disks in $\mathcal{S}^i$ whose centers reside in a common $2^i \times 2^i$ square. To obtain the latter bound we proceed in two steps: First we assume that the size-ratio is at most 2, and then we deal with the more general case.

The tiling. Assume that the size-ratio ρ is at most 2. By scaling, we may assume that every radius is in the interval $[1, 2]$. We partition the plane into 2×2 square tiles. We say that a disk S *belongs* to tile T if the center of S is in T. We denote the

subset of disks in $\mathcal{S}$ that belong to T by $\mathcal{S}(T)$. Note that the union of the disks in any given tile intersects at most nine different tiles. We assign a *palette* (i.e., a subset of colors) to each tile using nine different palettes, where the disks belonging to a particular tile are assigned colors from the tile's palette. Palettes are assigned to tiles by following a periodic 3×3 assignment. This assignment has the property that any two disks that belong to different tiles either do not intersect or their tiles are given different palettes (so that necessarily the two disks are assigned different colors). By the definition of local density we have that $|\mathcal{S}(T)| \leq \phi_2(\mathcal{S})$ for every tile T. Since we can color the set of disks $\mathcal{S}(T)$ belonging to tile T using $O(\log |\mathcal{S}(T)|)$ colors, and the total number of palettes is nine, we get the desired upper bound of $O(\log \phi_2(\mathcal{S}))$ colors. The general case of arbitrary size-ratio is dealt with by first partitioning the set of disks into classes according to their radius. The ith class, denoted $\mathcal{S}^i$, consists of disks, the radiuses of which are in the interval $[2^i, 2^{i+1})$. Within each class, the size-ratio is bounded by 2; hence we can CF-color each class using $O(\log \phi_{2^i}(\mathcal{S}^i))$ colors. By using a different (super-)palette per class, we obtain the desired bound on the number of colors, i.e., $\sum_{i=1}^{\log \rho+1} O(\log \phi_{2^i}(\mathcal{S}^i))$.

4.2. Bicriteria CF-coloring algorithms. In this section we prove Theorem 1.3. The first part of the theorem reveals a trade-off between the number of colors used and the fraction of the area that is served. The second part of the theorem reveals a trade-off between the number of colors used to serve the union of the unit disks and the radiuses of the serving disks.

We first derive the following corollary from Theorem 1.2.

COROLLARY 4.1. *Let $\mathcal{S}$ be a set of unit disks, and let $d_{\min}(\mathcal{S})$ be the minimum distance between the centers of disks in $\mathcal{S}$. If $d_{\min}(\mathcal{S}) \leq 2$, then every arrangement $\mathcal{A}(\mathcal{S})$ of unit disks can be CF-colored using $O\left(\log\left(\min\left\{|\mathcal{S}|, \frac{1}{d_{\min}(\mathcal{S})}\right\}\right)\right)$ colors.*

Observe that if $d_{\min}(\mathcal{S}) > 2$, then a single color suffices since the disks are disjoint.

Proof. Obviously $\phi_1(\mathcal{S}) \leq |\mathcal{S}|$. Since a unit square can be packed with at most $O(\frac{1}{d_{\min}(\mathcal{S}(T))^2})$ many disks of radius $d_{\min}(\mathcal{S}(T))$, it follows that $\phi_1(\mathcal{S}) = O(\frac{1}{d_{\min}(\mathcal{S}(T))^2})$. □

Let $X \subset \mathbb{R}^2$ denote a finite set of centers of disks. Recall that $\mathcal{S}_r(X) = \{B(x,r) \mid x \in X\}$, where $B(x,r)$ denotes a disk of radius r centered at x. Let $A_r(X) = \bigcup_{x \in X} B(x,r)$. The area of a region A in the plane is denoted by $|A|$. Let $L_r(X)$ denote the length of the boundary of $A_r(X)$. In order to prove Theorem 1.3 we shall need the following two lemmas, which are proved subsequently.

LEMMA 4.2. *For every finite set X of points in the plane,*

$$|A_1(X)| \geq \frac{1}{2} \cdot L_1(X).$$

LEMMA 4.3. *For every finite set X of points in the plane and every $\varepsilon > 0$,*

$$|A_{1+\varepsilon}(X) - A_1(X)| \leq (2\varepsilon + \varepsilon^2) \cdot L_1(X).$$

Proof of Theorem 1.3. We start with the second part. Let $X' \subseteq X$ denote a maximal subset with respect to inclusion such that $||x_1 - x_2|| \geq \varepsilon$ for every $x_1, x_2 \in X'$. Observe that $\bigcup \mathcal{S}_1(X) \subseteq \bigcup \mathcal{S}_{1+\varepsilon}(X')$. Corollary 4.1 implies that $\mathcal{S}_{1+\varepsilon}(X')$ can be CF-colored using $O(\log \frac{1+\varepsilon}{\varepsilon})$ colors. The second part follows.

We now turn to the first part. Let $\varepsilon_1 = \varepsilon/6$ and X' as above. Corollary 4.1 implies that there exists a CF-coloring χ of $\mathcal{S}_1(X')$ using $O\left(\log \frac{1}{\varepsilon}\right)$ colors. To complete the

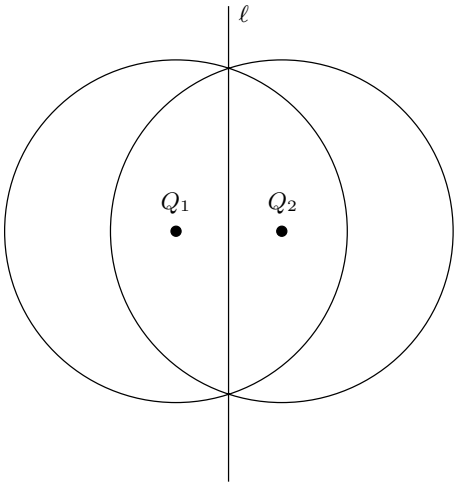

FIG. 4.1. *An illustration for the proof of Lemma* 4.4.

proof we need to show that

$$\frac{|A_1(X) - A_1(X')|}{|A_1(X)|} \leq \varepsilon.$$

Since $A_1(X) \subseteq A_{1+\varepsilon_1}(X')$ and $A_1(X') \subseteq A_1(X)$, it suffices to prove that

$$\frac{|A_{1+\varepsilon_1}(X') - A_1(X')|}{|A_1(X')|} \leq \varepsilon.$$

By Lemmas 4.2 and 4.3 it follows that

$$\frac{|A_{1+\varepsilon_1}(X') - A_1(X')|}{|A_1(X')|} \leq \frac{(2\varepsilon_1 + \varepsilon_1^2) \cdot L_1(X')}{\frac{1}{2} \cdot L_1(X')} = 4 \cdot \varepsilon_1 + 2\varepsilon_1^2.$$

Since $\varepsilon < 1$, it follows that $4 \cdot \varepsilon_1 + 2\varepsilon_1^2 \leq 6 \cdot \varepsilon_1 = \varepsilon$, and the corollary follows. □

4.2.1. Proving Lemmas 4.2 and 4.3. We denote a sector by $sect(Q, \alpha, r)$, where Q is its center, α is its angle, and r is its radius. A boundary sector of $A_1(X)$ is a sector $sect(Q, \alpha, 1)$ such that $Q \in X$ and its arc is on the boundary of $A_1(X)$. A boundary sector is maximal if it is not contained in another boundary sector. We measure angles in radians. Therefore, in a unit disk, (1) the angle of a sector equals the length of its arc, and (2) the area of a sector equals half its angle.

LEMMA 4.4. *The intersection of every two different maximal boundary sectors in* $A_1(X)$ *has zero area.*

Proof. The lemma is obvious if the boundary sectors belong to the same disk. Let $Q_1, Q_2 \in X$, and let D_i denote the circles centered at Q_i, for $i = 1, 2$, as depicted in Figure 4.1. Let $sect_i$ denote a boundary sector that belongs to circle D_i, for $i = 1, 2$. Let ℓ denote the line defined by the intersection points of the circles D_1 and D_2. The line ℓ separates the centers Q_1 and Q_2 so that they belong to different half-planes. The sector $sect_i$ is contained in the half-plane that contains Q_i, and hence $sect_1 \cap sect_2$ contains at most two points. The lemma follows. □

Proof of Lemma 4.2. The sum of the angles of the maximal boundary sectors of $A_1(X)$ equals $L_1(X)$. By Lemma 4.4, the maximal boundary sectors are disjoint, and

hence the sum of their areas is bounded by $|A_1(X)|$. However, the area of a sector of radius 1 whose angle equals α is $\alpha/2$. □

LEMMA 4.5. *Let X denote a finite set of points in the plane. For every $P \in A_{1+\varepsilon}(X) - A_1(X)$, there exists a point $Q \in X$ such that* (1) $P \in B(Q, 1+\varepsilon)$ *and* (2) *the segment $\overline{PQ}$ contains a boundary point of $A_1(X)$.*

Proof. Let Q denote a closest point in X to P. Since $P \in A_{1+\varepsilon}(X) - A_1(X)$, it follows that $P \in B(Q, 1+\varepsilon)$. Let Y denote the point at distance 1 from Q along the segment $\overline{QP}$. All we need to show is that Y is on the boundary of $A_1(X)$. If not, then Y is in the interior of a disk $B(Q', 1)$ for $Q' \in X - \{Q\}$. The triangle inequality implies that Q' is closer to P than Q, a contradiction. The lemma follows. □

Proof of Lemma 4.3. Lemma 4.5 implies that, for every point $P \in A_{1+\varepsilon}(X) - A_1(X)$, there exists boundary sector $sect(Q, \alpha, 1)$ of $A_1(X)$ (where $Q \in X$) such that

$$P \in sect(Q, \alpha, 1+\varepsilon) - sect(Q, \alpha, 1).$$

It follows that

$$\begin{aligned} |A_{1+\varepsilon}(X) - A_1(X)| &\leq \sum_{sect(Q,\alpha,1)} |sect(Q, \alpha, 1+\varepsilon) - sect(Q, \alpha, 1)| \\ &= \sum_{sect(Q,\alpha,1)} \alpha \cdot (2\varepsilon + \varepsilon^2), \end{aligned}$$

where $sect(Q, \alpha, 1)$ ranges over all maximal boundary sectors of $A_1(X)$. The claim follows by observing that the sum of the angles of the boundary sectors of $A_1(X)$ equals $L_1(X)$. □

5. Proof of Theorem 1.5. Theorem 1.5 follows from Theorem 1.7 similarly to the way that part 2 of Theorem 1.2 was shown to follow from Lemma 3.6.

Specifically, let C be a centrally symmetric convex region with a center point O, and X the set of centers that we are given. Consider a particular scaling factor r, and apply Corollary 2.3 to the arrangement $\mathcal{A}(\mathcal{C}_{r,O}(X))$. Let Y denote the set consisting of representatives from every cell in $cells(\mathcal{C}_{r,O}(X))$. The dual range-space is isomorphic to a range-space with (i) a ground set X and (ii) ranges induced by $\mathcal{C}_{r,O}(Y)$. We extend the range-space to ranges induced by all scaled translations of C. A CF-coloring of the points in X with respect to all scaled translations of C is also a CF-coloring of every arrangement $\mathcal{A}(\mathcal{C}_{r,O}(X))$. Theorem 1.5 now follows directly from Theorem 1.7.

6. Chains and CF-coloring of chains. In this section we introduce a combinatorial structure that we call a *chain*. Chains are used to establish the tightness of Theorem 1.2. They are also central to our $O(1)$ approximation algorithms for rectangles and hexagons.

6.1. Combinatorial structure. Consider an arrangement $\mathcal{A}(\mathcal{S})$ of a collection of regions in the plane $\mathcal{S}$. We associate with every cell $v \in cells(\mathcal{S})$ the subset $N(v) \subseteq \mathcal{S}$ of regions that contain the cell, namely, $N(v) = \{S \in \mathcal{S} : v \subseteq S\}$.

A set $\mathcal{S}$ of regions in the plane is said to be *indexed* if the regions are given indexes from 1 to $|\mathcal{S}|$. In the following definition we identify a region with its index. We refer to a set $\{i, i+1, \ldots, j\}$ of consecutive integers as an *interval* and denote it by $[i, j]$.

DEFINITION 6.1. *Let $\mathcal{S}$ denote an indexed set of n regions. The arrangement $\mathcal{A}(\mathcal{S})$ satisfies the* interval property *if $N(v)$ is an interval $[i, j] \subseteq [1, n]$ for every cell $v \in cells(\mathcal{S})$.*

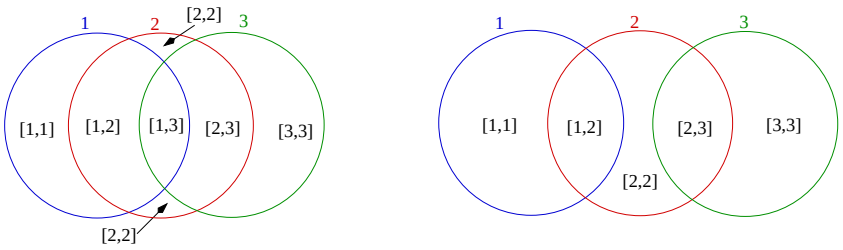

FIG. 6.1. *On the left is an arrangement of three disks that satisfies the full interval property, and on the right is an arrangement that satisfies the interval property but not the full interval property. In particular, in both cases the disks are unit disks and their centers reside on a line. However, in the arrangement on the right, the first and the third disk do not intersect, and hence there is no cell* v *such that* $N(v) = [1, 3]$.

The arrangement $\mathcal{A}(\mathcal{S})$ *satisfies the* full interval property *if it satisfies the interval property and if, in addition, for every interval* $[i, j] \subseteq [1, n]$*, there exists a cell* $v \in$ *cells*$(\mathcal{S})$ *such that* $N(v) = [i, j]$.

For an illustration of the interval and full interval properties, see Figure 6.1. The definition of the (full) interval property is sensitive to the indexing. Indexes of regions are usually based on the order of appearance of the regions along the boundary of the union of the regions. We refer, in short, to an arrangement of an indexed set of regions that satisfies the full interval property as a *chain*.

The definition of a chain implies that an arrangement $\mathcal{A}(\mathcal{S})$ is a chain if and only if the dual range-space is isomorphic to $(\{1, \ldots, n\}, \{[i, j] : 1 \leq i \leq j \leq n\})$, where $n = |\mathcal{S}|$. The next lemma, which follows directly from this observation, shows that the chain property is hereditary.

LEMMA 6.2. *Let* $\mathcal{S}$ *denote an indexed set of regions. Let* $\mathcal{S}' \subseteq \mathcal{S}$*, and let the indexes of regions* $\mathcal{S}'$ *agree with their order in* $\mathcal{S}$*. If* $\mathcal{A}(\mathcal{S})$ *is a chain, then* $\mathcal{A}(\mathcal{S}')$ *is also a chain.*

Before discussing colorings of chains, we observe that it is easy to construct chains. Consider a set $\mathcal{S}$ of n unit disks with centers positioned along a straight line at distance $\frac{1}{n+1}$ apart. Index the disks from 1 to n according to the position of their centers from left to right. The arrangement $\mathcal{A}(\mathcal{S})$ is depicted on the top of Figure 6.2. Observe that every two disks in the arrangement intersect.

We apply duality to prove that the arrangement $\mathcal{A}(\mathcal{S})$ is a chain. The arrangement is the range-space $(\mathit{cells}(\mathcal{S}), \mathcal{S})$. Let X denote a set of representatives of cells in $\mathit{cells}(\mathcal{S})$, and let Y denote the centers of unit disks in $\mathcal{S}$. The dual range-space is the pair $(Y, \{N(x)\}_{x \in X})$. Since the disks are unit disks, it follows that $N(x)$ is the intersection of Y with a unit disk centered at x. The set Y is indexed, and its points are located along a line sufficiently close so that they are included in a unit disk. Hence the collection of sets $\{N(x)\}_{x \in X}$ is simply the set of all intervals $[i, j] \subseteq [1, n]$. It follows that the arrangement $\mathcal{A}(\mathcal{S})$ is a chain, as claimed. For an illustration, see Figure 6.2 (bottom).

6.2. CF-colorings of chains. In this subsection we show that the number of colors both necessary and sufficient for CF-coloring a chain of n regions is $\Theta(\log n)$.

LEMMA 6.3. *Every CF-coloring of a chain of* n *regions uses* $\Omega(\log n)$ *colors.*

Proof. Let $I_{a,b}$ denote the set $\{[i, j] : a \leq i \leq j \leq b\}$, namely, the set of all subintervals of $[a, b]$. By definition, the dual range-space of a chain is isomorphic to the range-space $([1, n], I_{1,n})$. Therefore, CF-coloring a chain is equivalent to CF-

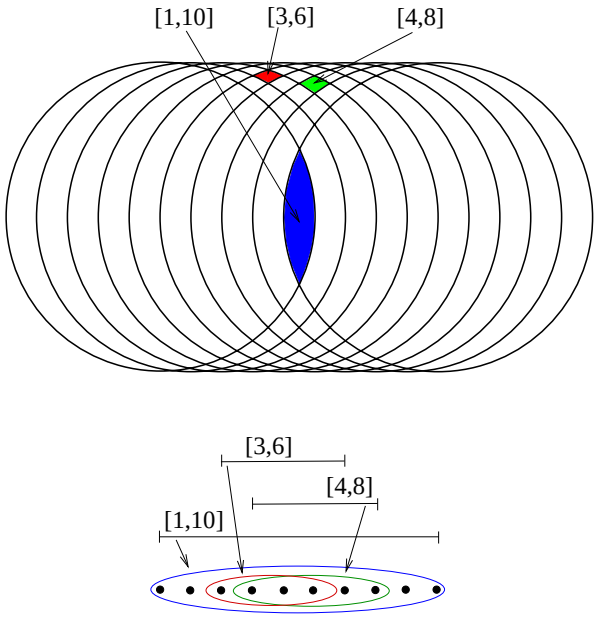

FIG. 6.2. *On the top is a chain of disks, where the disks are numbered* $1, \ldots, 10$ *from left to right. The three cells that are marked correspond to the three respective intervals. On the bottom is an illustration of the dual range-space. In the dual space there is a point for every disk in the primal space, and a subset for every cell in the primal space. Since the cells in the primal space correspond to intervals, the subsets in the dual space correspond to intervals* $[i, j] = \{i, i+1, \ldots, j\}$ *as well.*

coloring $[1, n]$ with respect to $I_{1,n}$. We hence focus on the latter problem. Let $f(n)$ denote the minimum number of colors required for such a coloring.

Consider an optimal CF-coloring χ_n of $[1, n]$ with respect to $I_{1,n}$. Let i denote the index that serves the interval $[1, n]$. It follows that for every index $j \neq i$, $\chi(j) \neq \chi(i)$. Since $\chi(i)$ is unique, it follows that every subinterval that contains i can be served by i.

We partition $I_{1,n}$ into three sets as follows: (i) $I_{1,(i-1)}$, the set of all subintervals of $[1, i-1]$; (ii) I', the set of all subintervals of $[1, n]$ that contain i; and (iii) $I_{(i+1),n}$, the set of all subintervals of $[i+1, n]$. (Observe that if $i = 1$ (respectively, $i = n$), then $I_{1,(i-1)}$ (respectively, $I_{(i+1),n}$) is empty.)

Since i can serve only intervals in I', we are left with two range-spaces that are the dual of (shorter) chains. Namely, the range-space $([1, (i-i)], I_{1,(i-1)})$ and the range-space $([(i+i), n], I_{(i+1),n})$.

Since $\chi(j)$ must differ from $\chi(i)$ for every $j \neq i$, it follows that $f(n)$ satisfies the following recurrence equation:

$$f(n) \geq 1 + \max_i \{f(i-1), f(n-i)\}.$$

Therefore, $f(n) = \Omega(\log n)$, and the lemma follows. □

LEMMA 6.4. *Every indexed arrangement of* n *regions that satisfies the interval property can be CF-colored with* $O(\log n)$ *colors.*

It suffices to prove the above lemma for chains. (In terms of the dual range-space, this simply means that we add constraints.) In fact, in section 3.1 we already presented a proof of the above lemma in the special case of unit disks whose centers

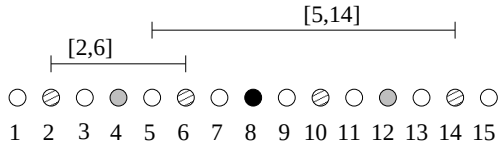

FIG. 6.3. *An illustration for Lemma* 6.4. *The* 15 *points in the figure are the points of the dual range-space. Point number* 8 *is colored with the "highest color" (corresponding to the densest filling in the illustration). Points* 4 *and* 12 *are colored with the next highest color, and points* 2, 6, 10, *and* 14 *with the next. The remaining points (all odd-numbered points) are colored with the lowest color. If we now consider, for example, the intervals (ranges in the dual space)* $[5, 14]$ *and* $[2, 6]$, *then the first can be served by point number* 8, *and the latter by point number* 4.

reside on a line. In section 6.1 we showed that a chain can be obtained from an arrangement of unit disks whose centers are collinear. Hence, the lemma follows. We provide an alternative proof of the above lemma that follows the spirit of the proof of the lower bound stated in Lemma 6.3.

Proof. We use the same notation as in the proof of the previous lemma. Without loss of generality the dual range-space is isomorphic to $([1, n], I_{1,n})$. (Adding ranges does not make CF-coloring a set of points with respect to a set of ranges any easier.) Hence, we focus on CF-coloring of such a dual range-space.

We show by induction that $f(n) \leq \lceil \log n \rceil + 1$ (see Figure 6.3). The induction basis $n = 1$ is trivial. For $n > 1$, let $i = \lceil n/2 \rceil$ and color it with the color $\lceil \log n \rceil$. The index i serves all the subintervals of $[1, n]$ that contain i. A subinterval of $[1, n]$ that does not contain i is either in $I_{1,(i-1)}$ or in $I_{(i+1),n}$. The induction hypothesis implies that the range-spaces $([1, (i-1)], I_{1,(i-1)})$ and $([(i+1), n], I_{(i+1),n})$ can each be colored by $1 + \lceil \log(n/2) \rceil = \lceil \log n \rceil$ colors. Since the ground sets of these range-spaces are disjoint, we may use the same set of colors for each. It follows that at most $\lceil \log n \rceil + 1$ colors are used, as required. □

7. An approximation algorithm for rectangles. In this section we prove Theorem 1.4 for the case of axis-parallel rectangles. For simplicity, most of the proof deals with the special case of axis-parallel unit squares. In section 7.4 we point out the modifications required for rectangles.

We begin with a high level description of the algorithm (for the special case of axis-parallel unit squares). The algorithm starts by partitioning the plane into square tiles of side-lengths 1/2. Given a set of $\mathcal{S}$ of unit squares, we say that a square $s \in \mathcal{S}$ belongs to a tile if its center resides inside the tile. Hence the tiling induces a partition of $\mathcal{S}$. We first observe that squares that belong to sufficiently distant tiles do not intersect. Therefore, as shown for the case of disks, we may assign each tile a palette of colors so that the total number of palettes used is constant, and any two different tiles whose squares may intersect are assigned different palettes. At this point we could simply apply Theorem 1.5 to separately color the squares that belong to each tile. This would give us a CF-coloring that uses $O(\log \phi(\mathcal{S}))$ colors, where $\phi(\mathcal{S})$ is the maximum number of centers of squares in $\mathcal{S}$ that are contained in a square tile of side-lengths 1/2. However, the resulting coloring may be far from optimal (recall that we are interested in a constant-ratio approximation algorithm). The reason is that squares whose centers reside in different, but neighboring, tiles may interact with each other in a manner that allows us to save in the number of colors used. For an illustration, see Figure 7.1.

Instead of coloring all squares as suggested above, our algorithm selects only a

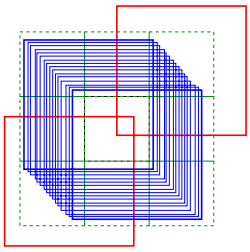

FIG. 7.1. *An example illustrating how, by taking into account intersections between squares that belong to different tiles, we may significantly reduce the number of colors required in a CF-coloring. Here there is a large number of squares that belong to the middle tile and constitute a chain. If we color the squares of each tile separately, the number of colors used is logarithmic in the size of the chain. However, there is a CF-coloring that uses only five colors: Simply color each of the thick squares by a distinct color and use the fifth color for the remaining squares.*

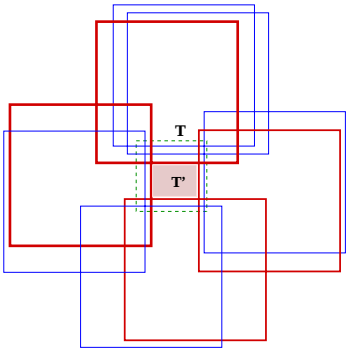

FIG. 7.2. *An illustration of the selection of squares that intersect an orphan tile T with an edge. The tile T is the dashed square, the selected squares are marked in bold, and the remaining unserved region T' is shaded.*

subset of squares, which are "essential" for serving the area covered by the union of the squares. Once this stage is over, we can "return" to each tile from which squares were requested, and color the requested squares by applying Theorem 1.5. The notion of essentialness is formalized later on in this section. It enables us to show that the total number of colors used is indeed necessary, up to a constant. Clearly, every tile that contains the center of at least one square can be completely served by any one of the squares that belong to it. Thus the main issue is serving tiles that lack centers of squares. We refer to such tiles as "orphan" tiles. In what follows we describe how an orphan tile selects the squares that are used to serve it.

Consider an orphan tile T (for which the set of squares that intersect it is nonempty). The squares that intersect it (and may hence serve parts of it) can be partitioned into two types: those that intersect it with an edge and those that intersect it with a corner. Each type can be further partitioned into four subtypes according to the edge type (respectively, corner type) with which they intersect T. We first observe that, within each subtype of squares that intersect T with an edge, we can select a single square that can serve the entire area within T that is covered by squares of this subtype. After selecting one square from each subtype, we are essentially left with the problem of serving a rectangular region, denoted by T', that is contained in T. For an illustration, see Figure 7.2.

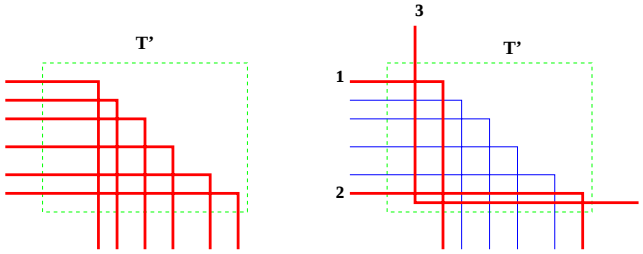

FIG. 7.3. *On the left is a subset of squares that intersect the rectangular region T' with their top-right corner. In order to cover the intersection of T' with their union it is necessary to select all squares. On the right is the same set of squares, together with one more square, which intersects T' with its bottom-left corner. Now only the 3 bold squares (labeled 1, 2, and 3) are necessary.*

Suppose that we now separately consider each subset of squares that intersect T' with a common corner type (e.g., top-right). For each corner type, it suffices to focus on the subset of squares that participate in the envelope of the squares that intersect T'. However, the envelopes of squares corresponding to different corner types may intersect in T'. Such intersections may help in reducing the number of squares needed to cover the intersection of T' with the union of all squares. For an illustration, see Figure 7.3.

In order to address the issue of "intersections" between envelopes of subsets of squares corresponding to different corner types, we consider these subsets of squares in pairs. Specifically, we first deal with "adjacent" pairs whose corresponding corners have a common edge (e.g., top-right and top-left), and then with "opposite" pairs (top-right with bottom-left, and bottom-right with top-left). For the first class of adjacent pairs, we show that by selecting at most two squares per pair we can serve the region of the intersection of each pair. For the second class of "opposite" pairs, we describe a procedure that selects a subset of squares that is at most a constant factor larger than necessary. Further details for these more involved steps are given in subsections 7.2 and 7.3.

7.1. Preliminaries. Let $\mathcal{R}$ be a set of axis-parallel rectangles of side-length at least 1. We denote a set of axis-parallel unit squares by $\mathcal{S}$. For simplicity, we assume that the rectangles (respectively, squares) in $\mathcal{R}$ (respectively, $\mathcal{S}$) are arranged in general position (i.e., no two corners of two distinct rectangles have the same x-coordinate or y-coordinate). Let $\Gamma = \{\urcorner, \ulcorner, \lrcorner, \llcorner\}$ denote the set of corner *types*. We denote the top-right corner of a rectangle R by $\urcorner(R)$. In general, for a corner $\gamma \in \Gamma$, we denote the γ-corner of R by $\gamma(R)$. The x-coordinate (y-coordinate) of a γ-corner of a rectangle R is denoted by $x_\gamma(R)$ ($y_\gamma(R)$). Let $\mathrm{op} : \Gamma \to \Gamma$ denote the permutation that swaps opposite corners (i.e., $\mathrm{op} = (\llcorner, \urcorner)(\ulcorner, \lrcorner)$). The *center* of a rectangle R is the intersection point of its two main diagonals.

The tiling. We partition the plane into "half-open" square tiles having side-lengths $1/2$, namely, $T_{i,j} = [i/2, (i+1)/2) \times [j/2, (j+1)/2)$. We say that a rectangle R *belongs* to tile T if the center of R is in T. We denote the set of rectangles in $\mathcal{R}$ that belong to tile T by $\mathcal{R}(T)$. A tile T is an *orphan* if $\mathcal{R}(T) = \emptyset$. A tile is *bare* if no rectangle in $\mathcal{R}$ intersects it. We say that two tiles are *e-neighbors* (respectively, *v-neighbors*) if they share an edge (respectively, a corner). The v-neighbor of T that shares its γ-corner with the $\mathrm{op}(\gamma)$ corner of T is denoted T_γ.

Tiles are half-open, and their side-length is defined to be half the minimum side-

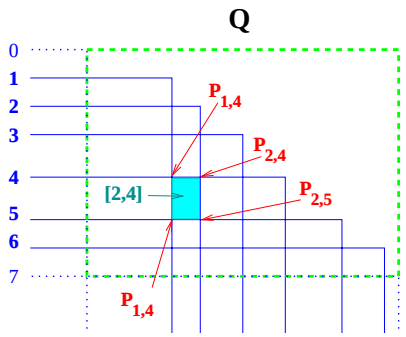

FIG. 7.4. *An illustration of a corner-chain consisting of six rectangles (the two dotted rectangles, numbered* 0 *and* 7*, are only for the sake of the analysis in the proof of Claim* 7.3*). The cell corresponding to the interval* $[2,4]$ *is filled, and its four defining corners are marked.*

length of a rectangle so that (i) if a rectangle R belongs to a tile T, then rectangle R covers the tile T; and (ii) a tile can contain at most one corner of a rectangle.

In the case of a set $\mathcal{S}$ of unit squares, squares belonging to T_γ intersect T with their γ-corner. Moreover, the corners of a unit square $S \in \mathcal{S}(T)$ reside in v-neighbors of T. Hence, a square S intersects only the tile it belongs to and the neighbors of that tile.

Corner-chains. We next consider chains determined by rectangles having the same corner in a common region. Let T be a fixed tile, and let $Q \subseteq T$ denote a rectangle. Let $\gamma \in \Gamma$ denote a corner type. Let $\mathcal{R}(Q,\gamma)$ denote the set of rectangles $R \in \mathcal{R}$ that satisfy $\gamma(R) \in Q$. The size of the tile T implies that every rectangle of side length at least 1 has at most one corner in T. Define the *Q-envelope* of $\mathcal{R}(Q,\gamma)$ to be the boundary of $\mathcal{R}(Q,\gamma)$ that is in Q (see Figure 7.4). The vertices of a Q-envelope are either corners $\gamma(R)$, for $R \in \mathcal{R}(Q,\gamma)$, or intersections of sides of two rectangles. Let $\widetilde{\mathcal{R}}(Q,\gamma)$ denote the subset of rectangles in $\mathcal{R}(Q,\gamma)$ that participate in the Q-envelope of $\mathcal{R}(Q,\gamma)$.

The next claim shows that the corner γ determines whether the Q-envelope is nonincreasing or nondecreasing.

CLAIM 7.1. *Let Q be a rectangular region with side-lengths at most* $1/2$*. If $\gamma \in \{\llcorner, \urcorner\}$, then the Q-envelope of $\mathcal{R}(Q,\gamma)$ is nonincreasing, and if $\gamma \in \{\ulcorner, \lrcorner\}$, then the Q-envelope of $\mathcal{R}(Q,\gamma)$ is nondecreasing.*

Proof. We prove the claim for $\gamma = \urcorner$. An analogous argument holds for the other cases. Let $R_1, \ldots, R_m$ $(m = |\widetilde{\mathcal{R}}(Q,\gamma)|)$ be an ordering of $\widetilde{\mathcal{R}}(Q,\gamma)$ which satisfies $x_\urcorner(R_1) < x_\urcorner(R_2) < \cdots < x_\urcorner(R_m)$. We show that $y_\urcorner(R_1) > y_\urcorner(R_2) > \cdots > y_\urcorner(R_m)$. Assume, in contradiction, that for some pair of squares $R_k, R_\ell \in \widetilde{\mathcal{R}}(Q,\gamma)$, where $k < \ell$ (so that $x_\urcorner(R_k) < x_\urcorner(R_\ell)$), we have that $y_\urcorner(R_k) < y_\urcorner(R_\ell)$. In such a case we would have that $(x_\urcorner(R_k), y_\urcorner(R_k)) \in R_\ell$, contradicting the fact that R_k belongs to the envelope $\widetilde{\mathcal{R}}(Q,\gamma)$. □

The next definition will be useful in all that follows.

DEFINITION 7.2. *Let Q be a region, and let $\mathcal{S}$ be an indexed set of regions. Let $\mathcal{S}_Q$ denote the set of regions $\{Q \cap S\}_{S \in \mathcal{S}}$. Assume that each region $Q \cap S \in \mathcal{S}_Q$ inherits the index of S. We say that* $\mathcal{S}$ is a chain with respect to Q *if the arrangement $\mathcal{A}(S_Q)$ is a chain.*

CLAIM 7.3. *Let Q be a rectangular region with side-lengths at most* $1/2$*. Index the*

rectangles of $\widetilde{\mathcal{R}}(Q,\gamma)$ according to the x-coordinate of their γ-corner. Then $\widetilde{\mathcal{R}}(Q,\gamma)$ is a chain with respect to Q.

Claim 7.3 justifies referring to $\widetilde{\mathcal{R}}(Q,\gamma)$ as a *corner-chain*.

Proof. We prove the claim for $\gamma = \urcorner$. The other three cases can be reduced to this case by "turning the picture." Let $R_1,\ldots,R_m$ ($m = |\widetilde{\mathcal{R}}(Q,\gamma)|$) be an ordering of $\widetilde{\mathcal{R}}(Q,\gamma)$ according to the x coordinates of their $\urcorner$-corner. Let R_0 and R_{m+1} be two "fictitious" rectangles, where the right side of R_0 coincides with the left side of Q, and the top side of R_{m+1} coincides with the bottom side of Q. Let $P_{i,j}$, for $0 \le i \le j \le m+1$, denote the intersection of the right side of R_i and the top side of R_j. Note that for every $1 \le i \le m$, $P_{i,i} = \urcorner(R_i)$, $P_{i,m+1}$ is the intersection of R_i with the bottom side of Q, and $P_{0,i}$ is the intersection of R_i with the left side of Q. By Claim 7.1, it follows that $P_{i,j}$ is well defined and that $P_{i,j} \in Q$ for every $1 \le i \le j \le m+1$. The arrangement of $\widetilde{\mathcal{R}}(Q,\gamma)$ in Q is a set of rectangular-shaped cells, the corners of which are the set of points $\{P_{i,j}\}$. Specifically, for every $1 \le i \le j \le m$, the cell v for which $N(v) = [i,j]$ is the rectangle whose corners are $P_{i-1,j+1}$, $P_{i-1,j}$, $P_{i,j}$, and $P_{i,j+1}$. ∎

Disjoint palettes. In the case of unit squares we assign a palette (i.e., a subset of colors) to each tile, using in total nine disjoint palettes. Palette distribution is such that neighboring tiles are assigned different palettes (i.e., we periodically assign nine different palettes to blocks of 3×3 tiles). The tile size implies that if two squares belong to different tiles that are assigned the same palette, then the squares have an empty intersection.

7.2. Main lemmas. In this section we lay the ground for our algorithm and its analysis by presenting our main lemmas. For simplicity we focus on a collection $\mathcal{S}$ of unit squares. In subsection 7.4 we discuss how to perform the extension to general rectangles. Specifically, in this section we provide our main lemmas concerning interactions between corner-chains of opposite corners and corner-chains of adjacent corners.

7.2.1. Corner-chains of adjacent corners. Consider a rectangle Q with side-lengths at most $1/2$. Let $\widetilde{\mathcal{S}}_{\urcorner} = \widetilde{\mathcal{S}}(Q,\urcorner)$ and $\widetilde{\mathcal{S}}_{\ulcorner} = \widetilde{\mathcal{S}}(Q,\ulcorner)$ denote corner-chains corresponding to adjacent corners $\urcorner$ and $\ulcorner$. (The other three cases of pairs of adjacent corners can be reduced to this case by "turning the picture.") We show that, by picking at most one square from each corner-chain, it is possible to "separate" between the chains. That is (as formalized in the next lemma), after picking one square from each chain, the squares having smaller indexes than those picked form a chain with respect to the remaining region.

Let $\{S_i\}_{i=1}^{m}$ (respectively, $\{S'_i\}_{i=1}^{m'}$) denote the ordering of the squares in $\widetilde{\mathcal{S}}_{\urcorner}$ (respectively, $\widetilde{\mathcal{S}}_{\ulcorner}$) in increasing (respectively, decreasing) order of the x-coordinate of their centers (or corners in Q). By Claim 7.3, both indexed sets $\widetilde{\mathcal{S}}_{\urcorner}$ and $\widetilde{\mathcal{S}}_{\ulcorner}$ are chains with respect to Q.

LEMMA 7.4. *There exist two squares, $S_k \in \widetilde{\mathcal{S}}_{\urcorner}$ and $S'_\ell \in \widetilde{\mathcal{S}}_{\ulcorner}$, such that*

1. *the prefixes $\{S_1,\ldots,S_{k-1}\}$ and $\{S'_1,\ldots,S'_{\ell-1}\}$ are disjoint; namely, for every $S_{k'}$ and $S'_{\ell'}$ such that $k' < k$ and $\ell' < \ell$, we have $S_{k'} \cap S'_{\ell'} = \emptyset$;*
2. *each of the prefixes $\{S_1,\ldots,S_{k-1}\}$ and $\{S'_1,\ldots,S'_{\ell-1}\}$ is a chain with respect to $Q \setminus (S_k \cup S'_\ell)$;*
3. *the union of S_k and S'_ℓ covers every point in Q that is covered by a square in one of the suffixes; namely, $(\bigcup_{t=k+1}^{m}(S_t \cap Q)) \bigcup (\bigcup_{t=\ell+1}^{m'}(S'_t \cap Q)) \subseteq S_k \cup S'_\ell$.*

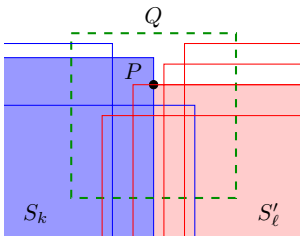

FIG. 7.5. *An illustration for Lemma 7.4. The region Q is depicted by a dashed rectangle. Only the corners of squares in the corner-chains are depicted. The two filled squares are the selected squares S_k and S'_ℓ.*

The implication of this lemma is that it is possible to select two squares S_k and S'_ℓ to serve all cells that are contained in the union $(\bigcup_{t=k}^{m}(S_t \cap Q)) \cup (\bigcup_{t=\ell}^{m'}(S'_t \cap Q))$. Furthermore, each of the prefixes is a chain with respect to the remaining region.

Proof. Consider the Q-envelopes of the two corner-chains. Both envelopes are "stairs" curves. By Claim 7.1, the Q-envelope of $\widetilde{\mathcal{S}}_\neg$ ($\widetilde{\mathcal{S}}_\ulcorner$) is nonincreasing (nondecreasing). Hence the Q-envelopes intersect at most once. If they do not intersect, then the claim is trivial (pick the last square from each chain). Otherwise, let P denote the intersection point. Let the selected squares S_k and S'_ℓ be the squares that intersect in point P. We assume that P is along the horizontal upper side of S'_ℓ (i.e., $P_y = y_\ulcorner(S'_\ell)$) and along the vertical right side of S_k (i.e., $P_x = x_\neg(S_k)$). (The reverse case is reduced to this case by "flipping the picture.")

Part 1 of the lemma follows by showing that the vertical line passing through P separates the prefixes. Namely, if $A \in S_{k'}$, $k' < k$, then $A_x < P_x$ (i.e., the x-coordinate of point A is less than the x-coordinate of point P). Similarly, if $B \in S'_{\ell'}$, $\ell' < \ell$, then $B_x > P_x$. Consider first any square $S_{k'} \in \widetilde{\mathcal{S}}_\neg$, where $k' < k$. By our assumption that P is along the vertical right side of S_k, we have that $P_x = x_\neg(S_k)$. By the ordering of the squares in $\widetilde{\mathcal{S}}_\neg$, we have that $x_\neg(S_{k'}) < x_\neg(S_k)$, and hence for every $A \in S_{k'}$, $A_x \leq x_\neg(S_{k'}) < x_\neg(S_k)$. It directly follows that $A_x < P_x$. Next consider a square $S'_{\ell'} \in \widetilde{\mathcal{S}}_\ulcorner$, where $\ell' < \ell$. By our assumption that P is along the horizontal upper side of S'_ℓ, and by the ordering of the squares in $\widetilde{\mathcal{S}}_\ulcorner$, necessarily $x_\ulcorner(S'_{\ell'}) > P_x$. But, for every point $B \in S'_{\ell'}$, $B_x \geq x_\ulcorner(S'_{\ell'})$, and so $B_x > P_x$.

To prove part 2 of the lemma it suffices to show that (i) $(S_{k'} \setminus S_k) \cap S'_\ell = \emptyset$ if $k' < k$, and (ii) $(S'_{\ell'} \setminus S'_\ell) \cap S_k = \emptyset$ if $\ell' < \ell$. This is sufficient since $\widetilde{\mathcal{S}}_\neg$ (respectively, $\widetilde{\mathcal{S}}_\ulcorner$) is a chain with respect to Q. Hence, every cell corresponding to an interval $[i,j] \subseteq [1,k-1]$ (respectively, $[i,j] \subseteq [1,\ell-1]$) of $\widetilde{\mathcal{S}}_\neg$ (respectively, $\widetilde{\mathcal{S}}_\ulcorner$) in Q is disjoint from $S_k \cup S'_\ell$, and the full interval property is preserved. For example, consider the two squares in Figure 7.5 that belong to the $\ulcorner$-chain and are above S'_ℓ. If we denote them by S_1 and S_2, then we see that the regions $S_1 \setminus S'_\ell$ and $S_2 \setminus S'_\ell$ are both disjoint from S_k and that $\{S_1, S_2\}$ form a chain with respect to $Q \setminus (S_k \cap S'_\ell)$.

In order to verify (i), consider a square $S_{k'}$ for $k' < k$. To show that $(S_{k'} \setminus S_k) \cap S'_\ell = \emptyset$, consider a point $A \in (S_{k'} \setminus S_k)$. The ordering of $\widetilde{\mathcal{S}}_\neg$ implies that $A_y > y_\neg(S_k)$, and by the definition of P, $y_\neg(S_k) \geq P_y$. Since $P_y = y_\ulcorner(S'_\ell)$, we get that A is above S'_ℓ and, in particular, $A \notin S'_\ell$ as claimed in (i). Item (ii) is proved analogously, and part 2 of the lemma follows.

It remains to prove part 3 of the lemma. Consider a point $A \in S_{k'} \cap Q$, for $k' > k$. There are two possibilities. (i) $A_x \leq P_x$: In this case, $A_y \leq y_\neg(S_{k'}) \leq y_\neg(S_k)$.

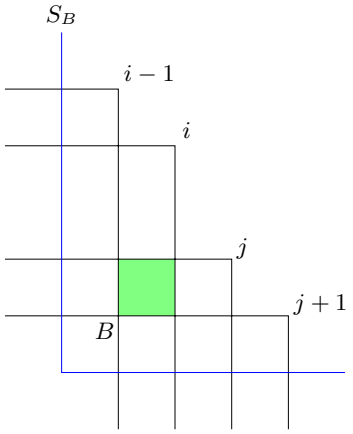

FIG. 7.6. *The construction in the proof of Lemma* 7.6.

Since $P_x = x_{\urcorner}(S_k)$, we get that $A \in S_k$. (ii) $A_x > P_x$: If $A_y \geq P_y$, then $\urcorner(S_{k'})$ is above and to the right of P, and hence $P \in S_{k'}$, a contradiction. It follows that $A_y < P_y = y_{\ulcorner}(S'_\ell)$. Since $P_x \geq x_{\ulcorner}(S'_\ell)$, we get that $A \in S'_\ell$. Therefore, the suffix of $\widetilde{\mathcal{S}}_{\urcorner}$ is covered by $S_k \cup S'_\ell$. The proof for the suffix of $\widetilde{\mathcal{S}}_{\ulcorner}$ is analogous, and part 3 of the lemma follows. □

7.2.2. Corner-chains of opposite corners. Consider a rectangle Q with side lengths at most 1/2. Let $\widetilde{\mathcal{S}}_{\urcorner} = \widetilde{\mathcal{S}}(Q, \urcorner)$ and $\widetilde{\mathcal{S}}_{\llcorner} = \widetilde{\mathcal{S}}(Q, \llcorner)$ denote corner-chains corresponding to opposite corners $\urcorner$ and $\llcorner$. (The case of the $\lrcorner$-corner and $\ulcorner$-corner is reduced to this case by "flipping or rotating the picture.") Let $Q_{\urcorner} = Q \cap \bigcup_{S \in \widetilde{\mathcal{S}}_{\urcorner}} S$ and $Q_{\llcorner} = Q \cap \bigcup_{S \in \widetilde{\mathcal{S}}_{\llcorner}} S$. Our goal is to select an approximately minimum subset from each corner-chain so as to cover $Q_{\urcorner} \cup Q_{\llcorner}$. To this end, we find minimal covers of $Q_{\urcorner} \setminus Q_{\llcorner}$, $Q_{\llcorner} \setminus Q_{\urcorner}$, and $Q_{\urcorner} \cap Q_{\llcorner}$.

DEFINITION 7.5. *A subset* $\widetilde{\mathcal{S}}^m_{\urcorner} \subseteq \widetilde{\mathcal{S}}_{\urcorner}$ *is a* minimal cover *of* $Q_{\urcorner} \setminus Q_{\llcorner}$ *if* (i) $\widetilde{\mathcal{S}}^m_{\urcorner}$ *covers* $Q_{\urcorner} \setminus Q_{\llcorner}$*, and* (ii) *no proper subset of* $\widetilde{\mathcal{S}}^m_{\urcorner}$ *covers* $Q_{\urcorner} \setminus Q_{\llcorner}$.

The following lemma shows that minimal covers of $(Q_{\urcorner} \setminus Q_{\llcorner})$ are chains with respect to $(Q_{\urcorner} \setminus Q_{\llcorner})$.

LEMMA 7.6. *If* $\widetilde{\mathcal{S}}^m_{\urcorner} \subseteq \widetilde{\mathcal{S}}_{\urcorner}$ *is a minimal cover of* $Q_{\urcorner} \setminus Q_{\llcorner}$*, and the squares in* $\widetilde{\mathcal{S}}^m_{\urcorner}$ *are indexed according to the* x*-coordinate of their* $\urcorner$*-corners, then* $\widetilde{\mathcal{S}}^m_{\urcorner}$ *is a chain with respect to* $Q_{\urcorner} \setminus Q_{\llcorner}$.

Proof. Let $\widetilde{\mathcal{S}}^m_{\urcorner} = \{S'_1, \ldots, S'_k\}$. Since $\widetilde{\mathcal{S}}_{\urcorner}$ is a chain with respect to Q, it follows that $\widetilde{\mathcal{S}}^m_{\urcorner}$ is also a chain with respect to $Q_{\urcorner}$. For simplicity, add "dummy" squares S'_0 and S'_{k+1} to $\widetilde{\mathcal{S}}^m_{\urcorner}$, where $\urcorner(S'_0) = \ulcorner(Q)$ and $\urcorner(S'_{k+1}) = \lrcorner(Q)$. Note that these dummy squares do not assist in covering $Q_{\urcorner} \setminus Q_{\llcorner}$. For the sake of contradiction, assume that $\widetilde{\mathcal{S}}^m_{\urcorner}$ is not a chain with respect to $Q_{\urcorner} \setminus Q_{\llcorner}$. Since $\widetilde{\mathcal{S}}^m_{\urcorner}$ is not a chain, it is not empty. Consider an interval $[i, j]$, for $0 < i \leq j < k+1$, such that the corresponding cell in $\mathcal{A}(\widetilde{\mathcal{S}}^m_{\urcorner})$ is contained in $Q_{\llcorner}$. (See Figure 7.6 for an illustration of this case.) Consider the corner B of the cell $[i, j]$ in Q defined by the intersection of the sides of S'_{i-1} and S'_{j+1} in Q. Since the cell $[i, j]$ is in $Q_{\llcorner}$, so is the point B. Let $S_B \in \widetilde{\mathcal{S}}_{\llcorner}$ denote a square that contains B. It follows that the whole cell $[i, j]$ as well as $\urcorner(S'_{i-1})$, $\urcorner(S'_i)$, $\urcorner(S'_j)$, and $\urcorner(S'_{j+1})$ are in S_B. It is easy to see that we may omit both S'_i and S'_j from $\widetilde{\mathcal{S}}^m_{\urcorner}$ while still covering $Q_{\urcorner} \setminus Q_{\llcorner}$, contradicting the assumption that $\widetilde{\mathcal{S}}^m_{\urcorner}$ is a minimal

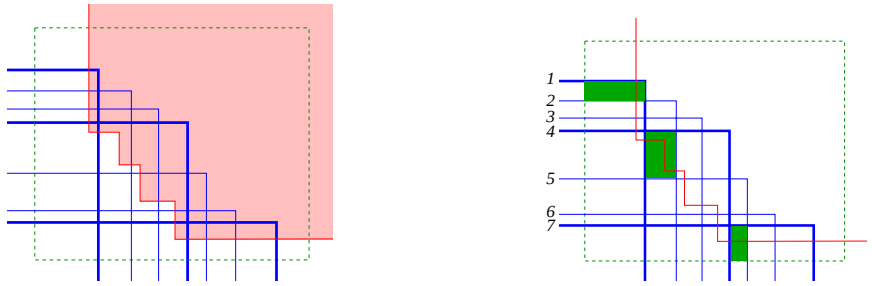

FIG. 7.7. *A minimal cover of the union of opposite corner-chains.* (A) *The rectangle Q is depicted by a dashed rectangle. The union of the "upper" corner-chain $Q_{\llcorner}$ is shaded (so that $Q_{\urcorner} \setminus Q_{\llcorner}$ is the unshaded region within Q). A minimal cover $\widetilde{\mathcal{S}}^m_{\urcorner} \subseteq \widetilde{\mathcal{S}}_{\urcorner}$ is depicted by thick $\urcorner$-corners.* (B) *An explanation of how $\widetilde{\mathcal{S}}^m_{\urcorner}$ is greedily computed. Here only the boundary of $Q_{\llcorner}$ is depicted. Cells $[1,1]$, $[2,4]$, and $[5,7]$ are shaded. Since cell $[1,1]$ is not completely covered by $Q_{\llcorner}$, we add square 1 to the cover. Cells $[2,2]$ and $[2,3]$ are covered by $Q_{\llcorner}$, but cell $[2,4]$ is not; therefore, square 4 is added to the cover. Now cells $[5,5]$ and $[5,6]$ are covered by $Q_{\llcorner}$, but cell $[5,7]$ is not; therefore, square 7 is added to the minimal cover.*

cover. □

An algorithm for finding a minimal cover. We now describe a greedy algorithm for finding a subset $\widetilde{\mathcal{S}}^m_{\urcorner} \subseteq \widetilde{\mathcal{S}}_{\urcorner}$ that is a minimal cover of $Q_{\urcorner} \setminus Q_{\llcorner}$. Let $S_1, \ldots, S_m$ be an ordering of the squares in $\widetilde{\mathcal{S}}_{\urcorner}$ according to the increasing value of $x_{\urcorner}(S_i)$. Recall that $\widetilde{\mathcal{S}}_{\urcorner}$ is a chain with respect to Q, and therefore every subset of $\widetilde{\mathcal{S}}_{\urcorner}$ is a chain with respect to Q. For any two indexes $1 \leq a \leq b \leq m$, let $\widetilde{\mathcal{S}}_{\urcorner}[a,b]$ denote the cell v in the arrangement $\mathcal{A}(\widetilde{\mathcal{S}}_{\urcorner})$ such that $N(v) = \{S_a, \ldots, S_b\}$.

The greedy algorithm works in an iterative fashion. Let k be the index of the square selected in the last iteration (where initially $k = 0$ and $\widetilde{\mathcal{S}}^m_{\urcorner} = \emptyset$). Consider all cells $\widetilde{\mathcal{S}}_{\urcorner}[k+1, \ell]$, where $(k+1) \leq \ell \leq m$, such that $\widetilde{\mathcal{S}}_{\urcorner}[k+1, \ell] \cap Q$ is not fully contained in $Q_{\llcorner}$. If there is no such cell, then the algorithm terminates. Otherwise, let ℓ be the minimum index such that $\widetilde{\mathcal{S}}_{\urcorner}[k+1, \ell]$ is not fully contained in $Q_{\llcorner}$, and add S_ℓ to $\widetilde{\mathcal{S}}^m_{\urcorner}$. For an example, see Figure 7.7(B).

CLAIM 7.7. *The greedy algorithm computes a minimal cover $\widetilde{\mathcal{S}}^m_{\urcorner} \subseteq \widetilde{\mathcal{S}}_{\urcorner}$ of $Q_{\urcorner} \setminus Q_{\llcorner}$.*

By "rotating the picture," we can obtain an analogous claim concerning a minimal cover $\widetilde{\mathcal{S}}^m_{\llcorner} \subseteq \widetilde{\mathcal{S}}_{\llcorner}$ of $Q_{\llcorner} \setminus Q_{\urcorner}$.

Proof. Let $k_1 < k_2 < \cdots < k_r$ denote the sequence of squares added to $\widetilde{\mathcal{S}}^m_{\urcorner}$ by the greedy algorithm. We show that the algorithm computes a cover $\widetilde{\mathcal{S}}^m_{\urcorner}$ of $Q_{\urcorner} \setminus Q_{\llcorner}$, by showing that the following invariant holds throughout the algorithm:

$$(Q_{\urcorner} \setminus Q_{\llcorner}) \cap \bigcup_{i=1}^{k_t} S_i \subseteq \bigcup_{j=1}^{t} S_{k_j}.$$

The invariant holds trivially when the algorithms starts (as $k_t = 0$). Assume, for the sake of contradiction, that a cell $\widetilde{\mathcal{S}}_{\urcorner}[i,j]$ (for $i \leq j < k_t$) in $Q_{\urcorner} \setminus Q_{\llcorner}$ is not covered by $\bigcup_{j \leq t} S_{k_j}$. If $i \leq k_{t-1}$, then there are two cases: (i) $j \leq k_{t-1}$, in which case the induction hypothesis already implies that cell $\widetilde{\mathcal{S}}_{\urcorner}[i,j]$ is contained in $\bigcup_{j<t} S_{k_j}$, and (ii) $j > k_{t-1}$, in which case cell $\widetilde{\mathcal{S}}_{\urcorner}[i,j]$ is contained in $S_{k_{t-1}}$. Both cases lead to a contradiction, so we assume that $i > k_{t-1}$. It can be verified that if the cell $\widetilde{\mathcal{S}}_{\urcorner}[i,j]$

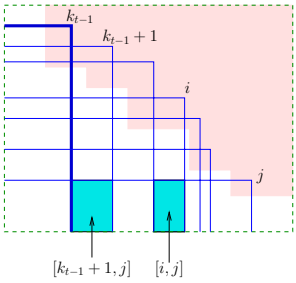

FIG. 7.8. *An illustration for the case $i > k_{t-1}$ in the proof of Claim 7.7.*

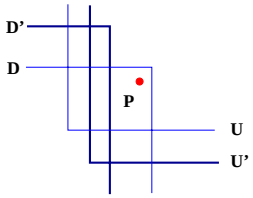

FIG. 7.9. *An illustration for Lemma 7.8. The point $P \in Q_\neg \cap Q_\llcorner$ is in $D \cap U$, where neither $D \in \widetilde{\mathcal{S}}^m_\neg$ nor $U \in \widetilde{\mathcal{S}}^m_\llcorner$. Here $D' \in \widetilde{\mathcal{S}}^m_\neg$ (the square that covers the cell that contains the point slightly to the left of $\llcorner(U)$) is such that $y_\neg(D') > P_y$. Finally, $U' = B_\llcorner(D')$, that is, it is the last square from $\widetilde{\mathcal{S}}_\llcorner$ that intersects D'.*

is in $Q_\neg \setminus Q_\llcorner$, then the cell $\widetilde{\mathcal{S}}_\neg[k_{t-1}+1, j]$ is also in $Q_\neg \setminus Q_\llcorner$, but in such a case, the greedy algorithm would have chosen S_{k_t} such that $k_{t-1}+1 \le k_t \le j$, a contradiction. For an illustration of this case, see Figure 7.8.

The stopping condition of the algorithm, combined with the invariant, guarantees that, when the algorithm terminates, $\widetilde{\mathcal{S}}^m_\neg$ covers $Q_\neg \setminus Q_\llcorner$.

Minimality of $\widetilde{\mathcal{S}}^m_\neg$ is proved as follows. Consider a square $S_j \in \widetilde{\mathcal{S}}^m_\neg$. When S_j was added to $\widetilde{\mathcal{S}}^m_\neg$, it was added due to a cell $[i, j]$, with i greater than the index of the square added to $\widetilde{\mathcal{S}}^m_\neg$ just before S_j. The cell $[i, j]$ is covered only by S_j (among the squares in $\widetilde{\mathcal{S}}^m_\neg$), and hence minimality follows. □

Let $m_\neg = |\widetilde{\mathcal{S}}^m_\neg|$, and let $m_\llcorner = |\widetilde{\mathcal{S}}^m_\llcorner|$. Let $m = \max\{m_\neg, m_\llcorner\}$. In the next lemma we show that it is possible to cover $Q_\neg \cup Q_\llcorner$ by $O(m)$ squares from $\widetilde{\mathcal{S}}_\neg \cup \widetilde{\mathcal{S}}_\llcorner$.

LEMMA 7.8. *There exists a subset $\mathcal{S}' \subseteq \widetilde{\mathcal{S}}_\neg \cup \widetilde{\mathcal{S}}_\llcorner$ of $O(m)$ squares that covers $Q_\neg \cup Q_\llcorner$.*

Proof. Since $\widetilde{\mathcal{S}}^m_\neg$ (respectively, $\widetilde{\mathcal{S}}^m_\llcorner$) covers $Q_\neg \setminus Q_\llcorner$ (respectively, $Q_\llcorner \setminus Q_\neg$) and $|\widetilde{\mathcal{S}}^m_\neg \cup \widetilde{\mathcal{S}}^m_\llcorner| \le 2m$, the remaining problem is to cover $Q_\neg \cap Q_\llcorner$ using $O(m)$ squares. For every square $S \in \widetilde{\mathcal{S}}^m_\neg$ consider the set $\widetilde{\mathcal{S}}_\llcorner(S)$ of squares in $\widetilde{\mathcal{S}}_\llcorner$ that intersect S. Define $A_\llcorner(S)$ (respectively, $B_\llcorner(S)$) to be the first (respectively, last) square in $\widetilde{\mathcal{S}}_\llcorner(S)$ when sorted according to the y-coordinates of their $\llcorner$-corners. We claim that $\bigcup_{S \in \widetilde{\mathcal{S}}^m_\neg}(A_\llcorner(S) \cup B_\llcorner(S))$ covers $(Q_\neg \cap Q_\llcorner) \setminus (\widetilde{\mathcal{S}}^m_\neg \cup \widetilde{\mathcal{S}}^m_\llcorner)$. Hence, we need to add at most two squares from $\widetilde{\mathcal{S}}_\llcorner$ per square in $\widetilde{\mathcal{S}}^m_\neg$ to cover $(Q_\neg \cap Q_\llcorner) \setminus (\widetilde{\mathcal{S}}^m_\neg \cup \widetilde{\mathcal{S}}^m_\llcorner)$.

Consider a point $P \in Q_\neg \cap Q_\llcorner$. Let $D \in \widetilde{\mathcal{S}}_\neg$ (respectively, $U \in \widetilde{\mathcal{S}}_\llcorner$) denote a square that contains P. If $D \in \widetilde{\mathcal{S}}^m_\neg$ or $U \in \widetilde{\mathcal{S}}^m_\llcorner$, then we are done. Otherwise, consider the cell in $\mathcal{A}(\widetilde{\mathcal{S}}_\neg)$ that contains a point slightly to the left of $\llcorner(U)$. This cell is in $Q_\neg \setminus Q_\llcorner$, and therefore there exists a square $D' \in \widetilde{\mathcal{S}}^m_\neg$ that covers this

cell. If $P \in D'$, we are done. Otherwise, we consider two cases: $y_{\neg}(D') \geq P_y$ and $y_{\neg}(D') < P_y$. In the first case consider the square $U' = B_{\llcorner}(D')$. Such a square exists since U intersects D'. We can now bound the coordinates of $_{\llcorner}(U')$ to show that $P \in U'$ as follows: (i) $x_{\llcorner}(U') \leq x_{\neg}(D') < P_x$ (the first inequality holds because U' and D' intersect, and the second inequality holds because $y_{\neg}(D') \geq P_y$ while $P \notin D'$); (ii) $y_{\llcorner}(U') \leq y_{\llcorner}(U) \leq P_y$ (the first inequality holds because $U' = B_{\llcorner}(D')$, and the second by the premise of this case). Thus $P \in U'$. For an illustration of this case, see Figure 7.9. The second case in which $y_{\neg}(D') < P_y$ is treated analogously, where here we let $U' = A_{\llcorner}(D')$. The claim follows. □

Remark 1. Lemmas 7.6 and 7.8 and Claim 7.7 regarding opposite corner-chains were stated with respect to a rectangle Q that is contained in a tile. The same lemmas and claim hold with respect to a region $Q \subseteq T$ that satisfies the following properties.

The region Q contains two designated points $C_{\llcorner}$ and $C_{\neg}$. (When Q is a rectangle, then $C_{\llcorner}$ is the bottom-left corner and $C_{\neg}$ is the top-right corner.) The point $C_{\llcorner}$ is contained in every square in $\widetilde{\mathcal{S}}_{\neg}$, and the point $C_{\neg}$ is contained in every square in $\widetilde{\mathcal{S}}_{\llcorner}$. Moreover, if a square $S \in \widetilde{\mathcal{S}}_{\neg}$ (respectively, $S \in \widetilde{\mathcal{S}}_{\llcorner}$) contains the point $C_{\neg}$ (respectively, $C_{\llcorner}$), then $Q_{\llcorner} \setminus Q_{\neg} = \emptyset$ (respectively, $Q_{\llcorner} \setminus Q_{\neg} = \emptyset$).

As we discuss in more detail shortly, if Lemma 7.4 is applied to separate corner-chains of adjacent corners, then the remaining uncovered region in a tile is a region that satisfies the above condition. Hence, after separating corner-chains of adjacent corners, we may apply Claim 7.7 and Lemma 7.8 for the covering of the remaining region in the tile.

Remark 2. After the separation of adjacent corner-chains in a tile, it is not possible for both pairs of opposite corner-chains to intersect. Namely, at most one pair of opposite corner-chains may intersect. We do not rely on this property, the proof of which is easy.

7.3. Coloring arrangements of squares. In this section we prove Theorem 1.4 for unit squares. The goal of the algorithm is to pick an "essential" subset of squares per tile whose union must be served. The coloring of the essential squares per tile is done according to Theorem 1.5. Recall that a tile is an orphan tile if it does not contain a center of a square. As noted at the start of this section, the main thrust of the algorithm and its analysis is in serving the covered regions in orphan tiles (i.e., the union of the squares minus the union of nonorphan tiles). The task of selecting a subset of squares that serves the covered parts of orphan tiles is "done independently" by the orphan tiles. The set of essential squares per nonorphan tile is the set of squares that belong to the tile and have been selected by one of the neighboring orphan tiles.

7.3.1. Selection of squares by nonbare orphan tiles. Consider a nonbare orphan tile T. In this section we describe how squares from neighboring tiles are selected by T so that these squares serve the area that is the intersection of T with their union.

Selection of squares consists of three steps: (1) selection of at most one square from each e-neighbor—this step maximizes service from e-neighbors; (2) selection of at most two squares from each v-neighbor—this step resolves all interactions between chains of squares corresponding to adjacent corners; (3) final selection of squares from the remaining chains corresponding to corners—this step takes into account interactions between chains corresponding to opposite corners.

Selecting squares from e-neighbors. Consider the tile T and the set of squares that

belong to an e-neighbor T^e of T. For brevity, assume that T^e is to the left of T and that $\mathcal{S}(T^e) \neq \emptyset$. Every square $S \in \mathcal{S}(T^e)$ covers a vertical strip of T. If we select the rightmost square S in $\mathcal{S}(T^e)$, then we get that for every $S' \in \mathcal{S}(T^e)$, $S' \cap T \subseteq S \cap T$. In the same fashion, we select the closest square to T from each e-neighbor of T. By selecting at most one square from each e-neighbor of T, the first substep covers all the points in $T \cap \bigcup_{T^e \in e\text{-neighbors}(T)} \mathcal{S}(T^e)$.

After this step, the region within the tile T that still needs to be served is a rectangle. Let us denote this rectangle by T'. Note that the union of squares in $\mathcal{S}$ may either fully cover or partly cover the rectangle T'. In any case, only squares that belong to v-neighbors of T intersect T'. An illustration of this step was provided in Figure 7.2.

Selecting squares from v-neighbors: Adjacent corners. Consider the rectangle $T' \subseteq T$ and a corner γ. The squares of $\mathcal{S}(T', \gamma)$ that participate in the T'-envelope are denoted by $\widetilde{\mathcal{S}}(T', \gamma)$. By Claim 7.3, $\widetilde{\mathcal{S}}(T', \gamma)$ is a chain with respect to T' when indexed according to the x-coordinate of its centers (or γ-corners). By applying Lemma 7.4 to the four appropriate pairs of chains corresponding to adjacent corners, we obtain at most eight squares that serve as "separators" between the pairs of chains. The selected squares cover all points in T' that are covered by squares in the tails of the chains. Each corner-chain is reduced to a consecutive block of squares between the two selected squares in that chain. The remaining portions of adjacent corner-chains are disjoint. Let T'' denote the subregion consisting of T' minus the union of the (at most eight) selected squares. By our notational convention, $\widetilde{\mathcal{S}}(T'', \gamma)$ denotes the subset of squares in $\mathcal{S}(T'', \gamma)$ that participate in the T'' envelope. Note that, by Lemma 7.4, $\widetilde{\mathcal{S}}(T'', \gamma)$ is a chain with respect to T''.

Selecting squares from v-neighbors: Opposite corners. In the third step we apply Claim 7.7 and Lemma 7.8 to each pair of subsets $\widetilde{\mathcal{S}}(T'', \gamma)$ and $\widetilde{\mathcal{S}}(T'', \mathrm{op}(\gamma))$. This application determines the subsets of $\widetilde{\mathcal{S}}(T'', \gamma)$ (and $\widetilde{\mathcal{S}}(T'', \mathrm{op}(\gamma))$) that suffice to serve the intersection of T'' with the union of each pair of chains. Note that, due to the separation of adjacent corner-chains (see Lemma 7.4), at most one pair of opposite corner-chains may intersect.

A subtle issue to be addressed is whether the remaining region $T'' \subseteq T' \subseteq T$ in the beginning of this step satisfies the premises of Remark 1 for each pair of opposite corner-chains. Consider, for example, the subset $\widetilde{\mathcal{S}}(T'', \urcorner)$. This subset is a consecutive block of squares from $\widetilde{\mathcal{S}}(T', \urcorner)$. Let $S^f_{\urcorner}$ and $S^{\ell}_{\urcorner}$ denote the squares in $\widetilde{\mathcal{S}}(T', \urcorner) \setminus \widetilde{\mathcal{S}}(T'', \urcorner)$ that "hug" this block (i.e., $S^f_{\urcorner}$ and $S^{\ell}_{\urcorner}$ were selected in the adjacent corner-chain stage). The designated point $C_{\llcorner} \in T''$ is the intersection of the right side of $S^f_{\urcorner}$ and the top side of $S^{\ell}_{\urcorner}$. One can define in this fashion all four designated points C_γ for $\gamma \in \Gamma$. We can now apply Lemma 7.8 to each pair of subsets $\widetilde{\mathcal{S}}(T'', \gamma)$ and $\widetilde{\mathcal{S}}(T'', \mathrm{op}(\gamma))$, where the corresponding designated points that satisfy the premise of Remark 1 are $C_{\mathrm{op}(\gamma)}$ and C_γ. For an illustration, see Figure 7.10.

7.3.2. Coloring the essential squares. In the previous steps, each orphan tile T_o selected a subset of squares used to serve the points in $T_o \cap \bigcup \mathcal{S}$. Given a nonorphan tile T, let $sel(T) \subseteq \mathcal{S}(T)$ denote the subset of squares whose centers reside in T that are selected by some tile in order to participate in its cover. If no square in $\mathcal{S}(T)$ is requested from orphan tiles, then we select an arbitrary square in $\mathcal{S}(T)$ to serve T, and let $sel(T)$ contain only this square. At this stage we apply Theorem 1.5 and color each subset $sel(T)$ by $O(\log |sel(T)|)$ colors; these colors are taken from the palette assigned to the tile T.

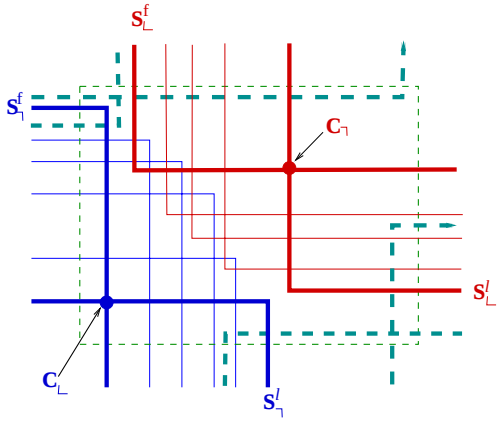

FIG. 7.10. *An illustration for the choice of points C_γ and $C_{\mathrm{op}(\gamma)}$ that satisfy the premise of Remark* 1. *The selected squares, which determine the two points, are labeled and marked in bold. The dashed bold corners of squares correspond to the four other selected squares that belong to the adjacent chains $\widetilde{\mathcal{S}}(T', \ulcorner)$ and $\widetilde{\mathcal{S}}(T', \lrcorner)$. The thin dashed rectangle is T', and T'' is the region obtained by removing the four bold and four dashed-bold squares from T'.*

Recall that at most one square from $\mathcal{S}(T)$ was requested from each of its four e-neighbors. Each of its four v-neighbors initially requested at most two squares (as "separators" between chains). These requests amount to at most twelve squares. The main contribution to $sel(T)$ is due to the subsets of squares that were requested by v-neighbors of T in the last selection step, that is, in the step that deals with opposite corner-chains.

For each corner type γ, let $sel_\gamma(T)$ denote the subset of squares in $sel(T)$ that were selected by $T_{\mathrm{op}(\gamma)}$ in the opposite-corners selection step. The γ-corners of squares in $sel_\gamma(T)$ are contained in the tile $T_{\mathrm{op}(\gamma)}$. Let $m_\gamma(T) = |sel_\gamma(T)|$. Since $|sel(T)| = O(\max_{\gamma\in\Gamma}\{m_\gamma(T)\})$, and since there are nine palettes, the next corollary follows.

COROLLARY 7.9. *For any given set of unit squares $\mathcal{S}$, it is possible to CF-color $\mathcal{S}$ using $O\left(\log\left(\max_{T,\gamma}\{m_\gamma(T)\}\right)\right)$ colors.*

7.3.3. A lower bound for optimal CF-coloring. In this section we lower-bound the number of colors required by an optimal CF-coloring. Recall that, for a tile T and corner $\gamma \in \Gamma$, the set of squares that intersect T with corner type γ is denoted by $\mathcal{S}(T,\gamma)$. Recall that $\widetilde{\mathcal{S}}(T,\gamma)$ denotes the subset of squares from $\mathcal{S}(T,\gamma)$ that appear in the T-envelope.

Let T be any (orphan) tile, and let γ be a corner. The following lemma states a lower bound on $\chi_{\mathrm{opt}}(\mathcal{S})$ in terms of the size of a subset $\mathcal{S}' \subseteq \widetilde{\mathcal{S}}(T,\gamma)$ that is a chain with respect to the region $Q = T \setminus \{S : S \notin \mathcal{S}(T,\gamma)\}$. That is, the region Q is what remains of T after we remove all squares that intersect T with the exception of squares in $\mathcal{S}(T,\gamma)$.

LEMMA 7.10. *Let T denote a tile, γ a corner type, and let $Q = T \setminus \{S : S \notin \mathcal{S}(T,\gamma)\}$. Let $\mathcal{S}' \subseteq \widetilde{\mathcal{S}}(T,\gamma)$ be a chain with respect to Q. Then every CF-coloring of $\mathcal{A}(\mathcal{S})$ requires $\Omega(\log|\mathcal{S}'|)$ colors.*

The proof of Lemma 7.10 follows the same outline as the proof of Lemma 6.3. In fact, the same lower bound holds also for CF-multicoloring, implying Theorem 9.2 (see section 9). The only difference is that here we need to take into account that squares from $\mathcal{S}(T,\gamma) \setminus \mathcal{S}'$ may cover points in Q and hence can potentially serve cells

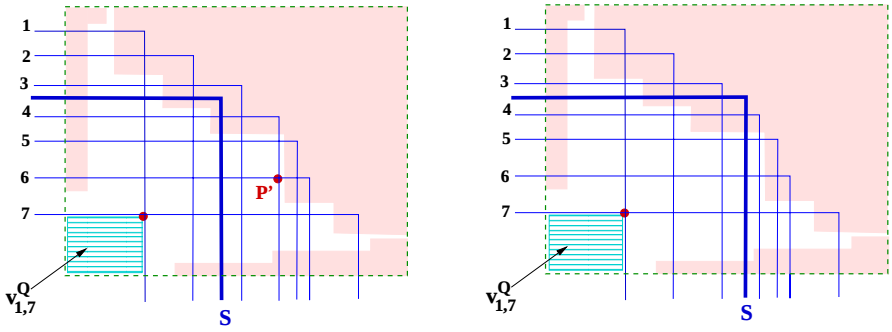

FIG. 7.11. *Illustration for the proof of Lemma* 7.10. *The squares of* $\mathcal{S}'$ *are labeled from* 1 *to* 7. *The region* Q *is the nonshaded region within the dashed rectangle. The point* P *is the top-right corner of* $v_{1,7}$ *(which here equals* $v^Q_{1,7}$*). On the left is an illustration of the case in which* P *is served (in an optimal CF coloring) by a square* S *such that* $S \cap Q \subseteq S_3 \cap Q$. *The point* P' *in this case is the top-right corner in a cell of the chain determined by* $S_4, \ldots, S_7$. *On the right is an illustration of the case in which* P *is served by a square* S *whose top-right corner does not reside in any square of* $\mathcal{S}'$.

in the chain $\mathcal{S}'$. For an illustration of the proof of the lemma, see Figure 7.11.

Proof. We consider the case $\gamma = \urcorner$. All other cases are proved analogously. Let $S_1, \ldots, S_m$ be an ordering of the squares in $\mathcal{S}'$ so that $x_\urcorner(S_1) < \cdots < x_\urcorner(S_m)$. For every $1 \le i \le j \le m$, let $v_{i,j}$ denote the cell in the arrangement $\mathcal{A}(\mathcal{S}')$ for which $N(v_{i,j}) = \{S_i, \ldots, S_j\}$. (Recall that for a cell v, $N(v)$ denotes the subset of regions that contain v.) Let $v^Q_{i,j} = v_{i,j} \cap Q$, where we know that $v^Q_{i,j}$ is nonempty for every $1 \le i \le j \le m$ because $\mathcal{S}'$ is a chain with respect to Q. Since we are dealing with squares (or, more generally, rectangles), we know that each $v_{i,j}$ is a rectangle. However, it may be the case that $v^Q_{i,j}$ is not a rectangle. The exact structure of $v^Q_{i,j}$ is actually immaterial to the proof. What will be needed is the following subclaim (where we assume that $m > 3$ or else Lemma 7.10 holds trivially).

Subclaim. For every $1 \le i, j \le m$ such that $i \le j - 2$, the top-right corner of $v_{i,j}$ is contained also in $v^Q_{i,j}$.

Proof of subclaim. Assume that the subclaim does not hold. This means that there exists some square $S' \notin \mathcal{S}(T, \urcorner)$ that contains the top-right corner of $v_{i,j}$. But in such a case either $S' \supseteq v_{i+1,j}$ or $S' \supseteq v_{i+1,j-1}$ or $S' \supseteq v_{i,j-1}$, contradicting the premise of the lemma that $\mathcal{S}'$ is a chain with respect to Q. The subclaim is thus established. For an illustration, see Figure 7.12.

Now consider an optimal CF-coloring χ_{opt} of $\mathcal{S}$. Let P be the top-right corner of $v_{1,m}$. By the above subclaim (assuming $m > 3$), $P \in v^Q_{1,m}$. Since $P \in Q$, only squares in $\mathcal{S}(T, \urcorner)$ contain P. Let $S \in \mathcal{S}(T, \urcorner)$ be a square that serves P in the coloring χ_{opt}. We first consider the case that $\urcorner(S)$, the top-right corner of S, is contained in some $S_k \in \mathcal{S}'$ (in particular, S_k may equal S). In this case, $S \cap Q \subseteq S_k \cap Q$.

We make two observations. The first is that both $\{S_1, \ldots, S_{k-1}\}$ and $\{S_{k+1}, \ldots, S_m\}$ are chains with respect to $Q \setminus S$. This is true since $\{S_1, \ldots, S_m\}$ is a chain with respect to Q, (hence both subsets must be chains with respect to $Q \setminus S_k$), and $Q \cap S \subseteq Q \cap S_k$. Thus, S cannot fully serve any of the cells in these two subchains. The second observation is that every square $S' \in \mathcal{S}(T, \urcorner)$ that serves the top-right corner P' of a cell in one of these chains (that corresponds to an interval of size at least 3) must also contain P. This is true because every top-right corner of such a

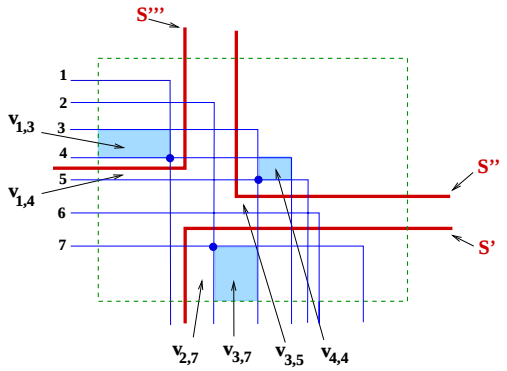

FIG. 7.12. *An illustration for the proof of the subclaim in the proof of Lemma* 7.10: (i) $i = 2$, $j = 7$, *and* S' *covers* $v_{3,7}$; (ii) $i = 3$, $j = 5$, *and* S'' *covers* $v_{4,4}$; *and* (iii) $i = 1$, $j = 4$, *and* S''' *covers* $v_{1,3}$.

cell dominates P (i.e., the x and y coordinates of such corners are not smaller than P_x and P_y, respectively). Since S serves P, it follows that the color of every square that contains P must be different from $\chi_{\text{opt}}(S)$.

If $\urcorner(S)$, the top-right corner of S, is not contained in any $S_k \in \mathcal{S}' = \{S_1, \ldots, S_m\}$, then define k as follows: $k = \max\{i : x_\urcorner(S_i) < x_\urcorner(S)\}$. Since $\mathcal{S}'$ is a chain with respect to Q, it follows that $\{S_1, \ldots, S_k\}$ and $\{S_{k+1}, \ldots, S_m\}$ are chains with respect to $Q \setminus S$. Furthermore, similarly to what was shown above, for any square $S' \in \mathcal{S}(T, \urcorner)$ that can serve the top-right corner of a cell in one of these chains (that corresponds to an interval of size at least 3) $\chi_{\text{opt}}(S') \neq \chi_{\text{opt}}(S)$. In either case we get the recurrence relation

$$|\chi_{\text{opt}}(\{S_1, \ldots, S_m\})| \geq 1 + \min_{1 \leq k \leq m} \{\max\{|\chi_{\text{opt}}(\{S_1, \ldots, S_{k-1}\})|, |\chi_{\text{opt}}(\{S_{k+1}, \ldots, S_m\})|\}\},$$

where for any subset $\mathcal{S}''$ of less than three squares, $|\chi_{\text{opt}}(\mathcal{S}'')| \geq 1$. Hence $|\chi_{\text{opt}}(\mathcal{S})| = \Omega(\log |\mathcal{S}'|)$, and the lemma follows. □

For any nonorphan tile T and corner γ, let $sel_\gamma(T)$ and $m_\gamma(T)$ $(= |sel_\gamma(T)|)$ be as defined preceding Corollary 7.9. Using Lemma 7.10, we establish the following lower bound.

LEMMA 7.11. *For any given set of unit squares* $\mathcal{S}$, *we have that* $|\chi_{\text{opt}}(\mathcal{S})| = \Omega\left(\log\left(\max_{T,\gamma}\{m_\gamma(T)\}\right)\right)$.

Proof. Consider a tile T and a corner type γ such that $m_\gamma(T)$ is maximal. Let W denote the tile $T_{\text{op}(\gamma)}$, which selected the squares in $sel_\gamma(T)$. Let Q denote the region remaining in W when the γ-corner chain and $\text{op}(\gamma)$-corner chain are considered in W. Assume, without loss of generality, that $\gamma = \urcorner$. The set $sel_\urcorner(T)$ consists of two kinds of squares: (i) squares that belong to the a minimal cover $\widetilde{\mathcal{S}}^m_\urcorner$ of $Q_\urcorner \setminus Q_\llcorner$ (these squares are selected by the greedy algorithm) and (ii) pairs of squares that were selected according to the procedure defined in Lemma 7.8. Let m' denote the number of squares of the first kind, and let m'' denote the number of squares of the second kind.

We consider first the case that $m' \geq m''$. The separation procedure of adjacent corner-chains combined with Lemma 7.6 implies that $\widetilde{\mathcal{S}}^m_\urcorner$ is a chain with respect to $W \setminus \{S : S \notin \mathcal{S}(W, \urcorner)\}$. By Lemma 7.10 we get that the number of required colors is

$\Omega(\log m') = \Omega(m_{\neg}(T))$.

We next consider the case that $m'' > m'$. Let V denote the tile $W_{\llcorner}$. The squares in $sel_{\llcorner}(V)$ were also selected by the tile W. The number of squares in $sel_{\llcorner}(V)$ that belong to a minimal cover $\widetilde{\mathcal{S}}^m_{\llcorner}$ of $Q_{\llcorner} \setminus Q_{\neg}$ is at least $m''/2$. By applying the same argument now on the tile V and the $\llcorner$-corner, the lemma follows. □

7.3.4. Wrapping up the proof of Theorem 1.4 for unit squares. Combining Corollary 7.9 and Lemma 7.11, and noting that the computational complexity of the algorithm is due only to sorting squares according their coordinates, Theorem 1.4 for unit squares directly follows.

7.4. General rectangles. Consider a collection $\mathcal{R}$ of rectangles with size-ratio ρ. Our goal is to prove the existence of an efficient algorithm for CF-coloring $\mathcal{R}$ that uses $O((\log \rho)^2) \cdot |\chi_{\text{opt}}(\mathcal{R})|$ colors. This means that if the size-ratio ρ is constant, then the algorithm is a constant-ratio approximation algorithm.

By separately scaling the x-axis and the y-axis, we may assume that the minimum width and height of rectangles in $\mathcal{R}$ are equal to 1. Hence, all side-lengths are in the range $[1, \rho]$.

The algorithm proceeds in two steps (as in the proof of Theorem 1.2). First, consider the case of $\rho \leq 2$. For this case we show that $O(|\chi_{\text{opt}}(\mathcal{R})|)$ colors suffice. For the more general case of $\rho > 2$, we partition the set of rectangles into $\log^2 \rho$ classes. For $1 \leq i, j < \log \rho + 1$, the class $\mathcal{R}^{i,j}$ consists of rectangles whose width is in the interval $[2^{i-1}, 2^i)$ and whose height is in the interval $[2^{j-1}, 2^j)$. Each class is colored using a distinct palette, to obtain a CF-coloring that uses $O((\log \rho + 1)^2) \cdot |\chi_{\text{opt}}(\mathcal{R})|$ colors, as required.

7.4.1. Rectangles with $\rho \leq 2$. We outline the algorithm for the case $\rho \leq 2$ below.

1. The tiling is the same as in the case of unit squares. The tiles are assigned 25 different palettes (instead of nine).
2. An orphan tile may now be completely covered by a rectangle. An orphan tile that is completely covered by a rectangle selects such a rectangle (this type of selection does not exist in the case of unit squares).
3. Instead of selecting closest rectangles from e-neighbors, every nonbare orphan tile that is not completely covered by a single rectangle selects the rightmost rectangle (if any) whose right edge intersects both the bottom and top side of the tile. The same selection takes place in the other three axis-parallel directions. In this stage an orphan cell selects at most four rectangles.
4. A nonbare orphan tile that still contains a region covered by $\mathcal{R}$ but not by the rectangles selected so far selects rectangles from the corner-chains as in the algorithm for unit squares. The reason that the same techniques apply is that the intersection of a rectangle with a tile contains at most one corner.
5. The essential (selected) rectangles from each tile are colored as described in the following paragraph.

Coloring the essential rectangles. Given a nonorphan tile T, let $sel(T)$ denote the set of rectangles that belong to T and were selected in the previous stages. For a corner type γ and a nonbare orphan tile W, let $\mathcal{R}'(W, \gamma)$ be the subset of rectangles selected by W whose γ-corner resides in W. Finally, let $m = \max_{W,\gamma}\{|\mathcal{R}'(W, \gamma)|\}$ denote the maximum (over all tiles W and corner types γ) of the number of rectangles selected by an orphan tile W due to their participation in a γ-corner-chain within the tile.

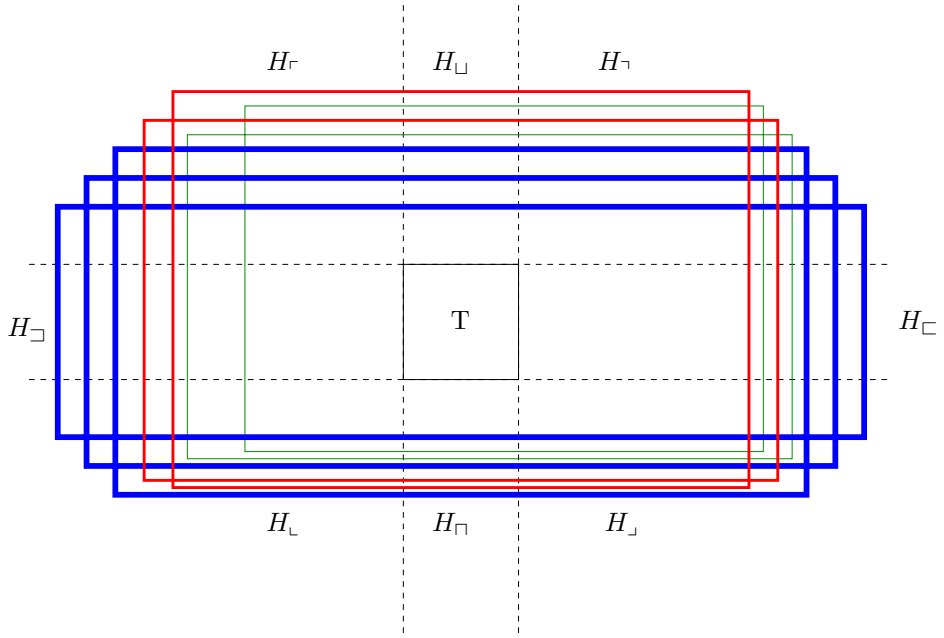

FIG. 7.13. *An illustration for the proof of Lemma* 7.12. *The thickest rectangles belong to all four chains. The second-thickest rectangles belong to the top-left and top-right chains, and the thinnest rectangles belong only to the top-right chain.*

In this section we show that for every nonorphan tile T, (i) $|sel(T)| \leq O(m)$, and (ii) $sel(T)$ can be CF-colored using $O(\log |sel(T)|)$ colors.

We begin by counting the number of rectangles in $sel(T)$. Since the side-length of every rectangle is in the range $[1, 2]$, and all the rectangles in $sel(T)$ are centered in T, it follows that $\bigcup_{S \in sel(T)} S$ intersects at most 25 tiles. Therefore, $|sel(T)| = O(m)$ for every tile T.

Similarly to Lemma 7.11, $|\chi_{\text{opt}}(\mathcal{R})| = \Omega(\log m)$. To obtain the constant-ratio approximation algorithm, we next show that $sel(T)$ can be CF-colored using $O(\log |sel(T)|)$ colors. Note that Theorem 1.5 is not applicable in this case since the rectangles are not congruent.

LEMMA 7.12. *Let $\mathcal{R}'$ be a set of axis-parallel rectangles with minimum width (height) at least* 1. *Assume that all centers of rectangles in $\mathcal{R}'$ reside in a square tile of side-length* 1/2. *Then it is possible to CF-color $\mathcal{R}'$ using $O(\log(|\mathcal{R}'|))$ colors.*

Proof. Let T be the $1/2 \times 1/2$ tile that contains the centers of the rectangles in $\mathcal{R}'$. Extend the sides of T into lines, and consider the subdivision of the plane into nine regions by these four lines. The subdivision consists of (i) the tile itself T, (ii) four corner regions denoted by $H_{\llcorner}$, $H_{\lrcorner}$, $H_{\urcorner}$, and $H_{\ulcorner}$, and (iii) four remaining regions denoted by $H_{\sqcup}$, $H_{\sqcap}$, $H_{\sqsubset}$, and $H_{\sqsupset}$. These regions are depicted in Figure 7.13.

Since each of the four regions $H_{\sqcup}$, $H_{\sqcap}$, $H_{\sqsubset}$, and $H_{\sqsupset}$ is of height/width 1/2, it suffices to select one rectangle for each and give it a unique color in order to serve the intersection of $\mathcal{R}'$ with each of them. In particular, for $H_{\sqcup}$ we take the rectangle whose top edge has the largest y coordinate; for $H_{\sqcap}$, the rectangle whose bottom edge has the smallest y coordinate, and similarly for $H_{\sqsubset}$ and $H_{\sqsupset}$. Any one of these (at most) four rectangles can serve all of T as well.

Next we observe that in order to serve each of the four corner regions $H_{\llcorner}$, $H_{\lrcorner}$, $H_{\ulcorner}$, and $H_{\urcorner}$, it suffices to focus on four corner-chains. Let $\widetilde{\mathcal{R}}'_{\llcorner}$, $\widetilde{\mathcal{R}}'_{\lrcorner}$, $\widetilde{\mathcal{R}}'_{\ulcorner}$, and $\widetilde{\mathcal{R}}'_{\urcorner}$, respectively, denote the set of rectangles that appear in the *envelope* of $\mathcal{R}'$ in each of the four corner parts. That is, those rectangles in $\mathcal{R}'$ whose corresponding corners ($\llcorner$ in $H_{\llcorner}$, $\lrcorner$ in $H_{\lrcorner}$, and, in general, γ in H_γ) are not contained in any other rectangle in $\mathcal{R}'$. The intersection of any other rectangle in $\mathcal{R}'$ with each H_γ, $\gamma \in \Gamma$, is contained in the intersection of the corresponding subset $\widetilde{\mathcal{R}}'_\gamma$ with H_γ. Note that the four subsets are not necessarily disjoint.

By a slight variant of Claim 7.3, each corner-chain $\widetilde{\mathcal{R}}'_{\mathrm{op}(\gamma)}$ is indeed a chain with respect to H_γ. While it is possible to apply Lemma 6.4 to each of these chains, we do not directly obtain a single consistent coloring because the different chains are not necessarily disjoint. Instead, we partition the rectangles into $2^4 - 1 = 15$ disjoint subsets, where each subset consists of rectangles that belong to the same nonempty subset of corner-chains (e.g., $\widetilde{\mathcal{R}}'_{\urcorner}$ and $\widetilde{\mathcal{R}}'_{\lrcorner}$ but not $\widetilde{\mathcal{R}}'_{\ulcorner}$ and $\widetilde{\mathcal{R}}'_{\llcorner}$).

The important observation regarding the envelope of $\mathcal{R}'$ is that if every boundary segment is given a symbol that corresponds to the rectangle it belongs to, then the sequence of symbols is a Davenport–Schinzel sequence $DS(n, 2)$ [SA95]. Namely, no two consecutive symbols are equal, and there is no alternating subsequence of length 4 (i.e., no "$\ldots a \ldots b \ldots a \ldots b \ldots$" for every pair of symbols $a \neq b$).

As a consequence, if two rectangles belong to more than one chain (that is to two, three, or even all four chains), then they appear *in the same order* (up to reversal) in all chains they belong to. Hence we can color each of the 15 subsets separately in a consistent manner (using 15 different palettes). The total number of colors used is hence $O(\log(|\widetilde{\mathcal{R}}|))$, as required. □

8. Coloring arrangements of regular hexagons. In this section we prove Theorem 1.5 for the case of regular hexagons. The proof follows the ideas used in the proof for the case of rectangles. We therefore provide a sketch of the proof (with accompanying illustrations) but do not give the full details of the proof.

8.1. Preliminaries. The sets of regular hexagons that we consider are axis-parallel; namely, two of the sides of the hexagons are parallel to the x-axis. The *type* of a vertex is determined by the slope of the segment connecting the center of the hexagon with the vertex (see Figure 8.1). In the same fashion, we define the type of an edge of the hexagon.

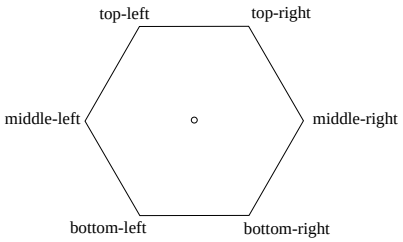

FIG. 8.1. *A hexagon and its vertices.*

The tiling. In the case of hexagons we consider a tiling of the plane by equilateral triangles with unit side-lengths; one side of each triangular tile is horizontal (see Figure 8.2). Triangular tiles have two possible orientations: In the *up* orientation, the vertex opposite the horizontal edge is above that edge, and in the *down* orientation, that vertex is below the horizontal edge.

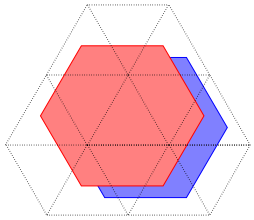

FIG. 8.2. *The triangular tiling and a pair of hexagons. The tile borders are depicted by dotted lines. Both centers of the hexagons are in the middle tile. Both hexagons completely cover the middle tile. Larger hexagons may intersect more than the* 12 *neighboring tiles.*

We adapt the notation of section 7 as follows. The set of hexagons is denoted by $\mathcal{H}$. We assume that the side-length of every hexagon is in the range $[1, \rho]$. For a tile T, we let $\mathcal{H}(T)$ denote the set of hexagons in $\mathcal{H}$ that belong to T (that is, whose center resides in T). A tile T is an *orphan* if $\mathcal{H}(T) = \emptyset$, and it is *bare* if no hexagon in $\mathcal{H}$ intersects it.

Since the tiles are equilateral triangles of side-length 1, the following holds for any set of hexagons $\mathcal{H}$ with side-lengths at least 1.

OBSERVATION 1. *For every tile T and hexagon $H \in \mathcal{H}$,* (i) *if $H \in \mathcal{H}(T)$, then $T \subset H$;* (ii) *T contains at most one vertex of H;* (iii) *if T intersects two edges e_1, e_2 of a hexagon H, then these edges are adjacent and T contains also the vertex $e_1 \cap e_2$.*

Disjoint palettes. As in the case of disks (cf. Theorem 1.2), we reduce the problem to the case of size-ratio 2 by paying a factor of $\log \rho$. Henceforth, we assume that $\rho \leq 2$. We assign a palette to every tile T. The colors assigned to hexagons in $\mathcal{H}(T)$ belong to the palette assigned to T. Palettes are disjoint, and the distribution of palettes is such that intersecting hexagons from different tiles are assigned different colors. This requires only a constant number of palettes. For example, consider a tiling of the plane with hexagonal supertiles that contain a constant number of triangular tiles. Assign every triangular tile within a hexagonal supertile a different palette, and extend this coloring periodically according to the hexagonal supertiles. The resulting assignment of palettes is as required.

8.2. Coloring arrangements of hexagons. As in the case of rectangles, the algorithm has two stages. In the first stage, each nonbare orphan tile T selects a subset of hexagons whose union serves the covered regions in T. For each nonorphan tile T, let $sel(T)$ denote the subset of hexagons in $\mathcal{H}(T)$ that were selected by orphan tiles in the first stage. In the second stage, the hexagons in $sel(T)$ are CF-colored, for every nonorphan tile T, using colors from the palette assigned to T.

8.2.1. Selection of hexagons by nonbare orphan tiles. Consider a nonbare orphan tile T. If there exists a hexagon that covers all of T, then we simply select one of these hexagons to serve it and no more selections are required. We now consider nonbare orphan tiles that are not covered by a single hexagon.

For an edge type e, let $\mathcal{H}(T, e)$ denote the set of hexagons that intersect T with an edge that is of type e (i.e., a nonempty intersection, but no vertex of the hexagon is contained in T). We claim that a single hexagon covers the intersection of T with hexagons from $\mathcal{H}(T, e)$. For example, let e be the top horizontal edge. The set of hexagons that intersect T with their top horizontal edge is hence denoted by $\mathcal{H}(T, e)$. Among these hexagons, pick the hexagon H with the highest center. The hexagon H covers the intersection of T with every hexagon in $\mathcal{H}(T, e)$. This completes

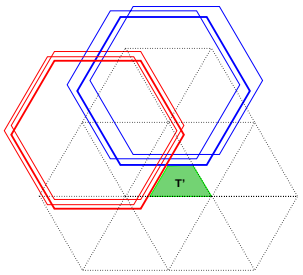

FIG. 8.3. *Let T be the central triangular tile in the figure, which is an orphan tile. The figure illustrates the choice of hexagons that intersect T with an edge. The selected hexagons are the two thick hexagons, and the region $T' \subset T$ that remains after their selection is filled.*

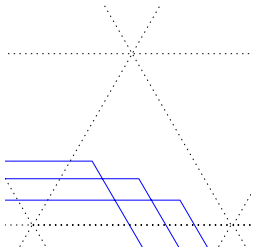

FIG. 8.4. *An example of a top-right chain. For simplicity, in this figure $T' = T$. That is, the dotted triangle is a tile T.*

the discussion of the selection of hexagons that intersect T with an edge. For an illustration, see Figure 8.3.

We denote by T' the region contained in T that remains after this choice of at most six hexagons (one per edge type). Note that if T' is nonempty, then T' is a polygon with at least three edges and at most six edges. The edges of Q are parallel to those of the hexagons in $\mathcal{H}$.

We now consider the selection of hexagons that intersect T' with a vertex. Let γ denote a vertex type (e.g., top-right), and let $\mathcal{H}(T', \gamma)$ denote the set of hexagons whose γ-vertex is in T'. Among the hexagons in $\mathcal{H}(T', \gamma)$, let $\widetilde{\mathcal{H}}(T', \gamma)$ denote the hexagons that participate in the envelope of $\mathcal{H}(T', \gamma)$ in T'. Similarly to the analysis in the case of rectangles, the latter cover all of the intersection of T' with the former, and furthermore they constitute a (corner) chain with respect to T'. We refer to the chain in terms of the vertex type (e.g., top-right chain). For an illustration, see Figure 8.4.

Thus, there are at most six corner-chains intersecting T', one for each vertex type. Here we have three types of "interactions" between chains, depending on the distance between the corresponding vertex types on the hexagons—that is, distance-one (e.g., top-right and top-left), distance-two (e.g., top-right and middle-left), and distance-three (e.g., top-right and bottom-left).

Interactions between distance-one and distance-two chains. Interactions between distance-one chains and distance-two chains are analogous to the interactions between corner-chains of adjacent corners in the case of rectangles. Specifically, for each such pair of chains, we can select a single hexagon from each chain so that (1) the union of the two selected hexagons covers the intersection between the chains, and (2) the remaining hexagons (not covered by the two selected hexagons) constitute disjoint

chains with respect to T' minus the two hexagons. For an illustration, see Figure 8.5.

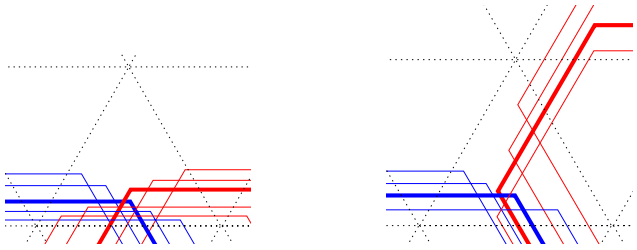

FIG. 8.5. *The two "benign" interactions between corner-chains in a tile T. On the left side is a distance-one interaction between a top-right chain and a top-left chain. On the right is a distance-two interaction between a top-right chain and a middle-left chain. In each figure, the two bold hexagons are those selected from the two chains.*

It follows that, by selecting at most four hexagons from each of the six chains that intersect T', it is possible to service all areas of intersections between such pairs of subsets of hexagons. Let $T'' \subseteq T'$ denote the remaining region in $T' \subseteq T$ that is not covered by these selected hexagons.

Interactions between pairs of distance-three (opposite) chains. The case of interactions between distance-three chains is analogous to the interaction between opposite chains in the case of rectangles. In particular, it is possible to select an approximately minimum subset of hexagons from the two chains so as to serve all the area in their union (within the region T''). For an illustration, see Figure 8.6.

8.3. Coloring the selected hexagons. We now return to each nonorphan tile T and assign colors to the hexagons requested from it. Note that Theorem 1.5 is not applicable since the hexagons are not congruent.

LEMMA 8.1. *Let $\widetilde{\mathcal{H}}$ be a subset of axis-aligned hexagons with side-lengths at least 1, which all belong to the same tile T. Then it is possible to CF-color $\widetilde{\mathcal{H}}$ using $O(\log(|\widetilde{\mathcal{H}}|)$ colors.*

Proof sketch. First, we assume, without loss of generality, that every hexagon in $\widetilde{\mathcal{H}}$ participated in the envelope (i.e., contains a vertex in $\bigcup_{H\in\widetilde{\mathcal{H}}} H$).

Similarly to the proof of Theorem 1.4 for rectangles, we extend the sides of a tile to partition the area covered by $\widetilde{\mathcal{H}}$ into several subregions (see Figure 8.7). The number of resulting regions is seven (including the tile T itself, which is covered by every hexagon in $\widetilde{\mathcal{H}}$). Three of these subregions have a common vertex with T (and are referred to as the "angular" subregions), and three have a common edge (and are referred to as the "trapeze" subregions). The vertices of every hexagon in $\widetilde{\mathcal{H}}$ are in the trapeze subregions. Hence, it is possible to select at most three hexagons to serve the angular subregions. Each of these hexagons is assigned a unique color (and thus T itself is also served).

We now deal with serving points in the trapeze regions. We wish to identify two chains in each trapeze region. Fix a trapeze region R. Every hexagon has two adjacent vertices in the trapeze region (as well as the edge connecting these vertices). Let u and v denote the vertex types that appear in R. Pick the hexagon H_R whose edge is farthest away from the corresponding edge of the triangular tile. Consider the sequence of vertices along the envelope of $\widetilde{\mathcal{H}}$ in R. This sequence starts with a block of vertices of type u and ends with a block of vertices of type v. The two vertices of H_R in R appear consecutively in this envelope. By picking H_R and assigning it a unique color, the envelope in R is separated into two parts. Moreover, the region

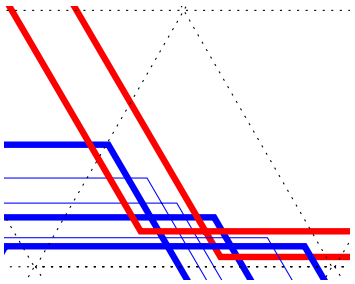

FIG. 8.6. *An interaction between the distance-three (opposite) chains top-right and bottom-left. The selected hexagons are bold.*

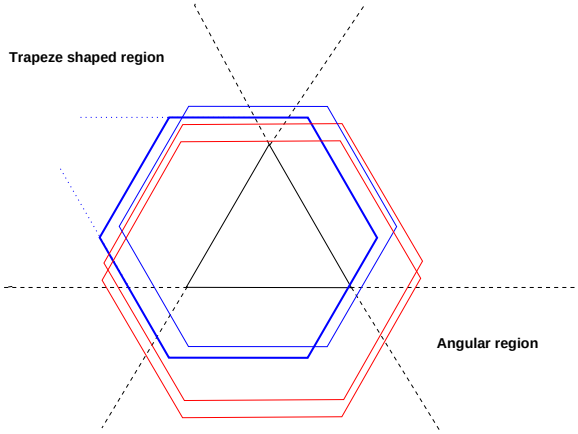

FIG. 8.7. *The partitioning of the area covered by hexagons that belong to the same tile. The six subregions H_R outside the tile are determined by the dashed lines that are extensions of sides of the tile. There are three angular regions, which can each be served by a single hexagon, and three trapeze-shaped regions. The two dotted lines within the top-left trapeze-shaped region are determined by the hexagon selected as in the proof (sketch) of Lemma* 8.1. *Each of the two dotted lines, paired with one of the dashed lines bounding the trapeze-shaped region, define the (angular) subregion that contains a (disjoint) corner-chain.*

$(R \setminus H_R) \cap (\bigcup_{H \in \tilde{\mathcal{H}}} H)$ consists of two disjoint connected parts. The hexagons whose vertices appear in the envelope in each part are chains with respect to $R \setminus H_R$. Thus, by picking at most six hexagons and assigning them unique colors, we have identified six disjoint chains.

As in the proof of Lemma 7.12, hexagons that belong to multiple chains appear in the same order (up to reversal) in these chains. Hence we partition the hexagons that appear in chains into at most $2^6 - 1$ subsets, where within each subset all hexagons belong to the same chains. (A finer counting argument is based on showing that for every three or more chains there can be at most one hexagon that belongs to all these chains. Hence we actually focus on subsets of hexagons that belong to one or two chains.) Each such subset is provided with a disjoint palette and can be colored using a logarithmic (in its size) number of colors. □

Finally, the proof of Theorem 1.4 for regular hexagons follows by combining the above lemma with a lower bound analogous to Lemma 7.10, the basic properties of the tiling, and the requesting process from orphan tiles.

9. Consequences.

9.1. Universal bounds for noncongruent rectangles and hexagons. As a corollary of Lemma 7.12 we also obtain a universal bound for the case of rectangles that is analogous to the case of disks (part 1 of Theorem 1.2).

Specifically, for each pair of integers $i, j \geq 1$, let $\mathcal{R}^{i,j}$ denote the subset of rectangles in $\mathcal{R}$ whose width is in the range $[2^{i-1}, 2^i)$ and whose height is in the range $[2^{j-1}, 2^j)$. Let $\phi_{2^i,2^j}(\mathcal{S}^{i,j})$ denote the maximum number of centers of rectangles in $\mathcal{R}^{i,j}$ that are contained in a rectangular tile of width 2^i and height 2^j. We refer to $\phi_{2^i,2^j}(\mathcal{R}^{i,j})$ as the *local density* of $\mathcal{R}^{i,j}$ (with respect to rectangular tiles of width 2^i and height 2^j).

THEOREM 9.1. *There exists an algorithm that, given a set $\mathcal{R}$ of axis-parallel rectangles with side-lengths in the interval $[1, \rho]$, finds a CF-coloring χ of $\mathcal{R}$ using $O\left(\min\left\{\sum_{i=1}^{\log(\rho)+1}\sum_{j=1}^{\log(\rho)+1}(1+\log\phi_{2^i,2^j}(\mathcal{R}^{i,j})), \log|\mathcal{R}|\right\}\right)$ colors.*

Lemma 8.1 implies an analogous theorem for hexagons.

9.2. CF-multicoloring. An interesting by-product of Theorem 1.4 and its analysis has to do with minimum *CF-multicoloring*. A CF-multicoloring of a collection $\mathcal{S}$ is a mapping χ from $\mathcal{S}$ to *subsets* of colors. The requirement is that for every point $x \in \bigcup_{S\in\mathcal{S}} S$ there exist a color i such that $\{S : x \in S,\ i \in \chi(S)\}$ contains a single subset. It has been observed by Bar-Yehuda ([B01], based on [BGI92]) that every set-system $(X, \mathcal{S})$ can be CF-multicolored using $O(\log|X| \cdot \log|\mathcal{S}|)$ colors. Since the problem of minimum graph coloring can be reduced to CF-coloring of set-systems, it follows that there exist set-systems for which there is an exponential gap between the minimum number of colors required in a CF-coloring and the minimum number of colors required in a CF-multicoloring. In particular, this is true when the set-system $(X, \mathcal{S})$ corresponds to a clique $G = (V, E)$ as follows: There is a set S_v for every vertex $v \in V$, and there is a point $x_e \in X$ for every edge $e \in E$. The set S_v contains the point x_e if and only if v is an endpoint of e. The number of colors required to CF-color this set-system is $|\mathcal{S}| = |V|$, in contrast to the $O(\log^2|\mathcal{S}|)$ colors that are sufficient for CF-multicoloring.

A natural question is whether, in the geometric setting that we study, the number of colors required for CF-multicoloring is significantly smaller than that required for CF-coloring. An example in which CF-multicoloring saves colors is a "circle" of five congruent squares such that every adjacent pair of squares intersects and no three squares intersect. Since the number of squares is odd, three colors are needed for CF-coloring. However, CF-multicoloring requires only two colors: Color the first square with two colors, and then color the rest of the squares with alternating colors. The lower bound proved in Lemma 6.3 also applies to CF-multicoloring, and hence CF-multicoloring does not save colors in chains. Furthermore, it follows from our analysis (cf. Lemma 7.10) that CF-multicoloring reduces the number of colors by at most a constant in the case of congruent squares (or hexagons).

THEOREM 9.2. *Let $\mathcal{S}$ denote a set of congruent axis-parallel squares, and let $\chi^{\text{multi}}_{\text{opt}}(\mathcal{S})$ denote an optimal CF-multicoloring of $\mathcal{S}$. Then $|\chi^{\text{multi}}_{\text{opt}}(\mathcal{S})| = \Theta(|\chi_{\text{opt}}(\mathcal{S})|)$.*

Acknowledgments. We thank the reviewers of this manuscript for careful reading and many helpful remarks. We thank an anonymous FOCS reviewer for suggesting that the NP-completeness of coloring intersection graphs of unit disks could be used to prove the NP-completeness of CF-coloring arrangements of unit disks. We thank Micha Sharir for helpful discussions.

COMMUNICATION COMPLEXITY OF SIMULTANEOUS MESSAGES*

LÁSZLÓ BABAI†, ANNA GÁL‡, PETER G. KIMMEL§, AND SATYANARAYANA V. LOKAM¶

Abstract. In the multiparty communication game (CFL game) of Chandra, Furst, and Lipton [*Proceedings of the 15th Annual ACM Symposium on Theory of Computing*, Boston, MA, 1983, pp. 94–99] k players collaboratively evaluate a function $f(x_0, \ldots, x_{k-1})$ in which player i knows all inputs except x_i. The players have unlimited computational power. The objective is to minimize communication.

In this paper, we study the SIMULTANEOUS MESSAGES (SM) model of multiparty communication complexity. The SM model is a restricted version of the CFL game in which the players are not allowed to communicate with each other. Instead, each of the k players simultaneously sends a message to a *referee*, who sees none of the inputs. The referee then announces the function value.

We prove lower and upper bounds on the SM complexity of several classes of explicit functions. Our lower bounds extend to randomized SM complexity via an entropy argument. A lemma establishing a tradeoff between average Hamming distance and range size for transformations of the Boolean cube might be of independent interest.

Our lower bounds on SM complexity imply an exponential gap between the SM model and the CFL model for up to $(\log n)^{1-\epsilon}$ players for any $\epsilon > 0$. This separation is obtained by comparing the respective complexities of the Generalized Addressing Function, $\mathsf{GAF}_{G,k}$, where G is a group of order n. We also combine our lower bounds on SM complexity with the ideas of Håstad and Goldmann [*Comput. Complexity*, 1 (1991), pp. 113–129] to derive superpolynomial lower bounds for certain depth-2 circuits computing a function related to the GAF function.

We prove some counterintuitive upper bounds on SM complexity. We show that $\mathsf{GAF}_{\mathbb{Z}_2^t,3}$ has SM complexity $O(n^{0.92})$. When the number of players is at least $c \log n$, for some constant $c > 0$, our SM protocol for $\mathsf{GAF}_{\mathbb{Z}_2^t,k}$ has polylog(n) complexity. We also examine a class of functions defined by certain depth-2 circuits. This class includes the Generalized Inner Product function and Majority of Majorities. When the number of players is at least $2 + \log n$, we obtain polylog(n) upper bounds for this class of functions.

1. Introduction.

1.1. The model. Chandra, Furst, and Lipton [CFL83] introduced the following multiparty communication game: Let $f(x_0, \ldots, x_{k-1})$ be a Boolean function, where

*Received by the editors July 31, 2000; accepted for publication (in revised form) February 17, 2003; published electronically November 14, 2003. This is a significantly expanded version of the conference paper [BaKL95]. A substantial part of the present work was done while the last three authors were students at the University of Chicago.

each x_i is a bit string of fixed length $\leq n$ bits. k players collaborate to evaluate $f(x_0, \ldots, x_{k-1})$. Each player has full knowledge of the function f. The ith player knows each input argument except x_i; we will refer to x_i as the input *missed* by player i. We can imagine input x_i written on the forehead of player i. Each player has unlimited computational power. They share a blackboard, viewed by all players, where in each round of the game some player writes a bit. The last bit written on the board must be the function value.

DEFINITION 1.1. *A* multiparty protocol *is a specification of which player writes in each round and what that player writes. The protocol must specify the following information for each possible sequence of bits that is written on the board so far:*

1. *Whether or not the game is over, and in case it is not over, which player writes the next bit: This information should be completely determined by the information written on the board so far.*
2. *What that player writes: This should be a function of the information written on the board so far and of the input seen by that player.*

The cost *of a multiparty protocol is the number of bits written on the board for the worst case input. The* multiparty communication complexity *of f, denoted $C(f)$, is the minimum cost of a protocol computing f.*

Fairly strong multiparty communication complexity lower bounds of the form n/c^k were obtained by Babai, Nisan, and Szegedy [BaNS92] for some families of explicit functions. However, it seems that those methods do not extend to logarithmic number of players and beyond.

Håstad and Goldmann [HG91] found a curious application of the [BaNS92] bounds to lower bounds for small depth threshold circuits. Subsequent work by Yao [Ya90] and Beigel and Tarui [BeT91] reduces ACC circuits (bounded depth, polynomial size circuits with Boolean and $\mathsf{MOD}\ m$ gates) to small depth circuits similar to those considered by [HG91]. These results imply that a superpolylogarithmic lower bound for the communication complexity of a function f with a superpolylogarithmic number of players would show that $f \notin \mathrm{ACC}$.

In fact, this separation would already follow from similar lower bounds in a weaker model, which we call the SIMULTANEOUS MESSAGES (SM) model (see Definition 2.1). This connection was pointed out to us by Avi Wigderson.

The SM model is a restricted version of the general multiparty communication model in which the players are not allowed to communicate with each other. Instead, each player can send a single message to a *referee*, who sees none of the inputs. The referee announces the value of the function based on the messages sent by the players.

The subject of this paper is the complexity of explicit functions in the SM model.

1.2. Lower bounds. We prove lower bounds on the SM complexity of the Generalized Addressing Function, $\mathsf{GAF}_{G,k}$, where G is a group of order n (see Definition 2.3). The input to $\mathsf{GAF}_{G,k}$ consists of $n + (k-1)\log n$ bits partitioned among the players as follows: player 0 gets a function $x_0 : G \longrightarrow \{0,1\}$ (represented as an n-bit string) on her forehead, whereas players 1 through $k-1$ get group elements $x_1, \ldots, x_{k-1}$, respectively, on their foreheads. The output of $\mathsf{GAF}_{G,k}$ for this input is the value of the function x_0 on the product $x_1 \cdot \ldots \cdot x_{k-1}$.

Our first result is an $\Omega(\frac{|G|^{1/(k-1)}}{k-1})$ lower bound on the SM complexity of $\mathsf{GAF}_{G,k}$ for any finite group G (Theorem 2.8).

The result uses a decomposition theorem for finite groups (Theorem 2.19). A related body of work, going back to a 1937 conjecture of Rohrbach [Ro37a, Ro37b], is discussed in a separate section, partly for the sake of its own interest (section 7).

In section 3, we prove a lower bound similar to Theorem 2.8 on the *randomized* SM complexity of $\mathsf{GAF}_{G,k}$. Specifically, we show that any randomized SM protocol for $\mathsf{GAF}_{G,k}$ with a success probability $\geq (1+\epsilon)/2$ must have a cost of $\Omega(\frac{|G|^{1/(k-1)}\epsilon^2}{k-1})$. The proof of this result is based on an "entropy loss lemma," which may be of independent interest (Lemmas 3.7 and 3.9). The lemma provides a tradeoff between the *average* Hamming distance travelled and the number of destinations reached by a transformation of the Boolean cube. Similar entropy based tools have been used earlier in [Man98] and [KaT00].

It is easy to see that the general multiparty communication complexity of $\mathsf{GAF}_{G,k}$ is at most $\log n + 1$. Hence the lower bounds stated above show that the SM model is exponentially weaker than the general model for up to $(\log n)^{1-\epsilon}$ players. In fact, we prove this *exponential gap* between the SM model and an intermediate model called the "one-way communication model" [NW93] (see Definition 2.6). This result supports the hope that it might be easier to obtain stronger lower bounds in the SM model than in the general communication model. On the other hand, as mentioned in section 1.1, sufficiently strong lower bounds in the SM model still have some of the same interesting consequences to circuit complexity as those in the general model.

As mentioned before, Håstad and Goldmann [HG91] relate lower bounds on multiparty communication complexity to lower bounds on certain depth-2 circuits. In this paper, we use ideas from [HG91] to relate SM complexity to depth-2 circuit complexity. In particular, we show that a circuit with an arbitrary symmetric gate at the top and AND gates at the bottom computing an explicit function on n variables derived from $\mathsf{GAF}_{\mathbb{Z}_2^t,k}$ must have size $\exp((\log n/\log\log n)^2)$. We note that similar techniques applying the general multiparty communication complexity lower bounds were used by Razborov and Wigderson [RaW93].

1.3. Upper bounds. A curious development concerning SM complexity is the discovery of unexpected upper bounds. It appeared natural to expect that, when the number of players is constant, the SM complexity of GAF should be $\Omega(n)$. This, however, is false. In fact, we give a counterintuitive upper bound of $O(n^{0.92})$ on the SM complexity[1] of $\mathsf{GAF}_{\mathbb{Z}_2^t,3}$. More generally, we show an upper bound of roughly $n^{O(\log k/k)} + \log n$ on the SM complexity of $\mathsf{GAF}_{\mathbb{Z}_2^t,k}$. This gives a polylog$(n)$ upper bound when the number of players is $\log n$; in fact, if the number of players is greater than $\log n$, an upper bound of $2 + \log n$ holds (sections 5.1 and 5.2).

The $O(n^{0.92})$ upper bound, first published in [BaKL95] (a preliminary version of this paper), together with related results about cyclic groups $\mathbb{Z}_n$ by Pudlák and Rödl [PR93] and Pudlák, Rödl, and Sgall [PRS97], has prompted a refinement of an approach proposed by Nisan and Wigderson [NW93] toward superlinear size lower bounds on log-depth circuits. This approach uses 3-party communication complexity lower bounds and exploits a graph-theoretic reduction due to Valiant [Va77], building on earlier results by Erdős, Graham, and Szemerédi [EGS75]. To explain this approach, let us consider a Boolean function $f_1 : \{0,1\}^{O(n)} \times \{0,1\}^{O(n)} \times \{0,1\}^{\log n} \longrightarrow \{0,1\}$. From this, let us construct an n-output function $f(x,y) = (z_1,\ldots,z_n)$ by setting $z_j := f_1(x,y,j)$. Then an $\Omega(n)$ lower bound on the *total* number of bits communicated in a 3-party SM protocol for f_1 (with x, y, and j on the foreheads of players 0, 1, and 2, respectively) would imply a superlinear lower bound on log-depth circuits computing the function f. In particular, if there were an $\Omega(n)$ lower bound on the 3-party SM communication complexity of $\mathsf{GAF}_{\mathbb{Z}_2^t,3}$, where $n = 2^t$, then the above

[1] This bound has subsequently been improved to $O(n^{0.73})$ in [AmL00].

connection would have yielded an explicit function requiring superlinear size circuits of log-depth.

However, we have a 3-party SM protocol for $\mathsf{GAF}_{\mathbb{Z}_2^t,3}$ that uses only $n^{0.92}$ bits of communication. Analogously, [PR93, PRS97] prove an $o(n)$ upper bound on the 3-party SM complexity of $\mathsf{GAF}_{\mathbb{Z}_n,k}$. On the other hand, these and several similar functions are conjectured to require superlinear size circuits of log-depth. This situation motivated a refined version of the approach from [NW93]. This refined version seeks 3-party SM lower bounds when there are certain constraints on the lengths of messages from individual players. Indeed, in response to the surprising upper bounds from [BaKL95] and [PR93], Kushilevitz and Nisan present such an approach in their book [KuN97, section 11.3]. We describe this new formulation below.

Let f be an n-bit output function and f_1 its single-bit output counterpart as defined above. Then Valiant's lemma implies the following: if f has log-depth linear size circuits, then f_1 has an SM protocol in which, for any fixed $\epsilon > 0$, (i) player 2 sends at most $O(n/\log\log n)$ bits, and (ii) players 0 and 1 send $O(n^\epsilon)$ bits each. Thus a lower bound showing that any 3-party SM protocol for an explicit f_1 must violate (i) or (ii) would yield an explicit f that cannot be computed simultaneously in linear size and logarithmic depth.

It is interesting to note that, in contrast to the lower bound, our upper bound depends heavily on the structure of the elementary abelian 2-group $G = \mathbb{Z}_2^t$. In particular, the upper bound does not apply to the cyclic group $G = \mathbb{Z}_n$. For $\mathsf{GAF}_{\mathbb{Z}_n,k}$, Pudlák, Rödl, and Sgall [PRS97] prove an upper bound of $O(n\log\log n/\log n)$ for $k = 3$ (three players) and of $O(n^{6/7})$ for $k \geq c\log n$. Their upper bounds have been significantly improved by Ambainis [Am96] to $O(\frac{n\log^{1/4} n}{2^{\sqrt{\log n}}})$ for $k = 3$ and to $O(n^\epsilon)$ for an arbitrary $\epsilon > 0$ for $k = O((\log n)^{c(\epsilon)})$. However, these bounds for $\mathbb{Z}_n$ are still much weaker than the corresponding bounds for $\mathbb{Z}_2^t$ presented in this paper.

We also give surprising upper bounds on the SM complexity of a different class of functions defined by certain depth-2 circuits (section 6). For this class of functions, we prove polylog(n) upper bounds on the SM complexity when the number of players is at least $\log n + 2$. This class of functions includes Generalized Inner Product (GIP) and Majority of Majorities. The special case of GIP improves a result due to Grolmusz [G94], where the same upper bound is given for 2-round protocols. We note that GIP is a prime example in the study and applications of multiparty communication complexity [BaNS92, G94, HG91, RaW93]. Majority of Majorities is an interesting candidate function to be outside ACC.

The circuits defining the class of functions mentioned above have an arbitrary symmetric gate of fan-in n at the top and gates of fan-in k (= number of players) at the bottom. Furthermore, each bottom gate is assumed to compute a symmetric function with very small 2-party, one-way communication complexity (we call such functions *compressible*; see Definition 6.1). We partition the input so that each player misses one bit from each bottom gate.

We also give an example of an explicit symmetric function that is not compressible (in the sense of Definition 6.1). The proof of this result uses Weil's character sum estimates.

1.4. Comparison with [BaKL95]. Finally, a comment on how the present paper relates to its preliminary version [BaKL95]. Most results of [BaKL95] have been superseded both in generality and in the elegance of the proof. This is especially true for the (deterministic and randomized) lower bounds which have been extended to all groups. A discussion of circuit complexity applications has been added. The

main new additions are the counterintuitive upper bounds for the case of more than $\log n$ players for a significant class of functions, including the Majority of Majorities function.

1.5. Organization of the paper. In section 2, we introduce the model of SM and prove a lower bound on the SM complexity of the Generalized Addressing Function (GAF) with respect to an arbitrary finite group G (see Definition 2.3). Section 3 extends this lower bound to the randomized SM complexity of $\mathsf{GAF}_{G,k}$. In section 4, we present some consequences of our lower bounds on SM complexity to certain depth-2 circuits. Sections 5 and 6 deal with upper bounds on SM complexity. In section 5, we give nontrivial upper bounds for GAF with respect to elementary abelian 2-groups, whereas in section 6 we define a natural class of functions and show very efficient SM protocols for them. In section 7, we discuss a group-decomposition problem arising from the GAF lower bounds; this section may be of interest in its own right. Section 8 concludes the paper with several open problems.

2. A Simultaneous Messages lower bound. Let $f(x_0, \ldots, x_{k-1})$ be a Boolean function, where each x_i is a bit string of fixed length $\leq n$. A referee and k players collaborate to evaluate $f(x_0, \ldots, x_{k-1})$. Each participant (referee and players) has full knowledge of the function f. For $0 \leq i \leq k-1$, the ith player, p_i, knows each input argument except x_i. The referee does not know any of the input. Each player p_i simultaneously passes a message of fixed length to the referee, after which the referee announces the function value. Each participant is a function of the arguments it "knows."

Definition 2.1. *An* SM protocol P for f *is a set of players along with a referee that correctly computes f on all inputs. The* cost *of an SM protocol for f is the length of the longest message sent to the referee by any individual player.*[2] *The* SM complexity *of f, denoted $C_0(f)$, is the minimum cost of a protocol computing f.*

Remark 2.2. This model is implicit in the work of Nisan and Wigderson [NW93, Theorem 7], where they consider the case $k = 3$. The first papers investigating the SM model in detail are the conference version of the current paper [BaKL95] and a paper by Pudlák, Rödl, and Sgall [PRS97]; the latter uses the name "oblivious communication complexity."

2.1. The Generalized Addressing Function $\mathsf{GAF}_{G,k}$. The function that we use to show an exponential gap between the SM and general multiparty communication models is the GAF, defined as follows.

Definition 2.3. *Let G be a group of order n. Elements of G are represented by binary strings of length* $\log n$. *Let $x_0 : G \longrightarrow \{0,1\}$ be a function represented as an n-bit string, and let $x_1, \ldots, x_{k-1} \in G$. Then the* Generalized Addressing Function *for the group G and k players, denoted by $\mathsf{GAF}_{G,k}$, is defined as follows:*

$$\mathsf{GAF}_{G,k}(x_0, \ldots, x_{k-1}) := x_0[x_1 \cdot \ldots \cdot x_{k-1}].$$

Here $\cdot$ denotes the group operation in G.

The notation $C_0(\mathsf{GAF}_{G,k})$ refers to the SM complexity of the $\mathsf{GAF}_{G,k}$ function under the natural partition of the input among the players; i.e., player i misses input x_i. Note that the partition of the input among the players is not balanced since

[2] This definition of the cost, as the ℓ_∞-norm of the vector of message lengths of the players, differs from that of the STACS '95 version [BaKL95], where we consider the ℓ_1-norm. We continue to use the total communication for C and C_1 (Definitions 1.1 and 2.6).

player 0 has $|x_0| = n$ bits "on her forehead," whereas player i for $1 \le i \le k-1$ has $|x_i| = \log n$ bits on her forehead.

Recall that $C(f)$ denotes the k-party communication complexity of the function f (where f is a function in k variables) (see section 1.1).

Observation 2.4. $C(\mathsf{GAF}_{G,k}) \le \log n + 1$.

Proof. Player p_0 writes $g = x_1 \cdot \ldots \cdot x_{k-1}$; then p_1 writes $x_0[g]$. □

Remark 2.5. This is a special case of the observation that $C(f) \le 1 +$ the length of the shortest input.

DEFINITION 2.6. *A special case of the communication model is* one-way communication*, in which each player may write on the blackboard only once, and they proceed in the prescribed order $p_0, p_1, \ldots, p_{k-1}$. Let $C_1(f)$ denote the* one-way communication complexity of f.

Clearly, $n \ge C_0(f) \ge C_1(f)/k \ge C(f)/k$ for any function f of k variables. For $\mathsf{GAF}_{G,k}$, the proof of Observation 2.4 gives a one-way protocol, so we obtain the following consequence.

COROLLARY 2.7. $C_1(\mathsf{GAF}_{G,k}) \le \log n + 1$. □

The main result of this section is an SM lower bound on the Generalized Addressing Function of the form $\Omega(n^{1/(k-1)}/(k-1))$. This bound implies an exponential separation between $C_0(f)$ and $C_1(f)$ (and hence also between $C_0(f)$ and $C(f)$) for up to $k = (\log n)^{1-\epsilon}$ players. We state the result.

THEOREM 2.8. *For any group G of order n and any $k \ge 2$,*

$$C_0(\mathsf{GAF}_{G,k}) \ge \frac{cn^{1/(k-1)}}{k-1},$$

where $c = (1 - 1/\sqrt{\mathrm{e}})/2 > 0.19$.

The proof of this lower bound is given in the next two subsections.

Remark 2.9. For $k = 3$, Theorem 2.8 gives an $\Omega(\sqrt{n})$ lower bound. Nisan and Wigderson [NW93] give an $\Omega(\sqrt{n})$ lower bound for a different function, based on hash functions [MNT93]. They actually show this lower bound for one-way complexity, establishing an exponential gap between $C_1(f)$ and $C(f)$ for $k = 3$.

Remark 2.10. Theorem 2.8 states an SM lower bound for all finite groups G. Special cases of this result were found independently by Pudlák, Rödl, and Sgall (the cyclic group $G = \mathbb{Z}_n$) [PRS97, Proposition 2.3] and by the authors of the conference version of the present paper (the elementary abelian group $G = \mathbb{Z}_2^t$) [BaKL95]. Those bounds were extended in a preliminary version of this paper to a large class of groups, including all solvable groups. For arbitrary groups, however, our original lower bound was worse by a logarithmic factor than the bound stated in Theorem 2.8. We express our gratitude to an anonymous referee for pointing out that a simple modification of our argument yields the improved result stated as Theorem 2.8.

All proofs use essentially the same strategy, an information-theoretic argument combined with a group-decomposition result. Simple cases of the group-decomposition result are discussed as Examples 2.14 and 2.15. The general group-decomposition theorem appears as Theorem 2.19.

2.2. SM lower bound for $\mathsf{GAF}_{G,k}$ and group decompositions. In this subsection, we give an SM lower bound for $\mathsf{GAF}_{G,k}$ in terms of a parameter ρ of G and k related to optimal decompositions of a large fragment of a group. In the next subsection we shall estimate ρ within a constant factor. From this bound, our SM lower bound for $\mathsf{GAF}_{G,k}$ (Theorem 2.8) will be immediate.

DEFINITION 2.11. *For a finite group G and $A, B \subseteq G$, the product AB is defined as $AB = \{a \cdot b : a \in A,\ b \in B\}$. Note that $|AB| \leq |A| \cdot |B|$.*

DEFINITION 2.12. *Let α be a real number, $0 < \alpha \leq 1$. For a finite group G and a positive integer u we define*

$$\rho_\alpha(G, u) = \min_{H_1, \ldots, H_u \subseteq G} \{\rho : |H_1 \cdot \ldots \cdot H_u| \geq \alpha |G| \text{ and } \forall i, |\widehat{H}_i| \leq \rho\},$$

where $\widehat{H}_i$ is defined to be the Cartesian product of all H_j except H_i.

Remark 2.13. Note that $|\widehat{H}_i| = \prod_{j \neq i} |H_j|$. Also note that $\widehat{H}_i$ is not the product $\prod_{j \neq i} H_j$ in the sense of Definition 2.11; in fact, $\widehat{H}_i$ is not even a subset of G. (It is a subset of $G \times \cdots \times G$ ($u - 1$ times).)

The following two examples give upper bounds on ρ for two special groups. In section 7, we will see that these upper bounds are optimal to within a constant factor.

EXAMPLE 2.14. *$\rho_1(\mathbb{Z}_2^t, u) \leq 2n^{1-1/u}$, where $n = 2^t$.*

Proof. Let $V = \mathbb{Z}_2^t$. Decompose V into a direct sum of u subspaces: $V = H_1 \oplus \cdots \oplus H_u$, where for each i, $1 \leq i \leq u$, $\lfloor t/u \rfloor \leq \dim H_i \leq \lceil t/u \rceil$. This implies

$$\begin{aligned} \rho_1(V, u) &\leq \max_i |\widehat{H}_i| = \max_i \frac{n}{|H_i|} = \frac{n}{\min_i |H_i|} \\ &\leq \frac{n}{2^{\lfloor t/u \rfloor}} \leq \frac{2n}{2^{t/u}} = \frac{2n}{n^{1/u}} = 2n^{1-1/u}. \end{aligned} \tag{2.1}$$

□

EXAMPLE 2.15. *$\rho_{1/2}(\mathbb{Z}_n, u) \leq 2n^{1-1/u}$ and $\rho_1(\mathbb{Z}_n, u) \leq 4n^{1-1/u}$.*

Proof. Let $2^t < n \leq 2^{t+1}$. We consider the elements of $\mathbb{Z}_n$ to be binary strings of length $t + 1$. Let K be the subset of $\mathbb{Z}_n$ given by binary strings with their most significant ($(t+1)$st) bit equal to zero. Identify K with $H_1 \oplus \cdots \oplus H_u$, where H_i is the set of binary numbers with t digits in which all digits are 0 except for the ith segment of $\lfloor t/u \rfloor$ or $\lceil t/u \rceil$ digits, which can be either 0 or 1. Thus each H_i has size $\geq 2^{\lfloor t/u \rfloor}$. Clearly, $|K| = 2^t \geq n/2$. By (2.1), we have that $\max_i |\widehat{H}_i| \leq 2|K|^{1-1/u} \leq 2n^{1-1/u}$. Hence $\rho_{1/2}(\mathbb{Z}_n, u) \leq 2n^{1-1/u}$.

To cover the entire group $\mathbb{Z}_n$, apply the above argument to bit strings of length $(t + 1)$ (but perform group operations in $\mathbb{Z}_n$). Then we get that $\max_i |\widehat{H}_i| \leq 2 \cdot 2^{(t+1)(1-1/u)} \leq 4n^{1-1/u}$, and this gives us the bound on $\rho_1(\mathbb{Z}_n, u)$.

As a concrete example, consider $\mathbb{Z}_{25}$, $u = 3$, and $\alpha = 1$. It is easy to see that a (complete) cover is given by $\mathbb{Z}_{25} = \{0, 16\} + \{0, 4, 8, 12\} + \{0, 1, 2, 3\}$. Note that in this cover, some elements (e.g., 5) have more than one factorization (under the group operation addition modulo 25). □

LEMMA 2.16. *For any finite group G and any α $(0 < \alpha \leq 1)$,*

$$C_0(\mathsf{GAF}_{G,k}) \geq \frac{\alpha |G|}{(k-1)\, \rho_\alpha(G, k-1)}.$$

Proof. We prove a lower bound on the length of the longest message sent by $p_1, \ldots, p_{k-1}$. We ignore p_0 by assuming that the referee knows whatever p_0 knows. This assumption can only make our lower bound stronger.

The proof is by an information-theoretic argument. Pick a factorization $K = \prod_{i=1}^{k-1} H_i$ of some subset $K \subseteq G$ which is optimal in the sense that $|K| \geq \alpha |G|$, $H_1, \ldots, H_{k-1} \subseteq G$, and $\max_i |\widehat{H}_i| = \rho_\alpha(G, k-1)$.

We shall restrict player p_0's inputs to functions $x_0 : G \longrightarrow \{0, 1\}$ such that $x_0(g) = 0$ for all $g \in G \setminus K$. For $i = 1, \ldots, k-1$, we shall restrict player p_i's inputs

to H_i. For a fixed x_0 (on p_0's forehead and hence visible to all p_i, $1 \le i \le k-1$), player p_i can send at most $|\widehat{H}_i|$ different messages. Hence the total number of bits received by the referee (for all combinations of these restricted inputs) is at most $\rho_\alpha(G, k-1)(k-1)\ell$, where ℓ is the length of the longest message sent by the players p_i, $1 \le i \le (k-1)$. But this collection of messages must determine every bit of x_0 corresponding to the set $K \subseteq G$. Hence we must have $\rho_\alpha(G, k-1)(k-1)\ell \ge \alpha n$, giving the claimed bound. The foregoing ideas are formalized below.

Let P be any SM protocol for $\mathsf{GAF}_{G,k}$. Let r denote the referee function. Let ℓ be the cost of P. For notational convenience, we assume, without loss of generality, that each player sends a message of length ℓ (padding their messages if necessary).

We define a function F in terms of the player and referee functions. The input to F will be a binary string of length $(k-1)\rho_\alpha(G, k-1)\ell$, and the output will be a $|K|$-bit string. We will then show that F is surjective, which will yield the theorem.

DEFINITION 2.17. *For each $g \in K$, we fix elements $h_1 \in H_1, \ldots, h_{k-1} \in H_{k-1}$ such that $g = h_1 \cdot \ldots \cdot h_{k-1}$ and refer to this as "the"* decomposition *of g.*

Now we define a function $F : \{0,1\}^{\ell|\widehat{H}_1|} \times \cdots \times \{0,1\}^{\ell|\widehat{H}_{k-1}|} \longrightarrow \{0,1\}^K$ as follows. Let $(w_1, w_2, \ldots, w_{k-1})$ be an input to F, where $w_i \in \{0,1\}^{\ell|\widehat{H}_i|}$. The ℓ-bit substrings of w_i are indexed by elements of $\widehat{H}_i$. The output bit $y(g)$ corresponding to $g \in K$ is determined as follows. Let $g = h_1 \cdot \ldots \cdot h_{k-1}$ be the decomposition of g. For $1 \le i \le k-1$, let $m_i(g)$ be the ℓ-bit substring of w_i at index $\widehat{h}_i := (h_1, \ldots, h_{i-1}, h_{i+1}, \ldots, h_{k-1}) \in \widehat{H}_i$. Let $m_0(g) = p_0(h_1, \ldots, h_{k-1})$. Now define $y(g) = r(m_0(g), m_1(g), \ldots, m_{k-1}(g))$.

CLAIM 2.18. *F is surjective.*

Proof. Let $x_0 \in \{0,1\}^G$ such that $x_0(g) = 0$ for all $g \in G \setminus K$. Define the input $w_{x_0} = (w_1, \ldots, w_{k-1})$ to F as follows: For each i, $1 \le i \le k-1$, and each $\widehat{h}_i \in \widehat{H}_i$, define the ℓ-bit substring of w_i at index $\widehat{h}_i$ to be $p_i(x_0, \widehat{h}_i)$, i.e., the message sent by p_i when she sees x_0 and $\widehat{h}_i$. We now show that $F(w_{x_0}) = x_0^K$ (the restriction of x_0 to K), which will prove the claim. Recalling our notation that $y = F(w_{x_0})$, we want to show that for each $g \in K$, $y(g) = x_0(g)$.

Let $g \in K$, and let $g = h_1 \cdot \ldots \cdot h_{k-1}$, $h_i \in H_i$ be the decomposition of g.

From the definition of w_{x_0}, for $1 \le i \le k-1$, we have $m_i(g) = (\ell$-bit substring of w_i at index $\widehat{h}_i) = p_i(x_0, \widehat{h}_i)$, and also $m_0(g) = p_0(h_1, \ldots, h_{k-1})$. Now using the definition of F we have

$$\begin{aligned} y(g) &= r(m_0(g), m_1(g), \ldots, m_{k-1}(g)) \\ &= r(p_0(h_1, \ldots, h_{k-1}), p_1(x_0, h_2, \ldots, h_{k-1}), \ldots, p_{k-1}(x_0, h_1, \ldots, h_{k-2})) \\ &= \mathsf{GAF}_{G,k}(x_0, h_1, \ldots, h_{k-1}) \qquad \text{by the correctness of the protocol} \\ &= x_0(g) \qquad \text{by definition of } \mathsf{GAF}_{G,k}. \end{aligned}$$

Thus $F(w_{x_0}) = x_0^K$ and F is surjective, and this completes the proof of the claim. □

Claim 2.18 implies that the domain of F is at least as large as the range of F. Thus $\ell(k-1)\rho_\alpha(G, k-1) \ge \ell(|\widehat{H}_1| + \cdots + |\widehat{H}_{k-1}|) \ge |K| \ge \alpha|G|$, and hence $\ell \ge n/(k-1)\rho_\alpha(G, k-1)$. This completes the proof of Lemma 2.16. □

2.3. Decomposition of groups. In this subsection we estimate the quantity $\rho_\alpha(G, u)$ for a specific positive constant α.

THEOREM 2.19. *Given a finite group G and a positive integer u, there exist subsets $H_1, \ldots, H_u \subseteq G$ such that $|\widehat{H}_i| < 2|G|^{1-1/u}$ for $i = 1, \ldots, u$, and $|H_1 \cdot \ldots \cdot H_u| >$*

$(1-1/\sqrt{\mathrm{e}})|G| > 0.39|G|$.

COROLLARY 2.20. *Let $\alpha = 1-1/\sqrt{\mathrm{e}} \approx 0.39$. Then for any finite group G and any positive integer u,*

$$\rho_\alpha(G,u) < 2|G|^{1-1/u}.$$

Combining Corollary 2.20 and Lemma 2.16, our lower bound for the SM complexity of $\mathsf{GAF}_{G,k}$ (Theorem 2.8) is immediate. □

For the proof of Theorem 2.19, we use the following result. Let G be a group and $a_1,\dots,a_k \in G$. The *cube* based on the sequence $a_1,\dots,a_k$ is the set $C(a_1,\dots,a_k) := \{1,a_1\}\cdot\ldots\cdot\{1,a_k\}$. In other words, $C(a_1,\dots,a_k)$ consists of the 2^k *subproducts* $a_1^{\epsilon_1}\dots a_k^{\epsilon_k}$, where $\epsilon_i \in \{0,1\}$.

THEOREM 2.21 (see [BaE82]). *Let G be a finite group of order n, and let ℓ be a positive integer. Then there exists a sequence of elements $a_1,\dots,a_\ell \in G$ such that $|C(a_1,\dots,a_\ell)| > n(1-\exp(-2^\ell/n))$.*

For completeness we include the proof.

LEMMA 2.22. *Let A be a subset of a finite group G. Then for some $x \in G$ we have*

$$\frac{|G\setminus(A\cup Ax)|}{|G|} \le \left(\frac{|G\setminus A|}{|G|}\right)^2. \tag{2.2}$$

Proof. Let $|G|=n$ and $|A|=k$. Let us select $x\in G$ at random from the uniform distribution. Then for every $g\in G$, the probability that $g\notin Ax$ is $(n-k)/n$. Therefore the expected number of those $g\in G\setminus A$ which do not belong to Ax is $(n-k)^2/n$. So this is the expected size of the set $G\setminus(A\cup Ax)$. Pick an x for which $|G\setminus(A\cup Ax)|$ is not less than its expected value. □

Proof of Theorem 2.21. We choose $a_1,\dots,a_\ell \in G$ successively as follows. Set $A_1=\{a_1\}$ and $A_{i+1}=A_i\cup A_i a_{i+1}$. Let $a_1\in G$ be arbitrary; given $a_1,\dots,a_i$, we choose $a_{i+1}\in G$ so as to maximize $|A_{i+1}|$.

Let $p_i = |G\setminus A_i|/n$.

We have $p_1 = 1-1/n$, and by Lemma 2.22 we have $p_{i+1}\le p_i^2$. Therefore

$$p_\ell \le \left(1-\frac{1}{n}\right)^{2^\ell} < \exp\left(-2^\ell/n\right). \tag{2.3}$$

Noting that $|C(a_1,\dots,a_\ell)| = n(1-p_\ell)$ completes the proof. □

Proof of Theorem 2.19. Let $n=|G|$, and let ℓ denote the integer satisfying $n/2 \le 2^\ell \le n$. Let $a_1,\dots,a_\ell\in G$ be the sequence of ℓ elements in G guaranteed by Theorem 2.21.

Let us split ℓ into u parts as evenly as possible: $\ell = k_1+\dots+k_u$, where $k_i \in \{\lfloor \ell/u\rfloor, \lceil \ell/u\rceil\}$. Let $H_j = C(a_{k_1+\dots+k_{j-1}+1},\dots,a_{k_1+\dots+k_j})$. (So H_1 is the cube based on the first k_1 members of the sequence $\{a_i\}$; H_2 is the cube based on the next k_2 members of the sequence, etc.) Then $H_1\dots H_u = C(a_1,\dots,a_\ell)$, and therefore $|H_1\dots H_u| > n(1-\exp(-2^\ell/n)) \ge n(1-1/\sqrt{\mathrm{e}})$.

Moreover, $|\widehat{H_i}| = 2^{\ell-k_i} < 2^{\ell(1-1/u)+1} \le 2n^{1-1/u}$. □

3. Randomized complexity of SIMULTANEOUS MESSAGES. In this section, we give lower bounds on the randomized SM complexity of the function $\mathsf{GAF}_{G,k}$ (Theorem 3.3, Lemma 3.4). Up to a constant factor, the bounds match our lower bounds on deterministic SM complexity (Theorem 2.8, Lemma 2.16).

In a *randomized SM protocol* all the players and the referee are allowed to use coin flips.

We consider public coin protocols, i.e., protocols where the random strings used are visible to all parties, including the referee. This is clearly the strongest possible model in the sense that it can simulate at no extra cost the models which allow private or partially private (e.g., hidden from the referee) coins. Therefore any lower bound in the public coin model will automatically remain valid in models with private or partially private coins.

DEFINITION 3.1. *A randomized SM protocol P for a function f is said to have ϵ* advantage *$(0 \le \epsilon \le 1)$ if*

$$\text{for every input } x, \quad \Pr[P(x) = f(x)] - \Pr[P(x) \neq f(x)] \ge \epsilon, \tag{3.1}$$

where the probability is taken over the random choices of the players and the referee.

DEFINITION 3.2. *The* cost *of a randomized SM protocol is the maximum number of bits communicated by any player on any input and for any choice of the random bits. We define the* ϵ-randomized SM complexity of f*, denoted $R_0^\epsilon(f)$, as the minimum cost of a randomized SM protocol for f achieving an advantage $\ge \epsilon$.*

Note that a deterministic protocol has advantage $\epsilon = 1$, so $C_0(f) = R_0^1(f)$.

We also note, for future reference, that inequality (3.1) is equivalent to the following:

$$\Pr[P(x) = f(x)] \ge \frac{1+\epsilon}{2}. \tag{3.2}$$

The main result of this section is a lower bound on the randomized SM complexity of the $\mathsf{GAF}_{G,k}$ function, extending the deterministic lower bound of Theorem 2.8.

THEOREM 3.3. *For any finite group G, and $k \ge 2$,*

$$R_0^\epsilon(\mathsf{GAF}_{G,k}) = \Omega\left(\frac{|G|^{1/(k-1)}\,\epsilon^2}{k-1}\right).$$

This bound will follow from Lemma 3.4 below.

In this and later sections we will express our bounds in terms of the *binary entropy function* H defined as follows:

$$\mathrm{H}(x) := -x\log_2 x - (1-x)\log_2(1-x) \qquad (0 \le x \le 1). \tag{3.3}$$

Note that $\mathrm{H}(0) = \mathrm{H}(1) = 0$. The maximum of H is taken at $x = 1/2$, where $\mathrm{H}(1/2) = 1$.

LEMMA 3.4. *For any finite group G, $0 \le \epsilon \le 1$, and $0 \le \alpha \le 1$,*

$$R_0^\epsilon(\mathsf{GAF}_{G,k}) \ge \frac{\alpha|G|}{(k-1)\rho_\alpha(G,k-1)}(1 - \mathrm{H}(1/2 - \epsilon/2)).$$

This lemma extends the deterministic lower bound of Lemma 2.16. Its proof generalizes the strategy from the deterministic case. While we completely recover x_0 (restricted to the part of the group covered by the decomposition) from all the messages of the players in the proof of Lemma 2.16, here we will be able only to recover "most" bits of an "average" x_0. Lemma 3.7 provides a means to lower bound the amount of information from which such a reconstruction is possible and can be thought of as a generalization of Claim 2.18.

Our main result for this section (Theorem 3.3) is now immediate by combining Corollary 2.20 and Lemma 3.4 and using the following well-known estimate for the binary entropy function:

$$\text{For } |\delta| \le 1/2, \quad 1 - \frac{\pi^2}{3\ln 2}\,\delta^2 \;\le\; \mathrm{H}\left(\frac{1}{2} - \delta\right) \;\le\; 1 - \frac{2}{\ln 2}\,\delta^2. \qquad \square \tag{3.4}$$

Following Yao [Ya83], we prove our lower bound on randomized complexity (Lemma 3.4) via a lower bound on *distributional complexity*.

DEFINITION 3.5. *Given a Boolean function f, a probability distribution μ on its input space, and an ϵ, $0 \le \epsilon \le 1$, a* (μ,ϵ)-SM protocol *for f is a* deterministic *SM protocol P such that*

$$\Pr_{\mu}[P(x) = f(x)] - \Pr_{\mu}[P(x) \ne f(x)] \ge \epsilon,$$

where the probability is with respect to the distribution μ on the input space. We define the (μ,ϵ)-distributional complexity of f, *denoted $C_0^{\mu,\epsilon}(f)$, as the minimum cost of a (μ,ϵ)-SM protocol for f.*

Next we state Yao's key observation, which reduces the question of lower bounds on randomized complexity to lower bounds on distributional complexity with respect to any distribution on inputs.

THEOREM 3.6 (see [Ya83]). *For any function f and any $0 \le \epsilon \le 1$,*

$$R_0^{\epsilon}(f) = \max_{\mu}\; C_0^{\mu,\epsilon}(f).$$

The following lemma provides a tradeoff between the *average* Hamming distance travelled and the number of destinations reached by a transformation of the Boolean cube. The lemma may be of independent interest, in addition to being central to our proof of Lemma 3.4.

LEMMA 3.7 (distance-range tradeoff). *Let $\phi : \{0,1\}^m \longrightarrow \{0,1\}^m$ be a function with range R. Let $0 \le \delta \le 1/2$. Suppose the average Hamming distance between $X \in \{0,1\}^m$ and $\phi(X)$ is $\le \delta m$. Then*

$$|R| \ge 2^{(1-\mathrm{H}(\delta))m}. \tag{3.5}$$

Remark 3.8. Using a random cover of the Boolean cube by Hamming balls one can show that for $\delta < 1/2$, the lower bound (3.5) is optimal within a factor of $c_1(\delta)\sqrt{m}$.

Lemma 3.7 is an immediate consequence of Lemma 3.9 below. $\mathbb{H}(X)$ denotes the entropy of the random variable X. For the concept of entropy of random variables and related facts, we refer to the second edition of Alon and Spencer [AlS00, section 14.6].

LEMMA 3.9 (entropy loss lemma). *Let $\phi : \{0,1\}^m \longrightarrow \{0,1\}^m$. Let $X \in \{0,1\}^m$ be a random element of the domain chosen according to a probability distribution μ. Let $0 \le \delta \le 1/2$. Suppose that*

$$\mathbb{E}[\mathrm{dist}(X, \phi(X))] \le \delta m,$$

where $\mathrm{dist}(\cdot,\cdot)$ *refers to Hamming distance and $\mathbb{E}(\cdot)$ denotes the expected value. Then*

$$\mathbb{H}(X) - \mathbb{H}[\phi(X)] \le \mathrm{H}(\delta)m.$$

Note that if μ is the uniform distribution, then the conditions in Lemmas 3.7 and 3.9 become identical, and $\mathbb{H}(X) = m$. So the conclusion of Lemma 3.7 follows

from the known fact that for any random variable Y with range R, the entropy of Y is bounded by

$$\mathbb{H}[Y] \le \log_2 |R|. \tag{3.6}$$

This completes the proof of Lemma 3.7. □

For the proof of the entropy loss lemma we will use the following elementary facts from information theory [AlS00, section 14.6]:

- For any two random variables U and V,

$$\mathbb{H}[U,V] = \mathbb{H}[V] + \mathbb{H}[U|V]. \tag{3.7}$$

-

$$\mathbb{H}[U|V] \le \mathbb{H}[U]. \tag{3.8}$$

- If V is completely determined by U, then

$$\mathbb{H}[U,V] = \mathbb{H}[U]. \tag{3.9}$$

- Let $X = (X_1, \ldots, X_m)$. Then

$$\mathbb{H}[X] = \mathbb{H}[X_1, \ldots, X_m] \le \sum_{i=1}^{m} \mathbb{H}[X_i]. \tag{3.10}$$

- The binary entropy function H defined in (3.3) is *concave*:

$$\sum_i \alpha_i = 1, \quad 0 \le \alpha_i \le 1 \implies \sum_i \alpha_i \mathrm{H}(p_i) \le \mathrm{H}\left(\sum_i \alpha_i p_i\right). \tag{3.11}$$

Proof of the entropy loss lemma. Let $Y = \phi(X)$. Note that

$$\mathbb{H}[X] - \mathbb{H}[Y] = \mathbb{H}[X,Y] - \mathbb{H}[Y] = \mathbb{H}[X|Y], \tag{3.12}$$

where the first equality follows from (3.9), since Y is completely determined by X, and the second follows from (3.7). So the conclusion of Lemma 3.9 is equivalent to the inequality

$$\mathbb{H}[X|Y] \le m\mathrm{H}(\delta). \tag{3.13}$$

Let $X = (X_1, \ldots, X_m)$ and $Y = (Y_1, \ldots, Y_m)$. For $1 \le i \le m$, let Z_i denote the indicator random variable of the event $X_i \ne Y_i$, i.e.,

$$Z_i := \begin{cases} 1 & \text{if } X_i \ne Y_i, \\ 0 & \text{otherwise.} \end{cases}$$

Let $\delta_i := \Pr[Z_i = 1] = \mathbb{E}[Z_i]$. Then $\sum_i Z_i = \mathrm{dist}(X,Y)$. It follows that

$$\sum_{i=1}^{m} \delta_i = \sum_{i=1}^{m} \mathbb{E}[Z_i] = \mathbb{E}\left[\sum_{i=1}^{m} Z_i\right] = \mathbb{E}[\mathrm{dist}(X,Y)] \le \delta m. \tag{3.14}$$

Claim 3.10. *For $1 \le i \le m$, we have*

$$\mathbb{H}[X_i|Y] \le \mathrm{H}(\delta_i). \tag{3.15}$$

Assuming the validity of the claim, the following string of inequalities yields the bound (3.13):

$$\begin{aligned}
\mathbb{H}[X|Y] &\le \sum_{i=1}^{m} \mathbb{H}[X_i|Y] \qquad \text{using (3.10)} \\
&\le \sum_{i=1}^{m} \mathrm{H}(\delta_i) \qquad \text{by the claim} \\
&\le m\mathrm{H}\left(\frac{1}{m}\sum_{i=1}^{m}\delta_i\right) \qquad \text{by (3.11)} \\
&\le m\mathrm{H}(\delta) \qquad \text{since for } 0 \le x \le 1/2,\ \mathrm{H}(x) \text{ is increasing.}
\end{aligned}$$

Finally, we need to prove Claim 3.10. We use $a \oplus b$ to denote the mod 2 sum of a and b.

$$\begin{aligned}
\mathbb{H}[X_i|Y] &= \mathbb{H}[X_i \oplus Y_i|Y] \quad \text{since for any fixed } y,\ X_i \text{ and } X_i \oplus y_i \text{ have identical entropies} \\
&\le \mathbb{H}[X_i \oplus Y_i] = \mathbb{H}[Z_i] \quad \text{using (3.8) and the definition of } Z_i \\
&= \mathrm{H}(\delta_i) \quad \text{since } Z_i \text{ is a binary random variable with } \Pr[Z_i = 1] = \delta_i.
\end{aligned}$$

This completes the proof of the entropy loss lemma. □

Next we prove our main result.

Proof of Lemma 3.4. We will prove a lower bound on $C_0^{\mu,\epsilon}(\mathsf{GAF}_{G,k})$ for some distribution μ and apply Theorem 3.6.

Let G be a group of order n. Let $H_1, \ldots, H_{k-1}$ be an optimal collection of subsets of G from Definition 2.12, and let $K = H_1 \cdot \ldots \cdot H_{k-1}$. Let $C = H_1 \times \cdots \times H_{k-1}$. Note that $K \subseteq G$ and $C \subseteq G \times \cdots \times G$ ($(k-1)$ times). Note further that $|K| \le |C|$ and multiplication provides a natural onto map $C \to K$. Let $B \subseteq C$ be a set of representatives of the preimages under this map; so $|K| = |B|$, and each element of $g \in K$ can be uniquely factored as $g = h_1 \cdot \ldots \cdot h_{k-1}$, where $(h_1, \ldots, h_{k-1}) \in B$.

The distribution μ we will use is the uniform distribution on $\{0,1\}^K \times B$; i.e., player 0 will be given a uniformly chosen $x_0 : K \longrightarrow \{0,1\}$, and players 1 through $k-1$ will be given a uniformly chosen $(k-1)$-tuple from B. (Strictly speaking, x_0 will be taken from functions $G \longrightarrow \{0,1\}$ that are fixed to zero on $G \setminus K$.)

Given $x_0 \in \{0,1\}^K$, we define $w_{x_0} \in \{0,1\}^{\ell|\widehat{H}_1|} \times \cdots \times \{0,1\}^{\ell|\widehat{H}_{k-1}|}$ as before in the proof of Lemma 2.16 from the players' functions p_i for $1 \le i \le k-1$. The ℓ-bit segment $(w_{x_0})_{\widehat{h}_i}$ of w_{x_0} corresponding to $\widehat{h}_i \in \widehat{H}_i$ is defined as $(w_{x_0})_{\widehat{h}_i} = p_i(x_0, \widehat{h}_i)$. We again define a function F:

$$F : \{0,1\}^{\ell|\widehat{H}_1|} \times \cdots \times \{0,1\}^{\ell|\widehat{H}_{k-1}|} \longrightarrow \{0,1\}^K.$$

The function F is defined as in the proof of Lemma 2.16 from the referee's function r and player 0's function p_0. Specifically, for $g \in K$, let $(h_1, \ldots, h_{k-1}) \in B$ be the unique factorization of g in B. For $w \in \mathrm{domain}(F)$, we set

$$(F(w))(g) = r\left(p_0(h_1, \ldots, h_{k-1}), w_{\widehat{h}_1}, \ldots, w_{\widehat{h}_{k-1}}\right).$$

For $x_0 \in \{0,1\}^K$, define $y_0 := F(w_{x_0}) \in \{0,1\}^K$. We claim that the average Hamming distance between x_0 and y_0 (averaging over $x_0 \in \{0,1\}^K$) is at most $|K|(1-\epsilon)/2$.

Indeed, let us form a $\{0,1\}^K \times B$ $(0,1)$-matrix M as follows: $M(x_0,(h_1,\ldots,h_{k-1}))=1$ if and only if the protocol P makes an error when player 0 has x_0 on her forehead and player i for $1 \le i \le k-1$ has h_i on her forehead, i.e., $x_0(h_1 \cdot \ldots \cdot h_{k-1}) \neq r(p_0(h_1,\ldots,h_{k-1}),p_1(x_0,\widehat{h}_1),\ldots,p_{k-1}(x_0,\widehat{h}_{k-1}))$. By the definition of y_0, we have $M(x_0,(h_1,\ldots,h_{k-1}))=1$ if and only if $x_0(h_1 \cdot \ldots \cdot h_{k-1}) \neq y_0(h_1 \cdot \ldots \cdot h_{k-1})$. Moreover, since the protocol P has ϵ advantage, by inequality (3.2) it follows that the fraction of 1's in M is at most $(1-\epsilon)/2$. Hence the average distance between x_0 and y_0 is at most $|K|(1-\epsilon)/2$.

Now an application of the distance-range tradeoff lemma (Lemma 3.7) concludes the proof as follows. Let $m = |K| = \alpha|G|$. Define $\phi : \{0,1\}^m \to \{0,1\}^m$ by setting $\phi(x_0) = y_0 = F(w_{x_0})$. Let $\delta = (1-\epsilon)/2$. We have just verified the average-distance condition, so Lemma 3.7 implies that the range R of y_0 satisfies $\log|R| \ge |K|\mathrm{H}(1/2-\epsilon/2)$. On the other hand, the range of y_0 is not larger than the domain of F:

$$(k-1)\ell\rho_\alpha(G,k-1) \ge \log|R| \ge \alpha|G|(1-\mathrm{H}(1/2-\epsilon/2)),$$

and hence

$$C_0^{\mu,\epsilon}(\mathsf{GAF}_{G,k}) = \ell \ge \frac{\alpha|G|}{(k-1)\rho_\alpha(G,k-1)}\left(1-\mathrm{H}(1/2-\epsilon/2)\right).$$

This completes the proof of Lemma 3.4. □

This also completes the proof of the main results of this section. The rest of the section is devoted to a discussion of the need to use information theory (entropy) arguments and to clarifying the connections with the papers [BJKS02] and [BaKL95].

Remark 3.11. Our central "entropy" tool was Lemma 3.7; its proof was the only place where the concept of entropy was used. The question arises whether the use of entropy was necessary at all.

The key word in Lemma 3.7 is "average." If we impose the bound $\mathrm{dist}(X,\phi(X)) \le \delta m$ on *all* $X \in \{0,1\}^m$, then the conclusion will follow from a straightforward Hamming bound on coverings of the Boolean cube. Indeed, in this case the Hamming balls of radius δm about R would cover the entire Boolean cube; therefore

$$2^m \le |R| \sum_{k \le \delta m} \binom{m}{k} \le |R| 2^{m\mathrm{H}(\delta)}, \tag{3.16}$$

proving the desired inequality. In the last step we used the bound $\sum_{k\le\delta m}\binom{m}{k} \le 2^{m\mathrm{H}(\delta)}$, which is valid for all m and δ $(0 \le \delta \le 1/2)$ (see, e.g., [MacS77, p. 310]). (For $\delta < 1/2$ and large m, the bound can be improved by a factor of $\sim c(\delta)/\sqrt{m}$; cf. (5.1).)

More significantly, even if the condition is on *average* distance, the use of entropy can be avoided to obtain a slightly weaker result by a Markov inequality argument combined with the Hamming bound indicated above.

Indeed, under the conditions of Lemma 3.7 one can prove, without the use of entropies, the following lower bound on $|R|$ for any constant $c > 0$:

$$|R| \ge \frac{c}{\delta+c} 2^{(1-\mathrm{H}(\delta+c))m}. \tag{3.17}$$

To see (3.17), note that by Markov's inequality on nonnegative random variables, there exists a subset $S \subseteq \{0,1\}^m$ such that $|S| \ge 2^m c/(\delta+c)$ and for *all* $X \in S$,

$\mathrm{dist}(X, \phi(X)) \leq (\delta + c)m$. Now apply the Hamming bound argument as in (3.16) above to get a lower bound on $|\phi(S)|$, and hence on $|R|$.

Furthermore, an application of this weaker inequality would essentially suffice for a proof of the main result of this section, the lower bound for R_0^ϵ (Lemma 3.4).

To deduce a lower bound on R_0^ϵ from inequality (3.17), we can choose $c = \epsilon/4$ and note that (cf. proof of Lemma 3.4) $\delta = (1-\epsilon)/2$. This implies $c/(\delta + c) \geq \epsilon/2$ and leads to a bound only slightly weaker than Lemma 3.4:

$$R_0^\epsilon(\mathsf{GAF}_{G,k}) \geq \frac{\alpha|G|(1 - \mathrm{H}(1/2 - \epsilon/4)) + \log(\epsilon/2)}{(k-1)\rho_\alpha(G, k-1)}.$$

Using this inequality we obtain the lower bound

$$R_0^\epsilon(\mathsf{GAF}_{G,k}) = \Omega\left(\frac{|G|^{1/(k-1)}\ \epsilon^2 + \log\epsilon}{k-1}\right),$$

which is only slightly weaker than the lower bound on R_0^ϵ given in Theorem 3.3.

The conclusion is that, in essence, entropy arguments are not needed for the main results of this section. On the other hand, our simple and elegant entropy argument makes the conclusions also more elegant.

Remark 3.12. A key step in our entropy argument is Claim 3.10. We note that the claim is in fact "Fano's inequality" [CT91] for the special case of Boolean variables.

First, we state Fano's inequality on the prediction errors for Boolean variables.

PROPOSITION 3.13 (Fano's inequality for Boolean variables). *Let X be a Boolean random variable and Y a random variable over the domain S_Y. Let $g : S_Y \to \{0,1\}$ be a "prediction function" (given the value of $Y \in S_Y$, g guesses the value of X). Let δ be the "prediction error": $\delta = \Pr[g(Y) \neq X]$. Then $\mathbb{H}[X \mid Y] \leq \mathrm{H}(\delta)$.*

Claim 3.10 follows from Proposition 3.13 as follows.

For $1 \leq i \leq m$, let us define $g_i : \{0,1\}^m \to \{0,1\}$ by setting $g_i(Y) = Y_i$. Let us use g_i to predict X_i given Y. The prediction error is $\delta_i = \Pr[X_i \neq Y_i]$. Fano's inequality gives $\mathbb{H}[X_i|Y] \leq \mathrm{H}(\delta_i)$, which is exactly inequality (3.15), completing the proof of Claim 3.10. □

Conversely, our proof of Claim 3.10 in effect proves Proposition 3.13. Indeed, our proof of Claim 3.10 can be found in the last three lines of the proof of the entropy loss lemma above. To see how to adapt those three lines to prove Proposition 3.13, replace X_i by X, Y_i by $g(Y)$, Z_i by $Z := X \oplus g(Y)$, and δ_i by δ. This completes the proof of Fano's inequality. □

Remark 3.14. (comparison with [BJKS02] and [BaKL95]) Independent of our work, Bar-Yossef et al. [BJKS02] describe an information-theoretic approach to proving lower bounds on the distributional SM complexity of $\mathsf{GAF}_{G,k}$ analogous to our Lemma 3.4.

The [BJKS02] result differs from ours in their definition of the ρ parameter (based, apparently, on an optimistic interpretation of the ρ parameter defined in the original [BaKL95] paper).

The [BJKS02] definition of ρ assumes a decomposition of the *entire* group G as a product of *subgroups*. These assumptions apparently lead to large values of ρ and thus to poor estimates of the complexity. [BJKS02] make no attempt to estimate the value of their ρ parameter.

The [BaKL95] definition of ρ used *subsets* rather than subgroups of G as factors in the decomposition of the entire group G. It is shown in [BaKL95] that this approach gives a bound for every group of order n which is only slightly worse than the bound

obtained for the "nicest" groups (cyclic and elementary abelian groups), namely, by a factor of $O(\sqrt{\log n})$. A positive outcome of the "Modified Rohrbach Problem (section 7)" would eliminate this factor.

In the present paper we eliminate this factor in a different way, by bypassing the obstacle posed by the Rohrbach problem. In section 2.3 we have constructed optimal (up to a constant factor) decompositions of a *positive fraction* of G into a product of *subsets* (Theorem 2.19). This approach yields SM lower bounds for *all groups* that are within a constant factor of the results for the "nicest" groups.

The foregoing comments apply to the deterministic lower bound. The actual contribution of [BJKS02] is an information-theoretic argument to extend the proof of the deterministic lower bound to distributional complexity. Specifically, [BJKS02] uses "Fano's inequality for Boolean variables" on prediction errors in terms of conditional entropy (see above in Proposition 3.13).

The information-theoretic arguments presented in [BJKS02] remain valid in the context of the more general decompositions considered in our paper which correspond to the ρ_α parameter defined in Definition 2.12.

[BJKS02] use their entropy argument to prove their analogue of Lemma 3.4. Although our proof of Lemma 3.4 is also entropy-based, the two proofs look rather different. Our attempt to find the "common core" of the two proofs yielded only a modest result (see Remark 3.12).

4. Applications to lower bounds in circuit complexity. In this section, we derive some consequences of the SM lower bounds from section 2.2 to superpolynomial lower bounds on certain depth-2 circuits. These circuits are described by the following definition.

DEFINITION 4.1. *A* (SYM,AND)*-circuit is defined to be a depth-*2 *circuit with a symmetric gate at the top and AND gates at the bottom. (We draw circuits with the output at the top. Hence inputs to the bottom gates are input variables and their negations).*

We note that Beigel and Tarui [BeT91] reduce ACC circuits to (SYM,AND)-circuits of quasi-polynomial size with bottom fan-in polylog(n). We present below a lower bound of $\exp((\log n/\log\log n)^2)$ on the size of (SYM,AND)-circuits (of arbitrary bottom fan-in) computing some very weak functions. In fact, our lower bound applies to a function in ACC that contains $\mathsf{GAF}_{\mathbb{Z}_2^t,k}$ as a subfunction.

The following remarkable observation by Håstad and Goldmann relates multiparty communication complexity to certain depth-2 circuits.

LEMMA 4.2 (see [HG91]). *Suppose a function f is computed by a depth-*2 *circuit consisting of an arbitrary symmetric gate of fan-in s at the top and bottom gates computing* arbitrary functions of at most $k-1$ variables*. Then, for any partition of the input among the players, the k-party communication complexity of f is $O(k\log s)$.*

For completeness, we give a proof of Lemma 4.2.

Proof. Since each bottom gate of the circuit has fan-in at most $k-1$, there is at least one player who can evaluate that gate. Partition the bottom gates among the players such that all the gates assigned to a player can be evaluated by that player. Now each player broadcasts the number of her gates that evaluate to 1. This takes $O(\log s)$ bits per player since the top gate has fan-in at most s. Now one of the players can add up all the numbers broadcasted to compute the symmetric function given by the top gate and announce the value of the function. □

It is obvious that this proof works in the SM model as well: each player sends to the referee the number of gates evaluating to 1 among his gates, and the referee adds

these numbers to compute f. The SM complexity of the protocol is clearly $O(\log s)$. Hence, we get the following corollary.

COROLLARY 4.3. *Suppose a function f is computed by a depth-2 circuit consisting of an arbitrary symmetric gate of fan-in s at the top and bottom gates computing* arbitrary functions of at most $k-1$ variables. *Then, for any partition of the input among the players, the k-party SM complexity of f is $O(\log s)$.*

This observation, pointed out to us by Avi Wigderson, serves as the main motivation for considering SM complexity.

The next lemma uses the method of random restrictions [Aj83, FSS84] to reduce the fan-in of the bottom gates and at the same time to ensure that the "target function" (with high SM complexity) is computed by the restricted circuit. We note that a similar technique is used by Razborov and Wigderson [RaW93].

First, we introduce a definition.

DEFINITION 4.4. *Let $f(x_1,\ldots,x_v)$ be a Boolean function of v variables. Let $S_1,\ldots,S_v$ be disjoint sets of variables, where $|S_i| = b$ for all i. Then the* Parity_b $\mathsf{Blow\text{-}up}$ *of f is the function g on vb variables defined by*

$$g(y_1,\ldots,y_{vb}) = f(\oplus_{i\in S_1} y_i,\ldots,\oplus_{i\in S_v} y_i).$$

DEFINITION 4.5. *For a set X of Boolean variables a* restriction *ρ is defined to be a mapping $\rho : X \longrightarrow \{0,1,*\}$. We interpret a variable assigned a $*$ to be "free," i.e., not fixed to a constant. Given a function f on X, its restriction $f_{|\rho}$ is the induced function on variables assigned a $*$ by ρ obtained by evaluating f when the nonfree variables are fixed according to ρ. For a circuit C, its restriction $C_{|\rho}$ is the circuit (with variables from $\rho^{-1}(*)$) obtained by fixing the variables of C assigned 0 or 1 by ρ and simplifying wherever possible.*

LEMMA 4.6. *Let g be the* Parity_b $\mathsf{Blow\text{-}up}$ *of f. Let ℓ be a parameter satisfying $\ell \le \log b - \log\ln v + 1$, and let $0 < c < 1$ be a constant. Suppose that g is computed by a circuit C consisting of at most $2^{c\cdot\ell^2}$ AND gates at the bottom. Then there is a restriction ρ such that*

- *all AND gates at the bottom level of $C_{|\rho}$ have fan-in at most ℓ,*
- *$C_{|\rho}$ has v input variables, exactly one from each block S_i, and*
- *$C_{|\rho}$ computes f.*

Proof. We define ρ in two stages. First, we obtain a random restriction ρ_1 that reduces the fan-in of each bottom AND gate to at most ℓ and keeps alive at least two variables from each block S_i. We prove the existence of ρ_1 below. Second, we define ρ_2 by assigning values to all but one of the variables from each S_i left alive by ρ_1 so that we are left with exactly one *unnegated* variable from each S_i; i.e., $\rho_2(\rho_1(\oplus_{j\in S_i} y_j)) = y_{i'}$ for some $y_{i'} \in S_i$. The desired restriction ρ is the composition of ρ_1 and ρ_2. Moreover, by the definition of g, the restricted circuit computes $f(y_{1'},\ldots,y_{v'})$.

Let $p := (2\ln v)/b$. Note that $p \le 2^{-\ell}$. We choose ρ_1 by independently assigning to each variable a $*$ (to keep it alive) with probability p and a 0 or 1, each with probability $(1-p)/2$. Let γ be a bottom level AND gate of C, and let m be the fan-in of γ.

First consider the case when $m \le \ell^2$. Without loss of generality, $m \ge \ell$. Then

$$\begin{aligned}\Pr[\gamma_{|\rho_1} \text{ has fan-in } > \ell] &\le \sum_{i>\ell} \binom{m}{i} p^i \left(\frac{1-p}{2}\right)^{m-i} \\ &\le (1+o(1))\binom{m}{\ell} p^\ell \left(\frac{1-p}{2}\right)^{m-\ell} \qquad \text{since } \ell \gg mp\end{aligned}$$

$$\leq (1+o(1))(pe\ell)^{\ell} \quad \text{since } m \leq l^2$$
$$\leq 2^{-\ell^2\cdot(1-o(1))} \quad \text{since } p \leq 2^{-\ell}.$$

Next consider the case when $m > \ell^2$. Then

$$\Pr[\gamma_{|\rho_1} \text{ has fan-in } > \ell] \leq \Pr[\gamma_{|\rho_1} \not\equiv 0] \leq \left(\frac{1+p}{2}\right)^m$$
$$\leq 2^{-\ell^2\cdot(1-o(1))} \quad \text{since } m > \ell^2 \text{ and } p \leq 2^{-\ell}.$$

Since C has at most $2^{c\cdot\ell^2}$ AND gates at the bottom (where $c < 1$ is a constant), from the preceding two cases it follows that

$$\Pr[\text{ some bottom AND gate of } C_{|\rho_1} \text{ has fan-in} > l] = o(1). \tag{4.1}$$

Moreover, for a fixed i, $1 \leq i \leq v$, we have

$$\Pr[\rho_1(S_i) \text{ has} < 2 *\text{'s}] = (1-p)^b + bp(1-p)^{b-1}$$
$$\leq e^{-pb}(1+bp/(1-p))$$
$$\leq O(\log v/v^2) \quad \text{since } p \geq 2\ln v/b.$$

Hence, we also have

$$\Pr[\ \rho_1 \text{ assigns fewer than 2 } *\text{'s to some block } S_i\ ] = o(1). \tag{4.2}$$

From (4.1) and (4.2), we see that with high probability all bottom AND gates of $C_{|\rho_1}$ have fan-in at most ℓ, and, furthermore, the inputs of $C_{|\rho_1}$ will have at least two variables from each block S_i. Hence such a restriction ρ_1 exists.

By composing ρ_1 with an additional restriction ρ_2 as described in the beginning of the proof, we complete the proof of the lemma. □

THEOREM 4.7. *Suppose an n variable function f has k-party SM complexity at least $c_0(n,k)$ for some partition of the input among the players. Then any* (SYM,AND)*-circuit computing the* Parity_n $\mathsf{Blow\text{-}up}$ *of f must have size at least* $\min\{\exp(k^2), \exp(c_0(n,k))\}$.

Proof. Let g denote the Parity_n $\mathsf{Blow\text{-}up}$ of f, and let C be a minimal size (SYM,AND)-circuit computing g. If C has size $> 2^{(k-1)^2}$, we are done.

Therefore, suppose size of C is $\leq 2^{(k-1)^2}$. We apply Lemma 4.6 to obtain a restriction ρ such that bottom gates of $C_{|\rho}$ have fan-in at most $k-1$ and $C_{|\rho}$ computes f.

Now applying Corollary 4.3, we see that the size of $C_{|\rho}$ must be exponential in the SM complexity $c_0(n,k)$ of f. Hence C itself must have size $\geq \exp(c_0(n,k))$. □

Using our lower bound on SM complexity from section 2 we immediately get the following corollary.

COROLLARY 4.8. *Let G be any group of order n, and let $k = \epsilon \log n/\log\log n$ for a sufficiently small constant $\epsilon > 0$. Then any* (SYM,AND)*-circuit computing the* Parity_n $\mathsf{Blow\text{-}up}$ *of* $\mathsf{GAF}_{G,k}$ *must have size* $\exp((\log n/\log\log n)^2)$.

Proof. From Theorem 2.8, we have that for $c_0(n,k) := C_0(\mathsf{GAF}_{G,k}) = \Omega(n^{1/(k-1)}/(k-1))$. Hence, if $k \leq \epsilon \log n/\log\log n$ for sufficiently small $\epsilon > 0$, $c_0(n,k) \geq k^2$. Now we get the claimed bound from Theorem 4.7. □

5. A Simultaneous Messages protocol for $\mathsf{GAF}_{\mathbb{Z}_2^t,k}$. In this section we give a nontrivial protocol for $\mathsf{GAF}_{G,k}$ for $G = \mathbb{Z}_2^t$. Our protocol yields an upper bound of about $n^{(\log k)/k}$, where $n = 2^t$ (see Theorem 5.5). In particular, for three players we obtain a nontrivial $O(n^{0.92})$ upper bound (see Theorem 5.3). These upper bounds have been subsequently improved in [AmL00], giving in particular an upper bound of $O(n^{0.73})$ for three players. These upper bounds should be compared with our lower bound of $\Omega(n^{1/(k-1)}/(k-1))$ (Theorem 2.8).

It is curious to remark that, in contrast to the lower bound, our protocol heavily depends on the specific structure of this group. In particular, it does not apply to the cyclic group $G = \mathbb{Z}_n$. For cyclic groups, Pudlák, Rödl, and Sgall [PRS97] give upper bounds of $O(n(\log\log n/\log n)^k)$, for constant k, and $O(n^{6/7})$ for $k \geq c\log n$ for some constant c. These upper bounds have been significantly improved by Ambainis [Am96] to $O(\frac{n\log^{1/4} n}{2^{\sqrt{\log n}}})$ for $k = 3$ and to $O(n^\epsilon)$ for an arbitrary $\epsilon > 0$ for $k = O((\log n)^{c(\epsilon)})$. However, the bounds for $\mathbb{Z}_n$ are still much weaker than the corresponding bounds for $\mathbb{Z}_2^t$ presented in this paper.

We will think of the n-bit string A held by p_0 (previously denoted x_0) as a Boolean function on $t := \log n$ variables $z_1, \ldots, z_t$, i.e., $A : \{0,1\}^t \longrightarrow \{0,1\}$. For $1 \leq i \leq k-1$, let x_i be the t-bit string held by player p_i. Then we have

$$\mathsf{GAF}_{\mathbb{Z}_2^t,k}(A, x_1, \ldots, x_{k-1}) = A(x_1 + \cdots + x_{k-1}),$$

where "+" denotes addition in $\mathbb{Z}_2^t$.

5.1. Three players. We will first describe the protocol for three players. The idea extends naturally to the general case. For simplicity of notation, let p_1 hold x and p_2 hold y. At the cost of $2t$ bits, p_0 sends the strings x and y to the referee. Since this communication will be insignificant, we can henceforth ignore p_0 and assume that the referee knows x and y (but not A). Then we want to minimize the number of bits sent by p_1 and p_2 that will enable the referee to compute $A(x+y)$.

The protocol will be based on the fact that the Boolean function A can be represented as a multilinear polynomial of (total) degree at most t. In fact, the following lemma is the crucial observation in the protocol. We use the notation

$$\Lambda(m,b) = \sum_{j=0}^{b} \binom{m}{j}$$

and the fact that for fixed δ, $0 < \delta < 1/2$,

$$\Lambda(m, \delta m) \sim c(\delta) 2^{m\mathrm{H}(\delta)}/\sqrt{m}. \tag{5.1}$$

Lemma 5.1. *Given the promise that A is a multilinear polynomial of degree d over $\mathbb{Z}_2$, $x, y \in \mathbb{Z}_2^t$, $\mathsf{GAF}_{\mathbb{Z}_2^t,3}(A,x,y)$ has an SM protocol with cost $\Lambda(t, \lfloor d/2 \rfloor)$.*

Proof. Let A be given by $A(z) = \sum_{S\subseteq[t],\,|S|\leq d} a_S Z_S$, where Z_S denotes the monomial $\prod_{i\in S} z_i$. Thus,

$$A(x+y) = \sum_{|S|\leq d} a_S \prod_{i\in S}(x_i + y_i) = \sum_{|S|\leq d} a_S \sum_{T_1 \dot\cup T_2 = S} X_{T_1} Y_{T_2},$$

where $X_{T_1} := \prod_{i\in T_1} x_i$ and $Y_{T_2} := \prod_{i\in T_2} y_i$.

We can rewrite this as follows:

$$A(x+y) = \sum_{|T_1|\le\lfloor d/2\rfloor} \left(\sum_{|T_1\dot\cup T_2|\le d} a_{T_1\dot\cup T_2}\, Y_{T_2} \right) \cdot X_{T_1} + \sum_{|T_2|\le\lfloor d/2\rfloor} \left(\sum_{|T_1\dot\cup T_2|\le d} a_{T_1\dot\cup T_2}\, X_{T_1} \right) \cdot Y_{T_2},$$

where T_1 and T_2 are disjoint subsets of $[t]$, and we assume without loss of generality that terms $a_{T_1\dot\cup T_2}\, X_{T_1}\, Y_{T_2}$ with both $|T_1|$ and $|T_2|$ less than or equal to $\lfloor d/2\rfloor$ are placed in the first sum.

We now observe that the first sum in the last equation is a polynomial in x whose coefficients (which depend only on $a_{T_1\dot\cup T_2}\, Y_{T_2}$) are known to p_1. Similarly, the second sum is a polynomial in y whose coefficients are known to p_2. The degree of both polynomials is bounded by $\lfloor d/2\rfloor$. Hence, using at most $\Lambda(t, \lfloor d/2\rfloor)$ bits, each player can communicate the coefficients of their corresponding polynomial to the referee. Since the referee already knows x and y, he can evaluate the two polynomials and add them up to announce the value of $A(x+y)$. Since p_0 used only $2t$ bits to send x and y to the referee, the cost of the protocol is simply $\Lambda(t, \lfloor d/2\rfloor)$. □

Remark 5.2. For small enough d, the protocol is a quadratic improvement over the trivial one where the entire function A is communicated to the referee.

Suppose now that A is an arbitrary Boolean function. We will use Lemma 5.1 on the low-degree part of A and the trivial protocol on the high-degree part. Since there are not too many high-degree terms, we will be able to keep the communication within n^c for some $c < 1$.

THEOREM 5.3. $C_0(\mathsf{GAF}_{\mathbb{Z}_2^t,3}) = o(n^{0.92})$.

Proof. Let $A : \mathbb{Z}_2^t \longrightarrow \{0,1\}$ and $x, y \in \mathbb{Z}_2^t$ be the inputs on the foreheads of players 0, 1, and 2, respectively. Write A as a multilinear polynomial over $\mathbb{Z}_2$ of degree at most t: $A(z) = \sum_{S\subseteq[t]} a_S\, Z_S$. Define A' to be the part of A corresponding to degree less than or equal to $2t/3$, and let A'' be the remaining part of A. That is,

$$A(z) = \sum_{|S|\le 2t/3} a_S\, Z_S \;+\; \sum_{|S|>2t/3} a_S\, Z_S = A'(z) + A''(z).$$

Players p_1 and p_2 use the protocol of Lemma 5.1 on A'. They just send the high-degree terms a_S for $|S| > 2t/3$ directly to the referee (each sends half of them). The number of bits used by each of p_1 and p_2 is at most

$$\Lambda(t, t/3) + \frac{1}{2} \sum_{j>2t/3} \binom{t}{j} \le \frac{3}{2}\Lambda(t, t/3) \le O(2^{t\,\mathrm{H}(1/3)}/\sqrt{t}),$$

using the estimate (5.1). Since p_0 sends fewer bits than p_1 or p_2 (p_0 sends only $2t$ bits), the protocol has cost $O(n^{\mathrm{H}(1/3)}/\sqrt{\log n})$. As $\mathrm{H}(1/3) = 0.91829\ldots$, the theorem follows. □

5.2. *k* players. We generalize the idea from the preceding section to k players. An extension of Lemma 5.1 follows.

LEMMA 5.4. *Given the promise that A is a t-variable multilinear polynomial of degree d over $\mathbb{Z}_2$, and for $1 \le i \le k-1$, $x_i \in \mathbb{Z}_2^t$, $\mathsf{GAF}_{\mathbb{Z}_2^t,k}(A, x_1, \ldots, x_{k-1})$ has an SM protocol with cost at most $\Lambda(t, \lfloor d/(k-1)\rfloor) + t$.*

Proof. In the 3-player protocol, player p_0 passes the two short inputs. In the k-player protocol, the task of passing the short inputs $x_1, \ldots, x_{k-1}$ will be divided

among players p_1 through p_{k-1}, and p_0 will remain silent. This avoids having one player (p_0) communicate too many bits in case k is large.

Letting $A(z) = \sum_{S\subseteq[t],\,|S|\le d} a_S\, Z_S$, we have

$$\begin{aligned} A(x_1 + \cdots + x_{k-1}) &= \sum_{|S|\le d} a_S \prod_{j\in S} (x_{1,j} + \cdots + x_{k-1,j}) \\ &= \sum_{|S|\le d} a_S \sum_{T_1 \dot\cup \cdots \dot\cup T_{k-1} = S} X_{1,T_1} \cdots X_{k-1,T_{k-1}}, \\ &\qquad\qquad \text{where } X_{i,T_i} = \prod_{j\in T_i} x_{ij}. \end{aligned}$$

Let us consider a monomial $a_S\, Z_S$. Since the T_i are disjoint, $\sum_{i=1}^{k-1} |T_i| = |S| \le d$, and hence the smallest T_i is of size at most $\lfloor d/(k-1)\rfloor$. Thus in the expansion

$$\sum_{T_1 \dot\cup \cdots \dot\cup T_{k-1} = S} a_S\, X_{1,T_1} \cdots X_{k-1,T_{k-1}},$$

each term can be "owned" by a player p_i such that T_i is the smallest set in that term. (In case of ties, take the smallest such i.) As a result, the value of this monomial on $x_1 + \cdots + x_{k-1}$ can be distributed among the k players by giving them each a polynomial of degree at most $\lfloor |S|/(k-1)\rfloor$.

The proof follows by linearity and proceeds similarly to that of Lemma 5.1. We conclude that for $1 \le i \le k-1$, player p_i needs to send $\Lambda(t, \lfloor d/(k-1)\rfloor)$ bits for the terms they own and t bits to send x_{i+1} (player p_{k-1} sends x_1). □

THEOREM 5.5. $C_0(\mathsf{GAF}_{\mathbb{Z}_2^t,k}) \le \frac{k}{k-1}\Lambda(t, \lfloor t/k\rfloor) + t$.

Proof. Let $A : \mathbb{Z}_2^t \longrightarrow \{0,1\}$ be player 0's input, and let $x_i \in \mathbb{Z}_2^t$ be player i's input for $1 \le i \le k-1$. The proof is similar to the proof of Theorem 5.3: separate the low-degree and high-degree parts of A as follows. Monomials of A of degree higher than $t(1-1/k)$ are sent directly to the referee. (For simplicity, we ignore floors and ceilings in this proof.) By dividing these high-degree monomials equally among the $k-1$ players, we see that each player sends at most $\frac{1}{k-1}\sum_{t(1-1/k)\le i\le t} \binom{t}{i} = \Lambda(t, t/k)/(k-1)$ bits. The remaining low-degree part of A has degree at most $t(1-1/k)$. Applying Lemma 5.4 with $d = t(1-1/k)$, each player sends at most $\Lambda(t, t/k) + t$ bits to handle the low-degree part and to transmit x_{i+1} (player p_{k-1} transmits x_1). Adding up, we get that each player sends at most $\frac{k}{k-1}\Lambda(t, t/k) + t$ bits to the referee. □

COROLLARY 5.6. *For* $3 \le k \le \log n$, $C_0(\mathsf{GAF}_{\mathbb{Z}_2^t,k}) \le n^{O((\log k)/k)} + \log n$.

Proof. Use estimate (5.1) and note that, for $k \ge 3$, $\mathrm{H}(1/k) \le \log(ek)/k$. □

Remark 5.7. It follows that if $k \ge c \log n$ for any constant $c > 0$, then each player sends at most polylog(n) bits to the referee. Moreover, it is easy to see from the proof of Lemma 5.4 that if $k = \log n + 1$, each player sends at most $2 + \log n$ bits and if $k > \log n + 1$, each player needs to send only at most $1 + \log n$ bits.

6. SM upper bounds for other functions. In this section, we give nontrivial upper bounds on the SM complexity of a class of functions defined by certain depth-2 circuits and for a partition of the input variables in which each of the k players misses one input bit from each bottom gate. The n bottom gates are identical with fan-in k and compute certain symmetric functions called symmetric *compressible* functions (see Definition 6.1). The top gate is an arbitrary symmetric gate. We call this class of communication problems the SYMCOM(n,k) problems (see Definition 6.7). It

includes, for example, Majority of Majorities, Generalized Inner Product, and Parity of Thresholds.

We start by defining the functions that are allowed on the bottom level, i.e., the *compressible* functions. Let $X = \{x_1, \ldots, x_k\}$ be a set of Boolean variables and $f(x_1, \ldots, x_k)$ a Boolean function. Alice sees a subset $A \subseteq X$ of the variables, and Bob sees the remaining set $B = X \setminus A$. Consider the one-way communication model where Alice sends a message to Bob, and Bob must deduce the value of f from Alice's message and the part of the input he sees. For a given partition of the set of variables $A \dot\cup B = X$, we denote by $C_{A\to B}(f)$ the minimum number of bits that Alice must send.

DEFINITION 6.1. *A class of Boolean functions $\mathcal{F}$ is called* compressible *if for any partition $A, B \neq \emptyset$, $A \dot\cup B = X$, and any $f \in \mathcal{F}$ we have $C_{A\to B}(f) = O(\log |B|)$.*

Remark 6.2. We refer to a function f as a compressible function if it belongs to a compressible class of functions. The constant implied by the O notation may depend on the class but not on the particular function.

We shall be interested only in compressible *symmetric* functions. Note that in this case, it is clear that $C_{A\to B} \leq \log(|A| + 1)$. The point of our definition is that we require $C_{A\to B} \leq \log |B|$ even when $|B|$ is very small compared to $|A|$. Indeed, we shall use this property for $|B| = \Theta(\log k)$.

EXAMPLE 6.3. *The following Boolean functions are compressible:*

1. $\mathsf{Parity}(x_1, \ldots, x_k) = x_1 \oplus \cdots \oplus x_k$.
2. $\mathsf{Mod}_{m,T}(x_1, \ldots, x_k) = 1$ *if and only if* $\sum_{i=1}^k x_i \in T \pmod m$.
3. $\mathsf{Th}_t^k(x_1, \ldots, x_k) = 1$ *if and only if* $\sum_{i=1}^k x_i \geq t$.

Remark 6.4. We will give an example of a function which is not compressible in section 6.1 below (see Definition 6.12 and Corollary 6.15).

PROPOSITION 6.5. *For every partition $A \dot\cup B = X = \{x_1, \ldots x_k\}$ $(A, B \neq \emptyset)$ we have the following:*

1. $C_{A\to B}(\mathsf{Parity}) \leq 1$.
2. $C_{A\to B}(\mathsf{Mod}_{m,T}) \leq \lceil \log m \rceil$.
3. $C_{A\to B}(\mathsf{Th}_t^k) \leq \lceil \log(|B| + 2) \rceil$.

Proof. The statements about the Parity and Mod_m functions are trivial. We prove the statement of the proposition for threshold functions. Let $A, B \neq \emptyset$, $A \dot\cup B = X = \{x_1, \ldots, x_k\}$ be some partition of the input variables. Let ℓ be the number of 1's in part A. If $\ell < t - |B|$, the value of Th_t^k must be 0, and if $\ell \geq t$ the result must be 1, regardless of part B of the input. For $\ell = t - i$, $i = 1, \ldots, |B|$, the value of the function depends on part $|B|$. Therefore, for Bob to compute the value of f, it is enough for Alice to send one of $|B| + 2$ messages to Bob: one for the case where $\ell < t - |B|$, one for the case where $\ell \geq t$, and one for each value of ℓ from $t - |B|$ to $t - 1$. This requires only $\lceil \log(|B| + 2) \rceil$ bits. □

Let $f : \{0,1\}^k \to \{0,1\}$ and $g : \{0,1\}^n \to \{0,1\}$ be Boolean functions. Consider the following depth-2 circuit. The first level has n f-gates whose inputs are disjoint, so there are nk input bits to the circuit. The second level consists of a g-gate which takes the outputs of the f-gates as its n inputs. We denote the function computed by this circuit by $g \circ f$ (see Figure 6.1).

DEFINITION 6.6. *We define the* (g, f)-communication problem *as the problem of k players computing $g \circ f$, where k is the same number as the fan-in of the f-gates, and the input variables are partitioned among the k players so that the jth player misses the jth input bit of each f-gate.*

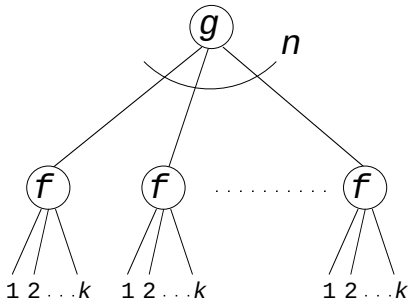

FIG. 6.1. *The depth-2 circuit defining $g \circ f$.*

DEFINITION 6.7. *We call the (g, f)-communication problem a* SYMCOM(n, k) PROBLEM *if the function g is symmetric and the function f is compressible and symmetric.*

Remark 6.8. Observe that the AND function is compressible (cf. Proposition 6.5(3)). Hence the circuits used to define a SYMCOM(n, k) communication problem above are somewhat similar to the (SYM,AND)-circuits defined in section 4. However, there are some crucial differences. First, inputs to distinct bottom gates of circuits in this section (Figure 6.1) are required to be *disjoint*, whereas no such restriction is imposed in (SYM,AND)-circuits. Second, the number of players in this section is *equal* to the bottom fan-in of the circuits, and this is not necessarily true of (SYM,AND)-circuits.

In Theorem 6.11, we will show that there are efficient SM protocols for SYMCOM(n, k) problems for $k > 1 + \log n$ players. First, we need two lemmas.

LEMMA 6.9. *Let t and n be positive integers such that $t > 1 + \log n$. Let $b_0, \ldots, b_{t-1}$ be integers. Consider the following system of t equations in $t + 1$ unknowns:*

$$(t-i)y_i + (i+1)y_{i+1} = b_i, \quad i = 0, 1, \ldots, t-1. \tag{6.1}$$

Assume further that

$$y_i \geq 0, \quad i = 0, 1, \ldots, t; \quad \sum_{i=0}^{t} y_i \leq n. \tag{6.2}$$

Then, under constraints (6.2)*, the system of equations* (6.1) *has at most one integral solution.*

Proof. Let $y = (y_0, \ldots, y_t)$ and $y' = (y'_0, \ldots, y'_t)$ be two solutions of (6.1), each consisting of nonnegative integers whose sum is at most n. For $i = 0, 1, \ldots, t$, let $d_i = y_i - y'_i$. Since $y \neq y'$, we know there exists at least one $d_i \neq 0$.

From (6.1), we obtain the following equations:

$$(t-i)d_i + (i+1)d_{i+1} = 0, \quad i = 0, 1, \ldots, t-1. \tag{6.3}$$

From the $i = 0$ equation, we can express d_1 in terms of d_0: $d_1 = -td_0 = -\binom{t}{1}d_0$. From this and the $i = 1$ equation, we get

$$d_2 = \frac{-(t-1)}{2}d_1 = \frac{(t-1)t}{2}d_0 = \binom{t}{2}d_0.$$

Continuing in this way, we see that for $i = 0$ to t, $d_i = (-1)^i\binom{t}{i}d_0$. Since some d_i is not 0, we know that $d_0 \neq 0$. Furthermore, since the d_i are integers, we know that $|d_0| \geq 1$, and thus $|d_i| \geq \binom{t}{i}$. We also note that since $y_i, y_i' \geq 0$, we have

$$y_i + y_i' \geq |y_i - y_i'| = |d_i|.$$

Now we use the fact that the sum of the y_i and the sum of the y_i' are both at most n to derive a contradiction and complete the proof:

$$2n \geq \sum_{i=0}^{t}(y_i + y_i') \geq \sum_{i=0}^{t}|d_i| \geq \sum_{i=0}^{t}\binom{t}{i} = 2^t > 2^{1+\log n} = 2n. \qquad \square$$

LEMMA 6.10. *Let n be a positive integer, and let M be a $t \times m$ $(0,1)$-matrix, with $m \leq n$ and $t = \lceil \log n \rceil + 2$. For $i = 0, 1, \ldots, t$, let y_i be the number of columns of M with i ones. For $j = 1, \ldots, t$, let player j see all of M except row j. Then there exists an SM protocol in which each player sends $O(\log^2 n)$ bits to the referee, after which the referee can calculate $y_0, \ldots, y_t$.*

Proof. For $j = 1, \ldots, t$, player j sends $(a_j(0), a_j(1), \ldots, a_j(t-1))$ to the referee, where $a_j(i)$ is the number of columns player j sees with i ones. Note that each player sees only $t - 1$ of the rows and thus cannot see t ones in any column. For $i = 0, 1, \ldots, t-1$, the referee computes $b_i := \sum_{j=1}^{t} a_j(i)$.

We observe that $y_0, \ldots, y_t$ are nonnegative integers whose sum is $m \leq n$ and that for the b_i defined above they satisfy the system of equations (6.1). Thus, by Lemma 6.9, there is no other such solution. The referee, being arbitrarily powerful, can thus compute $y_0, \ldots, y_t$.

How many bits does each player send? Clearly, each $a_j(i) \leq n$, so each $a_j(i)$ can be communicated with $\lceil \log n \rceil$ bits. Since each player communicates $t = 1 + \lceil \log(n+1) \rceil$ such numbers to the referee, the complexity of this SM protocol is $O(\log^2 n)$ as desired. $\square$

We now state the theorem regarding SM protocols for SYMCOM functions.

THEOREM 6.11. *If (g, f) is a SYMCOM(n, k) problem and $k > 1 + \log n$, then $C_0(g \circ f) \leq \text{polylog}(n)$.*

Proof. Arrange the nk input bits of $g \circ f$ in a $k \times n$ matrix M such that player i knows all of M except the ith row. Each column of M contains the k input bits of a given f-gate. Let $t = \lceil \log n \rceil + 2$. The first t players will be the only ones who speak, so we call them the *active players*. We also call their rows and the entries in those rows *active*. The remaining players, rows, and entries are called *passive*.

Consider a single column $v \in \{0,1\}^k$ of M. Since f is compressible, there is a one-way 2-party protocol P for Alice and Bob, where Alice sees the passive entries of v and Bob sees the active entries of v, such that Alice sends Bob $O(\log t) = O(\log \log n)$ bits. Note that since f is symmetric, the only thing that Bob needs to know about the input he sees is how many ones there are. Thus, the value of $f(v)$ is determined by the message Alice sends on v and the number of ones among v's active entries.

For every column v of M, the t active players see all of the passive entries of v and thus know what message Alice would send under P upon seeing v. Let $c > 0$ be such that Alice sends at most $c \log \log n$ bits, and hence at most $r = \log^c n$ possible messages. Let $m_1, \ldots, m_r$ be the possible messages Alice can send under P.

From M, the active players form r new matrices $M_1, \ldots, M_r$, where M_i consists of the columns of M for which Alice sends Bob message m_i under protocol P. For each j, $1 \leq j \leq r$, the t players and the referee execute the protocol of Lemma 6.10

on the submatrix of M_j consisting of the active rows. Thus the referee can deduce, for each i, $0 \le i \le t$, the number of columns of M_j which have i ones among their active entries. From this and the fact that under P Alice would send message m_j for every column of M_j, the referee can deduce the number of columns v of M_j for which $f(v) = 1$. By summing over all j, the referee calculates the total number of f-gates that evaluate to 1, which suffices to evaluate $g \circ f$, as g is symmetric.

The cost of this protocol is $r \cdot O(\log^2 n) = O(\log^{c+2} n)$. □

6.1. A function which is not compressible. It is easy to check that a random symmetric function is incompressible. In this subsection we give an example of an explicit symmetric function which is not compressible (see Definition 6.1).

DEFINITION 6.12. *For an odd prime p, we define the function "quadratic character of the sum of the bits"* $\mathsf{QCSB}_p : \{0,1\}^p \to \{0,1\}$ *by* $\mathsf{QCSB}_p(x_1, \ldots, x_p) = 1$ *if and only if $x_1 + \cdots + x_p$ is a quadratic residue mod p, where the x_i are single bits. Recall that $y \neq 0$ is a quadratic residue mod p if y is a square mod p.*

Let p be an odd prime, and let $r = \lfloor (\frac{1}{2} - c_1) \log p \rfloor$, for any constant c_1, $0 < c_1 < \frac{1}{2}$. Let M be the $(r+1) \times (p+1)$ ± 1-matrix defined by $M(i,j) = 1$ if and only if $i + j$ is a quadratic residue mod p and -1 otherwise for $0 \le i \le r$, $0 \le j \le p$.

LEMMA 6.13. *For any $y \in \{-1,1\}^{r+1}$, the number of columns of M identical to y is $O(p/2^r)$.*

Proof. This is an immediate consequence of André Weil's character sum estimates (cf. [Sch76]; see also [Bo85, pp. 311, 319]): Let q be an odd prime power, and let U_0, U_1 be disjoint subsets of $\mathbb{F}_q$. For x, y in $\mathbb{F}_q$, let $\chi(x) = 1$ if $x \neq 0$ is a square in $\mathbb{F}_q$, 0 if $x = 0$, and -1 otherwise. Let

$$S = \{x \in \mathbb{F}_q \mid \text{for } i = 0, 1, (\forall u \in U_i)(\chi(x - u_i) = (-1)^i)\}.$$

Let $m = |U_0 \cup U_1|$, and let $s = |S|$. Then

$$|s - 2^{-m} q| \le m\sqrt{q}. \tag{6.4}$$

Let $q := p$. Let $y = (y_0, y_1, \ldots, y_r) \in \{-1,1\}^{r+1}$. Let $U_0 = \{p - i : 0 \le i \le r,\ y_i = 1\}$. Let $U_1 = \{p - i : 0 \le i \le r,\ y_i = -1\}$. Clearly, column j of M is identical to y exactly if $j \in S$. Setting $m := |U_0 \cup U_1| = r + 1$ gives us

$$s \le p/2^{r+1} + (r+1)\sqrt{p} = O(p/2^r). \qquad \square$$

THEOREM 6.14. *Let p and r be as above, and let b be an integer $r < b < (1 - c_2)p$, for any constant c_2. For any 2-party one-way (Alice to Bob) protocol for* QCSB_p*, if Bob sees b of the p input bits and Alice sees the other $a = p - b$ bits, then Alice must send Bob $r - O(1)$ bits.*

Proof. Assume that there is such a one-way protocol P. We set $b - r$ of Bob's bits to 0 and tell both players this. This is extra information, so P will still work for this restricted problem.

This new communication problem can be represented by the $(r+1) \times (a+1)$ ± 1-matrix M', obtained by deleting the last b columns of M. The rows represent the number of ones that Bob sees, and the columns represent the number of ones Alice sees. From Lemma 6.13, we know that every $y \in \{-1,1\}^{r+1}$ occurs in M and thus in M' at most $O(p/2^r)$ times. Since there are $p - b = \Omega(p)$ columns in M', the number of distinct columns in M' is $\Omega(2^r)$, and so Alice must send Bob $r - O(1)$ bits. □

COROLLARY 6.15. *If p is an odd prime, then* QCSB_p *is not compressible.*

Proof. If Bob sees $b = (\log p)^{O(1)}$ bits, then Alice must send at least $r - O(1) = \Omega(\log p) = b^{\Omega(1)}$ bits, which greatly exceeds the requirement for compressible functions. □

7. Decompositions of groups: The Rohrbach conjecture. In this section, we prove results about $\rho(G,u) := \rho_1(G,u)$ (i.e., when $\prod_{i=1}^{u} H_i = G$ in Definition 2.12) and indicate related conjectures. We shall see that $\rho(G,u)$ behaves roughly as $|G|^{1-1/u}$.

First, we observe the following easy lower bound.

PROPOSITION 7.1. *For any finite group G, $\rho(G,u) \geq |G|^{1-1/u}$.*

Proof. Let $G = H_1 \cdot \ldots \cdot H_u$ be an optimal decomposition. If $|H_i| \geq |G|^{1/u}$ for each i, then $|\widehat{H}_i| \geq |G|^{1-1/u}$. Otherwise, assume $|H_i| < |G|^{1/u}$ for some fixed i. Observe that $|H_i| \cdot |\widehat{H}_i| \geq |G|$. Therefore, in this case also $|\widehat{H}_i| > |G|^{1-1/u}$. □

For arbitrary finite groups, an upper bound on $\rho(G,u)$ that is not too far from optimal follows from Theorem 2.21.

COROLLARY 7.2 (of Theorem 2.21). *For any finite group G of order n, $\rho(G,u) \leq 2(4n\ln n)^{1-1/u}$.*

Proof. Partition the two-element sets of Theorem 2.21 into u classes, each containing at least $\lfloor m/u \rfloor$ of the m two-element sets. This means that there are at most $m - \lfloor m/u \rfloor$ two-element sets in any $u-1$ of the classes. Therefore,

$$\rho(G,u) \leq \max_i |\widehat{H}_i| \leq 2^{m-\lfloor m/u \rfloor} \leq 2^{1+m-m/u} = 2 \cdot 2^{m(u-1)/u} \leq 2(4n\ln n)^{1-1/u}. \qquad \square$$

The parameter $\rho(G,u)$ is closely related to a question posed by Rohrbach [Ro37a, Ro37b] in 1937.

DEFINITION 7.3. *A sequence $H_1, \ldots, H_u$ of subsets of a finite group G is called a* u-decomposition *of G if $G = H_1 \cdot \ldots \cdot H_u$. If $H_1 = \cdots = H_u = H$, we denote $H^u = H_1 \cdot \ldots \cdot H_u$. A subset H of G is called a* u-basis *of G if $H^u = G$.*

Rohrbach's Problem. Is there a constant $c = c(u)$ such that every finite group G has a u-basis H, where $|H| \leq c|G|^{1/u}$?

Note that if Rohrbach's Problem has an affirmative answer, then we will have, for every finite group G, $\rho(G,u) \leq (c(u))^{u-1}|G|^{1-1/u}$. On the other hand, if we have a u-decomposition $G = H_1 \cdot \ldots \cdot H_u$ with $|H_i| \leq \alpha|G|^{1/u}$, then we will have a u-basis H of G with $|H| \leq (\alpha u)|G|^{1/u}$ by simply taking $H = H_1 \cup \cdots \cup H_u$. Moreover, such a decomposition will also give that $\rho(G,u) \leq \alpha^{u-1}|G|^{1-1/u}$. Hence the following question appears to be of more general interest.

Modified Rohrbach Problem. Is there an absolute constant c such that every finite group G has a u-decomposition $G = H_1 \cdot \ldots \cdot H_u$, where $|H_i| \leq c|G|^{1/u}$?

Both Rohrbach's Problem and its modified version have been answered affirmatively for several special classes of finite groups. Of particular interest in our context is the following result of Kozma and Lev [KoL94] (for our purposes, $\lambda_i = 1/u$ in the following theorem).

THEOREM 7.4 (see [KoL94]). *Let G be a finite group such that every composition factor of G is either a cyclic group or an alternating group. Then for every positive integer u and nonnegative real numbers λ_i such that $\lambda_1 + \cdots + \lambda_u = 1$, there is a u-decomposition $G = H_1 \cdot \ldots \cdot H_u$, where $|H_1| \leq |G|^{\lambda_1}$ and $H_i \leq 2|G|^{\lambda_i}$ for $2 \leq i \leq u$. In particular, this conclusion holds if G is an alternating group or if G is solvable.*

This result answers the Modified Rohrbach Problem affirmatively for some important special classes of finite groups. As a consequence, we have the following corollary about $\rho(G,u)$.

COROLLARY 7.5. *Let G be a finite group such that every composition factor of G is either a cyclic group or an alternating group. Then for every positive integer u, $\rho(G,u) \le 2^{u-1}|G|^{1-1/u}$. In particular, this bound holds if G is an alternating group or if G is solvable.*

These results have been extended to groups with linear ($PSL(n,q)$) and symplectic ($Psp(2n,q)$) composition factors (in addition to cyclic and alternating composition factors) with a suitable small constant in place of the coefficient 2 (Pyber [Py98]). There is hope that the Modified Rohrbach Problem will be settled in the affirmative in the foreseeable future. (As mentioned above, this will also settle Rohrbach's original problem.)

In Examples 2.14 and 2.15, we gave upper bounds of $O(|G|^{1-1/u})$ on $\rho(G,u)$ of two special cases of greatest interest to us, namely $G = \mathbb{Z}_2^t$ and $G = \mathbb{Z}_n$. Thus in these cases we reduce the gap between the trivial lower bound $|G|^{1-1/u}$ (Proposition 7.1) and the upper bound to an absolute constant. These bounds are therefore stronger than those implied by an affirmative answer to the Modified Rohrbach Problem.

We propose the following stronger version of the Modified Rohrbach Problem.

Problem. Is there an absolute constant c such that for any finite group G and any positive integer u, $\rho(G,u) \le c|G|^{1-1/u}$?

We have given the positive answer for cyclic groups and for elementary abelian 2-groups.

8. Open problems.

1. The main open problem in multiparty communication complexity theory remains to find a nontrivial lower bound for some explicit function for more than $\log n$ players. The following are some candidate functions:
   (a) Let $\mathsf{T}_t^{k,r}$ be defined as follows: $\mathsf{T}_t^{k,r}(x_1,\dots,x_k) = 1$ if and only if $x_1 + \cdots + x_k \ge t$, where the x_i are r-bit integers. The candidate function is majority of thresholds $\mathsf{MT}_{n,k,r}$, defined by the following depth-2 circuit: the bottom level has n $\mathsf{T}_t^{k,r}$ gates, whose inputs are disjoint (so MT is a function of knr bits), and the top gate is a majority gate. There are k players, and the ith player misses the ith integer of each threshold gate. We recommend $n = k = r$.
   The (majority, $\mathsf{T}_t^{k,1}$)-communication problem is a SYMCOM(n,k) problem (see section 6), and hence for $k \ge 2 + \log n$ it has an efficient SM protocol. However, for $r \ge 2$, $\mathsf{MT}_{n,k,r}$ does not fit our description of SYMCOM functions (because players miss more than one input bit at each "f-gate"). So our protocol does not work, even though, for bounded r, $\mathsf{T}_t^{k,r}$ is a compressible function.
   (b) Quadratic character of the sum of the coordinates, defined as follows: Let p be an n-bit prime, and for $1 \le i \le k$ let x_i be an n-bit integer missed by player i. $\mathsf{QCS}_{p,k}(x_1,\dots,x_k) := 1$ if and only if $x_1+\cdots+x_k$ is a quadratic residue mod p. It is shown in [BaNS92] that $C(\mathsf{QCS}_{p,k}) \ge \Omega(n/2^k)$.
   (c) Let F be a finite field of order q. Give each player a $t \times t$ matrix over F. Let M be the product (in a given order) of these matrices. Estimate the SM complexity of decision problems associated with M, such as, "Is trace(M) a quadratic residue in F?" (for odd q). Here $n \approx q^{t^2}$. The case $t = 2$ is of particular interest.
2. Consider the SM problem $\mathsf{GAF}_{G,3}$. Show that there exists an $\epsilon > 0$ such that in any SM protocol for $\mathsf{GAF}_{G,3}$, if player 2 sends at most n^ϵ bits, then player 1 must send $\omega(n/\log\log n)$ bits. As explained in section 1.3,

such a lower bound would imply that the n-bit output function $f(x_0, x_1) = (\mathsf{GAF}_{G,3}(x_0, x_1, x_2))_{x_2 \in G}$ cannot be computed by circuits of size $O(n)$ and depth $O(\log n)$. Note that our lower bound proof in section 2 implies[3] that for *any* $\epsilon > 0$, if player 2 sends at most n^ϵ bits, then player 1 must send $\Omega(n^{1-\epsilon})$ bits. On the other hand, by the upper bound of [AmL00] (improving the protocol in section 5), it suffices if both players send $O(n^{0.73})$ bits.

3. Find nontrivial SM lower or upper bounds for the majority of QCSBs for any partition of the input bits (see section 6).
4. Obtain an $n^{1-\epsilon}$ SM upper bound for $\mathsf{GAF}_{G,k}$ for the case where G is a cyclic group. The best upper bound known is due to Ambainis [Am96]. He shows that $C_0(\mathsf{GAF}_{\mathbb{Z}_n,3}) = O(\frac{n \log^{1/4} n}{2^{\sqrt{\log n}}})$ and that $C_0(\mathsf{GAF}_{\mathbb{Z}_n,k}) = O(n^\epsilon)$ for an arbitrary $\epsilon > 0$ for $k = O((\log n)^{c(\epsilon)})$.
5. The lower bound on the randomized SM complexity of $\mathsf{GAF}_{\mathbb{Z}_2^t,k}$ from section 3 is useful only when the advantage ϵ is $n^{-O(1/k)}$. Improve this to yield meaningful (polylog(n)) lower bounds on the randomized SM complexity even for advantages as small as $2^{-\mathrm{polylog}(n)}$. Such an improvement would enable the extension of circuit lower bounds from section 4 to depth-3 in the spirit of [HG91, RaW93] exploiting an "approximation lemma" from [HMPST87]. Note that the [BaNS92] lower bound in the CFL model works even for advantages as small as $2^{-n/c^k}$.
6. *This problem, stated as an open question in an earlier version of this paper* [BaKL95]*, was resolved in* [BaHK01]*. We repeat the problem and state its current status.*
   Find a function f for which the one-way complexity $C_1(f)$ is exponentially larger than $C(f)$ for $k \geq 4$ players.
   Such a gap was found for $k = 3$ [NW93]; cf. Remark 2.9. For all $k \leq c \log n$, the gap was established in [BaHK01]. We note that lower bounds for C_1 complexity have been applied in [BaNS92] to lower bounds on branching programs and formula size.

Acknowledgments. We are grateful to Avi Wigderson for suggesting to us the SM model and pointing out the connection of ACC with the model considered in this paper. In October of 1994, P. Pudlák kindly sent us the manuscript [PRS97] by P. Pudlák, V. Rödl, and J. Sgall. Among many other things, that paper considers SM complexity under the name "oblivious communication complexity" and deduces the $\mathsf{GAF}_{G,k}$ lower bound for cyclic groups by essentially the same methods as ours [PRS97, Proposition 2.3].

Finally, we are grateful to an anonymous referee for suggestions which have lead to considerable improvement of our paper in two ways: the improvement discussed in Remark 2.10 and the use of entropy arguments for distributional complexity. The referee also pointed out to us the use of entropy in [Man98] and [KaT00].

DESIGN AND ANALYSIS OF PRACTICAL PUBLIC-KEY ENCRYPTION SCHEMES SECURE AGAINST ADAPTIVE CHOSEN CIPHERTEXT ATTACK*

RONALD CRAMER† AND VICTOR SHOUP‡

Abstract. A new public-key encryption scheme, along with several variants, is proposed and analyzed. The scheme and its variants are quite practical and are proved secure against adaptive chosen ciphertext attack under standard intractability assumptions. These appear to be the first public-key encryption schemes in the literature that are simultaneously practical and provably secure.

Key words. cryptography, public-key encryption, chosen ciphertext security, decisional Diffie–Hellman assumption

AMS subject classifications. 94A60, 68P25

DOI. 10.1137/S0097539702403773

1. Introduction.

In this paper, we present and analyze a new public-key encryption scheme, and several variants, proving that they are secure against adaptive chosen ciphertext attack (as defined by Rackoff and Simon [50]) under standard intractability assumptions. The schemes are quite practical, requiring just a few exponentiations in a group for both encryption and decryption. Moreover, the proofs of security of these schemes rely only on standard intractability assumptions: one variant relies only on the hardness of the decisional Diffie–Hellman problem, while other, somewhat more practical, variants rely on a couple of other standard intractability assumptions.

The hardness of the decisional Diffie–Hellman problem is essentially equivalent to the semantic security of the basic ElGamal encryption scheme [30]. Thus, with just a bit more computation, we get security against adaptive chosen ciphertext attack, whereas the basic ElGamal scheme is completely insecure against this type of attack.

While there are several provably secure public-key encryption schemes in the literature, they are all quite impractical. Also, there are several practical encryption schemes that have been proposed, but none of them has been proven secure under standard intractability assumptions. The significance of our results is that they provide several schemes that are provably secure and practical at the same time. There appear to be no other public-key encryption schemes in the literature that enjoy both of these properties simultaneously.

1.1. Chosen ciphertext security.

Semantic security, defined by Goldwasser and Micali [34], captures the intuition that an adversary should not be able to obtain any partial information about a message given its encryption. However, this guarantee of secrecy is only valid when the adversary is completely passive, i.e., can only eavesdrop. Indeed, semantic security offers no guarantee of secrecy at all if an adversary

*Received by the editors March 11, 2002; accepted for publication (in revised form) August 31, 2003; published electronically December 31, 2003. This paper is a significantly revised and extended version of the extended abstract [22] and also includes results originally presented in the extended abstract [56].

can mount an active attack, i.e., inject messages into a network or otherwise influence the behavior of parties in the network.

To deal with active attacks, Rackoff and Simon [50] defined the notion of security against an *adaptive chosen ciphertext attack*. If an adversary can inject messages into a network, these messages may be ciphertexts, and the adversary may be able to extract partial information about the corresponding cleartexts through its interactions with the parties in the network. Rackoff and Simon's definition models this type of attack by simply allowing an adversary to obtain decryptions of its choice; i.e., the adversary has access to a "decryption oracle." Now, given an encryption of a message—the "target" ciphertext—we want to guarantee that the adversary cannot obtain any partial information about the message. To achieve this, we have to restrict the adversary's behavior in some way; otherwise, the adversary could simply submit the target ciphertext itself to the decryption oracle. The restriction proposed by Rackoff and Simon is the weakest possible: the adversary is not allowed to submit the target ciphertext itself to the oracle; however, it may submit any other ciphertext, including ciphertexts that are related to the target ciphertext.

A different notion of security against active attacks, called *nonmalleability*, was proposed by Dolev, Dwork, and Naor [27, 28]. Here, the adversary also has access to a decryption oracle, but his goal is not to obtain partial information about the target ciphertext but rather to create another encryption of a different message that is related in some interesting way to the original, encrypted message. For example, for a nonmalleable encryption scheme, given an encryption of n, it should be infeasible to create an encryption of $n + 1$. It turns out that nonmalleability and security against adaptive chosen ciphertext attack are equivalent [8, 28].

An encryption scheme secure against adaptive chosen ciphertext attack is a very powerful cryptographic primitive. It is essential in designing protocols that are secure against active adversaries. For example, this primitive is used in protocols for authentication and key exchange [29, 28, 54] and in protocols for escrow, certified e-mail, and more general fair exchange [3]. It is by now generally recognized in the cryptographic research community that security against adaptive chosen ciphertext attack is the "right" notion of security for a general-purpose public-key encryption scheme. This is exemplified by the adoption of Bellare and Rogaway's OAEP scheme [10] (a practical but only heuristically secure scheme) as the Internet encryption standard RSA PKCS#1 version 2 and for use in the SET protocol for electronic commerce. Another motivation for security against adaptive chosen ciphertext attack is Bleichenbacher's attack [13] on the widely used SSL key establishment protocol, which is based on RSA PKCS#1 version 1—Bleichenbacher showed how to break this protocol by mounting a specific chosen ciphertext attack (SSL still uses RSA PKCS#1 version 1, but the protocol has been patched so as to avoid Bleichenbacher's attack).

There are also intermediate notions of security between semantic security and adaptive chosen ciphertext security. Naor and Yung [47] propose an attack model where the adversary has access to the decryption oracle only *prior* to obtaining the target ciphertext, and the goal of the adversary is to obtain partial information about the encrypted message. Naor and Yung called this type of attack a *chosen ciphertext attack*; it has also been called a "lunch-time" or "midnight" attack, and also an *indifferent* chosen ciphertext attack. In this paper, we will use the phrase *adaptive* chosen ciphertext attack for Rackoff and Simon's definition to distinguish it from Naor and Yung's definition. Also, throughout this paper, unless otherwise specified, by "security" we will always mean "security against adaptive chosen ciphertext attack."

1.2. Previous work.

Provably secure schemes. Naor and Yung [47] presented the first scheme provably secure against lunch-time attacks. Subsequently, Dolev, Dwork, and Naor [27] presented a scheme that is provably secure against adaptive chosen ciphertext attack.

Rackoff and Simon [50] present and prove the security of an encryption scheme, but their scheme is actually not a public-key scheme in the traditional sense: in their scheme, *all users*—both senders and receivers—require public keys, and, moreover, a trusted center is required to perform certain functions. In contrast, all other schemes mentioned in this paper, including our own, are traditional public-key systems: encryption is a probabilistic function of the message and the receiver's public key, decryption is a function of the ciphertext and the receiver's secret key, and no trusted center is required. This distinction can be important: adding extra system requirements as in the Rackoff and Simon scheme can greatly restrict the range of application of the scheme.

All of the previously known schemes provably secure under standard intractability assumptions are completely impractical (albeit polynomial time), as they rely on general and expensive constructions for noninteractive zero-knowledge proofs. This includes nonstandard schemes like Rackoff and Simon's as well.

Practical schemes. Damgård [25] proposed a practical scheme that he conjectured to be secure against lunch-time attacks; however, this scheme is not known to be provably secure in this sense and is in fact demonstrably insecure against adaptive chosen ciphertext attack.

Zheng and Seberry [62] proposed practical schemes that are conjectured to be secure against chosen ciphertext attack, but again no proof based on standard intractability assumptions is known. Lim and Lee [39] also proposed practical schemes that were later broken by Frankel and Yung [31].

Bellare and Rogaway [9, 10] have presented practical schemes for which they give heuristic proofs of adaptive chosen ciphertext security; namely, they prove security based on the assumption of a one-way trapdoor permutation in an idealized model of computation, the so-called *random oracle* model, wherein a hash function is represented by a random oracle. Actually, it turns out that the proof of security of the OAEP scheme in [10] is flawed: as demonstrated in [57], there can be no standard "black box" security proof based on an arbitrary one-way trapdoor permutation. However, the negative result in [57] does not rule out the possibility that OAEP in conjunction with a specific one-way trapdoor permutation scheme is secure. Indeed, it is shown in [57] that OAEP with exponent-3 RSA is secure, and this result is generalized in [32] to arbitrary-exponent RSA. A new scheme, OAEP+, is also presented in [57], which can be proven secure in the random oracle model, using an arbitrary one-way trapdoor permutation. Further variations of OAEP and OAEP+ are discussed in [15].

Shoup and Gennaro [58] also give ElGamal-like schemes that are secure against adaptive chosen ciphertext attack in the random oracle model and that are also amenable to efficient threshold decryption.

We stress that although a security proof in the random oracle model is of some value, it is still only a heuristic proof. In particular, these types of proofs do not rule out the possibility of breaking the scheme without breaking the underlying intractability assumption. Nor do they even rule out the possibility of breaking the scheme without finding some kind of weakness in the hash function, as shown by Canetti, Goldreich, and Halevi [19].

1.3. Further progress. Subsequent to the publication of the extended abstract [22] on which the present paper is based, some further progress in this area has been made. Canetti and Goldwasser [20] presented a threshold-decryption variant of our scheme. Also, the authors of the present paper [24] have generalized and extended the basic ideas underlying our encryption scheme, obtaining new and quite practical encryption schemes that are secure against adaptive chosen ciphertext attack under different assumptions—one scheme relies on Paillier's decision composite residuosity assumption [49], while the other (somewhat less practical) scheme relies on the classical quadratic residuosity assumption.

1.4. Outline of paper. Our paper consists of two parts.

Part 1. In the first part, we take care of a number of preliminaries, after which we present a basic version of our new scheme, along with a few variants. This first part is organized as follows:

Section 2: We introduce some basic notation that will be used throughout the paper.

Section 3: We state the formal definition of a public-key encryption scheme and the notion of security against adaptive chosen ciphertext attack. We also discuss some implications of the definition of security that illustrate its utility.

Section 4: We state the formal definitions of several intractability assumptions related to the discrete logarithm problem: the discrete logarithm assumption, the computational Diffie–Hellman assumption, and the decisional Diffie–Hellman assumption. In doing this, we introduce the notion of a *computational group scheme*, which is a general framework that allows us to discuss in an abstract, yet sufficiently concrete way the different families of groups that may be used in cryptographic applications.

Section 5: We define the notion of a *target collision resistant hash function*, which is a special type of a *universal one-way hash function*. We will use this primitive in the most efficient variants of our encryption scheme.

Section 6: We present and analyze the basic version of our encryption scheme, which we call CS1, along with two variants, called CS1a and CS1b. We prove the security of these schemes based on the decisional Diffie–Hellman assumption and the assumption that a given family of hash functions is target collision resistant. We also present and analyze a somewhat less efficient scheme, called CS2, which does not require a target collision resistant hash function.

Part 2. The schemes presented in section 6 suffer from two drawbacks. First, the schemes require that plaintexts are, or can be encoded as, group elements, which may significantly restrict the range of application of the encryption scheme and/or the choice of computational group scheme; it would be nice to relax this restriction, allowing plaintexts to be, say, bit strings of arbitrary length. Second, if the decisional Diffie–Hellman assumption is false, these schemes can be trivially broken; it would be nice if we could provide a second level of defense so that if the decisional Diffie–Hellman assumption turns out to be false, we have a scheme that still offers some security—even if only heuristically.

It turns out that both of these drawbacks can be dealt with by using a technique called *hybrid encryption*. Basically, a hybrid encryption scheme uses public-key encryption techniques to derive a shared key that is then used to encrypt the actual message using standard symmetric-key techniques. The second part of the paper is devoted to developing the formal theory behind this technique and to designing and analyzing variations on our basic scheme that utilize this technique. This part is organized as follows:

Section 7: We lay the theoretical foundations for hybrid encryption. Although most of the ideas in this section appear to be "folklore," they have not been treated rigorously in the literature. In section 7.1, we introduce the notion of a *key encapsulation mechanism* and an appropriate notion of security against adaptive chosen ciphertext attack. A key encapsulation mechanism is like a public-key encryption scheme, except that the encryption algorithm can only be used to generate and encrypt a random bit string of fixed length, which we shall use as a key for a symmetric-key encryption scheme. In section 7.2, we state the formal properties of a symmetric-key encryption scheme that we need for use in a hybrid encryption scheme and discuss some simple constructions based on pseudorandom bit generators and message authentication codes. In section 7.3, we prove that an appropriately secure key encapsulation mechanism, combined with an appropriately secure symmetric-key encryption scheme, yields a public-key encryption scheme that is secure against adaptive chosen ciphertext attack.

In what follows, we concentrate exclusively on the problem of constructing secure key encapsulation mechanisms, since the problem of constructing symmetric-key encryption schemes is essentially solved.

Section 8: We discuss the notion of a secure *key derivation function*, which is a function that should map random group elements to pseudorandom bit strings of a given length. A key derivation function is an essential ingredient in our constructions of key encapsulation mechanisms.

Section 9: We present and analyze a key encapsulation mechanism, CS3, along with two variants, CS3a and CS3b, and prove their security under the decisional Diffie–Hellman assumption, and also assuming a target collision resistant hash function and a secure key derivation function.

Section 10: The hybrid encryption scheme obtained from CS3b is by far the most practical of the encryption schemes presented in this paper; moreover, it has other interesting security properties. We show that CS3b is no less secure than a more traditional key encapsulation mechanism that is a hashed variant of ElGamal encryption, which we call HEG. Second, we also show that CS3b is secure in the random oracle model (viewing the key derivation function as a random function), under the weaker *computational* Diffie–Hellman assumption, and also assuming a target collision resistant hash function. The results in this section show that there is virtually no risk in using scheme CS3b relative to more traditional encryption schemes, while at the same time CS3b provides a security guarantee that more traditional schemes do not.

We conclude in section 11 with a brief summary.

2. Some preliminaries.

2.1. Basic mathematical notation. $\mathbf{Z}$ denotes the ring of integers, $\mathbf{Z}_{\geq 0}$ denotes the set of nonnegative integers, and for positive integer k, $\mathbf{Z}_k$ denotes the ring of integers modulo k, and $\mathbf{Z}_k^*$ denotes the corresponding multiplicative group of units.

2.2. Algorithms and probability spaces. We write $\nu \leftarrow \alpha$ to denote the algorithmic action of assigning the value of α to the variable ν.

Let X be a finite probability space, i.e., a probability space on a finite set S. For $\alpha \in S$, we let $\Pr_X[\alpha]$ denote the probability that X assigns to α, and for $S' \subset S$ we let $\Pr_X[S']$ denote the probability that X assigns to S'.

We write $\nu \xleftarrow{R} X$ to denote the algorithmic action of sampling an element of S

according to the distribution X and assigning the result of this sampling experiment to the variable ν. We sometimes write $\nu_1, \ldots, \nu_k \xleftarrow{R} X$ as shorthand for $\nu_1 \xleftarrow{R} X; \ldots; \nu_k \xleftarrow{R} X$.

For any finite set S, $\mathbf{U}(S)$ denotes the uniform distribution on S. We write $\nu \xleftarrow{R} S$ as shorthand for $\nu \xleftarrow{R} \mathbf{U}(S)$.

For any probability space X on a finite set S, we denote by $[X]$ the subset of elements of S that are assigned nonzero probability by X, i.e., the "support" of X.

If $X_1, X_2, \ldots, X_k$ are finite probability spaces and ϕ is a k-ary predicate, then we write

$$\Pr[\phi(\nu_1, \ldots, \nu_k) : \nu_1 \xleftarrow{R} X_1; \ldots; \nu_k \xleftarrow{R} X_k]$$

to denote the probability that $\phi(\nu_1, \ldots, \nu_k)$ holds when ν_1 is sampled from X_1, ν_2 is sampled from X_2, etc. More generally, for $1 \leq i \leq k$, X_i may be a family of finite probability spaces parameterized by $(\nu_1, \ldots, \nu_{i-1})$, and we write

$$\Pr[\phi(\nu_1, \ldots, \nu_k) : \nu_1 \xleftarrow{R} X_1; \nu_2 \xleftarrow{R} X_2(\nu_1); \ldots; \nu_k \xleftarrow{R} X_k(\nu_1, \ldots, \nu_{k-1})]$$

to denote the probability that $\phi(\nu_1, \ldots, \nu_k)$ holds when ν_1 is sampled from X_1, after which ν_2 is sampled from $X_2(\nu_1)$, and so on. In this case, it is important that $\nu_1, \ldots, \nu_k$ are sampled in the order given.

Similarly, if F is a k-ary function, then

$$\{F(\nu_1, \ldots, \nu_k) : \nu_1 \xleftarrow{R} X_1; \nu_2 \xleftarrow{R} X_2(\nu_1); \ldots; \nu_k \xleftarrow{R} X_k(\nu_1, \ldots, \nu_{k-1})\}$$

denotes the probability space defined by sampling ν_1 from X_1, ν_2 from $X_2(\nu_1)$, and so on, and then evaluating the function $F(\nu_1, \ldots, \nu_k)$.

We shall consider polynomial-time probabilistic algorithms A. We shall insist that for all $\lambda \in \mathbf{Z}_{\geq 0}$ and all inputs of length λ, algorithm A *always* halts in time bounded by a polynomial in λ, regardless of the random choices that A may make. In particular, for any input tuple $(\alpha_1, \ldots, \alpha_k)$, the random choices made by A as well as the output of A on this input are finite probability spaces. We denote this output probability space of A for a given input $(\alpha_1, \ldots, \alpha_k)$ by $\mathsf{A}(\alpha_1, \ldots, \alpha_k)$. We stress that $\mathsf{A}(\alpha_1, \ldots, \alpha_k)$ is a *probability space* and not a *value*. As such, we may write $\nu \xleftarrow{R} \mathsf{A}(\alpha_1, \ldots, \alpha_k)$ to denote the algorithmic action of running A on input $(\alpha_1, \ldots, \alpha_k)$ and assigning the output to the variable ν. When we speak of the "running time" of A, we mean the worst-case running time of A for inputs of a given length.

To exercise the above notation a bit, note that $[\mathsf{A}(\alpha_1, \ldots, \alpha_k)]$ denotes the set of possible outputs of A on input $(\alpha_1, \ldots, \alpha_k)$. For a tertiary predicate ϕ, polynomial-time probabilistic algorithms A_1 and A_2, and a value α_0,

$$\Pr[\phi(\alpha_0, \alpha_1, \alpha_2) : \alpha_1 \xleftarrow{R} \mathsf{A}_1(\alpha_0); \alpha_2 \xleftarrow{R} \mathsf{A}_2(\alpha_0, \alpha_1)]$$

denotes the probability that $\phi(\alpha_0, \alpha_1, \alpha_2)$ holds when A_1 is run on input α_0, yielding an output α_1, and then A_2 is run on input (α_0, α_1), yielding an output α_2.

For $\lambda \in \mathbf{Z}_{\geq 0}$, $\mathtt{1}^\lambda$ denotes the bit string consisting of λ copies of the bit $\mathtt{1}$. The string $\mathtt{1}^\lambda$ will often be an input to an algorithm: this is a technical device that allows a polynomial-time algorithm to run in time bounded by a polynomial in λ, even if there are no other inputs to the algorithm or those inputs happen to be very short.

2.3. Statistical distance and negligible functions. Let X and Y be probability spaces on a finite set S. Define the *statistical distance* $\Delta(X,Y)$ *between* X *and* Y as

$$\Delta(X,Y) := \frac{1}{2}\sum_{\alpha\in S} |\Pr_X[\alpha] - \Pr_Y[\alpha]|.$$

One can easily verify that

$$\Delta(X,Y) = \max_{S'\subset S} |\Pr_X[S'] - \Pr_Y[S']|.$$

A function F mapping nonnegative integers to nonnegative reals is called *negligible* if for all positive numbers c there exists an integer $\lambda_0(c) \geq 0$ such that for all $\lambda > \lambda_0(c)$ we have $F(\lambda) < 1/\lambda^c$.

3. Secure public-key encryption. In this section, we state the basic properties of a public-key encryption scheme, along with the definition of security against adaptive chosen ciphertext attack. Although the notions here are relatively standard, we treat a number of details here that are not often dealt with in the literature. We also discuss some implications of the definition of security that illustrate its utility.

3.1. Public-key encryption schemes. A *public-key encryption scheme* PKE consists of the following algorithms:

- A probabilistic, polynomial-time *key generation algorithm* $\mathsf{PKE.KeyGen}$ that on input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$ outputs a public-key/secret-key pair $(\mathsf{PK}, \mathsf{SK})$. The structure of PK and SK depends on the particular scheme.
  For $\lambda \in \mathbf{Z}_{\geq 0}$, we define the probability spaces

  $$\mathsf{PKE.PKSpace}_\lambda := \{\mathsf{PK} : (\mathsf{PK},\mathsf{SK}) \xleftarrow{R} \mathsf{PKE.KeyGen}(1^\lambda)\}$$

  and

  $$\mathsf{PKE.SKSpace}_\lambda := \{\mathsf{SK} : (\mathsf{PK},\mathsf{SK}) \xleftarrow{R} \mathsf{PKE.KeyGen}(1^\lambda)\}.$$

- A probabilistic, polynomial-time encryption algorithm $\mathsf{PKE.Encrypt}$ that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a public key $\mathsf{PK} \in [\mathsf{PKE.PKSpace}_\lambda]$, and a message m and outputs a ciphertext ψ.
  A ciphertext is a bit string. The structure of a message may depend on the particular scheme; see below (section 3.1.1) for a discussion.
- A deterministic, polynomial-time decryption algorithm $\mathsf{PKE.Decrypt}$ that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key $\mathsf{SK} \in [\mathsf{PKE.SKSpace}_\lambda]$, and a ciphertext ψ and outputs either a message m or the special symbol reject.

3.1.1. Message spaces. Different public-key encryption schemes might specify different message spaces, and these message spaces might in fact vary with the choice of public key. Let us denote by $\mathsf{PKE.MSpace}_{\lambda,\mathsf{PK}}$ the message space associated with $\lambda \in \mathbf{Z}_{\geq 0}$ and $\mathsf{PK} \in [\mathsf{PKE.PKSpace}_\lambda]$. Although there may be other ways of categorizing message spaces, we shall work with schemes that specify message spaces in one of two ways:

unrestricted message space: $\mathsf{PKE.MSpace}_{\lambda,\mathsf{PK}} = \{0,1\}^*$ for all λ and PK.

restricted message space: $\mathsf{PKE.MSpace}_{\lambda,\mathsf{PK}}$ is a finite set that may depend on λ and PK.

There should be a deterministic, polynomial-time algorithm that on input 1^λ, PK, and α determines if $\alpha \in \mathsf{PKE.MSpace}_{\lambda,\mathsf{PK}}$.

Clearly, a public-key encryption scheme with an unrestricted message space will be most suitable in a setting where a very general-purpose encryption scheme is required. However, encryption schemes with restricted message spaces can be useful in some settings as well.

3.1.2. Soundness. A public-key encryption scheme should be *sound* in the sense that decrypting an encryption of a message should yield the original message.

Requiring that this *always* holds is a very strong condition which will not be satisfied by many otherwise quite acceptable encryption schemes.

A definition of soundness that is adequate for our purposes runs as follows. Let us say a public-key/secret-key pair $(\mathsf{PK}, \mathsf{SK}) \in [\mathsf{PKE.KeyGen}(1^\lambda)]$ is *bad* if for some $m \in \mathsf{PKE.MSpace}_{\lambda,\mathsf{PK}}$ and some $\psi \in [\mathsf{PKE.Encrypt}(1^\lambda, \mathsf{PK}, m)]$ we have $\mathsf{PKE.Decrypt}(1^\lambda, \mathsf{SK}, \psi) \neq m$. Then our requirement is that the probability that the key generation algorithm outputs a bad key pair grows negligibly in λ.

One could formulate even weaker notions of soundness that would still be adequate for many applications, but we shall not pursue them here.

3.2. Security against adaptive chosen ciphertext attack. An adversary A in an adaptive chosen ciphertext attack (CCA) is a probabilistic, polynomial-time *oracle query* machine.

The attack game is defined in terms of an interactive computation between the adversary and its *environment*. The adversary's environment responds to the oracle queries made by the adversary: each oracle query response is sampled from a probability space that is a function of the adversary's input and all the previous oracle queries made by the adversary. We require that A runs in time *strictly* bounded by a polynomial in the length of its input, regardless of its probabilistic choices and regardless of the responses to its oracle queries from its environment.

We now describe the attack game used to define security against adaptive chosen ciphertext attack; that is, we define (operationally) the environment in which A runs. We assume that the input to A is 1^λ for some $\lambda \in \mathbf{Z}_{\geq 0}$.

Stage 1: The adversary queries a *key generation oracle*. The key generation oracle computes $(\mathsf{PK}, \mathsf{SK}) \xleftarrow{R} \mathsf{PKE.KeyGen}(1^\lambda)$ and responds with PK.

Stage 2: The adversary makes a sequence of calls to a *decryption oracle*.

For each decryption oracle query, the adversary submits a bit string ψ, and the decryption oracle responds with $\mathsf{PKE.Decrypt}(1^\lambda, \mathsf{SK}, \psi)$.

We emphasize that ψ may be an arbitrary bit string, concocted by A in an arbitrary fashion—it certainly need not be an output of the encryption algorithm.

Stage 3: The adversary submits two messages $m_0, m_1 \in \mathsf{PKE.MSpace}_{\lambda,\mathsf{PK}}$ to an *encryption oracle*. In the case of an unrestricted message space, we require that $|m_0| = |m_1|$.

On input m_0, m_1, the encryption oracle computes

$$\sigma \xleftarrow{R} \{0,1\};\ \psi^* \xleftarrow{R} \mathsf{PKE.Encrypt}(1^\lambda, \mathsf{PK}, m_\sigma)$$

and responds with the "target" ciphertext ψ^*.

Stage 4: The adversary continues to make calls to the decryption oracle subject only to the restriction that a submitted bit string ψ is not *identical* to ψ^*.

Again, we emphasize that ψ is arbitrary and may even be computed by A as a function of ψ^*.

Stage 5: The adversary outputs $\hat{\sigma} \in \{0,1\}$.

We define the *CCA advantage of* A *against* PKE *at* λ, denoted $\mathsf{AdvCCA}_{\mathsf{PKE},\mathsf{A}}(\lambda)$, to be $|\Pr[\sigma = \hat{\sigma}] - 1/2|$ in the above attack game.

We say that PKE is *secure against adaptive chosen ciphertext attack* if

> *for all probabilistic, polynomial-time oracle query machines* A *the function* $\mathsf{AdvCCA}_{\mathsf{PKE},\mathsf{A}}(\lambda)$ *grows negligibly in* λ.

3.3. Alternative characterization of security. In applying the above definition of security, one typically works directly with the quantity

$$\mathsf{AdvCCA}'_{\mathsf{PKE},\mathsf{A}}(\lambda) := |\Pr[\hat{\sigma} = 1 \mid \sigma = 0] - \Pr[\hat{\sigma} = 1 \mid \sigma = 1]|\,.$$

If we view A as a statistical test, then the quantity $\mathsf{AdvCCA}'_{\mathsf{PKE},\mathsf{A}}(\lambda)$ measures A's advantage in distinguishing a game in which m_0 is always encrypted from a game in which m_1 is always encrypted. It is easy to verify that

$$\mathsf{AdvCCA}'_{\mathsf{PKE},\mathsf{A}}(\lambda) = 2 \cdot \mathsf{AdvCCA}_{\mathsf{PKE},\mathsf{A}}(\lambda).$$

We present here a sketch of another characterization of this notion of security that illustrates more fully its utility in reasoning about the security of higher-level protocols. This alternative characterization is a natural, high-level, simulation-based definition that in some ways provides a justification for the rather low-level, technical definition given above. Our treatment here will be somewhat less formal than elsewhere in this paper.

We start by defining the notion of a *channel*, which is an object that implements the following operations:

- KeyGen—outputs a public key PK.
- Encrypt—takes as input a message m and outputs a ciphertext ψ.
- Decrypt—takes as input a ciphertext ψ and outputs a message m (possibly a special reject symbol).

Additionally, a channel is parameterized by a security parameter λ.

To initialize a channel, the KeyGen operation is invoked, after which an arbitrary number of Encrypt and Decrypt operations may be invoked. A channel may maintain state between invocations of these operations. We shall assume that messages are arbitrary bit strings.

A channel may be implemented in several ways. One way, of course, is to simply "plug in" a public-key encryption scheme. We call such an implementation of a channel a *real channel*. We wish to describe another implementation, which we call an *ideal channel*.

Loosely speaking, an ideal channel acts essentially like a private storage and retrieval service: when an Encrypt operation is invoked with a message m, the ideal channel generates a corresponding ciphertext ψ without even "looking" at m and stores the pair (m, ψ) in a table; when a Decrypt operation is invoked with a ciphertext ψ such that (m, ψ) is in the table for some m, the ideal channel returns the message m. Thus, the "encryption" ψ of a message m is completely independent of m and essentially plays the role of a "receipt," which when presented to the Decrypt operation yields the message m. As such, the Encrypt operation might be better named Store and the Decrypt operation named Retrieve.

We now describe the operation of an ideal channel in a bit more detail.

An ideal channel is built using a *channel simulator*. A channel simulator is an object that implements an interface that is identical to that of a channel, except that

the Encrypt operation does not take as input a message but rather just the *length* of a message.

An ideal channel uses a channel simulator as follows. The KeyGen operation of the ideal channel is implemented directly in terms of the KeyGen operation of the channel simulator. The ideal channel maintains a set S of message/ciphertext pairs (m, ψ) and a set T of ciphertexts, both initially empty.

When the Encrypt operation of the ideal channel is invoked with input m, the ideal channel invokes the channel simulator with input $|m|$, obtaining a ciphertext ψ. If $\psi \in T$ or $(m', \psi) \in S$ for some m', the ideal channel becomes "broken," and this and all subsequent invocations of either Encrypt or Decrypt return a special symbol indicating this; otherwise, the ideal channel adds the pair (m, ψ) to S and returns ψ as the result of the Encrypt operation.

When the Decrypt operation of the ideal channel is invoked with input ψ, the ideal channel first checks if $(m, \psi) \in S$ for some m; if so, it simply returns the message m; otherwise, it adds ψ to T, invokes the Decrypt operation of the channel simulator to obtain m, and returns m.

That completes the description of how an ideal channel is implemented using a channel simulator.

Now we define a notion of security based on the indistinguishability of real and ideal channels for a public-key encryption scheme PKE with an unrestricted message space. Consider a game in which a polynomial-time probabilistic adversary A interacts with an arbitrary number of channels and at the end of the game outputs a 0 or 1. We say that PKE is *secure in the sense of channel indistinguishability* if there exists an efficient *channel simulator* such that, for the resulting ideal channel, A cannot effectively distinguish between a game played with all real channels and a game played with all ideal channels; i.e., the absolute difference between the probabilities that A outputs a 1 in the two games grows negligibly in the security parameter.

Note that since real channels never become broken, this definition of security implies that ideal channels become broken with only negligible probability.

It is straightforward to show that if PKE is secure against adaptive chosen ciphertext attack, then it is also secure in the sense of channel indistinguishability. To prove this, the channel simulator is implemented using the KeyGen and Decrypt algorithms of PKE, and the Encrypt operation of the channel simulator on input ℓ simply runs the Encrypt algorithm of PKE on input 1^ℓ. It can be shown using a standard "hybrid" argument that the resulting ideal channel is indistinguishable from the real channel.

In analyzing a higher-level protocol, one may substitute all real channels by ideal channels. Presumably, it is much more straightforward to then analyze the resulting idealized protocol, since in the idealized protocol ciphertexts are just "receipts" that are *completely independent* of the corresponding messages. Security implies that any (polynomial-time recognizable) event in the original protocol occurs with essentially the same probability as in the idealized protocol.

3.4. Further discussion. The definition of security we have presented here is from [50]. It is called *IND-CCA*2 in [8]. It is known to be equivalent to other notions, such as nonmalleability [27, 8, 28], which is called *NM-CCA*2 in [8].

There are other, weaker notions of security for a public-key encryption scheme. For example, [47] defines a notion that is sometimes called *security against indifferent chosen ciphertext attack*, or *security against lunchtime attack*. This definition of security is exactly the same as the one above in section 3.2, except that Stage 4 of the attack is omitted—that is, the adversary does not have access to the decryption

oracle after it obtains the target ciphertext. While this notion of security may seem natural, it is actually not sufficient in many applications; in particular, in the channel model discussed above in section 3.3 one could not allow the interleaving of Encrypt and Decrypt operations. This notion is called *IND-CCA*1 in [8].

An even weaker notion of security for a public-key encryption scheme is that of *security against a passive attack*, also known as *semantic security*. This definition of security is exactly the same as the one above in section 3.2, except that both Stages 2 and 4 of the attack are omitted— that is, the adversary does not have access to the decryption oracle at all. This notion was introduced in [34] and is called IND-CPA in [8]. This notion of security is quite limited: it is only adequate in situations where the adversary has only the power to eavesdrop network traffic but cannot modify network traffic or otherwise actively participate in a protocol using the encryption scheme.

For a similar, but slightly different, approach to modeling encryption as an "idealized" process, see [18]. See also [7] for another generalization of the definition of adaptive chosen ciphertext attack to a setting involving many users and messages.

Another notion of security is that of *plaintext awareness*, introduced in [10] and further refined in [8], where in a certain sense an adversary who submits a ciphertext for decryption must already "know" the corresponding plaintext, and hence the decryption oracle does not really help. The notion defined in these papers makes sense only in the random oracle model, but in that model security in the sense of [8] implies security against adaptive chosen ciphertext attack. Conversely, while security against adaptive chosen ciphertext attack does not imply that an adversary "knows" the plaintext corresponding to a submitted ciphertext, it does imply that it does not "hurt" to tell him the plaintext, and in this sense the notion of security against adaptive chosen ciphertext attack is probably just as good as any notion of plaintext awareness.

4. Intractability assumptions related to the discrete logarithm problem. In this section, we recall the discrete logarithm (DL) assumption, the computational Diffie–Hellman (CDH) assumption, and the decisional Diffie–Hellman (DDH) assumption. All of these assumptions are formulated with respect to a suitable group G of large prime order q generated by a given element g.

Informally, the DL assumption is this:

given g^x, it is hard to compute x.

Informally, the CDH assumption is this:

given g^x and g^y for random $x, y \in \mathbf{Z}_q$, it is hard to compute g^{xy}.

Informally, the DDH assumption is this:

it is hard to distinguish triples of the form (g^x, g^y, g^z) for random $x, y, z \in \mathbf{Z}_q$ from triples of the form (g^x, g^y, g^{xy}) for random $x, y \in \mathbf{Z}_q$.

It is clear that the DDH assumption is at least as strong as the CDH assumption, which in turn is at least as strong as the DL assumption. The rest of this section is devoted to describing these assumptions more formally, discussing appropriate groups, and discussing some variations and consequences of these assumptions.

4.1. Computational group schemes. To state these intractability assumptions in a general but precise way and in an appropriate asymptotic setting, we introduce the notion of a *computational group scheme*.

A computational group scheme $\mathcal{G}$ specifies a *sequence* $(\mathbf{S}_\lambda)_{\lambda \in \mathbf{Z}_{\geq 0}}$ *of group distributions*. For every value of a security parameter $\lambda \in \mathbf{Z}_{\geq 0}$, $\mathbf{S}_\lambda$ is a probability distribution of group descriptions. A group description Γ specifies a finite abelian

group $\hat{G}$, along with a prime order subgroup G, a generator g of G, and the order q of G. We use multiplicative notation for the group operation in $\hat{G}$, and we denote the identity element of $\hat{G}$ by 1_G.

We will write $\Gamma[\hat{G}, G, g, q]$ to indicate that Γ specifies $\hat{G}$, G, g, and q as above. The following is a simple example of this notation: "for all $\lambda \in \mathbf{Z}_{\geq 0}$, for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we have $g^q = 1_G$."

As usual, mathematical objects such as a group description Γ and elements of a group $\hat{G}$ are represented for computational purposes as bit strings bounded in length by a polynomial in λ. The interpretation of these bit strings is up to the algorithms comprising the group scheme (see below). However, we require that the encoding scheme used to represent group elements as bit strings be *canonical*; that is, every element of a group $\hat{G}$ has a *unique* binary encoding.

The group scheme should also provide several algorithms:

- a deterministic, polynomial-time algorithm for computing the group operation that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, along with $h_1, h_2 \in \hat{G}$, and outputs the group element $h_1 \cdot h_2 \in \hat{G}$;
- a deterministic, polynomial-time algorithm for computing the group inversion operation that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, and $h \in \hat{G}$ and outputs $h^{-1} \in \hat{G}$;
- a deterministic, polynomial-time algorithm that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, and $\alpha \in \{0,1\}^*$ and determines if α is a valid binary encoding of an element of $\hat{G}$;
- a deterministic, polynomial-time algorithm that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, and $h \in \hat{G}$ and determines if $h \in G$;
- a deterministic, polynomial-time algorithm that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$ and $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$ and outputs g and q;
- a probabilistic, polynomial-time approximate sampling algorithm $\hat{S}$ that on input 1^λ approximately samples $\mathbf{S}_\lambda$: the distributions $\mathbf{S}_\lambda$ and $\hat{S}(1^\lambda)$ should be statistically close; that is, the statistical distance $\Delta(\mathbf{S}_\lambda, \hat{S}(1^\lambda))$ should be a negligible function in λ.

Notice that we do not require that the output distribution $\hat{S}(1^\lambda)$ of the sampling algorithm is identical to $\mathbf{S}_\lambda$ but only that the distributions have a negligible statistical distance. In particular, not all elements of $[\hat{S}(1^\lambda)]$ are necessarily valid group descriptions. It would be impractical to require that these two distributions be identical.

Note that the requirement that the group order be easily computable from the group description is not a trivial requirement: it is easy to exhibit groups whose orders are not easy to compute, e.g., subgroups of $\mathbf{Z}_n^*$ for composite n.

The requirement that group elements have unique encodings is also an important, nontrivial requirement. It is easy to exhibit quotient groups in which the problem of computing canonical representatives of residue classes is nontrivial. An example of this is the group underlying Paillier's encryption scheme [49].

Let $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$. The value 1_G may be directly encoded in Γ, but if not we can always compute it as $g \cdot g^{-1}$.

Although we will not require it, typical group schemes will have the property that for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$ the only elements of $\hat{G}$ of order q lie in G. When this is the case, testing whether a given $h \in \hat{G}$ lies in the subgroup G can be implemented by testing if $h^q = 1_G$. However, a group scheme may provide a more efficient subgroup test.

Let $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$. For $a \in G \setminus \{1_G\}$ and $b \in G$, we denote by $\log_a b$ the discrete logarithm of b to the base a; that is, $\log_a b$ is the unique element $x \in \mathbf{Z}_q$ such that $b = a^x$.

As a notational convention, throughout this paper, the letters a–h (and decorated versions thereof) will denote elements of $\hat{G}$, and the letters r–z (and decorated versions thereof) will denote elements of $\mathbf{Z}_q$.

4.2. Examples of appropriate computational group schemes. There are several examples of computational group schemes that are appropriate for cryptographic applications.

Example 1. Let $\ell_1(\lambda)$ and $\ell_2(\lambda)$ be polynomially bounded integer-valued functions in λ such that $1 < \ell_1(\lambda) < \ell_2(\lambda)$ for all $\lambda \in \mathbf{Z}_{\geq 0}$. It should be the case that the function $2^{-\ell_1(\lambda)}$ is negligible. For a given $\lambda \in \mathbf{Z}_{\geq 0}$, the distribution $\mathbf{S}_\lambda$ is defined as the distribution of triples (q, p, g), where

- q is a random $\ell_1(\lambda)$-bit prime,
- p is a random $\ell_2(\lambda)$-bit prime with $p \equiv 1 \pmod{q}$, and
- g is a random generator of G, the unique subgroup of order q of the cyclic group $\hat{G} = \mathbf{Z}_p^*$.

Elements in $\mathbf{Z}_p^*$ can be encoded canonically as bit strings of length $\ell_2(\lambda)$. Group operations in $\mathbf{Z}_p^*$ are efficiently implemented using arithmetic modulo p, and group inversion is implemented using the extended Euclidean algorithm. To test if an element $(\alpha \bmod p) \in \mathbf{Z}_p^*$ lies in G, we can test if $\alpha^q \equiv 1 \pmod{p}$.

A random generator g of G may be obtained by generating a random element in $\mathbf{Z}_p^*$ and raising it to the power $(p-1)/q$ (repeating if necessary if this yields $(1 \bmod p)$).

The sampling algorithm $\hat{S}$ may use standard, practical algorithms for primality testing that may err with a small probability that grows negligibly in λ. See, e.g., [4] for more information on primality testing. Not all elements of $[\hat{S}(1^\lambda)]$ are valid group descriptions. Moreover, depending on other aspects of the implementation, the distribution on the valid group descriptions may also be slightly skewed away from $\mathbf{S}_\lambda$. In our formulation of various intractability assumptions, it is much more convenient to work with the natural distribution $\mathbf{S}_\lambda$ than with the more awkward distribution $\hat{S}(1^\lambda)$.

We should comment that the density of primes p such that $p \equiv 1 \pmod{q}$ has never been proven to be sufficiently large to ensure fast termination of the group generation algorithm. Dirichlet's theorem on primes in arithmetic progressions applies only to the case where q is fixed relative to p. However, provided $\ell_2(\lambda) \geq (2 + \delta)\ell_1(\lambda)$ for some fixed $\delta > 0$, for any $\ell_1(\lambda)$-bit prime q, the probability that a random $\ell_2(\lambda)$-bit number of the form $qk + 1$ is prime is $\Omega(1/\ell_2(\lambda))$, assuming the extended Riemann hypothesis (ERH). This follows from Theorem 8.8.18 in [4].

If the density of primes p such that $p \equiv 1 \pmod{q}$ cannot be proven to be sufficiently large to ensure fast termination of the group generation algorithm, even assuming the ERH, it may not be unreasonable to still conjecture that this is the case.

Example 2. This is the same as Example 1, except that $p = 2q + 1$, where q is a random $\ell_1(\lambda)$-bit prime. Such a prime q is known as a Sophie Germain prime. It is unknown if there exist infinitely many Sophie Germain primes. However, it is conjectured that there are, and specific conjectures on their density have been made [5, 6] that empirically seem to be valid. In particular, it is conjectured that the probability that a random $\ell_1(\lambda)$-bit number is a Sophie Germain prime is $\Omega(1/\ell_1(\lambda)^2)$. If such a density estimate were true, then a simple trial and error method for finding Sophie Germain primes would terminate quickly. See [23] for more information on efficiently generating such primes.

Since the subgroup G of $\mathbf{Z}_p^*$ of order q is just the subgroup of quadratic residues, testing if a given element $(\alpha \bmod p) \in \mathbf{Z}_p^*$ lies in G can be performed by computing the Legendre symbol $(\alpha \mid p)$, which is generally much more efficient than computing $\alpha^q \bmod p$.

A nice property of this construction is that the numbers $\{1, \ldots, q\}$ are easily encoded as elements of G. Given $\alpha \in \{1, \ldots, q\}$, we test if $(\alpha \mid p) = 1$; if so, then we encode α as $(\alpha \bmod p) \in G$, and otherwise we encode α as $(-\alpha \bmod p)$. Given a group element $h = (\alpha \bmod p) \in G$ with $1 \leq \alpha \leq p-1$, we decode h as α if $\alpha \leq q$, and otherwise we decode h as $p - \alpha$.

This encoding scheme clearly allows us to also easily encode arbitrary bit strings of length $\ell_1(\lambda) - 1$ as elements of G.

Example 3. One can also construct G as a prime order subgroup of an elliptic curve over a finite field. Elliptic curves and their application to cryptography is a very rich field, and we refer the reader to [12] for an introduction and further references. We note here only that some of the same minor technical problems that arose above in Example 1 also arise here; namely, we note that (1) the known procedures for generating elliptic curves whose orders have a suitably large prime factor are somewhat heuristic, simply because not enough has been proven about how the order of a randomly generated elliptic curve factors into primes, and (2) it is in general not easy to encode arbitrary bit strings of a given length as points on an elliptic curve. We also note that it is fairly easy to generate elliptic curves of prime order so that we do not have to work in a subgroup; i.e., we can take $G = \hat{G}$. This is useful, as then the subgroup test becomes trivial.

4.3. Intractability assumptions.

4.3.1. The DL assumption. Let $\mathcal{G}$ be a computational group scheme specifying a sequence $(\mathbf{S}_\lambda)_{\lambda \in \mathbf{Z}_{\geq 0}}$ of group distributions.

For all probabilistic, polynomial-time algorithms A and for all $\lambda \in \mathbf{Z}_{\geq 0}$, we define the *DL advantage of* A *against* $\mathcal{G}$ *at* λ as

$$\mathsf{AdvDL}_{\mathcal{G},\mathsf{A}}(\lambda) := \Pr[\ y = x : \Gamma[\hat{G}, G, g, q] \xleftarrow{R} \mathbf{S}_\lambda;\ x \xleftarrow{R} \mathbf{Z}_q;\ y \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, g^x)\ ].$$

The DL assumption for $\mathcal{G}$ is this:

> *For every probabilistic, polynomial-time algorithm* A*, the function* $\mathsf{AdvDL}_{\mathcal{G},\mathsf{A}}(\lambda)$ *is negligible in* λ*.*

4.3.2. The CDH assumption. Let $\mathcal{G}$ be a computational group scheme specifying a sequence $(\mathbf{S}_\lambda)_{\lambda \in \mathbf{Z}_{\geq 0}}$ of group distributions.

For all probabilistic, polynomial-time algorithms A and for all $\lambda \in \mathbf{Z}_{\geq 0}$, we define the *CDH advantage of* A *against* $\mathcal{G}$ *at* λ as

$$\mathsf{AdvCDH}_{\mathcal{G},\mathsf{A}}(\lambda) := \Pr[\ c = g^{xy} : \Gamma[\hat{G}, G, g, q] \xleftarrow{R} \mathbf{S}_\lambda;\ x, y \xleftarrow{R} \mathbf{Z}_q;\ c \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, g^x, g^y)\ ].$$

The CDH assumption for $\mathcal{G}$ is this:

> *For every probabilistic, polynomial-time algorithm* A*, the function* $\mathsf{AdvCDH}_{\mathcal{G},\mathsf{A}}(\lambda)$ *is negligible in* λ*.*

For all probabilistic, polynomial-time algorithms A, for all $\lambda \in \mathbf{Z}_{\geq 0}$, and for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we define the *CDH advantage of* A *against* $\mathcal{G}$ *at* λ *given* Γ as

$$\mathsf{AdvCDH}_{\mathcal{G},\mathsf{A}}(\lambda \mid \Gamma) := \Pr[\ c = g^{xy} : x \xleftarrow{R} \mathbf{Z}_q;\ y \xleftarrow{R} \mathbf{Z}_q;\ c \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, g^x, g^y)\ ].$$

4.3.3. The DDH assumption. Let $\mathcal{G}$ be a computational group scheme specifying a sequence $(\mathbf{S}_\lambda)_{\lambda\in\mathbf{Z}_{\geq 0}}$ of group distributions.

For all $\lambda \in \mathbf{Z}_{\geq 0}$ and for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we define the sets $\mathcal{D}_{\lambda,\Gamma}$ and $\mathcal{T}_{\lambda,\Gamma}$ as follows:

$$\begin{aligned}\mathcal{D}_{\lambda,\Gamma} &:= \{(g^x, g^y, g^{xy}) \in G^3 : x, y \in \mathbf{Z}_q\};\\ \mathcal{T}_{\lambda,\Gamma} &:= G^3.\end{aligned}$$

The set $\mathcal{D}_{\lambda,\Gamma}$ is the set of "Diffie–Hellman triples." Also, for $\rho \in G^3$, define $\mathsf{DHP}_{\lambda,\Gamma}(\rho) = 1$ if $\rho \in \mathcal{D}_{\lambda,\Gamma}$, and otherwise define $\mathsf{DHP}_{\lambda,\Gamma}(\rho) = 0$.

For all 0/1-valued, probabilistic, polynomial-time algorithms A and for all $\lambda \in \mathbf{Z}_{\geq 0}$, we define the *DDH advantage of* A *against* $\mathcal{G}$ *at* λ as

$$\begin{aligned}&\mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}}(\lambda)\\ &:= \Big|\Pr[\ \tau = 1 : \Gamma \xleftarrow{R} \mathbf{S}_\lambda;\ \rho \xleftarrow{R} \mathcal{D}_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho)\ ]\\ &\quad - \Pr[\ \tau = 1 : \Gamma \xleftarrow{R} \mathbf{S}_\lambda;\ \rho \xleftarrow{R} \mathcal{T}_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho)\ ]\Big|.\end{aligned}$$

The DDH assumption for $\mathcal{G}$ is this:

> *For every probabilistic, polynomial-time,* 0/1*-valued algorithm* A*, the function* $\mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}}(\lambda)$ *is negligible in* λ*.*

For all 0/1-valued, probabilistic, polynomial-time algorithms A, for all $\lambda \in \mathbf{Z}_{\geq 0}$, and for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we define the *DDH advantage of* A *against* $\mathcal{G}$ *at* λ *given* Γ as

$$\begin{aligned}&\mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}}(\lambda \mid \Gamma)\\ &:= \Big|\Pr[\ \tau = 1 : \rho \xleftarrow{R} \mathcal{D}_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho)\ ]\\ &\quad - \Pr[\ \tau = 1 : \rho \xleftarrow{R} \mathcal{T}_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho)\ ]\Big|.\end{aligned}$$

A minor variation. We will need the following variation on the DDH assumption.

For all $\lambda \in \mathbf{Z}_{\geq 0}$ and for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we define the sets $\mathcal{D}'_{\lambda,\Gamma}$ and $\mathcal{T}'_{\lambda,\Gamma}$ as follows:

$$\begin{aligned}\mathcal{D}'_{\lambda,\Gamma} &:= \{g^x, g^y, g^{xy} : x, y \in \mathbf{Z}_q, x \neq 0\};\\ \mathcal{T}'_{\lambda,\Gamma} &:= \{g^x, g^y, g^z : x, y, z \in \mathbf{Z}_q, x \neq 0, z \neq xy\}.\end{aligned}$$

That is, $\mathcal{D}'_{\lambda,\Gamma}$ is the set of triples $(\hat{g}, a, \hat{a}) \in G^3$ such that $\hat{g} \neq 1_G$ and $\log_g a = \log_{\hat{g}} \hat{a}$, and $\mathcal{T}'_{\lambda,\Gamma}$ is the set of triples $(\hat{g}, a, \hat{a}) \in G^3$ such that $\hat{g} \neq 1_G$ and $\log_g a \neq \log_{\hat{g}} \hat{a}$.

It is easy to verify the following:

$$\Delta(\mathbf{U}(\mathcal{D}_{\lambda,\Gamma}), \mathbf{U}(\mathcal{D}'_{\lambda,\Gamma})) \leq 1/q; \tag{4.1}$$

$$\Delta(\mathbf{U}(\mathcal{T}_{\lambda,\Gamma}), \mathbf{U}(\mathcal{T}'_{\lambda,\Gamma})) \leq 2/q. \tag{4.2}$$

For all 0/1-valued, probabilistic, polynomial-time algorithms A and for all $\lambda \in \mathbf{Z}_{\geq 0}$, we define

$$\begin{aligned}&\mathsf{AdvDDH}'_{\mathcal{G},\mathsf{A}}(\lambda)\\ &:= \Big|\Pr[\ \tau = 1 : \Gamma \xleftarrow{R} \mathbf{S}_\lambda;\ \rho \xleftarrow{R} \mathcal{D}'_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho)\ ]\\ &\quad - \Pr[\ \tau = 1 : \Gamma \xleftarrow{R} \mathbf{S}_\lambda;\ \rho \xleftarrow{R} \mathcal{T}'_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho)\ ]\Big|.\end{aligned}$$

For all 0/1-valued, probabilistic, polynomial-time algorithms A, for all $\lambda \in \mathbf{Z}_{\geq 0}$, and for all $\Gamma \in [\mathbf{S}_\lambda]$, we define

$$\begin{aligned}&\mathsf{AdvDDH}'_{\mathcal{G},\mathsf{A}}(\lambda \mid \Gamma)\\ &:= \Big|\Pr[\ \tau = 1 : \rho \xleftarrow{R} \mathcal{D}'_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho)\ ]\\ &\qquad - \Pr[\ \tau = 1 : \rho \xleftarrow{R} \mathcal{T}'_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho)\ ]\Big|.\end{aligned}$$

The inequalities (4.1) and (4.2) imply the following.

LEMMA 4.1. *For all 0/1-valued, probabilistic, polynomial-time algorithms* A*, for all* $\lambda \in \mathbf{Z}_{\geq 0}$*, and for all* $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$*,*

$$\big|\mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}}(\lambda \mid \Gamma) - \mathsf{AdvDDH}'_{\mathcal{G},\mathsf{A}}(\lambda \mid \Gamma)\big| \leq 3/q.$$

In particular, the DDH assumption holds for $\mathcal{G}$ *if and only if for every probabilistic, polynomial-time* 0/1*-valued algorithm* A *the function* $\mathsf{AdvDDH}'_{\mathcal{G},\mathsf{A}}(\lambda)$ *is negligible in* λ*.*

Random self-reducibility. In this section, we discuss the random self-reducibility property of the DDH problem and its implications.

The following lemma states the random self-reducibility property for the DDH problem.

LEMMA 4.2. *There exists a probabilistic, polynomial-time algorithm* RSR *such that for all* $\lambda \in \mathbf{Z}_{\geq 0}$*, for all* $\Gamma \in [\mathbf{S}_\lambda]$*, and for all* $\rho \in \mathcal{T}_{\lambda,\Gamma}$*, the distribution* $\mathsf{RSR}(1^\lambda, \Gamma, \rho)$ *is* $\mathbf{U}(\mathcal{D}_{\lambda,\Gamma})$ *if* $\rho \in \mathcal{D}_{\lambda,\Gamma}$ *and is* $\mathbf{U}(\mathcal{T}_{\lambda,\Gamma})$ *if* $\rho \notin \mathcal{D}_{\lambda,\Gamma}$*.*

This was first observed by Stadler [61], who needed the result to prove the security of a particular protocol, and later by Naor and Reingold [45], who also pointed out some of its broader implications.

The algorithm RSR is very simple. Given 1^λ, the group description $\Gamma[\hat{G}, G, g, q]$, and $\rho = (a, b, c) \in G^3$, the algorithm computes $(a', b', c') \in G^3$ as follows:

$$r \xleftarrow{R} \mathbf{Z}_q;\ s \xleftarrow{R} \mathbf{Z}_q;\ t \xleftarrow{R} \mathbf{Z}_q;\ a' \leftarrow a^r g^s;\ b' \leftarrow b g^t;\ c' \leftarrow c^r a^{rt} b^s g^{st}.$$

The implication of this random self-reduction is that if Diffie–Hellman tuples can be efficiently distinguished from random tuples with a nonnegligible advantage, then Diffie–Hellman tuples can be efficiently *recognized* with negligible error probability. More formally, we have the following.

LEMMA 4.3. *For every* 0/1*-valued, probabilistic, polynomial-time algorithm* A *and every polynomial* P *(with integer coefficients, taking positive values on* $\mathbf{Z}_{\geq 0}$*), there exists a* 0/1*-valued, probabilistic, polynomial-time algorithm* A_1 *such that for all* $\lambda \in \mathbf{Z}_{\geq 0}$*, for all* $\Gamma \in [\mathbf{S}_\lambda]$*, for all* $\rho \in \mathcal{T}_{\lambda,\Gamma}$*, and for all* $\kappa \in \mathbf{Z}_{\geq 0}$*,*

if $\mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}}(\lambda \mid \Gamma) \geq 1/P(\lambda)$*, then*

$$\Pr[\tau \neq \mathsf{DHP}_{\lambda,\Gamma}(\rho) : \tau \xleftarrow{R} \mathsf{A}_1(1^\lambda, \Gamma, \rho, 1^\kappa)] \leq 2^{-\kappa}.$$

Lemma 4.3 follows from Lemma 4.2 using standard "amplification" techniques, making use of standard results on tail inequalities for the binomial distribution (cf. section C.5 in [21]). Given 1^λ, Γ, ρ, and 1^κ, algorithm A_1 invokes algorithm A as a subroutine $O(P(\lambda)^2\kappa)$ times with inputs $(1^\lambda, \Gamma, \rho')$, where each $\rho' \in \mathcal{T}_{\lambda,\Gamma}$ is independently sampled from $\mathsf{RSR}(1^\lambda, \Gamma, \rho)$; additionally, algorithm A_1 has to run algorithm A as a subroutine $O(P(\lambda)^2\kappa)$ times to "calibrate" A, calculating an estimate of

$$\Pr[\ \tau = 1 : \rho' \xleftarrow{R} \mathcal{T}_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho')\ ].$$

4.4. Further discussion. The CDH assumption was introduced informally by [26]. Since then, there have been many papers that deal with the DL and CDH assumptions and cryptographic applications based on them. The DDH assumption appears to have first surfaced in the cryptographic literature in [16], although, as that paper notes, the DDH assumption is actually needed to prove the security of a number of previously proposed protocols. Indeed, the famous Diffie–Hellman key exchange cannot be proved secure in any reasonable and standard way just based on the CDH assumption: the DDH assumption (or some variant thereof) is required.

The DDH assumption underpins a number of cryptographic applications. See, for example, the work of Stadler [61] on publicly verifiable secret sharing and the construction by Naor and Reingold [45] of pseudorandom functions. Also, the well-known encryption scheme of ElGamal [30] relies on the DDH for its security against passive attacks (i.e., semantic security).

One variant of the ElGamal scheme is as follows. Let G be a group of prime order q generated by an element g. The public key consists of a group element $h = g^z$, where $z \in \mathbf{Z}_q$ is chosen at random; the secret key is z. To encrypt a message m, where we assume that $m \in G$, we compute

$$u \stackrel{R}{\leftarrow} \mathbf{Z}_q;\ a \leftarrow g^u;\ b \leftarrow h^u;\ c \leftarrow b \cdot m$$

to form a ciphertext $\psi = (a, c)$. To decrypt such a ciphertext using the secret key, one computes

$$b \leftarrow a^z;\ m \leftarrow c \cdot b^{-1}$$

to obtain the message m.

It is easy to show that the security of this encryption scheme against passive attack is equivalent to the DDH assumption. It is also easy to see that this scheme is completely insecure against adaptive chosen ciphertext attack: if (a, c) is an encryption of $m \in G$, then for any $m' \in G$, $(a, c \cdot m')$ is an encryption of $m \cdot m'$; thus, one can submit $(a, c \cdot m')$ to the decryption oracle, obtaining $m \cdot m'$, from which one then computes m.

There are some very special families of elliptic curves for which the DDH assumption does not hold but for which the CDH assumption still appears to stand [38]. How these results are to be interpreted is a bit unclear. On the one hand, perhaps they cast some doubt on the DDH assumption in general. On the other hand, perhaps they illustrate only that very specially crafted families of elliptic curves may exhibit some surprising security weaknesses, which would seem to counsel against using such special families of elliptic curves for cryptographic applications and instead to use generic, randomly generated elliptic curves; indeed, for another special class of elliptic curves, the DL assumption is false [60].

We refer the reader to two excellent surveys, [43] and [14]. The latter focuses exclusively on the DDH assumption, while the former discusses both the CDH and the DDH assumptions. Also see [53], where it is shown that the DDH is hard in a "generic" model of computation.

5. Target collision resistant hash functions. In this section, we define the notion of a *target collision resistant hash function*, which is a special kind of *universal one-way hash function*, tailored somewhat for our particular application.

We informally summarize this section as follows. We shall be working with a group G of order q, and we want to hash tuples of group elements to elements of $\mathbf{Z}_q$.

For this purpose, we will use a family of keyed hash functions such that given a randomly chosen tuple of group elements and randomly chosen hash function key, it is computationally infeasible to find a different tuple of group elements that hashes to the same value using the given hash key.

5.1. Definitions. Let k be a fixed positive integer, and let $\mathcal{G}$ be a computational group scheme specifying a sequence $(\mathbf{S}_\lambda)_{\lambda \in \mathbf{Z}_{\geq 0}}$ of group distributions.

A *k-ary group hashing scheme* HF *associated with* $\mathcal{G}$ specifies two items:

- A family of *key spaces* indexed by $\lambda \in \mathbf{Z}_{\geq 0}$ and $\Gamma \in [\mathbf{S}_\lambda]$. Each such key space is a probability space on bit strings denoted by $\mathsf{HF.KeySpace}_{\lambda,\Gamma}$.
  There must exist a probabilistic, polynomial-time algorithm whose output distribution on input 1^λ and Γ is equal to $\mathsf{HF.KeySpace}_{\lambda,\Gamma}$.
- A family of *hash functions* indexed by $\lambda \in \mathbf{Z}_{\geq 0}$, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, and $\mathsf{hk} \in [\mathsf{HF.KeySpace}_{\lambda,\Gamma}]$, where each such function $\mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}$ maps a k-tuple $\rho \in G^k$ of group elements to an element of $\mathbf{Z}_q$.
  There must exist a deterministic, polynomial-time algorithm that on input 1^λ, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, $\mathsf{hk} \in [\mathsf{HF.KeySpace}_{\lambda,\Gamma}]$, and $\rho \in G^k$ outputs $\mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(\rho)$.

Let A be a probabilistic, polynomial-time algorithm. For $\lambda \in \mathbf{Z}_{\geq 0}$, we define

$$\begin{aligned}&\mathsf{AdvTCR}_{\mathsf{HF},\mathsf{A}}(\lambda)\\ &:= \Pr[\ \rho \in G^k \ \wedge\ \rho \neq \rho^* \ \wedge\ \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(\rho^*) = \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(\rho) :\\ &\qquad \Gamma[\hat{G}, G, g, q] \xleftarrow{R} \mathbf{S}_\lambda;\ \rho^* \xleftarrow{R} G^k;\ \mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};\ \rho \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho^*, \mathsf{hk})\ ].\end{aligned}$$

The target collision resistance (TCR) assumption for HF is this:

For every probabilistic, polynomial-time algorithm A*, the function* $\mathsf{AdvTCR}_{\mathsf{HF},\mathsf{A}}(\lambda)$ *is negligible in* λ*.*

It will also be convenient to define the following. Let A be a probabilistic, polynomial-time algorithm. For $\lambda \in \mathbf{Z}_{\geq 0}$ and $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we define

$$\begin{aligned}&\mathsf{AdvTCR}_{\mathsf{HF},\mathsf{A}}(\lambda \mid \Gamma)\\ &:= \Pr[\ \rho \in G^k \ \wedge\ \rho \neq \rho^* \ \wedge\ \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(\rho^*) = \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(\rho) :\\ &\qquad \rho^* \xleftarrow{R} G;\ \mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};\ \rho \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \rho^*, \mathsf{hk})\ ].\end{aligned}$$

5.2. Further discussion. As already mentioned, our notion of a target collision resistant hash function is a special case of the more general notion of a universal one-way hash function, introduced by Naor and Yung [46]. In their presentation, the hash functions mapped bit strings to bit strings, but of course, using appropriate formatting, we can easily make such a function a map from tuples of elements of the group G to elements of $\mathbf{Z}_q$. The notion of security presented in [46] was also slightly stronger than ours: in their paper, the first input to the hash function (i.e., the "target" input) is chosen adversarially, but independent of the key of the hash function, whereas in our application the target input is a random tuple of group elements. Note that our usage of the term "target collision resistance" differs from that in [11], where it is used to mean a "nonasymptotic" version of security, but is otherwise identical to the notion of security for universal one-way hash functions.

As was shown in [46], universal one-way hash functions can be built from arbitrary one-way permutations. This result was extended by Rompel [51], who showed that universal one-way hash functions can be built (albeit less efficiently) from arbitrary one-way functions.

In practice, to build a universal one-way hash function one can use a dedicated cryptographic hash function, such as SHA-1 [52]. Constructions in [11] and [55] show how to build a general-purpose universal one-way hash function using the underlying compression function of SHA-1, assuming the latter is second preimage collision resistant. In practice, one might simply use SHA-1 directly without a key—it is not unreasonable to assume that this already satisfies our definition of target collision resistance.

Note that the notion of target collision resistance is both qualitatively and quantitatively weaker than the notion of (full) collision resistance, which is why we prefer to rely on the former rather than the latter. A *collision resistant* hash function is one where it is hard for an adversary to find two different inputs that hash to the same value; the difference between our notion of target collision resistance and collision resistance is that in the former, one of the two inputs is not under the control of the adversary, while in the latter both inputs are under the control of the adversary. Simon [59], in fact, gives a kind of separation result, which suggests that collision resistance is a strictly stronger notion of security than target collision resistance.

6. The new encryption scheme: Basic version.

6.1. Description of the scheme. In this section, we present the basic version, CS1, of our new scheme.

The scheme makes use of a computational group scheme $\mathcal{G}$ as described in section 4.1, defining a sequence $(\mathbf{S}_\lambda)_{\lambda \in \mathbf{Z}_{\geq 0}}$ of distributions of group descriptions and providing a sampling algorithm $\hat{S}$, where the output distribution $\hat{S}(1^\lambda)$ closely approximates $\mathbf{S}_\lambda$.

The scheme also makes use of a group hashing scheme HF associated with $\mathcal{G}$, as described in section 5.

The scheme is described in detail in Figure 6.1.

Remark 6.1. Note that this encryption scheme has a *restricted message space*: messages are elements of the group G. This limits to some degree the applicability of the scheme and the choice of group scheme; indeed, if one wants to encrypt arbitrary bit strings of some bounded length, then among the examples of group schemes discussed in section 4.2 only Example 2, based on Sophie Germain primes, is suitable.

Remark 6.2. Note that in step **D2** of the decryption algorithm, we test if a, $\hat{a}$, and c belong to the subgroup G. This test is essential to the security of the scheme. Although some group schemes may provide a more efficient method for performing these tests, in a typical implementation one may have to compute a^q, $\hat{a}^q$, and c^q, testing that each of these is 1_G.

Remark 6.3. Note that the key generation algorithm samples a group description Γ from $\hat{S}(1^\lambda)$. However, in describing the encryption scheme we assume that Γ is a valid group description. With negligible probability (in λ), Γ may not be a valid group description, in which case the behavior of the key generation, encryption, and decryption algorithms is implementation dependent.

Remark 6.4. It is straightforward to verify that this encryption scheme satisfies the basic requirements that any public-key encryption scheme should satisfy, as described in section 3.1. In particular, the *soundness* property will always hold when Γ is a valid group description.

Remark 6.5. Technically speaking, the output ψ of the encryption algorithm is actually a canonical binary encoding of the 4-tuple $(a, \hat{a}, c, d) \in G^4$. In particular, it is critical that for any two ciphertexts $\psi' \neq \psi$ the parsing algorithm in step **D1** of

Key Generation: On input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, compute

$$\Gamma[\hat{G}, G, g, q] \xleftarrow{R} \hat{S}(1^\lambda);\ \mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};$$
$$w \xleftarrow{R} \mathbf{Z}_q^*;\ x_1, x_2, y_1, y_2, z_1, z_2 \xleftarrow{R} \mathbf{Z}_q;$$
$$\hat{g} \leftarrow g^w;\ e \leftarrow g^{x_1}\hat{g}^{x_2};\ f \leftarrow g^{y_1}\hat{g}^{y_2};\ h \leftarrow g^{z_1}\hat{g}^{z_2}$$

and output the public key $\mathsf{PK} = (\Gamma, \mathsf{hk}, \hat{g}, e, f, h)$ and the secret key $\mathsf{SK} = (\Gamma, \mathsf{hk}, x_1, x_2, y_1, y_2, z_1, z_2)$.

Encryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a public key

$$\mathsf{PK} = (\Gamma[\hat{G}, G, g, q], \mathsf{hk}, \hat{g}, e, f, h) \in [\mathbf{S}_\lambda] \times [\mathsf{HF.KeySpace}_{\lambda,\Gamma}] \times G^4,$$

along with a message $m \in G$, compute

E1: $u \xleftarrow{R} \mathbf{Z}_q$;
E2: $a \leftarrow g^u$;
E3: $\hat{a} \leftarrow \hat{g}^u$;
E4: $b \leftarrow h^u$;
E5: $c \leftarrow b \cdot m$;
E6: $v \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a}, c)$;
E7: $d \leftarrow e^u f^{uv}$

and output the ciphertext $\psi = (a, \hat{a}, c, d)$.

Decryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key

$$\mathsf{SK} = (\Gamma[\hat{G}, G, g, q], \mathsf{hk}, x_1, x_2, y_1, y_2, z_1, z_2) \in [\mathbf{S}_\lambda] \times [\mathsf{HF.KeySpace}_{\lambda,\Gamma}] \times \mathbf{Z}_q^6,$$

along with a ciphertext ψ, do the following.

D1: Parse ψ as a 4-tuple $(a, \hat{a}, c, d) \in \hat{G}^4$; output reject and halt if ψ is not of this form.
D2: Test if a, $\hat{a}$, and c belong to G; output reject and halt if this is not the case.
D3: Compute $v \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a}, c)$.
D4: Test if $d = a^{x_1+y_1 v} \cdot \hat{a}^{x_2+y_2 v}$; output reject and halt if this is not the case.
D5: Compute $b \leftarrow a^{z_1}\hat{a}^{z_2}$.
D6: Compute $m \leftarrow c \cdot b^{-1}$ and output m.

FIG. 6.1. *The public-key encryption scheme* CS1.

the decryption algorithm should not output the same 4-tuple of group elements.

6.2. Security analysis of the scheme. We shall prove that CS1 is secure against adaptive chosen ciphertext attack if the DDH assumption holds for $\mathcal{G}$ and the TCR assumption holds for HF. However, we wish to state and prove a concrete security reduction. To this end, we need some auxiliary definitions.

Suppose PKE is a public-key encryption scheme that uses a group scheme in the following natural way: on input 1^λ, the key generation algorithm runs the sampling algorithm of the group scheme on input 1^λ, yielding a group description Γ. For a given probabilistic, polynomial-time oracle query machine A, $\lambda \in \mathbf{Z}_{\geq 0}$, and group description Γ, let us define $\mathsf{AdvCCA}_{\mathsf{PKE},\mathsf{A}}(\lambda \mid \Gamma)$ to be A's advantage in an adaptive chosen ciphertext attack, where the key generation algorithm uses the given value of Γ instead of running the sampling algorithm of the group scheme.

For all probabilistic, polynomial-time oracle query machines A, for all $\lambda \in \mathbf{Z}_{\geq 0}$,

let $Q_{\mathsf{A}}(\lambda)$ be an upper bound on the number of decryption oracle queries made by A on input 1^λ. We assume that $Q_{\mathsf{A}}(\lambda)$ is a strict bound in the sense that it holds regardless of the probabilistic choices of A and regardless of the responses to its oracle queries from its environment.

THEOREM 6.1. *If the DDH assumption holds for $\mathcal{G}$ and the TCR assumption holds for HF, then $\mathsf{CS1}$ is secure against adaptive chosen ciphertext attack.*

In particular, for all probabilistic, polynomial-time oracle query machines A, there exist probabilistic algorithms A_1 and A_2, whose running times are essentially the same as that of A, such that the following holds. For all $\lambda \in \mathbf{Z}_{\geq 0}$ and all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we have

$$\mathsf{AdvCCA}_{\mathsf{CS1},\mathsf{A}}(\lambda \mid \Gamma) \leq \mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma) + \mathsf{AdvTCR}_{\mathsf{HF},\mathsf{A}_2}(\lambda \mid \Gamma) + (Q_{\mathsf{A}}(\lambda)+4)/q. \tag{6.1}$$

The precise running times of algorithms A_1 and A_2 depend a good deal on details of the model of computation and on implementation details, and so we make no attempt to be more precise on this matter.

Before continuing, we state the following simple but useful lemma, which we leave to the reader to verify.

LEMMA 6.2. *Let U_1, U_2, and F be events defined on some probability space. Suppose that the event $U_1 \wedge \neg F$ occurs if and only if $U_2 \wedge \neg F$ occurs. Then $|\Pr[U_1] - \Pr[U_2]| \leq \Pr[F]$.*

To prove Theorem 6.1, let us fix a probabilistic, polynomial-time oracle query machine A, the value of the security parameter $\lambda \in \mathbf{Z}_{\geq 0}$, and the group description $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$.

The attack game is as described in section 3.2. We now describe the relevant random variables to be considered in analyzing the adversary's attack.

Suppose that the public key is $(\Gamma, \mathsf{hk}, \hat{g}, e, f, h)$ and that the secret key is $(\Gamma, \mathsf{hk}, x_1, x_2, y_1, y_2, z_1, z_2)$. Let $w := \log_g \hat{g}$, and define $x, y, z \in \mathbf{Z}_q$ as follows:

$$x := x_1 + x_2 w,\ \ y := y_1 + y_2 w,\ \ z := z_1 + z_2 w.$$

That is, $x = \log_g e$, $y = \log_g f$, and $z = \log_g h$.

As a notational convention, whenever a particular ciphertext ψ is under consideration in some context, the following values are also implicitly defined in that context:

- $a, \hat{a}, b, c, d \in G$, where $\psi = (a, \hat{a}, c, d)$ and $b := a^{z_1} \hat{a}^{z_2}$;
- $u, \hat{u}, v, r, s, t \in \mathbf{Z}_q$, where

$$u := \log_g a,\ \ \hat{u} := \log_{\hat{g}} \hat{a},\ \ v := \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a}, c),\ \ r := \log_g c,\ \ s := \log_g d,$$

and

$$t := x_1 u + y_1 uv + x_2 \hat{u} w + y_2 \hat{u} v w.$$

For the target ciphertext ψ^*, we also denote $a^*, \hat{a}^*, b^*, c^*, d^* \in G$ and $u^*, \hat{u}^*, v^*, r^*, s^*, t^* \in \mathbf{Z}_q$ the corresponding values.

The probability space defining the attack game is then determined by the following, mutually independent, random variables:

- the coin tosses Coins of A;
- the values $\mathsf{hk}, w, x_1, x_2, y_1, y_2, z_1, z_2$ generated by the key generation algorithm;
- the values $\sigma \in \{0, 1\}$ and $u^* \in \mathbf{Z}_q$ generated by the encryption oracle.

Let $\mathbf{G}_0$ be the original attack game, let $\hat{\sigma} \in \{0,1\}$ denote the output of A, and let T_0 be the event that $\sigma = \hat{\sigma}$ in $\mathbf{G}_0$ so that $\mathsf{AdvCCA}_{\mathsf{CS1},\mathsf{A}}(\lambda \mid \Gamma) = |\Pr[T_0] - 1/2|$.

Our overall strategy for the proof is as follows. We shall define a sequence $\mathbf{G}_1, \mathbf{G}_2, \ldots, \mathbf{G}_\ell$ of modified attack games. Each of the games $\mathbf{G}_0, \mathbf{G}_1, \ldots, \mathbf{G}_\ell$ operates on the same underlying probability space. In particular, the public key and secret key of the cryptosystem, the coin tosses Coins of A, and the hidden bit σ take on *identical* values across all games. Only some of the rules defining how the environment responds to oracle queries differ from game to game. For any $1 \leq i \leq \ell$, we let T_i be the event that $\sigma = \hat{\sigma}$ in game $\mathbf{G}_i$.

To assist the reader, here is a high-level "road map" of the games:

- In game $\mathbf{G}_1$, we modify the encryption oracle so that it uses the secret key to do the encryption rather than the public key. This change is purely conceptual, and $\Pr[T_1] = \Pr[T_0]$.
- In game $\mathbf{G}_2$, we modify the encryption oracle again so that the Diffie–Hellman triple $(\hat{g}, a^*, \hat{a}^*)$ is replaced by a random triple. Under the DDH assumption, A will hardly notice, and, in particular, $|\Pr[T_2] - \Pr[T_1]|$ will be negligible.
- In game $\mathbf{G}_3$, we modify the decryption oracle so that it rejects all ciphertexts ψ such that $u \neq \hat{u}$, i.e., such that $(\hat{g}, a, \hat{a})$ is not a Diffie–Hellman triple. We will see that $\Pr[T_2]$ and $\Pr[T_3]$ differ by an amount bounded by $\Pr[R_3]$, where R_3 is the event that a ciphertext is rejected in $\mathbf{G}_3$ that would not have been under the rules of game $\mathbf{G}_2$.
- In game $\mathbf{G}_4$, we modify the encryption oracle again so that now the ciphertext is constructed without even looking at either σ, m_0, or m_1. We will see that $1/2 = \Pr[T_4] = \Pr[T_3]$ and that $\Pr[R_4] = \Pr[R_3]$ (where R_4 is defined in the same way as R_3 but with respect to game $\mathbf{G}_4$).
- In game $\mathbf{G}_5$, we add another rejection rule to the decryption oracle, this time rejecting all ciphertexts ψ such that $(a, \hat{a}, c) \neq (a^*, \hat{a}^*, c^*)$, but $v = v^*$. If A were able to produce such a ciphertext, this would represent a collision in the hash function, and so this rejection rule will be applied with negligible probability. Under the TCR assumption, this implies that $|\Pr[R_5] - \Pr[R_4]|$ is negligible (where R_5 is defined in the same way as R_3 but with respect to game $\mathbf{G}_5$). We will also see that $\Pr[R_5]$ is negligible (unconditionally).

Tracing through the above steps, one sees that $|\Pr[T_0] - 1/2|$ is negligible.

We now present the details, but we shall defer the proofs of all lemmas to the end of the proof of the theorem.

Game $\mathbf{G}_1$. We now modify game $\mathbf{G}_0$ to obtain a new game $\mathbf{G}_1$. These two games are identical, except for a small modification to the encryption oracle. Instead of using the encryption algorithm as given to compute the target ciphertext ψ^*, we use a modified encryption algorithm in which steps **E4** and **E7** are replaced by

E4′: $b \leftarrow a^{z_1} \hat{a}^{z_2}$;

E7′: $d \leftarrow a^{x_1 + y_1 v} \cdot \hat{a}^{x_2 + y_2 v}$.

The change we have made is purely conceptual: the values of b^* and d^* are exactly the same in game $\mathbf{G}_1$ as they were in $\mathbf{G}_0$. Therefore,

$$\Pr[T_1] = \Pr[T_0]. \tag{6.2}$$

Note that the encryption oracle now makes use of some components of the secret key, which is something the original encryption oracle does not do.

Game $\mathbf{G}_2$. We now modify game $\mathbf{G}_1$ to obtain a new game $\mathbf{G}_2$. We again modify the encryption oracle, replacing step **E3** of the encryption algorithm by

E3′: $\hat{u} \xleftarrow{R} \mathbf{Z}_q \setminus \{u\}$; $\hat{a} \leftarrow \hat{g}^{\hat{u}}$.

Note that whereas in games $\mathbf{G}_0$ and $\mathbf{G}_1$ we had $u^* = \hat{u}^*$, in game $\mathbf{G}_2$ u^* and $\hat{u}^*$ are nearly independent, being subject only to $u^* \neq \hat{u}^*$. However, observe that games $\mathbf{G}_1$ and $\mathbf{G}_2$ are the same, except that in game $\mathbf{G}_1$ the triple $(\hat{g}, a^*, \hat{a}^*)$ is uniformly distributed in $\mathcal{D}'_{\lambda,\Gamma}$, and in game $\mathbf{G}_2$ the triple $(\hat{g}, a^*, \hat{a}^*)$ is uniformly distributed in $\mathcal{T}'_{\lambda,\Gamma}$. Thus, any difference in behavior between these two games immediately yields a statistical test for distinguishing Diffie–Hellman triples from random triples. More precisely, we have the following.

LEMMA 6.3. *There exists a probabilistic algorithm* A_1*, whose running time is essentially the same as that of* A*, such that*

$$|\Pr[T_2] - \Pr[T_1]| \leq \mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma) + 3/q. \tag{6.3}$$

Game $\mathbf{G_3}$. In this game, we modify the *decryption* oracle in game $\mathbf{G}_2$ to obtain a new game $\mathbf{G}_3$. Instead of using the original decryption algorithm, we modify the decryption algorithm, replacing steps **D4** and **D5** by

D4′: test if $\hat{a} = a^w$ and $d = a^{x+yv}$; output reject and halt if this is not the case;

D5′: $b \leftarrow a^z$.

Note that the decryption oracle now makes use of w but does not make use of $x_1, y_2, y_1, y_2, z_1, z_2$, except indirectly through the values x, y, z.

Now, let R_3 be the event that in game $\mathbf{G}_3$ some ciphertext ψ is submitted to the decryption oracle that is rejected in step **D4′** but that would have passed the test in step **D4**.

Note that if a ciphertext passes the test in **D4′**, it would also have passed the test in **D4**.

It is clear that games $\mathbf{G}_2$ and $\mathbf{G}_3$ proceed identically until the event R_3 occurs. In particular, the events $T_2 \wedge \neg R_3$ and $T_3 \wedge \neg R_3$ are identical. So, by Lemma 6.2, we have

$$|\Pr[T_3] - \Pr[T_2]| \leq \Pr[R_3], \tag{6.4}$$

and so it suffices to bound $\Pr[R_3]$. We introduce auxiliary games $\mathbf{G}_4$ and $\mathbf{G}_5$ below to do this.

Game $\mathbf{G_4}$. This game is identical to game $\mathbf{G}_3$, except for a small modification to the *encryption* oracle. We again modify the algorithm used by the encryption oracle, replacing step **E5** by

E5′: $r \xleftarrow{R} \mathbf{Z}_q$; $c \leftarrow g^r$.

It is clear by construction that

$$\Pr[T_4] = 1/2, \tag{6.5}$$

since in game $\mathbf{G}_4$ the variable σ is never used at all, and so the adversary's output is independent of σ.

Define the event R_4 to be the event in game $\mathbf{G}_4$ analogous to the event R_3 in game $\mathbf{G}_3$; that is, R_4 is the event that in game $\mathbf{G}_4$ some ciphertext ψ is submitted to the decryption oracle that is rejected in step **D4′** but that would have passed the test in step **D4**.

We show that this modification has no effect; more precisely, we have the following.

LEMMA 6.4. *We have*

$$\Pr[T_4] = \Pr[T_3], \tag{6.6}$$

$$\Pr[R_4] = \Pr[R_3]. \tag{6.7}$$

Game $\mathbf{G_5}$. This game is the same as game $\mathbf{G}_4$, except for the following modification.

We modify the *decryption* oracle so that it applies the following *special rejection rule*: if the adversary submits a ciphertext ψ for decryption at a point in time after the encryption oracle has been invoked such that $(a, \hat{a}, c) \neq (a^*, \hat{a}^*, c^*)$ but $v = v^*$, then the decryption oracle immediately outputs reject and halts (before executing step **D4′**).

To analyze this game, we define two events.

First, we define the event C_5 to be the event that the decryption oracle in game $\mathbf{G}_5$ rejects a ciphertext using the special rejection rule.

Second, we define the event R_5 to be the event in game $\mathbf{G}_5$ that some ciphertext ψ is submitted to the decryption oracle that is rejected in step **D4′** but that would have passed the test in step **D4**. Note that such a ciphertext is not rejected by the special rejection rule, since that rule is applied before step **D4′** is executed.

Now, it is clear that games $\mathbf{G}_4$ and $\mathbf{G}_5$ proceed identically until event C_5 occurs. In particular, the events $R_4 \wedge \neg C_5$ and $R_5 \wedge \neg C_5$ are identical. So, by Lemma 6.2, we have

$$|\Pr[R_5] - \Pr[R_4]| \leq \Pr[C_5]. \tag{6.8}$$

Now, if event C_5 occurs with nonnegligible probability, we immediately get an algorithm that contradicts the target collision resistance assumption; more precisely, we have the following.

LEMMA 6.5. *There exists a probabilistic algorithm* A_2*, whose running time is essentially the same as that of* A*, such that*

$$\Pr[C_5] \leq \mathsf{AdvTCR}_{\mathsf{HF},\mathsf{A}_2}(\lambda \mid \Gamma) + 1/q. \tag{6.9}$$

Finally, we show that event R_5 occurs with negligible probability, based on purely information-theoretic considerations.

LEMMA 6.6. *We have*

$$\Pr[R_5] \leq Q_{\mathsf{A}}(\lambda)/q. \tag{6.10}$$

The detailed proof of this lemma is presented below. However, the basic idea of the proof runs as follows. For a decryption query ψ, the only information the adversary has about (x_1, x_2, y_1, y_2) are the values of x, y, and possibly s^*, which are linear combinations of (x_1, x_2, y_1, y_2). As we will prove, the value of t, which the adversary must successfully guess in order to make the event R_5 happen, is an independent linear combination of (x_1, x_2, y_1, y_2) and is therefore unpredictable.

Inequality (6.1) now follows immediately from (6.2)–(6.10).

Proofs of lemmas. To complete the proof of Theorem 6.1, we now present the proofs of Lemmas 6.3, 6.4, 6.5, and 6.6.

Proof of Lemma 6.3. We describe the algorithm A_1 in detail. For a given value of $\lambda \in \mathbf{Z}_{\geq 0}$, it takes as input 1^λ, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, and $\rho = (\hat{g}, a^*, \hat{a}^*) \in G^3$.

Algorithm A_1 provides an environment for A, interacting with A as follows.

First, A_1 computes

$$\mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};\ x_1, x_2, y_1, y_2, z_1, z_2 \xleftarrow{R} \mathbf{Z}_q;$$
$$e \leftarrow g^{x_1}\hat{g}^{x_2};\ f \leftarrow g^{y_1}\hat{g}^{y_2};\ h \leftarrow g^{z_1}\hat{g}^{z_2}$$

in order to generate a public key $\mathsf{PK} = (\Gamma, \mathsf{hk}, \hat{g}, e, f, h)$ and a secret key $\mathsf{SK} = (\Gamma, \mathsf{hk}, x_1, x_2, y_1, y_2, z_1, z_2)$. It then gives PK to A.

Whenever A submits a ciphertext $\psi = (a, \hat{a}, c, d)$ to the decryption oracle, A_1 simply runs the decryption algorithm, using the secret key SK.

When A submits (m_0, m_1) to the encryption oracle, A_1 computes

$$\sigma \xleftarrow{R} \{0,1\};\ b^* \leftarrow (a^*)^{z_1}(\hat{a}^*)^{z_2};\ c^* \leftarrow b^* \cdot m_\sigma;$$
$$v^* \leftarrow \mathsf{HF}^{\lambda,\Gamma}_{\mathsf{hk}}(a^*, \hat{a}^*, c^*);\ d^* \leftarrow (a^*)^{x_1 + y_1 v^*}(\hat{a}^*)^{x_2 + y_2 v^*}$$

and responds with the "ciphertext" $\psi^* = (a^*, \hat{a}^*, c^*, d^*)$.

When A outputs $\hat{\sigma}$ and halts, A_1 outputs 1 if $\sigma = \hat{\sigma}$ and 0 if $\sigma \neq \hat{\sigma}$.

That completes the description of A_1. By construction, it is clear that for fixed λ and $\Gamma \in [\mathbf{S}_\lambda]$,

$$\Pr[T_1] = \Pr[\ \tau = 1 : \rho \xleftarrow{R} \mathcal{D}'_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}_1(1^\lambda, \Gamma, \rho)\ ];$$
$$\Pr[T_2] = \Pr[\ \tau = 1 : \rho \xleftarrow{R} \mathcal{T}'_{\lambda,\Gamma};\ \tau \xleftarrow{R} \mathsf{A}_1(1^\lambda, \Gamma, \rho)\ ].$$

Thus,

$$|\Pr[T_2] - \Pr[T_1]| = \mathsf{AdvDDH}'_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma),$$

and so (6.3) now follows directly from this and Lemma 4.1. □

Before continuing, we state and prove a simple but useful lemma. First, we introduce some notation: for a field K and positive integers k, n, we denote by $K^{k\times n}$ the set of all $k \times n$ matrices over K, i.e., matrices with k rows and n columns whose entries are in K; for a matrix M, we denote by M^T its transpose.

LEMMA 6.7. *Let k, n be integers with $1 \le k \le n$, and let K be a finite field. Consider a probability space with random variables $\vec{\alpha} \in K^{n\times 1}$, $\vec{\beta} = (\beta_1, \ldots, \beta_k)^T \in K^{k\times 1}$, $\vec{\gamma} \in K^{k\times 1}$, and $M \in K^{k\times n}$ such that $\vec{\alpha}$ is uniformly distributed over $K^{n\times 1}$, $\vec{\beta} = M\vec{\alpha} + \vec{\gamma}$, and for $1 \le i \le k$ the ith rows of M and $\vec{\gamma}$ are determined by $\beta_1, \ldots, \beta_{i-1}$.*

Then conditioning on any fixed values of $\beta_1, \ldots, \beta_{k-1}$ such that the resulting matrix M has rank k, the value of β_k is uniformly distributed over K in the resulting conditional probability space.

Proof. Consider fixed values of $\beta_1, \ldots, \beta_{k-1} \in K$, which determine M and $\vec{\gamma}$, and assume that the matrix M has rank k. For any $\beta_k \in K$, consider the corresponding vector $\vec{\beta} = (\beta_1, \ldots, \beta_k)^T$; there are exactly $|K|^{n-k}$ vectors $\vec{\alpha}$ such that $\vec{\beta} = M\vec{\alpha} + \vec{\gamma}$. Therefore, each possible value $\beta_k \in K$ is equally likely. □

Proof of Lemma 6.4. Consider the quantity

$$X := (\mathsf{Coins}, \mathsf{hk}, w, x_1, x_2, y_1, y_2, \sigma, u^*, \hat{u}^*)$$

and the quantity z. Note that X and z take on the same values in games $\mathbf{G}_3$ and $\mathbf{G}_4$.

Consider also the quantity r^*. This quantity takes on different values in games $\mathbf{G}_3$ and $\mathbf{G}_4$. For clarity, let us denote these values as $[r^*]_3$ and $[r^*]_4$, respectively.

It is clear by inspection that the events R_3 and T_3 are determined as functions of X, z, and $[r^*]_3$. Also, the events R_4 and T_4 have precisely the same functional dependence on X, z, and $[r^*]_4$. So to prove the lemma it suffices to show that the distributions of $(X, z, [r^*]_3)$ and $(X, z, [r^*]_4)$ are identical. Observe that by construction, conditioning on any fixed values of X and z, the distribution of $[r^*]_4$ is uniform over $\mathbf{Z}_q$. So it will suffice to show that conditioning on any fixed values of X and z, the distribution of $[r^*]_3$ is also uniform over $\mathbf{Z}_q$.

We have

$$\begin{pmatrix} z \\ [r^*]_3 \end{pmatrix} = \underbrace{\begin{pmatrix} 1 & w \\ u^* & w\hat{u}^* \end{pmatrix}}_{=:M} \cdot \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} + \begin{pmatrix} 0 \\ \log_g m_\sigma \end{pmatrix}.$$

Conditioning only on a fixed value of X, the matrix M is fixed, but the values z_1 and z_2 are still uniformly and independently distributed over $\mathbf{Z}_q$. Observe that $\det(M) = w(\hat{u}^* - u^*) \neq 0$. If we further condition on a fixed value of z, the value of m_σ is fixed, and by Lemma 6.7 the distribution of $[r^*]_3$ is uniform over $\mathbf{Z}_q$. □

Proof of Lemma 6.5. Algorithm A_2 provides an environment for A, interacting with A as follows.

Algorithm A_2 takes as input 1^λ, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, $\rho^* = (a^*, \hat{a}^*, c^*) \in G^3$, and $\mathsf{hk} \in [\mathsf{HF.KeySpace}_{\lambda,\Gamma}]$. It first constructs a public key PK and secret key SK for the encryption scheme using the standard key generation algorithm, except that the given values of Γ and hk are used. It also constructs the target ciphertext $\psi^* = (a^*, \hat{a}^*, c^*, d^*)$, where $a^*, \hat{a}^*, c^*$ are the given inputs as above and where d^* is computed as

$$v^* \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a^*, \hat{a}^*, c^*);\ d^* \leftarrow (a^*)^{x_1 + y_1 v^*} (\hat{a}^*)^{x_2 + y_2 v^*}.$$

Here, hk is the given input as above, and x_1, y_1, x_2, y_2 are the values taken from the secret key SK as computed above.

Now A_2 interacts with A using the rules of game $\mathbf{G}_5$ for the decryption oracle and giving A the target ciphertext ψ^* when A invokes the encryption oracle. However, if the decryption oracle ever invokes the special rejection rule in game $\mathbf{G}_5$ for a given ciphertext ψ, algorithm A_2 immediately outputs $(a, \hat{a}, c)$ corresponding to ψ and halts. Also, if the attack terminates without the special rejection rule ever having been invoked, then A_2 also halts (without producing any output).

That completes the description of A_2. If the input $(a^*, \hat{a}^*, c^*)$ to A_2 is sampled uniformly over all triples of group elements subject to $\log_g a^* \neq \log_{\hat{g}} \hat{a}^*$, then algorithm A_2 succeeds in finding a collision with probability exactly $\Pr[C_5]$. However, in the definition of AdvTCR the input is sampled from the uniform distribution over all triples, not subject to the above restriction. The bound (6.9) follows from the fact that the statistical distance between these two input distributions is $1/q$. □

Proof of Lemma 6.6. To prove (6.10), for $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$, let us define $R_5^{(i)}$ to be the event that there is an ith ciphertext submitted to the decryption oracle in game $\mathbf{G}_5$ and that the submitted ciphertext is rejected in step **D4′** but would have passed the test in step **D4**. For $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$, let us define $B_5^{(i)}$ to be the event that the ith decryption oracle query occurs *before* the encryption oracle query and that the submitted ciphertext passes the test in steps **D1** and **D2** of the decryption oracle. For $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$, let us define $\hat{B}_5^{(i)}$ to be the event that the ith decryption oracle query occurs *after* the encryption oracle query and that the submitted ciphertext passes the tests in steps **D1** and **D2** of the decryption oracle.

The bound (6.10) will follow immediately from Lemmas 6.8 and 6.9 below. □

LEMMA 6.8. *Notation is the same as in the proof of Lemma* 6.6. *For all* $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$, *we have* $\Pr[R_5^{(i)} | B_5^{(i)}] \leq 1/q$.

Proof. Fix $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$. Consider the quantities

$$X := (\mathsf{Coins}, \mathsf{hk}, w, z)$$

and

$$X' := (x, y).$$

The values of X and X' completely determine the behavior of the adversary up until the point when the encryption oracle is invoked, and, in particular, they completely determine the event $B_5^{(i)}$. Let us call X and X' *relevant* if the event $B_5^{(i)}$ occurs.

It will suffice to prove that conditioned on any fixed, relevant values of X and X', the probability that $R_5^{(i)}$ occurs is bounded by $1/q$.

Once relevant values of X and X' are fixed, the value ψ of the ith decryption query is also fixed, along with the corresponding values a, $\hat{a}$, b, c, d, u, $\hat{u}$, v, r, and s.

The test in **D4′** fails if and only if one of the two mutually exclusive conditions ($\hat{a} \neq a^w$) or ($\hat{a} = a^w$ and $d \neq a^{x+yv}$) holds. It is easy to verify that if the second condition holds, then in fact the test in **D4** fails. Thus, if the test in **D4′** fails but the one in **D4** passes, it must be the case that $\hat{a} \neq a^w$ and $d = a^{x_1+y_1v}\hat{a}^{x_2+y_2v}$. So we need only to consider values of X and X' such that $\hat{a} \neq a^w$. The condition $\hat{a} \neq a^w$ is equivalent to the condition $u \neq \hat{u}$, and the condition $d = a^{x_1+y_1v}\hat{a}^{x_2+y_2v}$ is equivalent to the condition $s = t$.

We have

$$\begin{pmatrix} x \\ y \\ t \end{pmatrix} = \underbrace{\begin{pmatrix} 1 & w & 0 & 0 \\ 0 & 0 & 1 & w \\ u & \hat{u}w & uv & \hat{u}vw \end{pmatrix}}_{=: M} \cdot \begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix}.$$

Let us first condition only on a fixed value of X, which fixes the first two rows of M but leaves the values x_1, x_2, y_1, and y_2 still uniformly distributed over $\mathbf{Z}_q$ and mutually independent. Let us further condition on a fixed value of X' such that X and X' are relevant and that $u \neq \hat{u}$. The third row of M is also fixed, along with the values x, y, and s. It is easy to see by inspection that the rows of M are linearly independent, since $\hat{u} \neq u$ and $w \neq 0$. From this, it follows by Lemma 6.7 that t is still uniformly distributed over $\mathbf{Z}_q$, but, since s is fixed, we have $\Pr[s = t] = 1/q$. □

LEMMA 6.9. *Notation is the same as in the proof of Lemma* 6.6. *For all* $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$, *we have* $\Pr[R_5^{(i)} | \hat{B}_5^{(i)}] \leq 1/q$.

Proof. Fix $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$. Consider the quantities

$$X := (\mathsf{Coins}, \mathsf{hk}, w, z, u^*, \hat{u}^*, r^*)$$

and

$$X' := (x, y, s^*).$$

The values of X and X' completely determine the adversary's entire behavior in game $\mathbf{G}_5$, and, in particular, they completely determine the event $\hat{B}_5^{(i)}$. Let us call X and X' *relevant* if the event $\hat{B}_5^{(i)}$ occurs.

It will suffice to prove that conditioned on any fixed, relevant values of X and X', the probability that $R_5^{(i)}$ occurs is bounded by $1/q$.

Once X and X' are fixed, the value ψ of the ith decryption query is also fixed, along with the corresponding values a, $\hat{a}$, b, c, d, u, $\hat{u}$, v, r, and s. As in the proof of Lemma 6.8, it suffices to consider values of X and X' for which $u \neq \hat{u}$ and then to

show that $\Pr[s = t] \leq q$. Notice that the value of X determines the value of v^*, and we may also assume that $v \neq v^*$. To see why we may do so, if $v = v^*$, then either $(a, \hat{a}, c) = (a^*, \hat{a}^*, c^*)$ or ψ is rejected by the special rejection rule. In the first case, since $\psi \neq \psi^*$, we must have $d \neq d^*$, but this implies that ψ fails the test in **D4**. In the second case, step **D4′** is not even executed.

We have

$$\begin{pmatrix} x \\ y \\ s^* \\ t \end{pmatrix} = \underbrace{\begin{pmatrix} 1 & w & 0 & 0 \\ 0 & 0 & 1 & w \\ u^* & \hat{u}^* w & u^* v^* & \hat{u}^* v^* w \\ u & \hat{u} w & uv & \hat{u} v w \end{pmatrix}}_{=: M} \cdot \begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix}.$$

Let us first condition only on a fixed value of X, which fixes the first three rows of M but leaves the values x_1, x_2, y_1, and y_2 still uniformly distributed over $\mathbf{Z}_q$ and mutually independent. Let us further condition on a fixed value of X' such that X and X' are relevant and that $u \neq \hat{u}$ and $v \neq v^*$. The fourth row of M is also fixed, along with the values x, y, s^*, and s. It is easy to see that the rows of M are linearly independent, since

$$\det(M) = w^2(\hat{u} - u)(\hat{u}^* - u^*)(v^* - v) \neq 0.$$

From this, it follows by Lemma 6.7 that t is still uniformly distributed over $\mathbf{Z}_q$, but, since s is fixed, we have $\Pr[s = t] = 1/q$. □

6.3. Two variations. Scheme CS1 was presented because it is in a form that is particularly easy to analyze. We now describe and analyze two variations of the scheme CS1, which we call CS1a and CS1b, that are a bit simpler than CS1 but require a bit more work to analyze. For both of these schemes, the public key has the same format and indeed the same probability distribution, as in CS1, and the encryption algorithm is the same as in CS1. The key generation and decryption algorithms are slightly different, however, and are described in detail in Figures 6.2 and 6.3.

Remark 6.6. Scheme CS1a is essentially the same scheme that was originally presented as the "main scheme" in [22]. Scheme CS1b is a minor variation of a scheme originally presented in [56].

Remark 6.7. Note that in scheme CS1b we do not have to separately test if $\hat{a}$ belongs to the subgroup G in step **D2′**, since this is already implied by the test in step **D4′**. The test that a and c belong to G may in some cases be implemented by testing if $a^q = 1_G$ and $c^q = 1_G$.

Remark 6.8. Note also in scheme CS1b that the decryption algorithm has to compute either three or four (if we test if $a^q = 1_G$) powers of a and possibly one power of c (if we test if $c^q = 1_G$). Special algorithmic techniques [17, 40] can be employed to compute these several powers of a significantly faster than computing several powers of different group elements.

Remark 6.9. In an actual implementation, it is strongly recommended to compute both exponentiations in step **D4′** of CS1b before rejecting the ciphertext, even if the first exponentiation performed already implies that the ciphertext should be rejected. The reason is that if the ciphertext is rejected after just one exponentiation, this may reveal some timing information that could be exploited by an attacker. Indeed, if we reject immediately upon detecting that $\hat{a} \neq a^w$, then based upon timing information an attacker could use the decryption box as a kind of Diffie–Hellman decision oracle.

Key Generation: On input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, compute

$$\Gamma[\hat{G}, G, g, q] \xleftarrow{R} \hat{S}(1^\lambda);\ \mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};$$
$$w \xleftarrow{R} \mathbf{Z}_q^*;\ x_1, x_2, y_1, y_2, z \xleftarrow{R} \mathbf{Z}_q;$$
$$\hat{g} \leftarrow g^w;\ e \leftarrow g^{x_1}\hat{g}^{x_2};\ f \leftarrow g^{y_1}\hat{g}^{y_2};\ h \leftarrow g^z$$

and output the public key $\mathsf{PK} = (\Gamma, \mathsf{hk}, \hat{g}, e, f, h)$ and the secret key $\mathsf{SK} = (\Gamma, \mathsf{hk}, x_1, x_2, y_1, y_2, z)$.

Decryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key

$$\mathsf{SK} = (\Gamma[\hat{G}, G, g, q], \mathsf{hk}, x_1, x_2, y_1, y_2, z) \in [\mathbf{S}_\lambda] \times [\mathsf{HF.KeySpace}_{\lambda,\Gamma}] \times \mathbf{Z}_q^5,$$

along with a ciphertext ψ, do the following.

D1: Parse ψ as a 4-tuple $(a, \hat{a}, c, d) \in \hat{G}^4$; output reject and halt if ψ is not of this form.

D2: Test if a, $\hat{a}$, and c belong to G; output reject and halt if this is not the case.

D3: Compute $v \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a}, c)$.

D4: Test if $d = a^{x_1+y_1 v}\hat{a}^{x_2+y_2 v}$; output reject and halt if this is not the case.

D5′: Compute $b \leftarrow a^z$.

D6: Compute $m \leftarrow c \cdot b^{-1}$ and output m.

FIG. 6.2. *Key generation and decryption algorithms for* CS1a.

Key Generation: On input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, compute

$$\Gamma[\hat{G}, G, g, q] \xleftarrow{R} \hat{S}(1^\lambda);\ \mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};$$
$$w \xleftarrow{R} \mathbf{Z}_q^*;\ x, y, z \xleftarrow{R} \mathbf{Z}_q;$$
$$\hat{g} \leftarrow g^w;\ e \leftarrow g^x;\ f \leftarrow g^y;\ h \leftarrow g^z$$

and output the public key $\mathsf{PK} = (\Gamma, \mathsf{hk}, \hat{g}, e, f, h)$ and the secret key $\mathsf{SK} = (\Gamma, \mathsf{hk}, w, x, y, z)$.

Decryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key

$$\mathsf{SK} = (\Gamma[\hat{G}, G, g, q], \mathsf{hk}, x, y, z) \in [\mathbf{S}_\lambda] \times [\mathsf{HF.KeySpace}_{\lambda,\Gamma}] \times \mathbf{Z}_q^3,$$

along with a ciphertext ψ, do the following.

D1: Parse ψ as a 4-tuple $(a, \hat{a}, c, d) \in \hat{G}^4$; output reject and halt if ψ is not of this form.

D2′: Test if a and c belong to G; output reject and halt if this is not the case.

D3: Compute $v \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a}, c)$.

D4′: Test if $\hat{a} = a^w$ and $d = a^{x+yv}$; output reject and halt if this is not the case.

D5′: Compute $b \leftarrow a^z$.

D6: Compute $m \leftarrow c \cdot b^{-1}$ and output m.

FIG. 6.3. *Key generation and decryption algorithms for* CS1b.

Our formal model of security does not model any notion of time at all, so such attacks fall outside of the model. While some cryptosystems are vulnerable to actual attacks given this type of timing information—notably, Manger's attack [41] on RSA

PKCS #1 version 2—we know of no actual timing attack along these lines on CS1b.

Remark 6.10. For the same reasons as discussed in the previous remark, it is important that any "error code" returned by the decryption algorithm in scheme CS1b not reveal the precise reason why a ciphertext was rejected. Again, we know of no actual "side channel" attack along these lines on CS1b.

THEOREM 6.10. *If the DDH assumption holds for $\mathcal{G}$ and the TCR assumption holds for* HF*, then* CS1a *and* CS1b *are secure against adaptive chosen ciphertext attack.*

In particular, for all probabilistic, polynomial-time oracle query machines A*, for all $\lambda \in \mathbf{Z}_{\geq 0}$, and for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we have*

$$|\mathsf{AdvCCA}_{\mathsf{CS1a},\mathsf{A}}(\lambda \mid \Gamma) - \mathsf{AdvCCA}_{\mathsf{CS1},\mathsf{A}}(\lambda \mid \Gamma)| \leq Q_{\mathsf{A}}(\lambda)/q \tag{6.11}$$

and

$$|\mathsf{AdvCCA}_{\mathsf{CS1b},\mathsf{A}}(\lambda \mid \Gamma) - \mathsf{AdvCCA}_{\mathsf{CS1},\mathsf{A}}(\lambda \mid \Gamma)| \leq Q_{\mathsf{A}}(\lambda)/q. \tag{6.12}$$

To prove this theorem, let us fix A, λ, and $\Gamma[\hat{G}, G, g, q]$. Consider the attack game $\mathbf{G}_0$ as defined in section 6.2: this is the game that A plays against the scheme CS1 for the given values of λ and Γ. We adopt all the notational conventions established at the beginning of section 6.2 (i.e., prior to the description of game $\mathbf{G}_1$).

We begin by defining two modifications of game $\mathbf{G}_0$.

Game $\mathbf{G}_{-1a}$. In this game, we modify the decryption oracle so that in place of step **D5** we execute step **D5′** as in the scheme CS1a. We emphasize that in game $\mathbf{G}_{-1a}$ we have $z = z_1 + z_2 w$, where w, z_1, and z_2 are generated by the key generation algorithm of CS1.

Game $\mathbf{G}_{-1b}$. In this game, we modify the decryption oracle so that in place of steps **D4** and **D5** we execute steps **D4′** and **D5′** as in the scheme CS1b. We emphasize that in game $\mathbf{G}_{-1b}$ we have $x = x_1 + x_2 w$, $y = x_1 + x_2 w$, and $z = z_1 + z_2 w$, where w, x_1, x_2, y_1, y_2, z_1, and z_2 are generated by the key generation algorithm of CS1.

Let T_{-1a} be the event that $\sigma = \hat{\sigma}$ in game $\mathbf{G}_{-1a}$ and T_{-1b} be the event that $\sigma = \hat{\sigma}$ in game $\mathbf{G}_{-1b}$.

We remind the reader that games $\mathbf{G}_0$, $\mathbf{G}_{-1a}$, and $\mathbf{G}_{-1b}$ all operate on the *same* underlying probability space: all of the variables

$$\mathsf{Coins}, \mathsf{hk}, w, x_1, x_2, y_1, y_2, z_1, z_2, \sigma, u^*$$

that ultimately determine the events T_0, T_{-1a}, and T_{-1b} have the same values in games $\mathbf{G}_0$, $\mathbf{G}_{-1a}$, and $\mathbf{G}_{-1b}$; all that changes is the functional behavior of the decryption oracle.

It is straightforward to verify that

$$\mathsf{AdvCCA}_{\mathsf{CS1a},\mathsf{A}}(\lambda \mid \Gamma) = |\Pr[T_{-1a} - 1/2]|$$

and

$$\mathsf{AdvCCA}_{\mathsf{CS1b},\mathsf{A}}(\lambda \mid \Gamma) = |\Pr[T_{-1b} - 1/2]|.$$

Let us define the event R_{-1b} to be the event that some ciphertext is rejected in game $\mathbf{G}_{-1b}$ in step **D4′** that would have passed the test in **D4**. It is clear that games $\mathbf{G}_0$, $\mathbf{G}_{-1a}$, and $\mathbf{G}_{-1b}$ all proceed identically until event R_{-1b} occurs. In particular, the

events $T_0 \wedge \neg R_{-1b}$, $T_{-1a} \wedge \neg R_{-1b}$, and $T_{-1b} \wedge \neg R_{-1b}$ are identical. So, by Lemma 6.2, we have

$$|\Pr[T_0] - \Pr[T_{-1a}]| \leq \Pr[R_{-1b}]$$

and

$$|\Pr[T_0] - \Pr[T_{-1b}]| \leq \Pr[R_{-1b}].$$

So it suffices to show that

$$\Pr[R_{-1b}] \leq Q_{\mathsf{A}}(\lambda)/q. \tag{6.13}$$

To do this, for $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$, let $R^{(i)}_{-1b}$ be the event that there is an ith ciphertext submitted to the decryption oracle in game $\mathbf{G}_{-1b}$ and that this ciphertext is rejected in step **D4′** but would have passed the test in step **D4**.

The bound (6.13) will follow immediately from the following lemma.

LEMMA 6.11. *For all* $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$*, we have* $\Pr[R^{(i)}_{-1b}] \leq 1/q$.

Proof. The proof of this is lemma is almost identical to that of Lemma 6.8. Note that in game $\mathbf{G}_{-1b}$ the encryption oracle uses the "real" encryption algorithm and so itself does not leak any additional information about (x_1, x_2, y_1, y_2). This is in contrast to game $\mathbf{G}_5$, where the encryption oracle does leak additional information.

Fix $1 \leq i \leq Q_{\mathsf{A}}(\lambda)$. Consider the quantities

$$X := (\mathsf{Coins}, \mathsf{hk}, w, z, \sigma, u^*)$$

and

$$X' := (x, y).$$

The values of X and X' completely determine the adversary's entire behavior in game $\mathbf{G}_5$, and hence determine if there is an ith decryption oracle query and, if so, the value of the corresponding ciphertext. Let us call X and X' *relevant* if for these values of X and X' there is an ith decryption oracle query and the corresponding ciphertext passes steps **D1** and **D2**.

It will suffice to prove that conditioned on any fixed, relevant values of X and X', the probability that $R^{(i)}_{-1b}$ occurs is bounded by $1/q$.

The remainder of the argument is *exactly* as in Lemma 6.8, except using X, X', and the notion of *relevant* as defined here. □

6.4. A hash-free variant. Our basic scheme CS1 requires a target collision resistant hash function. Qualitatively, the TCR assumption is much weaker than the DDH assumption, since one can build a target collision resistant hash function based on an arbitrary one-way function. Indeed, one can build a collision resistant hash function under the DL assumption; however, the hash functions arising from such a construction produce an output that is in G, whereas we need a hash function that maps into $\mathbf{Z}_q$. We cannot in general expect to find an easy-to-compute, injective map from G onto $\mathbf{Z}_q$; in Example 2 in section 4.2, we in fact do have such a map, but that is an exceptional case.

For these reasons, we present a variation CS2 of our basic scheme that does not require a hash function.

Key Generation: On input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, compute

$$\begin{array}{l}\Gamma[\hat{G}, G, g, q] \xleftarrow{R} \hat{S}(1^\lambda);\\ w \xleftarrow{R} \mathbf{Z}_q^*;\ x_1, x_2, z_1, z_2 \xleftarrow{R} \mathbf{Z}_q;\\ \text{for } i = 1, \ldots, N\text{: } y_1^{(i)}, y_2^{(i)} \xleftarrow{R} \mathbf{Z}_q;\\ \hat{g} \leftarrow g^w;\ e \leftarrow g^{x_1}\hat{g}^{x_2};\ h \leftarrow g^{z_1}\hat{g}^{z_2};\\ \text{for } i = 1, \ldots, N\text{: } f_i \leftarrow g^{y_1^{(i)}}\hat{g}^{y_2^{(i)}}\end{array}$$

and output the public key $\mathsf{PK} = (\Gamma, \hat{g}, e, (f_i)_{i=1}^N, h)$ and the secret key $\mathsf{SK} = (\Gamma, x_1, x_2, (y_1^{(i)}, y_2^{(i)})_{i=1}^N, z_1, z_2)$.

Encryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a public key

$$\mathsf{PK} = (\Gamma[\hat{G}, G, g, q], \hat{g}, e, (f_i)_{i=1}^N, h) \in [\mathbf{S}_\lambda] \times G^{N+3},$$

along with a message $m \in G$, compute

E1: $u \xleftarrow{R} \mathbf{Z}_q$;
E2: $a \leftarrow g^u$;
E3: $\hat{a} \leftarrow \hat{g}^u$;
E4: $b \leftarrow h^u$;
E5: $c \leftarrow b \cdot m$;
E6: $(v_1, \ldots, v_N) \leftarrow \mathsf{Chop}_{\lambda,\Gamma}(a, \hat{a}, c)$;
E7: $d \leftarrow e^u \prod_{i=1}^N f_i^{uv_i}$

and output the ciphertext $\psi = (a, \hat{a}, c, d)$.

Decryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key

$$\mathsf{SK} = (\Gamma[\hat{G}, G, g, q], x_1, x_2, (y_1^{(i)}, y_2^{(i)})_{i=1}^N, z_1, z_2) \in [\mathbf{S}_\lambda] \times \mathbf{Z}_q^{N+4},$$

along with a ciphertext ψ, do the following.

D1: Parse ψ as a 4-tuple $(a, \hat{a}, c, d) \in \hat{G}^4$; output reject and halt if ψ is not of this form.
D2: Test if a, $\hat{a}$, and c belong to G; output reject and halt if this is not the case.
D3: Compute $(v_1, \ldots, v_N) \leftarrow \mathsf{Chop}_{\lambda,\Gamma}(a, \hat{a}, c)$.
D4: Test if $d = a^{x_1 + \sum_{i=1}^N y_1^{(i)} v_i} \cdot \hat{a}^{x_2 + \sum_{i=1}^N y_2^{(i)} v_i}$; output reject and halt if this is not the case.
D5: Compute $b \leftarrow a^{z_1}\hat{a}^{z_2}$.
D6: Compute $m \leftarrow c \cdot b^{-1}$ and output m.

FIG. 6.4. *The public-key encryption scheme* CS2*, where* $N = N(\lambda, \Gamma)$.

This scheme requires a family $\{\mathsf{Chop}_{\lambda,\Gamma}\}$ of "chopping" functions associated with the group scheme $\mathcal{G}$ with the following properties. For $\lambda \in \mathbf{Z}_{\geq 0}$ and $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, the function $\mathsf{Chop}_{\lambda,\Gamma}$ *injectively* maps triples $\rho \in G^3$ of group elements to N-tuples $(v_1, \ldots, v_N) \in \mathbf{Z}_q^N$. Here, $N = N(\lambda, \Gamma)$ is bounded by a polynomial in λ, and the function $\mathsf{Chop}_{\lambda,\Gamma}$ should be computable by a deterministic, polynomial-time function that takes inputs 1^λ, Γ, and ρ.

In principle, such chopping functions always exist, since we can write down the binary representation of ρ and chop it into bit strings of length $\lfloor \log_2 q \rfloor$.

We present the details of scheme CS2 in Figure 6.4.

THEOREM 6.12. *If the DDH assumption holds for $\mathcal{G}$, then* CS2 *is secure against adaptive chosen ciphertext attack.*

In particular, for all probabilistic, polynomial-time oracle query machines A*, there exists a probabilistic algorithm* A_1*, whose running time is essentially the same as that of* A*, such that the following holds. For all $\lambda \in \mathbf{Z}_{\geq 0}$ and all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we have*

$$\mathsf{AdvCCA}_{\mathsf{CS2},\mathsf{A}}(\lambda \mid \Gamma) \leq \mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma) + (Q_{\mathsf{A}}(\lambda) + 3)/q.$$

The proof of this theorem follows along the same lines as the proof of Theorem 6.1. We present here a sketch of the proof, appealing in several places to arguments found in the proof of Theorem 6.1 so as to avoid repeating arguments that are identical or nearly identical.

Let us fix a probabilistic, polynomial-time oracle query machine A, the value of the security parameter $\lambda \in \mathbf{Z}_{\geq 0}$, and the group description $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$.

We define $x, z \in \mathbf{Z}_q$ as follows:

$$x := x_1 + x_2 w, \;\; z := z_1 + z_2 w.$$

We also define $y^{(i)} \in \mathbf{Z}_q$, for $1 \leq i \leq N$, as

$$y^{(i)} := y_1^{(i)} + y_2^{(i)} w.$$

As a notational convention, whenever a particular ciphertext ψ is under consideration in some context, the following values are also implicitly defined in that context:

- $a, \hat{a}, c, d \in G$, where $\psi = (a, \hat{a}, c, d)$;
- $u, \hat{u}, v_1, \ldots, v_N, r, s \in \mathbf{Z}_q$, where

$$u := \log_g a, \;\; \hat{u} := \log_{\hat{g}} \hat{a}, \;\; (v_1, \ldots, v_N) := \mathsf{Chop}_{\lambda,\Gamma}(a, \hat{a}, c),$$
$$r := \log_g c, \;\; s := \log_g d.$$

For the target ciphertext ψ^*, we also denote by $a^*, \hat{a}^*, c^*, d^* \in G$ and $u^*, \hat{u}^*, v_1^*, \ldots, v_N^*, r^*, s^* \in \mathbf{Z}_q$ the corresponding values.

The probability space defining the attack game is then determined by the following, mutually independent, random variables:

- the coin tosses of A;
- the values $w, x_1, x_2, y_1^{(1)}, \ldots, y^{(N)}, y_2^{(1)}, \ldots, y_2^{(N)}, z_1, z_2$ generated by the key generation algorithm;
- the values $\sigma \in \{0, 1\}$ and $u^* \in \mathbf{Z}_q$ generated by the encryption oracle.

Let $\mathbf{G}_0$ be the original attack game, let $\hat{\sigma} \in \{0, 1\}$ denote the output of A, and let T_0 be the event that $\sigma = \hat{\sigma}$ in $\mathbf{G}_0$ so that $\mathsf{AdvCCA}_{\mathsf{CS2},\mathsf{A}}(\lambda \mid \Gamma) = |\Pr[T_0] - 1/2|$.

As in the proof of Theorem 6.1, we shall define a sequence of modified games $\mathbf{G}_i$, for $i = 1, 2, \ldots$, and in game $\mathbf{G}_i$ the event T_i will be the event corresponding to event T_0 but in game $\mathbf{G}_i$. We remind the reader that all of these games operate on the same underlying probability space, and, except as otherwise specified, random variables have identical values between games.

Game $\mathbf{G}_1$. In game $\mathbf{G}_1$, we modify the algorithm used by the encryption oracle as follows. Steps **E4** and **E7** are replaced by

E4′: $b \leftarrow a^{z_1} \hat{a}^{z_2}$;

E7′: $d \leftarrow a^{x_1 + \sum_{i=1}^N y_1^{(i)} v_i} \cdot \hat{a}^{x_2 + \sum_{i=1}^N y_2^{(i)} v_i}$.

By the same reasoning as in the proof of Theorem 6.1, we have $\Pr[T_1] = \Pr[T_0]$.

Game $\mathbf{G_2}$. We again modify the encryption oracle, replacing step **E3** by

E3′: $\hat{u} \xleftarrow{R} \mathbf{Z}_q \setminus \{u\}$; $\hat{a} \leftarrow \hat{g}^{\hat{u}}$.

By the same reasoning as in the proof of Theorem 6.1, one sees that there exists a probabilistic algorithm A_1, whose running time is essentially the same as that of A, such that

$$|\Pr[T_2] - \Pr[T_1]| \leq \mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma) + 3/q.$$

Game $\mathbf{G_3}$. In this game, we modify the decryption oracle in game $\mathbf{G}_2$, replacing steps **D4** and **D5** by

D4′: test if $\hat{a} = a^w$ and $d = a^{x+\sum_{i=1}^{N} y^{(i)} v_i}$; output reject and halt if this is not the case;

D5′: $b \leftarrow a^z$.

Let R_3 be the event that in game $\mathbf{G}_3$ some ciphertext ψ is submitted to the decryption oracle that is rejected in step **D4′** but that would have passed the test in step **D4**.

As in the proof of Theorem 6.1, we have

$$|\Pr[T_3] - \Pr[T_2]| \leq \Pr[R_3].$$

We claim that

$$\Pr[R_3] \leq Q_{\mathsf{A}}(\lambda)/q.$$

We can prove the analogue of Lemma 6.6 (in game $\mathbf{G}_5$ in the proof of Theorem 6.1) by considering an $(N+3) \times (2N+2)$ matrix M over $\mathbf{Z}_q$ defined as

$$M := \begin{pmatrix} 1 & w & & & & & & \\ & & 1 & w & & & & \\ & & & & \ddots & & & \\ & & & & & 1 & w & \\ u^* & \hat{u}^* w & u^* v_1^* & \hat{u}^* v_1^* w & \cdots & u^* v_N^* & \hat{u}^* v_N^* w \\ u & \hat{u} w & u v_1 & \hat{u} v_1 w & \cdots & u v_N & \hat{u} v_N w \end{pmatrix},$$

where $w \neq 0$, $\hat{u} \neq u$, $\hat{u}^* \neq u^*$, and $v_i \neq v_i^*$ for some $i \in \{1, \ldots, N\}$. It will suffice to show that the rows of M are linearly independent.

If we choose i such that $v_i \neq v_i^*$ and consider the 4×4 submatrix M' of M consisting of the intersection of columns 1, 2, $2i+1$, $2i+2$ of M and rows 1, $i+1$, $N+2$, $N+3$ of M, we see that matrix M' has the same form as the matrix considered in Lemma 6.9, and hence is nonsingular. It follows that the rows of M are linearly independent, since any nontrivial linear relation among the rows of M implies a nontrivial linear relation among the rows of M'.

Game $\mathbf{G_4}$. We again modify the algorithm used by the encryption oracle, replacing step **E5** by

E5′: $r \xleftarrow{R} \mathbf{Z}_q$; $c \leftarrow g^r$.

By reasoning analogous to that in game $\mathbf{G}_4$ in the proof of Theorem 6.1, one can show that

$$\Pr[T_4] = \Pr[T_3].$$

Moreover, by construction it is evident that

$$\Pr[T_4] = 1/2.$$

That completes the proof sketch of Theorem 6.12. We leave it to the reader to work out the details of the design and analysis of variants CS2a and CS2b of scheme CS2, corresponding to the variants CS1a and CS1b of scheme CS1, which were discussed in section 6.3.

Remark 6.11. Note that the high-level structure of the proof of Theorem 6.12 is significantly simpler than that of Theorem 6.1. In particular, in the analysis of game $\mathbf{G}_3$ in the proof of Theorem 6.12 we were able to bound the quantity $\Pr[R_3]$ directly without deferring the analysis to a later game, as in the proof of Theorem 6.1. This simplification comes from the fact that we do not have to deal with a target collision resistant hash function in Theorem 6.12, as we did in Theorem 6.1. Indeed, if in the scheme CS1 we use a collision resistant hash function, we could prove the security of CS1 using a proof with essentially the same line of reasoning as that of the proof of Theorem 6.12, with one extra game between $\mathbf{G}_0$ and $\mathbf{G}_1$ to effectively ban hash function collisions.

7. Hybrid encryption. The encryption schemes presented in the previous section all had restricted message spaces. In some settings, an encryption scheme with an unrestricted message space is more desirable. A simple and efficient way to build an encryption scheme that has an unrestricted message is to build a *hybrid* encryption scheme. Loosely speaking, such a scheme uses public-key encryption techniques to encrypt a key K that is then used to encrypt the actual message using symmetric-key encryption techniques. In this section, we develop the necessary tools for building a hybrid public-key encryption scheme.

One key ingredient in any hybrid scheme is a *key encapsulation mechanism*. This is like a public-key encryption scheme, except that the job of the encryption algorithm is to generate the encryption of a random key K. Of course, one can always use a general-purpose public-key encryption scheme to do this by simply generating K at random and then encrypting it. However, there are typically more efficient ways to do this.

As a quick example of a key encapsulation mechanism, consider the following variation of the ElGamal encryption scheme. Let G be a group of prime order q generated by an element g. Let H be a cryptographic hash function, such as SHA-1. The public key consists of a group element $h = g^z$, where $z \in \mathbf{Z}_q$ is chosen at random; the secret key is z. To generate an encryption of a symmetric key K, we compute

$$u \xleftarrow{R} \mathbf{Z}_q;\ a \leftarrow g^u;\ b \leftarrow h^u;\ K \leftarrow H(b)$$

to form a ciphertext $\psi = a$. To decrypt a ciphertext $\psi = a$ using the secret key, one computes

$$b \leftarrow a^z;\ K \leftarrow H(b),$$

obtaining a symmetric key K.

To build a complete hybrid encryption scheme, we combine a key encapsulation mechanism with a symmetric-key encryption scheme.

7.1. Key encapsulation. A key encapsulation mechanism KEM consists of the following algorithms:

- A probabilistic, polynomial-time *key generation algorithm* $\mathsf{KEM.KeyGen}$ that on input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$ outputs a public-key/secret-key pair $(\mathsf{PK}, \mathsf{SK})$. The structure of PK and SK depends on the particular scheme.
  For $\lambda \in \mathbf{Z}_{\geq 0}$, we define the probability spaces

$$\mathsf{KEM.PKSpace}_\lambda := \{\mathsf{PK} : (\mathsf{PK}, \mathsf{SK}) \xleftarrow{R} \mathsf{KEM.KeyGen}(1^\lambda)\}$$

  and

$$\mathsf{KEM.SKSpace}_\lambda := \{\mathsf{SK} : (\mathsf{PK}, \mathsf{SK}) \xleftarrow{R} \mathsf{KEM.KeyGen}(1^\lambda)\}.$$

- A probabilistic, polynomial-time encryption algorithm $\mathsf{KEM.Encrypt}$ that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$ and a public key $\mathsf{PK} \in [\mathsf{KEM.PKSpace}_\lambda]$ and outputs a pair (K, ψ), where K is a *key* and ψ is a ciphertext.
  A key K is a bit string of length $\mathsf{KEM.KeyLen}(\lambda)$, where $\mathsf{KEM.KeyLen}(\lambda)$ is another parameter of the key encapsulation mechanism.
  A ciphertext is a bit string.
- A deterministic, polynomial-time decryption algorithm $\mathsf{KEM.Decrypt}$ that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key $\mathsf{SK} \in [\mathsf{KEM.SKSpace}_\lambda]$, and a ciphertext ψ and outputs either a key K or the special symbol reject.

7.1.1. Soundness. As for public key encryption, we need an appropriate notion of soundness. A definition of soundness that is adequate for our purposes runs as follows. Let us say a public-key/secret-key pair $(\mathsf{PK}, \mathsf{SK}) \in [\mathsf{KEM.KeyGen}(1^\lambda)]$ is *bad* if for some $(K, \psi) \in [\mathsf{KEM.Encrypt}(1^\lambda, \mathsf{PK})]$ we have $\mathsf{KEM.Decrypt}(1^\lambda, \mathsf{SK}, \psi) \neq K$. Let $\mathsf{BadKeyPair}_{\mathsf{KEM}}(\lambda)$ denote the probability that the key generation algorithm generates a bad key pair for a given value of λ. Then our requirement is that $\mathsf{BadKeyPair}_{\mathsf{KEM}}(\lambda)$ grows negligibly in λ.

7.1.2. Security against adaptive chosen ciphertext attack. For a key encapsulation mechanism, an adversary A in an adaptive chosen ciphertext attack is a probabilistic, polynomial-time oracle query machine that takes as input 1^λ, where $\lambda \in \mathbf{Z}_{\geq 0}$ is the security parameter. We now describe the attack game used to define security against adaptive chosen ciphertext attack, which is quite similar to that used to define the corresponding notion of security for a public-key encryption scheme.

Stage 1: The adversary queries a *key generation oracle*. The key generation oracle computes $(\mathsf{PK}, \mathsf{SK}) \xleftarrow{R} \mathsf{KEM.KeyGen}(1^\lambda)$ and responds with PK.

Stage 2: The adversary makes a sequence of calls to a *decryption oracle*.

For each decryption oracle query, the adversary submits a ciphertext ψ, and the decryption oracle responds with $\mathsf{KEM.Decrypt}(1^\lambda, \mathsf{SK}, \psi)$.

Stage 3: The adversary queries an *encryption oracle*.

The encryption oracle computes

$$(K^*, \psi^*) \xleftarrow{R} \mathsf{KEM.Encrypt}(1^\lambda, \mathsf{PK});\ K^+ \xleftarrow{R} \{0,1\}^\ell;\ \tau \xleftarrow{R} \{0,1\};$$
$$\text{if } \tau = 0, \text{ then } K^\dagger \leftarrow K^*; \text{ else } K^\dagger \leftarrow K^+,$$

where $\ell := \mathsf{KEM.KeyLen}(\lambda)$, and responds with the pair $(K^\dagger, \psi^*)$.

Stage 4: The adversary continues to make calls to the decryption oracle subject only to the restriction that a submitted ciphertext ψ is not *identical* to ψ^*.

Stage 5: The adversary outputs $\hat{\tau} \in \{0,1\}$.

We define $\mathsf{AdvCCA}_{\mathsf{KEM},\mathsf{A}}(\lambda)$ to be $|\Pr[\tau = \hat{\tau}] - 1/2|$ in the above attack game.

We say that KEM is *secure against adaptive chosen ciphertext attack* if
for all probabilistic, polynomial-time oracle query machines A *the function* $\mathsf{AdvCCA}_{\mathsf{KEM},\mathsf{A}}(\lambda)$ *grows negligibly in* λ.

In applying the above definition of security, one typically works directly with the quantity

$$\mathsf{AdvCCA}'_{\mathsf{KEM},\mathsf{A}}(\lambda) := |\Pr[\hat{\tau} = 1 \mid \tau = 0] - \Pr[\hat{\tau} = 1 \mid \tau = 1]|\,.$$

It is easy to verify that

$$\mathsf{AdvCCA}'_{\mathsf{KEM},\mathsf{A}}(\lambda) = 2 \cdot \mathsf{AdvCCA}_{\mathsf{KEM},\mathsf{A}}(\lambda).$$

7.2. One-time symmetric-key encryption. A *one-time symmetric-key encryption scheme* SKE consists of two algorithms:

- A deterministic, polynomial-time encryption algorithm $\mathsf{SKE.Encrypt}$ that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a key K, and a message m and outputs a ciphertext χ.
  The key K is a bit string of length $\mathsf{SKE.KeyLen}(\lambda)$.
  Here, $\mathsf{SKE.KeyLen}(\lambda)$ is a parameter of the encryption scheme, which we assume can be computed in deterministic polynomial time given 1^λ.
  The message m is a bit string of arbitrary, unbounded length.
  The ciphertext χ is a bit string.
  We denote by $\mathsf{SKE.CTLen}(\lambda, \ell)$ the maximum length of any encryption of a message of length at most ℓ when using security parameter λ.
- A deterministic, polynomial-time decryption algorithm $\mathsf{SKE.Decrypt}$ that takes as input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a key K, and a ciphertext χ and outputs a message m or the special symbol reject.
  The key K is a bit string of length $\mathsf{SKE.KeyLen}(\lambda)$.
  The ciphertext χ is a bit string of arbitrary length.

We require that SKE satisfy the following *soundness* condition: for all $\lambda \in \mathbf{Z}_{\geq 0}$, for all $K \in \{0,1\}^{\mathsf{SKE.KeyLen}(\lambda)}$, for all $m \in \{0,1\}^*$, we have

$$\mathsf{SKE.Decrypt}(1^\lambda, K, \mathsf{SKE.Encrypt}(1^\lambda, K, m)) = m.$$

7.2.1. Two definitions of security. We define two notions of security for a one-time symmetric-key encryption scheme: security against passive attacks and security against adaptive chosen ciphertext attacks.

As usual, an adversary A is a probabilistic, polynomial-time oracle query machine that takes as input 1^λ, where $\lambda \in \mathbf{Z}_{\geq 0}$ is the security parameter.

A *passive* attack runs as follows. The adversary A chooses two messages, m_0 and m_1, of equal length and gives these to an *encryption oracle*. The encryption oracle generates a random key K of length $\mathsf{SKE.KeyLen}(\lambda)$, along with random $\sigma \in \{0,1\}$, and encrypts the message m_σ using the key K. The adversary A is then given the resulting ciphertext χ^*. Finally, the adversary outputs $\hat{\sigma} \in \{0,1\}$.

We define $\mathsf{AdvPA}_{\mathsf{SKE},\mathsf{A}}(\lambda)$ to be $|\Pr[\sigma = \hat{\sigma}] - 1/2|$ in the above attack game.

We say that SKE is *secure against passive attacks* if
for all probabilistic, polynomial-time oracle query machines A *the function* $\mathsf{AdvPA}_{\mathsf{SKE},\mathsf{A}}(\lambda)$ *grows negligibly in* λ.

An *adaptive chosen ciphertext attack* is exactly the same as a passive attack, except that *after* the adversary A obtains the target ciphertext χ^* from the encryption oracle the adversary may then query a *decryption oracle* any number of times. In each

decryption oracle query, A submits a ciphertext $\chi \neq \chi^*$ and obtains the decryption of χ under the key K. As in the passive attack, A outputs $\hat{\sigma} \in \{0,1\}$.

We define $\mathsf{AdvCCA}_{\mathsf{SKE},\mathsf{A}}(\lambda)$ to be $|\Pr[\sigma = \hat{\sigma}] - 1/2|$ in the above attack game.

We say that SKE is *secure against adaptive chosen ciphertext attacks* if *for all probabilistic, polynomial-time oracle query machines* A *the function* $\mathsf{AdvCCA}_{\mathsf{SKE},\mathsf{A}}(\lambda)$ *grows negligibly in* λ.

7.2.2. Constructions. Our definition of a symmetric-key encryption scheme and the corresponding notions of security are tailored to the application of building a hybrid public-key encryption scheme. These definitions may not be appropriate for other settings. In particular, our definitions of security do not imply protection against chosen plaintext attack; however, this protection is not needed for hybrid public-key encryption schemes, since a symmetric key is only used to encrypt a single message.

It is easy to build a symmetric key encryption scheme that achieves security against passive attacks using standard symmetric-key techniques. For example, to encrypt a message m, one can expand the key K using a pseudorandom bit generator to obtain a "one time pad" α of length $|m|$ and then compute $\chi \leftarrow m \oplus \alpha$.

A pseudorandom bit generator can be built from an arbitrary one-way permutation [33] or even from an arbitrary one-way function [36, 35]. These constructions, however, are not very practical. In a practical implementation, it is perfectly reasonable to stretch the key K by using it as the key to a dedicated block cipher and then evaluate the block cipher at successive points (so-called counter mode) to obtain a sequence of pseudorandom bits (cf. [44, Chapter 7]).

Note that the above construction yields a scheme that is completely insecure against adaptive chosen ciphertext attack. However, it is also easy to build a symmetric key encryption scheme $\mathsf{SKE2}$ that achieves security against adaptive chosen ciphertext attack, given an arbitrary scheme $\mathsf{SKE1}$ that is only secure against passive attacks.

One technique is to simply build an $\mathsf{SKE2}$ ciphertext by attaching a *message authentication code* to the $\mathsf{SKE1}$ ciphertext. Although this technique seems to be "folklore," for completeness we develop the details here.

A *one-time message authentication code* MAC specifies the following items:

- For $\lambda \in \mathbf{Z}_{\geq 0}$, a *key length* parameter $\mathsf{MAC.KeyLen}(\lambda)$ and an *output length* parameter $\mathsf{MAC.OutLen}(\lambda)$.
  We assume that $\mathsf{MAC.KeyLen}(\lambda)$ can be computed in deterministic polynomial time given 1^λ.
- A family of functions indexed by $\lambda \in \mathbf{Z}_{\geq 0}$ and $\mathsf{mk} \in \{0,1\}^{\mathsf{MAC.KeyLen}(\lambda)}$, where each function $\mathsf{MAC}^\lambda_{\mathsf{mk}}$ maps arbitrary bit strings to bit strings of length exactly $\mathsf{MAC.OutLen}(\lambda)$.
  There must be a deterministic, polynomial-time algorithm that on input 1^λ, $\mathsf{mk} \in \{0,1\}^{\mathsf{MAC.KeyLen}(\lambda)}$, and $\alpha \in \{0,1\}^*$ outputs $\mathsf{MAC}^\lambda_{\mathsf{mk}}(\alpha)$.

To define security for MAC, we define an attack game as follows. As usual, an adversary A is a probabilistic, polynomial-time oracle query machine that takes as input 1^λ, where $\lambda \in \mathbf{Z}_{\geq 0}$ is the security parameter. The adversary A first chooses a bit string α and submits this to an oracle. The oracle generates a random key mk of length $\mathsf{MAC.KeyLen}(\lambda)$, computes $\beta \leftarrow \mathsf{MAC}^\lambda_{\mathsf{mk}}(\alpha)$, and returns β to the adversary. The adversary A then outputs a list

$$((\alpha_1, \beta_1), \ldots, (\alpha_k, \beta_k))$$

of pairs of bit strings. We say that A has *produced a forgery* if for some $1 \le i \le k$ we have $\alpha_i \ne \alpha$ and $\mathsf{MAC}^{\lambda}_{\mathsf{mk}}(\alpha_i) = \beta_i$.

We say that A is a $(L_1(\lambda), L_2(\lambda), N(\lambda))$ forging adversary if $|\alpha| \le L_1(\lambda)$, $k \le N(\lambda)$, and $|\alpha_i| \le L_2(\lambda)$ for all $1 \le i \le k$.

Define $\mathsf{AdvForge}_{\mathsf{MAC},\mathsf{A}}(\lambda)$ to be the probability that A produces a forgery in the above game. We say that MAC is secure if

> *for all probabilistic, polynomial-time oracle query machines* A *the function* $\mathsf{AdvForge}_{\mathsf{MAC},\mathsf{A}}(\lambda)$ *grows negligibly in* λ.

Message authentication codes have been extensively studied (cf. [44, Chapter 9]). Once can easily build secure one-time message authentication codes using an appropriate family of universal hash functions without relying on any intractability assumptions. There are also other ways to build message authentication codes which may be preferable in practice, even though the security of these schemes is not fully proven.

Now we demonstrate how to use $\mathsf{SKE1}$ and MAC to build $\mathsf{SKE2}$. The key length $\mathsf{SKE2.KeyLen}(\lambda)$ of $\mathsf{SKE2}$ will be equal to

$$\mathsf{SKE1.KeyLen}(\lambda) + \mathsf{MAC.KeyLen}(\lambda).$$

We will write such a key as (K, mk), where K is a bit string of length $\mathsf{SKE1.KeyLen}(\lambda)$ and mk is a bit string of length $\mathsf{MAC.KeyLen}(\lambda)$.

To encrypt a message m under a key (K, mk) as above, algorithm $\mathsf{SKE2.Encrypt}$ computes

$$\chi \leftarrow \mathsf{SKE1.Encrypt}(1^{\lambda}, K, m);\ \mathsf{tag} \leftarrow \mathsf{MAC}^{\lambda}_{\mathsf{mk}}(\chi);\ \chi' \leftarrow \chi \,\|\, \mathsf{tag}$$

and outputs the ciphertext χ'.

To decrypt a ciphertext χ' under a key (K, mk) as above, algorithm $\mathsf{SKE2.Decrypt}$ first parses χ' as $\chi' = \chi \,\|\, \mathsf{tag}$, where tag is a bit string of length $\mathsf{MAC.OutLen}(\lambda)$. If this parsing step fails (because χ' is too short), then the algorithm outputs reject; otherwise, it computes

$$\mathsf{tag}' \leftarrow \mathsf{MAC}^{\lambda}_{\mathsf{mk}}(\chi).$$

If $\mathsf{tag} \ne \mathsf{tag}'$, the algorithm outputs reject; otherwise, it computes

$$m \leftarrow \mathsf{SKE1.Decrypt}(1^{\lambda}, K, \chi)$$

and outputs m.

To analyze the security of $\mathsf{SKE2}$, we recall that for all probabilistic, polynomial-time oracle query machines A, for all $\lambda \in \mathbf{Z}_{\ge 0}$, we denote by $Q_{\mathsf{A}}(\lambda)$ an upper bound on the number of decryption oracle queries made by A on input 1^{λ}. Although we introduced this notation in the context of public-key encryption, we can adopt it here in the context of symmetric-key encryption as well. We remind the reader that $Q_{\mathsf{A}}(\lambda)$ should be a strict bound that holds for any environment.

For all probabilistic, polynomial-time oracle query machines A, for all $\lambda \in \mathbf{Z}_{\ge 0}$, we define $B_{\mathsf{A}}(\lambda)$ to be an upper bound on the length of the messages submitted by A to the encryption oracle and $B'_{\mathsf{A}}(\lambda)$ to be an upper bound on the ciphertexts submitted by A to the decryption oracle. As usual, these upper bounds should hold regardless of the environment of A.

THEOREM 7.1. *If* $\mathsf{SKE1}$ *is secure against passive attacks and* MAC *is a secure one-time message authentication code, then* $\mathsf{SKE2}$ *is secure against adaptive chosen ciphertext attacks.*

In particular, for every probabilistic, polynomial-time oracle query machine A*, there exist probabilistic oracle query machines* A_1 *and* A_2*, whose running times are essentially the same as that of* A*, such that for all* $\lambda \in \mathbf{Z}_{\geq 0}$*,*

$$\mathsf{AdvCCA}_{\mathsf{SKE2},\mathsf{A}}(\lambda) \leq \mathsf{AdvPA}_{\mathsf{SKE1},\mathsf{A}_1}(\lambda) + \mathsf{AdvForge}_{\mathsf{MAC},\mathsf{A}_2}(\lambda).$$

Moreover, A_2 *is a*

$$(\mathsf{SKE1.CTLen}(\lambda, B(\lambda)),\ B'(\lambda) - \mathsf{MAC.OutLen}(\lambda),\ Q_{\mathsf{A}}(\lambda))$$

forging adversary.

Proof. Fix A and λ, and let $\mathbf{G}_0$ denote the original chosen ciphertext attack game. Let T_0 be the event that $\sigma = \hat{\sigma}$ in game $\mathbf{G}_0$.

We next define a modified attack game $\mathbf{G}_1$ in which all ciphertexts submitted to the decryption oracle by A in game $\mathbf{G}_1$ are simply rejected.

Let T_1 be the event that $\sigma = \hat{\sigma}$ in game $\mathbf{G}_1$. Let R_1 be the event in game $\mathbf{G}_1$ that some ciphertext is rejected in game $\mathbf{G}_1$ that would not have been rejected under the rules of game $\mathbf{G}_0$.

Since games $\mathbf{G}_0$ and $\mathbf{G}_1$ proceed identically until event R_1 occurs, the events $T_0 \wedge \neg R_1$ and $T_1 \wedge \neg R_1$ are identical, and so, by Lemma 6.2, we have $|\Pr[T_0] - \Pr[T_1]| \leq \Pr[R_1]$.

It is straightforward to verify that

$$\Pr[R_1] \leq \mathsf{AdvForge}_{\mathsf{MAC},\mathsf{A}_2}(\lambda) \tag{7.1}$$

for an adversary A_2 as described above.

The theorem now follows by observing that the attack by A in game $\mathbf{G}_1$ is now a passive attack. That is, the adversary A_1 in the theorem simply runs the adversary A, and whenever A makes a decryption oracle query adversary A_1 simply lets A continue *as if* the decryption oracle rejected the ciphertext. □

Remark 7.1. Although the keys for SKE2 are longer than those for SKE1, this need not be the case if we use a pseudorandom bit generator to stretch a short key into a suitably long key. Indeed, the key length of any symmetric key encryption scheme need be no longer than the key length of a secure pseudorandom bit generator.

7.3. A hybrid construction. Let KEM be a key encapsulation mechanism (as defined in section 7.1), and let SKE be a one-time symmetric key encryption scheme (as defined in section 7.2). Further, let us assume that the two schemes are *compatible* in the sense that for all $\lambda \in \mathbf{Z}_{\geq 0}$ we have $\mathsf{KEM.KeyLen}(\lambda) = \mathsf{SKE.KeyLen}(\lambda)$. We now describe a hybrid public-key encryption scheme HPKE.

The key generation algorithm for HPKE is the same as that of KEM, and the public and secret keys are the same as those of KEM.

To encrypt a message m in the hybrid scheme, we run KEM.Encrypt to generate a symmetric key K and a ciphertext ψ encrypting K. We then encrypt m under the key K using SKE.Encrypt, obtaining a ciphertext χ. The output of the encryption algorithm is $\hat{\psi} = (\psi, \chi)$, encoded in a canonical fashion as a bit string.

The decryption algorithm for the hybrid scheme runs as follows. Given a ciphertext $\hat{\psi}$, we first verify that $\hat{\psi}$ properly encodes a pair (ψ, χ). If not, we output reject and halt. Next, we decrypt ψ using KEM.Decrypt; if this yields reject, then we output reject and halt. Otherwise, we obtain a symmetric key K and decrypt χ under K using SKE.Decrypt and output the resulting decryption (which may be reject).

THEOREM 7.2. *If* KEM *and* SKE *are secure against adaptive chosen ciphertext attacks, then so is* HPKE.

In particular, if A *is a probabilistic, polynomial-time oracle query machine, then there exist probabilistic oracle query machines* A_1 *and* A_2*, whose running times are essentially the same as that of* A*, such that for all* $\lambda \in \mathbf{Z}_{\geq 0}$ *we have*

$$\mathsf{AdvCCA}_{\mathsf{HPKE},\mathsf{A}}(\lambda) \leq \mathsf{BadKeyPair}_{\mathsf{KEM}}(\lambda) + \mathsf{AdvCCA}'_{\mathsf{KEM},\mathsf{A}_1}(\lambda) + \mathsf{AdvCCA}_{\mathsf{SKE},\mathsf{A}_2}(\lambda).$$

Proof. Fix A and λ, and let $\mathbf{G}_0$ be the original chosen ciphertext attack game played by A against HPKE. We let $\hat{\psi}^* = (\psi^*, \chi^*)$ denote the target ciphertext; σ is the hidden bit generated by the encryption oracle and $\hat{\sigma}$ is the bit output by A. Let T_0 be the event that $\sigma = \hat{\sigma}$. Also, let K^* denote the symmetric key output by the algorithm KEM.Encrypt during the encryption process within the encryption oracle.

We now define a modified game $\mathbf{G}_1$. In this game, whenever a ciphertext (ψ, χ) is submitted to the decryption oracle after the invocation of the encryption oracle, if $\psi = \psi^*$ (but $\chi \neq \chi^*$ of course), then the decryption oracle does not apply algorithm KEM.Decrypt to obtain the symmetric key but instead just uses the key K^* produced by the encryption oracle. Let T_1 be the event that $\sigma = \hat{\sigma}$ in game $\mathbf{G}_1$.

This change is slightly more than just conceptual, since KEM.KeyGen may generate a bad key pair with probability $\mathsf{BadKeyPair}_{\mathsf{KEM}}(\lambda)$. However, unless this occurs, games $\mathbf{G}_0$ and $\mathbf{G}_1$ proceed identically, and so, by Lemma 6.2, we have

$$|\Pr[T_1] - \Pr[T_0]| \leq \mathsf{BadKeyPair}_{\mathsf{KEM}}(\lambda).$$

Now we define a modified game $\mathbf{G}_2$. This game behaves just like game $\mathbf{G}_1$, except that we use a completely random symmetric key K^+ in place of the key K^* in both the encryption and decryption oracles. Let T_2 be the event that $\sigma = \hat{\sigma}$ in game $\mathbf{G}_2$.

It is straightforward to see that there is an oracle query machine A_1, whose running time is essentially the same as that of A, such that

$$|\Pr[T_2] - \Pr[T_1]| = \mathsf{AdvCCA}'_{\mathsf{KEM},\mathsf{A}_1}(\lambda).$$

The adversary A_1 basically just runs the adversary A. In the attack game that A_1 is playing against KEM, the value $K^\dagger$ is equal to K^* in game $\mathbf{G}_1$ and is equal to K^+ in game $\mathbf{G}_2$. Note that in games $\mathbf{G}_1$ and $\mathbf{G}_2$ the ciphertext ψ^* is never explicitly decrypted, and so A_1 need not submit this for decryption either.

Last, we observe that there is an oracle query machine A_2, whose running time is essentially the same as that of A, such that

$$|\Pr[T_2] - 1/2| = \mathsf{AdvCCA}_{\mathsf{SKE},\mathsf{A}_2}(\lambda).$$

To see this, note that in game $\mathbf{G}_2$ the ciphertext χ^* is produced using the random symmetric encryption key K^+, and also that some other ciphertexts $\chi \neq \chi^*$ are decrypted using K^+, but that the key K^+ plays no other role in game $\mathbf{G}_2$. Thus, in game $\mathbf{G}_2$ the adversary A is essentially just carrying out an adaptive chosen ciphertext attack against SKE. □

Remark 7.2. We stress that it is essential for both KEM and SKE to be secure against adaptive chosen ciphertext attack in order to prove that HPKE is as well. One cannot start with a "weak" KEM and hope to "repair" it with a hybrid construction: doing this may indeed foil some specific attacks, but we know of no way to formally reason about the security of such a scheme. It is also important not to waste the

chosen ciphertext security of KEM by using a "weak" SKE. Indeed, some popular methods of constructing a "digital envelope" use a SKE that may only be secure against passive attacks; even if the resulting composite ciphertext is digitally signed, this does not necessarily provide security against chosen ciphertext attack.

Remark 7.3. In Remarks 6.9 and 6.10, we cautioned that revealing the reason for rejecting a ciphertext may invalidate the proof of security. This is not the case for the above hybrid construction. There are two reasons a ciphertext may be rejected in this construction: either KEM.Decrypt rejects ψ or SKE.Decrypt rejects χ. We leave it to the reader to verify that the above security proof goes through, essentially unchanged, even if the adversary is told the reason for rejecting. This is a nice feature, since in most practical implementations it would be easy to distinguish these two rejection cases, assuming that χ was very long, and that the decryption algorithm halted immediately when KEM.Decrypt rejects.

8. Key derivation functions. In the next section, we will present and analyze a key encapsulation mechanism. The key will be derived by hashing a pair of group elements. In order not to clutter that section, we develop here the notion of such a key derivation function.

Let $\mathcal{G}$ be a computational group scheme specifying a sequence $(\mathbf{S}_\lambda)_{\lambda \in \mathbf{Z}_{\geq 0}}$ of group distributions.

A *key derivation scheme* KDF *associated with* $\mathcal{G}$ specifies two items:

- A family of *key spaces* indexed by $\lambda \in \mathbf{Z}_{\geq 0}$ and $\Gamma \in [\mathbf{S}_\lambda]$. Each such key space is a probability space, denoted $\mathsf{KDF.KeySpace}_{\lambda,\Gamma}$, on bit strings, called *derivation keys*.
  There must exist a probabilistic, polynomial-time algorithm whose output distribution on input 1^λ and Γ is equal to $\mathsf{KDF.KeySpace}_{\lambda,\Gamma}$.
- A family of *key derivation functions* indexed by $\lambda \in \mathbf{Z}_{\geq 0}$, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, and $\mathsf{dk} \in [\mathsf{KDF.KeySpace}_{\lambda,\Gamma}]$, where each such function $\mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}$ maps a pair $(a, b) \in G^2$ of group elements to a key K.
  A key K is a bit string of length $\mathsf{KDF.OutLen}(\lambda)$. The parameter $\mathsf{KDF.OutLen}(\lambda)$ should be computable in deterministic polynomial time given 1^λ.
  There must exist a deterministic, polynomial-time algorithm that on input 1^λ, $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, $\mathsf{dk} \in [\mathsf{KDF.KeySpace}_{\lambda,\Gamma}]$, and $(a, b) \in G^2$ outputs $\mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$.

We now define the security property that we shall require of KDF.

For all 0/1-valued, probabilistic, polynomial-time algorithms A, and for all $\lambda \in \mathbf{Z}_{\geq 0}$, define

$$
\begin{aligned}
&\mathsf{AdvDist}_{\mathsf{KDF},\mathsf{A}}(\lambda) \\
&:= \Big| \Pr[\ \tau = 1 : \Gamma \xleftarrow{R} \mathbf{S}_\lambda;\ \mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma};\ a, b \xleftarrow{R} G; \\
&\qquad\qquad \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \mathsf{dk}, a, \mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b))\ ] \\
&\quad - \Pr[\ \tau = 1 : \Gamma \xleftarrow{R} \mathbf{S}_\lambda;\ \mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma};\ a \xleftarrow{R} G;\ K \xleftarrow{R} \{0,1\}^{\mathsf{KDF.OutLen}(\lambda)}; \\
&\qquad\qquad \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \mathsf{dk}, a, K)\ ] \Big| .
\end{aligned}
$$

That is, $\mathsf{AdvDist}_{\mathsf{KDF},\mathsf{A}}(\lambda)$ measures the advantage that A has in distinguishing two distributions: in the first it is given $\mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$ and in the second it is given a random key K; in both distributions it is given the derivation key dk as well as the

auxiliary group element a, so, in effect, both dk and a are to be regarded as public data.

We shall say that KDF is *secure* if this distinguishing advantage is negligible; i.e.,

> *for all* 0/1*-valued, probabilistic, polynomial-time algorithms* A *the function* $\mathsf{AdvDist}_{\mathsf{KDF},\mathsf{A}}(\lambda)$ *grows negligibly in* λ.

It is also convenient to define a quantity analogous to $\mathsf{AdvDist}_{\mathsf{KDF},\mathsf{A}}(\lambda)$ but conditioned on a fixed group description. For all 0/1-valued, probabilistic, polynomial-time algorithms A, for all $\lambda \in \mathbf{Z}_{\geq 0}$, and all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$,

$$\begin{aligned}
&\mathsf{AdvDist}_{\mathsf{KDF},\mathsf{A}}(\lambda \mid \Gamma) \\
&:= \Big| \Pr[\ \tau = 1 : \mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma};\ a, b \xleftarrow{R} G; \\
&\qquad\qquad \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \mathsf{dk}, a, \mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a,b))\ ] \\
&\quad - \Pr[\ \tau = 1 : \mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma};\ a \xleftarrow{R} G;\ K \xleftarrow{R} \{0,1\}^{\mathsf{KDF.OutLen}(\lambda)}; \\
&\qquad\qquad \tau \xleftarrow{R} \mathsf{A}(1^\lambda, \Gamma, \mathsf{dk}, a, K)\ ] \Big| .
\end{aligned}$$

8.1. Constructions.

8.1.1. Unconditionally secure constructions. One can build a secure KDF for $\mathcal{G}$ without any assumptions, provided the groups defined by $\mathcal{G}$ are sufficiently large, which they certainly will be in our applications. Indeed, all we need is that KDF is *pairwise independent*.

In our context, we shall say that a KDF is pairwise independent if for all $\lambda \in \mathbf{Z}_{\geq 0}$, for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, for all $a, b, b' \in G$ with $b \neq b'$, the distribution

$$\{(\mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a,b), \mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a,b')) : \mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma}\}$$

is the uniform distribution over all pairs of bits strings of length $\mathsf{KDF.OutLen}(\lambda)$.

By the leftover hash lemma [36, 37], it follows that if KDF is pairwise independent, then for all 0/1-valued, probabilistic, polynomial-time algorithms A, for all $\lambda \in \mathbf{Z}_{\geq 0}$, and for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$,

$$\mathsf{AdvDist}_{\mathsf{KDF},\mathsf{A}}(\lambda \mid \Gamma) \leq 2^{-k},$$

where

$$k = \left\lfloor \frac{\lfloor \log_2 q \rfloor - \mathsf{KDF.OutLen}(\lambda)}{2} \right\rfloor .$$

We also point out that fairly efficient pairwise independent functions can be constructed without relying on any intractability assumptions.

8.1.2. Conditionally secure constructions. In practice, to build a key derivation function one might simply use a dedicated cryptographic hash function, such as SHA-1.

In this situation, we will simply be forced to assume that such a KDF is secure. However, such an intractability assumption is not entirely unreasonable. Moreover, a dedicated cryptographic hash function has several potential advantages over a pairwise independent hash function:

- it may not use a key, or it may use a very short key, which may lead to a significant space savings;

- it can usually be evaluated more quickly than a typical pairwise independent hash function;
- it can be safely used to derive output keys that are significantly longer than would be safe to derive with a typical pairwise independent hash function;
- it may, at least heuristically, provide even more security in applications than a typical pairwise independent hash function.

9. The new encryption scheme: Hybrid version.

9.1. Description of the scheme. In this section, we present a hybrid version of our new encryption scheme. Specifically, we present a key encapsulation mechanism $\mathsf{CS3}$, out of which one can easily construct a hybrid encryption scheme, as described in section 7.

The scheme makes use of a computational group scheme $\mathcal{G}$ as described in section 4.1, defining a sequence $(\mathbf{S}_\lambda)_{\lambda \in \mathbf{Z}_{\geq 0}}$ of distributions of group descriptions and providing a sampling algorithm $\hat{S}$, where the output distribution $\hat{S}(1^\lambda)$ closely approximates $\mathbf{S}_\lambda$.

The scheme also makes use of a binary group hashing scheme HF associated with $\mathcal{G}$, as described in section 5.

Finally, the scheme makes use of a key derivation scheme KDF, associated with $\mathcal{G}$, as described in section 8. Note that output key length $\mathsf{CS3.KeyLen}(\lambda)$ of the scheme is equal to $\mathsf{KDF.OutLen}(\lambda)$.

The scheme is described in detail in Figure 9.1.

9.2. Security analysis of the scheme. We shall prove that $\mathsf{CS3}$ is secure against adaptive chosen ciphertext attack if the DDH assumption holds for $\mathcal{G}$ and the TCR assumption holds for HF, and assuming that KDF is a secure key derivation scheme.

As we have done before, for all probabilistic, polynomial-time oracle query machines A and for all $\lambda \in \mathbf{Z}_{\geq 0}$, we let $Q_{\mathsf{A}}(\lambda)$ be an upper bound on the number of decryption oracle queries made by A on input 1^λ. We assume that $Q_{\mathsf{A}}(\lambda)$ is a strict bound in the sense that it holds regardless of the probabilistic choices of A and regardless of the responses to its oracle queries from its environment.

THEOREM 9.1. *If the DDH assumption holds for $\mathcal{G}$ and the TCR assumption holds for HF, and assuming that KDF is a secure key derivation scheme, then $\mathsf{CS3}$ is secure against adaptive chosen ciphertext attack*

In particular, for all probabilistic, polynomial-time oracle query machines A, there exist probabilistic algorithms A_1, A_2, and A_3, whose running times are essentially the same as that of A, such that the following holds. For all $\lambda \in \mathbf{Z}_{\geq 0}$ and all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we have

$$\begin{aligned} \mathsf{AdvCCA}_{\mathsf{CS3},\mathsf{A}}(\lambda \mid \Gamma) \;\leq\; & \mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma)\mathsf{AdvTCR}_{\mathsf{HF},\mathsf{A}_2}(\lambda \mid \Gamma) \\ & + \mathsf{AdvDist}_{\mathsf{KDF},\mathsf{A}_3}(\lambda \mid \Gamma) + (Q_{\mathsf{A}}(\lambda) + 3)/q. \end{aligned} \tag{9.1}$$

To prove Theorem 9.1, let us fix a probabilistic, polynomial-time oracle query machine A, the value of the security parameter $\lambda \in \mathbf{Z}_{\geq 0}$, and the group description $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$.

The proof follows the same line of argument as the proof of Theorem 6.1, and we will at several places appeal to arguments in that proof so as to avoid unnecessary repetition.

The attack game is as described in section 7.1.2. We now discuss the relevant random variables in this game.

Key Generation: On input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, compute

$$\Gamma[\hat{G}, G, g, q] \xleftarrow{R} \hat{S}(1^\lambda);\ \mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};\ \mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma};$$
$$w \xleftarrow{R} \mathbf{Z}_q^*;\ x_1, x_2, y_1, y_2, z_1, z_2 \xleftarrow{R} \mathbf{Z}_q;$$
$$\hat{g} \leftarrow g^w;\ e \leftarrow g^{x_1}\hat{g}^{x_2};\ f \leftarrow g^{y_1}\hat{g}^{y_2};\ h \leftarrow g^{z_1}\hat{g}^{z_2}$$

and output the public key $\mathsf{PK} = (\Gamma, \mathsf{hk}, \mathsf{dk}, \hat{g}, e, f, h)$ and the secret key $\mathsf{SK} = (\Gamma, \mathsf{hk}, \mathsf{dk}, x_1, x_2, y_1, y_2, z_1, z_2)$.

Encryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a public key

$$\mathsf{PK} = (\Gamma[\hat{G}, G, g, q], \mathsf{hk}, \mathsf{dk}, \hat{g}, e, f, h) \in [\mathbf{S}_\lambda] \times [\mathsf{HF.KeySpace}_{\lambda,\Gamma}] \times [\mathsf{KDF.KeySpace}_{\lambda,\Gamma}] \times G^4,$$

compute

E1: $u \xleftarrow{R} \mathbf{Z}_q$;
E2: $a \leftarrow g^u$;
E3: $\hat{a} \leftarrow \hat{g}^u$;
E4: $b \leftarrow h^u$;
E5: $K \leftarrow \mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$;
E6: $v \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a})$;
E7: $d \leftarrow e^u f^{uv}$

and output the symmetric key K and the ciphertext $\psi = (a, \hat{a}, d)$.

Decryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key

$$\mathsf{SK} = (\Gamma[\hat{G}, G, g, q], \mathsf{hk}, \mathsf{dk}, x_1, x_2, y_1, y_2, z_1, z_2) \in [\mathbf{S}_\lambda] \times [\mathsf{HF.KeySpace}_{\lambda,\Gamma}] \times [\mathsf{KDF.KeySpace}_{\lambda,\Gamma}] \times \mathbf{Z}_q^6,$$

along with a ciphertext ψ, do the following.

D1: Parse ψ as a 3-tuple $(a, \hat{a}, d) \in \hat{G}^3$; output reject and halt if ψ is not of this form.
D2: Test if a and $\hat{a}$ belong to G; output reject and halt if this is not the case.
D3: Compute $v \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a})$.
D4: Test if $d = a^{x_1+y_1 v}\hat{a}^{x_2+y_2 v}$; output reject and halt if this is not the case.
D5: Compute $b \leftarrow a^{z_1}\hat{a}^{z_2}$.
D6: Compute $K \leftarrow \mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$ and output the symmetric key K.

FIG. 9.1. *The key encapsulation mechanism* CS3.

Suppose that the public key is $(\Gamma, \mathsf{hk}, \mathsf{dk}, \hat{g}, e, f, h)$ and that the secret key is $(\Gamma, \mathsf{hk}, \mathsf{dk}, x_1, x_2, y_1, y_2, z_1, z_2)$. Let $w := \log_g \hat{g}$, and define $x, y, z \in \mathbf{Z}_q$ as follows:

$$x := x_1 + x_2 w,\ y := y_1 + y_2 w,\ z := z_1 + z_2 w.$$

As a notational convention, whenever a particular ciphertext ψ is under consideration in some context, the following values are also implicitly defined in that context:

- $a, \hat{a}, d \in G$, where $\psi = (a, \hat{a}, d)$;
- $u, \hat{u}, v, s \in \mathbf{Z}_q$, where

$$u := \log_g a,\ \hat{u} := \log_{\hat{g}} \hat{a},\ v := \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a}),\quad s := \log_g d.$$

For the target ciphertext ψ^*, we also denote by $a^*, \hat{a}^*, d^* \in G$, and $u^*, \hat{u}^*, v^*, s^* \in \mathbf{Z}_q$ the corresponding values.

The probability space defining the attack game is then determined by the following, mutually independent, random variables:

- the coin tosses of A;
- the values $\mathsf{hk}, \mathsf{dk}, w, x_1, x_2, y_1, y_2, z_1, z_2$ generated by the key generation algorithm;
- the values $\tau \in \{0,1\}$, $K^+ \in \{0,1\}^{\mathsf{KDF.OutLen}(\lambda)}$, and $u^* \in \mathbf{Z}_q$ generated by the encryption oracle in the attack game.

Let $\mathbf{G}_0$ be the original attack game, let $\hat{\tau} \in \{0,1\}$ denote the output of A, and let T_0 be the event that $\tau = \hat{\tau}$ in $\mathbf{G}_0$ so that $\mathsf{AdvCCA}_{\mathsf{CS3},\mathsf{A}}(\lambda \mid \Gamma) = |\Pr[T_0] - 1/2|$.

As in the proof of Theorem 6.1, we shall define a sequence of modified games $\mathbf{G}_i$, for $i = 1, 2, \ldots$, where in game $\mathbf{G}_i$ the event T_i will be the event corresponding to event T_0 but in game $\mathbf{G}_i$. The overall structure of the proof will differ a bit from that of Theorem 6.1, even though many of the low-level details will be very similar. Indeed, the proof of this theorem is conceptually a bit simpler (even though there are more steps) than that of Theorem 6.1, since the inputs to $\mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}$ in the encryption oracle are independent of any quantities computed by the adversary; we also save a term of $1/q$ in (9.1) because of this (compare with (6.1) in Theorem 6.1).

Game $\mathbf{G_1}$. We now modify game $\mathbf{G}_0$ to obtain a new game $\mathbf{G}_1$. These two games are identical, except that instead of using the encryption algorithm as given to compute the target ciphertext ψ^* we use a modified encryption algorithm in which steps **E4** and **E7** are replaced by

E4′: $b \leftarrow a^{z_1}\hat{a}^{z_2}$;

E7′: $d \leftarrow a^{x_1+y_1 v}\hat{a}^{x_2+y_2 v}$.

By the same reasoning as in the proof of Theorem 6.1, we have

$$\Pr[T_1] = \Pr[T_0].$$

Game $\mathbf{G_2}$. We again modify the encryption oracle, replacing step **E3** by

E3′: $\hat{u} \xleftarrow{R} \mathbf{Z}_q$; $\hat{a} \leftarrow \hat{g}^{\hat{u}}$.

By the same reasoning as in the proof of Theorem 6.1, one sees that there exists a probabilistic algorithm A_1, whose running time is essentially the same as that of A, such that

$$|\Pr[T_2] - \Pr[T_1]| \leq \mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma) + 2/q.$$

Note that unlike game $\mathbf{G}_2$ in the proof of Theorem 6.1, we do not impose the restriction $u^* \neq \hat{u}^*$ just yet; it is technically convenient to defer this until later. This is why the term $2/q$ appears in the above bound rather than $3/q$.

Game $\mathbf{G_3}$. This game is the same as game $\mathbf{G}_2$, except for the following modification.

We modify the decryption oracle so that it applies the following *special rejection rule*: if the adversary submits a ciphertext ψ for decryption at a point in time after the encryption oracle has been invoked such that $(a, \hat{a}) \neq (a^*, \hat{a}^*)$ but $v = v^*$, then the decryption oracle immediately outputs reject and halts (before executing step **D4′**).

We claim that there exists a probabilistic algorithm A_2, whose running time is essentially the same as that of A, such that

$$|\Pr[T_3] - \Pr[T_2]| \leq \mathsf{AdvTCR}_{\mathsf{HF},\mathsf{A}_2}(\lambda \mid \Gamma).$$

This follows from reasoning very similar to the proof of Lemma 6.5 in the analysis of game $\mathbf{G}_5$ in the proof of Theorem 6.1. Observe that we can impose the special

rejection rule already in this game, rather than deferring to a later game as in the proof of Theorem 6.1, because, as we mentioned above, the inputs to $\mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}$ in the encryption oracle are independent of any quantities computed by the adversary.

Game $\mathbf{G_4}$. We again modify the encryption oracle, replacing step **E3′** by

E3″: $\hat{u} \xleftarrow{R} \mathbf{Z}_q \setminus \{u\}$; $\hat{a} \leftarrow \hat{g}^{\hat{u}}$.

It is easy to verify that

$$|\Pr[T_4] - \Pr[T_3]| \leq 1/q.$$

Game $\mathbf{G_5}$. In this game, we modify the decryption oracle in game $\mathbf{G}_4$, replacing steps **D4** and **D5** by

D4′: test if $\hat{a} = a^w$ and $d = a^{x+yv}$; output reject and halt if this is not the case;

D5′: $b \leftarrow a^z$.

Let R_5 be the event that in game $\mathbf{G}_5$ some ciphertext ψ is submitted to the decryption oracle that is rejected in step **D4′** but that would have passed the test in step **D4**.

It is clear that

$$|\Pr[T_5] - \Pr[T_4]| \leq \Pr[R_5].$$

We also claim that

$$\Pr[R_5] \leq Q_{\mathsf{A}}(\lambda)/q.$$

This follows from reasoning analogous to that in Lemma 6.6 (in game $\mathbf{G}_5$ in the proof of Theorem 6.1).

Game $\mathbf{G_6}$. We again modify the algorithm used by the encryption oracle, replacing step **E4′** by

E4″: $r \xleftarrow{R} \mathbf{Z}_q$; $b \leftarrow g^r$.

By reasoning analogous to that in the analysis of game $\mathbf{G}_4$ in the proof of Theorem 6.1, one can easily show that

$$\Pr[T_6] = \Pr[T_5].$$

Game $\mathbf{G_7}$. In this game, we modify the encryption oracle, replacing step **E5** of the encryption algorithm by

E5′: $K \xleftarrow{R} \{0,1\}^{\mathsf{KDF.OutLen}(\lambda)}$.

It is straightforward to see that there exists a probabilistic algorithm A_3, whose running time is essentially the same as that of A, such that

$$|\Pr[T_7] - \Pr[T_6]| \leq \mathsf{AdvDist}_{\mathsf{KDF},\mathsf{A}_3}(\lambda \mid \Gamma).$$

Furthermore, it is clear by construction that

$$\Pr[T_7] = 1/2.$$

That completes the proof of Theorem 9.1.

9.3. Two variations. One can easily modify scheme CS3 to obtain two variants, which we call CS3a and CS3b, that are analogous to the variations CS1a and CS1b of CS1, discussed in section 6.3. Only the key generation and decryption algorithms differ. The details are presented in Figures 9.2 and 9.3.

Key Generation: On input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, compute

$$\Gamma[\hat{G}, G, g, q] \xleftarrow{R} \hat{S}(1^\lambda);\ \mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};\ \mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma};$$
$$w \xleftarrow{R} \mathbf{Z}_q^*;\ x_1, x_2, y_1, y_2, z \xleftarrow{R} \mathbf{Z}_q;$$
$$\hat{g} \leftarrow g^w;\ e \leftarrow g^{x_1}\hat{g}^{x_2};\ f \leftarrow g^{y_1}\hat{g}^{y_2};\ h \leftarrow g^z$$

and output the public key $\mathsf{PK} = (\Gamma, \mathsf{hk}, \mathsf{dk}, \hat{g}, e, f, h)$ and the secret key $\mathsf{SK} = (\Gamma, \mathsf{hk}, \mathsf{dk}, x_1, x_2, y_1, y_2, z)$.

Decryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key

$$\mathsf{SK} = (\Gamma[\hat{G}, G, g, q], \mathsf{hk}, \mathsf{dk}, x_1, x_2, y_1, y_2, z)$$
$$\in [\mathbf{S}_\lambda] \times [\mathsf{HF.KeySpace}_{\lambda,\Gamma}] \times [\mathsf{KDF.KeySpace}_{\lambda,\Gamma}] \times \mathbf{Z}_q^5,$$

along with a ciphertext ψ, do the following.

D1: Parse ψ as a 3-tuple $(a, \hat{a}, d) \in \hat{G}^3$; output reject and halt if ψ is not of this form.
D2: Test if a and $\hat{a}$ belong to G; output reject and halt if this is not the case.
D3: Compute $v \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a})$.
D4: Test if $d = a^{x_1+y_1 v}\hat{a}^{x_2+y_2 v}$; output reject and halt if this is not the case.
D5′: Compute $b \leftarrow a^z$.
D6: Compute $K \leftarrow \mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$ and output the symmetric key K.

FIG. 9.2. *Key generation and decryption algorithms for* CS3a.

Key Generation: On input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, compute

$$\Gamma[\hat{G}, G, g, q] \xleftarrow{R} \hat{S}(1^\lambda);\ \mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};\ \mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma};$$
$$w \xleftarrow{R} \mathbf{Z}_q^*;\ x, y, z \xleftarrow{R} \mathbf{Z}_q;$$
$$\hat{g} \leftarrow g^w;\ e \leftarrow g^x;\ f \leftarrow g^y;\ h \leftarrow g^z$$

and output the public key $\mathsf{PK} = (\Gamma, \mathsf{hk}, \mathsf{dk}, \hat{g}, e, f, h)$ and the secret key $\mathsf{SK} = (\Gamma, \mathsf{hk}, \mathsf{dk}, x, y, z)$.

Decryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key

$$\mathsf{SK} = (\Gamma[\hat{G}, G, g, q], \mathsf{hk}, \mathsf{dk}, x, y, z) \in [\mathbf{S}_\lambda] \times [\mathsf{HF.KeySpace}_{\lambda,\Gamma}] \times [\mathsf{KDF.KeySpace}_{\lambda,\Gamma}] \times \mathbf{Z}_q^3,$$

along with a ciphertext ψ, do the following.

D1: Parse ψ as a 3-tuple $(a, \hat{a}, d) \in \hat{G}^3$; output reject and halt if ψ is not of this form.
D2′: Test if a belongs to G; output reject and halt if this is not the case.
D3: Compute $v \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a, \hat{a})$.
D4′: Test if $\hat{a} = a^w$ and $d = a^{x+yv}$; output reject and halt if this is not the case.
D5′: Compute $b \leftarrow a^z$.
D6: Compute $K \leftarrow \mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$ and output the symmetric key K.

FIG. 9.3. *Key generation and decryption algorithms for* CS3b.

Remark 9.1. Scheme CS3b is essentially the same scheme that was originally presented in [56]. This scheme is the most efficient scheme among all those presented in this paper. It is also attractive in that it yields a public-key encryption scheme

with an unrestricted message space. Moreover, this scheme has some other attractive security properties that will be examined in section 10.

Remark 9.2. Analogous to Remark 6.7, we do not have to separately test if $\hat{a}$ belongs to the subgroup G in step **D2′** of the decryption algorithm of CS3b, and we may test if a belongs to G in some cases by testing if $a^q = 1_G$.

Remark 9.3. Analogous to Remark 6.8, in scheme CS3b the decryption algorithm has to compute either three or four (if we test if $a^q = 1_G$) powers of a, and special algorithmic techniques can be exploited to do this.

Remark 9.4. Analogous to Remarks 6.9 and 6.10, it is strongly recommended to *always* compute both exponentiations in step **D4′** of CS3b before rejecting the ciphertext and to not reveal the precise reason why any ciphertext was rejected. Again, we know of no actual attack given this information, and, in fact, it seems very unlikely—see section 10.7 below.

The following theorem can proved using an argument almost identical to the argument that was used to prove Theorem 6.10. We leave it to the reader to verify this.

THEOREM 9.2. *If the DDH assumption holds for $\mathcal{G}$ and the TCR assumption holds for* HF*, and assuming that* KDF *is a secure key derivation scheme, then* CS3a *and* CS3b *are secure against adaptive chosen ciphertext attack.*

In particular, for all probabilistic, polynomial-time oracle query machines A*, for all $\lambda \in \mathbf{Z}_{\geq 0}$, and for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we have*

$$|\mathsf{AdvCCA}_{\mathsf{CS3a},\mathsf{A}}(\lambda \mid \Gamma) - \mathsf{AdvCCA}_{\mathsf{CS3},\mathsf{A}}(\lambda \mid \Gamma)| \leq Q_{\mathsf{A}}(\lambda)/q$$

and

$$|\mathsf{AdvCCA}_{\mathsf{CS3b},\mathsf{A}}(\lambda \mid \Gamma) - \mathsf{AdvCCA}_{\mathsf{CS3},\mathsf{A}}(\lambda \mid \Gamma)| \leq Q_{\mathsf{A}}(\lambda)/q.$$

10. Further security considerations of scheme CS3b. The key encapsulation mechanism CS3b, which was described and analyzed in section 9.3, has some other interesting security properties, which we discuss in this section.

The main results we present here are the following. First, we show that CS3b is no less secure than a more traditional key encapsulation mechanism that is a hashed variant of ElGamal encryption, which we call HEG. Second, we also show that CS3b is secure in the random oracle model (viewing KDF as a random oracle) if the CDH and TCR assumptions hold. Along the way, we also give a security analysis of HEG in the random oracle model, based on a rather nonstandard intractability assumption.

10.1. Hashed ElGamal key encapsulation. We begin by presenting a fairly traditional version of ElGamal key encapsulation, which we call HEG.

The scheme makes use of a computational group scheme $\mathcal{G}$ as described in section 4.1, defining a sequence $(\mathbf{S}_\lambda)_{\lambda \in \mathbf{Z}_{\geq 0}}$ of distributions of group descriptions and providing a sampling algorithm $\hat{S}$, where the output distribution $\hat{S}(1^\lambda)$ closely approximates $\mathbf{S}_\lambda$.

Also, the scheme makes use of a key derivation scheme KDF, associated with $\mathcal{G}$, as described in section 8. Note that output key length $\mathsf{EG.KeyLen}(\lambda)$ of the scheme is equal to $\mathsf{KDF.OutLen}(\lambda)$.

The scheme is described in detail in Figure 10.1.

10.2. The random oracle model. We will analyze the security of both schemes HEG and CS3b in the random oracle model. In this approach, a cryptographic hash function—in this case KDF—is modeled for the purposes of analysis as a "black box"

Key Generation: On input 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, compute

$$\Gamma[\hat{G}, G, g, q] \xleftarrow{R} \hat{S}(1^\lambda);\ \mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma};\ z \xleftarrow{R} \mathbf{Z}_q;\ h \leftarrow g^z$$

and output the public key $\mathsf{PK} = (\Gamma, \mathsf{dk}, h)$ and the secret key $\mathsf{SK} = (\Gamma, \mathsf{dk}, z)$.

Encryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a public key

$$\mathsf{PK} = (\Gamma[\hat{G}, G, g, q], \mathsf{dk}, h) \in [\mathbf{S}_\lambda] \times [\mathsf{KDF.KeySpace}_{\lambda,\Gamma}] \times G,$$

compute

E1: $u \xleftarrow{R} \mathbf{Z}_q$;
E2: $a \leftarrow g^u$;
E3: $b \leftarrow h^u$;
E4: $K \leftarrow \mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$

and output the symmetric key K and the ciphertext $\psi = a$.

Decryption: Given 1^λ for $\lambda \in \mathbf{Z}_{\geq 0}$, a secret key

$$\mathsf{SK} = (\Gamma[\hat{G}, G, g, q], \mathsf{dk}, z) \in [\mathbf{S}_\lambda] \times [\mathsf{KDF.KeySpace}_{\lambda,\Gamma}] \times \mathbf{Z}_q,$$

along with a ciphertext ψ, do the following.

D1: Parse ψ as a group element $a \in \hat{G}$; output reject and halt if ψ is not of this form.
D2: Test if a belongs to G; output reject and halt if this is not the case.
D3: Compute $b \leftarrow a^z$.
D4: Compute $K \leftarrow \mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$ and output the symmetric key K.

FIG. 10.1. *The key encapsulation mechanism* HEG.

containing a random function to which the adversary and the algorithms implementing the cryptosystem have "oracle access." This approach has been used implicitly and informally for some time; however, it was formalized by Bellare and Rogaway [9] and has subsequently been used quite a bit in the cryptographic research community.

More precisely, we shall analyze the security of the scheme HEG and later CS3b in an idealized model of computation where for all $\lambda \in \mathbf{Z}_{\geq 0}$, all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, all $\mathsf{dk} \in [\mathsf{KDF.KeySpace}_{\lambda,\Gamma}]$, and all $a, b \in G$, we treat the values $\mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$ as mutually independent, random bit strings of length $\mathsf{KDF.OutLen}(\lambda)$; moreover, the only way to obtain the value of $\mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$ is to explicitly query an oracle with input $(\lambda, \Gamma, \mathsf{dk}, a, b)$. Actually, to be complete, we allow Γ, dk, a, and b to range over arbitrary bit strings, regardless of whether these are valid encodings of appropriate objects. Since in any of our applications only a finite number of the values $\mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$ will be relevant, experiments based on these values can be modeled using finite probability spaces.

When considering an adversary A that is carrying out an adaptive chosen ciphertext attack in the random oracle model, in addition to the usual types of oracle queries that A makes, the adversary A is also allowed to query the random oracle representing KDF. We shall denote by $Q'_{\mathsf{A}}(\lambda)$ a strict upper bound on the number of random oracle queries that A makes for a given value of the security parameter λ; as usual, this bound should hold regardless of the environment in which A actually runs.

10.3. CS3b is at least as secure as HEG. We now show that the scheme CS3b is at least as secure as HEG.

THEOREM 10.1. *If scheme* HEG *is secure against adaptive chosen ciphertext attack, then so is* CS3b*; moreover, this implication holds in either the standard or random oracle models.*

In particular, for all probabilistic, polynomial-time oracle query machines A*, there exists another oracle query machine* A_1*, whose running time is essentially the same as that of* A*, such that for all* $\lambda \in \mathbf{Z}_{\geq 0}$ *and all* $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$ *we have*

$$\mathsf{AdvCCA}_{\mathsf{CS3b},\mathsf{A}}(\lambda \mid \Gamma) \leq \mathsf{AdvCCA}_{\mathsf{HEG},\mathsf{A}_1}(\lambda \mid \Gamma);$$

moreover, $Q_{\mathsf{A}_1}(\lambda) \leq Q_{\mathsf{A}}(\lambda)$ *and (in the random oracle model)* $Q'_{\mathsf{A}_1}(\lambda) \leq Q'_{\mathsf{A}}(\lambda)$.

Proof. Fix A, λ, and $\Gamma[\hat{G}, G, g, q]$ as above. We construct an adversary A_1 that attacks HEG. The adversary A_1 makes use of A by providing an environment for A as follows.

First, suppose that A_1 is given a public key (Γ, dk, h) for scheme HEG, where Γ is fixed as above. Adversary A_1 then "dresses up" the HEG public key to look like a CS3b public key; namely, A_1 computes

$$\mathsf{hk} \xleftarrow{R} \mathsf{HF.KeySpace}_{\lambda,\Gamma};\ w \xleftarrow{R} \mathbf{Z}_q^*;\ x, y \xleftarrow{R} \mathbf{Z}_q;\ \hat{g} \leftarrow g^w;\ e \leftarrow g^x;\ f \leftarrow g^y$$

and presents A with the CS3b public key

$$(\Gamma, \mathsf{hk}, \mathsf{dk}, \hat{g}, e, f, h).$$

Second, whenever A submits a CS3b ciphertext $(a, \hat{a}, d) \in \hat{G}^3$ to the decryption oracle, adversary A_1 first performs the validity tests of the decryption algorithm of CS3b, making use of the values hk, w, x, y generated above; if these tests pass, then A_1 invokes the decryption oracle of HEG with input a.

Third, when A invokes the encryption oracle of CS3b, adversary A_1 does the following. It invokes the encryption oracle of HEG, obtaining a ciphertext $a^* \in G$ and a key $K^\dagger$. It then "dresses up" a^* to look like a CS3b ciphertext; namely, it computes

$$\hat{a}^* \leftarrow (a^*)^w;\ v^* \leftarrow \mathsf{HF}_{\mathsf{hk}}^{\lambda,\Gamma}(a^*, \hat{a}^*);\ d^* \leftarrow (a^*)^{x+yv^*}$$

and presents A with the CS3b ciphertext $(a^*, \hat{a}^*, d^*)$ along with the key $K^\dagger$.

Fourth, when A terminates and outputs a value, A_1 also terminates and outputs the same value.

That completes the description of the adversary A_1.

One has to check that A_1 carries out a legal adaptive chosen ciphertext attack in the sense that it should not attempt to submit the target ciphertext itself to the decryption oracle, subsequent to the invocation of the encryption oracle. Consider a ciphertext a submitted by A_1 to the decryption oracle. This was derived from a valid CS3b ciphertext $(a, \hat{a}, d)$ submitted by A to the decryption oracle. By the construction, it is easy to see that if $a = a^*$, then, in fact, $(a, \hat{a}, d) = (a^*, \hat{a}^*, d^*)$, which cannot happen if A itself carries out a legal attack.

Since the simulation by A_1 above is perfect, it is clear that whatever advantage A has in guessing the hidden bit, adversary A_1 has precisely the same advantage. It is also clear by construction that $Q_{\mathsf{A}_1}(\lambda) \leq Q_{\mathsf{A}}(\lambda)$ and in the random oracle model that $Q'_{\mathsf{A}_1}(\lambda) \leq Q'_{\mathsf{A}}(\lambda)$. □

10.4. The security of HEG in the random oracle model. As for the security of HEG, even in the random oracle model we do not know how to prove a very strong result. We content ourselves with a proof that the scheme HEG is secure against

adaptive chosen ciphertext attack in the random oracle model, provided the CDH assumption holds *relative to an oracle for the DDH problem.*

More precisely, for all probabilistic, polynomial-time oracle query machines A and for all $\lambda \in \mathbf{Z}_{\geq 0}$, we define

$$\mathsf{AdvCDH}^*_{\mathcal{G},\mathsf{A}}(\lambda) := \Pr[\ c = g^{xy} : \Gamma[\hat{G}, G, g, q] \xleftarrow{R} \mathbf{S}_\lambda;\ x \xleftarrow{R} \mathbf{Z}_q;\ y \xleftarrow{R} \mathbf{Z}_q; \\ c \xleftarrow{R} \mathsf{A}^{\mathsf{DHP}_{\lambda,\Gamma}}(1^\lambda, \Gamma, g^x, g^y)\ ],$$

where the notation $\mathsf{A}^{\mathsf{DHP}_{\lambda,\Gamma}}(\cdots)$ signifies that A runs with access to an oracle for the Diffie–Hellman predicate $\mathsf{DHP}_{\lambda,\Gamma}$ defined in section 4.3.3.

We say that the CDH assumption for $\mathcal{G}$ holds relative to an oracle for the DDH problem if

> *for all probabilistic, polynomial-time oracle query machines* A *the function* $\mathsf{AdvCDH}^*_{\mathcal{G},\mathsf{A}}(\lambda)$ *is negligible in* λ.

For all probabilistic, polynomial-time oracle query machines A, for all $\lambda \in \mathbf{Z}_{\geq 0}$, and for all $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$, we also define

$$\mathsf{AdvCDH}^*_{\mathcal{G},\mathsf{A}}(\lambda \mid \Gamma) := \Pr[\ c = g^{xy} : x \xleftarrow{R} \mathbf{Z}_q;\ y \xleftarrow{R} \mathbf{Z}_q;\ c \xleftarrow{R} \mathsf{A}^{\mathsf{DHP}_{\lambda,\Gamma}}(1^\lambda, \Gamma, g^x, g^y)\ ].$$

On the one hand, it has been proven (see [42]) that in a "generic" model of computation the CDH problem remains hard even in the presence of a DDH oracle, thus giving some justification for this assumption; on the other hand, if one works with the special elliptic curves discussed in the paper [38] already mentioned in section 4.4, then the DDH oracle actually has an efficient implementation, even though the CDH problem still appears hard.

THEOREM 10.2. *The scheme* HEG *is secure in the random oracle model if the CDH assumption for* $\mathcal{G}$ *holds relative to an oracle for the DDH problem.*

In particular, for all probabilistic, polynomial-time oracle query machines A*, there exists an oracle query machine* A_1*, whose running time is essentially the same as that of* A*, such that for all* $\lambda \in \mathbf{Z}_{\geq 0}$ *and for all* $\Gamma[\hat{G}, G, g, q] \in [\mathbf{S}_\lambda]$ *we have*

$$\mathsf{AdvCCA}_{\mathsf{HEG},\mathsf{A}}(\lambda \mid \Gamma) \leq \mathsf{AdvCDH}^*_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma) + Q_{\mathsf{A}}(\lambda)/q;$$

moreover, the number of DDH-oracle queries made by A_1 *is bounded by* $Q'_{\mathsf{A}}(\lambda)$.

To prove Theorem 10.2, let us fix A, λ, and $\Gamma[\hat{G}, G, g, q]$. The attack game is as described in section 7.1.2.

We begin by describing the relevant random variables in the attack game. The public key is (Γ, dk, h) and the secret key is (Γ, dk, z).

For a given ciphertext ψ, we let $a \in G$ denote the corresponding group element, and we let $b := a^z$, $u := \log_g a$, and $K := \mathsf{KDF}^{\lambda,\Gamma}_{\mathsf{dk}}(a, b)$. Note also that $b = a^u$. For the target ciphertext ψ^*, we let a^*, b^*, u^*, and K^* denote the corresponding values.

The encryption oracle also generates values $\tau \in \{0,1\}$ and $K^+ \in \{0,1\}^{\mathsf{KDF.OutLen}(\lambda)}$.

Let $\mathbf{G}_0$ be the original attack game, let $\hat{\tau}$ denote the output of A, and let T_0 be the event that $\tau = \hat{\tau}$ so that $\mathsf{AdvCCA}_{\mathsf{HEG},\mathsf{A}}(\lambda \mid \Gamma) = |\Pr[T_0] - 1/2|$.

As usual, we define a sequence of games $\mathbf{G}_1$, $\mathbf{G}_2$, etc., and in game $\mathbf{G}_i$ for $i \geq 1$ we define T_i to be the event in game $\mathbf{G}_i$ corresponding to event T_0 in game $\mathbf{G}_0$.

Game $\mathbf{G}_1$. We modify game $\mathbf{G}_0$ as follows. First, we run the encryption oracle at the beginning of the attack game, but we give the results of this to the adversary only when it actually invokes the encryption oracle. This is a purely conceptual change, since the adversary provides no input to the encryption oracle. Second, if the adversary ever submits a ciphertext $\psi = \psi^*$ to the decryption oracle *before* the

encryption algorithm is invoked, we abort the game immediately before responding to this decryption oracle invocation (the environment, say, goes silent at this point).

Let F_1 be the event that game $\mathbf{G}_1$ is aborted as above. It is clear that $\Pr[F_1] \leq Q_{\mathsf{A}}(\lambda)/q$. It is also clear that games $\mathbf{G}_0$ and $\mathbf{G}_1$ proceed identically until event F_1 occurs, and so, by Lemma 6.2, we have $|\Pr[T_1] - \Pr[T_0]| \leq \Pr[F_1]$.

Game $\mathbf{G}_2$. We next modify game $\mathbf{G}_1$ as follows. If the adversary ever queries the random oracle to obtain the value of $\mathsf{KDF}^{\lambda,\Gamma}_{\mathsf{dk}}(a^*, b^*)$, we immediately abort the game before responding to this random oracle invocation.

It is easy to see that $\Pr[T_2] = 1/2$. This follows directly from the fact that in game $\mathbf{G}_2$ the value of $\mathsf{KDF}^{\lambda,\Gamma}_{\mathsf{dk}}(a^*, b^*)$ is obtained from the random oracle only by the encryption oracle: the adversary never queries the random oracle directly at this point, nor does the decryption oracle.

Let F_2 be the event that game $\mathbf{G}_2$ is aborted as above. It is clear that $|\Pr[T_2] - \Pr[T_1]| \leq \Pr[F_2]$, so it suffices to bound $\Pr[F_2]$.

We claim that $\Pr[F_2] = \mathsf{AdvCDH}^*_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma)$ for an oracle query machine A_1 whose running time and number of oracle queries are bounded as in the statement of the theorem.

We now describe A_1. It takes as input 1^λ, $\Gamma[\hat{G}, G, g, q]$, along with group elements $a^*, h \in G$, and attempts to compute $b^* \in G$ such that $\mathsf{DHP}_{\lambda,\Gamma}(h, a^*, b^*) = 1$. The machine A_1 has access to an oracle for the function $\mathsf{DHP}_{\lambda,\Gamma}$.

Machine A_1 simulates the environment of game $\mathbf{G}_2$ for A as follows. It first computes $\mathsf{dk} \xleftarrow{R} \mathsf{KDF.KeySpace}_{\lambda,\Gamma}$ and gives A the public key (Γ, dk, h). For the target ciphertext, it of course sets $\psi^* := a^*$. For the other output $K^\dagger$ of the encryption oracle, A_1 simply generates this as a random bit string of length $\mathsf{KDF.OutLen}(\lambda)$.

Machine A_1 also needs to simulate the responses to the random oracle and decryption oracle queries. For the random oracle queries, the only values that are relevant are those corresponding to the given values of λ, Γ, and dk.

For the irrelevant random oracle queries, A_1 simply maintains a set of input/output pairs, generating outputs at random as necessary.

Machine A_1 processes relevant random oracle queries using the following data structures:

- a set $\mathcal{V}_1$ of triples (a, b, K), with $a, b \in G$ and $K \in \{0,1\}^{\mathsf{KDF.OutLen}(\lambda)}$, initially empty; this will contain those triples (a, b, K) for which A_1 has assigned the value K to $\mathsf{KDF}^{\lambda,\Gamma}_{\mathsf{dk}}(a, b)$;
- a set $\mathcal{V}_2$ of pairs (a, b), with $a, b \in G$, initially empty; this will contain precisely those pairs (a, b) such that $(a, b, K) \in \mathcal{V}_1$ for some K, and $\mathsf{DHP}_{\lambda,\Gamma}(h, a, b) = 1$;
- a set $\mathcal{V}_3$ of pairs (a, K), with $a \in G$ and $K \in \{0,1\}^{\mathsf{KDF.OutLen}(\lambda)}$, initially empty; this will contain pairs (a, K) for which A_1 has assigned the value K to $\mathsf{KDF}^{\lambda,\Gamma}_{\mathsf{dk}}(a, b)$ for $b \in G$ with $\mathsf{DHP}_{\lambda,\Gamma}(h, a, b) = 1$, even though A_1 does not actually know the value of b.

Given a request for the value $\mathsf{KDF}^{\lambda,\Gamma}_{\mathsf{dk}}(a, b)$, machine A_1 does the following:

- It tests if $(a, b, K) \in \mathcal{V}_1$ for some K. If so (which means that A has queried the value $\mathsf{KDF}^{\lambda,\Gamma}_{\mathsf{dk}}(a, b)$ before), it returns K as the value of $\mathsf{KDF}^{\lambda,\Gamma}_{\mathsf{dk}}(a, b)$; otherwise, it continues.
- It invokes its own DDH-oracle to determine if $\mathsf{DHP}_{\lambda,\Gamma}(h, a, b) = 1$.
- If $\mathsf{DHP}_{\lambda,\Gamma}(h, a, b) = 1$, then we have the following:
  - If $a = a^*$, it halts and outputs the solution $b^* := b$ to the given problem instance (this corresponds to the early-abort rule introduced in game $\mathbf{G}_2$); otherwise, it continues.

– It adds the pair (a, b) to the set $\mathcal{V}_2$.
– If $(a, K) \in \mathcal{V}_3$ for some K, then it adds the triple (a, b, K) to $\mathcal{V}_1$ and returns K as the value of $\mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$; otherwise, it continues.

- It generates K as a random bit string of length $\mathsf{KDF.OutLen}(\lambda)$, adds the triple (a, b, K) to $\mathcal{V}_1$, and returns K as the value of $\mathsf{KDF}_{\mathsf{dk}}^{\lambda,\Gamma}(a, b)$.

Machine A_1 processes decryption oracle queries as follows. Suppose it is given a ciphertext ψ, with $a \in G$ the corresponding group element. Then it does the following:

- If $\psi = \psi^*$ (which can only happen if the encryption oracle has not yet been invoked), then it simply halts (this corresponds to the early-abort rule introduced in game $\mathbf{G}_1$); otherwise, it continues.
- It tests if $(a, b) \in \mathcal{V}_2$ for some $b \in G$.
- If this is so, then it finds the (unique) triple in $\mathcal{V}_1$ of the form (a, b, K) for some K and returns this value of K as the result of the decryption oracle invocation; otherwise, it continues.
- It tests if $(a, K) \in \mathcal{V}_3$ for some K.
- If this is so, then it returns this value of K as the result of the decryption oracle; otherwise, it generates a random bit string K of length $\mathsf{KDF.OutLen}(\lambda)$, adds the pair (a, K) to $\mathcal{V}_3$, and returns this value of K as the result of the decryption oracle invocation.

It is straightforward to verify by inspection that A_1 as above does the job.

That completes the proof of Theorem 10.2.

10.5. The security of CS3b in the random oracle model. We can now prove the following security theorem for CS3b in the random oracle model.

THEOREM 10.3. *The scheme* CS3b *is secure in the random oracle model if the CDH assumption holds for* $\mathcal{G}$ *and the TCR assumption holds for* HF.

Proof. To prove this, let us assume by way of contradiction that the CDH assumption holds for $\mathcal{G}$ and the TCR assumption holds for HF, but CS3b is not secure in the random oracle model.

Now, the CDH assumption implies that for any polynomials P_1 and P_2 (with integer coefficients, taking positive values on $\mathbf{Z}_{\geq 0}$) there exists a $\lambda_0 \in \mathbf{Z}_{\geq 0}$ such that for all $\lambda \geq \lambda_0$

$$\Pr[q \leq P_1(\lambda) : \Gamma[\hat{G}, G, g, q] \stackrel{R}{\leftarrow} \mathbf{S}_\lambda] \leq 1/P_2(\lambda),$$

since otherwise a trivial, brute-force algorithm would have a CDH advantage that was not negligible. This implies, in particular, that when we model KDF as a random oracle, it acts as a secure key derivation scheme. From this it follows from Theorems 9.1 and 9.2 that CS3b is secure in the random oracle model if the DDH assumption holds; actually, since these two theorems do not deal with the random oracle model, one must make a cursory inspection of the proofs of these theorems to draw this conclusion, but this is very straightforward.

Let A be a polynomial-time adversary that breaks the security of CS3b in the random oracle model. This means that there exist polynomials P_1, P_2 (with integer coefficients, taking positive values on $\mathbf{Z}_{\geq 0}$), an infinite set $\Lambda \subset \mathbf{Z}_{\geq 0}$, and sets $\mathcal{Z}_\lambda \subset [\mathbf{S}_\lambda]$ for each $\lambda \in \Lambda$ such that

- for all $\lambda \in \Lambda$ and $\Gamma \in \mathcal{Z}_\lambda$, $\mathsf{AdvCCA}_{\mathsf{CS3b},\mathsf{A}}(\lambda \mid \Gamma) \geq 1/P_1(\lambda)$;
- for all $\lambda \in \Lambda$, $\Pr_{\mathbf{S}_\lambda}[\mathcal{Z}_\lambda] \geq 1/P_2(\lambda)$.

Theorems 9.1 and 9.2 (adapted to the random oracle model), together with our TCR assumption, imply that there exists a polynomial-time algorithm A_1 such that

for all sufficiently large $\lambda \in \Lambda$ and for all but a negligible fraction of Γ in $\mathcal{Z}_\lambda$ we have

$$\mathsf{AdvDDH}_{\mathcal{G},\mathsf{A}_1}(\lambda \mid \Gamma) \geq 1/(2P_1(\lambda)).$$

We now apply Lemma 4.3 using the above algorithm A_1 and choosing the value of κ in that lemma so that $2^{-\kappa} \cdot Q'_{\mathsf{A}}(\lambda) \leq 1/2$, yielding a polynomial-time algorithm A_2 such that for all sufficiently large $\lambda \in \Lambda$, for all but a negligible fraction of $\Gamma \in \mathcal{Z}_\lambda$, and for all $\rho \in \mathcal{T}_{\lambda,\Gamma}$,

$$\Pr[\mathsf{A}_2(1^\lambda, \Gamma, \rho) \neq \mathsf{DHP}_{\lambda,\Gamma}(\rho)] \leq 1/(2Q'_{\mathsf{A}}(\lambda)).$$

Applying Theorem 10.1 with the adversary A yields a polynomial-time adversary A_3 such that for all $\lambda \in \Lambda$ and $\Gamma \in \mathcal{Z}_\lambda$, $\mathsf{AdvCCA}_{\mathsf{HEG},\mathsf{A}_3}(\lambda \mid \Gamma) \geq 1/P_1(\lambda)$. Applying Theorem 10.2 with the adversary A_3 yields a polynomial-time oracle machine A_4 such that

$$\mathsf{AdvCDH}^*_{\mathcal{G},\mathsf{A}_4}(\lambda \mid \Gamma) \geq 1/(2P_1(\lambda))$$

for all sufficiently large $\lambda \in \Lambda$ and for all but a negligible fraction of $\Gamma \in \mathcal{Z}_\lambda$. Since for a given value of λ algorithm A_4 makes no more than $Q'_{\mathsf{A}}(\lambda)$ DDH-oracle queries, if we replace the DDH-oracle used by A_4 with algorithm A_2 above, we obtain a polynomial-time algorithm A_5 such that for all sufficiently large $\lambda \in \Lambda$ and for all but a negligible fraction of Γ in $\mathcal{Z}_\lambda$ we have $\mathsf{AdvCDH}_{\mathcal{G},\mathsf{A}_5}(\lambda \mid \Gamma) \geq 1/(4P_1(\lambda))$. But this contradicts the CDH assumption. □

10.6. Random oracles and pairwise independent key derivation functions: Getting the best of both. If we want to prove the security of CS3b in the standard model without making any intractability assumptions about KDF, then we may choose KDF to be pairwise independent. On the one hand, standard constructions for pairwise independent hash functions typically exhibit a lot of algebraic structure, and it is not very reasonable to assume that such a KDF can be safely modeled as a random oracle. On the other hand, typical dedicated cryptographic hash functions, such as SHA-1, may be modeled as random oracles, but they are certainly not pairwise independent.

We shall sketch here how to get the best of both worlds, i.e., how to implement the KDF so that we get a proof of security of CS3b in the standard model just under the DDH and TCR assumptions and in the random oracle model under the CDH and TCR assumptions.

The idea is this: compute KDF as the XOR of a pairwise independent hash KDF1 and a cryptographic hash KDF2.

It is clear that if KDF1 is pairwise independent, then so is KDF, and so the security of CS3b in the standard model under the DDH and TCR assumptions now follows directly from Theorem 9.2.

Now suppose we model the cryptographic hash KDF2 as a random oracle. It is easy to see that for any adversary A attacking CS3b given oracle access to KDF2 there is an adversary A_1, whose running time is roughly the same as that of A, that attacks CS3b given oracle access to KDF: the adversary A_1 just does whatever A does, except that whenever A queries the oracle for KDF2 adversary A_1 queries its oracle for KDF and computes the value of KDF2 as the XOR of the value of KDF and the value of KDF1. Note, however, that the output distribution of the oracle KDF is the same as that of a random oracle, and so the security of CS3b in the random oracle model under the CDH and TCR assumptions now follows directly from Theorem 10.3.

We do not necessarily advocate this approach to building a KDF in practical implementations: simply assuming that a KDF implemented directly using a dedicated cryptographic hash is secure is quite reasonable, and the resulting KDF is much simpler and more efficient than any approach that makes use of a pairwise independent hash function.

10.7. Further discussion. The scheme HEG is intended to represent a fairly traditional version of ElGamal key encapsulation. The only thing slightly nontraditional about it is the fact that the symmetric key K is derived by hashing both a (the ephemeral Diffie–Hellman public key) and b (the shared Diffie–Hellman key), rather than just b alone.

Hashing both the ephemeral and shared keys together has some quantitative security advantages. Notice that in Theorem 10.2 the implied CDH algorithm makes no more than $Q'_{\mathsf{A}}(\lambda)$ queries to the DDH-oracle. If we were to hash only the shared Diffie–Hellman key, we could still prove the security of HEG, but the reduction would be less efficient; in particular, the implied CDH algorithm might require up to $Q'_{\mathsf{A}}(\lambda) \cdot Q_{\mathsf{A}}(\lambda)$ queries to the DDH-oracle. A similar quantitative security advantage arises in the multiuser/multimessage model (see [7]). In this model, we can exploit the well-known random self-reducibility of the CDH problem to get a more efficient reduction if we hash both keys instead of just one. Of course, these improved security reductions for HEG carry over to the security reduction for CS3b in the random oracle model.

The DHAES encryption scheme [1], which is a hybrid ElGamal encryption scheme that has been proposed for standardization, also hashes both the ephemeral and shared Diffie–Hellman keys to derive a symmetric key. Indeed, the DHAES scheme can be constructed from the key encapsulation mechanism HEG using the hybrid constructions presented in section 7, and it is straightforward to verify that analogues of Theorems 10.1 and 10.2 hold for the DHAES scheme as well. The DHAES scheme needs to hash both group elements because it allows the possibility of a group G whose order is a composite number. In a revised version of DHAES, called DHIES [2], the group G is required to have prime order, and only the shared Diffie–Hellman key is hashed. However, as we have seen, there are still some security benefits to be gained from hashing both group elements, even if the group is of prime order, as we are assuming in this paper.

We should also point out that because any attack on scheme CS3b can be immediately translated into an attack on HEG (see Theorem 10.1), it seems very unlikely that any of the side channels discussed in Remark 9.4 could be used to break CS3b without breaking HEG. Thus, although the availability of such side channel information would invalidate the proof of security of CS3b under the DDH, it seems very unlikely that it could be exploited to break it.

Theorem 10.3 originally appeared in the paper [56]. The proof in that paper basically rolled all of the arguments used in the proofs of Theorems 10.1, 10.2, and 10.3, along with the arguments in section 10.6, into a single proof, which we have unraveled to some extent here. Our presentation here was somewhat influenced by the paper [48], which formally introduces the notion of the CDH assumption relative to an oracle for the DDH problem.

The security reduction in Theorem 10.3 is quite inefficient: we have to perform many simulations using the given adversary A just to solve one instance of the DDH problem, and then in a different simulation involving A we have to solve many instances of the DDH problem in order to solve one instance of the CDH problem. Of course, if the DDH problem for a given group scheme turns out not to be a hard

problem, then it may very well be the case that there is a much more efficient DDH algorithm than the one built using our security reduction involving A. In this case, the reduction in Theorem 10.3 becomes quite reasonable.

11. Summary. We conclude with a brief summary of the schemes presented in this paper:

- the public-key encryption scheme CS1, which is secure under the DDH and TCR assumptions, along with minor, slightly simpler, and more efficient variants CS1a and CS1b;
- the public-key encryption scheme CS2, which is a "hash free" variant of CS1 and which is secure under the DDH assumption;
- the key encapsulation mechanism CS3, along with variants CS3a and CS3b, which can be combined with an appropriate symmetric cipher to build a hybrid cipher; the hybrid cipher will be secure under the DDH and TCR assumptions, together with an appropriate "smoothing" assumption for the key derivation function, and an appropriate security assumption for the symmetric cipher.

Among these schemes, the one most likely to be used in practice is the hybrid construction based on CS3b. Over the other schemes, it has the following advantages:

- it is more efficient;
- it can be used to encrypt messages that are bit strings of arbitrary length;
- it is no less secure than traditional "hashed" ElGamal;
- it can be proven secure in the random oracle model under weaker CDH assumption.

A version of this scheme is currently included in a draft ISO standard for public key encryption.

Acknowledgments. Some of this work was done while the first author was at the Institute for Theoretical Computer Science, ETH, Zurich, and while the second author was at the IBM Zurich Research Lab, as well as visiting the Computer Science Department at Stanford University. Thanks to Ilia Mironov for comments on an early draft of this paper.

Thanks also to Moni Naor for his comments on an early draft of the *Crypto* '98 paper, on which this paper is based, and, in particular, for his suggestion of using a universal one-way hash function instead of a collision resistant hash function in the design of scheme CS1 and for his suggestion of a hash-free variant, upon which scheme CS2 is loosely based.

COUNTING COMPLEXITY CLASSES FOR NUMERIC COMPUTATIONS I: SEMILINEAR SETS*

PETER BÜRGISSER† AND FELIPE CUCKER‡

Abstract. We define a counting class $\#\mathrm{P}_{\mathrm{add}}$ in the Blum–Shub–Smale setting of additive computations over the reals. Structural properties of this class are studied, including a characterization in terms of the classical counting class $\#\mathsf{P}$ introduced by Valiant. We also establish transfer theorems for both directions between the real additive and the discrete setting. Then we characterize in terms of completeness results the complexity of computing basic topological invariants of semilinear sets given by additive circuits. It turns out that the computation of the Euler characteristic is $\mathrm{FP}_{\mathrm{add}}^{\#\mathrm{P}_{\mathrm{add}}}$-complete, while for fixed k the computation of the kth Betti number is $\mathrm{FPAR}_{\mathrm{add}}$-complete. Thus the latter is more difficult under standard complexity theoretic assumptions. We use all of the above to prove some analogous completeness results in the classical setting.

Key words. counting complexity, real complexity classes, Euler characteristic, Betti numbers

1. Introduction.

In 1989 Blum, Shub, and Smale [5] introduced a theory of computation over the real numbers with the goal of providing numerical computations (as performed, e.g., in numerical analysis or computational geometry) the kind of foundations classical complexity theory has provided to discrete computation. This theory describes the difficulty of solving numerical problems and provides a taxonomy of complexity classes capturing different degrees of such a difficulty.

Since its introduction, this Blum–Shub–Smale (BSS) theory has focused mainly on decisional problems. Functional problems attracted attention at the level of analysis of particular algorithms, but structural properties of classes of such problems were hardly studied. So far, the only systematic approach to study the complexity of certain functional problems within a framework of computations over the reals is Valiant's theory of VNP-completeness [7, 40, 43]. However, the relationship of this theory to the more general BSS setting is, as of today, poorly understood. A detailed account of the research on complexity of real functions within the classical framework can be found in [23].

A first step in the study of functional properties could focus on complexity classes related to counting problems, i.e., functional problems, whose associated functions count the number of solutions of some decisional problem.

In classical complexity theory, counting classes were introduced by Valiant in his seminal papers [41, 42]. Valiant defined $\#\mathsf{P}$ as the class of functions which count the number of accepting paths of nondeterministic polynomial time machines and proved that the computation of the permanent is $\#\mathsf{P}$-complete. This exhibited an unexpected difficulty for the computation of a function, whose definition is only slightly different from that of the determinant, a problem known to be in $\mathsf{FNC}^2 \subseteq \mathsf{FP}$, and thus

considered "easy." This difficulty was highlighted by a result of Toda [38] proving that $\mathsf{PH} \subseteq \mathsf{P}^{\#\mathsf{P}}$, i.e., that $\#\mathsf{P}$ has at least the power of the polynomial hierarchy.

In the continuous setting, i.e., over the reals, the only attempt to define counting classes was made by Meer [27]. He defined a real version of the class $\#\mathsf{P}$ and studied some of its logical properties in terms of metafinite model theory. Meer did not investigate complete problems for this class.

In this paper we will define and study counting classes in the model of additive BSS machines [24]. The computation nodes of these machines perform additions and subtractions but no multiplications and divisions. The corresponding complexity classes are denoted by $\mathrm{P}_{\mathrm{add}}$ and $\mathrm{NP}_{\mathrm{add}}$.[1]

The results in this paper can be seen as a first step towards a better understanding of the power of counting in the unrestricted BSS model over the reals (allowing also for multiplications and divisions). A sequel to this paper studying this setting is under preparation [11].

Our results can be grouped in two kinds: structural relationships between complexity classes and completeness results. The latter (for whose proofs the former are used) satisfy a driving motivation for this paper: to capture the complexity of computing basic topological invariants of geometric objects in terms of complexity classes and completeness results. In the following, we give an outline of the main results of this paper.

1.1. Counting classes. Recall that $\#\mathsf{P}$ is the class of functions $f\colon \{0,1\}^\infty \to \mathbb{N}$ for which there exists a polynomial time Turing machine M and a polynomial p with the property that for all $n \in \mathbb{N}$ and all $x \in \{0,1\}^n$, $f(x)$ counts the number of strings $y \in \{0,1\}^{p(n)}$ such that M accepts (x, y).

By replacing Turing machines with additive BSS machines in the above definition, we get a class of functions $f : \mathbb{R}^\infty \to \mathbb{N} \cup \{\infty\}$, which we denote by $\#\mathrm{P}_{\mathrm{add}}$. Thus $f(x)$ counts the number of vectors $y \in \mathbb{R}^{p(n)}$ such that M accepts (x, y). By counting only the number of "digital" vectors $y \in \{0,1\}^{p(n)}$, we obtain a smaller class of functions $f : \mathbb{R}^\infty \to \mathbb{N}$ denoted by $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$.

In Theorem 4.7 we show that a counting problem $f \in \mathrm{D}\#\mathrm{P}_{\mathrm{add}}$ is $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$-complete with respect to Turing reductions iff it is $\#\mathrm{P}_{\mathrm{add}}$-complete with respect to Turing reductions. Moreover, in section 4.3 we prove that there is a wealth of natural complete problems for the class $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$ with respect to Turing reductions. For instance, consider the following counting version of the real weighted perfect matching problem $\#\mathrm{PM}_{\mathbb{R}}$: given $w \in \mathbb{R}$ and a bipartite graph G with real weights on the edges, count the number of perfect matchings of G having weight at most w. (The weight of a matching is defined as the sum of the weights of its edges.) The problem $\#\mathrm{PM}_{\mathbb{R}}$ turns out to be $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$-complete with respect to Turing reductions. The same is true for the counting version of the real traveling salesman problem $\#\mathrm{TSP}_{\mathbb{R}}$ to count the number of Hamilton circuits of weight at most w of a given graph with real weights on the edges. It is an interesting open problem whether these problems are also $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$-complete with respect to parsimonious reductions; see section 7.

The above completeness results follow from a general principle (Proposition 4.13), which says that for proving $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$-completeness of the counting version of a problem in $\mathrm{DNP}_{\mathrm{add}}$ it is sufficient to show that the restriction of the corresponding counting problem to integer inputs is $\#\mathsf{P}$-complete. The proof of this principle is based on an

[1] To distinguish between classical and additive complexity complexity classes, we use the subscript "add" to indicate the latter. Also, to further emphasize this distinction, we write the former in sans serif.

extension of the structural relationships between the real additive and the discrete setting, discovered by Fournier and Koiran [16, 17], discussed next.

1.2. Structural relationships. The main result of section 4.1 is summarized in Theorem 4.1, which says that for several classical[2] complexity classes $\mathcal{C}$ consisting of decisional problems the corresponding additive complexity class $\mathcal{C}_{\mathrm{add}}$ is contained in, or even equal to, $\mathrm{P}^{\mathcal{C}}_{\mathrm{add}}$. That is, all problems in $\mathcal{C}_{\mathrm{add}}$ can be solved by an additive machine working in polynomial time and having access to a (discrete) oracle in $\mathcal{C}$. Likewise, if $\mathcal{C}$ is a classical complexity class of functions $\{0,1\}^\infty \to \{0,1\}^\infty$, we obtain that $\mathcal{C}_{\mathrm{add}} \subseteq \mathrm{FP}^{\mathcal{C}}_{\mathrm{add}}$. In particular, we have $\mathrm{FP}^{\#\mathrm{P}_{\mathrm{add}}}_{\mathrm{add}} = \mathrm{FP}^{\#\mathsf{P}}_{\mathrm{add}}$.

Theorem 4.1 is an extension of the work of Fournier and Koiran [16, 17], who discovered this close relationship between the real additive and the discrete setting. This relationship is based on Meyer auf der Heide's (nonuniform) construction of small depth linear decision trees for point location in arrangements of hyperplanes [29, 30] (see also Meiser [28] for an extension of these results). Fournier and Koiran showed that this construction can be made uniform if a classical NP-oracle is available. This way, they proved that $\mathrm{NP}_{\mathrm{add}} \subseteq \mathrm{P}^{\mathsf{NP}}_{\mathrm{add}}$. We have extended this result in various directions, in particular to the counting context.

An interesting application of the above insights is that Toda's famous result [38], as well as its extension by Toda and Watanabe [39], carry over to the real additive setting (Corollary 4.6). We use this to prove that the counting class $\#\mathrm{P}_{\mathrm{add}}$ is closely related to its digital variant $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$ in the sense that $\mathrm{FP}^{\#\mathrm{P}_{\mathrm{add}}}_{\mathrm{add}} = \mathrm{FP}^{\mathrm{D}\#\mathrm{P}_{\mathrm{add}}}_{\mathrm{add}}$. In other words, a $\#\mathrm{P}_{\mathrm{add}}$-oracle does not give more power to an additive polynomial time Turing machine than a $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$-oracle.

An important application of our structural insights is the following transfer result (Corollary 4.11):

$$\#\mathrm{P}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}} \Longleftrightarrow \mathrm{D}\#\mathrm{P}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}} \Longleftrightarrow \#\mathsf{P} \subseteq \mathsf{FP/poly}.$$

The proof uses the fact that the Boolean part of $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$, consisting of the restrictions of all functions in $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$ to the set of binary inputs $\{0,1\}^\infty$, is equal to $\#\mathsf{P/poly}$ (Proposition 4.10).

1.3. Topological invariants. Algebraic topology studies topological spaces X by assigning to X various algebraic objects in a functorial way. In particular, homeomorphic (or even homotopy equivalent) spaces lead to isomorphic algebraic objects. For a general reference in algebraic topology we refer the reader to [20, 33]. Typical examples of such algebraic objects studied are the (singular) homology vector spaces $H_k(X;\mathbb{Q})$ over $\mathbb{Q}$, defined for integers $k \in \mathbb{N}$. The dimension $b_k(X)$ of $H_k(X;\mathbb{Q})$ is called the kth *Betti number* of the space X. The zeroth Betti number $b_0(X)$ counts the number of connected components of X and for $k > 0$, $b_k(X)$, measures a more sophisticated "degree of connectivity." Intuitively speaking, for a three-dimensional space X, $b_1(X)$ counts the number of holes and $b_2(X)$ counts the number of cavities of X. It is known that $b_k(X) = 0$ for $k > n := \dim X$. The *Euler characteristic* of X defined by $\chi(X) := \sum_{k=0}^{n} (-1)^k b_k(X)$ is an important numerical invariant of X, enjoying several nice properties. For a finite set X, $\chi(X)$ is just the cardinality of X.

The notion of a cell complex [20, 33] will be of importance for our algorithms to compute the Euler characteristic and the Betti numbers. For instance, if X is

[2]Throughout this paper we use the words *discrete*, *classical*, or *Boolean* to emphasize that we are referring to the theory of complexity over a finite alphabet as exposed, e.g., in [2, 34].

decomposed as a finite cell complex having c_k cells of dimension k, then $\chi(X) := \sum_{k=0}^{n}(-1)^k c_k$.

We remark that the number of connected components, the Euler characteristic, and the Betti numbers lead to interesting lower complexity bounds for semialgebraic decision problems; see [3, 44, 45] and the survey [9].

1.4. Semilinear sets and additive circuits. In this paper, we will confine our investigations to *semilinear sets* $X \subseteq \mathbb{R}^n$, which are derived from closed halfspaces by taking a finite number of unions, intersections, and complements. Moreover, we assume that the closed halfspaces are given by linear inequalities of "mixed type" $a_1X_1 + \cdots + a_nX_n \leq b$ with integer coefficients a_i and real right-hand side b.

We will represent semilinear sets by a very compact data structure. An *additive circuit* $\mathcal{C}$ is a special arithmetic circuit [19], whose set of arithmetic operations is restricted to additions and subtractions. The circuit may have selection gates and use a finite set of real constants. (See Definition 2.9 for details.) The set of inputs accepted by an additive circuit is semilinear, and any semilinear set can be described this way.

The basic problem $\mathrm{CSAT}_{\mathrm{add}}$ to decide whether the semilinear set X given by an additive circuit is nonempty turns out to be $\mathsf{NP}_{\mathrm{add}}$-complete [4]. By contrast, the feasibility question for a system of linear inequalities of the above mixed type is solvable in $\mathrm{P}_{\mathrm{add}}$. This is just a rephrasing of a well-known result by Tardos [37] (cf. Remark 2.7).

Over the real numbers, space is not as meaningful a resource as it is in the discrete setting (cf. [31]). The role of space, however, is satisfactorily played by parallel time formalized by the notion of uniform arithmetic circuits (cf. [4, 14]). We denote by $\mathrm{PAR}_{\mathrm{add}}$ the class of decision problems for which there exists a $\mathrm{P}_{\mathrm{add}}$-uniform family $(\mathcal{C}_n)$ of additive circuits such that the depth of $\mathcal{C}_n$ grows at most polynomially in n (see section 2). $\mathrm{FPAR}_{\mathrm{add}}$ denotes the class of functions f which can be computed with such resources and such that the size of $f(x)$ is polynomially bounded in the size of x. (The size of a vector is defined as its length.)

1.5. Completeness results for topological invariants. In the computational problems listed below, it is always assumed that the input is an additive circuit $\mathcal{C}$ and X is the semilinear set accepted by $\mathcal{C}$. We also say that X is defined or given by $\mathcal{C}$.

Among the completeness results proved in this paper, the most important ones are the following (for a complete list see section 6).

1. The problem $\mathrm{DIM}_{\mathrm{add}}(d)$ to decide whether $\dim X \geq d$ is $\mathrm{NP}_{\mathrm{add}}$-complete (Theorem 5.1).

2. The problem $\mathrm{EULER}_{\mathrm{add}}$ to compute the Euler characteristic of a closed semilinear set X is $\mathrm{FP}_{\mathrm{add}}^{\#\mathrm{P}_{\mathrm{add}}}$-complete with respect to Turing reductions (Theorem 5.18).

3. The problem $\mathrm{BETTI}_{\mathrm{add}}(k)$ to compute the kth Betti number $b_k(X)$ of a closed semilinear set X is $\mathrm{FPAR}_{\mathrm{add}}$-complete with respect to Turing reductions (Theorem 5.19).

These results give a complexity theoretic distinction between the problems to compute the Euler characteristic and to compute Betti numbers. The computation of the Euler characteristic is strictly easier than the computation of the number of connected components, or more generally than the computation of the kth Betti number for any fixed k, under a standard complexity theoretic assumption (Corollary 5.23). Intuitively, the fact that $\mathrm{EULER}_{\mathrm{add}}$ is easier than $\mathrm{BETTI}_{\mathrm{add}}(k)$ can be explained by the various nice properties satisfied by the Euler characteristic.

Let us now restrict the inputs in the above three problems $\mathcal{P}$ to *constant-free* additive circuits and denote the resulting computational problem by $\mathcal{P}^0$. Note that constant-free circuits can be encoded over a finite alphabet and thus be handled by (classical) Turing machines. In section 5.3.6 we derive the following completeness results in the Turing model: $\mathrm{DIM}^0_{\mathrm{add}}(d)$ is NP-complete, $\mathrm{EULER}^0_{\mathrm{add}}$ is $\mathsf{FP}^{\#\mathsf{P}}$-complete, and $\mathrm{BETTI}^0_{\mathrm{add}}(k)$ is $\mathsf{FPSPACE}$-complete.

We briefly describe the proof idea for $\mathrm{BETTI}_{\mathrm{add}}(k)$. The lower bound is inspired by an early paper by Reif [35] (see also [36]), who showed the PSPACE-hardness of a generalized movers problem in robotics. The *reachability problem* $\mathrm{REACH}_{\mathrm{add}}$ is the following: given an additive circuit defining the semilinear set X and given two points $s, t \in X$, decide whether s and t are in the same connected component of X. Reif's result implies that the analogue of the reachability problem for semialgebraic sets (given by inequalities of rational polynomials) is PSPACE-hard. We cannot apply this result in our context, since we are dealing here with linear polynomials (of mixed type). However, we borrow from Reif's proof the idea to characterize PSPACE by symmetric polynomial space Turing machines [26] and prove that $\mathrm{REACH}_{\mathrm{add}}$ is $\mathrm{PAR}_{\mathrm{add}}$-hard (Proposition 5.9). From this lower bound result, one can derive the $\mathrm{PAR}_{\mathrm{add}}$-hardness of $\mathrm{BETTI}_{\mathrm{add}}(k)$ by standard constructions of algebraic topology.

The proof that $\mathrm{BETTI}_{\mathrm{add}}(k)$belongs to $\mathrm{FPAR}_{\mathrm{add}}$ proceeds by the following steps:

1. An additive circuit $\mathcal{C}$ accepting a set X defines a decomposition of X into leaf sets. This decomposition can be refined to a finite cell complex if X is compact (cf. section 5.3.3).
2. The matrices (a_{ij}) of the boundary maps of the corresponding cellular homology can be succinctly represented by Boolean circuits computing a_{ij} from the index pair (i, j) given in binary.
3. The rank of an integer matrix given in succinct representation can be computed in a space efficient manner (Lemma 5.21).

1.6. Organization of the paper. We start in section 2 by introducing some notation and recalling basic facts about additive machines. Then we define in section 3 the counting complexity class $\#\mathrm{P}_{\mathrm{add}}$ in the additive model as well as its digital variant $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$, introduce different notions of reductions, and prove some basic completeness results. Section 4 deals with structural relationships and can be seen as the first part of this paper. Section 5 about the complexity to compute topological invariants constitutes the second part of this paper. It contains completeness proofs for several natural computational problems, each of which are treated in separate subsections. Those problems are counting connected components, computing the Euler characteristic, and computing Betti numbers. We also present completeness results for the corresponding problems in the Turing model in section 5.3.6. Finally, we end the paper in section 6 with a summary of problems and results and with some selected open problems in section 7.

2. Preliminaries about additive machines. We denote by $\mathbb{R}^\infty$ the disjoint union $\mathbb{R}^\infty = \bigsqcup_{n\geq 0}\mathbb{R}^n$, where, for $n \geq 0$, $\mathbb{R}^n$ is the standard n-dimensional space over $\mathbb{R}$. The space $\mathbb{R}^\infty$ is a natural one to represent problem instances of arbitrarily high dimension. For $x \in \mathbb{R}^n \subset \mathbb{R}^\infty$, we call n the *size* of x, and we denote it by $\mathrm{size}(x)$. Contained in $\mathbb{R}^\infty$ is the set of bitstrings $\{0,1\}^\infty$ defined as the union of the sets $\{0,1\}^n$ for $n \in \mathbb{N}$.

Additive machines (in the sequel called simply "machines") are BSS machines whose computation nodes perform only additions and subtractions (see [4, 24] for details). To a machine M we naturally associate an input-output map $\varphi_M : \mathbb{R}^\infty \to$

$\mathbb{R}^\infty$. We shall say that a function $f : \mathbb{R}^\infty \to \mathbb{R}^k$, $k \leq \infty$, is *computable* when there is a machine M such that $f = \varphi_M$. Also, a set $A \subseteq \mathbb{R}^\infty$ is *decided* by a machine M if its characteristic function $\chi_A : \mathbb{R}^\infty \to \{0,1\}$ coincides with φ_M. So, for decision problems, we consider machines whose output space is $\{0,1\} \subset \mathbb{R}$.

We can now introduce some central complexity classes.

DEFINITION 2.1. *A machine M over $\mathbb{R}$ is said* to work in polynomial time *when there is a constant $c \in \mathbb{N}$ such that for every input $x \in \mathbb{R}^\infty$, M reaches its output node after at most* $\mathrm{size}(x)^c$ *steps. The class* $\mathrm{P}_{\mathrm{add}}$ *is then defined as the sets of all subsets of $\mathbb{R}^\infty$ that can be decided by a machine working in polynomial time. The class* $\mathrm{FP}_{\mathrm{add}}$ *is the class of functions computed by machines working in polynomial time.*

DEFINITION 2.2. *A set A belongs to* $\mathrm{NP}_{\mathrm{add}}$ *if there is a machine M satisfying the following condition: for all x, $x \in A$ iff there is $y \in \mathbb{R}^\infty$ such that M accepts the input (x, y) within time polynomial in* $\mathrm{size}(x)$. *In this case, the element y is said to be a* witness *for x. If we require the witness y to belong to $\{0,1\}^\infty$ we say that $A \in \mathrm{DNP}_{\mathrm{add}}$ (the D standing for* digital*). Abusing language we will call the machine M above an* $\mathrm{NP}_{\mathrm{add}}$-machine *(resp., a* $\mathrm{DNP}_{\mathrm{add}}$*-machine).*

Remark 2.3.

(i) In this model the element y can be seen as the sequence of guesses used in the Turing machine model (but note that in the case of $\mathrm{NP}_{\mathrm{add}}$ these guesses are not necessarily binary). However, we note that in this definition no nondeterministic machine is introduced as a computational model, and nondeterminism appears here as a new acceptance definition for the deterministic machine. Also, we note that w.l.o.g., the length of y can be bounded by the running time of M (which is of the form $p(\mathrm{size}(x))$ for a polynomial p).

(ii) The definitions of $\mathrm{NP}_{\mathrm{add}}$ and $\mathrm{DNP}_{\mathrm{add}}$ extend in a straightforward manner to all levels of the polynomial hierarchies $\mathrm{PH}_{\mathrm{add}}$ and $\mathrm{DPH}_{\mathrm{add}}$, respectively (i.e., to the classes Σ^k_{add} and Π^k_{add} for $k \geq 0$). For details see [4, 14].

DEFINITION 2.4. *We say that an additive machine* has no real constants *when the only machine constants appearing in its program are* 0 *and* 1. *Complexity classes for these machines are distinguished by the superscript* 0 *as in* $\mathrm{P}^0_{\mathrm{add}}$, $\mathrm{NP}^0_{\mathrm{add}}$.

Natural examples of sets in these classes exist. For instance, the real traveling salesman problem $\mathrm{TSP}_{\mathbb{R}}$ discussed in section 1.1 belongs to $\mathrm{DNP}_{\mathrm{add}}$ (actually to $\mathrm{DNP}^0_{\mathrm{add}}$). Problems which are known to be $\mathrm{NP}_{\mathrm{add}}$-complete for many-one reductions are scarce (for some known problems see [15]). In contrast, the following result by Fournier and Koiran [17] exhibits plenty of $\mathrm{NP}_{\mathrm{add}}$-complete problems with respect to Turing reductions. For a problem $S \subseteq \mathbb{R}^\infty$, we define its *integer part* to be $S_{\mathbb{Z}} = S \cap \mathbb{Z}^\infty$.

THEOREM 2.5 (see [17]). *Let $S \in \mathrm{NP}_{\mathrm{add}}$. If $S_{\mathbb{Z}}$ is* NP*-complete with respect to Turing reductions, then S is* $\mathrm{NP}_{\mathrm{add}}$*-complete with respect to Turing reductions.*

Of course, this theorem implies the $\mathrm{NP}_{\mathrm{add}}$-completeness for Turing reductions of a large number of decision problems, for instance for $\mathrm{TSP}_{\mathbb{R}}$ and $\mathrm{PM}_{\mathbb{R}}$ (for formal definitions of these problems, see section 6). Note that, in particular, every discrete NP-complete problem (e.g., SAT) is $\mathrm{NP}_{\mathrm{add}}$-Turing-complete.

A basic fact used in proving many results on additive machines is the existence of "small" rational points in polyhedra when the defining matrix has "small" integer entries. In what follows, for an integer $n \geq 1$, we denote the set $\{1, \ldots, n\}$ by $[n]$.

THEOREM 2.6 (see Theorem 3, Chapter 21 of [4]). *Let P be a nonempty polyhedron of $\mathbb{R}^n$ defined by a system*

$$A_1 y \leq b_1; \ A_2 y < b_2, \tag{2.1}$$

where $A_1 \in \mathbb{Z}^{N_1 \times n}, A_2 \in \mathbb{Z}^{N_2 \times n}, b_1 \in \mathbb{R}^{N_1}$, *and* $b_2 \in \mathbb{R}^{N_2}$. *The entries of* A_1 *and* A_2 *are integers of bit-size bounded by* L. *Then there is* $y \in P$ *with the following description:*

$$y_i = \sum_{j \in I_1} u_{ij} b_{1j} + \sum_{j \in I_2} v_{ij} b_{2j} + w_i, \qquad i = 1, \ldots, n,$$

where $I_1 \subseteq [N_1]$, $I_2 \subseteq [N_2]$, $|I_1| + |I_2| \leq n$, *and the coefficients* u_{ij}, v_{ij}, w_i *are rationals of bit-size at most* $(Ln)^c$ *for some constant* c.

Remark 2.7. The feasibility of a system (2.1) of linear inequalities for given integer matrices A_1, A_2 and real vectors b_1, b_2 can be decided in $\mathrm{P}_{\mathrm{add}}$. Moreover, a solution can be computed in $\mathrm{FP}_{\mathrm{add}}$, if it exists. This is just a rephrasing a of well-known and important result by Tardos [37]. We will not need this remark in the rest of the paper.

Recall from [4] or [10, Exercise 3.15] that a *linear decision tree* T is a regular binary tree, whose internal nodes are labeled by linear functions $\ell : \mathbb{R}^n \to \mathbb{R}$, and whose leaves are labeled with "accept" or "reject." Here, n is the dimension of the input space. At a given node, an input $x \in \mathbb{R}^n$ goes to the left child if $\ell(x) \geq 0$ and to the right child if $\ell(x) < 0$. Let $X \subseteq \mathbb{R}^n$ be the set accepted by the linear decision tree T. The set of inputs in $\mathbb{R}^n$, whose path in the computation tree T ends up with a specific leaf ν, shall be called the *leaf set* D_ν of ν. Note that the set D_ν can be described by a set of linear inequalities and is therefore convex. It is clear that the leaf sets corresponding to the accepting leaves form a partition of the set X. In particular, X is semilinear (cf. section 1.4).

We next use Theorem 2.6 to prove that $\mathrm{NP}_{\mathrm{add}} = \mathrm{DNP}_{\mathrm{add}}$. This is a well-known result [24], but the idea of the proof will be repeatedly used in this paper.

COROLLARY 2.8. $\mathrm{NP}_{\mathrm{add}} = \mathrm{DNP}_{\mathrm{add}}$.

Proof. Let $X \in \mathrm{NP}_{\mathrm{add}}$ and M be a machine deciding X as in Definition 2.2. By unwinding the computation of M on pairs $(x, y) \in \mathbb{R}^n \times \mathbb{R}^{p(n)}$ we obtain a linear decision tree T of depth polynomial in n. If z is a value tested for positivity at a branch node of this tree, then

$$z = \sum_{i=1}^{p(n)} a_i y_i + \sum_{i=1}^{n} b_i x_i + \sum_{i=1}^{k} c_i \alpha_i + d, \tag{2.2}$$

where $\alpha_1, \ldots, \alpha_k$ are the constants of M and the coefficients a_i, b_i, c_i, and d are integers of bit-size polynomial in n. Thus, for a given $x \in \mathbb{R}^n$, the leaf set D_ν of points y such that (x, y) reaches the accepting leaf ν in T is the set of solutions of a system of inequalities as in Theorem 2.6. We conclude that D_ν is nonempty iff D_ν contains a point y such that, for $i = 1, \ldots, p(n)$,

$$y_i = \sum_{j=1}^{n} b_{ij} x_j + \sum_{j=1}^{k} c_{ij} \alpha_j + d_i, \tag{2.3}$$

where the coefficients b_{ij}, c_{ij}, and d_i are rationals of bit-size polynomial in n (for a polynomial which does not depend on ν or x). Then, to decide whether $x \in X$, one can guess $b_{ij}, c_{ij}, d_i \in \mathbb{Q}$, compute y_i according to (2.3), and check whether M accepts $(x_1, \ldots, x_n, y_1, \ldots, y_{p(n)})$. Alternatively, one could also compute y in $\mathrm{FP}_{\mathrm{add}}$ according to Remark 2.7 and check whether M accepts $(x_1, \ldots, x_n, y_1, \ldots, y_{p(n)})$. □

Over the real numbers, space is not as meaningful a resource as it is in the discrete setting (cf. [31]). The role of space, however, is satisfactorily played by parallel time (cf. [4, 14]). To introduce parallel time, we briefly recall the model of additive circuits, a restriction of the more general model of arithmetic circuits introduced in [19].

DEFINITION 2.9. *An* additive circuit $\mathcal{C}$ *over* $\mathbb{R}$ *is an acyclic directed graph where each node has indegree* 0, 1, 2, *or* 3. *Nodes with indegree* 0 *are either labeled as* input nodes *or with elements of* $\mathbb{R}$ *(we shall call these* constant nodes*). Nodes with indegree* 2 *are labeled with one of* $\{+, -\}$. *They are called* arithmetic nodes. *Nodes with indegree* 1 *are* output nodes. *Nodes with indegree* 3 *are* selection nodes. *All output nodes have outdegree* 0. *Otherwise, there is no upper bound on the outdegree of the other nodes.*

For an additive circuit $\mathcal{C}$, *the* size *of* $\mathcal{C}$ *is the number of nodes in* $\mathcal{C}$. *The* depth *of* $\mathcal{C}$ *is the length of the longest path from some input node to some output node.*

The semantics of a selection node is as follows. With input (x, y, z) the node returns y if $x \geq 0$ and z otherwise. The semantics of all other nodes is obvious. If $\mathcal{C}$ is an additive circuit with n input nodes and m output nodes, we may talk about the function $\varphi_{\mathcal{C}} : \mathbb{R}^n \to \mathbb{R}^m$ *computed by the circuit.* We remark that the computation of an additive circuit can always be unwound to a linear decision tree.

Let $f : \mathbb{R}^\infty \to \mathbb{R}^\infty$. The family of additive circuits $\{\mathcal{C}_n\}_{n\in\mathbb{N}}$ *computes* f if for all $n \geq 1$, $\varphi_{\mathcal{C}_n}$ is the restriction of f to $\mathbb{R}^n$.

The other ingredient we need to define parallel complexity classes is a notion of uniformity.

Note that nodes of additive circuits can be described by five real numbers in the following way. If the nodes of the circuit are $g_1, \ldots, g_N$, then node g_j is described by the tuple $(j, t, i_\ell, i_r, i_m) \in \mathbb{R}^5$, where t represents the type of g_j according to the following (arbitrary) dictionary:

g_j	input	constant	+	−	selection	output
t	1	2	3	4	5	6

.

For nodes of indegree 2, i_ℓ and i_r denote the numbers of the nodes which provide left and right input to g_j, respectively. If g_j is a constant node, then i_ℓ equals its constant, and if g_j is an output node, then i_ℓ numbers the node which provides the input to g_j. Finally, if g_j is a selection node, then i_ℓ, i_r, and i_m number its left, right, and middle inputs. All components not mentioned above are set to 0. Thus, the whole circuit can be described by a point in $\mathbb{R}^{5N}$.

DEFINITION 2.10. *A family of circuits* $\{\mathcal{C}_n\}_{n\in\mathbb{N}}$ *is said to be* uniform *if there exists an additive machine* M *that, on input* (n, i), *outputs the description of the* i*th node of* $\mathcal{C}_n$. *If* M *works in time* $n^{\mathcal{O}(1)}$, *we shall say that the family is* $\mathrm{P}_{\mathrm{add}}$-uniform.

We denote by $\mathrm{PAR}_{\mathrm{add}}$ the class of decision problems whose characteristic function can be computed in parallel polynomial time, i.e., by a $\mathrm{P}_{\mathrm{add}}$-uniform family of circuits such that $\mathrm{depth}(\mathcal{C}_n) = n^{\mathcal{O}(1)}$. Also, $\mathrm{FPAR}_{\mathrm{add}}$ denotes the class of functions f which can be computed with such resources and for which there is a polynomial p such that $\mathrm{size}(f(x)) = p(\mathrm{size}(x))$ for all $x \in \mathbb{R}^\infty$.

Remark 2.11.

(i) Corollary 2.8 extends to all the polynomial hierarchy. That is, the power of real quantification is the same as that of digital quantification as long as the number of quantifier alternations is bounded. Surprisingly, if the number of quantifier alternations is not bounded, then the power of digital quantification is exactly $\mathrm{PAR}_{\mathrm{add}}$ and that of real quantification is at least additive exponential time, thus showing that the latter is more powerful than the former. For details see [4, 14].

(ii) In classical complexity theory, NP is a class of decision problems. Yet, if $S \in \mathsf{NP}$ and $x \in S$, a witness y for x can be computed in $\mathsf{FP}^{\mathsf{NP}}$ and thus in FPSPACE by computing its components one by one with an NP-routine. Looking at the proof of Corollary 2.8, we see that one can do the same with $\mathrm{NP}_{\mathrm{add}}$ and $\mathrm{FPAR}_{\mathrm{add}}$.

3. Counting classes. We now want to define counting classes, following the lines used in discrete complexity theory to define #P. This is the class of functions $f\colon \{0,1\}^\infty \to \mathbb{N}$ for which there exists an NP-machine M and a polynomial p such that, for all $n \in \mathbb{N}$, $x \in \{0,1\}^n$, $f(x) = |\{y \in \{0,1\}^{p(n)} \mid M \text{ accepts } (x,y)\}|$. That is, $f(x)$ is the number of witnesses for x. A first remark is that over the reals one can define two such complexity classes by counting the witnesses in an $\mathrm{NP}_{\mathrm{add}}$-machine or in a $\mathrm{DNP}_{\mathrm{add}}$-machine, respectively.

DEFINITION 3.1.

1. *We say that a function $f : \mathbb{R}^\infty \to \mathbb{N} \cup \{\infty\}$ belongs to the class $\#\mathrm{P}_{\mathrm{add}}$ if there exists a $\mathrm{NP}_{\mathrm{add}}$-machine M and a polynomial p such that, for all $n \in \mathbb{N}$, $x \in \mathbb{R}^n$,*

$$f(x) = |\{y \in \mathbb{R}^{p(n)} \mid M \text{ accepts } (x,y)\}|.$$

2. *We say that a function $f\colon \mathbb{R}^\infty \to \mathbb{N}$ belongs to the class $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$ if there exists a $\mathrm{DNP}_{\mathrm{add}}$-machine M and a polynomial p such that, for all $n \in \mathbb{N}$, $x \in \mathbb{R}^n$,*

$$f(x) = |\{y \in \{0,1\}^{p(n)} \mid M \text{ accepts } (x,y)\}|.$$

Remark 3.2.

(i) An unrestricted version of the class $\#\mathrm{P}_{\mathrm{add}}$ defined for machines over $\mathbb{R}$ which can multiply and divide was defined by Meer in [27].

(ii) Note that it is not clear that $\mathrm{NP}_{\mathrm{add}} = \mathrm{DNP}_{\mathrm{add}}$ implies $\#\mathrm{P}_{\mathrm{add}} = \mathrm{D}\#\mathrm{P}_{\mathrm{add}}$, since now we are counting witnesses instead of deciding their existence.

(iii) If f belongs to $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$, then the bit-size of $f(x)$ is bounded by a polynomial in the size of x. The same holds for $f \in \#\mathrm{P}_{\mathrm{add}}$ for those $x \in \mathbb{R}^n$ for which $f(x)$ is finite.

The next proposition locates the power of counting complexity classes within the landscape of known complexity classes. For interpreting the second inclusion, one should represent the value ∞ by some number in $\mathbb{R} \setminus \mathbb{N}$.

PROPOSITION 3.3. *We have the following inclusions of complexity classes over $\mathbb{R}$:*

$$\mathrm{D}\#\mathrm{P}_{\mathrm{add}} \subseteq \#\mathrm{P}_{\mathrm{add}} \subseteq \mathrm{FPAR}_{\mathrm{add}}.$$

To prove Proposition 3.3 we will use the following result. Let $\mathrm{CINF}_{\mathrm{add}}$ be the problem to decide whether the solution set described by an additive circuit has infinitely many points.

LEMMA 3.4. $\mathrm{CINF}_{\mathrm{add}}$ *is* $\mathrm{NP}_{\mathrm{add}}$*-complete.*

Proof. Recall from section 1.4 that the circuit satisfiability problem $\mathrm{CSAT}_{\mathrm{add}}$ is $\mathrm{NP}_{\mathrm{add}}$-complete. Adding a dummy variable to an additive circuit gives a (trivial) reduction from $\mathrm{CSAT}_{\mathrm{add}}$ to $\mathrm{CINF}_{\mathrm{add}}$, which shows the $\mathrm{NP}_{\mathrm{add}}$-hardness of $\mathrm{CINF}_{\mathrm{add}}$.

For the membership in $\mathrm{NP}_{\mathrm{add}}$, note that leaf sets are convex. So they are infinite iff they contain at least two points. Therefore, the following algorithm shows that membership of $\mathrm{CINF}_{\mathrm{add}}$ is in $\mathrm{NP}_{\mathrm{add}}$. On input $\mathcal{C}$ guess a leaf ν and guess $y^1, y^2 \in \mathbb{R}^n$. Then check whether $y^1 \neq y^2$ and whether y^1, y^2 reach the leaf ν. If yes, then accept; otherwise, reject. □

Proof of Proposition 3.3. The first inclusion is clear. For the second, consider the algorithm that, in parallel, checks for each accepting leaf ν whether there is any point in D_ν and, if yes, whether D_ν has infinitely many points. These verifications can be done in $\mathrm{NP}_{\mathrm{add}}$. If $|D_\nu| = \infty$ for some ν, then return ∞; else return the number of ν's such that $D_\nu \neq \emptyset$. This procedure clearly is in $\mathrm{FPAR}_{\mathrm{add}}^{\mathrm{NP}_{\mathrm{add}}} = \mathrm{FPAR}_{\mathrm{add}}$. ∎

We will see in Theorem 4.7 below that the difference in power of $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$ and $\#\mathrm{P}_{\mathrm{add}}$ is negligible.

We now focus on complete problems. To do so, we define the appropriate notions of reduction.

DEFINITION 3.5. *Let $f, g : \mathbb{R}^\infty \to \mathbb{N} \cup \{\infty\}$ and $\mathcal{C}$ be any of $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$ or $\#\mathrm{P}_{\mathrm{add}}$.*

1. *We say that $\varphi : \mathbb{R}^\infty \to \mathbb{R}^\infty$ is a* parsimonious reduction *from f to g if φ can be computed in polynomial time and, for all $x \in \mathbb{R}^\infty$, $f(x) = g(\varphi(x))$.*

2. *We say that f* Turing reduces *to g if there exists an oracle machine which, with oracle g computes f in polynomial time.*

3. *We say that a function g is $\mathcal{C}$-*hard *if, for every $f \in \mathcal{C}$, there is a parsimonious reduction from f to g. We say that g is $\mathcal{C}$-*complete *if, in addition, $g \in \mathcal{C}$.*

4. *The notions of hardness and completeness with respect to Turing reductions are defined similarly.*

Let $\#\mathrm{CSAT}_{\mathrm{add}}$ denote the problem of counting the number of points of a semilinear set given by an additive circuit. (Note that this requires computing a function with values in $\mathbb{N} \cup \{\infty\}$.)

THEOREM 3.6. *The counting problem $\#\mathrm{CSAT}_{\mathrm{add}}$ is $\#\mathrm{P}_{\mathrm{add}}$-complete.*

Proof. One just checks that the usual many-one reduction from the nondeterministic machine acceptance to additive circuit satisfiability is parsimonious. ∎

We close this section by recalling a principle introduced by Toda [38] and Toda and Watanabe [39], which allows us to assign to any complexity class $\mathcal{C}$ of decision problems a corresponding counting complexity class $\# \cdot \mathcal{C}$.

DEFINITION 3.7. *Given a set $A \in \{0,1\}^\infty$ and a polynomial p, we define the function $\#_A^p : \{0,1\}^\infty \to \mathbb{N}$ which associates to $x \in \{0,1\}^n$ the number*

$$\#_A^p(x) = |\{y \in \{0,1\}^{p(n)} \mid (x,y) \in A\}|.$$

If $\mathcal{C} \subseteq 2^{\{0,1\}^\infty}$ is a complexity class of decision problems, then we define

$$\# \cdot \mathcal{C} = \{\#_A^p \mid A \in \mathcal{C} \text{ and } p \text{ a polynomial}\}.$$

Similarly, one assigns $\# \cdot \mathcal{C}$ and $\mathrm{D}\# \cdot \mathcal{C}$ to a complexity class $\mathcal{C}$ over $\mathbb{R}$.

Note that $\# \cdot \mathsf{P} = \#\mathsf{P}$, $\# \cdot \mathrm{P}_{\mathrm{add}} = \#\mathrm{P}_{\mathrm{add}}$, and $\mathrm{D}\# \cdot \mathrm{P}_{\mathrm{add}} = \mathrm{D}\#\mathrm{P}_{\mathrm{add}}$.

We will use the following important result due to Toda and Watanabe several times.

THEOREM 3.8 (see [39]). *We have $\# \cdot \mathsf{PH} \subseteq \mathsf{FP}^{\#\mathsf{P}}$.*

4. Relationships between the real additive and the discrete setting. The work of Koiran [24], Cucker and Koiran [14], and Fournier and Koiran [16, 17] establishes close relationships between the real additive and the discrete model of computation. Building on these techniques, we show in section 4.1 that similar relationships hold for the counting classes. Then we use this in section 4.2 to derive transfer theorems for counting classes between the additive real and the discrete setting.

4.1. The power of discrete oracles. The main result of this section, Theorem 4.1 stated below, says that for several classical complexity classes $\mathcal{C}$ the corresponding additive complexity classes $\mathcal{C}_{\mathrm{add}}$ are contained in, or even equal to, $\mathrm{P}^{\mathcal{C}}_{\mathrm{add}}$. That is, all problems in $\mathcal{C}_{\mathrm{add}}$ can be solved by an additive machine working in polynomial time and having access to an oracle in $\mathcal{C}$.

This result was stated and proved for the class $\mathrm{NP}_{\mathrm{add}}$ in [17]. Moreover, in [17, Remark 2] it was already mentioned that the result for $\mathrm{NP}_{\mathrm{add}}$ can be extended to the classes of the polynomial hierarchy and to $\mathrm{PAR}_{\mathrm{add}}$. So what is new in Theorem 4.1 is the extension to the counting classes and to the functional class $\mathrm{FPAR}_{\mathrm{add}}$.

THEOREM 4.1. *The following statements hold* ($k \geq 0$):

1. $\Sigma^k_{\mathrm{add}} \subseteq \mathrm{P}^{\Sigma^k}_{\mathrm{add}}$, $\Pi^k_{\mathrm{add}} \subseteq \mathrm{P}^{\Pi^k}_{\mathrm{add}}$, $\mathrm{PH}_{\mathrm{add}} = \mathrm{P}^{\mathsf{PH}}_{\mathrm{add}}$.
2. $\mathrm{D}\#\cdot\Sigma^k_{\mathrm{add}} \subseteq \mathrm{FP}^{\#\cdot\Sigma^k}_{\mathrm{add}}$, $\mathrm{D}\#\cdot\Pi^k_{\mathrm{add}} \subseteq \mathrm{FP}^{\#\cdot\Pi^k}_{\mathrm{add}}$, $\mathrm{D}\#\cdot\mathrm{PH}_{\mathrm{add}} \subseteq \mathrm{FP}^{\#\cdot\mathsf{PH}}_{\mathrm{add}}$.
3. $\mathrm{PAR}_{\mathrm{add}} = \mathrm{P}^{\mathsf{PSPACE}}_{\mathrm{add}}$.
4. $\mathrm{FPAR}_{\mathrm{add}} = \mathrm{FP}^{\mathrm{PAR}_{\mathrm{add}}}_{\mathrm{add}} = \mathrm{FP}^{\mathsf{PSPACE}}_{\mathrm{add}}$.

Observe that part 2 of this theorem implies that $\mathrm{D}\#\mathrm{P}_{\mathrm{add}} \subseteq \mathrm{FP}^{\#\mathsf{P}}_{\mathrm{add}}$.

As in Fournier and Koiran [16, 17], the proof of Theorem 4.1 relies on Meyer auf der Heide's (nonuniform) construction of small depth linear decision trees for point location in arrangements of hyperplanes [29, 30]. Before giving the proof, we need to develop some lemmas.

First, let us recall some terminology regarding arrangements of hyperplanes. For $s, n \in \mathbb{N}$ we define $\mathcal{H}_{s,n}$ to be the set of linear polynomials $a_0 + \sum_{i=1}^n a_i X_i$ with integer coefficients a_i such that $\sum_{i=0}^n |a_i| \leq 2^s$. We denote by $\mathcal{F}_{s,n}$ the set of all nonempty sets

$$F = \bigcap_{f \in \mathcal{H}_{s,n}} \{x \in \mathbb{R}^n \mid f(x) = \sigma(f)\}$$

corresponding to some sign function $\sigma\colon \mathcal{H}_{s,n} \to \{-1, 0, 1\}$. The space $\mathbb{R}^n$ is the disjoint union of all $F \in \mathcal{F}_{s,n}$. We will call this the *universal cell decomposition* for the parameters s, n, and we call the sets $F \in \mathcal{F}_{s,n}$ the corresponding *faces* or *cells*.

By Theorem 2.6, each face $F \in \mathcal{F}_{s,n}$ contains a rational point of bit-size at most $(sn)^c$ for some fixed constant $c > 0$ (even though a face F may be described by a number of constraints exponential in n, s). Therefore, $\log |\mathcal{F}_{s,n}| \leq (sn)^c$.

In what follows, we will encode a face $F \in \mathcal{F}_{s,n}$ by a triple $(s, n, x) \in \mathbb{N}^2 \times \mathbb{Q}^n$ such that $x \in F$ and the bit-size of x is at most $(sn)^c$. This way, we can describe all faces in $\mathcal{F}_{s,n}$, but, of course, the description is not unique. Abusing notation, we will shortly express this by saying that the face F is represented by a "small rational point" x.

For a fixed polynomial t we define $\mathcal{H}_t$ as the union of the $\mathcal{H}_{t(n),n}$ over all $n \in \mathbb{N}$ and $\mathcal{F}_t$ as the union of the $\mathcal{F}_{t(n),n}$ over all $n \in \mathbb{N}$.

LEMMA 4.2. *Let M be an additive machine without real constants taking inputs in $\mathbb{R}^\infty \times \{0,1\}^\infty$ such that its running time is bounded by a polynomial t in the size of its first argument. The discrete relation*

$$R := \{(F, y) \in \mathcal{F}_t \times \{0,1\}^\infty \mid \forall x \in F \ \big(M \text{ accepts } (x, y)\big)\}$$

can be checked in P*, that is, in classical polynomial time.*

Proof. Running M on an input $(x, y) \in \mathbb{R}^n \times \{0,1\}^m$ takes at most $t(n)$ steps by assumption. On such an input, the machine M branches according to the signs of

expressions $a_0 + \sum_{i=1}^n a_i x_i + \sum_{j=1}^m b_j y_j$, where $\sum_{i=0}^n |a_i| + \sum_{j=1}^m |b_j| \le 2^{t(n)}$. Hence the hyperplane defined by $(a_0 + \sum_{j=1}^m b_j y_j) + \sum_{i=1}^n a_i X_i$ belongs to $\mathcal{H}_{t(n),n}$ for any $y \in \{0,1\}^m$. It follows that if x and x' belong to the same face F of $\mathcal{F}_{t(n),n}$, then for all y, (x,y) and (x',y) follow the same path in the decision tree induced by M. Therefore, if M accepts (x,y) for some $x \in F$, then it must accept (x,y) for all $x \in F$.

Therefore, checking that $(F,y) \in R$ can be done as follows. Let F be represented by the small rational point $x \in F$. Simulate the computation of the real machine M on input (x,y) by a Turing machine. Since M has no real constants and works in polynomial time, this simulation takes polynomial time (see [24, 4]). □

The following is an immediate consequence of Lemma 4.2 and the definition of Σ^k.

COROLLARY 4.3. *Let M be an additive machine as in Lemma 4.2, $k \in \mathbb{N}$, and $q_1, \dots, q_k$ be polynomials. Consider the discrete relation*

$$R := \{(F,y) \in \mathcal{F}_t \times \{0,1\}^\infty \mid \forall x \in F\ \exists z_1 \forall z_2 \dots Q z_k \\ \big(M \text{ accepts } (x, y, z_1, \dots, z_k)\big)\},$$

where quantifiers alternate (Q is either existential or universal depending on the parity of k) and the quantification is over $z_i \in \{0,1\}^{q_i(\mathrm{size}(x))}$. Then R can be checked in (classical) Σ^k.

Consider the following problem $\mathrm{FEVAL}_{\mathrm{add}}$: given a quantifier-free formula ψ of the first-order theory of $(\mathbb{R}, +, -, \le)$ with k free variables and a point $x \in \mathbb{R}^k$, decide whether $\psi(x)$ holds. Note that the formula ψ can be encoded as an element of $\mathbb{R}^\infty$ in a straightforward way. In the following, we will identify ψ with its encoding. It is well known that $\mathrm{FEVAL}_{\mathrm{add}} \in \mathrm{P}^0_{\mathrm{add}}$.

The next result is proved similarly as Lemma 4.2.

LEMMA 4.4. *Let M be a machine solving $\mathrm{FEVAL}_{\mathrm{add}}$ in time bounded by a polynomial t in $\mathrm{size}(\psi)$. Then the following set belongs to* PSPACE:

$$L := \{F \in \mathcal{F}_t \mid \forall \psi \in F\ Q_1 z_1 Q_2 z_2 \dots Q_n z_n\ \big(M \text{ accepts } (\psi, z_1, \dots, z_n)\big)\}.$$

Here $Q_i \in \{\forall, \exists\}$, $z_i \in \{0,1\}$. Moreover, n denotes the size of ψ. Hence the number of free variables of ψ is at most n, and the behavior of M on $(\psi, z_1, \dots, z_n)$ is well defined.

Given a polynomial t, the *point location problem* for t is the problem of computing, for a given input $x \in \mathbb{R}^\infty$, a small rational point of the uniquely determined face $F \in \mathcal{F}_{t(\mathrm{size}(x)),\mathrm{size}(x)}$ in which x lies. The following crucial statement is proved by Fournier and Koiran [17, Theorem 2].

PROPOSITION 4.5. *For any polynomial t, the point location problem can be solved in $(\mathrm{FP}^0_{\mathrm{add}})^{\mathsf{NP}}$. That is, a small rational point of the face $F \in \mathcal{F}_{t(n),n}$ containing the input point can be computed in polynomial time by an additive machine using a classical oracle in* NP.

We remark that in [17] a face F is represented by a system $\mathcal{S}$ of $n^{\mathcal{O}(1)}$ linear inequalities with integer coefficients of bit-size $n^{\mathcal{O}(1)}$ such that the polyhedral set defined by the system $\mathcal{S}$ is nonempty and is contained in the face F. However, note that since linear programming (discrete setting) is in polyomial time [21, 22], we can always compute from the system $\mathcal{S}$ a small rational point of F in polynomial time.

Proof of Theorem 4.1. 1. Assume that $A \in \Sigma^k_{\mathrm{add}}$. Then (cf. Remark 2.11(i)) there exist polynomials $q_1, \dots, q_k$ and $B \in \mathrm{P}_{\mathrm{add}}$ such that for all $x \in \mathbb{R}^\infty$

$$x \in A \iff \exists z_1 \forall z_2 \dots Q z_k\ (x,z) \in B,$$

where quantifiers alternate (Q is either existential or universal depending on the parity of k) and the quantification is over $z_i \in \{0,1\}^{q_i(\mathrm{size}(x))}$.

Let M_B be an additive machine deciding B in time bounded by some polynomial t and $\alpha_1, \ldots, \alpha_\ell$ be the constants occurring in the program of M_B other than 0 or 1. Denote $\alpha = (\alpha_1, \ldots, \alpha_\ell)$, and let

$$C = \{(x,z,v) \in \mathbb{R}^\infty \times \{0,1\}^\infty \times \mathbb{R}^\ell \mid M_B \text{ accepts } (x,z) \text{ when replacing } \alpha \text{ by } v \text{ in its program}\}.$$

Clearly, $C \in \mathrm{P}^0_{\mathrm{add}}$ and, for all $(x,z) \in \mathbb{R}^\infty \times \{0,1\}^\infty$, $(x,z) \in B \iff (x,z,\alpha) \in C$. In order to prove that $A \in \mathrm{P}^{\Sigma^k}_{\mathrm{add}}$, it is sufficient to show that the set

$$A' = \{(x,v) \in \mathbb{R}^\infty \times \mathbb{R}^\ell \mid \exists z_1 \forall z_2 \ldots Q z_k \ (x,z,v) \in C\}$$

belongs to the class $(\mathrm{P}^0_{\mathrm{add}})^{\Sigma^k}$. This reasoning shows that we may assume w.l.o.g. that M_B has no real constants, i.e., that $B \in \mathrm{P}^0_{\mathrm{add}}$.

Since $B \in \mathrm{P}^0_{\mathrm{add}}$, we may use Corollary 4.3 (used without the y in the input) to deduce that the discrete language

$$R = \{F \in \mathcal{F}_t \mid \forall x \in F \ \exists z_1 \forall z_2 \ldots Q z_k \ \big(M_B \text{ accepts } (x,z)\big)\}$$

lies in the class Σ^k. (Recall that t bounds the running time of M_B.) Consider now the following algorithm. On input $x \in \mathbb{R}^n$ locate x in a face F of $\mathcal{F}_{t(n),n}$ (due to Proposition 4.5, this can be done in $(\mathrm{FP}^0_{\mathrm{add}})^{\mathsf{NP}}$). Then decide whether $F \in R$ by an oracle call to Σ^k. This algorithm works in $\mathrm{P}^{\Sigma^k}_{\mathrm{add}}$ and decides A.

The above reasoning shows that $A \in \mathrm{P}^{\Sigma^k}_{\mathrm{add}}$. This immediately implies the inclusions for Π^k and PH. And, since $\mathrm{PH}_{\mathrm{add}}$ is closed under Turing reductions, we even get equality in this case.

2. Let $\varphi\colon \mathbb{R}^\infty \to \mathbb{N}$ be a counting problem in $\mathrm{D}\#\cdot\Sigma^k_{\mathrm{add}}$. Then there exist $B \in \mathrm{P}_{\mathrm{add}}$ and polynomials $p, q_1, \ldots, q_k$ such that for all $n \in \mathbb{N}$ and all $x \in \mathbb{R}^n$

$$\varphi(x) = |\{y \in \{0,1\}^{p(n)} \mid \exists z_1 \forall z_2 \ldots Q z_k \ (x,y,z_1,\ldots,z_k) \in B\}|,$$

where quantifiers alternate and the quantification is over $z_i \in \{0,1\}^{q_i(\mathrm{size}(x))}$.

Let M_B be some additive machine deciding B in time t for some polynomial t. As in the proof of part 1, we can assume that M_B has no real constants. By Corollary 4.3, the map $\psi\colon \mathcal{F}_t \to \mathbb{N}$ defined for $F \in \mathcal{F}_{t(n),n}$ by

$$\psi(F) := |\{y \in \{0,1\}^{p(n)} \mid \forall x \in F \ \exists z_1 \forall z_2 \ldots Q z_k \ (x,y,z_1,\ldots,z_k) \in B\}|$$

lies in the discrete counting class $\# \cdot \Sigma^k$. Note that $\varphi(x) = \psi(F)$ for $F \in \mathcal{F}_{t(n),n}$, $x \in F$.

Consider now the following algorithm. On input $x \in \mathbb{R}^n$, locate x in a face F of $\mathcal{F}_{t(n),n}$. Then compute $\psi(F)$ by an oracle call to $\# \cdot \Sigma^k$ and return $\psi(F)$. This algorithm works in $\mathrm{FP}^{\#\cdot\Sigma^k}_{\mathrm{add}}$ and computes $\varphi(x)$.

The above proves the inclusion $\mathrm{D}\# \cdot \Sigma^k_{\mathrm{add}} \subseteq \mathrm{FP}^{\#\cdot\Sigma^k}_{\mathrm{add}}$. The inclusion $\mathrm{D}\# \cdot \Pi^k_{\mathrm{add}} \subseteq \mathrm{FP}^{\#\cdot\Pi^k}_{\mathrm{add}}$ is proved similarly, and it follows that $\mathrm{D}\# \cdot \mathrm{PH}_{\mathrm{add}} \subseteq \mathrm{FP}^{\#\cdot\mathsf{PH}}_{\mathrm{add}}$.

3. The inclusion $\mathrm{P}^{\mathsf{PSPACE}}_{\mathrm{add}} \subseteq \mathrm{PAR}_{\mathrm{add}}$ is clear, since $\mathrm{PAR}_{\mathrm{add}}$ is closed under Turing reductions. Consider the subset DTRAO of the theory of the reals with addition and order which consists of the sentences all of whose variables z satisfy a constraint of

the form $z = 0 \vee z = 1$. In [14] it is proven that DTRAO is $\mathrm{PAR}_{\mathrm{add}}$-complete. It is therefore sufficient to show that $\mathrm{DTRAO} \in \mathrm{P}_{\mathrm{add}}^{\mathsf{PSPACE}}$.

Consider now the following algorithm. On input a digitally quantified first-order sentence $\varphi = Q_1 z_1 Q_2 z_2 \dots Q_k z_k \ \psi(z_1, \dots, z_k)$ of the theory of $(\mathbb{R}, +, -, \leq)$, where ψ is quantifier-free of size n, we locate ψ in a face $F \in \mathcal{F}_{t(n),n}$, where n is the size of ψ. By construction, φ is true iff F belongs to the set L in Lemma 4.4. We then decide this membership by an oracle call to PSPACE. This algorithm decides $\mathrm{DTRAO} \in \mathrm{P}_{\mathrm{add}}^{\mathsf{PSPACE}}$.

4. The equality $\mathrm{FP}_{\mathrm{add}}^{\mathrm{PAR}_{\mathrm{add}}} = \mathrm{FP}_{\mathrm{add}}^{\mathsf{PSPACE}}$ follows from the third statement of Theorem 4.1. To prove the first equality, let $f \in \mathrm{FPAR}_{\mathrm{add}}$, $x \in \mathbb{R}^n$, and $y = f(x) \in \mathbb{R}^{p(n)}$. Let $\alpha_1, \dots, \alpha_k$ be the constants occurring in the additive machine that generates the circuits computing f as described in Definition 2.10. For $\ell \leq p(n)$ we have

$$y_\ell = \sum_{i=1}^{n} u_i^{(\ell)} x_i + \sum_{j=1}^{k} v_j^{(\ell)} \alpha_j + b^{(\ell)}, \tag{4.1}$$

where $u_i^{(\ell)}, v_j^{(\ell)}$, and $b^{(\ell)}$ are integers of bit-size at most $q(n)$ for a polynomial q. Let B_x be the relation defined by

$$B_x = \{(s, i, \ell, x) \in \mathbb{N}^3 \times \mathbb{R}^\infty \mid \text{ the } s\text{th bit of } u_i^{(\ell)} \text{ is } 1\}$$

and B_α, B_1 the analogous relations for $v_j^{(\ell)}$ and $b^{(\ell)}$. We claim that $B_x, B_\alpha, B_1 \in \mathrm{PAR}_{\mathrm{add}}$. In fact, the parallel algorithm deciding any of these relations simulates the behavior of $\mathcal{C}_n$ (the circuit computing the restriction of f to $\mathbb{R}^n$) on input x, keeping expressions in the form (4.1) instead of actually performing the arithmetic operations.

To compute $f(x)$ in $\mathrm{FP}_{\mathrm{add}}^{\mathrm{PAR}_{\mathrm{add}}}$, one uses the oracles B_x, B_α, and B_1 to obtain the binary expansions of $u_i^{(\ell)}$, $v_j^{(\ell)}$, and $b^{(\ell)}$ for all ℓ, i, j. Then compute y by (4.1). □

The following corollary is a real analogue of Toda and Watanabe's Theorem 3.8.

COROLLARY 4.6. *We have* $\mathrm{D}\#\cdot\mathrm{PH}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}}^{\#\mathsf{P}}$.

Proof. We conclude from Theorem 4.1(2) and Theorem 3.8 that

$$\mathrm{D}\#\cdot\mathrm{PH}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}}^{\#\cdot\mathsf{PH}} \subseteq \mathrm{FP}_{\mathrm{add}}^{\mathsf{FP}^{\#\mathsf{P}}} = \mathrm{FP}_{\mathrm{add}}^{\#\mathsf{P}},$$

which proves the claim. □

We use this to prove that the counting class $\#\mathrm{P}_{\mathrm{add}}$ is closely related to its digital variant $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$ in the sense that a $\#\mathrm{P}_{\mathrm{add}}$-oracle does not give more power to an additive polynomial time Turing machine than a $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$-oracle.

THEOREM 4.7. *We have* $\mathrm{FP}_{\mathrm{add}}^{\#\mathrm{P}_{\mathrm{add}}} = \mathrm{FP}_{\mathrm{add}}^{\mathrm{D}\#\mathrm{P}_{\mathrm{add}}} = \mathrm{FP}_{\mathrm{add}}^{\#\mathsf{P}}$.

Proof. Clearly, it is enough to show that $\#\mathrm{P}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}}^{\#\mathsf{P}}$. For this, it is sufficient to prove that

$$\#\mathrm{P}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}}^{\mathrm{D}\#\cdot\mathrm{NP}_{\mathrm{add}}}. \tag{4.2}$$

Indeed, by Corollary 4.6 we know that $\mathrm{D}\#\cdot\mathrm{NP}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}}^{\#\mathsf{P}}$.

In order to prove (4.2), let $\varphi \in \#\mathrm{P}_{\mathrm{add}}$. Then there exist a polynomial p and an additive machine M working in polynomial time such that, for all $n \in \mathbb{N}$, $x \in \mathbb{R}^n$,

$$\varphi(x) = |\{y \in \mathbb{R}^{p(n)} \mid M \text{ accepts } (x, y)\}|.$$

Using Lemma 3.4 we can find out in $\mathrm{NP}_{\mathrm{add}}$ whether $\varphi(x)$ is infinite on input $x \in \mathbb{R}^n$. Assume then that $\varphi(x)$ is finite. Since leaf sets are convex, they are either infinite or consist of just one point. In the case that $\varphi(x)$ is finite, we have

$$\varphi(x) = |\{\nu \in \{0,1\}^{t(n)} \mid \exists y \in \mathbb{R}^{p(n)} \ \text{ input } (x, y) \text{ reaches the accepting leaf } \nu\}|,$$

since y is uniquely determined. Define $B := \cup_{n\in\mathbb{N}} B_n$, where

$$B_n := \{(x,\nu) \in \mathbb{R}^n \times \{0,1\}^{t(n)} \mid \exists y \in \mathbb{R}^{p(n)} \text{ input } (x,y) \text{ reaches the accepting leaf } \nu\}.$$

Then we have $B \in \mathrm{NP}_{\mathrm{add}}$. This implies that $\varphi \in \mathrm{D}\# \cdot \mathrm{NP}_{\mathrm{add}}$. □

Remark 4.8.

(i) Statements analogous to Theorem 4.1 hold in the constant-free setting, e.g.,

$$\mathrm{NP}^0_{\mathrm{add}} \subseteq (\mathrm{P}^0_{\mathrm{add}})^{\mathsf{NP}}, \quad \mathrm{D}\#\mathrm{P}^0_{\mathrm{add}} \subseteq (\mathrm{FP}^0_{\mathrm{add}})^{\#\mathsf{P}}, \quad \mathrm{FPAR}^0_{\mathrm{add}} = (\mathrm{FP}^0_{\mathrm{add}})^{\mathsf{PSPACE}}.$$

(ii) Similarly to Theorem 4.7, we have $\mathrm{FP}^{\#\Sigma^k_{\mathrm{add}}}_{\mathrm{add}} = \mathrm{FP}^{\mathrm{D}\#\cdot\Sigma^k_{\mathrm{add}}}_{\mathrm{add}} = \mathrm{FP}^{\#\mathsf{P}}_{\mathrm{add}}$ for $k \geq 0$.

4.2. Boolean parts and transfer theorems. A problem that has attracted much attention in real complexity is the computation of Boolean parts [8, 12, 13, 14, 24, 25]. Roughly speaking, this amounts to characterizing, in terms of classical complexity classes, the power of resource bounded machines over $\mathbb{R}$ when their inputs are restricted to be binary. In this section, we will be interested in the Boolean parts of counting classes.

DEFINITION 4.9. *Let $\mathcal{C}$ be a counting class over $\mathbb{R}$. Its* Boolean part *is the classical complexity class* $\mathrm{BP}(\mathcal{C}) = \{f : \{0,1\}^\infty \to \mathbb{N} \mid f = g_{|\{0,1\}^\infty} \text{ for some } g \in \mathcal{C}\}$.

PROPOSITION 4.10. *We have* $\mathrm{BP}(\mathrm{D}\#\mathrm{P}_{\mathrm{add}}) = \#\mathsf{P}/\mathsf{poly}$.

Proof. The proof closely follows that of [4, Theorem 2, Chapter 22]. Consider a function f in $\#\mathsf{P}/\mathsf{poly}$. There is a polynomial q and an advice function h such that $h(n)$ belongs to $\{0,1\}^{q(n)}$ for all n. Furthermore, there are an NP-machine M and a polynomial p such that M accepts for exactly $f(x)$ witnesses in $\{0,1\}^{p(n)}$ on input $(x,h(n))$ for all $x \in \{0,1\}^n$. Let us code in a single number $\xi_h \in \mathbb{R}$ the sequence of advices $h(1), h(2), \ldots$. Then we can consider a $\mathrm{DNP}_{\mathrm{add}}$-machine which, for each input $x \in \{0,1\}^n$, first produces the digits of ξ_h and obtains $h(n)$ and then simulates M on $(x,h(n))$. This shows that $\#\mathsf{P}/\mathsf{poly} \subseteq \mathrm{BP}(\mathrm{D}\#\mathrm{P}_{\mathrm{add}})$.

Conversely, let us consider a function f in the Boolean part of $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$ defined by a $\mathrm{DNP}_{\mathrm{add}}$-machine M with time bound q. The computation of M on inputs of size n is described by a linear decision tree T of depth $q(n)$. Therefore, if $\alpha_1, \ldots, \alpha_k$ are the real constants of M, then, for each $x \in \{0,1\}^n$, the test performed by T at a node i has the form $g_i(x,\alpha) \geq 0$ with

$$g_i(x,\alpha) = \sum_{j=1}^{n} a_{ij}x_j + \sum_{j=1}^{k} b_{ij}\alpha_j + c_i \tag{4.3}$$

and where a_{ij}, b_{ij}, and c_i are integers of bit-size polynomial in n. For a given $x \in \{0,1\}^n$, according to the outcome of the test (4.3), the point $\alpha \in \mathbb{R}^k$ satisfies then an inequality of the form $g_{i,x}(\alpha) \geq 0$ or $g_{i,x}(\alpha) < 0$, where $g_{i,x} \in \mathbb{Z}[Y_1, \ldots, Y_k]$ is defined by $g_{i,x}(y) = g_i(x,y)$. Let Φ be the system of all these linear inequalities for i varying over all branching nodes of T and x varying over the 2^n possible points of $\{0,1\}^n$. The system Φ is satisfied by α. Then, according to Theorem 2.6, there is a point $\beta_n \in \mathbb{Q}^k$ all of whose coordinates have polynomial bit-size in n, which also satisfies Φ. Thus, if we replace $\alpha = (\alpha_1, \ldots, \alpha_k)$ by β_n in the tree T, the path followed by any $x \in \{0,1\}^n$ will not change, and x will be accepted or rejected as in T.

Let us now consider the function $h : \mathbb{N} \to \mathbb{Q}^k$ defined by $h(n) = \beta_n$. Since the bit-size of β_n is polynomial in n we may interpret h as an advice function. The classical machine which, with input $(x, h(\mathrm{size}(x)))$, simulates the behavior of M with the constants $\alpha_1, \ldots, \alpha_k$ replaced by $h(\mathrm{size}(x))$ shows that $f \in \#\mathsf{P}/\mathsf{poly}$. □

Combining Proposition 4.10 with the results of section 4.1, we obtain the following corollary.

COROLLARY 4.11. *We have the following transfer results:*

1. $\#\mathrm{P}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}}$ *iff* $\mathrm{D}\#\mathrm{P}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}}$ *iff* $\#\mathsf{P} \subseteq \mathsf{FP/poly}$.
2. $\mathrm{FPAR}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}}^{\#\mathrm{P}_{\mathrm{add}}}$ *iff* $\mathsf{PSPACE} \subseteq \mathsf{P}^{\#\mathsf{P}}\mathsf{/poly}$.
3. *Similar equivalences hold for additive machines without constants and uniform classical complexity classes, respectively.*

Proof. The first equivalence of part 1 follows from Theorem 4.7. In the second equivalence of part 1, the direction from left to right follows from

$$\#\mathsf{P} \subseteq \#\mathsf{P/poly} = \mathrm{BP}(\mathrm{D}\#\mathrm{P}_{\mathrm{add}}) \subseteq \mathrm{BP}(\mathrm{FP}_{\mathrm{add}}) \subseteq \mathsf{FP/poly}.$$

Here, the equality holds by Proposition 4.10, the last inclusion holds by Remark 4.12 below, and the one before the last is true by assumption. For the other direction, we use Theorem 4.1(2) to get $\mathrm{D}\#\mathrm{P}_{\mathrm{add}} \subseteq \mathrm{FP}_{\mathrm{add}}^{\#\mathsf{P}} \subseteq \mathrm{FP}_{\mathrm{add}}^{\mathsf{FP/poly}} = \mathrm{FP}_{\mathrm{add}}$, where the second inclusion follows by assumption. The other equivalences can be shown similarly. ∎

Remark 4.12. One can extend the definition of Boolean parts to classes of (not necessarily counting) functions over the reals and consider, for instance,

$$\mathrm{BP}(\mathrm{FP}_{\mathrm{add}}) = \{f : \{0,1\}^\infty \to \{0,1\}^\infty \mid f = g_{|\{0,1\}^\infty} \text{ for some } g \in \mathrm{FP}_{\mathrm{add}}\}.$$

One can then use the same arguments to show that

$$\mathrm{BP}(\mathrm{FP}_{\mathrm{add}}) = \mathsf{FP/poly},\ \mathrm{BP}(\mathrm{FP}_{\mathrm{add}}^{\#\mathrm{P}_{\mathrm{add}}}) = \mathsf{FP}^{\#\mathsf{P}}\mathsf{/poly},\ \mathrm{BP}(\mathrm{FPAR}_{\mathrm{add}}) = \mathsf{FPSPACE/poly}.$$

Also, for machines without constants we have the following, easier to prove, results:

$$\mathrm{BP}(\mathrm{FP}_{\mathrm{add}}^0) = \mathsf{FP},\ \mathrm{BP}((\mathrm{FP}_{\mathrm{add}}^0)^{\#\mathrm{P}_{\mathrm{add}}^0}) = \mathsf{FP}^{\#\mathsf{P}},\ \mathrm{BP}(\mathrm{FPAR}_{\mathrm{add}}^0) = \mathsf{FPSPACE}.$$

4.3. Complete counting problems. We obtain from Theorem 4.1 the following result, providing us with plenty of complete problems for the class $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$.

PROPOSITION 4.13. *Let $f\colon \mathbb{R}^\infty \to \mathbb{N}$ belong to $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$, and assume that the restriction of f to $\mathbb{Z}^\infty$ is $\#\mathsf{P}$-complete with respect to Turing reductions. Then f is $\#\mathrm{P}_{\mathrm{add}}$-complete and thus $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$-complete with respect to Turing reductions.*

Proof. This is an immediate consequence of Theorem 4.7. ∎

Proposition 4.13 yields plenty of Turing complete problems in $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$. We just mention two particularly interesting ones. Assume that we are given a graph G with real weights on the edges and some $w \in \mathbb{R}$. We define the weight of a subgraph as the sum of the weights of its edges.

1. *Counting traveling salesman.* Let $\#\mathrm{TSP}_{\mathbb{R}}$ be the problem to count the number of Hamilton cycles of weight at most w in the graph G.
2. *Counting weighted perfect matchings.* Let $\#\mathrm{PM}_{\mathbb{R}}$ be the problem to count the number of perfect matchings of weight at most w in the graph G (here we assume that G is bipartite).

Valiant [41, 42] proved the $\#\mathsf{P}$-completeness of the problem to count the number of Hamilton cycles of a given graph and of the problem to count the number of perfect matchings of a given bipartite graph. Together with Proposition 4.13, this immediately implies the following corollary.

COROLLARY 4.14. *The problems $\#\mathrm{TSP}_{\mathbb{R}}$ and $\#\mathrm{PM}_{\mathbb{R}}$ are $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$-complete with respect to Turing reductions.*

Note that the problem to count the number of perfect matchings of a given bipartite graph is equivalent to the famous problem to evaluate the *permanent* of a matrix with entries in $\{0,1\}$.

Remark 4.15.

1. Results for $\mathrm{PAR}_{\mathrm{add}}$ and $\mathrm{FPAR}_{\mathrm{add}}$ similar to Proposition 4.13 follow from Theorem 4.1 in the same manner.

2. There is an algebraic theory of NP-completeness due to Valiant [7, 40, 43], which captures the complexity to evaluate the generating functions of graph properties. For instance, the generating function of the property "perfect matching" is the permanent of a real matrix, which turns out to be complete in this theory. The functional problems studied in this theory take real values on real inputs and thus differ substantially from the counting problems studied in this paper. It would be interesting to clarify the relationship between these two approaches.

5. Complexity to compute topological invariants. In the computational problems studied in this section, it is always assumed that the input is an additive circuit $\mathcal{C}$ and X is the semilinear set accepted by $\mathcal{C}$.

In the following subsections, we characterize the complexity to compute several basic invariants of a semilinear set X. These invariants are the dimension (section 5.1), the number of connected components (section 5.2), the Euler characteristic (section 5.3.4), and the Betti numbers (section 5.3.5). In section 6 we show that corresponding completeness results for the Turing model hold as well.

5.1. Complexity of computing the dimension. For all $d \geq 0$, the problem $\mathrm{DIM}_{\mathrm{add}}(d)$ consists of deciding whether the set X given by an additive circuit $\mathcal{C}$ has dimension at least d. We define $\dim \emptyset := -1$ so that we can decide for nonemptiness using the dimension function.

THEOREM 5.1. *For all $d \geq 0$, the problem $\mathrm{DIM}_{\mathrm{add}}(d)$ is $\mathrm{NP}_{\mathrm{add}}$-complete.*

The main tool in proving Theorem 5.1 is the following proposition. It states that if a polyhedron P has dimension at least d, then there is a projection of P onto a d-dimensional coordinate subspace containing a scaled down d-dimensional standard simplex. This can be used to construct an $\mathrm{NP}_{\mathrm{add}}$-certificate.

To formally state this proposition we define $e_j = (0,\dots,0,1,0,\dots,0)^{\mathrm{T}} \in \mathbb{R}^n$, the column unit vector with 1 in the jth place. Also, recall that we denote by $[m]$ the set $\{1,\dots,m\}$, for any $m \in \mathbb{N}$.

PROPOSITION 5.2. *Let P be a polyhedron in $\mathbb{R}^n$ of dimension $d \geq 0$ defined by a system $A_1 x \leq b_1$; $A_2 x < b_2$, where $A_1 \in \mathbb{R}^{N_1 \times n}, A_2 \in \mathbb{R}^{N_2 \times n}, b_1 \in \mathbb{R}^{N_1}$, and $b_2 \in \mathbb{R}^{N_2}$. Then there exist points $x^{(0)},\dots,x^{(d)} \in P$, $\rho > 0$, and an injective map $\pi\colon [d] \to [n]$ such that for all $\ell, i \in [d]$ we have $x^{(\ell)}_{\pi(i)} - x^{(0)}_{\pi(i)} = \rho\delta_{\ell,i}$. Here δ is the Kronecker's delta.*

Proof. We first prove the result for the case $d = n$. Let $N = N_1 + N_2$, $A = \left[\begin{smallmatrix} A_1 \\ A_2 \end{smallmatrix}\right] \in \mathbb{R}^{N \times n}$, $b = \left[\begin{smallmatrix} b_1 \\ b_2 \end{smallmatrix}\right] \in \mathbb{R}^N$, and denote by $a_i^{\mathrm{T}} \in \mathbb{R}^n$ the ith row of $A = (a_{i,j})$. W.l.o.g. $A \neq 0$. Since $d = n$, the polyhedron

$$P^* := \{x \in \mathbb{R}^n \mid Ax < b\}$$

is nonempty. Let $x^* \in P^*$, and put $y^* := b - Ax^* > 0$, $\varepsilon := \min_{i \leq N} y_i^* = y_{i_0}^*$. Then $a_i^{\mathrm{T}} x^* \leq b_i - \varepsilon$ for all $i \leq N$. Define $\rho = \varepsilon/(2\max_{i,j} |a_{ij}|)$. For all i, j we have $\rho |a_i^{\mathrm{T}} e_j| = \rho |a_{ij}| \leq \varepsilon/2$. This implies that, for all i,

$$|a_i^{\mathrm{T}}(x^* + \rho e_j)| \leq b_i - \varepsilon + \frac{\varepsilon}{2} < b_i.$$

The points $x^{(0)} = x^*$, $x^{(j)} = x^* + \rho e_j$, together with the identity map $\pi\colon [n] \to [n]$, satisfy the statement.

We now consider the general case, with $d \geq 1$ (the case $d = 0$ is trivial). Since $\dim P = d$, there exists $I \subseteq [N_1]$ with $|I| \geq n - d$ such that the set

$$P^* := \{x \in \mathbb{R}^n \mid a_i^{\mathrm{T}} x = b_i \text{ for } i \in I \text{ and } a_i^{\mathrm{T}} x < b_i \text{ for } i \notin I\}$$

is included in P and has dimension d. After eliminating redundant equalities, if necessary, we can assume $|I| = n - d$.

In what follows, if $x \in \mathbb{R}^n$ and $J \subseteq [n]$, we denote by x_J the vector obtained by removing from x the coordinates with index not in J. Write $\bar{J} = [n] - J$. Let H be the affine linear variety given by $a_i^{\mathrm{T}} x = b_i$ for $i \in I$. Since $\dim H = d$ there exists $J \subseteq [n]$, $|J| = d$, such that we can express the coordinates x_j, $j \notin J$, in terms of the coordinates x_j, $j \in J$. More precisely, there exist $S \in \mathbb{R}^{\bar{J} \times J}$ and $c \in \mathbb{R}^{\bar{J}}$ such that

$$x_{\bar{J}} = S x_J + c. \tag{5.1}$$

The projection of P^* on $\mathbb{R}^J$ has dimension d. It is given by the set of strict inequalities obtained by substituting $x_{\bar{J}}$ in the inequalities $a_i x < b_i$, $i \notin I$, according to (5.1).

We now apply the full-dimensional case to this set of inequalities to find points $x_J^{(\ell)} \in \mathbb{R}^J$, $\ell = 0, \ldots, d$, satisfying the statement in $\mathbb{R}^J$ (for some bijection $\pi\colon [d] \to J$). Finally, we lift these points to $x^{(\ell)} \in \mathbb{R}^n$, $\ell \in [d]$, by using (5.1). ∎

Proof of Theorem 5.1. The hardness is immediate since adding d dummy variables reduces circuit satisfiability $\mathrm{CSAT}_{\mathrm{add}}$ to $\mathrm{DIM}_{\mathrm{add}}(d)$. (Here we use the convention $\dim \emptyset = -1$.)

For the membership, note that leaf sets are convex. Therefore, if such a leaf set contains the vertices of a d-dimensional simplex in $\mathbb{R}^n$, it contains the whole simplex. This ensures the correctness of the following algorithm for $\mathrm{DIM}_{\mathrm{add}}(d)$.

input $\mathcal{C}$
`compute` n`, the number of input gates of` $\mathcal{C}$
`guess an accepting leaf` ν`,` $x^{(0)}, \ldots, x^{(d)} \in \mathbb{R}^n$`,` $\rho \in \mathbb{R}$`, and` $\pi\colon [d] \to [n]$
`check` whether $x^{(0)}, \ldots, x^{(d)}$, ρ, and π satisfy the statement of Proposition 5.2
if $x^{(0)}, \ldots, x^{(d)}$ reach the leaf ν **then** `ACCEPT` **else** `REJECT`

This is clearly an $\mathrm{NP}_{\mathrm{add}}$-algorithm. ∎

5.2. Counting connected components. Consider the *reachability problem* $\mathrm{REACH}_{\mathrm{add}}$ to decide for a given additive circuit $\mathcal{C}$ and two points s and t whether these points are in the same connected component of the semilinear set X defined by $\mathcal{C}$. The corresponding counting problem $\#^{\mathsf{cc}}\mathrm{CSAT}_{\mathrm{add}}$ is the problem of counting the number of connected components of X given by $\mathcal{C}$.

The main result of this section is the following.

THEOREM 5.3. *The problems* $\mathrm{REACH}_{\mathrm{add}}$ *and* $\#^{\mathsf{cc}}\mathrm{CSAT}_{\mathrm{add}}$ *are* $\mathrm{PAR}_{\mathrm{add}}$*-complete and* $\mathrm{FPAR}_{\mathrm{add}}$*-complete with respect to Turing reductions, respectively.*

This result is inspired by an early paper by Reif [35] (see also [36]), which showed the PSPACE-hardness of a generalized movers problem in robotics. Reif's result implies that the analogue of $\mathrm{REACH}_{\mathrm{add}}$ for semialgebraic sets given by inequalities of (nonlinear) rational polynomials is PSPACE-hard. We cannot apply this result in our context, since we are dealing here with linear polynomials. However, we borrow from Reif's proof the idea to describe PSPACE by symmetric polynomial space Turing machines; see section 5.2.1.

The problem $\mathrm{REACH}_{\mathrm{add}}$ has a similar flavor as the undirected reachability problem for succinctly represented graphs, which asks whether two nodes s, t of such a graph G are connected by a path. By a *succinct representation* of a graph [18] we understand a Boolean circuit which decides, for a pair of nodes given in binary encoding, whether they are adjacent. This representation allows a polynomial size representation of graphs with exponentially many nodes. It is known that the undirected reachability problem for succinctly represented graphs is PSPACE-complete. A detailed treatment of the complexity of succinct problems can be found in [1].

The rest of this section is devoted to the proof of Theorem 5.3. It is organized as follows: after two preparatory subsections on symmetric Turing machines and embedding graphs, we provide the lower bound part of the proof in section 5.2.3. The upper bound part of the proof is given in section 5.2.4.

5.2.1. Symmetric Turing machines. Roughly speaking, a symmetric Turing machine [26] is a nondeterministic Turing machine with the property that its transition relation is symmetric. Thus its configuration digraph is in fact a graph, which is essential for capturing the symmetric reachability relation of $\mathrm{REACH}_{\mathrm{add}}$.

We briefly recall the notions which are essential for our proof. A (one tape) *symmetric Turing machine* M is given by $(Q, \Sigma, \Sigma_0, s, t, \Delta)$, where Q is a finite state space, $s \in Q$ is the initial state, $t \in Q$ is the final state, and Δ is a finite set of transitions. We will assume that the input alphabet Σ_0 equals $\{0, 1\}$ and that the machine alphabet Σ contains $0, 1$, and the blank "♭." The transitions $\delta \in \Delta$ are either of the form $\delta_1 = (p, a, 0, b, q)$ or $\delta_2 = (p, ab, cd, q)$, where $p, q \in Q$ and $a, b, c, d \in \Sigma$. The transition δ_1 is to be interpreted as follows: If the current state of the machine is p and the head of the machine is above a cell containing the symbol a, then the machine may rewrite this symbol by b and enter the state q without moving the head. Similarly, reading backwards, if the machine is in state q and the head of the machine is above a cell containing the symbol b, then the machine may rewrite this symbol by a and enter the state p without moving the head. The interpretation of the transition δ_2 is as follows: If the current state is p, the head of the machine is above a cell containing a, and the symbol in the cell to the immediate right is b, then the machine may rewrite a by c and b by d, move one step to the right, and enter the state q. The transition δ_2 may also be read backwards with the obvious interpretation. A *configuration* of M is an element $(q, h, w) \in Q \times \mathbb{N} \times \Sigma^{\mathbb{N}}$, where q is the current state, h the position of the head, and w the current tape contents. (All but finitely many components of w are blanks.) The transitions induce a symmetric relation on the set of configurations, which defines the (undirected) configuration graph.

In [26, Theorem 1] it is shown that any language recognized by a deterministic Turing machine may be recognized by a symmetric Turing machine respecting the same space bound.

5.2.2. Embedding graphs by straight-line segments. We first define two types of products of graphs. Then we study embeddings of such graph products in Euclidean space such that point location in these embedded graphs can be done by additive circuits. This will be needed for the lower bound proof in section 5.2.3.

DEFINITION 5.4. *Let $G_i = (V_i, E_i)$ be graphs, where $1 \le i \le t$.*

1. *The* product *$G_1 \times \cdots \times G_t$ is defined as a graph with the set of nodes $V_1 \times \cdots \times V_t$; two distinct nodes $u = (u_1, \ldots, u_t)$ and $v = (v_1, \ldots, v_t)$ are adjacent iff there exists i such that $\{u_i, v_i\} \in E_i$ and $u_j = v_j$ for all $j \neq i$. If $G_i = G$ for all i we will write G^t instead of $G \times \cdots \times G$.*

2. *The* extended product $G_1 \otimes \cdots \otimes G_t$ *also has set of nodes* $V_1 \times \cdots \times V_t$. *Now two distinct nodes* $u = (u_1, \ldots, u_t)$ *and* $v = (v_1, \ldots, v_t)$ *are adjacent iff for all* i *either* $u_i = v_i$ *or* $\{u_i, v_i\} \in E_i$.

Let $G = (V, E)$ be a graph and $\varphi\colon V \to \mathbb{R}^n$ be an injective map. We assign to each edge $e = \{u, v\}$ the closed (straight-line) segment $\varphi(e) := \{t\varphi(u) + (1-t)\varphi(v) \mid t \in [0,1]\}$.

DEFINITION 5.5. *The injective map* $\varphi\colon V \to \mathbb{R}^n$ induces an embedding *of the graph* $G = (V, E)$ *into* $\mathbb{R}^n$ (*by straight-line segments*) *iff*

$$\forall v \in V\ \forall e, e' \in E\ \big(\varphi(v) \in \varphi(e) \Longrightarrow v \in e\big) \wedge \big(\varphi(e) \cap \varphi(e') \neq \emptyset \Longrightarrow e \cap e' \neq \emptyset\big).$$

The edge skeleton *of the embedding is defined as the union of the segments corresponding to all edges.*

We denote by K_m the complete graph on the set of nodes $[m]$ and embed it in $\mathbb{R}^m$ by sending the node i to the ith canonical basis vector e_i. Thus we interpret K_m as the standard simplex in $\mathbb{R}^m$.

LEMMA 5.6.

1. *Assume that* $\varphi_i\colon V_i \to \mathbb{R}^{n_i}$ *induces an embedding of* G_i *for* $i \in [t]$. *Then* $V_1 \times \cdots \times V_t \to \mathbb{R}^{n_1} \times \cdots \times \mathbb{R}^{n_t}, (v_1 \ldots, v_t) \mapsto (\varphi_1(v_1), \ldots, \varphi_t(v_t))$ *induces an embedding of* $G_1 \times \cdots \times G_t$.

2. *Let* $\varphi\colon V \to \mathbb{R}^n - \{0\}$ *induce an embedding of* $G = (V, E)$ *and* $m \in \mathbb{N}, m > 0$. *Assume further that* $\varphi(u), \varphi(v)$ *are linearly independent for all edges* $\{u, v\} \in E$. *Define* $\psi\colon [m] \times V \to (\mathbb{R}^n)^m$ *by* $\psi(i, v) := (0, \ldots, 0, \varphi(v), 0, \ldots, 0)$ *with* 0 *everywhere except at position* i. *Then* ψ *induces an embedding of the extended product* $K_m \otimes G$ *into* $(\mathbb{R}^n)^m$.

Proof. 1. This can be shown by straightforward verification.

2. The proof is a bit cumbersome, since it requires several case distinctions. Assume for simplicity that $m = 2$. Let $e = \{(1, u), (2, v)\}$, $e' = \{(1, u'), (2, v')\}$ be edges of $K_2 \otimes G$ such that $\psi(e) \cap \psi(e') \neq \emptyset$. Hence there exist $s, t \in [0, 1]$ such that $t\psi(1, u) + (1-t)\psi(2, v) = s\psi(1, u') + (1-s)\psi(2, v')$. This means that $t\varphi(u) = s\varphi(u')$ and $(1-t)\varphi(v) = (1-s)\varphi(v')$. We claim that $e \cap e' \neq \emptyset$.

If $t = 0$, then $s = 0$ (since $\mathrm{im}\varphi \subseteq \mathbb{R}^n - \{0\}$); hence $\varphi(v) = \varphi(v')$. Therefore $v = v'$, and we are done. Similarly, $t = 1$ implies $u = u'$. We may therefore assume that $s, t \notin \{0, 1\}$.

Suppose $u = v'$. Then either $u' = u$ or $\{u', u\} \in E$. In the latter case, $\varphi(u'), \varphi(u)$ are not linearly independent by assumption, which contradicts $t\varphi(u) = s\varphi(u')$. We may therefore assume that $u \neq v'$ and $v \neq u'$.

Since $s = t$ implies $u' = u$, we assume w.l.o.g. that $0 < s < t < 1$. It is easy to see that under these assumptions we have $\varphi(\{u, v\}) \cap \varphi(\{u', v'\}) \neq \emptyset$ (cf. Figure 5.1). As φ is an embedding, we deduce from this $\{u, v\} \cap \{u', v'\} \neq \emptyset$; hence $u = u'$ or $v = v'$, which proves the claim.

The other cases to be treated are simpler and are left to the reader. If $m > 2$, one can argue similarly. ∎

For positive integers a, b, p we define the graphs $G^p_{a,b} := K_a \otimes (K_b)^p$. Interpreting complete graphs as embedded via the standard simplices in Euclidean space and using the construction of the previous lemma, we get an embedding $\psi^p_{a,b}$ of $G^p_{a,b}$ in $\mathbb{R}^{abp}$. We denote the induced set of nodes in $\mathbb{R}^{abp}$ by R and the edge skeleton by T (omitting indices). The following property will be crucial.

LEMMA 5.7. *There are additive circuits of size polynomial in* a, b, p *depending uniformly on these parameters and performing the following tasks:*

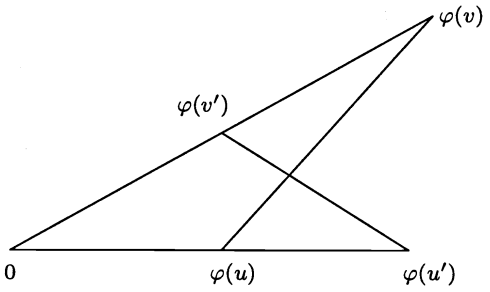

FIG. 5.1. *The segments $\varphi(\{u,v\})$ and $\varphi(\{u',v'\})$ intersect.*

1. *Compute the map $\psi^p_{a,b}\colon [a]\times[b]^p \to R$ and its inverse.*

2. *Decide in which set of the partition $\mathbb{R}^{abp} = (\mathbb{R}^{abp}\setminus T)\cup(T\setminus R)\cup R$ a given point in $\mathbb{R}^{abp}$ lies.*

3. *Compute the end points of the (unique) edge segment of $G^p_{a,b}$ in which a given point $x \in T\setminus R$ lies.*

Proof. To compute $\psi^p_{a,b}$ is straightforward. For its inverse, as well as for parts (2) and (3), note that the relevant information can be inferred from the signs of the components x_i of a given point in $x \in \mathbb{R}^{abp}$. No multiplications, not even scalar ones, are needed to perform these tasks. □

5.2.3. Lower bound for reachability. We are going to show the $\mathrm{PAR}_{\mathrm{add}}$-hardness of $\mathrm{REACH}_{\mathrm{add}}$ and $\#^{\mathsf{cc}}\mathrm{CSAT}_{\mathrm{add}}$. The next lemma tells us that it is sufficient to do this for $\mathrm{REACH}_{\mathrm{add}}$.

LEMMA 5.8. *The problem* $\mathrm{REACH}_{\mathrm{add}}$ *Turing reduces to* $\#^{\mathsf{cc}}\mathrm{CSAT}_{\mathrm{add}}$.

Proof. Let $X \subseteq \mathbb{R}^n$ be given by an additive circuit $\mathcal{C}$ accepting X, and suppose $s,t \in X$. Consider the following subset X' of $\mathbb{R}^{n+1}$:

$$X' := (X\times\{0\})\cup(\{s\}\times[0,1])\cup(\{t\}\times[0,1])\cup(\mathbb{R}^n\times\{1\}).$$

There is an $\mathrm{FP}_{\mathrm{add}}$-machine, which takes as input a circuit $\mathcal{C}$ together with $s,t\in\mathbb{R}^n$ and outputs an additive circuit $\mathcal{C}''$ deciding membership to X'. It is easy to check that s and t are connected in X iff X' has the same number of connected components as X (and one less otherwise). The latter condition can be tested by querying a $\#^{\mathsf{cc}}\mathrm{CSAT}_{\mathrm{add}}$-oracle twice, once with $\mathcal{C}$ and once with $\mathcal{C}''$. □

PROPOSITION 5.9. *The problem* $\mathrm{REACH}_{\mathrm{add}}$ *is* $\mathrm{PAR}_{\mathrm{add}}$*-hard with respect to Turing reductions.*

Proof. By Theorem 4.1(3) it is sufficient to prove that $\mathrm{REACH}_{\mathrm{add}}$ is PSPACE-hard. Thus let $L \subseteq \{0,1\}^\infty$ be any language in PSPACE. Let M be a symmetric Turing machine deciding membership in L with polynomial space bound function $p(n)$ (cf. section 5.2.1). For fixed input length n let H'_n denote the restriction of the configuration graph of M to the set of nodes $V_n := Q\times[p(n)]\times\Sigma^{p(n)}$. To an input $w\in\{0,1\}^n$ we assign the initial configuration $i(w) := (s,1,(w_1,\dots,w_n,\flat,\dots,\flat))$. We may assume w.l.o.g. that there is exactly one accepting configuration $f := (t,1,(\flat,\dots,\flat))$. Of course, the cardinality of V_n is exponential in n. However, it is clear that the graph H'_n can be succinctly represented by Boolean circuits of size polynomial in n.

Note that if $(q,h,w),(q',h',w')\in V_n$ are two configurations adjacent in H'_n, then $|h-h'|\le 1$, and the Hamming distance of w and w' is at most two. Let $\delta_2 = (p,ab,cd,q)$ be the transition between these configurations and w.l.o.g. $h' = h+1$.

We introduce an additional node $(\delta, h, \tilde{w})$, where $\tilde{w}$ is obtained from w by changing the hth entry to the one of w'. Thus the Hamming distances of both $w, \tilde{w}$ and $\tilde{w}, w'$ are at most one. We think of the node $(\delta, h, \tilde{w})$ as lying in between the nodes (q, h, w) and (q', h', w'). By this construction we obtain a *modified configuration graph* H_n on the set of nodes $V'_n := \tilde{Q} \times [p(n)] \times \Sigma^{p(n)}$ with the enlarged set of states $\tilde{Q} := Q \cup \Delta$. (Recall that Δ is the set of transitions of M.) If (q, h, w) and (q', h', w') are adjacent in H_n, then the Hamming distance of w and w' is at most one. Note that the graph H_n can also be succinctly represented by Boolean circuits of size polynomial in n.

By enumerating symbols we may assume that $\Sigma = [b]$ and $\tilde{Q} \times [p(n)] = [a(n)]$ with a polynomial function $a(n)$. From the above observations we conclude that the modified configuration graph H_n is a subgraph of the graph

$$G_n := G^{p(n)}_{a(n),b} := K_{a(n)} \otimes (K_b)^{p(n)}$$

defined in section 5.2.2. We embed G_n in $\mathbb{R}^{a(n)p(n)b}$ with the construction of section 5.2.2 using a map $\psi_n \colon \tilde{Q} \times [p(n)] \times \Sigma^{p(n)} \to R_n$ with induced set of nodes R_n. We denote the edge skeleton of this embedding by T_n and denote by S_n the edge skeleton of the induced embedding of the subgraph H_n of G_n.

By Lemma 5.7, membership in T_n can be decided by a uniform family of additive circuits of size polynomial in n. It is now easy to see that also membership in S_n can be decided by such a family $(\mathcal{C}_n)$ of additive circuits. In fact, we first find out whether a given point $x \in \mathbb{R}^{a(n)p(n)b}$ lies in R_n or T_n. If x lies in $T_n \setminus R_n$, then we compute the end points y, z of the (unique) edge segment of G_n in which x lies. Furthermore, we compute the inverse images $\eta := \psi_n^{-1}(y)$ and $\zeta := \psi_n^{-1}(z)$. Due to Lemma 5.7 all this can be done by a uniform family of additive circuits of size polynomial in n. Note that x lies in S_n iff η and ζ are adjacent in the modified configuration graph H_n. Since the latter can be succinctly described by Boolean circuits of size polynomial in n we can test this in polynomial time.

Consider the map φ associating $w \in \{0,1\}^n$ to $(\mathcal{C}_n, \psi_n(i(w)), \psi_n(f))$. By construction, $w \in L$ iff the configurations $i(w)$ and f can be connected in the modified configuration graph H_n. This in turn is equivalent to the statement that the points $\psi_n(i(w))$ and $\psi_n(f)$ are connected by a path in the skeleton S_n defined by $\mathcal{C}_n$. Therefore, φ is a reduction from L to $\mathrm{REACH}_{\mathrm{add}}$.

In addition, it is obvious that the additive circuit $\mathcal{C}_n$ for S_n as well as the points $\psi_n(i(w))$ and $\psi_n(f)$ can be computed in polynomial time from w. This completes the proof of the proposition. □

Remark 5.10. From the above proof it follows immediately that the problems $\mathrm{REACH}_{\mathrm{add}}$ and $\#^{\mathrm{cc}}\mathrm{CSAT}_{\mathrm{add}}$ restricted to closed input sets X remain complete for $\mathrm{PAR}_{\mathrm{add}}$ and $\mathrm{FPAR}_{\mathrm{add}}$, respectively.

5.2.4. Upper bound for reachability. In order to finish the proof of Theorem 5.3, it remains to show the following lemma.

LEMMA 5.11. *The problem* $\mathrm{REACH}_{\mathrm{add}}$ *is contained in* $\mathrm{PAR}_{\mathrm{add}}$, *and the problem* $\#^{\mathrm{cc}}\mathrm{CSAT}_{\mathrm{add}}$ *is contained* $\mathrm{FPAR}_{\mathrm{add}}$.

Proof. Let $\mathcal{C}$ be an additive circuit defining a set X. The computation of $\mathcal{C}$ can be unwound to a linear decision tree. We define a graph G, whose nodes consist of the accepting leaves of this tree and whose edges join two different leaves μ and ν iff the corresponding leaf sets D_μ and D_ν touch each other, that is, $\overline{D_\mu} \cap D_\nu \neq \emptyset$ or $D_\mu \cap \overline{D_\nu} \neq \emptyset$.

Let $K_1, \ldots, K_t$ be the connected components of the graph G. It is easy to see that X has exactly t connected components, namely the sets of the form $\bigcup_{\nu \in K_i} D_\nu$ for $i \in$

$[t]$. (Use the fact that leaf sets are convex and thus connected.) Therefore, the number of connected components of X is equal to the number of connected components of the graph G.

Of course, the graph G may be exponentially large. However, it can be represented by a weaker variant of the succinct representation discussed before. The nodes of G can be encoded by a word in $\{0,1\}^\infty$ encoding the corresponding path in the tree (0 means branching to the left, 1 means branching to the right). For two such given nodes μ, ν, we can decide in $\mathrm{NP}_{\mathrm{add}}$ whether they are connected in G by guessing a point $x \in \mathbb{R}^n$ and checking whether $x \in \overline{D_\mu} \cap D_\nu$ or $x \in D_\mu \cap \overline{D_\nu}$. The latter can be done as follows: we can easily write down the linear functions computed along the path of μ, thus obtaining a description of D_μ by a system of linear inequalities. A system describing the closure $\overline{D}_\mu$ can be obtained from the one describing D_μ by relaxing the occurring inequalities $<$ to $\leq$.

As in the proof of Savage's theorem we can decide in $\mathrm{PAR}_{\mathrm{add}}$ whether two nodes of G are connected by a path as follows. Let the predicate $\mathrm{PATH}(\mu, \nu, i)$ express that the nodes μ and ν are connected by a path of length at most 2^i. Then we implement $\mathrm{PATH}(\mu, \nu, i)$ by the recursive algorithm

`for all nodes` ω `test whether` $\mathrm{PATH}(\mu, \omega, i-1)$ `and` $\mathrm{PATH}(\omega, \nu, i-1)$

using only polynomial space (compare [34, p. 149]). By applying this procedure for every pair of nodes of G we can compute the number of connected components of G and thus that of X in $\mathrm{FPAR}_{\mathrm{add}}$. □

Remark 5.12. Let p be a prime. Then the problem of counting the number of connected components modulo p of a semilinear set given by an additive circuit is also $\mathrm{FPAR}_{\mathrm{add}}$-complete with respect to Turing reductions. For showing this, we have only to observe that the proof of Lemma 5.8 immediately extends to counting mod p.

5.3. Euler characteristic and Betti numbers. The main results of this section are the completeness results for $\mathrm{EULER}_{\mathrm{add}}$ and $\mathrm{BETTI}_{\mathrm{add}}(k)$ treated in section 5.3.4 and section 5.3.5. The following subsections prepare for the proofs.

5.3.1. Cell complexes and homology. We recall some notions from algebraic topology [20, 33]. A *cell* of dimension k is a topological space homeomorphic to the open k-dimensional unit ball $\mathrm{int}(B^k) := \{x \in \mathbb{R}^k \mid x_1^2 + \cdots x_k^2 < 1\}$. The closed unit ball will be denoted by B^k. Its boundary ∂B^k is homeomorphic to the $(k-1)$-dimensional unit sphere.

Assume that a topological Hausdorff space X is decomposed into a finite, disjoint union of cells: $X = \cup_{i=1}^N F_i$. The *k-skeleton* X^k is then defined as the union of the cells of dimension at most k. The cell decomposition is called a *finite cell complex* iff each cell F_i has a characteristic map, that is, a continuous map $h_i \colon B^k \to X$ mapping the boundary ∂B^k to X^{k-1} and such that h_i induces a homeomorphism of $\mathrm{int}(B^k)$ with F_i. In this case, X is necessarily compact.

In the following, we assume that X is a compact, semilinear subset of $\mathbb{R}^n$ decomposed into subsets F_i, $i \in [N]$, each described by a system

$$f_1 = a_1, \ldots, f_r = a_r,\ g_1 > d_1, \ldots, g_s > d_s,$$

where f_i, g_j are linear forms. Note that the F_i are bounded convex sets, which are open in their affine closure $\mathrm{aff}(F_i)$. In particular, each F_i is a cell, and ∂F_i is homeomorphic to a sphere. It is easy to see that this cell decomposition of X is a finite cell complex if the following *boundary condition* is satisfied:

$$\forall i, j \in [N], \quad F_i \cap \partial F_j \neq \emptyset \Longrightarrow F_i \subseteq \partial F_j. \tag{5.2}$$

This condition is equivalent to saying that the boundary ∂F_i of each cell is a union of cells. Such cell complexes will be called *semilinear cell complexes* in the sequel.

The following fact is well known [20, 33]. Let X be decomposed as a semilinear cell complex and denote by c_k the number of the k-cells of this decomposition. Then the Euler characteristic $\chi(X)$ can be computed as $\chi(X) = \sum_{k=0}^{n}(-1)^k c_k$.

We remark that the decomposition into leaf sets given by a ternary additive circuit may violate the boundary condition, which is a source of complications for our investigations. (For a definition of ternary circuits, see section 5.3.3.) For instance, consider the triangle X decomposed into the vertices $a := (0,0), b := (2,0), c := (0,2)$ and the open segments segments joining a with b, a with c, b with c, and a with $(1,1)$. Then the boundary point $(1,1)$ of the open segment joining a with $(1,1)$ is not a vertex.

In order to define the cellular homology of a semilinear cell complex, we first need to recall some facts about orientation.

Recall that an ordered basis of a finite-dimensional real vector space defines an *orientation* of this space. Two ordered bases are said to have the same orientation iff the transformation matrix sending one basis to the other has positive determinant. By an orientation of an affine linear subspace $A \subseteq \mathbb{R}^n$ we understand an orientation of its associated linear space $L(A)$. An orientation of a convex subset F of $\mathbb{R}^n$ is defined as an orientation of its affine hull $\mathrm{aff}(F)$. It will be convenient to write $L(F) := L(\mathrm{aff}(F))$.

Let $A \subseteq \mathbb{R}^n$ be given as the zero set of linear polynomials $f_1, \ldots, f_{n-k}$ in this order. Extend the sequence $f_1 - f_1(0), \ldots, f_{n-k} - f_{n-k}(0)$ to a basis of the space of linear forms such that the corresponding dual basis $(v_1, \ldots, v_n)$ is a positively oriented basis of $\mathbb{R}^n$. Then $(v_{n-k+1}, \ldots, v_n)$ is a basis of the linear space $L(A)$, which we define to be positively oriented. We will say that this is the orientation of A *induced by* $f_1, \ldots, f_{n-k}$. (Note that this is well defined.)

Let now A be the convex hull of a convex subset F of $\mathbb{R}^n$, and assume that H is a supporting hyperplane of F in A. That is, F lies on one side of H and the closure of F meets H. Then an *orientation of F induces an orientation of H* as follows: let y be a vector pointing from H outward of F. Then we say that a basis $v_1, \ldots, v_{n-1}$ of $L(H)$ is positively oriented with respect to the induced orientation iff $y, v_1, \ldots, v_{n-1}$ is a positively oriented basis of $L(A)$. (This is again well defined.)

Let now $X = \cup_{i=1}^{N} F_i$ be a semilinear cell complex, and assume that all the cells F_i are oriented. Let Φ_k denote the set of k-cells, and consider $F' \in \Phi_k$ and $F \in \Phi_{k+1}$. Assume that F' is contained in the closure of F. Then the affine hull of F' is a hyperplane in the affine hull of F supporting the convex set F. Therefore, the orientation of F induces an orientation on F' as explained above.

We define the *incidence number* $[F, F']$ of $F \in \Phi_{k+1}$ and $F' \in \Phi_k$ by

$$[F, F'] = \begin{cases} 0 & \text{iff } F' \text{ is not contained in the closure of } F, \\ 1 & \text{if the orientation } F \text{ induces on } F' \text{ is the same as that of } F', \\ -1 & \text{otherwise.} \end{cases}$$

For $k \geq 0$ the *incidence matrix* I_k is the matrix associated with $I_k \colon \Phi_{k+1} \times \Phi_k \to \mathbb{Z}$ by $I_k(F, F') = [F, F']$.

Let $\mathcal{C}_k$ be the $\mathbb{Q}$-vector space having Φ_k as a basis. The boundary map $\partial_k \colon \mathcal{C}_{k+1} \to \mathcal{C}_k$ is the $\mathbb{Q}$-linear map defined for $F \in \Phi_{k+1}$ by

$$\partial_k(F) = \sum_{F' \in \Phi_k} [F, F']\, F'.$$

The image $B_k := \mathrm{im}\partial_k$ of ∂_k is called the vector space of k-boundaries, and the kernel $Z_k := \ker \partial_{k-1}$ is called the space of k-cycles. The kth *cellular homology vector space* is defined as $H_k := Z_k/B_k$. It is well known [20, 33] that H_k is isomorphic to the singular homology vector space $H_k(X;\mathbb{Q})$. Therefore, $b_k(X) := \dim H_k$ is the kth Betti number, which is independent of the cell decomposition and of the choice of orientations for its cells. We have $b_k(X) = \dim Z_k - \dim B_k = c_k - \rho_{k-1} - \rho_k$, where $\rho_k := \mathrm{rank}\,\partial_k$ and $c_k = |\Phi_k|$.

5.3.2. Reduction to the compact case. The technical result developed in this section will be needed in the upper bound proofs for the problems $\mathrm{EULER}_{\mathrm{add}}$ and $\mathrm{BETTI}_{\mathrm{add}}(k)$. The purpose is to show that the closedness assumption on X can be strengthened to compactness w.l.o.g.

Let us first show that both closedness and compactness of a semilinear set can be checked within the allowed resources, that is, in additive polynomial time with access to a #P-oracle. We write $\|x\|_\infty := \max_{i\le n} |x_i|$ for $x \in \mathbb{R}^n$.

LEMMA 5.13. *Both closedness and compactness of a set X given by an additive circuit can be decided in $\mathrm{P}_{\mathrm{add}}^{\#\mathsf{P}}$.*

Proof. The boundedness of $X \subseteq \mathbb{R}^n$ can be expressed as follows:

$$\exists R \in \mathbb{R}\ \forall x\ (x \in X \Longrightarrow \|x\|_\infty \le R).$$

Hence this property can be decided in Σ^2_{add}. The closedness of $X \subseteq \mathbb{R}^n$ can be expressed by

$$\forall y\ \exists \epsilon\ \forall x\ (y \notin X, x \in X, \epsilon > 0 \Longrightarrow \|x - y\|_\infty \ge \epsilon).$$

Hence this property can be decided in Π^3_{add}. Now use Corollary 4.6. □

We recall a further notion from topology [20, 33]. A subspace A of a space X is called a *strong deformation retract* of X if there is a continuous map $F\colon X \times [0,1] \to X$ such that $F(x,0) = x$, $F(x,1) \in A$, and $F(a,t) = a$ for all $x \in X$, $a \in A$, and $t \in [0,1]$. It is a well-known fact that if A is a strong deformation retract of X, then the inclusion of A in X induces an isomorphism of the homology vector spaces $H_k(A;\mathbb{Q}) \simeq H_k(X;\mathbb{Q})$. In particular, the spaces A and X have the same Betti numbers.

LEMMA 5.14. *Let $X \subseteq \mathbb{R}^n$ be a closed semilinear set given by an additive circuit $\mathcal{C}$. As usual, we denote by D_ν the corresponding leaf sets. Then*

1. *we can compute from $\mathcal{C}$ in $\mathrm{FP}_{\mathrm{add}}$ a real number $R > 0$ such that*

$$\forall \nu\ \big(D_\nu \ne \emptyset \Longrightarrow D_\nu \cap [-R,R]^n \ne \emptyset\big); \tag{5.3}$$

2. *if R satisfies (5.3), then $X_R := X \cap [-R,R]^n$ is a strong deformation retract of X.*

Proof. 1. Each leaf set D_ν is defined by a set of sign conditions for the values computed by the circuit. On an input $y \in \mathbb{R}^n$ these values are of the form

$$z = \sum_{i=1}^{n} a_i y_i + \sum_{i=1}^{k} b_i \alpha_i + c,$$

where $\alpha_1, \dots, \alpha_k$ are the constants of $\mathcal{C}$ and the coefficients a_i, b_i, c are integers of bit-size at most $s := \mathrm{size}(\mathcal{C})$. If D_ν is not empty, Theorem 2.6 implies that there is a point $y \in D_\nu$ such that $y_i = \sum_{j=1}^{k} u_{ij}\alpha_j + w_i$, where the u_{ij}, w_i are rationals of

bit-size at most $L := (sn)^c$, c being some universal constant. Hence $\max_i |y_i| \leq R$, where $R := 2^L\big(1 + \sum_{j=1}^k |\alpha_j|\big)$. Therefore, the bound R satisfies the condition (5.3). Moreover, it is clear that R can be computed in $\mathrm{FP}_{\mathrm{add}}$ from $\mathcal{C}$.

2. Assume w.l.o.g. that X is not compact. Consider the one-point compactification $\dot{X}$ of X, which is explicitly defined as follows. Let $S^n \subset \mathbb{R}^{n+1}$ be the n-dimensional sphere and $N = (0, 0, \ldots, 0, 1) \in S^n$ be its north pole. Projection from N yields a homeomorphism between $S^n - \{N\}$ and $\mathbb{R}^n \times \{-1\}$ and therefore a homeomorphism between $S^n - \{N\}$ and $\mathbb{R}^n$. The closure $\dot{X}$ of the image of X in S^n (which consists of attaching N to this image) is called a *one-point compactification* of X. The decomposition into leaf sets of X becomes a cell decomposition of $\dot{X}$, which can be turned into a finite cell complex by refinement. The claim is now a consequence of the following intuitive topological fact, whose formal proof is left to the reader. Let Y be a finite cell complex and p be a vertex of Y. Assume that U is an open neighborhood of p so small that $\{p\}$ is the only cell of the complex contained in U. Then $Y \setminus U$ is a strong deformation retract of $Y \setminus \{p\}$. □

5.3.3. Universal cell decompositions. We adopt the notation $\mathcal{F}_{s,n}$ for the universal cell decomposition for the parameters s, n, introduced in section 4.1.

LEMMA 5.15. *If $X \subseteq \mathbb{R}^n$ is compact and a finite union of faces in $\mathcal{F}_{s,n}$, then the decomposition of X is a semilinear cell complex.*

Proof. It is obvious that the boundary condition (5.2) is satisfied. □

Let $\mathcal{C}'$ be an additive circuit defining the semilinear set $X \subseteq \mathbb{R}^n$. At the price of at most doubling the size of the circuit, we can transform $\mathcal{C}'$ into a *ternary additive circuit* $\mathcal{C}$, which branches according to the sign of intermediate results in a ternary way ($< 0, = 0, > 0$) instead of branching in a binary way according to $x \geq 0$ or $x < 0$. Each (nonempty) leaf set D_ν of $\mathcal{C}$ is described in the form

$$f_1 = a_1, \ldots, f_r = a_r,\ g_1 > d_1, \ldots, g_s > d_s,$$

where the $f_i - a_i$ and $g_j - d_j$ are the linear polynomials computed along the path leading to the leaf ν. Note that the linear forms f_i, g_j have integer coefficients of bit-size at most 2^s, where s is the size of the circuit $\mathcal{C}$. If the circuit uses only the constants $0, 1$, then a_i, d_j are also integers of bit-size at most 2^s. In the general case, however, a_i, d_j are real numbers. In the first case, each leaf set D_ν is a union of faces of $\mathcal{F}_{s,n}$. Thus, $\{F \in \mathcal{F}_{s,n} \mid F \subseteq X\}$ is a refinement of the decomposition of X into the leaf sets. By Lemma 5.15 this decomposition is a semilinear cell complex if X is compact.

Let X be a compact finite union of cells of $\mathcal{F}_{s,n}$. To define (and compute) the cellular homology groups of X we need to fix orientations on the cells $F \in \mathcal{F}_{s,n}$. The cellular homology groups are independent of the chosen orientations, so we will make this choice in a convenient way as explained below.

By identifying a sequence $(f_1, \ldots, f_k)$ in $(\mathcal{H}_{s,n})^k$ with the sequence of coefficients of $f_1, \ldots, f_k$ (in a fixed order) and using the lexicographical ordering, we may consider $(\mathcal{H}_{s,n})^k$ as a totally ordered set. We can extend this order to the union $\mathcal{H}_{s,n}^\infty$ of the $(\mathcal{H}_{s,n})^k$, for $k \in \mathbb{N}$, by requiring that elements of $(\mathcal{H}_{s,n})^k$ are strictly smaller than elements of $(\mathcal{H}_{s,n})^{k'}$ for $k < k'$.

For $F \in \mathcal{F}_{s,n}$ let $(f_1, \ldots, f_{n-k})$ be the smallest sequence in $\mathcal{H}_{s,n}^\infty$ such that F is contained in the zero set of $f_1, \ldots, f_{n-k}$. Then $k = \dim F$. We define the orientation of F as the orientation of $\mathrm{aff}(F)$ induced by this smallest sequence $(f_1, \ldots, f_{n-k})$ (cf. section 5.3.1).

In the sequel, $\mathcal{F}$ shall denote the union of the $\mathcal{F}_{s,n}$, and $\mathcal{H}$ the union of the $\mathcal{H}_{s,n}$, over all $s, n \in \mathbb{N}$, respectively. Recall that we encode the faces $F \in \mathcal{F}$ by triples $(s, n, x) \in \mathbb{N}^2 \times \mathbb{Q}^n$ with a rational point $x \in F$ of bit-size at most $(sn)^c$. Let the *incidence function* $I\colon \mathcal{F} \times \mathcal{F} \to \{-1, 0, 1\}$ be defined by $I(F, F') := [F, F']$, if $F, F' \in \mathcal{F}_{s,n}$ for some s, n and $\dim F = \dim F' + 1$, and $I(F, F') = 0$ otherwise.

LEMMA 5.16.

1. *The membership decision problem* $\{(F, x) \in \mathcal{F} \times \mathbb{R}^\infty \mid x \in F\}$ *is in* $\mathrm{PH}^0_{\mathrm{add}}$.
2. *The containment decision problem* $\{(F, f) \in \mathcal{F} \times \mathcal{H} \mid F \subseteq Z(f)\}$ *is in* PH.

Here $Z(f)$ *denotes the zero set of the polynomials of the sequence* f.

3. *The closure containment problem* $\{(F', F) \in \mathcal{F} \times \mathcal{F} \mid F' \subseteq \partial F\}$ *is in* PH.
4. *There is a function* $\mathcal{F} \to \mathbb{Q}^\infty$ *in* $\mathsf{FP}^{\mathsf{PH}}$ *mapping* F *to a positively oriented basis of the linear space* $L(F)$ *associated with the affine hull of* F.
5. *The incidence function* $I\colon \mathcal{F} \times \mathcal{F} \to \{-1, 0, 1\}$ *can be computed in* $\mathsf{FP}^{\mathsf{PH}}$.

Proof. 1. Let $F \in \mathcal{F}_{s,n}$ be given by the rational point $x_0 \in F$. We have

$$x \in F \iff \forall f \in \mathcal{H}_{s,n}\ \big(\mathrm{sgn} f(x) = \mathrm{sgn} f(x_0)\big).$$

This condition is expressible in $(\Pi^1_{\mathrm{add}})^0 \subseteq \mathrm{PH}^0_{\mathrm{add}}$, which shows the claim.

2. Replacing in the statement for all x ($x \in F \Rightarrow x \in Z(f)$) the predicate "$x \in F$" according to part 1, we obtain a $(\Pi^1_{\mathrm{add}})^0$-statement. Since F and f are discrete, the containment decision problem even belongs to the Boolean part of $(\Pi^1_{\mathrm{add}})^0$ and thus to Π^1 by [14] (cf. Remark 4.12).

3. Using part 1, we can express "$x \in \overline{F}$" by a $(\Pi^2_{\mathrm{add}})^0$-statement. Hence $F' \subseteq \partial F$ can also be expressed by a $(\Pi^2_{\mathrm{add}})^0$-statement. Since F, F' are discrete, this statement is even in Π^2.

4. Using part 2, we see that the following condition is in Π^2: $(f_1, \ldots, f_{n-k})$ is the smallest sequence in $\mathcal{H}^\infty_{s,n}$ such that F is contained in the zero set of $f_1, \ldots, f_{n-k}$. The assertion follows now by Remark 2.11(ii).

5. For given $F, F' \in \mathcal{F}_{s,n}$ we first check in PH whether $F' \subseteq \partial F$ and $\dim F' = \dim F - 1$ using parts 3 and 4. Then we compute positively oriented bases $u_1, \ldots, u_{k+1}$ of $L(F)$ and $v_1, \ldots, v_k$ of $L(F')$ in $\mathsf{FP}^{\mathsf{PH}}$ according to part 4. If F and F' are represented by the rational points x and x', respectively, then $y := x' - x$ is a vector in $L(F)$ pointing from $L(F')$ outside of F. The incidence number $[F, F']$ equals 1 iff the bases $y, v_1, \ldots, v_k$ and $u_1, \ldots, u_{k+1}$ have the same orientation, which can be checked in P. □

We extend now to the case when there are real constants what we have discussed before.

Let $s, n, \ell \in \mathbb{N}$ and $\eta \in \mathbb{R}^\ell$. By intersecting the universal cell decomposition of $\mathbb{R}^{n+\ell}$ for the parameters $s, n + \ell$ with the hyperplane $H(\eta) := \{(x, y) \in \mathbb{R}^{n+\ell} \mid y = \eta\}$, we get a cell decomposition of $\mathbb{R}^n \times \{\eta\}$, which we identify with $\mathbb{R}^n$. More specifically, each face $F \in \mathcal{F}_{s+\ell,n}$ induces a face $F(\eta)$ of this decomposition, defined by $F(\eta) \times \{\eta\} := F \cap H(\eta)$, provided this intersection is nonempty. Note that each $F(\eta)$ is defined by putting sign conditions on all polynomials of the form $a_0 + \sum_{j=1}^{\ell} b_j \eta_j + \sum_{i=1}^{n} a_i X_i$, where $\sum_{i=0}^{n} |a_i| + \sum_{j=1}^{\ell} |b_j| \le 2^s$. We write $\mathcal{F}_{s,n}(\eta) := \{F(\eta) \mid F \in \mathcal{F}_{s,n}\}$ and call this the *universal cell decomposition* of $\mathbb{R}^n$ for the parameters s, n and vector of constants $\eta \in \mathbb{R}^\ell$. Moreover, we write $\mathcal{F}(\eta)$ for the union of the $\mathcal{F}_{s,n}(\eta)$ over all $s, n \in \mathbb{N}$.

Most of the results shown so far in this subsection extend to this more general notion of universal cell decompositions in a natural way. For instance, Lemma 5.15

extends immediately to $\mathcal{F}_{s,n}(\eta)$. A face $F(\eta) \in \mathcal{F}(\eta)$ is encoded by $F \in \mathcal{F}$, which is itself encoded by a small rational point.

LEMMA 5.17. *An analogue of Lemma* 5.16 *holds, where the complexity classes* $\mathrm{PH}^0_{\mathrm{add}}$, FP, *and* PH *have to be replaced by* $\mathrm{PH}_{\mathrm{add}}$, $\mathsf{FP/poly}$, *and* $\mathsf{PH/poly}$, *respectively.*

The proof is a straightforward extension of the proof of Lemma 5.16. For instance, for treating the closure containment problem $\{(F', F) \in \mathcal{F}(\eta) \times \mathcal{F}(\eta) \mid F' \subseteq \partial F\}$ one first shows that this problem is in $\mathrm{PH}_{\mathrm{add}}$. Then, since this is a discrete problem, one concludes that it is in the Boolean part of $\mathrm{PH}_{\mathrm{add}}$ and thus in $\mathsf{PH/poly}$ by [14] (cf. Remark 4.12).

5.3.4. Euler characteristic. The Euler characteristic $\chi(X)$ is a fundamental invariant of a topological space.

Let $\mathrm{EULER}_{\mathrm{add}}$ denote the following problem: given an additive circuit $\mathcal{C}$ defining a *closed* semilinear set X, decide whether X is empty and, if not, compute its Euler characteristic $\chi(X)$. Hence only circuits defining closed semilinear sets are considered to be admissible inputs.

THEOREM 5.18. *The problem* $\mathrm{EULER}_{\mathrm{add}}$ *is* $\mathrm{FP}^{\#\mathrm{P}_{\mathrm{add}}}_{\mathrm{add}}$*-complete with respect to Turing reductions.*

Proof. We first show that $\mathrm{EULER}_{\mathrm{add}}$ is $\#\mathrm{P}_{\mathrm{add}}$-hard. Note that the problem $\mathrm{CSAT}_{\mathrm{add}}$ introduced in section 1.4 trivially reduces to $\mathrm{EULER}_{\mathrm{add}}$ by the definition of the latter problem. Hence $\mathrm{NP}_{\mathrm{add}} \subseteq \mathrm{P}^{\mathrm{EULER}_{\mathrm{add}}}_{\mathrm{add}}$. Therefore, by Theorem 5.1 we have $\mathrm{DIM}_{\mathrm{add}}(1) \in \mathrm{P}^{\mathrm{EULER}_{\mathrm{add}}}_{\mathrm{add}}$.

It is now easy to design a Turing reduction from $\#\mathrm{CSAT}_{\mathrm{add}}$ to $\mathrm{EULER}_{\mathrm{add}}$. On input of an additive circuit $\mathcal{C}$, first decide whether X is finite using oracle calls to $\mathrm{DIM}_{\mathrm{add}}(1)$, and hence to $\mathrm{EULER}_{\mathrm{add}}$. If no, return ∞; otherwise, return $\chi(X)$. Since $\#\mathrm{CSAT}_{\mathrm{add}}$ is $\#\mathrm{P}_{\mathrm{add}}$-complete by Theorem 3.6, this proves the hardness.

It remains to prove that $\mathrm{EULER}_{\mathrm{add}}$ is contained in $\mathrm{FP}^{\#\mathrm{P}_{\mathrm{add}}}_{\mathrm{add}}$. By Lemma 5.14, we may restrict our discussion to additive circuits defining a compact semilinear set $X \subseteq \mathbb{R}^n$. Assume that X is given by a ternary additive circuit $\mathcal{C}$ of size s using the real constants $\eta_1, \ldots, \eta_\ell$. Then each of the leaf sets of $\mathcal{C}$ is a union of faces in $\mathcal{F}_{s,n}(\eta)$. Hence the decomposition of X into the faces $F \in \mathcal{F}_{s,n}(\eta)$ contained in X is a semilinear cell complex. If $c_k(\mathcal{C})$ denotes the number of k-cells of this cell complex, we have $\chi(X) = \sum_{k=0}^{n} (-1)^k c_k(\mathcal{C})$.

Lemma 5.16 and its extension, Lemma 5.17, imply that on input $\mathcal{C}$ and $F \in \mathcal{F}_{s,n}(\eta)$ the property $F \in \Phi_k(\mathcal{C})$ can be tested in $\mathrm{DPH}_{\mathrm{add}}$. Therefore, $c_k(\mathcal{C})$ can be computed from $\mathcal{C}$ in $\mathrm{D}\#\cdot\mathrm{PH}_{\mathrm{add}}$, which is contained in $\mathrm{FP}^{\#\mathsf{P}}_{\mathrm{add}}$ by Corollary 4.6. This shows that $\mathrm{EULER}_{\mathrm{add}}$ belongs to $\mathrm{FP}^{\#\mathsf{P}}_{\mathrm{add}}$. ∎

5.3.5. Betti numbers. The kth Betti number $b_k(X)$ of a space X is defined as the dimension of the kth (singular) homology vector space $H_k(X; \mathbb{Q})$ ($k \in \mathbb{N}$). The Betti numbers modulo a prime p are defined by replacing the coefficient field $\mathbb{Q}$ by the finite field $\mathbb{F}_p$.

For $k \in \mathbb{N}$, we define $\mathrm{BETTI}_{\mathrm{add}}(k)$ to be the problem of computing the kth Betti number of a *closed* semilinear set given by an additive circuit. Recall that for $k = 0$ this is just the problem of counting the number of connected components. The problem of computing the kth Betti number modulo a prime p shall be denoted by $\mathrm{BETTI}_{\mathrm{add}}(k, \bmod p)$.

The goal of this section is the proof of the following result, extending Theorem 5.3.

THEOREM 5.19. *For any* $k \in \mathbb{N}$ *and any prime* p*, the problems* $\mathrm{BETTI}_{\mathrm{add}}(k)$ *and* $\mathrm{BETTI}_{\mathrm{add}}(k, \bmod p)$ *are* $\mathrm{FPAR}_{\mathrm{add}}$*-complete with respect to Turing reductions.*

The next lemma provides the lower bound part of the proof of Theorem 5.19.

LEMMA 5.20. $\mathrm{BETTI}_{\mathrm{add}}(k)$ *and* $\mathrm{BETTI}_{\mathrm{add}}(k, \mathrm{mod}\, p)$ *are* $\mathrm{FPAR}_{\mathrm{add}}$*-hard with respect to Turing reductions for any* $k \in \mathbb{N}$ *and any prime* p.

Proof. We will exhibit a Turing reduction from $\#^{\mathsf{cc}}\mathrm{CSAT}_{\mathrm{add}}$ to $\mathrm{BETTI}_{\mathrm{add}}(k)$. W.l.o.g., we assume $k > 0$.

The *suspension* $S(X)$ of a topological space X is defined as the space obtained from the cylinder $X \times [0,1]$ over X by identifying the points in each of the sets $X \times \{0\}$ and $X \times \{1\}$. Essentially, this is a double cone with basis X. It is well known that if $X \neq \emptyset$, the Betti numbers of $S(X)$ and X are related as follows (cf. [20, 33]):

$$b_{k+1}(S(X)) = \begin{cases} b_k(X) & \text{if } k > 0, \\ b_0(X) - 1 & \text{if } k = 0. \end{cases} \tag{5.4}$$

If $X \subseteq \mathbb{R}^n$ is given by an additive circuit, then we will use the following alternative definition for the suspension:

$$S_1(X) := (X \times [0,1]) \cup (\mathbb{R}^n \times \{0\}) \cup (\mathbb{R}^n \times \{1\}),$$

which, if $X \neq \emptyset$, is homotopy equivalent to $S(X)$ and therefore has the same Betti numbers. Also,

$$b_k(S_1(\emptyset)) = \begin{cases} 0 & \text{if } k > 0, \\ 2 & \text{if } k = 0. \end{cases} \tag{5.5}$$

This alternative definition of suspension has the advantage that it is easy to transform an additive circuit describing X to one describing $S_1(X)$. Note that $S_1(X)$ is closed if X is closed. If we iterate this construction $k+1$ times starting with $X \subseteq \mathbb{R}^n$, we get a set $S_{k+1}(X) \subseteq \mathbb{R}^{n+k+1}$, which satisfies, by (5.4) and (5.5),

$$b_k(S_{k+1}(X)) = b_0(S_1(X)) - 1 = \begin{cases} 0 & \text{if } X \neq \emptyset, \\ 1 & \text{if } X = \emptyset. \end{cases}$$

This allows one to decide whether $X = \emptyset$ by one query to $\mathrm{BETTI}_{\mathrm{add}}(k)$. If $X = \emptyset$, then we return 0. Otherwise, note that, by (5.4), $b_0(X) = b_k(S_k(X)) + 1$ (since $k > 0$), and we may return $b_0(X)$ after another query to $\mathrm{BETTI}_{\mathrm{add}}(k)$. Strictly speaking, this is a reduction from the restriction of $\#^{\mathsf{cc}}\mathrm{CSAT}_{\mathrm{add}}$ to closed input sets X. However, this is sufficient by Remark 5.10.

The same reduction can be made for the Betti numbers modulo a prime. The hardness follows in this case by appealing to Remark 5.12. □

Before proving the upper bound, we make a short digression on space efficient linear algebra. It is well known [32] that the rank of an $N \times N$ integer matrix A, whose entries have bit-size at most L, can be computed by uniform Boolean circuits with depth $(\log L + \log N)^{O(1)}$ (and similary for matrices over $\mathbb{F}_p$). Using Borodin's result [6], this can be translated to a polylogarithmic space computation of the rank of A by a Turing machine.

Similarly as for graphs, we will understand by a *succinct representation* of an integer matrix $A = (a_{ij})$ a Boolean circuit B computing the matrix entry a_{ij} from the index pair (i, j) given in binary. From the above discussion we conclude the following lemma.

LEMMA 5.21. *The rank of an* $N \times N$ *integer matrix* A *given in succinct representation by a Boolean circuit* B *can be computed by a Turing machine with space*

polynomial in $\log N$*, the depth of* B*, and the log of the maximal bit-size of the entries of* A*.*

We finish now the proof of Theorem 5.19 by showing the following upper bound.

PROPOSITION 5.22. $\mathrm{BETTI}_{\mathrm{add}}(k)$ *and* $\mathrm{BETTI}_{\mathrm{add}}(k, \mathrm{mod}\, p)$ *are both contained in* $\mathrm{FPAR}_{\mathrm{add}}$.

Proof. 1. We first prove that $\mathrm{BETTI}^0_{\mathrm{add}}(k)$ is in $\mathsf{FPSPACE}$. Let the closed semilinear set $X \subseteq \mathbb{R}^n$ be given by an additive circuit $\mathcal{C}'$, whose only constants are 0 and 1. By Lemma 5.14, we may assume w.l.o.g. that X is compact. We transform $\mathcal{C}'$ into a ternary additive circuit $\mathcal{C}$ of size s as in section 5.3.3. Consider the cell decomposition of X induced by $\mathcal{C}$. It is clear that each of its leaf sets is a union of faces in $\mathcal{F}_{s,n}$. Lemma 5.15 implies that the decomposition of X into the faces $F \in \mathcal{F}_{s,n}$ contained in X is a semilinear cell complex.

We put $\Phi_k(\mathcal{C}) := \{F \in \mathcal{F}_{s,n} \mid \dim F = k, F \subseteq X\}$ and $c_k(\mathcal{C}) := |\Phi_k(\mathcal{C})|$ for $k \in \mathbb{N}$. Let $\rho_k(\mathcal{C})$ denote the rank of the incidence matrix $I_k(\mathcal{C})\colon \Phi_{k+1}(\mathcal{C}) \times \Phi_k(\mathcal{C}) \to \mathbb{Z}, (F, F') \mapsto [F, F']$. In section 5.3.1 it was shown that the kth Betti number $b_k(X)$ of X can be expressed as $b_k(X) = c_k(\mathcal{C}) - \rho_{k-1}(\mathcal{C}) - \rho_k(\mathcal{C})$.

Lemma 5.16 implies that on input $\mathcal{C}$ and F the property $F \in \Phi_k(\mathcal{C})$ can be tested in PH. Therefore, $c_k(\mathcal{C})$ can be computed from $\mathcal{C}$ in $\# \cdot \mathsf{PH} \subseteq \mathsf{FPSPACE}$.

Thus it remains to show that for each $k \in \mathbb{N}$ the function $\mathcal{C} \mapsto \rho_k(\mathcal{C})$ can be computed in $\mathsf{FPSPACE}$. It follows from Lemma 5.16(5) that $I_k(\mathcal{C})(F, F')$ can be computed from $\mathcal{C}, F, F'$ in $\mathsf{FPSPACE}$. Hence, by Borodin's result [6] a succinct representation B of the incidence matrix $I_k(\mathcal{C})$ having depth polynomial in s can be computed from $\mathcal{C}$ in $\mathsf{FPSPACE}$. By Lemma 5.21, we can compute the rank $\rho_k(\mathcal{C})$ from B by a Turing machine in space polynomial in s. Altogether, we get a computation of $\rho_k(\mathcal{C})$ in $\mathsf{FPSPACE}$.

2. We now prove that $\mathrm{BETTI}_{\mathrm{add}}(k)$ belongs to $\mathrm{FPAR}_{\mathrm{add}}$. Assume that the compact semilinear set $X \subseteq \mathbb{R}^n$ is given by a ternary additive circuit $\mathcal{C}$ of size s using the real constants $\eta_1, \ldots, \eta_\ell$. Then each of the leaf sets of $\mathcal{C}$ is a union of faces in $\mathcal{F}_{s,n}(\eta)$. Hence the decomposition of X into the faces $F \in \mathcal{F}_{s,n}(\eta)$ contained in X is a semilinear cell complex. The rest of the argument is based on Lemma 5.17 and similar as before.

3. The case of positive characteristic can be settled similarly. □

COROLLARY 5.23. $\mathrm{BETTI}_{\mathrm{add}}(k)$ *Turing reduces to* $\mathrm{EULER}_{\mathrm{add}}$ *for some* $k \in \mathbb{N}$ *iff* $\mathsf{PSPACE} \subseteq \mathsf{P}^{\#\mathsf{P}}/\mathsf{poly}$*. It does so with a constant-free reduction iff* $\mathsf{PSPACE} \subseteq \mathsf{P}^{\#\mathsf{P}}$.

Proof. This follows from Theorem 5.18, Theorem 5.19, and Corollary 4.11. □

5.3.6. Some completeness results in the Turing model. The results of section 4 and sections 5.1–5.3 can be combined to show completeness results for natural geometric problems in the discrete setting.

An additive circuit $\mathcal{C}$ whose only constants are 0 and 1 can be encoded in $\{0,1\}^\infty$. Thus, one may consider discrete versions $\mathrm{EULER}^0_{\mathrm{add}}$ and $\mathrm{BETTI}^0_{\mathrm{add}}(k)$, which are defined as $\mathrm{EULER}_{\mathrm{add}}$ and $\mathrm{BETTI}_{\mathrm{add}}(k)$, respectively, but are restricted to constant-free circuits. Note that since $\mathrm{BP}((\Pi^3_{\mathrm{add}})^0) = \Pi^3$ (cf. [14]), a corresponding version of Lemma 5.13 holds; i.e., closedness and compactness of a set given by a constant-free additive circuit can be decided in $\mathsf{P}^{\#\mathsf{P}}$.

For these discrete problems the following results hold.

COROLLARY 5.24. *The problems* $\mathrm{EULER}^0_{\mathrm{add}}$ *and* $\mathrm{BETTI}^0_{\mathrm{add}}(k)$*,* $k \in \mathbb{N}$*, are complete with respect to Turing reductions in* $\mathsf{FP}^{\#\mathsf{P}}$ *and* $\mathsf{FPSPACE}$*, respectively. A similar statement holds for the computation of Betti numbers modulo a prime.*

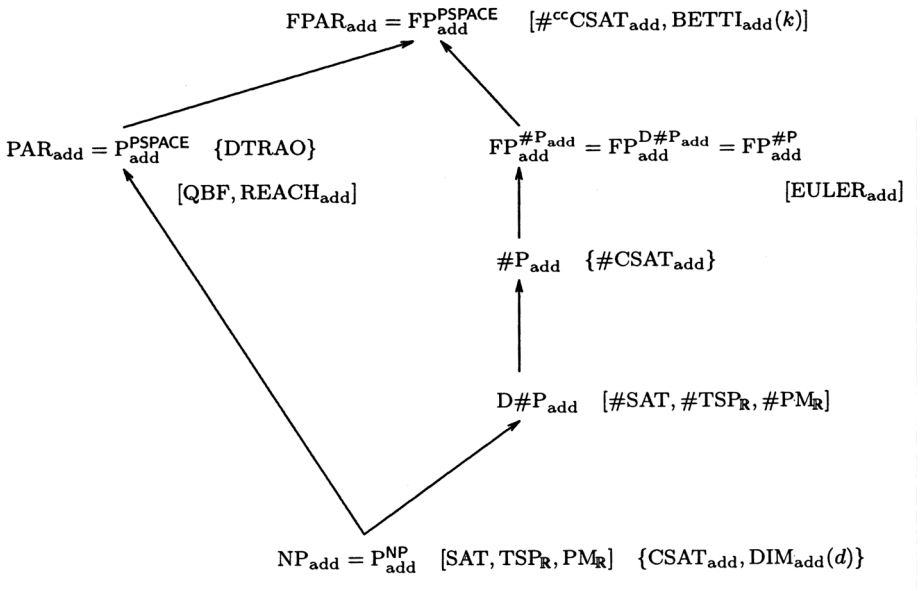

FIG. 6.1. *Survey of main results.*

Proof. This could be shown by checking in detail the proofs of Theorem 5.18 and Theorem 5.19. More elegantly, we can derive Corollary 5.24 from general principles using the concept of Boolean parts. We then need only to check that the reductions in the proofs of Theorem 3.6, Theorem 5.18, and Theorem 5.19 are constant-free. For instance, $\mathrm{EULER}^0_{\mathrm{add}} \in \mathrm{BP}((\mathrm{FP}^0_{\mathrm{add}})^{\#\mathrm{P}^0_{\mathrm{add}}}) = \mathsf{FP}^{\#\mathsf{P}}$ according to Remark 4.12. For the hardness note that

$$(\mathrm{FP}^0_{\mathrm{add}})^{\#\mathrm{P}^0_{\mathrm{add}}} = (\mathrm{FP}^0_{\mathrm{add}})^{\#\mathrm{CSAT}^0_{\mathrm{add}}} = (\mathrm{FP}^0_{\mathrm{add}})^{\mathrm{EULER}^0_{\mathrm{add}}}.$$

By taking Boolean parts und using Remark 4.12, we conclude $\mathsf{FP}^{\#\mathsf{P}} = \mathsf{FP}^{\mathrm{EULER}^0_{\mathrm{add}}}$.

The statement about $\mathrm{BETTI}^0_{\mathrm{add}}(k)$ is proved similarly. □

6. Summary. To facilitate the orientation of the reader, we have summarized the results of this paper in Figure 6.1. There an arrow denotes an inclusion, problems in square brackets are Turing-complete for the class at their left, and problems in curly brackets are many-one-complete for that class. The problems appearing in the figure are defined in the list below. We note that the completeness of SAT, $\mathrm{CSAT_{add}}$, $\mathrm{TSP}_{\mathbb{R}}$, $\mathrm{PM}_{\mathbb{R}}$, QBF, and DTRAO was already known.

SAT (*satisfiability*). Given a propositional formula φ, decide whether there is an assignment of Boolean values for the variables satisfying φ.

#SAT (*counting satisfiability*). Given φ as in SAT, count the number of satisfying assignments.

QBF (*quantified Boolean formulas*). Given a quantified Boolean formula, decide whether it is a tautology.

DTRAO (*digital theory of the reals with addition and order*). Given a sentence in the theory of the reals with addition and order, all of whose variables satisfy a constraint of the form $x = 0 \vee x = 1$, decide whether it is a tautology.

$\mathrm{TSP}_{\mathbb{R}}$ (*traveling salesman*). Given a complete graph G with real weights on the edges and $w \in \mathbb{R}$, decide whether there is a Hamilton circuit in G with weight at most w. (The weight of a subgraph is the sum of the weights of its edges.)

$\#\mathrm{TSP}_{\mathbb{R}}$ (*counting traveling salesman*). Given G and $w \in \mathbb{R}$ as in $\mathrm{TSP}_{\mathbb{R}}$, count the number of Hamilton circuits in G with weight at most w.

$\mathrm{PM}_{\mathbb{R}}$ (*weighted perfect matching*). Given a bipartite graph G with real weights on the edges and $w \in \mathbb{R}$, decide whether there is a perfect matching in G with weight at most w.

$\#\mathrm{PM}_{\mathbb{R}}$ (*counting weighted perfect matchings*). Given G and $w \in \mathbb{R}$ as in $\mathrm{PM}_{\mathbb{R}}$, count the number of perfect matchings in G with weight at most w.

$\mathrm{CSAT}_{\mathrm{add}}$ (*circuit satisfiability*). Decide whether the semilinear set given by an additive circuit is nonempty.

$\mathrm{DIM}_{\mathrm{add}}(d)$ (*dimension*). Given an additive circuit and $d \in \mathbb{N}$, decide whether the dimension of the semilinear set defined by the circuit is at least d.

$\mathrm{REACH}_{\mathrm{add}}$ (*reachability*). Given an additive circuit defining a semilinear set X and two points $s, t \in X$, decide whether s and t are in the same connected component of X.

$\#\mathrm{CSAT}_{\mathrm{add}}$ (*point counting*). Given an additive circuit defining a semilinear set X, compute the number of points in X.

$\#^{\mathrm{cc}}\mathrm{CSAT}_{\mathrm{add}}$ (*counting connected components*). Given an additive circuit defining a semilinear set X, compute the number of connected components of X.

$\mathrm{EULER}_{\mathrm{add}}$ (*Euler characteristic*). Given an additive circuit defining a closed semilinear set X, decide whether X is empty and, if not, compute its Euler characteristic.

$\mathrm{BETTI}_{\mathrm{add}}(k)$ (*Betti numbers*). Given an additive circuit defining a closed semilinear set X, compute the kth Betti number of X.

7. Open questions. We present some selected open problems.

PROBLEM 7.1. In this paper, we prove completeness with respect to Turing reductions. Do we also have completeness with respect to parsimonious reductions? For instance, how about the completeness of $\#\mathrm{TSP}_{\mathbb{R}}$ in $\mathrm{D}\#\mathrm{P}_{\mathrm{add}}$?

PROBLEM 7.2. What is the complexity to deciding connectedness of a semilinear set given by an additive circuit?

PROBLEM 7.3. In this paper we proved that computing the torsion-free part of the homology of semilinear sets is $\mathrm{FPAR}_{\mathrm{add}}$-complete. Is the complexity of computing the torsion part of this homology also $\mathrm{FPAR}_{\mathrm{add}}$-complete?

Acknowledgments. We thank Eric Allender and Saugata Basu for helpful discussions. We are grateful to the referees for many valuable comments, which helped to improve the presentation significantly.

AN EFFICIENT POLYNOMIAL TIME APPROXIMATION SCHEME FOR THE CONSTRAINED MINIMUM SPANNING TREE PROBLEM USING MATROID INTERSECTION*

REFAEL HASSIN† AND ASAF LEVIN†

Abstract. Given an undirected graph $G = (V, E)$ with $|V| = n$ and $|E| = m$, nonnegative integers c_e and d_e for each edge $e \in E$, and a bound D, the constrained minimum spanning tree problem (CST) is to find a spanning tree $T = (V, E_T)$ such that $\sum_{e \in E_T} d_e \leq D$ and $\sum_{e \in E_T} c_e$ is minimized. We present an efficient polynomial time approximation scheme (EPTAS) for this problem. Specifically, for every $\epsilon > 0$ we present a $(1 + \epsilon)$-approximation algorithm with time complexity $O((\frac{1}{\epsilon})^{O(\frac{1}{\epsilon})} n^4)$. Our method is based on Lagrangian relaxation and matroid intersection.

Key words. approximation algorithm, spanning tree, matroid intersection, bicriteria optimization

1. Introduction.

Given an undirected graph $G = (V, E)$ with $|V| = n$ and $|E| = m$, nonnegative integers c_e and d_e for each edge $e \in E$, and a bound D, the constrained minimum spanning tree problem (CST) is to find a spanning tree $T = (V, E_T)$ such that $\sum_{e \in E_T} d_e \leq D$ and $\sum_{e \in E_T} c_e$ is minimized. We refer to c_e and d_e of an edge e as its *cost* and *length*, respectively. Thus the problem we consider is that of finding a minimum cost spanning tree whose total length is at most D.

Aggarwal, Aneja, and Nair [1] proved that the problem is weakly NP-hard. With respect to approximation algorithms, Goemans and Ravi [9] presented a polynomial time approximation scheme (PTAS), i.e., a $(1 + \epsilon)$-approximation algorithm for every $\epsilon > 0$, with time complexity $O(n^{O(\frac{1}{\epsilon})} \log C_{max})$, where C_{max} is the largest cost. Their algorithm is based on Lagrangian relaxation (for an earlier work on this problem that uses a Lagrangian relaxation, see Jornsten and Migdalas [13]) and uses the adjacency relations for matroids. Recently, Hong, Chung, and Park [12] showed a pseudopolynomial time algorithm for this problem that is based on a two-variable extension of the tree-matrix theorem. We note that developing a fully polynomial time approximation scheme based on their pseudopolynomial time algorithm is not straightforward. Instead, [12] contains a fully polynomial *bicriteria* approximation scheme. Currently, the question whether there exists a fully polynomial time approximation scheme to CST is open. Andersen, Jornsten, and Lind [2] presented heuristic algorithms for CST.

In this paper we provide the first efficient polynomial time approximation scheme (EPTAS) to this problem: for every $\epsilon > 0$ we provide a $(1 + \epsilon)$-approximation with time complexity $g(\frac{1}{\epsilon})poly(n)$, where *poly* is some polynomial function, and g is any function. Specifically, the complexity of our algorithm is $O((\frac{1}{\epsilon})^{O(\frac{1}{\epsilon})} n^4)$. Our method adopts the basic ideas of Goemans and Ravi [9] and adds to them a novel application of a matroid intersection algorithm. We note that our method (as well as Goemans

†Department of Statistics and Operations Research, Tel-Aviv University, Tel-Aviv 69978, Israel (hassin@post.tau.ac.il, levinas@post.tau.ac.il).

and Ravi's) provides a similar EPTAS using the same analysis to finding a minimum cost base of a matroid with total length at most D, as long as there is a polynomial time independence oracle for the matroid (for example, a union of k forests).

Lagrangian relaxation is a well-known method to approximate a constrained optimization problem.

We now present some basic definitions and results in matroid theory (see [14] or [7]). An ordered pair $M = (E, \mathcal{F})$, where E is a set of elements and $\mathcal{F}$ is a family of subsets of E, is called a *matroid* if the following properties are satisfied: $\emptyset \in \mathcal{F}$, if $S \in \mathcal{F}$ and $S' \subseteq S$, then $S' \in \mathcal{F}$, and if $S_p, S_{p+1} \in \mathcal{F}$ are subsets with $p, p+1$ elements, respectively, then there is $e \in S_{p+1} \setminus S_p$ such that $S_p \cup \{e\} \in \mathcal{F}$. An element of $\mathcal{F}$ is an *independent set*. A maximal independent set is a *base* of the matroid. A *polynomial time independence oracle* for a matroid M is a polynomial time algorithm such that for a given subset $S \subseteq E$ the algorithm checks whether or not $S \in \mathcal{F}$. Given a matroid M with an element cost function c, the greedy algorithm finds a minimum (total) cost base of M. Therefore, for a matroid with a polynomial time independence oracle, the problem of finding a minimum cost base is polynomially solvable. Given a pair of matroids $M = (E, \mathcal{F})$ and $M' = (E, \mathcal{F}')$ with polynomial time independence oracles over common element set E and element cost function c, there is a polynomial time algorithm that computes a minimum cost common base of M and M' (i.e., a minimum cost subset S such that S is a base of both M and M') [3]. Computing the minimum total common base of two matroids is one of the well-studied variants of matroid intersection.

Matroid intersection is one of the strongest available tools that one can use in polynomial time algorithms. However, we are aware of only a few uses of it in the design of approximation algorithms (see, for example, Chalasani and Motwani [5]). Therefore, we also contribute to extending the uses of matroid intersection.

Denote by OPT the optimum value for our problem. Given a spanning tree $T = (V, E_T)$ and a function f defined over E, we denote $f(T) = \sum_{e \in E_T} f(e)$.

Goemans and Ravi presented the following results:

1. Given an $(\alpha, 1)$-approximation algorithm with time complexity T_{alg} (i.e., an algorithm that provides output T such that $d(T) \leq \alpha D$ and $c(T) \leq OPT$), there is a $(1+\epsilon)\alpha$-approximation algorithm with time complexity $O(T_{alg} \log_{1+\epsilon} C_{max})$ where C_{max} is the largest cost. To prove this, they suggested applying a binary search over OPT and replacing the roles of c and d in the bicriteria approximation algorithm.
2. A $(2, 1)$-approximation algorithm with time complexity $O(m \log^2 n + n \log^3 n)$; with the former result this gives a $2(1+\epsilon)$-approximation algorithm with time complexity $O((m \log^2 n + n \log^3 n) \log_{1+\epsilon} C_{max})$.
3. A $(1+\epsilon, 1)$-approximation algorithm with time complexity $O(n^{O(\frac{1}{\epsilon})})$ for every $1 > \epsilon > 0$; with the former result this gives a $(1+\epsilon)$-approximation algorithm with time complexity $O(n^{O(\frac{1}{\epsilon})} \log_{1+\epsilon} C_{max})$ for every $\epsilon > 0$.

REMARK 1. *The time complexity in result* 1 *can be reduced to* $O(T_{alg} \log \log_{1+\epsilon} n + T_{MST} \log n)$, *where* T_{MST} *is the time needed to compute a minimum spanning tree.*

Proof. We apply Hassin's method [11] and apply approximate geometric-mean binary search instead of arithmetic-mean binary search. This reduces the number of iterations to $\log_2 \log_{1+\epsilon} \frac{UB}{LB}$, where UB and LB are upper and lower bounds on OPT, respectively.

We use the method of Lorenz and Raz [15] to obtain good bounds. Let $S_c = \{c_e\}_{e \in E}$. Given a threshold value $c \in S_c$, we consider the subgraph $G_c = (V, \{e \in E : c_e \leq c\})$. We find a minimum value $c \in S_c$ such that G_c contains a spanning tree T

such that $d(T) \le D$, and then $c \le OPT \le (n-1)c$. Thus, by applying binary search with $O(\log n)$ iterations on S_c, we obtain bounds LB and UB such that $\frac{UB}{LB} \le n-1$. The time complexity of the binary search is $O(T_{MST} \log n)$. □

Assume that $\epsilon \le \frac{1}{4}$. We first compute a $2(1+\epsilon)$-approximation solution using result 2. The complexity of this phase is $O((m + n\log n)\log^2 n \log\log_{1+\epsilon} n)$. Denote by $\hat{C}$ the cost of this solution. Then $OPT \le \hat{C} \le 2(1+\epsilon)OPT$. We remove from E the edge set $\{e \in E : c_e > \hat{C}\}$.

2. The algorithm. First, we present the main tools that enable us to improve Goemans and Ravi's result. Given $\epsilon > 0$ and $\hat{C}$, we partition E into the following edge sets: $E_0 = \{e \in E : c_e < \epsilon\hat{C}\}$, and for $1 \le i \le I = \lceil \frac{1-\epsilon}{\epsilon^2} \rceil$, $E_i = \{e \in E : (\epsilon + (i-1)\epsilon^2)\hat{C} \le c_e < (\epsilon + i\epsilon^2)\hat{C}\}$.

Our algorithm enumerates all the possible vectors with $I+1$ nonnegative integer entries $(n_0, n_1, \ldots, n_I)$ such that the following conditions hold:

1. $\sum_{i=0}^{I} n_i = n-1$.
2. $\sum_{i=1}^{I} n_i \le \frac{1}{\epsilon}$.

For each such vector, our algorithm finds an approximate solution with exactly n_i edges from the set E_i if such a solution exists. Note that an optimal solution for CST may have at most $\frac{1}{\epsilon}$ edges with cost at least ϵOPT and, therefore, the second condition holds for every optimal solution for CST.

LEMMA 2. *There are $O(I^{\frac{1}{\epsilon}})$ vectors that satisfy both conditions.*

Proof. We have at most $\frac{1}{\epsilon}$ items in the last I components. We consider a bucket for each set E_i, $i \ge 1$, and we have another bucket $i = 0$ that collects $\frac{1}{\epsilon} - \sum_{i=1}^{I} n_i$ items. We have to place $\frac{1}{\epsilon}$ items in the $I+1$ buckets. Therefore, the number of possibilities is at most $(I+1)^{\frac{1}{\epsilon}} = O(I^{\frac{1}{\epsilon}})$. □

Given a cost function $c^{\lambda}(e)$, $e \in E$, and a vector $(n_0, n_1, \ldots, n_I)$, we can find a minimum cost spanning tree with n_i edges from the set E_i (if such a spanning tree exists). We do it via matroid intersection in the following manner: we define a *partition matroid* over the ground set E such that a set $E' \subseteq E$ is independent in this matroid if and only if $|E' \cap E_i| \le n_i$ for $i = 0, 1, \ldots, I$. We define a second matroid over E, the *graphic matroid*, where a set $E' \subseteq E$ is independent if and only if the graph (V, E') does not contain a cycle. We find a minimum cost common base of these two matroids. This is done by computing a minimum cost set (if one exists) that is independent in both matroids and has cardinality $n-1$. Since the number of sets in the partition matroid is $O(\frac{1}{\epsilon})$, we can find a minimum cost basis in the intersection of the two matroids in $O(mn + \frac{n^2}{\epsilon})$ time (see Brezovec, Cornuejols, and Glover [4]).

Next we describe the use of Lagrangian relaxation for our problem (see [9] and [13] for a similar idea). Given a graph $G = (V, E)$, a value $\hat{C}$, and $(n_0, n_1, \ldots, n_I)$, let S denote the set of incidence vectors of common bases of the graphic matroid and the partition matroid. Our problem is

$$
\begin{aligned}
C = \min \sum_{e \in E} c_e x_e & \\
\text{subject to} \quad & x \in S \\
& \sum_{e \in E} d_e x_e \le D.
\end{aligned} \tag{1}
$$

Consider the budget constraint (1) as the complicating constraint. We can obtain a lower bound on the optimum value C by dualizing it, and for any $\lambda \ge 0$ we consider

the problem defined as

$$C(\lambda) = \min \sum_{e \in E} (c_e + \lambda d_e) x_e - \lambda D$$
$$\text{subject to} \quad x \in S.$$

We let $c^\lambda(e) = c_e + \lambda d_e$ for every edge $e \in E$, and note that the problem $C(\lambda)$ is, exactly, to compute the minimum cost basis in the intersection of the two matroids as described above. In order to find the best lower bound on C we maximize $C(\lambda)$ over all $\lambda \geq 0$ to obtain

$$LR = \max_{\lambda \geq 0} C(\lambda).$$

It is well known that since $C(\lambda)$ is a minimum of a set of linear functions (one for every $x \in S$), $C(\lambda)$ is concave and piecewise linear (see, for example, Fact 1.1 in [10]). Let λ^* denote a value of λ that maximizes $C(\lambda)$, and let $c^*(e) = c^{\lambda^*}(e)$ for every $e \in E$.

To solve the Lagrangian relaxation, we need to find the minimum base in the matroid intersection with respect to c^* without knowing λ^*. In order to do so, we apply the combinatorial algorithm in [4] (the dual algorithm in section 3 of [4]) that solves the minimum cost basis in the intersection of the two matroid problem where one of them is a partition matroid. In each comparison we need to compare $a_1\lambda^* + b_1$ and $a_2\lambda^* + b_2$. This can be done by computing the breakpoint $\lambda_{br} = \frac{b_2 - b_1}{a_1 - a_2}$ (if $a_1 \neq a_2$—otherwise the comparison is independent of λ^*), and then we need to determine whether $\lambda^* \leq \lambda_{br}$, $\lambda^* = \lambda_{br}$, or $\lambda^* \geq \lambda_{br}$. This can be done using a pair of matroid intersection computations (with $\lambda = \lambda_{br}^-$ and with $\lambda = \lambda_{br}^+$). This leads to an $O([mn + \frac{n^2}{\epsilon}]^2) = O(m^2n^2 + \frac{n^4}{\epsilon^2})$ algorithm that solves (optimally) the Lagrangian relaxation.

Our algorithm is based on solving the Lagrangian relaxation, as well as deriving a good spanning tree out of it. We use an adjacency relationship on the polytope defined by $conv(S)$, where S is the set of incidence vectors of the common bases in the intersection of two matroids. This adjacency relationship holds when one of the matroids is a partition matroid (the other matroid can vary). The next lemma generalizes Lemma 3.2 in [9] (where it was stated for the trivial partition matroid, the case $I = 0$), and Lemma 9 in [8] (for a partition matroid with two sets, $I = 1$).

LEMMA 3. *Let $n_0, n_1, \ldots, n_I$ be the number of edges from $E_0, E_1, \ldots, E_I$, respectively, in an optimal solution. Let $\mathcal{O}$ denote the set of minimum cost common bases in the intersection of the two matroids with respect to c^*, when the partition matroid is defined with $n_0, n_1, \ldots, n_I$. Let $T, T' \in \mathcal{O}$. Then there is a series of trees $T = T_0 = (V, E_{T_0}), T_1 = (V, E_{T_1}), \ldots, T' = T_l = (V, E_{T_l})$ that satisfies the following:*

1. *$T_j \in \mathcal{O}$, for $j = 0, \ldots, l$.*
2. *Let $E^j = T_j \setminus T_{j+1}$ and $E'^j = T_{j+1} \setminus T_j$. Then $|E^j \cap E_i| = |E'^j \cap E_i| \leq 1$ for $i = 0, \ldots, I$ and $j = 0, \ldots, l-1$.*

Proof. We construct a path from T to T' of edge swaps. We prove the lemma by induction over $|T' \setminus T|$. For $|T' \setminus T| = 1$ the lemma holds trivially. Assume the lemma holds for any pair of optimal trees T, T' such that $|T' \setminus T| = x - 1$; we prove it for $|T' \setminus T| = x$.

We consider a perturbed cost function c' (for a small enough value of ϵ') defined as follows:

$$c'(e) = \begin{cases} \infty & \text{if } e \notin T \cup T', \\ c^*(e) + \epsilon' & \text{if } e \in T \setminus T', \\ c^*(e) - \epsilon' & \text{if } e \in T' \setminus T, \\ c^*(e) & \text{if } e \in T \cap T'. \end{cases}$$

We take T to be the initial solution to the primal algorithm in [4]. T is not optimal with respect to c' (because T' is the unique optimal solution with respect to c'), and therefore the algorithm finds a negative cycle in a graph S. We first define an auxiliary bipartite directed graph $B = (V, V', A)$ as follows (see [3] and [4]): For every $e \in T$ we have a node in V, and for every $e' \in E \setminus T$ we have a node in V'. For every $e_i \in T$ and $e'_j \in E \setminus T$ we construct an arc (e_i, e'_j) with cost $c(e_i, e'_j) = c'(e_i) - c'(e_j)$ provided that $(T \setminus \{e_i\}) \cup \{e'_j\}$ is independent in the graphic matroid, and we construct an arc (e'_j, e_i) with cost $c(e'_j, e_i) = 0$ provided that $(T \setminus \{e_i\}) \cup \{e'_j\}$ is independent in the partition matroid (i.e., e_i and e'_j belong to the same set of the partition). Since for $e \notin T \cup T'$, $c'(e) = \infty$, a negative cycle in B does not contain e. S is obtained from B (see [4]) by identifying the set of nodes corresponding to elements from $(E \setminus T) \cap E_i$ in V' to a single vertex v_i for every i, and removing parallel edges.

By Theorem 4 in [4], there is a common base T'' that has a smaller cost than T with respect to c' (and therefore, $T'' \in \mathcal{O}$) such that T'' is obtained from T by swapping edges along a negative cycle C that has a minimum number of arcs (among all the negative cycles in S). Suppose that the nodes along the cycle C correspond to edges $(e_1, e'_1, e_2, e'_2, \ldots, e_l, e'_l, e_1)$ such that $e_k \in E_{i_k}$ for $k = 1, \ldots, l$. C is simple, and therefore, $i_k \neq i_{k'}$ $\forall k \neq k'$ and $T'' \in \mathcal{O}$.

$T'' \subseteq T \cup T'$ and $T'' \neq T$, and therefore, $|T'' \setminus T'| < |T \setminus T'| = x$. Therefore, by the induction assumption, the lemma's claim holds. □

Our main result will follow from the next theorem.

THEOREM 4. *Let $n_0, n_1, \ldots, n_I$ be the number of edges from $E_0, E_1, \ldots, E_I$, respectively, in an optimal solution for CST. Let $\mathcal{O}$ denote the set of minimum cost common bases in the intersection of the two matroids with respect to c^*, when the partition matroid is defined with $n_0, n_1, \ldots, n_I$. Then there exists $T = (V, E_T) \in \mathcal{O}$ such that*

$$c(T) \leq LR + \sum_{i:n_i>0} (\max_{e \in E_i}\{c_e\} - \min_{e \in E_i}\{c_e\})$$

and

$$d(T) \leq D.$$

Proof. Let $\lambda = \lambda^* - \epsilon'$, where $\epsilon' > 0$. There is $T^- \in \mathcal{O}$ that is optimal also with respect to c^λ (for a small enough value of ϵ'). Since $c^\lambda(T^-) = C(\lambda) \leq C(\lambda^*)$, we obtain

$$c(T^-) + (\lambda^* - \epsilon')[d(T^-) - D] \leq c(T^-) + \lambda^*[d(T^-) - D] = LR.$$

Therefore, $d(T^-) \geq D$, and thus $c(T^-) \leq LR$. Similarly, for $\lambda = \lambda^* + \epsilon'$, there is $T^+ \in \mathcal{O}$ such that $d(T^+) \leq D$ and $c(T^+) \geq LR$.

By Lemma 3, there is a series $T^- = T_0, T_1, \ldots, T_l = T^+$ of spanning trees that satisfies the properties of the lemma. Since $c(T^-) \leq LR$ and $c(T^+) \geq LR$, there is an index j such that $c(T_j) \leq LR$ and $c(T_{j+1}) \geq LR$ (and therefore, $d(T_{j+1}) \leq D$). Therefore,

$$c(T_{j+1}) \leq c(T_j) + \sum_{i:n_i>0} (\max_{e \in E_i}\{c_e\} - \min_{e \in E_i}\{c_e\}). \qquad \square$$

REMARK 5.

$$\sum_{i:n_i>0} (\max_{e\in E_i}\{c_e\} - \min_{e\in E_i}\{c_e\}) \le 4(1+\epsilon)\epsilon OPT \le 5\epsilon OPT.$$

Proof. Note that $\max_{e\in E_0}\{c_e\} \le \epsilon\hat{C} \le 2(1+\epsilon)\epsilon OPT$, $\min_{e\in E_0}\{c_e\} \ge 0$, and therefore, the term that corresponds to $i = 0$ is at most $2(1+\epsilon)\epsilon OPT$. There are at most $\frac{1}{\epsilon}$ other terms in the summation. By the definition of E_i, each of them contributes at most $\epsilon^2\hat{C} \le 2(1+\epsilon)\epsilon^2 OPT$, and together they contribute at most $2(1+\epsilon)\epsilon OPT$. The second inequality follows for $\epsilon \le \frac{1}{4}$. ∎

REMARK 6. *The proof of Lemma 3 leads naively to an $O(\frac{n^3}{\epsilon})$ algorithm that, given T^- and T^+, finds T that satisfies the claimed properties.*

Proof. We construct the path of trees as in Lemma 3. In each step we first construct the graph S. S contains $O(n)$ vertices and $O(\frac{n}{\epsilon})$ edges. We construct S in $O(\frac{n^2}{\epsilon})$ time by identifying for each e_i the set $\{e'_j \in T' : (T\setminus\{e_i\})\cup\{e'_j\}$ is independent in the graphic matroid$\}$ in $O(n)$ time. Next, we find a negative cycle with a minimum number of edges using the Bellman–Ford algorithm in $O(\frac{n^2}{\epsilon})$ time. Finally, we identify the next tree along the path in $O(n)$ time. The total time complexity of a single step is $O(\frac{n^2}{\epsilon})$ time. Since the total number of trees along this path is $O(n)$, we conclude that computing the entire path takes $O(\frac{n^3}{\epsilon})$ time. ∎

Theorem 4 and Remarks 5 and 6 motivate the following algorithm: First, using the $2(1+\epsilon)$-approximation algorithm in [9], find a $2(1+\epsilon)$-approximation value $\hat{C}$ of OPT ($OPT \le \hat{C} \le 2(1+\epsilon)OPT$). Second, enumerate all the possible vectors $(n_0, n_1, \ldots, n_I)$, and for each of them apply the following procedure: Compute λ^* that optimizes the Lagrangian relaxation. Among all the optimum common bases (in the matroid intersection) for the cost function c^*, find a base that satisfies the conditions of Theorem 4.

Finally, pick the tree that minimizes $c(T)$ (among all the possible vectors $(n_0, n_1, \ldots, n_I)$ that lead to a feasible tree).

We note that for the correct guess of the vector $(n_0, n_1, \ldots, n_I)$, the cost of the minimum cost base is exactly OPT. Since $\hat{C} \le 2(1+\epsilon)OPT$, the tree that we find costs (by Theorem 4 and Remark 5) at most $OPT + 5\epsilon OPT = (1+5\epsilon)OPT$, and its length is at most D.

Computing $\hat{C}$ takes $O((m + n\log n)\log^2 n \log\log_{1+\epsilon} n)$. By Lemma 2, there are $O((\frac{1}{\epsilon^2})^{\frac{1}{\epsilon}})$ distinct vectors $(n_0, n_1, \ldots, n_I)$. For each of them we solve the Lagrangian relaxation in $O(m^2n^2 + \frac{n^4}{\epsilon^2})$ time, and by Remark 6 we find T in another $O(\frac{n^3}{\epsilon})$ time. Therefore, the total complexity of the algorithm is $O((\frac{1}{\epsilon^2})^{\frac{1}{\epsilon}}(m^2n^2))$.

We conclude with the following theorem.

THEOREM 7. *For every $\epsilon > 0$, there is a $(1+\epsilon)$-approximation algorithm that runs in $O(O(\frac{1}{\epsilon})^{O(\frac{1}{\epsilon})}(m^2n^2))$ time.*

3. Improved complexity. We first note that if there is a parallel algorithm for the minimum cost basis in the intersection of the two matroid problem, then it may be combined (similar to the use in [9]) with Megiddo's method [16] to improve the time complexity for solving the Lagrangian relaxation. However, we are not aware of such an algorithm.

In this section we provide a faster algorithm that solves the Lagrangian relaxation. Our algorithm solves the Lagrangian relaxation in $O(\frac{n^4}{\epsilon^2})$ time.

To present the algorithm we note that for every $\lambda \ge 0$ and $i \ge 0$, an edge $e \in E_i$

that participates in the minimum cost common base of the two matroids belongs to a minimum cost (with respect to $c^\lambda = c + \lambda d$) spanning forest $F_i(\lambda)$ of (V, E_i). $c^\lambda(F_i(\lambda))$ is a piecewise linear function of λ, and in each breakpoint of it $F_i(\lambda)$ changes by an edge swap (or a set of edge swaps in degenerate cases). Therefore, in each breakpoint there is a pair of edges that have the same cost. We define a set of potential breakpoints as $\{\lambda : \exists e, e' \in E,\ c^\lambda(e) = c^\lambda(e')\}$. Then, every breakpoint of $c^\lambda(F_i(\lambda))$ for all i belongs to the set of potential breakpoints. There are $O(m^2)$ potential breakpoints.

In a preprocessing step we compute the set of breakpoints. Afterwards, we apply a binary search over this set. Therefore, we find an interval (λ_1, λ_2) that contains λ^*, and such that no $F_i(\lambda)$ has a breakpoint in this interval beside λ^*.[1] Then, we compute $F_i(\hat{\lambda})$ for every i such that $n_i > 0$ for some $\hat{\lambda} \in (\lambda_1, \lambda_2)$. Now we remove from the two matroids all the edges that do not participate in $\bigcup_{i:n_i>0} F_i(\hat{\lambda})$. In the resulting common ground set, the number of elements is $O(\frac{n}{\epsilon})$. The total complexity of this preprocessing step is $O(\frac{mn \log n}{\epsilon})$.

We now apply our previous algorithm for solving the Lagrangian relaxation in $O(m^2n^2 + \frac{n^4}{\epsilon^2})$ to the resulting common ground set. The complexity of this procedure is $O(\frac{n^4}{\epsilon^2})$. By using the algorithm of this section in our approximation algorithm, we obtain the following theorem.

THEOREM 8. *For every $\epsilon > 0$ there is a $(1+\epsilon)$-approximation algorithm with time complexity $O(O(\frac{1}{\epsilon})^{O(\frac{1}{\epsilon})}(n^4))$.*

Note added in proof. By using the matroid intersection algorithm of Frederickson and Srinivas [8] instead of the algorithm of Brezovec, Cornuejols, and Glover [4], the complexity of our algorithm reduces to $O(O(\frac{1}{\epsilon})^{O(\frac{1}{\epsilon})}n^3)$.

Acknowledgment. We are grateful to Arie Tamir for many useful comments and in particular for helping us improve the time complexity of our algorithm from that stated in Theorem 7 to that stated in Theorem 8.

SHAPE FITTING WITH OUTLIERS*

SARIEL HAR-PELED† AND YUSU WANG‡

Abstract. Given a set $\mathcal{H}$ of n hyperplanes in $\mathbb{R}^d$, we present an algorithm that ε-approximates the extent between the top and bottom k levels of the arrangement of $\mathcal{H}$ in time $O(n+(k/\varepsilon)^c)$, where c is a constant depending on d. The algorithm relies on computing a subset of $\mathcal{H}$ of size $O(k/\varepsilon^{d-1})$, in near linear time, such that the k-level of the arrangement of the subset approximates that of the original arrangement. Using this algorithm, we propose efficient approximation algorithms for shape fitting with outliers for various shapes. These are the first algorithms to handle outliers efficiently for the shape fitting problems considered.

Key words. shape fitting, outliers, approximation

1. Introduction.

Shape fitting, a fundamental problem in computational geometry, computer vision, machine learning, data mining, and many other areas, is concerned with finding the best shape fitting a given input. For example, a widely used shape fitting problem asks for a shape that best fits a set of points P under some "fitting" criterion. Choices of such shapes include points, lines, hyperplanes, and spheres. One typical criterion for measuring how well a shape γ fits P, denoted as $\mu(P,\gamma)$, is the maximum distance between a point of P and its nearest point on γ, i.e., $\mu(P,\gamma) = \max_{p\in P} \min_{q\in\gamma} d(p,q)$. One would then like to find the extent measure of P, defined as $\mu(P) = \min_\gamma \mu(P,\gamma)$, where the minimum is taken over a family of shapes. For example, the problem of finding the point (resp., line) that fits P best is the same as finding the minimum radius sphere (resp., cylinder) enclosing P, and the problem of finding the hyperplane (resp., sphere, cylinder) that fits P best is the same as finding the smallest width slab (resp., spherical shell, cylindrical shell) containing P.

The exact algorithms for shape fitting are generally expensive; e.g., the best-known algorithms for computing the smallest volume bounding box or tetrahedron containing P in $\mathbb{R}^3$ require $O(n^3)$ time . Consequently, attention has shifted to developing approximation algorithms for computing extent measures. Recently, Agarwal et al. [3, 4, 19] provided a general technique for approximate shape fitting in low dimensions. Their technique relied on using linearization to reduce the problem into a convex shape fitting problem and then solve it by known convex shape approximation techniques. The most striking features of this technique are its wide applicability to numerous shape fitting problems, and that the resulting running time is $O(n+1/\varepsilon^c)$, where n is the input size, c is a constant that depends on the problem at hand, and ε is the quality of approximation requested.

However, in the real world, noise in the input is omnipresent and one has to assume that some of the input points are noise and as such should be ignored. To a certain extent, the problem of handling outliers in computational geometry is still open; see [7, 15, 22] for relevant results. While those results provide relatively efficient solutions, most of them are restricted to two and three dimensions (where intuitively the k-level has relatively low complexity) and are restricted in the type of problems that they can solve. For additional results about outliers in general, see [8, 14].

In this paper, we present approximation algorithms that can handle outliers efficiently in two or higher dimensions for a broad collection of shape fitting problems. For example, given a set P of n points in $\mathbb{R}^d$, we can find approximately the smallest cylinder that contains at least $n-k$ points of P in $O(n+(k/\varepsilon)^c)$ time, where c is a constant depending only on d.[1] Note that for a fixed ε, and a moderately small k, this is a linear time algorithm. Our algorithm can solve all the shape fitting problems considered in [3, 4, 19] efficiently under the additional constraint of k outliers. For most of those problems, this is the first efficient approximation algorithm to handle outliers.

Interestingly enough, our algorithm relies on computing a *coreset* to the given point set in *linear* time. Namely, we compute a subset $\mathfrak{C}$ of the points of cardinality $k/\varepsilon^{O(1)}$ such that instead of solving the problem on the original point set, one can solve it on $\mathfrak{C}$. In particular, in some cases, we just plug in the (exact) algorithms of [7, 12, 15, 22] on $\mathfrak{C}$ and get an efficient approximation algorithm.

To facilitate this, we investigate a related question, which is interesting in its own right: Given a set $\mathcal{H}$ of n hyperplanes in $\mathbb{R}^d$ and a subset $X \subseteq \mathbb{R}^{d-1}$, how does one compute efficiently the shortest vertical segment, with a vertical projection in X, that stabs (at least) $n-k$ of the hyperplanes of $\mathcal{H}$? In approximate form, one would like to find a vertical segment, with a vertical projection in X, that stabs at least $n-k$ of the hyperplanes of $\mathcal{H}$ and is of length at most a factor $(1+\varepsilon)$ of that of the optimal segment. (Note that linear programming with violations [22] can be applied directly when $X = \mathbb{R}^{d-1}$ or X is a convex polytope, as the problem can then be formulated as an LP-type problem. For our applications, however, X arises from our linearization technique and is not necessarily a convex set. In particular, the set X is a semi-algebraic set of constant complexity.) The direct approach for solving this problem involves computing the bottom/top k levels of $\mathcal{A}(\mathcal{H})$ and enumerating by brute force all possible such vertical segments (with vertical projection in X), where $\mathcal{A}(\mathcal{H})$ denotes the arrangement of hyperplanes of $\mathcal{H}$. The approach implemented in this fashion is doomed, as it leads to an inefficient algorithm with running time (roughly) of $O(n^d k^d)$. At the same time, since the k-level of $\mathcal{A}(\mathcal{H})$ is not necessarily convex for $k > 1$, we can no longer take advantage of known convex shape approximation techniques as was done in [3, 4, 19].

Instead, we study the question of approximating the first/last k levels directly. Note that the *combinatorial* approximation of k levels is relatively well understood (see [22, 2, 18]) and can be performed by random sampling or cuttings. (In the combinatorial settings, we are interested in finding a curve γ that lies close to the k-level under the crossing metric. Namely, any vertical segment connecting a point on γ to the k-level crosses at most εn lines.) However, our notion of approximation is stronger as it combines both the geometry and the combinatorial structure of the levels. In particular, we show that there is a coreset for this problem; namely, one can compute a

[1] In all our discussions, we consider the dimension to be a small constant, and as such the $O(\cdot)$ notation hides constants that depend solely on d.

subset of $O(k/\varepsilon^{d-1})$ hyperplanes such that the rth level of the coreset ε-approximates the r-level of the arrangement $\mathcal{A}(\mathcal{H})$ for $1 \le r \le k$. Here the approximation is the Euclidean distance between the level and the approximate level, compared with the length of the shortest vertical segment that connects the k-level with the $n-k$ level of the arrangement $\mathcal{A}(\mathcal{H})$. This can be done in $O(n + k/\varepsilon^{d-1})$ time. (All algorithms in this paper are randomized and their results are correct with high probability.)

We can apply the above results to a large number of shape fitting problems, including those considered in [3, 4, 19]. To name a few, we can approximate the following measures with k outliers: diameter, width, projection width, minimum enclosing ball, minimum-width annulus, minimum-volume spherical shell, minimum-width cylindrical shell, and also those measures for moving points. Note that most of those optimization problems fall outside the paradigm of linear programming and as such can not be solved using linear programming with violations. We can further extend our technique to handle insertions and deletions with polylogarithmic time per update.

In section 3, we present an algorithm to compute a small coreset for a set of hyperplanes in $\mathbb{R}^d$. We extend the results for a set of polynomials or their roots in section 4. In section 5, we present our results for various shape fitting problems with outliers. Finally, we conclude with section 6.

2. Preliminaries. Throughout the paper, we refer to the x_d-parallel direction in $\mathbb{R}^d$ as *vertical*. Given a point $x = (x_1, \ldots, x_{d-1})$ in $\mathbb{R}^{d-1}$, let (x, x_d) denote the point $(x_1, \ldots, x_{d-1}, x_d)$ in $\mathbb{R}^d$. Each point $x \in \mathbb{R}^d$ is also a vector in $\mathbb{R}^d$. Given a geometric object A, $A + x$ represents the object obtained by translating each point in A by x.

A *surface* is a subset of $\mathbb{R}^d$ that intersects any vertical line in a single point. Let A and B be either a point, a hyperplane, or a surface in $\mathbb{R}^d$. We say that A lies *above* (resp., *below*) B, denoted by $A \succeq B$ (resp., $A \preceq B$), if for any vertical line ℓ intersecting both A and B, we have that $x_d \ge y_d$ (resp., $x_d \le y_d$), where $(x_1, \ldots, x_{d-1}, x_d) = A \cap \ell$ and $(x_1, \ldots, x_{d-1}, y_d) = B \cap \ell$.

DEFINITION 2.1. *For a set of n hyperplanes $\mathcal{H}$ in $\mathbb{R}^d$, the* level *of a point $x \in \mathbb{R}^d$ in the arrangement $\mathcal{A}(\mathcal{H})$ is the number of hyperplanes of $\mathcal{H}$ lying vertically below x. For $k = 0, \ldots, n-1$, let $\mathbf{L}_{\mathcal{H},k}$ represent the surface which is the closure of all points on the hyperplanes of $\mathcal{H}$ whose level is k. We define the* top k-level *of $\mathcal{H}$ to be $\mathbf{U}_{\mathcal{H},k} = \mathbf{L}_{\mathcal{H},n-k-1}$ for $k = 0, \ldots, n-1$. Let $\mathbf{L}_{\mathcal{H},\le k}$ and $\mathbf{U}_{\mathcal{H},\le k}$ denote $\cup_{i=0}^{k} \mathbf{L}_{\mathcal{H},i}$ and $\cup_{i=0}^{k} \mathbf{U}_{\mathcal{H},i}$, respectively. Note that both $\mathbf{L}_{\mathcal{H},k}$ and $\mathbf{L}_{\mathcal{H},\le k}$ are subsets of the arrangement of $\mathcal{H}$. For $x \in \mathbb{R}^{d-1}$, we slightly abuse notation and define $\mathbf{L}_{\mathcal{H},k}(x)$ to be the value x_d such that $(x, x_d) \in \mathbf{L}_{\mathcal{H},k}$.*

DEFINITION 2.2. *The (k,r)-*extent *$\mathcal{H}|_r^k : \mathbb{R}^{d-1} \to \mathbb{R}$ is defined as the vertical distance between the r-level and the top k-level of $\mathcal{A}(\mathcal{H})$, i.e., for any $x \in \mathbb{R}^{d-1}$,*

$$\mathcal{H}|_r^k(x) = \mathbf{U}_{\mathcal{H},k}(x) - \mathbf{L}_{\mathcal{H},r}(x).$$

*The k-*extent *of $\mathcal{H}$ is the (k,k)-extent of $\mathcal{H}$ and is denoted by $\mathcal{E}_{\mathcal{H},k} = \mathcal{H}|_k^k$.*

DEFINITION 2.3. *Given a parameter $\varepsilon > 0$, a function $\mathcal{E}_\varepsilon : \mathbb{R}^{d-1} \to \mathbb{R}$ is an ε-*approximation *to $\mathcal{H}|_r^k(\cdot)$ if, for any $x \in \mathbb{R}^{d-1}$, we have $(1-\varepsilon)\mathcal{H}|_r^k(x) \le \mathcal{E}_\varepsilon(x) \le \mathcal{H}|_r^k(x)$.*

Our approximation relies on the idea that one can find a small subset of hyperplanes, which are "crucial" as far as the top/bottom k levels are concerned.

DEFINITION 2.4. *For a point $x \in \mathbb{R}^{d-1}$, a subset of hyperplanes $\mathcal{H}' \subseteq \mathcal{H}$ in $\mathbb{R}^d$ is*

a (k, ε, δ)-coreset at x *if the following holds: for any* $r \leq k$*, we have*

$$\mathbf{L}_{\mathcal{H},r}(x) \leq \mathbf{L}_{\mathcal{H}',r}(x) \leq \mathbf{L}_{\mathcal{H},r}(x) + \varepsilon \mathcal{E}_{\mathcal{H},k}(x) + \delta$$

and

$$\mathbf{U}_{\mathcal{H},r}(x) - \varepsilon \mathcal{E}_{\mathcal{H},k}(x) - \delta \leq \mathbf{U}_{\mathcal{H}',r}(x) \leq \mathbf{U}_{\mathcal{H},r}(x).$$

If $\mathcal{H}'$ *is a* (k, ε, δ)*-coreset at all points of* $\mathbb{R}^{d-1}$*, then it is* (k, ε, δ)-coreset *for* $\mathcal{H}$*.*

We omit δ from the above notation when $\delta = 0$. One of the main contributions of this paper is showing the existence of (k, ε)-coresets of size $O(k/\varepsilon^{d-1})$ for a set of hyperplanes in $\mathbb{R}^d$ for any given $k, \varepsilon > 0$. Note that if $\mathcal{H}'$ is a $(k, \varepsilon/2)$-coreset for $\mathcal{H}$, then the (r, t)-extent of $\mathcal{H}'$ ε-approximates that of $\mathcal{H}$ for any $r, t \leq k$. Therefore, in order to compute an ε-approximation of $\mathcal{E}_{\mathcal{H},k}$, one just needs to compute $\mathbf{L}_{\mathcal{H}',k}$ and $\mathbf{U}_{\mathcal{H}',k}$, and the resulting $\mathcal{E}_{\mathcal{H}',k}$ is the required approximation.

3. (k, ε)-coresets. In this section, given a set $\mathcal{H} = \{h_1, \ldots, h_n\}$ of hyperplanes in $\mathbb{R}^d$, and parameters $\varepsilon > 0$ and $1 \leq k \leq n$, we show how to compute a small (k, ε)-coreset for $\mathcal{H}$. Let $\Delta^{opt}(\mathcal{H}, k)$ denote the shortest vertical distance between the k-level and the top k-level of $\mathcal{A}(\mathcal{H})$, i.e., $\Delta^{opt}(\mathcal{H}, k) = \min_{x \in \mathbb{R}^{d-1}} \mathcal{E}_{\mathcal{H},k}(x)$. The algorithm first computes a set of $O(1)$ vertical segments, the length of each being at most $\Delta^{opt}(\mathcal{H}, k)$, such that, with high probability, all but $O(k)$ hyperplanes of $\mathcal{H}$ intersect at least one of those segments. Next, we subdivide $\mathcal{H}$ into $O(1/\varepsilon)$ disjoint subsets and show that the union of the $(k, \varepsilon, \varepsilon\Delta^{opt}(\mathcal{H}, k))$-coreset of each subset forms a (k, ε)-coreset for $\mathcal{H}$. Furthermore, we show that a coreset of size $O(k/\varepsilon^{d-2})$ can be computed efficiently for each subset, resulting in a coreset of size $O(k/\varepsilon^{d-1})$ for $\mathcal{H}$.

3.1. Short segments.

LEMMA 3.1. *Let* $\mathcal{J}$ *be a set of* n *hyperplanes in* $\mathbb{R}^d$*. In* $O(n)$ *time, one can compute a set* S *of* $O(1)$ *vertical segments such that with high probability* (i) *all the segments of* S *are no longer than* $\Delta^{opt}(\mathcal{J}, k)$*, and* (ii) $|\mathcal{J}_0| = O(k)$*, where* $\mathcal{J}_0$ *denotes the set of all hyperplanes of* $\mathcal{J}$ not *stabbed by the segments of* S*.*

Proof. The algorithm is iterative. Let $\mathcal{Q}_1 = \mathcal{J}$, $S_1 = \emptyset$. For $i > 1$, let S_i be the set of vertical segments computed in the beginning of the ith iteration. Let $\mathcal{Q}_i = \mathcal{J} \setminus S_i$ and $m_i = |\mathcal{Q}_i|$, where $\mathcal{J} \setminus S_i$ denotes the set of all hyperplanes of $\mathcal{J}$ not intersecting any segment of S_i. That is, $\mathcal{Q}_i$ is the set of hyperplanes not yet handled by the algorithm.

If $m_i = O(k)$, we are done, and set $\mathcal{J}_0$ to be $\mathcal{Q}_i$. Otherwise, if $m_i \leq n^{1/(3d)}$, we compute the k-level and the top k-level of the arrangement $\mathcal{A}(\mathcal{Q}_i)$ and the shortest vertical segment between those two levels. Let h_i^* denote this segment; then $|h_i^*| \leq \Delta^{opt}(\mathcal{J}, k)$. Set $S_{i+1} = S_i \cup \{h_i^*\}$ and observe that S_{i+1} is the required set, as $|\mathcal{J} \setminus S_{i+1}| = 2k$. Clearly, a naive implementation of the algorithm for this step would take $O(m_i^{2d+1}) = O(n)$ time.

Otherwise, if $m_i > n^{1/(3d)}$, then let $\mathcal{R}_i$ be a random sample from $\mathcal{Q}_i$ of size $O(n^{1/3d} \log n)$. Now consider the range space $\Sigma = (\mathcal{J}, \mathcal{X})$, where $\mathcal{X}$ consists of all subsets of $X \subseteq \mathcal{J}$ where there is a vertical segment s such that $X = s \cap \mathcal{J}$, where $s \cap \mathcal{J}$ denote the hyperplanes of $\mathcal{J}$ that intersect s. The size of $\mathcal{X}$ is bounded by $O(n^{d+1})$. Furthermore, the range space Σ has a bounded Vapnik–Chervonenkis dimension (VC-dimension). Therefore, by the ε-sample theorem [6], with high probability, $\mathcal{R}_i$ is an τ-sample of $\mathcal{Q}_i$, where $\tau = 1/n^{1/6d}$. That is, for any vertical segment s, with high probability, we have

$$\frac{|\mathcal{Q}_i \cap s|}{|\mathcal{Q}_i|} - \tau \leq \frac{|\mathcal{R}_i \cap s|}{|\mathcal{R}_i|} \leq \frac{|\mathcal{Q}_i \cap s|}{|\mathcal{Q}_i|} + \tau,$$

where $X \cap s$ denotes the set of hyperplanes of X that intersects s. Compute the arrangement $\mathcal{A}(\mathcal{R}_i)$, and compute the shortest vertical segment h_i^* between the K_i-level and the top K_i-level of $\mathcal{A}(\mathcal{R}_i)$, where

$$K_i = \left\lceil |\mathcal{R}_i| \left(\frac{k}{|\mathcal{Q}_i|} + \tau \right) \right\rceil.$$

Since $\mathcal{R}_i$ is a τ-sample of $\mathcal{Q}_i$, we have, with high probability, that

$$\mathbf{L}_{\mathcal{Q}_i,k} \preceq \mathbf{L}_{\mathcal{R}_i,K_i} \preceq \mathbf{U}_{\mathcal{R}_i,K_i} \preceq \mathbf{U}_{\mathcal{Q}_i,k}.$$

Thus, with high probability, the segment h_i^* is shorter than $\Delta^{opt}(\mathcal{J},k)$, and h_i^* intersects at least $m_i(1-4\tau)-2k$ hyperplanes of $\mathcal{Q}_i$. Let $S_{i+1} = S_i \cup \{h_i^*\}$, and let $\mathcal{Q}_{i+1} = \mathcal{Q}_i \setminus \{h_i^*\}$. This step takes $O(|\mathcal{R}_i|^{2d+1}) = O(n)$ time.

We are left with the task of bounding the number of iterations of the algorithm. Clearly, with high probability, $m_{i+1} \leq 4\tau m_i + 2k$. Therefore, for $m_i \geq 4k/\tau$, we have $m_{i+1} \leq 8\tau m_i \leq 8m_i/n^{1/6d}$. On the other hand, if $m_i \leq 4k/\tau$, then $m_{i+1} \leq 6k$ and the algorithm stops in the next iteration. We conclude that the number of iterations performed by the algorithm is $O(\log_{1/\tau} n) = O(6d) = O(1)$ with high probability, which implies the lemma. □

The algorithm of Lemma 3.1 can be derandomized using deterministic construction of ε-samples [9]. This results in a somewhat slower algorithm. Note that the algorithm of Lemma 3.1 can be modified to output, together with each vertical segment of S, the corresponding set of hyperplanes of $\mathcal{J}$ that intersect it within the same time bound.

3.2. Disjoint subsets. Apply Lemma 3.1 to $\mathcal{H}$. Let S denote the set of segments generated, and let $\mathcal{H}_0$ be the set of hyperplanes of $\mathcal{H}$ not stabbed by any segment of S. Break every segment of S into $\lceil 4/\varepsilon \rceil$ equal-length subsegments. For any such subsegment s, we have $|s| \leq \varepsilon \Delta^{opt}(\mathcal{H},k)/4$. Let $S' = \{s_1, \ldots, s_m\}$ denote the resulting set of segments, where $m = O(1/\varepsilon)$ with high probability. We distribute the hyperplanes of $\mathcal{H} \setminus \mathcal{H}_0$ into the sets associated with the subsegment of S' that they intersect. If a hyperplane is stabbed by more than one segment from S', it is only distributed to (an arbitrary) one of them. Let $\mathcal{H}_i$ be the resulting set of hyperplanes associated with segment s_i for $i = 1, \ldots, m$. By construction $|\mathcal{H}| = \sum_{i=0}^{m} |\mathcal{H}_i|$, and $|\mathcal{H}_0| = O(k)$. This redistribution process can be easily performed in linear time by using the floor function and by observing that each of the hyperplanes of $\mathcal{H} \setminus \mathcal{H}_0$ is already associated with one of the segments of S.

DEFINITION 3.2. *A set of hyperplanes $\mathcal{J}$ is a* δ-sheaf *if there exists a vertical segment s of length δ such that all the hyperplanes of $\mathcal{J}$ stab s. The vertical segment s is the* axis *of $\mathcal{J}$.*[2] *A 0-sheaf is referred to as a* sheaf*; in this case all hyperplanes in $\mathcal{J}$ pass through a common point, which is referred to as the* focal point *of $\mathcal{J}$. See* Figure 3.1.

Using the above splitting approach, together with Lemma 3.1, implies the following theorem.

THEOREM 3.3. *Given a set $\mathcal{J}$ of n hyperplanes in $\mathbb{R}^d$ and parameters $k, \varepsilon > 0$, one can compute, in $O(n + 1/\varepsilon)$ time, a partition of $\mathcal{J}$ into $m = O(1/\varepsilon)$ sets, $\mathcal{J}_0, \ldots, \mathcal{J}_m$, such that, with high probability, $|\mathcal{J}_0| = O(k)$, and $\mathcal{J}_i$ is an $(\varepsilon \Delta^{opt}(\mathcal{J},k))$-sheaf for $i = 1, \ldots, m$.*

[2] We will refer to it as the *axis of evil* when appropriate.

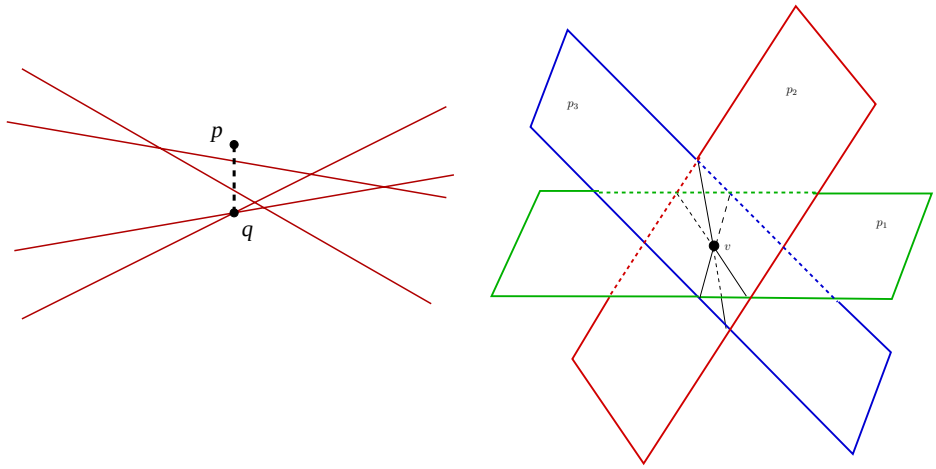

FIG. 3.1. (a) *A δ-sheaf in $\mathbb{R}^2$ with axis pq.* (b) *A sheaf in $\mathbb{R}^3$ with focal point v.*

LEMMA 3.4. *Let $\mathcal{J} = \cup_{i=0}^{m} \mathcal{J}_i$, and let $\mathcal{J}' = \cup_{i=0}^{m} \mathcal{J}'_i$, where $\mathcal{J}'_i \subseteq \mathcal{J}_i$ is a (k, ε, δ)-coreset for $\mathcal{J}_i$ for $i = 0, \ldots, m$. Then $\mathcal{J}'$ is a (k, ε, δ)-coreset for $\mathcal{J}$.*

Proof. Fix any $r \leq k$ and consider any point $x \in \mathbb{R}^{d-1}$. Let $p = (x, \mathbf{L}_{\mathcal{J},r}(x))$, and let $i_0, \ldots, i_m$ be the number of hyperplanes lying below p in $\mathcal{J}_0, \ldots, \mathcal{J}_m$, respectively, such that $i_0 + \cdots + i_m = r$. Observe that $\mathbf{L}_{\mathcal{J},r}(x) = \max_j \mathbf{L}_{\mathcal{J}_j,i_j}(x)$ and that for any subset $\mathcal{Q} \subseteq \mathcal{J}$, we have $\mathbf{L}_{\mathcal{J},r}(x) \leq \mathbf{L}_{\mathcal{Q},r}(x)$ and $\mathbf{U}_{\mathcal{J},r}(x) \geq \mathbf{U}_{\mathcal{Q},r}(x)$, implying that $\mathcal{E}_{\mathcal{Q},k}(x) \leq \mathcal{E}_{\mathcal{J},k}(x)$. Therefore,

$$\begin{aligned}
\mathbf{L}_{\mathcal{J},r}(x) &\leq \mathbf{L}_{\mathcal{J}',r}(x) \leq \max_{j=1}^{m} \mathbf{L}_{\mathcal{J}'_j,i_j}(x) \\
&\leq \max_{j=1}^{m} \big(\mathbf{L}_{\mathcal{J}_j,i_j}(x) + \varepsilon \mathcal{E}_{\mathcal{J}_j,k}(x) + \delta \big) \\
&\leq \left(\max_{j=1}^{m} \mathbf{L}_{\mathcal{J}_j,i_j}(x) \right) + \varepsilon \mathcal{E}_{\mathcal{J},k}(x) + \delta \\
&= \mathbf{L}_{\mathcal{J},r}(x) + \varepsilon \mathcal{E}_{\mathcal{J},k}(x) + \delta.
\end{aligned}$$

A symmetric argument proves the claim for $\mathbf{U}_{\mathcal{J},r}(x)$. ∎

The above lemma implies that if we can compute a (k, ε, δ)-coreset of a small size for each $\mathcal{H}_i$, then we can easily compute such a coreset for $\mathcal{H}$.

LEMMA 3.5. *For a set $\mathcal{J}$ of n hyperplanes in $\mathbb{R}^d$ and a parameter $\delta > 0$, let $\underline{\mathcal{J}}$ be the set of hyperplanes resulting by translating each hyperplane h of $\mathcal{J}$ downward by a vertical distance δ_h, where $0 \leq \delta_h \leq \delta$. Then for any $x \in \mathbb{R}^{d-1}$ and $1 \leq r, k \leq n$, we have*

(i) $\mathbf{L}_{\mathcal{J},r}(x) - \delta \leq \mathbf{L}_{\underline{\mathcal{J}},r}(x) \leq \mathbf{L}_{\mathcal{J},r}(x)$ *and* $\mathbf{U}_{\mathcal{J},r}(x) - \delta \leq \mathbf{U}_{\underline{\mathcal{J}},r}(x) \leq \mathbf{U}_{\mathcal{J},r}(x)$.
(ii) $\mathcal{E}_{\mathcal{J},k}(x) - \delta \leq \mathcal{E}_{\underline{\mathcal{J}},k}(x) \leq \mathcal{E}_{\mathcal{J},k}(x) + \delta$.

Proof. The second part follows immediately from the first one. As for the first claim, observe that $\mathbf{L}_{\underline{\mathcal{J}},r}(x) \leq \mathbf{L}_{\mathcal{J},r}(x)$ holds since all the planes of $\underline{\mathcal{J}}$ are copies of hyperplanes of $\mathcal{J}$ which were translated downward.

Next, fix any $x \in \mathbb{R}^{d-1}$, and let $h_1, \ldots, h_{n-r}$ be the hyperplanes of $\mathcal{J}$ lying above $\mathbf{L}_{\mathcal{J},r}(x)$, and let $\underline{h}_0, \ldots, \underline{h}_{n-r}$ be the corresponding hyperplanes in $\underline{\mathcal{J}}$. Clearly, $\underline{h}_0, \ldots, \underline{h}_{n-r}$ lie above point $(x, \mathbf{L}_{\mathcal{J}}(x) - \delta)$, as each hyperplane was translated down

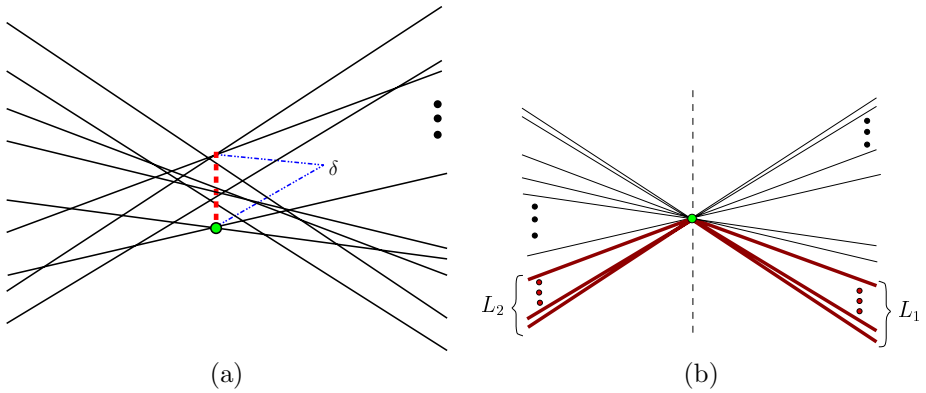

FIG. 3.2. (a) *L is a δ-sheaf. By shifting all lines downward we have $\underline{L}$ in* (b). *$\underline{L}'$ is composed of L_1, the set of k lines with smallest slope; and L_2, the set of k lines with largest slope. Thick segments form the $\leq k$-levels of L.*

by a distance at most δ. Thus $\mathbf{L}_{\mathcal{J},r}(x) - \delta \leq \mathbf{L}_{\underline{\mathcal{J}},r}(x)$. ∎

Observation 3.6. Given a set $\mathcal{H}$ of hyperplanes in $\mathbb{R}^d$, and a (k,ε,δ)-coreset $\mathcal{H}'$ for $\mathcal{H}$, the set $\mathcal{H}'$ is a (k,μ)-coreset for $\mathcal{H}$, where $\mu = \varepsilon + \delta/\Delta^{opt}(\mathcal{H},k)$.

3.3. The two-dimensional case.

LEMMA 3.7. *Let L be a set of n lines in the plane which is a δ-sheaf. Given $k > 0$, one can compute, in $O(n+k)$ time, a subset $L' \subseteq L$ such that* (i) $|L'| = 2k$, *and* (ii) *L' is a $(k,0,\delta)$-coreset for L.*

Proof. Translate each line in L downward so that it passes through the point q, where q is the bottom endpoint of the axis of the δ-sheaf. Call the resulting set $\underline{L}$; $\underline{L}$ is a sheaf in the plane with focal point q. Let $\underline{L}'$ be the union of the set of k lines of $\underline{L}$ with the largest slope and the set of k lines of $\underline{L}$ with the smallest slope. It is easy to verify that $\underline{L}'$ is a $(k,0)$-coreset for $\underline{L}$ (i.e., $\mathcal{A}(\underline{L})$ and $\mathcal{A}(\underline{L}')$ have the same top and bottom k levels), and $\left|\underline{L}'\right| = 2k$. See Figure 3.2.

Let $L' \subseteq L$ be the set of original lines that corresponds to the lines of $\underline{L}'$. By Lemma 3.5, for any $x \in \mathbb{R}$ and $0 \leq r \leq k$, we have

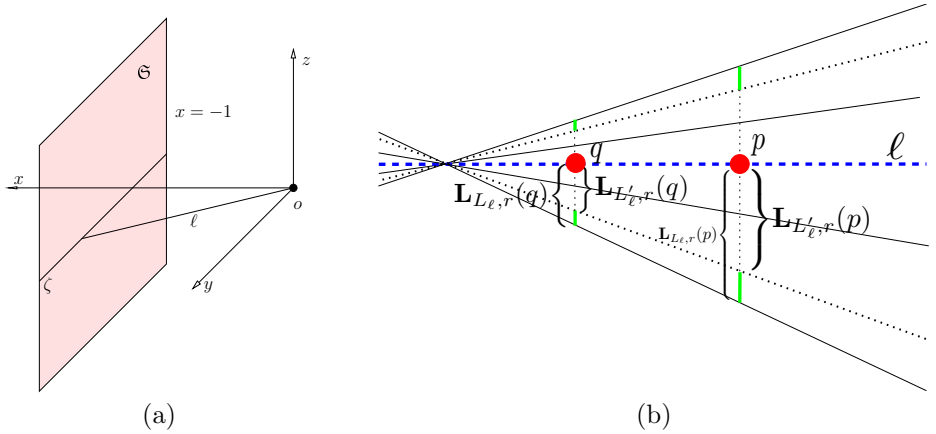
$$\mathbf{L}_{L,r}(x) \leq \mathbf{L}_{L',r}(x) \leq \mathbf{L}_{\underline{L}',r}(x) + \delta = \mathbf{L}_{\underline{L},r}(x) + \delta \leq \mathbf{L}_{L,r}(x) + \delta$$

and

$$\mathbf{U}_{L,r}(x) \geq \mathbf{U}_{L',r}(x) \geq \mathbf{U}_{\underline{L}',r}(x) = \mathbf{U}_{\underline{L},r}(x) \geq \mathbf{U}_{L,r}(x) - \delta. \quad ∎$$

THEOREM 3.8. *Given a set L of n lines in the plane and parameters $k, \varepsilon > 0$, one can compute, in $O(n + k/\varepsilon)$ time, with high probability, a set $L' \subseteq L$ such that* (i) *L' is a (k,ε)-coreset for L, and* (ii) $|L'| = O(k/\varepsilon)$.

Proof. Apply Theorem 3.3 to L, and let $L = \cup_{i=0}^{m} L_i$ be the resulting set, where $m = O(1/\varepsilon)$. With high probability, the sets $L_1, \ldots, L_m$ are δ-sheaves, and L_0 has size $O(k)$, where $\delta = \varepsilon\Delta^{opt}(L,k)$. Apply Lemma 3.7 to each L_i for $i = 1, \ldots, m$, and let $L_i' \subseteq L_i \subseteq L$ be the resulting $(k,0,\delta)$-coreset. It then follows from Lemma 3.4 that $L' = L_0 \cup \bigcup_{i=1}^{m} L_i'$ is a $(k,0,\delta)$-coreset for L. By Observation 3.6 the set L' is a (k,ε)-coreset for L. ∎



(a) (b)

FIG. 3.3. (a) *Illustration of the plane* $\mathfrak{S}$ *and line* ζ*;* (b) *The set of lines* L'_ℓ *(dashed lines) is a* (k,ε)*-coreset for the set of lines* L_ℓ *if and only if for an arbitrary point* p *on* ℓ*, which is different from the origin,* L'_ℓ *is a* (k,ε)*-coreset at* p*.*

3.4. The three-dimensional case.

LEMMA 3.9. *Given a sheaf* $\mathcal{J}$ *of* n *planes in three dimensions with its focal point at the origin* o *and parameters* k*,* $0<\varepsilon<1$*, one can compute, in* $O(n+k/\varepsilon)$ *time, a subset* $\mathcal{J}'$ *such that, with high probability,* $\mathcal{J}'$ *is a* (k,ε)*-coreset for* $\mathcal{J}$ *and* $|\mathcal{J}'|=O(k/\varepsilon)$*.*

Proof. Consider the plane $\mathfrak{S}\equiv(x=-1)\equiv\{(-1,y,z)\;\big|\;y,z\in\mathbb{R}\}$. Let $\zeta\subseteq\mathfrak{S}$ be the line

$$(x=-1)\cap(z=0)\equiv\left\{(-1,y,0)\;\middle|\;y\in\mathbb{R}\right\},$$

that is, the intersection between plane $\mathfrak{S}$ and the xy-plane (see Figure 3.3(a)). Consider the set L_ζ of lines obtained by intersecting $\mathfrak{S}$ with the planes of $\mathcal{J}$. By Theorem 3.8, one can compute a subset $L'_\zeta\subseteq L_\zeta$ of size $O(k/\varepsilon)$ which is a (k,ε)-coreset for L_ζ. Let $\mathcal{J}'$ be set of planes of $\mathcal{J}$ corresponding to L'_ζ. We claim that $\mathcal{J}'$ is a (k,ε)-coreset for $\mathcal{J}$ at any point in the xy-plane, which implies that it is a (k,ε)-coreset for $\mathcal{J}$.

Indeed, let ℓ be any line on the xy-plane that passes through the origin, and let h_ℓ be the vertical plane perpendicular to the xy-plane, with ℓ being its intersection with the xy-plane. Let L_ℓ be the set of lines formed by the intersection of h_ℓ and planes of $\mathcal{J}$. Clearly, L_ℓ form a sheaf structure on h_ℓ, as illustrated in Figure 3.3(b).

We claim that if $\mathcal{J}'\subset\mathcal{J}$ is a (k,ε)-coreset at p for any $p\in\ell$ (different from the origin), then it is (k,ε)-coreset at all points in ℓ. Indeed, first observe that $\mathbf{L}_{L_\ell,r}(p)=\mathbf{L}_{\mathcal{J},r}(p)$ and $\mathbf{L}_{L'_\ell,r}(p)=\mathbf{L}_{\mathcal{J}',r}(p)$, where L'_ℓ is the set of lines induced by the intersection of h_ℓ with planes of $\mathcal{J}'$. Now since $\mathcal{J}'$ is a (k,ε)-coreset at p, we have

$$\mathbf{L}_{L_\ell,r}(p)\le\mathbf{L}_{L'_\ell,r}(p)\le\mathbf{L}_{L_\ell,r}(p)+\varepsilon\mathcal{E}_{L_\ell,k}(p)$$

for any $1\le r\le k$, which implies that, for any $q\in\ell$ (without loss of generality, we assume that q and p are on the same side of the origin on ℓ), we have $\mathbf{L}_{L_\ell,r}(q)\le\mathbf{L}_{L'_\ell,r}(q)\le\mathbf{L}_{L_\ell,r}(q)+\varepsilon\mathcal{E}_{L_\ell,k}(q)$. The last step follows from similarity of triangles since

$$\frac{\mathbf{L}_{L_\ell,r}(p)}{\mathbf{L}_{L_\ell,r}(q)}=\frac{\mathbf{L}_{L'_\ell,r}(p)}{\mathbf{L}_{L'_\ell,r}(q)}=\frac{\mathcal{E}_{L_\ell,k}(p)}{\mathcal{E}_{L_\ell,k}(q)},$$

as illustrated in Figure 3.3(b).

Now consider any line ℓ that passes through the origin and assume that it intersects ζ at point u. Recall that L'_ζ is a (k,ε)-coreset for L_ζ, implying that $\mathcal{J}'$ is a (k,ε)-coreset at point u. Hence, by the above discussion, $\mathcal{J}'$ is a (k,ε)-coreset for all points on ℓ. It then follows that $\mathcal{J}'$ is a (k,ε)-coreset for all points on the xy-plane, except the points lying on the y-axis. It is now straightforward to use a limit argument to show that $\mathcal{J}'$ is a (k,ε)-coreset for all the points in the xy-plane, as required.

Note that for the sake of simplicity, we argued only about $\mathbf{L}_{L_\ell,r}$ in the preceding discussion, since the same analysis holds for $\mathbf{U}_{L_\ell,r}$ by symmetry. □

LEMMA 3.10. *Given a δ-sheaf $\mathcal{J}$ of n planes in three dimensions and parameters k, $0<\varepsilon<1$, one can compute, in $O(n+k/\varepsilon)$ time, a subset $\mathcal{J}'$ such that, with high probability, $\mathcal{J}'$ is a $(k,\varepsilon,2\delta)$-coreset for $\mathcal{J}$, and $|\mathcal{J}'|=O(k/\varepsilon)$.*

Proof. Translate the planes of $\mathcal{J}$ downward by a distance at most δ such that they all pass through o, which is the bottom vertex of the axis of $\mathcal{J}$. Let $\underline{\mathcal{J}}$ denote the resulting sheaf, and assume that the focal point o of $\underline{\mathcal{J}}$ is in the origin. By Lemma 3.9, one can compute a subset $\underline{\mathcal{J}'}\subseteq\underline{\mathcal{J}}$, which is a (k,ε)-coreset for $\underline{\mathcal{J}}$, $\left|\underline{\mathcal{J}'}\right|=O(k/\varepsilon)$, and this set can be computed in $O(n+k/\varepsilon)$ time.

Let $\mathcal{J}'$ be the set of original planes that corresponds to the planes of $\underline{\mathcal{J}'}$. Then $\mathcal{J}'$ is a $(k,\varepsilon,2\delta)$-coreset for $\mathcal{J}$. Indeed, by Lemma 3.5, for any $p\in\mathbb{R}^2$,

$$\begin{aligned}\mathbf{L}_{\mathcal{J},r}(p)&\le\mathbf{L}_{\mathcal{J}',r}(p)\le\mathbf{L}_{\underline{\mathcal{J}'},r}(p)+\delta\le\mathbf{L}_{\underline{\mathcal{J}},r}(p)+\varepsilon\mathcal{E}_{\underline{\mathcal{J}},k}(p)+\delta\\&\le\mathbf{L}_{\mathcal{J},r}(p)+\varepsilon\mathcal{E}_{\underline{\mathcal{J}},k}(p)+\delta\le\mathbf{L}_{\mathcal{J},r}(p)+\varepsilon\mathcal{E}_{\mathcal{J},k}(p)+2\delta,\end{aligned}$$

since $\mathcal{E}_{\underline{\mathcal{J}},k}(p)\le\mathcal{E}_{\mathcal{J},k}(p)+\delta$ and $\varepsilon<1$. □

THEOREM 3.11. *Given a set $\mathcal{H}$ of n planes in three dimensions and parameters k,ε, one can compute, in $O(n+k/\varepsilon^2)$ time, a subset $\mathcal{H}'\subseteq\mathcal{H}$ such that, with high probability, it holds that* (i) *$\mathcal{H}'$ is a (k,ε)-coreset for $\mathcal{H}$, and* (ii) *$|\mathcal{H}'|=O(k/\varepsilon^2)$.*

Proof. Apply Theorem 3.3 to $\mathcal{H}$ with $\varepsilon/4$ and k. This results in a partition of $\mathcal{H}$ into sets $\mathcal{H}_0,\mathcal{H}_1,\ldots,\mathcal{H}_m\subseteq\mathcal{H}$, where $\mathcal{H}_1,\ldots,\mathcal{H}_m$ are δ-sheafs, $\delta=(\varepsilon/4)\Delta^{opt}(\mathcal{H},k)$, $m=O(1/\varepsilon)$, and $|\mathcal{H}_0|=O(k)$ with high probability.

Applying Lemma 3.10 to $\mathcal{H}_i$ for $i=1,\ldots,m$ results in a $(k,\varepsilon/2,2\delta)$-coreset $\mathcal{H}'_i$ for $\mathcal{H}_i$, where $|\mathcal{H}'_i|=O(k/\varepsilon)$.

Let $\mathcal{H}'=\mathcal{H}_0\cup\bigcup_{i=1}^m\mathcal{H}'_i$. By Lemma 3.4, $\mathcal{H}'$ is a $(k,\varepsilon/2,2\delta)$-coreset for $\mathcal{H}$, which in turn implies that $\mathcal{H}'$ is a (k,ε)-coreset for $\mathcal{H}$, by Observation 3.6.

Finally, $|\mathcal{H}'|=|\mathcal{H}_0|+\sum_{i=1}^m|\mathcal{H}'_i|=O(k+(1/\varepsilon)(k/\varepsilon))=O(k/\varepsilon^2)$. The overall running time is $O(n+1/\varepsilon+n+k/\varepsilon^2)=O(n+k/\varepsilon^2)$. □

3.5. The higher-dimensional case. Let $f(n,k,\varepsilon,d)$ denote a bound on the size of (k,ε)-coreset of n hyperplanes in $\mathbb{R}^d$. We know that $f(n,k,\varepsilon,2)=O(k/\varepsilon)$ and $f(n,k,\varepsilon,3)=O(k/\varepsilon^2)$ by Theorems 3.8 and 3.11, respectively. Let $T(n,k,\varepsilon,d)$ denote the time needed to compute such a set.

The proof of the following lemma is a direct extension of the proof of Lemma 3.10.

LEMMA 3.12. *Given a δ-sheaf $\mathcal{J}$ of n hyperplanes in $\mathbb{R}^d$ and parameters $k,\varepsilon>0$, then one can compute, in $O(T(n,k,\varepsilon,d-1))$ time, a subset $\mathcal{J}'$ such that $\mathcal{J}'$ is a $(k,\varepsilon,2\delta)$-coreset for $\mathcal{J}$, and $|\mathcal{J}'|=f(n,k,\varepsilon,d-1)$.*

THEOREM 3.13. *Given a set $\mathcal{H}$ of n hyperplanes in $\mathbb{R}^d$ and parameters $k,\varepsilon>0$, with high probability, one can compute, in $T(n,k,\varepsilon,d)=O(n+k/\varepsilon^{d-1})$ time, a subset $\mathcal{H}'$ such that* (i) *$\mathcal{H}'$ is a (k,ε)-coreset for $\mathcal{H}$, and* (ii) *$f(n,k,\varepsilon,d)=|\mathcal{H}'|=O(k/\varepsilon^{d-1})$.*

Proof. The proof of the theorem is a straightforward extension of the proof of Theorem 3.11, and as such we verify only the bounds on the coreset size and running

time. We have

$$f(n,k,\varepsilon,d) = O(k) + O\left(\frac{1}{\varepsilon} f(n,k,\varepsilon,d-1)\right) = O\left(\frac{k}{\varepsilon^{d-1}}\right).$$

As for the running time, we have

$$T(n,k,\varepsilon,d) = O\left(n + \frac{1}{\varepsilon}\right) + \sum_{i=1}^{O(1/\varepsilon)} T(n_i,k,\varepsilon,d-1),$$

where $\sum_i n_i \leq n$ and $T(n,k,\varepsilon,3) = O(n+k/\varepsilon^2)$, by Theorem 3.11. Thus, $T(n,k,\varepsilon,d) = O(n+k/\varepsilon^{d-1})$, as claimed. ∎

4. Polynomials and their roots. In this section, we extend previous results to the extent of a family of polynomials and their roots.

4.1. Polynomials. Let $\mathcal{F} = \{f_1, \ldots, f_n\}$ be a family of d-variate polynomials and let $u_1, \ldots, u_d$ be the variables over which the functions of $\mathcal{F}$ are defined. Each f_i corresponds to a surface in $\mathbb{R}^{d+1}$. For example, any d-variate linear function can be considered as a hyperplane in $\mathbb{R}^{d+1}$ (and vice versa). We extend, in the natural way, the definitions of k-level, (k,r)-extent, ε-approximation, and (k,ε,δ)-coreset for the arrangement $\mathcal{A}(\mathcal{F})$.

Each monomial over $u_1, \ldots, u_d$ appearing in $\mathcal{F}$ can be mapped to a distinct variable x_i. Let $x_1, \ldots, x_s$ be the resulting variables. As such $\mathcal{F}$ can be linearized into a set $\mathcal{H} = \{h_1, \ldots, h_n\}$ of linear functions over $\mathbb{R}^s$. In particular, $\mathcal{H}$ is a set of n hyperplanes in $\mathbb{R}^{s+1}$. Note that the surface induced by f_i in $\mathbb{R}^{d+1}$ corresponds only to a subset of the surface of h_i in $\mathbb{R}^{s+1}$. This technique is called *linearization* and has been widely used in fields such as machine learning [11] and computational geometry [5].

For example, consider a family of polynomials $\mathcal{F} = \{f_1, \ldots, f_n\}$, where $f_i(x,y) = a_i(x^2+y^2) + b_i x + c_i y + d_i$, and $a_i, b_i, c_i, d_i \in \mathbb{R}$ for $i = 1, \ldots, n$. This family of polynomials defined over $\mathbb{R}^2$ can be linearized to a family of linear functions defined over $\mathbb{R}^3$, by $h_i(x,y,z) = a_i z + b_i x + c_i y + d_i$, and setting $\mathcal{H} = \{h_1, \ldots, h_n\}$. Clearly, $\mathcal{H}$ is a set of hyperplanes in $\mathbb{R}^4$, and $f_i(x,y) = h_i(x,y,x^2+y^2)$. Thus, for any point $(x,y) \in \mathbb{R}^2$, instead of evaluating $\mathcal{F}$ on (x,y), we can evaluate $\mathcal{H}$ on $\eta(x,y) = (x,y,x^2+y^2)$, where $\eta(x,y)$ is the *linearization image* of (x,y). The advantage of this linearization is that $\mathcal{H}$, being a family of linear functions, is now easier to handle than $\mathcal{F}$. There is a general technique for finding the best possible linearization (i.e., a mapping η with the target dimension as small as possible); see [5] for details. Observe that $X = \eta(\mathbb{R}^2)$ is a *subset* of $\mathbb{R}^3$ (this is the "standard" paraboloid), and we are interested in the value of $\mathcal{H}$ only on points belonging to X. In particular, the set X is not necessarily convex. The set X resulting from the linearization is a semialgebraic set of constant complexity, and as such basic manipulation operations of X can be performed in constant time.

Note that for each $1 \leq i \leq n$, $f_i(p) = h_i(\eta(p))$ for $p \in \mathbb{R}^d$. As such, if $\mathcal{H}' \subseteq \mathcal{H}$ is a (k,ε)-coreset for $\mathcal{H}$, then clearly the corresponding subset in $\mathcal{F}$ is a (k,ε)-coreset for $\mathcal{F}$. The following theorem is a restatement of Theorem 3.13 in this settings.

THEOREM 4.1. *Given a family of d-variate polynomials $\mathcal{F} = \{f_1, \ldots, f_n\}$ and parameters k and ε, one can compute, in $O(n + k/\varepsilon^s)$ time, a subset $\mathcal{F}' \subseteq \mathcal{F}$ of $O(k/\varepsilon^s)$ polynomials such that $\mathcal{F}'$ is a (k,ε)-coreset for $\mathcal{F}$, with high probability. Here s is the number of different monomials present in the polynomials of $\mathcal{F}$.*

4.2. Roots of polynomials. It turns out that for roots of polynomials the definition of coreset (Definition 2.4) is somewhat too restrictive. However, we can get a similar notion of a coreset by slightly relaxing the requirements.

DEFINITION 4.2. *Let $\mathcal{F}$ be a set of nonnegative functions defined over $\mathbb{R}^d$. A subset $\mathcal{F}' \subseteq \mathcal{F}$ is* (k,ε)-sensitive *if, for any $r \leq k$ and $x \in \mathbb{R}^d$, we have*

$$\mathbf{L}_{\mathcal{F},r}(x) \leq \mathbf{L}_{\mathcal{F}',r}(x) \leq \mathbf{L}_{\mathcal{F},r}(x) + \frac{\varepsilon}{2}\mathcal{F}|_r^k(x),$$

$$\mathbf{U}_{\mathcal{F},r}(x) - \frac{\varepsilon}{2}\mathcal{F}|_k^r(x) \leq \mathbf{U}_{\mathcal{F}',r}(x) \leq \mathbf{U}_{\mathcal{F},r}(x).$$

Note that any (k,ε)-coreset is $(k,2\varepsilon)$-sensitive (while the inverse is not necessarily true).

LEMMA 4.3. *If $\mathcal{F}'$ is (k,ε)-sensitive for $\mathcal{F}$, then*

$$(1-\varepsilon)\,\mathcal{F}|_r^t(x) \leq \mathcal{F}'|_r^t(x) \leq \mathcal{F}|_r^t(x)$$

for any $t, r \leq k$ and $x \in \mathbb{R}^d$.

Proof.

$$\begin{aligned}
\mathcal{F}|_r^t(x) &\geq \mathcal{F}'|_r^t(x) = \mathbf{U}_{\mathcal{F}',t}(x) - \mathbf{L}_{\mathcal{F}',r}(x) \\
&\geq \Big(\mathbf{U}_{\mathcal{F},t}(x) - \frac{\varepsilon}{2}\mathcal{F}|_k^t(x)\Big) - \Big(\mathbf{L}_{\mathcal{F},r}(x) + \frac{\varepsilon}{2}\mathcal{F}|_r^k(x)\Big) \\
&= (\mathbf{U}_{\mathcal{F},t}(x) - \mathbf{L}_{\mathcal{F},r}(x)) - \frac{\varepsilon}{2}\Big(\mathcal{F}|_k^t(x) + \mathcal{F}|_r^k(x)\Big) \\
&\geq \mathcal{F}|_r^t(x) - \varepsilon\mathcal{F}|_r^t(x) = (1-\varepsilon)\,\mathcal{F}|_r^t(x). \qquad \square
\end{aligned}$$

THEOREM 4.4. *Let $\mathcal{F} = \{f_1^{1/2}, \ldots, f_n^{1/2}\}$ be a family of d-variate functions defined over $\mathbb{R}^d$, where f_i is a d-variate polynomial for $i = 1, \ldots, n$. Given k and $0 < \varepsilon < 1$, one can compute, in $O(n + k/\varepsilon^{2s})$ time, a subset $\mathcal{F}' \subseteq \mathcal{F}$ such that, with high probability, $\mathcal{F}'$ is (k,ε)-sensitive for $\mathcal{F}$ and $|\mathcal{F}'| = O(k/\varepsilon^{2s})$, where s is the number of distinct monomials present in the polynomials of $\mathcal{F}$.*

Proof. Let $\mathcal{G} = \{f_i \mid f_i^{1/2} \in \mathcal{F}\}$ denote the set of d-variate polynomials which are the square of the functions in $\mathcal{F}$. Let $\mathcal{H}$ be the set of hyperplanes in $\mathbb{R}^{s+1}$ obtained by linearization of f_i's, and let $\eta : \mathbb{R}^d \to \mathbb{R}^s$ be the linearization used. Given any $k, \varepsilon > 0$, one can compute in $O(n + k/\delta^s)$ time, a (k,δ)-coreset $\mathcal{H}' \subseteq \mathcal{H}$ of size $O(k/\delta^s)$ for $\mathcal{H}$, where $\delta = \varepsilon^2/32$. Clearly, $\mathcal{H}'$ is $(k,2\delta)$-sensitive for $\mathcal{H}$.

Let $\mathcal{G}' \subseteq \mathcal{G}$ be the set of functions of $\mathcal{G}$ that corresponds to $\mathcal{H}'$. Let α be any point in $\mathbb{R}^d$, and let $x = \eta(\alpha) \in \mathbb{R}^s$ be the linearized image of α. Let $a = \mathbf{L}_{\mathcal{G},r}(\alpha) = \mathbf{L}_{\mathcal{H},r}(x)$, $A = \mathbf{L}_{\mathcal{G}',r}(x) = \mathbf{L}_{\mathcal{H}',r}(x)$, $b = \mathbf{U}_{\mathcal{G},k}(\alpha) = \mathbf{U}_{\mathcal{H},k}(x)$. By the definition of $(k,2\delta)$-sensitivity, we have that $A - a \leq \delta\, \mathcal{G}|_r^k(x) = \delta(b-a)$.

Now, if $\sqrt{A} + \sqrt{a} \leq 2(\delta/\varepsilon)(\sqrt{b} + \sqrt{a})$, then $\sqrt{A} + \sqrt{a} \leq 4\sqrt{b}\delta/\varepsilon \leq \sqrt{b}\varepsilon/8$. Thus,

$$\begin{aligned}
\sqrt{A} - \sqrt{a} \leq \sqrt{A} + \sqrt{a} &\leq \frac{\sqrt{b}\varepsilon}{8} \leq \Big(\frac{\varepsilon}{2} - \frac{\varepsilon}{8}\Big)\sqrt{b} = \frac{\varepsilon}{2}\sqrt{b} - \frac{\varepsilon}{8}\sqrt{b} \leq \frac{\varepsilon}{2}\sqrt{b} - \sqrt{a} \\
&\leq \frac{\varepsilon}{2}(\sqrt{b} - \sqrt{a}),
\end{aligned}$$

since $\sqrt{a} \leq \sqrt{A} + \sqrt{a} \leq \sqrt{b}\varepsilon/8$.

Otherwise, $\sqrt{A}+\sqrt{a} \geq 2(\delta/\varepsilon)(\sqrt{b}+\sqrt{a})$ and

$$\begin{aligned}\mathbf{L}_{\mathcal{F}',r}(\alpha) - \mathbf{L}_{\mathcal{F},r}(\alpha) &= \sqrt{A}-\sqrt{a} = \frac{A-a}{\sqrt{A}+\sqrt{a}} \leq \frac{\delta(b-a)}{\sqrt{A}+\sqrt{a}} \leq \frac{\delta(b-a)}{2(\delta/\varepsilon)(\sqrt{b}+\sqrt{a})} \\ &= (\varepsilon/2)(\sqrt{b}-\sqrt{a}) \\ &\leq \frac{\varepsilon}{2}\mathcal{F}|_r^k(\alpha). \qquad \square\end{aligned}$$

5. Applications. In this section, we briefly present some of the results that follow from our technique for various shape fitting problems with outliers. Some of the other results mentioned in the introduction follow by a straightforward application of our techniques, as demonstrated in this section. To avoid tedious repetition we present only the more interesting ones here.

The general framework is as follows: First, reduce the problem of finding the best fitting shape to that of computing the smallest extent over a family of polynomials or roots of polynomials. Next, apply the following theorems to approximate the smallest extent with outliers. The details are described later in this section.

THEOREM 5.1. *Given a $(k,\varepsilon/2)$-sensitive subset $\mathcal{F}'$ of a family $\mathcal{F}$ of d-variate functions, where $0<\varepsilon<1$, one can compute*

(i) *a point $x' \in \mathbb{R}^d$ and $\delta' = \mathcal{E}_{\mathcal{F},k}(x')$ such that $\Delta^{opt}(\mathcal{F},k) \leq \delta' \leq (1+\varepsilon)\Delta^{opt}(\mathcal{F},k)$;*

(ii) *a point $\widehat{x} \in \mathbb{R}^d$ and $\widehat{\delta} = \mathcal{F}|_{\widehat{t}}^{\widehat{r}}(\widehat{x})$ such that $\widehat{r}+\widehat{t}=k$ and $\omega^* \leq \widehat{\delta} \leq (1+\varepsilon)\omega^*$, where $\omega^* = \min_{x\in\mathbb{R}^d, r+t=k} \mathcal{F}|_t^r(x)$.*

The running time is $O(n+\mathcal{C}(\mathcal{F}')^2)$, where $n=|\mathcal{F}|$ and $\mathcal{C}(\mathcal{F}')$ is the complexity of the arrangement $\mathcal{A}(\mathcal{F}')$.

Proof. We prove the first claim, as the second claim follows from a similar argument.

Each function in $\mathcal{F}$ induces a surface in $\mathbb{R}^{d+1}$. Set $x' \in \mathbb{R}^d$ to be the point such that $\mathcal{E}_{\mathcal{F}',k}(x') = \Delta^{opt}(\mathcal{F}',k) = \min_{x\in\mathbb{R}^d} \mathcal{E}_{\mathcal{F}',k}(x)$. Note that $\delta' = \mathcal{E}_{\mathcal{F},k}(x')$ can be computed in linear time once x' is specified, while x' can be obtained by computing the levels $\mathbf{L}_{\mathcal{F}',\leq k}$ and $\mathbf{U}_{\mathcal{F}',\leq k}$ and then searching, by brute force, for the shortest extent in the arrangement $\mathcal{A}(\mathcal{F}')$. It is easy to verify that this can be done in $O(n+\mathcal{C}(\mathcal{F}')^2)$ time.

Let $x^* \in \mathbb{R}^d$ be the point realizing $\mathcal{E}_{\mathcal{F},k}(x^*) = \Delta^{opt}(\mathcal{F},k)$. Since $\mathcal{F}'$ is a $(k,\varepsilon/2)$-sensitive, and $\varepsilon<1$, then by Lemma 4.3 we have

$$\begin{aligned}\Delta^{opt}(\mathcal{F},k) \leq \delta' = \mathcal{E}_{\mathcal{F},k}(x') &\leq \frac{\mathcal{E}_{\mathcal{F}',k}(x')}{1-\varepsilon/2} \\ &\leq (1+\varepsilon)\mathcal{E}_{\mathcal{F}',k}(x') \leq (1+\varepsilon)\mathcal{E}_{\mathcal{F}',k}(x^*) \\ &\leq (1+\varepsilon)\mathcal{E}_{\mathcal{F},k}(x^*) = (1+\varepsilon)\Delta^{opt}(\mathcal{F},k). \qquad \square\end{aligned}$$

Note that the above theorem implies that we not only can approximate the value of the smallest extend, but we can also find an instance that achieves the approximate value. The running time of Theorem 5.1 can be slightly improved by being more careful in the analysis, and by applying the Clarkson–Shor technique [10] to bound more tightly the number of pairs of facets of the arrangement that should be considered when computing $\Delta^{opt}(\mathcal{F}',k)$.

All the results in the remainder of this section hold with high probability, as they all rely on the randomized algorithm of Lemma 3.1.

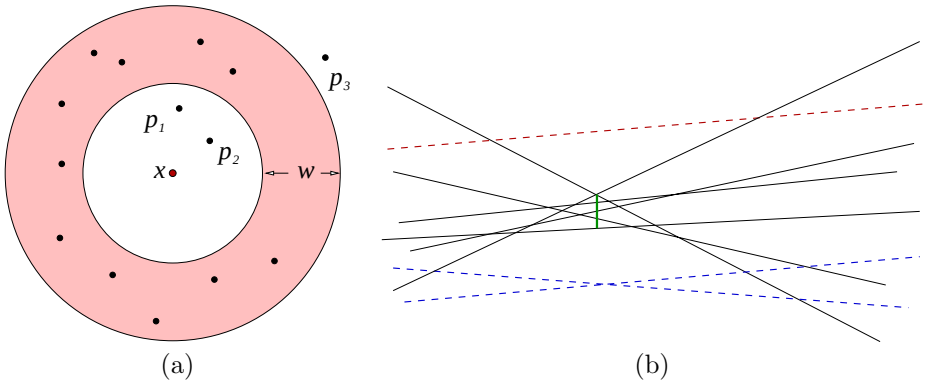


FIG. 5.1. (a) *Annulus with center x (dark region) has a width w. p_1, p_2, and p_3 are outliers.* (b) *After linearization, the thick vertical segment is the shortest extent with 3 outliers, with dotted lines corresponding to outliers p_1, p_2, and p_3.*

5.1. Minimum-width annulus/spherical shell. Given a set $P = \{p_1, \ldots, p_n\}$ of points in $\mathbb{R}^d$ and parameters $k, \varepsilon > 0$, let $\omega_{opt,k}$ denote the width of the thinnest annulus containing all but k points in P. See Figure 5.1. We would like to compute the annulus that contains at least $n - k$ points of P and whose width is at most $(1+\varepsilon)\omega_{opt,k}$. More precisely, let $d(x,p)$ denote the distance between two points $x, p \in \mathbb{R}^d$ and

$$\mu(x, P, k) = \min_{P' \subseteq P, |P'| = n-k} \left(\max_{p \in P'} d(x,p) - \min_{p \in P'} d(x,p) \right).$$

We omit k from the notation when $k = 0$. We have $\omega_{opt,k} = \min_{x \in \mathbb{R}^d} \mu(x, P, k)$, and we wish to compute a subset $P^* \subseteq P$ of size at least $n - k$ and a point $x^* \in \mathbb{R}^d$ such that $\mu(x^*, P^*) \leq (1+\varepsilon)\omega_{opt,k}$.

Let $p_i = (\xi_1, \ldots, \xi_d)$ be a point from the set P, and let $x = (x_1, \ldots, x_d)$ be an arbitrary point in $\mathbb{R}^d$. Under the Euclidean distance, we define

$$f_i(x) = d(p_i, x) = \sqrt{\sum_{1 \leq j \leq d} x_j^2 - 2 \sum_{1 \leq j \leq d} \xi_j x_j + \sum_{1 \leq j \leq d} \xi_j^2}.$$

Let $\mathcal{F} = \{f_1, \ldots, f_n\}$ denote the set of functions defined by the points of P.

Observe that $\omega_{opt,k}$ is in fact the shortest (r,t)-extent for $\mathcal{F}$ such that $r + t = k$. By Theorem 4.4, we can compute, in $O(n + k/\varepsilon^{2d})$ time, a subset $\mathcal{F}' \subseteq \mathcal{F}$ which is a (k, ε)-sensitive for $\mathcal{F}$ and $|\mathcal{F}'| = O(k/\varepsilon^{2d})$. Since the image of each function of $\mathcal{F}$ is a cone in $\mathbb{R}^{d+1}$, one can thus approximate $\omega_{opt,k}$ in

$$O\left(n + |\mathcal{F}'|^{2(d+1)}\right) = O\left(n + \frac{k^{2(d+1)}}{\varepsilon^{4d(d+1)}}\right)$$

time using the algorithm of Theorem 5.1.

THEOREM 5.2. *Given a set P of n points and parameters $k, \varepsilon > 0$, one can compute an $x^* \in \mathbb{R}^d$, and $P^* \subseteq P$, where $|P^*| \geq n - k$ such that $\mu(x^*, P^*) \leq (1+\varepsilon)\omega_{opt,k}$ in $O(n + k^{2d+1}/\varepsilon^{4d(d+1)})$ time.*

5.2. Minimum-volume annulus/spherical shell. Let $\mathcal{B}(x, R, r)$ denote the shell between two concentric balls, centered at point x, with radii R and r, respectively.

That is, $\mathcal{B}(x, R, r)$ is composed of all points inside the outer ball and outside the inner ball. Given a set of points $P \in \mathbb{R}^d$, we would like to find a spherical shell whose volume is minimized, and which contains at least $n - k$ points of P, over all $x \in \mathbb{R}^d$ and $R, r \in \mathbb{R}$. Let $\mathcal{SS}_{opt,k}(P)$ denote the volume of this spherical shell. This problem is easier than the minimum-width variant, as it can be reduced to linear programming (this is folklore; it is also described in [1]).

The current fastest algorithm for the exact problem, in two dimensions, with k outliers is due to Chan [7], and it works in $O\big(n \log k + k^{11/4} n^{1/4} \log^c k\big)$ time.

THEOREM 5.3. *Given a set P of n points and parameters $k, \varepsilon > 0$, one can compute a set P such that* (i) $P' \subseteq P$, (ii) P *is a (k, ε)-coreset for the minimum area spherical shell measure, and* (iii) $|P'| = O(k/\varepsilon^d)$.

In particular, one can compute a spherical shell whose volume ε-approximates $\mathcal{SS}_{opt,k}(P)$ in $O(n+k^{2(d+1)}/\varepsilon^{2d(d+1)})$ time for $d > 2$ and in $O(n+\frac{k}{\varepsilon^2}\log\frac{k}{\varepsilon}+\frac{k^3}{\varepsilon^{1/2}}\log^c k)$ time for $d = 2$, where c is a constant.

Proof. Using linearization, computing $\mathcal{SS}_{opt}(P)$ is reduced to computing the extent of n hyperplanes in $\mathbb{R}^{d+1}$ [4]. Thus, by Theorem 3.13, there is a subset P' of P, which is (k, ε)-sensitive for the measure $\mathcal{SS}_{opt}(\cdot)$, and $|P'| = O(k/\varepsilon^d)$.

For $d > 2$, the running time is just the result of applying Theorem 5.1. As for $d = 2$, we use the algorithm of Chan [7] on the subset P'. ∎

5.3. Minimum-width cylindrical shell. Given a line ℓ in $\mathbb{R}^d$ and two real numbers $0 \le r \le R$, the cylindrical shell $S(\ell, r, R)$ is the closed region lying between the two coaxial cylinders of radii r and R, respectively, with ℓ as their axis. The width of shell $S(\ell, r, R)$ is $R - r$. Given a set of n points P, let $\mathcal{CS}^*$ denote the minimum width among all cylindrical shells that enclose at least $n - k$ points of P. In the *approximate minimum-width cylindrical shell with outliers* problem, we would like to compute a cylindrical shell containing at least $n - k$ points from P whose width is at most $(1 + \varepsilon)\mathcal{CS}^*$.

THEOREM 5.4. *Given a set P of n points in $\mathbb{R}^d$ and parameters $k, \varepsilon > 0$, one can compute in $O(n + k^{cd^2}/\varepsilon^{c'd^4})$ time a line ℓ^* and $P^* \subseteq P$, where $|P^*| \ge n - k$, such that the minimum width of the cylindrical shell containing P^* with axis ℓ^* is smaller than $(1 + \varepsilon)\mathcal{CS}^*$. Here c, c' are constants independent of d, ε, and n.*

Proof. Using linearization, computing $\mathcal{CS}^*$ is reduced to computing the extent of n hyperplanes in $\mathbb{R}^{O(d^2)}$ [4]. Thus, by Theorem 3.13, there is a subset P' of P, which is (k, ε)-sensitive for the width measure, and $|P'| = O(k/\varepsilon^{O(d^2)})$. The running time is just the result of applying Theorem 5.1 to this set. ∎

5.4. Moving points. The same technique can also be extended to approximate various measures of moving points. More precisely, given a set P of n points moving in $\mathbb{R}^d$, for each $p \in P$, let $p(t) = (\xi_1(t), \ldots, \xi_d(t))$ denote the position of point p at time t, and let $P(t)$ denote the set P at time t. We say that the motion of P is *algebraic* of degree ν if the functions $\xi_1(t), \ldots, \xi_d(t)$ are polynomials of degree at most ν for all the points of P. For simplicity, we assume in the remaining part that $\nu = 1$; i.e., each point moves along a straight line.

Let $\mu_k(P)$ denote some measure of the point set P, such as width (with at most k outliers). For any $\varepsilon > 0$, we say that a subset $Q \subseteq P$ ε-approximates P with respect to μ_k if at any time t, $(1 - \varepsilon)\mu_k(P(t)) \le \mu_k(Q(t)) \le \mu_k(P(t))$. Arguing as in [4], we get the following result.

THEOREM 5.5. *Given a point-set P with n linearly moving points and parameters $k, \varepsilon > 0$, one can compute, in $O(n + k/\varepsilon^c)$ time, a subset $Q \subseteq P$ of size $O(k/\varepsilon^c)$ such*

that Q is an ε-approximation to P under measures with k outliers such as diameter, width, minimum-radius enclosing ball, projection width, minimum-width annulus, and minimum-width cylindrical shell. Here c is a constant that depends on the dimension d and the measure considered.

5.5. Handling updates—insertions and deletions. By building a balanced binary tree over the given point set and maintaining in each node the coreset of all the points in its subtree, one can maintain a coreset under insertions and deletions, where every insertion and deletion is handled in polylogarithmic time. The following theorem follows in a plug-and-play fashion by combining the techniques of [3] with our techniques.

THEOREM 5.6. *Let P be a set of points in $\mathbb{R}^d$, let k and $\varepsilon > 0$ be parameters, and let $\mu(\cdot)$ be one of the measures discussed before. Suppose that for any $Q \subseteq P$, we can compute a (k, ε)-sensitive (for $\mu(\cdot)$) subset S of Q of size $O(k/\varepsilon^\rho)$ in $O(|Q| + f(\varepsilon))$ time. Then we can maintain a (k, ε)-sensitive subset of P of size $O(k/\varepsilon^\rho)$ under insertion/deletion operations in $O(((\log n)/\varepsilon)^\rho + f(\varepsilon/\log n)\log n)$ time per update.*

Note that Theorem 5.6 implies that we can maintain the approximate optimal solution for *all* of the measures discussed above, under insertions and deletions, with k outliers. The time to handle an update is $O(\mathrm{poly}(k, 1/\varepsilon, \log n))$, where $\mathrm{poly}(\cdots)$ is a constant degree polynomial in its parameters, where the constant is a function of d and the measure being approximated.

6. Conclusions. We presented a general approximation algorithm for shape fitting that can handle outliers efficiently with near linear running time when the number of outliers is small. The main contribution of this paper is the proof that there exists a small coreset for various shape fitting problems when considering outliers. The authors believe that the existence of such a small coreset is quite surprising.

6.1. Comparison to linear programming with violations. It is beneficial to compare our result to the algorithms known for linear programming with violations. Mulmuley [23] showed, using the Clarkson–Shor technique, that in an arrangement of n hyperplanes in d dimensions, there are at most $O(k^d)$ *local* minima in the top k-level. The argument relies on picking a random sample of n/k hyperplanes and showing that the probability that a local minima in the top k-level is the minimum of the sample (i.e., the lowest point on the upper envelope of the sample of hyperplanes) is $\Omega(1/k^d)$, and since there is only one local minima in the upper envelope of the sample, it follows that the global number of local minima in the first top k-levels is $O(k^d)$. Matoušek [22] solves the linear programming with violations by generating all those local minima explicitly (in amortized $O(n)$ time for each one by solving instances of linear programming) and returning the best one.

A straightforward adaption of this argument shows that there are $O(k^{d+1})$ minima to the k-extent function $\mathcal{E}_{\mathcal{H},k}$. In our setting, since we are interested only in the extent in a subspace $X \subseteq \mathbb{R}^{d-1}$, it is no longer true that such a bound (that depends only on k) holds on the number of minima of the extent when restricted to X. Specifically, it is easy to find examples where the number of local minima of the k-extent is $\Omega(n)$ when restricted to X. We briefly describe such an example below. Imagine a set of functions $\mathcal{F}$ where each $f \in \mathcal{F}$ is a parabola $f(x) = ax^2 + bx + c$ (see Figure 6.1). The number of local minima of the 0-extent is $\Omega(n)$, as indicated by the dotted vertical segments in Figure 6.1. Now we linearize each f into a plane $h(x, y) = ay + bx + c$ in $\mathbb{R}^3$, with the linearization image being $\eta(x) = (x, x^2)$; call the resulting set of planes $\mathcal{H}$. The set X, in this case, is the image of the linearization, namely, $X = \eta(\mathbb{R}) = \{(x, x^2) \mid x \in \mathbb{R}\}$.

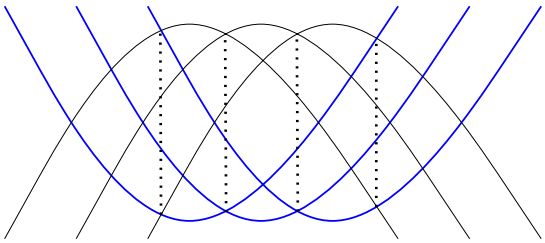

FIG. 6.1. *The graphs of a set of functions $\mathcal{F}$, with each being a parabola. Dotted vertical segments depict the local minima of* 0*-extent in the arrangement of $\mathcal{F}$.*

Observe, that the number of local minima of the 0-extent along $\eta(\mathbb{R})$ for $\mathcal{H}$ remains the same. Therefore, while the number of minima of the 0-extent with respect to $\mathbb{R}^2$ is $O(1)$ (i.e., there is one minimum in the upper and lower envelop of the arrangement of $\mathcal{H}$), the number of minima when restricted to X is $\Omega(n)$. Furthermore, the problem of finding the shortest vertical segment when restricted to X (even without outliers) is no longer an LP-type problem, and as such we can no longer move efficiently from one minimum to another using Matoušek's approach.

Nevertheless, this gives a new interpretation of our result. It implies that if we are interested only in approximation, the number of approximate local minima is bounded by a polynomial in k (while the exact one is *not*). Furthermore, our coreset result yields a direct way to generate those local minima.

6.2. General discussion. A limitation of our technique is that the number of outliers has to be moderately small (i.e., $O(n^{1/2d})$) to achieve near linear running time. Erickson and Seidel [17, 16] show that to determine whether a set of n points in $\mathbb{R}^d$ contains $d+1$ points on a common hyperplane requires $\Omega(n^d)$ sidedness queries. (Given $d+1$ points $p_0, \ldots, p_d$, the *sidedness query* decides on which side of the oriented hyperplane defined by $p_1, \ldots, p_n$ the point p_0 lies.) This lower bound holds in a decision tree model of computation in which every decision is based on the result of a sidedness query, which they argue is a reasonable model. Their result implies that when the number of outliers is huge (i.e., $k = n - d - 1$), a near-linear time approximation algorithm cannot be achieved. We leave the problem of improving the running time of our algorithm as an open question for further research.

This raises the question whether one can find "universal" approximation algorithms with outliers—namely, approximation algorithms that have near-linear running time independent of the number of outliers. Currently, the only case the authors are aware of that such an algorithm exists is for the case of minimum enclosing circles with k outliers; see [21] for the currently fastest algorithm known for this problem.

Of course, using standard ε-sampling techniques, one can achieve *combinatorial* approximation of k levels for relatively large k efficiently. However, this provides a different and *weaker* type of approximation than the one presented in the paper. In particular, our results imply that we can compute an approximation when the number of outliers is fixed, while the geometric measure is approximated. Using ε-sampling implies a result where the number of outliers is approximated. This is acceptable only when the number of outliers is relatively large.

Another limitation of our technique (which is inherent in almost all the work concerning outliers [13]) is that the number of outliers, k, has to be specified in the input. In practice, there are situations when this information is not known beforehand.

How to formulate a reasonable problem without k being the input, and then solving it, are among some of the future directions of research.

Finally, note that, for $k = 0$, this paper provides an alternative construction to the techniques of [4]. The approximation techniques presented here are simpler to implement, but the resulting coresets (not surprisingly) are larger.

Acknowledgment. The authors would like to thank the anonymous referees for their useful comments.

NEW STABILITY RESULTS FOR ADVERSARIAL QUEUING*

ZVI LOTKER†, BOAZ PATT-SHAMIR†, AND ADI ROSÉN‡

Abstract. We consider the model of "adversarial queuing theory" for packet networks introduced by Borodin et al. [*J. ACM*, 48 (2001), pp. 13–38]. We show that the scheduling protocol first-in-first-out (FIFO) can be unstable at any injection rate larger than $1/2$ and that it is always stable if the injection rate is less than $1/d$, where d is the length of the longest route used by any packet. We further show that *every* work-conserving (i.e., greedy) scheduling policy is stable if the injection rate is less than $1/(d+1)$.

Key words. adversarial queuing theory, network protocols, stability, lower bounds

1. Introduction.

Recent years have seen a growing amount of work being concentrated on analyzing packet networks under nonprobabilistic scenarios rather than under probabilistic assumptions (see, e.g., [7, 4, 1, 14, 12, 13, 3, 5]). Much of this work makes use of the model of "adversarial queuing theory" proposed by Borodin et al. [7]. The model can be briefly described as follows. Time proceeds in discrete steps. In each step, packets are injected into the network with their routes. Each packet traverses its respective route hop by hop in a store-and-forward fashion. In each time step, one packet may cross each link, and all other packets waiting for that link are stored in a buffer at the tail of that link. The behavior of the system is determined by the *queuing policy*. The queuing policy chooses, at each time step, for each link, which of the competing packets should be forwarded over that link. One of the main questions in the adversarial queuing model is the question of *stability*. That is, under what conditions is there a bound on the size of the link buffers, as opposed to them growing to infinity as time proceeds? The conditions involve the topology of the network, the queuing policy used, and the injection pattern of the packets. The latter is characterized in the framework of adversarial queuing theory by the *rate* at which packets are injected. Intuitively, the rate of injection is said to be r if, for every link e in the network, the average number of packets requiring e, injected by the adversary in any time step, is at most r (a formal definition of the model is given in section 2). Note that in this model one does not assume any probabilistic assumptions on the behavior of the traffic. Rather, answers are sought under the only assumption that the total bandwidth requested by the adversary is not more than the total bandwidth the network provides.

In the framework of adversarial queuing theory, it is known that some networks are stable for *every* greedy protocol as long as the rate of injection is less than 1, while other networks do not exhibit this phenomenon [7, 4]. The networks which

are always stable have been named "universally stable" networks [7] and have been fully characterized [14, 2]. From the point of view of protocols, some protocols are known to be universally stable; i.e., they are stable on any network topology for any rate of injection $r < 1$. Such protocols are, for example, longest-in-system (LIS) and furthest-to-go (FTG). Other natural protocols, however, are known not to always be stable, e.g., first-in-first-out (FIFO), nearest-to-go (NTG), last-in-first-out (LIFO), and furthest-from-source (FFS) [4]. Furthermore, the protocol NTG (and FFS and LIFO) exhibit the phenomenon of being unstable on certain networks even at arbitrarily low injection rates [7]. Previous papers in this area mentioned as one of the main interesting open problems the question of determining the rate at which the (very commonly used) FIFO policy is guaranteed to be stable and if such rate exists at all. Prior to the present work, it was known that FIFO is not universally stable and that it can be unstable for $r > 0.85$ [4]. This bound was improved to 0.8357 by Díaz et al. [11] and further improved to 0.749 by Koukopoulos, Nikoletseas, and Spirakis [15]. Díaz et al. [11] also presented a formula to calculate, for any given network, a bound so that FIFO is stable on that network if the injection rate is below that bound. In particular, they consider as parameters the number of edges in the network, denoted m, the length of the longest route used by any packet, denoted d, and the maximum in-degree in the network, denoted α; their bound is at most $\frac{1}{2dm\alpha}$ for any network.

The contribution of this paper is twofold. First, we show that FIFO can be unstable for any rate greater than $1/2$ and that, on the other hand, FIFO is always stable if the rate is less than $1/d$. Second, we extend the stability proof for FIFO to show that *any* greedy policy is stable if the injection rate is less than $1/(d+1)$, while previously it was only known for general greedy protocols that the system is stable if the injection rate is bounded by $1/m$ [6].[1] We remark that our stability proofs do not only show that the buffers have bounded size if the rate is sufficiently low. They show, in addition, that the buffer size in this case has an upper bound independent of network parameters (depending only on the parameters of the adversary).

Our instability proof entails new techniques that greatly simplify the analysis of the FIFO policy. In particular, we develop a technique that enables us to construct adversaries for some *acyclic* parameterized networks that we call "gadgets" and then compose these gadgets and adversaries to form a cyclic network and a single adversary that together show instability. Furthermore, we simplify the specification of the adversary by defining conditions under which the adversary is allowed to "reroute" packets, thus allowing us to specify routes for the packets "on the fly."

Recently, subsequent to the initial publication of the present work [17], Bhattacharjee and Goel proved that FIFO can be unstable at arbitrarily low injection rates [8]. Some of the techniques used in their work (such as concatenation of parameterized gadgets and packet rerouting) are similar to the techniques we use in the present work.

Organization. The rest of this paper is organized as follows. In section 2 we define the model formally. In section 3 we prove that FIFO can be unstable for any rate greater than $1/2$. In section 4 we prove our stability results. We conclude with some remarks in section 5.

2. Formal model. We use the adversarial queuing model [7], defined as follows. The communication network is modeled by a directed graph $G = (V, E)$, and we

[1] Recently, we learned that Zhang, Duan, and Hou [18] proved that FIFO is stable for injection rates less than $1/d$. This result was obtained independently of ours.

denote $|V| = n$, $|E| = m$. Each node $v \in V$ represents a communication switch, and each edge $e \in E$ represents a link between two switches. In each node, there is a *buffer* associated with each outgoing link. Buffers store *packets*. Packets are *injected* into the network with a *route*, which is a simple directed path in G. When a packet is injected, it is placed in the buffer of the first link on its route. The system proceeds in global time steps numbered $0, 1, \ldots$. Each time step is divided into two substeps. In the first substep, one packet is sent from each nonempty buffer over its corresponding link. In the second substep, packets are received by the nodes at the other end of the links; they are absorbed (eliminated) if that node is their destination, and otherwise they are placed in the buffer of the next link on their respective routes. In addition, new packets are injected in the second substep.

The task of the *protocol* is to select which packet to send over a link if there is more than one packet in the buffer associated with that link. We remark that we are interested in *greedy* protocols (in fact, the definitions above allow only such protocols), in which a link cannot be idle in a time step if its buffer is nonempty in the first substep. The protocol FIFO selects the packets to be sent from a buffer in the same order as their arrival order at that buffer.

The injection of the packets into the network is modeled as being done by an *adversary*. Following [7], we use the following parameterized definition for the adversary.

DEFINITION 2.1. *Let $\mathcal{A}$ be an adversary. $\mathcal{A}$ is called a (w, r) adversary if, for some $r \leq 1$, called the* rate *of $\mathcal{A}$, and some integer $w \geq 1$, called the* window size *of $\mathcal{A}$, the following holds. For any time $t \in \mathcal{N}$, let $\mathcal{I}^t$ be the set of packets injected during the w time steps from t to $t + w - 1$, inclusive. Let Π^t be the set of paths that the packets in $\mathcal{I}^t$ have to follow. Then the maximum number of times any edge appears in Π^t is at most rw.*

For our instability results we use a weaker adversary, which is not allowed to inject bursty traffic. We call this adversary a *rate-r adversary* [4]: for every interval of time of length t and every edge e, a rate-r adversary may inject at most $\lceil rt \rceil$ packets whose routes require e.

3. Instability of FIFO. In this section we prove that FIFO can be unstable at rate $\frac{1}{2} + \epsilon$ for any $\epsilon > 0$. The high level view of the proof is as follows. First, we define a small acyclic graph called "gadget," which has special "ingress" and "egress" edges. Gadgets can be composed in series by identifying the egress edge of one gadget with the ingress edge of its successor, getting a "daisy chain." We show that a rate-r adversary (for $r > \frac{1}{2}$) can increase the size of a given queue in the ingress edge of the chain by any desired factor to get a large queue at the egress edge of the chain (using a sufficiently long chain). We then prove that a queue in the egress edge of the chain can be translated to a queue of fresh packets in the ingress edge of the chain by losing only a fraction of the size of the queue.

Since in our construction packets have long routes, we find it more convenient to specify the routes in an "on-line" fashion. That is, when we construct the adversary, we do not specify the complete routes of the packets when they are injected (even though we can, in principle). Rather, we prove below some conditions that allow us to reroute packets without violating the capacity constraints. Formally, this is done by altering the adversary. We find this technique useful in the sense that it makes the construction more "localized." We stress that this is just a matter of representation: the actual adversary used to prove the results is the same rate-r adversary used, e.g., in [4, 11, 15].

The proof is structured as follows. In section 3.1 we specify the conditions under which packets can be rerouted. In section 3.2 we specify and analyze a rate-r adversary for two daisy-chained gadgets. Some small adversaries used for "gluing" and the overall adversary are specified in section 3.3.

3.1. Packet rerouting. In this section we prove a technical lemma that allows us to construct adversaries "on the fly" for FIFO. Informally, it says that if there is a set of packets that have routes that already share a single edge, then these packets can be arbitrarily rerouted as long as they are routed to new edges. In fact, the rerouting technique can be applied to a large class of queuing policies defined below.

DEFINITION 3.1. *A queue policy is called* historic *if the scheduling decisions are independent of the remaining routes beyond the next edge of each packet.*

Note that policies that are based on the arrival time at the buffer (such as FIFO and LIFO), on the injection time (e.g., LIS and NIS), or on the route from the source (e.g., FFS) are examples of historic policies. Note that a historic queue policy must not even depend on the destinations of the packets. For example, FTG and NTG are not historic. (Historic policies are called *nonpredictive* in [16].)

First, we define formally the notion of new edges.

DEFINITION 3.2. *Let G be a graph, $\mathcal{Q}$ a queuing policy, and $\mathcal{A}$ a rate-r adversary. Let t be a time step in the execution of $\mathcal{Q}$ in G under $\mathcal{A}$. Let P be a subset of the packets that are in the network at time t. Let t^* be the minimum injection time of all packets in P. An edge e is* new to P *if e is not a member of any route of a packet (either in P or not) injected by $\mathcal{A}$ at times $\tau \geq t^* - \lceil \frac{1}{r} \rceil$.*

We remark that since in this paper we deal with rates larger than $\frac{1}{2}$, then $\lceil \frac{1}{r} \rceil \leq 2$.

We can now state and prove our rerouting claim.

LEMMA 3.3. *Let $\mathcal{Q}$ be a deterministic historic queue policy, G a graph, $\mathcal{A}$ a rate-r adversary, and t a time step. Let $P(t)$ be the set of packets in the network at time t. For each $p \in P(t)$, denote the next edge to be traversed by p at time t by e_p, and denote the complete path of p by $q_p e_p r_p$. Let $P_0 \subseteq P(t)$ be a set of packets whose routes have at least one edge common to all. Then for any set of paths $\{r'_p \mid p \in P_0\}$ that consist of edges that are new to $P(t)$, there exists a rate-r adversary $\mathcal{A}'$ such that the following holds true.*

1. *The execution of the system under $\mathcal{A}$ and $\mathcal{A}'$ is identical until time t.*
2. *For every packet p injected by $\mathcal{A}$ there is a packet p injected by $\mathcal{A}'$ at the same time.*
3. *If $p \in P_0$, then its route under $\mathcal{A}'$ is $q_p e_p r'_p$.*
4. *If $p \notin P_0$, then its route under $\mathcal{A}'$ is $q_p e_p r_p$.*

Proof. Define $\mathcal{A}'$ as follows. $\mathcal{A}'$ injects the same number of packets as $\mathcal{A}$ and at the same times. For $p \in P_0$, set the route of p to $q_p e_p r'_p$. For $p \notin P_0$ set the route of p to $q_p e_p r_p$. Clearly, claims (1), (2), (3), and (4) follow directly from the assumption that $\mathcal{Q}$ is historic and by the construction. We need only to verify that $\mathcal{A}'$ is a rate-r adversary. To see this, first note that the load on any non-new edge may have only been reduced. Now, consider any edge e in $\bigcup_{p \in P_0} r'_p$. Let $\hat{e}$ be the edge common to the routes of all $p \in P_0$. Let t^* be the minimum injection time over all packets in $P(t)$.

Consider any time interval $[t_1, t_2]$. If $t_2 < t^*$, then the number of packets injected in $[t_1, t_2]$ by $\mathcal{A}'$ and that require e is equal to the number of packets injected in $[t_1, t_2]$ by $\mathcal{A}$ and that require e. If $t_2 \geq t^*$ we consider time intervals $I = [t_1, t^*)$ and $I' = [t^*, t_2]$. For interval I the number of packets injected by $\mathcal{A}'$ and that require e is the same as for $\mathcal{A}'$, which is at most $\lceil ((t^* - \lceil \frac{1}{r} \rceil) - t_1) r \rceil$, since e is a new edge with

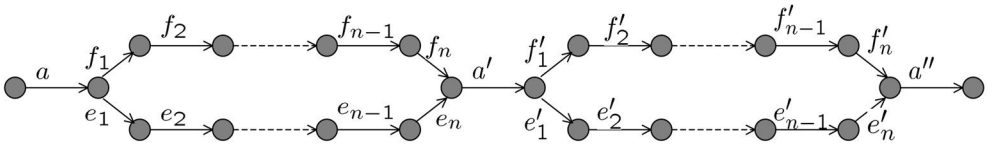

FIG. 3.1. *The graph F_n^2: two F_n gadgets glued together. The left gadget is called F, and the right gadget is called F'. Edge a' is the egress of F and the ingress of F'.*

respect to $P_0 \subseteq P(t)$ and time t^* is the minimum injection time of all packets in $P(t)$ (see Definition 3.2). For interval I' the number of packets injected in I' by $\mathcal{A}'$ and that require e is at most the number of packets injected in I' by $\mathcal{A}$ and that require $\hat{e}$. This is at most $\lceil (t_2 - t^* + 1)r \rceil$. The total number of packets injected by $\mathcal{A}'$ in $[t_1, t_2]$ and that require e is therefore at most $\lceil ((t^* - \lceil \frac{1}{r} \rceil) - t_1)r \rceil + \lceil (t_2 - t^* + 1)r \rceil$. This is at most $\lceil (t_2 - t_1 + 1)r \rceil$, as required. □

Remark 1. Lemma 3.3 allows us to use a "dynamic" adversary that changes the routes of packets on-line. However, this is only a matter of presentation: we do not change the power of the adversary; we only construct it in a succession of refinements. The main advantage of the lemma is that it allows us to modify the remainder of the routes arbitrarily, under the specified restrictions (shared edge in old routes, new edges in modified routes, and historic policy); we do not have to worry about capacity constraints of new edges.

Remark 2. Note that a packet may be rerouted several times, as long as the number of reroutings is finite.

3.2. Gadgets and their adversaries. We now define the gadgets that we use and their local adversaries.

DEFINITION 3.4. *A* gadget *is a directed acyclic graph with one edge called* ingress *emanating from a degree-*1 *source, and one edge called* egress*, leading to a degree-*1 *sink. Given two gadgets G, H, define $G \circ H$ to be the gadget that results from identifying the egress of G with the ingress of H. The ingress of $G \circ H$ is the ingress of G, and the egress of $G \circ H$ is the egress of H.*

For any gadget F, let F^0 denote the single edge graph which is both ingress and egress. For $i > 0$, we denote $F^i = F^{i-1} \circ F$. We call the "$\circ$" operation *daisy-chaining*.

We will use a parametric gadget denoted F_n, which consists of ingress edge a, egress edge a', and two parallel paths of length n from the ingress edge to the egress edge, whose edges are denoted $e_1, \ldots, e_n$ and $f_1, \ldots, f_n$. Figure 3.1 shows F_n^2.

We will construct an adversary that maintains the following *gadget invariant*.

DEFINITION 3.5. *$C(S, F_n)$ is said to be true at a given time if the following holds at that time on graph F_n.*

1. *The total number of packets in the buffers of $e_1, \ldots, e_n$ is S.*
2. *For each $i = 1, \ldots, n$, the buffer of e_i is nonempty, and the packets in e_i have remaining routes $e_i, e_{i+1}, \ldots, e_n, a'$.*
3. *There are S packets in the buffer of edge a, all with the same remaining route $a, f_1, \ldots, f_n, a'$.*
4. *There are no other packets in F_n.*

In our construction, we use a daisy chain of many gadgets. However, we start by considering two daisy-chained gadgets, namely the graph F_n^2 (Figure 3.1). We denote the first gadget of F_n^2 by F, and the second by F', and add a prime to the name of all edges in F'. The conditions of the following lemma are designed to allow repeated

rerouting, but essentially the idea is to have the condition $C(S,F)$ carry over from one gadget to the next, with a larger value S.

LEMMA 3.6. *Let $r = \frac{1}{2} + \epsilon$ for some $\epsilon > 0$. There exist numbers n and S_0 that depend on ϵ, such that for any $S > S_0$, if in the graph F_n^2 we have that for some time τ, all packets present at time τ were injected after time τ_0, and*

- *$C(S,F)$ holds at time τ, and*
- *F' is empty at time τ, and*
- *no packets using edges in F' were injected in the time interval $[\tau_0 - \lceil 1/r \rceil, \tau]$,*

then there exists a rate-r adversary for F_n^2 such that at time $\tau + 2S + n$, $C(S', F')$ holds for some $S' \geq S(1+\epsilon)$, and F is empty.

Proof. To define the adversary, we use the notation $R_i \stackrel{\text{def}}{=} \frac{1-r}{1-r^i}$ for $1 \leq i \leq n$. Note, for later reference, that for all i,

$$\frac{R_i}{r + R_i} = R_{i+1} \ . \tag{3.1}$$

We first choose parameters under the constraints below:

$$n > \max\left(\frac{\log\epsilon - 2}{\log r}, \quad 1 - \frac{1}{\log r}\right),$$
$$S_0 > \max\left(2n, \quad \frac{n}{2(R_n - R_{n+1})}\right).$$

We remark that for small ϵ values, we get $n = \Theta(\log \frac{1}{\epsilon})$ and $S_0 = \Theta(nr^{-n}) = \Theta(\frac{1}{\epsilon}\log\frac{1}{\epsilon})$ (see the appendix for a detailed derivation of the asymptotic bounds).

Let us assume, for simplicity of notation, that $\tau = 0$. We now specify the adversary that will create a situation where $C(S', F')$ holds for $S' = 2S(1 - R_n)$. In the adversary specification, as well as in the ensuing analysis, we ignore floors and ceilings for the sake of simplicity of presentation. We remark that carrying these throughout the computations would add only additive terms that can be compensated for by using a larger S_0 value (cf. [4, 11, 15]).

The adversary is as follows.

(1) Extend the routes of all packets stored in F at time 0 by adding the path $e'_1, \ldots, e'_n, a''$.
(2) For every edge e'_i in F' ($i = 1, \ldots, n$), packets are injected at rate r in the time steps $i, i+1, \ldots, i+t_i$, where $t_i \stackrel{\text{def}}{=} \frac{2S}{r+R_i}$. The route of each of these packets is the single edge e'_i.
(3) In the time interval $[1, S]$, rS packets are injected, at rate r, with route $a, f_1, \ldots, f_n, a', f'_1, \ldots, f'_n, a''$.
(4) Let $X = S' - rS + n$. X packets are injected in the first $X \cdot \frac{1}{r}$ time steps of the interval $[S+n+1, S+n+S]$, with routes $a', f'_1, \ldots, f'_n, a''$. (We show later that $0 \leq X \leq rS$.)

First, note that this is a rate-r adversary: part (1) is justified by Lemma 3.3, since the routes of all packets stored in F share the edge a', and the extensions are for new edges as defined in Definition 3.2.

Edges $e'_1, \ldots, e'_n$ are used only by part (2) at rate r. Edges $f'_1, \ldots, f'_n$ and a'' are used at rate r in parts (3) and (4), which cover disjoint time intervals. It remains to show that $0 \leq X \leq rS$.

CLAIM 3.7. *For every $r < 1$, we have $0 < X \leq rS$.*

Proof. First we prove that $X > 0$. By definitions,

$$\begin{aligned} X \;>\; X - n &= S' - rS \\ &= 2S(1 - R_n) - rS \\ &= S\left(2 - \frac{2-2r}{1-r^n} - r\right) . \end{aligned}$$

Now,

$$\begin{aligned} 2 - \frac{2-2r}{1-r^n} - r &= \frac{r - 2r^n + r^{n+1}}{1-r^n} \\ &> \frac{r-2r^n}{1-r^n} \\ &> 2r(1-2r^{n-1}) \\ &> 0 , \end{aligned}$$

since $r^n < r^{n-1} < 1/2$ by the choice of n, and hence $X > 0$. Next we prove that $X \le rS$. By the definitions,

$$\begin{aligned} rS - X &= rS - (2S(1-R_n) - rS + n) \\ &= 2S(r + R_n - 1) - n . \end{aligned}$$

Since $S \ge S_0 > \frac{n}{2(R_n - R_{n+1})} \ge \frac{n}{2(r+R_n-1)}$ by assumption, we get $rS - X > 0$. □

We now show that in fact at time $2S + n$, $C(S', F')$ holds and that F is empty. This will be sufficient, since by the definition of S' we have that

$$\begin{aligned} S' &= 2S(1-R_n) \\ &= 2S\left(\frac{r}{1-r^n} - \frac{r^n}{1-r^n}\right) \\ &\ge 2S(r - 2r^n) \\ &\ge 2S\left(\frac{1}{2} + \epsilon - \frac{\epsilon}{2}\right) \\ &= S(1+\epsilon) . \end{aligned}$$

(The inequalities follow from the fact that $1 - r^n \le 1$ and since $r^n \le 1/2$ and $4r^n < \epsilon$ by the choice of n.)

We now proceed to prove that $C(S', F')$ holds at time $2S + n$. Let us call the packets described in part (1) of the definition of the adversary *old* packets, the packets described in part (2) *new short* packets, and the packets described in parts (3) and (4) *new long* packets.

We start with the following straightforward property.

CLAIM 3.8. *In each step in the time interval* $[1, 2S]$*, one old packet crosses* a'*.*

Proof. Since there are S old packets in the buffers of edges e_i, there are no other packets in these buffers, and none of them is empty at time 0, then these S packets will arrive at the tail of a' one in each time step in time interval $[1, S]$. The S packets stored at the tail of a at time 0 will arrive at the tail of a', one in each time step, in the time interval $[n, S + n]$. Since $S > n$, the claim follows. □

The next claim shows that old packets cross edges e'_i at rates that decrease as i grows. This is due to the injection of the new short packets.

CLAIM 3.9. *The following holds for any edge* e'_i*,* $i \in [1, n]$*.*

(1) *At times* $[0, i]$*, no packet arrives at the tail of* e'_i*.*
(2) *At times* $[i+1, 2S+i]$*, old packets arrive at the tail of* e'_i *at rate* R_i*.*
(3) *At time* $i+2S+1$*, there are no new short packets in the buffer of* e'_i*.*

Proof. Part (1) is straightforward by the fact that old packets must cross at least $i+1$ edges before they arrive at the tail of e'_i and because no new packet is injected for e'_i before time i. Part (2) is proven by induction on i. For the basis $i = 1$ we have that packets arrive at the tail of e'_1 at rate $R_1 = 1$ by Claim 3.8. For the induction step, let $i > 1$. The induction hypothesis says that packets arrive at the tail of e'_{i-1} at rate R_{i-1}. By part (2) of the definition of the adversary, new packets are injected at the tail of e'_{i-1} at rate r. Note that $R_{i-1} + r > 1$. Since the queue policy is FIFO, it follows that old packets cross e'_{i-1}, and hence arrive at the tail of e'_i, at rate $\frac{R_{i-1}}{R_{i-1}+r}$. By (3.1) this is exactly R_i. This proves part (2). To see that part (3) is true, note that as a consequence of part (2), we have that short new packets cross e'_i at rate $\frac{r}{R_i+r}$. The last short new packet for e'_i is injected at time $i + t_i = i + \frac{2S}{r+R_i}$, in which time there are $t_i(r + R_i - 1)$ packets in the buffer of e'_i. Using the definition of t_i, it follows that all new short packets of e'_i will be absorbed by time

$$i + t_i + t_i(r + R_i - 1) = i + t_i(r + R_i) = i + 2S \ . \qquad \square$$

Using the above claims, we show that $C(S', F')$ holds at time $2S + n$. We start with part (1) of $C(S', F')$.

Claim 3.10. *At time* $2S+n$*, there is a total of* S' *old packets stored in the buffers of edges* e'_i*.*

Proof. By Claim 3.9, $2S \cdot R_n$ old packets cross a'' by time $2S + n$. On the other hand, by Claim 3.8, all the $2S$ old packets crossed a' by time $2S$. The claim follows. $\square$

Next, we prove that part (2) of $C(S', F')$ holds.

Claim 3.11. *If* $S > S_0$*, then none of the buffers of* e'_i *is empty at time* $2S + n$*. Moreover, the route of any packet stored in* e'_i *at that time is* $e'_i, \ldots, e'_n, a''$*.*

Proof. The claim on the remaining routes is obvious from the construction. We now prove that the buffer of e'_i is not empty. The last short packet for e'_i is injected in e'_i at time $i + t_i$, and, as argued in the proof of Claim 3.9, it crosses e'_i at time $2S + i$. Hence all packets that arrive at the buffer of e'_i in the time interval $[i + t_i, 2S + i]$ are still in the buffer of e'_i at time $2S + i$. All these packets are old packets that arrive from e_{i-1}. By Claim 3.9, there are $(2S - t_i)R_i$ such packets. Let $Q_i \stackrel{\text{def}}{=} (2S - t_i)R_i$ be the number of packets in the buffer of e'_i at time $2S + i$. Note that by definition, $t_i \le t_{i+1}$ and $R_i \ge R_{i+1}$, and hence $Q_i \ge Q_{i+1}$ for $1 \le i < n$. In addition, since only $n - i$ packets may leave the buffer of e'_i in the time interval $[2S + i, 2S + n]$, it is sufficient to prove that $Q_n \ge n$. Substituting the values we get

$$\begin{aligned} Q_n &= (2S - t_n)R_n \\ &= 2SR_n - t_nR_n \\ &= 2S\left(R_n - \frac{R_n}{r + R_n}\right) \\ &= 2S\left(R_n - R_{n+1}\right) \ . \end{aligned}$$

Since $S \ge S_0 > \frac{n}{2(R_n - R_{n+1})}$, we get that $Q_n \ge n$. $\square$

We now prove that part (3) of $C(S', F')$ holds.

Claim 3.12. *The number of packets at the tail of* a' *at time* $2S + n$ *is* S'*.*

Proof. First, observe that in time interval $[1, S+n]$ the number of packets that arrive at the tail of a' is exactly $2S$, and they start arriving at time 1. Therefore at time $S+n$ there are exactly $S-n$ packets in the buffer of a'. In addition, by part (3) of the definition of the adversary, rS new long packets are injected at the tail of a in the time interval $[1, S]$. These packets start crossing a at time $S+1$, since they are queued behind the S old packets stored in a at time 0. Hence the new long packets start arriving at a' at time $S+n+1$. In addition, part (4) of the definition of the adversary says that X new long packets are injected at the tail of a' during time interval $[S+n, 2S+n]$. In conclusion, there are $X+rS$ new long packets arriving at a' in the interval $[S+n, 2S+n]$. Together with the $S-n$ packets stored at the tail of a' at time $S+n$, we have that at time $2S+n$, the number of packets stored in the buffer of a' is exactly $rS+X-n=S'$, by definition of X. All these packets have the paths that are required by $C(S', F')$. □

To conclude the proof of Lemma 3.6, we argue that F is empty at time $2S+n$. This follows from the fact that there are no injections into edges of F during time interval $[0, 2S+n]$ and that all the $2S$ packets present in F at time 0 arrive at the tail of the ingress of F' by time $S+n$. □

3.3. Putting the gadgets together. In this section we describe how to construct the overall adversary, using the gadget adversary described in section 3.2, and a few other simple adversaries used to glue things together.

The idea of the proof is to use a sufficiently long daisy chain of gadgets that blows up the queue size by a sufficiently large factor (that depends on the length of the chain and r) and then "stitch together" the egress of the chain to its ingress, getting a queue of fresh packets. The stitching process loses a fraction (that depends on r) of the queue size, but this loss is more than compensated by the chain of gadgets.

Fix $r = \frac{1}{2} + \epsilon$ for $\epsilon > 0$ and S_0 and n as in the proof of Lemma 3.6. Consider the graph F_n^M that consists of a daisy chain of M F_n gadgets, where M is a parameter. Let the kth gadget be denoted by $F(k)$ for $1 \le k \le M$. We now prove the following lemma.

LEMMA 3.13. *Let M be a positive integer, and consider the graph F_n^M. If for some time τ we have that all packets present in the network were injected after time τ_0, and*

- *$C(S, F(1))$ holds at time τ for $S \ge S_0$,*
- *there are no other packets in F_n^M at time τ, and*
- *the edges of $F_n^M \setminus F(1)$ were not used by any injection in the time interval $[\tau_0 - \lceil 1/r \rceil, \tau]$,*

then there is a rate-r adversary such that at some time $t > \tau$, there are S' packets at the egress of F_n^M, for $S' \ge S(1+\epsilon)^{M-1}/2$, and there are no other packets in F_n^M.

Proof. We first prove the following claim.

CLAIM 3.14. *Let $1 \le i \le n$. If at time τ we have that all packets present in the network were injected after time τ_0, and*

- *$C(S, F(1))$ holds for $S \ge S_0$,*
- *there are no other packets in $F(1), \ldots, F(i)$, and*
- *the edges of $F(2), \ldots, F(M)$ were not used by any injection in the time interval $[\tau_0 - \lceil 1/r \rceil, \tau]$,*

then there is a rate-r adversary and time $t_i \ge \tau$ such that

- *$C(S', F(i))$ holds for $S' \ge S(1+\epsilon)^{i-1}$ at time t_i,*
- *there are no other packets in F_n^M, and*

- *the edges of* $F(i+1), \ldots, F(M)$ *were not used by any injection in the time interval* $[\tau_0 - \lceil 1/r \rceil, t_i]$.

Proof. The proof is by induction on i. For $i = 1$ the claim is trivial with $t_1 = \tau$. For the induction step, assume that the lemma holds for $1 < i < M$, i.e., that there exists an adversary $\mathcal{A}_i$ and time t_i such that at time t_i, $C(S_i, F(M))$ holds for $S_i \geq S(1+\epsilon)^{i-1}$. Consider now the subgraph that consists of $F(i)$ and $F(i+1)$. By the induction hypothesis, we may apply Lemma 3.6 to know that there exists an adversary $\mathcal{A}$ such that at time $t_i + 2S_i + n$, $C(S', F(i+1))$ holds for $S' \geq S_i(1+\epsilon) \geq S(1+\epsilon)^i$. We note that the packets injected by $\mathcal{A}$ (as specified in Lemma 3.6) do not use any edge in $F(i+2), \ldots, F(M)$ and that the application of this adversary leaves $F(i)$ empty of packets. This proves the claim with $t_{i+1} = t_i + 2S_i + n$ and the adversary that results from concatenating the adversaries $\mathcal{A}_i$ and $\mathcal{A}$. □

To complete the proof of Lemma 3.13, we observe that if at time t we have that $C(S, F_n)$ holds for some gadget F_n and $S \geq S_0$, and if no injections are done in the interval $[t, t+S+n]$, then at time $t+S+n$ there are at least $S/2$ packets queued at the egress of F_n. This is true since during time interval $[t+1, t+S+n]$ exactly $2S$ packets arrive at the tail of the egress of F_n, and, therefore, at time $t+S+n$ there are $S - n \geq S_0 - n \geq S/2$ packets in the egress buffer.

Note that a packet may be rerouted in the whole construction at most $M-1$ times: once for each gadget $F(2), \ldots, F(M)$. This completes the proof of Lemma 3.13. □

We now specify two more constructions. The first shows how to establish $C(S, F_n)$ starting from a state in which the only packets in F_n are in the buffer of the ingress of F_n. The second construction shows how to replace a queue of packets with another queue of *fresh* packets. This is necessary so we can stitch the end of the daisy chain to its beginning.

We now claim the existence of an adversary that establishes $C(S, F_n)$ starting from a single buffer. The construction is a variant of the adversary presented in the proof of Lemma 3.6.

LEMMA 3.15. *For any* $\epsilon > 0$, *let* n *and* S_0 *be as in Lemma* 3.6. *Let* $S > S_0$, *and let* τ *be a time step. Suppose that at time* τ *all the packets in the network are* $2S$ *packets stored in the ingress edge of* F_n, *they all have remaining routes of length* 1, *and they were all injected after time* τ_0 *for some* τ_0. *If the other edges of* F_n *were not used by any injection in the time interval* $[\tau_0 - \lceil 1/r \rceil, \tau]$, *then there is a rate-*r *adversary for* $r = \frac{1}{2} + \epsilon$ *such that at time* $\tau + 2S + n$ *condition* $C(S', F_n)$ *holds for* $S' \geq S(1+\epsilon)$.

Proof. Let us again assume for convenience of notation that $\tau = 0$. We use the notations and definitions of t_i and R_i from the proof of Lemma 3.6. We also define $S' = 2S(1 - R_n)$. The adversary is defined as follows.

(1) Extend the route of the packets stored in the ingress edge a to be $a, e_1, e_2, \ldots, e_n, a'$.
(2) For each $1 \leq i \leq n$, inject packets at rate r with the single edge route e_i in the time interval $[i, t_i]$.
(3) In the first $(S'+n)/r$ time steps of time interval $[1, 2S]$ inject $S'+n$ packets at rate r. The first n packets have path of length 1 (i.e., a only), and the rest have the path $a, f_1, \ldots, f_n, a'$. Observe that indeed $(S'+n)/r \leq 2S$, by the choice of n and S_0.

We first note that this is a rate-r adversary by Lemma 3.3. We now prove that $C(S', F_n)$ holds at time $2S+n$. First, observe that in each step of the interval $[1, 2S]$,

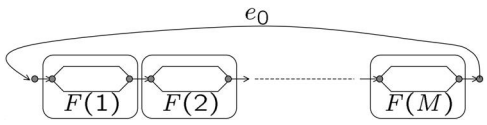

FIG. 3.2. *The graph used in the proof of Theorem* 3.17. *The edge between $F(i)$ and $F(i+1)$ is the egress of $F(i)$ and the ingress of $F(i+1)$, and it is part of both $F(i)$ and $F(i+1)$.*

a single packet crosses a. By the same arguments as those in the proofs of Claims 3.9, 3.10, and 3.11 (applied here to F_n, instead of F' there), we have that at time $2S+n$ there are S' packets in the buffers of edges $e_1, \ldots, e_n$, that none of these buffers is empty, and that the packets in e_i have remaining routes $e_i, e_{i+1}, \ldots, e_n, a'$. Next, consider a. After $2S$ time steps, all old packets leave a; after additional n time steps all packets with path of length 1 injected in step (3) disappear too, and therefore, at time $2S+n$, we have exactly S' packets in a, with remaining routes $a, f_1, \ldots, f_n, a'$, as required. □

We now show the existence of an adversary that replaces a queue of old packets with another (smaller) queue of fresh packets. To do this, we consider a graph of three edges in series, called a_0, a_1, and a_2. The routes that will be traversed by old packets will all end at a_0, and the fresh packets all start at the tail of a_2. (We use three edges instead of two so as to avoid cyclic routes in our final construction.)

LEMMA 3.16. *Suppose that at time τ there are S packets stored in the buffer of a_0 with remaining routes of length* 1. *Then for any $r > 0$ there exists a rate-r adversary such that at time $\tau + S + rS + r^2S$ there are r^3S packets stored in the buffer of a_2 and there are no other packets in the network. Moreover, all the packets stored in the buffer of a_2 were injected at the tail of a_2 after time $\tau + S$.*

Proof. Let us assume for convenience of notation that $\tau = 0$. Call the packets that exist in the network at time 0 *old packets*. The execution is as follows.

(1) In the time interval $[1, S]$, rS packets are injected at the tail of a_0. These packets have routes a_0, a_1, a_2. All these packets are queued behind the old packets, and they start to move only at time S.
(2) In the time interval $[S+1, S+rS]$, r^2S packets are injected at the tail of a_2. These packets mix with the packets that were injected in step (1). At time $S + rS$, there is a queue of r^2S packets waiting for a_2, and no other packets exist in the network.
(3) In the time interval $[S + rS, S + rS + r^2S]$, r^3S new packets are injected at the tail of a_2. These packets are queued behind the packets injected in steps (1) and (2).

Note that by time $S+rS+r^2S$, all packets from steps (1) and (2) are absorbed. □

We are now ready to prove our main result. Note that the assumption of a specific initial state does not restrict the generality of the statement (see, e.g., [4]).

THEOREM 3.17. *For every $\epsilon > 0$ there exists a graph G_ϵ, a rate-r adversary for $r = \frac{1}{2} + \epsilon$, and an initial configuration such that FIFO is unstable on G_ϵ under that adversary starting from that initial configuration.*

Proof. The graph is defined as follows. Let S_0 and n be as required by Lemma 3.6 for ϵ. Choose M such that $\frac{r^3(1+\epsilon)^M}{4} > 1$. The graph consists of F_n^M (i.e., M daisy-chained gadgets), with one additional edge called e_0 connecting the head of the egress edge of the last gadget in the chain ($F(M)$) to the ingress edge of the first gadget in the chain ($F(1)$). See Figure 3.2.

In the initial configuration, there are $S^* > 2S_0$ packets in the ingress edge of

$F(1)$, all with paths of length 1 (i.e., their paths are composed of the ingress of $F(1)$). The adversary is defined by an iterative construction that works as follows. Let $S_1 = S^*$.

(1) Apply the adversary of Lemma 3.15 to get a configuration where $C(S_2, F(1))$ holds for $S_2 \geq \frac{S_1}{2}(1+\epsilon)$.
(2) Apply the adversary of Lemma 3.13 to get a configuration where S_3 packets are stored in the egress of $F(M)$ for $S_3 \geq S_2 \frac{(1+\epsilon)^{M-1}}{2}$.
(3) Apply the adversary of Lemma 3.16 to the three-edge path that consists of the egress of $F(M)$, then e_0, and then the ingress of $F(1)$. This results in S_4 packets stored at the tail of the ingress of $F(1)$, all with paths of length 1, for $S_4 \geq r^3 S_3$. Let $S_1 \leftarrow S_4$, and go to step (1).

We first claim that the above construction is indeed a valid rate-r adversary. We claim inductively that the conditions that allow the construction of each adversary by Lemmas 3.15, 3.13, and 3.16 hold when these constructions are applied. We base the proof for each iteration of the adversary on the following condition, which we will prove by induction on time to hold at the start of each iteration. The condition is that when the iteration starts at time τ, then it holds that all the buffers in the network are empty except the buffer of the ingress of $F(1)$; that all packets in this buffer have routes of length 1; and that in time interval $[\tau_0 - \lceil 1/r \rceil, \tau]$ there were no injections of packets requiring any other edge in the network, where τ_0 is the earliest injection time of any packet residing in the buffer of the ingress of $F(1)$ at time τ. This condition clearly holds for time $\tau = 0$ when we start with the initial configuration as described above.

Now assume that the above condition holds at time τ when an iteration starts. Then the conditions of Lemma 3.15 hold. We therefore can apply the adversary of Lemma 3.15. The resulting situation is the situation as required by the conditions of Lemma 3.13. Observe that the adversary of Lemma 3.15 does not use any edge in the network beyond the edges of $F(1)$; therefore the conditions of that lemma on the nonuse of the edges of $F_n^M \setminus F(1)$ hold. We can therefore apply the adversary of Lemma 3.13. The resulting situation is the situation in the conditions of Lemma 3.16. Observe also that by Lemma 3.13 there are no other packets in the network at that time. We can now apply the adversary of Lemma 3.16. This results in a set of packets in the buffer of the ingress of $F(1)$. Note that now there are no other packets in the network. Further observe that all the packets at the ingress of $F(1)$ were injected at least S time steps into the activation of the adversary of Lemma 3.16 and that once they start being injected, no other packet is injected. Therefore it follows that no edge of the graph, except the ingress of $F(1)$, was used by the adversary after time $\tau_0 - \lceil 1/r \rceil$, where τ_0 is the earliest injection time of the packets at the ingress of $F(1)$. We therefore have that the condition for the start of the iteration holds again.

We note that no packet is rerouted more than M times: once in step (1) and at most $M-1$ times in step (2).

Finally, we show that S_1 grows unboundedly under this adversary. After step (1) is executed, we have that $S_2 \geq \frac{S_1}{2} \cdot (1+\epsilon)$. Hence, after step (2) we have that $S_3 \geq S_2 \frac{(1+\epsilon)^{M-1}}{2} \geq S_1 \frac{(1+\epsilon)^M}{4}$. Finally, after step (3), we have that the number of packets stored at the tail of the ingress edge of $F(1)$ is $S_4 \geq r^3 S_3 \geq S_1 \frac{r^3(1+\epsilon)^M}{4}$. By the choice of M we have that $S_4 > S_1$. □

4. Stability under low injection rates. In this section we show that FIFO, and in fact any greedy protocol, is stable if the injection rate is below some threshold.

We start with the case where the network is initiated with empty buffers. We later consider the case where the adversary starts the system with an arbitrary initial configuration of an arbitrary set of packets in the buffers.

We start with the case where the network starts with empty buffers. We prove that any network is stable with *any greedy* protocol in the face of a (w, r) adversary, if $r \leq 1/(d+1)$, where d denotes the length (in edges) of the longest path followed by any packet. In particular, we prove below that any packet stays in any one queue no more that $\lfloor wr \rfloor$ time steps. For a certain class of protocols, which includes the protocol FIFO, the bound can be improved to $1/d$.

THEOREM 4.1. *For any network, if the sequence of packets is injected by a (w, r) adversary, with $r \leq 1/(d+1)$, and the schedule is a greedy schedule, then no packet stays in the same buffer more than $\lfloor wr \rfloor$ time steps.*

Proof. We prove, by induction on t, that any packet that arrives at a buffer at time step t leaves this buffer by time $t + \lfloor wr \rfloor$.

The base of the induction is any $t \leq dwr+1$. Let p be a packet that arrives at the buffer at the tail of edge e at time $t \leq dwr+1$. Assume towards a contradiction that p is in the same buffer at the end of time step $t+\lfloor wr \rfloor$. This means that for each of the $\lfloor wr \rfloor$ time steps in $[t+1, t+\lfloor wr \rfloor]$ some other packet was sent over edge e (since we consider a *greedy* protocol). Therefore we can identify $\lfloor wr \rfloor + 1$ packets that require edge e and are injected into the network by the end of time step $t + \lfloor wr \rfloor - 1$ (these are the packet p itself and the $\lfloor wr \rfloor$ packets that were sent over e). Since $t \leq dwr+1$, we have $t + \lfloor wr \rfloor - 1 \leq (d+1)wr$. By the definition of the adversary the number of packets that require e and are injected by the end of any time step $t' \leq (d+1)wr$ is at most $\lceil (d+1)r \rceil \lfloor wr \rfloor$. Since we assume $r \leq 1/(d+1)$ this is at most $\lfloor wr \rfloor$. This is a contradiction to the fact that we identified $\lfloor wr \rfloor + 1$ packets.

We now prove the claim for any $t > dwr+1$. This is done based on the induction hypothesis that for any packet that arrives at some buffer at time $t' < t$, this packet leaves the buffer by time step $t' + \lfloor wr \rfloor$. Let p be a packet that arrives at the buffer at the tail of edge e at some time step t. Consider any packet that requires edge e and was injected by time step $t - d\lfloor wr \rfloor$. Using the induction hypothesis we know that such a packet left the buffer into which it was injected by time step $t - d\lfloor wr \rfloor + \lfloor wr \rfloor$, left the next buffer by time step $t - d\lfloor wr \rfloor + 2\lfloor wr \rfloor$, and left the ith buffer on its path by time step $t - d\lfloor wr \rfloor + i\lfloor wr \rfloor$. It therefore arrived at its destination by time step $t - d\lfloor wr \rfloor + d\lfloor wr \rfloor = t$ (since the length of its path is at most d, and all its "arrival times" are earlier than t, so the induction hypothesis holds). It follows that any packet that can delay packet p from going over edge e must be injected at time step $t - d\lfloor wr \rfloor + 1$ or later. Now assume towards a contradiction that packet p is still at the tail of edge e at the end of time step $t + \lfloor wr \rfloor$. That is, there are $\lfloor wr \rfloor$ other packets that crossed edge e in $[t+1, t+\lfloor wr \rfloor]$. As before, this identifies $\lfloor wr \rfloor + 1$ distinct packets that require edge e, are present in the network at the end of time step t or later, and are injected by time step $t + \lfloor wr \rfloor - 1$. However, we know that any packet injected by time step $t - d\lfloor wr \rfloor$ already left the network by the end of time step t. Therefore those $\lfloor wr \rfloor + 1$ packets must have been injected in $[t - d\lfloor wr \rfloor + 1, t + \lfloor wr \rfloor - 1]$. There are $\lfloor wr \rfloor (d+1) - 1$ time steps in this interval; therefore the number of packets that require e and can be injected during this interval is bounded by $\lceil (d+1)r \rceil \lfloor wr \rfloor$. Since $r \leq 1/(d+1)$ this is at most $\lfloor wr \rfloor$, a contradiction. ∎

For protocols where a packet arriving at a certain buffer at time t has priority over any packet injected after time t, we can relax the condition that $r \leq 1/(d+1)$ to be $r \leq 1/d$. Note that among such protocols are the protocols FIFO and LIS.

Specifically, we define the following concept.

DEFINITION 4.2. *A* time priority *protocol is a greedy protocol under which a packet arriving at a buffer at time t has priority over any other packet that is injected after time t.*

For time priority protocols, we have the following.

THEOREM 4.3. *For any network, if the sequence of packets is injected by a (w, r) adversary, with $r \leq 1/d$, and the protocol is a time priority protocol, then no packet stays in the same buffer more than $\lfloor wr \rfloor$ time steps.*

The proof of Theorem 4.3 is the same as the proof of Theorem 4.1 with one change applied at two places: in the present case, when assuming towards a contradiction that packet p is still in the same buffer at the end of time step $t+\lfloor wr \rfloor$ and identifying the packets that cause this delay, we know that those packets must have been injected no later than time step t (rather than time $t + \lfloor wr \rfloor - 1$). This is because packets injected after time step t will not delay packet p if the protocol is a time priority protocol. This allows us to prove the lemma with the relaxed condition that $r \leq 1/d$. For completeness we give below the full proof.

Proof. We prove that any packet that arrives at any buffer at time step t leaves this buffer by time step $t + \lfloor wr \rfloor$. The proof is by induction on t.

We prove the base of the induction for any $t \leq dwr$. Let p be a packet that arrives at the buffer at the tail of edge e at time $t \leq dwr$. Assume towards a contradiction that p is in the same buffer at the end of time step $t + \lfloor wr \rfloor$. This means that during the $\lfloor wr \rfloor$ time steps in $[t+1, t+\lfloor wr \rfloor]$ some other packet was sent over edge e (since we consider a *greedy* protocol). We can therefore identify $\lfloor wr \rfloor + 1$ packets that require edge e (these packets are the packet p itself and the $\lfloor wr \rfloor$ packets that were sent over e). These packets must have been injected into the system by the end of time step t; any packet injected after t will not delay p according to a time priority protocol. Now, by the definition of the adversary the number of packets that require e and are injected by the end of any time step $t \leq dwr$ is at most $\lceil dr \rceil \lfloor wr \rfloor$. Since we assume $r \leq 1/d$ this is at most $\lfloor wr \rfloor$. This is a contradiction to the fact that we identified $\lfloor wr \rfloor + 1$ packets.

We now prove the claim for any $t > dwr$. This is done based on the induction hypothesis that for any packet that arrives at some buffer at time $t' < t$, this packet leaves this buffer by time step $t' + \lfloor wr \rfloor$. Let p be a packet that arrives at the buffer at the tail of edge e at some time step t. Consider any packet that requires edge e and was injected by time step $t - d\lfloor wr \rfloor$. Using the induction hypothesis we know that such a packet left the buffer into which it was injected by time step $t - d\lfloor wr \rfloor + \lfloor wr \rfloor$, left the next buffer by time step $t - d\lfloor wr \rfloor + 2\lfloor wr \rfloor$, and left the ith buffer on its path by time step $t - d\lfloor wr \rfloor + i\lfloor wr \rfloor$. It therefore arrived at its destination by time step $t - d\lfloor wr \rfloor + d\lfloor wr \rfloor = t$ (since the length of its path is at most d, and all its "arrival times" are earlier than t, so the induction hypothesis holds). It follows that any packet that can delay packet p from going over edge e must be injected at time step $t - d\lfloor wr \rfloor + 1$ or later. Now assume towards a contradiction that packet p is still at the tail of edge e at the end of time step $t + \lfloor wr \rfloor$. That is, there are $\lfloor wr \rfloor$ other packets that crossed edge e in $[t + 1, t + \lfloor wr \rfloor]$. As before, this identifies $\lfloor wr \rfloor + 1$ distinct packets that require edge e and are injected by the end of time step t; any packet injected after t will not delay p since the protocol is a time priority protocol. However, we know that any packet injected by time step $t - d\lfloor wr \rfloor$ already left the network by the end of time step t. Therefore those $\lfloor wr \rfloor + 1$ packets must have been injected in $[t - d\lfloor wr \rfloor + 1, t]$. There are $\lfloor wr \rfloor d$ time steps in this interval; therefore the

number of packets that require e and can be injected during this interval is bounded by $\lceil dr \rceil \lfloor wr \rfloor$. Since $r \leq 1/d$ this is at most $\lfloor wr \rfloor$, a contradiction. □

We now show that similar results hold when the adversary is allowed to initiate the system with an arbitrary set of packets in the network. In this case, the requirement for the rate is that it is less than (rather than at most) $1/(d+1)$ (or $1/d$ for time priority protocols). This follows from the fact that if an adversary starts the system with some initial set of packets and then injects packets as a (w, r) adversary, then the same sequence of packets can be given by an adversary that starts the system with an empty initial configuration and then injects packets as a (w^*, r^*) adversary for any $r^* > r$ and an appropriately chosen w^*. In the following we call an initial configuration an *S-initial-configuration*, for $S \geq 0$, if S is the maximum, over the edges $e \in E$, of the number of packets requiring e, in the initial configuration. We now give the following observation.

OBSERVATION 4.4. *Any sequence of packets given by a (w, r) adversary that starts with an S-initial-configuration can be given by a (w^*, r^*) adversary that starts with a 0-initial-configuration (i.e., with empty buffers) for any $r^* > r$ and $w^* = \lceil \frac{S+w+1}{r^*-r} \rceil$.*

Proof. We show that indeed a (w^*, r^*) adversary can inject the same sequence of packets without the need of an initial nonempty configuration. The new adversary will start with an empty configuration, will inject the packets of the initial state in time step 1, and will later inject in every time step t the same packets that the old adversary injected in time step $t-1$. By construction the new adversary starts with an empty configuration. It remains therefore to show that it is a valid (w^*, r^*) adversary.

To see that we show that in every consecutive w^* time steps the adversary injects at most $\lfloor w^* r^* \rfloor$ packets requiring any particular edge. We first note that

$$\lfloor w^* r^* \rfloor - w^* r > w^* r^* - 1 - w^* r = w^*(r - r^*) - 1 = \left\lceil \frac{S + w^* + 1}{r^* - r} \right\rceil (r - r^*) - 1 \geq S + w \, .$$

Therefore,

$$\lfloor w^* r^* \rfloor > S + w + w^* r \geq S + wr + w^* r \geq S + \left\lceil \frac{w^*}{w} \right\rceil \lfloor wr \rfloor \ .$$

We have two types of time intervals: one time interval that includes time step 1 (i.e., $[1, w^*]$) and any other time interval of w^* consecutive time steps. For the latter case, the new adversary injects in some time interval $[\tau, \tau + w^* - 1]$ the same packets as the old adversary injected in time interval $[\tau - 1, \tau - 1 + w^* - 1]$. For every edge e the maximum number of packets requiring e injected by the (w, r) adversary is at most $\lceil \frac{w^*}{w} \rceil \lfloor wr \rfloor$, so the new adversary does not violate its constraints. For time interval $[1, w^*]$, the number of packets requiring any particular edge given by the (w, r) adversary, either in the initial configuration or the first w^* time steps, is at most $S + \lceil \frac{w^*}{w} \rceil \lfloor wr \rfloor$. □

The following two corollaries now follow immediately from the above observation and from Theorems 4.1 and 4.3.

COROLLARY 4.5. *For any network, if the system is started with an S-initial-configuration, the sequence of packets is injected by a (w, r) adversary with $r < 1/(d+1)$ and the schedule is a greedy schedule, then no packet stays in the same buffer more than $\lfloor \lceil \frac{S+w+1}{\frac{1}{d+1} - r} \rceil \cdot \frac{1}{d+1} \rfloor$ time steps.*

COROLLARY 4.6. *For any network, if the system is started with an S-initial-configuration, the sequence of packets is injected by a (w, r) adversary with $r < 1/d$*

and the protocol is a time priority protocol, then no packet stays in the same buffer more than $\lfloor \lceil \frac{S+w+1}{\frac{1}{d}-r} \rceil \cdot \frac{1}{d} \rfloor$ *time steps.*

5. Conclusions. In this paper we show upper and lower bounds on the rates at which FIFO is stable. These results improve upon previous bounds [4, 11, 15]. We note that our lower bounds use shortest-paths (and hence noncircular) routes.

We also show that any greedy protocol is always stable against a (w, r) adversary for $r < 1/(d+1)$, where d is the length of the longest route used (or $r < 1/d$ for a certain class of protocols). Results in [7] show that the protocol FTG (and in fact also LIFO and NTS) can be unstable for arbitrarily low rates. The proofs there use a network and a set of paths such that in order to show that FTG is unstable for rate r, packets with paths of length $16/r$ are used. In view of these results, our bounds on r, in terms of d, are optimal up to a small constant factor. Furthermore, our stability results indicate that in order to show that FIFO can be unstable at arbitrarily low rates, one would need correspondingly long paths for the packets, as opposed to the (small) constant size networks (and hence constant size packet routes) used to prove previous results on the instability of FIFO.

The technique we use for the instability result, of constructing gadgets and chaining them, can be applied to various gadgets. For example, one can extract a gadget structure from the constructions of [4] or [11], compose them as in Theorem 3.17, and improve on the original bounds. Conceptually, our lower bound consists of two elements: the chain idea and a "good" gadget. We believe that this technique may lead to further improvements.

Appendix: Asymptotic bounds for Lemma 3.6. In this appendix we give asymptotic bounds for the parameters n and S_0 used in Lemma 3.6. Specifically, we show the following. Let $\epsilon > 0$ be given. We define the following quantities:

$$r = \frac{1}{2} + \epsilon \ , \tag{5.1}$$

$$R_i = \frac{1-r}{1-r^i} \quad \text{for all } i \geq 0 \ , \tag{5.2}$$

$$n = \max\left(\frac{\log\epsilon - 2}{\log r}, \quad 1 - \frac{1}{\log r}\right) \ , \tag{5.3}$$

$$S_0 = \max\left(2n, \quad \frac{n}{2(R_n - R_{n+1})}\right) \ . \tag{5.4}$$

We prove that $n = \Theta(\log \frac{1}{\epsilon})$ and $S_0 = \Theta(nr^{-n}) = \Theta(\frac{1}{\epsilon}\log\frac{1}{\epsilon})$ when $\epsilon \to 0^+$ (i.e., since all quantities are functions of ϵ, we may consider the case when $\epsilon \to 0^+$).

We remark that in what follows we do not attempt to get tight constant factors. We use only crude estimates that, however, allow us to prove tight asymptotic bounds.

We start with n. Note first that by (5.1), $\log\epsilon < \log r$, and hence $\log\epsilon - 2 < \log r - 1$. For $\epsilon < \frac{1}{2}$, we also have $\log r < 0$, and hence $\frac{\log\epsilon-2}{\log r} > 1 - \frac{1}{\log r}$. It follows from (5.3) that for $\epsilon < 1/2$, $n = \frac{\log\epsilon-2}{\log r}$. Moreover, for $0 < \epsilon < 1/\sqrt{2} - 1/2$, we have $1/2 < r < 1/\sqrt{2}$, and therefore

$$\frac{\log\epsilon - 2}{-1} \ < \ n \ < \ \frac{\log\epsilon - 2}{-1/2} \ .$$

The latter bounds are equivalent to

$$\log\frac{1}{\epsilon} + 2 < \ n \ < 2\log\frac{1}{\epsilon} + 4 \ , \tag{5.5}$$

and hence, for $\epsilon \to 0^+$, we have that

$$n = \Theta\left(\log \frac{1}{\epsilon}\right) . \tag{5.6}$$

We now consider S_0. To show the claim, we bound S_0 for $0 < \epsilon < 1/4$. We start by estimating the difference $R_n - R_{n+1}$. Using (5.2) we have

$$\begin{aligned} R_n - R_{n+1} &= \frac{1-r}{1-r^n} - \frac{1-r}{1-r^{n+1}} \\ &= \frac{(1-r)(1-r^{n+1}) - (1-r)(1-r^n)}{(1-r^n)(1-r^{n+1})} \\ &= \frac{1 - r^{n+1} - r + r^{n+2} - 1 + r^n + r - r^{n+1}}{(1-r^n)(1-r^{n+1})} \\ &= r^n \cdot \frac{1 + r^2 - 2r^{n+1}}{(1-r^n)(1-r^{n+1})} . \end{aligned} \tag{5.7}$$

Using (5.7), we bound $(R_n - R_{n+1})/r^n$ from both sides by constants as follows. For $0 < \epsilon < 1/4$ we have $\frac{1}{2} < r < \frac{3}{4}$, and by (5.5) we have $n > 4$. Hence

$$1 < 1 + r^2 - 2r^{n+1} \ < \ \frac{1 + r^2 - 2r^{n+1}}{(1-r^n)(1-r^{n+1})} \ < \ \frac{1 + r^2 - 2r^{n+1}}{\frac{1}{4}} < 8 . \tag{5.8}$$

Therefore, $R_n - R_{n+1} = \Theta(r^n)$ for $\epsilon \to 0^+$. Moreover, for $0 < \epsilon < 1/32$ we have by (5.7), (5.8), and (5.5) that $R_n - R_{n+1} < \frac{1}{4}$, and hence $2n < \frac{n}{2(R_n - R_{n+1})}$. It therefore follows from (5.4) that for $\epsilon \to 0^+$,

$$S_0 \ = \ \frac{n}{2(R_n - R_{n+1})} \ = \ \Theta(nr^{-n}) , \tag{5.9}$$

as desired. Finally, note that by (5.3) we have that for $\epsilon < 1/2$,

$$nr^{-n} = nr^{-\frac{\log \epsilon - 2}{\log r}} = 4n2^{-\log \epsilon} = \frac{4n}{\epsilon} . \tag{5.10}$$

Combining (5.6), (5.9), and (5.10), we conclude that $S_0 = \Theta\left(\frac{1}{\epsilon} \log \frac{1}{\epsilon}\right)$ for $\epsilon \to 0^+$.

ON IDENTIFYING CODES IN THE TRIANGULAR AND SQUARE GRIDS*

IIRO HONKALA† AND TERO LAIHONEN†

Abstract. It is shown that in the infinite square grid the density of every $(r, \leq 2)$-identifying code is at least $1/8$ and that there exists a sequence C_r of $(r, \leq 2)$-identifying codes such that the density of C_r tends to $1/8$ when $r \to \infty$. In the infinite triangular grid a sequence C'_r of $(r, \leq 2)$-identifying codes is given such that the density of C'_r tends to 0 when $r \to \infty$.

Key words. identifying code, multiprocessor system, triangular lattice, square lattice, density

1. Introduction. Assume that G is an undirected graph and $r > 0$. Denote by V the set of vertices of G. The graphic distance $d(x, y)$ between any two vertices $x, y \in V$ is the number of edges on any shortest path from x to y. A subset $C \subseteq V$ is called an $(r, \leq l)$-identifying code in G if for every subset $F \subseteq V$ of size at most l, the set of codewords (i.e., elements of C) that are within graphic distance r from at least one element in F uniquely identifies F. In other words, if we denote

$$B_r(v) = \{x \in V \mid d(x, v) \leq r\},$$

and

$$I_r(v) = B_r(v) \cap C$$

for all $v \in V$, and

$$I_r(F) = \bigcup_{v \in F} I_r(v)$$

for all $F \subseteq V$, then C is $(r, \leq l)$-identifying in G if the sets $I_r(F)$ are different for all F of size at most l. In particular, since $I_r(\emptyset) = \emptyset$, this implies that $I_r(F) \neq \emptyset$ whenever $F \neq \emptyset$. The set $I_r(F)$ is called the *I-set* of F.

Such codes were introduced in [15]. The motivation is that G represents a multiprocessor architecture: each vertex corresponds to a processor and each edge to a dedicated link between two processors. When maintaining the system, some processors (the codewords) are assigned the task of testing their r-neighbors, and each of them sends the central controller one bit of information telling whether it detected any problems or not. Based on the complete set of answers, the central controller should be able to identify the problem points under the assumption that there are at most l of them. The requirement is clearly that the codewords should form an $(r, \leq l)$-identifying code.

The architectures that have been mainly studied are the (infinite) square grid (in which $V = \mathbb{Z}^2$, and two vertices are adjacent if their Euclidean distance is 1), the (infinite) king grid (in which $V = \mathbb{Z}^2$, and two vertices are adjacent if their Euclidean distance is 1 or $\sqrt{2}$), the (infinite) triangular grid T (in which

$$V = \left\{ i(1,0) + j\left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right) \mid i,j \in \mathbb{Z} \right\},$$

and two vertices are adjacent if their Euclidean distance is 1), and finally the hexagonal mesh and binary hypercubes, which will not be considered in this paper.

Denote $R_n = \{(x,y) \in \mathbb{Z}^2 \mid |x| \le n, |y| \le n\}$. In the square and king grids the density D of a code C is defined as

$$D = \limsup_{n\to\infty} \frac{|C \cap R_n|}{|R_n|}.$$

Quite a lot is known about how small the density D of an $(r, \le l)$-identifying code can be in the king grid, as summarized in the following table:

King grid			
	$l = 1$	$l = 2$	$l \ge 3$
$r = 1$	$\frac{2}{9}$ [7, 3]	$\frac{9}{22} \le D \le \frac{3}{7}$ [11]	do not exist [11]
$r = 2$	$\frac{1}{4r}$ [2]	$\frac{31}{120} \le D \le \frac{3}{10}$ [11]	do not exist [11]
$r \ge 3$	$\frac{1}{4r}$ [2]	$\frac{1}{4}$ [11]	do not exist [11]

An entry like $\frac{2}{9}$ means that there is such an identifying code with density $\frac{2}{9}$, and that the density of any such code is at least $\frac{2}{9}$; the entry $\frac{9}{22} \le D \le \frac{3}{7}$ means that the density must be at least $\frac{9}{22}$ and that there exists a code with density $D = \frac{3}{7}$.

The purpose of this paper is to consider the triangular and square grids in the case $l = 2$ and $r \ge 2$.

In the triangular grid we denote

$$v(i,j) = i(1,0) + j\left(\frac{1}{2}, \frac{\sqrt{3}}{2}\right)$$

and

$$T_n = \{v(i,j) \mid |i| \le n, |j| \le n\},$$

and the density D of a code C is

$$D = \limsup_{n\to\infty} \frac{|C \cap T_n|}{|T_n|}.$$

For the triangular grid, the corresponding table reads as follows:

Triangular grid			
	$l = 1$	$l = 2$	$l \ge 3$
$r = 1$	$\frac{1}{4}$ [15]	$\frac{9}{16}$ [12]	do not exist [12]
$r \ge 2$	$\frac{2}{6r+3} \le D \le \begin{cases} \frac{1}{2r+4} & \text{if } 4 \mid r \\ \frac{1}{2r+2} & \text{otherwise} \end{cases}$ [1]	$D \to 0$ when $r \to \infty$	do not exist [12]

For $l = 1$, $r = 3$, $D \le \frac{2}{17}$ and for $l = 1$, $r = 5$, $D \le \frac{1}{13}$; see [3].

By the entry $D \to 0$, when $r \to \infty$, we mean that there is a sequence of $(r, \leq 2)$-identifying codes with densities D_r such that $D_r \to 0$ when $r \to \infty$ (see Theorem 1).

Finally, we have the corresponding table for the square grid:

Square grid			
	$l = 1$	$l = 2$	$l \geq 3$
$r = 1$	$\frac{15}{43} \leq D \leq \frac{7}{20}$ [4, 5, 8]	$\frac{1}{2}$ [10]	1 if $l = 3$ [10] do not exist if $l \geq 4$ [10, 16]
$r \geq 2$	$\frac{3}{8r+4} \leq D \leq \begin{cases} \frac{2}{5r} & \text{if } 2 \mid r \\ \frac{2r}{5r^2-2r+1} & \text{if } 2 \not\mid r \end{cases}$ [1, 14]	$D \to \frac{1}{8}$ when $r \to \infty$	do not exist

For $l = 1$, $r = 2$, $D \leq \frac{5}{29}$ by [14];

for $l = 1$, $r = 3, 4, 5, 6$, we have the upper bounds $\frac{1}{8}$, $\frac{8}{85}$, $\frac{2}{25}$, $\frac{3}{46}$ from [3].

Here the entry $D \to \frac{1}{8}$ when $r \to \infty$ comes from Theorems 3 and 5; see also Theorem 6. To be precise, what we prove is that for all r, the density of an $(r, \leq 2)$-identifying code in the square grid must be at least $\frac{1}{8}$, and that there is a sequence of $(r, \leq 2)$-identifying codes with densities D_r such that $D_r \to \frac{1}{8}$ when $r \to \infty$.

For results in the hexagonal mesh, we refer to [1, 3, 6, 8, 13, 15].

In a closely related problem, the requirement is that the sets $I_r(v)$ for $v \in V \setminus C$ are nonempty and no two are the same set; such a code is called r-locating-dominating. For results on such codes, see, e.g., [9, 17, 18].

2. On the triangular grid. The following theorem shows that in the triangular grid we have a sequence of $(r, \leq 2)$-identifying codes with densities D_r such that $D_r \to 0$ when $r \to \infty$.

THEOREM 1. *In the triangular grid there is an $(r, \leq 2)$-identifying code with density $\frac{3r+1}{(2r+1)(r+1)}$.*

Proof. Denote

$$L_k = \{v(i, k(r+1)) \mid i \in \mathbb{Z}\}$$

and

$$C_1 = \bigcup_{k \in \mathbb{Z}} L_k.$$

Denote further

$$C_2 = \{v(i, j) \mid i \equiv 0 \bmod 2r+1\}.$$

We claim that $C_1 \cup C_2$ is $(r, \leq 2)$-identifying. It is easy to check that it has the required density.

We first make two preliminary observations: if $v = v(a, k(r+1)+h)$, then

- $I_r(v) \cap L_k$ is trivially empty if $|h| > r$, and $I_r(v) \cap L_k$ has cardinality $2r+1-|h|$ if $|h| \leq r$, and
- the set $I_r(v) \cap L_k$ is symmetric with respect to the vertical line passing through v.

Assume that $F \subseteq V$ has cardinality at most two and is unknown to us, but that we know $I_r(F)$.

Obviously $I_r(F)$ is empty if and only if F is empty.

Assume first that $I_r(F)$ contains elements from at least three different lines L_k; the lines L_{high} and L_{low} being the highest and lowest among them. Then $|F| = 2$,

and only the vertex v_{high} in F with higher y-coordinate affects $I_r(F) \cap L_{high}$. The two observations made above now immediately tell us the x- and y-coordinates of v_{high}. In the same way we find the other vertex in F by considering $I_r(F) \cap L_{low}$.

Assume then that $I_r(F)$ contains only vertices from one of the lines L_k, say L_s. Then $F \subseteq L_s$. If $v(i_{min}, s(r+1))$ and $v(i_{max}, s(r+1))$ are the vertices in $I_r(F) \cap L_s$ with the smallest and largest x-coordinates, then F consists of the points $v(i_{min} + r, s(r+1))$ and $v(i_{max} - r, s(r+1))$ (which may coincide).

Assume finally that $I_r(F)$ contains elements from exactly two different lines L_k. If they are L_s and L_{s+j} for some $j \geq 2$, then F consists of the middle point in $I_r(F) \cap L_s$ and the middle point in $I_r(F) \cap L_{s+j}$. So assume that they are L_s and L_{s+1}. Then $F \subseteq A$, where $A = \{v(i,j) \mid s(r+1) \leq j \leq (s+1)(r+1)\}$.

We now define four lines H_1, H_2, K_1, and K_2 as follows:

- By considering the leftmost point in $I_r(F) \cap L_{s+1}$, we find a line H_1 with slope $\sqrt{3}$ such that $H_1 \cap A$ must contain a point in F—and the other point in F (if there is one) belongs to $H_1 \cup L_s$ or lies to the right of H_1.
- By considering the rightmost point in $I_r(F) \cap L_s$, we find a line H_2 with slope $\sqrt{3}$ such that $H_2 \cap A$ must contain a point in F—and the other point in F (if there is one) belongs to $H_2 \cup L_{s+1}$ or lies to the left of H_2.
- By considering the leftmost point in $I_r(F) \cap L_s$, we find a line K_1 with slope $-\sqrt{3}$ such that $K_1 \cap A$ must contain a point in F—and the other point in F (if there is one) is in $K_1 \cup L_{s+1}$ or lies to the right of K_1.
- By considering the rightmost point in $I_r(F) \cap L_{s+1}$, we find a line K_2 with slope $-\sqrt{3}$ such that $K_2 \cap A$ must contain a point in F—and the other point in F (if there is one) is in $K_2 \cup L_s$ or lies to the left of K_2.

If $H_1 = H_2$, then by the above description F is a subset of the set consisting of $H_1 \cap A$, the part of L_s which lies to the left of $H_1 \cap L_s$ and of the part of L_{s+1} which lies to the right of $H_1 \cap L_{s+1}$. But due to the structure of this path (and C_1), the points in F are the one obtained by taking r steps to the right along this path from the leftmost codeword in $I_r(F) \cap L_s$, and the one obtained by taking r steps to the left along this path from the rightmost codeword in $I_r(F) \cap L_{s+1}$ (and these two points of F may coincide).

In the same way we find F if $K_1 = K_2$; so assume that $H_1 \neq H_2$ and $K_1 \neq K_2$.

Since H_1, H_2, K_1, and K_2 each contain at least one point of F, we know that either F is the set F_1 consisting of the vertices in $H_1 \cap K_2$ and $H_2 \cap K_1$ (the top and bottom corners of the parallelogram formed by H_1, H_2, K_1, and K_2) or F is the set F_2 consisting of the vertices in $H_1 \cap K_1$ and $H_2 \cap K_2$.

But we can separate between these two remaining cases using C_2. Denote $A_i = \{v(i,j) \mid j \in \mathbb{Z}\}$. Then $H_1 = A_i$ and $H_2 = A_j$ for some $i < j$. By the definition of C_2, there is an index k such that $A_k \subseteq C_2$ and $|k - i| \leq r$. If $k < j$, then the highest point in $I_r(F_1) \cap A_k$ is not in $I_r(F_2)$; if $k \geq j$, then the lowest point in $I_r(F_1) \cap A_k$ is not in $I_r(F_2)$. □

3. On the square grid. We now consider the square grid.

Because always $I_r((-1,-1),(1,1)) = I_r((-1,-1),(0,0),(1,1))$ for $r \geq 2$, there cannot exist an $(r, \leq l)$-identifying code with $r \geq 2$ and $l \geq 3$.

The following theorem gives a useful sufficient condition for a code to be $(r, \leq 2)$-identifying in the square grid.

THEOREM 2. *Assume that $E \subseteq \mathbb{Z}^2$. If every translate of the set*

$$A = \{(-r-1,0),(-r,0),(0,r+1),(0,r),(r+1,0),(r,0),(0,-r-1),(0,-r)\},$$

every translate of the set

$$B = \{(-r, 0), (-r + 1, 1), (-r + 2, 2), \ldots, (0, r)\},$$

and every translate of the set

$$C = \{(0, r), (1, r - 1), (2, r - 2), \ldots, (r, 0)\}$$

contain at least one element of E, then E is $(r, \leq 2)$-identifying in the square grid.

Proof. If $F \neq \emptyset$, say $v \in F$, then $(v + B) \cap E \neq \emptyset$ by the assumption, and hence $I_r(F) \neq \emptyset$.

Assume that F_1 and F_2 are two different nonempty subsets of $\mathbb{Z}^2$ each containing at most two elements and that $I_r(F_1) = I_r(F_2)$. Let R be the smallest rectangle which contains $F_1 \cup F_2$ and whose sides have slopes 1 and -1; possibly R reduces to a line segment.

Assume first that R is a line segment. Assume, for instance, that R has slope -1 and the upper left-hand endpoint v is in F_1 but not F_2 (the other cases are treated similarly). Then $(v + B) \cap E \neq \emptyset$, and any codeword in $(v + B) \cap E$ belongs to $I_r(F_1)$ but not to $I_r(F_2)$.

Assume therefore that R does not reduce to a line segment.

Each side of R must contain a point from both F_1 and F_2. Indeed, assume that, for instance, the upper left-hand side contains a vertex $v \in F_1$ but no point of F_2 (the other cases are similar). By assumption, the set $v + B$ contains a codeword of E, and clearly this codeword belongs to $I_r(F_1)$ but not to $I_r(F_2)$.

But since each side of R contains a point from F_1, and $|F_1| \leq 2$, the only possibility is that F_1 consists of two diagonally opposite corners of R. By the same argument, F_2 must then consist of the other two diagonally opposite corners.

If any of the sides of R contains more than $r + 1$ grid points, say the upper left-hand side (the other cases are similar), and $v \in F_2$, say, is its upper endpoint, then $v + B$ contains a codeword, by assumption, and this codeword is in $I_r(F_2)$ but not in $I_r(F_1)$.

Assume therefore that each side of R contains at most $r + 1$ grid points. Without loss of generality, the leftmost corner of R is the point $(-1, 0)$, and this point belongs to F_1. In particular, this point belongs to $B_{r-1}((-r, 0))$. The bottom corner belongs to F_2 and is one of the points $(0, -1)$, $(1, -2)$, $\ldots$, $(r - 1, -r)$; in particular, it lies in the ball $B_{r-1}((0, -r))$. The top corner of R also belongs to F_2 and is one of the points $(0, 1)$, $(1, 2)$, $\ldots$, $(r - 1, r)$; in particular it lies in the ball $B_{r-1}((0, r))$. Finally the rightmost corner of R must be one of the grid points in the square with the corners $(1, 0)$, $(r, r - 1)$, $(r, -r + 1)$, $(2r - 1, 0)$, so it lies in the ball $B_{r-1}((r, 0))$. Now the claim follows from the fact that A contains at least one codeword. Any two points in A which are not neighbors in the graph are at least graphic distance $2r$ apart. This, the triangle inequality, and what we have just proved show that every element of A is within distance r from a unique corner of R, and any codeword in A therefore belongs to $I_r(F_1) \setminus I_r(F_2)$ or $I_r(F_2) \setminus I_r(F_1)$. □

The following theorem is useful when we want to determine the asymptotic behavior of the density of $(r, \leq 2)$-identifying codes.

THEOREM 3. *For all r, if a code is $(r, \leq 2)$-identifying in the square grid, then its density is at least $\frac{1}{8}$.*

Proof. The set A of Theorem 2 always contains at least one codeword of an $(r, \leq 2)$-identifying code since the I-sets of the sets $\{(-1, 0), (1, 0)\}$ and $\{(0, -1), (0, 1)\}$ (and any of their translates) must be distinct. Because A consists of eight elements,

independently of r, the claim follows by going through all translates of the set A; cf. [1, section 2]. □

For small values of r we get a better lower bound.

THEOREM 4. *If a code is $(r, \leq 2)$-identifying in the square grid, then its density is at least $\frac{1}{(2r+1)}$.*

Proof. The I-sets of $\{(-1,-1)\}$ and $\{(-1,-1),(0,0)\}$ (and any of their translates) must be distinguishable. The symmetric difference of $B_r((-1,-1))$ and $B_r((-1,-1)) \cup B_r((0,0))$ contains $2r+1$ vertices. The claim follows for a fixed r as in the previous proof. □

THEOREM 5. *There is a sequence (D_r) such that $D_r \to \frac{1}{8}$ when $r \to \infty$, and for every r there exists an $(r, \leq 2)$-identifying code in the square grid with density D_r.*

Proof. Denote by H the set of residue classes of 0, 2, 4, ..., $2r$ modulo $4r+1$, and by K the set of residue classes of 0, 1, 2, ..., $2r+1$ modulo $4r+1$.

We claim that the code $C_1 = \{(a,b) \mid a+b \in H, a-b \in K\}$ has the property that every set $(x,y)+A$ (where A is as in Theorem 2) contains at least one codeword; the density of C_1 is clearly $2(r+1)^2/(4r+1)^2$. It is easy to check that for any integer n the set $\{n-r-1, n-r, n+r, n+r+1\}$ contains an element of H. Apply this to $n = x+y$. If $x+y-r-1 \in H$, then at least one of the points $(x-r-1, y)$ and $(x, y-r-1)$ of $(x,y)+A$ belong to C_1, because $x-y-r-1$ or $x-y+r+1$ belongs to K. If $x+y-r \in H$, then $(x-r, y) \in C_1$ or $(x, y-r) \in C_1$; if $x+y+r \in H$, then $(x+r, y) \in C_1$ or $(x, y+r) \in C_1$; if $x+y+r+1 \in H$, then $(x+r+1, y) \in C_1$ or $(x, y+r+1) \in C_1$.

To complete the construction, we take $C_2 = \{(a,b) \mid a \equiv 0 \bmod r+1\}$. Then $C_1 \cup C_2$ clearly satisfies the conditions of Theorem 2, and is hence $(r, \leq 2)$-identifying, and its density tends to $\frac{1}{8}$, when r tends to infinity. □

The previous proof was quite simple, because we did not pay too much attention to the density of the resulting codes.

THEOREM 6. *Let $r \equiv 2 \bmod 8$, $r \geq 18$. Then there exists an $(r, \leq 2)$-identifying code in the square grid with density $\frac{r+1}{8r+4}$.*

Proof. Suppose $r \equiv 2 \bmod 8$ and $r \geq 18$. Denote (see Figure 1 for the case $r = 18$)

$$S = \{(-r-1, 0) + k(8,8) \mid k \in \mathbb{Z}\}$$

and further

$$F = \bigcup_{i \in \mathbb{Z}} (S + i(2,1)).$$

In what follows, by a line with slopes 1 and -1 we always mean a diagonal which intersects with $\mathbb{Z}^2$.

Obviously, every eighth point in a line with slope 1 belongs to F. Also in any line with slope -1 every eighth point is in F. Indeed, if $f \in F$, then $f + q(8,-8) \in F$ for $q \in \mathbb{Z}$ (also $f + q(2,-3) \in F$ and thus every diagonal with slope -1 has an element of F).

Let

$$E_0 = \left(\bigcup_{i \in \{0,1,\ldots,2r\}} (S + i(2,1)) \right) \cup \{(r-1+3+8k, 3+8k) \mid k \in \mathbb{Z}\}.$$

Thus E_0 consists of a part of F with some additional points on the diagonal $(r-1, 0) + (a,a)$, $a \in \mathbb{Z}$.

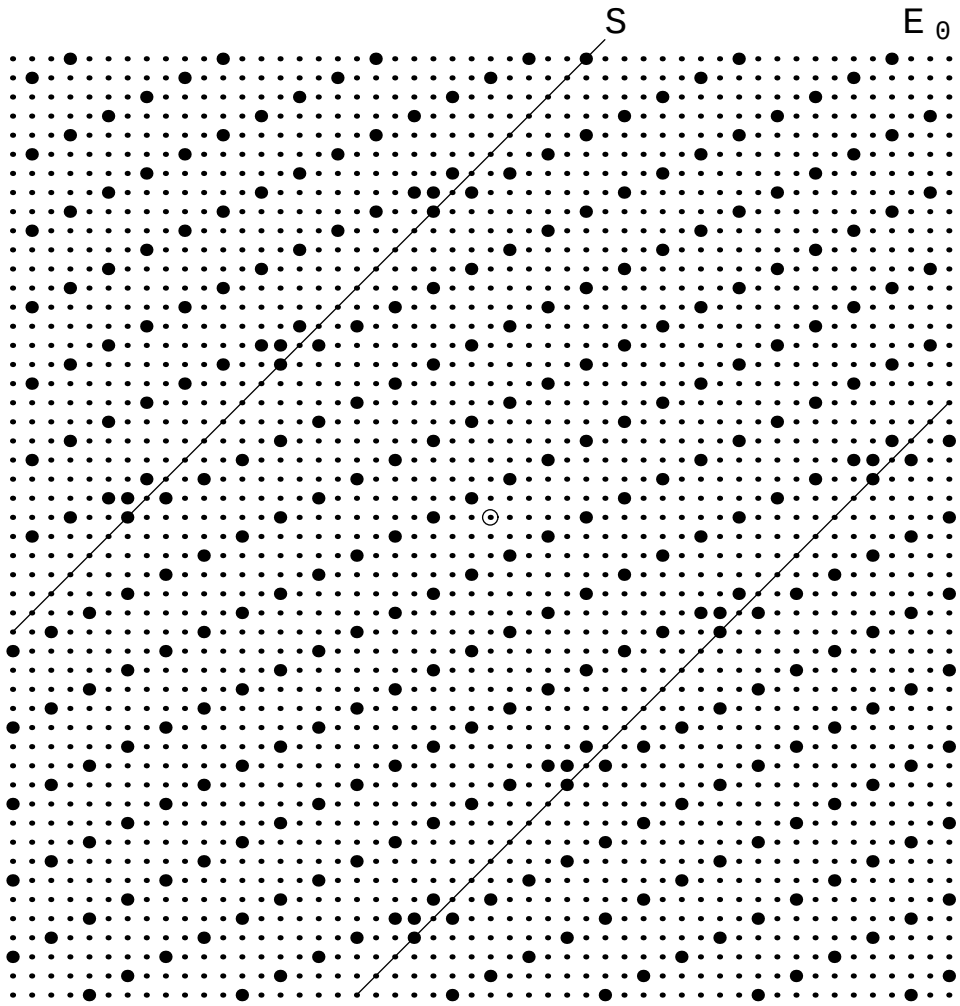

FIG. 1. *A part of the code E for $r = 18$. Codewords are the large black circles and the circled dot is the origin.*

We define the code

$$E = E_r = \bigcup_{j \in \mathbb{Z}} (E_0 + j(2r + 1 + 2, 2)).$$

Hence E consists of translates of E_0 shifted diagonally up by $j(2, 2)$ and horizontally by $j(2r + 1, 0)$.

Observe that E_0 is periodic with period $(8, 8)$ and hence the density of E equals $\frac{2r+2}{8(2r+1)} = \frac{r+1}{8r+4}$.

In what follows we show that E is $(r, \leq 2)$-identifying. This is done by checking the conditions of Theorem 2. We will use the same notation in this theorem for the sets A, B, and C.

Every translate of B contains trivially at least one codeword of E, since at least every eighth point in a diagonal with slope 1 belongs to E.

Every translate of C also contains at least one codeword. Indeed, there can be at most 14 consecutive noncodewords in a line with slope -1. This follows since in $E_0 \cap F$ there can be a gap of at most seven noncodewords and in its translate $E_0 + (2r+1+2, 2)$ there can be another seven. Because $|C| = r+1 \geq 19$, there must be a codeword in every translate of C.

Consider an arbitrary translate $(s+a, a) + A$.

The part

$$A_1 = (s+a, a) + \{(-r-1, 0), (-r, 0), (0, r), (0, r+1)\}$$

of $(s+a, a) + A$ consists of points on two diagonals $(s-r-1, 0) + (b, b)$ and $(s-r, 0) + (b, b)$, $b \in \mathbb{Z}$, and the other half

$$A_2 = \{(s+r+1, 0) + (a, a), (s+r+1, 0) + (a-r-1, a-r-1)\}$$

$$\cup\{(s+r, 0) + (a, a), (s+r, 0) + (a-r, a-r)\}$$

of $(s+a, a) + A$ consists of points on two other diagonals, which are the same two diagonals shifted diagonally up by $(2, 2)$ and horizontally by $(2r+1, 0)$. Shifting back, we know that A_2 contains at least one codeword if and only if the set

$$A_3 := \{(s-r, 0) + (a-2, a-2), (s-r, 0) + (a-r-3, a-r-3)\}$$

$$\cup\{(s-r-1, 0) + (a-2, a-2), (s-r-1, 0) + (a-r-2, a-r-2)\}$$

does. We now consider $A_1 \cup A_3$ instead.

If $s \not\equiv 2r \bmod 2r+1$, then our two diagonals are from the same translate of E_0. If none of the four points of $A_1 \cup A_3$ in

$$(s-r, 0) + \{(a, a), (a+r, a+r), (a-2, a-2), (a-r-3, a-r-3)\}$$

is in the code, then (shifting back by $(2, 1)$) none of the points in

$$(s-r-1, 0) + \{(a-1, a-1), (a+r-1, a+r-1), (a-3, a-3), (a-r-4, a-r-4)\}$$

is in the code either. But then at least one of the points of $A_1 \cup A_3$ in

(1)
$$(s-r-1, 0) + \{(a, a), (a+r+1, a+r+1), (a-2, a-2), (a-r-2, a-r-2)\}$$

must be in the code, because

$$a, a+r+1, a-2, a-r-2, a-1, a+r-1, a-3, a-r-4$$

belong to distinct residue classes modulo eight when $r \equiv 2 \bmod 8$.

If $s \equiv 2r \bmod 2r+1$, then our two diagonals are the rightmost diagonal in a translate of E_0 and the leftmost diagonal in the next translate of E_0. Choose j so that $s-r-1 = r-1+j(2r+1)$. Then E contains all the points $(s-r-1, 0) + (b, b)$, where $b \equiv 3+2j \bmod 8$ or $b \equiv 4+2j \bmod 8$; and in particular, for all $b \equiv 4+2j \bmod 8$ also the point obtained by shifting by $-2r(2, 1)$ is in E. From (1) and the fact that the residue classes of a, $a+r+1$, $a-2$, and $a-r-2$ are a, $a+3$, $a+4$, and $a+6$, we see that the only way none of the points in (1) would be in the code is if $3+2j \equiv a+1 \bmod 8$ and $4+2j \equiv a+2 \bmod 8$, and then $(s-r-1, 0) + (a+2r-2, a+2r-2) \in E$, and hence $v = (s-r-1, 0) + (a+2r-2, a+2r-2) - 2r(2, 1) \in E$ (as we observed earlier), and finally $(s-r, 0) + (a, a) = v + (2r+1+2, 2) \in E$, which proves the claim, because this point is in $A_1 \cup A_3$. □

A BOUND ON THE CAPACITY OF BACKOFF AND ACKNOWLEDGMENT-BASED PROTOCOLS*

LESLIE ANN GOLDBERG†, MARK JERRUM‡, SAMPATH KANNAN§, AND MIKE PATERSON†

Abstract. We study contention-resolution protocols for multiple-access channels. We show that *every* backoff protocol is transient if the arrival rate, λ, is at least 0.42 and that the capacity of every backoff protocol is at most 0.42. Thus, we show that backoff protocols have (provably) smaller capacity than full-sensing protocols. Finally, we show that the corresponding results, with the larger arrival bound of 0.531, also hold for every acknowledgment-based protocol.

Key words. contention-resolution, backoff, multiple-access channel, stability, protocol

1. Introduction.

A *multiple-access channel* is a broadcast channel that allows multiple users to communicate with each other by sending messages onto the channel. If two or more users simultaneously send messages, then the messages interfere with each other (collide), and the messages are not transmitted successfully. The channel is not centrally controlled. Instead, the users use a contention-resolution protocol to resolve collisions. Thus, after a collision, each user involved in the collision waits a random amount of time (which is determined by the protocol) before resending.

Following previous work on multiple-access channels, we work in a *time-slotted* model in which time is partitioned into discrete *time steps*. At the beginning of each time step, a random number of messages enter the system, each of which is associated with a new user which has no other messages to send. The number of messages that enter the system is drawn from a Poisson distribution with mean λ. During each time step, each message chooses independently whether to send to the channel. If *exactly* one message sends to the channel during the time step, then this message leaves the system and we call this a *success*. Otherwise, all of the messages remain in the system and the next time step is started. Note that when a message sends to the channel this may or may not result in a success, depending on whether any other messages send to the channel.

The quality of a protocol can be measured in several ways. Typically, one models the execution of the protocol as a Markov chain. If the protocol is good (for a given arrival rate λ), the corresponding Markov chain will be *recurrent* (with probability 1, it will eventually return to the empty state in which no messages are waiting). Otherwise, the chain is said to be *transient* (and we also say that a protocol is tran-

sient). Note that transience is a very strong form of instability. In particular, if we focus on any finite set of "good" states, then if the chain is transient, the probability of visiting these states at least N times during the infinite run of the protocol is exponentially small in N. (This follows because the relevant Markov chain is irreducible and aperiodic.)

Another way to measure the quality of a protocol is to measure its *capacity*. A protocol is said to achieve *full throughput* at rate λ if, when it is run with input rate λ, the average success rate is λ. The *capacity* of the protocol [4] is the maximum arrival rate at which it achieves full throughput.

The protocols that we consider in this paper are *acknowledgment-based* protocols. In the acknowledgment-based model, the only information that a user receives about the state of the system is the history of its own transmissions. An alternative model is the *full-sensing* model, in which *every* user listens to the channel at *every* step, regardless of whether it sends during the step.[1]

One particularly simple and easy-to-implement class of acknowledgment-based protocols is the class of *backoff protocols*. A backoff protocol is a sequence of probabilities $p_0, p_1, \ldots$. If a message has sent unsuccessfully i times before a time step, then, with probability p_i, it sends during the time step. Otherwise, it does not send. Kelly and MacPhee [13, 14, 17] gave a formula for the *critical arrival rate*, λ^*, of a backoff protocol, which is the minimum arrival rate for which the expected number of successful transmissions that the protocol makes is finite.[2]

Perhaps the best-known backoff protocol is the *binary exponential backoff protocol* in which $p_i = 2^{-i}$. This protocol is the basis of the Ethernet protocol of Metcalfe and Boggs [18].[3] Kelly and MacPhee showed that the critical arrival rate of this protocol is $\ln 2$. Thus, if $\lambda > \ln 2$, then binary exponential backoff achieves only a finite number of successful transmissions (in expectation). Aldous [1] showed that the binary exponential backoff protocol is not a good protocol for *any* positive arrival rate λ. In particular, it is transient and the expected number of successful transmissions in t steps is $o(t)$. MacPhee [17] posed the question of whether there exists a backoff protocol which is recurrent for some positive arrival rate λ.

In this paper, we show that there is no backoff protocol which is recurrent for $\lambda \geq 0.42$. (Thus, *every* backoff protocol is transient if $\lambda \geq 0.42$.) Also, every backoff protocol has capacity at most 0.42. As far as we know, our result is the first proof showing that backoff protocols have smaller capacity than full-sensing protocols. In particular, Mosely and Humblet [20] have discovered a full-sensing protocol with capacity 0.48776.[4] Finally, we show that *no* acknowledgment-based protocol is recurrent for $\lambda \geq 0.530045$.

[1] In practice, it is possible to implement the full-sensing model when there is a single channel, but this becomes increasingly difficult in situations where there are multiple shared channels, such as optical networks. Thus, acknowledgment-based protocols are sometimes preferable to full-sensing protocols. For work on contention-resolution in the multiple-channel setting, see [6].

[2] If $\lambda > \lambda^*$, then the expected number of successes is finite, even if the protocol runs forever. They showed that the critical arrival rate is 0 if the expected number of times that a message sends during the first t steps is $\omega(\log t)$.

[3] There are several differences between the "real-life" Ethernet protocol and "pure" binary exponential backoff, but we do not describe these here.

[4] Mosely and Humblet's protocol is a "tree protocol" in the sense of Capetanakis [3] and Tsybakov and Mikhailov [25]. For a simple analysis of the protocol, see [26]. Vvedenskaya and Pinsker have shown how to modify Mosely and Humblet's protocol to achieve an improvement in the capacity (in the seventh decimal place) [27].

1.1. Related work. Backoff protocols and acknowledgment-based protocols have also been studied in an n-user model, which combines contention-resolution with queueing. In this model, it is assumed that n users maintain queues of messages, and that new messages arrive at the tails of the queues. At each step, the users use contention-resolution protocols to try to send the messages at the heads of their queues. It turns out that the queues have a stabilizing effect, so some protocols (such as "polynomial backoff") which are unstable in our model [14] are stable in the queueing model [12]. We will not describe queueing-model results here but refer the reader to [2, 9, 12, 22].

Much work has gone into determining upper bounds on the capacity that can be achieved by a full-sensing protocol. The current best result is due to Tsybakov and Likhanov [24], who have shown that no protocol can achieve capacity higher than 0.568. (For more information, see [4, 10, 19, 23].) In the full-sensing model, one typically assumes that messages are born at real "times" which are chosen uniformly from the unit interval. Recently, Loher [15, 16] has shown that if a protocol is required to respect these birth times, in the sense that packets must be successfully delivered in their birth order, then no protocol can achieve capacity higher than 0.4906. Intuitively, the "first-come-first-served" restriction seems very strong, so it is somewhat surprising that the best-known algorithm without the restriction (that of Vvedenskaya and Pinsker) does not beat this upper bound. The algorithm of Humblet and Mosely satisfies the first-come-first-served restriction.

2. Markov chain background. A Markov chain $X = \{X_0, X_1, \ldots\}$ with a countable state space Ω (see [11]) is *time-homogeneous* if its transition probabilities are independent of time so $\Pr(X_{n+1} = j \mid X_n = i) = \Pr(X_1 = j \mid X_0 = i)$ for all n, i, j. It is *irreducible* if every pair (i, j) of states is connected in the sense that there is an $n > 0$ such that $\Pr(X_{n+m} = j \mid X_m = i) > 0$. It is *aperiodic* if every state i satisfies $\gcd\{n \mid \Pr(X_{n+m} = i \mid X_m = i) > 0\} = 1$. If the chain is irreducible and aperiodic, then we say that it is *recurrent* if it returns to its start state with probability 1. That is, it is recurrent if for some state i (and therefore for all i), $\text{Prob}[X_t = i \text{ for some } t \geq 1 \mid X_0 = i] = 1$. Otherwise, X is said to be *transient*. X is *positive recurrent* (or ergodic) if the expected number of steps that it takes before returning to its start state is finite. A chain is positive recurrent if and only if it has a unique stationary distribution. The standard way to prove that a Markov chain is positive recurrent is Foster's theorem.

THEOREM 1 (Foster [7]). *A time-homogeneous irreducible aperiodic Markov chain X with a countable state space Ω is positive recurrent if and only if there exists a positive function $f(\rho)$, $\rho \in \Omega$, a number $\epsilon > 0$, and a finite set $\mathcal{A} \subseteq \Omega$ such that the following inequalities hold:*

$$E[f(X(t+1)) - f(X(t)) \mid X(t) = \rho] \leq -\epsilon, \quad \rho \notin \mathcal{A}, \tag{1}$$

$$E[f(X(t+1)) \mid X(t) = \rho] < \infty, \quad \rho \in \mathcal{A}. \tag{2}$$

Basically, the idea is to use a "potential function" f to follow the progress of the chain. The chain is positive recurrent if and only if there is a potential function f which

1. usually decreases (equation (1)), and
2. cannot increase much (equation (2))

in a single step. Equation (1) implies that, from any state $\rho \notin \mathcal{A}$, the expected time to reach $\mathcal{A}$ from ρ is at most $f(\rho)/\epsilon$. This (combined with (2)) implies that the expected return time to $\mathcal{A}$ is finite, which in turn implies that the chain is positive recurrent.

(For more details, see [5].) Theorems like Theorem 1 are called "drift theorems" because the progress of the Markov chain X is studied by focusing on the "drift" of the potential function f. The function f is sometimes called a *Lyapunov function* or a *test function*.

We can also use drift theorems to show that a Markov chain is *not* positive recurrent. To do this we want to find a potential function f which "drifts" towards larger potentials. Here is the theorem that we will use.

THEOREM 2 (Fayolle, Malyshev, and Menshikov [5]). *An irreducible aperiodic time-homogeneous Markov chain X with countable state space Ω is not positive recurrent if there is a function f with domain Ω and there are constants C and d such that*

1. *there is a state x with $f(x) > C$, and a state y with $f(y) \leq C$,*
2. *$E[f(X_1) - f(X_0) \mid X_0 = x] \geq 0$ for all x with $f(x) > C$, and*
3. *$E[\,|f(X_1) - f(X_0)| \mid X_0 = x] \leq d$ for every state x.*

We will use a similar theorem to show that a Markov chain is transient (which is stronger than saying that it is not positive recurrent).

THEOREM 3 (Fayolle, Malyshev, and Menshikov [5]). *An irreducible aperiodic time-homogeneous Markov chain X with countable state space Ω is transient if there is a positive function f with domain Ω and there are positive constants C, d, and ε such that*

1. *there is a state x with $f(x) > C$, and a state y with $f(y) \leq C$,*
2. *$E[f(X_1) - f(X_0) \mid X_0 = x] \geq \varepsilon$ for all x with $f(x) > C$, and*
3. *if $|f(x) - f(y)| > d$, then the probability of moving from x to y in a single move is 0.*

3. Stochastic domination and monotonicity. Suppose that X is a Markov chain and that the (countable) state space Ω of the chain is a *partial order* with binary relation $\leq$. If A and B are random variables taking states as values, then B *dominates* A if and only if there is a joint sample space for A and B in which the value of A is always less than or equal to the value of B. Note that there will generally be other joint sample spaces in which the value of A can exceed the value of B. We write $A \leq B$ to indicate that B dominates A. We say that X is *monotonic* if for any states $x \leq x'$, the next state conditioned on starting at x' dominates the next state conditioned on starting at x. (Formally, $(X_1 \mid X_0 = x')$ dominates $(X_1 \mid X_0 = x)$.)

When an acknowledgment-based protocol is viewed as a Markov chain, the state is just the collection of messages in the system. (Each message is identified by the history of its transmissions.) Thus, the state space is countable and forms a partial order with respect to the subset inclusion relation $\subseteq$ (for multisets). We say that a protocol is *deletion resilient* [8] if its Markov chain is monotonic with respect to the subset-inclusion partial order.

OBSERVATION 4. *Every acknowledgment-based protocol is deletion resilient.*

Proof. Consider the states x and x' with $x \subseteq x'$. Recall that each state is a set of messages, each message being identified by its transmission history. Thus, x' contains all of the messages in x and possibly others. Now consider one step of the protocol. We wish to show that the random variable denoting the next state $z' = (X_1 \mid X_0 = x')$ dominates the random variable $z = (X_1 \mid X_0 = x)$. z' does dominate z because we can draw z and z' from a joint sample space in which

- the messages in x do the same thing in both copies, and
- both copies have the same number of new arrivals, which make the same number of send attempts in both copies.

Now consider any message m which is either a new arrival or a member of x.

1. If m is silent during the step, then its transmission history in z' is the same as in z.
2. If m has a collision during the transition to z, then it also has a collision during the transition to z', so its transmission history in z' is the same as in z.

Thus, $z \subseteq z'$. □

As we indicated earlier, we will generally assume that the number of messages entering the system at a given step is drawn from a Poisson process with mean λ. However, it will sometimes be useful to consider other message-arrival distributions. If I and I' are message-arrival distributions, we write $I \leq I'$ to indicate that the number of messages generated under I is dominated by the number of messages generated under I'.

OBSERVATION 5. *If the acknowledgment-based protocol P is recurrent under the message-arrival distribution I' and $I \leq I'$, then P is also recurrent under I.*

Proof. Let X be the Markov chain corresponding to protocol P with arrival distribution I with X_0 as the empty state. Let X' be the analogous Markov chain with arrival distribution I'. Consider the evolution of the stochastic process (X_0, X'_0), $(X_1, X'_1), \ldots$. We will choose the random variable (X_i, X'_i) from a joint probability distribution in which

1. every message which is common to X_i and X'_i does the same thing in both copies;
2. the new arrivals which are drawn from I arrive in both copies and make the same number of send attempts in both copies;
3. some additional messages may arrive in X'_i (according to I').

Note that items (2) and (3) are possible since $I \leq I'$. We can now show by induction on t that X'_t dominates X_t. That is, when this joint distribution is used, X_t is a subset of X'_t. This holds for $t = 0$ since $X_0 = X'_0$. The inductive step is the same as in the proof of Observation 4. Consider any message m which is in X_t or arrives (according to I) just before step $t + 1$.

1. If m is silent during the step, then its transmission history in X'_{t+1} is the same as in X_{t+1}.
2. If m has a collision during the transition to X_{t+1}, then it also has a collision during the transition to X'_{t+1}.

Thus, $X_{t+1} \subseteq X'_{t+1}$. Finally, since X'_t dominates X_t, the recurrence of X'_t implies the recurrence of X_t. □

4. Backoff protocols. In this section, we will show that there is no backoff protocol which is recurrent for $\lambda \geq 0.42$. Our method will be to use the drift theorems in section 2. Let $p_0, p_1, \ldots$ be a backoff protocol. Without loss of generality, we can assume $p_0 = 1$, since we can ignore new arrivals until they first send.[5] Let $\lambda = 0.42$. Let X be the Markov chain described in section 3 which describes the behavior of the protocol with arrival rate λ. First, we will construct a potential function (Lyapunov function) f which satisfies the conditions of Theorem 2, that is, a potential function which has a bounded positive drift. We will use Theorem 2 to conclude that the chain is not positive recurrent. Next, we will consider the behavior of the protocol under a *truncated* arrival distribution, and we will use Theorem 3 to show that the protocol

[5] Since the arrivals are Poisson, and Poisson random variables are additive, the number of messages making their very first send on a given time step is Poisson, and the mean of this distribution approaches λ.

is transient. Using Observation 5 (domination), we will conclude that the protocol is also transient with Poisson arrivals at rate λ or higher. Finally, we will show that the *capacity* of every backoff protocol is at most 0.42.

We will use the following technical lemma.

LEMMA 6. *Let* $1 \le t_i \le d$ *for* $i \in [1,k]$ *and* $\prod_{i=1}^{k} t_i = c$. *Then* $\sum_{i=1}^{k}(t_i - 1) \le (d-1)\frac{\log c}{\log d}$.

Proof. Let $S = \sum_{i=1}^{k} t_i$. S can be viewed as a function of $k-1$ of the t_i's; for example, $S = \sum_{i=1}^{k-1} t_i + c/\prod_{i=1}^{k-1} t_i$. For $i \in \{1,\ldots,k-1\}$, the derivative of S with respect to t_i is $1 - c/(t_i \prod_{j=1}^{k-1} t_j)$. Thus, the derivative is positive if $t_i > t_k$. Thus, S is maximized (subject to c) by setting some t_i's to 1, some t_i's to d, and at most one t_i to some intermediate value $t \in [1,d)$. Given this, the maximum value of $\sum_{i=1}^{k}(t_i - 1)$ is $s(d-1) + t - 1$, where $c = d^s t$ and $s = \lfloor (\log c)/(\log d) \rfloor$. Let α be the fractional part of $(\log c)/(\log d)$, that is, $\alpha = (\log c)/(\log d) - s$. We want to show that $s(d-1) + t - 1 \le (d-1)(\log c)/(\log d)$. This is true, since

$$\begin{aligned}(d-1)\frac{\log c}{\log d} - s(d-1) - (t-1) &= \alpha(d-1) - c/d^s + 1 \\ &= \alpha(d-1) - d^\alpha + 1 \\ &\ge 0.\end{aligned}$$

The final inequality holds since we have equality for $d = 1$, and the partial derivative with respect to d proves that the inequality holds for $d > 1$. □

We now define some parameters of a state x. Let $k(x)$ denote the number of messages in state x. If $k(x) = 0$, then $p(x) = r(x) = u(x) = 0$. Otherwise, let $m_1,\ldots,m_{k(x)}$ denote the messages in state x, with send probabilities $\rho_1 \ge \cdots \ge \rho_{k(x)}$. Let $p(x) = \rho_1$ and let $r(x)$ denote the probability that at least one of $m_2,\ldots,m_{k(x)}$ sends on the next step. Let $u(x)$ denote the probability that exactly one of $m_2,\ldots,m_{k(x)}$ sends on the next step. Clearly $u(x) \le r(x)$. If $p(x) < r(x)$, then we use the following (tighter) upper bound for $u(x)$.

LEMMA 7. *If* $p(x) < r(x)$, *then* $u(x) \le \frac{r(x) - r(x)^2/2}{1 - p(x)/2}$.

Proof. Fix a state x. We will use $k, p, r, \ldots$ to denote $k(x), p(x), r(x), \ldots$. Since $p < r$, we have $k \ge 2$.

$$u = \sum_{i=2}^{k} \frac{\rho_i}{1-\rho_i} \prod_{i=2}^{k}(1-\rho_i) = \sum_{i=2}^{k}(t_i - 1)(1-r),$$

where $t_i = 1/(1-\rho_i)$. Let $d = 1/(1-p)$, and note that $1 \le t_i \le d$. By Lemma 6

$$\begin{aligned}u \le (1-r)(d-1)\frac{\log(\prod_{i=2}^{k} t_i)}{\log d} &= (1-r)\frac{p}{1-p}\frac{\log(1/(1-r))}{\log d} \\ &= (1-r)\frac{p}{1-p}\frac{(-\log(1-r))}{(-\log(1-p))}.\end{aligned}$$

Now we wish to show that

$$(1-r)\frac{p}{1-p}\frac{(-\log(1-r))}{(-\log(1-p))} \le \frac{r - r^2/2}{1 - p/2},$$

i.e., that

$$(1-r)\frac{(-\log(1-r))}{r - r^2/2} \le (1-p)\frac{(-\log(1-p))}{p - p^2/2}.$$

This is true, since the function $(1-r)^{\frac{(-\log(1-r))}{r-r^2/2}}$ is decreasing in r. To see this, note that the derivative of this function with respect to r is $y(r)/(r-r^2/2)^2$, where

$$\begin{aligned} y(r) &= (1-r+r^2/2)\log(1-r) + (r-r^2/2) \\ &\leq (1-r+r^2/2)(-r-r^2/2) + (r-r^2/2) = -r^4/4. \end{aligned}$$ □

Let $\mathcal{S}(x)$ denote the probability that there is a success when the system is run for one step starting in state x. (Recall that a success occurs if *exactly* one message sends during the step. This single sender might be a new arrival, or it might be an old message from state x.) Let

$$g(r,p) = e^{-\lambda}\left[(1-r)p + (1-p)\min\left\{r, \frac{r-r^2/2}{1-p/2}\right\} + (1-p)(1-r)\lambda\right].$$

We now have the following corollary of Lemma 7.

COROLLARY 8. *For any state x, $\mathcal{S}(x) \leq g(r(x),p(x))$.*

Let $s(x)$ denote the probability that at least one message in state x sends on the next step. That is, $s(x)$ is the probability that at least one *existing* message in x sends. New arrivals may also send. There may or may not be a success. (Thus, if x is the empty state, then $s(x) = 0$.) Let $A = 0.9$ and $B = 0.41$. For every $z \in [0,1]$, let $c(z) = \max(0, -A\,z + B)$. For every state x, let $f(x) = k(x) + c(s(x))$. The function f is the potential function alluded to earlier, which plays a leading role in Theorems 2 and 3. To a first approximation, $f(x)$ counts the number of messages in the state x, but the small correction term is crucial. Finally, let

$$h(r,p) = \lambda - g(r,p) - [1 - e^{-\lambda}(1-p)(1-r)(1+\lambda)]c(r+p-r\,p) + e^{-\lambda}p(1-r)c(r).$$

Now we have the following.

OBSERVATION 9. *For any state x, $E[\,|f(X_1) - f(X_0)|\mid X_0 = x] \leq 1 + B$.*

LEMMA 10. *For any state x, $E[f(X_1) - f(X_0) \mid X_0 = x] \geq h(r(x),p(x))$.*

Proof. The result follows from the following chain of inequalities, each link of which is justified below:

$$\begin{aligned} &E[f(X_1) - f(X_0) \mid X_0 = x] \\ &\quad = \lambda - \mathcal{S}(x) + E[c(s(X_1)) \mid X_0 = x] - c(s(x)) \\ &\quad \geq \lambda - g(r(x),p(x)) + E[c(s(X_1)) \mid X_0 = x] - c(s(x)) \\ &\quad \geq \lambda - g(r(x),p(x)) + e^{-\lambda}(1-p(x))(1-r(x))(1+\lambda)c(s(x)) \\ &\qquad\quad + e^{-\lambda}p(x)(1-r(x))c(r(x)) - c(s(x)) \\ &\quad = h(r(x),p(x)). \end{aligned}$$

The first inequality follows from Corollary 8. The second comes from substituting exact expressions for $c(s(X_1))$ whenever the form of X_1 allows it, and using the bound $c(s(X_1)) \geq 0$ elsewhere. If none of the existing messages sends and there is at most one arrival, then $c(s(X_1)) = c(s(x))$, giving the third term; if message m_1 alone sends and there are no new arrivals, then $c(s(X_1)) = c(r(x))$, giving the fourth term. The final equality uses the fact that $s(x) = p(x) + r(x) - p(x)r(x)$. □

LEMMA 11. *For any $r \in [0,1]$ and $p \in [0,1]$, $h(r,p) \geq 0.003$.*

Proof. We defer the proof of this lemma to the appendix. Figure 1 contains a (Mathematica-produced) plot of $-h(r,p)$ over the range $r \in [0,1]$, $p \in [0,1]$. The plot suggests that $-h(r,p)$ is bounded below zero.

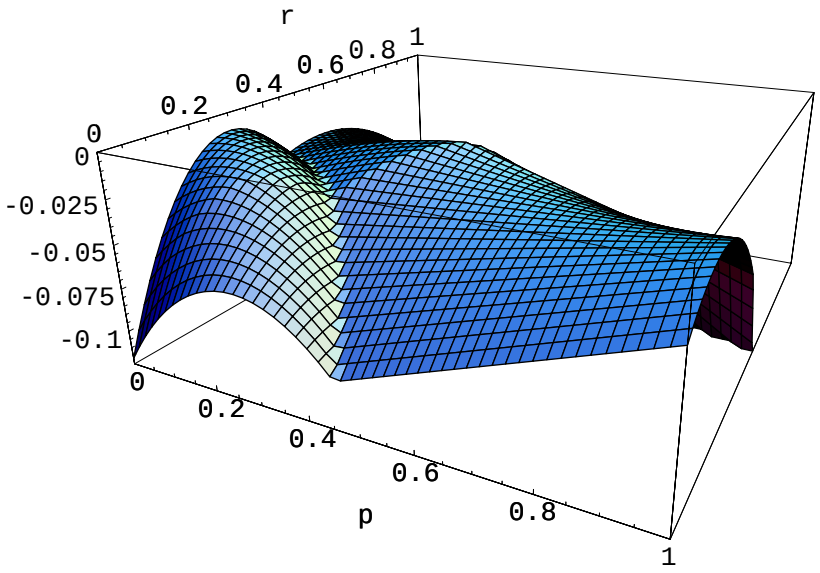

FIG. 1. $-h(r,p)$ *over the range* $r \in [0,1]$, $p \in [0,1]$.

We note here that our proof of the lemma (in the appendix) involves evaluating certain polynomials at about 40,000 points, and we did this using Mathematica. □

We now have the following theorem.

THEOREM 12. *No backoff protocol is positive recurrent when the arrival rate is* $\lambda = 0.42$.

Proof. This follows from Theorem 2, Observation 9, and Lemmas 10 and 11. The value C in Theorem 2 can be taken to be 1 and the value d can be taken to be $1 + B$. □

Now we wish to show that every backoff protocol is transient for $\lambda \geq 0.42$. Once again, fix a backoff protocol $p_0, p_1, \ldots$ with $p_0 = 1$. Notice that our potential function f almost satisfies the conditions in Theorem 3. The main problem is that there is no absolute bound on the amount that f can change in a single step, because the arrivals are drawn from a Poisson distribution. We get around this problem by first considering a *truncated-Poisson* distribution, $T_{M,\lambda}$, in which the probability of r inputs is $e^{-\lambda}\lambda^r/r!$ (as for the Poisson distribution) when $r < M$, but $r = M$ for the remaining probability. By choosing M sufficiently large we can have $E[T_{M,\lambda}]$ arbitrarily close to λ.

LEMMA 13. *Every backoff protocol is transient for the input distribution* $T_{M,\lambda}$ *when* $\lambda = 0.42$ *and* $\lambda' = E[T_{M,\lambda}] > \lambda - 0.001$.

Proof. The proof is almost identical to that of Theorem 12, except that the first term, λ, in the definition of $h(r,p)$ (for Lemmas 10 and 11) must be replaced by λ'. The corresponding function h' satisfies $h'(r,p) \geq h(r,p) - 0.001$. Thus Lemma 11 shows that $h'(r,p) \geq 0.002$ for all $r \in [0,1]$ and $p \in [0,1]$.

The potential function $f(x)$ is defined as before, but under the truncated input distribution we have the property required for Theorem 3. If $|f(x) - f(y)| > M + B$, then the probability of moving from x to y in a single move is 0.

The lemma follows from Theorem 3, where the values of C, ε, and d can be taken to be 1, 0.002, and $M + B$, respectively. □

We now have the following theorem.

THEOREM 14. *Every backoff protocol is transient under the Poisson distribution with arrival rate* $\lambda \geq 0.42$.

Proof. The proof is immediate from Lemma 13 and Observation 5. □

Finally, we bound the capacity of every backoff protocol.

THEOREM 15. *The capacity of every backoff protocol is at most* 0.42.

Proof. Let $p_0, p_1, \ldots$ be a backoff protocol, let $\lambda'' \geq 0.42$ be the arrival rate, and let $\lambda = 0.42$. View the arrivals at each step as Poisson(λ) "ordinary" messages and Poisson($\lambda'' - \lambda$) "ghost" messages. We will show that the protocol does not achieve average success rate λ''. Let $Y_0, Y_1, \ldots$ be the Markov chain describing the protocol. Let $k(Y_t)$ be the number of ordinary messages in the system after t steps. Clearly, the expected number of successes in the first t steps is at most $\lambda'' t - E[k(Y_t)]$. Now let $X_1, X_2, \ldots$ be the Markov chain describing the evolution of the backoff protocol with arrival rate λ (with no ghost messages). By deletion resilience (Observation 4), $E[k(Y_t)] \geq E[k(X_t)]$. Now by Lemmas 10 and 11, $E[k(X_t)] \geq E[f(X_t)] - B \geq 0.003\,t - B$. Thus, the expected number of successes in the first t steps is at most $(\lambda'' - 0.003)t + B$, which is less than $\lambda'' t$ if t is sufficiently large. (If X_0 is the empty state, then we do not require t to be sufficiently large, because $E[f(X_t)] \geq 0.003t + B$.) □

4.1. Improvements. We choose $\lambda = 0.42$ in order to make the proof of Lemma 11 (see the appendix) as simple as possible. The lemma seems to be true for λ down to about 0.41 and presumably the parameters A and B could be tweaked to get λ slightly smaller.

5. Acknowledgment-based protocols. We will prove that every acknowledgment-based protocol is transient for all $\lambda > 0.531$; see Theorem 21 for a precise statement of this claim.

An acknowledgment-based protocol can be viewed as a system which, at every step t, decides which subset of the old messages to send. The decision is a probabilistic one dependent on the histories of the messages held. As a technical device for proving our bounds, we introduce the notion of a "genie," which (in general) has more freedom in making these decisions than a protocol.

Since we consider only acknowledgment-based protocols, the behavior of each new message is independent of the other messages and of the state of the system until after its first send. This is why we ignore new messages until their first send—for Poisson arrivals this is equivalent to the convention that each message sends at its arrival time.

A *genie* is a random variable over the natural numbers, dependent on the complete history (of arrivals and sends of messages) up to time $t - 1$, which gives a natural number representing the number of messages that the genie will send at time t. Note that the number of messages that the genie sends at step t is independent of the number of newly arriving messages which send at step t. Also, the genie may send any number of messages at step t—possibly even more than the number of messages that arrived during steps $1, \ldots, t-1$. It is clear that for every acknowledgment-based protocol there is a corresponding genie. However, there are genies which do not behave like any protocol; e.g., a genie may give a cumulative total number of "sends" up to time t which exceeds the actual number of arrivals up to that time.

First, we consider the class of all genies. In Lemma 16, we show that if the arrival rate, λ, exceeds 0.567, then the backlog of messages (the difference between the cumulative number of arrivals and the cumulative number of successes) tends to infinity as time goes on. This implies that no genie has capacity greater than 0.567.

To get a better result, we consider a constrained class of genies called bucket genies. An ordinary genie (as defined previously) has no control over new inputs making their first send but has complete control over any other messages. (In particular, it can even send a message if none has arrived.) A bucket genie has no control over new inputs or over the "bucket" of messages that have already tried exactly once but has complete control over any other messages. We consider a particular type of bucket genie called an "eager" bucket genie. In Lemma 18 we show that for $\lambda \geq 0.531$, the backlog tends to infinity for eager bucket genies. In Lemma 19 we show how any bucket genie (including the acknowledgment-based protocol under consideration) can be coupled with an eager bucket genie in such a way that the the arbitrary bucket genie doesn't have many more successes than the eager bucket genie. This, combined with Lemma 16 (which shows that the eager genie doesn't have enough successes), proves the theorem.

Let $I(t), G(t)$ be the number of arrivals and the genie's send value, respectively, at step t. It is convenient to introduce some indicator variables to express various outcomes at the step under consideration. We use i_0, i_1 for the events of no new arrival, or exactly one arrival, respectively, and g_0, g_1 for the events of no send and exactly one send from the genie. The indicator random variable $S(t)$ for a success at time t is given by $S(t) = i_0 g_1 + i_1 g_0$. Let $\mathrm{In}(t) = \sum_{j \leq t} I(j)$ and $\mathrm{Out}(t) = \sum_{j \leq t} S(j)$. Define $\mathrm{Backlog}(t) = \mathrm{In}(t) - \mathrm{Out}(t)$. Let $\lambda = \lambda_0 \approx 0.567$ be the (unique) root of $\lambda = e^{-\lambda}$.

LEMMA 16. *For any genie and input rate $\lambda > \lambda_0$, there exists $\varepsilon > 0$ such that*

$$\mathrm{Prob}[\mathrm{Backlog}(t) > \varepsilon t \text{ for all } t \geq T] \to 1 \text{ as } T \to \infty.$$

Proof. Let $3\varepsilon = \lambda - e^{-\lambda} > 0$. At any step t, $S(t)$ is a Bernoulli variable with expectation $0, e^{-\lambda}, \lambda e^{-\lambda}$, according to whether $G(t) > 1$, $G(t) = 1$, $G(t) = 0$, respectively, which is dominated by the Bernoulli variable with expectation $e^{-\lambda}$. Therefore $\mathrm{E}[\mathrm{Out}(t)] \leq e^{-\lambda} t$, and also $\mathrm{Prob}[\mathrm{Out}(t) - e^{-\lambda} t < \varepsilon t \text{ for all } t \geq T] \to 1$ as $T \to \infty$. (To see this note that, by a Chernoff bound, $\mathrm{Prob}[\mathrm{Out}(t) - e^{-\lambda} t \geq \varepsilon t] \leq e^{-\delta t}$ for a positive constant δ. Thus,

$$\mathrm{Prob}[\exists t \geq T \text{ such that } \mathrm{Out}(t) - e^{-\lambda} t \geq \varepsilon t] \leq \sum_{t \geq T} e^{-\delta t},$$

which goes to 0 as T goes to ∞.)

We also have $\mathrm{E}[\mathrm{In}(t)] = \lambda t$ and $\mathrm{Prob}[\lambda t - \mathrm{In}(t) \leq \varepsilon t \text{ for all } t \geq T] \to 1$ as $T \to \infty$, since $\mathrm{In}(t) = \mathrm{Poisson}(\lambda t)$.

Since

$$\begin{aligned} \mathrm{Backlog}(t) &= \mathrm{In}(t) - \mathrm{Out}(t) \\ &= (\lambda - e^{-\lambda})t + (\mathrm{In}(t) - \lambda t) + (e^{-\lambda} t - \mathrm{Out}(t)) \\ &= \varepsilon t + (\varepsilon t + \mathrm{In}(t) - \lambda t) + (\varepsilon t + e^{-\lambda} t - \mathrm{Out}(t)), \end{aligned}$$

the result follows. □

COROLLARY 17. *No acknowledgment-based protocol is recurrent for $\lambda > \lambda_0$ or has capacity greater than λ_0.*

To strengthen the above result we introduce a restricted class of genies. We think of the messages which have failed exactly once as being contained in *the bucket*. (More generally, we could consider an array of buckets, where the jth bucket contains those messages which have failed exactly j times.) A 1-*bucket genie*, here called simply

a *bucket genie*, is a genie which simulates a given protocol for the messages in the bucket and is required to choose a send value which is at least as great as the number of sends from the bucket. Thus, on a given step, some number, say b, of the messages in the bucket will decide to send. Each of these decisions is made independently by each message, which is simulating the protocol. Then the genie will choose a number $x \geq b$, which is the number of sends that it will make. As before, g_0 is the indicator for $x = 0$ and g_1 is the indicator for $x = 1$. The indicator for success is $S(t) = i_0 g_1 + i_1 g_0$. At the end of the step, the b messages from the bucket which have sent leave the bucket. Also, any new arrivals which have collided join the bucket. Note that if the messages in the bucket decide not to send (i.e., $b = 0$) and there are no new arrivals (i.e., $i_0 = 1$), then $S(t)$ can be either 1 or 0, depending on whether or not $x = 1$. No matter what x is, no messages enter or leave the bucket during this step. For such constrained genies, we can improve the bound of Corollary 17.

For the range of arrival rates we consider, an excellent strategy for a genie is to ensure that at least one message is sent at each step. Of course a bucket genie has to respect the bucket messages and is obliged sometimes to send more than one message (inevitably failing). An *eager* genie always sends at least one message, but otherwise sends as few as possible. In particular, it sends $x = \min(1, b)$.

An eager bucket genie is easy to analyze, since every arrival is blocked by the genie and enters the bucket.

Let $\lambda = \lambda_1 \approx 0.531$ be the (unique) root of $\lambda = (1 + \lambda)e^{-2\lambda}$.

LEMMA 18. *For any eager bucket genie and input rate $\lambda > \lambda_1$, there exists $\varepsilon > 0$ such that*

$$\text{Prob}[\text{Backlog}(t) > \varepsilon t \text{ for all } t \geq T] \to 1 \text{ as } T \to \infty.$$

Proof. Let *Eager* be an eager bucket genie. Let r_i be the probability that a message in the bucket sends for the first time (and hence exits from the bucket) i steps after its arrival. Assume $\sum_{i=1}^{\infty} r_i = 1$; otherwise there is a positive probability that the message never exits from the bucket, and the result follows trivially.

The generating function for the Poisson distribution with rate λ is $e^{\lambda(z-1)}$ (i.e., the coefficient of z^k in this function gives the probability of exactly k arrivals; see, e.g., [11]). Consider the sends from the bucket at step t. Since *Eager* always blocks arriving messages, the generating function for messages entering the bucket i time steps in the past, $1 \leq i \leq t$, is $e^{\lambda(z-1)}$. Some of these messages may send at step t; the generating function for the number of sends is $e^{\lambda[(1-r_i)+r_i z-1]} = e^{\lambda r_i(z-1)}$. Finally, the generating function for all sends from the bucket at step t is the convolution of all these functions, i.e.,

$$\prod_{i=1}^{t} \exp(\lambda r_i(z-1)) = \exp\left[\lambda(z-1)\sum_{i=1}^{t} r_i\right].$$

For any $\delta > 0$, we can choose t sufficiently large so that $\sum_{i=1}^{t} r_i > 1 - \delta$. The number of sends from the bucket at step t is distributed as Poisson(λ'), where $(1-\delta)\lambda < \lambda' \leq \lambda$. The number of new arrivals sending at step t is independently Poisson(λ). The only situation in which a message succeeds under *Eager* is when there are no new arrivals and the number of sends from the bucket is zero or one. Thus the success probability at step t is $e^{-\lambda}e^{-\lambda'}(1 + \lambda')$. For sufficiently small δ, we have $\lambda_1 < \lambda' \leq \lambda$, and so $e^{-\lambda'}(1 + \lambda') < e^{-\lambda_1}(1 + \lambda_1) = e^{\lambda_1}\lambda_1 < e^{\lambda}\lambda$. Hence $e^{-\lambda}e^{-\lambda'}(1 + \lambda') \leq \lambda - 3\epsilon$ for ϵ sufficiently small. Thus the success event is dominated

by a Bernoulli variable with expectation $\lambda - 3\epsilon$. Hence, as in the previous lemma,

$$\text{Prob}[\text{Backlog}(t) > \varepsilon t \text{ for all } t \geq T] \to 1 \text{ as } T \to \infty,$$

completing the proof. □

Let *Any* be an arbitrary bucket genie and let *Eager* be the eager bucket genie based on the same bucket parameters. We may couple the executions of *Eager* and *Any* so that the same arrival sequences are presented to each. At any stage the set of messages in *Any*'s bucket is a subset of those in *Eager*'s bucket, with any differences arising from steps when there is exactly one arrival, there are no sends from the bucket, and *Eager* sends but *Any* is silent. We may further couple the behavior of the common subset of messages.

Let $\lambda = \lambda_2 \approx 0.659$ be the (unique) root of $\lambda = 1 - \lambda e^{-\lambda}$.

LEMMA 19. *For the coupled genies* Any *and* Eager *defined above, if* Out_A *and* Out_E *are the corresponding output functions, we define*

$$\Delta\text{Out}(t) = \text{Out}_E(t) - \text{Out}_A(t).$$

For any $\lambda \leq \lambda_2$ *and any* $\varepsilon > 0$,

$$\text{Prob}[\Delta\text{Out}(t) \geq -\varepsilon t \text{ for all } t \geq T] \to 1 \text{ as } T \to \infty.$$

Proof. Let c_0 be the indicator for the event that no common messages are sent. Let c_1 be the indicator for the event that exactly one common message is sent. Let c_* be the indicator for the event that more than one common message is sent. In addition, for the messages which are only in *Eager*'s bucket, we use the similar indicators e_0, e_1, e_*. Let a_0, a_1 represent *Any* not sending, or sending, *additional* messages, respectively. (Note that *Eager*'s behavior is fully determined since it will always send exactly one additional message if none of the messages in its bucket send. Otherwise, it will send no additional messages.)

We write $Z(t)$ for $\Delta\text{Out}(t) - \Delta\text{Out}(t-1)$, for $t > 0$, so Z represents the difference in success between *Eager* and *Any* in one step. In terms of the indicators we have

$$\begin{aligned} Z(t) &= S_E(t) - S_A(t) \\ &= i_0 g_{E1}(t) + i_1 g_{E0}(t) - i_0 g_{A1}(t) - i_1 g_{A0}(t), \end{aligned}$$

where $S_E(t)$ is the indicator random variable for a success of *Eager* at time t and $g_{E1}(t)$ is the event that *Eager* sends exactly one message during step t (and so on) as in the paragraph before Lemma 16. Thus,

$$Z(t) \geq i_0 c_0 (a_0(e_0 + e_1) - a_1 e_*) - i_0 c_1 (e_1 + e_*) - i_1 c_0 a_0.$$

Note that if the number of arrivals plus the number of common bucket sends is more than 1, then neither genie can succeed. We also need to keep track of the number, ΔB, of extra messages in *Eager*'s bucket. At any step, at most one new extra message can arrive; the indicator for this event is $i_1 c_0 a_0$, i.e., there is a single arrival and no sends from the common bucket, so if *Any* does not send, then this message succeeds but *Eager*'s send will cause a failure. The number of "extra" messages leaving *Eager*'s bucket at any step is unbounded, given by a random variable we could show as $\mathbf{e} = 1 \cdot e_1 + 2 \cdot e_2 + \cdots$. However, $\mathbf{e}$ dominates $e_1 + e_*$ and it is sufficient to use the latter. The change at one step in the number of extra messages satisfies

$$\Delta B(t) - \Delta B(t-1) = i_1 c_0 a_0 - \mathbf{e} \leq i_1 c_0 a_0 - (e_1 + e_*).$$

Next we define $Y(t) = Z(t) - \alpha(\Delta B(t) - \Delta B(t-1))$ for some positive constant α to be chosen below. Note that $X(t) = \sum_{j=1}^{t} Y(j) = \Delta\mathrm{Out}(t) - \alpha\Delta B(t)$. We also define

$$Y'(t) = i_0c_0(a_0(e_0+e_1) - a_1e_*) - i_0c_1(e_1+e_*) - i_1c_0a_0 - \alpha(i_1c_0a_0 - (e_1+e_*))$$

and $X'(t) = \sum_{j=1}^{t} Y'(j)$. Note that $Y(t) \geq Y'(t)$. That is, $Y(t)$ dominates $Y'(t)$.

We can identify five (exhaustive) cases A, B, C, D, E, depending on the values of the c's, a's, and e's, such that in each case $Y'(t)$ dominates a given random variable depending only on $I(t)$:

A.	c_*:	$Y'(t) \geq 0$.
B.	$(c_1 + c_0a_1)(e_1 + e_*)$:	$Y'(t) \geq \alpha - i_0$.
C.	$(c_1 + c_0a_1)e_0$:	$Y'(t) \geq 0$.
D.	$c_0a_0(e_0 + e_1)$:	$Y'(t) \geq i_0 - (1+\alpha)i_1$.
E.	$c_0a_0e_*$:	$Y'(t) \geq \alpha - (1+\alpha)i_1$.

For example, the correct interpretation of case B is "conditioned on $(c_1 + c_0a_1)(e_1 + e_*) = 1$, the value of $Y'(t)$ is at least $\alpha - i_0$." Since $\mathrm{E}[i_0] = e^{-\lambda}$ and $\mathrm{E}[i_1] = \lambda e^{-\lambda}$, we have $\mathrm{E}[Y'(t)] \geq 0$ in each case, provided that $\max\{e^{-\lambda}, \lambda e^{-\lambda}/(1-\lambda e^{-\lambda})\} \leq \alpha \leq 1/\lambda - 1$. There exists such an α for any $\lambda \leq \lambda_2$; for such λ we may take the value, say, $\alpha = e^{-\lambda}$.

Let $\mathcal{F}_t$ be the σ-field generated by the first t steps of the coupled process. Let $\hat{Y}(t) = Y'(t) - E[Y'(t) \mid \mathcal{F}_{t-1}]$ and let $\hat{X}(t) = \sum_{i=1}^{t} \hat{Y}(t)$. The sequence $\hat{X}(0), \hat{X}(1), \ldots$ forms a *martingale* (see Definition 4.11 of [21]) since $E[\hat{X}(t) \mid \mathcal{F}_{t-1}] = \hat{X}(t-1)$. Furthermore, there is a positive constant c such that $|\hat{X}(t) - \hat{X}(t-1)| \leq c$. Thus, we can apply the Hoeffding–Azuma inequality (see Theorem 4.16 of [21]).

THEOREM 20 (Hoeffding–Azuma). *Let $X_0, X_1, \ldots$ be a martingale sequence such that for each k*

$$|X_k - X_{k-1}| \leq c_k,$$

where c_k may depend upon k. Then, for all $t \geq 0$ and any $\lambda > 0$,

$$\mathrm{Prob}[\,|X_t - X_0| \geq \lambda] \leq 2\exp\left(-\frac{\lambda^2}{2\sum_{k=1}^{t} c_k^2}\right).$$

In particular, we can conclude that

$$\mathrm{Prob}[\hat{X}_t \leq -\epsilon t] \leq 2\exp\left(-\frac{\epsilon^2 t}{2c^2}\right).$$

Our choice of α above ensured that $E[Y'(t) \mid \mathcal{F}_{t-1}] \geq 0$. Hence $Y'(t) \geq \hat{Y}(t)$ and $X'(t) \geq \hat{X}(t)$. We observed earlier that $X(t) \geq X'(t)$. Thus, $X(t) \geq \hat{X}(t)$ so we have

$$\mathrm{Prob}[X_t \leq -\epsilon t] \leq 2\exp\left(-\frac{\epsilon^2 t}{2c^2}\right).$$

Since $\sum_{t\geq 0} 2\exp(-\frac{\epsilon^2 t}{2c^2})$ converges, we deduce that

$$\mathrm{Prob}[X(t) \geq -\varepsilon t \text{ for all } t \geq T] \to 1 \text{ as } T \to \infty.$$

Since $\Delta\mathrm{Out}(t) = X(t) + \alpha\Delta B(t) \geq X(t)$ for all t, we obtain the required conclusion. ∎

Finally, we can prove the main results of this section.

THEOREM 21. *Let P be an acknowledgment-based protocol. Let $\lambda = \lambda_1 \approx 0.531$ be the (unique) root of $\lambda = (1+\lambda)e^{-2\lambda}$. Then*

1. *P is transient for arrival rates greater than λ_1;*
2. *P has capacity no greater than λ_1.*

Proof. Let λ be the arrival rate, and suppose $\lambda > \lambda_1$. If $\lambda > \lambda_0 \approx 0.567$, then the result follows from Lemma 16. Otherwise, we can assume that $\lambda < \lambda_2 \approx 0.659$. If E is the eager genie derived from P, then the corresponding Backlogs satisfy $\text{Backlog}_P(t) = \text{Backlog}_E(t) + \Delta\text{Out}(t)$. The results of Lemmas 18 and 19 show that, for some $\varepsilon > 0$, both $\text{Prob}[\text{Backlog}_E(t) > 2\varepsilon t \text{ for all } t \geq T]$ and $\text{Prob}[\Delta\text{Out}(t) \geq -\varepsilon t \text{ for all } t \geq T]$ tend to 1 as $T \to \infty$. The conclusion of the theorem follows. □

Appendix. Proof of Lemma 11. Let $j(r,p) = -h(r,p)$. We will show that for any $r \in [0,1]$ and $p \in [0,1]$, $j(r,p) \leq -0.003$.

Case 1. *$r + p - rp \geq r \geq B/A$ and $p \geq r$.* In this case we have

$$g(r,p) = e^{-\lambda}((1-r)p + (1-p)r + (1-p)(1-r)\lambda),$$
$$j(r,p) = g(r,p) - \lambda.$$

Observe that

$$j(r,p) = e^{-\lambda} \sum_{i=0}^{1} \sum_{j=0}^{1} c_{i,j} p^i r^j,$$

where the coefficients $c_{i,j}$ are defined as follows:

$$c_{0,0} = \lambda(1 - e^{\lambda}),$$
$$c_{1,0} = 1 - \lambda,$$
$$c_{0,1} = 1 - \lambda,$$
$$c_{1,1} = -2 + \lambda.$$

Note that the only positive coefficients are $c_{1,0}$ and $c_{0,1}$. Thus, if $p \in [p_1, p_2]$ and $r \in [r_1, r_2]$, then $j(r,p)$ is at most $\mathcal{U}(p_1, p_2, r_1, r_2)$, which we define as

$$e^{-\lambda}(c_{0,0} + c_{1,0}p_2 + c_{0,1}r_2 + c_{1,1}p_1 r_1).$$

Now we need only check that for all $r_1 \in (B/A - 0.01, 1)$ and $p_1 \in [r_1, 1)$ such that p_1 and r_1 are multiples of 0.01, $\mathcal{U}(p_1, p_1 + 0.01, r_1, r_1 + 0.01)$ is at most -0.003. This is the case. (The highest value is $\mathcal{U}(0.45, 0.46, 0.45, 0.46)$, which is -0.00366228.)

Case 2. *$r + p - rp \geq r \geq B/A$ and $p < r$.* Now we have

$$g(r,p) = e^{-\lambda}\left((1-r)p + (1-p)\frac{r - r^2/2}{1 - p/2} + (1-p)(1-r)\lambda\right),$$
$$j(r,p) = g(r,p) - \lambda.$$

Observe that

$$(1 - p/2)j(r,p) = e^{-\lambda} \sum_{i=0}^{2} \sum_{j=0}^{2} c_{i,j} p^i r^j,$$

where the coefficients $c_{i,j}$ are defined as follows:

$$\begin{aligned}
c_{0,0} &= \lambda(1-e^{\lambda}),\\
c_{1,0} &= 1-3\lambda/2+e^{\lambda}\lambda/2,\\
c_{0,1} &= 1-\lambda,\\
c_{1,1} &= -2+3\lambda/2,\\
c_{2,0} &= -1/2+\lambda/2,\\
c_{0,2} &= -1/2,\\
c_{2,1} &= 1/2-\lambda/2,\\
c_{1,2} &= 1/2,\\
c_{2,2} &= 0.
\end{aligned}$$

Note that the only positive coefficients are $c_{1,0}$, $c_{0,1}$, $c_{2,1}$, and $c_{1,2}$. Thus, if $p \in [p_1, p_2]$ and $r \in [r_1, r_2]$, then $j(r,p)$ is at most $\mathcal{U}(p_1, p_2, r_1, r_2)$, which we define as

$$\frac{c_{0,0}+c_{1,0}p_2+c_{0,1}r_2+c_{1,1}p_1r_1+c_{2,0}p_1^2+c_{0,2}r_1^2+c_{2,1}p_2^2r_2+c_{1,2}p_2r_2^2+c_{2,2}p_1^2r_1^2}{e^{\lambda}(1-p_2/2)}.$$

Now we need only check that for all $r_1 \in (B/A-0.005, 1)$ and $p_1 \in [0, r_1]$ such that p_1 and r_1 are multiples of 0.005, $\mathcal{U}(p_1, p_1+0.005, r_1, r_1+0.005)$ is at most -0.003. This is the case. (The highest value for these parameters is $\mathcal{U}(0.45, 0.455, 0.455, 0.46) = -0.00479648$.)

Case 3. $r+p-rp \geq B/A \geq r$ *and* $p \geq r$. In this case we have

$$\begin{aligned}
g(r,p) &= e^{-\lambda}((1-r)p+(1-p)r+(1-p)(1-r)\lambda),\\
j(r,p) &= g(r,p)-\lambda-(-Ar+B)e^{-\lambda}(1-r)p.
\end{aligned}$$

Observe that

$$j(r,p) = e^{-\lambda}\sum_{i=0}^{2}\sum_{j=0}^{2} c_{i,j}p^i r^j,$$

where the coefficients $c_{i,j}$ are defined as follows:

$$\begin{aligned}
c_{0,0} &= \lambda(1-e^{\lambda}),\\
c_{1,0} &= 1-B-\lambda,\\
c_{0,1} &= 1-\lambda,\\
c_{1,1} &= -2+A+B+\lambda,\\
c_{2,0} &= 0,\\
c_{0,2} &= 0,\\
c_{2,1} &= 0,\\
c_{1,2} &= -A,\\
c_{2,2} &= 0.
\end{aligned}$$

Note that the only positive coefficients are $c_{1,0}$ and $c_{0,1}$. Thus, if $p \in [p_1, p_2]$ and $r \in [r_1, r_2]$, then $j(r,p)$ is at most $\mathcal{U}(p_1, p_2, r_1, r_2)$, which we define as

$$\frac{c_{0,0}+c_{1,0}p_2+c_{0,1}r_2+c_{1,1}p_1r_1+c_{2,0}p_1^2+c_{0,2}r_1^2+c_{2,1}p_1^2r_1+c_{1,2}p_1r_1^2+c_{2,2}p_1^2r_1^2}{e^{\lambda}}.$$

Now we need only check that for all $p_1 \in [0,1)$ and $r_1 \in [0,p_1]$ such that p_1 and r_1 are multiples of 0.01, $\mathcal{U}(p_1, p_1+0.01, r_1, r_1+0.01)$ is at most -0.003. This is the case. (The highest value is $\mathcal{U}(0.44, 0.45, 0.44, 0.45) = -0.00700507$.)

Case 4. $r + p - rp \geq B/A \geq r$ *and* $p < r$. Now we have

$$g(r,p) = e^{-\lambda}\left((1-r)p + (1-p)\frac{r - r^2/2}{1-p/2} + (1-p)(1-r)\lambda\right),$$
$$j(r,p) = g(r,p) - \lambda - (-Ar + B)e^{-\lambda}(1-r)p.$$

Observe that

$$j(r,p) = e^{-\lambda}(1/2)\frac{\sum_{i=0}^{2}\sum_{j=0}^{2} c_{i,j}p^i r^j}{1-p/2},$$

where the coefficients $c_{i,j}$ are defined as follows:

$$\begin{aligned}
c_{0,0} &= 2\lambda(1-e^{\lambda}),\\
c_{1,0} &= 2 - 2B - 3\lambda + \lambda e^{\lambda},\\
c_{0,1} &= 2 - 2\lambda,\\
c_{1,1} &= -4 + 2A + 2B + 3\lambda,\\
c_{2,0} &= -1 + B + \lambda,\\
c_{0,2} &= -1,\\
c_{2,1} &= 1 - A - B - \lambda,\\
c_{1,2} &= 1 - 2A,\\
c_{2,2} &= A.
\end{aligned}$$

Note that the coefficients are all negative except $c_{1,0}$, $c_{0,1}$, and $c_{2,2}$. Thus, if $p \in [p_1, p_2]$ and $r \in [r_1, r_2]$, then $j(r,p)$ is at most $\mathcal{U}(p_1, p_2, r_1, r_2)$, which we define as

$$\frac{c_{0,0} + c_{1,0}p_2 + c_{0,1}r_2 + c_{1,1}p_1r_1 + c_{2,0}p_1^2 + c_{0,2}r_1^2 + c_{2,1}p_1^2r_1 + c_{1,2}p_1r_1^2 + c_{2,2}p_2^2r_2^2}{2e^{\lambda}(1-p_2/2)}.$$

Now we need only check that for all $p_1 \in [0,1)$ and $r_1 \in [p_1,1)$ such that p_1 and r_1 are multiples of 0.01, $\mathcal{U}(p_1, p_1+0.01, r_1, r_1+0.01)$ is at most -0.003. This is the case. (The highest value is $\mathcal{U}(0.44, 0.45, 0.44, 0.45) = -0.00337716$.)

Case 5. $B/A \geq r + p - rp \geq r$ *and* $p \geq r$. In this case we have

$$\begin{aligned}
g(r,p) &= e^{-\lambda}((1-r)p + (1-p)r + (1-p)(1-r)\lambda),\\
j(r,p) &= g(r,p) - \lambda\\
&\quad + (-A(r+p-rp) + B)(1 - (1-r)(1-p)e^{-\lambda}(1+\lambda))\\
&\quad - (-Ar + B)e^{-\lambda}(1-r)p.
\end{aligned}$$

Observe that

$$j(r,p) = e^{-\lambda}\sum_{i=0}^{2}\sum_{j=0}^{2} c_{i,j}p^i r^j,$$

where the coefficients $c_{i,j}$ are defined as follows:

$$\begin{aligned}
c_{0,0} &= -B + Be^{\lambda} + \lambda - B\lambda - e^{\lambda}\lambda,\\
c_{1,0} &= 1 + A - Ae^{\lambda} - \lambda + A\lambda + B\lambda,\\
c_{0,1} &= 1 + A + B - Ae^{\lambda} - \lambda + A\lambda + B\lambda,\\
c_{1,1} &= -2 - 2A + Ae^{\lambda} + \lambda - 3A\lambda - B\lambda,\\
c_{2,0} &= -A - A\lambda,\\
c_{0,2} &= -A - A\lambda,\\
c_{2,1} &= 2A + 2A\lambda,\\
c_{1,2} &= A + 2A\lambda,\\
c_{2,2} &= -A - A\lambda.
\end{aligned}$$

Note that the only positive coefficients are $c_{1,0}$, $c_{0,1}$, $c_{2,1}$, and $c_{1,2}$. Thus, if $p \in [p_1, p_2]$ and $r \in [r_1, r_2]$, then $j(r,p)$ is at most $\mathcal{U}(p_1, p_2, r_1, r_2)$, which we define as

$$\frac{c_{0,0} + c_{1,0}p_2 + c_{0,1}r_2 + c_{1,1}p_1r_1 + c_{2,0}p_1^2 + c_{0,2}r_1^2 + c_{2,1}p_2^2r_2 + c_{1,2}p_2r_2^2 + c_{2,2}p_1^2r_1^2}{e^{\lambda}}.$$

Now we need only check that for all $p_1 \in [0,1)$ and $r_1 \in [0, p_1]$ such that p_1 and r_1 are multiples of 0.01, $\mathcal{U}(p_1, p_1 + 0.01, r_1, r_1 + 0.01)$ is at most -0.003. This is the case. (The highest value is $\mathcal{U}(0.19, 0.2, 0.19, 0.2) = -0.0073656$.)

Case 6. $B/A \geq r + p - rp \geq r$ *and* $p < r$. Now we have

$$\begin{aligned}
g(r,p) &= e^{-\lambda}\left((1-r)p + (1-p)\frac{r - r^2/2}{1 - p/2} + (1-p)(1-r)\lambda\right),\\
j(r,p) &= g(r,p) - \lambda\\
&\quad + (-A(r + p - rp) + B)(1 - (1-r)(1-p)e^{-\lambda}(1+\lambda))\\
&\quad - (-Ar + B)e^{-\lambda}(1-r)p.
\end{aligned}$$

Observe that

$$(1 - p/2)j(r,p) = e^{-\lambda}\sum_{i=0}^{3}\sum_{j=0}^{2} c_{i,j}p^i r^j,$$

where the coefficients $c_{i,j}$ are defined as follows:

$$\begin{aligned}
c_{0,0} &= -B + Be^{\lambda} + \lambda - B\lambda - e^{\lambda}\lambda,\\
c_{1,0} &= 1 + A + B/2 - Ae^{\lambda} - Be^{\lambda}/2 - 3\lambda/2 + A\lambda + 3B\lambda/2 + e^{\lambda}\lambda/2,\\
c_{0,1} &= 1 + A + B - Ae^{\lambda} - \lambda + A\lambda + B\lambda,\\
c_{1,1} &= -2 - 5A/2 - B/2 + 3Ae^{\lambda}/2 + 3\lambda/2 - 7A\lambda/2 - 3B\lambda/2,\\
c_{2,0} &= -1/2 - 3A/2 + Ae^{\lambda}/2 + \lambda/2 - 3A\lambda/2 - B\lambda/2,\\
c_{0,2} &= -1/2 - A - A\lambda,\\
c_{2,1} &= 1/2 + 3A - Ae^{\lambda}/2 - \lambda/2 + 7A\lambda/2 + B\lambda/2,\\
c_{1,2} &= 1/2 + 3A/2 + 5A\lambda/2,\\
c_{2,2} &= -3A/2 - 2A\lambda,\\
c_{3,0} &= A/2 + A\lambda/2,\\
c_{3,1} &= -A - A\lambda,\\
c_{3,2} &= A/2 + A\lambda/2.
\end{aligned}$$

Note that the only positive coefficients are $c_{1,0}$, $c_{0,1}$, $c_{2,1}$, $c_{1,2}$, $c_{3,0}$, and $c_{3,2}$. Thus, if $p \in [p_1, p_2]$ and $r \in [r_1, r_2]$, then $j(r,p)$ is at most $\mathcal{U}(p_1, p_2, r_1, r_2)$, which we define as

$$c_{0,0} + c_{1,0}p_2 + c_{0,1}r_2 + c_{1,1}p_1r_1 + c_{2,0}p_1^2 + c_{0,2}r_1^2 + c_{2,1}p_2^2r_2 + c_{1,2}p_2r_2^2 + c_{2,2}p_1^2r_1^2 + c_{3,0}p_2^3 + c_{3,1}p_1^3r_1 + c_{3,2}p_2^3r_2^2$$

divided by $e^\lambda(1 - p_2/2)$.

Now we need only check that for all $p_1 \in [0, 1)$ and $r_1 \in [p_1, 1)$ such that p_1 and r_1 are multiples of 0.005, $\mathcal{U}(p_1, p_1 + 0.005, r_1, r_1 + 0.005)$ is at most -0.003. This is the case. (The highest value is $\mathcal{U}(0.01, 0.015, 0.3, 0.305) = -0.00383814$.)

STACKELBERG SCHEDULING STRATEGIES*

TIM ROUGHGARDEN†

Abstract. We study the problem of optimizing the performance of a system shared by selfish, noncooperative users. We consider the concrete setting of scheduling small jobs on a set of shared machines possessing latency functions that specify the amount of time needed to complete a job, given the machine load. We measure system performance by the *total latency* of the system.

Assigning jobs according to the selfish interests of individual users, who wish to minimize only the latency that their own jobs experience, typically results in suboptimal system performance. However, in many systems of this type there is a mixture of "selfishly controlled" and "centrally controlled" jobs. The congestion due to centrally controlled jobs will influence the actions of selfish users, and we thus aspire to contain the degradation in system performance due to selfish behavior by scheduling the centrally controlled jobs in the best possible way.

We formulate this goal as an optimization problem via *Stackelberg games*, games in which one player acts a *leader* (here, the centralized authority interested in optimizing system performance) and the rest as *followers* (the selfish users). The problem is then to compute a strategy for the leader (a *Stackelberg strategy*) that induces the followers to react in a way that (approximately) minimizes the total latency in the system.

In this paper, we prove that it is NP-hard to compute an optimal Stackelberg strategy and present simple strategies with provably good performance guarantees. More precisely, we give a simple algorithm that computes a strategy inducing a job assignment with total latency no more than a constant times that of the optimal assignment of all of the jobs; in the absence of centrally controlled jobs and a Stackelberg strategy, no result of this type is possible. We also prove stronger performance guarantees in the special case where every machine latency function is linear in the machine load.

Key words. selfish routing, Stackelberg equilibria, scheduling

1. Introduction.

Coping with selfishness. One of the most basic problems arising in the management of a set of resources is that of optimizing system performance. A concrete example of such a problem is as follows: given a large set of small jobs to be assigned to a set of machines, each with a latency function that specifies the amount of time needed to complete a job given the machine load, find the allocation of jobs to machines minimizing the *total latency* of the system.

In many such systems, including the Internet and other large-scale communication networks, there is no central authority controlling the allocation of shared resources; instead, system users are free to act in a selfish manner [7]. This observation has led many authors (e.g., [13, 26, 30, 37, 45, 48]) to model the behavior of users in such a system by a *noncooperative game* and to study the resulting *Nash equilibria*. (See [38] for an introduction to basic game-theoretic concepts.)

Motivated by the well-known fact that Nash equilibria may be *inefficient* [16]

†Department of Computer Science, Cornell University, Ithaca, NY 14853. Current address: Computer Science Division, UC Berkeley, Soda Hall, Berkeley, CA 94720 (timr@cs.berkeley.edu).

(i.e., they need not optimize system performance), researchers have proposed several different approaches for *coping with selfishness*—that is, for ensuring that selfish behavior results in a desirable outcome. Recent examples abound in the computer science literature: to name a few, Korilis, Lazar, and Orda [27, 28] give methods for improving system performance by adding additional capacity to system resources, Cocchi et al. [8] and Cole, Dodis, and Roughgarden [9, 10] investigate the control of selfish users through various pricing policies, Shenker [48] demonstrates that an appropriate (centralized) protocol at a network switch induces selfish users to exhibit good flow control behavior, and Roughgarden [42] studies the problem of designing networks that exhibit good performance when used selfishly.

A related area of research concerned with controlling selfish behavior with efficient algorithms is that of *algorithmic mechanism design* [2, 19, 35, 36, 41], which in turn is inspired by classical mechanism design (see, e.g., Mas-Colell, Whinston, and Green [33, Chap. 23]). In this setting, an algorithm is designed to collect data from users and compute an outcome using this data. For example, the algorithm might compute the set of users that will receive some good, perhaps a movie multicast over the Internet, based on the bids of the users of the system. The difficulty of these problems stems from the assumptions that the algorithm is publicly known and that users are selfish and may report false data, if doing so improves their personal objective function. This problem is typically resolved via a *payment scheme*, where the algorithm distributes payments to users according to the outcome and the data collected so that all users have a strong incentive to report truthful data.

In this paper, we pursue a different approach. In many systems, there will be a mix of "selfishly controlled" and "centrally controlled" jobs—that is, the shared resource is used by both selfish individuals and some central authority. For example, clients of a system may be charged at two different prices: clients paying the higher price are given access to the system and the ability to schedule their own tasks (presumably in a way that accomplishes them as quickly as possible), while clients paying only the "bargain rate" can use the system but have no control over which resources their jobs consume (and thus these jobs qualify as centrally controlled). A more concrete example of such a system arises in networks that allow a large customer to set up a so-called *virtual private network* consisting of guaranteed and preassigned virtual paths for ongoing use [6, 17, 20, 22, 26]. The bandwidth needed for the virtual private network may be viewed as centrally controlled (its routes may be chosen by the network manager), while individual users of the network continue to behave in a selfish and independent fashion.

We investigate the following question: Given a system with centrally and selfishly controlled jobs, *how should centrally controlled jobs be assigned to resources to induce "good" (albeit selfish) behavior from the noncooperative users?* This approach has several appealing aspects: no communication is required between the system users and an algorithm, no notion of currency is needed, no resources need to be added to or removed from the system, and the assignment of centrally controlled jobs is often easily modified as the amount of job traffic evolves over time.

Stackelberg games. We are thus led to consider a type of game in which the roles of different players are asymmetric. One player, responsible for assigning the centrally controlled jobs to resources and interested in optimizing social welfare, acts as a *leader*. The leader may hold its assignment (its *strategy*) fixed while all other agents (the *followers*) react independently and selfishly to the leader's strategy, reaching a Nash equilibrium relative to the leader's strategy. These types of games, called

Stackelberg games, and the resulting *Stackelberg equilibria* have been well studied in the game theory literature (see, e.g., [3, sect. 2.3] or [4, sect. 3.6] for an introduction and [49] for their origin) and have been previously studied in the contexts of both competitive facility location [40] and networking [14, 15, 18, 26]. With the exception of [26], however, the leader/follower hierarchy has been used to model classes of selfish agents with different priority levels; this setting differs from ours in that no agent is interested in optimizing system performance.[1] The paper of Korilis, Lazar, and Orda [26], while more similar in spirit to ours, focuses on deriving necessary and sufficient conditions (on the number of selfish users, the fraction of the job traffic that is centrally controlled, etc.) for the existence of a leader strategy inducing an optimal assignment of jobs to resources; moreover, only one type of latency function is considered. By contrast, we are interested in simple leader strategies that *always* induce optimal or near-optimal behavior from the system users for *any* set of latency functions.

Problems studied in this paper. We focus on the problem, described at the beginning of the paper, of scheduling jobs on a set of machines with load-dependent latencies in order to minimize the total latency. In addition to being one of the most commonly studied models [11, 12, 18, 26, 29, 30, 34, 35, 36, 41], occasionally in the equivalent formulation of routing on a set of parallel links, the simple setting of scheduling jobs on machines permits a study of the effects of different leader strategies in Stackelberg games without any additional complications, such as the issue of path-selection in a complicated network. We also focus on a scenario in which there is a large number of jobs, each of very small size. We note that this differs from nearly all scheduling research in the theoretical computer science and discrete optimization communities (surveyed in, for example, Hall [23]). This assumption is, however, consistent with a large body of existing literature on Nash equilibria in congested systems—see [5, 13, 44, 47] and the references therein—and greatly aids our analysis. For example, this assumption ensures the existence and essential uniqueness of the equilibrium reached by selfish users relative to any Stackelberg strategy. While it is clearly desirable to study more general networks as well as jobs of nonnegligible size, we nonetheless feel that the simple model considered in this paper is sufficient to illustrate the main issues that arise in centrally scheduling traffic in the presence of selfish users.

We may now restate our central questions quantitatively:

(1) Among all leader strategies for a given set of machines and jobs, can we characterize and/or compute the strategy inducing the *Stackelberg equilibrium*—i.e., the equilibrium of minimum total latency?

(2) What is the worst-case ratio between the total latency of the Stackelberg equilibrium and that of the optimal assignment of jobs to machines?

Our results. We give a simple polynomial-time algorithm for computing a leader strategy that induces a job assignment with total latency no more than $\frac{1}{\alpha}$ times that of the optimal assignment of jobs to machines, where α denotes the fraction of jobs that are centrally controlled. We also exhibit, for each value of α, an instance in which *no* strategy can achieve a better performance guarantee. This result stands in sharp contrast to known results about *Nash* equilibria in this model; in particular, the total latency of the Nash equilibrium may be arbitrarily larger than that of the

[1] Typically, Stackelberg games model *selfish* agents with asymmetric roles; our use of them is somewhat unconventional.

optimal assignment of jobs to machines, even in the special case of two machines [45].

In the well-studied special case where every machine possesses a latency function linear in the congestion, we give a simple $O(m^2)$ algorithm for computing a strategy inducing a job assignment with total latency no more than $\frac{4}{3+\alpha}$ times that of the optimal assignment, where α is the fraction of centrally controlled jobs, and m is the number of machines. We again give instances in which no strategy can provide a stronger guarantee.

Finally, we consider the optimization problem of computing the strategy inducing the Stackelberg equilibrium and show that it is NP-hard, even in the special case where every latency function is linear.

We note that our results give a (sharp) trade-off between the optimal assignment and the Nash equilibrium, as a function of the fraction of centrally controlled jobs, in the following sense. Roughgarden and Tardos [45], motivated by a paper of Koutsoupias and Papadimitriou [30], showed that in general the Nash equilibrium can be arbitrarily more costly than the optimal assignment, but if every machine latency function is linear, then the total latency of the Nash equilibrium is no more than $\frac{4}{3}$ times that of the optimal assignment. Thus, our results reduce to those of [45] when $\alpha = 0$, give the trivial result that the Stackelberg equilibrium for $\alpha = 1$ is the optimal assignment, and quantify the worst possible ratio between the cost of the Stackelberg equilibrium—in some sense, a "mixture" of the Nash equilibrium and the optimal assignment—and the cost of the optimal assignment for all intermediate values of α.

Our approach also adds an algorithmic dimension to the existing studies comparing Nash equilibria and optimal solutions [1, 11, 12, 24, 29, 30, 34, 43, 45, 46], in that one aspect of our analysis of Stackelberg equilibria is the design of algorithms for efficiently computing good Stackelberg strategies. Further, while Nash and optimal assignments in our model can be characterized and computed efficiently via convex programming [13, 45]—a fact that is crucial for existing comparisons of optima and equilibria [43, 45, 46]—our hardness result implies that no such characterization of Stackelberg equilibria is possible. With the central approach of earlier works ruled out, new techniques are required for our results.

Organization. In section 2 we formalize our model and state several preliminary lemmas. In section 3 we introduce three simple algorithms for computing Stackelberg strategies. In sections 4 and 5, we prove that our third algorithm achieves the best possible worst-case performance guarantee for instances with general and linear latency functions, respectively. In section 6, we prove that computing the optimal strategy is NP-hard, even when every latency function is linear. Section 7 concludes with directions for future work.

2. Preliminaries.

2.1. The model. We consider a set M of m machines $1, 2, \ldots, m$, where machine i is endowed with a *latency function* $\ell_i(\cdot)$ that measures the load-dependent time required to complete a job. We require that each latency function be nonnegative, continuous, and nondecreasing in its argument. For our algorithms to be implemented efficiently, we also require the weak condition that $x_i \cdot \ell_i(x_i)$ is a convex function for each machine i (where x_i denotes the machine load).[2] We assume a finite and positive *rate* r of job arrivals; an *assignment* of the jobs to the machines is an m-vector $x \in \mathcal{R}_+^m$

[2]Thus, $\ell_i(x_i)$ may be any convex function, or $\log(1 + x_i)$, etc. Continuous approximations of step functions, however, do not satisfy this condition.

such that $\sum_{i=1}^{m} x_i = r$. When we are interested in the total load on a subset $M' \subseteq M$ of the machines, we write $x(M') = \sum_{i \in M'} x_i$. We measure system performance via the *cost* or *total latency* $C(x)$ of an assignment x, defined by $C(x) = \sum_{i=1}^{m} x_i \ell_i(x_i)$. We note that all jobs assigned to the same machine experience the same latency; again, this differs from much of the traditional scheduling literature but agrees with common models of equilibria in congested systems where a particular allocation of resources represents a "steady-state solution" with jobs arriving continuously over time.

We will consider instances with and without centrally controlled jobs. We denote an instance with machines M, rate r, and no centrally controlled jobs by (M, r). An instance with centrally controlled jobs (a *Stackelberg instance*) will be denoted by (M, r, α), where the third parameter $\alpha \in (0, 1)$ indicates the fraction of the overall traffic that is centrally controlled.

2.2. Nash equilibria and optimal assignments. If jobs are generated and assigned to machines by noncooperative agents who wish to minimize the amount of time it takes for their work to complete, we expect the assignment to be "stable" or "at equilibrium" in the following sense: no job can strictly decrease the latency it experiences by changing machines. The following definition is motivated by this notion of a stable assignment by noncooperative agents.

DEFINITION 2.1. *An assignment x to M is* at Nash equilibrium *(or is a* Nash assignment*) if whenever $i, j \in M$ with $x_i > 0$, $\ell_i(x_i) \leq \ell_j(x_j)$.*

In particular, all machines in use by an assignment at Nash equilibrium have equal latency. We may thus express the cost of a Nash assignment in the following simple form.

LEMMA 2.2. *If x is an assignment at Nash equilibrium for (M, r) such that all machines in use have common latency L, then*

$$C(x) = rL.$$

Example 2.3. An assignment at Nash equilibrium does not in general optimize the system performance. To see this, consider a two-machine example, in which the first machine has constant latency function $\ell_1(x_1) = 1$ and the second has latency function $\ell_2(x_2) = x_2$. If we put $r = 1$, we see that the (optimal) assignment $(\frac{1}{2}, \frac{1}{2})$ has total latency $\frac{3}{4}$, whereas the (unique) assignment at Nash equilibrium assigns all work to the second machine, thereby incurring a cost of 1.

We end our preliminary discussion of Nash assignments by noting that they exist and are essentially unique.

LEMMA 2.4 (see [5, 13, 45]). *Suppose M is a set of machines with continuous, nondecreasing latency functions. Then*

(a) *for any rate $r > 0$ of job traffic, there exists an assignment of jobs to M at Nash equilibrium;*

(b) *if x, x' are assignments at Nash equilibrium for (M, r), then $\ell_i(x_i) = \ell_i(x'_i)$ for each machine i.*

In particular, Definition 2.1 and Lemma 2.4(b) imply that any two Nash assignments for an instance (M, r) have equal cost.

For our final preliminary result, we give an analogous characterization of optimal assignments that will be useful in section 5. For a machine i with differentiable latency function ℓ_i, define ℓ_i^* as the marginal cost of increasing the load of machine i—formally, by $\ell_i^*(x_i) = [\frac{d}{dy}(y \cdot \ell_i(y))](x_i) = \ell_i(x_i) + x_i \cdot \ell_i'(x_i)$. We will call ℓ_i^* the *marginal cost function* of machine i. Then the following lemma holds.

LEMMA 2.5 (see [5, 13, 45]). *Suppose M is a set of machines with differentiable latency functions ℓ and that $x_i \cdot \ell_i(x_i)$ is a convex function for each machine i. Then an assignment x to M is optimal if and only if, whenever $i, j \in M$ with $x_i > 0$, $\ell_i^*(x_i) \leq \ell_j^*(x_j)$. Moreover, the optimal assignment can be computed in polynomial time.*

Lemma 2.5 clearly gives a characterization of *locally* optimal assignments; in particular, if the condition fails, moving a few jobs from a machine with a large marginal cost to a machine with a small marginal cost yields a new assignment with smaller cost. That it also characterizes *globally* optimal solutions follows from the fact that the optimal assignment minimizes a convex function ($C(x)$) over a convex set (the polytope of assignments) and that the local and global minima of a convex function on a convex set coincide (see, for example, [39, Thm. 2.3.4]). This observation also implies that the optimal solution can be computed in polynomial time via convex programming.

Definition 2.1 and Lemma 2.5 yield the following useful corollary.

COROLLARY 2.6 (see [5, 13, 45]). *Suppose M is a set of machines with differentiable latency functions ℓ and that $x_i \cdot \ell_i(x_i)$ is a convex function for each machine i. Then an assignment x to M is optimal if and only if x is a Nash assignment with respect to latency functions ℓ^*.*

Remark 2.7. We will typically denote the optimal assignment for an instance by x^*. The marginal cost functions are denoted by ℓ^* as they are "optimal latency functions" in a sense made precise by Corollary 2.6: the optimal assignment x^* arises as an assignment at Nash equilibrium with respect to latency functions ℓ^*.

2.3. Stackelberg strategies and induced equilibria. In this subsection we define our notion of a Stackelberg game and consider two examples. Recall that we desire a hierarchical game, where a leader assigns centrally controlled jobs to machines and, holding this strategy fixed, the selfish users of the system react in a noncooperative and selfish manner. This idea is formalized in the next two definitions.

DEFINITION 2.8. *A* (Stackelberg) strategy *for the Stackelberg instance (M, r, α) is an assignment feasible for $(M, \alpha r)$.*

DEFINITION 2.9. *Let s be a strategy for Stackelberg instance (M, r, α) where machine $i \in M$ has latency function ℓ_i, and let $\tilde{\ell}_i(x_i) = \ell_i(s_i + x_i)$ for each $i \in M$. An* equilibrium induced by strategy *s is an assignment t at Nash equilibrium for the instance $(M, (1-\alpha)r)$ with respect to latency functions $\tilde{\ell}$. We then say that $s + t$ is an* assignment induced by *s for (M, r, α).*

Existence and essential uniqueness of induced equilibria follow easily from Lemmas 2.2 and 2.4.

LEMMA 2.10. *Let s be a strategy for a Stackelberg instance with continuous, nondecreasing latency functions. Then there exists an assignment induced by s, and any two such induced assignments have equal cost.*

The following simple observation will be useful in sections 4 and 5.

LEMMA 2.11. *Let s be a strategy for Stackelberg instance (M, r, α) inducing equilibrium t. Let M' denote the machines on which $t_i > 0$. Then $s + t$, restricted to M', is an assignment at Nash equilibrium for the instance $(M', s(M') + t(M'))$. In particular, all machines on which $t_i > 0$ have a common latency with respect to $s+t$.*

We next consider two examples that demonstrate both the usefulness and the limitations of Stackelberg strategies.

Example 2.12. Recall that in Example 2.3, with two machines with latency functions $\ell_1(x_1) = 1$ and $\ell_2(x_2) = x_2$, in the absence of centrally controlled jobs the

assignment at Nash equilibrium incurs total latency $\frac{4}{3}$ times that of the optimal assignment. Suppose instead that half of the jobs are controlled by the system manager (i.e., that $\alpha = \frac{1}{2}$) and consider the strategy $s = (\frac{1}{2}, 0)$. Then, as all remaining jobs will be assigned to the second machine in the equilibrium induced by s, the assignment induced by s is precisely the optimal assignment of all of the jobs. Thus, in this particular instance, system performance can be optimized via a Stackelberg strategy.

Example 2.13. Now modify Example 2.12 by replacing the latency function of the second machine with the latency function $\ell_2(x_2) = 2x_2$. The assignment at Nash equilibrium puts half of the jobs on each machine (for a cost of 1) while the optimal assignment is $(\frac{3}{4}, \frac{1}{4})$ (with a cost of $\frac{7}{8}$). On the other hand, if we again allow the system manager to assign half of the jobs, we see that for *any* strategy s, the assignment induced by s is $(\frac{1}{2}, \frac{1}{2})$ and hence is not optimal. In this example, there is no available strategy by which the system manager can improve system performance.

3. Three Stackelberg strategies.

3.1. Two natural strategies. We initiate our investigation of Stackelberg strategies by considering two natural approaches that provide suboptimal performance guarantees. To motivate our results in the simplest possible way, throughout this subsection we will consider examples in which all latency functions are linear and half of the jobs are centrally controlled ($\alpha = \frac{1}{2}$). We are thus hoping for strategies that always induce an assignment of cost at most $\frac{8}{7}$ times that of the optimal assignment (this is the best possible by Example 2.13).

First consider the following strategy for an instance $(M, r, \frac{1}{2})$: if x^* is the optimal assignment for instance $(M, \frac{1}{2}r)$, put $s = x^*$. In words, we choose the strategy of minimum cost, ignoring the existence of jobs that are not centrally controlled. We call this the *aloof* strategy since it refuses to acknowledge the rest of the jobs in the system. Example 2.3 shows that this strategy performs quite poorly: the strategy is $(0, \frac{1}{2})$ and the induced assignment is $(0, 1)$, an assignment that we have seen to incur total latency $\frac{4}{3}$ times that of the optimal assignment.

A second attempt for a good strategy might be as follows: if x^* is the optimal assignment for (M, r), put $s = \frac{1}{2}x^*$. We call this the *scale* strategy, since it is simply the optimal assignment of all the jobs, suitably scaled. Unfortunately, a simple example shows that the scale strategy also fails to provide the performance guarantee of $\frac{8}{7}$ that we are looking for: in a two-machine example with latency functions $\ell_1(x_1) = 1$ and $\ell_2(x_2) = \frac{3}{2}x_2$ and rate 1, the optimal assignment is $(\frac{2}{3}, \frac{1}{3})$ (with total cost $\frac{5}{6}$), and thus the scale strategy will be $(\frac{1}{3}, \frac{1}{6})$, which induces the assignment $(\frac{1}{3}, \frac{2}{3})$ having cost 1. Hence, the scale strategy may result in an induced assignment with total latency $\frac{6}{5}$ times the cost of the optimal assignment.[3]

3.2. The largest latency first (LLF) strategy. Intuitively, both the aloof and scale strategies suffer from a common flaw: both allocate jobs to machines that will subsequently be inundated in any induced equilibrium while assigning too little work to machines that selfish users are prone to ignore. This observation suggests that a good strategy should give priority to the machines that are least appealing to selfish users—machines with relatively high latency. With this intuition in mind, the following strategy for a Stackelberg instance (M, r, α), which we call the *largest latency first* (LLF) strategy, should seem natural:

(1) Compute the optimal assignment x^* for (M, r).

[3] In addition, the aloof and scale strategies can perform arbitrarily badly for instances with general latency functions.

(2) Index the machines of M so that $\ell_1(x_1^*) \leq \cdots \leq \ell_m(x_m^*)$.
(3) Let $k \leq m$ be minimal with $\sum_{i=k+1}^{m} x_i^* \leq \alpha r$.
(4) Put $s_i = x_i^*$ for $i > k$, $s_k = \alpha r - \sum_{i=k+1}^{m} x_i^*$, and $s_i = 0$ for $i < k$.

We will say that a machine i is *saturated* by a strategy s if $s_i = x_i^*$. The LLF strategy thus saturates machines one by one, in order from the largest latency with respect to x^* to the smallest, until there are no centrally controlled jobs remaining. Note that Lemma 2.5 implies that the LLF strategy can be computed in polynomial time (the bottleneck is step (1)); in section 5 we will see that it can be computed in $O(m^2)$ time when every latency function is linear.

The next two sections are devoted to proving that the LLF strategy always induces an assignment with near-optimal total latency.

4. A $\frac{1}{\alpha}$ performance guarantee for arbitrary latency functions. In this section we prove that the LLF strategy induces a near-optimal assignment for any set of latency functions and any number of machines. We note that *no* performance guarantee is possible in the absence of centrally controlled jobs: without additional restrictions on machine latency functions, the Nash assignment may incur arbitrarily more latency than the optimal assignment [45]. Thus, the benefit of a leader (and of a carefully chosen leader strategy) is particularly striking in this general setting.

A simple variation on previous examples demonstrates the limits of Stackelberg strategies. In a two-machine instance with $\alpha = \frac{1}{2}$ and latency functions $\ell_1(x_1) = 1$ and $\ell_2(x_2) = 2^k x_2^k$ for $k \in \mathcal{Z}^+$, any Stackelberg strategy induces the assignment $(\frac{1}{2}, \frac{1}{2})$ (having total latency 1) while the optimal assignment is $(\frac{1}{2} + \delta_k, \frac{1}{2} - \delta_k)$ having cost $\frac{1}{2} + \epsilon_k$, where $\delta_k, \epsilon_k \to 0$ as $k \to \infty$. Thus the best induced assignment may be (arbitrarily close to) twice as costly as the optimal assignment. Similar examples show that for any $\alpha \in (0, 1)$, the best induced assignment may be $\frac{1}{\alpha}$ times as costly as the optimal assignment.

The main result of this section is that the LLF strategy always induces an assignment of cost no more than $\frac{1}{\alpha}$ times that of the optimal assignment. A rough outline of the proof is as follows. Our goal is to exploit the iterative structure of the LLF strategy and proceed by induction on the number of machines. If the LLF strategy first saturates the mth machine, a natural idea is to apply the inductive hypothesis to the remainder of the LLF strategy on the first $m-1$ machines to derive a performance guarantee. This idea nearly succeeds, but there are two difficulties. First, it is possible that the LLF strategy fails to saturate any machines; we will see below that this case is easy to analyze and causes no trouble. Second, in order to obtain a clean application of the inductive hypothesis to the first $m-1$ machines, we require that the optimal and LLF-induced assignments place the same total amount of jobs on these machines—i.e., that the LLF-induced equilibrium eschews the mth machine.[4] We resolve this difficulty with the following lemma, which states that if the LLF strategy saturates the mth machine, then *some* induced equilibrium assigns all jobs to the first $m-1$ machines; this suffices for our purposes, since different induced assignments have equal cost.

LEMMA 4.1. *Let (M, r, α) denote a Stackelberg instance with optimal assignment x^* and index the machines of M so that $\ell_m(x_m^*) \geq \ell_i(x_i^*)$ for all i. If s is a strategy with $s_m = x_m^*$, then there exists an induced equilibrium t with $t_m = 0$.*

[4] To see a trivial example in which this does not occur, put $r = 1, \alpha = \frac{1}{2}$ and consider two machines each with the constant latency function $\ell_i(x_i) = 1$. One particular optimal assignment is $(\frac{2}{3}, \frac{1}{3})$, and a corresponding LLF strategy is $(\frac{1}{6}, \frac{1}{3})$; one particular induced assignment is $(\frac{1}{3}, \frac{2}{3})$. Even though the LLF strategy saturated the second machine, the induced equilibrium uses it.

Proof. Consider an arbitrary induced equilibrium t and suppose $t_m > 0$. Roughly speaking, the idea is to prove that this scenario occurs only when several latency functions (that of the mth machine, and others) are locally constant; then jobs assigned to machine m in the induced equilibrium can be evacuated to other machines with locally constant latency functions to provide a new induced equilibrium.

Formally, let $L = \ell_m(s_m + t_m) = \ell_m(x^*_m + t_m)$ denote the common latency with respect to $s + t$ of every machine with $t_i > 0$ (see Lemma 2.11). We must have $\ell_m(x^*_m) \geq L$; otherwise $\ell_i(x^*_i) < L$ for all i, yet $\ell_i(s_i + t_i) \geq L$ for all i, contradicting that x^* and $s + t$ are assignments at the same rate. Thus, since ℓ_m is nondecreasing, ℓ_m is locally constant: ℓ_m is equal to L in the interval $[x^*_m, x^*_m + t_m]$.

Next, let M' denote the machines on which $s_i + t_i < x^*_i$; since $s_m + t_m > x^*_m$, M' is nonempty. For each $i \in M'$, we know that $\ell_i(s_i + t_i) \geq L$, $\ell_i(x^*_i) \leq \ell_m(x^*_m) = L$, and ℓ_i is nondecreasing, so ℓ_i is equal to L on $[s_i + t_i, x^*_i]$. Since x^* and $s + t$ are assignments at the same rate, we must have $\sum_{i \in M'}[x^*_i - (s_i + t_i)] \geq t_m$. Finally, consider modifying t as follows: move all jobs previously assigned to machine m to machines in M', subject to the constraints $s_i + t_i \leq x^*_i$. We have already observed that there is sufficient "room" on machines in M' for this operation, and that all latency functions are constant in the domain of our modifications. We have thus exhibited a new induced equilibrium with no jobs assigned to machine m, completing the proof. ∎

We are now prepared to prove the main result of this section.

THEOREM 4.2. *Let $\mathcal{I} = (M, r, \alpha)$ denote a Stackelberg instance. If s is an LLF strategy for $\mathcal{I}$ inducing equilibrium t and x^* is an optimal assignment for the instance (M, r), then $C(s + t) \leq \frac{1}{\alpha} C(x^*)$.*

Proof. We proceed by induction on the number of machines m (for each fixed m, we will prove the theorem for arbitrary ℓ, r, and α). The case of one machine is trivial.

Fix a Stackelberg instance $\mathcal{I} = (M, r, \alpha)$ with at least two machines, and let x^* denote an optimal assignment to the instance (M, r) and s the corresponding LLF strategy. Index the machines so that $\ell_1(x^*_1) \leq \ell_2(x^*_2) \leq \cdots \leq \ell_m(x^*_m)$. By scaling, we may assume that $r = 1$ (use latency functions $\tilde{\ell}$ with $\tilde{\ell}_i(x_i) = \ell_i(r x_i)$). Let L denote the common latency with respect to $s + t$ of every machine with $t_i > 0$ (see Lemma 2.11).

Case 1. Suppose $t_k = 0$ for some machine k. Let M_1 denote the machines i for which $t_i = 0$ and M_2 the machines for which $t_i > 0$; both of these sets are nonempty. For $i = 1, 2$ let α_i denote the amount of centrally controlled jobs assigned to machines in M_i (so $\alpha_i = s(M_i)$) and C_i the cost incurred by $s + t$ on machines in M_i. By Lemma 2.11, $C_2 = (1 - \alpha_1)L$ and $C_1 \geq \alpha_1 L$. Further, since x^* restricted to M_2 is an optimal assignment for $(M_2, 1 - \alpha_1)$, s restricted to M_2 is an LLF strategy for the instance $\mathcal{I}_2 = (M_2, 1 - \alpha_1, \alpha')$, where $\alpha' = \frac{\alpha_2}{1 - \alpha_1}$.

Applying the inductive hypothesis to $\mathcal{I}_2$ and using the fact that $x^*_i \geq s_i = s_i + t_i$ for all $i \in M_1$, we obtain

$$C(x^*) \geq C_1 + \alpha' C_2.$$

Proving that $C(s + t) \leq \frac{1}{\alpha} C(x^*)$ thus reduces to showing

$$\alpha(C_1 + C_2) \leq C_1 + \alpha' C_2.$$

Since $\alpha \leq 1$ and $C_1 \geq \alpha_1 L$, it suffices to prove this inequality with C_1 replaced by $\alpha_1 L$. Writing $C_2 = (1 - \alpha_1)L$ and $\alpha' = \frac{\alpha_2}{1 - \alpha_1}$ and dividing through by L, we need

only check that

$$\alpha(\alpha_1 + (1-\alpha_1)) \le \alpha_1 + \frac{\alpha_2}{1-\alpha_1}(1-\alpha_1),$$

which clearly holds (both sides are equal to α).

Case 2. Suppose $t_i > 0$ for every machine i, so $C(s+t) = L$. We may assume that the LLF strategy failed to saturate machine m; otherwise, by Lemma 2.10, we can finish by applying the previous case to the better-behaved induced assignment guaranteed by Lemma 4.1. Thus, $\alpha < x^*_m$.

As in the proof of Lemma 4.1, we must have $\ell_m(x^*_m) \ge L$; otherwise, $\ell_i(x^*_i) < L$ for all machines i, while $\ell_i(s_i + t_i) = L$ for all i, contradicting that x^* and $s+t$ are assignments at the same rate. Having established that machine m has large latency with respect to x^* and that x^*_m is fairly large, it is now a simple matter to lower bound $C(x^*)$:

$$C(x^*) \ge x^*_m \ell_m(x^*_m) \ge \alpha L = \alpha C(s+t). \qquad \square$$

5. A $\frac{4}{3+\alpha}$ performance guarantee for linear latency functions.

5.1. Properties of the Nash and optimal assignments. In this subsection we undertake a deeper study of the Nash and optimal assignments for instances with linear latency functions. The results of this subsection will be instrumental in proving a stronger performance guarantee for the LLF strategy for these instances.

Fix a set of machines M with latency functions $\ell_i(x_i) = a_i x_i + b_i$ for each i ($a_i, b_i \ge 0$) and index them so that $b_1 \le b_2 \le \cdots \le b_m$. We may assume that at most one machine has a constant latency function ($a_i = 0$) since all but the fastest may be safely discarded; under this assumption, the Nash and optimal assignments are always unique. We may similarly assume that a machine with a constant latency function is the last machine.

Our first goal is to understand the structure of the Nash assignment $\bar{x}$ as a function of the rate r. It is useful to imagine r increasing from 0 to a large value, with the corresponding Nash assignment changing in a continuous fashion; an intuitive description of this process is as follows. Initially, when r is nearly zero, all jobs will be assigned to the machine having the smallest constant term. Once the first machine is sufficiently loaded, the second machine looks equally attractive. This occurs when $a_1\bar{x}_1 + b_1 = b_2$—when the load on machine 1 is $\frac{b_2 - b_1}{a_1}$. At this point, new jobs will be assigned to both of the first two machines, at rates proportional to $\frac{1}{a_1}$ and $\frac{1}{a_2}$ so that these two machines continue to have equal latency. Once $(b_3 - b_2)(\frac{1}{a_1} + \frac{1}{a_2})$ further units of work have arrived and been assigned to the first two machines, machine 3 will be equally attractive and new jobs will be spread out among the first three machines, and so on. We may thus envision the Nash assignment as being constructed in phases: within phase i jobs are assigned to the first i machines according to fixed relative proportions and at the end of the phase, after enough new jobs have been assigned, an additional machine is put into use.

We now formalize this intuitive description of the Nash assignment $\bar{x}$. For $i = 1, \ldots, m$, let v_i denote the m-vector $(\frac{1}{a_1}, \frac{1}{a_2}, \ldots, \frac{1}{a_i}, 0, 0, \ldots, 0) \in \mathcal{R}^m_+$; if $a_m = 0$, put $v_m = (0, 0, \ldots, 1)$. The vector v_i should be interpreted as a specification of the way jobs are assigned to the first i machines during the ith phase. Next, define δ_i for $i = 0, 1, \ldots, m-1$ inductively by $\delta_0 = 0$ and $\delta_i = \min\{(b_{i+1} - b_i)\|v_i\|_1, r - \sum_{j=0}^{i-1} \delta_i\} \ge 0$, where $\|\cdot\|_1$ denotes the L_1-norm. We also put $\delta_m = r - \sum_{j=0}^{m-1} \delta_i$. The scalar δ_i is the amount of jobs assigned in the ith phase. We can then describe $\bar{x}$ as follows.

LEMMA 5.1. *Let $\mathcal{I}$ be an instance with linear latency functions, as above. Then the Nash assignment for $\mathcal{I}$ is given by*

$$\bar{x} = \sum_{i=1}^{m} \delta_i \frac{v_i}{\|v_i\|_1}.$$

Our characterization of optimal assignments (Lemma 2.5 and Corollary 2.6) yields an analogous result for computing them by an explicit formula. Note that when a latency function has the form $\ell_i(x_i) = a_i x_i + b_i$, the corresponding marginal cost function is $\ell_i^*(x_i) = 2a_i x_i + b_i$. Recalling from Corollary 2.6 that an optimal assignment is simply a Nash assignment with respect to latency functions ℓ^*, we see that the optimal assignment is created by the same process as the Nash assignment, except that new machines are incorporated at a more rapid pace so as to spread jobs over a wider range of machines and thus achieve a smaller total latency.

Formally, let v_i be as above and define δ_i^* inductively by $\delta_0^* = 0$, $\delta_i^* = \min\{\frac{1}{2}(b_{i+1} - b_i)\|v_i\|_1, r - \sum_{j=0}^{i-1} \delta_i^*\}$, and $\delta_m^* = r - \sum_{j=0}^{m-1} \delta_i^*$. Letting x^* denote the optimal assignment to (M, r), the analogue of Lemma 5.1 is as follows.

LEMMA 5.2. *Let $\mathcal{I}$ be an instance with linear latency functions, as above. Then the optimal assignment for $\mathcal{I}$ is given by*

$$x^* = \sum_{i=1}^{m} \delta_i^* \frac{v_i}{\|v_i\|_1}.$$

Lemmas 5.1 and 5.2 have several useful corollaries. We summarize them below.

COROLLARY 5.3. *Let M be a set of machines with latency functions $\{\ell_i(x_i) = a_i x_i + b_i\}_{i \in M}$ and at most one machine with a constant latency function. Let b_i be nondecreasing in i. Then*

(a) *if x^* and $\bar{x}$ denote the optimal and Nash assignments to (M, r), then $x_m^* \geq \bar{x}_m$;*

(b) *if x^* and $\bar{x}$ denote the optimal and Nash assignments to (M, r), then $x_1^* \leq \bar{x}_1 \leq 2x_1^*$;*

(c) *if x^* is the optimal assignment for (M, r_1) and y^* is the optimal assignment for (M, r_2) with $r_1 \geq r_2$, then $x_i^* \geq y_i^*$ for each i;*

(d) *for any rate r, the optimal and Nash assignments of (M, r) can be computed in $O(m^2)$ time.*

Proof. Parts (c) and (d) are immediate from Lemmas 5.1 and 5.2. For the remaining parts, fix an instance (M, r) and define v_i, δ_i, and δ_i^* as in Lemmas 5.1 and 5.2. Our first observation is that, for any $i \in \{1, 2, \ldots, m\}$, the Nash assignment schedules at least as many jobs in the first i phases as the optimal assignment—formally, that $\sum_{k=1}^{i} \delta_k \geq \sum_{k=1}^{i} \delta_k^*$ for all i. Since $\sum_{k=1}^{m} \delta_k = \sum_{k=1}^{m} \delta_k^* = r$, we obtain $\delta_m^* \geq \delta_m$ and hence $x_m^* \geq x_m$, proving (a).

It remains to prove part (b) of the corollary. We may assume that $m > 1$ (otherwise $\bar{x}_1 = x_1^* = r$). Letting m' equal m if there is no machine with constant latency function and $m - 1$ otherwise, Lemmas 5.1 and 5.2 give

$$x_1^* = \frac{1}{a_1} \sum_{i=1}^{m'} \frac{\delta_i^*}{\|v_i\|_1}$$

and

$$\bar{x}_1 = \frac{1}{a_1} \sum_{i=1}^{m'} \frac{\delta_i}{\|v_i\|_1}.$$

By the definitions of δ_i and δ_i^*, we have $\delta_i \le 2\delta_i^*$ for $i = 1, 2, \ldots, m$ and hence $\bar{x}_1 \le 2x_1^*$. For the other inequality, we recall that $\sum_{k=1}^{i} \delta_k^* \le \sum_{k=1}^{i} \delta_k$ for each i and observe that $\|v_i\|_1$ is increasing in i (for $i \in \{1, 2, \ldots, m'\}$); it follows that $x_1^* \le \bar{x}_1$. □

Corollary 5.3(d) implies that the LLF strategy can be computed in $O(m^2)$ time for instances with linear latency functions.

5.2. Proof of performance guarantee. In subsection 2.3 we saw an example with linear latency functions and $\alpha = \frac{1}{2}$ in which *no* strategy can induce an assignment with cost less than $\frac{8}{7}$ times that of the optimal assignment. This example is easily modified to show that, for any $\alpha \in (0, 1)$, the minimum-cost induced assignment for a Stackelberg instance (M, r, α) with linear latency functions may be $\frac{4}{3+\alpha}$ times as costly as the optimal assignment for (M, r). The main result of this section is a matching upper bound for the LLF strategy.

Before proving this result, we give an alternative description of LLF that is more convenient for our analysis. This description is based on the following lemma.

LEMMA 5.4. *Let x^* be an optimal assignment for (M, r) where machine i has latency function $\ell_i(x_i) = a_i x_i + b_i$. Then $\ell_i(x_i^*) \ge \ell_j(x_j^*)$ if and only if $b_i \ge b_j$.*

Proof. The lemma is clear when $x_i^* = x_j^* = 0$. Otherwise, we will make use of our characterization of optimal assignments via machine marginal cost functions (Lemma 2.5). If exactly one of x_i^*, x_j^* is 0 (say x_i^*), then by Lemma 2.5 we know that the marginal cost $\ell_i^*(x_i^*) = \ell_i^*(0) = b_i$ of machine i is at least the marginal cost $\ell_j^*(x_j^*) = 2a_j x_j^* + b_j$ of machine j. Thus we necessarily have both $\ell_i(x_i^*) \ge \ell_j(x_j^*)$ and $b_i \ge b_j$. Finally, if $x_i^*, x_j^* > 0$, then by Lemma 2.5 we have $2a_i x_i^* + b_i = 2a_j x_j^* + b_j = L^*$ for some L^*; thus $b_i \ge b_j$ if and only if $a_i x_i^* \le a_j x_j^*$. The lemma follows by writing $\ell_i(x_i^*) = L^* - a_i x_i^*$ and $\ell_j(x_j^*) = L^* - a_j x_j^*$. □

Lemma 5.4 gives the following equivalent description of the LLF strategy: saturate machines one by one, in decreasing order of constant terms, until no centrally controlled jobs remain. It may seem surprising that the LLF strategy makes no use of the a_i-values in ordering the machines; however, this is consistent with our observation in subsection 5.1 that the order in which machines are used by the optimal assignment, if we think of the rate as increasing from 0 to some large value, depends only on the constant terms of the machines' latency functions.

We are finally prepared to prove a $\frac{4}{3+\alpha}$ performance guarantee for the LLF strategy for instances with linear latency functions. The general approach is similar to that of Theorem 4.2 and is again by induction on the number of machines. However, new difficulties arise in proving a stronger performance guarantee. The case in which there is some machine k on which the induced equilibrium assigns no jobs (i.e., $t_k = 0$ for some k) is nearly identical to the first case of Theorem 4.2: the desired performance guarantee can easily be extracted from the inductive guarantee for the smaller instance of machines on which $t_i > 0$. The second case, in which the induced equilibrium assigns jobs to all machines, is substantially more complicated. In particular, the simple approach in the proof of Theorem 4.2 does *not* use any inductive guarantee in this case and is thus not strong enough to prove a guarantee better than $\frac{1}{\alpha}$. For this reason, much of the proof is devoted to defining an appropriate smaller instance that allows for clean application of the inductive hypothesis and for extending the inductive guarantee into one for the original instance.

THEOREM 5.5. *Let $\mathcal{I} = (M, r, \alpha)$ denote a Stackelberg instance with linear latency functions. If s is an LLF strategy for $\mathcal{I}$ inducing equilibrium t and x^* is an optimal assignment for (M, r), then $C(s + t) \le \frac{4}{3+\alpha} C(x^*)$.*

Proof. We proceed by induction on the number of machines m (for each fixed m,

we will prove the theorem for arbitrary (linear) ℓ, r, and α). The case of one machine is trivial.

Fix a Stackelberg instance $\mathcal{I} = (M, r, \alpha)$ with at least two machines and let $\ell_i(x_i) = a_i x_i + b_i$ (with $a_i, b_i \geq 0$). Let x^* denote an optimal assignment to (M, r). We begin with several simplifying assumptions, each made with no loss of generality. As in Theorem 4.2, we may assume that $r = 1$. We assume as usual that there is at most one machine with a constant latency function. It will also be convenient to assume that some machine i has constant term 0. To enforce this assumption we may subtract $\min_i b_i$ from every latency function before applying our argument: assuming $r = 1$, this modification decreases the cost of every assignment by precisely $\min_i b_i$ and will only increase the ratio in costs between any two assignments. Finally, we assume that no machine has latency function $\ell_i(x_i) = 0$ (otherwise the instance is trivial).

Let s denote an LLF strategy for $\mathcal{I}$ and t the induced equilibrium. Let $L > 0$ denote the common latency of every machine used by t (see Lemma 2.11). Index the machines of M as in the second description of the LLF strategy (see Lemma 5.4), so that $0 = b_1 \leq b_2 \leq \cdots \leq b_m$ and $a_1 > 0$. We will need to apply the inductive hypothesis in two different ways, and our analysis breaks into two cases.

Case 1. Suppose $t_k = 0$ for some k. Our argument will be essentially identical to the first case in the proof of Theorem 4.2. Let M_1 denote the machines on which $t_i = 0$ and M_2 the machines on which $t_i > 0$. For $i = 1, 2$, let α_i denote the amount of centrally controlled jobs on machines in M_i. For $i = 1, 2$ let C_i denote the cost incurred by $s + t$ on machines in M_i. Observe that $C_1 \geq \alpha_1 L$ and $C_2 = (1 - \alpha_1)L$. Since x^* restricted to M_2 is an optimal assignment for $(M_2, 1 - \alpha_1)$, s restricted to M_2 is an LLF strategy for $\mathcal{I}_2 = (M_2, 1 - \alpha_1, \alpha')$, where $\alpha' = \frac{\alpha_2}{1-\alpha_1}$. The inductive hypothesis, applied to $\mathcal{I}_2$, and the fact that $x^*_i \geq s_i = s_i + t_i$ for all $i \in M_1$ imply that

$$C(x^*) \geq C_1 + \frac{3 + \alpha'}{4} C_2.$$

Proving that $C(s + t) \leq \frac{4}{3+\alpha} C(x^*)$ thus reduces to showing

$$(3 + \alpha)(C_1 + C_2) \leq 4C_1 + (3 + \alpha')C_2.$$

Since $\alpha \leq 1$ and $C_1 \geq \alpha_1 L$, it suffices to prove this inequality with C_1 replaced by $\alpha_1 L$. Writing $C_2 = (1 - \alpha_1)L$, $\alpha' = \frac{\alpha_2}{1-\alpha_1}$, and dividing through by L verifies the result.

Case 2. Suppose $t_i > 0$ for all machines $i \in M$. This implies that $s + t$ is a Nash assignment for $(M, 1)$; by Corollary 5.3(a) we have $s_m < s_m + t_m \leq x^*_m$ (in particular, we must have $x^*_m > 0$). It follows that the LLF strategy s failed to saturate machine m, so $s_m = \alpha$ and $s_i = 0$ for $i < m$.

Our first goal is to show that s is an LLF strategy not only for $\mathcal{I}$ but also for $\mathcal{I}' = (M', 1 - t_1, \frac{\alpha}{1-t_1})$, where $M' = M \setminus \{1\}$ (we may then apply the inductive hypothesis to s in this smaller instance). Toward this end, let y^* denote the optimal assignment to the instance $(M', 1 - t_1)$. Since $s + t$ restricted to M' is a Nash assignment for $(M', 1 - t_1)$, we must have $y^*_m \geq s_m + t_m$ (see Corollary 5.3(a)); since $\alpha = s_m < s_m + t_m \leq y^*_m$, the LLF strategy for $\mathcal{I}'$ is precisely s (restricted to M').

Let C^*_1, C^*_2 denote the total latency incurred by x^* on machine 1 and in M', respectively. The next claim gives a lower bound on C^*_2, as a function of the amount of jobs assigned to machines in M' in the optimal assignment.

CLAIM. *If $r' \geq 1 - t_1$, then the cost of the optimal assignment for (M', r') is at least*

$$\frac{3+\alpha'}{4}(1-t_1)L + (r' - 1 + t_1)L,$$

where $\alpha' = \frac{\alpha}{1-t_1}$.

Proof. The claim is proved for $r' = 1 - t_1$ by applying the inductive hypothesis to the instance $\mathcal{I}' = (M', 1 - t_1, \alpha')$ and using the fact that s is an LLF strategy for M' inducing an assignment of cost $(1-t_1)L$. Suppose now that $r' > 1-t_1$. We again denote the optimal assignment for $(M', 1 - t_1)$ by y^*. Since y^* and $s + t$ (restricted to M') are assignments at the same rate (namely, $1 - t_1$) and the common latency of every machine with respect to $s + t$ is L, there is some machine i with $y_i^* > 0$ and $\ell_i(y_i^*) \geq L$. Since the marginal cost of a machine is at least its latency, Lemma 2.5 implies that the marginal cost of every machine in M' is at least L with respect to y^*. By Corollary 5.3(c) and the observation that marginal costs are nondecreasing functions of the machine load, extending y^* from an optimal assignment for $(M', 1-t_1)$ to an optimal assignment for (M', r') involves the assignment of $r' - (1 - t_1)$ units of jobs, all assigned at a marginal cost of at least L. Thus, the overall cost of an optimal assignment to (M', r') must be at least $C(y^*) + (r' - 1 + t_1)L \geq \frac{3+\alpha'}{4}(1 - t_1)L + (r' - 1 + t_1)L$. ∎

Our goal is to prove that $(3 + \alpha)C(s + t) \leq 4C(x^*) = 4(C_1^* + C_2^*)$; with the claim in hand, we have reduced the proof of the theorem to proving the inequality

$$(3+\alpha)L \leq (3+\alpha')(1-t_1)L + 4(t_1 - x_1^*)L + 4a_1(x_1^*)^2,$$

where $\alpha' = \frac{\alpha}{1-t_1}$ (recall that $\ell_1(x_1) = a_1 x_1$ and hence $C_1^* = a_1(x_1^*)^2$). For any fixed value of t_1, $x_1^* \in [\frac{1}{2}t_1, t_1]$ (see Corollary 5.3(b)). Using the identity $a_1 t_1 = L$ and differentiating, we find that the right-hand side is minimized by $x_1^* = \frac{1}{2}t_1$. Since the left-hand side is independent of x_1^*, it suffices to prove that

$$(3+\alpha)L \leq (3+\alpha')(1-t_1)L + 2t_1 L + a_1 t_1^2.$$

Substituting for α', using the identity $a_1 t_1 = L$, and dividing by L gives

$$3 + \alpha \leq \left(3 + \frac{\alpha}{1-t_1}\right)(1-t_1) + 3t_1,$$

which clearly holds, proving the theorem. ∎

6. The complexity of computing optimal strategies. Thus far, we have measured the performance of a Stackelberg strategy by comparing the cost of the corresponding induced assignment to the cost of the optimal assignment of all of the jobs. Another natural approach for evaluating a strategy is to compare the cost of the induced assignment to that of the *least costly assignment induced by some Stackelberg strategy*, i.e., to the cost of the assignment induced by the *optimal* strategy. Motivated by the latter measure, in this section we study the optimization problem of computing the optimal Stackelberg strategy.

We have seen that the LLF strategy provides the best possible (worst-case) performance guarantee relative to the cost of the optimal assignment, and in particular that the algorithm of subsection 3.2 may be viewed as a $\frac{1}{\alpha}$-approximation algorithm[5]

[5] A *c-approximation algorithm* for a minimization problem runs in polynomial time and returns a solution no more than c times as costly as an optimal solution. The value c is the *approximation ratio* or *performance guarantee* of the algorithm.

for computing the optimal strategy, and a $\frac{4}{3+\alpha}$-approximation algorithm for instances with linear latency functions. However, simple examples show that the LLF strategy is *not* always the optimal strategy, and thus our algorithm fails to solve this optimization problem exactly.[6] Our main result in this section is strong evidence that no such polynomial-time algorithm exists.

THEOREM 6.1. *The problem of computing the optimal Stackelberg strategy is NP-hard, even for instances with linear latency functions.*

Proof. We reduce from a problem we call $\frac{1}{3}$-$\frac{2}{3}$ PARTITION: given n positive integers $a_1, a_2, \ldots, a_n$, is there a subset $S \subseteq \{1, 2, \ldots, n\}$ satisfying $\sum_{i \in S} a_i = \frac{1}{3} \sum_{i=1}^{n} a_i$? The canonical reduction from the NP-complete problem SUBSET SUM to PARTITION is easily modified to show that $\frac{1}{3}$-$\frac{2}{3}$ PARTITION is NP-hard; see Garey and Johnson [21] for problem definitions and Karp [25] or Kozen [31, p. 129] for the canonical reduction. We will show that deciding the problem $\frac{1}{3}$-$\frac{2}{3}$ PARTITION reduces to deciding whether or not a given Stackelberg scheduling instance with linear latency functions admits a Stackelberg strategy inducing an assignment with a given cost.

Given an arbitrary instance $\mathcal{I}$ of $\frac{1}{3}$-$\frac{2}{3}$ PARTITION specified by positive integers $a_1, \ldots, a_n$, put $A = \sum_{i=1}^{n} a_i$ and define a Stackelberg scheduling instance $\mathcal{I}' = (\{1, 2, \ldots, n+1\}, 2A, \frac{1}{4})$ with $n+1$ machines and with linear latency functions $\ell_i(x_i) = \frac{x_i}{a_i} + 4$ for $i = 1, \ldots, n$ and $\ell_{n+1}(x_{n+1}) = \frac{3x_{n+1}}{A}$. It is clear that $\mathcal{I}'$ can be constructed from $\mathcal{I}$ in polynomial time. We claim that $\mathcal{I}$ is a "yes instance" (that is, admits a $\frac{1}{3}$-$\frac{2}{3}$ partition) if and only if there is a Stackelberg strategy for instance $\mathcal{I}'$ inducing an assignment with cost at most $\frac{35}{4}A$.

First suppose $\mathcal{I}$ is a "yes instance" of $\frac{1}{3}$-$\frac{2}{3}$ PARTITION, with $S \subseteq \{1, 2, \ldots, n\}$ satisfying $\sum_{i \in S} a_i = \frac{2}{3}A$, and consider the strategy defined by $s_i = \frac{3}{4}a_i$ for $i \in S$ and $s_i = 0$ otherwise (since $\sum_{i=1}^{n+1} s_i = \frac{3}{4} \sum_{i \in S} a_i = \frac{3}{4}\frac{2}{3}A = \frac{1}{2}A$, this defines a Stackelberg strategy). The induced equilibrium is then $t_i = 0$ for $i \in S$, $t_i = \frac{1}{4}a_i$ for $i \in \{1, 2, \ldots, n\} \setminus S$, and $t_{n+1} = \frac{17}{12}A$. In the induced assignment $s + t$, the $A/2$ units of jobs on machines corresponding to S experience $\frac{19}{4}$ units of latency, while the other $3A/2$ units of jobs experience $\frac{17}{4}$ units of latency. The cost of $s + t$ is thus

$$\frac{A}{2}\frac{19}{4} + \frac{3A}{2}\frac{17}{4} = \frac{35}{4}A.$$

Now suppose that $\mathcal{I}$ is a "no instance" of $\frac{1}{3}$-$\frac{2}{3}$ PARTITION, and consider any Stackelberg strategy s for $\mathcal{I}'$, inducing equilibrium t. We need to show that $C(s+t) > \frac{35}{4}A$. Call machine i *heavy* if $t_i = 0$ and *light* otherwise. Our first observation is that machine $n + 1$ must be light (even if all centrally controlled jobs are assigned to machine $n + 1$, some selfishly controlled jobs are subsequently assigned to it). Next, we note that for $i, j \in \{1, 2, \ldots, n\}$, the marginal cost $\frac{2(s_i+t_i)}{a_i} + 4$ of machine i is at most the marginal cost $\frac{2(s_j+t_j)}{a_j} + 4$ of machine j if and only if the latency $\ell_i(s_i + t_i)$ of machine i is at most $\ell_j(s_j + t_j)$. We may assume that all heavy machines have the same marginal cost with respect to $s + t$, as reassigning some centrally controlled jobs from a heavy machine with large marginal cost to a heavy machine with small marginal cost does not affect the induced equilibrium and can only decrease the cost of the induced assignment. All heavy machines must then have equal latency with

[6] For example, consider a three-machine instance with latency functions $\ell_1(x_1) = x_1$, $\ell_2(x_2) = 1 + x_2$, $\ell_3(x_3) = 1 + x_3$, with $r = 1$ and $\alpha = \frac{1}{6}$. The optimal assignment is $(\frac{2}{3}, \frac{1}{6}, \frac{1}{6})$ and thus the LLF strategy is $(0, 0, \frac{1}{6})$ inducing the assignment $(\frac{5}{6}, 0, \frac{1}{6})$ with cost $\frac{8}{9}$. On the other hand, the strategy $(0, \frac{1}{12}, \frac{1}{12})$ induces the assignment $(\frac{5}{6}, \frac{1}{12}, \frac{1}{12})$ having cost $\frac{7}{8}$.

respect to $s+t$. Naturally, Lemma 2.11 implies that all light machines possess a common latency with respect to $s+t$. That all machines have one of two latencies will make the cost of $s+t$ easy to compute.

With the induced assignment $s+t$ still fixed, let $S \subseteq \{1,2,\ldots,n\}$ denote the set of heavy machines. If $S=\emptyset$, then $s+t$ is the Nash assignment for $\mathcal{I}'$ with $s_i+t_i=\frac{a_i}{2}$ for $i \in \{1,2,\ldots,n\}$ and $s_{n+1}+t_{n+1}=\frac{3}{2}A$, satisfying $C(s+t)=9A>\frac{35}{4}A$. So suppose S is nonempty and define $\beta \in (0,1]$ by the equation $\sum_{i\in S} a_i = \beta A$. Define $\gamma \in (0,\frac{1}{2}]$ by the equation $\sum_{i\in S} s_i = \gamma A$. Our aim is to lower bound the cost of $s+t$ as a function of the parameters β and γ.

Since all heavy machines have equal latency, for i heavy we must have $s_i+t_i = s_i = \frac{\gamma}{\beta}a_i$ with $\ell_i(s_i+t_i)=4+\frac{\gamma}{\beta}$. Since all light machines have equal latency, we must have

$$s_i+t_i = a_i\frac{2-3\gamma}{4-3\beta}$$

with

$$\ell_i(s_i+t_i)=4+\frac{2-3\gamma}{4-3\beta}$$

for $i \in \{1,2,\ldots,n\}\setminus S$ and

$$s_{n+1}+t_{n+1}=A\left(\frac{4}{3}+\frac{2-3\gamma}{12-9\beta}\right)$$

with

$$\ell_{n+1}(s_{n+1}+t_{n+1})=4+\frac{2-3\gamma}{4-3\beta}.$$

The total cost of this solution is

$$\begin{aligned} C(s+t) &= \gamma A\left(4+\frac{\gamma}{\beta}\right)+(2-\gamma)A\left(4+\frac{2-3\gamma}{4-3\beta}\right) \\ &= A\left(8+\frac{(4-3\beta)\gamma^2+\beta(2-\gamma)(2-3\gamma)}{\beta(4-3\beta)}\right). \end{aligned}$$

Holding β fixed and differentiating with respect to γ, we find that this expression has unique minimizer $\gamma=\beta$ when $\beta \le \frac{1}{2}$ and $\gamma=\frac{1}{2}$ when $\beta \ge \frac{1}{2}$ (subject to the condition $\gamma \in (0,\frac{1}{2}]$). There are now two cases to analyze. First suppose that $\beta \le \frac{1}{2}$. Setting $\gamma=\beta$ we obtain

$$C(s+t)=A\left(8+\frac{4-4\beta}{4-3\beta}\right);$$

differentiating with respect to β, we see that the expression has a unique minimizer $\beta=\frac{1}{2}$ (subject to the condition $\beta \in (0,\frac{1}{2}]$) yielding cost $A(8+\frac{4}{5})>\frac{35}{4}A$. Finally, assume that $\beta \ge \frac{1}{2}$. Setting $\gamma=\frac{1}{2}$ we find that the cost of $s+t$ is given by

$$C(s+t)=A\left(8+\frac{1}{\beta(4-3\beta)}\right);$$

differentiating with respect to β, we find that this expression has unique minimizer $\beta=\frac{2}{3}$, at which point the equation reads $C(s+t)=\frac{35}{4}A$. However, since $\mathcal{I}$ is a "no instance" of $\frac{1}{3}$-$\frac{2}{3}$ PARTITION, we must have $\beta \ne \frac{2}{3}$ and hence $C(s+t)>\frac{35}{4}A$. We have exhausted all possible cases, and the reduction is complete. ∎

7. Directions for future work. The results of this paper suggest a number of problems deserving further study. An important and general open question is to what extent our machine-scheduling results carry over to the more complex domain of general networks. For example, given a directed graph G with a source vertex s and a sink t, a rate r of network traffic that wishes to travel from s to t, a latency function on each arc, and a parameter α specifying the fraction of traffic that is centrally controlled, how should the managed traffic be routed so as to induce the best possible equilibrium?[7] On the one hand, an example in a four-vertex network shows that a worst-case performance guarantee as small as $1/\alpha$ is impossible to attain with general latency functions [44]. On the other hand, the example does not rule out the possibility of a guarantee that is a larger function of α. Is it always possible to induce an assignment with cost no more than a constant—depending on α, but *not* on the size of the network—times that of the optimal assignment of traffic to s-t paths? Is a performance guarantee of $\frac{4}{3} - \epsilon$ possible for the special case of linear latency functions?

There are also unexplored avenues in the machine-scheduling setting. In section 6, we considered the optimization problem of computing the optimal Stackelberg strategy and observed that the LLF strategy achieves the best approximation ratio possible using the cost of the optimal assignment as a lower bound. Can a better approximation ratio be proved for LLF via a better lower bound on the cost of the assignment induced by the optimal strategy? In a different direction, to what extent do the results of this paper extend to systems with jobs of nonnegligible size?

Another natural question is whether more sophisticated approximation algorithms can achieve a better approximation ratio. This question has been resolved in the affirmative by Kumar and Marathe [32], who have given a fully polynomial-time approximation scheme[8] for the problem under mild conditions on the machine latency functions.

Acknowledgments. We thank Éva Tardos for several helpful discussions and for comments on an earlier draft of this paper. We also thank Anupam Gupta for useful discussions, Ben Atkin and Jon Kleinberg for pointing out relevant references, and the anonymous referees for their helpful comments.

HYPERGRAPHS IN MODEL CHECKING: ACYCLICITY AND HYPERTREE-WIDTH VERSUS CLIQUE-WIDTH*

GEORG GOTTLOB† AND REINHARD PICHLER‡

Abstract. The principal aim of model checking is to provide efficient decision procedures for the evaluation of certain logical formulae over finite relational structures. Graphs and hypergraphs are important examples of such structures. If no restrictions are imposed on the logical formulae and on the structures under consideration, then this problem of model checking has a very high computational complexity. Hence, several restrictions have been proposed in the literature on the logical formulae and/or on the structures under consideration in order to guarantee the tractability of this decision problem, e.g., acyclicity, bounded tree-width, query-width and hypertree-width in the case of queries, as well as bounded tree-width and clique-width in the case of structures. The aim of this paper is a detailed comparison of the expressive power of these restrictions.

Key words. model checking, hypergraphs, tractability, database queries, clique-width, acyclicity, hypertree-width

1. Introduction.

Model checking is the problem of deciding whether a logical formula or query Q is satisfied by a finite structure $\mathcal{S}$, which is formally written as $\mathcal{S} \models Q$. Q may be a formula in first-order logic, monadic second-order logic, existential second-order logic, and so on. Model checking is a central issue in database systems [1], where $\mathcal{S}$ represents a database and the formula Q represents a database query. If Q is a closed formula, then Q is a Boolean query; otherwise $Q(\mathbf{x})$ with free variables $\mathbf{x}$ represents the query whose output consists of all tuples of domain values $\mathbf{a}$ such that $\mathcal{S} \models Q(\mathbf{a})$. Model checking is also a basic issue in the area of constraint satisfaction, which is essentially the same problem as conjunctive query evaluation [5, 33]. Finally, model checking is used in computer-aided verification [13], where $\mathcal{S}$ represents a state transition graph and Q is typically a formula of modal logic describing some temporal system behavior. The results of the present paper are, however, more relevant to the former applications, namely, conjunctive database queries and constraint satisfaction.

Without any further restriction on the form of the structures and/or the queries, these problems have a very high computational complexity. Hence, several restrictions have been proposed in the literature both for the structures and the queries in order to make these problems tractable. In particular, the evaluation problem for acyclic queries or for queries whose tree-width, query-width, or hypertree-width is bounded by some fixed constant k is tractable on arbitrary finite structures (combined complexity). On the other hand, arbitrary but fixed formulae of monadic second-order logic (precisely, so-called MS_1 formulae) can be evaluated in polynomial time on graphs whose tree-width or clique-width is bounded by some fixed constant k [16, 18, 19].

In other words, MS_1 queries have polynomial data complexity in the case of bounded tree-width or bounded query-width. MS_1 extends first-order logic by the possibility of quantifying over monadic relational variables representing sets of vertices. Note that only the concept of bounded tree-width has so far been applied both to the queries and the structures. On the other hand, acyclicity, bounded query-width, and hypertree-width have primarily been investigated as restrictions on the queries, while bounded clique-width has been considered only as a restriction on the structures. In this paper, we apply all of these restrictions both to the queries and to the structures. For reasons to be explained in section 2, we consider the clique-width of a hypergraph as the clique-width of its *incidence* graph (for definitions, see section 2.1). We shall thus answer the following questions:

(i) *Question* 1: How do the various notions of acyclicity and of bounded hypertree-width relate to the concept of bounded clique-width?

(ii) *Question* 2: Are Boolean conjunctive queries tractable if their clique-width is bounded by some fixed constant k?

(iii) *Question* 3: Bounded clique-width is currently the most general restriction on structures which makes the model checking problem for MS_1 formulae tractable. Can the tractability barrier be pushed any further by using known generalizations of acyclicity that are more powerful than clique-width?

As for the first question, we provide an exact classification of the expressive power of the various restrictions. The result is depicted in Figure 1.1. (Definitions of all these concepts are provided in section 2.1.) The arrows in the figure point from the less powerful concept to the more powerful one. In particular, it is shown in this paper that if a class $\mathcal{C}$ of hypergraphs is of bounded clique-width, then $\mathcal{C}$ is of bounded query-width (and, hence, also of bounded hypertree-width). Moreover, it is also shown, e.g., that β-acyclicity is uncomparable with bounded clique-width.

In [29] it was shown that the evaluation of a class $\mathcal{C}$ of Boolean conjunctive queries is tractable (actually, it is even in LOGCFL) if $\mathcal{C}$ is of bounded hypertree-width. Putting this together with our new result that bounded clique-width implies bounded query-width (see Figure 1.1), we immediately obtain that the evaluation of a class $\mathcal{C}$ of Boolean conjunctive queries is tractable if $\mathcal{C}$ is of bounded clique-width. Thus Question 2 is positively answered.

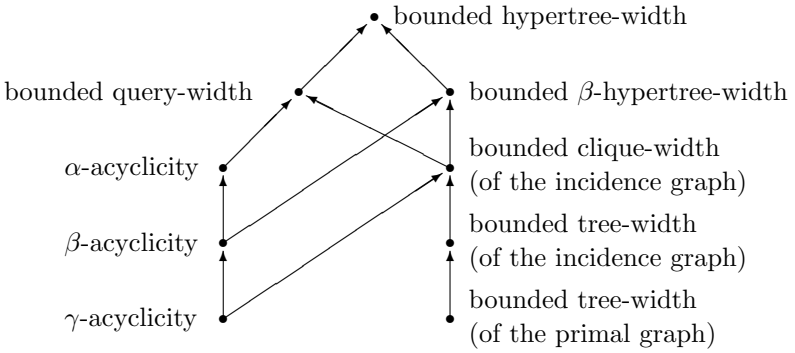

FIG. 1.1. *Expressive power of various restrictions on hypergraphs.*

As for the third question, we prove that the restriction to hypergraphs of bounded query-width or bounded β-hypertree-width is not sufficient to guarantee tractability of MS_1 queries. Thus bounded clique-width remains so far the most general restriction

on structures that guarantees the tractability of arbitrary fixed MS_1 queries.

While tree-width can be recognized in linear time [7], it is currently unclear whether bounded clique-width can be recognized in polynomial time. We therefore propose *generalized tree-width (gtw)*, a cyclicity measure located between tree-width and clique-width. It will be easy to see that bounded *gtw* is recognizable in polynomial time. Moreover, we shall prove that the evaluation of MS_1 queries over structures of bounded *gtw* is indeed tractable.

This paper is structured as follows: In section 2 we recall some basic notions and results. Restrictions on the form of the queries and of the structures will be considered in sections 3 and 4, respectively. In section 5, we show how the considerations of section 4 can be used for defining generalized tree-width. Finally, in section 6, we give some concluding remarks.

2. Preliminaries.

2.1. Various notions of width and acyclicity. A *graph* is a pair $\mathcal{G} = \langle \mathcal{V}, \mathcal{E} \rangle$ consisting of a set $\mathcal{V}$ of vertices (or nodes) and a set $\mathcal{E}$ of edges. We consider only undirected graphs without self-loops and without multiple edges here. Hence, in particular, every edge $E \in \mathcal{E}$ is a two-element subset of $\mathcal{V}$. Two vertices are called *adjacent* iff they are the endpoints of an edge in $\mathcal{E}$. A set $\mathcal{W} \subseteq \mathcal{V}$ is a *module* of a graph iff the elements in $\mathcal{W}$ cannot be distinguished by the other vertices; i.e., every vertex in $\mathcal{V} - \mathcal{W}$ is adjacent either to all vertices $W \in \mathcal{W}$ or to none. A *subgraph* is a graph $\langle \mathcal{V}', \mathcal{E}' \rangle$ such that (s.t.) $\mathcal{V}' \subseteq \mathcal{V}$ and $\mathcal{E}' \subseteq \mathcal{E}$ hold. A subgraph is *induced* iff $\mathcal{E}'$ is the restriction of $\mathcal{E}$ to those edges with both endpoints in $\mathcal{V}'$. In a *labeled graph*, every vertex has exactly one label. A *k-graph* is a labeled graph with k labels. Usually, these labels are taken from the set $\{1, \ldots, k\}$. A k-graph can be represented as $\langle \mathcal{V}, \mathcal{E}, \mathcal{V}_1, \ldots, \mathcal{V}_k \rangle$, where $\mathcal{V}$ is a set of vertices, $\mathcal{E}$ is a set of edges, and the sets $\mathcal{V}_1, \ldots, \mathcal{V}_k$ are (possibly empty) subsets of $\mathcal{V}$ that form a partition of $\mathcal{V}$.

A *hypergraph* is a pair $\mathcal{H} = \langle \mathcal{V}, \mathcal{E} \rangle$ consisting of a set $\mathcal{V}$ of vertices and a set $\mathcal{E}$ of hyperedges. A hyperedge $H \in \mathcal{E}$ is a subset of $\mathcal{V}$. A *subhypergraph* $\langle \mathcal{V}', \mathcal{E}' \rangle$ of $\langle \mathcal{V}, \mathcal{E} \rangle$ is obtained by deleting vertices and/or hyperedges; i.e., $\mathcal{V}' \subseteq \mathcal{V}$ and there exists a subset $\mathcal{F} \subseteq \mathcal{E}$ s.t. $\mathcal{E}' = \{H \cap \mathcal{V}' \mid H \in \mathcal{F}\}$. With every hypergraph $\mathcal{H} = \langle \mathcal{V}, \mathcal{E} \rangle$, we can associate the following two graphs: The *primal graph* (which is also called the *Gaifmann graph*) $\mathcal{P}(\mathcal{H})$ has the same vertices $\mathcal{V}$ as $\mathcal{H}$. Moreover, two vertices $V_1, V_2 \in \mathcal{V}$ are connected by an edge in $\mathcal{P}(\mathcal{H})$ iff there is a hyperedge $H \in \mathcal{E}$ s.t. both V_1 and V_2 are contained in $\mathcal{E}$. The *incidence graph* $\mathcal{I}(\mathcal{H})$ is a bipartite graph with vertices in $\mathcal{V} \cup \mathcal{E}$. Moreover, there is an edge in $\mathcal{I}(\mathcal{H})$ between two vertices $V \in \mathcal{V}$ and $H \in \mathcal{E}$ iff (in the hypergraph $\mathcal{H}$) V occurs in the hyperedge H. The incidence graph can be considered either as an unlabeled graph or as a 2-graph, with the labels $\mathcal{V}$ and $\mathcal{E}$, respectively.

In order to determine the *clique-width* of a (labeled or unlabeled) graph, we have to deal with so-called *k-expressions* t and the graphs $G(t)$ generated by such k-expressions:

(i) Let $i \in \{1, \ldots, k\}$ and let V be a vertex. Then $i(V)$ is a k-expression. The corresponding graph consists of a single vertex V whose label is i.

(ii) Let r and s be k-expressions that have no vertices in common. Then $r \oplus s$ is also a k-expression. The graph thus generated is the (disjoint) union of the graphs $G(r)$ and $G(s)$.

(iii) Let $i, j \in \{1, \ldots, k\}$ with $i \neq j$ and let r be a k-expression. Then $\eta_{i,j}(r)$ is also a k-expression. The corresponding graph is the same as $G(r)$ augmented by edges from every vertex with label i to every vertex with label j.

(iv) Let $i, j \in \{1, \ldots, k\}$ with $i \neq j$ and let r be a k-expression. Then $\rho_{i \to j}(r)$ is also a k-expression whose graph is the same as $G(r)$ except that all vertices with label i in $G(r)$ are relabeled to j.

The graph generated by a k-expression t can be considered either as a labeled graph with labels in $\{1, \ldots, k\}$ or as an unlabeled graph (by ignoring the labels assigned by t). Every subexpression s of a k-expression t generates a subgraph $G(s)$ of $G(t)$ (when considered as an unlabeled graph). The clique-width $cw(\mathcal{G})$ of a (labeled or unlabeled) graph $\mathcal{G}$ is the minimum k s.t. there exists a k-expression that generates $\mathcal{G}$. Obviously, $cw(\mathcal{G}) \leq n$ for every graph with n vertices. It can be shown that every clique has clique-width 2; e.g., the clique with four nodes V_1, V_2, V_3, V_4 can be generated by the 2-expression $\eta_{1,2}(2(V_4) \oplus \rho_{2 \to 1}(\eta_{1,2}(2(V_3) \oplus \rho_{2 \to 1}(\eta_{1,2}(2(V_2) \oplus 1(V_1))))))$.

A *tree decomposition* of a graph $\langle \mathcal{V}, \mathcal{E} \rangle$ is a pair $\langle T, \lambda \rangle$, where $T = \langle N, F \rangle$ is a tree and λ is a labeling function with $\lambda(p) \subseteq \mathcal{V}$ for every node $p \in N$ s.t. the following conditions hold:

(i) $\forall V \in \mathcal{V}$, $\exists p \in N$ s.t. $V \in \lambda(p)$.

(ii) $\forall E \in \mathcal{E}$ with endpoints V_1 and V_2, $\exists p \in N$ s.t. $V_1 \in \lambda(p)$ and $V_2 \in \lambda(p)$.

(iii) $\forall V \in \mathcal{V}$, the set $\{p \in N : V \in \lambda(p)\}$ induces a connected subtree of T.

The width of a tree decomposition $\langle T, \lambda \rangle$ is $\max(\{|\lambda(p)| - 1 : p \in N\})$. The tree-width $tw(\mathcal{G})$ of a graph $\mathcal{G}$ is the minimum width over all its tree decompositions.

A *join tree* of a hypergraph $\langle \mathcal{V}, \mathcal{H} \rangle$ is a labeled tree $\langle T, \lambda \rangle$ with $T = \langle N, F \rangle$ and a labeling function λ with $\lambda(p) \in \mathcal{H}$ for every node $p \in N$. Moreover, the following conditions hold:

(i) $\forall H \in \mathcal{H}$, $\exists p \in N$ s.t. $\lambda(p) = H$.

(ii) "Connectedness condition": Let $\lambda(p_1) = H_1$ and $\lambda(p_2) = H_2$ for two distinct nodes p_1 and p_2. Moreover, suppose that some vertex $V \in \mathcal{V}$ occurs in both hyperedges H_1 and H_2. Then V must also occur in all hyperedges that are used as labels on the path from p_1 to p_2.

A hypergraph is *α-acyclic* iff it has a join tree.

In [12], a *query decomposition* of a hypergraph $\langle \mathcal{V}, \mathcal{H} \rangle$ is defined as a pair $\langle T, \lambda \rangle$ where $T = \langle N, F \rangle$ is a tree and λ is a labeling function with $\lambda(p) \subseteq (\mathcal{V} \cup \mathcal{H})$ for every $p \in N$ and

(i) $\forall H \in \mathcal{H}\ \exists p \in N$ s.t. $H \subseteq \{V \mid V \in \lambda(p) \cap \mathcal{V}$ or $\exists H' \in \lambda(p) \cap \mathcal{H}$ with $V \in H'\}$;

(ii) "Connectedness condition": $\forall V \in \mathcal{V}$, the set $\{p \in N : V \in \lambda(p)\} \cup \{q \in N : \exists H \in \mathcal{H}$ s.t. $H \in \lambda(q)$ and V occurs in the hyperedge $H\}$ induces a connected subtree of T.[1]

The width of a query decomposition $\langle T, \lambda \rangle$ is $\max(\{|\lambda(p)| : p \in N\})$. The query-width $qw(\mathcal{H})$ of a hypergraph $\mathcal{H}$ is the minimum width over all its query decompositions. From [12] we know that a hypergraph $\mathcal{H}$ is α-acyclic iff $qw(\mathcal{H}) = 1$ holds.

In [29], a *hypertree decomposition* of a hypergraph $\langle \mathcal{V}, \mathcal{H} \rangle$ is defined as a triple $\langle T, \chi, \lambda \rangle$ where $T = \langle N, F \rangle$ is a tree and χ and λ are labeling functions with $\chi(p) \subseteq \mathcal{V}$ and $\lambda(p) \subseteq \mathcal{H}$ for every $p \in N$. Moreover, the following conditions hold:

(i) $\forall H \in \mathcal{H}$, $\exists p \in N$ s.t. $H \subseteq \chi(p)$ i.e., "p covers H."

(ii) "Connectedness condition": $\forall V \in \mathcal{V}$, the set $\{p \in N : V \in \chi(p)\}$ induces a connected subtree of T.

(iii) $\forall p \in N$, $\chi(p)$ contains only vertices that actually occur in at least one hyperedge of $\lambda(p)$.

[1] Note that in the original definition in [12], it is also required that $\forall H \in \mathcal{H}$, the set $\{p \in N : H \in \lambda(p)\}$ is a connected subtree of T. However, this restriction is of no use as far as the tractability of the evaluation of queries is concerned. We have therefore omitted this condition here.

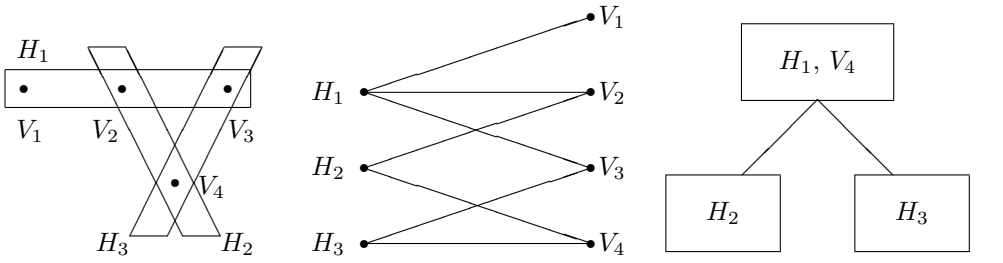
(iv) For every $p \in N$, if a vertex V occurs in some hyperedge $H \in \lambda(p)$ and if V is contained in $\chi(q)$ for some node q in the subtree below p, then V must also be contained in $\chi(p)$.

The width of a hypertree decomposition $\langle T, \chi, \lambda \rangle$ is $\max(\{|\lambda(p)| : p \in N\})$. The hypertree-width $hw(\mathcal{H})$ of a hypergraph $\mathcal{H}$ is the minimum width over all its hypertree decompositions.

A conjunctive query Q is a first-order formula in prenex form whose only connectives are $\exists$ and $\wedge$. With every conjunctive query, we can associate a hypergraph $\mathcal{H}$, whose vertices $V_1, \ldots, V_n$ correspond to the variables $x_1, \ldots, x_n$ occurring in Q. Moreover, for every atom A with variables $Var(A) = \{x_{i_1}, \ldots, x_{i_\alpha}\}$, there is a hyperedge $H = \{V_{i_1}, \ldots, V_{i_\alpha}\}$ in the hypergraph, and vice versa. Then the notions of hypertree-width, query-width, and acyclicity carry over in a natural way from hypergraphs to conjunctive queries. Likewise, the incidence graph or the primal graph of a conjunctive query Q is simply the corresponding graph of the associated hypergraph $\mathcal{H}$. Actually, the clique-width or tree-width of a hypergraph $\mathcal{H}$ can be defined as the corresponding width of either the incidence graph or the primal graph. If not indicated otherwise, we shall assume that the clique-width and the tree-width of a hypergraph $\mathcal{H}$ refer to the incidence graph (considered as an unlabeled graph). As a justification of this choice, note that there are NP-hard classes of queries s.t. the clique-width of their primal graphs is bounded by some fixed constant k. Consider, for example, the class $\mathcal{C}$ of conjunctive queries $CLIQUE_m$ asking whether a graph $(\mathcal{V}, \mathcal{E})$ has a clique of size m for integers m. This class of queries is well known to be NP-hard (cf. [26, problem GT19]). $CLIQUE_m$ is expressed by the formula $\exists x_1, \exists x_2, \ldots, \exists x_m : \bigwedge_{1 \leq i < j \leq m} ((x_i \neq x_j) \wedge E(x_i, x_j))$. The primal graph associated to $CLIQUE_m$ is a clique of m vertices and has clique-width $k = 2$ for any $m > 1$. Thus, *Question* 2 asked in the introduction has a trivial negative answer in case the clique-width of a query is defined based on its primal graph. The question becomes highly nontrivial if instead, as done in the present paper, we define the clique-width of a query (or of a hypergraph) on the basis of its incidence graph.

Clique-width and tree-width are *hereditary* properties in that $cw(\mathcal{G}') \leq cw(\mathcal{G})$ and $tw(\mathcal{G}') \leq tw(\mathcal{G})$ hold for every induced subgraph $\mathcal{G}'$ of a graph $\mathcal{G}$. Moreover, any subhypergraph $\mathcal{H}'$ of a hypergraph $\mathcal{H}$ gives rise to an induced subgraph $\mathcal{I}(\mathcal{H}')$ of the incidence graph $\mathcal{I}(\mathcal{H})$. Hence, if $\mathcal{H}'$ is an arbitrary subhypergraph of $\mathcal{H}$, then $cw(\mathcal{H}') \leq cw(\mathcal{H})$ and $tw(\mathcal{H}') \leq tw(\mathcal{H})$ hold, where cw and tw are defined via the incidence graph of a hypergraph. In contrast, α-acyclicity, query-width, and hypertree-width do not share this property, e.g., a hypergraph $\mathcal{H}$ can be α-acyclic even though some subhypergraph $\mathcal{H}'$ is not. Likewise, $\mathcal{H}$ can have a subhypergraph $\mathcal{H}'$ s.t. $qw(\mathcal{H}) < qw(\mathcal{H}')$ or $hw(\mathcal{H}) < hw(\mathcal{H}')$ hold. The notions of *β-acyclicity* and *β-hypertree-width* can be regarded as the hereditary counterparts of α-acyclicity and hypertree-width: In [24], a hypergraph $\mathcal{H}$ is defined to be β-acyclic iff every (not necessarily induced) subhypergraph $\mathcal{H}'$ of $\mathcal{H}$ is α-acyclic. Analogously, we can define the β-hypertree-width of $\mathcal{H}$ as the $\max(\{hw(\mathcal{H}') : \mathcal{H}' \text{ is a subhypergraph of } \mathcal{H}\})$. In [24], another notion of acyclicity is presented, namely, γ-acyclicity. Any hypergraph that is γ-acyclic is also β-acyclic. An algorithmic definition of γ-acyclicity will be given in section 4.1.

In this work, we shall compare the expressive power of the above defined notions of width. Let $x, y \in \{\text{tree, clique, query, hypertree, } \beta\text{-hypertree}\}$. Moreover, let $\mathcal{C}$ be a class of hypergraphs (or graphs). We say that $\mathcal{C}$ is of *bounded x-width* if there exists some constant k s.t. every hypergraph (or graph, respectively) in $\mathcal{C}$ has x-width less than or equal to k. Moreover, we say that *bounded x-width implies bounded y-width* if



(a) hypergraph $\mathcal{H}$ (b) incidence graph $\mathcal{I}(\mathcal{H})$ (c) query decomposition QD

FIG. 2.1. *$\mathcal{H}$, $\mathcal{I}(\mathcal{H})$, and QD.*

every class $\mathcal{C}$ of hypergraphs (or graphs) that is of bounded x-width is also of bounded y-width.

We conclude this section with an example, which should help to illustrate some of the main concepts used in this paper.

Example. Consider the *conjunctive query* $Q = A(x_1, x_2, x_3) \wedge B(x_2, x_4) \wedge C(x_3, x_4)$ consisting of 3 atoms and 4 variables. Consequently, the corresponding *hypergraph* $\mathcal{H} = \langle \mathcal{V}, \mathcal{E} \rangle$ is made up of 4 vertices $\mathcal{V} = \{V_1, V_2, V_3, V_4\}$ and 3 hyperedges $\mathcal{E} = \{H_1, H_2, H_3\}$ with $H_1 = \{V_1, V_2, V_3\}$, $H_2 = \{V_2, V_4\}$, and $H_3 = \{V_3, V_4\}$. Then the *incidence graph* $\mathcal{I}(\mathcal{H})$ is the bipartite graph with vertices in $\{V_1, V_2, V_3, V_4, H_1, H_2, H_3\}$ s.t. 2 nodes V_i and H_j are adjacent in $\mathcal{I}(\mathcal{H})$ iff, in the hypergraph $\mathcal{H}$, V_i occurs in the hyperedge H_j.

The hypergraph $\mathcal{H}$ and the incidence graph $\mathcal{I}(\mathcal{H})$ are displayed in Figure 2.1. Moreover, a *query decomposition* QD of $\mathcal{H}$ is shown there also. Note that QD has width 2. Due to the cycle $\{V_2, V_3\}$, $\{V_3, V_4\}$, $\{V_4, V_2\}$, the hypergraph $\mathcal{H}$ is not acyclic and, therefore, $\mathcal{H}$ cannot have a query decomposition of width 1. Hence, we have in fact $qw(\mathcal{H}) = 2$. Finally, a k-expression t (with $k = 5$) generating the graph $\mathcal{I}(\mathcal{H})$ can be obtained via the following algorithm:

Initialization (nodes H_i): First we introduce all nodes H_1, H_2, and H_3 with pairwise distinct labels; i.e., we set $s_0 := 1(H_1) \oplus 2(H_2) \oplus 3(H_3)$.

Iteration (nodes V_j): In a loop over all nodes $V_1, \ldots, V_4$, we carry out the following steps: Introduce the node V_j with label 4, draw all required edges between V_j and the H_i's and relabel V_j to 5, i.e.,

$$s_1 := \rho_{4\to5}(\eta_{4,1}(4(V_1) \oplus s_0)), \qquad s_2 := \rho_{4\to5}(\eta_{4,1}(\eta_{4,2}(4(V_2) \oplus s_1))),$$

$$s_3 := \rho_{4\to5}(\eta_{4,1}(\eta_{4,3}(4(V_3) \oplus s_2))), \quad s_4 := \rho_{4\to5}(\eta_{4,2}(\eta_{4,3}(4(V_4) \oplus s_3))).$$

Then s_4 is the desired k-expression that generates $\mathcal{I}(\mathcal{H})$. Note that the above algorithm is applicable to any bipartite graph. Hence, in any bipartite graph $\mathcal{B}$ with nodes in $\mathcal{N}_1 \cup \mathcal{N}_2$, the condition $cw(\mathcal{B}) \leq \min(|\mathcal{N}_1|, |\mathcal{N}_2|) + 2$ is fulfilled.

2.2. Tractability via bounded width or acyclicity. In model checking, one is interested in the (efficient) evaluation of certain logical formulae (= "queries") over finite relational structures. To this end, the various notions of width and acyclicity recalled in the previous section have been explored in two principal ways: They have been used to restrict either the relational structures or the queries. Restrictions on the

structures in terms of tree-width and clique-width have been investigated in the area of graph grammars and graph algorithms. On the other hand, restrictions imposed on the queries such as the various forms of acyclicity as well as bounded query-width and hypertree-width have been mainly analyzed in database theory and constraint satisfaction. Note that, so far, only tree-width is common ground for both directions of research.

In this paper, we shall first deal with restrictions on the form of the queries. Recall that the evaluation of arbitrary first-order queries is PSPACE-complete (cf. [34, 35]). Actually, even if we restrict the form of first-order queries to conjunctive queries (where only conjunctions and existential quantification are allowed), then the query evaluation is still NP-complete (see [11]). If conjunctive queries are further restricted to α-acyclic conjunctive queries, then this problem becomes tractable (cf. [36]). However, acyclicity is a very severe restriction. Hence, in recent years, several attempts to deal with "almost acyclic queries" have been made. In particular, several notions of width have been introduced in order to extend the class of tractable conjunctive queries, namely, tree-width, query-width, and hypertree-width (cf. [12, 25, 29, 31, 33]). In [28] and [29], it has been shown that, for some fixed k, the class of conjunctive queries with hypertree-width $\leq k$ properly contains the classes where the tree-width (of the incidence graph or of the primal graph) or the query-width, respectively, is bounded by k. Moreover, the concept of hypertree-width is a generalization of α-acyclicity in that a conjunctive query is acyclic iff it has hypertree-width 1.

In [15], the complexity of testing certain graph properties is investigated. In terms of model checking, this corresponds to evaluating a fixed query over finite graphs. If the queries are (arbitrary but fixed) first-order formulae, then this problem is tractable for all finite graphs without any further restrictions. However, the expressive power of first-order logic is comparatively weak. Hence, attempts were made to investigate larger classes of queries. In fact, many interesting graph properties like 3-colorability, Hamiltonian circuit, partition into triangle, etc. (cf. [15, 26]), are expressible as *monadic second-order* queries. Note that there are basically two ways of representing a graph by a logical structure, namely, either the domain consists of both vertices and edges or the domain consists of vertices only. In the former case, quantified variables of a monadic second-order formula may refer to edges or vertices, whereas in the latter case, only quantification over vertices is allowed. Formulae in the former case are referred to as MS_1 formulae, while formulae in the latter case are called MS_2 formulae. It has been shown that MS_2 formulae can be evaluated in polynomial time (in fact, even linear time suffices) over a class $\mathcal{C}$ of graphs if $\mathcal{C}$ is of bounded tree-width. The restriction to bounded clique-width has proved to allow for a much larger class of structures than bounded tree-width. In particular, bounded tree-width implies bounded clique-width (cf. [19]), while the converse is in general not true; e.g., the class of cliques is of bounded clique-width (where the bound is simply 2) but of unbounded tree-width. It has been shown that the evaluation of fixed MS_1 formulae over a class $\mathcal{C}$ of graphs is tractable if $\mathcal{C}$ is of bounded clique-width (cf. [15, 16, 17]).

3. Restricting the form of the queries. In this section we consider the case of conjunctive queries over arbitrary relational structures, where the queries are subjected to restrictions that guarantee tractability. It has already been noted in the previous section that bounded hypertree-width is the most powerful concept studied so far. We shall now show that bounded clique-width does not allow for a bigger class of conjunctive queries than does bounded hypertree-width. More precisely, in the

proof of Theorem 3.1, we shall provide an algorithm that, when given a k-expression for (the incidence graph of) some hypergraph $\mathcal{H}$, constructs a query decomposition of $\mathcal{H}$ whose width is $\leq k$.

It is convenient to introduce some additional notation first. In the proof of Theorem 3.1, we are going to deal with three kinds of graphs or hypergraphs, respectively, i.e., a hypergraph $\mathcal{H}'$, the incidence graph $\mathcal{I}'$ of $\mathcal{H}'$, and the query decomposition QD' of $\mathcal{H}'$. We shall therefore speak about H-vertices, I-vertices, and Q-vertices (or, equivalently, H-nodes, I-nodes, and Q-nodes) when referring to the vertices in $\mathcal{H}'$, $\mathcal{I}'$, or QD', respectively. Likewise, we shall encounter two kinds of labels, namely, the labels assigned by the k-expression t' and the labels of the Q-nodes in the query decomposition QD'. In order to avoid confusion, we shall refer to these labels as t-labels (for the labels of the I-vertices according to the k-expression t') and Q-labels (in case of the Q-nodes), respectively. Strictly speaking, t' assigns t-labels to the nodes in $\mathcal{I}'$ (i.e., the I-nodes). However, every I-node uniquely corresponds either to a hyperedge or to an H-vertex in $\mathcal{H}'$. Hence, as an abbreviation, we shall speak about the "t-label of a hyperedge" or the "t-label of an H-vertex" when we refer to the t-label of the I-vertex corresponding to this hyperedge or H-vertex, respectively. We shall say that a Q-node q of the query decomposition QD' "*covers*" an H-vertex V iff either V is contained in the Q-label $\lambda'(q)$ or $\lambda'(q)$ contains some hyperedge H s.t. V is an H-vertex occurring in this hyperedge H. Finally, for every $\ell \in \{1, \ldots, k\}$, we define the set $\mathcal{Q}_\ell(QD')$ of Q-nodes as $\mathcal{Q}_\ell(QD') = \{p : p \text{ is a } Q\text{-node in } QD' \text{ and the } Q\text{-label of } p \text{ contains a hyperedge or an } H\text{-vertex with } t\text{-label } \ell\}$.

THEOREM 3.1 (query-width is bounded by clique-width). *Let $\mathcal{H}$ be an arbitrary hypergraph with incidence graph $\mathcal{I}(\mathcal{H})$. Then $qw(\mathcal{H}) \leq cw(\mathcal{I}(\mathcal{H}))$ holds.*

Proof. Let $\mathcal{H}$ be a hypergraph with incidence graph $\mathcal{I}$ and let t be a k-expression that generates $\mathcal{I}$. Note that every subexpression t' of t generates a subgraph $\mathcal{I}'$ of the incidence graph $\mathcal{I}$. Moreover, every such $\mathcal{I}'$ uniquely defines a hypergraph $\mathcal{H}'$. Then we construct a query decomposition QD' of $\mathcal{H}'$ inductively on the structure of t' with the following properties:

1. *QD' is a query decomposition of $\mathcal{H}'$ of width $\leq k$.*
2. *For every $\ell \in \{1, \ldots, k\}$, the above defined set $\mathcal{Q}_\ell(QD')$ of Q-vertices, if not empty, forms a connected subtree of QD' s.t. the root of this subtree coincides with the root of QD' itself. Moreover, if the incidence graph $\mathcal{I}'$ actually contains an I-node with t-label ℓ, then the Q-label $\lambda(r)$ of the root r of QD' also contains at least one I-node with t-label ℓ.*
3. *Suppose that p is a Q-node in QD', V is an H-vertex with t-label ℓ, and p covers V. Moreover, let the Q-node q be the parent of p in QD'. Then either q also covers V or the Q-label $\lambda'(q)$ contains some I-node N whose t-label is ℓ.*

For the construction of QD', we consider each of the four basic operations of a k-expression separately.

Introduction of a new vertex. Let $t' = i(N)$ for some node N in $\mathcal{I}$; i.e., N either corresponds to a hyperedge or to an H-vertex in $\mathcal{H}'$. In either case, the corresponding query decomposition QD' consists of a single node r whose Q-label is the singleton $\{N\}$. Thus, QD' trivially fulfills the above conditions 1 through 3.

Disjoint union. Let $t' = s_1 \oplus s_2$. Moreover, let $\mathcal{J}_1$ and $\mathcal{J}_2$ be the (disjoint) subgraphs of $\mathcal{I}$ defined by s_1 and s_2, respectively, and let $\mathcal{H}_1$ and $\mathcal{H}_2$ be the corresponding hypergraphs. By the induction hypothesis, there exist query decompositions $QD_1 = \langle T_1, \lambda_1 \rangle$ and $QD_2 = \langle T_2, \lambda_2 \rangle$ of $\mathcal{H}_1$ and $\mathcal{H}_2$, respectively, for which the above three conditions hold. Let r_1 and r_2 denote the root nodes of T_1 and T_2, respectively.

Then we construct the new query decomposition $QD' = \langle T', \lambda' \rangle$ in the following way: T' has a new root node r and the subtrees T_1 and T_2 s.t. r_1 and r_2 are the child nodes of r. As for the labeling function λ', the Q-labels of the Q-nodes in QD_1 and QD_2 are left unchanged. The Q-label $\lambda'(r)$ of the new root r is defined from the Q-labels of r_1 and r_2 as follows: Let $\mathcal{R} = \lambda_1(r_1) \cup \lambda_2(r_2)$. By assumption, the H-vertices and hyperedges in $\mathcal{R}$ are assigned at most k different t-labels by t'. Then we construct the Q-label $\lambda'(r)$ by selecting one representative from $\mathcal{R}$ for each t-label according to t'. Of course, there can be at most k such representatives. We shall now show that conditions 1 through 3 hold for QD':

(i) *Condition* 1. By the above construction of λ' and by the induction hypothesis, the width of QD' is clearly $\leq k$. It remains to prove that QD' is indeed a query decomposition of $\mathcal{H}'$. By the induction hypothesis, every hyperedge of $\mathcal{H}_1$ occurs in some Q-label of QD_1 and every hyperedge of $\mathcal{H}_2$ occurs in some Q-label of QD_2 and, thus, also in some Q-label of QD'. Moreover, the connectedness condition follows from the induction hypothesis and the fact that $\mathcal{I}'$ is obtained as the *disjoint* union of $\mathcal{J}_1$ and $\mathcal{J}_2$. Hence, in particular, the hypergraphs $\mathcal{H}_1$ and $\mathcal{H}_2$ have no H-vertices in common.

(ii) *Condition* 2. Let $\ell \in \{1, \ldots, k\}$. By the induction hypothesis, $\mathcal{Q}_\ell(QD_1)$ and $\mathcal{Q}_\ell(QD_2)$ form connected subtrees of the query decompositions QD_1 and QD_2, respectively. Moreover, the roots of these subtrees coincide with the roots of QD_1 and QD_2, respectively, and if $\mathcal{J}_1$ or $\mathcal{J}_2$ contains an I-node with label ℓ, then $\lambda_1(r_1)$ or $\lambda_1(r_2)$, respectively, indeed contains an I-node with t-label ℓ. By our construction, $\mathcal{Q}_\ell(QD')$ is obtained as follows:

$$\mathcal{Q}_\ell(QD') = \begin{cases} \mathcal{Q}_\ell(QD_1) & \\ \quad \cup\ \mathcal{Q}_\ell(QD_2) \cup \{r\} & \text{if } s_1 \text{ and } s_2 \text{ contain an } I\text{-node with } t\text{-label } \ell, \\ \mathcal{Q}_\ell(QD_1) \cup \{r\} & \text{if only } s_1 \text{ contains an } I\text{-node with } t\text{-label } \ell, \\ \mathcal{Q}_\ell(QD_2) \cup \{r\} & \text{if only } s_2 \text{ contains an } I\text{-node with } t\text{-label } \ell, \\ \emptyset & \text{otherwise.} \end{cases}$$

In all of these four cases, condition 2 clearly holds.

(iii) *Condition* 3. Let p be a Q-node in QD' and let q be the parent of p in QD'. In particular, p is not the new root node r in QD' and, therefore, p already existed before, say, in QD_1. Now suppose that V is an H-vertex with t-label ℓ s.t. p covers V in QD'. If p is the root r_1 of QD_1, then q is the new root r in QD', which (by condition 2) contains some I-node N with t-label ℓ. On the other hand, if $p \neq r_1$, then also q is a Q-node of QD_1 and condition 3 holds by the induction hypothesis.

Introduction of edges. Let $t' = \eta_{i,j}(s_1)$. Moreover, let $\mathcal{J}_1$ be the subgraph of $\mathcal{I}$ defined by s_1 and let $\mathcal{H}_1$ be the corresponding hypergraph. Note that the $\eta_{i,j}$ operation may have added some new edges in the incidence graph and, therefore, a hyperedge H in $\mathcal{H}'$ will, in general, contain more H-vertices than if we consider H as a hyperedge in $\mathcal{H}_1$. In fact, we may assume without loss of generality (w.l.o.g.) that the application of $\eta_{i,j}$ to s_1 indeed creates a new edge in $\mathcal{I}'$, which did not exist in $\mathcal{J}_1$. Otherwise, the hypergraphs $\mathcal{H}'$ and $\mathcal{H}_1$ would be identical and the query decomposition QD_1 of $\mathcal{H}_1$ would also be the desired query decomposition of $\mathcal{H}'$.

In order to distinguish between hyperedges in $\mathcal{H}'$ and $\mathcal{H}_1$, we shall write H and H^-, respectively; i.e., by H^-, we denote a hyperedge in $\mathcal{H}_1$ and by H we denote the corresponding hyperedge in $\mathcal{H}'$. Of course, we have $H^- \subseteq H$ but, in general, $H^- = H$ is not true.

By the induction hypothesis, there exists a query decomposition $QD_1 = \langle T_1, \lambda_1 \rangle$ of $\mathcal{H}_1$ for which the above three conditions hold. Then we construct the query de-

composition $QD' = \langle T_1, \lambda' \rangle$ of $\mathcal{H}'$ in such a way that the tree T_1 is left unchanged. As for the labeling function λ' of QD', recall that $\mathcal{I}'$ is a bipartite graph. Moreover, by assumption, $\eta_{i,j}$ creates at least one new edge in $\mathcal{I}'$. Hence, we may assume w.l.o.g. that i is the t-label of H-vertices only and j is the t-label of hyperedges only. By condition 2 of the induction hypothesis, $\mathcal{Q}_j(QD_1)$ is a connected subtree of QD_1 whose root coincides with the root r_1 of QD_1. Thus, the Q-label $\lambda_1(r_1)$ contains a hyperedge G^- with t-label j. Then λ' is defined as follows: The Q-label of the root r_1 is left unchanged, i.e., $\lambda'(r_1) := \lambda_1(r_1)$. Likewise, if the Q-label of some Q-node $p \neq r_1$ does not contain an H-vertex with label i, then we do not alter this Q-label. In the Q-label of all other Q-nodes, we replace the H-vertices with t-label i by the hyperedge G.[2]

Now it can be easily checked that condition 2 holds for QD'; i.e., by our construction of the labeling function λ', the sets $\mathcal{Q}_\ell(QD')$ are obtained from $\mathcal{Q}_\ell(QD_1)$ for $\ell \in \{1, \ldots, k\}$ in the following way:

$$\mathcal{Q}_\ell(QD') = \begin{cases} \{r_1\} & \text{if } \ell = i, \\ \mathcal{Q}_i(QD_1) \cup \mathcal{Q}_j(QD_1) & \text{if } \ell = j, \\ \mathcal{Q}_\ell(QD_1) & \text{otherwise.} \end{cases}$$

In all of these three cases, condition 2 obviously holds.

For the proof of condition 3, let p be a Q-node in QD' and let q be the parent of p in QD'. Moreover, let V be an H-vertex with t-label ℓ s.t. p covers V. Then we have to show that either q also covers V or the Q-label $\lambda'(q)$ contains some I-node N whose t-label is ℓ. Of course, p and q are also Q-nodes in QD_1. Then we distinguish the following cases:

Case 1. Suppose that $\ell \neq i$. If V occurs in some hyperedge H of the Q-label $\lambda'(p)$ s.t. the corresponding hyperedge H^- already occurred in the Q-label $\lambda_1(p)$ in QD_1, then condition 3 follows immediately from the induction hypothesis. Likewise, if V itself is contained in $\lambda'(p)$, then V was already contained in $\lambda_1(p)$, and we may again conclude by the induction hypothesis that condition 3 still holds for QD'. On the other hand, suppose that V occurs in some hyperedge H from the Q-label $\lambda'(p)$ s.t. the corresponding hyperedge H^- did not occur in the Q-label $\lambda_1(p)$ in QD_1. In other words, $H = G$ and G was introduced into $\lambda'(p)$ when we replaced the H-vertices with label i by the hyperedge G in the Q-labels of all Q-nodes except for the root node r_1 of QD'. If $q = r_1$, then condition 3 clearly holds, since $\lambda'(q)$ also contains G. Otherwise, by condition 2 of the induction hypothesis, the parent node q of p in QD_1 also contains some I-node N with t-label i in its Q-label $\lambda_1(q)$. By our construction, N is replaced by the hyperedge G in $\lambda'(q)$. Hence, V is also covered by q in QD'.

Case 2. Suppose that $\ell = i$. W.l.o.g., we may assume that $q \neq r_1$, since otherwise q contains some I-node with t-label i by condition 2, and we are done. By our construction, V (with t-label i) itself cannot occur in the Q-label of the Q-node $p \neq r_1$ in QD'. Hence, there exists some hyperedge H in $\mathcal{H}'$ s.t. V occurs in H and $H \in \lambda'(p)$. We distinguish two subcases for the t-label of H:

(i) If H has the t-label j, then, by condition 2, $\lambda'(q)$ also contains some hyperedge H' with t-label j. Moreover, by the application of the $\eta_{i,j}$ operation in the

[2]Actually, this formulation is slightly inaccurate. Recall that, in general, a hyperedge H in $\mathcal{H}'$ may have some additional vertices, which are not contained in the corresponding hyperedge H^- in $\mathcal{H}_1$; e.g., strictly speaking, we would have to write $\lambda'(r_1) := \{H : H^- \in \lambda_1(r_1)\} \cup \{V \in \lambda_1(r_1)\}$ rather than $\lambda'(r_1) := \lambda_1(r_1)$. However, the meaning of the latter formulation is clear. Moreover, as far as the incidence graph is concerned, H^- and H refer to exactly the same I-node, anyway.

incidence graph $\mathcal{I}'$, the hyperedge H' in $\mathcal{H}'$ indeed contains all H-vertices with t-label i. Thus, q clearly covers V in QD'.

(ii) Finally, suppose that H has a t-label different from j. Then H^- already existed in $\lambda_1(p)$ and the H-vertex V already occurred in the hyperedge H^- of the hypergraph $\mathcal{H}_1$. Hence, we may apply condition 3 of the induction hypothesis; i.e., either V occurs in some hyperedge F^- in $\mathcal{H}_1$ s.t. $F^- \in \lambda_1(q)$ or $\lambda_1(q)$ contains some I-node N whose t-label is i. In the former case, $F \in \lambda'(q)$ and, therefore, q also covers V in QD'. In the latter case, N is replaced by G in $\lambda'(q)$ and, again, q covers V in QD'.

It remains to prove that also condition 1 still holds; i.e., QD' indeed is a query decomposition of $\mathcal{H}'$ with width $\leq k$. Actually, the bound on the width follows immediately from the induction hypothesis and the fact that $|\lambda'(p)| \leq |\lambda_1(p)|$ holds for every Q-node $p \in T_1$. Moreover, for every hyperedge H in $\mathcal{H}'$, QD_1 contains a Q-node p with $H^- \in \lambda_1(p)$ and, therefore, $H \in \lambda'(p)$ also holds. The only difficult part of the proof is to show that QD' fulfills the connectedness condition. In fact, this is the only place in the whole proof of Theorem 3.1 where we actually need conditions 2 and 3 of our construction.

Now let V be an arbitrary H-vertex of $\mathcal{H}'$ and let ℓ denote the t-label of V. Then we have to show that the set of Q-nodes that cover V form a connected subtree in QD'. To this end we distinguish the following cases:

Case 1. Let $\ell \neq i$. In this case, for every hyperedge H in $\mathcal{H}'$ with $V \in H$, we know that $V \in H^-$ also holds. Moreover, by the induction hypothesis, the set of Q-nodes $\mathcal{P}_1 = \{p \in T_1 : V \in \lambda_1(p)\} \cup \{q \in T_1 : \exists H^- \text{ s.t. } H^- \text{ is a hyperedge in } \mathcal{H}_1,\ H^- \in \lambda_1(q) \text{ and } V \in H^-\}$ induces a connected subtree of T_1. First, suppose that V does not occur in the hyperedge G by which all H-vertices with t-label i were replaced when we constructed λ' from λ_1. In this case, the set of Q-nodes $\mathcal{P}' = \{p \in T_1 : V \in \lambda'(p)\} \cup \{q \in T_1 : \exists H \text{ s.t. } H \text{ is a hyperedge in } \mathcal{H}',\ H \in \lambda'(q) \text{ and } V \in H\}$ coincides with $\mathcal{P}_1$, and we are done. So suppose that V occurs in the hyperedge G. But then, by our construction, $\mathcal{P}' = \mathcal{Q}_i(QD_1) \cup \mathcal{P}_1$ holds, where both of the sets $\mathcal{Q}_i(QD_1)$ and $\mathcal{P}_1$ are connected subtrees of T_1 containing the root r_1 of T_1. Thus, $\mathcal{P}'$ is also connected.

Case 2: Suppose that $\ell = i$. It suffices to show the following fact: *Let q be an arbitrary Q-node that covers V and let $q_0, q_1, \ldots, q_m$ for some $m \geq 0$ denote the path in QD' from the root $r_1 = q_0$ of T_1 to the Q-node $q = q_m$. Then every Q-node q_α along this path covers V.*

Of course, the root $r_1 = q_0$ covers V, since $\lambda'(r_1)$ contains the hyperedge G with t-label j, which (by the $\eta_{i,j}$ operation) is adjacent to the H-vertex V in $\mathcal{I}'$. For the other Q-nodes q_α with $\alpha > 0$, we know that they can no longer contain the H-vertex V itself in their Q-label $\lambda'(q_\alpha)$. Hence, in particular, $\lambda'(q_m)$ contains some hyperedge H s.t. the H-vertex V occurs in H. Similarly to Case 2 in the proof of condition 2 above, we have to distinguish two subcases depending on whether the t-label of H equals j or not.

(i) If H has the t-label j, then we know by condition 2 that every Q-node q_α on the path from q_m to the root r_1 of QD' contains some hyperedge H' with t-label j in its Q-label $\lambda'(q_\alpha)$. Moreover (by the $\eta_{i,j}$ operation), the hyperedge H' in $\mathcal{H}'$ contains all H-vertices with t-label i. Hence, in this case, every such Q-node q_α in QD' indeed covers V.

(ii) On the other hand, suppose that the t-label of H is different from j. Then no H-vertex is added to this hyperedge by the $\eta_{i,j}$ operation. Hence, V already

occurred in the corresponding hyperedge H^- of the hypergraph $\mathcal{H}_1$ and also the Q-label $\lambda_1(q_m)$ in QD_1 already contained the hyperedge H^-. Hence, we may apply condition 3 of the induction hypothesis; i.e., either V occurs in some hyperedge F^- in $\mathcal{H}_1$ s.t. $F^- \in \lambda_1(q_{m-1})$ or $\lambda_1(q_{m-1})$ contains some I-node N whose t-label is i. In the former case, $F \in \lambda'(q_{m-1})$ and, therefore, q also covers V in QD'. In the latter case, N is replaced by G in $\lambda'(q_{m-1})$ and, hence, again q covers V in QD'. By an easy induction argument, we can show that in fact every Q-node $q_{m-\beta}$ with $\beta \in \{1, \ldots, m-1\}$ covers V in QD'.

Renaming of labels. Let $t' = \rho_{i \to j}(s_1)$. Moreover, let $\mathcal{J}_1$ be the subgraph of $\mathcal{I}$ defined by s_1 and let $\mathcal{H}_1$ be the corresponding hypergraph. By the induction hypothesis, there exists a query decomposition QD_1 of $\mathcal{H}_1$ for which the above three conditions hold. We claim that then QD_1 is also the desired query decomposition QD' of $\mathcal{H}'$. Note that by the renaming of labels, no new vertices or edges are introduced in $\mathcal{I}'$. Hence, $\mathcal{H}'$ is identical to $\mathcal{H}_1$ and, therefore, QD_1 is clearly a query decomposition of $\mathcal{H}'$, i.e., condition 1 holds.

The sets of Q-nodes $\mathcal{Q}_\ell(QD')$ with $\ell \in \{1, \ldots, k\}$ are obtained from the sets $\mathcal{Q}_\ell(QD_1)$ in the following way:

$$\mathcal{Q}_\ell(QD') = \begin{cases} \emptyset & \text{if } \ell = i, \\ \mathcal{Q}_i(QD_1) \cup \mathcal{Q}_j(QD_1) & \text{if } \ell = j, \\ \mathcal{Q}_\ell(QD_1) & \text{otherwise.} \end{cases}$$

Hence, condition 2 also follows immediately from the induction hypothesis.

As for condition 3, let p be a Q-node in QD' and let q be the parent of p in QD'. Moreover, let V be an H-vertex with t-label ℓ s.t. p covers V. The only interesting case is that the t-label of V was changed from i to j by the $\rho_{i \to j}$ operation. But then, by the induction hypothesis, either q covers V in QD_1 or the Q-label $\lambda_1(q)$ contains some I-node N whose t-label (in s_1) is i. In the former case, q still covers V in QD' and in the latter case the Q-label $\lambda'(q)$ contains the I-node N, which now has the t-label j. Hence, in either case, condition 3 holds. □

The converse of Theorem 3.1 is clearly not true. This is due to the fact that the clique-width is a hereditary property with respect to (w.r.t.) induced subgraphs (and any subhypergraph $\mathcal{H}'$ of a hypergaph $\mathcal{H}$ indeed gives rise to an induced subgraph $\mathcal{I}(\mathcal{H}')$ of the incidence graph $\mathcal{I}(\mathcal{H})$), whereas α-acyclicity, query-width, and hypertree-width are not. In particular, we can take any hypergraph $\mathcal{H}'$ with high clique-width and possibly high hypertree-width and transform it into the following hypergraph $\mathcal{H}$: Let H be a new hyperedge that contains all vertices of $\mathcal{H}'$ and let $\mathcal{H}$ be the result of adding H to $\mathcal{H}'$. Then $\mathcal{H}$ is α-acyclic and, therefore, $qw(\mathcal{H}) = hw(\mathcal{H}) = 1$ holds. On the other hand, the incidence graph of $\mathcal{H}'$ is an induced subgraph of the incidence graph of $\mathcal{H}$. Hence, the clique-width of $\mathcal{H}$ is at least as high as in the case of $\mathcal{H}'$.

The following example will help to illustrate the construction in the proof of Theorem 3.1.

Example. Consider the conjunctive query $A(x_1, x_2, x_3) \wedge B(x_2, x_3, x_4)$. The corresponding hypergraph $\mathcal{H}$ has 4 vertices, $\{V_1, V_2, V_3, V_4\}$, and 2 hyperedges, $H_1 = \{V_1, V_2, V_3\}$ and $H_2 = \{V_2, V_3, V_4\}$. The incidence graph $\mathcal{I}$ of $\mathcal{H}$ and the tree representation of a k-expression t (with $k = 3$) generating $\mathcal{I}$ are displayed in Figure 3.1.

Now let us traverse the tree representation of t bottom-up and see what the various subexpressions of t and the corresponding query decompositions look like. Actually, we shall discuss only the subexpressions s_i along the left-most path of the tree representation of t in detail. The corresponding query decompositions QD_i are depicted in Figure 3.2.

a) incidence graph $\mathcal{I}$: b) k-expression t:

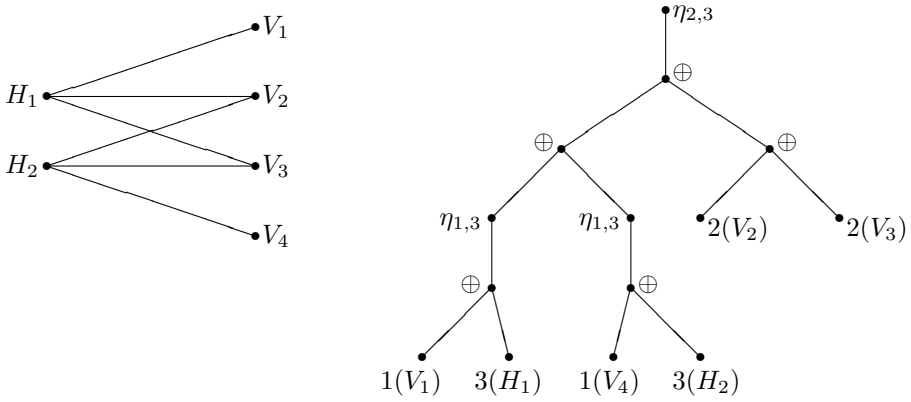


FIG. 3.1. *$\mathcal{I}$ and t.*

The query decomposition QD_1 corresponding to $s_1 = 1(V_1)$ consists of a single node labeled by V_1. Likewise, from $3(H_1)$ we get a query decomposition with a single node labeled by H_1. Hence, the labeling of the new root in the query decomposition QD_2 corresponding to $s_2 = 1(V_1) \oplus 3(H_1)$ contains both V_1 and H_1 from its child nodes, since they have different labels in s_2. In the query decomposition QD_3 obtained from $s_3 = \eta_{1,3}(s_2)$, we have to replace all occurrences of V_1 outside the root of QD_2 by the hyperedge H_1. Actually, in this case, this step was not really necessary. However, when we discuss the k-expression s_6 below, it will become clear why this replacement is, in general, required.

Now consider the query decomposition QD_4 corresponding to the k-expression $s_4 = s_3 \oplus \eta_{1,3}[1(V_4) \oplus 3(H_2)]$. The subtree in QD_4 corresponding to $\eta_{1,3}[1(V_4) \oplus 3(H_2)]$ is obtained analogously to the query decomposition QD_3 corresponding to s_3. Moreover, in the root of QD_4, we are only allowed to select one representative from the sets $\{V_1, V_4\}$ and $\{H_1, H_2\}$, respectively, since V_1 and V_4 (when considered as nodes in the graph generated by s_4), on the one hand, and H_1 and H_2, on the other hand, have the same label in s_4.

No new ideas are required for the construction of the query decomposition QD_5 corresponding to the k-expression $s_5 = s_4 \oplus (2(V_2) \oplus 2(V_3))$. Note that in the query decomposition QD_6 corresponding to $s_6 = t = \eta_{2,3}(s_5)$, it is indeed necessary to replace the occurrences of V_2 and V_3 by the hyperedge H_1. In particular, QD_5 is no longer a valid query decomposition after the $\eta_{2,3}$ operation has been applied to the incidence graph. This is due to the fact that after this operation, the hyperedge H_1 contains the vertex V_3 in the corresponding hypergraph. But then the connectedness condition would be violated by QD_5, since the root covers the vertex V_3 (since this vertex is now contained in H_1) and also the right-most leaf node of QD_5 covers the vertex V_3. However, in QD_5, the node lying in between them contains only V_2.

Recall from [29] that $qw(\mathcal{H}) \geq hw(\mathcal{H})$ holds for every hypergraph $\mathcal{H}$. Hence, by Theorem 3.1, we immediately get the following corollary.

COROLLARY 3.2 (hypertree-width is bounded by clique-width). *Let $\mathcal{H}$ be an arbitrary hypergraph with incidence graph $\mathcal{I}(\mathcal{H})$. Then $hw(\mathcal{H}) \leq cw(\mathcal{I}(\mathcal{H}))$ holds.*

Moreover, by the correspondence between queries and hypergraphs, we have the following.

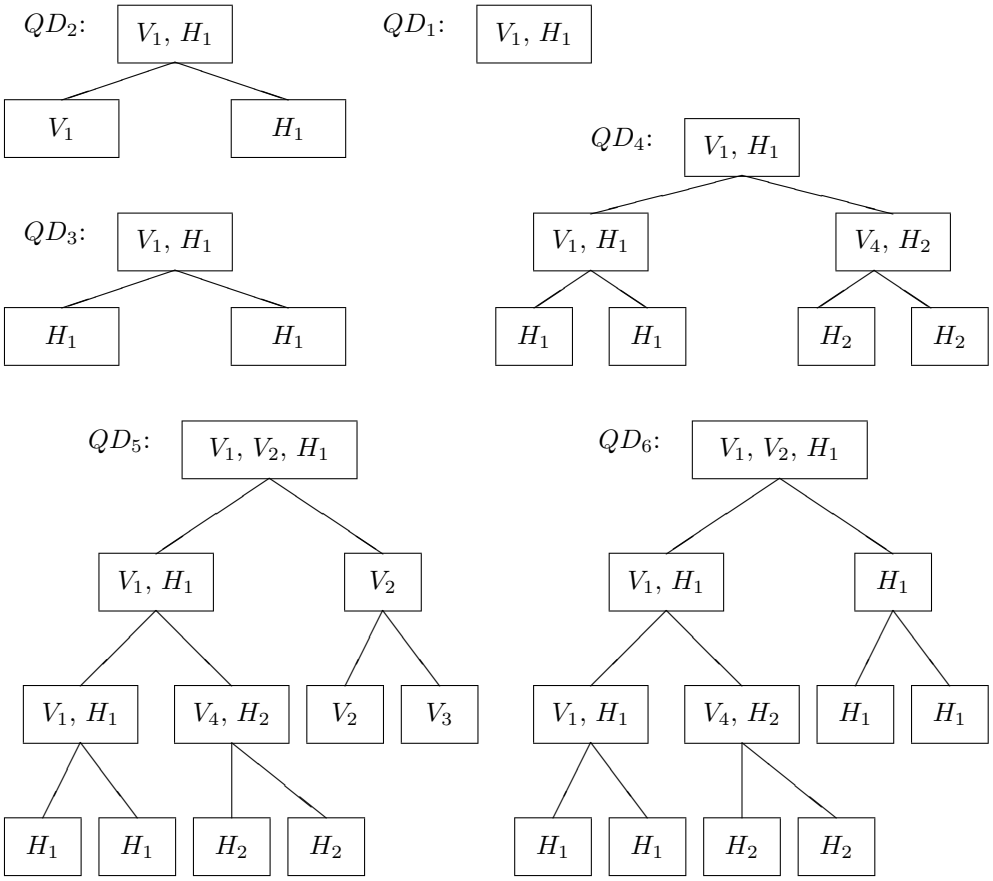

FIG. 3.2. *Query decompositions* $QD_1, \ldots, QD_6$.

COROLLARY 3.3 (width of a conjunctive query). *Let Q be a conjunctive query with incidence graph $\mathcal{I}(Q)$. Then $hw(Q) \leq qw(Q) \leq cw(\mathcal{I}(Q))$ holds.*

The above corollary has another interesting aspect: Apart from the special case of $k \leq 3$, it is not known whether graphs with clique-width $\leq k$ can be recognized in polynomial time for fixed k (cf. [14]). In contrast, conjunctive queries (or, equivalently, hypergraphs) with hypertree-width $\leq k$ actually can be recognized in polynomial time. In fact, this decision problem is highly parallelizable since it is even contained in the low complexity class LOGCFL (cf. [29]). In other words, apart from being the more general concept, bounded hypertree-width also has better properties as far as recognizing such conjunctive queries is concerned.

4. Restricting the form of the structures. In this section we consider monadic second-order queries over hypergraphs, where quantification is allowed over variables that stand for vertices or hyperedges. Moreover, there are two unary predicates P_V, P_H and a binary predicate *edg* with the following meaning: $P_V(x)$, $P_H(x)$ state that the argument x is a vertex or a hyperedge, respectively, of the hypergraph. By $edg(v, h)$ we can express that the vertex v is contained in the hyperedge h. Clearly,

these formulae correspond to MS_1 formulae that are evaluated over the incidence graphs (when considered as a labeled graph with two labels) of hypergraphs. Thus, the evaluation of such formulae is tractable if the incidence graphs under consideration are of bounded clique-width. From [16] we know that a class of labeled graphs with p labels (for fixed $p \geq 1$) is of bounded clique-width iff the same graphs without labels are of bounded clique-width. Hence, in what follows, we shall ignore the two different labels of the nodes of the incidence graph, since they have no effect on the tractability of the evaluation of MS_1 formulae.

It has already been mentioned that clique-width is a hereditary property, while α-acyclicity and hypertree-width are not. In case of restrictions on the queries, this does not matter. However, if we look for appropriate restrictions on the structures, then it can be easily verified that α-acyclicity or bounded hypertree-width will clearly not suffice to make the evaluation of any fixed MS_1 formula tractable. Instead, we shall consider β-acyclicity and β-hypertree-width here as well as γ-acyclicity, which is even slightly more restrictive than β-acyclicity. It will turn out that γ-acyclic hypergraphs have clique-width ≤ 3 and that the β-hypertree-width of any hypergraph is less than or equal to the clique-width (of the incidence graph). Hence, γ-acyclicity of a class of hypergraphs implies bounded clique-width (w.r.t. the incidence graph), which, in turn, implies bounded β-hypertree-width. In other words, γ-acyclicity and bounded β-hypertree-width can be considered as "lower and upper bounds," respectively, on the expressive power of the notion of bounded clique-width. However, we shall also show that bounded β-hypertree-width is not sufficient to ensure the tractability of the evaluation of an arbitrary but fixed MS_1 formula.

In the second part of this section, we shall have a brief look at the primal graph of hypergraphs.

4.1. Clique-width of the incidence graph. In [20], D'Atri and Moscarini provided an algorithm for recognizing γ-acyclic hypergraphs. (For details, see the original paper or [24].) In terms of the incidence graph of a hypergraph, we get an algorithm consisting of the following rules:

1. *Deletion of isolated nodes*: If a node N in $\mathcal{I}$ has no adjacent node, then N may be deleted.
2. *Deletion of "ear nodes"*: If a node N in $\mathcal{I}$ has exactly one adjacent node, then N may be deleted.
3. *Contraction of two-element modules*: If two nodes N and N' in $\mathcal{I}$ are adjacent to exactly the same nodes in $\mathcal{V} - \{N, N'\}$, then one of them may be deleted.

Moreover, we assume that an edge is deleted from the incidence graph if one of its endpoints is deleted by one of these rules. Then a hypergraph $\mathcal{H}$ is γ-acyclic iff the exhaustive, nondeterministic application of the above rules transforms the incidence graph $\mathcal{I}(\mathcal{H})$ into the empty graph.

As far as the clique-width (of the incidence graphs) of γ-acyclic hypergraphs is concerned, several known results can be combined to get the following.

THEOREM 4.1 (γ-acyclicity implies bounded clique-width). *Every γ-acyclic hypergraph has clique-width ≤ 3 (w.r.t. the incidence graph).*

Proof. (See [8].) Let $\mathcal{H}$ be an arbitrary γ-acyclic hypergraph. We know from [2] that the incidence graph $\mathcal{I}(\mathcal{H})$ is "(6,2)-chordal." Building upon a characterization of "distance-hereditary" graphs in [4], it was shown in [21] that a graph is bipartite, (6,2)-chordal iff it is bipartite, distance-hereditary. Finally, in [27], it is shown that any distance-hereditary graph has clique-width ≤ 3. □

When we define the notion of generalized tree-width in section 5, we shall revisit the algorithm from [27], which constructs a 3-expression of any given distance-hereditary graph. In particular, this algorithm can be used to compute a 3-expression for the incidence graph of a given γ-acyclic hypergraph. The example in section 5 for a modified version of this algorithm will also help to illustrate the above theorem.

In the remainder of this section, we compare the clique-width (of the incidence graph) with β-acyclicity and β-hypertree-width.

THEOREM 4.2 (clique-width of the incidence graph versus β-acyclicity). *The class of β-acyclic hypergraphs is of unbounded clique-width (w.r.t. the incidence graph).*

Proof. Consider the sequence $(\mathcal{H}_n)_{n\geq 1}$ of hypergraphs, where $\mathcal{H}_n$ has the vertices $V = \{y_1, \ldots, y_n\} \cup \{x_{ij} : 1 \leq i < j \leq n\}$ and n hyperedges $H_1, \ldots, H_n$ with

$$H_l = \{y_l\} \cup \{x_{\alpha\beta} : \alpha < \beta \leq l\} \cup \{x_{l\gamma} : l < \gamma \leq n\} \text{ for } l \in \{1, \ldots, n\};$$

i.e., $H_1 = \{y_1, x_{12}, x_{13}, \ldots, x_{1n}\}$, $H_2 = \{y_2, x_{12}, x_{23}, \ldots, x_{2n}\}$, $H_3 = \{y_3, x_{12}, x_{13}, x_{23}, x_{34}, \ldots, x_{3n}\}$, $\ldots$, $H_n = \{y_n, x_{12}, \ldots, x_{1n}, x_{23}, \ldots, x_{2n}, \ldots, x_{(n-1)n}\}$. The β-acyclicity of $\mathcal{H}_n$ can be shown via the following observation: Let H_i, H_j, H_k be hyperedges of $\mathcal{H}_n$ with $i < j < k$. Then the relation $H_i \cap H_j \subseteq H_k$ holds. Now let $\mathcal{H}'$ be a subhypergraph of $\mathcal{H}_n$ with vertices $V' \subseteq V$ and m hyperedges $H'_{i_1}, \ldots, H'_{i_m}$ s.t. $H_{i_1}, \ldots, H_{i_m}$ are hyperedges in $\mathcal{H}_n$ and $H'_{i_j} = H_{i_j} \cap V'$ holds for every $j \in \{1, \ldots, m\}$. W.l.o.g., let $1 \leq i_1 < i_2 < \cdots < i_m \leq n$. Then $\mathcal{H}'$ is α-acyclic, since a join tree of $\mathcal{H}'$ can be obtained by labeling the root node with H'_{i_m} and attaching $m-1$ child nodes with the labels $H'_{i_1}, \ldots, H'_{i_{(m-1)}}$ to the root.

It remains to prove that the incidence graphs $(\mathcal{I}_n)_{n\geq 1}$ of $(\mathcal{H}_n)_{n\geq 1}$ are of unbounded clique-width. In fact, we show that $cw(\mathcal{I}_n) \geq n$ holds for every $n \geq 2$. Suppose on the contrary that $\mathcal{I}_n$ is defined by some k-expression t with $k \leq n-1$. Moreover, let t' be a subexpression in t s.t. for some $i \in \{1, \ldots, n\}$ the nodes H_i and y_i as well as at least $n-2$ nodes from the set $\{x_{1i}, \ldots, x_{(i-1)i}, x_{i(i+1)}, \ldots, x_{in}\}$ (consisting of $n-1$ nodes) have already been introduced in t', and let t' be minimal with this property; i.e., no proper subexpression t'' of t' has this property. By the minimality of t', this subexpression t' is of the form $t' = r \oplus s$ for appropriately chosen k-expressions r and s. Then we derive a contradiction in the following way.

Fact 1. Suppose that two vertices H_α and H_β with $\alpha \neq \beta$ have been introduced by the k-expression t'. Then H_α and H_β have different labels in the graph generated by t'. This can be seen as follows: Suppose on the contrary that H_α and H_β have the same label. W.l.o.g., let $\alpha < \beta$. Then the vertices in $V_\beta = \{y_\beta\} \cup \{x_{1\beta}, \ldots, x_{(\alpha-1)\beta}, x_{(\alpha+1)\beta}, \ldots, x_{(\beta-1)\beta}, x_{\beta(\beta+1)}, \ldots, x_{\beta n}\}$ distinguish the vertices H_α and H_β. Hence, all of the edges connecting H_β with the vertices in V_β must already exist in t'. Thus, all of the vertices in $\{H_\beta\} \cup V_\beta$ must have already been introduced in one of the subexpressions r or s of t', which contradicts the minimality of t'.

Fact 2. Suppose that the vertices H_α and $x_{\beta\gamma}$ with arbitrary α, β, and γ have been introduced by the k-expression t'. Note that H_α is adjacent to all of the vertices in $V_\alpha = \{y_\alpha\} \cup \{x_{1\alpha}, \ldots, x_{(\alpha-1)\alpha}, x_{\alpha(\alpha+1)}, \ldots, x_{\alpha n}\}$, while $x_{\beta\gamma}$ is not. Hence, one can show analogously to Fact 1 above that H_α and $x_{\beta\gamma}$ have different labels.

Fact 3. If the vertices H_α and y_β with arbitrary α and β have been introduced by the k-expression t', then H_α and y_β have different labels, since H_α and y_β are also distinguished by the vertices in the above set V_α.

In order to conclude the proof, we define a set $\mathcal{S}$ of n vertices of t' s.t. these vertices have pairwise distinct labels in t'.

(i) H_i is in $\mathcal{S}$.

(ii) Let X denote those vertices in $\{x_{1i}, \ldots, x_{(i-1)i}, x_{i(i+1)}, \ldots, x_{in}\}$, which already exist in the k-expression t'. By assumption, X has at least $n-2$ elements. Now we traverse X from right to left. If the label of some $x_{\alpha\beta} \in X$ does not occur in X to the right of $x_{\alpha\beta}$, then we add $x_{\alpha\beta}$ to $\mathcal{S}$. Otherwise, suppose that $x_{\gamma\delta}$ is a vertex to the right of $x_{\alpha\beta}$ s.t. $x_{\alpha\beta}$ and $x_{\gamma\delta}$ have the same label. Then we distinguish two cases: If $\alpha < i$ and $\beta = i$ hold, then H_α distinguishes the nodes $x_{\alpha i}$ and $x_{\gamma\delta}$. Hence, H_α already exists in t' and we may add H_α to $\mathcal{S}$. Otherwise (i.e., $\alpha = i$ and $\beta > i$ hold), H_β distinguishes the nodes $x_{i\beta}$ and $x_{\gamma\delta}$. Hence, H_β already exists in t' and we add H_β to $\mathcal{S}$.

(iii) Finally we consider y_i. Let $X \subseteq \{x_{1i}, \ldots, x_{(i-1)i}, x_{i(i+1)}, \ldots, x_{in}\}$ be defined as above. If the label of y_i does not occur in X, then we add y_i to $\mathcal{S}$. Otherwise, let $x_{\alpha\beta}$ denote the right-most vertex in X that has the same label as y_i. Then we distinguish the same cases as above: If $\alpha < i$ and $\beta = i$ hold, then H_α distinguishes the nodes $x_{\alpha i}$ and y_i. Hence, we may add H_α to $\mathcal{S}$. Otherwise (i.e., $\alpha = i$ and $\beta > i$ hold), we add H_β to $\mathcal{S}$.

Then $\mathcal{S}$ contains n vertices. In particular, all of the vertices H_α and H_β that are added to $\mathcal{S}$ by the above construction are pairwise distinct. Moreover, by the construction of $\mathcal{S}$ and by Facts 1 through 3 above, all of the vertices in $\mathcal{S}$ have pairwise distinct labels. □

Actually, the above lower bound on the clique-width of the incidence graphs $(\mathcal{I}_n)_{n\geq 1}$ is quite tight. This follows from the fact that the incidence graphs $(\mathcal{I}_n)_{n\geq 1}$ are bipartite graphs, where one part of the partition has n nodes (namely, $\{H_1, \ldots, H_n\}$). Hence, as we have seen in the example in section 2.1, $\mathcal{I}_n$ has clique-width $\leq n + 2$.

Remark. Theorem 4.2 was shown independently in [8] as follows: It was shown in [2] that β-acyclic hypergraphs have bipartite, "chordal" incidence graphs. Moreover, we know from [9] that bipartite permutation graphs are a subclass of bipartite, chordal graphs. Finally, in [10] it was shown that the clique-width of bipartite permutation graphs is unbounded.

Now recall from Corollary 3.2 that the hypertree-width of any hypergraph $\mathcal{H}$ is less than or equal to the clique-width of the incidence graph of a hypergraph. Moreover, as has already been mentioned, the incidence graph $\mathcal{I}(\mathcal{H}')$ of any subhypergraph $\mathcal{H}'$ of $\mathcal{H}$ is an induced subgraph of $\mathcal{I}(\mathcal{H})$. Thus, $cw(\mathcal{I}(\mathcal{H}')) \leq cw(\mathcal{I}(\mathcal{H}))$ holds. We therefore immediately get the following corollary.

COROLLARY 4.3 (β-hypertree-width is bounded by clique-width). *Let $\mathcal{H}$ be a hypergraph with clique-width $= k$ (w.r.t. the incidence graph). Then $\mathcal{H}$ has β-hypertree-width $\leq k$.*

It has already been recalled from [29] that α-acyclic hypergraphs have hypertree-width $= 1$. Consequently, the β-acyclic hypergraphs have β-hypertree-width $= 1$. Thus, by Theorem 4.2 and Corollary 4.3, we know that bounded clique-width implies bounded β-hypertree-width, while the converse is not true. Now the question naturally arises as to whether bounded β-hypertree-width of the structures under consideration suffices to guarantee the tractability of the evaluation of any MS_1 formula. Unfortunately, the answer given in Theorem 4.5 below is negative. Thus, bounded clique-width remains the concept with the highest expressive power known so far s.t. MS_1 queries are still tractable (cf. Figure 1.1). The proof of this result will be based on the following lemma.

LEMMA 4.4 (β-hypertree-width of hypergraphs with big hyperedges). *Let $\mathcal{H} = \langle \mathcal{V}, \mathcal{E} \rangle$ be a hypergraph, where every hyperedge $H \in \mathcal{E}$ has at least $|\mathcal{V}| - 2$ vertices.*

Then the β-hypertree-width of $\mathcal{H}$ is ≤ 3.

Proof. Let $\mathcal{H}' = \langle \mathcal{V}', \mathcal{E}' \rangle$ be an arbitrary subhypergraph of $\mathcal{H}$, i.e., $\mathcal{H}'$ is obtained from $\mathcal{H}$ by deleting some hyperedges and/or vertices. Note that then $\mathcal{H}'$ also contains only "big" hyperedges; i.e., every hyperedge $H' \in \mathcal{E}'$ has at least $|\mathcal{V}'| - 2$ vertices.

We have to show that $\mathcal{H}'$ has a *hypertree decomposition* of width ≤ 3. In fact, we show that $\mathcal{H}'$ even has a *query decomposition* of width ≤ 3. Let $H \in \mathcal{E}'$ be an arbitrary hyperedge. Then $|\mathcal{V}' - H| \leq 2$ holds. Let $V_1, V_2 \in \mathcal{V}'$ s.t. $H \cup \{V_1, V_2\} = \mathcal{V}'$. Now we can construct a query decomposition QD of width ≤ 3 for $\mathcal{H}'$ as follows: Let the root r of QD be labeled with $\lambda(r) = \{H, V_1, V_2\}$. Moreover, for every $H' \in \mathcal{H}' - \{H\}$, we attach one child node p to r with label $\lambda(p) = \{H'\}$. □

THEOREM 4.5 (MS_1 queries and bounded β-hypertree-width). *The evaluation of an arbitrary fixed MS_1 query over a class $\mathcal{C}$ of hypergraphs is, in general, not tractable, even if $\mathcal{C}$ is of bounded β-hypertree-width.*

Proof. Let $\mathcal{G} = \langle V, E \rangle$ be an arbitrary graph and let $\mathcal{H} = \langle V, H \rangle$ be a hypergraph, where the set H of hyperedges is defined as follows: $H = \{V - \{x, y\} : \{x, y\}$ is an edge in $E\}$; i.e., every edge e of $\mathcal{G}$ is encoded by a hyperedge which contains all vertices of V except for the endpoints of e. Then every hyperedge of $\mathcal{H}$ has $|V| - 2$ vertices. Thus, by Lemma 4.4 above, this hypergraph $\mathcal{H}$ has β-hypertree-width at most 3. Moreover, the well-known NP-complete problem of graph-3-colorability can be expressed as an MS_1 query on the incidence graph of $\mathcal{H}$ (when considered as a labeled graph with two distinct labels for the nodes corresponding to vertices and hyperedges in $\mathcal{H}$, respectively; the unary predicates P_V and P_H refer to these labels) in the following way:

$$(\exists C_1)(\exists C_2)(\exists C_3)\ \text{“}C_1, C_2, \text{ and } C_3 \text{ provide a partition of } V\text{”}$$
$$\wedge\ (\forall x)(\forall y)[\,(P_V(x) \wedge P_V(y) \wedge (\exists h)(P_H(h) \wedge \neg edg(x,h) \wedge \neg edg(y,h)))$$
$$\rightarrow \text{“}x \text{ and } y \text{ have different colors”}].$$

Of course, the sentences "C_1, C_2, and C_3 provide a partition of V" and "x and y have different colors" can be easily expressed as MS_1 formulae, namely,

$(\forall x)[x \in C_1 \wedge x \notin C_2 \wedge x \notin C_3] \vee [x \in C_2 \wedge x \notin C_1 \wedge x \notin C_3] \vee [x \in C_3 \wedge x \notin C_1 \wedge x \notin C_2]$ and $[x \in C_1 \wedge y \notin C_1] \vee [x \in C_2 \wedge y \notin C_2] \vee [x \in C_3 \wedge y \notin C_3]$, respectively. □

4.2. Clique-width of the primal graph. In this section we compare the β-acyclicity and β-hypertree-width with clique-width of the primal graph. By Corollary 4.3, we know that bounded clique-width of the *incidence graph* implies bounded hypertree-width. It can be easily checked that this implication is no longer true if we consider the clique-width of the *primal graph* instead. This can be seen by inspecting the class of cliques, whose primal graphs (which coincide with the cliques themselves) have clique-width 2. On the other hand, the class of cliques is of unbounded tree-width and, therefore, also of unbounded β-hypertree-width, since—in contrast to *hypergraphs*—bounded tree-width and bounded hypertree-width coincide on *graphs*. This is due to the fact that, for every graph, a hypertree decomposition $\langle T, \chi, \lambda \rangle$ of width k corresponds to a tree decomposition $\langle T, \chi \rangle$ of width $\leq 2k$.

Now the question naturally arises as to whether bounded clique-width of the primal graphs allows for a strictly larger class of hypergraphs than bounded hypertree-width or at least than bounded β-hypertree-width. Below, we give a negative answer.

THEOREM 4.6 (clique-width of the primal graph versus β-acyclicity). *The class of β-acyclic hypergraphs is of unbounded clique-width w.r.t. the primal graphs.*

Proof. We consider again the class $(\mathcal{H}_n)_{n \geq 1}$ of β-acyclic hypergraphs of Theorem 4.2, where $\mathcal{H}_n$ has the vertices $V = \{y_1, \ldots, y_n\} \cup \{x_{ij} : 1 \leq i < j \leq n\}$ and the

hyperedges $H_1, \ldots, H_n$ with $H_l = \{y_l\} \cup \{x_{\alpha\beta} : \alpha < \beta \leq l\} \cup \{x_{l\gamma} : l < \gamma \leq n\}$ for $l \in \{1, \ldots, n\}$.

Similarly to Theorem 4.2, we show that the clique-width of the primal graph $\mathcal{P}_n$ of $\mathcal{H}_n$ increases with n. Note, however, that the situation here is a bit different from Theorem 4.2. In particular, $\mathcal{P}_n$ contains only nodes y_i and x_{ij}, but no H_i's. Moreover, the x_{ij}'s form a big clique in $\mathcal{P}_n$, since all of these vertices occur in the hyperedge H_n. Nevertheless, we can show that $cw(\mathcal{P}_n) \geq \frac{n-1}{2}$ holds for every $n \geq 2$.

Suppose on the contrary that $\mathcal{P}_n$ is defined by some k-expression t with $k < \frac{n-1}{2}$. Moreover, let t' be a subexpression in t s.t. for some $i \in \{1, \ldots, n\}$ the node y_i and at least $n-2$ nodes from the set $\{x_{1i}, \ldots, x_{(i-1)i}, x_{i(i+1)}, \ldots, x_{in}\}$ have already been introduced in t'. Moreover, let t' be minimal with this property. Then t' is again of the form $t' = r \oplus s$. We derive a contradiction in the following way.

Fact 1. Suppose that two vertices y_α and y_β with $\alpha \neq \beta$ have been introduced by the subexpression t' of t. Then y_α and y_β have different labels in the graph generated by t'. This is due to the fact that, for $\alpha < \beta$, the vertices in $X_\beta = \{x_{1\beta}, \ldots, x_{(\alpha-1)\beta}, x_{(\alpha+1)\beta}, \ldots, x_{(\beta-1)\beta}, x_{\beta(\beta+1)}, \ldots, x_{\beta n}\}$ distinguish the vertices y_α and y_β.

Fact 2. Let X_i be defined as $X_i = \{x_{1i}, \ldots, x_{(i-1)i}, x_{i(i+1)}, \ldots, x_{in}\}$. Moreover, suppose that $x_{\alpha i}$ and $x_{\gamma\delta}$ are nodes in X_i s.t. $\alpha < \gamma$ (i.e., $x_{\alpha i}$ occurs in X_i "to the left" of $x_{\gamma\delta}$) and both nodes already exist in t'. Then either $x_{\alpha i}$ and $x_{\gamma\delta}$ have distinct labels in t' or y_α already exists in t'. This follows immediately from the fact that $x_{\alpha i}$ is adjacent to y_α in $\mathcal{P}_n$, whereas $x_{\gamma\delta}$ is not.

Fact 3. Let X_i be defined as above and suppose that $x_{i\beta}$ and $x_{\gamma\delta}$ are vertices in X_i s.t. both vertices already exist in t' and $\beta < \delta$ holds (i.e., again $x_{i\beta}$ occurs in X_i "to the left" of $x_{\gamma\delta}$). Then either $x_{i\beta}$ and $x_{\gamma\delta}$ have distinct labels in t' or y_β already exists in t', since y_β is adjacent to $x_{i\beta}$ in $\mathcal{P}_n$ but not to $x_{\gamma\delta}$.

Now we define two sets $\mathcal{X}$ and $\mathcal{Y}$ of vertices which have already been introduced by t'. These two sets together will contain $n-1$ vertices in total. Moreover, we can show that the vertices contained in each of these sets have pairwise distinct labels.

(i) Initially, we set $\mathcal{X} := \emptyset$ and $\mathcal{Y} := \{y_i\}$.

(ii) Let X denote the set of those vertices in $\{x_{1i}, \ldots, x_{(i-1)i}, x_{i(i+1)}, \ldots, x_{in}\}$ that already exist in the k-expression t'. By assumption, there are $n-2$ such vertices. Now we traverse the elements in X from right to left. If the label of some $x_{\alpha\beta} \in X$ does not occur in X to the right of $x_{\alpha\beta}$, then we add $x_{\alpha\beta}$ to $\mathcal{X}$. Otherwise, suppose that $x_{\gamma\delta}$ is a vertex to the right of $x_{\alpha\beta}$ s.t. $x_{\alpha\beta}$ and $x_{\gamma\delta}$ have the same label. Then we distinguish two cases: If $\alpha < i$ and $\beta = i$ hold, then y_α already exists in the k-expression t' by Fact 2. Hence, we may add y_α to $\mathcal{Y}$. Otherwise (i.e., $\alpha = i$ and $\beta > i$ hold), y_β must already exist in t' by Fact 3 and we add y_β to $\mathcal{Y}$.

We have $|\mathcal{X}| + |\mathcal{Y}| = n - 1$. Thus, one of the sets $\mathcal{X}$ or $\mathcal{Y}$ must have at least $\frac{n-1}{2}$ vertices. Moreover, these vertices have pairwise distinct labels in t' by the construction (in the case of $\mathcal{X}$) and by Fact 1 above (in the case of $\mathcal{Y}$). □

By Theorem 4.6 above and the fact that β-acyclic hypergraphs have β-hypertree-width 1, we know that bounded β-hypertree-width does not necessarily imply bounded clique-width of the primal graph. Moreover, it has already been explained above that bounded clique-width of the primal graph does not necessarily imply bounded β-hypertree-width. We thus get the following result.

COROLLARY 4.7 (uncomparability). *The concepts of bounded β-hypertree-width of hypergraphs and bounded clique-width of the corresponding primal graphs are uncomparable; i.e., on the one hand, there exists a class $\mathcal{C}_1$ of hypergraphs s.t. the β-*

hypertree-width of the hypergraphs in $\mathcal{C}_1$ is bounded by some fixed constant k, while the corresponding class of primal graphs is of unbounded clique-width. On the other hand, there exists a class $\mathcal{C}_2$ of hypergraphs s.t. the β-hypertree-width of the hypergraphs in $\mathcal{C}_2$ is unbounded while the clique-width of the corresponding primal graphs is bounded by some fixed constant k.

5. Generalized tree-width. As was already mentioned in section 2, clique-width is much more powerful than tree-width. On the other hand, the lack of an efficient procedure for recognizing graphs with clique-width $\leq k$ for some arbitrary but fixed k is a major drawback of clique-width. Hence, it is worth trying to extend the notion of tree-width to some kind of "generalized tree-width," which is more powerful than tree-width and which is still efficiently recognizable. One such generalization is proposed below.

Recall from [23] that the existence of a big complete bipartite graph as a subgraph of a graph $\mathcal{G}$ has a very bad effect on the tree-width of $\mathcal{G}$, e.g., consider the sequence $(\mathcal{H}_n)_{n\geq 1}$ of hypergraphs, where $\mathcal{H}_n$ has vertices $V = \{x_1, \ldots, x_n\} \cup \{y_1, \ldots, y_n\}$ and n hyperedges $H_1, \ldots, H_n$ with $H_i = \{y_i, x_1, \ldots, x_n\}$. Then, for every n, the (incidence graph $\mathcal{I}_n$ of the) hypergraph $\mathcal{H}_n$ has tree-width n, since it contains the complete bipartite graph with nodes $\{x_1, \ldots, x_n\}$ and $\{H_1, \ldots, H_n\}$, respectively. On the other hand, for every n, $\mathcal{H}_n$ is γ-acyclic; i.e., the simple transformations of the γ-acyclicity algorithm in [20] (recalled in section 4.1) suffice to reduce the incidence graph of $\mathcal{H}_n$ to the empty graph. In particular, the complete bipartite graph contained in the incidence graph of any such hypergraph can be eliminated by these simple transformations. It therefore makes sense to consider the following generalization of the tree-width.

DEFINITION 5.1 (generalized tree-width). *Let $\mathcal{G}$ be an arbitrary graph and let $\mathcal{G}'$ be the graph that results from exhaustive application of the following rules: deletion of isolated nodes, deletion of ear nodes, and contraction of two-element modules. Then we define the* generalized tree-width *of $\mathcal{G}$ as $gtw(\mathcal{G}) = tw(\mathcal{G}')$.*

In order to make sure that $gtw(\mathcal{G})$ is well defined, we need the following property of the above transformation rules.

PROPOSITION 5.2. *Let $\mathcal{G}$ be an arbitrary graph and let $\mathcal{G}'$ and $\mathcal{G}''$ be graphs that result from exhaustive application of the following rules: deletion of isolated nodes, deletion of ear nodes, and contraction of two-element modules. Then $\mathcal{G}'$ and $\mathcal{G}''$ are isomorphic.*

Proof. The number of possible applications of the above transformation rules is clearly finite. Hence, by general considerations on rewrite systems (cf. [3, 22]), it suffices to prove the following "local confluence" property: Let $\mathcal{G}_1$ and $\mathcal{G}_2$ be graphs that can be obtained from some graph $\mathcal{G}$ via a single rule application. Then there exist graphs $\mathcal{G}_1'$ and $\mathcal{G}_2'$ s.t. $\mathcal{G}_1'$ and $\mathcal{G}_2'$ are isomorphic and $\mathcal{G}_i$ can be transformed into $\mathcal{G}_i'$ (for $i \in \{1, 2\}$) via finitely many applications of the above transformation rules. This can be easily shown by a case distinction over all 3×3 possibilities of rules that lead to $\mathcal{G}_1$ and $\mathcal{G}_2$, respectively; e.g., suppose that $\mathcal{G}_1$ is obtained from $\mathcal{G}$ via the first rule (i.e., deletion of isolated nodes) and that $\mathcal{G}_2$ is obtained from $\mathcal{G}$ via the third rule (i.e., contraction of two-element modules). Moreover, let N_i with $i \in \{1, 2\}$ denote the node that is deleted from $\mathcal{G}$ in order to arrive at $\mathcal{G}_i$. Then $\mathcal{G}_1' = \mathcal{G}_2'$ is simply obtained from $\mathcal{G}_1$ by deleting also N_2 (via the third rule) and by deleting N_1 from $\mathcal{G}_2$ (via the first rule), respectively. The remaining cases are handled similarly. □

A polynomial time algorithm for recognizing the graphs with $gtw \leq k$ for some fixed k can be constructed in the obvious way, namely: First, an input graph $\mathcal{G}$ is

transformed into $\mathcal{G}'$ via the transformation given in Definition 5.1 above. Then we can apply the algorithm of [6], which decides in linear time whether $tw(\mathcal{G}') \leq k$ holds.

For our considerations on the tractability of evaluating MS_1 formulae, we are ultimately interested in the relationship between generalized tree-width and clique-width. In Theorem 5.7 we shall show that bounded generalized tree-width implies bounded clique-width. For the proof of this result, we have to revisit and appropriately modify the algorithm in [27] for constructing a 3-expression of an arbitrary distance-hereditary graph.

The notions of "pruning sequence" and "pruning tree" are central to the algorithm in [27]. By slightly modifying these notions for our purposes here, we get the following definitions.

DEFINITION 5.3 (pruning sequence). *Let $\mathcal{G}_0 = \mathcal{G}$, $\mathcal{G}_1, \ldots, \mathcal{G}_n = \mathcal{G}'$ be a sequence of graphs s.t., for every $i \geq 1$, $\mathcal{G}_i$ is obtained from $\mathcal{G}_{i-1}$ by deleting some node V_{α_i} via one of the following rules: deletion of isolated nodes, deletion of ear nodes, and contraction of two-element modules. Then $S = s_1, \ldots, s_n$ is called a* pruning sequence *from $\mathcal{G}$ to $\mathcal{G}'$, where s_i with $1 \leq i \leq n$ is defined as follows:*[3]

(i) *If V_{α_i} is an isolated node in $\mathcal{G}_{i-1}$, then $s_i = \langle (V_{\alpha_i}, *), isolated \rangle$.*

(ii) *If V_{α_i} is an ear node in $\mathcal{G}_{i-1}$ s.t. its only neighbor is V_{β_i}, then $s_i = \langle (V_{\alpha_i}, V_{\beta_i}), ear \rangle$.*

(iii) *If V_{α_i} and V_{β_i} form a two-element module in $\mathcal{G}_{i-1}$ s.t. V_{α_i} and V_{β_i} are adjacent, then $s_i = \langle (V_{\alpha_i}, V_{\beta_i}), true \rangle$. In this case, V_{α_i} is called a* true twin *of V_{β_i} in $\mathcal{G}_{i-1}$.*

(iv) *If V_{α_i} and V_{β_i} form a two-element module in $\mathcal{G}_{i-1}$ s.t. V_{α_i} and V_{β_i} are not adjacent, then $s_i = \langle (V_{\alpha_i}, V_{\beta_i}), false \rangle$. In this case, V_{α_i} is called a* false twin *of V_{β_i} in $\mathcal{G}_{i-1}$.*

DEFINITION 5.4 (pruning trees). *Let $\mathcal{G}_0 = \mathcal{G}, \mathcal{G}_1, \ldots, \mathcal{G}_n = \mathcal{G}'$ be a sequence of graphs with $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ and $\mathcal{G}' = (\mathcal{V}', \mathcal{E}')$. Moreover, let $S = s_1, \ldots, s_n$ be a pruning sequence from $\mathcal{G}$ to $\mathcal{G}'$ and let $\mathcal{V}'' \subseteq \mathcal{V}$ be defined as*

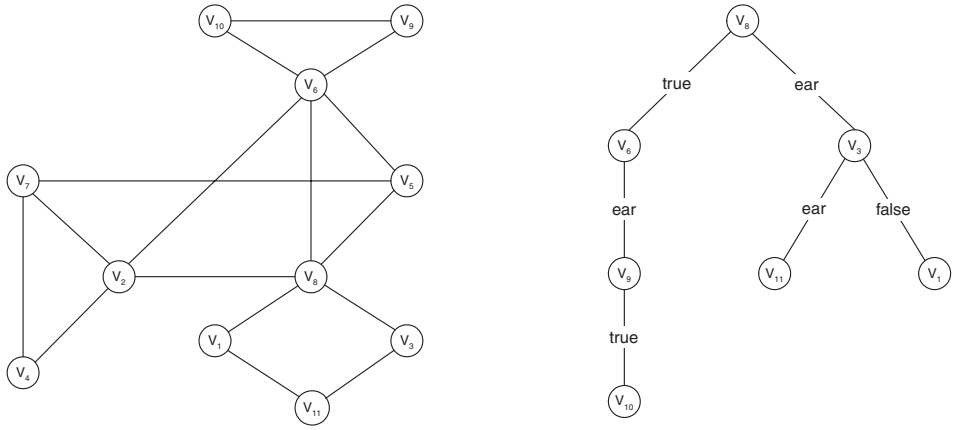
$$\begin{aligned} \mathcal{V}'' = &\{V_{\alpha_i} \mid s_i = \langle (V_{\alpha_i}, *), isolated \rangle\} \\ &\cup \{V_{\beta_i} \mid s_i = \langle (V_{\alpha_i}, V_{\beta_i}), x \rangle \text{ with } x \in \{ear, true, false\} \text{ and } V_{\beta_i} \in \mathcal{V}'\}; \end{aligned}$$

i.e., $\mathcal{V}''$ contains those nodes from $\mathcal{V}$ that were eventually deleted as isolated nodes plus those nodes which were "responsible" for the deletion of other nodes (i.e., of ear nodes or true/false twins) without ever being deleted themselves.

Now let $m = |\mathcal{V}''|$. Moreover, w.l.o.g., we assume that $\mathcal{V}'' = \{V_1, \ldots, V_m\}$. Then there exist m pruning trees *$\mathcal{T}_1, \ldots, \mathcal{T}_m$ corresponding to the pruning sequence S. These pruning trees are directed, edge-labeled trees. They are obtained by the algorithm* CONSTRUCT-PRUNING-TREES *given below.*

ALGORITHM CONSTRUCT-PRUNING-TREES.
begin
/* initialization of the pruning trees */
  for $i := 1$ **to** m **do**
    $\mathcal{T}_i :=$ the tree consisting of the root node V_i only;
  od;
/* adding the nodes deleted from $\mathcal{G}$ to the pruning trees */

[3] In [27] and [32], emphasis is put on the introduction of nodes rather than on their deletion. Hence, in the former papers, the order of the elements in a pruning sequence is reversed w.r.t. the definition here. However, the pruning trees defined next have essentially the same form as in [27].



(a) graph $\mathcal{G}$ (b) pruning tree $\mathcal{T}$

FIG. 5.1. *$\mathcal{G}$ and $\mathcal{T}$.*

for $i := n$ **downto** 1 **do**
if $s_i = \langle (V_{\alpha_i}, V_{\beta_i}), ear \rangle$ **then** append V_{α_i} as right-most child to V_{β_i} and label the edge from V_{β_i} to V_{α_i} as "ear";
elsif $s_i = \langle (V_{\alpha_i}, V_{\beta_i}), true \rangle$ **then** append V_{α_i} as right-most child to V_{β_i} and label the edge from V_{β_i} to V_{α_i} as "true";
elsif $s_i = \langle (V_{\alpha_i}, V_{\beta_i}), false \rangle$ **then** append V_{α_i} as right-most child to V_{β_i} and label the edge from V_{β_i} to V_{α_i} as "false";
fi;
od;
end.

This algorithm is illustrated by the following example.

Example. Let the graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be defined as $\mathcal{V} = \{V_1, \ldots, V_{11}\}$ and $\mathcal{E} = \{\{V_1, V_8\}, \{V_1, V_{11}\}, \{V_2, V_4\}, \{V_2, V_7\}, \{V_2, V_8\}, \{V_3, V_8\}, \{V_3, V_{11}\}, \{V_4, V_7\}, \{V_5, V_6\}, \{V_5, V_7\}, \{V_5, V_8\}, \{V_6, V_8\}, \{V_6, V_9\}, \{V_6, V_{10}\}, \{V_9, V_{10}\}\}$. The graph $\mathcal{G}$ is displayed in Figure 5.1(a).

The nodes $\{V_1, V_3, V_6, V_9, V_{10}, V_{11}\}$ can be deleted via the following pruning sequence: $\langle (V_1, V_3), false \rangle$, $\langle (V_{11}, V_3), ear \rangle$, $\langle (V_3, V_8), ear \rangle$, $\langle (V_{10}, V_9), true \rangle$, $\langle (V_9, V_6), ear \rangle$, $\langle (V_6, V_8), true \rangle$. We thus get the graph $\mathcal{G}' = (\mathcal{V}', \mathcal{E}')$ with $\mathcal{V}' = \{V_2, V_4, V_5, V_7, V_8\}$ and $\mathcal{E}' = \{\{V_2, V_4\}, \{V_2, V_7\}, \{V_2, V_8\}, \{V_4, V_7\}, \{V_5, V_7\}, \{V_5, V_8\}\}$. Note that no isolated node was thus deleted. Moreover, V_8 is the only node in $\mathcal{G}'$ that was responsible for the deletion of other nodes. Hence, by the algorithm CONSTRUCT-PRUNING-TREES, only one pruning tree $\mathcal{T}$ can be constructed, which is depicted in Figure 5.1(b).

In [27], several fundamental properties of pruning trees are proven. In particular, it is shown how a pruning tree $\mathcal{T}$ can be used to construct a 3-expression for the subgraph of $\mathcal{G}$ that is induced by the nodes of $\mathcal{T}$. Before we come to this algorithm, we recall the following terminology from [27]: For a node V in the pruning tree $\mathcal{T}$, we write $\mathcal{T}_V$ to denote the set of nodes of the subtree of $\mathcal{T}$ rooted at V. Moreover, we call a node U in $\mathcal{T}_V$ a *twin descendant* of V iff either $V = U$ or all the edges along the path from V to U are labeled with "true" or "false." Finally, by $\mathcal{G}[\mathcal{T}_V]$ we denote the subgraph of $\mathcal{G}$ that is induced by the nodes in $\mathcal{T}_V$.

LEMMA 5.5 (pruning tree and adjacency). *Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ and $\mathcal{G}' = (\mathcal{V}', \mathcal{E}')$ be*

graphs and let S be a pruning sequence from $\mathcal{G}$ to $\mathcal{G}'$. Moreover, let $\mathcal{T}$ with root V be a pruning tree that is obtained from S via the algorithm CONSTRUCT-PRUNING-TREES. *Finally let U and U' be nodes in $\mathcal{V}$ s.t. U is in $\mathcal{T}$ and U' is outside $\mathcal{T}$. Then U and U' are adjacent in $\mathcal{G}$ iff V is adjacent to U' in $\mathcal{G}$ and U is a twin descendant of V.*

Proof. The proof is implicit in the proof of Lemma 3.7 in [27]. □

Example. Recall the graph $\mathcal{G}$ and the pruning tree $\mathcal{T}$ with root V_8 in Figure 5.1. The only twin descendants of V_8 are the nodes V_6 and V_8 itself. On the one hand, the nodes V_6 and V_8 are indeed adjacent to exactly the same nodes outside $\mathcal{T}$, namely, V_2 and V_5. On the other hand, the other nodes in $\mathcal{T}$ (namely, $V_1, V_3, V_9, V_{10}, V_{11}$) are not adjacent to any node outside $\mathcal{T}$.

LEMMA 5.6 (3-expressions). *Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ and $\mathcal{G}' = (\mathcal{V}', \mathcal{E}')$ be graphs and let S be a pruning sequence from $\mathcal{G}$ to $\mathcal{G}'$. Moreover, let $\mathcal{T}$ denote a pruning tree that is obtained from S via the algorithm* CONSTRUCT-PRUNING-TREES. *Finally, let V be an arbitrary node in $\mathcal{T}$ with child nodes $U_1, \ldots, U_l$ from left to right. Then there exists a 3-expression t_V that defines the graph $\mathcal{G}[\mathcal{T}_V]$ s.t. all twin descendants of V are labeled with 2 in $\mathcal{G}[\mathcal{T}_V]$ and all other nodes in $\mathcal{T}_V$ are labeled with 1. Such a 3-expression can be computed inductively by the algorithm* CONSTRUCT-3-EXPRESSION *given below.*

Proof. See Claim 3.9 in [27]. □

ALGORITHM CONSTRUCT-3-EXPRESSION.

begin
  $t := 2(V)$;
  let $U_1, \ldots, U_l$ denote the child nodes of V from left to right;
  for $i := l$ **downto** 1 **do**
    if the edge from V to U_i is labeled with "ear" **then**
      $t := \rho_{3\to 1}(\eta_{2,3}(\rho_{2\to 3}(t_{U_i}) \oplus t))$;
    if the edge from V to U_i is labeled with "true" **then**
      $t := \rho_{3\to 2}(\eta_{2,3}(\rho_{2\to 3}(t_{U_i}) \oplus t))$;
    if the edge from V to U_i is labeled with "false" **then**
      $t := t_{U_i} \oplus t$;
    fi;
  od;
  $t_v := t$;
end.

Note that if the pruning sequence from $\mathcal{G}$ to $\mathcal{G}'$ contains the deletion of an isolated node V, then the subgraph $\mathcal{G}[\mathcal{T}_V]$ of $\mathcal{G}$ is a distance-hereditary connected component of $\mathcal{G}$. As has already been noted in section 4.1, the incidence graphs of γ-acyclic hypergraphs are precisely the distance-hereditary, bipartite graphs. Hence, the above algorithm can be used to compute the 3-expression of (every connected component of) the incidence graph of any γ-acyclic hypergraph. Moreover, it is now also clear why we never had to delete an isolated node in the example above, since the graph $\mathcal{G}$ of Figure 5.1(a) consists of a single connected component, and this connected component is not distance-hereditary.

Example. We put the algorithm CONSTRUCT-3-EXPRESSION to work by continuing the above example. The 3-expressions t_V for the nodes V in the pruning tree $\mathcal{T}$ of Figure 5.1(b) are obtained as follows. As a shorthand notation, we shall write t_i to denote the 3-expression t_{V_i} for any i.

$$t_1 = 2(V_1),$$

$$t_{11} = 2(V_{11}),$$

$$t_3 = \rho_{3\to 1}(\eta_{2,3}(\rho_{2\to 3}(t_{11}) \oplus (t_1 \oplus 2(V_3)))),$$

$$t_{10} = 2(V_{10}),$$

$$t_9 = \rho_{3\to 2}(\eta_{2,3}(\rho_{2\to 3}(t_{10}) \oplus 2(V_9))),$$

$$t_6 = \rho_{3\to 1}(\eta_{2,3}(\rho_{2\to 3}(t_9) \oplus 2(V_6))),$$

$$t_8 = \rho_{3\to 2}(\eta_{2,3}(\rho_{2\to 3}(t_6) \oplus \rho_{3\to 1}(\eta_{2,3}(\rho_{2\to 3}(t_3) \oplus 2(V_8))))).$$

We are now ready to prove the following desirable property of the generalized tree-width.

THEOREM 5.7 (bounded generalized tree-width implies bounded clique-width). *Let $\mathcal{C}$ be a class of graphs and let k be some fixed constant s.t. $gtw(\mathcal{G}) \leq k$ for all $\mathcal{G} \in \mathcal{C}$. Then there exists a constant k' s.t. $cw(\mathcal{G}) \leq k'$ for all $\mathcal{G} \in \mathcal{C}$.*

Proof. Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be an arbitrary graph and let $\mathcal{G}' = (\mathcal{V}', \mathcal{E}')$ be the graph obtained from $\mathcal{G}$ by exhaustive application of the rules in Definition 5.1 (i.e., deletion of isolated nodes, deletion of ear nodes, and contraction of two-element modules). Moreover, let $gtw(\mathcal{G}) \leq k$; i.e., the condition $tw(\mathcal{G}') \leq k$ holds. Recall from [19] that then we have $cw(\mathcal{G}') \leq \tau$ with $\tau = 2^{k+1} + 1$. It suffices to show that then also $cw(\mathcal{G}) \leq k'$ with $k' = \tau + 1$ holds.

Let t' be a τ-expression that generates $\mathcal{G}'$. We assume that t' uses the τ labels $\{2, \ldots, k'\}$. Let S be a pruning sequence from $\mathcal{G}$ to $\mathcal{G}'$ and let $\mathcal{T}_1, \ldots, \mathcal{T}_m$ denote the corresponding pruning trees with root nodes $V_1, \ldots, V_m$. Moreover, for every $i \in \{1, \ldots, m\}$, let t_i denote the 3-expression obtained by the above algorithm CONSTRUCT-3-EXPRESSION for the subgraph $\mathcal{G}[\mathcal{T}_i]$ of $\mathcal{G}$. From these 3-expressions $t_1, \ldots, t_m$ together with t', we construct a k'-expression s for $\mathcal{G}$ as follows.

First we transform t' into t'' by the following replacement steps: For every V_i with $i \in \{1, \ldots, m\}$ s.t. V_i is still contained in $\mathcal{G}'$, we know that V_i is eventually introduced in t' by some subexpression of the form $\ell(V_i)$. By Lemma 5.6, V_i has the label 2 in t_i. Then we replace the subexpression $\ell(V_i)$ in t' either by t_i (if $\ell = 2$) or by $\rho_{2\to\ell}(t_i)$ (if $\ell \neq 2$).

Finally, all 3-expressions in $\{t_1, \ldots, t_m\}$, whose root node does not occur in $\mathcal{G}'$ anymore, are added to t'' via the $\oplus$-operator. We thus set

$$s := t'' \oplus \bigoplus_{V_i \notin \mathcal{V}'} t_i.$$

Obviously, t' is thus transformed into a k'-expression s using the labels $\{1, \ldots, k'\}$. It remains to show that s indeed generates the original graph $\mathcal{G}$.

As far as the nodes are concerned, every node in $\mathcal{V}$ either is introduced by some 3-expression t_i or is still contained in $\mathcal{V}'$. In the latter case, it is introduced by t'. Hence, by construction, s indeed introduces every node $V \in \mathcal{V}$. On the other hand, no node of $\mathcal{G}$ is introduced twice in s. This is due to the fact that any two distinct pruning trees $\mathcal{T}_i$ and $\mathcal{T}_j$ have no nodes from $\mathcal{V}$ in common, and for any pruning tree $\mathcal{T}_i$, only the root node of $\mathcal{T}_i$ can be contained in $\mathcal{V}'$.

As far as the edges of $\mathcal{G}$ are concerned, we know that each 3-expression t_i clearly introduces all edges in the subgraph $\mathcal{G}[\mathcal{T}_i]$ of $\mathcal{G}$. Likewise, t' introduces the edges in $\mathcal{E}'$. Hence, in order to show that s indeed introduces all edges $\{U, V\}$ it remains only to consider the following cases:

(i) Suppose that the nodes U and V occur in two distinct pruning trees $\mathcal{T}_i$ and $\mathcal{T}_j$, respectively. Moreover, let V_i and V_j denote the root nodes of these pruning trees. It follows from Lemma 5.5 that then V_i and V_j are also adjacent. Moreover, V_i and V_j must still be contained in $\mathcal{V}'$. Hence, this edge $\{V_i, V_j\}$ is eventually introduced by t' and thus by s. Moreover, by our construction of s and by Lemma 5.6, we know that U has the same label ℓ as V_i when the subexpression $\ell(V_i)$ in t' is replaced by t_i (if $\ell = 2$) or by $\rho_{2\to\ell}(t_i)$ (if $\ell \neq 2$). Likewise, U gets the same label as V_j. Hence, when eventually the edge between V_i and V_j is introduced in s, then the edge between U and V will be introduced as well.

(ii) Suppose that the node U occurs in some pruning tree $\mathcal{T}_i$ with root node V_i and that V is contained in $\mathcal{V}'$. By the same considerations as above, we know from Lemma 5.5 that then V_i and V are also adjacent. Moreover, U is introduced with the same label ℓ as V_i when the subexpression $\ell(V_i)$ in t' is replaced by t_i or by $\rho_{2\to\ell}(t_i)$, respectively. Hence, when eventually the edge between V_i and V is introduced in s, then the edge between U and V will be introduced as well.

Now consider also the opposite direction; i.e., we have to show that all edges $\{U, V\}$ introduced by s indeed exist in $\mathcal{G}$. Again, if both nodes U and V are in the same pruning tree $\mathcal{T}_i$ or if both nodes are left in $\mathcal{V}'$, then this is obviously the case. As above, it remains to consider the following two cases:

(i) Suppose that the nodes U and V occur in two distinct pruning trees $\mathcal{T}_i$ and $\mathcal{T}_j$, respectively. Moreover, let V_i and V_j denote the root nodes of these pruning trees. In order to introduce the edge $\{U, V\}$, the expression s and, therefore, t' actually introduces the edge $\{V_i, V_j\}$. Hence, V_i and V_j are indeed adjacent in $\mathcal{G}$. Moreover, U must have the same label as V_i in t_i. Likewise, V and V_j have the identical labels in t_j. Hence, by Lemma 5.6, U is a twin descendant of V_i in the pruning tree $\mathcal{T}_i$ and V is a twin descendant of V_j in $\mathcal{T}_j$. Thus, by Lemma 5.5, U and V are indeed adjacent in $\mathcal{G}$.

(ii) Suppose that the node U occurs in some pruning tree $\mathcal{T}_i$ with root node V_i and that V is contained in $\mathcal{V}'$. By the same considerations as above, we may conclude by Lemmas 5.5 and 5.6 that V_i and V are indeed adjacent, that V_i is a twin descendant of V_i in the pruning tree $\mathcal{T}_i$, and, finally, that U and V are indeed adjacent in $\mathcal{G}$.

In other words, the k'-expression s introduces exactly the nodes in $\mathcal{V}$ and exactly the edges in $\mathcal{E}$. Hence, s is indeed the desired k'-expression. □

Example. Let $\mathcal{G}$ and $\mathcal{G}'$ be the graphs from the example above. The graph $\mathcal{G}$ together with the pruning tree $\mathcal{T}$ are shown in Figure 5.1. Recall that $\mathcal{G}'$ has the form $\mathcal{G}' = (\mathcal{V}', \mathcal{E}')$ with $\mathcal{V}' = \{V_2, V_4, V_5, V_7, V_8\}$ and $\mathcal{E}' = \{\{V_2, V_4\}, \{V_2, V_7\}, \{V_2, V_8\}, \{V_4, V_7\}, \{V_5, V_7\}, \{V_5, V_8\}\}$. A 4-expression t' of $\mathcal{G}'$ can be constructed as follows.

$$(\mathit{introduce}\ V_4)\ s_1 := 2(V_4),\ (\mathit{introduce}\ V_2)\ s_2 := 3(V_2) \oplus s_1,$$

$$(\mathit{connect}\ V_2, V_4)\ s_3 := \eta_{2,3}(s_2),\ (\mathit{introduce}\ V_7)\ s_4 := 4(V_7) \oplus s_3,$$

$$(\mathit{connect}\ V_4, V_7)\ s_5 := \eta_{2,4}(s_4),\ (\mathit{connect}\ V_2, V_7)\ s_6 := \eta_{3,4}(s_5),$$

$$(\mathit{introduce}\ V_8)\ s_7 := 5(V_8) \oplus s_6,\ (\mathit{connect}\ V_2, V_8)\ s_8 := \eta_{3,5}(s_7),$$

$$(\mathit{relabel}\ V_2)\ s_9 := \rho_{3\to 2}(s_8),\ (\mathit{introduce}\ V_5)\ s_{10} := 3(V_5) \oplus s_9,$$

$$(\mathit{connect}\ V_5, V_7)\ s_{11} := \eta_{3,4}(s_{10}),\ (\mathit{connect}\ V_5, V_8)\ s_{12} := \eta_{3,5}(s_{11}).$$

Then s_{12} is the desired 4-expression t' using the labels $\{2, \ldots, 5\}$.

Now recall that the 3-expression t of $\mathcal{G}[\mathcal{T}]$ has already been computed above. The 5-expression s that generates $\mathcal{G}$ can be constructed according to the proof of Theorem 5.7 by redefining s_7 as $s_7 := \rho_{2\to 5}(t) \oplus s_6$. Then s_{12} yields the 5-expression s that generates $\mathcal{G}$. Note that in s, the $\eta_{3,5}$ operation applied to s_7 introduces not only the edge $\{V_2, V_8\}$ but also $\{V_2, V_6\}$. Likewise, by the $\eta_{3,5}$ operation applied to s_{11}, the edge $\{V_5, V_6\}$ is introduced.

By the tractability results recalled in section 2.2, Theorem 5.7 immediately yields the following.

COROLLARY 5.8 (MS_1 queries and generalized tree-width). *The evaluation of an arbitrary fixed MS_1 query over a class $\mathcal{C}$ of graphs is tractable if $\mathcal{C}$ is of bounded generalized tree-width.*

By Theorem 5.7, bounded generalized tree-width implies bounded clique-width, while the converse is clearly not true. Just consider the class of cliques, whose generalized tree-width is unbounded while the clique-width of all these graphs is 2. Hence, the concept of bounded generalized tree-width does not allow us to push the tractability barrier for the evaluation of MS_1 queries any further. However, the advantage of this new concept is that, in contrast to bounded clique-width, it can be efficiently recognized.

6. Conclusion. In this paper, we have compared query-width, hypertree-width, and several notions of acyclicity of hypergraphs with clique-width. Note that we have mainly considered the clique-width of the *incidence graph* here. When considering restrictions on conjunctive queries, this choice is somehow justified by the fact that the clique-width of the *primal graph* is irrelevant for the tractability. In particular, as we have pointed out in section 2, there are NP-hard classes of queries whose primal graphs are of bounded clique-width. On the other hand, when considering restrictions on the form of the structures, the primal graphs also play an important role. Actually, we have shown that β-acyclicity and bounded clique-width of the primal graph are uncomparable. However, the exact position of bounded clique-width of the primal graph in Figure 1.1 has yet to be determined.

In section 5 we have shown how the insights from the comparison of γ-acyclicity with bounded clique-width can be used for an easy generalization of the tree-width. As long as no polynomial time algorithm for recognizing graphs with clique-width $\leq k$ (for some arbitrary but fixed k) has been found, the search for an appropriate generalization of the tree-width is an interesting research area. We have provided a first and very simple step in this direction, to which further steps should be added; e.g., rather than just considering two-element modules, we might take arbitrary modules and investigate recursively the generalized tree-width of such a module. Likewise, rather than just deleting ear nodes, we might consider the splitting of a graph into its biconnected components. Here we also have the effect that a single biconnected component may contain a module, which was not a module in the overall graph. Likewise, contraction of a module to a single node may allow us to further decompose a graph into biconnected components. The interplay between these two kinds of decompositions deserves further research efforts.

Acknowledgments. We are very grateful to Andreas Brandstädt for pointing out numerous references in the literature. In particular, he suggested the proof of Theorem 4.1, which uses known results and which is thus much simpler than the proof originally provided in this paper. We also thank the anonymous referees, whose detailed comments have greatly helped us to improve the presentation of this work.

THE MINIMUM ALL-ONES PROBLEM FOR TREES*

WILLIAM Y. C. CHEN†, XUELIANG LI†, CHAO WANG†, AND XIAOYAN ZHANG†

Abstract. The minimum all-ones problem was shown to be NP-complete for general graphs. Therefore, it becomes an interesting problem to identify special classes of graphs for which one can find polynomial time algorithms. In this paper we consider this problem for trees. First, for any solution to the all-ones problem for a tree, we give a characterization of the elements in the solution by introducing the concept of the quasi all-ones problem. Then we give the enumeration for the number of solutions in a tree. By using the minimum odd (even) sum problem as subprocess, we obtain a linear time algorithm for the minimum all-ones problem for trees. We also get a linear time algorithm for finding solutions to the all-ones problem in a unicyclic graph.

1. Introduction. The term *all-ones problem* was introduced by Sutner [9]. The problem has applications in linear cellular automata (see [10] and the references therein) and is cited as follows: Suppose each square of an $n \times n$ chessboard is equipped with an indicator light and a button. If the button of a square is pressed, the light of that square will change from off to on, and vice versa; the same happens to the lights of all the edge-adjacent squares. Initially all lights are off. Now, consider the following questions: is it possible to press a sequence of buttons in such a way that in the end all lights are on? This is referred to as the *all-ones problem*. If there is such a solution, how can we find it? And finally, how can we find a solution that presses as few buttons as possible? This is referred to as the *minimum all-ones problem*. All the above questions can be asked for arbitrary graphs. Here and in what follows, we consider connected simple undirected graphs only. One can deal with disconnected graphs component by component. For all terminology and notation on graphs, we refer to [6]. An equivalent version of the all-ones problem was proposed by Peled in [7], where it was called the *lamp lighting problem*. The rule of the all-ones problem is called the σ^+ rule on graphs, which means that a button lights not only its neighbors but also its own light. If a button lights only its neighbors but not its own light, this rule on graphs is called the σ rule.

The all-ones problem has been extensively studied recently; see Sutner [11, 12], Barua and Ramakrishnan [1], and Dodis and Winkler [2]. Using linear algebra, Sutner [10] proved that it is always possible to light every lamp in any graph by the σ^+ rule. Lossers [5] gave another beautiful proof also by using linear algebra. A graph-theoretic proof was given by Erikisson, Eriksson, and Sjöstrand [3]. So, the existence of solutions of the all-ones problem for general graphs was solved already. Galvin [4] gave a graph-theoretic algorithm of linear time to find solutions for trees. In [8], Sutner proved that the minimum all-ones problem is NP-complete in general. Therefore, it becomes an interesting question to identify special classes of graphs for

†Center for Combinatorics and LPMC, Nankai University, Tianjin 300071, People's Republic of China (x.li@eyou.com).

which one can find polynomial time algorithms. It is the main result of this paper that there exists a linear time algorithm for the minimum all-ones problem for trees.

In graph-theoretic terminology, a solution to the all-ones problem with σ^+-rule can be stated as follows: Given a graph $G = (V, E)$, where V and E denote the node-set and the edge-set of G, respectively, a subset X of V is a solution if and only if for every node v of G the number of nodes in X adjacent to or equal to v is odd. Such a subset X is called an *odd parity cover* in [10]. So, the all-ones problem can be formulated as follows: Given a graph $G = (V, E)$, does a subset X of V exist such that for all nodes $v \in V - X$, the number of nodes in X adjacent to v is odd, while for all nodes $v \in X$, the number of nodes in X adjacent to v is even? If there exists a solution, how can one find it with minimum cardinality?

This paper is organized as follows. In section 2, we give, for any solution to the all-ones problem for a tree, a characterization of the elements in the solution by introducing the concept of the quasi all-ones problem. This leads to an enumeration for the number of solutions in a tree. In section 3, we give a linear time algorithm to the minimum all-ones problem for trees. In the concluding section, section 4, we give a linear time algorithm for constructing solutions to the all-ones problem in a unicyclic graph. An open problem on the all-colors problem is also proposed, generalizing the concept of the all-ones problem.

2. Characterization and enumeration of solutions for trees. It is easy to see that if a given graph G can be partitioned into two disjoint subgraphs G_1 and G_2 such that G_1 is Eulerian and every node of G_2 is adjacent to an odd number of nodes of G_1, then by pressing all the buttons on the nodes of G_1 all the lights will be on, and vice versa. However, it is very difficult to find an Eulerian subgraph with such a property in a large graph G. Sutner [9] posed the question of whether there is a graph-theoretic method to find a solution for the all-ones problem for trees. Galvin [4] solved this question in the following way: Consider a rooted tree, drawn like a family tree, with the root at the top. The nodes will be divided into 3 classes: outcasts, oddballs, and rebels. The classification is defined inductively, from the bottom up, as follows:

- All of the childless nodes or leaves are rebels.
- A node, other than a leaf, is called a *rebel* if it has no oddball children and an even number of its children are rebels.
- A node is called an *oddball* if it has no oddball children and an odd number of its children are rebels.
- A node is called an *outcast* if at least one of its children is an oddball.

We sometimes simply call a node *r-type, b-type, or o-type* if it belongs to the rebel class, the oddball class, or the outcast class, respectively. For examples, see Figure 1.

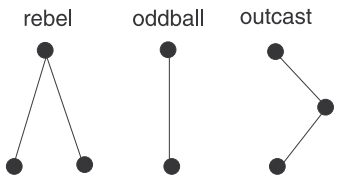

FIG. 1. *The roots of the rooted trees are r-type, b-type, and o-type.*

GALVIN ALGORITHM [4]. Membership in a solution C is defined inductively from the top down. An outcast is excluded from the membership in C. A rebel will be

a member of C if and only if its parent is not a member of C; in particular, if the parentless node (the root) is a rebel, then it will be a member of C. The oddballs will join C in whatever numbers are needed to make their parents' closed neighborhood contain an odd number of members. It is easy to check that C is a solution.

In this section, from the idea of the Galvin algorithm we determine whether or not the root of a tree is in a solution of the all-ones problem and the quasi all-ones problem, defined next. This will be used in enumerating the number of solutions for the all-ones problem. This will also be used in solving the minimum all-ones problem for trees and in constructing solutions to the all-ones problem for unicyclic graphs.

DEFINITION 2.1. *For a rooted tree, the quasi all-ones problem is to find a subset C of nodes such that for every node v except for the root of the tree, the number of nodes in C adjacent to v or equal to v is odd, while for the root, the number is even. C is called a solution to the quasi all-ones problem.*

THEOREM 2.1. *For a rooted tree,*

(1) *if the root is a rebel, then*
   (1.1) *the all-ones problem has a solution if and only if the root belongs to the solution;*
   (1.2) *the quasi all-ones problem has a solution if and only if the root does not belong to the solution;*
(2) *if the root is an oddball, then*
   (2.1) *the all-ones problem has a solution no matter whether the root belongs to the solution;*
   (2.2) *the quasi all-ones problem does not have any solution no matter whether the root belongs to the solution;*
(3) *if the root is an outcast, then*
   (3.1) *the all-ones problem has a solution if and only if the root does not belong to the solution;*
   (3.2) *the quasi all-ones problem has a solution if and only if the root does not belong to the solution.*

Proof. We prove this theorem by induction on the depth s of the rooted tree, which is defined as the maximal distance from root to leaves. In particular, a rooted tree with only one node is of depth 0. It is easy to see that if the root of a tree is a rebel, then the depth can be any nonnegative integer. For a tree with an oddball root, the depth will be at least 1, while for a tree with an outcast root, the depth will be at least 2.

If a rooted tree is of depth 0, then the root must be a rebel node. Any solution to the all-ones problem must contain the root and any solution to the quasi all-ones problem does not contain the root, which means that (1.1) and (1.2) hold when the depth is 0. It is also easy to check that (2.1) and (2.2) hold when the (least possible) depth is 1, and (3.1) and (3.2) hold when the (least possible) depth is 2.

Next, suppose that for any rooted tree whose depth is less than s, all the statements of the theorem are true. Then, for a rooted tree whose depth is s, we distinguish three cases.

Case 1. *The root is a rebel.* Assume that the children of the root are $t_1^{(r)}, \ldots, t_{2k}^{(r)}$, $t_{2k+1}^{(o)}, \ldots, t_m^{(o)}$, where $k \geq 0$, the subtree rooted at $t_i^{(r)}$ $(1 \leq i \leq 2k)$, denoted by $T_i^{(r)}$, is a subtree with a rebel root and with depth less than s, and the subtree rooted at $t_j^{(o)}$ $(2k+1 \leq j \leq m)$, denoted by $T_j^{(o)}$, is a subtree with an outcast root and with depth less than s. Then, from the induction hypothesis, for an outcast-rooted tree the all-ones problem or quasi all-ones problem has a solution if and only if the outcast

root does not belong to the solution. So we can ignore the case for outcast-rooted subtree.

Suppose that the all-ones problem for the rebel-rooted tree has a solution, denoted by C. If the root $r \notin C$, then $C(T_i^{(r)})$ $(1 \le i \le 2k)$ (which is the restriction of C on the subtree $T_i^{(r)}$) is the solution to the all-ones problem for the rebel-rooted subtree $T_i^{(r)}$ with depth less than s. From the induction hypothesis, $t_i^{(r)} \in C(T_i^{(r)})$, and so $t_i^{(r)} \in C$. However, we know that the number of rebel children of the rebel root is even. So, the root cannot be covered odd times by C, and hence C is not an odd parity cover, a contradiction. Thus, if the all-ones problem for a rebel-rooted tree with depth s has a solution, then the root must belong to the solution.

Conversely, consider each rebel-rooted subtree $T_i^{(r)}$ $(1 \le i \le 2k)$ and each outcast-rooted subtree $T_j^{(o)}$ $(2k+1 \le j \le m)$, whose root $t_i^{(r)}, t_j^{(o)}$ is a rebel child and an outcast child of the root r, respectively. Then the quasi all-ones problem for each of them has a solution, denoted by $C(T_i^{(r)}), C(T_j^{(o)})$, respectively. Note that

$$t_i^{(r)} \notin C(T_i^{(r)}) \ (1 \le i \le 2k), \qquad t_j^{(o)} \notin C(T_j^{(o)}) \ (2k+1 \le j \le m).$$

It is easy to check that $C = \{r\} \bigcup (\bigcup_{i=1}^{2k} C(T_i^{(r)})) \bigcup (\bigcup_{j=2k+1}^{m} C(T_j^{(o)}))$ is a solution to the all-ones problem for the original rebel-rooted tree with depth s. So (1.1) holds when the depth is s.

Similarly we can prove (1.2).

Case 2. *The root is an oddball.* Assume that the children of the root are $t_1^{(r)}, \ldots, t_{2k-1}^{(r)}, t_{2k}^{(o)}, \ldots, t_m^{(o)}$, where $k \ge 1$, the subtree rooted at $t_i^{(r)}$ $(1 \le i \le 2k-1)$, denoted by $T_i^{(r)}$, is a rebel-rooted subtree with depth less than s, and the subtree rooted at $t_j^{(o)}$ $(2k \le j \le m)$, denoted by $T_j^{(o)}$, is an outcast-rooted subtree with depth less than s. Similar to the above discussion, we can ignore the case for outcast-rooted subtree.

Suppose that the quasi all-ones problem for the oddball-rooted tree has a solution, denoted by C. If the root $r \in C$ (or $r \notin C$), then $C(T_i^{(r)})$ $(1 \le i \le 2k-1)$ is a solution to the quasi all-ones problem (or the all-ones problem) for the rebel-rooted subtree $T_i^{(r)}$ with depth less than s. From the induction hypothesis, we have that $t_i^{(r)} \notin C(T_i^{(r)})$ (or $t_i^{(r)} \in C(T_i^{(r)})$), and so $t_i^{(r)} \notin C$ (or $t_i^{(r)} \in C$). However, we know that the number of rebel children of the oddball root is odd. So, the root is covered odd times by C, which means that C is a solution to the all-ones problem for the original oddball-rooted tree, a contradiction. Thus (2.2) holds when the depth is s.

Next, we prove (2.1). Consider each rebel-rooted subtree $T_i^{(r)}$ $(1 \le i \le 2k-1)$ and each outcast-rooted subtree $T_j^{(o)}$ $(2k \le j \le m)$, whose root $t_i^{(r)}, t_j^{(o)}$ is a rebel child and an outcast child of the root r, respectively. We discuss the following two cases.

First, the quasi all-ones problem for each of them has a solution, denoted by $C(T_i^{(r)}), C(T_j^{(o)})$, respectively. Note that

$$t_i^{(r)} \notin C(T_i^{(r)}) \ (1 \le i \le 2k-1), \qquad t_j^{(o)} \notin C(T_j^{(o)}) \ (2k \le j \le m).$$

It is easy to check that $C = \{r\} \bigcup (\bigcup_{i=1}^{2k-1} C(T_i^{(r)})) \bigcup (\bigcup_{j=2k}^{m} C(T_j^{(o)}))$ is a solution to the all-ones problem for the original oddball-rooted tree with depth s. Here the root belongs to the solution.

Second, the all-ones problem for each rebel-rooted subtree $T_i^{(r)}$ $(1 \le i \le 2k-1)$ has a solution, denoted by $C(T_i^{(r)})$. Then the all-ones problem for each outcast-rooted subtree $T_j^{(o)}$ $(2k \le j \le m)$ has a solution, denoted by $C(T_j^{(o)})$. Note that

$$t_i^{(r)} \in C(T_i^{(r)}) \ (1 \le i \le 2k-1), \qquad t_j^{(o)} \notin C(T_j^{(o)}) \ (2k \le j \le m).$$

It is easy to check that $C = (\bigcup_{i=1}^{2k-1} C(T_i^{(r)})) \bigcup (\bigcup_{j=2k}^{m} C(T_j^{(o)}))$ is a solution to the all-ones problem for the original oddball-rooted tree with depth s. Here the root does not belong to the solution. Thus (2.1) holds when the depth is s.

Case 3. *The root is an outcast.* Assume that the children of the root are $t_1^{(b)}, \ldots, t_k^{(b)}, t_{k+1}^{(r)}, \ldots, t_l^{(r)}, t_{l+1}^{(o)}, \ldots, t_m^{(o)}$, where $k \ge 1$, the subtree rooted at $t_i^{(b)}$ $(1 \le i \le k)$, denoted by $T_i^{(b)}$, is an oddball-rooted subtree with depth less than s, the subtree rooted at $t_i^{(r)}$ $(k+1 \le i \le l)$, denoted by $T_i^{(r)}$, is a rebel-rooted subtree with depth less than s, and the subtree rooted at $t_i^{(o)}$ $(l+1 \le i \le m)$, denoted by $T_i^{(o)}$, is an outcast-rooted subtree with depth less than s. A similar argument can cover the proof of this case. □

From the theorem, we have the following remarks.

Remark 2.1.

1. For any solution to the all-ones problem for a rooted tree,
   (a) if the root is a rebel, it must belong to the solution;
   (b) if the root is an outcast, it cannot belong to the solution;
   (c) if the root is an oddball, both cases are possible; i.e., it may or may not belong to the solution.
2. If there exists a solution to the quasi all-ones problem for a rooted tree, then the root cannot be an oddball and
   (a) if the root is a rebel, then it cannot belong to the solution;
   (b) if the root is an outcast, then it cannot belong to the solution.

Remark 2.2. If there exists a solution to the all-ones problem or the quasi all-ones problem for a rooted tree, then

1. if the root is a rebel or an oddball, both cases are possible; i.e., it may or may not belong to the solution;
2. if the root is an outcast, it cannot belong to the solution.

From the above clear analysis, we can get the following enumeration result.

THEOREM 2.2. *If a rooted tree has p oddball nodes and q outcast nodes, then the number of solutions to the all-ones problem for the tree is 2^{p-q}.*

Proof. From Theorem 2.1 and Remarks 2.1 and 2.2, we can deduce the following facts: First, for a rebel node v, if its parent node is not contained in a solution C, then v is contained in C, whereas if its parent node is contained in C, then v is not contained in C. Second, the outcast nodes cannot be contained in any solution.

If the root of the tree is a rebel or an outcast node, then every outcast node needs one of its oddball children to match its rebel children so that the outcast node will be lighted without itself in the solution. So, at each outcast node, its oddball children have degrees of freedom equal to the number of oddball children minus 1. Therefore, the number of solutions to the all-ones problem for a tree is exactly 2^{p-q}. If the root of the tree is an oddball, since the root can have two choices, i.e., in a solution, or not, we have that the number of solutions is $2(2^{p-1-q}) = 2^{p-q}$. The proof is complete. □

From the results so far, we can say that the all-ones problem for trees has a satisfactory solution. It is natural to ask about the minimum all-ones problem for

trees. The minimum all-ones problem is NP-complete for general graphs [8]. However, it can be solved easily for some special classes of graphs; for example, a path with n nodes has an optimal solution with $\lceil \frac{n}{3} \rceil$ nodes, and a cycle with n nodes has an optimal solution with $\frac{n}{3}$ nodes if $n = 0 \mod 3$, and n nodes otherwise. For an arbitrary tree, no such succinct formula has been known for the number of nodes in an optimal solution. However, we can ask whether there is a polynomial time algorithm for trees. At first look, we cannot see if there is such an algorithm, because from our Theorem 2.2 we know that the number of solutions could be exponentially large. However, we do obtain a polynomial time algorithm for trees by using the characterization in Theorem 2.1 and Remarks 2.1 and 2.2. Actually, what we get is a linear time algorithm.

3. The minimum all-ones problem for trees. In order to give our algorithm, we need to introduce a new problem, called the *minimum odd (even) sum problem*, which is described as the following linear program.

For the matrix $M_{2\times n} = (m_{ij})_{2\times n}$, $i \in \{0,1\}$, $j \in \{1,2,\cdots,n\}$, $m_{ij} \in Z^+$, the *minimum odd sum problem* is defined as

$$\min \sum_{j=1}^{n} m_{0j}x_{0j} + m_{1j}x_{1j},$$

$$\begin{cases} \sum_{j=1}^{n} x_{1j} = 1 \mod 2 \\ x_{0j} + x_{1j} = 1, \quad j = 1,2,\ldots,n \\ x_{ij} \in \{0,1\}, \quad i \in \{0,1\}. \end{cases}$$

Note that $m_{0j}x_{0j} + m_{1j}x_{1j}$ is equal to m_{1j} if $x_{1j} = 1$, or m_{0j} if $x_{1j} = 0$. So $m_{0j}x_{0j} + m_{1j}x_{1j}$ can be written as $m_{x_{1j}j}$. For convenience, we replace x_{1j} by y_j. Then it is easy to see that the above linear program is equivalent to the following one:

$$\min \sum_{j=1}^{n} m_{y_j j},$$

$$\begin{cases} \sum_{j=1}^{n} y_j = 1 \mod 2 \\ y_j \in \{0,1\} \end{cases}$$

Algorithm for the minimum odd sum problem.

Input. A matrix $M_{2\times n}$.

Step 1. Choose a minimum element from every column of $M_{2\times n}$ (if both elements in a column are the same, choose one of the them). Then sum up the first subscripts of all the chosen elements, denoted by S. If $S = 1 \mod 2$, go to Step 3; otherwise, go to Step 2;

Step 2. Calculate the absolute value of the difference of the two elements in every column. Choose one of the columns with the minimum absolute values. In this column, we choose the hitherto unselected element and forget about the chosen element, then go to Step 3;

Step 3. Sum up all the chosen elements, which gives the optimal value $\min \sum_{j=1}^{n} m_{y_j j}$.

Theorem 3.1. *The above algorithm correctly solves the minimum odd sum problem, and the time complexity is linear.*

Proof. The first statement of the theorem is proved as follows. Since the minimum odd sum problem asks for a unique element from every column, our greedy algorithm

picks up the minimum element from every column. If the sum of the first subscripts of all the chosen elements satisfies that $\sum_{j=1}^{n} y_j = 1 \bmod 2$, then the sum of all the chosen elements is exactly the optimal value $\min \sum_{j=1}^{n} m_{y_j j}$. If $\sum_{j=1}^{n} y_j \neq 1 \bmod 2$, we only need to adjust the elements slightly so that the sum of the first subscripts of all the chosen elements satisfies that $\sum_{j=1}^{n} y_j = 1 \bmod 2$. Because we adjust elements in the column where the minimum absolute value of the difference of the two elements is attained from Step 2, it is easy to see that the chosen elements after adjusting have the minimum sum among the feasible solutions to the odd sum problem; i.e., the chosen elements consist of an optimal solution.

For the second statement of the theorem, since every step uses linear time, the total time is $O(n)$. The proof is complete. □

From the above discussion, we can enumerate the number of optimal solutions to the minimum odd sum problem. Suppose that the absolute value of the difference of the two elements in the ith column is $|d_i|$.

If $\min\{|d_i| \mid i = 1, 2, \ldots, n\} = s > 0$, then

1. if the sum of the first subscripts of all the chosen elements satisfies that $\sum_{j=1}^{n} y_j = 1 \bmod 2$ in Step 1, it is straightforward to see that the problem has a unique optimal solution;

2. if $\sum_{j=1}^{n} y_j \neq 1 \bmod 2$, the only possible ways to adjust the chosen elements have to be done in the set of the columns $\{i \mid |d_i| = s,\ i = 1, 2, \ldots, n\}$, say, r such columns in all. Since we can do the adjustment in any one of the r such columns, the problem has r optimal solutions.

If $\min\{|d_i| \mid i = 1, 2, \ldots, n\} = s = 0$, and supposing $|\{i \mid |d_i| = 0,\ i = 1, 2, \ldots, n\}| = r$, then

1. if $\sum_{j=1}^{n} y_j = 1 \bmod 2$, the only possible ways to adjust the chosen elements have to be done in an even number of the columns $\{i \mid |d_i| = 0,\ i = 1, 2, \ldots, n\}$. So, the problem has T_0 optimal solutions, where $T_0 = \binom{r}{0} + \binom{r}{2} + \binom{r}{4} + \cdots = 2^{r-1}$;

2. if $\sum_{j=1}^{n} y_j \neq 1 \bmod 2$, the only possible ways to adjust the chosen elements have to be done in an odd number of the columns $\{i \mid |d_i| = 0,\ i = 1, 2, \ldots, n\}$. So, the problem has T_1 optimal solutions, where $T_1 = \binom{r}{1} + \binom{r}{3} + \binom{r}{5} + \cdots = 2^{r-1}$.

Replacing $\sum_{j=1}^{n} y_j = 1 \bmod 2$ in the minimum odd sum problem by $\sum_{j=1}^{n} y_j = 0 \bmod 2$, we then get a new problem, called the *even sum problem*. It can be solved in the same way as above. The details are omitted.

Now we give our linear time algorithm to the minimum all-ones problem for trees. The algorithm uses induction on the number of layers of a tree and the minimum odd or even sum algorithm as subprocess.

First of all, we give the definition of layers for a rooted tree as follows: The ith *layer* of the tree is composed of the nodes with distance i from the root for $i = 0, 1, 2, \ldots$. Suppose the tree has s layers. Then for any $i < s$, every node except the leaves in the ith layer can be considered the root of a small tree with depth 1, which is simply called a *small tree* in what follows. We divide the small trees into the following three types.

Type I. A type I small tree has an r-type root. For such a small tree, we can assume that the children of its root are $t_1^{(r)}, \ldots, t_{2k}^{(r)}, t_{2k+1}^{(o)}, \ldots, t_m^{(o)}$, where $k \geq 0$, the subtree rooted at $t_i^{(r)}$ $(1 \leq i \leq 2k)$ is denoted by $T_i^{(r)}$, and the subtree rooted at $t_j^{(o)}$ $(2k + 1 \leq j \leq m)$ is denoted by $T_j^{(o)}$. An example of type I small trees is shown in Figure 2(a).

Type II. A type II small tree has a b-type root. For such a small tree, we can

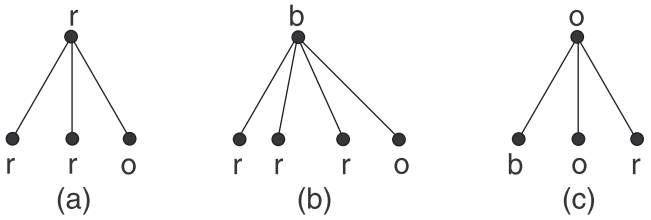

FIG. 2. *Examples of small trees of types* I, II, *and* III.

assume that the children of its root are $t_1^{(r)}, \ldots, t_{2k-1}^{(r)}, t_{2k}^{(o)}, \ldots, t_m^{(o)}$, where $k \geq 1$, the subtree rooted at $t_i^{(r)}$ $(1 \leq i \leq 2k-1)$ is denoted by $T_i^{(r)}$, and the subtree rooted at $t_j^{(o)}$ $(2k \leq j \leq m)$ is denoted by $T_j^{(o)}$. An example of type II small trees is shown in Figure 2(b).

Type III. A type III small tree has an o-type root. For such a small tree, we can assume that the children of its root are $t_1^{(b)}, \ldots, t_k^{(b)}, t_{k+1}^{(r)}, \ldots, t_l^{(r)}, t_{l+1}^{(o)}, \ldots, t_m^{(o)}$, where $k \geq 1$, the subtree rooted at $t_i^{(b)}$ $(1 \leq i \leq k)$ is denoted by $T_i^{(b)}$, the subtree rooted at $t_i^{(r)}$ $(k+1 \leq i \leq l)$ is denoted by $T_i^{(r)}$, and the subtree rooted at $t_i^{(o)}$ $(l+1 \leq i \leq m)$ is denoted by $T_i^{(o)}$. An example of type III small trees is shown in Figure 2(c).

By executing our algorithm layer by layer, from the bottom up, we are going to tag each node v in the present layer with a pair of sets of nodes. Then we can get an optimal solution in linear time. If v is a leaf, it is tagged by Step 0 of our algorithm; if not, its tagged pair of sets can be obtained from the following three cases.

Case 1. For every r-type leaf t_i^r of the small trees rooted at v, since the leaf is in the previous layer, we have an optimal solution $C_1(T_i^{(r)})$ to the all-ones problem for the subtree rooted at $t_i^{(r)}$ and an optimal solution $C_2(T_i^{(r)})$ to the quasi all-ones problem for the same subtree.

Case 2. For every b-type leaf t_i^b of the small trees rooted at v, we have an optimal solution $C_1(T_i^{(b)})$ to the all-ones problem for the subtree rooted at t_i^b such that the root of the subtree belongs to $C_1(T_i^{(b)})$ and an optimal solution $C_2(T_i^{(b)})$ to the all-ones problem for this subtree such that the root of the subtree does not belong to $C_2(T_i^{(b)})$.

Case 3. For every o-type leaf t_i^o of the small trees rooted at v, we have an optimal solution $C_1(T_i^{(o)})$ to the all-ones problem for the subtree rooted at t_i^o and an optimal solution $C_2(T_i^{(o)})$ to the quasi all-ones problem for the subtree.

Note that the above pair for every leaf of a tree is clearly determined at the beginning of our algorithm.

ALGORITHM FOR THE MINIMUM ALL-ONES PROBLEM FOR TREES.

Input. A rooted tree T with s layers, and a pair $\{C_1(v), C_2(v)\}$ of sets for each node v of the tree.

Step 0. Initially, for every leaf $t^{(r)}$ of T, set $\{\{t^{(r)}\}, \emptyset\}$, which means that $\{t^{(r)}\}$ is the optimal solution to the all-ones problem for the subtree with the single node $t^{(r)}$, and $\emptyset$ is the optimal solution to the quasi all-ones problem for the single node subtree.

Step 1. Inductively generate the pair for every node of T layer by layer, from the bottom up, till we arrive at the root of the tree. Suppose that the present layer is the ith layer. If $i \geq 0$, go to Step 2; otherwise, go to Step 4;

Step 2. We distinguish the following three cases to generate the pairs. For every small tree rooted in the ith layer, the algorithm works as follows:

1. The tree is type I. Denote its root by r^*. Suppose that the children of r^* are $t_1^{(r)}, \ldots, t_{2k}^{(r)}, t_{2k+1}^{(o)}, \ldots, t_m^{(o)}$, where $k \geq 0$. We already knew that $C_1(t_i^{(r)}) = C_1(T_i^{(r)})$ and $C_2(t_i^{(r)}) = C_2(T_i^{(r)})$ for every r-type leaf as a root for the subtree $T_i^{(r)}$, where $1 \leq i \leq 2k$, and $C_1(t_i^{(o)}) = C_1(T_i^{(o)})$ and $C_2(t_i^{(o)}) = C_2(T_i^{(o)})$ for every o-type leaf as a root for the subtree $T_i^{(o)}$, where $2k+1 \leq i \leq m$. Then set
$$C_1(r^*) = \{r^*\} \bigcup \left(\bigcup_{i=1}^{2k} C_2(t_i^{(r)}) \right) \bigcup \left(\bigcup_{j=2k+1}^{m} C_2(t_j^{(o)}) \right)$$
as the optimal solution to the all-ones problem of the subtree rooted at r^*, and set
$$C_2(r^*) = \left(\bigcup_{i=1}^{2k} C_1(t_i^{(r)}) \right) \bigcup \left(\bigcup_{j=2k+1}^{m} C_1(t_j^{(o)}) \right)$$
as the optimal solution to the quasi all-ones problem of the subtree rooted at r^*.
2. The tree is type II. Denote its root by b^*. Suppose that the children of b^* are $t_1^{(r)}, \ldots, t_{2k-1}^{(r)}, t_{2k}^{(o)}, \ldots, t_m^{(o)}$, where $k \geq 1$. We already knew that $C_1(t_i^{(r)}) = C_1(T_i^{(r)})$ and $C_2(t_i^{(r)}) = C_2(T_i^{(r)})$ for every r-type leaf as a root for the subtree $T_i^{(r)}$, where $1 \leq i \leq 2k-1$, and $C_1(t_i^{(o)}) = C_1(T_i^{(o)})$ and $C_2(t_i^{(o)}) = C_2(T_i^{(o)})$ for every o-type leaf as a root for the subtree $T_i^{(o)}$, where $2k-1 \leq i \leq m$. Then set
$$C_1(b^*) = \{b^*\} \bigcup \left(\bigcup_{i=1}^{2k-1} C_2(t_i^{(r)}) \right) \bigcup \left(\bigcup_{j=2k}^{m} C_2(t_j^{(o)}) \right)$$
as the optimal solution to the all-ones problem of the subtree rooted at b^* such that b^* belongs to the optimal solution, and set
$$C_2(b^*) = \left(\bigcup_{i=1}^{2k-1} C_1(t_i^{(r)}) \right) \bigcup \left(\bigcup_{j=2k}^{m} C_1(t_j^{(o)}) \right)$$
as the optimal solution to the all-ones problem of the subtree rooted at b^* such that b^* does not belong to the optimal solution.
3. The tree is type III. Denote its root by o^*. Suppose that the children of o^* are $t_1^{(b)}, \ldots, t_k^{(b)}, t_{k+1}^{(r)}, \ldots, t_l^{(r)}, t_{l+1}^{(o)}, \ldots, t_m^{(o)}$, where $k \geq 1$. Use the pairs of sets on the nodes $t_1^{(b)}, \ldots, t_k^{(b)}$ to make a two-dimensional matrix $C_{2\times k} = (c_{ij})_{2\times k}$ such that $|C_2(t_i^{(b)})|$ is the value of the element c_{0i} in $(c_{ij})_{2\times k}$ and $|C_1(t_i^{(b)})|$ is the value of the element c_{1i}.

Remark 3.1. From Theorem 2.1 and Remarks 2.1 and 2.2, any solution to the all-ones problem (or the quasi all-ones problem) of the subtree rooted at o^* cannot contain the o-type root o^*. This means that all the r-type children of the o-type

root must be contained in the solution. Because the solution must contain an odd (or even) number of children of the o-type root, we have to employ our minimum odd sum algorithm or the minimum even sum algorithm to choose some of the b-type children into an optimal solution, according to the parity of $l-k$.

Step 2 (cont'd). If $l-k$ is even (odd), we use the minimum odd (even) sum algorithm to choose the elements in $(c_{ij})_{2\times k}$. Suppose that the union of the elements chosen from the 0th row in $(c_{ij})_{2\times k}$ is $\bigcup_{p=1}^{n_1} c_{0j_p}$, and the union of the elements chosen from the first row in $(c_{ij})_{2\times k}$ is $\bigcup_{q=1}^{n_2} c_{1j_q}$, where $n_1+n_2=k$. Then we set

$$C_1(o^*)=\left(\bigcup_{p=1}^{n_1} C_2(t_{j_p}^{(b)})\right)\bigcup\left(\bigcup_{q=1}^{n_2} C_1(t_{j_q}^{(b)})\right)\bigcup\left(\bigcup_{i=k+1}^{l} C_1(t_i^{(r)})\right)\bigcup\left(\bigcup_{i=l+l}^{m} C_1(t_i^{(o)})\right)$$

as the optimal solution to the all-ones problem of the subtrees rooted at o^*. Next, we use the minimum even (odd) sum algorithm to choose the elements in $(c_{ij})_{2\times k}$. Suppose that the union of the elements chosen from the 0th row in $(c_{ij})_{2\times k}$ is $\bigcup_{p=1}^{n_1} c_{0j_p}$, and the union of the elements chosen from the first row in $(c_{ij})_{2\times k}$ is $\bigcup_{q=1}^{n_2} c_{1j_q}$, where $n_1+n_2=k$. Then we set

$$C_2(o^*)=\left(\bigcup_{p=1}^{n_1} C_2(t_{j_p}^{(b)})\right)\bigcup\left(\bigcup_{q=1}^{n_2} C_1(t_{j_q}^{(b)})\right)\bigcup\left(\bigcup_{i=k+1}^{l} C_1(t_i^{(r)})\right)\bigcup\left(\bigcup_{i=l+l}^{m} C_1(t_i^{(o)})\right)$$

as the optimal solution to the quasi all-ones problem of the subtrees rooted at o^*.

Step 3. $i := i-1$, go to Step 1;

Step 4. We are now ready to give an optimal solution for the rooted tree T from the pair on the root by distinguishing the following three cases: (i) If the root is of r-type, denoted by r^*, then the $C_1(r^*)$ of the pair is an optimal solution. (ii) If the root is of b-type, denoted by b^*, then the $C_1(b^*)$ of the pair is a candidate for the optimal solution such that b^* belongs to the candidate solution, and the $C_2(b^*)$ of the pair is another candidate for the optimal solution such that b^* does not belong to the candidate solution. Now, compare the values of $|C_1(b^*)|$ and $|C_2(b^*)|$. Suppose that $|C_t(b^*)| = \min\{|C_1(b^*)|, |C_2(b^*)|\}$, $t\in\{1,2\}$. Then we choose $C_t(b^*)$ as an optimal solution. (iii) If the root is of o-type, denoted by o^*, then the $C_1(o^*)$ of the pair is an optimal solution.

THEOREM 3.2. *The above algorithm outputs an optimal solution to the all-ones problem of a given tree T, and the time complexity is linear.*

Proof. In Step 0, we regard every leaf in the bottom of the tree as a subtree whose unique optimal solution to the all-ones problem and the quasi all-ones problem contains exactly the node itself and nothing, respectively. Then the initial values of all the leaves of the tree can be completely determined. The algorithm now proceeds inductively on the number of layers of the tree. Then from the method for constructing solutions in the proof of Theorem 2.1 and from Remarks 2.1, 2.2, and 3.1, it is easy to conclude that the algorithm ensures that all the leaves v of the small trees of all types I, II, and III in every layer have recorded the right information, i.e., the pairs $\{C_1(v), C_2(v)\}$. From these pairs of sets, we can choose the optimal solution for the given tree according to the type of the root of the tree. The first statement of the theorem is thus proved.

For the second statement of the theorem, it is not hard to see that for every layer, the algorithm uses time linear in the number of nodes in the layer, even though

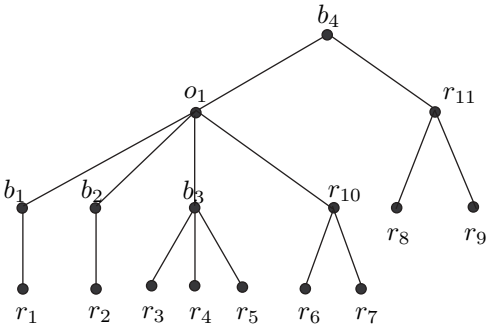

FIG. 3. *Labeling the type for every node.*

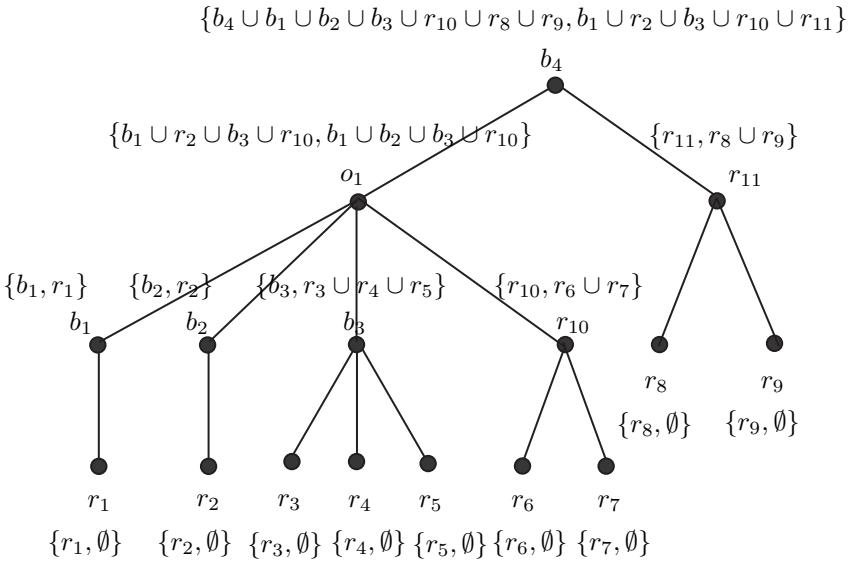

FIG. 4. *An example of our algorithm for the minimum all-ones problem for trees.*

sometimes the minimum odd or even sum algorithm has to be used. Therefore, the total time used by the algorithm is linear for the minimum all-ones problem of the given tree. The proof is complete. □

An example to show our algorithm at work is given in Figures 3 and 4. For every node in Figure 3, the label, by ignoring its subscript, is the type of that node. In Figure 4 we simply use x to denote the set $\{x\}$ with a single element x. Initially, our algorithm sets a pair $\{v, \emptyset\}$ for every leaf v. Then, from the bottom up, the pair for each node in every layer can be generated. Note that the children of o_1 are b_1, b_2, b_3, and r_{10}, and the pairs on the b-type nodes can form a matrix as described in our algorithm: $P_{23} = \left(\begin{smallmatrix} r_1 & r_2 & r_3 \cup r_4 \cup r_5 \\ b_1 & b_2 & b_3 \end{smallmatrix}\right)$. The corresponding numerical matrix is $C_{23} = \left(\begin{smallmatrix} 1 & 1 & 3 \\ 1 & 1 & 1 \end{smallmatrix}\right)$, which will be used in the minimum odd (even) sum algorithm. Note that only r_{10} is an r-type node. Then use the minimum even sum algorithm to get $b_1 \cup r_2 \cup b_3$ (possibly, $r_1 \cup b_2 \cup b_3$) union r_{10} and form $C_1(o_1)$. Use the minimum odd

sum algorithm to get $b_1 \cup b_2 \cup b_3$ (possibly, $r_1 \cup r_2 \cup b_3$) union r_{10} and form $C_2(o_1)$. In the end, by comparing $|C_1(b_4)| = 7$ with $|C_2(b_4)| = 5$, we get an optimal solution $C_2(b_4) = b_1 \cup r_2 \cup b_3 \cup r_{10} \cup r_{11}$. The details about the pair $\{C_1(v), C_2(v)\}$ for every node v are recorded in Figure 4.

4. Concluding remarks. Although the existence of solutions to the all-ones problem for general graphs was proved by linear algebraic methods (see [10, 5]), in [10] Sutner asked whether there is a graph-theoretic proof for the existence. Eriksson, Eriksson, and Sjöstrand [3] gave such a proof. However, how to find a solution efficiently by graph-theoretic algorithms remains unknown. Although, based on the result in [3], one can get a graph-theoretic algorithm inductively, the time complexity is not polynomial, which is upper bounded by $O(n!)$. It is easy to see that for the empty graph with n nodes, their algorithm runs in time $O(n!)$. So, to find a graph-theoretic algorithm of polynomial time for general graphs, some other ideas are needed. For trees, Galvin [4] gave a graph-theoretic algorithm of linear time. In this concluding section, based on the discussion in section 2 we would like to give such an algorithm of linear time for unicyclic graphs.

For convenience, we say that the truth value of a node in G is 1 if it belongs to the solution to the all-ones problem (or the quasi all-ones problem) for G, and 0 otherwise. Recall that a graph G is called *unicyclic* if it contains a unique cycle. In other words, we can regard a unicyclic graph as a cycle attached with each node to a rooted tree, called a *suspended tree*. Note that the depth of a suspended tree can be 0. For simplicity, we say that a node t in the cycle has the same type as the type of the root t of the suspended tree.

Algorithm for unicyclic graphs.

Input. A unicyclic graph G, each node in the unique cycle being labeled by types.

Step 1. If none of the nodes on the cycle is an outcast, then let the truth values of all nodes on the cycle be 1; i.e., take the union of the solutions, each of which is a solution to the all-ones problem for each suspended tree whose root belongs to the solution. Then the union is a solution to the all-ones problem for the whole unicyclic graph.

Step 2. If there are outcast nodes, we fix an order to the nodes on the cycle. Then we cut the cycle by deleting the edge between an outcast node u and the node v before it on the cycle. The unicyclic graph becomes a tree with root v, denoted as T, and the type of every node on the original cycle will be changed as in Figure 5, where the changing of the type of each node is from on the original cycle to on the tree T, and the changing rule is just the same as that in the Galvin method.

By Galvin's algorithm, we can construct a solution X for the tree T. Then we add an edge to connect the node u and the node v in T; then the tree T returns to the original unicyclic graph with a solution X. Because u is an outcast node, no matter whether it is in the unicyclic graph or in the tree, it will not belong to the solution, and hence will not affect the other nodes' truth values, while u's on or off status will probably be affected by v if v belongs to X. If v does not belong to X, then X is a solution to the all-ones problem for the unicyclic graph; otherwise, we only need to change the solution to the all-ones problem into the solution to the quasi all-ones problem, or the other way around for the suspended tree with root u according to the construction method in the proof of Theorem 2.1; then the modified solution is a solution to the all-ones problem for the unicyclic graph. An example is shown in Figure 6.

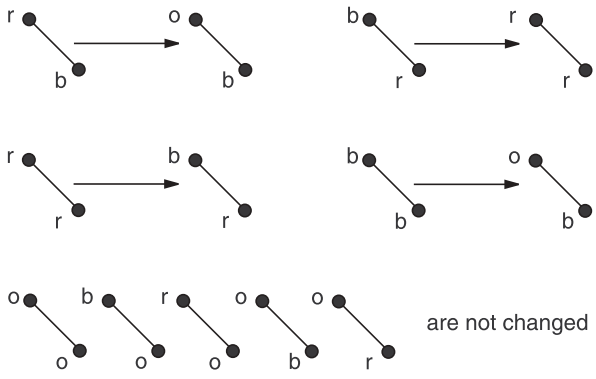

FIG. 5. *Changing of types.*

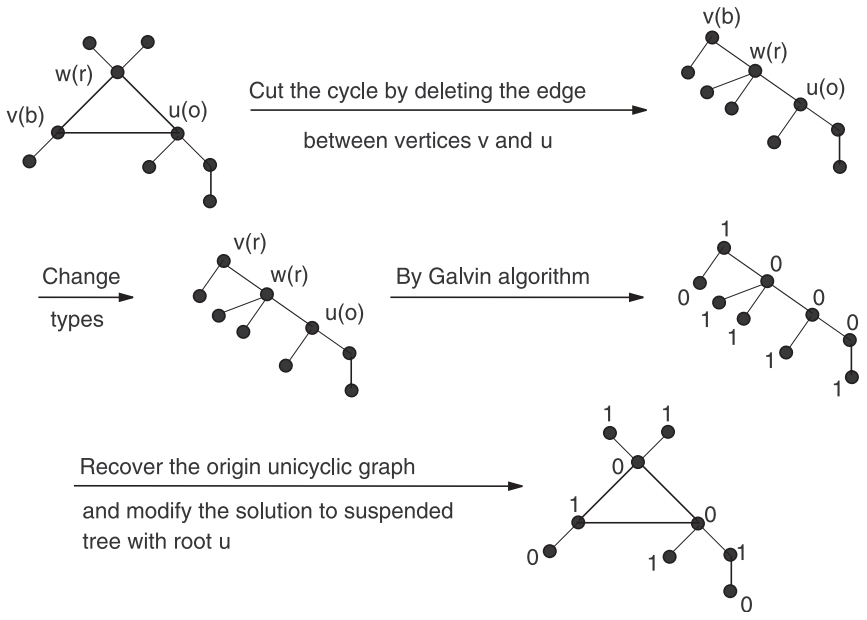

FIG. 6. *An example of our algorithm for unicyclic graphs.*

So, we get the following result.

THEOREM 4.1. *The above algorithm outputs solutions to the all-ones problem for unicyclic graphs, and the time complexity is linear.*

To end this paper, we propose the following problem.

All-colors problem. The so-called *all-colors problem* on graphs is described as follows, which is a natural generalization for the all-ones problem:

For any node of a graph G, it has a color value between 0 and $r-1$. If a node is pressed one time, then the color values of the node and its neighbors are added by 1 under the meaning of modular r. If the initial status is that the color value of every node is 0, then we ask how to press some nodes (maybe many times) to make the color value of every node equal to $r-1$ (or any fixed k such that $1 \leq k \leq r-1$) under

the meaning of modular r. If we ask that the sum of color values of all nodes attains the minimum, the problem is called the *minimum all-colors problem*.

Acknowledgment. The authors are greatly indebted to the referees for their invaluable suggestions and comments, which have substantially improved the presentation of the paper.

SCHEDULING WITH AND/OR PRECEDENCE CONSTRAINTS*

ROLF H. MÖHRING†, MARTIN SKUTELLA‡, AND FREDERIK STORK§

Abstract. In many scheduling applications it is required that the processing of some job be postponed until some other job, which can be chosen from a pregiven set of alternatives, has been completed. The traditional concept of precedence constraints fails to model such restrictions. Therefore, the concept has been generalized to so-called AND/OR *precedence constraints* which can cope with this kind of requirement. In the context of traditional precedence constraints, feasibility, transitivity, and the computation of earliest start times for jobs are fundamental, well-studied problems. The purpose of this paper is to provide efficient algorithms for these tasks for the more general model of AND/OR precedence constraints. We show that feasibility as well as many questions related to transitivity can be solved by applying essentially the same linear-time algorithm. In order to compute earliest start times we propose two polynomial-time algorithms to cope with different classes of time distances between jobs.

Key words. project scheduling, AND/OR precedence constraints, earliest start schedule, mean payoff games

1. Introduction.

Definition and motivation of AND/OR precedence constraints. For a given set V of jobs, a precedence constraint comprehends the requirement that a job j cannot be started before another job i has been completed. Precedence constraints are usually given by a set A of ordered pairs (i, j), $i \neq j \in V$, inducing an acyclic digraph $D = (V, A)$ where each node corresponds to a job and each arc represents a precedence constraint. In a feasible implementation of the project, the jobs have to be executed in accordance with the partial order defined by D. Since, in this setting, each job j can only start after the completion of *all* its predecessors in D, we call these precedence constraints AND-*constraints*. However, there are many applications where jobs can be executed as soon as *any* of its predecessors has been completed; we refer to such temporal restrictions as OR-*constraints*. Traditional precedence constraints fail to model this requirement and consequently, the model has been generalized to so-called AND/OR *precedence constraints*. AND/OR precedence constraints can be represented by a set $\mathcal{W}$ of pairs (X, j) with the meaning that job $j \in V$ cannot be executed before some job $i \in X \subseteq (V \setminus \{j\})$ has been completed. We

call such (X, j) pairs *waiting conditions* and job j the *waiting job* for (X, j). Notice that for a singleton $X = \{i\}$, the constraint (X, j) is a traditional AND-constraint (i, j).

An intuitive motivation for AND/OR precedence constraints is noted by Gillies and Liu [12]. An engine head has to be fixed by four bolts. However, one of the bolts may secure the engine head well enough to allow further work on it. If the set X consists of the four jobs to secure the bolts and j represents the further work on the engine head, then the waiting condition (X, j) obviously models the desired temporal dependencies among the jobs. Another motivation is studied by Goldwasser and Motwani [13]. They consider the problem of partially disassembling a given product to reach a single part (or component). In order to remove a certain part, one previously may have to remove other parts which can be modeled by traditional (AND) precedence constraints. However, one may choose to remove that same part of the product from another geometric direction, in which case some other parts must be removed previously. This freedom of choice can be modeled by AND/OR precedence constraints. A third motivation is given by Dinic [6], who considers the setup of new technologies and products. In his model, a new technology requires certain products; on the other hand, a new product can be obtained as an output of one of several new technologies. The latter requirement leads to an OR-constraint, while the first requirement is a classical AND-constraint.

Our research is motivated by problems occurring in resource-constrained project scheduling. Resource constraints can be represented by so-called *minimal forbidden sets*, i.e., inclusion-minimal sets of jobs that cannot be scheduled simultaneously. In order to resolve the resource conflict that occurs due to a minimal forbidden set F, one may choose a job $j \in F$ to be a waiting job for $F \setminus \{j\}$ and introduce the corresponding waiting condition $(F \setminus \{j\}, j)$. Thus, we are able to represent solutions of project scheduling problems by a set $\mathcal{W}$ of waiting conditions. For details we refer to [26].

Connections to other fields and related work. The combinatorial structure of a system $\mathcal{W}$ of waiting conditions occurs in different fields of discrete mathematics and theoretical computer science. In the context of *directed hypergraphs* each $(X, j) \in \mathcal{W}$ represents a hyperarc with a set X of source nodes and a single target node j. Ausiello, d'Atri, and Saccà [3] (see also [4]) generalize transitive closure and reduction algorithms from directed graphs to directed hypergraphs. Another related class of combinatorial objects are *antimatroids* (special greedoids) which can be defined via a set of waiting conditions; see, e.g., [17, page 22]. Furthermore, many problems stemming from artificial intelligence can be formulated by hierarchies of subproblems where different alternatives exist to solve these subproblems; see, e.g., [23]. There, a graphical representation of such hierarchies is called an AND/OR graph.

In the context of scheduling, Goldwasser and Motwani [13] derive inapproximability results for two single-machine scheduling problems with AND/OR precedence constraints. Gillies and Liu [12] consider single- and parallel-machine scheduling problems with different structures of AND/OR precedence constraints; they prove NP-completeness of finding feasible schedules in some settings that are polynomially solvable with traditional precedence constraints. Moreover, they give approximation algorithms for some makespan minimization problems.

A basic, important task in scheduling applications is the computation of earliest start times of jobs. The research on this topic will be discussed in more detail in section 7.1.

Contribution of this paper. For AND-constraints, fundamental problems such as deciding feasibility, finding transitive AND-constraints, and computing earliest start times of jobs can be solved efficiently by applying simple well-known graph algorithms. Most important for the algorithmic treatment is the fact that AND-constraints define acyclic structures on the set V of jobs such that many problems can be solved by considering jobs in the order of a topological sort. Since this is not the case for AND/OR precedence constraints, the algorithms for AND-constraints cannot be applied in that setting.

In the first part of the paper we provide efficient algorithms and structural insights for the more general and complex model of AND/OR precedence constraints. We show that feasibility as well as questions related to generalized transitivity can be solved by applying essentially the same linear-time algorithm. Moreover, we discuss a natural generalization of AND/OR precedence constraints and prove that the same problems become NP-complete in this setting.

The second part of this paper is concerned with the computation of earliest start times if AND/OR precedence constraints are imposed among jobs. We consider different ranges of minimal *time distances* (or time lags) d_{ij} between the start times of two jobs i and j that are coupled within a precedence constraint. For AND/OR precedence constraints, the problem then reduces to finding a solution to a system of *min-max-inequalities* which also has applications in many other fields. We discuss polynomial equivalence to finding optimal strategies for a class of two-person games played on directed graphs. For the case that such time lags are strictly positive (nonnegative) we devise polynomial-time algorithms.

Outline. The paper is organized as follows. After stating some basic requirements in section 2, we discuss feasibility and aspects of transitivity as well as an application thereof in sections 3 to 5. A generalization of AND/OR precedence constraints is considered in section 6. While we consider only the combinatorial structure of AND/OR precedence constraints in sections 3 to 6, we additionally deal with temporal data such as job processing times or time lags between jobs in section 7, where we provide algorithms for computing earliest job start times.

2. Preliminaries. In order to illustrate the presentation we use the following example throughout the paper.

Example 1. Let $V := \{j_1, \dots, j_7\}$ be the set of jobs and $\mathcal{W} := \{w_1 = (\{j_1, j_5\}, j_4)$, $w_2 = (\{j_2, j_6\}, j_4)$, $w_3 = (\{j_4, j_3\}, j_6)$, $w_4 = (\{j_4\}, j_5)$, $w_5 = (\{j_4, j_5, j_6\}, j_7)\}$ the set of waiting conditions.

Graph representation. We use a natural representation of AND/OR precedence constraints by a directed graph D on the set $\mathcal{V} = V \cup \mathcal{W}$ of nodes. The set A of arcs is constructed in the following way: For every waiting condition $w = (X, j) \in \mathcal{W}$, we introduce arcs (i, w), for each $i \in X$, and one additional arc (w, j). Notice that the size of the resulting digraph D is linear in the input size of the problem. The sets V and $\mathcal{W}$ form a bipartition of D. Similar digraphs are used to represent directed hypergraphs; see, e.g., [10] and [9]. For a node $j \in V \cup \mathcal{W}$, we use $in(j)$ and $out(j)$ to denote the sets $\{i \in V \cup \mathcal{W} : (i, j) \in A\}$ and $\{i \in V \cup \mathcal{W} : (j, i) \in A\}$, respectively. We also sometimes use the notation $in_D(j)$ and $out_D(j)$ to stress the underlying digraph D.

The digraph resulting from Example 1 is depicted in Figure 2.1. For the moment, the numbers associated with the arcs can be ignored; they come into play in section 7 when earliest job start times are computed. As usual, a cycle in D is a sequence $(v_0, v_1, \dots, v_k, v_0)$, $v_\ell \in \mathcal{V}$, where $(v_0, v_1, \dots, v_k)$ is a directed path and there exists an

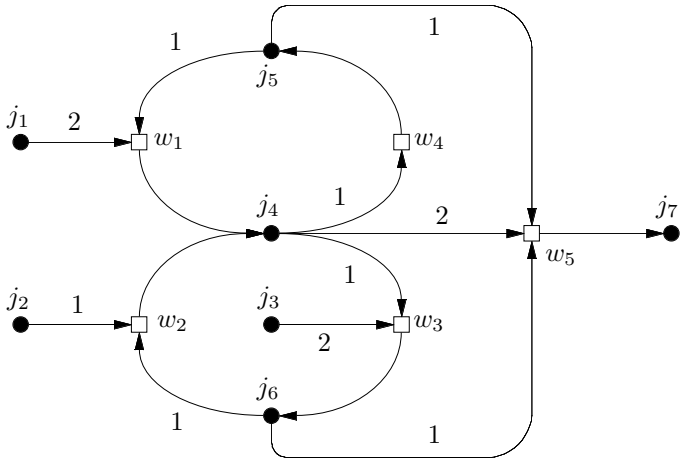

FIG. 2.1. *The digraph resulting from Example* 1. *Circular nodes correspond to jobs (*AND*-nodes), while square nodes represent waiting conditions (*OR*-nodes). Numbers associated with arcs define time lags used in section* 7 *(the time lags of arcs without a number are* 0*).*

arc from v_k to v_0. We also consider *generalized cycles*, which are induced subgraphs D' of D that consist of node sets $V' \subseteq V$ and $\mathcal{W}' \subseteq \mathcal{W}$ such that $in_D(j) \cap \mathcal{W}' \neq \emptyset$ for each $j \in V'$ and $\emptyset \neq in_D(w) \subseteq V'$ for each $w \in \mathcal{W}'$.

Realizations. Given a set V of jobs and a set $\mathcal{W}$ of waiting conditions, an implementation of the corresponding project requires a decision for each waiting condition (X, j): One has to determine a job $i \in X$ that job j should wait for. The entirety of these decisions must lead to a partial order $R = (V, \prec_R)$ on the set V of jobs (the introduction of a cycle would lead to infeasibility) such that

$$\text{for each } (X, j) \in \mathcal{W}, \text{ there exists an } i \in X \text{ with } i \prec_R j. \tag{2.1}$$

Conversely, every partial order R with property (2.1) defines an implementation of the project and is therefore called a *realization* for the set $\mathcal{W}$ of waiting conditions. In what follows, a set $\mathcal{W}$ of waiting conditions is called *feasible* if and only if there exists a realization for $\mathcal{W}$. Since any extension $R' = (V, \prec_{R'})$ of a realization R (i.e., if $i \prec_R j$, then $i \prec_{R'} j$) fulfills property (2.1), R' is also a realization. In particular, a set of AND/OR precedence constraints is feasible if and only if there exists a total order of the jobs which is a realization; we call such a realization *linear*.

Possible linear realizations of Example 1 are, for instance, $j_1 \prec \cdots \prec j_7$ and $j_3 \prec j_6 \prec j_7 \prec j_2 \prec j_1 \prec j_4 \prec j_5$.

3. Feasibility. In order to check whether a given set $\mathcal{W}$ of AND/OR precedence constraints is feasible, we try to construct a linear realization L in a greedy way: While there exists a job $i \in V$ that is not a waiting job of any waiting condition in $\mathcal{W}$, it is inserted at the end of L. Whenever a waiting condition (X, j) becomes satisfied (which is the case if some $i \in X$ is being added to L), (X, j) is deleted from $\mathcal{W}$. Computational details are provided in Algorithm 1. We use a data structure Q to temporarily store jobs from V. Implementing Q as a stack or a queue leads to a linear-time algorithm.

THEOREM 3.1. *A set of* AND/OR *precedence constraints is feasible if and only if the list L obtained from Algorithm* 1 *contains all jobs of V.*

Algorithm 1: Feasibility check of a set of waiting conditions.

Input : A set V of jobs and waiting conditions $\mathcal{W}$.
Output: A list L of jobs from V.

```
Q := ∅; L := ∅;
for jobs j ∈ V do
    a(j) := |{(X, j) ∈ W}|;
    if a(j) = 0 then add j to Q;
while Q ≠ ∅ do
    remove a job i from Q;
    insert i at the end of L;
1   for waiting conditions (X, j) ∈ W with i ∈ X do
        decrease a(j) by 1;
        if a(j) = 0 then add j to Q;
        remove (X, j) from W;
return L;
```

Proof. If L contains all jobs, it follows from the construction of Algorithm 1 that, for each waiting condition $(X, j) \in \mathcal{W}$, there is at least one job $i \in X$ with $i \prec_L j$; therefore, according to (2.1), L is a linear realization. Suppose now that the algorithm returns an incomplete list L although the set of waiting conditions is feasible. Consider a linear realization R and let $j \in V \setminus L$ be minimal with respect to the total order $\prec_R$. Since the algorithm was not able to add j to L, there is a waiting condition $(X, j) \in \mathcal{W}$ with $X \subseteq V \setminus L$. Since R is a realization, there exists a job $i \in X$ with $i \prec_R j$ which is a contradiction of the minimal choice of j. □

As a consequence of Theorem 3.1 we can formulate the following structural characterization of feasible waiting conditions. The lemma appears implicitly already in the work of Igelmund and Radermacher [14] within the context of stochastic resource-constrained project scheduling.

LEMMA 3.2. *A set of* AND/OR *precedence constraints is feasible if and only if there exists no generalized cycle in the associated digraph D.*

Note that Example 1 is feasible (recall that we already stated two linear realizations). However, if $w_1 = (\{j_1, j_5\}, j_4)$ is replaced by $(\{j_5\}, j_4)$, the instance becomes infeasible because $V' = \{j_4, j_5\}$ and $\mathcal{W}' = \{(\{j_5\}, j_4), (\{j_4\}, j_5)\}$ form a generalized cycle.

The following corollary states an algorithmic consequence of the structural insight of Lemma 3.2.

COROLLARY 3.3. *Job $j \in V$ is not contained in the list L returned by Algorithm* 1 *if and only if j is contained in a set $V' \subseteq V$ such that for all $i \in V'$ there is a waiting condition $(X, i) \in \mathcal{W}$ with $X \subseteq V'$.*

In particular, L as a *set* does not depend on the individual jobs chosen from Q in the while-loop of Algorithm 1.

In the proof of Theorem 3.1 we have shown that, for a feasible set of AND/OR precedence constraints $\mathcal{W}$, the list L returned by Algorithm 1 is a linear realization of $\mathcal{W}$. In fact, it is an easy observation that Algorithm 1 can generate every linear realization of $\mathcal{W}$ through an appropriate choice of jobs from Q in the while-loop.

Remark. The problem of checking feasibility of $\mathcal{W}$ can alternatively be solved by transforming it into a satisfiability problem (SAT) where each clause is of *Horn*

type. Such SAT instances are well known to be solvable in linear time; see [7]. The transformation and more details can be found in [26].

4. Detecting implicit AND/OR precedence constraints.

4.1. Problem definition and related work. We now focus on detecting "new" waiting conditions that can be deduced from the given set $\mathcal{W}$ of constraints. For $U \subset V$ and $j \in V \setminus U$, we say that the waiting condition (U, j) is *implied* by $\mathcal{W}$ if and only if

(4.1) for every realization $R = (V, \prec_R)$ of $\mathcal{W}$, there exists some $i \in U$ with $i \prec_R j$.

By property (2.1), this is equivalent to the requirement that adding the waiting condition (U, j) to $\mathcal{W}$ does not change the set of realizations for $\mathcal{W}$. Notice that it is sufficient to claim property (4.1) for every *linear* realization of $\mathcal{W}$.

For traditional precedence constraints the detection of implied waiting conditions is an easy task because the transitive closure which represents all such implicit constraints can be efficiently computed by standard graph algorithms. However, in general, the total number of implicit AND/OR precedence constraints is exponential in the input size of V and $\mathcal{W}$. In particular, it is not possible to compute all implicit constraints efficiently. For the restricted case of AND/OR precedence constraints where the associated digraph D is acyclic, Gillies [11] proposes an algorithm to determine jobs that have to wait for a single job i.

In the context of directed hypergraphs, Ausiello, d'Atri, and Saccà [3] (see also [4]) consider problems similar to those discussed in this section and in section 5 below. However, the results we present are not contained in their work because their definition of implicit hyperarcs differs from our definition of implicit waiting conditions. Their definition is based on three rules which are known as *Armstrong's axioms* within the context of functional dependencies in relational databases (see, e.g., [27]). In particular, [3, Definition 4] does not cover implications that can be deduced from the requirement of feasibility. For instance, in Example 1, the waiting condition $(\{j_1\}, j_4)$ is implied by $\mathcal{W}$, but it is not implied according to [3, Definition 4].

4.2. Result. For a given set $U \subseteq V$ we show that Algorithm 1 can be used to detect all implicit waiting conditions of the form (U, j). For an arbitrary subset $Y \subseteq V$ the set $\mathcal{W}_Y$ of *induced* waiting conditions is given by $\mathcal{W}_Y := \{(X \cap Y, j) \mid (X, j) \in \mathcal{W}, j \in Y\}$. For $(X, j) \in \mathcal{W}$ with $j \in Y$ and $X \cap Y = \emptyset$, the resulting waiting condition $(\emptyset, j) \in \mathcal{W}_Y$ means that job j cannot be planned at all with respect to $\mathcal{W}_Y$; in particular, $\mathcal{W}_Y$ is infeasible in this case.

THEOREM 4.1. *For given $U \subset V$ let L be the output of Algorithm 1 with input $V \setminus U$ and $\mathcal{W}_{V \setminus U}$. The set of waiting conditions of the form (U, j) which are implied by $\mathcal{W}$ is precisely $\{(U, j) \mid j \in V \setminus (L \cup U)\}$.*

The proof is deferred to section 4.3 below. For Example 1 and $U := \{j_2, j_3\}$, the algorithm computes $L = \{j_1\}$, while for $U := \{j_1, j_2\}$ we obtain $L = \{j_3, j_6, j_7\}$. Thus, the waiting condition $(\{j_2, j_3\}, j_7)$ is implied by $\mathcal{W}$, while $(\{j_1, j_2\}, j_7)$ is not.

We can directly deduce the following corollary.

COROLLARY 4.2. *Given $U \subset V$, the set of waiting conditions of the form (U, j) that are implied by $\mathcal{W}$ can be computed in linear time.*

4.3. Correctness. We next state some rather technical lemmas which directly show the validity of Theorem 4.1. The theorem can alternatively be proved by a simpler argumentation (similar to the proof of Theorem 3.1), but we need the lemmas

to establish other results in section 5 below. In addition, with the extended argumentation, we are able to strengthen Theorem 4.1 slightly (see Corollary 4.6). The following definition will be useful throughout the discussion: For a given feasible set $\mathcal{W}$ of waiting conditions and a set $U \subseteq V$ let

$$\begin{aligned} Y_U &:= \{j \in V \setminus U \mid (U,j) \text{ is not implied by } \mathcal{W}\}, \\ Z_U &:= \{j \in V \setminus U \mid (U,j) \text{ is implied by } \mathcal{W}\} = V \setminus (U \cup Y_U) \ . \end{aligned}$$

LEMMA 4.3. *Let $\mathcal{W}$ be a feasible set of waiting conditions and let $U \subseteq V$. Then there exists a (linear) realization $R = (V, \prec_R)$ of $\mathcal{W}$ such that Y_U is an order ideal of R; i.e., R "starts" with the jobs in Y_U.*

Proof. Let $R' = (V, \prec_{R'})$ be a linear realization of $\mathcal{W}$ that maximizes the cardinality of the largest order ideal J of R' with $J \subseteq Y_U$. To show that $J = Y_U$, by contradiction, we assume that there is a job $j' \in Y_U \setminus J$. Since, by definition of Y_U, the waiting condition (U, j') is not implied by $\mathcal{W}$, there is a linear realization $R = (V, \prec_R)$ of $\mathcal{W}$ with $j' \prec_R U$ (j' precedes all elements in U). Let $j \in Y_U \setminus J$ be minimal with respect to R. By maximality of J, job j cannot be moved to the position directly after J in R' without violating a waiting condition. Thus, there exists $(X, j) \in \mathcal{W}$ with $X \subseteq V \setminus J$. By (2.1), there exists an $i \in X$ with $i \prec_R j$. Notice that we have $i \notin U$ because $i \prec_R j \preceq_R j' \prec_R U$. Moreover, due to the minimal choice of j and the fact that $i \notin J$ it follows that $i \notin Y_U$. As a consequence we obtain $i \in X \setminus (U \cup Y_U)$. By definition of Z_U, this yields $i \in Z_U$. Thus, the waiting condition (U, i) is implied by $\mathcal{W}$, which is a contradiction of $i \prec_R j \preceq_R j' \prec_R U$. □

Let us call a set $Y \subseteq V$ *feasible with respect to* $\mathcal{W}$ if and only if the induced set $\mathcal{W}_Y$ of waiting conditions is feasible. The result in Corollary 3.3 can then be restated as follows.

COROLLARY 4.4. *Algorithm* 1 *returns the unique maximal feasible subset of V with respect to $\mathcal{W}$.*

In conjunction with the following lemma, Corollary 4.4 provides an efficient way of detecting waiting conditions implied by $\mathcal{W}$. This concludes the proof of Theorem 4.1 (in fact, the lemma essentially is a reformulation of Theorem 4.1).

LEMMA 4.5. *Let $\mathcal{W}$ be a feasible set of* AND/OR *precedence constraints, $U \subset V$, and $j \in V \setminus U$. Then the waiting condition (U, j) is implied by $\mathcal{W}$ if and only if j is not contained in the unique maximal feasible subset of $V \setminus U$ with respect to $\mathcal{W}_{V \setminus U}$.*

Proof. We have to show that Y_U is the unique maximal feasible subset F of $V \setminus U$ with respect to $\mathcal{W}_{V \setminus U}$. By Lemma 4.3, there exists a linear realization R of $\mathcal{W}$ starting with the jobs in Y_U. This induces a linear realization of $\mathcal{W}_{Y_U}$ and consequently, by definition, Y_U is feasible with respect to $\mathcal{W}$. Moreover, since $\mathcal{W}_{Y_U} = (\mathcal{W}_{V \setminus U})_{Y_U}$, the subset Y_U is feasible with respect to $\mathcal{W}_{V \setminus U}$, which yields $Y_U \subseteq F$.

To show that $F \subseteq Y_U$, by contradiction, assume that $F \setminus Y_U \neq \emptyset$. Since $F \cap U = \emptyset$ we then have $F \cap Z_U \neq \emptyset$. Let $R' = (F, \prec_{R'})$ be a linear realization of $\mathcal{W}_F$ and choose $i \in F \cap Z_U$ minimal with respect to R'. Since $i \in Z_U$, by definition of Z_U, the waiting condition (U, i) is implied by $\mathcal{W}$. Therefore, moving job i to the position directly after Y_U in R violates a waiting condition $(X, i) \in \mathcal{W}$ with $X \subseteq U \cup Z_U$. Let us consider the induced waiting condition $(X \cap F, i) \in \mathcal{W}_F$. It follows from the minimal choice of i that $i' \notin F \cap Z_U$ for all i' with $i' \prec_{R'} i$. With $F \cap U = \emptyset$, this implies $i' \notin X \cap F$, which is a contradiction of the fact that R' is a realization for $\mathcal{W}_F$. □

Finally, notice that there may exist (implicit) waiting conditions (X, j) inside the considered set U, i.e., $X \subset U$ and $j \in U \setminus X$. Theorem 4.1 can be strengthened in the following way. Consider the situation after the execution of Algorithm 1 with input

$V \setminus U$ and $\mathcal{W}_{V\setminus U}$ and let L be the resulting list of jobs. Furthermore, let $U' \subseteq U$ denote the set of jobs from U that can be added to L without violating any waiting condition of $\mathcal{W}$.

COROLLARY 4.6. *For given $U \subseteq V$ the set of waiting conditions (U', j) which is implied by $\mathcal{W}$ is precisely $\{(U', j) \mid j \in V \setminus (L \cup U')\}$.*

Proof. We show that the maximal feasible subsets F and F' of $V \setminus U$ and $V \setminus U'$, respectively, coincide. The corollary then follows from Lemma 4.5. It is clear that $F \subseteq F'$ since $U' \subseteq U$. Conversely, suppose by contradiction that $F' \setminus F \neq \emptyset$. Denote by $R = (V, \prec_R)$ and $R' = (V, \prec_{R'})$ linear realizations of $\mathcal{W}$ where F and F' are order ideals, respectively (the existence of R and R' follows from Lemmas 4.3 and 4.5). Let $j \in F' \setminus F$ be the smallest job in $F' \setminus F$ with respect to R'. Since $j \notin F$, moving job j in R to the position directly after F violates a waiting condition (X, j) with $X \cap F = \emptyset$. Since R' is a realization there must exist some $i \in X$ with $i \prec_{R'} j$. But $i \in F' \setminus F$, which contradicts the minimal choice of j. ∎

The results presented in this section turn out to be useful in the context of minimal representations of AND/OR precedence constraints discussed in section 5. Besides this, Corollary 4.6 led to a considerable speedup of computation time within branch-and-bound procedures for stochastic resource-constrained project scheduling; see [26] for details.

5. Minimal representations of AND/OR precedence constraints. While for traditional precedence constraints a minimal representation without redundancies is given by the transitive reduction and can be computed by simply removing redundant (i.e., transitive) constraints, the situation is slightly more complicated for AND/OR precedence constraints. In order to obtain a *unique* minimal representation, it is not sufficient to iteratively remove redundant waiting conditions that are implied by the others.

DEFINITION 5.1. *A set $\mathcal{W}$ of waiting conditions is called* minimal *if*

(i) *no waiting condition $(X, j) \in \mathcal{W}$ is implied by $\mathcal{W} \setminus \{(X, j)\}$, and*

(ii) *for each waiting condition $(X, j) \in \mathcal{W}$, the set X is minimal with respect to inclusion; i.e., for all $i \in X$, the waiting condition $(X \setminus \{i\}, j)$ is not implied by $\mathcal{W}$.*

Two sets $\mathcal{W}$ and $\mathcal{W}'$ of waiting conditions are called equivalent *if their sets of (linear) realizations coincide. Moreover, if $\mathcal{W}'$ is minimal, then $\mathcal{W}'$ is called a* minimal reduction *of $\mathcal{W}$.*

The set $\mathcal{W}$ from Example 1 is not minimal: If the waiting condition $(\{j_4, j_5, j_6\}, j_7)$ is replaced by $(\{j_4, j_6\}, j_7)$, the resulting instance is equivalent to Example 1. This follows from waiting condition $(\{j_4\}, j_5)$, which ensures that whenever $j_5 \prec_R j_7$ in some realization $R = (V, \prec_R)$ we also have $j_4 \prec_R j_5$ and $j_4 \prec_R j_7$. Note that if we additionally replace $(\{j_1, j_5\}, j_4)$ by $(\{j_1\}, j_4)$, the resulting set of waiting conditions is minimal (and still equivalent to Example 1).

THEOREM 5.2. *Each feasible set of waiting conditions has a unique minimal reduction.*

To prove the theorem we need the following technical lemma.

LEMMA 5.3. *Let $\mathcal{W}$ be a feasible set of waiting conditions with $(U, j) \in \mathcal{W}$. The waiting condition (U, j) is implied by $\mathcal{W}' := \mathcal{W} \setminus \{(U, j)\}$ if and only if there exists some $(X, j) \in \mathcal{W}'$ with $X \subseteq U \cup Z_U$.*

Proof. If (U, j) is implied by $\mathcal{W}'$, then any ordering of V where Y_U is an ideal and j is placed directly after Y_U is not a realization of $\mathcal{W}'$. Thus, there exists some $(X, j) \in \mathcal{W}$ with $X \subseteq U \cup Z_U$. Contrarily, suppose that there exists some $(X, j) \in \mathcal{W}'$

Algorithm 2: Computation of a minimal reduction.

Input : A set V of jobs and waiting conditions $\mathcal{W}$.
Output: A minimal reduction of $\mathcal{W}$

```
for each (U, j) ∈ W do
    L := call Algorithm 1 with input V \ U and W_{V\U} and
         compute a(i) for each i ∈ V;
    if a(j) > 1 then
        delete (U, j) from W;
    else for i ∈ U do
        if a(i) > 0 then delete i from U;
return W;
```

with $X \subseteq U \cup Z_U$ but (U, j) is not implied by $\mathcal{W}'$. Then there exists some $h \in X \setminus U$ and a linear realization $R' = (V, \prec_{R'})$ of $\mathcal{W}'$ with $Y_U \prec_{R'} h \prec_{R'} j \prec_{R'} U$. Since $\mathcal{W}$ is feasible, there exists some $i \in U$ that can be moved to the position directly after h without violating a waiting condition of $\mathcal{W}'$ (this follows from Corollary 4.6). In addition, the resulting linear realization $R = (V, \prec_R)$ satisfies the waiting condition (U, j) and thus should be a realization with respect to $\mathcal{W}$. However, we have $h \prec_R i \prec_R j \prec_R U \setminus \{i\}$, which is a contradiction of $h \in Z_U$. □

Proof of Theorem 5.2. Let $\mathcal{W}$ and $\mathcal{W}'$ be equivalent and both minimal. It suffices to show that $(U, j) \in \mathcal{W}$ implies $(U, j) \in \mathcal{W}'$. By Lemma 4.3, there exists a linear realization R of $\mathcal{W}$ starting with Y_U. Since the order obtained by moving j to the position directly after Y_U in R is not a realization, there exists a waiting condition $(X, j) \in \mathcal{W}'$ with $X \subseteq U \cup Z_U$. We show next that $U \subseteq X$. By minimality of $\mathcal{W}'$ this implies $X = U$, which concludes the proof.

Assume that $X \not\supseteq U$ and let $i \in U \setminus X$. We obtain a linear realization R' by moving i to the position directly after Y_U in R; otherwise, there exists a waiting condition $(Z, i) \in \mathcal{W}$ with $Z \subseteq U \cup Z_U$. Since all jobs in Z_U have to wait for a job in U, the waiting condition $(U \setminus \{i\}, i)$, and thus $(U \setminus \{i\}, j)$, is implied by $\mathcal{W}$, which is a contradiction of the minimality of $\mathcal{W}$.

Since moving j to the position directly after $Y_U \cup \{i\}$ in R' violates the waiting condition (X, j), there exists a waiting condition $(Z, j) \in \mathcal{W}$ with $Z \subseteq (U \setminus \{i\}) \cup Z_U$. However, by Lemma 5.3, the set $\mathcal{W} \setminus \{(U, j)\}$ implies the waiting condition (U, j), which is a contradiction of the minimality of $\mathcal{W}$. □

Let us next consider the following straightforward polynomial-time algorithm to compute a minimal reduction of a set $\mathcal{W}$ of waiting conditions. For each $(X, j) \in \mathcal{W}$, apply Algorithm 1 with input $V \setminus X$ and $\mathcal{W}_{V \setminus X}$. If, besides (X, j), some other waiting condition prevents j from being added to L, then remove (X, j) from $\mathcal{W}$. Otherwise, remove all i from X, which cannot be added to L because some waiting condition of $\mathcal{W}$ is violated. Finally, output the resulting set of waiting conditions. An implementation of this rough scheme is given in Algorithm 2. There, $a(j)$, $j \in V$, denotes the number of waiting conditions of the form (X, j) that are left in $\mathcal{W}_{V \setminus U}$ after Algorithm 1 was called with input $V \setminus U$ and $\mathcal{W}_{V \setminus U}$. Notice that $a(j)$ is computed within the execution of Algorithm 1. In the following theorem we prove the correctness of the algorithm (as defined earlier, A is the set of arcs in the digraph induced by $\mathcal{W}$).

THEOREM 5.4. *Algorithm* 2 *computes the minimal reduction of a set* $\mathcal{W}$ *of waiting conditions in* $O(|\mathcal{W}| \cdot |A|)$ *time.*

Proof. We first show that, through the procedure, the transformed set of waiting conditions is equivalent to $\mathcal{W}$ given as input. We then argue that, once the algorithm has finished, the obtained set of waiting conditions is minimal.

Denote by $\mathcal{W}^k$, $k \in \{1, \dots, |\mathcal{W}|\}$, the set of waiting conditions after the kth iteration of the outer for-loop of Algorithm 2. Furthermore, let $\mathcal{W}^0 := \mathcal{W}$. Suppose that some (U, j) is removed from $\mathcal{W}^{k-1}$ in the kth iteration of the algorithm. Since $a(j) > 1$ in the kth iteration, there exists a waiting condition $(X, j) \in \mathcal{W}^{k-1}$ with $X \neq U$ and $X \subset U \cup Z_U$. With Lemma 5.3, (U, j) is implied by $\mathcal{W}^k = \mathcal{W}^{k-1} \setminus \{(U, j)\}$ and can thus be deleted from $\mathcal{W}^{k-1}$. Now assume that, in (U, j), some job i was deleted from U in the kth iteration. Then $a(i) > 0$ and with Corollary 4.6 it follows that $(U \setminus \{i\}, i)$ is implied by $\mathcal{W}^{k-1}$. Together with (U, j) this shows that $(U \setminus \{i\}, j)$ is implied by $\mathcal{W}^{k-1}$. Thus, $\mathcal{W}^{k-1}$ is equivalent to $\mathcal{W}^k$ for all $k \in \{1, \dots, |\mathcal{W}|\}$, which directly implies that $\mathcal{W}$ and $\mathcal{W}' := \mathcal{W}^{|\mathcal{W}|}$ are equivalent.

We now show that $\mathcal{W}'$ is minimal. Let us first suppose that some $(U, j) \in \mathcal{W}'$ is implied by $\mathcal{W}' \setminus \{(U, j)\}$. Then, by Lemma 5.3, there exists another waiting condition $(X, j) \in \mathcal{W}' \setminus \{(U, j)\}$ with $X \subseteq U \cup Z_U$. Notice that Z_U in dependence of $\mathcal{W}' \setminus \{(U, j)\}$ and all $\mathcal{W}^k$, $k \in \{0, \dots, |\mathcal{W}|\}$, is constant because the associated sets of realizations coincide. The waiting conditions (U, j) and (X, j) have been constructed in some iterations k and k', respectively, in which waiting conditions $(U', j) \in \mathcal{W}$ with $U \subseteq U'$ and $(X', j) \in \mathcal{W}$ with $X \subseteq X'$ have been treated by the algorithm. If $(X, j) \in \mathcal{W}^{k-1}$, then, by Lemma 5.3, (U', j) would have been removed from $\mathcal{W}^{k-1}$. Consequently, $k' > k$. Since U was obtained from U' (in the kth iteration of the algorithm), by Corollary 4.6, there exists a linear realization R which starts with Y_U and is followed first by an *arbitrary* job $i \in U$ and then by job j. Since, by assumption, $\mathcal{W}^{k-1}$ and $\mathcal{W}' \setminus \{(U, j)\}$ are equivalent, (X, j) must be respected by R; hence $U \subseteq X$. But then (X', j) is deleted in iteration $k' > k$, a contradiction. Next, suppose that $\mathcal{W}'$ contains a waiting condition (U, j) such that, for some $i \in U$, the waiting condition $(U \setminus \{i\}, j)$ is implied by $\mathcal{W}'$. Since i was not removed from U' in the kth iteration of the algorithm, it follows from Corollary 4.6 that $(U' \setminus \{i\}, j)$ is not implied by $\mathcal{W}^{k-1}$. Thus there exists a linear realization $R = (V, \prec_R)$ of $\mathcal{W}^{k-1}$ with $j \prec_R (U' \setminus \{i\})$ and in particular $j \prec_R (U \setminus \{i\})$. Since R is also a realization for $\mathcal{W}'$, the waiting condition $(U \setminus \{i\}, j)$ is not implied by $\mathcal{W}'$—a contradiction.

The above argumentation shows that $\mathcal{W}'$ is minimal and thus Algorithm 2 computes a minimal reduction of $\mathcal{W}$. Finally, the running time follows from the fact that Algorithm 1 is called $|\mathcal{W}|$ times. ∎

Notice that the cardinality of a minimal set of waiting conditions might still be exponential in the number of jobs $|V|$: Let $V = \{1, 2, \dots, 2\ell + 1\}$; in order to model the constraint that job $2\ell + 1$ can be planned only after at least ℓ other jobs, we need exactly $\binom{2\ell}{\ell}$ waiting conditions.

6. An NP-complete generalization. Suppose that we generalize the definition of waiting conditions from (X, j), $X \subset V$, $j \in V \setminus X$ to (X, X') with $X, X' \subset V$ and $X \cap X' = \emptyset$. The generalized waiting condition (X, X') is fulfilled if at least one job $j \in X'$ is waiting for at least one job $i \in X$. We show in the theorem below that the problems considered in sections 3 and 4 become NP-complete in this generalized setting.

THEOREM 6.1. *Given a set of jobs with generalized waiting conditions, it is NP-complete to decide whether or not a waiting condition* $(\{i\}, \{j\})$ *is implied for two jobs* i *and* j.

Proof. We construct a reduction from the satisfiability problem SAT. Given an instance of SAT, we introduce for each Boolean variable x two jobs which correspond to the two literals x and $\bar{x}$ (negation of x); to keep notation simple, we denote these jobs also by x and $\bar{x}$. Moreover, for each clause C we introduce a corresponding job (also denoted by C) and a waiting condition $(X_C, \{C\})$, where X_C denotes the set of literals in clause C; in other words, job C may not be started before at least one job corresponding to a literal of clause C has been completed. Finally, we introduce two additional jobs s and t together with the following waiting conditions: For each variable x, at least one of the jobs x and $\bar{x}$ has to wait for s; i.e., we have the waiting condition $(\{s\}, \{x, \bar{x}\})$. For each clause C, job t has to wait for the corresponding job, which is given by the waiting condition $(\{C\}, \{t\})$.

It is easy to check that in the constructed scheduling instance job t has to wait for job s if and only if the underlying instance of SAT does not have a satisfying truth assignment. If there is a satisfying truth assignment, then we can construct a linear realization where t precedes s in the following way: First we take all jobs corresponding to literals with value "true" in an arbitrary order; next we append all jobs corresponding to clauses in some order; afterwards we add t, then s, and finally all remaining jobs corresponding to literals with the value "false." On the other hand, if there is a linear realization where t precedes s, we can define a corresponding satisfying truth assignment in the following way: For each variable x, assign x the value true (false) if the job corresponding to x ($\bar{x}$) precedes s; notice that at most one of the two cases can happen: if neither job x nor $\bar{x}$ precedes s, we assign an arbitrary value to the variable x. □

As a consequence of Theorem 6.1, we obtain that the problem of deciding feasibility for a set of generalized waiting conditions is also NP-complete. To see this, add to the construction in the proof the waiting condition $(\{t\}, \{s\})$. Then the given instance of SAT is feasible if and only if the constructed instance of the scheduling problem with generalized waiting conditions is feasible.

7. Computing earliest job start times. This section is concerned with the computation of earliest job start times subject to AND/OR precedence constraints. The underlying problem is to find a solution to a system of *min-max-inequalities*. There are several other applications of such systems of inequalities; we will mention some of them below.

7.1. Problem definition and related work. For the remainder of the paper we assume that together with each waiting condition $w = (X, j) \in \mathcal{W}$ and each job $i \in X$ we are given an integral time lag $-M < d_{iw} < M$, $M \geqslant 0$. We aim at finding a vector of earliest start times $S = (S_1, \ldots, S_n)$ such that for each waiting condition $(X, j) \in \mathcal{W}$ the constraint

$$S_j \;\geqslant\; \min_{i \in X}(S_i + d_{iw}) \tag{7.1}$$

is satisfied. Job processing times p_i can be modeled by setting $d_{iw} := p_i$ for all $w = (X, j)$ with $i \in X$. Negative values d_{iw} represent so-called *maximal time lags* that define latest possible start times of jobs $i \in X$ relative to j.

In order to simplify the presentation, we sometimes interpret nodes of the digraph D that represent waiting conditions as dummy jobs. We then assume that the vector S also contains start times of these dummy jobs and constraint (7.1) is replaced by

$$S_w \;\geqslant\; \min_{i \in X}(S_i + d_{iw}) \qquad \text{and} \qquad S_j \;\geqslant\; S_w.$$

We call the jobs in V AND-*nodes* and the jobs in $\mathcal{W}$ OR-*nodes* of the digraph D. We assume that a dummy AND-node s precedes all other AND-nodes; i.e., we introduce a waiting condition $(\{s\}, j)$ for all $j \in V$. In D, time lags can easily be integrated by associating each d_{iw} as a weight to the arc (i, w); see Figure 2.1.

The problem of finding earliest start times can then be formulated on D as follows: Find a componentwise minimal schedule $S \in \mathbb{Z}^{|\mathcal{V}|}$ fulfilling $S_s \geqslant 0$ and

$$\text{(ES)} \qquad \begin{aligned} S_j &\geqslant \max_{(w,j)\in A} (S_w + d_{wj}), \qquad j \in V, \\ S_w &\geqslant \min_{(j,w)\in A} (S_j + d_{jw}), \qquad w \in \mathcal{W}. \end{aligned}$$

In the above formula we added the term d_{wj} for symmetry reasons. Without loss of generality we assume that $d_{wj} = 0$. The case $d_{wj} \neq 0$ can be handled by replacing $d_{wj} \neq 0$ by 0 and d_{iw} by $d_{iw} + d_{wj}$ for all $i \in in(w)$. Besides schedules $S \in \mathbb{Z}^{|\mathcal{V}|}$ we also consider *partial schedules* $S \in (\mathbb{Z} \cup \{\infty\})^{|\mathcal{V}|}$ where the start time of a job may be infinite, meaning that the job is not planned. As usual, a (partial) schedule fulfilling the constraints of (ES) is called *feasible*. In particular, the partial schedule $S = (\infty, \ldots, \infty)$ fulfills all inequalities of (ES) and is thus feasible. Moreover, it is easy to see that if S' and S'' are feasible partial schedules, then their componentwise minimum $S := \min\{S', S''\}$ is also feasible. In particular, there always exists a (unique) componentwise minimal partial schedule S^*, called the *optimal* partial schedule (notice that $S^* \geqslant 0$ for all AND-nodes). It follows that, instead of considering the above system of inequalities, we alternatively may consider the corresponding system of equations (which is obtained from (ES) by replacing each "$\geqslant$" by "$=$").

Presuming different restrictions on the range of arc weights, several algorithms have been suggested to solve (ES). Note that all restrictions on arc weights are meant to refer to arcs (j, w) between AND-nodes j and OR-nodes w only. For the case of nonnegative arc weights without cycles of zero length in D, a modification of Dijkstra's shortest path algorithm can be applied. An algorithm suggested by Knuth [16] has running time $O(|\mathcal{V}| \log |\mathcal{V}| + |A|)$. Other approaches are proposed in [6], [10], and, in the context of resource-constrained project scheduling, [14] (see also [22]). Levner, Sung, and Vlach [18] consider a generalized model of AND/OR precedence constraints where a so-called *threshold value* $1 \leqslant \ell_w \leqslant |X|$ is associated with each waiting condition $w = (X, j)$, indicating that j may start if at least ℓ_w jobs from X have been completed. They show that Dijkstra's shortest path algorithm can also be generalized to solve their model (with positive arc weights). For a discussion of the case with nonnegative arc weights *and* cycles of zero length we refer to subsection 7.4. The general case $-M < d_{jw} < M$ is a frequently studied problem with applications in many different areas, e.g., *game theory* [29] and *interface timing verification* (see [24] and [20]). Moreover, there are applications stemming from online optimization; see [29, section 7] for a collection of examples. Interestingly, although a pseudopolynomial algorithm to solve this case of (ES) is easily obtained, no algorithm polynomial in $|\mathcal{V}|$ and $\log(M)$ is currently known.

7.2. Arbitrary arc weights. In this section we study the case of arbitrary arc weights $-M < d_{jw} < M$.

7.2.1. Feasibility. For arbitrary arc weights the feasibility results stated in section 3 are no longer valid. They are based on the requirement that all $d_{jw} = p_j > 0$, and, consequently, an AND-node j can start if and only if for all $(X, j) \in \mathcal{W}$ at least one $i \in X$ has previously been started (compare with condition (2.1)). However, if we

allow $d_{jw} \leqslant 0$, this is no longer the case. In what follows we derive a necessary and sufficient feasibility criterion for (ES) with arbitrary arc weights which generalizes the feasibility criterion given in Lemma 3.2. For the remainder of the section we call a set $\mathcal{W}$ of waiting conditions *feasible* if and only if there exists a feasible schedule for (ES).

Before we derive the criterion, we discuss how a given instance can be simplified without changing the optimal partial schedule S^*. First, we make the problem more restrictive by removing all but one incoming arc of each OR-node w. If the remaining arc (j, w) fulfills $S_j^* + d_{jw} \leqslant S_w^*$, clearly, all inequalities of (ES) are still satisfied. Consequently, S^* and the optimal (partial) schedule of the more restrictive instance coincide. In a similar fashion we can remove all but one incoming arc (w, j) of each AND-node j without changing the earliest start times. However, removing such arcs means relaxing the problem, and some more work has to be done in order to obtain the desired result.

LEMMA 7.1. *For each digraph D representing a set of* AND/OR *precedence constraints, there exists a subdigraph $\bar{D}$ on the same set $\mathcal{V}$ of nodes with $|in_{\bar{D}}(j)| \leqslant 1$ for all* AND*-nodes $j \in V$ such that $S^* = \bar{S}^*$, where $\bar{S}^*$ denotes the optimal (partial) schedule of $\bar{D}$.*

Proof. We construct $\bar{D}$ by iteratively removing arcs (w, j) from D that do not affect the earliest start time of the AND-node j. By contradiction, assume that once all such arcs have been removed, there is some AND-node j with $|in_{\bar{D}}(j)| > 1$. Thus, removing any incoming arc of j reduces the earliest start time of j. Denote by S^1 and S^2 the optimal (partial) schedules obtained if two different incoming arcs (w_1, j) and (w_2, j) are removed from $\bar{D}$; then $S_j^* > S_j^1$ and $S_j^* > S_j^2$. Without loss of generality let $S_j^1 \leqslant S_j^2$; we define a new (partial) schedule S through

$$S_i \;:=\; \min\{S_i^1 + S_j^2 - S_j^1, S_i^2\} \qquad \text{for all } i \in \mathcal{V}.$$

By definition, $S \leqslant S^2$ and $S_j = S_j^2$. For each arc (w, j) with $w \neq w_2$ we have $S_j^2 \geqslant S_w^2$, which yields $S_j = S_j^2 \geqslant S_w^2 \geqslant S_w$. For $w = w_2$ we get $S_j = S_j^1 + S_j^2 - S_j^1 \geqslant S_w^1 + S_j^2 - S_j^1 \geqslant S_w$. We obtain $S_j \geqslant \max_{(w,j)\in A}(S_w)$. Furthermore, S also fulfills all other inequalities of (ES), because both $S^1 + S_j^2 - S_j^1$ and S^2 fulfill the inequalities and so does its minimum S. Consequently, S is a feasible (partial) schedule, which is a contradiction of the minimality of S^* since $S_j < S_j^*$. ∎

For the subsequent presentation, recall the definition of a (generalized) cycle from section 2. Note that we assume all cycles to be directed cycles.

COROLLARY 7.2. *Let $\bar{D}$ be as in Lemma* 7.1*. Then all cycles in $\bar{D}$ have strictly positive length.*

Proof. Assume that there is a cycle $(w_1, j_1, w_2, j_2, \dots, w_k, j_k, w_1)$ of nonpositive length in $\bar{D}$. By definition of $\bar{D}$, (w_ℓ, j_ℓ) is the only incoming arc for node j_ℓ, $\ell = 1, \dots, k$. Thus, one can construct a feasible partial schedule for $\bar{D}$ satisfying

$$S_{w_1} = S_{j_1} = -1 \qquad \text{and} \qquad S_{w_\ell} = S_{j_\ell} = -1 + \sum_{q=2}^{\ell} d_{j_{q-1}w_q} \quad \text{for } \ell = 2, \dots, k.$$

With Lemma 7.1, this is also possible for the original digraph D, which yields a contradiction of the requirement $S_{j_1}^* \geqslant 0$. ∎

LEMMA 7.3. *A set of* AND/OR *precedence constraints with arbitrary arc weights is feasible if and only if each generalized cycle in D contains a cycle of nonpositive length.*

Proof. Let C be a generalized cycle which contains only cycles of positive length and suppose that some node $v \in C$ can be scheduled at $S_v < \infty$. Since v has at least one incoming arc, there must exist a node $u \in in(v)$ with $S_v \geqslant S_u + d_{uv}$. Iterating this argument, since $|C|$ is finite, we obtain a cycle in C with nonpositive length—a contradiction.

Conversely, suppose that the given instance is infeasible. Let $Z \neq \emptyset$ denote the set of nodes whose earliest start times are ∞. By Lemma 7.1, we can relax the problem by removing all but one incoming arc of each AND-node such that the earliest start times remain unchanged for the resulting digraph $\bar{D}$. Remove all OR-nodes from Z whose out-degree is 0 in $\bar{D}$ and denote the resulting set of nodes by Z'. Then Z' induces a generalized cycle C in D. Moreover, by definition of Z', every cycle in C is also contained in $\bar{D}$ and therefore has positive length by Corollary 7.2. ∎

Lemma 7.3 reduces to Lemma 3.2 if all the arc weights d_{jw} are strictly positive. Lemma 7.3 enables us to show that the decision problem of (ES) is in both NP and co-NP. The decision problem corresponding to (ES) is to decide whether or not a feasible schedule $S < \infty$ for (ES) exists.

LEMMA 7.4. *The decision problem corresponding to* (ES) *is in NP ∩ co-NP.*

Proof. It is clear that the decision problem corresponding to (ES) is in NP because, for a given feasible schedule S of some instance I, it is easy to verify all constraints of $\mathcal{W}$. Moreover, it follows from Lemma 7.3 that the decision problem corresponding to (ES) is in co-NP. We can guess a generalized cycle violating the condition in Lemma 7.3, which can be verified in polynomial time by, for example, some standard minimum mean weight cycle algorithm. ∎

7.2.2. A simple pseudopolynomial time algorithm. For the case of (ES) with arbitrary arc weights several pseudopolynomial algorithms (partly independent of each other) have been proposed; see, e.g., [5] and [25] as well as [24] and [29]. A very simple (pseudopolynomial) algorithm is as follows: First, initialize $S_j := 0$ for all $j \in V$. Then, while S violates some waiting condition $w = (X, j) \in \mathcal{W}$, set $S_j := \min_{i \in X}(S_i + d_{iw})$. If S_j becomes larger than a given time horizon T, then stop and return that the given instance is infeasible. The time horizon T can be chosen as $T := \sum_{j \in V}(\max_{w \in out(j)} |d_{jw}|)$. One can show straightforwardly by induction that $S \leqslant S^*$ in each iteration of the algorithm. If the recurrence stops with $S_j \leqslant T$ for all $j \in V$, then all constraints are obviously fulfilled. Hence $S \geqslant S^*$ and thus we have $S = S^*$. Moreover, at least one start time of a job is increased by 1 in each iteration. Thus the number of iterations is $O(|V| \cdot T)$. Finding a violated waiting condition obviously requires at most $O(|A|)$ time and thus the total complexity is $O(|V| \cdot |A| \cdot T)$. Note that for the special case that D is acyclic, earliest job start times can easily be computed in linear time along a topological sort. Moreover, if each AND-node (OR-node) has at most one incoming arc, node start times can be computed by, for example, a slight modification of the Bellman–Ford shortest (longest) path algorithm in time $O(|V| \cdot |A|)$.

7.2.3. A game-theoretic application. We next consider a class of two-player games played on bipartite directed graphs which are directly related to the problem (ES). There exists substantial literature on different variations of this game; see, e.g., [29], [8], [15], [28], and references therein. Each player is identified with one of the node partitions of the graph. The game starts at a fixed node j_0 and the player associated with that node chooses an incoming arc (w_0, j_0). Then, at node w_0, the other player chooses an incoming arc (j_1, w_0) and so on. The objective and the stopping criterion depend on the considered variation of the game.

One variant is the so-called *mean payoff game* (MPG), where an integer weight is associated to each arc of the digraph. Furthermore, it is assumed that each node has at least one incoming arc. The MPG is finished as soon as the path P resulting from the game contains a cycle and the *outcome* ν of the game is the mean weight of the arcs of that cycle. One player wants to maximize the outcome, while the other player wants to minimize it. It has been shown by Ehrenfeucht and Mycielski [8] that both players have positional optimal strategies; that is, the decisions of both players depend on neither previous choices nor the start node j_0. In the following we always assume that j_0 is associated with the maximization player.

The decision problem corresponding to MPG is to decide whether the outcome of the game is positive. Zwick and Paterson [29] have noted that this problem is in NP $\cap$ co-NP. Even more, Jurdziński [15] showed that the problem is in UP $\cap$ co-UP. It seems to be intuitively clear that MPG and (ES) are closely related. We next show that this is indeed the case.

LEMMA 7.5. *The decision problems corresponding to MPG and* (ES) *are polynomially equivalent.*

Proof. Given an instance of (ES), we construct an instance of MPG in the following way. First, we add an additional job t and a waiting condition $w_j = (\{j\}, t)$ with $d_{jw_j} = 0$ for every job $j \in V$; moreover, we add a waiting condition $w = (\{t\}, s)$ with $d_{tw} = -T$, where T is the time horizon discussed in section 7.2.2. Notice that there exists a feasible schedule for the original instance of (ES) if and only if the earliest start time of the new job t is finite. The game digraph D is now the digraph representing the new scheduling instance. The starting node is $j_0 := t$ and the maximization player starts. We show that the set of AND/OR precedence constraints is feasible if and only if $\nu \leqslant 0$.

Only if: Based on an optimal schedule $S^* < \infty$, we give a strategy for the minimization player which ensures $\nu \leqslant 0$: In each OR-node w, choose an incoming arc (j, w) with $S^*_j + d_{jw} = S^*_w$. Then, for two vertices v_1 and v_2 on the path formed by the game, the weight of the (directed) subpath from v_1 to v_2 is at most $S^*_{v_2} - S^*_{v_1}$ (for each arc (w, j) on the path we have $S^*_j \geqslant S^*_w$ and for each arc (j, w) on the path we have $S^*_w = S^*_j + d_{jw}$). In particular, the length of the cycle terminating the game is at most 0 (choose $v_1 = v_2$).

If: For an infeasible scheduling instance it follows from Lemma 7.3 that there exists a generalized cycle C in D which contains only cycles of positive length. Without loss of generality, C contains the node t (if t is not in C, then consider the generalized cycle where all waiting conditions $(\{j\}, t)$ with j in C are added to C). We give a strategy for the maximization player which ensures $\nu > 0$: In each step, choose an arc which starts at a node in C. Such an arc always exists by the definition of generalized cycles. Moreover, again by the definition of generalized cycles, the minimization player is not able to leave C. This yields $\nu > 0$.

Given a digraph D representing an instance of MPG, we construct an instance I of (ES) in the following way. First, we assume without loss of generality that every node in D associated to the minimization player has out-degree one—it is an easy observation that a node with out-degree $q > 1$ can be replaced by q copies with out-degree one without changing the outcome of the game. Moreover, we assume that the weight of the only arc (w, j) leaving a node w associated to the minimization player is 0. The case of $d_{wj} \neq 0$ can be handled by replacing $d_{wj} \neq 0$ by 0 and d_{iw} by $d_{iw} + d_{wj}$ for all $i \in in(w)$; recall the transformation in the second paragraph of section 7.1.

The set V of jobs in the instance I of (ES) is the set of nodes associated to the maximization player. For each node w of the minimization player, we introduce a waiting condition $w = (in_D(w), j)$ where $out_D(w) = \{j\}$. The time lag d_{iw} for $i \in in_D(w)$ is given by the corresponding arc weight in D. Moreover, we add a dummy start node a preceding all other AND-nodes. We refer to this scheduling instance as I'. Finally, in order to obtain the instance I, we modify every waiting condition $w = (X, j)$ with $j \neq j_0$ and $j_0 \notin X$ by adding j_0 to X and setting $d_{j_0 w} = T + 1$; in other words, if job j_0 can be planned, then all other jobs can be planned, too. In particular, instance I is feasible if and only if the earliest start time $S^*_{j_0}$ of job j_0 in instance I' is finite. Thus, it remains to show that $S^*_{j_0} < \infty$ if and only if $\nu \leqslant 0$.

Only if: Consider instance I'. Based on the optimal partial schedule S^* of instance I' ($S_{j_0} < \infty$), we give a strategy for the minimization player which ensures $\nu \leqslant 0$: In each OR-node w with $S^*_w < \infty$, choose an incoming arc (j, w) with $S^*_j + d_{jw} = S^*_w$. As a consequence, $S^*_i < \infty$ for all nodes i visited during the game. Moreover, for two vertices v_1 and v_2 on the path formed by the game, the weight of the (directed) subpath from v_1 to v_2 is at most $S^*_{v_2} - S^*_{v_1}$. In particular, the length of the cycle terminating the game is at most 0.

If: For an infeasible scheduling instance I, by Lemma 7.3, there exists a generalized cycle C in the corresponding digraph D_I which contains only cycles of positive length. Without loss of generality, C contains the node j_0. Notice that C also forms a generalized cycle for the digraph D. We give a strategy for the maximization player which ensures $\nu > 0$: In each step, choose an arc which starts at a node in C. Such an arc always exists by the definition of generalized cycles. Moreover, again by the definition of generalized cycles, the minimization player is not able to leave C. This yields $\nu > 0$. □

With Lemma 7.5, it follows from [15] that the decision problem corresponding to the scheduling problem (ES) is in UP ∩ co-UP. Moreover, MPG and hence also (ES) can be computed in subexponential time: Zwick and Paterson [29] have shown that so-called *simple stochastic games* are at least as hard as MPGs. The outcome of simple stochastic games can be computed in subexponential time, as has been shown by Ludwig [19]. Despite these observations, there is no polynomial-time algorithm for (ES) with arbitrary arc weights known.

7.3. Positive arc weights. In this section we restrict ourselves to the case of positive arc weights or, more generally, nonnegative arc weights without cycles of length 0 in D. As in [16] and [6] we basically obtain a slight generalization of Dijkstra's shortest path algorithm. During the course of the algorithm we call a job *planned* as soon as its start time has been fixed.

The algorithm maintains a partial schedule $S \in (\mathbb{Z} \cup \{\infty\})^{|\mathcal{V}|}$ where initially $S_w = \infty$ for all OR-nodes w. All OR-nodes which are not yet planned are maintained in a heap where the sorting key for node w is its tentative start time S_w (initially $S_w = \infty$).

Having set $S_s = 0$ (and also $S_w = 0$ for all $w \in out(s)$) we proceed over time by always choosing an OR-node $w = (X, j)$ with minimum start time from the heap and plan w at its tentative start time S_w. If all other OR-nodes (X', j) preceding j have already been planned, we also plan j at the current time. In this case, the start times of all OR-nodes w' with $w' \in out(j)$ are updated to $S_{w'} := \min\{S_{w'}, S_j + d_{jw'}\}$. If after termination some OR-node w is started at $S_w = \infty$, the considered instance is infeasible. Implementational details are given in Algorithm 3.

If we apply Algorithm 3 to Example 1 (arc weights are given in Figure 2.1), we

Algorithm 3: Computation of earliest job start times for digraphs without cycles of length 0.

Input : A directed graph D representing a set V of jobs and waiting conditions $\mathcal{W}$ with positive arc weights on the arcs in $V \times \mathcal{W}$.

Output: A feasible (partial) schedule $S \in (\mathbb{Z} \cup \{\infty\})^{|\mathcal{V}|}$.

```
Heap := ∅;
for AND-nodes j ∈ V do a(j) := |in(j)|;
1 S_s := 0;    // AND-node s is planned at time 0
for OR-nodes w ∈ W do
    if w ∈ out(s) then insert w in Heap with key S_w := 0;
    else insert w in Heap with key S_w := ∞;

while Heap ≠ ∅ do
2   remove next OR-node w_0 = (X, j) from Heap;  // OR-node is planned
    reduce a(j) by 1;
    if a(j) = 0 then
3       S_j := max_{w∈in(j)} S_w; // AND-node is planned
        for OR-nodes w ∈ out(j) do
            S_w := min{S_w, S_j + d_jw};
            decrease key of w in Heap to S_w;
    delete node w_0 and all incident arcs from D;
return S;
```

obtain the start times $(0, 0, 0, 2, 3, 2, 3)$ for AND-nodes and $(2, 1, 2, 3, 3)$ for OR-nodes. One possible order in which start times get fixed is $j_1 \prec j_2 \prec j_3 \prec w_2 \prec w_1 \prec j_4 \prec w_3 \prec j_6 \prec w_5 \prec j_7 \prec w_4 \prec j_5$.

THEOREM 7.6. *For a given set of* AND/OR *precedence constraints represented by a digraph $D = (V \cup \mathcal{W}, A)$ with nonnegative arc weights and without cycles of length* 0*, Algorithm* 3 *computes an optimal partial schedule S. In particular, the instance is infeasible if and only if $S_w = \infty$ for some* OR*-node w.*

Proof. In this proof we say that an AND-node is *planned* if its start time is fixed (lines 1 and 3), while an OR-node is planned if it is removed from the heap (line 2).

By construction of Algorithm 3, S is a feasible partial schedule. Assume that S is not optimal and let v be a node with $S_v > S^*_v$ and S^*_v minimal. If v is an AND-node, then there must exist an OR-node $w = (X, v)$ with $S_w = S_v > S^*_v \geqslant S^*_w$ and we set $v := w$. Otherwise, if v is an OR-node (X, j), then there must exist an AND-node $i \in X$ with $S^*_v = S^*_i + d_{iv}$ (otherwise S^* is not minimal). Moreover, $S_i > S^*_i$. To see this suppose that $S_i = S^*_i$. Then, at the stage of Algorithm 3 where S_i is planned, v has already been removed from D. Since start times (in the order in which nodes are planned) are nondecreasing we have $S_v \leqslant S^*_i$, and hence $S_v \leqslant S_v + d_{iv} \leqslant S^*_i + d_{iv} = S^*_v$, a contradiction of $S_v > S^*_v$.

Since v was chosen such that S^*_v is minimal, we have $S^*_i \geqslant S^*_v = S^*_i + d_{iv}$. Thus $d_{iv} = 0$ and we set $v := i$. Iterating this argument, we can construct a cycle (since there are only finitely many nodes) of length 0—a contradiction. □

LEMMA 7.7. *Algorithm* 3 *can be implemented to run in* $O(|\mathcal{W}| \log |\mathcal{W}| + |A| + |V|)$ *time.*

Proof. Since each OR-node enters the heap precisely once, the while-loop is exe-

cuted $|\mathcal{W}|$ times. Each AND-node is planned only once and therefore the inner for-loop is executed at most $|A|$ times. If we choose a Fibonacci-heap for maintaining the OR-nodes, the cost of line 2 is $\log|\mathcal{W}|$ and we obtain the claimed running time. □

In contrast to previously proposed algorithms, the heap data structure maintains only OR-nodes, which leads to the improved running time $O(|\mathcal{W}|\log|\mathcal{W}|+|A|+|V|)$ instead of $O((|V|+|\mathcal{W}|)\log(|V|+|\mathcal{W}|)+|A|)$.

7.4. Nonnegative arc weights. As an extension of the case discussed in section 7.3 we present an $O(|V|+|A|\cdot|\mathcal{W}|)$ algorithm that is capable of dealing with arbitrary arc weights $d_{jw} \geqslant 0$ and thus with cycles of length 0 in D. Levner, Sung, and Vlach [18] observed that the algorithm proposed by Knuth [16] fails to compute earliest job start times when cycles of length 0 occur.

After submission of this paper for publication, we learned that Adelson-Velsky and Levner [1] also discovered a polynomial-time algorithm for the problem. Their algorithm proceeds over time starting at time $t = 0$. For each t, the algorithm determines all jobs to be started at t by an appropriate labeling procedure which runs in $O(|A|)$ time. Thereafter, t is increased to the next tentative start time of some job. It may happen, however, that for some t considered, no job is started. Adelson-Velsky and Levner [1], [2] show that the number of times t is increased is bounded by $|A|$. Consequently, they obtain an $O(|A|^2)$ algorithm. Due to a more careful update of (tentative) start times of jobs, our algorithm's worst-case running time is $O(|V|+|A|\cdot|\mathcal{W}|)$.

Adelson-Velsky and Levner [2] misleadingly claim that our algorithm solves only a special case of the problem (in which only a single arc leaves each OR-node). A digraph D with multiple arcs (w,j) leaving an OR-node w can obviously be polynomially transformed into a digraph where only a single arc leaves each OR-node as follows: Add a new AND-node i, a new arc (w,i), and add a waiting condition $(i,\{j\})$ for each arc (w,j). Then remove all arcs (w,j). With this transformation our algorithm's worst-case complexity is also $O(|A|^2)$ in the original input size. However, in Lemma 7.9 below we argue that our algorithm can also handle the case of multiple arcs leaving an OR-node directly without a transformation.

A rough scheme of the algorithm is as follows. Analogously to Algorithm 3 we maintain all OR-nodes w in a heap where the sorting key is its tentative start time S_w (initially $S_w = \infty$). Furthermore, whenever an AND-node j is planned, the start times of all OR-nodes $w \in out(j)$ are updated to $S_w = \min\{S_w, S_j + d_{jw}\}$. We proceed over time starting at $t = 0$. For the current time t we compute a set U of (nonstarted) nodes that can be started at t. The set U is computed by maintaining the induced subgraph D^0 of D where all planned nodes and all arcs of positive weight have been deleted. In D^0, the set U is computed as a set of nodes such that for each AND-node j, all predecessors $w \in in_{D^0}(j)$ are also in U, and for each OR-node w, at least one predecessor $j \in in_{D^0}(w)$ is also in U. Then, as we will prove in Theorem 7.8 below, all nodes of U can be started at the current time t. Next we remove a new OR-node w from the heap and increase t to S_w. If $t = \infty$, the algorithm stops. Then either no OR-node was left in the heap (and we have computed a feasible schedule) or all OR-nodes w in the heap fulfill $S_w = \infty$ (indicating that the given instance is infeasible). Details are provided in Algorithm 4.

If we apply Algorithm 4 to Example 1 with arc weights as in Figure 2.1 except $d_{5w_1} = 0$ and $d_{4w_4} = 0$, we get the following:

Iteration 1: $U = \{j_1, j_2, j_3\}$, $w = w_2$, $t := 1$.

Iteration 2: $U = \{j_4, j_5, w_1, w_4\}$, $w = w_3$, $t := 2$.

Algorithm 4: Computation of earliest job start times for nonnegative time lags.

Input : A directed graph D representing a set V of jobs and waiting conditions $\mathcal{W}$ with nonnegative arc weights on the arcs in $V \times \mathcal{W}$.

Output: A feasible (partial) schedule $S \in (\mathbb{Z} \cup \{\infty\})^{|\mathcal{V}|}$.

```
set D^0 := D and remove all arcs with positive weight from D^0;
t := 0;
Heap := ∅;
for OR-nodes w ∈ W do
    S_w := ∞;
    insert w in Heap with key S_w;
while t < ∞ do
    compute U ⊆ V(D^0) maximal with
1       (in_{D^0}(j) ⊆ U   ∀ j ∈ U ∩ V) and (in_{D^0}(w) ∩ U ≠ ∅   ∀ w ∈ U ∩ W);
    for AND-nodes j ∈ U  (j ∈ U ∩ V)  do
        S_j := t;        // node j is planned at time t
        for OR-nodes w ∈ out_D(j) do
2           S_w := min{S_w, S_j + d_jw};
3           decrease key of w in Heap to S_w;
    for OR-nodes w ∈ U  (w ∈ U ∩ W)  do
4       S_w := t;        // node w is planned at time t
        remove w from Heap;
    Delete all nodes from U in D and D^0;
    if Heap ≠ ∅ then
5       remove the next OR-node w from Heap;
6       t := S_w;
7       remove w from D and D^0;        // node w is planned at time t
    else  t := ∞;
return S;
```

Iteration 3: $U = \{j_6\}$, $w = w_5$, $t := 2$.
Iteration 4: $U = \{j_7\}$, $Heap = \emptyset$, $t := \infty$.

Thus, we obtain start times $(0, 0, 0, 1, 1, 2, 2)$ for AND-nodes and $(1, 1, 2, 1, 2)$ for OR-nodes.

THEOREM 7.8. *For a given set of* AND/OR *precedence constraints represented by a digraph $D = (V \cup \mathcal{W}, A)$ with nonnegative weights on the arcs, Algorithm* 4 *computes an optimal partial schedule S. In particular, the instance is infeasible if and only if $S_w = \infty$ for some* OR*-node w.*

Proof. We first prove that the variable t never decreases; i.e., the algorithm proceeds over time and tries to plan the jobs (and remove them from D and D^0) as early as possible in order of nondecreasing start times. Assume that t decreases in line 6 of the algorithm and let t_0 denote its value before the decrease. Since the OR-node w determining t was not chosen in line 5 during the last iteration of the while-loop (when t was set to t_0), its tentative start time S_w has decreased during the current iteration in lines 2 and 3. This is a contradiction of $S_j = t_0$ and $d_{jw} \geqslant 0$.

Observe that the start time S_i of any node $i \in \mathcal{V}$ is never changed after the node is planned (and thus deleted from the graphs D and D^0).

We can now prove that the partial schedule S returned by Algorithm 4 is feasible by verifying all constraints of (ES). By construction of the algorithm, for an AND-node $j \in V$, every OR-node $w \in in(j)$ either has been planned before or is planned together with j in the same iteration of the while-loop; this follows from the first property of U in line 1. Thus, the constraint in (ES) corresponding to j is fulfilled.

Consider now an arbitrary OR-node $w \in \mathcal{W}$. If w is planned as part of a subset U in line 4, it follows from the second property of U in line 1 that there is a job $j \in in(w)$ with $d_{jw} = 0$, and j is planned at the same time as w. Otherwise, if w is planned in line 7 and $S_w < \infty$, the start time S_w of w must have been decreased in some iteration of the while-loop in line 2; since the start time S_j of the node $j \in V$ causing the last decrease of S_w has not changed since then, $S_w = S_j + d_{jw}$ in the final partial schedule S. Thus, the constraint in (ES) corresponding to w is fulfilled.

Next we prove that the partial schedule S returned by Algorithm 4 is optimal. Let S^* be the optimal partial schedule and assume that there are nodes $i \in \mathcal{V}$ with $S_i^* < S_i$; we choose such an i' with minimum $S_{i'}^*$ and set $t_0 := S_{i'}^*$; let $U_0 = \{i \in \mathcal{V} \mid t_0 = S_i^* < S_i\}$. We distinguish two cases.

First case. In some iteration of Algorithm 4, t adopts the value t_0. We consider the iteration of the while-loop in which t is increased above t_0 in line 6. Let D^0 be the digraph at the beginning of the iteration and U the set computed at the start of this iteration. Then $U \cap U_0 = \emptyset$ and, by maximality of U, the set $U \cup U_0$ cannot satisfy the conditions in line 1. Since S^* is a feasible partial schedule, the first condition of line 1 is valid for $U \cup U_0$, i.e., $in_{D^0}(j) \subseteq U \cup U_0$ for all $j \in (U \cup U_0) \cap V$. Thus, the second condition is violated: there exists a node $w \in U_0 \cap \mathcal{W}$ with $in_{D^0}(w) \cap (U \cup U_0) = \emptyset$. Moreover, by optimality of S^*, there exists a node $j \in in_D(w)$ with $S_w^* = S_j^* + d_{jw}$, in particular $S_j^* \leqslant t_0$. We next show that $S_j = S_j^*$. If $S_j^* < t_0$, the claim follows from the minimality of t_0. Otherwise, observe that $j \notin U_0$ (if $j \in U_0$, we have $j \in in_{D^0}(w)$, which contradicts $in_{D^0}(w) \cap (U \cup U_0) = \emptyset$). Then with $S_j^* = t_0$ and $j \notin U_0$ it follows from the definition of U_0 that $S_j = S_j^*$. In particular, S_w has been set to $S_j + d_{jw} = S_w^*$ in line 2 after j was planned. Since S_w is never increased in Algorithm 4, we get a contradiction of $S_w > S_w^*$.

Second case. The variable t never adopts the value t_0 in Algorithm 4; in particular, $t_0 > 0$ and $U_0 = \{i \in \mathcal{V} \mid S_i^* = t_0\}$. Since S^* is optimal, decreasing all start times S_j^* for $j \in U_0$ to $t_0 - 1$ violates a constraint of (ES). Thus, there exists a node $w \in U_0 \cap \mathcal{W}$ such that $S_w^* = S_j^* + d_{jw}$ for some $j \in V$ with $d_{jw} > 0$, i.e., $S_j^* < t_0$. Therefore, $S_j = S_j^*$ and S_w has been set to $S_j + d_{jw} = S_w^*$ in line 2 after j was planned. Since S_w is never increased in Algorithm 4, we get a contradiction of $S_w > S_w^*$. ∎

The bottleneck for the running time of Algorithm 4 is the computation of the set U in each iteration of the while-loop. In fact, it turns out that the linear-time algorithm for checking feasibility of a set of AND/OR precedence constraints (for the case of positive arc weights) provides an elegant and fast solution for this problem.

LEMMA 7.9. *Given a bipartite digraph D with node set $N \cup M$ and arc set A, the (unique) maximal set $U \subseteq N \cup M$ with $in_D(w) \subseteq U$ for all $w \in U \cap N$ and $in_D(j) \cap U \neq \emptyset$ for all $j \in U \cap M$ can be computed in linear time.*

Proof. First, for U and U' fulfilling the conditions given in the lemma, their union $U \cup U'$ also fulfills those conditions. Therefore, such a unique maximal subset U exists.

We show that U can be computed by applying essentially Algorithm 1 to an appropriately constructed instance. Define the set $V = M$ of jobs and the following set $\mathcal{W}$ of waiting conditions: For each $w \in N$ and each $j \in out_D(w)$, introduce a waiting condition $(in_D(w), j)$. Notice that the input size of this instance is not necessarily

linear in the input size of the given digraph D since the set $in_D(w)$ is stored once for every $j \in out_D(w)$. We can avoid this undesired increase in the input size by storing, for each $w \in N$, the corresponding waiting conditions as $(in_D(w), out_D(w))$ with the interpretation that every job in the second set is a waiting job for the first set. Algorithm 1 can easily be adapted to handle this compactified input in linear time by replacing the for-loop starting in line 1 with

for *waiting conditions* $(X, Y) \in \mathcal{W}$ *with* $i \in X$ **do**
  for $j \in Y$ **do**
    decrease $a(j)$ by 1;
    if $a(j) = 0$ **then** add j to Q;
  remove (X, Y) from $\mathcal{W}$;

By Corollary 3.3, Algorithm 1 computes a set $L \subseteq V$ such that $V' := V \setminus L$ is a maximal subset of V with the following property: For all $j \in V'$ there exists a waiting condition $(X, j) \in \mathcal{W}$ with $X \subseteq V'$. Thus, the set

$$U = \big(\{w \in N \mid in(w) \subseteq V'\} \cup V'\big) \subseteq N \cup M$$

fulfills the conditions given in the lemma, i.e., $in_D(w) \subseteq U$ for all $w \in U \cap N$ and $in_D(j) \cap U \neq \emptyset$ for all $j \in U \cap M$. Assume that there is a bigger set $U^* \supset U$ that also fulfills these conditions. By construction of U, there exists a node $j \in M \cap (U^* \setminus U)$. Since the set $U^* \cap M$ of jobs has the property described in Corollary 3.3, we get a contradiction of the maximality of V'. □

With the help of this lemma, we can now give a bound on the running time of Algorithm 4.

COROLLARY 7.10. *Algorithm* 4 *can be implemented to run in* $\mathrm{O}(\,|\mathcal{W}| \cdot |A| + |V|\,)$ *time.*

Proof. First, all isolated AND-nodes are planned and thus removed from D^0 in the first iteration of the while-loop. Moreover, in each iteration, at least one OR-node is removed from D^0 and the number of iterations is thus bounded by $|\mathcal{W}|$. Finally, the running time of each iteration is dominated by the computation of U, which can be done in $\mathrm{O}(\,|A|\,)$ time. □

Notice that, in the sense of Lemma 7.9, Algorithm 4 and its worst-case complexity (Corollary 7.10) are both valid for digraphs D where OR-jobs have multiple outgoing arcs (of length 0).

8. Concluding remarks. The contribution of the paper is twofold. On the one hand we have provided efficient algorithms for various basic problems that occur when scheduling jobs subject to AND/OR precedence constraints (i.e., generalized feasibility, transitivity, and the computation of earliest start times of jobs for nonnegative arc weights). On the other hand we have provided further insights for solving the problem (ES) with arbitrary arc weights ($-M \leq d_{jw} \leq M$) that may help to design a polynomial-time algorithm for this important problem. In particular, the feasibility criterion (Lemma 7.3) and the algorithm for nonnegative arc weights (Algorithm 4) may be helpful.

Acknowledgments. We would like to thank Gerhard Woeginger for helpful discussions and for bringing the references [29], [15], and [24] to our attention. Furthermore, we thank Martin Zachariasen for pointing us to the work of Adelson-Velsky and Levner [1].

THE COMPLEXITY OF CHOOSING AN H-COLORING (NEARLY) UNIFORMLY AT RANDOM*

LESLIE ANN GOLDBERG†, STEVEN KELK†, AND MIKE PATERSON†

Abstract. Cooper, Dyer, and Frieze [*J. Algorithms*, 39 (2001), pp. 117–134] studied the problem of sampling H-colorings (nearly) uniformly at random. Special cases of this problem include sampling colorings and independent sets and sampling from statistical physics models such as the Widom–Rowlinson model, the Beach model, the Potts model and the hard-core lattice gas model. Cooper et al. considered the family of "cautious" ergodic Markov chains with uniform stationary distribution and showed that, for every fixed connected "nontrivial" graph H, every such chain mixes slowly. In this paper, we give a complexity result for the problem. Namely, we show that for *any* fixed graph H with no trivial components, there is unlikely to be any *polynomial almost uniform sampler* (PAUS) for H-colorings. We show that if there were a PAUS for the H-coloring problem, there would also be a PAUS for sampling independent sets in bipartite graphs, and, by the self-reducibility of the latter problem, there would be a *fully polynomial randomized approximation scheme* (FPRAS) for #BIS—the problem of counting independent sets in bipartite graphs. Dyer, Goldberg, Greenhill, and Jerrum have shown that #BIS is complete in a certain logically defined complexity class. Thus, a PAUS for sampling H-colorings would give an FPRAS for the entire complexity class. In order to achieve our result we introduce the new notion of *sampling-preserving* reduction which seems to be more useful in certain settings than approximation-preserving reduction.

Key words. graph coloring, graph homomorphism, computational complexity, random sampling

1. Introduction.

Let $H = (V(H), E(H))$ be any fixed graph. An *H-coloring* of a graph $G = (V(G), E(G))$ is just a homomorphism from G to H: The vertices of H correspond to "colors," and the edges of H specify which colors may be adjacent. Thus, an H-coloring of G is a function C from $V(G)$ to $V(H)$ such that for every edge $(u, v) \in E(G)$ the corresponding edge $(C(u), C(v))$ is in $E(H)$. Informally, colors $C(u)$ and $C(v)$ are allowed to be adjacent in the coloring C of G because the edge $(C(u), C(v))$ is an edge of H.

Many combinatorial problems can be viewed as special cases of H-coloring. For example, if H is a k-clique with no self-loops, then H-colorings of G correspond to proper k-colorings of G. (In such a coloring, k colors are available for coloring the vertices of G, but no color may be adjacent to itself.) Here is another example. If H is the graph depicted in Figure 1, then H-colorings of G correspond to independent sets of G—vertices which are colored "a" are in the independent set, and vertices which are colored "b" are not. Several models from statistical physics are special cases of H-coloring, including the Widom–Rowlinson model, the Beach model, and (for weighted H-colorings) the Potts model and the hard-core lattice gas model. See [2, 10] for details.

The complexity of H-coloring has been well studied. Many papers considered the

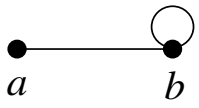

FIG. 1. *Homomorphisms from G to this graph are independent sets of G.*

following problem: Given a fixed graph H, determine, for an input graph G, whether G has an H-coloring. Hell and Nešetřil [14] completely characterized the set of graphs for which this problem is NP-complete. They observed that the problem is in P if H has a loop or is bipartite, and they showed that it is NP-complete for any other fixed H. See [14] for references to earlier work on this question and [13] for extensions to the case in which the maximum degree of G is bounded. See [4, 5] for extensions to parameterized complexity.

Dyer and Greenhill [10] considered the problem of *counting* H-colorings. Intriguingly, they were able to completely characterize the graphs H for which this problem is #P-complete. A connected component of H is said to be "trivial" if it is a complete graph with all loops present or a complete bipartite graph with no loops present.[1] Dyer and Greenhill showed that counting H-colorings is #P-complete if H has a nontrivial component and that it is in P otherwise. They also extended their result to the case in which the maximum degree of G is bounded.

Other work has focused on the complexity of *sampling* H-colorings (nearly) uniformly at random.[2] Positive results for particular graphs H (specifically for the case in which H-colorings are independent sets and for the case in which H-colorings are proper colorings) appear in works such as [9, 15, 18]. A negative result for the independent-set case appears in [6]. The first paper to study the complexity of sampling H-colorings in the general case was Cooper, Dyer, and Frieze [3]. They focused on connected graphs H for which the decision problem "Is there an H-coloring?" is in P, but the counting problem "How many H-colorings are there?" is #P-complete. They showed that for any such H, H-colorings cannot be sampled efficiently using "cautious" Markov chains, which are Markov chains which can change only a constant fraction of the colors of the vertices in a single step. In particular, the mixing time of all such chains is exponential in the number of vertices of G. They also give positive results for certain weighted cases, which are extended in [12]. In particular, [12] shows that for every fixed "dismantleable" H and every degree bound Δ there are positive vertex weights which can be assigned to the vertices of H so that weighted H-colorings can be sampled for degree-Δ graphs G. Borgs et al. [1] consider the problem of sampling H-colorings on rectangular subsets of the hypercubic lattice. They show that for every nontrivial connected H there is an assignment of weights to colors for which cautious chains are slowly mixing.

In this work, we study the complexity of sampling H-colorings. We show that if H has no trivial components, then the problem of nearly uniformly sampling H-colorings is intractable in a complexity-theoretic sense. In particular, we show that for

[1] Following the usual notation in the area, we will treat self-loops specially, so it makes sense to refer to bipartite graphs with or without loops. The loop-free single vertex is viewed as a complete bipartite graph.

[2] Some of this work has been motivated by the well-known connection between almost uniform sampling and approximate counting [17, 8]. For some graphs H, it can be shown that the problem of approximately counting H-colorings is equivalent to the problem of sampling H-colorings (nearly) uniformly at random. See section 8.

any fixed H with no trivial components there is unlikely to be any *polynomial almost uniform sampler* (PAUS) for H-colorings. We show that if there were a PAUS for the H-coloring problem, there would also be a PAUS for sampling independent sets in bipartite graphs, and, by the self-reducibility of the latter problem, there would be a *fully polynomial randomized approximation scheme* (FPRAS) for #BIS—the problem of counting independent sets in bipartite graphs. Dyer, Goldberg, Greenhill and Jerrum have shown that #BIS is complete in a certain logically defined subclass of #P which includes problems such as counting downsets in partial orders and counting satisfying assignments in "restricted Horn" CNF Boolean formulas. Thus, a PAUS for sampling H-colorings would give an FPRAS for the entire complexity class. In fact, our result holds even if the input G is restricted to be a connected bipartite graph.

In order to achieve our result we introduce the new notion of *sampling-preserving* reduction. The notion of approximation-preserving reduction (AP-reducibility) from [11] seems to be too demanding. In particular, since AP-reducibility is about *counting* (as opposed to sampling), an AP-reduction is not allowed to inflate the size of the set of structures by a factor which is difficult to compute. Sampling-preserving reductions allow this flexibility while achieving the same final result. The definition of sampling reduction (section 2) is essentially many-one. Nevertheless, the reductions get used in a "Turing reduction" way. In particular, our reduction from SampleBIS to Sample$H$-Col takes an instance of SampleBIS and constructs many Sample$H$-Col instances. Since the resulting maps between H-colorings and independent sets are many-one, several reductions can be combined even though they may involve different amounts of inflation of the state space.

The paper is structured as follows. Section 2 gives the relevant definitions including the definition of a sampling-preserving reduction. Section 3 presents some technical lemmas which we need in our proofs. Section 4 outlines a general proof technique for demonstrating the existence of an SP-reduction. Section 5 uses the new proof technique to reduce SampleBIS to a crucial intermediate problem, SampleFixed$H$-Col. Section 6 proves the main result. Sections 7 and 8 discuss extensions.

2. Definitions. The total variation distance between two distributions π and π' on a countable set Ω is given by

$$\mathrm{d_{TV}}(\pi, \pi') = \frac{1}{2} \sum_{\omega \in \Omega} |\pi(\omega) - \pi'(\omega)| = \max_{A \subseteq \omega} |\pi(A) - \pi'(A)|.$$

A sampling problem X maps each instance σ to a set of structures $X(\sigma)$. The goal is to produce a member of $X(\sigma)$ uniformly at random. The size of each structure in $X(\sigma)$ is at most a polynomial in $|\,\sigma\,|$. For a given graph H, the sampling problem Sample$H$-Col will be defined as follows.

Name. Sample$H$-Col.
Instance. A loop-free graph G.
Output. An H-coloring of G chosen uniformly at random.

We will be particularly interested in the special case of this problem in which the input graph, G, is connected and bipartite.

Name. SampleBH-Col.
Instance. A loop-free connected bipartite graph G.
Output. An H-coloring of G chosen uniformly at random.

The problem SampleBIS will be defined as follows.

Name. SAMPLEBIS.
Instance. A loop-free connected bipartite graph G.
Output. An independent set of G chosen uniformly at random.

An *almost uniform sampler* [8, 16, 17] for X is a randomized algorithm that takes input σ and accuracy parameter $\epsilon \in (0, 1]$ and gives an output such that the variation distance between the output distribution of the algorithm and the uniform distribution on $X(\sigma)$ is at most ϵ. We will say that algorithm is a *polynomial almost uniform sampler (PAUS)* if its running time is bounded from above by a polynomial in the size of the instance $|\sigma|$ and $1/\epsilon$.

A *sampling-preserving reduction* (SP-reduction) from a sampling problem X to a sampling problem Y (denoted $X \leq_{\mathrm{SP}} Y$) consists of the following:

1. A function f which takes an input (σ, ϵ), in which σ is an instance of X and $\epsilon \in (0, 1]$ is an accuracy parameter, and produces an instance $f(\sigma, \epsilon)$ of Y. If $X(\sigma)$ is nonempty, then $Y(f(\sigma, \epsilon))$ must be nonempty.
2. A function g which maps each tuple (σ, ϵ, y) with $y \in Y(f(\sigma, \epsilon))$ to a member of $X(\sigma) \cup \{\perp\}$, where "$\perp$" is an error symbol and for every (σ, ϵ) and every $x \in X(\sigma)$,

$$(1) \quad e^{-\epsilon}\frac{|Y(f(\sigma,\epsilon))|}{|X(\sigma)|} \leq |\{y \in Y(f(\sigma,\epsilon)) \mid g(\sigma,\epsilon,y) = x\}| \leq e^{\epsilon}\frac{|Y(f(\sigma,\epsilon))|}{|X(\sigma)|}.$$

Equation (1) says that for every $x \in X(\sigma)$ the number of $y \in Y(f(\sigma, \epsilon))$ which are mapped to x by g is roughly $\frac{|Y(f(\sigma,\epsilon))|}{|X(\sigma)|}$. Thus, each $x \in X(\sigma)$ is roughly equally represented, and the error symbol $\perp$ is represented by only about an ϵ-fraction of $Y(f(\sigma, \epsilon))$.

The functions f and g must be computable in time which is bounded by a polynomial in $|\sigma|$ and $1/\epsilon$.

The motivation for this definition is the following lemma.

LEMMA 1. *If $X \leq_{\mathrm{SP}} Y$ and Y has a PAUS, then X has a PAUS.*

Proof. Let (f, g) be the reduction from X to Y, and let $\mathcal{A}$ be a PAUS for Y. Here is a PAUS for X: On input (σ, ϵ), let y be the output of $\mathcal{A}$ when it is run with inputs $f(\sigma, \epsilon/4)$ and $\epsilon/2$; return $g(\sigma, \epsilon/4, y)$. We must show that the variation distance between the output distribution of this algorithm and the uniform distribution on $X(\sigma)$ is at most ϵ. Let σ be an input with $|X(\sigma)| \geq 1$. Consider any subset A_x of $X(\sigma)$. Let

$$A_y = \{y \in Y(f(\sigma, \epsilon/4)) \mid g(\sigma, \epsilon/4, y) \in A_x\}.$$

Then the probability that $\mathcal{A}$ gives an output in A_y is at most

$$\begin{aligned}
&\frac{|A_y|}{|Y(f(\sigma,\epsilon/4))|} + \frac{\epsilon}{2} \\
&\leq \frac{e^{\epsilon/4}|A_x|}{|X(\sigma)|} + \frac{\epsilon}{2} \\
&\leq \frac{(1+\epsilon/2)|A_x|}{|X(\sigma)|} + \frac{\epsilon}{2} \\
&\leq \frac{|A_x|}{|X(\sigma)|} + \frac{(\epsilon/2)|A_x|}{|X(\sigma)|} + \frac{\epsilon}{2} \\
&\leq \frac{|A_x|}{|X(\sigma)|} + \epsilon.
\end{aligned}$$

Also, the probability that $\mathcal{A}$ gives an output in A_y is at least

$$\begin{aligned}
&\frac{|A_y|}{|Y(f(\sigma,\epsilon/4))|} - \frac{\epsilon}{2} \\
&\geq \frac{e^{-\epsilon/4}|A_x|}{|X(\sigma)|} - \frac{\epsilon}{2} \\
&\geq \frac{(1-\epsilon/2)|A_x|}{|X(\sigma)|} - \frac{\epsilon}{2} \\
&\geq \frac{|A_x|}{|X(\sigma)|} - \frac{|A_x|(\epsilon/2)}{|X(\sigma)|} - \frac{\epsilon}{2} \\
&\geq \frac{|A_x|}{|X(\sigma)|} - \epsilon. \qquad \square
\end{aligned}$$

The problem #BIS is defined as follows.
Name. #BIS.
Instance. A loop-free bipartite graph G.
Output. The number of independent sets of G.

A component of H is *trivial* if it is a complete graph with all loops present or a complete bipartite graph with no loops present. Recall from Dyer and Greenhill [10] that counting H-colorings is in P if H is trivial. The main result of this paper is as follows.

THEOREM 2. *Suppose that H is a fixed graph with no trivial components. If* SAMPLEBH-COL *has a PAUS then* SAMPLEBIS *has a PAUS, and* #BIS *has an FPRAS. Thus, every problem which is AP-interreducible with* #BIS *(see* [11]*) has an FPRAS.*

3. Technical lemmas. Let $\nu(a,b)$ denote the number of onto functions from a set of size a to a set of size b. We need to use the following lemma, which is Lemma 18 of [11].

LEMMA 3 (DGGJ). *If a and b are positive integers and $a \geq 2b\ln b$, then*

$$b^a\left(1-\exp(-a/(2b))\right) \leq \nu(a,b) \leq b^a.$$

We also need the following technical lemma.

LEMMA 4. *Suppose c_1 and c_2 are fixed positive reals with $c_1 < c_2$. For any $\delta > 0$ and any nonnegative integers q and a_0, there are nonnegative integers a and b with $a \geq a_0$ which are in $O((a_0+q)/\delta)$ and satisfy*

$$e^{-\delta}c_2^{a+q} \leq c_1^{b+q} \leq e^{\delta}c_2^{a+q}.$$

Proof. First, note that it would suffice to find nonnegative integers a' and b' which are in $O(q'/\delta)$ and satisfy

$$e^{-\delta}c_2^{a'+q'} \leq c_1^{b'+q'} \leq e^{\delta}c_2^{a'+q'},$$

where $q' = q + a_0$ because we could simply set $a = a' + a_0$ and $b = b' + a_0$ which would imply $a' + q' = a + q$ and $b' + q' = b + q$.

Taking logarithms, what we need is

$$\left| b' - \frac{a'\log c_2 + q'\log(c_2/c_1)}{\log c_1} \right| \leq \frac{\delta}{\log c_1}. \tag{2}$$

Now let ρ be defined by $c_2 = c_1^{1+\rho}$. Then we want

$$|b' - (a'(1+\rho) + q'\rho)| \leq \frac{\delta}{\log c_1}. \tag{3}$$

For a positive integer r, we will choose $a' = q'r$, so we want

$$|b' - a' - \rho q'(r+1)| \leq \frac{\delta}{\log c_1}. \tag{4}$$

Let $R = \lceil 2 \log c_1/\delta \rceil$. Lemma 19 of [11] says the following: *For any real $z > 0$ and any positive integer R there is an $x \in [1, \ldots, R]$ such that*

$$\min(zx - \lfloor zx \rfloor, \lceil zx \rceil - zx) \leq 1/R.$$

Thus, there is an $x \in [1, \ldots, R]$ such that $\rho q' x$ is within $1/R$ of a nonnegative integer. If $x > 1$ we will set $r + 1 = x$. If $x = 1$, then note that $\rho q' 2$ is within $2/R$ of a nonnegative integer, so we will set $r = 1$.

Now recall that $a' = q'r$, so $a' \in O(q'/\delta)$ as required. □

4. Demonstrating the existence of SP-reductions: A proof technique. When we introduce an SP-reduction from a sampling problem X to a sampling problem Y, we will need to show that (1) is satisfied. We will typically do this by partitioning $Y(f(\sigma, \epsilon))$ into disjoint sets $Y_0, \ldots, Y_k$. We will show that each of $Y_1, \ldots, Y_k$ is fairly representative of $X(\sigma)$. In particular, for every $x \in X(\sigma)$ and every $i \in [1, k]$,

$$e^{-\epsilon/2} \frac{|Y_i|}{|X(\sigma)|} \leq |\{y \in Y_i \mid g(\sigma, \epsilon, y) = x\}| \leq e^{\epsilon/2} \frac{|Y_i|}{|X(\sigma)|}. \tag{5}$$

For every $y \in Y_0$, we will have $g(\sigma, \epsilon, y) = \perp$, but we will show that Y_0 is a small part of $Y(f(\sigma, \epsilon))$. In particular,

$$\sum_{i=1}^{k} |Y_i| \geq e^{-\epsilon/2} |Y(f(\sigma, \epsilon))|. \tag{6}$$

Together, (5) and (6) imply (1). Note that (6) follows from

$$|Y_0| \leq (\epsilon/4)|Y(f(\sigma, \epsilon))|, \tag{7}$$

since (7) implies $|Y| - |Y_0| \geq (1 - \epsilon/4)|Y(f(\sigma, \epsilon))| \geq e^{-\epsilon/2}|Y(f(\sigma, \epsilon))|$.

Quite often the reduction $X \leq_{\mathrm{SP}} Y$ will involve several subproblems $Z_1, Z_2, \ldots$ such that, for each of these, an SP-reduction (f_i, g_i) from X to Z_i is already known. The instance $f(\sigma, \epsilon)$ of Y is then formed by "gluing" together instances $f_1(\sigma, \epsilon/2)$ of Z_1, $f_2(\sigma, \epsilon/2)$ of Z_2, and so on. Y_i is (roughly) the portion of $Y(f(\sigma, \epsilon))$ for which, within each $y \in Y_i$, we can "zoom in" on a structure $z \in Z_i(f_i(\sigma, \epsilon/2))$. Each structure in $Z_i(f_i(\sigma, \epsilon/2))$ is represented by an equal number of $y \in Y_i$ so we can get (5) by referring to the SP-reduction from X to Z_i. Establishing (7) is essentially showing that, although $Y(f(\sigma, \epsilon))$ has some structures which do not allow us to "zoom in" on an appropriate subproblem to find our sample, these are not so numerous.

Finally, let $Y_i(x) = \{y \in Y_i \mid g(\sigma, \epsilon, y) = x\}$. Suppose that no $y \in Y_i$ has $g(\sigma, \epsilon, y) = \perp$. In this case we can show (5) by showing that for all $x, x' \in X(\sigma)$,

$$|Y_i(x)| \leq e^{\epsilon/2} |Y_i(x')|. \tag{8}$$

To see this, note that

$$\frac{|Y_i|}{|X(\sigma)|} = \frac{\sum_{x' \in X(\sigma)} |Y_i(x')|}{|X(\sigma)|} \geq e^{-\epsilon/2} \frac{\sum_{x' \in X(\sigma)} |Y_i(x)|}{|X(\sigma)|} = e^{-\epsilon/2} |Y_i(x)|.$$

5. Sampling *fixed H*-colorings. Suppose that H is connected, loop-free, and bipartite. Denote the vertex partition of H by $(V_L(H), V_R(H))$. We will define the *fixed* H-coloring problem as follows.

Name. SampleFixed$H$-Col.

Instance. A loop-free connected bipartite graph G with vertex partition $(V_L(G), V_R(G))$.

Output. An H-coloring of G chosen uniformly at random from the set of H-colorings in which vertices of $V_L(G)$ receive colors from $V_L(H)$.

We will study the problem SampleFixed$H$-Col as an intermediate step on the way to the proof of Theorem 2.

A vertex in $V_L(H)$ is said to be *full* if it is adjacent to every vertex in $V_R(H)$. Similarly, a vertex in $V_R(H)$ is said to be *full* if it is adjacent to every vertex in $V_L(H)$. The graph H is said to be *full* if both $V_L(H)$ and $V_R(H)$ contain at least one full vertex. The following lemma is the key ingredient in the proof of Theorem 2.

Lemma 5. *Suppose that H is a connected nontrivial full loop-free bipartite graph. Then* SampleBIS $\leq_{\text{SP}}$ SampleFixed$H$-Col.

Proof. We will prove the lemma by induction on the number of vertices in H. For the base case, suppose that H has at most 4 vertices. The only connected nontrivial full loop-free bipartite graph H with at most 4 vertices is the path of length 3. Let G be an input to SampleBIS. There is a one-to-one correspondence between independent sets of G and fixed H-colorings of G: The endpoints of H point out the vertices which are in the independent set (see the proof of Theorem 5 of [11]).

We will now move on to the inductive step. The high-level idea is the following. By considering the graph H, we will construct several graphs $H_{S_1}, \ldots, H_{S_{j+k}}$, each of which is smaller than H and satisfies certain conditions. By induction, for each i, there is an SP-reduction from SampleBIS to SampleFixedH_{S_i}-Col. If we apply this reduction to our instance G of SampleBIS, we get an instance G_i of SampleFixedH_{S_i}-Col. Our goal is to construct an instance $f(G, \epsilon)$ of SampleFixed$H$-Col. We do this by "gluing together" the various G_i's. Now consider the constructed instance $f(G, \epsilon)$ of SampleFixed$H$-Col. When we sample from the output distribution SampleFixed$H$-Col$(f(G, \epsilon))$, we would like to recover the output distribution of $SampleBIS(G)$. Curiously, we cannot determine during the reduction itself the relative weights of the subinstances $G_1, G_2, \ldots$. Nevertheless, once we have an output to SampleFixed$H$-Col$(f(G, \epsilon))$, the output itself tells us which H_i is relevant. From this, we can recover an output to SampleFixedH_{S_i}-Col(G_i) and from this we can recover an output to SampleBIS(G). The main technical difficulty lies in showing that the distributions are correct. In particular, since the subreductions are SP-reductions (i.e., the equations in section 4 are satisfied in the construction of $G_1, G_2, \ldots$), the combined reduction is also an SP-reduction.

We now describe the details. Let F_L be the set of full vertices in $V_L(H)$, and let F_R be the set of full vertices in $V_R(H)$. Let $f_L = |F_L|$ and $f_R = |F_R|$ and $v_L = |V_L(H)|$ and $v_R = |V_R(H)|$. For a subset S of $V_R(H)$, let $N(S)$ be the set of mutual neighbors of S:

$$N(S) = \{v \in V_L(H) \mid \forall u \in S, (u, v) \in E(H)\}.$$

Note that $F_L \subseteq N(S) \subseteq V_L(H)$. S is said to be *left-reducing* if $F_L \subset N(S) \subset V_L(H)$. If S is left-reducing, let H_S be the subgraph of H induced by vertex partition $(N(S), V_R(H))$. Note that H_S has fewer vertices than H. Also, it is connected, full, and nontrivial: The set of full vertices in $V_L(H_S)$ is F_L; the set of full vertices in $V_R(H_S)$ includes all of F_R, but it does not equal $V_R(H)$ since $N(S) \supset F_L$.

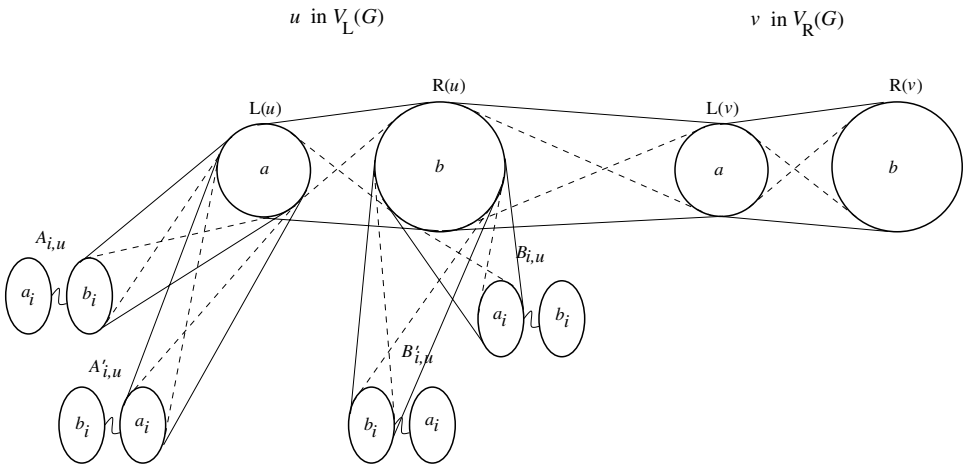

FIG. 2. *The construction of $f(G,\epsilon)$ in the proof of Lemma 5.*

Similarly, a subset S of $V_L(H)$ is *right-reducing* if $F_R \subset N(S) \subset V_R(H)$. If S is right-reducing, let H_S be the subgraph of H induced by vertex partition $(V_L(H), N(S))$. H_S has fewer vertices than H and is connected, full, and nontrivial.

Now, let $S_1, \ldots, S_k$ be the left-reducing subsets of $V_R(H)$, and let $S_{k+1}, \ldots, S_{k+j}$ be the right-reducing subsets of $V_L(H)$. (Either or both of k and j could be zero.) For every $i \in \{1, \ldots, k+j\}$, let (f_i, g_i) be an SP-reduction from SAMPLEBIS to SAMPLEFIXEDH_{S_i}-COL. Take the input (G,ϵ) to SAMPLEBIS, and let $G_i = f_i(G, \epsilon/2)$. Let $a_i = |V_L(G_i)|$, and let $b_i = |V_R(G_i)|$. Let $q = \sum_{i=1}^{k+j}(a_i + b_i)$, and let $n = |V_L(G)| + |V_R(G)|$.

Let $f(G,\epsilon)$ be the graph which is constructed as follows, where a and b will be chosen later to satisfy

$$a \geq 2v_L \lceil q \ln(v_R/f_R) + \ln(16n/\epsilon) \rceil \tag{9}$$

and

$$b \geq 2v_R \lceil q \ln(v_L/f_L) + \ln(16n/\epsilon) \rceil . \tag{10}$$

See Figure 2. For every vertex u of G, put a size-a set $L(u)$ into $V_L(f(G,\epsilon))$ and a size-b set $R(u)$ into $V_R(f(G,\epsilon))$. Also, add edges $L(u) \times R(u)$ to $E(f(G,\epsilon))$. If $u \in V_L(G)$ is connected to $v \in V_R(G)$ by an edge of G, then add edges $R(u) \times L(v)$ to $E(f(G,\epsilon))$.

Also, for every vertex u of G and every $i \in [1, \ldots, k+j]$, let $A_{i,u}$ and $B_{i,u}$ be copies of G_i, and let $A'_{i,u}$ and $B'_{i,u}$ be copies of G_i in which left vertices and right vertices are switched (so the vertices in $V_L(A'_{i,u})$ correspond to the vertices in $V_R(G_i)$ and the vertices in $V_R(A'_{i,u})$ correspond to the vertices in $V_L(G_i)$). Add edges $L(u) \times V_R(A_{i,u})$ and $L(u) \times V_R(A'_{i,u})$ and $R(u) \times V_L(B_{i,u})$ and $R(u) \times V_L(B'_{i,u})$ to $E(f(G,\epsilon))$.

Let

$$V_L(f(G,\epsilon)) = \bigcup_u L(u) \cup \bigcup_{u,i} \{V_L(A_{i,u}) \cup V_L(A'_{i,u}) \cup V_L(B_{i,u}) \cup V_L(B'_{i,u})\},$$

and let Y be the set of fixed H-colorings of $f(G,\epsilon)$. We will partition Y into sets $Y_0, \ldots, Y_{k+j+1}$.

For $i \in [1, \ldots, k]$, Y_i is the set of colorings which are not in $Y_1, \ldots, Y_{i-1}$ but in which some $u \in V_L(G)$ has $R(u)$ colored with (exactly) the colors in S_i. For $i \in [k+1, \ldots, k+j]$, Y_i is the set of colorings which are not in $Y_1, \ldots, Y_{i-1}$ but in which some $v \in V_R(G)$ has $L(v)$ colored with S_i.

The high-level structure of our construction is as follows. For every $i \in \{1, \ldots, k+j\}$, we will use the colorings in Y_i by focusing on the induced colorings of the subgraph G_i. These are H_{S_i}-colorings of G_i and from these we can (by induction) recover a random independent set of G. As usual, the colorings in Y_0 are not useful for pointing out independent sets, but there are not too many of these. Every coloring in Y_{k+j+1} has a special form—every vertex u of G has either $R(u)$ colored $V_R(H)$ or has $L(u)$ colored $V_L(H)$. These colorings point out independent sets of G in a natural way, and each independent set comes up about the same number of times in this way.

We now look at the details. Note that for any colorings in Y_0 or Y_{k+j+1} we have the following property—every vertex $u \in V_L(G)$ has $R(u)$ colored with a set S of colors such that $N(S)$ is either F_L or $V_L(H)$. Similarly, every vertex $v \in V_R(G)$ has $L(v)$ colored with a set S of colors such that $N(S)$ is either F_R or $V_R(H)$.

Consider a coloring y. Vertex $u \in V_L(G)$ satisfies *Condition* (A) if $R(u)$ is colored with a set S of colors with $N(S) = F_L$ but $S \subset V_R(H)$. It satisfies *Condition* (B) if $R(u)$ is colored with a set S of colors with $N(S) = V_L(H)$ but $L(u)$ is colored with a proper subset of $V_L(H)$. Vertex $v \in V_R(G)$ satisfies *Condition* (C) if $L(v)$ colored with a set S of colors with $N(S) = F_R$ but $S \subset V_L(H)$. It satisfies *Condition* (D) if $L(v)$ is colored with a set S of colors with $N(S) = V_R(H)$ but $R(v)$ is colored with a proper subset of $V_R(H)$.

We now define

$$Y_0 = \{y \in Y - \{Y_1 \cup \cdots \cup Y_{k+j}\} \mid \text{some vertex satisfies Condition (A), (B), (C), or (D)}\}.$$

Now note that colorings in Y_{k+j+1} have the following property. Every vertex u of G has either $R(u)$ colored $V_R(H)$ or has $L(u)$ colored $V_L(H)$.

We will first work on establishing (7). Let $Y_{u,A}$ denote the subset of Y in which u satisfies (A). Define $Y_{u,B}$, $Y_{u,C}$, and $Y_{u,D}$ similarly. We will show that the size of each of $Y_{u,A}$, $Y_{u,B}$, $Y_{u,C}$, and $Y_{u,D}$ is at most $(\epsilon/(16n))|Y|$. Equation (7) follows since

$$|Y_0| \leq \sum_{u \in V(G)} |Y_{u,A}| + |Y_{u,B}| + |Y_{u,C}| + |Y_{u,D}|.$$

First, let us show that $|Y_{u,A}| \leq (\epsilon/(16n))|Y|$. Consider the set of colorings in Y in which all neighbors of vertices in $R(u)$ have colors from F_L, and let ψ be the number of induced colorings on vertices other than the vertices of $R(u)$. If $\psi = 0$, then $|Y_{u,A}| = 0$, so the claim is trivial. Otherwise, $|Y_{u,A}| \leq \psi(v_R^b - \nu(b, v_R))$ which is at most $\psi v_R^b \exp(-b/(2v_R))$ by Lemma 3. On the other hand, $|Y| \geq \psi v_R^b$, so the claim follows from (10). The proof that $|Y_{u,C}|$ is sufficiently small is similar.

Next, let us show that $|Y_{u,B}| \leq (\epsilon/(16n))|Y|$. Consider the set of colorings in Y in which $R(u)$ is colored with a subset of F_R, and let ψ be the number of induced colorings on all vertices except those in $L(u)$ and $A_{i,u}$ and $A'_{i,u}$ (for $i \in [1, \ldots, j+k]$). If $\psi = 0$, then $|Y_{u,B}| = 0$, so the claim is trivial. Otherwise, $|Y_{u,B}| \leq \psi(v_L^a - \nu(a, v_L))v_R^q v_L^q$ which is at most $\psi v_L^a \exp(-a/(2v_L))v_R^q v_L^q$ by Lemma 3. On the other hand, $|Y| \geq \psi v_L^a f_R^q v_L^q$, so the claim follows from (9). The proof that $|Y_{u,D}|$ is sufficiently small is similar.

We will now work on establishing (5). First consider $i \in [1, \ldots, k]$. Let $Y_{u,i}$ be the set of colorings in Y_i for which $u \in V_L(G)$ is the first vertex in $V_L(G)$ with

$R(u)$ colored S_i. Let Γ be the set of induced colorings on $B_{i,u}$. Note that Γ is the set of fixed H_{S_i}-colorings of $G_i = f_i(G, \epsilon/2)$. Also, each coloring in Γ comes up ψ times in $Y_{u,i}$ for some ψ. (In particular, ψ is the number of colorings of vertices other than $B_{i,u}$ which are induced by colorings in $Y_{u,i}$.) For coloring $y \in Y_{u,i}$ we will let $g(G, \epsilon, y) = g_i(G_i, \epsilon/2, y')$, where y' is the induced coloring on $B_{i,u}$. Then for every independent set x in the set $\mathcal{I}(G)$ of independent sets of G,

$$|\{y \in Y_{u,i} \mid g(G, \epsilon, y) = x\}| = \psi\, |\{y' \in \Gamma \mid g_i(G_i, \epsilon/2, y') = x\}|. \tag{11}$$

Since (f_i, g_i) is an SP-reduction, (1) gives

$$e^{-\epsilon/2} \frac{|\Gamma|}{|\mathcal{I}(G)|} \le |\{y' \in \Gamma \mid g_i(G_i, \epsilon/2, y') = x\}| \le e^{\epsilon/2} \frac{|\Gamma|}{|\mathcal{I}(G)|}, \tag{12}$$

and (5) follows for $Y_{u,i}$ from (11) and (12) since $|Y_{u,i}| = \psi\, |\Gamma|$. Colorings in $Y_{k+1}, \ldots, Y_{k+j}$ are handled similarly except that we look at induced colorings of $A_{i,u}$ rather than $B_{i,u}$.

It remains to satisfy (5) for $i = k + j + 1$. Note that any coloring y in Y_{k+j+1} points out an independent set of G. A vertex $u \in V_L(G)$ is in the independent set if $R(u)$ is colored $V_R(H)$. A vertex $v \in V_R(G)$ is in the independent set if $L(v)$ is colored $V_L(H)$. We will define $g(G, \epsilon, y)$ to be this independent set. Let us focus attention on a given independent set containing w_L vertices in $V_L(G)$ and w_R vertices in $V_R(G)$. We will now calculate how many colorings in Y_{k+j+1} correspond to this independent set.

For any bipartite graph G' with vertex partition $(V_L(G'), V_R(G'))$, let $\phi_H(G')$ denote the number of fixed H-colorings of G'. Then the number of times that this independent set comes up as a coloring in Y_{k+j+1} is the product of the following two quantities:

$$\left(\nu(b, v_R) f_L^a \prod_{i=1}^{k+j} \phi_H(A_{i,u}) \phi_H(A'_{i,u}) f_L^{a_i+b_i} v_R^{a_i+b_i}\right)^{w_L + v_R - w_R},$$

$$\left(f_R^b \nu(a, v_L) \prod_{i=1}^{k+j} \phi_H(B_{i,u}) \phi_H(B'_{i,u}) v_L^{a_i+b_i} f_R^{a_i+b_i}\right)^{v_L - w_L + w_R}.$$

Now note that $\phi_H(A_{i,u}) = \phi_H(B_{i,u})$ and $\phi_H(A'_{i,u}) = \phi_H(B'_{i,u})$. So if we let

$$Z = \left(\prod_{i=1}^{k+j} \phi_H(A_{i,u}) \phi_H(A'_{i,u})\right)^{v_L + v_R} (f_L^a \nu(b, v_R) f_L^q v_R^q)^{v_R} \left(f_R^b \nu(a, v_L) v_L^q f_R^q\right)^{v_L},$$

the contribution of the independent set becomes

$$Z(\nu(b, v_R) f_L^a f_L^q v_R^q)^{w_L - w_R} \left(f_R^b \nu(a, v_L) v_L^q f_R^q\right)^{w_R - w_L},$$

which is

$$Z\left(\frac{\nu(b, v_R) v_L^a}{v_R^b \nu(a, v_L)}\right)^{w_L - w_R} \left(\left(\frac{v_R}{f_R}\right)^{b+q} \left(\frac{f_L}{v_L}\right)^{a+q}\right)^{w_L - w_R}.$$

To get (8) we will show that a and b can be chosen so that

$$e^{-\epsilon/(8n)} \leq \left(\frac{\nu(b, v_R)v_L^a}{v_R^b \nu(a, v_L)}\right) \leq e^{\epsilon/(8n)} \tag{13}$$

and

$$e^{-\epsilon/(8n)} \leq \left(\frac{v_R}{f_R}\right)^{b+q}\left(\frac{f_L}{v_L}\right)^{a+q} \leq e^{\epsilon/(8n)}. \tag{14}$$

This guarantees that the contribution of this independent set is in the range $[e^{-\epsilon/4}Z, e^{\epsilon/4}Z]$, and (8) follows for Y_{k+j+1}. To establish (13), use Lemma 3 to observe that

$$\left(\frac{\nu(b, v_R)v_L^a}{v_R^b \nu(a, v_L)}\right) \leq \frac{1}{1 - \exp(-a/(2v_L))}.$$

Since (9) gives $1 - \exp(-a/(2v_L)) \geq 1 - \epsilon/(16n) \geq e^{-\epsilon/(8n)}$, the right-hand inequality of (13) follows. The left-hand inequality is similar.

We will now show how to choose the values of a and b to satisfy (14). If $v_R/f_R = v_L/f_L$, then simply choose $a = b$ and make them large enough to satisfy (9) and (10). Suppose that $v_R/f_R < v_L/f_L$. Then use Lemma 4 with $c_1 = v_R/f_R$, $c_2 = v_L/f_L$, $\delta = \epsilon/(8n)$, and

$$a_0 = 2v_L \left\lceil q \ln(v_R/f_R) + \ln(16n/\epsilon)\right\rceil + 2v_R \left\lceil q \ln(v_L/f_L) + \ln(16n/\epsilon)\right\rceil.$$

The lemma gives values of a and b which are in $O((a_0 + q)/\delta)$, which is not too large. Thus, our reduction is sampling-preserving. Note that the reduction can be done in polynomial time—the calculation of a and b does not involve computing Z. The case where $v_L/f_L < v_R/f_R$ is similar. □

6. The proof of Theorem 2. We start with some definitions. First, for every graph H we will define a loop-free bipartite graph $B[H]$ (this construction was used in [10]). Let the vertices of H be $v_1, \ldots, v_h$. The vertex set of $B[H]$ is $\{x_1, \ldots, x_h\} \cup \{y_1, \ldots, y_h\}$. The edge set of $B[H]$ is

$$\{(x_i, y_j) \mid (v_i, v_j) \in E(H)\}.$$

Thus, a loop (v_i, v_i) in H corresponds to the edge (x_i, y_i) in $B[H]$, and a nonloop (v_i, v_j) in H (for which $i \neq j$) corresponds to two edges (x_i, y_j) and (y_i, x_j) in $B[H]$. For every edge (v_i, v_j) of H, let

$$V_L(H_{i,j}) = \{x_\ell \mid (v_\ell, v_j) \in E(H)\}$$

and

$$V_R(H_{i,j}) = \{y_\ell \mid (v_i, v_\ell) \in E(H)\},$$

and let $H_{i,j}$ be the subgraph of $B[H]$ induced by vertex set $V_L(H_{i,j}) \cup V_R(H_{i,j})$. Note that $x_i \in V_L(H_{i,j})$ and $y_j \in V_R(H_{i,j})$ and x_i is adjacent to all of $V_R(H_{i,j})$ in $H_{i,j}$ and y_j is adjacent to all of $V_L(H_{i,j})$. Thus, $H_{i,j}$ is connected and full. Let $\Delta_1(H)$ be the degree of H. That is,

$$\Delta_1(H) = \max\{\deg(v) \mid v \in V(H)\}.$$

Similarly, let $\Delta_2(H)$ be the maximum degree amongst neighbors of vertices with degree $\Delta_1(H)$:

$$\Delta_2(H) = \max\{\deg(v) \mid \text{ for some } u \in V(H) \text{ with } \deg(u) = \Delta_1(H),\ (u,v) \in E(H)\}.$$

Let

$$R(H) = \{(v_i, v_j) \mid ((v_i, v_j) \in E(H) \text{ and } \deg(v_i) = \Delta_1(H) \text{ and } \deg(v_j) = \Delta_2(H)\}.$$

We will start with the following lemma.

LEMMA 6. *Let H be any fixed graph with no trivial components. Then $R(H)$ is nonempty, and $\Delta_1(H) > 1$ and $\Delta_2(H) > 1$. Also, for all $(v_i, v_j) \in R(H)$, $H_{i,j}$ is connected, loop-free, bipartite, full, and nontrivial.*

Proof. Since H has no trivial components, $R(H)$ is nonempty, and $\Delta_1(H) > 1$ and $\Delta_2(H) > 1$. Suppose $(v_i, v_j) \in R(H)$. Recall that $H_{i,j}$ is connected, loop-free, bipartite, and full. Suppose for contradiction that $H_{i,j}$ is a complete bipartite graph (so vertices in $V_L(H_{i,j})$ have degree $\Delta_1(H)$ in $H_{i,j}$ and vertices in $V_R(H_{i,j})$ have degree $\Delta_2(H)$ in $H_{i,j}$).

This assumption guarantees that $H_{i,j}$ is a connected component of $B[H]$: $B[H]$ cannot have an edge with exactly one endpoint in $V_L(H_{i,j})$—the endpoint would then have degree exceeding $\Delta_1(H)$ in $B[H]$, which is a contradiction; similarly, $B[H]$ cannot have an edge with exactly one endpoint in $V_R(H_{i,j})$.

Thus, for any $x_\ell \in V_L(H_{i,j})$,

$$\{v_r \mid (v_\ell, v_r) \in E(H)\} = \{v_r \mid y_r \in V_R(H_{i,j})\}. \tag{15}$$

Similarly, for any $y_\ell \in V_R(H_{i,j})$,

$$\{v_r \mid (v_\ell, v_r) \in E(H)\} = \{v_r \mid x_r \in V_L(H_{i,j})\}. \tag{16}$$

Now if H has a vertex v_ℓ such that $(v_i, v_\ell) \in E(H)$ and $(v_j, v_\ell) \in E(H)$, then $x_\ell \in V_L(H_{i,j})$ and $y_\ell \in V_R(H_{i,j})$, so (15) and (16) imply that

$$\{v_r \mid y_r \in V_R(H_{i,j})\} = \{v_r \mid x_r \in V_L(H_{i,j})\}.$$

Thus, $H_{i,j}$ corresponds to a component of H, and that component is a looped clique, which contradicts the fact that H has no trivial component.

On the other hand, if there is no v_ℓ with $(v_i, v_\ell) \in E(H)$ and $(v_j, v_\ell) \in E(H)$, then $H_{i,j}$ corresponds to a connected component of H which is a complete bipartite graph, again giving a contradiction. ∎

We can now prove the main lemma.

LEMMA 7. *Suppose that H is a fixed graph with no trivial components. Then* SAMPLEBIS $\leq_{\text{SP}}$ SAMPLEBH-COL.

Proof. Let (G, ϵ) be an input to SAMPLEBIS. For each $(v_i, v_j) \in R(H)$, Lemma 6 and Lemma 5 guarantee that there is a sampling-preserving reduction $(f_{i,j}, g_{i,j})$ from SAMPLEBIS to SAMPLEFIXED$H_{i,j}$-COL. Let $G_{i,j} = f_{i,j}(G, \epsilon/2)$. Let $f(G, \epsilon)$ be the graph which is constructed as follows. See Figure 3. Let $q = \sum_{(v_i,v_j)\in R(H)} |V_L(G_{i,j})| + |V_R(G_{i,j})|$. Let

$$V_L(f(G,\epsilon)) = A \cup \{w_L\} \cup \bigcup_{(v_i,v_j)\in R(H)} V_L(G_{i,j})$$

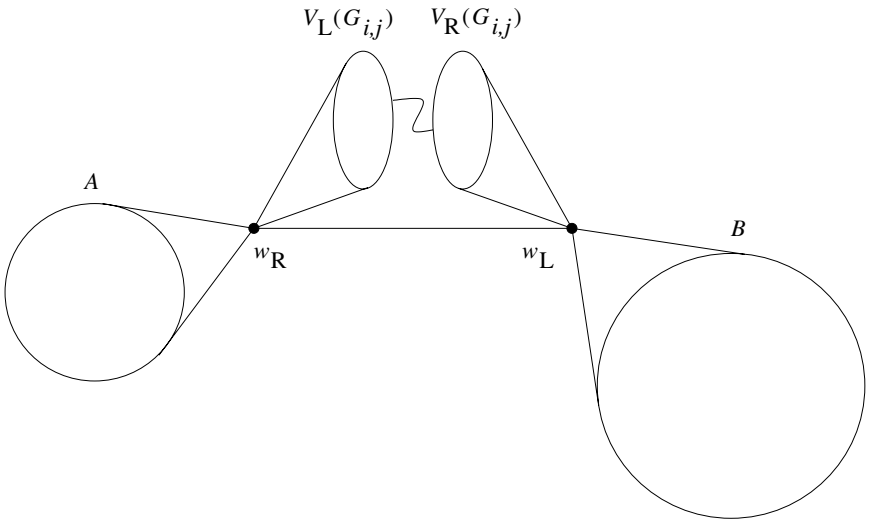

FIG. 3. *The construction of $f(G,\epsilon)$ in the proof of Lemma 7.*

and

$$V_R(f(G,\epsilon)) = B \cup \{w_R\} \cup \bigcup_{(v_i,v_j)\in R(H)} V_R(G_{i,j}),$$

where A and B are sets of vertices with

$$|A| = \left\lceil \frac{q\ln(|V(H)|) + \ln(8|E(H)|/\epsilon)}{\ln(\Delta_2(H)/(\Delta_2(H)-1))} \right\rceil$$

and

$$|B| = \left\lceil \frac{(q+|A|+1)\ln(|V(H)|) + \ln(8|V(H)|/\epsilon)}{\ln(\Delta_1(H)/(\Delta_1(H)-1))} \right\rceil.$$

Note that there is no division by zero, since $\Delta_1(H)$ and $\Delta_2(H)$ are bigger than one (by Lemma 6). In addition to the edges in the graphs $G_{i,j}$, we add edge (w_L, w_R) and $w_L \times B$ and $w_R \times A$ and, for all $(v_i, v_j) \in R(H)$, we add edges $w_L \times V_R(G_{i,j})$ and $w_R \times V_L(G_{i,j})$.

Let Y be the set of H-colorings of $f(G,\epsilon)$. Y_0 will be the set of colorings in Y in which (w_L, w_R) is not colored with an edge (v_i, v_j) from $R(H)$. We will now establish (7). For every $v \in V(H)$ with $\deg(v) < \Delta_1(H)$ let $Y_0(v)$ be the set of colorings in Y in which w_L is colored v. Now

$$|Y_0(v)| \le (\Delta_1(H)-1)^{|B|}|V(H)|^{q+|A|+1}.$$

Now consider any $(v_i, v_j) \in R(H)$. There are at least $\Delta_2(H)^{|A|}\Delta_1(H)^{|B|}$ colorings of $f(G,\epsilon)$ with (w_L, w_R) colored (v_i, v_j) (for example, the colorings in which all of the vertices of the graphs $G_{i,j}$ are colored with either v_i or v_j). Thus, $|Y| \ge \Delta_2(H)^{|A|}\Delta_1(H)^{|B|} \ge \Delta_1(H)^{|B|}$. We conclude that

$$|Y_0(v)| \le (\epsilon/(8|V(H)|))|Y|. \tag{17}$$

Now consider any edge $(v_i, v_k) \in E(H)$ such that $\deg(v_i) = \Delta_1(H)$ but $\deg(v_k) < \Delta_2(H)$. Let $Y_0(v_i, v_k)$ be the set of colorings in Y in which (w_L, w_R) is colored (v_i, v_k). Now

$$|Y_0(v_i, v_k)| \leq \Delta_1(H)^{|B|}(\Delta_2(H) - 1)^{|A|}|V(H)|^q.$$

Also, from before $|Y| \geq \Delta_2(H)^{|A|}\Delta_1(H)^{|B|}$, so

$$|Y_0(v_i, v_k)| \leq (\epsilon/(8|E(H)|))|Y|. \tag{18}$$

Equations (17) and (18) imply (7) since $|Y_0| \leq \sum_{v \in V(H)} Y_0(v) + \sum_{(v_i,v_k)} |Y_0(v_i, v_k)|$.

For an edge $(v_i, v_j) \in R(H)$, let $Y_{i,j}$ be the set of colorings of $f(G, \epsilon)$ with (w_L, w_R) colored (v_i, v_j). Let Γ be the set of induced colorings on $G_{i,j}$. Note that Γ is the set of fixed $H_{i,j}$-colorings of $G_{i,j}$. Also, each coloring in Γ comes up ψ times in $Y_{i,j}$, where ψ is the number of induced colorings on the vertices other than $G_{i,j}$. For a coloring $y \in Y_{i,j}$ we will set $g(G, \epsilon, y) = g_{i,j}(G_{i,j}, \epsilon/2, y')$, where y' is the induced coloring on $G_{i,j}$. Then (5) follows from the fact that $(f_{i,j}, g_{i,j})$ is an SP-reduction. □

Theorem 2 follows from Lemma 1 and Lemma 7 and from Lemma 8 below. Recall the following definitions. A *randomized approximation scheme* (RAS) for a counting problem F is a randomized algorithm that takes input σ and accuracy parameter $\epsilon \in (0, 1)$ and produces as output an integer random variable Y satisfying the condition $\Pr(e^{-\epsilon}F(\sigma) \leq Y \leq e^{\epsilon}F(\sigma)) \geq 3/4$. It is a "fully polynomial" randomized approximation scheme (FPRAS) if it runs in time $\text{poly}(|\sigma|, \epsilon^{-1})$. The problem #BIS is "self-reducible," so the following lemma follows from [17].

LEMMA 8 (JVV). *If* SAMPLEBIS *has a PAUS, then* #BIS *has an FPRAS.*

Proof. The lemma is a special case of Theorem 6.4 of [17]. In order to apply Theorem 6.4 directly we would need to define "self-reducible" formally and to deal with some easy (though annoying) issues:

(i) Inputs to #BIS may be disconnected, but inputs to SAMPLEBIS may not.
(ii) In order to apply Theorem 6.4 we technically need a *fully* polynomial almost uniform sampler (FPAUS) for SAMPLEBIS. This can be obtained from a PAUS, as [17] explains.

Rather than dealing with these issues, we prefer to simply provide a proof for the lemma. The details given here are from the proof of Proposition 3.4 of [16]. Technically, Jerrum's proof from [16] is about counting *matchings*, but the few changes that are needed to yield our lemma are completely routine.

Let (G, ϵ) be an input to #BIS. Suppose that G has components $G_1, \ldots, G_k$. For each i, let the two parts of the vertex set be $V_L(G_i)$ and $V_R(G_i)$, and let the sizes of these parts be ℓ_i and r_i, respectively. Let $N_i = \ell_i r_i$, and let $E(G_i) = \{e_i(1), \ldots, e_i(m_i)\}$. Denote the nonedges of G_i by $\{e_i(m_i + 1), \ldots, e_i(N_i)\}$. For $j \in \{1, \ldots, N_i\}$, let $G_i(j)$ be the graph $(V(G_i), \{e_i(1), \ldots, e_i(j)\})$. For any graph G', let $\mathcal{I}(G')$ denote the set of independent sets of G'. Let

$$\rho_i(j) = \frac{|\mathcal{I}(G_i(j+1))|}{|\mathcal{I}(G_i(j))|}.$$

Note that

$$|\mathcal{I}(G_i)| = (\rho_i(m_i)\rho_i(m_i + 1) \cdots \rho_i(N_i - 1))^{-1}|\mathcal{I}(G_i(N_i))|.$$

Also, the number of independent sets of the complete bipartite graph $G_i(N_i)$ is $2^{\ell_i} + 2^{r_i} - 1$, so

$$|\mathcal{I}(G_i)| = (2^{\ell_i} + 2^{r_i} - 1) \prod_{j=m_i}^{N_i-1} \rho_i(j)^{-1}. \tag{19}$$

Furthermore,

$$|\mathcal{I}(G)| = \prod_{i=1}^{k} |\mathcal{I}(G_i)| = \prod_{i=1}^{k} (2^{\ell_i} + 2^{r_i} - 1) \prod_{j=m_i}^{N_i-1} \rho_i(j)^{-1}. \tag{20}$$

Now let $z = \sum_{i=1}^{k} (N_i - m_i)$. In order to estimate $|\mathcal{I}(G)|$, we need to estimate the z ratios $\rho_i(j)$.

For each ratio $\rho_i(j)$ we can make some observations.

(i) $\rho_i(j) \leq 1$, since $\mathcal{I}(G_i(j+1)) \subseteq \mathcal{I}(G_i(j))$.

(ii) $\rho_i(j) \geq 1/2$, since $\mathcal{I}(G_i(j)) \backslash \mathcal{I}(G_i(j+1))$ can be mapped injectively into $\mathcal{I}(G_i(j+1))$ by removing the lexicographically least endpoint of $e_i(j+1)$.

(iii) Let $\mathcal{A}$ be a PAUS for SampleBIS. For $i \in [1, \ldots, k]$ and $j \in [m_i, \ldots, N_i - 1]$, let $Z_i(j)$ be the indicator variable for the event that, when we run $\mathcal{A}$ with input $G_i(j)$ and accuracy parameter δ, the output is an independent set of $G_i(j+1)$. Note that $\rho_i(j) - \delta \leq E[Z_i(j)] \leq \rho_i(j) + \delta$. This follows immediately from the definition of PAUS, but it is important to note that the input to $\mathcal{A}$, $G_i(j)$, is connected (since all inputs to SampleBIS must be connected).

Let $\overline{Z_i(j)}$ be the result obtained by calling $\mathcal{A}$ $\lceil 74\epsilon^{-2}z \rceil$ times with input $G_i(j)$ and accuracy parameter $\delta = \epsilon/(6z)$ and averaging the value of $Z_i(j)$ which occurs each time. Jerrum shows in his proof that with probability at least 3/4,

$$e^{-\epsilon} \prod_{i=1}^{k} \prod_{j=m_i}^{N_i-1} \rho_i(j) \leq \prod_{i=1}^{k} \prod_{j=m_i}^{N_i-1} \overline{Z_i(j)} \leq e^{\epsilon} \prod_{i=1}^{k} \prod_{j=m_i}^{N_i-1} \rho_i(j).$$

Thus, the quantity

$$\prod_{i=1}^{k} (2^{\ell_i} + 2^{r_i} - 1) \prod_{j=m_i}^{N_i-1} \overline{Z_i(j)}^{-1}$$

is a sufficiently accurate estimate of $|\mathcal{I}(G)|$.

For each of the z pairs (i, j), $O(\epsilon^{-2}z)$ samples were needed, each of which is produced in time $\text{poly}(|G|, z/\epsilon)$. Since $z \leq |V(G)|^2$, the total running time is $\text{poly}(|G|, \epsilon^{-1})$, and we have an FPRAS. □

7. The presence of trivial components. Theorem 2 shows that sampling H-colorings is difficult if every component of H is nontrivial. Recall from [10] that exactly counting H-colorings is #P-complete if H has even one nontrivial component. Thus, it might appear that Theorem 2 can be improved. In this section, we show that the existence of a single nontrivial component is not enough to make sampling difficult. In particular, we give an example of a graph H with a nontrivial component for which Sample$H$-Col has a PAUS. Specifically, let H be the graph depicted in Figure 4.

Observation 9. Suppose that H is the graph depicted in Figure 4. Sample$H$-Col has a PAUS.

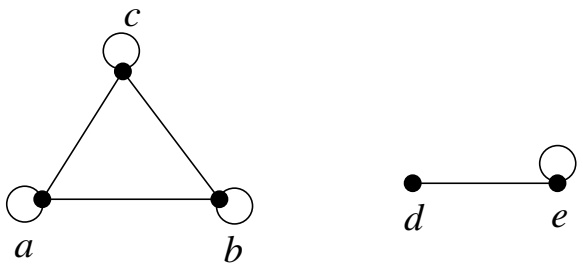

FIG. 4. *An H with a nontrivial component for which* SAMPLEH-COL *has a PAUS.*

Proof. Here is a PAUS for SAMPLEH-COL. The input is an instance (G, ϵ) where G has n vertices and, without loss of generality,[3] is connected. If $\epsilon < 2^n/(2^n + 3^n)$ then the algorithm simply runs for 5^n steps, constructs all of the H-colorings of G (and counts them) and selects one uniformly at random. Note that the running time is at most poly$(1/\epsilon)$ in this case. Otherwise, the algorithm chooses i uniformly at random from $1, \ldots, 3^n + 2^n$. If $i \leq 3^n$, then the algorithm outputs the i'th coloring from the 3^n colorings with colors "a", "b", and "c". Otherwise, let C be the $(i - 3^n)$th of the 2^n (proper and improper) colorings with colors "d" and "e". If C is a legal H-coloring of G, then the algorithm outputs it. Otherwise, it outputs the error symbol $\perp$. The variation distance between the output distribution of the algorithm and the uniform distribution on H-colorings of G is at most the probability that the algorithm outputs $\perp$, which is at most $2^n/(2^n + 3^n) \leq \epsilon$. □

8. Sampling and counting. Let #BH-COL be defined as follows.

Name. #BH-COL.
Instance. A loop-free connected bipartite graph G.
Output. The number of H-colorings of G.

For certain graphs H, the problem #BH-COL can be expressed as the counting problem associated with a "self-reducible p-relation." For such an H, Theorem 6.3 of Jerrum, Valiant, and Vazirani's paper [17] guarantees that if there is an FPRAS for #BH-COL, then there is a PAUS for SAMPLEBH-COL. If H has no trivial components, this in turn guarantees (by Theorem 2) an FPRAS for #BIS. Dyer and Greenhill [8] have given a more general framework in which these ideas work: If, for a given graph H, the problem #BH-COL is "self-partitionable," then an FPRAS for #BH-COL can be turned into a PAUS for SAMPLEBH-COL. It is not clear for which graphs H these ideas can be applied, and this is an interesting open question.

A related problem (which is also open) is to determine for which graphs H an FPRAS for counting H-colorings can be turned into a PAUS for SAMPLEH-COL. Dyer, Goldberg, and Jerrum [7] have shown that for every fixed H a PAUS for SAMPLEH-COL can be turned into an FPRAS for counting H-colorings.

Acknowledgments. We thank Martin Dyer, Paul Goldberg, and Mark Jerrum for useful conversations.

[3] We can assume that the input is a connected graph without losing generality because we can obtain an H-coloring of a k-component graph G by independently calling our PAUS for each component, specifying accuracy parameter ϵ/k. The final variation distance (between the output distribution and the uniform distribution on H-colorings of G) is at most ϵ.

THE POTENTIAL OF THE APPROXIMATION METHOD*

KAZUYUKI AMANO† AND AKIRA MARUOKA†

Abstract. Developing certain techniques for the approximation method, we establish precise versions of the following statements concerning lower bounds for circuits that detect cliques of size s in a graph with m vertices: For $5 \leq s \leq m/4$, a monotone circuit computing CLIQUE(m, s) contains at least $(1/2)1.8^{\min(\sqrt{s-1}/2, m/(4s))}$ gates: If a nonmonotone circuit computes CLIQUE using a "small" amount of negation, then the circuit contains an exponential number of gates. The former is proved by using so-called bottleneck counting argument within the framework of approximation, and the latter is verified by introducing a notion of restricting negation in circuits and generalizing these arguments to nonmonotone cases.

Key words. circuit complexity, lower bounds, clique function, approximation method, monotone circuit, negation-limited circuit

1. Introduction.

Since Razborov introduced the approximation method [9] and used it successfully to prove a superpolynomial lower bound on the size of monotone circuits computing the clique function, much effort has been devoted to exploring the method and to deriving good lower bounds using it (e.g., [1, 2, 7, 8, 9, 10, 11, 13]). Alon and Boppana [1] obtained an exponential lower bound on the size of monotone circuits that compute the clique function, through a clever use of the approximation method. Using an apparently different argument, called *bottleneck counting*, Haken [4] derived an exponential lower bound on the size of monotone circuits that compute a variant of the clique function. Razborov, in subsequent work, showed that the approximation method can, in principle, provide tight lower bounds for nonmonotone circuits [10]. In spite of these advances, it remains a challenging problem to apply the method successfully to obtain good lower bounds on the size of circuits computing a given problem. This is especially hard when we deal with nonmonotone circuits.

In this paper, we extend our knowledge of the method in two ways. First, we show how to use the bottleneck counting argument within the framework of the approximation method. This allows us to present better lower bounds for a certain clique problem and to simplify considerably the proof both for the clique problem and for a problem that Alon and Boppana addressed. Second, we extend the method for nonmonotone circuits for the clique problem, although we must restrict ourselves to circuits with a restricted amount of negation.

More precisely, the results obtained in these ways are as follows. First, denoting by CLIQUE(m, s) the clique function detecting cliques of size s in a graph with m vertices, we obtain a lower bound of $(1/2)1.8^{\min(\sqrt{s-1}/2, m/(4s))}$ for $5 \leq s \leq m/4$. This lower bound should be contrasted with the best current lower bound for the clique function, $(1/8)(m/(4s^{3/2} \log m))^{\sqrt{s+1}/2}$ for $3 \leq s \leq (1/4)(m/\log m)^{2/3}$, obtained by

Alon and Boppana [1]. So, as for the largest monotone lower bound for the clique function, our bound is $\exp(\Omega(m^{1/3}))$ for $s = \lceil m^{2/3} \rceil$, whereas the one due to Alon and Boppana is $\exp(\Omega((m/\log m)^{1/3}))$ for $s = (1/4)(m/\log m)^{2/3}$. To derive these lower bounds, we define approximators, instead of relying on the sunflower contraction, in terms of DNF and CNF formulas such that the size (or the length) of terms and clauses in the formulas is limited appropriately. In this way, we succeeded in simplifying greatly the proofs to obtain these bounds, using only elementary combinatorics. The similarity between the method of approximations and the bottleneck counting arguments were independently found by Berg and Ulfberg [3], Jukna [6], and Simon and Tsai [12]. More recently, Harnik and Raz [5] proved a higher lower bound of $2^{\Omega((n/\log n)^{1/3})}$ on the monotone circuit size of an explicit function by introducing the *monotone switching lemma* between DNF and CNF approximators.

Second, we extend the method discussed in the first part of this paper so as to apply for the case of nonmonotone circuits, provided that the amount of negation in circuits is restricted. To do so, we introduce a notion of restricting negation used in a circuit. For circuit C with input variables $x_1, \ldots x_n, \bar{x}_1, \ldots \bar{x}_n$, let its monotone analogue, denoted C_{ex}, be the monotone circuit obtained by replacing each negated variable $\bar{x}_i$ in C with a new input variable y_i. There exists an obvious correspondence between minterms of the function computed by a circuit C and those of the function computed by the corresponding circuit C_{ex}. When we deal with circuit C_{ex} we pay attention only to such minterms. Then we consider the maximum number of variables $y_1, \ldots, y_n$ appearing in such a minterm computed by C_{ex} as the parameter indicating an amount of negation used in C. Setting the parameter to an integer between 0 and n, we get a variety of restricted negation circuits, ranging from monotone circuits to general Boolean circuits. Based on the notion of restricting negation, we verify that if a nonmonotone circuit C computes CLIQUE(m, m^c) with the parameter at most $m^{c/2-\epsilon}$, then the size of the circuit C is given by $\exp(\Omega(m^{c/2}))$, where c and ϵ are any constants such that $0 < c \leq 2/3$ and $0 < \epsilon < c$. One might think of the result as showing the extent to which an argument based on bottleneck counting can be generalized to apply in nonmonotone cases.

2. Preliminaries. A *Boolean circuit* is a directed acyclic graph where each node has indegree 0 or 2. The nodes of indegree 0 are called input nodes, and are labeled with a variable x_i or its negation $\bar{x}_i$. The nodes of indegree 2 are called gates and are labeled with the Boolean functions AND and OR. AND and OR gates are also called $\wedge$ and $\vee$ gates, respectively. A circuit represents a Boolean function computed at a node in the circuit designated as the output node. In particular, a Boolean circuit without input nodes labeled with negated variables is called *monotone*. The *size* of a circuit C is the number of gates in the circuit C.

For ease of arguments, in section 3 a monotone circuit is further assumed to satisfy the following conditions: Any input of an $\vee$ gate is connected to either an output of $\wedge$ gate or an input node, and any input of an $\wedge$ gate is connected to either an output of $\vee$ gate or an input node. The output gate is an $\wedge$ gate. Any monotone circuit can be easily converted to the one satisfying these conditions by replacing, if necessary, a line connecting gates by a dummy gate (that can be thought of as an $\vee$ gate or an $\wedge$ gate, appropriately) with their two inputs being connected to an output of the same gate and hence by at most doubling the size of the circuit. The *circuit complexity* (*monotone circuit complexity*) of a function f is the size of the smallest circuit (monotone circuit) computing f.

3. Lower bounds for monotone circuit complexity based on CNF and DNF based approximators. In this section, we derive lower bounds for the clique problem and also those for a problem defined in terms of polynomials. The clique function, denoted CLIQUE(m, s), of $m(m-1)/2$ variables $\{x_{i,j} \mid 1 \le i < j \le m\}$ is defined to take value 1 if and only if the undirected graph on m vertices, with adjacency matrix X such that $x_{i,j}$ is the upper triangular submatrix of X, contains a clique of size s. The graphs will be identified with the assignments to the variables specifying the graphs.

THEOREM 3.1. *If $5 \le s \le m/4$, then any monotone circuit that computes the function CLIQUE(m, s) contains at least $(1/2)1.8^{\min(\sqrt{s-1}/2, m/(4s))}$ gates. In particular, the monotone circuit complexity of CLIQUE$(m, \lceil m^{2/3} \rceil)$ is $\exp(\Omega(m^{1/3}))$.*

We now proceed to proving Theorem 3.1 in the framework of approximation method. We define good and bad graphs which are used as test inputs to compare the circuit's behavior with the behavior of the clique function. A graph is called *good* if it consists of a clique on some set of s vertices and no other edges. A graph is called *bad* if there exists a partition of the vertices into $m \bmod (s-1)$ sets of size $\lceil m/(s-1) \rceil$ and $s - 1 - (m \bmod (s-1))$ sets of size $\lfloor m/(s-1) \rfloor$ such that any two vertices chosen from different sets have an edge between them, and no other edges exist. Note that the function CLIQUE(m, s) outputs value 1 on every good graph and outputs 0 on every bad graph. The following fact is obvious.

FACT 3.2. *There are*

$$\frac{m!}{s!(m-s)!}$$

good graphs and

$$\frac{m!}{(\lceil m/(s-1) \rceil !)^w (\lfloor m/(s-1) \rfloor !)^{s-1-w} w!(s-1-w)!}$$

bad graphs, where $w = m \bmod (s-1)$.

Let t be a term or a clause. The *endpoint set* of t is a set of all endpoints of the edges corresponding to variables in t. The *size* of t is the cardinality of the endpoint set of t.

We are ready to define an approximator circuit to approximate a monotone circuit. An approximator circuit $\overline{C}$ for a Boolean circuit C is the same graph as C, with $\vee$ and $\wedge$ gates replaced by $\overline{\vee}$ and $\overline{\wedge}$ gates. The nodes of the approximator circuit compute *approximators* defined as follows: the approximator corresponding to input variable x_i is defined to be x_i itself. The functions of an $\overline{\vee}$ gate and an $\overline{\wedge}$ gate are defined as follows (the integers l and r in the definition are chosen later):

- $\overline{\vee}$: Let f_1^D and f_2^D be two approximators, represented by monotone DNF formulas, feeding into an $\overline{\vee}$ gate. The approximate OR of these approximators is the monotone CNF formula obtained by transforming the monotone DNF formula $f_1^D \vee f_2^D$ into the equivalent monotone CNF formula and then taking away all the clauses whose sizes exceed r.
- $\overline{\wedge}$: Let f_1^C and f_2^C be two approximators, represented by monotone CNF formulas, feeding into an $\overline{\wedge}$ gate. The approximate AND of these approximators is the monotone DNF formula obtained by transforming the monotone CNF formula $f_1^C \wedge f_2^C$ into the equivalent monotone DNF formula and then taking away all the terms whose sizes exceed l.

Since we assumed that no output of an $\vee$ (resp., $\wedge$) gate is connected to an $\vee$ (resp., $\wedge$) gate, an approximator computed at an $\overline{\vee}$ gate is given by a monotone CNF

formula, and an approximator computed at an $\overline{\wedge}$ gate is given by a monotone DNF formula, where both formulas satisfy the size requirements. For Boolean functions f and g, let us denote $f \leq g$ if and only if $f(x) \leq g(x)$ holds for any input vector x. Note that the definition $(f_1 \,\overline{\vee}\, f_2) \geq (f_1 \vee f_2)$ holds for any monotone DNF formulas f_1 and f_2. Similarly, $(f_1 \,\overline{\wedge}\, f_2) \leq (f_1 \wedge f_2)$ holds for any monotone CNF formulas f_1 and f_2.

Let C be a monotone circuit computing CLIQUE(m, s), and let $\overline{C}$ (called the approximator circuit corresponding to C) denote the circuit obtained by replacing all of the $\vee$ and $\wedge$ gates in C by $\overline{\vee}$ and $\overline{\wedge}$ gates, respectively. Since the computation in $\overline{C}$ proceeds from bottom to top, it is easy to see that for any good graph that makes approximator circuit $\overline{C}$ output 0, there exists an $\overline{\wedge}$ gate that outputs 0 for the good graph due to taking the terms away in defining its output approximator. So, an $\wedge$ gate feeds the same input approximators as those to the $\overline{\wedge}$ gate outputs 1. Similarly, for any bad graph that makes approximator circuit $\overline{C}$ output 1, there exists an $\overline{\vee}$ gate that outputs 1 for the bad graph because of taking the clauses away in defining its output approximator.

The proof of Theorem 3.1 proceeds as follows: First, show that either of the number of good graphs that are incorrectly classified by the approximator circuit or the number of bad graphs incorrectly classified is large (Lemma 3.3). Second, show that the number of bad graphs for which an approximate gate $\vee$ (i.e., $\overline{\vee}$ gate) behaves differently from an $\vee$ gate is small (Lemma 3.4) and similarly the number of good graphs for which an approximate $\wedge$ gate (i.e., $\overline{\wedge}$ gate) behaves differently from a $\wedge$ gate is small (Lemma 3.5). Finally, calculate the numbers obtained by dividing the numbers of bad and good graphs incorrectly classified by an approximator circuit by the numbers of graphs for which the corresponding approximate gates behaves differently, respectively, and show that the larger of the two numbers calculated becomes large, completing the proof of Theorem 3.1. It is worthwhile to note that it is straightforward to extend our proofs to arbitrary fan-in circuit without changing the lower bounds we obtained.

The parameters l and r are chosen to be $l = \lfloor \sqrt{s-1}/2 \rfloor$ and $r = \lfloor m/(4s) \rfloor$.

LEMMA 3.3. *An approximator circuit either outputs identically* 0 *or outputs* 1 *on at least one half of the bad graphs.*

Proof. Let $\overline{f}$ be the approximator function that an approximator circuit computes. Because of the assumption that the output gate of an approximator circuit is $\wedge$ gate, $\overline{f}$ can be represented by a monotone DNF formula consisting of terms of size at most l. If $\overline{f}$ is identically 0, then the first conclusion holds. If not, then there is a term t whose size is less than or equal to l such that $\overline{f} \geq t$ holds. In what follows, bad graphs are represented as one-to-one mappings from vertex set $\{v_1, \ldots, v_m\}$ to $\{(1,1),\ldots,(1, \lceil m/(s-1) \rceil), \ldots, (w,1),\ldots,(w, \lceil m/(s-1) \rceil), (w+1,1), \ldots, (w+1, \lfloor m/(s-1) \rfloor), (w+2,1), \ldots, (s-1, \lfloor m/(s-1) \rfloor)\}$. Such a mapping specifies a bad graph in the obvious way: Two vertices in the graph have an edge between them if and only if the mapping assigns to the vertices a pair with different first components. Note that there exist many mappings corresponding to one bad graph. It is easy to see that the ratio of mappings that satisfy the condition that there is a variable x in the term t such that two vertices incident to x are assigned a pair with the same first component, i.e., the term t outputs 0 on bad graphs specified by such mappings, is at most $(l(l-1)/2)(\lceil m/(s-1) \rceil / m)$. Recalling $l = \lfloor \sqrt{s-1}/2 \rfloor$, the quantity above is bounded from above by $1/2$. Therefore, the ratio of bad graphs such that $\overline{f}$ outputs 1 on them is at least $1/2$. □

LEMMA 3.4. *Suppose that an $\vee$ gate and an $\overline{\vee}$ gate are given as input the same monotone DNF formulas such that the size of terms in the formulas is equal to or less than l. Then the number of bad graphs for which the $\vee$ and $\overline{\vee}$ gates produce different outputs (the $\vee$ gate produces 0, whereas the $\overline{\vee}$ gate produces 1) is at most*

$$\frac{(m/2)^{r+1}(m-r-1)!}{(\lceil m/(s-1)\rceil !)^w(\lfloor m/(s-1)\rfloor !)^{s-1-w}w!(s-1-w)!}. \tag{3.1}$$

Proof. Suppose that an $\vee$ gate and an $\overline{\vee}$ gate are given as input the same monotone DNF formulas, denoted f_1^D and f_2^D, such that the size of any term in the formulas is equal to or smaller than l. Let $f_1^D \vee f_2^D$ and $f_1^D \,\overline{\vee}\, f_2^D$ be denoted by f^D and f^C, respectively. Let $t_1, \ldots, t_q$ be the complete list of terms in f^D. Then each t_i contains at most $l(l-1)/2$ variables. We shall count the number of bad graphs x such that both $f^D(x) = 0$ and $f^C(x) = 1$ hold. As in the proof of Lemma 3.3, bad graphs are represented as mappings described there. Instead of counting bad graphs directly, we count mappings corresponding to bad graphs. The number in question is bounded from above by the number of the mappings corresponding to bad graphs x such that $f^D(x) = 0$ and $f^C(x) = 1$ divided by the number of mappings corresponding to one bad graph. (The number of mappings is independent of the bad graph chosen.) Since the latter is given by the denominator of (3.1), it suffices to estimate the former. The former is the number of mappings corresponding to bad graphs x that do not satisfy any of $t_1, \ldots, t_q$ but satisfy all clauses in f^C. We count how many ways one could choose variables from terms t_1 up to t_q and assign pairs of integers to the endpoints associated with the variables chosen so that the corresponding bad graphs x satisfy $f^D(x) = 0$ and $f^C(x) = 1$.

Suppose that we proceed to term t_i, and hence some of the endpoints associated with variables from terms t_1 to t_{i-1} are already assigned distinct pairs of integers. This partial assignment assigns 0 and 1 to some of variables in the way mentioned above. We first consider the extreme cases. If there exists a variable in term t_i already assigned 0 by the partial assignment, we skip to the next term t_{i+1}. The other extreme case occurs when all the variables in term t_i are assigned 1 so far. In this case term t_i will never take value 0, hence we don't need to consider the case.

If neither of these extreme cases happens, choose a variable from term t_i such that at least one of the vertices associated with the variable is not assigned a pair of integers. There are two cases to consider: If exactly one of the vertices is assigned so far, then assign to the remaining vertex a pair whose first component is identical to the first component of the pair of integers assigned to the other vertex so that the variable associated with the two vertices is assigned 0. In this case, there are at most $\lceil m/(s-1)\rceil - 1 \le m/(s-1)$ ways of assigning pairs of integers to the vertex. On the other hand, if both of the vertices have not been chosen so far, assign to these vertices pairs of integers with the same first components, so that the variable associated with the two vertices is assigned 0. So, for the two vertices, there are at most $(s-1)(\lceil m/(s-1)\rceil)(\lceil m/(s-1)\rceil - 1) \le 2m^2/(s-1)$ ways of assigning pairs of integers.

Suppose that there exist k variables in term t_i such that exactly one of the vertices corresponding to the variables is assigned a pair of integers so far. Then there exist at most $l(l-1)/2 - k$ variables in term t_i such that none of the vertices associated with the variables is assigned a pair of integers so far. So the number of ways of choosing an unassigned vertex in the endpoints of variables in t_i and assigning a pair of integers

to the chosen vertex is bounded from above by

$$\max_k(km/(s-1) + \sqrt{(l(l-1)/2-k)(2m^2/(s-1))}), \tag{3.2}$$

where integer k ranges from 0 to $l(l-1)/2$. This is because doing something to two vertices in i ways can be regarded as doing something to a vertex appropriately in $\sqrt{i}$ ways twice successively. Because of $l \leq \sqrt{s-1}/2$, a simple calculation shows that the quantity above is maximized when $k = 0$, and is bounded from above by $m/2$.

By the definition of $\overline{\vee}$ gate, it is easy to see that the graphs x corresponding to the mappings specified in this way satisfy $f^D(x) = 0$ and $f^C(x) = 1$ only if there exist more than r vertices assigned pairs of integers in the above procedure. So the number of mappings corresponding to such bad graphs is bounded from above by the number of mappings such that $r+1$ vertices are assigned pairs of integers multiplied by the number of ways of assigning arbitrarily distinct pairs of integers to the remaining $m-r-1$ vertices. The resulting number is given by the numerator of (3.1), completing the proof. □

LEMMA 3.5. *Suppose that an $\wedge$ gate and an $\overline{\wedge}$ gate are given as input the same monotone CNF formulas such that the size of terms in the formulas is equal to or less than r. Then the number of good graphs for which the $\wedge$ gate and the $\overline{\wedge}$ gate produce different outputs (the $\wedge$ gate produces 1, whereas the $\overline{\wedge}$ gate produces 0) is at most*

$$\frac{(m/2)^{l+1}(m-l-1)!}{s!(m-s)!}.$$

Proof. The proof is similar to that of Lemma 3.4. Suppose that an $\wedge$ gate and an $\overline{\wedge}$ gate are given as input the same monotone CNF formulas, denoted f_1^C and f_2^C, as in the lemma. Let $f^C = f_1^C \wedge f_2^C$ and $f^D = f_1^C \,\overline{\wedge}\, f_2^C$. Let $c_1, \ldots, c_q$ be the complete list of clauses in f^C, where each c_i contains at most $r(r-1)/2$ variables. The number in question is equal to the number of good graphs x such that $f^C(x) = 1$ and $f^D(x) = 0$ hold.

Instead of the mappings from vertices to the integer pairs in the case of Lemma 3.4, we consider one-to-one mappings from the vertex set $\{v_1, \ldots, v_m\}$ to the integer set $\{1, \ldots, m\}$. Such a mapping can be thought of as specifying a good graph such that the set of vertices assigned integers from 1 to s forms a clique. The number mentioned in the lemma is at most the number of mappings corresponding to good graphs x that satisfy all clauses of $c_1, \ldots, c_q$ but do not satisfy any term in f^D divided by the number of mappings corresponding to one good graph.

As in the case of Lemma 3.4, we count how many ways one could choose variables each from clauses of $c_1, \ldots, c_q$ and assign integers to the vertices associated with the variables chosen so that all of the clauses are satisfied but the disjunctive normal form formulas $f_1^C \,\overline{\wedge}\, f_2^C$ is not satisfied. Suppose that we proceed to clause c_i and, hence, some of the vertices are assigned integers from 1 to s so that all of the clauses from c_1 to c_{i-1} are satisfied. Such an assignment is called a partial assignment. If there exists a variable in c_i assigned 1 by the partial assignment, we skip to the next clause c_{i+1}.

The variable $x_{j,k}$ is said to be incident to vertices v_j and v_k. To count the number of ways of making clause c_i take value 1, there are two cases to consider: Choose a variable in c_i incident to two vertices; one is assigned an integer by the partial assignment and the other is not. Choose a variable in c_i incident to two vertices that are not assigned integers so far.

As in the proof of Lemma 3.4, the number of ways of choosing unassigned vertices and assigning integers to the vertices so as to make clause c_i take value 1 is bounded from above by

$$r(s-1)+\sqrt{(r(r-1)/2)s(s-1)} < 2rs. \tag{3.3}$$

Since $r \le m/(4s)$, this quantity is bounded from above by $m/2$. The rest of the proof is similar to that of Lemma 3.4. □

Now we proceed to the proof of Theorem 3.1.

Proof of Theorem 3.1. In view of Fact 3.2 and Lemmas 3.3, 3.4, and 3.5, the size of a monotone circuit that computes CLIQUE(m,s) is at least

$$\min\left(\frac{m!}{2(m/2)^{r+1}(m-r-1)!}\ ,\ \frac{m!}{(m/2)^{l+1}(m-l-1)!}\right),$$

which is bounded from below by

$$\min\left(\frac{(m-r)^{r+1}}{2(m/2)^{r+1}}\ ,\ \frac{(m-l)^{l+1}}{(m/2)^{l+1}}\ \right). \tag{3.4}$$

Since $5 \le s \le m/4$, we have $r \le m/10$ and $l \le m/10$. Hence, $m-r \ge 9m/10$ and $m-l \ge 9m/10$ hold. Therefore, (3.4) is bounded from below by

$$\min(1.8^{r+1}/2\ ,\ 1.8^{l+1}).$$

Thus, noticing $r+1 \ge m/(4s)$ and $l+1 \ge \sqrt{s-1}/2$, the proof is completed. □

One might expect that the definitions of approximate operations in the proof of Theorem 3.1 can be simplified by replacing "size" with "length," which is the number of variables appearing in terms and clauses. However, it turns out that such a simplification yields a weaker (although still exponential) lower bound.

Consider that we define the approximate operations based on "length" with suitable choices of l and r and apply the same argument as in the proof of Theorem 3.1. By the same counting argument as in the proof of Lemmas 3.4 and 3.5, the upper bound of the number of choices corresponding to (3.2) in the proof of Lemma 3.4 is

$$\max_k\{km(s-1)+\sqrt{(l-k)(2m^2/(s-1))}\}, \tag{3.5}$$

and the one corresponding to (3.3) in the proof of Lemma 3.5 is

$$\max_k\{k(s-1)+\sqrt{(r-k)s(s-1)}\}. \tag{3.6}$$

It is easy to see that if $r=\lfloor m/(4s)\rfloor$ and $l=\lfloor (s-1)/8\rfloor$, then the quantities of (3.5) and (3.6) are both smaller than $m/2$. It is also easy to see that the Lemma 3.3 holds for such l. However, Lemmas 3.4 and 3.5 may not hold this time. For example, in the proof of Lemma 3.4, the condition that there exist more than r vertices assigned pairs of integers in the procedure described in the proof is not a necessary condition to satisfy $f^D(x)=0$ and $f^C(x)=1$. Because if $r'(r'-1)/2 > r$, then there is a clause with more than r variables corresponding to the assignment that only r' vertices assigned pairs of integers. So we must replace the variable r in the statement of Lemma 3.4 with r' such that $r'(r'-1)/2 \le r$. By a similar reason, we also have to replace the variable l in the statement of Lemma 3.5 with l' such that $l'(l'-1)/2 \le l$. By using these lemmas and the similar argument as in the proof of Theorem 3.1,

we can obtain the $\exp(\Omega(\min(r', l')))) = \exp(\Omega(\min(\sqrt{m/s}, \sqrt{s})))$ lower bound for the size of a monotone circuit that computes CLIQUE(m, s). This lower bound is an exponential in m for a suitable choice of s; however, it is slightly weaker than the $\exp(\Omega(\min(m/s, \sqrt{s})))$ lower bound of Theorem 3.1.

We now consider another problem to show that our CNF and DNF based approximators make lower bound proofs simple.

Let $n = q^2$ and $x = \{x_{i,j} \mid 1 \leq i, j \leq q\}$, where q is a prime. Let $G(x)$ be the bipartite graph on $V = \{v_1, \ldots, v_q\}$ and $W = \{w_1, \ldots, w_q\}$ with edge set $\{(v_i, w_j) \mid x_{i,j} = 1\}$. The function POLY$(q, s)(x)$ of q^2 variables $\{x_{i,j}\}$ is defined as POLY$(q, s)(x) = 1$ if and only if there is a polynomial p over the field Z_q of degree at most $s - 1$ such that $G(x)$ includes all edges $(v_i, w_{p(i)})$ for $1 \leq i \leq q$.

The next theorem gives the same lower bound as the one due to Alon and Boppana [1].

THEOREM 3.6 (Alon and Boppana [1]). *If $s \leq (1/2)\sqrt{q/\ln q}$, then any monotone circuit that computes the function POLY(q, s) contains $q^{\Omega(s)}$ gates.*

To prove Theorem 3.6, we need a few lemmas. A graph is called *good* if there exists a polynomial p of degree at most $s - 1$ such that the set of edges of the graph is given as $\{(v_i, w_{p(i)}) \mid 1 \leq i \leq q\}$. Notice that the number of good graphs is q^s. For $0 \leq \epsilon \leq 1/2$, let NG$_\epsilon$ be the probability distribution on bipartite graphs with each edge appearing independently with probability $1 - \epsilon$. We choose $\epsilon = (2s \ln q)/q$. It is easy to see that

$$\Pr_{x \in NG_\epsilon}[\text{POLY}(q, s)(x) = 1] \leq q^s(1 - \epsilon)^q \leq q^s e^{-\epsilon q} = 1/q^s \leq 1/4. \tag{3.7}$$

So a graph x chosen according to NG$_\epsilon$ makes the value of the function POLY(q, s) to 0 with probability at least 3/4. These graphs serve as the bad graphs in the previous case.

Instead of defining approximators in terms of the size of terms and clauses, we define approximators this time in terms of the length of terms and clauses, i.e., the number of variables appearing in terms and clauses. Approximate operations of $\overline{\vee}$ gate and $\overline{\wedge}$ gate are defined exactly the same way as the previous case except that "size" is replaced with "length." As in the previous case, approximators are defined in bottom-up fashion, taking the approximator corresponding to input variable x_i to be x_i itself. The parameters l and r are put this time as $l = s$ and $r = \lceil \sqrt{q \ln q} \rceil$.

To prove Theorem 3.6, we need Lemmas 3.7, 3.8, and 3.9, which correspond to Lemmas 3.3, 3.4, and 3.5, respectively. We now proceed to the proof of the theorem.

LEMMA 3.7. *Let $\overline{f}$ be a function computed by an approximator circuit. Then $\overline{f}$ is identically* 0 *or*

$$\Pr_{x \in NG_\epsilon}[\textit{POLY}(q, s)(x) = 0 \textit{ and } \overline{f}(x) = 1] \geq 1/4.$$

Proof. If $\overline{f}$ is identically 0, then the first conclusion holds. If not, then there exists a term t of length at most l such that $\overline{f} \geq t$. Recall that the output gate is assumed to be an $\wedge$ gate, and, hence, $\overline{f}$ is given as a monotone DNF formula. Since $\epsilon = (2s \ln q)/q$, $l = s$ and $s \leq (1/2)\sqrt{q/\ln q}$, we have $\epsilon l \leq 1/2$. Since $0 \leq \epsilon 1/2$, we therefore have

$$\Pr_{x \in NG_\epsilon}[\overline{f}(x) = 1] \geq (1 - \epsilon)^l \geq (1/4)^{\epsilon l} \geq (1/4)^{1/2} = 1/2. \tag{3.8}$$

Thus the lemma follows from (3.8) and (3.7). □

LEMMA 3.8. *Let f_1^D and f_2^D be monotone DNF formulas such that the length of each term in them is at most l. Then*

$$\Pr_{x \in NG_\epsilon}[(f_1^D \vee f_2^D)(x) = 0 \text{ and } (f_1^D \overline{\vee} f_2^D)(x) = 1] \leq (1/2)^r.$$

Proof. Let f^D denote the monotone DNF formula $f_1^D \vee f_2^D$. We construct a decision tree computing f^D as follows. We start with a vertex associated with f^D, which becomes the root of the decision tree we shall construct. Take a term whose length is, say i, out of terms in f^D, and construct the path consisting of i vertices labeled with variables in the term and a leaf labeled 1. Furthermore, all the edges on the path is labeled with 1. Draw i edges out of all the vertices except the leaf together with distinct endpoints added and label these edges with 0. Each path from the root to one of the i vertices added specifies in the obvious way an assignment of 1 and 0 to the variables on the path except the endpoint of the path. Associate these endpoints with the functions obtained by substituting the Boolean values to the variables of f^D according to the corresponding assignments. Then repeat the procedure mentioned above with the vertices added until all the vertices are assigned with the constant functions.

Let $path_x$ denote the path from the root to a leaf specified, in the obvious way, by assignment x. Let (u, v) be an arbitrary edge labeled with 0 on $path_x$. Clearly, the probability that the $path_x$ doesn't pass any edge labeled with 0 after (u, v) on the condition that $path_x$ passes edge (u, v) is at least $(1 - \epsilon)^l$. This is because $path_x$ has at most l consecutive edges labeled with 1. Therefore, the probability that $path_x$ passes more that r edges labeled with 0 is at most $(1 - (1 - \epsilon)^l)^r$. Clearly, if both $(f_1^D \vee f_2^D)(x) = 0$ and $(f_1^D \overline{\vee} f_2^D)(x) = 1$ hold, then $path_x$ passes more than r edges labeled with 0. So the probability mentioned in the lemma is bounded from above by $(1 - (1 - \epsilon)^l)^r$. From the inequality $(1 - \epsilon)^l \geq 1/2$ in (3.8), this quantity is at most $(1 - 1/2)^r = (1/2)^r$. This completes the proof. □

LEMMA 3.9. *Let an $\wedge$ gate and an $\overline{\wedge}$ gate be given as input the same monotone CNF formulas such that the length of clauses in the formulas is equal to or less than r. Then the number of good graphs for which the $\wedge$ gate and the $\overline{\wedge}$ gate produce different outputs is at most r^l.*

Proof. The proof is similar to that of Lemma 3.5. Suppose that an $\wedge$ gate and an $\overline{\wedge}$ gate are given as input the same monotone CNF formulas, denoted f_1^C and f_2^C, such that the size of any clause in the formulas is equal to or less than r. Let $f_1^C \wedge f_2^C$ be denoted by f^C and let $c_1, \ldots, c_q$ be the complete list of clauses of f^C. Let f^D denote the DNF formula equivalent to f^C. Clearly, f^D is the Boolean sum of terms of distinct variables, each being chosen from c_1 up to c_p. Since $f_1^C \overline{\wedge} f_2^C$ is equal to the DNF formula obtained from f^D by taking away all the terms whose sizes exceed l and $l(= s)$ variables $x_{i,j}$ with distinct first indices i's specify a polynomial with degree $s - 1$, hence a good graph, it is easily seen that the number of good graphs x's such that $(f_1^C \wedge f_2^C)(x) = 1$ and $(f_1^C \overline{\wedge} f_2^C)(x) = 0$ is bounded from above by the number of ways of choosing a variable out of r variables (appearing in a clause) l times. Thus the number of such good graphs is at most r^l, completing the proof. □

Theorem 3.6 easily follows from Lemmas 3.7, 3.8, and 3.9.

Proof of Theorem 3.6. In view of Lemmas 3.7, 3.8, and 3.9, it is concluded that the size of the monotone circuit computing POLY(q, s) is at least $\min((q/r)^l, (1/4)2^r)$. Thus, the equations $l = s$ and $r = \lceil \sqrt{q \ln q} \rceil$ give the desired bound, completing the proof. □

4. Lower bounds for nonmonotone circuit complexity based on negation-based approximators. For two vectors v and v' in $\{0,1\}^n$, we denote $v' \lneq v$ if $v \neq v'$ and $v'_i \leq v_i$ for any $1 \leq i \leq n$, where v_i denotes the ith component of v. A vector v is called a *minimal true vector* for a Boolean function f if $f(v) = 1$ and, for any $v' \lneq v$, $f(v') = 0$. Let $\mathrm{Min}(f)$ be the set of all minimal true vectors of f. Similarly, when circuit C computes a function f, $\mathrm{Min}(C)$ denotes $\mathrm{Min}(f)$. Given a nonmonotone circuit C with input literals $x_1, \ldots, x_n, \bar{x}_1, \ldots, \bar{x}_n$, let C_{ex} denote the monotone circuit obtained from C by simply replacing each negated input variable $\bar{x}_i$ in C with a new input variable y_i for $1 \leq i \leq n$ without making any further modification. In what follows, C_{ex} will be called the monotone analogue of the original circuit C. Let the input vectors to circuits C and C_{ex} be denoted by $(x_1, \ldots, x_n, \bar{x}_1, \ldots, \bar{x}_n)$ and $(x_1, \ldots, x_n, y_1, \ldots, y_n)$, respectively. Obviously, these circuits produce the same output values for inputs represented as $(x_1, \ldots, x_n, \bar{x}_1, \ldots, \bar{x}_n)$.

Suppose that a circuit C computes a function f. When an input vector is given, all the wires in C are assigned 0 or 1 in the obvious way. We call a wire assigned the value 1 an *activated* wire. Given a positive vector, i.e., a vector that makes circuit C output 1, we have the collection of activated wires in the circuit C which contains at least one path from an input node to the output node. On the other hand, in the case of a negative vector, i.e., a vector that makes C output 0, such a collection of wires does not contain any path from an input node to the output node.

Now suppose that a positive vector x is given to the circuit C. In the nonmonotone case, not only the wires connected to inputs x_i with $x_i = 1$, but also the ones connected to inputs $\bar{x}_i$ with $x_i = 0$, which do not appear in monotone circuits, are activated. Since the circuit C contains only AND and OR gates in its inside, the entire collection of activated wires increases monotonically as the collection of activated wires at the input level increases. Hence, viewing the computation of a circuit like this, one might imagine that the more negated variables we are allowed to use, the more economically the collections of activated wires can reach the output node. These considerations lead us to the following definition, which formalizes a measure of the amount of negation used in the process of computation in a circuit.

DEFINITION 4.1. *Let C be a circuit computing a monotone function f on n variables and let C_{ex} be the monotone analogue of C. For v and u in $\{0,1\}^n$, $|v|_1$ denotes the number of 1's among v, and $v \circ u$ denotes the concatenation of v and u. For $0 \leq k \leq n$, we define $\mathrm{Min}_k(C)$ as follows:*

$$\mathrm{Min}_k(C) = \{v \in \mathrm{Min}(f) \,|\exists y \in \{0,1\}^n (|y|_1 \leq k) \wedge (v \circ y \in \mathrm{Min}(C_{ex}))\}.$$

In other words, a minterm v in f is in $\mathrm{Min}_k(C)$ when the minimum number of variables $y_1, \ldots, y_n$ appearing in the minterm of the function computed by C_{ex}, which corresponds to the minterm v, is at most k.

Note that by the definition

$$\mathrm{Min}_0(C) \subseteq \mathrm{Min}_1(C) \subseteq \cdots \subseteq \mathrm{Min}_n(C) = \mathrm{Min}(f).$$

In particular, if C is monotone, then $\mathrm{Min}_0(C) = \mathrm{Min}(f)$. We can think of the minimum i satisfying $\mathrm{Min}_i(C) = \mathrm{Min}(f)$ as a sort of measure indicating an amount of negation used in computing f. The condition $\mathrm{Min}_{m^{c/2-\epsilon}}(C) = \mathrm{Min}(\mathrm{CLIQUE}(m, m^c))$ in the theorem below can be thought of as saying that C uses a "small" amount of negation in the sense of Definition 4.1 because $m^{c/2-\epsilon}$ is much smaller than $n = m(m-1)/2$, namely the number of variables of CLIQUE. So, roughly, the theorem says that if a

nonmonotone circuit computes the clique function using a small amount of negation, then the circuit has an exponential number of gates.

THEOREM 4.2. *Let c and ϵ be constants such that $0 < c \leq 2/3$ and $0 < \epsilon < c/2$. Suppose that a circuit C computes the function CLIQUE(m, m^c). If $\mathrm{Min}_{m^{c/2-\epsilon}}(C) = \mathrm{Min}(CLIQUE(m, m^c))$ holds, then the size of C is $\exp(\Omega(m^{c/2}))$.*

The proof of the theorem will be done by a generalized argument based on the approximation method.

Let f be the function CLIQUE(m, s), where $s = m^c$. Let C be a circuit computing f whose monotone analogue is denoted by C_{ex}. Without loss of generality, we assume that m is divisible by s. Note that C_{ex} is assumed to be layered with alternating AND and OR layers, i.e., every AND gate is connected to an OR gate and vice versa, and the output gate of C_{ex} is an AND gate. Let $n = \binom{m}{2}$ be the number of input variables of CLIQUE. A vector $v \circ y$ of length $2n$ is called a *good* vector if $v \in \mathrm{Min}(f)$, $|y|_1 \leq k$, and $v \circ y \in \mathrm{Min}(C_{ex})$, where k is an integer whose value will be determined later. By the definition of $\mathrm{Min}(C_{ex})$, if $v \circ y$ is a good vector, then $v \circ y' \notin \mathrm{Min}(C_{ex})$ for any $y' \lneq y$. Let V be the set of m vertices of the graph associated with CLIQUE. A one-to-one mapping from V to the set $\{0, 1, \ldots, s-1\} \times \{1, \ldots, m/s\}$ is called a *bad* mapping. The definition of the bad mapping is the same to that for the monotone case except that we added the value 0 to the range of the first component of the bad mapping. We consider a bad mapping ϕ as the graph that has an edge between u and v whenever the first elements of $\phi(u)$ and $\phi(v)$ are different and both of them are not 0. For each bad mapping ϕ, the bad vector associated with ϕ is the vector $u \circ \bar{u}$, where $\bar{u} = (u\bar{}_1, u\bar{}_2, \ldots, u\bar{}_n)$. Note that every good vector makes the circuit C_{ex} output 1, whereas every bad vector makes the circuit C_{ex} output 0. The following fact is obvious.

FACT 4.3. *There are at least $|\mathrm{Min}_k(C_{ex})|$ good vectors and $m!$ bad mappings.*

We are now ready to define approximators as well as approximate operations. Put $X = \{x_1, \ldots, x_n\}$ and $Y = \{y_1, \ldots, y_n\}$. Let $\mathcal{N}(k)$ denote the collection of subsets of Y of size at most k. For a set of variables $L \subseteq X$, let $\lfloor L \rfloor$ denote the set of all endpoints of the edges corresponding to variables in L. For $W \subseteq V$, the set of variables whose both endpoints are in W is denoted by $\lceil W \rceil$. $\lceil W \rceil$ can be thought of as the subset of X which corresponds to the clique on W. As in the previous section, the *size* of a term or a clause t is the cardinality of the endpoint set of variables in t. In what follows, for a set of literals L, the product of all literals in L is denoted by $\wedge L$.

An approximator is defined to be a set of monotone functions denoted $\{f_Y\}_{Y \in \mathcal{N}(k)}$, where all of f_Y's are either monotone DNF formulas on X or monotone CNF formulas on X. We interpret the approximator $\{f_Y\}_{Y \in \mathcal{N}(k)}$ to represent the function written as $\vee_{Y \in \mathcal{N}(k)}(\wedge Y \cdot f_Y)$.

- $\overline{\vee}$: Let $\{f^D_{1,Y}\}_{Y \in \mathcal{N}(k)}$ and $\{f^D_{2,Y}\}_{Y \in \mathcal{N}(k)}$ be two approximators, each being sets of monotone DNF formulas. The approximate OR of these approximators, denoted $\{f^D_{1,Y}\}_{Y \in \mathcal{N}(k)} \overline{\vee} \{f^D_{2,Y}\}_{Y \in \mathcal{N}(k)}$, is defined as the set of monotone CNF formulas, denoted $\{f^C_Y\}_{Y \in \mathcal{N}(k)}$, where, for each $Y \in \mathcal{N}(k)$, f^C_Y is the monotone CNF formula obtained by transforming $f^D_{1,Y} \vee f^D_{2,Y}$ into the equivalent monotone CNF formula and then taking away all the clauses whose size exceed r.
- $\overline{\wedge}$: Let $\{f^C_{1,Y}\}_{Y \in \mathcal{N}(k)}$ and $\{f^C_{2,Y}\}_{Y \in \mathcal{N}(k)}$ be two approximators, each being sets of monotone CNF formulas. The approximate AND of these approximators, denoted $\{f^C_{1,Y}\}_{Y \in \mathcal{N}(k)} \overline{\wedge} \{f^C_{2,Y}\}_{Y \in \mathcal{N}(k)}$, is defined as the set of monotone DNF

formulas, denoted $\{f^D_Y\}_{Y\in\mathcal{N}(k)}$, where, for each $Y \in \mathcal{N}(k)$, f^D_Y is defined as follows:

1. For each $Y_1, Y_2 \in \mathcal{N}(k)$, let $f^D_{Y_1,Y_2}$ be the DNF formula obtained from the CNF formula $f^C_{Y_1} \wedge f^C_{Y_2}$ by transforming into the equivalent monotone DNF formula and then taking away all the clauses whose size exceed l.
2. For each $Y \in \mathcal{N}(k)$, set f'^D_Y to

$$f'^D_Y = \bigvee_{Y_1,Y_2:Y=Y_1\cup Y_2} f^D_{Y_1,Y_2}.$$

3. For each $Y \in \mathcal{N}(k)$, let f^D_Y be the monotone DNF formula obtained by replacing each term $\wedge L$ of f'^D_Y with the term $\wedge\lceil\lfloor L\rfloor\rceil$.

In what follows, an approximator $\{f_Y\}_{Y\in\mathcal{N}(k)}$ will be simply denoted by $\{f_Y\}_Y$. Note that $(\{f^D_{1,Y}\}_Y \overline{\vee} \{f^D_{2,Y}\}_Y) \geq (\{f^D_{1,Y}\}_Y \vee \{f^D_{2,Y}\}_Y)$ holds for any approximators $\{f^D_{1,Y}\}_Y$ and $\{f^D_{2,Y}\}_Y$ and that $(\{f^C_{1,Y}\}_Y \overline{\wedge} \{f^C_{2,Y}\}_Y) \leq (\{f^C_{1,Y}\}_Y \wedge \{f^C_{2,Y}\}_Y)$ holds for any approximators $\{f^C_{1,Y}\}_Y$ and $\{f^C_{2,Y}\}_Y$.

Now that the approximate operations are defined for nonmonotone circuits, approximators computed by gates are determined from the bottom to the top. In order to get approximators determined in this way, we need to specify the approximator corresponding to input variables: The approximator corresponding to x_i is simply defined to be x_i itself.

The proof of Theorem 4.2 proceeds in a similar way to those in the previous section. We first prove that the total error in an approximator circuit is large (Lemma 4.4) and then prove that the local error at any single gate is small (Lemmas 4.5 and 4.6). Using these lemmas, the theorem follows from a simple calculation; let $s = m^c$, $l = m^{c/2}/4$, $k = m^{c/2-\epsilon}$, and $r = m^{1-c}/4$.

LEMMA 4.4. *Let $\overline{f}$ be a function computed by an approximator circuit. Then $\overline{f}$ is identically* 0 *or the number of bad mappings for which $\overline{f}$ outputs* 1 *on the corresponding bad vector is at least* $(1/2)(1/2s)^k$.

Proof. If $\overline{f}$ is identically 0, then the first conclusion of the lemma holds. If not, because of the assumption that the output gate of an approximator circuit is $\wedge$ gate, $\overline{f} \geq \wedge Y\lceil W\rceil$ for some $Y \in \mathcal{N}(k)$ and for some $W \subseteq V$ with $|W| \leq l$. Then a bad mapping ϕ satisfying the following conditions makes the approximator $\overline{f}$ take the value 1 : (i) For every variable $y \in Y$, at least one endpoint of y has value 0 on the first element of ϕ, and (ii) the first elements of $\phi(v)$ for $v \in W$ are all distinct and none of them are 0. The number of such bad mappings is at least

$$\begin{aligned}
\binom{s-1}{l}\left(\frac{m}{s}\right)^l\binom{m/s}{k}(m-k-l)! &= m!\frac{\binom{s-1}{l}\left(\frac{m}{s}\right)^l\binom{m/s}{k}(m-k-l)!}{m!} \\
&\geq \prod_{i=0}^{l-1}\left(\frac{(m/s)(s-1-i)!}{m-i}\right)\prod_{i=0}^{k-1}\left(\frac{m/s-i}{m-k-i}\right) \\
&\geq \left(\frac{(m/s)(s-l)}{m-l+1}\right)^l\left(\frac{m/s-k+1}{m-l-k+1}\right)^k \\
&\geq \left(\frac{(m/s)(s-l)}{m}\right)^l\left(\frac{m/s-k+1}{m-l-k+1}\right)^k \\
&\geq \left(1-\frac{l}{sm}\right)^l\left(\frac{m/s-k+1}{m-l-k+1}\right)^k
\end{aligned}$$

$$\geq \left(1-\frac{1}{m}\right)^{l}\left(\frac{m/s-k+1}{m-l-k+1}\right)^{k} \geq \frac{1}{2}\left(\frac{1}{2s}\right)^{k}.$$

This completes the proof of Lemma 4.4. □

LEMMA 4.5. *Suppose that an $\vee$ gate and an $\overline{\vee}$ gate are given as input the same pair of approximators. Then the number of bad mappings for which the $\vee$ and the $\overline{\vee}$ gates produce different outputs on the corresponding bad vectors is at most*

$$m^{2k}(m/2)^{r+1}(m-r-1)!.$$

Proof. Suppose that an $\vee$ gate and an $\overline{\vee}$ gate are given as input the same pair of approximators, denoted $\{f^D_{1,Y}\}_Y$ and $\{f^D_{2,Y}\}_Y$, respectively. Let $\{f^D_{1,Y}\}_Y \overline{\vee} \{f^D_{2,Y}\}_Y$ be denoted by $\{f^C_Y\}_Y$.

Let $Y \in \mathcal{N}(k)$ be fixed arbitrarily. We first estimate the number of bad mappings for which $f^D_{1,Y} \vee f^D_{2,Y}$ outputs 0 and f^C_Y outputs 1 on the corresponding bad vectors by following the arguments in the proof of Lemma 3.4. The condition $l \leq \sqrt{s-1}/2$ in the proof of Lemma 3.4 is satisfied. Thus we can estimate the number of such bad mappings by using the same argument to the proof of the lemma except for replacing all the formulas $(s-1)$ in that proof by s. This modification is needed since the size of the ranges of the first components of the bad mappings is changed from $s-1$ to s. Thus we can verity that, for each $Y \in \mathcal{N}(k)$, the number of bad mappings for which $f^D_{1,Y} \vee f^D_{2,Y}$ outputs 0 and f^C_Y outputs 1 on the corresponding bad vectors is at most $(m/2)^{r+1}(m-r-1)!$. Thus, since the number of elements in $|\mathcal{N}(k)|$ is at most m^{2k}, we obtain the desired bound. □

LEMMA 4.6. *Suppose that an $\wedge$ gate and an $\overline{\wedge}$ gate are given as input the same approximators. Then the number of good vectors for which the $\wedge$ and the $\overline{\wedge}$ gates produce different outputs is at most*

$$\frac{m^{4k}(m/2)^{l+1}(m-l-1)!}{s!(m-s)!}.$$

Proof. Suppose that an $\wedge$ gate and an $\overline{\wedge}$ gate are given as input the same approximators, denoted $\{f^C_{1,Y}\}_Y$ and $\{f^C_{2,Y}\}_Y$, respectively. Let $\{f^D_Y\}_Y = \{f^C_{1,Y}\}_Y \overline{\wedge} \{f^D_{2,C}\}_Y$. It is easy to observe that steps 2 and 3 in the definition of the approximator $\overline{\wedge}$ introduce no error on good vectors. Thus we have only to estimate the amount of errors on good vectors introduced by replacing the product of two CNF formulas $f^C_{1,Y_1} \wedge f^C_{2,Y_2}$ by a DNF formula $f^D_{Y_1,Y_2}$ for each $Y_1, Y_2 \in \mathcal{N}(k)$.

Consider $Y_1, Y_2 \in \mathcal{N}(k)$ to be arbitrarily fixed. We estimate the number of good vectors for which $f^C_{1,Y_1} \wedge f^C_{2,Y_2}$ outputs 1 and $f^D_{Y_1,Y_2}$ outputs 0 by the argument of the proof of Lemma 3.4. Note that the condition $r \leq m/(4s)$ in the proof of Lemma 3.4 holds. Thus we can verify that the number of such good vectors is at most $(m/2)^{l+1}(m-l-1)!/\{(s!(m-s)!\}$ by the same argument as in the proof of Lemma 3.4. Thus, since the number of choices of Y_1 and Y_2 is at most $|\mathcal{N}(k)|^2 \leq m^{4k}$, we obtain the desired bound. □

We now proceed to the proof of Theorem 4.2. Instead of proving Theorem 4.2, we prove Theorem 4.7, which claims a stronger statement. Intuitively, Theorem 4.7 says that the condition "$\mathrm{Min}_k(C)$ is identical to $\mathrm{Min}(\mathrm{CLIQUE}(m,s))$," which appears in Theorem 4.2, can be replaced by the somewhat weaker condition, "the cardinality of $\mathrm{Min}_k(C)$ is not too small."

THEOREM 4.7. *Let c and ϵ be constants such that $0 < c \leq 2/3$ and $0 < \epsilon < c/2$. Suppose that a circuit C computes the function CLIQUE(m, m^c) and suppose that $h = h(m) = o(m^{c/2-\epsilon})$. If*

$$|\mathrm{Min}_{m^{c/2-\epsilon}}(C)| > \frac{1}{m^h}|\mathrm{Min}(\mathit{CLIQUE}(m, m^c))|$$

holds, then the size of C is $\exp(\Omega(m^{c/2}))$.

Proof. Recall that $s = m^c$, $l = m^{c/2}/4$, $k = m^{c/2-\epsilon}$ and $r = m^{1-c}/4$. Let C be a circuit which computes the function CLIQUE(m, s) and let $\overline{f}$ be the function computed by the approximator circuit of the monotone analogue of the circuit C. Suppose that $h = h(m) = o(m^c)$ and $|\mathrm{Min}_k(C)| > \frac{1}{m^h}|\mathrm{Min}_k(\mathrm{CLIQUE}(m, s))| = \frac{1}{m^h}\frac{m!}{s!(m-s)!}$. By Fact 4.3 and Lemmas 4.5 and 4.6, the size of the circuit C is at least

$$\min\left(\frac{m!}{m^h m^{4k}(m/2)^{l+1}(m-l-1)!}\ ,\ \frac{m!}{2(2s)^k m^{2k}(m/2)^{r+1}(m-r-1)!}\right).$$

This is lower bounded by

$$\min\left(\frac{(m-l)^{l+1}}{m^{5k}(m/2)^{l+1}}\ ,\ \frac{(m-r)^{r+1}}{m^{3k}(m/2)^{r+1}}\right) = \frac{1}{m^{5k}}\exp(\Omega(\min(l, r)))$$
$$= \exp(\Omega(m^{c/2} - 5k\log m)) = \exp(\Omega(m^{c/2})).$$

The second equality holds since $1 - c \geq c/2$ if $c \leq 2/3$. This completes the proof of Theorem 4.7. □

Before closing this section we comment on how our results relate to Razborov's results [11] pointing out the limitations of the approximation method. His result says that $\omega(n^2)$ lower bounds for nonmonotone circuits could not be obtained using the approximation method. Our results, which establish exponential lower bounds for nonmonotone circuits, apparently conflict with the results due to Razborov. From these conflicting results we may conclude that the amount of negations in the circuits we deal with in this paper is too small to make Razborov's arguments valid. It is an interesting open problem to show a bound on the amount of negation beyond which we have to go to make Razborov's arguments valid.

Acknowledgment. We would like to thank anonymous referees for making many suggestions for improving the presentation of this paper.

ALGORITHMS FOR DATA MIGRATION WITH CLONING*

SAMIR KHULLER†, YOO-AH KIM‡, AND YUNG-CHUN (JUSTIN) WAN‡

Abstract. Our work is motivated by the problem of managing data on storage devices, typically a set of disks. Such high-demand storage servers are used as Web servers or as multimedia servers for handling high demand for data. As the system is running, it needs to dynamically respond to changes in demand for different data items. In this work we study the *data migration problem*, which arises when we need to quickly change one storage configuration into another. We show that this problem is NP-hard. In addition, we develop polynomial-time approximation algorithms for this problem and prove a worst-case bound of 9.5 on the approximation factor achieved by our algorithm.

Key words. approximation algorithms, multicast, broadcast, gossip

1. Introduction.

To handle high demand, especially for multimedia data, a common approach is to replicate data objects within the storage system. Typically, a large storage server consists of several disks connected by a dedicated network, called a *storage area network*. Disks typically have constraints on storage as well as the number of clients that can access data from a single disk simultaneously. With the recent interest in autonomic computing,[1] a relevant goal is to have the system automatically respond to changes in demand patterns and to recompute data layouts.

Approximation algorithms have been developed [24, 25, 9, 17] to map known demand for data to a specific data layout pattern to maximize utilization, where the utilization is the total number of clients that can be assigned to a disk that contains the data they want. In the layout, we compute not only how many copies of each item we need but also a layout pattern that specifies the precise subset of items on each disk. The problem is NP-hard, but there are polynomial-time approximation schemes [9, 25, 17]. Given the relative demand for data, the algorithm computes an almost optimal layout.

Over time as the demand for data changes, the system needs to create *new* data layouts. The problem we are interested in is the problem of computing a data migration plan for the set of disks to convert an initial layout to a target layout. We assume that data objects have the same size (these could be data blocks, or files) and that it takes the same amount of time to migrate any data item from one disk to another disk. The crucial constraint is that each disk can participate in the transfer of only one item—either as a sender or as a receiver. Our goal is to find a migration schedule to minimize the time taken to complete the migration (makespan).

A special case of this was studied by Hall et al. [11]—they compute a movement schedule, but this *does not allow* the creation of new copies of any data object. It

[1] http://www.research.ibm.com/autonomic/

addresses only the data *movement* problem. (So, for example, one cannot create extra copies of any data item, but can only change which disks they are stored on.) The problem they studied is formally defined as follows: Given a set of disks, with each storing a subset of items and a specified set of move operations (each move operation specifies which data object needs to be moved from one disk to another), how do we schedule these move operations? If there are no storage constraints, then this is exactly the problem of edge coloring the following multigraph. Create a graph that has a node corresponding to each disk, and a directed edge corresponding to each move operation that is specified. Algorithms for edge-coloring multigraphs can now be applied to produce a migration schedule since each color class represents a matching in the graph that can be scheduled simultaneously. Computing a solution with the minimum number of rounds is NP-hard, but several good approximation algorithms are available for edge coloring. With space constraints on the disk, the problem becomes challenging. Hall et al. [11] showed that with the assumption that each disk has one spare unit of storage, very good constant factor approximations can be developed. The algorithms use at most $4\lceil\Delta_G/4\rceil$ colors with at most $n/3$ bypass nodes, or at most $6\lceil\Delta_G/4\rceil$ colors without bypass nodes, where Δ_G is the maximum degree of a node and n is the number of nodes. Note that a bypass node is a node that is not the target of a move operation but is used as an intermediate holding point for a data item.

On the other hand, to handle high demand for popular objects, new copies will have to be dynamically created and stored on different disks. This means that we crucially need the ability to have a "copy" operation in addition to "move" operations. In fact, one of the crucial lower bounds used in the work on data migration [11] is based on a degree property of the multigraph. For example, if the maximum degree of a node is δ, then this is a lower bound on the number of rounds that are required, since in each round at most one transfer operation involving this node may be done. For copying operations, clearly this lower bound is not valid. For example, suppose we have a single copy of a data item on a disk. Suppose we wish to create δ copies of this data item on δ distinct disks. Using the transfer graph approach, we could specify a "copy" operation from the source disk to each of the δ disks. Notice that this would take at least δ rounds. However, by using newly created copies as additional sources, we can create δ copies in $\lceil\log(\delta+1)\rceil$ rounds, as in the classic problem of broadcasting by using newly created copies as sources for the data object. (Essentially each copy spawns a new copy in each round.)

The most general problem of interest is the *data migration problem with cloning* when data item i resides in a specified (source) subset S_i of disks and needs to be moved to a (destination) subset D_i. In other words, each data item that initially belongs to a subset of disks needs to be moved to another subset of disks. (We might need to create new copies of this data item and store it on an additional set of disks.) See Figure 1.1 for an example. If each disk had exactly one data item and needs to copy this data item to every other disk, then it is exactly the problem of gossiping. We show that this problem is NP-hard by reduction from edge coloring and develop a polynomial-time 9.5-approximation algorithm for it. For all our algorithms, we move data only to disks that need the data. Thus we use no bypass nodes. The total number of data transfers performed is thus the minimum possible. In addition, we have implemented our algorithm and compared its performance to several other heuristics [10].

Different communication models can be considered based on how the disks are connected. We use the same model as in the work by Hall et al. [11] and Anderson

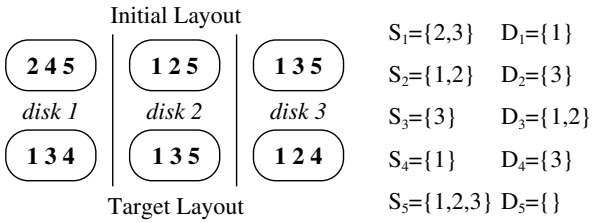

FIG. 1.1. *An initial and target layout and their corresponding S_i's and D_i's.*

et al. [1] where the disks may communicate on any matching; in other words, the underlying communication graph allows for communication between any pair of devices via a matching (a switched storage network with unbounded backplane bandwidth). Moreover, to model the limited switching capacity of the network connecting the disks, one could allow for choosing any matching of bounded size as the set of transfers that can be done in each round. We call this a *bounded-size matching model*. Using the constant factor approximation algorithm for the unbounded matching model, we can also develop a constant factor approximation algorithm for the bounded-size matching model.

One interesting generalization would be for the situation when clusters of disks are connected in a wide area network. The time required to transfer one unit of data between a pair of disks in different clusters may be an order of magnitude higher than the time required to transfer data between a pair of disks in the same cluster. We can model this by a communication graph model where the number of rounds required to transfer one unit of data between a pair of disks in different clusters is a certain number of rounds, and one round is required to transfer one unit of data between a pair of disks in the same cluster.

1.1. Relationship to gossiping and broadcasting. The problems of gossiping and broadcasting have been the subject of extensive study [19, 13, 15, 3, 4, 16, 7, 8]. These play an important role in the design of communication protocols in various kinds of networks. The *gossip problem* is defined as follows: There are n individuals. Each individual has an item of gossip that they wish to communicate to everyone else. Communication is typically done in rounds, where in each round an individual may communicate with at most one other individual. Some communication models allow for the full exchange of all items of gossip known to each individual in a single round. Other models allow the sending of only one item of gossip from one to the other (half-duplex) or allow each individual to send an item to the individual they are communicating with in this round (full-duplex). In addition, there may be a communication graph whose edges indicate which pairs of individuals are allowed to communicate directly in each round. (In the classic gossip problem, also called the telephone model, communication may take place between any pair of individuals; in other words, the communication graph is the complete graph.) In the *broadcast problem*, one individual needs to convey an item of gossip to every other individual. The two parameters typically used to evaluate the algorithms for this problem are (i) the number of communication rounds, and (ii) the total number of telephone calls placed.

The problems we study are generalizations of the above-mentioned gossiping and broadcasting problems. The basic generalizations we are interested in are of three kinds: (a) each item of gossip needs to be communicated to only a subset of

individuals; (b) several items of gossip may be known to an individual; and (c) a single item of gossip can initially be shared by several individuals.

The communication model we use is the half-duplex model, where only one item of gossip may be communicated between two communicating individuals during a single round. Each individual may communicate (either send or receive an item of data) with at most one other individual in a round. This model best captures the connection of parallel storage devices that are connected on a network and is most appropriate for our application. This model is one of the most widely used in all the work related to gossiping and broadcasting.

1.2. Contributions and outline of paper. In section 2 we define the basic model of communication and the notation used in the paper.

This is the first work that relates broadcasting and gossiping with the data migration problem. In section 3 we develop a 9.5-approximation algorithm for the general data migration problem. This is the first approximation algorithm for this problem. While two of the lower bounds used are quite simple, we develop a new lower bound using network flows and use this in the algorithm. (Without this lower bound, the best bound we can obtain is a $O(\log n)$ factor.) We show the data migration problem is NP-hard at the end of section 3.

In section 4 we develop a constant factor approximation algorithm for the bounded-size matching model.

1.3. Other related work. The paper by Liben-Nowell [21] considers a problem very similar to multisource multicast, which is exactly the data migration problem with restrictions that each disk contain at most one source item and that each item have at most one source. However, the model used is different than the one that we use. In that model, in each telephone call, a pair of users can exchange all the items of gossip that they know. The objective is to simply minimize the total number of phone calls required to convey item i of gossip to set D_i of users. In our case, since each item of gossip is a data item that might take considerable time to transfer between two disks, we cannot assume that an arbitrary number of data items can be exchanged in a single round. Several other papers use the same telephone call model [2, 6, 12, 16, 28].

Other related problems that have been studied are the set-to-set gossiping problem [20, 23], where we are given two possibly intersecting sets A and B of gossipers and the goal is to minimize the number of calls required to inform all gossipers in A of all the gossip known to members in B. Liben-Nowell [21] generalizes this work by defining for each gossiper i the set of relevant gossip that they need to learn. This is just like our multisource multicast problem when the number of items is equal to the number of disks, except that the communication model is different, as well as the objective function.

We have also studied several special cases of the data migration problem with cloning, where each data item has only one copy initially, and have developed algorithms with better performance guarantees [18]. One special case we studied is the multisource multicast problem. We showed that this problem is NP-hard by a reduction from a restricted version of 3SAT and gave a polynomial-time algorithm with approximation ratio of $3 + o(1)$ using a simplified version of the algorithm developed in this paper.[2] Allowing bypass nodes, we improved the approximation ratio to 3.

[2]The work in [18] presents a 4-approximation algorithm. The improvement to $3 + o(1)$ can be obtained from the full version of [18], available at http://www.cs.umd.edu/projects/smart/papers/multicast.pdf.

Another special case is the *multisource broadcast* problem, which is the same as the multisource multicast problem except that all disks demand all items; i.e., D_i is all the disks minus its source. We developed a polynomial-time algorithm using at most 3 more rounds than the optimal. The last special case we studied is the *single-source multicast* problem, when Δ data items, each having only one copy, are all stored on the same disk, and data item i needs to be sent to a specified subset D_i of disks. We developed a polynomial-time algorithm using at most Δ more rounds than the optimal. Farley [8] solved a simpler case optimally, namely, the *single-source broadcast* problem, where Δ data items are stored on a single disk, and all items need to be broadcast to all disks.

2. Models and definitions. In the *data migration problem*, we have N disks and Δ data items. For each item i, there is a subset of disks S_i and D_i. Initially only the disks in S_i have item i, and all disks in D_i want to receive i. Note that after a disk in D_i receives item i, it can be a source of item i for other disks in D_i that have not received the item as yet. Our goal is to find a migration schedule using the minimum number of rounds, that is, to minimize the total amount of time to finish the schedule. We assume that the underlying network is fully connected and the data items are all the same size; in other words, it takes the same amount of time to migrate an item from one disk to another. The crucial constraint is that each disk can participate in the transfer of only one item—either as a sender or receiver. Moreover, as we do not use any bypass nodes, all data is sent only to disks that desire it.

Our algorithms make use of known results on edge coloring of multigraphs. Given a graph G with max degree Δ_G and multiplicity μ, the following results are known (see Bondy and Murty [5], for example). Let χ' be the edge chromatic number of G.

THEOREM 2.1 (Vizing [29]). *If G has no self-loops, then $\chi' \leq \Delta_G + \mu$.*

THEOREM 2.2 (Shannon [26]). *If G has no self-loops, then $\chi' \leq \lfloor \frac{3}{2}\Delta_G \rfloor$.*

3. The data migration algorithm. Define β_j as $|\{i | j \in D_i\}|$, i.e., the number of different sets D_i to which a disk j belongs. We then define β as $\max_{j=1,\ldots,N} \beta_j$. In other words, β is an upper bound on the number of items a disk may need. Note that β is a lower bound on the optimal number of rounds, since the disk j that attains the maximum needs at least β rounds to receive all the items i such that $j \in D_i$, since it can receive at most one item in each round.

Moreover, we may assume that $D_i \neq \emptyset$ and $D_i \cap S_i = \emptyset$. This is because we can define the destination set D_i as the set of disks that need item i and do not currently have it.

Since the algorithm is somewhat complex, we first give a high-level description of the algorithm and then discuss the various steps in the following lemmas. Dealing with multiple data items sharing common disks causes some difficulty.

DATA MIGRATION ALGORITHM.

1. For an item i decide a source $s_i \in S_i$ so that $\alpha = \max_{j=1,\ldots,N}(|\{i | j = s_i\}| + \beta_j)$ is minimized. In other words, α is the maximum number of items for which a disk may be a source (s_i) or destination. *Note that α is also a lower bound on the optimal number of rounds.* In Lemma 3.1 we will show how we can find a source for each item.
2. Find a transfer graph for items that have $|D_i| \geq \beta$ as follows:
   (a) We first compute a disjoint collection of subsets G_i, $i = 1, \ldots, \Delta$. Moreover, $G_i \subseteq D_i$ and $|G_i| = \lfloor \frac{|D_i|}{\beta} \rfloor$. Figure 3.1(a) shows an example of choosing sets G_i. (In Lemma 3.2, we will show how such G_i's can be obtained.)

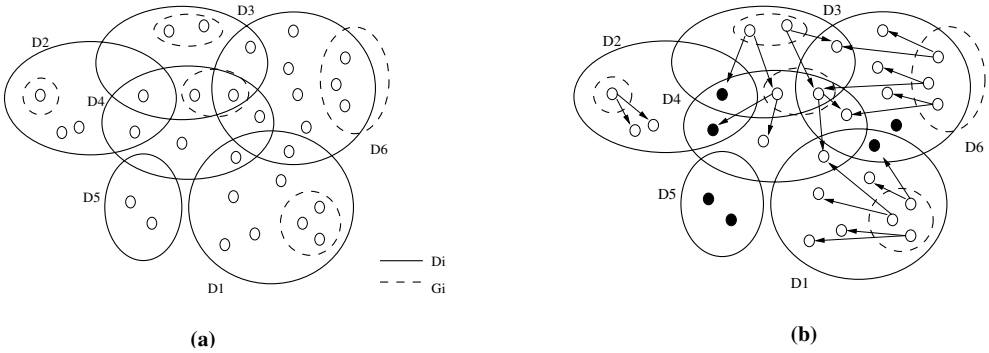

FIG. 3.1. (a) *An example of choosing G_i in step* 2(a)*, where $\Delta = 6$ and $\beta = 3$.* (b) *Transfer graph constructed in step* 2(c)*. Disks marked as black do not receive some data items and will be taken care of in step* 3.

(b) We have each item i sent to the set G_i as shown in Lemma 3.5.
(c) We create a transfer graph as follows. Each disk is a node in the graph. We add directed edges from disks in G_i to $(\beta-1)\lfloor\frac{|D_i|}{\beta}\rfloor$ disks in $D_i \setminus G_i$ such that the out-degree of each node in G_i is at most $\beta - 1$ and the in-degree of each node in $D_i \setminus G_i$ from G_i is 1. Figure 3.1(b) shows an example of the transfer graph constructed in this step. We redefine D_i as the set of $|D_i \setminus G_i| - (\beta-1)\lfloor\frac{|D_i|}{\beta}\rfloor$ disks which do not receive item i so that they can be taken care of in step 3. Note that the redefined set D_i has size $< \beta$.

3. Find a transfer graph for items such that $|D_i| < \beta$ as follows:
   (a) For each item i, find a new source s_i' in D_i. A disk j can be a source s_i' for several items as long as $\sum_{i\in I_j} |D_i| \le 2\beta - 1$, where I_j is a set of items for which j is a new source. See Lemma 3.7 for the details of this step.
   (b) Send each item i from s_i to s_i'.
   (c) Create a transfer graph. We add a directed edge from s_i' to all disks in $D_i \setminus \{s_i'\}$. Lemma 3.9 will show that the out-degree of a disk does not exceed $2\beta - 4$.
4. We now find an edge coloring of the transfer graph obtained by merging two transfer graphs in steps 2(c) and 3(c). The number of colors used is an upper bound on the number of rounds required to ensure that each disk in D_i gets item i. In Lemma 3.10 we derive an upper bound on the number of required colors.

LEMMA 3.1. *We can find a source $s_i \in S_i$ for each item i so that* $\max_{j=1,\ldots,N}(|\{i|j = s_i\}| + \beta_j)$ *is minimized, using a flow network.*

Proof. We create a flow network with a source s and a sink t as shown in Figure 3.2. We have two sets of nodes corresponding to disks and items. Add directed edges from s to nodes for items and also directed edges from item i to disk j if $j \in S_i$. The capacities of all these edges is one. Finally we add an edge from the node corresponding to disk j to t with capacity $\alpha - \beta_j$. We want to find the minimum α so that the maximum (integral) flow of the network is Δ. We can do this by checking if there is a flow of Δ with α starting from $\max \beta_j$ and increasing by one until it is satisfied. If there is outgoing flow from item i to disk j, then we set j as s_i. ∎

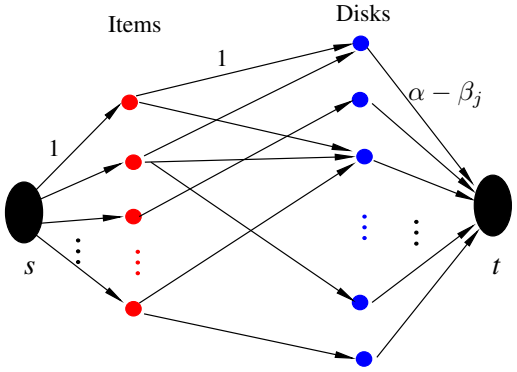

FIG. 3.2. *Flow network to find* α.

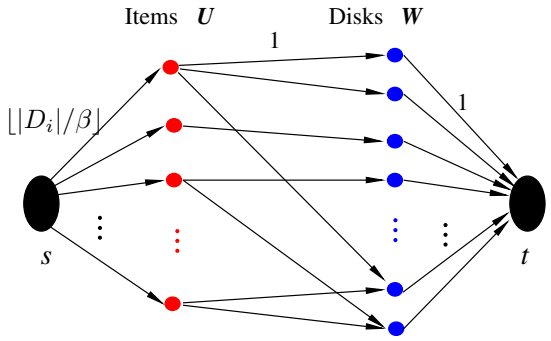

FIG. 3.3. *Flow network to find* G_i.

LEMMA 3.2. *There is a way to choose disjoint sets* G_i *for each* $i = 1, \ldots, \Delta$ *such that* $|G_i| = \lfloor \frac{|D_i|}{\beta} \rfloor$ *and* $G_i \subseteq D_i$.

Proof. First note that the total size of the sets G_i is at most N.

$$\sum_{i=1}^{\Delta} |G_i| \leq \sum_{i=1}^{\Delta} \frac{|D_i|}{\beta} = \frac{1}{\beta} \sum_{i=1}^{\Delta} |D_i|.$$

Note that $\sum_{i=1}^{\Delta} |D_i|$ is at most βN by definition of β. This proves the upper bound of N on the total size of all sets G_i.

We now show how to find the sets G_i. As shown in Figure 3.3, we create a flow network with a source s and sink t. In addition we have two sets of vertices U and W. The first set U has Δ nodes, each corresponding to an item. The set W has N nodes, each corresponding to a disk in the system. We add directed edges from s to each node in U such that the edge (s, i) has capacity $\lfloor \frac{|D_i|}{\beta} \rfloor$. We also add directed edges with unit capacity from node $i \in U$ to $j \in W$ if $j \in D_i$. We add unit capacity edges from nodes in W to t. We find a max-flow from s to t in this network. The min-cut in this network is obtained by simply selecting the outgoing edges from s. To see this, note that we can find a fractional flow of this value as follows: saturate all the outgoing edges from s. From each node i there are $|D_i|$ edges to nodes in W. Suppose $\lambda_i = \lfloor \frac{|D_i|}{\beta} \rfloor$. Send $\frac{1}{\beta}$ units of flow along $\lambda_i \beta$ outgoing edges from i. Note that

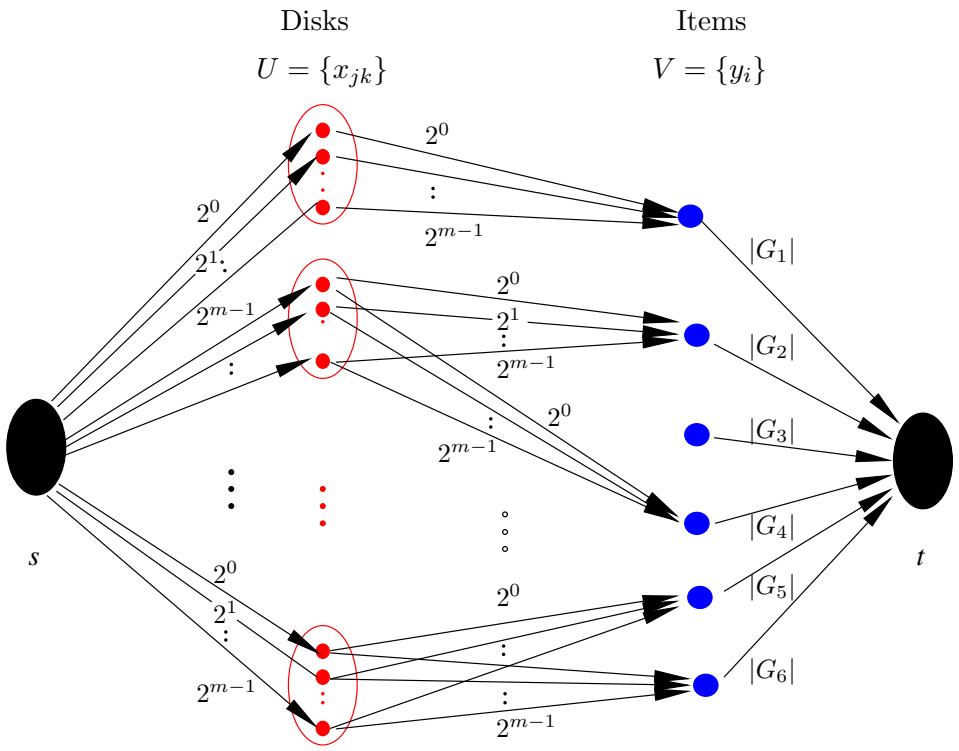

FIG. 3.4. *An example of constructing F_m where $\Delta = 6$.*

since $\lambda_i \beta \leq |D_i|$ this can be done. Observe that the total incoming flow to a vertex in W is at most 1 since there are at most β incoming edges, each carrying at most $\frac{1}{\beta}$ units of flow. An integral max-flow in this network will correspond to $|G_i|$ units of flow going from s to i and from i to a subset of vertices in D_i before reaching t. The vertices to which i has nonzero flow will form the set G_i. □

For step 2(b), a simple solution would be to broadcast the data to each group G_i from the chosen source, since the groups are disjoint. The only thing we have to be careful of is that the sources for many data items are shared. However, this broadcast takes at least $\max_i \log |G_i|$ rounds. Unfortunately, we cannot argue that this is a valid lower bound since even though D_i is large, if S_i is large, then there could be a solution using $O(1)$ rounds. This would give us an $O(\log N)$ approximation guarantee. The method described below develops stronger lower bounds for this situation.

Let M be the number of steps required to send all items i to all disks in G_i in an optimal schedule of step 2(b). To find a lower bound for M, we construct the following flow network F_m (parameterized by an integer m) as shown in Figure 3.4. We have a source s and two sets of nodes U and V. U has $N \cdot m$ nodes x_{jk} ($j = 1, \ldots, N$, $k = 1, \ldots, m$). V has Δ nodes y_i ($i = 1, \ldots, \Delta$) and y_i has demand $|G_i|$. There is an edge e_{ijk} from x_{jk} to y_i and its capacity c_{ijk} is 2^{m-k} if a disk j has item i initially. There are edges from s to nodes x_{jk} in U with capacity 2^{m-k}.

LEMMA 3.3. *If m' is the smallest number such that we can construct a solution of $F_{m'}$ that satisfies all demands $|G_i|$, then $M \geq m'$.*

Proof. Suppose that $M < m'$. Given an optimal schedule of step 2(b), we can construct a solution of the flow network F_M as follows. If a disk j sends item i to

a disk in G_i at round $t \leq M$, which makes f copies in G_i subsequently, we send a flow f from x_{jt} to y_i. Note that f cannot be more than 2^{M-t}, and therefore it does not violate the capacity constraint. Since all disks in G_i receive item i after M rounds with this schedule, the corresponding flow satisfies all demands $|G_i|$. This is a contradiction to the assumption that m' is the smallest number to satisfy all demands $|G_i|$. □

In the solution of the flow network $F_{m'}$, a node x_{jk} may send flow to several nodes. But since in our schedule, a disk can copy only one item to a disk in a round, the solution of the flow in $F_{m'}$ may not correspond to a valid schedule.

LEMMA 3.4. *Given a solution of $F_{m'}$, we can convert it to a solution satisfying the following properties:*

- *Node x_{jk} sends flow to at most one node in V.*
- *The solution satisfies at least $|G_i| - 2^{m'-1}$ demands for each item i.*

Proof. First, we define a variable z_{ijk} for an edge from x_{jk} to y_i and set $z_{ijk} = f_{ijk}/c_{ijk}$, where f_{ijk} is the flow through e_{ijk} in solution $F_{m'}$. We substitute nodes y_{il} $(l = 1, \ldots, \lfloor \sum_{j,k} z_{ijk} \rfloor)$ for each node y_i in V. We distribute edges having nonzero flow to y_i as follows. Sort edges in nonincreasing order of their capacities. Assign edges to y_{i1} until the sum of z values of assigned edges is greater than or equal to one. If the sum is greater than one, we split the last edge (denote as $e_{ij'k'}$) into $e_{ij'k'_1}$ and $e_{ij'k'_2}$. Assign $e_{ij'k'_1}$ to y_{i1} and define $z_{ij'k'_1}$ so that the sum of z values of edges assigned to y_{i1} is exactly one. Set $z_{ij'k'_2} = z_{ij'k'} - z_{ij'k'_1}$. We repeat this so that for all nodes y_{il}, the sums of z values of the assigned edges are one. Let E_{il} be the set of edges assigned to y_{il} and let c_{il}^{max} (c_{il}^{min}) be the maximum (minimum) capacity of the edges in E_{il}. In addition, we denote the edges not assigned to any y_{il} $(l = 1, \ldots, \lfloor \sum_{j,k} z_{ijk} \rfloor)$ as $E_{il'}$ and the maximum capacity of edges in $E_{il'}$ as $c_{il'}^{max}$, where l' is $\lfloor \sum_{j,k} z_{ijk} \rfloor + 1$.

In the resulting bipartite graph with U and $V' = \{y_{il}\}$, z makes a *fractional* matching which matches all vertices in V' but not necessarily all vertices in U. Therefore, we can find an integral matching that matches all vertices in V', and the matching satisfies the first property in the lemma.

Now we merge nodes y_{il} into y_i. Then each y_i matches exactly $\lfloor \sum_{j,k} z_{ijk} \rfloor$ edges. We prove that the sum of capacities of edges matched to y_i is at least $|G_i| - c^{max}$, where c^{max} is the maximum capacity of any edge from U to V, using an analysis similar to that in Shmoys and Tardos [27]. The sum of capacities of edges matched to y_i is at least

$$\begin{aligned}
\sum_{l=1}^{\lfloor \sum_{j,k} z_{ijk} \rfloor} c_{il}^{min} &\geq \sum_{l=2}^{\lfloor \sum_{j,k} z_{ijk} \rfloor + 1} c_{il}^{max} \\
&= \sum_{l=1}^{\lfloor \sum_{j,k} z_{ijk} \rfloor + 1} c_{il}^{max} - c_{i1}^{max} \\
&\geq \sum_{l=1}^{\lfloor \sum_{j,k} z_{ijk} \rfloor + 1} \sum_{e_{ijk} \in E_{il}} c_{ijk} z_{ijk} - c_{i1}^{max} \\
&= \sum_{l=1}^{\lfloor \sum_{j,k} z_{ijk} \rfloor + 1} \sum_{e_{ijk} \in E_{il}} f_{ijk} - c_{i1}^{max} \\
&\geq |G_i| - c^{max}.
\end{aligned}$$

Since $c^{max} \leq 2^{m'-1}$, the second property can be satisfied by setting flow through e_{ijk} as c_{ijk} if e_{ijk} is matched. ∎

LEMMA 3.5. *Step* 2(b) *can be done in* $\alpha + 2m' + 1$ *rounds.*

Proof. We can do this with the following schedule. First we choose $\min(\lfloor \sum_{j,k} z_{ijk} \rfloor + 1, |G_i|)$ disks in G_i and denote those disks as H_i. Disk j sends item i to a disk in H_i if edge e_{ijk} is matched for some k. If $|H_i| > \lfloor \sum_{j,k} z_{ijk} \rfloor$, there is one disk in H_i which cannot receive item i. The disk receives item i from s_i. Then the maximum degree of a disk is at most $m' + \alpha$ and the multiplicity of the undirected version of the transfer graph is 2, since the out-degree of disk j is at most $m' + \alpha - \beta_j$ and the in-degree is at most $\min(\beta_j, 1)$. By Theorem 2.1, it can be done in $m' + \alpha + 2$ rounds.

Now $|H_i|$ nodes in G_i have item i. Since $|G_i|/|H_i| \leq (\sum_{l=1}^{\lfloor \sum_{j,k} z_{ijk} \rfloor} c_{il}^{min} + c^{max})/(\lfloor \sum_{j,k} z_{ijk} \rfloor + 1) \leq c^{max} \leq 2^{m'-1}$, we can make all disks in G_i have item i in an additional $m' - 1$ rounds. ∎

Lemma 3.7 will show how step 3(a) works. The lemma uses the following result from Shmoys and Tardos [27].

THEOREM 3.6 (Shmoys and Tardos [27]). *We are given a collection of jobs* $\mathcal{J}$*, each of which is to be assigned to exactly one machine among the set* $\mathcal{M}$*; if job* $j \in \mathcal{J}$ *is assigned to machine* $i \in \mathcal{M}$*, then it requires* p_{ij} *units of processing time and incurs a cost* c_{ij}*. Suppose that there exists a fractional solution (that is, a job can be assigned fractionally to machines) with makespan* P *and total cost* C*. Then in polynomial time we can find a schedule with makespan* $P + \max p_{ij}$ *and total cost* C*.*

LEMMA 3.7. *For each item* i *we wish to choose a source disk* s_i' *from* D_i*. Let* I_j *be the set of items for which disk* j *is chosen as a source. There is a way to choose the sources such that the following properties hold:*

- *If* $i \in I_j$*, then* $j \in D_i$*.*
- $\sum_{i \in I_j} |D_i| \leq 2\beta - 1$*.*

Proof. We use Theorem 3.6 for this step. For example, we can create an instance of the problem of scheduling machines with costs. Items correspond to jobs and disks correspond to machines. For each item i we define a cost function as follows. $C(i, j) = 1$ if and only if $j \in D_i$; otherwise it is a large constant. The processing time of job i (corresponding to item i) is $|D_i|$ (uniform processing time on all machines). Using Theorem 3.6 [27], the scheduling algorithm finds a schedule that assigns each job (item) to a machine (disk) to minimize the makespan. They show that the makespan is at most the makespan in a fractional solution plus the processing time of the largest job. Moreover, the cost of their solution is at most the cost of the optimal solution, namely, the number of items. We cannot assign an item (job) to a disk (machine) if the disk is not in the destination set for the item.

In our case, it is easy to see that the maximum processing time of any job is $\beta - 1$. We will argue that there is a fractional solution with makespan β. It thus follows that by defining I_j to be the set of items (jobs) assigned to disk (machine) j, the result follows. The fractional solution is obtained by assigning each job fractionally to each machine by setting the assignment variable for job i on machine j to $\frac{1}{|D_i|}$ if $j \in D_i$; then the job is fully assigned fractionally and the fractional load on each machine is at most β. This also gives us a way of finding a fractional solution efficiently. ∎

LEMMA 3.8. *Step* 3(b) *can be done in* $\lfloor \frac{3}{2}\alpha \rfloor$ *rounds.*

Proof. Since disk j can be s_i' in step 3(a) only if $j \in D_i$, $|I_j| \leq \beta_j$. Therefore, a disk j may need to send $\alpha - \beta_j$ items and receive β_j items. That means the maximum degree is α and this transfer can make a multigraph. Given a multigraph with maximum degree Δ_G, we can find an edge coloring using $\lfloor \frac{3}{2}\Delta_G \rfloor$ colors (see

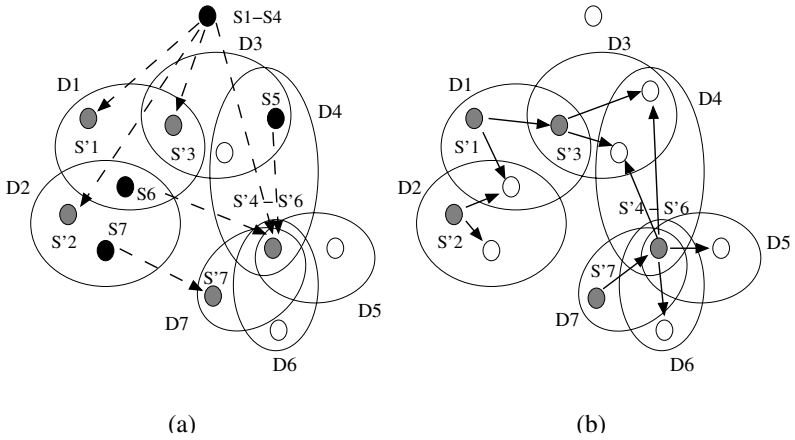

FIG. 3.5. *An example of step* 3 *where* $\alpha = 4$ *and* $\beta = 4$. (a) *Migration from* s_i *to* s'_i. (b) *Migration from* s'_i *to* $D_i \setminus \{s'_i\}$.

Theorem 2.2) and the lemma follows. □

LEMMA 3.9. *The maximum out-degree of a disk in the transfer graph in step* 3(c) *is at most* $2\beta - 4$.

Proof. If disk j is a new source for k items (in other words, $|I_j| = k$), then the out-degree of disk j is $\sum_{i \in I_j} |D_i \setminus \{s'_i\}| = \sum_{i \in I_j} |D_i| - k$.

It is easy to see that the lemma is true for $k \geq 3$ since $\sum_{i \in I_j} |D_i| \leq 2\beta - 1$. For $k = 1$, the lemma is also true since $\sum_{i \in I_j} |D_i| \leq \beta - 1$ and $\beta \geq 2$ (otherwise, there is no set with size less than β). For $k = 2$, $\sum_{i \in I_j} |D_i| \leq 2\beta - 2$, and therefore we have the lemma. □

Figure 3.5 shows an example of migrations in step 3.

LEMMA 3.10. *The number of colors we need for the final transfer graph in step* 4 *is* $(4\beta - 5) + (\beta + 2)$.

Proof. The out-degree of a disk j can be at most $3\beta - 5$ ($\beta - 1$ in step 2(c) and $2\beta - 4$ in step 3(c)). The in-degree is at most β by definition. We claim that the multiplicity of the undirected version of the final transfer graph is $\beta + 2$. Consider all the edges added in step 2(c); we will show the multiplicity induced by these edges is 2. Since all G_i's are disjoint and each disk in G_i sends only item i to disks in $D_i \setminus G_i$, for any pair of disks j_1 and j_2, there can be at most one edge in each direction. Now consider all the edges added in step 3(c); if there is an edge between disk j_1 and disk j_2, no matter which disk is the sender, both disks belong to D_i for some i. Thus, there are at most β edges between j_1 and j_2 since a disk can belong to at most β different D_i's. Therefore, the result follows by Theorem 2.1. □

THEOREM 3.11. *The total number of rounds required for the data migration is at most* $\alpha + 2m' + \lfloor \frac{3}{2}\alpha \rfloor + 5\beta - 2$.

Proof. We need $\alpha + 2m' + 1$ rounds for step 2(b) by Lemma 3.5 and $\lfloor \frac{3}{2}\alpha \rfloor$ rounds for step 3(b) by Lemma 3.8. Migration according to the coloring of the final transfer graph needs $(4\beta - 5) + (\beta + 2)$ by Lemma 3.10. Therefore, we have the theorem. □

COROLLARY 3.12. *Our algorithm is* 9.5*-approximation for the data migration problem.*

Proof. Since α, β, m' are lower bounds for the problem, the corollary follows. □

THEOREM 3.13. *The data migration problem (with copy operation) is NP-hard.*

Proof. We give a reduction from the problem of edge coloring a simple graph with the smallest number of colors (which is known to be NP-hard [14]). Given a graph $G = (V, E)$, we create an instance of a data migration problem with $N = |V|$ disks. For each edge $e_i = (u, v)$ in the graph, we create a new item i, where S_i is $\{u\}$ and D_i is $\{v\}$. It is not difficult to see that the minimum number of colors required in the edge coloring instance is the same as the minimum number of rounds in the corresponding data migration instance. ∎

3.1. A bad example. Here we give an example when our data migration algorithm does not perform very well. Consider the problem where there are Δ source disks, each disk having a separate item; in addition, there are $\Delta - 1$ destination disks, and each disk requests all Δ items. Thus N is equal to $2\Delta - 1$, β is equal to Δ, and $|D_i|$, the number of disks requesting item i, is equal to $\beta - 1$ for all i. In step 3 of our data migration algorithm, we need to find Δ new sources s'_i, but we have only $\Delta - 1$ destination disks. At least one disk d has to be a new source for two items. Therefore step 3(b) takes at least 2 rounds. In disk d, each item in d has to be sent to the remaining $\Delta - 2$ destination disks. The out-degree is exactly $2\Delta - 4$. The in-degree is $\Delta - 2$. So, we have a node of degree $3\Delta - 6$ in the transfer graph, and the total number of rounds is at least $3\Delta - 4$. The optimal strategy is to have $\Delta - 1$ of Δ source disks sending items to destination disks in a round-robin fashion. This method takes only Δ rounds. Therefore, our algorithm cannot perform better than $(3 - \epsilon)$-approximation.

4. Bounded-size matching model. The following algorithm gives a constant factor approximation when at most C transfers are allowed in each round. Let E_i be the transfers in the ith round in the algorithm for the full matching model. Then we split each E_i into $\lceil |E_i|/C \rceil$ sets of size at most C and perform each set in a round.

THEOREM 4.1. *Given ρ-approximation algorithm for the full matching model, we have a $1 + \rho(1 - 1/C)$-approximation algorithm for the bounded-size matching model, where C is the maximum number of transfers allowed in a round.*

Proof. Let us denote the number of rounds required in an optimal solution for the full matching model and bounded-size matching model as OPT and OPT', respectively. Denote the number of rounds in our algorithm as t and t'.

Note that since we move data only to disks that need the data, the total number of data transfers performed by the algorithm is the minimum possible. Thus $OPT' \geq \sum_i |E_i|/C$. Since $t \leq \rho OPT$ and $OPT \leq OPT'$, we have $t \leq \rho OPT'$.

Therefore,

$$\begin{aligned} t' &= \sum_{i=1}^{t} \left\lceil \frac{|E_i|}{C} \right\rceil \\ &\leq \sum_{i=1}^{t} \left(\frac{|E_i| - 1}{C} + 1 \right) \\ &= \frac{1}{C} \sum_{i=1}^{t} |E_i| + t \left(1 - \frac{1}{C} \right) \\ &\leq OPT' + \rho OPT' \left(1 - \frac{1}{C} \right) \\ &= \left(1 + \rho \left(1 - \frac{1}{C} \right) \right) OPT'. \end{aligned}$$

∎

COROLLARY 4.2. *We have a* $1 + 9.5(1 - 1/C)$*-approximation algorithm for the bounded-size matching model.*

When we consider only move operations, we can obtain better bounds for the bounded-size matching model. Without space constraints, the problem can be reduced to edge-coloring multigraphs, which has a 1.1-approximation algorithm with a 0.8 additive term [22].

COROLLARY 4.3. *With only move operations, we have a* $1 + 1.1(1 - 1/C)$*-approximation algorithm with a* 0.8 *additive term for the bounded-size matching model.*

With space constraints, the algorithm by Hall et al. [11] gives $\frac{3}{\Delta_G}\lceil\frac{\Delta_G}{2}\rceil$-approximation. We thus obtain the following.

COROLLARY 4.4. *With only move operations and space constraints, we have a* $1 + \frac{3}{\Delta_G}\lceil\frac{\Delta_G}{2}\rceil(1 - \frac{1}{C})$*-approximation algorithm for the bounded-size matching model.*

In addition, using at most $n/3$ bypass nodes, Hall et al. [11] obtained algorithms which give $\frac{2}{\Delta_G}\lceil\frac{\Delta_G}{2}\rceil$-approximation without space constraints and $\frac{4}{\Delta_G}\lceil\frac{\Delta_G}{4}\rceil$-approximation with space constraints. The algorithms add one transfer for every odd cycle. For a transfer graph with sets of cycles of length 3, the algorithms take 4 rounds, while OPT' may take only 3 rounds. Thus we have $4OPT'/3 \geq \sum |E_i|/C$.

THEOREM 4.5. *When we allow only move operations and use at most* $n/3$ *bypass nodes, there is a* $\frac{4}{3} + \frac{2}{\Delta_G}\lceil\frac{\Delta_G}{2}\rceil(1 - \frac{1}{C})$*-approximation algorithm without space constraints and a* $\frac{4}{3} + \frac{4}{\Delta_G}\lceil\frac{\Delta_G}{4}\rceil(1 - \frac{1}{C})$*-approximation algorithm with space constraints.*

Proof. We use the same notation as in Theorem 4.1. Since $4OPT'/3 \geq \sum |E_i|/C$, we have

$$\begin{aligned} t' &= \sum_{i=1}^{t} \left\lceil \frac{|E_i|}{C} \right\rceil \\ &\leq \sum_{i=1}^{t} \left(\frac{|E_i| - 1}{C} + 1 \right) \\ &= \frac{1}{C} \sum_{i=1}^{t} |E_i| + t \left(1 - \frac{1}{C} \right) \\ &\leq \frac{4}{3} OPT' + \rho OPT' \left(1 - \frac{1}{C} \right) \\ &= \left(\frac{4}{3} + \rho \left(1 - \frac{1}{C} \right) \right) OPT'. \end{aligned}$$

□

Acknowledgments. We would like to thank Sudarshan Chawathe, Leana Golubchik, Liviu Iftode, and John Kubiatowicz for useful discussions related to the definition of the problem considered.

AN OPTIMAL COMPETITIVE STRATEGY FOR WALKING IN STREETS*

CHRISTIAN ICKING†, ROLF KLEIN‡, ELMAR LANGETEPE‡, SVEN SCHUIERER§, AND INES SEMRAU¶

Abstract. A simple polygon P with two distinguished vertices, s and t, is called a *street* if the two boundary chains from s to t are mutually weakly visible. We present an on-line strategy that walks from s to t, in any unknown street, on a path at most $\sqrt{2}$ times longer than the shortest path. This matches the best lower bound previously known and settles an open problem in the area of competitive path planning. (The result was simultaneously and independently obtained by the first three authors and by the last two authors. Both papers, [C. Icking, R. Klein, and E. Langetepe, *Proceedings of the* 16*th Symposium on Theoretical Aspects in Computer Science*, Lecture Notes in Comput. Sci. 1563, Springer-Verlag, Berlin, 1999, pp. 110–120] and [S. Schuierer and I. Semrau, *Proceedings of the* 16*th Symposium on Theoretical Aspects of Computer Science*, pp. 121–131], were presented at STACS'99. The present paper contains a joint full version.)

1. Introduction.

The path planning problem of autonomous mobile robots has received a lot of attention in the communities of robotics, computational geometry, and on-line algorithms; see, e.g., Rao et al. [37], Blum, Raghavan, and Schieber [6], and the surveys by Berman [4] in Fiat and Woeginger [15] and by Mitchell [35] in Sack and Urrutia [38].

In on-line navigation one has to perform a certain task in an initially unknown environment. We are interested in strategies that are correct, in that the objective will always be achieved whenever this is possible, and in performance guarantees of the following kind. Given a navigation problem Q, we want to relate the cost of solving any problem instance $P \in Q$ by means of strategy S to the cost of solving P optimally, using an off-line strategy. If the former never exceeds the latter times a certain constant factor, c, then strategy S is said to be a *c-competitive* solution of Q; this notion was coined by Sleator and Tarjan in their seminal paper [43]. Surveys on general on-line algorithms can be found in Fiat and Woeginger [15] and Ottmann, Schuierer, and Hipke [36].

Given an on-line problem Q, three questions arise: Does a competitive solution exist? If S is a solution, what is its true *competitive factor*, i.e., the smallest c such that S is c-competitive? And finally, what is the smallest factor c that can be attained by *any* strategy solving Q? This number is called the *competitive complexity* of problem Q.

There are not so many navigation tasks we are aware of whose competitive com-

plexities are precisely known. One of them is searching for a point on m halflines that meet at the start point; see Baeza-Yates, Culberson, and Rawling [2] and also Bellman [3], Gal [16], Schuierer [39], López-Ortiz and Schuierer [34], and Alpern and Gal [1].

Another one is looking around a corner in a wall; see Icking, Klein, and Ma [22]. Recently, matching lower and upper bounds for some restricted on-line TSP problems where shown by Blom et al. [5]. More often, there is a gap between the smallest competitive factor known and the best lower bound, such as in the polygon exploration problem; see Hoffmann et al. [18].

In this paper we prove that walking in an unknown street is of competitive complexity $\sqrt{2}$, thus settling a problem that has been open for a decade. A *street* is a simple polygon P with two vertices, s and t, that mark the start and target point of the walk, subject to the condition that the two boundary chains connecting s to t are mutually weakly visible[1]; see Figure 1.1 for an example. This is equivalent to saying that from each s-to-t path inside P, each point of P can be seen at least once. Streets were introduced in Klein [24] to model racetracks and rivers like the Rhine that may contain curves and bays but no cul-de-sacs winding away from the main route. It was shown in [24, 25] that there exists a strategy that is competitive with a factor of 5.72, and that no factor smaller than $\sqrt{2}$ can be achieved, not even by a randomized strategy.

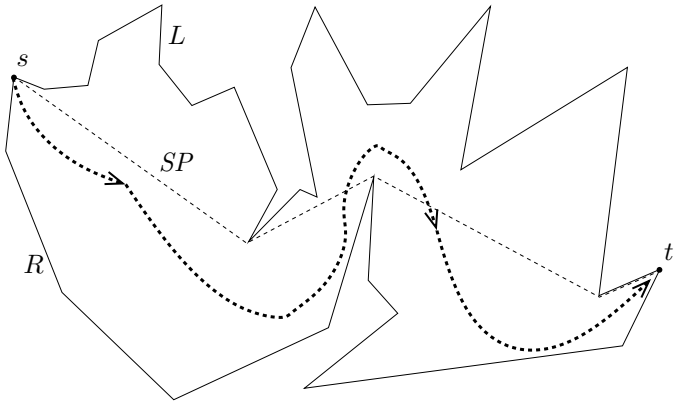

FIG. 1.1. *A street.*

Since then, the street problem has attracted considerable attention. Some research was devoted to structural properties. Tseng, Heffernan, and Lee [44] have shown how to report all pairs of vertices (s, t) of a given polygon for which it is a street; for star-shaped polygons many such vertex pairs exist. Das, Heffernan, and Narasimhan [10] have improved on this result by giving an optimal linear time algorithm. Ghosh and Saluja [17] have described how to walk an unknown street with a minimum number of turns.

For arbitrary polygons it is quite easy to see that in general no strategy can guarantee a search path whose length is at most a constant times the length of the shortest path from start to target.[2] Therefore, some researchers have designed competitive search strategies for classes of polygons more general than streets; see Datta

[1] Two sets are mutually weakly visible if each point of one set can see at least one point of the other.

[2] If n L-shaped legs of unit length lead away from a central place, the search path can be of length $2n - 1$, in the worst case, while the shortest path is of length 1.

and Icking [13, 14], Datta, Hipke, and Schuierer [12], and López-Ortiz and Schuierer [30, 33].

Other authors have shown that more general search problems can be solved for the original street polygons. Indeed, not only can we walk to vertex t starting from vertex s, where s, t are the two special vertices defining the street, but it has also been shown in Bröcker and Schuierer [8] and Bröcker and López-Ortiz [7] that one can find any boundary point from any starting point on the boundary of a street by means of a 69.216-competitive strategy.

Carlsson and Nilsson [9] have shown that the art gallery problem remains NP-hard for street polygons. However, the problem of computing the minimum number of guards located on a given watchman route can be solved very efficiently for streets, while it is NP-hard for general polygons.

Other research has addressed the gap between the $\sqrt{2}$ lower bound and the first upper bound of 5.72 for the original street problem. The upper bound was lowered to 4.44 in Icking [19], then to 2.61 in Kleinberg [26], to 2.05 in López-Ortiz and Schuierer [29], and to 1.73 in López-Ortiz and Schuierer [31]. López-Ortiz and Schuierer [32] showed that a particular strategy called CAB has the true competitive ratio 1.6837. Using different search strategies, the upper bound was further decreased to 1.57 in Semrau [42], and to 1.51 in Icking et al. [23]. Further attempts were made by Dasgupta, Chakrabarti, and DeSarkar [11] and by Kranakis and Spatharis [27].

But it remained an open question whether there existed a search strategy with optimal competitive factor $\sqrt{2}$; this was mentioned open problem no. 13 in Mitchell [35].

In this paper the problem is finally solved. We introduce a new strategy and prove that the search path it generates, in any particular street, is at most $\sqrt{2}$ times the length of the shortest path from s to t. Unlike many approaches discussed in previous work, the optimal strategy we are presenting here is not a mere artifact. Rather, its definition is well motivated by backward reasoning, as we shall now explain.

The crucial subproblem can be parametrized by a single angle, ϕ. For each possible value of ϕ a lower bound can be established; see section 3.1. For the maximum value $\phi = \pi$ the existence of a strategy matching this bound follows from the properties of a street. We state a requirement in section 3.2 that would allow us to extend an optimal strategy from a given value of ϕ to smaller values. From this requirement we can infer how the strategy should proceed; see section 3.3. One of the problems is to prove that the requirement can be fulfilled; see section 3.4.

2. Definitions and basic properties. First, we briefly recall some basic definitions.

A simple polygon P is considered as a room, with its edges as opaque walls. By ∂P we denote the boundary of polygon P. Two points inside P are mutually *visible*, i.e., see each other, if the connecting line segment is contained within P. As usual, two sets of points are said to be *mutually weakly visible* if each point of one set can see at least one point of the other set.

DEFINITION 2.1. *A simple polygon P in the plane with two distinguished vertices s and t is called a* street *if the two boundary chains from s to t are weakly mutually visible; for an example, see Figure* 1.1. *Streets are sometimes also called* LR-visible polygons [10, 44]*, where L and R denote the left and the right boundary chains from s to t, respectively.*

A strategy for searching a target in an unknown street is an on-line algorithm for a mobile robot, modeled by a point, that starts at vertex s, moves around inside the

polygon, and eventually arrives at the target, t. The robot is equipped with a vision system that provides the visibility polygon for its actual position at each time, and everything that has been visible is memorized. When the target becomes visible the robot goes there, and its task is accomplished.

As the room's floor plan is not known in advance, the robot's path can be longer than the shortest path, SP, from s to t inside P. Our goal is to bound that detour.

DEFINITION 2.2. *A strategy for searching a target, t, in a street is called* competitive with factor c *(or c-*competitive*, for short) if its path is never longer than c times the length of the shortest path from s to t.*

All existing algorithms for walking along a street are making use of some geometric properties that can be derived from the definition of a street; these facts and their complete proofs can be found in [25]. For the convenience of the reader these properties, together with an outline of their proofs, will now be stated.

First, we consider the situation at the beginning. As the robot starts from vertex s, it may not be able to see the whole polygon. The parts invisible to the robot are called *caves*. Each cave is hidden behind a reflex vertex, v, which is one whose internal angle exceeds 180°. Such a reflex vertex—and its associated cave—is called *left* if its adjacent edges in ∂P lie to the left of the ray emanating from the robot's position through v. Right reflex vertices are defined analogously.

If s is the start point of a street, these caves can occur only in a certain order. As the robot scans ∂P in a clockwise direction, it encounters a consecutive sequence of left caves with left reflex vertices $v_l^{-a}, v_l^{-a+1}, \ldots, v_l^0, v_l^1$ followed by a consecutive sequence of right caves with right reflex vertices $v_r^1, v_r^0, \ldots, v_r^{-b+1}, v_r^{-b}$; see Figure 2.1. Either sequence can be empty. The reason for this ordering is that a right cave cannot be predecessor of a left cave. Assuming the contrary, let v be a right reflex vertex that appears before the left reflex vertex w in clockwise order on ∂P. Let v^- be the predecessor vertex of v, and let w^+ denote the successor of w. If v were a vertex of chain L, then v^- would not be able to see a point of chain R, in contradiction to the street property. Thus, $v \in R$ holds. Similarly, we have $w \in L$. But this is impossible since L and R are connected and meet at s.

Of all the left caves visible from s only the clockwise-most can contain the target; see Figure 2.1. The reason is similar to the proof above. In fact, the reflex vertex v_l of the clockwise-most left cave cannot belong to chain R, or its successor on the boundary would not be able to see a point of L. Analogously, only the counterclockwise-most right cave with reflex vertex v_r can contain the target vertex t.

Consequently, if only v_l exists, then its cave must contain the target, and the robot walks straight to v_l; see Figure 2.1(ii). We observe that this reflex vertex must also be visited by the shortest path from s to t. The same holds if only v_r exists.

A more interesting situation arises if both v_l and v_r exist. Then the target can be situated in either of their caves, but the robot does not know in which one; see Figure 2.1(i). We call this a *funnel situation*. The angle, ϕ, between the directions from the actual position to v_l and to v_r is called the *opening angle*; it is always smaller than π, as another consequence of the street property. Most search strategies cause the robot to walk into this funnel of angle ϕ. They differ in choosing the direction into the funnel.

As the robot leaves the start vertex s, the vertices v_l and v_r are maintained by the robot. Essentially, v_l is the reflex vertex of the clockwise-most left cave in front of the robot, and v_r is the entrance vertex of the counterclockwise-most right cave. The vertices v_l and v_r are known to belong to L and R, respectively; but the horizon,

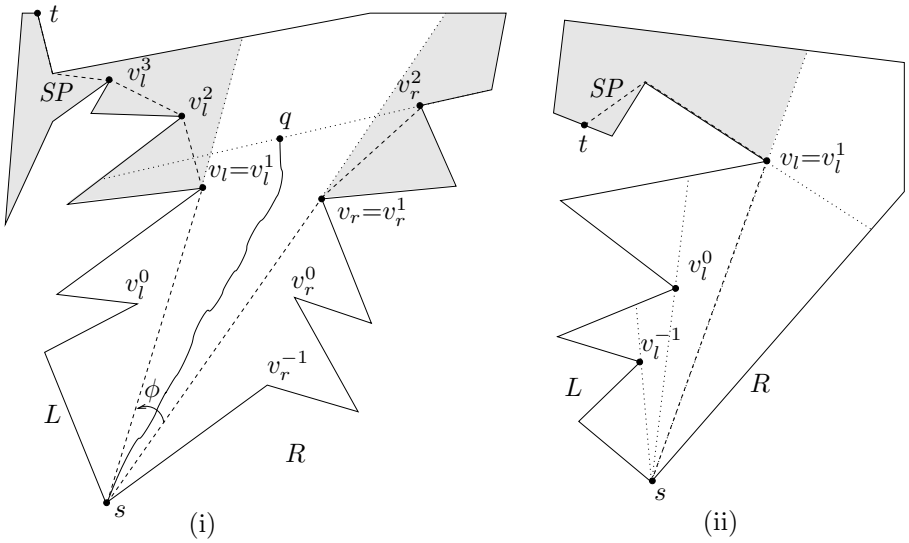

FIG. 2.1. *Typical situations in streets.*

that is, the boundary part between v_l and v_r, can belong to either chain, depending on the position of the target.

To summarize, the robot behaves as follows. If the target is visible from the robot's current position, the robot walks straight to the target. If only one of the vertices v_l, v_r exists, then the robot walks straight to this vertex, which is also visited by the shortest path. If both v_l and v_r exist, then the robot walks into the funnel defined by its current position, c_0, and by v_l and v_r.

As the robot moves into the funnel, three events can happen. The most important event occurs when a new reflex vertex, say $v_l{}'$, appears behind vertex v_l. In this case, we know from the discussion above that the target cannot be contained in the cave of $v_l{}'$; it must be situated in the caves of $v_l{}'$ or v_r. Now the robot proceeds with $v_l{}'$ and v_r. This event can occur repeatedly on both sides. It generates convex chains of reflex vertices $v_l^1, v_l^2, \ldots, v_l^m$ and $v_r^1, v_r^2, \ldots, v_r^n$ that form a funnel with apex c_0.

Another event can occur when one of the two innermost caves, say the left, becomes completely visible. In this case, the target must be situated in the right cave, and the robot walks to its associated reflex vertex, v_r^n. On reaching v_r^n, the funnel situation is resolved, and we know that the chain $v_r^1, v_r^2, \ldots, v_r^n$ belongs to the shortest path from s to t.

The third event occurs when the target becomes visible, e.g., in the right cave; then the robot walks straight to t, visiting the reflex vertex v_r^n on the way.

This analysis shows that detour is only caused by funnels, and that the overall competitive factor of a search strategy for streets depends only on its performance in funnels.

As a consequence, we can restrict our attention to the subclass of funnel polygons. They consist of two chains of reflex vertices with a common start point s; see Figure 2.2 for an example. The two reflex chains end in vertices t_l and t_r, respectively, and the line segment $t_l\, t_r$ closes the polygon. A funnel polygon represents a funnel situation in which the target t lies arbitrarily close behind either t_l or t_r, and the strategy will know which case applies only when the line segment $t_l t_r$ is reached. For analyzing

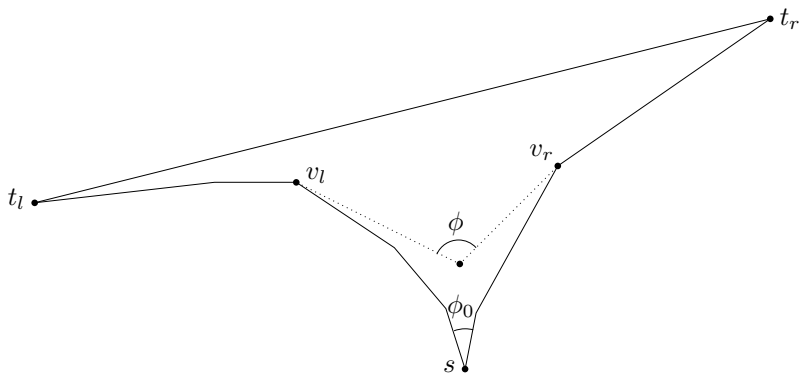

FIG. 2.2. *A funnel.*

a strategy, both cases have to be considered and the worse of them determines the competitive factor. Other funnel situations, which end before line segment $t_l t_r$ is reached or where the goal is further away from t_l or t_r, will produce a smaller detour.

Since the walking direction is always within the opening angle, ϕ is always *strictly increasing*. It starts at the angle, ϕ_0, between the two edges adjacent to s, and reaches, but never exceeds, 180° when finally the goal becomes visible. By this property, it is quite natural to take the opening angle ϕ for *parameterizing a strategy*.

3. A strategy which always takes the worst case into account. In the previous section we have seen that a crucial situation occurs when the robot is faced with two caves, one left and one right, and does not know in which of them the target, t, is situated. This situation can be parametrized by the funnel's opening angle ϕ.

Let us assume that $\frac{\pi}{2} \leq \phi$ holds. We will see in section 3.1 that for each value of ϕ, a *lower* bound for the competitive ratio is given by

$$K_\phi = \sqrt{1 + \sin \phi}.$$

If $\phi = \pi$, then $K_\pi = 1$. The street properties ensure that the robot is able to look into the caves and see the target. Hence, the optimal strategy is given by walking straight to t. That means, for $\phi = \pi$ we have a strategy matching the lower bound.

Now assume that $\frac{\pi}{2} \leq \phi_1 < \phi_2 < \pi$ holds, and that we have already found a strategy with (optimum) competitive factor K_{ϕ_2} for all opening angles $\geq \phi_2$. We would like to extend it to a K_{ϕ_1}-competitive strategy for opening angles ϕ_1. This is possible iff a certain geometric condition can be met, which will be stated in section 3.2. This condition gives rise to a certain curve (see section 3.3), and this curve will then be shown to have the required properties in section 3.4. Finally, in section 3.5, we deal with opening angles less than π.

3.1. A generalized lower bound. We start with a generalized lower bound for initial opening angles $\geq \frac{\pi}{2}$. For an arbitrary angle ϕ, let

$$K_\phi := \sqrt{1 + \sin \phi}\,.$$

LEMMA 3.1. *Assume an initial opening angle $\phi_0 \geq \frac{\pi}{2}$. Then no strategy can guarantee a smaller competitive factor than K_{ϕ_0}.*

Proof. We take an isosceles triangle with an angle ϕ_0 at vertex s; the other vertices are t_l and t_r; see Figure 3.1.

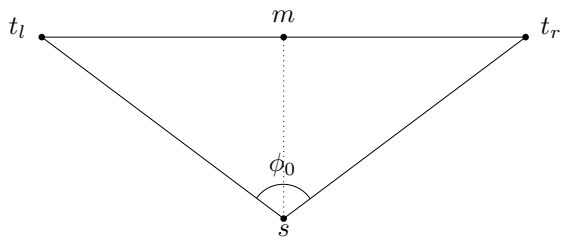

FIG. 3.1. *Establishing a generalized lower bound.*

The goal becomes visible only when the line segment $t_l\, t_r$ is reached. If this happens to the left of the midpoint m, the goal may be to the right, and vice versa. In any case the path length is at least the distance from s to m plus the distance from m to t_l. For the ratio, c, of the path length to the shortest path we obtain by simple trigonometry

$$c \geq \cos\frac{\phi_0}{2} + \sin\frac{\phi_0}{2} = \sqrt{1+\sin\phi_0} = K_{\phi_0}\,. \qquad \square$$

For $\phi_0 = \frac{\pi}{2}$, we have the well-known lower bound of $\sqrt{2}$ stemming from a rectangular isosceles triangle; see Klein [25].

Note that the lower bound K_{ϕ_0} also applies to any nonsymmetric situation, since at the start the funnel is unknown except for the two edges adjacent to s, and it may turn into a nearly symmetric case immediately after the start. In other words this means that for an initial opening angle ϕ_0, a competitive factor of K_{ϕ_0} is always the best we can hope for.

In the following we develop a strategy that is K_ϕ-competitive in all funnel polygons of opening angle ϕ.

3.2. Sufficient requirements for an optimal strategy. In a funnel with opening angle π the goal is visible and there is a trivial strategy that achieves the optimal competitive factor $K_\pi = 1$. So we look backwards to decreasing angles.

Let us assume for the moment that the funnel is a triangle, and that we have a strategy with a competitive factor of K_{ϕ_2} for all triangular funnels with initial opening angle ϕ_2. How can we extend this to initial opening angles ϕ_1 with $\pi \geq \phi_2 > \phi_1 \geq \frac{\pi}{2}$?

Starting with an angle ϕ_1 at point p_1 we walk a certain path of length w until we reach an angle of ϕ_2 at point p_2, from where we can continue with the known strategy; see Figure 3.2. We assume for the moment that the left and right reflex vertices, v_l and v_r as defined in section 2, do not change.

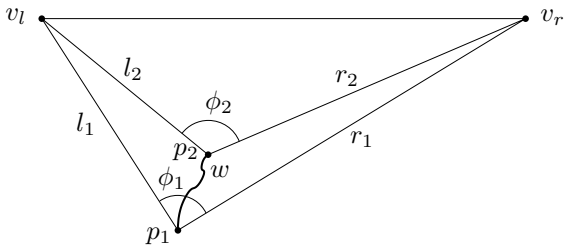

FIG. 3.2. *Getting from angle ϕ_1 to ϕ_2.*

Let l_1 and l_2 denote the distances from p_1, respectively, p_2, to v_l at the left side, and r_1 and r_2 the corresponding distances at the right. If $t = v_l$, the length of the robot's path from p_1 to t is not greater than $w + K_{\phi_2} l_2$. If now $K_{\phi_1} l_1 \geq w + K_{\phi_2} l_2$ holds and the analogous inequality $K_{\phi_1} r_1 \geq w + K_{\phi_2} r_2$ for the right side, we have a competitive factor not bigger than K_{ϕ_1} for triangles with initial opening angle ϕ_1. By combining the two inequalities we can express the condition as

$$w \leq \min(K_{\phi_1} l_1 - K_{\phi_2} l_2, K_{\phi_1} r_1 - K_{\phi_2} r_2)\,, \tag{3.1}$$

which will prove useful later on.

Note that condition (3.1) is additive in the following sense. If it holds for a path w_{12} from ϕ_1 to ϕ_2 and for a continuing path w_{23} from ϕ_2 to ϕ_3, it is also true for the combined path $w_{12} + w_{23}$ from ϕ_1 to ϕ_3. This will turn out to be very useful: if (3.1) holds for arbitrarily small, successive steps w, then it is also true for all bigger ones.

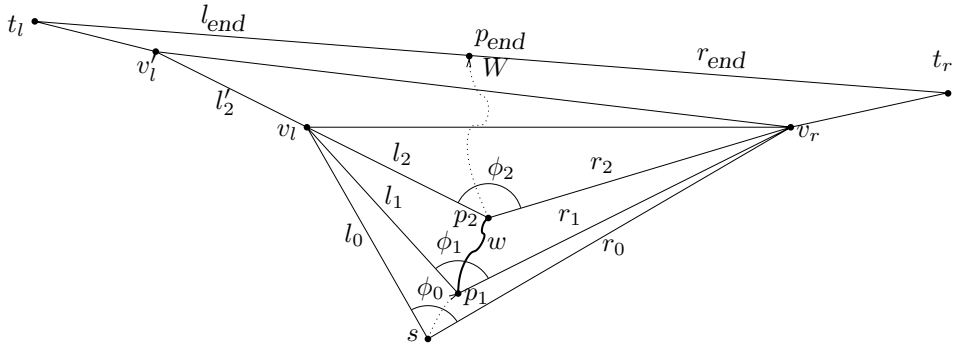

FIG. 3.3. *When p_2 is reached, the most advanced visible point to the left jumps from v_l to v_l'.*

Now let us go further backwards and observe what happens if one of the current vertices v_l or v_r change. We assume that condition (3.1) holds for path w from p_1 to p_2 and that v_l changes at p_2; see Figure 3.3. The visible left chain is extended by l_2'. Nothing changes on the right side of the funnel, and for the left side of the funnel we have

$$\begin{aligned} w \leq K_{\phi_1} l_1 - K_{\phi_2} l_2 &= K_{\phi_1} l_1 - K_{\phi_2} l_2 + K_{\phi_2} l_2' - K_{\phi_2} l_2' \\ &\leq K_{\phi_1}(l_1 + l_2') - K_{\phi_2}(l_2 + l_2')\,. \end{aligned} \tag{3.2}$$

The last inequality holds because $K_\phi = \sqrt{1 + \sin\phi}$ is decreasing with increasing $\phi \in [\frac{\pi}{2}, \pi]$. Here, $l_1 + l_2'$ and $l_2 + l_2'$ are the lengths of the shortest paths from p_1 and p_2 to v_l', respectively. But (3.2) in fact means that (3.1) remains valid even if changes of v_l or v_r occur.

Under the assumption that (3.1) holds for all small steps where v_l and v_r do not change we can make use of the additivity of (3.1) and obtain the following expression for the path length, W, from an initial opening angle ϕ_0 to the point p_{end} where the line segment $t_l\, t_r$ is reached; see Figure 3.3.

$$W \leq \min\Big(\begin{array}{l} K_{\phi_0}(\text{length of left chain}) - K_\pi l_{end}, \\ K_{\phi_0}(\text{length of right chain}) - K_\pi r_{end} \end{array}\Big).$$

But, since $K_\pi = 1$, this inequality exactly means that we have a competitive factor not larger than K_{ϕ_0}. Only a curve remains to be found that satisfies (3.1) for small steps.

3.3. Developing the curve. One could try to satisfy condition (3.1) by analyzing, for fixed p_1, ϕ_1, and ϕ_2, which points p_2 meet that requirement. To avoid this tedious task, we argue as follows. For fixed ϕ_2, the point p_2 lies on a circular arc U_{ϕ_2} through v_l and v_r. While p_2 moves along the arc U_{ϕ_2}, the length l_2 is strictly increasing while r_2 is strictly decreasing. Heuristically, we maximize our chances to satisfy (3.1) if we require that

$$K_{\phi_1} l_1 - K_{\phi_2} l_2 = K_{\phi_1} r_1 - K_{\phi_2} r_2$$

or, equivalently,

$$K_{\phi_2}(l_2 - r_2) = K_{\phi_1}(l_1 - r_1)\,. \tag{3.3}$$

We claim that inside the triangle defined by ϕ_1 and segments of length l_1 and r_1 there exists a point p_2 on U_{ϕ_2} that satisfies (3.3). Indeed, while p_2 moves along U_{ϕ_2} between the intersections of U_{ϕ_2} with the segments of length l_1 and r_1, the continuous expression $K_{\phi_2}(l_2 - r_2) - K_{\phi_1}(l_1 - r_1)$ changes its sign; see Figure 3.4. If p_2 is the intersection of U_{ϕ_2} with the segment of length r_1, we have $r_2 < r_1$ and $K_{\phi_2} < K_{\phi_1}$, and $K_{\phi_2}(l_2 - r_2) - K_{\phi_1}(l_1 - r_1)$ is positive if $K_{\phi_1} l_1 \le K_{\phi_2} l_2$. Using the law of sine, $K_{\phi_1} l_1 \le K_{\phi_2} l_2$ is equivalent to $\frac{K_{\phi_1}}{\sin\phi_1} \le \frac{K_{\phi_2}}{\sin\phi_2}$. The expression $\frac{K_\phi}{\sin\phi}$ is monotonically increasing for $\frac{\pi}{2} \le \phi < \pi$. For the same reason $K_{\phi_2}(l_2 - r_2) - K_{\phi_1}(l_1 - r_1) < 0$ holds if p_2 is the intersection of U_{ϕ_2} with the segment of length l_1.

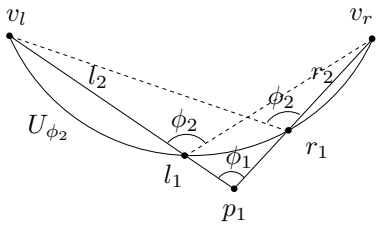

FIG. 3.4. *$K_{\phi_2}(l_2 - r_2) - K_{\phi_1}(l_1 - r_1)$ changes its sign along the circular arc U_{ϕ_2}.*

Altogether, if we start with the initial values ϕ_0, l_0, r_0, we define the fixed constant $A := K_{\phi_0}(l_0 - r_0)$, and for any $\phi_0 \le \phi \le \pi$ with corresponding lengths l_ϕ and r_ϕ we want that

$$K_\phi(l_\phi - r_\phi) = A \tag{3.4}$$

holds as long as v_l and v_r do not change. In the symmetric case $l_0 = r_0$ this condition means that we walk along the bisector of v_l and v_r. Otherwise, condition (3.4) defines a curve which can be determined in the following way. We choose a coordinate system with horizontal axis $v_l\, v_r$, the midpoint being the origin. We scale the coordinate system so that the distance from v_l to v_r equals 1. With this choice we have

$$|A| = |K_\phi(l_\phi - r_\phi)| \le K_\phi = \sqrt{1 + \sin\phi} \tag{3.5}$$

for every l_ϕ, r_ϕ, and K_ϕ in the triangle defined by ϕ_0, l_0, r_0.

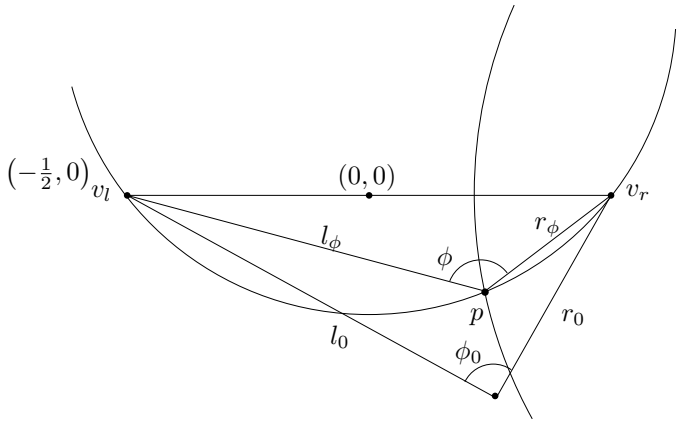

FIG. 3.5. *The right arc of the hyperbola defined by v_l, v_r, and $(l-r) = \frac{A}{K_\phi}$ and the circle through v_l and v_r defined by angle ϕ meet in $p = (X(\phi), Y(\phi))$.*

W.l.o.g. let $l_0 > r_0$. For any $\phi_0 \le \phi < \pi$ the corresponding point of the curve is the intersection of the hyperbola

$$\frac{X^2}{\left(\frac{A}{2K_\phi}\right)^2} - \frac{Y^2}{\left(\frac{1}{2}\right)^2 - \left(\frac{A}{2K_\phi}\right)^2} = 1 \tag{3.6}$$

with the circle

$$X^2 + \left(Y + \frac{\cot\phi}{2}\right)^2 = \frac{1}{4\sin^2\phi}; \tag{3.7}$$

see Figure 3.5 and the details found in section A.1 of the appendix.

Solving these equations leads us, after some transformations, to the following solutions (for details see section A.2 of the appendix):

$$X(\phi) = \frac{A}{2} \cdot \frac{\cot\frac{\phi}{2}}{1+\sin\phi}\sqrt{\left(1+\tan\frac{\phi}{2}\right)^2 - A^2}, \tag{3.8}$$

$$Y(\phi) = \frac{1}{2}\cot\frac{\phi}{2}\left(\frac{A^2}{1+\sin\phi} - 1\right). \tag{3.9}$$

Since $|A| < \sqrt{1+\sin\phi} < 1 + \tan\frac{\phi}{2}$ holds, the functions $X(\phi)$ and $Y(\phi)$ are well defined and continuous while the curve stays below the line segment $v_l v_r$.

Figure 3.6 shows how these curves look for all possible values of ϕ and A. All points with an initial opening angle of $\frac{\pi}{2}$ lie on the lower half circle.

Two cases can be distinguished. If $|A| < 1$, then the curves can be continuously extended to a point $(\frac{A}{2}, 0)$ on the line segment $v_l\, v_r$. For $|A| > 1$ the curves end up in v_l and v_r, respectively, with a limit of opening angles $\phi = \pi - \arcsin(A^2 - 1)$, which satisfies $X(\phi) = \pm\frac{1}{2}$, $Y(\phi) = 0$, and $|A| = K_\phi$. The curves for the limiting cases $|A| = 1$ are emphasized with a thick line in Figure 3.6.

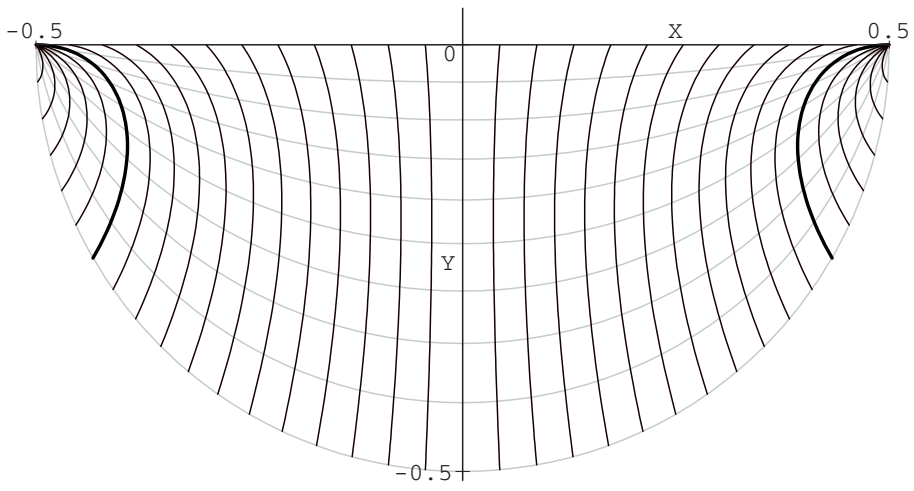

FIG. 3.6. *The curves fulfilling condition* (3.4) *for all values of* ϕ *and* A.

3.4. Checking the requirements. We want to check that the curve defined by (3.8) and (3.9) in section 3.3 satisfies condition (3.1). The arc length of the curve from angle ϕ_1 to ϕ_2 has to be compared to the right side of (3.1). Because of (3.3) the min in (3.1) can be dropped.

For $l_0 = r_0$ we trivially have equality in (3.1). W.l.o.g. we can assume $l_0 > r_0$ and $A > 0$. The other case is symmetric. It suffices to check

$$\int_{\phi_1}^{\phi_2} \sqrt{X'(\phi)^2 + Y'(\phi)^2}\, d\phi \le K_{\phi_1} l_{\phi_1} - K_{\phi_2} l_{\phi_2} \qquad \text{for all } \frac{\pi}{2} \le \phi_1 < \phi_2 < \pi\,.$$

Here, $X'(\phi)$ and $Y'(\phi)$ denote the derivatives of $X(\phi)$ and $Y(\phi)$ from (3.8) and (3.9) in ϕ. The inequality is equivalent to

$$\int_{\phi_1}^{\phi_2} \sqrt{X'(\phi)^2 + Y'(\phi)^2}\, d\phi \le \int_{\phi_1}^{\phi_2} -(K_\phi l_\phi)'\, d\phi \qquad \text{for all } \frac{\pi}{2} \le \phi_1 < \phi_2 < \pi\,, \tag{3.10}$$

since $K_\phi l_\phi$ is a differentiable function in ϕ. It is sufficient to show that in (3.10) one integrant dominates the other. In the following we will try to simplify this task.

By some transformations (for details see section A.3 of the appendix), we obtain

$$l_\phi = \frac{K_\phi}{A} X(\phi) + \frac{A}{2K_\phi} \quad \text{and therefore} \quad K_\phi l_\phi = \frac{K_\phi^2}{A} X(\phi) + \frac{A}{2}\,. \tag{3.11}$$

Thanks to an idea by Seidel [41] we can make use of the substitution $t = \tan\frac{\phi}{2}$

in K_ϕ, $X(\phi)$, $Y(\phi)$, and $K_\phi l_\phi$. Thus, we get the functions

$$\overline{K}(t) := \sqrt{\frac{(1+t)^2}{1+t^2}},$$
$$\overline{X}(t) := \frac{A}{2t\overline{K}^2(t)}\sqrt{(1+t)^2 - A^2} = \frac{A(1+t^2)\sqrt{(1+t)^2-A^2}}{2t(1+t)^2},$$
$$\overline{Y}(t) := \left(\frac{A^2}{\overline{K}^2(t)} - 1\right)\frac{1}{2t} = \frac{A^2(1+t^2)-(1+t)^2}{2t(1+t)^2},$$
$$\overline{Kl}(t) := \frac{\overline{K}^2(t)}{A}\overline{X}(t) + \frac{A}{2} = \frac{\sqrt{(1+t)^2-A^2}}{2t} + \frac{A}{2}$$

with the identities $\overline{K}(\tan\frac{\phi}{2}) = K_\phi$, $\overline{X}(\tan\frac{\phi}{2}) = X(\phi)$, $\overline{Y}(\tan\frac{\phi}{2}) = Y(\phi)$, and $\overline{Kl}(\tan\frac{\phi}{2}) = K_\phi l_\phi$. The simple identities are proven in section A.4 of the appendix.

We will now simplify (3.10) using terms of the identities above. The left-hand side of (3.10) is equivalent to

$$\begin{aligned}(3.12)\quad &\int_{\phi_1}^{\phi_2} \sqrt{\left(\frac{d}{d\phi}\left(\overline{X}\left(\tan(\phi/2)\right)\right)\right)^2 + \left(\frac{d}{d\phi}\left(\overline{Y}\left(\tan(\phi/2)\right)\right)\right)^2}\, d\phi \\ &= \int_{\phi_1}^{\phi_2} \frac{d}{d\phi}\left(\tan(\phi/2)\right)\sqrt{\left(\left(\frac{d}{dt}\overline{X}\right)\left(\tan(\phi/2)\right)\right)^2 + \left(\left(\frac{d}{dt}\overline{Y}\right)\left(\tan(\phi/2)\right)\right)^2}\, d\phi,\end{aligned}$$

whereas the right-hand side of (3.10) is equivalent to

$$(3.13)\quad \int_{\phi}^{\phi_2} -\frac{d}{d\phi}\left(\overline{Kl}\left(\tan(\phi/2)\right)\right)\, d\phi = \int_{\phi}^{\phi_2} -\frac{d}{d\phi}\left(\tan(\phi/2)\right)\left(\frac{d}{dt}\overline{Kl}\right)\left(\tan(\phi/2)\right)\, d\phi.$$

By applying the rule of substitution to (3.12) and (3.13), (3.10) is equivalent to

$$(3.14)\quad \int_{\tan\frac{\phi_1}{2}}^{\tan\frac{\phi_2}{2}} \sqrt{\left(\frac{d}{dt}\overline{X}(t)\right)^2 + \left(\frac{d}{dt}\overline{Y}(t)\right)^2}\, dt \le \int_{\tan\frac{\phi_1}{2}}^{\tan\frac{\phi_2}{2}} -\frac{d}{dt}\overline{Kl}(t)\, dt\,.$$

The function $\tan\frac{\phi}{2}$ is positive, continuous, and monotonically increasing for $\frac{\pi}{2} \le \phi < \pi$. Then it suffices to show that in (3.14) one integrand dominates the other one for every t in the integration interval $[\tan\frac{\phi_1}{2}, \tan\frac{\phi_2}{2}]$ for all $\frac{\pi}{2} \le \phi_1 < \phi_2 < \pi$. We make use of the following facts. For every $t \in [\tan\frac{\phi_1}{2}, \tan\frac{\phi_2}{2}]$ there is always a unique $\phi \in [\phi_1, \phi_2]$ with $t = \tan\frac{\phi}{2}$. Additionally we can assume $A < \sqrt{1+\sin\phi}$ from (3.5).

Altogether, it suffices to prove that

$$(3.15)\quad \sqrt{\overline{X}'(t)^2 + \overline{Y}'(t)^2} \le -\overline{Kl}'(t)$$

holds for $t = \tan\frac{\phi}{2}$, $\frac{\pi}{2} \le \phi < \pi$, and $0 < A < \sqrt{1+\sin\phi}$. Here for convenience $\overline{X}'(t)$, $\overline{Y}'(t)$, and $\overline{Kl}'(t)$ denote the derivatives of the corresponding functions in t. We insert the following identities (see section A.5 of the appendix for details) into (3.15).

$$-\overline{Kl}'(t) = \frac{(1+t) - A^2}{2t^2\sqrt{(1+t)^2 - A^2}},$$

$$\overline{X}'(t) = \frac{A\left(A^2\left((1+t)^3 - 4t^2\right) - 1 - 4t - 4t^2 + t^4\right)}{2(1+t)^3 t^2\sqrt{(1+t)^2 - A^2}},$$

$$\overline{Y}'(t) = \frac{(1+t)^3 - A^2\left((1+t)^3 - 4t^2\right)}{2(1+t)^3 t^2}\,.$$

Note that $-\overline{Kl}'(t) > 0$ follows from $t \geq \tan\frac{\pi}{4} = 1$ and $A^2 < 2$; see (3.5). Thus, after squaring, the following remains to be shown:

$$F(t,A) \geq 0 \text{ for all } t = \tan\frac{\phi}{2},\ \frac{\pi}{2} \leq \phi < \pi, \text{ and } 0 < A < \sqrt{1+\sin\phi} \text{ where}$$

$$\begin{aligned} F(t,A) &:= \left(\overline{Kl}'(t)\right)^2 - \left(\overline{X}'(t)^2 + \overline{Y}'(t)^2\right) \\ &= \frac{-(t-1)A^2\left((A^2-1)(t^2+3) - 4t\right)}{4(1+t)^3 t^2\left((1+t)^2 - A^2\right)}. \end{aligned}$$

The last inequality is proven in section A.6 of the appendix. The denominator of $F(t,A)$ is positive since $t \geq \tan\frac{\pi}{4} = 1$ and $A^2 < 2$ holds; see (3.5). Therefore it suffices to show that

$$(A^2-1)(t^2+3) - 4t \leq 0\,. \tag{3.16}$$

We minimize our chances to satisfy (3.16) if A achieves a maximal value greater than 1. Substituting A^2 by $1+\sin(\phi)$, the greatest possible value for A^2, and t by $\tan\frac{\phi}{2}$, the inequality (3.16) holds if

$$2\cos\phi\tan\frac{\phi}{2} \leq 0\,.$$

The details are given in section A.7 of the appendix. The last inequality holds for $\frac{\pi}{2} \leq \phi < \pi$. This proves (3.15) and therefore (3.1) for the curves of section 3.3.

3.5. Opening angles below 90°. So far we have seen that there is a strategy that is competitive with factor $\sqrt{2}$ for opening angles greater than or equal to $\frac{\pi}{2}$. There are already methods to accomplish the task for funnels with opening angles running from an initial angle $\phi_0 < \frac{\pi}{2}$ to an opening angle of $\frac{\pi}{2}$. As was already shown by Semrau [42] and also in López-Ortiz [28], any strategy which achieves a factor $\geq\sqrt{2}$ for all funnels with $\phi_0 \geq \frac{\pi}{2}$ can be adapted to the general case without changing its factor. They suggest a walk along the fixed angular bisector of the current pair v_l and v_r until an opening angle of $\frac{\pi}{2}$ is reached. If the opening angle of $\frac{\pi}{2}$ is reached, one can proceed, for example, with the strategy given in section 3.3. So we are done here.

In the following we show that our idea is universal, and for completeness we consider the case $0 < \phi < \frac{\pi}{2}$ analogously. Looking backwards as in section 3.2 we can assume that there is a strategy which is competitive with factor $\sqrt{2}$ starting at point p_2 with a opening angle $\frac{\pi}{2} \geq \phi_2 > 0$. Again we want to extend the strategy to initial opening angles ϕ_1 at starting points p_1 with $\frac{\pi}{2} \geq \phi_2 > \phi_1 > 0$; see again Figure 3.2. The only difference to the former consideration is that the factor need not vary any longer with respect to the opening angle. The worst-case factor of $\sqrt{2}$ is already in use, and we want to achieve this factor when starting at p_1.

Thus, with the same arguments and notation as in section 3.2, it suffices to show that there is a strategy so that

$$w \le \min(\sqrt{2}\,l_1 - \sqrt{2}\,l_2, \sqrt{2}\,r_1 - \sqrt{2}\,r_2) \tag{3.17}$$

holds between the changes of v_l and v_r as long as the opening angle is smaller than $\frac{\pi}{2}$.

Again, similar to section 3.3, we want to satisfy (3.17) and therefore require that

$$\sqrt{2}\,(l_1 - l_2) = \sqrt{2}\,(r_1 - r_2) \text{ or, equivalently, } (l_2 - r_2) = (l_1 - r_1)\,. \tag{3.18}$$

We consider two cases: For $l_0 = r_0$ we follow the fixed angular bisector in the triangle defined by l_0, r_0, and ϕ_0. In this case, as already stated in the beginning of section 3.4 with $l_0 = r_0$, the equality

$$w = K_{\phi_1} l_1 - K_{\phi_2} l_2 = K_{\phi_1} r_1 - K_{\phi_2} r_2$$

holds. Then (3.17) follows from $K_{\phi_1} \le K_{\phi_2} \le \sqrt{2}$ for $\frac{\pi}{2} \ge \phi_2 > \phi_1 > 0$.

If we start with an initial difference $1 > D := (l_0 - r_0) > 0$ at point s, (3.18) means that we follow the current angular bisector (CAB) of v_l and v_r, and the resulting curve is a hyperbola through s with fix-points v_l and v_r; see Icking, Klein, and Langetepe [20]. For the street problem the strategy CAB was already successfully analyzed for small angles in López-Ortiz and Schuierer [31]. We show that our approach works as well. The transformations of sections 3.3 and 3.4 become much easier since the constant does not depend on ϕ, and all transformations are presented in detail in section A.8 of the appendix. We proceed as before and obtain the coordinates

$$X(\phi) = \frac{D}{2} \cot\frac{\phi}{2} \sqrt{\left(1 + \tan^2\frac{\phi}{2}\right) - D^2},$$
$$Y(\phi) = \frac{1}{2} \cot\frac{\phi}{2} (D^2 - 1).$$

Now $K_\phi l_\phi$ simplifies to

$$\sqrt{2}\,l_\phi = \frac{\sqrt{2}}{D} X(\phi) + \frac{D}{\sqrt{2}}\,.$$

In this case there is no need to simplify the terms by a substitution. In analogy to the previous section it suffices to prove that in (3.10) one integrand dominates the other one; that is,

$$\sqrt{X'(\phi)^2 + Y'(\phi)^2} \le -(K_\phi l_\phi)' \tag{3.19}$$

for all $\frac{\pi}{2} \ge \phi > 0$ and $0 < D < 1$. Altogether it suffices to show

$$F(\phi, D) \ge 0 \quad \text{for all} \quad 0 < \phi \le \frac{\pi}{2} \quad \text{and} \quad 0 < D < 1, \quad \text{where}$$
$$F(\phi, D) := X'(\phi)^2 \left(\frac{2}{D^2} - 1\right) - Y'(\phi)^2$$
$$= \frac{(D^2 - 1)^2 \left(1 - \tan^2\frac{\phi}{2}\right)}{4(\cos\phi - 1)^2 \left(\left(1 + \tan^2\frac{\phi}{2}\right) - D^2\right)}.$$

It remains to be shown that

$$1 - \tan^2 \frac{\phi}{2} \geq 0 \quad \text{and} \quad 1 + \tan^2 \frac{\phi}{2} - D^2 \geq 0$$

holds, which follows from $D^2 < 1$ and $\tan \frac{\phi}{2} \leq 1$ for $\frac{\pi}{2} \geq \phi > 0$. See section A.8 of the appendix for all details.

3.6. The main result. To summarize, our strategy for searching a goal in an unknown street works as follows.

Strategy WCA (worst-case aware). If the initial opening angle is less than $\frac{\pi}{2}$, walk along the current angular bisector of v_l and v_r until a right opening angle is reached.

Depending on the actual parameters ϕ_0, l_0, and r_0, walk along the corresponding curve from section 3.3 until one of v_l and v_r changes. Switch over to the curve corresponding to the new parameters ϕ_1, l_1, and r_1. Continue until the line $t_l\, t_r$ is reached.

THEOREM 3.2. *By using strategy* WCA *we can search a goal in an unknown street with a competitive factor of* $\sqrt{2}$ *at the most. This is optimal.*

The proof can be found in sections 3.1 through 3.5. In Figure 3.7 a complete path of *WCA* inside a street is shown.

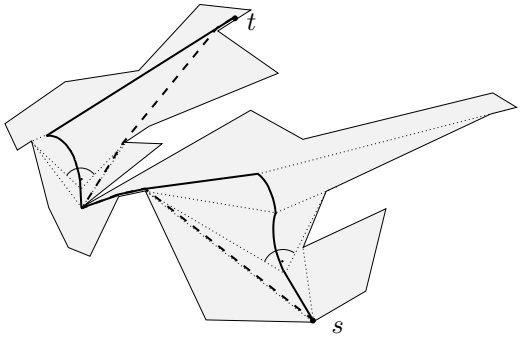

FIG. 3.7. *A street and the path generated by WCA.*

4. Conclusions. We have developed a competitive strategy for walking in streets which guarantees an optimal factor of $\sqrt{2}$ at the most in the worst case, thereby settling an old open problem. Furthermore, the strategy is even better for an initial opening angle $\phi_0 > \frac{\pi}{2}$, in which case an optimal factor $K_{\phi_0} = \sqrt{1 + \sin \phi_0}$ between 1 and $\sqrt{2}$ is achieved.

It would be interesting to see if there are substantially different but also optimal strategies.

Appendix. Formal calculations. This appendix contains the formal calculations needed in the main text. They are presented in a resolution that makes it possible to follow step by step. Nevertheless, the reader might prefer to enter start and target formulae into some math-tool, for example, Maple or Mathematica, and have correctness checked automatically.

A.1. Definition of the circle and the hyperbola. We choose a coordinate system with horizontal axis $v_l\, v_r$, the midpoint being the origin. We scale the coordinate system so that the distance from v_l to v_r equals 1. Let p be the point at a fixed opening angle ϕ on the curve we want to construct. Then two constraints must be met. First, the difference $l(p)-r(p)$ of the length from p to v_l and v_r, correspondingly, must equal $\frac{A}{K_\phi}$. The locus of all such points p is a hyperbola. Second, p sees v_l and v_r at the angle ϕ. The locus of all these points p is a circle; see Figure A.1.

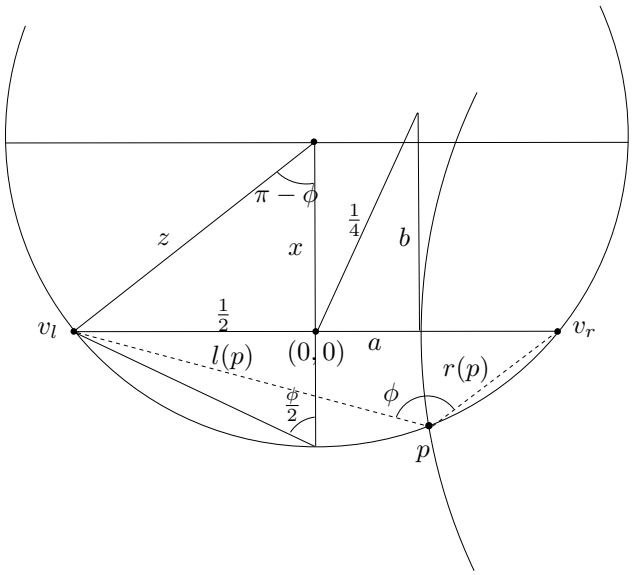

FIG. A.1. *The right arc of the hyperbola defined by v_l, v_r, and $(l(p) - r(p)) = \frac{A}{K_\phi}$ and the circle through v_l and v_r defined by angle ϕ.*

The hyperbola reads

$$\frac{X^2}{a^2} - \frac{Y^2}{b^2} = 1\,,$$

where $2a = (l(p) - r(p)) = \frac{A}{K_\phi}$ and $b^2 + a^2 = e^2 = \frac{1}{4}$ hold. So we have $a^2 = (\frac{A}{2K_\phi})^2$ and $b^2 = \frac{1}{4} - (\frac{A}{2K_\phi})^2$. The circle is defined by

$$X^2 + (Y - x)^2 = z^2\,. \tag{A.1}$$

It remains to compute the parameters of the circle, x and z. From the law of sine we get

$$\frac{z}{\sin\frac{\pi}{2}} = \frac{1}{2\sin(\pi-\phi)} = \frac{1}{2\sin\phi},$$
$$\frac{z-x}{\sin\left(\pi - \frac{\pi}{2} - \frac{\phi}{2}\right)} = \frac{z-x}{\cos\frac{\phi}{2}} = \frac{1}{2\sin\frac{\phi}{2}},$$

and therefore $z = \frac{1}{2\sin\phi}$ and

$$x = z - \frac{1}{2}\cot\frac{\phi}{2} = \frac{1}{2\sin\phi} - \frac{1}{2}\cot\frac{\phi}{2} = \frac{1-2\cos^2\frac{\phi}{2}}{4\sin\frac{\phi}{2}\cos\frac{\phi}{2}} = -\frac{\cot\phi}{2}\,.$$

A.2. Intersection of the circle and the hyperbola. In order to verify the expressions

$$X(\phi) = \frac{A}{2} \cdot \frac{\cot\frac{\phi}{2}}{1+\sin\phi}\sqrt{\left(1+\tan\frac{\phi}{2}\right)^2 - A^2}, \tag{A.2}$$

$$Y(\phi) = \frac{1}{2}\cot\frac{\phi}{2}\left(\frac{A^2}{1+\sin\phi} - 1\right), \tag{A.3}$$

we insert them into the equations

$$\frac{X^2}{\left(\frac{A}{2K_\phi}\right)^2} - \frac{Y^2}{\left(\frac{1}{2}\right)^2 - \left(\frac{A}{2K_\phi}\right)^2} = 1, \tag{A.4}$$

$$X^2 + \left(Y + \frac{\cot\phi}{2}\right)^2 = \frac{1}{4\sin^2\phi}. \tag{A.5}$$

For (A.4) we have

$$\begin{aligned}
&\frac{\left(\frac{A}{2}\cdot\frac{\cot\frac{\phi}{2}}{1+\sin\phi}\sqrt{\left(1+\tan\frac{\phi}{2}\right)^2 - A^2}\right)^2}{\left(\frac{A}{2K_\phi}\right)^2} - \frac{\left(\frac{1}{2}\cot\frac{\phi}{2}\left(\frac{A^2}{1+\sin\phi}-1\right)\right)^2}{\left(\frac{1}{2}\right)^2 - \left(\frac{A}{2K_\phi}\right)^2} \\
&= \left(\frac{\cot\frac{\phi}{2}}{K_\phi}\right)^2\left(\left(1+\tan\frac{\phi}{2}\right)^2 - A^2\right) - \frac{\cot^2\frac{\phi}{2}\left(\left(\frac{A}{K_\phi}\right)^2 - 1\right)^2}{1-\left(\frac{A}{K_\phi}\right)^2} \\
&= \left(\frac{\cot\frac{\phi}{2}}{K_\phi}\right)^2\left(\left(1+\tan\frac{\phi}{2}\right)^2 - A^2\right) + \cot^2\frac{\phi}{2}\left(\left(\frac{A}{K_\phi}\right)^2 - 1\right) \\
&= \cot^2\frac{\phi}{2}\left(\frac{\left(1+\tan\frac{\phi}{2}\right)^2}{1+\sin\phi} - 1\right) = 1\,.
\end{aligned}$$

The conclusion is true since the identity

$$1+\sin\phi = 1 + \frac{2\tan\frac{\phi}{2}}{1+\tan^2\frac{\phi}{2}} = \frac{\left(1+\tan\frac{\phi}{2}\right)^2}{1+\tan^2\frac{\phi}{2}} \tag{A.6}$$

holds.

For proving (A.5) we argue as follows:

$$\begin{aligned}
&\left(\frac{A}{2}\cdot\frac{\cot\frac{\phi}{2}}{1+\sin\phi}\sqrt{\left(1+\tan\frac{\phi}{2}\right)^2 - A^2}\right)^2 + \left(\frac{1}{2}\cot\frac{\phi}{2}\left(\frac{A^2}{1+\sin\phi}-1\right) + \frac{\cot\phi}{2}\right)^2 \\
&= \left(\frac{A}{2}\cdot\frac{\cot\frac{\phi}{2}}{1+\sin\phi}\right)^2\left(\left(1+\tan\frac{\phi}{2}\right)^2 - A^2\right)
\end{aligned}$$

$$
\begin{aligned}
&+\left(\frac{1}{2}\cot\frac{\phi}{2}\left(\frac{A^2}{1+\sin\phi}-1\right)\right)^2+\cot\frac{\phi}{2}\left(\frac{A^2}{1+\sin\phi}-1\right)\frac{\cot\phi}{2}+\left(\frac{\cot\phi}{2}\right)^2\\
&=\left(\frac{A}{2}\cdot\frac{\cot\frac{\phi}{2}}{1+\sin\phi}\right)^2\left(1+\tan\frac{\phi}{2}\right)^2\\
&\quad+\left(\frac{1}{2}\cot\frac{\phi}{2}\right)^2\left(-2\frac{A^2}{1+\sin\phi}+1\right)+\cot\frac{\phi}{2}\left(\frac{A^2}{1+\sin\phi}-1\right)\frac{\cot\phi}{2}+\left(\frac{\cot\phi}{2}\right)^2\\
&=\left(\frac{\cot\frac{\phi}{2}}{2}-\frac{\cot\phi}{2}\right)^2+\frac{A^2\cot^2\frac{\phi}{2}}{4(1+\sin\phi)}\left(\frac{\left(1+\tan\frac{\phi}{2}\right)^2}{1+\sin\phi}-2+2\frac{\cot\phi}{\cot\frac{\phi}{2}}\right)\\
&=\frac{1}{4\sin^2\phi}+\frac{A^2\cot^2\frac{\phi}{2}}{4(1+\sin\phi)}\left(\tan^2\frac{\phi}{2}+1-2+\frac{1-\tan^2\frac{\phi}{2}}{\tan\frac{\phi}{2}}\tan\frac{\phi}{2}\right)\\
&=\frac{1}{4\sin^2\phi}+\frac{A^2\cot^2\frac{\phi}{2}}{4(1+\sin\phi)}\cdot 0=\frac{1}{4\sin^2\phi}\,.
\end{aligned}
$$

Here we made use of (A.6) and the identities

$$
\left(\frac{\cot\frac{\phi}{2}}{2}-\frac{\cot\phi}{2}\right)^2=\frac{1}{4}\left(\frac{\sin\phi}{1-\cos\phi}-\frac{\cos\phi}{\sin\phi}\right)^2=\frac{1}{4}\frac{1}{\sin^2\phi}
$$

and

$$
\cot\phi=\frac{1-\tan^2\frac{\phi}{2}}{2\tan\frac{\phi}{2}}\,.
$$

A.3. Representation of l_ϕ. Considering the hyperbola (see Figure 3.5), we have

$$
\begin{aligned}
l_\phi &= \sqrt{\left(X(\phi)+\frac{1}{2}\right)^2+Y^2(\phi)}\\
&\overset{(3.6)}{=} \sqrt{\left(X(\phi)+\frac{1}{2}\right)^2-X^2(\phi)-\left(\frac{1}{2}\right)^2+\left(\frac{A}{2K_\phi}\right)^2+\frac{\left(\frac{1}{2}\right)^2}{\left(\frac{A}{2K_\phi}\right)^2}X^2(\phi)}\\
&= \sqrt{\left(\frac{K_\phi}{A}\right)^2X^2(\phi)+X(\phi)+\left(\frac{A}{2K_\phi}\right)^2}\\
&= \sqrt{\left(\frac{K_\phi}{A}X(\phi)+\frac{A}{2K_\phi}\right)^2}=\frac{K_\phi}{A}X(\phi)+\frac{A}{2K_\phi}\,.
\end{aligned}
$$

A.4. Applying the substitution $t=\tan\frac{\phi}{2}$. Applying (A.6) and $t=\tan\frac{\phi}{2}$ we have

$$
K_\phi=\sqrt{1+\sin\phi}=\sqrt{\frac{(1+t)^2}{1+t^2}}=:\overline{K}(t)\,. \tag{A.7}
$$

A straightforward application of (A.7) and $t = \tan\frac{\phi}{2}$ to (A.2) and (A.3) leads to

$$X(\phi) = \frac{A}{2t\overline{K}^2(t)}\sqrt{(1+t)^2 - A^2} = \frac{A(1+t^2)\sqrt{(1+t)^2-A^2}}{2t(1+t)^2} =: \overline{X}(t)\ ,$$
$$Y(\phi) = \left(\frac{A^2}{\overline{K}^2(t)} - 1\right)\frac{1}{2t} \qquad = \quad \frac{A^2(1+t^2) - (1+t)^2}{2t(1+t)^2} \quad =: \overline{Y}(t)\ .$$

Using the representations of $\overline{X}(t)$ and $\overline{K}(t)$ we conclude that

$$K_\phi l_\phi = \frac{K_\phi}{A}X(\phi) + \frac{A}{2K_\phi} = \frac{\overline{K}^2(t)}{A}\overline{X}(t) + \frac{A}{2} = \frac{\sqrt{(1+t)^2-A^2}}{2t} + \frac{A}{2} =: \overline{Kl}(t)$$

holds.

A.5. Computing the derivatives in t. We apply simple derivation rules:

$$\begin{aligned}
-\overline{Kl}'(t) &= -\left(\frac{(1+t)}{2t\sqrt{(1+t)^2-A^2}} - \frac{\sqrt{(1+t)^2-A^2}}{2t^2}\right)\\
&= -\left(\frac{t(1+t) - (1+t)^2 + A^2}{2t^2\sqrt{(1+t)^2-A^2}}\right)\\
&= \frac{(1+t) - A^2}{2t^2\sqrt{(1+t)^2-A^2}},\\
\overline{Y}'(t) &= \left(\frac{A^2(1+t^2)}{2t(1+t)^2} - \frac{1}{2t}\right)'\\
&= \frac{2tA^2}{2t(1+t)^2} + A^2(1+t^2)\left(-\frac{(1+t)^2 + 2(1+t)t}{2(1+t)^4t^2}\right) + \frac{1}{2t^2}\\
&= \frac{(1+t)^3 - A^2\left(-2t^2(1+t) + (1+t^2)(1+3t)\right)}{2(1+t)^3t^2}\\
&= \frac{(1+t)^3 - A^2\left((1+t)^3 - 4t^2\right)}{2(1+t)^3t^2},\\
\overline{X}'(t) &= \left(\frac{A(1+t^2)}{2t(1+t)^2}\sqrt{(1+t)^2-A^2}\right)'\\
&= \left(\frac{2tA}{2t(1+t)^2} + A(1+t^2)\left(-\frac{(1+t)^2+2(1+t)t}{2(1+t)^4t^2}\right)\right)\sqrt{(1+t)^2-A^2}\\
&\quad + \frac{1+t}{\sqrt{(1+t)^2-A^2}}\frac{A(1+t^2)}{2t(1+t)^2}\\
&= \frac{-A((1+t)^3-4t^2)}{2(1+t)^3t^2\sqrt{(1+t)^2-A^2}}((1+t)^2-A^2) + \frac{t(1+t)^2A(1+t^2)}{2(1+t)^3t^2\sqrt{(1+t)^2-A^2}}
\end{aligned}$$

$$= \frac{-A((1+t)^3-4t^2)((1+t)^2-A^2)+t(1+t)^2A(1+t^2)}{2(1+t)^3t^2\sqrt{(1+t)^2-A^2}}$$

$$= \frac{A(A^2\left((1+t)^3-4t^2\right))-A\left(((1+t)^3-4t^2)(1+t)^2-t(1+t)^2(1+t^2)\right)}{2(1+t)^3t^2\sqrt{(1+t)^2-A^2}}$$

$$= \frac{A(A^2\left((1+t)^3-4t^2\right))-A((1+t)^5-(1+t)^2(4t^2+t+t^3))}{2(1+t)^3t^2\sqrt{(1+t)^2-A^2}}$$

$$= \frac{A(A^2\left((1+t)^3-4t^2\right))-A((1+t)^5-(1+2t+t^2)(4t^2+t+t^3))}{2(1+t)^3t^2\sqrt{(1+t)^2-A^2}}$$

$$= \frac{A(A^2\left((1+t)^3-4t^2\right))-A((1+t)^5-t-6t^2-10t^3-6t^4-t^5)}{2(1+t)^3t^2\sqrt{(1+t)^2-A^2}}$$

$$= \frac{A\left(A^2\left((1+t)^3-4t^2\right)-1-4t-4t^2+t^4\right)}{2(1+t)^3t^2\sqrt{(1+t)^2-A^2}}.$$

A.6. How to get $F(t, A)$. We will make use of the following identities:

$$2(t^2-2t-1)-(4t^2-(1+t)^3)+2(1+t) = (1+t)(t^2+1), \tag{A.8}$$

$$(t^2-2t-1)(1+t)^2 = (t^4-1-4t-4t^2), \tag{A.9}$$

$$\begin{aligned}(t-1)(t+3)t^2 &= -3t^2+2t^3+t^4\\ &= -2(1+t)^3-(t^2-2t-1)^2\\ &\quad +(1+t)^2-8t^2(1+t)+2(1+t)^4,\end{aligned} \tag{A.10}$$

$$(1+t)^3+(4t^2-(1+t)^3)(t^2+1) = t^2(1-t)(t^2+3)\ . \tag{A.11}$$

$$\begin{aligned}F(t,A) &:= \overline{Kl}'(t)^2-\overline{X}'(t)^2-\overline{Y}'(t)^2\\ &= \left(\frac{(1+t)-A^2}{2t^2\sqrt{(1+t)^2-A^2}}\right)^2-\left(\frac{A\left(A^2\left((1+t)^3-4t^2\right)-1-4t-4t^2+t^4\right)}{2(1+t)^3t^2\sqrt{(1+t)^2-A^2}}\right)^2\\ &\quad -\left(\frac{(1+t)^3-A^2\left((1+t)^3-4t^2\right)}{2(1+t)^3t^2}\right)^2\\ &= \frac{\left(((1+t)-A^2)(1+t)^3\right)^2}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)}-\frac{\left(A\left(A^2\left((1+t)^3-4t^2\right)-1-4t-4t^2+t^4\right)\right)^2}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)}\\ &\quad -\frac{\left((1+t)^3-A^2\left((1+t)^3-4t^2\right)\right)^2\left((1+t)^2-A^2\right)}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)}\\ &= \frac{(1+t)^6A^4-2(1+t)^7A^2+(1+t)^8}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)}\end{aligned}$$

$$
\begin{aligned}
&- \frac{((1+t)^3-4t^2)^2A^6 + 2(t^4-1-4t-4t^2)((1+t)^3-4t^2)A^4}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)} \\
&\qquad - \frac{(t^4-1-4t-4t^2)^2A^2}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)} \\
&- \frac{-((1+t)^3-4t^2)^2A^6 + (-2(1+t)^3(4t^2-(1+t)^3) + (4t^2-(1+t)^3)^2(1+t)^2)A^4}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)} \\
&\qquad - \frac{(-(1+t)^6 + 2(1+t)^5(4t^2-(1+t)^3))A^2 + (1+t)^8}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)}
\end{aligned}
$$

$$
\begin{aligned}
\overset{(A.9)}{=}\ & A^4 \frac{(1+t)^6 + 2(t^2-2t-1)(1+t)^2(4t^2-(1+t)^3)}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)} \\
&+ A^4 \frac{-(-2(1+t)^3(4t^2-(1+t)^3) + (4t^2-(1+t)^3)^2(1+t)^2)}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)} \\
&+ A^2 \frac{-2(1+t)^7 - (t^2-2t-1)^2(1+t)^4 - (-(1+t)^6 + 2(1+t)^5(4t^2-(1+t)^3))}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)} \\
=\ & A^4 \frac{(1+t)^6 + (1+t)^2(4t^2-(1+t)^3)(2(t^2-2t-1) - (4t^2-(1+t)^3) + 2(1+t))}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)} \\
&+ A^2 \frac{-2(1+t)^7 - (1+t)^4(t^2-2t-1)^2 + (1+t)^6 - 2(1+t)^5(4t^2-(1+t)^3))}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)} \\
\overset{(A.8)}{=}\ & A^4 \frac{(1+t)^6 + (1+t)^2(4t^2-(1+t)^3)(1+t)(t^2+1)}{\left(2(1+t)^3t^2\right)^2\left((1+t)^2-A^2\right)} \\
&+ A^2 \frac{(1+t)\left(-2(1+t)^3 - (t^2-2t-1)^2 + (1+t)^2 - 8t^2(1+t) + 2(1+t)^4\right)}{(1+t)^3(2t^2)^2\left((1+t)^2-A^2\right)} \\
\overset{(A.10)}{=}\ & A^4 \frac{(1+t)^3 + (4t^2-(1+t)^3)(t^2+1)}{(1+t)^3(2t^2)^2\left((1+t)^2-A^2\right)} + A^2 \frac{(1+t)(t-1)(t+3)t^2}{(1+t)^3(2t^2)^2\left((1+t)^2-A^2\right)} \\
\overset{(A.11)}{=}\ & A^4 \frac{-t^2(t-1)(t^2+3)}{(1+t)^3(2t^2)^2\left((1+t)^2-A^2\right)} + A^2 \frac{(1+t)(t-1)(t+3)}{4t^2(1+t)^3\left((1+t)^2-A^2\right)} \\
=\ & \frac{-(t-1)A^2\left((A^2-1)(t^2+3) - 4t\right)}{4(1+t)^3t^2\left((1+t)^2-A^2\right)}.
\end{aligned}
$$

A.7. Transformation of the nominator of $F(t, A)$.

$$
\sin\phi\left(\tan^2\frac{\phi}{2}+3\right) - 4\tan\frac{\phi}{2} = \sin\phi\left(\frac{2\tan\frac{\phi}{2}}{\sin\phi}+2\right) - 4\tan\frac{\phi}{2}
$$

$$
\begin{aligned}
&= 2\sin\phi - 2\tan\frac{\phi}{2}\\
&= 2\sin\frac{\phi}{2}\left(2\cos\frac{\phi}{2} - \frac{1}{\cos\frac{\phi}{2}}\right)\\
&= 2\sin\frac{\phi}{2}\left(\frac{2\cos^2\frac{\phi}{2}-1}{\cos\frac{\phi}{2}}\right)\\
&= 2\sin\frac{\phi}{2}\left(\frac{\cos\phi}{\cos\frac{\phi}{2}}\right) = 2\cos\phi\tan\frac{\phi}{2}.
\end{aligned}
$$

A.8. The simple case $\phi < \frac{\pi}{2}$. In order to obtain

$$
\begin{aligned}
X(\phi) &= \frac{D}{2}\cot\frac{\phi}{2}\sqrt{\left(1+\tan^2\frac{\phi}{2}\right) - D^2},\\
Y(\phi) &= \frac{1}{2}\cot\frac{\phi}{2}(D^2-1),
\end{aligned}
$$

and

$$
K_\phi l_\phi := \sqrt{2}\, l_\phi = \frac{\sqrt{2}}{D}X(\phi) + \frac{D}{\sqrt{2}},
$$

we simply replace $\frac{A}{K_\phi}$ by D in (3.8), (3.9), and (3.11). For (3.8), which corresponds to $X(\phi)$, we have to make use of identity (A.6).

Since we did not make use of a substitution here, the derivatives in ϕ are given as follows:

$$
\begin{aligned}
-(K_\phi l_\phi)' &= -\frac{\sqrt{2}}{D}X'(\phi),\\
Y'(\phi) &= -\frac{1}{4\sin^2\frac{\phi}{2}}(D^2-1)\\
&= \frac{(D^2-1)}{2(\cos\phi-1)},\\
X'(\phi) &= \left(\frac{D}{2}\cot\frac{\phi}{2}\sqrt{\left(1+\tan^2\frac{\phi}{2}\right)-D^2}\right)'\\
&= \frac{D}{2(\cos\phi-1)}\sqrt{\left(1+\tan^2\frac{\phi}{2}\right)-D^2} + \frac{D}{2}\cot\frac{\phi}{2}\left(\frac{-\tan\frac{\phi}{2}\frac{1}{\cos^2\frac{\phi}{2}}}{2\sqrt{\left(1+\tan^2\frac{\phi}{2}\right)-D^2}}\right)\\
&= \frac{\frac{D}{(\cos\phi-1)}\left(\left(1+\tan^2\frac{\phi}{2}\right)-D^2\right) - \frac{D}{2}\frac{1}{\cos^2\frac{\phi}{2}}}{2\sqrt{\left(1+\tan^2\frac{\phi}{2}\right)-D^2}}\\
&= \frac{\frac{D(1-D^2)}{(\cos\phi-1)} + \frac{D\tan^2\frac{\phi}{2}}{(\cos\phi-1)} - \frac{D}{2}\frac{1}{\cos^2\frac{\phi}{2}}}{2\sqrt{\left(1+\tan^2\frac{\phi}{2}\right)-D^2}}
\end{aligned}
$$

$$= \frac{D(1-D^2)}{2(\cos\phi - 1)\sqrt{\left(1+\tan^2\frac{\phi}{2}\right) - D^2}}.$$

It remains to compute $F(\phi, D)$.

$$\begin{aligned}
F(\phi, D) &:= (K_\phi l_\phi)^2 - (X'(\phi))^2 - (Y'(\phi))^2 \\
&= X'(\phi)^2 \left(\frac{2}{D^2} - 1\right) - Y'(\phi)^2 \\
&= \frac{D^2(1-D^2)^2\left(\frac{2}{D^2}-1\right)}{4(\cos\phi-1)^2\left(\left(1+\tan^2\frac{\phi}{2}\right)-D^2\right)} - \frac{(D^2-1)^2}{4(\cos\phi-1)^2} \\
&= \frac{(D^2-1)^2\left((2-D^2) - \left(\left(1+\tan^2\frac{\phi}{2}\right)-D^2\right)\right)}{4(\cos\phi-1)^2\left(\left(1+\tan^2\frac{\phi}{2}\right)-D^2\right)} \\
&= \frac{(D^2-1)^2\left(1-\tan^2\frac{\phi}{2}\right)}{4(\cos\phi-1)^2\left(\left(1+\tan^2\frac{\phi}{2}\right)-D^2\right)}.
\end{aligned}$$

LEARNING A HIDDEN MATCHING*

NOGA ALON†, RICHARD BEIGEL‡, SIMON KASIF§,
STEVEN RUDICH¶, AND BENNY SUDAKOV‖

Abstract. We consider the problem of learning a matching (i.e., a graph in which all vertices have degree 0 or 1) in a model where the only allowed operation is to query whether a set of vertices induces an edge. This is motivated by a problem that arises in molecular biology. In the deterministic nonadaptive setting, we prove a $(\frac{1}{2}+o(1))\binom{n}{2}$ upper bound and a nearly matching $0.32\binom{n}{2}$ lower bound for the minimum possible number of queries. In contrast, if we allow randomness, then we obtain (by a randomized, nonadaptive algorithm) a much lower $O(n \log n)$ upper bound, which is best possible (even for randomized fully adaptive algorithms).

Key words. matchings in graphs, combinatorial search problems, genome sequencing, finite projective planes

1. Introduction.

This paper is motivated by an important and timely problem in computational biology that arises in whole-genome shotgun sequencing. Shotgun sequencing is a high throughput technique that has resulted in the sequencing of a large number of bacterial genomes (over 70 at the time of this writing), as well as *Drosophila* (fruit fly) and mouse genomes and the celebrated human genome (at Celera). In all such projects, we are left with a collection of contigs (long DNA sequences) that for various biological or computational reasons cannot be assembled with even the best sequence assembly algorithms. The contigs must be ordered and oriented and the *gaps* between them must be sequenced using slower, more tedious methods. When the number of gaps is small (e.g., less than ten) biologists often use polymerase chain reaction (PCR). This technique initiates a set of "bidirectional molecular walks" along the gaps in the sequence; these walks are facilitated by PCR.

In order to initiate the molecular walks biologists use primers.[1] Primers are

[1]Primers are short preconstructed single-stranded polynucleotide chains to which new deoxyribonucleotides can be "appended" by DNA polymerase.

designed so that they bind to unique (with respect to the entire DNA sequence) templates occurring at the end of each contig. A primer (at the right temperature and concentration) anneals to the designated unique DNA substring and promotes copying of the template starting from the primer binding site, initiating a one-directional walk along the gap in the DNA sequence. A PCR reaction occurs, and can be observed as a DNA ladder, when two primers that bind to positions on two ends of the same gap are placed in the same test tube.

If we are left with N contigs, the combinatorial (exhaustive) PCR technique tests all possible pairs (quadratically many) of $2N$ primers by placing two primers per tube with the original uncut DNA strand. PCR products can be detected using gels, or they can be read using sequencing technology or DNA mass-spectometry. When the number of gaps is large, the quadratic number of PCR experiments is prohibitive, so primers are pooled using $K > 2$ primers per tube; this technique is called multiplex PCR.[2] Our paper provides optimal strategies for pooling the primers to minimize the number of biological experiments needed in the gap-closing process.

Our gap-closing problem can be stated more generally as follows. We are given a set of chemicals, a guarantee that each chemical reacts with at most one of the others (because only primers on opposite sides of the same gap create a reaction), and an experimental mechanism to determine whether a reaction occurs when several chemicals are combined in a test tube. We wish to determine which pairs of chemicals react with each other with a minimum number of experiments.

Our problem can be modeled as the problem of identifying or learning a hidden matching given a vertex set and an allowed query operation ([9, 2]; see [5, 6] for an alternative formulation). A vertex will represent a chemical, an edge of the matching will represent a reaction, and a query will represent checking for a reaction when a set of chemicals are combined in a test tube. Let $V = \{1, 2, \ldots, n\}$. We wish to identify an unknown (not necessarily perfect) matching M on V by asking a small number of queries of the form

$$Q_F: \quad \text{does } F \text{ contain at least one edge of } M? \tag{1.1}$$

where F is a subset of V. This problem is of interest even in the deterministic, fully nonadaptive case. We say that a family $\mathcal{F}$ of subsets of V *solves the matching problem* on V if for any two distinct matchings M_1 and M_2 on V there is at least one $F \in \mathcal{F}$ that contains an edge of one of the matchings and does not contain any edge of the other. Obviously, any such family enables us to learn an unknown matching deterministically and nonadaptively by asking the questions Q_F defined in (1.1) for each $F \in \mathcal{F}$.

Our objective is to estimate the minimum possible cardinality of a family that solves the matching problem on a set of n vertices. Toward this end, we will generalize the matching problem to finding matchings contained in a graph H (not necessarily complete) and produce an H for which we can solve the matching problem with a family of size roughly half the number of edges of H. By applying a partitioning theorem of Wilson, we can then solve the matching problem on n vertices with a family of size $(\frac{1}{2} + o(1))\binom{n}{2}$.

[2]The earliest reference to multiplex PCR is [3]. Since then hundreds of papers report using the multiplex PCR technique to answer a diverse set of questions in molecular biology. Multiplex PCR using a simple, nonoptimal pooling strategy has recently been applied successfully at The Institute for Genomic Research (TIGR) to close gaps in a number of genomes, including *Streptococcus* [9].

We show that our construction is tight up to a constant factor, as stated in the following theorem.

THEOREM 1.1. *For every $n > 2$, every family $\mathcal{F}$ that solves the matching problem on n vertices satisfies*

$$|\mathcal{F}| \geq \frac{49}{153}\binom{n}{2}.$$

The proof of the lower bound is presented in sections 3 and 4.

Next we consider randomized nonadaptive algorithms. In contrast to the 1-round deterministic case we produce, somewhat surprisingly, an $O(n \log n)$ solution in this model. This solution is asymptotically optimal up to a constant factor, because of the information-theoretic $\Omega(n \log n)$ lower bound, even if we do not restrict the number of rounds. We believe that the sharp difference between deterministic and randomized nonadaptive algorithms here is remarkable; while one can hardly beat the trivial $\binom{n}{2}$ bound in the deterministic case, the randomized fully nonadaptive algorithm is already as efficient (up to a constant factor) as the best possible fully adaptive algorithm for the problem. Moreover, the same technique shows that a hidden copy of any sparse graph, that is, a graph with a linear number of edges in which all degrees are $O(\sqrt{n})$, can be found, with high probability, in a 1-round randomized algorithm making only $O(n \log n)$ queries.

Finally we present a deterministic k-round algorithm for learning a hidden matching which makes $O(kn^{1+1/(2(k-1))}\text{polylog}n)$ queries. Our deterministic 2-round algorithm asks $\frac{5}{4}n^{3/2}(1 + o(1))$ queries of size at most $n^{1/4}$ each. This is optimal up to a factor of $5/4$ among *all* algorithms that make queries of size at most $n^{1/4}$, which may be useful in view of practical limitations on multiplexing. For $k \geq 3$ our algorithms are based on a coloring lemma for projective planes that may be interesting in its own right.

Our techniques combine combinatorial and probabilistic tools with results about graph decomposition and about the existence of certain designs. Throughout the paper, we omit all floor and ceiling signs, whenever these are not crucial. All logarithms are in base 2, unless otherwise specified.

2. Related work. In an earlier paper with Fortnow and Apaydin [2] we obtained a randomized, adaptive algorithm that solves the matching problem in 8 rounds with an expected number of approximately $0.72n \log_2 n$ queries. Our results here improve the number of rounds to 1 in the randomized case. (This comes at the cost of doubling the number of queries. If we allow 2 rounds, we can, in fact, keep the total number of queries to be roughly $0.72n \log_2 n$.) We further show here that in the 1-round, deterministic case, far more queries are needed, though some saving over the trivial algorithm is possible.

Grebinski and Kucherov [5, 6] consider the problem of finding a Hamilton cycle. They obtain an $O(n \log n)$ *adaptive* algorithm. (They also have an $O(n)$ purely nonadaptive solution using more powerful queries, i.e., queries that report the *number* of edges induced by a set of vertices. See [4, 7] as well.) Using our methods here we can show that $\Omega(n^2)$ queries are needed for finding a Hamilton cycle in the deterministic nonadaptive case in our model. A similar $\Omega(n^2)$ lower bound can be proved for the problem of determining the *number* of edges of a hidden matching, as well as for the problem of finding a hidden copy of any given bounded degree graph with $\Omega(n)$ edges.

3. Sparse families. A family of sets $\mathcal{A} = \{A_1, \ldots, A_k\}$ is *sparse* if there is a collection of pairwise disjoint pairs of members of $V = \bigcup_{i=1}^{k} A_i$ such that each A_i

contains at least one of the pairs. Therefore, $\mathcal{A}$ is sparse iff there is a matching on V such that the answer to each question Q_A for $A \in \mathcal{A}$ is "yes." It is easy to see that any set of more than $(p^2+p+1)/2$ lines in a projective plane of order p (in which each line is of size $p+1$) is not sparse, and our results here will imply that every family consisting of at most $0.32\binom{m+2}{2}$ sets, each of size at least m, is sparse.

For a family $\mathcal{F}$ of subsets define the *t-weight* of the family, denoted $w_t(\mathcal{F})$, as follows:

$$w_t(\mathcal{F}) = \sum_{F \in \mathcal{F}} \frac{1}{\binom{|F|+t}{2}}.$$

The 2-weight is simply called the *weight* and is denoted, for short, by $w(\mathcal{F})$. The main lemma of this section is the following.

LEMMA 3.1. *Every family $\mathcal{F}$ of sets whose weight is at most 49/153 is sparse.*

Proof. If $\mathcal{F}$ contains a set of size 1, then $w(\mathcal{F}) \geq 1/3 > 49/153$. Thus we may and will assume that all sets in $\mathcal{F}$ are of size at least 2. Let $M \in \mathcal{F}$ be a set of minimum cardinality, $|M| = m$.

For a pair of distinct elements p, q, define

$$\mathcal{F}(p,q) = \{F - \{p,q\} : F \in \mathcal{F}, \{p,q\} \not\subseteq F\}.$$

Note that if we pick the pair $\{p,q\}$ as a member of the matching we are trying to construct to show that $\mathcal{F}$ is sparse, then the members of $\mathcal{F}(p,q)$ are precisely those that will have to be handled by the rest of the matching. This suggests proving the following claim.

Claim. There exists a pair of distinct elements p, q of M such that $w(\mathcal{F}(p,q)) \leq w(\mathcal{F})$.

To prove the claim we choose p, q randomly and uniformly among all pairs of distinct members of M and show that the expected value $\mathbb{E}(w(\mathcal{F}(p,q)))$ is at most $w(\mathcal{F})$.

Henceforth F will denote an element of $\mathcal{F} - \{M\}$. Let $\kappa(F)$ denote $|F \cap M|$. We have that $\mathbb{E}(w(\mathcal{F}(p,q)))$ equals

$$= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \sum_{F \neq M} \left(\frac{\kappa(F)(m-\kappa(F))}{\binom{m}{2}} \left(\frac{1}{\binom{|F|+1}{2}} - \frac{1}{\binom{|F|+2}{2}} \right) - \frac{\binom{\kappa(F)}{2}}{\binom{m}{2}} \frac{1}{\binom{|F|+2}{2}} \right)$$

$$= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \sum_{k<m} \sum_{\kappa(F)=k} \left(\frac{k(m-k)}{\binom{m}{2}} \left(\frac{1}{\binom{|F|+1}{2}} - \frac{1}{\binom{|F|+2}{2}} \right) - \frac{\binom{k}{2}}{\binom{m}{2}} \frac{1}{\binom{|F|+2}{2}} \right)$$

$$= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \sum_{k<m} \sum_{\kappa(F)=k} \left(k(m-k) \left(\frac{\binom{|F|+2}{2}}{\binom{|F|+1}{2}} - 1 \right) - \binom{k}{2} \right) \frac{1}{\binom{|F|+2}{2}}$$

$$= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \sum_{k<m} \sum_{\kappa(F)=k} \left(\frac{2k(m-k)}{|F|} - \binom{k}{2} \right) \frac{1}{\binom{|F|+2}{2}}$$

$$\leq w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \sum_{k<m} \sum_{\kappa(F)=k} \left(\frac{2k(m-k)}{m} - \binom{k}{2} \right) \frac{1}{\binom{|F|+2}{2}}$$

$$= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \sum_{k<m} \left(\frac{2k(m-k)}{m} - \binom{k}{2} \right) \sum_{\kappa(F)=k} \frac{1}{\binom{|F|+2}{2}}$$

$$= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \sum_{k<m} \mu(m,k) \sum_{\kappa(F)=k} \frac{1}{\binom{|F|+2}{2}},$$

where we define $\mu(m,k) = \frac{2k(m-k)}{m} - \binom{k}{2}$. For all m, we have $\mu(m,0) = 0$, $\mu(m,1) = 2 - 2/m$, $\mu(m,2) = 3 - 8/m$, and $k \geq 2 \Rightarrow \mu(m,k) \leq \mu(m,2)$. Thus $\mu(m,k)$ is maximized at $k = 1$ or $k = 2$. Define $\mu(m) = \max_{k<m} \mu(m,k)$. Now we have

$$\begin{aligned}
\mathbb{E}(w(\mathcal{F}(p,q))) &\leq w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \sum_{k<m} \mu(m,k) \sum_{\kappa(F)=k} \frac{1}{\binom{|F|+2}{2}} \\
&\leq w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \sum_{k<m} \mu(m) \sum_{\kappa(F)=k} \frac{1}{\binom{|F|+2}{2}} \\
&= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \mu(m) \sum_{k<m} \sum_{\kappa(F)=k} \frac{1}{\binom{|F|+2}{2}} \\
&= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \mu(m) \sum_{F \neq M} \frac{1}{\binom{|F|+2}{2}} \\
&= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m}{2}} \mu(m) \left(w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} \right) \\
&= w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} + \frac{1}{\binom{m+2}{2}} \frac{(m+2)(m+1)}{m(m-1)} \mu(m) \left(w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} \right).
\end{aligned}$$

Thus it suffices to prove that

$$\frac{(m+2)(m+1)}{m(m-1)} \mu(m) \left(w(\mathcal{F}) - \frac{1}{\binom{m+2}{2}} \right) \leq 1$$

or, equivalently, that

$$w(\mathcal{F}) \leq \frac{m(m-1)}{(m+2)(m+1)\mu(m)} + \frac{1}{\binom{m+2}{2}}.$$

As noted above, $\mu(m)$ is either $\mu(m,1)$ or $\mu(m,2)$. In the first case, we have

$$\frac{m(m-1)}{(m+2)(m+1)\mu(m)} + \frac{1}{\binom{m+2}{2}} = \frac{m^2+4}{2(m+2)(m+1)} \geq \frac{13}{40}$$

for $m > 1$ (with equality at $m = 3$). In the second case, we have

$$\frac{m(m-1)}{(m+2)(m+1)\mu(m)} + \frac{1}{\binom{m+2}{2}} = \frac{1}{3} \frac{m^2(m-1) + 6m - 16}{(m+2)(m+1)(m-8/3)} \geq \frac{49}{153}$$

for $m > 2$ (with equality at $m = 16$). By assumption, $w(\mathcal{F}) \leq 49/153 < 13/40$, completing the proof of the claim.

By repeatedly applying the claim we get smaller and smaller families of sets whose weights remain bounded by 49/153. This process must terminate with a matching that captures all members of $\mathcal{F}$, showing that $\mathcal{F}$ is sparse and completing the proof of the lemma. □

4. The proof of the main result for the fully nonadaptive case. In this short section we present the proof of Theorem 1.1. We need the following simple fact.

LEMMA 4.1. *Let $\mathcal{F}$ be a family of subsets of $V = \{1, 2, \ldots, n\}$ that solves the matching problem on V. Then, for every two distinct $a, b \in V$, the family $\mathcal{F}_{a,b} = \{F - \{a,b\} : F \in \mathcal{F} \text{ and } \{a,b\} \subseteq F\}$ is not sparse.*

Proof. Assume that this is false, and that $\mathcal{F}_{a,b}$ is sparse for some $a, b \in V$. Then there is a matching M in $V - \{a, b\}$ so that each member of $\mathcal{F}_{a,b}$ contains an edge of M. But then the answers to each question Q_F with $F \in \mathcal{F}$ for the two matchings M and $M \cup \{a, b\}$ are identical, contradicting the fact that $\mathcal{F}$ solves the matching problem. □

Proof of Theorem 1.1. Let $\mathcal{F}$ be a family of subsets of $V = \{1, 2, \ldots, n\}$ that solves the matching problem on V. Let a, b be any pair of distinct vertices in V. We know by Lemma 4.1 that the family $\mathcal{F}_{a,b} = \{F - \{a, b\} : F \in \mathcal{F} \text{ and } \{a, b\} \subseteq F\}$ is not sparse. Therefore, by Lemma 3.1,

$$\sum_{F \in \mathcal{F}, \{a,b\} \subseteq F} \frac{1}{\binom{|F|}{2}} = \sum_{F' \in \mathcal{F}_{a,b}} \frac{1}{\binom{|F'|+2}{2}} > \frac{49}{153}.$$

We can now assign, for each $F \in \mathcal{F}$ a weight of $1/\binom{|F|}{2}$ to each pair of distinct elements $a, b \in F$. The total weight distributed in this way is precisely $|\mathcal{F}|$, as the total contribution of each $F \in \mathcal{F}$ is 1. On the other hand, the total weight assigned to each pair $a, b \in V$ is at least $\frac{49}{153}$, implying that $|\mathcal{F}| \geq \frac{49}{153}\binom{n}{2}$, as needed. □

Note that the same proof supplies a $\frac{49}{153}\binom{n}{2}$ lower bound for the number of queries in any 1 round deterministic algorithm that determines the *number* of edges of a hidden matching on n vertices.

5. Other hidden graphs. In this section we show how to extend the methods described in the previous two sections and obtain a lower bound for the number of queries needed to find a hidden copy of a member of a given family of graphs with certain properties. Throughout the section, we make no attempt to optimize the absolute constants in our various estimates.

Let $\mathcal{H}$ be a family of labeled graphs on the set $V = \{1, 2, \ldots, n\}$, and suppose $\mathcal{H}$ is closed under isomorphism. Thus, for example, $\mathcal{H}$ may be the set of all Hamilton cycles on V, or all matchings on V, or all perfect matchings on V. Our objective is to learn a hidden copy of some member of $\mathcal{H}$ by asking a small number of queries Q_F as given in (1.1). We say that a family $\mathcal{F}$ solves the $\mathcal{H}$-problem if for any two distinct members H_1 and H_2 in $\mathcal{H}$ there is at least one $F \in \mathcal{F}$ that contains an edge of one of the graphs H_i and does not contain any edge of the other. Obviously, any such family enables us to learn an unknown member of $\mathcal{H}$ deterministically and nonadaptively by asking the questions Q_F defined in (1.1) for each $F \in \mathcal{F}$.

THEOREM 5.1. *There exists an absolute constant $c > 0$ such that the following holds. Let $\mathcal{H}$ be a family of graphs on V, closed under isomorphism, and suppose that there are two distinct graphs $H_1, H_2 \in \mathcal{H}$ and a set of vertices $D \subset V$, $|D| = d$ satisfying the following:*

(i) *The graphs obtained from H_1 and from H_2 by omitting all edges connecting two vertices of D are identical; and*

(ii) *there is a matching of at least pn edges in H_1 which contains no vertices of D (clearly this matching is also a matching in H_2).*

Then, if $1/p > d$, every family $\mathcal{F}$ that solves the $\mathcal{H}$-problem satisfies $|\mathcal{F}| \geq c\frac{p^2}{d^2}\binom{n}{2}$.

Note that this result provides an $\Omega(n^2)$ lower bound for the problem of learning a *perfect* matching or a Hamilton cycle, and, more generally, the problem of learning a hidden copy of any fixed, bounded-degree graph with $\Omega(n)$ edges. It also provides an $\Omega(n^2)$ lower bound for the problem of finding a hidden copy of a vertex disjoint union of a clique of size $n - 3$ and a single edge, but *not* for the problem of finding a hidden copy of a vertex disjoint union of a clique of size $n - 2$ and a single edge (and

indeed it is easy to see that $O(n)$ queries suffice for the latter problem).

A family $\mathcal{F}$ of subsets of V is *p-sparse* if there is a collection of at most pn pairwise disjoint pairs of members of V such that each $F \in \mathcal{F}$ contains at least one of the pairs. Therefore, $\mathcal{F}$ is p-sparse iff there is a matching on V consisting of at most pn edges such that the answer to each query Q_F for $F \in \mathcal{F}$ is "yes."

LEMMA 5.2. *There is an absolute constant $c_1 > 0$ such that every family $\mathcal{F}$ of subsets of V of weight at most $c_1 p^2$ is p-sparse.*

Proof. Let V_1 be a random subset of V obtained by picking each $v \in V$, randomly and independently, to lie in V_1 with probability p. As the expected size of V_1 is pn, it follows that with probability at least one-half, its size is at most $2pn$. For each set $F \in \mathcal{F}$, the expected size of $F \cap V_1$ is clearly $p|F|$, and as this size is a binomial random variable, it follows, by the standard estimates for binomial distributions (see, e.g., [1, Appendix A, Theorem A.1.13], that the probability that it is less than $p|F|/2$ does not exceed $e^{-p|F|/8}$. Since the weight of $\mathcal{F}$ is at most $c_1 p^2$ for some (small) c_1, we conclude that each set in $\mathcal{F}$ is of size at least, say, $100/p$. As $e^{-px/8} < 1/p^2 \binom{x+2}{2}$ for all $x > 100/p$, it follows that the probability that there is some set $F \in \mathcal{F}$ such that $|F \cap V_1| < p|F|/2$ is smaller than $\frac{w(\mathcal{F})}{p^2} \leq c_1 < 1/2$. Therefore, there exists a set $V_1 \subset V$ of cardinality at most $2pn$ so that $|F \cap V_1| \geq p|F|/2$ for all $F \in \mathcal{F}$. As $|F| > 100/p$ for each $F \in \mathcal{F}$, this implies that the weight of the family $\mathcal{F}_1 = \{F \cap V_1 : F \in \mathcal{F}\}$ is at most, say, $\frac{8}{p^2} w(\mathcal{F}) \leq 8c_1 < 49/153$ (assuming c_1 is sufficiently small). By Lemma 3.1, $\mathcal{F}_1$ is sparse, and as $|V_1| \leq 2pn$, it follows that $\mathcal{F}$ is p-sparse. □

LEMMA 5.3. *Let $\mathcal{H}$, V, n, d, and p be as in Theorem 5.1. Let $\mathcal{F}$ be a family of subsets of $V = \{1, 2, \ldots, n\}$ that solves the $\mathcal{H}$-problem. Then, for every subset $D \subset V$, $|D| = d$, the family $\mathcal{F}_D = \{F - D : F \in \mathcal{F},\ |F \cap D| \geq 2\}$ is not p-sparse.*

Proof. Assume this is false, and suppose $\mathcal{F}_D$ is p-sparse for some $D' \subset V$, $|D'| = d$. Then there is a matching M of size at most pn in $V - D'$ so that each member of $\mathcal{F}_{D'}$ contains an edge of M. The matching M can be completed to a graph with no edges in D' which is isomorphic to the graph obtained from H_1 (or H_2) by omitting the edges inside D, where the isomorphism maps D onto D'. It is now possible to extend this graph to a copy of H_1, or to a copy of H_2, only by adding edges inside D'. But then the answers to each question Q_F with $F \in \mathcal{F}$ for these two distinct members of $\mathcal{H}$ are identical, contradicting the fact that $\mathcal{F}$ solves the $\mathcal{H}$-problem. □

Proof of Theorem 5.1. Let $\mathcal{F}$ be a family of subsets of $V = \{1, 2, \ldots, n\}$ that solves the $\mathcal{H}$-problem. By Lemmas 5.2 and 5.3, for every set D consisting of d vertices of V, the weight of the family $\mathcal{F}_D = \{F - D : F \in \mathcal{F}, |F \cap D| \geq 2\}$ is at least $c_1 p^2$. We claim that

$$\sum_{F \in \mathcal{F}, |F \cap D| \geq 2} \frac{1}{\binom{|F|}{2}} \geq c_2 p^2$$

for every D as above (and for an appropriately chosen $c_2 > 0$). Indeed, if there is a set $F \in \mathcal{F}$ of size at most, say, $10/p$, that intersects D in at least 2 elements, this follows immediately. Otherwise, by the assumption that $1/p > d$,

$$\frac{1}{\binom{|F|-d+2}{2}} \leq 2 \frac{1}{\binom{|F|}{2}},$$

and the claim follows from the fact that the weight of $\mathcal{F}_D$ is at least $c_1 p^2$.

If D is a random subset of d vertices of V, then for every $F \in \mathcal{F}$, the probability that $|D \cap F| \geq 2$ is at most $\binom{d}{2}\binom{|F|}{2}/\binom{n}{2}$. It follows that the expected value of the

random variable

$$\sum_{F\in\mathcal{F},|F\cap D|\geq 2}\frac{1}{\binom{|F|}{2}}$$

is at most $\binom{d}{2}|\mathcal{F}|/\binom{n}{2}$, and as this random variable is always at least c_2p^2, the desired result follows. □

6. An upper bound for the fully nonadaptive case. In this section we show how to design families of size $(\frac{1}{2}+o(1))\binom{n}{2}$ to solve the matching problem on n vertices. It will be helpful if we first generalize the matching problem. We say that a family $\mathcal{F}$ of cliques contained in G *solves the matching problem* on G if for any two distinct matchings contained in G there is at least one clique in $\mathcal{F}$ that contains an edge of one of the matchings and does not contain any edge of the other. (Note, for example, that if G is triangle free, then $\mathcal{F}$ must be a set of edges.) The matching problem on n vertices is thus the same as the matching problem on K_n. Let $f(G)$ denote the size of the smallest family that solves the matching problem on G.

Throughout this section, let $E(H)$ denote the edge set of a graph H, and let $\gcd(H)$ denote the greatest common divisor of the degrees of all vertices in H.

THEOREM 6.1 (Wilson [10]). *For every graph H there exists a constant N such that for all $n\geq N$, K_n is the union of $\binom{n}{2}/|E(H)|$ pairwise edge-disjoint graphs isomorphic to H iff $\binom{n}{2}$ is divisible by $|E(H)|$ and $n-1$ is divisible by $\gcd(H)$.*

COROLLARY 6.2. *For every fixed graph H,*

$$f(K_n)\leq\frac{f(H)}{|E(H)|}\binom{n}{2}+O(n).$$

Furthermore, for fixed H, the solution to the matching problem for K_n is constructive.

Proof. By Wilson's theorem, K_n is the union of $\binom{n}{2}/|E(H)|$ graphs isomorphic to H. Solve the matching problem in each of those graphs with a family of size $f(H)$. □

We say that a family $\mathcal{F}$ determines the status of an edge e if for every pair of matchings M_1, M_2 such that $e\in M_1$ and $e\notin M_2$ there is at least one clique $\mathcal{F}$ that contains an edge of one of the matchings and does not contain any edge of the other.

The reader may easily verify the following lemma.

LEMMA 6.3 (two-thirds). *Let a,b,c,x be four distinct vertices. Assume that $\mathcal{F}$ determines the status of $\{a,b\}$ and $\{b,c\}$. If $\mathcal{F}$ contains the two triangles $\{a,b,x\}$ and $\{b,c,x\}$, then $\mathcal{F}$ also determines the status of $\{a,x\}$, $\{b,x\}$, and $\{c,x\}$.*

We note in passing that one may easily apply the two-thirds lemma to obtain a solution of size $\frac{2}{3}\binom{n}{2}+O(n)$.

DEFINITION 6.4 (HEX_s^+). *Let $s\geq 1$. Tile a hexagon having side length s with unit equilateral triangles. Add one more vertex Z and edges from Z to every vertex in the tiling. Call the resulting graph HEX_s^+.*

The tiling above, depicted in Figure 6.1, contains $v=3s^2+3s+1$ vertices, $e=9s^2+3s$ edges, and $f=6s^2$ triangles. Therefore the graph HEX_s^+ contains $v+e=12s^2+6s+1$ edges. We solve the matching problem on HEX_s^+ with the following tests:

Tetrahedra $T\cup\{Z\}$ for every triangle T in the tiling.

Boundary every boundary edge of the tiling, and every edge from Z to a point on the boundary.

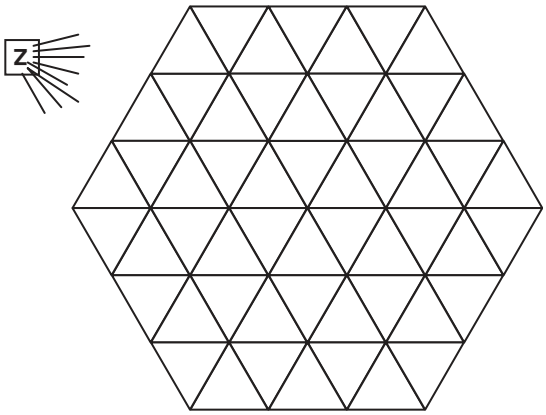

FIG. 6.1. *The graph* HEX_s^+.

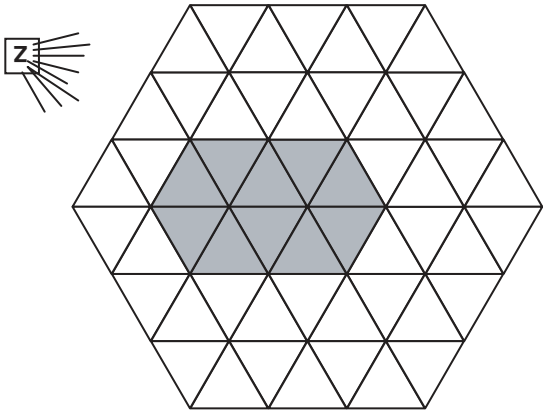

FIG. 6.2. *Locate* Z*'s mate (if it exists).*

As a warm-up, let us see why these tests suffice, assuming that Z is unmatched. In this case, the tetrahedra queries are equivalent to triangles, and we just apply the two-thirds lemma repeatedly, starting at the boundary of the tiling.

Now let us see why these tests suffice in general. Try the following cases in order.

Case 1. For some Y on the boundary of the tiling, $ZY \in M$. This edge is tested, so we know $ZY \in M$. Finish as in the warm-up.

Case 2. For some Y in the interior of the tiling, $ZY \in M$. In this case all six tests containing Y say yes (see Figure 6.2). Call that the 6-triangle property for Y. If only one point has the 6-triangle property, then we know that that point is matched to Z. If three distinct points have the 6-triangle property, it is easy to check that they must be adjacent in a straight line, and the middle one must be matched to Z. Consequently, no more than three points can have the 6-triangle property. In either of those subcases we finish as in the warm-up (see Figures 6.3 and 6.4).

If exactly two points have the 6-triangle property, then they must be adjacent; we proceed as in the warm-up until we reach the 10 triangles containing those two points. With the aid of the tests already performed, a simple case analysis tells us

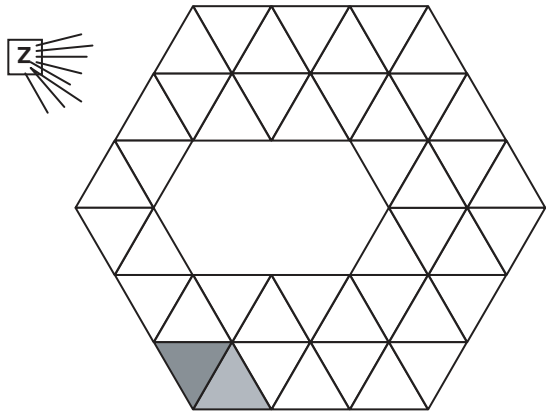

FIG. 6.3. *Test corners using Lemma* 6.3.

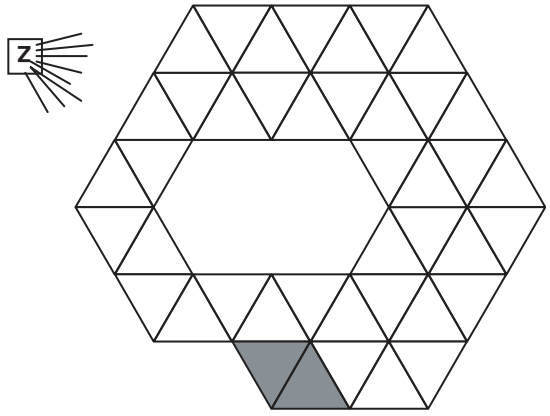

FIG. 6.4. *Continue, using Lemma* 6.3.

which point is matched to Z.

Case 3. For all Y in the tiling, $ZY \notin M$. Then no point has the 6-triangle property, so we know that Z is unmatched. Proceed as in the warm-up.

The total number of tests is $f + 12s = 6s^2 + 12s$. The ratio of tests to edges is

$$(6s^2 + 12s)/(12s^2 + 6s + 1) = \frac{1}{2} + \frac{18s - 1}{24s^2 + 12s + 2}.$$

Combining this with the corollary of Wilson's theorem, we see that $f(K_n) = (1/2 + O(1/s))\binom{n}{2}$. Letting s be a slowly growing function of n, we obtain the following.

COROLLARY 6.5.

$$f(K_n) \leq \left(\frac{1}{2} + o(1)\right)\binom{n}{2}.$$

7. Probabilistic nonadaptive algorithms. In this section we present a very efficient randomized algorithm for the matching problem. The simplest version of the

algorithm queries $bn \log n$ random subsets of size $c\sqrt{n}$ each. The analysis below shows that for an appropriate choice of b and c, the algorithm solves, with high probability, the matching problem in one round. Since we believe that this algorithm and some of its variants may be of practical interest, we do make here some efforts to optimize the absolute constant obtained in the estimate for the total number of queries. It turns out that in order to improve the constant, it is better to ask the queries according to randomly shifted (modified) projective planes. The details follow. For completeness, we include a brief description of the relevant properties of finite projective planes. A projective plane $PG(2,p)$ of order p consists of p^2+p+1 points and p^2+p+1 lines. Each line contains exactly $p+1$ points and each point lies in precisely $p+1$ lines. Every two distinct points are contained in a unique common line, and every two distinct lines intersect in a unique common point. Such a plane exists for every prime power p and can be constructed by the following simple algebraic description. Let B denote the set of all nonzero vectors $\bar{x} = (x_0, x_1, x_2)$ of length 3 over the finite field $GF(p)$, and define an equivalence relation on B by calling two vectors equivalent if one is a multiple of the other by an element of the field. The points of $PG(2,p)$ as well as the hyperplanes can be represented by the equivalence classes of B with respect to this relation, where a point $\bar{x} = (x_0, x_1, x_2)$ lies in the hyperplane $\bar{y} = (y_0, y_1, y_2)$ iff their inner product $\langle x, y\rangle = x_0y_0 + x_1y_1 + x_2y_2$ over $GF(p)$ is zero. More details about projective planes can be found, for example, in [8].

Procedure RPP: Testing according to a random projective plane. We assume now that $n = p^2+p+1$ for some prime p. Testing according to a random projective plane consists of the following: Randomly permute our n vertices and identify them with the points of the projective plane P of order p. Perform one test for each line.

Now consider a pair (x, y). Exactly one line in P contains x and y. The probability that that line contains no (other) edge of M is at least the value of this probability when the matching is perfect and xy is not a matching edge. It is not difficult to see that in this case, the probability is precisely

$$\frac{(n-4)(n-6)\dots(n-2p)}{(n-2)(n-3)\dots(n-p)}.$$

Indeed, the number is the number of ways to choose an ordered set of the other $p-1$ points of the line (besides x and y) without containing any matching edge, as after i points (including x and y) have already been chosen, there are $n-2i$ possibilities for choosing the next point, which has to be different from the chosen points and their mates. The denominator is the total number of possibilities for choosing an ordered set of $p-1$ points. The last expression is at least

$$e^{-(1-o(1))\frac{p^2}{2n}} = e^{-1/2}(1-o(1)).$$

Testing according to $d \log n$ random projective planes. Perform procedure RPP $d \log n$ times independently in parallel, for some real number d. The probability that every line containing x and y contains an edge of M (other than possibly (x, y)) is at most $\pi(d) = ((1-e^{-1/2})^d(1+o(1)))^{\log n}$. If we choose $d = (1+o(1)) \ln 2/\ln(1/(1-e^{-1/2})) \approx 0.74$, then $\pi(d) \le 1/n$.

Consequently, those tests suffice to identify all but $n/2$ nonmatching edges on average. Those remaining nonedges and all matching edges can be identified in a second round with only n tests. Thus we have a 2-round algorithm for the matching problem that makes an expected number of approximately $0.74n \log n$ tests and makes no errors.

If we choose d twice as large, i.e., $d = 2\ln 2/\ln(1/(1-e^{-1/2})) + \epsilon$ for some arbitrarily small ϵ (say $d \approx 1.49$), then $\pi(d) = o(1/n^2)$. Consequently, those tests suffice to identify all nonmatching edges with high probability. Once we have identified all nonedges, the same reasoning shows that all the matching edges are identified with high probability as well. Thus we have a 1-round algorithm for the matching problem that makes an expected number of approximately $1.49n\log n$ tests and makes no errors.

Point doubling. These constants can be improved. When every vertex is in the same number of tests, the ideal test size is approximately $\sqrt{(2\ln 2)n}$, but there are no designs like the projective plane with sets of size greater than $\sqrt{n}$. Fortunately, we do not need every pair of points to belong to exactly one set. It suffices to construct designs in which every pair of points belongs to at least one set, provided that we do not generate too many sets in the process. This can be accomplished rather easily by randomly "doubling" some of the points in the projective plane. We double a point x by adding a new point x' to each line that contains x.

To be precise, we assume now that $n = \lceil(2\ln 2)m\rceil$, where $m = p^2+p+1$ and p is prime. We start with the projective plane of order p and double $\lceil(2\ln 2 - 1)m\rceil$ randomly chosen points. This results in n points. We still have $m \approx n/(2\ln 2)$ lines. By standard estimates, with high probability each of those lines has approximately $2\ln 2\sqrt{m} \approx \sqrt{(2\ln 2)n}$ points.

Now, let us look at a single design and a single pair of points x, y. Consider a "line" containing x and y. (If x and y are not the duplicates of a single point, there is one such line; otherwise, there are $p+1$ such lines, and then it suffices to consider one of them.) Let $t \approx \sqrt{(2\ln 2)n}$ be the number of points on this line. The probability that it contains no (other) edge of M—besides, possibly, xy—is, by the same reasoning described above, at least

$$\frac{(n-4)(n-6)\dots(n-2t+2)}{(n-2)(n-3)\dots(n-t+1)} = e^{-(1+o(1))\frac{t^2}{2n}} = (1/2)(1+o(1)).$$

Now take $d\log n$ random projective planes with doubled points of the type above. The probability that every "line" containing x and y contains an edge of M (other than possibly (x,y)) is at most $\pi'(d) = \big((1/2)^d\big(1+o(1)\big)\big)^{\log n}$. Thus $\pi'(1+o(1)) = 1/n$ and $\pi'(2+o(1)) = 1/n^2$. Since each design contains approximately $n/(2\ln 2)$ "lines," we obtain the following.

THEOREM 7.1. *The matching problem on n vertices can be solved by probabilistic algorithms with the following parameters:*

- 2 *rounds and* $(1/(2\ln 2))n\log n(1+o(1)) \approx 0.72n\log n$ *tests;*
- 1 *round and* $(1/\ln 2)n\log n(1+o(1)) \approx 1.44n\log n$ *tests.*

Note that the algorithms make no errors in the sense that when we get the answers we know which edges are matching edges and which are not. With high probability, we get all the information in the 1-round algorithm; in the rare event we do not, we know it, and we can make an additional set of queries for all the edges whose status has not been determined. In the 2-round algorithm we always get all the information, but with positive probability we will have to ask more than n queries in the second round.

Note also that the algorithms described here can be easily modified to find a hidden copy of any graph with $O(n)$ edges and with maximum degree $O(\sqrt{n})$ in one randomized round, using $O(n\log n)$ queries.

8. Deterministic k-round algorithms. In this section we present *deterministic* k-round algorithms that make at most $O(n^{1+1/(2(k-1))}\text{polylog}n)$ queries per round. In the special case $k = 2$, we do not need the polylog$n$ factor. All of our deterministic algorithms are constructive.

A lemma about the chromatic number of the graph consisting of all edges contained in half the lines of a projective plane will allow us to reduce the general problem to a bipartite matching problem. The lemma, which may be interesting in its own right, is proved by considering the eigenvalues of the plane's incidence matrix.

LEMMA 8.1 (coloring). *Let P be a finite projective plane with n points. Obtain Q by deleting at least $n/2$ of P's lines. Let $G = (V, E)$, where V is P's point set and E consists of all pairs (x, y) such that there is a line in Q containing both x and y. Then G is $\sqrt{n}\ln n(1 + o(1))$ colorable using color classes of size less than $\sqrt{n}$. Furthermore such a coloring can be found in time polynomial in n.*

Proof. The basic idea in the proof of this lemma is as follows. Consider a set B of points. On average, a line will contain about $|B|/\sqrt{n}$ points. We will show that if B is not very small, then most lines contain at least half that number of points. This will allow us to greedily choose our color classes from among the lines that were deleted from P. We need the following lemma, whose proof is essentially identical to that of Lemma 9.2.4 of [1].

LEMMA 8.2. *Let $G = (U, V; E)$ be a d-regular bipartite graph with classes of vertices U and V of size n each. Let $A = (A_{u,v} : u \in U, v \in V)$ be the (bipartite) adjacency matrix of G given by $A_{u,v} = 1$ iff $uv \in E$, and $A_{u,v} = 0$ otherwise. Suppose, further, that every eigenvalue of A^tA except the largest (which is d^2) is at most λ^2. Then, for every $B \subseteq V$,*

$$\sum_{u\in U}\left(|N(u)\cap B| - d\frac{|B|}{n}\right)^2 \le \lambda^2|B|\left(1 - \frac{|B|}{n}\right).$$

Let P be a projective plane of order p. Thus it has $n = p^2 + p + 1$ points. Let G be the incidence graph of P, i.e., the bipartite graph with classes of vertices U and V, with $|U| = |V| = n$, in which V is the set of points and U is the set of lines, where uv is an edge iff the line u contains the point v. If A is the adjacency matrix of G, then A^tA is a matrix in which all diagonal entries are $p+1$ and all other entries are 1. Consequently, the largest eigenvalue of A^tA is $(p+1)^2$ and all its other eigenvalues are equal to p. It follows that for every set of points $B \subset U$, we can bound the number of lines v containing less than $\frac{d|B|}{2n}$ points of B by the above lemma. Namely,

$$\begin{aligned}\left|\left\{v \in V : |N(v)\cap B| < \frac{d}{2}\frac{|B|}{n}\right\}\right| &< \frac{4\lambda^2}{d^2}\frac{n^2}{|B|}\\ &= \frac{4p}{(p+1)^2}\frac{n^2}{|B|}\\ &\le \frac{4n^{3/2}}{|B|}.\end{aligned}$$

Therefore, if $|B| > 10\sqrt{n}$, then every set consisting of $0.4n$ lines contains a line that contains at least $\frac{\sqrt{n}}{2}\frac{|B|}{n} = \frac{|B|}{2\sqrt{n}}$ elements of B. Now we are in a position to prove the following.

COROLLARY 8.3. *Every set S consisting of at least $0.4n$ lines contains a subset consisting of at most $\sqrt{n}\ln n$ lines covering all but at most $10\sqrt{n}$ points.*

Proof. Initially, let $B = V$. As long as $|B| \geq 10\sqrt{n}$, we may choose a line in S that contains at least a $\frac{1}{2\sqrt{n}}$ fraction of the points in B and then remove those points from B. After at most $2\sqrt{n}\ln[n/(10\sqrt{n})] < \sqrt{n}\ln n$ iterations, we will have reduced B to size at most $10\sqrt{n}$. □

To complete the proof of the coloring lemma, we take our set of lines to be the ones deleted from P. Our color classes are the $\sqrt{n}\ln n$ lines promised by the preceding corollary as well as the $10\sqrt{n}$ singletons not covered by those lines. If a point belongs to more than one of those lines, then we can choose its color class arbitrarily from among them. □

LEMMA 8.4 (first bipartite). *Assume that M is a nonempty matching on V. Let V be the disjoint union of L and R, where $|R| \geq 2$, and assume we know that neither L nor R contains an edge of M. We can learn M with a k-round algorithm that makes at most $|M||L|^{1/k}\log|R|$ tests per round.*

Proof. The proof is by induction on k. If $k = 1$, then we can perform a parallel binary search for each element of L to find its match, if any, in R. The number of tests performed is $|L|\log|R|$.

Now let $k \geq 2$ and assume we have a $(k-1)$-round algorithm that makes at most $|M||L|^{1/(k-1)}\log|R|$ tests per round. Let $t = |L|^{1/k}$. Partition L into t pieces $L_1, \ldots, L_t$ of size $|L|/t$. In round 1, test $L_i \cup R$ for each i. At most $|M|$ of those sets can contain an edge, say $L_{i_1} \cup R, \ldots, L_{i_m} \cup R$, where $m \leq |M|$. Apply the inductive hypothesis to the matching problems on those m sets. Let e_j denote the number of edges in L_{i_j}. The number of tests per round is at most

$$\sum_j e_j(|L|/t)^{1/(k-1)}\log|R| = |M||L|^{1/k}\log|R| \qquad \square$$

LEMMA 8.5 (second bipartite). *Assume that M is a nonempty matching on V. Let V be the disjoint union of L and R, and assume we know that neither L nor R contains an edge of M. Let c be a real number such that $0 < c < 1$, $c|L|^{1/k} \geq 1$. Let $k \geq 2$. We can learn M with a k-round algorithm that makes at most $c|L|^{1/k}$ tests in the first round and at most $|M||L|^{1/k}\log|R|/c^{1/(k-1)}$ tests in each subsequent round.*

Proof. Let $t = c|L|^{1/k}$. Partition L into t pieces $L_1, \ldots, L_t$ of size $|L|/t$. In round 1, test $L_i \cup R$ for each i. At most $|M|$ of those sets can contain an edge, say $L_{i_1} \cup R, \ldots, L_{i_m} \cup R$, where $m \leq |M|$. Apply the first bipartite lemma to the matching problems on those m sets. Let e_j denote the number of edges in L_{i_j}. The number of tests performed in round 1 is $t = c|L|^{1/k}$, and in each subsequent round it is at most

$$\sum_j e_j(|L|/t)^{1/(k-1)}\log|R| = |M||L|^{1/k}\log|R|/c^{1/(k-1)} \qquad \square$$

THEOREM 8.6. *For $3 \leq k \leq \log n$, there is a deterministic k-round algorithm for the matching problem that asks $O(n^{1+1/(2(k-1))}(\log n)^{1+1/(k-1)})$ queries per round.*

Proof. After adding $o(n)$ virtual unmatched points we may assume that n is of the form $p^2 + p + 1$, where p is prime; these virtual points will be omitted from any actual tests. In round 1, construct a projective plane with n points, and perform one test for each line. Delete every line that contains no edge of the matching. Construct G and its color classes as in the coloring lemma. If $(x, y) \in M$, then x and y must belong to distinct color classes of G. For each pair of color classes apply the bipartite lemma with $c = \log n^{1/(k-1)}/\log n$ and the number of rounds $= k - 1$. The number

of tests in round 2 is at most

$$O\left(\binom{\sqrt{n}\log n}{2} c\sqrt{n}^{1/(k-1)}\right) = O(n^{1+1/(2(k-1))}(\log n)^{1+1/(k-1)}).$$

The number of tests performed in any of the rounds 3 through k is bounded by

$$O\left((n/2)\sqrt{n}^{1/(k-1)} \log \sqrt{n}/c^{1/(k-2)}\right) = O(n^{1+1/(2(k-1))}(\log n)^{1+1/(k-1)}). \qquad \square$$

Our 2-round deterministic algorithm uses finite projective spaces of dimension 4 in a somewhat different way. It has the advantage of using queries whose size is approximately $n^{1/4}$ or less.

THEOREM 8.7. *There is a deterministic* 2*-round algorithm that asks* $\frac{5}{4}n^{3/2}(1 + o(1))$ *queries of size at most* $n^{1/4}$ *each.*

Proof. Choose $m \approx n^{1/4}$ such that K_n is the disjoint union of approximately $n^{3/2}$ copies of K_m. (Use a projective or affine space of dimension 4 where each line has length m.) (1) Ask one query for each copy of K_m. At most $n/2$ of them can contain an edge. (2) Use brute force to find those edges. $\square$

9. Open problems.

- Determine the smallest possible constant c such that there is a deterministic nonadaptive algorithm for the matching problem on n vertices that makes $c\binom{n}{2}(1 + o(1))$ queries.
- Find more efficient deterministic k-round algorithms or prove lower bounds for the number of queries in such algorithms.

Acknowledgments. We would like to thank Lance Fortnow, László Lovász, and Oded Regev for helpful discussions. The second author gratefully acknowledges a Temple University study leave.

ON RATIONAL NUMBER RECONSTRUCTION AND APPROXIMATION*

VICTOR Y. PAN† AND XINMAO WANG‡

Abstract. The celebrated LKS algorithm by Lehmer, Knuth, and Schönhage, combined with the product tree technique, enables an equivalently rapid alternative to our recent modification of the extended Euclidean algorithm for the reconstruction of a rational number from its modular as well as numerical approximations.

Key words. rational number reconstruction, rational number approximation, extended Euclidean algorithm, LKS algorithm, product tree technique

AMS subject classifications. 68W40, 68W30, 68Q25

DOI. 10.1137/S0097539703437181

Our algorithm in [7] uses $O(M(d)\log d)$ bit-operations to solve the rational number reconstruction problem of recovering a unique rational number x/y from three integers k, v, and $u = (x/y) \bmod v$, where it is assumed that $k, v, |x|$, and y are integers in $2^{O(d)}$, v and y are coprime, $k > 2|x|, v/k > y > 0$, the problem has a solution, and $M(d)$ bit-operations suffice to multiply two integers modulo 2^d. In a dual variation, our algorithm solves the rational number approximation problem; that is, for a given triple of positive integers k, m, and $n > m$, it computes a unique pair of coprime integers p and q such that $0 < q < k + 1$ and $|m/n - p/q| < 1/(2k^2)$. The bit-cost is in $O(M(d)\log d)$ provided k, m, and n are in $2^{O(d)}$ and the problem has a solution. (For more details see [7] and the bibliography therein.)

Now we wish to point out an alternative solution algorithm for both problems which also uses $O(M(d)\log d)$ bit-operations. It relies on the well-known LKS algorithm by Lehmer, Knuth, and Schönhage (see [5], [3], [6]), which uses $O(M(d)\log d)$ bit-operations to compute all partial quotients in the extended Euclidean algorithm applied to two positive integers u and v in $2^{O(d)}$ (the quotients are represented by 2-by-2 matrices P_i in [7], and our algorithm computes only some selected quotients). Having all the quotients available, one may apply the product tree technique [3, Theorem 1] and easily arrive at the desired solutions x/y and p/q to the problems of the rational number reconstruction and approximation, respectively. Namely, one may apply this technique to compute (within the desired time bound of $O(M(d)\log d)$) an appropriate positive integer j and a pair of 2-by-2 matrices Q_j and Q_{j-1} (which are the products of the matrices P_i from 1 to j and $j-1$, respectively) such that the desired ratio x/y is recovered from them immediately, e.g., in the same way as in [7]. Similarly the ratio p/q can be computed. We refer the readers to the paper [1] and the bibliography therein (also see the relevant chapters in the books [4] and [2]) for the detailed technical and historical account on the LKS algorithm and the product tree technique.

ON UNIVERSAL CLASSES OF EXTREMELY RANDOM CONSTANT-TIME HASH FUNCTIONS*

ALAN SIEGEL†

Abstract. A family of functions F that map $[0, m-1]$ into $[0, n-1]$ is said to be κ-wise independent if any tuple of κ distinct points in $[0, m-1]$ have a corresponding image, for a randomly selected $f \in F$, that is uniformly distributed in $[0, n-1]^\kappa$. This paper shows that for suitably fixed $\epsilon < 1$ and any $\kappa < m^\epsilon$, there are families of κ-wise independent functions that can be evaluated in constant time for the standard random access model of computation. It is also proven that any such family requires a storage array of m^δ random seeds for a suitable $\delta < 1$. These seeds can be pseudorandom values precomputed from an initial $O(\kappa)$ random seeds. A simple adaptation yields n^ϵ-wise independent functions that require n^δ storage in many cases where $m \gg n$. Lower bounds are presented to show that neither storage requirement can be materially reduced. Previous constructions of random functions having constant evaluation time and sublinear storage exhibited only a constant degree of independence. Unfortunately, the explicit randomized constructions, while requiring a constant number of operations, are far too slow for any practical application. However, nonconstructive existence arguments are given, which suggest that this factor might be eliminated. The problem of eliminating this factor is shown to be equivalent to a fundamental open question in graph theory. As a consequence of these constructions, many probabilistic algorithms—from traditional hashing to Ranade's emulation of common PRAM algorithms—can for the first time be shown to achieve, up to constant factors, their expected asymptotic performance for a programmable, albeit formal and currently impractical, model of computation, and a research direction is now available that may eventually lead to implementations that are fast and provably sound.

Key words. hash functions, universal hash functions, hashing, limited independence, optimal speedup, PRAM emulation, storage-time tradeoff

1. Introduction.

Hash functions have been a mainstay in the design of many randomized and high performance algorithms, and their use has been especially important for theoretical developments in large-scale parallel and distributed computation. In particular, storage is often hashed to distribute data evenly across memory modules, to balance access patterns to memory, and to balance load requirements across networks. Although some algorithms can achieve optimal performance improvements via precomputed randomization, and others can exploit adaptive methods to achieve maximum performance, many fundamental problems have yet to be solved without the statistically uniform randomness supported by idealized or by (the more pragmatic) universal classes of hash functions. Ranade, for example, uses polynomials of degree $8 \log n$ to randomize routing and memory accesses in his emulation scheme for the common PRAM [20]. To date, his results have yet to be matched without such a hashing procedure.

Of course, good hash functions are also important for sequential computation. For example, it is well known that for uniform hashing, the expected cost to insert the $(\alpha n + 1)$st item into a table of size n is $\frac{1}{1-\alpha} - o(1)$ probes when fully random hash functions are used [12]. Yet the significance of even this performance bound is by no means clear. The difficulty is that the result has been proven for idealized

fully independent hash functions, which cannot be efficiently computed. Suppose, for example, we wish to select a random mapping from $[0, n^2 - 1]$ into $[0, n - 1]$. Since there are n^{n^2} such mappings, it follows that the program length of such a function must be at least $n^2 \log n$ bits, on average, which is much larger than the hash table it is intended to service.

On the other hand, results based on idealized randomness sometimes translate into average case performance guarantees for real computation. For example, double hashing uses the same insertion and retrieval strategies as uniform hashing, but defines the jth probe for a key x to be $(d(x) + (j-1)f(x)) \bmod p$, for prime p and random functions d and f, with ranges $[0, p-1]$ and $[1, p-1]$. This scheme requires about $2\lceil \log p \rceil$ random bits per hash key, and we could take these bits to be any fixed portions of the key itself, provided it is at least $2\lceil \log p \rceil$ bits long. Then a performance analysis for the truly random case can be viewed as an average case argument for this deterministic formulation, where the averaging is over all possible sequences of data keys. However, for uniform hashing—or indeed any hashing scheme where each probe sequence is defined by more bits than are available in a hash key—even this weak interpretation would seem to lack adequate justification.

Accordingly, it is to notions of computable randomness that we now turn our attention.

1.1. Background and overview. Carter and Wegman introduced *universal classes of hash functions* [5] to provide a theoretically sound and pragmatic framework for programmable hash functions with limited degrees of freedom. Subsequent developments in universal hashing (cf. [36, 18]) have used comparable formulations which are all basically as follows.

DEFINITION 1.1. *A family of hash functions F with domain D and range R is* (κ, μ)-wise independent *if it is finite and for all $y_1, y_2, \ldots, y_\kappa \in R$, for all* distinct *$x_1, x_2, \ldots, x_\kappa \in D$,*

$$|\{f \in F : f(x_i) = y_i,\ i = 1, 2, \ldots, \kappa\}| \leq \mu \frac{|F|}{|R|^\kappa}. \tag{1.1}$$

Consequently, if a function $f \in F$ is chosen at random with all elements equally likely to be selected, then f will map any fixed set of κ distinct points from D into R^κ according to a probability distribution that is, in some sense, roughly uniform.

In these definitions, D and R are always finite. It is worth pointing out that any function is a hash function, and from the perspective of universal hashing, any function is a bad hash function. What matters are the statistical characteristics of the family members as quantified in (1.1). (Of course, we are also concerned with the program size and operation count associated with evaluating the functions in such a family.) It is important to notice that (κ, μ)-wise independence implies (j, μ)-wise independence for $j < \kappa$. Indeed, if we sum both sides of (1.1) over all $y_\kappa \in R$, the constraint on $f(x_\kappa)$ becomes the trivial $f(x_\kappa) \in R$, and the bound reverts to the exact requirement for $(\kappa - 1, \mu)$-wise independence.

For expositional simplicity, we will, unless stated otherwise, set $\mu = 1$ and simply refer to (κ)-wise independence. Likewise, we will use *limited independence* to refer to families where the independence parameter κ is much smaller than $|D|$, and take *fully independent* to mean that $\kappa = |D|$.

Carter and Wegman exhibited the following families of (κ, μ)-wise independent

hash functions where $D = [0, p-1]$, $R = [0, n-1]$, and p is prime:

$$F_{(\kappa)} = \left\{ f \mid f(x) = \left(\sum_{j=0}^{\kappa-1} a_j x^j \bmod p \right) \bmod n,\ a_j \in [0, p-1] \right\}. \tag{1.2}$$

They showed (among other results) that these functions give a performance for hashing with separate chaining that is effectively indistinguishable from that for fully random functions. In this hashing scheme, the elements of a set $\aleph \subseteq [0, p-1]$ are mapped by a randomly selected function $f \in F_{(\kappa)}$ (chosen independent of $\aleph$) into linked lists that are accessed via an array $B[0, n-1]$. When multiple items are mapped to a common address location j, the items are chained together in a list with the head list item stored in $B[j]$. The remaining list members are kept in auxiliary storage outside of B. Carter and Wegman used the fact that the sum of the expected jth moments of the list lengths, when fully random hash functions are used, is essentially the same as that resulting from the use of random functions in $F_{(\kappa)}$, provided $j \leq \kappa$. For hashing with separate chaining, the expected average of the second moments of the list lengths determines the expected retrieval time, whence pairwise independence guarantees an expected performance that is equivalent to that resulting from fully independent hash functions.

Subsequently, Mehlhorn and Vishkin presented an extensive collection of different hash functions that meet the requirements of (κ, μ)-wise independence [18]. Yet despite a surprising diversity of definitions and algebraic structures, every one of their (κ)-wise independent functions—like all such families ever discovered—requires at least κ arithmetic operations per evaluation. Under the circumstances, it is natural to wonder if this is a coincidence. We ask:

Is there an inherent κ-time penalty for computing
(κ)-wise independent hash functions, or can we do better?

The answer will turn out to be that faster functions are indeed programmable. However, a complete solution is fairly technical and cannot be stated in terms of the standard formulations for limited randomness. The definitions must be extended to expose additional statistical characteristics that affect the computational resources in cases where the independence exceeds the number of random seeds used to hash an individual key.

Families of random hash functions are often defined as a three-tier mapping $g \circ f \circ h$, where $h : D \to D_1$, $f : D_1 \to D_1$, and $g : D_1 \to R$. The underlying domain D might be huge, in which case a preliminary mapping h is used to map the hash keys into a smaller domain that is better suited for efficient computation. Thus, D_1 might be a finite field with elements that can be represented by, say, a finite number of machine words, and the actual target range R might be a table index that is less well suited for defining families of uniformly distributed hash functions. For example, the Carter–Wegman class (1.2) actually defines a $(\kappa, 1)$-wise independent family $f \in F$ on the field of integers mod$p$, and then uses $g(x) \equiv x \bmod n$ to project the hashing onto the intended range $[0, n-1]$. Consequently, the resulting composition fails to achieve $(\kappa, 1)$-wise independence because the first $p \bmod n$ points in $[0, n-1]$ have $\lceil \frac{p}{n} \rceil$ preimage points, whereas the remaining $n - (p \bmod n)$ points have $\lfloor \frac{p}{n} \rfloor$ preimage points. This mild nonuniformity in the postprocessing was the reason for introducing the parameter μ in the definition of (κ, μ)-wise independence. However, for the problems we consider, the pathologies associated with g are insignificant, whereas the irregularities associated with h turn out to have a greater effect on the underlying computational resources.

Formally, we analyze the computational costs for computing (κ)-wise independent mappings from a domain D into a range R. The underlying parameters are 1) the number σ of initializing random seeds, 2) the number of operations $T < \kappa$ that must be executed per evaluation of the hash function, 3) the size of the hashing program, and 4) the size of a provably necessary auxiliary storage array M, which, it will turn out, we can presume to hold pseudorandom numbers that have been precomputed from σ initial seeds. Additional parameters are the domain and range sizes $|D|$ and $|R|$. This paper gives a lower bound to show that M must store at least $|D|^\epsilon$ words from R for suitable fixed $\epsilon < 1$. We also show how to circumvent this lower bound. By allowing an asymptotically negligible chance (which is yet another parameter) that the hash function family will fail to achieve (κ)-wise independence for a given data set, the lower bound will still apply, but for an effective domain size $|D_1|$, which might be far smaller than $|D|$.

The exact details include additional parameters, but they play a minor role in the resource requirements. In all cases, the requisite number of random seeds remains modest: $\sigma = \Theta(\kappa)$.[1]

We present two kinds of algorithmic formulations for such high performance hash functions. In particular, nonconstructive existence arguments are used to show that algorithms might, in principle, match the resource constraints predicted by the lower bound. Our (nonconstructive) hash functions require a precomputation phase where the σ random seeds are used to precompute $|D|^\epsilon$ pseudorandom values that are stored in an auxiliary array M. Then a suitable algorithm can compute highly random hash values by using its hash key deterministically to select a small number T of elements from M and by simply returning the sum of these elements $\bmod |R|$, or, say, their bitwise exclusive-or. The computation can be formulated to use, say, just twice as many elements from M as are proved necessary by our bound. Moreover, this number T turns out to be constant: $T = \Theta(1)$. On the other hand, the question of which T words should be selected from M lies at the heart of the nonconstructive existence argument.

Although the question of how to select these T random words effectively is still open, we show that hash functions with very high independence are indeed programmable, provided we accept the less satisfactory evaluation time of $T^{\Theta(T)}$, where T is the $O(1)$ operation count predicted by nonconstructive methods.

1.2. Related work. A preliminary version of this work appeared as an extended abstract in [26]. The current presentation includes more efficient existential formulations, better probabilistic constructions, a stronger and more general lower bound, and an improvement in the applications. In the interim, several works have appeared that use the properties of these high performance hash functions [9, 11, 16].

The theory of hashing has also progressed along several independent lines. In particular, Dietzfelbinger et al. [7] pursued the perfect hashing methods begun by Fredman, Komlós, and Szemerédi [8] to develop hash functions that can locate data without collisions. The processing is fully dynamic, with an average insertion time of $O(1)$ steps per insertion, and a resulting 1 table probe per data request. While these techniques have many useful properties, and might comprise the methods of choice for many applications, they do not construct functions with the statistical randomness that is the primary objective of this work. Further, the functions require auxiliary

[1] For very large domains, the prehashing in the appendix, which is based on [8, 17], uses an additional $\log\log|D|$ bits, which are provably necessary (cf. [8, 17]). On the other hand, the convention that words can be processed in unit time is suspect for domains where such a term would matter.

storage of $\Omega(n)$ bits, which is in excess of the storage we will use.

Many works have used universal classes of hash functions to reduce the resource conflicts that arise in distributed computation. For example, Karp, Luby, and auf der Heide use the highly random constant-time hash functions described in the preliminary version of this work to resolve various problems of contention at the memory module level [11]. Their model is designed to avoid some of the idealized characteristics of PRAMs, where contention occurs only at the level of memory cells. Other such uses include developments by Goldberg, Matias, and Rao [9] and Matias and Schuster [16]. On the other hand, some machine contention can be resolved with much simpler hash functions. For example, Kruskal, Rudolph, and Snir use such an approach to emulate an $(n^{1+\epsilon})$-processor PRAM on an n-processor machine [13].

1.3. The organization. This paper is organized as follows. Section 1 concludes with a brief description of the computational model and an introduction to the calculus of limited independence. Section 2 analyzes three random function formulations, which range from the nonconstructively defined but extremely efficient to the programmable (with code). They all run in constant time and can be as much as $(|D|^{\delta})$-wise independent for different, suitably small constants $\delta > 0$.

Section 3 presents lower bounds for the resource requirements of fast hash functions. Section 4 discusses the intrinsic resource tradeoffs for the general hashing formulations of section 2, their lower bounds, and their equivalence to a fundamental problem in graph theory. Section 5 gives a few applications and section 6 presents the conclusions.

1.4. Computational assumptions. The performance results are based on a variety of assumptions that characteristically hold for most hashing problems, as well as some decisions to use problem descriptors aimed at keeping the parameters at hand as simple as possible. The first point of clarification is that the main problem size parameter, in all hashing problems, will be n. For example, we will typically have $\theta(n)$ hash keys that must be mapped into some range. Similarly, some applications feature n processors that at a given time step each hash one memory address. With pipelining, the n processors might each have as many as $\log n$ addresses to hash. We state this explicit dependence on n because n will sometimes be only implicitly represented by, say, a domain size parameter m, which might be set to n^{ℓ}, for suitable ℓ. Second, we assume that for some constant $r \geq 2$, the family of hash functions we construct will only need to be (κ, μ)-wise independent with a probability exceeding $1 - n^{-r}$, so that a negligible percentage of the hash functions might be seriously defective.

It is easy to adapt the results to larger data sets, but to avoid clutter we will use these adaptations only when necessary. In addition, we will either suppose that the domain size $|D|$ is polynomial in n, or assume that there is "no computation charge" for premapping elements from a very large space D into, say, $[0, n^{\ell} - 1]$ for some constant $\ell \geq r + 2$. It will suffice to use a pairwise independent hash function (i.e., a randomly selected member of a universal class of pairwise independent hash functions) for the premapping $h : D \to [0, n^{\ell} - 1]$.

We will typically suppose that the range R is no larger than n^{γ} for some constant γ. Otherwise, the presumption that simple arithmetic operations take constant time is again somewhat suspect. It is also the case that for much larger number ranges, the size of the initializing random seeds will have to grow. Our constructions and lower bounds can accommodate these changes, and the total operation count for the hash functions will remain constant. We will sometimes assume that $n \leq |R|$. This assumption is harmless; if $|R|$ is much less than n, it will suffice to use a range $[0, \hat{R}-1]$,

where $\hat{R}$ is a multiple of $|R|$, and postprocess the hash functions mod$|R|$.

The underlying computational model (once the domain is reduced in size) is the standard Random Access Machine.

Last, we assume that there is a source of truly independent uniformly distributed random seeds in any interval $[0, \rho-1]$, and that modest quantities of them are available for use. In particular, if a hash function is to be (κ)-wise independent, then $\Theta(\kappa)$ random seeds can be supplied as initializing input to the hashing algorithm. Of course, if strings of $\theta(\kappa)$ seeds have relative probabilities of occurrence that are not equal but instead differ by as much as a factor of μ, then the resulting hash functions will have statistics that exhibit the same multiplicative variability.

1.5. A primer on limited independence and the simplest derived inequalities. The probabilistic inequalities used in this paper all follow from a few closely related formulations. Let $\mathcal{X}(*) : (T, F) \to (1, 0)$ be the indicator function, which maps Boolean expressions into 1 when they are true and 0 otherwise. Let g be a nonnegative increasing function, and let X be a random variable. Then $\frac{g(X)}{g(a)}$ is at least 1 whenever $X > a$, and is nonnegative everywhere. Thus $\text{Prob}\{X > a\} = \text{Prob}\{g(X) > g(a)\} = \text{E}[\mathcal{X}(\frac{g(X)}{g(a)} > 1)] \le \text{E}[\frac{g(X)}{g(a)}] = \frac{\text{E}[g(X)]}{g(a)}$. Several functions g are commonly used for proving probabilistic inequalities of the form

$$\text{Prob}\{X > a\} \le \frac{\text{E}[g(x)]}{g(a)}. \tag{1.3}$$

When X is itself nonnegative, setting $g(x) = x$ gives what is sometimes referred to as Markov's inequality.

This scheme also works if g is an increasing multinomial or multivariate function that is never negative on its domain. Let, for example, the random variable Φ be the sum of n Bernoulli trials: $\Phi = z_1 + z_2 + \cdots + z_n$, where z_k is 1 if, say, the hash function f maps x_k to memory module 1, and 0 otherwise. In this case, z_k is itself the disjoint sum of many atomic events: $z_k = \bigvee_j (f(x_k) = j)$, where the j index ranges over all addresses in module 1. If f is selected from a (κ, μ)-wise independent family, then, as is straightforward to verify, the Bernoulli trials will be (κ, μ)-wise independent. A suitable multinomial g would be $g(z_1, z_2, \ldots, z_n) = \binom{\Phi}{\kappa}$, which has a very natural interpretation. In this case, $\binom{\Phi}{\kappa}$ is the sum of all products of subsets of κ distinct z's: $\binom{\Phi}{\kappa} = \sum_{1 \le i_1 < i_2 < \cdots < i_\kappa \le n} z_{i_1} z_{i_2} \cdots z_{i_\kappa}$.

We recall that the expectation and multiplication commute for independent random variables: $\text{E}[YX] = \text{E}[X]\text{E}[Y]$ if X and Y are independent. In the case of (κ, μ)-wise independence, $\text{E}_\kappa[X_1 X_2 \cdots X_\kappa] \le \mu \prod_{1 \le j \le \kappa} \text{E}_\infty[X_j]$, for nonnegative (κ, μ)-wise independent random variables $X_1, X_2, \ldots, X_\kappa$, where E_κ denotes the expectation under (κ, μ)-wise independence, and E_∞ denotes the expectation under full randomness. More generally, we note that if the X_i are (κ, μ)-independent, then so are $\{g_i(X_i)\}_{j=1}^{\kappa}$ for any set of functions g_i. (These facts can be verified by formulating events as the logical-or of κ-way atomic events that assign each X_i fixed values.) Under (κ, μ)-wise independence, it follows that

$$\text{Prob}\{\Phi > a\} \le \frac{\text{E}_\kappa[\binom{\Phi}{\kappa}]}{\binom{a}{\kappa}} \le \frac{\mu}{\binom{a}{\kappa}} \sum_{1 \le i_1 < i_2 < \cdots < i_\kappa \le n} \text{E}_\infty[z_{i_1}]\text{E}_\infty[z_{i_2}] \cdots \text{E}_\infty[z_{i_\kappa}].$$

The bound is useless if $a < \kappa$, since the denominator would be zero; in such a case, we might replace κ with a smaller value.

In many of our applications, $\mathrm{E}_\infty[z_k] = p$ for some expression p that is independent of k. In these cases, $\mathrm{E}_\infty[\binom{\Phi}{\kappa}] = \binom{n}{\kappa}p^\kappa$, and hence $\mathrm{Prob}\{\Phi > a\} \le \mu\frac{\binom{n}{\kappa}p^\kappa}{\binom{a}{\kappa}}$.

These formulations can also be used to bound tail expectations as well as probabilities. For example, if X is integer valued and nonnegative, then

$$\mathrm{E}[X \cdot \mathcal{X}(X \ge a)] \le k\mathrm{E}\left[\frac{\binom{X}{k}}{\binom{a-1}{k-1}}\right]$$

for $k \le a$. Similarly,

$$\mathrm{E}[X] \le a + \mathrm{E}[X \cdot \mathcal{X}(X \ge a)]$$

for $a \ge 0$, and likewise

$$\mathrm{E}[X^2] \le a^2 + k(k-1)\mathrm{E}\left[\frac{\binom{X+1}{k}}{\binom{a-1}{k-2}}\right],$$

provided that X is nonnegative and integer valued. If $X_1, X_2, \ldots, X_n$ are random variables, then

$$\mathrm{E}[\max_i X_i] \le a + \sum_i \mathrm{E}[X_i \cdot \mathcal{X}(X_i \ge a)],$$

and if the X_i are identically distributed, then

$$\mathrm{E}[\max_i X_i] \le a + n\mathrm{E}[X_1 \cdot \mathcal{X}(X_1 \ge a)].$$

These formulations suggest that we will need some basic combinatorial inequalities. Some use the notation $n^{\underline{k}} \equiv n(n-1)\cdots(n-k+1)$. For example, when $m > n$, then we can write $\frac{n^{\underline{\kappa}}}{m^{\underline{\kappa}}} < (\frac{n}{m})^\kappa$, and $\frac{m^{\underline{\kappa}}}{n^{\underline{\kappa}}} > (\frac{m}{n})^\kappa$ without appealing to any estimate for factorials.

A fairly elementary form of Stirling's formula says that $n! > n^{n+1/2}e^{-n}$. Sometimes even more naive formulations such as $n! > n^n e^{-n}$ will suffice. For example, the last inequality implies that $n^{\underline{k}} > n^k e^{-k}$. (Indeed, to see that the former implies the latter, observe that $n^{\underline{\kappa}} > \frac{\kappa^\kappa}{e^\kappa \kappa!}n^{\underline{\kappa}} = \frac{\kappa^\kappa}{e^\kappa} \cdot \frac{n^{\underline{\kappa}}}{\kappa^{\underline{\kappa}}} > (\frac{\kappa}{e})^\kappa \cdot (\frac{n}{\kappa})^\kappa = (\frac{n}{e})^\kappa$.) It now follows that

$$\frac{n^k e^{-k}}{k!} \le \binom{n}{k} \le \frac{n^k}{k!},$$

and we will bound many combinatorial expressions by replacing $\binom{n}{k}$ by $\frac{n^k}{k!}$, if the expression appears in a numerator, and by $\frac{n^k e^{-k}}{k!}$, if it is in a denominator. As an immediate application, we have

$$\mu\frac{\binom{n}{\kappa}p^\kappa}{\binom{a}{\kappa}} \le \mu\frac{(np)^\kappa}{a^{\underline{\kappa}}} \le \mu\left(\frac{npe}{a}\right)^\kappa,$$

which further simplifies the preceding estimates for $\mathrm{Prob}\{\Phi > a\}$, when Φ is the sum of n (κ, μ)-wise independent Bernoulli trials with probability of success p. Although much better estimates can be derived, they will not be needed.

Many powerful inequalities come from setting $g(X) = e^{\lambda X}$, in (1.3), and then solving for the value of $\lambda > 0$ that gives the best bound. If X is the sum of n mutually independent identically distributed random variables z_i, then $\mathrm{E}[e^{\lambda X}] = \mathrm{E}[e^{\lambda z_1}]^n$, and $\mathrm{Prob}\{X > a\} < e^{-\lambda a}\mathrm{E}[e^{\lambda z_1}]^n$. If $X = z_1 + z_2 + \cdots + z_\kappa$, where $\{z_i\}_{i=1}^{\kappa}$ are random variables that enjoy (κ, μ)-wise independence, then $\mathrm{E}_\kappa[e^{\lambda X}] \le \mu \prod_{i=1}^{\kappa} \mathrm{E}_\infty[e^{\lambda z_i}]$. A more complete set of these estimates for cases with limited independence can be found in [24].

Sometimes an event $\mathcal{E}$ will have a corresponding predicate $\mathrm{Pred}(*, *)$ and sets U and W that satisfy the following: if $\mathcal{E}$ occurs, then there exist $u \subset U$ and $w \subset W$ such that $\mathrm{Pred}(u, w)$ is true. This implies that $\mathrm{Prob}\{\mathcal{E}\} \le \sum_{u \subset U,\, w \subset W} \mathrm{E}[\mathcal{X}(\mathrm{Pred}(u, w))]$, where $\mathcal{X}$ is the 0–1 indicator function. We will take care to ensure that these expectations can be evaluated (or estimated) under the restrictions of (κ, μ)-wise independence. For example, a predicate $\mathcal{E}$ might have a decomposition as a disjoint sum of atomic κ-way events:

$$\mathcal{E} = \bigvee_{(y_1, y_2, \ldots, y_\kappa) \in \Omega} \left(\bigwedge_{1 \le i \le \kappa} f(x_i) = y_i \right)$$

for some set Ω of κ-tuples. Any such $\mathcal{E}$ has a probability that is, up to the factor μ, bounded by the analogous probability that results from full independence and the uniform distribution.

Armed with this set of counting arguments, we proceed to the problem of building fast computable hash functions.

2. The hash functions. The first step is to formalize a somewhat stronger and occasionally more applicable notion of restricted randomness.

DEFINITION 2.1. *A family of hash functions F with domain D and range R is* r-practical (κ, μ)-wise independent *if for any subset $D_0 \subset D$, with $|D_0| \le \sqrt{|R|^r}/2$, there is a subset of functions $\widehat{F} \subseteq F$ where $|\widehat{F}| \ge |F|(1 - 2\frac{\binom{|D_0|}{2}}{|R|^r})$ and for all $y_1, y_2, \ldots, y_\kappa \in R$, for all* distinct *$x_1, x_2, \ldots, x_\kappa \in D_0$,*

$$\frac{|\widehat{F}|}{\mu |R|^\kappa} \le |\{f \in \widehat{F} : h(x_i) = y_i,\ i = 1, 2, \ldots, \kappa\}| \le \frac{\mu |\widehat{F}|}{|R|^\kappa}. \tag{2.1}$$

We define F to be uniformly r-practical (κ, μ)-wise independent *if* (2.1) *holds for some $|\widehat{F}| \ge |F|(1 - \frac{1}{|R|^r})$ with $D_0 = D$.*

This definition differs from those in the literature in two respects. First, the r-practical part of the formulation has been introduced to formalize the notion that a negligible fraction of the hash functions might be defective for the specific data that is to be processed. The reason for weakening the definition is the following. For very large domains, a prehashing function h should be used to map the data into a smaller domain D_1. But then a collection of n keys from D will, with a probability of (about) $\binom{n}{2}/|D_1|$, have a collision under the projection h. Consequently, under the best of circumstances, the composition of h with a well-designed hash function on D_1 will only be able to achieve high degrees of independence with a probability of $1 - \binom{n}{2}/|D_1|$, since once two keys are mapped to the same value, any subsequent processing will preserve this equality. We will typically set $|D_1| \approx n^4$. With this understanding, we can focus on the design of hash functions defined on domains of reasonable size, and just revisit the issue of highly disparate domain sizes when establishing the corresponding lower bounds.

In addition to accommodating small percentages of faulty hash functions, this definition differs from the usual formulations by specifying two-sided constraints. This formulation (which becomes an equality when $\mu = 1$) is intended to support inclusion-exclusion arguments based on (κ)-wise independent hash functions. (In [22], for example, such a two-sided bound is essential.) As a practical matter, this additional constraint is not particularly burdensome. While most constructions of (κ, μ)-wise independent function classes have focused on one-sided constraints as typified by Definition 1.1, actual constructions, such as the polynomials $F_{(\kappa)}$ of (1.2), usually satisfy the more restrictive standard[2] of Definition 2.1.

2.1. Existence arguments. We now examine the problem of constructing families of (κ)-wise independent hash functions that map a domain $D = [0, m-1]$ into a range $R = [0, \rho - 1]$. The basic motivation for the approach comes from considering the following question. Imagine, for the moment, that $D = R$, and is of prime size. Then we can use κ random elements from D as coefficients in (1.2) to construct a (κ)-wise independent hash function. Evidently, evaluation requires $O(\kappa)$ time. If m random elements are provided, then table lookup gives an $O(1)$ time (m)-wise independent hash function. What sort of random functions can be constructed from m^ϵ random seeds?

For the purposes of this section, we will require that the underlying storage be sufficient to hold the random function code, including its random seeds. Our model of computation is the Random Access Machine, where both memory access and the basic arithmetic and logic operations can be executed on words in unit time (cf. [1, Chap. 1]). Each word will comprise $\lceil \log_2 \rho \rceil$ or possibly $\lceil \log_2 m \rceil$ bits.

We temporarily suppress the issue of program size and prove the existence of families of fast highly independent hash functions that map $[0, m-1]$ into $[0, \rho - 1]$ and use m^ϵ words of random input. We will also initially ignore all preprocessing and postprocessing steps as well as any concern associated with huge domains to study the problem of constructing fully $(\kappa, 1)$-wise independent hash functions that map $D = [0, m-1]$ into a suitable $R = [0, \rho - 1]$, given an auxiliary array of m^ϵ random words from R, for some[3] $\epsilon < 1$. Evidently, any random hash function must have a mechanism to associate each element in D with a few of these random words, as otherwise no random computation can result. If the association is not adaptive,[4] then it can be represented by a bipartite graph G on the vertex sets D and $D^\epsilon \equiv [0, m^\epsilon - 1]$. Such a bipartite graph must associate at least l random numbers with each set of l elements from D, for $l \leq \kappa$, as otherwise there are not enough degrees of freedom to achieve (κ)-wise independence. Suitable graphs are formalized as follows.

DEFINITION 2.2. *Let an* (m, ϵ, d, κ) local concentrator *be a bipartite graph on sets of vertices* I *(inputs) and* O *(outputs), where* $|I| = m$, $|O| = m^\epsilon$, *and the following hold. Each input has outdegree* d. *Every set of* j *inputs, for* $j \leq \kappa$, *has edges to some set of* j *or more outputs.*

Our next observation is that such graphs exist, even with very small outdegree d. From this narrow perspective, the parameter r is extraneous in the following lemma

[2]For some applications, the y_i of Definition 2.1 might be required to be distinct. Alternatively, the functions of (1.2) might include the additional term x^κ.

[3]We will avoid the clutter of floors and ceilings as long as possible, and assume that the exponent ϵ has been chosen to make the resulting expression such as m^ϵ an integer.

[4]The lower bound will include adaptive probing, where the location of the next random key to retrieve can depend on the value of other such data that has already been read. We discuss nonadaptive approaches because they are more intuitive, and explain all of our constructions, which turn out to be nonadaptive.

because the existence result holds for $r = 0$. However, by increasing r from 0 some positive quantity, a suitably structured random graph will be as described with a probability exceeding $1-m^{-rd}$, which can be with overwhelming likelihood as opposed to a probability exceeding zero. The same issue applies to the r in Lemma 2.9.

LEMMA 2.3. *Let d, κ, m, and m^ϵ be positive integers with $\epsilon < 1$. Suppose that $r \geq 0$ and $d \geq \frac{1+\epsilon+r}{\epsilon - \frac{\log \kappa}{\log m}}$. Let $G = (V, E)$ be a random bipartite graph with input vertices I, and output vertices O, where $|I| = m$ and $|O| = m^\epsilon$, and where each vertex in I has edges to d distinct randomly selected neighbors in O. Then with probability exceeding $1 - m^{-rd}$, G is an (m, ϵ, d, κ) local concentrator.*

Proof. We use standard probabilistic arguments (cf. [29]) to estimate the probability that G fails to have j outputs for some set of j inputs for $j \leq \kappa$. By construction, failure cannot occur for $j \leq d$. For larger aggregates of size at most κ, the probability of a failure is bounded by the expected number of pairs $(u \subset I, w \subset O)$, where $|u| = j$, $|w| = j-1$, and all jd edges from u have destinations within w for $d < j \leq \kappa$. Evidently, the probability that the jd edges are so selected, for any fixed (u, w), is

$$\left(\frac{\binom{j-1}{d}}{\binom{m^\epsilon}{d}}\right)^j < \left(\frac{j-1}{m^\epsilon}\right)^{jd}$$

(where the inequality is strict because $d > 1$). The number of candidate (u, w) pairs is just

$$\binom{m}{j}\binom{m^\epsilon}{j-1}.$$

Thus

$$\begin{aligned}
\text{Prob\{failure\}} &< \sum_{d<j\leq\kappa} \binom{m}{j}\binom{m^\epsilon}{j-1}\left(\frac{j-1}{m^\epsilon}\right)^{jd} \\
&< \sum_{d<j\leq\kappa} \frac{m^j m^{j\epsilon-\epsilon} j^{jd}}{j!(j-1)!m^{\epsilon jd}} \\
&< m^{-\epsilon} \sum_{d<j\leq\kappa} \frac{1}{j!(j-1)!}\frac{m^{j+j\epsilon}\kappa^{jd}}{m^{\epsilon jd}}.
\end{aligned}$$

Now, the constraint for d can be written as $m^{d\epsilon} \geq \kappa^d m^{1+\epsilon+r}$, whence $m^{-r} \geq \frac{\kappa^d m^{1+\epsilon}}{m^{d\epsilon}}$. Substituting gives

$$\begin{aligned}
\text{Prob\{failure\}} &< m^{-\epsilon} \sum_{d<j\leq\kappa} \frac{m^{-rj}}{j!(j-1)!} \\
&< m^{-rd}. \qquad \square
\end{aligned}$$

Setting $r = 0$, we see that a randomly constructed graph fails to be an (m, ϵ, d, κ) local concentrator with a probability that is less than 1. It follows that such a construction will succeed with positive probability, and hence these graphs do indeed exist.

We have, as yet, no hash function, but each element, at least, is now associated with a few random values. The obvious use for these values is as coefficients of a hashing polynomial. By increasing the number of random values used in this calculation, we can turn a local concentrator into a calculation procedure for $(\kappa, 1)$-wise independent hash functions.

Let G be an (m, ϵ, d, κ) local concentrator. Let p be prime. For each input i in G, let i's d neighbors in G be stored in the set $\mathrm{Adj}(i)$. Let M_w be an $m^\epsilon \times d$ array of words in $[0, p-1]$, whose concatenated contents are the very long word $w \in [0, p-1]^{m^\epsilon d}$.

Define the random hash function

$$f_w^G(i) = \left(\sum_{0 \le k < d} \sum_{j \in \mathrm{Adj}(i)} i^k M_w(j,k) \right) \bmod p.$$

Thus, computing $f_w^G(i)$ requires $d^2 - 1$ additions and $d-1$ multiplications plus a comparable number of modular divisions. The result turns out to be (κ)-wise independent when the concatenated contents of the storage array M_w are equally likely to be any value in $[0, p-1]^{dm^\epsilon}$.

THEOREM 2.4. *Let G be an (m, ϵ, d, κ) local concentrator. Then $\{f_w^G\}_{w \in [0, p-1]^{dm^\epsilon}}$ is a $(\kappa, 1)$-wise independent family of hash functions mapping $[0, m-1]$ into $[0, p-1]$.*

Proof. Let $x_1, x_2, \ldots, x_\kappa$ be any κ distinct values in $[0, m-1]$, and $y_1, y_2, \ldots, y_\kappa$ be κ arbitrary values in $[0, p-1]$. We must show that for all x and y assignments, there are exactly the same number of functions f_w that satisfy the system

$$f_w^G(x_i) = y_i \bmod p \quad \text{for } i = 1, 2, \ldots, \kappa. \tag{2.2}$$

Now the unknowns, in this system, are the word assignments to the array M_w, and the system is linear in these variables. The equations in (2.2) comprise κ constraints in dm^ϵ unknowns. So if the system enjoys linear independence, then the set of κ equations in (2.2) will have exactly $p^{dm^\epsilon - \kappa}$ different w words that are solutions, which ensures the precise uniformity required of (κ)-wise independence. It follows that we need only establish the linear independence of all systems defined in (2.2).

We prove the linear independence by contradiction. In the context of Lemma 2.3, $[0, m-1]$ plays the role of I, and $[0, m^\epsilon - 1]$ is O. The linear system $f_w^G(x_i) = y_i$ for $i = 0, 1, 2, \ldots, m-1$ has the explicit formulation

$$\sum_{k=0}^{d-1} (\mathcal{N})^k \times \mathcal{A} \times (M_{j,k})_{j \in O} = (y_0, y_1, \ldots, y_{m-1})^T \bmod p, \tag{2.3}$$

where $\mathcal{N}^k$ is the diagonal matrix with i^k in location (i, i), for $i = 0, 1, \ldots, m-1$ (with $\mathcal{N}^0$ set to the identity matrix), and $\mathcal{A} = (a_{i,j})_{i \in I,\, j \in O}$ is the adjacency matrix for G, which has m rows, m^ϵ columns, and d 1's in each row. The representation $(M_{j,k})_{j \in O}$ is intended to denote the kth of d column vectors, which each have $|O| = m^\epsilon$ rows. Taken together, they comprise the entries in the auxiliary array M of random words.

The proof will exploit the structural characteristic of G to establish the linear independence of any subsystem of $|I_0| \le \kappa$ equations for $I_0 \subset [0, m-1]$. Such subsystems can be written as follows:

$$\sum_{0 \le k < d} \sum_{j \in \mathrm{Adj}(i)} i^k M_w(j,k) = y_i \bmod p \quad \text{for } i \in I_0.$$

Let I_0 be a set of row indices in a subsystem of (2.3) that is linearly dependent and has no proper subset of equations that is linearly dependent. Suppose $|I_0| \le k$.

By definition, I_0, in the local concentrator, has $d|I_0|$ edges, which reach at least $|I_0|$ outputs. Let O_0 comprise the vertices adjacent to I_0 in G. Then the average number of edges received from I_0 by a vertex in O_0 is $d|I_0|/|O_0|$ which is at least 1 and at

most d, since $|I_0| \le O_0 \le d|I_0|$. By the pigeonhole principle, there must be an output $o \in O_0$ having exactly q edges that originate in I_0 for some q, where $1 \le q \le d$. Let I_1 be this set of neighbors of o in I_0: $I_1 = \{i \in I_0 : o \in \mathrm{Adj}(i)\}$. Let $I_1 = \{i_1, i_2, \ldots, i_q\}$, where $1 \le q \le d$. Now consider the linear subsystem with rows indexed by I_1 and columns restricted to the variables $M(o,k)$, where $k = 0, 1, \ldots, d-1$. This system comprises the following submatrix of a Vandermonde matrix:

$$\begin{pmatrix} 1 & i_1 & i_1^2 & \ldots & i_1^{d-1} \\ 1 & i_2 & i_2^2 & \ldots & i_2^{d-1} \\ \vdots & \vdots & \vdots & & \vdots \\ 1 & i_q & i_q^2 & \ldots & i_q^{d-1} \end{pmatrix}.$$

As is well known, such a subsystem cannot be linearly dependent since no two rows are the same, and $q \le d$. Since none of the rows with indices in $I_0 - I_1$ has any of the variables $M(o,0), M(o,1), \ldots, M(o,d-1)$ present (that is, they are present with coefficients of zero), the only way a linear combination of the rows can add to the zero vector is if each row in I_1 has a coefficient of zero. Thus, the assumption that the system is dependent and minimal is contradicted. □

So far, we have a probabilistic fast hashing procedure that is (κ)-wise independent, uses dm^ϵ random words of $\log p$ bits, and requires $\Theta(d^2)$ operations. The construction gives a generic transformation from a graph rich in matchings to a family of highly random functions. We now give a more efficient construction that makes better use of random graph properties. The graph will require an outdegree d that is slightly larger than before, but only one random value will be stored in each output destination. The construction uses a sparse bipartite graph where every set of κ rows of its adjacency matrix is linearly independent, and this independence even extends to computations over finite commutative groups such as the integers $\bmod \rho$ for any integer ρ.

Definition 2.5. *Let G be a bipartite graph on sets of vertices I (inputs) and O (outputs), where $|I| = m$, $|O| = m^\epsilon$. Let* $\mathrm{Adj}(i)$*, for $i \in I$, be the set of i's neighbors in O. We say that G is* (m, ϵ, d, κ) locally peelable *if each input node has an outdegree of at most d and the following holds: for any set I_0 of κ or fewer input vertices, some node in I_0 has a neighbor that is not a neighbor of any other node in I_0. Formally, for all $I_0 \subset I$, where $|I_0| \le \kappa$, there is an $i_0 \in I_0$ such that*

$$\mathrm{Adj}(i_0) - \bigcup_{i \in I_0 - \{i_0\}} \mathrm{Adj}(i) \neq \emptyset.$$

Lemma 2.6. *Let $D = [0, m-1]$, and $R = [0, \rho-1]$. Let $\bigoplus$ denote addition* $\bmod \rho$ *or any other commutative group operator that is closed over R. Let G be (m, ϵ, d, κ) locally peelable, with $\epsilon < 1$. For each input i in G, let i's neighbors in G be stored in the set* $\mathrm{Adj}(i)$*. Let M_w be an array of m^ϵ words from R, where the concatenated content of M_w comprises the very long word $w \in [0, \rho-1]^{m^\epsilon}$.*

Define the hash function

$$f_w^G(i) = \bigoplus_{j \in \mathrm{Adj}(i)} M_w(j) \quad \text{for } i \in D.$$

Then $\{f_w^G\}_{w \in [0, \rho-1]^{m^\epsilon}}$ is a $(\kappa, 1)$-wise independent family of hash functions mapping D into R.

Proof. Consider the subsystem (in unknowns w) $f_w^G(x_i) = y_i$, for $i = 1, 2, \ldots, \kappa$, which assigns κ values in R to κ distinct input vertices in D. Since the system is

locally peelable, it can be permuted into a system where the first κ columns comprise an upper triangular matrix with 1's along its diagonal. The first row corresponds to an input x_{i_0} reaching an output o_0 that is not a neighbor of any node in $\{x_i\}_{i=1}^{\kappa} - \{x_{i_0}\}$. The columns are permuted so that the first column corresponds to o_0. Then the same reordering is recursively applied to the remaining $\kappa - 1$ equations in unknowns $O - \{o_0\}$. Given such an upper triangular permutation of the system, there are $m^\epsilon - \kappa$ column variables that are not among the columns that contain the κ diagonal entries, and we are free to assign arbitrary values from R to these variables. Then the remaining κ variables will have a unique solution that can be found by back-solving via the $\bigoplus$ operator. Thus, the number of solutions to any κ such equations in the m^ϵ unknowns is exactly $\rho^{m^\epsilon - \kappa}$, which ensures that the f_w^G are $(\kappa, 1)$-wise independent. □

We now show that some random graphs are locally peelable.

DEFINITION 2.7. *Let an* (m, ϵ, d, κ) local expander *be a bipartite graph on sets of vertices I (inputs) and O (outputs), where $|I| = m$ and $|O| = m^\epsilon$, and the following hold. Each input has a positive outdegree bounded by d. Any set of j inputs, for $1 < j \le \kappa$, has edges to at least $\lfloor jd/2 \rfloor + 1$ different outputs.*

LEMMA 2.8. *An* (m, ϵ, d, κ) local expander *is* (m, ϵ, d, κ) *locally peelable.*

Proof. The proof is by contradiction. Suppose that I_0 is a smallest set of input variables that is not locally peelable. Obviously $|I_0| > 1$. Suppose $|I_0| \le \kappa$. By definition, the input variables of I_0 have at least $\lfloor jd/2 \rfloor + 1$ different output variables, which have, on average, at most $jd/(\lfloor jd/2 \rfloor + 1) < 2$ different input neighbors in I_0. By the pigeonhole principle, some output vertex o_0 must therefore have just one input neighbor i_0 in I_0. We peel off this input, and observe that the subgraph with $|I_0| - 1$ input variables is locally peelable, whence the supposition that $|I_o| \le \kappa$ must be false. □

As with Lemma 2.3, the following existence argument includes the parameter r to increase the likelihood of success from something positive to a probability overwhelmingly close to 1.

LEMMA 2.9. *Let d, κ, m, and m^ϵ be positive integers with $\epsilon < 1$. Suppose that $r \ge 0$ and $\epsilon > \frac{2+r}{d} + \frac{1+\ln \frac{d}{2} + \ln \kappa}{\ln m}$. Let $G = (V, E)$ be a random bipartite graph with input vertices I and output vertices O, where $|I| = m$ and $|O| = m^\epsilon$, and where each vertex in I has edges to d distinct randomly selected neighbors in O. Then with probability exceeding $1 - m^{-r}$, G is an (m, ϵ, d, κ) local expander.*

Proof. Rewriting the bound for ϵ gives $m^{\epsilon d/2} > m(\kappa de/2)^{d/2} m^{r/2}$, so that

$$\frac{m(jde/2)^{d/2}}{m^{\epsilon d/2}} < m^{-r/2} \quad \text{for } j \le \kappa. \tag{2.4}$$

Proceeding as in Lemma 2.3 gives the following estimates for the probability that G is not a local expander:

$$\begin{aligned} \text{Prob\{failure\}} &< \sum_{1<j\le\kappa} \binom{m}{j} \binom{m^\epsilon}{\lfloor jd/2 \rfloor} \left(\frac{\lfloor jd/2 \rfloor}{m^\epsilon} \right)^{jd} \\ &< \sum_{1<j\le\kappa} \frac{m^j m^{\epsilon jd/2} (\lfloor jd/2 \rfloor)^{jd}}{j! (\lfloor jd/2 \rfloor)! m^{\epsilon jd}}, \end{aligned}$$

whence approximating $(\lfloor jd/2 \rfloor)!$ via our two Stirling estimates (depending on the

parity of jd) and simplifying give

$$\text{Prob}\{\text{failure}\} < \sum_{2\le j\le\kappa} \left(\frac{m(jde/2)^{d/2}}{m^{\epsilon d/2}}\right)^j \frac{1}{j!}.$$

Applying (2.4) gives

$$\text{Prob}\{\text{failure}\} < \sum_{2\le j\le\kappa} m^{-rj/2}/j! < m^{-r}\sum_{2\le j}\frac{1}{j!} < m^{-r}. \qquad \square$$

Setting $r = 0$ shows that such a graph exists. Of course, actual use of this lemma will require that ϵ be less than 1, which requires that $d \ge 3$.

Combining Lemmas 2.6, 2.8, and 2.9 gives the following.

THEOREM 2.10. *Let d, κ, m, and m^ϵ be positive integers with $\epsilon < 1$. Suppose that $1 > \epsilon \ge \frac{2}{d} + \frac{1+\ln d+\ln\kappa}{\ln m}$. Let G be an (m,ϵ,d,κ) local expander. Let $\bigoplus$ define a commutative group over $[0,\rho-1]$. Let*

$$f_w^G(i) = \bigoplus_{j\in \text{Adj}(i)} M_w(j).$$

Then $\{f_w^G\}_{w\in[0,\rho-1]^{m^\epsilon}}$ is a $(\kappa,1)$-wise independent family of hash functions mapping $[0,m-1]$ into $[0,\rho-1]$.

Proof. Lemma 2.9 ensures that G exists, when $\epsilon \ge \frac{2}{d} + \frac{1+\ln d+\ln\kappa}{\ln m}$. Lemma 2.8 ensures that G is (m,ϵ,d,κ) locally peelable. Lemma 2.6 shows that $\{f_w^G\}_{w\in[0,\rho-1]^{m^\epsilon}}$ is $(\kappa,1)$-wise independent. $\square$

In particular, $\bigoplus$ can be addition modρ, or $\bigoplus$ can be the bitwise exclusive-or operator, where ρ is power of 2 and the integers in $[0,\rho-1]$ are regarded as binary strings of length $\log\rho$.

It is worth observing that the m^ϵ-word seeds w as used in Theorem 2.10 can be produced by random members of a universal class H of $(d\kappa,\mu)$-wise independent hash functions.

COROLLARY 2.11. *Let H be a universal class of $(d\kappa,\mu)$-wise independent hash functions that map $[0,m^\epsilon-1]$ into $[0,\rho-1]$. For $h\in H$, let w_h be the concatenation of $h(0),h(1),\ldots,h(m^\epsilon-1)$. Then the family $\{f_{w_h}^G\}_{h\in H}$ is (κ,μ)-wise independent.*

Proof. Observe that each set of range assignments to a κ-tuple of elements in D induces a (locally peelable) linear system of κ equations in at most $d\kappa$ index locations (i.e., variables) of the auxiliary array M. We can extend the set to include exactly $d\kappa$ such variables. Then the solution set can be represented by $\rho^{d\kappa-\kappa}$ different $d\kappa$-tuple assignments for this collection. So if each assignment occurs with probability $\rho^{-d\kappa}$, then the resulting functions will be $(\kappa,1)$-wise independent by Theorem 2.10. If each tuple of $d\kappa$ assignments has a probability of occurrence that is reweighted by a factor of $\mu\in[\mu_1,\mu_2]$, then the resulting aggregate probability that F computes the prespecified κ-tuple of range assignments is likewise reweighted by a factor that is within this interval. $\square$

Consequently, the space-time tradeoff, for families of fast highly independent hash functions, is not a function of the number of random seeds that must be specified (which is just $\Theta(\kappa)$) but is really a matter of intrinsic storage requirements for the auxiliary storage array M.

Although the second construction gives a more efficient family of hash functions and also provides a generic procedure that turns a good graph into a family of hash

functions, it does not quite supersede the first construction because there are no known explicit graphs of either type. Should a short (deterministic or effective probabilistic) algorithm be found to define local concentrators where an input's adjacency list can be generated from a small number of instructions, then fast, highly independent hash functions will follow. Similarly, effective procedures for constructing local expanders will yield even better hash functions.

2.2. Asymptotically compact constructions and their randomization. From a positive perspective, we have proven that one good graph is all we need: the contents of the auxiliary random seed array M defines the different members in the associated family of hash functions. Furthermore, we have shown that good graphs not only exist, but can even be formulated so that randomized constructions can build them with very high likelihood.

Unfortunately, no deterministically defined graph has been proven, as yet, to satisfy either expander-like formulation. We now show that from a theoretical perspective where impractical constants might be tolerated, there are asymptotically spatially compact programmable formulations of constant-time (n^ϵ)-wise independent hash functions. In particular, we will show that Cartesian products can be used to obtain compact representations of (wildly) less efficient hash functions, where we forgo some randomness and increase the $O(1)$ operation count by an exponentially larger constant, but reduce the overall storage requirements to $O(n^\epsilon)$ for suitable $\epsilon < 1$. These variations can be applied to either of our nonconstructive formulations, but we will focus on those built from locally peelable graphs, since they appear to be more efficient.

The first step is to show that such compact representations exist. The second is to observe that simple changes in the random constructions yield locally peelable graphs with a high probability, so that the graph itself can be part of the random seed specification. The result will be a uniform r-practical family where a good graph need not be found. Instead, the initializing random seeds will include values to define G. As a consequence, an asymptotically negligible fraction of these implicitly defined graphs will fail to have the necessary expander-like properties.

DEFINITION 2.12. *Let the* Cartesian product $G \bigotimes H$ *of two bipartite graphs* $G = (I, O; E)$ *and* $H = (J, Q; F)$ *be the graph* $\mathcal{G} = (\mathcal{I}, \mathcal{O}; \mathcal{E})$*, with input vertex set* $\mathcal{I} = I \times J$*, output set* $\mathcal{O} = O \times Q$*, and edge set* $\mathcal{E}$*, which contains the edge from* $(i, j) \in \mathcal{I}$ *to* $(o, q) \in \mathcal{O}$ *if and only if* $\text{edge}(i, o) \in E$ *and* $\text{edge}(j, q) \in F$.

LEMMA 2.13. *Let* $G = (I, O; E)$ *be* (m, ϵ, d, κ) *locally peelable, and* $H = (J, Q; F)$ *be* (n, ϵ, c, κ) *locally peelable. Then the Cartesian product* $G \bigotimes H$ *is* $(mn, \epsilon, cd, \kappa)$ *locally peelable.*

Proof. We need only verify the local peelability property for $G \bigotimes H$. The proof is by contradiction. Let X be a smallest set of input variables for $G \bigotimes H$ that is not locally peelable. Obviously $|X| > 1$. Suppose $|X| \leq \kappa$. Let $I_G = \{i \mid \exists j : (i, j) \in X\}$. Now $|I_G| \leq \kappa$, and hence there is an $\hat{\imath} \in I_G$ with a neighbor o_1 that is not a neighbor of any node in $I_G - \{\hat{\imath}\}$. Now let $J_G = \{j \mid \exists j : (\hat{\imath}, j) \in X\}$, and let $\ell = |J_G|$. By definition, J_G is locally peelable in H. So let $q_1, q_2, \ldots, q_\ell$ be a sequence of outputs peeled one-by-one in order from J_G. It is easy to see that $(o_1, q_1), (o_1, q_2), \ldots, (o_1, q_\ell)$ now gives a comparable peeling for $\{o_1 \times J_G\}$ in X. But then the remaining $|X| - \ell$ variables (if any) are by assumption locally peelable, whence the supposition that there is a subgraph with at most κ input vertices that is not locally peelable must be false. ∎

Consequently, if G is an $(m^\epsilon, \epsilon_1, d, \kappa)$ local expander, then applying Lemma 2.13 a

total of $c = \lceil \frac{1}{\epsilon_1} \rceil - 1$ times shows that the Cartesian product $\bigotimes_{j=1}^{\lceil 1/\epsilon \rceil} G$ is $(m^{c\epsilon}, \epsilon_1, d^c, \kappa)$ locally peelable.

Lemma 2.13 plus the constructions of Theorem 2.10 establishes the following.

THEOREM 2.14. *Let the positive integers m, m^ϵ, κ, d, and ρ be specified with $m > \rho$, and suppose that $\frac{1}{2} \geq \frac{\epsilon}{2} \geq \frac{2}{d} + \frac{1+\ln d + \ln \kappa}{\epsilon \ln m}$, and $m^{\epsilon^2/2} > \frac{1}{\epsilon}$. Let $c = \lceil \frac{1}{\epsilon} \rceil$ and set $\epsilon_1 = \frac{\log \lceil m^{\epsilon/c} \rceil}{\epsilon \log m}$. Let $\mathcal{G}$ be the set of all graphs $G = (V, E)$ that are bipartite with m^ϵ input vertices and $m^{\epsilon_1 \epsilon}$ output vertices, and where each input vertex has edges to d distinct neighbors among the outputs. Then the following holds.*

There is a $G \in \mathcal{G}$ that is $(m^{c\epsilon}, \epsilon_1, d^c, \kappa)$ locally peelable.

Let $\widehat{G} = \bigotimes_{i=1}^{c} G$. The set $\{f_w^{\widehat{G}}\}_{w \in [0, \rho-1]^{m^{\epsilon_1 \epsilon}}}$ is a universal class of $(\kappa, 1)$-wise independent hash functions that map $[0, m-1]$ into $[0, \rho - 1]$.

The program for $f_w^{\widehat{G}}$ comprises $O(\epsilon^2 d) m^\epsilon \log m$ bits and computes a hash value by retrieving no more than $d^{1+1/\epsilon}$ words from an auxiliary storage array of $O(m^\epsilon)$ random words in $[0, \rho - 1]$.

Proof. Lemma 2.9 establishes the existence of a suitable G. Programmatically, G will be stored and used as part of the hash function. A value $i \in [0, m-1]$ is hashed by computing the adjacency list for i in the implicitly defined $\widehat{G} \equiv \bigotimes_{j=1}^{c} G$. Given the local peelability of G, Lemma 2.13 shows that $\widehat{G}$ is $(m^{c\epsilon}, \epsilon_1, d^c, \kappa)$ locally peelable, which is adequate for use in Theorem 2.10, since $c\epsilon > 1$.

It is not difficult to verify that all parameter sizes are as stated. In particular, there are three issues: the local peelability of G, the size of the auxiliary array, and the outdegree of each vertex in $\widehat{G}$.

Parameter ϵ_1 satisfies $\frac{1}{c} \leq \epsilon_1$. By construction, $c < \frac{1}{\epsilon} + 1$, whence $\frac{1}{c} > \frac{\epsilon}{1+\epsilon} > \frac{\epsilon}{2}$. Hence $\frac{\epsilon}{2} < \frac{\epsilon}{1+\epsilon} < \epsilon_1$, so ϵ_1 satisfies the local peelability inequality of Lemma 2.9 since $\frac{\epsilon}{2}$ does.

By definition,

$$\epsilon_1 = \frac{\ln \lceil m^{\epsilon/c} \rceil}{\epsilon \ln m} < \frac{\ln(m^{\epsilon/c} + 1)}{\epsilon \ln m} = \frac{1}{c} + \frac{\ln(1 + m^{-\epsilon/c})}{\epsilon \ln m} < \frac{1}{c} + \frac{m^{-\epsilon/c}}{\epsilon \ln m} \leq \frac{1}{c} + \frac{m^{-\epsilon^2/2}}{\epsilon \ln m}.$$

Now, $m^{\epsilon^2/2} \geq \frac{1}{\epsilon}$, so $\epsilon_1 - \frac{1}{c} < \frac{1}{\ln m}$. Consequently, the word count for the auxiliary array is

$$m^{\epsilon \epsilon_1 c} = m^{\epsilon(\epsilon_1 - 1/c + 1/c)c} \leq m^\epsilon m^{\frac{\epsilon c}{\ln m}} = m^\epsilon (m^{\frac{1}{\ln m}})^{c\epsilon} = m^\epsilon e^{\epsilon c} < m^\epsilon e^2.$$

The outdegree is $d^c < d^{\frac{1}{\epsilon}+1}$.

Thus, the hash function has three parts. One part comprises the array M of $m^{c\epsilon\epsilon_1} = O(m^\epsilon)$ random words from $[0, p-1]$, which requires $O(m^\epsilon \log p)$ bits. Another stores the graph G, which requires m^ϵ strings of d words that are each $O(\log(m^{\epsilon^2}))$ bits long. The requisite storage for G (i.e., part 2) is, therefore, $O(\epsilon^2 d m^\epsilon \log m)$ bits. The third part of the function is the finite program that uses G and M to evaluate the hash function for an element in $[0, m-1]$. ∎

Remarks. Theorem 2.14 can be used with m replaced by n^k, ϵ replaced by ϵ/k, κ replaced by n^δ, and d unchanged. The inequality for ϵ then becomes

$$\frac{\epsilon}{2k} \geq \frac{2}{d} + \frac{1 + \ln d + \delta \ln n}{\epsilon \ln n}, \tag{2.5}$$

which we can write as $\epsilon \geq \frac{4k}{d} + 2k \frac{1+\ln d + \delta \ln n}{\epsilon \ln n}$. Upon applying the simplification $\epsilon > a + \sqrt{b}$ implies $\epsilon \geq a + b/\epsilon$, we can conclude that the requirement for ϵ is met if

$\epsilon \geq \frac{4k}{d} + \sqrt{2k(\delta + \frac{1+\ln d}{\ln n})}$. The corresponding hash functions can be evaluated with $O(d^{k/\epsilon})$ operations, and have a program size of $O(n^\epsilon)$ words. It is worth pointing out that (2.5) can permit ϵ to be any sufficiently small positive constant provided, say, $d > 12k/\epsilon$, $\delta < \epsilon/6$, $n > d^{6/\epsilon}$, and $n^{k\epsilon^2/2} > \frac{1}{\epsilon}$. The resulting functions are $(n^{\epsilon/6}, 1)$-wise independent.

For completeness, we state without proof the analogous compaction/expansion formulation for local concentrators.

LEMMA 2.15. *Let G be an $(m^\epsilon, \epsilon, d, \kappa)$ local concentrator. Then the Cartesian product $\bigotimes_{j=1}^{1/\epsilon} G$ is an $(m, \epsilon, d^{1/\epsilon}, \kappa)$ local concentrator.*

So far, families of hash functions mapping D into R have been "demonstrated" only in a probabilistic sense; no explicit constructions have been given. However, by increasing, slightly, the degrees of freedom in our probabilistic constructions, the same counting arguments ensure that with probability $1 - \frac{1}{|R|^r}$, a randomly selected graph is a local concentrator or expander. Consequently, we can include, in the initial seeding, enough random data to build a local expander as well as the array of random words it will be used to access. The graph will not be prohibitively large if it defines a compact version as formulated in Theorem 2.14 and adapted in (2.5). The only necessary accommodation is to keep the probability of failure appropriately tiny in the rescaled parameters, which can be done by increasing r by a factor of $\frac{1}{\epsilon}$. The resulting randomized construction $F_M^{G(m,\epsilon,d)}$ is an explicit family of $O(1)$ time hash functions that is uniformly r-practical (κ)-wise independent as characterized by Definition 2.1. Last, it is worth pointing out that the graph structure suggests that the number of initializing random seeds need not change by more than a constant factor; it is sufficient to build G from pseudorandom numbers generated from a traditional $(\kappa d^{k/\epsilon})$-wise independent hash function. To see that this is so, it suffices to observe that the proof of Lemma 2.9 was based on expectations of disjunctions of atomic events comprising the conjunction of $d\kappa$ random edge assignments.

These observations are formalized in the following theorem, where the bipartite graph G is just a collection of $(\kappa d^{k/\epsilon})$-wise independent pseudorandom numbers. A simple algorithm to process this graph and compute the actual hash function it encodes is presented after Theorem 2.16. The construction is randomized and asymptotically compact.

THEOREM 2.16. *Let the positive integers n, k, n^ϵ, κ, d, ρ, and r be specified, and suppose that $\frac{\epsilon}{k+1} \geq \frac{2}{d} + \frac{r}{d\epsilon} + \frac{1+\ln d+\ln\kappa}{\epsilon \ln n}$. Let $c = \lceil \frac{k}{\epsilon} \rceil$ and set $\epsilon_1 = \frac{\log\lceil n^{\epsilon/c}\rceil}{\epsilon \log n}$. Suppose that $\epsilon < \frac{k}{k+1}$ and $n^{\epsilon^2/(k+1)} > \frac{1}{\epsilon}$. Let $\mathcal{G}(d, \kappa d^{kc})$ be a set of pseudorandomly generated bipartite graphs with n^ϵ input vertices and $n^{\epsilon\epsilon_1}$ output vertices and where each vertex has edges to d distinct randomly selected neighbors, and let these d-tuple assignments of neighbors be (κd^{kc-1})-wise independent. Let M be a collection of long words that are the concatenation of (κd^{kc})-wise independent sequences of $n^{\epsilon\epsilon_1 c}$ words that individually belong to $[0, \rho - 1]$. For any $G \in \mathcal{G}(d, \kappa d^{kc})$, let $\widehat{G} = \bigotimes_{i=1}^{ck} G$. Given $w \in M$ and $G \in \mathcal{G}$, let f_w^G be the hash function defined by $f_w^{\widehat{G}}$ as in Lemma 2.6. Let $F_M^{\mathcal{G}} = \{f_w^G\}_{w \in M,\, G \in \mathcal{G}}$.*

Then $F_M^{\mathcal{G}}$ is an explicit family of uniformly r-practical $(\kappa, 1)$-wise independent hash functions that map $[0, n^k - 1]$ into $[0, \rho - 1]$. Furthermore, each $w \in M$ comprises $|w| = n^{\epsilon\epsilon_1 c} \leq e^{k+1} n^\epsilon$ words from $[0, \rho - 1]$. The long words in M can be generated from κd^{kc} random seeds that belong to $[0, \rho - 1]$. Each $G \in \mathcal{G}$ can be stored as a sequence of n^ϵ words of $O(\frac{\epsilon^2}{k} \log n)$ bits, and can be generated from (κd^{kc}) random seeds that

are evenly distributed among the ranges $[0, n^{\epsilon\epsilon_1} - 1], [0, n^{\epsilon\epsilon_1} - 2], \ldots, [0, n^{\epsilon\epsilon_1} - d]$. *The probability that a specific* $F_*^{\widehat{G}}$ *fails to be* $(\kappa, 1)$*-wise independent is bounded by* n^{-r}.

Proof. The arguments are just a combination of the reasoning given in Lemma 2.9, the rescaling listed in (2.5), and, mutatis mutandis, the calculations given in the proof of Theorem 2.14.

However, a few comments should be made about how to generate the two tables of pseudorandom data. One potential difficulty is that we need, at initialization time, a small (traditional) hash function to expand some count σ of truly random seeds into a much larger collection of n^δ pseudorandom seeds belonging to $[0, \rho - 1]$, even when $[0, \rho - 1]$ cannot define a finite field. Perhaps the mathematically cleanest solution is to factor ρ into its product of powers of distinct primes, and use a (κd^{ck})-wise independent hash function over each of these fields. Then the Chinese remainder theorem can be used to reconstruct the comparably random $(\kappa d^{kc}, 1)$-wise independent pseudorandom seeds as needed.

Last, we note that straightforward encoding suffices to transform tuples of random values into distinct random values. □

The first requirement for ϵ is satisfied if $\epsilon \geq \frac{2(k+1)}{d} + \sqrt{(k+1)(\frac{r}{d} + \frac{1+\ln d + \ln \kappa}{\ln n})}$.

For applications of Theorem 2.16, a new hash function family (which might have to be found in case $F_*^{\widehat{G}}$ fails to be $(\kappa, 1)$-wise independent) would include new seeds to select a new pseudorandom graph $G \in \mathcal{G}$ as well as new pseudorandom seeds to select a new $w \in M$.

For completeness, this subsection closes with a rather crudely transparent iterative version of the hashing algorithm. The treatment of $\frac{1}{\epsilon}$ and related algebraic expressions as if they were integers is for conceptual transparency and lack of clutter.

function Hash(i: in $[0, n^k - 1]$): in $[0, n^k - 1]$;
  Global M: array of n^ϵ words in $[0, \rho - 1]$;
  Global G: $n^\epsilon \times d$ array of words in $[0, n^{\epsilon^2/k} - 1]$;
  Local $l_1, l_2, \ldots, l_{k/\epsilon}$: in $[0, d - 1]$;
  Local $i_1, i_2, \ldots, i_{k/\epsilon}$: in $[0, n^\epsilon - 1]$;
  Local j: in $[0, n^\epsilon - 1]$;
  Local val: in $[0, n^k - 1]$;
  $val \leftarrow 0$;

  endallfors; {Altogether, $d^{k/\epsilon}$ $\bigoplus$'s take place.}
return(val).

3. Lower bounds. We now show that the size of our random word array cannot be materially reduced without affecting the running time of the hash function. A family of (κ, μ)-wise independent hash functions $F_M = \{f_m(x)\}_{m \in M}$, where $f_m : D \rightarrow R$, will be modeled as follows. Each f_m is defined by the same algorithm, which inputs x and then reads d locations in an array $A[1..z]$ that contains z values belonging to R. The index m is a very long word comprising the concatenated data contained in A. We can suppose that each computation of f examines exactly d

entries in A. The randomness in the system comes from the choice of input seed strings $m \in M \subseteq R^z$. The set M need not contain all possible sequences of z words from R and can be a multiset, which means that some strings could have several copies present in M. More generally, each $m \in M$ could be assigned a positive real weight, and an element in M could be selected with a probability equal to its fraction of the total weight in M. Although our proof extends directly to cover this case, we will simply assume that all strings are equally likely to be selected. This avoids unnecessary clutter by keeping the lower bound restricted to a more manageable six parameters.

The algorithm can even be viewed as adaptive since we allow a key x to be hashed by a scheme that, for $j = 0, 1, \ldots, d-1$, uses x and the first j values found in A to determine which A location to read for the $(j+1)$st value. In any case, x and the retrieved array values are then used deterministically to compute the random function value in R.

The forthcoming lower bound argument will exploit the following independence constraint. Let $X = \{x_1, x_2, \ldots, x_\kappa\}$ be a set of κ keys in D, and let, for $j = 1, 2, \ldots, \kappa$, the sequence of seed values read to compute $f_M(x_j)$ be $s_{j,1}, s_{j,2}, \ldots, s_{j,d}$. Then the hashing of X, over all possible seed strings in M, cannot cause the same fixed sequence of κd seed values to be read with a probability that exceeds $\frac{\mu}{|R|^\kappa}$, since X would otherwise be mapped into the same κ-tuple with a probability that is too high. Since the determination of the sequence of seed locations can be adaptive, we are obliged to formulate the proof with respect to the triples $(\zeta, M_i^\zeta, D(\zeta, i))$, where ζ is a subset of $\kappa - 1$ locations in the seed array A, i is a string that can result from concatenating the seed values in ζ, M_i^ζ is the subset of seed data sets $m \in M$ for which the concatenation of the seed values on ζ is i, and $D(\zeta, i)$ is the subset of keys in D that are hashed by seeds read solely from ζ, when the seed data is restricted to M_i^ζ. Given these triples, the proof proceeds by summing their respective weights and bounding the respective sums. Bounds are attained by selecting the "good" triples, where $|M_i^\zeta|$ is large enough to ensure that $|D(\zeta, i)| < \kappa$. The lower bound quantifies the intuition that if most $|D(\zeta, i)|$ are small, then A must be big.

THEOREM 3.1. *Let $F_M = \{f_m\}_{m \in M}$ denote a family of (κ, μ)-wise independent hash functions mapping D into R, where $M \subseteq R^z$. Then the number of probes T that must be used to evaluate $f \in F_M$ satisfies either $T \geq \kappa$ or*

$$z^{\frac{T}{}} > (\kappa - 2)^{\frac{T-1}{}} |D| \left(1 - \frac{\mu}{|R|}\right).$$

Proof. Let every evaluation of f examine exactly d entries in the array A. We show that d satisfies the constraint for T. We can also suppose that $\mu < |R|$ as otherwise there is nothing to prove.

For each set ζ of $\kappa - 1$ locations in the z-element array A, let the locations in ζ be sorted by the value of their indices in A, so that each ζ has a fixed sequencing for the values stored in its locations. Then any string $m \in M$ will have, on its restriction to ζ, $\kappa - 1$ values in a fixed order. We can view the concatenation of this subsequence as a number in $[0, |R|^{\kappa-1} - 1]$, so that any such ζ defines an implicit projection of any $m \in M$ into $[0, |R|^{\kappa-1} - 1]$. Given ζ, let M be partitioned into $M^\zeta = \langle M_1^\zeta, M_2^\zeta, \ldots, M_{|R|^{\kappa-1}}^\zeta \rangle$, where M_i^ζ is the set of strings in M that have projections equal, on ζ, to the value $i \in [0, |R|^{\kappa-1} - 1]$. Let $D(\zeta, i)$ be the set of domain elements $x \in D$ that, when computing $f_m(x)$ for $m \in M_i^\zeta$, have their d A-locations read from

within ζ. Let

$$D_0(\zeta,i)=\begin{cases}D(\zeta,i), & \text{provided } |M_i^\zeta|>\mu|M|/|R|^\kappa,\\ \emptyset & \text{if } |M_i^\zeta|\le\mu|M|/|R|^\kappa.\end{cases} \tag{3.1}$$

Given an $x\in D(\zeta,i)$, $f_m(x)$ will be computed by probing the same d-tuple of locations within ζ for all $m\in M_i^\zeta$. It follows that $|D_0(\zeta,i)|<\kappa$ since otherwise there are κ elements in D that hash to some κ-tuple of values in R with a probability that exceeds $\mu/|R|^\kappa$.

There are $\binom{z}{\kappa-1}$ subsets ζ, and each subset induces a partition of M indexed by the m-values restricted to ζ. Let $\Sigma=\sum_\zeta\sum_i|M_i^\zeta||D(\zeta,i)|$, and likewise define the slightly more restricted form $\Sigma_0=\sum_\zeta\sum_i|M_i^\zeta||D_0(\zeta,i)|$. Since $|D_0(\zeta,i)|<\kappa$, $\Sigma_0\le\sum_\zeta\sum_i(\kappa-1)|M_i^\zeta|=\sum_\zeta(\kappa-1)|M|$, whence

$$\Sigma_0\le(\kappa-1)\binom{z}{\kappa-1}|M|. \tag{3.2}$$

On the other hand, Σ has an alternative description, which gives a precise combinatorial formulation. Let $D^+(\zeta,i)$ be the set of pairs (m,x), with $x\in D$ and $m\in M$, such that, when computing $f_m(x)$ for $m\in M_i^\zeta$, all d probes to A-locations lie within ζ. By definition, $|D^+(\zeta,i)|=|M_i^\zeta||D(\zeta,i)|$. Furthermore, since the probing for x uses exactly d locations, each pair (m,x) is counted in exactly $\binom{z-d}{\kappa-1-d}$ different $D^+(\zeta,i)$. Hence

$$\Sigma=\binom{z-d}{\kappa-1-d}|D||M|. \tag{3.3}$$

Finally, the hashing of an $x\in D$ uses d probes that retrieve d specific values in a fixed order from d locations in A. There are at most $|R|^d$ different sequences that can be retrieved, and each sequence corresponds to d distinct locations (since the program need not reread a location when hashing an individual key). Consequently, for a given key x, each possible probe data tuple in R^d could correspond to a specific sequence of d probe locations in A, which can belong to at most $\binom{z-d}{\kappa-1-d}$ different ζ sets, which would have $\kappa-1-d$ unprobed locations that could have up to $|R|^{\kappa-1-d}$ different assignments. Thus, any $x\in D$ belongs to at most $|R|^d\binom{z-d}{\kappa-1-d}|R|^{\kappa-1-d}$ different $D(\zeta,i)$. Hence

$$\Sigma_\zeta\Sigma_i|D(\zeta,i)|\le|D|\binom{z-d}{\kappa-1-d}|R|^{\kappa-1}. \tag{3.4}$$

From (3.1) and the definitions for Σ and Σ_0, we can count that

$$\Sigma-\Sigma_0\le\Sigma_\zeta\Sigma_i\frac{\mu|M|}{|R|^\kappa}|D(\zeta,i)|=\frac{\mu|M|}{|R|^\kappa}\Sigma_\zeta\Sigma_i|D(\zeta,i)|. \tag{3.5}$$

Applying (3.4) to (3.5) shows that $\Sigma-\Sigma_0\le\frac{\mu|M|}{|R|^\kappa}|D|\binom{z-d}{\kappa-1-d}|R|^{\kappa-1}$, whence

$$\Sigma-\Sigma_0\le\binom{z-d}{\kappa-1-d}\mu|M|\frac{|D|}{|R|}. \tag{3.6}$$

Combining (3.3) and inequality (3.6) gives

$$\Sigma_0 \geq \binom{z-d}{\kappa-1-d}|M||D|\left(1-\frac{\mu}{|R|}\right). \tag{3.7}$$

We remark that (3.7) cannot hold as an equality. Indeed, suppose that it did. Then (3.6) and the first inequality in (3.5) would hold as equalities. But if (3.5) were an equality, then $D_0(\zeta,i)$ would have to be the empty set for all i and ζ, since the definitions of $D(\zeta,i)$ and $D_0(\zeta,i)$ ensure that $|M_i^\zeta|(|D(\zeta,i)|-|D_0(\zeta,i)|) \leq \frac{\mu|M|}{|R|^k}|D(\zeta,i)|$, and equality can occur only if $|D_0(\zeta,i)|=0$. So if (3.5) is an equality, then Σ_0 must be zero, which contradicts (3.7), since $\mu<|R|$, $d<\kappa$, and $z\geq\kappa$. Hence

$$\Sigma_0 > \binom{z-d}{\kappa-1-d}|M||D|\left(1-\frac{\mu}{|R|}\right). \tag{3.8}$$

Combining inequalities (3.2) and (3.8) gives

$$(\kappa-1)\binom{z}{\kappa-1}|M| > \binom{z-d}{\kappa-1-d}|M||D|\left(1-\frac{\mu}{|R|}\right).$$

Eliminating common factors establishes that

$$\frac{z^{\underline{d}}}{(\kappa-2)^{\underline{d-1}}} > |D|\left(1-\frac{\mu}{|R|}\right). \qquad \square \tag{3.9}$$

The derivation of (3.9) is valid only if $d<\kappa$, but it is nevertheless reassuring to observe that if we (unjustifiably) set d to κ in the inequality $z^{\underline{d}} > (\kappa-2)^{\underline{d-1}}|D|(1-\frac{\mu}{|R|})$, then the resulting expression collapses to the requirement $z^{\underline{\kappa}}>0$, which is to say that $z\geq\kappa$. Of course κ random numbers are necessary and sufficient, in this trivial case.

There are more significant conclusions to be drawn from Theorem 3.1 and its relationship to Theorem 2.10. These observations are deferred to section 4. Meanwhile, we close this section with two immediate corollaries.

The counting argument for Theorem 3.1 also gives an average case time bound.

COROLLARY 3.2. *Let z, D, and R be fixed. Let $F_M=\{f_m\}_{m\in M}$ denote a family of (κ,μ)-wise independent hash functions mapping D into R, where $M\subseteq R^z$ is the collection of z-word auxiliary array data used to evaluate functions in F_M. Suppose that $\mu\leq|R|/2$. Let T be a lower bound for the worst-case count of the number of probes to the array data that must be used to evaluate some function in any such F_M. Let $\overline{T}$ be the average probe count for any such family, which is averaged over all of D and all of F_M.*

Then $\overline{T}\geq T-\frac{2}{|D|}(\frac{z^{\underline{T-1}}}{(\kappa-2)^{\underline{T-2}}}+\frac{z^{\underline{T-2}}}{(\kappa-2)^{\underline{T-3}}}+\cdots+z)$, which can be expressed as $\overline{T}\geq T-o(1)$ when $z>c\kappa$ for fixed $c>1$.

Proof. The proof is generic. Let Δ_h be the size of the largest domain that can be serviced by a (κ,μ)-wise independent hash function that maps Δ_h into R and uses h probes or less. Let T be a lower bound for the number of probes that are necessary, in the worst case, for a (κ,μ)-wise independent function that services D. Then a lower bound for the total number of probes necessary to service all of D is $|D|T-|\Delta_{T-1}|-|\Delta_{T-2}|-\cdots-|\Delta_1|$, since the negative terms comprise overcorrections for the numbers of probes that are miscounted by the principal term $|D|T$. The

result now follows from Theorem 3.1—which says that $\frac{1}{2}\Delta_d < \frac{z^{\frac{d}{}}}{(\kappa-2)^{\frac{d-1}{}}}$, provided $\mu \leq |R|/2$—and from division by $|D|$. □

Of course Theorem 3.1 also gives an admissible estimate to use for T.

Theorem 3.1 suggests that T has a very mild dependence on the parameter μ, and our constructions have typically allowed μ to remain at 1. On the other hand, it is worth noticing that the lower bound exhibits a far greater dependence on $|D|$, which could be dramatically larger than $|R|$. In such cases, we can use a simple, randomly chosen linear congruence (cf. F_0^k in the appendix) to premap $|D|$ into, say, R^4, whence the resource requirements dictated by Theorem 3.1 would depend on $|R|^4$ rather than $|D|$. Thus there is a significant benefit, in some cases, in allowing an asymptotically negligible fraction of hash functions to be defective, due to distinct data values colliding at the premapping stage. Corollary 3.2 proves that unless this possibility of failure is permitted, the storage requirement for the family will be of size $|D|^\delta$ for some suitable $\delta < 1$, instead of $|R|^\delta$.

Finally, it is worth observing that Theorem 3.1 can be used quite simply to give a moderately satisfactory lower bound for the running time of r-practical hash functions, where this prehashing step is used to reduce the effective size of the domain.

COROLLARY 3.3. *Suppose $|D| \gg |R|^{r/2}$, and let F be a family of hash functions F with domain D and range R that is r-practical (κ, μ)-wise independent. Then*

$$z^{\frac{T}{}} > (\kappa-2)^{\frac{T-1}{}} \frac{|R|^{r/2}}{2}\left(1 - \frac{\mu}{|R|}\right).$$

Proof. The inequality follows as a straightforward application of Theorem 3.1. □

Although the exponent $r/2$ in this bound is surely too small by a factor of 2, its influence on the probe count T is still fairly acceptable. Notice that if the data can be examined during the function selection stage, then the prehashing step can be made one to one, and Theorem 3.1 will be applicable with D replaced by the reduced domain. The resulting function family, in this case, can then be $(\kappa, 1)$-wise independent without appealing to r-practicality.

4. A space-time tradeoff and problem equivalence. We have already observed the dramatic change in the requirements for z when d, the number of random seeds read per hash function evaluation, drops from κ to $\kappa - 1$. However, the lower bound in Theorem 3.1 requires some effort to decode. Suppose that $\mu < |R|/2$ and $\kappa > 3$. We can weaken (3.9) to the statement $z^d > |D|$. Let $|D| = n^k$ and $z = n^\epsilon$. It follows that $d > \frac{k}{\epsilon}$ is a necessary condition for d.

Theorem 2.10 gives a matching sufficiency result. With the same domain and array size parameters as above, the formulation reads

$$\epsilon \geq \frac{2k}{d} + \frac{1 + \ln d + \ln \kappa}{\ln n}.$$

We can require that $\ln n \gg \ln \kappa$ and view the last term as insignificant. In this case, the number of probes to the auxiliary array of z random words that is necessary per evaluation of a (κ)-wise independent hash function that maps $[0, n^k - 1]$ into $[0, n^\ell - 1]$ satisfies

$$d = \Theta(k/\epsilon) \quad \text{for } d < \kappa.$$

Restated, we have a time-log(space) tradeoff: $d \times \log(CacheSize) \geq \log(DomainSize)$, where $CacheSize$ is the dimension z of the random word array A, which contains

words from R, and $DomainSize = |D|$. This lower bound and tradeoff apply to any algorithm including those with random precomputation (that is oblivious to the data) as long as any internal storage and precomputed values are counted as part of the array as measured by z. Furthermore, the program need not be uniform, and the storage and time used by a deterministic precomputation that precedes the reading of the random seeds need not be charged in this space-time tradeoff. (The point of these remarks is that the tradeoff need not include the generation of G, which could be probabilistic or based on exhaustive search, which would entail an extravagant use of time and space, but result in an optimally structured graph.)

From a more abstract perspective, we have exposed a very close equivalence between the operation count T_f for evaluating (κ)-wise independent hash functions that map, say, $[0, n-1]$ into $[0, n-1]$, and the operation count T_G needed to compute the neighbors of an input vertex of bipartite graphs on $[0, n-1] \times [0, n^\epsilon - 1]$ that have low outdegree d and good expansion properties for small vertex sets. A spatially compact graph representation that can be used to compute the adjacency list of an input vertex in time $T_G = cd$ gives a time $T_f \approx cT_G$ hash function with a high degree of independence, when augmented with an array of n^ϵ random numbers. Similarly, a set of ϵd functions that are independent and are selected from a (κ)-wise independent family can be used to construct such an adjacency list in time $T_G \approx \epsilon d T_f$, albeit with an additive spatial cost of $\epsilon d n^\epsilon$ for the random number arrays: The equivalence holds in this direction because our probability estimates in section 2 were calculated from κ-way expectations, and never used full independence. The resource blowup is the modest factor ϵd because a random function value in $[0, n-1]$ gives $\frac{1}{\epsilon}$ points in $[0, n^\epsilon - 1]$ (where all expressions, for expositional simplicity, are assumed to be integers). A crude application of our lower bound imposes the requirement that $d > 1/\epsilon$, while our existential Theorem 2.10 establishes sufficiency for $d = 2/\epsilon + 1$, provided $\log \kappa \ll \log n$.

Taken together, these upper and lower bounds show that up to a fairly fine granularity of instruction counting, the computational complexities of these two algorithms problems are within a factor of 2 of each other.

5. Formal applications. Because of the graphs needed to construct explicit $O(\log n)$-wise independent constant-time hash functions, all applications must be presently viewed as theoretical. Nevertheless, the constructions in section 2 show that (κ)-wise independent hash functions, for nonconstant $\kappa < n^\delta$ and sufficiently small constant $\delta > 0$, can, in principle, be programmed as constant-time subroutines. Thus, we have established the formal feasibility of any probabilistic algorithm that is based on these functions.

The most fundamental application for hash functions is, of course, to compute randomized mappings of data. Specific applications where constant-time computations and high independence are needed can be found in [9, 11, 16]. Additional uses can be found at http://citeseer.nj.nec.com/context/122560/0. In the next three subsections, we give additional examples.

The hashing applications of section 5.1 are immediate, although the referenced papers are necessary to see that the hash functions are adequate for the strong bounds we report.

Section 5.2 establishes a variety of results about distributed hashing with universal classes that exhibit $O(\log n)$-wise independence. Section 5.3 presents one of the main consequences for parallel processing, which is that constant-time $O(\log n)$-wise independent hash functions enable Ranade's PRAM emulation scheme to be run

on an $n \times \log n$ butterfly network with just one column of processors and memory modules. Each processor has $\log n$ pipelined processes, and the machine comprising n processors, n memory modules, and $n \log n$ switches can emulate a T-time, $n \log n$ processor common PRAM algorithm with an expected running time of $O(T \log n)$. Thus, the processor efficiency is optimal, up to constant factors, although $(T \log^2 n)$ switching operations are required. No other results are known for emulating the common PRAM with an optimal speedup (in processor cycles) and a comparable degree of parallel processing.

However, for brevity, we omit any discussion about how to restructure Ranade's algorithm to work in this new setting; the specifics are straightforward, and can be deduced from the original algorithm [20]. Instead, we focus on the generic randomization arguments for the performance analysis. In some cases, similar results have appeared elsewhere (cf. [35]), although the method of proof has sometimes precluded the use of our hash functions.[5] For purposes of achieving full generality, all of the proofs in this section will be based solely on the independence characteristics of universal classes of hash functions.

5.1. Hashing. Our first application concerns double hashing, uniform hashing, and linear probing. The performances of these hashing schemes with $O(\log n)$-wise independent functions are analyzed in an elaborate proof that begins in [22] and is completed in [23, 25]. In view of these results, the following is immediate.

COROLLARY 5.1. *For any fixed load factor $\alpha < 1$, $O(\log n)$-wise independent hash functions can be used for double hashing with constant time per probe and an expected cost of $\frac{1}{1-\alpha} + O(\frac{1}{n})$ probes for unsuccessful search.*

The results extend directly to uniform hashing, and the optimality of such functions for linear probing is likewise direct, given the developments in [25]. All previous analyses required the data to be random, or used idealized, fully random hash functions, which cannot be effectively programmed.

5.2. The statistics of distributed hashing. The bulk of this section concerns the statistical analysis of distributed hashing with separate chaining in a model of limited independence.

DEFINITION 5.2. *Let the model M denote the following scenario. The hash function f is randomly selected from a family of $(\kappa, 1)$-wise independent hash functions with domain and range $D = [0, nm - 1]$. The data set S comprises all mn elements in D, and is hashed by f. The range $[0, mn - 1]$ is distributed across n modules, each with an address space of size m. Keys that hash to the same location are linked together via separate chaining within the module.*

There are no limitations on the size of m, although we implicitly presume that the hashing and comparison of address locations require a constant number of operations.

The point of hashing all of D is to establish conservative performance bounds based on collision chains that have sustained full growth. The underlying randomization assumes that the hash function is chosen prior to the program execution and, barring failure, is used throughout the computation. A failure occurs if f maps too many domain elements to a given memory module. Such events require a new hash function to be chosen and the parallel program to be run afresh.

[5] In particular, some proofs exploit the fact that a degree k hashing polynomial has at most k roots in a finite field. The requisite randomness can require that $k = \Theta(\log n)$. For our hashing formulations, the number of keys hashing to a single value can be much larger, and can even be the entire data set.

All data references are presumed to be independent of the hash function.

For specificity, let module j store the keys hashing into $[jm, (j+1)m-1]$. In separate chaining, a key x that is the first to hash to a location $f(x)$ is stored there. Subsequent keys hashing to $f(x)$ are called colliders, and are inserted into the chain headed by x. The standard algorithm stores all colliders in memory that is external to the hash-based address space. There are many variants; it is also possible to store colliders in vacant locations within the table, which, absent relocation procedures, will accelerate the chain growth (in what is known as coalesced hashing). Alternatively, it is possible to relocate colliders when new items are hashed to their current locations. Typically, the initialization overhead is ignored, since it is possible to initialize a hash table in constant time via software techniques (cf. [1, Prob. 2.12, p. 71]) or in hardware. We will follow the usual conventions of ignoring initialization overhead and storing colliders outside of the hash space.

The total storage requirement for a module, therefore, is the number of keys that hash into its address space plus the number of vacant locations that remain in the address space once all of $[0, mn-1]$ is hashed. The statistics for these two random variables are established in Lemmas 5.3 and 5.4. The first result is standard and is included for completeness. The second seems to have received less attention for models of universal hashing.

The performance statistics for data access will be based on processing $n \log n$ memory references with modules servicing their hash-based requests in parallel independently of the other modules. The reason we analyze $n \log n$ requests is that $cn \log n$ data accesses, for $c > 1$, will turn out to have a performance that can be modeled as c sets of $n \log n$ requests. For significantly smaller collections, the variance in behavior for each module will degrade the overall performance. Restated, the size $s = n \log n$ is, up to constant factors, the smallest value that will have an expected parallel service time of $\Theta(\frac{s}{n})$, which is optimal.

An analysis of storage requirements begins with the observation that a fully random hashing of mn elements will distribute, on average, m elements to each module. Typically, $m \gg n$, but the uniformity requirements will just need m to be at least $g \log n$ for some large constant g. The result will be that with high probability, $\Theta(\log n)$-wise independence is adequate to distribute the mn keys fairly evenly among all n modules.

LEMMA 5.3. *In model M, let d_i be the size of the preimage of $[im, (i+1)m-1]$, so that $d_i = |\{x : f(x) \in [im, (i+1)m-1]\}|$. Let $\kappa = \beta \log n$, where β is a positive constant, and suppose that $m \geq \kappa$. Then for any fixed $c > 0$, there is a fixed d such that $\text{Prob}\{d_i > dm\} \leq \frac{1}{n^c}$. Furthermore, for any fixed $d > 1$ and fixed c, there is a suitably large constant β such that for any $m > \frac{\kappa}{d-1}$, $\text{Prob}\{d_i > dm\} \leq \frac{1}{n^c}$ in model M.*

Proof. Suppose $d \geq 1 + \epsilon + \frac{\kappa}{m}$. The $(\kappa, 1)$-wise independence facilitates the straightforward calculation

$$\begin{aligned}
\text{Prob}\{d_i > dm\} &= \text{Prob}\left\{\binom{d_i}{\kappa} > \binom{dm}{\kappa}\right\} \\
&\leq \frac{\text{E}[\binom{d_i}{\kappa}]}{\binom{(1+\epsilon)m+\kappa}{\kappa}} \\
&\leq \frac{\binom{nm}{\kappa}\frac{1}{n^\kappa}}{\binom{(1+\epsilon)m+\kappa}{\kappa}} < \frac{(nm)^\kappa \frac{1}{n^\kappa}}{((1+\epsilon)m)^\kappa} = \left(\frac{1}{1+\epsilon}\right)^\kappa.
\end{aligned}$$

Setting $(1+\epsilon) = 2^{c/\beta}$ establishes the first bound.

The second bound follows from setting $\epsilon = (d-1) - \frac{\kappa}{m}$, observing that $\frac{\kappa}{m} < (d-1)$ by supposition, and choosing β so large that $(1+\epsilon) = 2^{c/\beta}$. □

The next task is to bound, with high probability, the number of keys that will be hashed into the auxiliary storage of a given module. Since Lemma 5.3 ensures that with high probability, no more than $(1+\epsilon)m$ keys are distributed to each module, the remaining task is to determine how many locations in a module are left vacant. As before, our expectations are based on the easy analysis for models with full randomness.

Suppose that n items are assigned integer values in the range $[0, n-1]$, with the assignments uniformly distributed and equally likely. The probability that a fixed integer is not assigned to any item is $(1-\frac{1}{n})^n \approx \frac{1}{e}$. It follows that the expected number of vacant locations in a module ought to be about $\frac{m}{e}$, if all mn values are hashed. The next lemma shows that with $(\kappa \log n)$-wise independent hash functions, this statistic is about right, and bounds the probability of large deviations.

LEMMA 5.4. *In model M, let $\alpha > 0$ and $\epsilon > 0$ be fixed constants, and suppose that $m > e\alpha^2 \log^2 n$. Let V be the number of address locations in the hash space of module 1 that remain vacant after all of $[0, mn-1]$ has been hashed. Suppose that $\kappa \geq (1 + e^{1+1/e})\alpha \log n$. Then*

$$\text{Prob}\{V > (1+\epsilon)\frac{m}{e} < 4\left(\frac{1}{1+\epsilon}\right)^{\alpha \log n}.$$

Proof. The proof has two steps. We show that $(e^{1+1/e}\alpha \log n)$-wise independence is adequate to ensure that any fixed set of $\alpha \log n$ locations in the hash table will be vacant with a probability below $2e^{-\alpha \log n}$. Given the aforementioned probability, we bound $\text{Prob}\{V \geq (1+\epsilon)\frac{m}{e}\}$ by estimating the number of $(\alpha \log n)$-tuples of locations in module 1 that are vacant. This latter bound is established as follows:

$$\begin{aligned}
\text{Prob}\left\{\binom{V}{\alpha \log n} \geq \binom{(1+\epsilon)\frac{m}{e}}{\alpha \log n}\right\} &\leq \frac{\binom{m}{\alpha \log n} \times 2e^{-\alpha \log n}}{\binom{(1+\epsilon)\frac{m}{e}}{\alpha \log n}} \\
&\leq \frac{m^{\alpha \log n} 2e^{-\alpha \log n}}{((1+\epsilon)m/e)^{\alpha \log n} \prod_{j=0}^{\alpha \log n - 1}\left(1 - \frac{je}{(1+\epsilon)m}\right)} \\
&\leq \frac{1}{1 - \frac{e\alpha^2 \log^2 n}{2m}}\left(\frac{e}{1+\epsilon}\right)^{\alpha \log n} 2e^{-\alpha \log n} \\
&\leq 4\left(\frac{1}{1+\epsilon}\right)^{\alpha \log n}.
\end{aligned}$$

It is clear that this formulation requires $\alpha \log n$ degrees of freedom in the form of hashing independence.

As for the first calculation, let X be the event that a given set of $\alpha \log n$ locations are vacant. Let $t = \lceil e^{1+1/e}\alpha \log n \rceil$.

From basic inclusion-exclusion (and limited independence) it follows that

$$\text{Prob}\{X\} = \sum_{0 \leq j < t} (-1)^j \binom{mn}{j}\left(\frac{\alpha \log n}{nm}\right)^j + \delta(-1)^t \binom{mn}{t}\left(\frac{\alpha \log n}{nm}\right)^t$$

for some δ satisfying $0 < \delta < 1$. Consequently,

$$\left|\text{Prob}\{X\} - \left(1 - \frac{\alpha \log n}{mn}\right)^{mn}\right| < \binom{mn}{t}\left(\frac{\alpha \log n}{nm}\right)^t < \left(\frac{e\alpha \log n}{t}\right)^t < e^{-\alpha \log n}$$

(and a stronger Stirling estimate for $t!$ would show that the difference is actually less than $\frac{e^{-\alpha \log n}}{\sqrt{t}}$). Applying the triangle inequality to the previous display gives

$$\text{Prob}\{X\} < \left(1 - \frac{\alpha \log n}{mn}\right)^{mn} + e^{-\alpha \log n}.$$

Since $(1 - \frac{|a|}{x})^x$ is increasing in x, it follows that $(1 - \frac{\alpha \log n}{mn})^{mn} < e^{-\alpha \log n}$, and step 1 is now complete. Altogether, the calculations used $t + \alpha \log n$ degrees of freedom. □

Lemmas 5.3 and 5.4 show that for suitable $\kappa = O(\log n)$, each module can have a storage capacity of $(1 + \epsilon)(1 + 1/e)m$ records, and the probability of a hash-induced overflow will be polynomially small, for large enough $\kappa = O(\log n)$. The hashing model is just traditional separate chaining, and no auxiliary hash functions are needed. Of course, the excess storage can be reduced to ϵm by other storage procedures.

The remaining issue is to bound the processing time for an arbitrary collection of $n \log n$ data references. Lemma 5.5 begins this process by proving that an arbitrary set of $n \log n$ references will be distributed among the n modules fairly evenly.

LEMMA 5.5. *In model M, let $\widehat{D}$ be a set of $n \log n$ address keys in D. Let $\widehat{d}_i$, for $i = 0, 1, \ldots, n-1$, be the number of keys in $\widehat{D}$ that are hashed into $[im, (1+i)m - 1]$, so that $\widehat{d}_i = |\{x \in \widehat{D} : im \le f(x) < (i+1)m\}|$. Suppose $\kappa \ge \log n$. Then for any $d > 3$,*

$$\text{Prob}\{\widehat{d}_i > d \log n\} \le \frac{1}{(d-1)^{\log n}}.$$

Proof.

$$\text{Prob}\{\widehat{d}_i \ge d \log n\} \le \frac{\binom{n \log n}{\log n}\left(\frac{1}{n}\right)^{\log n}}{\binom{d \log n}{\log n}} \le \frac{(\log n)^{\log n}}{(d \log n)^{\underline{\log n}}} < \frac{1}{(d-1)^{\log n}}. \qquad \square$$

By itself, Lemma 5.5 says little about the cost of memory accesses when separate chaining is used to store the data. We need to bound the expected sum of the accessed chain lists to determine the access time. The bound will be established in two steps. Lemma 5.6 shows that the sum of $\log n$ chain lengths is, with high probability and on average, just $O(\log n)$. The proof will not assume a priori limitations on the number of items that might collide to a given location; the count could even be mn. Lemma 5.7 extends Lemma 5.6 to include the random number of chains that must be traversed in each module. The chief issue is to establish this accommodation without materially affecting the size requirements for κ.

LEMMA 5.6. *In model M, let κ be at least $2 \log n$. Let $\widehat{D_j} = \{z_i\}_{i=1}^{\log n}$ be a set of $\log n$ memory references that hash to module j. Let Δ_i comprise the elements of $D - z_i$ that collide with z_i under f : $\Delta_i = \{x \in D : f(x) = f(z_i) \bigwedge x \ne z_i\}$. Let $d^* = \sum_{i \le \log n}(|\Delta_i|)$. Let c be a fixed constant greater than 3. Then*

$$\text{E}[d^* \cdot \mathcal{X}(d^* > c \log n)] = O\left(\frac{\log n}{(c-1)^{\log n}}\right).$$

Proof. Counting the number of $(\log n)$-tuples in $\cup_{i=1}^{\log n}\Delta_i$ shows that

$$\begin{aligned}\mathrm{E}[d^*\cdot\mathcal{X}(d^*>c\log n)] &\le (\log n)\mathrm{E}\left[\frac{\binom{d^*}{\log n}}{\binom{c\log n}{-1+\log n}}\right]\\ &\le \frac{(\log n)\binom{mn}{\log n}\left(\frac{\log n}{mn}\right)^{\log n}}{\binom{c\log n}{-1+\log n}}\\ &\le \frac{(\log n)^{\log n}}{((c-1)\log n)^{-1+\log n}}\\ &\le \frac{\log n}{(c-1)^{-1+\log n}}. \qquad \square\end{aligned}$$

The reason that κ is taken to be at least $2\log n$ is to ensure that the requirement that $\widehat{D_j}$ hashes to one module does not impart any conditioning to the hashing statistics for samples of $\log n$ keys in $D-\widehat{D_j}$.

Markedly simple facts about random variables will suffice to extend the bound of Lemma 5.6 to larger numbers of chain lengths. In particular, let $X_1, X_2, \ldots, X_\ell$ be a sequence of arbitrary (possibly dependent) random variables.

Recall that $\mathrm{E}[\sum_i X_i] = \sum_i \mathrm{E}[X_i]$.

Observe that for $a \ge 0$, $\mathrm{E}[\max_i(X_i\cdot\mathcal{X}(X_i\ge a))] \le \sum_i \mathrm{E}[X_i\cdot\mathcal{X}(X_i\ge a)]$.

Finally, let $Y=\sum_{1\le i\le\ell}X_i$, and suppose that the X_i are identically distributed. Then for $a\ge 0$, $Y\cdot\mathcal{X}(Y\ge\ell a)\le\sum_i(X_i\cdot\mathcal{X}(X_i\ge a)+a\sum_{j\ne i}\mathcal{X}(X_j>a))$ because the right-hand side is an overestimate of what would result from rounding X_i up to the value a in the event that $X_i<a$ and $X_j>a$ for some $j\ne i$. Hence

$$\begin{aligned}\mathrm{E}[Y\cdot\mathcal{X}(Y\ge\ell a)] &\le \ell\mathrm{E}[X_1\cdot\mathcal{X}(X_1\ge a)]+\ell(\ell-1)a\,\mathrm{Prob}\{X_1>a\}\\ &\le \ell^2 E[X_1\cdot\mathcal{X}(X_1\ge a)].\end{aligned} \tag{5.1}$$

As unsatisfactory as these bounds may seem, they are tight in the worst case. (However, there are more appealing formulations when, for example, the expectations are replaced by standard overestimates.)

These simple facts, plus Lemmas 5.5 and 5.6, are sufficient to bound the fraction of time spent executing exceptionally slow parallel data accesses.

LEMMA 5.7. *In model M, let $\widehat{D}$ be a set of $n\log n$ address keys in D. Let $\widehat{\Delta}_i$ be the elements in $\widehat{D}$ that hash to memory module i : $\widehat{\Delta}_i=\{x\in\widehat{D} : im\le f(x)<(i+1)m\}$. Let $\widehat{d}_i=|\widehat{\Delta}_i|$. Let Δ_i be the elements in $D-\widehat{D}$ that hash to locations in $\{f(\widehat{\Delta}_i)\}$, and set $\delta_i=|\Delta_i|$. Let $\delta=\max_i\delta_i$. Suppose that $\kappa\ge 2\log n$.*

Then for any integer $c\ge 2$,

$$\mathrm{E}[\delta\cdot\mathcal{X}(\delta\ge(4c+1)(8c+1)\log n)] = O\left(\frac{1}{c^{\log n}}\right).$$

Proof. According to Lemma 5.5,

$$\mathrm{Prob}\{\widehat{d}_i\ge(8c+1)\log n\}<\frac{1}{n^3c^{\log n}} \quad \text{for } i=1,2,\ldots,n.$$

If $\widehat{d}_i\le(8c+1)\log n$, then δ_i is statistically dominated by $Y_1+Y_2+\cdots+Y_\ell$, where $\ell=8c+1$, and each Y_i has the same distribution as d^* in Lemma 5.6. Because of

limited independence, we cannot assume that the Y_i are even pairwise independent. However, it follows from inequality (5.1) and Lemma 5.6 that as long as $\widehat{d}_i$ is bounded by $\ell \log n$,

$$\mathrm{E}[\delta_i \cdot \mathcal{X}(\delta_i > \ell(4c+1)\log n)] \leq \frac{4c\ell^2 \log n}{n^2 c^{\log n}}.$$

So if $\widehat{d}_i \leq \ell \log n$ for $i = 0, \ldots, n-1$, then

$$\mathrm{E}[\max_i(\delta_i \cdot \mathcal{X}(\delta_i > \ell(4c+1)\log n))] \leq n\frac{4c\ell^2 \log n}{n^2 c^{\log n}} \leq \frac{4c\ell^2}{c^{\log n}}.$$

If some $\widehat{d}_i$ is too large, we bound the resulting time by $\sum_i \delta_i$, which is as if all of $\widehat{D}$ were hashed to just one module. This sum is statistically dominated by $Y = Y_1 + Y_2 + \cdots + Y_n$. Since the probability that some $\widehat{d}_i$ is too large is bounded by $n\frac{1}{n^3 c^{\log n}}$, no estimate is needed for the event that some $\widehat{d}_i$ is too large and $Y \leq n^2$. We need only observe that $\mathrm{E}[Y \cdot \mathcal{X}(Y > n^2)] \leq n^2 \mathrm{E}[d^* \cdot \mathcal{X}(d^* > n)]$, and this latter expectation is insignificant by Lemma 5.6.

Last, we note that these calculations impose no requirements on κ, apart from the restrictions resulting from applications of Lemmas 5.5 and 5.6. In fact, the requisite independence is just the maximum of the requirements for κ as used in these two lemmas. To verify this requirement for κ, we need to bound $\mathrm{E}[\max_i(\delta_i \cdot \mathcal{X}(\delta_i > \ell(4c+1)\log n))]$ by a sum of expectations that are each bounded by $O(\frac{1}{c^{\log n}})$, provided $\kappa \geq 2\log n$. We do so as follows:

$$\begin{aligned}
&\max_i(\delta_i \cdot \mathcal{X}(\delta_i > \ell(4c+1)\log n)) \\
&\quad \leq \mathcal{X}(\forall i : \widehat{d}_i \leq \ell \log n) \cdot \max_i(\delta_i \cdot \mathcal{X}(\delta_i > \ell(4c+1)\log n)) \\
&\qquad + \mathcal{X}(\exists i : \widehat{d}_i > \ell \log n) \cdot n^2 \cdot \mathcal{X}\left(\sum_{i \leq n} \delta_i \leq n^2\right) + \left(\sum_{i \leq n} \delta_i\right) \cdot \mathcal{X}\left(\sum_i \delta_i > n^2\right),
\end{aligned}$$

whence

$$\begin{aligned}
&\mathrm{E}[\max_i(\delta_i \cdot \mathcal{X}(\delta_i > \ell(4c+1)\log n))] \\
&\quad \leq n\ell^2 \mathrm{E}[d^* \cdot \mathcal{X}(d^* \geq (4c+1)\log n)] \\
&\qquad + n^3 \operatorname{Prob}\{\widehat{d}_1 > \ell \log n\} + n^2 \mathrm{E}[d^* \cdot \mathcal{X}(d^* > n)],
\end{aligned}$$

where unnecessary constraints have been dropped to reduce the independence requirements for the last three terms on the right. □

Together, these lemmas show that in model M, $O(\log n)$-wise independent hash functions can be used to implement distributed hashing with separate chaining with high efficiency.

THEOREM 5.8. *In model M, let $\kappa = \beta \log n$ for some constant $\beta \geq 2$. Then a universal class of $(\kappa, 1)$-wise independent hash functions can be used to implement distributed hashing with separate chaining so that $n \log n$ data access requests will have, on average and with overwhelming probability (i.e., probability $1 - 1/n^c$, for any constant c), a parallel service time of $\Theta(\log n)$, which is optimal for systems with n independent memory modules. Furthermore, suppose that $m \gg \log^2 n$. Then given $\epsilon > 0$, there is a fixed $\beta > 0$ such that a family of $(\beta \log n, 1)$-wise independent*

hash functions will, on average and with overwhelming probability, distribute the data among the modules with a density that is, up to a factor of $1+\epsilon$*, no worse than the expected distribution that results from fully random hashing.*

Proof. The first statement follows from Lemmas 5.5 and 5.7. In particular, Lemma 5.5 shows that each module receives only $\Theta(\log n)$ of the $n \log n$ hash keys on average, and with overwhelming probability. Lemma 5.7 shows that the sum of the hash chain lengths for $\Theta(\log n)$ addresses is $\Theta(\log n)$ on average and with overwhelming probability. Lemma 5.7 also affirms that in the overwhelmingly improbable case where some module receives more than $\Theta(\log n)$ of the $n \log n$ hash keys, the sum of the chain lengths will, on average and with overwhelming probability, be bounded by $O(n^2)$, which is statistically insignificant since by Lemma 5.5, the probability that at least $(d+1)\log n$ of the $n \log n$ hash keys are mapped to one module, for $d > 2$, is bounded by $\frac{n}{n^{\log d}}$.

The second assertion summarizes Lemmas 5.3 and 5.4.

The inclusion-exclusion argument of Lemma 5.4 is sensitive to small statistical errors, which requires that μ be set to 1. Since the hashing application uses the same domain and range, no prehashing function (as described in section 2) is necessary, and μ can be set to 1. □

It is worth noting that the requirement that $\mu = 1$ is unnecessary for the first part of Theorem 5.8. Setting $\mu > 1$ would cause the derived performance results to degrade by just a factor of μ. However, the bounds for the memory requirements would not hold for $\mu > 1$, although they would only change by a small constant factor. As presented, Lemma 5.7 requires an independence as high as $\kappa = \beta \log n$ with $\beta = 2$. However, the decomposition method used to establish Lemma 5.7 can be applied to give corresponding results for any constant $\beta > 0$, and the resulting performance results would degrade by constant factors.

5.2.1. Hashing failures. For models of randomized computation, and for distributed randomized computation in particular, some of the complications associated with hashing failures are worthy of analysis.

Our model of computation assumes that a hash-based program can be rerun afresh if the hashing for some reason turns out to be unsuccessful. There are several different policies that can be used to manage the consequences of hashing failures. The random variables X and C will represent the execution time of a randomized program. In particular, X will be the running time of a probabilistic program that completes its execution successfully with a hash function that is randomly selected from a family of κ-wise independent functions. C can model the additional execution time that is used when the program completes successfully but has some kind of nonfatal irregularity in the construction of hash function family. Alternatively, C can represent the additional time used in an unsuccessful execution of the program when there is no preemptive termination of the processing.

The following random variables extend these formulations to running times for different processing policies, including some where programs are terminated prematurely. Such programs are then run afresh with new random seeds. Technically, the following would be defined in terms of random stopping times. However, program formulations give equivalent definitions with more transparent semantics.

Define $R(X;C)$ via the following program.
Let X_i and C_i be independent identically distributed copies of X and C.
$sum \leftarrow 0$;
$i \leftarrow 0$;

Repeat
  $i \leftarrow i + 1$;
  $sum \leftarrow sum + X_i + C_i$;
Until $C_i = 0$;
$R(X; C) \leftarrow sum$.

Define $F(X; C; \rho)$ via the following program.
Let X_i and C_i be independent identically distributed copies of X and C.
$sum \leftarrow 0$;
$i \leftarrow 0$;
Repeat
  $i \leftarrow i + 1$;
  $sum \leftarrow sum + \min(X_i + C_i, \rho)$;
Until $X_i + C_i \leq \rho$;
$F(X; C; \rho) \leftarrow sum$.

Define $G(X; C; \rho)$ via the following program.
Let X_i and C_i be independent identically distributed copies of X and C.
$i \leftarrow 1$;
$sum \leftarrow 0$;
Repeat
  $i =\leftarrow i + 1$;
  $sum \leftarrow sum + \min(\rho^i, X_i + C_i)$;
Until $X_i + C_i \leq \rho^i$;
$G(X; C) \leftarrow sum$.

The program execution policies corresponding to these random variables are as follows. R models running a probabilistic program to termination repeatedly until the execution is successful. F models running the program repeatedly for ρ time steps and then starting afresh until an execution is successful. G corresponds to running the ith trial of a program for ρ^i time steps and repeating the effort afresh with trial $i + 1$ until a trial executes successfully.

Section 2 presented several types of hash functions that exhibit different types of performance degradation depending on what goes wrong. If a prehashing function h is used to reduce the effective size of the domain D, then a (mild) failure would occur if two keys in the data have the same image under h. Of course prehashing failures could be much worse.

If the hash function uses a probabilistically constructed expander-like graph, then a failure can occur if the graph does not achieve the required characteristics. As mentioned in section 5.2, a failure can also occur in a distributed model of computation if, for any reason, the hashing does not distribute the data evenly enough to satisfy the physical storage limitations for each module. This event is a fatal distributional failure. Another type of distributional irregularity would occur if the chain lengths (that result from hashing with separate chaining) have a distribution that deviates significantly from the predictions of Lemma 5.7. Similarly, a distributional irregularity can occur in a distributed model of computation if the module access patterns (as characterized by Lemma 5.5) are highly deviant.

These sources of performance inefficiency can be modeled as follows.

Let d be a positive constant. For $k = 1, 2, \ldots, T$, let P_k be a random variable satisfying $\mathrm{E}[P_k] = \tau$ and $\mathrm{E}[\max(0, P_k - d\tau)] < \frac{\tau}{n^r}$. Each P_j will represent the processing time for a single block of $n \log n$ data access requests in model M in the case that the underlying family of hash functions satisfies the requirements of the model. These random variables can be dependent.

To model failures that erode parallel processing, let A be a random variable

satisfying $\text{Prob}\{A = 0\} = 1 - \frac{1}{n^{r+1}}$ and $\text{Prob}\{A = nT\tau\} = \frac{1}{n^{r+1}}$. In the rare event that $A \neq 0$, A will turn out to be n times slower than the expected time for a T-step parallel program, and will correspond to the case where each instruction is executed sequentially with no concurrent processing.

To model more catastrophic failures, let $B(\epsilon)$ for $0 < \epsilon < 1$ be a random variable satisfying $\text{Prob}\{B = 0\} = \epsilon$ and $\text{Prob}\{B = \infty\} = 1 - \epsilon$. $B(1 - \frac{1}{n^r})$ gives a very conservative overestimate of performance losses due to severe deficiencies in the construction of the hash function.

Given these definitions, the performance consequences of hashing irregularities are now readily quantified.

LEMMA 5.9. *Let $(y)^+ = \max(y, 0)$. Let the execution styles R, F, and G be as defined above. Let A, B, $P_1, P_2, \ldots, P_T$ be random variables satisfying the following:*

$\text{Prob}\{A = 0\} = 1 - \frac{1}{n^{r+1}}$, $\text{Prob}\{A = nT\tau\} = \frac{1}{n^{r+1}}$;

$\text{Prob}\{B = 0\} = \epsilon$, $\text{Prob}\{B = \infty\} = 1 - \epsilon$;

$\text{E}[P_k] = \tau$ *and* $\text{E}[\max(0, P_k - d\tau)] < \frac{\tau}{n^r}$.

Let $X = \sum_{k=1}^{T} P_k$.

Then

(i) $\text{E}[R(X; A)] = \Theta(T\tau)$.

$\text{E}[(R(X; A) - dT\tau)^+] = O(\frac{T\tau}{n^r})$.

$\text{E}[F(X; B(1 - \frac{1}{n^r}); (d+1)T\tau)] = \Theta(T\tau)$.

For any constant $s \geq 1$,

$\text{E}[(F(X; B(1 - \frac{1}{n^r}); (d+1)T\tau) - s(d+1)T\tau)^+] = O(\frac{T\tau}{n^{rs}})$.

$\text{E}[G(X; B(1 - \frac{1}{n^r}); 2)] = O(T\tau)$.

$\text{E}[(G(X; B(1 - \frac{1}{n^r}); 2) - 4dT\tau)^+] = O(\frac{T\tau}{n^r})$.

(ii) *For any constant* ϵ, *where* $0 < \epsilon < 1$,

$\text{E}[F(X; B(\epsilon); (d+1)T\tau)] = \Theta(T\tau)$.

For any constant ρ, *there is a constant* σ *such that*

$\text{E}[(F(X; B(\epsilon); (d+1)T\tau) - \sigma T\tau \log n)^+] = O(\frac{T\tau}{n^\rho})$.

For any constant ρ, *where* $1 < \rho < \frac{1}{1-\epsilon}$, $\text{E}[G(X; B(\epsilon); \rho)] = \Theta(T\tau)$.

Proof. (i) By definition of X,

$$\text{E}[X] = \sum_{k=1}^{T} \text{E}[P_k] = T\tau.$$

The first assertion in (i) is now immediate since

$$\text{E}[R(X, A)] = T\tau + (T\tau + nT\tau) \sum_{i=1}^{\infty} \left(\frac{1}{n^{r+1}}\right)^i,$$

where $T\tau$ corresponds to the expected time for the successful execution, and $T\tau + nT\tau$ bounds the expected time used in each unsuccessful execution.

Since $\max(0, x)$ is convex,

$$\text{E}[\max(0, X - dT\tau)] \leq \sum_{i=1}^{T} \text{E}[\max(0, P_k - d\tau)]$$

by Jensen's inequality. So

$$\text{E}[\max(0, X - dT\tau)] \leq \sum_{i=1}^{T} \frac{\tau}{n^r} = \frac{T\tau}{n^r}.$$

By definition, $R(X, A)$ corresponds to i consecutive samples of X and A with $A \neq 0$ in each sample, followed by a sample where $A = 0$, for a probabilistically determined i. So

$$\mathrm{E}[\max(0, R(X; A) - dT\tau)] \leq \mathrm{E}[\max(0, X - dT\tau)] + \sum_{i=1}^{\infty} (\mathrm{E}[X] + nT\tau) \left(\frac{1}{n^{r+1}}\right)^i$$
$$= O\left(\frac{T\tau}{n^r}\right).$$

The extension of these results to $F(X; B(1 - \frac{1}{n^r}); (d+1)T\tau)$ is fairly straightforward. Note that $\mathrm{Prob}\{X+B > (d+1)T\tau\} \leq \mathrm{Prob}\{B \neq 0\}+\mathrm{Prob}\{X > (d+1)T\tau\}$, and that $\mathrm{Prob}\{X > (d+1)T\tau\} \leq \frac{\mathrm{E}[\max(0, X - dT\tau)]}{T\tau} \leq \frac{1}{n^r}$. So $\mathrm{Prob}\{X + B > (d+1)T\tau\} \leq \frac{2}{n^r}$. Consequently,

$$\mathrm{E}\left[\max\left(0, F\left(X; B\left(1 - \frac{1}{n^r}\right); (d+1)T\tau\right) - s(d+1)T\tau\right)\right] \leq \sum_{i=s}^{\infty} ((d+1)T\tau)\left(\frac{2}{n^r}\right)^i$$
$$= O\left(\frac{T\tau}{n^{rs}}\right).$$

As for policy G, the sum of the geometric progression is comparable to its largest term, and once the time trials are as large as $(d+1)T\tau$, the probability of a successful completion is $1 - O(\frac{1}{n^r})$ per iteration.

(ii) The proofs are straightforward and are omitted. □

Policy G was designed to facilitate computations where the expected execution time of a program is unknown. The error B was defined to accommodate the possibility that a hash function might be highly defective but still partition the keys so evenly that the storage limitation for each module is not exceeded. The application of Lemma 5.9 to hashing is straightforward, and is included in the performance analysis of section 5.3.

5.3. A pipelined version of Ranade's PRAM algorithm. The results of section 5.2 help establish that constant-time hash functions can be used in a pipelined version of Ranade's PRAM emulation architecture.

Another stepping-stone in proving optimal speedup concerns the fast sorting of random numbers and is independent of the underlying hashing, apart from the fact that κ-wise independence results in κ distinct elements being assigned statistically random values.

The need for linear-time sorting is due to the step in Ranade's algorithm where each row in the network uses its $\log n$ processors for an $O(\log n)$-time systolic bubblesort of the row's $\log n$ locally generated hash values. If each row is to have one processor available for sorting the same data, an optimal scheme will (on average) have just $\Theta(\log n)$ time available for the slowest row to complete this sorting step.

As stated below, Lemma 5.11 (with $\log n$ substituted for n) will ensure that for any $\alpha > 0$, there is a d such that each of the n pipelined processors can (after straightforward preprocessing has combined identical hash values) sort its $\log n$ local hash packets in $d \log n$ steps with a probability that exceeds $1 - \frac{1}{n^\alpha}$.

Let S be a set of n integers in the range $[0, m-1]$. For $s \in S$, let $s_{top} = \lfloor n\frac{s}{m} \rfloor$ be the $\log_2 n$ most significant bits of s. Suppose that s_{top} can be computed in constant time and that any two elements $s, t \in S$ can be compared in constant time. We make no other assumptions about the relationship between m and n.

DEFINITION 5.10. *Let the following sorting procedure be* Algorithm S.

For each $s \in S$, insert s into Bin$[s_{top}]$.

For $j \leftarrow 0$ to $n-1$, Mergesort the contents of Bin$[j]$.

Concatenate the contents of the sorted Bins.

The mean performance of Algorithm S is, as the next lemma states, within a constant factor of optimal.

LEMMA 5.11. *Let S be a random sequence of n integers selected uniformly from $[0, m-1]$. Then for any fixed $c > 0$, there is a fixed d such that Algorithm S sorts a fraction exceeding $1-e^{-cn}$ of all $S \in [0, m-1]^n$ in dn steps, where $c = d-2-\ln(d-1)$.*

Proof. See [27, Theorem 4.1, p. 208]. □

All of the data processing characteristics are now established. We now define a kind of best-case performance characteristic for networks and then combine all of the results in the optimal performance formulation of Corollary 5.13.

DEFINITION 5.12. *Let $\mathcal{N}$ be a network. We say that a* no-load memory reference *takes time t on $\mathcal{N}$ if, in the worst case, a single memory access (with all other process requests suspended) can be executed on $\mathcal{N}$ in a worst-case time of t.*

COROLLARY 5.13. *Let Ω be a pipelined n-processor analogue of Ranade's architecture that includes an $n \times \log n$ butterfly switching network. Let each processor execute a $\log n$-deep pipeline that corresponds to a row of processors in Ranade's organization, and manage a memory module of $O(m)$ words. Suppose that a no-load memory reference can be processed on Ω in $O(\log n)$ time.*

Then a T-time $n \log n$-processor common PRAM algorithm for mn words of shared memory can be emulated on Ω in an expected time of $O(T \log n)$. Furthermore, for any fixed r, there is a fixed d such that the algorithm runs on Ω in a time that is bounded by $dT \log n$ with probability exceeding $1 - \frac{1}{n^r}$. The hash function can be selected from a family of uniformly r-practical $(\beta \log n, 1)$-wise independent hash functions for fixed $\beta \geq 8$, and separate chaining can be used to resolve collisions as in model M. In addition, if $m \gg \log^2 n$, and, for fixed $\epsilon > 0$, β is set to a sufficiently large constant, then the requisite auxiliary storage will, with overwhelming probability, be within a factor of $1+\epsilon$ of the expected storage used by fully random hash functions.

Proof. The performance of the algorithm is a consequence of its probability of failure and the running time of each step of the algorithm in the event that no failure occurs.

We first consider the performance when the hash function meets the requirements of model M.

The PRAM program is executed in blocks of $n \log n$ instructions and has execution times for each of the T instruction blocks. Let R_j be the round-trip network routing time for the jth block of instructions as defined (and analyzed) in Ranade's emulation algorithm [20]. The analysis requires that β be at least 8. Let S_j, for the jth block of instructions, be the time used for the concurrent local sortings of the n sets of $\log n$ hash-based packet addresses as required in Ranade's routing algorithm, implemented by Algorithm S and analyzed in Lemma 5.11. Let M_j be the time expended executing the concurrent memory references for the n modules as required by the jth block of instructions. We take the fixed overhead associated with each $(n \log n)$-instruction block to require $O(\log n)$ time and presume that it is absorbed by the other random variables.

Let

$$X = \sum_{j=1}^{T} (R_j + S_j + M_j),$$

so that X accounts for the running time of the pipelined PRAM emulation, provided the hashing meets the requirements of Ranade's theorem and model M. Ranade's analysis, Lemma 5.11, and Theorem 5.8 ensure that $\mathrm{E}[X] = \Theta(T \log n)$. Similarly, these analyses show that for any r there is a d such that for all j, $\mathrm{E}[S_j \cdot \mathcal{X}(S_j > d \log n)] < \frac{1}{n^r}$, and likewise for all R_j and M_j.

Even if the hashing uses $(\kappa, 1)$-wise independent hash functions, failure can occur if too many keys hash to some module. In this case, the algorithm must be started afresh with a new hash function. We might anticipate that if an emulation attempt does not run to completion, then it ought to have statistics that are dominated by those of X. However, it is possible that a failed computation could comprise the execution of almost all T blocks of instructions, and that each round might be somewhat slower than that for a successful execution because some module is almost out of memory. Thus, a failure can skew the running time to be worse than average. We need only argue that the expected performance, given that such a failure occurs, does not degrade by more than a factor of n, which corresponds to the worst-case event where all data hashes to just one module and the amount of data (up to the last instruction block) just fills up all of the available storage. We can assume that the expected length (and sum of $n \log n$ lengths) of the collision chains is still governed by the randomness of the hash functions, since these values are not changed by more than a small constant factor when the amount of data in a module is at its maximum. The probability that such a hashing scheme fails to distribute the data adequately well among the modules is, by Lemma 5.3, polynomially small. Thus, the emulation scheme in this case (of ∞-practical hashing) has a performance that is modeled by $R(X, A)$ in Lemma 5.9 of section 5.2.

If the underlying hash function depends on a randomized graph construction of section 2, then the graph could be defective with a probability of $\frac{1}{(mn)^r}$. Formally, this form of hashing failure lies within the model of uniformly r-practical $(\kappa, 1)$-wise independent hash functions as quantified by Definition 2.1.

In the worst case, the physical storage restrictions for each module would be satisfied, but the collision chains would be unacceptably long. In such a circumstance, we must presume that $\Theta(m)$ keys hash to a single location in each module. Even these delays cause an expected performance degradation that is nominal. Alternatively, the delays can be viewed as infinite, modeled by the error random variable $B(1 - \frac{1}{n^r})$ and accommodated by emulation policies F or G. Lemma 5.9 shows that in all cases, the resulting performance has the statistical characteristics asserted in this corollary.

Last, the claims about the storage requirements are just a restatement of facts established in section 5.2. □

As in Theorem 5.8, none of these performance characteristics, apart from the tight bounds on the requisite storage for each module, require μ to be 1. For larger values of μ all of the other bounds would again degrade by just a factor of μ, and the requisite auxiliary storage would increase by a small constant factor.

Of course, any reasonable strategy can be used to resolve the case of module overflow since its probability of occurrence is statistically insignificant. Similarly, the data in each memory module can be stored via any reasonable secondary hashing scheme.

Remarks. Although the main result of this paper suggests that there is little additional cost in creating constant-time hash functions that are far more random than $O(\log n)$-wise independent, our analyses of distributed hashing and PRAM emulation have followed a more parsimonious path by restricting the randomness allocated to

these functions to be $\beta \log n$ for a fixed value of β. The reasons for this restriction are twofold. First, the sufficiency of $O(\log n)$-wise independence gives hope that even less randomness might suffice for real implementations. Second, the realization of fast random functions really awaits the discovery of suitable graphs; it is conceivable (and indeed likely) that good graphs might first be found for more moderate degrees of randomness, such as those which give $O(\log n)$-wise independence. Of course, the results of this section are just feasibility proofs, and not a blueprint for future architectures even if ideal graphs are found.

For completeness, we note that Kruskal, Rudolph, and Snir use pipelines of depth n^ϵ to get a parallel emulation time that is optimal up to a factor of $\frac{1}{\epsilon}$ [13]. Versions of some of the basic counting estimates can also be found elsewhere [13, 18, 20, 35]. For example, formulations comparable to Lemmas 5.5 and 5.6 can be found in [20]. Ranade uses the fact that polynomials of degree $\log n$ have at most $\log n$ roots to bound the preimage size to $O(\log n)^2$ for the fetches that must be executed by a single row of $\log n$ processors. Valiant uses the root bound, parallel sorting, and secondary hashing (with separate chaining) to control the fetch time for a variety of architectures [35].

It should also be noted that the fast Fourier transform can be used to compute k evaluations of a degree k polynomial in $O(k \log^2 k)$ steps (cf. [1, Cor. 2, p. 224]). Thus, it is possible to use the above pipeline strategy on n processors with $\log n$ degree hash functions to attain a performance cost of $O(\log \log n)^2$ operations per memory reference rather than a naive $\log n$. We have shown that this multiplicative performance penalty can, in theory, be reduced to an asymptotic $O(1)$.

6. Conclusions. The high independence exhibited by our hash functions enriches the class of probabilistic algorithms that can be shown to achieve their expected performance in formal models of real computation. Proofs need not be restricted to (κ)-wise independence for constant κ, and probability estimates can use the probabilistic method to calculate the expected number of κ-tuples satisfying various behavior criteria for these larger values of κ.

On the other hand, it is worth noting that the fast hash functions described in this paper are not really necessary for pure routing problems. After all, if an adequately random assignment of intermediate destinations provides, with very high probability, nearly optimal performance in a Valiant–Brebner style of routing [33], then the same destinations could be used for many consecutive routings.

What these fast hash functions really provide are nearly uniform random mappings of data and a convenient way to assert that with high probability, various maldistributions are very unlikely to occur. In addition, hash functions computed from destination addresses provide a way for common memory references to be fully combined en route in Ranade's elegant queue management scheme, and this might be important if combining is required to avoid hot spot contention.

But while the asymptotic characteristics of fast hash functions are now well understood, the feasibility question remains wide open. Without doubt, the most significant open problem is to find good local expander-like graphs that are defined by short efficient programs. The discovery of such structures might have a very beneficial effect on the practicality of these classes of functions. Interestingly, recent progress suggests that this prospect might be within reach [4, 14, 21].

Appendix. For completeness, we state the two combinatorial lemmas that are needed to analyze the basic prehashing functions of section 1.1.

Fact 1 (cf. [17, 8]). Let $P_k = \{p \mid p \text{ is prime and } p \in (n^k \ln m, (2+\beta)n^k \ln m)\}$ for some small suitably fixed $\beta > 0$. Then

$$\forall x \neq y \in [0, m-1] : \text{Prob}_{p \in P_k}\{x = y \bmod p\} < n^{-k}.$$

Proof [17, 8]. The prime number theorem says that $|P_k| = \frac{(1+\beta)n^k \ln m}{k \ln n + \ln \ln m}(1 - o(1))$, whence fewer than $1/n^k$ of the elements of P_k can divide $|x - y|$, since $\prod_{p \in P_k} p > (n^k \ln m)^{|P_k|} > (m)^{n^k}$. □

Fact 2 (cf. [5]). Let $F_0(p) = \{h \mid h(x) = (ax + b \bmod p) \bmod n^k,\ a \neq 0, b \in [0, p-1]\}$, where $p > n^k$ is prime. Then

$$\forall x \neq y \in [0, p-1] : \text{Prob}_{f \in F_0(p)}\{f(x) = f(y)\} \leq n^{-k}.$$

Proof [5]. Given x and y, $x, y \in [0, p-1]$, $x \neq y$, the number of different $f \in F_0(p)$, where $f(x) = f(y)$, is precisely the number of 2×2 linear systems in a and b:

$$\begin{cases} ax + b = c + dn^k \bmod p \\ ay + b = c + en^k \bmod p \end{cases} \qquad c, d, e \geq 0;\ c + dn^k < p;\ c < n^k;\ e \neq d;\ c + en^k < p.$$

This system is designed so that $c + dn^k$ can have p different values: c ranges from 0 to $n^k - 1$, and dn^k gives increments of n^k. The same is true of $c + en^k$, since it has the same format. Both expressions equal c when taken modn^k, and all possible values are captured by this representation. The parameters e and d cannot be equal because the solution to the system would then give $a = 0$. Furthermore, a cannot be zero if $e \neq d$, which is required for x and y to be distinct. Straightforward counting shows that there are at most $\lceil p/n^k - 1 \rceil$ different values available for e. Since there are $p(p-1)$ different functions in F_0, and $f(x) = f(y)$ for at most $p\lceil p/n^k - 1 \rceil \leq p\frac{p-1}{n^k}$ of them, the result follows. □

Combining Facts 1 and 2 shows that a hash function selected at random from $F_0^k = \cup_{p \in P_k} F_0(p)$ will, with probability exceeding $1 - 2\binom{n}{2}n^{-k}$, map n items from $[0, m-1]$ into $[0, n^k - 1]$ with no collisions at all among its $\binom{n}{2}$ pairs. We could take $k = 4$, so that the probability of a collision is below $1/n^2$, and assume the functions $F_0(p)$ are defined as in Fact 2 for $p \approx n^4 \ln m$.

Acknowledgments. It is a pleasure to thank the two anonymous referees for their many helpful suggestions, which have improved the presentation and clarity of this paper. Similarly, I would like to thank the editorial chain of SICOMP for their effort on behalf of this submission.

LOCAL SEARCH HEURISTICS FOR k-MEDIAN AND FACILITY LOCATION PROBLEMS*

VIJAY ARYA†, NAVEEN GARG†, ROHIT KHANDEKAR†, ADAM MEYERSON‡, KAMESH MUNAGALA‡, AND VINAYAKA PANDIT§

Abstract. We analyze local search heuristics for the metric k-median and facility location problems. We define the *locality gap* of a local search procedure for a minimization problem as the maximum ratio of a locally optimum solution (obtained using this procedure) to the global optimum. For k-median, we show that local search with swaps has a locality gap of 5. Furthermore, if we permit up to p facilities to be swapped simultaneously, then the locality gap is $3 + 2/p$. This is the first analysis of a local search for k-median that provides a bounded performance guarantee with only k medians. This also improves the previous known 4 approximation for this problem. For uncapacitated facility location, we show that local search, which permits adding, dropping, and swapping a facility, has a locality gap of 3. This improves the bound of 5 given by M. Korupolu, C. Plaxton, and R. Rajaraman [*Analysis of a Local Search Heuristic for Facility Location Problems*, Technical Report 98-30, DIMACS, 1998]. We also consider a capacitated facility location problem where each facility has a capacity and we are allowed to open multiple copies of a facility. For this problem we introduce a new local search operation which opens one or more copies of a facility and drops zero or more facilities. We prove that this local search has a locality gap between 3 and 4.

Key words. local search, approximation algorithm, facility location

1. Introduction.

The problem of locating facilities in a manner so that they can effectively serve a set of clients has been the subject of much research. While one could consider fairly general measures of effectiveness of a set of locations in serving the clients, one measure that is typically used is the distance between the client and the facility that is serving it. Since by opening a lot of facilities, we can be near every client, it also makes sense to take into account the number of facilities opened in judging the quality of a solution. These two measures, typically referred to as the service cost and the facility cost, can be combined in many ways to obtain interesting variants to the general facility location problem. For instance, in *k-median* we require that at most k facilities be opened and the total service cost, measured as the sum of the distance of each client to the nearest open facility, be minimum. Instead of setting a limit on the total number of facilities that could be opened, we sometimes associate with every facility a cost of opening that facility. The facility cost of a solution is then the sum of the costs of the facilities that are opened, and the quality of the solution is measured by the sum of the facility and service costs. This, in fact, is the

classical *facility location problem*. Note that in this setting the facility costs need not be the same and would, in general, depend on the location at which the facility is being opened. A generalization of the classical facility location problem arises when we associate a capacity with each facility, which measures the maximum number of clients that the facility can serve. Further variants of this *capacitated facility location* (CFL) problem arise when we bound the number of facilities that can be opened at a certain location. Thus in k-CFL, we can open at most k facilities at any location.

Local search techniques have been very popular as heuristics for hard combinatorial optimization problems. The 1-exchange heuristic by Lin and Kernighan [15] for the metric-TSP remains the method of choice for practitioners. However, most of these heuristics have poor worst-case guarantees, and very few approximation algorithms that rely on local search are known. Könemann and Ravi [13] used local search algorithms for degree-bounded minimum spanning trees. Chandra, Karloff, and Tovey [3] show an approximation factor of $4\sqrt{n}$ for the 2-exchange local search heuristic for the Euclidean traveling salesman problem. Khuller, Bhatia, and Pless [12] give a local search approximation algorithm for finding a feedback edge-set incident upon the minimum number of vertices. Local search has also been used for set packing problems by Arkin and Hassin [2]. Here, we provide worst-case analysis of local search algorithms for facility location problems.

For an instance I of a minimization problem, let $\texttt{global}(I)$ denote the cost of the global optimum and $\texttt{local}(I)$ be the cost of a locally optimum solution provided by a certain local search heuristic. We call the supremum of the ratio $\texttt{local}(I)/\texttt{global}(I)$ the *locality gap* of this local search procedure. For 1-CFL with uniform capacities, Korupolu, Plaxton, and Rajaraman [14] argued that any procedure that permits adding, dropping, or swapping a facility has a locality gap of at most 8. Their analysis was subsequently refined and tightened by Chudak and Williamson [8] to yield a locality gap of at most 6. Pál, Tardos, and Wexler [19] present a local search algorithm for 1-CFL with nonuniform capacities which has a locality gap of 9. Mahdian and Pál [16] considered the universal facility location problem where the cost of opening a facility is any arbitrary but monotone function of the demand that the facility serves; note that this problem generalizes k-CFL. Mahdian and Pál extended the algorithm of [19] to obtain a local search algorithm with a locality gap of 8. For uncapacitated facility location (UFL), Korupolu, Plaxton, and Rajaraman [14] provided a bound of 5 on the locality gap when the only operations permitted are those of adding, dropping, or swapping a facility. Charikar and Guha [4] introduced an operation which permits adding a facility and dropping many and showed that this local search procedure has a locality gap of exactly 3. For k-median, Korupolu, Plaxton, and Rajaraman [14] gave a local search procedure which permitted adding, deleting, and swapping facilities and gave a solution with $k(1+\epsilon)$ facilities having a service cost at most $3+5/\epsilon$ times the optimum k-median solution.

A different approach to facility location was employed by Shmoys, Tardos, and Aardal [20] and Charikar et al. [5]. They formulated the problems as linear programs and rounded the optimum fractional solution to obtain a 3 approximation for the UFL problem and a $6\frac{2}{3}$ approximation for k-median. Jain and Vazirani [11] gave an alternate 3 approximation algorithm for UFL using the primal-dual schema. They also observed that UFL can be viewed as a Lagrange-relaxation of k-median and utilized this to give a 6 approximation algorithm for k-median. Later, Charikar and Guha [4] improved this to a 4 approximation. Recently, Archer, Rajagopalan, and Shmoys [1] showed that the algorithm due to Jain and Vazirani can be made to satisfy the "continuity" property and established an integrality gap of at most 3 for the most

natural LP relaxation for the k-median problem. However, their proof gives only an exponential time algorithm. Guha and Khuller [9] employed randomization to improve the approximation guarantee of UFL to 2.408. This was further improved to $(1+2/e)$ by Chudak [6] and finally to 1.728 by Charikar and Guha [4]. Similar ideas were used by Chudak and Shmoys [7] to obtain a 3 approximation algorithm for ∞-CFL when the capacities are uniform. Jain et al. [10] used the method of dual fitting and factor revealing LP to design two greedy algorithms for the UFL problem with approximation guarantees of 1.861, 1.61 and running times of $O(m \log m)$, $O(n^3)$, respectively, where n is the number of vertices and m is the number of edges in the underlying graph. Mahdian, Ye, and Zhang [17] combined the ideas in [10] with the idea of cost scaling to obtain an approximation factor of 1.52 for UFL, which is also the best known. Jain and Vazirani [11] obtained a 4 approximation algorithm for ∞-CFL when the capacities were nonuniform by solving a related UFL problem using their primal-dual algorithm. Recently, Mahdian, Ye, and Zhang [18] gave a 2 approximation for the ∞-CFL with nonuniform capacities by reducing it to a linear-cost facility location problem.

Our results. In this paper, we analyze local search heuristics for three problems.

1. For metric k-median, we show that the local search with single swaps has a locality gap of 5. This is the first analysis of a local search for k-median that provides a bounded performance guarantee with only k medians. We also show that doing multiple swaps, that is, dropping at most p facilities and opening the same number of new facilities, yields a locality gap of $3 + 2/p$. This improves on the 4 approximation algorithm for k-median by Charikar and Guha [4]. Our analysis of the locality gap is tight; that is, for an infinite family of instances there is a locally optimum solution whose service cost is nearly $(3 + 2/p)$ times that of the global optimum.
2. For metric UFL, we show that local search, which permits adding, dropping, and swapping a facility, has a locality gap of 3. This improves the bound of 5 given by Korupolu, Plaxton, and Rajaraman [14]. Again, our analysis of the algorithm is tight. We show how our algorithm can be improved to achieve a $1 + \sqrt{2} + \epsilon \approx 2.414 + \epsilon$ approximation using ideas from [4].
3. For metric ∞-CFL, we consider the setting when the capacities may be nonuniform and argue that local search, where the only operation permitted is to add multiple copies of a facility and drop zero or more facilities, has a locality gap of at most 4. We give a polynomial time algorithm that uses `Knapsack` as a subroutine to search for a lower cost solution in the neighborhood. We also show that there is a locally optimum solution with cost 3 times the optimum. We show how our algorithm can be improved to achieve a $1 + \sqrt{3} + \epsilon \approx 3.732 + \epsilon$ approximation using ideas from [4].

The paper is organized as follows. Section 2 introduces some notation and defines the problems addressed in this paper formally. In section 3, we first prove a locality gap of 5 for the k-median problem when only single swaps are permitted and then extend the analysis to argue a locality gap of $3 + 2/p$ when up to p facilities can be swapped simultaneously. Sections 4 and 5 discuss the algorithms for UFL and ∞-CFL, respectively. Section 6 concludes with some open problems.

2. Notation and preliminaries. In the k-median and facility location problems, we are given two sets: F, the set of *facilities*, and C, the set of *clients*. Let $c_{ij} \geq 0$ denote the cost of serving client $i \in C$ by a facility $j \in F$; we will think of this as the distance between client i and facility j. The goal in these problems is to

identify a subset of facilities $S \subseteq F$ and to serve all clients by facilities in S such that some objective function is minimized. The facilities in S are said to be *open*. The metric versions of these problems assume that distances c_{ij} are symmetric and satisfy the triangle inequality. The problems considered in this paper are defined as follows.

1. The metric k-median problem. Given integer k, identify a set $S \subseteq F$ of at most k facilities to open such that the total cost of serving all clients by open facilities is minimized.
2. The metric UFL problem. For each facility $i \in F$, we are given a cost $f_i \geq 0$ of opening the facility i. The goal is to identify a set of facilities $S \subseteq F$ such that the total cost of opening the facilities in S and serving all the clients by open facilities is minimized.
3. The metric ∞-CFL problem. For each facility $i \in F$, we are given a cost $f_i \geq 0$ of opening a copy of facility i and an integer capacity $u_i > 0$, which is the maximum number of clients that a single copy of the facility i can serve. The output is a set of facilities $S \subseteq F$ and the number of copies of each facility in S to be opened. The goal is to serve each client by a copy of a facility in S such that the number of clients served by a copy of a facility is at most its capacity. The objective is to minimize the total facility cost and the cost of serving all the clients.

Thus for all the problems we consider, a solution can be specified by giving the set of open facilities together with their multiplicities. In the rest of this paper we will think of a solution as a multiset of facilities.

Algorithm `Local Search.`

1. $S \leftarrow$ an arbitrary feasible solution in $\mathcal{S}$.
2. While $\exists\, S' \in \mathcal{B}(S)$ such that $cost(S') < cost(S)$,
   do $S \leftarrow S'$.
3. return S.

FIG. 1. *A generic local search algorithm.*

A generic local search algorithm (Figure 1) can be described by a set $\mathcal{S}$ of all feasible solutions, a cost function $cost : \mathcal{S} \to \mathbb{R}$, a *neighborhood* structure $\mathcal{B} : \mathcal{S} \to 2^{\mathcal{S}}$, and an oracle that, given any solution S, finds (if possible) a solution $S' \in \mathcal{B}(S)$ such that $cost(S') < cost(S)$. A solution $S \in \mathcal{S}$ is called *locally optimum* if $cost(S) \leq cost(S')$ for all $S' \in \mathcal{B}(S)$; the algorithm in Figure 1 always returns one such solution. The cost function and the neighborhood structure $\mathcal{B}$ will be different for different problems and algorithms.

If S is a locally optimum solution, then for all $S' \in \mathcal{B}(S)$,

$$cost(S') - cost(S) \geq 0.$$

Our proof of the locality gap proceeds by considering a suitable, polynomially large (in the input size) subset $\mathcal{Q} \subseteq \mathcal{B}(S)$ of neighboring solutions and arguing that

$$\sum_{S' \in \mathcal{Q}} (cost(S') - cost(S)) \leq \alpha \cdot cost(O) - cost(S),$$

where O is an optimum solution and $\alpha > 1$ a suitable constant. This implies that $cost(S) \leq \alpha \cdot cost(O)$, which gives a bound of α on the locality gap.

To translate the proof of the locality gap into an approximation algorithm with polynomial running time, we modify step 2 of the algorithm as follows.

2. While $\exists\, S' \in \mathcal{B}(S)$ such that $cost(S') \leq (1 - \epsilon/Q)\ cost(S)$, do $S \leftarrow S'$.

Here $\epsilon > 0$ is a constant and $Q = |\mathcal{Q}|$. Thus, in each local step, the cost of the current solution decreases by a factor of at least ϵ/Q. If O denotes an optimum solution and S_0 denotes the initial solution, then the number of steps in the algorithm is at most $\log(cost(S_0)/cost(O))/\log\frac{1}{1-\epsilon/Q}$. As $Q, \log(cost(S_0))$, and $\log(cost(O))$ are polynomial in the input size, the algorithm terminates after polynomially many local search steps.

To analyze the quality of this locally optimum solution S, we note that for all $S' \in \mathcal{Q}$, $cost(S') > (1 - \epsilon/Q)cost(S)$. Hence

$$\alpha \cdot cost(O) - cost(S) \geq \sum_{S' \in \mathcal{Q}} (cost(S') - cost(S)) > -\epsilon \cdot cost(S),$$

which implies that $cost(S) \leq \frac{\alpha}{(1-\epsilon)} cost(O)$. Thus our proof that a certain local search procedure has a locality gap of at most α translates into an $\alpha/(1-\epsilon)$ approximation algorithm with a running time that is polynomial in the input size and $1/\epsilon$.

We use the following notation. Given a solution A, let A_j denote the *service cost* of client j, which is the distance between j and the facility in A which serves it. For every facility $a \in A$, we use $N_A(a)$ to denote the set of clients that a serves (Figure 2). For a subset of facilities, $T \subseteq A$, let $N_A(T) = \bigcup_{a \in T} N_A(a)$.

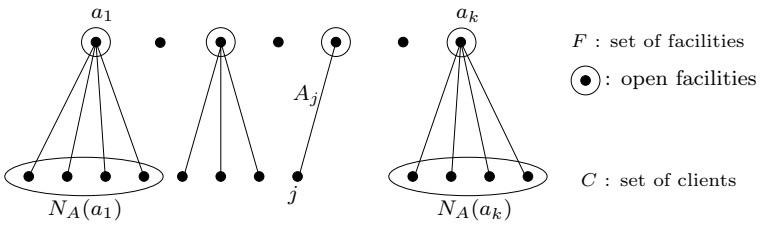

FIG. 2. *Illustration of neighborhood and service costs.*

3. The *k*-median problem. The k-median problem is to open a subset $S \subseteq F$ of at most k facilities so that the total service cost is minimized. Thus, if a client j is served by a facility $\sigma(j) \in S$, then we wish to minimize $cost(S) = \sum_{j \in C} c_{j\sigma(j)}$. For a fixed S, serving each client by the nearest facility in S minimizes this cost.

3.1. Local search with single swaps. In this section, we consider a local search using single swaps. A swap is effected by closing a facility $s \in S$ and opening a facility $s' \notin S$ and is denoted by $\langle s, s' \rangle$; hence $\mathcal{B}(S) = \{S - \{s\} + \{s'\} \mid s \in S\}$. We start with an arbitrary set of k facilities and keep improving our solution with such swaps until we reach a locally optimum solution. The algorithm is described in Figure 1. We use $S - s + s'$ to denote $S - \{s\} + \{s'\}$.

3.2. The analysis. We now show that this local search procedure has a locality gap of 5. Let S be the solution returned by the local search procedure and let O be an optimum solution. From the local optimality of S, we know that

$$cost(S - s + o) \geq cost(S) \quad \text{for all } s \in S, o \in O. \tag{1}$$

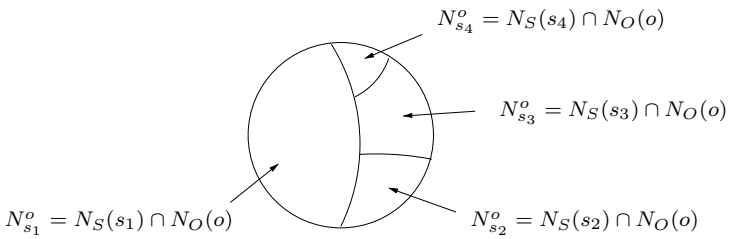

FIG. 3. *Partitioning* $N_O(o)$.

Note that even if $S \cap O \neq \emptyset$, the above inequalities hold. We combine these inequalities to show that $cost(S) \leq 5 \cdot cost(O)$.

Consider a facility $o \in O$. We partition $N_O(o)$ into subsets $N^o_s = N_O(o) \cap N_S(s)$ as shown in Figure 3.

DEFINITION 3.1. *We say that a facility* $s \in S$ captures *a facility* $o \in O$ *if* s *serves more than half the clients served by* o*, that is,* $|N^o_s| > \frac{1}{2}|N_O(o)|$.

It is easy to see that a facility $o \in O$ is captured by at most one facility in S. We call a facility $s \in S$ *bad*, if it captures some facility $o \in O$, and *good* otherwise. Fix a facility $o \in O$ and consider a 1-1 and onto function $\pi : N_O(o) \to N_O(o)$ satisfying the following property (Figure 4).

PROPERTY 3.1. *If* s *does not capture* o*, that is,* $|N^o_s| \leq \frac{1}{2}|N_O(o)|$*, then* $\pi(N^o_s) \cap N^o_s = \emptyset$.

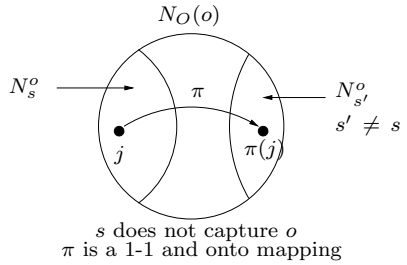

FIG. 4. *The mapping* π *on* $N_O(o)$.

We outline how to obtain one such mapping π. Let $D = |N_O(o)|$. Order the clients in $N_O(o)$ as $c_0, \ldots, c_{D-1}$ such that for every $s \in S$ with a nonempty N^o_s, the clients in N^o_s are consecutive; that is, there exists p, q, $0 \leq p \leq q \leq D-1$, such that $N^o_s = \{c_p, \ldots, c_q\}$. Now, define $\pi(c_i) = c_j$, where $j = (i + \lfloor D/2 \rfloor)$ modulo D. For contradiction assume that both $c_i, \pi(c_i) = c_j \in N^o_s$ for some s, where $|N^o_s| \leq D/2$. If $j = i + \lfloor D/2 \rfloor$, then $|N^o_s| \geq j - i + 1 = \lfloor D/2 \rfloor + 1 > D/2$. If $j = i + \lfloor D/2 \rfloor - D$, then $|N^o_s| \geq i - j + 1 = D - \lfloor D/2 \rfloor + 1 > D/2$. In both cases we have a contradiction, and hence function π satisfies property 3.1.

The notion of *capture* can be used to construct a bipartite graph $H = (S, O, E)$ (Figure 5). For each facility in S we have a vertex on the S-side, and for each facility in O we have a vertex on the O-side. We add an edge between $s \in S$ and $o \in O$ if s captures o. It is easy to see that each vertex on the O-side has degree at most one, while vertices on the S-side can have degree up to k. We call H the *capture graph*.

We now consider k swaps, one for each facility in O. If some bad facility $s \in S$

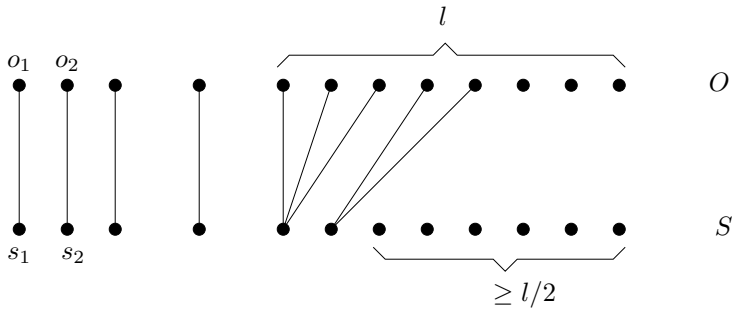

FIG. 5. *Capture graph* $H = (S, O, E)$.

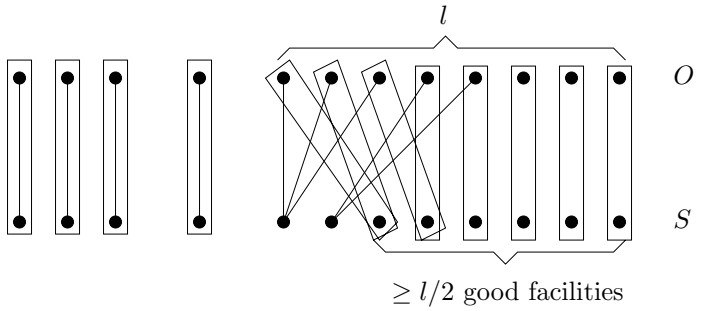

FIG. 6. *k swaps considered in the analysis.*

captures exactly one facility $o \in O$, then we consider the swap $\langle s, o\rangle$. Suppose l facilities in S (and hence l facilities in O) are not considered in such swaps. Each facility out of these l facilities in S is either good or captures at least two facilities in O. Hence there are at least $l/2$ good facilities in S. Now, consider l swaps in which the remaining l facilities in O get swapped with the good facilities in S such that each good facility is considered in at most two swaps (Figure 6). The bad facilities which capture at least two facilities in O are not considered in any swaps. The swaps considered above satisfy the following properties.

1. Each $o \in O$ is considered in exactly one swap.
2. A facility $s \in S$ which captures more than one facility in O is not considered in any swap.
3. Each good facility $s \in S$ is considered in at most two swaps.
4. If swap $\langle s, o\rangle$ is considered, then facility s does not capture any facility $o' \neq o$.

We now analyze these swaps one by one. Consider a swap $\langle s, o\rangle$. We place an upper bound on the increase in the cost due to this swap by reassigning the clients in $N_S(s) \cup N_O(o)$ to the facilities in $S - s + o$ as follows (Figure 7). The clients $j \in N_O(o)$ are now assigned to o. Consider a client $j' \in N_s^{o'}$ for $o' \neq o$. As s does not capture o', by Property 3.1 of π we have that $\pi(j') \notin N_S(s)$. Let $\pi(j') \in N_S(s')$. Note that the distance that the client j' travels to the nearest facility in $S - s + o$ is at most $c_{j's'}$. From triangle inequality, $c_{j's'} \leq c_{j'o'} + c_{\pi(j')o'} + c_{\pi(j')s'} = O_{j'} + O_{\pi(j')} + S_{\pi(j')}$. The clients which do not belong to $N_S(s) \cup N_O(o)$ continue to be served by the same facility. From inequality (1) we have

$$cost(S - s + o) - cost(S) \geq 0.$$

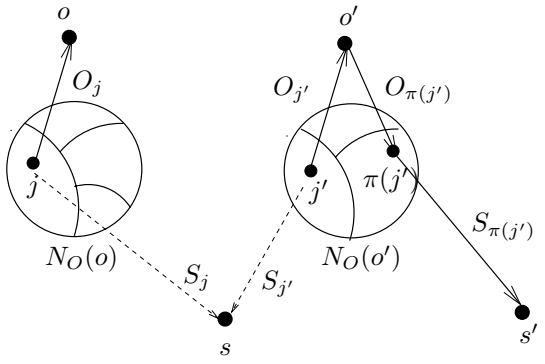

FIG. 7. *Reassigning the clients in* $N_S(s) \cup N_O(o)$.

Therefore,

$$\sum_{j \in N_O(o)} (O_j - S_j) + \sum_{\substack{j \in N_S(s), \\ j \notin N_O(o)}} (O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) \geq 0. \tag{2}$$

As each facility $o \in O$ is considered in exactly one swap, the first term of inequality (2) added over all k swaps gives exactly $cost(O) - cost(S)$. For the second term, we will use the fact that each $s \in S$ is considered in at most two swaps. Since S_j is the shortest distance from client j to a facility in S, using triangle inequality we get $O_j + O_{\pi(j)} + S_{\pi(j)} \geq S_j$. Thus the second term of inequality (2) added over all k swaps is no greater than $2\sum_{j \in C}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j)$. But since π is a 1-1 and onto mapping, $\sum_{j \in C} O_j = \sum_{j \in C} O_{\pi(j)} = cost(O)$ and $\sum_{j \in C}(S_{\pi(j)} - S_j) = 0$. Thus, $2\sum_{j \in C}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) = 4 \cdot cost(O)$. Combining the two terms, we get $cost(O) - cost(S) + 4 \cdot cost(O) \geq 0$. Thus we have the following theorem.

THEOREM 3.2. *A local search procedure for the metric k-median problem with the local neighborhood structure defined by* $\mathcal{B}(S) = \{S - \{s\} + \{s'\} \mid s \in S\}$ *has a locality gap of at most* 5.

The above algorithm and analysis extend very simply to the case when the clients $j \in C$ have arbitrary demands $d_j \geq 0$ to be served.

3.3. Local search with multiswaps. In this section, we generalize the algorithm in section 3 to consider multiswaps in which up to $p > 1$ facilities could be swapped simultaneously. The neighborhood structure is now defined by

$$\mathcal{B}(S) = \{(S \setminus A) \cup B \mid A \subseteq S,\ B \subseteq F, \text{ and } |A| = |B| \leq p\}. \tag{3}$$

The neighborhood captures the set of solutions obtainable by deleting a set of at most p facilities A and adding a set of facilities B where $|B| = |A|$; this swap will be denoted by $\langle A, B \rangle$. We prove that the locality gap of the k-median problem with respect to this operation is exactly $(3 + 2/p)$.

3.4. Analysis. We extend the notion of capture as follows. For a subset $A \subseteq S$, we define

$$capture(A) = \{o \in O \mid |N_S(A) \cap N_O(o)| > |N_O(o)|/2\}.$$

It is easy to observe that if $X, Y \subseteq S$ are disjoint, then $capture(X)$ and $capture(Y)$ are disjoint and if $X \subset Y$, then $capture(X) \subseteq capture(Y)$. We now partition S into sets $A_1, \ldots, A_r$ and O into sets $B_1, \ldots, B_r$ such that

procedure Partition;
  $i = 0$
  while $\exists$ a bad facility in S **do**
    1. $i = i + 1$ {iteration i}
    2. $A_i \leftarrow \{b\}$ where $b \in S$ is any bad facility
    3. $B_i \leftarrow capture(A_i)$
    4. while $|A_i| \neq |B_i|$ **do**
      4.1. $A_i \leftarrow A_i \cup \{g\}$ where $g \in S \setminus A_i$ is any good facility
      4.2. $B_i \leftarrow capture(A_i)$
    5. $S \leftarrow S \setminus A_i$
      $O \leftarrow O \setminus B_i$
  $A_r \leftarrow S$
  $B_r \leftarrow O$
end.

FIG. 8. *A procedure to define the partitions.*

1. for $1 \leq i \leq r-1$, we have $|A_i| = |B_i|$ and $B_i = capture(A_i)$; since $|S| = |O|$, it follows that $|A_r| = |B_r|$;
2. for $1 \leq i \leq r-1$, the set A_i has exactly one bad facility;
3. the set A_r contains only good facilities.

A procedure to obtain such a partition is given in Figure 8.

CLAIM 3.1. *The procedure defined in Figure* 8 *terminates with partitions of S and O, satisfying the properties listed above.*

Proof. The condition in the while loop in step 4 and the assignment in step 5 of the procedure maintain the invariant that $|S| = |O|$. Steps 3 and 4.2 of the procedure ensure that for $1 \leq i \leq r-1$, we have $B_i = capture(A_i)$, and steps 2 and 4.1 ensure that each for $1 \leq i \leq r-1$, the set A_i has exactly one bad facility. Now before each execution of step 4.1, we have $|A_i| < |B_i|$. This together with the invariant that $|S| = |O|$ implies that in step 4.1, we can always find a good facility in $S \setminus A_i$. Since with each execution of the while loop in step 4 the size of A_i increases, the loop terminates. The condition in step 4 then ensures that for $1 \leq i \leq r-1$, we have $|A_i| = |B_i|$. Since there are no bad facilities left when the procedure comes out of the outer while loop, we have that the set A_r contains only good facilities. □

We now use this partition of S and O to define the swaps we would consider for our analysis. We also associate a positive real weight with each such swap.

1. If $|A_i| = |B_i| \leq p$ for some $1 \leq i \leq r$, then we consider the swap $\langle A_i, B_i \rangle$ with weight 1. From the local optimality of S we have

$$cost((S \setminus A_i) \cup B_i) - cost(S) \geq 0.$$

   Note that even if $A_i \cap B_i \neq \emptyset$ or $S \cap B_i \neq \emptyset$, the above inequality continues to hold.
2. If $|A_i| = |B_i| = q > p$, we consider all possible swaps $\langle s, o \rangle$ where $s \in A_i$ is a good facility and $o \in B_i$. Note that if $i \neq r$, there are exactly $q-1$ good facilities in A_i, and for $i = r$ we select any $q-1$ out of the q good facilities in A_r. We associate a weight of $1/(q-1)$ with each of these $q(q-1)$ swaps. For each such swap $\langle s, o \rangle$, we have

$$cost(S - s + o) - cost(S) \geq 0.$$

Note that any good facility in A_i is considered in swaps of total weight at most $q/(q-1) \leq (p+1)/p$. The swaps we have considered and the weights we assigned to them satisfy the following properties:

1. For every facility $o \in O$, the sum of weights of the swaps $\langle A, B\rangle$ with $o \in B$ is exactly one.
2. For every facility $s \in S$, the sum of weights of the swaps $\langle A, B\rangle$ with $s \in A$ is at most $(p+1)/p$.
3. If a swap $\langle A, B\rangle$ is considered, then $capture(A) \subseteq B$.

For each facility $o \in O$, we partition $N_O(o)$ as follows:

1. For $|A_i| \leq p, 1 \leq i \leq r$, let $N^o_{A_i} = N_S(A_i) \cap N_O(o)$ be a set in the partition.
2. For $|A_i| > p, 1 \leq i \leq r$, and all $s \in A_i$, let $N^o_s = N_S(s) \cap N_O(o)$ be a set in the partition.

As before, for each facility $o \in O$, we consider a 1-1 and onto mapping $\pi : N_O(o) \to N_O(o)$ with the following property.

PROPERTY 3.2. *For all sets P, in the partition of $N_O(o)$ for which $|P| \leq \frac{1}{2}|N_O(o)|$, we have $\pi(P) \cap P = \emptyset$.* Such a mapping π can be defined in a manner identical to the one described in section 3.2. The analysis is similar to the one presented for the single-swap heuristic. For each of the swaps defined above, we upper-bound the increase in the cost by reassigning the clients. Property 3.2 ensures that the function π can be used to do the reassignment as described in section 3.2. We take a weighted sum of the inequalities corresponding to each of the swaps considered above. Recall that in the single-swap analysis, we used the fact that each facility in S was considered in at most two swaps and upper-bounded the second term of (2) by $2\sum_{j \in C}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) = 4 \cdot cost(O)$. Similarly, we can now make use of the fact that each facility in S is considered in swaps with total weight at most $(p+1)/p$ and upper-bound the second term by $(p+1)/p \cdot \sum_{j \in C}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) = 2(p+1)/p \cdot cost(O)$. This gives us a locality gap of $1 + 2(p+1)/p = 3 + 2/p$.

3.5. Tight example. In Figure 9, we show an instance of the k-median problem in which a solution that is locally optimum for the 2-swap heuristic ($p = 2$) has cost at least $4 - o(1)$ times the cost of the global optimum. Since $3 + 2/p = 3 + 2/2 = 4$ is also the locality gap proved, it shows that the analysis of the 2-swap heuristic is tight. This tight example can be generalized for p-swaps for any $p \geq 1$. In Figure 9, the black squares are the facilities $\{o_1, o_2, \ldots, o_k\}$ opened by a solution O, the gray squares are the facilities $\{s_1, s_2, \ldots, s_k\}$ opened by a locally optimum solution S, and the circles are the clients. In the graph in Figure 9 each edge has a label which is its length. The cost of serving a client j by a facility i is length of the shortest path between client j and facility i in the graph; the cost is infinite if there is no path.

Note that $cost(S) = \frac{8k-10}{3}, cost(O) = \frac{2k+2}{3}$, and hence the ratio $cost(S)/cost(O)$ approaches 4 as k approaches ∞. We now show that S is a locally optimum solution; that is, if we swap $\{o_l, o_m\}$ for $\{s_i, s_j\}$, then the cost does not decrease. To show this we consider various cases:

1. $i, j \leq r$. Then o_l, o_m will have to lie in the connected components containing s_i, s_j. But in this case the cost would increase by 4.
2. $i \leq r < j$. At least one of o_l, o_m would have to lie in the connected component containing s_i; let this be o_l. If o_m also lies in this component, then the cost remains unchanged. If o_m is in a different component and $m \leq k-2$, then the cost increases by 2. If $m > k-2$, then the cost of the solution increases by 3.

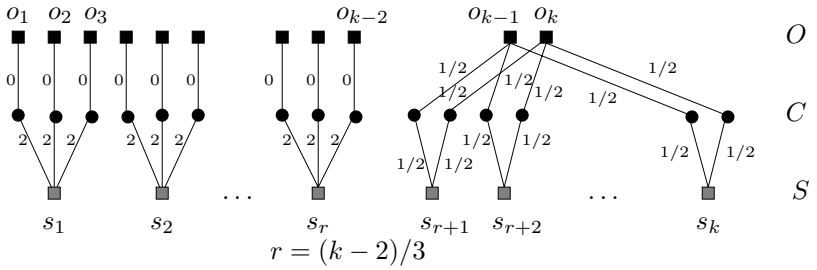

FIG. 9. *Tight example for* 2*-swap. The same example can be generalized to p-swap.*

3. $i, j > r$. If both l, m are at most $k-2$, then the cost of the solution remains unchanged. The cost remains unchanged even if $l \leq k-2 < m$. If both l, m are larger than $k-2$, then, once again, the cost of the solution remains unchanged.

4. Uncapacitated facility location. In facility location problems, we can open any number of facilities, but each facility $i \in F$ has a cost $f_i \geq 0$ of opening it. The UFL problem is to identify a subset $S \subseteq F$ and to serve the clients in C by the facilities in S such that the sum of facility costs and service costs is minimized. That is, if a client $j \in C$ is assigned to a facility $\sigma(j) \in S$, then we want to minimize $cost(S) = \sum_{i \in S} f_i + \sum_{j \in C} c_{\sigma(j)j}$. Note that for a fixed S, serving each client by the nearest facility in S minimizes the service cost.

4.1. A local search procedure. We present a local search procedure for the metric UFL problem with a locality gap of 3. The operations allowed in a local search step are adding a facility, deleting a facility, and swapping facilities. Hence the neighborhood $\mathcal{B}$ is defined by

$$\mathcal{B}(S) = \{S + \{s'\}\} \cup \{S - \{s\} \mid s \in S\} \cup \{S - \{s\} + \{s'\} \mid s \in S\}. \tag{4}$$

As the number of neighbors to be checked at each local search step is polynomial, the algorithm can be run in polynomial time as described earlier.

Charikar and Guha [4] proved a locality gap of 3 for a local search procedure where the operation was of adding a facility and dropping zero or more facilities. Korupolu, Plaxton, and Rajaraman [14] considered the operations of adding, deleting, and swapping a facility but could only prove a locality gap of at most 5.

4.2. The analysis. For any set of facilities $S' \subseteq F$, let $cost_f(S') = \sum_{i \in S'} f_i$ denote the facility cost of the solution S'. Also, let $cost_s(S')$ be the total cost of serving the clients in C by the nearest facilities in S'. The total cost of a solution S' is denoted by $cost(S')$. We use S to denote a locally optimum solution. The following bound on the service cost of S has earlier been proved by Korupolu, Plaxton, and Rajaraman [14].

LEMMA 4.1 (service cost).

$$cost_s(S) \leq cost_f(O) + cost_s(O).$$

Proof. Consider an operation in which a facility $o \in O$ is added. Assign all the clients $N_O(o)$ to o. From the local optimality of S we get $f_o + \sum_{j \in N_O(o)} (O_j - S_j) \geq 0$. Note that even if $o \in S$, this inequality continues to hold. If we add such inequalities for every $o \in O$, we get the desired inequality. ∎

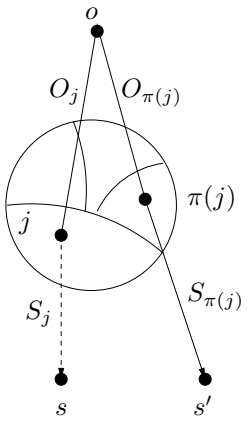

FIG. 10. *Bounding the facility cost of a good facility s.*

The following lemma gives a bound on the facility cost of S.

LEMMA 4.2 (facility cost).

$$cost_f(S) \leq cost_f(O) + 2 \cdot cost_s(O).$$

Proof. As before, we assume that for a fixed $o \in O$, the mapping $\pi : N_O(o) \to N_O(o)$ is 1-1 and onto and satisfies Property 3.1. In addition, we assume that if $|N_s^o| > \frac{1}{2}|N_O(o)|$, then for all $j \in N_s^o$ for which $\pi(j) \in N_s^o$, we have that $\pi(j) = j$. Here we give an outline of how to define such a function π. Let $|N_s^o| > \frac{1}{2}|N_O(o)|$. We pick any $|N_s^o| - |N_O(o) \setminus N_s^o|$ clients j from N_s^o and set $\pi(j) = j$. On the remaining clients in $N_O(o)$, the function π is defined in the same manner as in section 3.2.

Recall that a facility $s \in S$ is *good* if it does not capture any o, that is, for all $o \in O$, $|N_s^o| \leq \frac{1}{2}|N_O(o)|$. The facility cost of good facilities can be bounded easily as follows (see Figure 10). Consider an operation in which a good facility $s \in S$ is dropped. Let $j \in N_S(s)$ and $\pi(j) \in N_S(s')$. As s does not capture any facility $o \in O$, we have that $s' \neq s$. If we assign j to s', then we have $-f_s + \sum_{j \in N_S(s)}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) \geq 0$. Since for all $j \in N_S(s), \pi(j) \neq j$, the term $\sum_{\substack{j \in N_S(s) \\ \pi(j)=j}} O_j$ is trivially zero and hence we can rewrite the above inequality as

$$-f_s + \sum_{\substack{j \in N_S(s) \\ \pi(j) \neq j}} (O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) + 2 \sum_{\substack{j \in N_S(s) \\ \pi(j)=j}} O_j \geq 0. \tag{5}$$

For bounding the facility cost of a bad facility $s \in S$ we proceed as follows. Fix a bad facility $s \in S$. Suppose s captures the facilities $P \subseteq O$. Let $o \in P$ be the facility nearest to s. We consider the swap $\langle s, o \rangle$. The clients $j \in N_S(s)$ are now assigned to the facilities in $S - s + o$ as follows:

1. Suppose $\pi(j) \in N_S(s')$ for $s' \neq s$. Then j is assigned to s'. Let $j \in N_O(o')$. We have, $c_{js'} \leq c_{jo'} + c_{\pi(j)o'} + c_{\pi(j)s'} = O_j + O_{\pi(j)} + S_{\pi(j)}$ (Figure 11).
2. Suppose $\pi(j) = j \in N_S(s)$ and $j \in N_O(o)$. Then j is assigned to o.
3. Suppose $\pi(j) = j \in N_S(s)$ and $j \in N_O(o')$ for $o' \neq o$. By Property 3.1 of the mapping π, facility s captures facility o' and hence $o' \in P$. The client j is now assigned to facility o. From triangle inequality, $c_{jo} \leq c_{js} + c_{so}$. Since $o \in P$ is the closest facility to s, we have $c_{so} \leq c_{so'} \leq c_{js} + c_{jo'}$. Therefore, $c_{jo} \leq c_{js} + c_{js} + c_{jo'} = S_j + S_j + O_j$ (Figure 11).

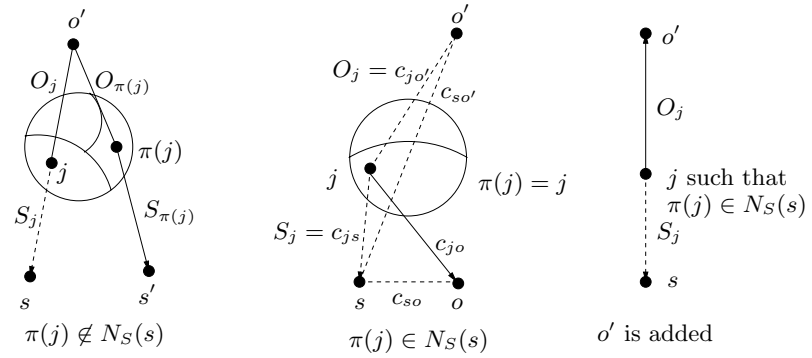

FIG. 11. *Bounding the facility cost of a bad facility s. The figures on the left and in the middle show reassignment when s is dropped, and the figure on the right shows reassignment when o' is added.*

Thus for the swap $\langle s, o\rangle$ we get the following inequality:

$$f_o - f_s + \sum_{\substack{j \in N_S(s) \\ \pi(j) \neq j}} (O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) + \sum_{\substack{j \in N_O(o), \\ \pi(j) = j \in N_S(s)}} (O_j - S_j) + \sum_{\substack{j \notin N_O(o), \\ \pi(j) = j \in N_S(s)}} (S_j + S_j + O_j - S_j) \geq 0. \tag{6}$$

Now consider an operation in which a facility $o' \in P - o$ is added (Figure 11). The clients $j \in N_O(o')$ for which $\pi(j) = j \in N_S(s)$ are now assigned to the facility o', and this yields the following inequality.

$$f_{o'} + \sum_{\substack{j \in N_O(o') \\ \pi(j) = j \in N_S(s)}} (O_j - S_j) \geq 0 \qquad \text{for each } o' \in P - o. \tag{7}$$

Adding inequality (6) to inequalities (7) we get, for a bad facility $s \in S$,

$$\sum_{o' \in P} f_{o'} - f_s + \sum_{\substack{j \in N_S(s), \\ \pi(j) \neq j}} (O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) + 2 \sum_{\substack{j \in N_S(s), \\ \pi(j) = j}} O_j \geq 0. \tag{8}$$

The last term on the left is an upper bound on the sum of the last two terms on the left of inequality (6) and the last term on the left of the inequality (7) added for all $o' \in P - o$.

Now we add inequalities (5) for all good facilities $s \in S$, inequalities (8) for all bad facilities $s \in S$, and inequalities $f_o \geq 0$ for all $o \in O$, which are not captured by any $s \in S$, to obtain

$$\sum_{o \in O} f_o - \sum_{s \in S} f_s + \sum_{\pi(j) \neq j} (O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) + 2 \sum_{\pi(j) = j} O_j \geq 0.$$

Note that $\sum_{j:\pi(j)\neq j} O_j = \sum_{j:\pi(j)\neq j} O_{\pi(j)}$ and $\sum_{j:\pi(j)\neq j} S_j = \sum_{j:\pi(j)\neq j} S_{\pi(j)}$. Therefore we have $\sum_{j:\pi(j)\neq j}(O_j + O_{\pi(j)} + S_{\pi(j)} - S_j) = 2\sum_{j:\pi(j)\neq j} O_j$ and hence $cost_f(O) - cost_f(S) + 2 \cdot cost_s(O) \geq 0$. This proves the desired lemma. □

Combining Lemmas 4.1 and 4.2, we get the following result.

THEOREM 4.3. *The local search procedure for the metric UFL problem with the neighborhood structure* $\mathcal{B}$ *given by* $\mathcal{B}(S) = \{S + \{s'\}\} \cup \{S - \{s\} \mid s \in S\} \cup \{S - \{s\} + \{s'\} \mid s \in S\}$ *has a locality gap of at most* 3.

The algorithm described above extends very simply to the case when the clients $j \in C$ have arbitrary demands $d_j \geq 0$ to be served. We now show how to use a technique from [4] to obtain $1 + \sqrt{2} + \epsilon \approx 2.414 + \epsilon$ approximation to the UFL. The main idea is to exploit the asymmetry in the service and facility cost guarantees.

Note that Lemmas 4.1 and 4.2 hold for any solution O and not just the optimal solution. We multiply the facility costs by a suitable factor $\alpha > 0$ and solve the new instance using local search.

THEOREM 4.4. *The metric UFL problem can be approximated to factor* $1+\sqrt{2}+\epsilon$ *using a local search procedure.*

Proof. As before, we denote the facility cost and the service cost of an optimum solution O by $cost_f(O)$ and $cost_s(O)$, respectively. Let $cost'_f(A)$ and $cost'_s(A)$ denote the facility and service costs of a solution A in the scaled instance and let S be a locally optimum solution. Then

$$\begin{aligned} cost_f(S) + cost_s(S) &= \frac{cost'_f(S)}{\alpha} + cost'_s(S) \\ &\leq \frac{cost'_f(O) + 2cost'_s(O)}{\alpha} + cost'_f(O) + cost'_s(O) \\ &= (1+\alpha)cost_f(O) + \left(1 + \frac{2}{\alpha}\right) cost_s(O). \end{aligned}$$

The inequality follows from Lemmas 4.1 and 4.2. Now, by setting $\alpha = \sqrt{2}$, we get $cost(S) \leq (1 + \sqrt{2})cost(O)$. Thus local search can be used to obtain a $1 + \sqrt{2} + \epsilon$ approximation. ∎

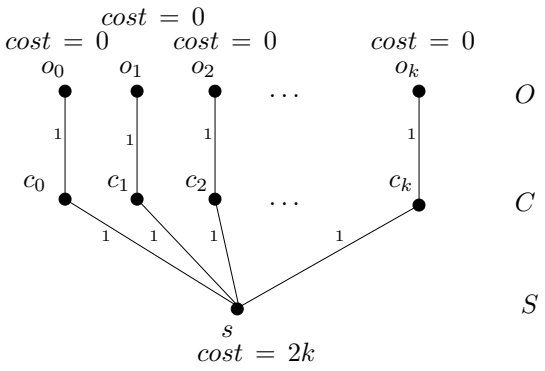

FIG. 12. *Tight example for the locality gap of UFL.*

4.3. Tight example. In Figure 12, we show an instance where a local optimum has cost at least $3 - o(1)$ times the cost of the global optimum. The locally optimum solution S consists of a single facility s while the optimum solution O consists of facilities $\{o_0, o_1, \ldots, o_k\}$. All edges shown have unit lengths, and the cost of serving client j by facility f is the length of the shortest path between client j and facility f in the graph. The cost of opening facility s is $2k$, while that of opening any other facility is zero. To argue that the solution S is locally optimum, note that we cannot delete

facility s. It is also easy to verify that we cannot decrease the cost of our solution by either the addition of any facility from O or by any swap which involves bringing in a facility from O and deleting s. Thus S is locally optimum and has cost $3k+1$, while the cost of O is $k+1$. Since the ratio $cost(S)/cost(O)$ tends to 3 as k tends to ∞, our analysis of the local search algorithm is tight.

5. The capacitated facility location problem. In the CFL problem, along with the facility costs $f_i \geq 0$, we are given integer capacities $u_i > 0$ for each $i \in F$. We can open multiple copies of a facility i. Each copy incurs a cost f_i and is capable of serving at most u_i clients. Note that the capacities u_i may be *different* for different facilities i. The problem is to identify a multiset S of facilities and to serve the clients in C by the facilities in S such that the capacity constraints are satisfied and the sum of the facility costs and the service costs is minimized. Since the clients have unit demands and the facilities have integer capacities, every client will get assigned to a single facility. If a client $j \in C$ is assigned to a facility $\sigma(j) \in S$, then we want to minimize $cost(S) = \sum_{i \in S} f_i + \sum_{j \in C} c_{j\sigma(j)}$. Given an S, the service cost can be minimized by solving a min-cost assignment problem.

In the remainder of this section we let S and O be the multisets of the facilities opened in the locally optimum solution and an optimum solution, respectively.

5.1. A local search algorithm. In this section, we prove a locality gap of at most 4 on a local search procedure for the CFL problem. The operations allowed at each local search step are adding a single copy of a facility $s' \in F$ or adding $l \geq 1$ copies of a facility $s' \in F$ and dropping a subset of the open facilities, $T \subseteq S$. For the second operation l should be sufficiently large so that the clients $j \in N_S(T)$ can be served by these new copies of s', that is, $l \cdot u_{s'} \geq |N_S(T)|$. So the neighborhood structure $\mathcal{B}$ is defined by

$$\mathcal{B}(S) = \{S + s' \mid s' \in F\} \cup \{S - T + l \cdot \{s'\} \mid s' \in F, T \subseteq S, l \cdot u_{s'} \geq |N_S(T)|\}, \tag{9}$$

where $l \cdot \{s'\}$ represents l new copies of s'. If we service all clients in $N_S(T)$ by the new copies of facility s', the cost of the new solution is at most

$$cost(S) + l \cdot f_{s'} + \sum_{s \in T} \left(-f_s + \sum_{j \in N_S(s)} (c_{js'} - c_{js}) \right).$$

Given a facility $s' \in F$, we use the procedure `T-hunt` described in Figure 13 to find a subset, $T \subseteq S$, of facilities to close. Here $m = |C|$ is an upper bound on the number of new copies of s' that we need to open. Closing a facility $s \in S$ gives an extra $|N_S(s)|$ clients to be served by the new facility s'. A client $j \in N_S(s)$ now travels an extra distance of at most $(c_{s'j} - c_{sj})$. Thus, closing facility s gives a *savings* of $f_s - \sum_{j \in N_S(s)} (c_{s'j} - c_{sj})$. Due to capacity constraints, a copy of s' can serve at most $u_{s'}$ clients. This motivates us to define the following `Knapsack` problem. For a facility $s \in S$, define $\texttt{weight}(s) = |N_S(s)|$ and $\texttt{profit}(s) = f_s - \sum_{j \in N_S(s)} (c_{s'j} - c_{sj})$. The oracle $\texttt{Knapsack}(W)$ returns a multiset $T \subseteq S$ such that $\sum_{s \in T} \texttt{weight}(s) \leq W$ and $\texttt{profit}(T) = \sum_{s \in T} \texttt{profit}(s)$ is maximized.

It is interesting to note that since we permit any subset of facilities T from our current solution S to be dropped, the number of operations is exponential in $|S|$. However, by counting the change in cost due to each such operation in a specific way, we are able to give a polynomial time procedure (the procedure `T-hunt`) to identify a local operation which improves the cost. It might be the case that `T-hunt` is not able

Procedure `T-Hunt`.

1. For $l = 1$ to m do,
2. $\quad T \leftarrow \texttt{Knapsack}(l \cdot u_{s'})$.
3. $\quad$ If $cost(S) + l \cdot f_{s'} - \texttt{profit}(T) < cost(S)$, then return T.
4. return "could not find a solution that reduces the cost."

FIG. 13. *A procedure to find a subset $T \subseteq S$ of facilities.*

to identify a local operation which improves the cost even though such operations exist. However, our analysis will work only with the assumption that `T-hunt` could not find a solution which improves the cost.

5.2. The analysis. As the output S is locally optimum with respect to additions, Lemma 4.1 continues to bound the service cost of S. We restate Lemma 4.1 here.

LEMMA 5.1 (service cost).

$$cost_s(S) \leq cost_f(O) + cost_s(O).$$

LEMMA 5.2. *For any $U \subseteq S$ and any $s' \in F$, we have*

$$\lceil |N_S(U)|/u_{s'} \rceil \cdot f_{s'} + \sum_{s \in U} |N_S(s)| \cdot c_{ss'} \geq \sum_{s \in U} f_s.$$

Proof. The algorithm terminated with the output S. Hence for the solution S and for the facility s', the procedure `T-hunt` must have returned "could not find a solution that reduces the cost." Consider the run of the for-loop for $l = \lceil |N_S(U)|/u_{s'} \rceil$. Since $\sum_{s \in U} \texttt{weight}(s) = N_S(U) \leq l \cdot u_{s'}$, the solution T returned by the knapsack oracle has profit at least as large as `profit`(U). Hence,

$$0 \leq l \cdot f_{s'} - \texttt{profit}(T) \leq l \cdot f_{s'} - \texttt{profit}(U) = l \cdot f_{s'} - \sum_{s \in U} \left(f_s - \sum_{j \in N_S(U)} (c_{js'} - c_{js}) \right).$$

However, by triangle inequality we have $c_{js'} - c_{js} \leq c_{ss'}$. Therefore we have proved the lemma. ∎

We are now ready to bound the facility cost of S.

LEMMA 5.3 (facility cost).

$$cost_f(S) \leq 3 \cdot cost_f(O) + 2 \cdot cost_s(O).$$

To prove the above lemma, we consider a directed graph $G = (V, E)$ with lengths on edges, where

$$V = \{v_s \mid s \in S\} \cup \{w_o \mid o \in O\} \cup \{sink\},$$

$$E = \{(v_s, w_o) \mid s \in S, o \in O\} \cup \{(w_o, sink) \mid o \in O\}.$$

The lengths of (v_s, w_o) and $(w_o, sink)$ are c_{so} and f_o/u_o, respectively (see Figure 14). The cost of routing unit flow along any edge is equal to the length of that edge. We want to simultaneously route $|N_S(s)|$ units of flow from each v_s to the *sink*.

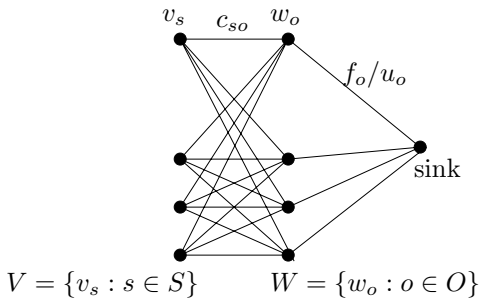

FIG. 14. *The flow graph.*

LEMMA 5.4. *We can simultaneously route $|N_S(s)|$ units of flow from each v_s to the sink such that the total routing cost is at most $cost_s(S) + cost_s(O) + cost_f(O)$.*

Proof. Consider a client $j \in C$. If $j \in N_s^o$, then route one unit of flow along the path $v_s \to w_o \to sink$. Triangle inequality implies $c_{so} \le S_j + O_j$. If for each client we route a unit flow in this manner, then the edge $(w_o, sink)$ carries $N_O(o)$ units of flow at cost $|N_O(o)| \cdot f_o/u_o \le \lceil |N_O(o)|/u_o \rceil \cdot f_o$, which is the contribution of o to $cost_f(O)$. Thus, the routing cost of this flow is at most $cost_s(S) + cost_s(O) + cost_f(O)$. ∎

Since there are no capacities on the edges of graph G, any minimum cost flow must route all $N_S(s)$ units of flow from v_s to the sink along the shortest path. This would be a path (v_s, w_o, sink), where o is such that $c_{so} + f_o/u_o$ is minimized with ties broken arbitrarily. For each $o \in O$, let $T_o \subseteq S$ denote the set of facilities s that route their flow via w_o in this minimum cost flow. From Lemma 5.4, we have

$$cost_s(S) + cost_s(O) + cost_f(O) \ge \sum_{o \in O} \sum_{s \in T_o} |N_S(s)|(c_{so} + f_o/u_o). \tag{10}$$

Now, applying Lemma 5.2 to T_o and o, we get

$$\lceil |N_S(T_o)|/u_o \rceil \cdot f_o + \sum_{s \in T_o} |N_S(s)| \cdot c_{so} \ge \sum_{s \in T_o} f_s.$$

Hence,

$$f_o + |N_S(T_o)|/u_o \cdot f_o + \sum_{s \in T_o} |N_S(s)| \cdot c_{so} \ge \sum_{s \in T_o} f_s.$$

Adding these inequalities for all $o \in O$, we get

$$\sum_{o \in O} f_o + \sum_{o \in O} \sum_{s \in T_o} |N_S(s)|(c_{so} + f_o/u_o) \ge \sum_{o \in O} \sum_{s \in T_o} f_s = cost_f(S). \tag{11}$$

The inequalities (10) and (11) together imply

$$cost_f(S) \le 2 \cdot cost_f(O) + cost_s(O) + cost_s(S).$$

This inequality, together with Lemma 5.1, gives Lemma 5.3. Combining Lemmas 5.1 and 5.3, we obtain the following result.

THEOREM 5.5. *A local search procedure for the metric CFL problem where in each step we can either add a facility or delete a subset of facilities and add multiple copies of a facility has a locality gap of at most* 4.

Using an argument similar to the one in Theorem 4.4 with $\alpha = \sqrt{3} - 1$ we obtain a $2 + \sqrt{3} + \epsilon \approx 3.732 + \epsilon$ approximation. The tight example given in section 4.3 for the UFL problem shows that a locally optimum solution for this problem can have cost three times the cost of the global optimum.

6. Conclusions and open problems. In this paper, we provided tighter analysis of local search procedures for the k-median and UFL problems. Our sharper analysis leads to a $3 + 2/p + \epsilon$ approximation algorithm for the k-median in which there are polynomially many local search steps, each of which can be performed in time $n^{O(p)}$. For CFL, when multiple copies of a facility can be opened, we introduce a new operation and show how a weaker version of this operation can be performed in polynomial time. This leads to a local search procedure with a locality gap of at most 4. We leave open the problem of obtaining tight bounds on the locality gap of this procedure. It would be interesting to identify such operations for other variants of facility location problems.

Acknowledgments. Arya, Garg, Khandekar, and Pandit first published a preliminary version of this paper which did not include the results in sections 3.3 and 3.4. After this version was distributed, Meyerson–Munagala and Arya–Garg–Khandekar–Pandit independently obtained the results in sections 3.3 and 3.4. Garg and Khandekar would like to thank R. Ravi, Amitabh Sinha, and Goran Konjevod for useful discussions.

BUFFER OVERFLOW MANAGEMENT IN QoS SWITCHES*

ALEXANDER KESSELMAN†, ZVI LOTKER‡, YISHAY MANSOUR†,
BOAZ PATT-SHAMIR‡, BARUCH SCHIEBER§, AND MAXIM SVIRIDENKO§

Abstract. We consider two types of buffering policies that are used in network switches supporting Quality of Service (QoS). In the *FIFO* type, packets must be transmitted in the order in which they arrive; the constraint in this case is the limited buffer space. In the *bounded-delay* type, each packet has a maximum delay time by which it must be transmitted, or otherwise it is lost. We study the case of overloads resulting in packet loss. In our model, each packet has an intrinsic value, and the goal is to maximize the total value of transmitted packets.

Our main contribution is a thorough investigation of some natural greedy algorithms in various models. For the FIFO model we prove tight bounds on the competitive ratio of the greedy algorithm that discards packets with the lowest value when an overflow occurs. We also prove that the greedy algorithm that drops the earliest packets among all low-value packets is the best greedy algorithm. This algorithm can be as much as 1.5 times better than the tail-drop greedy policy, which drops the latest lowest-value packets.

In the bounded-delay model we show that the competitive ratio of any on-line algorithm for a uniform bounded-delay buffer is bounded away from 1, independent of the delay size. We analyze the greedy algorithm in the general case and in three special cases: delay bound 2, link bandwidth 1, and only two possible packet values.

Finally, we consider the off-line scenario. We give efficient optimal algorithms and study the relation between the bounded-delay and FIFO models in this case.

Key words. buffer overflows, competitive analysis, Quality of Service, FIFO scheduling, deadline scheduling

1. Introduction.

Unlike the "best effort" service provided by the Internet today, next-generation networks will support guaranteed Quality of Service (QoS) features. In order for the network to support QoS each network switch must be able to guarantee a certain level of QoS in some predetermined parameters of interest, including packet loss probability, queuing delay, jitter, and others.

In this work, we consider models based on the IP environment. Implementing QoS in an IP environment is receiving growing attention, since it is widely recognized that future networks would most likely be IP based. There have been a few proposals that address the integration of QoS in the IP framework, and our models are based on some of these proposals, specifically in the general area of providing *differentiated network services* in an IP environment. For example, different customers may get different levels of service, which might depend on the price they pay for the service.

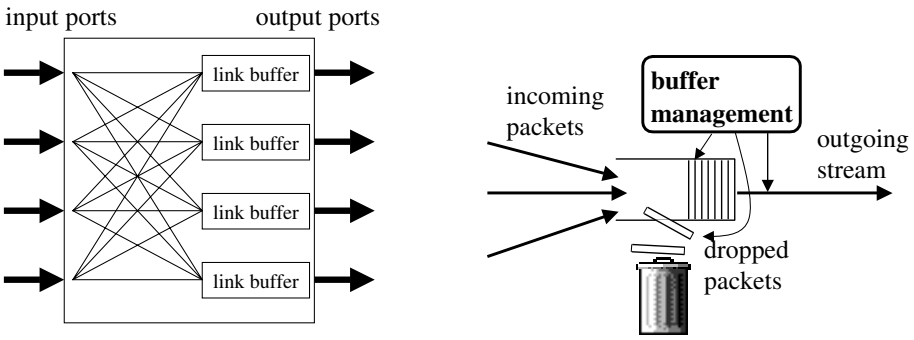

FIG. 1.1. *Schematic representation of the model. Left: general switch structure. Right: output port structure. Packets are placed in the buffer, and the buffer management algorithm controls which packet will be discarded and which will be transmitted.*

One way of guaranteeing QoS is by committing resources to each admitted connection, so that each connection has its dedicated resource set that will guarantee its required level of service regardless of all other connections. This conservative policy (implemented in the specification of CBR traffic in asynchronous transfer mode (ATM) networks [23]) might be extremely wasteful since network traffic tends to be bursty. Specifically, this policy does not take into consideration the fact that *usually*, the worst-case resource requirements of different connections do not occur simultaneously. Recognizing this phenomenon, most modern QoS networks allow some "overbooking," employing the policy popularly known as *statistical multiplexing*. While statistical multiplexing tends to be very cost-effective, it requires satisfactory solutions to the unavoidable events of overload. In this paper we consider such scenarios in the context of *buffering*. The basic situation we consider is an output port of a network switch with the following activities (see Figure 1.1). At each time step, an arbitrary set of packets arrives, but only a fixed number of packets can be transmitted. The buffer management algorithm controls which packets are admitted to the buffer, which are discarded, and which are transmitted at each step.

We consider two types of buffer models. In the *FIFO model*, packets can never be sent out of order: formally, for any two packets p, p' sent at times t, t', respectively, we have that if $t' > t$, then packet p did not arrive after packet p'. The main constraint in this classical model is that the buffer size is fixed, so when too many packets arrive, *buffer overflow* occurs and some packets must be discarded. In most implementations the discard policy is the natural *tail-drop* policy, in which the latest packets are discarded.

The second model we consider is the *bounded delay model*. This model is relatively new, and is warranted by networks that guarantee the QoS parameter of end-to-end delay. Specifically, in the bounded-delay model each packet arrives with a prescribed *allowed delay* time. A packet must be transmitted within its allowed delay time or else it is lost. In this model, the buffer management policy can reorder packets. We consider two variants of the model. In the *uniform* bounded delay model, the switch has a single fixed bound on the delay of all packets, and in the *variable* bounded delay model, the switch may have a different delay bound for each packet.

The focus of our paper is the following simple refinement of the models described above. Each packet arrives with its intrinsic *value*, and the goal of the buffer management algorithm is to discard packets so as to maximize the total value of packets

transmitted. All we assume about the value of the packets is that it is additive; that is, the value of a set of packets is the sum of the values of packets in the set.

In this paper we present a thorough investigation of the natural greedy algorithms in the various models. In the FIFO model, the greedy algorithm discards the lowest-value packets whenever an overflow occurs, with ties broken arbitrarily. We prove a tight bound of $2 - \frac{W}{B+W}$ on the competitive factor of this algorithm, where B is the buffer size and W is the link bandwidth. For the case where the ratio of the maximum to minimum value is bounded by some $\alpha \geq 1$, we prove a tight bound of $2 - \frac{2}{\alpha+1}$ on the competitive factor. The proof of the upper bound is quite involved. We then consider different variants of the greedy algorithms, since the greedy policy does not specify which packet to drop in case there is more than one packet with the lowest value. Specifically, we consider the head-drop greedy policy, which drops the earliest lowest-value packets. We show that for *any* input sequence the head-drop greedy policy achieves equal or better value than any other greedy policy. This is somewhat surprising, since most implementations use the tail-drop policy. Furthermore, we show that the ratio of the value served by the head-drop greedy policy to the value served by the tail-drop policy can be as high as 3/2 in some cases. We also prove a lower bound on the competitive ratio of any on-line algorithm in the FIFO model.

For the bounded delay model we have the following results. First, we show that the competitive ratio of any on-line algorithm for a uniform bounded delay buffer is bounded away from 1, independent of the delay size. This holds even if all packets have an arbitrarily long allowed delay. Next, we consider the simple greedy algorithm, which in this model always sends the packet with the highest value. We prove that the competitive ratio of this algorithm is exactly 2. In the common case when there are only two possible values of packets (i.e., "cheap" and "expensive" packets) the competitive factor of the greedy algorithm is exactly $1 + 1/\alpha$, where $\alpha \geq 1$ is the ratio of the expensive value to the cheap value. We then consider the special case where the delay is less than 2, namely, a packet, if not dropped, is sent when it arrives or in the next time step. We show that in this case, the bound of 2 can be improved: we give algorithms that achieve a competitive ratio of 1.618 for the variable delay model. We also prove lower bounds of 1.11 on the competitive ratio for the uniform delay model and 1.17 for the bounded delay model. Better bounds are presented for the case where the bandwidth link is 1. We show that in this variant slight modifications of the greedy algorithm guarantee better performance.

Lastly, we consider the off-line case. We prove that the overflow management problem has matroid structure in both buffer models, and hence admits efficient optimal off-line algorithms.

Related work. There is a myriad of research papers about packet drop policies in communication networks; see, for example, the survey of [16] and references therein. Some of the drop mechanisms, such as random early detection (RED) [11], are designed to signal congestion to the sending end. The approach abstracted in our model, where each packet has an intrinsic value and the goal is to maximize the total throughput value, is implicit in the recent DiffServ model [8, 9] and ATM [23]. The bounded delay model is an abstraction of the model described in [13].

There has been work on analyzing various aspects of the model using classical queuing theory and assuming Poisson arrivals [21]. The Poisson arrival model has been seriously undermined by the discovery of the heavy tail nature of traffic [18] and the chaotic nature of TCP [24]. In this work we use competitive analysis, which makes no probabilistic assumptions.

The work of [2] concentrated on the case where one cannot discard a packet already in the buffer. The authors give tight bounds on the competitive factor of various algorithms for the special case where there are only two different weights. In [20], the question of video smoothing is studied. One of the results in that paper, which we improve here, is an upper bound of 4 on the competitive ratio of the greedy algorithm for the FIFO model. The work of [14] deals with the loss-competitive analysis rather than the throughput-competitive analysis. The authors show how to translate the loss guarantee to the throughput guarantee and obtain an almost tight upper bound for the case of two packet values. A similar result is presented in this paper for the bounded delay model. The work of [3] studies bandwidth allocation from the competitive analysis viewpoint, disregarding buffer overflows.

The bounded delay model can be viewed as a scheduling problem. In this problem we are given parallel machines (whose number is the link bandwidth) and jobs with release time and deadline that correspond to the packets arriving to the pool. The goal is to maximize the throughput, defined as the sum of the weights of the jobs that terminate by their deadline. In our case we also have the additional constraint that all jobs have the same processing time. The off-line variant of this scheduling problem denoted by $P \,|\, r_i; p_i = p \,|\, \sum w_i(1 - U_i)$ in the standard scheduling notation can be solved in polynomial time using maximum matching. To the best of our knowledge the on-line variant of this problem has not been considered elsewhere. The more general off-line problem, where the processing time is not fixed, is NP-hard. Recently, approximation algorithms for this problem were considered in [5, 4, 22]. The more general on-line problem, where the processing time is not fixed, was considered in [19], where the authors prove competitive ratios that are substantially larger than those in our case. Slightly better ratios can be achieved for the case where processing time is not fixed if preemption is allowed. This case was considered in [6, 7, 15]. For the unweighted version of this problem, i.e., when the goal is to maximize the number of jobs completed by their deadline (which is trivial if all processing times are the same), [6] showed a tight competitive factor of 4. For the weighted version the tight bound is $\sqrt{1 + k^2}$, where k is the ratio of the maximum value density to the minimum value density of a job [15].

Paper organization. The remainder of this paper is organized as follows. In section 2 we define the models and some notation. In section 3 we consider the FIFO model and in section 4 we consider the bounded delay models. Finally in section 5 we discuss off-line algorithms.

2. Model and notation. In this section we formalize the model and the notation we use. We consider two main models: the FIFO model and the bounded-delay switch model. First, we list the assumptions and define quantities that are common to both models.

We assume that time is discrete. Fix an algorithm A. At each time step t, there is a set of *packets* $Q_A(t)$ stored at the *buffer* (initially empty). Each packet p has a positive real *value* denoted by $v(p)$. At time t, a set of packets $A(t)$ arrives. A set of packets from $Q_A(t) \cup A(t)$, denoted by $S_A(t)$, is *transmitted*. We denote by $S_A = \cup_t S_A(t)$ the set of packets transmitted by the algorithm A and by $S_A^{val} = \{p : p \in S_A, v(p) = val\}$ the set of packets of value val sent by A. Note that we consider the so-called cut-through model in which a packet may arrive and be transmitted at the same step. A subset of $Q_A(t) \cup A(t) \setminus S_A(t)$, denoted by $D_A(t)$, is *dropped*. The set of packets in the buffer at time $t + 1$ is $Q_A(t + 1) = Q_A(t) \cup A(t) \setminus (D_A(t) \cup S_A(t))$. We omit subscripts when no confusion arises.

The input is the packet arrival function $A(\cdot)$ and the packet value function $v(\cdot)$. Packets may have other attributes as well, depending on the specific model. The buffer management algorithm has to decide at each step which of the packets to drop and which to transmit, satisfying some constraints specified below. For a given input, the value *served* by the algorithm is the sum of the values of all packets transmitted by the algorithm. For a set P of packets define $v(A)$ to be the total value of the packets in the set. In this notation the value served by algorithm A is $\sum_t v(S_A(t))$.

The sequence of packets transmitted by the algorithm must obey certain restrictions.

Output link bandwidth. We assume that there is an integer number W called the *link bandwidth* such that the algorithm cannot transmit more than W packets in a single time unit; i.e., $|S(t)| \leq W$ for all t. For simplicity, we usually assume that $W = 1$ unless stated otherwise.

FIFO buffers. In the FIFO model there are two additional constraints. First, the sequence of transmitted packets has to be a subsequence of the arriving packets. That is, if a packet p is transmitted after packet p', then p could not have arrived before p'. Second, the number of packets in the buffer is bounded by the *buffer size* parameter, denoted by B. Formally, the constraint is that for all times t, $|Q(t)| \leq B$. (Note that our model allows for a larger number of packets in the transient period of each step, starting with packets' arrival and ending with packets' drop and transmission.)

Bounded-delay buffers. In this model we assume that packets have another attribute: for each packet p there is the *slack time* of p, denoted by $sl(p)$. The requirement is that a packet $p \in A(t)$ must be either transmitted or dropped before time $t + sl(p)$ (i.e., in one of the steps $t, t+1, \ldots, t+sl(p)-1$). The time $t + sl(p)$ is also called the *deadline* of p, denoted by $dl(p)$. We emphasize that in this model there is no explicit bound on the size of the buffer, and that packets may be reordered.

Uniform and variable bounded-delay buffers. One case of special interest within the bounded-delay buffers model is when the slack of all packets is equal to some known parameter δ. We call this model *δ-uniform bounded-delay buffers.* If all packet slacks are only *bounded* by some number δ, we say that the buffer is *δ-variable bounded-delay.*

On-line and off-line algorithms. We call an algorithm *on-line* if for all time steps t, it has to decide which packets to transmit and which to drop at time t without any knowledge of the packets arriving at steps $t' > t$. If future packet arrival is known, the algorithm is called *off-line.* We denote the optimal policy by OPT and the set of packets sent by the optimal policy by S_O. The *competitive ratio* (or *competitive factor*) of an algorithm A is an upper bound, over all input sequences P, on the ratio of the maximal value that can be transmitted by OPT to the value that is transmitted by A, that is, $\max_P(\frac{v(OPT)}{v(A)})$. Note that since we deal with a maximization problem this ratio will always be at least 1. In what follows, we denote by S_O and S_G the sets of packets transmitted by OPT and by the on-line algorithm considered, respectively, if it is not explicitly stated otherwise.

3. The FIFO model. In this section we consider the FIFO model. Recall that in this model a buffer of size B is used to store the incoming packets. Packets have to be transmitted in the order in which they arrive. Each packet has a value associated with it and the goal is to maximize the value of the transmitted packets.

First, we prove a lower bound on the competitive ratio of any on-line algorithm in the FIFO model. This proof improves the 1.25 bound proved in [20].

THEOREM 3.1. *The competitive ratio of any deterministic on-line algorithm in the FIFO model is at least* 1.281.

Proof. Assume that the link rate is 1 packet per time unit. Fix an on-line algorithm A, and let C_A denote its competitive ratio. We consider two scenarios. In both scenarios, B packets of value 1 arrive at time $t = 0$. In each of the next time steps a single packet of value $\alpha > 1$ arrives. This continues until we reach time B or until A sends an α value packet (which means that A has dropped all the remaining packets of value 1 from the buffer). Let t be that time.

In the first scenario, the input stream ends at time t. The benefit of A is $1 \cdot t + \alpha \cdot t$, while the off-line benefit is $1 \cdot B + \alpha \cdot t$.

In the second scenario, at time $t+1$ a burst of B packets, each of value α, arrive. The off-line benefit in this case is $\alpha(B + t)$, while the benefit of A is $1 \cdot t + \alpha \cdot B$.

Thus, the competitive ratio of A is

$$C_A \geq \max\left(\frac{B + \alpha t}{t + \alpha t}, \frac{\alpha(B + t)}{t + \alpha B}\right). \tag{3.1}$$

In our model, the adversary first chooses α so as to maximize C_A, then the algorithm chooses t (possibly depending on α) so as to minimize C_A, and then the competitive ratio is computed from (3.1). We work backwards, assuming first that α is a parameter. It is easy to see that (3.1) is minimized when

$$\frac{B + \alpha t}{t + \alpha t} = \frac{\alpha(B + t)}{t + \alpha B}. \tag{3.2}$$

Solving (3.2) for t, we get that its only nonnegative root is

$$t_0(B, \alpha) = B\frac{\sqrt{(\alpha - 1)^2 + 4\alpha^3} - \alpha + 1}{2\alpha^2}.$$

Define $t_0'(\alpha) = t_0(B, \alpha)/B$. With this notation, it follows from (3.1) that the competitive ratio of A satisfies

$$C_A \geq \frac{1 + \alpha t_0'(\alpha)}{t_0'(\alpha) + \alpha t_0'(\alpha)}. \tag{3.3}$$

Using numerical methods, we find that the right-hand side of (3.3), viewed as a function of α, is maximized when $\alpha \approx 4.01545$. Substituting in (3.1), we obtain that the competitive ratio of A cannot be better than 1.28197. □

3.1. Tight analysis of the greedy algorithm. We consider the greedy algorithm for output link bandwidth W, for any integer $W > 0$. In this algorithm no packets are dropped in time step t in which $|Q(t)|+|A(t)| \leq B+W$. If $|Q(t) \cup A(t)| = k > 0$, then the earliest $\min(W, k)$ packets are transmitted and the rest are stored in the buffer. If $|Q(t)| + |A(t)| = k > B + W$, the $k - B - W$ packets with the lowest value are dropped, ties broken arbitrarily. Among the remaining $B + W$ packets, the W earliest packets are transmitted and the rest are stored in the buffer.

For the sake of simplicity, we assume that B is a multiple of W.[1] Let $B_W = B/W$ denote the number of time steps that is needed to transmit the whole buffer. We first show that the competitive ratio of the greedy algorithm is no worse than 2. Later, we improve this bound and show that the improved bounds are tight.

[1] If W does not divide B, one can think of "fractions" of time steps in which sets of less than W packets are transmitted. This makes the analysis somewhat cumbersome, but the results of this section carry over to the general case as well.

THEOREM 3.2. *The competitive ratio of the greedy algorithm is at most* 2 *for any output link bandwidth* W.

Proof. Consider a sequence of packets. We need to show that $v(OPT) \leq 2v(Greedy)$. Let $D_G^O(t) = S_O \cap D_G(t)$ denote the set of packets that were dropped by the greedy algorithm at time t but were transmitted by the optimal algorithm. Let D_G^O be the union of all these sets. We show a mapping from the packets in D_G^O to packets in S_G with the following properties: (i) a packet from D_G^O is mapped to a packet in S_G with at least the same value, (ii) at most one packet from D_G^O is mapped to any packet in $S_G \cap S_O$, and (iii) at most two packets from D_G^O are mapped to any packet in $S_G \setminus S_O$. Clearly, the existence of the mapping implies the theorem.

We construct the mapping iteratively. At each iteration we consider a packet from D_G^O and map it to a packet in S_G. The packets in D_G^O are considered in the order of their drop time. Suppose that the current packet to be mapped is $p \in D_G^O(t)$. This means that all the packets in $D_G^O(s)$, for $s < t$, and maybe some of the packets in $D_G^O(t)$ have been mapped already. Given the partially defined mapping, define a set of "available" packets in S_G as follows. A packet in $q \in S_G \cap S_O$ is available if so far no packet is mapped to q. A packet in $q \in S_G \setminus S_O$ is available if so far at most one packet is mapped to q. The packet p is mapped to the earliest available packet that was transmitted by the greedy algorithm at or after time t.

Clearly, the mapping defined above satisfies the second and third properties. It remains to be shown is that it satisfies the first property as well. Consider the mapping process step by step, where in each step a single packet is mapped. We prove that the first property holds by induction on the steps of the mapping process. For the basis of the induction note that if $p \in D_G^O(t)$ is the first packet to be dropped, then it is mapped to the packet transmitted by the greedy algorithm at time t. Clearly, the value of this packet is at least $v(p)$.

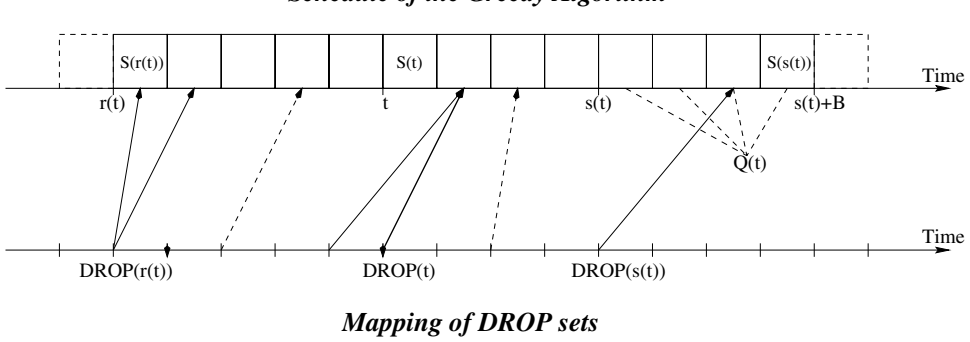

FIG. 3.1. *An example of the mapping from* D_G^O *to* S_G.

Suppose that the first property holds for all packets mapped before $p \in D_G^O(t)$. We show that it also holds for p. Let $s(t)$ be the earliest time at or after t such that the buffer maintained by the greedy algorithm at time $s(t)$ is full and all the packets in the buffer at time $s(t)$ are transmitted by the greedy algorithm (see Figure 3.1). Observe that since the buffer is full at time t, $s(t)$ is well defined.

CLAIM 1. *The value of each of the packets transmitted by Greedy at times* $t, \ldots, s(t) + B_W$ *is at least* $v(p)$.

Proof. Consider the greedy algorithm in the time interval $t, \ldots, s(t) + B_W$. Construct a sequence of time steps inductively as follows:

- $t_0 = t$.
- For $t_i < s(t)$, define t_{i+1} to be the first step after t_i in which a packet that was in the buffer at time t_i is dropped.

Let t_k be the last time step in this sequence. Note that $t_k = s(t_i)$ for all $0 \leq i \leq k$ by definition. We prove the claim by induction on k. For the case $k = 0$ we have that $s(t) = t$, and since all packets in the buffer at time $s(t)$ are transmitted in steps $s(t), \ldots, s(t) + B_W$, and all these packets have value at least $v(p)$ by the greedy rule, we are done. For the induction step, assume that the claim holds for k and consider $k + 1$. Let q be a packet that was in the buffer at time t_0 and dropped at time t_1. By the FIFO ordering, all packets transmitted in steps $t_0, \ldots, t_1$ were in the buffer at time t_0. By the greedy rule we have that (i) all packets transmitted at times $t_0, \ldots, t_1$ have value at least $v(p)$, and (ii) $v(q) \geq v(p)$. The claim follows by combining fact (i) with the induction hypothesis applied to q and time t_1. □

To prove that the first property holds for p, we show that it is mapped to one of the packets transmitted at times $t, \ldots, s(t) + B_W$. For this we need to show that at least one of the packets transmitted at times $t, \ldots, s(t) + B_W$ remains available at the time p is mapped. The "number of availabilities" at the time packet p is mapped is defined as the maximum number of packets that can still be mapped to the packets transmitted at times $t, \ldots, s(t) + B_W$. Specifically, every available packet (at the time p is mapped) among the packets transmitted at times $t, \ldots, s(t) + B_W$ that is also in S_O contributes 1 to the number of availabilities. Every available packet (at the time p is mapped) among the packets transmitted at times $t, \ldots, s(t) + B_W$ that is not in S_O contributes 2 to the number of availabilities if it is not mapped and contributes 1 if one packet has been mapped to it already.

Claim 2. *The number of availabilities before any of the packets dropped at time t is mapped is at least $\sum_{i=t}^{s(t)} |D_G^O(i)|$.*

Proof. Let $r(t)$ be the latest time before or at t such that no packets dropped by the greedy algorithm at time $r(t) - 1$ or earlier are mapped to packets transmitted at time $r(t)$ or later. If no such $r(t)$ exists, then define $r(t) = 0$ (the first step).

Intuitively, we start by showing that each interval $r(t), \ldots, s(t) + B_W$ is independent of the other intervals. Specifically, we claim that the number of availabilities before any of the packets dropped at time $r(t)$ and later is mapped is at least $\sum_{i=r(t)}^{s(t)} |D_G^O(i)|$. To see that, let $C(t)$ denote the set of packets available to the greedy algorithm at times $r(t), \ldots, s(t)$ that were transmitted by the optimal algorithm. In other words, $C(t)$ is the subset of packets transmitted by the optimal algorithm that were considered (stored at the beginning of the interval or arrived during the interval) by the greedy algorithm at times $r(t), \ldots, s(t)$. Note that $|C(t)| \leq W \cdot (s(t) - r(t) + 2B_W + 1)$, because packets in $C(t)$ cannot be transmitted by the optimal algorithm in time steps other than $r(t) - B_W, \ldots, s(t) + B_W$.

Next, let $x(t)$ be the number of packets of $C(t)$ that are transmitted by the greedy algorithm at times $r(t), \ldots, s(t) + B_W$. Observe that no packet from S_O that arrives at times $s(t), \ldots, s(t) + B_W$ is transmitted by the greedy algorithm at times $s(t), \ldots, s(t)+B_W$. This is because by definition, all packets stored by Greedy at time $s(t)$ are transmitted, a process that lasts B_W time units. It follows that exactly $x(t)$ packets from $C(t)$ are transmitted by the greedy algorithm at times $r(t), \ldots, s(t)+B_W$. This implies that the number of availabilities before any of the packets dropped at time $r(t)$ and later is mapped is at least $2W \cdot (s(t) + B_W - r(t) + 1) - x(t)$. This is true since by definition of $r(t)$, none of the packets that are dropped before time $r(t)$

is mapped to packets transmitted at times $r(t), \ldots, s(t) + B_W$. It follows that

$$\sum_{i=r(t)}^{s(t)} |D_G^O(i)| \leq W(s(t) - r(t) + 2B_W + 1) - x(t)$$

$$\leq 2W(s(t) + B_W - r(t) + 1) - x(t). \tag{3.4}$$

We can now prove the claim. Since by (3.4) the maximum number of packets that can be mapped to the packets transmitted at times $r(t), \ldots, s(t) + B_W$ is at least $\sum_{i=r(t)}^{s(t)} |D_G^O(i)|$, we have, by the definition of $r(t)$, that the maximum number of packets that can be mapped to the packets transmitted at times $r(t), \ldots, t-1$ is strictly less than $\sum_{i=r(t)}^{t-1} |D_G^O(i)|$. We conclude that the number of availabilities before the packets dropped at t are mapped is at least $\sum_{i=t}^{s(t)} |D_G^O(i)|$. □

The theorem follows directly from Claims 1 and 2. □

We now refine the analysis above to get tighter bounds. Let α be the ratio of the largest value of a packet to the smallest value of a packet (clearly we can assume without loss of generality that all packets have positive values).

THEOREM 3.3. *The competitive ratio of the greedy algorithm is at most* $2(1-\frac{1}{\alpha+1})$ *for any output link bandwidth* W*, where* $\alpha \stackrel{\text{def}}{=} \frac{\max_p\{v_p\}}{\min_p\{v_p\}}$.

Proof. Given the mapping defined above, partition S_G into three subsets as follows.

- G_1 is the set of packets in S_G that are not in S_O and that are not the image of (i.e., not mapped to by) any packet in D_G^O.
- G_2 is the set of packets in S_G that are unavailable after the mapping is done, namely, all packets in $S_G \cap S_O$ that are the image of one packet in D_G^O, and all packets in $S_G \setminus S_O$ that are the image of two packets in D_G^O.
- $G_3 = S_G \setminus (G_1 \cup G_2)$, that is, the packets in $S_G \cap S_O$ that are not the image of any packet in D_G^O, and the packets in $S_G \setminus S_O$ that are the image of one packet in D_G^O.

We associate two packets from S_O with each packet in $q \in G_2$ as follows. If $q \in G_2 \cap S_O$, then the two packets are q itself and the packet mapped to q. If $q \in G_2 \setminus S_O$, then the two packets are the two packets mapped to q. Similarly, we associate a packet from S_O with each packet in $q \in G_3$ as follows. If $q \in G_3 \cap S_O$, then this packet is q. If $q \in G_3 \setminus S_O$, then this packet is the packet mapped to q. Note that this way we associate every packet in S_O with some packet in S_G. Note that $v(q)$ is always at least the value of each of its associated packets, and the fact that no packet is associated with more than two packets implies the bound on the competitive ratio. We are able to improve the bound of 2 on this ratio using the fact that no packet is associated with packets in G_1.

Note that $|S_G| \geq |S_O|$. It follows that $|G_1| \geq |G_2|$, and thus we can match any packet $q \in G_2$ with a mate $p \in G_1$. We move a $\frac{1}{\alpha+1}$ "fraction" of the value of the packets associated with q and associate it with p. Note that after the move the total value associated with q is no more than $2(1-\frac{1}{\alpha+1})v(q)$. Since $v(q) \leq \alpha v(p)$, the total value associated with p is no more than

$$2\frac{1}{\alpha+1}v(q) \leq 2\frac{\alpha}{\alpha+1}v(p) = 2\left(1 - \frac{1}{\alpha+1}\right)v(p). \qquad \square$$

THEOREM 3.4. *The competitive ratio of the greedy algorithm is at most* $2-\frac{W}{B+W}$ *for any output link bandwidth* W.

Proof. Modify the mapping defined in the proof of Theorem 3.2 as follows. For each time t such that $D_G^O(t) \neq \emptyset$, decrease by W the number of availabilities contributed by the packets transmitted by the greedy algorithm at time t. Specifically, if $p \in S_O$, then no packet is mapped to p and if $p \notin S_O$, at most one packet is mapped to p.

We need to show that Claim 2 still holds. For this, it suffices to show that the number of availabilities before any of the packets dropped at time $r(t)$ and later is mapped is at least $\sum_{i=r(t)}^{s(t)} |D_G^O(i)|$. Notice that the number of availabilities is decreased by at most $W(s(t) - r(t) + 1)$. Claim 2 follows for the modified mapping since

$$\begin{aligned}\sum_{i=r(t)}^{s(t)} |D_G^O(i)| &\leq W(s(t) - r(t) + 2B_W + 1) - x(t) \\ &\leq 2W(s(t) + B_W - r(t) + 1) - x(t) - W(s(t) - r(t) + 1).\end{aligned}$$

Notice that the value of the packet transmitted at time t is at least the minimal value of the packets in $D_G^O(t)$. We "shift" a $W/(|D_G^O(t)| + W)$ fraction of the value of each of the packets in $D_G^O(t)$ from the packet to which it has been mapped originally and associate it to one of the packets transmitted by the greedy algorithm at time t. Since $|D_G^O(t)| \leq B$ and $|S_G(t)| = W$, we get that each packet transmitted by the greedy algorithm is associated with at most $1 + \frac{B}{B+W} = 2 - \frac{W}{B+W}$ packets of at most the same value from S_O. □

Finally, we observe that the last two bounds are tight. Consider the following scenario. At the first time step, $B + W$ packets of value 1 arrive; W are transmitted and the rest are kept in the buffer. Then, at each time $t \in \{1, \ldots, B_W\}$, W packets of value $\alpha \geq 1$ arrive and are kept in the buffer. At time $B_W + 1$ the buffer contains B packets of value α; at this time another $B + W$ packets of value α arrive. The greedy algorithm transmits only $B + W$ of these packets, while the optimal algorithm transmits $2B + W$ of value α and only W of value 1. We get that the competitive ratio for this scenario is

$$\frac{(2B + W)\alpha + W}{(B + W)(\alpha + 1)} = 2 - \frac{\alpha(W + 1) + 2B}{(B + W)(\alpha + 1)}.$$

Letting α go to infinity we get the ratio $2 - \frac{W}{B+W}$, and letting B go to infinity we get the ratio $2 - \frac{2}{\alpha+1}$.

3.2. The best greedy algorithm. The greedy algorithm is underspecified: when there are several packets with the same low value, it is not specified which of them is discarded by the greedy algorithm. It is easy to see that for any link bandwidth, the number of packets transmitted is the same for all variants of the greedy algorithm. However, is there a difference between the variants of the greedy algorithm in terms of weighted throughput? In this section we show that, perhaps surprisingly, it is always better to discard the earliest packets, i.e., the packets which spent the most time in the buffer. We call this policy *head-drop*, as the algorithm prefers to drop packets from the head of the buffer. Head-drop is in contrast to the common practice of *tail-drop*, where the newest packets are discarded. We show that there exist scenarios in which tail-drop results in significantly more losses than head-drop. We remark that the head-drop policy [17] enjoys additional advantages in the TCP/IP environment, namely, it helps the congestion avoidance mechanism.

The following theorem proves that the head-drop greedy algorithm is, in a certain sense, the best greedy algorithm.

THEOREM 3.5. *Let G be any greedy algorithm, and let GH be the greedy head-drop algorithm. For any input sequence, the total value transmitted by GH is at least the total value transmitted by G.*

Proof. Fix an input sequence. First, observe that the number of packets in the buffer of G and the number in the buffer of GH at time t are equal for all times t. (This follows from an easy induction on time, which shows that for any given arrival sequence and link bandwidth, the size of the queue in each step is the same for all algorithms that drop packets only when an overflow occurs.) To prove the theorem, we define, for each time step t, a 1-1 mapping from $Q_{GH}(t)$ to $Q_G(t)$ such that each packet $p \in Q_{GH}(t)$ is mapped to a packet $q \in Q_G(t)$ with at least the same value; i.e., $v(p) \leq v(q)$.
