# FAST UNIVERSALIZATION OF INVESTMENT STRATEGIES[*]

KARHAN AKCOGLU[†], PETROS DRINEAS[‡], AND MING-YANG KAO[§]

**Abstract.** A *universalization* of a parameterized investment strategy is an online algorithm whose average daily performance approaches that of the strategy operating with the optimal parameters determined offline in hindsight. We present a general framework for universalizing investment strategies and discuss conditions under which investment strategies are universalizable. We present examples of common investment strategies that fit into our framework. The examples include both trading strategies that decide positions in individual stocks, and portfolio strategies that allocate wealth among multiple stocks. This work extends in a natural way Cover's universal portfolio work. We also discuss the runtime efficiency of universalization algorithms. While a straightforward implementation of our algorithms runs in time exponential in the number of parameters, we show that the efficient universal portfolio computation technique of Kalai and Vempala [*Proceedings of the 41st Annual IEEE Symposium on Foundations of Computer Science*, Redondo Beach, CA, 2000, pp. 486–491] involving the sampling of log-concave functions can be generalized to other classes of investment strategies, thus yielding provably good approximation algorithms in our framework.

**Key words.** universal portfolios, computational finance, portfolio optimization, investment strategies, portfolio strategies, trading strategies, constantly rebalanced portfolios

## 1. Introduction.

An age-old question in finance deals with how to manage money on the stock market to obtain an "acceptable" return on investment. An *investment strategy* is an online algorithm that attempts to address this question by applying a given set of rules to determine how to invest capital. Typically, an investment strategy is parameterized by a vector $\mathbf{w} \in \mathbb{R}^* = \bigcup_{i=1}^{\infty} \mathbb{R}^i$ that dictates how the strategy operates. The optimal parameters that maximize the strategy's return are unknown when the algorithm is run, and the parameters are usually chosen quite arbitrarily. A *universalization* of an investment strategy is an online algorithm based on the strategy whose average daily performance approaches that of the strategy operating with the optimal parameters determined offline in hindsight.

Consider the *constantly rebalanced portfolio* (CRP) investment strategy universalized by Cover [5] and the subject of several extensions and generalizations [3, 6, 11, 14, 16, 20]. The CRP strategy maintains a constant proportion of total wealth in each stock, where the proportions are dictated by the parameters given to the strategy. In

a stock market with $m$ stocks, the parameter space for the CRP strategy is

$$\mathcal{W}_m = \left\{ \mathbf{w} \in [0,1]^m \mid \sum_{i=1}^{m} w_i = 1 \right\},$$

the set of vectors in $\mathbb{R}^m$ whose components are between 0 and 1 and add up to 1. Given a *portfolio vector* $\mathbf{w} = (w_1, \ldots, w_m) \in \mathcal{W}_m$, $w_i$ tells us the proportion of wealth to invest in stock $i$ for $1 \leq i \leq m$. At the beginning of each day, the holdings are *rebalanced*; i.e., money is taken out of some stocks and put into others, so that the desired proportions are maintained in each stock. As an example of the robustness of the CRP strategy, consider the following market with two stocks [11, 16]. The price of one stock remains constant, while the other stock doubles and halves in price on alternate days. Investing in a single stock will at most double our money. With a CRP $(\frac{1}{2}, \frac{1}{2})$ strategy, however, our wealth will increase exponentially, by a factor of $(\frac{1}{2} \cdot 1 + \frac{1}{2} \cdot 2) \times (\frac{1}{2} \cdot 1 + \frac{1}{2} \cdot \frac{1}{2}) = \frac{3}{2} \times \frac{3}{4} = \frac{9}{8}$ every two days.

Cover developed an investment strategy that effectively distributes wealth uniformly over all portfolio vectors $\mathbf{w} \in \mathcal{W}_m$ on the first day and executes the CRP strategy with daily rebalancing according to each $\mathbf{w}$ on the (infinitesimally small) proportion of wealth initially allocated to each $\mathbf{w}$. Cover showed that the *average daily log-performance*[1] of such a strategy approaches that of the CRP strategy operating with the optimal return-maximizing parameters chosen with hindsight.

This paper generalizes previous results and introduces a framework that allows universalizations of other parameterized investment strategies. As we see in section 2, investment strategies typically fall under two categories: *trading strategies* operate on a single stock and dictate when to buy and short[2] the stock; *portfolio strategies*, such as CRP, operate on the stock market as a whole and dictate how to allocate wealth among multiple stocks. We present several examples of common trading and portfolio strategies that can be universalized in our framework. We discuss our universalization framework in section 3. The proofs of our results are very general, and, as with previous universal portfolio results, we make no assumptions on the underlying distribution of the stock prices; our results are applicable for all sequences of stock returns and market conditions. The running times of universalization algorithms are, in general, exponential in the number of parameters used by the underlying investment strategy. Kalai and Vempala [14] presented an efficient implementation of the CRP algorithm that runs in time polynomial in the number of parameters. In section 4, we present general conditions on investment strategies under which the universalization algorithm can be efficiently implemented. We also give some investment strategies that satisfy these conditions. Section 5 concludes with directions for further research.

**2. Types of investment strategies.** Suppose we would like to distribute our wealth among $m$ stocks.[3] *Investment strategies* are general classes of rules that dictate how to invest capital. At time $t > 0$, a strategy $S$ takes as input an *environment vector* $\mathcal{E}_t$ and a *parameter vector* $\mathbf{w}$, and returns an *investment description* $S_t(\mathbf{w})$ specifying how to allocate our capital at time $t$. The environment vector $\mathcal{E}_t$ contains historic

[1]The average daily log-performance is the average of the logarithms of the factors by which our wealth changes on a daily basis. This notion is discussed further in section 3.1.

[2]A short position in a stock, discussed in section 2.1, allows us to earn a profit when the stock declines in value.

[3]We use the term “stocks” in order to keep our terminology consistent with previous work, but we actually mean a broader range of investment instruments, including both long and short positions in stocks.

market information, including stock price history, trading volumes, etc.; the parameter vector $\mathbf{w}$ is independent of $\mathcal{E}_t$ and specifies exactly how the strategy $S$ should operate; the investment description $S_t(\mathbf{w}) = (S_{t1}(\mathbf{w}), \ldots, S_{tm}(\mathbf{w}))$ is a vector specifying the proportion of wealth to put in each stock, where we put a fraction $S_{ti}(\mathbf{w})$ of our holdings in stock $i$, for $1 \leq i \leq m$. For example, CRP is an investment strategy; coupled with a portfolio vector $\mathbf{w}$, it tells us to "rebalance our portfolio on a daily basis according to $\mathbf{w}$"; its investment description, $\mathrm{CRP}_t(\mathbf{w}) = \mathbf{w}$, is independent of the market environment $\mathcal{E}_t$.

There are two general types of investment strategies that we focus upon in this paper. *Trading strategies* tell us whether we should take a *long* (bet that the stock price will rise) or a *short* (bet that the stock price will fall) position on a given stock. *Portfolio strategies* tell us how to distribute our wealth among various stocks. We should note here that these two classes do not exhaust all investment strategies; there exist strategies that take both long and short positions in several stocks (as in [21]). Trading strategies are denoted by $T$, and portfolio strategies are denoted by $P$. We use $S$ to denote either kind of strategy. For $k \geq 2$, let

$$\mathcal{W}_k = \left\{ \mathbf{w} = (w_1, \ldots, w_k) \in [0,1]^k \mid \sum_{i=1}^{k} w_i = 1 \right\}. \tag{2.1}$$

REMARK 1. *$\mathcal{W}_k$ is a $(k-1)$-dimensional simplex in $\mathbb{R}^k$. The investment strategies that we describe below are parameterized by vectors in $\mathcal{W}_k^\ell = \mathcal{W}_k \times \cdots \times \mathcal{W}_k$ ($\ell$ times) for some $k \geq 2$ and $\ell \geq 1$. We may write $\mathbf{w} \in \mathcal{W}_k^\ell$ in the form $\mathbf{w} = (\mathbf{w}_1, \ldots, \mathbf{w}_\ell)$, where $\mathbf{w}_\iota = (w_{\iota 1}, \ldots, w_{\iota k})$ for $1 \leq \iota \leq \ell$.*

**2.1. Trading strategies.** Suppose that our market contains a single stock. We have $m = 2$ potential investments: either a *long position* or a *short position* in the stock. To take a *long position*, we buy shares in hopes that the share price will rise. We *close a long position* by selling the shares. The money we use to buy the shares is our *investment in the long position*; the *value* of the investment is the money we get when we close the position. If we let $p_t$ denote the stock price at the beginning of day $t$, the value of our investment will change by a factor of $x_t = \frac{p_{t+1}}{p_t}$ from day $t$ to $t+1$.

To take a *short position*, we borrow shares from our broker and sell them on the market in hopes that the share price will fall. We *close a short position* by buying the shares back and returning them to our broker. As collateral for the borrowed shares, our broker has a *margin requirement*: a fraction $\alpha$ of the value of the borrowed shares must be deposited in a *margin account*. Should the price of the security rise sufficiently, the collateral in our margin account will not be enough, and the broker will issue a *margin call*, requiring us to deposit more collateral. The margin requirement is our *investment in the short position*; the *value* of the investment is the money we get when we close the position.

LEMMA 2.1. *Let the margin requirement for a short position be $\alpha \in (0,1]$. Suppose that a short position is opened on day t and that the price of the underlying stock changes by a factor of $x_t = \frac{p_{t+1}}{p_t} < 1 + \alpha$ during the day. Then the value of our investment in the short position changes by a factor of $x_t' = 1 + \frac{1-x_t}{\alpha}$ during the day.*

*Proof.* Suppose that we have \$$v$ to deposit in the zero-interest margin account. Using this as our investment in the short position, we can sell \$$v/\alpha$ worth of shares. Combining the proceeds of the stock sale with our margin account balance, we will have a total of $v + v/\alpha$ dollars. At the end of the day, it will cost $x_t v/\alpha$ dollars to buy the shares back, and we will be left with $v + \frac{v}{\alpha} - x_t \frac{v}{\alpha}$ dollars, which is positive since $x_t < 1 + \alpha$. Thus, our investment of \$$v$ in the short position has changed by a factor of $1 + \frac{1-x_t}{\alpha}$, as claimed. $\square$

Should the price of the underlying stock change by a factor greater than $1 + \alpha$, we will lose more money than we initially put in. We will assume that the margin requirement $\alpha$ is sufficiently large that the daily price change of the stock is always less than $1 + \alpha$.

REMARK 2. *This assumption can be eliminated by purchasing a* call option *on the stock with some strike price $p < (1 + \alpha)p_t$. Should the stock price get too high, the call allows us to purchase the stock back for \$$p$. Though its price detracts from the performance of our short trading strategy, the call protects us from potentially unlimited losses due to rising stock price.*

If a short position is held for several days, assume that it is *rebalanced* at the beginning of each day: either part of the short is closed (if $x_t > 1$) or additional shares are shorted (if $x_t < 1$) so that the collateral in the margin account is exactly an $\alpha$ fraction of the value of the shorted shares. This ensures that the value of a short position changes by a factor $x'_t = 1 + \frac{1-x_t}{\alpha}$ each day. Treating short positions in this way, they can simply be viewed as any other stock, so trading strategies are effectively investment strategies that decide between two potential investments: a long or a short position in a given stock. The investment description of a trading strategy $T$ is $T_t = (T_{t1}, T_{t2})$, where $T_{t1}$ and $T_{t2}$ are the fractions of wealth to put in a long and short position, respectively.

REMARK 3. *Let $D = T_{t1} - T_{t2}/\alpha$ be the* net long position *of the investment description. In practice, if $D > 0$, investors should put a $D$ fraction of their money in the long position and a $1 - D$ fraction in cash; if $D < 0$, investors should invest $D$ in the short position and $1 - D$ in cash; if $D = 0$, investors should avoid the stock completely and keep all their money in cash. From a practical standpoint, it is desirable for the trading strategy to be* decisive*, i.e., $|D| = 1$, so that our allocation of money to the stock is always fully invested in the stock (either as a long or a short position). We show in section 3 that investment strategies that are continuous in their parameter spaces are universalizable. Though decisive trading strategies $T$ are discontinuous, they can be approximated by continuous strategies whose investment descriptions converge almost everywhere to $T_t$ as $t \to \infty$ (see, for example,* (2.3) *below).*

We now describe some commonly used and researched trading strategies [4, 10, 18, 22] and show how they can be parameterized.

*MA[k]: Moving average cross-over with k-day memory.* In traditional applications [10] of this rule, we compare the current stock price with the moving average over, say, the previous 200 days: if the price is above the moving average, we take a long position; otherwise we take a short position. Some generalizations of this rule have been made, where we compare a fast moving average (over, for example, the past 5 to 20 days) with a slow moving average (over the past 50 to 200 days). We generalize this rule further. Given day $t \geq 0$, let $\mathbf{v}_t = (v_{t1}, \ldots, v_{tk})$ be the *price-history vector* over the previous $k$ days, where $v_{tj}$ is the stock price on day $t - j$. Assume that the stock prices have been normalized such that $0 < v_{tj} \leq 1$. Let $(\mathbf{w}_F, \mathbf{w}_S) \in \mathcal{W}_k^2$ (where $\mathcal{W}_k$ is defined in (2.1)) be the weights used to compute the fast moving and slow moving averages, so that these averages on day $t$ are given by $\mathbf{w}_F \cdot \mathbf{v}_t$ and $\mathbf{w}_S \cdot \mathbf{v}_t$, respectively. Since the prices have been normalized to the interval $(0, 1]$, $-1 \leq (\mathbf{w}_F - \mathbf{w}_S) \cdot \mathbf{v}_t \leq 1$, let $g : [-1, 1] \to [0, 1]$ be the *long/short allocation function.* The idea is that $g((\mathbf{w}_F - \mathbf{w}_S) \cdot \mathbf{v}_t)$ represents the proportion of wealth that we invest in a long position. The full investment description for the MA $=$ MA$[k]$ trading strategy is

$$\mathrm{MA}_t(\mathbf{w}_F, \mathbf{w}_S) = \big(g((\mathbf{w}_F - \mathbf{w}_S)\cdot \mathbf{v}_t),\ 1 - g((\mathbf{w}_F - \mathbf{w}_S)\cdot \mathbf{v}_t)\big).$$

Note that the dimension of the parameter space for MA$[k]$ is $2(k-1)$ since each of $\mathbf{w}_F$ and $\mathbf{w}_S$ are taken from $(k-1)$-dimensional spaces. Possible functions for $g$ include

$$g_s(x) = \begin{cases} 0 & \text{if } x < 0, \\ 1 & \text{otherwise,} \end{cases} \qquad \text{(step function)} \tag{2.2}$$

$$g_{(t)}(x) = \begin{cases} 0 & \text{if } x < -\frac{1}{t}, \\ \frac{t}{2}(x + \frac{1}{t}) & \text{if } -\frac{1}{t} \le x \le \frac{1}{t}, \\ 1 & \text{if } \frac{1}{t} < x, \end{cases} \qquad \text{(linear step approximation)} \tag{2.3}$$

and the line

$$g_\ell(x) = \frac{x+1}{2} \tag{2.4}$$

that intersects $g_s(x)$ at the extreme points $x = \pm 1$ of its domain. Note that $g_{(t)}(x)$ is parameterized by the day $t$ during which it is called and that it converges to $g_s(x)$ on $[-1,1] \setminus \{0\}$ as $t$ increases.

Remark 4. *The long/short allocation function used in traditional applications of this rule is the step function $g_s(\cdot)$. As we see in section 3, in order for an investment strategy to be universalizable, its allocation function must be continuous, necessitating the continuous approximation $g_{(t)}(\cdot)$. The linear approximation $g_\ell(\cdot)$ can be used with the results of section 4, to allow for efficient computation of the universalization algorithm.*

*SR$[k]$: Support and resistance breakout with k-day memory.* Discussed as early as the work of Wyckoff [22] in 1910, this strategy uses the idea that the stock price trades in a *range* bounded by *support* and *resistance* levels. Should the price fall below the support level, the idea is that it will continue to fall, and a short position should be taken in the stock. Similarly, should the price rise above the resistance level, the idea is that it will continue to rise, and a long position should be taken in the stock. If the stock price remains between the support and resistance levels, the idea is that it will continue to trade in this range in an unpredictable pattern, and the stock should be avoided. Support and resistance levels are defined quite arbitrarily in practice, usually as the minimum and maximum prices over the past $k$ days, where $k$ is usually taken to be 50, 150, or 200 [4]. To generalize this rule, given day $t \ge 0$, let $\underline{\mathbf{v}}_t = (\underline{v}_{t1}, \dots, \underline{v}_{tk})$ and $\overline{\mathbf{v}}_t = (\overline{v}_{t1}, \dots, \overline{v}_{tk})$ be the minimum and maximum price histories, where $\underline{v}_{tj}$ and $\overline{v}_{tj}$ are the minimum and maximum prices over the previous $j$ days, normalized so that they are in the range $(0,1]$. Let $\mathbf{w} \in \mathcal{W}_k$ be the weights for computing the support and resistance levels, so that these levels on day $t$ are given by $s_t = \mathbf{w} \cdot \underline{\mathbf{v}}_t$ and $r_t = \mathbf{w} \cdot \overline{\mathbf{v}}_t$, respectively.

Lemma 2.2. *The support level is bounded above by the resistance level: $s_t \le r_t$.*

*Proof.* This follows from the fact that for all $1 \le j \le k$, $\underline{v}_{tj} \le \overline{v}_{tj}$. $\square$

The long/short allocation function will be denoted by $h : \{(x,y) \in [-1,1]^2 \,|\, x \le y\} \to [0,1]$. Let $p_t$ be the current stock price (normalized to $(0,1]$ along with $\underline{\mathbf{v}}_t$ and $\overline{\mathbf{v}}_t$). The idea is that $h(p_t - r_t, p_t - s_t)$ tells us the proportion of wealth that we invest in a long position. The full investment description for the $\mathrm{SR} = \mathrm{SR}[k]$ trading strategy is

$$\mathrm{SR}_t(\mathbf{w}) = \big(h(p_t - r_t, p_t - s_t),\ 1 - h(p_t - r_t, p_t - s_t)\big).$$

The value of $h$ need only be defined on $\{(x,y) \in [-1,1]^2 \mid x \le y\}$ since, by Lemma 2.2, $s_t \le r_t$. A possible function for $h$ is

$$h_s(x,y) = \begin{cases} 0 & \text{if } x \le y \le 0, \\ \frac{1}{\alpha+1} & \text{if } x < 0 < y, \\ 1 & \text{if } y \ge x \ge 0, \end{cases} \qquad \text{(step function)} \tag{2.5}$$

where the investment allocation $\frac{1}{\alpha+1}$ long, $1 - \frac{1}{\alpha+1} = \frac{\alpha}{\alpha+1}$ short is equivalent to having no position in the stock, since the return from such an allocation is $\frac{x_t}{\alpha+1} + (1 + \frac{1-x_t}{\alpha})\frac{\alpha}{\alpha+1} = 1$. Other possibilities include a continuous function

$$h_{(t)}(x,y), \tag{2.6}$$

which approximates $h_s(x,y)$ with maximum slope at most $\frac{1}{t}$ (defined similarly to $g_{(t)}(x)$), or the plane

$$h_p(x,y) = \frac{(x+1)\alpha}{2(\alpha+1)} + \frac{y+1}{2(\alpha+1)} \tag{2.7}$$

that intersects $h_s(x,y)$ at the extreme points $(x,y) = (-1,-1)$, $(-1,1)$, and $(1,1)$ of its domain.

**2.2. Portfolio strategies.** Portfolio strategies are investment strategies that distribute wealth among $m$ stocks. The investment description of a portfolio strategy $P$ is $P_t = (P_{t1}, \ldots, P_{tm})$, where $0 \le P_{ti} \le 1$ and $\sum_{i=1}^{m} P_{ti} = 1$. We put a fraction $P_{ti}$ of our wealth in stock $i$ at time $t$.

*CRP: Constantly rebalanced portfolio* [5]. The parameter space for the CRP strategy is $\mathbb{W} = \mathcal{W}_m$. The investment description is $\mathrm{CRP}_t(\mathbf{w}) = \mathbf{w}$: at the beginning of each day, we invest a $w_i$ proportion of our wealth in stock $i$.

*CRP-S: Constantly rebalanced portfolio with side information.* Cover and Ordentlich [6] consider a generalization of CRP. Rather than rebalancing our holdings according to a single portfolio vector $\mathbf{w} \in \mathcal{W}_m$ every day, we have $k$ vectors $\mathbf{w}_1, \ldots, \mathbf{w}_k \in \mathcal{W}_m$ and a side information state $y_t \in \{1, \ldots, k\}$ that classifies each day $t$ into one of $k$ possible categories; on day $t$ we rebalance our holdings according to $\mathbf{w}_{y_t}$. By partitioning the time interval into $k$ subsequences corresponding to each of the $k$ side information states and running $k$ instances of the universalization algorithm (one instance for each state), Cover and Ordentlich show that the average daily return approaches that of the underlying strategy operating with $k$ optimal parameters, $\mathbf{w}_1^*, \ldots, \mathbf{w}_k^* \in \mathcal{W}_m$, where $\mathbf{w}_j^*$ is used on days $t$ when the side information state is $y_t = j$. We generalize this further by allowing portions of our wealth to be rebalanced according to several of the $\mathbf{w}_j$ every day. Suppose that the side information is encapsulated in some vector $\mathbf{v} \in \mathbb{R}^\ell$ for some $\ell$. This vector can contain information about specific stocks, such as historic performance and company fundamentals, or macroeconomic indicators such as inflation and unemployment. Let $\mathbf{f} = (f_1, \ldots, f_k) : \mathbb{R}^\ell \to [0,1]^k$ be some function satisfying

$\sum_{j=1}^{k} f_j(\mathbf{v}) = 1$ for all $\mathbf{v} \in \mathbb{R}^\ell$. The parameter space is $\mathcal{W}_m^k$; the investment description is $\text{CRP-S}_t(\mathbf{w}_1, \dots, \mathbf{w}_k) = \sum_{j=1}^{k} f_j(\mathbf{v}_t)\mathbf{w}_j$, where $\mathbf{v}_t$ is the indicator vector for day $t$. Under such a scheme, we have the flexibility of splitting our wealth among multiple sets of portfolios $\mathbf{w}_1, \dots, \mathbf{w}_k$ on any given day, rather than being forced to choose a single one. For example, assume that $\mathbf{v}$ is a $k$-dimensional vector, with each $v_i$ corresponding to portfolio $\mathbf{w}_i$. Define $\mathbf{f} : \mathbb{R}^k \to [0,1]^k$ by $f_i(\mathbf{v}_t) = \frac{v_{ti}}{\sum_{\iota=1}^{k} v_{t\iota}}$, so that our allocation is biased towards portfolios corresponding to higher indicators while still maintaining a position in the others.

*IA*[$k$]*: $k$-way indicator aggregation.* For each day $t \geq 0$, suppose that each stock $i$ has a set of $k$ indicators $\mathbf{v}_{ti} = (v_{ti1}, \dots, v_{tik})$, where each $v_{tij} \in (0,1]$ and, for $1 \leq j \leq k$, $v_{t1j}, \dots, v_{tmj}$ have been normalized such that there is at least one $i$ such that $v_{tij} = 1$. Examples of possible indicators include historic stock performance and trading volumes, and company fundamentals. Our goal is to aggregate the indicators for each stock to get a measure of the stock's attractiveness and put a greater proportion of our wealth in stocks that are more attractive. We will aggregate the indicators by taking their weighted average, where the weights will be determined by the parameters. The parameter space is $\mathbb{W} = \mathcal{W}_k$, and the investment description is

$$\text{IA}_t(\mathbf{w}) = \left( \frac{\mathbf{w} \cdot \mathbf{v}_{t1}}{\sum_{i=1}^{m} \mathbf{w} \cdot \mathbf{v}_{ti}}, \dots, \frac{\mathbf{w} \cdot \mathbf{v}_{tm}}{\sum_{i=1}^{m} \mathbf{w} \cdot \mathbf{v}_{ti}} \right).$$

## 3. Universalization of investment strategies.

**3.1. Universalization defined.** In a typical stock market, wealth grows geometrically. On day $t \geq 0$, let $\mathbf{x}_t$ be the *return vector* for day $t$, the vector of factors by which stock prices change on day $t$. The return vector corresponding to a trading strategy on a single stock is $(x_t, 1 + \frac{1-x_t}{\alpha})$, where $x_t$ is the factor by which the price of the stock changes and $1 + \frac{1-x_t}{\alpha}$ is the factor by which our investment in a short position changes, as described in Lemma 2.1; the return vector corresponding to a portfolio strategy is $(x_{t1}, \dots, x_{tm})$, where $x_{ti}$ is the factor by which the price of stock $i$ changes, where $1 \leq i \leq m$. Henceforth, we do not make a distinction between return vectors corresponding to trading and portfolio strategies; we assume that $\mathbf{x}_t$ is appropriately defined to correspond to the investment strategy in question. For an investment strategy $S$ with parameter vector $\mathbf{w}$, the *return of* $S(\mathbf{w})$ during the $t$th day—the factor by which our wealth changes on the $t$th day when invested according to $S(\mathbf{w})$—is $S_t(\mathbf{w}) \cdot \mathbf{x}_t = \sum_{i=1}^{m} S_{ti}(\mathbf{w}) \cdot x_{ti}$. (Recall that $S_t(\mathbf{w})$ is the investment description of $S(\mathbf{w})$ for day $t$, which is a vector specifying the proportion of wealth to put in each stock.) Given time $n > 0$, let $\mathcal{R}_n(S(\mathbf{w})) = \prod_{t=0}^{n-1} S_t(\mathbf{w}) \cdot \mathbf{x}_t$ be the *cumulative return of* $S(\mathbf{w})$ *up to time* $n$; we may write $\mathcal{R}_n(\mathbf{w})$ in place of $\mathcal{R}_n(S(\mathbf{w}))$ if $S$ is obvious from context. We analyze the performance of $S$ in terms of the *normalized log-return* $\mathcal{L}_n(\mathbf{w}) = \mathcal{L}_n(S(\mathbf{w})) = \frac{1}{n} \log \mathcal{R}_n(\mathbf{w})$ of the wealth achieved.

For investment strategy $S$, let $\mathbf{w}_n^* = \arg\max_{\mathbf{w} \in \mathbb{R}^*} \mathcal{R}_n(S(\mathbf{w}))$ be the parameters that maximize the return of $S$ up to day $n$.[4] An investment strategy $U$ *universalizes* (or *is universal for*) $S$ if[5]

$$\mathcal{L}_n(U) = \mathcal{L}_n(S(\mathbf{w}_n^*)) - \text{o}(1)$$

[4]As mentioned above, $\mathbf{w}_n^*$ can be computed only with hindsight.

[5]Unlike previously discussed investment strategies, the behavior of $U$ is fully defined without an additional parameter vector $\mathbf{w}$.

for all environment vectors $\mathcal{E}_n$. That is, $U$ is universal for $S$ if the average daily log-return of $U$ approaches the optimal average daily log-return of $S$ as the length $n$ of the time horizon grows, regardless of stock price sequences.

**3.2. General techniques for universalization.** Given an investment strategy $S$, let $\mathbb{W}$ be the parameter space for $S$ and let $\mu$ be the uniform measure over $\mathbb{W}$. Our universalization algorithm for $S$, $\mathcal{U}(S)$, is a generalization of Cover's original result [5]; we note that a similar algorithm appeared in [20] under the name "Aggregating Algorithm." The investment description $\mathcal{U}_t(S)$ for the universalization of $S$ on day $t > 0$ is a weighted average of $S_t(\mathbf{w})$ over $\mathbf{w} \in \mathbb{W}$, with greater weight given to parameters $\mathbf{w}$ that have performed better in the past (i.e., $\mathcal{R}_t(\mathbf{w})$ is larger). Formally, the investment description is

$$\mathcal{U}_t(S) = \frac{\int_{\mathbb{W}} S_t(\mathbf{w})\mathcal{R}_t(\mathbf{w})d\mu(\mathbf{w})}{\int_{\mathbb{W}} \mathcal{R}_t(\mathbf{w})d\mu(\mathbf{w})} = \frac{\int_{\mathbb{W}} S_t(\mathbf{w})\mathcal{R}_t(S(\mathbf{w}))d\mu(\mathbf{w})}{\int_{\mathbb{W}} \mathcal{R}_t(S(\mathbf{w}))d\mu(\mathbf{w})}, \tag{3.1}$$

where we take $\mathcal{R}_0(\mathbf{w}) = 1$ for all $\mathbf{w} \in \mathbb{W}$.[6] Equivalently, the above integral might be interpreted as "splitting our money" equally among all the different strategies and "letting it sit." In the following lemma, we will prove that this strategy has the same expected gain as picking one strategy at random.

REMARK 5. *The definition of universalization can be expanded to include measures other than $\mu$, but we consider only $\mu$ in our results.*

LEMMA 3.1 (see [3, 6]). *The cumulative $n$-day return of $\mathcal{U}(S)$ is*

$$\mathcal{R}_n(\mathcal{U}(S)) = \int_{\mathbb{W}} \mathcal{R}_n(\mathbf{w})d\mu(\mathbf{w}) = \mathbb{E}\big(\mathcal{R}_n(\mathbf{w})\big),$$

*which is the $\mu$-weighted average of the cumulative returns of the investment strategies $\{S(\mathbf{w}) \mid \mathbf{w} \in \mathbb{W}\}$.*

*Proof.* The return of $\mathcal{U}(S)$ on day $t$ is $\mathcal{U}_t(S) \cdot \mathbf{x}_t$, where $\mathbf{x}_t$ is the return vector for day $t$. The cumulative $n$-day return of $\mathcal{U}(S)$ is

$$\begin{aligned}\mathcal{R}_n(\mathcal{U}(S)) &= \prod_{t=0}^{n-1} \mathcal{U}_t(S) \cdot \mathbf{x}_t = \prod_{t=0}^{n-1} \frac{\int_{\mathbb{W}} S_t(\mathbf{w})\mathcal{R}_t(\mathbf{w})d\mu(\mathbf{w})}{\int_{\mathbb{W}} \mathcal{R}_t(\mathbf{w})d\mu(\mathbf{w})} \cdot \mathbf{x}_t \\ &= \prod_{t=0}^{n-1} \frac{\int_{\mathbb{W}} (S_t(\mathbf{w}) \cdot \mathbf{x}_t)\mathcal{R}_t(\mathbf{w})d\mu(\mathbf{w})}{\int_{\mathbb{W}} \mathcal{R}_t(\mathbf{w})d\mu(\mathbf{w})} = \prod_{t=0}^{n-1} \frac{\int_{\mathbb{W}} \mathcal{R}_{t+1}(\mathbf{w})d\mu(\mathbf{w})}{\int_{\mathbb{W}} \mathcal{R}_t(\mathbf{w})d\mu(\mathbf{w})}.\end{aligned}$$

The result follows from the fact that this product telescopes. □

Rather than directly universalizing a given investment strategy $S$, we instead focus on a modified version of $S$ that puts a nonzero fraction of wealth into each of the $m$ stocks. Define the investment strategy $\bar{S}$ by

$$\bar{S}_t(\mathbf{w}) = \left(1 - \frac{\varepsilon}{2(t+1)^2}\right) S_t(\mathbf{w}) + \frac{\varepsilon}{2m(t+1)^2}$$

for $t \geq 0$ and some fixed $0 < \varepsilon < 1$. Rather than universalizing $S$, we instead universalize $\bar{S}$. Lemma 3.2 tells us that we do not lose much by doing this.

LEMMA 3.2. *For all $n \geq 0$, (1) $\mathcal{R}_n(\mathcal{U}(\bar{S})) \geq (1-\varepsilon)\mathcal{R}_n(\mathcal{U}(S))$ and (2) $\mathcal{L}_n(\mathcal{U}(\bar{S})) = \mathcal{L}_n(\mathcal{U}(S)) - \frac{o(n)}{n}$. (3) If $\mathcal{U}(S)$ is a universalization of $S$, then $\mathcal{U}(\bar{S})$ is a universalization of $S$ as well.*

[6] Cover's algorithm is a special case of this, replacing $S_t(\mathbf{w})$ with $\mathbf{w}$.

*Proof.* Statements (2) and (3) follow directly from (1). Statement (1) follows from the fact that for all $\mathbf{w} \in \mathbb{W}$, $\mathcal{R}_n(\bar{S}(\mathbf{w})) = \prod_{t=0}^{n-1} \bar{S}_t(\mathbf{w}) \cdot \mathbf{x}_t \geq \prod_{t=0}^{n-1}(1 - \frac{\varepsilon}{2(t+1)^2})S_t(\mathbf{w}) \cdot \mathbf{x}_t \geq (1 - \sum_{t=0}^{n-1} \frac{\varepsilon}{2(t+1)^2})\mathcal{R}_n(S(\mathbf{w})) \geq (1-\varepsilon)\mathcal{R}_n(S(\mathbf{w}))$. ◻

REMARK 6. *Henceforth, we assume that suitable modifications have been made to $S$ to ensure that $S_{ti}(\mathbf{w}) \geq \frac{\varepsilon}{2m(t+1)^2}$ for all $1 \leq i \leq m$ and $t \geq 0$.*

THEOREM 3.3. *Given an investment strategy $S$, let $\mathbb{W} = \mathcal{W}_k^\ell$ (for some $k \geq 2$ and $\ell \geq 1$) be its parameter space. For $1 \leq i \leq m$, $1 \leq \iota \leq \ell$, and $1 \leq j \leq k$, assume that there is a constant $c$ such that $\left|\frac{\partial S_{ti}(\mathbf{w})}{\partial w_{\iota j}}\right| \leq c(t+1)$ for all $\mathbf{w} \in \mathbb{W}$. Then $\mathcal{U}(S)$ is a universalization of $S$.*

To prove Theorem 3.3, we first prove some preliminary results; the proof follows the same general strategy as in [5, 6].

LEMMA 3.4. *For nonnegative vector $\mathbf{a}$ and strictly positive vectors $\mathbf{b}$ and $\mathbf{x}$,*

$$\min_i \frac{a_i}{b_i} \leq \frac{\mathbf{a} \cdot \mathbf{x}}{\mathbf{b} \cdot \mathbf{x}} \leq \max_i \frac{a_i}{b_i}.$$

*Proof.* Assume that the components of $\mathbf{a}$ and $\mathbf{b}$ are strictly positive. Otherwise, the lemma holds trivially. Let $i_{\max} = \arg\max_i \frac{a_i}{b_i}$ and $i_{\min} = \arg\min_i \frac{a_i}{b_i}$, so that

$$\frac{a_i}{b_i} \leq \frac{a_{i_{\max}}}{b_{i_{\max}}} \Leftrightarrow \frac{a_i}{a_{i_{\max}}} \leq \frac{b_i}{b_{i_{\max}}} \quad \text{and} \quad \frac{a_i}{b_i} \geq \frac{a_{i_{\min}}}{b_{i_{\min}}} \Leftrightarrow \frac{a_i}{a_{i_{\min}}} \geq \frac{b_i}{b_{i_{\min}}}.$$

Then

$$\frac{a_{i_{\min}}(x_{i_{\min}} + \sum_{i \neq i_{\min}} \frac{a_i}{a_{i_{\min}}} x_i)}{b_{i_{\min}}(x_{i_{\min}} + \sum_{i \neq i_{\min}} \frac{b_i}{b_{i_{\min}}} x_i)} = \frac{\mathbf{a} \cdot \mathbf{x}}{\mathbf{b} \cdot \mathbf{x}} = \frac{a_{i_{\max}}(x_{i_{\max}} + \sum_{i \neq i_{\max}} \frac{a_i}{a_{i_{\max}}} x_i)}{b_{i_{\max}}(x_{i_{\max}} + \sum_{i \neq i_{\max}} \frac{b_i}{b_{i_{\max}}} x_i)}.$$

Therefore,

$$\frac{a_{i_{\min}}}{b_{i_{\min}}} \leq \frac{\mathbf{a} \cdot \mathbf{x}}{\mathbf{b} \cdot \mathbf{x}} \leq \frac{a_{i_{\max}}}{b_{i_{\max}}}. \quad ◻$$

Our next two results are related to the $(k-1)$-dimensional volumes of some subsets of $\mathbb{R}^k$.

LEMMA 3.5. *The $(k-1)$-dimensional volume of the simplex $\mathcal{W}_k = \{\mathbf{w} \in [0,1]^k \mid \sum_{i=1}^k w_i = 1\}$, defined in (2.1), is $\frac{\sqrt{k}}{(k-1)!}$.*

*Proof.* By induction on $k$, it can be shown that the $k$-dimensional volume of the solid $W_k(s) = \{\mathbf{w} \mid \sum_{i=1}^k w_i \leq s\}$ is $\frac{s^k}{k!}$. Written in terms of the length $r$ of the line segment passing between the origin and $(\frac{s}{k}, \ldots, \frac{s}{k}) \in \mathbb{R}^k$, the volume is $\frac{1}{k!} r^k k^{\frac{k}{2}}$ since $s = r\sqrt{k}$. Upon differentiation with respect to $r$, $\frac{1}{(k-1)!} r^{k-1} k^{\frac{k}{2}} = \frac{1}{(k-1)!}\sqrt{k} s^{k-1}$, we arrive at the $(k-1)$-dimensional volume of the simplex $\mathcal{W}_k(s) = \{\mathbf{w} \mid \sum_{i=1}^k w_i = s\}$. Setting $s = 1$ yields the desired result. ◻

LEMMA 3.6. *The $(k-1)$-dimensional volume of a $(k-1)$-dimensional ball of radius $\rho$ embedded in $\mathcal{W}_k$ is $\frac{\pi^{\frac{k-1}{2}} \rho^{k-1}}{\Gamma(\frac{k-1}{2}+1)}$, where*

$$\Gamma(\ell) = (\ell - 1)! \quad \textit{and} \quad \Gamma\left(\ell + \frac{1}{2}\right) = \left(\ell - \frac{1}{2}\right)\left(\ell - \frac{3}{2}\right) \cdots \left(\frac{1}{2}\right)\sqrt{\pi}.$$

*Proof.* This result is proven in Folland [8, Corollary 2.56]. ◻

*Proof of Theorem* 3.3. From Lemma 3.1, the return of $\mathcal{U}(S)$ is the average of the cumulative returns of the investment strategies $\{S(\mathbf{w}) \mid \mathbf{w} \in \mathbb{W}\}$. Let $\mathbf{w}^* = \arg\max_{\mathbf{w}\in\mathbb{W}} \mathcal{R}_n(S(\mathbf{w}))$ be the parameters that maximize the return of $S$. We show that there is a set $B$ of nonzero volume around $\mathbf{w}^*$ such that for $\mathbf{w} \in B$ the return $\mathcal{R}_n(\mathbf{w})$ is close to the optimal return $\mathcal{R}_n(\mathbf{w}^*)$. We then show that the contribution of $B$ to the average return is sufficiently large to ensure universalizability. We begin by bounding the magnitude of the gradient vector $\nabla\mathcal{R}_n(\mathbf{w})$. From Remark 6 and our assumption in the statement of the theorem, for all $\mathbf{w}$, $t$, $i$, $\iota$, and $j$,

$$\frac{\left|\frac{\partial S_{ti}(\mathbf{w})}{\partial w_{\iota j}}\right|}{S_{ti}(\mathbf{w})} \le c'm(t+1)^3,$$

where $c' = \frac{2c}{\varepsilon}$. Using this fact and Lemma 3.4, the partial derivative of the return function $\mathcal{R}_n(\mathbf{w}) = \mathcal{R}_n(S(\mathbf{w})) = \prod_{t=0}^{n-1} r_t(S(\mathbf{w}))$ with respect to parameter $w_{\iota j}$ is

$$\begin{aligned}\left|\frac{\partial\mathcal{R}_n(\mathbf{w})}{\partial w_{\iota j}}\right| &\le \mathcal{R}_n(\mathbf{w}) \sum_{t=0}^{n-1} \frac{\left|\frac{\partial(S_t(\mathbf{w})\cdot\mathbf{x}_t)}{\partial w_{\iota j}}\right|}{S_t(\mathbf{w})\cdot\mathbf{x}_t} \le \mathcal{R}_n(\mathbf{w}) \sum_{t=0}^{n-1} \frac{\sum_{i=1}^m \left|\frac{\partial S_{ti}(\mathbf{w})}{\partial w_{\iota j}}\right| \cdot x_{ti}}{\sum_{i=1}^m S_{ti}(\mathbf{w})\cdot x_{ti}} \\ &\le \mathcal{R}_n(\mathbf{w}) \sum_{t=0}^{n-1} c'm(t+1)^3 \le c'\mathcal{R}_n(\mathbf{w})mn^4\end{aligned}$$

and

$$|\nabla\mathcal{R}_n(\mathbf{w})| \le c'\mathcal{R}_n(\mathbf{w})mn^4\sqrt{k\ell}. \tag{3.2}$$

We would like to take our set $B$ to be some $d$-dimensional ball around $\mathbf{w}^*$; unfortunately, if $\mathbf{w}^*$ is on (or close to) an edge of $\mathbb{W}$, the reasoning introduced at the beginning of this proof is not valid. We instead perturb $\mathbf{w}^*$ to a point $\tilde{\mathbf{w}}$ that is at least

$$\rho = \frac{\gamma}{c'mn^4k^2\ell}$$

away from all edges, where $0 < \gamma < 1$ is a constant, and such that $\mathcal{R}_n(\tilde{\mathbf{w}})$ is close to $\mathcal{R}_n(\mathbf{w}^*)$. To illustrate the perturbation, let $\mathbf{w}^* = (\mathbf{w}_1^*, \ldots, \mathbf{w}_\ell^*)$, where $\mathbf{w}_\iota^* = (w_{\iota 1}^*, \ldots, w_{\iota k}^*)$ and $w_{\iota k}^* = 1 - \sum_{i=1}^{k-1} w_{\iota i}^*$ for $1 \le \iota \le \ell$. We perturb each $\mathbf{w}_\iota^*$ in the same way. Let $\tilde{\mathbf{w}}_\iota^0 = \mathbf{w}_\iota^*$. For $1 \le j \le k$, given $\tilde{\mathbf{w}}_\iota^{j-1}$, define $\tilde{\mathbf{w}}_\iota^j$ as follows. Let $j_{\max}$ be the index of the maximum coordinate of $\tilde{\mathbf{w}}_\iota^{j-1}$. If $0 \le \tilde{w}_{\iota j}^j < \rho$, define $\tilde{w}_{\iota j}^j = \tilde{w}_{\iota j}^{j-1} + \rho$, $\tilde{w}_{\iota j_{\max}}^j = \tilde{w}_{\iota j_{\max}}^{j-1} - \rho$ and leave all other coordinates unchanged. Otherwise, let $\tilde{\mathbf{w}}_{j_0}^j = \tilde{\mathbf{w}}_{j_0}^{j-1}$. The final perturbation is $\tilde{\mathbf{w}} = (\tilde{\mathbf{w}}_1, \ldots, \tilde{\mathbf{w}}_\ell)$, where $\tilde{\mathbf{w}}_\iota = \tilde{\mathbf{w}}_\iota^k$. By construction, $\tilde{\mathbf{w}} \in \mathbb{W}$, $\tilde{\mathbf{w}}$ is at least $\rho$ away from the edges of $\mathbb{W}$ and $|w_{\iota j}^* - \tilde{w}_{\iota j}| \le k\rho$ for all $\iota$ and $j$. We bound $\frac{\mathcal{R}_n(\mathbf{w}^*)}{\mathcal{R}_n(\tilde{\mathbf{w}})}$ by the multivariate mean value theorem and the Cauchy–Schwarz inequality:

$$\begin{aligned}\mathcal{R}_n(\tilde{\mathbf{w}}) &= \mathcal{R}_n(\mathbf{w}^*) + \mathcal{R}_n(\tilde{\mathbf{w}}) - \mathcal{R}_n(\mathbf{w}^*) \\ &\ge \mathcal{R}_n(\mathbf{w}^*) - |\nabla\mathcal{R}_n(\mathbf{w}')\cdot(\tilde{\mathbf{w}} - \mathbf{w}^*)| \qquad (\text{for some } \mathbf{w}' \text{ between } \tilde{\mathbf{w}} \text{ and } \mathbf{w}^*) \\ &\ge \mathcal{R}_n(\mathbf{w}^*) - |\nabla\mathcal{R}_n(\mathbf{w}')|\cdot|\tilde{\mathbf{w}} - \mathbf{w}^*| \ge \mathcal{R}_n(\mathbf{w}^*) - c'\mathcal{R}_n(\mathbf{w}')mn^4\sqrt{k\ell}\cdot k\rho\sqrt{k\ell} \\ &\ge \mathcal{R}_n(\mathbf{w}^*) - c'\mathcal{R}_n(\mathbf{w}^*)mn^4\sqrt{k\ell}\cdot k\rho\sqrt{k\ell} \ge \mathcal{R}_n(\mathbf{w}^*)(1-\gamma).\end{aligned}$$

For $0 \le \iota \le \ell$ let $C_\iota = \{\mathbf{w}_\iota \in \mathbb{R}^k \mid |\tilde{\mathbf{w}}_\iota - \mathbf{w}_\iota| \le \rho\}$. From the construction of $\tilde{\mathbf{w}}$, $B_\iota = C_\iota \cap \mathcal{W}_k$ is a $(k-1)$-dimensional ball of radius $\rho$. Let $\tilde{\mathbf{w}}^*_\iota = \arg\max_{\mathbf{w}\in B_\iota} \mathcal{R}_n(\mathbf{w})$, and let $\tilde{\mathbf{w}}^* = (\tilde{\mathbf{w}}^*_1, \dots, \tilde{\mathbf{w}}^*_\ell)$ be the profit-maximizing parameters in $B = B_1 \times \cdots \times B_\ell$. For $\mathbf{w} \in B$,

$$\begin{aligned}
\mathcal{R}_n(\mathbf{w}) &= \mathcal{R}_n(\tilde{\mathbf{w}}^*) + \mathcal{R}_n(\mathbf{w}) - \mathcal{R}_n(\tilde{\mathbf{w}}^*) \\
&\ge \mathcal{R}_n(\tilde{\mathbf{w}}^*) - |\nabla \mathcal{R}_n(\mathbf{w}')| \cdot |\tilde{\mathbf{w}}^* - \mathbf{w}| \qquad (\text{for some } \mathbf{w}' \text{ between } \tilde{\mathbf{w}}^* \text{ and } \mathbf{w}) \\
&\ge \mathcal{R}_n(\tilde{\mathbf{w}}^*) - c'\mathcal{R}_n(\tilde{\mathbf{w}}^*) m n^4 \sqrt{k\ell} \cdot 2\rho\sqrt{\ell} \ge \mathcal{R}_n(\tilde{\mathbf{w}}^*)(1-\gamma) \\
&\ge \mathcal{R}_n(\mathbf{w}^*)(1-2\gamma).
\end{aligned}$$

By Lemma 3.1,

$$\begin{aligned}
\mathcal{R}_n(\mathcal{U}(S)) &= \int_{\mathbb{W}} \mathcal{R}_n(S(\mathbf{w})) d\mu(\mathbf{w}) \ge \int_B \mathcal{R}_n(\mathbf{w}) d\mu(\mathbf{w}) \ge (1-2\gamma)\mathcal{R}_n(\mathbf{w}^*) \int_B d\mu(\mathbf{w}) \\
&\ge (1-2\gamma)\mathcal{R}_n(\mathbf{w}^*) \frac{\int_B d\mathbf{w}}{\int_{\mathbb{W}} d\mathbf{w}} \\
&= (1-2\gamma)\mathcal{R}_n(\mathbf{w}^*) \left( \frac{\pi^{\frac{k-1}{2}} \rho^{k-1}}{\Gamma(\frac{k-1}{2}+1)} \cdot \frac{(k-1)!}{\sqrt{k}} \right)^\ell \qquad (\text{from Lemmas 3.5 and 3.6}) \\
&= \mathcal{R}_n(\mathbf{w}^*) \Lambda(\gamma, m, k, \ell) n^{-4k\ell},
\end{aligned}$$

where $\Lambda$ is some constant depending on $\gamma$, $m$, $k$, and $\ell$. Therefore,

$$\mathcal{L}_n(\mathbf{w}^*) - \mathcal{L}_n(\mathcal{U}(S)) \le \frac{\log \Lambda(\gamma, m, k, \ell)}{n} + 4k\ell \frac{\log n}{n} = \frac{\mathrm{o}(n)}{n}, \tag{3.3}$$

as claimed. □

REMARK 7. *The techniques used in the proof of Theorem* 3.3 *can be generalized to other investment strategies with bounded parameter spaces* $\mathbb{W}$ *that are not necessarily of the form* $\mathcal{W}_k^\ell$.

**3.3. Increasing the number of parameters with time.** The reader may notice from the proof of Theorem 3.3 that an investment strategy $S$ may be universalizable even if the dimensions of its parameter space $\mathbb{W}$ grow with time. In fact, even if the dimension of the parameter space (the coefficient of $\frac{\log n}{n}$ in (3.3)) is $\mathcal{O}(\frac{n}{\phi(n)\log n})$, where $\phi(n)$ is a monotone increasing function, the strategy is still universalizable. This introduces an interesting possibility for investment strategies whose parameter spaces grow with time as more information becomes available. As a simple example, consider *dynamic universalization*, which allows us to track a higher-return benchmark than basic universalization. Partition the time interval $\mathcal{I} = [0, n)$ into $\psi = \mathcal{O}(\frac{n}{\phi(n)\log n})$ subintervals $\mathcal{I}_1, \dots, \mathcal{I}_\psi$, and let $\mathbf{w}^*_{\mathcal{I}_j}$ be the parameters that optimize the return during $\mathcal{I}_j$. In $\mathcal{I}_1$, we run the universalization algorithm given by (3.1) over the basic parameter space $\mathbb{W}$ of $S$. In $\mathcal{I}_2$, we run the algorithm over $\mathbb{W} \times \mathbb{W}$; to compute the investment description for a day $t \in \mathcal{I}_2$ using (3.1), we compute the return $\mathcal{R}_t(\mathbf{w}_1, \mathbf{w}_2)$ as the product of the returns we would have earned in $\mathcal{I}_1$ using $\mathbf{w}_1$ and what we would have earned up to day $t$ in $\mathcal{I}_2$ using $\mathbf{w}_2$. We proceed similarly in intervals $\mathcal{I}_3$ through $\mathcal{I}_\psi$. This will allow us to track the strategy that uses the optimal parameters $\mathbf{w}^*_{\mathcal{I}_j}$ corresponding to each $\mathcal{I}_j$. Such a strategy is useful in environments where optimal investment styles (and the optimal investment strategy parameters that go with them) change with time. Finally, we note that similar ideas appear in the area of "tracking the best expert" in the theory of prediction with expert advice; we refer the reader to [12, 19] for more details.

**3.4. Applications to trading strategies.** By proving an upper bound on $\left|\frac{\partial T_{ti}(\mathbf{w})}{\partial w_j}\right|$ for our trading strategies $T$, we show that they are universalizable.

COROLLARY 3.7. *The moving average cross-over trading strategy, MA*$[k]$*, is universalizable for the long/short allocation functions* $g_{(t)}(x)$ *and* $g_\ell(x)$ *defined in* (2.3) *and* (2.4)*, respectively.*

*Proof.* The parameters for MA$[k]$ are of the form $\mathbf{w}_F = (w_{F1}, \dots, w_{F(k-1)}, 1 - w_{F1} - \cdots - w_{F(k-1)})$ and $\mathbf{w}_S = (w_{S1}, \dots, w_{S(k-1)}, 1 - w_{S1} - \cdots - w_{S(k-1)})$. Using the long/short allocation function $g_{(t)}(x)$ defined in (2.3), the partial derivative of the investment description with respect to a parameter $w_{Fj}$ (or similarly $w_{Sj}$) is

$$\left|\frac{\partial \mathrm{MA}_{ti}(\mathbf{w}_F, \mathbf{w}_S)}{\partial w_{Fj}}\right| = \left|\frac{\partial g((\mathbf{w}_F - \mathbf{w}_S)\cdot \mathbf{v}_t)}{\partial w_{Fj}}\right| \le \frac{t}{2}\cdot(v_{tj} - v_{tk}) \le \frac{t}{2},$$

where $1 \le j < k$ and $i \in \{1, 2\}$. Similarly, we can show that using the long/short allocation function $g_\ell(x)$ defined in (2.4), $\left|\frac{\partial \mathrm{MA}_{ti}(\mathbf{w}_F, \mathbf{w}_S)}{\partial w_{Fj}}\right| \le \frac{1}{2}$. ∎

COROLLARY 3.8. *The support and resistance breakout trading strategy, SR*$[k]$*, is universalizable for the long/short allocation functions* $h_{(t)}(x, y)$ *and* $h_p(x, y)$ *defined in* (2.6) *and* (2.7)*, respectively.*

*Proof.* We arrive at the result by differentiating the long/short allocation functions $h_{(t)}(x, y)$ and $h_p(x, y)$ with respect to an arbitrary parameter $w_j$ and showing that the partial derivative is $\mathcal{O}(t)$, as in the proof of Corollary 3.7. ∎

**3.5. Applications to portfolio strategies.**

COROLLARY 3.9. *The constantly rebalanced portfolio, CRP, and CRP with side information, CRP-S, portfolio strategies are universalizable.*

*Proof.* The partial derivatives of CRP$_{ti}$ and CRP-S$_{ti}$ with respect to an arbitrary parameter $w_j$ are at most 1. ∎

COROLLARY 3.10. *The* $k$*-way indicator aggregation portfolio strategy, IA*$[k]$*, is universalizable.*

*Proof.* First, we show that $\sum_{\ell=1}^m \mathbf{w}\cdot \mathbf{v}_{t\ell} \ge \frac{1}{k}$ for all $t$. Since $\sum_{j=1}^k w_j = 1$, there exists $j_0$ such that $w_{j_0} \ge \frac{1}{k}$. Then $\sum_{\ell=1}^m \mathbf{w}\cdot\mathbf{v}_{t\ell} \ge \sum_{\ell=1}^m w_{j_0}\cdot v_{t\ell j_0} \ge \frac{1}{k}\sum_{\ell=1}^m v_{t\ell j_0} \ge \frac{1}{k}$, since the $\{v_{t\ell j_0}\}_{1\le \ell\le m}$ have been normalized such that there is at least one $\ell_0$ such that $v_{t\ell_0 j_0} = 1$.

Now, let $S = \mathrm{IA}[k]$. By Theorem 3.3, we need only show that $\frac{\partial S_{ti}(\mathbf{w})}{\partial w_j} = \mathcal{O}(t)$ for $1 \le j \le k-1$. For $t \ge 0$ and $1 \le i \le m$ recall that $S_{ti}(\mathbf{w}) = \frac{\mathbf{w}\cdot\mathbf{v}_{ti}}{\sum_{\ell=1}^m \mathbf{w}\cdot\mathbf{v}_{t\ell}}$. Then, for $1 \le j \le k-1$, since $\mathbf{w} = (w_1, \dots, w_{k-1}, 1 - (w_1 + \cdots + w_{k-1}))$,

$$\begin{aligned}\frac{\partial S_{ti}(\mathbf{w})}{\partial w_j} &= \frac{v_{tij} - v_{tik}}{\sum_{\ell=1}^m \mathbf{w}\cdot\mathbf{v}_{t\ell}} - \frac{\mathbf{w}\cdot\mathbf{v}_{ti}}{(\sum_{\ell=1}^m \mathbf{w}\cdot\mathbf{v}_{t\ell})^2}\cdot\sum_{\ell=1}^m (v_{t\ell j} - v_{t\ell k}) \\ &\le \frac{1}{\sum_{\ell=1}^m \mathbf{w}\cdot\mathbf{v}_{t\ell}} + \frac{m}{(\sum_{\ell=1}^m \mathbf{w}\cdot\mathbf{v}_{t\ell})^2} \le k + mk^2,\end{aligned}$$

as we wanted to show. ∎

## 4. Fast computation of universal investment strategies.

**4.1. Approximation by sampling.** The running time of the universalization algorithm depends on the time needed to compute the integral in (3.1). A straightforward evaluation takes time exponential in the number of parameters. Following Kalai and Vempala [14], we propose to approximate this integral by sampling the parameters according to a biased distribution, giving greater weight to better performing parameters. Define the measure $\zeta_t$ on $\mathbb{W}$ by

$$d\zeta_t(\mathbf{w}) = \frac{\mathcal{R}_t(S(\mathbf{w}))}{\int_{\mathbb{W}} \mathcal{R}_t(S(\mathbf{w}))d\mu(\mathbf{w})} d\mu(\mathbf{w}).$$

LEMMA 4.1 (see [14]). *The investment description $\mathcal{U}_t(S)$ for universalization is the average of $S_t(\mathbf{w})$ with respect to the $\zeta_t$ measure.*

*Proof.* The average of $S_t(\mathbf{w})$ with respect to $\zeta_t$ is

$$\begin{aligned}\mathbb{E}_{\mathbf{w}\in(\mathbb{W},\zeta_t)}(S_t(\mathbf{w})) &= \int_{\mathbb{W}} S_t(\mathbf{w})d\zeta_t(\mathbf{w}) \\ &= \int_{\mathbb{W}} S_t(\mathbf{w}) \frac{\mathcal{R}_t(S(\mathbf{w}))}{\int_{\mathbb{W}} \mathcal{R}_t(S(\mathbf{w}))d\mu(\mathbf{w})} d\mu(\mathbf{w}) = \mathcal{U}_t(S),\end{aligned}$$

where the final equality follows from (3.1). □

We now briefly outline our approach, which follows the lines of [2, 14]. The main technical complication is that sampling efficiently with respect to $\zeta_t$ is not, in general, an easy problem. As a result, we will need some (rather generic) assumption on the investment strategies from which we can sample efficiently.

- *Investment strategies with log-concavity properties.* In section 4.3, we use straightforward manipulations to prove that any investment strategy $S$ which is linear in the vector of parameters $\mathbf{w}$ (such strategies include MA[$k$], SR[$k$], CRP, and CRP-S) has a cumulative return function $\mathcal{R}_t(S(\mathbf{w}))$ that is log-concave. Our efficient sampling techniques are applicable only on such strategies.
- *Approximating $\zeta_t$ by $\bar{\zeta}_t$.* In section 4.2, we show that for strategies whose cumulative return function is log-concave, it is possible to efficiently sample from a distribution $\bar{\zeta}_t$ that is "close" to $\zeta_t$. This "distribution approximation" incurs some small, bounded error (see Lemma 4.2).
- *Approximating the integral for $\bar{\zeta}_t$ via sampling.* With such sampling abilities, it is easy to approximate the average of $S_t(\mathbf{w})$ with respect to $\bar{\zeta}_t$: simply pick $N_t$ (as defined in Lemma 4.3) sample parameter vectors $\mathbf{w}$ with respect to $\bar{\zeta}_t$ and compute their average. The error incurred by this approximation of the average can be bounded in a straightforward manner using Chernoff bounds.
- *Sampling with respect to $\bar{\zeta}_t$.* The critical issue (addressed in section 4.2) is how to pick vectors $\mathbf{w} \in \mathbb{W}$ with respect to $\bar{\zeta}_t$. In order to tackle this problem, we "discretize" it by placing a grid on $\mathbb{W}$, and then we perform a Metropolis random walk. The convergence properties of this random walk are discussed in Theorems 4.12 and 4.13.

In section 4.2, we show that for certain strategies we can efficiently sample from a distribution $\bar{\zeta}_t$ that is "close" to $\zeta_t$; i.e., given $\gamma_t > 0$, we generate samples from $\bar{\zeta}_t$ such that

$$\int_{\mathbb{W}} \left|\zeta_t(\mathbf{w}) - \bar{\zeta}_t(\mathbf{w})\right| d\mu(\mathbf{w}) \le \gamma_t. \tag{4.1}$$

Assume for now that we can sample from $\bar{\zeta}_t$, with $\gamma_t = \frac{\varepsilon^2}{4m(t+1)^4}$, where $\varepsilon$ is the constant appearing in Remark 6. Let $\bar{\mathcal{U}}_t(S) = \int_{\mathbb{W}} S_t(\mathbf{w})d\bar{\zeta}_t(\mathbf{w})$ be the corresponding approximation to $\mathcal{U}(S)$. Lemma 4.2 tells us that we do not lose much by sampling from $\bar{\zeta}_t$.

LEMMA 4.2. *For all $n \geq 0$, (1) $\mathcal{R}_n(\bar{\mathcal{U}}(S)) \geq (1-\varepsilon)\mathcal{R}_n(\mathcal{U}(S))$ and (2) if $\mathcal{U}(S)$ is a universalization of $S$, then $\bar{\mathcal{U}}(S)$ is a universalization of $S$ as well.*

*Proof.* Statement (2) follows directly from (1). To see (1), we need only show that the fraction of wealth that we put into each stock $i$ on day $t$ under $\bar{\mathcal{U}}(S)$ is within a $1-\frac{\varepsilon}{2(t+1)^2}$ factor of the corresponding amount under $\mathcal{U}(S)$; i.e., $\bar{\mathcal{U}}_{ti}(S) \geq (1-\frac{\varepsilon}{2(t+1)^2})\mathcal{U}_{ti}(S)$ for $0 \leq t < n$ and $1 \leq i \leq m$. For $\mathbf{w} \in \mathbb{W}$, let $\gamma_t(\mathbf{w}) = |\bar{\zeta}_t(\mathbf{w}) - \zeta_t(\mathbf{w})|$, so that $\int_{\mathbb{W}} \gamma_t(\mathbf{w})d\mathbf{w} = \gamma_t \leq \frac{\varepsilon^2}{4m(t+1)^4}$. We have

$$\begin{aligned}
\bar{\mathcal{U}}_{ti}(S) &= \int_{\mathbb{W}} S_{ti}(\mathbf{w})\bar{\zeta}_t(\mathbf{w})d\mu(\mathbf{w}) \geq \int_{\mathbb{W}} S_{ti}(\mathbf{w})(\zeta_t(\mathbf{w}) - \gamma_t(\mathbf{w}))d\mu(\mathbf{w}) \\
&= \mathcal{U}_{ti}(S) - \int_{\mathbb{W}} S_{ti}(\mathbf{w})\gamma_t(\mathbf{w})d\mu(\mathbf{w}) \geq \mathcal{U}_{ti}(S) - \gamma_t \qquad (\text{since } S_{ti}(\mathbf{w}) \leq 1) \\
&\geq \left(1 - \frac{\varepsilon}{2(t+1)^2}\right)\mathcal{U}_{ti}(S) \\
&\qquad \left(\text{since } \mathcal{U}_{ti}(S) \geq \min_{\mathbf{w}} S(\mathbf{w}) \geq \frac{\varepsilon}{2m(t+1)^2} \text{ and } \gamma_t \leq \tfrac{\varepsilon^2}{4m(t+1)^4}\right),
\end{aligned}$$

as we wanted to show. ∎

By sampling from $\bar{\zeta}_t$, we use a generalization of the Chernoff bound to get an approximation $\tilde{\mathcal{U}}(S)$ to $\bar{\mathcal{U}}(S)$ such that with high probability $\tilde{\mathcal{U}}_{ti}(S) \geq (1-\frac{\varepsilon}{2(t+1)^2})\bar{\mathcal{U}}_{ti}(S)$ for $0 \leq t < n$ and $1 \leq i \leq m$. Using an argument similar to that in the proof of Lemma 4.2, we see that if $\bar{\mathcal{U}}(S)$ is a universalization of $S$, then such a $\tilde{\mathcal{U}}(S)$ is a universalization of $S$ as well. Choose $\mathbf{w}_1, \ldots, \mathbf{w}_{N_t} \in \mathbb{W}$ at random according to distribution $\bar{\zeta}_t$, and let $\tilde{\mathcal{U}}_{ti}(S) = \frac{1}{N_t}\sum_{i=1}^{N_t} S_{ti}(\mathbf{w}_i)$. Lemma 4.3 discusses the number of samples $N_t$ required to get a sufficiently good approximation to $\bar{\mathcal{U}}_t(S)$.

LEMMA 4.3. *Given $0 < \delta < 1$, use $N_t \geq \frac{8m^2(t+1)^8}{\varepsilon^4}\log\frac{2m(t+1)^2}{\delta}$ samples to compute $\tilde{\mathcal{U}}_t(S)$, where $\varepsilon$ is the constant appearing in Remark 6. With probability $1-\delta$, $\tilde{\mathcal{U}}_{ti}(S) \geq (1-\frac{\varepsilon}{2(t+1)^2})\bar{\mathcal{U}}_{ti}(S)$ for all $1 \leq i \leq m$ and $t \geq 0$.*

*Proof.* Hoeffding [13] proves a general version of the Chernoff bound. For random variables $0 \leq X_i \leq 1$ with $\mathbb{E}(X_i) = \mu$ and $\tilde{X} = \frac{1}{N}\sum_{i=1}^{N} X_i$, the bound states that $\Pr(\tilde{X} \leq (1-\alpha)\mu) \leq e^{-2N\alpha^2\mu^2}$. In our case, we would like $\tilde{\mathcal{U}}_{ti} \geq (1-\frac{\varepsilon}{2(t+1)^2})\bar{\mathcal{U}}_{ti}$. As this must hold for $1 \leq i \leq m$ and $t \geq 0$ with total probability $1-\delta$, we require $\Pr(\tilde{\mathcal{U}}_{ti} \leq (1-\frac{\varepsilon}{2(t+1)^2})\bar{\mathcal{U}}_{ti}) \leq \frac{\delta}{2m(t+1)^2}$ for each $i$ and $t$. From our assumption stated in Remark 6, $\mu = \bar{\mathcal{U}}_{ti} \geq \frac{\varepsilon}{2m(t+1)^2}$, and the desired probability bound is achieved with $N_t \geq \frac{8m^2(t+1)^8}{\varepsilon^4}\log\frac{2m(t+1)^2}{\delta}$ samples. ∎

**4.2. Efficient sampling.** We now discuss how to sample from $\mathbb{W} = \mathcal{W}_k^\ell = \mathcal{W}_k \times \cdots \times \mathcal{W}_k$ according to distribution $\zeta_t(\cdot) \propto \mathcal{R}_t(\cdot) = \mathcal{R}_t(S(\cdot))$. $\mathbb{W}$ is a convex set of diameter $d = \sqrt{2\ell}$. We focus on a discretization of the sampling problem. Choose an orthogonal coordinate system on each $\mathcal{W}_k$, and partition it into hypercubes of side length $\delta_t$, where $\delta_t$ is a constant chosen below. Let $\Omega$ be the set of centers of cubes that intersect $\mathbb{W}$, and choose the partition such that the coordinates of $\mathbf{w} \in \Omega$ are multiples of $\delta_t$. For $\mathbf{w} \in \Omega$, let $C(\mathbf{w})$ be the cube with center $\mathbf{w}$. We show how to choose $\mathbf{w} \in \Omega$ with probability "close to"

$$\pi_t(\mathbf{w}) = \frac{\mathcal{R}_t(\mathbf{w})}{\sum_{\mathbf{w}\in\Omega} \mathcal{R}_t(\mathbf{w})}.$$

In particular, we sample from a distribution $\tilde{\pi}_t$ that satisfies

$$\sum_{\mathbf{w}\in\Omega} |\pi_t(\mathbf{w}) - \tilde{\pi}_t(\mathbf{w})| \leq \gamma_t = \frac{\varepsilon^2}{4m(t+1)^4}. \tag{4.2}$$

Note that this is a discretization of (4.1). We will also have that for each $\mathbf{w} \in \Omega$,

$$\frac{\tilde{\pi}_t(\mathbf{w})}{\pi_t(\mathbf{w})} \leq 2. \tag{4.3}$$

We would like to choose $\delta_t$ sufficiently small that $\mathcal{R}_t$ is "nearly constant" over $C(\mathbf{w})$; i.e., there is a small constant $\nu > 0$ such that

$$(1+\nu)^{-1}\mathcal{R}_t(\mathbf{w}) \leq \mathcal{R}_t(\mathbf{w}') \leq (1+\nu)\mathcal{R}_t(\mathbf{w}) \tag{4.4}$$

for all $\mathbf{w}' \in C(\mathbf{w})$. Such a $\delta_t$ can be chosen for investment strategies $S$ that have bounded derivative, as we see in Lemma 4.4.

LEMMA 4.4. *Suppose that investment strategy $S$ satisfies the condition for universalizability given in Theorem 3.3; i.e., $\left|\frac{\partial S_{ti}(\mathbf{w})}{\partial w_j}\right| \leq c(t+1)$. Given $\nu > 0$, let $\delta_t = \delta_t(\nu) = \frac{\nu}{3c'mt^4k\ell}$, where $c'$ is defined in the proof of Theorem 3.3. For $\mathbf{w}, \mathbf{w}' \in \mathbb{W}$ such that $|w_{ij} - w'_{ij}| \leq \delta_t(\nu)$ for all $1 \leq i \leq \ell$ and $1 \leq j \leq k$, $(1+\nu)^{-1}\mathcal{R}_t(\mathbf{w}) \leq \mathcal{R}_t(\mathbf{w}') \leq (1+\nu)\mathcal{R}_t(\mathbf{w})$.*

*Proof.* Note that $|\mathbf{w} - \mathbf{w}'| \leq \delta_t\sqrt{k\ell}$. Let $\mathbf{w}^*$ be the parameters that maximize the return on the line between $\mathbf{w}$ and $\mathbf{w}'$. By the multivariate mean value theorem and the bound for $|\nabla\mathcal{R}_t|$ given in (3.2),

$$\begin{aligned}
\mathcal{R}_t(\mathbf{w}^*) &= \mathcal{R}_t(\mathbf{w}) + \mathcal{R}_t(\mathbf{w}^*) - \mathcal{R}_t(\mathbf{w}) \\
&\leq \mathcal{R}_t(\mathbf{w}) + |\nabla\mathcal{R}_t(\mathbf{w}_m)| \cdot |\mathbf{w} - \mathbf{w}^*| \quad \text{(for some } \mathbf{w}_m \text{ between } \mathbf{w}^* \text{ and } \mathbf{w}) \\
&\leq \mathcal{R}_t(\mathbf{w}) + c'\mathcal{R}_t(\mathbf{w}_m)mn^4\sqrt{k\ell} \cdot \delta_t\sqrt{k\ell} \leq \mathcal{R}_t(\mathbf{w}) + \mathcal{R}_t(\mathbf{w}^*)\frac{\nu}{3} \\
\Rightarrow \quad \mathcal{R}_t(\mathbf{w}) &\geq \mathcal{R}_t(\mathbf{w}^*)\left(1 - \frac{\nu}{3}\right) \geq \mathcal{R}_t(\mathbf{w}')\left(1 - \frac{\nu}{3}\right)
\end{aligned}$$

so that $\mathcal{R}_t(\mathbf{w}') \leq (1+\nu)\mathcal{R}_t(\mathbf{w})$. By similar reasoning,

$$\begin{aligned}
\mathcal{R}_t(\mathbf{w}') &= \mathcal{R}_t(\mathbf{w}^*) + \mathcal{R}_t(\mathbf{w}') - \mathcal{R}_t(\mathbf{w}^*) \\
&\geq \mathcal{R}_t(\mathbf{w}^*) - |\nabla\mathcal{R}_t(\mathbf{w}_m)| \cdot |\mathbf{w}' - \mathbf{w}^*| \qquad \text{(for some } \mathbf{w}_m \text{ between } \mathbf{w}^* \text{ and } \mathbf{w}') \\
&\geq \mathcal{R}_t(\mathbf{w}^*)\left(1 - \frac{\nu}{3}\right) \geq \mathcal{R}_t(\mathbf{w})\left(1 - \frac{\nu}{3}\right) \geq \mathcal{R}_t(\mathbf{w})(1+\nu)^{-1},
\end{aligned}$$

completing the proof. ∎

We use a Metropolis algorithm [15] to sample from $\tilde{\pi}_t$. We generate a random walk on $\Omega$ according to a Markov chain whose stationary distribution is $\pi_t$. Begin by selecting a point $\mathbf{w}_0 \in \Omega$ according to either $\tilde{\pi}_{t-1}$ or $\tilde{\pi}_{t-2}$;[7] Remark 8 explains how to do this.

[7]Ideally, we would like to begin with a point selected according to $\tilde{\pi}_{t-1}$, but, as discussed in Remark 8, this is not always possible.

REMARK 8. *We can select a point according to $\tilde{\pi}_{t-1}$ by "saving" our samples that were generated at time $t-1$. By Lemma 4.3, we would have generated $N_{t-1} \geq \frac{8m^2t^8}{\varepsilon^4}\log\frac{2mt^2}{\delta}$ samples at time $t-1$, which is not enough to generate the $N_t \geq \frac{8m^2(t+1)^8}{\varepsilon^4}\log\frac{2m(t+1)^2}{\delta}$ samples necessary at time $t$. Instead, we can "save" samples that were generated at times $t-1$ and $t-2$. For sufficiently large $t$, $N_t \leq N_{t-1}+N_{t-2}$ and our initial point $\mathbf{w}_0$ would be picked according to either $\tilde{\pi}_{t-1}$ or $\tilde{\pi}_{t-2}$. As we see in the proof of Lemma 4.10, this distinction is not important.*

If $\mathbf{w}_\tau$ is the position of our random walk at time $\tau \geq 0$, we pick its position at time $\tau+1$ as follows. Note that $\mathbf{w}_\tau$ has $2(k-1)\ell$ neighbors, two along each axis in the Cartesian product of $\ell$ $(k-1)$-dimensional spaces. Let $\mathbf{w}$ be a neighbor of $\mathbf{w}_\tau$, selected uniformly at random. If $\mathbf{w} \in \Omega$, set

$$\mathbf{w}_{\tau+1} = \begin{cases} \mathbf{w} & \text{with probability } p = \min(1, \frac{\mathcal{R}_t(\mathbf{w})}{\mathcal{R}_t(\mathbf{w}_\tau)}), \\ \mathbf{w}_\tau & \text{with probability } 1-p. \end{cases}$$

If $\mathbf{w} \notin \Omega$, let $\mathbf{w}_{\tau+1} = \mathbf{w}_\tau$. It is well known that the stationary distribution of this random walk is $\pi_t$. We must determine how many steps of the walk are necessary before the distribution has gotten sufficiently close to stationary. Let $p_\tau$ be the distribution attained after $\tau$ steps of the random walk. That is, $p_\tau(\mathbf{w})$ is the probability of being at $\mathbf{w}$ after $\tau$ steps.

REMARK 9. *A distinction should be made between $t$ and $\tau$. We use $t$ to refer to the time step in our universalization algorithm. We use $\tau$ to refer to "sub-" time steps used in the Markov chain to sample from $\pi_t$. When $t$ is clear from context, we may drop it from the subscripts in our notation.*

Applegate and Kannan [2] show that if the desired distribution $\pi_t$ is proportional to a log-concave function $F$ (i.e., $\log F$ is concave), then the Markov chain is *rapidly mixing* and reaches its steady state in polynomial time. Frieze and Kannan [9] give an improved upper bound on the mixing time using logarithmic Sobolev inequalities [7].

THEOREM 4.5 (Theorem 1 of [9]). *Assume the diameter $d$ of $\mathbb{W}$ satisfies $d \geq \delta_t\sqrt{k\ell}$ and that the target distribution $\pi$ is proportional to a log-concave function. There is an absolute constant $\kappa > 0$ such that*

$$2\left(\sum_{\mathbf{w}\in\Omega} |\pi(\mathbf{w}) - p_\tau(\mathbf{w})|\right)^2 \leq e^{-\frac{\kappa\tau\delta_t^2}{k\ell d^2}}\log\frac{1}{\pi_*} + \frac{M\pi_e k\ell d^2}{\kappa\delta_t^2}, \tag{4.5}$$

*where $\pi_* = \min_{\mathbf{w}\in\Omega}\pi(\mathbf{w})$, $M = \max_{\mathbf{w}\in\Omega}\frac{p_0(\mathbf{w})}{\pi(\mathbf{w})}\log\frac{p_0(\mathbf{w})}{\pi(\mathbf{w})}$, $p_0(\cdot)$ is the initial distribution on $\Omega$, $\pi_e = \sum_{\mathbf{w}\in\Omega_e}\pi(\mathbf{w})$, and $\Omega_e = \{\mathbf{w} \in \Omega \,|\, \mathrm{Vol}(C(\mathbf{w}) \cap \mathbb{W}) < \mathrm{Vol}(C(\mathbf{w}))\}$. (The "e" in the subscripts of $\pi_e$ and $\Omega_e$ stands for "edge.")*

In the random walk described above, if $\mathbf{w}_\tau$ is on an edge of $\Omega$, so that it has many neighbors outside $\Omega$, the walk may get "stuck" at $\mathbf{w}_\tau$ for a long time, as seen in the "$\pi_e$" term of Theorem 4.5. We must ensure that the random walk has a low probability of reaching such edge points. We do this by applying a "damping function" to $\mathcal{R}_t$, which becomes exponentially small near the edges of $\mathbb{W}$. For $1 \leq i \leq \ell$, $1 \leq j \leq k$, and $\mathbf{w} = (\mathbf{w}_1, \ldots, \mathbf{w}_\ell) = ((w_{11}, \ldots, w_{1k}), \ldots, (w_{\ell 1}, \ldots, w_{\ell k})) \in \mathbb{W}$ let

$$f_{ij}(\mathbf{w}) = e^{\Gamma\min(-\sigma+w_{ij},0)}, \tag{4.6}$$

where $\sigma > 0$ and $\Gamma > 2$ are constants that we choose below, and let

$$F_t(\mathbf{w}) = \mathcal{R}_t(\mathbf{w})\prod_{i=1}^{\ell}\prod_{j=1}^{k} f_{ij}(\mathbf{w}).$$

LEMMA 4.6. *$F_t$ is log-concave if and only if $\mathcal{R}_t$ is log-concave.*[8]

*Proof.* This follows from the fact that log-concave functions are closed under multiplication and the fact that $\log f_{ij}(\mathbf{w}) = \Gamma \min(-\sigma + w_{ij}, 0)$, which is concave. $\square$

Choose $\sigma = \frac{1}{k}\delta_t(\frac{\gamma_t}{2})$, where $\delta_t(\cdot)$ is defined in Lemma 4.4 and $\gamma_t$ is defined in (4.2). Let $\zeta_F \propto F_t$ be the probability measure proportional to $F_t$. We need to show that, for our purposes, sampling from $\zeta_F$ is not much different than sampling from $\zeta_t$. By Lemma 4.2, we can do this by showing that $\int_{\mathbb{W}} |\zeta_t(\mathbf{w}) - \zeta_F(\mathbf{w})| d\mathbf{w} \leq \gamma_t$, which we do in Lemma 4.7.

REMARK 10. *Before continuing, we show how $\mathbb{W}$ can be scaled, which will be useful in future proofs. Take $\mathbf{p} = (\frac{1}{k}, \dots, \frac{1}{k}) \in \mathcal{W}_k$; given $\chi \in (-1, 1)$, let*

$$\mathbf{w}^{(\chi)} = (1 + \chi)(\mathbf{w} - \mathbf{p}) + \mathbf{p},$$

*and let*

$$\mathcal{W}_k^{(\chi)} = \{\mathbf{w}^{(\chi)} \mid \mathbf{w} \in \mathcal{W}_k\}$$

*be a scaled version of $\mathcal{W}_k$ about $\mathbf{p}$, where the scaling factor is $1 + \chi$. To extend this scaling to $\mathbb{W} = \mathcal{W}_k^\ell$, given $\mathbf{w} = (\mathbf{w}_1, \dots, \mathbf{w}_\ell) \in \mathbb{W}$, let $\mathbf{w}^{(\chi)} = (\mathbf{w}_1^{(\chi)}, \dots, \mathbf{w}_\ell^{(\chi)})$ and*

$$\mathbb{W}^{(\chi)} = \{\mathbf{w}^{(\chi)} \mid \mathbf{w} \in \mathbb{W}\}.$$

*A fact we use is that for $1 \leq i \leq \ell$, $1 \leq j \leq k$, and $\mathbf{w} = (\mathbf{w}_1, \dots, \mathbf{w}_\ell) \in \mathbb{W}$,*

$$|w_{ij}^{(\chi)} - w_{ij}| = \left| (1 + \chi)\left(w_{ij} - \frac{1}{k}\right) + \frac{1}{k} - w_{ij} \right| \leq |\chi|.$$

LEMMA 4.7. $\int_{\mathbb{W}} |\zeta_t(\mathbf{w}) - \zeta_F(\mathbf{w})| d\mathbf{w} \leq \gamma_t$.

*Proof.* Let $\mathbb{W}' = \mathbb{W}^{(-k\sigma)}$ be the "scaled-in" version of $\mathbb{W}$, as defined in Remark 10. By Lemma 4.4, since $|w_{ij} - w'_{ij}| \leq k\sigma = \delta_t(\frac{\gamma_t}{2})$ for all $i$ and $j$, $\mathcal{R}_t(\mathbf{w}') \geq \frac{1}{1+\frac{\gamma_t}{2}} \mathcal{R}_t(\mathbf{w})$ and

$$\int_{\mathbb{W}'} \mathcal{R}_t(\mathbf{w}) d\mathbf{w} \geq \frac{1}{1 + \frac{\gamma_t}{2}} \int_{\mathbb{W}} \mathcal{R}_t(\mathbf{w}) d\mathbf{w}. \tag{4.7}$$

Let $\mathbb{W}_{eq} = \{\mathbf{w} \in \mathbb{W} \mid F_t(\mathbf{w}) = \mathcal{R}_t(\mathbf{w})\}$ be the subset of $\mathbb{W}$ where $F_t(\cdot)$ and $\mathcal{R}_t(\cdot)$ are equal; $\mathbb{W}' \subset \mathbb{W}_{eq}$ since, by construction of $\mathbf{w}'$, $w'_{ij} \geq \sigma$ for all $i$ and $j$. Let $\mathbb{W}_+ = \{\mathbf{w} \in \mathbb{W} \mid \zeta_F(\mathbf{w}) \geq \zeta_t(\mathbf{w})\}$ be the subset of $\mathbb{W}$ where $\zeta_F(\cdot)$ is at least $\zeta_t(\cdot)$ and let $\mathbb{W}_- = \mathbb{W} - \mathbb{W}_+$. We bound

$$\int_{\mathbb{W}} |\zeta_F(\mathbf{w}) - \zeta_t(\mathbf{w})| d\mathbf{w} = \int_{\mathbb{W}_+} (\zeta_F(\mathbf{w}) - \zeta_t(\mathbf{w})) d\mathbf{w} + \int_{\mathbb{W}_-} (\zeta_t(\mathbf{w}) - \zeta_F(\mathbf{w})) d\mathbf{w}$$

by bounding $\int_{\mathbb{W}_-} (\zeta_t - \zeta_F)$, which also gives a bound for $\int_{\mathbb{W}_+} (\zeta_F - \zeta_t)$, since

$$\int_{\mathbb{W}_+} (\zeta_F - \zeta_t) = \left(1 - \int_{\mathbb{W}_-} \zeta_F\right) - \left(1 - \int_{\mathbb{W}_-} \zeta_t\right) = \int_{\mathbb{W}_-} (\zeta_t - \zeta_F).$$

[8]We characterize investment strategies for which $\mathcal{R}_t$ is log-concave in Theorem 4.14.

Since $F_t \leq \mathcal{R}_t$, $\int_{\mathbb{W}} F_t \leq \int_{\mathbb{W}} \mathcal{R}_t$ and $\zeta_F(\mathbf{w}) = \frac{F_t(\mathbf{w})}{\int_{\mathbb{W}} F_t} \geq \frac{\mathcal{R}_t(\mathbf{w})}{\int_{\mathbb{W}} \mathcal{R}_t} = \zeta_t(\mathbf{w})$ for $\mathbf{w} \in \mathbb{W}_{eq}$; thus $\mathbb{W}' \subset \mathbb{W}_{eq} \subset \mathbb{W}_+$ and $\mathbb{W}_- \subset \mathbb{W} - \mathbb{W}'$. We have

$$\int_{\mathbb{W}_-} (\zeta_t(\mathbf{w}) - \zeta_F(\mathbf{w}))d\mathbf{w} \leq \int_{\mathbb{W}-\mathbb{W}'} \zeta_t(\mathbf{w})d\mathbf{w} = \frac{\int_{\mathbb{W}-\mathbb{W}'} \mathcal{R}_t(\mathbf{w})d\mathbf{w}}{\int_{\mathbb{W}} \mathcal{R}_t(\mathbf{w})d\mathbf{w}} = 1 - \frac{\int_{\mathbb{W}'} \mathcal{R}_t(\mathbf{w})d\mathbf{w}}{\int_{\mathbb{W}} \mathcal{R}_t(\mathbf{w})d\mathbf{w}}$$
$$\leq 1 - \frac{1}{1+\frac{\gamma_t}{2}} \leq \frac{\gamma_t}{2},$$

where the second-to-last inequality follows from (4.7). This completes the proof. ∎

Henceforth, we are concerned with sampling from $\mathbb{W}$ with probability proportional to $F_t(\cdot)$. We use the Metropolis algorithm described above, replacing $R_t(\cdot)$ with $F_t(\cdot)$; we must refine our grid spacing $\delta_t$ so that (4.4) is satisfied by $F_t$; let $\delta'_t$ be the new grid spacing.

LEMMA 4.8. *Suppose that the conditions of Lemma 4.4 are satisfied. Given $\nu > 0$, let $\delta'_t(\nu) = \delta'_t = \frac{\nu}{3\Gamma c' m t^4 k\ell} = \delta_t(\frac{\nu}{\Gamma})$, where $\Gamma$ appears in (4.6). For $\mathbf{w}, \mathbf{w}' \in \mathbb{W}$ such that $|w_{ij} - w'_{ij}| \leq \delta'_t(\nu)$ for all $1 \leq i \leq \ell$ and $1 \leq j \leq k$, $(1+\nu)^{-1}F_t(\mathbf{w}) \leq F_t(\mathbf{w}') \leq (1+\nu)F_t(\mathbf{w})$.*

*Proof.* By Lemma 4.4, $\mathcal{R}_t(\mathbf{w})$ and $\mathcal{R}_t(\mathbf{w}')$ differ by at most a factor of $1 + \frac{\nu}{\Gamma}$. For each $i$ and $j$, $f_{ij}(\mathbf{w})$ and $f_{ij}(\mathbf{w}')$ differ by at most a factor of $e^{\Gamma\delta'_t(\nu)}$, and hence $\prod_{i=1}^{\ell}\prod_{j=1}^{k} f_{ij}(\mathbf{w})$ and $\prod_{i=1}^{\ell}\prod_{j=1}^{k} f_{ij}(\mathbf{w}')$ differ by at most a factor of $e^{k\ell\Gamma\delta'_t(\nu)} = e^{\frac{\nu}{3c'mt^4}}$. Hence, for $\Gamma \geq 2$ and sufficiently large $t$, $F_t(\mathbf{w})$ and $F_t(\mathbf{w}')$ differ by at most a factor of $1+\nu$. ∎

We are now ready to use Theorem 4.5 to select $\tau$ so that the resulting distribution $p_\tau$ satisfies (4.2) (Theorem 4.12) and (4.3) (Theorem 4.13), with $p_\tau$ in place of $\tilde{\pi}_t$ and $F_t$ in place of $\mathcal{R}_t$. We begin with some preliminary lemmas.

LEMMA 4.9. *There is a constant $\beta > 0$ such that $\log\frac{1}{\pi_*} \leq k\ell\Gamma\sigma + k\ell\log\frac{\beta}{\delta'_t} + t\log\frac{2mt^2}{\varepsilon}$, where $\varepsilon$ is defined in Remark 6.*

*Proof.* Take $\beta$ such that the number of points in $\Omega$ is at most $(\frac{\beta}{\delta'_t})^{(k-1)\cdot\ell}$. For $\mathbf{w}_1, \mathbf{w}_2 \in \Omega$, the ratio of single-day returns on day $t'$ using $\mathbf{w}_1$ and $\mathbf{w}_2$ is

$$\frac{S_{t'}(\mathbf{w}_1)\cdot\mathbf{x}_{t'}}{S_{t'}(\mathbf{w}_2)\cdot\mathbf{x}_{t'}} \geq \frac{\varepsilon}{2m(t'+1)^2},$$

by Remark 6 and Lemma 3.4. The ratio of the cumulative returns up to day $t$ is

$$\frac{\mathcal{R}_t(\mathbf{w}_1)}{\mathcal{R}_t(\mathbf{w}_2)} \geq \Big(\frac{\varepsilon}{2mt^2}\Big)^t,$$

and thus $\frac{\mathcal{R}_t(\mathbf{w})}{\sum_{\mathbf{w}\in\Omega}\mathcal{R}_t(\mathbf{w})} \geq (\frac{\delta'_t}{\beta})^{(k-1)\ell}\big(\frac{\varepsilon}{2mt^2}\big)^t$. Factoring in the maximum dampening effect of the $f_{ij}$, $\pi_* \geq e^{-k\ell\Gamma\sigma}(\frac{\delta'_t}{\beta})^{(k-1)\ell}\big(\frac{\varepsilon}{2mt^2}\big)^t$ and $\log\frac{1}{\pi_*} \leq k\ell\Gamma\sigma + k\ell\log\frac{\beta}{\delta'_t} + t\log\frac{2mt^2}{\varepsilon}$. ∎

LEMMA 4.10. $M \leq 4\big(\frac{2m(t+1)^2}{\varepsilon}\big)^2\log\frac{2m(t+1)^2}{\varepsilon}$.

*Proof.* As stated in Remark 8, the initial distribution is either $p_0 = \tilde{\pi}_{t-1}$ or $\tilde{\pi}_{t-2}$. It turns out that the worst case happens when $p_0 = \tilde{\pi}_{t-2}$. For all $\mathbf{w} \in \Omega$, $\frac{\tilde{\pi}_{t-2}(\mathbf{w})}{\pi_{t-2}(\mathbf{w})} \leq 2$ by (4.3) and the following:

$$\begin{aligned}
\frac{\pi_{t-2}(\mathbf{w})}{\pi_t(\mathbf{w})} &= \frac{F_{t-2}(\mathbf{w})}{\sum_{\mathbf{w}\in\Omega} F_{t-2}(\mathbf{w})} \cdot \frac{\sum_{\mathbf{w}\in\Omega} F_t(\mathbf{w})}{F_t(\mathbf{w})} \\
&\leq \frac{F_{t-2}(\mathbf{w})}{F_t(\mathbf{w})} \cdot \frac{F_t(\mathbf{w}')}{F_{t-2}(\mathbf{w}')} \qquad \left(\text{by Lemma 3.4, where } \mathbf{w}' = \arg\max_{\mathbf{w}\in\Omega} \frac{F_t(\mathbf{w})}{F_{t-2}(\mathbf{w})}\right) \\
&= \frac{\mathcal{R}_{t-2}(\mathbf{w})}{\mathcal{R}_t(\mathbf{w})} \cdot \frac{\mathcal{R}_t(\mathbf{w}')}{\mathcal{R}_{t-2}(\mathbf{w}')} \qquad (\text{since the } \{f_{ij}(\cdot)\}_{i,j} \text{ remain constant with time}) \\
&= \frac{(S_t(\mathbf{w}')\cdot\mathbf{x}_t)(S_{t-1}(\mathbf{w}')\cdot\mathbf{x}_{t-1})}{(S_t(\mathbf{w})\cdot\mathbf{x}_t)(S_{t-1}(\mathbf{w})\cdot\mathbf{x}_{t-1})} \leq \left(\frac{2m(t+1)^2}{\varepsilon}\right)^2,
\end{aligned}$$

where the final inequality follows from the discussion in the proof of Lemma 4.9. This proves the result since $\frac{\tilde{\pi}_{t-2}(\mathbf{w})}{\pi_t(\mathbf{w})} = \frac{\tilde{\pi}_{t-2}(\mathbf{w})}{\pi_{t-2}(\mathbf{w})}\frac{\pi_{t-2}(\mathbf{w})}{\pi_t(\mathbf{w})}$. ∎

LEMMA 4.11. *$\pi_e \leq (1+\nu)^4(1+\frac{\gamma_t}{2})e^{-\Gamma\sigma}$, where $\nu$ appears in the definition of $\delta'_t$ in Lemma 4.8, $\gamma_t$ appears in (4.2), and $\Gamma$ and $\sigma$ appear in (4.6).*

*Proof.* Extend our $\delta'_t$-hypercube partition of $\mathbb{W}$ to the hyperplane containing $\mathbb{W}$, and let $\Psi$ be the set of centers of the hypercubes in this extended partition. For $K \subset \mathbb{R}^{k\ell}$, let $\Psi_K$ be the set of grid points $\mathbf{w} \in \Psi$ such that $C(\mathbf{w}) \cap K \neq \emptyset$, so that $\Omega = \Psi_{\mathbb{W}}$. By Lemma 4.8, for $K \subset \mathbb{W}$,

(4.8)
$$\frac{1}{1+\nu}\sum_{\mathbf{w}\in\Psi_K} F_t(\mathbf{w})\mathrm{Vol}(C(\mathbf{w})\cap K) \leq \int_K F_t(\mathbf{w})d\mathbf{w} \leq (1+\nu)\sum_{\mathbf{w}\in\Psi_K} F_t(\mathbf{w})\mathrm{Vol}(C(\mathbf{w})\cap K).$$

Using the notation of Lemma 4.7, let $\mathbb{W}' = \mathbb{W}^{(-k\sigma)}$ be a "scaled-in" version of $\mathbb{W}$; we showed in Lemma 4.7 that for $\mathbf{w} \in \mathbb{W}'$, $F_t(\mathbf{w}) = \mathcal{R}_t(\mathbf{w})$, and that

$$\int_{\mathbb{W}'} F_t(\mathbf{w})d\mathbf{w} = \int_{\mathbb{W}'} \mathcal{R}_t(\mathbf{w})d\mathbf{w} \geq \frac{1}{1+\frac{\gamma_t}{2}}\int_{\mathbb{W}} \mathcal{R}_t(\mathbf{w})d\mathbf{w}. \tag{4.9}$$

Let $\mathbb{W}'' = \mathbb{W}^{(\delta'_t(\nu))}$ be a "scaled-out" version of $\mathbb{W}$, and extend the domains of $F_t(\cdot)$ and $\mathcal{R}_t(\cdot)$ to $\mathbb{W}''$ by defining $F_t(\mathbf{w}'') = F_t(\bar{\mathbf{w}}'')$ and $\mathcal{R}_t(\mathbf{w}'') = \mathcal{R}_t(\bar{\mathbf{w}}'')$ for $\mathbf{w}'' \in \mathbb{W}'' - \mathbb{W}$, where $\bar{\mathbf{w}}''$ is the point where the line between $\mathbf{w}''$ and $\mathbf{p}^\ell = (\mathbf{p},\dots,\mathbf{p}) \in \mathbb{W}$ intersects the boundary of $\mathbb{W}$. By Lemma 4.8 and the construction of the extension of $\mathcal{R}_t$, $\mathcal{R}_t(\mathbf{w}'') \leq (1+\nu)\mathcal{R}_t(\mathbf{w})$ and

$$\int_{\mathbb{W}''} \mathcal{R}_t(\mathbf{w})d\mathbf{w} \leq (1+\nu)\int_{\mathbb{W}} \mathcal{R}_t(\mathbf{w})d\mathbf{w}. \tag{4.10}$$

By construction of $\mathbb{W}''$, $C(\mathbf{w}) \subset \mathbb{W}''$ for $\mathbf{w} \in \Omega_e$; from the definition of $F_t$ and the choice of $\delta'_t$, $F_t(\mathbf{w}) \leq (1+\nu)e^{-\Gamma\sigma}\mathcal{R}_t(\mathbf{w})$ for $\mathbf{w} \in \Omega_e$. Using these facts,

$$\begin{aligned}
\pi_e = \frac{\sum_{\mathbf{w}\in\Omega_e} F_t(\mathbf{w})}{\sum_{\mathbf{w}\in\Omega} F_t(\mathbf{w})} &\leq \frac{\delta_t^{(k-1)\ell}}{\delta_t^{(k-1)\ell}} \cdot \frac{(1+\nu)e^{-\Gamma\sigma}\sum_{\mathbf{w}\in\Omega_e} \mathcal{R}_t(\mathbf{w})}{\sum_{\mathbf{w}\in\Omega} F_t(\mathbf{w})} \\
&\leq (1+\nu)e^{-\Gamma\sigma}\frac{\sum_{\mathbf{w}\in\Psi_{\mathbb{W}''}} \mathrm{Vol}(C(\mathbf{w})\cap\mathbb{W}'')\mathcal{R}_t(\mathbf{w})}{\sum_{\mathbf{w}\in\Psi_{\mathbb{W}}} \mathrm{Vol}(C(\mathbf{w})\cap\mathbb{W})F_t(\mathbf{w})} \qquad \left(\text{since } \mathrm{Vol}(C(\mathbf{w})) = \delta_t^{(k-1)\ell}\right) \\
&\leq (1+\nu)e^{-\Gamma\sigma}\frac{(1+\nu)\int_{\mathbb{W}''} \mathcal{R}_t(\mathbf{w})d\mathbf{w}}{\frac{1}{(1+\nu)}\int_{\mathbb{W}} F_t(\mathbf{w})d\mathbf{w}} \qquad (\text{by } (4.8)) \\
&\leq (1+\nu)^3 e^{-\Gamma\sigma}\frac{\int_{\mathbb{W}''} \mathcal{R}_t(\mathbf{w})d\mathbf{w}}{\int_{\mathbb{W}'} F_t(\mathbf{w})d\mathbf{w}} \leq (1+\nu)^4\left(1+\frac{\gamma_t}{2}\right)e^{-\Gamma\sigma}
\end{aligned}$$

(by (4.9) and (4.10)). ∎

REMARK 11. *We simplify notation below by using $\mathcal{O}^*(\cdot)$ notation, which ignores logarithmic and constant terms. For our purposes, $f(\cdot) = \mathcal{O}^*(g(\cdot))$ if there exists a constant $C \geq 0$ such that $f(\cdot) = \mathcal{O}(g(\cdot)\log^C(k\ell mt/\varepsilon))$. The values derived above in this notation are $\gamma_t = \mathcal{O}^*(\frac{\varepsilon^2}{mt^4})$, $\delta_t = \mathcal{O}^*(\frac{\nu}{mt^4k\ell})$, $\sigma = \mathcal{O}^*(\frac{\varepsilon^2}{m^2t^8k^2\ell})$, $\delta'_t = \mathcal{O}^*(\frac{\nu}{\Gamma mt^4k\ell})$, $\log\frac{1}{\pi_*} = \mathcal{O}^*(k\ell\Gamma\sigma + t)$, $M = \mathcal{O}^*(\frac{m^2t^4}{\varepsilon^2})$, and $\pi_e = \mathcal{O}^*(e^{-\Gamma\sigma})$.*

THEOREM 4.12. *Letting $\Gamma = \mathcal{O}^*(\frac{1}{\sigma}) = \mathcal{O}^*(\frac{m^2t^8k^2\ell}{\varepsilon^2})$, the random walk reaches a distribution $\tilde{\pi}$ that satisfies (4.2) after $\tau = \mathcal{O}^*(\frac{k^7\ell^6m^6t^{24}}{\kappa\nu^2\varepsilon^4})$ steps.*

*Proof.* We show how to bound the right-hand side of (4.5), where the grid spacing $\delta_t$ has been replaced by $\delta'_t$. The second term, $\frac{M\pi_e k\ell d^2}{\kappa{\delta'_t}^2}$, can be made exponentially small in $\Gamma$ by choosing $\Gamma = \mathcal{O}^*(\frac{1}{\sigma})$. The value of $\tau$ stated in the theorem is large enough to make the first term, $e^{-\frac{\kappa\tau{\delta'_t}^2}{k\ell d^2}}\log\frac{1}{\pi_*}$, exponentially small in $\tau$. □

THEOREM 4.13. *Suppose that the distribution $p_{\tau_0}$ obtained after $\tau_0$ steps satisfies*

$$\sum_{\mathbf{w}\in\Omega} |\pi(\mathbf{w}) - p_{\tau_0}(\mathbf{w})| \leq \gamma_t.$$

*After $\tau'_0 \geq \frac{\tau_0}{\tau_0 - \log\frac{1}{\pi_*} - \log\frac{1}{\gamma_t}}\log\frac{1}{\pi_*} = \mathcal{O}^*(\tau_0(k\ell + t))$ steps, the resulting distribution $p_{\tau'_0}$ satisfies*

$$\max_{\mathbf{w}\in\Omega}\frac{p_{\tau'_0}(\mathbf{w})}{\pi(\mathbf{w})} - 1 \leq 1,$$

*which implies (4.3).*

*Proof.* Let $d(\tau) = \frac{1}{2}\sum_{\mathbf{w}\in\Omega}|\pi(\mathbf{w}) - p_\tau(\mathbf{w})|$ and $\hat{d}(\tau) = \max_{\mathbf{w}\in\Omega}\frac{p_\tau(\mathbf{w})}{\pi(\mathbf{w})} - 1$ so that $d(\tau_0) \leq \frac{1}{2}\gamma_t$. Aldous and Fill [1, (5) and (6)] prove that if $\tau \geq \frac{1}{\lambda}\log\frac{1}{\pi_*}$, then $\hat{d}(\tau) \leq 1$, where $\pi_* = \min_{w\in\Omega}\pi_t(w)$ is as defined in the statement of Theorem 4.5 and $\lambda$ is the second-largest eigenvalue of the steady-state transition matrix $P$ of $\pi_t$.

To prove the bound on $\tau'_0$, we show that $\lambda \geq \frac{\tau_0 - \log\frac{1}{\pi_*} - \log\frac{1}{\gamma_t}}{\tau_0} = 1 - \frac{\log\frac{1}{\pi_*} + \log\frac{1}{\gamma_t}}{\tau_0}$. We do this by appealing to a result from Sinclair [17, Proposition 1(i)], which states that

$$\tau_0 \leq \frac{\log\frac{1}{\pi_*} + \log\frac{1}{\gamma_t}}{1-\lambda}.[9]$$

Solving for $\lambda$ yields the bound for $\tau'_0$. The $\mathcal{O}^*(\cdot)$ bound comes from the fact that $\Gamma\sigma = \mathcal{O}^*(1)$ and that $\log\frac{1}{\gamma_t}$ and $\log\frac{1}{\pi_*}$ are low-order terms relative to the $\tau_0$ obtained in Theorem 4.12. □

**4.3. Application to investment strategies.** The efficient sampling techniques of this section are applicable to investment strategies $S$ whose return functions $\mathcal{R}_n(S(\cdot))$ are log-concave. Theorem 4.14 and Corollary 4.15 characterize such functions.

THEOREM 4.14. *Given investment strategy $S$, suppose that $S$ is linear on $\mathbf{w}$, or, more formally, that for all parameters $w_i$ and $w_j$, $\frac{\partial^2 S}{\partial w_i \partial w_j} = 0$. Then $\mathcal{R}_t(\mathbf{w}) = \mathcal{R}_t(S(\mathbf{w}))$ is log-concave.*

[9]Strictly speaking, this result pertains to $\lambda_{\max}$, the second-largest absolute value of the eigenvalues of $P$, but as Sinclair discusses [17, p. 355], the smallest eigenvalue is unimportant, as $P$ can be modified so that all eigenvalues are positive without affecting mixing times beyond a constant factor.

*Proof.* Let $r_t(\mathbf{w}) = S_t(\mathbf{w}) \cdot \mathbf{x}_t$, so that $\mathcal{R}_n(\mathbf{w}) = \prod_{t=0}^{n-1} r_t(\mathbf{w})$. Since log-concave functions are closed under multiplication, we need only show that $r_t(\mathbf{w})$ is log-concave. The gradient vector of $\log r_t(\mathbf{w})$ has $i$th element $\frac{\partial \log r_t(\mathbf{w})}{\partial w_i} = \frac{1}{r_t(\mathbf{w})} \frac{\partial r_t(\mathbf{w})}{\partial w_i}$, and the matrix of second derivatives has $(i, j)$th element

$$-\frac{1}{r_t(\mathbf{w})^2} \frac{\partial r_t(\mathbf{w})}{\partial w_i} \frac{\partial r_t(\mathbf{w})}{\partial w_j} + \frac{1}{r_t(\mathbf{w})} \frac{\partial^2 r_t(\mathbf{w})}{\partial w_i \partial w_j} = -\frac{1}{r_t(\mathbf{w})^2} \frac{\partial r_t(\mathbf{w})}{\partial w_i} \frac{\partial r_t(\mathbf{w})}{\partial w_j},$$

since $\frac{\partial^2 r_t(\mathbf{w})}{\partial w_i \partial w_j} = \sum_{\iota=1}^{m} \frac{\partial^2 S_{t\iota}(\mathbf{w})}{\partial w_i \partial w_j} \cdot x_{t\iota} = 0$ by assumption. The matrix of second derivatives is negative semidefinite, implying that $\log r_t(\mathbf{w})$ is a concave function. ☐

COROLLARY 4.15. *Universalizations of the following investment strategies can be computed using the sampling techniques of this section:*

1. *the trading strategies MA[k] and SR[k] with long/short allocation functions $g_\ell(x)$ and $h_p(x, y)$, respectively, and*
2. *the portfolio strategies CRP and CRP-S.*

*Proof.* The result follows from a straightforward differentiation of the investment descriptions of these strategies. ☐

**5. Further research.** We have introduced in this paper a general framework for universalizing parameterized investment strategies. It would be interesting to relax the condition of Theorem 3.3 and generalize the theorem. Likewise, it would be interesting to see whether the proof of Theorem 3.3 can be optimized so that existing universal portfolio proofs for CRP [3, 5, 6] are a special case of Theorem 3.3. These proofs not only prove that $\mathcal{L}_n(\mathcal{U}(\text{CRP}))$ converges to $\mathcal{L}_n(\text{CRP}(\mathbf{w}_n^*))$, but also prove a bound on the rate of convergence,

$$\frac{\mathcal{R}_n(\text{CRP}(\mathbf{w}_n^*))}{\mathcal{R}_n(\mathcal{U}(\text{CRP}))} \leq \binom{n+m-1}{m-1} \leq (n+1)^{m-1}.$$

It would also be interesting to study other trading and portfolio strategies that fit into our universalization framework and to see how our universalization algorithms perform in empirical tests.

**Acknowledgments.** We would like to thank two anonymous reviewers for their comments, which significantly improved the presentation of our work.

# LABELING SCHEMES FOR FLOW AND CONNECTIVITY[*]

MICHAL KATZ[†], NIR A. KATZ[†], AMOS KORMAN[‡], AND DAVID PELEG[‡]

**Abstract.** This paper studies labeling schemes for flow and connectivity functions. A flow labeling scheme using $O(\log n \cdot \log \hat{\omega} + \log^2 n)$-bit labels is presented for general $n$-vertex graphs with maximum (integral) capacity $\hat{\omega}$. This is shown to be asymptotically optimal. For edge-connectivity, this yields a tight bound of $\Theta(\log^2 n)$ bits. A $k$-vertex connectivity labeling scheme is then given for general $n$-vertex graphs using at most $3\log n$ bits for $k = 2$, $5\log n$ bits for $k = 3$, and $2^k \log n$ bits for $k > 3$. Finally, a lower bound of $\Omega(k \log n)$ is established for $k$-vertex connectivity on $n$-vertex graphs, where $k$ is polylogarithmic in $n$.

## 1. Introduction.

### 1.1. Problem and motivation.

Network representations play an extensive role in the areas of distributed computing and communication networks. Their goal is to cheaply store useful information about the network and make it readily and conveniently accessible. This is particularly significant when the network is large and geographically dispersed and information about its structure must be accessed from various local points in it.

The current paper deals with a network representation method based on assigning *informative labels* to the vertices of the network. In most traditional network representations, the names or identifiers given to the vertices contain no useful information, and they serve only as pointers to entries in the data structure, which forms a *global* representation of the network. In contrast, the labeling schemes studied here use more informative and localized labels for the network vertices. The idea is to associate with each vertex a label selected in a such way that will allow us to infer information about any two vertices *directly* from their labels, without using *any* additional information sources. Hence, in essence this method bases the entire representation on the set of labels alone.

Obviously, labels of unrestricted size can be used to encode any desired information including, in particular, the entire graph structure. Our focus is thus on informative labeling schemes using relatively *short* labels (say, of length polylogarithmic in $n$). Labeling schemes of this type were developed in the past for different graph families and for a variety information types, including vertex adjacency [5, 4, 14, 6], distance [17, 11, 10, 8, 13, 9, 1], tree ancestry [3, 12, 2], and various other tree functions, such as center, least common ancestor, separation level, and Steiner weight of a given subset of vertices [18].

The current paper studies informative labeling schemes for flow and connectivity problems. Flow and connectivity information is useful in the decision making process required for various reservation-based routing and connection establishment mechanisms in communication networks, in which it is desirable to have accurate information about the potential capacity of available routes between any two given endpoints. This flow and connectivity information is particularly useful when it represents online the current availability of route capacity in a dynamically changing setting. The methods presented in the current paper are limited to a static graph with fixed topology and edge capacities. Hence, our results constitute only a preliminary step toward handling the full problem in the dynamic setting. Initial studies of the dynamic setting are presented in [16, 15].

**1.2. Labeling schemes.** Let us first formalize the notion of informative labeling schemes. A *vertex-labeling* of the graph $G$ is a function $L$ assigning a label $L(u)$ to each vertex $u$ of $G$. A labeling scheme is composed of two major components. The first is a *marker* algorithm $\mathcal{M}$ which, given a graph $G$, selects a label assignment $L = \mathcal{M}(G)$ for $G$. The second component is a *decoder* algorithm $\mathcal{D}$ which, given a set of labels $\hat{L} = \{L_1, \ldots, L_k\}$, returns a value $\mathcal{D}(\hat{L})$. The time complexity of the decoder is required to be polynomial in its input size.

Let $f$ be a function defined on sets of vertices in a graph. Given a family $\mathcal{G}$ of weighted graphs, an $f$ *labeling scheme* for $\mathcal{G}$ is a marker-decoder pair $\langle \mathcal{M}_f, \mathcal{D}_f \rangle$ with the following property. Consider any graph $G \in \mathcal{G}$, and let $L = \mathcal{M}_f(G)$ be the vertex-labeling assigned by the marker $\mathcal{M}_f$ to $G$. Then for any set of vertices $W = \{v_1, \ldots, v_k\}$ in $G$, the value returned by the decoder $\mathcal{D}_f$ on the set of labels $\hat{L}(W) = \{L(v) \mid v \in W\}$ satisfies $\mathcal{D}_f(\hat{L}(W)) = f(W)$.

It is important to note that the decoder $\mathcal{D}_f$, responsible for the $f$-computation, is independent of $G$ as well as of the number of vertices in it. Thus $\mathcal{D}_f$ can be viewed as a method for computing $f$-values in a "distributed" fashion, given any set of labels and the knowledge that the graph belongs to some specific family $\mathcal{G}$. In particular, it must be possible to define $\mathcal{D}_f$ as a constant size algorithm. In contrast, the labels contain some information that can be precomputed by considering the whole graph structure.

For a labeling $L$ for the graph $G = \langle V, E \rangle$, let $|L(u)|$ denote the number of bits in the (binary) string $L(u)$. Given a graph $G$ and a marker algorithm $\mathcal{M}$, which assigns the labeling $L$ to $G$, denote $\mathcal{L}_{\mathcal{M}}(G) = \max_{u \in V} |L(u)|$. For a finite graph family $\mathcal{G}$, set $\mathcal{L}_{\mathcal{M}}(\mathcal{G}) = \max\{\mathcal{L}_{\mathcal{M}}(G) \mid G \in \mathcal{G}\}$. Finally, given a function $f$ and a graph family $\mathcal{G}$, let

$$\mathcal{L}(f, \mathcal{G}) = \min\{\mathcal{L}_{\mathcal{M}}(\mathcal{G}) \mid \exists \mathcal{D},\ \langle \mathcal{M}, \mathcal{D} \rangle \text{ is an } f \text{ labeling scheme for } \mathcal{G}\}.$$

**1.3. Flow and connectivity.** In the current paper we focus on flow and connectivity labeling schemes. Let $G = \langle V, E, \omega \rangle$ be a weighted undirected graph where, for every edge $e \in E$, the weight $\omega(e)$ is integral and represents the *capacity* of the edge. For two vertices $u, v \in V$, the *maximum flow* possible between them (in either direction), denoted $\mathtt{flow}(u, v)$, can be defined in this context as follows. Denote by $G'$ the multigraph obtained by replacing each edge $e$ in $G$ with $\omega(e)$ parallel edges of capacity 1. A set of paths $P$ in $G'$ is *edge-disjoint* if each edge $e \in E$ appears in no more than one path $p \in P$. Let $\mathcal{P}_{u,v}$ be the collection of all sets $P$ of edge-disjoint paths in $G'$ between $u$ and $v$. Then $\mathtt{flow}(u, v) = \max_{P \in \mathcal{P}_{u,v}} \{|P|\}$. See Figure 1.

As a special case of the flow function, the *edge-connectivity* $\mathtt{e\text{-}conn}(u, w)$ of two vertices $u$ and $w$ in a graph can be given an alternative definition as the maximum

FIG. 1. *A capacitated graph $G$ and the (symmetric) flow between its vertices.*

flow between the two vertices, assuming each edge is assigned one capacity unit.

A set of paths $P$ connecting the vertices $u$ and $w$ in $G$ is *vertex-disjoint* if each vertex, except $u$ and $w$, appears in at most one path $p \in P$. The *vertex-connectivity* $\texttt{v-conn}(u, w)$ of two vertices $u$ and $w$ in an unweighted graph equals the cardinality of the largest set $P$ of vertex-disjoint paths connecting them. By Menger's theorem (cf. [7]), for nonadjacent $u$ and $w$, $\texttt{v-conn}(u, w)$ equals the minimum number of vertices in $G \setminus \{u, w\}$ whose removal from $G$ disconnects $u$ from $w$. (When a vertex is removed, all its incident edges are removed as well.)

**1.4. Our results.** In this paper we present a number of results concerning labeling schemes for maximum flow, edge-connectivity, and vertex-connectivity. In section 2 we present a flow labeling scheme for general graphs, with label size $O(\log n \cdot \log \hat{\omega} + \log^2 n)$ over $n$-vertex graphs with maximum (integral) capacity $\hat{\omega}$. The scheme relies on the fact that the relation "$x$ and $y$ admit a flow of $k$ or more" is an equivalence relation. In section 3 we establish the optimality of our flow labeling scheme by proving a tight lower bound of $\Omega(\log n \cdot \log \hat{\omega} + \log^2 n)$ on the required label size for flow labeling schemes on the class of $n$-vertex trees with maximum capacity $\hat{\omega}$. For edge-connectivity, this yields a tight bound of $\Theta(\log^2 n)$.

In comparison, vertex-connectivity seems to require a more involved labeling scheme whose label size depends on the connectivity parameter $k$. In section 4 we present a $k$-vertex-connectivity labeling scheme for general $n$-vertex graphs. The label sizes we achieve are $\log n$ for $k = 1$, $3 \log n$ for $k = 2$, $5 \log n$ for $k = 3$, and $2^k \log n$ for $k > 3$. In section 5 we present a lower bound of $\Omega(k \log n)$ for the required label size for $k$-vertex connectivity on general $n$-vertex graphs, where $k$ is polylogarithmic in $n$.

## 2. Flow labeling schemes for general graphs.

In this section we consider the family $\mathcal{G}(n, \hat{\omega})$ of undirected capacitated connected $n$-vertex graphs with maximum (integral) capacity $\hat{\omega}$ and present a flow labeling scheme for this family with label size $O(\log n \cdot \log \hat{\omega} + \log^2 n)$. Given a graph $G = \langle V, E, \omega \rangle$ in this family and an integer $1 \le k \le \hat{\omega}$, let us define the following relation:

$$R_k \;=\; \{(x, y) \mid x, y \in V,\;\; \texttt{flow}(x, y) \ge k\}. \tag{2.1}$$

We use the following easy-to-prove fact.

LEMMA 2.1. *The relation $R_k$ is an equivalence relation.*

For every $k \ge 1$, the relation $R_k$ induces a collection of equivalence classes on $V$, $\mathcal{C}_k = \{C_k^1, \ldots, C_k^{m_k}\}$ such that $C_k^i \cap C_k^j = \emptyset$ and $\bigcup_i C_k^i = V$. Note that for $k < k'$, the relation $R_{k'}$ is a *refinement* of $R_k$; namely, for every class $C_{k'}^i$ there is a class $C_k^j$ such that $C_{k'}^i \subseteq C_k^j$.

Given $G$, let us construct a tree $T_G$ corresponding to its equivalence relations. The $k$th level of $T_G$ corresponds to the relation $R_k$, i.e., it has $m_k$ nodes, marked by the classes $C_k^1, \ldots, C_k^{m_k}$. In particular, the root of $T_G$ is marked by the unique equivalence class of $R_1$, which is $V$. The tree is truncated at a node once the equivalence class associated with it is a singleton. For every vertex $v \in G$, denote by $t(v)$ the leaf in $T_G$ associated with the singleton set $\{v\}$. Figure 2 describes the tree $T_G$ corresponding to the flow equivalence classes for the graph $G$ of Figure 1.

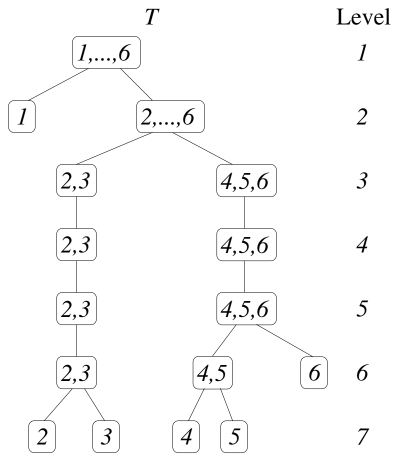

FIG. 2. *The tree $T_G$ corresponding to the graph $G$ of Figure* 1.

For two nodes $x, y$ in a tree $T$ rooted at $r$, define the *separation level* of $x$ and $y$, denoted $\texttt{SepLevel}_T(x, y)$, as the depth of $z = lca(x, y)$, the least common ancestor of $x$ and $y$. In other words, $\texttt{SepLevel}_T(x, y) = dist_T(z, r)$, the distance of $z$ from the root. As an immediate consequence of the construction, we have the following connection.

LEMMA 2.2. *For every two vertices $v, w \in V$,*

$$\texttt{flow}_G(v, w) = \texttt{SepLevel}_T(t(v), t(w)) + 1.$$

It is proven in [18] that for the class $\mathcal{T}(n)$ of $n$-node unweighted trees, there exists a `SepLevel` labeling scheme with $O(\log^2 n)$-bit labels. (This is also shown to be optimal, in the sense that any such scheme must label some node of some $n$-node unweighted tree with an $\Omega(\log^2 n)$-bit label.)

Observe that if the maximum capacity of any edge in the $n$-vertex graph $G$ is $\hat{\omega}$, then the depth of the tree $T_G$ cannot exceed $n\hat{\omega}$ levels; and it may have at most $n$ nodes per level; hence the total number of nodes in $T_G$ is $O(n^2\hat{\omega})$. We immediately have that $\mathcal{L}(\texttt{flow}, \mathcal{G}(n, \hat{\omega})) = O(\log^2(n\hat{\omega}))$.

A more careful design of the tree $T_G$ can improve the bound on the label size. This is achieved by canceling all nodes of degree 2 in the tree $T_G$ and adding appropriate edge weights. Specifically, a subpath $(v_0, v_1, \ldots, v_k)$ in $T_G$ such that $k \geq 2$, $v_0$ and $v_k$ have degree 3 or higher, and $v_1, \ldots, v_{k-1}$ have degree 2 (with $v_1, \ldots, v_k$ all marked by the same set $C$) is compacted into a single edge $(v_0, v_k)$ with weight $k$, eliminating the nodes $v_1, \ldots, v_{k-1}$ and leaving the sets, marking the remaining nodes unchanged. Let $\tilde{T}_G$ denote the resulting compacted tree. Figure 3 describes the tree $\tilde{T}_G$ corresponding to the tree $T_G$ of Figure 2.

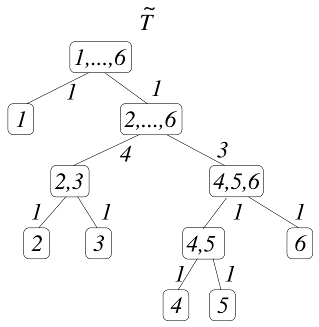

FIG. 3. *The compacted tree $\tilde{T}_G$ corresponding to the tree $T_G$ of Figure* 2.

The notion of separation level can be extended to weighted rooted trees in a natural way by defining $\texttt{SepLevel}_T(x, y)$ as the weighted depth of $z = lca(x, y)$, i.e., its weighted distance from the root. The upper (and lower) bound presented in [18] regarding `SepLevel` labeling schemes for unweighted trees can also be extended in a straightforward manner to weighted trees, yielding `SepLevel` labeling schemes for the class $\mathcal{T}(n, \hat{\omega})$ of weighted $n$-node trees with maximum weight $\hat{\omega}$ using $O(\log n \log \hat{\omega} + \log^2 n)$-bit labels. We give a short overview of this extension.

LEMMA 2.3. $\mathcal{L}(\texttt{SepLevel}, \mathcal{T}(n, \hat{\omega})) \leq \mathcal{L}(distance, \mathcal{T}(n, \hat{\omega})) + \log(n\hat{\omega})$.

*Proof.* Given a distance labeling scheme $\langle \mathcal{M}_{dist}, \mathcal{D}_{dist} \rangle$ for the weighted distance function in $\mathcal{T}(n, \hat{\omega})$, define a `SepLevel` labeling scheme $\langle \mathcal{M}, \mathcal{D} \rangle$ for $\mathcal{T}(n, \hat{\omega})$ as follows. Given a tree $T \in \mathcal{T}(n, \hat{\omega})$, let $L$ be the labeling assigned by $\mathcal{D}_{dist}$ for $T$. The `SepLevel`-marker $\mathcal{M}$ augments each label $L(v)$ into a label $L'(v)$ with an additional $\log(n\hat{\omega})$-bit field containing $v$'s weighted depth, $d(v)$.

For two vertices $x$ and $y$, denote by $d(x, y)$ the weighted distance between $x$ and $y$. Consider two vertices $v, w$ with $z = lca(v, w)$. Let $l_v = d(z, v)$, $l_w = d(z, w)$. Given the labels $L'(v) = \langle L(v), d(v) \rangle$ and $L'(w) = \langle L(w), d(w) \rangle$, the fields $L(v)$ and $L(w)$ allow the `SepLevel`-decoder $\mathcal{D}$ to deduce the weighted distance $d(v, w) = l_v + l_w$, and the two additional fields provide it with $d(v) = l_v + d(z)$ and $d(w) = l_w + d(z)$. Combined, these three equations allow $\mathcal{D}$ to deduce $d(z)$. Thus $\langle \mathcal{M}, \mathcal{D} \rangle$ is a `SepLevel` labeling scheme, and the labels it uses are larger by $\log(n\hat{\omega})$ than those used by $\langle \mathcal{M}_{dist}, \mathcal{D}_{dist} \rangle$. $\square$

Based on the upper bounds of [17, 10] for distance labeling schemes for trees, we get the following.

LEMMA 2.4. $\mathcal{L}(\texttt{SepLevel}, \mathcal{T}(n, \hat{\omega})) = O(\log n \log \hat{\omega} + \log^2 n)$.

It is also easy to verify that for two nodes $x, y$ in $G$, the separation level of the leaves $t(x)$ and $t(y)$ associated with $x$ and $y$ in the tree $\tilde{T}_G$ is still related to the flow between the two vertices, as characterized in Lemma 2.2.

Finally, note that as $\tilde{T}_G$ has exactly $n$ leaves, and every nonleaf node in it has at least two children, the total number of nodes in $\tilde{T}_G$ is $\tilde{n} \leq 2n - 1$. Moreover, the maximum edge weight in $\tilde{T}_G$ is $\tilde{\omega} \leq \hat{\omega} \cdot n$.

Combining the above observations, we have the following.

THEOREM 2.5. $\mathcal{L}(\texttt{flow}, \mathcal{G}(n, \hat{\omega})) = O(\log n \cdot \log \hat{\omega} + \log^2 n)$.

As proved in the next section, this bound is asymptotically optimal.

The above theorem immediately yields the following upper bound for edge-connectivity (which is also shown to be tight in the next section). Let $\mathcal{G}(n)$ denote the class of $n$-vertex unweighted graphs.

COROLLARY 2.6. *$\mathcal{L}(\texttt{e-conn}, \mathcal{G}(n)) = O(\log^2 n)$.*

*Remark.* We note that a similar algorithm applies to any graph function $g$ whose induced relations $R^g_k$, defined as in (2.1), are equivalence relations.

**3. A lower bound for flow labeling schemes on trees.** In this section we establish a lower bound of $\Omega(\log n \cdot \log \hat{\omega} + \log^2 n)$ on the label size for flow on the class $\mathcal{T}(n, \hat{\omega})$ of $n$-vertex trees with maximum edge capacity $\hat{\omega}$ (which is assumed to be integral). The proof idea is based on a modification of the lower bound proof of [10] for distance labeling schemes. Let us first define two more functions on tree vertex pairs, named Max$E$ and Min$E$. For two vertices $u, v$ in a tree $T$, let $Path(u, v)$ denote the unique path from $u$ to $v$ in $T$. Then Max$E(u, v)$ (respectively, Min$E(u, v)$) is the maximum (resp., minimum) weight of an edge on $Path(u, v)$.

Observe that, on a tree, the maximum flow between two vertices $u$ and $v$ equals simply the minimum capacity of an edge on $Path(u, v)$, i.e., $\texttt{flow}(u, v) = \text{Min}E(u, v)$. Hence

$$\mathcal{L}(\texttt{flow}, \mathcal{T}(n, \hat{\omega})) = \mathcal{L}(\text{Min}E, \mathcal{T}(n, \hat{\omega})). \tag{3.1}$$

A Max$E$ labeling scheme $\langle \mathcal{M}, \mathcal{D} \rangle$ can be transformed into a Min$E$ labeling scheme (and vice versa) as follows. Given a weighted tree $T$, let $\hat{\omega}$ denote the maximum weight of an edge in $T$, and let $T'$ be the weighted tree obtained by replacing the weight $\omega(e)$ of every edge $e$ with weight $\omega'(e) = \hat{\omega} - \omega(e)$. The Min$E$ marker $\mathcal{M}'$ will transform $T$ into $T'$ and then apply $\mathcal{M}$. The Min$E$ decoder $\mathcal{D}'$ will invoke $\mathcal{D}$ and then apply the inverse transformation on the resulting weight. As this scheme requires us to encode $\hat{\omega}$ in the labels, we have that

$$\mathcal{L}(\text{Min}E, \mathcal{T}(n, \hat{\omega})) \geq \mathcal{L}(\text{Max}E, \mathcal{T}(n, \hat{\omega})) - \log \hat{\omega}. \tag{3.2}$$

Combining the two relationships (3.1) and (3.2), it follows that, to prove our lower bound on the label sizes required by flow labeling schemes on trees, it suffices to prove it instead for the maximum edge function Max$E$.

We focus on a special subclass of binary weighted trees referred to hereafter as *$(h, \mu)$-trees* for integer $h, \mu \geq 1$. Each tree of this class is a full binary tree with $h$ levels. Number the levels starting from the bottom of the tree, i.e., with the level of the leaves numbered 0. Each edge $e$ is associated with a weight $\omega(e)$ according to its level. The two edges that connect a vertex at level $i + 1$ to its two children at level $i$ are assigned the same weight, taken from the set $Q_i(\mu)$ defined as follows. For $i \geq 0$, let $Z_i(\mu) = i \cdot \mu$ and

$$Q_i(\mu) = \{Z_i(\mu) + j \mid 0 \leq j \leq \mu - 1\}.$$

*Example.* Figure 4 shows a $(3, \mu)$-tree. The weights assigned satisfy $x_{0,i} \in Q_0(\mu)$ for $1 \leq i \leq 4$, $x_{1,i} \in Q_1(\mu)$ for $1 \leq i \leq 2$, and $x_{2,1} \in Q_2(\mu)$.

Note that an $(h, \mu)$-tree $T$ is completely defined by the triple $T = (T_0, T_1, x)$, where $x$ is the weight associated with the two edges of the top level of the tree, and $T_0$ and $T_1$ are the two $(h - 1, \mu)$-trees attached to the endpoints of those two edges. Let $\mathcal{C}(h, \mu)$ be the class of $(h, \mu)$-trees and let $\mathcal{C}(h, \mu, x)$ be the subclass of $\mathcal{C}(h, \mu)$ consisting of $(h, \mu)$-trees with topmost weight $x$. Hence $\mathcal{C}(h, \mu) = \bigcup_{x=0}^{\mu-1} \mathcal{C}(h, \mu, x)$. By the definition of these binary trees we have the following.

OBSERVATION 3.1. *For every two leaves $a, a'$ of a tree $T \in \mathcal{C}(h, \mu, x)$,*

(1) *if $a, a' \in T_i$ (for $i \in \{0, 1\}$), then* $\text{Max}E_T(a, a') = \text{Max}E_{T_i}(a, a')$.

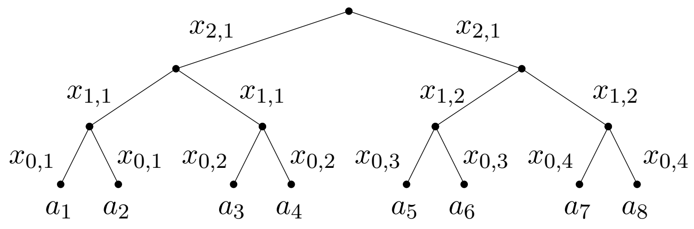

FIG. 4. *A $(3,\mu)$-tree.*

(2) *if $a \in T_0$ and $a' \in T_1$, then* $\mathrm{Max}E_T(a,a') = x$.

This implies the following lemma.

LEMMA 3.2. *Consider two $(h,\mu)$-trees $T = (T_0, T_1, x)$ and $T' = (T'_0, T'_1, x')$. For any leaves $a_0 \in T_0$, $a_1 \in T_1$, $a'_0 \in T'_0$, and $a'_1 \in T'_1$,*

$$\mathrm{Max}E_T(a_0,a_1) \;=\; \mathrm{Max}E_{T'}(a'_0,a'_1) \iff x = x'.$$

We assume that labels are nonnegative integers in $\mathbb{N}$. Define an $(h,\mu)$-*legal* $\mathrm{Max}E$ labeling scheme as a scheme $\langle \mathcal{M}, \mathcal{D}\rangle$ on all binary $(h,\mu)$-trees that correctly provides $\mathrm{Max}E(a_i,a_j)$ between any two leaves $a_i, a_j$. Namely, $\mathcal{D}$ is a decoder function $\mathcal{D} : \mathbb{N}^2 \mapsto \mathbb{N}$, and $\mathcal{M}$ is a marker algorithm assigning a label $L(a,T)$ to each leaf $a$ of any binary $(h,\mu)$-tree $T$, such that for every two leaves $a$ and $a'$ with labels $\lambda = L(a,T)$ and $\lambda' = L(a',T)$, $\mathcal{D}$ computes the maximum weight of an edge between $a$ and $a'$, i.e., $\mathcal{D}(\lambda,\lambda') = \mathrm{Max}E(a,a')$.

For an $(h,\mu)$-*legal* $\mathrm{Max}E$ labeling scheme $\langle \mathcal{M}, \mathcal{D}\rangle$, let $W(\mathcal{M},h,\mu)$ denote the set of all labels assigned by $\mathcal{M}$ to nodes in trees of $\mathcal{C}(h,\mu)$, and let $g(h,\mu)$ denote the minimum cardinality $|W(\mathcal{M},h,\mu)|$ over all flow labeling schemes on $\mathcal{C}(h,\mu)$.

Hereafter, we fix $\langle \hat{\mathcal{M}}, \hat{\mathcal{D}}\rangle$ to be some $\mathrm{Max}E$ labeling scheme attaining $g(h,\mu)$, i.e., such that $|W(\hat{\mathcal{M}},h,\mu)| = g(h,\mu)$.

Let $W(x)$ denote the set of all possible pairs of labels assigned by $\hat{\mathcal{M}}$ to some leaves $a_j \in T_0$ and $a_t \in T_1$, respectively, for some tree $T = (T_0,T_1,x) \in \mathcal{C}(h,\mu,x)$. Let $\mathcal{W} = \bigcup_{x=0}^{\mu-1} W(x)$. As $\mathcal{W} \subseteq W(\hat{\mathcal{M}},h,\mu) \times W(\hat{\mathcal{M}},h,\mu)$, we have the following.

LEMMA 3.3. $|\mathcal{W}| \le g(h,\mu)^2$.

CLAIM 3.4. *For every $0 \le x \ne x' < \mu$, the sets $W(x)$ and $W(x')$ are disjoint.*

*Proof.* Consider two different weights $0 \le x \ne x' < \mu$, and assume by way of contradiction that there exists a pair $(\lambda_1,\lambda_2) \in W(x) \cap W(x')$. Then there exist two $(h-1,\mu)$-trees $T_0, T_1$ such that $T = (T_0,T_1,x)$ uses the label $\lambda_1$ for some leaf $a_{j_1} \in T_0$ and the label $\lambda_2$ for some leaf $a_{j_2} \in T_1$, and there exist two $(h-1,\mu)$-trees $T'_0, T'_1$ such that $T' = (T'_0,T'_1,x')$ uses the label $\lambda_1$ for some leaf $a_{j_3} \in T'_0$ and the label $\lambda_2$ for some leaf $a_{j_4} \in T'_1$. Therefore, by the definition of $\mathcal{D}$,

$$x \;=\; \mathrm{Max}E(a_{j_1},a_{j_2}) \;=\; \mathcal{D}(\lambda_1,\lambda_2) \;=\; \mathrm{Max}E(a_{j_3},a_{j_4}) \;=\; x',$$

implying $x = x'$, a contradiction. □

The following is our main lemma.

LEMMA 3.5. *For every $x \in Q_h(\mu)$, $|W(x)| \ge g(h-1,\mu^2)$.*

*Proof.* In any $(h-1,\mu^2)$-tree, and for every edge that connects a vertex on level $i+1$ to its child on level $0 \le i \le h-1$, a weight $\omega_i \in Q_i(\mu^2)$, $\omega_i = i\cdot\mu^2 + j$, for $0 \le j \le \mu^2 - 1$, can be represented by the pair of weights

$$y_0 \;=\; \omega_i \bmod \mu \;=\; j \bmod \mu \qquad \text{and} \qquad y_1 \;=\; \left\lfloor \frac{\omega_i \bmod \mu^2}{\mu} \right\rfloor \;=\; \left\lfloor \frac{j}{\mu} \right\rfloor,$$

such that $y_0, y_1 \in [0, \mu - 1]$ and $\omega_i = y_0 + \mu y_1 + Z_i(\mu^2)$.

Consequently, one can associate with any $(h-1, \mu^2)$-tree $T'$ a pair of $(h-1, \mu)$-trees $T_0$ and $T_1$ as follows. For any edge $e$ of $T'$ with weight $\omega_i = y_0 + \mu \cdot y_1 + Z_i(\mu^2)$, let the corresponding weight of $e$ in $T_0$ (respectively, $T_1$) be $\omega_{i_0} = Z_i(\mu) + y_0$ (respectively, $\omega_{i_1} = Z_i(\mu) + y_1$). These two trees define also an $(h, \mu)$-tree $T = (T_0, T_1, x)$ in $\mathcal{C}(h, \mu, x)$.

Every leaf $a_j$ of $T'$ is now associated with two homologous leaves of $T$, namely, the leaf $a_j^0 = a_j$ (occurring in the left part of $T$, i.e., $T_0$) and the leaf $a_j^1 = a_{j+2^{h-1}}$ (occurring in $T_1$). For every two leaves $a_j, a_t$ of $T'$ we now have

$$\begin{aligned}\mathrm{Max}E_{T'}(a_j, a_t) &= \mathrm{Max}E_{T_0}(a_j^0, a_t^0) \bmod \mu \\ &\quad + \mu \cdot (\mathrm{Max}E_{T_1}(a_j^1, a_t^1) \bmod \mu) \;+\; \mu^2 \cdot \left\lfloor \frac{\mathrm{Max}E_{T_1}(a_j^1, a_t^1)}{\mu} \right\rfloor \\ &= \mathrm{Max}E_{T}(a_j^0, a_t^0) \bmod \mu \\ &\quad + \mu \cdot (\mathrm{Max}E_{T}(a_j^1, a_t^1) \bmod \mu) \;+\; \mu^2 \cdot \left\lfloor \frac{\mathrm{Max}E_{T}(a_j^1, a_t^1)}{\mu} \right\rfloor .\end{aligned}$$

We use this observation to derive a labeling scheme for all $(h-1, \mu^2)$-trees using at most $|W(x)|$ labels. Given an $(h-1, \mu^2)$-tree $T'$, consider the pair of $(h-1, \mu)$-trees $T_0$, $T_1$ defined above, and use the marker algorithm $\hat{\mathcal{M}}$ to label the tree $T = (T_0, T_1, x)$. Now use the resulting labeling $\hat{L}$ to define a labeling function $L'$ for the nodes of $T'$ as follows. A leaf $a_j \in T'$ receives as its label the pair $\langle L'(a_j, T') = \{\hat{L}(a_j^0, T), \hat{L}(a_j^1, T)\rangle$. Note that this pair belongs to $W(x)$.

The Max$E$ decoder $\mathcal{D}'$ for $(h-1, \mu^2)$-trees, is now obtained by setting

$$\begin{aligned}\mathcal{D}'(L'(a_j, T'), L'(a_t, T')) &= \mathcal{D}'\left(\left\langle \hat{L}(a_j^0, T), \hat{L}(a_j^1, T)\right\rangle, \left\langle \hat{L}(a_t^0, T), \hat{L}(a_t^1, T)\right\rangle\right) \\ &= \hat{\mathcal{D}}(\hat{L}(a_j^0, T), \hat{L}(a_t^0, T)) \bmod \mu \\ &\quad + \mu \cdot \hat{\mathcal{D}}(\hat{L}(a_j^1, T), \hat{L}(a_t^1, T)) \bmod \mu \\ &\quad + \mu^2 \cdot \left\lfloor \frac{\hat{\mathcal{D}}(\hat{L}(a_j^1, T), \hat{L}(a_t^1, T))}{\mu} \right\rfloor .\end{aligned}$$

As $\langle \hat{\mathcal{M}}, \hat{\mathcal{D}} \rangle$ is a Max$E$ labeling scheme for $(h, \mu)$-trees, we have

$$\mathcal{D}(\hat{L}(a_j^0, T), \hat{L}(a_t^0, T)) \;=\; \mathrm{Max}E_T(a_j^0, a_t^0)$$

and

$$\mathcal{D}(\hat{L}(a_j^1, T), \hat{L}(a_t^1, T)) \;=\; \mathrm{Max}E_T(a_j^1, a_t^1);$$

therefore

$$\begin{aligned}\mathcal{D}'(L'(a_j, T'), L'(a_t, T')) &= \mathrm{Max}E_T(a_j^0, a_t^0) \bmod \mu \\ &\quad + \mu \cdot \mathrm{Max}E_T(a_j^1, a_t^1) \bmod \mu \;+\; \mu^2 \cdot \left\lfloor \frac{\mathrm{Max}E_T(a_j^1, a_t^1)}{\mu} \right\rfloor \\ &= \mathrm{Max}E_{T'}(a_j, a_t).\end{aligned}$$

So we have obtained a labeling scheme $\langle \mathcal{M}', \mathcal{D}' \rangle$ labeling any $(h-1, \mu^2)$-tree with labels taken from $W(x)$. It follows that $|W(x)| \geq g(h-1, \mu^2)$. $\square$

Combining Claim 3.4 and Lemmas 3.3 and 3.5, we deduce the following.

Corollary 3.6. $g(h, \mu) \geq \sqrt{\mu} \cdot \sqrt{g(h-1, \mu^2)}$.

Subsequently, we have the following.

Lemma 3.7. $g(h, \mu) \geq \mu^{h/2}$.

This allows us to conclude with the lower bound. Let $\mathcal{BT}(n, \hat{\omega})$ denote the family of $n$-vertex balanced binary trees with height $h = \log(n+1)$ and weights from the range $[0, \hat{\omega}]$, where $\hat{\omega} = h \cdot \mu - 1$.

Theorem 3.8.

$$\mathcal{L}(\text{Max}E, \mathcal{BT}(n, \hat{\omega})) \;\geq\; \frac{1}{2} \cdot \log(n+1) \log(\hat{\omega}+1) - \frac{1}{2} \cdot \log(n+1) \log\log(n+1).$$

*Proof.* By Lemma 3.7, for the class $\mathcal{C}(h, \mu)$ we have $\mathcal{L}(\hat{\omega}, \mathcal{C}(h, \mu)) \geq \frac{h}{2} \cdot \log \mu$. This yields the theorem, as

$$\begin{aligned}\mathcal{L}(\hat{\omega}, \mathcal{BT}(n, \hat{\omega})) \geq \mathcal{L}(\hat{\omega}, \mathcal{C}(h, \mu)) \;&\geq\; \frac{1}{2} h \log \mu \;=\; \frac{1}{2} \log(n+1) \cdot \log\left(\frac{\hat{\omega}+1}{h}\right) \\ &= \frac{1}{2} \cdot \log(n+1) \log(\hat{\omega}+1) - \frac{1}{2} \cdot \log(n+1) \log\log(n+1)\;.\end{aligned}$$

Hence assuming $\hat{\omega} + 1 > \log(n+1)$, there is a lower bound of $\Omega(\log n \log \hat{\omega})$ for the label size of Max$E$ labeling schemes on trees. Finally, by the relationships (3.1) and (3.2) mentioned above between Min$E$ and flow on trees, we get the following.

Corollary 3.9. *For* $\hat{\omega} > \log(n+1) - 1$, $\mathcal{L}(\texttt{flow}, \mathcal{T}(n, \hat{\omega})) = \Omega(\log n \log \hat{\omega})$.

Each tree $T$ of $\mathcal{BT}(n, \hat{\omega})$ can be modified into an unweighted multigraph $G_T$ of $n$ nodes and $O(n\hat{\omega})$ edges by replacing each edge $e$ of weight $\omega(e)$ with $\omega(e)$ parallel edges connecting the same endpoints. This multigraph can in turn be transformed into a simple (unweighted) graph of $O(n\hat{\omega})$ vertices by adding a new vertex $p_{u,v}$ in the middle of every edge $(u, v)$, splitting it into a path of length 2 consisting of the two successive edges $(u, p_{u,v})$ and $(p_{u,v}, v)$. Starting with $\mathcal{BT}(\sqrt{n}, \hat{\omega})$ and looking at the class of unweighted $O(n)$-vertex graphs obtained by setting $\hat{\omega} = \sqrt{n}$, we get the following tight lower bound on the required label size of schemes for flow and edge-connectivity.

Theorem 3.10.

(1) $\mathcal{L}(\texttt{flow}, \mathcal{G}(n)) = \Theta(\log n \log \hat{\omega} + \log^2 n)$.

(2) $\mathcal{L}(\texttt{e-conn}, \mathcal{G}(n)) = \Theta(\log^2 n)$.

## 4. Vertex-connectivity labeling schemes for general graphs.

In this section we turn to $k$-vertex-connectivity and present a labeling scheme for general $n$-vertex graphs. The label sizes we achieve are $\log n$ for $k = 1$, $3 \log n$ for $k = 2$, $5 \log n$ for $k = 3$, and $2^k \log n$ for $k > 3$.

### 4.1. Preliminaries.

We start with some preliminary definitions. In an undirected graph $G$, two vertices are called *$k$-connected* if there exist at least $k$ vertex-disjoint paths between them. A set $S \subseteq V$ *separates* $u$ from $v$ in $G = \langle V, E \rangle$ if $u$ and $v$ are not connected in the vertex-induced subgraph $G \setminus S$.

Theorem 4.1 (Menger (cf. [7])). *In an undirected graph $G$, two nonadjacent vertices $u$ and $v$ are $k$-connected iff no set $S \subset G \setminus \{u, v\}$ of $k-1$ vertices can separate $u$ from $v$ in $G$.*

The *k-connectivity graph* of $G = \langle V, E\rangle$ is $C_k(G) = \langle V, E'\rangle$, where $(u, v) \in E'$ iff $u$ and $v$ are $k$-connected in $G$. A graph $G$ is *closed under k-connectivity* if it has the property that, if $u$ and $v$ are $k$-connected in $G$, then they are neighbors in $G$. Let $\mathcal{C}(k)$ be the family of all graphs $G$ which are closed under $k$-connectivity.

Observation 4.2.

(1) *If $G \in \mathcal{C}(k)$, then each connected component of $G$ belongs to $\mathcal{C}(k)$.*

(2) *If $G = H \cup F$, where $H, F \in \mathcal{C}(k)$ are vertex-disjoint subgraphs of $G$, then $G \in \mathcal{C}(k)$.*

Lemma 4.3. *Let $G' = \langle V, E'\rangle$, where $E' = E \cup \{(u, v)\}$ for some pair of $k$-connected vertices $u$ and $v$. Then $G$ and $G'$ have the same $k$-connectivity graph, i.e., $C_k(G) = C_k(G')$.*

*Proof.* Use induction on $k$. For $k = 1$ the lemma is obvious. Assume the lemma is true for $k - 1$. It suffices to show that if two vertices $w$,$w'$ are not $k$-connected in $G$, then they are not $k$-connected in $G'$. Suppose that $w$,$w'$ are not $k$-connected in $G$. If $w$, $w'$ are neighbors in $G$, then let $G^- = G \setminus \{u, v\}$. In $G^-$, $w$ and $w'$ are not $(k - 1)$-connected and, since $u$ and $v$ are $(k - 1)$ connected in $G^-$, by the induction hypothesis, $w$ and $w'$ are not $(k-1)$-connected in $G' \setminus \{u, v\}$. This implies that they are not $k$-connected in $G'$ as desired. If $w$,$w'$ are not neighbors in $G$, then by Menger's theorem there exists a set of vertices $S = \{x_1, x_2, \ldots, x_{k-1}\}$ that separates $w$ from $w'$ in $G$. We claim that $S$ separates $w$ from $w'$ also in $G'$. The proof breaks down into the following cases.

*Case* 1. One or more of the $x_i$'s is $u$ or $v$. Then $G \setminus S = G' \setminus S$.

*Case* 2. None of the $x_i$'s is $u$ or $v$. If $u$ and $v$ belong to the same connectivity component of $G \setminus S$, then the connectivity components of $G' \setminus S$ will be the same as the connectivity components of $G \setminus S$, implying that $S$ separates $w$ from $w'$ also in $G'$, which is what we wanted to prove. If $u$ and $v$ belong to different connectivity components of $G \setminus S$, then $S$ separates $u$ from $v$ in $G$ or, in other words, $u$ and $v$ are not $k$-connected in $G$, contradicting our assumption. □

Corollary 4.4. *For every graph $G$, if $u$ and $v$ are $k$-connected in $C_k(G)$, then they are neighbors in $C_k(G)$, i.e., $C_k(G) \in \mathcal{C}(k)$.*

*Proof.* Transform a given graph $G$ into $G+ = G \cup C_k(G)$ by adding the edges of $C_k(G)$ to $G$ one by one. By induction on the steps of this process using the previous lemma, we get $C_k(G^+) = C_k(G)$. Therefore if $u$ and $v$ were $k$-connected in $C_k(G)$, then they are $k$-connected in $G^+$ and are therefore neighbors in $C_k(G^+) = C_k(G)$. □

For a connectivity component $C$ of $C_k(G)$, a *leftmost breadth-first search* (*BFS*) tree for $C$, denoted $T(C, k)$, is a *BFS* tree spanning $C$, constructed in the following way. Take a vertex $r$ from $C$ to be the root of $T(C, k)$. Let $level(r) = 1$. Assume we constructed $i$ levels of $T(C, k)$ and haven't used all vertices of $C$. Construct the $(i + 1)$st level of $T(C, k)$ as follows. Repeatedly take a vertex $v$ of level $i$ and connect it to all the vertices adjacent to it in $C_k(G)$ that haven't been included so far in the tree construction. For each such new vertex $w$ let $level(w) = i + 1$, and let $v$ be $w$'s parent in $T(C, k)$.

When the context is clear we use the notation $T$ instead of $T(C, k)$.

For $T = T(C, k)$, we make the following definitions. Let $W_i$ denote the set of vertices of level $i$ in $T$, and let $H_i = H_i(C, k) = \langle W_i, E_i\rangle$ be the subgraph of $C$ induced by $W_i$. For vertices $u$ and $v$, denote $u's$ parent in $T$ by $p(u)$, and let $lca(u, v)$ be the highest level common ancestor of both $u$ and $v$ in $T$. Let $W'_{i+1}$ denote the set of vertices of $W_{i+1}$ that are neighbors of at least $k$ vertices of $W_i$ in $C_k(G)$. Let

$F_i = F_i(C, k)$ be the subgraph of $C$ induced by $W_i \cup W'_{i+1}$.

LEMMA 4.5.

(1) *For* $T = T(C, k)$, $H_i \in \mathcal{C}(k-1)$.

(2) *For* $T = T(C, k)$, $F_i \in \mathcal{C}(k-1)$.

*Proof.* To prove (1), we show that every two vertices $u, v \in W_i$ that are $(k-1)$-connected in $H_i$ are neighbors in $C_k(G)$ and therefore in $H_i$, implying $H_i \in \mathcal{C}(k-1)$. Assume, for contradiction, that $u$ and $v$ are not neighbors in $C_k(G)$. By Corollary 4.4 they are also not $k$-connected in $C_k(G)$; i.e., there exists a set $S = \{x_1, \ldots, x_{k-1}\}$ that separates them in $C_k(G)$. Let $S' = S \cap W_i$. Since $S'$ separates $u$ from $v$ in $H_i$ and since $u$ and $v$ are $(k-1)$-connected in $H_i$, we get that $|S'| = k-1$, and hence $S' = S$, so all the vertices in $S$ must be of level $i$. This implies, however, that $S$ does not separate $u$ from $v$ even in $T$, which is a subgraph of $C_k(G)$, contradicting our assumption.

Turning to (2), let $u$ and $v$ be $(k-1)$-connected in $F_i$. As before, it suffices to show that they are neighbors in $C_k(G)$. Assume for contradiction that $u$ and $v$ are not neighbors in $C_k(G)$. Therefore they are also not $k$-connected in $C_k(G)$; i.e., there exists a set $S = \{x_1, \ldots, x_{k-1}\}$ that separates them in $C_k(G)$. Since $S' = S \cap F_i$ separates $u$ from $v$ in $F_i$ and since $u$ and $v$ are $(k-1)$-connected in $F_i$ we get, as before, that all the vertices of $S$ must belong to $F_i$. We claim that $S$ cannot separate either $u$ or $v$ from the root $r$, and therefore we get that $u$ and $v$ are connected in $C_k(G) \setminus S$, contradicting our assumption. If $u$ (or $v$) is of level $i$, then the claim is clear since $u$ is connected to $r$ in $C_k(G) \setminus S$ via the edges of $T$. If $u$ (or $v$) is of level $i+1$, then $u$ has at least $k$ neighbors in $C_k(G)$ of level $i$. Therefore, $u$ has at least one neighbor $w$ of level $i$ in $C_k(G) \setminus S$. Since all vertices of $S$ are in $F_i$, $w$ is connected to $r$ in $C_k(G) \setminus S$ via the edges of $T$. ☐

**4.2. Overview of the scheme.** We rely on the basic observation that labeling $k$-connectivity for some graph $G$ is equivalent to labeling adjacencies for $C_k(G)$. By Corollary 4.4, $C_k(G) \in \mathcal{C}(k)$. Therefore, instead of presenting a $k$-connectivity labeling scheme for general graphs, we present an adjacency labeling scheme for the graphs of $\mathcal{C}(k)$.

The general idea used for labeling adjacencies for some $G \in \mathcal{C}(k)$, especially for $k > 3$, is to decompose $G$ into at most three "simpler" graphs. One of these graphs is a $k$-orientable graph $K$, and the other two, called $G_{even}$ and $G_{odd}$, belong to $\mathcal{C}(k-1)$. The labeling algorithm for $G \in \mathcal{C}(k)$ recursively labels subgraphs of $G$ that belong to $\mathcal{C}(t)$ for $t < k$. When we are concerned with labeling some $n$-vertex graph $G \in \mathcal{C}(k)$ for $k > 1$, the first step in the labeling is to assign each vertex $u$ in $G$ a distinct identity $id(u)$ from 1 to $n$. This identity will always appear as the last $\log n$ bits of the label $L(G, u)$. Thus, when labeling the subgraphs of $G$ in the recursion we may assume that the *id*'s for the vertices are given.

For graphs $G = \langle V, E\rangle$ and $G_i = \langle V_i, E_i\rangle$, $i > 1$, we say that $G$ can be *decomposed* into the $G_i$'s if $\bigcup_i V_i = V$, $\bigcup_i E_i = E$, and the $E_i$'s are pairwise disjoint.

LEMMA 4.6. *Let* $\mathcal{G}, \mathcal{G}_1$, *and* $\mathcal{G}_2$ *be families of graphs such that each* $G \in \mathcal{G}$ *can be decomposed into* $G_1 \in \mathcal{G}_1$ *and* $G_2 \in \mathcal{G}_2$. *If* $\mathcal{G}_1$ *and* $\mathcal{G}_2$ *have adjacency labeling schemes of sizes* $l_1$ *and* $l_2$, *respectively, then* $\mathcal{G}$ *has adjacency labeling scheme of size* $l_1 + l_2$.

*Proof.* The general idea in the proof is to use concatenation of the labels of the decomposed graphs. Let $\langle \mathcal{M}_i, \mathcal{D}_i\rangle$ be adjacency labeling schemes for $\mathcal{G}_i$ $(i = 1, 2)$. Let us construct an adjacency labeling scheme $\langle \mathcal{M}, \mathcal{D}\rangle$ for $\mathcal{G}$ as follows.

*The marker algorithm* $\mathcal{M}$ *for* $\mathcal{G}$. For a given graph $G \in \mathcal{G}$, decompose $G$ into $G_i \in \mathcal{G}_i$ $(i = 1, 2)$. Let $L_i = \mathcal{M}_i(G_i)$ for $i = 1, 2$. We construct $L = \mathcal{M}(G)$ as follows.

For a vertex $u$ in $G$, let $L(u) = \langle L_1(u), L_2(u)\rangle$, where the first $l_1$ bits of the label $L(u)$ consist of $L_1(u)$ and the next $l_2$ bits give $L_2(u)$. Altogether we use $l_1 + l_2$ bits.

*The decoder algorithm $\mathcal{D}$ for $\mathcal{G}$.* Let $G, G_1$, and $G_2$ be as before. Given the two labels $L(u) = \langle L_1(u), L_2(u)\rangle$ and $L(v) = \langle L_1(v), L_2(v)\rangle$ let $\mathcal{D}(L(u), L(v)) = \mathcal{D}_1(L_1(u), L_1(v)) \vee \mathcal{D}_2(L_2(u), L_2(v))$.

Since $G$ was decomposed into $G_1, G_2$, the vertices $u$ and $v$ are neighbors in $G$ iff they are neighbors in either $G_1$ or $G_2$; hence the decoding algorithm is correct. □

COROLLARY 4.7. *Let $\mathcal{G}, \mathcal{G}_1, \ldots, \mathcal{G}_m$ be families of graph such that each $G \in \mathcal{G}$ can be decomposed into $G_1, \ldots, G_m$, where $G_i \in \mathcal{G}_i$ for $i = 1$ to $m$. If the $\mathcal{G}_i$'s have adjacency labeling schemes of size $l_i$, then $\mathcal{G}$ has an adjacency labeling scheme of size $\sum l_i$.*

A graph $G$ is called *$k$-orientable* if there exists an orientation of the edges such that the out-degree of each vertex is bounded above by $k$. The class of $k$-orientable graphs is denoted $\mathcal{J}_{or}(k)$.

OBSERVATION 4.8. *If $G = H \cup F$, where $H, F \in \mathcal{J}_{or}(k)$ are vertex-disjoint subgraphs of $G$, then $G \in \mathcal{J}_{or}(k)$.*

LEMMA 4.9. *Let $\mathcal{J}_n(k)$ be the family of $n$-vertex graphs in $\mathcal{J}_{or}(k)$. Assuming id's are given, $\mathcal{L}(\texttt{adjacency}, \mathcal{J}_n(k)) \leq k \log n$.*

*Proof.* Suppose $G \in \mathcal{J}_n(k)$. Then $G$ is a $k$-orientable graph with $n$ vertices. Hence there exists an orientation to the edges of $G$ such that the out-degree of each vertex is bounded above by $k$. In this orientation, for each $u$ there exist at most $k$ outgoing edges, say $(u, v_1)$, $(u, v_2)$,..., $(u, v_t)$, for $t \leq k$.

*The marker algorithm $\mathcal{M}$ for $\mathcal{J}_n(k)$.* Label $u$ by $L(u) = \langle id(v_1), id(v_2), \ldots, id(v_t)\rangle$, i.e., use the first $\log n$ bits to write $id(v_1)$, the second $\log n$ bits to write $id(v_2)$, etc. Hence, for every $u$'s, the size of $L(u)$ is at most $k \log n$ bits.

*The decoder algorithm $\mathcal{D}$ for $\mathcal{J}_n(k)$.* Given $L(u)$ and $L(v)$ check whether $u$'s id appears in $L(v)$, by inspecting each block of $\log n$ bits in $L(v)$ separately. Analogously, check if $v$'s id appears in $L(u)$.

As $u$ and $v$ are neighbors in $G$ iff one of the two cases applies, the decoding algorithm is correct. □

To illustrate the approach, we preface the treatment of the general case with a discussion of the cases $k = 1, 2, 3$, for which slightly better schemes are available. The simple case of $k = 1$ is handled in section 4.2.1. For $k = 2$ we show in section 4.2.2 that a connected graph $G \in \mathcal{C}(2)$ can be decomposed into a tree and disjoint graphs in $\mathcal{C}(1)$. Graphs in $\mathcal{C}(1)$ are collections of cliques. It follows that each $G \in \mathcal{C}(2)$ can be decomposed into a forest (which is a 1-orientable graph) and a graph made of disjoint cliques. For $k = 3$ we show in section 4.2.3 that a connected graph $G \in \mathcal{C}(3)$ can be decomposed into a graph in $\mathcal{C}(2)$ and a 2-orientable graph.

#### 4.2.1. A 1-connectivity labeling scheme.

Let us give a labeling scheme for 1-connectivity for $\mathcal{G}_n$, the family of all $n$-vertex graphs.

*The marker algorithm $\mathcal{M}$ for $\mathcal{G}_n$.* Fix $G = \langle V, E\rangle \in \mathcal{G}_n$. To each connected component $C$ of $G$ assign a distinct identity $id(C)$ from the range $\{1, \ldots, n\}$. For a vertex $u \in V$, let $C_u$ be the connected component of $G$ to which $u$ belongs. The marker algorithm sets $L(u) = id(C_u)$.

*The decoder $\mathcal{D}$ for $\mathcal{G}_n$.* Let $D(L(u), L(v)) = 1$ iff $L(u) = L(v)$.

Clearly $u$ and $v$ are 1-connected in $G$ iff they are in the same connected component; hence the decoder's response is correct. The size of the label is bounded above by $\log n$.

THEOREM 4.10. $\mathcal{L}(1-\texttt{v-conn}, \mathcal{G}_n) \leq \log n$.

**4.2.2. A 2-connectivity labeling scheme.** As explained earlier, labeling 2-connectivity for a family of graphs $\mathcal{G}$ is equivalent to labeling adjacencies for the family $\{C_2(G) \mid G \in \mathcal{G}\} \subseteq \mathcal{C}(2)$. In this section we present an efficient adjacency labeling scheme for $\mathcal{C}(2)$.

Consider a graph $G \in \mathcal{C}(2)$ and let $C_1, \ldots, C_m$ be its connected components. By Observation 4.2(1), $C_i \in \mathcal{C}(2)$ for every $i$. Fix $i$ and let $T = T(C_i, 2)$.

CLAIM 4.11. *The only neighbor of $u$ in $G$ which has a strictly lower level than $u$ in $T$ is $p(u)$.*

*Proof.* Suppose, for contradiction, that there exist neighbors $v$ and $w$ such that $level(w) > level(v)$ but $v$ is not $p(w)$ in $T$. In this case, $w$ and $z = lca(v, w)$ are 2-connected in $T \cup \{(v, w)\}$, which is a subgraph of $G$. Since $G \in \mathcal{C}(2)$, $v$ must be a neighbor of $w$. Since $level(w) < level(u) - 1$ we get a contradiction to the way $T$ was constructed. □

CLAIM 4.12. *$G \in \mathcal{C}(2)$ can be decomposed into a forest $F$ and a graph $H$ of disjoint cliques.*

*Proof.* Fix a connected component $C_i$ of $G$ and let $T = T(C_i, 2)$. Since, by Lemma 4.5(1), each $H^i_j$ subgraph of $C_i$ induced by level $j$ of $T$ is in $\mathcal{C}(1)$, it follows that $H^i_j$ is a collection of disjoint cliques. Hence $G$ can be decomposed into a forest $F$ and a graph $H$ of disjoint cliques, composed of the collection of all the $H^i_j$ from all $i$'s and $j$'s. □

Let $\mathcal{C}_n(2)$ be the family of $n$-vertex graphs in $\mathcal{C}(2)$. Let us now give an adjacency labeling scheme for the graphs of $\mathcal{C}_n(2)$.

*The marker algorithm $\mathcal{M}$ for $\mathcal{C}_n(2)$.* Decompose $G$ into $F$ and $H$ as in Claim 4.12. Fix a vertex $u$ of $G$. Let $p(u)$ be $u$'s parent in $F$. To each clique $C$ in $H$ give a distinct identity from the range $\{1, \ldots, n\}$, $id(C)$. Let $C(u)$ be the clique in $H$ that contains $u$.

The marker algorithm for $G$ assigns $L(u) = \langle id(c(u)), id(p(u)), id(u)\rangle$. As before, we use the first $\log n$ bits for $id(c(u))$, the second $\log n$ bits for $id(p(u))$, etc. The label size is bounded above by $3 \log n$.

*The decoder $\mathcal{D}$ for $\mathcal{C}_n(2)$.* Given $L(u)$ and $L(v)$ we compare $id(p(u))$ with $id(v)$ and $id(p(v))$ with $id(u)$ to check whether one is the parent of the other in the forest $F$. We also check if $id(C(u)) = id(C(v))$ to see whether $u$ and $v$ are neighbors in $H$. We do this by looking at the corresponding bits in the label; for example, $id(p(u))$ is written in the second block of $\log n$ bits of $L(u)$. Let $\mathcal{D}(L(u), L(v)) = 1$ iff either $id(C(u)) = id(C(v))$, $id(p(u)) = id(v)$, or $id(p(v)) = id(u)$.

Clearly, $u$ and $v$ are neighbors in $G$ iff they are neighbors in $F$ or in $H$; hence the decoder's response is correct. We get the following.

THEOREM 4.13. *Let $\mathcal{G}_n$ be the family of $n$-vertex graphs. Then $\mathcal{L}(2\text{−}\texttt{v-conn}, \mathcal{G}_n) \leq 3 \log n$ bits.*

**4.2.3. A 3-connectivity labeling scheme.** Again, labeling 3-connectivity for a family $\mathcal{G}$ is equivalent to labeling adjacencies for the family $\{C_3(G) \mid G \in \mathcal{G}\} \subseteq \mathcal{C}(3)$. In this section we show how to label adjacencies for $\mathcal{C}(3)$.

Consider a graph $G \in \mathcal{C}(3)$, and let $C_1, \ldots, C_m$ be its connected components. By observation 4.2(1), $C_i \in \mathcal{C}(3)$ for all $i$. Fix $i$ and let $T = T(C_i, 3)$.

LEMMA 4.14. *Each vertex $u$ has at most one neighbor of $G$ which has a strictly lower level than $u$ in $T$ apart from $p(u)$.*

*Proof.* Assume, for contradiction, that there exists a vertex $u$ with two neighbors in $G$, $v$ and $w$, both with a strictly lower level than $u$ and both different from $p(u)$. In this case, $u$ must be 3-connected in $G$ to either $lca(u, v)$, $lca(u, w)$, or $lca(v, w)$, whichever has the highest level number. However, the levels of $lca(u,v)$, $lca(u,w)$, $lca(v,w)$ are all smaller than $level(u)-1$, and since $G \in \mathcal{C}(3)$, $u$ is adjacent to one of them, contradicting the way $T$ was constructed. (See Figure 5.) ∎

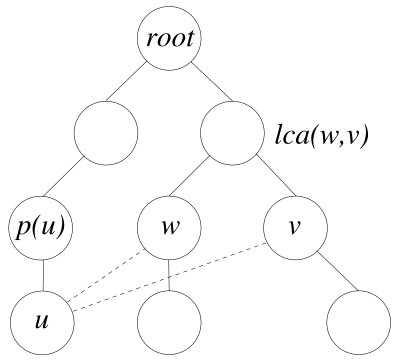

FIG. 5. *An illustration of the contradiction in the proof of Lemma* 4.14.

LEMMA 4.15. *Each $G \in \mathcal{C}(3)$ can be decomposed into a graph $H \in \mathcal{C}(2)$ and a* 2*-orientable graph.*

*Proof.* First, it suffices to show the lemma for connected graphs $C \in \mathcal{C}(3)$, since by Observations 4.2(2) and 4.8, $\mathcal{C}(2)$ and $\mathcal{J}_{or}(2)$ are closed under vertex-disjoint unions. Consider a connected graph $C \in \mathcal{C}(3)$ and let $T = T(C,3)$. By Lemma 4.5(1), each subgraph $H_j$ of $C$ induced by the vertices of level $j$ in $T$ is in $\mathcal{C}(2)$. All the subgraphs $H_j$ are vertex-disjoint; hence by letting $H$ be the union of all the $H_j$, we get $H \in \mathcal{C}(2)$. Let $U$ be the graph $C$ after deleting the edges of $H$. By Lemma 4.14, each vertex $u$ of $U$ has at most two neighbors of a strictly lower level (one of which is $u$'s parent in $T$). Hence directing the edges of $U$ from higher level vertices to lower level vertices, each $u$ has out-degree at most 2; i.e., $U$ is 2-orientable. ∎

By Lemmas 4.6 and 4.9 and from Theorem 4.13 we get the following theorem.

THEOREM 4.16. *Let $\mathcal{G}_n$ be the family of $n$-vertex graphs. Then $\mathcal{L}(3-\texttt{v-conn}, \mathcal{G}_n) \leq 5\log n$ bits.*

## 4.3. A $k$-connectivity labeling scheme.

Finally, labeling $k$-connectivity for a family $\mathcal{G}$ is equivalent to labeling adjacencies for the family $\{C_k(G) \mid G \in \mathcal{G}\} \subseteq \mathcal{C}(k)$. In this section we show how to label adjacencies for $\mathcal{C}(k)$.

Consider a graph $G \in \mathcal{C}(k)$, and let $C_1, \ldots, C_m$ be its connected components. By observation 4.2(1), $C_i \in \mathcal{C}(k)$ for all $i$. Fix $i$ and let $T = T(C_i, k)$.

LEMMA 4.17. *Each $G \in \mathcal{C}(k)$ can be decomposed into two graphs in $\mathcal{C}(k-1)$ and a $(k-1)$-orientable graph.*

*Proof.* Again, it suffices to prove the lemma for connected graphs $C \in \mathcal{C}(k)$ since, by Observations 4.2(2) and 4.8, both $\mathcal{C}(k-1)$ and $\mathcal{J}_{or}(k)$ are closed under vertex-disjoint unions. Consider a connected graph $C \in \mathcal{C}(k)$ and let $T = T(C,k)$.

All the $F_i$'s for odd $i$'s are vertex-disjoint, and $F_i \in \mathcal{C}(k-1)$ for all $i$'s by Lemma 4.5(2). Therefore, by letting $G_{odd}$ be the union of all the $F_i$'s for odd $i$'s, we get $G_{odd} \in \mathcal{C}(k-1)$. By the same reasoning, by letting $G_{even}$ be the union of all the $F_i$'s for even $i$'s, we get $G_{even} \in \mathcal{C}(k-1)$.

Let $K$ be the graph $C$ after omitting the edges of $G_{odd}$ and $G_{even}$ (or equivalently, omitting all edges of all the $F_i$'s). The proof is completed once we show that $K$ is $(k-1)$-orientable. Since all edges $(u,v)$ of $C$ such that $level(u) = level(v) = i$ for some

$i$ are in $F_i$ for the appropriate $i$, if $(u,v)$ is an edge of $K$, then $level(u) \neq level(v)$. By the way $T$ was constructed, we can see that the difference between the levels is 1.

Let us direct the edges of $K$ from higher level vertices to lower level vertices. Assume, for contradiction, that for some $u$ and some $i$, $level(u) = i+1$ and the out-degree of $u$ in $K$ is at least $k$. Then $u$ must have at least $k$ neighbors of level $i$ in $C$, in which case all edges $(u,v)$ for $v$ such that $level(v) = i$ appear in $F_i$ and therefore not in $K$. Thus, the out-degree of $u$ in $K$ is 0, contradicting our assumption. ∎

Before stating and proving the next theorem, let us remark that we can get a weaker upper bound of $3^k \log n$ label size for $\mathcal{L}(\mathtt{adjacency}, \mathcal{C}_n(k))$ in the following way. Use induction on $k$. For $k = 1,2,3$ our remark holds. For $k > 3$ fix $k$ and assume that the remark holds for $k-1$. The remark for $k$ follows from Lemmas 4.9 and 4.17 and Corollary 4.7.

To prove the next theorem, we show that instead of concatenating $u$'s labels in the three decomposed graphs $(G_{odd}, G_{even}, K)$, it suffices to give $u$ its label in only two of the three decomposed graphs. This yields the desired $2^k \log n$ bits bound on $\mathcal{L}(\mathtt{adjacency}, \mathcal{C}_n(k))$.

THEOREM 4.18. *Let $\mathcal{C}_n(k)$ be the family of $n$-vertex graphs in $\mathcal{C}(k)$. Then*

$$\mathcal{L}(\mathtt{adjacency}, \mathcal{C}_n(k)) \;\leq\; 2^k \log n.$$

*Proof.* Use induction on $k$. For $k = 1$, 2, or 3 the theorem holds as seen in Theorems 4.10, 4.13, and 4.16. For $k > 3$, fix $k$ and assume that the theorem holds for $k-1$. Consider a graph $G \in \mathcal{C}_n(k)$. For a vertex $u$ in $G$, let $C$ be its connected component in $G$, let $T = T(C,k)$, and let $i = level(u)$. Let us now give a labeling scheme for adjacency on $G \in \mathcal{C}(k)$.

*The marker algorithm $\mathcal{M}_k$ for $\mathcal{C}(k)$.* For $t \leq k$, $G \in \mathcal{C}_n(t)$, and $u$, a vertex of $G$, denote the adjacency labeling on $G$ by $L_t(G)$ and $u$'s label by $L_t(G,u)$. Let $G \in \mathcal{C}_n(k)$ and let $u$ be a vertex in $G$. We define $\mathsf{State}(u)$ according to the following three cases.

*Case* 1. $u$ participates in both $G_{odd}$ and $G_{even}$. Let $\mathsf{State}(u) = \mathsf{Dual}$. Note that in this case the out-degree of $u$ in $K$ is 0. The marker algorithm assigns to $u$ the label $L_k(G,u) = \langle L_{k-1}(G_{odd},u), L_{k-1}(G_{even},u)\rangle$, where the first $2^{k-1}\log n$ bits are reserved for $L_{k-1}(G_{odd},u)$ and the last $2^{k-1}\log n$ bits are reserved for $L_{k-1}(G_{even},u)$.

*Case* 2. $u$ doesn't participate in $G_{odd}$; i.e., $u$ participates only in $G_{even}$ and in $K$. Let $\mathsf{State}(u) = \mathsf{Even}$. Let $L_k(G,u) = \langle 0^{k\log n}, 10, L(u,K), 00\ldots000, L_{k-1}(G_{even},u)\rangle$, where the two bits in the second field, 10, indicate that $\mathsf{State}(u) = \mathsf{Even}$. The next $k \log n$ bits are reserved for $L(u,K)$ and the last $2^{k-1}\log n$ bits are reserved for $L_{k-1}(G_{even},u)$.

*Case* 3. $u$ doesn't participate in $G_{even}$; i.e., $u$ participates only in $G_{odd}$ and in $K$. Let $\mathsf{State}(u) = \mathsf{Odd}$. Let $L_k(G,u) = \langle 0^{k\log n}, 11, L(u,K), 00\ldots00, L_{K-1}(G_{odd},u)\rangle$, where the two bits in the second field, 11, indicate that $\mathsf{State}(u) = \mathsf{Odd}$, the next $k\log n$ bits are reserved for $L(u,K)$, and the last $2^{k-1}\log n$ bits are reserved for $L_{K-1}(G_{odd},u)$.

The size of the label $L_k(G,u)$ is, by induction, at most $2^k \log n$ since, by Lemma 4.9, the size of $L(v,K)$ is at most $k\log n$ and both sizes of $L_{k-1}(G_{odd},u)$ and $L_{k-1}(G_{even},u)$ are at most $2^{k-1}\log n$.

By the definition of $K$, it is clear that the out-degree of some $u$ in $K$ is higher than 0 iff $\mathsf{State}(u) = \mathsf{Even}$ or $\mathsf{Odd}$.

*The decoder $\mathcal{D}_k$ for $\mathcal{C}(k)$.* For $t \leq k$ denote the decoder for $\mathcal{C}(t)$ by $\mathcal{D}_t$. Denote the decoder for $\mathcal{J}_{or}(k)$ (from Lemma 4.9) by $\mathcal{D}_{or}$. Given $L_k(G,u)$ and $L_k(G,v)$ we will first want to know the states of $u$ and $v$. Take for example $L_k(G,u)$. For $k > 3$, the first $k \log n$ bits are 0 iff $\mathsf{State}(u) \neq \mathsf{Dual}$. So by looking at the first $k \log n + 2$ bits of $L_k(G,u)$ and $L_k(G,v)$ we know the states of $u$ and $v$. Consider the following cases.

*Case* a. $\mathsf{State}(u) = \mathsf{State}(v) = \mathsf{Dual}$: Then $\mathcal{D}_k$ for $G$ uses $\mathcal{D}_{k-1}$ on $G_{even}$ and $G_{odd}$ as follows:

$$\begin{aligned}&\mathcal{D}_k(L_k(G,u), L_k(G,v))\\&= (\mathcal{D}_{k-1}(L_{k-1}(G_{odd},u), L_{k-1}(G_{odd},v)))\\&\vee(\mathcal{D}_{k-1}(L_{k-1}(G_{even},u), L_{k-1}(G_{even},v))).\end{aligned}$$

*Case* b. $\mathsf{State}(u) = \mathsf{State}(v) = \mathsf{Even}$. Then $\mathcal{D}_k$ for $G$ uses $\mathcal{D}_{k-1}$ on $G_{even}$ and $\mathcal{D}_{or}$ for $K$ as follows:

$$\begin{aligned}&\mathcal{D}_k(L_k(G,u), L_k(G,v))\\&= \mathcal{D}_{or}(L(u,K), L(v,K)) \vee \mathcal{D}_{k-1}(L_{k-1}(G_{even},u), L_{k-1}(G_{even},v)).\end{aligned}$$

*Case* c. $\mathsf{State}(u) = \mathsf{State}(v) = \mathsf{Odd}$. Then $\mathcal{D}_k$ for $G$ uses $\mathcal{D}_{k-1}$ on $G_{odd}$ and $\mathcal{D}_{or}$ for $K$ as follows:

$$\begin{aligned}&\mathcal{D}_k(L_k(G,u), L_k(G,v))\\&= \mathcal{D}_{or}(L(u,K), L(v,K)) \vee \mathcal{D}_{k-1}(L_{k-1}(G_{odd},u), L_{k-1}(G_{odd},v)).\end{aligned}$$

*Case* d. $\mathsf{State}(u) = \mathsf{Dual}$, $\mathsf{State}(v) = \mathsf{Even}$. Then let $\mathcal{D}_k(L_k(G,u), L_k(G,v)) = 1$ iff $\mathcal{D}_{k-1}(L_{k-1}(G_{even},u), L_{k-1}(G_{even},v)) = 1$ or $id(u)$ appears in $L(v,K)$.

*Case* e. $\mathsf{State}(u) = \mathsf{Dual}$, $\mathsf{State}(v) = \mathsf{Odd}$. Then let $\mathcal{D}_k(L_k(G,u), L_k(G,v)) = 1$ iff $\mathcal{D}_{k-1}(L_{k-1}(G_{odd},u), L_{k-1}(G_{odd},v)) = 1$ or $id(u)$ appears in $L(v,K)$.

*Case* f. $\mathsf{State}(u) = \mathsf{Even}$, $\mathsf{State}(v) = \mathsf{Odd}$. Then

$$\mathcal{D}_k(L_k(G,u), L_k(G,v)) = \mathcal{D}_{or}(L(u,K), L(v,K)).$$

To prove correctness, use induction on $k$. If $u$ and $v$ are neighbors of level $i$, then the edge $(u,v)$ appears in $F_i$ and therefore both $u$ and $v$ participate in either $G_{odd}$ or $G_{even}$ depending on the parity of $i$. Thus, by comparing the appropriate labels, say $L_{k-1}(G_{odd},u)$ and $L_{k-1}(G_{odd},v)$, we can deduce that $u$ and $v$ are indeed neighbors by the induction hypothesis.

If $u$ and $v$ are neighbors, $u$ is of level $i$, and $v$ is of level $i+1$, then the edge $(u,v)$ either appears in $F_i$ and $\mathsf{State}(v) = \mathsf{Dual}$ or appears in $K$ and $\mathsf{State}(v) = \mathsf{Even}$ or $\mathsf{Odd}$. Thus, if $(v,u)$ is in $F_i$ then, if $i$ is even, both vertices participate in $G_{even}$ and, if $i$ is odd, then both vertices participate in $G_{odd}$. By comparing the appropriate labels of $u$ and $v$ (either their $L(k-1, G_{even})$ label or their $L(k-1, G_{odd})$ label) and by using the induction hypothesis we are able to deduce that $u$ and $v$ are indeed neighbors.

If $\mathsf{State}(v) = \mathsf{Even}$ or $\mathsf{Odd}$, then the edge $(v,u)$ is in $K$, so by looking at $L(v,K)$ in $L_k(G,v)$ and detecting $id(u)$ appearing there, we conclude that $u$ and $v$ are indeed neighbors.

It is clear that if $u$ and $v$ are *not* neighbors in $G$, then they are not neighbors in either one of the decomposed subgraphs, and therefore, by the induction hypothesis we can never deduce that they are neighbors by our procedure. $\square$

We get the following corollary.

COROLLARY 4.19. *Let $\mathcal{G}_n$ be the family of $n$-vertex graphs. Then* $\mathcal{L}(k\text{–}\mathtt{v\text{-}conn}, \mathcal{G}_n) \leq 2^k \log n$.

**5. A lower bound for vertex-connectivity on general graphs.** In this section we establish a lower bound of $\Omega(k \log n)$ on the required label size for $k$-vertex-connectivity on the class of $n$-vertex graphs, where $k$ is polylogarithmic in $n$. Fix a constant integer $c \geq 1$, assume that $k \leq \log^c n$, and for $m = \frac{n}{2(k^2-k)}$ let $\mathcal{G}_m$ be the class of all $m$-vertex graphs $\langle V, E \rangle$ with fixed id's $\{v_1, \ldots, v_m\}$ and degree at most $k-1$. Transform a given graph $G \in \mathcal{G}_m$ into a graph $T(G) = H$ with $n$ vertices in the following way. Replace each edge $e_{i,j} = (v_i, v_j)$ in $G$ with $k$ vertices $w^1_{i,j}$ through $w^k_{i,j}$ and connect all the $w^l_{i,j}$'s to both $v_i$ and $v_j$. Since $G$ has at most $\frac{n}{2k}$ edges, $H$ has at most $n$ vertices. If necessary, add arbitrary isolated vertices to $H$ so that it has precisely $n$ vertices.

Observation 5.1. *Two vertices $v_i, v_j$ are adjacent in $G$ iff $u$ and $v$ are $k$-vertex-connected in $T(G) = H$.*

Assume we have a labeling scheme $\langle \mathcal{M}, \mathcal{D} \rangle$ for $k$-vertex connectivity on $n$-vertex graphs.

Observation 5.2. *Consider two distinct graphs $G_1, G_2 \in \mathcal{G}_m$, and let $L_i = \mathcal{M}(T(G_i))$ for $i = 1, 2$. Then there exists a vertex $v_j$ in $V$ such that $L_1(v_j) \neq L_2(v_j)$, i.e., $\{L_1(v_1), \ldots, L_1(v_m)\} \neq \{L_2(v_1), \ldots, L_2(v_m)\}$.*

Since the number of graphs in $\mathcal{G}_m$ is $(\frac{m}{k})^{\Omega(km)}$, which is $m^{\Omega(km)}$ for $k$ polylogarithmic in $n$, we get the following corollary.

Corollary 5.3. *There exists a graph $G \in \mathcal{G}(k)$ such that $\{L(v_1), \ldots, L(v_m)\}$ consists of at least $\log m^{\Omega(km)} = \Omega(km \log m)$ bits, where $L = \mathcal{M}(G)$.*

We get the following theorem.

Theorem 5.4. *$\mathcal{L}(k\text{−}\texttt{v-conn}, \mathcal{G}_n) = \Omega(k \log m) = \Omega(k \log n)$ for $k$ polylogarithmic in $n$.*

# A CHARACTERIZATION OF UNIVERSAL STABILITY IN THE ADVERSARIAL QUEUING MODEL[*]

CARME ÀLVAREZ[†], MARIA BLESA[†], AND MARIA SERNA[†]

**Abstract.** We study universal stability of directed and undirected graphs in the adversarial queuing model for static packet routing. In this setting, packets are injected in some edge and have to traverse a predefined path before leaving the system. Restrictions on the allowed packet trajectory provide a way to analyze stability under different packet trajectories. We consider five packet trajectories, two for directed graphs and three for undirected graphs, and provide polynomial time algorithms for testing universal stability when considering each of them. In each case we obtain a different characterization of the universal stability property in terms of a set of forbidden subgraphs. Thus we show that variations of the allowed packet trajectory lead to nonequivalent characterizations.

Using those characterizations we are also able to provide polynomial time algorithms for testing stability under the NTG-LIS (Nearest To Go-Longest In System) protocol.

**Key words.** interconnection networks, adversarial queueing theory, greedy scheduling protocols, network stability, graph algorithms

## 1. Introduction.

One of the main goals in the study of the behavior of packet-switched communication networks is to determine the conditions of *stability*, i.e., the fact that the number of packets in the system remains bounded as the system dynamically evolves in time. Stability is studied considering that a communication system is formed by three main components: the network, the scheduling protocol, and the traffic pattern. *Networks* are modeled with (directed or undirected) graphs in which nodes represent the hosts and edges represent the links between these hosts. The *protocol* is used to schedule a packet when more than one packet wants to cross the same edge at the same time step. Packets waiting to traverse an edge are kept in a queue at the tail of the edge. The protocol determines the order in which the waiting packets cross the edge. The *traffic pattern* controls where and how packets join the system and defines their trajectory.

*Adversarial models.* The problem of deciding stability has been investigated under various models of packet routing [8, 9, 7, 12, 3]. Some models make probabilistic assumptions on the traffic pattern, while others replace more traditional stochastic arrival assumptions by worst-case inputs in the traffic pattern to perform a worst-case analysis. These latter models are closer to the traditional analysis of algorithms and to real network configurations. The *adversarial queuing theory* proposed by Borodin et al. [6], which is a robust model of queuing theory in network traffic, can be considered as the pioneering work in studying stability via worst-case analysis.

Adversarial models consider the time evolution of a packet-routing network as a game between an adversary and a protocol. The adversary may inject a set of packets at some nodes at each time step. In this work, we consider static packet routing; in this setting, the adversary also specifies for each packet the complete path that the packet must traverse.

Adversarial models have been shown to be good theoretical frameworks for traffic patterns in modern communication networks. These models can reflect the behavior of connection-oriented networks with transient connections (such as ATM networks) as well as connectionless networks (such as the Internet). Different factors are used in those adversarial models to describe the adversary and quantify its power. Three of these factors refer to the *injection rate* (i.e., the frequency at which the adversary introduces packets into the network), the *burstiness* (i.e., the maximum number of packets that can be injected in an edge in one step), and the *initial configuration* (i.e., the initial quantity of packets distributed over the network at time zero). Restrictions on the quantity of packets injected are introduced in order to avoid adversaries that could trivially collapse the system. In general, during each interval of time (that can be defined in different ways), the number of packets injected during that time interval requiring any edge in their trajectory cannot exceed a certain bound proportional to the length of the time interval. Two main adversarial models have been considered in the last years, both of them assuming an empty initial configuration:

*The windowed adversarial (queuing) model* by Borodin et al. [6]. An adversary in this model is restricted by two parameters $(w, r)$, where $w \geq 1$ is the window size and $0 < r \leq 1$ is the injection rate. The adversary is allowed to inject sequences of packets under the restriction that, at any $w$ consecutive time steps, the total number of packets requiring any concrete edge $e$ is at most $\lceil rw \rceil$.

*The leaky-bucket adversarial model* by Andrews et al. [4]. An adversary in this model is also restricted by two parameters $(b, r)$, where $b \geq 0$ is the burstiness and $0 < r \leq 1$ is the injection rate. The adversary is allowed to inject sequences of packets under the load condition that, of the packets that the adversary injects in any interval $T$, at most $\lceil r|T| \rceil + b$ may have paths that contain the same particular edge.

In a recent work Rosén compares the relative power of the *windowed* and the *leaky-bucket* adversarial models [18]. For injection rates $r < 1$, adversaries in one model can be simulated by adversaries in the other model injecting the same sequence of packets. Thus, the results for one model also hold for the other model. However, when $r \leq 1$ a leaky-bucket adversary is more powerful than a windowed adversary, since there are some sequences of packets that can be produced by the former when $r = 1$, but cannot be produced by the latter.

In this work we will study universal stability of directed and undirected graphs when $r < 1$ under the leaky-bucket adversarial model, as it is done in [4]. In general, stability results are shown for any network with an empty initial configuration, while instability results are shown starting from a network with a given nonempty initial configuration (see [6] or [4]). The results in [4] show that any instability result for a network with a given initial configuration can be translated into an instability result with empty initial configuration for a different network. These results can be used to show the nonuniversal stability of a given protocol but not to characterize universal stability of networks. However, we will show that network stability is independent of whether the initial configuration is empty or not.

*Greedy protocols* are those that forward a packet across an edge $e$ whenever there is at least one packet stored in the queue of $e$ waiting to traverse the edge. Some natural greedy protocols are FIFO (First In First Out), in which highest priority is given to the packet that has arrived first in the queue; LIS (Longest In System), in which every queue gives priority to the packet that has been in the system the longest and; and NTG (Nearest To Go), in which highest priority is assigned to the packet that still has to cross the smallest number of edges. Other protocols are FTG (Furthest To Go), NTS (Nearest To Source), SIS (Shortest In System), LIFO (Last In First Out), and FFS (Farthest From Source).

In this paper, as customary in the literature about stability, we consider only greedy protocols. All the instability results in this paper will be shown under the NTG-LIS protocol, which works as the NTG protocol and solves ties using LIS.

*The packet trajectory* refers to the form of the paths that packets are allowed to follow over the network. For directed graphs, two different types of paths have been considered in the literature. Borodin et al. [6] and Andrews et al. [4] assumed that when a packet is injected, its assigned path does not contain any edge more than once (see page 45 of [4]); however, a different definition of packet trajectory was considered by Goel in [14]. Although a detailed definition is not given in [14], only paths that do not contain any vertex more than once are allowed (see, for example, the comment just before Lemma 2.4 on page 221 of [14]). Hence, the paths considered by Goel (referred to in the following as *simple paths*) are a restrictive version of the paths considered by Andrews et al. (referred to in the following as *paths*).

In the case of undirected graphs, Andrews et al. assume that packets can use only paths that do not cross the same edge twice. This means that a packet cannot traverse the same edge in both directions (see page 57 of [4]). We refer to these paths as *undirected paths.* Together with this type of path, we will also consider *paths* and *simple paths* defined over the directed version of the undirected graph.

Gamarnik [13] considers undirected graphs and uses a different model for the allowed packet traffic: each edge is undirected and can carry only a single packet in one step. This contrasts with the Andrews et al. model in which the edges can be seen as bidirected, and each edge can carry a packet in each direction at each step.

*Known results.* A network is said to be universally stable when the systems composed by that concrete network are stable regardless of the selected protocol and traffic pattern. A protocol is said to be universally stable when all the systems that use it are stable. The existence of networks and scheduling protocols that are (respectively, are not) universally stable was initially shown in [6] and [4].

Until the work of Rosén [18], it was not clear if both the windowed and the leaky-bucket models were equivalent. Since it was shown that they are for injection rates $r < 1$, results for one model also hold for the other model when the injection ratio accomplishes this condition. Keeping this equivalence in mind, let us summarize some of the most important results obtained in the respective models.

In the windowed adversarial model, universal stability of networks with tree, mesh, and directed acyclic topologies was shown to hold in [6]. On ring topologies, protocols LIS and FIFO were shown to be nonstable with injection rate $r = 1$, whereas FTG was shown to be stable. Concerning only protocols, it was also shown in [6] that, for every $r > 0$, there exists a queuing network for which NTG is nonstable at rate $r$. Every greedy protocol is shown in [16] to be stable if the injection rate is not more than $1/(d + 1)$, where $d$ denotes the diameter of the network.[1] Much effort has been

[1]The diameter of a graph is the length of the longest path in it that does not pass twice over the same edge.

dedicated to the FIFO protocol, for which the best known lower bound for instability was improved in [16] down to 0.5.

In the leaky-bucket adversarial model with $r < 1$, stability of networks describing a ring topology was shown to hold under any greedy protocol (see [4]). In the same work, some commonly used simple greedy protocols (namely, FTG, NTS, SIS, and LIS) were shown to be universally stable, while some others (namely, FIFO, LIFO, NTG, and FFS) were shown not to be universally stable. Considering that the system might have initial configuration, stability and instability properties of FIFO have been recently studied in this model. A network-dependent constant is provided in [10] such that FIFO is stable against any adversary with a smaller injection rate. A lower bound of 0.749 for the instability of FIFO was given in [15], where the stability of networks with heterogeneous protocols also was addressed. Moreover, in [19] it was shown that FIFO is stable when the injection rate is smaller than $1/(d-1)$. In this model, FIFO has been shown to be unstable at arbitrarily low injection rates [5].

With regard to the universal stability of networks one of the first questions that arose was whether it would be possible to detect stability from the knowledge of the topological structure of the network and the scheduling protocols. For undirected graphs, Andrews et al. show in [4] that, for a particular type of packet trajectory (the one we call *undirected path*), cycles and trees are universally stable. Furthermore, they also show that the family of *undirected-path universally stable* graphs is minor-closed and that there exists a finite set of basic undirected graphs such that a graph is stable if and only if it does not contain as a minor any of the graphs in that set. These results guarantee decidability in polynomial time; however, a constructive proof is not presented.

*Our results.* In this paper we consider the computational complexity of deciding universal stability of directed and undirected graphs. We consider different restrictions on the type of path that the packets can follow, i.e., the packet trajectory. We would like to highlight the importance of specifying the type of path since, for each category, the characterization of universal stability is different. For each considered case we obtain a characterization in terms of forbidden subgraphs and provide an explicit polynomial time algorithm for deciding the property of stability. Concerning directed graphs, and under the assumption that packets follow simple paths, we obtain a characterization of universal stability that disproves the characterization in [14] under the same assumption (which was presented in terms of the forbidden minors given in Figure 1). Further comments concerning this fact will be given after presenting our characterization.

An interesting question concerning stability is that of deciding the stability of a concrete network under a fixed protocol. Using the fact that all the instability results obtained in this paper apply to networks under the NTG-LIS protocol, we can show that the problem of deciding whether a network is stable under the NTG-LIS protocol can also be solved in polynomial time.

*Organization.* Section 2 sets out the definitions of all models considered in this work and some preliminary results. In section 3, universal stability of some particular directed and undirected graphs is shown. Section 4 contains the basic results on instability of directed and undirected graphs. Finally, section 5 details the characterizations for universal stability in terms of forbidden subgraphs, and section 6 provides alternative characterizations in terms of graph properties together with the algorithms that check them. Finally, section 7 shows the polynomial time decidability of checking for stability under the NTG-LIS protocol. For sake of readability several technical proofs have been delayed to the appendix.

## 2. Preliminaries.

**2. Preliminaries.** All the graphs in this paper may have multiple edges but no loops. Multiple edges share the same pair of different endpoints, while the endpoints of a loop are the same vertex. We will use the term *digraph* to refer to a directed graph and simply *graph* for an undirected graph. For a digraph we will use the term *arc* instead of edge. Given a graph $G$, $G^d$ denotes the digraph formed from the same vertex set as $G$ but replacing every edge $\{u, v\}$ in $G$ with the two arcs $(u, v)$ and $(v, u)$.

Two edges are *incident* if they share at least one vertex. A *walk* is an alternating sequence of vertices and edges (respectively, arcs) in the form

$$v_0, e_1, v_1, \dots, v_{n-1}, e_n, v_n,$$

where for each $i$, $1 \leq i \leq n$, $e_i = \{v_{i-1}, v_i\}$ (respectively, $e_i = (v_{i-1}, v_i)$) and each $v_j$ is a vertex. A *path* is a walk in which all the edges (respectively, arcs) are different. A *simple path* is a walk in which all the vertices, and thus necessarily all the edges (respectively, arcs) are different. A walk is *closed* if $v_0 = v_n$. A closed walk is an $n$-*cycle* provided its $n$ vertices are distinct.

In this work we adopt, without loss of generality, the leaky-bucket definition of adversary which is defined by two parameters $(r, b)$, where $b \geq 0$ and $0 < r \leq 1$. An $(r, b)$-*adversary* (or just an *adversary*) is allowed to inject sequences of packets under the load condition that, of the packets that the adversary injects in any interval $T$, at most $\lceil r|T| \rceil + b$ packets may have trajectories that contain any particular edge. Rosén [18] showed that adversaries in the windowed and in the leaky-bucket models (starting with an empty configuration) have the same power provided that $r < 1$. The equivalence requires only a change in the parameters of the adversary, not in the sequence of packet trajectories; therefore it provides a valid equivalence for all our subclasses of adversaries.

When in addition to an $(r, b)$-adversary $\mathcal{A}$, we are given an initial configuration $C$, we can define a new $(r, b')$-adversary $\mathcal{A}$' as follows:

Let $b' = b + |C|$; then $\mathcal{A}'$ injects all the packets in $C$ at time step 1, and at any other time step $t > 1$, the same set of packets that $\mathcal{A}$ would inject at time $t - 1$.

Here the initial configuration means the set of packets that are in the system initially. Both systems, with empty or nonempty initial configuration, behave alike; hence we can work equivalently with empty or not empty initial configuration. Since only the parameters of the adversary have to be changed, this remark is also valid for any system with some restrictions on the packet trajectory. Notice that this is a stronger result than the analogous result given in [4] since here the graph does not need to be changed (if the graph topology is changed, then results on stability of networks cannot be translated from one model to the other).

Throughout the paper we will use the leaky-bucket adversarial model with empty

Table 1
*Summary of concepts.*

| Directed Graphs | | |
|---|---|---|
| Packet trajectory | Characteristics of the route | Stability term |
| path | walk with nonrepeated edges | stability |
| simple path | walk with nonrepeated vertices | simple-path stability |

| Undirected Graphs | | |
|---|---|---|
| Packet trajectory | Characteristics of the route | Stability term |
| path | path in $G^d$ | stability |
| undirected path | path in $G$ | undirected-path stability |
| simple path | simple path in $G^d$ | simple-path stability |

initial configuration and $r < 1$. However, for the sake of simplicity, we will use nonempty initial configurations when describing adversaries causing network instability. In the following, we establish the definitions of stability in the adversarial queuing model used in this work. The different definitions are summarized in Table 1.

Definition 1. *Given a network $G$, a protocol $P$, and an adversary $\mathcal{A}$, we say that the system $(G, P, \mathcal{A})$ is* stable *if the number of packets in the system is always bounded.*

**2.1. Networks as digraphs.** When the network is represented by a digraph $G$, we consider two classes of packet trajectories, thus giving rise to two adversary classes: an *adversary* can use as packet trajectory any path in $G$, while a *simple-path adversary* can use as packet trajectory only simple paths in $G$. Accordingly we set the two definitions of stability under a protocol.

Definition 2. *Given a digraph $G$ and a protocol $P$, we say that*

– *$G$ is* stable *under protocol $P$ (the pair $(G, P)$ is stable) if for any adversary $\mathcal{A}$, the system $(G, P, \mathcal{A})$ is stable.*
– *$G$ is* simple-path stable *under protocol $P$ (the pair $(G, P)$ is simple-path stable) if for any simple-path adversary $\mathcal{A}$, the system $(G, P, \mathcal{A})$ is stable.*

Similarly, we define universal stability of digraphs in the following form.

Definition 3. *A digraph $G$ is* universally stable *if, for any protocol $P$, the pair $(G, P)$ is* stable*. A digraph $G$ is* simple-path universally stable *if, for any protocol $P$, the pair $(G, P)$ is* simple-path stable.

Observe that any universally stable digraph is also simple-path universally stable, but the opposite, as we will see, is not true.

The property of simple-path universal stability was shown in [14] to be maintained when acyclically joining simple-path universally stable digraphs. A closer inspection of the proof reveals its validity for the two proposed models for directed graphs proposed in this work.

Lemma 1. *If digraphs $G_1$ and $G_2$ are (simple-path) universally stable, then so is any graph $G$ formed by joining them with edges that go only from $G_1$ to $G_2$.*

As a consequence of the previous result we have the following theorem.

Theorem 1. *A digraph $G$ is (simple-path) universally stable if and only if all its strongly connected components are (simple-path) universally stable.*

**2.2. Networks as graphs.** When representing networks by undirected graphs, we consider three different packet trajectory restrictions: given a graph $G$, an *adversary* can use as packet trajectory any path in $G^d$; an *undirected-path adversary* can use as packet trajectory any path in $G$; and a *simple-path adversary* can use as packet trajectory only simple paths in $G^d$.

Observe that, in the first case, an edge can be used twice by the same packet provided it is traversed in opposite directions, but both directions have different queues and thus this model is different from Gamarnik's proposal [13]. In the second model the same edge can be traversed only once. This corresponds with the model used by Andrews et al. in [4]. The third model does not allow a packet to pass twice through the same vertex. Notice that, in this latter model, a multiedge can be traversed only once and only in one direction. Observe that the condition *simple-path in G* is equivalent to *simple-path in $G^d$*, so the fourth possible model has already been considered.

As before, we set the definitions of stability under a protocol.

Definition 4. *Given a graph $G$ and a protocol $P$, we say that*

- *$G$ is* stable *under protocol $P$ (the pair $(G,P)$ is stable) if for any adversary $\mathcal{A}$, the system $(G,P,\mathcal{A})$ is stable.*
- *$G$ is* undirected-path stable *under protocol $P$ (the pair $(G,P)$ is undirected-path stable) if for any undirected-path adversary $\mathcal{A}$, the system $(G,P,\mathcal{A})$ is stable.*
- *$G$ is* simple-path stable *under protocol $P$ (the pair $(G,P)$ is simple-path stable) if for any simple-path adversary $\mathcal{A}$, the system $(G,P,\mathcal{A})$ is stable.*

It is straightforward to show that if a pair $(G,P)$ is stable, then $(G,P)$ is also undirected-path stable, and if $(G,P)$ is undirected-path stable, then $(G,P)$ is simple-path stable. As we will see later, these inclusions are strict. Now we can write the corresponding definitions of universal stability.

Definition 5. *A graph $G$ is* universally stable *if for any protocol $P$ the pair $(G,P)$ is* stable*. A graph $G$ is* undirected-path universally stable *if for any protocol $P$ the pair $(G,P)$ is* undirected-path stable*. A graph $G$ is* simple-path universally stable *if for any protocol $P$ the pair $(G,P)$ is* simple-path stable*.*

The universal stability of graphs under the undirected-path model (as defined above) was addressed in [4] where it is proved to be closed under minors and therefore decidable in polynomial time; however, no constructive algorithm is known. For the other models this question was unresolved. We show a constructive way of deciding the universal stability property also for the other models.

We can also state an equivalent result to that in Theorem 1 for the three forms of universal stability for undirected graphs presented here. Note that in the case of undirected graphs, each pair of connected components are independent, i.e., there is no edge connecting them.

Theorem 2. *A graph $G$ is (simple-path $|$ undirected-path) universally stable if and only if all its connected components are (simple-path $|$ undirected-path) universally stable.*

Finally, let us remark that in any of the five packet trajectory models considered in this paper (i.e., two for digraphs and three for graphs), the instability of a sub(di)graph implies the instability of the whole (di)graph.

## 3. Some universally stable graphs and digraphs.

In the following, we use standard graph terminology to denote the following graphs and digraphs: directed and undirected *trees*, the *cycle* on $k$ vertices ($k \geq 2$), the *directed cycle* on $k$ vertices ($k \geq 2$), and *directed acyclic* graphs. For graphs and digraphs with multiple edges we define

- a *unicyclic graph* as those graphs that contain only one cycle (see Figure 2(b.3));

– a *multi-tree* as an undirected tree with multiple edges (see Figure 2(c.1));
– a *decorated cycle* as being obtained from a $k$-cycle with $k \geq 3$, and some multitrees (see Figure 2(c.2)), after identifying one vertex from each tree with a vertex from the cycle;
– an *oriented multitree* as the directed version of an undirected tree in which each edge is substituted by two arcs (one in each direction), and which can also contain multiple arcs (see Figure 2(c.3)). Note that all the simple directed cycles have two vertices;
– a *decorated directed cycle* as the directed version of a $k$-cycle with $k \geq 3$, and some oriented multitrees, after identifying one vertex from each "tree" with a vertex from the cycle (see Figure 2(c.4)). Note that the obtained graph is strongly connected.

In this section we prove the universal stability of some graphs and digraphs according to the different packet trajectories considered. Previous results from [6] and [4] are rewritten as Lemmas 2 and 3 according to the terminology introduced in this work.

LEMMA 2. *All acyclic digraphs and the directed cycle on any number of vertices are universally stable.*

As we have commented before, universal stability of digraphs implies simple-path universal stability; therefore, acyclic digraphs and directed cycles are also simple-path universally stable. Concerning graphs, we know that the following lemmas hold.

LEMMA 3. *All trees and cycles on any number of vertices are undirected-path universally stable.*

Now we give another family of undirected-path universally stable graphs, thus extending the previous result.

LEMMA 4. *All unicyclic graphs are undirected-path universally stable.*

*Proof.* Observe that, if $G$ is a unicyclic graph, removing the edges in the cycle results in a forest. We root each tree in this forest at the vertex that is common with the cycle; this gives an orientation *upwards* or *downwards* to every arc in $G^d$.

We classify the packets into three flow types. Flow type $\alpha$ is formed by those packets injected in an upward arc. Flow type $\beta$ is formed by packets injected in a cycle arc; in fact, we will consider this flow split into two flows, depending on whether the initial arc follows one of the two cycle orientations. Finally, flow type $\gamma$ is formed by the packets injected in a downward arc.

Observe that packets starting in a downward arc can follow only downward arcs; otherwise they will use twice an edge in $G$. Similarly, packets starting in the cycle cannot change the initial cycle orientation. Therefore they either die in the cycle or leave the cycle using a downward arc. This provides a directed acyclic interaction of the three flow types. Upward edges can carry only packets from $\alpha$ flow. As directed acyclic graphs are undirected-path stable, the corresponding queues will have bounded maximum size. The edges in the cycle can be considered as two directed cycles, as no flow can be passed from one to the other. These cycle edges can get packets from $\alpha$ flow and $\beta$ flow. In this situation we have a stable network (upward edges) entering in another stable network (one of the directed cycles) and, by Lemma 1, the corresponding queues will have bounded maximum size. For the downward arcs we have the same situation, a flow coming from a stable network entering in another stable network. Thus the result follows. $\square$

All the families of graphs which are undirected-path universally stable are also simple-path universally stable. However, we can enlarge the set of simple-path universally stable graphs by allowing multiple edges.

LEMMA 5. *A multitree is simple-path universally stable.*

*Proof.* Observe that a packet can use only once, and only in one direction, one of the multiple edges connecting the same pair of vertices. The argument is similar to the one in Lemma 4: we root the tree in order to assign an upward/downward direction to the edges in $G^d$. The simple-path requirement prevents packets starting in a downward arc from using an upward arc (even in the case where the arcs in $G^d$ come from different edges in $G$), because in this case, a vertex would be visited twice. Thus, we can conclude the simple-path universal stability of a multitree. □

LEMMA 6. *A decorated cycle is simple-path universally stable.*

*Proof.* The result follows from Lemmas 4 and 5 using the same arguments as in Lemma 5. □

LEMMA 7. *A oriented multitree and a decorated directed cycle are simple-path universally stable.*

*Proof.* The result follows from Lemmas 5 and 7 using the arguments similar to those in Lemmas 4 and 5. □

Figure 2 summarizes and classifies the families of graphs and digraphs that are universally stable according to the different packet trajectories considered.

## 4. Some graphs and digraphs that are not universally stable.

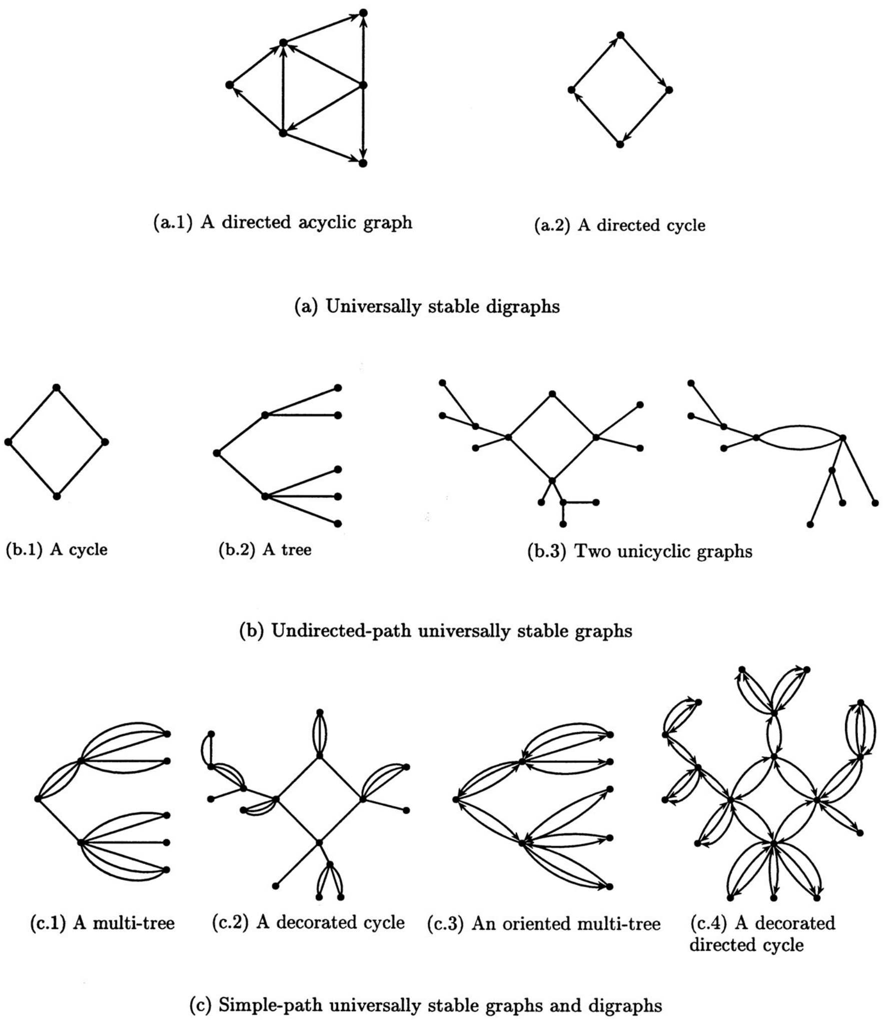
Once the families of universally stable graphs and digraphs are identified for each of the cases considered, we focus on detecting which are the simplest graphs and digraphs that are not stable. By iteratively applying subdivision operations to those simplest graphs and digraphs we will "extend" them and we will define families of graphs. Each family will characterize one of the cases of universal stability introduced in this work. We consider the following subdivision operations on graphs and digraphs:

- The *subdivision of an edge* $\{u, v\}$ in a graph $G$ consists of the addition of a new vertex $w$ and the replacement of $\{u, v\}$ by the two edges $\{u, w\}$ and $\{w, v\}$.
- The *subdivision of an arc* $(u, v)$ in a digraph $G$ consists of the addition of a new vertex $w$ and the replacement of $(u, v)$ by the two arcs $(u, w)$ and $(w, v)$.
- The *subdivision of a 2-cycle* $(u, v)$, $(v, u)$ in a digraph $G$ consists of the addition of a new vertex $w$ and the replacement of $(u, v)$, $(v, u)$ by the arcs $(u, w)$, $(w, u)$, $(v, w)$, and $(w, v)$.

Given a graph $G$, $\mathcal{E}(G)$ denotes the family of graphs formed by $G$ and all the graphs obtained from $G$ by successive edge subdivisions. Given a digraph $G$, $\mathcal{E}(G)$ denotes the family of digraphs formed by $G$ and all the digraphs obtained from $G$ by successive arc or 2-cycle subdivisions. Observe that, for a graph $G$, $\mathcal{E}(G)^d \subseteq \mathcal{E}(G^d)$, but it might be the case that $\mathcal{E}(G)^d \neq \mathcal{E}(G^d)$; see Figure 3 for an example.

In this section we will prove instability results of networks under the NTG-LIS protocol. To simplify the notation, a path is specified by the sequence of its edges. First we show that some simple graphs are not stable and second we apply subdivision operations to these graphs and also show their instability. Observe that, as we are using the NTG protocol, if the length of the path that a packet has to traverse is increased, then its priority at a given edge can be changed. Therefore, edges composing a packet path cannot be replaced indistinctly with paths. However, for the particular graphs and adversaries we will deal with, the adversary can be adapted to provide an instability proof. The names used to denote the graphs correspond to the ones depicted in Figures 4 and 5.

THEOREM 3. *All the digraphs in* $\mathcal{E}(U_1) \cup \mathcal{E}(U_2)$ *are not stable under the* NTG-LIS *protocol.*



(a.1) A directed acyclic graph
(a.2) A directed cycle
(a) Universally stable digraphs

(a) A graph $G$
(b) The graph $G^d$
(c) A graph in $\mathcal{E}(G)$
(d) A graph in $\mathcal{E}(G)^d$ and $\mathcal{E}(G^d)$
(e) A graph in $\mathcal{E}(G^d)$ but not in $\mathcal{E}(G)^d$

FIG. 3. *An example illustrating the differences between* $\mathcal{E}(G)^d$ *and* $\mathcal{E}(G^d)$.

*Proof.* We sketch here the main lines and refer the reader to Appendix A where some of the most technical auxiliary results are proved. We start by showing that the pair $(U_1, \text{NTG-LIS})$ is not stable; to do so we provide an adversary and an initial configuration. The adversary works in rounds, and at the end of the presented rounds the network has a configuration with the same type of packets as in the initial con-

FIG. 5. *Some not universally stable graphs.*

figuration but with an increased number of them. By repeatedly playing the set of rounds the system shows instability.

*Initial configuration.* At the beginning there are $s$ packets that want to traverse edge $f$; half of them are of the form $(e_1\ f)$, and half of them are of the form $(e_2\ f)$. The adversary $\mathcal{A}$ will play injections in four rounds.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(f\ e_2)$. These injections get mixed with the initial packets at edge $f$ and are blocked there because the queuing protocol is NTG.

*Round* 2. For the next $rs$ steps, the adversary injects a set of $r^2s$ packets of the form $(f\ e_1)$ and $r^2s$ packets of the form $(e_2)$. Injections $(f\ e_1)$ are blocked by the packets $(f\ e_2)$ from the first round because they are at the same distance to their destination and the secondary protocol that we apply is LIS. The $r^2s$ injections of the form $(e_2)$ are also blocked.

*Round* 3. For the next $r^2s$ steps, the adversary injects $r^3s$ packets of the form $(e_2)$ and $r^3s$ of the form $(e_1\ f)$. The simple injections on $e_2$ will be blocked by the packets at $e_2$ from the previous round. The $(e_1\ f)$ injections get mixed with the packets of the form $(f\ e_1)$ from the previous round at edge $f$, where the injections get blocked because their distance to destination is longer.

*Round* 4. For the next $r^3s$ steps, the adversary injects $r^4s$ packets of the form $(e_2\ f)$ and $r^4s$ packets of the form $(e_1)$. The simple injections at $e_1$ block the packets $(e_1\ f)$ from the previous round because their distance to destination is shorter. The $(e_2\ f)$ injections are blocked by the $(e_2)$ packets from the previous round.

At the end there are $2r^4s$ packets queued at $e_1$ and $e_2$ that want to traverse edge $f$, $r^4s$ are of the form $(e_1\ f)$, and $r^4s$ are of the form $(e_2\ f)$. If cycles are allowed, the adversary $\mathcal{A}$ described above makes the network $U_1$ nonstable when $2r^4s > s$, i.e., at injection rate $r > 0.84089$.

The second step is to prove instability for the pair $(U_2, \text{NTG-LIS})$, as is done in Lemma 9 of Appendix A. Once the two base digraphs are shown not to be stable, we have to show instability for any extension of them. Observe that only the extensions obtained by arc subdivision have to be considered since the extensions obtained by 2-cycle subdivision already contain $U_2$ as a subgraph. Therefore, we have only to consider the two extensions depicted in Figures 6(a) and 6(b) whose corresponding instability results are given in Lemmas 10 and 11 (see Appendix A). ∎

We remark that, for digraphs, simple-path stability and stability are not equivalent. The pair $(U_1,\text{NTG-LIS})$ is not stable although $U_1$ is simple-path universally stable. The last result is easy to obtain as the set of simple-paths in $U_1$ is the set $\{(e_1), (e_2), (f)\}$, and any adversary using this set of disjoint packet trajectories is equivalent to an adversary playing on a digraph with three isolated arcs. The latter digraph is acyclic and therefore universally stable. Similar reasoning can be applied to $U_2$. These considerations lead to digraphs $S_1$, $S_2$, $S_3$, and $S_4$ (see Figure 4(b)) as the smallest digraphs which are not simple-path universally stable.

THEOREM 4. *All the digraphs in $\mathcal{E}\,(S_1) \cup \mathcal{E}\,(S_2) \cup \mathcal{E}\,(S_3) \cup \mathcal{E}\,(S_4)$ are not simple-path stable under the* NTG-LIS *protocol.*

*Proof.* The proof follows the same lines as for Theorem 3. We first prove that $S_1$, $S_2$, $S_3$, and $S_4$ are not simple-path stable (Lemmas 12, 13, 14, and 15). The restriction on considering simple-path trajectories justifies the need for having cycles of length at least 3 in a simple-path nonstable digraph. Extensions by 2-cycle subdivision are applicable only to $S_4$. Therefore, to finish the proof we show that the digraphs corresponding to the extensions depicted in Figures 7(a), 7(b), 7(c), and 7(d) are not simple-path stable (Lemmas 16, 17, 18, 19, and 11). See Appendix B for details. □

THEOREM 5. *All the graphs in $\mathcal{E}(H_1) \cup \mathcal{E}(H_2)$ are not stable under the* NTG-LIS *protocol.*

*Proof.* First observe that $H_1^d$ contains $U_1$ as a subgraph and that $H_2^d$ is $U_2$. Furthermore, any graph in $\mathcal{E}(H_1) \cup \mathcal{E}(H_2)$ can be oriented to contain, as a subgraph, a graph in $\mathcal{E}(U_1) \cup \mathcal{E}(U_2)$; therefore its instability under NTG-LIS follows from Theorem 3. □

Observe that the graph $H_1$ is undirected-path universally stable; again the set of possible undirected-path packet trajectories is formed by nonoverlapping paths with length 1. Therefore, undirected-path stability and stability are nonequivalent properties. Similar reasoning can be applied to $H_2$.

To characterize undirected-path stability we need to consider some larger graphs. Furthermore, instead of considering a fully directed version of the graph, we will need to fix an orientation to all the edges, with the exception of those that are graph separators, as those edges may have to be crossed in both directions.

THEOREM 6. *All the graphs in $\mathcal{E}(F_1) \cup \mathcal{E}(F_2) \cup \mathcal{E}(F_3)$ are not undirected-path stable under the* NTG-LIS *protocol.*

*Proof.* Let us prove first that the graphs $F_1$ and $F_2$ are NTG-LIS undirected-path nonstable. Giving an adequate orientation to the edges in $F_1$ and $F_2$, we get the digraphs $U_1$ and $U_2$ and as each arc corresponds to a different edge, the instability follows. Maintaining these orientations, any graph in $G \in \mathcal{E}(F_1) \cup \mathcal{E}(F_2)$ can be identified with a digraph in $\mathcal{E}(U_1) \cup \mathcal{E}(U_2)$ and therefore $G$ is not undirected-path stable under NTG-LIS.

For the graph $F_3$ we can fix an orientation for the edges forming the 2-cycles but we have to keep both directions, where possible, for the middle edge. Although no packet can use both, different packets may traverse the edge in different directions. Starting with the proof of NTG-LIS instability for the graph $U_2$ and working in a similar way as in Lemmas 15 and 19 it follows that $F_3$ and any graph in $\mathcal{E}(F_3)$ are not undirected-path stable under NTG-LIS. □

The graph $F_1$ is simple-path universally stable but not undirected-path stable; therefore simple-path stability differs from undirected-path stability. Cycles of length 3 or longer are needed to obtain simple-path nonstable graphs, thus obtaining $K_1$, $K_2$, and $K_3$ as the smallest graphs which are not simple-path stable.

THEOREM 7. *All the graphs in $\mathcal{E}(K_1) \cup \mathcal{E}(K_2) \cup \mathcal{E}(K_3)$ are not simple-path stable under* NTG-LIS.

*Proof.* Observe that we can give an orientation to the edges in $K_1$ and $K_2$ to obtain the digraphs $S_1$ and $S_3$ that are not simple-path stable under NTG-LIS. For the graph $K_3$ we can orient the two cycles and maintain the two opposite arcs for the middle edge, obtaining the graph $S_4$. Theorem 4 gives the simple-path instability under NTG-LIS for any graph in $\mathcal{E}(K_1) \cup \mathcal{E}(K_2) \cup \mathcal{E}(K_3)$. □

**5. Characterizing universal stability.** In this section we provide characterizations for the universal stability property of digraphs and graphs for each of the five proposed adversarial models. As before, the graph nomenclature corresponds to Figures 4 and 5.

We first show the characterization of the simple-path universal stability property since, in our opinion, the properties defining the simple-path stability for graphs are easier to understand once the corresponding properties for simple-path stability of digraphs are given.

THEOREM 8. *A digraph is universally stable if and only if it does not contain as subgraphs any of the digraphs in* $\mathcal{E}(U_1) \cup \mathcal{E}(U_2)$.

*Proof.* The "only if" part follows from Theorem 3 and the fact that the instability of a subgraph implies the instability of the whole graph. If $G$ does not contain as a subgraph a digraph in $\mathcal{E}(U_1) \cup \mathcal{E}(U_2)$, then all its strongly connected components must consist of a simple cycle. Therefore, according to Lemma 2 and Theorem 1 we have that $G$ is universally stable. □

Using the arguments in the previous proof, Theorem 8 gives the following property.

COROLLARY 1. *A strongly connected digraph $G$ with $n$ vertices is universally stable if and only if $G$ is the directed cycle on $n$ vertices.*

For the case of universal stability of graphs, the basic set of forbidden subgraphs is given in Figure 5(a).

THEOREM 9. *A graph is universally stable if and only if it does not contain as subgraphs any of the graphs in* $\mathcal{E}(H_1) \cup \mathcal{E}(H_2)$.

*Proof.* The "only if" part follows from Theorem 5. If a graph $G$ does not contain as a subgraph any of the graphs in $\mathcal{E}(H_1) \cup \mathcal{E}(H_2)$, then $G$ has no incident edges, so it is universally stable. □

For the case of universal stability the corresponding graph property is the following corollary.

COROLLARY 2. *A graph $G$ is universally stable if and only if all the vertices in $G$ have degree at most* 1.

For the case of undirected-path universal stability of graphs, the basic set of forbidden subgraphs is given in Figure 5(b).

THEOREM 10. *A graph $G$ is undirected-path universally stable if and only if $G$ does not contain as a subgraph any of the graphs in* $\mathcal{E}(F_1) \cup \mathcal{E}(F_2) \cup \mathcal{E}(F_3)$.

*Proof.* The "only if" part follows from Theorem 6. Assume now that $G$ does not contain as a subgraph any of the graphs in $\mathcal{E}(F_1) \cup \mathcal{E}(F_2) \cup \mathcal{E}(F_3)$. In this case $G$ does not contain any edge with multiplicity 3, and all the connected components of $G$ contain at most one cycle. Therefore, all the connected components of $G$ are undirected-path universally stable by Lemma 3. □

For the case of undirected-path universal stability of graphs, the corresponding property is the following corollary.

COROLLARY 3. *A connected graph $G$ is undirected-path universally stable if and only $G$ is a subgraph of a unicyclic graph.*

For the case of simple-path universal stability of graphs, the basic set of forbidden subgraphs is given in Figure 5(c).

THEOREM 11. *A graph $G$ is simple-path universally stable if and only if $G$ does not contain as a subgraph any of the graphs in* $\mathcal{E}(K_1) \cup \mathcal{E}(K_2) \cup \mathcal{E}(K_3)$.

*Proof.* The "only if" part follows from Theorem 7. When $G$ does not contain as subgraphs any of the graphs in $\mathcal{E}(K_1) \cup \mathcal{E}(K_2) \cup \mathcal{E}(K_3)$, all the connected components of $G$ can have at most one cycle with more than two vertices, so they must be subgraphs of a decorated cycle graph. Therefore, using Lemma 6, $G$ is simple-path universally stable. □

COROLLARY 4. *A connected graph $G$ is simple-path universally stable if and only if $G$ is a subgraph of a decorated cycle graph.*

The case of simple-path universal stability is needed to complete the characterization for digraphs. In this case the basic set of forbidden subgraphs is given in Figure 4(b).

THEOREM 12. *A digraph $G$ is simple-path universally stable if and only if $G$ does not contain as a subgraph any of the graphs in $\mathcal{E}(S_1) \cup \mathcal{E}(S_2) \cup \mathcal{E}(S_3) \cup \mathcal{E}(S_4)$.*

*Proof.* As before, the "only if" part follows from Theorem 4. When $G$ excludes the family of forbidden subgraphs, each strongly connected component of $G$ must contain at most one directed cycle with more than two vertices. Therefore all the strongly connected components are subgraphs of a decorated directed cycle graph. Therefore, by Lemma 7, all the strongly connected components are simple-path universally stable, and by Theorem 1, $G$ is simple-path universally stable. ∎

COROLLARY 5. *A strongly connected digraph $G$ is simple-path universally stable if and only if $G$ is a subgraph of a decorated directed cycle graph.*

We have shown that the graph $S_1$ in Figure 4(b) is not simple-path stable under the NTG-LIS protocol. The only graph transformation proposed by Goel in [14] consists of replacing arcs by disjoint directed paths (see Corollaries 2.5 and 2.7 in [14]). Hence, our graph $S_1$ is a minor of the first minor proposed there. We also show that the digraph $S_4$ is not simple-path stable; however, $S_4$ does not contain as minor any of the forbidden minors in the characterization in [14], and therefore must be universally stable according to Goel's result. However, we have shown this is not the case. These facts disprove the characterization proposed by Goel in [14] and they establish the set $\{S_1, S_2, S_3, S_4\}$ (see Figure 4(b)) as the set of forbidden subgraphs characterizing the property of simple-path stability for digraphs.

## 6. Deciding universal stability.

In this section we show that the five cases of universal stability presented in this work can be decided in polynomial time. For undirected graphs we could use the polynomial time algorithm for checking subgraph homeomorphism of the corresponding forbidden subgraphs given in [17]; however, our algorithms are much simpler. Notice that for directed graphs checking subdigraph homeomorphism to a fixed digraph is NP-complete. In particular this is the case for the digraphs $S_1$, $S_2$, and $S_3$ (see [11]). However, the combination of several digraphs and the properties outlined in Corollaries 1, 2, 3, 4, and 5 are, as we will see, easier to test.

THEOREM 13. *The universal stability of a given graph or digraph can be decided in polynomial time.*

*Proof.* According to Corollary 2, to decide universal stability for graphs we only have to check if the graph has two incident edges. To check universal stability for digraphs, following Corollary 1, we have to compute the strongly connected components of the graph and then check whether all of them are just one directed cycle. Both tests can be performed in polynomial time. ∎

For the remaining adversarial models we first need to characterize the graphs that are subgraphs of a unicyclic graph.

LEMMA 8. *A connected graph $G$ with $m$ edges and without multiple edges is a subgraph of a unicyclic graph if and only if any spanning tree of $G$ has $m$ or $m-1$ edges.*

According to the previous lemma, Algorithm 1 checks whether a connected graph $G$, without multiple edges, is a subgraph of a unicyclic graph, in polynomial time. The algorithms to decide universal stability combine this checking with some additional testing for the multiedges.

THEOREM 14. *The undirected-path universal stability of a given graph can be decided in polynomial time.*

*Proof.* Algorithm 2 checks the undirected-path universal stability of a given connected graph $G$ according to Corollary 3. Its total execution time is polynomial. Then,

**Algorithm 1 :** Subgraph of a unicyclic graph

```
INPUT: A connected graph $G$
Compute a spanning tree of $G$
if there are more than one edge left then
  return no
else
  return yes
end if
```

**Algorithm 2 :** Graph undirected-path stability

```
INPUT: A connected graph $G$
if some edge has multiplicity 3 then
  return no
else
  compute the connected components of $G$
  if a connected component has two edges with multiplicity 2 then
    return no
  end if
  || Now all the connected components have at most one edge with multiplicity 2
  if there is a connected component of $G$ that is not a subgraph of a unicyclic graph then
    return no
  else
    return yes
  end if
end if
```

by combining this algorithm with the computation of the connected components of the given graph, we obtain a polynomial time algorithm. ∎

THEOREM 15. *The simple-path universal stability of a given graph can be decided in polynomial time.*

*Proof.* Algorithm 3 checks the simple-path universal stability of a given connected graph $G$ according to Corollary 4. The total execution time is polynomial. Thus, combining this algorithm with the computation of the connected components of the given graph, we can check the property in polynomial time. ∎

THEOREM 16. *The simple-path universal stability of a given digraph can be decided in polynomial time.*

*Proof.* Algorithm 4 checks the simple-path universal stability of a given strongly connected digraph $G$ according to Corollary 5. The total execution time is polynomial. By combining this algorithm with the computation of the strongly connected components of the given digraph, we obtain a polynomial time algorithm. ∎

All the algorithms presented in this section run in polynomial time. Note that the most expensive operations are the computation of the strongly connected components of a digraph, the computation of the connected components of a graph, and the computation of a spanning tree of a connected graph.

**7. Stability under NTG-LIS.** An interesting question concerning stability is that of deciding the stability of a concrete network under a fixed protocol. Since all the instability results in this work hold for the NTG-LIS protocol, we can conclude that

**Algorithm 3 :** Graph simple-path stability

```
INPUT: A connected graph $G$
Let $G'$ be the graph obtained from $G$ by setting all edge multiplicities to one
Compute the connected components of $G'$
**if** there is a connected component $H$ of $G'$ s.t. $H$ is not a subgraph of a unicyclic graph **or** $H$ is a unicyclic graph having $k \geq 3$ vertices in the cycle and with some cycle edge having multiplicity bigger than 1 in $G$ **then**
  return no
**else**
  return yes
**end if**
```

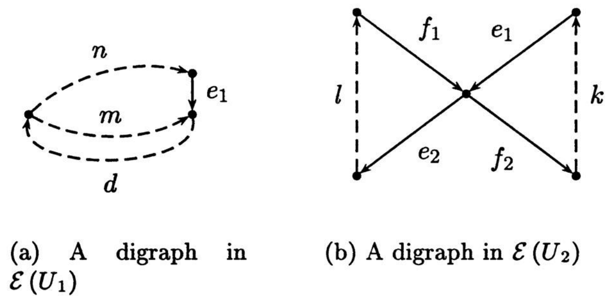
**Algorithm 4 :** Digraph simple-path stability

```
INPUT: A strongly connected digraph $G$
**if** $G$ does not have a directed $k$-cycle with $k \geq 3$ **then**
  return yes
**else**
  compute a directed cycle $C = (v_k, e_1, v_1, \dots , v_{k-1} e_k, v_k)$ in $G$ ($k \geq 3$)
  **if** any of the cycle arcs has multiplicity bigger than one **then**
    return no
  **end if**
  Let $e'_i$ be the arc opposite to $e_i$, $1 \leq i \leq k$
  **if** all the arcs $e'_i$ are present in $G$ and some of them have multiplicity bigger than one **then**
    return no
  **end if**
  Let $G'$ be the digraph obtained by setting the multiplicity of all arcs in $G$ to one and by removing the arcs in $C$ and all the opposite arcs $e'_i$ (if any).
  **if** there are 2-cycle vertices connected by a directed path in $G'$ **then**
    return no
  **else**
    Compute the strongly connected components of $G'$
    **if** a strongly connected component of $G'$ contains a directed $k$-cycle with $k \geq 3$ **then**
      return no
    **else**
      return yes
    **end if**
  **end if**
**end if**
```

testing universal stability is equivalent to testing stability under NTG-LIS. Moreover, deciding whether a network is stable under the NTG-LIS protocol can also be solved in polynomial time. The equivalences hold for all the cases of universal stability considered in this work, as we state in the following theorem.

THEOREM 17. *The following equivalences hold:*

- *A digraph G is stable under* NTG-LIS *if and only if G is universally stable.*
- *A digraph G is simple-path stable under* NTG-LIS *if and only if G is simple-*



n

$f_1$
$e_1$
$l$
$k$
$e_2$
$f_2$
(b) A digraph in $\mathcal{E}(U_2)$

FIG. 6. *Family of digraphs formed by extensions of $U_1$ and $U_2$.*

*path universally stable.*

- *A graph G is stable under* NTG-LIS *if and only if G is universally stable.*
- *A graph G is undirected-path stable under* NTG-LIS *if and only if the graph G is undirected-path universally stable.*
- *A graph G is simple-path stable under* NTG-LIS *if and only if G is simple-path universally stable.*

A similar result was obtained in [1] for the universal stability of digraphs under the FFS protocol, for which the same characterization (i.e., in terms of the family of graphs generated from $U_1$ and $U_2$; see Figure 4(a)) is obtained. The technique can be easily extended to show the equivalence of stability under FFS and universal stability in all the models of adversary considered in this work. To the best of our knowledge the complexity of deciding stability under other nonuniversally stable protocols is still open, in particular for FIFO and LIFO. Even though much effort has been devoted to the study of the FIFO protocol, it is still not known whether deciding stability under FIFO is polynomial time decidable. The bottleneck, with regard to the characterization of universal stability, is whether the pair $(U_1, \text{FIFO})$ is stable, as the pair $(U_2, \text{FIFO})$ was shown to be not stable in [2].

## Appendix A. Proof of Theorem 3.

All the instability proofs are based on induction. A set of rounds compose a step of the induction reasoning. The goal is to demonstrate that the number of packets in the system can increase from one step to the next (and, by applying the inductive hypothesis, they can increase indefinitely). The configuration of the system at the end of every step must be the same as the configuration at the beginning of each inductive step (in terms of the type of packets and their location), but with an increased number of packets. In these appendices we reproduce only the inductive step.

LEMMA 9. *The pair $(U_2, \text{NTG-LIS})$ is not stable.*

*Proof.* At the beginning there are $s$ packets that must traverse edge $f_2$. Half of them are of the form $(e_1\ f_2)$, and half are of the form $(e_2\ f_1\ f_2)$. Then the adversary will play injections in four rounds.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(f_2\ e_1)$. These injections get mixed with the initial packets at edge $f_2$ and are blocked there because the queuing protocol is NTG.

*Round* 2. For the next $rs$ steps, the adversary injects a set of $r^2s$ packets of the form $(f_2\ e_1\ e_2)$ that are blocked by the remaining packets at $f_2$ from the previous round because the protocol is NTG.

*Round* 3. For the next $r^2s$ steps, the adversary injects $r^3s$ packets of the form

$(e_2)$ and $r^3s$ of the form $(e_1\ f_2)$. A total number of $r^3s$ packets of the from $(e_2)$ will remain at $e_2$. Injections of the form $(e_1\ f_2)$ will meet packets from the previous round at edge $e_1$ and, because the secondary protocol is LIS, they all will be blocked at this edge.

*Round* 4. For the next $r^3s$ steps, the adversary injects $r^4s$ packets of the form $(e_2\ f_1\ f_2)$ and $r^4s$ packets of the form $(e_1)$. The simple injections at $e_1$ block the packets $(e_1\ f_2)$ from the previous round because their distance to destination is shorter. The $(e_2\ f_1\ f_2)$ injections are blocked by the $(e_2)$ packets from the previous round.

At the end of the fourth round there are $r^4s$ packets of the form $(e_2\ f_1\ f_2)$ and $r^4s$ packets of the form $(e_1\ f_2)$. If cycles are allowed, the adversary described above makes the network $U_2$ nonstable when $2r^4s > s$, i.e., at injection rate $r > 0.84089$. □

LEMMA 10. *Any graph in* $\mathcal{E}(U_1)$ *is not stable for* NTG-LIS.

*Proof.* Let $G$ be the graph in $\mathcal{E}(U_1)$ described in Figure 6(a). This graph is obtained from $\mathcal{S}_1$ by replacing the edges by paths. Let us denote by $p_n$, $p_m$, and $p_d$ the path replacing the edges. Let us assume that $n \geq m-1$. The adversary operates in four rounds. Initially, there are $s$ packets wanting to traverse $p_d$ and they are distributed in the following way: $x$ packets of the form $(p_n\ e_1\ p_d)$ and $y$ packets of the form $(p_m\ p_d)$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(p_d\ p_m)$. These injections are blocked by the initial packets because the queuing protocol is NTG, but $rm$ of them are lost. We consider a big enough $s$ to guarantee that a continuous flow arrives to the first edge of $p_d$ after the arrival of the first packet.

*Round* 2. For the next $rs - rm$ steps, the adversary injects a set of $r^2s - r^2m$ packets of the form $(p_d\ p_n\ e_1)$ and $r^2s - r^2m$ packets of the form $(p_m)$. These injections are blocked by the remaining packets from the previous round because the queuing protocol is NTG (or because of the LIS protocol if $n = m-1$). Note that $rd$ injections of the form $(p_m)$ will be lost.

*Round* 3. For the next $r^2s - r^2m$ steps, the adversary injects $r^3s - r^3m$ packets of the form $(p_m)$ that will all be blocked by packets from the previous round. The adversary also injects $r^3s - r^3m$ packets of the form $(p_n\ e_1\ p_d)$ that will collapse with packets from the previous round. These injections will be blocked there because their distance to destination is longer at that point, but $rd$ of them will be lost. At the end of this round there are $r^3s - r^3m - r^2d$ packets of the form $(p_m)$ and $r^3s - r^3m - rd$ packets of the form $(p_n\ e_1\ p_d)$.

*Round* 4. For the next $r^3s - r^3m - r^2d$ steps, the adversary injects $r^4s - r^4m - r^3d$ packets of the form $(p_n\ e_1)$ and $r^4s - r^4m - r^3d$ packets of the form $(p_m\ p_d)$. The injections on $p_n$ will keep some packets of the previous round blocked, and the injections on $p_m$ will be blocked by the remaining packets from the previous round.

At the end of the fourth round, there are $r^4s - r^4m + r^3d - r^2d$ packets of the form $(p_n\ e_1\ p_d)$ and $r^4s - r^4m - r^3d$ packets of the form $(p_m\ p_d)$. The adversary described above uses packets describing cycles and makes the graph $G$ described above nonstable when $2r^4s - 2r^4m - r^2d > s$. Note that $C = 2r^4m + r^2d > 2m + d$ and, for a big enough $s$, an injection rate $r$ can be found such that $2r^4s - C > s$ holds. □

LEMMA 11. *Any graph in* $\mathcal{E}(U_2)$ *is not stable for* NTG-LIS.

*Proof.* Let $G$ be a graph in $\mathcal{E}(U_2)$ described in Figure 6(b). This graph is formed from $\mathcal{S}_2$ by extending its cycles with paths. We call $p_k$ and $p_l$ the additional edges in the two sides, noting that $k$, $l$, or both may be zero. The adversary operates in four rounds. Initially, there are $\frac{s}{2}$ packets of the form $(e_1\ f_2)$ and $\frac{s}{2}$ packets of the form $(e_2\ p_l\ f_1\ f_2)$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(f_2\ p_k\ e_1)$. These injections are blocked by the initial packets because the queuing protocol is NTG. Note that $rl$ of such new packets are lost.

*Round* 2. For the next $rs - rl$ steps, the adversary injects a set of $r^2s - r^2l$ packets of the form $(f_2\ p_k\ e_1\ e_2)$. These injections are blocked by the remaining packets from the previous round because the queuing protocol is NTG.

*Round* 3. For the next $r^2s - r^2l$ steps, the adversary injects $r^3s - r^3l$ packets of the form $(e_2)$ and $r^3s - r^3l$ of the form $(e_1\ f_2)$. These injections will be blocked by packets from the previous round when collapsing at edges $e_2$ and $e_1$, respectively, but $rk$ of them will be lost.

*Round* 4. For the next $r^3s - r^3l - rk$ steps, the adversary injects $r^4s - r^4l - r^2k$ packets of the form $(e_1)$ that will block packets from the previous round at $e_1$ because they are closer to their destination. The adversary also injects $r^4s - r^4l - r^2k$ packets of the form $(e_2\ p_l\ f_1\ f_2)$ that will be blocked by the $(e_2)$ remaining packets from the previous round.

At the end of the fourth round, there are $r^4s - r^4l - r^2k$ packets of the form $(e_2\ p_l\ f_1\ f_2)$ and $r^4s - r^4l - r^2k$ packets of the form $(e_1\ f_2)$. The adversary described above uses packets describing cycles and makes the graph $G$ described above nonstable when $2(r^4s - r^4l - r^2k) > s$. Note that $C = 2(l + k) > 2(r^4l + r^2k)$, and, for a big enough $s$, an injection rate $r$ can be found such that $2r^4s - C > s$ holds. □

## Appendix B. Proof of Theorem 4.

LEMMA 12. *The pair $(S_1,$ NTG-LIS$)$ is not simple-path stable.*

*Proof.* The adversary operates in five rounds. Initially, there are $\frac{s}{2}$ packets of the form $(e_1\ f_1)$ and $\frac{s}{2}$ of the form $(e_2\ f_1)$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(f_1\ f_2)$. These injections get mixed with the initial packets at edge $f_1$ and are blocked there because the protocol is NTG.

*Round* 2. For the next $rs$ steps, the adversary injects a set of $r^2s$ packets of the form $(f_2\ e_2)$ that are blocked at $f_2$ by the packets from the first round because, at that point, they are at longer distance to their destination.

*Round* 3. For the next $r^2s$ steps, the adversary injects $r^3s$ packets of the form $(e_2)$ and $r^3s$ of the form $(f_2\ e_1)$. All these injections are blocked by the remaining packets from the previous round because the secondary protocol is LIS.

*Round* 4. For the next $r^3s$ steps, the adversary injects $r^4s$ packets of the form $(e_1)$ and $r^4s$ packets of the form $(e_2\ f_1)$. A total number of $r^4s$ simple packets will remain at $e_1$. The injections of the form $(e_2\ f_1)$ are blocked at $e_2$ by packets from the previous round because distance to their destination is longer.

*Round* 5. For the next $r^4s$ steps, the adversary injects $r^5s$ packets of the form $(e_1\ f_1)$ and $r^5s$ packets of the form $(e_2)$. The simple packets queued at $e_1$ from the previous round will block the injections introduced at this edge. The simple injections at $e_2$ will block the packets of the form $(e_2\ f_1)$ from the previous round.

At the end of the fifth round, there are $r^5s$ packets of the form $(e_2\ f_1)$ and $r^5s$ packets of the form $(e_1\ f_1)$. The adversary described above uses only packets describing simple paths and makes network $U_1$ nonstable when $2r^5s > s$, i.e., at injection rate $r > 0.87055$. □

LEMMA 13. *The pair $(S_2,$ NTG-LIS$)$ is not simple-path stable.*

*Proof.* The adversary operates in four rounds in this case. Initially, there are $\frac{s}{2}$ packets of the form $(e_{12}\ f)$ and $\frac{s}{2}$ of the form $(e_{22}\ f)$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(f\ e_{21})$. These injections get mixed with the initial packets and are blocked in edge $f$ because the protocol is NTG.

*Round* 2. For the next $rs$ steps, the adversary injects a set of $r^2s$ packets of the form $(f\ e_{11})$ and $r^2s$ packets of the form $(e_{21}\ e_{22})$. The injections made on $f$ are blocked by old packets because in this situation the secondary protocol LIS is applied. When the $(f\ e_{21})$ packets from the previous round reach edge $e_{21}$, they block the injections made on $e_{21}$. So at this round all the injections introduced are blocked.

*Round* 3. For the next $r^2s$ steps, the adversary injects $r^3s$ packets of the form $(e_{22}\ f)$ and $r^3s$ of the form $(e_{11}\ e_{12})$. The injections on $e_{22}$ are blocked by packets of the form $(e_{21}\ e_{22})$ from the previous round. The injections introduced on $e_{11}$ are blocked by packets from the previous round at $e_{11}$ because their destination is farther.

*Round* 4. For the next $r^3s$ steps, the adversary injects $r^4s$ packets of the form $(e_{12}\ f)$ and $r^4s$ packets of the form $(e_{22})$. Injections on $e_{12}$ are blocked by old packets, and injections on $e_{22}$ block old packets of the form $(e_{22}\ f)$.

At the end of the fourth round, there are $2r^4s$ packets queued at $e_{12}$ and $e_{22}$ that want to traverse edge $f$; $r^4s$ are of the form $(e_{12}\ f)$ and $r^4s$ are of the form $(e_{22}\ f)$. The adversary described above uses only simple paths and makes network $S_2$ nonstable when $2r^4s > s$, i.e., at injection rate $r > 0.84089$. $\square$

LEMMA 14. *The pair* $(S_3, \text{NTG-LIS})$ *is not simple-path stable.*

*Proof.* The adversary operates in four rounds. Initially, there are $\frac{s}{2}$ packets of the form $(e_1\ f_{21})$ and $\frac{s}{2}$ of the form $(e_{22}\ f_1\ f_{21})$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(f_{21}\ f_{22})$. These injections get mixed with the initial packets and get blocked in edge $f_{21}$ because the protocol is NTG.

*Round* 2. For the next $rs$ steps, the adversary injects a set of $r^2s$ packets of the form $(f_{22}\ e_1\ e_{21})$ that are blocked at $f_{22}$ by the packets from the first round because, at that point, they are at longer distance to their destination.

*Round* 3. For the next $r^2s$ steps, the adversary injects $r^3s$ packets of the form $(e_{21}\ e_{22})$ and $r^3s$ of the form $(e_1\ f_{21})$. The injections introduced at $e_1$ reach the packets from the previous round at this edge, but they are blocked there because the secondary protocol is LIS. Old packets block the injections introduced at their last edge $e_{21}$.

*Round* 4. For the next $r^3s$ steps, the adversary injects $r^4s$ packets of the form $(e_{22}\ f_1\ f_{21})$ and $r^4s$ packets of the form $(e_1)$. The simple injections on $e_1$ will block the packets queued at this edge from the previous round. Injections of the form $(e_{22}\ f_1\ f_{21})$ are blocked at $e_{22}$ by packets from the previous round because distance to their destination is longer.

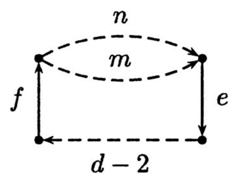
At the end of the fourth round, there are $r^4s$ packets of the form $(e_{22}\ f_1\ f_{21})$ queued at $e_{22}$, and $r^4s$ of the form $(e_1\ f_{21})$ queued at $e_1$. The adversary described above uses only simple paths and makes network $S_3$ nonstable when $2r^4s > s$, i.e., at rate $r > 0.84089$. $\square$

LEMMA 15. *The pair* $(S_4, \text{NTG-LIS})$ *is not simple-path stable.*

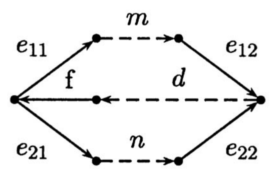
*Proof.* The adversary operates in four rounds. Initially, there are $\frac{s}{2}$ packets of the form $(e_1\ f_{21})$ and $\frac{s}{2}$ of the form $(e_{22}\ f_1\ g_2\ f_{21})$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(f_{21}\ f_{22})$. These injections get mixed with the initial packets and are blocked in edge $f_{21}$ because the protocol is NTG.

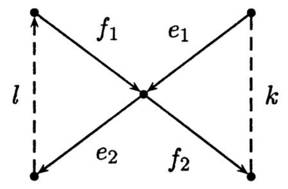
*Round* 2. For the next $rs$ steps, the adversary injects a set of $r^2s$ packets of the



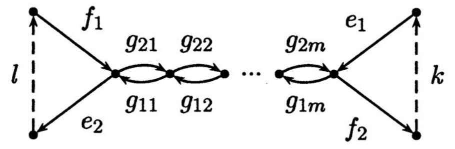
**(a) A digraph in $\mathcal{E}(S_1)$**



**(b) A digraph in $\mathcal{E}(S_2)$**



**(c) A graph in $\mathcal{E}(S_3)$**



**(d) A digraph in $\mathcal{E}(S_4)$**

FIG. 7. *Family of digraphs formed by extensions of $S_1$, $S_2$, $S_3$, and $S_4$.*

form $(f_{22}\ e_1\ g_1)$ that are blocked at $f_{22}$ by the packets from the first round because, at that point, they are at longer distance to their destination.

*Round* 3. For the next $r^2s$ steps, the adversary injects $r^3s$ packets of the form $(g_1\ e_{21}\ e_{22})$ and $r^3s$ of the form $(e_1\ f_{21})$. The injections introduced at $e_1$ reach the packets from the previous round at this edge, but they are blocked there because the secondary protocol is LIS. When the old packets arrive at their last edge $g_1$, they block the injections introduced at that edge. So, at this round, all the injections are blocked.

*Round* 4. For the next $r^3s$ steps, the adversary injects $r^4s$ packets of the form $(e_{22}\ f_1\ g_2\ f_{21})$ and $r^4s$ packets of the form $(e_1)$. The simple injections on $e_1$ will block the packets queued at this edge from the previous round. Injections of the form $(e_{22}\ f_1\ g_2\ f_{21})$ are blocked at $e_{22}$ by packets from the previous round because distance to their destination is longer.

At the end of the fourth round, there are $r^4s$ packets of the form $(e_{22}\ f_1\ g_2\ f_{21})$ queued at $e_{22}$, and $r^4s$ packets of the form $(e_1\ f_{21})$ queued at $e_1$. The adversary described above uses only packets defining simple paths and makes the $S_4$ network nonstable when $2r^4s > s$, i.e., at injection rate $r > 0.84089$. ☐

LEMMA 16. *Any graph in $\mathcal{E}(S_1)$ is not stable for* NTG-LIS.

*Proof.* Let $G$ be the graph in $\mathcal{E}(S_1)$ described in Figure 7(a). There are two vertices $a$ and $b$ with two paths $p_n$ and $p_m$ from $a$ to $b$ and a path $p_d$ from $b$ to $a$, with $d \geq 2$. We assume that $n \geq m$. We call $e$ and $f$ the first and last edges in $p_d$, respectively. By including a whole path (e.g., $p_d$) in the description of the form of a packet, we mean that the path to be followed by the packet must include all of this path. The adversary operates in five rounds. Initially, there are $\frac{s}{2}$ packets of the form $(p_n\ e)$ and $\frac{s}{2}$ of the form $(p_m\ e)$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(p_d)$. These injections get mixed with the initial packets at edge $e$. Except for the first $rm$ injections, the rest are blocked there because the queuing protocol is NTG ($m$ is the time in which a first packet arrives to $e$). We consider $s$ big enough to guarantee that a continuous flow arrives to edge $e$ after the arrival of the first packet.

*Round* 2. For the next $rs - rm$ steps, the adversary injects a set of $r^2s - r^2m$ packets of the form $(f\ p_m)$. These packets will be blocked at $f$ by the packets from the first round because they will be at longer distance to their destination, but notice that $rd$ of them will not be blocked ($d$ is the time needed for the first packet in $e$ to reach $f$).

*Round* 3. For the next $r^2s - r^2m - rd$ steps, the adversary injects $r^3s - r^3m - r^2d$ packets of the form $(p_m)$ and $r^3s - r^3m - r^2d$ packets of the form $(f\ p_n)$. The first injections are blocked because secondary protocol is LIS. The later injections are blocked because $n \geq m$ (or also because of the LIS protocol if $n = m$).

*Round* 4. For the next $r^3s - r^3m - r^2d$ steps, the adversary injects $r^4s - r^4m - r^3d$ packets of the form $(p_n)$, which are blocked due to the LIS effect. Also $r^4s - r^4m - r^3d$ packets of the form $(p_m\ e)$ are injected, which are blocked at the first edge of $p_m$ by packets from the previous round because distance to their destination is longer.

*Round* 5. For the next $r^4s - r^4m - r^3d$ steps, the adversary injects $r^5s - r^5m - r^4d$ packets of the form $(p_n\ e)$, all of which will be blocked by the packets of the form $(p_n)$ from the previous round. The adversary also introduces $r^5s - r^5m - r^4d$ injections of the form $(p_m)$, which will block the packets of the form $(p_m\ e)$ queued since the previous round.

At the end of the fifth round, there are $r^5s - r^5m - r^4d$ packets of the form $(p_n\ e)$ and $r^5s - r^5m - r^4d$ packets of the form $(p_m\ e)$. The adversary described above uses only packets describing simple paths and makes the graph $G$ described above nonstable when $2(r^5s - r^5m - r^4d) > s$. Note that $C = 2(m + d) > 2(r^5m + r^4d)$ is a constant quantity and then, for a big enough $s$, an injection rate $r$ can be found such that $2r^5s - C > s$ holds. $\square$

LEMMA 17. *Any graph in $\mathcal{E}(S_2)$ is not simple-path path stable for* NTG-LIS.

*Proof.* Let $G$ be a digraph in $\mathcal{E}(S_2)$ described in Figure 7(b). This graph is formed from $S_2$ by extending its cycles with paths of length $m$, $n$, and $d$, with $m, n, d \geq 0$. We denote by $p_m$, $p_n$, and $p_d$ the additional path in the respective side. The adversary operates in four rounds. Initially, there are $\alpha$ packets of the form $(e_{12}\ p_d\ f)$ and $\beta$ packets of the form $(e_{22}\ p_d\ f)$, where $\alpha + \beta = s$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(p_d\ f\ e_{21})$. These injections are blocked at the first edge of $p_d\ f$ because the queuing protocol is NTG.

*Round* 2. For the next $rs$ steps, the adversary injects a set of $r^2s$ packets of the form $(f\ e_{11}\ p_m)$ and also $r^2s$ packets of the form $(e_{21}\ p_n\ e_{22})$. Both types of injections will collapse with the remaining packets from the previous round but their destination is always farther; thus they are blocked. Note, however, that $rd$ of each type of packets are lost.[2]

*Round* 3. For the next $r^2s - rd$ steps, the adversary injects $r^3s - r^2d$ packets of the form $(e_{11}\ p_m\ e_{12})$, which are blocked by the remaining packets from the previous round because the protocol is NTG. The adversary also injects $r^3s - r^2d$ packets of the form $(p_n\ e_{22}\ p_d\ f)$, which block $r^3s - r^2d$ of the remaining packets from the previous round because of the same reason.

*Round* 4. For the next $r^3s - r^2d$ steps, the adversary injects $r^4s - r^3d$ packets of the form $(e_{12}\ p_d\ f)$ and also $r^4s - r^3d$ packets of the form $(e_{22})$. The injections on $e_{12}$ are blocked by packets from the previous round, but $rm$ of them are lost. The

[2]More exactly, $r(d + 1)$ of the type $(e_{21}\ p_n\ e_{22})$ are lost, but we round to $rd$ to clarify the proof.

simple injections on $e_{22}$ block packets queued at the previous round, but $rn$ of them are lost.

At the end of the fourth round, there are $r^4 s - r^3 d - rm$ packets of the form $(e_{12}\ p_d\ f)$ queued at $e_{12}$ and $r^4 s - r^3 d - rn$ packets of the form $(e_{22}\ p_d\ f)$ queued at $e_{22}$. The adversary described above uses only packets defining simple paths and makes the digraph described in Figure 7(b) nonstable when $2(r^4 s - r^3 d) - rm - rn > s$. Note that $C = 2d + m + n > 2r^3 d + rm + rn$ and, for a big enough $s$, an injection rate $r$ can be found such that $2r^4 - C > s$ holds. □

LEMMA 18. *Any digraph $G$ in $\mathcal{E}(S_3)$ is not simple-path stable for* NTG-LIS.

*Proof.* Let $G$ be a digraph in $\mathcal{E}(S_3)$ described in Figure 7(c). This graph is formed from $S_3$ by extending its cycles with paths of length $l$ and $k$, $l, k \geq 1$. We denote by $p_k$ and $p_l$ the additional path in the respective side. The adversary operates in four rounds. Initially, there are $\frac{s}{2}$ packets of the form $(e_1\ f_2)$ and $\frac{s}{2}$ packets of the form $(p_l\ f_1\ f_2)$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(f_2\ p_k)$. These injections are blocked by the initial packets because the queuing protocol is NTG. Note that $rl$ of such new packets are lost.

*Round* 2. For the next $rs - rl$ steps, the adversary injects a set of $r^2 s - r^2 l$ packets of the form $(p_k\ e_1\ e_2)$. These injections are blocked by the remaining packets from the previous round because the queuing protocol is NTG.

*Round* 3. For the next $r^2 s - r^2 l$ steps, the adversary injects $r^3 s - r^3 l$ packets of the form $(e_2\ p_l)$ and $r^3 s - r^3 l$ of the form $(e_1\ f_2)$. These injections will be blocked by packets from the previous round when collapsing at edges $e_2$ and $e_1$, respectively, but $rk$ of them will be lost.

*Round* 4. For the next $r^3 s - r^3 l - rk$ steps, the adversary injects $r^4 s - r^4 l - r^2 k$ packets of the form $(e_1)$ that will block packets from the previous round at $e_1$ because they are closer to their destination. The adversary also injects $r^4 s - r^4 l - r^2 k$ packets of the form $(p_l\ f_1\ f_2)$ that will be blocked by the remaining $(e_2\ p_l)$ packets from the previous round.

At the end of the fourth round, there are $r^4 s - r^4 l - r^2 k$ packets of the form $(p_l\ f_1\ f_2)$ and $r^4 s - r^4 l - r^2 k$ packets of the form $(e_1\ f_2)$. The adversary described above uses packets following simple paths and makes the graph $G \in \mathcal{E}(S_3)$ nonstable when $2(r^4 s - r^4 l - r^2 k) > s$. Note that $C = 2(l + k) > 2(r^4 l + r^2 k)$ and, for a big enough $s$, an injection rate $r$ can be found such that $2r^4 s - C > s$ holds. □

LEMMA 19. *Any digraph $G$ in $\mathcal{E}(S_4)$ is not simple-path path stable for* NTG-LIS.

*Proof.* Let $G$ be a digraph in $\mathcal{E}(S_4)$. Notice that if one of the arcs in the 2-cycle is subdivided, $G$ contains as a subgraph a graph in $\mathcal{E}(S_3)$ that by Lemma 18 is NTG-LIS nonstable. Therefore we will consider the case described in Figure 7(d). This graph is formed from $S_4$ by extending its 3-cycles with paths of length $l$ and $k$, $l, k \geq 1$, and its 2-cycle by $m$, $m \geq 1$, 2-cycle successive subdivisions. Let us denote by $p_l$ and $p_k$ the paths of length $l$ and $k$, by $p_m^1$ the path $(g_{11}\ g_{12}\ \dots\ g_{1m})$, and by $p_m^2$ the path $(g_{21}\ g_{22}\ \dots\ g_{2m})$. The adversary operates in four rounds. Initially, there are $\frac{s}{2}$ packets of the form $(e_1\ f_2)$ and $\frac{s}{2}$ of the form $(p_l\ f_1\ p_m^2\ f_2)$.

*Round* 1. For $s$ steps, the adversary injects $rs$ packets of the form $(f_2\ p_k)$. These injections get mixed with the initial packets at edge $f_2$ and are blocked there because the queuing protocol is NTG. Note that $r(m + l)$ of such new packets are lost.

*Round* 2. For the next $rs - r(m + l)$ steps, the adversary injects a set of $r^2 s - r^2(m + l)$ packets of the form $(p_k\ e_1\ g_{1m})$ that are blocked at the first edge of $p_k$ by the packets from the first round because, at that point, they are at longer distance to their destination.

*Round* 3. For the next $r^2s - r^2(m+l)$ steps, the adversary injects $r^3s - r^3(m+l)$ packets of the form $(p_m^1\ e_2\ p_l)$ and $r^3s - r^3(m+l)$ of the form $(e_1\ f_2)$. The injections introduced at $e_1$ reach the packets from the previous round at this edge, but they are blocked there because the secondary protocol is LIS. When the old packets arrive at their last edge $g_{1k}$, they block the injections introduced.

*Round* 4. For the next $r^3s - r^3(m+l)$ steps, the adversary injects $r^4s - r^4(m+l)$ packets of the form $(p_l\ f_1\ p_m^2\ f_2)$ and $r^4s - r^4(m+k)$ packets of the form $(e_1)$. The simple injections on $e_1$ will block the packets queued at this edge from the previous round. The other injections are blocked at the first edge of $p_l$ by packets from the previous round because distance to their destination is longer, but note that $rm$ of them are lost.

At the end of the fourth round, there are $r^4s - r^4(m+l)$ packets of the form $(e_1\ f_2)$ queued at $e_1$ and $r^4s - r^4(m+l) - rm$ packets of the form $(p_l\ f_1\ p_m^2\ f_2)$ queued at the first edge of $p_l$. The adversary described above uses only packets following simple paths and makes the digraph $G$ described in Figure 7(d) nonstable when $2(r^4s - r^4(m+l)) - rm > s$. Note that $C = 2(m+l) > 2r^4(m+l) - rm$ and, for a big enough $s$, an injection rate $r$ can be found such that $2r^4 - C > s$ holds. ∎

# PSEUDORANDOM GENERATORS IN PROPOSITIONAL PROOF COMPLEXITY[*]

MICHAEL ALEKHNOVICH[†], ELI BEN-SASSON[‡], ALEXANDER A. RAZBOROV[§], AND AVI WIGDERSON[¶]

**Abstract.** We call a pseudorandom generator $G_n : \{0,1\}^n \to \{0,1\}^m$ *hard* for a propositional proof system $P$ if $P$ cannot efficiently prove the (properly encoded) statement $G_n(x_1, \dots, x_n) \neq b$ for *any* string $b \in \{0,1\}^m$. We consider a variety of "combinatorial" pseudorandom generators inspired by the Nisan–Wigderson generator on the one hand, and by the construction of Tseitin tautologies on the other. We prove that under certain circumstances these generators are hard for such proof systems as resolution, polynomial calculus, and polynomial calculus with resolution (PCR).

**Key words.** generator, propositional proof complexity, resolution, polynomial calculus

## 1. Introduction.

The notion of a pseudorandom generator, originally introduced by Yao [Yao82], has become by now one of the most important concepts in theoretical computer science, penetrating virtually all its subareas. In its simplest form it says the following: a mapping $G_n : \{0,1\}^n \to \{0,1\}^m$ is (computationally) secure with respect to (w.r.t.) some circuit class $\mathcal{C}$ if no "small" circuit $C(y_1, \dots, y_m) \in \mathcal{C}$ can distinguish between the two probabilistic distributions $G_n(\boldsymbol{x})$ and $\boldsymbol{y}$ in the sense that $|\mathbf{P}[C(G_n(\boldsymbol{x})) = 1] - \mathbf{P}[C(\boldsymbol{y}) = 1]|$ is small ($\boldsymbol{x}$ is picked at random from $\{0,1\}^n$, and $\boldsymbol{y}$ is picked at random from $\{0,1\}^m$).

Propositional proof complexity is an area of study that has seen rapid development over the last decade. It plays as important a role in the theory of feasible proofs as the role of the complexity of Boolean circuits plays in the theory of efficient computations. Although the original motivations for this study were in many cases different (and originated from proof-theoretical questions about first-order theories), it turns out after all that the complexity of propositional proofs revolves around the following basic question: What can be *proved* (in the ordinary mathematical sense!) by a prover whose *computational* abilities are limited to small circuits from some circuit class $\mathcal{C}$ (see, e.g., [BP98])? Thus, propositional proof complexity is in a sense complementary to (nonuniform) computational complexity; moreover, there exist extremely rich and productive relations between the two areas (see [Raz96, BP98]).

Given the importance of pseudorandom generators for computational complexity, it is natural to wonder which mappings $G_n : \{0,1\}^n \to \{0,1\}^m$ should be considered

hard from the perspective of proof complexity. In this paper we propose the following paradigm: a generator $G_n : \{0,1\}^n \to \{0,1\}^m$ is hard for some propositional proof system $P$ if and only if for *any* string $b \in \{0,1\}^m$ there is no efficient $P$-proof of the (properly encoded) statement $G(x_1, \dots, x_n) \neq b$ ($x_1, \dots, x_n$ are treated as propositional variables). A similar suggestion is independently made in the recent paper by Krajíček [Kra01].

This definition is very natural: it simply says (to the extent allowed by our framework) that $P$ cannot efficiently prove even the most basic thing about the behavior of $G_n$, namely, that it is not an onto mapping. In fact, one a priori reasonable concern might be precisely whether this exceedingly natural requirement is not too strong, namely, whether nontrivial generators (say, with $m \geq n+1$) can exist at all. This concern is best addressed by exhibiting how several known results fit into our framework; these examples also explain some of our motivations for introducing this concept.

*Example* 1 (Tseitin tautologies). Let $G = (V, E)$ be a connected undirected graph. Consider the ($\mathbb{F}_2$-linear) mapping $T_G : \{0,1\}^E \to \{0,1\}^V$ given by $T_G(\vec{x})_v \overset{\text{def}}{=} \oplus_{e \ni v} x_e$, where $\vec{x} \in \{0,1\}^E$ is a $\{0,1\}$-valued function on edges. Then $b \in \{0,1\}^V$ is not in $\mathrm{im}(T_G)$ if and only if $\oplus_{v \in V} b_v = 1$, and if we properly encode this statement in propositional logic, we arrive exactly at the tautologies introduced by Tseitin in his seminal paper [Tse68]. These tautologies turned out to be extremely useful in propositional proof complexity, and the many strong lower bounds proved for them [Tse68, Urq87, BW99, Gri98, BGIP01, Gri01, ABRW02] never depend on the particular choice of $b \in \{0,1\}^V$. This means that all of them can be viewed as showing that the generators $T_G$ are hard for the corresponding proof system, as long as the graph $G$ itself has good expansion properties.

Tseitin generators $T_G : \{0,1\}^E \to \{0,1\}^V$ make little sense from the computational point of view since the size of the seed $|E|$ is larger than the size of the output $|V|$. Our remaining examples are more satisfactory in this respect.

*Example* 2 (natural proofs). Let $G_n : \{0,1\}^{n^k} \to \{0,1\}^{2^n}$ be any pseudorandom *function generator* that stretches $n^k$ random bits to a Boolean function in $n$ variables viewed as a string of length $2^n$ in its truth-table representation. Assume that $G_n$ is hard w.r.t. $2^{O(n)}$-sized circuits. Razborov and Rudich [RR97] proved that there is no "natural" (in the strict sense also defined in that paper) proof of superpolynomial lower bounds for any complexity class $C$ that can efficiently compute $G_n$. Their argument shows in fact that any natural circuit lower bound techniques fail to prove that a given function $f_n$ does not belong to the image of $G_n$. Stating it equivalently, for *any* function $f_n$ there is no natural proof of the fact that $f_n \notin \mathrm{im}(G_n)$. Although in this result we are primarily interested in the case when $f_n$ is the restriction of SAT (or any other **NP**-complete predicate) onto strings of length $n$, the argument, as in Example 1, absolutely does not depend on the particular choice of $f_n$.

One might argue that natural proofs do not correspond to a propositional proof system at all, and that their definition rather explicitly includes the transition "the proof works for a single $f_n \Rightarrow$ it works for many $f_n$," which provides the link to the ordinary (randomized) definition of a pseudorandom generator. The last two examples illustrate that this drawback sometimes can be circumvented.

*Example* 3 (hardness in presence of feasible interpolation). Let $G_n : \{0,1\}^n \to \{0,1\}^m$ be an arbitrary pseudorandom generator that is hard w.r.t. polynomial size (in $m+n$) circuits, and let $n < m/2$. Following Razborov [Raz95b], let us take bitwise XOR of two independent copies of this generator $G'_n : \{0,1\}^{2n} \to \{0,1\}^m$;

$G'_n(x_1, \ldots, x_n, x'_1, \ldots, x'_n) \overset{\text{def}}{=} G_n(x_1, \ldots, x_n) \oplus G_n(x'_1, \ldots, x'_n)$. Then $G'_n$ is hard for any propositional proof system $P$ which has the property of feasible interpolation (for a definition, see, e.g., [Kra97] or [BP98]).

Indeed, assume for the sake of contradiction that $G'_n$ is easy for a proof system that possesses feasible interpolation. This means that in this system there exists a polynomial size proof of $b \notin \mathrm{im}(G'_n)$ for some string $b \in \{0,1\}^m$. Let $\boldsymbol{r}$ be picked uniformly and at random from $\{0,1\}^m$, and consider the propositional formula encoding the statement $\boldsymbol{r} \notin \mathrm{im}(G_n) \vee \boldsymbol{r} \notin \mathrm{im}(G_n \oplus b)$. The fact $b \notin \mathrm{im}(G'_n)$ implies that this is a tautology and thus, by feasible interpolation, there exists a polynomial size circuit $C$ that given $\boldsymbol{r}$ correctly tells us whether $\boldsymbol{r} \notin \mathrm{im}(G_n)$ or $\boldsymbol{r} \notin \mathrm{im}(G_n \oplus b)$. One of these answers occurs with probability at least 1/2; thus, $C$ can be used to break the generator $G$.

The study of such a keystone concept in computational complexity as pseudorandom generators, but in the new framework of proof complexity, should be interesting in its own right. As suggested by the examples above, we also keep one quite pragmatic goal in mind: we believe that pseudorandomness is methodologically the right way to think of lower bounds in the proof-theoretic setting for really strong proof systems. Whenever we have a generator $G_n : \{0,1\}^n \to \{0,1\}^{n+1}$ which is hard for a propositional proof system $P$, we have lower bounds for $P$. Suppose we manage to increase significantly the number of output bits and construct a polynomial time computable function generator $G_n : \{0,1\}^{n^k} \to \{0,1\}^{2^n}$ that is hard for $P$. Then, similarly to [RR97, Raz95b], we can conclude that the tautologies $\neg Circuit_t(f_n)$, expressing the fact that the function $f_n$ cannot be computed by a circuit of size $t$, do not have efficient $P$-proofs.[1] Our final example shows that, modulo a concrete complexity assumption (namely, that randomness helps in interactive proofs), the tautologies $\neg Circuit_t(f_n)$ are hard for *every* proof system.

*Example* 4. Assume that there is *some* proof system $P$, which efficiently proves $\neg Circuit_t(f_n)$ for *some* Boolean function $f_n$. This proof constitutes an **NP**-certificate of hardness of $f_n$. Using the derandomization machinery of the $NW$-generator [NW94, BFNW93, IW97, IKW01], it follows that for, say, $t = 2^{\epsilon n}$ (with arbitrary $\epsilon > 0$), such a certificate implies that $\mathbf{MA} = \mathbf{NP}$ (and in particular $\mathbf{BPP} \subseteq \mathbf{NP}$).[2]

Put differently, let $G_n$ be the mapping that takes (the encoding of) a circuit of size $t$ to the truth-table of the function computed by it [Raz95a, Appendix C]. Then, assuming $\mathbf{MA} \neq \mathbf{NP}$, we conclude that for an appropriate choice of $t$, there are no efficient proofs of $f_n \notin \mathrm{im}(G_n)$ for any sequence of functions $f_n$. In other words, the generator $G_n$ is hard for any propositional proof system whatsoever!

It should be stressed, however, that some of the authors believe the conclusion far more than the assumption. Nevertheless, the connection illuminates another relationship between computational and proof complexity, and the importance of generators in both.

In this paper we begin by looking at a class of generators inspired by the Nisan–

[1]Note that for $f_n$ an **NP**-complete function and $t$ superpolynomial in $n$, the tautologies $\neg Circuit_t(f_n)$ express the statement $\mathbf{NP} \not\subseteq \mathbf{P}/poly$. The general idea of this reduction to the hardness of generators is similar to the reduction in Example 2: the propositional system cannot prove efficiently that any given $f_n$ does not belong to the image of $G$. However, for every particular system the details of implementation are a little bit different, and one has to be extra careful for weak proof systems.

[2]Follows from $\mathbf{BPP} \subseteq \mathbf{MA}$ of Goldreich and Zuckerman [GZ97]. This weaker conclusion $\mathbf{BPP} \subseteq \mathbf{NP}$ of the existence of efficient proofs for $\neg Circuit_t(f_n)$ was also independently observed by Impagliazzo.

Wigderson generator [NW94] on the one hand, and by Example 1 on the other. Let $A$ be an $(m \times n)$ 0-1 matrix, let $g_1(x_1, \dots, x_n), \dots, g_m(x_1, \dots, x_n)$ be Boolean functions such that $g_i$ essentially depends only on the variables $X_i(A) \overset{\text{def}}{=} \{x_j \mid a_{ij} = 1\}$, and let $G_n : \{0,1\}^n \to \{0,1\}^m$ be given by $G_n(x_1, \dots, x_n) \overset{\text{def}}{=} (g_1(x_1, \dots, x_n), \dots, g_m(x_1, \dots, x_n))$. Nisan and Wigderson [NW94] proved that if $A$ satisfies certain combinatorial conditions (namely, if it is a $(k, s)$-design for suitable choice of parameters), and the functions $g_i$ are computationally hard, then $G_n$ is a good pseudorandom generator in the computational sense. In this paper we study which combinatorial properties of the matrix $A$ and which hardness assumptions imposed on $g_i$ guarantee that the resulting generator $G_n$ is hard for such proof systems as resolution or polynomial calculus.

The framework of proof complexity, however, adds also the third specific dimension that determines hardness properties of $G_n$. Namely, in our examples the base functions $g_i$ are at least supposed to be hard for the circuit class underlying the propositional proof system $P$. Thus, $P$ cannot even express the base functions, and we should encode them using certain extension variables. Using these extension variables, our tautologies can be written as 3-CNFs and thus can be expressed in any proof system. The choice of encoding makes an important part of the framework. We propose three different encodings: functional, circuit, and linear encodings, all natural from both computational and proof complexity viewpoints.

Our results are strong lower bounds for each of these encodings (and appropriate choices of base functions and combinatorial properties of the matrix $A$) in such standard proof systems as resolution, polynomial calculus, and PCR (which combines the power of both). Naturally, the results get weaker as the encoding strength increases.

We strongly believe that this set of tautologies can serve as hard examples for much stronger systems, and specifically that the hardness of the base functions in the generators should be a key ingredient in the proof. This factor is evident in our modest results above, and if extended to stronger systems, it may be viewed as a generalization of the feasible interpolation results, reducing in a sense proof complexity to computational complexity.

The paper is organized as follows. In section 2 we give necessary definitions and describe precisely combinatorial properties of the matrix $A$, hardness conditions imposed on the base functions $g_i$, and types of their encodings needed for our purposes.

Section 3 contains our hardness results for resolution width and polynomial calculus degree that hold for the most general functional encoding similar in spirit to the functional calculus from [ABRW02]. These can be considered as far-reaching generalizations of lower bounds for Tseitin tautologies from [BW99, BGIP01]. We also state here size lower bounds directly implied by our results via the known width/size and degree/size relations.

Section 4 contains a stronger lower bound for the weaker linear encoding. In section 5 we consider the question of maximizing the number of output bits $m = m(n)$ in the generators constructed in the previous sections. For that purpose we show that with high probability a random matrix $A$ has very good expansion properties. The paper is concluded in sections 6 and 7 with a brief account of some recent developments and several remaining open questions.

## 2. Preliminaries.

Let $x$ be a Boolean variable, i.e., a variable that ranges over the set $\{0, 1\}$. A *literal* of $x$ is either $x$ (denoted sometimes as $x^1$) or $\bar{x}$ (denoted sometimes as $x^0$). A *clause* is a disjunction of literals.

For any Boolean function $f : \{0,1\}^n \to \{0,1\}$, $Vars(f)$ will denote the set of its essential variables. An *assignment to* $f$ is a mapping $\alpha : Vars(f) \to \{0,1\}$. A *restriction of* $f$ is a mapping $\rho : Vars(f) \to \{0,1,\star\}$. We denote by $|\rho|$ the number of assigned variables, $|\rho| \overset{\text{def}}{=} |\rho^{-1}(\{0,1\})|$.

The *restriction of* $f$ *by* $\rho$, denoted $f|_\rho$, is the Boolean function obtained from $f$ by setting the value of each $x \in \rho^{-1}(\{0,1\})$ to $\rho(x)$ and leaving each $x \in \rho^{-1}(\star)$ as a variable.

We say that an assignment $\alpha$ *satisfies* $f$ if $f(\alpha) = 1$. For Boolean functions $f_1, \ldots, f_k, g$ we say that $f_1, \ldots, f_k$ *semantically imply* $g$ (denoted $f_1, \ldots, f_k \models g$) if every assignment to $V \overset{\text{def}}{=} Vars(f_1) \cup \cdots \cup Vars(f_k) \cup Vars(g)$ satisfying $f_1, \ldots, f_k$ satisfies $g$ as well (i.e., for all $\alpha \in \{0,1\}^V (f_1(\alpha) = \cdots = f_k(\alpha) = 1 \Rightarrow g(\alpha) = 1)$).

For $n$ a nonnegative integer, let $[n] \overset{\text{def}}{=} \{1, 2, \ldots, n\}$.

Let $A$ be an $(m \times n)$ 0-1 matrix,

$$J_i(A) \overset{\text{def}}{=} \{ j \in [n] \mid a_{ij} = 1 \}, \tag{1}$$

and let $X_i(A) \overset{\text{def}}{=} \{ x_j \mid j \in J_i(A) \}$ and $g_1(x_1, \ldots, x_n), \ldots, g_m(x_1, \ldots, x_n)$ be Boolean functions such that $Vars(g_i) \subseteq X_i(A)$. We will be interested in systems of Boolean equations,

$$\begin{cases} g_1(x_1, \ldots, x_n) = 1, \\ \qquad \cdots \\ g_m(x_1, \ldots, x_n) = 1. \end{cases} \tag{2}$$

We want to state combinatorial properties of the matrix $A$ and hardness conditions of the base functions $g_i$ such that if we properly encode the system (2) as a CNF $\tau(A, \vec{g})$, then this CNF does not possess efficient refutations in a propositional proof system $P$. This sentence has four ingredients, and the necessary definitions for each of them are provided fairly independently.

**2.1. Combinatorial properties of the matrix *A*.** All hardness results proved in this paper will be based on the following combinatorial property generalizing the "edge-expansion" property for ordinary graphs. It is similar to the expansion defined in [BW99].

DEFINITION 2.1. *For a set of rows* $I \subseteq [m]$ *in the matrix* $A$, *we define its* boundary $\partial_A(I)$ *as the set of all* $j \in [n]$ *(called* boundary elements*) such that* $\{ a_{ij} \mid i \in I \}$ *contains exactly one* 1. *We say that* $A$ *is an* $(r, s, c)$-expander *if* $|J_i(A)| \leq s$ *for all* $i \in [m]$ *and for all* $I \subseteq [m] (|I| \leq r \Rightarrow |\partial_A(I)| \geq c \cdot |I|)$.

Let us relate $(r, s, c)$-expanders to several other combinatorial properties already known from the literature.

*Example* 5. For an ordinary graph $G = (V, E)$, its *edge-expansion coefficient* $c_E(G)$ is defined by

$$c_E(G) \overset{\text{def}}{=} \min_{|U| \leq |V|/2} \frac{e(U, V - U)}{|U|},$$

where $e(U, W)$ is the number of edges between $U$ and $W$ (see, e.g., [Alo98] and the references therein). Let $A_G$ be the incidence matrix of a graph $G$ with $m$ vertices and $n$ edges (i.e., $a_{ve} \overset{\text{def}}{=} 1$ if and only if $v \in e$), and let $d$ be the maximal degree of a vertex in $G$. Then $A_G$ is an $(m/2, d, c)$-expander if and only if $c_E(G) \geq c$.

*Example* 6. Let us turn to the combinatorial property originally used in [N91, NW94]. A matrix $A$ is called $(k,s)$-*design* if $|J_i(A)| = s$ for all $i \in [m]$ and

$$|J_{i_1}(A) \cap J_{i_2}(A)| \le k \tag{3}$$

for all $1 \le i_1 < i_2 \le m$. We have the following.

FACT 1. *Every $(k,s)$-design is also an $(r, s, s-kr)$-expander for any parameter $r$.*

*Proof.* Let $I \subseteq [m]$ and $|I| \le r$. Then, due to the property (3), every $J_i(A)$ with $i \in I$ has at most $k \cdot (r-1)$ elements which are *not* in $\partial_A(I)$. Hence it contains at least $s - k \cdot (r-1)$ elements which *are* in $\partial_A(I)$. □

**2.2. Hardness conditions on the base functions.** As explained in the introduction, we are interested in the methods which, given a mapping $G_n : \{0,1\}^n \to \{0,1\}^m$, allow us to show that the fact $b \notin \mathrm{im}(G_n)$ is hard to prove *for any* $b \in \{0,1\}^m$. This means that we want our lower bounds on the refutation complexity to work uniformly not only for system (2) but also for *all* $2^m$ shifted systems,

$$\begin{cases} g_1(x_1, \ldots, x_n) = b_1, \\ \qquad \cdots \\ g_m(x_1, \ldots, x_n) = b_m, \end{cases}$$

$b \in \{0,1\}^m$. We will enforce this simply by requiring that the conditions placed on the base functions $g_1, \ldots, g_m$ be symmetric; i.e., they are satisfied by some $f$ if and only if they are satisfied by $(\neg f)$.

DEFINITION 2.2. *A Boolean function $f$ is $\ell$-*robust *if every restriction $\rho$ such that $f|_\rho = \mathrm{const}$ satisfies $|\rho| \ge \ell$.*

Clearly, this property is symmetric. The most important example of robust functions are the PARITY functions $x_1 \oplus \cdots \oplus x_n \oplus b$, $b \in \{0,1\}$, which are $n$-robust. Our strongest hardness results for the polynomial calculus work only for this specific function.

In fact, $\ell$-robust functions are already very familiar from the computational complexity literature. [FSS84, Ajt83, Yao85, Hås86] proved *computational* lower bounds for $\ell$-robust functions (when $\ell$ is close to $n = |Vars(f)|$) w.r.t. bounded-depth circuits. $(1-\theta)n$-robust functions (where $\theta$ is meant to be a small positive constant) were recently used in [BST98] for obtaining strong lower bounds for branching programs (property "$\mathcal{P}(\theta)$"). In this paper we will use $\ell$-robust functions for constructing generators that are hard for propositional *proof* systems. It is easy to see that most functions on $n$-bits are (say) $0.9n$-robust.

**2.3. Encodings.** Having constructed system (2), we still should decide how to represent it in propositional logic. This step is nontrivial since we are deliberately interested in the case when the propositional system $P$ cannot directly speak of the functions $g_1, \ldots, g_m$. We consider three major possibilities: *functional*, *circuit*, and *linear* encodings; all of them lead to CNFs that in fact without loss of generality (w.l.o.g.) can be further restricted to 3-CNFs (see the proof of Corollary 3.5 below).

**2.3.1. Functional encoding.** This is the strongest possible encoding which is also universal in the sense that it obviously simulates any other conceivable encoding (in fact, it is a "localized" variant of the functional calculus system considered in [ABRW02]).

DEFINITION 2.3. *Let $A$ be an $(m \times n)$* 0-1 *matrix. For every Boolean function $f$ with the property $\exists i \in [m](Vars(f) \subseteq X_i(A))$, we introduce a new* extension *variable $y_f$. Let $Vars(A)$ be the set of all these variables. For the sake of convenience, single variables sometimes will be denoted as $x_i$ instead of $y_{x_i}$. For a clause $C = y_{f_1}^{\epsilon_1} \vee \cdots \vee y_{f_w}^{\epsilon_w}$ in the variables $Vars(A)$, denote by $||C||$ the Boolean function in the variables $x_1, \ldots, x_n$ given by $||C|| \overset{\text{def}}{=} f_1^{\epsilon_1} \vee \cdots \vee f_w^{\epsilon_w}$.*

*Given Boolean functions $\vec{g} = (g_1, \ldots, g_m)$ such that $Vars(g_i) \subseteq X_i(A)$, we denote by $\tau(A, \vec{g})$ the CNF in the variables $Vars(A)$ that consists of all the clauses $C = y_{f_1}^{\epsilon_1} \vee \cdots \vee y_{f_w}^{\epsilon_w}$ for which there exists $i \in [m]$ such that*

$$Vars(f_1) \cup \cdots \cup Vars(f_w) \subseteq X_i(A) \tag{4}$$

*and*

$$g_i \models ||C||. \tag{5}$$

Fact 2. *$\tau(A, \vec{g})$ is satisfiable if and only if system (2) is consistent.*

*Proof.* If $(a_1, \ldots, a_n)$ is a solution to (2), then the assignment which assigns every $y_f$ to $f(a_1, \ldots, a_n)$ is satisfying for $\tau(A, \vec{g})$. For the other direction, let $\vec{b} = (b_f | y_f \in Vars(A))$ be a satisfying assignment for $\tau(A, \vec{g})$. Let $a_j \overset{\text{def}}{=} b_{x_j}$; then, using those axioms $y_{f_1}^{\epsilon_1} \vee \cdots \vee y_{f_w}^{\epsilon_w}$ from $\tau(A, \vec{g})$ for which $f_1^{\epsilon_1} \vee \cdots \vee f_w^{\epsilon_w} \equiv 1$, we can show by induction on the circuit size of $f$ that $b_f = f(a_1, \ldots, a_n)$ for every $y_f \in Vars(A)$. In particular, $g_i(a_1, \ldots, a_n) = b_{g_i} = 1$ (since $\tau(A, \vec{g})$ contains the axiom $y_{g_i}$). Thus, the vector $(a_1, \ldots, a_n)$ is a solution to the system (2). ∎

**2.3.2. Circuit encoding.** This encoding is much more economical in terms of the number of variables than functional encoding. Also, it looks more natural and conforms better to the underlying idea of the extended Frege proof system. The tautologies under this encoding will be polynomial size as long as all $g_i$'s have polynomial size circuits, and thus are potentially hard for Frege (assuming $\mathbf{P}/poly$ contains functions computationally hard for $\mathbf{NC^1}/poly$).

Definition 2.4. *Let $A$ be an $(m \times n)$ 0-1 matrix, and let $C_1, \ldots, C_m$ be single-output Boolean circuits over an arbitrary fixed finite basis, $C_i$ being a circuit in the variables $X_i(A)$. For every $i \in [m]$ and every gate $v$ of the circuit $C_i$, we introduce a special* extension variable *$y_v$, and we identify extension variables corresponding to input gates labeled by the same variable $x_j$. Let $Vars_{\vec{C}}(A)$ be the set of all these extension variables.*

*By $\tau(A, \vec{C})$ we denote the CNF that consists of the following clauses:*

1. *$y_{v_1}^{\bar{\epsilon}_1} \vee \cdots \vee y_{v_d}^{\bar{\epsilon}_d} \vee y_v^{\pi(\epsilon_1, \ldots, \epsilon_d)}$ whenever $v := \pi(v_1, \ldots, v_d)$ is an instruction of one of the circuits $C_1, \ldots, C_m$ and $\epsilon \in \{0,1\}^d$ is an arbitrary vector;*
2. *$y_{v_i}$ when $v_i$ is the output gate of $C_i$ for all $i \in [m]$.*

For a circuit $C$ in the variables $x_1, \ldots, x_n$, let $||C||$ be the Boolean function (in the same variables $x_1, \ldots, x_n$) it computes.

Fact 3. *$\tau(A, \vec{C})$ is satisfiable if and only if the system $||C_1|| = \cdots = ||C_m|| = 1$ is consistent.*

*Proof.* The proof is similar to that of Fact 2. ∎

Fact 4. *There exists a substitution $\sigma$ of variables from $Vars_{\vec{C}}(A)$ by variables from $Vars(A)$ such that $\sigma(\tau(A, \vec{C}))$ is a subset of the set of clauses $\tau(A, ||\vec{C}||)$. In particular, every refutation of $\tau(A, \vec{C})$ in every "reasonable" propositional proof system can be transformed (by applying $\sigma$) into a refutation of $\tau(A, ||\vec{C}||)$ in the same system, which is simpler w.r.t. any "reasonable" complexity measure.*

*Proof.* Let $\sigma(y_v) \overset{\text{def}}{=} y_{||v||}$, where $||v||$ is the function computed by the gate $v$. ∎

**2.3.3. Linear encoding.** This encoding makes sense only when the functions $g_i$ are $\mathbb{F}_2$-linear forms (for historical reasons, this special case of NW-generators is often referred to as *Nisan generators*). In some cases it is more economical than functional encoding in terms of the number of variables. Also, it is much better structured, and we will take advantage of this in section 4.

DEFINITION 2.5. *Let $A$ be an $(m \times n)$ 0-1 matrix. For every $J \subseteq [n]$ such that $\exists i \in [m](J \subseteq J_i(A))$, we introduce a new* extension variable *$y_J$ (with the intended meaning $y_J \sim \oplus_{j \in J} x_j$). Let $Vars_{\oplus}(A)$ be the set of all these variables.*

*Given a Boolean vector $b \in \{0,1\}^m$, we denote by $\tau_{\oplus}(A,b)$ the CNF in the variables $Vars_{\oplus}(A)$ that consists of the following clauses:*

1. *$y_{J_1}^{\epsilon_1} \vee \cdots \vee y_{J_d}^{\epsilon_d}$ whenever there exists $i \in [m]$ such that $J_1 \cup \cdots \cup J_d \subseteq J_i(A)$, the symmetric difference $J_1 \triangle \cdots \triangle J_d$ is empty, and $\bar{\epsilon}_1 \oplus \cdots \oplus \bar{\epsilon}_d = 1$;*
2. *$y_{J_i(A)}^{b_i}$ for all $i \in [m]$.*

Let us denote by $\Sigma_i(A, b_i)$ the Boolean function $\bigoplus_{j \in J_i(A)} x_j \oplus \bar{b}_i$.

FACT 5. *$\tau_{\oplus}(A,b)$ is satisfiable if and only if the system $\Sigma_1(A,b_1) = \Sigma_2(A,b_2) = \cdots = \Sigma_m(A,b_m) = 1$ of linear equations over $\mathbb{F}_2$ is consistent.*

*Proof.* The proof follows from the observation that the conjunction of clauses $y_{J_1}^{\epsilon_1} \vee \cdots \vee y_{J_d}^{\epsilon_d}$ for all $\bar{\epsilon}_1 \oplus \cdots \oplus \bar{\epsilon}_d = 1$ is semantically equivalent to the formula $\bigoplus_{i=1}^{d} y_{J_i} = 0$. □

FACT 6. *There exists a substitution $\sigma$ of variables from $Vars_{\oplus}(A)$ by variables from $Vars(A)$ such that $\sigma(\tau_{\oplus}(A,b))$ is a subset of the set of clauses $\tau(A, \vec{\Sigma}(A,b)) \overset{\text{def}}{=} \tau(A, \Sigma_1(A,b_1), \Sigma_2(A,b_2), \ldots, \Sigma_m(A,b_m))$.*

*Proof.* $\sigma(y_J) \overset{\text{def}}{=} y_{\bigoplus_{j \in J} x_j}$. □

It might be instructive to look at the place occupied in our framework by original Tseitin tautologies (cf. Examples 1 and 5). Let $A_G$ be the incidence matrix of an undirected graph $G$. Then our framework provides three different ways[3] to talk of Tseitin tautologies for graphs $G$ of *arbitrary* degree. All these possibilities are *reasonable* in the sense that although the resulting CNF $\tau$ may have a huge size, it always possesses a sub-CNF of *polynomial* size that is still unsatisfiable. The fourth (unreasonable!) encoding is *primitive*: we allow no extension variables at all and simply represent the functions $\Sigma_i(A, b_i)$ themselves as CNFs of exponential size. For graphs of bounded degree (which is the only case researchers were interested in prior to this paper), the subtle differences between the four encodings disappear, and the whole rich spectrum of various possibilities collapses into ordinary Tseitin tautologies.

In fact, the unreasonable primitive encoding can in principle be considered in the framework of our paper as well. Namely, as we will see in section 5, good $(r,s,c)$-expanders exist even for large constants $s$ (say, $s = 10$). And for constant values of $s$, results proved in any of our reasonable encodings can be translated to the primitive encoding with only constant time increase in the size of the tautology. The primitive encoding, however, is very counterintuitive to the main idea that the base functions $g_i$ should be hard for the circuit class underlying our propositional theory, and to the hope of using these tautologies for stronger proof systems. For this reason we do not discuss in this paper either the primitive encoding itself or the trade-off between the tautology size and the bounds appearing in this encoding when $s \to \infty$.

[3]For circuit encoding we must additionally fix some natural circuits computing the functions $\Sigma_i(A, b_i)$.

## 2.4. Propositional proof systems.

**2.4.1. Resolution.** Resolution is the simplest and probably the most widely studied proof system. It operates with clauses and has one rule of inference called the *resolution rule*:

$$\frac{A \vee x \qquad B \vee \bar{x}}{A \vee B}.$$

A *resolution refutation* of a CNF formula $\tau$ is a resolution proof of the empty clause from the clauses appearing in $\tau$.

The *size* of a resolution proof is the number of different clauses within it. The *width* $w(C)$ *of a clause* $C$ is the number of literals in $C$. The *width* $w(\tau)$ *of a set of clauses* $\tau$ (in particular, the width of a resolution proof) is the maximal width of a clause appearing in this set.

The story of propositional proof complexity began some 35 years ago when, in the seminal paper [Tse68], Tseitin proved superpolynomial lower bounds on the size of any resolution refutation of (what was afterwards called) Tseitin tautologies under one extra regularity assumption on the structure of refutation. Haken [Hak85] was the first to remove this restriction and prove exponential lower bounds for general resolution (for the pigeonhole principle). Urquhart [Urq87] proved exponential lower bounds on the size of general resolution refutations for Tseitin tautologies.

Ben-Sasson and Wigderson [BW99], strengthening a result from [CEI96] (cf. section 2.4.2 below), proved the following width-size relation.

PROPOSITION 2.6. *Let $\tau$ be an unsatisfiable CNF in $n$ variables that has a resolution refutation of size $S$. Then $\tau$ has a resolution refutation of width at most $w(\tau) + O(\sqrt{n \log S})$.*

[BW99] also established a linear lower bound on the width of resolution refutation for Tseitin tautologies. In combination with Proposition 2.6, this gave an alternate (and much simpler) proof of the size lower bound from [Urq87].

**2.4.2. Polynomial calculus and PCR.** Polynomial calculus, introduced by Clegg, Edmonds, and Impagliazzo in [CEI96], is a proof system that models common algebraic reasoning. Despite its algebraic nature, polynomial calculus (PC) turned out extremely useful for studying "pure" propositional proof systems.

PC operates with polynomials $P \in F[x_1, \ldots, x_n]$ for some fixed field $F$; a polynomial $P$ is interpreted as, and often identified with, the polynomial equation $P = 0$. PC has polynomials $x_i^2 - x_i$ ($i \in [n]$) as *default axioms* and has two inference rules:

$$\frac{P_1 \qquad P_2}{\alpha P_1 + \beta P_2};\ \alpha, \beta \in F \quad \text{(scalar addition)}$$

and

$$\frac{P}{x \cdot P} \quad \text{(variable multiplication)}.$$

A *PC refutation* of a set of polynomials $\Gamma$ is a PC proof of 1 from $\Gamma$. The *degree of a PC proof* is the maximal degree of a polynomial appearing within it. The *size of a PC proof* is the total number of monomials within the proof.

First nontrivial lower bounds on the degree of PC refutations were proved by Razborov [Raz98] (for the pigeonhole principle). Grigoriev [Gri98] proved linear lower bounds on the degree of Nullstellensatz refutations (which is a subsystem of PC) for Tseitin tautologies. Finally, Buss et al. [BGIP01] extended the latter bound to arbitrary PC proofs. Following [BGIP01] and the research whose outcome is presented in this paper, Ben-Sasson and Impagliazzo [BI99] further simplified this argument and derived linear degree lower bounds for random CNFs.

[CEI96] proved that small size resolution proofs can be simulated by low degree PC proofs (Proposition 2.6 is a later improvement of this result). [IPS99] observed that the same simulation works also for small size *polynomial calculus* proofs.

Motivated in part by this similarity, [ABRW02] proposed considering the following natural system PCR extending both PC and resolution. PCR operates with polynomials $P \in F[x_1, \dots, x_n, \bar{x}_1, \dots, \bar{x}_n]$, where $\bar{x}_1, \dots, \bar{x}_n$ are treated as new formal variables. PCR has all default axioms and inference rules of PC (including, of course, those that involve new variables $\bar{x}_i$), plus additional default axioms $x_i + \bar{x}_i = 1$ $(i \in [n])$. The *size* and *degree of a PCR proof* are defined in the same way as for PC. It should be noted that there is not much sense in giving a separate definition for the degree of PCR proofs since the linear transformation $\bar{x}_i \mapsto 1 - x_i$ takes a PCR proof to (essentially) a PC proof while preserving degree. This system, however, becomes extremely convenient when it is the number of clauses which matters (see [ABRW02]).

PCR is an extension of PC by definition. Also, PCR extends resolution via the following translation. For a clause $C$, let $C_+$ $[(C_-)]$ be the set of positive (respectively, negative) literals appearing within it. Then a CNF formula $\tau$ gets translated into the set of polynomials $\Gamma_\tau$ defined by $\Gamma_\tau \overset{\text{def}}{=} \{(\prod_{\bar{x} \in C_-} x \cdot \prod_{x \in C_+} \bar{x}) | C \in \tau\}$. Clearly, $\tau$ is satisfiable if and only if $\Gamma_\tau$ has a common root in $F$ satisfying all default axioms

$$x_i^2 = x_i;\ \bar{x}_i^2 = \bar{x}_i;\ x_i + \bar{x}_i = 1. \tag{6}$$

Moreover, it is easy to see that every width $w$ size $S$ resolution refutation of $\tau$ can be transformed into degree $(w+1)$ size $O(nS)$ PCR refutations of the associated set of polynomials $\Gamma_\tau$ (cf. [BG99, section 5]). For ease of notation, we will omit the translation and define a *PCR refutation of a CNF* $\tau$ as a PCR refutation of $\Gamma_\tau$. A *PC refutation* of $\tau$ is a PC refutation of the set of polynomials

$$\Gamma'_\tau \overset{\text{def}}{=} \left\{ \left( \prod_{\bar{x} \in C_-} x \cdot \prod_{x \in C_+} (1 - x) \right) \middle|\ C \in \tau \right\} \tag{7}$$

obtained from $\Gamma_\tau$ by the linear transformation $\bar{x}_i \mapsto 1 - x_i$.

In fact all our lower bounds for PC hold also for PCR, so we will usually use the translation to PCR and prove PCR lower bounds which imply the hardness for PC.

[ABRW02] observed that the two simulations from [CEI96, IPS99] can be merged into one, as follows.

PROPOSITION 2.7. *Let* $\Gamma$ *be a system of polynomials in the variables* $x_1, \dots, x_n$, $\bar{x}_1, \dots, \bar{x}_n$ *that have no common roots in* $F$ *satisfying all default axioms* (6), *and let* $d(\Gamma) \overset{\text{def}}{=} \max\{\deg(P) \mid P \in \Gamma\}$. *Then every size* $S$ *PCR refutation of* $\Gamma$ *can be transformed into another PCR refutation of* $\Gamma$ *that has degree at most* $d(\Gamma) + O(\sqrt{n \log S})$.

**3. Lower bounds on width and degree in the functional encoding.** In this section we establish strong lower bounds on the resolution width and PC degree in the most general functional encoding, and we derive from them some size lower bounds. Our results in this section can be viewed as a far-reaching generalization of the corresponding lower bounds for Tseitin tautologies from [BW99, BGIP01].

But first a word about important and less important parameters. The parameters $s, c, l$ of the defining tautologies will feature in most of the calculations. (Recall that $s$ is the number of 1's in each row of the matrix $A$, which is also the number of arguments to each function $g_i$; $c$ is the expansion factor of the matrix $A$; and $\ell$ will lower bound the robustness of the $g_i$'s.) We will show in section 5 that almost all matrices satisfy $c > 0.9s$. Similarly, most functions satisfy $\ell > 0.9s$. Assuming this, Theorems 3.1 and 3.7 provide $\Omega(r)$ lower bounds on the width of resolution and degree of PC, respectively. (Recall that $r$ is the key parameter defining what size sets expand and can be taken to be essentially $n/s$; see section 5 for details.) Our corollaries for the size lower bounds implied by the width and degree lower bounds will be stated (for simplicity) only for this situation.

Theorem 3.1. *Let $A$ be an $(r, s, c)$-expander of size $(m \times n)$, and let $g_1, \dots, g_m$ be $\ell$-robust functions with $Vars(g_i) \subseteq X_i(A)$, where $c + \ell \geq s + 1$. Then every resolution refutation of $\tau(A, \vec{g})$ must have width $> \frac{r(c+\ell-s)}{2\ell}$.*

*Proof.* The proof follows the ideology developed in [BW99]. We define a measure $\mu$ with subadditive growth on the clauses, and we show that the measure of the empty clause is large ($\mu(0) > r$); hence there must be a clause with medium size measure ($r/2 < \mu(C) \leq r$). We show that such a clause must have large width.

Fix an $(r, s, c)$-expander $A$ of size $(m \times n)$ and $\ell$-robust functions $g_1, \dots, g_m$ with $Vars(g_i) \subseteq X_i(A)$, where $c + \ell \geq s + 1$.

Definition 3.2. *For $C$ a clause in the variables $Vars(A)$, define $\mu(C)$ to be the minimal size of $I \subseteq [m]$ such that the following pair of conditions hold:*

$$\forall y_f^\epsilon \in C \ \exists i \in I \ (Vars(f) \subseteq X_i(A)); \tag{8}$$

$$\{g_i \mid i \in I\} \models ||C||. \tag{9}$$

Claim 3.3.

1. *For a clause $C$ with $r/2 < \mu(C) \leq r$, $w(C) \geq \frac{r(c+\ell-s)}{2\ell}$.*
2. *$\mu(0) > r$.*

*Proof. Part* 1. Let $I$ be a set of minimal size satisfying Definition 3.2. Since $|I| \leq r$, we get $|\partial_A(I)| \geq c \cdot |I|$. Let us partition $I$ into $I_0$, any minimal subset satisfying (8), and $I_1 = I \setminus I_0$. Notice that by the minimality of $I$, removing any row from $I_1$ will ruin property (9).

We claim that for any $i_1 \in I_1$, $J_{i_1}(A)$ has small intersection with $\partial_A(I)$. Namely,

$$|J_{i_1}(A) \cap \partial_A(I)| \leq s - \ell. \tag{10}$$

Indeed, as we note above, $\{g_i \mid i \in I \setminus \{i_1\}\} \not\models ||C||$. Let $\alpha$ be any assignment such that $g_i(\alpha) = 1$ $(i \in I \setminus \{i_1\})$ but $||C||(\alpha) = 0$. Let $\rho$ be the restriction given by

$$\rho(x_j) \overset{\text{def}}{=} \begin{cases} \alpha(x_j) \text{ if } j \notin \partial_A(I) \cap J_{i_1}(A), \\ \star \text{ if } j \in \partial_A(I) \cap J_{i_1}(A). \end{cases}$$

Then, since $\rho$ is totally defined on $Vars(g_i)$ for $i \neq i_1$, and also on $Vars(||C||)$ (by (8) and $i_1 \notin I_0$), we have $g_i|_\rho \equiv 1$ $(i \neq i_1)$ and $C|_\rho \equiv 0$. Hence, using (9), we conclude that $g_{i_1}|_\rho \equiv 0$. Since $g_{i_1}$ is $\ell$-robust and $|J_{i_1}(A)| \leq s$, this implies the desired inequality (10).

Now we may sum up:

$$(11)\qquad \begin{cases} c\cdot|I| \le |\partial_A(I)| \\ \qquad \le s\cdot|I_0| + (s-\ell)|I_1| \\ \qquad = (s-\ell)|I| + \ell\cdot|I_0| \\ \qquad \le (s-\ell)|I| + \ell\cdot w(C), \end{cases}$$

which implies $w(C) \ge \frac{|I|(c+\ell-s)}{\ell}$. Recalling that $|I| > r/2$, we get our bound. Part 1 is proven.

*Part* 2. Suppose the contrary, that is, $\mu(0) \le r$. Then we can repeat the first part of the above argument (since that part did not use the condition $|I| > r/2$) and still get (11). But now $I_0 = \emptyset$, and hence (11) alone implies a contradiction with the expansion property. This proves part 2. ◻

CLAIM 3.4. *Any resolution refutation of $\tau(A, \vec{g})$ must include a clause $C$ with $r/2 < \mu(C) \le r$.*

*Proof.* $\mu$ is subadditive; i.e., if $C$ was derived from $C_0, C_1$ by a single resolution step, then $\mu(C) \le \mu(C_0) + \mu(C_1)$. Additionally, for any axiom $C$, $\mu(C) = 1$. The statement now follows from Claim 3.3(2). ◻

Theorem 3.1 is immediately implied by Claims 3.4 and 3.3(1). ◻

In order to see which *size* lower bounds are implied by Theorem 3.1 via Proposition 2.6, we consider only the typical (and most important) case $c+\ell-s = \Omega(s)$, for which our width lower bound is $\Omega(r)$.

COROLLARY 3.5. *Let $\epsilon > 0$ be an arbitrary fixed constant, let $A$ be an $(r, s, \epsilon s)$-expander of size $(m\times n)$, and let $g_1, \dots, g_m$ be $(1-\epsilon/2)s$-robust functions. Then every resolution refutation of $\tau(A, \vec{g})$ must have size $\exp(\Omega(\frac{r^2}{m\cdot 2^{2^s}}))/2^s$.*

*Proof.* Fix a resolution refutation of $\tau(A, \vec{g})$ that has size $S$. It is easy to see that every axiom in $\tau(A, \vec{g})$ contains a subclause of width $\le 2^s$ which is also an axiom of $\tau(A, \vec{g})$. Moreover, this latter clause can be easily inferred in $O(2^s)$ steps from those axioms in $\tau(A, \vec{g})$ that have width $\le 3$. This allows us to replace the original refutation by a refutation that may have a slightly bigger size $O(S\cdot 2^s)$ but uses only those axioms from $\tau(A, \vec{g})$ that have width $\le 3$. In this new refutation we infer all clauses of $\tau(A, \vec{g})$ that were used in the original refutation from width 3 clauses and then apply the original refutation itself. Hence, by Proposition 2.6, $\tau(A, \vec{g})$ also has a resolution refutation of width $O(\sqrt{|Vars(A)|\cdot\log(S\cdot 2^s)}) \le O(\sqrt{m\cdot 2^{2^s}\cdot\log(S\cdot 2^s)})$. Comparing this with the lower bound of $\Omega(r)$ that comes from Theorem 3.1, we finish the proof of Corollary 3.5. ◻

We can obtain much better size lower bounds (i.e., get rid of the disappointing term $2^{2^s}$ in the denominator) for the circuit encoding. We further confine ourselves to the optimal case when the circuits $C_1, \dots, C_m$ have size $O(s)$.

COROLLARY 3.6. *Let $\epsilon > 0$ be an arbitrary fixed constant, let $A$ be an $(r, s, \epsilon s)$-expander of size $(m\times n)$, and let $C_1, \dots, C_m$ be single-output Boolean circuits over arbitrary fixed finite basis such that $C_i$ is a circuit of size $O(s)$ in the variables $X_i(A)$, and all functions $||C_i||$ are $(1-\epsilon/2)s$-robust. Then every resolution refutation of $\tau(A, \vec{C})$ must have size $\exp(\Omega(\frac{r^2}{ms}))$.*

*Proof.* By Fact 4 and Theorem 3.1, every resolution refutation of $\tau(A, \vec{C})$ must have width $\Omega(r)$. Since $\left|Vars_{\vec{C}}(A)\right| \le O(ms)$, the required bound immediately follows from Proposition 2.6. ◻

Our second major result in this section generalizes the bound from [BGIP01]. Unfortunately, it also inherits all the limitations of their technique: essentially the only base functions $g_1, \ldots, g_m$ we can handle are $\mathbb{F}_2$-linear forms, and for $char(F) = 2$ our approach fails completely (cf. [Gri98]). On the positive side, note that although we do require the linearity of the base functions, the bound itself still holds for the most general *functional* framework.

THEOREM 3.7. *Let $A$ be an $(r, s, c)$-expander of size $(m \times n)$, and let $b_1, \ldots, b_m \in \{0, 1\}$. Then every PCR refutation of $\tau(A, \vec{\Sigma}(A, b))$ over an arbitrary field $F$ with $char(F) \neq 2$ must have degree $\geq \frac{rc}{4s}$.*

*Proof.* As the first step toward proving Theorem 3.7, we show one simple reduction to a lower bound problem about PC refutations in the *original* variables $x_1, \ldots, x_n$. This step is very general and does not depend on the linearity of the base functions $g_i$.

DEFINITION 3.8. *For a Boolean function $f(x_1, \ldots, x_n)$, $P_f(x_1, \ldots, x_n)$ is the (unique) multilinear polynomial such that*

$$P_f(\alpha) = \begin{cases} 0 \text{ if } f(\alpha) = 1, \\ 1 \text{ if } f(\alpha) = 0 \end{cases}$$

*for all $\alpha \in \{0, 1\}^n$.*

LEMMA 3.9. *For any $(m \times n)$ 0-1 matrix $A$ and any functions $g_1, \ldots, g_m$ with $Vars(g_i) \subseteq X_i(A)$, every degree $d$ PCR refutation of $\tau(A, \vec{g})$ can be transformed into a PC refutation of the system*

$$P_{g_1} = \cdots = P_{g_m} = 0 \tag{12}$$

*(in the* original *variables $x_1, \ldots, x_n$) that has degree $\leq s \cdot d$.*

*Proof of Lemma* 3.9. Let us consider some PCR refutation $\pi$ of $\tau(A, \vec{g})$. Substitute in $\pi$ the polynomial $P_{f^\epsilon}(x_1, \ldots, x_n)$ for every variable $y_f^\epsilon$. Since $\deg(P_{f^\epsilon}) \leq s$ for any $f(x_1, \ldots, x_n)$ such that $Vars(f) \subseteq X_i(A)$ for some $i \in [m]$, the degrees of all lines resulting from this substitution are at most $s \cdot d$. Moreover, any axiom from $\tau(A, \vec{g})$, as well as default axioms, gets transformed into a polynomial $P$ such that for some $i \in [m]$ $P$ contains only variables from $X_i(A)$ and is a semantical corollary of $P_{g_i}$ on $\{0, 1\}^{X_i(A)}$. Hence, it can be inferred from $P_{g_i}$ in degree $\leq s$ using only variables from $X_i(A)$. Appending these auxiliary inferences to the beginning of the transformed refutation $\pi$, we obtain the required PC refutation of the system (12). Lemma 3.9 is proved. □

Thus, in order to complete the proof of Theorem 3.7, we should establish the $\frac{rc}{4}$ lower bound on the degree of any PC refutation $\pi$ of the system (12) for $g_i = \Sigma_i(A, b_i)$.

The proof is based on the connection between PC degree and Gaussian width found in [BI99]. With this connection in hand, we may quote here, word for word, Theorem 3.3 from [BI99], plugging in our current parameters.

THEOREM 3.10. *For $A$ an $(r, s, c)$-expander, $\{g_i\}$ linear equations mod 2, and $F$ a field of characteristic $\neq 2$, any PCR refutation of $P_{g_1} = \cdots = P_{g_m} = 0$ has degree $\geq \frac{rc}{4}$.*

Theorem 3.7 follows. □

COROLLARY 3.11. *Let $\epsilon > 0$ be an arbitrary fixed constant, let $A$ be an $(r, s, \epsilon s)$-expander of size $(m \times n)$, and let $b_1, \ldots, b_m \in \{0, 1\}$. Then every PCR refutation of $\tau(A, \vec{\Sigma}(A, b))$ over an arbitrary field $F$ with $char(F) \neq 2$ must have size $\exp(\Omega(\frac{r^2}{m \cdot 2^{2s}}))/2^s$.*

*Proof.* The proof is identical to that of Corollary 3.5, using Proposition 2.7. □

COROLLARY 3.12. *Let $\epsilon > 0$ be an arbitrary fixed constant, let $A$ be an $(r, s, \epsilon s)$-expander of size $(m \times n)$, let $b_1, \ldots, b_m \in \{0, 1\}$, and let $C_1, \ldots, C_m$ be single-output*

*Boolean circuits over an arbitrary fixed finite basis such that $C_i$ is a circuit of size $O(s)$ in the variables $X_i(A)$ that computes the function $\Sigma_i(A, b_i)$. Then every PCR refutation of $\tau(A, \vec{C})$ over an arbitrary field $F$ with $char(F) \neq 2$ must have size* $\exp(\Omega(\frac{r^2}{ms}))$.

*Proof.* The proof is identical to that of Corollary 3.6, using Proposition 2.7. ∎

**4. Size lower bounds for linear encoding.** In this section we show better lower bounds (although our requirement on the expansion rate is somewhat stronger) on the size of PCR refutation for the more structured linear encoding than those provided by Corollaries 3.11 and 3.12. We will apply the random restriction method for killing large clauses rather than directly referring to the general degree/size relation from Proposition 2.7. In this sense our approach is similar in spirit to that of [BP96].

THEOREM 4.1. *Let $A$ be an $(r, s, \frac{3}{4}s)$-expander of size $(m \times n)$, and let $b_1, \dots, b_m \in \{0, 1\}$. Then every PCR refutation of $\tau_\oplus(A, \vec{b})$ over an arbitrary field $F$ with $char(F) \neq 2$ must have size* $\exp(\Omega(\frac{r^2}{m}))$.

*Proof.* As the first step toward proving Theorem 4.1, we show how to get rid of the variables $y_J$ for large (= of size $> s/2$) sets $J$. For technical reasons, we also switch during this step from the linear encoding to the functional one.

DEFINITION 4.2. *For an $(m \times n)$-matrix $A$, the set of variables $Vars_\oplus(A) \subseteq Vars(A)$ consists of those $y_f \in Vars(A)$ for which $f$ has the form $\bigoplus_{j \in J} x_j$. Also let*

$$\widetilde{Vars}_\oplus(A) \stackrel{\text{def}}{=} \left\{ y_{\left(\bigoplus_{j\in J} x_j\right)} \in Vars_\oplus(A) \mid |J| \le s/2 \right\}.$$

*$\tau_\oplus(A, b)$ (respectively, $\tilde{\tau}_\oplus(A, b)$) is the set of those axioms in $\tau(A, \vec{\Sigma}(A, b))$ that contain variables only from $Vars_\oplus(A)$ (respectively, from $\widetilde{Vars}_\oplus(A)$).*

It is worth noting that $\tau_\oplus(A, b)$ possesses the following clean algebraic description: if $g_i = \Sigma_i(a, b_i)$, and $f_1, \dots, f_w$ are $\mathbb{F}_2$-linear forms, then (5) holds if *either* the system of linear equations $f_1 = \bar{\epsilon}_1, \dots, f_w = \bar{\epsilon}_w$ is inconsistent *or* the vector space spanned by these equations contains $\bar{g}_i$.

LEMMA 4.3. *Suppose that $A$ is an $(2, s, \frac{3}{4}s)$-expander. Then every PCR refutation of $\tau_\oplus(A, b)$ can be transformed into a PCR refutation of $\tilde{\tau}_\oplus(A, b)$ that has the same size.*

*Proof of Lemma* 4.3. For every two distinct rows $i_1$ and $i_2$ we have $|\partial_A(\{i_1, i_2\})| \ge \frac{3}{2}s$, which implies $|J_{i_1}(A) \cap J_{i_2}(A)| \le s/2$. Hence, for every $J \subseteq [n]$ with $|J| > s/2$ there can exist at most one row $i \in [m]$ such that $J \subseteq J_i(A)$. Therefore, the mapping

$$y_J \mapsto \begin{cases} y_{\bigoplus\{x_j \mid j \in J\}} & \text{if } |J| \le s/2, \\ y_{\bigoplus\{x_j \mid j \in J_i(A) \setminus J\}} \oplus b_i & \text{if } |J| > s/2 \text{ and } J \subseteq J_i(A) \end{cases}$$

is well-defined. It is easy to see that it takes every axiom from $\tau_\oplus(A, b)$ to an axiom from $\tilde{\tau}_\oplus(A, b)$, which proves Lemma 4.3. ∎

Now, for a monomial $m = y_{f_1}^{\epsilon_1} \dots y_{f_d}^{\epsilon_d}$ in the variables $\widetilde{Vars}_\oplus(A)$, we define its *$A$-degree* $\deg_A(m)$ as the minimal cardinality of a set of rows $I$ with the property $Vars(f_1) \cup \dots \cup Vars(f_d) \subseteq \bigcup_{i \in I} X_i(A)$. The *$A$-degree of a polynomial* is the maximal $A$-degree of a monomial within it, and similarly the *$A$-degree of a PCR* proof is the maximal $A$-degree of a polynomial within it. The following lemma rephrases Theorem 3.7 for $\deg_A$.

LEMMA 4.4. *Let $A$ be an $(r, s, c)$-expander of size $(m \times n)$, and let $b_1, \ldots, b_m \in \{0, 1\}$. Then every PCR refutation of $\tau(A, \vec{\Sigma}(A, b))$ over an arbitrary field $F$ with $char(F) \neq 2$ must have $A$-degree $\geq \frac{rc}{4s}$.*

*Proof of Lemma* 4.4. The only difference from Theorem 3.7 is that we consider here $A$-degree instead of an ordinary one. It is easy to see by inspection that this change does not affect the reduction in Lemma 3.9, and the same proof applies here as well. $\square$

Lemmas 4.3 and 4.4 determine the strategy of the rest of the proof (cf. [BP96]). We want to hit the prospective refutation of $\tilde{\tau}_{\oplus}(A, b)$ by a random restriction $\boldsymbol{\rho}$ in such a way that $\boldsymbol{\rho}$ preserves the structure of $\tau(A, \vec{\Sigma}(A, b))$ and, if the size of the original refutation is small, with a high probability also kills all monomials in the variables $\widetilde{Vars}_{\oplus}(A)$ that have high $A$-degree.

DEFINITION 4.5. *For a set of rows $I$, let us denote by $M_I$ the set of all restrictions $\rho$ such that $\rho^{-1}(\{0, 1\}) = \bigcup_{i \in I} X_i(A)$ and $\rho$ satisfies all equations $\Sigma_i(A, b_i) = 1$ for all $i \in I$.*

Note that if $|I| \leq r$, then, since $A$ is an $(r, s, \frac{3}{4}s)$-expander, the linear forms $\bigoplus \{x_j \mid x_j \in X_i(A)\} = \Sigma_i(A, b_i) \oplus \bar{b}_i$ $(i \in I)$ are linearly independent (because each of its subsets has a form that contains a boundary variable) and thus $M_I$ is a nonempty linear subspace.

Let $A|_I$ be the result of removing from the matrix $A$ all rows $i \in I$ and all columns $j \in \bigcup_{i \in I} J_i(A)$. Any restriction $\rho \in M_I$ can be naturally extended to the variables from $Vars(A)$ by letting $\rho(y_f) \overset{\text{def}}{=} y_{f|_\rho}$. $\rho$ takes variables from $Vars(A)$ to variables from $Vars(A|_I)$. Moreover, those $y_f$ for which $\exists i \in I$ $(Vars(f) \subseteq X_i(A))$ are set to a constant. Finally, $\rho$ always takes axioms from $\tau(A, \vec{g})$ to axioms from $\tau(A|_I, \vec{g}|_\rho)$. The only remaining problem is that $A|_I$ may not inherit good expansion properties: it is easy to get an example showing that it may even contain an empty row! We circumvent this difficulty by further removing all rows that have large intersection with $\bigcup_{i \in I} J_i(A)$ and show in the following lemma that this can always be done in an efficient manner.

LEMMA 4.6. *Let $A$ be an $(r, s, c)$-expander. Then every set of rows $I$ with $|I| \leq r/2$ can be extended to a larger set of rows $\hat{I} \supseteq I$ such that $|\hat{I}| \leq 2 \cdot |I|$ and $A|_{\hat{I}}$ is an $(r, s, 3c - 2s)$-expander.*

*Proof of Lemma* 4.6. Let us recursively add to $I$ new rows (one row $i_0$ at a time) with the property $\left|J_{i_0}(A) \cap \left(\bigcup_{i \in I'} J_i(A)\right)\right| > 2(s - c)$, where $I'$ is the current value of $I$. We claim that this process will terminate (i.e., no new row can be added) in less than $|I|$ steps.

Suppose the contrary, and let $\hat{I}$ be the set of cardinality $2 \cdot |I|$ reached after $|I|$ steps. Then every row $i_0 \in \hat{I} \setminus I$ contains less than $|J_{i_0}(A) - 2(s - c)| \leq (2c - s)$ boundary elements from $\partial_A(\hat{I})$. Hence, $|\partial_A(\hat{I})| < s \cdot |I| + (2c - s) \cdot |I| = 2c \cdot |I|$, a contradiction.

We choose as our $\hat{I}$ the result of termination of this process. Let $I_0$ be a set of rows in $A|_{\hat{I}}$ (i.e., $I_0 \cap \hat{I} = \emptyset$) of cardinality at most $r$. Then $\partial_{A|_{\hat{I}}}(I_0) = \partial_A(I_0) \setminus \bigcup_{i \in \hat{I}} J_i(A)$. Since for every $i \in I_0$, $\left|J_{i_0}(A) \cap \left(\bigcup_{i \in \hat{I}} J_i(A)\right)\right| \leq 2(s - c)$, we have the bound $\left|\partial_{A|_{\hat{I}}}(I_0)\right| \geq |\partial_A(I_0)| - 2(s - c) \cdot |I_0| \geq c \cdot |I_0| - 2(s - c)|I_0| = (3c - 2s) \cdot |I_0|$. Lemma 4.6 is proved. $\square$

Now we are ready to finish the proof of Theorem 4.1. Fix a PCR refutation $\pi$ of $\tilde{\tau}_{\oplus}(A, b)$. Assume w.l.o.g. that 18 divides $r$, and pick at random a set of rows $\boldsymbol{I}$ of cardinality $r/3$ (we are using boldface to stress that it is a random variable).

Choose arbitrarily $\hat{\boldsymbol{I}} \supseteq \boldsymbol{I}$ according to Lemma 4.6, i.e., such that $|\hat{\boldsymbol{I}}| \leq \frac{2r}{3}$ and $A|_{\hat{\boldsymbol{I}}}$ is an $(r, s, s/4)$-expander. Pick $\boldsymbol{\rho} \in M_{\hat{\boldsymbol{I}}}$ at random, and apply this restriction to our PCR refutation $\pi$. This will produce a PCR refutation $\boldsymbol{\rho}(\pi)$ of $\tilde{\tau}_{\oplus}(A|_{\hat{\boldsymbol{I}}}, \boldsymbol{\rho}(\vec{\Sigma}(A, b)))$. By Lemma 4.4 (with $c = s/4$), $\boldsymbol{\rho}(\pi)$ must contain a nonzero monomial $\boldsymbol{\rho}(m)$ of $A|_{\hat{\boldsymbol{I}}}$-degree $> r/18$. Thus, $\pi$ contains a monomial $m$ that has $A$-degree $> r/18$ and *is not killed by* $\boldsymbol{\rho}$. In order to finish the proof, we only have to estimate from above the probability $\mathbf{P}[\boldsymbol{\rho}(m) \neq 0]$ for every individual monomial $m$ with $\deg_A(m) > r/18$.

Fix any such $m = y_{f_1}^{\epsilon_1} \dots y_{f_d}^{\epsilon_d}$, and recall that $f_1, \dots, f_d$ are $\mathbb{F}_2$-linear forms of weight $\leq s/2$. W.l.o.g. assume that $f_1, \dots, f_t$ form a linear basis of the space $Span(f_1, \dots, f_d)$. Then $\bigcup_{\nu=1}^{t} Vars(f_\nu) = \bigcup_{\nu=1}^{d} Vars(f_\nu)$ and, therefore, $\deg_A(y_{f_1}^{\epsilon_1} \dots y_{f_t}^{\epsilon_t}) = \deg_A(m) > r/18$. Hence, w.l.o.g. we can assume from the very beginning that $f_1, \dots, f_d$ are linearly independent.

Let us now introduce one variation of the notion of $A$-degree. Namely, for $m = y_{f_1}^{\epsilon_1} \dots y_{f_d}^{\epsilon_d}$, let $\deg'_A(m)$ be the minimal cardinality of a set of rows $I$ such that these rows "cover" $m$ in the stronger sense for all $\nu \in [d] \exists i \in I (Vars(f_\nu) \subseteq X_i(A))$. Clearly, $\deg_A(m) \leq \deg'_A(m)$ (and $\leq \deg(m)$). Also, $\deg'_A$ is "continuous" in the sense that for every monomial $m$, and for every variable $y_f^\epsilon$, $\deg'_A(m) \leq \deg'_A(m \cdot y_f^\epsilon) \leq \deg'_A(m)+1$. Therefore, we can gradually remove variables from the monomial $m$, one variable at a time, until we find in it a submonomial $m'$ such that $\deg'_A(m')$ is *exactly* equal to $r/18$. For ease of notation, assume w.l.o.g. that $\deg'_A(m) = r/18$ for the original monomial $m$.

Fix now any set of rows $I_0$ with $|I_0| = r/18$ and such that

$$\forall \nu \in [d]\ \exists i \in I_0\ (Vars(f_\nu) \subseteq X_i(A)). \tag{13}$$

We estimate the probability $\mathbf{P}[\boldsymbol{\rho}(m) \neq 0]$ as follows:

$$\mathbf{P}[\boldsymbol{\rho}(m) \neq 0] \leq \mathbf{P}\left[|I_0 \cap \boldsymbol{I}| < \frac{r^2}{100m}\right] + \max_{\substack{|I| = r/3 \\ |I_0 \cap I| \geq \frac{r^2}{100m}}} \mathbf{P}[\,\boldsymbol{\rho}(m) \neq 0\,|\,|\boldsymbol{I} = I|\,].$$

Since $|I_0| = r/18$ and $|\boldsymbol{I}| = r/3$, we can estimate the first term by Chernoff inequality as

$$\mathbf{P}\left[|I_0 \cap \boldsymbol{I}| < \frac{r^2}{100m}\right] \leq \exp\left(-\Omega\left(r^2/m\right)\right). \tag{14}$$

For estimating the second term, fix any individual $I$ such that $|I| = r/3$ and $|I_0 \cap I| \geq \frac{r^2}{100m}$, and let $\hat{I} \supseteq I$ be a corresponding set of rows satisfying the conclusion of Lemma 4.6. We want to estimate $\mathbf{P}\left[\boldsymbol{\rho}_{\hat{I}}(m) \neq 0\right]$, where $\boldsymbol{\rho}_{\hat{I}}$ is picked at random from $M_{\hat{I}}$ (thus, $\boldsymbol{\rho}_{\hat{I}}$ is a random variable that results from $\boldsymbol{\rho}$ after revealing $\hat{\boldsymbol{I}} = \hat{I}$).

Let $I'_0 = I_0 \cap \hat{I}$, $I'_0 = \{i_1, \dots, i_\ell\}$; $\ell \geq r^2/100m$. Since $I_0$ is minimal with the property (13), for every $\nu \in [\ell]$ we can choose $f \in \{f_1, \dots, f_d\}$ such that $Vars(f) \subseteq X_{i_\nu}(A)$ but $Vars(f) \not\subseteq X_i(A)$ for any other $i \in I_0$. Hence, we can assume w.l.o.g. that $Vars(f_\nu) \subseteq X_{i_\nu}(A)$ for $\nu = 1, \dots, \ell$.

Now, let $V_0 \overset{\text{def}}{=} Span(f_1, \dots, f_\ell)$ be the $\mathbb{F}_2$-linear space generated by the linear functions $f_1, \dots, f_\ell$, and let $\hat{V} \overset{\text{def}}{=} Span\left(\{\bigoplus_{j \in J_i(A)} x_j | i \in \hat{I}\}\right)$. $\mathbf{P}\left[\boldsymbol{\rho}_{\hat{I}}(m) \neq 0\right] \leq \mathbf{P}[\boldsymbol{\rho}_{\hat{I}}(y_{f_1}^{\epsilon_1} \dots y_{f_\ell}^{\epsilon_\ell}) \neq 0]$, and the latter probability is less than or equal to $2^{-(V_0 : V_0 \cap \hat{V})}$ (here $(V_0 : V_0 \cap \hat{V}) \overset{\text{def}}{=} \dim(V_0) - \dim(V_0 \cap \hat{V})$ is the standard codimension of linear spaces). To see this, note that $\boldsymbol{\rho}_{\hat{I}}$ gives $\{0,1\}$-values to all variables of $f_1,\ldots,f_\ell$. Let $k = (V_0 : V_0 \cap \hat{V})$. We can choose $k$ linear forms $f_{i_1}, f_{i_2}, \ldots, f_{i_k} \in \{f_1,\ldots,f_\ell\}$ such that the family $f_{i_1},\ldots,f_{i_k}$ is linearly independent modulo $\hat{V}$. Then the values $\boldsymbol{\rho}_{\hat{I}}(f_{i_1}),\ldots,\boldsymbol{\rho}_{\hat{I}}(f_{i_k})$ are independent, and each equal 0 with probability 1/2. Thus, the probability that no $y_{f_i}$ is killed is less than or equal to $2^{-k}$.

Clearly, $2^{-(V_0:V_0\cap\hat{V})} = 2^{\dim(V_0\cap\hat{V})-\ell}$. Hence, we only have to upper bound $\dim(V_0\cap\hat{V})$. Let us denote by $\hat{I}^+$ the set of all rows $i\in\hat{I}$ which appear with coefficient $\alpha_i \neq 0$ in *at least one* sum of the form

$$\bigoplus_{i\in\hat{I}} \alpha_i \cdot \left( \bigoplus_{j\in J_i(A)} x_j \right) \tag{15}$$

that happens to belong to $V_0$, and let $\hat{V}^+ \overset{\text{def}}{=} Span(\{\bigoplus_{j\in J_i(A)} x_j | i \in \hat{I}^+\})$. Then $V_0\cap\hat{V} \subseteq V_0\cap\hat{V}^+$ by our choice of $\hat{I}^+$, and $\dim(V_0\cap\hat{V}) \le \dim(\hat{V}^+) \le |\hat{I}^+|$.

In order to bound from above $|\hat{I}^+|$, we apply the expansion property to $I_0'\cup\hat{I}^+$ (its cardinality does not exceed $r/18+2r/3<r$). We get $|\partial_A(I_0'\cup\hat{I}^+)| \ge \frac{3}{4}s\cdot|I_0'\cup\hat{I}^+|$. Note that rows from $\hat{I}^+\setminus I_0'$ may not contain elements from $\partial_A(I_0'\cup\hat{I}^+)$ at all; otherwise, the corresponding variable would not cancel out in the sum (15), and this would prevent the latter from being in $V_0$ (note that for any form $f\in V_0$, $Vars(f) \subseteq \bigcup_{i\in I_0'} X_i(A)$).

The key observation is that every row $i_\nu$ from $\hat{I}^+\cap I_0'$ may also contain only a relatively small number of boundary elements, namely, at most $(s/2)$. Indeed, $|Vars(f_\nu)| \le s/2$ (see Definition 4.2). Therefore, if $J_{i_\nu}$ would have contained $> s/2$ boundary elements, then at least one boundary variable $x_j \in X_{i_\nu}(A)$ would not belong to $Vars(f_\nu)$, and would once more prevent the sum (15) from lying in $V_0$ (since $j$ belongs to the boundary, $x_j$ may not occur in other forms appearing in this sum).

Summing up the above remarks, we have the upper bound $|\partial_A(I_0'\cup\hat{I}^+)| \le s\cdot|I_0'\setminus\hat{I}^+| + \frac{s}{2}\cdot|I_0'\cap\hat{I}^+|$. Comparing it with the lower bound given by expansion, we get

$$\frac{3}{4}s\cdot|I_0'\cup\hat{I}^+| \le |\partial_A(I_0'\cup\hat{I}^+)| \le s\cdot|I_0'\setminus\hat{I}^+| + \frac{s}{2}\cdot|I_0'\cap\hat{I}^+|,$$

$$\frac{3}{4}s\left(|\hat{I}^+| + |I_0'\setminus\hat{I}^+|\right) \le s\cdot|I_0'\setminus\hat{I}^+| + \frac{s}{2}\cdot|I_0'\cap\hat{I}^+|,$$

and

$$\frac{3}{4}s|\hat{I}^+| \le \frac{1}{4}s\cdot|I_0'\setminus\hat{I}^+| + \frac{s}{2}\cdot|I_0'\cap\hat{I}^+|,$$

which implies $|\hat{I}^+| \le \frac{2}{3}|I_0'| = \frac{2\ell}{3}$.

Therefore, $\dim(V_0\cap\hat{V}) \le \frac{2\ell}{3}$ and $\mathbf{P}\left[\boldsymbol{\rho}_{\hat{I}}(m)\neq 0\right] \le 2^{-\ell/3} \le \exp\left(-\Omega\left(r^2/m\right)\right)$. Together with (14) this implies $\mathbf{P}[\boldsymbol{\rho}(m)\neq 0] \le \exp\left(-\Omega\left(r^2/m\right)\right)$. Hence, $\pi$ must contain at least $\exp\left(\Omega\left(r^2/m\right)\right)$ monomials (of $A$-degree $\ge r/18$) since otherwise we could find a restriction $\rho$ that kills all of them, contrary to Lemma 4.4. The proof of Theorem 4.1 is complete. $\square$

**5. Existence of strong expanders and hard generators.** All our hardness results in the previous two sections are based upon the notion of an $(r, s, c)$-expander. As we noted in the introduction, one of our eventual goals is to be able to stretch $n$ seed bits to as many output bits $m$ as possible so that the resulting generator is hard for as strong propositional proof systems $P$ as possible. In this section we will see what I/O ratio we can achieve with the results from the two previous sections.

All explicit constructions of $(r, s, c)$-expanders that we know of are based upon Examples 5 and 6 from section 2.1. Unfortunately, the resulting expanders turn out to be virtually useless for our purposes since they cannot even break the barrier $m = n$. Let us turn instead to a simple probabilistic argument. We note that in the context of proof complexity, there is not much advantage in having explicit constructions of hard tautologies over existence proofs.

THEOREM 5.1. *For any parameters $s, n$ there exists an $\left(\Omega(n/s) \cdot n^{-O(1/s)}, s, \frac{3}{4}s\right)$-expander of size $(n^2 \times n)$.*

*Proof.* Let us construct a random $(n^2 \times n)$ matrix $\boldsymbol{A}$ as follows. For every $i \in [n^2]$, let $J_i(\boldsymbol{A}) \overset{\text{def}}{=} \{\boldsymbol{j_{i1}}, \ldots, \boldsymbol{j_{is}}\}$, where all $\boldsymbol{j_{i\nu}}$ $(i \in [n^2], \nu \in [s])$ are picked from $[n]$ independently and at random (in fact, we would also obtain the same result by letting $J_i(\boldsymbol{A})$ be uniformly and independently distributed over all $s$-subsets of $[n]$, but with our choice of $J_i(\boldsymbol{A})$ calculations become simpler). We wish to show that

$$\mathbf{P}[\boldsymbol{A} \text{ is not an } (r, s, 3s/4)\text{-expander}] < 1$$

for some $r \geq \Omega(n/s) \cdot n^{-O(1/s)}$. Let $p_\ell$ be the probability that any given $\ell$ rows of the matrix $\boldsymbol{A}$ violate the expansion property. Then, clearly,

$$\mathbf{P}[\boldsymbol{A} \text{ is not an } (r, s, 3s/4)\text{-expander}] \leq \sum_{\ell=1}^{r} n^{2\ell} p_\ell. \tag{16}$$

Fix an arbitrary $I$ of cardinality $\ell \leq r$. Since every column $j \in \bigcup_{i \in I} J_i(\boldsymbol{A}) \setminus \partial_{\boldsymbol{A}}(I)$ belongs to at least two sets $J_i(\boldsymbol{A})$, we have the bound $\left|\bigcup_{i \in I} J_i(\boldsymbol{A})\right| \leq |\partial_{\boldsymbol{A}}(I)| + \frac{1}{2} \cdot \left(\sum_{i \in I} |J_i(\boldsymbol{A})| - |\partial_{\boldsymbol{A}}(I)|\right) \leq \frac{1}{2}(s\ell + |\partial_{\boldsymbol{A}}(I)|)$. Hence $\partial_{\boldsymbol{A}}(I) < \frac{3}{4}s\ell$ implies also $\left|\bigcup_{i \in I} J_i(\boldsymbol{A})\right| < \frac{7}{8}s\ell$, and $p_\ell$ can be estimated by the union bound as

$$p_\ell \leq \binom{n}{\frac{7}{8}s\ell} \cdot \left(\frac{7s\ell}{8n}\right)^{s\ell} \leq (O(s\ell/n))^{s\ell/8} \leq (O(sr/n))^{s\ell/8}.$$

Substituting this bound into (16), we obtain

$$\mathbf{P}[\boldsymbol{A} \text{ is not an } (r, s, 3s/4)\text{-expander}] \leq \sum_{\ell=1}^{r} n^{2\ell} \cdot \left(O\left(\frac{sr}{n}\right)\right)^{s\ell/8}. \tag{17}$$

The sum in the right-hand side is the geometric progression with the base $n^2 \cdot (O(sr/n))^{\Omega(s)}$. Hence, if $r = (\epsilon n/s) \cdot n^{-1/s\epsilon}$ for a sufficiently small $\epsilon > 0$, the right-hand side of (17) is less than $(1/2)$, which completes the proof of Theorem 5.1. $\square$

COROLLARY 5.2. *There exists a family of $(m \times n)$ matrices $A^{(m,n)}$ such that for every $b = (b_1, \ldots, b_m) \in \{0,1\}^m$, any PCR refutation of $\tau(A^{(m,n)}, \vec{\Sigma}(A^{(m,n)}, b))$ over an arbitrary field with $char(F) \neq 2$ must have size $\exp(\frac{n^{2-O(1/\log\log n)}}{m})$.*

*Proof.* Since for $m \geq n^2$ the bound becomes trivial, we can assume that $m \leq n^2$. Apply Theorem 5.1 with $s = \frac{1}{2}\log_2 \log_2 n$, and cross out in the resulting matrix all rows but (arbitrarily chosen) $m$. This will result in an $(r, s, \frac{3}{4}s)$-expander $A^{(m,n)}$ of size $(m \times n)$, where $r \geq n^{1-O(1/\log\log n)}$. Now we only have to apply Corollary 3.11 and notice that $2^{2^s} = 2^{\sqrt{\log n}} \leq n^{1/\log\log n}$. ◻

Corollary 5.2 shows that in the functional encoding we can stretch $n$ random bits to $n^{2-O(1/\log\log n)}$ bits so that this generator will be hard for (polynomial size) PCR proofs over an arbitrary field $F$ with $char(F) \neq 2$. In particular, it is hard for resolution.

COROLLARY 5.3. *There exists a family of $(m \times n)$ matrices $A^{(m,n)}$ such that $\left|J_i\left(A^{(m,n)}\right)\right| \leq \log_2 n$ for all $i \in [m]$, and for every $b = (b_1, \ldots, b_m) \in \{0,1\}^m$ we have the following bounds:*

1. *Let $C_1, \ldots, C_m$ be single-output Boolean circuits over an arbitrary fixed finite basis, where $C_i$ is a circuit of size $O(\log n)$ in the variables $X_i(A^{(m,n)})$ that computes the function $\Sigma_i(A^{(m,n)}, b_i)$. Then every PCR refutation of $\tau(A^{(m,n)}, \vec{C})$ over an arbitrary field with $char(F) \neq 2$ must have size $\exp(\Omega(\frac{n^2}{m(\log n)^3}))$.*
2. *Every PCR refutation of $\tau_{\oplus}(A^{(m,n)}, b)$ over an arbitrary field with $char(F) \neq 2$ must have size $\exp(\Omega(\frac{n^2}{m(\log n)^2}))$.*

*Proof.* The proof is the same as that of Corollary 5.2, only this time we let $s = \log_2 n$. Namely, Theorem 5.1 provides us with an $(r, s, \frac{3}{4}s)$-expander for $r \geq \Omega(n/\log n)$. The proof now follows by Corollary 3.6 and Theorem 4.1. ◻

Corollary 5.3 allows us to construct generators that stretch $n$ bits to $m = o(n^2/(\log n)^4)$ bits in the circuit encoding, and to $m = o(n^2/(\log n)^3)$ bits in linear encoding, which are hard for polynomial size PCR proofs in odd characteristic.

## 6. Recent developments.

Since the preliminary version of this paper (see Report TR00-23 of the Electronic Colloquium on Computational Complexity, and the Proceedings of the 41st IEEE Symposium on Foundations of Computer Science) was disseminated, many open problems presented there have been solved, and many other related developments have occurred.

Alekhnovich and Razborov [AR01] extended our lower bounds for the PC degree (Theorems 3.10 and 3.7) to a large natural class of base functions $g_1, \ldots, g_m$. This class is defined by the requirement that the ideal spanned by every individual $g_i$ does not contain any nonzero multilinear polynomials of low degree.

The principles studied in this paper expressing that Nisan–Wigderson generators are not onto bear a striking similarity to the pigeonhole principle $PHP_n^m$ (with the same meaning of the parameters $m, n$). At the time this paper was written, one of the most interesting open problems, both for NW-generators and for $PHP_n^m$, was to break through the quadratic barrier $m \geq n^2$ for (at least) the resolution size. This has been solved in both contexts.

The pigeonhole principle $PHP_n^m$ was the first to yield. Raz [RanRaz02] proved exponential lower bounds on the size of its resolution refutations when $m \gg n$. Razborov [Raz02a] gave a simpler proof of a somewhat better bound that also holds for the more general functional onto version of this principle.

The quadratic barrier for pseudorandom generators did not stand for much longer. Razborov [Raz02b] constructed Nisan generators (that is, when the base functions $g_i$ are $\mathbb{F}_2$-linear forms) that allow $m \geq n^{\Omega(\log n)}$ output bits and are exponentially hard not only for resolution but also for its extensions $\mathrm{Res}(\epsilon \log n)$ (operating with $(\epsilon \log n)$-DNF instead of clauses) and PCR when $char(F) \neq 2$.

Another question asked in the earlier version of our paper was whether any structural theory of pseudorandom generators is possible within the framework of proof complexity. In particular, we asked whether it is possible to formulate and prove any reasonable statement that would say, possibly in a restricted way, that the composition of hard generators is hard (for a given propositional proof system). This was satisfactorily answered by Krajíček [Kra02], who showed that this is indeed the case, provided hardness is replaced by a stronger notion of $s$-iterability (inspired by the so-called counterexample interpretation).

It was also conjectured in the earlier version that such a composition result might provide an alternate approach to the quadratic barrier problem (but for more complicated generators). This has indeed turned out to be the case. Krajíček [Kra02] proved (independently of [Raz02b]) that our generator from section 4 can be iterated with itself once, which immediately allowed him to get as many as $m = n^{3-\epsilon}$ output bits. The Nisan generator from [Raz02b] turned out to be particularly suitable for Krajíček's notion of $s$-iterability, and it can be composed with itself exponentially many times while preserving hardness. In this way [Raz02b] constructed a function generator with $m = 2^{n^\epsilon}$ outputs which is hard for $\mathrm{Res}(\epsilon \log n)$ and for PCR with $char(F) \neq 2$. Along the lines described in the discussion after Example 3, this immediately implied that neither of these systems possess efficient proofs of $\mathbf{NP} \not\subseteq \mathbf{P}/poly$ (the same conclusion for resolution had already followed from [RanRaz02, Raz02a]).

Finally, [CRVW02] took an important step toward constructing explicit expanders (called there and in [Raz02b] "lossless") with very good expansion properties (even if not sufficient yet for many of our purposes).

## 7. Open problems.

As indicated in the previous section, the most intriguing open problems asked by us in earlier versions have been solved. Some of them, however, remain open.

Can we reduce the devastating $2^{2^s}$ factor in our size lower bounds for the functional framework (Corollaries 3.5 and 3.11)? One way to approach this would be to look for generalizations of the basic Proposition 2.6 that would take into account the structure of the variables $y_f$ (which can be originally divided into $m$ large groups).

Find explicit constructions of $(r, s, c)$-expanders with parameters that would be sufficient for (at least some of) the applications in the current paper and in [Raz02b] (as we remarked above, one step in this direction was made in [CRVW02]).

The bound from [AR01] on the PC degree mentioned in the previous section is not entirely satisfactory since for this bound we need rather good expanders with the expansion ratio $c > 3s/4$. Can we improve it in such a way that it will work under less restrictive conditions, such as similar bounds in Theorems 3.1, 3.7, and 3.10?

More open problems representing the next generation of tasks faced by this theory can be found in [Raz02b].

**Acknowledgment.** We are grateful to both anonymous referees for many useful remarks.

# ALGORITHMS FOR RH MAPPING: NEW IDEAS AND IMPROVED ANALYSIS*

LARS IVANSSON† AND JENS LAGERGREN†

**Abstract.** Radiation hybrid (RH) mapping is a technique for constructing a physical map describing the locations of $n$ markers on a chromosome of an organism. In [*J. Comput. Biol.*, 4 (1997), pp. 517–533], Ben-Dor and Chor presented new algorithms for the RH problem and gave the first performance guarantees for such algorithms. We improve the lower bounds on the number of experiments in a way that is sufficient for two of these algorithms to give a correct ordering of the markers with high probability. Not only are the new bounds tighter, but our analysis also captures to a much higher extent how the bounds depend on the actual arrangement of the markers. Furthermore, we modify the two algorithms to utilize RH mapping data produced with several radiation intensities. We show that the new algorithms are almost insensitive to the problem of using the correct intensity.

**Key words.** RH mapping, algorithms, performance bounds, multiple intensities

## 1. Introduction.

Physical mapping is an important problem in large-scale sequencing of DNA as well as for locating genes. In RH (radiation hybrid) mapping, a physical map describing the locations of $n$ markers on a chromosome of an organism is constructed. The markers can be genes or arbitrary DNA sequences, and the resulting information consists of the relative order of these markers and the distance between them on the chromosome. The RH mapping procedure can be divided into an experimental and an algorithmic part. In the experimental part a series of RH experiments is made, which yields pairwise distances between markers. In the algorithmic part an algorithm generates a map of the markers, given these distances. Here, we study the latter algorithmic part, called the RH problem.

There exist several algorithms for the RH problem. Most algorithms are heuristics [4, 10, 13], but for a few algorithms theoretical results exist as well. In [2], for instance, Ben-Dor and Chor presented three algorithms for the RH problem, together with bounds on the number of experiments that is sufficient for the algorithms to give the correct order of the markers in the map. In [7], an approximation algorithm for the Matrix-To-Line problem was used to generate a map from pairwise distances. Arrangements produced with this algorithm were shown to converge to the true arrangements.

The three algorithms in [2] are called `P-Order`, `K-Order`, and `MST-Order`. The traveling salesman problem (TSP)-based algorithm `MST-Order` was developed into the program `RHO` [3], which has been even further developed using the combinatorial optimization package CONCORDE [1]. TSP/CONCORDE has been compared to other RH mapping software [8], and has been practically used to create RH maps for the canine genome [6] as well as the feline genome [12]. In this paper we improve the analysis of the other two algorithms: `P-Order` and `K-Order`, inspired by Prim's and Kruskal's algorithms (see [5]), respectively. We obtain better lower bounds on the

†Stockholm Bioinformatics Center, Department of Numerical Analysis and Computer Science, KTH, Stockholm, Sweden (ivan@nada.kth.se, jensl@nada.kth.se).

number of experiments sufficient to obtain the correct order of the markers with high probability. Furthermore, our bounds capture the impact that the true arrangement of the markers has on the performance of the two algorithms. In fact, it is possible to construct instances for which the gap between our bound and the previous known bounds are arbitrarily large. Our analysis also allows us to gain insight into the question of for which arrangements the algorithms are likely to perform well and for which arrangements they are more likely to fail. The improved analysis suggests that the `K-Order` algorithm is the better of the two algorithms in most cases.

The new analysis of the `P-Order` and `K-Order` algorithms suggests that the use of several intensities for the radiation in the RH experiments could improve the performance bounds for the two algorithms. We propose modified versions of the `P-Order` and `K-Order` algorithms, which allow for the use of RH data produced with several intensities. We show that, given $O(\log n)$ series of experiments, using a range of intensities, the dependency on the choice of intensity can be removed from the performance bounds, under the assumption that the markers are uniformly distributed along the chromosome. Although multiple intensity algorithms have been proposed before [11], this is, to our knowledge, the first performance bound for such an algorithm.

## 2. The probabilistic model.

A marker is a gene or an arbitrary DNA sequence the presence of which can be detected in any DNA fragment via a laboratory test. To obtain information about the order of and distance between a pair of markers on a fragment of DNA, an RH experiment is performed. In an RH experiment the chromosome is exposed to gamma radiation, which shatters it into fragments. Some of the fragments are incorporated into (retained in) a hamster cell, which is grown to yield a hybrid cell line. Cells from this cell line are then tested for the presence of each DNA marker. The outcome of one experiment is represented by a vector in $\{0,1\}^n$, where 1 in the $i$th position corresponds to the presence of the $i$th marker; the outcome from $m$ experiments is in the natural way represented by an $m \times n$-matrix consisting of 0's and 1's.

The probabilistic model as well as the notation used in this paper are the same as, for instance, those used in [2] and [7]. We let $\lambda$ be the intensity of the gamma radiation used in the RH experiment. We let $p$ be the retention probability, i.e., the probability that a fragment is incorporated into the hamster cell. To simplify the calculations in section 4, we assume that this probability is independent of the radiation intensity. In practice, the retention probability goes down when the intensity goes up. In testing for the presence of a marker, we allow for errors. We let $\alpha$ be the probability of a false positive answer, and $\beta$ be the probability of a false negative answer. Furthermore, we assume that the retention of the different fragments, as well as the tests for presence, are independent events.

In [7] it was shown that, under this model, the separation probability for two markers $a$ and $b$ is

$$\varphi_{a,b} = 2pq(1 - e^{-\lambda \ell_{ab}})(1 - (\alpha + \beta))^2 + g(\alpha, \beta, p), \tag{2.1}$$

where $q = 1 - p$, $\ell_{ab}$ is the distance between $a$ and $b$, and

$$g(\alpha, \beta, p) = 2p(\alpha - \beta)(\alpha + \beta - 1) + 2\alpha(1 - \alpha). \tag{2.2}$$

The separation probabilities can be estimated from a series of RH experiments. With

$S_i(a,b)$ as the random variable defined by

$$S_i(a,b) = \begin{cases} 1 & \text{if } a \text{ and } b \text{ are separated in experiment } i, \\ 0 & \text{otherwise,} \end{cases} \tag{2.3}$$

for $i = 1, \ldots, m$, we get an estimate $\hat{\varphi}_{a,b}$ through

$$\hat{\varphi}_{a,b} = \frac{1}{m} \sum_{i=1}^{m} S_i(a,b). \tag{2.4}$$

We note that this estimate is unbiased since $E[\hat{\varphi}_{a,b}] = \varphi_{a,b}$. From (2.1), an expression can be obtained for the distance between two markers as a function of the separation probability. Using the estimates $\hat{\varphi}_{a,b}$ in this expression, we obtain estimates $\hat{d}(a,b)$ of the physical distances between any two markers $a$ and $b$, i.e.,

$$\hat{d}(a,b) = -\frac{1}{\lambda} \ln \left( 1 - \frac{\hat{\varphi}_{a,b} - g(\alpha, \beta, p)}{2pq(1-(\alpha+\beta))^2} \right). \tag{2.5}$$

However, we are not as interested in the estimated distance between two markers $a$ and $b$ as in whether the estimated distance between them is greater than the estimated distance between two other markers $c$ and $d$. Since the separation probability is an increasing function of the distance, this is equivalent to the question of whether $\hat{\varphi}_{a,b} > \hat{\varphi}_{c,d}$. More precisely, we are interested in the probability that this inequality holds, given that $d(a,b) > d(c,d)$. In this context it is natural to define a *distance comparator.*

DEFINITION 2.1. *A function $\mathcal{C}(a,b;c,d)$ from quadruples of markers to the set of integers $\{-1,0,1\}$ is a distance comparator if, for all choices of markers $a$, $b$, $c$, and $d$,*

1. $\mathcal{C}(a,b;c,d) = \mathcal{C}(b,a;c,d)$,
2. $\mathcal{C}(a,b;c,d) = \mathcal{C}(a,b;d,c)$,
3. $\mathcal{C}(a,b;c,d) + \mathcal{C}(c,d;a,b) = 0$.

We should think of a distance comparator as any procedure that compares pairs of distances between markers. If the procedure decides that the distance between two markers $a$ and $b$ is greater than the distance between two other markers $c$ and $d$, then $\mathcal{C}(a,b;c,d) = 1$; if it decides that the distance between $a$ and $b$ is less than the distance between $c$ and $d$, then $\mathcal{C}(a,b;c,d) = -1$; and if it decides that the distances are equal, then $\mathcal{C}(a,b;c,d) = 0$.

The specific distance comparator induced by the distance estimate $\hat{d}(a,b)$ above will be denoted $\widehat{\mathcal{C}}$.

DEFINITION 2.2. *Let $\hat{d}(x,y)$ be the distance estimate defined by* (2.5). *Define*

$$\widehat{\mathcal{C}}(a,b;c,d) = \begin{cases} 1 & \text{if } \hat{d}(a,b) > \hat{d}(c,d), \\ 0 & \text{if } \hat{d}(a,b) = \hat{d}(c,d), \\ -1 & \text{if } \hat{d}(a,b) < \hat{d}(c,d). \end{cases} \tag{2.6}$$

This means that $\widehat{\mathcal{C}}$ is the distance comparator used to compare distances in the `P-Order` and `K-Order` algorithms. Using Definition 2.2, we can rewrite the probability for which we want to find a lower bound as the probability that $\widehat{\mathcal{C}}(a,b;c,d) = 1$, given that $d(a,b) > d(c,d)$.

As was pointed out above, the question of whether $\widehat{\mathcal{C}}(a,b;c,d) = 1$, given that $d(a,b) > d(c,d)$, is equivalent to the question of whether $\hat{\varphi}_{a,b} > \hat{\varphi}_{c,d}$, given that $d(a,b) > d(c,d)$. This question bears close resemblance to the question of whether the estimated separation probabilities are what Ben-Dor and Chor call *consistent* or not [2]. The difference is that to show consistency, the inequality has to be true only for the case when $c$ and $d$ are consecutive in the true order and are located between $a$ and $b$. It turns out, however, that the calculations in [2] can be carried through in this more general case as well.

LEMMA 2.3. *Let $a, b, c,$ and $d$ be four markers such that $d(a,b) > d(c,d)$. Then*

$$\Pr\big[\widehat{\mathcal{C}}(a,b;c,d) \neq 1\big] \leq e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda)^2}, \tag{2.7}$$

*where $f_{\ell_1,\ell_2}(\lambda) = (1-e^{-\lambda\ell_1})e^{-\lambda\ell_2}$.*

*Proof.* Let $X_i$, $i = 1,\dots,m$, be the random variables defined by $X_i = 1$ if $a, b$ but not $c, d$ are separated in experiment $i$; $X_i = -1$ if $c, d$ but not $a, b$ are separated in experiment $i$; and $X_i = 0$ otherwise. We observe that if we let

$$Y = \sum_{i=1}^{m} X_i, \tag{2.8}$$

then $\hat{\varphi}_{a,b} - \hat{\varphi}_{c,d} = Y/m$. Hence $Y > 0$ if and only if $\widehat{\mathcal{C}}(a,b;c,d) = 1$. From (2.1) it follows that

$$\begin{aligned} \varphi_{a,b} - \varphi_{c,d} &= 2pq(1-(\alpha+\beta))^2(1-e^{-\lambda(\ell_{ab}-\ell_{cd})})e^{-\lambda\ell_{cd}} \\ &= 2pq(1-(\alpha+\beta))^2 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda), \end{aligned} \tag{2.9}$$

which means that the expectation $E[Y]$ can be written

$$\begin{aligned} E[Y] &= m(\varphi_{a,b} - \varphi_{c,d}) \\ &= 2mpq(1-(\alpha+\beta))^2 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda). \end{aligned} \tag{2.10}$$

Our aim is to bound the probability that $Y < 0$, given that $E[Y] > 0$, i.e., the probability that $Y$ deviates from $E[Y]$ toward zero by more than $E[Y]$. Since the variables $X_i$ are independent, Hoeffding's inequality [9] immediately yields that

$$\begin{aligned} \Pr\big[E[Y] - Y \geq E[Y]\big] &\leq e^{-2E[Y]^2/4m} \\ &= e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda)^2}. \end{aligned} \tag{2.11}$$ ∎

The function $f_{\ell_1,\ell_2}(\lambda)$ can be given the following interpretation. If $I_1$ and $I_2$ are two intervals of length $\ell_1$ and $\ell_2$, respectively, then

$$\begin{aligned} &\Pr\big[(\text{at least one break occurs in } I_1) \wedge (\text{no breaks occur in } I_2)\big] \\ &\quad = (1-e^{-\lambda\ell_1})e^{-\lambda\ell_2} = f_{\ell_1,\ell_2}(\lambda). \end{aligned} \tag{2.12}$$

This function will be explored in more detail later, but for now the following intuitively obvious properties will be sufficient to carry through our derivations.

LEMMA 2.4. *Let $\lambda > 0$. If $\ell \geq \ell_1 > 0$, then $f_{\ell,\ell_2}(\lambda) \geq f_{\ell_1,\ell_2}(\lambda)$. If $\ell \geq \ell_2 > 0$, then $f_{\ell_1,\ell}(\lambda) \leq f_{\ell_1,\ell_2}(\lambda)$. If $\ell_1 \geq \ell_2 > 0$, then $f_{\ell_1,\ell_2}(\lambda) \geq f_{\ell_2,\ell_1}(\lambda)$.*

*Proof.* Assume that $\lambda > 0$. If $\ell \geq \ell_1 \geq 0$, then

$$f_{\ell,\ell_2}(\lambda) = (1-e^{-\lambda\ell})e^{-\lambda\ell_2} \geq (1-e^{-\lambda\ell_1})e^{-\lambda\ell_2} = f_{\ell_1,\ell_2}(\lambda). \tag{2.13}$$

If $\ell \geq \ell_2 \geq 0$, then

$$f_{\ell_1,\ell}(\lambda) = (1 - e^{-\lambda\ell_1})e^{-\lambda\ell} \leq (1 - e^{-\lambda\ell_1})e^{-\lambda\ell_2} = f_{\ell_1,\ell_2}(\lambda). \tag{2.14}$$

If $\ell_1 \geq \ell_2 \geq 0$, then

$$f_{\ell_1,\ell_2}(\lambda) = (1 - e^{-\lambda\ell_1})e^{-\lambda\ell_2} \geq (1 - e^{-\lambda\ell_2})e^{-\lambda\ell_1} = f_{\ell_2,\ell_1}(\lambda). \qquad \square \tag{2.15}$$

## 3. An improved analysis of known algorithms.

In [2], Ben-Dor and Chor proposed two simple algorithms for the calculation of the marker order: the `P-Order` and `K-Order` algorithms. In the `P-Order` algorithm a chain of markers is built in a stepwise fashion. Initially, a chain is constructed by connecting the two markers with the shortest estimated distance. Then, in each step of the algorithm, the marker with the shortest estimated distance to any of the two ends of the chain is connected to that end of the chain. In the `K-Order` algorithm, a collection of chains is maintained. Initially there are $n$ chains of length 1. Then, in each step of the algorithm, the two endmarkers with the shortest estimated distance between them are connected.

It was shown in [2] that if $\delta_{\max}$ and $\delta_{\min}$ are the longest and shortest, respectively, distances between any pair of consecutive markers on the chromosome, then given

$$m \geq \log\left(\frac{n^3}{\epsilon}\right) \frac{1}{2p^2q^2(1-(\alpha+\beta))^4 f_{\delta_{\min},\delta_{\max}}(\lambda)^2} \tag{3.1}$$

experiments, the estimated distances are *consistent* with probability $1-\epsilon$, i.e., that $\hat{d}(a,d) > \hat{d}(b,c)$ for *all* markers $a$, $b$, $c$, and $d$, appearing in this order on the genome, such that $b$ and $c$ are consecutive and $d(a,d) > d(b,c)$. Furthermore, they showed that if the estimated distances are consistent, both the `P-Order` and the `K-Order` algorithms yield a correct order of the markers. We prove new tighter bounds for both the `P-Order` and the `K-Order` algorithms. These new bounds improve the above bound, by taking into account the actual arrangement of the markers.

### 3.1. Analyzing the `P-Order` algorithm.

In the `P-Order` algorithm one marker at a time is added to the chain that is being built. In order to show correctness of the `P-Order` algorithm we thus need to assert that, with high probability, a marker adjacent to an endmarker of the chain is added to that marker in each step, i.e., that the estimated distance between the endmarker and the marker adjacent to that marker is smaller than the estimated distance between the endmarker and any other marker. The following definition will be useful for this purpose.

DEFINITION 3.1. *A distance comparator $\mathcal{C}$ satisfies the* `P-Order` *condition with parameter $\gamma$ if, for any markers $a$, $b$, $c$, and $d$ appearing in this order on the chromosome such that $b$ and $c$ are consecutive and $d(a,d) > d(b,c)$, the probability that $\mathcal{C}(a,d;b,c) = 1$ is at least $1-\gamma$.*

Note the difference between the concept of consistency and the `P-Order` condition. For a distance estimate to be consistent it is required that $\hat{d}(b,c) \leq \hat{d}(a,d)$ for *all* markers $a$, $b$, $c$, and $d$ appearing in this order on the chromosome such that $b$ and $c$ are consecutive and $d(a,d) > d(b,c)$. It turns out to be sufficient that the `P-Order` condition hold for $n^2$ such quadruples of markers simultaneously, namely, the pairs of distances actually compared in the algorithm.

THEOREM 3.2. *If a distance comparator $\mathcal{C}$ satisfying the* `P-Order` *condition with parameter $\gamma$ is used in the* `P-Order` *algorithm, then the* `P-Order` *algorithm will give the correct order of the markers with probability greater than $1-\gamma n^2$.*

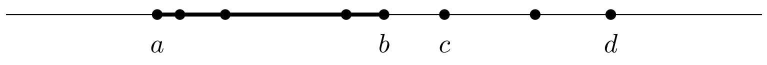

FIG. 3.1. *The kth step of the* `P-Order` *algorithm.*

*Proof.* Let $a$ be an arbitrarily chosen marker, and let $b$ be the marker immediately to the right of $a$. From the `P-Order` condition it follows that $\mathcal{C}(a,b;a,c) = -1$ with probability at least $1-\gamma$ for any marker $c$ to the right of $b$. Since there are at most $n-2$ markers to the right of $b$, this means that, with probability at least $1-\gamma(n-2)$, $\mathcal{C}(a,b;a,c) = -1$ for all markers $c$ to the right of $b$. Let $A_1$ be the event that the first two markers connected in the `P-Order` algorithm are adjacent, and let $L(i)$ be the event that the $i$th marker is the leftmost marker of the two markers chosen. Then

$$\begin{aligned} \Pr\bigl[A_1\bigr] &= \sum_{i=1}^{n-1} \Pr\bigl[A_1 \mid L(i)\bigr] \cdot \Pr\bigl[L(i)\bigr] \\ &\geq \sum_{i=1}^{n-1} (1-\gamma(n-2)) \cdot \Pr\bigl[L(i)\bigr] \\ &= 1-\gamma(n-2). \end{aligned} \tag{3.2}$$

Hence, the first two markers connected in the `P-Order` algorithm are adjacent with probability $\geq 1-\gamma(n-2)$.

Now, assume that the `P-Order` algorithm has correctly constructed a chain consisting of $k$ markers ($k \geq 2$). Let $a$ be the left endpoint of the chain, and let $b$ be the right endpoint of the chain. Finally, let $c$ be the marker immediately to the right of $b$; see Figure 3.1. From the `P-Order` condition it follows that $\mathcal{C}(b,c;b,d) = -1$ with probability $\geq 1-\gamma$ for any marker $d$ to the right of $c$. Furthermore, it follows that $\mathcal{C}(b,c;a,d) = -1$ with probability $\geq 1-\gamma$ for any marker $d$ to the right of $b$. The same derivations can obviously be carried through for the markers to the left of $a$.

In the $k$th step of the algorithm ($k \geq 2$) there are $n-k$ nonconnected markers. Let $A_k$ be the event that a marker adjacent to one of the endmarkers of the chain is connected to that endmarker in step $k$. Let $L$ be the event that the new marker is added to the left endmarker of the chain, and let $R$ be the event that the new marker is added to the right endmarker of the chain. Then

$$\begin{aligned} \Pr\bigl[A_k \mid A_1,\dots,A_{k-1}\bigr] &= \Pr\bigl[A_k \mid L, A_1,\dots,A_{k-1}\bigr] \cdot \Pr\bigl[L \mid A_1,\dots,A_{k-1}\bigr] \\ &\quad + \Pr\bigl[A_k \mid R, A_1,\dots,A_{k-1}\bigr] \cdot \Pr\bigl[R \mid A_1,\dots,A_{k-1}\bigr] \\ &\geq (1-2\gamma(n-k)) \cdot \Pr\bigl[L \mid A_1,\dots,A_{k-1}\bigr] \\ &\quad + (1-2\gamma(n-k)) \cdot \Pr\bigl[R \mid A_1,\dots,A_{k-1}\bigr] \\ &= 1-2\gamma(n-k). \end{aligned} \tag{3.3}$$

We thus conclude that if only adjacent markers have been connected in the first $k-1$ steps of the `P-Order` algorithm, then the marker being connected to an endmarker in the $k$th step is adjacent to that marker with probability $\geq 1-2\gamma(n-k)$.

If we sum up all steps of the algorithm, including the first step, we get an upper bound on the error probability $\epsilon$:

$$\epsilon \leq \gamma(n-2) + \sum_{k=2}^{n} 2\gamma(n-k) < \sum_{j=1}^{n-1} 2\gamma j = \gamma n(n-1) \leq \gamma n^2. \tag{3.4}$$

We have thus shown that with probability greater than $1-\gamma n^2$ the `P-Order` algorithm gives the correct order of the markers. ◻

Now, we will show how to find an expression for the parameter in the `P-Order` condition such that the distance comparator $\widehat{\mathcal{C}}$ satisfies the `P-Order` condition. This expression will obviously be heavily dependent on how the markers are arranged on the chromosome, as well as on the radiation intensity used in the experiment.

DEFINITION 3.3. *Define the function* $f_{\mathtt{P}}(\lambda)$ *as*

$$f_{\mathtt{P}}(\lambda) = \min_{1<i<n} \{ f_{\ell_{i-1,i},\ell_{i,i+1}}(\lambda), f_{\ell_{i,i+1},\ell_{i-1,i}}(\lambda) \}. \tag{3.5}$$

LEMMA 3.4. *Given* $m$ *experiments, the distance comparator* $\widehat{\mathcal{C}}$*, defined in Definition* 2.2*, satisfies the* `P-Order` *condition with parameter*

$$e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{P}}(\lambda)^2}. \tag{3.6}$$

*Proof.* Let $a$, $b$, $c$, and $d$ be four markers appearing in this order on the chromosome; assume that $b$ and $c$ are consecutive and that $d(a,d) > d(b,c)$. Without loss of generality we assume that $d \neq c$. Let $e$ be the marker immediately to the right of $c$. Note that $e$ may be identical to the marker $d$. Now, it follows from Lemmas 2.3 and 2.4 that

$$\begin{aligned} \Pr\big[\widehat{\mathcal{C}}(a,d;b,c) \neq 1\big] &\leq e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ad}-\ell_{bc},\ell_{bc}}(\lambda)^2} \\ &= e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ce},\ell_{bc}}(\lambda)^2} \\ &\leq e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{P}}(\lambda)^2}, \end{aligned} \tag{3.7}$$

where the last inequality follows from the fact that the markers $b$, $c$, $e$ are consecutive, together with Definition 3.3. Hence, for any four markers $a$, $b$, $c$, and $d$ appearing in this order on the chromosome such that $b$ and $c$ are consecutive and $d(a,d) > d(b,c)$,

$$\Pr\big[\widehat{\mathcal{C}}(a,d;b,c) = 1\big] \geq 1 - e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{P}}(\lambda)^2}. \tag{3.8}$$ ◻

If we use Lemma 3.4 in combination with Theorem 3.2, we get the following theorem, which gives an upper bound on the number of experiments that is sufficient for the `P-Order` algorithm to give the correct order of the markers.

THEOREM 3.5. *Given*

$$m \geq \ln\left(\frac{n^2}{\epsilon}\right) \frac{1}{2p^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{P}}(\lambda)^2} \tag{3.9}$$

*experiments, the* `P-Order` *algorithm gives the correct order of the markers with probability greater than* $1-\epsilon$.

*Proof.* From Lemma 3.4 it follows that with

$$m \geq \ln\left(\frac{n^2}{\epsilon}\right) \frac{1}{2p^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{P}}(\lambda)^2} \tag{3.10}$$

experiments, $\widehat{\mathcal{C}}$ satisfies the `P-Order` condition with parameter $\leq \epsilon/n^2$. By Theorem 3.2, this implies that the `P-Order` algorithm will give the correct order of the markers with probability greater than $1-\epsilon$. ◻

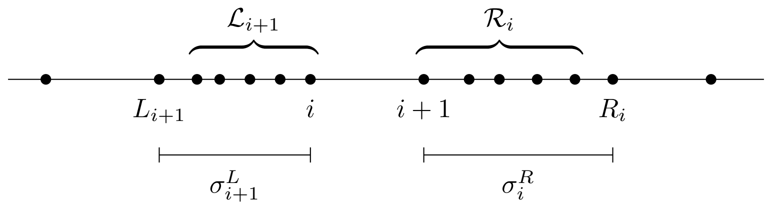

FIG. 3.2. *Notation used in the analysis of the* `K-Order` *algorithm.*

**3.2. Analyzing the `K-Order` algorithm.** In the `K-Order` algorithm the two markers with the shortest estimated distance are joined in each step. This suggests that sequences of tightly packed markers surrounded by long distances probably will be connected to each other before any of the markers are connected to surrounding markers that are far away. This will greatly facilitate the objective of correctly ordering the tightly packed markers, since in this case we just have to order the distances between the surrounding markers and the ends of the chain, instead of the distances between the surrounding markers and the individual markers in the cluster. In order to analyze the algorithm rigorously we will use the following notation (for an illustration, see Figure 3.2).

DEFINITION 3.6.

$$L_i = \max\left(\left\{k : k < i, \ell_{k-1,k} > \frac{\ell_{i-1,i}}{2}\right\} \cup \{1\}\right), \tag{3.11}$$

$$R_i = \min\left(\left\{k : k > i, \ell_{k,k+1} > \frac{\ell_{i,i+1}}{2}\right\} \cup \{n\}\right), \tag{3.12}$$

$$\mathcal{L}_i = \{j : L_i < j \leq i-1\}, \qquad \mathcal{R}_i = \{j : i+1 \leq j < R_i\}, \tag{3.13}$$

$$m_i = \max(\{\ell_{j-1,j} : j \in \mathcal{L}_i\} \cup \{\ell_{j,j+1} : j \in \mathcal{R}_i\}), \tag{3.14}$$

$$\sigma^L_i = \ell_{i-2,i-1} + \sum_{j=L_i+1}^{i-2} \ell_{j-1,j}, \qquad \sigma^R_i = \ell_{i+1,i+2} + \sum_{j=i+2}^{R_i-1} \ell_{j,j+1}. \tag{3.15}$$

The idea is thus to make sure that before we connect the markers $i$ and $i+1$, all short edges to the left of $i$ and to the right of $i+1$ are connected. To capture this idea we define what we call the `K-Order` conditions, which have two parameters.

DEFINITION 3.7. *A distance comparator $\mathcal{C}$ satisfies the* `K-Order` *conditions with parameters $\gamma$ and $\zeta$ if*

1. *for any markers $a$, $b$, $c$, and $d$ appearing in this order on the chromosome such that $b$ and $c$ are consecutive, $d(a,d) > d(b,c)$, and $d \notin \mathcal{R}_b$ or $a \notin \mathcal{L}_c$, the probability that $\mathcal{C}(a,d;b,c) = 1$ is at least $1-\gamma$;*
2. *for each $a \in [2,n]$ and $b \in \mathcal{L}_a$ the probability that $\mathcal{C}(a-1,a;b-1,b) = 1$ is at least $1-\zeta$;*
3. *for each $a \in [1,n-1]$ and $b \in \mathcal{R}_a$ the probability that $\mathcal{C}(a,a+1;b,b+1) = 1$ is at least $1-\zeta$.*

It turns out that if a distance comparator satisfies these `K-Order` conditions, then it is possible to show that the `K-Order` algorithm using this distance comparator will find the true order of the markers with high probability.

THEOREM 3.8. *If a distance comparator $\mathcal{C}$ satisfying the* `K-Order` *condition with parameters $\gamma$ and $\zeta$ is used in the* `K-Order` *algorithm, then the* `K-Order` *algorithm will*

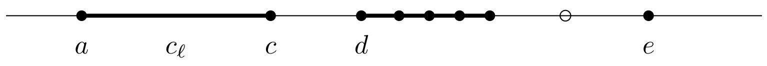

FIG. 3.3. *A step in the* `K-Order` *algorithm.*

*give the correct order of the markers with probability greater than* $1 - 2\gamma n^2 - \zeta n^2$.

*Proof.* We say that a distance comparator $\mathcal{C}$ is $\mathcal{L}$*-closed* if, for all $a \in [2, n]$ and $b \in \mathcal{L}_a$, we have $\mathcal{C}(a-1, a; b-1, b) = 1$; analogously, we say that $\mathcal{C}$ is $\mathcal{R}$*-closed* if, for all $a \in [1, n-1]$ and $b \in \mathcal{R}_a$, we have $\mathcal{C}(a, a+1; b, b+1) = 1$. This means that if $\mathcal{C}$ is $\mathcal{L}$-closed and if the `K-Order` algorithm has only connected adjacent markers, then all markers in $\mathcal{L}_a$ will be connected before the markers $a-1$ and $a$ are connected to each other. Analogously, if $\mathcal{C}$ is $\mathcal{R}$-closed and if the `K-Order` algorithm has only connected adjacent markers, then all markers in $\mathcal{R}_a$ will be connected before the markers $a$ and $a+1$ are connected to each other.

To prove the theorem, we will therefore show that if the distance comparator $\mathcal{C}$, used in the `K-Order` algorithm, satisfies the `K-Order` conditions with parameters $\gamma$ and $\zeta$, then

1. $\mathcal{C}$ is $\mathcal{L}$-closed and $\mathcal{R}$-closed, with probability at least $1 - \zeta n^2$;
2. if $\mathcal{C}$ is $\mathcal{L}$-closed and $\mathcal{R}$-closed, then only adjacent markers will be connected by the `K-Order` algorithm with probability at least $1 - 2\gamma n^2$.

From the `K-Order` conditions it follows that for any marker $a$ and any marker $b \in \mathcal{L}_a$, $\mathcal{C}(a-1, a; b-1, b) = 1$ with probability at least $1 - \zeta$. There are at most $\binom{n}{2}$ pairs of markers altogether, so with probability at least $1 - \zeta n^2/2$, $\mathcal{C}(a-1, a; b-1, b) = 1$ for all markers $a$ and all markers $b \in \mathcal{L}_a$. Hence, $\mathcal{C}$ is $\mathcal{L}$-closed with probability at least $1 - \zeta n^2/2$. Analogously, from the `K-Order` conditions it follows that for any marker $a$ and any marker $b \in \mathcal{R}_b$, $\mathcal{C}(a, a+1; b, b+1) = 1$ with probability at least $1 - \zeta$. Hence, with probability at least $1 - \zeta n^2/2$, $\mathcal{C}(a, a+1; b, b+1) = 1$ for all markers $a$ and all markers $b \in \mathcal{R}_a$. Thus, $\mathcal{C}$ is $\mathcal{R}$-closed with probability at least $1 - \zeta n^2/2$ as well. To sum up, this means that $\mathcal{C}$ is $\mathcal{L}$-closed and $\mathcal{R}$-closed with probability at least $1 - \zeta n^2$.

Now, assume that the `K-Order` algorithm has connected only adjacent markers in its first $k-1$ steps and that $\mathcal{C}$ is $\mathcal{L}$-closed and $\mathcal{R}$-closed. Let $c_\ell$ be the leftmost chain that is connected in the $k$th step. Let $a$ and $c$ be the left and right endpoints, respectively, of the chain $c_\ell$ (note that in the singleton case $c$ is identical to $a$). Let $d$ be the marker immediately to the right of $c$, and let $e$ be any free marker to the right of $d$; see Figure 3.3. Notice that, since $\mathcal{C}$ is $\mathcal{R}$-closed, no free marker to the right of $d$ belongs to $\mathcal{R}_c$. From the `K-Order` condition it thus follows that $\mathcal{C}(c, d; c, e) = -1$ with probability $\geq 1 - \gamma$. For the same reason, in the case where $a$ and $c$ are distinct, the `K-Order` condition implies that $\mathcal{C}(c, d; a, e) = -1$ with probability $\geq 1 - \gamma$. Since $\mathcal{C}$ is $\mathcal{L}$-closed, $a$ does not belong to $\mathcal{L}_d$, which means that if $a$ and $c$ are distinct, $\mathcal{C}(c, d; a, d) = -1$ with probability $\geq 1 - \gamma$ as well.

Let $e_k$ be the number of endmarkers in the $k$th step. In the case where $a$ and $c$ are distinct, the number of endmarkers not belonging to $c_\ell$ is $e_k - 2$, and the probability that an adjacent marker is connected to $c_\ell$ is $\geq 1 - 2\gamma(e_k - 2)$, given that $c_\ell$ is the leftmost chain in the connection. In the case where $a$ and $c$ are identical, the number of endmarkers not belonging to $c_\ell$ is $e_k - 1$, so the probability that an adjacent marker is connected to $c_\ell$ is $\geq 1 - \gamma(e_k - 1)$, given that $c_\ell$ is the leftmost chain in the connection. Since $1 - 2\gamma(e_k - 2) \leq 1 - \gamma(e_k - 1)$ for $e_k \geq 3$, we thus conclude that the probability that an adjacent marker is connected to $c_\ell$ is $\geq 1 - 2\gamma(e_k - 2)$, given that $c_\ell$ is the leftmost chain in the connection.

Let $A_k$ be the event that two adjacent markers are connected in the $k$th step, and let $L(i)$ be the event that the $i$th chain from the left is chosen as the leftmost chain in the connection. Then

$$\begin{aligned}\Pr\big[A_k \mid A_1, \dots, A_{k-1}\big] \\ &= \sum_{i=1}^{n-k+1} \Pr\big[A_k \mid L(i), A_1, \dots, A_{k-1}\big] \cdot \Pr\big[L(i) \mid A_1, \dots, A_{k-1}\big] \\ &\geq (1 - 2\gamma(e_k - 2)) \sum_{i=1}^{n-k+1} \Pr\big[L(i) \mid A_1, \dots, A_{k-1}\big] \\ &= 1 - 2\gamma(e_k - 2).\end{aligned} \tag{3.16}$$

We know that the number of endpoints in step $k$ is at most twice the number of chains in step $k$, i.e., at most $2(n-k+1)$. If we sum up the error probabilities for the $k-1$ steps of the algorithm, we get an upper bound on the error probability $\epsilon$ for the `K-Order` algorithm, given that $\mathcal{C}$ is $\mathcal{L}$-closed and $\mathcal{R}$-closed:

$$\epsilon \leq \sum_{k=1}^{n-1} 2\gamma(e_k - 2) \leq \sum_{k=1}^{n-1} 4\gamma(n-k) = 2\gamma n(n-1) \leq 2\gamma n^2. \tag{3.17}$$

Let $A$ be the event that the `K-Order` algorithm gives a correct order of the markers. What we have shown is that

$$\Pr\big[\mathcal{C} \text{ is } \mathcal{L}\text{-closed} \wedge \mathcal{C} \text{ is } \mathcal{R}\text{-closed}\big] > 1 - \zeta n^2 \tag{3.18}$$

and that

$$\Pr\big[A \mid \mathcal{C} \text{ is } \mathcal{L}\text{-closed} \wedge \mathcal{C} \text{ is } \mathcal{R}\text{-closed}\big] > 1 - 2\gamma n^2. \tag{3.19}$$

Hence the probability that `K-Order` gives the correct order of the markers is

$$\begin{aligned}\Pr\big[A\big] &\geq \Pr\big[A \wedge (\mathcal{C} \text{ is } \mathcal{L}\text{-closed} \wedge \mathcal{C} \text{ is } \mathcal{R}\text{-closed})\big] \\ &> (1 - 2\gamma n^2)(1 - \zeta n^2) \\ &> 1 - 2\gamma n^2 - \zeta n^2. \qquad \square\end{aligned} \tag{3.20}$$

The number of experiments required to make the distance comparator $\widehat{\mathcal{C}}$ satisfy the `K-Order` conditions is naturally dependent on how the markers are arranged on the particular chromosome. Using the distances defined in Definition 3.6, we find expressions for the parameters $\gamma$ and $\zeta$ such that the distance comparator $\widehat{\mathcal{C}}$ satisfies the `K-Order` conditions.

Definition 3.9. *Define the functions* $f_{\mathrm{k}\gamma}(\lambda)$ *and* $f_{\mathrm{k}\zeta}(\lambda)$ *as*

$$f_{\mathrm{k}\gamma}(\lambda) = \min\left\{ \min_{2 \leq i \leq n-1} \{f_{\sigma^L_{i+1}, \ell_{i,i+1}}(\lambda)\}, \min_{1 \leq i \leq n-2} \{f_{\sigma^R_i, \ell_{i,i+1}}(\lambda)\} \right\}, \tag{3.21}$$

$$f_{\mathrm{k}\zeta}(\lambda) = \min_{\substack{1 \leq i \leq n-1 \\ \mathcal{L}_{i+1} \cup \mathcal{R}_i \neq \emptyset}} \{f_{\ell_{i,i+1} - m_i, m_i}(\lambda)\}, \tag{3.22}$$

*and let* $f_{\mathrm{k}}(\lambda) = \min\{f_{\mathrm{k}\gamma}(\lambda), f_{\mathrm{k}\zeta}(\lambda)\}$.

Lemma 3.10. *Given $m$ experiments, the distance comparator $\widehat{\mathcal{C}}$, defined in Definition 2.2, satisfies the `K-Order` condition with parameters*

$$\gamma = e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{k}\gamma}(\lambda)^2} \quad \text{and} \quad \zeta = e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{k}\zeta}(\lambda)^2}. \tag{3.23}$$

*Proof.* Lemma 2.3 states that for any four markers $a$, $b$, $c$, and $d$ such that $d(a,d) > d(b,c)$

$$\Pr\bigl[\widehat{\mathcal{C}}(a,d;b,c) \neq 1\bigr] \le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ad}-\ell_{bc},\ell_{bc}}(\lambda)^2}. \tag{3.24}$$

Let $a$, $b$, $c$, and $d$ be four markers appearing in this order on the chromosome, and assume that $b$ and $c$ are consecutive, that $d(a,d) > d(b,c)$, and that $d \notin \mathcal{R}_b$. If we let $e = R_b$, it follows from Lemma 2.4 and Definition 3.6 that

$$\begin{aligned}\Pr\bigl[\widehat{\mathcal{C}}(a,d;b,c) \neq 1\bigr] &\le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ad}-\ell_{bc},\ell_{bc}}(\lambda)^2}\\ &\le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{be}-\ell_{bc},\ell_{bc}}(\lambda)^2}\\ &= e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\sigma_b^R,\ell_{bc}}(\lambda)^2}.\end{aligned} \tag{3.25}$$

In a similar way we can show that if $a \notin \mathcal{L}_c$, then

$$\Pr\bigl[\widehat{\mathcal{C}}(a,d;b,c) \neq 1\bigr] \le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\sigma_c^L,\ell_{bc}}(\lambda)^2}. \tag{3.26}$$

Hence, from Definition 3.9 it follows that, for any four markers $a$, $b$, $c$, and $d$ appearing in this order on the chromosome such that $b$ and $c$ are consecutive, $d(a,d) > d(b,c)$, and either $d \notin \mathcal{R}_b$ or $a \notin \mathcal{L}_c$,

$$\Pr\bigl[\widehat{\mathcal{C}}(a,d;b,c) = 1\bigr] > 1 - e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{k}\gamma}(\lambda)^2}. \tag{3.27}$$

Let $a \in [2,n]$ be an arbitrary marker, and assume that $b \in \mathcal{L}_a$. From Lemma 2.4, Definition 3.6, and Definition 3.9 it follows that

$$\begin{aligned}\Pr\bigl[\widehat{\mathcal{C}}(a-1,a;b-1,b) \neq 1\bigr] &\le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{a-1,a}-\ell_{b-1,b},\ell_{b-1,b}}(\lambda)^2}\\ &\le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{a-1,a}-m_{a-1},m_{a-1}}(\lambda)^2}\\ &\le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{k}\zeta}(\lambda)^2}.\end{aligned} \tag{3.28}$$

In the same way it is possible to show that for any $a \in [1, n-1]$ and $b$ in $\mathcal{R}_a$

$$\begin{aligned}\Pr\bigl[\widehat{\mathcal{C}}(a,a+1;b,b+1) \neq 1\bigr] &\le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{a,a+1}-m_a,m_a}(\lambda)^2}\\ &\le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{k}\zeta}(\lambda)^2}. \qquad \square\end{aligned} \tag{3.29}$$

If we use Lemma 3.10 in combination with Theorem 3.8, we get the following theorem, which gives an upper bound on the number of experiments that is sufficient for the `K-Order` algorithm to give the correct order of the markers.

Theorem 3.11. *Given*

$$m \ge \ln\left(\frac{4n^2}{\epsilon}\right) \frac{1}{2p^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{k}}(\lambda)^2} \tag{3.30}$$

*experiments, the `K-Order` algorithm gives the correct order of the markers with probability greater than $1-\epsilon$.*

*Proof.* From Lemma 3.10 it follows that with

$$m \geq \ln\left(\frac{4n^2}{\epsilon}\right)\frac{1}{2p^2q^2(1-(\alpha+\beta))^4 f_{\mathtt{k}}(\lambda)^2} \tag{3.31}$$

experiments, $\widehat{\mathcal{C}}$ satisfies the `K-Order` condition with parameters $\gamma \leq \epsilon/4n^2$ and $\zeta \leq \epsilon/4n^2$. By Theorem 3.8, this implies that the `K-Order` algorithm will give the correct order of the markers with probability greater than $1-\epsilon$. $\square$

**4. New multiple intensity algorithms.** It is clear from the bounds in Theorems 3.5 and 3.11 that the number of experiments needed for the `P-Order` and `K-Order` algorithms to compute the correct marker order is heavily dependent on the radiation intensity used, or more precisely, on the relation between intensity and the distances compared given by the function $f_{\ell_1,\ell_2}(\lambda)$. Here we present the `Modified-P-Order` and `Modified-K-Order` algorithms which are able to use RH data from several series of experiments, performed with different intensities of the radiation. We show that if the output from $O(\log(n))$ series of experiments with suitably chosen intensities is used, the dependency on the intensity of the radiation can be removed from the performance bounds if we assume that the markers are uniformly distributed.

In each step of both the `K-Order` and `P-Order` algorithms, we look for the minimum distance in a set of given distances (between pairs of markers $\ell_i$). This is done through a sequence of pairwise comparisons between separation probabilities. In the `Modified-P-Order` and `Modified-K-Order` algorithms, each such comparison is made with the estimates calculated from the series of experiments giving the greatest difference in the estimated separation probabilities for the two pairs of markers. We thus get the following distance comparator.

DEFINITION 4.1. *Let $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_t)$ be the intensities used in the $t$ experiment series, and let $\hat{d}_{\lambda_i}(x,y)$ be the distance estimate obtained by applying the distance estimate defined by* (2.5) *to the data from series $i$. For any four markers $a$, $b$, $c$, and $d$, let $\tilde{\lambda}$ be the intensity maximizing the difference in separation probability between $a$, $b$ and $c$, $d$ among the $t$ intensities $\lambda_i$. Define*

$$\mathcal{C}_{t,\boldsymbol{\lambda}}(a,b;c,d) = \begin{cases} 1 & \text{if } \hat{d}_{\tilde{\lambda}}(a,b) > \hat{d}_{\tilde{\lambda}}(c,d), \\ 0 & \text{if } \hat{d}_{\tilde{\lambda}}(a,b) = \hat{d}_{\tilde{\lambda}}(c,d), \\ -1 & \text{if } \hat{d}_{\tilde{\lambda}}(a,b) < \hat{d}_{\tilde{\lambda}}(c,d). \end{cases} \tag{4.1}$$

The use of this distance comparator is motivated by Lemma 2.3 and (2.1). Lemma 2.3 states that if $a$, $b$, $c$, and $d$ are four markers such that $d(a,b) > d(c,d)$, then $\Pr\big[\hat{d}(a,b) \leq \hat{d}(c,d)\big] \leq e^{-O(f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda)^2)}$. This means that we get the best bound for the error probability when using the intensity $\lambda$ that maximizes $f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda)$. Unfortunately, this value is unknown, since the distances between the markers are unknown. However, (2.9) implies that the difference in separation probability between $a$, $b$ and $c$, $d$ is proportional to $f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda)$; we would thus expect the optimal intensity to be the one maximizing this difference.

To analyze the modified algorithms, we will start by showing an upper bound on the probability of misjudging a pair of distances when using the distance comparator $\mathcal{C}_{t,\boldsymbol{\lambda}}$. This bound will be similar to the bound in Lemma 2.3.

Assume that two series of RH experiments have been made, each consisting of $m$ experiments. In the first series the intensity $\lambda_1$ was used, and in the second series the intensity $\lambda_2$ was used. For $i = 1, \ldots, m$ and $j = 1, 2$ we define $X_i^j = 1$ if $a, b$ but not

$c, d$ are separated in the $i$th experiment of series $j$; $X_i^j = -1$ if $c, d$ but not $a, b$ are separated in the $i$th experiment of series $j$; and $X_i^j = 0$ otherwise. Furthermore, for $j = 1, 2$, we let

$$Y_j = \sum_{i=1}^{m} X_i^j. \tag{4.2}$$

Equation (2.10), states that in this case

$$E[Y_j] = 2mpq(1-(\alpha+\beta))^2 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda_j). \tag{4.3}$$

Assume that $d(a, b) > d(c, d)$, and that $Y_1 > 0$, i.e., that the series of experiments using intensity $\lambda_1$ has given the correct ordering of the distances. We will bound the probability that, in the algorithm, the results from the second series of experiments will mislead us into drawing the incorrect conclusion about the two distances $d(a, b)$ and $d(c, d)$. This will happen when $Y_2 < -Y_1$, i.e., when $Y_1 + Y_2 < 0$. Let

$$Z = \sum_{i=1}^{m} X_i^1 + \sum_{i=1}^{m} X_i^2 = Y_1 + Y_2. \tag{4.4}$$

Since $d(a, b) > d(c, d)$, it is clear that

$$E[Z] = E[Y_1] + E[Y_2] > 0. \tag{4.5}$$

Using the Hoeffding inequality and (4.3), we see that

$$\begin{aligned} \Pr\big[Z < 0\big] &= \Pr\big[E[Z] - Z \geq E[Z]\big] = \Pr\left[\frac{E[Z]-Z}{2m} \geq \frac{E[Z]}{2m}\right] \\ &\leq e^{-2E[Z]^2/8m} = e^{-2(E[Y_1]+E[Y_2])^2/8m} \\ &= e^{-mp^2q^2(1-(\alpha+\beta))^4(f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda_1)+f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda_2))^2}. \end{aligned} \tag{4.6}$$

This inequality will be used to prove the following lemma.

LEMMA 4.2. *Let $a, b, c$ and $d$ be four markers such that $d(a, b) > d(c, d)$. Then*

$$\Pr\big[\mathcal{C}_{\boldsymbol{\lambda},t}(a, b; c, d) \neq 1\big] \leq te^{-mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda^*)^2}, \tag{4.7}$$

*where $\lambda^*$ is the intensity maximizing $f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda)$ among the $t$ intensities $\lambda_1, \dots, \lambda_t$ in $\boldsymbol{\lambda}$.*

*Proof.* Let $B_1$ be the event that the decision based on the series of experiments using intensity $\lambda^*$ is incorrect, and let $B_2$ be the event that the series of experiments using intensity $\lambda^*$ is correct but some other series is chosen and the decision based on that series is incorrect. From Lemma 2.3 follows that

$$\Pr\big[B_1\big] \leq e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda^*)^2}, \tag{4.8}$$

and from (4.6) follows that

$$\Pr\big[B_2\big] \leq \sum_{\lambda_i \neq \lambda^*} e^{-mp^2q^2(1-(\alpha+\beta))^4(f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda^*)+f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda_i))^2}. \tag{4.9}$$

This means that

$$\begin{aligned}\Pr\big[\mathcal{C}_{\boldsymbol{\lambda},t}(a,b;c,d)\neq 1\big] &\le \Pr\big[B_1\big]+\Pr\big[B_1\big]\\ &\le e^{-2mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda^*)^2}\\ &\qquad+\sum_{\lambda_i\neq\lambda^*} e^{-mp^2q^2(1-(\alpha+\beta))^4(f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda^*)+f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda_i))^2}\\ &\le te^{-mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda^*)^2}. \qquad \square\end{aligned} \tag{4.10}$$

To eliminate the dependency on the intensity $\lambda$ from the bound in Lemma 4.2 we need to investigate the function $f_{\ell_1,\ell_2}(\lambda)$ in more detail. Differentiation of the function $f_{\ell_1,\ell_2}(\lambda)$ with respect to $\lambda$ yields that

$$\frac{df_{\ell_1,\ell_2}(\lambda)}{d\lambda}=(\ell_1+\ell_2)e^{-\lambda(\ell_1+\ell_2)}-\ell_2e^{-\lambda\ell_2}, \tag{4.11}$$

$$\frac{d^2f_{\ell_1,\ell_2}(\lambda)}{d\lambda^2}=-(\ell_1+\ell_2)^2e^{-\lambda(\ell_1+\ell_2)}+\ell_2^2e^{-\lambda\ell_2}. \tag{4.12}$$

We observe that

$$\hat\lambda=\frac{1}{\ell_1}\ln\frac{\ell_1+\ell_2}{\ell_2} \tag{4.13}$$

is the only stationary point for $f_{\ell_1,\ell_2}(\lambda)$ when $\ell_1,\ell_2>0$, and that this stationary point is in fact a maximum since

$$\frac{d^2f_{\ell_1,\ell_2}(\hat\lambda)}{d\lambda^2}=-\ell_1\ell_2\left(\frac{\ell_2}{\ell_1+\ell_2}\right)^{\frac{\ell_2}{\ell_1}}<0 \tag{4.14}$$

for $\ell_1,\ell_2>0$. Furthermore, we see that the corresponding optimal value is

$$f_{\ell_1,\ell_2}(\hat\lambda)=\left(\frac{\ell_1}{\ell_1+\ell_2}\right)\left(\frac{\ell_2}{\ell_1+\ell_2}\right)^{\frac{\ell_2}{\ell_1}}. \tag{4.15}$$

If an intensity $\tilde\lambda$ is sufficiently close to the optimal intensity $\hat\lambda$, the value of $f_{\ell_1,\ell_2}(\tilde\lambda)$ should not be too far from the optimal value $f_{\ell_1,\ell_2}(\hat\lambda)$. The following lemma states that for $\tilde\lambda\in[\hat\lambda/2,2\hat\lambda]$ a lower bound on $f_{\ell_1,\ell_2}(\tilde\lambda)$ can be given that is independent of the intensity.

LEMMA 4.3. *Let $\hat\lambda$ be the unique optimum for $f_{\ell_1,\ell_2}(\lambda)$, i.e.,*

$$\hat\lambda=\frac{1}{\ell_1}\ln\frac{\ell_1+\ell_2}{\ell_2}. \tag{4.16}$$

*Then, for any $\tilde\lambda\in[\hat\lambda/2,2\hat\lambda]$,*

$$f_{\ell_1,\ell_2}(\tilde\lambda)\ge\frac{1}{2e^2}\frac{\ell_1}{\ell_1+\ell_2}. \tag{4.17}$$

*Proof.* Since $f_{\ell_1,\ell_2}(\lambda)$ has a single stationary point which is a local maximum, we know that for any $\tilde\lambda$ such that $\tilde\lambda\in[\hat\lambda/2,2\hat\lambda]$,

$$f_{\ell_1,\ell_2}(\tilde\lambda)\ge\min\left\{f_{\ell_1,\ell_2}\left(\frac{\hat\lambda}{2}\right),f_{\ell_1,\ell_2}(2\hat\lambda)\right\}. \tag{4.18}$$

From the definition of $f_{\ell_1,\ell_2}(\lambda)$ it follows that for any $k > 0$

$$f_{\ell_1,\ell_2}(k\hat{\lambda}) = \left(1 + \frac{\ell_1}{\ell_2}\right)^{-k\frac{\ell_2}{\ell_1}} \left(1 - \left(1 - \frac{\ell_1}{\ell_1 + \ell_2}\right)^k\right). \tag{4.19}$$

Since we know that $(1 + 1/x)^{-kx} \geq e^{-k}$ for $x > 0$, this means that

$$f_{\ell_1,\ell_2}(k\hat{\lambda}) \geq e^{-k} \left(1 - \left(1 - \frac{\ell_1}{\ell_1 + \ell_2}\right)^k\right). \tag{4.20}$$

If we insert $k = 1/2$ and $k = 2$ into this equation and use the inequality

$$\min\{1 - (1 - x)^2, 1 - (1 - x)^{1/2}\} \geq \frac{x}{2} \tag{4.21}$$

for $0 < x < 1$, we thus get that

$$f_{\ell_1,\ell_2}(\tilde{\lambda}) \geq \frac{1}{2e^2} \frac{\ell_1}{\ell_1 + \ell_2}. \qquad \square \tag{4.22}$$

Lemma 4.3 implies that by using a range of intensities, the choice of intensities is eliminated completely from the bound in Lemma 4.2.

LEMMA 4.4. *Let a, b, c, and d be four markers such that* $d(a, b) > d(c, d)$. *Let* $\boldsymbol{\lambda} = (\lambda_1, \ldots , \lambda_t)$, *where* $\lambda_i = 4\lambda_{i-1}$, *for* $2 \leq i \leq t$. *Let* $\hat{\lambda}$ *be the intensity maximizing* $f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda)$, *and assume that* $\lambda_1 \leq \hat{\lambda} \leq \lambda_t$. *Then,*

$$\Pr\left[\mathcal{C}_{\boldsymbol{\lambda},t}(a, b; c, d) \neq 1\right] \leq te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\ell_{ab}-\ell_{cd}}{2e^2\ell_{ab}}\right)^2}. \tag{4.23}$$

*Proof.* By assumption, the intensities used in the $t$ series will satisfy $\lambda_{i+1} = 4\lambda_i$, for $i = 1, \ldots , t - 1$. Since the optimal intensity $\hat{\lambda}$ satisfies $\lambda_1 \leq \hat{\lambda} \leq \lambda_t$, this means that there is some intensity $\tilde{\lambda} \in \{\lambda_i\}$ such that $\hat{\lambda}/2 \leq \tilde{\lambda} \leq 2\hat{\lambda}$. Let $\lambda^*$ be the intensity maximizing $f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda)$ among the $t$ intensities $\lambda_1, \ldots , \lambda_t$. Then, from Lemma 4.3 it follows that

$$f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda^*) \geq f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\tilde{\lambda}) \geq \frac{\ell_{ab} - \ell_{cd}}{2e^2\ell_{ab}}. \tag{4.24}$$

If we use this inequality in Lemma 4.2, we get that

$$\begin{aligned} \Pr\left[\mathcal{C}_{\boldsymbol{\lambda},t}(a, b; c, d) \neq 1\right] &\leq te^{-mp^2q^2(1-(\alpha+\beta))^4 f_{\ell_{ab}-\ell_{cd},\ell_{cd}}(\lambda^*)^2} \\ &\leq te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\ell_{ab}-\ell_{cd}}{2e^2\ell_{ab}}\right)^2}. \qquad \square \end{aligned} \tag{4.25}$$

To be able to use Lemma 4.4 in the same way as we used Lemma 2.3 in the proof of the original `P-Order` and `K-Order` algorithms, we need to make sure that the optimal intensity $\hat{\lambda}$ satisfies $\lambda_1 \leq \hat{\lambda} \leq \lambda_t$, for all parameters $\ell_1$ and $\ell_2$ of the function $f_{\ell_1,\ell_2}(\lambda)$ considered in the analyses. The following lemma shows that the constraint on the optimal intensity can be transformed into a constraint on the two parameters $\ell_1$ and $\ell_2$.

LEMMA 4.5. *Let* $\ell_1$ *and* $\ell_2$ *be two distances such that* $0 < \ell_{\min} \leq \ell_1, \ell_2 \leq \ell_{\max}$, *and let* $\hat{\lambda}$ *be the optimal value of* $f_{\ell_1,\ell_2}(\lambda)$. *Then* $\hat{\lambda} \in [\ln 2/\ell_{\max}, \ln 2/\ell_{\min}]$.

*Proof.* Above, we observed that $f_{\ell_1,\ell_2}(\lambda)$ is maximized by $\hat{\lambda} = \ln((\ell_1+\ell_2)/\ell_2)/\ell_1$. Differentiation yields that

$$\frac{d\hat{\lambda}}{d\ell_1} = \frac{1}{\ell_1^2}\left(\frac{1}{1+\ell_2/\ell_1} - \ln\left(1+\frac{\ell_1}{\ell_2}\right)\right), \tag{4.26}$$

$$\frac{d\hat{\lambda}}{d\ell_2} = -\frac{1}{\ell_2+\ell_1\ell_2}. \tag{4.27}$$

It follows immediately from (4.27) that $\hat{\lambda}$ is decreasing when $\ell_2$ is increasing. To see that $\hat{\lambda}$ is also decreasing when $\ell_1$ is increasing, we observe that

$$\frac{d}{dx}\left(\frac{1}{1+1/x} - \ln(1+x)\right) = \frac{1}{(1+x)^2} - \frac{1}{1+x} < 0, \tag{4.28}$$

for $x > 0$, and that

$$\lim_{x\to 0}\left(\frac{1}{1+1/x} - \ln(1+x)\right) = 0. \tag{4.29}$$

Hence, if $0 < \ell_{\min} \le \ell_1, \ell_2 \le \ell_{\max}$, we are guaranteed that $\ln 2/\ell_{\max} \le \hat{\lambda} \le \ln 2/\ell_{\min}$. $\square$

If we look carefully at the analyses of the `P-Order` and `K-Order` algorithms, we observe that the parameters $\ell_1$ and $\ell_2$ of the function $f_{\ell_1,\ell_2}(\lambda)$ always are less than or equal to the longest distance between any pair of markers, and greater than or equal to the shortest distance between any pair of markers. The longest distance between any pair of markers can obviously be bounded by the length of the genome. Furthermore, if we assume that the markers are uniformly distributed along the genome, we can derive a probabilistic lower bound on the shortest distance between any two markers.

LEMMA 4.6. *Let $L$ be the length of a genome containing $n$ uniformly distributed markers. Then the distance between any two markers is at least $L/(2n^{2+\delta})$, with probability* $1 - n^{-\delta}$.

*Proof.* Divide the genome into $2n^{2+\delta}$ disjoint intervals, each of length $L/(2n^{2+\delta})$. Define the $\binom{n}{2}$ random variables $X_{ij}$ in the following way:

$$X_{ij} = \begin{cases} 1 & \text{if } i \text{ and } j \text{ are in the same or neighboring subintervals,} \\ 0 & \text{otherwise.} \end{cases} \tag{4.30}$$

Since the markers are assumed to be uniformly distributed, we know that

$$\Pr\big[X_{ij} = 1\big] \le \frac{3}{2n^{2+\delta}}. \tag{4.31}$$

Let

$$Y = \sum_{i<j} X_{ij}. \tag{4.32}$$

It is clear that $Y \ge 1$ if and only if some pair of markers are in the same or neighboring subintervals. From the Markov inequality it follows that

$$\Pr\big[Y \ge 1\big] \le E[Y] \le \binom{n}{2}\frac{3}{2n^{2+\delta}} < \frac{1}{n^{\delta}}. \tag{4.33}$$

Hence, the distance between any two markers will be at least $L/(2n^{2+\delta})$, with probability $1 - n^{-\delta}$. $\square$

**4.1. Analyzing the `Modified-P-Order` algorithm.** The similarity between the bound in Lemmas 2.3 and 4.4 makes it possible to carry through derivations similar to those in section 3. The role of the intensity-dependent function $f_{\mathtt{P}}(\lambda)$ will be played by the function $f^*_{\mathtt{P}}$ defined below.

DEFINITION 4.7. *Define the parameter $f^*_{\mathtt{P}}$ as*

$$f^*_{\mathtt{P}} = \min_{1<i<n} \left\{ \frac{\ell_{i-1,i}}{\ell_{i-1,i+1}}, \frac{\ell_{i,i+1}}{\ell_{i-1,i+1}} \right\}. \tag{4.34}$$

LEMMA 4.8. *Assume that $n$ markers are uniformly distributed along a chromosome of length $L$. Assume that $t = \lceil (1+\delta/2)\log(n) + 3/2 \rceil$ series of experiments have been made, each consisting of $m$ experiments using intensities $\boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_t)$, where $\lambda_i = 4^{i-1}\ln 2/L$. Then, with probability greater than $1 - n^{-\delta}$, the distance comparator $\mathcal{C}_{\boldsymbol{\lambda},t}$ satisfies the* `P-Order` *condition with parameter*

$$te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{f^*_{\mathtt{P}}}{2e^2}\right)^2}. \tag{4.35}$$

*Proof.* From Lemmas 4.5 and 4.6 follows that, with probability greater than $1-n^{-\delta}$, the optimal intensities $\hat{\lambda}$, for all choices of $\ell_1$ and $\ell_2$ such that $\ell_{\min} \le \ell_1, \ell_2 \le L$, will satisfy $\hat{\lambda} \in [\lambda_1, \lambda_t]$, where $\ell_{\min}$ is the shortest distance between any two markers and $t$ is chosen as above.

Let $a$, $b$, $c$, and $d$ be four markers, appearing in this order on the genome, such that $b$ and $c$ are consecutive and $d(a,d) > d(b,c)$. Without loss of generality, we assume that $d \ne c$. Let $e$ be the marker immediately to the right of $c$. Note that $e$ may be identical to the marker $d$. Then, under the condition above, it follows from Lemma 4.4 that

$$\begin{aligned} \Pr\left[\mathcal{C}_{\boldsymbol{\lambda},t}(a,d;b,c) \ne 1\right] &\le te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\ell_{ad}-\ell_{bc}}{2e^2\ell_{ad}}\right)^2} \\ &\le te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\ell_{ce}}{2e^2\ell_{be}}\right)^2} \\ &\le te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{f^*_{\mathtt{P}}}{2e^2}\right)^2}, \end{aligned} \tag{4.36}$$

where the last inequality follows from the fact that the markers $b$, $c$, $e$ are consecutive, together with Definition 4.7. □

THEOREM 4.9. *Assume that $n$ markers are uniformly distributed along a chromosome of length $L$. Assume that $t = \lceil (1+\delta/2)\log(n) + 3/2 \rceil$ series of experiments have been made using intensities $\boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_t)$, where $\lambda_i = 4^{i-1}\ln 2/L$, each consisting of*

$$m \ge \ln\left(\frac{tn^2}{\epsilon}\right) \frac{4e^4}{p^2q^2(1-(\alpha+\beta))^4(f^*_{\mathtt{P}})^2} \tag{4.37}$$

*experiments. Then the* `Modified-P-Order` *algorithm, i.e., the* `P-Order` *algorithm using the distance comparator $\mathcal{C}_{\boldsymbol{\lambda},t}$, gives the correct order of the $n$ markers with probability greater than $1 - \epsilon - n^{-\delta}$.*

*Proof.* From Lemma 4.8 it follows that, given

$$m \ge \ln\left(\frac{tn^2}{\epsilon}\right) \frac{4e^4}{p^2q^2(1-(\alpha+\beta))^4\left(f^*_{\mathtt{P}}\right)^2} \tag{4.38}$$

experiments, the distance comparator $\mathcal{C}_{\boldsymbol{\lambda},t}$ satisfies the `P-Order` condition with parameter $\leq \epsilon/n^2$ with probability greater than $1-n^{-\delta}$. By Theorem 3.2, this implies that the `P-Order` algorithm using this distance comparator will compute the correct order of the markers with probability greater than $1-\epsilon$. Hence, the `Modified-P-Order` algorithm will compute the correct order of the markers with probability greater than $1-\epsilon-n^{-\delta}$. □

**4.2. Analyzing the `Modified-K-Order` algorithm.** The equivalents of the functions $f_{\mathtt{k}\gamma}(\lambda)$, $f_{\mathtt{k}\zeta}(\lambda)$, and $f_{\mathtt{k}}(\lambda)$ in section 3 will in the modified case be denoted $f^*_{\mathtt{k}\gamma}$, $f^*_{\mathtt{k}\zeta}$, and $f^*_{\mathtt{k}}$, respectively.

DEFINITION 4.10. *Define the parameters $f^*_{\mathtt{k}\gamma}$ and $f^*_{\mathtt{k}\zeta}$ as*

$$f^*_{\mathtt{k}\gamma} = \min\left\{\min_{2\leq i\leq n-1}\left\{\frac{\sigma^L_{i+1}}{\sigma^L_{i+1}+\ell_{i,i+1}}\right\}, \min_{1\leq i\leq n-2}\left\{\frac{\sigma^R_i}{\sigma^R_i+\ell_{i,i+1}}\right\}\right\}, \tag{4.39}$$

$$f^*_{\mathtt{k}\zeta} = \min_{\substack{1\leq i\leq n-1\\ \mathcal{L}_{i+1}\cup\mathcal{R}_i\neq\emptyset}}\left\{\frac{\ell_{i,i+1}-m_i}{\ell_{i,i+1}}\right\}, \tag{4.40}$$

*and let $f^*_{\mathtt{k}} = \min\{f_{\mathtt{k}\gamma}, f_{\mathtt{k}\zeta}\}$.*

LEMMA 4.11. *Assume that $n$ markers are uniformly distributed along a chromosome of length $L$. Assume that $t = \lceil(1+\delta/2)\log(n)+3/2\rceil$ series of experiments have been made, each consisting of $m$ experiments, using intensities $\boldsymbol{\lambda} = (\lambda_1,\dots,\lambda_t)$, where $\lambda_i = 4^{i-1}\ln 2/L$. Then, with probability greater than $1-n^{-\delta}$, the distance comparator $\mathcal{C}_{\boldsymbol{\lambda},t}$ satisfies the `K-Order` conditions with parameters*

$$\gamma = te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{f^*_{\mathtt{k}\gamma}}{2e^2}\right)^2} \quad \text{and} \quad \zeta = te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{f^*_{\mathtt{k}\zeta}}{2e^2}\right)^2}. \tag{4.41}$$

*Proof.* From Lemmas 4.5 and 4.6 it follows that, with probability greater than $1-n^{-\delta}$, the optimal intensities $\hat{\lambda}$, for all choices of $\ell_1$ and $\ell_2$ such that $\ell_{\min}\leq \ell_1,\ell_2\leq L$, will satisfy $\hat{\lambda}\in[\lambda_1,\lambda_t]$, where $\ell_{\min}$ is the shortest distance between any two markers and $t$ is chosen as above.

Let $a$, $b$, $c$, and $d$ be four markers appearing in this order on the genome; assume that $b$ and $c$ are consecutive; assume that $d(a,d) > d(b,c)$; and assume that $d\notin\mathcal{R}_b$. If we let $e = R_b$, it follows from Definition 3.6 and Lemma 4.4 that, under the condition above,

$$\begin{aligned}\Pr\left[\mathcal{C}_{\boldsymbol{\lambda},t}(a,d;b,c)\neq 1\right] &\leq te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\ell_{ad}-\ell_{bc}}{2e^2\ell_{ad}}\right)^2}\\ &\leq te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\ell_{be}-\ell_{bc}}{2e^2\ell_{be}}\right)^2}\\ &= te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\sigma^R_b}{2e^2(\sigma^R_b+\ell_{bc})}\right)^2}.\end{aligned} \tag{4.42}$$

In a similar way we can show that if $a\notin\mathcal{L}_c$, then

$$\Pr\left[\mathcal{C}_{\boldsymbol{\lambda},t}(a,d;b,c)\neq 1\right] \leq te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\sigma^L_c}{2e^2(\sigma^L_c+\ell_{bc})}\right)^2}. \tag{4.43}$$

Hence, from Definition 4.10 it follows that, for any four markers $a$, $b$, $c$, and $d$ appearing in this order on the genome such that $b$ and $c$ are consecutive, $d(a,d) > d(b,c)$, and either $d\notin\mathcal{R}_b$ or $a\notin\mathcal{L}_c$,

$$\Pr\left[\mathcal{C}_{\boldsymbol{\lambda},t}(a,d;b,c) = 1\right] \geq 1 - te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{f^*_{\mathtt{k}\gamma}}{2e^2}\right)^2}. \tag{4.44}$$

Let $a \in [2, n]$ be an arbitrary marker, and assume that $b \in \mathcal{L}_a$. From the definition of $\mathcal{L}_a$ it follows that $\ell_{a-1,a} - \ell_{b-1,b} \geq \ell_{b-1,b}$. Hence, from Definition 3.6, Definition 4.10, and Lemma 4.4 it follows, under the condition above, that

$$\begin{aligned}\Pr\big[\mathcal{C}_{\boldsymbol{\lambda},t}(a-1,a;b-1,b) \neq 1\big] &\leq te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\ell_{a-1,a}-\ell_{b-1,b}}{2e^2\ell_{a-1,a}}\right)^2} \\ &\leq te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{\ell_{a-1,a}-m_a}{2e^2\ell_{a-1,a}}\right)^2} \\ &\leq te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{f^*_{\mathtt{k}\zeta}}{2e^2}\right)^2}.\end{aligned} \tag{4.45}$$

In the same way it is possible to show that for any $a \in [1, n-1]$ and $b$ in $\mathcal{R}_a$

$$\Pr\big[\mathcal{C}_{\boldsymbol{\lambda},t}(a,a+1;b,b+1) \neq 1\big] \leq te^{-mp^2q^2(1-(\alpha+\beta))^4\left(\frac{f^*_{\mathtt{k}\zeta}}{2e^2}\right)^2}. \qquad \square \tag{4.46}$$

THEOREM 4.12. *Assume that $n$ markers are uniformly distributed along a chromosome of length $L$. Assume that $t = \lceil(1 + \delta/2)\log(n) + 3/2\rceil$ series of experiments have been made using intensities $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_t)$, where $\lambda_i = 4^{i-1}\ln 2/L$, each consisting of*

$$m \geq \ln\left(\frac{4tn^2}{\epsilon}\right)\frac{4e^4}{p^2q^2(1-(\alpha+\beta))^4(f^*_{\mathtt{k}})^2} \tag{4.47}$$

*experiments. Then the* `Modified-K-Order` *algorithm, i.e., the* `K-Order` *algorithm using the distance comparator $\mathcal{C}_{\boldsymbol{\lambda},t}$, gives the correct order of the $n$ markers with probability greater than $1 - \epsilon - n^{-\delta}$.*

*Proof.* From Lemma 4.11 it follows that, if the number of experiments $m$ satisfies (4.47), then the distance comparator $\mathcal{C}_{\boldsymbol{\lambda},t}$ satisfies the `K-Order` conditions with parameters $\gamma \leq \epsilon/4n^2$ and $\zeta \leq \epsilon/4n^2$ with probability greater than $1 - n^{-\delta}$. By Theorem 3.8, this implies that the `K-Order` algorithm using this distance comparator will compute the correct order of the markers with probability greater than $1 - \epsilon$. Hence, the `Modified-K-Order` algorithm will compute the correct order of the markers with probability greater than $1 - \epsilon - n^{-\delta}$. $\square$

**5. Discussion.** In [2], Ben-Dor and Chor presented the `P-Order` and `K-Order` algorithms for the RH problem. As support for the algorithms, they also proved an upper bound on the number of RH experiments sufficient for both algorithms to compute the correct marker order with high probability.

We have improved the analysis of the `P-Order` and `K-Order` algorithms. By taking into account what decisions the two algorithms actually need to make, we derive tighter bounds than those in [2]. The major improvement is the replacement of $f_{\delta_{\min},\delta_{\max}}(\lambda)$ with $f_{\mathtt{P}}(\lambda)$ and $f_{\mathtt{k}}(\lambda)$, respectively. It is easy to see from their definitions that $f_{\delta_{\min},\delta_{\max}}(\lambda) \leq f_{\mathtt{P}}(\lambda) \leq f_{\mathtt{k}}(\lambda)$. In fact, for any constant $c > 0$ it is possible to construct marker arrangements such that $f_{\mathtt{k}}(\lambda)/f_{\mathtt{P}}(\lambda) > c$ and $f_{\mathtt{P}}(\lambda)/f_{\delta_{\min},\delta_{\max}}(\lambda) > c$. The new analysis thus suggests that the `K-Order` algorithm is to be preferred to the `P-Order` algorithm, a suggestion which is confirmed by experimental results not shown here. The introduction of distance comparators has allowed us to formulate very general results. The bounds in Theorems 3.2 and 3.8 apply to any `P-Order`- and `K-Order`-like strategy for ordering points on the line, such that the probability for errors in the distance comparisons can be bounded.

The new analysis of the `P-Order` and `K-Order` algorithms shows that the intensity of the radiation used in the RH experiments is less suitable for some distance comparisons than for others. This suggests that the use of RH data produced with several different intensities would improve the stability of the algorithms with respect to the choice of intensity. The `Modified-P-Order` and `Modified-K-Order` algorithms are modified versions of the original `P-Order` and `K-Order` algorithms, designed to be able to use multiple intensity data. We show that using RH data from $O(\log n)$ series of experiments, produced with suitable intensities, the dependency on the choice of intensity can be removed from the performance bounds, under the assumption that the markers are uniformly distributed.

Although the analysis of the modified algorithms assumes that a specified range of intensities is used, the algorithms can be used on any experimental data involving different intensities. Experimental studies on synthetic data (omitted here) suggest that the `Modified-K-Order` algorithm works especially well in practice. The use of only three different intensities makes the algorithm more stable against the effects of the choice of intensity. However, the most important conclusion that can be drawn from these results is that the use of multiple intensity data does have a positive effect on the performance of `P-Order`- and `K-Order`-like RH algorithms.

**6. Acknowledgment.** We would like to thank Johan Håstad for useful ideas and fruitful discussions.

# PERFECTNESS IS AN ELUSIVE GRAPH PROPERTY[*]

STEFAN HOUGARDY[†] AND ANNEGRET WAGLER[‡]

**Abstract.** A graph property is called elusive (or evasive) if every algorithm for testing this property has to read in the worst case $\binom{n}{2}$ entries of the adjacency matrix of the given graph. Several graph properties have been shown to be elusive, e.g., planarity or $k$-colorability. A famous conjecture of Karp says that every nontrivial monotone graph property is elusive. We prove that a nonmonotone but hereditary graph property is elusive: perfectness.

**Key words.** perfect graph, elusiveness, evasiveness, graph property testing

## 1. Introduction.

Given a graph property, consider the following two-player game to define elusiveness. Player A wants to know whether an unknown simple graph on a given node set has the graph property in question by asking Player B one pair of nodes at a time whether this pair of nodes is an edge. At each stage Player A makes full use of the information of edges and nonedges he has up to that point in order to decide whether the graph has the property or not. Player A wants to minimize the number of his questions; Player B wants to force him to ask as many questions as possible. The number of questions needed for the decision if both players play optimally from their point of view is the recognition complexity of the studied graph property. The property is said to be *elusive* (or also *evasive*) if there is a strategy enabling Player B to force Player A to test *every* pair of nodes, respectively, to ask all possible $\binom{n}{2}$ questions before coming to a decision. (More precisely, such a strategy has to exist for all nontrivial cases, i.e., for all $n$ such that there are graphs on $n$ nodes with and without the studied property.)

Several graph properties are known to be elusive, e.g., having a clique of a certain size or a coloring with a certain number of color classes (Bollobás [3]) or being planar (Best, van Emde Boas, and Lenstra [2]); see [4, 14, 18] for more examples. On the other hand, it is well known that there exist nontrivial graph properties that need only $O(n)$ questions; see [2, 4].

Aanderaa and Rosenberg conjectured [2] that there exist some $\gamma > 0$ such that the complexity of every nontrivial monotone graph property (i.e., a property preserved under deleting edges) is at least $\gamma n^2$. This conjecture has been proved by Rivest and Vuillemin [12] for $\gamma = \frac{1}{16}$. The value of $\gamma$ has been improved over the years. Currently the largest value of $\gamma$ for which the conjecture of Aanderaa and Rosenberg is known to be true is $\frac{1}{4} - o(1)$. This result was established by Kahn, Saks, and Sturtevant [9]. A sharpened version of the Aanderaa–Rosenberg conjecture is due to Karp [13]. He conjectures that every nontrivial monotone graph property is elusive; i.e., he conjectures that $\gamma = \frac{1}{2} - o(1)$ holds.

Karp's conjecture has been verified for several graph properties, some of which have already been mentioned above. The most general result in this area is due to Kahn, Saks, and Sturtevant [9], who proved Karp's conjecture for all $n$ that are prime powers.

Karp's conjecture is a very challenging open problem. But even more challenging is the problem of getting a complete characterization of all graph properties that are elusive. Currently we still seem to be far away from even formulating a reasonable conjecture. Recent progress in this direction has been made by Chakrabarti, Khot, and Shi [6], who proved that any minor closed graph property (which need not be monotone) is elusive. The subject of the present paper is to prove elusiveness for some other nonmonotone graph property.

THEOREM 1.1. *Perfectness is an elusive graph property.*

Perfectness is a property which is not monotone but hereditary (preserved under deleting nodes) and concerned with the relation of maximum cliques and optimal colorings. Perfect graphs behave nicely from an algorithmic point of view [8] and have interesting relationships to surprisingly many other fields of scientific enquiry [11].

Berge [1] proposed calling a graph $G$ *perfect* if, for each of its (node-)induced subgraphs $G' \subseteq G$, the chromatic number equals the clique number (i.e., if we need as many stable sets to cover all nodes of $G'$ as a maximum clique of $G'$ has nodes). This means that identifying one induced imperfect subgraph would enable Player A to make the final decision: the graph in question is not perfect. For that, so-called *minimally imperfect graphs* are of particular interest. These are imperfect graphs, and all of their proper induced subgraphs are perfect. As was proved recently by Chudnovsky et al. [7], the only minimally imperfect graphs are chordless odd cycles of length $\geq 5$, termed *odd holes*, and their complements, called *odd antiholes*. This result was conjectured by Berge in 1960 and is called the strong perfect graph theorem. In our proof for Theorem 1.1 we do not need to rely on this deep result, nor would it help to simplify our proofs.

Player B has to answer in such a way that no minimally imperfect induced subgraph appears until Player A asks the last question but that the last answer can create a minimally imperfect induced subgraph.

The odd hole of length five is the smallest imperfect graph. Hence, the cases with $n \leq 4$ nodes are trivial: Player A knows without asking any question that the studied graph is perfect. In order to show that perfectness is an elusive graph property we have to treat the nontrivial cases $n \geq 5$.

The idea for providing a strategy to Player B is as follows. Find perfect graphs such that you cannot reach another perfect graph by deleting or adding one edge. We call an edge $e$ of a perfect graph $G$ *critical* if $G - e$ is imperfect. Analogously, we call an edge $e$ not contained in a perfect graph $G$ *anticritical* if $G + e$ is imperfect. A perfect graph $G$ is *critical* if $G$ has only critical edges. The complement of a critically perfect graph is again perfect (due to Lovász [10]) and has the property that adding an edge not contained in the graph so far yields an imperfect graph. We call the complements of critically perfect graphs *anticritically perfect.* We look for *bicritically perfect graphs*, which are both critically *and* anticritically perfect: the deletion and addition of an *arbitrary* edge yields an imperfect graph.

If there exists a bicritically perfect graph $G_n$, then Player B has only to answer all but the last question "$ij \in E$?" of Player A as in $G_n$. That is, Player B has only to apply the following strategy for graphs on $n$ nodes.

STRATEGY 1. *Let $G_n$ be a bicritically perfect graph on $n$ nodes.*

*For questions* 1 *to* $\binom{n}{2} - 1$*: Answer "*$ij \in E$*?" with* YES *if* $ij \in E(G_n)$*,* NO *otherwise.*

Then no induced imperfect subgraph appears during the first $\binom{n}{2} - 1$ questions, and the answer to the last question yields the following decision:

$$\text{Answer "}ij \in E\text{?" with } \begin{cases} \text{YES} & \text{if } ij \in E(G_n); \text{ then the graph is perfect.} \\ \text{NO} & \text{if } ij \in E(G_n); \text{ then the graph is imperfect.} \\ \text{YES} & \text{if } ij \notin E(G_n); \text{ then the graph is imperfect.} \\ \text{NO} & \text{if } ij \notin E(G_n); \text{ then the graph is perfect.} \end{cases}$$

In order to prove Theorem 1.1, our task is as follows.

PROBLEM 1. *Find, for as many* $n$ *as possible, a bicritically perfect graph* $G_n$ *on* $n$ *nodes.*

A first step towards solving Problem 1 was a computer search enumerating which perfect graphs on up to 10 nodes are critically perfect.

THEOREM 1.2. *No critically perfect graphs with fewer than* 9 *nodes exist. On* 9*,* 10*, and* 11 *nodes there are precisely* 3*,* 10*, and* 52 *critically perfect graphs.*

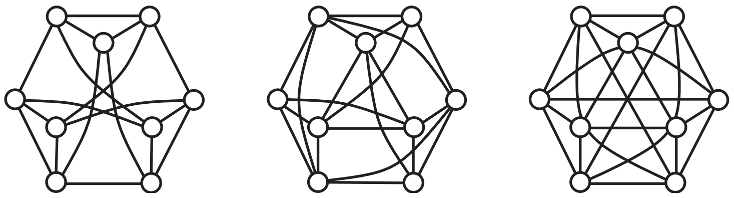

FIG. 1.1. *The three smallest critically perfect graphs.*

Clearly, Theorem 1.2 remains true if "critically perfect" is replaced by "anticritically perfect." Figure 1.1 shows the three critically perfect graphs on nine nodes. The first graph, $G_9$, is self-complementary and, therefore, also anticritical. That is, it is our first example of a bicritically perfect graph. The other two graphs are not anticritical, but only their complements are. Each of the critically perfect graphs with ten nodes is not anticritical (see the next section). This means particularly that there are no bicritically perfect graphs $G_n$ with $n \leq 8$ and $n = 10$. In section 2, we present a technique of constructing examples of bicritically perfect graphs based on the characterization of critically and anticritically perfect line graphs. In section 3, we apply the knowledge from the previous section to construct bicritically perfect graphs $G_n$ if $n \geq 12$. Section 4 provides a slightly different strategy for the cases $n = 10, 11$.

The cases $5 \leq n \leq 8$ are treated as follows. The odd hole $C_5$ is the *only* imperfect graph on five nodes (note: the $C_5$ is self-complementary, and hence so is the odd antihole on five nodes). Consequently, one cannot reach another imperfect graph from the $C_5$ by deleting or adding one edge. Thus, the $C_5$ is bicritically imperfect and Strategy 1 does also work for $n = 5$ when choosing $G_n = C_5$. For $6 \leq n \leq 8$ there is no bicritically imperfect graph with $n$ nodes. In order to treat these cases we do not provide an explicit strategy, but we show in section 5 that there *exists* a strategy: we prove elusiveness for $6 \leq n \leq 8$ with the help of a result of Rivest and Vuillemin [12] by using a parity argument and doing some computer searches.

In summary, we show the existence of a strategy in all nontrivial cases $n \geq 5$ which proves Theorem 1.1: *perfectness is an elusive graph property.*

**2. Bicritically perfect line graphs.** This section provides a construction for bicritically perfect line graphs established in [17]. We obtain the *line graph* $L(F)$ of a graph $F$ by taking the edges of $F$ as nodes of $L(F)$ and joining two nodes of $L(F)$ by an edge iff the corresponding edges of $F$ are incident. It is well known [15] that the line graph $L(F)$ of a graph $F$ is perfect iff $F$ is *line-perfect*, i.e., iff $F$ does not contain any odd cycle of length at least 5 as a (not necessarily induced) subgraph.

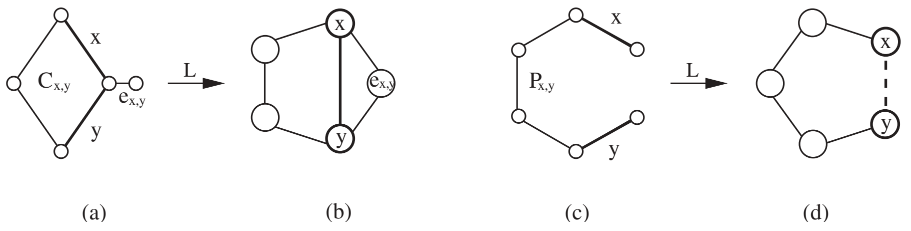

FIG. 2.1. *Definition of H-pairs and A-pairs.*

In order to obtain critical and anticritical edges in $L(F)$, we define two structures in $F$.

We say that two incident edges $x$ and $y$ form an *H-pair* in $F$ if there is an edge $e_{x,y}$ different from $x$ and $y$ incident to the common node of $x$ and $y$ and if there is an even cycle $C_{x,y}$ containing $x$ and $y$ but only one endnode of $e_{x,y}$ (see Figure 2.1(a)). $L(C_{x,y})$ is an even hole, and the node in $L(F)$ corresponding to $e_{x,y}$ has precisely two neighbors on $L(C_{x,y})$, namely, $x$ and $y$ (see Figure 2.1(b)).

Two nonincident edges $x$ and $y$ are called an *A-pair* if they are the endedges of an odd path $P_{x,y}$ with length at least five (see Figure 2.1(c)). $L(P_{x,y})$ is an even, chordless path of length at least four with endnodes $x$ and $y$ (see Figure 2.1(d)).

It is straightforward that deleting and adding the edge $xy$ in $L(C_{x,y} \cup e_{x,y})$ and $L(P_{x,y})$, respectively, yields an odd hole. Consequently, if $L(F)$ is intended to be critically (anticritically) perfect, it is sufficient to obtain that *every* pair of incident (nonincident) edges in $F$ forms an H-pair (A-pair). We define a graph with at least two incident (nonincident) edges to be an *H-graph* (*A-graph*) if each pair of incident (nonincident) edges forms an H-pair (A-pair).

Obviously, the line graph $L(F)$ of any bipartite H-graph (A-graph) is critically (anticritically) perfect. A line graph $L(F)$ is bicritically perfect iff the graph $F$ is a bipartite A- and H-graph [16]. The three smallest critically perfect graphs are the complements of the line graphs of the three bipartite A-graphs presented in Figure 2.2. $A_1$ is also an H-graph, and hence $L(A_1)$ is bicritical (it is in fact self-complementary). Furthermore, $A_1$ is the only bipartite H-graph with 3 nodes in each color class. If there are 4 nodes in one color class, then an H-graph has at least 12 edges since it has minimum degree 3 by definition. Hence, the second smallest H-graph admits 12 edges and there cannot be any bicritically perfect *line* graph on 10 or 11 nodes. By complete enumeration we proved that bicritically perfect graphs on 10 or 11 nodes do not exist at all.

The following sufficient condition for a bipartite graph $F$ to be an H-graph *and* an A-graph is established in [17].

LEMMA 2.1 (see [17]). *Every simple,* 3*-connected, bipartite graph is an H-graph as well as an A-graph.*

*Proof.* Let $F = (A \cup B, E)$ be a simple, 3-connected, bipartite graph. First, consider two arbitrary incident edges $ab_1, ab_2$ of $F$ with $a \in A$ and $b_1, b_2 \in B$. We

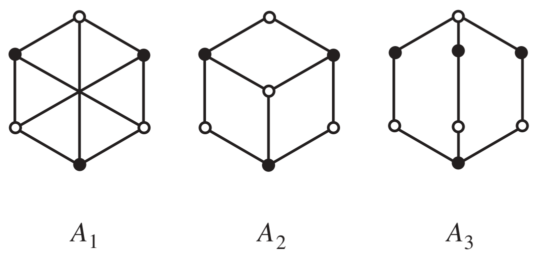

FIG. 2.2. *The three smallest bipartite A-graphs.*

show that $ab_1$ and $ab_2$ form an H-pair in $F$. Since $F$ is 3-connected, there is a third node $b_3 \neq b_1, b_2$ adjacent to $a$ and $F - \{a, b_3\}$ is still connected. In particular, $b_1$ and $b_2$ are linked by a path $P$ in $F - \{a, b_3\}$. Hence, we obtain $C_{ab_1,ab_2} = P \cup \{b_2a, ab_1\}$ and $e_{ab_1,ab_2} = ab_3$; i.e., $ab_1$ and $ab_2$ form an H-pair in $F$.

Now, consider two nonincident edges $a_1b_1$ and $a_2b_2$ of $F$ with $a_i \in A$, $b_i \in B$. We show that $a_1b_1$ and $a_2b_2$ form an A-pair in $F$. Since $F$ is 3-connected, there are internally disjoint, odd $(a_1, b_2)$-paths $P_1, \ldots, P_k$ with $k \geq 3$. At most two paths among $P_1, \ldots, P_k$ can contain $a_2$ or $b_1$. Without loss of generality, let $P_3, \ldots, P_k$ be $a_2, b_1$-free. If there is a path $P_i$ with $3 \leq i \leq k$ of length $\geq 3$, then $b_1P_ia_2$ is the studied path $P_{a_1b_1,a_2,b_2}$. Otherwise, the only $a_2, b_1$-free $(a_1, b_2)$-path is the edge $a_1b_2$. We obtain $k = 3$ and let $b_1 \in P_1$, $a_2 \in P_2$. By the 3-connectivity of $F$ again, there must be an $a_1, b_2$-free $(a_2, b_1)$-path $Q$ of odd length $\geq 3$, and we get $P_{a_1b_1,a_2,b_2} = b_2Qa_1$. Otherwise, if the edge $a_2b_1$ were the only $a_1, b_2$-free $(a_2, b_1)$-path, $\{a_1, a_2\}$ would be a cutset of size two, separating the nodes of $P_1$ between $b_1$ and $b_2$ from the nodes of $P_2$ between $a_1$ and $a_2$—a contradiction, as $F$ is 3-connected. □

*Remark* 2.2. Note that duplicating edges preserves the property of being an A-graph (since no new pair of nonincident edges occurs), while it does not preserve the property of being an H-graph (since parallel edges are incident but never form an H-pair).

## 3. Construction of the graphs $G_n$ for $n \geq 12$.

In order to treat Problem 1, this section is intended to present a bicritically perfect graph $G_n$ for each $n \geq 12$. Lemma 2.1 ensures that $L(F)$ is bicritically perfect whenever $F$ is a simple, 3-connected, bipartite graph. Hence we will construct simple, 3-connected, bipartite graphs $F_n$ with $n \geq 12$ edges to obtain the studied bicritically perfect graphs $G_n = L(F_n)$ on $n \geq 12$ nodes. Consider the graphs $F_{3k} = (A \cup B, E_1 \cup E_2)$ with $k \geq 3$ and

$$\begin{aligned} A &= \{1, 3, \ldots, 2k-1\}, \\ B &= \{2, 4, \ldots, 2k\}, \\ E_1 &= \{ii+1 : 1 \leq i \leq 2k\}, \\ E_2 &= \{ii+3 : i \in A\}, \end{aligned}$$

where all indices are taken modulo $2k$. The three smallest examples of graphs $F_{3k}$ for $k \in \{3, 4, 5\}$ are shown in Figure 3.1 (note $A_1 = F_9$). $F_{3k}$ is an even cycle $(A \cup B, E_1)$ on its $2k$ nodes with $k$ chords $E_2$ outgoing from a node in $A$ with odd index and ending in a node in $B$ with even index. Thus, the graphs $F_{3k}$ are bipartite and simple by construction. We have to show that they are 3-connected.

LEMMA 3.1. *The graphs $F_{3k}$ are 3-connected for $k \geq 3$.*

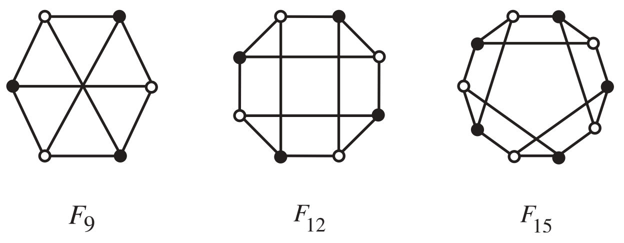

FIG. 3.1. *The graphs $F_{3k}$ with $k = 3, 4, 5$.*

*Proof.* We have to show that the graph obtained from $F_{3k}$ by removing two arbitrary nodes $i$ and $j$ is still connected. Let $i < j$. Recall that $F_{3k} = (A \cup B, E_1 \cup E_2)$ has a Hamilton cycle $C = (A \cup B, E_1)$ and additional chords $ii + 3 \in E_2$ with $i \in A$ odd, $i + 3 \in B$ even. If $i$ and $j$ are neighbors on $C$ (i.e., $j = i + 1$), then the remaining nodes $i + 2 = j + 1, \ldots, 2k, 1, \ldots, i - 1$ of $F_{3k}$ are connected by a path with edges in $E_1$. Otherwise, removing $i$ and $j$ divides the cycle $C$ into two paths, $P_1 = i + 1, \ldots, j - 1$ and $P_2 = j + 1, \ldots, 2k, 1, \ldots, i - 1$. It is easy to see that there is always an edge $e \in E_2$ which connects $P_1$ and $P_2$: If $i$ is odd, then $i + 1$ is even and $i - 2i + 1 \in E_2$. We have $e = i - 2i + 1$ as the studied edge connecting $P_1$ and $P_2$ if $i - 2$ is a node of $P_2$ or else $V(P_2) = \{i - 1\}$ and $j = i - 2$ holds. But then $i - 4$ is a node of $P_1$ (since $k \geq 3$) and we obtain $e = i - 4i - 1$ (all indices are taken modulo $2k$). Analogously, if $i$ is even, then $i - 1i + 2 \in E_2$. We have $e = i - 1i + 2$ if $i + 2$ is a node of $P_1$ or else $V(P_1) = \{i + 1\}$ and $j = i + 2$. But then $i + 4$ is a node of $P_2$ (by $k \geq 3$ again) and we get $e = i + 1i + 4$. Hence, the graph obtained from $F_{3k}$ by removing two arbitrary nodes is still connected. ☐

Thus, we can choose $G_n$ as the line graph of $F_n$ whenever $n = 3k, k \geq 3$, by Lemma 2.1. To close the gaps with $n = 3k + 1, 3k + 2$ for $k \geq 4$ we use the following immediate consequence of Lemma 2.1.

LEMMA 3.2. *If $F = (A \cup B, E)$ is a simple, 3-connected, bipartite graph and $ab \notin E$ with $a \in A, b \in B$, then $F + ab$ is a simple bipartite A- and H-graph.*

Thus, we obtain the studied bipartite A- and H-graphs $F_n$ for $n = 3k + 1$ and $n = 3k + 2$ if $k \geq 4$ by adding one and two edges, respectively, to $F_{3k}$ such that the resulting graph is simple and bipartite. This is possible for each $F_{3k}$ with $k \geq 4$ (but not for the complete bipartite graph $F_9$). We obtain, therefore, the studied bicritically perfect graphs $G_n = L(F_n)$ for $n \geq 12$ and can apply Strategy 1 for all cases with $n \geq 12$ nodes.

## 4. Construction of the graphs $G_n$ for $n = 10, 11$.

As mentioned in section 2 there are no bicritically perfect graphs on 10 or 11 nodes. Therefore we construct bipartite A-graphs with 10 and 11 edges which are as close to H-graphs as possible.

Duplicating an arbitrary edge of $F_9 = A_1$ yields the graph $F_{10}$ shown in Figure 4.1. $F_{10}$ is an A-graph but not an H-graph by Remark 2.2. However, $L(F_{10})$ has only one noncritical edge, namely, the edge connecting the nodes that correspond to the parallel edges of $F_{10}$. Next, the bipartite graph $F_{11}$ in Figure 4.1 can be obtained by adding two edges to the A-graph $A_2$ from Figure 2.2. It is easy to check that $F_{11}$ is an A-graph and that the two edges incident to the only node of degree two in $F_{11}$ form the only non-H-pair. $L(F_{11})$ is anticritically perfect and all edges but one are critical, too.

Let us call a graph $G$ *almost bicritically perfect* if $G$ is anticritically perfect and all

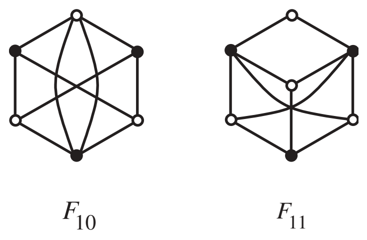

FIG. 4.1. *The graphs $F_{10}$ and $F_{11}$.*

edges but one are critical. Then we slightly modify Strategy 1 for almost bicritically perfect graphs as follows.

STRATEGY 2. *Let $G_n$ be an almost bicritically perfect graph on $n$ nodes and let $uv$ be its only noncritical edge. For question* 1*: Answer "$ij \in E$?" with* YES*; number the nodes of $G_n$ s.t. $i = u$, $j = v$. For questions* 2 *to* $\binom{n}{2} - 1$*: Answer "$ij \in E$?" with YES if $ij \in E(G_n)$,* NO *otherwise.*

Then no imperfect subgraph appears during the first $\binom{n}{2} - 1$ questions, and the answer to the last question yields the decision again. Since $L(F_{10})$ and $L(F_{11})$ are almost bicritically perfect graphs by construction, we choose $G_{10} = L(F_{10})$ and $G_{11} = L(F_{11})$ and apply Strategy 2.

**5. The remaining cases $6 \leq n \leq 8$.** To prove that perfectness is an elusive graph property for $6 \leq n \leq 8$ we use a parity argument due to Rivest and Vuillemin. In [12] they proved the following: If a property $\mathcal{P}$ is *not* elusive for graphs on $n$ nodes, then the number $G(\mathcal{P}, n, \text{even})$ of labeled graphs on $n$ nodes with property $\mathcal{P}$ having an even number of edges equals the number $G(\mathcal{P}, n, \text{odd})$ of labeled graphs on $n$ nodes with property $\mathcal{P}$ that have an odd number of edges. In particular, $G(\mathcal{P}, n, \text{even}) \neq G(\mathcal{P}, n, \text{odd})$ implies that $\mathcal{P}$ *is* elusive for graphs on $n$ nodes. In Table 5.1 we show the numbers $G(\mathcal{P}, n, \text{even})$ and $G(\mathcal{P}, n, \text{odd})$ for perfect graphs on $6 \leq n \leq 8$ nodes, which we calculated with the help of a computer program. For the calculation we used a very simple brute force approach: We generated all graphs on up to 8 nodes. Such a graph is perfect iff it does not contain a $C_5$, a $C_7$, or a complement of a $C_7$ as an induced subgraph. Now one simply has to count how many of these graphs have an even, respectively, odd number of edges. As one can see from Table 5.1, for $n = 8$ perfectness is an elusive graph property, as the values in columns 3 and 4 differ.

TABLE 5.1
*The number of perfect graphs with an even, respectively, odd number of edges.*

| $n$ | # perfect graphs | $G(\mathcal{P}, n, \text{even})$ | $G(\mathcal{P}, n, \text{odd})$ |
|---|---|---|---|
| 6 | 30824 | 15412 | 15412 |
| 7 | 1741616 | 870808 | 870808 |
| 8 | 174494128 | 87264704 | 87229424 |

For $n = 6$ and $n = 7$ we apply an extension of the previously used argument. If perfectness is not elusive for graphs on $n$ nodes, then it is also not elusive for the graphs containing one fixed edge, say $ij$. Therefore the number of labeled perfect graphs on $n$ nodes which contain the edge $ij$ and have an even number of edges must equal the number of these graphs with an odd number of edges. The last two columns in Table 5.2 show these numbers for $n = 6$ and $n = 7$. Note that they add up to half the number of labeled perfect graphs, as the complement of a perfect graph is

TABLE 5.2
*The number of perfect graphs with a fixed edge and an even, respectively, odd number of edges.*

| $n$ | # perfect graphs | $G(\mathcal{P}, n, \text{even})$, $ij \in E$ | $G(\mathcal{P}, n, \text{odd})$, $ij \in E$ |
|---|---|---|---|
| 6 | 30824 | 7712 | 7700 |
| 7 | 1741616 | 435284 | 435524 |

again perfect [10]. As the numbers in columns 3 and 4 are different in both cases, this finishes the proof that perfectness is elusive for $n = 6, 7, 8$.

## 6. Summary.

In order to figure out whether perfectness is an elusive graph property, we used the following as our main idea: Find, for as many numbers $n$ of nodes as possible, a bicritically perfect graph $G_n$ (Problem 1). Since one cannot reach another perfect graph from $G_n$ by deleting or adding one edge, there is a simple strategy for Player B in that case: Answer all but the last question as in the bicritically perfect graph $G_n$ (Strategy 1). We constructed bicritically perfect graphs $G_n$ with $n = 9$ and $n \geq 12$ (section 3) and almost bicritically perfect graphs $G_{10}$ and $G_{11}$ (section 4) where a slightly different strategy has to be used (Strategy 2). Moreover, the $C_5$ is bicritically imperfect and Strategy 1 does also work for $n = 5$ with choosing $G_n = C_5$. Consequently, our main idea works for $n = 5$ and for all cases with $n \geq 9$ nodes. We used a parity argument from [12] in order to show the desired result for the remaining cases with $6 \leq n \leq 8$ nodes (section 5).

In summary, we showed the *existence* of a strategy for Player B in all nontrivial cases $n \geq 5$, which finally proves Theorem 1.1: *Perfectness is an elusive graph property.*

**Acknowledgment.** The authors are grateful to Günter M. Ziegler for drawing their attention to the result of Rivest and Vuillemin [12].

# ALMOST PERFECT LATTICES, THE COVERING RADIUS PROBLEM, AND APPLICATIONS TO AJTAI'S CONNECTION FACTOR[*]

DANIELE MICCIANCIO[†]

**Abstract.** Lattices have received considerable attention as a potential source of computational hardness to be used in cryptography, after a breakthrough result of Ajtai [in *Proceedings of the* 28*th Annual ACM Symposium on Theory of Computing*, Philadelphia, PA, 1996, pp. 99–108] connecting the average-case and worst-case complexity of various lattice problems. The purpose of this paper is twofold. On the expository side, we present a rigorous self-contained proof of results along the lines of Ajtai's seminal work. At the same time, we explore to what extent Ajtai's original results can be quantitatively improved. As a by-product, we define a random class of lattices such that computing short nonzero vectors in the class with nonnegligible probability is at least as hard as approximating the length of the shortest nonzero vector in *any* $n$-dimensional lattice within worst-case approximation factors $\gamma(n) = n^3\omega(\sqrt{\log n \log\log n})$. This improves previously known best connection factor $\gamma(n) = n^{4+\epsilon}$ [J.-Y. Cai and A. P. Nerurkar, in *Proceedings of the* 38*th Annual IEEE Symposium on Foundations of Computer Science*, Miami Beach, FL, 1997, pp. 468–477]. We also show how our reduction implies the existence of collision resistant cryptographic hash functions based on the worst-case inapproximability of the shortest vector problem within the same factors $\gamma(n) = n^3\omega(\sqrt{\log n \log\log n})$.

In the process we distill various new lattice problems that might be of independent interest, related to the covering radius, the bounded distance decoding problem, approximate counting of lattice points inside convex bodies, and the efficient construction of lattices with good geometric and algorithmic decoding properties. We also show how further investigation of these new lattice problems might lead to even stronger connections between the average-case and worst-case complexity of the shortest vector problem, possibly leading to connection factors as low as $\gamma(n) = n^{1.5}\omega(\log n)$.

## 1. Introduction.

It has long been realized that the relevant notion of hardness in cryptography is *average-case* hardness: if the key of a cryptographic function is chosen at random, then no probabilistic polynomial time algorithm can break the scheme with nonnegligible probability. In the past few years, computational problems on point lattices have attracted considerable interest for their potential cryptographic applications because of the following remarkable discovery of Ajtai [2]: a certain natural computational problem (namely, finding small nonzero solutions to a suitably chosen random system of homogeneous linear equations) is at least as hard *on the average* as the *worst-case* instance of various lattice problems, e.g., approximating the length of the shortest nonzero vector in a lattice within a worst-case factor $\gamma(n)$

polynomial in the dimension $n$ of the lattice. This immediately gives provably secure cryptographic functions based on the conjectured *worst-case* intractability of lattice problems.[1] Moreover, since the set of integer solutions of a linear system forms a lattice, the result in [2] can also be regarded as a connection between the complexity of finding short nonzero vectors in suitably chosen random lattices *on the average*,[2] and the complexity of approximating the length of the shortest nonzero vector (as well as solving various other lattice problems) in any lattice *in the worst case*.

We remark that building cryptographic functions that are as hard to break as the *worst-case* instance of the underlying mathematical problem is especially important in the case of lattices because lattice approximation algorithms (like the Lenstra–Lenstra–Lovász (LLL) algorithm [27]) are believed to perform much better on the average than their worst-case theoretical upper bounds. Moreover, since lattice problems get easier and easier as the approximation factor $\gamma(n)$ increases, determining the smallest worst-case inapproximability factor $\gamma(n)$ that implies the average-case hardness of solving Ajtai's random equations is both a theoretically interesting and a practically important problem, and it has been the subject of subsequent work by Cai and Nerurkar [11] and Micciancio [35] in a preliminary version of this paper.

*Our contribution.* The purpose of this paper is twofold. First, we give a full, self-contained proof of Ajtai's original result [2] and a detailed account of all relevant techniques introduced in subsequent improvements by Cai and Nerurkar [11]. Previous papers [2, 11] appeared only in the form of extended abstracts or technical reports that left to the reader the burden of reconstructing the details of many technical steps. In this paper we develop a number of elementary, still useful, general techniques that allow us both to cover all the steps in great detail, and at the same time also offer a cleaner high level picture of the proof. Second, we explore to what extent the worst-case inapproximability factors $\gamma(n)$ for lattice problems (shown to imply the average-case hardness of solving random linear equations in [2, 11]) can be further reduced. In the process, we introduce and start investigating various new lattice problems that might be of independent interest and that are discussed in more detail in the following subsections. These technical contributions are summarized as follows. On the average-case complexity side, we introduce a kind of lattice (that we call *almost perfect* in analogy with perfect codes), and use lattices of this kind to define a *new random class* of linear equations such that finding small solutions on the average is potentially harder than in the random class proposed by Ajtai. On the worst-case complexity side, we consider various *new lattice problems*, like approximating the *covering radius* of a lattice. Using these new problems, we are able to improve the connection factor for the shortest vector problem (SVP) established in [2, 11]. Specifically, we show that finding small solutions to our random equations (with nonnegligible probability) is at least as hard as the *worst-case* instance of

(i) approximating the length of the shortest nonzero vector in any $n$-dimensional

[1]In particular, Ajtai [2] showed that if no algorithm can efficiently approximate the length of the shortest nonzero vector in any $n$-dimensional lattice within (worst-case) polynomial approximation factors $\gamma(n) = n^{O(1)}$, then *one-way functions* exist. Subsequently, Goldreich, Goldwasser, and Halevi [18] observed that under essentially the same assumptions as Ajtai's, one can prove the existence of *collision resistant hash functions*, a particularly useful kind of one-way function family with many applications in cryptography.

[2]For clarity, in the rest of the paper we always refer to this average-case problem as "finding small solutions to random equations," while lattices are used only to describe worst-case problems. However, we remark that the two formulations are equivalent, and all results discussed in this paper can be regarded as connections between the average-case and worst-case complexity of (different) lattice problems.

lattice within a factor $\gamma(n) = \tau(n) \cdot n^{2.5}\omega(\log n)$, where $\tau(n) \in [1, \sqrt{n}]$ is a parameter that depends on the almost perfect lattices used in the construction and $\omega(\log n)$ is an arbitrary superlogarithmic function.

Even for $\tau(n) = \sqrt{n}$ this improves the connection factor $\gamma(n) = n^{4+\epsilon}$ of [11] by more than a factor $n$. (See section 1.3 for details about the results of [11].) We remark that function $\tau(n)$ is a parameter that depends on the construction of the random equations, and it equals $\sqrt{n}$ in Ajtai's construction as studied in [2, 11]. In this paper we give a better construction showing that smaller values of $\tau(n)$ are possible. The improvement we present is quantitatively modest (namely, $\tau(n) = \sqrt{n \log\log n / \log n}$) but qualitatively interesting, as it shows that Ajtai's class of random equations is not necessarily optimal, and there is room to hope that more substantial improvements are possible.

We also relate the average-case complexity of computing small solutions to our random equations to other lattice problems, like the *worst-case* instances of the following:

(ii) computing maximal sets of linearly independent vectors that are within a factor $\gamma(n) = \tau(n) \cdot n^2 \cdot \omega(\log n)$ from the shortest,[3]

(iii) approximating within a factor $\gamma(n) = \tau(n) \cdot n^2 \cdot \omega(\log n)$ the covering radius of any $n$-dimensional lattice, i.e., the maximum possible distance $\rho(\mathcal{L}(\mathbf{B})) = \max_{\mathbf{t}} \operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}))$ where $\mathbf{t}$ ranges over the entire space spanned by $\mathbf{B}$,

(iv) finding, given an $n$-dimensional lattice basis $\mathbf{B}$ and a target point $\mathbf{t}$, a lattice point whose distance from the target $\mathbf{t}$ is at most $\gamma(n) = \tau(n) \cdot n^2 \cdot \omega(\log n)$ times the covering radius of the lattice.

Even for $\tau(n) = \sqrt{n}$, the first relation improves previously known best connection factor $n^{3+\epsilon}$ of [11] by more than $\sqrt{n}$. (See section 1.3 for details about the results of [11].) The other two relations are the first results explicitly connecting the complexity of finding small solutions to random equations to the covering radius problem (CRP). Although neither problem has been previously considered in computational complexity, they are both natural computational problems on lattices that might be of independent interest. The last problem is a "guaranteed distance" variant of the well-studied closest vector problem (CVP), where the error, instead of being measured with respect to the distance of the given target, is measured with respect to the worst-case distance over all possible target vectors.

All our results are obtained as corollaries to a main theorem that shows that finding small solutions to our random equations is at least as hard as the worst-case instance of finding maximal sets of linearly independent vectors of length at most $\gamma(n) = \tau(n)\sqrt{n} \cdot \omega(\log n)$ times a new lattice invariant that we call the *generalized uniform radius*. Notice how this factor is extremely small: depending on the value of $\tau(n)$, $\gamma(n)$ can be as small as $\sqrt{n} \cdot \omega(\log n)$. This suggests that further investigation of almost perfect lattices and the connection between the uniform radius and other lattice invariants might lead to even stronger connections between the average-case and worst-case complexity of computing short lattice vectors. In particular, we conjecture that there exist random classes of linear equations such that finding small solutions on the average is at least as hard as approximating the length of the shortest nonzero vector in any $n$-dimensional lattice within a factor $\gamma(n) = n^{1.5} \cdot \omega(\log n)$ in the worst case.

[3]Here, and throughout the rest of the paper, the length of a finite set of (linearly independent) vectors is defined as the maximum length of the vectors in the set.

In the following subsections we give a more detailed description of the new lattice problems introduced in this paper and then review previous work in related areas.

**1.1. New lattice problems.** A lattice is the set of intersection points of a regular, but not necessarily orthogonal, $n$-dimensional grid. Mathematically, it can be described as the set of all integer linear combinations $x_1\mathbf{b}_1 + \cdots + x_n\mathbf{b}_n$ (with $x_1, \ldots, x_n \in \mathbb{Z}$) of a sequence of linearly independent vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n$ in Euclidean space $\mathbb{R}^m$. The simplest example is the *integer lattice* $\mathbb{Z}^n$, i.e., the set of all $n$-dimensional vectors with integer coordinates. Two fundamental constants associated to any lattice are the *packing radius* and the *covering radius*: the packing radius is the largest radius such that (open) spheres centered at distinct lattice points do not intersect, and the covering radius is the smallest radius such that (closed) spheres centered at all lattice points cover the entire space. Equivalently, the *packing radius* can be defined as the largest $r$ such that any (open) sphere of radius $r$ (not necessarily centered around a lattice point) contains *at most one* lattice point. Similarly, the *covering radius* can be defined as the smallest $r$ such that any (closed) sphere of radius $r$ contains *at least one* lattice point. In this paper we introduce a new quantity, the *uniform radius*, defined as the smallest $r$ such that all spheres of radius $r$ contain *approximately the same number* of lattice points. (See section 3 for a formal definition.) For technical reasons, we also introduce a variant of the uniform radius, the *generalized uniform radius*, which considers not only spheres but also arbitrary convex bodies.

Of all these quantities, only the *packing radius* has received considerable attention from a computational complexity point of view. It is easy to see that for any lattice, the packing radius equals half the length of the shortest nonzero lattice vector, so (approximately) computing the packing radius is computationally equivalent to computing the (approximate, within the same approximation factor) length of the shortest nonzero lattice vector. (See section 2.3 for a discussion of the computational complexity of this problem.)

Determining the *covering radius* of a lattice is a classic problem in the geometry of numbers, but so far it has received very little attention from a computational complexity point of view. We suggest that the covering radius is, by itself, an interesting problem to be studied as a potential source of computational hardness. We conjecture that computing the covering radius is NP-hard. We remark that even for the exact version of the problem, no NP-hardness result is currently known. However, the exact solution to the CRP is not even known to be computable in *nondeterministic* polynomial time (NP), and the analogous problem for linear codes is known to be complete for the second level of the polynomial hierarchy [30], a class of problems presumably much harder than NP-complete ones.

The problem of estimating the *(generalized) uniform radius* has been implicitly considered before in connection with vector quantization[4] [29] and volume estimation problems [25] but only for the special case of the integer lattice $\mathbb{Z}^n$ and specific convex bodies (spheres or polyhedra). In this paper we generalize this natural geometric problem to arbitrary lattices and convex bodies and show that the generalized uniform radius is always within a factor $O(n)$ from the covering radius.

**1.2. Almost perfect lattices.** The packing radius and covering radius have been extensively studied in coding theory. *Codes* are sets of strings (called *codewords*) of some fixed length $n$ over a finite alphabet $\Sigma$, with the (Hamming) distance between

[4]Vector quantization is the problem of mapping arbitrary real vectors to a discrete set of points (e.g., the points of a lattice) in such a way that each vector is mapped to a nearby point.

strings measured as the number of positions in which the two strings differ. Similarly to lattices, the packing radius and covering radius of a code are defined as the largest and smallest radii such that the Hamming spheres centered at codewords are disjoint or cover the entire space $\Sigma^n$, respectively. A code is called *perfect* if the packing radius equals the covering radius. In other words, the code is perfect if it is possible to partition the entire space $\Sigma^n$ with equal (Hamming) spheres centered at the codewords. Interestingly, perfect codes are rare but do exist (see [21, section 5]). However, the same is not true for lattices: it is not possible to partition the Euclidean space $\mathbb{R}^n$ with equal spheres of radius bounded away from 0. However, one can attempt to partition the space with almost spherical bodies. Any lattice naturally defines a partition of space into regions, the *Voronoi cells*, obtained by mapping each point in space to the closest lattice point (with ties broken in some standard way). It is easy to see that each Voronoi cell contains an open sphere of radius equal to the packing radius and is completely contained in a closed sphere of radius equal to the covering radius. The covering radius is always at least as large as the packing radius, and the smaller the gap between the two radii, the closer the Voronoi cells are to perfect spheres. We say that a lattice is $\tau$-perfect if the covering radius is at most $\tau$ times the packing radius. We are interested in lattices that are $\tau$-perfect for $\tau > 1$ as small as possible. Notice that the integer lattice $\mathbb{Z}^n$ is $\tau(n)$-perfect for $\tau(n) = \sqrt{n}$, so—is trying to minimize $\tau(n)$—we may assume without loss of generality that $\tau(n) \in [1, \sqrt{n}]$. We say that a sequence of lattices is *almost perfect* if it is $\tau(n)$-perfect for some function $\tau(n) = o(\sqrt{n})$ asymptotically smaller than $\sqrt{n}$. Ideally, we would like to find almost perfect lattices with $\tau(n) = O(1)$ equal to a constant independent of the dimension.

Another fundamental problem in coding theory is the maximum likelihood decoding: given a target point, find the codeword closest to the target. The analogous problem on lattices, called the CVP, is as follows: given a lattice and a target vector, find the lattice point closest to it. Differently from lattices, in coding theory most work has focused on finding efficient decoding algorithms for specific codes, whereas in the CVP the lattice is usually considered part of the input. In this paper, we consider the lattice decoding problem for specific lattices. We say that a lattice is *easily decodable* if there is an efficient algorithm that, on input a target point, outputs the lattice point closest to the target. (Formally, we need to consider a sequence of lattices in higher and higher dimensions. See section 4 for details.) For example, the integer lattice $\mathbb{Z}^n$ is easily decodable: given a target point $\mathbf{y} \in \mathbb{Q}^n$, the closest lattice point is easily found by rounding each coordinate of $\mathbf{y}$ to the closest integer.

The random classes of equations defined in this paper are based on easily decodable $\tau(n)$-perfect lattices, and the smaller $\tau(n)$ is, the harder it is to find small solutions to the random equations. So, it is natural to ask, What is the smallest value of $\tau(n)$ for which we can efficiently build *easily decodable* $\tau(n)$-perfect lattices? It is known [40, 10] that very good almost perfect lattices exist, achieving constant $\tau(n) = O(1)$. Unfortunately, the proofs in [40, 10] do not give an efficient procedure to build and decode these lattices. Various examples of easily decodable lattices are given in [12], but none of them is almost perfect; i.e., they achieve only $\tau(n) = \Theta(\sqrt{n})$. It is natural to ask if almost perfect easily decodable lattices exist at all. In this paper we initiate the study of almost perfect lattices from a computational point of view, and we give the first efficient construction of easily decodable almost perfect lattices with $\tau(n) = O(\sqrt{n \log\log n / \log n})$.

Our almost perfect lattices allow us to slightly improve (by a multiplicative factor $O(\sqrt{\log n / \log\log n})$) the worst-case/average-case connection factor $\gamma(n)$ for all lattice problems considered in this paper. Although not substantial, this improvement in the connection factor is qualitatively important because it shows that there are random classes of linear equations for which finding small solutions is potentially harder than for the random class originally considered by Ajtai. Moreover, it suggests that it might be possible to find even better easily decodable almost perfect lattices that allow us to further reduce the connection factors for all lattice problems considered in this paper by almost $\sqrt{n}$.

**1.3. Related work.** This work directly builds upon techniques of Ajtai [2], Cai and Nerurkar [11] and Goldreich, Goldwasser, and Halevi [18], and it is the final version of [35]. In [2] Ajtai showed[5] that if one can efficiently find small solutions to random linear equations on the average with nonnegligible probability $\delta(n) = 1/n^{O(1)}$, then one can efficiently approximate the length of the shortest nonzero vector in any $n$-dimensional lattice within a (worst-case) polynomial factor $\gamma(n) = n^{O(1)}/\delta(n)$, where the smaller the success probability $\delta(n)$, the larger the approximation factor $\gamma(n)$.[6] Moreover, even for large values of $\delta(n)$ (say, $\delta(n) = 1/2$), the factor $\gamma(n)$ given by [2] is rather large.[7] Following Ajtai's seminal work, Cai and Nerurkar [11] showed that finding small solutions to Ajtai's random linear equations (with nonnegligible probability $\delta(n) = 1/n^{O(1)}$) is at least as hard as computing maximal sets of linearly independent vectors that are within a worst-case factor $n^{3+\epsilon}$ from the shortest[8] (for any fixed $\epsilon > 0$, independently of the success probability $\delta(n)$). It immediately follows (using standard relations between lattice problems [26, 7]) that Ajtai's random problem is at least as hard to solve on the average as approximating the length of the shortest nonzero vector in any $n$-dimensional lattice within a factor $\gamma(n) = n^{4+\epsilon}$ in the worst case.[9]

The question of determining under what conditions the number of lattice points inside a convex body $\mathcal{Q}$ is roughly proportional to the volume has been extensively studied, but mostly for the case of the integer lattice $\mathbb{Z}^n$. For example Mazo and Odlyzko [29] study the problem when $\mathcal{Q}$ is a sphere of radius $r$, in connection with

[5]To be precise, [2] proves only the result for $\delta(n) = 1/2$ and remarks that the proof can be generalized to any nonnegligible $\delta(n) = 1/n^{O(1)}$.

[6]It should be remarked that, as observed in [2], setting $\delta(n) = 1/2$ already gives weak one-way functions, which can be transformed (using standard techniques; see [16]) into strong one-way functions based on the worst-case hardness of approximating the shortest vector problem (SVP) within a fixed polynomial factor $\gamma(n) = n^{O(1)}$. However, in order to argue that no efficient algorithm can solve Ajtai's original problem with nonnegligible probability, [2] seems to require that no efficient algorithm can approximate the worst-case lattice problems within *any* polynomial factors.

[7]No specific value of $\gamma(n)$ is given in [2], but [11] estimates that a factor $\gamma(n) = n^8$ can be derived from the proof.

[8]Cai and Nerurkar [11] prove only the result for the shortest basis problem, but it is easy to modify their proof to yield a result for the shortest independent vector problem (SIVP). (See footnote 9 for more information.)

[9] To be precise, Cai and Nerurkar [11] claim only a $\gamma(n) = n^{5+\epsilon}$ connection factor, which is proved in three steps: (1) first they use small solutions (say, of size $O(n)$) of random linear equations to find linearly independent lattice vectors within an $n^{3+\epsilon}$ factor from the shortest *basis* in the lattice; (2) then, they use these linearly independent vectors to get an $n^{3.5+\epsilon}$ approximation to the shortest basis problem; and (3) finally, they connect the shortest basis problem to the SVP, losing an additional $n^{1.5}$ factor. We observe that the linear equations of [11] have solutions as small as $n^{0.5+\epsilon}$, which, if used in the proof, result in linearly independent lattice vectors within an $n^{2.5+\epsilon}$ factor from the shortest lattice basis. Then, we observe that the same technique used in [11] to transform these vectors into an $n^{3+\epsilon}$-approximate solution to the shortest basis problem can also be used to show that the original vectors are an $n^{3+\epsilon}$-approximate solution to the SIVP. This allows us to use known results [26, 7] to solve the SVP by losing only an additional factor $n$ (instead of $n^{1.5}$), leading to an $n^{4+\epsilon}$-approximate solution to the SVP.

universal quantization and low density subset-sum problems. (See [29] and references therein for a description of these problems.) In particular, they show that for $r = O(\sqrt{n})$ the number of integer lattice points in the sphere can deviate from the expected value by factors exponential in $n$, but they claim that if $r = n^{1/2+\epsilon}$ (for any $\epsilon > 0$), then the number of integer lattice points in the sphere is always asymptotic to the volume, no matter where the center is located. A different class of convex bodies is considered by Kannan and Vempala in [25], but, as usual, only for the special case of the integer lattice $\mathbb{Z}^n$. In [25] $\mathcal{Q}$ is an $n$-dimensional convex polytope with $m$ facets, and the result is that the number of integer lattice points in $\mathcal{Q}$ is approximately proportional to the volume provided that $\mathcal{Q}$ contains a sphere of radius $\Omega(n \cdot \sqrt{\log m})$.[10] A result for arbitrary convex bodies is proved by Dyer, Frieze, and Kannan [14], who show that the number of integer lattice points in $\mathcal{Q}$ is approximately proportional to the volume of $\mathcal{Q}$, provided $\mathcal{Q}$ contains a sphere of radius $\Omega(n^{1.5})$. In section 3 we generalize the result of [14] to arbitrary lattices and show that the number of lattice points in $\mathcal{Q}$ is approximately proportional to the volume provided that $\mathcal{Q}$ contains a sphere of radius $\Omega(n)$ times bigger than the covering radius of the lattice (see Theorem 3.6).

The CRP has been extensively studied from a mathematical point of view, leading, for example, to the transference theorems of Banaszczyk [7], but it has received little or no attention from a computational perspective. Two relevant results about the CRP are McLoughlin's proof [30] that the analogous problem on linear codes is hard for the second level of the polynomial hierarchy and Kannan's algorithm [24] showing that a variant of the CRP for lattices (where the norm defined by an input parallelotope is used, instead of the usual Euclidean norm) can be solved in polynomial time for any fixed dimension. Partly motivated by our work [35], some initial progress toward understanding the computational complexity of (approximately) computing the covering radius of lattices and linear codes has been recently made by Guruswami, Micciancio, and Regev [20]. The reader is referred to that paper and section 2.3 for further information about the computational complexity of the CRP.

The problem of decoding specific lattices has been considered in coding theory, for example, in connection with vector quantization. In [12] Conway and Sloane give polynomial time decoding algorithms for the root lattices $A_n, D_n$ and their duals $A_n^*, D_n^*$, as well as various other low-dimensional lattices.[11] From a computational complexity point of view, the problem has been considered under the name *closest vector problem with preprocessing*. Adapting similar results of Bruck and Naor [9] and Lobstein [28] for coding and subset-sum problems, Micciancio [31] showed that there are sequences of lattices such that solving the CVP is NP-hard. These results have been improved by Feige and Micciancio [15] and then Regev [38] to show that (unless P = NP) there are lattices and codes that cannot be efficiently decoded even approximately for any constant approximation factor smaller than $\sqrt{3}$. Notice that the goal of [31, 15, 38] is opposite ours: while [31, 15, 38] give explicit constructions of lattices that cannot be easily decoded, in this paper we search for explicit constructions of easily decodable lattices.

Almost perfect lattices have been extensively studied from a mathematical point of

[10] As a side remark, the motivation to study this problem in [25] is somehow opposite ours, as they count the number of lattice points in a polytope to estimate its volume. Here, we try to get a bound on the number of lattice points for convex bodies $\mathcal{Q}$ of known volume.

[11] Asymptotically, only results for infinite families of lattices are interesting because the CVP is known to be solvable in polynomial time in any fixed dimension [23].

view. In particular, Rogers [40] proved that there exist $\tau(n)$-perfect lattices for $\tau(n) < 3$ and any dimension $n$, and Butler [10] improved the result to $\tau(n) = 2 + o(1)$. Our exponential time construction of almost perfect lattices in Theorem 4.4 is essentially an algorithmic variant of Rogers's proof.

In this paper we consider the worst-case complexity of computing short vectors (as well as solving other computational lattice approximation problems) in *any* lattice. In a recent breakthrough paper [39], Regev has given encryption schemes and collision resistant hash functions that are as hard to break as computing shortest nonzero vectors in lattices with *special structure*. The results proved in [39] achieve approximation factors $O(n^{1.5})$ which are smaller than any other known reduction, but only for lattices where the shortest vector is *unique* is some technical sense. This special structure is common in the construction of lattice-based public key encryption schemes [4] but does not seem necessary to build one-way or collision resistant hash functions. In section 8 we explain how the techniques presented in this paper might lead to one-way and collision resistant hash functions that are as hard to break as solving the SVP (or other lattice problems) in *any* lattice, within approximation factors similar to those established in [39] for the special class of lattices possessing unique shortest vectors.

Another relevant paper establishing results similar to ours, but for a special class of lattices, is [34], where the goal is to obtain hard-on-average problems with very compact representation, rather than improving the connection factor. In [34] Micciancio shows that if approximating the SVP (or various other lattice problems) is hard in the worst case over a class of lattices with a special *cyclic* property, then one can define random linear equations with only $\omega(\log n)$ variables that are hard to solve on the average. This yields random equations (and cryptographic one-way functions) with a much smaller representation size than those considered in this paper, possibly leading to practical and provably secure lattice-based cryptographic functions.

**1.4. Outline.** The rest of the paper is organized as follows. In section 2 we introduce basic definitions and notation used throughout the paper and give background about lattice problems and computational complexity. In section 3 we define the (generalized) uniform radius and relate it to other lattice quantities. In section 4 we initiate the algorithmic study of almost perfect lattices and present the first polynomial time construction of easily decodable almost perfect lattices. These lattices are used in section 5 to define a new random class of equations that generalizes Ajtai's. In section 6 we prove the main technical result of the paper: finding small solutions to the random linear equations of section 5 is at least as hard as finding short (relative to the generalized uniform radius) linearly independent lattice vectors in the worst case. In section 7 we relate this problem to other well-known lattice problems, like approximating the length of the shortest vector in a lattice. Section 8 concludes with a brief summary of our main results and some open problems whose solution would allow us to further improve the connection factors established in this paper.

## 2. Preliminaries.

In this section, we introduce the notation that will be used in the rest of the paper, and then we briefly recall basic notions about lattices, statistical distance, and iterative reductions. For more background material about lattices the reader is referred to the book [36].

**2.1. Notation.** For any finite set $S$, the size of $S$ is denoted $\#S$. For any real $x$, $\lfloor x \rfloor$ denotes the largest integer not greater than $x$, and $\lfloor x \rceil = \lfloor x + 1/2 \rfloor$ is the rounding of $x$ to the closest integer. For any string $s$, the length of $s$ is denoted $|s|$. For any positive real $\epsilon > 0$, we write $[1 \pm \epsilon]$ to denote the interval $[1-\epsilon, 1+\epsilon]$. Arithmetic operations on intervals are defined in the obvious way by extending the standard arithmetic operations pointwise; e.g., $x \cdot [1 \pm \epsilon]$ denotes the interval $[x - \epsilon x, x + \epsilon x]$. Notice that $a \in b \cdot [1 \pm \epsilon]$ if and only if the relative additive error $|a-b|/|b|$ is at most $\epsilon$. For any two positive reals $a, b \geq 0$, we write $a \gtrsim b$ if $a \geq (1/2) \cdot b$ and $a \lesssim b$ if $a \leq (3/2) \cdot b$. We say that $a$ is approximately equal to $b$ (written $a \approx b$) if both $a \lesssim b$ and $a \gtrsim b$, i.e., $a \in b \cdot [1 \pm 1/2]$. Notice that $a \approx b$ is not a symmetric relation; i.e., $a \approx b$ does not imply $b \approx a$. For any $a, b, c \geq 0$, if $a \approx c$ and $b \approx c$, then $a$ and $b$ are within a factor 3 one from the other, i.e.,

$$\forall a, b, c.\ (a \approx c) \wedge (b \approx c) \Rightarrow (a/3 \leq b \leq 3a). \tag{2.1}$$

In the paper we use the standard asymptotic notation for functions. For any two positive real functions $f, g$, we write $f = O(g)$ or $g = \Omega(f)$ if there exists a constant $c > 0$ such that $f(x) \leq c \cdot g(x)$ for all sufficiently large $x$. We write $f = \Theta(g)$ if $f = O(g)$ and $f = \Omega(g)$. We write $f = o(g)$ or $g = \omega(f)$ if $f(x) < c \cdot g(x)$ for all $c > 0$ and all sufficiently large $x$. We also use notation $O(f)$, (resp., $\Omega(f), o(f), \omega(f)$) to denote the class of all functions $g$ such that $g = O(f)$ (resp., $g = \Omega(f)$, etc.), or an arbitrary, but fixed, function from that class. For example, we write $O(1)$ to denote an arbitrary constant or $n^{O(1)}$ to denote an arbitrary polynomially bounded function of $n$. A function $f$ is negligible if $f(n) = n^{-\omega(1)}$, i.e., if $f(n)$ is asymptotically smaller than any inverse polynomial in $n$.

Let $\mathbb{R}$, $\mathbb{Q}$, and $\mathbb{Z}$ be the sets of the reals, the rationals, and the integers, respectively. The $m$-dimensional Euclidean space is denoted $\mathbb{R}^m$. We use bold lowercase letters (e.g., $\mathbf{x}$) to denote vectors and bold uppercase letters (e.g., $\mathbf{M}$) to denote matrices. The $n$-dimensional identity matrix, i.e., the $n \times n$ diagonal matrix with 1's on the diagonal, is denoted $\mathbf{I}_n$ or simply $\mathbf{I}$ when the dimension is clear from the context. The columns of a matrix $\mathbf{M}$ are usually denoted by the corresponding lowercase letters, e.g., $\mathbf{m}_1, \ldots, \mathbf{m}_n$. As an exception, the standard unit vectors, i.e., the columns of the identity matrix $\mathbf{I}_n$, are denoted $\mathbf{e}_1, \ldots, \mathbf{e}_n$. If $\mathcal{Q} \subseteq \mathbb{R}^n$ is an arbitrary region of space and $\mathbf{x} \in \mathbb{R}^n$ is a vector, $\mathcal{Q} + \mathbf{x} = \{\mathbf{y} + \mathbf{x} : \mathbf{y} \in \mathcal{Q}\}$ denotes a copy of $\mathcal{Q}$ shifted by $\mathbf{x}$. The $\ell_2$ norm of a vector $\mathbf{x} \in \mathbb{R}^n$ is $\|\mathbf{x}\| = \sqrt{\sum x_i^2}$, and the associated distance is $\operatorname{dist}(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|$. For a matrix $\mathbf{M} = [\mathbf{m}_1, \ldots, \mathbf{m}_n]$, we define $\|\mathbf{M}\| = \max_i \|\mathbf{m}_i\|$, where $\mathbf{m}_i$ are the columns of $\mathbf{M}$. For vector $\mathbf{v} \in \mathbb{R}^n$ and set $\mathcal{Q} \subseteq \mathbb{R}^n$, let $\operatorname{dist}(\mathbf{v}, \mathcal{Q}) = \inf_{\mathbf{w} \in \mathcal{Q}} \|\mathbf{v} - \mathbf{w}\|$ be the distance between $\mathbf{v}$ and $\mathcal{Q}$. For vector $\mathbf{v} \in \mathbb{R}^n$ and real $r$, let $\mathcal{B}(\mathbf{v}, r) = \{\mathbf{w} \in \mathbb{R}^n : \operatorname{dist}(\mathbf{v}, \mathbf{w}) < r\}$ be the open ball of radius $r$ centered in $\mathbf{v}$ and $\bar{\mathcal{B}}(\mathbf{v}, r) = \{\mathbf{w} \in \mathbb{R}^n : \operatorname{dist}(\mathbf{v}, \mathbf{w}) \leq r\}$ its topological closure. When the center $\mathbf{v} = \mathbf{0}$ is the origin, we simply write $\mathcal{B}(r)$ and $\bar{\mathcal{B}}(r)$. We often use matrix notation to denote sets of vectors. For example, matrix $\mathbf{S} \in \mathbb{R}^{m \times n}$ represents the set of $m$-dimensional vectors $\{\mathbf{s}_1, \ldots, \mathbf{s}_n\}$, where $\mathbf{s}_1, \ldots, \mathbf{s}_n$ are the columns of $\mathbf{S}$. The linear space spanned by a set of vectors $\mathbf{S}$ is denoted $\operatorname{span}(\mathbf{S}) = \{\sum_i x_i \cdot \mathbf{s}_i : \text{for all } i.x_i \in \mathbb{R}\}$. For any set of linearly independent vectors $\mathbf{S}$, we define the centered half-open parallelepiped $\mathcal{P}(\mathbf{S}) = \{\mathbf{S}\mathbf{x} : -1/2 \leq x_i < 1/2\}$.

**2.2. Lattices.** An $m$-dimensional *lattice* is the set of all integer combinations $\{\sum_{i=1}^n x_i \mathbf{b}_i : x_i \in \mathbb{Z}\}$ of $n$ linearly independent vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n$ in $\mathbb{R}^m$ ($m \geq n$). The set of vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n$ is called a *basis* for the lattice, and the integer $n = \dim(\operatorname{span}(\mathbf{B}))$ is called the *rank* of the lattice. If the rank $n$ equals the dimension $m$, then the lattice is called *full rank* or *full dimensional*. Lattices are infinite Abelian groups with respect to the vector addition operation and can be equivalently defined as discrete additive subgroups of $\mathbb{R}^m$. A basis can be compactly represented by the matrix $\mathbf{B} = [\mathbf{b}_1|\dots|\mathbf{b}_n] \in \mathbb{R}^{m\times n}$ having the basis vectors as columns. The lattice generated by $\mathbf{B}$ is denoted $\mathcal{L}(\mathbf{B})$. Notice that $\mathcal{L}(\mathbf{B}) = \{\mathbf{Bx}\colon \mathbf{x} \in \mathbb{Z}^n\}$, where $\mathbf{Bx}$ is the usual matrix-vector multiplication. We use the notation $\mathcal{L}(\mathbf{B})$ to denote the set $\{\mathbf{Bx}\colon \mathbf{x} \in \mathbb{Z}^n\}$ even when vectors $\mathbf{B}$ are not linearly independent. The dual of a lattice $\mathcal{L}(\mathbf{B})$ is the set

$$\mathcal{L}(\mathbf{B})^* = \{\mathbf{x} \in \operatorname{span}(\mathcal{L}(\mathbf{B}))\colon \forall \mathbf{y} \in \mathcal{L}(\mathbf{B}).\langle \mathbf{x}, \mathbf{y}\rangle \in \mathbb{Z}\}$$

of all vectors in the linear span of $\mathcal{L}(\mathbf{B})$ that have integer scalar product with all lattice vectors. The dual of a lattice is a lattice, and a possible basis for the dual of $\mathcal{L}(\mathbf{B})$ is given by $\mathbf{B}^* = \mathbf{B}(\mathbf{B}^T\mathbf{B})^{-1}$, where $\mathbf{B}^T$ is the transpose of $\mathbf{B}$. (Notice that if $\mathbf{B}$ is a basis, it has full column rank and the square matrix $\mathbf{B}^T\mathbf{B}$ is invertible.)

The *minimum distance* of a lattice $\mathcal{L}(\mathbf{B})$ (denoted $\lambda_1(\mathcal{L}(\mathbf{B}))$) is the minimum distance between any two (distinct) lattice points and equals the length of the shortest nonzero lattice vector:

$$\lambda_1(\mathcal{L}(\mathbf{B})) = \min\{\operatorname{dist}(\mathbf{x}, \mathbf{y}) : \mathbf{x} \neq \mathbf{y} \in \mathcal{L}(\mathbf{B})\} = \min\{\|\mathbf{x}\| : \mathbf{x} \in \mathcal{L}(\mathbf{B}) \setminus \{\mathbf{0}\}\}.$$

This definition can be generalized to define the $i$th successive minimum as the smallest $\lambda_i$ such that $\bar{\mathcal{B}}(\lambda_i)$ contains $i$ linearly independent lattice points:

$$\lambda_i(\mathcal{L}(\mathbf{B})) = \min\{r\colon \dim(\operatorname{span}(\mathcal{L}(\mathbf{B}) \cap \bar{\mathcal{B}}(r))) \geq i\}.$$

Another important constant associated to a lattice is the covering radius. The covering radius $\rho(\mathcal{L}(\mathbf{B}))$ of a lattice is the maximum distance $\operatorname{dist}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ when $\mathbf{x}$ ranges over the linear span of $\mathbf{B}$:

$$\rho(\mathcal{L}(\mathbf{B})) = \max_{\mathbf{x}\in\operatorname{span}(\mathbf{B})}\{\operatorname{dist}(\mathbf{x}, \mathcal{L}(\mathbf{B}))\}.$$

A sublattice of $\mathcal{L}(\mathbf{B})$ is a lattice $\mathcal{L}(\mathbf{S})$ such that $\mathcal{L}(\mathbf{S}) \subseteq \mathcal{L}(\mathbf{B})$. $\mathcal{L}(\mathbf{S})$ is a *full rank* sublattice of $\mathcal{L}(\mathbf{B})$ if it has the same rank as $\mathcal{L}(\mathbf{B})$. The determinant of a (rank $n$) lattice $\det(\mathcal{L}(\mathbf{B}))$ is the ($n$-dimensional) volume of the fundamental parallelepiped $\mathcal{P}(\mathbf{B})$, and it does not depend on the choice of the basis $\mathbf{B}$. If $\mathcal{L}(\mathbf{B})$ is full dimensional, then $\det(\mathcal{L}(\mathbf{B}))$ equals the absolute value of the determinant of the $n \times n$ basis matrix $|\det(\mathbf{B})|$. Hadamard's bound gives a simple way to bound the determinant of a lattice as $\det(\mathcal{L}(\mathbf{B})) \leq \prod_i \|\mathbf{b}_i\|$. Hadamard's bound can be much larger than the actual value of the determinant, and it equals the determinant if and only if the basis $\mathbf{B}$ is orthogonal. Minkowski's first theorem (see [36, pp. 11–14]) implies that any rank $n$ lattice $\mathcal{L}(\mathbf{B})$ contains a nonzero vector of length at most

$$\lambda_1(\mathcal{L}(\mathbf{B})) \leq \sqrt{n}\det(\mathcal{L}(\mathbf{B}))^{1/n}. \tag{2.2}$$

The Voronoi cells of a lattice, defined below, play an important role in our proofs. For uniformity, and by analogy with the definition of the half-open parallelepiped, we first define the half-open Voronoi cells. However, we remark that in the rest of the paper we need only the more standard notions of open and closed Voronoi cells.

Definition 2.1. *Let $\preceq$ be the total order on $\mathbb{R}^n$ where $\mathbf{x} \preceq \mathbf{y}$ if and only if $\|\mathbf{x}\| < \|\mathbf{y}\|$ or $\|\mathbf{x}\| = \|\mathbf{y}\|$ and $\mathbf{x}$ precedes $\mathbf{y}$ lexicographically; i.e., $x_i < y_i$ for the first coordinate $i$ such that $x_i \neq y_i$. For any lattice $\mathcal{L}(\mathbf{B})$ and lattice point $\mathbf{x} \in \mathcal{L}(\mathbf{B})$, the (half-open)* Voronoi *cell of $\mathbf{x}$ is the set*

$$\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B})) = \{\mathbf{z} \in \operatorname{span}(\mathcal{L}(\mathbf{B}))\colon \forall \mathbf{y} \in \mathcal{L}(\mathbf{B}).(\mathbf{z} - \mathbf{x}) \preceq (\mathbf{z} - \mathbf{y})\}.$$

*The closed (resp., open) Voronoi cell* $\bar{\mathcal{V}}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ *(resp.,* $\mathcal{V}^o(\mathbf{x}, \mathcal{L}(\mathbf{B}))$*) is defined as the topological closure (resp., interior) of* $\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$.

For simplicity, the Voronoi cell of the origin $\mathbf{x} = \mathbf{0}$ is denoted $\mathcal{V}(\mathcal{L}(\mathbf{B}))$. Notice that the Voronoi cell of the integer lattice equals the half-open unit cube: $\mathcal{V}(\mathbb{Z}^n) = \mathcal{P}(\mathbf{I}_n)$. We need some simple properties about Voronoi cells, as listed below. All properties are easily verified and their proof is left to the reader.

Proposition 2.2. *For any lattice* $\mathcal{L}(\mathbf{B})$*, the Voronoi cells of* $\mathcal{L}(\mathbf{B})$ *satisfy the following properties:*

(i) *The half-open Voronoi cells form a partition of* $\operatorname{span}(\mathcal{L}(\mathbf{B}))$*; i.e., for any* $\mathbf{y} \in \operatorname{span}(\mathcal{L}(\mathbf{B}))$ *there exists a unique lattice point* $\mathbf{x} \in \mathcal{L}(\mathbf{B})$ *such that* $\mathbf{y} \in \mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$.

(ii) *All Voronoi cells* $\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ *(for* $\mathbf{x} \in \mathcal{L}(\mathbf{B})$*) are shifted copies* $\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B})) = \mathcal{V}(\mathcal{L}(\mathbf{B})) + \mathbf{x}$ *of the fundamental cell associated to the origin.*

(iii) *Each cell* $\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ *contains the open sphere* $\mathcal{B}(\mathbf{x}, \lambda_1(\mathcal{L}(\mathbf{B}))/2)$*, and it is contained in the closed sphere* $\bar{\mathcal{B}}(\mathbf{x}, \rho(\mathcal{L}(\mathbf{B})))$.

(iv) *The volume of a Voronoi cell equals* $\operatorname{vol}(\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}))) = \det(\mathcal{L}(\mathbf{B}))$.

(v) *The open Voronoi cell* $\mathcal{V}^o(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ *is the set of all points in* $\operatorname{span}(\mathcal{L}(\mathbf{B}))$ *which are strictly closer to* $\mathbf{x}$ *than to any other lattice point.*

(vi) *The closed Voronoi cell* $\bar{\mathcal{V}}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ *is the set of all points in* $\operatorname{span}(\mathcal{L}(\mathbf{B}))$ *which are at least as close to* $\mathbf{x}$ *as to any other lattice point.*

(vii) *The cells* $\mathcal{V}^o(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ *and* $\bar{\mathcal{V}}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ *are convex and symmetric about their center* $\mathbf{x}$.

**2.3. Computational problems on lattices.** When discussing computational issues related to lattices, it is customary to assume that the lattices are represented by a basis matrix $\mathbf{B}$ and that $\mathbf{B}$ has integer entries. Other representations are possible; e.g., a sublattice of $\mathbb{Z}^n$ can be defined as the set of integer solutions to a system of homogeneous modular linear equations. These alternative representations are computationally equivalent to giving a basis, i.e., for example, given a system of homogeneous modular linear equations one can compute in polynomial time a basis for the corresponding lattice.

In this paper we consider the following problems on lattices. All problems are defined in their approximation version, where the approximation factor $\gamma(n)$ can be a function of the rank $n$ of the lattice. The exact version of the problems corresponds to approximation factor $\gamma(n) = 1$.

Definition 2.3. *The* shortest vector problem (SVP)*, given a lattice basis* $\mathbf{B}$*, asks for a nonzero lattice vector* $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ *of length at most* $\gamma(n) \cdot \lambda_1(\mathcal{L}(\mathbf{B}))$*, where* $n$ *is the rank of* $\mathbf{B}$ *and* $\gamma(n) \geq 1$ *is the approximation factor. The problem can be defined also in a* length estimation *version, where given a basis* $\mathbf{B}$*, one has only to find a value* $\hat{\lambda}_1$ *such that* $\lambda_1(\mathcal{L}(\mathbf{B})) \leq \hat{\lambda}_1 \leq \gamma(n) \cdot \lambda_1(\mathcal{L}(\mathbf{B}))$*. The promise problem*[12] *naturally associated to the length estimation version of* SVP *(denoted* GapSVP$_\gamma$*) is as follows: given* $(\mathbf{B}, d)$*, where* $\mathbf{B}$ *is a lattice basis and* $d$ *is a (rational) number, decide if* $\lambda_1(\mathcal{L}(\mathbf{B})) \leq d$ *or* $\lambda_1(\mathcal{L}(\mathbf{B})) > \gamma(n) \cdot d$.

The promise problem is easily shown to be equivalent to the length estimation version of SVP. (See, for example, [36, pp. 20–21].) However, the promise and length

[12]Promise problems are a natural generalization of decision problems where one is asked whether a given input satisfies one of two mutually exclusive properties (e.g., tell if a given input lattice contains a short nonzero vector, or it does not). However, differently from decision problems, the two properties are not necessarily exhaustive. The problem is, under the promise that the given input satisfies one of the two conditions, tell which of the two properties is satisfied. If the input satisfies neither property, then any answer is acceptable.

estimation problems are not known to be equivalent to the search (vector finding) version of SVP for $\gamma(n) > 1$; i.e., given an oracle to (approximately) compute the length of the shortest nonzero vector in any lattice, it is not clear how to find short lattice vectors.[13] The SVP is NP-hard (under randomized reductions), even in its promise version, for any constant approximation factor $\gamma(n) < \sqrt{2}$ [3, 33]. The promise version of the problem is clearly solvable in NP. For $\gamma(n) = \Omega(\sqrt{n/\log n})$, the problem is in coAM [17], and for $\gamma(n) = \Omega(\sqrt{n})$ it is also in coNP [1]. (See [26, 7] for earlier results with approximation factor $\gamma(n) = \Omega(n)$.) Finally, when $\gamma(n) = e^{\Omega(n \log\log n/\log n)}$ the problem can be solved in random polynomial time [5], and deterministic polynomial time solutions are known only for $\gamma(n) = e^{\Omega(n(\log\log n)^2/\log n)}$ [41].

DEFINITION 2.4. *The* shortest independent vectors problem (SIVP)*, given a lattice basis* $\mathbf{B}$ *of rank* $n$*, asks for a set of* $n$ *linearly independent lattice vectors* $\mathbf{S} \subseteq \mathcal{L}(\mathbf{B})$ *such that* $\|\mathbf{S}\| \leq \gamma(n) \cdot \lambda_n(\mathcal{L}(\mathbf{B}))$*. The problem can be defined also in a* length estimation *version, where given a basis* $\mathbf{B}$*, one has only to find a value* $\hat{\lambda}_n$ *such that* $\lambda_n(\mathcal{L}(\mathbf{B})) \leq \hat{\lambda}_n \leq \gamma(n) \cdot \lambda_n(\mathcal{L}(\mathbf{B}))$*. The promise problem naturally associated to the length estimation version of* SIVP *(denoted* GAPSIVP$_\gamma$*) is as follows: given* $(\mathbf{B}, d)$*, where* $\mathbf{B}$ *is a lattice basis and* $d$ *is a (rational) number, decide if* $\lambda_n(\mathcal{L}(\mathbf{B})) \leq d$ *or* $\lambda_n(\mathcal{L}(\mathbf{B})) > \gamma(n) \cdot d$*.*

SIVP is NP-hard (as usual, already in its promise version) for any constant approximation factor [8]. The (promise version of) SIVP is clearly in NP. For $\gamma(n) = \Omega(\sqrt{n/\log n})$ the problem is in coAM [20, 17], and for $\gamma(n) = \Omega(\sqrt{n})$ it is also in coNP [20, 1]. On the algorithmic side, it is possible to reduce approximating SIVP within a factor $\sqrt{n}\cdot\gamma(n)$ to approximating SVP within a factor $\gamma(n)$, where both SIVP and SVP are considered in their search version. (See, for example, [36, Chapter 7].) For the promise version of the problems, the transference theorems of [26, 7] immediately give a reduction from GAPSIVP$_{n\cdot\gamma(n)}$ to (the complement of) GAPSVP$_{\gamma(n)}$. These reductions from SIVP to SVP immediately give deterministic polynomial time algorithms for approximating SIVP within factors $\gamma(n) = e^{O(n(\log\log n)^2/\log n)}$ and probabilistic polynomial time algorithms for $\gamma(n) = e^{O(n(\log\log n)/\log n)}$.

DEFINITION 2.5. *The* covering radius problem (CRP)*, given a lattice basis* $\mathbf{B}$*, asks for a value* $\hat{\rho}$ *such that* $\rho(\mathcal{L}(\mathbf{B})) \leq \hat{\rho} \leq \gamma(n) \cdot \rho(\mathcal{L}(\mathbf{B}))$*. The promise problem naturally associated to* CRP*, (denoted* GAPCRP$_\gamma$*) is as follows: given* $(\mathbf{B}, d)$ *where* $\mathbf{B}$ *is a lattice basis and* $d$ *is a (rational) number, decide if* $\rho(\mathcal{L}(\mathbf{B})) \leq d$ *or* $\rho(\mathcal{L}(\mathbf{B})) > \gamma(n) \cdot d$*.*

Currently, no NP-hardness result is known for CRP. However, we do not even know how to solve the problem (in its exact version, i.e., for $\gamma(n) = 1$) in nondeterministic polynomial time (NP), and the analogous problem for linear codes is known to be hard for the second level of the polynomial hierarchy [30]. So, we can reasonably conjecture that the same is true for the CRP on lattices.

*Conjecture.* The CRP for lattices (GAPCRP$_1$) is $\Pi_2$-hard.

Recently, [20] has shown that GAPCRP$_\gamma$ is in AM for $\gamma = 2$, in coAM for $\gamma(n) = \Omega(\sqrt{n/\log(n)})$, and in NP $\cap$ coNP for $\gamma(n) = \Omega(\sqrt{n})$. The problem can also be approximated within $\gamma = 1 + \epsilon$ (for any constant $\epsilon > 0$) in random exponential time [20], $\gamma(n) = e^{O(n(\log\log n)/\log n)}$ in random polynomial time, and $\gamma(n) = e^{O(n(\log\log n)^2/\log n)}$ in deterministic polynomial time.

[13] A reduction for the exact case ($\gamma = 1$) is given in [22]. This is the only direct reduction known to date. Technically, a (trivial) reduction between the two problems also exists for approximation factors $\gamma$ for which approximating $\lambda_1$ is NP-hard or finding short vectors is solvable in polynomial time. No reduction is known for any other intermediate approximation factor.

DEFINITION 2.6. *The* closest vector problem (CVP)*, given a lattice basis* $\mathbf{B}$ *and target vector* $\mathbf{t}$*, asks for a lattice point* $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ *such that* $\operatorname{dist}(\mathbf{t}, \mathbf{v}) \leq \gamma(n) \cdot \operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}))$*. The problem can be defined also in a* distance estimation *version, where given a basis* $\mathbf{B}$ *and target* $\mathbf{t}$*, one has only to find a value* $\hat{d}$ *such that* $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \leq \hat{d} \leq \gamma(n) \cdot \operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}))$*. The promise problem naturally associated to* CVP *(denoted* GAPCVP$_\gamma$*) is as follows: given* $(\mathbf{B}, \mathbf{t}, d)$*, where* $\mathbf{B}$ *is a lattice basis,* $\mathbf{t}$ *is a target vector, and* $d$ *is a (rational) number, decide if* $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) \leq d$ *or* $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B})) > \gamma(n) \cdot d$*.*

The CVP is known to be at least as hard as the SVP [19] for any approximation factor $\gamma(n)$. Moreover, it is NP-hard for quasi-polynomial approximation factors $\gamma(n) = n^{1/O(\log\log n)}$ [13]. For $\gamma(n) = \Omega(\sqrt{n/\log n})$ the problem is in coAM [17], and for $\gamma(n) = \Omega(\sqrt{n})$ it is also in coNP [1]. (See [26, 7, 38] for earlier results with approximation factor $\gamma(n) = \Omega(n)$.) Finally, the problem can be approximated in deterministic polynomial time within $\gamma(n) = e^{\Omega(n(\log\log n)^2/\log n)}$ [41, 22].

In the CVP, the target point $\mathbf{t}$ can be arbitrarily far from the lattice. In coding theory, Vardy [42] has considered a variant of the CVP where the distance of the target from the code is guaranteed to be less than the packing radius of the code. This problem (called the *bounded distance decoding* problem (BDD)) is interesting because decoding within the packing radius, if solvable, has a unique solution. (For this reason, the packing radius is sometimes also called the "unique decoding" radius.) For lattices, the analogous problem would be the following: given a lattice $\mathbf{B}$ and a point $\mathbf{t}$ within distance $d < \lambda_1(\mathcal{L}(\mathbf{B}))/2$ from $\mathcal{L}(\mathbf{B})$, find the (unique) lattice point within distance $d$ from $\mathbf{t}$. In general we can consider a similar problem for values of $d$ different from $\lambda_1(\mathcal{L}(\mathbf{B}))/2$, although when $d \geq \lambda_1(\mathcal{L}(\mathbf{B}))/2$ the solution is not necessarily unique. We consider the case when $d = \rho(\mathcal{L}(\mathbf{B}))$ equals the covering radius of the lattice. This case is interesting because there is always a lattice point within distance $\rho(\mathcal{L}(\mathbf{B}))$ from the target. Below we formally define an approximation version of this problem. Since for any lattice $\mathcal{L}(\mathbf{B})$ and target $\mathbf{t}$, there is always a lattice point within distance $\rho(\mathcal{L}(\mathbf{B}))$ from $\mathbf{t}$, we do not define distance estimation or promise versions of this problem.

DEFINITION 2.7. *The* guaranteed distance decoding *problem* (GDD$_\gamma$)*, given a lattice* $\mathbf{B}$ *and a target point* $\mathbf{t} \in \operatorname{span}(\mathbf{B})$*, asks for a lattice point* $\mathbf{x} \in \mathcal{L}(\mathbf{B})$ *such that* $\operatorname{dist}(\mathbf{t}, \mathbf{x}) \leq \gamma(n)\rho(\mathcal{L}(\mathbf{B}))$*, where* $n$ *is the rank of the lattice.*

The following relations are known among the parameters of a lattice $\mathcal{L}(\mathbf{B})$.

PROPOSITION 2.8. *For any rank* $n$ *lattice* $\mathbf{B}$*,*

$$\lambda_1(\mathcal{L}(\mathbf{B})) \leq \lambda_n(\mathcal{L}(\mathbf{B})) \leq 2\rho(\mathcal{L}(\mathbf{B})) \leq \sqrt{n}\lambda_n(\mathcal{L}(\mathbf{B})). \tag{2.3}$$

*Moreover, if* $\mathcal{L}(\mathbf{B})^*$ *is the dual lattice of* $\mathcal{L}(\mathbf{B})$*, then*

$$1 \leq \lambda_1(\mathcal{L}(\mathbf{B}))2\rho(\mathcal{L}(\mathbf{B})^*) \leq n \tag{2.4}$$

*and*

$$1 \leq \lambda_1(\mathcal{L}(\mathbf{B}))\lambda_n(\mathcal{L}(\mathbf{B})^*) \leq n. \tag{2.5}$$

*Proof.* See [36, Theorem 7.9] for (2.3) and [7] for (2.4) and (2.5). ◻

**2.4. Lattices and groups.** Let $\mathcal{L}(\mathbf{L})$ be a lattice. Any sublattice $\mathcal{L}(\mathbf{M}) \subseteq \mathcal{L}(\mathbf{L})$ defines a natural equivalence relation on $\mathcal{L}(\mathbf{L})$ as follows: two lattice points $\mathbf{x}, \mathbf{y} \in \mathcal{L}(\mathbf{L})$ are equivalent (written $\mathbf{x} \equiv_{\mathbf{M}} \mathbf{y}$) if and only if $\mathbf{x} - \mathbf{y} \in \mathcal{L}(\mathbf{M})$. The reader can easily check that $\equiv_{\mathbf{M}}$ is an equivalence relation; i.e., it is reflexive ($\mathbf{x} \equiv_{\mathbf{M}} \mathbf{x}$), symmetric ($\mathbf{x} \equiv_{\mathbf{M}} \mathbf{y} \Leftrightarrow \mathbf{y} \equiv_{\mathbf{M}} \mathbf{x}$), and transitive ($\mathbf{x} \equiv_{\mathbf{M}} \mathbf{y} \wedge \mathbf{y} \equiv_{\mathbf{M}} \mathbf{z} \Rightarrow \mathbf{x} \equiv_{\mathbf{M}} \mathbf{z}$). The $\equiv_{\mathbf{M}}$-equivalence class of $\mathbf{x} \in \mathcal{L}(\mathbf{L})$ (denoted $[\mathbf{x}]_{\mathbf{M}}$) is the set of all $\mathbf{y} \in \mathcal{L}(\mathbf{L})$ such that $\mathbf{x} \equiv_{\mathbf{M}} \mathbf{y}$. The quotient $\mathcal{L}(\mathbf{L})/\mathcal{L}(\mathbf{M}) = \{[\mathbf{x}]_{\mathbf{M}}: \mathbf{x} \in \mathcal{L}(\mathbf{L})\}$ is the set of all $\equiv_{\mathbf{M}}$-equivalence classes of $\mathcal{L}(\mathbf{L})$. The equivalence relation $\equiv_{\mathbf{M}}$ is a congruence with respect to the addition operation; i.e., if $\mathbf{x} \equiv_{\mathbf{M}} \mathbf{x}'$ and $\mathbf{y} \equiv_{\mathbf{M}} \mathbf{y}'$, then $(\mathbf{x}+\mathbf{y}) \equiv_{\mathbf{M}} (\mathbf{x}'+\mathbf{y}')$. It follows that for any two equivalence classes $[\mathbf{x}]_{\mathbf{M}}$ and $[\mathbf{y}]_{\mathbf{M}}$, the sum $[\mathbf{x}]_{\mathbf{M}} + [\mathbf{y}]_{\mathbf{M}} = [\mathbf{x}+\mathbf{y}]_{\mathbf{M}}$ is well defined; i.e., it does not depend on the choice of representatives $\mathbf{x}$, $\mathbf{y}$, and the quotient $\mathcal{L}(\mathbf{L})/\mathcal{L}(\mathbf{M})$ is an additive group with the sum operation just described. Notice that if $\mathcal{L}(\mathbf{L})$ is regarded as an Abelian group, then sublattice $\mathcal{L}(\mathbf{M})$ is a subgroup of $\mathcal{L}(\mathbf{L})$ and $(\mathcal{L}(\mathbf{L})/\mathcal{L}(\mathbf{M}), +)$ is just the standard quotient group.

Group $\mathcal{L}(\mathbf{L})/\mathcal{L}(\mathbf{M})$ is finite if and only if $\mathcal{L}(\mathbf{M})$ is a full rank sublattice of $\mathcal{L}(\mathbf{L})$, in which case the cardinality of the group is

$$\#(\mathcal{L}(\mathbf{L})/\mathcal{L}(\mathbf{M})) = \frac{\det(\mathcal{L}(\mathbf{M}))}{\det(\mathcal{L}(\mathbf{L}))}.$$

Elements of this group can be represented using several standard techniques, e.g., selecting a unique representative from each equivalence class. It is easy to see that for every equivalence class $[\mathbf{x}]_{\mathbf{M}}$ there exists a unique element $\mathbf{x}' \in \mathcal{L}(\mathbf{L}) \cap \mathcal{P}(\mathbf{M})$ such that $\mathbf{x} \equiv_{\mathbf{M}} \mathbf{x}'$. So, a possible set of (unique) representatives is given by the set

$$\mathcal{L}(\mathbf{L}) \cap \mathcal{P}(\mathbf{M})$$

of all lattice points that belong to the half-open parallelepiped $\mathcal{P}(\mathbf{M})$. Given an arbitrary lattice point $\mathbf{x} \in \mathcal{L}(\mathbf{B})$, the corresponding representative can be efficiently computed as follows: write $\mathbf{x}$ as $\mathbf{Mz}$, let $z_i' = \lfloor z_i \rceil$ for all $i = 1, \dots, n$, and set $\mathbf{x}' = \mathbf{M}(\mathbf{z} - \mathbf{z}')$.

The representation of group elements using vectors in $\mathcal{P}(\mathbf{M}) \cap \mathcal{L}(\mathbf{L})$, although polynomial, is not very efficient. In particular, the number of bits necessary to store a single group element can be much larger than $\log_2 \#G$. Other more efficient ways to represent group elements are possible—for example, using the Hermite normal form or the Smith normal form. These representations allow us to store group elements using only $\log |G|$ bits and perform the group operations in linear time. The techniques described in this paper are largely independent from the way group elements are represented, so we do not elaborate on this any further, and we refer the reader to [32, 36] for more details.

Later in this paper we need to sample elements from group $G = \mathcal{L}(\mathbf{L})/\mathcal{L}(\mathbf{M})$ uniformly at random. This can be easily done using an elementary group theoretic technique described in the following proposition.

PROPOSITION 2.9. *Let $G$ be a finite Abelian group and $g_1, \dots, g_n$ a generating set for $G$. Then, if $d_1, \dots, d_n$ are chosen uniformly at random in $\{1, \dots, \#G\}$, then the group element*

$$g = \sum_{i=1}^{n} d_i g_i$$

*is distributed uniformly at random over $G$.*

*Proof.* Since elements $g_1, \dots, g_n$ generate the entire group, we know that for any group element $a \in G$ there exists an integer vector $\mathbf{d}_a = [d_{a,1}, \dots, d_{a,n}]$ such that $\sum_{i=1}^{n} d_{a,i} g_i = a$. Let $K$ be the set of all integer vectors $\mathbf{d} = [d_1, \dots, d_n]$ such that $\sum d_i g_i = 0$ (in $G$). Notice that for any $a \in G$ and $\mathbf{d} \in \mathbb{Z}^n$, $\sum_i d_i g_i = a$ if and only if $\mathbf{d} \in K + \mathbf{d}_a$. Therefore, if $d_1, \ldots, d_n$ are chosen uniformly at random in $\{1, \ldots, \#G\}$, then the probability that $\sum_i d_i g_i = a$ equals exactly the size of $(K + \mathbf{d}_a) \cap \{1, \ldots, \#G\}^n$ divided by $(\#G)^n$. Since $K$ is periodic modulo $\#G$ (i.e., it is invariant under translations by vectors in $\#G \cdot \mathbb{Z}^n$), all sets $(K + \mathbf{d}_a) \cap \{1, \ldots, \#G\}^n$ have the same size, and the probability that $\sum_i d_i g_i = a$ is the same for all $a \in G$. $\square$

Of particular interest in this paper are quotient groups $G = \mathcal{L}(\mathbf{L})/\mathcal{L}(\mathbf{M})$, where $\mathbf{M}$ defines an almost *orthogonal* sublattice of $\mathcal{L}(\mathbf{L})$. The following lemma gives a possible way to build almost orthogonal sublattices for any input lattice $\mathcal{L}(\mathbf{L})$.

LEMMA 2.10. *Let $\mathcal{L}(\mathbf{B})$ be a lattice of rank $n$, $\sigma$ be a positive real, and $D$ be a decoding procedure that on input a vector $\mathbf{y} \in \operatorname{span}(\mathbf{B})$ returns a lattice point $D(\mathbf{y}) \in \mathcal{L}(\mathbf{B})$ such that $\operatorname{dist}(D(\mathbf{y}), \mathbf{y}) \le \sigma$. For any $\alpha \ge 2\sqrt{n} \cdot \sigma$, one can efficiently find (with $n$ calls to $D$) a basis of a full rank sublattice $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$ such that for all $\mathbf{x} \in \mathbb{R}^n$*

$$\|\mathbf{S}\mathbf{x}\| \approx \alpha \cdot \|\mathbf{x}\|.$$

*Proof.* Let $\mathbf{s}_i = D(\alpha \cdot \mathbf{t}_i)$, where $\mathbf{t}_1, \ldots, \mathbf{t}_n$ are an orthonormal basis of $\operatorname{span}(\mathbf{B})$; e.g., if $\mathcal{L}(\mathbf{B})$ is a full rank lattice, set $\mathbf{t}_i = \mathbf{e}_i$. Clearly $\mathbf{s}_i \in \mathcal{L}(\mathbf{B})$ for all $i = 1, \ldots, n$. Let $\mathbf{x} \in \mathbb{R}^n$ be an arbitrary vector. We want to prove that $\|\mathbf{S}\mathbf{x}\| \approx \alpha \cdot \|\mathbf{x}\|$. We know that $\mathbf{s}_i = \alpha \cdot \mathbf{t}_i + \mathbf{r}_i$, where $\|\mathbf{r}_i\| = \|D(\alpha \cdot \mathbf{t}_i) - \alpha \cdot \mathbf{t}_i\| \le \sigma$. Therefore,

$$\|\mathbf{S}\mathbf{x}\| = \|(\alpha \cdot \mathbf{T} + \mathbf{R})\mathbf{x}\| = \|\alpha \cdot \mathbf{T}\mathbf{x} + \mathbf{R}\mathbf{x}\|.$$

By the triangle inequality, and using $\|\mathbf{T}\mathbf{x}\| = \|\mathbf{x}\|$ (which follows from the fact that $\mathbf{T}$ is an orthonormal set of vectors), we get

$$\alpha \cdot \|\mathbf{x}\| - \|\mathbf{R}\mathbf{x}\| \le \|\mathbf{S}\mathbf{x}\| \le \alpha \cdot \|\mathbf{x}\| + \|\mathbf{R}\mathbf{x}\|.$$

So, we need to prove that $\|\mathbf{R}\mathbf{x}\| \le \frac{\alpha}{2}\|\mathbf{x}\|$. By the triangle inequality and Cauchy–Schwarz,

$$\|\mathbf{R}\mathbf{x}\| \le \sum_{i=1}^{n} \|\mathbf{r}_i\| \cdot |x_i| \le \sigma \cdot \sum_{i=1}^{n} |x_i| \le \sqrt{n}\sigma \cdot \|\mathbf{x}\| \le \frac{\alpha}{2} \cdot \|\mathbf{x}\|.$$

This proves that $\|\mathbf{S}\mathbf{x}\| \approx \alpha \cdot \|\mathbf{x}\|$. The linear independence of vectors $\mathbf{S}$ immediately follows because if $\mathbf{S}$ were linearly dependent, then one could find a nonzero vector $\mathbf{x}$ such that $\mathbf{S}\mathbf{x} = \mathbf{0}$, contradicting $\|\mathbf{S}\mathbf{x}\| \approx \alpha \cdot \|\mathbf{x}\| > 0$. $\square$

So far, we have shown how to use lattices and sublattices to define finite Abelian groups. It is also possible to use finite Abelian groups to define lattices.

PROPOSITION 2.11. *Let $G$ be a finite Abelian group, and let $g_1, \ldots, g_n$ be a sequence of elements of $G$. Then, the set*

$$\Lambda(g_1, \ldots, g_n) = \left\{ \mathbf{x} \in \mathbb{Z}^n \colon \sum_{i=1}^{n} x_i g_i = 0 \right\}$$

*is a lattice, and its determinant satisfies $\det(\Lambda(g_1, \ldots, g_n)) \le \#G$, with equality if and only if $g_1, \ldots, g_n$ generate the entire group $G$.*

*Proof.* $\Lambda(g_1, \ldots, g_n)$ is a lattice because it is an additive subgroup of $\mathbb{Z}^n$. Let $G'$ be the subgroup generated by $g_1, \ldots, g_n$. Notice that the quotient $\mathbb{Z}^n / \Lambda(g_1, \ldots, g_n)$ is isomorphic to $G'$, with isomorphism given by $\phi([\mathbf{x}]) = \sum_i x_i g_i$. It follows that the size of $G'$ is $\det(\Lambda(g_1, \ldots, g_n))/\det(\mathbb{Z}^n) = \det(\Lambda(g_1, \ldots, g_n))$, and $\det(\Lambda(g_1, \ldots, g_n)) = \#G' \le \#G$. $\square$

**2.5. Statistical distance.** The statistical distance is a measure of how two probability distributions are far apart from each other, and it is a convenient tool in the analysis of randomized algorithms and reductions. In this subsection we define the statistical distance and state some simple facts that will be used in the analysis of the algorithms in this paper. All the properties of the statistical distance stated in this subsection are easily verified. For more details the reader is referred to [36, Chapter 8].

DEFINITION 2.12. *Let $X$ and $Y$ be two discrete random variables over a (countable) set $A$. The statistical distance between $X$ and $Y$ is the quantity*

$$\Delta(X,Y) = \frac{1}{2}\sum_{a\in A} |\Pr\{X=a\} - \Pr\{Y=a\}|.$$

We say that two random variables $X, Y$ are identically distributed (written $X \equiv Y$) if and only if $\Pr\{X=a\} = \Pr\{Y=a\}$ for every $a \in A$. The reader can easily check that the statistical distance satisfies the usual properties of distance functions, i.e., $\Delta(X,Y) \geq 0$ (with equality if and only if $X \equiv Y$), $\Delta(X,Y) = \Delta(Y,X)$, and $\Delta(X,Z) \leq \Delta(X,Y) + \Delta(Y,Z)$.

The following proposition shows that applying a (possibly randomized) function to two distributions does not increase the statistical distance.

PROPOSITION 2.13. *Let $X, Y$ be two random variables over a common set $A$. For any (possibly randomized) function $f$ with domain $A$, the statistical distance between $f(X)$ and $f(Y)$ is at most*

$$\Delta(f(X), f(Y)) \leq \Delta(X,Y). \tag{2.6}$$

Another useful property of the statistical distance is the following.

PROPOSITION 2.14. *Let $X_1, \ldots, X_k$ and $Y_1, \ldots, Y_k$ be two lists of totally independent random variables. Then*

$$\Delta((X_1,\ldots,X_k),(Y_1,\ldots,Y_k)) \leq \sum_{i=1}^{k} \Delta(X_i, Y_i). \tag{2.7}$$

The next proposition and corollary show how to use the statistical distance to estimate expectations and probabilities.

PROPOSITION 2.15. *If $X$ and $Y$ are random variables over set $A$ and $f\colon A \to [a,b]$ is a real valued function, then*

$$|\operatorname{Exp}[f(X)] - \operatorname{Exp}[f(Y)]| \leq |b-a| \cdot \Delta(X,Y). \tag{2.8}$$

As a corollary, we immediately obtain the following.

COROLLARY 2.16. *If $X$ and $Y$ are random variables over set $A$ and $p\colon A \to \{0,1\}$ is a predicate, then*

$$|\Pr[p(X)=1] - \Pr[p(Y)=1]| \leq \Delta(X,Y). \tag{2.9}$$

The following proposition gives a standard amplification technique that allows us to generate almost uniform samples from a group by adding a relatively small number of independent samples that are not too far from uniform.

PROPOSITION 2.17. *Let $(G,+)$ be a finite group, and let $A_1,\dots,A_k$ be $k$ independent (but possibly not identically distributed) random variables over $G$ such that $\Pr\{A_i = g\} \approx 1/\#G$ for all $i = 1,\dots,k$ and any $g \in G$. Then, for any $g \in G$,*

$$\Pr\left\{\sum_{i=1}^{k} A_i = g\right\} \in \frac{1}{\#G} \cdot \left[1 \pm \frac{1}{2^k}\right].$$

*In particular, the statistical distance between the sum $A = \sum_{i=1}^{k} A_i$ and the uniform distribution $U$ over $G$ is at most*

$$\Delta\left(\sum_{i=1}^{k} A_i, U\right) \leq \frac{1}{2^{k+1}}.$$

The next proposition gives a way to estimate how much a given distribution is affected by conditioning.

PROPOSITION 2.18. *For any random variable $X$ over set $A$, and event $Y$, the statistical distance between distribution $X$ and the conditional distribution of $X$ given $Y$ is exactly half the expected relative additive error of $Y$ given $X$; i.e.,*

$$\Delta(X, (X|Y)) = \frac{1}{2} \operatorname*{Exp}_{X}\left[\left|\frac{\Pr\{Y \mid X\}}{\Pr\{Y\}} - 1\right|\right] \leq \frac{1}{2} \max_{a \in A}\left|\frac{\Pr\{Y|X = a\}}{\Pr\{Y\}} - 1\right|.$$

**2.6. Iterative algorithms and reductions.** Many lattice algorithms work by first computing a relatively poor solution to the problem in question, and then iteratively improving it until a solution meeting some desired condition is found. Examples of such iterative algorithms are the LLL basis reduction algorithm [27] and the Ajtai worst- to average-case reduction and variants [2, 11, 35, 34]. Many other fundamental algorithms can also be described as an iterative process; e.g., Euclid's algorithm starts from two input numbers $a, b$ and iteratively computes smaller and smaller numbers until the greatest common divisor of $a$ and $b$ is found.

The high level structure of many iterative algorithms is the same, and it can be formulated abstractly without any reference to the specific problem in question. Although the method is now standard and has been repeatedly used to solve many lattice problems, it has never been explicitly formulated. In order to avoid unnecessary repetitions and highlight both the similarities and differences among all these algorithms, below we give an abstract formulation of this iterative method and present a general proof that the method implies standard polynomial time algorithms and reductions.

Computational problems can be abstractly defined by giving a binary relation consisting of all problem-solution pairs.

DEFINITION 2.19. *The language associated to a binary relation $R$ is the set $L_R$ of all strings $x$ such that $(x,w) \in R$ for some $w$. The problem defined by relation $R$ is as follows: given a string $x \in L_R$, find a $w$ such that $(x,w) \in R$. For any $(x,w) \in R$, we say that $w$ is a solution to problem $x$.*

Since no polynomial time algorithm (or reduction) can possibly output a solution $w$ of size superpolynomial in $|x|$, it is usually assumed that there exists a polynomial $p$ such that $|w| \leq p(|x|)$ for all $(x,w) \in R$. This is the case for all problems considered in this paper. However, we remark that in general relation $R$ is not required to be polynomial time computable. For example, in the $\gamma$ approximate SVP, membership in the associated relation $R = \{(\mathbf{B},\mathbf{v})\colon \mathbf{v} \in \mathcal{L}(\mathbf{B}) \setminus \{\mathbf{0}\} \wedge \|\mathbf{v}\| \leq \gamma \cdot \lambda_1(\mathcal{L}(\mathbf{B}))\}$ is probably not polynomial time computable for $\gamma < \sqrt{2}$ (unless NP = RP [33]). If membership in $R$ is polynomial time computable (and there exists a polynomial $p$ such that $|w| \leq p(|x|)$ for all $(x, w) \in R$), then $R$ is an NP-relation.

A deterministic algorithm $\mathcal{F}$ solves problem $R$ if for any $x \in L_R$ the output $w = \mathcal{F}(x)$ satisfies $(x, w) \in R$. If $\mathcal{F}$ is a randomized algorithm, then we say that $\mathcal{F}$ solves $R$ *in the worst case* with probability $p$ (possibly a function of the input length); if for any $x \in L_R$ the probability (over the internal randomness of $\mathcal{F}$ alone) that $(x, \mathcal{F}(x)) \in R$ is at least $p(|x|)$. Algorithm $\mathcal{F}$ solves $R$ *on the average* if $(x, \mathcal{F}(x)) \in R$ with probability at least $p(|x|)$, when the probability is computed over the internal randomness of $\mathcal{F}$ and the random selection of the input $x$ according to some specified distribution over all strings in $L_R$ of length $|x|$.

For all worst-case problems considered in this paper, given two tentative solutions $w_0, w_1$ for a problem $x$, it is possible to efficiently select the "best" of the two; i.e., there is a polynomial time algorithm that selects a $w_i$ such that if $(x, w_0) \in R$ or $(x, w_1) \in R$, then $(x, w_i) \in R$. It follows that any algorithm that solves the problem with nonnegligible probability $p(|x|) \geq |x|^{-O(1)}$ can be easily transformed into an algorithm that solves the problem with probability exponentially close to 1, by repeatedly executing the basic algorithm a polynomial (e.g., $|x| \ / \ p(|x|)$) number of times and selecting the best solution. So, we describe any such algorithm as solving the problem with *high probability*, without explicitly stating the exact value of the success probability. Notice, however, that this applies only to (randomized) algorithms that solve a problem in the *worst case*. The success probability amplification technique we just described may not work when applied to an algorithm that solves a problem with nonnegligible probability, but only *on the average*, when the input is chosen at random.

Before we give the general definition of iterative reduction (or algorithm), we illustrate it with a familiar example. Consider Euclid's algorithm. The input is a pair of numbers $x = (a, b)$, and we want to find the greatest common divisor $w = \gcd(a, b)$. The algorithm works iteratively, maintaining at each iteration a pair $s = (s_0, s_1)$ such that $s_0 \geq s_1$ and $\gcd(s_0, s_1) = w$. At every iteration, if $s_1 \neq 0$, the state is updated from $(s_0, s_1)$ to $(s_1, s_0 \bmod s_1)$. Polynomial time termination is guaranteed because at every iteration the function $f(s_0, s_1) = s_0 \cdot s_1 + 1$ decreases at least by a factor 2. When $s_1 = 0$ no more progress is possible, and the algorithm terminates with output $s_0$. In the case of lattice problems, the input is usually a lattice basis $x = \mathbf{B}$, and the algorithm maintains a set of linearly independent vectors $s = \mathbf{S} \subset \mathcal{L}(\mathbf{B})$, or a basis for the input lattice $\mathcal{L}(\mathbf{S}) = \mathcal{L}(\mathbf{B})$. Typically, the goal is to find a set of short vectors $\mathbf{S}$. This set is found by initially setting $\mathbf{S}$ to the input basis and then iteratively applying an algorithm that on input $\mathbf{B}$ and $\mathbf{S}$ outputs a better set $\mathbf{S}'$. This general idea is formalized in the following definition. (See Figure 1 for a pictorial representation of the intended use of iterative reductions and the proof of Theorem 2.21 below for further explanations.)

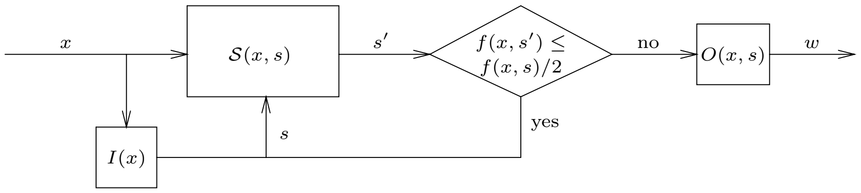

FIG. 1. *Iterative reduction.*

DEFINITION 2.20. *An* iterative reduction *from problem $P$ to a target problem $P'$ is a tuple $(R, f, I, O, \mathcal{S})$, where the following hold:*

(i) *$R$ is a relation (defining the set $R_x = \{s\colon (x, s) \in R\}$ of valid internal states) such that $|s| \le p(|x|)$ for some polynomial $p$ and all $(x, s) \in R$.*

(ii) *$f : R \to \mathbb{Q}^+$ (the* progress function*) is a polynomial time computable function mapping pairs $(x, s) \in R$ to positive rational numbers $f(x, s) \in \mathbb{Q}^+$.*

(iii) *$I$ (the* initialization function*) is a polynomial time computable function mapping each problem instance $x \in L_R$ to an initial state $I(x)$ satisfying $(x, I(x)) \in R$.*

(iv) *$O$ (the* output function*) is a polynomial time computable function mapping valid pairs $(x, s) \in R$ to tentative solutions $O(x, s)$, possibly satisfying $(x, O(x, s)) \in P$.*

(v) *$\mathcal{S}^{(\cdot)}$ (the* iterative step*) is a polynomial time oracle algorithm such that for any oracle $\mathcal{F}$ solving problem $P'$, and for all $(x, s) \in R$, the output $s' = \mathcal{S}^{\mathcal{F}}(x, s)$ satisfies*

(a) *$(x, s') \in R$; and*

(b) *if $P(x, O(x, s))$ is false, then $f(x, s') \le f(x, s)/2$.*

The following theorem shows that iterative reductions easily imply the existence of standard Cook reductions. We remark that the notion of iterative reduction formulated in Definition 2.20 and used in Theorem 2.21 below considers both $P$ and $P'$ as *worst-case* problems. The definition can be easily extended to the case where $P'$ is an average-case problem; however, this is not needed in this paper. In section 6 we will show that the iterative reduction implicit in Ajtai's worst-case to average-case connection and variants can be easily factored into an iterative reduction between two worst-case problems and a worst- to average-case reduction that involves no iteration.

THEOREM 2.21. *If there is an iterative reduction from problem $P$ to problem $P'$, then there is a polynomial time (Cook) reduction from $P$ to $P'$.*

*Proof.* Let $(R, f, I, O, \mathcal{S})$ be an iterative reduction from $P$ to $P'$. We define a standard polynomial time reduction between the two problems. The reduction works as follows (see Figure 1):

1. On input $x$, compute $s = I(x)$.
2. Compute $\mathcal{S}^{\mathcal{F}}(x, s) = s'$ and check if $f(x, s') \le f(x, s)/2$.
3. If the check succeeds, replace $s$ with $s'$ and repeat the previous step.
4. If the check fails, then terminate and output $w = O(x, s)$.

It is immediate to verify that the algorithm satisfies the invariant $(x, s) \in R$ at all iterations. Moreover, the termination condition $f(x, s') > f(x, s)/2$ implies $P(x, O(x, s))$, and therefore the final output is a correct solution. We need to prove that the running time is polynomial in $|x|$. Notice that since $(x, s) \in R$, $|s|$ is bounded by a fixed polynomial in $|x|$ in all iterations, and all steps can be performed in polynomial time. We need to bound the number of iterations. Let $p$ be a polynomial such that $|s| \le p(|x|)$ for all $(x, s) \in R$, and let $q$ be a polynomial bounding the running time of $f$. It follows that the initial value of $f(x, s)$ is at most $2^{q(|x|+p(|x|))}$ and that $f(x, s)$ is always at least $2^{-q(|x|+p(|x|))}$. Since at every iteration $f(x, s)$ decreases by a factor 2, the maximum number of iterations is at most $2q(|x| + p(|x|))$, which is polynomial in $|x|$. $\square$

**3. Covering radius and uniform radius.** Let $\mathcal{L}(\mathbf{B})$ be an $n$-dimensional lattice, and let $\mathcal{Q}$ be a convex body in $\mathbb{R}^n$. It can be shown that if we consider a randomly shifted copy of the body $\mathcal{Q} + \mathbf{x}$ (where $\mathbf{x}$ is chosen uniformly at random[14] ), then the expected number of lattice points in $\mathcal{Q} + \mathbf{x}$ equals exactly

$$\operatorname*{Exp}_{\mathbf{x}}\left[\#(\mathcal{L}(\mathbf{B}) \cap (\mathcal{Q} + \mathbf{x}))\right] = \frac{\operatorname{vol}(\mathcal{Q})}{\det(\mathcal{L}(\mathbf{B}))}.$$

In particular, if $\mathcal{Q}$ is a sphere of radius $r$, then

$$\operatorname*{Exp}_{\mathbf{x}}\left[\#(\mathcal{L}(\mathbf{B}) \cap \mathcal{B}(\mathbf{x}, r))\right] = \frac{\operatorname{vol}(\mathcal{B}(r))}{\det(\mathcal{L}(\mathbf{B}))}.$$

This corresponds to the intuition that the determinant $\det(\mathcal{L}(\mathbf{B}))$ is the inverse of the density of lattice points in space. Notice that the actual number of lattice points in a specific $\mathcal{Q}$ may deviate arbitrarily from the expectation, even for the special case of spherical $\mathcal{Q}$. Consider, for example, a lattice generated by two orthogonal vectors $\mathbf{e}_1$ and $D\mathbf{e}_2$, where $D$ is a large constant. Notice that the determinant of the lattice is $D$, so on the average we would expect to find $\operatorname{vol}(\mathcal{Q})/D$ lattice points inside $\mathcal{Q}$. Now, let $\mathcal{Q} = \mathcal{B}(\mathbf{x}, \sqrt{D})$ be the open disc of radius $\sqrt{D}$. The area of $\mathcal{Q}$ is $\operatorname{vol}(\mathcal{Q}) = \pi D$, so on the average we would expect to find $\pi$ lattice points in $\mathcal{Q}$. However, if $\mathbf{x} = 0$, the number of lattice points in $\mathcal{Q}$ is $2\lceil\sqrt{D}\rceil - 1$. Even worse, if $\mathbf{x} = (D/2)\mathbf{e}_2$, then $\mathcal{Q}$ does not contain any lattice point at all.

We define the *uniform radius* of a lattice as the smallest value $r = \zeta(\mathcal{L}(\mathbf{B}))$ such that any sphere $\mathcal{B}(\mathbf{x}, r)$ contains a number of lattice points close to the expected value.

DEFINITION 3.1. *For any $n$-dimensional lattice $\mathcal{L}(\mathbf{B})$, the* uniform radius $\zeta(\mathcal{L}(\mathbf{B}))$ *is the smallest positive real $r$ such that*

$$\#(\mathcal{L}(\mathbf{B}) \cap \mathcal{B}(\mathbf{x}, r)) \approx \frac{\operatorname{vol}(\mathcal{B}(r))}{\det(\mathcal{L}(\mathbf{B}))}$$

*for any* $\mathbf{x} \in \operatorname{span}(\mathcal{L}(\mathbf{B}))$.

The following proposition shows that the uniform radius $\zeta(\mathcal{L}(\mathbf{B}))$ is at least as large as the covering radius $\rho(\mathcal{L}(\mathbf{B}))$. Later we will also show that the uniform radius is never much bigger than that.

PROPOSITION 3.2. *For any lattice $\mathcal{L}(\mathbf{B})$, $\rho(\mathcal{L}(\mathbf{B})) < \zeta(\mathcal{L}(\mathbf{B}))$.*

*Proof.* The proof is immediate because for $r \le \rho(\mathcal{L}(\mathbf{B}))$ any sphere of radius $r$ centered in a deep hole (i.e., a point in space at distance $\rho(\mathcal{L}(\mathbf{B}))$ from the lattice) does not contain any lattice point. ☐

The uniform radius can be used to estimate the number of lattice points contained in a sphere. Later in this paper, we need to estimate the number of lattice points inside arbitrary convex bodies. So, we generalize the definition of the uniform radius to arbitrary convex bodies.

DEFINITION 3.3. *For any $n$-dimensional lattice $\mathcal{L}(\mathbf{B})$, the* generalized uniform radius $\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ *is the smallest positive real $r$ such that for any convex body $\mathcal{Q}$ containing a sphere $\mathcal{B}(\mathbf{x}, r) \subseteq \mathcal{Q}$ of radius $r$, the number of lattice points inside the body satisfies*

$$\#(\mathcal{L}(\mathbf{B}) \cap \mathcal{Q}) \approx \frac{\operatorname{vol}(\mathcal{Q})}{\det(\mathcal{L}(\mathbf{B}))}.$$

[14]Intuitively, we would like to choose $\mathbf{x}$ uniformly at random from $\mathbb{R}^n$, but this is not possible because $\mathbb{R}^n$ has infinite measure. This problem is easily solved observing that it is enough to choose $\mathbf{x}$ uniformly at random from the fundamental region $\mathcal{P}(\mathbf{B})$ of the lattice, because the lattice repeats identically when translated by $\mathbf{Bx}$ for $\mathbf{x} \in \mathbb{Z}^n$.

Clearly, the generalized uniform radius is at least as large as the uniform radius: for any lattice $\mathcal{L}(\mathbf{B})$, $\zeta(\mathcal{L}(\mathbf{B})) \leq \hat{\zeta}(\mathcal{L}(\mathbf{B}))$. In particular, $\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ is always larger than the covering radius $\rho(\mathcal{L}(\mathbf{B}))$. We bound the (generalized) uniform radius from above and show that for any lattice $\mathcal{L}(\mathbf{B})$, the (generalized) uniform radius is not much larger than the covering radius. Specifically, we show that $\hat{\zeta}(\mathcal{L}(\mathbf{B})) = O(n) \cdot \rho(\mathcal{L}(\mathbf{B}))$. A similar result was proved by Dyer, Frieze, and Kannan in [14] for the special case of $\mathcal{L}(\mathbf{B}) = \mathbb{Z}^n$. We observe that the proof of [14] is a general volume argument and does not use any special property of lattice $\mathbb{Z}^n$. So, it can be easily adapted to arbitrary lattices. Below we recall two simple geometric lemmas proved in [14] and then use them to prove the bound on $\hat{\zeta}(\mathcal{L}(\mathbf{B}))$.

Lemma 3.4 (see [14, Proposition 1]). *Suppose $\mathcal{Q}$ is a convex body in $\mathbb{R}^n$ containing the unit ball $\mathcal{B}(1)$, and let $\epsilon > 0$ be any positive real. Then all points within distance $\epsilon$ from $\mathcal{Q}$ belong to $(1+\epsilon)\mathcal{Q}$.*

Lemma 3.5 (see [14, Proposition 2]). *Suppose $\mathcal{Q}$ is a convex body in $\mathbb{R}^n$ containing the unit ball $\mathcal{B}(1)$, and let $0 < \epsilon \leq 1$. Then, all points within distance $\epsilon$ from $(1-\epsilon)\mathcal{Q}$ belong to $\mathcal{Q}$.*

We can now prove the bound on the uniform radius in terms of the covering radius.

Theorem 3.6. *For any $n$-dimensional lattice $\mathcal{L}(\mathbf{B})$,*

$$\hat{\zeta}(\mathcal{L}(\mathbf{B})) \leq 3n\rho(\mathcal{L}(\mathbf{B})).$$

*Proof.* Let $\mathcal{L}(\mathbf{B})$ be a full rank lattice in $\mathbb{R}^n$ with covering radius $\rho(\mathcal{L}(\mathbf{B}))$, and let $\mathcal{Q}$ be a convex body containing a sphere of radius $r = 3n\rho(\mathcal{L}(\mathbf{B}))$. We want to prove that $\#(\mathcal{L}(\mathbf{B}) \cap \mathcal{Q}) \approx \frac{\mathrm{vol}(\mathcal{Q})}{\det(\mathcal{L}(\mathbf{B}))}$. Let $\mathcal{L}(\mathbf{B}') = \mathcal{L}(\mathbf{B})/r$ and $\mathcal{Q}' = \mathcal{Q}/r$ be scaled versions of $\mathcal{L}(\mathbf{B})$ and $\mathcal{Q}$, and consider the set of points

$$S = \mathcal{L}(\mathbf{B}') \cap \mathcal{Q}' = \frac{\mathcal{L}(\mathbf{B}) \cap \mathcal{Q}}{r}.$$

Clearly, $\#S = \#(\mathcal{L}(\mathbf{B}') \cap \mathcal{Q}') = \#(\mathcal{L}(\mathbf{B}) \cap \mathcal{Q})$. We want to prove that

$$\#S \approx \frac{\mathrm{vol}(\mathcal{Q}')}{\det(\mathcal{L}(\mathbf{B}'))} = \frac{\mathrm{vol}(\mathcal{Q})}{\det(\mathcal{L}(\mathbf{B}))}.$$

Consider the union of all Voronoi cells $\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}'))$ with centers $\mathbf{x} \in S$. Notice that all points $\mathbf{y} \in \mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}'))$ are within distance $\rho(\mathcal{L}(\mathbf{B}')) = \rho(\mathcal{L}(\mathbf{B}))/r$ from $\mathbf{x}$. Moreover, $\mathcal{Q}'$ contains a sphere of radius 1. Therefore, by Lemma 3.4, for all $\mathbf{x} \in S \subset \mathcal{Q}'$ and $\mathbf{y} \in \mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}'))$, we have $\mathbf{y} \in \mathcal{Q}' \cdot (1+\rho(\mathcal{L}(\mathbf{B}))/r)$, i.e., $\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}')) \subseteq (1+\rho(\mathcal{L}(\mathbf{B}))/r) \cdot \mathcal{Q}'$. (Scaling, this time, was performed using as origin the center of the unit sphere contained in $\mathcal{Q}'$.) Since Voronoi cells are disjoint and have the same volume, we have

$$\begin{aligned}
\#S &= \frac{\sum_{\mathbf{x} \in S} \mathrm{vol}\left(\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}'))\right)}{\mathrm{vol}(\mathcal{V}(\mathcal{L}(\mathbf{B}')))} \\
&= \frac{\mathrm{vol}\left(\bigcup_{\mathbf{x} \in S} \mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}'))\right)}{\mathrm{vol}(\mathcal{V}(\mathcal{L}(\mathbf{B}')))} \\
&\leq \frac{\mathrm{vol}(\mathcal{Q}' \cdot (1 + \rho(\mathcal{L}(\mathbf{B}))/r))}{\det(\mathcal{L}(\mathbf{B}'))} \\
&= \left(1 + \frac{\rho(\mathcal{L}(\mathbf{B}))}{r}\right)^n \frac{\mathrm{vol}(\mathcal{Q}')}{\det \mathcal{L}(\mathbf{B}')}.
\end{aligned}$$

Finally, using the assumption $r \geq 3n\rho(\mathcal{L}(\mathbf{B}))$, we get

$$\begin{aligned}\left(1+\frac{\rho(\mathcal{L}(\mathbf{B}))}{r}\right)^n &< \left(1+\frac{1}{3n-1}\right)^n \\ &= \frac{1}{\left(1-\frac{1}{3n}\right)^n} \\ &\leq \frac{1}{1-\frac{1}{3}} = \frac{3}{2}.\end{aligned}$$

This proves the upper bound $\#S \lesssim \mathrm{vol}(\mathcal{Q}')/\det\mathcal{L}(\mathbf{B}')$.

We now turn to the lower bound. Let $S'$ be the set of all lattice points $\mathbf{x} \in \mathcal{L}(\mathbf{B}')$ such that the Voronoi cell $\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}'))$ intersects $(1-\rho(\mathcal{L}(\mathbf{B}))/r)\mathcal{Q}'$. Notice that if $\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}'))$ intersects $(1-\rho(\mathcal{L}(\mathbf{B}))/r)\mathcal{Q}'$, then $\mathbf{x}$ must be within distance $\rho(\mathcal{L}(\mathbf{B}')) = \rho(\mathcal{L}(\mathbf{B}))/r$ from $(1-\rho(\mathcal{L}(\mathbf{B}))/r)\cdot\mathcal{Q}'$. So, by Lemma 3.5, $\mathbf{x} \in \mathcal{Q}'$. This proves that $S' \subseteq S$, and $\#S \geq \#S'$. Since Voronoi cells cover $\mathbb{R}^n$, $(1-\rho(\mathcal{L}(\mathbf{B}))/r)\mathcal{Q}'$ is fully contained in the union $\bigcup_{\mathbf{x}\in S'} \mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}'))$, and

$$\begin{aligned}\#S' &= \frac{\sum_{\mathbf{x}\in S'} \mathrm{vol}(\mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}')))}{\mathrm{vol}(\mathcal{V}(\mathcal{L}(\mathbf{B}')))} \\ &= \frac{\mathrm{vol}(\bigcup_{\mathbf{x}\in S'} \mathcal{V}(\mathbf{x}, \mathcal{L}(\mathbf{B}')))}{\mathrm{vol}(\mathcal{V}(\mathcal{L}(\mathbf{B}')))} \\ &\geq \frac{\mathrm{vol}((1-\rho(\mathcal{L}(\mathbf{B}))/r)\mathcal{Q}')}{\det(\mathcal{L}(\mathbf{B}'))} \\ &= \left(1-\frac{\rho(\mathcal{L}(\mathbf{B}))}{r}\right)^n \frac{\mathrm{vol}(\mathcal{Q}')}{\det(\mathcal{L}(\mathbf{B}'))}.\end{aligned}$$

Using the assumption $r \geq 3n\rho(\mathcal{L}(\mathbf{B}))$, we immediately get

$$\left(1-\frac{\rho(\mathcal{L}(\mathbf{B}))}{r}\right)^n > \left(1-\frac{1}{2n}\right)^n \geq 1-\frac{1}{2}.$$

This proves the lower bound $\#S \gtrsim \mathrm{vol}(\mathcal{Q}')/\det(\mathcal{L}(\mathbf{B}'))$ and completes the proof of the theorem. $\square$

Using inequality $\rho(\mathcal{L}(\mathbf{B})) \leq \sqrt{n}\cdot\lambda_n(\mathcal{L}(\mathbf{B}))/2$ from (2.3), we can bound $\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ in terms of $\lambda_n(\mathcal{L}(\mathbf{B}))$:

$$\hat{\zeta}(\mathcal{L}(\mathbf{B})) \leq \frac{3}{2}n^{1.5}\lambda_n(\mathcal{L}(\mathbf{B})). \tag{3.1}$$

Similarly, using the transference theorem (2.4), we can bound $\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ in terms of the length of the shortest nonzero vector in the dual lattice:

$$\hat{\zeta}(\mathcal{L}(\mathbf{B})) \leq \frac{3}{2}n^2\frac{1}{\lambda_1(\mathcal{L}(\mathbf{B})^*)}. \tag{3.2}$$

These bounds can be used to relate the average-case complexity of finding small solutions to random equations to the worst-case complexity of approximating SIVP or GapSVP.

It would be interesting to improve bounds (3.1) and (3.2). In particular, is it true that $\hat{\zeta}(\mathcal{L}(\mathbf{B})) = O(n)\cdot\lambda_n(\mathcal{L}(\mathbf{B}))$ for any $n$-dimensional lattice $\mathcal{L}(\mathbf{B})$? Is it true that $\hat{\zeta}(\mathcal{L}(\mathbf{B})) = O(n)/\lambda_1(\mathcal{L}(\mathbf{B})^*)$? Proving these improved bounds would immediately result in a reduction of the connection factor for SIVP by a factor $O(\sqrt{n})$ and for GapSVP by a factor $O(n)$.

**4. Easily decodable almost perfect lattices.** We are interested in lattices that have both good algorithmic and geometric properties. Algorithmically, we would like lattices where the CVP can be efficiently solved. Notice that, despite the NP-hardness of CVP, the CVP may be efficiently solvable for *specific* lattices. For example, in the integer lattice $\mathbb{Z}^n$, a lattice vector $\mathbf{x} \in \mathbb{Z}^n$ closest to a given target $\mathbf{t} \in \mathbb{Q}^n$ can be easily found rounding each coordinate of $\mathbf{t}$ to the closest integer $x_i = \lfloor t_i \rceil$. Since for any fixed dimension the CVP can be solved in polynomial time, in order to properly formulate this problem one needs to consider not a single lattice but an infinite sequence of lattices in increasing dimension. For simplicity, in the definition below we focus on full rank lattices, although this restriction is not necessary.

DEFINITION 4.1. *Let $\{\mathbf{L}_n\}_{n\geq 1}$ be a sequence of full rank lattices $\mathcal{L}(\mathbf{L}_n) \subseteq \mathbb{R}^n$. We say that the sequence $\{\mathbf{L}_n\}_{n\geq 1}$ is* easily decodable *if there exists a polynomial time algorithm* $\mathrm{CVP}_{\mathbf{L}}$ *such that for any $n \geq 1$ and $\mathbf{t} \in \mathbb{Q}^n$,* $\mathrm{CVP}_{\mathbf{L}}(\mathbf{t})$ *outputs a lattice vector in $\mathcal{L}(\mathbf{L}_n)$ closest to $\mathbf{t}$.*

The simplest example of an easily decodable sequence of lattices is given by the integer lattices $\mathbb{Z}^n$ defined by matrices $\mathbf{L}_n = \mathbf{I}_n$. Other easily decodable lattices considered in [12] are the *root lattices* $A_n$ and $D_n$ and their duals $D_n^*$ and $A_n^*$.[15]

From a geometric point of view, we would like the Voronoi cells of the lattice to be as spherical as possible. Remember that the Voronoi cell $\mathcal{V}(\mathcal{L}(\mathbf{L}))$ contains a sphere $\mathcal{B}(\lambda_1(\mathcal{L}(\mathbf{L}))/2)$ with radius equal to the packing radius and is completely contained in a sphere $\bar{\mathcal{B}}(\rho(\mathcal{L}(\mathbf{L})))$ with radius equal to the covering radius. So, the closer the covering radius is to the packing radius, the better the Voronoi cells are approximated by spheres. This motivates the following definition.

DEFINITION 4.2. *For any $\tau \geq 1$, a lattice $\mathcal{L}(\mathbf{L})$ is $\tau$-perfect if*

$$\rho(\mathcal{L}(\mathbf{L})) \leq \tau \cdot \left(\frac{\lambda_1(\mathcal{L}(\mathbf{L}))}{2}\right).$$

*For any function $\tau(n)$, a sequence of (full rank) lattices $\{\mathbf{L}_n\}_{n\geq 1}$ (where $n$ is the dimension of $\mathcal{L}(\mathbf{L}_n)$) is $\tau(n)$-perfect if $\mathcal{L}(\mathbf{L}_n)$ is $\tau(n)$-perfect for any $n \geq 1$. A sequence of (full rank) lattices $\{\mathbf{L}_n\}_{n\geq 1}$ is almost perfect if it is $\tau(n)$-perfect for some $\tau(n) = o(\sqrt{n})$.*

We are interested in sequences of lattices such that $\tau(n)$ is as small as possible. Moreover, we would like the lattices to be easily decodable. The integer lattice $\mathbb{Z}^n$, as well as all other sequences $A_n, A_n^*, D_n, D_n^*$ of easily decodable lattices considered in [12], are $\tau(n)$-perfect for $\tau(n) = \Theta(\sqrt{n})$, so they are not almost perfect. It is natural to ask if nontrivial easily decodable almost perfect lattices (i.e., $\tau(n)$-perfect lattices with $\tau(n) = o(\sqrt{n})$) exist, or if the almost perfectness and easy decodability requirements are incompatible.

In this section we start the algorithmic study of almost perfect lattices and give the first efficient construction of nontrivial easily decodable almost perfect lattices. Our lattices are $\tau(n)$-perfect for $\tau(n) = \sqrt{n \log\log n/\log n} = o(\sqrt{n})$. Although this is not a substantial improvement over $\tau(n) = \Theta(\sqrt{n})$ from a quantitative point of view, it is qualitatively interesting because it shows that nontrivial easily decodable almost perfect lattices exist.

We first present a construction of 3-perfect lattices such that the construction and the decoding algorithm run in exponential time $n^{O(n)}$. Then we show how to

[15]Conway and Sloane [12] also describe other efficient decoding algorithms for specific lattices, but $\mathbb{Z}^n, A_n, A_n^*, D_n, D_n^*$ are the only infinite sequences of lattices considered for which the problem of efficient decoding admits an interesting asymptotic formulation.

use small-dimensional lattices obtained using this construction to efficiently construct $O(\sqrt{n \log\log n / \log n})$-perfect lattices such that the CVP can be solved in polynomial time. The construction is based on the following simple lemma.

LEMMA 4.3. *For any lattice $\mathcal{L}(\mathbf{B})$, there exists a lattice vector $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ such that* $\operatorname{dist}(\mathbf{v}/3, \mathcal{L}(\mathbf{B})) \geq (2/3)\rho(\mathcal{L}(\mathbf{B}))$. *In particular, if $\rho(\mathcal{L}(\mathbf{B})) \geq 3 \cdot \lambda_1(\mathcal{L}(\mathbf{B}))/2$, then* $\operatorname{dist}(\mathbf{v}/3, \mathcal{L}(\mathbf{B})) \geq \lambda_1(\mathcal{L}(\mathbf{B}))$.

*Proof.* Let $\mathbf{h}$ be a deep hole, i.e., a point in $\operatorname{span}(\mathcal{L}(\mathbf{B}))$ at distance $\rho(\mathcal{L}(\mathbf{B}))$ from $\mathcal{L}(\mathbf{B})$. Consider the point $3\mathbf{h}$, and let $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ be a lattice point closest to $3\mathbf{h}$. By definition of the covering radius, it must be $\|\mathbf{v} - 3\mathbf{h}\| \leq \rho(\mathcal{L}(\mathbf{B}))$. Therefore, dividing by 3, we get $\|\mathbf{v}/3 - \mathbf{h}\| \leq \rho(\mathcal{L}(\mathbf{B}))/3$, and by the triangle inequality

$$\begin{aligned}\operatorname{dist}(\mathbf{v}/3, \mathcal{L}(\mathbf{B})) &\geq \operatorname{dist}(\mathbf{h}, \mathcal{L}(\mathbf{B})) - \operatorname{dist}(\mathbf{v}/3, \mathbf{h}) \\ &\geq \rho(\mathcal{L}(\mathbf{B})) - \frac{1}{3}\rho(\mathcal{L}(\mathbf{B})) \\ &= \frac{2}{3} \cdot \rho(\mathcal{L}(\mathbf{B})). \qquad \square\end{aligned}$$

We use the lemma to give an algorithmic construction of $\tau$-perfect lattices with $\tau < 3$. The following theorem is essentially an algorithmic variant of the proof of existence given in [40]. Both the procedure to build the lattice and the one to decode it run in time $n^{O(n)}$. It should be noted that for any $n$-dimensional lattice, in principle the CVP can always be solved in time $n^{O(n)}$ [23]. However, the algorithm of [23] for general lattices is rather complex. In the theorem below we show how to build a lattice $\mathcal{L}(\mathbf{B})$ together with some (polynomial size) auxiliary information $\mathbf{V}$ that allows us to solve the CVP in lattice $\mathcal{L}(\mathbf{B})$, still in time $n^{O(n)}$ as in [23], but with a much simpler algorithm.

THEOREM 4.4. *There is an algorithm running in time $n^{O(n)}$ that on input $n$ outputs an $n$-dimensional* 3*-perfect lattice $\mathbf{L}_n$. Moreover, the sequence of lattices $\{\mathbf{L}_n\}_{n\geq 1}$ is decodable in time $n^{O(n)}$; i.e., there is an algorithm* $\mathrm{CVP}_{\mathbf{L}}$ *running in time $n^{O(n)}$ that on input a vector $\mathbf{t} \in \mathbb{Q}^n$ outputs a lattice vector* $\mathrm{CVP}_{\mathbf{L}}(\mathbf{t}) \in \mathcal{L}(\mathbf{L}_n)$ *closest to* $\mathbf{t}$.

*Proof.* The algorithm starts from an arbitrary $n$-dimensional easily decodable lattice $\mathcal{L}(\mathbf{B}_0)$, e.g., the integer lattice $\mathcal{L}(\mathbf{B}_0) = \mathbb{Z}^n$ generated by the identity matrix $\mathbf{B}_0 = \mathbf{I}$. Notice that the closest vector in $\mathbb{Z}^n$ to a target $\mathbf{t}$ can be easily found by rounding each coordinate of $\mathbf{t}$ to the closest integer. Below we assume that $\mathbf{B}_0 = \mathbf{I}$ and, in particular, $\det(\mathcal{L}(\mathbf{B}_0)) = 1$ and $\lambda_1(\mathcal{L}(\mathbf{B}_0)) = 1$, but the construction works for any easily decodable lattice.

Starting from $\mathbf{B}_0$, we iteratively build a sequence of lattice bases $\mathbf{B}_i$ and auxiliary vectors $\mathbf{v}_i$ for $i = 1, \ldots, m$ for some $m = O(n \log n)$ to be determined. The final output are basis $\mathbf{B} = \mathbf{B}_m$ and set of vectors $\mathbf{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_m]$. For each $k = 1, \ldots, m$, vector $\mathbf{v}_k$ and basis $\mathbf{B}_k$ are computed as follows:

1. For any vector $\mathbf{s} \in \{-1, 0, +1\}^n$, let $\mathbf{t} = (1/3)\mathbf{B}_{k-1}\mathbf{s}$ and compute the distance of $\mathbf{t}$ from the lattice $\mathcal{L}(\mathbf{B}_{k-1})$. (We will show below how this can be done in time $n^{O(1)} \cdot 3^k$.)
2. If for all $\mathbf{s} \in \{-1, 0, +1\}^n$, $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}_{k-1})) < 1$, then set $m = k - 1$, and terminate with output $\mathbf{B} = \mathbf{B}_{k-1}$ and $\mathbf{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_{k-1}]$.
3. Otherwise (if $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}_{k-1})) \geq 1$ for some $\mathbf{s}$), proceed as follows. Notice that since $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}_{k-1})) > 0$, it must be $\mathbf{s} \neq \mathbf{0}$.
4. Let $i \in \{1, \ldots, n\}$ such that $s_i \neq 0$.
5. Set $\mathbf{v}_k = \mathbf{t}$.
6. Set $\mathbf{B}_k$ to the matrix obtained by replacing the $i$th vector in $\mathbf{B}_{k-1}$ with $\mathbf{v}_k$.

The algorithm uses a procedure to find closest vectors in lattice $\mathcal{L}(\mathbf{B}_k)$. We will show that the maximum number of iterations performed by the algorithm is $m \leq (n/2)\log_3 n = O(n \log n)$, and that for any $k$, the CVP in $\mathcal{L}(\mathbf{B}_k)$ can be solved in time $n^{O(1)} \cdot 3^k$. It follows that the total running time of the algorithm is

$$O(m \cdot n^{O(1)} \cdot 3^m) = n^{O(n)}$$

and that the CVP in $\mathcal{L}(\mathbf{B})$ can also be solved in time $n^{O(n)}$.

The correctness of the algorithm is based on the fact that for any $k$,

(i) vector $3\mathbf{v}_k$ belongs to the lattice $\mathcal{L}(\mathbf{B}_{k-1})$,
(ii) $\mathbf{B}_k$ is a basis for the lattice generated by $[\mathbf{B}_{k-1}|\mathbf{v}_k]$,
(iii) the shortest vector in $\mathcal{L}(\mathbf{B}_k)$ has length 1.

The first property immediately follows by construction. For the second property, it is clear that $\mathcal{L}(\mathbf{B}_k)$ is a subset of $\mathcal{L}([\mathbf{B}_{k-1}|\mathbf{v}_k])$. In order to prove $\mathcal{L}(\mathbf{B}_k) = \mathcal{L}([\mathbf{B}_{k-1}|\mathbf{v}_k])$ we need only to show that the $i$th vector of $\mathbf{B}_{k-1}$ (namely, $\mathbf{B}_{k-1}\mathbf{e}_i$) belongs to $\mathcal{L}(\mathbf{B}_k)$. Notice that $3\mathbf{v}_k = \mathbf{B}_{k-1}\mathbf{s} = \sum_j s_j \mathbf{B}_{k-1}\mathbf{e}_j$. So, $s_i \cdot \mathbf{B}_{k-1}\mathbf{e}_i = 3\mathbf{v}_k - \sum_{j\neq i} s_j \mathbf{B}_{k-1}\mathbf{e}_j = 3\mathbf{B}_k\mathbf{e}_i - \sum_{j\neq i} s_j \mathbf{B}_k \mathbf{e}_j$ belongs to $\mathcal{L}(\mathbf{B}_k)$. Since $s_i = \pm 1$, also $\mathbf{B}_{k-1}\mathbf{e}_i = \pm(s_i \cdot \mathbf{B}_{k-1}\mathbf{e}_i)$ belongs to $\mathcal{L}(\mathbf{B}_k)$. Now, let us get to the third property. Consider any nonzero vector in $\mathcal{L}(\mathbf{B}_k)$. Since $\mathcal{L}(\mathbf{B}_k) = \mathcal{L}([\mathbf{B}_{k-1}|\mathbf{v}_k])$, any such a vector can be written as $\mathbf{B}_{k-1}\mathbf{x} + \mathbf{v}_k \cdot y$. Moreover, since $3\mathbf{v}_k \in \mathcal{L}(\mathbf{B}_{k-1})$, we can assume without loss of generality that $y \in \{-1, 0, +1\}$. So, the length of $\mathbf{B}_{k-1}\mathbf{x} + \mathbf{v}_k \cdot y$ is at least the minimum of $\lambda_1(\mathcal{L}(\mathbf{B}_{k-1}))$ (if $y = 0$) or $\mathrm{dist}(\pm\mathbf{v}_k, \mathcal{L}(\mathbf{B}_{k-1}))$ (if $y = \pm 1$). But $\lambda_1(\mathcal{L}(\mathbf{B}_{k-1})) \geq 1$ by induction, and $\mathrm{dist}(\pm\mathbf{v}_k, \mathcal{L}(\mathbf{B}_{k-1})) = \mathrm{dist}(\mathbf{v}_k, \mathcal{L}(\mathbf{B}_{k-1})) \geq 1$ by construction. It follows that $\lambda_1(\mathcal{L}(\mathbf{B}_k)) \geq 1$.

It is also easy to see that for any $k$, the determinant of lattice $\mathcal{L}(\mathbf{B}_k)$ equals $\det(\mathcal{L}(\mathbf{B}_k)) = 3^{-k}\det(\mathcal{L}(\mathbf{B}_0)) = 3^{-k}$ because each $\mathbf{B}_k$ can be obtained from $\mathbf{B}_{k-1}$ by first performing some elementary integer column operations, and then dividing a column by 3. We can now prove that the algorithm performs at most $m = O(n \log n)$ iterations. Since $\lambda_1(\mathcal{L}(\mathbf{B}_k)) = 1$ and $\det(\mathcal{L}(\mathbf{B}_k)) = 3^{-k}$, by Minkowski's first theorem (2.2),

$$1 = \lambda_1(\mathcal{L}(\mathbf{B}_k)) \leq \sqrt{n}\det(\mathcal{L}(\mathbf{B}_k))^{1/n} = \sqrt{n}3^{-(k/n)}.$$

It follows that

$$k \leq (1/2)n\log_3 n = O(n \log n)$$

is an upper bound on the maximum number of iterations. (It can also be shown by a volume argument that $m = \Theta(n \log n)$ iterations are required in order to reach termination.)

Next we prove that upon termination $\rho(\mathcal{L}(\mathbf{L}_n)) < 3 \cdot \lambda_1(\mathcal{L}(\mathbf{L}_n))/2$. We show that if $\rho(\mathcal{L}(\mathbf{L}_n)) \geq (3/2)\cdot\lambda_1(\mathcal{L}(\mathbf{L}_n))$, then the algorithm certainly performs one more iteration. By Lemma 4.3, if $\rho(\mathcal{L}(\mathbf{L}_n)) \geq (3/2)\lambda_1(\mathcal{L}(\mathbf{L}_n))$, then there exists a vector $\mathbf{v} = \mathbf{B}_{k-1}\mathbf{x} \in \mathcal{L}(\mathbf{B}_{k-1})$ such that

$$\mathrm{dist}(\mathbf{v}/3, \mathcal{L}(\mathbf{B}_{k-1})) \geq \lambda_1(\mathcal{L}(\mathbf{B}_{k-1})) \geq 1.$$

Let $\mathbf{s} \in \{-1, 0, +1\}^n$ be such that $\mathbf{s} \equiv \mathbf{x} \pmod 3$, i.e., $(\mathbf{s} - \mathbf{x})/3 \in \mathbb{Z}^n$. We claim that the distance of $\mathbf{t} = (1/3)\mathbf{B}_{k-1}\mathbf{s}$ from the lattice $\mathcal{L}(\mathbf{B}_{k-1})$ is at least 1. Notice that

$$\mathbf{t} = (1/3)\mathbf{B}_{k-1}\mathbf{s} = \mathbf{B}_{k-1}\mathbf{x}/3 + \mathbf{B}_{k-1}(\mathbf{s} - \mathbf{x})/3 \in \mathbf{v}/3 + \mathcal{L}(\mathbf{B}_{k-1}).$$

It follows that $\operatorname{dist}(\mathbf{t}, \mathcal{L}(\mathbf{B}_{k-1})) = \operatorname{dist}(\mathbf{v}/3, \mathcal{L}(\mathbf{B}_{k-1})) \geq 1$, and therefore the algorithm does not terminate at iteration $k$.

We conclude the proof of the theorem by giving a simple algorithm to solve the CVP in $\mathcal{L}(\mathbf{B}_k)$ in time $n^{O(1)} \cdot 3^k \leq n^{O(n)}$. Notice that any lattice point in $\mathcal{L}(\mathbf{B}_k)$ can be written as $\mathbf{B}_0\mathbf{x} + [\mathbf{v}_1, \ldots, \mathbf{v}_k]\mathbf{y}$, where $\mathbf{x} \in \mathbb{Z}^n$ and $\mathbf{y} \in \{-1, 0, +1\}^k$. So, in order to find the lattice point closest to some target $\mathbf{t}$, we can consider all vectors of the form $\mathbf{t} - [\mathbf{v}_1, \ldots, \mathbf{v}_k]\mathbf{y}$ and compute their distance from $\mathcal{L}(\mathbf{B}_0)$. Let $\mathbf{y}$ be such that $\operatorname{dist}(\mathbf{t} - [\mathbf{v}_1, \ldots, \mathbf{v}_k]\mathbf{y}, \mathcal{L}(\mathbf{B}_k))$ is minimized, and let $\mathbf{B}_0\mathbf{x}$ be the lattice vector closest to $\mathbf{t} - [\mathbf{v}_1, \ldots, \mathbf{v}_k]\mathbf{y}$. The lattice vector in $\mathcal{L}(\mathbf{B}_k)$ closest to $\mathbf{t}$ is $\mathbf{B}_0\mathbf{x} + [\mathbf{v}_1, \ldots, \mathbf{v}_k]\mathbf{y}$. $\square$

The theorem gives an algorithmic construction of almost perfect lattices and an algorithm to solve the CVP; however, the running time is huge. The next theorem shows how to use these lattices for small values of $n$ to get a construction that runs in polynomial time.

THEOREM 4.5. *There exists a family of $\tau(n)$-perfect easily decodable lattices with $\tau(n) = O(\sqrt{n \log\log n / \log n})$.*

*Proof.* In order to keep the construction polynomial in $n$, we use Theorem 4.4 to build a 3-perfect lattice $\mathbf{M}$ in dimension $m = \log n / \log\log n$. Notice that such a lattice can be constructed in time

$$2^{O(m \log m)} = 2^{O(\log n \log(\log n / \log\log n) / \log\log n)} = n^{O(1)}$$

polynomial in $n$. Moreover, the CVP in this lattice can also be solved in polynomial time $2^{O(m \log m)} = n^{O(1)}$.

Now set $\mathcal{L}(\mathbf{L}_n)$ to the direct sum of $(n/m)$ copies of $\mathcal{L}(\mathbf{M})$, i.e., the lattice generated by the block diagonal matrix with $n/m$ blocks, all equal to $\mathbf{M}$. The lattice vector in $\mathcal{L}(\mathbf{L}_n)$ closest to a target $\mathbf{t}$ is easily found by breaking $\mathbf{t}$ into $n/m$ blocks, each with $m$ coordinates in it, and finding the $\mathcal{L}(\mathbf{M})$ vector closest to each block. Moreover, the length of the shortest nonzero vector in $\mathcal{L}(\mathbf{L}_n)$ is $\lambda_1(\mathcal{L}(\mathbf{M}))$ because vectors from different copies of $\mathbf{M}$ are orthogonal. Finally, the covering radius of $\mathcal{L}(\mathbf{L}_n)$ is $\sqrt{n/m}$ times $\rho(\mathcal{L}(\mathbf{M}))$. So, $\mathcal{L}(\mathbf{L}_n)$ is $\tau(n)$-perfect for

$$\tau(n) = \frac{\sqrt{n/m}\rho(\mathcal{L}(\mathbf{M}))}{\lambda_1(\mathcal{L}(\mathbf{M}))/2} \leq 3\sqrt{n/m} = O(\sqrt{n \log\log n / \log n}). \qquad \square$$

**5. A generalized class of random equations.** In this section we define a class of random equations that generalizes Ajtai's one. Ajtai's problem can be described as finding a small (e.g., with respect to the bound proved in Theorem 5.5 below) nonzero integer solution to a homogeneous linear equation in $m(n)$ variables with coefficients chosen uniformly at random from the group $G_n = \mathbb{Z}^n_{q(n)}$ of $n$-dimensional vectors modulo $q(n)$, for appropriately chosen functions $q(n)$ and $m(n)$. Here we consider equations with coefficients in a group $G_n$ possibly different from $\mathbb{Z}^n_{q(n)}$. In general, we define the following problem.

DEFINITION 5.1. *Let $\{G_n\}$ be a sequence of finite Abelian groups, and let $m(n)$ and $\beta(n)$ be two arbitrary (polynomial time computable) functions. For any $m(n)$-dimensional vector $\mathbf{g} = [g_1, \ldots, g_{m(n)}]^T \in G_n^{m(n)}$, define the set of solutions to the associated homogeneous linear equation*

$$\Lambda(\mathbf{g}) = \left\{ \mathbf{z} \in \mathbb{Z}^{m(n)} \colon \sum_{i=1}^{m(n)} z_i \cdot g_i = 0 \right\}. \tag{5.1}$$

*The* homogeneous small integer solution *problem* $\mathrm{HSIS}_{G,m,\beta}$ *(in the $\ell_2$ norm) is as follows: given a (random) homogeneous linear equation $\mathbf{g} \in G_n^{m(n)}$, find a nonzero solution $\mathbf{z} \in \Lambda(\mathbf{g}) \setminus \{\mathbf{0}\}$ of $\ell_2$ norm at most $\|\mathbf{z}\| \leq \beta(n)$.*

Of course, the problem is interesting only when a solution of length at most $\beta(n)$ exists. Below we define a family of groups (that includes Ajtai's groups as a special case) and give conditions under which a solution of length at most $\beta(n)$ is guaranteed to exist.

Our groups are parametrized by an easily decodable family of lattices $\{\mathcal{L}(\mathbf{L}_n)\}_{n>0}$ and a function $\alpha(n)$, and each group $G_n = \mathcal{G}(\mathcal{L}(\mathbf{L}_n), \alpha(n))$ is defined as the quotient of $\mathcal{L}(\mathbf{L}_n)$ modulo an appropriately chosen full dimensional sublattice $\mathcal{L}(\mathbf{M}_n) \subseteq \mathcal{L}(\mathbf{L}_n)$.

Definition 5.2. *For any easily decodable family of lattices $\{\mathcal{L}(\mathbf{L}_n)\}_{n>0}$ (with decoding algorithm $\mathrm{CVP}_{\mathbf{L}}$) and function $\alpha(n)$ satisfying $\alpha(n) \geq 2\sqrt{n}\rho(\mathcal{L}(\mathbf{L}_n))$, define the sequence of quotient groups*

$$G_n = \mathcal{G}(\mathcal{L}(\mathbf{L}_n), \alpha(n)) = \mathcal{L}(\mathbf{L}_n)/\mathcal{L}(\mathbf{M}_n), \tag{5.2}$$

*where for any $n > 0$, $\mathcal{L}(\mathbf{M}_n)$ is the full rank sublattice of $\mathcal{L}(\mathbf{L}_n)$ obtained by applying Lemma* 2.10 *with value $\alpha(n)$ and decoding procedure* $\mathrm{CVP}_{\mathbf{L}}$.

From Lemma 2.10 we immediately obtain the following corollary.

Corollary 5.3. *For any family of lattices $\{\mathcal{L}(\mathbf{L}_n)\}_{n>0}$ and function $\alpha(n)$ satisfying the conditions in Definition* 5.2, *the groups $\mathcal{G}(\mathcal{L}(\mathbf{L}_n), \alpha(n)) = \mathcal{L}(\mathbf{L}_n)/\mathcal{L}(\mathbf{M}_n)$ can be computed in time polynomial in $n$ and the matrix $\mathbf{M}_n$ satisfies*

$$\forall \mathbf{x} \in \mathbb{R}^n. \|\mathbf{M}_n\mathbf{x}\| \approx \alpha(n) \cdot \|\mathbf{x}\|.$$

*Proof.* Matrix $\mathbf{M}_n$ is polynomial time computable because lattice $\mathcal{L}(\mathbf{L}_n)$ is easily decodable, so the decoding procedure $\mathrm{CVP}_{\mathbf{L}}$ runs in polynomial time. In order to bound $\|\mathbf{M}_n\mathbf{x}\|$, simply observe that $\mathcal{L}(\mathbf{L}_n)$, $\alpha(n)$ and $\mathrm{CVP}_{\mathbf{L}}$ satisfy the conditions of Lemma 2.10 because $\alpha(n) \geq 2\sqrt{n}\rho(\mathcal{L}(\mathbf{L}_n)) \geq 2\sqrt{n}\,\mathrm{dist}(\mathbf{x}, \mathrm{CVP}_{\mathbf{L}}(\mathbf{x}))$ for all $\mathbf{x} \in \mathbb{R}^n$. $\square$

Notice that if $\mathcal{L}(\mathbf{L}_n) = \mathbb{Z}^n$ is the integer lattice and $\alpha(n) = q(n)$, then Definition 5.2 gives matrix $\mathbf{M}_n = q(n) \cdot \mathbf{I}$ and Ajtai's group $\mathcal{G}(\mathcal{L}(\mathbf{L}_n), \alpha(n)) = \mathbb{Z}^n_{q(n)}$ as a special case. We will see that this choice of group $G_n$ is not the best possible for our analysis, and setting $\mathcal{L}(\mathbf{L}_n)$ to an almost perfect lattice leads to better results. In the rest of this section, we prove that for any $\mathbf{g} \in G_n^{m(n)}$ and all sufficiently large $m(n)$, the set $\Lambda(\mathbf{g})$ always contains small nonzero solutions. The main result of this paper (proved in section 6) is that although these small solutions are guaranteed to exist, they are computationally hard to find when $\mathbf{g}$ is chosen uniformly at random.

We know from Proposition 2.11 that $\Lambda(\mathbf{g})$ is a lattice with determinant at most $\det(\Lambda(\mathbf{g})) \leq \#G_n$. We show that $\Lambda(\mathbf{g})$ always contains small solutions by bounding the size of group $G_n$ and then applying Minkowski's first theorem.

Lemma 5.4. *For any $n$, the group $G_n = \mathcal{G}(\mathcal{L}(\mathbf{L}_n), \alpha(n))$ defined in Definition* 5.2 *has size at most*

$$\#G_n \leq \left(\frac{3\alpha(n)\sqrt{n}}{2\lambda_1(\mathcal{L}(\mathbf{L}_n))}\right)^n.$$

*Proof.* The size of the group is $\#G_n = \det(\mathcal{L}(\mathbf{M}_n))/\det(\mathcal{L}(\mathbf{L}_n))$. We bound the two determinants separately. By Corollary 5.3, the columns of $\mathbf{M}_n$ have length at most

$$\|\mathbf{M}_n\mathbf{e}_i\| \leq (3/2)\alpha(n) \cdot \|\mathbf{e}_i\| = 3\alpha(n)/2.$$

Therefore, by Hadamard's inequality

$$\det(\mathcal{L}(\mathbf{M}_n)) \le (3\alpha(n)/2)^n.$$

We bound the determinant of $\mathcal{L}(\mathbf{L}_n)$ using Minkowski's inequality (2.2) $\lambda_1(\mathcal{L}(\mathbf{L}_n)) \le \sqrt{n}\det(\mathcal{L}(\mathbf{L}_n))^{1/n}$. Solving for $\det(\mathcal{L}(\mathbf{L}_n))$, we get that the determinant of $\mathcal{L}(\mathbf{L}_n)$ is at least $(\lambda_1(\mathcal{L}(\mathbf{L}_n))/\sqrt{n})^n$. Combining the two bounds, we get that group $G_n$ has cardinality

$$\#G_n = \frac{\det(\mathcal{L}(\mathbf{M}_n))}{\det(\mathcal{L}(\mathbf{L}_n))} \le \left(\frac{3\alpha(n)\sqrt{n}}{2\lambda_1(\mathcal{L}(\mathbf{L}_n))}\right)^n. \qquad \Box \tag{5.3}$$

A bound on the size of the smallest nonzero solution to equation $\mathbf{g}$ easily follows from Proposition 2.11 and Minkowski's first theorem (2.2).

THEOREM 5.5. *For any equation $\mathbf{g} \in G_n^{m(n)}$ in $m(n) = \Omega(n \log n)$ variables with coefficients in a group $G_n$ of size $\#G_n \le n^{O(n)}$ (e.g., $G_n = \mathcal{G}(\mathcal{L}(\mathbf{L}_n), \alpha(n))$ for some $\alpha(n) = n^{O(1)} \cdot \lambda_1(\mathcal{L}(\mathbf{L}_n))$), there exists a nonzero solution $\mathbf{z} \in \Lambda(\mathbf{g})$ of length at most $\|\mathbf{z}\| = O(\sqrt{m(n)})$.*

## 6. The worst- to average-case reduction.

In this section we prove the main technical result of the paper. Namely, we show that finding short solutions to random linear equations as defined in section 5 (on the average and with nonnegligible probability) is at least as hard as finding linearly independent vectors of length not much bigger than the generalized uniform radius in any lattice (in the worst case and with high probability). Formally, we prove the hardness of the HSIS of Definition 5.1 over groups $\mathcal{G}(\mathcal{L}(\mathbf{L}_n), \alpha(n))$, by reduction from the following variant of SIVP, where the quality of a solution $\|\mathbf{S}\|$, instead of being measured with respect to the size of the smallest possible solution $\lambda_n(\mathcal{L}(\mathbf{B}))$, is measured with respect to some other parameter of interest $\phi(\mathcal{L}(\mathbf{B}))$.

DEFINITION 6.1. *Let $\phi$ be an arbitrary function mapping lattices to positive reals. The* generalized independent vectors problem $\mathrm{GIVP}_\gamma^\phi$*, given a lattice basis $\mathbf{B}$ of rank $n$, asks for a set of $n$ linearly independent lattice vectors $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$ such that $\|\mathbf{S}\| \le \gamma(n) \cdot \phi(\mathcal{L}(\mathbf{B}))$.*

Notice that $\mathrm{SIVP}_\gamma$ is a special case of $\mathrm{GIVP}_\gamma^\phi$, where $\phi = \lambda_n$. Here we are interested in $\mathrm{GIVP}_\gamma^{\hat{\zeta}}$, i.e., the problem of finding a maximal independent set of lattice vectors which are not much longer than the generalized uniform radius.

The reduction is performed in two steps. First we reduce $\mathrm{GIVP}_\gamma^\phi$ to an intermediate problem. Next, we reduce this intermediate problem to the problem of solving random instances of $\mathrm{HSIS}_{G,m,\beta}$. We remark that the intermediate problem is a worst-case one; i.e., the first part of the reduction is a standard worst-case to worst-case Cook reduction. Only the second part of the reduction, from the intermediate problem to the problem of solving random equations, is a worst- to average-case reduction. The advantage of introducing the intermediate problem is that the first part of the reduction (which involves solving many instances of the target problem) is a standard reduction where all problems are solved in the worst case. Once the GIVP problem has been reduced to the intermediate problem, the worst-case to average-case reduction can be expressed in a conceptually simpler setting where a single (worst-case) instance of the intermediate problem is reduced to a single (random) instance of the average-case problem.

The rest of this section is organized as follows. In section 6.1 we reduce GIVP to the intermediate problem and give sufficient conditions for the solutions of the latter.

TABLE 1
*Symbols used in the reduction from* $\mathrm{GIVP}_{\gamma}^{\hat{\zeta}}$ *to* $HSIS_{G,m,\beta}$.

| Symbol | Explanation | Reference |
|---|---|---|
| $\mathbf{L}_n$ | easily decodable $\tau(n)$-perfect lattice | Theorem 6.5 |
| $\mathbf{M}_n$ | almost orthogonal sublattice of $\mathcal{L}(\mathbf{L}_n)$ | Equation (6.2) |
| $\mathbf{B}$ | GIVP input lattice | |
| $\mathbf{C}$ | almost orthogonal sublattice of $\mathcal{L}(\mathbf{B})$ | Equation (6.3) |
| $\mathbf{S}$ | full rank sublattice of $\mathcal{L}(\mathbf{B})$ | |
| $G_n$ | Abelian group ($\mathcal{L}(\mathbf{L}_n)$ modulo $\mathcal{L}(\mathbf{M}_n)$) | Definition 5.1 |
| $\psi$ | Linear function mapping $\mathbf{M}_n$ to $\mathbf{C}$ | Equation (6.4) |
| $(\mathbf{w}_{i,j}, \mathbf{v}_{i,j})$ | vectors in $\mathcal{L}(\mathbf{L}_n) \times \mathcal{L}(\mathbf{B})$ output by the sampling algorithm | Lemma 6.6 |
| $a_{i,j}$ | group element $(\mathbf{w}_{i,j} \bmod \mathbf{M}_n) \in G_n$ | |
| $a_i$ | sum of $a_{i,j}$ for $j = 1, \ldots, k(n)$ | |
| $k(n)$ | Number of samples used to generate each $a_i$ | Equation (6.7) |
| $\mathbf{a}$ | homogeneous linear equation over $G_n$ (input to $\mathcal{F}$) | |
| $\Lambda(\mathbf{a})$ | set of solutions to equation $\mathbf{a}$ | Definition 5.1 |
| $\mathbf{z}$ | solution to equation $\mathbf{a}$ output by $\mathcal{F}$ | |
| $n$ | rank of $\mathbf{L}_n, \mathbf{M}_n, \mathbf{B}, \mathbf{C}$ and $\mathbf{S}$ | |
| $m(n)$ | number of variables in $\mathbf{a}$ | |
| $\alpha(n)$ | scaling factor used in the definition of $\mathbf{M}_n$ | Equation (6.1) |
| $\beta(n)$ | length of the solution $\mathbf{z}$ returned by $\mathcal{F}$ | Theorem 6.5 |
| $\gamma(n)$ | GIVP approximation factor | Theorem 6.5 |
| $\tau(n)$ | upper bound on $2\rho(\mathcal{L}(\mathbf{B}))/\lambda_1(\mathcal{L}(\mathbf{B}))$ | |
| $\mathbf{y}_{i,j}$ | offset vector $\mathbf{v}_{i,j} - \psi(\mathbf{w}_{i,j})$ | |
| $\mathbf{s}$ | output of $\mathcal{A}$ | Equation (6.5) |

In section 6.2 we present the worst- to average-case reduction from the intermediate problem to HSIS (Theorem 6.5). The reduction is based on a sampling procedure (Lemma 6.6) that is described and analyzed in section 6.3. Three technical lemmas (Lemmas 6.8, 6.9, and 6.10) used in the proof of Theorem 6.5 are proved in section 6.4 after establishing some important properties of the sampling procedure. For reference, the notation and symbols used in the reduction are listed in Table 1.

**6.1. The intermediate problem.** In this subsection, we define the intermediate problem, reduce GIVP to it, and present sufficient conditions for its solution. The intermediate problem is essentially an incremental version of GIVP, where given a set of linearly independent vectors $\mathbf{S}$, one has to find a single slightly shorter lattice vector.

DEFINITION 6.2. *The* incremental generalized independent vectors problem ($\mathrm{IncGIVP}_{\gamma}^{\phi}$)*, given a rank n lattice basis* $\mathbf{B}$*, a set of n linearly independent vectors* $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$ *satisfying* $\|\mathbf{S}\| > \gamma(n) \cdot \phi(\mathcal{L}(\mathbf{B}))$*, and an* $(n-1)$*-dimensional hyperplane* $\mathcal{H} \subset \mathrm{span}(\mathbf{B})$*, asks for a lattice vector* $\mathbf{s} \in \mathcal{L}(\mathbf{B}) \setminus \mathcal{H}$ *such that* $\|\mathbf{s}\| \leq \|\mathbf{S}\|/2$.

The following theorem shows that $\mathrm{GIVP}_{\gamma}^{\phi}$ is easily reducible to $\mathrm{IncGIVP}_{\gamma}^{\phi}$.

THEOREM 6.3. *For any functions* $\phi$ *and* $\gamma$*, there is a polynomial time (Cook) reduction from* $\mathrm{GIVP}_{\gamma}^{\phi}$ *to* $\mathrm{IncGIVP}_{\gamma}^{\phi}$.

*Proof.* We give an iterative reduction (see section 2.6) from $\mathrm{GIVP}_{\gamma}^{\phi}$ to $\mathrm{IncGIVP}_{\gamma}^{\phi}$. By Theorem 2.21, this immediately implies a standard Cook reduction between the two problems. Let $\mathcal{A}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ be an algorithm solving $\mathrm{IncGIVP}_{\gamma}^{\phi}$ in the worst case. The iterative reduction $(R, f, I, O, \mathcal{S})$ is defined as follows. Relation $R$ is the set of all $(\mathbf{B}, \mathbf{S})$ where $\mathbf{B}$ is the GIVP input lattice, and $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$ is a maximal set of linearly independent lattice vectors such that $\|\mathbf{S}\| \leq \|\mathbf{B}\|$. (This condition is introduced to make sure that the size of $\mathbf{S}$ is polynomial in the input size.) Initially, $\mathbf{S}$ is set to the input basis $I(\mathbf{B}) = \mathbf{B}$. Upon termination, the iterative reduction outputs the current set $O(\mathbf{B}, \mathbf{S}) = \mathbf{S}$. Progress at each iteration is measured by the function $f(\mathbf{B}, \mathbf{S}) = \prod_{i=1}^{n} \|\mathbf{s}_i\|^2$. Notice that function $f$ is polynomial time computable. In order to complete the iterative reduction we give a polynomial time oracle algorithm $\mathcal{S}^{\mathcal{A}}$ (the iterative step) that on input a rank $n$ lattice basis $\mathbf{B}$ and $n$ linearly independent lattice vectors $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$ such that $\gamma(n) \cdot \phi(\mathcal{L}(\mathbf{B})) < \|\mathbf{S}\| \leq \|\mathbf{B}\|$, finds a set of linearly independent lattice vectors $\mathbf{S}'$ such that $\|\mathbf{S}'\| \leq \|\mathbf{B}\|$ and $f(\mathbf{S}') \leq f(\mathbf{S})/2$.

Algorithm $\mathcal{S}^{\mathcal{A}}(\mathbf{B}, \mathbf{S})$ works as follows. Let $i$ be the index of a longest vector in $\mathbf{S}$, i.e., $\|\mathbf{s}_i\| = \|\mathbf{S}\|$, and let $\mathcal{H} = \operatorname{span}(\mathbf{s}_1, \ldots, \mathbf{s}_{i-1}, \mathbf{s}_{i+1}, \ldots, \mathbf{s}_n)$ be the $(n-1)$-dimensional hyperplane spanned by the other vectors. The iterative step $\mathcal{S}$ computes $\mathbf{s} = \mathcal{A}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ and checks that vector $\mathbf{s}$ satisfies $\mathbf{s} \in \mathcal{L}(\mathbf{B}) \setminus \mathcal{H}$ and $\|\mathbf{s}\| \leq \|\mathbf{S}\|/2$. If so, then $\mathcal{S}$ replaces $\mathbf{s}_i$ with $\mathbf{s}$ and outputs $\mathbf{S}' = [\mathbf{s}_1, \ldots, \mathbf{s}_{i-1}, \mathbf{s}, \mathbf{s}_{i+1}, \ldots, \mathbf{s}_n]$. Otherwise, $\mathcal{S}$ simply outputs the input set $\mathbf{S}' = \mathbf{S}$. Notice that in both cases, the output $\mathbf{S}'$ satisfies the relation $(\mathbf{B}, \mathbf{S}') \in R$; i.e., $\mathbf{S}' \subset \mathcal{L}(\mathbf{B})$ is a set of $n$ linearly independent lattice vectors and $\|\mathbf{S}'\| \leq \|\mathbf{S}\| \leq \|\mathbf{B}\|$. Moreover, if $\|\mathbf{S}\| > \gamma(n) \cdot \phi(\mathcal{L}(\mathbf{B}))$, then $\mathcal{A}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ successfully returns a vector $\mathbf{s} \in \mathcal{L}(\mathbf{B}) \setminus \mathcal{H}$ satisfying $\|\mathbf{s}\| \leq \|\mathbf{S}\|/2$, and

$$f(\mathbf{B}, \mathbf{S}') = f(\mathbf{B}, \mathbf{S}) \frac{\|\mathbf{s}\|^2}{\|\mathbf{s}_i\|^2} = f(\mathbf{B}, \mathbf{S}) \frac{\|\mathbf{s}\|^2}{\|\mathbf{S}\|^2} \leq \frac{f(\mathbf{B}, \mathbf{S})}{4}. \qquad \square$$

The following lemma establishes sufficient conditions for reducing IncGIVP (in the worst case) to HSIS (on the average).

Lemma 6.4. *Let $\mathcal{A}^{(\cdot)}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ be a probabilistic polynomial time oracle algorithm that on input a rank $n$ lattice basis $\mathbf{B}$, a full rank subset $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$, and an $(n-1)$-dimensional hyperplane $\mathcal{H} \subset \operatorname{span}(\mathbf{B})$, makes a single oracle call $\mathbf{a} \in G_n^{m(n)}$ and (provided the query is answered with a valid solution $\mathbf{z} \in \Lambda(\mathbf{a})$) outputs a lattice vector $\mathbf{s} \in \mathcal{L}(\mathbf{B})$. Assume that for any input $(\mathbf{B}, \mathbf{S}, \mathcal{H})$ such that $\|\mathbf{S}\| > \gamma(n) \cdot \phi(\mathcal{L}(\mathbf{B}))$, the vectors $\mathbf{a}, \mathbf{z}, \mathbf{s}$ produced by $\mathcal{A}^{(\cdot)}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ satisfy the following properties:*

(i) *the statistical distance between the query $\mathbf{a}$ and a uniformly distributed $\mathbf{u} \in G_n^{m(n)}$ is negligible, i.e.,*

$$\Delta(\mathbf{a}, \mathbf{u}) = n^{-\omega(1)},$$

(ii) *for any $\hat{\mathbf{a}} \in G_n^{m(n)}$ and $\hat{\mathbf{z}} \in \Lambda(\hat{\mathbf{a}}) \setminus \{\mathbf{0}\}$, the conditional probability that $\mathbf{s} \notin \mathcal{H}$ is at least*

$$\Pr\{\mathbf{s} \notin \mathcal{H} \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}\} = \Omega(1),$$

(iii) *for any $\hat{\mathbf{a}} \in G_n^{m(n)}$ and $\hat{\mathbf{z}} \in \Lambda(\hat{\mathbf{a}})$, the conditional expectation of $\|\mathbf{s}\|$ is at most*

$$\operatorname{Exp}[\|\mathbf{s}\| \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}] = o\left(\frac{\|\hat{\mathbf{z}}\| \cdot \|\mathbf{S}\|}{\beta(n)}\right).$$

*Then, for any randomized procedure $\mathcal{F}$ that solves $\mathrm{HSIS}_{G,m,\beta}$ on the average with nonnegligible probability $\delta(n)$, $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ solves $\mathrm{IncGIVP}_{\gamma}^{\phi}$ in the worst case with high probability*[16] *$\Omega(\delta(n))$.*

*Proof.* Let $\mathcal{F}$ be a randomized procedure that solves $\mathrm{HSIS}_{G,m,\beta}$ with nonnegligible probability $\delta(n)$. We want to prove that, for any valid input, $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ solves

[16]Remember that, since $\mathcal{A}$ solves IncGIVP in the *worst case*, and given a vector $\mathbf{s}$ it is easy to check if $\mathbf{s}$ is a correct solution to an IncGIVP instance, the success probability of $\mathcal{A}$ can be efficiently boosted from any nonnegligible fraction to exponentially close to one.

$\text{IncGIVP}_\gamma^\phi$ with probability $\Omega(\delta(n))$. Namely, we want to prove that for any rank $n$ lattice basis $\mathbf{B}$, full rank subset $\mathbf{S} \subset \mathcal{L}(\mathbf{B})$ such that $\|\mathbf{S}\| > \gamma(n) \cdot \phi(\mathcal{L}(\mathbf{B}))$, and $(n-1)$-dimensional hyperplane $\mathcal{H} \subset \operatorname{span}(\mathbf{B})$, procedure $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ outputs a lattice vector $\mathbf{s} \in \mathcal{L}(\mathbf{B}) \setminus \mathcal{H}$ of length $\|\mathbf{s}\| \le \|\mathbf{S}\|/2$ with nonnegligible probability $\Omega(\delta(n))$.

Assume without loss of generality that $\mathcal{F}(\mathbf{a})$ always returns a (possibly zero) solution $\mathcal{F}(\mathbf{a}) \in \Lambda(\mathbf{a})$ of length $\|\mathcal{F}(\mathbf{a})\| \le \beta(n)$. The assumption on $\mathcal{F}$ is that $\Pr\{\mathcal{F}(\mathbf{u}) \neq \mathbf{0}\} = \delta(n)$ when $\mathbf{u} \in G_n^{m(n)}$ is chosen uniformly at random. Since $\mathcal{F}(\mathbf{a})$ always returns a valid solution $\mathbf{z} \in \Lambda(\mathbf{a})$, the output vector $\mathbf{s}$ is guaranteed to belong to the lattice $\mathcal{L}(\mathbf{B})$. We need to bound the probability that $\mathbf{s}$ also satisfies $\mathbf{s} \notin \mathcal{H}$ and $\|\mathbf{s}\| \le \|\mathbf{S}\|/2$. Consider an execution of $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathcal{H}) = \mathbf{s}$, and let $\mathcal{F}(\mathbf{a}) = \mathbf{z}$ be the oracle call made by $\mathcal{A}$. Conditioning on the value of $\mathbf{a}$ and $\mathbf{z}$, and restricting our attention to the nonzero solutions $\mathbf{z} \neq \mathbf{0}$, we get

$$\begin{aligned}
&\Pr\{\mathbf{s} \notin \mathcal{H} \wedge \|\mathbf{s}\| \le \|\mathbf{S}\|/2\} \\
&\qquad = \sum_{\hat{\mathbf{a}}, \hat{\mathbf{z}}} \Pr\{\mathbf{a} = \hat{\mathbf{a}} \wedge \mathbf{z} = \hat{\mathbf{z}}\} \cdot \Pr\{\mathbf{s} \notin \mathcal{H} \wedge \|\mathbf{s}\| \le \|\mathbf{S}\|/2 \mid \mathbf{a} = \hat{\mathbf{a}} \wedge \mathbf{z} = \hat{\mathbf{z}}\} \\
&\qquad \ge \sum_{\hat{\mathbf{a}}, \hat{\mathbf{z}} : \hat{\mathbf{z}} \neq \mathbf{0}} \Pr\{\mathbf{a} = \hat{\mathbf{a}} \wedge \mathbf{z} = \hat{\mathbf{z}}\} \\
&\qquad\qquad \cdot \left(\Pr\{\mathbf{s} \notin \mathcal{H} \mid \mathbf{a} = \hat{\mathbf{a}} \wedge \mathbf{z} = \hat{\mathbf{z}}\} - \Pr\{\|\mathbf{s}\| > \|\mathbf{S}\|/2 \mid \mathbf{a} = \hat{\mathbf{a}} \wedge \mathbf{z} = \hat{\mathbf{z}}\}\right),
\end{aligned}$$

where the summations range over all $\hat{\mathbf{a}} \in G_n^{m(n)}$ and $\hat{\mathbf{z}} \in [\mathcal{F}(\hat{\mathbf{a}})] \subseteq \Lambda(\hat{\mathbf{a}}) \cap \mathcal{B}(\beta(n))$. By assumption on $\mathcal{A}$, for any $\hat{\mathbf{a}} \in G_n^{m(n)}$ and $\hat{\mathbf{z}} \in \Lambda(\hat{\mathbf{a}})$ such that $0 < \|\hat{\mathbf{z}}\| \le \beta(n)$, the two conditional probabilities in the last expression satisfy

$$\Pr\{\mathbf{s} \notin \mathcal{H} \mid \mathbf{a} = \hat{\mathbf{a}} \wedge \mathbf{z} = \hat{\mathbf{z}}\} = \Omega(1),$$

and, using Markov's inequality,

$$\begin{aligned}
\Pr\{\|\mathbf{s}\| > \|\mathbf{S}\|/2 \mid \mathbf{a} = \hat{\mathbf{a}} \wedge \mathbf{z} = \hat{\mathbf{z}}\} &\le \frac{\operatorname{Exp}[\|\mathbf{s}\| \mid \mathbf{a} = \hat{\mathbf{a}} \wedge \mathbf{z} = \hat{\mathbf{z}}]}{\|\mathbf{S}\|/2} \\
&\le o\left(\frac{2\|\hat{\mathbf{z}}\| \cdot \|\mathbf{S}\|}{\|\mathbf{S}\| \cdot \beta(n)}\right) = o(1).
\end{aligned}$$

Adding up for all possible values of $\hat{\mathbf{a}}$ and $\hat{\mathbf{z}} \neq \mathbf{0}$, we get

$$\begin{aligned}
\Pr\{\mathbf{s} \notin \mathcal{H} \wedge \|\mathbf{s}\| \le \|\mathbf{S}\|/2\} &\ge \sum_{\hat{\mathbf{a}}, \hat{\mathbf{z}} : \hat{\mathbf{z}} \neq \mathbf{0}} \Pr\{\mathbf{a} = \hat{\mathbf{a}} \wedge \mathbf{z} = \hat{\mathbf{z}}\} \cdot (\Omega(1) - o(1)) \\
&= \Omega(\Pr\{\mathbf{z} \neq \mathbf{0}\}).
\end{aligned}$$

Notice that $\mathbf{z} = \mathcal{F}(\mathbf{a})$ and $\Pr\{\mathcal{F}(\mathbf{u}) \neq \mathbf{0}\} = \delta(n)$ when $\mathbf{u} \in G_n^{m(n)}$ is uniformly distributed. By assumption, the statistical distance $\Delta(\mathbf{a}, \mathbf{u})$ between $\mathbf{a}$ and $\mathbf{u}$ is negligible. Therefore, by Corollary 2.16,

$$\begin{aligned}
\Pr\{\mathbf{z} \neq \mathbf{0}\} &= \Pr\{\mathcal{F}(\mathbf{a}) \neq \mathbf{0}\} \\
&\ge \Pr\{\mathcal{F}(\mathbf{u}) \neq \mathbf{0}\} - \Delta(\mathbf{a}, \mathbf{u}) \\
&\ge \delta(n) - n^{-\omega(1)}.
\end{aligned}$$

So, for all nonnegligible $\delta(n)$, $\Pr\{\mathbf{s} \notin \mathcal{H} \wedge \|\mathbf{s}\| \le \|\mathbf{S}\|/2\} \ge \Omega(\delta(n) - n^{-\omega(1)}) = \Omega(\delta(n))$. $\square$

**6.2. The main reduction.** In this subsection we show that for appropriate choice of groups $G_n$, and parameters $\beta(n), m(n), \gamma(n)$, there is a reduction from solving $\text{IncGIVP}_\gamma^{\hat{\zeta}}$ in the worst case to solving $\text{HSIS}_{G,m,\beta}$ on the average.

THEOREM 6.5. *Let $\tau(n) \geq 1$ such that there exists an easily decodable family of $\tau(n)$-perfect lattices. Then, for any $\beta(n) \geq 1$, $m(n) = n^{O(1)}$ and $\gamma(n) = \beta(n)\tau(n) \cdot \sqrt{\omega(\log n)}$, there is a sequence of efficiently computable Abelian groups $G_n$ of size $\#G_n \leq (n^{1.5}\gamma(n)/8)^n$ such that solving $\text{IncGIVP}_\gamma^{\hat{\zeta}}$ in the worst case with high probability reduces to solving $\text{HSIS}_{G,m,\beta}$ on the average with nonnegligible probability.*

*Proof.* Let $\{\mathcal{L}(\mathbf{L}_n)\}$ be a family of easily decodable $\tau(n)$-perfect lattices. For any $\beta(n) \geq 1$ and $m(n) = n^{O(1)}$, let $\gamma(n) = \beta(n)\tau(n) \cdot \sqrt{\omega(\log n)}$ and

$$\alpha(n) = \frac{n\lambda_1(\mathcal{L}(\mathbf{L}_n))\gamma(n)}{12}. \tag{6.1}$$

Notice that from the definition of $\alpha(n)$ and $\gamma(n)$, and the assumption that $\mathcal{L}(\mathbf{L}_n)$ is $\tau(n)$-perfect, we get

$$\begin{aligned}\alpha(n) &= \frac{n\lambda_1(\mathcal{L}(\mathbf{L}_n))\beta(n)\tau(n)\sqrt{\omega(\log n)}}{12} \\ &\geq \left(\frac{\beta(n)\sqrt{n \cdot \omega(\log n)}}{12}\right) 2\sqrt{n}\rho(\mathcal{L}(\mathbf{L}_n)) \\ &\geq 2\sqrt{n}\rho(\mathcal{L}(\mathbf{L}_n)).\end{aligned}$$

So, $\alpha(n)$ satisfies the condition in Definition 5.2, and we can define a full rank subset $\mathbf{M}_n \subseteq \mathcal{L}(\mathbf{L}_n)$ and quotient group $G_n = \mathcal{G}(\mathcal{L}(\mathbf{L}_n), \alpha(n)) = \mathcal{L}(\mathbf{L}_n)/\mathcal{L}(\mathbf{M}_n)$ such that Corollary 5.3 and Lemma 5.4 hold true; i.e.,

$$\forall \mathbf{x} \in \mathbb{R}^n. \|\mathbf{M}_n\mathbf{x}\| \approx \alpha(n) \cdot \|\mathbf{x}\| \tag{6.2}$$

and group $G_n$ has size at most

$$\#G_n \leq \left(\frac{3\alpha(n)\sqrt{n}}{2\lambda_1(\mathcal{L}(\mathbf{L}_n))}\right)^n = \left(\frac{n^{1.5}\gamma(n)}{8}\right)^n.$$

We define a probabilistic polynomial time oracle algorithm $\mathcal{A}^{(\cdot)}$ satisfying the conditions in Lemma 6.4 with $\phi = \hat{\zeta}$. It follows from Lemma 6.4 that $\mathcal{A}^{(\cdot)}$ is a probabilistic polynomial time worst-case to average-case reduction from $\text{IncGIVP}_\gamma^{\hat{\zeta}}$ to $\text{HSIS}_{G,m,\beta}$. The intuition behind procedure $\mathcal{A}^{(\cdot)}$ is the following. (See Figure 2.) Map $\mathcal{L}(\mathbf{M}_n)$ to a sublattice $\mathcal{L}(\mathbf{C}) = \psi(\mathcal{L}(\mathbf{M}_n)) \subset \mathcal{L}(\mathbf{B})$ using a linear function $\psi$ with small distortion, i.e., a function that approximately preserves distance ratios. One possible way to achieve this is to map the almost orthogonal set $\mathbf{M}_n$ to an almost orthogonal subset $\mathbf{C} = \psi(\mathbf{M}_n) \subset \mathcal{L}(\mathbf{B})$ and extend $\psi$ to span$(\mathbf{M}_n)$ by linearity. Now, consider the Voronoi cells $\mathcal{V}(\mathbf{w}, \mathcal{L}(\mathbf{L}_n))$ of the $\tau(n)$-perfect lattice $\mathcal{L}(\mathbf{L}_n)$. Function $\psi$ maps each cell to a corresponding region $\psi(\mathcal{V}(\mathbf{w}, \mathcal{L}(\mathbf{L}_n)))$ centered around $\psi(\mathbf{w})$. Partition the points of $\mathcal{L}(\mathbf{B})$ into subsets, according to these regions. Pick $m(n)$ points $\mathbf{v}_i \in \mathcal{L}(\mathbf{B})$ at random, and map each of them to the center $\psi(\mathbf{w}_i)$ of the corresponding region. Notice that each region $\psi(\mathcal{V}(\mathbf{w}, \mathcal{L}(\mathbf{L}_n)))$ is associated to a group element $[\mathbf{w}]_{\mathbf{M}_n} \in G_n$. So, the points $\mathbf{v}_i$ define $m(n)$ group elements $a_i = [\mathbf{w}_i]_{\mathbf{M}_n} \in G_n$. Use $\mathcal{F}$ to find a small nonzero solution $\mathbf{z} = \mathcal{F}(\mathbf{a})$ to the equation $\mathbf{a} = [a_1, \ldots, a_{m(n)}]$. The output of $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ is vector $\mathbf{s} = \sum_i z_i(\mathbf{v}_i - \psi(\mathbf{w}_i))$. Notice that $\mathbf{s} \in \mathcal{L}(\mathbf{B})$ because $\sum z_i\mathbf{v}_i$ is

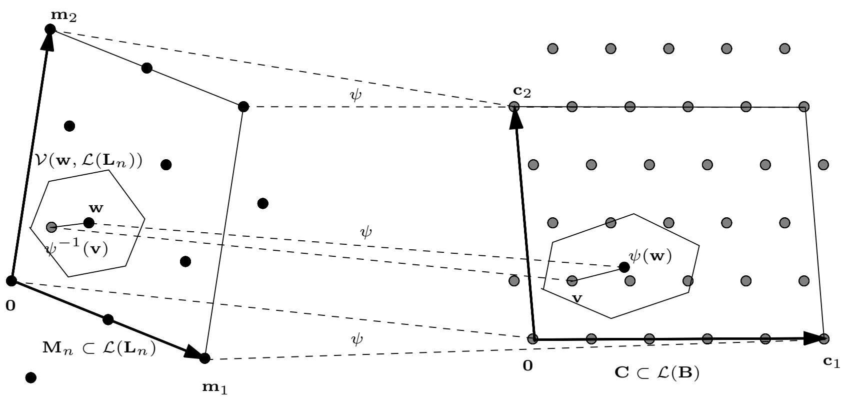

FIG. 2. *Sampling lattice points.*

an integer combination of lattice vectors, and $\sum_i z_i \mathbf{w}_i \in \mathcal{L}(\mathbf{M}_n) \subseteq \psi^{-1}(\mathcal{L}(\mathbf{B}))$. (See Lemma 6.7 for details.) Before moving to the actual proof, we informally explain why vectors $\mathbf{a}, \mathbf{z}, \mathbf{s}$ are expected to satisfy the three conditions in Lemma 6.4. (1) Vector $\mathbf{a}$ is distributed almost uniformly at random because coefficients $a_i = [\mathbf{w}_i]_{\mathbf{M}_n}$ are chosen independently, and each region $\psi(\mathcal{V}(\mathbf{w}, \mathcal{L}(\mathbf{L}_n)))$ contains roughly the same number of lattice points from $\mathcal{L}(\mathbf{B})$. (2) Vector $\mathbf{s}$ does not belong to any fixed hyperplane $\mathcal{H}$ with high probability because each $\mathbf{v}_i - \psi(\mathbf{w}_i)$ is somehow randomly distributed within $\psi(\mathcal{V}(\mathcal{L}(\mathbf{L}_n)))$. (3) Finally, $\mathbf{s}$ is short because it is a small combination of short vectors $\mathbf{v}_i - \psi(\mathbf{w}_i)$, each one lying within the region $\psi(\mathcal{V}(\mathcal{L}(\mathbf{L}_n)))$. This is an oversimplified description of the reduction. For example, Lemma 6.4 requires distribution $\mathbf{a}$ to be extremely close to uniform. In order to ensure the almost uniform distribution of $\mathbf{a}$, we will need to slightly modify the above procedure by sampling many points $(\mathbf{w}_{i,j}, \mathbf{v}_{i,j})$ and adding up the corresponding $a_{i,j} = [\mathbf{w}_{i,j}]_{\mathbf{M}_n}$ to obtain group elements $a_i = \sum_j a_{i,j}$ whose distribution is extremely close to uniform.

We now give a detailed description of procedure $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathcal{H})$. Notice that the procedure outlined above does not use the input hyperplane $\mathcal{H}$, and condition $\mathbf{s} \notin \mathcal{H}$ holds with high probability for any fixed hyperplane $\mathcal{H}$. Therefore, below we simply write $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S})$ instead of $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S}, \mathcal{H})$ to emphasize the fact that $\mathcal{A}$ does not use the input hyperplane $\mathcal{H}$.

Procedure $\mathcal{A}^{(\cdot)}(\mathbf{B}, \mathbf{S})$ works as follows. First, notice that using Babai's nearest plane algorithm [6], matrix $\mathbf{S}$ allows us to approximate any vector $\mathbf{x} \in \operatorname{span}(\mathbf{B})$ with a lattice point $\mathbf{y} \in \mathcal{L}(\mathbf{S}) \subseteq \mathcal{L}(\mathbf{B})$ within distance $\sigma = (\sqrt{n}/2)\|\mathbf{S}\|$ from $\mathbf{x}$.[17] Therefore, using Lemma 2.10, we can find an almost orthogonal sublattice $\mathcal{L}(\mathbf{C}) \subset \mathcal{L}(\mathbf{B})$ such that

$$\forall \mathbf{x} \in \mathbb{R}^n . \|\mathbf{C}\mathbf{x}\| \approx n\|\mathbf{S}\| \cdot \|\mathbf{x}\|. \tag{6.3}$$

Let $\psi(\mathbf{x}) = \mathbf{C}\mathbf{M}_n^{-1}\mathbf{x}$ be the linear transformation that maps $\mathbf{m}_i$ to $\mathbf{c}_i$ for all $i = 1, \ldots, n$. Combining (6.2) and (6.3), and using (2.1), we get

$$\forall \mathbf{x} \in \mathbb{R}^n . \frac{1}{3}\left(\frac{n\|\mathbf{S}\|}{\alpha(n)}\right) \cdot \|\mathbf{x}\| \le \|\psi(\mathbf{x})\| \le 3\left(\frac{n\|\mathbf{S}\|}{\alpha(n)}\right) \cdot \|\mathbf{x}\|; \tag{6.4}$$

[17]This is not a particularly critical part of the reduction, and using poorer rounding procedures (e.g., rounding off the coordinates of $\mathbf{x}$ with respect to basis $\mathbf{S}$ to the closest integers as done in [2]) results in substantially the same connection factors as using Babai's nearest plane algorithm [6].

i.e., the linear function $\psi$ is close to an orthogonal transformation that scales all distances by a factor $n\|\mathbf{S}\|/\alpha(n)$.

Notice that $\mathcal{L}(\mathbf{M}_n)$ is a common sublattice of both $\mathcal{L}(\mathbf{L}_n)$ and $\psi^{-1}(\mathcal{L}(\mathbf{B}))$. The following lemma shows how to use function $\psi$ together with decoding algorithm $\mathrm{CVP}_{\mathbf{L}}$ to simultaneously sample from groups $G_n = \mathcal{L}(\mathbf{L}_n)/\mathcal{L}(\mathbf{M}_n)$ and $\mathcal{L}(\mathbf{B})/\mathcal{L}(\mathbf{C}) \equiv \psi^{-1}(\mathcal{L}(\mathbf{B}))/\mathcal{L}(\mathbf{M}_n)$.

LEMMA 6.6. *There is a sampling algorithm that on input two rank $n$ lattices $\mathbf{L}_n$ and $\mathbf{B}$, a full rank sublattice $\mathbf{M}_n \subset \mathcal{L}(\mathbf{L}_n)$, and a nonsingular linear transformation $\psi$ such that $\mathbf{C} = \psi(\mathbf{M}_n) \subset \mathcal{L}(\mathbf{B})$, outputs two vectors $\mathbf{w} \in \mathcal{L}(\mathbf{L}_n)$ and $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ such that the following hold:*

1. *The group element $[\mathbf{v}]_{\mathbf{C}}$ is uniformly distributed over $\mathcal{L}(\mathbf{B})/\mathcal{L}(\mathbf{C})$.*
2. *$\psi^{-1}(\mathbf{v}) \in \bar{\mathcal{V}}(\mathbf{w}, \mathcal{L}(\mathbf{L}_n))$, or, equivalently, $\mathbf{v} - \psi(\mathbf{w}) \in \psi(\bar{\mathcal{V}}(\mathcal{L}(\mathbf{L}_n)))$.*
3. *The distribution of $\mathbf{v} - \psi(\mathbf{w})$ is symmetric about the origin, and, in particular, $\operatorname{Exp}[\mathbf{v} - \psi(\mathbf{w})] = 0$.*
4. *$\mathbf{w} \in \mathcal{P}(\mathbf{M}_n)$.*

*Moreover, if lattice $\mathbf{L}_n$ is easily decodable, then the sampling procedure runs in polynomial time.*

The actual properties of the sampling algorithm are not important at this point, and the proof of Lemma 6.6 is deferred to section 6.3. All that matters for now is that the sampling algorithm generates pairs of vectors $(\mathbf{w}, \mathbf{v}) \in \mathcal{L}(\mathbf{L}_n) \times \mathcal{L}(\mathbf{B})$. Below we describe how to use any such sampling procedure to compute a lattice vector $\mathbf{s} \in \mathcal{L}(\mathbf{B})$. After defining the full rank sublattice $\mathbf{C} \subset \mathcal{L}(\mathbf{S})$ and linear function $\psi(\mathbf{M}_n) = \mathbf{C}$ satisfying (6.4), algorithm $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S})$ proceeds as follows:

1. Run the sampling procedure of Lemma 6.6 $m(n) \cdot k(n)$ times (where $k(n) = \omega(\log n)$ is a superlogarithmic function to be specified) to generate vectors $\mathbf{w}_{i,j} \in \mathcal{L}(\mathbf{L}_n)$ and $\mathbf{v}_{i,j} \in \mathcal{L}(\mathbf{B})$ for $i = 1, \ldots, m(n)$ and $j = 1, \ldots, k(n)$.
2. Let $a_{i,j} = [\mathbf{w}_{i,j}]_{\mathbf{M}_n} \in G_n$ be the group elements corresponding to lattice points $\mathbf{w}_{i,j}$ and, for every $i = 1, \ldots, m(n)$, define group element $a_i = \sum_{j=1}^{k(n)} a_{i,j}$.
3. Use oracle $\mathcal{F}$ to compute a nonzero solution $\mathbf{z} = \mathcal{F}(\mathbf{a}) \in \Lambda(\mathbf{a}) \setminus \{\mathbf{0}\}$ to the equation $\mathbf{a} = [a_1, \ldots, a_{m(n)}]$.
4. For any $i, j$, let $\mathbf{y}_{i,j} = \mathbf{v}_{i,j} - \psi(\mathbf{w}_{i,j})$, and output

$$\mathbf{s} = \sum_{i=1}^{m(n)} z_i \sum_{j=1}^{k(n)} \mathbf{y}_{i,j}. \tag{6.5}$$

Notice that randomness is used twice in the routine: first in step 1 and then in step 3. In step 1, randomness is used to run the sampling procedure $m(n) \cdot k(n)$ times and generate a random equation $\mathbf{a}$ to be passed as input to $\mathcal{F}$. In step 3 randomness is used to run the probabilistic procedure $\mathcal{F}$ on input $\mathbf{a}$ to compute a solution $\mathbf{z}$. Since $\mathcal{F}$ is only guaranteed to work *on the average*, it is important that both the input $\mathbf{a}$ and the internal randomness of $\mathcal{F}$ are chosen (almost) uniformly and independently at random. We remark that, although the value of $\mathbf{z}$ depends on both the randomness used by the sampling procedure and that used directly by $\mathcal{F}$, the two procedures use independent sources of randomness. So, for example, given the value of $\mathbf{a}$, the conditional distribution of $\mathbf{z}$ is independent from the conditional distribution of the samples $(\mathbf{w}_{i,j}, \mathbf{v}_{i,j})$. We will use this fact in the probabilistic analysis of the success probability of the reduction.

In the following lemma we prove that algorithm $\mathcal{A}^{\mathcal{F}}$ is correct, i.e., the output vector $\mathbf{s}$ belongs to lattice $\mathcal{L}(\mathbf{B})$, provided query $\mathbf{a}$ is answered with a valid solution $\mathbf{z} \in \Lambda(\mathbf{a})$.

Lemma 6.7. *Let* $\mathbf{s}$ *be the output vector defined in* (6.5). *If* $\mathbf{z} \in \Lambda(\mathbf{a})$, *then* $\mathbf{s} \in \mathcal{L}(\mathbf{B})$.

*Proof.* Define the vector

$$\mathbf{w} = \sum_{i=1}^{m(n)} z_i \sum_{j=1}^{k(n)} \mathbf{w}_{i,j}.$$

Using the definition of $\mathbf{y}_{i,j}$ and the linearity of $\psi$, we get

$$\mathbf{s} = \sum_{i=1}^{m(n)} z_i \sum_{j=1}^{k(n)} \mathbf{y}_{i,j} = \sum_{i,j} z_i(\mathbf{v}_{i,j} - \psi(\mathbf{w}_{i,j})) = \left(\sum_{i,j} z_i \mathbf{v}_{i,j}\right) - \psi(\mathbf{w}).$$

The first term $\sum_{i,j} z_i \mathbf{v}_{i,j}$ clearly belongs to $\mathcal{L}(\mathbf{B})$ because it is an integer linear combination of lattice vectors $\mathbf{v}_{i,j} \in \mathcal{L}(\mathbf{B})$. We need to prove that the second term $\psi(\mathbf{w})$ also belongs to $\mathcal{L}(\mathbf{B})$. We show that $\mathbf{w} \in \mathcal{L}(\mathbf{M}_n)$. Since $\psi$ maps $\mathcal{L}(\mathbf{M}_n)$ to $\mathcal{L}(\mathbf{C})$, it follows that $\psi(\mathbf{w}) \in \mathcal{L}(\mathbf{C}) \subseteq \mathcal{L}(\mathbf{B})$.

Remember that $\mathbf{z} = \mathcal{F}(\mathbf{a}) \in \Lambda(\mathbf{a})$, i.e., $\sum_i z_i a_i = 0$ (in $G_n$). Since all $\mathbf{w}_{i,j}$ belong to $\mathcal{L}(\mathbf{L}_n)$, $\mathbf{w}$ is also a lattice point of $\mathcal{L}(\mathbf{L}_n)$ and $[\mathbf{w}]_{\mathbf{M}_n} \in G_n$. The group element corresponding to lattice vector $\mathbf{w}$ is

$$[\mathbf{w}]_{\mathbf{M}_n} = \sum_{i=1}^{m(n)} z_i \sum_{j=1}^{k(n)} [\mathbf{w}_{i,j}]_{\mathbf{M}_n} = \sum_i z_i \sum_j a_{i,j} = \sum_i z_i a_i = 0.$$

Since $G_n$ is the quotient of $\mathcal{L}(\mathbf{L}_n)$ modulo $\mathcal{L}(\mathbf{M}_n)$, this proves that $\mathbf{w} \in \mathcal{L}(\mathbf{M}_n)$. ◻

The following three lemmas show that, provided $\alpha(n)$ is in a prescribed range, procedure $\mathcal{A}$ satisfies the conditions in Lemma 6.4. The lemmas are proved in section 6.4, after establishing some useful properties of the sampling procedure in section 6.3.

The first lemma shows that the equation $\mathbf{a}$ passed as input to oracle $\mathcal{F}$ is almost uniformly distributed.

Lemma 6.8. *If* $n\|\mathbf{S}\|\lambda_1(\mathcal{L}(\mathbf{L}_n)) \geq 6\alpha(n)\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ *and* (6.4) *holds true, then the statistical distance between vector* $\mathbf{a}$ *(passed as input to* $\mathcal{F}$ *during the execution of* $\mathcal{A}^{\mathcal{F}}(\mathbf{B},\mathbf{S})$*) and a uniformly distributed* $\mathbf{u} \in G_n^{m(n)}$ *is at most* $\Delta(\mathbf{a},\mathbf{u}) \leq m(n)/2^{k(n)+1}$. *In particular, for any polynomially bounded* $m(n) = n^{O(1)}$ *and superlogarithmic function* $k(n) = \omega(\log n)$, *the statistical distance* $\Delta(\mathbf{a},\mathbf{u}) = n^{-\omega(1)}$ *is negligible.*

The other two lemmas show that the output vector $\mathbf{s}$ of procedure $\mathcal{A}^{\mathcal{F}}$ is sufficiently random and usually short, even after conditioning on the input and output values of oracle $\mathcal{F}$.

Lemma 6.9. *Assume* $n\|\mathbf{S}\|\lambda_1(\mathcal{L}(\mathbf{L}_n)) \geq 12\alpha(n)\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ *and* (6.4) *holds true. Then, for any* $\hat{\mathbf{a}} \in G_n^{m(n)}$, $\hat{\mathbf{z}} \in \Lambda(\hat{\mathbf{a}}) \setminus \{\mathbf{0}\}$, *and* $(n-1)$*-dimensional hyperplane* $\mathcal{H} \subset \operatorname{span}(\mathbf{B})$,

$$\Pr\{\mathbf{s} \notin \mathcal{H} \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}\} = \Omega(1).$$

Lemma 6.10. *If* $n\|\mathbf{S}\|\lambda_1(\mathcal{L}(\mathbf{L}_n)) \geq 6\alpha(n)\hat{\zeta}(\mathcal{L}(\mathbf{B}))$, (6.4) *holds true, and function* $\alpha(n)$ *satisfies* $\alpha(n) = \omega(n\sqrt{k(n)}\beta(n)\rho(\mathcal{L}(\mathbf{L}_n)))$, *then for any* $\hat{\mathbf{a}} \in G_n^{m(n)}$ *and* $\hat{\mathbf{z}} \in \Lambda(\hat{\mathbf{a}})$,

$$\operatorname{Exp}[\|\mathbf{s}\| \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}] = o\left(\frac{\|\hat{\mathbf{z}}\| \cdot \|\mathbf{S}\|}{\beta(n)}\right) \cdot \sqrt{1 + \frac{m(n)k(n)}{2^{k(n)}}}.$$

*In particular, for any polynomially bounded $m(n) = n^{O(1)}$ and superlogarithmic function $k(n) = \omega(\log n)$,*

$$\mathrm{Exp}[\|\mathbf{s}\| \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}] = o\left(\frac{\|\hat{\mathbf{z}}\| \cdot \|\mathbf{S}\|}{\beta(n)}\right).$$

We complete the proof of the theorem by showing that if $k(n)$ is appropriately chosen, then the hypotheses of Lemmas 6.8, 6.9, and 6.10 are satisfied. Notice that from the definition of $\alpha(n) = n\lambda_1(\mathcal{L}(\mathbf{L}_n))\gamma(n)/12$ and the assumption that $\|\mathbf{S}\| > \gamma(n)\hat{\zeta}(\mathcal{L}(\mathbf{B}))$, we immediately get

$$12\alpha(n)\hat{\zeta}(\mathcal{L}(\mathbf{B})) = n\lambda_1(\mathcal{L}(\mathbf{L}_n))\gamma(n)\hat{\zeta}(\mathcal{L}(\mathbf{B})) < n\lambda_1(\mathcal{L}(\mathbf{L}_n))\|\mathbf{S}\|. \tag{6.6}$$

So, the first condition in Lemmas 6.8, 6.9, and 6.10 is satisfied. We already observed that (6.4) follows from (6.2) and (6.3). In order to satisfy the third hypothesis of Lemma 6.10, we set

$$k(n) = \frac{\gamma(n) \cdot \sqrt{\log n}}{\beta(n) \cdot \tau(n)} = \omega(\log n). \tag{6.7}$$

Solving (6.7) for $\gamma(n) = k(n)\beta(n)\tau(n)/\sqrt{\log n}$ and substituting this value in the definition of $\alpha(n)$, we get

$$\begin{aligned}\alpha(n) &= \frac{n\lambda_1(\mathcal{L}(\mathbf{L}_n))}{12}\frac{k(n)\beta(n)\tau(n)}{\sqrt{\log n}} \\ &\geq \omega(n\sqrt{k(n)}\beta(n)\rho(\mathcal{L}(\mathbf{L}_n))),\end{aligned}$$

where we have used the perfectness condition $\rho(\mathcal{L}(\mathbf{L}_n)) \leq \tau(n)\lambda_1(\mathcal{L}(\mathbf{L}_n))/2$ and the fact that $k(n)/\sqrt{\log n} = \sqrt{k(n)/\log n}\sqrt{k(n)} = \omega(\sqrt{k(n)})$. This proves that for any polynomially bounded function $m(n) = n^{O(1)}$, and $k(n)$ as defined in (6.7), the hypotheses of Lemmas 6.8, 6.9, and Lemma 6.10 are satisfied, and algorithm $\mathcal{A}$ satisfies the conditions in Lemma 6.4. Therefore, for any (possibly probabilistic) oracle $\mathcal{F}$ solving $\mathrm{HSIS}_{G,m,\beta}$ on the average with nonnegligible probability, $\mathcal{A}^{\mathcal{F}}$ solves $\mathrm{IncGIVP}_{\gamma}^{\hat{\zeta}}$ in the worst case with high probability. $\square$

**6.3. The sampling procedure.** In this subsection we give a simple sampling procedure that satisfies the conditions in Lemma 6.6. Then, we establish some additional properties of the output of the sampling procedure that will be useful in section 6.4. The sampling procedure is illustrated in Figure 2.

*Proof of Lemma* 6.6. We first show how to achieve the first two properties in the lemma. Choose integers

$$d_1, \ldots, d_n \in \{1, \ldots, \det(\mathcal{L}(\mathbf{C}))/\det(\mathcal{L}(\mathbf{B}))\}$$

uniformly at random and let $\mathbf{v}'' = \sum_i d_i\mathbf{b}_i \in \mathcal{L}(\mathbf{B})$. By Proposition 2.9, $[\mathbf{v}'']_{\mathbf{C}}$ is distributed uniformly at random, in $\mathcal{L}(\mathbf{B})/\mathcal{L}(\mathbf{C})$. Then, compute $\mathbf{w}'' = \mathrm{CVP}_{\mathbf{L}}(\psi^{-1}(\mathbf{v}''))$. Clearly, $\psi^{-1}(\mathbf{v}'')$ belongs to the Voronoi cell $\bar{\mathcal{V}}(\mathbf{w}'', \mathcal{L}(\mathbf{L}_n))$. So, the pair $(\mathbf{v}'', \mathbf{w}'')$ satisfies the first two properties.

Now, choose $b \in \{0, 1\}$ uniformly at random and set $\mathbf{v}' = (-1)^b\mathbf{v}''$ and $\mathbf{w}' = (-1)^b\mathbf{w}''$. Clearly, for any $\mathbf{v}''$ and $\mathbf{w}''$, the distribution of $\mathbf{v}' - \psi(\mathbf{w}') = (-1)^b(\mathbf{v}'' - \psi(\mathbf{w}''))$ is symmetric about the origin. So, $(\mathbf{v}', \mathbf{w}')$ satisfies the third property. We need to check that the first two properties are preserved. Since $[\mathbf{v}'']_{\mathbf{C}}$ is uniformly distributed, $[-\mathbf{v}'']_{\mathbf{C}} = -[\mathbf{v}'']_{\mathbf{C}}$ is also uniform. It follows that $[\mathbf{v}']_{\mathbf{C}}$ is uniformly distributed because $\mathbf{v}'$ is a convex combination of distributions $\mathbf{v}''$ and $-\mathbf{v}''$. Finally, since closed Voronoi cells of a lattice are symmetric,

$$\mathbf{v}' - \psi(\mathbf{w}') = (-1)^b(\mathbf{v}'' - \psi(\mathbf{w}'')) \in (-1)^b\bar{\mathcal{V}}(\mathcal{L}(\mathbf{L}_n)) = \bar{\mathcal{V}}(\mathcal{L}(\mathbf{L}_n)).$$

This proves that $(\mathbf{v}', \mathbf{w}')$ satisfies the first three properties in the lemma.

In order to also achieve the fourth property, set $\mathbf{w} = (\mathbf{w}' \bmod \mathbf{M}_n)$ and $\mathbf{v} = (\mathbf{v}' - \psi(\mathbf{w}' - \mathbf{w}))$. Property $\mathbf{w} \in \mathcal{P}(\mathbf{M}_n)$ immediately follows by the definition of $\mathbf{w}$. We show that the first three properties are preserved. By the definition of $\mathbf{v}$, we have $\mathbf{v}' - \mathbf{v} = \psi(\mathbf{w}' - \mathbf{w})$ and $\mathbf{v} - \psi(\mathbf{w}) = \mathbf{v}' - \psi(\mathbf{w}')$. So, the second and third properties are satisfied because they depend only on $\mathbf{v} - \psi(\mathbf{w})$. In order to prove the first property, notice that $\mathbf{w}' - \mathbf{w} = \mathbf{w}' - (\mathbf{w}' \bmod \mathbf{M}_n) \in \mathcal{L}(\mathbf{M}_n)$. Therefore, $\mathbf{v}' - \mathbf{v} \in \psi(\mathcal{L}(\mathbf{M}_n)) = \mathcal{L}(\mathbf{C})$, and $[\mathbf{v}]_{\mathbf{C}} = [\mathbf{v}']_{\mathbf{C}}$, proving that $[\mathbf{v}]_{\mathbf{C}}$ is distributed identically to $[\mathbf{v}']_{\mathbf{C}}$. ∎

The sampling procedure produces vectors $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ such that $[\mathbf{v}]_{\mathbf{C}}$ is distributed uniformly at random over the group $\mathcal{L}(\mathbf{B})/\mathcal{L}(\mathbf{C})$. However, vector $\mathbf{v}$ (before the reduction modulo $\mathbf{C}$) is not necessarily uniformly distributed over any set of lattice vectors. (This is due to lattice points $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ such that $\psi^{-1}(\mathbf{v})$ lies on the boundary of Voronoi cells $\mathcal{V}(\mathbf{w}, \mathcal{L}(\mathbf{L}_n))$.) In the next lemma, we give simple upper and lower bounds on the probability of outputting any specific vector $\mathbf{v} \in \mathcal{L}(\mathbf{B})$.

Lemma 6.11. *Let* $(\mathbf{w}, \mathbf{v})$ *be generated according to a sampling procedure of Lemma* 6.6. *Then, for any* $\hat{\mathbf{v}} \in \mathcal{L}(\mathbf{B})$, $\Pr\{\mathbf{v} = \hat{\mathbf{v}}\} \le \det(\mathcal{L}(\mathbf{B}))/\det(\mathcal{L}(\mathbf{C}))$. *Moreover, if* $\psi^{-1}(\hat{\mathbf{v}})$ *belongs to the interior of a Voronoi cell* $\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))$ *for some* $\hat{\mathbf{w}} \in \mathcal{L}(\mathbf{L}_n) \cap \mathcal{P}(\mathbf{M}_n)$, *then* $\Pr\{\mathbf{v} = \hat{\mathbf{v}}\} = \det(\mathcal{L}(\mathbf{B}))/\det(\mathcal{L}(\mathbf{C}))$.

*Proof.* The upper bound is easy: for any $\hat{\mathbf{v}} \in \mathcal{L}(\mathbf{B})$,

$$\Pr\{\mathbf{v} = \hat{\mathbf{v}}\} \le \Pr\{[\mathbf{v}]_{\mathbf{C}} = [\hat{\mathbf{v}}]_{\mathbf{C}}\} = \det(\mathcal{L}(\mathbf{B}))/\det(\mathcal{L}(\mathbf{C}))$$

because $[\mathbf{v}]_{\mathbf{C}}$ is uniformly distributed over a quotient group $\mathcal{L}(\mathbf{B})/\mathcal{L}(\mathbf{C})$ whose size equals $\det(\mathcal{L}(\mathbf{C}))/\det(\mathcal{L}(\mathbf{B}))$.

Now assume $\psi^{-1}(\hat{\mathbf{v}}) \in \mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))$ for some $\hat{\mathbf{w}} \in \mathcal{L}(\mathbf{L}_n) \cap \mathcal{P}(\mathbf{M}_n)$. We claim that if $[\mathbf{v}]_{\mathbf{C}} = [\hat{\mathbf{v}}]_{\mathbf{C}}$, then $\mathbf{v} = \hat{\mathbf{v}}$, and therefore

$$\Pr\{\mathbf{v} = \hat{\mathbf{v}}\} \ge \Pr\{[\mathbf{v}]_{\mathbf{C}} = [\hat{\mathbf{v}}]_{\mathbf{C}}\} = \det(\mathcal{L}(\mathbf{B}))/\det(\mathcal{L}(\mathbf{C})).$$

Let $[\mathbf{v}]_{\mathbf{C}} = [\hat{\mathbf{v}}]_{\mathbf{C}}$, i.e., $\mathbf{v} - \hat{\mathbf{v}} \in \mathcal{L}(\mathbf{C})$. It follows that vector

$$\mathbf{y} = \psi^{-1}(\mathbf{v}) - \psi^{-1}(\hat{\mathbf{v}}) = \psi^{-1}(\mathbf{v} - \hat{\mathbf{v}})$$

belongs to lattice $\psi^{-1}(\mathcal{L}(\mathbf{C})) = \mathcal{L}(\mathbf{M}_n)$. Since $\mathcal{L}(\mathbf{M}_n)$ is a sublattice of $\mathcal{L}(\mathbf{L}_n)$, and $\hat{\mathbf{w}} \in \mathcal{L}(\mathbf{L}_n)$, $\hat{\mathbf{w}} + \mathbf{y}$ is also a lattice point in $\mathcal{L}(\mathbf{L}_n)$. Consider the open Voronoi cells $\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))$ and $\mathcal{V}^o(\hat{\mathbf{w}} + \mathbf{y}, \mathcal{L}(\mathbf{L}_n))$. Using the definition of $\mathbf{y}$ and the hypothesis $\psi^{-1}(\hat{\mathbf{v}}) \in \mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))$, we get

$$\psi^{-1}(\mathbf{v}) = \psi^{-1}(\hat{\mathbf{v}}) + \mathbf{y} \in \mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)) + \mathbf{y} = \mathcal{V}^o(\hat{\mathbf{w}} + \mathbf{y}, \mathcal{L}(\mathbf{L}_n));$$

i.e., $\psi^{-1}(\mathbf{v})$ is closer to $\hat{\mathbf{w}} + \mathbf{y}$ than to any other lattice point in $\mathcal{L}(\mathbf{L}_n)$. But we know from Lemma 6.6 that $\psi^{-1}(\mathbf{v})$ belongs to the Voronoi cell $\bar{\mathcal{V}}(\mathbf{w}, \mathcal{L}(\mathbf{L}_n))$; i.e., $\psi^{-1}(\mathbf{v})$ is at least as close to $\mathbf{w} \in \mathcal{L}(\mathbf{L}_n)$ as to any other lattice point. Therefore, it must be

$\mathbf{w} = \hat{\mathbf{w}} + \mathbf{y}$. We also know that both $\mathbf{w}$ and $\hat{\mathbf{w}}$ belong to $\mathcal{P}(\mathbf{M}_n)$, and $\mathbf{y} \in \mathcal{L}(\mathbf{M}_n)$. So, $\mathbf{w} = \hat{\mathbf{w}} + \mathbf{y}$ is possible only if $\mathbf{y} = \mathbf{0}$, which implies $\mathbf{v} = \hat{\mathbf{v}}$. ◻

Lemma 6.11 can be used to establish two important properties of the sampling algorithm of Lemma 6.6. The distribution $[\mathbf{v}]_{\mathbf{C}}$ produced by the sampling algorithm is uniform. However, $[\mathbf{w}]_{\mathbf{M}_n}$ is not in general uniformly distributed over $G_n$. The first property is that, provided $\|\mathbf{S}\|$ is large enough, the distribution of $[\mathbf{w}]_{\mathbf{M}_n}$ is relatively close to uniform.

LEMMA 6.12. *Let* $(\mathbf{w}, \mathbf{v})$ *be generated according to the sampling procedure of Lemma* 6.6. *If* $n\|\mathbf{S}\|\lambda_1(\mathcal{L}(\mathbf{L}_n)) \geq 6\alpha(n)\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ *and* (6.4) *holds true, then for any group element* $g \in G_n$,

$$\Pr\{[\mathbf{w}]_{\mathbf{M}_n} = g\} \approx \frac{1}{\#G_n}.$$

*Proof.* Fix group element $g$, and let $\hat{\mathbf{w}}$ be the unique lattice point in $\mathcal{L}(\mathbf{L}_n) \cap \mathcal{P}(\mathbf{M}_n)$ such that $[\hat{\mathbf{w}}]_{\mathbf{M}_n} = g$. Since $\mathbf{w} \in \mathcal{P}(\mathbf{M}_n)$, $[\mathbf{w}]_{\mathbf{M}_n} = g$ if and only if $\mathbf{w} = \hat{\mathbf{w}}$. We estimate the probability that $\mathbf{w} = \hat{\mathbf{w}}$.

Notice that if $\mathbf{v} \in \psi(\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)))$, then $\mathbf{w} = \hat{\mathbf{w}}$. Therefore,

$$\Pr\{\mathbf{w} = \hat{\mathbf{w}}\} \geq \sum_{\hat{\mathbf{v}} \in \psi(\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))) \cap \mathcal{L}(\mathbf{B})} \Pr\{\mathbf{v} = \hat{\mathbf{v}}\}.$$

By Lemma 6.11, for any $\hat{\mathbf{v}} \in \psi(\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))) \cap \mathcal{L}(\mathbf{B})$,

$$\Pr\{\mathbf{v} = \hat{\mathbf{v}}\} = \det(\mathcal{L}(\mathbf{B}))/\det(\mathcal{L}(\mathbf{C})).$$

So,

$$\Pr\{\mathbf{w} = \hat{\mathbf{w}}\} \geq \frac{\det(\mathcal{L}(\mathbf{B}))}{\det(\mathcal{L}(\mathbf{C}))} \cdot \#(\psi(\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))) \cap \mathcal{L}(\mathbf{B})).$$

Similarly, if $\mathbf{w} = \hat{\mathbf{w}}$, then $\mathbf{v} \in \psi(\bar{\mathcal{V}}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)))$. Therefore,

$$\begin{aligned}\Pr\{\mathbf{w} = \hat{\mathbf{w}}\} &\leq \sum_{\hat{\mathbf{v}} \in \psi(\bar{\mathcal{V}}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))) \cap \mathcal{L}(\mathbf{B})} \Pr\{\mathbf{v} = \hat{\mathbf{v}}\} \\ &\leq \frac{\det(\mathcal{L}(\mathbf{B}))}{\det(\mathcal{L}(\mathbf{C}))} \cdot \#(\psi(\bar{\mathcal{V}}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))) \cap \mathcal{L}(\mathbf{B})).\end{aligned}$$

In order to complete the proof, we need to estimate the number of lattice points from $\mathcal{L}(\mathbf{B})$ that belong to $\psi(\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)))$ and $\psi(\bar{\mathcal{V}}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)))$. Since $\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))$ contains an open sphere of radius $\lambda_1(\mathcal{L}(\mathbf{L}_n))/2$, using (6.4) we get that the set $\psi(\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)))$ (and therefore, also $\psi(\bar{\mathcal{V}}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))$ contains a sphere of radius

$$\frac{n\|\mathbf{S}\|}{3\alpha(n)} \cdot \frac{\lambda_1(\mathcal{L}(\mathbf{L}_n))}{2} \geq \hat{\zeta}(\mathcal{L}(\mathbf{B})).$$

Therefore, by definition of the generalized uniform radius $\hat{\zeta}(\mathcal{L}(\mathbf{B}))$, the number of lattice points in $\psi(\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)))$ (and $\psi(\bar{\mathcal{V}}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))$ is approximately equal to

$$\frac{\operatorname{vol}(\psi(\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))}{\det(\mathcal{L}(\mathbf{B}))} = \frac{\operatorname{vol}(\psi(\bar{\mathcal{V}}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))}{\det(\mathcal{L}(\mathbf{B}))} = \frac{\operatorname{vol}(\psi(\mathcal{V}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))}{\det(\mathcal{L}(\mathbf{B}))}.$$

Combining this estimate with the upper and lower bounds on the probability that $\mathbf{w} = \hat{\mathbf{w}}$, we get

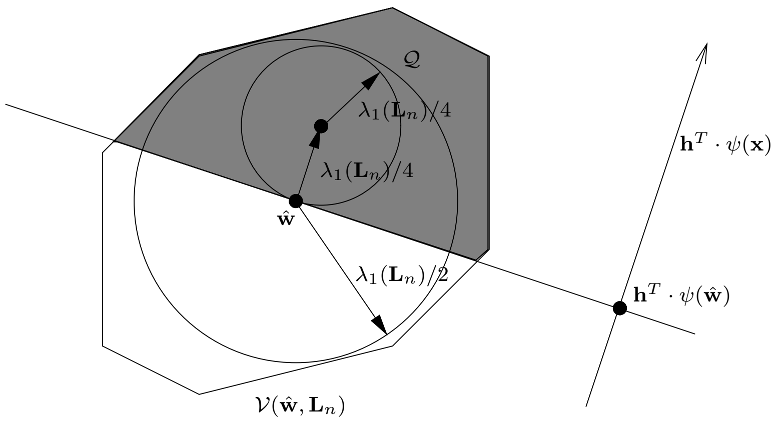
$$\begin{aligned}\Pr\{[\mathbf{w}]_{\mathbf{M}_n} = g\} &\approx \frac{\det(\mathcal{L}(\mathbf{B}))}{\det(\mathcal{L}(\mathbf{C}))} \cdot \frac{\mathrm{vol}(\psi(\mathcal{V}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))}{\det(\mathcal{L}(\mathbf{B}))} \\ &= \frac{\mathrm{vol}(\psi(\mathcal{V}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))}{\det(\psi(\mathcal{L}(\mathbf{M}_n)))} \\ &= \frac{\mathrm{vol}(\mathcal{V}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)))}{\det(\mathcal{L}(\mathbf{M}_n))} \\ &= \frac{\det(\mathcal{L}(\mathbf{L}_n))}{\det(\mathcal{L}(\mathbf{M}_n))} = \frac{1}{\#G_n}. \qquad \square\end{aligned}$$

The second property implies that, provided $\|\mathbf{S}\|$ is large enough, the distribution of $\mathbf{v} - \psi(\mathbf{w})$, as generated by the sampling procedure, is not concentrated over any fixed $(n-1)$-dimensional hyperplane. In fact, we prove a stronger property and show that $\mathbf{v} - \psi(\mathbf{w})$ belongs to any of the two half-spaces defined by the hyperplane with high probability. This is true even for the conditional distribution of $\mathbf{v} - \psi(\mathbf{w})$ given $\mathbf{w}$.

LEMMA 6.13. *Let* $(\mathbf{w}, \mathbf{v})$ *be generated according to the sampling procedure of Lemma* 6.6. *If* $n\|\mathbf{S}\|\lambda_1(\mathcal{L}(\mathbf{L}_n)) \geq 12\alpha(n)\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ *and* (6.4) *holds true, then for any* $\mathbf{h} \in \mathrm{span}(\mathbf{B}) \setminus \{\mathbf{0}\}$ *and* $g \in G_n$,

$$\Pr\{\mathbf{h}^T \cdot (\mathbf{v} - \psi(\mathbf{w})) > 0 \mid [\mathbf{w}]_{\mathbf{M}_n} = g\} \geq \frac{1}{6}.$$

*Proof.* Fix group element $g$, and let $\hat{\mathbf{w}}$ be the unique lattice point in $\mathcal{L}(\mathbf{L}_n) \cap \mathcal{P}(\mathbf{M}_n)$ such that $[\hat{\mathbf{w}}]_{\mathbf{M}_n} = g$. Since Lemma 6.6 guarantees $\mathbf{w} \in \mathcal{P}(\mathbf{M}_n)$, condition $[\mathbf{w}]_{\mathbf{M}_n} = g$ is equivalent to $\mathbf{w} = \hat{\mathbf{w}}$. Let $\mathcal{Q} = \{\mathbf{x} \in \mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)) \colon \mathbf{h}^T \cdot \psi(\mathbf{x} - \hat{\mathbf{w}}) > 0\}$ be one of the two (open) halves of the Voronoi cell $\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))$ defined by the hyperplane $\mathbf{h}^T \cdot \psi(\mathbf{x}) = \mathbf{h}^T \cdot \psi(\hat{\mathbf{w}})$. (See Figure 3.) First we estimate the probability



$\mathcal{Q}$
$\lambda_1(\mathbf{L}_n)/4$
$\lambda_1(\mathbf{L}_n)/4$
$\hat{\mathbf{w}}$
$\lambda_1(\mathbf{L}_n)/2$
$\mathbf{h}^T \cdot \psi(\mathbf{x})$
$\mathbf{h}^T \cdot \psi(\hat{\mathbf{w}})$
$\mathcal{V}(\hat{\mathbf{w}}, \mathbf{L}_n)$

FIG. 3. *The conditional distribution of sampled lattice points.*

that $\mathbf{v} \in \psi(\mathcal{Q})$. Since $\mathcal{Q}$ is contained in the open Voronoi cell $\mathcal{V}^o(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))$, by Lemma 6.11,

$$\Pr\{\mathbf{v} \in \psi(\mathcal{Q})\} = \sum_{\hat{\mathbf{v}} \in \psi(\mathcal{Q}) \cap \mathcal{L}(\mathbf{B})} \Pr\{\mathbf{v} = \hat{\mathbf{v}}\} = \frac{\det(\mathcal{L}(\mathbf{B}))}{\det(\mathcal{L}(\mathbf{C}))} \cdot \#(\psi(\mathcal{Q}) \cap \mathcal{L}(\mathbf{B})).$$

Notice that $\mathcal{Q}$ contains an open sphere of radius $\lambda_1(\mathcal{L}(\mathbf{L}_n))/4$. (See Figure 3.) Therefore, by (6.4), $\psi(\mathcal{Q})$ contains a sphere of radius

$$\frac{n\|\mathbf{S}\|}{3\alpha(n)} \cdot \frac{\lambda_1(\mathcal{L}(\mathbf{L}_n))}{4} \geq \hat{\zeta}(\mathcal{L}(\mathbf{B})).$$

By definition of $\hat{\zeta}(\mathcal{L}(\mathbf{B}))$, the number of lattice points in $\psi(\mathcal{Q})$ satisfies

$$\#(\psi(\mathcal{Q}) \cap \mathcal{L}(\mathbf{B})) \approx \frac{\operatorname{vol}(\psi(\mathcal{Q}))}{\det(\mathcal{L}(\mathbf{B}))} = \frac{1}{2} \frac{\operatorname{vol}(\psi(\mathcal{V}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))}{\det(\mathcal{L}(\mathbf{B}))}$$

and

$$\begin{aligned}\Pr\{\mathbf{v} \in \psi(\mathcal{Q})\} &\approx \frac{1}{2} \frac{\det(\mathcal{L}(\mathbf{B}))}{\det(\mathcal{L}(\mathbf{C}))} \cdot \frac{\operatorname{vol}(\psi(\mathcal{V}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))}{\det(\mathcal{L}(\mathbf{B}))} \\ &= \frac{1}{2} \frac{\operatorname{vol}(\psi(\mathcal{V}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n))))}{\det(\psi(\mathcal{L}(\mathbf{M}_n)))} \\ &= \frac{1}{2} \frac{\operatorname{vol}(\mathcal{V}(\hat{\mathbf{w}}, \mathcal{L}(\mathbf{L}_n)))}{\det(\mathcal{L}(\mathbf{M}_n))} \\ &= \frac{1}{2 \cdot \# G_n}.\end{aligned}$$

Notice that if $\mathbf{v} \in \psi(\mathcal{Q})$, then $\mathbf{w} = \hat{\mathbf{w}}$ and $\mathbf{h}^T \cdot (\mathbf{v} - \psi(\hat{\mathbf{w}})) > 0$. Therefore,

$$\Pr\{[\mathbf{w}]_{\mathbf{M}_n} = g \wedge \mathbf{h}^T \cdot (\mathbf{v} - \psi(\hat{\mathbf{w}})) > 0\} \geq \Pr\{\mathbf{v} \in \psi(\mathcal{Q})\} \geq \frac{1}{4 \cdot \# G_n}.$$

We can now compute the conditional probability,

$$\begin{aligned}\Pr\{\mathbf{h}^T \cdot (\mathbf{v} - \psi(\mathbf{w})) > 0 \mid [\mathbf{w}]_{\mathbf{M}_n} = g\} &= \frac{\Pr\{\mathbf{h}^T \cdot (\mathbf{v} - \psi(\mathbf{w})) > 0 \wedge [\mathbf{w}]_{\mathbf{M}_n} = g\}}{\Pr\{[\mathbf{w}]_{\mathbf{M}_n} = g\}} \\ &\geq \frac{1}{4 \cdot \# G_n \cdot \Pr\{[\mathbf{w}]_{\mathbf{M}_n} = g\}}.\end{aligned}$$

Using Lemma 6.12, $\Pr\{[\mathbf{w}]_{\mathbf{M}_n} = g\} \lesssim 1/\# G_n$, i.e., $\# G_n \cdot \Pr\{[\mathbf{w}]_{\mathbf{M}_n} = g\} \leq 3/2$. Substituting in the previous inequality we get

$$\Pr\{\mathbf{h}^T \cdot (\mathbf{v} - \psi(\mathbf{w})) > 0 \mid [\mathbf{w}]_{\mathbf{M}_n} = g\} \geq \frac{1}{6}. \qquad \square$$

**6.4. Proofs of the lemmas.** In this subsection we prove Lemmas 6.8, 6.9, and 6.10 used in the analysis the algorithm $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S})$ in section 6.2. The intuition behind Lemma 6.8 is that since group elements $a_{i,j}$ are independent and not too far from uniformly distributed, their sums $a_i = \sum_j a_{i,j}$ are extremely close to uniform.

*Proof of Lemma* 6.8. First consider the distribution of a single group element $a_{i,j} = [\mathbf{w}_{i,j}]_{\mathbf{M}_n}$ as output by the sampling procedure. Since $n\|\mathbf{S}\|\lambda_1(\mathcal{L}(\mathbf{L}_n)) \geq$

$6\alpha(n)\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ and (6.4) holds true by assumption, Lemma 6.12 tells us that for any group element $g \in G_n$,

$$\Pr\{a_{i,j} = g\} \approx \frac{1}{\#G_n}.$$

So, the probability distribution of each $a_{i,j}$ is not too far from uniform. Adding up a relatively small number of $a_{i,j}$ we get a group element $a_i = \sum_{j=1}^{k(n)} a_{i,j}$ which is almost uniformly distributed. In particular, by Proposition 2.17, the statistical distance between $a_i$ and a uniformly distributed $u_i \in G$ is at most

$$\Delta(a_i, u_i) \le \frac{1}{2^{k(n)+1}}. \tag{6.8}$$

Since the random variables $a_i$ are independent, by Proposition 2.14 the statistical distance between vector $\mathbf{a} = [a_1, \ldots, a_{m(n)}]^T$ and a uniformly distributed $\mathbf{u} \in G_n^{m(n)}$ is at most

$$\Delta(\mathbf{a}, \mathbf{u}) \le \sum_{i=1}^{m(n)} \Delta(a_i, u_i) \le \frac{m(n)}{2^{k(n)+1}} = \frac{n^{O(1)}}{n^{\omega(1)}} = n^{-\omega(1)}. \qquad \square \tag{6.9}$$

The intuition behind Lemma 6.9 is that since each $\mathbf{y}_{i,j} = \mathbf{v}_{i,j} - \psi(\mathbf{w}_{i,j})$ has the property described in Lemma 6.13, then also $s$ (which is a nonzero linear combination of the $\mathbf{y}_{i,j}$'s) has a similar property.

*Proof of Lemma* 6.9. Fix $\hat{\mathbf{a}} \in G_n^{m(n)}$, $\hat{\mathbf{z}} \in \Lambda(\hat{\mathbf{a}}) \setminus \{\mathbf{0}\}$, and $(n-1)$-dimensional hyperplane $\mathcal{H} \subset \operatorname{span}(\mathbf{B})$. Since $\hat{\mathbf{z}} \neq \mathbf{0}$, there exists a coordinate $i$ such that $\hat{z}_i \neq 0$. Assume without loss of generality that $\hat{z}_1 \neq 0$.

The output of $\mathcal{A}^{\mathcal{F}}(\mathbf{B}, \mathbf{S})$ is a random variable that depends on the randomness of oracle $\mathcal{F}$ and the randomness used during the execution of the sampling procedure in the computation of $(\mathbf{w}_{i,j}, \mathbf{v}_{i,j})$ for $i = 1, \ldots, m(n)$ and $j = 1, \ldots, k(n)$. Fix the randomness of $\mathcal{F}$ and sampling procedure, except for $(i,j) = (1,1)$. Finally, for this remaining run of the sampling procedure, fix the value of $\mathbf{w}_{1,1}$ and consider the conditional distribution of $\mathbf{v}_{1,1}$. Notice that this uniquely determines

(i) the values of $\mathbf{v}_{i,j}$ for all $(i,j) \neq (1,1)$,
(ii) the values of $\mathbf{w}_{i,j}$ for all $i, j$,
(iii) the value of $\mathbf{a} = \sum_{i,j} [\mathbf{w}_{i,j}]_{\mathbf{M}_n} \mathbf{e}_i$, and
(iv) the value of $\mathbf{z} = \mathcal{F}(\mathbf{a})$.

We prove a stronger statement than the one in the lemma. Namely, we show that the conditional probability

$$\Pr\{\mathbf{s} \notin \mathcal{H} \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}, \forall(i,j).\mathbf{w}_{i,j} = \hat{\mathbf{w}}_{i,j}, \forall(i,j) \neq (1,1).\mathbf{v}_{i,j} = \hat{\mathbf{v}}_{i,j}\}$$

is at least $1/6$. Notice that this probability depends only on the conditional distribution of $\mathbf{v}_{1,1}$, because all other vectors are fixed by conditioning. Averaging over all cases such that $\mathbf{a} = \hat{\mathbf{a}}$ and $\mathbf{z} = \hat{\mathbf{z}}$, we get that $\Pr\{\mathbf{s} \notin \mathcal{H} \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}\} \ge 1/6$.

For any fixed values $\hat{\mathbf{w}}_{i,j}$, $\hat{\mathbf{v}}_{i,j}$, and $\hat{\mathbf{a}}$, define the vector

$$\mathbf{y} = \sum_{(i,j) \neq (1,1)} \hat{z}_i \cdot (\hat{\mathbf{v}}_{i,j} - \psi(\hat{\mathbf{w}}_{i,j})).$$

Notice that, given $\mathbf{z} = \hat{\mathbf{z}}$, $\mathbf{w}_{i,j} = \hat{\mathbf{w}}_{i,j}$ for all $i,j$, and $\mathbf{v}_{i,j} = \hat{\mathbf{v}}_{i,j}$ for all $(i,j) \neq (1,1)$,

$$\mathbf{s} = \sum_{i,j} z_i \cdot (\mathbf{v}_{i,j} - \psi(\mathbf{w}_{i,j})) = \mathbf{y} + \hat{z}_1 \cdot (\mathbf{v}_{1,1} - \psi(\hat{\mathbf{w}}_{1,1})).$$

We want to bound the conditional probability that $\mathbf{s} \in \mathcal{H}$ or, equivalently,

$$\mathbf{v}_{1,1} - \psi(\hat{\mathbf{w}}_{1,1}) \in \frac{\mathcal{H} - \mathbf{y}}{\hat{z}_1} = \mathcal{H}'.$$

Let $\mathbf{h} \in \operatorname{span}(\mathbf{B})$ be a vector orthogonal to $\mathcal{H}'$ such that $\mathbf{h}^T \cdot \mathbf{x} \leq 0$ for any $\mathbf{x} \in \mathcal{H}'$. (Notice that since $\mathbf{h}$ is orthogonal to $\mathcal{H}'$, the function $\mathbf{x} \mapsto \mathbf{h}^T \cdot \mathbf{x}$ is constant over $\mathcal{H}'$.) Since $\mathbf{h}^T \cdot \mathbf{x} > 0$ implies $\mathbf{x} \notin \mathcal{H}'$ for all vectors $\mathbf{x}$, the conditional probability that $\mathbf{v}_{1,1} - \psi(\hat{\mathbf{w}}_{1,1}) \notin \mathcal{H}'$ is at least as big as the conditional probability that $\mathbf{h}^T \cdot (\mathbf{v}_{1,1} - \psi(\hat{\mathbf{w}}_{1,1})) > 0$. Since $n\|\mathbf{S}\|\lambda_1(\mathcal{L}(\mathbf{L}_n)) \geq 12\alpha(n)\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ and (6.4) holds true by assumption, Lemma 6.13 tells us that the latter probability is at least 1/6. □

The intuition behind Lemma 6.10 is that vector $\mathbf{s}$ is short because it is a linear combination (with small coefficients $z_i$) of short vectors $\mathbf{y}_{i,j}$ lying within $\psi(\bar{\mathcal{V}}(\mathcal{L}(\mathbf{L}_n)))$. A bound on the length of $\|\mathbf{s}\|$ can be easily computed using the triangle inequality. This would lead to a result similar to the one in Theorem 6.5, but with a larger (by approximately $\sqrt{m(n) \cdot k(n)}$) value of $\gamma(n)$. Here we use cancellations between the $\mathbf{y}_{i,j}$ vectors to prove a better bound.

*Proof of Lemma* 6.10. First, we prove an upper bound on the length of $\mathbf{y}_{i,j} = \mathbf{v}_{i,j} - \psi(\mathbf{w}_{i,j})$ for all $(\mathbf{w}_{i,j}, \mathbf{v}_{i,j})$ in the range of the sampling algorithm of Lemma 6.6. We know from Lemma 6.6 that $\psi^{-1}(\mathbf{v}_{i,j}) \in \bar{\mathcal{V}}(\mathbf{w}_{i,j}, \mathcal{L}(\mathbf{L}_n))$, and therefore $\|\psi^{-1}(\mathbf{v}_{i,j}) - \mathbf{w}_{i,j}\| \leq \rho(\mathcal{L}(\mathbf{L}_n))$. Using (6.4) we immediately get that $\mathbf{y}_{i,j} = \psi(\psi^{-1}(\mathbf{v}_{i,j}) - \mathbf{w}_{i,j})$ has length at most

$$\|\mathbf{y}_{i,j}\| \leq \frac{3n\|\mathbf{S}\| \cdot \rho(\mathcal{L}(\mathbf{L}_n))}{\alpha(n)}. \tag{6.10}$$

Substituting $\alpha(n) = \omega(n\sqrt{k(n)}\beta(n)\rho(\mathcal{L}(\mathbf{L}_n)))$ into (6.10), we get

$$\|\mathbf{y}_{i,j}\| \leq \frac{3\|\mathbf{S}\|}{\omega(\sqrt{k(n)}\beta(n))} = o\left(\frac{\|\mathbf{S}\|}{\sqrt{k(n)}\beta(n)}\right). \tag{6.11}$$

By the triangle inequality and Cauchy–Schwarz, it immediately follows that

$$\|\mathbf{s}\| \leq \sum_{i=1}^{m(n)} |z_i| \sum_{j=1}^{k(n)} \|\mathbf{y}_{i,j}\| \leq \sqrt{m(n)k(n)} \cdot o\left(\frac{\|\mathbf{S}\| \cdot \|\mathbf{z}\|}{\beta(n)}\right).$$

We want to prove a better (probabilistic) bound by computing the conditional expectation of $\|\mathbf{s}\|^2$. Using the definition of $\mathbf{s}$ (6.5), we get

$$\begin{aligned}
\operatorname{Exp}[\|\mathbf{s}\|^2 \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}] &= \operatorname{Exp}\left[\left\langle \sum_{i=1}^{m(n)} \hat{z}_i \sum_{j=1}^{k(n)} \mathbf{y}_{i,j}, \sum_{i'=1}^{m(n)} \hat{z}_{i'} \sum_{j'=1}^{k(n)} \mathbf{y}_{i',j'} \right\rangle \middle| \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}\right] \\
&= \sum_{i,i'} \hat{z}_i \hat{z}_{i'} \sum_{j,j'} \operatorname{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'} \rangle \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}] \\
&\leq \sum_{i,i'} |\hat{z}_i \hat{z}_{i'}| \sum_{j,j'} |\operatorname{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'} \rangle \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}]|.
\end{aligned}$$

We bound each term $\operatorname{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'} \rangle \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}]$ separately. Notice that, given $\mathbf{a} = \hat{\mathbf{a}}$, vector $\mathbf{z} = \mathcal{F}(\mathbf{a}) = \mathcal{F}(\hat{\mathbf{a}})$ depends only on the randomness of oracle $\mathcal{F}$. Therefore, given $\mathbf{a} = \hat{\mathbf{a}}$, $\mathbf{z}$ is independent from $\mathbf{y}_{i,j}$ and $\mathbf{y}_{i',j'}$, and

$$\operatorname{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'} \rangle \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}] = \operatorname{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'} \rangle \mid \mathbf{a} = \hat{\mathbf{a}}]. \tag{6.12}$$

We will bound the value of (6.12) and show that

$$\text{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'}\rangle \mid \mathbf{a} = \hat{\mathbf{a}}] = \begin{cases} o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right) & \text{if } (i,j) = (i',j'), \\ \\ o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)} \cdot \frac{1}{2^{k(n)}}\right) & \text{otherwise.} \end{cases} \tag{6.13}$$

Using (6.13) in the expression for $\text{Exp}[\|\mathbf{s}\|^2 \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}]$, we get

$$\begin{aligned} \text{Exp}[\|\mathbf{s}\|^2 \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}] &\le \left(\sum_{i,j} \hat{z}_i^2 + \sum_{(i,j)\ne(i',j')} \frac{|\hat{z}_i| \cdot |\hat{z}_{i'}|}{2^{k(n)}}\right) \cdot o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right) \\ &\le \left(k(n) \cdot \|\hat{\mathbf{z}}\|^2 + \frac{k(n)^2 \cdot (\sqrt{m(n)}\|\hat{\mathbf{z}}\|)^2}{2^{k(n)}}\right) \cdot o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right) \\ &\le \left(1 + \frac{m(n)k(n)}{2^{k(n)}}\right) \cdot o\left(\frac{\|\mathbf{S}\|^2 \|\hat{\mathbf{z}}\|^2}{\beta(n)^2}\right). \end{aligned}$$

It follows from the concavity of the square root function that

$$\begin{aligned} \text{Exp}[\|\mathbf{s}\| \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}] &= \text{Exp}[\sqrt{\|\mathbf{s}\|^2} \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}] \\ &\le \sqrt{\text{Exp}[\|\mathbf{s}\|^2 \mid \mathbf{a} = \hat{\mathbf{a}}, \mathbf{z} = \hat{\mathbf{z}}]} \\ &\le o\left(\frac{\|\mathbf{S}\| \cdot \|\hat{\mathbf{z}}\|}{\beta(n)}\right) \cdot \sqrt{1 + \frac{m(n)k(n)}{2^{k(n)}}}. \end{aligned}$$

In order to complete the proof of the lemma, we need to prove bound (6.13). The case $(i,j) = (i',j')$ immediately follows from (6.11):

$$\text{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j}\rangle \mid \mathbf{a} = \hat{\mathbf{a}}] \le \max \|\mathbf{y}_{i,j}\|^2 = o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right),$$

where the maximum is over all $\mathbf{y}_{i,j}$ in the support of the sampling algorithm. Now assume $i = i'$, but $j \ne j'$, and let us bound $\text{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'}\rangle \mid \mathbf{a} = \hat{\mathbf{a}}]$. Notice that $a_h$ is independent from $\mathbf{y}_{i,j}$ and $\mathbf{y}_{i,j'}$ for all $h \ne i$. Therefore,

$$\text{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'}\rangle \mid \mathbf{a} = \hat{\mathbf{a}}] = \text{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'}\rangle \mid a_i = \hat{a}_i].$$

We want to bound the conditional expectation of $\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'}\rangle$ given $a_i = \hat{a}_i$. Notice that vectors $\mathbf{y}_{i,j}$ and $\mathbf{y}_{i,j'}$ are statistically independent (because they come from different runs of the sampling procedure) and symmetrically distributed (by Lemma 6.6). Therefore,

$$\text{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'}\rangle] = \langle \text{Exp}[\mathbf{y}_{i,j}], \text{Exp}[\mathbf{y}_{i,j'}]\rangle = \langle \mathbf{0}, \mathbf{0}\rangle = 0. \tag{6.14}$$

Using (6.14), we immediately get

$$|\,\text{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'}\rangle \mid a_i = \hat{a}_i]| = |\,\text{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'}\rangle \mid a_i = \hat{a}_i] - \text{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'}\rangle]|. \tag{6.15}$$

Notice that, by (6.11), for any $\mathbf{y}_{i,j}$ and $\mathbf{y}_{i,j'}$ in the range of the sampling procedure,

$$|\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'}\rangle| \le \|\mathbf{y}_{i,j}\| \cdot \|\mathbf{y}_{i,j'}\| = o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right).$$

Therefore, by Proposition 2.15, the difference (6.15) is at most

$$2 \cdot o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right) \cdot \Delta((\mathbf{y}_{i,j}, \mathbf{y}_{i,j'} \mid a_i = \hat{a}_i), (\mathbf{y}_{i,j}, \mathbf{y}_{i,j'})),$$

where $(\mathbf{y}_{i,j}, \mathbf{y}_{i,j'} \mid a_i = \hat{a}_i)$ is the conditional distribution of $(\mathbf{y}_{i,j}, \mathbf{y}_{i,j'})$ given $a_i$. In the following lemma, we bound $\Delta((\mathbf{y}_{i,j}, \mathbf{y}_{i,j'} \mid a_i = \hat{a}_i), (\mathbf{y}_{i,j}, \mathbf{y}_{i,j'}))$.

LEMMA 6.14. *The statistical distance between* $(\mathbf{y}_{i,j}, \mathbf{y}_{i,j'} \mid a_i = \hat{a}_i)$ *and* $(\mathbf{y}_{i,j}, \mathbf{y}_{i,j'})$ *is at most*

$$\Delta((\mathbf{y}_{i,j}, \mathbf{y}_{i,j'} \mid a_i = \hat{a}_i), (\mathbf{y}_{i,j}, \mathbf{y}_{i,j'})) \le \frac{5}{2(2^{k(n)} - 1)}.$$

*Proof.* Notice that $(\mathbf{y}_{i,j}, \mathbf{y}_{i,j'}) = (\mathbf{v}_{i,j} - \psi(\mathbf{w}_{i,j}), \mathbf{v}_{i,j'} - \psi(\mathbf{w}_{i,j'}))$ is a randomized function of $(\mathbf{w}_{i,j}, \mathbf{w}_{i,j'})$, where $\mathbf{v}_{i,j}$ and $\mathbf{v}_{i,j'}$ are computed according to the conditional distribution of the sampling algorithm (given $\mathbf{w} = \mathbf{w}_{i,j}$ or $\mathbf{w} = \mathbf{w}_{i,j'}$). Therefore, by Proposition 2.13,

$$\Delta((\mathbf{y}_{i,j}, \mathbf{y}_{i,j'} \mid a_i = \hat{a}_i), (\mathbf{y}_{i,j}, \mathbf{y}_{i,j'})) \le \Delta((\mathbf{w}_{i,j}, \mathbf{w}_{i,j'} \mid a_i = \hat{a}_i), (\mathbf{w}_{i,j}, \mathbf{w}_{i,j'})).$$

By Proposition 2.18, the distance between $(\mathbf{w}_{i,j}, \mathbf{w}_{i,j'} \mid a_i = \hat{a}_i)$ and $(\mathbf{w}_{i,j}, \mathbf{w}_{i,j'})$ is at most

$$\begin{aligned}
&\Delta((\mathbf{w}_{i,j}, \mathbf{w}_{i,j'} \mid a_i = \hat{a}_i), (\mathbf{w}_{i,j}, \mathbf{w}_{i,j'})) \\
&\qquad \le \frac{1}{2} \max_{\hat{\mathbf{w}}, \hat{\mathbf{w}}'} \left| \frac{\Pr\{a_i = \hat{a}_i \mid \mathbf{w}_{i,j} = \hat{\mathbf{w}}, \mathbf{w}_{i,j'} = \hat{\mathbf{w}}'\}}{\Pr\{a_i = \hat{a}_i\}} - 1 \right| \\
&\qquad = \frac{1}{2} \max_{\hat{\mathbf{w}}, \hat{\mathbf{w}}'} \left| \frac{\Pr\{\sum_{h \notin \{j,j'\}} a_{i,h} = \hat{a}_i - [\hat{\mathbf{w}}]_{\mathbf{M}_n} - [\hat{\mathbf{w}}']_{\mathbf{M}_n}\}}{\Pr\{\sum_{h=1}^{k(n)} a_{i,h} = \hat{a}_i\}} - 1 \right|.
\end{aligned}$$

By Proposition 2.17, the probability at the denominator equals $(1/\#G_n)(1+\epsilon)$ for some $|\epsilon| \le 2^{-k(n)}$. Similarly, the probability at the numerator equals $(1/\#G_n)(1+\epsilon')$ for some $|\epsilon'| \le 2^{-(k(n)-2)}$. It follows that

$$\begin{aligned}
\Delta((\mathbf{w}_{i,j}, \mathbf{w}_{i,j'} \mid a_i = \hat{a}_i), (\mathbf{w}_{i,j}, \mathbf{w}_{i,j'})) &\le \frac{1}{2} \left| \frac{(1/\#G_n)(1+\epsilon')}{(1/\#G_n)(1+\epsilon)} - 1 \right| \\
&= \frac{1}{2} \left| \frac{\epsilon' - \epsilon}{1+\epsilon} \right| \\
&\le \frac{1}{2} \frac{|\epsilon'| + |\epsilon|}{1 - |\epsilon|} \\
&\le \frac{5}{2(2^{k(n)} - 1)}. \qquad \square
\end{aligned}$$

Using Lemma 6.14, we get that

$$\operatorname{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i,j'} \rangle \mid \mathbf{a} = \hat{\mathbf{a}}] \le 2 \cdot o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right) \cdot \frac{5}{2(2^{k(n)} - 1)} = o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)} \cdot \frac{1}{2^{k(n)}}\right),$$

proving (6.13) for the case when $i = i'$ and $j \ne j'$.

The case when $i \ne i'$ is similar. Consider the conditional distribution of $\mathbf{y}_{i,j}, \mathbf{y}_{i',j'}$ given $\mathbf{a} = \hat{\mathbf{a}}$. Notice that $a_h$ is independent from $\mathbf{y}_{i,j}$ and $\mathbf{y}_{i',j'}$ for all $h \notin \{i, i'\}$. Therefore,

$$\operatorname{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'} \rangle \mid \mathbf{a} = \hat{\mathbf{a}}] = \operatorname{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'} \rangle \mid a_i = \hat{a}_i, a_{i'} = \hat{a}_{i'}].$$

Moreover, $\mathbf{y}_{i,j}$ and $a_i$ are independent from $\mathbf{y}_{i',j'}$ and $a_{i'}$ because they come from different runs of the sampling algorithm. Therefore,

$$\begin{aligned}\mathrm{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'}\rangle \mid a_i = \hat{a}_i, a_{i'} = \hat{a}_{i'}] &= \mathrm{Exp}[\langle (\mathbf{y}_{i,j} \mid a_i = \hat{a}_i), (\mathbf{y}_{i',j'} \mid a_{i'} = \hat{a}_{i'})\rangle] \\ &= \langle \mathrm{Exp}[\mathbf{y}_{i,j} \mid a_i = \hat{a}_i], \mathrm{Exp}[\mathbf{y}_{i',j'} \mid a_{i'} = \hat{a}_{i'}]\rangle,\end{aligned}$$

where, as usual, $(\mathbf{y}_{i,j} \mid a_i = \hat{a}_i)$ (resp., $(\mathbf{y}_{i',j'} \mid a_{i'} = \hat{a}_{i'})$) is the conditional distribution of $\mathbf{y}_{i,j}$ given $a_i$ (resp., $\mathbf{y}_{i',j'}$ given $a_{i'}$). Let $\mathbf{y} = \mathrm{Exp}[\mathbf{y}_{i',j'} \mid a_{i'} = \hat{a}_{i'}]$. We know from (6.11) that $\|\mathbf{y}\| = o(\|\mathbf{S}\|/(\beta(n)\sqrt{k(n)}))$. Since $\mathbf{y}_{i,j}$ is symmetrically distributed, $\langle \mathrm{Exp}[\mathbf{y}_{i,j}], \mathbf{y}\rangle = \langle \mathbf{0}, \mathbf{y}\rangle = 0$, and

$$\begin{aligned}\mathrm{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'}\rangle \mid a_i = \hat{a}_i, a_{i'} = \hat{a}_{i'}] &= \langle \mathrm{Exp}[\mathbf{y}_{i,j} \mid a_i = \hat{a}_i], \mathbf{y}\rangle \\ &= \langle \mathrm{Exp}[\mathbf{y}_{i,j} \mid a_i = \hat{a}_i], \mathbf{y}\rangle - \langle \mathrm{Exp}[\mathbf{y}_{i,j}], \mathbf{y}\rangle \\ &= \mathrm{Exp}[\langle (\mathbf{y}_{i,j} \mid a_i = \hat{a}_i), \mathbf{y}\rangle] - \mathrm{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}\rangle].\end{aligned}$$

Notice that, by (6.11), for all $\mathbf{y}_{i,j}$ in the range of the sampling algorithm

$$|\langle \mathbf{y}_{i,j}, \mathbf{y}\rangle| \le \|\mathbf{y}_{i,j}\| \cdot \|\mathbf{y}\| = o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right).$$

Therefore, by Proposition 2.15, the difference between $\mathrm{Exp}[\langle (\mathbf{y}_{i,j} \mid a_i = \hat{a}_i), \mathbf{y}\rangle]$ and $\mathrm{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}\rangle]$ is at most

$$2 \cdot o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right) \cdot \Delta((\mathbf{y}_{i,j} \mid a_i = \hat{a}_i), (\mathbf{y}_{i,j})).$$

Since (for any $j'$) vector $\mathbf{y}_{i,j}$ is a function of $(\mathbf{y}_{i,j}, \mathbf{y}_{i,j'})$, by Proposition 2.13 and Lemma 6.14,

$$\Delta((\mathbf{y}_{i,j} \mid a_i = \hat{a}_i), (\mathbf{y}_{i,j})) \le \Delta((\mathbf{y}_{i,j}, \mathbf{y}_{i,j'} \mid a_i = \hat{a}_i), (\mathbf{y}_{i,j}, \mathbf{y}_{i,j'})) \le \frac{5}{2(2^{k(n)} - 1)}.$$

So, also in this case we have

$$\begin{aligned}\mathrm{Exp}[\langle \mathbf{y}_{i,j}, \mathbf{y}_{i',j'}\rangle \mid \mathbf{a} = \hat{\mathbf{a}}] &\le 2 \cdot o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)}\right) \cdot \frac{5}{2(2^{k(n)} - 1)} \\ &= o\left(\frac{\|\mathbf{S}\|^2}{\beta(n)^2 k(n)} \cdot \frac{1}{2^{k(n)}}\right). \qquad \square\end{aligned}$$

**7. Applications.** In the previous section we proved (Theorems 6.3 and 6.5) that the problem of finding $n$ linearly independent lattice vectors of length not much bigger than the generalized uniform radius (in the worst case) reduces to the problem of finding small integer solutions to random linear equations on the average. In this section we show how this result can be reformulated as a connection between the average-case and worst-case complexity of various lattice approximation problems. As usual, we refer to the average-case problem as the problem of finding a nonzero integer solution to a random linear equation, but we stress that this is equivalent to finding (approximately) shortest vectors in a random lattice.

We also show that our results imply the existence of provably secure cryptographic (collision resistant) hash functions based on the worst-case hardness of lattice approximation problems.

COROLLARY 7.1. *Let $\tau(n) = n^{O(1)}$ be a function such that there exists a family of $\tau(n)$-perfect easily decodable lattices. For every polynomially bounded function $\mu(m) = m^{O(1)}$ and $m(n) = \Omega(n \log n)$, there exists a sequence of groups $\{G_n\}$ of size $\#G_n = n^{O(n)}$ such that the following is true. If there is a probabilistic polynomial time algorithm $\mathcal{F}$ that on input a uniformly chosen random equation $\mathbf{g} \in G_n^{m(n)}$, outputs with nonnegligible probability a nonzero solution $\mathcal{F}(\mathbf{g}) \in \Lambda(\mathbf{g})$ of length within a factor $\mu(m(n))$ from the shortest (or, more generally, within a factor $\mu(m(n))$ from Minkowski's bound* (2.2)*), then there is a probabilistic polynomial time algorithm that on input any rank $n$ lattice basis $\mathbf{B}$ solves, in the worst case and with high probability, any of the following problems, where $\omega(1)$ is an arbitrary superconstant and polynomially bounded function of $n$:*

1. [SIVP] *Find a set $\mathbf{S} \subseteq \mathcal{L}(\mathbf{B})$ of $n$ linearly independent vectors such that*

$$\|\mathbf{S}\| \leq \omega(1) \cdot \mu(m(n)) \cdot n^{1.5} \cdot \tau(n) \cdot \sqrt{m(n) \cdot \log n} \cdot \lambda_n(\mathcal{L}(\mathbf{B})).$$

2. [GAPSVP] *Compute an approximation $\hat{\lambda}_1$ such that*

$$\frac{\lambda_1(\mathcal{L}(\mathbf{B}))}{\omega(1) \cdot \mu(m(n)) \cdot n^2 \cdot \tau(n) \cdot \sqrt{m(n) \cdot \log n}} \leq \hat{\lambda}_1 \leq \lambda_1(\mathcal{L}(\mathbf{B})).$$

3. [GAPCRP] *Compute an approximation $\hat{\rho}$ such that*

$$\rho(\mathcal{L}(\mathbf{B})) \leq \hat{\rho} \leq \omega(1) \cdot \mu(m(n)) \cdot n^{1.5} \cdot \tau(n) \cdot \sqrt{m(n) \cdot \log n} \cdot \rho(\mathcal{L}(\mathbf{B})).$$

4. [GDD] *Given also a target vector $\mathbf{t} \in \operatorname{span}(\mathbf{B})$, find a lattice vector $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ such that*

$$\|\mathbf{v} - \mathbf{t}\| \leq \omega(1) \cdot \mu(m(n)) \cdot n^{1.5} \cdot \tau(n) \cdot \sqrt{m(n) \cdot \log n} \cdot \rho(\mathcal{L}(\mathbf{B})).$$

*Proof.* Let $\beta(n) = \sqrt{\omega(1) \cdot m(n)} \cdot \mu(m(n))$, $\gamma(n) = \beta(n)\tau(n)\sqrt{\omega(1) \cdot \log n}$ and $G_n$ be as defined in Theorem 6.5. Notice that $\gamma(n) \leq \omega(1) \cdot \sqrt{m(n) \cdot \log n} \cdot \tau(n) \cdot \mu(m(n)) = n^{O(1)}$ and $\#G_n \leq (n^{1.5}\gamma(n)/8)^n = n^{O(n)}$. Therefore, by Theorem 5.5, any equation $\mathbf{g} \in G_n^{m(n)}$ has a nonzero solution of length at most $O(\sqrt{m(n)})$. Let $\mathcal{F}(\cdot)$ be a probabilistic polynomial time algorithm to find nonzero solutions of length within a factor $\mu(m(n))$ from the shortest (with nonnegligible probability). We know that, when successful, $\mathcal{F}(\cdot)$ finds solutions of length at most

$$\|\mathcal{F}(\mathbf{g})\| \leq \mu(m(n)) O(\sqrt{m(n)}) \leq \beta(n).$$

So, algorithm $\mathcal{F}(\cdot)$ solves $\mathrm{HSIS}_{G,m,\beta}$ on the average with nonnegligible probability. Combining $\mathcal{F}$ with the reductions from Theorems 6.5 and 6.3, we get a polynomial time algorithm $\mathcal{S}(\cdot)$ that solves $\mathrm{GIVP}_\gamma^{\hat{\zeta}}$ (in the worst case and with high probability) for approximation factor

$$\gamma(n) = \beta(n) \cdot \tau(n) \cdot \sqrt{\omega(1) \cdot \log n} = \omega(1) \cdot \sqrt{m(n) \cdot \log n} \cdot \mu(m(n)) \cdot \tau(n).$$

We show how to use this algorithm to solve all the worst-case problems in the conclusion of the corollary.

1. [SIVP] Just run $\mathbf{S} = \mathcal{S}(\mathbf{B})$ and output $\mathbf{S}$. By (3.1),

$$\begin{aligned}\|\mathbf{S}\| \leq \gamma(n) \cdot \hat{\zeta}(\mathcal{L}(\mathbf{B})) &\leq \frac{3}{2} n^{1.5} \cdot \gamma(n) \cdot \lambda_n(\mathcal{L}(\mathbf{B})) \\ &= \frac{3}{2} \omega(1) \cdot n^{1.5} \cdot \tau(n) \cdot \mu(m(n)) \cdot \sqrt{m(n) \cdot \log n} \cdot \lambda_n(\mathcal{L}(\mathbf{B})).\end{aligned}$$

2. [GapSVP] On input basis $\mathbf{B}$, run $\mathbf{S} = \mathcal{S}(\mathbf{B}^*)$, where $\mathbf{B}^*$ is the basis of the dual lattice, and output $1/\|\mathbf{S}\|$. By (2.5),

$$\|\mathbf{S}\| \geq \lambda_n(\mathcal{L}(\mathbf{B})^*) \geq \frac{1}{\lambda_1(\mathcal{L}(\mathbf{B}))}.$$

Also, by (3.2),

$$\begin{aligned}\|\mathbf{S}\| \leq \gamma(n) \cdot \hat{\zeta}(\mathcal{L}(\mathbf{B})^*) &\leq \frac{3}{2}n^2 \cdot \gamma(n)/\lambda_1(\mathcal{L}(\mathbf{B})) \\ &= \frac{3}{2}\omega(1) \cdot n^2 \cdot \tau(n) \cdot \mu(m(n)) \cdot \sqrt{m(n) \cdot \log n}/\lambda_1(\mathcal{L}(\mathbf{B})).\end{aligned}$$

3. [GapCRP] This time, we run $\mathbf{S} = \mathcal{S}(\mathbf{B})$ and output $\sqrt{n}\|\mathbf{S}\|/2$. By (2.3),

$$\sqrt{n}\|\mathbf{S}\|/2 \geq (\sqrt{n}/2)\lambda_n(\mathcal{L}(\mathbf{B})) \geq \rho(\mathcal{L}(\mathbf{B})).$$

Moreover, by Theorem 3.6,

$$\sqrt{n}\|\mathbf{S}\|/2 \leq \frac{3}{2}n^{1.5}\cdot\gamma(n)\cdot\rho(\mathcal{L}(\mathbf{B})) = \frac{3}{2}\omega(1)\cdot n^{1.5}\cdot\tau(n)\cdot\mu(m(n))\cdot\sqrt{m(n)\cdot\log n}\cdot\rho(\mathcal{L}(\mathbf{B})).$$

4. [GDD] In order to find a lattice point close to target $\mathbf{t}$, we first run $\mathbf{S} = \mathcal{S}(\mathbf{B})$ and then execute Babai's nearest plane algorithm [6] using sublattice $\mathbf{S}$ and target $\mathbf{t}$. The result is a point within distance $\sqrt{n}\|\mathbf{S}\|/2$ from the target. As in the proof for the CRP, this bound satisfies

$$\sqrt{n}\|\mathbf{S}\|/2 \leq \frac{3}{2}\omega(1) \cdot n^{1.5} \cdot \tau(n) \cdot \mu(m(n)) \cdot \sqrt{m(n) \cdot \log n} \cdot \rho(\mathcal{L}(\mathbf{B})). \qquad \square$$

Notice that in the proof of Corollary 7.1, the definition of group $G_n$ implicitly depends on the function $m(n)$. This is because in Theorem 6.5 the definition of group $G_n$ depends on the value of $\alpha(n)$, which in turn depends (via $\gamma(n)$) on the value of $\beta(n)$. Moreover, the definition of $\beta(n)$ in the proof of Corollary 7.1 depends on $\mu(m(n))$. So, unless $\mu(\cdot)$ is a constant function, group $G_n$ can be selected only after the value of $m(n)$ has been chosen. The following corollary immediately follows from Corollary 7.1 by setting $m(n) = \Theta(n \log n)$ and $\mu(m) = 1$ and observing that the definition of group $G_n$ does not depend on $m(n)$ when $\mu(m)$ is constant.

Corollary 7.2. *Let $\tau(n) = n^{O(1)}$ be a function such that there exists a family of $\tau(n)$-perfect easily decodable lattices. For every superlogarithmic function $\omega(\log n)$, there exists a sequence of groups $\{G_n\}$ of size $\#G_n = n^{O(n)}$ such that for any $m(n) = \Theta(n \log n)$, the following is true. If there is a probabilistic polynomial time algorithm $\mathcal{F}(\cdot)$ that on input a uniformly chosen random equation $\mathbf{g} \in G_n^{m(n)}$, outputs with non-negligible probability a shortest nonzero solution $\mathcal{F}(\mathbf{g}) \in \Lambda(\mathbf{g})$ (or, more generally, a solution satisfying Minkowski's bound* (2.2) $\|\mathcal{F}(\mathbf{g})\| \leq \sqrt{m(n)}\cdot\det(\Lambda(\mathbf{g}))^{1/m(n)}$*), then there is a probabilistic polynomial time algorithm that on input any rank n lattice basis* $\mathbf{B}$ *solves, in the worst case and with high probability, any of the following problems:*

1. [SIVP] *Find a maximal set of linearly independent vectors of length within* $n^2 \cdot \tau(n) \cdot \omega(\log n)$ *from the shortest.*
2. [GapSVP] *Approximate* $\lambda_1(\mathcal{L}(\mathbf{B}))$ *within a factor* $n^{2.5} \cdot \tau(n) \cdot \omega(\log n)$.
3. [GapCRP] *Approximate* $\rho(\mathcal{L}(\mathbf{B}))$ *within a factor* $n^2 \cdot \tau(n) \cdot \omega(\log n)$.
4. [GDD] *Given also a target vector* $\mathbf{t} \in \operatorname{span}(\mathbf{B})$, *find a lattice vector* $\mathbf{v} \in \mathcal{L}(\mathbf{B})$ *within distance* $n^2 \cdot \tau(n) \cdot \omega(\log n) \cdot \rho(\mathcal{L}(\mathbf{B}))$ *from* $\mathbf{t}$.

We now turn to the construction of collision resistant hash functions. Following [18], for any $\mathbf{g} \in G_n^{m(n)}$, define function $h_{\mathbf{g}}\colon \{0,1\}^{m(n)} \to G_n$ by

$$h_{\mathbf{g}}(\mathbf{x}) = \sum_{i=1}^{n} g_i x_i.$$

Notice that function $h_{\mathbf{g}}$ maps $m(n)$ bits to $\log_2 \#G$ bits. If $m(n) > \log_2 \#G$, then the function compresses the input $\mathbf{x}$, and collisions $h_{\mathbf{g}}(\mathbf{x}) = h_{\mathbf{g}}(\mathbf{y})$ (for $\mathbf{x} \neq \mathbf{y}$) are guaranteed to exist by the pigeon hole principle. We prove that, if the key $\mathbf{g}$ is chosen at random, then these collisions are computationally hard to find.

COROLLARY 7.3. *Let $\tau(n) = n^{O(1)}$ be a function such that there exists a family of $\tau(n)$-perfect easily decodable lattices. For every superlogarithmic function $\omega(\log n)$, there exists a sequence of groups $\{G_n\}$ of size $\#G_n = n^{O(n)}$ such that the following is true. Assume no probabilistic polynomial time algorithm can solve problems* SIVP, GAPSVP, GAPCRP, *or* GDD *(in the worst case and with high probability) within the factors specified in Corollary 7.2. Then for any $c > 1$ and $m(n) = \max\{c \cdot \log_2 \#G_n, \Theta(n \log n)\}$, there exists no probabilistic polynomial time algorithm that on input a random key $\mathbf{g} \in G_n^{m(n)}$ outputs with nonnegligible probability an $h_{\mathbf{g}}$-collision, i.e., two binary vectors $\mathbf{x} \neq \mathbf{y}$ such that $h_{\mathbf{g}}(\mathbf{x}) = h_{\mathbf{g}}(\mathbf{y})$.*

*Proof.* Notice that $m(n) \geq c \cdot \log_2 \#G_n$, so function $h_{\mathbf{g}}$ is a hash function with compression ratio $c$. Assume, for contradiction, that $\mathcal{F}(\mathbf{g}) = (\mathbf{x}, \mathbf{y})$ is a collision finder algorithm with nonnegligible success probability, and notice that if $\mathcal{F}$ is successful, then $\mathbf{x} - \mathbf{y} \in \Lambda(\mathbf{g}) \setminus \{\mathbf{0}\}$ is a nonzero solution to equation $\mathbf{g}$ of length at most

$$\|\mathbf{x} - \mathbf{y}\| \leq \sqrt{m(n)}.$$

Since $\Lambda(\mathbf{g})$ is a sublattice of $\mathbb{Z}^n$, $\det(\Lambda(\mathbf{g})) \geq \det(\mathbb{Z}^n) = 1$, and solution $\mathbf{x} - \mathbf{y} \in \Lambda(\mathbf{g})$ satisfies Minkowski's bound (2.2)

$$\|\mathbf{x} - \mathbf{y}\| \leq \sqrt{m(n)} \leq \sqrt{m(n)}\det(\Lambda(\mathbf{g}))^{1/m(n)}.$$

In order to apply Corollary 7.2 and get a contradiction, we need only to show that $m(n) = \Theta(n \log n)$. The lower bound $m(n) = \Omega(n \log n)$ immediately follows from the definition of $m(n) \geq \Theta(n \log n)$. The upper bound $m(n) = O(n \log n)$ follows from the fact that $\#G_n = n^{O(n)}$. This proves that $m(n) = \Theta(n \log n)$, and by Corollary 7.2 there exist probabilistic polynomial time algorithms to approximately solve SIVP, GAPSVP, GAPCRP, and GDD in the worst case and with high probability. ∎

We conclude the section with two remarks about the choice of the groups $G_n$ in the previous corollaries.

*Remark.* It can be shown that the groups $G_n$ defined in the proofs of Corollaries 7.1, 7.2, and 7.3 have size $\#G_n = n^{\Theta(n)}$. In particular, in Corollary 7.3, we could have simply defined $m(n) = c \log_2 \#G_n$, instead of $\max\{c \log_2 \#G_n, \Theta(n \log n)\}$, because $c \log_2 \#G_n = \Theta(n \cdot \log n)$.

*Remark.* Corollaries 7.1, 7.2, and 7.3 are pretty flexible in terms of the choice of group $G_n$. The only property required for the proof to go through is that $G_n$ is a group of size $n^{\Theta(n)}$ that can be represented as the quotient of an easily decodable $\tau(n)$-perfect lattice $\mathcal{L}(\mathbf{L}_n)$ modulo a sublattice $\mathcal{L}(\mathbf{M}_n)$ such that (6.2) holds true.

**8. Conclusion and open problems.** We related the computational complexity of finding (approximately) shortest nonzero integer solutions to random linear equations with coefficients in a suitably chosen group (on the average and with non-negligible probability) to the worst-case complexity of approximating various lattice problems. Since the set of integer solutions to a homogeneous linear equation forms a lattice, the result can be interpreted as a connection between the average-case and worst-case complexity of various lattice problems. The connection immediately also gives provably secure cryptographic hash functions that are as hard to break on the average as the worst-case complexity of approximating various lattice problems within polynomial factors. The worst-case approximation factors achieved depend on the class of easily decodable lattices used in the definition of the class of equations (or cryptographic hash functions). In particular, if $\tau(n)$-perfect easily decodable lattices are used, then finding shortest solutions to random equations (or finding collisions to hash functions) is at least as hard as approximating the length of the shortest vector in any lattice, in the worst case, within a factor $\gamma(n) = n^{2.5}\tau(n)\omega(\log n)$. Even for $\tau(n) = \sqrt{n}$ (which corresponds, as a special case, to Ajtai's random class of equations), this improves the previously known best connection factor of [11] by more than $O(n)$. We also showed that finding shortest solutions to random equations is at least as hard as approximating within a factor $n^2\tau(n)\omega(\log n)$ any of the following problems:

(i) [SIVP] computing a maximal set of shortest linearly independent vectors,
(ii) [GapCRP] computing the covering radius, and
(iii) [GDD] computing a lattice vector within distance $\max_{\mathbf{x}} \operatorname{dist}(\mathbf{x}, \mathcal{L}(\mathbf{B}))$ from a given target,

improving [11] in the case of SIVP by more than $O(\sqrt{n})$, and connecting the average case complexity of solving random equations to two new computational problems on lattices that might be of independent interest.

We also gave polynomial time constructions of easily decodable $\tau(n)$-perfect lattices with $\tau(n) = o(\sqrt{n})$. These constructions allow us to achieve approximation factors $n^{2.5}\omega(\sqrt{\log n \log\log n})$ (for SIVP, GapCRP, and GDD) and $n^3\omega(\sqrt{\log n \log\log n})$ (for SVP). While this improvement over $\tau(n) = \sqrt{n}$ is not substantial, it suggests that further investigation of almost perfect lattices might allow us to find easily decodable $\tau(n)$-perfect lattices with much smaller $\tau(n)$, e.g., $\tau(n) = n^\epsilon$ or even $\tau(n) = O(1)$. This would immediately reduce the approximation factor for all the above problems by about $\sqrt{n}$.

Another possible source of improvement are better bounds relating the fundamental constants associated to a lattice. Our main theorem (Theorem 6.5) shows that finding short solutions on the average is at least as hard as finding vectors that are not much longer than a new lattice quantity called the generalized uniform radius. All other results are obtained by first relating the generalized uniform radius to the covering radius (Theorem 3.6), and then bounding the covering radius in terms of other lattice constants using standard transference theorems and other well-known bounds (Proposition 2.8). In particular, (3.1) and (3.2) show that the generalized uniform radius $\hat{\zeta}(\mathcal{L}(\mathbf{B}))$ is at most $O(n^{1.5})$ times $\lambda_n(\mathcal{L}(\mathbf{B}))$ or at most $O(n^2)$ times $1/\lambda_1(\mathcal{L}(\mathbf{B})^*)$. It would be interesting to improve (3.1) and (3.2) to show, for example, that

$$\hat{\zeta}(\mathcal{L}(\mathbf{B})) \leq O(n)\lambda_n(\mathcal{L}(\mathbf{B})) \tag{8.1}$$

and

$$\hat{\zeta}(\mathcal{L}(\mathbf{B})) \leq O(n)/\lambda_1(\mathcal{L}(\mathbf{B})^*). \tag{8.2}$$

Whether these bounds hold true is a natural geometric question, and proving them would be of independent interest. Moreover, it would allow us to reduce the approximation factors for SIVP and SVP by $O(\sqrt{n})$ and $O(n)$, respectively. Together with the construction of better almost perfect easily decodable lattices, this would immediately improve the approximation factors for both SVP and SIVP to just $n^{1.5}\omega(\log n)$. Connections with such small approximation factors are currently known only for restrictions of the (worst-case) SVP to lattices with special structure where the shortest vector is unique in some technical sense [39].

Notice that by (2.5), bound (8.2) would also imply (8.1). Also, (8.2), if correct, would be asymptotically optimal because Conway and Thompson (see [37]) showed that there exist self-dual lattices such that $\rho(\mathcal{L}(\mathbf{B})) \cdot \lambda_1(\mathcal{L}(\mathbf{B})^*) \geq O(n)$, and by Proposition 3.2 $\rho(\mathcal{L}(\mathbf{B})) \leq \zeta(\mathcal{L}(\mathbf{B})) \leq \hat{\zeta}(\mathcal{L}(\mathbf{B}))$. We conjecture that (8.2) holds true and that there exist classes of random equations such that finding shortest nonzero solutions on the average (with nonnegligible probability) is at least as hard as approximating the length of the shortest nonzero vector (or finding a maximal set of shortest linearly independent vectors) in any $n$-dimensional lattice within a factor $n^{1.5}\omega(\log n)$.

**Acknowledgments.** The author would like to thank Ravi Kannan and Alex Vardy for interesting discussions and pointers to relevant references, Oded Regev and an anonymous reviewer for their many and valuable comments that helped to simplify and improve the presentation, and Oded Goldreich for his invaluable feedback about the paper.

# SMALL SPANS IN SCALED DIMENSION*

JOHN M. HITCHCOCK†

**Abstract.** Juedes and Lutz [*SIAM J. Comput.*, 24 (1995), pp. 279–295] proved a *small span theorem* for polynomial-time many-one reductions in exponential time. This result says that for language $A$ decidable in exponential time, either the class of languages reducible to $A$ (the lower span) or the class of problems to which $A$ can be reduced (the upper span) is small in the sense of resource-bounded measure and, in particular, that the degree of $A$ is small. Small span theorems have been proved for increasingly stronger polynomial-time reductions, and a small span theorem for polynomial-time Turing reductions would imply BPP $\neq$ EXP. In contrast to the progress in resource-bounded measure, Ambos-Spies et al. [*Proceedings of the* 16*th IEEE Conference on Computational Complexity*, Philadelphia, PA, IEEE Computer Society, Los Alamitos, CA, 2001, pp. 210–217] showed that there is no small span theorem for the resource-bounded dimension of Lutz [*SIAM J. Comput.*, 32 (2003), pp. 1236–1259], even for polynomial-time many-one reductions.

Resource-bounded scaled dimension, recently introduced by Hitchcock, Lutz, and Mayordomo [*J. Comput. System Sci.*, 69 (2004), pp. 97–122], provides rescalings of resource-bounded dimension. We use scaled dimension to further understand the contrast between measure and dimension regarding polynomial-time spans and degrees. We strengthen prior results by showing that the small span theorem holds for polynomial-time many-one reductions in the $-3$rd-order scaled dimension, but fails to hold in the $-2$nd-order scaled dimension. Our results also hold in exponential space.

As an application, we show that determining the $-2$nd- or $-1$st-order scaled dimension in ESPACE of the many-one complete languages for E would yield a proof of P = BPP or P $\neq$ PSPACE. On the other hand, it is shown unconditionally that the complete languages for E have $-3$rd-order scaled dimension 0 in ESPACE and $-2$nd- and $-1$st-order scaled dimension 1 in E.

**Key words.** resource-bounded dimension, small span theorems, polynomial-time degrees

## 1. Introduction.

Resource-bounded measure [16] defines the relative size of classes of decision problems and has been used very successfully to study polynomial-time reductions within exponential-time complexity classes. Measure-theoretic arguments were the first to show that for all $\alpha < 1$, every $\leq^{\mathrm{p}}_{n^\alpha-\mathrm{tt}}$-hard language for exponential time is exponentially dense [19]. The first plausible hypothesis on NP to separate the $\leq^{\mathrm{p}}_{\mathrm{m}}$ and $\leq^{\mathrm{p}}_{\mathrm{T}}$ reducibilities within NP came from resource-bounded measure [20].

The *degrees* and *spans* of languages under polynomial-time reductions have also been studied by several researchers using resource-bounded measure. For a reducibility $\leq^{\mathrm{p}}_r$ and any $A \subseteq \{0,1\}^*$, the $\leq^{\mathrm{p}}_r$-*lower span of* $A$ is the class $\mathrm{P}_r(A)$ of all languages that are $\leq^{\mathrm{p}}_r$-reducible to $A$, the $\leq^{\mathrm{p}}_r$-*upper span of* $A$ is the class $\mathrm{P}_r^{-1}(A)$ of all languages to which $A$ is $\leq^{\mathrm{p}}_r$-reducible, and the $\leq^{\mathrm{p}}_r$-*degree of* $A$ is the class $\deg^{\mathrm{p}}_r(A) = \mathrm{P}_r(A) \cap \mathrm{P}_r^{-1}(A)$. Juedes and Lutz [12] proved the following *small span theorem* for $\leq^{\mathrm{p}}_{\mathrm{m}}$-reductions in both E and in EXP. Here the notation $\mu(\mathcal{C} \mid \mathcal{D})$ denotes the *measure of* $\mathcal{C}$ *within* $\mathcal{D}$, where $\mathcal{D}$ is a suitable complexity class. If $\mu(\mathcal{C} \mid \mathcal{D}) = 0$, then intuitively $\mathcal{C} \cap \mathcal{D}$ is a negligible subset of $\mathcal{D}$.

THEOREM 1.1 (Juedes and Lutz [12]). *Let $\mathcal{D} \in \{\mathrm{E}, \mathrm{EXP}\}$. For every $A \in \mathcal{D}$,*

$$\mu(\mathrm{P_m}(A) \mid \mathcal{D}) = 0$$

*or*

$$\mu(\mathrm{P_m^{-1}}(A) \mid \mathcal{D}) = 0.$$

*In particular,* $\mu(\deg^{\mathrm{p}}_{\mathrm{m}}(A) \mid \mathcal{D}) = 0$.

That is, at least one of the upper or lower spans of $A$ is small within $\mathcal{D}$. Using a result of Bennett and Gill [4], Juedes and Lutz [12] noted that strengthening Theorem 1.1 from $\leq^{\mathrm{p}}_{\mathrm{m}}$-reductions to $\leq^{\mathrm{p}}_{\mathrm{T}}$-reductions would achieve the separation BPP $\neq$ EXP. Pursuing this program, small span theorems for reductions of progressively increasing strength between $\leq^{\mathrm{p}}_{\mathrm{m}}$ and $\leq^{\mathrm{p}}_{\mathrm{T}}$ have been obtained by Lindner [14], Ambos-Spies, Neis, and Terwijn [3], and Buhrman and van Melkebeek [6].

Resource-bounded dimension was introduced by Lutz [18] as an effectivization of Hausdorff dimension [9] to investigate the fractal structure of complexity classes. Just like resource-bounded measure, resource-bounded dimension is defined within suitable complexity classes $\mathcal{D}$. For any complexity class $\mathcal{C}$, the *dimension of $\mathcal{C}$ within $\mathcal{D}$* is a real number in $[0, 1]$ and is denoted by $\dim(\mathcal{C} \mid \mathcal{D})$. If $\dim(\mathcal{C} \mid \mathcal{D}) < 1$, then $\mu(\mathcal{C} \mid \mathcal{D}) = 0$, but the converse may fail. This means that resource-bounded dimension is capable of quantitatively distinguishing among the measure 0 sets. With regard to the measure 0 sets in Theorem 1.1, Ambos-Spies, Merkle, Reimann, and Stephan [2] proved the following.

THEOREM 1.2 (Ambos-Spies et al. [2]). *For every $A \in \mathrm{E}$,*

$$\dim(\deg^{\mathrm{p}}_{\mathrm{m}}(A) \mid \mathrm{E}) = \dim(\mathrm{P_m}(A) \mid \mathrm{E}).$$

In particular, as $\dim(\mathrm{E} \mid \mathrm{E}) = 1$, the $\leq^{\mathrm{p}}_{\mathrm{m}}$-complete degree for E has dimension 1 within E. This implies that replacing "$\mu$" by "dim" in Theorem 1.1 makes the statement for E no longer true. In other words, there is no analogue of the small span theorem for dimension in E. Dimension in E cannot distinguish between lower spans and degrees.

To overcome limitations of resource-bounded dimension for investigating complexity classes within ESPACE, Hitchcock, Lutz, and Mayordomo [11] introduced for each integer $i \in \mathbb{Z}$ an *ith-order scaled dimension* $\dim^{(i)}(\cdot \mid \mathcal{D})$. For any class $\mathcal{C}$ and $i \in \mathbb{Z}$, $\dim^{(i)}(\mathcal{C} \mid \mathcal{D}) \in [0, 1]$, and if it is less than 1, then $\mu(\mathcal{C} \mid \mathcal{D}) = 0$. The quantity $\dim^{(i)}(\mathcal{C} \mid \mathcal{D})$ is nondecreasing in $i$, and there is at most one $i \in \mathbb{Z}$ for which $0 < \dim^{(i)}(\mathcal{C} \mid \mathcal{D}) < 1$. The 0th-order dimension, $\dim^{(0)}(\cdot \mid \mathcal{D})$, is precisely the standard unscaled dimension, and the other orders can be more useful than it for certain complexity classes. To illustrate this, we mention some examples from circuit-size complexity. For a function $s : \mathbb{N} \to \mathbb{N}$, let $\mathrm{SIZE}(s(n))$ consist of all languages decidable by nonuniform Boolean circuit families of size at most $s(n)$. Lutz [18] showed that

$$\dim\left(\mathrm{SIZE}\left(\alpha\frac{2^n}{n}\right)\middle|\,\mathrm{ESPACE}\right) = \alpha \tag{1.1}$$

for all $\alpha \in (0, 1)$. Circuit size bounds of the form $2^{\alpha n}$ and $2^{n^\alpha}$ are typically of more interest in complexity theory, but (1.1) implies that $\mathrm{SIZE}(2^{\alpha n})$ and $\mathrm{SIZE}(2^{n^\alpha})$ have dimension 0 in ESPACE for all $\alpha \in (0,1)$. For these size bounds, the scaled dimensions are useful; in [11] it is shown that

$$\dim^{(1)}(\mathrm{SIZE}(2^{\alpha n}) \mid \mathrm{ESPACE}) = \alpha$$

and

$$\dim^{(2)}(\mathrm{SIZE}(2^{n^\alpha}) \mid \mathrm{ESPACE}) = \alpha$$

for any $\alpha \in (0,1)$.

This paper uses scaled dimension to investigate polynomial-time spans and degrees and further understand the contrast between Theorems 1.1 and 1.2. We show that the same dichotomy also occurs between the −3rd- and −2nd-orders of scaled dimension. The main contribution of this paper is a strengthening of Theorem 1.1 to give a small span theorem for scaled dimension. (The following is a corollary of a stronger result proved in Theorem 6.3.)

Theorem 1.3. *Let* $\mathcal{D} \in \{\mathrm{E}, \mathrm{EXP}, \mathrm{ESPACE}, \mathrm{EXPSPACE}\}$. *For every* $A \in \mathcal{D}$,

$$\dim^{(-3)}(\mathrm{P_m}(A) \mid \mathcal{D}) = 0$$

*or*

$$\dim^{(-3)}(\mathrm{P_m^{-1}}(A) \mid \mathcal{D}) = 0.$$

*In particular,* $\dim^{(-3)}(\deg^{\mathrm{p}}_{\mathrm{m}}(A) \mid \mathcal{D}) = 0$.

In contrast, Theorem 1.2 is extended to scaled dimension at orders $i$ with $|i| \leq 2$.

Theorem 1.4. *Let* $\mathcal{D} \in \{\mathrm{E}, \mathrm{EXP}, \mathrm{ESPACE}, \mathrm{EXPSPACE}\}$. *For every* $A \in \mathcal{D}$ *and* $-2 \leq i \leq 2$,

$$\dim^{(i)}(\deg^{\mathrm{p}}_{\mathrm{m}}(A) \mid \mathcal{D}) = \dim^{(i)}(\mathrm{P_m}(A) \mid \mathcal{D}).$$

This implies that Theorem 1.3 cannot be improved to −2nd-order scaled dimension.

As an application of these results, we consider the scaled dimension of $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$, the class of polynomial-time many-one complete sets for E, within ESPACE. Let $i \in \{-2, -1\}$. We extend a theorem of Lutz [15] to show that

$$\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE}) > 0 \Rightarrow \mathrm{P} = \mathrm{BPP}.$$

On the other hand, we show that

$$\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE}) < 1 \Rightarrow \mathrm{P} \neq \mathrm{PSPACE}.$$

Therefore, determining the −1st- or −2nd-order scaled dimension of $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$ in ESPACE would derandomize BPP or separate P from PSPACE. In contrast, we also show that

$$\dim^{(-3)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE}) = 0$$

and

$$\dim^{(-2)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{E}) = \dim^{(-1)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{E}) = 1$$

hold without any hypothesis.

This paper is organized as follows. Section 2 contains the basic preliminaries, and section 3 reviews resource-bounded scaled dimension. We develop some new tools for computing scaled dimension in section 4. The scaled dimensions of some auxiliary classes involving polynomial reductions are calculated in section 5. Our small span theorem for scaled dimension is proved in section 6. Section 7 shows that lower spans and degrees have the same dimension in orders $i$ with $-2 \leq i \leq 2$. Extensions of the results to $\leq^{\mathrm{p}}_{1-\mathrm{tt}}$-reductions are discussed in section 8. The results on the scaled dimension of the complete sets for E are presented in section 9. Section 10 concludes with a brief summary.

## 2. Preliminaries.

The set of all finite binary strings is $\{0,1\}^*$. The empty string is denoted by $\lambda$. We use the standard enumeration of binary strings $s_0 = \lambda, s_1 = 0, s_2 = 1, s_3 = 00, \ldots$. The length of a string $x \in \{0,1\}^*$ is denoted by $|x|$. We use the notation $\{0,1\}^{\leq n} = \{x \in \{0,1\}^* \mid |x| \leq n\}$ and $\{0,1\}^{>n} = \{x \in \{0,1\}^* \mid |x| > n\}$.

All *languages* (decision problems) in this paper are encoded as subsets of $\{0,1\}^*$. For a language $A \subseteq \{0,1\}^*$, we define $A_{\leq n} = \{x \in A \big| |x| \leq n\}$. We routinely identify $A$ with its infinite binary characteristic sequence according to the standard enumeration of binary strings. We write $A \upharpoonright n$ for the $n$-bit prefix of the characteristic sequence of $A$, and $A[n]$ for the $n$th-bit of its characteristic sequence.

Let $\leq^{\mathrm{p}}_r$ be a polynomial-time reducibility. For any $A \subseteq \{0,1\}^*$, let

$$\mathrm{P}_r(A) = \{B \subseteq \{0,1\}^* \mid B \leq^{\mathrm{p}}_r A\}$$

be the $\leq^{\mathrm{p}}_r$*-lower span of* $A$,

$$\mathrm{P}_r^{-1}(A) = \{B \subseteq \{0,1\}^* \mid A \leq^{\mathrm{p}}_r B\}$$

be the $\leq^{\mathrm{p}}_r$*-upper span of* $A$, and

$$\deg^{\mathrm{p}}_r(A) = \mathrm{P}_r(A) \cap \mathrm{P}_r^{-1}(A)$$

be the $\leq^{\mathrm{p}}_r$*-degree of* $A$. For any complexity class $\mathcal{D}$, the class of $\leq^{\mathrm{p}}_r$*-hard languages for* $\mathcal{D}$ is

$$\mathcal{H}^{\mathrm{p}}_r(\mathcal{D}) = \{A \subseteq \{0,1\}^* \mid \mathcal{D} \subseteq \mathrm{P}_r(A)\},$$

and the class of $\leq^{\mathrm{p}}_r$*-complete languages for* $\mathcal{D}$ is

$$\mathcal{C}^{\mathrm{p}}_r(\mathcal{D}) = \mathcal{D} \cap \mathcal{H}^{\mathrm{p}}_r(\mathcal{D}).$$

Let resource $\in$ {time, space} and let $t(n)$ be a resource bound. Let $l \in \mathbb{N}$. A function $f : \mathbb{N}^l \times \{0,1\}^* \to [0,\infty) \cap \mathbb{Q}$ is $t(n)$*-resource exactly computable* if there is a Turing machine that computes $f(k_1, \ldots, k_l, w)$ using at most $t(k_1 + \cdots + k_l + |w|)$ resource for all $(k_1, \ldots, k_l, w) \in \mathbb{N}^l \times \{0,1\}^*$. Let $g : \mathbb{N}^l \times \{0,1\}^* \to [0,\infty)$ be a real-valued function. An *approximation* of $g$ is a function $\hat{g} : \mathbb{N}^{l+1} \times \{0,1\}^* \to [0,\infty)$ such that

$$|g(x) - \hat{g}(r,x)| \leq 2^{-r}$$

for all $x \in \mathbb{N}^l \times \{0,1\}^*$ and $r \in \mathbb{N}$. We say that $g$ is $t(n)$*-resource computable* if there is an exactly $t(n)$-resource computable approximation $\hat{g}$ of $g$. A family of functions $(f_i : \mathbb{N}^l \times \{0,1\}^* \to [0,\infty) \mid i \in \mathbb{N})$ is *uniformly* $t(n)$*-resource (exactly) computable* if the function $f(i,x) = f_i(x)$ is $t(n)$-resource (exactly) computable.

A function $f$ is p-*computable* (respectively, pspace-*computable*) if it is $O(n^k)$-time (respectively, $O(n^k)$-space) computable for some $k \in \mathbb{N}$, and $f$ is $\mathrm{p}_2$-*computable* (respectively, $\mathrm{p}_2$space-*computable*) if it is $O(2^{(\log n)^k})$-time (respectively, $O(2^{(\log n)^k})$-space) computable for some $k \in \mathbb{N}$. Throughout this paper, unless otherwise specified, $\Delta$ denotes any of the *resource bounds* p, $\mathrm{p}_2$, pspace, or $\mathrm{p}_2$space. The concept of an *exactly* $\Delta$-*computable* function is defined analogously.

**3. Scaled dimension.** Hitchcock, Lutz, and Mayordomo [11] introduced resource-bounded scaled dimension. This section briefly reviews the essentials of this theory.

The principle concept is a *scale*, which is a function $g : H \times [0,\infty) \to \mathbb{R}$, where $H = (a,\infty)$ for some $a \in \mathbb{R} \cup \{-\infty\}$. A scale must satisfy certain properties that are given in [11] and will not be discussed here.

The canonical example of a scale is the function $g_0 : \mathbb{R} \times [0,\infty) \to \mathbb{R}$ defined by $g_0(m,s) = sm$. This scale is used in the standard (unscaled) dimension. Other scales of interest are obtained from $g_0$ by rescaling and reflection operations.

*Definition.* Let $g : H \times [0,\infty) \to \mathbb{R}$ be a scale.

1. The *first rescaling* of $g$ is the scale $g^\# : H^\# \times [0,\infty) \longrightarrow \mathbb{R}$ defined by

$$H^\# = \{2^m \mid m \in H\},$$

$$g^\#(m,s) = 2^{g(\log m, s)}.$$

2. The *reflection* of $g$ is the scale $g^R : H \times [0,\infty) \to \mathbb{R}$ defined by

$$g^R(m,s) = \begin{cases} m + g(m,0) - g(m,1-s) & \text{if } 0 \le s \le 1, \\ g(m,s) & \text{if } s \ge 1. \end{cases}$$

A family of scales, one for each integer, is defined as follows.

*Definition.*

1. For each $i \in \mathbb{N}$, define $a_i$ by the recurrence $a_0 = -\infty, a_{i+1} = 2^{a_i}$.
2. For each $i \in \mathbb{Z}$, define the $i$th *scale* $g_i : (a_{|i|},\infty) \times [0,\infty) \to \mathbb{R}$ by the following recursion:
   (a) $g_0(m,s) = sm$.
   (b) For $i \ge 0$, $g_{i+1} = g_i^\#$.
   (c) For $i < 0$, $g_i = g_{-i}^R$.

For clarity, we compute the first few scales. For all $s \in [0,1]$, if $m > a_{|i|}$, then $g_i(m,s)$ is defined by

$$\begin{aligned} g_3(m,s) &= 2^{2^{(\log\log m)^s}}, \\ g_2(m,s) &= 2^{(\log m)^s}, \\ g_1(m,s) &= m^s, \\ g_0(m,s) &= sm, \\ g_{-1}(m,s) &= m + 1 - m^{1-s}, \\ g_{-2}(m,s) &= m + 2 - 2^{(\log m)^{1-s}}, \\ g_{-3}(m,s) &= m + 4 - 2^{2^{(\log\log m)^{1-s}}}. \end{aligned}$$

Scaled dimension is defined using functions called *scaled gales*. The more familiar concepts of *gales* [18] and *martingales* [16] are special cases in the following definition.

*Definition.* Let $i \in \mathbb{Z}$ and let $s \in [0,\infty)$.

1. An *ith-order scaled s-gale* (briefly, an $s^{(i)}$*-gale*) is a function $d : \{0,1\}^{>a_{|i|}} \to [0,\infty)$ such that for all $w \in \{0,1\}^*$ with $|w| > a_{|i|}$,
$$d(w) = 2^{-\Delta g_i(|w|,s)}[d(w0) + d(w1)],$$
where $\Delta g_i : (a_{|i|},\infty) \times [0,\infty) \to \mathbb{R}$ is defined by
$$\Delta g_i(m,s) = g_i(m+1,s) - g_i(m,s).$$
2. An *s-gale* is an $s^{(0)}$-gale, that is, a function $d : \{0,1\}^* \to [0,\infty)$ satisfying
$$d(w) = 2^{-s}[d(w0) + d(w1)]$$
for all $w \in \{0,1\}^*$.
3. A *martingale* is a 1-gale, that is, a function $d : \{0,1\}^* \to [0,\infty)$ satisfying
$$d(w) = \frac{d(w0) + d(w1)}{2}$$
for all $w \in \{0,1\}^*$.

*Success sets* are a crucial concept for resource-bounded measure and also for scaled dimension.

*Definition.* Let $d : \{0,1\}^{>a} \to [0,\infty)$, where $a \in \mathbb{Z}$.
1. We say that $d$ *succeeds* on a language $A \subseteq \{0,1\}^*$ if
$$\limsup_{n\to\infty} d(A \restriction n) = \infty.$$
2. The *success set* of $d$ is
$$S^\infty[d] = \{A \subseteq \{0,1\}^* \mid d \text{ succeeds on } A\}.$$

Resource-bounded measure is defined using success sets of martingales. Here $\Delta$ denotes any of the resource bounds $\{\mathrm{p}, \mathrm{p}_2, \mathrm{pspace}, \mathrm{p}_2\mathrm{space}\}$, and $R(\Delta)$ is the following exponential-time or exponential-space complexity class:
$$\begin{array}{rcccl} R(\mathrm{p}) & = & \mathrm{E} & = & \mathrm{DTIME}(2^{O(n)}), \\ R(\mathrm{p}_2) & = & \mathrm{EXP} & = & \mathrm{DTIME}(2^{n^{O(1)}}), \\ R(\mathrm{pspace}) & = & \mathrm{ESPACE} & = & \mathrm{DSPACE}(2^{O(n)}), \\ R(\mathrm{p}_2\mathrm{space}) & = & \mathrm{EXPSPACE} & = & \mathrm{DSPACE}(2^{n^{O(1)}}). \end{array}$$

*Definition.* Let $\mathcal{C}$ be a class of languages.
1. We say that $\mathcal{C}$ has $\Delta$*-measure 0* and write $\mu_\Delta(\mathcal{C}) = 0$ if there is a $\Delta$-computable martingale $d$ such that $\mathcal{C} \subseteq S^\infty[d]$.
2. We say that $\mathcal{C}$ has *measure 0 in* $R(\Delta)$ and write $\mu(\mathcal{C} \mid R(\Delta)) = 0$ if $\mu_\Delta(\mathcal{C} \cap R(\Delta)) = 0$.

The *measure conservation theorem* of Lutz [16] asserts that $\mu_\Delta(R(\Delta)) \neq 0$, justifying the definition of measure in $R(\Delta)$ above.

Success sets of scaled gales are used to define scaled dimension.

*Definition.* Let $\mathcal{C}$ be a class of languages and $i \in \mathbb{Z}$.
1. The $i$th-order scaled $\Delta$-dimension of $\mathcal{C}$ is
$$\dim_\Delta^{(i)}(\mathcal{C}) = \inf\left\{ s \;\middle|\; \begin{array}{l} \text{there exists a } \Delta\text{-computable} \\ s^{(i)}\text{-gale } d \text{ for which } \mathcal{C} \subseteq S^\infty[d] \end{array} \right\}.$$

2. The $i$th-order scaled dimension of $\mathcal{C}$ within $R(\Delta)$ is

$$\dim^{(i)}(\mathcal{C} \mid R(\Delta)) = \dim_\Delta^{(i)}(\mathcal{C} \cap R(\Delta)).$$

The 0th-order dimension $\dim_\Delta^{(0)}(\cdot)$ is precisely the dimension $\dim_\Delta(\cdot)$ of Lutz [18], and the other orders are interpreted as rescalings of this concept.

The following lemma relates resource-bounded scaled dimension to resource-bounded measure.

LEMMA 3.1 ([11]). *For any class $\mathcal{C}$ of languages and $i \in \mathbb{Z}$,*

$$\dim_\Delta^{(i)}(\mathcal{C}) < 1 \Rightarrow \mu_\Delta(\mathcal{C}) = 0$$

*and*

$$\dim^{(i)}(\mathcal{C} \mid R(\Delta)) < 1 \Rightarrow \mu(\mathcal{C} \mid R(\Delta)) = 0.$$

The following is another key property of scaled dimension.

THEOREM 3.2 (see [11]). *Let $\mathcal{C}$ be a class of languages and $i \in \mathbb{Z}$. If $\dim_\Delta^{(i+1)}(\mathcal{C}) < 1$, then $\dim_\Delta^{(i)}(\mathcal{C}) = 0$.*

This theorem tells us that for every class $\mathcal{C}$, the sequence of dimensions $\dim_\Delta^{(i)}(\mathcal{C})$ for $i \in \mathbb{Z}$ satisfies exactly one of the following three conditions:

(i) $\dim_\Delta^{(i)}(\mathcal{C}) = 0$ for all $i \in \mathbb{Z}$.
(ii) $\dim_\Delta^{(i)}(\mathcal{C}) = 1$ for all $i \in \mathbb{Z}$.
(iii) There exist $i^* \in \mathbb{Z}$ such that $\dim_\Delta^{(i)}(\mathcal{C}) = 0$ for all $i < i^*$ and $\dim_\Delta^{(i)}(\mathcal{C}) = 1$ for all $i > i^*$.

**4. Measures, log-loss, and scaled dimension.** This section provides some tools involving measures and the log-loss concept that are useful for working with the scaled dimensions. It was shown in [10] that *log-loss unpredictability* is equivalent to dimension. Here we characterize scaled dimension using the log-loss of *measures.* A similar approach to classical fractal dimension using measures has been used by Cutler [7] (see also [8]).

*Definition.* A *measure* is a function $\rho : \{0,1\}^* \to [0,\infty)$ satisfying

$$\rho(w) = \rho(w0) + \rho(w1)$$

for all $w \in \{0,1\}^*$.

Measures have the following fundamental relationship with scaled gales. This extends Schnorr's "likelihood ratio" characterization of martingales [23].

OBSERVATION 4.1. *Let $i \in \mathbb{Z}$ and $s \in [0,\infty)$.*

1. *If $\rho : \{0,1\}^* \to [0,\infty)$ is a measure, then the function $d_\rho : \{0,1\}^{>a_{|i|}} \to [0,\infty)$ defined by*

$$d_\rho(w) = 2^{g_i(|w|,s)}\rho(w)$$

*for all $w \in \{0,1\}^{>a_{|i|}}$ is an $s^{(i)}$-gale.*

2. *If $d : \{0,1\}^{>a_{|i|}} \to [0,\infty)$ is an $s^{(i)}$-gale, then the function $\rho_d : \{0,1\}^* \to [0,\infty)$ defined by*

$$\rho_d(w) = 2^{-g_i(|w|,s)}d(w)$$

*for all* $w \in \{0,1\}^{>a_{|i|}}$ *and*

$$\rho_d(w) = \sum_{|v|=a_{|i|}+1-|w|} \rho_d(wv)$$

*for all* $w \in \{0,1\}^{\leq a_{|i|}}$ *is a measure.*

The following lemma relates the scaled dimension of a class to limits involving scales and logarithms of measures.

LEMMA 4.2. *Let* $\mathcal{C}$ *be a class of languages and let* $i \in \mathbb{Z}$.

1. *If* $s > \dim_\Delta^{(i)}(\mathcal{C})$, *then there is a* $\Delta$*-computable measure* $\rho$ *such that*

$$\limsup_{n\to\infty} \left[g_i(n,s) + \log \rho(A \upharpoonright n)\right] = \infty$$

*for all* $A \in \mathcal{C}$.

2. *If* $s < \dim_\Delta^{(i)}(\mathcal{C})$, *then for any* $\Delta$*-computable measure* $\rho$ *there is an* $A_\rho \in \mathcal{C}$ *such that*

$$\lim_{n\to\infty} \left[g_i(n,s) + \log \rho(A_\rho \upharpoonright n)\right] = -\infty.$$

*Proof.* Let $r$ be rational with $s > r > \dim_\Delta^{(i)}(\mathcal{C})$ and let $d$ be a $\Delta$-computable $r^{(i)}$-gale succeeding on $\mathcal{C}$. Then the measure $\rho_d$ from Observation 4.1 is also $\Delta$-computable. Let $A \in \mathcal{C}$. There are infinitely many $n \in \mathbb{N}$ such that $d(A \upharpoonright n) \geq 1$ since $A \in S^\infty[d]$. For such $n$,

$$\begin{aligned} g_i(n,s) + \log \rho_d(A \upharpoonright n) &= g_i(n,s) - g_i(n,r) + \log d(A \upharpoonright n) \\ &\geq g_i(n,s) - g_i(n,r). \end{aligned}$$

Part 1 follows because $r < s$.

For part 2, let $\rho$ be a $\Delta$-computable measure. Let $t$ be rational with $s < t < \dim_\Delta^{(i)}(\mathcal{C})$ and obtain the $t^{(i)}$-gale $d_\rho$ from Observation 4.1. Then $\mathcal{C} \not\subseteq S^\infty[d_\rho]$ because $d_\rho$ is $\Delta$-computable; thus there are an $A_\rho \in \mathcal{C}$ and a constant $c$ such that $d(A \upharpoonright n) \leq c$ for all $n > a_{|i|}$. Then

$$\begin{aligned} g_i(n,s) + \log \rho(A \upharpoonright n) &= g_i(n,s) - g_i(n,t) + \log d_\rho(A \upharpoonright n) \\ &\leq g_i(n,s) - g_i(n,t) + \log c, \end{aligned}$$

and therefore the claim follows because $s < t$. □

Lemma 4.2 asserts that if the $i$th-order scaled dimension of a class $\mathcal{C}$ is less than $s$, then there is a measure $\rho$ such that for every $A \in \mathcal{C}$, there are prefixes $w \sqsubseteq A$ where the *log-loss* quantity

$$-\log \rho(w)$$

is arbitrarily less than $g_i(|w|, s)$.

It is often convenient to replace computable measures by exactly computable measures. The following lemma is proved in the same way as the exact computation lemma for martingales [13].

LEMMA 4.3. *Let* $\rho$ *be a measure that is computable in* $t(n)$ *time (respectively, space), where* $t(n) \geq n$ *is nondecreasing. Then there is a measure* $\tilde{\rho}$ *that is exactly computable in* $n \cdot t(2n+2)$ *time (respectively, space) such that* $\tilde{\rho}(w) \geq \rho(w)$ *for all* $w \in \{0,1\}^*$.

The measures that are exactly computable within a fixed time or space bound are uniformly exactly computable with slightly more time or space.

LEMMA 4.4. *For any nondecreasing time constructible function $t(n) \geq n$ the family of exactly $t(n)$-time computable measures is uniformly exactly computable in $O(n^2 t(n) \log t(n))$ time. The family of exactly $t(n)$-space computable measures is uniformly exactly computable in $O(t(n))$ space.*

*Proof.* There is a uniform enumeration $(M_i \mid i \in \mathbb{N})$ of all $t(n)$-time clocked Turing machines such that for all $i \in \mathbb{N}$, $M_i(w)$ can be computed in $i \cdot t(|w|) \log t(|w|)$ time for all $w \in \{0,1\}^*$. Define $\rho_i : \{0,1\}^* \to [0,\infty)$ inductively by $\rho_i(\lambda) = M_i(\lambda)$ and

$$\rho_i(w0) = \begin{cases} M_i(w0) & \text{if } M_i(w0) \leq \rho_i(w), \\ \rho_i(w) & \text{otherwise,} \end{cases}$$

$$\rho_i(w1) = \rho_i(w) - \rho_i(w0)$$

for all $w \in \{0,1\}^*$. Then each $\rho_i$ is a measure. Also, if $\nu$ is a measure that is exactly computed by $M_i$ in $t(n)$ time, then $\rho_i(w) = \nu(w)$ for all $w$. We can compute $\rho_i(w)$ by using $|w|$ computations of $M_i$ on strings of length at most $|w|$; thus the function $\rho : \mathbb{N} \times \{0,1\}^* \to [0,\infty)$ defined by $\rho(i,w) = \rho_i(w)$ is computable in $O(n^2 t(n) \log t(n))$ time. The argument for space is similar. □

Uniformly exactly computable families of measures can be combined into a single measure in an efficient manner.

LEMMA 4.5. *Let $(\rho_k \mid k \in \mathbb{N})$ be a uniformly exactly $\Delta$-computable family of measures. There is a $\Delta$-computable measure $\rho^*$ such that for any $k$, there is a constant $c_k$ such that*

$$\log \rho^*(w) \geq \log \rho_k(w) - c_k$$

*for all $w \in \{0,1\}^*$.*

*Proof.* Define

$$\rho^*(w) = \sum_{k=0}^{\infty} \frac{\rho_k(w)}{2^k \rho_k(\lambda)}.$$

Then $\rho$ is a measure by linearity. Also, $\rho^*$ is $\Delta$-computable by the approximation function $\hat{\rho}^* : \mathbb{N} \times \{0,1\}^* \to [0,\infty)$ defined by

$$\hat{\rho}^*(r,w) = \sum_{k=0}^{r} \frac{\rho_k(w)}{2^k \rho_k(\lambda)}$$

since

$$\begin{aligned} \left|\rho^*(w) - \hat{\rho}^*(r,w)\right| &= \sum_{k=r+1}^{\infty} \frac{\rho_k(w)}{2^k \rho_k(\lambda)} \\ &\leq \sum_{k=r+1}^{\infty} \frac{\rho_k(\lambda)}{2^k \rho_k(\lambda)} \\ &= 2^{-r}. \end{aligned}$$

Let $k \in \mathbb{N}$. For any $w \in \{0,1\}^*$,

$$\begin{aligned}\log \rho^*(w) &\geq \log \frac{\rho_k(w)}{2^k \rho_k(\lambda)} \\ &= \log \rho_k(w) - k - \rho_k(\lambda),\end{aligned}$$

and thus the lemma holds with $c_k = k + \rho_k(\lambda)$. □

We now combine the preceding lemmas to obtain a tool that will be useful in calculating scaled dimensions.

THEOREM 4.6. *Let $\mathcal{C}$ be a class of languages, $i \in \mathbb{Z}$, and $k \in \mathbb{N}$.*

1. *If for each $A \in \mathcal{C}$ there is a measure $\rho_A$ computable in $O(n^k)$ time such that*

$$(\exists c_A \in \mathbb{Z})(\exists^\infty n) g_i(n,s) + \log \rho_A(A \upharpoonright n) \geq c_A, \tag{4.1}$$

   *then $\dim_{\mathrm{p}}^{(i)}(\mathcal{C}) \leq s$.*
2. *If for each $A \in \mathcal{C}$ there is a measure $\rho_A$ computable in $O(2^{(\log n)^k})$ time such that (4.1) holds, then $\dim_{\mathrm{p}_2}^{(i)}(\mathcal{C}) \leq s$.*
3. *If for each $A \in \mathcal{C}$ there is a measure $\rho_A$ computable in $O(n^k)$ space such that (4.1) holds, then $\dim_{\mathrm{pspace}}^{(i)}(\mathcal{C}) \leq s$.*
4. *If for each $A \in \mathcal{C}$ there is a measure $\rho_A$ computable in $O(2^{(\log n)^k})$ space such that (4.1) holds, then $\dim_{\mathrm{p}_2\mathrm{space}}^{(i)}(\mathcal{C}) \leq s$.*

*Proof.* From Lemmas 4.3, 4.4, and 4.5 we obtain an exactly $\Delta$-computable measure $\rho$ such that $\log \rho(w) \geq \log \rho_A(w) - b_A$ for all $w \in \{0,1\}^*$ where $b_A$ is a constant that depends on $A$ but not on $w$.

Let $t > s$. For any $A \in \mathcal{C}$,

$$g_i(n,t) + \log \rho(A \upharpoonright n) \geq g_i(n,t) - g_i(n,s) + c_A - b_A$$

for infinitely many $n$. Therefore

$$\limsup_{n \to \infty} g_i(n,t) + \log \rho(A \upharpoonright n) = \infty$$

since $t > s$. It follows from the contrapositive of Lemma 4.2(2) that $\dim_\Delta(\mathcal{C}) \leq t$. □

**5. Scaled non-bi-immunity and compressibility.** In this section we introduce some classes involving scales, non-bi-immunity, and compressibility by polynomial-time reductions and calculate their scaled dimensions.

A Turing machine $M$ is *consistent* with a language $A \subseteq \{0,1\}^*$ if for all $x \in \{0,1\}^*$,

$$M(x) \text{ halts} \iff M(x) = A(x).$$

Let $t$ be a time bound. The *fast set of $M$ with respect to $t$* is

$$F_M^t = \{x \in \{0,1\}^* \mid \mathrm{time}_M(x) \leq t(|x|)\}.$$

Recall that $A$ is *not* DTIME($t$)*-bi-immune* if there is a machine $M$ consistent with $A$ such that $F_M^t$ is infinite.

*Definition.* For any time bound $t$, let $X(t)$ be the class of all languages that are not DTIME($t$)-bi-immune.

Let $A \subseteq \{0,1\}^*$ and $f : \{0,1\}^* \to \{0,1\}^*$. We say that $f$ is a *many-one reduction of* $A$ if there is some $B \subseteq \{0,1\}^*$ such that $x \in A \iff f(x) \in B$. The *collision set* of $f$ is

$$C_f = \{s_i | (\exists j < i) f(s_i) = f(s_j)\}.$$

Recall that $A$ is *compressible by* $\leq_{\mathrm{m}}^{\mathrm{DTIME}(t)}$*-reductions* if there exists an $f \in \mathrm{DTIMEF}(t)$ that is a many-one reduction of $A$ and has $C_f$ infinite [12].

*Definition.* For any time bound $t$, let $C(t)$ be the class of all languages that are compressible by $\leq_{\mathrm{m}}^{\mathrm{DTIME}(t)}$-reductions.

The following theorem asserts that almost every language in E is DTIME($2^{cn}$)-bi-immune [21] and incompressible by $\leq_{\mathrm{m}}^{\mathrm{DTIME}(2^{cn})}$-reductions [12].

THEOREM 5.1 (Mayordomo [21], Juedes and Lutz [12]). *For all* $c \in \mathbb{N}$,

$$\mu_{\mathrm{p}}(X(2^{cn})) = \mu_{\mathrm{p}}(C(2^{cn})) = 0$$

*and*

$$\mu_{\mathrm{p}_2}(X(2^{n^c})) = \mu_{\mathrm{p}_2}(C(2^{n^c})) = 0.$$

The next two definitions introduce scaled versions of $X(t)$ and $C(t)$.

*Definition.* For any $i \in \mathbb{Z}$, $\alpha \in [0,1]$, and time bound $t$, let

$$X_\alpha^{(i)}(t) = \left\{ A \subseteq \{0,1\}^* \;\middle|\; \begin{array}{l} (\exists M) M \text{ is consistent with } A \text{ and} \\ (\exists^\infty n) \#(1, F_M^t \restriction n) \geq n - g_i(n,\alpha) \end{array} \right\}.$$

That is, $X_\alpha^{(i)}(t)$ consists of the languages that are not DTIME($t$)-bi-immune in a particular strong way: for infinitely many $n$, all but $g_i(n,\alpha)$ of the first $n$ strings can be decided in less than $t$ time by a consistent Turing machine.

*Definition.* For any $i \in \mathbb{Z}$, $\alpha \in [0,1]$, and time bound $t$, let

$$C_\alpha^{(i)}(t) = \left\{ A \in \{0,1\}^* \;\middle|\; \begin{array}{l} (\exists f \in \mathrm{DTIMEF}(t))\ f \text{ is a many-one reduction of } A \\ \text{and } (\exists^\infty n) \#(1, C_f \restriction n) \geq n - g_i(n,\alpha) \end{array} \right\}.$$

In other words, $C_\alpha^{(i)}(t)$ is the class of languages compressible by $\leq_{\mathrm{m}}^{\mathrm{DTIME}(t)}$-reductions where for infinitely many $n$, all but $g_i(n,\alpha)$ of the first $n$ strings have downward collisions under some reduction.

For $\alpha < 1$, $X_\alpha^{(i)}(2^n) \subseteq X(2^n)$ and $C_\alpha^{(i)}(2^n) \subseteq C(2^n)$, and thus Theorem 5.1 implies that $X_\alpha^{(i)}(2^n)$ and $C_\alpha^{(i)}(2^n)$ have measure 0. We now refine this by calculating their scaled dimensions.

THEOREM 5.2. *For all* $i \in \mathbb{Z}$, $c \geq 1$, *and* $\alpha \in [0,1]$,

$$\dim_{\mathrm{p}}^{(i)}(X_\alpha^{(i)}(2^{cn})) = \dim_{\mathrm{p}}^{(i)}(C_\alpha^{(i)}(2^{cn})) = \alpha$$

*and*

$$\dim_{\mathrm{p}_2}^{(i)}(X_\alpha^{(i)}(2^{n^c})) = \dim_{\mathrm{p}_2}^{(i)}(C_\alpha^{(i)}(2^{n^c})) = \alpha.$$

*Proof.* We focus on the p-dimension portion of the theorem; the argument for $\mathrm{p}_2$-dimension is identical. Let $\alpha \in (0,1)$ and let $s, t > 0$ be arbitrary rationals with $s < \alpha < t$. It suffices to show that

$$s \leq \dim_{\mathrm{p}}^{(i)}(X_\alpha^{(i)}(2^{cn})) \leq \dim_{\mathrm{p}}^{(i)}(C_\alpha^{(i)}(2^{cn})) \leq t.$$

The inequality $\dim_{\mathrm{p}}^{(i)}(X_\alpha^{(i)}(2^{cn})) \leq \dim_{\mathrm{p}}^{(i)}(C_\alpha^{(i)}(2^{cn}))$ holds because of the inclusion $X_\alpha^{(i)}(2^{cn}) \subseteq C_\alpha^{(i)}(2^{cn})$.

For the lower bound, let $\rho$ be any p-computable measure; assume without loss of generality that $\rho(\lambda) \leq 1$. We define a language $A$ inductively by lengths. Let $s < s'' < s' < \alpha$ with $s'$ rational. The first $\lceil g_i(2^n, s')\rceil$ bits of $A_{=n}$ are set by diagonalization to minimize $\rho$. The remaining $2^n - \lceil g_i(2^n, s')\rceil$ bits are identically 0. More formally, if $x$ is the characteristic string of $A_{\leq n-1}$, we choose $v \in \{0,1\}^{\lceil g_i(2^n,s')\rceil}$ so that $\rho(xv)$ is minimized, and we let $A_{=n}$ have characteristic string $v0^{2^n - \lceil g_i(2^n,s')\rceil}$. Then $A$ is in $X_\alpha^{(i)}(2^{cn})$. Let $w \sqsubseteq A$, and let $n$ be such that $2^n - 1 \leq |w| < 2^{n+1} - 1$. Then

$$\log \rho(w) \leq \left(\sum_{j=0}^{n-1} -g_i(2^j, s')\right) - \min\{|w| - (2^n - 1), g_i(2^n, s')\},$$

which is at most $-g_i(|w|, s'')$ if $|w|$ is sufficiently large by Lemma 5.3 below. Then

$$\log \rho(w) + g_i(|w|, s) \leq -g_i(|w|, s'') + g_i(|w|, s),$$

and thus

$$\lim_{n\to\infty} \log \rho(A \upharpoonright n) + g_i(n, s) = -\infty$$

since $s'' > s$. Since $\rho$ is an arbitrary p-computable measure, the contrapositive of Lemma 4.2(1) implies that $\dim_{\mathrm{p}}^{(i)}(X_\alpha^{(i)}(2^{cn})) \geq s$.

Now we prove the upper bound. Let $A \in C_\alpha^{(i)}(2^{cn})$ by a function $f \in \mathrm{DTIMEF}(2^{cn})$. Define a measure $\rho$ inductively by $\rho(\lambda) = 1$ and for all $w \in \{0,1\}^*, b \in \{0,1\}$,

1. if $f(s_i) \neq f(s_{|w|})$ for all $i < |w|$, then
$$\rho(wb) = \frac{\rho(w)}{2};$$
2. otherwise, let $i = \min\{i < |w| \mid f(s_i) = f(s_{|w|})\}$ and define
$$\rho(wb) = \begin{cases} \rho(w) & \text{if } b = w[i], \\ 0 & \text{if } b \neq w[i]. \end{cases}$$

Then for all $w \sqsubseteq A$,

$$\begin{aligned} \log \rho(w) &= -\#(0, C_f \upharpoonright |w|) \\ &= \#(1, C_f \upharpoonright |w|) - |w|. \end{aligned}$$

Whenever $\#(1, C_f \upharpoonright n) \geq n - g_i(n, \alpha)$, we have

$$\begin{aligned} g_i(n,t) + \log \rho(A \upharpoonright n) &= g_i(n,t) + \#(1, C_f \upharpoonright n) - n \\ &\geq g_i(n,t) - g_i(n,\alpha). \end{aligned}$$

This happens infinitely often; thus

$$\limsup_{n\to\infty} g_i(n,t) + \log \rho(A \upharpoonright n) = \infty$$

because $t > \alpha$. Also, $\rho$ is computable in $O(|w| \cdot 2^{c\log|w|}) = O(|w|^{c+1})$ time. Such a $\rho$ can be defined for each $A \in C_\alpha^{(i)}(2^{cn})$, and thus $\dim_{\mathrm{p}}^{(i)}(C_\alpha^{(i)}(2^{cn})) \leq t$ follows by Theorem 4.6. □

LEMMA 5.3. *Let $i \in \mathbb{Z}$, $0 < r < r' < 1$. Then for all sufficiently large $n$ and $k$ with $2^n - 1 \leq k < 2^{n+1} - 1$,*

$$\sum_{j=0}^{n-1} g_i(2^j, r') + \min\{k - (2^n - 1), g_i(2^n, r')\} \geq g_i(k, r).$$

*Proof.* If $i = 0$, then the left-hand side is

$$r'(2^n - 1) + \min\{k - (2^n - 1), r'2^n\} \geq r'k = g_0(k, r') > g_0(k, r).$$

If $i = 1$, then the left-hand side is

$$\sum_{j=0}^{n-1} 2^{jr'} + \min\{k - (2^n - 1), 2^{nr'}\} > 2^{(n-1)r'} > 2^{(n+1)r} > k^r = g_1(k, r)$$

when $n$ is large enough. The argument for $i > 1$ is similar.

If $i = -1$, then the left-hand side is

$$\begin{aligned} 2^n - 1 - \sum_{j=0}^{n-1} 2^{j(1-r')} + n + \min\{k - (2^n - 1), 2^n - 2^{n(1-r')} + 1\} \\ &\geq k - (n+1)2^{n(1-r')} \\ &\geq k - 2^{n(1-r)} + 1 \\ &= g_{-1}(k, r) \end{aligned}$$

if $n$ is sufficiently large. The argument for $i < -1$ is similar. □

**6. Small span theorem.** In this section we establish our small span theorem for scaled dimension. We begin with a simple, but important, lemma about the scales.

LEMMA 6.1. *For all $k \geq 1$ and $s, t \in (0, 1)$, $g_3(2^{n^k}, s) = o(g_2(2^n, t))$.*

*Proof.* We have

$$g_3(2^{n^k}, s) = 2^{2^{\left(\log\log 2^{n^k}\right)^s}} = 2^{2^{(k\log n)^s}}$$

and

$$g_2(2^n, t) = 2^{(\log 2^n)^t} = 2^{n^t} = 2^{2^{t\log n}}.$$

The lemma holds since $(k \log n)^s = o(t \log n)$. □

Juedes and Lutz [12] proved that the upper spans of incompressible languages are small. Specifically, for any language $A \in \mathrm{EXP}$ that is incompressible by $\leq_{\mathrm{m}}^{\mathrm{p}}$-reductions, they showed that $\mu_{\mathrm{p}_2}(\mathrm{P}_{\mathrm{m}}^{-1}(A)) = 0$, and if additionally $A \in \mathrm{E}$, then

$\mu_{\mathrm{p}}(\mathrm{P}_{\mathrm{m}}^{-1}(A)) = 0$. The following theorem is a scaled dimension analogue of this. For any $i \in \mathbb{Z}$, let

$$C_\alpha^{(i)}(\mathrm{poly}) = \bigcup_{c\in\mathbb{N}} C_\alpha^{(i)}(n^c + c).$$

THEOREM 6.2. *Let $\alpha \in (0,1)$.*

1. *Let $\Delta \in \{\mathrm{p}, \mathrm{pspace}\}$. For any $B \in R(\Delta) - C_\alpha^{(1)}(\mathrm{poly})$, $\dim_\Delta^{(-3)}(\mathrm{P}_{\mathrm{m}}^{-1}(B)) = 0$.*
2. *Let $\Delta \in \{\mathrm{p}_2, \mathrm{p}_2\mathrm{space}\}$. For any $B \in R(\Delta) - C_\alpha^{(2)}(\mathrm{poly})$, $\dim_\Delta^{(-3)}(\mathrm{P}_{\mathrm{m}}^{-1}(B)) = 0$.*

*Proof.* We first give the proof for $\Delta = \mathrm{p}$. Let $B \in \mathrm{E} - C_\alpha^{(1)}(\mathrm{poly})$ and let $M$ be a Turing machine that decides $B$ in $O(2^{cn})$ time. Assume $B \leq_{\mathrm{m}}^{\mathrm{p}} C$ via $f$ where $f$ is computable in $n^k$ time almost everywhere. Then for all sufficiently large $n$,

$$f(\{0,1\}^{\leq n}) \subseteq \{0,1\}^{\leq n^k} \tag{6.1}$$

and

$$\left|f(\{0,1\}^{\leq n})\right| \geq g_1(2^{n+1}-1, \alpha) \geq g_1(2^n, \alpha), \tag{6.2}$$

with the latter holding because $B \notin C_\alpha^{(1)}(\mathrm{poly})$.

Let $r \in \mathbb{N}$ such that $\frac{1}{r} < \alpha$. Define $d : \mathbb{N} \to \mathbb{N}$ by $d(n) = \lfloor n/r \rfloor$. For each $n \in \mathbb{N}$ we define a measure $\rho_n : \{0,1\}^* \to [0,1]$ by

$$\rho_n(\lambda) = 2^{-n}$$

and for all $w \in \{0,1\}^*$ and $b \in \{0,1\}$,

1. If $|w| < 2^{d(n)}$ or $\left[(\forall i < 2^{n+1}-1) f(s_i) \neq f(s_{|w|})\right]$, then
$$\rho_n(wb) = \frac{\rho_n(w)}{2}.$$
2. Otherwise, let $i = \min\left\{ i < 2^{n+1}-1 \,\middle|\, f(s_i) = f(s_{|w|}) \right\}$ and define
$$\rho_n(wb) = \begin{cases} \rho_n(w) & \text{if } b = B[i], \\ 0 & \text{if } b \neq B[i]. \end{cases}$$

If $|w| < 2^{d(n)}$, then $\rho_n(w)$ is computable in $O(|w|)$ time. If $|w| \geq 2^{d(n)}$, we can compute $\rho_n(w)$ by using $2^{n+1} - 1 = O(|w|^{n/d(n)}) = O(|w|^r)$ computations of $M$ and $f$ on strings with length at most $n = O(\log|w|)$. Therefore $\rho_n(w)$ is computable in $O(|w|^r(2^{c\log|w|} + (\log|w|)^k)) = O(|w|^{r+c})$ time for all $w \in \{0,1\}^*$.

Let $w_n = C \restriction 2^{n^k+1} - 1$ be the characteristic string of $C_{\leq n^k}$. Then letting

$$m(n) = \left| \left\{ j < |w_n| \,\middle|\, (\forall i < 2^{n+1}-1) f(s_i) \neq f(s_j) \right\} \right|,$$

we have

$$\rho_n(w_n) \geq \rho_n(\lambda) 2^{-2^{d(n)} - m(n)} = 2^{-2^{d(n)} - m(n) - n}.$$

By (6.1) and (6.2), we have

$$m(n) \leq 2^{n^k+1} - 1 - g_1(2^n, \alpha)$$

if $n$ is sufficiently large. In this case,

$$\log \rho_n(w_n) \geq g_1(2^n, \alpha) - 2^{d(n)} - 2^{n^k+1} - n. \tag{6.3}$$

The function $\rho : \{0,1\}^* \to [0, \infty)$ defined by

$$\rho(w) = \sum_{n=0}^{\infty} \rho_n(w)$$

for all $w$ is a measure by linearity. Notice that $\rho(w)$ can be approximated to a precision of $2^{-l}$ in $O(|w|^{r+c}l)$ time by adding the first $l+1$ terms of the sum.

Using (6.3), for all sufficiently large $n$, we have

$$\begin{aligned} g_{-3}(|w_n|, s) + \log \rho_n(w_n) &= 2^{n^k+1} + 4 - g_3(2^{n^k+1} - 1, 1-s) + \log \rho_n(w_n) \\ &\geq g_1(2^n, \alpha) - g_3(2^{n^k+1} - 1, 1-s) - 2^{d(n)} - n. \end{aligned}$$

By Lemma 6.1, $g_3(2^{n^k+1} - 1, 1-s) = o(g_1(2^n, \alpha))$. Also, $2^{d(n)} = 2^{\lfloor n/r \rfloor}$ is little-$o$ of $g_1(2^n, \alpha) = 2^{\alpha n}$ because $\alpha > 1/r$. Using these facts, it follows that

$$\limsup_{n \to \infty} \; g_{-3}(n, s) + \log \rho_n(C \restriction n) = \infty.$$

Appealing to Theorem 4.6, we establish $\dim_{\mathrm{p}}^{(-3)}(\mathrm{P}_{\mathrm{m}}^{-1}(B)) \leq s$. As $s > 0$ is arbitrary, the $\Delta = \mathrm{p}$ part of the theorem holds. The argument is identical for $\Delta = \mathrm{pspace}$.

The proof for $\Delta \in \{\mathrm{p}_2, \mathrm{p}_2\mathrm{space}\}$ is very similar, so we sketch only the differences for $\Delta = \mathrm{p}_2$. Let $B \in \mathrm{EXP} - C_\alpha^{(2)}(2^n)$ and let $M$ be a Turing machine that decides $B$ in $O(2^{n^c})$ time. Assume $B \leq_{\mathrm{m}}^{\mathrm{p}} C$ via $f$. The measures $\rho_n$ and $\rho$ are defined in the same way, except we use a different function $d(n)$. For this, we let $r > 1/\alpha$ and define $d(n) = \lfloor n^\epsilon \rfloor$, where $\epsilon = 1/r$. Then, if $|w| \geq 2^{d(n)}$, as before we can compute $\rho_n(w)$ by using $2^{n+1} - 1$ computations of $M$ and $f$ on strings with length at most $n = O(\log |w|)$. Since $2^n = 2^{(\log 2^{n^\epsilon})^r} = O(2^{(\log |w|)^r})$, we can compute $\rho_n(w)$ in $O(2^{(\log |w|)^r} \cdot 2^{(\log |w|)^c}) = O(2^{(\log |w|)^{\max(r,c)}})$ time. Instead of (6.3), we arrive at $\log \rho_n(w_n) \geq g_2(2^n, \alpha) - 2^{d(n)} - 2^{n^k+1} - n$. The proof is completed in the same way using the fact that $2^{d(n)} = o(g_2(2^n, \alpha))$ because $\epsilon < \alpha$. $\square$

We are now ready to prove our main theorem.

THEOREM 6.3.

1. *Let* $\Delta \in \{\mathrm{p}, \mathrm{pspace}\}$. *For every* $A \in R(\Delta)$,

$$\dim^{(1)}(\mathrm{P}_{\mathrm{m}}(A) \mid R(\Delta)) = 0$$

*or*

$$\dim^{(-3)}(\mathrm{P}_{\mathrm{m}}^{-1}(A) \mid R(\Delta)) = \dim_\Delta^{(-3)}(\mathrm{P}_{\mathrm{m}}^{-1}(A)) = 0.$$

2. *Let* $\Delta \in \{\mathrm{p}_2, \mathrm{p}_2\mathrm{space}\}$. *For every* $A \in R(\Delta)$,

$$\dim^{(2)}(\mathrm{P}_{\mathrm{m}}(A) \mid R(\Delta)) = 0$$

*or*

$$\dim^{(-3)}(\mathrm{P}_{\mathrm{m}}^{-1}(A) \mid R(\Delta)) = \dim_\Delta^{(-3)}(\mathrm{P}_{\mathrm{m}}^{-1}(A)) = 0.$$

*Proof.* Let $\Delta \in \{\mathrm{p}, \mathrm{pspace}\}$ and let $A \in R(\Delta)$. As in the proof of the small span theorem in [12], we consider two cases.

(I) Suppose that

$$\mathrm{P_m}(A) \cap R(\Delta) \subseteq \bigcap_{\alpha \in (0,1)} C_\alpha^{(1)}(2^n).$$

Then $\dim_\Delta^{(1)}(\mathrm{P_m}(A) \cap R(\Delta)) \leq \dim_\mathrm{p}^{(1)}(C_\alpha^{(1)}(2^n)) \leq \alpha$ by Theorem 5.2 for all $\alpha \in (0,1)$, and thus $\dim^{(1)}(\mathrm{P_m}(A) \mid R(\Delta)) = \dim_\Delta^{(1)}(\mathrm{P_m}(A) \cap R(\Delta)) = 0$.

(II) Otherwise, there is an $\alpha \in (0,1)$ such that

$$\mathrm{P_m}(A) \cap R(\Delta) \not\subseteq C_\alpha^{(1)}(2^n).$$

Let $B \in \mathrm{P_m}(A) \cap R(\Delta) - C_\alpha^{(1)}(2^n)$. Then by Theorem 6.2, $\dim_\Delta^{(-3)}(\mathrm{P_m^{-1}}(B)) = 0$. Since $\mathrm{P_m^{-1}}(A) \subseteq \mathrm{P_m^{-1}}(B)$, we have $\dim_\Delta^{(-3)}(\mathrm{P_m^{-1}}(A)) = 0$.

Part 2 is proved in the same way. □

Theorem 6.3 implies that there is a small span theorem for $-3$rd-order scaled dimension, but it is stronger than the following.

Corollary 6.4. *For every $A \in R(\Delta)$,*

$$\dim^{(-3)}(\mathrm{P_m}(A) \mid R(\Delta)) = 0$$

*or*

$$\dim^{(-3)}(\mathrm{P_m^{-1}}(A) \mid R(\Delta)) = \dim_\Delta^{(-3)}(\mathrm{P_m^{-1}}(A)) = 0.$$

*Proof.* This follows immediately from Theorem 6.3 using Theorem 3.2. □

The small span theorem of Juedes and Lutz [12] is also a corollary.

Corollary 6.5 (Juedes and Lutz [12]). *Let $\Delta \in \{\mathrm{p}, \mathrm{p_2}\}$. For every $A \in R(\Delta)$,*

$$\mu(\mathrm{P_m}(A) \mid R(\Delta)) = 0$$

*or*

$$\mu(\mathrm{P_m^{-1}}(A) \mid R(\Delta)) = \mu_\Delta(\mathrm{P_m^{-1}}(A)) = 0.$$

*Proof.* This follows immediately from Theorem 6.3 and Lemma 3.1. □

We also have the following regarding the scaled dimensions of the hard languages for EXP and NP.

Corollary 6.6.

1. $\dim_\mathrm{p}^{(-3)}(\mathcal{H}_\mathrm{m}^\mathrm{p}(\mathrm{EXP})) = \dim_{\mathrm{p_2}}^{(-3)}(\mathcal{H}_\mathrm{m}^\mathrm{p}(\mathrm{EXP})) = 0$.
2. *If* $\dim^{(1)}(\mathrm{NP} \mid \mathrm{E}) > 0$, *then* $\dim_\mathrm{p}^{(-3)}(\mathcal{H}_\mathrm{m}^\mathrm{p}(\mathrm{NP})) = 0$.
3. *If* $\dim^{(2)}(\mathrm{NP} \mid \mathrm{EXP}) > 0$, *then* $\dim_{\mathrm{p_2}}^{(-3)}(\mathcal{H}_\mathrm{m}^\mathrm{p}(\mathrm{NP})) = 0$.

*Proof.* Let $H \in \mathcal{C}_\mathrm{m}^\mathrm{p}(\mathrm{E})$. Then also $H \in \mathcal{C}_\mathrm{m}^\mathrm{p}(\mathrm{EXP})$, so $\mathrm{P_m^{-1}}(H) = \mathcal{H}_\mathrm{m}^\mathrm{p}(\mathrm{EXP})$. Since $\dim(\mathrm{P_m}(H) \mid \mathrm{E}) = \dim_\mathrm{p}(\mathrm{E}) = 1$, Theorem 6.3 tells us that $\dim_\mathrm{p}(\mathcal{H}_\mathrm{m}^\mathrm{p}(\mathrm{EXP})) = \dim_\mathrm{p}(\mathrm{P_m^{-1}}(H)) = 0$.

Parts 2 and 3 follow from Theorem 6.3 using any NP-complete language $A$. □

Juedes and Lutz [12] concluded from their small span theorem that *every* $\leq_\mathrm{m}^\mathrm{p}$-degree has measure 0 in E and in EXP. From Theorem 6.3 we similarly derive a stronger version of this fact: every $\leq_\mathrm{m}^\mathrm{p}$-degree actually has $-3$rd-order dimension 0.

Corollary 6.7. *For every $A \subseteq \{0,1\}^*$,*

$$\dim^{(-3)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A) \mid R(\Delta)) = 0.$$

*Proof.* If $\deg_{\mathrm{m}}^{\mathrm{p}}(A)$ is disjoint from $R(\Delta)$, then $\dim^{(-3)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A) \mid R(\Delta)) = \dim_{\mathrm{p}}^{(-3)}(\emptyset) = 0$, so assume that there is some $B \in \deg_{\mathrm{m}}^{\mathrm{p}}(A) \cap R(\Delta)$. Because $\deg_{\mathrm{m}}^{\mathrm{p}}(A) = \deg_{\mathrm{m}}^{\mathrm{p}}(B) = \mathrm{P}_{\mathrm{m}}(B) \cap \mathrm{P}_{\mathrm{m}}^{-1}(B)$, we have

$$\dim^{(-3)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A) \mid R(\Delta)) \leq \dim^{(-3)}(\mathrm{P}_{\mathrm{m}}(B) \mid R(\Delta))$$

and

$$\dim^{(-3)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A) \mid R(\Delta)) \leq \dim^{(-3)}(\mathrm{P}_{\mathrm{m}}^{-1}(B) \mid R(\Delta)).$$

By Corollary 6.4, we have either $\dim^{(-3)}(\mathrm{P}_{\mathrm{m}}(B) \mid R(\Delta)) = 0$ or $\dim^{(-3)}(\mathrm{P}_{\mathrm{m}}^{-1}(B) \mid R(\Delta)) = 0$. Therefore $\dim^{(-3)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A) \mid R(\Delta)) = 0$. □

The $\leq_{\mathrm{m}}^{\mathrm{p}}$-complete languages for any complexity class have −3rd-order dimension 0 in every $R(\Delta)$.

Corollary 6.8. *For any class $\mathcal{D}$ of languages,* $\dim^{(-3)}(\mathcal{C}_{\mathrm{m}}^{\mathrm{p}}(\mathcal{D}) \mid R(\Delta)) = 0$.

*Proof.* If $\mathcal{C}_{\mathrm{m}}^{\mathrm{p}}(\mathcal{D}) = \emptyset$, this is trivial. Assume $\mathcal{C}_{\mathrm{m}}^{\mathrm{p}}(\mathcal{D}) \neq \emptyset$ and let $A \in \mathcal{C}_{\mathrm{m}}^{\mathrm{p}}(\mathcal{D})$. Then $\mathcal{C}_{\mathrm{m}}^{\mathrm{p}}(\mathcal{D}) \subseteq \deg_{\mathrm{m}}^{\mathrm{p}}(A)$, so this follows from Corollary 6.7. □

**7. Lower spans versus degrees in orders −2 through 2.** We now present some results that stand in contrast to the small span theorem of the previous section. We begin by extending the work of Ambos-Spies et al. [2] to show that lower spans and degrees have the same scaled dimension in orders $i$ with $|i| \leq 2$.

Theorem 7.1. *For any $A \in R(\Delta)$ and $-2 \leq i \leq 2$,*

$$\dim^{(i)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A) \mid R(\Delta)) = \dim^{(i)}(\mathrm{P}_{\mathrm{m}}(A) \mid R(\Delta))$$

*and*

$$\dim_{\Delta}^{(i)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A)) = \dim_{\Delta}^{(i)}(\mathrm{P}_{\mathrm{m}}(A)).$$

*Proof.* We write the proof for dimension in $R(\mathrm{p}) = \mathrm{E}$; the rest of the theorem is proved in the same manner. The proof is based on [2].

Let $A \in \mathrm{E}$ be decidable in $O(2^{cn})$ time. By monotonicity, $\dim^{(i)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A) \mid \mathrm{E}) \leq \dim^{(i)}(\mathrm{P}_{\mathrm{m}}(A) \mid \mathrm{E})$. For the other inequality, let $t > s > \dim^{(i)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A) \mid \mathrm{E})$. By Lemmas 4.2 and 4.3, for some $l \in \mathbb{N}$ there is an exactly $n^l$-time computable measure $\rho$ satisfying

$$\limsup_{m\to\infty} g_i(m,s) + \log \rho(C \upharpoonright m) = \infty \tag{7.1}$$

for all $C \in \deg_{\mathrm{m}}^{\mathrm{p}}(A) \cap \mathrm{E}$.

Letting $k \geq 1$ be a natural number to be specified later, we define a padding function $f : \{0,1\}^* \to \{0,1\}^*$ by

$$f(x) = 0^{|x|^k - |x|}x$$

for all $x$. Let $R = f(\{0,1\}^*)$ be the range of $f$.

Let $B \in \mathrm{P_m}(A)$. We define another language $B'$ as

$$B' = (B - R) \cup f(A).$$

Then $B' \in \deg_{\mathrm{m}}^{\mathrm{p}}(A)$. Intuitively, $B'$ is a language that is very similar to $B$ but has $A$ encoded sparsely in it. Define a function $\tau : \{0,1\}^* \to \{0,1\}^*$ inductively by $\tau(\lambda) = 1$ and

$$\tau(wb) = \begin{cases} \tau(w)b & \text{if } s_{|w|} \notin R, \\ \tau(w)1 & \text{if } s_{|w|} \in R \cap B', \\ \tau(w)0 & \text{if } s_{|w|} \in R - B' \end{cases}$$

for all $w \in \{0,1\}^*$ and $b \in \{0,1\}$. Notice that

$$\tau(B \upharpoonright n) = B' \upharpoonright n$$

for all $n$.

Define a measure $\gamma$ by $\gamma(\lambda) = 1$ and

$$\gamma(wb) = \begin{cases} \frac{\gamma(w)}{2} & \text{if } s_{|w|} \in R, \\ \frac{\rho(\tau(w)b)}{\rho(\tau(w))}\gamma(w) & \text{if } s_{|w|} \notin R \end{cases}$$

for all $w \in \{0,1\}^*$ and $b \in \{0,1\}$. Intuitively, $\gamma$ is designed to have performance on $B$ that is similar to $\rho$'s performance on $B'$. This is done by mimicking the conditional probabilities of $\rho$ for strings that are not in $R$. Note that $\gamma(w)$ can be exactly computed in $O(|w| \cdot (|w|^l + 2^{c \log |w|}) = O(|w|^{\max(l,c)+1})$ time.

Let $n \in N$ and let $2^{(n-1)^k+1} \leq m \leq 2^{n^k+1} - 1$. Then

$$\begin{aligned} \log \gamma(B \upharpoonright m) &= \sum_{1 \leq i \leq m} \log \frac{\gamma(B \upharpoonright i)}{\gamma(B \upharpoonright i-1)} \\ &= \sum_{\substack{1 \leq i \leq m \\ s_i \notin R}} \log \frac{\rho(\tau(B \upharpoonright i-1)B[i])}{\rho(\tau(B \upharpoonright i-1))} + \sum_{\substack{1 \leq i \leq m \\ s_i \in R}} \log \frac{1}{2} \\ &= \sum_{\substack{1 \leq i \leq m \\ s_i \notin R}} \log \frac{\rho(B' \upharpoonright i)}{\rho(B' \upharpoonright i-1)} - \left|\{1 \leq i \leq m \mid s_i \in R\}\right| \\ &\geq \sum_{1 \leq i \leq m} \log \frac{\rho(B' \upharpoonright i)}{\rho(B' \upharpoonright i-1)} - \left|\{1 \leq i \leq 2^{n^k+1} - 1 \mid s_i \in R\}\right| \\ &= \log \rho(B' \upharpoonright m) - \sum_{i=0}^{n} 2^n \\ &= \log \rho(B' \upharpoonright m) - 2^{n+1} + 1. \end{aligned}$$

Now assume that $g_i(m,s) + \log \rho(B' \upharpoonright m) \geq 1$. Then we have $g_i(m,t) + \log \gamma(B \upharpoonright m) \geq 1$ if

$$2^{n+1} + g_i(m,s) < g_i(m,t). \tag{7.2}$$

To establish

$$\limsup_{n\to\infty} g_i(m,t) + \log \gamma(B \upharpoonright m) \geq 1, \tag{7.3}$$

it now suffices to show we can choose $k$ so that (7.2) holds for all sufficiently large $m$. For each $-2 \le i \le 2$, we now give an appropriate choice of $k$ that yields this.

- $i = 2$: Let $k > 1/t$. Then $g_2(m,t) \ge g_2(2^{(n-1)^k}, t) = 2^{(n-1)^{kt}}$, so $2^{n+1} = o(g_2(m,t))$ because $kt > 1$. Also, $g_2(m,s) = o(g_2(m,t))$ since $s < t$, so (7.2) holds when $m$ is sufficiently large.
- $i = 1$: Let $k = 2$. Then $g_1(m,t) \ge g_1(2^{(n-1)^2}, t) = 2^{t(n-1)^2}$, so $2^{n+1} = o(g_1(m,t))$. Also, $g_1(m,s) = o(g_1(m,t))$, so (7.2) holds for sufficiently large $m$.
- $i = 0$: Let $k = 2$. Then $g_0(m,t) \ge g_0(2^{(n-1)^2}, t) = t2^{(n-1)^2}$, so $2^{n+1} = o(g_0(m,t))$. Also, $g_0(m,s) = o(g_0(m,t))$, so (7.2) holds for sufficiently large $m$.
- $i = -1$: We have $g_{-1}(m,t) = m + 1 - g_1(m, 1-t)$, so (7.2) is true if $2^{n+1} + g_1(m, 1-t) < g_1(m, 1-s)$. Taking $k = 2$, this follows from the argument for $i = 1$ above since $1 - s > 1 - t$.
- $i = -2$: Just as in the $i = -1$ case, (7.2) is true if $2^{n+1} + g_2(m, 1-t) < g_2(m, 1-s)$. Taking $k > 1/(1-s)$, this follows from the argument for $i = 2$ above since $1 - s > 1 - t$.

For each $B \in \mathrm{P_m}(A)$, we have given a $O(n^{\max(l,c)})$-time computable measure $\gamma$ such that (7.3) holds. By Theorem 4.6, $\dim^{(i)}(\mathrm{P_m}(A) \mid \mathrm{E}) \le t$. As $t > \dim^{(i)}(\deg^{\mathrm{p}}_{\mathrm{m}}(A) \mid \mathrm{E})$ is arbitrary, this establishes $\dim^{(i)}(\mathrm{P_m}(A) \mid \mathrm{E}) \le \dim^{(i)}(\deg^{\mathrm{p}}_{\mathrm{m}}(A) \mid \mathrm{E})$. $\square$

Theorem 7.1 for (unscaled) dimension was proved in [2] for $\Delta = \mathrm{p}$.

Corollary 7.2 (Ambos-Spies et al. [2]). *For any $A \in \mathrm{E}$,*

$$\dim(\deg^{\mathrm{p}}_{\mathrm{m}}(A) \mid \mathrm{E}) = \dim(\mathrm{P_m}(A) \mid \mathrm{E})$$

*and*

$$\dim_{\mathrm{p}}(\deg^{\mathrm{p}}_{\mathrm{m}}(A)) = \dim_{\mathrm{p}}(\mathrm{P_m}(A)).$$

Theorem 7.1 implies that Theorem 6.3 cannot be improved in one respect. For any $i, j \in \mathbb{Z}$, let $\mathrm{SST}[i,j]$ be the following statement.

$\mathrm{SST}[i,j]$: *For every $A \in \mathrm{E}, \dim^{(i)}(\mathrm{P_m}(A) \mid \mathrm{E}) = 0$ or $\dim^{(j)}(\mathrm{P_m^{-1}}(A) \mid \mathrm{E}) = 0$.*

Let $H \in \mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$. Then

$$\dim^{(i)}(\mathrm{P_m}(H) \mid \mathrm{E}) = \dim^{(i)}(\mathrm{E} \mid \mathrm{E}) = 1$$

for all $i$ and $\dim^{(-2)}(\deg^{\mathrm{p}}_{\mathrm{m}}(H) \mid \mathrm{E}) = 1$ by Theorem 7.1, which in turn implies

$$\dim^{(-2)}(\mathrm{P_m^{-1}}(H) \mid \mathrm{E}) = 1.$$

Therefore, $\mathrm{SST}[i,j]$ is false if $j \ge -2$. Theorem 6.3 says that $\mathrm{SST}[1,-3]$ is true; now we know that the $-3$ in it cannot be improved to $-2$.

We have the following corollary regarding the classes of complete sets for E, EXP, and NP.

Corollary 7.3. *Let $-2 \le i \le 2$.*

1. $\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{E}) = \dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{EXP}) \mid \mathrm{EXP}) = 1$.
2. $\dim^{(i)}(\mathrm{NP} \mid \mathrm{E}) = \dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{NP}) \mid \mathrm{E})$.
3. $\dim^{(i)}(\mathrm{NP} \mid \mathrm{EXP}) = \dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{NP}) \mid \mathrm{EXP})$.

*Proof.* Let $H \in \mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$. Then $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) = \deg^{\mathrm{p}}_{\mathrm{m}}(H) \cap \mathrm{E}$, so $\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{E}) = \dim^{(i)}(\deg^{\mathrm{p}}_{\mathrm{m}}(H) \mid \mathrm{E}) = \dim^{(i)}(\mathrm{P}_{\mathrm{m}}(H) \mid \mathrm{E}) = \dim^{(i)}_{\mathrm{p}}(\mathrm{E}) = 1$ by Theorem 7.1. The other statements follow similarly. □

We can now observe a difference between the −3rd- and −2nd-order scaled dimensions regarding complete degrees. Corollaries 6.8 and 7.3 together with Theorem 3.2 tell us that for $\mathcal{D} \in \{\mathrm{E}, \mathrm{EXP}\}$,

$$\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathcal{D}) \mid \mathcal{D}) = \begin{cases} 0 & \text{if } i \leq -3, \\ 1 & \text{if } i \geq -2 \end{cases}$$

and

$$\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{NP}) \mid \mathcal{D}) = \begin{cases} 0 & \text{if } i \leq -3, \\ \dim^{(i)}(\mathrm{NP} \mid \mathcal{D}) & \text{if } i \geq -2. \end{cases}$$

In section 9 we will discuss the scaled dimension of $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$ within ESPACE. The following extension of Theorem 7.1 will be useful.

THEOREM 7.4. *For all* $-2 \leq i \leq 2$,

$$\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE}) = \dim^{(i)}(\mathrm{E} \mid \mathrm{ESPACE}).$$

*Proof.* We use the construction from the proof of Theorem 7.1. Let $t > s > \dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE})$ and take an exactly $n^l$-space computable measure $\rho$ satisfying (7.1) for all $C \in \mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$. Fix an $A \in \mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$. For any $B \in \mathrm{E}$, the set $B'$ constructed from $A$ and $B$ is in $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$. The arguments then show $\dim^{(i)}(\mathrm{E} \mid \mathrm{ESPACE}) \leq t$. □

**8. $\leq^{\mathrm{p}}_{1-\mathrm{tt}}$-lower spans versus $\leq^{\mathrm{p}}_{\mathrm{m}}$-lower spans.** Theorem 7.1 is also true for most other polynomial-time reducibilities. (This fact was mentioned in [2] for Corollary 7.2 when it was proved.) To replace $\leq^{\mathrm{p}}_{\mathrm{m}}$ by $\leq^{\mathrm{p}}_{r}$ in the theorem, we need only to have $B' \in \deg^{\mathrm{p}}_{r}(A)$ for the set $B'$ that was constructed in the proof from $B \in \mathrm{P}_r(A)$. In particular, Theorem 7.1 is true for the $\leq^{\mathrm{p}}_{1-\mathrm{tt}}$ reducibility. In this section we show that this holds because of another reason: the scaled dimensions of $\leq^{\mathrm{p}}_{1-\mathrm{tt}}$-lower spans and $\leq^{\mathrm{p}}_{\mathrm{m}}$-lower spans are always the same.

The following proposition was used to show that a set is weakly $\leq^{\mathrm{p}}_{\mathrm{m}}$-complete for exponential time if and only if it is $\leq^{\mathrm{p}}_{1-\mathrm{tt}}$-complete.

PROPOSITION 8.1 (Ambos-Spies et al. [1]). *Let* $A \leq^{\mathrm{p}}_{1-\mathrm{tt}} B$. *Then there is a language* $C \in \mathrm{P}$ *such that*

$$\hat{A} = (A \cap C) \cup (A^c \cap C^c) \leq^{\mathrm{p}}_{\mathrm{m}} B.$$

The idea of the following lemma also comes from [1].

LEMMA 8.2. *Let* $i \in \mathbb{Z}$. *Let* $\mathcal{C}, \hat{\mathcal{C}}$ *be classes of languages such that for any* $A \in \mathcal{C}$, *there is some* $C \in R(\Delta)$ *such that* $\hat{A} = (A \cap C) \cup (A^c \cap C^c) \in \hat{\mathcal{C}}$. *Then* $\dim^{(i)}_{\Delta}(\mathcal{C}) \leq \dim^{(i)}_{\Delta}(\hat{\mathcal{C}})$.

*Proof.* We prove this for $\Delta = \mathrm{p}$. The other cases are proved by identical arguments.

Let $s > \dim^{(i)}_{\mathrm{p}}(\hat{\mathcal{C}})$ be rational and obtain $\rho$ computable in $O(n^r)$ time from Lemma 4.2 such that

$$\limsup_{n\to\infty} g_i(n,s) + \log \rho(\hat{A} \upharpoonright n) = \infty \tag{8.1}$$

for all $\hat{A} \in \hat{\mathcal{C}}$.

Let $A \in \mathcal{C}$ and let $C \in \mathrm{DTIME}(n^k)$ such that $\hat{A} = (A \cap C) \cup (A^c \cap C^c) \in \hat{\mathcal{C}}$. Define a function $\tau : \{0,1\}^* \to \{0,1\}^*$ by

$$\tau(w)[j] = \begin{cases} w[j] & \text{if } s_j \in C, \\ 1 - w[j] & \text{if } s_j \notin C \end{cases}$$

for each $0 \leq j < |w|$. Define another measure $\rho'$ by

$$\rho'(w) = \rho(\tau(w)).$$

Then for all $n$,

$$\rho'(A \upharpoonright n) = \rho(\tau(A \upharpoonright n)) = \rho(\hat{A} \upharpoonright n).$$

Therefore

$$\limsup_{n\to\infty} g_i(n, s) + \log \rho'(A \upharpoonright n) = \infty$$

because of (8.1). As $\rho'$ is computable in time $O(|w| \cdot (\log |w|)^k + |w|^r)$, it follows by Theorem 4.6 that $\dim_{\mathrm{p}}^{(i)}(\mathcal{C}) \leq s$. □

We now show that the scaled dimension of a $\leq_{\mathrm{m}}^{\mathrm{p}}$-lower span is always equal to the scaled dimension of the $\leq_{1-\mathrm{tt}}^{\mathrm{p}}$-lower span.

THEOREM 8.3. *Let $B \subseteq \{0,1\}^*$ and let $i \in \mathbb{Z}$. Then*

$$\dim_{\Delta}^{(i)}(\mathrm{P}_{\mathrm{m}}(B)) = \dim_{\Delta}^{(i)}(\mathrm{P}_{1-\mathrm{tt}}(B))$$

*and*

$$\dim^{(i)}(\mathrm{P}_{\mathrm{m}}(B) \mid R(\Delta)) = \dim^{(i)}(\mathrm{P}_{1-\mathrm{tt}}(B) \mid R(\Delta)).$$

*Proof.* By Proposition 8.1, for each $A \in \mathrm{P}_{1-\mathrm{tt}}(B)$ there is a language $C \in \mathrm{P}$ such that $\hat{A} = (A \cap C) \cup (A^c \cap C^c) \in \mathrm{P}_{\mathrm{m}}(B)$. Let $\hat{\mathcal{C}}$ be the set of all such $\hat{A}$ as $A$ ranges over $\mathrm{P}_{1-\mathrm{tt}}(B)$. Then by Lemma 8.2,

$$\dim_{\Delta}^{(i)}(\mathrm{P}_{1-\mathrm{tt}}(B)) \leq \dim_{\Delta}^{(i)}(\hat{\mathcal{C}}).$$

As $\hat{\mathcal{C}} \subseteq \mathrm{P}_{\mathrm{m}}(B) \subseteq \mathrm{P}_{1-\mathrm{tt}}(B)$, we also have

$$\dim_{\Delta}^{(i)}(\hat{\mathcal{C}}) \leq \dim_{\Delta}^{(i)}(\mathrm{P}_{\mathrm{m}}(B)) \leq \dim_{\Delta}^{(i)}(\mathrm{P}_{1-\mathrm{tt}}(B)),$$

so the first equality holds. The proof for dimension in $R(\Delta)$ is analogous. □

We can now give a stronger version of Theorem 7.1.

COROLLARY 8.4. *For any $A \in R(\Delta)$ and $-2 \leq i \leq 2$,*

$$\begin{array}{ccc} \dim^{(i)}(\mathrm{P}_{\mathrm{m}}(A) \mid R(\Delta)) & = & \dim^{(i)}(\deg_{\mathrm{m}}^{\mathrm{p}}(A) \mid R(\Delta)) \\ \shortparallel & & \shortparallel \\ \dim^{(i)}(\mathrm{P}_{1-\mathrm{tt}}(A) \mid R(\Delta)) & = & \dim^{(i)}(\deg_{1-\mathrm{tt}}^{\mathrm{p}}(A) \mid R(\Delta)), \end{array}$$

*and similarly when $\dim^{(i)}(\cdot \mid R(\Delta))$ is replaced by $\dim_{\Delta}^{(i)}(\cdot)$.*

*Proof.* From Theorems 7.1 and 8.3 we have

$$\dim^{(i)}(\mathrm{deg}^{\mathrm{p}}_{\mathrm{m}}(A) \mid R(\Delta)) = \dim^{(i)}(\mathrm{P}_{\mathrm{m}}(A) \mid R(\Delta)) = \dim^{(i)}(\mathrm{P}_{1-\mathrm{tt}}(A) \mid R(\Delta)).$$

By monotonicity, we have

$$\dim^{(i)}(\mathrm{deg}^{\mathrm{p}}_{\mathrm{m}}(A) \mid R(\Delta)) \le \dim^{(i)}(\mathrm{deg}^{\mathrm{p}}_{1-\mathrm{tt}}(A) \mid R(\Delta)) \le \dim^{(i)}(\mathrm{P}_{1-\mathrm{tt}}(A) \mid R(\Delta)),$$

so the corollary follows. The proof for $\dim^{(i)}_{\Delta}(\cdot)$ is analogous. □

Theorem 8.3 also yields a strengthening of Theorem 6.3: the $\mathrm{P}_{\mathrm{m}}(A)$ in it can be replaced by $\mathrm{P}_{1-\mathrm{tt}}(A)$. In fact, it is also possible to replace the $\mathrm{P}^{-1}_{\mathrm{m}}(A)$ in Theorem 6.3 by $\mathrm{P}^{-1}_{1-\mathrm{tt}}(A)$ by extending Theorems 5.2 and 6.2 to deal with $\le^{\mathrm{p}}_{1-\mathrm{tt}}$-reductions. We omit the details.

## 9. The scaled dimension of $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$ in ESPACE.

Lutz [17] proved a small span theorem for nonuniform Turing reductions in ESPACE. This implies that $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$ has measure 0 in ESPACE. In Corollary 6.8 we saw that $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$ actually has −3rd-order scaled dimension 0 in ESPACE. In this section we show that determining the −2nd- or −1st-order scaled dimension of $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$ in ESPACE would yield a proof of P = BPP or P ≠ PSPACE.

The P = BPP hypothesis was related to the measure of E in ESPACE by Lutz [15].

THEOREM 9.1 (Lutz [15]). *If* $\mu(\mathrm{E} \mid \mathrm{ESPACE}) \neq 0$, *then* P = BPP.

We will extend this result to scaled dimension. We now recall the tools Lutz used to prove it.

Nisan and Wigderson [22] showed that BPP can be derandomized if there is a decision problem in E that requires exponential-size circuits to be approximately solved. The *hardness* of a decision problem at a given length is the minimum size of a circuit that can approximately solve it. The details of the definition of this hardness are not needed in this paper; we need only to recall existing results regarding classes of languages with exponential hardness.

*Definition.* Let $H_\alpha$ be the class of all languages that have hardness at least $2^{\alpha n}$ almost everywhere in the sense of [22].

The aforementioned derandomization of BPP can be stated as follows.

THEOREM 9.2 (see Nisan and Wigderson [22]). *If* $\mathrm{E} \cap H_\alpha \neq \emptyset$ *for some* $\alpha > 0$, *then* P = BPP.

We will also need space-bounded Kolmogorov complexity.

*Definition.* Given a machine $M$, a space bound $s : \mathbb{N} \to \mathbb{N}$, a language $L \subseteq \{0,1\}^*$, and a natural number $n$, the *s-space-bounded Kolmogorov complexity* of $L_{=n}$ with respect to $M$ is

$$\mathrm{KS}^s_M(L_{=n}) = \min \left\{ |\pi| \middle| M(\pi, n) = \chi_{L_{=n}} \text{ in } \le s(2^n) \text{ space} \right\},$$

i.e., the length of the shortest program $\pi$ such that $M$, on input $(\pi, n)$, outputs the characteristic string of $L_{=n}$ and halts without using more than $s(2^n)$ workspace.

Well-known simulation techniques show that there exists a machine $U$ which is *optimal* in the sense that for each machine $M$ there is a constant $c$ such that for all $s$, $L$, and $n$ we have

$$\mathrm{KS}^{cs+c}_U(L_{=n}) \le \mathrm{KS}^s_M(L_{=n}) + c.$$

As usual, we fix such a universal machine and omit it from the notation.

*Definition.* For each space bound $s : \mathbb{N} \to \mathbb{N}$ and function $f : \mathbb{N} \to \mathbb{N}$ define the complexity class

$$\mathrm{KS}^{s}_{\mathrm{i.o.}}(f) = \{L \subseteq \{0,1\}^* \mid (\exists^\infty n)\mathrm{KS}^s(L_{=n}) < f(n)\}.$$

Lutz showed that $H_\alpha$ has measure 1 in ESPACE (i.e., that $H_\alpha^c$ has measure 0 in ESPACE) if $\alpha < 1/3$ by showing that languages not in $H_\alpha$ have low space-bounded Kolmogorov complexity.

LEMMA 9.3 (Lutz [15]). *There exist a polynomial $q$ and a constant $c$ such that for all $0 < \alpha < \beta < 1$,*

$$H_\alpha^c \subseteq \mathrm{KS}^{q}_{\mathrm{i.o.}}(2^n - c2^{(1-2\alpha)n} + 2^{\beta n}).$$

The class on the right-hand side in Lemma 9.3 has measure 0 in ESPACE [16]. The scaled dimensions of similar space-bounded Kolmogorov complexity classes were studied in [11].

THEOREM 9.4 (see Hitchcock, Lutz, and Mayordomo [11]). *For any $i \leq -1$, polynomial $q(n) = \Omega(n^2)$, and $\alpha \in [0,1]$,*

$$\dim^{(i)}(\mathrm{KS}^{q}_{\mathrm{i.o.}}(g_i(2^n, \alpha)) \mid \mathrm{ESPACE}) = \alpha.$$

Lemma 9.3 and Theorem 9.4 provide an easy upper bound on the $-1$st-order scaled dimension of $H_\alpha^c$ in ESPACE.

COROLLARY 9.5. *If $0 < \alpha < 1/3$, then*

$$\dim^{(-1)}(H_\alpha^c \mid \mathrm{ESPACE}) \leq 2\alpha.$$

*Proof.* Let $\epsilon > 0$ and $\beta \in (\alpha, 1 - 2\alpha)$. Then for all sufficiently large $n$,

$$\begin{aligned} 2^n - c2^{(1-2\alpha)n} + 2^{\beta n} &< 2^n + 1 - 2^{(1-2\alpha-\epsilon)n} \\ &= g_{-1}(2^n, 2\alpha + \epsilon), \end{aligned}$$

so Lemma 9.3 implies $H_\alpha^c \subseteq \mathrm{KS}^{q}_{\mathrm{i.o.}}(g_{-1}(2^n, 2\alpha+\epsilon))$. Therefore $\dim^{(-1)}(H_\alpha^c \mid \mathrm{ESPACE}) \leq 2\alpha + \epsilon$ by Theorem 9.4. $\square$

We can now state a stronger version of Theorem 9.1. The hypothesis has been weakened, but the conclusion remains the same.

THEOREM 9.6. *If $\dim^{(-1)}(\mathrm{E} \mid \mathrm{ESPACE}) > 0$, then $\mathrm{P} = \mathrm{BPP}$.*

*Proof.* Assume the hypothesis and let $s = \min\{1/2, \dim^{(-1)}(\mathrm{E} \mid \mathrm{ESPACE})\}$. Then by Corollary 9.5, $\mathrm{E} \not\subseteq H_{s/2}^c$, i.e., $\mathrm{E} \cap H_{s/2} \neq \emptyset$. Therefore $\mathrm{P} = \mathrm{BPP}$ by Theorem 9.2. $\square$

We now relate the scaled dimension of $\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E})$ to the $\mathrm{P} \overset{?}{=} \mathrm{PSPACE}$ and $\mathrm{P} \overset{?}{=} \mathrm{BPP}$ problems.

THEOREM 9.7. *For $i \in \{-2, -1\}$,*

$$\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE}) < 1 \Rightarrow \mathrm{P} \neq \mathrm{PSPACE}$$

*and*

$$\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE}) > 0 \Rightarrow \mathrm{P} = \mathrm{BPP}.$$

*Proof.* From Theorem 7.4 we know that $\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE}) = \dim^{(i)}(\mathrm{E} \mid \mathrm{ESPACE})$. Also, $\dim^{(i)}(\mathrm{E} \mid \mathrm{ESPACE}) < 1$ implies $\mathrm{E} \neq \mathrm{ESPACE}$, which implies $\mathrm{P} \neq \mathrm{PSPACE}$ [5]. This proves the first implication. The second one follows from Theorem 9.6 since $\dim^{(i)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE}) > 0$ implies $\dim^{(-1)}(\mathrm{E} \mid \mathrm{ESPACE}) > 0$. ▯

In other words, establishing any nontrivial upper or lower bound on $\dim^{(-1)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE})$ or $\dim^{(-2)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{ESPACE})$ would derandomize BPP or separate P from PSPACE. This is in contrast to the unconditional facts from Corollaries 6.7 and 7.3 that

$$\dim^{(-3)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{E}) = 0$$

and

$$\dim^{(-2)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{E}) = \dim^{(-1)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{E}) \mid \mathrm{E}) = 1.$$

## 10. Conclusion.

Our main results, Theorems 6.3 and 7.1, use resource-bounded scaled dimension to strengthen from both ends the contrasting theorems of Juedes and Lutz [12] and Ambos-Spies et al. [2] regarding spans under polynomial-time reductions.

1. The *small span theorem* for $\leq^{\mathrm{p}}_{\mathrm{m}}$-reductions [12] was strengthened from measure to $-3$rd-order scaled dimension. (In fact, Theorem 6.3 is even stronger than this.)
2. The result that lower spans and degrees have the same dimension [2] was extended to all orders $-2 \leq i \leq 2$ of scaled dimension. This implies that there is no small span theorem in $-2$nd-order scaled dimension.

These results suggest that the contrast between the $-2$nd- and $-3$rd-orders of resource-bounded scaled dimension will be useful for studying complexity classes involving polynomial-time reductions. For example, regarding the many-one complete degree of NP, Corollaries 6.7 and 7.3 say that

$$\dim^{(-3)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{NP}) \mid \mathrm{E}) = 0$$

and

$$\dim^{(-2)}(\mathcal{C}^{\mathrm{p}}_{\mathrm{m}}(\mathrm{NP}) \mid \mathrm{E}) = \dim^{(-2)}(\mathrm{NP} \mid \mathrm{E}).$$

Scaled dimension therefore provides two different types of dimension for studying NP. The NP-complete degree provides all the dimension of NP in order $-2$, but in order $-3$ the NP-complete degree unconditionally has dimension 0.

**Acknowledgments.** I thank Jack Lutz for suggesting this line of research and Xiaoyang Gu for comments on a draft. I also thank the anonymous referees for very helpful comments and corrections.

# RANDOM WALKS ON TRUNCATED CUBES AND SAMPLING 0-1 KNAPSACK SOLUTIONS[*]

BEN MORRIS[†] AND ALISTAIR SINCLAIR[‡]

**Abstract.** We solve an open problem concerning the mixing time of symmetric random walk on the $n$-dimensional cube truncated by a hyperplane, showing that it is polynomial in $n$. As a consequence, we obtain a fully polynomial randomized approximation scheme for counting the feasible solutions of a 0-1 knapsack problem. The results extend to the case of any fixed number of hyperplanes. The key ingredient in our analysis is a combinatorial construction we call a "balanced almost uniform permutation," which is of independent interest.

**Key words.** random walks, Markov chains, hypercubes, random sampling, knapsack problem, random permutations, balanced permutations

## 1. Introduction.

For a positive real vector $\mathbf{a} = (a_i)_{i=1}^n$ and real number $b$, let $\Omega$ denote the set of 0-1 vectors $\mathbf{x} = (x_i)_{i=1}^n$ for which

$$\mathbf{a} \cdot \mathbf{x} \equiv \sum_{i=1}^{n} a_i x_i \le b.$$

Geometrically, we can view $\Omega$ as the set of vertices of the $n$-dimensional cube $\{0,1\}^n$ which lie on one side of the hyperplane $\mathbf{a} \cdot \mathbf{x} = b$. Combinatorially, $\Omega$ is the set of feasible solutions to the 0-1 knapsack problem defined by $\mathbf{a}$ and $b$: if we think of the $a_i$ as the weights of a set of $n$ items and $b$ as the capacity (weight limit) of a knapsack, then there is a 1-1 correspondence between vectors $\mathbf{x} \in \Omega$ and subsets of items $X$ whose aggregated weight does not exceed the knapsack capacity, given by $X = \{i : x_i = 1\}$. We shall write $a(X)$ for the weight of $X$, i.e., $a(X) = \sum_{i \in X} a_i$.

This paper is concerned with the natural nearest neighbor random walk on the "truncated cube" $G_\Omega$ (i.e., the subgraph of the cube induced by $\Omega$), in which the probability of moving to any neighbor is $\frac{1}{n}$. In the knapsack terminology, this walk is described by the following transition rule from any state $X \in \Omega$:

1. with probability $\frac{1}{2}$ do nothing; else
2. pick an item $i \in \{1, \ldots, n\}$ uniformly at random (u.a.r.);
3. if $i \in X$, move to $X - \{i\}$; if $i \notin X$ and $a(X \cup \{i\}) \le b$, move to $X \cup \{i\}$; else do nothing.

(We have added a uniform holding probability of $\frac{1}{2}$ at every state to avoid technical issues involving periodicity.)

It is easy to check that this walk converges to the uniform distribution over $\Omega$ for any choice of $\mathbf{a}$ and $b$. Our main concern in this paper is with the number of steps required until the distribution is close to uniform, starting from an arbitrary initial state. We refer to this as the *mixing time* of the walk (see section 2 for a precise definition).

The question of determining good bounds on the mixing time of this random walk has been posed as an open problem in several places (e.g., [5, 12, 14, 17]) and is of interest for two main reasons. First, despite the development over the past decade of several powerful tools for analyzing the mixing time of combinatorial Markov chains, which have led to a string of surprising results in the field (see, e.g., [12, 9, 14, 17] for surveys), this natural and deceptively simple example remains a challenge to all existing techniques. In particular, the mixing time is not known to be bounded by any polynomial function of $n$. There is strong geometric intuition that it should be: random walk on the entire cube $\{0,1\}^n$ has a mixing time of only $\mathrm{O}(n \log n)$, and truncation by a hyperplane presumably cannot create "bottlenecks" that would severely slow down convergence. Nonetheless, the best known bound on the mixing time remains $\exp\bigl(\mathrm{O}(\sqrt{n}(\log n)^{5/2})\bigr)$ [5], which beats the trivial bound of $\exp(\mathrm{O}(n))$ but is still exponential.

The second reason for the interest in this random walk is its connection to approximate counting. Because the walk converges to the uniform distribution over $\Omega$, it provides an algorithm for sampling (almost) uniformly at random from $\Omega$: just simulate the walk for sufficiently many steps, starting from an arbitrary vertex of $G_\Omega$, and output the final vertex. (This is often known as the "Markov chain Monte Carlo" paradigm.) The running time of the algorithm will be essentially the mixing time of the walk. Now by a well-known relationship based on self-reducibility, for most natural combinatorial structures (including 0-1 knapsack solutions) the problems of approximate counting and of sampling from an (almost) uniform distribution are polynomial time reducible to one another [13, 12]. Therefore, a proof that the above random walk has mixing time polynomial in $n$ would immediately imply the existence of a polynomial time approximation algorithm (actually a *full polynomial randomized approximation scheme*, or *fpras* [12]) for computing $|\Omega|$, the number of feasible knapsack solutions. This problem is #P-complete in exact form, so an fpras is essentially the best we can hope for. Again, following a string of approximate counting algorithms for #P-complete problems in recent years (many of them based on the Markov chain Monte Carlo technique), this problem remains one of the canonical unresolved examples.

In this paper we prove that the above random walk is indeed rapidly mixing, with a mixing time of $\mathrm{O}(n^{9/2+\epsilon})$ steps for any $\epsilon > 0$. This immediately implies the existence of the first fpras for counting 0-1 knapsack solutions.[1] Along the way we develop some new machinery for bounding the mixing time of Markov chains which we believe will be useful for tackling other examples of a similar flavor, and possibly beyond.

We also present a nontrivial extension of these results to the case of multiple hyperplanes (more precisely, multiple constraints of the form $\mathbf{a}_j \cdot \mathbf{x} \leq b_j$ for nonnegative vectors $\mathbf{a}_j$).[2] Here we are also able to prove a mixing time of $\mathrm{O}(n^c)$ (where $c$ is a

[1]Very recently, and after the appearance of the conference version of this paper [16], Martin Dyer gave an algorithm for random sampling and approximate counting of knapsack solutions with running time only $\mathrm{O}(n^{2.5})$ [4]. However, Dyer's algorithm is based on dynamic programming and gives no insight into the mixing time of the random walk.

constant) for any fixed number of hyperplanes. The exponent $c$ depends on the number $d$ of hyperplanes, but this is inevitable as it is not hard to prove a lower bound of $n^{\Omega(d)}$ on the mixing time. Moreover, it is possible to encode NP-hard problems if the number of hyperplanes is permitted to depend on $n$, so we would not expect any polynomial time sampling algorithm for this case.

To prove rapid mixing we use a technique based on multicommodity flow (see [18]): if we can route unit flow between each pair of vertices $X, Y$ in $G_\Omega$ simultaneously in such a way that no edge carries too much flow, then the random walk is rapidly mixing. This technique is well known, but most previous applications (e.g., [10, 11]) have made use of "degenerate" flows in which all $X \to Y$ flow is routed along a single canonical path (though see [2, 18] for exceptions). Our analysis seems to rely essentially on spreading out the flow along multiple paths.

The key ingredient in our analysis is the specification of these paths, which we achieve via an auxiliary combinatorial construction that we believe is of independent interest and will find further applications elsewhere.[3] Note that a shortest path between a pair of vertices $X, Y$ of $G_\Omega$ can be viewed as a *permutation* of the symmetric difference $X \oplus Y$, the set of items that must be added to or removed from the knapsack in passing from $X$ to $Y$. A natural approach to defining a good flow is to use a *random* permutation, so that the flow is spread evenly among all shortest paths and no edge is overloaded. However, a fundamental problem with this approach is that a random permutation will tend to violate the knapsack constraint, as too many items will have been added at some intermediate point. Slightly less obviously, a symmetric problem arises because a random permutation will tend to remove too many items at some intermediate point, causing congestion among edges of the hypercube near the origin. To avoid these problems, we want our permutations to remain "balanced" in the sense that items are added and removed at approximately the correct rates throughout the path; but we also want them to be "sufficiently random" to ensure a well-spread flow. More specifically, it turns out that we require the distribution of the initial segment $\{\pi(1), \dots, \pi(k)\}$, viewed as an unordered set, to be "almost uniform." We call permutations with these properties *balanced almost uniform* permutations. A main contribution of this paper is to show the existence of such permutations.

The remainder of the paper is structured as follows. We begin with some necessary background on flows and rapid mixing in section 2. Then in section 3 we define the notion of balanced almost uniform permutations and show how to construct them; this section is independent of the random walk analysis and should be of wider interest. We go on to use these balanced permutations to define a good flow for the knapsack random walk in section 4. The extension to multiple constraints is handled in section 5; this involves extending our construction of balanced almost uniform permutations in a nontrivial way from scalar weights to vectors in arbitrary dimension, which is again of independent interest. We conclude with the proofs of some technical lemmas in section 6.

## 2. The mixing time and multicommodity flow.

As indicated earlier, we will view elements of $\Omega$ either as 0-1 vectors $\mathbf{x} = (x_i)_{i=1}^n$ or, more commonly, as subsets $X \subseteq \{1, \dots, n\}$, under the equivalence $X = \{i : x_i = 1\}$. Recall that $a(X) = \sum_{i \in X} a_i$

[2]We mention in passing that all our results extend from the 0-1 case to more general cubes of the form $[0, \dots, L]^n$. This extension is purely technical and does not require any substantial new ideas, so we omit the details.

[3]Indeed, these ideas have already been used by Cryan et al. in the analysis of Markov chain Monte Carlo algorithms for contingency tables [1].

is the weight of $X$ so that $\Omega = \{X : a(X) \leq b\}$. Without loss of generality, we will assume that $a_i \leq b$ for all $i$.

We consider the symmetric random walk defined in the introduction on the portion $G_\Omega$ of the hypercube $\{0,1\}^n$. This walk is connected (all states communicate via the zero vector) and aperiodic (because of the holding probabilities), and since the transition probabilities are symmetric, the distribution at time $t$ converges to the uniform distribution over $\Omega$ as $t \to \infty$, regardless of the initial state. Our goal is to bound the rate of convergence as measured by the *mixing time*, defined as

$$\tau_{\mathrm{mix}} = \max_{X_0} \min \left\{ t : \|P_t - \mathcal{U}\| \leq \tfrac{1}{4} \right\},$$

where $X_0$ is the initial state, $P_t$ is the distribution of the walk at time $t$, $\mathcal{U}$ is the uniform distribution over $\Omega$, and $\|\cdot\|$ denotes variation distance.[4] Thus $\tau_{\mathrm{mix}}$ is the number of steps required, starting from any initial state, to get the variation distance from the uniform distribution down to $\frac{1}{4}$. By standard facts about geometric convergence, $\mathrm{O}(\tau_{\mathrm{mix}} \log \epsilon^{-1})$ steps suffice to reduce the variation distance to any desired $\epsilon$.

Fairly standard techniques (see [18]) allow us to estimate $\tau_{\mathrm{mix}}$ by setting up a suitable multicommodity flow on the underlying graph $G_\Omega$. Our task is to route one unit of flow from $X$ to $Y$ for each ordered pair of vertices $X, Y \in \Omega$ simultaneously. For any such flow $f$ and any oriented edge $e$ in $G_\Omega$, let $f(e)$ denote the total flow along $e$; i.e., $f(e)$ is the sum over all ordered pairs $X, Y$ of the $X \to Y$ flow carried by $e$. Define the *congestion* $\mathcal{C}(f) = \frac{1}{|\Omega|} \max_e f(e)$, i.e., the maximum flow along any edge normalized by $|\Omega|$, and the *length* $\mathcal{L}(f)$ to be the length of a longest flow-carrying path. The following theorem[5] is a special case of results in [18], which in turn generalize those in [3].

THEOREM 2.1. *For any flow $f$ on $G_\Omega$, the mixing time is bounded by $\tau_{\mathrm{mix}} \leq 4n(n+1)\mathcal{C}(f)\mathcal{L}(f)$.*

We will bound $\tau_{\mathrm{mix}}$ by constructing a flow $f$ with congestion $\mathcal{C}(f) = \mathrm{O}(n^{3/2+\epsilon})$ for any $\epsilon > 0$, and length $\mathcal{L}(f) = \mathrm{O}(n)$. By Theorem 2.1 this implies $\tau_{\mathrm{mix}} = \mathrm{O}(n^{9/2+\epsilon})$.

*Remark.* We note that our bound on the mixing time is only slightly larger than the upper bound of $\mathrm{O}(n^3)$ which one obtains by applying Theorem 2.1 to the hypercube itself (without the hyperplane constraint); see, e.g., [19]. This is in turn somewhat off from the true mixing time of $\mathrm{O}(n \log n)$. On the other hand, it is fairly easy to obtain a lower bound of $\Omega(n^2/\log n)$ for the mixing time of the truncated cube; consider, for example, an instance in which $\log n$ items have weight 1, the other $n - \log n$ items have weight $n$, and the knapsack capacity is $b = n$.

As explained in the introduction, our flow will be based on the idea of a balanced almost uniform permutation. We devote the next section to this topic and then return to the knapsack random walk in section 4.

**3. Balanced almost uniform permutations.** We begin by defining the notions of "balanced" and "almost uniform" permutations. We will write $\mathcal{S}_m$ to denote the set of all permutations of $\{1, \ldots, m\}$.

DEFINITION 3.1. *Let $\{w_i\}_{i=1}^m$ be a set of real (not necessarily positive) weights, with $M = \max_{i \leq m} |w_i|$ and $W = \sum_i w_i$, and let $\Delta \geq 1$ be a nonnegative number. A*

[4]For probability distributions $\mu, \nu$ on $\Omega$, the variation distance is defined as $\|\mu - \nu\| = \frac{1}{2}\sum_{x \in \Omega} |\mu(x) - \nu(x)| = \max_{S \subseteq \Omega} |\mu(S) - \nu(S)|$.

[5]This theorem applies to symmetric random walk on *any* connected subgraph of the hypercube $\{0,1\}^n$ in which transitions are made to each neighbor with probability $\frac{1}{2n}$.

*permutation $\pi \in \mathcal{S}_m$ is* $\Delta$-balanced *if, for all $k$ with $1 \le k \le m$,*

$$\min\{W, 0\} - \Delta M \le \sum_{i=1}^{k} w_{\pi(i)} \le \max\{W, 0\} + \Delta M. \tag{3.1}$$

Thus a balanced permutation is one whose partial sums do not fluctuate widely. In particular, if $\sum_i w_i = 0$, then condition (3.1) becomes $|\sum_{i=1}^{k} w_{\pi(i)}| \le \Delta M$.

DEFINITION 3.2. *Let $\pi$ be a random permutation in $\mathcal{S}_m$, and let $\lambda \in \mathbf{R}$. We call $\pi$ a* $\lambda$-uniform *permutation if*

$$\Pr\bigl[\pi\{1, \dots, k\} = U\bigr] \le \lambda \times \binom{m}{k}^{-1} \tag{3.2}$$

*for every $k$ with $1 \le k \le m$ and every $U \subseteq \{1, \dots, m\}$ of cardinality $k$. (Here $\pi\{1, \dots, k\}$ denotes the initial segment $\{\pi(1), \dots, \pi(k)\}$.)*

Note that, if $\pi$ were a uniform random permutation, the probability in (3.2) would be exactly $\binom{m}{k}^{-1}$ for every $U$. In a $\lambda$-uniform permutation the probabilities are permitted to vary with $U$, but only by an amount specified by the parameter $\lambda$. In our applications, $\lambda$ will be a fixed polynomial function of $m$; in this case we call $\pi$ an *almost uniform* permutation. The perhaps surprising result of this section is that, for any set of weights $\{w_i\}$, it is possible to construct an almost uniform permutation that is guaranteed to be balanced.

**3.1. The bounded ratio case.** In this section, we prove that there are balanced almost uniform permutations when the ratios of the weights are bounded by a constant. In section 3.2 we will show how to dispense with any restrictions on the weights.

LEMMA 3.3. *Let $\{w_i\}_{i=1}^{m}$ be an arbitrary set of weights with $1 \le |w_i| \le B$ for a constant $B \in [1, 2]$. Then there exists a 1-balanced permutation $\pi$ on $\{w_i\}$ which is $p(m)$-uniform, where $p(m) = Cm^{10(B-1)^2+1/2}$ for a universal constant $C$.*

*Proof.* Let $M = \max_i |w_i|$ and $W = \sum_{i=1}^{m} w_i$. Assume first that $W = 0$; we will show how to discharge this assumption later. Let $I_1 = \{i : w_i > 0\}$, $I_2 = \{i : w_i < 0\}$, $m_1 = |I_1|$, and $m_2 = |I_2|$. Define the means $\mu_1 = \frac{1}{m_1} \sum_{i \in I_1} w_i$ and $\mu_2 = -\frac{1}{m_2} \sum_{i \in I_2} w_i$. Note that $m_1\mu_1 = m_2\mu_2$ since $W = 0$.

Consider an arbitrary permutation $\nu \in \mathcal{S}_m$. This induces permutations $\nu_1, \nu_2$ on $I_1, I_2$, respectively.[6] We call $\nu_1$ $\alpha$*-good* if, for every $k_1$ with $1 \le k_1 \le m_1$,

$$\left|\sum_{i=1}^{k_1} w_{\nu_1(i)} - k_1\mu_1\right| \le \alpha(M-1)\sqrt{k_1^*}, \tag{3.3}$$

where $k_1^* = \min\{k_1, m_1 - k_1\}$, with an analogous definition for $\nu_2$. We call $\nu$ $\alpha$*-good* if both $\nu_1$ and $\nu_2$ are $\alpha$-good. Thus in a good permutation, the partial sums of both positive and negative weights are reasonably close to their expected values.

Now suppose $\nu$ is chosen u.a.r. from $\mathcal{S}_m$. A routine application of Hoeffding's bound to the partial sums (see Lemma 6.1 later) yields

$$\Pr[\nu \text{ is not } \alpha\text{-good}] \le 2m\exp(-2\alpha^2). \tag{3.4}$$

If we set $\alpha = \sqrt{\ln m}$, this probability is at most $\frac{2}{m} \le \frac{1}{2}$ for $m \ge 4$.

[6]Formally, we view $\nu_1$ as a bijection from $\{1, \dots, m_1\}$ to $I_1$, and similarly for $\nu_2$. Throughout we shall adopt this convention where appropriate, without comment.

Consider now a modified sample space in which $\nu$ is selected u.a.r. among all $\sqrt{\ln m}$-good permutations. We shall write $\Pr_{\text{unif}}$ for probabilities in the original uniform space to distinguish them from those in this modified space. By the above calculation, for any event $\mathcal{E} \subseteq \mathcal{S}_m$ we have

$$\Pr[\mathcal{E}] \le 2 \Pr_{\text{unif}}[\mathcal{E}]. \tag{3.5}$$

We are now in a position to construct our balanced almost uniform permutation. Let $\nu$ be chosen u.a.r. from all $\sqrt{\ln m}$-good permutations, and let $\nu_1, \nu_2$ be the induced permutations on $I_1, I_2$. To get a balanced permutation $\pi$, we *interleave* $\nu_1$ and $\nu_2$ as follows. We take the first element from $\nu_1$, i.e., set $\pi(1) = \nu_1(1)$. Thereafter, for each $k > 1$ in turn we set $\pi(k)$ to be the next element in $\nu_2$ if $\sum_{i=1}^{k-1} w_{\pi(i)} > 0$, and the next element in $\nu_1$ otherwise. Since $\sum_i w_i = 0$, this process is well defined and yields a permutation $\pi \in \mathcal{S}_m$. Moreover, since $|w_i| \le M$ for all $i$, it is clear that $\pi$ satisfies the balance condition (3.1) with $\Delta = 1$.

We now need to verify the uniformity condition (3.2) for $\lambda = p(m)$. Let $U \subseteq \{1, \dots, m\}$ be any subset of items with $|U| = k$ and $\Pr[\pi\{1, \dots, k\} = U] > 0$, and define

$$U_1 = U \cap I_1, \qquad U_2 = U \cap I_2, \qquad k_1 = |U_1|, \qquad k_2 = |U_2|.$$

Then we have

$$\begin{aligned} \Pr\bigl[\pi\{1, \dots, k\} = U\bigr] &\le \Pr\bigl[\nu_1\{1, \dots, k_1\} = U_1 \text{ and } \nu_2\{1, \dots, k_2\} = U_2\bigr] \\ &\le 2 \Pr_{\text{unif}}\bigl[\nu_1\{1, \dots, k_1\} = U_1 \text{ and } \nu_2\{1, \dots, k_2\} = U_2\bigr] \\ &= \frac{2}{\binom{m_1}{k_1}\binom{m_2}{k_2}}, \end{aligned} \tag{3.6}$$

where the second inequality follows from (3.5).

Now some routine calculations involving Stirling's formula (see Lemma 6.2 later) allow us to relate $\binom{m_1}{k_1}\binom{m_2}{k_2}$ to $\binom{m_1+m_2}{k_1+k_2} = \binom{m}{k}$. Specifically, (3.6) becomes

$$\Pr\bigl[\pi\{1, \dots, k\} = U\bigr] \le \frac{A m^{1/2}}{\binom{m}{k}} \exp\biggl\{ \frac{l^2 + \frac{1}{2}|l|}{\gamma(1-\gamma)} \biggl( \frac{1}{m_1} + \frac{1}{m_2} \biggr) \biggr\}, \tag{3.7}$$

where $\gamma = \frac{k}{m}$, $l = \frac{m_1 k_2 - m_2 k_1}{m}$, and $A > 0$ is a universal constant. The quantity $l$ measures the deviation of the numbers $k_1, k_2$ of positive and negative elements in $U$ from the "expected" values $\gamma m_1, \gamma m_2$, respectively. But since $\pi$ is balanced, $\nu$ is good, and the element sizes do not vary too much, $|l|$ cannot in fact be very large. To formalize this intuition, note first that

$$l = (k_2 \mu_2 - k_1 \mu_1) \frac{m_2}{\mu_1 m}, \tag{3.8}$$

since $\frac{m_2}{m_1} = \frac{\mu_1}{\mu_2}$. Now by the goodness condition (3.3) on $\nu_1, \nu_2$ we have

$$\begin{aligned} \biggl| \sum_{i=1}^{k} w_{\pi(i)} - (k_1 \mu_1 - k_2 \mu_2) \biggr| &= \biggl| \biggl( \sum_{i=1}^{k_1} w_{\nu_1(i)} + \sum_{i=1}^{k_2} w_{\nu_2(i)} \biggr) - (k_1 \mu_1 - k_2 \mu_2) \biggr| \\ &\le 2(M-1)\sqrt{k^* \ln m}, \end{aligned}$$

where $k^* = \min\{k, m-k\}$. Since $\pi$ is 1-balanced we also know that $|\sum_{i=1}^{k} w_{\pi(i)}| \le M$, and therefore

$$|k_1\mu_1 - k_2\mu_2| \le 2(M-1)\sqrt{k^* \ln m} + M.$$

Together with (3.8) and our assumption that $M \le B$, this implies the following bound on $|l|$:

$$|l| \le \Big(2(B-1)\sqrt{k^* \ln m} + B\Big)\frac{m_2}{\mu_1 m}.$$

Plugging in this value for $|l|$, we see that the exponent in (3.7) is bounded above, when $|l|$ is sufficiently large, by

$$\begin{aligned} &5(B-1)^2 k^* \ln m \frac{m_2^2}{\mu_1^2 m^2}\frac{m^2}{k(m-k)}\frac{m}{m_1 m_2} \\ &= 5(B-1)^2 \ln m \frac{k^* m}{k(m-k)}\frac{1}{\mu_1\mu_2} \\ &\le 10(B-1)^2 \ln m, \end{aligned} \tag{3.9}$$

since $k(m-k) \ge \frac{k^* m}{2}$ and $\mu_1, \mu_2 \ge 1$. Note also that if $|l|$ is bounded, then so is the exponent in (3.7), since

$$\frac{1}{\gamma(1-\gamma)}\left(\frac{1}{m_1} + \frac{1}{m_2}\right) = \frac{m^2}{k(m-k)}\frac{m}{m_1 m_2} \le \frac{m^3}{(m/2)(m/3)(m/3)} \le 18,$$

where we have used the fact that $m_1, m_2 \ge \frac{m}{3}$ which follows because $B \le 2$ and $W = 0$.

Thus (3.7) becomes

$$\Pr\big[\pi\{1,\dots,k\} = U\big] \le C\tbinom{m}{k}^{-1} m^{10(B-1)^2+1/2} \tag{3.10}$$

for a universal constant $C$, which verifies the uniformity condition (3.2) with $\lambda = p(m) = Cm^{10(B-1)^2+1/2}$.

This concludes the proof of the theorem for the case $W = \sum_i w_i = 0$. We can extend the argument to general values of $W$ using a simple trick. We will assume $W > 0$; the case $W < 0$ is entirely symmetrical. We begin by padding the sequence of weights with $d = \lceil W/M \rceil$ values $w_{m+1}, \dots, w_{m+d}$ each of which (except possibly the last) is $-M$, so that $\sum_{i=1}^{m+d} w_i = 0$. Note that $d \le m$. By the above argument for the $W = 0$ case, we can construct a 1-balanced almost uniform permutation $\pi'$ on this padded sequence (though see the remark immediately following this proof). Let $\pi$ be the *induced* permutation on the weights $\{w_i\}_{i=1}^n$. We claim that $\pi$ is also 1-balanced and almost uniform.

To see that $\pi$ is 1-balanced, note that

$$\begin{aligned} &\sum_{i=1}^{k} w_{\pi(i)} \ge \sum_{i=1}^{k'} w_{\pi'(i)} \ge -M \quad \text{and} \\ &\sum_{i=1}^{k} w_{\pi(i)} \le \sum_{i=1}^{k'} w_{\pi'(i)} + W \le M + W \end{aligned}$$

for some $k' \ge k$, using the balance property of $\pi'$.

To see that $\pi$ is almost uniform, let us call the indices $\{1,\dots,m\}$ *true* and the remainder *fake*. Let $U$ be an arbitrary subset of true indices of cardinality $k$. We need to show that

$$\Pr\bigl[\pi\{1,\dots,k\}=U\bigr]\le \tbinom{m}{k}^{-1}p(m). \tag{3.11}$$

Since $\pi$ is induced by $\pi'$, this probability is bounded above by $\sum_S \Pr[\mathcal{E}_S]$, where for $S\subseteq\{1,\dots,m+d\}$, $\mathcal{E}_S$ is the event that $\pi'\{1,\dots,|S|\}=S$ and the sum is over all $S$ of the form $U\cup U'$, where all elements of $U'$ are fake. Now by the almost uniformity of $\pi'$, this sum is at most

$$p(m+d)\sum_S \Pr_{\mathrm{unif}}[\mathcal{E}_S], \tag{3.12}$$

where $\Pr_{\mathrm{unif}}$ denotes probability under the uniform distribution on permutations in $\mathcal{S}_{m+d}$. But the sum in (3.12) is just the expectation, under the uniform distribution, of the random variable $X=\sum_S X_S$, where $X_S$ is the indicator random variable of $\mathcal{E}_S$. Thus $X$ counts the number of events $\mathcal{E}_S$ that occur. We claim that

$$\mathrm{E}(X)=\tbinom{m}{k}^{-1}\left(1+\frac{d}{m+1}\right). \tag{3.13}$$

This will complete the verification of condition (3.11), for replacing the sum in (3.12) by $\mathrm{E}(X)$ gives

$$\begin{aligned}\Pr\bigl[\pi\{1,\dots,k\}=U\bigr]&\le \tbinom{m}{k}^{-1}\left(1+\frac{d}{m+1}\right)p(m+d)\\ &\le \tbinom{m}{k}^{-1}2C(2m)^{10(B-1)^2+1/2},\end{aligned}$$

where the second inequality holds because $d\le m$. Thus, if we incorporate into $C$ an extra factor $2^{10(2-1)^2+3/2}$, we see that $\pi$ is $\lambda$-balanced for $\lambda=p(m)=Cm^{10(B-1)^2+1/2}$, as required.

To see the claim in (3.13), let $\mathcal{E}$ be the event that $\pi\{1,\dots,k\}=U$. Clearly $\Pr_{\mathrm{unif}}[\mathcal{E}]=\binom{m}{k}^{-1}$, and $X=0$ unless $\mathcal{E}$ occurs, so we have

$$\mathrm{E}(X)=\tbinom{m}{k}^{-1}\mathrm{E}(X|\mathcal{E}). \tag{3.14}$$

Conditioning now on $\mathcal{E}$, let $r$ be the position in $\pi'$ of the last element of $U$, so that $U\subseteq\pi'\{1,\dots,r\}$ and $\pi'(r)\in U$. Also, let $s$ be the position of the *next* true element; i.e., $\pi'(s)$ is true and $\pi'(t)$ is fake for $r<t<s$. (If no such element exists, let $s=m+d+1$.) Then $\mathcal{E}_S$ holds for precisely those sets $S=\pi'\{1,\dots,t\}$, where $r\le t<s$. The number of such sets is just the number of fake elements that fall between the true element at position $r$ and the next true element (at position $s$), plus one. The expectation of this quantity under the uniform distribution is plainly $1+\frac{d}{m+1}$. Plugging this into (3.14), we get the value claimed in (3.13), which concludes the proof that $\pi$ is almost uniform. ∎

*Remark.* We should point out that the padded sequence we introduced in the second part of the above proof might contain one weight whose absolute value is less than one. Thus it is not, in a strict sense, a special case of the earlier $W=0$ case, where we assumed that all the weights had absolute values in the range $[1,B]$. However, as the reader may easily verify, the analysis leading up to (3.10) still holds (with minor modifications) even when there is a single small weight.

**3.2. The general case.** In this section we extend our construction of balanced almost uniform permutations to handle arbitrary weights. The chief obstacle here is that it is no longer true (as in the bounded ratio case) that each item of positive weight can be balanced by a bounded number of items of negative weight. To overcome this difficulty, we will need to group items into "intervals" so that each interval has approximately the same (positive or negative) weight. We can then reduce to the bounded ratio case.

The following theorem is a generalization of Lemma 3.3; it says that we can construct a balanced almost uniform permutation for an arbitrary set of weights. Moreover, we can bound the uniformity parameter $\lambda$ by a polynomial whose degree is arbitrarily close to 1/2 at the cost of a modest increase in the balance parameter $\Delta$. This is almost the best that one can hope for; we encourage the reader to check by a simple counting argument that, if we have $m/2$ weights of $+1$ and $m/2$ of $-1$, then for any constants $\Delta$, $C$, and $p < 1/2$, there can be no $\Delta$-balanced $Cm^p$-uniform permutation if $m$ is sufficiently large.

In order to achieve the tightest possible bound in our random walk analysis in the next subsection, we shall actually prove a slightly stronger uniformity property which can be obtained with no additional effort. Call $\pi$ *strongly $\lambda$-uniform* if

$$\Pr\bigl[\pi\{1,\dots,k\} = U \text{ and } \pi(k+1) = l\bigr] \le \lambda \times \binom{m}{k,\ m-k-1,\ 1}^{-1} \tag{3.15}$$

for every $k$ with $1 \le k \le m$, every $U \subseteq \{1,\dots,m\}$ of cardinality $k$, and every $l \notin U$. Note that the expression on the right-hand side of (3.15) is just $\lambda$ times the probability of the given event if $\pi$ were chosen uniformly at random. Plainly (3.15) is a strengthening of (3.2) in Definition 3.2.

THEOREM 3.4. *Fix $0 < \epsilon < 2$ and let $\Delta = 1 + \sqrt{90/\epsilon}$. For any $m$ and set of weights $\{w_i\}_{i=1}^m$, there exists a $\Delta$-balanced, strongly $Cm^{1/2+\epsilon}$-uniform permutation, where $C$ is a universal constant.*

To illustrate this theorem, if we plug in the value $\epsilon = 3/2$ (say), we obtain the following corollary.

COROLLARY 3.5. *For any set of weights $\{w_i\}_{i=1}^m$, there exists a 9-balanced, $Cm^2$-uniform permutation.*

*Proof of Theorem* 3.4. First, we observe that the permutation constructed in the proof of Lemma 3.3 actually satisfies the strong uniformity property (3.15), provided that we incorporate an extra factor of 3 into the constant $C$. To see why, note that the permutation must first choose $U$ and then $l$. Suppose that the sum of the weights of the indices of $U$ is positive. Then $l$ is chosen uniformly from the remaining indices of negative weight. But these must constitute at least 1/3 of all of the remaining indices since $B \le 2$. Hence the restriction on the choice of $l$ introduces a factor of at most 3 into the uniformity parameter.

Now let $\{w_i\}$ be an arbitrary set of weights, let $M = \max_i |w_i|$, and set $\widehat{\Delta} = \frac{\Delta-1}{3}$. Let $\beta$ be a uniform random permutation in $\mathcal{S}_m$, and let $T_1$ be the smallest $t$ such that the partial sum $\sum_{i=1}^t w_{\beta(i)}$ has absolute value greater than $\widehat{\Delta}M$ (or $T_1 = m$ if no such $t$ exists). Similarly, let $T_2$ be the smallest $t > T_1$ such that $|\sum_{i=T_1+1}^t w_{\beta(i)}| > \widehat{\Delta}M$. Define $T_3, T_4, \dots$ in the same way. Then let $I_1$ be the sequence $\{\beta(i)\}_{i=1}^{T_1}$ and $I_2$ the sequence $\{\beta(T_1+i)\}_{i=1}^{T_2-T_1}$. Continue in this way, dividing $\beta$ into *intervals* $I_1, \dots, I_q$ (so that $T_q = m$).

Now let $\alpha_i$ be the aggregated weight of interval $I_i$ for $i = 1, 2, \dots, q-1$. Note that $|\alpha_i| \in [\widehat{\Delta}M, (\widehat{\Delta}+1)M]$ for all $i < q$, so the ratio of the weights of any two of these intervals is at most $(\widehat{\Delta}+1)/\widehat{\Delta} \in [1,2]$. Thus, by Lemma 3.3, there exists a 1-balanced $\lambda$-uniform permutation on $\{\alpha_i\}_{i=1}^{q-1}$ for $\lambda = Cq^{10\left((\widehat{\Delta}+1)/\widehat{\Delta}-1\right)^2+1/2} = Cq^{1/2+\epsilon}$, where $C$ is a universal constant. Moreover, as argued above, we can in fact assume that this permutation is *strongly* $\lambda$-uniform. Call this permutation $\pi_I$. We claim that the permutation

$$\pi = I_{\pi_I(1)} I_{\pi_I(2)} \cdots I_{\pi_I(q-1)} I_q$$

obtained by rearranging the first $q-1$ intervals according to $\pi_I$ is a $\Delta$-balanced strongly $Cm^{1/2+\epsilon}$-uniform permutation on the original $m$ weights.

We prove the balance property first. Let $W' = \sum_{i=1}^{q-1} \alpha_i = W - \alpha_q$. Since $\pi_I$ is 1-balanced, $\pi$ satisfies

$$\min\{0, W'\} - (\widehat{\Delta}+1)M \le \sum_{i=1}^{T_j} w_{\pi(i)} \le \max\{0, W'\} + (\widehat{\Delta}+1)M$$

for all $1 \le j \le q$. Hence we have, for all $j$,

$$\min\{0, W'\} - (2\widehat{\Delta}+1)M \le \sum_{i=1}^{j} w_{\pi(i)} \le \max\{0, W'\} + (2\widehat{\Delta}+1)M,$$

since the partial sums within any interval lie in the range $[-\widehat{\Delta}M, \widehat{\Delta}M]$. Finally, note that $|W - W'| = |\alpha_q| \le \widehat{\Delta}M$. It follows that for all $j$,

$$\min\{0, W\} - (3\widehat{\Delta}+1)M \le \sum_{i=1}^{j} w_{\pi(i)} \le \max\{0, W\} + (3\widehat{\Delta}+1)M,$$

and hence $\pi$ is $\Delta$-balanced.

To verify the strong uniformity property, consider first an alternative experiment in which the permutation $\pi_I$ is chosen u.a.r. from $\mathcal{S}_{q-1}$, without regard to the balance property. Note that, conditional on the value of $q$, the distribution of $(I_1, \dots, I_{q-1})$ is exchangeable. Thus, rearranging the intervals according to a uniform $\pi_I$ is a *measure-preserving* transformation, so $\pi$ itself has the uniform distribution. Thus we need to show that for any $U$ and any index $l \notin U$, the likelihood ratio

$$\frac{\Pr[\pi\{1,\dots,k\} = U \text{ and } \pi(k+1) = l]}{\Pr_{\text{unif}}[\pi\{1,\dots,k\} = U \text{ and } \pi(k+1) = l]} \le Cm^{1/2+\epsilon},$$

where we write $\Pr_{\text{unif}}$ for the probability when $\pi_I$ is uniform and Pr for the probability when $\pi_I$ is $Cm^{1/2+\epsilon}$-uniform. In fact, it suffices to show that the above bound on the likelihood ratio holds conditional on any $\beta$. So fix a permutation $\beta$. In order for the numerator to be nonzero, only the interval containing $l$ can contain elements from both $U$ and $U^c$ (the complement of $U$). Additionally, in the interval containing $l$, all the elements before $l$ must be in $U$ and all those after $l$ must be in $U^c$. Let $A_1$ be the collection of intervals in $\{I_i\}_{i=1}^{q-1}$ containing only elements of $U$, and let $A_2$ be the collection of intervals containing only elements of $U^c$. Then $|A_1| + |A_2|$ must have value either $q-1$ or $q-2$. Writing $\mathcal{E}_1$ for the event $\pi_I\{1, \dots, |A_1|\} = A_1$ and $\mathcal{E}_2$ for the event $\pi_I\{q-1, \dots, q-|A_2|\} = A_2$, the above likelihood ratio is

$$\frac{\Pr[\mathcal{E}_1 \text{ and } \mathcal{E}_2]}{\Pr_{\text{unif}}[\mathcal{E}_1 \text{ and } \mathcal{E}_2]} \le Cq^{1/2+\epsilon} \le Cm^{1/2+\epsilon}.$$

In the case where $|A_1| + |A_2| = q - 1$, this is just the $Cq^{1/2+\epsilon}$-uniformity property; when $|A_1| + |A_2| = q - 2$ it is the strong $Cq^{1/2+\epsilon}$-uniformity property. Thus $\pi$ is strongly $Cm^{1/2+\epsilon}$-uniform, and the proof is complete. ∎

## 4. Constructing a good flow.

We now return to the random walk for the knapsack problem and show how to construct a flow $f$ with small congestion $\mathcal{C}(f)$ and length $\mathcal{L}(f)$. Our construction will make heavy use of the balanced almost uniform permutations discussed in the previous section. In the first subsection below, we present a slightly informal high-level sketch of the argument, concentrating on showing how the balance and almost uniformity properties of the permutations are used. In section 4.2 we will give the full details of the flow.

### 4.1. High-level sketch.

Let $X, Y$ be two arbitrary vertices of $G_\Omega$, viewed as subsets of $\{1, \dots, n\}$. We need to specify how to route one unit of flow from $X$ to $Y$. The high-level idea is the following. Let $S = X \oplus Y$ (where $\oplus$ denotes symmetric difference) and $m = |S|$, and let $\{w_i\}_{i=1}^m$ be an arbitrary enumeration of the weights of the items in $S$, with the weights of items in $X, Y$ appearing with negative and positive signs, respectively. Note that each permutation of these items specifies a geodesic path from $X$ to $Y$. Thus a balanced almost uniform permutation on the $\{w_i\}$ specifies a scheme for routing unit flow between $X$ and $Y$ along geodesic paths; the amount of flow allocated to a given path is just the probability assigned to the corresponding permutation. Moreover, the weight of the $k$th point along the path is given by $a(X) + \sum_{i=1}^k w_{\pi(i)}$. We would like to use the balance property to argue that these paths remain within $\Omega$, and the almost uniformity property to argue that they are "well spread out" and thus lead to small congestion. In what follows, we assume the existence of $\Delta$-balanced, $p(m)$-uniform permutations on any set of weights $\{w_i\}_{i=1}^m$, where $\Delta$ is a fixed positive integer and $p$ is a fixed polynomial. (By Corollary 3.5 we know we can take, e.g., $\Delta = 9$ and $p(m) = \mathrm{O}(m^2)$.)

The problem with the above idea is that we need $X$ and $Y$ to be at least some small distance below the bounding hyperplane to accommodate the fluctuations that are still present within the balanced permutations. At this point, for the purposes of illustration, we make a simplifying assumption: we assume that there exists a fixed constant $h$ (independent of $n$ and the $a_i$) such that, by removing at most $h$ items from $X \oplus Y$, we arrive at vertices $X'$ and $Y'$ which satisfy $a(X'), a(Y') \le b - \Delta M$, where $M = \max_{i \in X' \oplus Y'} a_i$. Note that removing the $h = 2\Delta$ heaviest items from $X \oplus Y$ ensures this for at least one of $X', Y'$. In fact, if we increase $h$ by a constant factor, then the same holds for both $X'$ and $Y'$ for most pairs $(X, Y) \in \Omega \times \Omega$. For now, however, we simply assume this property for all pairs. Denote by $X_0, Y_0$ the sets of items removed from $X, Y$, respectively (i.e., $X = X' \cup X_0$ and $Y = Y' \cup Y_0$, with $|X_0 \cup Y_0| \le h$).

We can now describe the flow from $X$ to $Y$ in three stages:

*Stage* 1. Send the entire unit flow along a single path from $X$ to $X'$ by removing the items in $X_0$ in index order.

*Stage* 2. Distribute the unit flow along geodesic paths from $X'$ to $Y'$ according to a balanced almost uniform permutation $\pi$ on the (signed) weights $\{w_i\}_{i=1}^m$ of the items in $S = X' \oplus Y'$, where $m = |S|$.

*Stage* 3. Send the entire unit flow along a single path from $Y'$ to $Y$ by adding the items in $Y_0$ in index order.

Figure 4.1 gives a schematic illustration of this flow. Notice how the upper bound in the balance property keeps the path below the hyperplane, while the lower bound

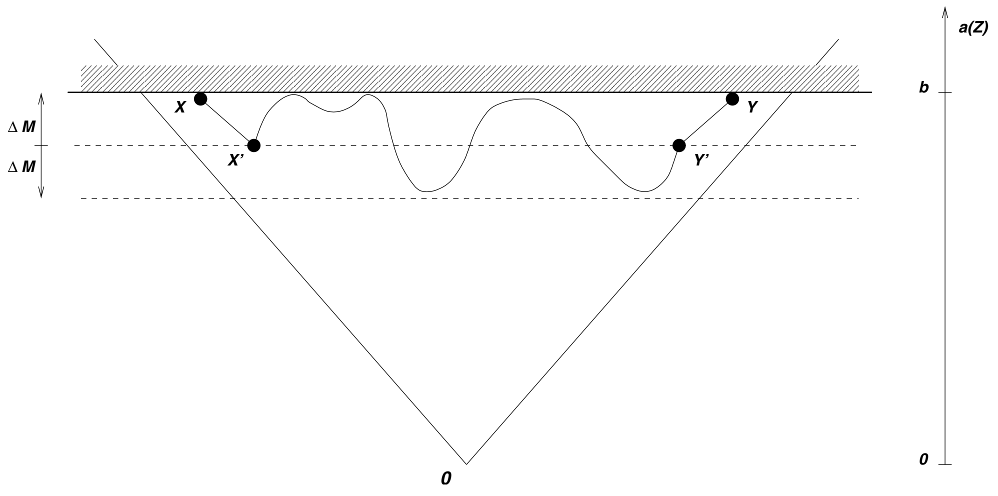

FIG. 4.1. *Schematic illustration of flow from $X$ to $Y$. The function $a(\cdot)$ increases in the vertical direction; the bounding hyperplane is $a(Z) = b$. In the case shown, $a(X') = a(Y')$; the balance property of the permutation of $X' \oplus Y'$ ensures that the path remains within $\pm\Delta M$ of this level.*

keeps the path from passing too close to the origin (thus avoiding a potential bottleneck).

Let us first observe that the above flow is valid. For this, we just need to check that all the flow-carrying paths remain within the set $\Omega$. This is obvious for stages 1 and 3. For stage 2 it follows from the balance property of $\pi$; for if $Z$ is the $k$th point along a flow-carrying path from $X'$ to $Y'$, then

$$\begin{aligned} a(Z) &= a(X') + \sum_{i=1}^{k} w_{\pi(i)} \\ &\le a(X') + \max\{a(Y') - a(X'), 0\} + \Delta M \\ &= \max\{a(Y'), a(X')\} + \Delta M \\ &\le b, \end{aligned} \tag{4.1}$$

where in the last line we have used the fact that $a(X'), a(Y') \le b - \Delta M$. Hence $Z \in \Omega$.

Next we must bound the quantities $\mathcal{C}(f)$ and $\mathcal{L}(f)$ for this flow $f$, as defined in section 2. $\mathcal{L}(f)$, the length of a longest flow-carrying path, is plainly at most $m \le n$. To estimate the congestion $\mathcal{C}(f)$, we must bound the flow along any edge of $G_\Omega$. For convenience in this sketch, we will in fact bound the flow $f(Z)$ through any *vertex* $Z$; clearly this is also an upper bound on the flow along any edge.

So let $Z$ be an arbitrary vertex of $G_\Omega$. Define $\mathcal{P}(Z)$ to be the set of pairs $(X, Y)$ such that some $X \to Y$ flow passes through $Z$. Note that $\mathcal{P}(Z) = \bigcup_{i=1}^{3} \mathcal{P}_i(Z)$, where $\mathcal{P}_i(Z)$ are the pairs whose paths pass through $Z$ in stage $i$. We shall bound the contribution to $f(Z)$ from each $\mathcal{P}_i(Z)$ separately. For $i = 1, 3$ this is simple: since stage-1 paths have length at most $h$, for any given $Y \in G_\Omega$ the number of vertices $X$ such that $(X, Y) \in \mathcal{P}_1(Z)$ is (crudely) at most $(h+1)n^h$, so the contribution to $f(Z)$ from such paths is no more than $(h+1)n^h|\Omega|$. The same bound holds symmetrically for $\mathcal{P}_3(Z)$. The main portion of the paths, $\mathcal{P}_2(Z)$, presents more of a challenge.

We shall actually work with $\mathcal{P}_2'(Z)$, the set of pairs $(X',Y')$ such that $Z$ lies on the stage-2 path with endpoints $X',Y'$. By the observation in the previous paragraph, the flow contribution from $\mathcal{P}_2(Z)$ will be (again crudely) at most $(h+1)^2n^{2h}$ times that from $\mathcal{P}_2'(Z)$. Recall that we are really interested in the ratio $\frac{f(Z)}{|\Omega|}$, rather than in $f(Z)$ itself. Accordingly, following earlier analyses of this general type (see, e.g., [10, 11]), we measure the set $\mathcal{P}_2'(Z)$ by associating with each of its elements $(X',Y')$ an "encoding" $\widetilde{Z}$, which belongs to $\Omega$. This is defined by

$$\widetilde{Z} = X' \oplus Y' \oplus Z.$$

To see that $\widetilde{Z} \in \Omega$, we need to check that $a(\widetilde{Z}) \le b$. But this follows because

$$\begin{aligned} a(\widetilde{Z}) &= a(X') + a(Y') - a(Z) \\ &\le a(X') + a(Y') - t(\min\{a(X'), a(Y')\} - \Delta M) \\ &= \max\{a(X'), a(Y')\} + \Delta M \\ &\le b, \end{aligned}$$

where in the second line we have used the balance property of $\pi$ as in (4.1) to bound $a(Z)$, this time from below.

How many pairs $(X',Y')$ could be mapped to a given $\widetilde{Z}$? First note that $\widetilde{Z}$ uniquely determines both $S = X' \oplus Y'$ and $I = X' \cap Y'$ via the relations

$$S = \widetilde{Z} \oplus Z, \qquad I = \widetilde{Z} \cap Z.$$

Thus, in particular, such pairs share the same symmetric difference, $S$, of cardinality $m$, say. To determine $X'$ and $Y'$ uniquely, it suffices to specify the subset $U \subseteq S$ of elements that have already been processed (i.e., added or deleted) by the stage-2 path by the time it reaches $Z$. For then we know, from the fact that all stage-2 paths are geodesic, that $X'$ agrees with $Z$ on $S-U$ and with $\widetilde{Z}$ on $U$, and vice versa for $Y'$. More formally,

$$X' = Z \oplus U, \qquad Y' = \widetilde{Z} \oplus U.$$

The upshot of the foregoing discussion is that we can define a mapping from $\mathcal{P}_2'(Z)$ to pairs of the form $(\widetilde{Z},U)$, where $\widetilde{Z} \in \Omega$ and $U$ is a subset of $Z \oplus \widetilde{Z}$. Moreover, and crucially, this mapping is *injective*. It therefore effectively enumerates the set $\mathcal{P}_2'(Z)$.

Finally, we need to take account of the actual quantity of flow traveling along the paths. Consider a pair $(X',Y') \in \mathcal{P}_2'(Z)$, corresponding to the pair $(\widetilde{Z},U)$. Recall that the flow distribution between $X'$ and $Y'$ is determined by a balanced almost uniform permutation $\pi$ of the weights in $S = X' \oplus Y'$. The proportion of this flow that passes through $Z$ is precisely

$$\Pr\bigl[\pi\{1,\dots,|U|\} = U\bigr] \le \tbinom{m}{|U|}^{-1} p(m),$$

by the almost uniform property of $\pi$.

Putting all this together, we can bound the total contribution to $f(Z)$ from $\mathcal{P}_2'(Z)$ as follows:

$$\begin{aligned} \sum_{\widetilde{Z}\in\Omega} \sum_{U\subseteq Z\oplus\widetilde{Z}} \Pr\bigl[\pi\{1,\dots,|U|\} = U\bigr] &\le \sum_{\widetilde{Z}\in\Omega} \sum_{k} \sum_{U\subseteq Z\oplus\widetilde{Z},\,|U|=k} \tbinom{m}{k}^{-1} p(m) \\ &\le p(n) \sum_{\widetilde{Z}\in\Omega} \sum_{k} \tbinom{m}{k}\tbinom{m}{k}^{-1} \\ &\le np(n)|\Omega|, \end{aligned}$$

where in the summations $m = |Z \oplus \widetilde{Z}|$. The total contribution from all stage-2 paths is thus at most $(h+1)^2 n^{2h+1} p(n)|\Omega|$.

Combining this with our earlier bounds for stages 1 and 3, we obtain that $f(Z) \leq (2(h+1)n^h + (h+1)^2 n^{2h+1} p(n))|\Omega|$, and hence $\mathcal{C}(f) \leq p'(n)$ (for a different polynomial $p'$). Since both $\mathcal{L}(f)$ and $\mathcal{C}(f)$ are bounded polynomially in $n$, we obtain immediately from Theorem 2.1 that the mixing time, $\tau_{\text{mix}}$, is polynomial in $n$ as required.

In the above sketch, we assumed that we could remove a fixed number of items from $X$ and $Y$ and thereby ensure that they are well separated from the bounding hyperplane. The main extra work in the full description of the flow in the next subsection is concerned with discharging this assumption. In addition, we will be more precise in our accounting so as to achieve the tightest possible bound on $\mathcal{C}(f)$.

**4.2. Complete description.** In this subsection, we present a complete construction, for an arbitrary instance of the 0-1 knapsack problem, of a flow $f$ with congestion $\mathcal{C}(f) = \mathrm{O}(n^{3/2+\epsilon})$ for any $\epsilon > 0$ and length $\mathcal{L}(f) = \mathrm{O}(n)$. By Theorem 2.1, this will imply that the mixing time of the random walk on $G_\Omega$ is $\mathrm{O}(n^{9/2+\epsilon})$. From now on we assume that $\epsilon > 0$ is arbitrary but fixed.

Let $X, Y$ be arbitrary vertices of $G_\Omega$. Recall the scheme for constructing a flow from $X$ to $Y$ in the sketch of section 4.1; we essentially followed a balanced almost uniform permutation of $X \oplus Y$, except that we removed a constant number of items from consideration (processing them at the beginning and end of the path) to ensure that both path endpoints were far enough from the hyperplane so that the path remained within $G_\Omega$. In reality this property is not guaranteed by the removal of a fixed number of items because of the possibly large variations in weights between $X$ and $Y$. (For example, if all the items in $X$ are much larger than those in $Y$, then removing any fixed number of items from $X$ and $Y$ could still leave $Y$ too close to the hyperplane relative to the size of the largest remaining item in $X \oplus Y$.) However, it turns out that after removing a fixed number of heavy items from $X \oplus Y$, we can perform a "preprocessing" operation by randomly switching items between $X$ and $Y$ to roughly balance their weights. Moreover, we will need to add and delete the removed items repeatedly along the path to maintain fine balance. The resulting flow-carrying paths will not in general be geodesics, as before, though they will have length only $\mathrm{O}(n)$.

In preparation for describing the flow, we first describe the preprocessing operation. We assume that $a(X) + a(Y) \leq 2b - 6\Delta M$, where $M = \max_{i \in X \oplus Y} a_i$ and $\Delta = \Delta(\epsilon)$ is the constant appearing in Theorem 3.4. (We will reduce to this case by first deleting a fixed number of items from $X \oplus Y$.) Call the pair $(X, Y)$ *full* if either $a(X) > b - \Delta M$ or $a(Y) > b - \Delta M$. Our goal is to shift items randomly between $X$ and $Y$ and thereby reach a pair $(X', Y')$ that is not full.

Consider the following random walk on $\{(X', Y') : X' \cup Y' = X \cup Y,\ X' \cap Y' = X \cap Y,\ a(X'), a(Y') \leq b\}$. If the current state is $(X', Y')$, choose an index $i \in X' \oplus Y'$ u.a.r. With probability $\frac{1}{2}$, do nothing; else move $i$ from $X'$ to $Y'$ or $Y'$ to $X'$ if possible. We call this the *preprocessing random walk* (PRW). We claim in the following lemma that, if we run the PRW for a number of steps chosen randomly between 1 and $\mathrm{O}(n)$, we will with reasonable probability arrive at a pair $(X', Y')$ that is not full. The proof uses a martingale argument and is deferred to section 6.

LEMMA 4.1. *Let $(X, Y)$ be a full pair of vertices in $G_\Omega$ with $a(X) + a(Y) \leq 2b - 6\Delta M$, where $M = \max_{i \in X \oplus Y} a_i$. Pick $T$ u.a.r. from $\{1, 2, \ldots, C_1 m\}$, where $m = |X \oplus Y|$ and $C_1$ is a suitable constant (which depends only on $\Delta$), and let*

*$(X', Y')$ be the result of running the PRW for $T$ steps starting from $(X, Y)$. Then* $\Pr[(X', Y')$ *is not full*$] \geq 1/C_2$ *for a positive constant $C_2$ (which again depends only on $\Delta$).*

We are now ready to construct and analyze the flow.

LEMMA 4.2. *For arbitrary weights and any $\epsilon > 0$, it is possible to construct a multicommodity flow $f$ in $G_\Omega$ with $\mathcal{C}(f) = \mathrm{O}(n^{3/2+\epsilon})$ and $\mathcal{L}(f) = \mathrm{O}(n)$.*

*Proof.* Let $X, Y$ be arbitrary vertices of $G_\Omega$. Viewing $X$ and $Y$ as subsets of $\{1, \ldots, n\}$, let $H$ be the $h = \lceil 6\Delta \rceil$ elements of $X \oplus Y$ having largest weight (or let $H = X \oplus Y$ if $|X \oplus Y| \leq h$), with ties broken according to index order. Define $X' = X - H$, $Y' = Y - H$, and $S = X' \oplus Y'$. Let $m = |S|$ and $M = \max_{i \in S} a_i$.

We will say that a set of indices $Z$ is *good* if $Z - H \in \Omega$ and $(Z \oplus X \oplus Y) - H \in \Omega$. For a set of indices $Z$ and an index $i$, define

$$Zi = \begin{cases} Z \oplus \{i\} & \text{if } Z \oplus \{i\} \text{ is good,} \\ Z & \text{otherwise.} \end{cases}$$

Define $Zi_1i_2 = ((Zi_1)i_2)$ and so on. Note that if $Y = Xi_1 \cdots i_l$, then the sequence $i_1, \ldots, i_l$ defines a path from $X$ to $Y$ in the unit hypercube of length at most $l$. This path need not in general lie within $G_\Omega$; however, it is "close to" $G_\Omega$ in the sense that for every point $Z$ of the path, $Z - H \in \Omega$.

If $(X', Y')$ is not full, set $T = 0$; otherwise, choose $T$ u.a.r. from $\{1, \ldots, C_1 m\}$, where $C_1$ is the constant in Lemma 4.1. Next, let $i_1, \ldots, i_T$ be chosen independently from the uniform distribution over $S$. Define $X'' = X'i_1 \cdots i_T$ and $Y'' = X'' \oplus X' \oplus Y' = Y'i_1 \cdots i_T$. Thus $(X'', Y'')$ is the result of running the PRW for $T$ steps starting from $(X', Y')$. Note that $a(X') + a(Y') \leq 2b - a(H) \leq 2b - 6\Delta M$. So, by Lemma 4.1, we can condition on the event that the pair $(X'', Y'')$ is not full and thus increase the probability of any path by a factor of at most $C_2$.

Now let $\{w_i\}_{i=1}^m$ be an arbitrary enumeration of the weights of the items in $S$, with the weights of items in $X'', Y''$ appearing with negative and positive signs, respectively, and let $\pi$ be a $\Delta$-balanced, strongly $Cm^{1/2+\epsilon}$-uniform permutation on the $\{w_i\}$ whose existence is guaranteed by Theorem 3.4. We claim that the sequence

$$i_1, \ldots, i_T, \pi(1), \ldots, \pi(m), i_T \ldots, i_1 \tag{4.2}$$

defines a path from $X$ to $Y$ in the hypercube. This is true because the condition that $(X'', Y'')$ be not full, together with the fact that $\pi$ is balanced, guarantees that all of the transitions indicated by $\pi$ will actually take place.

Set

$$j_k = \begin{cases} i_k & \text{if } 1 \leq k \leq T, \\ \pi(k - T) & \text{if } T < k \leq T + m, \\ i_{2T+m-k-1} & \text{if } T + m < k \leq 2T + m, \end{cases}$$

and let $l = 2T + m$. Then $j_1, \ldots, j_l$ is the sequence in (4.2). Our flow from $X$ to $Y$ will essentially follow the sequence $j_k$, except that along the way elements of $H$ will be used to keep the knapsack as full as possible but will be removed as necessary to make room for new items $j_k$ to be added. Thus each intermediate state $Z$ will be of the form $\overline{H} \oplus Xj_1 \cdots j_k$, for some $\overline{H} \subseteq H$ and $k \leq l$.

Suppose that, after processing the first $k \leq l$ elements of the sequence in (4.2), we have $Z = \overline{H} \oplus Xj_1 \cdots j_k$ for some $\overline{H} \subseteq H$. The transition rule will be as follows.

1. If $k < l$ and $j_{k+1} \notin Z$, then move to $Zj_{k+1}$ if possible (i.e., if the result is an element of $\Omega$); otherwise, delete an element from $H$.

2. If $k < l$ and $j_{k+1} \in Z$, then add an element from $H$ if possible; otherwise, move to $Zj_{k+1}$.
3. If $k = l$, then add an element from $H \cap Y$ if possible; otherwise, delete an element from $H \cap X$.

The fact that all of the sets $Xj_1 \cdots j_k$ are good ensures that sufficient elements of $H$ can always be removed so as to make room to add the next element $j_{k+1}$ when necessary; hence the above rule defines a feasible random path from $X$ to $Y$. Similarly, goodness also implies that $a(Z \oplus X \oplus Y - H) \le b$ for every intermediate state $Z$; since our rule keeps the weight as large as possible, this implies that, at any intermediate edge $(Z, W)$ along the path, there exists (at most) one element $u \in H$ such that

$$a(Z \oplus X \oplus Y - \{u, z\}) \le b, \tag{4.3}$$

where $z$ is the index such that $\{z\} = Z \oplus W$. Then $(\widetilde{Z} - \{u, z\}) \in \Omega$, where, exactly as in the analysis in section 4.1, we define the "encoding" $\widetilde{Z}$ by

$$\widetilde{Z} = X \oplus Y \oplus Z.$$

Thus, for any given edge $(Z, W)$, the number of encodings $\widetilde{Z}$ is at most $n|\Omega|$.

Note that the path from $X$ to $Y$ can be naturally divided into three *stages*, corresponding to the three parts of the sequence $j_k$. We will write the flow through any given edge $(Z, W) \in G_\Omega$ as $f(Z, W) = f_1(Z, W) + f_2(Z, W) + f_3(Z, W)$, where $f_i(Z, W)$ is the contribution of stage-$i$ paths. We will bound $f$ by bounding each of the three contributions $f_i$ separately.

Consider stage 1 first, and focus on a particular edge $(Z, W)$. For any pair $(X, Y)$ that sends flow through $(Z, W)$ in stage 1, we can write $Z = \overline{H} \oplus Xj_1 \cdots j_k$, where $j_1, \dots, j_k$ are the first $k$ elements processed along the path. Thus the pair $(X, Y)$ is completely specified by $k$, $j_1, \dots, j_k$, $\widetilde{Z}$, and $\overline{H}$, via the easily verified relations

$$X = \overline{H} \oplus Zj_k \cdots j_1, \qquad Y = \overline{H} \oplus \widetilde{Z}j_k \cdots j_1.$$

The amount of flow corresponding to a given sequence $j_1, \dots, j_k$ is bounded above by the probability that $j_1, \dots, j_k, z$ were the first $k+1$ indices chosen in the PRW, which is at most $C_2 m^{-(k+1)}$. (The factor $C_2$ here arises from our earlier conditioning on the event that $(X'', Y'')$ is not full.) Thus we can bound the stage-1 flow $f_1(Z, W)$ as in section 4.1. We have

$$\begin{aligned} f_1(Z, W) &\le \sum_{\widetilde{Z}} \sum_{k} \sum_{j_1, \dots, j_k} \sum_{\overline{H}} C_2 m^{-(k+1)} \\ &\le \sum_{\widetilde{Z}} \sum_{k} 2^h C_2 m^{-1} \\ &\le \sum_{\widetilde{Z}} C_1 m 2^h C_2 m^{-1} \\ &\le C_1 C_2 2^h n|\Omega|, \end{aligned}$$

where the factors $C_1 m$ and $2^h$ arise from summing over $k$ and $\overline{H}$, respectively.

The flow $f_3(Z, W)$ from stage-3 paths can be handled symmetrically, so consider now the stage-2 paths. For a given edge $(Z, W)$, every pair $(X, Y)$ that sends flow through $(Z, W)$ in stage 2 can be completely specified by $\widetilde{Z}$, $T$, $k$, $j_1, \dots, j_T$, $U$, and $\overline{H}$, where $k$ is the number of elements of the sequence in (4.2) processed along the path from $X$ to $Z$ and $U = \{\pi(1), \ldots, \pi(k-T)\}$, via

$$X = \overline{H} \oplus (Z \oplus U)j_T \cdots j_1, \qquad Y = \overline{H} \oplus (\widetilde{Z} \oplus U)j_T \cdots j_1.$$

Let $k' = k - T$. The amount of flow corresponding to a given $j_1, \ldots, j_T$ and $U$ is bounded above by

$$(C_2 m^{-T})(C_1 m)^{-1}\left[Cm^{1/2+\epsilon}\tbinom{m}{k', m-k'-1, 1}^{-1}\right],$$

where the first factor comes from the PRW, the second factor is the probability of choosing a particular $T$, and the third factor is an upper bound on the probability $\Pr[\pi\{1, \ldots, k'\} = U \text{ and } \pi(k'+1) = z]$, which comes from the strong almost uniformity of $\pi$. Thus we can again bound the flow $f_2(Z, W)$ as in section 4.1. We have

$$\begin{aligned} f_2(Z,W) &\le \sum_{\widetilde{Z}} \sum_{T} \sum_{k} \sum_{j_1,\ldots,j_T} \sum_{U} \sum_{\overline{H}} (C_2 m^{-T})(C_1 m)^{-1}\left[Cm^{1/2+\epsilon}\tbinom{m}{k', m-k'-1, 1}^{-1}\right] \\ &\le \sum_{\widetilde{Z}} (C_1 m) m m^T \tbinom{m-1}{k'} 2^h (C_2 m^{-T})(C_1 m)^{-1}\left[Cm^{1/2+\epsilon}\tbinom{m}{k', m-k'-1, 1}^{-1}\right] \\ &= \sum_{\widetilde{Z}} 2^h C_2 \left[m\tbinom{m-1}{k'}\tbinom{m}{k', m-k'-1, 1}^{-1}\right] Cm^{1/2+\epsilon} \\ &= \sum_{\widetilde{Z}} 2^h C_2 C m^{1/2+\epsilon} \\ &\le 2^h C C_2 n^{3/2+\epsilon} |\Omega|, \end{aligned}$$

where the factors in the second line are written in the same order as the sums they arise from.

Adding the contributions $f_1$, $f_2$, and $f_3$, we see that the above flow satisfies $\mathcal{C}(f) = \mathrm{O}(n^{3/2+\epsilon})$, while plainly $\mathcal{L}(f) = \mathrm{O}(n)$. Since $\epsilon > 0$ was arbitrary, this completes the proof. $\square$

Given such a flow, we need only invoke Theorem 2.1 to derive our main result.

THEOREM 4.3. *Let $\Omega$ be the set of solutions to an arbitrary instance of the* 0-1 *knapsack problem. The mixing time of the random walk on $G_\Omega$ is $\tau_{\text{mix}} = \mathrm{O}(n^{9/2+\epsilon})$ for any $\epsilon > 0$.*

As mentioned in the introduction, this immediately yields an fpras for computing $|\Omega|$, via a standard reduction to random sampling (whose details are spelled out in [12]).

*Remark.* The mixing time bound of $\mathrm{O}(n^{9/2+\epsilon})$ in Theorem 4.3 is reasonably tight for this type of analysis. If we apply Theorem 2.1 to analyze random walk on the entire cube $\{0,1\}^n$, we get a bound of $\mathrm{O}(n^3)$ even with an optimal flow. Thus the truncation introduces an extra factor of only $\mathrm{O}(n^{3/2+\epsilon})$ into the bound. It is instructive to see where this extra factor comes from; $\mathrm{O}(n^{1/2+\epsilon})$ is due to the balanced almost uniform permutation construction (Theorem 3.4, which is tight), while $\mathrm{O}(n)$ comes from the fact that the "encoding" $\widetilde{Z}$ may lie just outside $\Omega$.

## 5. Multiple hyperplanes.

### 5.1. Introduction.

In this section, we will extend our earlier results to handle multiple hyperplanes. For a nonnegative real $d \times n$ matrix $A = (a_{ij})$ and a positive real vector $\mathbf{b} = (b^1, \ldots, b^d)$, let $\Omega$ denote the set of 0-1 vectors $\mathbf{x} = (x_i)_{i=1}^n$ for which $A\mathbf{x} \leq \mathbf{b}$. The vertices in $\Omega$ constitute the set of feasible solutions to the multidimensional knapsack problem with the $d$ simultaneous constraints

$$\mathbf{a}^j \cdot \mathbf{x} \equiv \sum_{i=1}^n a_i^j x_i \leq b^j \quad \text{for } 1 \leq j \leq d, \tag{5.1}$$

where $a_i^j \equiv a_{ji}$. (In (5.1) the superscript $j$ indexes the $j$th linear constraint; we will follow this convention throughout.)

Geometrically, $\Omega$ is obtained by truncating the unit cube by $d$ hyperplanes, each of which corresponds to a knapsack constraint. The essential geometric property of these "knapsack" hyperplanes is that their normal vectors all lie in the same quadrant. The results of this section will easily extend to any collection of hyperplanes with this property.[7]

Following our earlier notation, we identify a 0-1 vector $\mathbf{x} = (x_i)_{i=1}^n$ with the set of indices $X = \{i : x_i = 1\}$ and write $a(X) = (a^1(X), \ldots, a^d(X))$ for the (now $d$-dimensional) weight of $X$. As before we denote by $G_\Omega$ the subgraph of the hypercube $\{0,1\}^n$ induced by the vertices in $\Omega$, and we again study symmetric random walk on $G_\Omega$; i.e., transitions from a given state $X \subseteq \{1, \ldots, n\}$ are made as follows:

1. pick an item $i \in \{1, \ldots, n\}$ u.a.r.;
2. if $i \in X$, move to $X - \{i\}$; if $i \notin X$ and $a^j(X \cup \{i\}) \leq b^j$ for all $j$, move to $X \cup \{i\}$; otherwise, do nothing.

Again, to avoid issues involving periodicity, we add to every state a holding probability of $\frac{1}{2}$.

In this section we will prove that this random walk on $G_\Omega$ has mixing time that is polynomially bounded in $n$ for any fixed dimension $d$. Just as in the one-dimensional case, this immediately gives a polynomial time algorithm for sampling (almost) uniformly at random from $\Omega$ and an fpras for computing $|\Omega|$.

We note that the degree of our polynomial upper bound for the mixing time will depend on the dimension $d$, but this is unavoidable as the following simple example shows. Consider a $d$-dimensional knapsack problem in which there are $\frac{n}{2d}$ items having each of the $d$ weight vectors $(n, 0, \ldots, 0), (0, n, \ldots, 0), \ldots, (0, \ldots, 0, n)$, and the remaining $\frac{n}{2}$ items have weight vector $(1, 1, \ldots, 1)$; the knapsack capacity is $\mathbf{b} = (n, \ldots, n)$. Let $S$ be the set of feasible solutions in $\Omega$ which do not contain any of the $(1, \ldots, 1)$ items. Then $|S| = (\frac{n}{2d} + 1)^d$, but $S$ is connected to $\Omega - S$ only through the origin. It follows easily that the mixing time is $n^{\Omega(d)}$.

In fact, for arbitrary $d$ there can be no uniform polynomial upper bound for the running time of *any* sampling algorithm unless RP = NP. This follows immediately by reduction from the problem of sampling independent sets in a graph. By Theorem 1.17 of [19], there is no algorithm for (almost) uniformly sampling independent sets in a graph unless RP = NP. Now if $G = (V, E)$ is an arbitrary (undirected) graph, there is a 1-1 correspondence between the independent sets in $G$ and the feasible solutions to the knapsack problem with $|V|$ variables and the $|E|$ constraints $x_u + x_v \leq 1$ for all $\{u, v\} \in E$.

To prove rapid mixing of the random walk on $G_\Omega$ for any fixed $d$, we use the multicommodity flow technique as before. Recall that Theorem 2.1, which bounds

[7]However, we cannot allow the hyperplanes to be arbitrary. If arbitrary truncations were allowed, then it would be possible to use just two hyperplanes to cause exponential bottlenecks or even disconnect the graph $G_\Omega$.

the mixing time in terms of the cost of a flow $f$, holds for symmetric random walk on any connected subset of the hypercube, so it again suffices to come up with a flow of small cost. As before, the idea is to spread each $X \to Y$ flow evenly using a balanced almost uniform permutation. However, since the weight function $a(\,\cdot\,)$ is now vector-valued, we first need to extend the definition of balance to higher dimensions.

DEFINITION 5.1. *Fix an integer $d > 0$, and let $\{w_i\}_{i=1}^m$ be a set of weights in $\mathbf{R}^d$ satisfying $\sum_{i=1}^m w_i = 0$. For a positive real number $\Delta$, a permutation $\pi \in \mathcal{S}_m$ is* $\Delta$-balanced *if*

$$\max_k \left| \sum_{i=1}^k w^j_{\pi(i)} \right| \le \Delta M^j \quad \textit{for } 1 \le j \le d, \tag{5.2}$$

*where $w_i = (w_i^1, \dots, w_i^d)$ and $M^j = \max_{1\le i\le m} |w_i^j|$.*

Thus $\pi$ is balanced with respect to vector weights $\{w_i\}$ if and only if it satisfies the $d$ one-dimensional balance conditions given by (5.2). Note that this generalizes Definition 3.1 for the one-dimensional case (except that, for simplicity, we have assumed that $\sum_i w_i = 0$).

Constructing balanced almost uniform permutations is significantly more difficult in higher dimensions since one has to control fluctuations in all dimensions simultaneously. In fact, for $d \ge 2$, it is nontrivial to prove for an arbitrary set of vector weights that even a *single* balanced permutation exists. (For $d = 1$, of course, this is trivial.) The existence of such a permutation follows at once from a lemma due to Grinberg and Sevast'yanov [7], which was proved in an entirely different context.

LEMMA 5.2 (see [7]). *Let $x_1, \dots, x_n$ be vectors in $\mathbf{R}^d$ such that $\sum_i x_i = 0$. Then there exists a permutation $\nu \in \mathcal{S}_n$ such that*

$$\sum_{i=1}^k x_{\nu(i)} \in d \times \operatorname{conv}\{x_1, \dots, x_n\} \quad \textit{for } 1 \le k \le n,$$

*where $d \times \operatorname{conv}$ denotes the dilation of the convex hull by $d$.*

Of course, we need something much stronger than this, namely, *almost uniform* permutations with a similar balance property. Perhaps surprisingly, we will show that balanced almost uniform permutations exist in arbitrary dimension $d$. To illustrate the main ideas involved in extending from one to higher dimensions, we now give a sketch of the proof in the special case where $d = 2$ and the weights satisfy $1 \le |w_i^j| \le 2$ for all $i$ and $j$.

In this setting, let $I_1 = \{i : w_i^2 \ge 0\}$, $I_2 = \{i : w_i^2 < 0\}$, and define $v = \sum_{i \in I_1} w_i$. For every $i \le m$, let $y_i$ be the projection of $w_i$ onto $v^\perp$. Let $\pi_1$ be an almost uniform permutation on $I_1$ which is balanced (in the one-dimensional sense) with respect to $\{y_i\}_{i\in I_1}$, with a similar definition for $\pi_2$. Finally, interleave $\pi_1$ and $\pi_2$ to give a permutation on $\{1, \dots, m\}$ which is balanced with respect to $\{w_i^2\}_{i=1}^m$ (the projections of the $w_i$ onto the second coordinate axis). Since $\pi_1$ and $\pi_2$ are both almost uniform, so is $\pi$, by an argument similar to that in the proof of Lemma 3.3.

Furthermore, since $\pi_1$ and $\pi_2$ are each balanced with respect to projections onto $v^\perp$, so is $\pi$. (Note that the projections $y_i$ satisfy $\sum_{i\in I_1} y_i = \sum_{i \in I_2} y_i = 0$.) Thus, for every $k$, the projections of $\sum_{i=1}^k w_{\pi(i)}$ onto the second coordinate axis and onto $v^\perp$ are both bounded, and since the $w_i^j$ are all in $[1, 2]$, the angle between the coordinate axis and $v^\perp$ is bounded away from zero. Thus, the partial sums $\sum_{i=1}^k w_{\pi(i)}$

stay inside a parallelogram of bounded diameter. Hence $\pi$ is balanced with respect to the weights $\{w_i\}_{i=1}^m$.

This concludes the sketch proof for the above special case with $d = 2$. Note that it is a straightforward reduction to the one-dimensional result. Unfortunately, in general the reduction from $d$ to $d-1$ dimensions is not quite so straightforward; we deal with the extra technical difficulties in the next subsection.

**5.2. Balanced almost uniform permutations in arbitrary dimensions.** The following theorem says that one can always construct balanced almost uniform permutations when the dimension $d$ is fixed.

THEOREM 5.3. *Let $d$ be any positive integer. There is a constant $c_d$ and a polynomial function $p_d$ such that, for any set of weights $\{w_i\}_{i=1}^m$ in $\mathbf{R}^d$ with $\sum_i w_i = 0$, there exists a $c_d$-balanced, $p_d(m)$-uniform permutation.*

*Proof.* The proof will be by induction on $d$. The base case $d = 1$ follows from Corollary 3.5, with $c_1 = 9$ and $p_1(m) = Cm^2$. Now let $d > 1$ be arbitrary, and suppose that the result holds for dimensions up to $d-1$. Let $\{w_i\}_{i=1}^m$ be a set of weights in $\mathbf{R}^d$. Suppose first that the weights satisfy

$$M^j = 2 \qquad \text{for all } j, \tag{5.3}$$

$$1 \le \max_{1\le j\le d} |w_i^j| \le 2 \qquad \text{for all } i. \tag{5.4}$$

Thus each weight is at least half as large as the maximum (positive or negative) weight in some coordinate. Then

$$\max_{1\le j\le d} \sum_{i=1}^m |w_i^j| \ge \frac{m}{d}.$$

Without loss of generality, suppose that the sum in the left-hand side is maximized by $j = d$. Then we have

$$\sum_{i=1}^m (w_i^d)^+ = \sum_{i=1}^m (w_i^d)^- \ge \frac{m}{2d},$$

where we are using the notation $z^+ = \max\{z, 0\}$ and $z^- = \max\{-z, 0\}$.

Let $I_1 = \{i : w_i^d \ge 0\}$, $I_2 = \{i : w_i^d < 0\}$, $m_1 = |I_1|$, and $m_2 = |I_2|$. Define the means $\mu_1 = \frac{1}{m_1}\sum_{i\in I_1} w_i^d$ and $\mu_2 = -\frac{1}{m_2}\sum_{i\in I_2} w_i^d$. Note that $\mu_1, \mu_2 \ge \frac{1}{2d}$. For $1 \le j < d$, let

$$\gamma^j = \frac{\sum_{i\in I_1} w_i^j}{\sum_{i\in I_1} w_i^d} = \frac{\sum_{i\in I_2} w_i^j}{\sum_{i\in I_2} w_i^d}.$$

For all $i \le m$ and $j < d$, let $y_i^j = w_i^j - \gamma^j w_i^d$, and let $y_i = (y_i^1, \dots, y_i^{d-1})$. Note that $|\gamma^j| \le 1$, $|y_i^j| \le 4$, and $\sum_{i\in I_1} y_i = \sum_{i\in I_2} y_i = 0$.

Now, for $s = 1, 2$ let $\pi_s$ be a $p_{d-1}(m)$-uniform permutation on $I_s$ which is $c_{d-1}$-balanced with respect to $\{y_i\}_{i\in I_s}$. Call $\pi_1$ *$\alpha$-good* if for every $k_1$ with $1 \le k_1 \le m_1$ we have

$$\left|\sum_{i=1}^{k_1} w_{\pi_1(i)}^d - k_1\mu_1\right| \le 2\alpha\sqrt{k_1^*}, \tag{5.5}$$

where $k_1^* = \min\{k_1, m_1 - k_1\}$. In similar fashion to the proof of Lemma 6.1, Hoeffding's bounds [8] imply that for a particular value of $k_1$ we have

$$\Pr_{\text{unif}}[\pi_1 \text{ does not satisfy (5.5)}] \le 2\exp(-2\alpha^2),$$

and since the event depends only on the initial segment $\pi_1\{1, \ldots, k_1\}$, we also have

$$\begin{aligned}\Pr[\pi_1 \text{ does not satisfy (5.5)}] &\le p_{d-1}(m) \cdot \Pr_{\text{unif}}[\pi_1 \text{ does not satisfy (5.5)}] \\ &\le p_{d-1}(m) \cdot 2\exp(-2\alpha^2).\end{aligned}$$

Hence

$$\Pr[\pi_1 \text{ is not } \alpha\text{-good}] \le m p_{d-1}(m) \cdot 2\exp(-2\alpha^2). \tag{5.6}$$

Suppose that for some constants $C$ and $r$, the polynomial $p_{d-1}$ satisfies $p_{d-1}(k) \le Ck^r$ for all $k$. If we let $\alpha = \sqrt{(r+1)\ln(m)}$, then the right-hand side of (5.6) is at most $2Cm^{r+1-2(r+1)} \le \frac{1}{2}$ for sufficiently large $m$. Thus, we can assume that $\pi_1$ is $\alpha$-good with probability 1 and only increase $C$ by a constant factor. Similar arguments apply to $\pi_2$.

Finally, note that it is always possible to interleave $\pi_1$ and $\pi_2$ to give a permutation on $\{1, \ldots, m\}$ which is 1-balanced with respect to $\{w_i^d\}_{i=1}^m$. Let $\pi$ be such a permutation. Then we have $|\sum_{i=1}^k w_{\pi(i)}^d| \le 2$, and

$$\begin{aligned}\left|\sum_{i=1}^k w_{\pi(i)}^j\right| &= \left|\sum_{\substack{i\in I_1:\\ i\le k}} w_{\pi(i)}^j + \sum_{\substack{i\in I_2:\\ i\le k}} w_{\pi(i)}^j\right| \\ &= \left|\sum_{\substack{i\in I_1:\\ i\le k}} y_{\pi(i)}^j + \sum_{\substack{i\in I_2:\\ i\le k}} y_{\pi(i)}^j + \gamma^j \sum_{i=1}^k w_{\pi(i)}^d\right| \\ &\le \left|\sum_{\substack{i\in I_1:\\ i\le k}} y_{\pi(i)}^j\right| + \left|\sum_{\substack{i\in I_2:\\ i\le k}} y_{\pi(i)}^j\right| + |\gamma^j|\left|\sum_{i=1}^k w_{\pi(i)}^d\right| \\ &\le 4c_{d-1} + 4c_{d-1} + 2|\gamma^j| \\ &\le 8c_{d-1} + 2\end{aligned}$$

for all $j < d$ and $k$. Hence $\pi$ is $c_d'$-balanced for $c_d' = 4c_{d-1} + 1$ by assumption (5.3).

To verify that $\pi$ is almost uniform, we follow the proof of Lemma 3.3. Let $U \subseteq \{1, \ldots, m\}$ be arbitrary with $|U| = k$, and let $U_1 = U \cap I_1$, $U_2 = U \cap I_2$, $k_1 = |U_1|$, and $k_2 = |U_2|$. Then we have

$$\begin{aligned}\Pr\big[\pi\{1, \ldots, k\} = U\big] &\le \Pr\big[\pi_1\{1, \ldots, k_1\} = U_1 \text{ and } \pi_2\{1, \ldots, k_2\} = U_2\big] \\ &\le (Cm^r)^2 \Pr_{\text{unif}}\big[\pi_1\{1, \ldots, k_1\} = U_1 \text{ and } \pi_2\{1, \ldots, k_2\} = U_2\big] \\ &= \frac{C'm^{2r}}{\binom{m_1}{k_1}\binom{m_2}{k_2}}.\end{aligned}$$

Now we can bound the quantity $\binom{m_1}{k_1}\binom{m_2}{k_2}$ by mimicking (with minor modifications) the calculations from (3.7) to (3.10) in the proof of Lemma 3.3. In our current setting, we have $\mu_1, \mu_2 \ge \frac{1}{2d}$, and the $|w_i^d|$ are in $[0, 2]$. Because we have changed the definition of $\alpha$-good and the value of $\alpha$, we also have to make the substitutions $(B-1)^2 \to 2^2$ and $\ln m \to (r+1)\ln m$, respectively. Thus the bound on the exponent given in (3.9) becomes

$$\frac{10 \cdot 2^2}{(\frac{1}{2d})^2}(r+1)\ln m = 160d^2(r+1)\ln m. \tag{5.7}$$

Hence $\pi$ is $p_d(m)$-uniform for $p_d(m) = C'' m^{160d^2(r+1)+2r+1/2}$.

We have shown how to make balanced almost uniform permutations if the weights satisfy (5.3) and (5.4). To generalize to arbitrary weights $\{w_i\}_{i=1}^m$, we use the interval trick introduced in section 3.2. Let $\beta$ be a uniform random permutation in $\mathcal{S}_m$, and let $T_1 = \min\{t : |\sum_{i=1}^t w_i^j| > M^j \text{ for some } j\}$. Define $T_2, T_3, \ldots$ similarly. Now use the $T_i$ to divide $\beta$ into intervals $I_1, \ldots, I_q$. Let $\{\alpha_i\}_{i=1}^{q-1}$ be the aggregated ($d$-dimensional) weights of the first $q-1$ intervals. Note that if we divide each $\alpha_i^j$ by $\frac{1}{2}\max_i |\alpha_i^j|$, then the resulting weights satisfy (5.3) and (5.4). Hence these weights admit a $c'_d$-balanced, $p_d(q)$-uniform permution (though see the remark immediately following this proof). Rearranging the intervals $\{I_i\}_{i=1}^{q-1}$ according to such a permutation gives a permutation on $\{1, \ldots, m\}$ which is $p_d(m)$-uniform and $c_d$-balanced for $c_d = 2c'_d + 1$. ◻

*Remark.* We should point out that the weights $\{\alpha_i\}_{i=1}^{q-1}$ of the first $q-1$ intervals will not in general sum to zero. However, we can easily get around this by introducing a dummy weight $\alpha_q$ which is equal to the weight of interval $I_q$. The presence of this single small weight does not affect (5.7) for sufficiently large $m$. Hence there is a $c'_d$-balanced, $p_d$-uniform permutation on this padded sequence $\{\alpha_i\}_{i=1}^{q}$. This induces a permutation on $\{\alpha_i\}_{i=1}^{q-1}$ which is $(c'_d+1)$-balanced and $cp_d(q)$-uniform for some constant $c$. Thus, if we incorporate an extra $+1$ into the constant $c'_d$ and an extra factor of $c$ into $p_d$, then the argument in the above proof is still valid.

Before we specify our flow, we need one more definition.

DEFINITION 5.4. *Let $\{w_i\}_{i=1}^m$ be a sequence in $\mathbf{R}^d$, with $w_i = (w_i^1, \ldots, w_i^d)$, let $\mu = (\mu^1, \ldots, \mu^d) = \frac{1}{m}\sum_{i=1}^m w_i$, and let $l$ be a positive integer. A permutation $\pi$ is* strongly $l$-balanced *if, for all $k \le m$ and $j \le d$, there exists a set $S \subseteq \{1, \ldots, m\}$ with $|S \oplus \pi\{1, \ldots, k\}| \le l$ such that $(\sum_{i=1}^k w_{\pi(i)}^j - k\mu^j)$ and $(\sum_{i \in S} w_{\pi(i)}^j - k\mu^j)$ have opposite signs (or either is $0$).*

Thus, in a strongly balanced permutation, whenever the initial segment $\{\pi(i)\}_{i=1}^k$ is "above average" with respect to a particular coordinate $j$, it can be made "below average" by flipping at most some fixed number $l$ of items, and vice versa. As the name suggests, the strong balance condition is stricter than the usual balance condition. Nonetheless, the following lemma says that strongly balanced permutations always exist.

LEMMA 5.5. *For any sequence $\{w_i\}_{i=1}^m$ in $\mathbf{R}^d$, there exists a strongly $16d^2$-balanced permutation.*

Note that this lemma claims only that a *single* strongly balanced permutation exists; unlike Theorem 5.3, it makes no claims regarding almost uniformity. The proof of the lemma relies heavily on the result of Grinberg and Sevast'yanov quoted earlier (Lemma 5.2); the proof is straightforward but rather technical, so we defer it to section 6.

**5.3. A good flow.** Now that we have multidimensional balanced almost uniform permutations and strongly balanced permutations, we are ready to construct a good flow.

LEMMA 5.6. *Fix any number of knapsack constraints $d$. For arbitrary item weights, it is possible to construct a multicommodity flow $f$ in $G_\Omega$ with $\mathcal{C}(f)$ bounded by a polynomial in $n$ and $\mathcal{L}(f) = \mathrm{O}(n)$.*

*Proof.* Recall that we identify a vertex $\mathbf{x} \in \Omega$ with the index set $X = \{i : x_i = 1\}$. Let $\widehat{\Omega} = \{X \in \Omega : a^j(X) \le b^j - 3c_d \max_{i\in X} a_i^j\}$, where $c_d$ is the constant in the construction of balanced almost uniform permutations as in Theorem 5.3. Our main goal will be to construct a flow $\widehat{f}$ which, simultaneously for every $X, Y \in \widehat{\Omega}$, sends one unit of flow from $X$ to $Y$. This flow will satisfy $\mathcal{C}(\widehat{f}) \le \mathrm{poly}(n)$ and $\mathcal{L}(\widehat{f}) = \mathrm{O}(n)$.

Note that, from any vertex $X \in \Omega$, we can obtain a vertex $\widehat{X} \in \widehat{\Omega}$ by removing at most $3dc_d$ items. Thus, we can use an approach similar to that in section 4.1 to extend $\widehat{f}$ to a multicommodity flow $f$ on the whole of $\Omega$, and $f$ will satisfy $\mathcal{C}(f) \le \mathrm{O}(n^{6dc_d})\,\mathrm{poly}(n) \le \mathrm{poly}'(n)$ and $\mathcal{L}(f) \le \mathcal{L}(\widehat{f}) + 6dc_d = \mathrm{O}(n)$.

It remains to define the flow $\widehat{f}$ and show that it has the properties claimed. Fix $X, Y \in \widehat{\Omega}$. As in the one-dimensional case, the high-level idea is to route the flow from $X$ to $Y$ according to a balanced almost uniform permutation on the symmetric difference $X \oplus Y$. Recall from the one-dimensional case that we want both path endpoints to be far enough below the hyperplane before we apply the balanced permutation; recall also that we cannot in general ensure this by removing only a fixed number of items from $X$ and $Y$ (e.g., if the items in $X$ are much larger than those in $Y$). In the one-dimensional case (see section 4.2), we overcame this obstacle using the preprocessing random walk. Here we will use a different mechanism based on considering the "large" and the "small" items in $X \oplus Y$ separately. This mechanism is cruder but more robust and works in the multidimensional setting.

Let $M = (M^1, \dots, M^d)$, where $M^j = \min\{\max_{i\in X} a_i^j, \max_{i\in Y} a_i^j\}$. Let $L = \{i \in X \oplus Y : a_i^j > M^j \text{ for some } j\}$ and $S = (X \oplus Y) - L$. ($L$ and $S$ are the "large" and "small" items, respectively.) Let $\{w_i\}_{i\in X\oplus Y}$ be an enumeration of the weights of the items in $X \oplus Y$, where weights from $Y$ appear with a positive sign and weights from $X$ appear with a negative sign. Let $\mu_1 = \frac{1}{|L|}\sum_{i\in L} w_i$, and let $\mu_2 = \frac{1}{|S|}\sum_{i\in S} w_i$. Let $\pi_1$ be a permutation on $L$ which is strongly $16d^2$-balanced with respect to the weights $\{w_i\}_{i\in L}$, and let $\pi_2$ be a $p_d(|S|)$-uniform permutation which is $c_d$-balanced with respect to the weights $\{w_i - \mu_2\}_{i\in S}$. The existence of $\pi_1$ and $\pi_2$ is guaranteed by Lemma 5.5 and Theorem 5.3, respectively. To obtain $\pi$, we will interleave the strongly balanced permutation $\pi_1$ and the balanced permutation $\pi_2$. The rule for interleaving will be as follows. Suppose that $\pi(1), \dots, \pi(k)$ have already been assigned and that $\pi\{1, \dots, k\} = \pi_1\{1, \dots, k_1\} \cup \pi_2\{1, \dots, k_2\}$. Now, either $\frac{k_1}{k} \le \frac{|L|}{|L|+|S|}$ or $\frac{k_2}{k} < \frac{|S|}{|L|+|S|}$, so we can define $\pi(k+1)$ by

$$\pi(k+1) = \begin{cases} \pi_1(k_1+1) & \text{if } \frac{k_1}{k} \le \frac{|L|}{|L|+|S|}, \\ \pi_2(k_2+1) & \text{if } \frac{k_2}{k} < \frac{|S|}{|L|+|S|}. \end{cases}$$

Now let $\mu = \frac{1}{|X\oplus Y|}\sum_{i\in X\oplus Y} w_i = \frac{|L|\mu_1 + |S|\mu_2}{|L|+|S|}$. We claim that $\pi$ satisfies the following condition. Fix $j$ and $k$. Then there exist sets of indices $V_1$ and $V_2$, with $|V_i \oplus \{1, \dots, k\}| \le 17d^2$, such that

$$\sum_{i\in V_1} w_{\pi(i)}^j \le (k-1)\mu^j + 3c_d M^j, \tag{5.8}$$

$$\sum_{i\in V_2} w_{\pi(i)}^j \ge (k-1)\mu^j - 3c_d M^j. \tag{5.9}$$

We will prove this in the case ${\mu_1}^j \geq {\mu_2}^j$; if ${\mu_1}^j < {\mu_2}^j$, the proof is similar. Again, let $k_1 = |L \cap \pi\{1, \dots, k\}|$ and $k_2 = |S \cap \pi\{1, \dots, k\}|$, so that $\pi\{1, \dots, k\} = \pi_1\{1, \dots, k_1\} \cup \pi_2\{1, \dots, k_2\}$. The method of interleaving ensures that

$$\frac{k_1 - 1}{k - 1} \leq \frac{|L|}{|L| + |S|}, \quad \frac{k_2 - 1}{k - 1} \leq \frac{|S|}{|L| + |S|}.$$

Therefore, since ${\mu_1}^j \geq {\mu_2}^j$, we have

$$(k_1 - 1)\mu_1^j + k_2 \mu_2^j \leq (k - 1)\mu^j, \tag{5.10}$$

$$k_1 \mu_1^j + (k_2 - 1)\mu_2^j \geq (k - 1)\mu^j. \tag{5.11}$$

Clearly, the strong balance condition on $\pi_1$ implies that there exist $A, A'$, with $|A \oplus \{1, \dots, k_1\}| \leq 16d^2 + 1$ and similarly for $A'$, such that

$$\sum_{i \in A} w^j_{\pi_1(i)} \leq (k_1 - 1)\mu_1^j, \tag{5.12}$$

$$\sum_{i \in A'} w^j_{\pi_1(i)} \geq k_1 \mu_1^j. \tag{5.13}$$

Also, by the balance condition on $\pi_2$ we have

$$\sum_{i=1}^{k_2} w^j_{\pi_2(i)} \leq k_2 \mu_2^j + c_d \max_{i \in S}\{|w_i^j - \mu_2^j|\} \leq k_2 \mu_2^j + 3c_d M^j, \tag{5.14}$$

$$\sum_{i=1}^{k_2} w^j_{\pi_2(i)} \geq k_2 \mu_2^j - c_d \max_{i \in S}\{|w_i^j - \mu_2^j|\} \geq (k_2 - 1)\mu_2^j - 3c_d M^j. \tag{5.15}$$

Now, let $B = \pi^{-1}(\pi_1(A) \cup \pi_2\{1, \dots, k_2\})$ and $B' = \pi^{-1}(\pi_1(A') \cup \pi_2\{1, \dots, k_2\})$. Then we have $|B \oplus \{1, \dots, k\}| \leq 16d^2 + 1 \leq 17d^2$, and

$$\sum_{i \in B} w^j_{\pi(i)} = \sum_{i \in A} w^j_{\pi_1(i)} + \sum_{i=1}^{k_2} w^j_{\pi_2(i)}.$$

Exactly analogous relations hold with $B, A$ replaced by $B', A'$. Combining this with (5.10)–(5.15) gives (5.8) and (5.9).

Now, $\pi$ determines a path $\{Z_i\}_{i=0}^{|X \oplus Y|}$ from $X$ to $Y$, where $Z_0 = X$ and $Z_i = X \oplus \{\pi(1), \dots, \pi(i)\}$ for $1 \leq i \leq |X \oplus Y|$. This path might not stay in $\Omega$, but we can alter it slightly so that it does. Inequalities (5.8) and (5.9) imply that for every $k$ and $j$, there exists a set of indices $W_k^j$ with $|W_k^j| \leq 34d^2$ such that

$$a^j(Z_k - W_k^j) \leq \max\{a^j(X), a^j(Y)\} + 3c_d M^j \leq b^j, \tag{5.16}$$

$$a^j(Z_k \cup W_k^j) \geq \min\{a^j(X), a^j(Y)\} - 3c_d M^j. \tag{5.17}$$

Let $W_0 = \emptyset$ and for $k = 1, \dots, |X \oplus Y|$, let $W_k = \bigcup_{j=1}^d W_k^j$. Then, for all $k$, $|W_k| \leq 34d^3$ and $a(Z_k - W_k) \leq \mathbf{b}$. For $0 \leq k \leq |X \oplus Y|$, define

$$\overline{Z}_k = Z_k - W_k.$$

Then each $\overline{Z}_k \in \Omega$. Our flow from $X$ to $Y$ will pass through each of the $\overline{Z}_k$ in turn. To get from $\overline{Z}_k$ to $\overline{Z}_{k+1}$, we perform the following steps:

1. Remove each item in $\overline{Z}_k - (\overline{Z}_k \cap \overline{Z}_{k+1})$ in index order.
2. Add each item in $\overline{Z}_{k+1} - (\overline{Z}_k \cap \overline{Z}_{k+1})$ in index order.

Define $W_x = (W_k \cup W_{k+1}) \cap X$ and $W_y = (W_k \cup W_{k+1}) \cap Y$. By analogy with section 4, for each intermediate point $Z$ along the path define the "encoding" $\widetilde{Z}$ by

$$\widetilde{Z} = (X \oplus Y - Z) \cup (X \cap Y) - (W_k \cup W_{k+1}),$$

and let $U = \pi\{1, \dots, k\}$. By analogy with our earlier analysis, one can see that, for a given $Z$, $X$ and $Y$ are completely specified by the 4-tuple $(\widetilde{Z}, U, W_x, W_y)$. We also have

$$\begin{aligned} a^j(\widetilde{Z}) &= a^j(X) + a^j(Y) - a^j(Z \cup W_k \cup W_{k+1}) \\ &\le a^j(X) + a^j(Y) - \min\{a^j(Z_k \cup W_k), a^j(Z_{k+1} \cup W_{k+1})\} \\ &\le a^j(X) + a^j(Y) - (\min\{a^j(X), a^j(Y)\} - 3c_d M^j) \\ &= \max\{a^j(X), a^j(Y)\} + 3c_d M^j \\ &\le b^j, \end{aligned}$$

where the second inequality follows from (5.17). Hence $\widetilde{Z} \in \Omega$. We can therefore bound the flow $\widehat{f}(Z)$ through $Z$ by

$$\widehat{f}(Z) \le \sum_{\widetilde{Z} \in \Omega} \sum_{W_x, W_y, U} \Pr\big[\{\pi(1), \dots, \pi(|U|)\} = U\big]. \tag{5.18}$$

Finally, for a given $X$ and $Y$, let $L^j = \{i \in X \cup Y : a_i^j > M^j\}$, so that $L = \bigcup_{j=1}^d L^j$. Note that for every $j$, $L^j \cap Y$ is equal to either $L^j$ or $\emptyset$. Thus, if we define $k_2 = |U \cap S|$, then for given values of $M$ and $k_2$, there are at most $2^d\binom{|S|}{k_2}$ possible values for $U$ in the inner sum of (5.18). Therefore, we have

$$\begin{aligned} \widehat{f}(Z) &\le \sum_{\widetilde{Z} \in \Omega} \sum_{M, W_x, W_y, k_2} \sum_{U : |U \cap S| = k_2} \Pr\big[\{\pi_2(1), \dots, \pi_2(k_2)\} = U \cap S\big] \\ &\le \sum_{\widetilde{Z} \in \Omega} \sum_{M, W_x, W_y, k_2} \sum_{U : |U \cap S| = k_2} p_d(|S|) \binom{|S|}{k_2}^{-1} \\ &\le \sum_{\widetilde{Z} \in \Omega} \sum_{M, W_x, W_y, k_2} 2^d p_d(|S|) \\ &\le \sum_{\widetilde{Z} \in \Omega} n^d \left[\binom{n}{68d^3} 2^{68d^3}\right] n \times 2^d p_d(n) \\ &= \mathrm{poly}(n)|\Omega|, \end{aligned}$$

where in the second line we have appealed to the almost uniformity of permutation $\pi_2$. This completes the proof. ◻

Given such a flow, we can appeal to Theorem 2.1 to derive the main result of this section.

THEOREM 5.7. *Fix any dimension $d > 0$, and let $\Omega$ be the set of solutions to an arbitrary instance of the $d$-dimensional* 0-1 *knapsack problem. The mixing time of the random walk on $G_\Omega$ is* $\mathrm{poly}_d(n)$.

As in one dimension, this immediately implies the existence of an fpras for computing $|\Omega|$ in this more general setting.

*Remark.* In the multidimensional case we have made no attempt to optimize the exponent in our polynomial bound on the mixing time. Indeed, tracing through the proof of Lemma 5.6, we see that the bound is of the form $n^{\mathrm{O}((3d)!)}$. This is much larger than the lower bound $n^{\Omega(d)}$ mentioned earlier. It would be interesting to try to close this gap.

**6. Proofs of technical lemmas.** In this final section we supply the proofs of some technical results that were omitted from the main text.

**6.1. Lemmas for section 3.1.** The following two lemmas were used in the proof of Lemma 3.3.

LEMMA 6.1. *Let $\nu$ be a uniform random permutation in $\mathcal{S}_m$. Then*

$$\Pr[\nu \textit{ is not } \alpha\textit{-good}] \le 2m\exp(-2\alpha^2).$$

*Proof.* We adopt the notation of the proof of Lemma 3.3. Let $1 \le k_1 \le m_1$. It suffices to show that

$$\Pr\left[\left|\sum_{i=1}^{k_1} w_{\nu_1(i)} - k_1\mu_1\right| > \alpha(M-1)\sqrt{k_1}\right] \le 2\exp(-2\alpha^2),$$

for then the lemma follows from the union bound and from symmetry (which allows us to replace $k_1$ by $k_1^* = \min\{k_1, m_1 - k_1\}$). But this inequality is a direct consequence of Hoeffding's bound on deviations in sampling without replacement [8]. □

LEMMA 6.2. *Let $m_1, m_2, k_1, k_2$ be nonnegative integers and $m = m_1 + m_2$, $k = k_1 + k_2$. Then*

$$\frac{\binom{m_1}{k_1}\binom{m_2}{k_2}}{\binom{m}{k}} \ge Am^{-1/2}\exp\left\{-\frac{l^2 + \frac{1}{2}|l|}{\gamma(1-\gamma)}\left(\frac{1}{m_1} + \frac{1}{m_2}\right)\right\},$$

*where $\gamma = \frac{k}{m}$, $l = \frac{m_1k_2 - m_2k_1}{m}$, and $A > 0$ is a universal constant.*

*Proof.* Note that $k = \gamma m$, $k_1 = \gamma m_1 - l$, and $k_2 = \gamma m_2 + l$. By the symmetry of binomial coefficients, we may assume that $l \ge 0$. We shall prove the lemma by showing the two inequalities

$$\frac{\binom{m_1}{\gamma m_1}\binom{m_2}{\gamma m_2}}{\binom{m}{\gamma m}} \ge A_1 m^{-1/2} \tag{6.1}$$

and

$$\frac{\binom{m_1}{\gamma m_1 - l}\binom{m_2}{\gamma m_2 + l}}{\binom{m_1}{\gamma m_1}\binom{m_2}{\gamma m_2}} \ge A_2\exp\left\{-\frac{l^2 + \frac{1}{2}|l|}{\gamma(1-\gamma)}\left(\frac{1}{m_1} + \frac{1}{m_2}\right)\right\} \tag{6.2}$$

for positive constants $A_1, A_2$.

The first inequality is an immediate consequence of Stirling's approximation, $\sqrt{2\pi n}(\frac{n}{\mathrm{e}})^n \le n! \le A_3\sqrt{2\pi n}(\frac{n}{\mathrm{e}})^n$, where $A_3 = 1 + \mathrm{e}^{1/12}$ is a constant. To prove the second inequality, we apply Stirling's approximation to all four binomial coefficients to get the following lower bound on the left-hand side of (6.2):

$$\begin{aligned}&\left[\frac{\mathrm{P}(\gamma m_1)\mathrm{P}((1-\gamma)m_1)\mathrm{P}(\gamma m_2)\mathrm{P}((1-\gamma)m_2)}{\mathrm{P}(\gamma m_1 - l)\mathrm{P}((1-\gamma)m_1 + l)\mathrm{P}(\gamma m_2 + l)\mathrm{P}((1-\gamma)m_2 - l)}\right] \\ &\times\left[\frac{\gamma m_1(1-\gamma)m_1\gamma m_2(1-\gamma)m_2}{(\gamma m_1 - l)((1-\gamma)m_1 + l)(\gamma m_2 + l)((1-\gamma)m_2 - l)}\right]^{1/2},\end{aligned} \tag{6.3}$$

where $\mathrm{P}(x)$ denotes $x^x$. Now we have

$$\frac{\mathrm{P}(\gamma m_1)}{\mathrm{P}(\gamma m_1 - l)} = (\gamma m_1)^l \left(1 + \frac{l}{\gamma m_1 - l}\right)^{\gamma m_1 - l}$$
$$\geq (\gamma m_1)^l \exp\left\{\frac{l(\gamma m_1 - l)}{\gamma m_1}\right\},$$

where we have used the inequality $(1 + \frac{x}{y})^y \geq \exp(\frac{xy}{x+y})$, valid for $x, y > 0$. Handling the three other pairs of factors in the numerator and denominator in a similar fashion (using in addition the inequality $(1 - \frac{x}{y})^y \geq \exp(\frac{-xy}{y-x})$, valid for $y > x > 0$), we see that the first parenthesis in (6.3) is bounded below by

$$\exp\left\{-\frac{l^2}{\gamma(1-\gamma)}\left(\frac{1}{m_1} + \frac{1}{m_2}\right)\right\}. \tag{6.4}$$

A similar calculation bounds the second parenthesis in (6.3) by

$$\exp\left\{-\frac{|l|}{\gamma(1-\gamma)}\left(\frac{1}{m_1} + \frac{1}{m_2}\right)\right\}. \tag{6.5}$$

Combining (6.4) and (6.5) completes the verification of inequality (6.2) above and hence the proof of the lemma. ☐

**6.2. Proof of Lemma 4.1.** By removing $X \cap Y$ from both $X$ and $Y$ and replacing $b$ by $b - a(X \cap Y)$, we may assume that $X \cap Y = \emptyset$. Moreover, by scaling all the $a_i$ and $b$ we may assume that $M = \max_i a_i = 1$. Finally, we may assume that $b \geq 3\Delta$ since otherwise there are no pairs $(X, Y)$ satisfying the hypothesis of the lemma.

Define

$$\mathcal{F} = \{(X', Y') : a(X') \geq b - \Delta \text{ or } a(Y') \geq b - \Delta\},$$
$$\mathcal{E} = \{(X', Y') : a(X') \leq b - 2\Delta \text{ and } a(Y') \leq b - 2\Delta\}.$$

Note that $\mathcal{F}$ contains all full pairs $(X', Y')$, and $\mathcal{E}, \mathcal{F}$ are disjoint. Also, define the hitting times

$$\mathcal{T} = \max_{(X',Y') \in \mathcal{F}} \mathrm{E}(\text{number of PRW steps to hit } \mathcal{E} \text{ starting at } (X', Y')),$$
$$\mathcal{U} = \min_{(X',Y') \in \mathcal{E}} \mathrm{E}(\text{number of PRW steps to hit } \mathcal{F} \text{ starting at } (X', Y')).$$

Now we claim that the lemma will follow if we can show the following:

(i) $\mathcal{T} \leq \alpha m$ for some constant $\alpha > 0$;

(ii) $\mathcal{U}/\mathcal{T} \geq \beta$ for some constant $\beta > 0$.

To see this, set the length of the PRW to be $C_1 m = 4\alpha m$, and let $(X_t, Y_t)$ denote the sequence of pairs visited by the PRW, with $(X_0, Y_0) = (X, Y) \in \mathcal{F}$. Let $T_0$ be the first time $t$ at which $(X_t, Y_t) \in \mathcal{E}$ (or $T_0 = C_1 m$ if the walk ends before this occurs); then let $U_1$ be the first $t$ for which $(X_{T_0+t}, Y_{T_0+t}) \in \mathcal{F}$, and $T_1$ the first $t$ for which $(X_{T_0+U_1+t}, Y_{T_0+U_1+t}) \in \mathcal{E}$. Continue defining a sequence of hitting times $U_2, T_2, U_3, T_3, \ldots$ in this way until the end of the walk is reached. Note that the PRW is not full for at least $\sum_i U_i$ steps and that $\sum_{i \geq 0} T_i + \sum_{i \geq 1} U_i = 4\alpha m$ is the total walk length. Now from facts (i) and (ii) we have

$$\mathrm{E}\left(\sum_{i \geq 0} T_i - \tfrac{1}{\beta} \sum_{i \geq 1} U_i\right) = \mathrm{E}\left(T_0 + \sum_{i \geq 1} (T_i - \tfrac{1}{\beta} U_i)\right) \leq \alpha m.$$

An application of Markov's inequality then ensures that $\sum_{i\geq 0} T_i - \frac{1}{\beta}\sum_{i\geq 1} U_i \leq 2\alpha m$ with probability at least $\frac{1}{2}$. Conditioning on this event, we have $(1+\frac{1}{\beta})\sum U_i \geq 2\alpha m$, and thus the proportion of steps during which the PRW is not full is at least $1/2(1+\frac{1}{\beta})$, a constant. The lemma now follows easily.

It remains to verify facts (i) and (ii) above: these are immediate consequences of the following two claims. Let $\sigma^2 = \frac{1}{m}\sum_{i\in X\cup Y} a_i^2$ be the second moment of the item weights, and note that $\sigma^2 \geq 1/m$ since $\max_i a_i = 1$.

Claim 1. *$\mathcal{T} \leq \gamma_1/\sigma^2$ for a constant $\gamma_1 > 0$.*

Claim 2. *$\mathcal{U} \geq \gamma_2/\sigma^2$ for a constant $\gamma_2 > 0$.*

*Proof of Claim* 1. Choose an initial pair $(X_0, Y_0) \in \mathcal{F}$ that maximizes the expected time until the PRW hits $\mathcal{E}$, and let $(X_t, Y_t)$ denote the PRW starting at $(X_0, Y_0)$. We may assume without loss of generality that $a(X_0) > a(Y_0)$, so that $a(X_0) \in [b-\Delta, b]$ and $\mathcal{T}$ is the expected time until $a(X_t) \leq b-2\Delta$. We estimate $\mathcal{T}$ by coupling the PRW with the *unconstrained* random walk, which behaves exactly like the PRW except that the constraint $\sum a_i \leq b$ is ignored. (Thus it is just simple random walk on an $m$-dimensional hypercube with holding probability $\frac{1}{2}$ at every step.) Write $(\widehat{X}_t, \widehat{Y}_t)$ for the unconstrained random walk, with $(\widehat{X}_0, \widehat{Y}_0) = (X_0, Y_0)$, and consider the first time $t = \widehat{T}$ at which $|a(\widehat{X}_t) - a(X_0)| \geq 2\Delta$. Now $a(\widehat{X}_t)$ is a supermartingale up to time $\widehat{T}$, since $\mathrm{E}(a(\widehat{X}_{t+1}) - a(\widehat{X}_t)|\widehat{X}_t) = \frac{1}{2m}(a(\widehat{Y}_t) - a(\widehat{X}_t)) < 0$. Thus with constant probability $a(\widehat{X}_{\widehat{T}}) \leq a(\widehat{X}_0) - 2\Delta$, and so $(X_{\widehat{T}}, Y_{\widehat{T}}) \in \mathcal{E}$. Hence $\mathcal{T}$ is bounded above by a constant times $\mathrm{E}(\widehat{T})$. But we also have $\mathrm{E}((a(\widehat{X}_{t+1}) - a(\widehat{X}_t))^2|\widehat{X}_t) = \frac{1}{2m}\sum_i a_i^2 = \frac{\sigma^2}{2}$. So $\mathrm{E}(\widehat{T})$ is the expected time for a supermartingale with increments bounded by $\pm 1$ and with second moment $\sigma^2/2$ to move a distance $\pm 2\Delta$ from its initial value. A standard application of the martingale optional stopping theorem (see, e.g., [6, section 12.5]) now yields that $\mathrm{E}(\widehat{T}) \leq \frac{(4\Delta+1)^2}{\sigma^2/2} = \gamma_1/\sigma^2$ for a positive constant $\gamma_1$. This completes the proof of Claim 1.

*Proof of Claim* 2. As above, let $(X_t, Y_t)$ denote the PRW, but now with $(X_0, Y_0) \in \mathcal{E}$. We follow the random variable $Z_t = a(X_t) - a(Y_t)$, which always has a drift toward 0 (i.e., $\mathrm{E}(Z_{t+1} - Z_t|X_t) \times Z_t \leq 0$ for all $t$). Note that initially $|Z_0| \leq 2(b-2\Delta) - V$, where $V = a(X_t) + a(Y_t) = \sum_i a_i$ is independent of $t$. And when $(X_t, Y_t) \in \mathcal{F}$ we have $|Z_t| \geq 2(b-\Delta) - V$. Thus $\mathcal{U}$ is bounded below by the minimum expected time for $|Z_t|$ to increase by $2\Delta$ from its initial value. But the second moment is $\mathrm{E}((Z_{t+1} - Z_t)^2|X_t) = \frac{1}{2m}\sum_i (2a_i)^2 = 2\sigma^2$, so by a similar application of the optional stopping theorem we conclude that $\mathcal{U} \geq \gamma_2/\sigma^2$, as claimed.

This completes the verification of Claims 1 and 2 and hence the proof of the lemma. □

**6.3. Proof of Lemma 5.5.** First suppose that $\sum_{i=1}^m w_i = 0$. We will show that, in this case, there exists a strongly $8d^2$-balanced permutation $\pi$. Let $L$ be the set containing the $4d$ indices $i$ with the largest values of $w_i^j$ and the $4d$ indices $i$ with the largest values of $-w_i^j$ for each $j \leq d$. Then $|L| \leq 8d^2$.

The permutation $\pi$ we construct will satisfy $\{\pi(m), \ldots, \pi(m-|L|+1)\} = L$. It will be enough to check that the strong balance condition holds for $1 \leq k \leq m-|L|$. It suffices to show that, for all $j \leq d$ and $k \leq m-|L|$, we have

$$-s^{j+} \leq \sum_{i=1}^{k} w_{\pi(i)}^j \leq s^{j-}, \tag{6.6}$$

where

$$s^{j+} \equiv \sum_{i\in L}(w_i^j)^+, \qquad s^{j-} \equiv \sum_{i\in L}(w_i^j)^-.$$

We will need the Grinberg–Sevast'yanov result (Lemma 5.2), which states that for any set of vectors $x_1,\dots,x_n$ in $\mathbf{R}^d$ with $\sum_i x_i = 0$, there exists a permutation $\nu \in \mathcal{S}_n$ such that

$$\sum_{i=1}^{k} x_{\nu(i)} \in d \times \operatorname{conv}\{x_1,\dots,x_n\} \quad \text{for } 1 \le k \le n.$$

Note that the permutation $\nu'$ defined by $\nu'(i) = \nu(n+1-i)$ for all $i$ satisfies

$$\sum_{i=1}^{k} x_{\nu'(i)} \in -d \times \operatorname{conv}\{x_1,\dots,x_n\} \quad \text{for } 1 \le k \le n,$$

because $\sum_{i=1}^{k} x_{\nu'(i)} = \sum_{i=m-k+1}^{m} x_{\nu(i)} = -\sum_{i=1}^{k} x_{\nu(i)}$.

Let $S_1 = \{1,\dots,m\} - L$, let $m' = m - |L|$, and let $\pi_1$ be a permutation on $S_1$ such that

$$\sum_{i=1}^{k}(w_{\pi_1(i)} - \mu_1) \in -d \times \operatorname{conv}\{w_i - \mu_1 : i \in S_1\}$$

for all $k$, where $\mu_1 = \frac{1}{m'}\sum_{i\in S_1} w_i$. Suppose that $m'$ is even and $m' = 2r$; if $m'$ is odd, the proof is similar. Now, let $S_2 = \{\pi_1(r+1),\dots,\pi_1(m')\}$, and let $\pi_2$ be a permutation on $S_2$ such that

$$\sum_{i=1}^{k}(w_{\pi_2(i)} - \mu_2) \in d \times \operatorname{conv}\{w_i - \mu_2 : i \in S_2\}, \tag{6.7}$$

where $\mu_2 = \frac{1}{r}\sum_{i\in S_2} w_i$. Define the permutation $\pi$ by

$$\pi(i) = \begin{cases} \pi_1(i) & \text{if } i \le r, \\ \pi_2(i-r) & \text{if } r < i \le m'. \end{cases}$$

We must check that $\pi$ satisfies (6.6). Fix $j$. Without loss of generality, $s^{j+} \le s^{j-}$, so that $\mu_1^j \ge 0$. For $k \le r$ we have

$$\begin{aligned}
\sum_{i=1}^{k} w^j_{\pi(i)} &= \sum_{i=1}^{k} w^j_{\pi_1(i)} \\
&\ge \sum_{i=1}^{k}(w^j_{\pi_1(i)} - \mu_1^j) \\
&\ge -d \max_{1\le i\le m'}\{w_i^j - \mu_1^j\} \\
&\ge -d \max_{1\le i\le m'}\{w_i^j\} \\
&\ge -\tfrac{1}{4}s^{j+} \qquad (6.8)\\
&\ge -s^{j+}
\end{aligned}$$

and

$$\begin{aligned}
\sum_{i=1}^{k} w^j_{\pi(i)} &= \sum_{i=1}^{k} w^j_{\pi_1(i)} \\
&= k\mu_1^j + \sum_{i=1}^{k}(w_{\pi_1(i)} - \mu_1^j) \\
&\le r\mu_1^j + d \max_{1\le i\le m'}\{-(w_i^j - \mu_1^j)\} \\
&= \tfrac{1}{2}(s^{j-} - s^{j+}) + d \max_{1\le i\le m'}\{-w_i^j\} + d\mu_1^j \\
&\le \tfrac{1}{2}(s^{j-} - s^{j+}) + \tfrac{1}{4}s^{j-} + \tfrac{1}{4}s^{j+} \\
&= \tfrac{3}{4}s^{j-} - \tfrac{1}{4}s^{j+} \\
&\le s^{j-} - \tfrac{1}{4}s^{j+}. \qquad (6.9)
\end{aligned}$$

(We will need the extra $-\frac{1}{4}s^{j+}$ in the second part of the proof.) For $r < k \le 2r$ we have

$$\sum_{i=1}^{k} w^j_{\pi(i)} = \sum_{i=1}^{r} w^j_{\pi_1(i)} + \sum_{i=1}^{k-r} w^j_{\pi_2(i)}. \qquad (6.10)$$

Now if $\mu_2^j < 0$, then the conditional expectation of $\sum_{i=1}^{k} w^j_{\pi(i)}$ given $\pi_1$ is at least $-s^{j+} + s^{j-}$. Hence we must have

$$\begin{aligned}
\sum_{i=1}^{k} w^j_{\pi(i)} &\ge -s^{j+} + s^{j-} - d \max_{i\in S_2}\{-(w_i^j - \mu_2^j)\} \\
&\ge -s^{j+} + s^{j-} - d \max_{i\in S_2}\{-w_i^j\} \\
&\ge -s^{j+} + s^{j-} - \tfrac{1}{4}s^{j-} \\
&\ge -s^{j+}.
\end{aligned}$$

On the other hand, if $\mu_2^j \ge 0$, the right-hand side of (6.10) can be bounded below as follows:

$$\begin{aligned}
\sum_{i=1}^{r} w^j_{\pi_1(i)} + \sum_{i=1}^{k-r} w^j_{\pi_2(i)} &= \left[\sum_{i=1}^{r} w^j_{\pi_1(i)} + (k-r)\mu_2^j\right] + \sum_{i=1}^{k-r}(w^j_{\pi_2(i)} - \mu_2^j) \\
&\ge \left[\tfrac{1}{2}(s^{j-} - s^{j+}) - d \max_{1\le i\le m'}\{w_i^j - \mu_1^j\}\right] - d \max_{i\in S_2}\{-(w_i^j - \mu_2^j)\} \\
&\ge \left[\tfrac{1}{2}(s^{j-} - s^{j+}) - d \max_{1\le i\le m'}\{w_i^j\}\right] - d \max_{i\in S_2}\{-w_i^j\} - d\mu_2^j \\
&\ge \left[\tfrac{1}{2}(s^{j-} - s^{j+}) - \tfrac{1}{4}s^{j+}\right] - \tfrac{1}{4}s^{j-} - \tfrac{1}{4}s^{j-} \\
&= -\tfrac{3}{4}s^{j+} \\
&\ge -s^{j+}.
\end{aligned}$$

For a corresponding upper bound, we can write

$$\sum_{i=1}^{k} w^j_{\pi(i)} \le \sum_{i=1}^{r} w^j_{\pi_1(i)} + (k-r)\mu_2^j + \min\{d, k-r\} \max_{i\in S_2}\{w_i^j - \mu_2^j\}. \qquad (6.11)$$

If $\mu_2^j \geq 0$, the right-hand side of (6.11) is bounded above by

$$(s^{j-} - s^{j+}) + d \max_{i \in S_2}\{w_i^j\} \leq (s^{j-} - s^{j+}) + \tfrac{1}{4}s^{j+} \leq s^{j-}.$$

If $\mu_2^j < 0$, the right-hand side of (6.11) is bounded above by

$$\sum_{i=1}^{r} w_{\pi_1(i)}^j + \min\{d, k-r\} \max_{i \in S_2}\{w_i^j\} \leq (s^{j-} - \tfrac{1}{4}s^{j+}) + \tfrac{1}{4}s^{j+} \leq s^{j-},$$

where in the first inequality we have used (6.9).

Putting all the above together, we see that $\pi$ is strongly $8d^2$-balanced. Furthermore, in light of (6.6), we know also that, for all $k$ and $j$, there exists a set of indices $S \supseteq \{1, \ldots, k\}$, with $|S| \leq k+8d^2$, such that $\sum_{i=1}^{k} w_{\pi(i)}^j$ and $\sum_{i \in S} w_{\pi(i)}^j$ have opposite signs.

Now let $\{w_i\}_{i=1}^m$ be arbitrary. From the above, there exists a permutation $\pi$ which is strongly $8d^2$-balanced with respect to the sequence $\{w_i - \mu\}_{i=1}^m$, where $\mu = \frac{1}{m}\sum_{i=1}^m w_i$. We claim that $\pi$ is also strongly $16d^2$-balanced with respect to the original sequence $\{w_i\}_{i=1}^m$. Fix $k$ and $j$, and define $\mu^j = \frac{1}{m}\sum_{i=1}^m w_i^j$. Without loss of generality, $\mu^j \geq 0$. Then there exists $S \supseteq \{1, \ldots, k\}$ with $|S| \leq k + 8d^2$ such that

$$\sum_{i \in S} w_{\pi(i)}^j - k\mu^j \geq \sum_{i \in S} w_{\pi(i)}^j - |S|\mu^j \geq 0.$$

In addition, there exists $S \supseteq \{1, \ldots, k\}$, with $|S| \leq k + 8d^2$ such that $\sum_{i \in S} w_{\pi(i)}^j \leq |S|\mu^j$. It follows that, for some $S' \subseteq S$ with $|S'| = k$, we have $\sum_{i \in S'} w_{\pi(i)}^j \leq k\mu^j$. Since $|S' \oplus \{1, \ldots, k\}| \leq 16d^2$, this completes the proof. ☐

# BALANCED-REPLICATION ALGORITHMS FOR DISTRIBUTION TREES[*]

EDITH COHEN[†] AND HAIM KAPLAN[‡]

**Abstract.** In many Internet applications, requests for a certain object are routed bottom-up over a tree where the root of the tree is the node containing the object. When an object becomes popular, the root node of the tree may become a hot-spot. Therefore, many applications allow intermediate nodes to acquire the ability to serve the requests, for example, by caching the object. We call such distinguished nodes *primed*. We propose and analyze different algorithms where nodes decide when to become primed; these algorithms balance the maximum load on a node and the number of primed nodes.

Many applications require both fully distributed decisions and smooth convergence to a stable set of primed nodes. We first present optimal algorithms which require communication across the tree. We then consider the natural previously proposed THRESHOLD algorithm, where a node becomes primed when the incoming flow of requests exceeds a threshold. We show examples where THRESHOLD exhibits undesirable behavior during convergence. Finally, we propose another fully distributed algorithm, GAP, which converges gracefully.

## 1. Introduction.

The Internet provides a platform for decentralized applications where content or services are requested, stored, and provided by a very large number of loosely coupled hosts. In these applications, there is no centralized support. Requests are forwarded from peer to peer, and each peer can become a server for each item.

Many supporting architectures for such applications are such that the search pattern for each request is "routed"; that is, every peer has a list of neighbors, and for each request a peer might receive, there is a preferred neighbor that brings the request "closer" to its destination. Therefore, the forwarding pattern of each request forms a tree, with edges directed toward the root. We call this tree a *distribution tree.* The stream of requests traveling up the distribution tree is called a *flow.*

When a certain request becomes popular, the respective root of its distribution tree can become a hot-spot. In this case, hosts further down the tree can "replicate" the service, that is, acquire the ability to satisfy these requests, e.g., by "caching" data or duplicating code. The focus of this paper is proposing and evaluating algorithms for hosts to decide when to become replicas.

Before providing further details on our model, we describe some concrete applications and architectures where this setup arises. A relatively old existing application is the domain name service (DNS). The DNS already offers caching of records at intermediate nodes; in fact, caching is the default at all "intermediate" servers, and DNS records are cached until they expire. A forward-looking application is to place

HTTP caches "near" Internet routers, augmenting these routers with the capability to intercept and forward HTTP traffic; such a service can shorten latency and network load. The growing popularity of peer-to-peer applications (e.g., [8, 2]) sparked the development of architectures for fully distributed name-lookup, which enable clients to locate objects or services. Two such proposed architectures are Chord [18] (which is based on consistent hashing [9]) and CAN (content addressable network) [15]. With Chord and CAN, objects have keys which are hashed to points in some metric space $S$. Each node is responsible for some segment of the space $S$. Note that the metric of $S$ has no correspondence to the underlying network distances. Each node maintains a small number of pointers $P(v)$ to nodes responsible for other regions of $S$. When a node receives a request for an object with key $k$, it forwards it to the node in $P(v)$ responsible for a region containing the point closest to the hash of $k$ (according to the metric on $S$). Thus, the search paths for each object form a distribution tree, with the root of the tree being the node responsible for the region of the metric space where the hash of the object lies. Note that even though these hashing-based architectures balance the load well across different objects, replication is still necessary for avoiding hot-spots caused by highly skewed per-object demands. Thus, to alleviate hot-spots, it is proposed in [15, 18] that intermediate nodes cache items (or keys).

In all these applications, replication on intermediate nodes constitutes a tool in avoiding "hot-spots" at the roots of distribution trees. Such hot-spots are caused by flash-crowd events or objects with persistent high demand. We would like to emphasize that generally, each distribution tree corresponds to a single "item," and thus one might worry about interaction of flows from different trees. In many of these applications, however, the balance between trees is taken care of by the process selecting these trees; e.g., in CAN and Chord, the trees are such that nodes are essentially assigned randomly to their positions in different trees. Thus, it is reasonable to consider the trees independently of each other and focus on a single tree, which is the problem we model and address in this paper.

We say that we *prime* a node when we give it the ability to serve requests. We refer to a set of primed nodes as an *allocation*. We look for algorithms that select an allocation. We model the problem and propose metrics for the quality of a solution. The objective is to balance two parameters: the maximum load of a node, which we would like to be as small as possible, and the total size of the allocation (number of primed nodes), which we would also like to be as small as possible. The objective of minimizing the number of primed nodes models a wide range of applications where being primed consumes resources (e.g., storage space). Other desirable properties pertain to the complexity and communication requirements of the algorithm and the stability of the allocation. We consider two models: The first, called the *must-serve* model, requires that a primed node will serve all the flow it gets. The second, called the *serve-or-forward* model, allows a node to serve some of the flow it gets and forward the rest to its parent.

In the first part of the paper we assume that there is a strict upper bound of $C$ on the amount of flow that a primed node can serve and on the amount of flow that a single leaf can generate. Then it is obvious that to serve a total of $R$ flow we need to prime at least $\lceil R/C \rceil$ nodes. We prove in section 3 that if the tree has large degrees, then we may in fact have to prime $\Omega(R\Delta/C)$ nodes, where $\Delta$ is the maximum degree.

In section 4 we consider the problem of finding the optimal allocation. Both for the *must-serve* and the *serve-or-forward* models, we present algorithms that given the tree and the flow generated at each leaf calculate a smallest allocation in time almost linear in the size of the tree. These algorithms can be implemented distributively but with some overhead of two rounds of passing messages up and down the tree.

In section 5 we consider a simple and natural algorithm proposed with both Chord and CAN which we call the THRESHOLD algorithm. The THRESHOLD algorithm runs locally at each node and primes the node when the incoming flow is above a certain threshold. An advantage of the THRESHOLD algorithm is that it requires no communication other than the incoming flow itself. We provide bounds on the size of the allocation obtained by THRESHOLD and show that it is no more than $R\Delta/C$, the same as the worst-case lower bound.

According to the THRESHOLD algorithm, the decision of a node whether to prime itself or not depends on its incoming flow, which in turn depends on the priming decisions of its descendants. This implies that when nodes run THRESHOLD asynchronously, they may change their state from primed to unprimed multiple times before reaching a stable allocation. This dependency may result in instability. In particular, when the incoming flow changes, the size of interim allocations may be much larger than the size of the final stable one. Furthermore, small changes in the incoming flow may cause large changes in the allocation. Such instability is a disadvantage for any application where there is a cost associated with a change of state from primed to unprimed or vice versa. For example, to serve requests for a particular big file you have to store a copy of the file. This may be an overhead even when this storage is only temporary, particularly if the node participates in several such trees.

Finally, in section 6, we propose a different local algorithm called GAP. Like THRESHOLD, GAP also runs independently at each node and makes a local decision. Unlike THRESHOLD, GAP makes its decision at a node $v$ based on the total flow generated at leaf descendants of $v$. Notice that the value of the total flow generated below a particular node is independent of the decisions made by other nodes. Thus GAP converges immediately to an allocation which is stable. Furthermore, GAP's allocation is unlikely to change significantly due to minor changes in the flow.

The algorithm GAP is randomized, and as a result a node primed by GAP may end up serving more than $C$ units of flow. We show that, with an appropriate choice of parameters, the probability that a primed node serves more than $C$ units of flow is small. Furthermore, we show that by running GAP iteratively logarithmically many times, one can find an allocation of expected size $O(\frac{R\Delta}{C})$ in which no node serves more than $C$ units of flow with high probability.

**Related work.** There has been extensive work on caching and replicating content in order to improve response time and reduce the load on particular servers. In particular, several groups have proposed and analyzed many aspects of cooperating caches [5, 7, 13, 3, 10]. This work is related to ours only in the sense that load is distributed among many caches. The main question considered in these papers is how to distribute the load among the cooperating caches assuming typically that each client can send requests to any cache. We ask a different question: Which nodes should we distinguish as caches so that there are no hot-spots on one hand, and not too many nodes become caches on the other hand?

A recent analysis of traffic of Internet content delivery systems [16] suggests that peer-to-peer traffic now accounts for the majority of HTTP bytes transferred, exceeding traffic due to WWW accesses by nearly a factor of three. Peer-to-peer documents are large, so peer-to-peer flows last longer, and many of them are concurrently open. All this, and the fact that a small number of extremely large objects accounts for a large fraction of the traffic, indicates the large possible gain of replication in a peer-to-peer system. The large file sizes also indicate that there is a nonnegligible overhead in priming a node, even temporarily.

The same study [16] also observed that outbound and inbound peer-to-peer traffic through a node at the border of some local network may be imbalanced. This indicates that the location of a node in the underlying network may affect the load it has in the overlay distribution trees which it belongs to. It is an interesting topic for future work to try to model this relation between distribution trees and the underlying overlay network, and its effect on the ideas that we present here.

Plaxton, Rajaraman, and Richa proposed a related scheme that also takes into account the underlying topology when overlaying the distribution network [14]. Other related work focused on balancing load through replication but mainly addressed a different aspect—the layout of the distribution trees (placing caches as "nodes") on top of a larger network (e.g., [1, 11]). A conceptually similar problem is that of placing proxy caches in an existing distribution tree to minimize the average number of hops. This problem was explored by Li et al., who provided a quadratic dynamic programming algorithm [12]. The difference between the objective function we use and the one in [12] is due to a basic difference between the applications we consider and those they consider. Placing caches in a network is a slow manual operation that is better optimized via a centralized calculation. In our setting, nodes already have "cache" capabilities, and the goal is to best utilize resources and to do so in a distributed manner.

## 2. Model.

A *distribution tree* is a rooted tree with flow generated at the leaves and flowing toward the root. We suggest algorithms that would *prime* some nodes in the tree. A primed node can serve flow coming into it, while a nonprimed node only forwards flow to its parent. The goal is to prime as few nodes as possible such that all flow is serviced subject to constraints that we define below. As explained in the introduction, flow corresponds to requests, and *priming* corresponds to configuring the node such that it is able to service requests.

Formally, the input to our problem is the tree $T$ and a function $f : \{v \mid v \text{ is a leaf}\} \rightarrow R_+$ mapping each leaf $v$ to a nonnegative real which describes the flow generated at $v$. We also assume another input parameter, denoted by $C$, which is a number that bounds the maximum amount of flow a node can serve. We also assume that each leaf generates at most $C$ units of flow.

An algorithm that solves the problem outputs an *allocation*, which is a subset of the nodes that are primed. The conditions which the allocation has to satisfy vary in the following two service models. These two models differ by whether a primed node is allowed to forward flow or not.

1. *The must-serve model.* In this model a primed node serves all its incoming flow. An allocation constitutes a solution in this model if, when we cut the tree by removing the edge from each primed node to its parent, then the flow generated at the leaves of each subtree is at most $C$ (and therefore can be served at the root of this subtree). In other words, an allocation is a good solution if, when we process nodes from the leaves up, forwarding all the flow into an unprimed node to its parent, then each time we reach a primed node it has at most $C$ units of flow coming into it.
2. *The serve-or-forward model.* In this model a primed node serves at most $C$ units of the flow coming into it and forwards the rest. Here an allocation constitutes a solution if the following process ends such that the amount of flow reaching the root is at most $C$ if it is primed and 0 if it is not primed. We

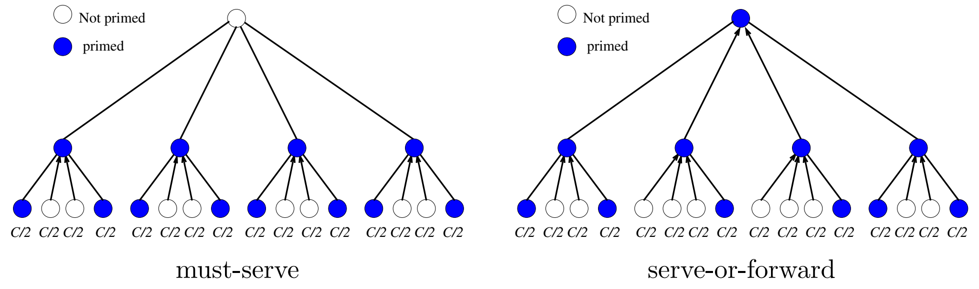

Fig. 2.1. *Example of optimal allocation for the two variants of the problem. The tree has* 16 *leaves, each generating a flow of* $C/2$*; thus the total flow is* $8C$*. Serve-or-forward primes* 11 *nodes and must-serve primes* 12 *nodes.*

process the nodes from the leaves up. When an unprimed node is processed we "forward" all its flow to the parent; when a primed node is processed we assign it to serve all the flow it receives, up to $C$ units, and forward the rest to its parent.

In both models an allocation constitutes a solution if there is an *assignment* of all flow to primed nodes (each unit of flow is assigned to a node on its way to the root) such that the *load* (assigned flow) of each primed node is at most $C$ and the load of other nodes is 0. The *size* of an allocation is the number of nodes it primes. An allocation is *optimal* if it is correct and of minimum size.

The must-serve model is more restrictive than the serve-or-forward model; thus must-serve allocations constitute serve-or-forward allocations. Figure 2.1 illustrates an example flow serviced in the two service models. The serve-or-forward model is appropriate for applications where "servicing" is a more expensive operation than "forwarding" (e.g., when servicing involves intensive computation or large file transfers). The must-serve model is appropriate for applications with low service cost such as simple database lookups. In the must-serve model the traffic traversing each edge (link) is also bounded by $C$, which is important in some applications.

We analyze a static setting where the flow generated by each leaf remains fixed through time.[1] We consider both centralized and distributed algorithms. For distributed algorithms we assume that each node is able to communicate with its parent and children. In the distributed settings, priming decisions of different nodes can depend on each other, and we consider the "convergence" process until the nodes decide on a stable allocation. We measure the convergence time in units of the maximum "reaction time" of a node, that is, the maximum elapsed time until it reacts to a new input.

One of our distributed algorithms, GAP, assumes flow reporting, where each child reports to its parent on the flow generated below it (regardless of whether it is served or not). This reporting process is similar to "hit count" reporting in cache hierarchies.

## 3. What allocation size is necessary?

Let $R$ be the total flow generated in the tree. An obvious lower bound on the required allocation size is $R/C$. This bound can be further refined if we also consider the maximum number of children of a node, which we denote by $\Delta$. The following lemma shows a better bound for the must-serve model.

[1]The algorithms, however, are applicable in a dynamic context where flow changes.

LEMMA 3.1. *For any $C$ and $\Delta > 4$, there are instances such that $\Delta R/(4C)$ primed nodes are necessary in the must-serve model.*

*Proof.* Consider a complete $\Delta$-ary tree of depth $d$, where each leaf generates $2C/\Delta$ flow. Therefore, the total flow is $R = 2C\Delta^{d-1}$.

Consider a two-level subtree of this tree consisting of a node $x$ of depth $d-1$ and its $\Delta$ children which are leaves. At least $\lceil \Delta/2 \rceil$ of the children of $x$ must be primed, since otherwise $x$ receives more than $C$ units of flow. Furthermore, there is an optimal selection that primes exactly $\lceil \Delta/2 \rceil$ of the children of $x$. This is because we can always prime $x$ instead of all but $\lceil \Delta/2 \rceil$ of its primed children without increasing the allocation size.

Let $s(x)$ be the nearest primed ancestor of $x$. (Note that $s(x) = x$ if $x$ is primed.) Since the combined value of the flow of all the unprimed children of $x$ strictly exceeds $C/2$, it follows that if $x \neq y$ are two nodes of the depth $d-1$, then $s(x) \neq s(y)$. (Otherwise $s(x)$ must serve more than $C$ units of flow.) Thus, there is one primed internal node for each node $x$ of depth $d-1$.

Since there are $\Delta^{d-1}$ nodes of depth $d-1$, we obtain that the size of an optimal solution of this instance is $\Delta^{d-1}(1 + \lceil \Delta/2 \rceil) \geq \frac{R\Delta}{4C}$. ☐

A similar bound for the serve-or-forward model is given by the following lemma.

LEMMA 3.2. *For any $C$ and $\Delta > 5$, there are instances such that $\Delta R/(5C)$ storage is necessary with serve-or-forward.*

*Proof.* Consider a complete $\Delta$-ary tree of depth $d$ where all leaf nodes generate $2C/\Delta$ flow and therefore the total flow is $R = 2C\Delta^{d-1}$, as in the proof of Lemma 3.1. The total number of internal nodes is $(\Delta^d - 1)/(\Delta - 1)$, and therefore the total amount of flow which these nodes can serve is $C(\Delta^d - 1)/(\Delta - 1)$. The remaining flow must be served, less efficiently, at primed leaves. The amount of flow remaining for leaves to serve is at least

$$R - C(\Delta^d - 1)/(\Delta - 1) \geq C\Delta^d \left( \frac{2}{\Delta} - \frac{1}{(\Delta - 1)} \right)$$

flow. Each leaf generates $2C/\Delta$ flow, and hence this is the greatest amount of flow any leaf can serve. So we need to prime at least

$$\Delta^d \left( \frac{2}{\Delta} - \frac{1}{(\Delta - 1)} \right) \frac{\Delta}{2} \geq \frac{R\Delta}{5C}$$

leaf nodes for $\Delta \geq 6$. ☐

*Remark.* Note that the proof of Lemma 3.2 applies also to the must-serve model and gives a slightly worse constant than the proof of Lemma 3.1.

## 4. Optimal algorithms.

In this section we present algorithms that find an optimal allocation in both the serve-or-forward and must-serve models. In section 4.1 we present an optimal algorithm for the serve-or-forward model, and in section 4.2 we present an optimal algorithm for the must-serve model.

### 4.1. Serve-or-forward.

The algorithm OPT_SOF works in two phases. In the first phase it processes the nodes from the leaves upward and makes some priming decisions. In the second phase additional nodes are primed throughout the tree. Each node primed in the first phase is assigned $C$ units of flow that are generated below it. Nodes primed in the second phase may be assigned less than $C$ units of flow.[2]

[2]Note that there could be several such mappings for each optimal allocation, including mappings where nodes assigned in the first phase obtain less than $C$ units of flow. We consider particular assignments where this holds.

Our algorithm utilizes the notion of a *residual problem*. In each iteration of the first phase the algorithm primes a node and allocates $C$ units of flow for it to serve. Then it generates a residual instance by transferring children of the primed node $v$ that have remaining unserved flow to $v$'s parent. In the following we denote by $f(v)$ the flow into node $v$ at the "current" residual problem.

ALGORITHM 1 (OPT_SOF).

Phase 1. *While there is a node $v$ other than the root such that $f(v) > C$, do the following. Let $v$ be a deepest nonroot node such that $f(v) > C$, and let $v_1, v_2, \ldots$ be the children of $v$ ordered by increasing flow value, i.e., $f(v_1) \le f(v_2) \le \cdots$.*[3] *Let $j$ be the smallest integer such that $\sum_{i \le j} f(v_i) \ge C$. Prime the node $v$. Assign to $v$ all the flow coming up from $v_1, \ldots, v_{j-1}$ and $C - \sum_{i \le j-1} f(v_i)$ of the flow from leaf descendants of $v_j$ (chosen arbitrarily). Make the children $v_{j+1}, v_{j+2}, \ldots$ of $v$ with their respective flow values $f(v_{j+1}), f(v_{j+2}), \ldots$ children of the parent of $v$. Make $v_j$, with the $f(v_j) - C + \sum_{i<j} f(v_i)$ units of flow generated in its subtree and not served by $v$, a child of the parent of $v$.*[4]

Phase 2. *Let $v$ be the root, and let $v_1, v_2, \ldots$ be the children of the root ordered by increasing flow value, i.e., $f(v_1) \le f(v_2) \le \cdots$. If $f(v) > C$ let $j$ be the smallest integer such that $\sum_{i \le j} f(v_i) \ge C$.*

*Prime the nodes $v_{j+1}, v_{j+2}, \ldots$, and assign each of them to serve all the flow generated in its subtree.*

*If $\sum_{i \le j} f(v_i) > C$, prime also the node $v_j$, and assign it to serve all the flow generated in its subtree.*

*If $f(v) > 0$, prime $v$, and assign it to serve all remaining unserved flow in the tree.*

We can implement OPT_SOF to run in $O(n \log n)$ time, where $n$ is the number of nodes in the tree. To do that we maintain the children of every node in a heap. When processing a node $v$ we do a series of delete-mins on the heap of $v$ until we have accumulated the lightest children whose weight is above $C$. We reinsert the last deleted child back into the heap with its adjusted flow value if the cumulative flow of the deleted children is greater than $C$. Finally, we meld the heap of $v$ with the heap of the parent of $v$.

A distributed implementation of OPT_SOF follows these two phases. In the first "upward" phase, communication occurs from the leaves to the root with nodes primed along the way. In this phase each node sends to its parent the identity and the current flow value of each transferred child. In the second "downward" phase, the root "decides" to prime a subset of its children. Since some of these children are nodes that have been transferred up during the first phase, we then communicate these priming decisions to the nodes themselves. The amount of communication passed when children are transferred could be (in the worst case) of the order of the number of descendants of the transferring node.

We now establish the correctness and optimality of OPT_SOF.

THEOREM 4.1. OPT_SOF *produces a correct allocation of minimum size.*

*Proof.* To establish correctness we have to verify that each primed node is assigned to serve no more than $C$ units of flow and that all flow is served. By the definition of the algorithm it is clear that each node $v$ which gets primed at the first phase is assigned to serve exactly $C$ units of flow. When the first phase ends all children of

[3]If there is more than one node $v$ which is deepest with $f(v) > C$, we break ties arbitrarily.

[4]In the residual problem we eliminate the flow served by $v$. Other than that, the subtrees hanging off of the children of $v$, which are made children of the parent of $v$, remain the same.

the root receive less than $C$ units of flow. Therefore, having a subset of these children serve the flow they generate, and having the root serve the rest, produces a legal solution as long as the subset is large enough that at most $C$ units of flow are served at the root. The subset primed by the second phase clearly satisfies this requirement.

We now show that the allocation produced is of minimum size. Consider an iteration of the first phase. Let $T$ be the network when the iteration starts, let $v$ be the node which is primed during the iteration, and let $A$ be the flow assigned to $v$. Let $T'$ be the residual problem generated from $T$ at the end of the iteration. It is not hard to see that if $T$ has an optimal allocation in which $v$ is primed and serves $A$, then we can obtain an optimal solution to $T$ from any optimal solution of $T'$, by using the allocation of the optimal solution of $T'$ together with priming $v$ and assigning $v$ to serve $A$. Thus by induction on the iterations of the first phase, it suffices to show that the choice of $v$ and $A$ can be extended to an optimal solution of $T$. As a base case of the induction we show that the solution of the residual problem obtained by the second phase is optimal. The optimality of the allocation of the second phase follows since we prime the children of the root with largest incoming flow. Therefore, we prime as small a subset of them as possible so that the root can serve the remaining flow.

It remains to show that $T$ has an optimal solution in which $v$ is primed and serves $A$. Consider any optimal solution $O$ to $T$. We show that we can change it to another solution with the same number of primed nodes in which $v$ serves $A$.

If $v$ is not primed in $O$, then we first change $O$ so $v$ is primed as follows. If $v$ has a primed descendant, then let $v'$ be such a primed descendant where the nodes on the path from $v$ to $v'$ are not primed. Clearly if we prime $v$ instead of $v'$ and have $v$ serve the flow previously served by $v'$, we still have an optimal solution. In case $v$ does not have a primed descendant, let $u$ be the closest ancestor of $v$ which is primed. Since $f(v) > C$ if $u$ serves flow which is not generated below $v$, some ancestor of $u$ serves flow generated below $v$. It follows that by interchanging flow assigned to $u$ with flow assigned to its ancestors, we can change the flow assignment so that all the flow that $u$ serves is generated below $v$. Finally, since all the flow which $u$ serves is generated below $v$, we can prime $v$ instead of $u$ and have it serve the flow that $u$ serves.

Last, we have to show that we can change the allocation and the flow assignment so that $v$ serves $A$. First notice that since the flow reached to each child of $v$ is at most $C$ we may assume that $O$ does not contain prime descendants of $v$ which are not immediate children of $v$. (We can prime a child of $v$ instead of each such primed descendant of $v$ without increasing the allocation.) Furthermore, if $v$ has a primed child $v_1$, and a child $v_2$ which is not primed, such that $f(v_2) > f(v_1)$, we can change $O$ and prime $v_2$ instead of $v_1$. Ancestors of $v$ that served the flow coming up from $v_2$ are now assigned to serve the flow coming up from $v_1$ instead. Since less flow is coming up from $v_1$ this allocation is still legal and hence optimal. So we may assume that the primed children of $v$ are those from which the largest amount of flow originates.

Finally, if $v$ serves $C$ units of flow but this flow is not identical to $A$, we can interchange the flow assigned to $v$ with the flow assigned to its ancestors so that $v$ serves exactly the flow in $A$. If $v$ serves less than $C$ units of flow, we can increase the flow assigned to it so that it serves exactly the flow in $A$ and assign less flow to $v$'s primed child that serves the smallest amount of flow among the children of $v$. ∎

**4.2. Must-serve.** Must-serve instances have a simpler definition of the residual problem: Given an instance and a subset of primed nodes, the residual problem is obtained by eliminating all subtrees rooted at primed nodes along with the flow generated in them.

Unlike the case with serve-or-forward instances, we do not need to consider flow assignments for obtaining the residual instance. The identity of the primed nodes suffices.

We now state the optimal must-serve algorithm, OPT_MS. The algorithm iteratively primes nodes; it considers the residual network after each priming step. Computationally, the algorithm performs one bottom-up pass, but information can propagate one level down from parents back to children during that pass.

ALGORITHM 2 (OPT_MS). *Let $v$ be a deepest node with $f(v) > C$.*

*Order the children of $v$ by decreasing flow $v_1, v_2, \ldots$ with $f(v_1) \geq f(v_2) \ldots$.*

*Let $j$ be the smallest integer such that $\sum_{i \leq j} f(v_i) \geq f(v) - C$. Prime the nodes $v_1, \ldots, v_j$.*

*If there is no $v$ with $f(v) > C$ and positive flow enters the root, then prime the root.*

The correctness and optimality analysis is similar to (and somewhat simpler than) the one performed in the serve-or-forward model.

LEMMA 4.2. *Algorithm* OPT_MS *is correct and finds a minimum-size must-serve allocation.*

*Proof.* Consider a deepest node $v$ with $f(v) > C$. We claim that any solution with the heaviest child of $v$ being unprimed can be transformed to a solution with the same number of primed nodes where the heaviest child of $v$ is primed and with $v$ serving or transferring at most the same amount of flow. The claim concludes the correctness proof since it implies that the repeated step of choosing a deepest node with $f(v) > C$, priming its heaviest child, and focusing on the residual problem is consistent with an optimal solution.

We now prove the claim. Consider an optimal solution where the heaviest child of $v$ is not primed. First observe that no node can receive flow value that exceeds $C$ in a solution; the first primed ancestor that this flow arrives at will have to serve it all, which is a contradiction. Therefore, node $v$ must have at least one primed proper descendant in its subtree. First we show that there is an optimal solution where one of the children of $v$ is primed. Suppose no one of the children of $v$ is primed. It follows that $v$ must have a primed descendant $u$ which is not a child of $v$. Then the child of $v$ which is an ancestor of $u$ can be primed instead of $u$. This child can serve all the flow that $u$ was serving plus additional flow.

Suppose now that the heaviest child of $v$ is not primed and another child $u$ is primed. If we prime the heaviest child and unprime $u$, then the total unserved flow reaching $v$ can only decrease. ∎

We next consider algorithms where nodes make local decisions on when to become primed, by simply observing incoming flow.

## 5. The THRESHOLD algorithm.

The THRESHOLD$(C, \Delta)$ algorithm runs independently at each node. The only communication it receives is the amount of incoming flow. We also assume each node knows $\Delta$, the indegree of its parent node (or some bound on it). THRESHOLD produces an allocation which is good for the must-serve model.

A copy of THRESHOLD running at a node $v$ performs as follows.

ALGORITHM 3 (THRESHOLD$(C, \Delta)$). *Let $f(v)$ be the flow into the node $v$ with respect to the current allocation assuming each primed descendant of $v$ serves all the flow it gets.*

*The node $v$ is primed if and only if*

- *$f(v) > C/\Delta$, or*
- *$v$ is the root and $f(v) > 0$.*

In our model nodes may make their decisions asynchronously. Let $u$ be an ancestor of $v$ such that there is no primed node which is a proper descendant of $u$ and a proper ancestor of $v$ in the current allocation. We assume that if node $v$ decides to change its priming status from primed to unprimed or vice versa, the flow into $u$ changes instantaneously to reflect this change. We also assume that each node runs the algorithm above at least every $t$ seconds. Therefore, if the incoming flow into a node changes so that it crosses the threshold $C/\Delta$, and it remains stable at its new value for at least $t$ seconds, then the priming status of $v$ would change.

In reality there may be a delay from the moment a node $v$ changes its priming status until an ancestor $u$ of $v$ realizes that its incoming flow has changed. Furthermore, this delay may be proportional to the distance between $u$ and $v$. We discuss at the end of this section how this may affect the performance of THRESHOLD.

Initially, the algorithm starts with some configuration of primed nodes (possibly no primed nodes). Since each node makes local decisions that depend on decisions made by the nodes below it, it may change its decision multiple times. We argue that eventually, a stable allocation is reached which is good for the must-serve model. In fact, THRESHOLD$(C, \Delta)$ converges to the same allocation generated by the following iterative centralized algorithm (assuming it starts with an empty allocation).

- Prime all nodes such that the flow generated below them exceeds $C/\Delta$, and the flow generated below each of their children does not exceed $C/\Delta$.
- Truncate the tree by removing these newly primed nodes along with all nodes and flow generated below them, and repeat this process.

Let $N$ be the set containing each node $v$ such that the total flow generated in the subtree of $v$ exceeds $C/\Delta$ and the total flow generated below each child of $v$ is no larger than $C/\Delta$. The centralized algorithm above primes the nodes in $N$ in its first iteration. We claim that THRESHOLD also primes $N$ and unprimes all descendants of nodes in $N$, after at most $2t$ seconds, starting with any allocation. Indeed, regardless of the initial allocation, descendants of nodes in $N$ must see incoming flow of at most $C/\Delta$. Thus, THRESHOLD cannot prime them, and if they started out being primed, then after at most $t$ seconds THRESHOLD will unprime them. Once all descendants of nodes in $N$ are unprimed, each node in $N$ receives flow exceeding $C/\Delta$ so it will become primed in the following $t$ seconds. Once the nodes in $N$ are primed and all their descendants are unprimed, this state will prevail as long as the input flow does not change. By induction one can complete this argument to show that above the nodes of $N$, THRESHOLD also primes exactly the same nodes as the iterative algorithm above when applied to the truncated tree.

Observe that since each child of a node in $N$ sends to its parent at most $C/\Delta$ flow, the total flow that each node in $N$ receives is at most $C$. So when THRESHOLD primes a node in $N$, this node can serve all the flow generated below it, and it transfers 0 flow to its parent. The following lemma follows from this equivalence between these two algorithms.

LEMMA 5.1. THRESHOLD$(C, \Delta)$ *eventually reaches a correct stable allocation. The allocation produced is legal in the must-serve model and thus also applies to the serve-or-forward model. The final allocation is of size at most $R\Delta/C$ (since each primed node serves at least $C/\Delta$ flow).*

We define the *convergence time* of THRESHOLD as the time it takes for it to reach the stable state. To bound the convergence time of THRESHOLD recall that we defined

$t$ to be the maximum time it takes for a node to respond to a change in its incoming flow, where by *responding* we mean a change of state from prime to unprime or vice versa. It is easy to prove by induction on $i$ that after $i * t$ seconds all nodes of depth at least $d-(i-1)$ have reached their stable state. Indeed, after $t$ seconds the nodes of depth $d$ reach their final state, since their incoming flow does not depend on decisions made by other nodes and therefore cannot change. Once the nodes of depth $d$ are stable, the incoming flow into nodes of depth $d-1$ will not change anymore. So after an additional $t$ seconds nodes of depth $d-1$ reach their stable allocation as well. In general, after $k*t$ seconds nodes of depth at least $d-(k-1)$ have reached their stable state, so the flow into nodes of depth $d-k$ will not change anymore, and consequently these nodes of depth $d-k$ reach their stable state during the next $t$ seconds.

How far can THRESHOLD be from the optimal solution? We provide examples where the worst-case ratio approaches $\Delta$ for both the serve-or-forward and must-serve models. We start with the serve-or-forward model. For an integer $i$, construct a binary tree of depth $i$, and then attach $\Delta$ children to each of the $2^i$ leaves of the binary tree. Now suppose that each of the $\Delta 2^i$ leaves of the modified tree generates flow of value $C/\Delta+\epsilon$ ($\epsilon < C/(\Delta 2^i)$). The THRESHOLD algorithm will prime all leaves, and this results in an allocation of size $\Delta 2^i$. The algorithm OPT_SoF will prime all depth-$i$ nodes and the root node of the tree and thus will obtain an allocation of size $2^i+1$. The ratio of the allocation size obtained by THRESHOLD to the optimal allocation of OPT_SoF approaches $\Delta$ as $i$ increases.

For the must-serve model consider a tree of depth one consisting of a node and $\Delta$ children. Among these $\Delta$ children $\Delta-1$ generate $C/\Delta+\epsilon$ flow, and the remaining child generates $C/\Delta-(\Delta-1)\epsilon$ flow. The THRESHOLD algorithm primes all $\Delta-1$ children and the root node, thus producing an allocation of size $\Delta$. The optimal algorithm OPT_MS primes only the root. A family of examples with arbitrarily large values of total flow can be obtained by attaching $\Delta$ children generating flow as defined above to each of the leaves of a binary tree. For small enough $\epsilon$, the THRESHOLD algorithm will prime $(\Delta-1)2^i$ of the leaves and all $2^{i-1}$ nodes of depth $i-1$. The algorithm OPT_MS will prime all depth-$i$ nodes. The ratio between the size of the allocation of THRESHOLD and the size of the allocation of OPT_MS is $\Delta-0.5$.

Observe that any algorithm that takes independent local decisions at each node would not be able to improve on this approximation ratio. Intuitively, since no information is available to a node on what its siblings send to its parent, the algorithm cannot allow sending more than $C/\Delta$ units of flow to the parent and at the same time guarantee that every node receives at most $C$ units of flow.

**5.1. Convergence of THRESHOLD.** We learned that the worst-case final allocation obtained by THRESHOLD is within $\Delta$ of optimal. We now consider the "intermediate" allocations obtained during the convergence process.

Consider a tree that consists of a path of $n$ nodes $v_1,\dots,v_n$ (ordered from the bottom to the root); each path node has $\Delta-1$ leaves attached to it. The $\Delta-1$ leaves at each path node generate together $\epsilon C/\Delta$ flow. (To simplify the presentation we assume that $1/\epsilon$ is integral.) The total flow entering the tree is $R=n\epsilon C/\Delta$. Observe that THRESHOLD will never prime a leaf node; thus only the nodes on the path get primed.

Consider the following possible convergence scenario. (1) Initially, all nodes are not primed; thus the $i$th path node $v_i$ sees $i\epsilon C/\Delta$ flow. (2) Every $v_i$ for $i \geq 1/\epsilon$ receives more than $C/\Delta$ flow and primes itself. (3) Next, all primed nodes above $v_{1+1/\epsilon}$ see only $\epsilon C/\Delta$ flow and unprime themselves. (4) The deepest primed path node $v_{1/\epsilon}$ remains primed from now on, since all nodes below it remain unprimed. (5) The process continues on the new tree obtained after truncating the current tree at $v_{1/\epsilon}$. The new tree has the same structure with $n' = n - 1/\epsilon$ interior path nodes.

It is not hard to see that convergence takes $\epsilon n = R\Delta/C$ such "iterations." The average number of nodes that change state (from primed to unprimed or vice versa) in an iteration is $\Omega(n)$. The largest intermediate allocation occurs at the first iteration and is of size $n - 1/\epsilon = (R\Delta/C - 1)/\epsilon$. That is, there is a factor of $1/\epsilon$ between intermediate and final allocation sizes.

Interestingly, these undesirable properties are not merely an artifact of the "sharp" threshold exhibited by THRESHOLD: a similar convergence pattern with very large size of intermediate allocation and slow convergence time is possible even under a natural modification of THRESHOLD. In this modification we prime a node when the incoming flow exceeds $C/\Delta$ and unprime a node when its flow drops to $L/\Delta$ or below (for some $\epsilon C < L < C$). This variant of THRESHOLD would result in worse-quality final allocations (which can be $C/L$ times the allocation size obtained by the original version of THRESHOLD). The worst-case convergence patterns, however, are similar.

In our model we assumed that the flow incoming into any node $v$ changes instantaneously to reflect any change in the allocation of the descendants of $v$. Clearly the scenario above where intermediate allocations are large used this property of the model. Such bad convergence patterns are less likely to happen in cases where, by the time a node $v$ figures out the value of its incoming flow, the allocation in its subtree is stable or close to stable. We can force this to happen if each node $v$ starts out primed and unprimes itself only when the allocation in its subtree is final and the local decision of THRESHOLD at $v$ is to be unprimed. Notice, however, that the bad convergence pattern of THRESHOLD may reoccur at any time where the input changes even if we manage to avoid it at initialization time. Furthermore, for some applications priming a large number of nodes even temporarily may be undesirable.

Another undesirable property of THRESHOLD occurs when the flow incoming into the leaves changes and THRESHOLD adjusts its allocation to the new flow. It is not hard to see that relatively small changes in the input may trigger large changes in the allocation. In particular, a node $v$ may change its allocation even if the total flow generated in its subtree has not changed. Consider, for example, a node $v$ with three children $v_1$, $v_2$, and $v_3$ that are leaves. Assume $v_1$ generates $2\epsilon$ flow, $v_2$ generates $\frac{C}{\Delta} - \epsilon$ flow, and $v_3$ generates $\frac{C}{\Delta} + \epsilon$ flow. THRESHOLD will prime $v_3$ and $v$. Assume now that the flow changes slightly so that $v_1$ generates 0 flow, $v_2$ generates $\frac{C}{\Delta} + \epsilon$, and $v_3$ still generates $\frac{C}{\Delta} + \epsilon$ flow. Then, THRESHOLD primes $v_2$ and unprimes $v$, even though the total flow generated below $v$ has not changed.

To summarize, we showed that the simple local THRESHOLD algorithm can have certain convergence and instability patterns that may be considered as serious drawbacks for some applications. In section 6 we propose and analyze a different local algorithm, called GAP, that overcomes some of problems of THRESHOLD.

**5.2. Parent priming.** By the definition of THRESHOLD, no node can send to its parent more than $C/\Delta$ units of flow in the final allocation. This requirement is necessary to guarantee that no node serves more than $C$ units of flow in situations where a node has no information on what its siblings send to the parent. As a result, THRESHOLD may converge to an allocation of size $\frac{R\Delta}{C}$. Indeed we showed in section 3 that for some trees and flows an allocation of size about $\frac{R\Delta}{C}$ may be necessary, but for other inputs THRESHOLD may produce an allocation that is off from the optimal by a factor of $\Delta$. In this section we suggest a technique that improves this worst-case approximation ratio of $\Delta$ by a constant factor and may perform even better in practice.

Consider running THRESHOLD using the bound $C' = \Delta C$ rather than $C$. This, of course, can result in a primed node serving up to $\Delta C$ units of flow. To solve this problem, and turn the solution into a valid one, we allow a correcting *parent priming* phase, where nodes that were primed in the first phase are allowed to prime some of their children. Specifically, a node that ends up with more than $C$ units of flow (that is, flow in $(C, \Delta C]$) primes its children, in decreasing order of flow value, until its own flow drops to $C$ or fewer units.

It is easy to see that this additional local phase will always result in a correct allocation since before the parent priming phase each unprimed child was delivering at most $C$ units of flow. The next lemma upper bounds the approximation ratio of an allocation produced using the parent priming technique with respect to the optimal allocation.

LEMMA 5.2. *The approximation ratio of* THRESHOLD *with parent priming is* $(\Delta + 2)^2/(4\Delta)$.

*Proof.* Every node that is primed in the first phase serves at least $C$ (and at most $\Delta C$) units of flow. Consider a node primed in the first phase that serves $\alpha C \geq C$ units of flow. An optimal algorithm must use at least $\alpha$ primed nodes to serve the flow. Our algorithm primes at most $\lceil \Delta(\alpha - 1)/\alpha \rceil$ children and thus uses at most $2 + \Delta(\alpha - 1)/\alpha$ primed nodes to serve the flow. The ratio is thus $(2 + \Delta)/\alpha - \Delta/\alpha^2$. The maximum on the interval $\alpha \in [1, \Delta]$ is obtained at $\alpha = (2\Delta)/(\Delta + 2)$ and is $(\Delta + 2)^2/(4\Delta)$. ◻

## 6. The GAP algorithm.

The GAP algorithm runs locally at each node. Like THRESHOLD, GAP makes its decisions locally. However, in contrast to THRESHOLD, decisions made by each node are independent of the state of other nodes. The only information GAP relies on at each node is the total amount of flow generated below each of its children (regardless of where it is served). Note that if nodes are running THRESHOLD and all start unprimed, then the initial value of the incoming flow to each node is the total flow generated in its subtree. In practice, nodes can propagate this information bottom-up on the distribution tree by periodic reports from children to parents.

Let $F(v)$ be the total flow generated under a node $v$, and let $F_s(v)$ be the flow generated under its heaviest child, that is, $F_s(v) = \max\{F(u) \mid u \in \text{children}(v)\}$. If $v$ is a leaf, then we define $F_s(v) = 0$.[5]

We consider GAP in the must-serve model. GAP is a randomized algorithm which depends on two parameters. The first is $C$, which is also an upper bound on the maximum flow generated by a leaf. In previous sections we used $C$ as an upper bound on the flow a primed node is allowed to serve. Here, since GAP is randomized, we will allow some nodes to serve more than $C$ units of flow. The second parameter of GAP is a fraction $0 \leq \mu \leq 1$. This fraction controls the average number of primed nodes, which increases as $\mu$ decreases. As $\mu$ decreases, the probability that a node will serve more than $C$ units of flow also decreases.

Specifically, $\mu$ determines the expected amount of flow served by a primed node. However, whatever this expectation is, the probability that we deviate from it decreases exponentially. For example, if $\mu = \frac{1}{\Delta}$, then the expected amount of flow that

[5]We use here $F(v)$ to distinguish it from $f(v)$, which we used in the previous section to denote the flow entering node $v$.

a node will serve is no greater than $C$, and the probability that a node will have to serve more than $L * C$ units of flow decreases exponentially with $L$.

ALGORITHM 4 (GAP$(C, \mu)$ algorithm). *At each node $v$, GAP$(C, \mu)$ performs the following.*

1. *If $F(v) < \mu C$, then $v$ is not primed.*
2. *If $F(v) \geq \mu C$, then*
   - *if $F_s(v) < \mu C$, $v$ is primed;*
   - *otherwise, $v$ is primed with probability* $\min\{1, (F(v) - F_s(v))/(\mu C)\}$.
3. *If $v$ is the root, it did not get primed in 2, and it has flow entering it, then prime $v$.*

In our subsequent analysis, we assume that only leaf nodes have flow below $\mu C$. We do that without loss of generality since the operation of GAP on an instance is equivalent to GAP operating on the same instance when maximal subtrees rooted at a node $v$ with $F(v) < \mu C$ are contracted to a single leaf with flow $F(v)$.

We first bound the expected size of the allocation produced by GAP.

LEMMA 6.1. *The expected number of nodes primed by* GAP *at step 2 is at most $2R/(\mu C) - 1$, for $R \geq \mu C$. (The actual expected number of primed nodes is at most one larger because of priming the root, and it is one if $R < \mu C$.)*

*Proof.* Let $M(x)$ be the maximum, over flow trees with flow $x$, of the expected number of primed nodes allocated by GAP in step 2. By the definition of GAP, $M(x)$ satisfies the following. If $x < \mu C$, then $M(x) = 0$. For $x \geq \mu C$ we have that

$$M(x) = \max\Bigg( \{\min\{1, (x - S)/(\mu C)\} + M(S) \mid S < x\}$$

$$\cup \left\{ 1 + M(S_1) + \cdots + M(S_i) \mid \sum_{j=1}^{i} S_j \leq x \text{ and } \forall j\ S_j \geq \mu C \text{ and } i \geq 2 \right\} \Bigg). \tag{6.1}$$

The first set over which we take the maximum takes into account all trees where all children of the root except possibly the largest one get fewer than $\mu C$ units of flows. In this case there cannot be primed descendants of any child of the root except the largest one. The second set takes into account trees where more than one child of the root gets at least $\mu C$ units of flow. In this case by the definition of GAP we always mark the root at step 2.

Using induction on the flow value $x$, and relation (6.1), it is easy to establish that $M(x) \leq 2x/(\mu C) - 1$. ∎

Since GAP is a randomized algorithm, there is a positive probability that nodes are assigned flow that exceeds $C$. The following lemma gives probabilistic bounds on the maximum flow entering a node when we apply GAP. Notice that since each leaf generates at most $C$ units of flow, it is clear that a primed leaf never serves more than $C$ units of flow. So the lemma considers only the maximum flow entering a prime internal node.

LEMMA 6.2. *The expected amount of flow serviced by a primed internal node is at most $\Delta \mu C$. Furthermore, the probability that the serviced flow exceeds $L \Delta \mu C$ is at most $(1 - 1/e)^L$.*

*Proof.* To simplify the calculations, we normalize the flow to be in units of $\mu C$. In these units we first have to show that the expected amount of flow serviced by a primed node is at most $\Delta$.

Consider an internal node $v_0$. Since $v_0$ is internal, $F(v_0) \geq 1$. Consider a child $v_1$ of $v_0$. We claim that the expected value of flow that $v_0$ receives from $v_1$ is at most 1.

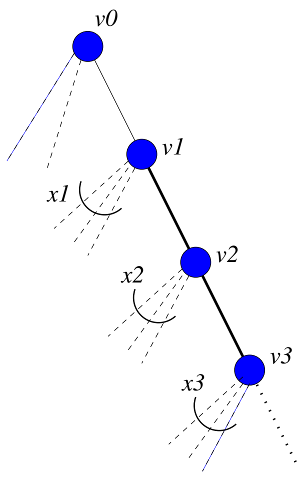

FIG. 6.1. *Illustration for the proof of Lemma* 6.2. *Thick lines represent edges to heaviest child.*

Thus the total expected flow passed to $v_0$ from all its children together is at most $\Delta$.

We now prove the claim. We can assume without loss of generality that $F(v_1) > 1$ (since otherwise the claim trivially follows). We may also assume that $v_1$ is not a leaf, since, if it was, then it is primed and therefore does not contribute any flow to $v_0$. Let $v_2$ be the child of $v_1$ with the largest amount of flow generated below it and in general let $v_{i+1}$ be the child of $v_i$ with the largest amount of flow generated below it, if $v_i$ is not a leaf. We call $v_1, v_2, \ldots, v_\ell$ the *heavy path* hanging from $v_1$. (See Figure 6.1.) Note that $v_\ell$ is a leaf. Let $x_i = F(v_i) - F_s(v_i) = F(v_i) - F(v_{i+1})$ $(i \geq 1)$ be the flow getting into $v_i$ from all its children but $v_{i+1}$. We define a node on the *heavy path* hanging from $v_1$ to be *always-primed* if one of the following conditions holds.

1. $x_i \geq 1$. That is, the flow that enters $v_i$ from children other than $v_{i+1}$ is at least 1.
2. $F(v_i) \geq 1$ and $i = \ell$. That is, $v_i$ is the leaf at the end of the path and it generates at least one unit of flow.
3. $F(v_i) \geq 1$, $i < \ell$, and $F(v_{i+1}) < 1$. Note that this case can happen only if $i = \ell - 1$ since we assume that only leaves can have $F(v) < 1$.

Note that by the definition of GAP an *always-primed* node is primed with probability one. Furthermore, either $v_\ell$ or $v_{\ell-1}$ must be always-primed, so in particular we have at least one always-primed node on the path. If $v_1$ is always-primed, then the claim obviously holds; otherwise, let $k \geq 1$ be the maximum such that $v_k$ is not always-primed. Observe that we must have that $x_i < 1$ for $1 \leq i \leq k$.

Consider a run of GAP, and let $p \leq k$ be the lowest index such that $v_p$ is primed; define $p = k+1$ if there is no primed node before $v_{k+1}$ on the path. By definition, the maximum amount of flow that $v_0$ gets from $v_1$ is $\sum_{j \leq k+1} x_j$. To estimate the expected amount of flow that $v_0$ gets from $v_1$, we define $G_i$, $1 \leq i \leq k$, to be a random variable describing the flow value passed to $v_{i-1}$ from $v_i$. We also denote the expectation of $G_i$ by $g_i$. Since GAP leaves node $v_i$ unmarked with probability $1 - x_i$, we have that $g_k = (1 - x_k)x_k$, and for $i < k$

$$g_i = (1 - x_i)(x_i + g_{i+1}).$$

So, in particular,

$$g_1 = (1-x_1)(x_1 + (1-x_2)(x_2 + (1-x_3)(\cdots + (1-x_{k-1})(x_{k-1} + (1-x_k)x_k)\cdots))).$$

We show by a backward induction on $i$ that $g_i \leq 1$. It is easy to see that $g_k = (1-x_k)x_k \leq 1$. Assume inductively that $g_i \leq 1$; then $g_{i-1} = (1-x_i)(x_i + g_i) \leq (1-x_i)(x_i+1) \leq 1$. For $i = 1$ we obtain that $g_1 \leq 1$ and the claim follows.

We now prove the second part of the lemma. We start with the following claim.

Claim 6.1. *The probability that the value of $G_i$ exceeds $L$ is at most $(1-1/e)^L$ for all $L \geq 0$.*

We prove the claim by downward induction on $i$. The base of the induction is the random variable $G_k$. The outcome is $x_k$ with probability $1-x_k$ and 0 otherwise. The likelihood that the outcome exceeds $L > x_k$ is 0. The likelihood that it exceeds $L \leq x_k$ is $(1-x_k) \leq (1-1/e)^{x_k} \leq (1-1/e)^L$. (We use the tautology $(1-a) \leq (1-1/e)^a$ for $0 \leq a$.)

For the random variable $G_i$ and $L \leq x_i$ we have

$$P[G_i \geq L] = (1-x_i) \leq (1-1/e)^{x_i} \leq (1-1/e)^L.$$

For $L > x_i$ we have the relation

$$P[G_i \geq L] = (1-x_i)P[G_{i+1} \geq L - x_i].$$

From the induction hypothesis we have $P[G_{i+1} \geq L-x_i] \leq (1-1/e)^{L-x_i}$. Substituting the above, we obtain that

$$P[G_i \geq L] \leq (1-x_i)(1-1/e)^{L-x_i} \leq (1-1/e)^L.$$

(The last inequality follows again from the inequality $(1-a) \leq (1-1/e)^a$ for $(0 < a < 1)$.) This completes the proof of the claim.

Claim 6.1 shows that the probability that one child passes more than $L$ units of flow to its parent is at most $(1-1/e)^L$. To complete the proof of the lemma we need to show that when a node has $\Delta$ children then the probability that it receives $\Delta L$ units of flow from all of them is still at most $(1-1/e)^L$. This intuitively should hold since priming decisions at nodes which are unrelated (neither is a descendant of another) are independent. The following claim establishes this fact and finishes the proof of the lemma.

Claim 6.2. *Let $Y_1, \ldots, Y_\Delta$ be independent random variables such that $P(Y_i \geq L) \leq (1-1/e)^L$ for all $L \geq 0$. Let $Z = Y_1 + Y_2 + \cdots + Y_\Delta$. Then $P(Z \geq \Delta L) \leq (1-1/e)^L$ for all $L \geq 0$.*

We prove Claim 6.2 using the notion of stochastic domination between random variables. We say that a random variable $Z$ *stochastically dominates* a random variable $X$ if $P(X \geq a) \leq P(Z \geq a)$ for every $a$. It is known (see, e.g., [17, p. 52]) that if $Z_1, \ldots, Z_k$ are independent, $X_1, \ldots, X_k$ are independent, and $Z_i$ stochastically dominates $X_i$ for every $1 \leq i \leq k$, then $\sum_{i=1}^k Z_i$ stochastically dominates $\sum_{i=1}^k X_i$. For completeness we prove this here.

Since $Z_k$ stochastically dominates $X_k$, we obtain that

$$P\left(\sum_{i=1}^k X_i \geq a\right)$$
$$= \int_{x_1=0}^{\infty}\int_{x_2=0}^{\infty}\cdots\int_{x_{k-1}=0}^{\infty} P(X_1 = x_1)\cdots P(X_{k-1} = x_{k-1})P(X_k \geq a - x_1 - \cdots x_{k-1})$$

$$\leq \int_{x_1=0}^{\infty}\int_{x_2=0}^{\infty}\cdots\int_{x_{k-1}=0}^{\infty} P(X_1 = x_1)\cdots P(X_{k-1} = x_{k-1})P(Z_k \geq a - x_1 - \cdots x_{k-1})$$
$$= P\left(\sum_{i=1}^{k-1} X_i + Z_k \geq a\right).$$

We can now apply the same argument to the variable $X_1, \ldots, X_{k-1}$ and $Z_k$ and show that

$$P\left(\sum_{i=1}^{k-1} X_i + Z_k \geq a\right) \leq P\left(\sum_{i=1}^{k-2} X_i + Z_{k-1} + Z_k \geq a\right).$$

For that we expand $P(\sum_{i=1}^{k-1} X_i + Z_k \geq a)$ as a multiple integral whose variables are the values of $X_1, \ldots, X_{k-2}$ and $Z_k$, and we use the fact that the probability of a tail of $X_{k-1}$ is dominated by the probability of the same tail of $Z_{k-1}$. By repeating this argument $k$ times we finally obtain that

$$P\left(\sum_{i=1}^{k} X_i \geq a\right) \leq P\left(\sum_{i=1}^{k} Z_i \geq a\right).$$

To prove Claim 6.2, let $D$ be an exponential random variable whose cumulative distribution function is $F(x) = P(D \leq x) = 1 - e^{-\lambda x}$ for $x \geq 0$, where $\lambda = -\ln(1 - 1/e)$. Notice that for every $L \geq 0$, $P(Y_i \geq L) \leq P(D \geq L)$, and so $D$ stochastically dominates $Y_i$ for every $1 \leq i \leq \Delta$. (For every $a < 0$, $P(Y_i \geq a) = P(D \geq a) = 0$.) It follows that if $D_1, \ldots, D_\Delta$ are $\Delta$ independent copies of $D$, then $\sum_{i=1}^{\Delta} D_i$ stochastically dominates $\sum_{i=1}^{\Delta} Y_i$. So

$$P\left(\sum_{i=1}^{\Delta} Y_i \geq \Delta L\right) \leq P\left(\sum_{i=1}^{\Delta} D_i \geq \Delta L\right).$$

To finish the proof we observe [6] that the distribution of the sum of $\Delta$ exponential random variables with parameter $\lambda$ is $Gamma(\Delta, \lambda)$ whose density is

$$g(x) = \frac{\lambda e^{(-\lambda x)}(\lambda x)^{(\Delta-1)}}{(\Delta - 1)!}.$$

Next we show that $g(a\Delta) \leq f(a)$ for every $a \geq 0$, where $f(x) = \lambda e^{-\lambda x}$ is the density function of the exponential random variable $D$. Then the lemma follows since $P(\sum_{i=1}^{\Delta} D_i > \Delta L) \leq P(D > L)$.

To see that $g(a\Delta) \leq f(a)$ we substitute $a\Delta$ and $a$ into $g(x)$ and $f(x)$, respectively, and obtain that we have to show that

$$\frac{\lambda e^{(-\lambda a\Delta)}(\lambda a\Delta)^{(\Delta-1)}}{(\Delta - 1)!} \leq \lambda e^{-\lambda a}.$$

Dividing both sides by $\lambda e^{-\lambda a} e^{(-\lambda a\Delta)}$, we obtain the equivalent inequality

$$\frac{e^{(\lambda a)}(\lambda a\Delta)^{(\Delta-1)}}{(\Delta - 1)!} \leq e^{\lambda a\Delta}. \tag{6.2}$$

Using the Taylor expansion of the exponential function, we obtain that (6.2) is equivalent to

$$\left(1+\lambda a+\frac{(\lambda a)^2}{2!}+\cdots\right)\frac{(\lambda a\Delta)^{(\Delta-1)}}{(\Delta-1)!}\leq\left(1+\lambda a\Delta+\frac{(\lambda a\Delta)^2}{2!}+\cdots\right)\ . \tag{6.3}$$

Since

$$\frac{1}{k!}\leq\frac{\Delta^k}{\Delta(\Delta+1)(\Delta+2)\cdots(\Delta+(k-1))},$$

we obtain that (6.3) holds since term $i$ of the series on the left-hand side is not larger than term $i+(\Delta-1)$ of the series on the right-hand side. □

The analysis of GAP implies that if we set $\mu=\frac{1}{c\Delta\log(R\Delta/C)}$ for some small constant $c$, then there is a constant probability that the load served by any primed node is at most $C$. We next show how we can use $\mu=1/(\Delta+1)$ together with iterative application of GAP in order to obtain better trade-off.

**6.1. Applying GAP iteratively.** GAP can be applied iteratively as follows. We apply the first iteration of GAP as described before. After the iteration ends, if we chop off primed nodes from their parents, we get a forest. We apply the next iteration only to trees of the forest where the root serves more than $C$ units of flow. When an iteration ends we further partition the forest by chopping off primed nodes and apply the next iteration only to trees where the root serves more than $C$ units of flow. The algorithm terminates when all primed nodes serve fewer than $C$ units of flow. We show that for an appropriate choice of $\mu$ the algorithm terminates, and we analyze the expected number of iterations until it stops.

We can apply this algorithm distributively by passing messages between nodes as follows. For each unprimed node $v$ we define $F_i(v)$ to be the amount of flow generated in the subtree rooted by $v$ at iteration $i$. For a node $v$ which was primed at iteration $j<i$ we define $F_i(v)=0$. Each unprimed node $v$ locally waits until it knows $F_i(v)$ for increasing values of $i$. When $v$ knows $F_i(v)$ it runs GAP locally and decides whether it gets primed at iteration $i$.

Each node $v$ can calculate $F_i(v)$ if nodes report their $F_i()$ values to their parents. If $v$ was primed at iteration $j<i$, then no flow travels from $v$ to its parent at iteration $i$. So in this case $v$ reports to its parent that $F_i(v)$ is 0. Otherwise, $v$ waits for its children to report their $F_i()$ values. Once $v$ gets all these values, then $F_i(v)$ is $\sum F_i(u)$, where the sum is over all children $u$ of $v$. Node $v$ then reports $F_i(v)$ to its parent.

When we apply this distributed implementation, unprimed nodes continue to apply GAP in subsequent iterations although they may already have a primed ancestor which serves fewer than $C$ units of flow. Therefore, to make our distributed algorithm complete, each node $v$ which is primed at iteration $i$ and $F_{i+1}(v)\leq C$ sends a message downward to its descendants announcing that they may stop running GAP. A node $v$ that receives a message that it has an ancestor that got primed at iteration $i$ and serves no more than $C$ does the following.

1. Node $v$ propagates the message further down to its descendants.
2. If $v$ got primed at iteration $j$ and $i<j$, then $v$ unprimes itself.
3. Node $v$ does not have to run GAP or propagate $F_j(v)$ in any iteration $i<j$.

Our key lemma below shows that if we apply GAP with $\mu=\frac{1}{\Delta+1}$, then on average a constant fraction of the flow is served by primed nodes that serve fewer than $C$ units of flow. This lemma implies the following theorem about the performance of iterative GAP.

THEOREM 6.3. *Iterative* GAP *with* $\mu = \frac{1}{\Delta+1}$ *stops after* $O(\log(R/C))$ *iterations with probability at least* $1 - (\frac{C}{R})^c$, *where c is some constant. The expected size of the allocation that iterative* GAP *produces is* $O(R\Delta/C)$.

*Proof.* By Lemma 6.4, at each iteration of GAP, the probability that a unit flow is served by a primed node which serves fewer than $C$ units of flow is at least $p = 1/e^2$. Each such unit of flow does not participate in subsequent iterations. So the probability that a unit of flow participates at iteration $i+1$ is at most $(1-p)^i$. For $i = \frac{1}{p} a \ln(R/C)$ this probability is at most $(\frac{C}{R})^a$. Let $X$ be a random variable which equals the expected amount of flow participating at iteration $i+1$. Multiplying our bound on the probability that a unit of flow participates at iteration $i+1$ by the total amount of flow, we obtain that $E(X) = R * (\frac{C}{R})^a = C(\frac{C}{R})^{a-1}$. By Markov's inequality the probability that the amount of flow that participates at iteration $i+1$ exceeds $C$ is bounded by

$$\text{Prob}(X \geq C) \leq \frac{E(x)}{C} = \frac{C(\frac{C}{R})^{a-1}}{C} = \left(\frac{C}{R}\right)^{a-1} .$$

Clearly if the total flow which participates at iteration $i+1$ is not larger than $C$, then iteration $i+1$ is the last. So we obtained that, for $i = \frac{1}{p} a \ln(R/C)$, iteration $i+1$ is the last, with probability at least $1 - \left(\frac{C}{R}\right)^{a-1}$. If we define $c = a-1$, the first part of the theorem follows.

By Lemma 6.1, the expected number of primed nodes in each iteration is bounded by $(\Delta+1)/C$ times the expected flow value at that iteration. Since the expected flow value decreases geometrically by a factor of at least $1-p$ from one iteration to the next, we obtain an allocation of expected size $O(R\Delta/C)$. ∎

We now prove our key lemma saying that a unit of flow does not go through to the next iteration of GAP with some constant probability.

LEMMA 6.4. *Consider a unit of flow generated at a leaf. When nodes are primed according to* GAP, *then with probability at least* $1/e^2$ *the primed node serving the flow (the deepest primed node on the path from the leaf to the root) serves a total of at most* $(\Delta+1)\mu C$ *units of flow.*

*Proof.* In the proof of Lemma 6.2 (using Claim 6.2) we proved that the probability that the $\Delta$ children of a node $x$ transfer more than $\Delta L \mu C$ units of flow to $x$ is at most $(1-1/e)^L$. It is easy to see that the same argument in fact shows that any set of $M$ independent nodes (that is, a set of nodes such that neither is an ancestor of the other but they are not necessarily siblings) transfer to their parents $ML\mu C$ units of flow with probability at most $(1-1/e)^L$. We shall repeatedly invoke this observation in the proof.

Consider a unit of flow generated at a leaf and its path to the root. Let $v$ be the deepest node on the path with $F(v) \geq \mu C$. We split the rest of the proof into the following cases.

*Case* 1. For every child $u$ of $v$, $F(u) < \mu C$. In this case $v$ is primed and therefore serves our flow-unit. By the observation above the probability that $v$ receives more than $\Delta \mu C$ flow from its $\Delta$ children is at most $1 - 1/e$.

*Case* 2. Node $v$ has a child $u$ such that $F(u) \geq \mu C$. Let $w$ be the heaviest child of $v$, and let $v_0$ be the closest ancestor of $v$ which is not a heaviest child of its parent, or the root in case every ancestor of $v$ is a heaviest child of its parent. (Note that $v_0 = v$ in case $v$ is not the heaviest child of its parent.) Denote by $v_0, v_1, \ldots, v_i = w$ the nodes on the path from $v_0$ to $w$. Note that $v_{i-1} = v$. Let $x_j$, $0 \leq j < i$, be the flow generated at the children of $v_j$ other than $v_{j+1}$. (See Figure 6.1.)

*Subcase* 2a. $\sum_{j=0}^{i-1} x_j \leq \mu C$. Assume first that $v_0$ is not the root and let $p(v_0)$ be the parent of $v_0$. Since $F(v_0) \geq F(v_i) \geq \mu C$ and $v_0$ is not the heaviest child of $p(v_0)$, we obtain that $F(p(v_0)) - F_s(p(v_0)) \geq \mu C$, so $p(v_0)$ is primed by the definition of GAP. Therefore, our unit flow is served either by $p(v_0)$ or by some $v_j$, where $0 \leq j \leq i-1$.

If our unit flow is served by $v_j$, where $0 \leq j \leq i-1$, then the probability that $v_j$ serves more than $\Delta\mu C$ units of flow is at most the probability that $v_i$ passes up more than $(\Delta-1)\mu C$ units of flow. That happens with probability at most $(1-1/e)^{\Delta-1}$ by Claim 6.1.

If our unit flow is served by $p(v_0)$, then the probability that $p(v_0)$ serves more than $(\Delta+1)\mu C$ units of flow is at most the probability that its $\Delta - 1$ children other than $v_0$ and the node $v_i = w$ transfer to their parents more than $\Delta\mu C$ units of flow. By the observation above this probability is at most $1 - 1/e$.

If $v_0$ is the root, then clearly our unit of flow is served by $v_j$ for some $0 \leq j \leq i-1$. The probability that $v_j$ serves more than $\Delta\mu C$ units of flow is at most the probability that $v_i$ passes up more than $(\Delta-1)\mu C$ units of flow. That happens with probability at most $(1-1/e)^{\Delta-1}$.

*Subcase* 2b. $\sum_{j=0}^{i-1} x_j > \mu C$. Let $k$ be the maximum such that $\sum_{j=k}^{i-1} x_j > \mu C$. If $v_k$ is the root or $x_k > \mu C$, then clearly one of $v_k, \ldots, v_{i-1}$ serves our unit flow. Otherwise, since by Claim 6.1 node $v_{k-1}$, the parent of $v_k$, receives from $v_k$ more than $\mu C$ flow with probability at most $1 - 1/e$, it follows that with probability at least $1/e$ one of $v_k, \ldots, v_{i-1}$ is primed.

Let $v_j$ be the deepest primed node among $v_k, \ldots, v_{i-1}$ given that one of these nodes is primed. The probability that $v_j$ serves more than $(\Delta+1)\mu C$ units of flow is at most the probability that its $\Delta - 1$ children other than $v_{j+1}$ and $v_i$ transfer to their parents more than $\Delta\mu C$ units of flow. By the observation above this probability is at most $1 - 1/e$.

To summarize we obtained that with probability at least $1/e$ one of $v_k, \ldots, v_{i-1}$ is primed, and assuming that one of $v_k, \ldots, v_{i-1}$ is primed, the deepest node among them which is primed served fewer than $(\Delta+1)\mu C$ units of flow with probability at least $1/e$. $\square$

# MULTIEMBEDDING OF METRIC SPACES[*]

YAIR BARTAL[†] AND MANOR MENDEL[†]

**Abstract.** Metric embedding has become a common technique in the design of algorithms. Its applicability is often dependent on how large the embedding's distortion is. For example, embedding finite metric space into trees may require linear distortion as a function of the size of the metric. Using probabilistic metric embeddings, the bound on the distortion reduces to logarithmic in the size of the metric.

We make a step in the direction of bypassing the lower bound on the distortion in terms of the size of the metric. We define "multiembeddings" of metric spaces, in which a point is mapped onto a set of points, while keeping the target metric of polynomial size and preserving the distortion of paths. The distortion obtained with such multiembeddings into ultrametrics is at most $O(\log \Delta \log\log \Delta)$, where $\Delta$ is the *aspect ratio* of the metric. In particular, for expander graphs, we are able to obtain *constant* distortion embeddings into trees, in contrast with the $\Omega(\log n)$ lower bound for all previous notions of embeddings.

We demonstrate the algorithmic application of the new embeddings for two optimization problems: *group Steiner tree* and *metrical task systems*.

## 1. Introduction.

Finite metric spaces and their analysis play a significant role in the design of combinatorial algorithms. Many algorithmic techniques were introduced in recent years concerning and using metric spaces and their approximate embedding in other spaces; see the surveys [20, 21] for an overview of this topic.

DEFINITION 1.1. *An embedding of a metric space $M = (V_M, d_M)$ into a metric space $N = (V_N, d_N)$ is a mapping $\phi : V_M \to V_N$. The embedding is called* noncontractive *if for all $u, v \in V_M$, $d_M(u, v) \le d_N(\phi(u), \phi(v))$ and has distortion at most $\alpha$ if, in addition, for all $u, v \in V_M$, $d_N(\phi(u), \phi(v)) \le \alpha \cdot d_M(u, v)$. A noncontractive embedding whose distortion is at most $\alpha$ is called an $\alpha$-embedding.*

The general framework for applying metric embeddings in optimization problems is to embed a given metric space into a metric space from some "nice" family and then apply an algorithm for that space. As a result, the approximation ratio increases by a factor equal to the embedding's distortion.

Among others, embeddings into low dimensional normed spaces [12, 24] as well as probabilistic embeddings into trees [2, 3, 15, 4] have many algorithmic applications. In both cases the distortions of the embeddings are logarithmic in the size of the metric. Unfortunately, there is a matching lower bound on the distortion of these embeddings as well, which sets a limit to their applicability. This paper presents a partial remedy for this problem.

Tree metrics, and in particular ultrametrics, seem a natural choice as a target class of "simple" metric spaces. Unfortunately, standard embedding is not useful when the target space is a tree metric. Embedding arbitrary metric spaces into trees requires distortion linear in the size of the metric space [27]. Probabilistic embedding [2] provides a way to bypass this problem.

DEFINITION 1.2 (probabilistic embeddings). *A metric space $M = (V_M, d_M)$ is* $\alpha$-probabilistically embedded *in a set of metric spaces $\mathcal{S}$ if there exists a distribution $\mathcal{D}$ over $\mathcal{S}$ and, for every $N \in \mathcal{S}$, a noncontractive embedding $\phi_N : V_M \to V_N$, such that for all $u, v \in V_M$, $\mathbb{E}_{N \in \mathcal{D}}[d_N(\phi_N(u), \phi_N(v))] \leq \alpha \cdot d_M(u, v)$.*

Using probabilistic embeddings, it is possible to obtain much better bounds on the distortion [1, 2, 3, 15, 4]. The following bound is shown in [15, 4].

THEOREM 1.3. *Any metric space on $n$ points can be $O(\log n)$ probabilistically embedded in a set of $n$-point ultrametrics. Moreover, the distribution can be sampled efficiently.*

Theorem 1.3 found many algorithmic applications in approximation algorithms, online algorithms, and distributed algorithms; see, for example, [2, 17, 16, 23, 7]. The bound on the distortion in Theorem 1.3 is tight even for probabilistic embeddings into tree metrics for which there is an $\Omega(\log n)$ lower bound [2].

Theorem 1.3 was originally formulated for a class of metric spaces defined by the following natural generalization of ultrametrics.

DEFINITION 1.4 (after [2]). *For $k \geq 1$, a* $k$-hierarchically well-separated tree *($k$-HST) is a metric space defined on the leaves of a rooted tree $T$. To each vertex $u \in T$ there is associated a label $\Delta(u) \geq 0$ such that $\Delta(u) = 0$ if and only if $u$ is a leaf of $T$. The labels are such that if a vertex $v$ is a child of a vertex $u$, then $\Delta(v) \leq \Delta(u)/k$. The distance between two leaves $x, y \in T$ is defined as $\Delta(\mathrm{lca}(x, y))$, where $\mathrm{lca}(x, y)$ is the least common ancestor of $x$ and $y$ in $T$.*

The definition of a finite ultrametric is the same as a 1-HST. Any $k$-HST is therefore, in particular, an ultrametric, and any finite ultrametric can be $k$-embedded in some $k$-HST [3]. We can therefore restrict our attention to ultrametrics, while all results generalize to $k$-HSTs.

The main contribution of this paper is in offering a new type of metric embedding that makes it possible to bypass lower bounds for the standard and even probabilistic metric embeddings. There are two key observations that lead to this new type of embedding. The first is that in some applications it is natural to match a point onto a set of points in the target metric space. Motivated by two applications of Theorem 1.3—the *group Steiner tree problem* (henceforth, GST) and the *metrical task systems problem* (henceforth, MTS)—we propose the following definition.

DEFINITION 1.5 (multi embedding). *A multiembedding of $M$ in $N$ is a partial surjective function $\mathsf{f}$ from $N$ on $M$; i.e., each point $x \in M$ is embedded into a non-empty set $\mathsf{f}^{-1}(x)$. Points in $\mathsf{f}^{-1}(x)$ are called* representatives *of $x$ in $N$.*

The role of $\mathsf{f}^{-1}$ in Definition 1.5 is analogous to the role of $\phi$ in the Definitions 1.1 and 1.2 of embedding and probabilistic embedding. Another way to define multiembedding is by $\phi : M \to 2^N$, in which $\phi(u) \cap \phi(v) = \emptyset$ for every $u \neq v$. In our notation we have $\phi(x) = \mathsf{f}^{-1}(x)$. Since the $\mathsf{f}$ notation will be more convenient, henceforth we will use it exclusively.

The second observation is that for many applications, including those mentioned above, there is no need to approximate the original distance for every pair of representatives. What is really needed is that every path in the original space be approximated well by *some* path in the target space.

A path in a metric space is an arbitrary finite sequence of points in the space. The length of a simple path $p = \langle u_1, u_2, \ldots, u_m\rangle$ in a metric space $M = (V, d)$ is defined as $\ell(p) = \sum_{i=1}^{m-1} d(u_i, u_{i+1})$.

DEFINITION 1.6 (path distortion). *A multiembedding* $\mathsf{f}$ *of* $M$ *in* $N$ *is called* noncontractive *if for any* $u, v \in N$, $d_N(u, v) \geq d_M(\mathsf{f}(u), \mathsf{f}(v))$. *The path-distortion of a noncontractive multiembedding of* $M$ *in* $N$, $\mathsf{f} : N \to M$, *is the infimum over* $\alpha$, *for which any path* $p = \langle u_1, u_2, \ldots, u_m\rangle$ *in* $M$ *has a path* $p' = \langle u'_1, u'_2, \ldots, u'_m\rangle$ *in* $N$ *such that* $\mathsf{f}(u'_i) = u_i$ *and* $\ell(p') \leq \alpha \cdot \ell(p)$.

*A multiembedding whose path-distortion is at most* $\alpha$ *is called an* $\alpha$*-path embedding.*

A crucial parameter for multiembeddings is the size of the target space $\Gamma$. In general, it will be desirable that $\Gamma$ be polynomial in the size of the source space. In fact, if $\Gamma = \infty$, then there is a simple 1-path embedding of any finite metric space by trees: Take all finite paths, convert each path to a simple path (by duplicating points, if necessary), and put them under a single root with an edge of length half the diameter. This motivates a study of the trade-off between $\Gamma$ and the path distortion of arbitrary metric spaces by tree metrics. In section 4 we study path embedding of expander graphs and the hypercube into tree metrics. We show, e.g., that $n$-point Ramanujan graphs have 3-path embedding into tree metrics of size $\Gamma(n) \leq \text{poly}(n)$. This is in sharp contrast to the status of expander graphs for previous notions of embeddings, for which they are considered "worst case" examples with $\Omega(\log n)$ distortion [24]. These results directly imply nearly tight results on the approximation ratio for GST on expander graphs and hypercubes.

We consider multiembeddings when the class of target metric spaces are ultrametrics. First, we observe that probabilistic embedding into ultrametrics directly implies a bound for path embedding by putting all the trees in $\mathcal{S}$ (the set used in the probabilistic embedding) under a common new root. This results in an $\alpha$-path embedding into an ultrametric of size $|\mathcal{S}|n$. Using the bound of [13] on the number of ultrametrics needed in Theorem 1.3, we obtain an $O(\log n)$ path embedding into an ultrametric of size $O(n^2 \log n)$.[1]

An important parameter of the metric spaces appearing in practice is the aspect ratio of the metric, which is the ratio between the diameter and minimum nonzero distance in the metric space. It will be convenient for us to assume that the minimum distance is 1, and so the aspect ratio becomes the diameter. It turns out that the aspect ratio of the metric plays a significant role in the path distortion of multiembeddings. In section 3 we prove the following result.

THEOREM 1.7. *Fix* $\beta > 1$. *For any metric space* $M = (V, d)$ *on* $|V| = n$ *points and aspect ratio* $\Delta$, *there exists an efficiently constructible multiembedding into an ultrametric of size* $n^\beta$, *whose path distortion is at most*

$$O_\beta(\min\{\log n \cdot \log\log n,\ \log \Delta \cdot \log\log \Delta\}).$$

Our construction beats the probabilistic embedding-based constructions on metrics with small aspect ratio. Expander graphs are examples where a lower bound of $\Omega(\Delta)$ exists on probabilistic embedding using trees [24].

[1]In a preliminary version of this paper [10], we also introduced the notion of *probabilistic multiembedding.* Using that notion we were able to show probabilistic multiembedding into ultrametrics of polynomial size and path distortion $O(\log n \log\log\log n)$. Since an $O(\log n)$ bound now follows from Theorem 1.3 [15, 4], we have decided to drop the probabilistic multiembedding result from this version of the work.

The constructions of multiembeddings are in a sense dual to Ramsey-type theorems for metric spaces [6, 8], where the goal is to find a large subset which is well approximated by some ultrametric.

We also provide a simple example in which Theorem 1.7 is almost tight: Any $\alpha$-path embedding into ultrametrics of a simple unweighted path of length $n$ has $\alpha = \Omega(\log n)$. It follows, in particular, that any $\alpha$-path embedding into ultrametrics of the metric defined by an unweighted graph of diameter $\Delta$ has $\alpha = \Omega(\log \Delta)$. Path embedding is motivated by two intensively studied algorithmic minimization problems: GST and MTS, mentioned above. For both, the best known algorithms use probabilistic embedding into trees/ultrametrics. In section 2 we prove that in order to reduce these problems to other metric spaces it is sufficient to use path embedding. We therefore achieve improved algorithms for these problems whenever the path embedding distortion beats that of probabilistic embedding, and in particular, when the underlying metric is of small aspect ratio.

## 2. Applications.

In this section we define MTS and GST and show that path distortion of multiembeddings reduces these problems to similar problems with different underlying metrics.

MTS [11] was introduced as a framework for many online minimization problems. An MTS on metric space $M = (S, d)$, $|S| = n$, is defined as follows. A "system" has a set of $n$ possible internal states $S$. It receives a sequence of *tasks* $\sigma = \tau_1\tau_2 \cdots \tau_m$. Each task $\tau$ is a vector $\tau : S \to \mathbb{R}^+ \cup \{\infty\}$ of nonnegative costs for serving $\tau$ in each of the internal states of the system. The system may switch states (say, from $u$ to $v$), paying a cost equal to the distance $d(u, v)$ in $M$, and then pays the service cost $\tau(v)$ associated with the new state. The major limiting factor for the system is the requirement to process the sequence in an online fashion, i.e., serving each task without knowing the future tasks.

As is customary in the analysis of online algorithms, MTS is analyzed using the notion of a *competitive ratio*. A randomized online algorithm $A$ is called $r$-competitive if there exists some constant $c$ such that for any task sequence $\sigma$, $\mathbb{E}[\mathrm{cost}_A(\sigma)] \le r \cdot \mathrm{cost}_{\mathrm{OPT}}(\sigma) + c$, where $\mathrm{cost}_A(\sigma)$ is the random variable of the cost for serving $\sigma$ by $A$, and $\mathrm{cost}_{\mathrm{OPT}}(\sigma)$ is the optimal (offline) cost for serving $\sigma$. The current best online algorithm for the MTS problem in $n$-point metric spaces is $O(\log^2 n \log\log n)$-competitive [16, 15] (an improvement of [5, 3]). Both papers [5, 16] actually solve the MTS problem for ultrametrics, and then reduce arbitrary metric spaces to ultrametrics using Theorem 1.3. We next show that path embedding suffices, as follows.

PROPOSITION 2.1. *Assume that a metric space $M$ is $\alpha$-path embedded in $N$. Assume also that $N$ has an $r$-competitive MTS algorithm. Then there is an $\alpha r$-competitive algorithm for $M$.*

*Proof.* We construct an online algorithm $\mathcal{A}$ for $M$ as follows: Let $\mathcal{A}_N$ be an $r$-competitive online algorithm for $N$, and $\mathsf{f} : N \to M$ an $\alpha$ path embedding of $M$ in $N$. The task sequence $\sigma$ is translated to a task sequence $\sigma^N$ for $N$ task by task as follows. A task $\tau$ for $M$ is translated into a task $\tau^N$ for $N$ such that $\tau^N(u') = \tau(\mathsf{f}(u'))$. $\mathcal{A}$ maintains the invariant that if $\mathcal{A}_N$ is in state $v'$, then $\mathcal{A}$ is in state $\mathsf{f}(v')$.

It is easy to verify that $\mathrm{cost}_{\mathcal{A}}(\sigma) \le \mathrm{cost}_{\mathcal{A}_N}(\sigma^N)$, since the service costs are the same, and the distances in $N$ are larger. Consider $\mathrm{OPT}(\sigma)$; it defines a path $p$ serving $\sigma$ in $M$. Thus there exists a path $p^N$ as in the statement of Definition 1.6. The path $p^N$ is the way $\sigma^N$ would be served in $N$. In this way, since $\mathsf{f}(p^N) = p$, the service costs in $N$ are the same as the service costs in $M$, and $\ell(p^N) \le \alpha\ell(p)$. Thus

$\mathrm{cost}_{\mathrm{OPT}_N}(\sigma^N) \leq \alpha \cdot \mathrm{cost}_{\mathrm{OPT}}(\sigma)$. Summarizing,

$$\mathbb{E}[\mathrm{cost}_{\mathcal{A}}(\sigma)] \leq \mathbb{E}[\mathrm{cost}_{\mathcal{A}_N}(\sigma^N)] \leq r \cdot \mathrm{cost}_{\mathrm{OPT}_N}(\sigma^N) + c \leq \alpha r \cdot \mathrm{cost}_{\mathrm{OPT}}(\sigma) + c. \qquad \square$$

COROLLARY 2.2. *There is an* $O(\log \Delta \log\log \Delta \cdot \log n \log\log n)$*-competitive randomized MTS algorithm for MTS defined on metric spaces with diameter* $\Delta$.

*Proof.* Apply Theorem 1.7 on the original metric and obtain an $O(\log \Delta \log\log \Delta)$-path embedding into an ultrametric of size $\Gamma(n) = \mathrm{poly}(n)$. This ultrametric has $O(\log \Gamma(n) \log\log \Gamma(n))$ competitive algorithm [16]. Now apply Proposition 2.1 to obtain the claim. $\square$

The GST [29] can be stated as follows: Given a graph $G = (V, E)$ on $n$ vertices with a weight function $c : E \to \mathbb{R}_+$, and subsets of the vertices $g_1, \ldots, g_k \subset V$ (called *groups*), the objective is to find a minimum weight subtree $T$ of $G$ that contains at least one vertex from each $g_i$, $i \in [k]$. Under certain standard complexity assumptions, this is hard to approximate by a factor better than $\max\{\log^{2-\varepsilon} k, \log^{2-\varepsilon} n\}$ [19]. The current best upper bound on the approximation factor is $O(\log^2 n \log k)$ [17, 15]. In [17], an $O(\log n \log k)$ approximation algorithm for tree metrics is given, and the general case is reduced to tree metrics using Theorem 1.3. Again, we show that it is actually sufficient to use multiembedding for this problem.

As a first step we observe that the problem can be easily cast in terms of metric spaces instead of graphs: Given a graph $G = (V, E)$ with weights $w : E \to \mathbb{R}_+$, let $M = (V, d)$ be the shortest path metric induced by $G$ and $w$ on $V$. A tree $T$ in $M$ can be transformed into a tree $\hat{T}$ in $G$ such that the total weight in $\hat{T}$ is not larger than the total weight in $T$, and $\hat{T}$ contains all the vertices in $T$. This is done by replacing each edge in $T$ by the shortest path between its endpoints in $G$ and taking a spanning tree of the resulting subgraph. It therefore suffices to solve GST on metric spaces.

PROPOSITION 2.3. *Assume that a metric space* $M$ *is* $\alpha$*-path embedded in a metric space* $N$. *Assume in addition that there is a [randomized] polynomial time* $r$*-approximation algorithm for any GST instance with* $k$ *groups defined on* $N$. *Then there exists a [randomized] polynomial time* $2\alpha r$*-approximation algorithm for any GST instance with* $k$ *groups defined on* $M$.

*Proof.* We construct an approximation algorithm $\mathcal{A}$ for the instance $\sigma = (M; g_1, \ldots, g_k)$ as follows. Denote by $\mathsf{f} : N \to M$ the $\alpha$-path embedding of $M$ in $N$. Consider the following instance of GST: $\sigma_N = (N; \mathsf{f}^{-1}(g_1), \ldots, \mathsf{f}^{-1}(g_k))$. Let $\mathcal{A}_N$ be an $r$-approximation algorithm for $\sigma_N$. Let $T_N = \mathcal{A}_N(\sigma_N)$ be the tree constructed by $A_N$. Denote by $\mathsf{f}(T_N)$ the image graph of $T_N$; i.e., if $T_N = (V_N, E_N)$, then $\mathsf{f}(T_N) = (\mathsf{f}(V_N), \{\mathsf{f}(u)\mathsf{f}(v) | \ uv \in E_N\})$. The graph $\mathsf{f}(T_N)$ is connected, and its weight is at most the weight of $T_N$. It also spans at least one representative from each group. Algorithm $\mathcal{A}$ returns a spanning tree of $\mathsf{f}(T_N)$. This tree is a feasible solution and it satisfies $\mathrm{cost}_{\mathcal{A}}(\sigma) \leq \mathrm{cost}_{\mathcal{A}_N}(\sigma_N)$.

Consider the tree $\mathrm{OPT}(\sigma)$, double each edge in $\mathrm{OPT}(\sigma)$, and take an Euler tour $p$ of this graph. There exists a path in $N$, $p_N$, as in the statement of Definition 1.6, such that $\mathsf{f}(p_N) = p$. The path $p_N$ is a connected graph and spans at least one representative from each group $\mathsf{f}^{-1}(g_j)$. As the weight of $p$ is twice the weight of $\mathrm{OPT}(\sigma)$, we have

$$\mathrm{cost}_{\mathrm{OPT}_N}(\sigma_N) \leq \ell(p_N) \leq \alpha \ell(p) \leq 2\alpha \mathrm{cost}_{\mathrm{OPT}}(\sigma).$$

Summarizing,

$$\mathbb{E}[\mathrm{cost}_{\mathcal{A}}(\sigma)] \leq \mathbb{E}[\mathrm{cost}_{\mathcal{A}_N}(\sigma_N)] \leq r \, \mathrm{cost}_{\mathrm{OPT}_N}(\sigma_N) \leq 2\alpha r \, \mathrm{cost}_{\mathrm{OPT}}(\sigma). \qquad \square$$

Corollary 2.4. *There exists a polynomial time $O(\log\Delta\log\log\Delta\log n\log k)$-approximation algorithm for GST on metric spaces with diameter $\Delta$.*

**3. Multiembedding into ultrametrics.** The following theorem is a restatement of Theorem 1.7 in a more general form.

Theorem 3.1. *Given any metric space $M=(V,d)$ on $|V|=n$ points and diameter $\Delta$, for any $t\in\mathbb{N}$, $M$ is $O(t\min\{\log\Delta,\log n\})$-path embedded into an efficiently constructible ultrametric of size $\Gamma\le n^{\beta}$, where $\beta=\min\{(\log n)^{1/t},[t\log(4\Delta)]^{2/t}\}$.*

*Proof.* The construction of the multiembedding is motivated by the construction of subspaces approximating ultrametric in [6, 8], but instead of deleting points, we *duplicate* them. We then prove the bounds on the path distortion.

Let $\Delta$ be the diameter of $M$. Let $x$ and $\bar{x}$ be two points realizing the diameter of $M$, and assume without loss of generality that $|\{y\in M:\ d(x,y)<\Delta/4\}|\le n/2$ (otherwise, switch the roles of $x$ and $\bar{x}$). Define a series of sets $A_0=\{x\}$, and for $i\in\{1,2,\dots,t\}$, $A_i=\{y\in M|\ d(x,y)<i\Delta/4t\}$, and "shells" $S_i=A_i\setminus A_{i-1}$. Let $|V|=n$ and let $\varepsilon_i=|A_i|/n$.

The algorithm for constructing the multiembedding works as follows: Choose a shell $S_i$, $i\in[t]$. Recursively, construct a multiembedding of the subspace $A_i$ into an ultrametric $T_1$ and a multiembedding of the subspace $V\setminus A_{i-1}$ into an ultrametric $T_2$. To construct the multiembedding for $M$, we construct an ultrametric $T$ with root labelled with $\Delta$ and two children, one being $T_1$ and the other $T_2$. This is a multiembedding since the points in $S_i$ are essentially being "duplicated" at this stage. Note that this is a noncontractive multiembedding.

Next we prove an upper bound on the size of the resulting ultrametric $T$, assuming that the shell was chosen carefully enough. The bound we prove is $n^{\beta}$, where $\beta=\min\{(\log n)^{1/t},[t\log(4\Delta)]^{2/t}\}$.

We begin with the first bound. Let $\beta=\beta(n)=(\log n)^{1/t}$. The proof proceeds by induction on $n$ (whereas $t$ is fixed). There must exist $i\in[t]$ such that $\varepsilon_{i-1}\ge\varepsilon_i^{\beta}$. Indeed, note that $n^{-1}\le\varepsilon_0\le\varepsilon_{t+1}\le 1/2$. Assume on the contrary that $\varepsilon_{i-1}<\varepsilon_i^{\beta}$ for all $i\in[t]$; then

$$\varepsilon_0<\varepsilon_1^{\beta}<\cdots<\varepsilon_t^{\beta^t}\le\left(\frac{1}{2}\right)^{\log n}=\frac{1}{n},$$

which is a contradiction. Therefore we can fix $i$ such that $\varepsilon_{i-1}\ge\varepsilon_i^{\beta}$. Inductively, assume that the recursive process results in at most $(\varepsilon_i n)^{\beta(\varepsilon_i n)}\le(\varepsilon_i n)^{\beta}$ leaves in $T_1$ and at most $((1-\varepsilon_{i-1})n)^{\beta((1-\varepsilon_{i-1})n)}\le((1-\varepsilon_{i-1})n)^{\beta}$ leaves in $T_2$. Thus $|T|\le(\varepsilon_i^{\beta}+(1-\varepsilon_{i-1})^{\beta})n^{\beta}$. Since $\varepsilon_{i-1}\ge\varepsilon_i^{\beta}$, we have $\varepsilon_i^{\beta}+(1-\varepsilon_{i-1})^{\beta}\le\varepsilon_{i-1}+(1-\varepsilon_{i-1})=1$, and we are done.

We next prove the second bound. Let $\beta=\beta(\Delta)=[t\log(4\Delta)]^{2/t}$. The proof is by induction on (the rounded value of) $\Delta$. We claim that

$$\exists i\in[t]\quad\text{such that}\quad\varepsilon_{i-1}\ge\varepsilon_i^{\beta(\Delta/2)}n^{\beta(\Delta/2)-\beta(\Delta)}. \tag{3.1}$$

Indeed, assume on the contrary that no such $i$ exists. Set $a=\log(2\Delta)\ge 1$, so that $\beta(\Delta/2)=(ta)^{2/t}$ and $\beta(\Delta)=[t(a+1)]^{2/t}$. Denote $b=n^{(ta)^{2/t}-[t(a+1)]^{2/t}}$ and $c=(ta)^{2/t}$. The opposite of (3.1) then becomes $\varepsilon_{i-1}<\varepsilon_i^{c}b$ for any $i\in[t]$. Iterating this $t$ times, we get

$$\frac{1}{n}=\varepsilon_0<\varepsilon_t^{c^t}b^{1+c+c^2+\cdots+c^{t-1}}\le\varepsilon_t^{c^t}b^{c^{t-1}}\le b^{c^{t-1}}.$$

Thus

$$n^{(ta)^{2-2/t}\left[[t(a+1)]^{2/t}-(ta)^{2/t}\right]} < n,$$

but this is a contradiction, since an application of the mean value theorem implies the existence of $\xi \in [a, a+1]$, for which

$$(ta)^{2-2/t}\left[[t(a+1)]^{2/t}-(ta)^{2/t}\right]$$
$$= (ta)^{2-2/t}[2t^{-1+2/t}\xi^{-1+2/t}] = 2(ta)\left(\frac{a}{\xi}\right)^{1-2/t} \geq ta \geq 1.$$

Choose an index $i \in \{1, \ldots, t\}$ satisfying (3.1). Since $i \leq t$, $\Delta(A_i) \leq \Delta/2$. The choice of the index $i$, and using the inductive hypothesis, gives the required lower bound on the cardinality of $T$, since

$$|T| \leq (\varepsilon_i n)^{\beta(\Delta/2)} + [(1-\varepsilon_{i-1})n]^{\beta(\Delta)} \leq \varepsilon_{i-1} n^{\beta(\Delta)} + (1-\varepsilon_{i-1})n^{\beta(\Delta)} \leq n^{\beta(\Delta)}.$$

We note that the running time of the algorithm above is $O(n^2)$ on each vertex in the tree and therefore $O(n^{\beta+2})$ for the whole tree . A slight variation on this algorithm (and a more careful analysis) has an $O(n^{\max\{\beta,2\}})$ running time.

The multiembedding described above has the following properties:

1. The multiembedding is noncontractive.
2. The tree structure defining the ultrametric is a binary tree.[2]

Let $u$ be an internal vertex in the binary tree defining the ultrametric, and $T$ the subtree rooted at $u$. We can rename the subtrees rooted with the children of $u$ as $T_1$ and $T_2$ such that the following hold:

3. Let $x$ and $y$ be two points in $M$. If $\emptyset \neq \mathsf{f}^{-1}(x) \cap T \subset T_1$ and $\emptyset \neq \mathsf{f}^{-1}(y) \cap T \subset T_2$, then $d(x,y) \geq \Delta(T)/4t$.
4. $|\mathsf{f}(T_1)| \leq |\mathsf{f}(T)|/2$.
5. $\Delta(T_1) \leq \Delta(T)/2$.

We next show, using the properties above, that the path distortion of this multiembedding is at most $8t \log \min\{n, \Delta\}$. Let $p = \langle u_1, u_2, \ldots, u_m \rangle$ be a path in $M$ whose length is $\ell(p)$. We construct a path $\bar{p}$ on the leaves of $T$ whose length satisfies $\ell(\bar{p}) \leq 8t \log \min\{n, \Delta\} \cdot \ell(p)$. The proof proceeds by induction on the height of the tree defining the ultrametric.

We partition $p$ into subpaths as follows. Define a sequence of indices and a sequence of subtrees of the root: Let $j_1 = 1$, and let $\hat{T}_1 \in \{T_1, T_2\}$ be the subtree of the root that includes the longest prefix of $p$. Assume that inductively that we have already defined $j_{i-1}$ and $\hat{T}_{i-1} \in \{T_1, T_2\}$. Define $j_i$ to be the minimum index such that $u_{j_i}$ is the first point in $p$ after $u_{j_{i-1}}$ with no representative in $\hat{T}_{i-1}$. Let $\hat{T}_i \in \{T_1, T_2\}$ be the other subtree of the root. Assume that this process is finished with $j_s$, $\hat{T}_s$. Next we define another sequence of indexes: $k_s = m$; for $i < m$ we define $k_i$ to be the largest number, smaller than $j_{i+1}$, such that $u_{k_i}$ does not have a representative in $\hat{T}_{i+1}$. By the construction of $\hat{T}_i$, we have that $j_i \leq k_i$ and $u_{k_i}$ has a representative in $\hat{T}_i$. See Figure 3.1 for an example of such partition. We have partitioned $p$ into subpaths $(\langle u_{j_i}, \ldots, u_{k_i} \rangle)_i$ and $(\langle u_{k_i}, \ldots, u_{j_{i+1}} \rangle)_i$. Informally, a subpath $\langle u_{j_i}, \ldots, u_{k_i} \rangle$ will be realized in $\hat{T}_i$, while subpath $\langle u_{k_i}, \ldots, u_{j_{i+1}} \rangle$ will be realized in $T_1$.

[2]Note that, more generally, any ultrametric can be defined by a binary tree.

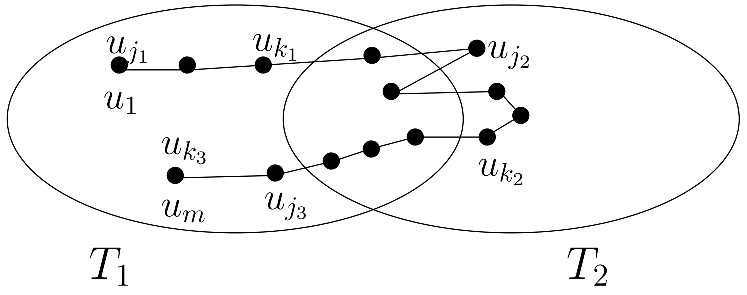

FIG. 3.1. *A partition of the path into subpaths.*

More formally, let $L = \ell(p)$, $L_{i_1,i_2} = \ell(\langle u_{i_1}, u_{i_1+1}, \dots, u_{i_2}\rangle)$, $n = |\mathsf{f}(T)|$, $n_1 = |\mathsf{f}(T_1)|$, $n_2 = |\mathsf{f}(T_2)|$, and $\Delta = \Delta(T)$, $\Delta_1 = \Delta(T_1)$, and $\Delta_2 = \Delta(T_2)$. We construct by induction on the tree structure $T$ a path $\bar{p}$ in $T$ whose length satisfies $\bar{L} = \ell(\bar{p}) \leq 8t \log\min\{\Delta, n\} \cdot L$.

By the induction hypothesis it is possible to construct, for any $i$, a path in $\hat{T}_i$ of representatives of $\langle u_{j_i}, \dots, u_{k_i}\rangle$ whose length is

$$\bar{L}_{j_i,k_i} \leq L_{j_i,k_i} \cdot 8t \log\min\{n, \Delta\}.$$

Next, for any $i$, we construct a path of representatives of $\langle u_{k_i}, \dots, u_{j_{i+1}}\rangle$. Note that $u_{k_i+1}, \dots, u_{j_{i+1}-1}$ have representatives in both $\hat{T}_i$ and $\hat{T}_{i+1}$. Therefore, we construct inductively a path from a representative of $u_{k_i+1}$ to a representative of $u_{j_{i+1}-1}$ in $T_1$, so $\bar{L}_{k_i,j_{i+1}} \leq L_{k_i,j_{i+1}} 8t \log\min\{n_1, \Delta_1\}$. We then connect the representative of $u_{k_i}$ with the representative of $u_{k_i+1}$ and the representative of $u_{j_{i+1}-1}$ with the representative of $u_{x_{i+1}}$; each such edge is of length at most the diameter of $T$, $\Delta$. We have therefore constructed a path of representatives of $\langle u_{k_i}, \dots, u_{j_{i+1}}\rangle$ whose length is $\bar{L}_{k_i,j_{i+1}} + 2\Delta$.

Since $u_{k_i}$ does not have a representative in $\hat{T}_{i+1}$ and $u_{j_{i+1}}$ does not have representative in $\hat{T}_i$, we conclude, using property 3 above, that $d_M(u_{k_i}, u_{j_{i+1}}) \geq \Delta/4t$, and so $\Delta \leq 4t \cdot L_{k_i,j_{i+1}}$. To summarize,

$$\begin{aligned}\bar{L}_{k_i,j_{i+1}} &\leq L_{k_i,j_{i+1}} 8t \log\min\{n_1, \Delta_1\} + 2\Delta \\ &\leq L_{k_i,j_{i+1}} 8t \big(\log\min\{n/2, \Delta/2\} + 1\big) \\ &= L_{k_i,j_{i+1}} 8t \log\min\{n, \Delta\}.\end{aligned}$$

We conclude

$$\begin{aligned}\bar{L} &= \sum_{i=1}^{s} \bar{L}_{j_i,k_i} + \sum_{i=1}^{s-1} \bar{L}_{k_i,j_{i+1}} \\ &\leq 8t \log\min\{n, \Delta\} \cdot \left(\sum_{i=1}^{s} L_{j_i,k_i} + \sum_{i=1}^{s-1} L_{k_i,j_{i+1}}\right) \\ &= 8t \log\min\{n, \Delta\} L. \qquad \square\end{aligned}$$

We end the discussion on multiembedding into ultrametrics with the following impossibility result.

PROPOSITION 3.2. *Consider the metric defined by a simple $N$-point path. Then any $\alpha$-path embedding of this metric in an ultrametric must have $\alpha = \Omega(\log n)$.*

*Proof.* Let $M = \{v_1, v_2, \ldots, v_n\}$ be the metric space on $n$ points such that $d_M(v_i, v_j) = |i - j|$. We prove that for any noncontractive multiembedding into an ultrametric $T$, any path of representatives of $\langle v_1, v_2, \ldots, v_n\rangle$ is of length at least $g(n) = \frac{n}{2}\log n$.

The proof proceeds by induction on $n$. For $n = 1$ the claim is trivial. For $n > 1$, let $\langle v'_1, v'_2, \ldots, v'_n\rangle$ be a path of representatives in $T$. Let $u = \mathrm{lca}_T(v'_1, v'_n)$, $\Delta(u) = d_T(v'_1, v'_n) \geq d_M(v_1, v_n) = n - 1$. Let $T_1$ be the subtree of the child of $u$ that contains $v'_1$. $T_1$ does not contain $v'_n$. Let $i_1 < n$ be the maximal $i$ such that $\{v'_1, \ldots, v'_{i_1}\} \subset T_1$. As $i_1 + 1$ is not contained in $T_1$, it must be that $d_T(v'_{i_1}, v'_{i_1+1}) \geq \Delta(u) \geq n - 1$. By the induction hypothesis,

$$\ell_T(\langle v'_1, \ldots, v'_{i_1}\rangle) \geq g(i_1), \qquad \ell_T(\langle v'_{i_1+1}, \ldots, v'_n\rangle) \geq g(n - i_1).$$

Since $g$ is a convex function, $(g(i_1) + g(n - i_1))/2 \geq g((i_1 + (n - i_1))/2) = g(n/2)$. We conclude

$$\begin{aligned}\ell_T(\langle v'_1, \ldots, v'_n\rangle) &\geq g(i_1) + (n-1) + g(n - i_1)\\ &\geq 2g\left(\frac{n}{2}\right) + n - 1 = 2\frac{n}{4}\log\frac{n}{2} + (n-1) \geq \frac{n}{2}\log n. \qquad \square\end{aligned}$$

**4. Multiembedding into trees.** In this section we consider multiembeddings into *arbitrary tree metrics*. We only have preliminary results. Specifically, we only consider two important types of metric spaces: expander graphs and the discrete cube with the Hamming metric, for which we obtain better results. For both of them the preceding sections proved an upper bound of $O(\log\log n \log\log\log n)$ and a lower bound of $\Omega(\log\log n)$ on the path distortion of multiembeddings into ultrametrics. (The lower bound follows since both metrics contain a path of length $\Omega(\log n)$.)

We begin with the observation that for $\Gamma = \infty$ it is easy to obtain 1-path embedding of any finite metric space into trees. This is achieved by defining an infinite tree metric as follows: joining all possible finite paths with a common root, where the first node in the path is connected with an edge weight of $\frac{\Delta}{2}$ to the root. Moreover, we have the following result.

Proposition 4.1. *Given a metric space $M$ defined by an unweighted graph of maximum degree $d$ and diameter $\Delta$, let $s \in \mathbb{N}$. Then $M$ can be $(2 + \frac{\Delta}{s})$-path embedded into a tree metric of size $nd^s$.*

*Proof.* Along the lines of the construction described above, we take all paths of length $s$ and join these with a common root, where the first node in the path is connected with an edge weight of $\frac{\Delta}{2}$ to the root. Obviously, there are at most $nd^s$ such paths. Notice that our choice of weights to the edges adjacent to the root guarantees that distances in the resulting tree are no smaller than the original distances. We next claim that the path distortion is at most $(2 + \frac{\Delta}{s})$. To see this, consider a path $p = \langle v_1, \ldots, v_\ell\rangle$ of length $\ell$. We partition $p$ into subpaths of length $s$: $p = p_1 p_2 \cdots p_t$, where $t = \lceil \ell/s \rceil$, $p_j = \langle v_{(j-1)s+1}, \ldots, v_{js}\rangle$ for $j < t$, and $p_t = \langle v_{(t-1)s+1}, \ldots, v_\ell\rangle$. Now the subpath $p_j$ is mapped to the appropriate path in the tree. Note that the length of the image path is $2\ell + (t-1)\Delta$. $\square$

This simple fact is particularly interesting for its implication for expander graphs. Let $G$ be an $(n, d, \gamma d)$ graph, i.e., a $d$-regular $n$-vertex graph whose second eigenvalue in absolute value is at most $\gamma d$. It is known [14] that such a graph has diameter at most $1 + \log_{1/\gamma} n$, and so we obtain the following.

Corollary 4.2. *Any $(n, d, \gamma d)$-graph has 3-path embedding in a tree of size $dn^{1+\log_{1/\gamma} d}$.*

We also note that, for the trees constructed in the proof of Proposition 4.1, it is particularly easy to obtain a better approximation algorithm for GST.

LEMMA 4.3. *Consider a tree metric $M = (V, d)$, where $V = P_1 \cup P_2 \cup \cdots \cup P_\ell$, $P_i = \langle v_1^i, v_2^i, \ldots, v_s^i \rangle$ is an unweighted simple path of length $s$, and $d(v_1^i, v_1^j) = \Delta$ for $i \neq j$. Then an instance of the GST with $k$ groups defined on $M$ has a $(1+\frac{2s}{\Delta})(1+\ln k)$ approximation algorithm.*

*Proof.* Consider a GST instance $g_1, \ldots, g_k$ defined on $M$. We first check whether there is a solution that is completely contained in one $P_i$. This can be checked in polynomial time by noting that if an optimal solution is contained in one $P_i$, then it is an interval. Thus we need to check only $\ell\binom{s+1}{2}$ intervals.

Otherwise, the optimal solution intersects $t > 1$ of the paths $P_1, \ldots, P_\ell$. Define a hitting set instance whose ground set is $\{P_1, \ldots, P_\ell\}$ and whose subsets are $g_1', \ldots, g_k'$, where $g_i' = \{P_j;\ P_j \cap g_i \neq \emptyset\}$. It follows that the optimal cost of the hitting set problem is at least $t-1$. The hitting set problem has a polynomial time $1+\ln k$-approximation algorithm [22, 25]. Let $S$ be the approximate solution for the hitting set. We define a solution for the GST instance by taking a natural path over $\cup\{P_i;\ P_i \in S\}$. Note that its length is at most $(\Delta + 2s)|S| \leq (\Delta + 2s)(t-1)(1 + \ln k)$. However, the cost of the optimal GST algorithm is at least $(t-1)\Delta$. $\square$

COROLLARY 4.4. *For fixed $d > \lambda$ there exist constants $c = c_{d,\lambda}$, $C = C_{d,\lambda}$, and polynomial $p(t) = p_{d,\lambda}(t)$ such that GST on $(n, d, \lambda)$ graphs has $p(n)$-time $(C \log k)$-approximation algorithm, and it is NP-hard to approximate within a factor of $c \log k$.*

*Proof.* The approximation algorithm follows from Proposition 4.1 and Lemma 4.3, by setting $s = \Delta$. The hardness result follows since an $(n, d, \lambda)$ graph contains a subset of $n^{\Omega_{d,\lambda}(1)}$ points that is $O_{d,\lambda}(1)$-approximated by an equilateral space [8]. GST on equilateral space is equivalent to a standard hitting set problem, which is NP-hard to approximate within a factor of $c \ln k$ [28, 26]. Usage of points not in this subspace ("Steiner points") can improve the approximation factor by at most a factor of two [29, 18]. $\square$

We next examine multiembedding of the $h$-dimensional hypercube with $n = 2^h$ vertices. Using Proposition 4.1 with $s = h/\log h$, and using $d = h$ and $\Delta = h$, we obtain $(\log\log n + 2)$-path embedding into trees of size $\Gamma(n) \leq n^2$. By applying Lemma 4.3 to that path-embedding, we obtain a polynomial time $O(\log k \log\log n)$-approximation algorithm to GST on the cube. Similarly to the expander graphs, it is hard to approximate instances of GST on the cube to within a $c \log k$ factor, for some constant $c > 0$, since the cube contains a subset of $n^{\Omega(1)}$ points that is $O(1)$-approximated by an equilateral space.

## 5. Discussion.

An interesting open problem is to determine worst case bounds for path distortion of multiembedding into trees of polynomial size. As indicated by the case of expander graphs, such bounds may be better than those for ultrametrics.

Results on multiembedding into trees directly reflect on the approximability of GST. As shown for expanders and hypercubes, it is possible that for special classes of metric spaces, a combination of improved path embedding and a specialized solution would yield (nearly) tight upper bounds. Our approach to showing the (near) tightness of the results in those cases stems from metric Ramsey-type considerations (i.e., the existence of large approximately equilateral subspace). Such considerations are, in fact, more general and may lead to more results of this type.[3]

Multiembedding into ultrametrics also implies multiembedding into $\ell_p^d$, where

[3]In [8] it is shown that any metric space contains a "large" subspace which is approximately an ultrametric, or a $k$-HST. Such trees were used in [19] to prove inapproximability results for GST. It is plausible that these techniques can be combined to obtain tight bounds for GST in specific metric

$d = O(\log n)$ with similar path distortion [9]. It is natural to ask whether better path distortion is possible for multiembedding into $\ell_1$ or $\ell_2$. Further study of multiembeddings in other settings and their applications seems an attractive direction for future research.

# BOUNDED-DEPTH FREGE LOWER BOUNDS FOR WEAKER PIGEONHOLE PRINCIPLES[*]

JOSHUA BURESH-OPPENHEIM[†], PAUL BEAME[‡], TONIANN PITASSI[†], RAN RAZ[§], AND ASHISH SABHARWAL[‡]

**Abstract.** We prove a quasi-polynomial lower bound on the size of bounded-depth Frege proofs of the pigeonhole principle $PHP^m_n$ where $m = (1 + 1/\text{polylog } n)n$. This lower bound qualitatively matches the known quasi-polynomial-size bounded-depth Frege proofs for these principles. Our technique, which uses a switching lemma argument like other lower bounds for bounded-depth Frege proofs, is novel in that the tautology to which this switching lemma is applied remains random throughout the argument.

**Key words.** propositional proof complexity, pigeonhole principle

**AMS subject classifications.** 03F20, 68Q17, 68R10

**DOI.** 10.1137/S0097539703433146

## 1. Introduction.

The propositional pigeonhole principle asserts that $m$ pigeons cannot be placed in $n$ holes with at most one pigeon per hole whenever $m$ is larger than $n$. It is an exceptionally simple fact that underlies many theorems in mathematics and is the most extensively studied combinatorial principle in proof complexity. (See [24] for an excellent survey on the proof complexity of pigeonhole principles.) It can be formalized as a propositional formula, denoted $PHP^m_n$, in a standard way.

Proving superpolynomial lower bounds on the length of propositional proofs of the pigeonhole principle when $m = n+1$ has been a major achievement in proof complexity. The principle can be made weaker (and hence easier to prove) by increasing the number of pigeons relative to the number of holes, or by considering fewer of the possible mappings of pigeons to holes. Two well-studied examples of the latter weakenings, the onto pigeonhole principle and the functional pigeonhole principle, only rule out, respectively, surjective and functional mappings from pigeons to holes. In this paper, we will prove lower bounds that apply to all of these variations of the basic pigeonhole principle.

For all $m > n$, Buss [10] has given polynomial-size Frege proofs of $PHP^m_n$. He uses families of polynomial-size formulas that count the number of 1's in an $N$-bit string and Frege proofs of their properties to show that the number of pigeons successfully mapped injectively can be at most the number of holes.

In weaker proof systems, where such formulas cannot be represented, the proof complexity of the pigeonhole principle depends crucially on the number of pigeons, $m$, as a function of the number of holes, $n$. As $m$ increases, the principle becomes weaker (easier to prove) and in turn the proof complexity question becomes more

difficult. We review the basics of what is known for resolution and bounded-depth Frege systems below. Generally, the weak pigeonhole principle has been used to refer to $PHP_n^m$ whenever $m$ is at least a constant factor larger than $n$. We will be primarily concerned with forms of the pigeonhole principle that are significantly weaker than the usual pigeonhole principle but somewhat stronger than these typical weak forms.

For the resolution proof system, the complexity of the pigeonhole principle is essentially resolved. In 1985, Haken proved the first superpolynomial lower bounds for unrestricted resolution proofs of $PHP_n^m$ for $m = n+1$ [13]. This lower bound was generalized by Buss and Turán [11] for $m < n^2$. For the next ten years, the resolution complexity of $PHP_n^m$ for $m \geq n^2$ was completely open. A recent result due to Raz [22] gives exponential resolution lower bounds for the weak pigeonhole principle, and subsequently Razborov resolved the problem for most interesting variants of the pigeonhole principle [25].

Substantially less is known about the complexity of the pigeonhole principle in bounded-depth Frege systems, although strong lower bounds are known when the number of pigeons $m$ is close to the number of holes $n$. Ajtai proved superpolynomial lower bounds for $PHP_n^{n+1}$ with an ingenious blend of combinatorics and nonstandard model theory [2, 3]. This result was improved to exponential lower bounds in [7, 21, 17]. It was observed in [5] that the above lower bounds can in fact be applied to $PHP_n^m$ for $m \leq n + n^{\epsilon}$ for some $\epsilon$ that falls off exponentially in the depth of the formulas involved in the proof.

For the case of larger $m$ (the topic of this paper), the complexity of bounded-depth Frege proofs of $PHP_n^m$ is slowly emerging, with surprising and interconnected results. There are several deep connections between the complexity of the weak pigeonhole principle and other important problems. First, lower bounds for bounded-depth Frege proofs of the weak pigeonhole principles suffice to show unprovability results for the $P$ versus $NP$ statement (see [24]). Second, the long-standing question of whether or not the existence of infinitely many primes has an $I\Delta_0$ proof is closely related to the complexity of weak pigeonhole principle in bounded-depth Frege systems [20]. Third, the question is closely related to the complexity of approximate counting [19].

In bounded-depth Frege systems more powerful than resolution, there are a few significant prior results concerning the proof complexity of weak pigeonhole principles: There are bounded-depth Frege proofs of $PHP_n^m$ for $m$ as small as $n + n/\text{polylog } n$ of quasi-polynomial size [20, 16, 18]; thus exponential lower bounds for the weak pigeonhole principle are out of the question. In fact, this upper bound is provable in a very restricted form of bounded-depth Frege where all lines in the proof are disjunctions of polylog $n$-sized conjunctions, a proof system known as $Res(\text{polylog } n)$. On the other hand, [26] shows exponential lower bounds for $PHP_n^{2n}$ in $Res(k)$, a proof system which allows lines to be disjunctions of size-$k$ conjunctions for $k$ almost $\sqrt{\log n}$.

In this paper we prove quasi-polynomial lower bounds for the weak pigeonhole principle whenever $m \leq n + n/\text{polylog } n$. More precisely, we show the following.

Main Result. *For any integers $a, h > 0$, there exists an integer $c$ such that any depth-$h$ proof of $PHP_n^m$, where $m \leq n + n/\log^c n$, requires size $2^{\log^a n}$.*

This is a substantial improvement over previous lower bounds. Furthermore, the quantification of $a$, $h$, and $c$ cannot be easily improved without running into the upper bound of [4]. Our proof technique applies a switching lemma to a weaker tautology based on certain bipartite graphs. This type of tautology was introduced in [9]. Although we rely heavily on the simplified switching lemma arguments presented in [6, 27], one major difference from previous switching-lemma-based proofs is that both the tautologies themselves and the restrictions we consider remain random throughout most of the argument.

## 2. Overview.

The high-level schema of our proof is not new. Ignoring parameters for a minute, we start with an alleged proof of $PHP^m_n$ of small size. We then show that assigning values to some of the variables in the proof leaves us with a sequence of formulas, each of which can be represented as a particular type of decision tree of small height. This part of the argument is generally referred to as the switching lemma. We then prove that the leaves of any such short tree corresponding to a formula in the proof must all be labelled 1 if the proof is to be sound. Finally, we show that the tree corresponding to $PHP^m_n$ has leaves labelled 0, which is a contradiction since it must appear as a formula in the alleged proof. We now overview the lower bound components in more detail.

The lower bounds for bounded-depth Frege proofs of $PHP^{n+1}_n$ [3, 7, 21, 17] used *restrictions*, partial assignments of values to input variables, and iteratively applied "switching lemmas" with respect to random choices of these restrictions. The first switching lemmas [12, 1, 14] showed that after one applies a randomly chosen restriction that assigns values to many, but far from all, of the input variables, with high probability one can convert an arbitrary DNF formula with small terms into a CNF formula with small clauses (hence the name). More generally, such switching lemmas allow one to convert arbitrary DNF formulas with small terms into small height decision trees (which implies the conversion to CNF formulas with small clauses). The basic idea is that for each level of the formulas/circuits, one proves that a randomly chosen restriction will succeed with positive probability for all subformulas/gates at that level. One then fixes such a restriction for that level and continues to the next level. To obtain a lower bound, one chooses a family of restrictions suited to the target of the analysis. In the case of $PHP^m_n$, the natural restrictions to consider correspond to partial matchings between pigeons and holes.

The form of the argument by which switching lemmas are proven generally depends on the property that the ratio of the probability that an input variable remains unassigned to the probability that it is set to 0 (respectively, to 1) is sufficiently less than 1. In the case of a random partial matching that contains $(1-p)n$ edges applied to the variables of $PHP^m_n$, there are $pn$ unmatched holes and at least $pm$ unmatched pigeons. Hence, the probability that any edge-variable remains unassigned (i.e., neither used nor ruled out by the partial matching) is at least $p^2$. However, the partial matching restrictions set less than a $1/m$ fraction of variables to 1. Thus the proofs required that $p^2n < p^2m < 1$ and thus $p < n^{-1/2}$. This compares with choices of $p = n^{-O(1/h)}$ for depth-$h$ circuit lower bounds in the best arguments for parity proven in [14]. Hence, the best-known lower bound on the size of depth-$h$ circuits computing parity is of the form $2^{n^{\Omega(1/h)}}$, while the best-known lower bound on the size of depth-$h$ proofs of $PHP^{n+1}_n$ is of the form $2^{n^{2^{-O(h)}}}$.

A problem with extending the lower bounds to $PHP^m_n$ for larger $m$ is that, after a partial matching restriction is applied, the absolute difference between the number of pigeons and holes does not change, but the number of holes is dramatically reduced. This can qualitatively change the ratio between pigeons and holes. If this is too large, then the probability that variables remain unassigned grows dramatically and, in the next level, the above argument does not work at all. For example, with the above argument, if the difference between the number of pigeons and holes is as large as $n^{3/4}$, then after only one round the above argument will fail. The extension in [5] to lower bound proofs for $PHP^{n+n^{\epsilon_h}}_n$ for formulas of depth $h$ relies on the fact that even after $h$ rounds of restrictions the gap is small enough that there is no such qualitative change; but this is the limit using the probabilities as above.

We are able to resolve the above difficulties for $m$ as large as $n + n/\text{polylog } n$. In particular, we increase the probability that variables are set to 1 to $1/\text{polylog } n$ from $1/m$ by restricting the matchings to be contained in bipartite graphs $G$ of polylog $n$ degree. Thus we can keep as many as $n/\text{polylog } n$ of the holes unmatched in each round. Therefore, by choosing the exponents in the polylog $n$ carefully as a function of the depth of the formulas, we can tolerate gaps between the number of pigeons and the number of holes that are also $n/\text{polylog } n$.

A difficulty with this outline is that one must be careful throughout the argument that the restrictions one chooses do not remove all the neighbors of a node without matching it, which would simplify the pigeonhole principle to a triviality. It is not at all clear how one could explicitly construct low-degree graphs such that some simple additional condition on the restrictions that we choose at each stage could enforce the desired property. It is unclear even how one might do this nonconstructively because it is not clear what property of the random graph would suffice.

Instead, unlike previous arguments, we do not fix the graph in advance; we keep the input graph random throughout the argument and consider for each such graph $G$ its associated proof of the pigeonhole principle restricted to $G$. Since we do not know what $G$ is at each stage, we cannot simply fix the restriction as we deal with each level; we must keep that random as well. Having done this, we can use simple Chernoff bounds to show that, for almost all combinations of graphs and restrictions, the degree at each level will not be much smaller than the expected degree, so the pigeonhole principle will remain far from trivial. We adjust parameters to reduce the probability that a restriction fails to simplify a given level so that it is much smaller than the number of levels. Then we apply the probabilistic method to the whole experiment involving the graph $G$ as well as the sequence of restrictions.

There is one other technical point that is important in the argument. In order for the probabilities in the switching lemma argument to work out, it is critical that the degrees of vertices in the graph after each level of restriction is applied are decreased significantly at each step as well as being small in the original graph $G$. Using another simple Chernoff bound we show that the degrees of vertices given almost all combinations of graphs and restrictions will not be much larger than their expected value, and this suffices to yield the decrease in degree.

Overall, our argument is expressed in much the same terms as those in [6, 27], although we find it simpler to omit formally defining $k$-evaluations as separate entities. One way of looking at our technique is that we apply two very different kinds of random restrictions to a proof of $PHP^m_n$: first, one that sets many variables to 0, corresponding to the restriction of the problem to the graph $G$, and then one that sets partial matchings for use with the switching lemma.

## 3. Frege proofs and $PHP(G)$.

A *formula* is a tree whose internal nodes are labelled by either $\vee$ (fanin 2) or $\neg$ (fanin 1) and whose leaves are labelled by variables. Given a node in this tree, the full tree rooted at that node is called a (not necessarily proper) *subformula* of the original formula. If a formula contains no connectives, then it has *depth* 0. Otherwise, the *depth* of a (sub)formula $A$ is the maximum number of alternations of connectives along any path from the root to leaf, plus one. The *merged form* of a formula $A$ is the tree such that all $\vee$'s labelling adjacent vertices of $A$ are identified into a single node of unbounded fanin, also labelled $\vee$.

A *Frege proof system* is specified by a finite set of sound and complete *inference* *rules*, rules for deriving new propositional formulas from existing ones by consistent substitution of formulas for variables in the rule. A typical example is the following, due to Schoenfield, in which $p, q, r$ are variables that stand for formulas and $p, q \vdash r$ denotes that $p$ and $q$ yield $r$ in one step:

Excluded middle: $\vdash \neg p \vee p$. Expansion rule: $p \vdash q \vee p$.

Contraction rule: $p \vee p \vdash p$. Associative rule: $p \vee (q \vee r) \vdash (p \vee q) \vee r$.

Cut rule: $p \vee q,\ \neg p \vee r \vdash q \vee r$.

We will say that the *size* of a Frege rule is the number of distinct subformulas mentioned in the rule. For example, the size of the cut rule above is 7; the subformulas mentioned are $p, q, r, \neg p, p \vee q, \neg p \vee r, q \vee r$.

DEFINITION 3.1. *A proof of a formula $A$ in Frege system $\mathcal{F}$ is a sequence of formulas $A_1, \dots, A_r = A$ such that $\vdash A_1$ and for all $i > 1$ there is some (possibly empty) subset $\mathcal{A} \subset \{A_1, \dots, A_{i-1}\}$ such that $\mathcal{A} \vdash A_i$ is a substitution instance of a rule of $\mathcal{F}$.*

In what follows, let $\mathcal{F}$ be any fixed Frege system whose rules have size bounded by $f$.

DEFINITION 3.2. *For an $\mathcal{F}$-proof $\Pi$, let $\mathrm{cl}(\Pi)$ denote the closure of the set of formulas in $\Pi$ under subformulas. The size of a Frege proof $\Pi$ is $|\mathrm{cl}(\Pi)|$, the total number of distinct subformulas that appear in the proof. The depth of a proof is the maximum depth of the formulas in the proof.*

Let $G = (V_1 \cup V_2, E)$ be a bipartite graph where $|V_2| = n$ and $|V_1| = m > n$. We use $L(G)$ to denote the language built from the set of propositional variables $\{X_e : e \in E\}$, the connectives $\{\vee, \neg\}$, and the constants 0 and 1.

The following is a formulation of the onto and functional weak pigeonhole principle on the graph $G$. Note that if $G$ is not the complete graph $K_{m,n}$, then this principle is weaker than the standard onto and functional weak pigeonhole principle.

DEFINITION 3.3. *$PHP(G)$ is the OR of the following four (merged forms of) formulas in $L(G)$. In general, $i, j, k$ represent vertices in $G$, and $\Gamma(i)$ represents the set of neighbors of $i$ in $G$.*

1. $\bigvee_{(e,e') \in I} \neg(\neg X_e \vee \neg X_{e'})$ *for* $I = \{(e, e') : e, e' \in E; e = \{i, k\}, e' = \{j, k\}; i, j \in V_1; i \neq j; k \in V_2\}$*: two different pigeons go to the same hole.*
2. $\bigvee_{(e,e') \in I} \neg(\neg X_e \vee \neg X_{e'})$ *for* $I = \{(e, e') : e, e' \in E; e = \{k, i\}, e' = \{k, j\}; i, j \in V_2; i \neq j; k \in V_1\}$*: one pigeon goes to two different holes.*
3. $\bigvee_{i \in V_1} \neg \bigvee_{j \in \Gamma(i)} X_{\{i,j\}}$*: some pigeon has no hole.*
4. $\bigvee_{j \in V_2} \neg \bigvee_{i \in \Gamma(j)} X_{\{i,j\}}$*: some hole remains empty.*

*In fact, we consider an arbitrary orientation of the above formula whereby each $\vee$ is binary.*

## 4. Representing matchings by trees.

In this section we make minor modifications to standard definitions from [6, 27] to apply to the edge-variables given by bipartite graphs and not just complete bipartite graphs.

Let $G$ be a bipartite graph as in the last section and let $D$ denote the set of Boolean variables $X_e$ in $L(G)$. Assume there is an ordering on the nodes of $G$.

DEFINITION 4.1. *Two edges of $G$ are said to be inconsistent if they share exactly one endpoint. Two partial matchings $\rho_1, \rho_2$ on the graph $G$ are said to be consistent if no edge in $\rho_1$ is inconsistent with an edge in $\rho_2$. For a partial matching $\rho$, let $\mathrm{Im}(\rho)$ denote the set of nodes of $V_2$ that are matched by $\rho$.*

Definition 4.2. *For $\rho$ a partial matching on the graph $G$ that matches nodes $V_1' \subset V_1$ to nodes $V_2' \subset V_2$, we define $G|_\rho$ as the bipartite graph $((V_1 \setminus V_1') \cup (V_2 \setminus V_2'), E - (V_1' \times V_2 \cup V_1 \times V_2'))$.*

Definition 4.3. *A matching decision tree $T$ for $G$ is a tree where each internal node $u$ is labelled by a node of $G$, $v$, and each edge from a node $u$ is labelled by an edge of $G$ that touches $v$. Furthermore, given any path in the tree from the root to a node $u$, the labels of the edges along the path constitute a partial matching on $G$, called $path(u)$. Let $path(T) = \{path(u) : u \text{ is a leaf of } T\}$. If $v$ is a node of $G$ that appears as a label of some node in $T$, then $T$ is said to mention $v$.*

*Furthermore, each leaf of $T$ is labelled by $0$ or $1$ (if a tree satisfies the above conditions but its leaves remain unlabelled, we will call it a leaf-unlabelled matching decision tree). Let $T^c$ be the same as $T$ except with the value of each leaf-label flipped. If $U$ is the set of leaves of $T$ labelled $1$, let $disj(T)$ be the DNF formula $\bigvee_{u \in U} \bigwedge_{e \in path(u)} X_e$.*

Definition 4.4. *A complete (leaf-unlabelled) matching decision tree for $G$ is one in which, for each internal node $u$ labelled $v$ and each neighbor $v'$ of $v$ in $G|_{path(u)}$, there is an outgoing edge from $u$ labelled by $v'$.*

Definition 4.5. *Let $K$ be a subset of the nodes in $G$. The full matching tree for $K$ over $G$ is a leaf-unlabelled matching decision tree for $G$ defined inductively: If $K = \{k\}$, then the root of the tree is labelled by $k$, and for each edge $e$ in $G$ that touches $k$, there is an edge from the root of the tree labelled $e$. If there are no such edges, then we say that the full matching tree is empty.*

*If $K$ contains more than one node, let $k$ be its first node under the ordering and assume we have a full matching tree for $k$ called $T$. If $T$ is empty, then the entire tree is empty. Otherwise, at each leaf $u$ of $T$, attach the full matching tree for $K \setminus \{k\}$ over $G|_{path(u)}$. If this tree is empty, then remove the leaf $u$.*

Note that the full matching tree for any subset $K$ is complete. If the degree of each node in $K$ is at least $|K|$, then the full matching tree for $K$ is guaranteed to mention all nodes in $K$. Otherwise, it might not.

Lemma 4.6. *Let $T$ be a complete matching tree for $G$, and let $\rho$ be any partial matching on $G$. Let $d$ be the minimal degree of any node in $G$ mentioned by $T$. If $d > |\rho| + height(T)$, then there is a matching in $path(T)$ that is consistent with $\rho$.*

*Proof.* Assume we have found an internal node $u$ in $T$ labelled by $v$ in $G$ such that $path(u)$ is consistent with $\rho$. We will find a child $u'$ of $u$ such that $path(u')$ is still consistent with $\rho$. If $\rho$ includes the edge $\{v, v'\}$ for some $v'$, then there must be a $u'$ that matches $v$ with $v'$ in $T$, since $path(u)$ is consistent with $\rho$ (so $v'$ isn't already matched by $path(u)$) and since $T$ is complete. If not, then there must be a neighbor $v'$ of $v$ in $G$ that remains unmatched by $\rho$ and $path(u)$ because $d > |\rho| + height(T)$. Again, since $T$ is complete, there is a node $u'$ that matches $v$ with $v'$. ◻

Definition 4.7. *We call $F$ a matching disjunction if it is one of the constants $0$ or $1$, or it is a DNF formula with no negations over the variables $D$ such that the edges of $G$ corresponding to the variables in any one term constitute a partial matching. In the latter case, order the terms lexicographically based on the nodes they touch and the order of the nodes in $G$.*

Definition 4.8. *For $F$ a matching disjunction, the restriction $F|_\rho$ for $\rho$ a partial matching is another matching disjunction generated from $F$ as follows: Set any variable in $F$ corresponding to an edge of $\rho$ to $1$ and set any variable corresponding to an edge not in $\rho$ but incident to one of $\rho$'s nodes to $0$. If a variable in term $t$ is set to $0$, remove $t$ from $F$. Otherwise, if a variable in term $t$ is set to $1$, remove that variable from $t$.*

The DNF $disj(T)$ for a matching decision tree $T$ is always a matching disjunction.

DEFINITION 4.9. *A matching decision tree $T$ is said to represent a matching disjunction $F$ if, for every leaf $l$ of $T$, $F|_{path(l)} \equiv 1$ when $l$ is labelled 1 and $F|_{path(l)} \equiv 0$ when $l$ is labelled 0.*

A matching decision tree $T$ always represents $disj(T)$. Furthermore, if $\rho$ extends some matching $path(l)$ for $l$ a leaf of $T$, then $disj(T)|_\rho \equiv 0$ (1, respectively) if $l$ is labelled 0 (1).

DEFINITION 4.10. *Let $F$ be a matching disjunction. We define a tree $Tree_G(F)$ called the canonical decision tree for $F$ over $G$: If $F$ is constant, then $Tree_G(F)$ is one node labelled by that constant. Otherwise, let $C$ be the first term of $F$. Let $K$ be the nodes of $G$ touched by variables in $C$. The top of $Tree_G(F)$ is the full matching tree on $K$ over $G$. We replace each leaf $u$ of that tree with the tree $Tree_{G|_{path(u)}}(F|_{path(u)})$.*

The tree $Tree_G(F)$ will have all of its leaves labelled. It is designed to represent $F$ and to be complete.

DEFINITION 4.11. *For $T$ a matching decision tree and $\rho$ a matching, $T$ restricted by $\rho$, written $T|_\rho$, is a matching decision tree obtained from $T$ by first removing all edges of $T$ that are inconsistent with $\rho$ and retaining only those nodes of $T$ that remain connected to the root of $T$. Each remaining edge that corresponds to an element of $\rho$ is then contracted (its endpoints are identified and labelled by the label of the lower endpoint).*

LEMMA 4.12 (see [27, Lemma 4.8]). *For $T$ a matching decision tree and $\rho$ a matching,*

(a) *$disj(T)|_\rho \equiv disj(T|_\rho)$;*

(b) *$(T|_\rho)^c = T^c|_\rho$;*

(c) *if $T$ represents a matching disjunction $F$, then $T|_\rho$ represents $F|_\rho$.*

## 5. The lower bound.

Let $m = n+n/\log^c n$ for some integer $c > 0$, and let $h > 0$ be an integer (all log's are base 2). We generally assume that $n$ is large compared to the other parameters and that all subsequent expressions are integers. We will show that for any $a$ such that $8^h(a+3) < c$, any proof of $PHP^m_n = PHP(K_{m,n})$ of depth $h$ is of size greater than $2^{\log^a n}$. To do this we do not work directly with proofs of $PHP(K_{m,n})$ but rather with proofs of $PHP(G)$ for randomly chosen subgraphs $G$ of $K_{m,n}$.

More precisely, let $b = 8^h(a+3)$, define $d = \log^b n$, and observe that $a < b < c$.

Let $\mathcal{G}(m, n, d/n)$ be the uniform distribution on all bipartite graphs from $m$ nodes to $n$ nodes where each edge is present independently with probability $d/n$.

DEFINITION 5.1. *Let $H = (V_1 \cup V_2, E)$ be a fixed bipartite graph. Define $M^\ell(H)$ to be the set of all partial matchings of size $\ell$ in $H$, and for $I \subseteq V_2$ with $|I| = \ell$, let $M^\ell_I(H)$ be the set of all $\rho \in M^\ell(H)$ with $\mathrm{Im}(\rho) = I$. Define a partial distribution $\mathcal{M}^\ell(H)$ on $M^\ell(H)$ by first choosing a set $I \in V_2$ uniformly at random among all subsets of $V_2$ of size $\ell$, then choosing a $\rho \in M^\ell_I(H)$ uniformly at random; if $M^\ell_I(H)$ is empty, then no matching is chosen and the experiment fails.*

We now define several sequences of parameters for a probabilistic experiment. The meanings of these parameters will be explained after the definition of the experiment. For initial values, let

$$m_0 = m, \quad n_0 = n, \quad b_0 = b$$

and

$$k_0 = 7b_0/8, \quad \ell_0 = n_0 - n_0/\log^{k_0} n.$$

Then, for $1 \leq i \leq h$, we define recursively

$$m_i = m_{i-1} - \ell_{i-1}, \quad n_i = n_{i-1} - \ell_{i-1}, \quad b_i = b_{i-1} - k_{i-1}$$

and

$$k_i = 7b_i/8, \quad \ell_i = n_i - n_i/\log^{k_i} n.$$

In closed form,

$$n_i = n/(\log n)^{\sum_{j=0}^{i-1} k_j} = n/(\log n)^{b-b/8^i}, \quad m_i = n_i + (m-n), \quad b_i = b - \sum_{j=0}^{i-1} k_j = b/8^i$$

and

$$k_i = 7b/8^{i+1}, \quad \ell_i = (1 - 1/\log^{k_i} n)(n/(\log n)^{b-b/8^i}).$$

Now we are ready to define the experiment: Let $G_0 = G$ be a graph chosen randomly from the distribution $\mathcal{G}(m, n, d/n)$. For $0 \leq i \leq h-1$, let $\rho_i \sim \mathcal{M}^{\ell_i}(G_i)$ and define $G_{i+1} = G_i|_{\rho_i}$. (We say that the experiment fails during stage $i+1$ if the partial distribution $\mathcal{M}^{\ell_i}(G_i)$ fails to return an element $\rho_i$.) Observing that the choice of $\rho_i$ depends only on the edges of $G_i$ that are incident to $\mathrm{Im}(\rho_i)$, and that these are among the edges of $G_i$ that are removed to produce $G_{i+1}$, we have the following.

Proposition 5.2. *If this experiment succeeds up to stage $i$, then the distribution induced on $G_i$ is $\mathcal{G}(m_i, n_i, d/n)$.*

Thus, the expected degree of any pigeon in $G_i$ is $n_i d/n = \log^{b_i} n$. The expected degree of any hole in $G_i$ is $m_i d/n$, which is between $\log^{b_i} n$ and $2\log^{b_i} n$ since $n_i < m_i < 2n_i$ (because $c > b$). Let $\Delta_i \overset{def}{=} 6\log^{b_i} n$.

We make several observations about "bad" events in this experiment. Specifically, we bound the probability that any of the following fail:

$E_i$: The experiment succeeds up to stage $i$.

$A_i$: Every node in $G_i$ has degree at most $\Delta_i$.

$B_i$: Every node in $G_i$ has degree at least $(1/2)\log^{b_i} n$.

Lemma 5.3. *For $0 \leq i \leq h$, the probability, given $E_i$, of $\neg A_i$ is at most $(m_i + n_i)2^{-\log^{b_i} n} < 2^{-\log^{b_i - 1} n}$.*

*Proof.* The expected degree of any hole at stage $i$ will be $m_i d/n$. The expected degree of any pigeon will be $n_i d/n$. By the conditions on $m$ and $n$, the former quantity is at most twice the latter, which is equal to $\log^{b_i} n$. Fix a node in the graph and let $X$ be the random variable that represents its degree. This is a sum of Bernoulli trials since the edges occur independently with the same probability. Chernoff's bound tells us that $\mathbf{Pr}(X > 3\mu(X)) < (e^2/27)^{\mu(X)} < (1/2)^{\mu(X)}$. We know that $\log^{b_i} n \leq \mu(X) \leq 2\log^{b_i} n$ and $b_i \geq 2$, so we have the bound. ∎

Lemma 5.4. *For $0 \leq i \leq h$, the probability, given $E_i$, of $\neg B_i$ is at most $(m_i + n_i)2^{-\frac{1}{16}\log^{b_i} n} < 2^{-\log^{b_i - 1} n}$.*

*Proof.* The expected degree of any particular node in $G_i$ is at least $\log^{b_i} n$. Applying a Chernoff bound in the form $\mathbf{Pr}(X < \frac{1}{2}\mu(X)) < \exp(-\frac{1}{8}\mu(X))$, we have the result. ∎

Lemma 5.5. *For $0 \leq i \leq h-1$, the probability, given $E_i$, of $\neg E_{i+1}$ is at most $2^{-\log^{b_i - 1} n}$.*

*Proof.* This is less than the probability that a random graph from $\mathcal{G}(m_i, n_i, d/n)$ does not contain a perfect matching, which by Hall's theorem is less than the probability that there is a proper subset $S$ of the holes that has at least $n_i - |S|$ nonneighbors among the first $n_i$ pigeons. This is at most

$$\begin{aligned}\sum_{j=1}^{n_i-1} \binom{n_i}{j}^2 (1-d/n)^{j(n_i-j)} &\le \sum_{1\le j\le n_i/2} \binom{n_i}{j}^2 (1-d/n)^{j(n_i-j)} \\ &\quad + \sum_{n_i/2\le j\le n_i-1} \binom{n_i}{n_i-j}^2 (1-d/n)^{j(n_i-j)} \\ &\le 2 \sum_{1\le j\le n_i/2} [n_i^2(1-d/n)^{n_i-j}]^j \\ &\le 2 \sum_{1\le j\le n_i/2} [n_i^2 e^{-d(n_i-j)/n}]^j \\ &\le 2 \sum_{1\le j\le n_i/2} [n_i^2 e^{-dn_i/(2n)}]^j.\end{aligned}$$

By construction $dn_i/(2n) = \frac{1}{2}\log^{b_i} n$ and $n_i \le n$, so the failure probability is at most $2^{-\log^{b_i-1} n}$. □

We now develop the switching lemma argument. The overall structure uses the simplified counting techniques of [23] and [6]; however, the statement and proof are both complicated by the need to use probabilistic properties of the formulas themselves as well as the relationship of those properties to the restrictions under consideration. We first need some definitions.

DEFINITION 5.6. *For a bipartite graph $H = (V_1 \cup V_2, E)$ and integers $\ell$ and $\Delta$, let $N^{\ell,\Delta}(H)$ be the set of all $\rho$ in $M^\ell(H)$ such that all nodes of $H|_\rho$ have degree at most $\Delta$. For a set $I \subseteq V_2$ with $|I| = \ell$, let $N_I^{\ell,\Delta}(H)$ be the set of elements $\rho \in N^{\ell,\Delta}(H)$ with* $\mathrm{Im}(\rho) = I$.

For a particular $i$, the set $N^{\ell_i,\Delta_{i+1}}(G_i)$ represents in some sense the usable or "good" portion of all the matchings in $M^{\ell_i}(G_i)$. We therefore define the following event:

$C_i$: $\frac{|N^{\ell_i,\Delta_{i+1}}(G_i)|}{|M^{\ell_i}(G_i)|} \ge 1 - 2^{-\log^{b_{i+1}-2} n}$. Here $i < h$.

LEMMA 5.7. *For $0 \le i < h$, the probability, given $E_{i+1}$, of $\neg C_i$ is at most $1/n$.*

*Proof.* Observe that the expectation of

$$\frac{|N^{\ell_i,\Delta_{i+1}}_{\mathrm{Im}(\rho_i)}(G_i)|}{|M^{\ell_i}_{\mathrm{Im}(\rho_i)}(G_i)|},$$

conditional on success up to stage $i+1$, is precisely the probability that $\rho_i \in N^{\ell_i,\Delta_{i+1}}(G_i)$, conditional on success up to stage $i+1$, which is $> 1 - 2^{-\log^{b_{i+1}-1} n}$ by Lemma 5.3. Now, since

$$\frac{|N^{\ell_i,\Delta_{i+1}}_{\mathrm{Im}(\rho_i)}(G_i)|}{|M^{\ell_i}_{\mathrm{Im}(\rho_i)}(G_i)|}$$

is bounded above by 1, we can apply Markov's inequality to yield that the probability, conditional on success up to stage $i+1$, that

$$\frac{|N^{\ell_i,\Delta_{i+1}}_{\mathrm{Im}(\rho_i)}(G_i)|}{|M^{\ell_i}_{\mathrm{Im}(\rho_i)}(G_i)|} \leq 1 - n \cdot 2^{-\log^{b_{i+1}-1} n}$$

is at most $1/n$. The result follows by observing that $n \cdot 2^{-\log^{b_{i+1}-1} n} \leq 2^{-\log^{b_{i+1}-2} n}$, which is less than 1 because $b_j \geq 3$ for all $j$. $\square$

We are now ready to state the switching lemma.

LEMMA 5.8 (switching lemma). *Let $i, s, r$ be any integers such that $0 \leq i < h$, $0 < s \leq \Delta_{i+1}/\log^3 n$, and $r > 0$. Suppose $E_{i+1}$ and $A_i$ hold. Let $F$ be any matching disjunction with conjunctions of size $\leq r$ over the edge-variables of $G_i$. The probability that $Tree_{G_{i+1}}(F|_{\rho_i})$ has height $\geq s$ conditioned on the events (1) $\rho_i \in N^{\ell_i,\Delta_{i+1}}(G_i)$ and (2) $C_i$ is at most $2(720r/\log^{b_i/2} n)^{s/2}$.*

DEFINITION 5.9. *Let $stars(r,j)$ be the set of all sequences $\beta = (\beta_1, \dots, \beta_k)$ such that for each $i$, $\beta_i \in \{*, -\}^r \setminus \{-\}^r$ and the total number of $*$'s in $\beta$ is $j$.*

LEMMA 5.10 (see [6]). $|stars(r,j)| < (r/\ln 2)^j$.

LEMMA 5.11. *For $H$ a fixed bipartite graph with an ordering on its nodes, let $F$ be a matching disjunction with conjunctions of size $\leq r$ over the edge-variables of $H$, and let $S$ be the set of matchings $\rho \in N^{\ell,\Delta}(H)$ such that $Tree_{H|_\rho}(F|_\rho)$ has height $\geq s$. There is an injection from the set $S$ to the set*

$$\bigcup_{s/2 \leq j \leq s} M^{\ell+j}(H) \times stars(r,j) \times [\Delta]^s.$$

*Furthermore, the first component of the image of $\rho \in S$ is an extension of $\rho$.*

*Proof.* Let $F = C_1 \vee C_2 \vee \cdots$. If $\rho \in S$, then let $\pi$ be the partial matching labelling the first path in $Tree_{H|_\rho}(F|_\rho)$ of length $\geq s$ (actually, we consider only the first $s$ edges in $\pi$, starting from the root, and hence we assume $|\pi| = s$). Let $C_{\gamma_1}$ be the first term in $F$ not set to 0 by $\rho$, and let $K_1$ be the variables of $C_{\gamma_1}$ not set by $\rho$. Let $\sigma_1$ be the unique partial matching over $K_1$ that satisfies $C_{\gamma_1}|_\rho$, and let $\pi_1$ be the portion of $\pi$ that touches $K_1$.

Now define $\beta_1 \in \{*, -\}^r \setminus \{-\}^r$, so that the $p$th component of $\beta_1$ is an $*$ if and only if the $p$th variable in $C_{\gamma_1}$ is set by $\sigma_1$.

Continue this process to define $\pi_i$, $\sigma_i$, $K_i$, etc. (replacing $\rho$ with $\rho\pi_1 \dots \pi_{i-1}$ and $\pi$ with $\pi \setminus \pi_1 \dots \pi_{i-1}$) until some stage $k$ when we've exhausted all of $\pi$. Let $\sigma$ be the matching $\sigma_1 \dots \sigma_k$, and let $\beta$ be the vector $(\beta_1, \dots, \beta_k)$. Let $j = |\sigma|$ be the number of edges in $\sigma$. Note that $s/2 \leq j \leq s$. Observe that $\beta \in stars(r,s)$ and that $\rho\sigma \in M^{\ell+j}(H)$ and is an extension of $\rho$.

We now encode the differences between all the corresponding $\pi_i$ and $\sigma_i$ pairs in a single vector $\delta$ consisting of $|\pi| = s$ components, each in $\{1, \dots, \Delta\}$. Let $u_1$ be the smallest numbered node in $K_1$ and suppose that $\pi$ (in particular $\pi_1$) matches $u_1$ with some node $v_1$. Then the first component of $\delta$ is the natural number $x$ such that $v_1$ is the $x$th neighbor (under the ordering of nodes) of $u_1$ in the graph $H|_{\rho\sigma_2\sigma_3\dots\sigma_k}$. More generally, until the mates of all nodes in $K_1$ under $\pi_1$ have been determined, we determine the $p$th component of $\delta$ by finding the smallest numbered node $u_p$ of $K_1 \setminus \{u_1, \dots, u_{p-1}, v_1, \dots, v_{p-1}\}$ and then find its mate $v_p$ under $\pi_1$ and encode the position $x$ of $v_p$ in the order of the neighbors of $u_p$ in $H|_{\rho\sigma_2\sigma_3\dots\sigma_k}$. Once $K_1$ (and thus $\pi_1$) has been exhausted, the next component is based on the mates of the smallest numbered nodes in $K_2$ under $\pi_2$, until that is exhausted, etc., where the ordering about each vertex when dealing with $K_i$ is with respect to the graph $H|_{\rho\sigma_{i+1}\sigma_{i+2}\dots\sigma_k}$.

Finally, we define the image of $\rho \in S$ under the injection to be $(\rho\sigma, \beta, \delta)$. To prove that this is indeed an injection, we show how to invert it: Given $\rho\sigma_1 \dots \sigma_k$, we can identify $\gamma_1$ as the index of the first term of $F$ that is not set to 0 by it. Then, using $\beta_1$, we can reconstruct $\sigma_1$ and $K_1$. Next, reading the components of $\delta$ and the graph $H|_{\rho\sigma_2\dots\sigma_k}$, until all of $K_1$ is matched, we can reconstruct $\pi_1$. Then we can derive $\rho\pi_1\sigma_2 \dots \sigma_k$.

At a general stage $i$ of the inversion, we will know $\pi_1, \dots, \pi_{i-1}$ and $\sigma_1, \dots, \sigma_{i-1}$ and $K_1, \dots, K_{i-1}$. We use $\rho\pi_1 \dots \pi_{i-1}\sigma_i \dots \sigma_k$ to identify $\gamma_i$ and, hence, $\sigma_i$ and $K_i$ (using $\beta$). Then we get $\pi_i$ from $\delta$, $K_i$, and $\rho\sigma_{i+1} \dots \sigma_k$. After $k$ stages, we know all of $\sigma$ and can recover $\rho$. □

*Proof of Lemma* 5.8. Let $R_i$ be the set of $\rho_i \in N^{\ell_i, \Delta_{i+1}}(G_i)$ such that $C_i$ holds. By Lemma 5.7, the total probability of $R_i$ under the distribution $\mathcal{M}^{\ell_i}(G_i)$ is at least $(1 - 1/n)(1 - 2^{-\log^{b_{i+1}-2} n}) \geq 1 - 2/n$.

By Lemma 5.11 with $H \leftarrow G_i$, $\ell \leftarrow \ell_i$, and $\Delta \leftarrow \Delta_{i+1}$, a *bad* $\rho_i \in R_i$, for which $Tree_{G_{i+1}}(F|_{\rho_i})$ has height at least $s$, can be mapped uniquely to a triple $(\rho_i', \beta, \delta) \in M^{\ell_i + j}(G_i) \times stars(r, j) \times [\Delta_{i+1}]^s$, where $\rho_i'$ extends $\rho_i$ for some integer $j \in [s/2, s]$. We compute the probability of all such $\rho_i \in R_i$ associated with a given $j$, sum up over $j$, and then divide by the probability of $R_i$ to get the probability of a bad restriction conditioned on $R_i$. For fixed $j$, we can bound the probability of all bad $\rho_i \in R_i$ by bounding the ratio of the probability of each such $\rho_i$ to the probability of its image, $(\rho_i', \beta, \delta)$.

Let $I = \mathrm{Im}(\rho_i)$ and $I' = \mathrm{Im}(\rho_i')$. By definition, $I \subset I'$. The ratio of the probability of $\rho_i$ under $\mathcal{M}^{\ell_i}(G_i)$ to that of $\rho_i'$ under $\mathcal{M}^{\ell_i + j}(G_i)$ is precisely

$$\frac{\binom{n_i}{\ell_i + j} |M_{I'}^{\ell_i + j}(G_i)|}{\binom{n_i}{\ell_i} |M_I^{\ell_i}(G_i)|}.$$

Now any matching $\tau' \in M_{I'}^{\ell_i + j}(G_i)$ is an extension of some unique matching $\tau \in M_I^{\ell_i}(G_i)$. If $\tau \in N_I^{\ell_i, \Delta_{i+1}}(G_i)$, then the degrees of all nodes in $G_i|_\tau$ are at most $\Delta_{i+1}$, and so there are at most $\Delta_{i+1}^j$ matchings $\tau' \in M_{I'}^{\ell_i + j}(G_i)$ extending $\tau$. If $\tau \notin N_I^{\ell_i, \Delta_{i+1}}(G_i)$, then the degrees of all nodes in $G_i|_\tau$ are at most $\Delta_i$ because that is true of $G_i$ itself by assumption. Therefore there are at most $\Delta_i^j$ extensions $\tau' \in M_{I'}^{\ell_i + j}(G_i)$ of $\tau$. Since $\rho_i \in R_i$, $|N_I^{\ell_i, \Delta_{i+1}}(G_i)| / |M_I^{\ell_i}(G_i)|$ is at least $1 - 2^{-\log^{b_{i+1}-2} n}$, so the probability ratio is at most

$$\frac{\binom{n_i}{\ell_i + j}}{\binom{n_i}{\ell_i}} [\Delta_{i+1}^j + 2^{-\log^{b_{i+1}-2} n} \Delta_i^j] \leq \left[1 + 2^{1 - \log^{b_{i+1}-2} n} \left(\frac{\Delta_i}{\Delta_{i+1}}\right)^j\right] \left(\frac{\Delta_{i+1}(n_i - \ell_i)}{\ell_i}\right)^j$$

$$< \left[1 + 2^{1 - \frac{\Delta_{i+1}}{6 \log^2 n}} (\log n)^{k_i s}\right] \left(\frac{\Delta_{i+1} n_i}{\ell_i \log^{k_i} n}\right)^j \tag{5.1}$$

$$< \left[1 + 2^{1 - \frac{\Delta_{i+1}}{6 \log^2 n}} (\log n)^{k_i \Delta_{i+1} / \log^3 n}\right] \left(\frac{\Delta_{i+1} n_i}{\ell_i \log^{k_i} n}\right)^j \tag{5.2}$$

$$< \left(\frac{2\Delta_{i+1}}{\log^{k_i} n}\right)^j \tag{5.3}$$

$$= \left(\frac{12 \log^{b_{i+1}} n}{\log^{k_i} n}\right)^j.$$

Inequalities (5.1) and (5.2) follow from $j \leq s \leq \Delta_{i+1}/\log^3 n$ and the definitions of $\Delta_i$ and $\Delta_{i+1}$. Inequality (5.3) follows since $12k_i \log\log n < \log n$ for $n$ sufficiently large and the fact that $n_i/\ell_i = 1/(1-1/\log^{k_i} n)$, which is close to 1. Therefore the total probability of bad $\rho_i \in R_i$ associated with a given $j$ is at most

$$(12\log^{b_{i+1}-k_i} n)^j \times (r/\ln 2)^j \times \Delta_{i+1}^s \leq (20r\log^{b_{i+1}-k_i} n)^j \times (6\log^{b_{i+1}} n)^s.$$

Thus the total probability in question is at most

$$(1-2/n)^{-1}(6\log^{b_{i+1}} n)^s \times \sum_{s/2\leq j\leq s} (20r\log^{b_{i+1}-k_i} n)^j.$$

Since $b_{i+1} = b_i - k_i$ and without loss of generality $20r\log^{b_i-2k_i} n < 1/3$ (otherwise the probability bound in the lemma statement is meaningless), this quantity is at most $2(720r\log^{3b_i-4k_i} n)^{s/2} \leq 2(720r/\log^{b_i/2} n)^{s/2}$ since $3b_i - 4k_i = -b_i/2$. ∎

The above switching lemma will be used to show that, with respect to most matching restrictions, a depth-$h$ formula $A$ over $G$ can be represented by a short decision tree. We build these decision trees inductively on the subformulas of $A$. The tricky part, then, is when we are considering a $\vee$-gate of $A$, all of whose children already have short decision trees. This is exactly where we need to apply a restriction in order to get a "switch." The following definition formalizes this inductive representation by decision trees.

Definition 5.12. *For any graph $G$, let $S_G$ be a set of formulas of depth at most $h$ that is closed under subformulas and defined over $G$. For $\rho = \rho_0 \ldots \rho_{h-1}$ a matching on $G$, we define, for every $0 \leq i < h$, $\mathcal{T}_{\rho_0\ldots\rho_i}$, a mapping from formulas with depth $\leq i+1$ in $S_G$ to matching decision trees. It is defined inductively as follows: For a variable $X_e$, $\mathcal{T}_{\rho_0}(X_e)$ is $Tree_G(X_e)|_{\rho_0}$. For $0 < i < h$, for all formulas $A$ of depth $< i+1$, $\mathcal{T}_{\rho_0\ldots\rho_i}(A)$ is $\mathcal{T}_{\rho_0\ldots\rho_{i-1}}(A)|_{\rho_i}$. For $0 \leq i < h$, for all formulas $A$ of depth $i+1$, if $A = \neg B$, then $\mathcal{T}_{\rho_0\ldots\rho_i}(A)$ is $(\mathcal{T}_{\rho_0\ldots\rho_i}(B))^c$, and otherwise, if the merged form of $A$ is $\bigvee_{j\in J} B_j$, let $F$ be the matching disjunction $\bigvee_{j\in J} disj(\mathcal{T}_{\rho_0\ldots\rho_{i-1}}(B_j))$ and let $\mathcal{T}_{\rho_0\ldots\rho_i}(A)$ be the canonical matching tree $Tree_{G_{i+1}}(F|_{\rho_i})$.*

From the definition of $\mathcal{T}_\rho$, we have that if $\neg A$ is a formula in $S_G$, then $\mathcal{T}_\rho(\neg A) = (\mathcal{T}_\rho(A))^c$. Also, by Lemma 4.12, if $\bigvee_{i\in I} A_i$ is the merged form of some formula $A$ in $S_G$, then $\mathcal{T}_\rho(A)$ represents $\bigvee_{i\in I} disj(\mathcal{T}_\rho(A_i))$.

We would like to bound the heights of the decision trees in the image of $\mathcal{T}_\rho$ with respect to our experiment. Accordingly, we define the following events ($A$ is a formula over the variables of $G$ and $S_G$ is a set of such formulas):

$D_i(A)$: $\mathcal{T}_{\rho_0\ldots\rho_{i-1}}(A)$ has height at most $\log^a n$ if $A$ has depth at most $i$. Here $i \geq 1$.

$D_i(S_G)$: $D_i(A)$ holds for all formulas $A$ in $S_G$. Again, $i \geq 1$.

Lemma 5.13. *Let $a$ and $h$ be positive integers. For each graph $G$, let $S_G$ be a set of formulas closed under subformulas defined on the variables of $G$ such that $|S_G| \leq 2^{\log^a n}$ and each formula $A \in S_G$ has depth at most $h$. There exists a choice of $G$ and $\rho = \rho_0, \ldots, \rho_{h-1}$ such that the following conditions hold:*

1. *$\mathcal{T}_\rho(A)$ has height at most $\log^a n$ for all $A \in S_G$, and*
2. *every node in $G|_\rho$ has degree at least $\log^{a+3} n$.*

*Proof.* We proceed using the probabilistic method and the experiment above. We need to show that $E_h \cap B_h \cap D_h(S_G)$ has nonzero probability.

Now by Lemma 5.5, $\mathbf{Pr}[\neg E_{i+1} \mid E_i] < 2^{-\log^{b_i-1} n}$; by Lemma 5.3, $\mathbf{Pr}[\neg A_i \mid E_i] < 2^{-\log^{b_i-1} n}$; and by Lemma 5.4, $\mathbf{Pr}[\neg B_i \mid E_i] < 2^{-\log^{b_i-1} n}$. Furthermore, by Lemma 5.7,

$\mathbf{Pr}[\neg C_i \mid E_{i+1}] \le 1/n$. Let $A \in S_G$ be of depth $i < h$ with the merged form of $A$ equal to $\bigvee_{j\in J} Q_j$, and let $F$ be the matching disjunction $\bigvee_{j\in J} disj(\mathcal{T}_{\rho_0\ldots\rho_{i-1}}(Q_j))$. Observing that $b_h = b/8^h = (a+3)$, by Lemma 5.8 applied to $F$ with $r = s = \log^a n \le \Delta_h/\log^3 n$, we have

$$\begin{aligned}\mathbf{Pr}[\neg D_{i+1}(A) \mid E_{i+1} \wedge A_i \wedge D_i \wedge A_{i+1} \wedge C_i] &\le 2(720/\log^{b_i/2-a} n)^{(\log^a n)/2}\\ &\le 2(720/\log^{b_{h-1}/2-a} n)^{(\log^a n)/2}\\ &\le 2(720/\log^{3a+3} n)^{(\log^a n)/2} < 2^{-\log^a n}/n.\end{aligned}$$

Therefore, $\mathbf{Pr}[\neg D_{i+1} \mid E_{i+1} \wedge A_i \wedge D_i \wedge A_{i+1} \wedge C_i] \le 1/n$ since each $S_G$ contains at most $2^{\log^a n}$ disjunctions of depth $i+1$.

Therefore the total probability that some $E_i$, $A_i$, $B_i$, $C_i$, or $D_i$ fails is at most

$$\begin{aligned}&\sum_{i=0}^{h-1}\mathbf{Pr}[\neg E_{i+1} \mid E_i] + \sum_{i=0}^{h}\mathbf{Pr}[\neg A_i \mid E_i] + \sum_{i=0}^{h}\mathbf{Pr}[\neg B_i \mid E_i] + \sum_{i=0}^{h-1}\mathbf{Pr}[\neg C_i \mid E_{i+1}]\\ &\quad + \mathbf{Pr}[\neg D_1 \mid E_1 \wedge A_0 \wedge A_1 \wedge C_0]\\ &\quad + \mathbf{Pr}[\neg D_2 \mid E_2 \wedge A_1 \wedge D_1 \wedge A_2 \wedge C_1] + \cdots\\ &\quad + \mathbf{Pr}[\neg D_h \mid E_h \wedge A_{h-1} \wedge D_{h-1} \wedge A_h \wedge C_{h-1}].\end{aligned}$$

In total there are $5h+2$ terms in this sum, each of which is at most $1/n$, and thus the whole probability is $< 1$. □

The following three lemmas are adapted from [27].

LEMMA 5.14. *For any $G$, $\rho = \rho_0 \ldots \rho_{h-1}$, let $\Pi_G$ be a depth-$h$ $\mathcal{F}$-proof of $PHP(G)$, and let $\mathcal{T}_\rho$ be the mapping associated with* cl$(\Pi)$. *Let $C$ be a line in $\Pi$, and let $\mathcal{A}$ be the immediate ancestors of $C$ (if there are any), so that $\mathcal{A} \vdash C$. Let $\mathcal{B}$ be the subformulas of $\mathcal{A}$ and $C$ mentioned in the application of the rule which derives $C$ from $\mathcal{A}$. Finally, let $\sigma$ be a matching which extends soundly some $\sigma_A \in path(\mathcal{T}_\rho(A))$ for each $A \in \mathcal{A}$, some $\sigma_B \in path(\mathcal{T}_\rho(B))$ for each $B \in \mathcal{B}$, and some $\sigma_C \in path(\mathcal{T}_\rho(C))$. If $disj(\mathcal{T}_\rho(A))|_\sigma \equiv 1$ for all $A \in \mathcal{A}$, then $disj(\mathcal{T}_\rho(C))|_\sigma \equiv 1$.*

*Proof.* Let $\Lambda = \mathcal{A} \cup \mathcal{B} \cup \{C\}$. First note the following facts, where $\alpha, \beta \in \Lambda$ and $D(\alpha)$ is an abbreviation for $disj(\mathcal{T}_\rho(\alpha))$:

- $D(\alpha)|_\sigma \equiv 0$ or $D(\alpha)|_\sigma \equiv 1$;
- if $\neg\alpha \in \Lambda$, then $D(\neg\alpha)|_\sigma \equiv 1$ if and only if $D(\alpha)|_\sigma \equiv 0$;
- if $(\alpha \vee \beta) \in \Lambda$, then $D(\alpha \vee \beta)|_\sigma \equiv 1$ if and only if $D(\alpha)|_\sigma \equiv 1$ or $D(\beta)|_\sigma \equiv 1$.

Now consider the rule $R$ used to derive $C$ formulated as in the examples from section 3. The application of $R$ substitutes subformulas $A_p, A_q, A_r, \ldots$ in $\Lambda$ for each of the atoms $p, q, r, \ldots$ in $R$, and there is a derived correspondence mapping subformulas $F$ appearing in $R$ to formulas $A_F \in \Lambda$. Define a function $\tau$ on the atoms of $R$ by $\tau(p) = D(A_p)|_\sigma$ for each such atom $p$. By the first property, $\tau$ is a truth assignment to these atoms. Furthermore, by the other two properties, the truth assignment $\tau$ extends to all subformulas $F$ in $R$ so that $\tau(F) = D(A_F)|_\sigma$. Since $R$ is sound, if $\tau$ satisfies all formulas in $\mathcal{A}$, it will satisfy $C$ and thus $D(C)|_\sigma \equiv 1$. □

LEMMA 5.15. *Let $a, h > 0$. For each $G$, assume that $\Pi_G$ is a proof in $\mathcal{F}$ of $PHP(G)$ of size at most $2^{\log^a n}$ and depth at most $h$. There exists a choice of $G$ and $\rho = \rho_0, \ldots, \rho_{h-1}$ such that, for any line $C$ in $\Pi$, all leaves of $\mathcal{T}_\rho(C)$ are labelled by* 1.

*Proof.* Let $\rho$ and $G$ be as defined in Lemma 5.13 applied with $S_G = cl(\Pi_G)$. We proceed by (complete) induction on the lines in the proof. Assume every leaf of $\mathcal{T}_\rho$ for any line preceding $C$ is labelled 1. Let $\mathcal{A}$, $\mathcal{B}$, $\Lambda$ be as in Lemma 5.14. For any leaf

$l$ of $\mathcal{T}_\rho(C)$, we use Lemma 4.6 to find $\sigma$ that extends $path(l)$ and extends a matching in each of the sets $path(\mathcal{T}_\rho(A))$ for all $A \in \mathcal{A}$ and $path(\mathcal{T}_\rho(B))$ for all $B \in \mathcal{B}$. This is possible since there are at most $f$ trees to consider, and by Lemma 5.13 the sum of their heights is at most $f \log^a n < \log^{a+1} n$, which is less than the degree of $G_h$.

By assumption, $disj(\mathcal{T}_\rho(A))|_\sigma \equiv 1$ for all $A$ in $\mathcal{A}$. Hence, by Lemma 5.14, $disj(\mathcal{T}_\rho(C))|_\sigma \equiv 1$, so $l$ must be labelled 1. □

LEMMA 5.16. *For any $G$ and any $\rho = \rho_0, \ldots, \rho_{h-1}$, all leaves of $\mathcal{T}_\rho(PHP(G))$ have label* 0.

*Proof.* It suffices to show that $\mathcal{T}_\rho$ applied to each of the following types of formulas has all leaves labelled 0:

1. $\neg(\neg X_e \vee \neg X_{e'})$ for $e, e' \in E; e = \{i, k\}, e' = \{j, k\}; i, j \in V_1; i \neq j; k \in V_2$.
2. $\neg(\neg X_e \vee \neg X_{e'})$ for $e, e' \in E; e = \{k, i\}, e' = \{k, j\}; i, j \in V_2; i \neq j; k \in V_1$.
3. $\neg \bigvee_{j\in\Gamma(i)} X_{\{i,j\}}$ for $i \in V_1$.
4. $\neg \bigvee_{i\in\Gamma(j)} X_{\{i,j\}}$ for $j \in V_2$.

In fact, we will show that $\mathcal{T}_\rho$ applied to the complement of each of these formulas has all leaves labelled 1.

For a formula of the first type, $T = \mathcal{T}_\rho(\neg X_e \vee \neg X_{e'})$ must represent $disj(\mathcal{T}_\rho(\neg X_e)) \vee disj(\mathcal{T}_\rho(\neg X_{e'}))$. If $\rho$ sets the value of either $X_e$ or $X_{e'}$, then it must set one of $\neg X_e$ or $\neg X_{e'}$ to 1, and thus all leaves of $\mathcal{T}_\rho(\neg X_e \vee \neg X_{e'})$ are certainly labelled 1. Otherwise, for $l$ a leaf of $T$, $path(l)$ cannot contain both $e$ and $e'$. Without loss of generality, it does not contain $e$. By Lemma 4.6 applied to graph $G_h$, we can find $\sigma$ that extends $path(l)$ and is an extension of some matching in $\mathcal{T}_\rho(\neg X_e)$. But then $disj(\mathcal{T}_\rho(\neg X_e))|_\sigma \equiv 1$, so $l$ must be labelled 1. The argument is the same for formulas of the second type.

For a formula of the third type, $T = \mathcal{T}_\rho(\bigvee_{j\in\Gamma(i)} X_{\{i,j\}})$ must represent $\bigvee_{j\in\Gamma(i)} disj(\mathcal{T}_\rho(X_{\{i,j\}}))$. Hence, if $\rho$ sets $X_{\{i,j\}}$ to 1 for some $j \in \Gamma(i)$, then all leaves of $T$ are certainly labelled 1. Otherwise, for a leaf $l$ of $T$, if $path(l)$ touches node $i$, then $\bigvee_{j\in\Gamma(i)} disj(\mathcal{T}_\rho(X_{\{i,j\}}))|_{path(l)} \equiv 1$. Finally, if $path(l)$ does not touch node $i$, extend it to $\sigma = path(l) \cup \{i, j\}$ for some $j$ such that $X_{\{i,j\}}$ is not set by $\rho$. Then $disj(\mathcal{T}_\rho(X_{\{i,j\}}))|_\sigma \equiv 1$, so $l$ is labelled 1. Formulas of the fourth type follow in the same way. □

THEOREM 5.17. *For any $a, h > 0$, there exists a $c$ such that there is a bipartite graph $G$ from $m = n + n/\log^c n$ pigeons to $n$ holes that has no depth-$h$, $2^{\log^a n}$-size $\mathcal{F}$-proof of $PHP(G)$*

*Proof.* Assume that for all such $G$, there is a proof $\Pi_G$ of the required depth and size. For the $G$ in Lemma 5.15 there exists a $\rho$ such that, for every line $A$ in $\Pi_G$, $\mathcal{T}_\rho(A)$ has all leaves labelled 1. But $\mathcal{T}_\rho(PHP(G))$ has all leaves labelled 0 by Lemma 5.16. If $\Pi_G$ is to be a proof of $PHP(G)$, then $PHP(G)$ must appear in $\Pi_G$, so we have a contradiction. □

COROLLARY 5.18. *For any $a, h > 0$, there exists a $c$ such that there is no depth-$h$, $2^{\log^a n}$-size $\mathcal{F}$-proof of $PHP = PHP(K_{m,n})$ from $m = n + n/\log^c n$ pigeons to $n$ holes.*

## 6. Open questions.

Among the many unresolved proof complexity questions regarding the pigeonhole principle (see [24]) the most important open problem is to resolve the complexity of the weak pigeonhole principle with $2n$ or more pigeons and $n$ holes. This would have many implications for the metamathematics of the $P$ versus $NP$ statement, the complexity of approximate counting, and the proof-theoretic strength underlying elementary number theory.

In the proof presented here, we derived a switching lemma using simple restrictions that limit the space of truth assignments to a subcube where certain variables are set to 0 or to 1. While this fails with $2n$ pigeons, a more general class of restrictions may suffice. Possible generalizations include the projections suggested in [28], which also allow identification of variables, or restrictions given by linear equations. Two important results [15, 8] for bounded-depth Frege systems already employ such generalized switching lemmas in cases where direct restrictions fail (although the latter use is implicit). Bounded-depth Frege reductions, such as those in [8], may also be useful for resolving the $2n$ to $n$ case.

A potentially simpler problem that still gets to the heart of the matter is to prove quasi-polynomial lower bounds for $Res(\text{polylog } n)$ proofs of the weak pigeonhole principle which would match the upper bounds in [18]. New techniques seem to be required, however: it is interesting to note that our technique does not suffice for proving a lower bound on $PHP_n^{2n}$ even in $Res(\log n)$ (i.e., when $m = 2n$, our experiment is not likely to succeed even in the first round). This is because a successful switch is predicated on the restricted graph's having low degree. In this case, it would require a degree so low that the decision tree argument could not be carried out.

**Acknowledgments.** We are very grateful to Alan Woods for suggesting this problem a while back and for the many valuable comments and insights that he shared with us. We also want to thank Mike Molloy for some helpful discussions. Finally, we are grateful to Miki Ajtai for hinting that there may just not be a polynomial-size bounded-depth proof.

# A COMPLETE CHARACTERIZATION OF THE ALGEBRAS OF MINIMAL BILINEAR COMPLEXITY[*]

MARKUS BLÄSER[†]

**Abstract.** Let $R(A)$ denote the rank (also called bilinear complexity) of a finite dimensional associative algebra $A$. A fundamental lower bound for $R(A)$ is the so-called Alder–Strassen bound $R(A) \geq 2\dim A - t$, where $t$ is the number of maximal twosided ideals of $A$. An algebra is called an algebra of minimal rank if the Alder–Strassen bound is tight, i.e., $R(A) = 2\dim A - t$.

As the main contribution of this work, we characterize all algebras of minimal rank over arbitrary fields. This finally solves an open problem in algebraic complexity theory; see, for instance, [V. Strassen, *Handbook of Theoretical Computer Science*, J. van Leeuwen, ed., Elsevier Science, New York, 1990, Vol. A, pp. 634–672, section 12, Problem 4] or [P. Bürgisser, M. Clausen, and M. A. Shokrollahi, *Algebraic Complexity Theory*, Springer, New York, 1997, Problem 17.5].

**Key words.** associative algebras, Alder–Strassen bound, bilinear complexity, rank

**DOI.** 10.1137/S0097539703438277

## 1. Introduction.

One of the most important problems in algebraic complexity theory is the question about the costs of multiplication, say of matrices, triangular matrices, or polynomials (modulo a fixed polynomial). Let $A$ be a finite dimensional associative $k$-algebra with identity 1. By fixing a basis of $A$, say $v_1, \dots, v_N$, we can define a set of bilinear forms corresponding to the multiplication in $A$. If $v_\mu v_\nu = \sum_{\kappa=1}^N \alpha_{\mu,\nu}^{(\kappa)} v_\kappa$ for $1 \leq \mu, \nu \leq N$ with *structural constants* $\alpha_{\mu,\nu}^{(\kappa)} \in k$, then these constants and the equation

$$\left(\sum_{\mu=1}^N X_\mu v_\mu\right)\left(\sum_{\nu=1}^N Y_\nu v_\nu\right) = \sum_{\kappa=1}^N b_\kappa(X,Y) v_\kappa$$

define the desired bilinear forms $b_1, \dots, b_N$. The *rank* (also called *bilinear complexity*) of $b_1, \dots, b_N$ is the smallest number of essential bilinear multiplications necessary and sufficient to compute $b_1, \dots, b_N$ from the indeterminates $X_1, \dots, X_N$ and $Y_1, \dots, Y_N$. More precisely, the bilinear complexity of $b_1, \dots, b_N$ is the smallest number $r$ of products $p_\rho = f_\rho(X) \cdot g_\rho(Y)$ with linear forms $f_\rho$ and $g_\rho$ in the $X_i$ and $Y_j$, respectively, such that $b_1, \dots, b_N$ are contained in the linear span of $p_1, \dots, p_r$. From this definition, it is obvious that the bilinear complexity of $b_1, \dots, b_N$ is independent of the choice of $v_1, \dots, v_N$; thus we may speak about the rank $R(A)$ (also called bilinear complexity) of (the multiplication in) $A$. For a modern introduction to this topic and to algebraic complexity theory in general, we recommend [9].

A fundamental lower bound for the rank of an associative algebra $A$ is the so-called Alder–Strassen bound [1]. It states that the rank of $A$ is bounded by

$$R(A) \geq 2\dim A - t, \tag{1}$$

[*]Received by the editors December 3, 2003; accepted for publication (in revised form) July 28, 2004; published electronically December 1, 2004. Parts of this work were presented at the 17th Annual IEEE Computational Complexity Conference, Montreal, 2002 [5], and at the 19th Annual Symposium on Theoretical Aspects of Computer Science, Berlin, 2003 [6].

where $t$ is the number of maximal twosided ideals in $A$. This bound is tight in the sense that there are algebras for which equality holds. Such algebras are called *algebras of minimal rank*. These are the structures that allow the most efficient multiplication. While the property that (1) is tight of course completely characterizes the algebras of minimal rank, it is desirable to have an algebraic characterization, too, i.e., a characterization in terms of their algebraic structure. A lot of effort has been spent to achieve such an algebraic characterization. There has been some success for certain classes of algebras, like division algebras, commutative algebras, etc., but up to now, the general case is still unsolved. As the main contribution of the present work, we determine *all* algebras of minimal rank over *arbitrary* fields, thus solving this problem completely.

**1.1. Previous results.** One prominent algebra of minimal rank is $k^{2\times 2}$, the algebra of $2 \times 2$-matrices [20]. It has been a longstanding open problem whether $k^{3\times 3}$ is of minimal rank or not; see [9, Problem 17.1]. The idea was that if one could characterize all algebras of minimal rank in terms of their algebraic structure, then one would simply have to verify whether $k^{3\times 3}$ has this structure or not. Meanwhile, we know that $k^{3\times 3}$ is not of minimal rank [3]. Nevertheless, the characterization of the algebras of minimal rank is an interesting and important topic in algebraic complexity theory; see, e.g., [21, section 12, Problem 4] or [9, Problem 17.5].

De Groote [14] determined all division algebras $D$ of minimal rank. Over infinite fields, these are all simply generated extension fields of $k$. If $k$ is finite, then $D$ has minimal rank if, in addition, $\#k \geq 2\dim D - 2$; the latter result follows from the classification of the algorithm variety of polynomial multiplication modulo some irreducible polynomial by Winograd [22]. De Groote and Heintz [16] characterize all commutative algebras of minimal rank over infinite fields. Next Büchi and Clausen [8] describe all local algebras of minimal rank over infinite fields. Then Heintz and Morgenstern [18] determine all basic algebras over algebraically closed fields. Finally, all semisimple algebras of minimal rank over arbitrary fields and all algebras of minimal rank over algebraically closed fields have been characterized [4]: Semisimple algebras of minimal rank are isomorphic to a finite direct product of division algebras of minimal rank (as described by de Groote and Winograd) and of copies of $k^{2\times 2}$. Algebras of minimal rank over algebraically closed fields are isomorphic to a direct product of copies $k^{2\times 2}$ and a basic algebra of minimal rank (as characterized by Heintz and Morgenstern).

**1.2. New results.** As our main result, we characterize all algebras of minimal rank over arbitrary fields (Theorem 35). After more than two decades, this completely answers a major open problem in algebraic complexity theory.

An algebra $A$ over an arbitrary field $k$ is an algebra of minimal rank iff

$$A \cong C_1 \times \cdots \times C_s \times \underbrace{k^{2\times 2} \times \cdots \times k^{2\times 2}}_{u \text{ times}} \times B, \tag{2}$$

where $C_1, \ldots, C_s$ are local algebras of minimal rank with $\dim(C_\sigma / \operatorname{rad} C_\sigma) \geq 2$ (as characterized by Büchi and Clausen) and $B$ is a superbasic algebra of minimal rank. Any of the integers $s$ and $u$ may be zero, and the factor $B$ is optional. This decomposition is unique (up to permutations and isomorphms), as there are essentially three types of algebras involved and each of them has a different image modulo $\operatorname{rad} A$.

A local algebra $C_\sigma$ with $\dim(C_\sigma / \operatorname{rad} C_\sigma) \geq 2$ is of minimal rank iff $C_\sigma \cong k[X]/(p_\sigma(X)^{d_\sigma})$ for some irreducible polynomial $p_\sigma$ with $\deg p_\sigma \geq 2$, $d_\sigma \geq 1$ and the ground field $k$ fulfills $\#k \geq 2\dim C_\sigma - 2$.

An algebra $B$ is called superbasic if $B/\operatorname{rad} B = k^t$ for some $t$. A superbasic algebra $B$ is of minimal rank iff there exist $w_1, \dots, w_m \in \operatorname{rad} B$ with $w_i^2 \neq 0$ and $w_i w_j = 0$ for $i \neq j$ such that

$$\operatorname{rad} B = \mathsf{L}_B + Bw_1B + \cdots + Bw_mB = \mathsf{R}_B + Bw_1B + \cdots + Bw_mB$$

and $k$ fulfills $\#k \geq 2N(B) - 2$, where $N(B)$ denotes the largest natural number $s$ such that $(\operatorname{rad} B)^s \neq \{0\}$. Here $\mathsf{L}_B$ and $\mathsf{R}_B$ denote the left and right annihilator of $\operatorname{rad} B$ (see section 2.1 for exact definitions). The integer $m$ may be zero.

**1.3. Algorithmic aspects.** How can the characterization result be applied? Given a particular algebra, one can of course check by hand whether it fulfills the properties stated in our characterization result. An example for this is, for instance, given by Heintz and Morgenstern [18].

One can also consider the algorithmic variant, that is, given the structural constants with respect to some basis, decide algorithmically whether the corresponding algebra $A$ is an algebra of minimal rank. One possible route is the following. We only give a sketch since a full algorithm would be beyond the scope of this paper. The algorithm uses two black-boxes: computing a basis of the radical and computing a set of orthogonal primitive idempotents. The efficiency of the algorithm depends on how well these tasks can be performed for the class of algebras in consideration. Friedl and Rónyai [13] are the first to deal with this problem. For the latest result, see [12] and the references given there.

We first compute a basis of the radical. If we compute all possible products of two elements from this basis, we get a set of generators for $(\operatorname{rad} A)^2$. Any maximal subset of the basis of the radical that is linearly independent modulo $(\operatorname{rad} A)^2$ generates $(\operatorname{rad} A)$. Denote such a set by $g_1, \dots, g_m$. Any element in the radical can be expressed as a polynomial in $g_1, \dots, g_m$.

Next we compute a set of orthogonal primitive idempotents $w_1, \dots, w_s$ of $A$ with $w_1 + \cdots + w_s = 1$. From this, it is possible to compute a central decomposition $e_1, \dots, e_t$ of the identity in $A/\operatorname{rad} A$ such that each $e_\tau$ is the identity of a simple component of $A/\operatorname{rad} A$. Using $w_1, \dots, w_s$, these elements can be lifted to a decomposition $f_1, \dots, f_t$ of the identity in $A$.

We first check whether $e_\tau(A/\operatorname{rad} A)e_\tau$ has dimension one (i.e., is isomorphic to $k$) or dimension at least two.

In the second case, we first check whether $e_\tau(A/\operatorname{rad} A)e_\tau$ is simply generated, i.e., it has only one primitive idempotent. In this case $e_\tau(A/\operatorname{rad} A)e_\tau$ is a division algebra. Then we check whether $f_\tau A f_\tau$ is simply generated. Since everything is finite dimensional, we just can choose a random element and check whether it generates the radical, i.e., whether it generates a vector space whose dimension equals $\dim(f_\tau A f_\tau)$. (Here a random element means that we choose the coefficients in the linear combination of basis vectors uniformly at random from some small subset of $k$. If $f_\tau A f_\tau$ is simply generated, then this is a generator with high probability.) If $f_\tau A f_\tau$ is not simply generated, we just check whether it is isomorphic to $k^{2\times 2}$.

We are left with the first case. Let $f$ denote the sum of the $f_\tau$ corresponding to all $e_\tau$ in the first case. Then $fAf = B$. Since we know a set of generators for $\operatorname{rad} A$, we can compute a set of generators for $B \cap \operatorname{rad} A$ by multiplying by $f$ from the left and the right. We now try to find a set of generators such that one of them annihilates all the others. Once we achieve this, we can proceed inductively. We replace our generators $g_1, \dots, g_q$ by $g_1, g_2 - \alpha_2 g_1, \dots, g_q - \alpha_q g_1$ and check whether there are choices of $\alpha$ such that $g_1 \cdot (g_i - \alpha_i g_1)$ is contained in the ideal generated by $g_2, \dots, g_q$. Let $g_i' = g_i - \alpha_i g_2$. Then we try to find scalars $\beta_2, \dots, \beta_q$ such that $g_1 - \beta_2 g_2' - \dots - \beta_q g_q'$ now annihilates all the $g_i'$. (Everything is linear algebra here.) Finally we take all the generators of $\operatorname{rad} B$ whose square is nonzero, compute the left and right annihilators of $\operatorname{rad} B$, and check whether $\operatorname{rad} A$ can be written as in the characterization result.

**1.4. Organization of the paper.** In section 2, we first recall some basic facts about the structure of associative algebras. Then we describe the model of bilinear complexity. Finally, we briefly mention some important lower bounds, most of them due to Alder and Strassen, to which we will refer frequently in our proofs.

In section 3, we characterize superbasic algebras of minimal rank. We follow ideas used by Heintz and Morgenstern over algebraically closed fields and give a smoothened and simplified proof.

The proof of the preliminary characterization results over algebraically closed [4] and perfect [5] fields made use of the existence of a subalgebra $B$ of $A$ with $B \oplus \operatorname{rad} A = A$ and $B \cong A/\operatorname{rad} A$. Over perfect (and henceforth over algebraically closed) fields, such an algebra always exists by the so-called Wedderburn–Malcev theorem. Over a nonperfect field, there are examples for which such an algebra does not exist. In section 4, we show that there always exists a subalgebra $B' \subseteq A$ that is sufficiently "similar" to the algebra $B$. Using this algebra $B'$, we finally prove our main result in section 5.

## 2. Preliminaries.

**2.1. Structure of associative algebras.** We collect some elementary properties of associative algebras. The term *algebra* always means a finite dimensional associative algebra with identity 1 over some field $k$. The terms *left module* and *right module* always mean a finitely generated left module and right module, respectively, over some algebra $A$. By the embedding $\alpha \mapsto \alpha \cdot 1$, $k$ becomes a subalgebra of $A$. Hence, every $A$-left module and $A$-right module is also a finite dimensional $k$-vector space. If we speak of a basis of an algebra or a module, we always mean a basis of the underlying vector space. Further material as well as proofs of the mentioned properties can be found in [19, 10, 11].

A left ideal $I$ (and in the same way, a right ideal or twosided ideal) is called *nilpotent* if $I^n = \{0\}$ for some positive integer $n$.

FACT 1. *For all finite dimensional algebras $A$ the following hold:*

1. *The sum of all nilpotent left ideals of $A$ is a nilpotent twosided ideal, which contains every nilpotent right ideal of $A$. This twosided ideal is called the* radical *of $A$ and is denoted by* $\operatorname{rad} A$.
2. *The quotient algebra $A/\operatorname{rad} A$ contains no nilpotent ideals other than the zero ideal.*
3. *The radical of $A$ is contained in every maximal twosided ideal of $A$.*
4. *The algebras $A$ and $A/\operatorname{rad} A$ have the same number of maximal twosided ideals.*

We call an algebra $A$ *semisimple* if $\operatorname{rad} A = \{0\}$. By the above fact, $A/\operatorname{rad} A$ is semisimple. An algebra $A$ is called *simple* if there are no twosided ideals in $A$ except the zero ideal and $A$ itself.

We now describe some of the most important ways to construct new algebras from given ones: If $A$ and $B$ are $k$-algebras, then the direct product $A \times B$ with componentwise addition and multiplication is again a $k$-algebra. The set of all $n \times n$-matrices with entries from $A$ forms a $k$-algebra (with the usual definition of addition and multiplication of matrices). This algebra is denoted by $A^{n\times n}$.

We denote the set of all units of an algebra $A$, that is, the set of all invertible elements, by $A^\times$. An algebra $D$ is called a *division algebra* if $D^\times = D \setminus \{0\}$. An algebra $A$ is called *local* if $A/\operatorname{rad} A$ is a division algebra, and $A$ is called *basic* if $A/\operatorname{rad} A$ is a direct product of division algebras. Since we do not know a better name, we call $A$ *superbasic* if $A/\operatorname{rad} A \cong k^t$ for some $t$.

For an algebra $A$, $\mathsf{L}_A$ and $\mathsf{R}_A$ denote the *left and right annihilator* of $\operatorname{rad} A$; that is,

$$\begin{aligned} \mathsf{L}_A &= \{x \in \operatorname{rad} A \mid x(\operatorname{rad} A) = \{0\}\} \quad \text{and} \\ \mathsf{R}_A &= \{x \in \operatorname{rad} A \mid (\operatorname{rad} A)x = \{0\}\}. \end{aligned}$$

If $x \in A$, we denote by $AxA$ the ideal generated by $x$. If $A$ is commutative, we will also write $(x)$ for short. Furthermore, $k[x]$ denotes the smallest subalgebra of $A$ that contains $x$. If $x_1, \dots, x_m \in A$ mutually commute, then $k[x_1, \dots, x_m]$ denotes the smallest subalgebra of $A$ that contains $x_1, \dots, x_m$. For elements $v_1, \dots, v_n$ of some vector space, $\operatorname{lin}\{v_1, \dots, v_n\}$ denotes their linear span. Occasionally, we will denote this span also by $kv_1 + \cdots + kv_n$.

The following fundamental theorem describes the structure of semisimple algebras.

THEOREM 2 (Wedderburn). *Every finite dimensional semisimple algebra is isomorphic to a finite direct product of simple algebras. Every finite dimensional simple $k$-algebra $A$ is isomorphic to an algebra $D^{n\times n}$ for an integer $n \geq 1$ and a $k$-division algebra $D$. The integer $n$ and the algebra $D$ are uniquely determined by $A$ (the latter up to isomorphism).*

Wedderburn's theorem holds in a similar manner for modules over simple algebras. If $A$ is an algebra, let $A^{n\times m}$ denote the vector space of all $n \times m$-matrices with entries from $A$.

THEOREM 3 (Wedderburn). *Let $A$ be a simple algebra with $A \cong D^{n\times n}$ for some division algebra $D$. For every $A$-left module $M \neq \{0\}$ there is a (unique) integer $m \geq 1$ such that $M$ is isomorphic to $D^{n\times m}$.*

If $C$ and $D$ are algebras and $M$ is a $C$-left module that is also a $D$-right module, then the module $M$ is called a *$(C, D)$-bimodule* if, in addition, $(am)b = a(mb)$ for all $a \in C$, $m \in M$, and $b \in D$. If $C = D$, $M$ is also called a $C$-bimodule for short.

We will also need the following consequence of Nakayama's lemma. It is a useful criterion for checking whether an element in an algebra is invertible or not.

LEMMA 4 (Nakayama). *An element $x$ of an associative algebra $A$ is invertible iff its image under the canonical projection in $A/\operatorname{rad} A$ is invertible.*

This version of Nakayama's lemma can be easily derived from the more general version [11, Lemma, 3.1.4].

$A/\operatorname{rad} A$ is a semisimple algebra. It is an interesting question whether $A/\operatorname{rad} A$ is also a subalgebra of $A$. This question is answered by the Wedderburn–Malcev theorem. For its proof, see [11, Theorem 6.2.1].

THEOREM 5 (Wedderburn–Malcev). *If $A/\operatorname{rad} A$ is a separable algebra, then there is a subalgebra $S \subseteq A$ such that $S \cong A/\operatorname{rad} A$ and $S \oplus \operatorname{rad} A = A$.*

It is not necessary to define precisely what a separable algebra is. We only need the following two sufficient conditions: Every algebra over a perfect field is separable. If an algebra is of the form $k^{n_1\times n_1} \times \cdots \times k^{n_t\times n_t}$, then it is separable.

**2.2. Model of computation.** We use a coordinate-free definition of rank, which is appropriate when dealing with algebras of minimal rank; see [9, Chapter 14]. For a vector space $V$, $V^*$ denotes the dual space of $V$, that is, the vector space of all linear forms on $V$.

DEFINITION 6. *Let $k$ be a field; $U$, $V$, and $W$ be finite dimensional vector spaces over $k$; and $\phi : U \times V \to W$ be a bilinear map.*

1. *A sequence $\beta = (f_1, g_1, w_1, \dots, f_r, g_r, w_r)$ such that $f_\rho \in U^*$, $g_\rho \in V^*$, and $w_\rho \in W$ is called a* bilinear computation *of length $r$ for $\phi$ if*

$$\phi(u, v) = \sum_{\rho=1}^{r} f_\rho(u) g_\rho(v) w_\rho \quad \textit{for all } u \in U, v \in V.$$

2. *The length of a shortest bilinear computation for $\phi$ is called the* bilinear complexity *or the* rank *of $\phi$ and is denoted by $R(\phi)$.*
3. *If $A$ is a finite dimensional associative $k$-algebra, then the rank of $A$ is defined as the rank of the multiplication map of $A$, which is a bilinear map $A \times A \to A$. The rank of $A$ is denoted by $R(A)$.*

Let $\beta = (f_1, g_1, w_1, \dots, f_r, g_r, w_r)$ be a bilinear computation for an algebra $A$. Let $a, b, c \in A^\times$. We have

$$xy = a^{-1}(axb^{-1})(byc^{-1})c = \sum_{\rho=1}^{r} f_\rho(axb^{-1}) g_\rho(byc^{-1}) a^{-1} w_\rho c$$

for all $x, y \in A$. Therefore $\tilde{\beta} = (\tilde{f}_1, \tilde{g}_1, \tilde{w}_1, \dots, \tilde{f}_r, \tilde{g}_r, \tilde{w}_r)$ is a bilinear computation for $A$, where $\tilde{f}_\rho$, $\tilde{g}_\rho$, and $\tilde{w}_\rho$ are defined by $\tilde{f}_\rho(x) = f_\rho(axb^{-1})$ for all $x \in A$, $\tilde{g}_\rho(y) = g_\rho(byc^{-1})$ for all $y \in A$, and $\tilde{w}_\rho = a^{-1} w_\rho c$. This defines an equivalence relation on the set of all computations of length $r$ for $A$. This process of replacing $\beta$ by $\tilde{\beta}$ is called *sandwiching.*

We will mainly use sandwiching in the following situation: Assume that the linear forms $f_1, \dots, f_N$ of $\beta$ form a basis of $A^*$. Let $x_1, \dots, x_N$ be the dual basis of $f_1, \dots, f_N$. Now $a^{-1}x_1 b, \dots, a^{-1}x_N b$ is the dual basis of the linear forms $\tilde{f}_1, \dots, \tilde{f}_N$ of $\tilde{\beta}$. Sandwiching allows us to replace $x_1, \dots, x_N$ by $a^{-1}x_1 b, \dots, a^{-1}x_N b$.

**2.3. Lower bound techniques.** Next, we gather some of the lower bound techniques utilized by Alder and Strassen. Beside the original paper [1], [15, Chapter IV.2] and [9, Chapter 17] are excellent treatments of the results of Alder and Strassen. We have taken the term *separate* and the extension lemma from those sources, but everything is also contained in the work of Alder and Strassen [1].

DEFINITION 7. *Let $U$, $V$, and $W$ be vector spaces over some field $k$, and let $\beta = (f_1, g_1, w_1, \dots, f_r, g_r, w_r)$ be a computation for a bilinear map $\phi : U \times V \to W$. Let $U_1 \subseteq U$, $V_1 \subseteq V$, and $W_1 \subseteq W$ be subspaces. The computation $\beta$* separates $(U_1, V_1, W_1)$ *if there are disjoint sets of indices $I, J \subseteq \{\rho \mid w_\rho \notin W_1\}$ such that*

$$U_1 \cap \bigcap_{i \in I} \ker f_i = \{0\} \quad \textit{and} \quad V_1 \cap \bigcap_{j \in J} \ker g_j = \{0\}.$$

The latter condition is equivalent to the condition that $(f_i|_{U_1})_{i \in I}$ and $(g_j|_{V_1})_{j \in J}$ generate the dual spaces $U_1^*$ and $V_1^*$, respectively.

If $\phi : U \times V \to W$ is a bilinear map and $U_1 \subseteq U$ and $V_1 \subseteq V$ are subspaces, then $(u + U_1, v + V_1) \mapsto \phi(u, v) + \tilde{W}$ defines a bilinear map $U/U_1 \times V/V_1 \to W/\tilde{W}$, where

$\tilde{W} := \mathrm{lin}\{\phi(U_1, V) + \phi(U, V_1)\}$. We denote this map by $\phi/(U_1 \times V_1)$. It is called the *quotient* of $\phi$ by $U_1$ and $V_1$. The following lemma (see [9] for a proof) provides a lower bound for the rank of a bilinear map in terms of the rank of a quotient of it.

LEMMA 8. *Let $U$, $V$, and $W$ be vector spaces, and let $\beta = (f_1, g_1, w_1, \dots, f_r, g_r, w_r)$ be a bilinear computation for some bilinear map $\phi : U \times V \to W$. Let $U_1 \subseteq U$, $V_1 \subseteq V$, and $W_1 \subseteq W$ be subspaces such that $\beta$ separates $(U_1, V_1, W_1)$. Let $\pi$ be an endomorphism of $W$ such that $W_1 \subseteq \ker \pi$. Then*

$$r \geq R\,(\pi \circ \phi/U_1 \times V_1) + \dim U_1 + \dim V_1 + \#\{\rho \mid w_\rho \in W_1\}.$$

COROLLARY 9. *Let $A$ be an algebra and $I \subseteq A$ a twosided ideal. Let $\beta$ be a bilinear computation for $A$ of length $r$ that separates $(I, I, \{0\})$. Then*

$$r \geq R\,(A/I) + 2 \dim I.$$

Together with Corollary 9, the next lemma yields the first of the two important bounds established by Alder and Strassen, namely, for any algebra $A$

$$R(A) \geq R\,(A/\mathrm{rad}\, A) + 2 \dim A. \tag{3}$$

LEMMA 10. *Let $\beta$ be a bilinear computation for an associative algebra $A$. Then $\beta$ separates* $(\mathrm{rad}\, A, \mathrm{rad}\, A, \{0\})$.

Having dealt with the radical, Alder and Strassen turn to semisimple algebras. Their second important result is subsumed in the following lemma.

LEMMA 11. *If $A = B \times B'$, with $B$ being a simple $k$-algebra and $B'$ being an arbitrary $k$-algebra, then*

$$R(A) \geq 2 \dim B - 1 + R(B').$$

To achieve good lower bounds by means of Lemma 8, one has to find an optimal bilinear computation that separates a "large" triple. An important tool for solving this task is the following "extension lemma," which is essentially due to Alder and Strassen.

LEMMA 12. *Let $U$, $V$, $W$ be vector spaces over a field $k$, and let $\beta$ be a computation for a bilinear map $\phi : U \times V \to W$. Let $U_1 \subseteq U_2 \subseteq U$, $V_1 \subseteq V$, and $W_1 \subseteq W$ be subspaces such that $\beta$ separates the triple $(U_1, V_1, W_1)$. Then $\beta$ separates also $(U_2, V_1, W_1)$, or there is some $u \in U_2 \setminus U_1$ such that*

$$\phi(u, V) \subseteq \mathrm{lin}\{\phi(u, V_1)\} + W_1.$$

**3. Superbasic algebras of minimal rank.** We characterize superbasic algebras of minimal rank, thus generalizing the results of Heintz and Morgenstern [18]. (Note that, over algebraically closed fields, the notions of basic and superbasic coincide, since there are no proper division algebras over algebraically closed fields.) Our main result is Theorem 22. It turns out that, over infinite fields, superbasic algebras of minimal rank have the same structure as (super)basic algebras over algebraically closed fields. If the underlying field $k$ is finite, then a superbasic algebra $A$ of minimal rank also fulfils $\#k \geq 2N(A) - 2$, where $N(A)$ denotes the largest natural number $s$ such that $(\mathrm{rad}\, A)^s \neq \{0\}$. (Since $A$ is finite dimensional, this is well defined.)

Inspired by Heintz and Morgenstern, we introduce the class $\mathsf{M}_k$ of superbasic algebras as an intermediate concept. This class plays an important role in our proof.

DEFINITION 13. *Let $A$ be a superbasic algebra over some field $k$ with* $\dim A = n$ *and* $\dim A/\mathrm{rad}\, A = t$. *The algebra $A$ belongs to the class $\mathsf{M}_k$ if there are bases $x_1, \dots, x_n$ and $y_1, \dots, y_n$ of $A$ such that*

1. *$x_\mu y_\nu \in kx_\mu + ky_\nu$ for $t+1 \le \mu, \nu \le n$,*
2. *$x_\tau = y_\tau$ for $1 \le \tau \le t$,*
3. *$x_\tau^2 = x_\tau$ and $x_\sigma x_\tau = 0$ for $1 \le \sigma, \tau \le t$, and $\tau \ne \sigma$,*
4. *$x_1 + \cdots + x_t = 1$, and*
5. *$x_\sigma y_\nu \in ky_\nu$ and $x_\mu y_\tau \in kx_\mu$ for $1 \le \sigma, \tau \le t$ and $t+1 \le \mu, \nu \le n$.*

*Such two bases are called an* $\mathsf{M}$*-pair of bases for $A$.*

Superbasic algebras of minimal rank are in $\mathsf{M}_k$.

LEMMA 14. *If a superbasic algebra $A$ has minimal rank, then $A$ is in $\mathsf{M}_k$.*

*Proof.* Assume that $\dim A = n$ and $\dim A/\operatorname{rad} A = t$. Moreover, let $\beta = (f_1, g_1, w_1, \dots, f_{2n-t}, g_{2n-t}, w_{2n-t})$ be an optimal computation for $A$. By permuting the products, we can achieve that $f_1, \dots, f_n$ form a basis of $A^*$. Furthermore, we may assume that for $S := \bigcap_{\nu=1}^{n-t} \ker f_\nu$, $S + \operatorname{rad} A = A$. $S$ contains an invertible element $e$ of $A$ by Nakayama's lemma (Lemma 4).

Thus $g_{n-t+1}, \dots, g_{2n-t}$ form a basis of $A^*$, because otherwise there would be some nonzero $a \in \bigcap_{\nu=1}^{n} \ker g_{n-t+\nu}$. But then

$$e \cdot a = \sum_{\rho=1}^{2n-t} f_\rho(e) g_\rho(a) w_\rho = 0,$$

which is a contradiction. By permuting the products $n-t+1, \dots, 2n-t$, we can achieve that for $T := \bigcap_{\nu=n+1}^{2n-t} \ker g_\nu$, $T + \operatorname{rad} A = A$. This permutation affects neither $f_1, \dots, f_{n-t}$ nor $S$. In particular, we still have $e \in \bigcap_{\nu=1}^{n-t} \ker f_\nu$. Again by Nakayama's lemma (Lemma 4), $T$ contains an invertible element $e'$ of $A$. With $e'$ instead of $e$, we can conclude that the new $f_1, \dots, f_n$ still form a basis of $A^*$, in the same way we have shown that $g_{n-t+1}, \dots, g_{2n-t}$ is a basis.

By sandwiching with $e^{-1}$ from the left and $(e')^{-1}$ from the right (see section 2.2), we may assume that $e = e' = 1$. Let $x_{t+1}, \dots, x_n, x_1, \dots, x_t$ denote the dual basis of $f_1, \dots, f_n$. (The odd numbering will become clear in a moment.) Furthermore, let $y_1, \dots, y_n$ be the dual basis of $g_{n-t+1}, \dots, g_{2n-t}$. By construction, $x_1, \dots, x_t$ span $S$ and $y_1, \dots, y_t$ span $T$. The properties of the $f_1, \dots, f_{2n-t}$, $g_1, \dots, g_{2n-1}$, and the dual bases $x_1, \dots, x_n$ as well as $y_1, \dots, y_n$, can be depicted as follows:

$$\begin{array}{cccccccccc}
f_1 & \cdots & f_{n-t} & f_{n-t+1} & \cdots & f_n & f_{n+1} & \cdots & f_{2n-t} & \\
x_1 & \cdots & x_{n-t} & x_1 & \cdots & x_t & & & & \text{(dual basis)} \\
 & & & & & & & & & \\
g_1 & \cdots & g_{n-t} & g_{n-t+1} & \cdots & g_n & g_{n+1} & \cdots & g_{2n-t} & \\
 & & & y_1 & \cdots & y_t & y_{t+1} & \cdots & y_n & \text{(dual basis).}
\end{array}$$

By appropriate scaling, we can achieve that $1 = \delta_1 x_1 + \cdots + \delta_t x_t$ with $\delta_\tau \in \{0, 1\}$. Since

$$1 \cdot y = \sum_{\tau=1}^{t} \delta_\tau g_{n-t+\tau}(y) w_{n-t+\tau} + \sum_{\nu=1}^{n-t} f_{n+\nu}(1) g_{n+\nu}(y) w_{n+\nu}$$

for any $y \in A$,

$$A = \operatorname{lin}\{\delta_1 w_{n-t+1}, \dots, \delta_t w_n, w_{n+1}, \dots, w_{2n-t}\}.$$

Thus $\delta_\tau = 1$ for all $1 \le \tau \le t$ by a dimension argument. The same reasoning shows $1 = y_1 + \cdots + y_t$. This establishes the fourth condition of the $\mathsf{M}$-pair for $x_1, \dots, x_n$ and $y_1, \dots, y_n$.

By the construction of $S$ and $T$ and the definition of dual basis,

$$x_\nu = x_\nu \cdot 1 = \sum_{\rho=1}^{2n-t} f_\rho(x_\nu) g_\rho(1) w_\rho = \underbrace{g_{\nu-t}(1)}_{\neq 0} w_{\nu-t}$$

and

$$y_\nu = 1 \cdot y_\nu = \sum_{\rho=1}^{2n-t} f_\rho(1) g_\rho(y_\nu) w_\rho = \underbrace{f_{n-t+\nu}(1)}_{\neq 0} w_{n-t+\nu}$$

for all $t+1 \leq \nu \leq n$. In other words, $x_\nu$ and $w_{\nu-t}$ as well as $y_\nu$ and $w_{n-t+\nu}$ are multiples of each other, respectively. This yields

$$\begin{aligned} x_\mu y_\nu &= \sum_{\rho=1}^{2n-t} f_\rho(x_\mu) g_\rho(y_\nu) w_\rho \\ &= g_{\mu-t}(y_\nu) w_{\mu-t} + f_{n-t+\nu}(x_\mu) w_{n-t+\nu} \\ &\in kx_\mu + ky_\nu \end{aligned}$$

for $t+1 \leq \mu, \nu \leq n$, which shows that our bases fulfil the first condition.

The second condition follows from the fact that

$$x_\tau = x_\tau \cdot 1 = w_{n-t+\tau} \quad \text{and} \quad y_\tau = 1 \cdot y_\tau = w_{n-t+\tau}$$

for $1 \leq \tau \leq t$. (Note that since $1 = y_1 + \cdots + y_t$, $g_{n-t+\tau}(1) = 1$. $f_{n-t+\tau}(1) = 1$ follows similarly.)

This also establishes the third condition, as for $\tau \neq \sigma$,

$$x_\tau^2 = x_\tau y_\tau = w_{n-t+\tau} = x_\tau \quad \text{and} \quad x_\sigma x_\tau = x_\sigma y_\tau = 0.$$

It remains to show that the two bases meet the fifth condition: This is again shown by exploiting the property of dual bases. We have

$$x_\sigma y_\nu = f_{n-t+\nu}(x_\sigma) w_{n-t+\nu} \in ky_\nu$$

for $1 \leq \sigma \leq t$ and $t+1 \leq \nu \leq n$. The fact $x_\mu y_\tau \in kx_\mu$ follows in the same manner. □

The bases of an $\mathsf{M}$-pair can be further normalized.

Definition 15. *A superbasic algebra in $\mathsf{M}_k$ has a normalized $\mathsf{M}$-pair of bases $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$ if, in addition to the conditions in Definition 13, the bases $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$ fulfil*

1. $x_{t+1}, \ldots, x_n \in \operatorname{rad} A$ *and* $y_{t+1}, \ldots, y_n \in \operatorname{rad} A$,
2. $x_{n-d+1}, \ldots, x_n$ *and* $y_{n-d+1}, \ldots, y_n$ *are both bases of* $\mathsf{L}_A \cap \mathsf{R}_A$, *where* $d = \dim \mathsf{L}_A \cap \mathsf{R}_A$, *and*
3. $x_{n-\ell+1}, \ldots, x_n$ *is a basis of* $\mathsf{L}_A$ *and* $y_{n-r+1}, \ldots, y_n$ *is a basis of* $\mathsf{R}_A$, *where* $\ell = \dim \mathsf{L}_A$ *and* $r = \dim \mathsf{R}_A$.

Lemma 16. *Every superbasic algebra $A \in \mathsf{M}_k$ has a normalized $\mathsf{M}$-pair of bases.*

*Proof.* Since $A \in \mathsf{M}_k$, it has an $\mathsf{M}$-pair of bases $x_1, \ldots, x_n$ and $y_1, \ldots, y_n$. By the third condition, $x_1, \ldots, x_t$ are a system of mutually orthogonal idempotents of $A$, none of them being zero; thus their images $\bar{x}_1, \ldots, \bar{x}_t$ under the canonical projection

$A \to A/\operatorname{rad} A$ are linearly independent. Comparing dimensions shows that they even form a basis. Thus for any $t+1 \le \mu \le n$ there are scalars $\xi_{\mu,\tau}$ such that

$$x'_\mu := x_\mu - \sum_{\tau=1}^{t} \xi_{\mu,\tau} x_\tau \in \operatorname{rad} A.$$

We define scalars $\eta_{\nu,\tau}$ and elements $y'_\nu$ in the same manner. We claim that the bases $x_1, \dots, x_t, x'_{t+1}, \dots, x'_n$ and $y_1, \dots, y_t, y'_{t+1}, \dots, y'_n$ are an $\mathsf{M}$-pair. By construction, we only have to verify the first and fifth condition in Definition 13. For the first, note that

$$\begin{aligned} x'_\mu y'_\nu &= \left(x_\mu - \sum_{\tau=1}^{t} \xi_{\mu,\tau} x_\tau\right)\left(y_\nu - \sum_{\tau=1}^{t} \eta_{\nu,\tau} y_\tau\right) \\ &= \xi x_\mu + \eta y_\nu + \sum_{\tau=1}^{t} \alpha_\tau x_\tau \\ &= \xi x'_\mu + \eta y'_\nu + \sum_{\tau=1}^{t} \alpha'_\tau x_\tau \qquad (4) \end{aligned}$$

for suitable scalars $\xi, \eta, \alpha_1, \dots, \alpha_t, \alpha'_1, \dots, \alpha'_t$. Since $x'_\mu y'_\nu$, $x'_\mu$, and $x'_\nu$ are contained in $\operatorname{rad} A$ but $\operatorname{lin}\{x_1, \dots, x_t\} \cap \operatorname{rad} A = \{0\}$, $\alpha'_1 = \dots = \alpha'_t = 0$ in (4).

In a similar manner, one can verify that $x_\tau y'_\nu \in k y'_\nu$ and $x'_\nu y_\tau \in k x'_\nu$ for $1 \le \tau \le t$ and $t+1 \le \nu \le n$: We have

$$x_\tau y'_\nu = x_\tau \left(y_\nu - \sum_{\tau=1}^{t} \eta_{\nu,\tau} y_\tau\right) = \eta y'_\nu + \sum_{\tau=1}^{t} \alpha'_\tau x_\tau$$

for suitable $\eta, \alpha'_1, \dots, \alpha'_t$. Again we conclude that $\alpha'_1 = \dots = \alpha'_t = 0$. The statement $x'_\nu y_\tau \in k x'_\nu$ follows similarly. Thus $x_1, \dots, x_t, x'_{t+1}, \dots, x'_n$ and $y_1, \dots, y_t, y'_{t+1}, \dots, y'_n$ are an $\mathsf{M}$-pair. For convenience, we call these bases again $x_1, \dots, x_n$ and $y_1, \dots, y_n$, respectively.

Let $a_1, \dots, a_d$ and $b_1, \dots, b_{\ell-d}, a_1, \dots, a_d$ and $c_1, \dots, c_{r-d}, a_1, \dots, a_d$ be bases of $\mathsf{L}_A \cap \mathsf{R}_A$ and $\mathsf{L}_A$ and $\mathsf{R}_A$, respectively. We can achieve that each $a_\delta$, $b_\lambda$, and $c_\rho$ is contained in exactly one of the subspaces $x_\sigma(\mathsf{L}_A \cap \mathsf{R}_A)x_\tau$, $\mathsf{L}_A x_\tau$, and $x_\sigma \mathsf{R}_A$, respectively. We show this for $a_1, \dots, a_d$, and the other two cases follow along the same lines: We take any basis $a_1, \dots, a_d$. Since $1 = x_1 + \dots + x_t$, the set of all $x_\sigma a_\delta x_\tau$, $1 \le \sigma, \tau \le t$, $1 \le \delta \le d$, generates the same space as $a_1, \dots, a_d$. Any maximally linearly independent set of the $x_\sigma a_\delta x_\tau$ is a basis such that each element is contained in one of the subspaces $x_\sigma(\mathsf{L}_A \cap \mathsf{R}_A)x_\tau$. To see that each element is contained in exactly one such subspace, note that their pairwise intersections are the nullspace: Let $V$ be any subspace. Assume that there is an $a$ in $x_\sigma V x_\tau \cap x_{\sigma'} V x_{\tau'}$ with $\sigma \ne \sigma'$, say. (The case $\tau \ne \tau'$ is symmetric.) That means we can write $a = x_\sigma v = x_{\sigma'} v'$. But then

$$a = x_\sigma v = x_\sigma^2 v = x_\sigma x_{\sigma'} v' = 0,$$

which proves the claim.

By a suitable renumbering of $x_{t+1}, \dots, x_n$ and $y_{t+1}, \dots, y_n$, we can achieve that

$$\begin{aligned} &x_1, \dots, x_{n-\ell}, b_1, \dots, b_{\ell-d}, a_1, \dots, a_d \quad \text{and} \\ &y_1, \dots, y_{n-r}, c_1, \dots, c_{r-d}, a_1, \dots, a_d \end{aligned}$$

are bases of $A$. (We have only to renumber the $x_{t+1}, \dots, x_n$, since $x_1, \dots, x_t \notin \operatorname{rad} A$ whereas $x_{t+1}, \dots, x_n \in \operatorname{rad} A$. We want to exchange with $b_1, \dots, b_{\ell-d}, a_1, \dots, a_d$, which are all in $\operatorname{rad} A$ by the definition of the left annihilator. Hence, $x_1, \dots, x_t$ cannot be exchanged. The same holds for $y_1, \dots, y_t$.) We assert that this is an $\mathsf{M}$-pair for $A$. To prove this, we have to check the first and fifth conditions in Definition 13. The first is clearly fulfilled, since the $x_\nu$ and $y_\nu$ with $t+1 \le \nu$ are in $\operatorname{rad} A$ (since they were before) and $\mathsf{L}_A$ and $\mathsf{R}_A$ are the left and right annihilator, respectively, of $\operatorname{rad} A$.

The fifth condition is also true by construction: Each $a_\delta$ can be written as $x_\sigma a'_\delta x_\tau$ for some $a'_\delta \in \mathsf{L}_A \cap \mathsf{R}_A$. Thus for $1 \le i \le t$, $x_i a_\delta = x_i x_\sigma a'_\delta x_\tau$ is either $a_\delta$ or 0, depending on whether $i = \sigma$ or not. The same is true for $a_\delta x_i$, $b_\lambda x_i$, and $x_i c_\rho$. This completes the proof. $\square$

The next two lemmas describe the structure of the algebras in $\mathsf{M}_k$.

LEMMA 17. *Let $A \in \mathsf{M}_k$; let $x_1, \dots, x_n$ and $y_1, \dots, y_n$ be a normalized $\mathsf{M}$-pair of bases for $A$; and let $\ell = \dim \mathsf{L}_A$ and $r = \dim \mathsf{R}_A$. Then $x_\mu y_\nu = 0$ or $k[x_\mu] = k[y_\nu]$ for all $t+1 \le \mu, \nu \le n$. Moreover, $x_\mu^2 \ne 0$ and $y_\nu^2 \ne 0$ for all $1 \le \mu \le n-\ell$ and $1 \le \nu \le n-r$.*

*Proof.* If $\mu \ge n-\ell+1$ or $\nu \ge n-r+1$, the first statement of the lemma is true by the definition of $\mathsf{L}_A$ or $\mathsf{R}_A$, respectively. Thus assume that $\mu \le n-\ell$ and $\nu \le n-r$. If $x_\mu y_\nu = 0$, we are done. Otherwise, assume that

$$x_\mu y_\nu = \xi x_\mu + \eta y_\nu. \tag{5}$$

Let $m$ be the largest integer $\ge 1$ such that $x_\mu y_\nu \in (\operatorname{rad} A)^m$. Since $x_\mu, y_\nu \in \operatorname{rad} A$, neither $x_\mu \in (\operatorname{rad} A)^m$ nor $y_\nu \in (\operatorname{rad} A)^m$. Thus $\xi \ne 0$ and $\eta \ne 0$ in (5). It follows that $(x_\mu - \eta)(y_\nu - \xi) = \xi\eta \in A^\times$, and hence

$$k[x_\mu] = k[x_\mu - \eta] = k[y_\nu - \xi] = k[y_\nu].$$

For the second statement, note that since $x_\mu \notin \mathsf{L}_A$, there is an $i$ with $t+1 \le i \le n-r$ such that $x_\mu y_i \ne 0$, particularly $k[x_\mu] = k[y_i]$. As $x_\mu, y_i \in \operatorname{rad} A$ and therefore are nilpotent, $k[x_\mu]$ and $k[y_i]$ are both isomorphic to $k[X]/(X^m)$ for the same $m$. The isomorphism is given by $x_\mu \mapsto X$ and $y_i \mapsto X$. Since $k[x_\mu] = k[y_i]$, we can write $x_\mu$ as a polynomial in $y_i$ without constant term and nonvanishing linear term, i.e.,

$$x_\mu = \alpha_1 y_i + \alpha_2 y_i^2 + \dots + \alpha_m y_i^m \qquad \text{with } \alpha_1 \ne 0. \tag{6}$$

Since both $x_\mu, y_i \in \operatorname{rad} A$,

$$x_\mu^2 = \underbrace{\alpha_1 x_\mu y_i}_{\ne 0} + \text{higher order terms} \ne 0.$$

The result $y_\nu^2 \ne 0$ is proven identically. $\square$

LEMMA 18. *Let $A \in \mathsf{M}_k$; let $x_1, \dots, x_n$ and $y_1, \dots, y_n$ be a normalized $\mathsf{M}$-pair of bases for $A$; and let $\ell = \dim \mathsf{L}_A$ and $r = \dim \mathsf{R}_A$. Then either $x_\mu x_\nu = x_\nu x_\mu = 0$ or $k[x_\mu] = k[x_\nu]$ for all $t+1 \le \mu, \nu \le n-\ell$. Moreover, $x_1, \dots, x_{n-\ell}$ mutually commute. The same holds for $y_1, \dots, y_{n-r}$.*

*Proof.* We start by proving the first statement. This also shows that $x_{t+1}, \dots, x_{n-\ell}$ mutually commute. Let $x_\mu$ and $x_\nu$ with $t+1 \le \mu, \nu \le n-\ell$ be given. By assumption, there are $t+1 \le i, j \le n-r$ such that $x_\mu y_i \ne 0$ and $x_\nu y_j \ne 0$. Thus $k[x_\mu] = k[y_i]$ and $k[x_\nu] = k[y_j]$, by Lemma 17. We distinguish two cases: $k[x_\mu] \ne k[y_j]$ or $k[x_\mu] = k[y_j]$.

In the first case, also $k[x_\nu] \neq k[y_i]$, and hence $x_\mu y_j = x_\nu y_i = 0$ by Lemma 17. Since $k[x_\mu] = k[y_i]$, we can write $x_\mu$ as a polynomial in $y_i$ as in (6). Therefore,

$$x_\nu x_\mu = x_\nu(\alpha_1 y_i + \alpha_2 y_i^2 + \cdots + \alpha_m y_i^m) = 0.$$

In the same way, $x_\mu x_\nu = 0$. In the second case, obviously $k[x_\mu] = k[x_\nu]$. We have to show that $x_\mu x_\nu \neq 0$. But $x_\mu x_\nu = 0$ would mean that $x_\mu \in \mathsf{L}_A$, since $k[x_\mu] = k[x_\nu]$, a contradiction.

To prove the second statement, it suffices to show that $x_\tau x_\nu = x_\nu x_\tau$ for $1 \leq \tau \leq t$ and $t+1 \leq \nu \leq n-\ell$, since $x_1, \dots, x_t$ mutually commute by the definition of an $\mathsf{M}$-pair. Because $x_\tau = y_\tau$, we have $x_\nu x_\tau = \xi x_\nu$. Since $x_\tau$ is idempotent, $\xi \in \{0,1\}$; that is, $x_\nu x_\tau \in \{0, x_\nu\}$. On the other hand, as $x_\nu \notin \mathsf{L}_A$, there is some $y_i$ such that $x_\nu y_i \neq 0$. By Lemma 17, $k[x_\nu] = k[y_i]$. As in (6), we can write $x_\nu$ as a polynomial in $y_i$ without constant term. A similar argument as above shows that $x_\tau y_i \in \{0, y_i\}$. Together with (6), this implies $x_\tau x_\nu \in \{0, x_\nu\}$.

From $x_\tau x_\nu, x_\nu x_\tau \in \{0, x_\nu\}$, we can conclude that $x_\tau$ and $x_\nu$ commute. Assume on the contrary that, say, $x_\tau x_\nu = x_\nu$ but $x_\nu x_\tau = 0$. Then $x_\nu^2 = x_\nu(x_\tau x_\nu) = (x_\nu x_\tau)x_\nu = 0$, contradicting the second statement of Lemma 17.

In a similar fashion, one proves the statement for $y_1, \dots, y_{n-r}$. □

COROLLARY 19. *Let $A \in \mathsf{M}_k$. Then there is a commutative subalgebra $S \subseteq A$ such that $S + \mathsf{L}_A = S + \mathsf{R}_A = A$. Moreover,* $\operatorname{rad} S = (w_1) + \cdots + (w_m)$ *with nilpotent $w_1, \dots, w_m$ such that $w_i^2 \neq 0$ for all $1 \leq i \leq m$ and $w_i w_j = 0$ for $i \neq j$.*

*Proof.* Let $x_1, \dots, x_n$ and $y_1, \dots, y_n$ be a normalized $\mathsf{M}$-pair of bases of $A$. By Lemma 18, $k[x_1, \dots, x_{n-\ell}]$ is a commutative algebra. By Lemma 17, $k[y_1, \dots, y_{n-r}] = k[x_1, \dots, x_{n-\ell}]$. Hence, we set $S := k[x_1, \dots, x_{n-\ell}]$. By the definition of a normalized $\mathsf{M}$-pair, $S + \mathsf{L}_A = S + \mathsf{R}_A = A$.

We have $\operatorname{rad} S = (x_{t+1}, \dots, x_{n-\ell})$. We define an equivalence relation $\equiv$ on the elements $x_{t+1}, \dots, x_{n-\ell}$ by

$$x_\mu \equiv x_\nu \quad \text{iff} \quad x_\mu x_\nu \neq 0.$$

By Lemma 18, $k[x_\mu] = k[x_\nu]$ in this case. Take a set $w_1, \dots, w_m$ of the representatives for the $\equiv$-classes. Then $\operatorname{rad} S = (w_1, \dots, w_m) = (w_1) + \cdots + (w_m)$. We also may assume $w_i^2 \neq 0$ because otherwise $w_i \in \mathsf{L}_A \cap \mathsf{R}_A$. □

COROLLARY 20. *If $A \in \mathsf{M}_k$, then* $\dim \mathsf{L}_A = \dim \mathsf{R}_A$.

*Proof.* By Corollary 19, $A = S + \mathsf{L}_A = S + \mathsf{R}_A$ for a commutative subalgebra $S$ of $A$. As $S$ is commutative and $\mathsf{L}_A^2 = \mathsf{R}_A^2 = \{0\}$, $S \cap \mathsf{L}_A = S \cap \mathsf{R}_A$. We have

$$\dim S + \dim \mathsf{L}_A - \dim S \cap \mathsf{L}_A = \dim A = \dim S + \dim \mathsf{R}_A - \dim S \cap \mathsf{R}_A.$$

Thus $\dim \mathsf{L}_A = \dim \mathsf{R}_A$. □

The next lemma basically states that if there is an algebra $A \in \mathsf{M}_k$ with $N(A) = d$, then we can simulate univariate polynomial multiplication mod $X^{d+1}$ efficiently.

LEMMA 21. *Assume there is an $A \in \mathsf{M}_k$ with $N(A) = d$. Then $k[X]/(X^{d+1})$ has minimal rank, where $X$ denotes some indeterminate.*

*Proof.* If $d \leq 1$, then $k[X]/(X^{d+1})$ has minimal rank by using the trivial algorithm. So we may assume $d > 1$. Let $x_1, \dots, x_n$ and $y_1, \dots, y_n$ be a normalized $\mathsf{M}$-pair of bases for $A$ as asserted by Lemma 16. There is some index, say $t+1$, such that $x_{t+1}^d \neq 0$. Furthermore $x_{t+1}^d \in \mathsf{L}_A \cap \mathsf{R}_A$ by the maximality of $d$. By Lemmas 17 and 18, there are indices $i_1 = t+1, \dots, i_{d-1}$ as well as indices $j_1, \dots, j_{d-1}$ such that

$$\begin{aligned} k[x_{t+1}] &= \operatorname{lin}\{1, x_{i_1}, \dots, x_{i_{d-1}}, x_{t+1}^d\} \\ &= \operatorname{lin}\{1, y_{j_1}, \dots, y_{j_{d-1}}, x_{t+1}^d\}. \end{aligned}$$

We claim that $R(k[x_{t+1}]) = 2d + 1$: By the definition of an $\mathsf{M}$-pair,

$$x_\mu y_\nu = \xi_{\mu,\nu} x_\mu + \eta_{\mu,\nu} y_\nu \tag{7}$$

for suitable scalars $\xi_{\mu,\nu}$ and $\eta_{\mu,\nu}$.

Define a computation

$$(f_1, g_1, w_1, \dots, f_{2d+1}, g_{2d+1}, w_{2d+1}) \quad \text{for } k[x_{t+1}]$$

as follows: As the elements $w_1, \dots, w_{2d+1}$, we choose $1, x_{i_1}, \dots, x_{i_{d-1}}, x_{t+1}^d$, $y_{j_1}, \dots, y_{j_{d-1}}, x_{t+1}^d$. Let $f_1, \dots, f_{d+1}$ be the dual basis of $1, x_{i_1}, \dots, x_{i_{d-1}}, x_{t+1}^d$ and let $g_1, g_{d+2}, \dots, g_{2d+1}$ be the dual basis of $1, y_{j_1}, \dots, y_{j_{d-1}}, x_{t+1}^d$. Next the $f_\delta$ with $d+2 \le \delta \le 2d$ are defined by $f_\delta(x_{i_\tau}) = \eta_{i_\tau, j_\delta}$ for $1 \le \tau \le d-1$ and $f_\delta(1) = f_\delta(x_{t+1}^d) = 0$. The $g_\delta$ with $2 \le \delta \le d$ are defined accordingly. Finally, $f_{2d+1}$ is defined by $f_{2d+1}(x_{t+1}^d) = 0$, $f_{2d+1}(1) = 1$, and $f_{2d+1}(x_{j_\tau}) = 0$ for $1 \le \tau \le d-1$. The linear form $g_{d+1}$ is defined in the same manner.

Exploiting (7), it is easy to see that this defines a computation for $k[x_{t+1}]$. Noting that $k[x_{t+1}] \cong k[X]/(X^{d+1})$ completes the proof. □

THEOREM 22. *Let $A$ be a superbasic algebra. Then the following statements are equivalent:*

1. *$A$ has minimal rank.*
2. *$A \in \mathsf{M}_k$.*
3. *There exist $w_1, \dots, w_m \in \operatorname{rad} A$ with $w_i^2 \neq 0$ for all $i$ and $w_i w_j = 0$ for $i \neq j$ such that*

$$\begin{aligned} \operatorname{rad} A &= \mathsf{L}_A + A w_1 A + \dots + A w_m A \\ &= \mathsf{R}_A + A w_1 A + \dots + A w_m A \end{aligned}$$

*and $\#k \ge 2N(A) - 2$.*

*Proof.* 1. ⇒ 2.: This follows at once from Lemma 14.

2. ⇒ 3.: Corollary 19 implies the first part of 3. For the second part, let $d = N(A)$. By Lemma 21, the algebra $k[X]/(X^{d+1})$ has minimal rank. From the classification of the algorithm variety of $k[X]/(X^{d+1})$ given by Averbuch, Galil, and Winograd [2], it follows that this can be the case only if $\#k \ge 2d - 2$.

3. ⇒ 1.: Let $\bar{A} = A/\operatorname{rad} A = k^t$ and let $\bar{e}_1, \dots, \bar{e}_t$ denote a decomposition of the identity of $A/\operatorname{rad} A$. By [11, Corollary 3.3.9], we can lift this decomposition to a decomposition $e_1, \dots, e_t$ of the identity of $A$. In particular, $\operatorname{lin}\{e_1, \dots, e_t\}$ forms a subalgebra $S$ of $A$. Consider $\mathsf{L}_A$ and $\mathsf{R}_A$ as $S$-right module and $S$-left module, respectively. Since $S$ is semisimple, $\mathsf{L}_A$ and $\mathsf{R}_A$ are semisimple modules, too. Hence there are bases $b_1, \dots, b_\ell$ and $c_1, \dots, c_r$ of $\mathsf{L}_A$ and $\mathsf{R}_A$, respectively, such that

$$b_\lambda A = k b_\lambda \quad \text{for all } 1 \le \lambda \le \ell \qquad \text{and} \qquad A c_\rho = k c_\rho \quad \text{for all } 1 \le \rho \le r. \tag{8}$$

By Corollary 20, $\ell = r$. Choose $q_i \ge 2$ such that $w_i^{q_i} \neq 0$ and $w_i^{q_i+1} = 0$. Since each $w_\mu^{q_\mu} \in \mathsf{L}_A \cap \mathsf{R}_A$,

$$\begin{aligned} &e_1, \dots, e_t, w_1, \dots, w_1^{q_1-1}, \dots, w_m, \dots, w_m^{q_m-1}, b_1, \dots, b_\ell \qquad \text{and} \\ &e_1, \dots, e_t, w_1, \dots, w_1^{q_1-1}, \dots, w_m, \dots, w_m^{q_m-1}, c_1, \dots, c_\ell \end{aligned}$$

are bases of $A$. Call these bases $x_1, \dots, x_n$ and $y_1, \dots, y_n$.

Given two generic elements $\xi_1 x_1 + \cdots + \xi_n x_n$ and $\eta_1 y_1 + \cdots + \eta_n y_n$, we now have to show how to compute the coefficients (which are bilinear forms in the $\xi_i$ and $\eta_j$) of their product with $2n - t$ bilinear multiplications.

We first compute $\xi_\tau \eta_\tau$ for $1 \le \tau \le t$ with $t$ bilinear multiplication.

Since $e_1, \dots, e_t$ annihilate each other, for each $\lambda$ there is exactly one $\tau$ such that $b_\lambda e_\tau \ne 0$ by (8). In the same way, for each $\lambda$ there is exactly one $\tau$ such that $e_\tau c_\lambda \ne 0$. Thus we compute the coefficients of $b_1, \dots, b_\ell$ and $c_1, \dots, c_\ell$ with $2\ell$ bilinear products.

For each $\mu$, there is exactly one $\tau_\mu$ such that $e_{\tau_\mu} w_\mu \ne 0$. As $w_1, \dots, w_m$ annihilate each other, we can consider the multiplication in $\operatorname{lin}\{e_{\tau_\mu}, w_\mu, \dots, w_\mu^{q_\mu}\}$ separately for each $\mu$. This is merely univariate polynomial multiplication. We have already computed the product corresponding to $e_{\tau_\mu} w_\mu^{q_\mu}$ and $w_\mu^{q_\mu} e_{\tau_\mu}$, since $w_\mu^{q_\mu} \in \mathsf{L}_A \cap \mathsf{R}_A$. Thus it is sufficient to compute the product of two elements in $\operatorname{lin}\{e_{\tau_\mu}, w_\mu, \dots, w_\mu^{q_\mu - 1}\}$ up to the term $w_\mu^{q_\mu}$. This can be done with $2q_\mu - 1$ multiplications via evaluation and interpolation. However, we have already computed the product $\xi_{\tau_\mu} \eta_{\tau_\mu}$. (This corresponds to evaluation at zero.) Hence $2q_\mu - 2$ multiplications suffice. The condition $\#k \ge 2N(A) - 2$ ensures that there are enough scalars to perform evaluation and interpolation.

The total number of multiplications is $t + 2\ell + 2(n - \ell - t) = 2 \dim A - t$. This completes the proof. □

**4. Structural insights.** In the proof of the preliminary characterization results over algebraically closed [4] and perfect [5] fields, the existence of a subalgebra $B$ of $A$ with $B \oplus \operatorname{rad} A = A$ and $B \cong A/\operatorname{rad} A$ played a crucial role. Over perfect (and henceforth over algebraically closed) fields, such an algebra always exists by the Wedderburn–Malcev theorem (Theorem 5). Over nonperfect fields, such an algebra need not exist; see [11, Chapter 6, Example 4] for an example.

Instead of the above algebra $B$, we use a slightly larger subalgebra of $A$. This algebra will be induced by a lifting of the idempotents in $A/\operatorname{rad} A$. Let $\bar{.} : A \to A/\operatorname{rad} A$ denote the canonical projection defined by $a \mapsto \bar{a} = a + \operatorname{rad} A$. Let $A_1 \oplus \cdots \oplus A_t$ be the decomposition of $A/\operatorname{rad} A$ into simple factors. We here write the decomposition of $A/\operatorname{rad} A$ in an additive way; that is, we consider the $A_\tau$ as subspaces of $A/\operatorname{rad} A$. This is done to simplify notation, mainly to write $A_\tau$ instead of $\{0\} \times \cdots \times \{0\} \times A_\tau \times \{0\} \times \cdots \times \{0\}$, which would be the corresponding subspace of $A_1 \times \cdots \times A_t$. Let $e_\tau$ denote the identity of $A_\tau$ for $1 \le \tau \le t$. Then $e_1 + \cdots + e_t$ is a *decomposition of the identity* of $A/\operatorname{rad} A$; that is,

1. $1 = e_1 + \cdots + e_t$,
2. the $e_\tau$ are idempotents, i.e., $e_\tau^2 = e_\tau$ for all $\tau$, and
3. the $e_\tau$ annihilate each other, i.e., $e_\sigma e_\tau = 0$ for $\sigma \ne \tau$.

(It is actually more precise to call $e_1, \dots, e_t$ the decomposition of the identity, since $e_1 + \cdots + e_t$ is simply 1. We will, however, use the notation $e_1 + \cdots + e_t$.) Now the crucial point is that this decomposition can be lifted to $A$: By [11, Corollary 3.3.9], there is a corresponding decomposition of the identity $f_1 + \cdots + f_t$ in $A$ (i.e., $f_1, \dots, f_t$ fulfill the three conditions above, where 1 is the identity of $A$) such that

$$e_\tau = \bar{f}_\tau = f_\tau + \operatorname{rad} A \qquad \text{for all } \tau. \tag{9}$$

We remark that the decomposition $e_1 + \cdots + e_t$ is a *central* decomposition of the identity in $A/\operatorname{rad} A$; i.e., $e_\tau a = a e_\tau$ holds for all $\tau$ and for all $a \in A/\operatorname{rad} A$.

The following theorem is useful in what follows. For a proof, see [11, Theorem 3.5.3].

THEOREM 23. *Let $e_1 + \cdots + e_t$ be a central decomposition of the identity in $A/\operatorname{rad} A$. Then $f_i(\operatorname{rad} A)f_j = f_iAf_j$ for all $i \neq j$ and $f_i(\operatorname{rad} A)f_i = \operatorname{rad}(f_iAf_i)$ for all $i$. (Here $f_1 + \cdots + f_t$ is the lifted decomposition in $A$ defined above.)*

The next lemma shows that $B := f_1Af_1 + \cdots + f_tAf_t$ is a subalgebra of $A$ such that $B/\operatorname{rad} B \cong A_1 \oplus \cdots \oplus A_t$. Note that the algebra $B$ always exists; in particular, its existence does not depend on the perfectness of the ground field. The important point is that we have found an algebra with $B/\operatorname{rad} B \cong A_1 \oplus \cdots \oplus A_t = A/\operatorname{rad} A$ for which $B \cap f_iAf_j = \{0\}$ holds for all $i \neq j$. This is needed in the proof of Lemma 31.

LEMMA 24. *Let $A$ be an algebra over an arbitrary field and $A_1 \oplus \cdots \oplus A_t$ be its decomposition into simple algebras. Let $f_1 + \cdots + f_t$ be a decomposition of the identity as in* (9)*. Then the following hold:*

1. *$B := f_1Af_1 + f_2Af_2 + \cdots + f_tAf_t$ is a subalgebra of $A$,*
2. *$B_\tau := f_\tau Af_\tau$ is an algebra for all $\tau$,*
3. *$B_\sigma \cdot B_\tau = \{0\}$ for all $\sigma \neq \tau$,*
4. *$\operatorname{rad} B_\tau = f_\tau(\operatorname{rad} A)f_\tau$ for all $\tau$, and*
5. *$B_\tau/\operatorname{rad} B_\tau \cong A_\tau$ for all $\tau$.*

*Proof.*

1. $B$ is clearly closed under addition and scalar multiplication. $1 \in B$, too. It remains to show that $B$ is also closed under multiplication. This follows from the fact that the $f_\tau$ annihilate each other: We have

$$(f_1a_1f_1 + \cdots + f_ta_tf_t)(f_1b_1f_1 + \cdots + f_tb_tf_t) = f_1a_1f_1b_1f_1 + \cdots + f_ta_tf_tb_tf_t \in B, \tag{10}$$

since $f_\sigma f_\tau = 0$ for $\sigma \neq \tau$.

2. $B_\tau$ is obviously closed under addition, scalar multiplication, and multiplication. Furthermore, $f_\tau$ is the identity of $B_\tau$.
3. We have $f_\sigma af_\sigma \cdot f_\tau bf_\tau = 0$ for all $f_\sigma af_\sigma \in B_\sigma$ and $f_\tau bf_\tau \in B_\tau$, as $f_\sigma \cdot f_\tau = 0$.
4. Since $e_1 + \cdots + e_t$ is a central decomposition, this follows from Theorem 23.
5. We have $A_\tau \cong e_\tau(A/\operatorname{rad} A)e_\tau$, where $e_1 + \cdots + e_t$ is a decomposition of the identity of $A/\operatorname{rad} A$ as in (9). On the other hand, $\operatorname{rad} B_\tau = f_\tau Af_\tau/f_\tau(\operatorname{rad} A)f_\tau$ by the second and fourth statements. We define a mapping $i : A_\tau \to B_\tau/\operatorname{rad} B_\tau$ by $e_\tau(a + \operatorname{rad} A)e_\tau \mapsto f_\tau af_\tau + f_\tau(\operatorname{rad} A)f_\tau$. We claim that $i$ is an isomorphism. First, $i$ is well defined: Consider elements $a$ and $b$ fulfilling $e_\tau(a + \operatorname{rad} A)e_\tau = e_\tau(b + \operatorname{rad} A)e_\tau$. Then by (9),

$$\begin{aligned} f_\tau af_\tau + \operatorname{rad} A &= (f_\tau + \operatorname{rad} A)(a + \operatorname{rad} A)(f_\tau + \operatorname{rad} A) \\ &= (f_\tau + \operatorname{rad} A)(b + \operatorname{rad} A)(f_\tau + \operatorname{rad} A) \\ &= f_\tau bf_\tau + \operatorname{rad} A. \end{aligned} \tag{11}$$

Thus $i$ is well defined.
Obviously, $i(\alpha x) = \alpha i(x)$ and $i(x + y) = i(x) + i(y)$ for all $x, y \in A_\tau$. For $x = e_\tau(a + \operatorname{rad} A)e_\tau$ and $y = e_\tau(b + \operatorname{rad} A)e_\tau$ in $B_\tau$, we have

$$xy = e_\tau(a + \operatorname{rad} A)e_\tau \cdot e_\tau(b + \operatorname{rad} A)e_\tau = e_\tau(af_\tau b + \operatorname{rad} A)e_\tau. \tag{12}$$

Hence,

$$\begin{aligned} i(xy) &= f_\tau af_\tau bf_\tau + f_\tau(\operatorname{rad} A)f_\tau \\ &= (f_\tau af_\tau + f_\tau(\operatorname{rad} A)f_\tau)(f_\tau bf_\tau + f_\tau(\operatorname{rad} A)f_\tau) \\ &= i(x)i(y). \end{aligned}$$

Finally, since $f_\tau a f_\tau \in f_\tau(\operatorname{rad} A)f_\tau$ iff $e_\tau(a + \operatorname{rad} A)e_\tau \subseteq \operatorname{rad} A$, $i$ is also bijective. □

## 5. Main result.

Throughout this section, $A$ denotes a $k$-algebra of minimal rank and $A_1 \oplus \cdots \oplus A_t$ denotes the decomposition of $A/\operatorname{rad} A$ into simple algebras. Again we write the decomposition in an additive way.

By Corollary 9 and Lemma 10, $A/\operatorname{rad} A$ is of minimal rank. By [4, Theorem 2], either $A_\tau \cong k$ or $A_\tau \cong k^{2\times 2}$ or $A_\tau$ is a proper extension field of $k$ for all $\tau$. In the latter case, $\#k \geq 2\dim A_\tau - 2$ also has to hold.

Let $e_\tau$ be the identity of $A_\tau$, and let $f_1 + \cdots + f_t$ be a decomposition of the identity of $A$ as in (9). Consider the *Peirce decomposition* (see [11, p. 26]) of $A$ with respect to $f_1, \dots, f_t$:

$$A = \bigoplus_{1\leq \sigma,\tau \leq t} f_\sigma A f_\tau \qquad \text{and} \qquad \operatorname{rad} A = \bigoplus_{1\leq \sigma,\tau \leq t} f_\sigma (\operatorname{rad} A) f_\tau.$$

Since $f_1, \dots, f_t$ are idempotents that annihilate each other, the pairwise intersections of the $f_\sigma A f_\tau$ equal in fact $\{0\}$.

Compared to the proof over perfect fields, the algebra $f_1 A f_1 \oplus \cdots \oplus f_t A f_t$ now plays the role of the subalgebra $S$ of $A$ with $S \cong A/\operatorname{rad} A = A_1 \oplus \cdots \oplus A_t$ in [5]. The proof in this section is almost the same as that of [5], since we need only the following property (in the proof of Lemma 31): The intersection of each $f_\tau A f_\tau$ with any $f_i(\operatorname{rad} A)f_j$ with $i \neq j$ is the nullspace. Furthermore, the $f_\tau A f_\tau$ annihilate each other like the $A_\tau$ do. The only thing which slightly complicates matters is that instead of knowing that $A_\tau$ is simple, we here have only that $f_\tau A f_\tau / \operatorname{rad} f_\tau A f_\tau$ is simple and in fact equal to $A_\tau$.

### 5.1. A first decomposition step.

If an idempotent, say, $f_1$ fulfils $f_1(\operatorname{rad} A)f_j = f_j(\operatorname{rad} A)f_1 = \{0\}$ for all $j \geq 2$, then the characterization problem splits into two subproblems.

Lemma 25. *If $f_1(\operatorname{rad} A)f_j = f_j(\operatorname{rad} A)f_1 = \{0\}$ for all $2 \leq j \leq t$, then*

$$A \cong f_1 A f_1 \times (f_2 + \cdots + f_t) A (f_2 + \cdots + f_t).$$

*Proof.* Let $f' := f_2 + \cdots + f_t$. First note that $f_1 A f_1$ is an algebra by Lemma 24(2). Along the same lines, it is easy to see that $f' A f'$ is an algebra.

Since $e_\tau = f_\tau + \operatorname{rad} A$ is the identity of $A_\tau$ for all $\tau$, $e_\tau$ is contained in the center of $A/\operatorname{rad} A$ (i.e., $e_\tau a = a e_\tau$ for all $a \in A/\operatorname{rad} A$). Thus by Theorem 23, we have $f_\sigma A f_\tau = f_\sigma(\operatorname{rad} A) f_\tau$ for all $\sigma \neq \tau$. In particular, $f_1 A f_j = f_j A f_1 = \{0\}$ for all $j \geq 2$.

Let $a \in A$ be arbitrary. We can write $a = a_1 + a'$ with unique $a_1 \in f_1 A f_1$ and $a' \in f' A f'$, since $f_1 A f_1 \oplus f' A f' = A$. We define a mapping $A \to f_1 A f_1 \times f' A f'$ by $a \mapsto (a_1, a')$. Exploiting the fact that $f_1 A f' = f' A f_1 = \{0\}$, it is easy to verify that this is an isomorphism of algebras. □

Next we show that if $A$ has minimal rank, both $f_1 A f_1$ and $f' A f'$ have minimal rank. This follows directly from the work of Alder and Strassen.

Lemma 26. *Let $B_1$ and $B_2$ be two algebras. The algebra $B = B_1 \times B_2$ has minimal rank iff both $B_1$ and $B_2$ have minimal rank.*

*Proof.* Assume that $B$ has minimal rank. Let $t_1$, $t_2$, and $t$ be the number of twosided maximal ideals of $B_1$, $B_2$, and $B$, respectively. We have $t = t_1 + t_2$. Note that $\operatorname{rad} B = \operatorname{rad} B_1 \times \operatorname{rad} B_2$. By Corollary 9 and Lemma 10, $R(B) \geq 2\dim \operatorname{rad} B_1 + R((B_1/\operatorname{rad} B_1) \times B_2)$. If we now apply Lemma 11 repeatedly, we obtain $R(B) \geq$

$2\dim B_1 - t_1 + R(B_2)$. Thus $B_2$ has to have minimal rank. $B_1$ is treated completely the same way.

The other direction is trivial. □

Now assume that, say, $A_1$ is either an extension field of dimension at least two or isomorphic to $k^{2\times 2}$. Moreover, let $f_1(\operatorname{rad} A)f_j = f_j(\operatorname{rad} A)f_1 = \{0\}$ for all $2 \le j \le t$. By Lemma 26, the algebra $f_1Af_1$ has to have minimal rank. By Lemma 24(5), we obtain $(f_1Af_1)/\operatorname{rad}(f_1Af_1) = e_1(A/\operatorname{rad} A)e_1 \cong A_1$.

If $A_1$ is an extension field, then $f_1Af_1$ is local and $\dim f_1Af_1/(\operatorname{rad} f_1Af_1) \ge 2$. Such algebras have been characterized by Büchi and Clausen [8]. They are isomorphic to $k[X]/(p(X)^m)$ for some irreducible polynomial $p$ with $\deg p \ge 2$ and some $m \ge 1$ and $\#k \ge 2m \deg p$. The case that $A_1$ is isomorphic to $k^{2\times 2}$ is settled by the following lemma. It turns out that, in this case, we necessarily have $f_1Af_1 \cong k^{2\times 2}$.

LEMMA 27. *Let $C$ be an algebra fulfilling $C/\operatorname{rad} C \cong k^{2\times 2}$. Then $R(C) \ge \frac{5}{2}\dim C - 4$. In particular, if $\operatorname{rad} C \ne \{0\}$, then $C$ is not of minimal rank.*

*Proof.* Let $\beta = (f_1, g_1, w_1, \dots, f_r, g_r, w_r)$ be a bilinear computation for $C$. We may assume w.l.o.g. that $f_1, \dots, f_N$ is a basis of $C^*$, where $N = \dim C$. Let $u_1, \dots, u_N$ be its dual basis. Furthermore, assume that $\bar u_{N-3}, \dots, \bar u_N$ is a basis of $C/\operatorname{rad} C \cong k^{2\times 2}$, where $\bar{\ } : C \to C/\operatorname{rad} C$ denotes the canonical projection. Choose $\alpha_1, \dots, \alpha_4$ such that $1 = \alpha_1\bar u_{N-3} + \dots + \alpha_4 \bar u_N$ (in $C/\operatorname{rad} C$). By Nakayama's lemma (Lemma 4), $\alpha_1 u_{N-3} + \dots + \alpha_4 u_N$ is invertible in $C$. Exploiting sandwiching (see section 2.2), we can achieve that $1 = \alpha_1 u_{N-3} + \dots + \alpha_4 u_N$ in $C$. Choose $\xi_1, \dots, \xi_4$ and $\eta_1, \dots, \eta_4$ such that for $x = \xi_1 u_{N-3} + \dots + \xi_4 u_N$ and $y = \eta_1 u_{N-3} + \dots + \eta_4 u_N$,

$$\bar x = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \quad \text{and} \quad \bar y = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

An easy calculation shows that $\bar x\bar y - \bar y \bar x$ is invertible in $C/\operatorname{rad} C$. Once more by Lemma 4, $xy - yx$ is invertible in $C$. Now by [4, Lemma 3.8] (with $m = N - 4$),

$$r \ge 5/2 \dim C - 4. \tag{13}$$

Since $C/\operatorname{rad} C \cong k^{2\times 2}$, the algebra $C/\operatorname{rad} C$ is separable; that is, for any extension field $K$ of $k$, $(C/\operatorname{rad} C) \otimes K \cong K^{2\times 2}$ is semisimple. By the Wedderburn–Malcev theorem (Theorem 5), $C$ contains a subalgebra $C' \cong k^{2\times 2}$ with $C' \oplus \operatorname{rad} C = C$. Hence $\operatorname{rad} C$ is a $k^{2\times 2}$-bimodule. By [4, Fact 8.5], $\operatorname{rad} C \ne \{0\}$ implies $\dim \operatorname{rad} C \ge 4$. Now we can rewrite (13) as

$$r \ge 5/2 \dim C - 4 = 2\dim C + \underbrace{1/2(4 + \dim \operatorname{rad} C) - 4}_{\ge 0 \text{ if } \operatorname{rad} C \ne \{0\}}.$$

This proves the second statement. □

By Theorem 23, $\operatorname{rad}(f'Af') = f'(\operatorname{rad} A)f'$ holds. From this, it follows that $(f'Af')/\operatorname{rad}(f'Af') = e'(A/\operatorname{rad} A)e' = A_2 \oplus \dots \oplus A_t$, as in the proof of Lemma 24(5), where $e' = e_2 + \dots + e_t$. Hence we can proceed recursively with $f'Af'$. The following lemma summarizes these considerations.

LEMMA 28. *Let $A$ be an algebra of minimal rank over an arbitrary field $k$. Then*

$$A \cong C_1 \times \dots \times C_s \times \underbrace{k^{2\times 2} \times \dots \times k^{2\times 2}}_{u \text{ times}} \times B,$$

*where*

1. *the $C_\sigma$ are local algebras of minimal rank with* $\dim C_\sigma/\operatorname{rad} C_\sigma \geq 2$ *and*
2. *$B$ is an algebra of minimal rank.*

*Furthermore, if $B_1 \oplus \cdots \oplus B_r$ is a decomposition of $B/\operatorname{rad} B$ into simple factors, $e_\rho$ denotes the identity of $B_\rho$ for $1 \leq \rho \leq r$, and $f_1 + \cdots + f_r$ is a decomposition of the identity of $B$ as in* (9)*, then for all $B_\rho$ such that $B_\rho$ is either isomorphic to $k^{2\times 2}$ or a proper extension field of $k$ there is a $j_\rho \neq \rho$ such that $f_\rho(\operatorname{rad} B)f_{j_\rho} \neq \{0\}$ or $f_{j_\rho}(\operatorname{rad} B)f_\rho \neq \{0\}$. Above, $s$ and $u$ may be zero and the factor $B$ is optional.*

**5.2. *B* is superbasic.** Next we show that the algebra $B$ in Lemma 28 is always superbasic; that is, all the $B_\rho$ in the decomposition of $B/\operatorname{rad} B$ into simple algebras are isomorphic to $k$. Thereafter, we apply Theorem 22 and obtain our characterization result.

To do so, under the assumption that one of the factors $B_\rho$ is not isomorphic to $k$, we construct some algebras that have to have minimal rank because $B$ has minimal rank. Then we prove that none of the constructed algebras has minimal rank, obtaining a contradiction.

The next lemma shows that it suffices to consider the problem modulo $(\operatorname{rad} B)^2$ in the sense that, modulo $(\operatorname{rad} B)^2$, the algebra $B/(\operatorname{rad} B)^2$ still has the same properties as $B$ in Lemma 28. For any algebra $C$, let $\tilde{ } : C \to C/(\operatorname{rad} C)^2$ denote the canonical projection defined by $a \mapsto \tilde{a} = a + (\operatorname{rad} C)^2$.

LEMMA 29. *Let $A$ be an algebra of minimal rank over an arbitrary field $k$. Let $A \cong C_1 \times \cdots \times C_s \times k^{2\times 2} \times \cdots \times k^{2\times 2} \times B$, as in Lemma 28, and let $\tilde{B}$ and $\tilde{B}_1, \ldots, \tilde{B}_r$ be the images of $B$ and $B_1, \ldots, B_r$ under the canonical projection $B \to B/(\operatorname{rad} B)^2$. Then $\tilde{B}$ has minimal rank, and for all $\tilde{B}_\rho$ such that $\tilde{B}_\rho$ is either isomorphic to $k^{2\times 2}$ or a proper extension field of $k$, there is a $j'_\rho \neq \rho$ such that $\tilde{f}_\rho(\operatorname{rad} \tilde{B})\tilde{f}_{j'_\rho} \neq \{0\}$ or $\tilde{f}_{j'_\rho}(\operatorname{rad} \tilde{B})\tilde{f}_\rho \neq \{0\}$.*

*Proof.* If $B$ has minimal rank, so has $\tilde{B}$, by Corollary 9. Since for each $B_\rho$ that is either isomorphic to $k^{2\times 2}$ or a proper extension field of $k$, there is a $j_\rho \neq \rho$ such that $f_\rho(\operatorname{rad} B)f_{j_\rho} \neq \{0\}$ or $f_{j_\rho}(\operatorname{rad} B)f_\rho \neq \{0\}$, the next lemma shows the existence of the index $j'_\rho$. ◻

LEMMA 30. *Let $C$ be an algebra and $C_1 \oplus \cdots \oplus C_r$ be the decomposition of $C/\operatorname{rad} C$ into simple factors. Let $e_\rho$ be the identity of $C_\rho$ for all $\rho$, and let $f_1 + \cdots + f_r$ be a decomposition of the identity as in* (9)*. For all indices $i$ and $j$ with $i \neq j$ such that $f_i(\operatorname{rad} C)f_j \neq \{0\}$, there is an index $j'$ with $i \neq j'$ such that $\tilde{f}_i(\operatorname{rad} \tilde{C})\tilde{f}_{j'} \neq \{0\}$. In the same way, there is an index $i'$ with $i' \neq j$ such that $\tilde{f}_{i'}(\operatorname{rad} \tilde{C})\tilde{f}_j \neq \{0\}$.*

*Proof.* Let $x$ be such that $f_i x f_j \neq 0$ and $f_i x f_j \in f_i(\operatorname{rad} C)f_j$. Since $f_i C f_j = f_i(\operatorname{rad} C)f_j$ by Theorem 23, we may assume $x \in \operatorname{rad} C$. Let $n \geq 1$ be the unique number such that $x \in (\operatorname{rad} C)^n \setminus (\operatorname{rad} C)^{n+1}$. By definition, there are $x_1, \ldots, x_n \in \operatorname{rad} C \setminus (\operatorname{rad} C)^2$ such that $x = x_1 \cdots x_n$. Since $1 = f_1 + \cdots + f_r$,

$$f_i x_1(f_1 + \cdots + f_r)x_2(f_1 + \cdots + f_r) \cdots (f_1 + \cdots + f_r)x_n f_j = f_i x f_j \neq 0.$$

Thus there are indices $h_1, \ldots, h_{n-1}$ such that

$$f_i x_1 f_{h_1} x_2 f_{h_2} \cdots f_{h_{n-1}} x_n f_j \neq 0.$$

If all $h_\nu$ equal $i$, then $f_{h_{n-1}} x_n f_j = f_i x_n f_j \neq 0$, and we set $j' = j$. Since $f_i x_n f_{j'} \in \operatorname{rad} C \setminus (\operatorname{rad} C)^2$, $\tilde{f}_i \tilde{x}_n \tilde{f}_{j'} \neq 0$, and hence we are done. Otherwise let $\nu_0$ be the smallest index such that $h_{\nu_0} \neq i$. Now we set $j' = h_{\nu_0}$ and can conclude in the same way as before that $\tilde{f}_i(\operatorname{rad} \tilde{C})\tilde{f}_{j'} \neq \{0\}$.

The index $i'$ is constructed in the identical way. ∎

W.l.o.g. we assume from now on that $(\operatorname{rad} B)^2 = \{0\}$. $B_1$ is either isomorphic to $k^{2\times 2}$ or a (not necessarily proper) extension field of $k$. We first construct two algebras, which have to have minimal rank since $B$ has minimal rank. Next we prove that these algebras cannot have minimal rank if $B_1$ is isomorphic to $k^{2\times 2}$ or a proper extension field of $k$. Hence $B_1 \cong k$ must hold. By symmetry, this has to hold for all $B_1, \dots, B_r$. It follows that $B$ is superbasic.

The next lemma shows how to construct these two algebras. By symmetry, the lemma also holds for $(\operatorname{rad} B) f_1 \neq \{0\}$.

LEMMA 31. *If $f_1(\operatorname{rad} B) \neq \{0\}$, then there is an index $2 \leq j \leq s$ and a nonzero $(B_1, B_j)$-bimodule $M$ such that the algebra $B_1 \times B_j \times M$ (as vector spaces) with multiplication law $(a, b, x) \cdot (a', b', x') = (aa', bb', ax' + xb')$ has minimal rank.*

*Proof.* We decompose $\operatorname{rad} B$ as

$$\operatorname{rad} B = \bigoplus_{1 \leq \rho, \eta \leq r} f_\rho (\operatorname{rad} B) f_\eta. \tag{14}$$

By Lemma 29, there is an index $j \geq 2$ such that $f_1(\operatorname{rad} B) f_j \neq \{0\}$. W.l.o.g. we may assume that $j = 2$.

Consider $C := f_1 B f_1 + f_2 B f_2$. As in Lemma 24(1), it is easy to see that $C$ is a subalgebra of $B$. As in Lemma 24(4), $\operatorname{rad} C = f_1(\operatorname{rad} B) f_1 + f_2(\operatorname{rad} B) f_2$. Finally $C/\operatorname{rad} C \cong B_1 \oplus B_2$. Since the pairwise intersection of the $f_\rho(\operatorname{rad} B) f_\eta$ in (14) are the nullspace, we also have $C/\operatorname{rad} B \cong B_1 \oplus B_2$.

Let

$$I = \bigoplus_{(\rho,\eta) \neq (1,2)} f_\rho (\operatorname{rad} B) f_\eta.$$

$I$ is a twosided ideal of $B$ (see also [4, p. 105]). Since $B$ is of minimal rank and $I \subseteq \operatorname{rad} B$, $B/I$ is also of minimal rank by Corollary 9 and Lemma 10. By [11, Corollary 3.1.14], we have $\operatorname{rad}(B/I) = (\operatorname{rad} B)/I \cong f_1(\operatorname{rad} B) f_2 / I \neq \{0\}$. Let $\hat{\ } : B \to B/I$ denote the canonical projection defined by $a \mapsto \hat{a} = a + I$. Since $I \subseteq \operatorname{rad} B$, $\hat{f}_1, \dots, \hat{f}_r$ are idempotent elements that annihilate each other, because this also holds for $f_1, \dots, f_r$. Let $\hat{f} = \hat{f}_3 + \cdots + \hat{f}_r$. Then for all $a \in \hat{f}(B/I)\hat{f}$, we have $a(\operatorname{rad} B/I) = (\operatorname{rad} B/I)a = \{0\}$, since the $\hat{f}_\rho$ annihilate each other. This means that the elements in $(\hat{f}_1 + \hat{f}_2)(B/I)(\hat{f}_1 + \hat{f}_2)$ annihilate the elements in $\hat{f}(B/I)\hat{f}$ and vice versa. Then $B/I$ is isomorphic to the product of these two algebras (see, e.g., [4, Lemma 8.3] for a proof), i.e.,

$$B/I \cong (\hat{f}_1 + \hat{f}_2)\,(B/I)\,(\hat{f}_1 + \hat{f}_2) \times \hat{f}\,(B/I)\,\hat{f}.$$

By Lemma 26, $B/I$ is of minimal rank only if $D := (\hat{f}_1 + \hat{f}_2)(B/I)(\hat{f}_1 + \hat{f}_2)$ is of minimal rank.

Because $C := f_1 B f_1 + f_2 B f_2$ is a subalgebra of $(f_1 + f_2) B (f_1 + f_2)$, $\hat{C}$ is a subalgebra of $D$. This subalgebra $\hat{C}$ is isomorphic to $B_1 \oplus B_2$, since $\operatorname{rad} C = f_1(\operatorname{rad} B) f_1 + f_2(\operatorname{rad} B) f_2$. Hence $D$ has a subalgebra that is isomorphic to $B_1 \oplus B_2$. The radical of $D$ is $\operatorname{rad} D \cong f_1(\operatorname{rad} B) f_2 / I \neq \{0\}$.

Noting that $\operatorname{rad} D$ is a $(B_1, B_2)$-bimodule that fulfills the multiplication law in the lemma completes the proof. ∎

The two lemmas below show that the algebras constructed in Lemma 31 cannot have minimal rank. Hence we have obtained the following result.

Lemma 32. *The algebra $B$ in Lemma 28 is superbasic.*

We have two possible choices for $B_1$ in Lemma 31, namely, $B_1 \cong k^{2\times 2}$ and $B_1$ is a proper extension field of $k$. We split them into several subcases depending on $B_2$. The cases $B_1 \cong k^{2\times 2}$ and $B_2$ isomorphic to either $k$ or to $k^{2\times 2}$ are treated in [4, Lemmas 8.7, 8.8]. Lemma 33 below treats the case where $B_1$ is a proper extension field of $k$ and $B_2$ is either also a proper extension field of $k$ or $k$ itself. Finally, Lemma 34 settles the case where $B_1 \cong k^{2\times 2}$ and $B_2$ is a proper extension field. By symmetry this also settles the remaining case where the roles of $B_1$ and $B_2$ are interchanged.

Lemma 33. *Let $K$ be a proper extension field of $k$ and $L$ be a (not necessarily proper) extension field of $k$. Let $M$ be a nonzero $(K, L)$-bimodule, and define the algebra $A = K \times L \times M$ (as vector spaces) with multiplication law $(a, b, x)\cdot(a', b', x') = (aa', bb', ax' + xb')$. Then*

$$R(A) \geq 2\dim L + \dim M + (2\dim K - 1)\frac{\dim M}{\dim K + 1} - 1.$$

*In particular, $A$ is not of minimal rank.*

*Proof.* Let $\beta = (f_1, g_1, w_1, \ldots, f_r, g_r, w_r)$ be an optimal computation for $A$, and let $n = \dim A$. We can achieve that $w_1, \ldots, w_n$ form a basis of $A$. W.l.o.g. we may assume that $\mathrm{lin}\{w_1, \ldots, w_\ell\} + (K \times \{0\} \times M) = A$, where $\ell = \dim L$. Let $W_1 = \mathrm{lin}\{w_1, \ldots, w_{\ell-1}\}$. By definition, $\beta$ separates the triple $(\{0\}, \{0\}, W_1)$.

Next we show that the computation $\beta$ also separates the triple $(\{0\} \times \{0\} \times M, \{0\}, W_1)$. If this were not the case, then there would be a nonzero $a \in \{0\}\times\{0\}\times M$ by Lemma 12 such that

$$a \cdot A \subseteq (\{0\} \times \{0\} \times M) \cdot \{0\} + W_1 = W_1,$$

which cannot be the case, as $W_1 \cap (\{0\} \times \{0\} \times M) = \{0\}$.

We claim that $\beta$ even separates $(\{0\} \times L \times M, \{0\}, W_1)$. Otherwise, Lemma 12 implies that there would be some $a \in (\{0\} \times L \times M) \setminus (\{0\} \times \{0\} \times M)$ such that

$$a \cdot A \subseteq (\{0\} \times L \times M) \cdot \{0\} + W_1 = W_1.$$

As $a \in (\{0\} \times L \times M) \setminus (\{0\} \times \{0\} \times M)$, we have $\dim a \cdot A \geq \dim L = \ell$, contradicting $\dim W_1 \leq \ell - 1$.

Define $\beta' = (f_1, g_1', w_1, \ldots, f_r, g_r', w_r)$ through $g_\rho' = g_\rho'|_{K\times\{0\}\times M}$ for all $\rho$. From the definition of "separate," it follows that $\beta'$ also separates $(\{0\} \times L \times M, \{0\}, W_1)$.

Let $\phi$ be the multiplication map of $A$. Then $\beta'$ is a computation for the bilinear map $\psi := \phi|_{A\times(K\times\{0\}\times M)}$, which we can view as the multiplication $a \cdot (a', x') \mapsto (aa', ax')$ of the $K$-left module $K \times M$. Let $\pi$ be a projection of $A$ onto $K \times \{0\} \times M$ with $W_1 \subseteq \ker \pi$. Since $\mathrm{im}\, \psi \subseteq K \times \{0\} \times M$, $\pi \circ \psi = \psi$.

Now by Lemma 8

$$\begin{aligned} R(A) &\geq R\big(\psi/((\{0\} \times L \times M) \times \{0\})\big) + \dim L + \dim M + \#W_1 \\ &\geq R\big(\psi/((\{0\} \times L \times M) \times \{0\})\big) + 2\dim L + \dim M - 1. \end{aligned} \tag{15}$$

Since we have $\psi(\{0\} \times L \times M, K \times \{0\} \times M) = \{0\}$, we can still view $\psi/((\{0\} \times L \times M) \times \{0\})$ as the multiplication of the $K$-left module $K \times M$. By Wedderburn's theorem for modules [19], $K \times M \cong K^m$, where $m = \dim(K \times M)/\dim K$. (It also follows that $m$ is necessarily an integer strictly greater than one.) By Hartmann's lower bounds for the rank of modules [17, Theorem 2],

$$R\big(\psi/((\{0\} \times L \times M) \times \{0\})\big) \geq (2\dim K - 1) \cdot \frac{\dim M}{\dim K + 1}.$$

This proves the first claim of the lemma.

To see that the last bound implies that $A$ is not of minimal rank, we rewrite the bound as

$$R(A) \geq 2\dim L + 3\dim M + 2\dim K - \frac{\dim M}{\dim K} - 2.$$

Since $A$ has two maximal ideals, the second claim of the lemma is proven if $\dim M - \dim M/\dim K - 1 \geq 0$. But this is clearly true, because $\dim K \geq 2$ and $\dim M \geq \dim K \geq 2$. □

LEMMA 34. *Let $L$ be a proper extension field of $k$, and let $M$ be a nonzero $(k^{2\times 2}, L)$-bimodule. Define the algebra $A = k^{2\times 2} \times L \times M$ (as vector spaces) with multiplication law $(a, b, x) \cdot (a', b', x') = (aa', bb', ax' + xb')$. Then*

$$R(A) \geq 2\dim L + \frac{5}{2}\dim M + 6.$$

*In particular, $A$ is not of minimal rank.*

*Proof.* Let $\phi$ denote the multiplication of $A$, and define the bilinear map $\psi := \phi|_{A\times(k^{2\times 2}\times\{0\}\times M)}$. The same reasoning as in Lemma 33 shows that

$$R(A) \geq R\big(\psi/((\{0\} \times L \times M) \times \{0\})\big) + 2\dim L + \dim M - 1,$$

since we did not make use of fact that $K$ is an extension field in the proof of (15) in Lemma 33.

Since $(\{0\} \times L \times M) \cdot (k^{2\times 2} \times \{0\} \times M) = \{0\}$, $\psi/((\{0\} \times L \times M) \times \{0\})$ is the multiplication of the $k^{2\times 2}$-module $k^{2\times 2} \times M$. By Wedderburn's theorem for modules, this multiplication corresponds to the multiplication of $2 \times 2$-matrices with $2 \times m$-matrices, where $m = \frac{1}{2}(\dim k^{2\times 2} \times M) = 2 + \frac{1}{2}\dim M$. Since the rank of the multiplication of $2 \times 2$-matrices with $2 \times m$-matrices has the lower bound $3m + 1$ (see [7]), we obtain

$$R(A) \geq 2\dim L + \frac{5}{2}\dim M + 6.$$

To see that this implies that the algebra $A$ does not have minimal rank, note that $\dim A = 4 + \dim L + \dim M$, $A$ has two maximal ideals, and $\frac{1}{2}\dim M > 0$. □

**5.3. The final proof.** By Lemma 28, $A$ is isomorphic to

$$A \cong C_1 \times \cdots \times C_s \times \underbrace{k^{2\times 2} \times \cdots \times k^{2\times 2}}_{u \text{ times}} \times B,$$

where the $C_\sigma$ are local algebras of minimal rank with $\dim C_\sigma/\operatorname{rad} C_\sigma \geq 2$. By Lemma 32, $B$ is a superbasic algebra of minimal rank. By Theorem 22, we obtain the desired characterization of algebras of minimal rank over arbitrary fields.

THEOREM 35. *An algebra $A$ over an arbitrary field $k$ is an algebra of minimal rank iff*

$$A \cong C_1 \times \cdots \times C_s \times \underbrace{k^{2\times 2} \times \cdots \times k^{2\times 2}}_{u \text{ times}} \times B, \tag{16}$$

*where $C_1, \ldots, C_s$ are local algebras of minimal rank with $\dim(C_\sigma/\operatorname{rad} C_\sigma) \geq 2$, i.e., $C_\sigma \cong k[X]/(p_\sigma(X)^{d_\sigma})$ for some irreducible polynomial $p_\sigma$ with $\deg p_\sigma \geq 2$, $d_\sigma \geq 1$,* *and* $\#k \geq 2\dim C_\sigma - 2$, *and* $B$ *is a superbasic algebra of minimal rank; that is, there exist* $w_1, \dots, w_m \in \operatorname{rad} B$ *with* $w_i^2 \neq 0$ *and* $w_i w_j = 0$ *for* $i \neq j$ *such that*

$$\operatorname{rad} B = \mathsf{L}_B + Bw_1B + \cdots + Bw_mB = \mathsf{R}_B + Bw_1B + \cdots + Bw_mB$$

*and* $\#k \geq 2N(B) - 2$. *Any of the integers* $s$, $u$, *or* $m$ *may be zero, and the factor* $B$ *in* (16) *is optional.*

# NONINDEPENDENT RANDOMIZED ROUNDING AND AN APPLICATION TO DIGITAL HALFTONING*

BENJAMIN DOERR†

**Abstract.** We investigate the problem of rounding a given $[0,1]$-valued matrix to a $0,1$ matrix such that the rounding error with respect to $2 \times 2$ boxes is small. Such roundings yield good solutions for the digital halftoning problem, as shown by Asano et al. [*Proceedings of the* 13*th Annual ACM-SIAM Symposium on Discrete Algorithms*, San Francisco, 2002, SIAM, Philadelphia, 2002, pp. 896–904]. We present a randomized algorithm computing roundings with expected error at most 0.5463 per box, improving the 0.75 nonconstructive bound of Asano et al. Our algorithm is the first to solve this problem fast enough for practical application, namely, in linear time.

Of broader interest might be our rounding scheme, which is a modification of randomized rounding. Instead of independently rounding the variables, we impose a number of suitable dependencies. Thus, by equipping the rounding process with some of the problem information, we reduce the rounding error significantly compared to independent randomized rounding, which leads to an expected error of 0.82944 per box. Finally, we give a characterization of realizable dependencies.

**Key words.** randomized rounding, discrepancy, digital halftoning

## 1. Introduction.

In this paper, we are concerned with rounding problems. In their general form, these problems are of the following type: Given some numbers $x_1, \dots, x_n$, one is looking for roundings $y_1, \dots, y_n$ such that some given error measures are small. By rounding we always mean that $y_i = \lfloor x_i \rfloor$ or $y_i = \lceil x_i \rceil$. Since there are $2^n$ possibilities, such rounding problems are good candidates for hard problems. In fact, even several restricted versions like the discrepancy problem are known to be NP-hard. An example related to the problems considered in this paper can be found in Asano, Matsui, and Tokuyama [3, 4].

On the other hand, there are cases that can be solved optimally in polynomial time. Knuth [17], for example, has shown that there exists a rounding such that the errors $|\sum_{i=1}^{k}(y_i - x_i)|$ and $|\sum_{i=1}^{k}(y_{\pi(i)} - x_{\pi(i)})|$ for a fixed permutation $\pi$ and all $1 \le k \le n$ are at most $\frac{n}{n+1}$. Such roundings can be obtained by computing a maximum flow in a network. A recent generalization [7] shows this bound for arbitrary totally unimodular rounding problems.

### 1.1. The digital halftoning problem: A matrix rounding problem.

The rounding problem considered in this paper is motivated by an application from image processing. The *digital halftoning problem* is to convert a continuous-tone intensity image (each pixel may have an arbitrary "color" on the white-to-black scale) into a binary image (only black and white dots are allowed). An intensity image can be represented by a $[0,1]$-valued $m \times n$ matrix $A$. Each entry $a_{ij}$ corresponds to the brightness level of the pixel with coordinates $(i,j)$. Since many devices, e.g., laser

printers, can output only white and black dots, we have to round $A$ towards a $0, 1$ matrix. Naturally, this has to be done in such a way that the resulting image looks similar to the original.

This notion of similarity is a crucial point. From the viewpoint of application, similarity is defined via the human visual system: A rounding is good if an average human being can retrieve most of the original information from the rounded image. Using this "criterion," several algorithms turned out to be useful. Floyd and Steinberg [11] proposed the error diffusion algorithm, which rounds the entries one by one and distributes the rounding error over neighboring not-yet-rounded entries. Lippel and Kurland [21] and Bayer [5] investigated the ordered dither algorithm, which partitions the image into fixed size submatrices and rounds each submatrix by comparing its entries with a threshold matrix of the same size. One advantage of this approach is that it can be parallelized easily. Knuth [16] combined ideas from both approaches to get an algorithm called dot diffusion.

Though some work has been done in this direction, less understanding seems to be present on the theoretical side. In particular, a good mathematical formulation of similarity seems hard to find. Such a similarity measure is desirable for two reasons. First, it would allow us to compare algorithms without extensive experimental testing. This is particularly interesting, since comparing different halftonings is a delicate issue. For example, it makes a huge difference whether the images are viewed on a computer screen or are printed on a laser printer. Different printers can also give different impressions. Therefore, a more objective criterion would be very helpful. A second reason is that, in attaining a good criterion, one would have a clearer indication of how a digital halftoning algorithm should work. Thus developing good algorithms would be easier.

So far, the most widely accepted criterion for a good halftoning algorithm is that it has the "blue noise" property (first detected by Ulichney [34]; cf. also the surveys Ulichney [33] and Lau and Arce [19]). This refers not to a similarity measure comparing two images, but an analysis of how the algorithm performs on constant grey level areas. Thus, on the other hand, it gives no information on how changing intensities, in particular shapes, are reproduced. This work has been extended by Sullivan, Ray, and Miller [32], who use a model based on the human visual system to compute good halftoning patterns for constant intensity areas.

Significant research has been done on "global" (regarding the whole image) similarity measures; see, e.g., Lieberman and Allebach [20] and the references therein. However, in many cases the complexity of these measures makes a theoretical investigation almost impossible. Even computing approximations efficiently is often difficult.

At the 2002 international ACM/SIAM Symposium on Discrete Algorithms, Asano et al. [2] presented a structurally much simpler similarity measure, together with several theoretical results. Their experimental studies indicate that good digital halftonings have small error with respect to all $2 \times 2$ subregions. This yields the following problem.

**1.2. Problem statement and results.** Let $A \in [0,1]^{m \times n}$ denote our input matrix. The set $R_{ij} := \{i, i+1\} \times \{j, j+1\} = \{(i,j), (i+1,j), (i,j+1), (i+1,j+1)\}$ for some $i \in [m-1], j \in [n-1]$, is called a $2 \times 2$ subregion (or box) in $[m] \times [n]$.[1] Denote by $\mathcal{R}$ the set of all these boxes. We write $A_{R_{ij}}$ for the $2 \times 2$ matrix $\left(\begin{smallmatrix} a_{i,j} & a_{i,j+1} \\ a_{i+1,j} & a_{i+1,j+1} \end{smallmatrix}\right)$

[1]For an arbitrary number $r$ we denote by $[r]$ the set of positive integers not exceeding $r$.

induced by $R_{ij}$. For any matrix $A$ set $\Sigma A := \sum_{i,j} a_{ij}$, the sum of all its entries.

For a matrix $B \in \{0,1\}^{m \times n}$—which is a rounding of $A$ unless we have $a_{ij}, b_{ij} \in \mathbb{Z}$ and $a_{ij} \neq b_{ij}$ for some $i, j$—we define the rounding error of $A$ with respect to $B$ by

$$d_{\mathcal{R}}(A,B) := \sum_{R \in \mathcal{R}} |\Sigma A_R - \Sigma B_R| \,.$$

We usually omit the subscript $\mathcal{R}$ when there is no danger of confusion.

Asano et al. [2] demonstrated that roundings $B$ such that $d(A,B)$ is small yield good digital halftonings. They showed that for any $A$ an optimal rounding $B^*$ satisfies $d(A,B^*) \leq 0.75|\mathcal{R}|$. They also gave a polynomial time algorithm computing a rounding $B$ such that $d(A,B) - d(A,B^*) \leq 0.5625|\mathcal{R}|$. It is easy to see that there are matrices $A$ such that all roundings (and in fact all integral matrices) $B$ have $d(A,B) \geq 0.5|\mathcal{R}|$.

A major drawback of the algorithm given in [2] is that it is not very practical, as it requires the solution of an integer linear program with totally unimodular constraint matrix. This leads to a run-time bound that is at least quadratic in the number $nm$ of pixels. As pointed out in [2], this is too slow for a real world application.

In this paper, we present a randomized algorithm that runs in linear time. It may be implemented in parallel without problems. This divides the run-time by the number of processors available. The roundings computed by our algorithm have an expected error that exceeds the optimal one by at most $0.3125|\mathcal{R}|$ (instead of $0.5625|\mathcal{R}|$). They also satisfy the absolute bound $E(d(A,B)) \leq 0.5463|\mathcal{R}|$, beating the nonalgorithmic bound of $0.75|\mathcal{R}|$ in [2].

The distribution of the rounding error resulting from this algorithm is highly concentrated around the expected value. The probability that the error exceeds the expected one by more than $\varepsilon|\mathcal{R}|$ is bounded by $\exp(-\Omega(\varepsilon^2\sqrt{|\mathcal{R}|}))$. Our algorithm can also be derandomized. This yields a deterministic linear time algorithm computing roundings with an error guarantee at most equal to that of the randomized version.

For an experimental study of how well our algorithm performs in practice, we refer to Schnieder [25]. Some of these results are also contained in [9].

**1.3. Nonindependent randomized rounding.** The key idea of our algorithm might also be of broader interest. We develop a randomized rounding scheme where the individual roundings are not independent. The classical approach of randomized rounding due to Raghavan and Thompson [23] and Raghavan [22] is to round each variable independently with probability depending on the fractional part of its value. This allows the use of Chernoff-type large deviation inequalities, showing that a sum of independent random variables is highly concentrated around its expectation.

Randomized rounding has been applied to numerous combinatorial optimization problems that can be formulated as integer linear programs (cf. Srinivasan [28]). Though very effective in the general case, a known difficulty with randomized rounding is how to use structural information about the underlying problem. Since only the solution of the linear relaxation is used, further information about the underlying problem cannot be exploited. One idea to overcome this is to use correlation among the events in the analysis of randomized rounding. This allows us to strengthen the classical bounds for packing and covering problems, as shown by Srinivasan [29].

In this paper, we try so use such structure in an earlier phase, namely, in the design of the random experiment. This leads to randomized roundings where the variables are not rounded independently. There have been few attempts to use nonindependent roundings. A straightforward one already appeared in the work of Raghavan and

Thompson and is highly motivated by the structure of the problem. In many cases, the linear program under consideration contains constraints of the kind

$$x_{i_1} + \cdots + x_{i_k} = 1. \tag{1}$$

Typical examples are the vector selection problem (exactly one vector has to be chosen from each of the given sets; cf. Raghavan [22]) or multicommodity flow problems (exactly one path has to be chosen from a nonintegral mixture of paths adding up to the flow; cf. Raghavan and Thompson [23]). In these cases, the probability that an independent randomized rounding is feasible, i.e., that $y_{i_1} + \cdots + y_{i_k} = 1$, can be arbitrarily close to $\frac{1}{e}$. If the number of equations of type (1) is large, this yields an exponentially small success probability.

The solution is to pick one of the variables $x_{i_1}, \ldots, x_{i_k}$ with probability given by its value in the relaxation, and set this variable to one and all others to zero. Thus the rounding is not done independently, but subject to the constraint that exactly one variable receives the value of one. A recent work of Srinivasan [30] extend this to constraints where sums of variables are required to have a particular value other than one.

Another paper on nonindependent roundings is Bertsimas, Teo, and Vohra [6]. They use dependent roundings to give alternative proofs of integrality for several classical polyhedra. They also use "global" dependencies that impose restrictions on the number of variables rounded up or down. For the integrality gap of MINSAT with clauses having at most $k$ literals, this reduces the trivial upper bound of 2 to the sharp bound of $2(1 - 2^{-k})$.

Looking at these results on dependent randomized rounding, we feel that the option of designing the random experiment in such a way that it reflects the structure of the underlying problem has not been exploited sufficiently. In this paper we try to move a step forward in this direction. We impose dependencies that are not necessary in the sense of feasibility but that are helpful in minimizing our objective function $d(A, B)$. For the rounding problem studied in the present paper, this improves the bound of $0.82944|\mathcal{R}|$ obtained by independent randomized rounding to $0.5463|\mathcal{R}|$.

In addition to the randomized rounding condition for single variables, we impose dependencies of the type

$$P\left(\sum_{i \in I_k} y_i = \left\lfloor \sum_{i \in I_k} x_i \right\rfloor + 1\right) = \left\{\sum_{i \in I_k} x_i\right\} \tag{2}$$

for some sets $I_k$ (we write $\{r\} := r - \lfloor r \rfloor$ to denote the fractional part of $r$). Hence our roundings are randomized roundings not only concerning the single variables, but also with respect to the sums $\sum_{i \in I_k} x_i$.[2] By choosing suitable dependencies, we obtain the above mentioned result.

We also consider the question of what dependencies can be realized. More formally, we ask how the sets $I_k$ have to be chosen such that for all values of the input variables a randomized rounding satisfying (2) exists. Surprisingly, there is a simple characterization: Such roundings exist if and only if the hypergraph consisting of the sets $I_k$ is totally unimodular. Of course, with this characterization at hand, the search for suitable dependency sets is much easier.

[2] The dependencies (1) used in [23] actually are a special case of this type where it is also required that (in the notation of (2)) $\sum_{i \in I_k} x_i = 1$ hold.

**2. Independent randomized rounding.** For a number $x$ we write $\lfloor x \rfloor$ for the largest integer not exceeding $x$; $\lceil x \rceil$ for the smallest, being not less than $x$; and $\{x\} := x - \lfloor x \rfloor$ for the fractional part of $x$. We say that some random variable $X$ is a *randomized rounding* of $x$ if $\Pr(X = \lfloor x \rfloor + 1) = \{x\}$ and $\Pr(X = \lfloor x \rfloor) = 1 - \{x\}$. In particular, if $x \in [0,1]$, we have $\Pr(X = 1) = x$ and $\Pr(X = 0) = 1 - x$.

We first analyze what can be achieved with independent randomized rounding. We say that $B$ is an *independent randomized rounding* of $A$ if each entry $b_{ij}$ is a randomized rounding of $a_{ij}$ and all these roundings are mutually independent. Let us remark that we do not expect this to be a competitive approach for the digital halftoning problem. In fact, this idea was experimented with already in the 1950s by Goodall [13] (see also Roberts [24]), long before the seminal work of Raghavan and Thompson. At that time, this was known under the name *thresholding with white noise* or *random dither*.

We use the result below both to estimate the effect of adding dependencies to the rounding process and in the proofs of some of our later results. Note that the proof is different from typical randomized rounding applications: Since the boxes are small, using a large deviation bound makes no sense, and one has to compute the expected error exactly.

THEOREM 2.1. *Let $A \in [0,1]^{m\times n}$, $B$ be an independent randomized rounding of $A$, and $B^*$ be an optimal rounding of $A$ (that is, $d(A, B^*)$ is minimal among all roundings of $A$). Then*

$$E(d(A,B)) \le 0.82944|\mathcal{R}|,$$

$$E(d(A,B)) \le 0.75|\mathcal{R}| + d(A,B^*).$$

*Proof.* By linearity of expectation, $E(d(A,B)) = \sum_{R\in\mathcal{R}} E(d(A_R, B_R)) = \sum_{R\in\mathcal{R}} E(|\Sigma A_R - \Sigma B_R|)$. Hence our analysis is reduced to the rounding problem of a single box $R$. The expected rounding error of a box $\binom{a_1\, a_2}{a_3\, a_4}$ is

$$f(a_1,a_2,a_3,a_4) = \sum_{S\subseteq[4]} \prod_{i\in S} a_i \prod_{i\notin S}(1-a_i) \left| |S| - \sum_{i\in[4]} a_i \right|.$$

Let $a_1,\dots,a_4 \in [0,1]$ such that $f(a_1,a_2,a_3,a_4)$ is maximal. Assume $a_1 < a_2$. Let $0 < \varepsilon \le \frac{1}{2}(a_2 - a_1)$. Then

$$f(a_1,a_2,a_3,a_4) < f(a_1+\varepsilon, a_2-\varepsilon, a_3, a_4) \tag{3}$$

is easily computed, contradicting the maximality of $f(a_1,a_2,a_3,a_4)$. Hence $a_1 \ge a_2$. We have $f(a_1,a_2,a_3,a_4) = f(a_{\sigma(1)}, a_{\sigma(2)}, a_{\sigma(3)}, a_{\sigma(4)})$ for all $a_1,\dots,a_4 \in [0,1]$ and all permutations $\sigma \in S_4$. Thus we conclude that $a_i = a_j$ for all $i,j \in [4]$. Finally, we only need to check that $\overline{f} : [0,1] \to \mathbb{R}; a \mapsto f(a,a,a,a)$ never exceeds $0.82944 = \overline{f}(0.4)$. This is not hard to see, as $\overline{f}$ is piecewise a polynomial of degree 5.

For an arbitrary number $x$ denote by $d(x,\mathbb{Z}) := \min\{x - \lfloor x \rfloor, \lceil x \rceil - x\}$ its distance to the integers. Obviously, $\sum_{R\in\mathcal{R}} d(\Sigma A_R, \mathbb{Z})$ is a lower bound for the optimal error $\min_{B^*} d(A,B^*)$. Analyzing $\tilde{f} : [0,1]^4 \to \mathbb{R}$ defined by $\tilde{f}(a_1,a_2,a_3,a_4) = f(a_1,a_2,a_3,a_4) - d(a_1+a_2+a_3+a_4, \mathbb{Z})$ in a similar manner as above yields that $\tilde{f}$ is bounded from above by 0.75. This shows the second bound of Theorem 2.1. ∎

The two bounds of Theorem 2.1 are tight, as shown by matrices with all entries 0.4 and 0.5, respectively.

**3. Nonindependent randomized rounding.** In this section we improve the previous bounds by adding some dependencies to the rounding process. We start with an elementary approach called *joint randomized rounding*, which reduces the chance that neighboring matrix entries are both rounded in the wrong way. This leads to a first improvement in Corollary 3.3. We then add further dependencies leading to our final bound.

**3.1. Joint randomized rounding.**

DEFINITION 3.1 (joint randomized rounding). *Let $a_1, a_2 \in [0,1]$. We say that $(b_1, b_2)$ is a* joint randomized rounding *of $(a_1, a_2)$ if*

(i) *for all $i \in [2]$, $b_i$ is a randomized rounding of $a_i$;*

(ii) *$b_1 + b_2$ is a randomized rounding of $a_1 + a_2$.*

It is clear that joint randomized roundings exist for all $a_1, a_2 \in [0,1]$: Define $(b_1, b_2)$ through

$$\begin{aligned}
\Pr(b_1 = 1 \wedge b_2 = 0) &= a_1,\\
\Pr(b_1 = 0 \wedge b_2 = 1) &= a_2,\\
\Pr(b_1 = 0 \wedge b_2 = 0) &= 1 - a_1 - a_2
\end{aligned}$$

in the case $a_1 + a_2 \le 1$, and

$$\begin{aligned}
\Pr(b_1 = 1 \wedge b_2 = 0) &= 1 - a_2,\\
\Pr(b_1 = 0 \wedge b_2 = 1) &= 1 - a_1,\\
\Pr(b_1 = 1 \wedge b_2 = 1) &= a_1 + a_2 - 1
\end{aligned}$$

in the case $a_1 + a_2 > 1$. The next lemma shows that two joint randomized roundings are superior to four independent randomized roundings in terms of the rounding error.

LEMMA 3.2. *Let $A = (a_{11}, a_{12}, a_{21}, a_{22})$ be a box. Let $(b_{11}, b_{12})$ be a joint randomized rounding of $(a_{11}, a_{12})$, and $(b_{21}, b_{22})$ one of $(a_{21}, a_{22})$ independent of the first. Set $B = (b_{11}, b_{12}, b_{21}, b_{22})$. Let $B^*$ be an optimal rounding of $A$. Then*

$$\begin{aligned}
E(d(A,B)) &\le \tfrac{16}{27} \le 0.5926,\\
E(d(A,B)) &\le 0.5 + d(A, B^*).
\end{aligned}$$

*Proof.* $b_{11} + b_{12}$ is a randomized rounding of $a_{11} + a_{12}$, and the same holds for the second row. Hence all we have to do is to bound the expected deviation of a sum of two independent randomized roundings from the sum of the original values. We show that $g : [0,1]^2 \to \mathbb{R}$ defined by

$$\begin{aligned}
g(x,y) := {} & xy(2 - x - y) + (x(1-y) + (1-x)y)|1 - x - y|\\
& + (1-x)(1-y)(x+y)
\end{aligned}$$

never exceeds 0.5926. As in the proof of Theorem 2.1, we find that $g(x,y)$ is maximal for $x = y$. Maximizing $x \mapsto g(x,x)$ is straightforward and yields maxima at $(\frac{1}{3}, \frac{1}{3})$ and $(\frac{2}{3}, \frac{2}{3})$, both having objective value $\frac{16}{27} \le 0.5926$. The second bound follows from maximizing $\tilde{g}$ defined by $\tilde{g}(x,y) := g(x,y) - d(x+y, \mathbb{Z})$. $\square$

The bounds in Lemma 3.2 are sharp, as shown by matrices having $a_{11} + a_{12} = a_{21} + a_{22} = \frac{1}{3}$ and $a_{11} + a_{12} = a_{21} + a_{22} = \frac{1}{2}$, respectively. Plastering the grid with independent joint randomized roundings already yields a first improvement over independent randomized rounding, as follows.

COROLLARY 3.3. *Let $A \in [0,1]^{m\times n}$. Compute $B \in \{0,1\}^{m\times n}$ by independently obtaining $(b_{i,2j-1}, b_{i,2j})$ from $(a_{i,2j-1}, a_{i,2j})$ by joint randomized rounding for all $i \in [m], j \in [\frac{n}{2}]$, and also independently obtaining $b_{in}$ from $a_{in}$, $i \in [m]$, by usual randomized rounding if $n$ is odd. Then*

$$E(d(A,B)) \leq 0.7111|\mathcal{R}|,$$
$$E(d(A,B)) \leq 0.625|\mathcal{R}| + d(A,B^*),$$

*where $B^*$ shall be an optimal rounding of $A$.*

*Proof.* At least half of the boxes, namely all $R_{ij}$ such that $j$ is odd, are rounded in the manner of Lemma 3.2. The remaining boxes contain four independent randomized roundings. Thus

$$E(d(A,B)) \leq \tfrac{1}{2}\tfrac{16}{27}|\mathcal{R}| + \tfrac{1}{2}0.82944|\mathcal{R}| \leq 0.7111|\mathcal{R}|,$$
$$E(d(A,B)) - d(A,B^*) \leq \tfrac{1}{2}0.5|\mathcal{R}| + \tfrac{1}{2}0.75|\mathcal{R}| \leq 0.625|\mathcal{R}|,$$

by Theorem 2.1 and Lemma 3.2. ☐

**3.2. Block randomized rounding.**

DEFINITION 3.4 (block randomized rounding). *Let $A = (a_{11}, a_{12}, a_{21}, a_{22})$ be a box. We call $B = (b_{11}, b_{12}, b_{21}, b_{22})$ a* block randomized rounding *of $A$ if*

(i) *each single entry of $B$ is a randomized rounding of the corresponding entry of $A$; i.e.,* $\Pr(b_{ij} = 1) = a_{ij}$ *and* $\Pr(b_{ij} = 0) = 1 - a_{ij}$ *for all $i, j \in [2]$;*

(ii) *each pair of neighboring entries has the distribution of the corresponding joint randomized rounding; i.e., in addition to* (i) *we have for all $(i,j),(i',j') \in [2]\times[2]$ such that either $i \neq i'$ or $j \neq j'$,*

$$\Pr(b_{ij} + b_{i'j'} = \lfloor a_{ij} + a_{i'j'}\rfloor + 1) = \{a_{ij} + a_{i'j'}\},$$
$$\Pr(b_{ij} + b_{i'j'} = \lfloor a_{ij} + a_{i'j'}\rfloor) = 1 - \{a_{ij} + a_{i'j'}\};$$

(iii) *the box in total behaves like a randomized rounding; i.e., we have*

$$\Pr(\Sigma B = \lfloor \Sigma A\rfloor + 1) = \{\Sigma A\},$$
$$\Pr(\Sigma B = \lfloor \Sigma A\rfloor) = 1 - \{\Sigma A\}.$$

LEMMA 3.5. *Let $B$ be a block randomized rounding of a $2\times 2$ matrix $A$, and $B^*$ an optimal rounding of $A$. Then*

$$E(d(A,B)) \leq 0.5,$$
$$E(d(A,B)) \leq 0.125 + d(A,B^*).$$

*Proof.* This follows as a direct consequence of item (iii) of the definition. ☐

Both bounds are sharp, as demonstrated by matrices $A$ such that $\{\sum A\} = \frac{1}{2}$ and $\{\sum A\} = \frac{1}{4}$, respectively. The interesting point is that block randomized roundings always exist. In fact, even more complicated roundings exist, as shown by the following definition and lemma.

DEFINITION 3.6 (continuous block randomized rounding). *Let $A \in [0,1]^{m\times n}$. We say that $B$ is a* continuous block randomized rounding *of $A$ if*

(i) *for all $i \in [\frac{m}{2}], j \in [n-1]$, $R := \{2i-1, 2i\} \times \{j, j+1\}$, $B_{|R}$ is a block randomized rounding of $A_{|R}$;*

(ii) *if $m$ is odd, then for all $j \in [n-1]$, $(b_{m,j}, b_{m,j+1})$ is a joint randomized rounding of $(a_{m,j}, a_{m,j+1})$ as in Definition* 3.1*;*

(iii) *$b_{i,j}$ is mutually independent of all $b_{i',j'}$ such that $\lceil i/2\rceil \neq \lceil i'/2\rceil$.*

LEMMA 3.7. *For any $A \in [0,1]^{m\times n}$, a continuous block randomized rounding $B$ of $A$ exists and can be computed in linear time.*

*Proof.* We may assume that $m$ is even. If not, add an extra row to $A$ with all entries zero, compute $B$ as a continuous block randomized rounding of this matrix, and note that $B$ without the last row—which will be all zero—is a continuous block randomized rounding of $A$.

We propose the following randomized algorithm:

```
Input: $A = (a_{ij}) \in [0,1]^{m \times n}$.
Output: $B = (b_{ij}) \in \{0,1\}^{m \times n}$, a continuous block randomized rounding of $A$.
For all odd $i \in [m]$ do {
    Compute $(b_{i,1}, b_{i+1,1})$ as a joint randomized rounding of $(a_{i,1}, a_{i+1,1})$.
    For all $j \in [n-1]$ use the fact that $(b_{i,j}, b_{i+1,j})$ is a joint randomized
        rounding of $(a_{i,j}, a_{i+1,j})$ to compute $(b_{i,j+1}, b_{i+1,j+1})$ such that $B_{R_{ij}}$
        is a block randomized rounding of $A_{R_{ij}}$}.
```

Clearly, the algorithm is correct if the roundings can be computed efficiently in the inner loop. To simplify notation, we assume $i = 1$ and $j = 1$. Let $a_{11}, a_{12}, a_{21}, a_{22} \in [0,1]$. Assume that $(b_{11}, b_{21})$ is a joint randomized rounding of $(a_{11}, a_{21})$. In the remainder of this proof we show that there is a rounding $(b_{12}, b_{22})$ of $(a_{12}, a_{22})$ such that $(b_{11}, b_{12}, b_{21}, b_{22})$ is a block randomized rounding of $(a_{11}, a_{12}, a_{21}, a_{22})$.

Set $s := a_{11} + a_{12} + a_{21} + a_{22}$. We first show that it is enough to consider the case $s \leq 2$. Assume $s > 2$. Let $a'_{ij} := 1 - a_{ij}$ for all $i, j \in [2]$ as well as $b'_{11} = 1 - b_{11}$ and $b'_{21} = 1 - b_{21}$. Then $a'_{11} + a'_{12} + a'_{21} + a'_{22} < 2$ and $(b'_{11}, b'_{21})$ is a joint randomized rounding of $(a'_{11}, a'_{21})$. Let $(b'_{12}, b'_{22})$ be such that $(b'_{11}, b'_{12}, b'_{21}, b'_{22})$ is a block randomized rounding of the corresponding $a'$ values. Set $b_{12} := 1 - b'_{12}$ and $b_{22} := 1 - b'_{22}$. Now $(b_{11}, b_{12}, b_{21}, b_{22})$ is easily shown to be a block randomized rounding of $(a_{11}, a_{12}, a_{21}, a_{22})$.

Hence, from now on let $s \leq 2$. We distinguish a number of cases.

*Case* 1. $s \leq 1$. If $b_{11} = 1$ or $b_{21} = 1$, then set $b_{12} := 0$ and $b_{22} = 0$. Otherwise choose $b_{12}$ and $b_{22}$ with probabilities

$$\begin{aligned}
\Pr(b_{12} = 1 \wedge b_{22} = 0) &= \tfrac{a_{12}}{1 - a_{11} - a_{21}},\\
\Pr(b_{12} = 0 \wedge b_{22} = 1) &= \tfrac{a_{22}}{1 - a_{11} - a_{21}},\\
\Pr(b_{12} = 0 \wedge b_{22} = 0) &= 1 - \tfrac{a_{12} + a_{22}}{1 - a_{11} - a_{21}}.
\end{aligned}$$

We compute that $(b_{11}, b_{12}, b_{21}, b_{22})$ is a block randomized rounding. Note that the "otherwise" case occurs only if $b_{11} + b_{21} = 0$. Since $(b_{11}, b_{21})$ is a joint randomized rounding of $(a_{11}, a_{21})$, this happens with probability $1 - a_{11} - a_{21}$. Hence the probability that $b_{12}$ becomes 1 is this probability of $1 - a_{11} - a_{21}$ times the probability that $b_{12}$ becomes 1 in the "otherwise" case, which is $a_{12}/(1 - a_{11} - a_{21})$. Hence $\Pr(b_{12} = 1) = a_{12}$, as required. Similarly, the remaining probabilities are proven to be correct.

*Case* 2. $1 < s \leq 2$ and $a_{ij} + a_{i'j'} \leq 1$ for all $i, i', j, j' \in [2]$ such that either $i = i'$ or $j = j'$. We compute $b_{12}$ and $b_{22}$ according to the rule

```
If $b_{11} + b_{21} = 0$
then set $b_{12} := 1$ with probability $\frac{a_{12}}{(a_{12}+a_{22})}$;[3] set $b_{22} := 1 - b_{12}$
else if $b_{11} = 1$
then $b_{12} := 0$; set $b_{22} := 1$ with probability $\frac{a_{22}(s-1)}{(a_{12}+a_{22})a_{11}}$
else if $b_{21} = 1$
then $b_{22} := 0$; set $b_{12} := 1$ with probability $\frac{a_{12}(s-1)}{(a_{12}+a_{22})a_{21}}$.
```

[3]We use the phrase "set $y := 1$ with probability $p$" to describe these actions: Generate a number $r \in [0,1]$ uniformly at random. If $r \leq p$, set $y := 1$; else set $y := 0$.

Using the fact that $(b_{11}, b_{21})$ is a joint randomized rounding of $(a_{11}, a_{21})$, we compute exemplary

$$\begin{aligned}\Pr(b_{12}+b_{22}=1) &= \Pr(b_{11}+b_{21}=0)+\Pr(b_{11}=1)\Pr(b_{22}=1 \mid b_{11}=1)\\ &\quad +\Pr(b_{21}=1)\Pr(b_{22}=1 \mid b_{21}=1)\\ &= (1-a_{11}-a_{21})+a_{11}\cdot\frac{a_{22}(s-1)}{(a_{12}+a_{22})a_{11}}+a_{21}\cdot\frac{a_{12}(s-1)}{(a_{12}+a_{22})a_{21}}\\ &= a_{12}+a_{22}.\end{aligned}$$

*Remaining cases.* Let us call $e=(i,j,i',j')\in[2]^4$ an edge if either $i=i'$ or $j=j'$. We call *e heavy* if $a_{ij}+a_{i'j'}>1$ holds. Exploiting symmetry, we continue this case distinction, treating separately three cases such that there is one heavy edge and two cases such that there are two (intersecting) heavy edges. None of these cases is particularly difficult. In fact, the conditional probabilities arising are uniquely determined; hence working them out is an easy exercise. $\square$

Unfortunately, we could not find a more concise way of computing these roundings. But this is more or less an aesthetic problem: Concerning computing times, a division into many simple cases is rather preferable. Assuming the remaining cases proven, we have given a linear time algorithm for computing continuous block randomized roundings.

We shall first analyze the error of continuous block randomized roundings and then turn to the computational aspects of this approach. We use the following variant of the Chernoff inequality, which can be derived, for example, from Appendix A of Alon and Spencer [1].

LEMMA 3.8. *Let $X_1,\dots,X_r$ be mutually independent random variables such that each two values of a fixed $X_i$ differ by no more than d. Let $X=\sum_{i\in[r]}X_i$. Then*

$$\Pr(X>E(X)+\varepsilon)<\exp\left(\frac{-2\varepsilon^2}{d^2r}\right)$$

*holds for all $\varepsilon\ge 0$.*

THEOREM 3.9. *Let B be a continuous block randomized rounding of $A\in[0,1]^{m\times n}$. Then*

(i) *the expected rounding error satisfies $E(d(A,B))\le 0.5463|\mathcal{R}|$;*
(ii) *if $B^*$ is an optimal rounding, then $E(d(A,B))-d(A,B^*)\le 0.3125|\mathcal{R}|$;*
(iii) *for all $\varepsilon>0$, $\Pr\big(d(A,B)>E(d(A,B))+\varepsilon|\mathcal{R}|\big)<3\exp(-\frac{1}{6}\varepsilon^2(m-3))$.*

*Proof.* At least a half of all boxes (those $R_{ij}$ where $i$ is odd) are block randomized roundings. The remaining boxes contain two independent joint randomized roundings. Thus Lemmas 3.2 and 3.5 yield the bounds (i) and (ii):

$$E(d(A,B))\le\frac{1}{2}\cdot\frac{16}{27}|\mathcal{R}|+\frac{1}{2}\cdot\frac{1}{2}|\mathcal{R}|=\frac{59}{108}|\mathcal{R}|,$$

$$E(d(A,B))-d(A,B^*)\le\frac{1}{2}\cdot\frac{1}{2}|\mathcal{R}|+\frac{1}{2}\cdot\frac{1}{8}|\mathcal{R}|=\frac{5}{16}|\mathcal{R}|.$$

To prove the large deviation bound, let $X_i=\sum_{j=1}^{n-1}d(A_{R_{ij}},B_{R_{ij}})$ for $i\in[m-1]$. Then $X_i$ is a nonnegative random variable bounded by $X_i\le 2(n-1)$. Note that $X_i$ is mutually independent of all $X_{i'}$ such that $|i-i'|\ge 3$. For $k\in[3]$ let $I_k=\{i\in$

$[m-1] \mid i \equiv k \pmod 3\}$ and $Y_k = \sum_{i \in I_k} X_i$. From Lemma 3.8 we conclude

$$\begin{aligned} &\Pr(d(A,B) > E(d(A,B)) + \varepsilon(n-1)(m-1)) \\ &\quad \le \Pr(\exists k \in [3] : Y_k > E(Y_k) + \varepsilon(n-1)|I_k|) \\ &\quad < \sum_{k \in [3]} \exp\left(\frac{-2\varepsilon^2(n-1)^2|I_k|^2}{4(n-1)^2|I_k|}\right) \\ &\quad \le 3\exp\left(-\frac{1}{6}\varepsilon^2(m-3)\right). \qquad \square \end{aligned}$$

In the proof we estimated the rounding error by the worst case rounding errors for the two cases of joint and block randomized rounding. Both worst cases cannot occur simultaneously in all corresponding $2 \times 2$ boxes. In his diploma thesis [25], Schnieder shows that, for the matrix $A$ with all entries $\frac{4-\sqrt{10}}{6} \approx 0.1396$, a continuous block randomized rounding $B$ satisfies $E(d(A,B)) = \frac{40\sqrt{10}-112}{27}|\mathcal{R}| \approx 0.536708|\mathcal{R}|$. In fact, this is asymptotically the worst case, as a tedious analysis reveals.

For the same reason, the relative bound is not sharp. Again the loss is not too large: Let $A$ be such that $a_{ij} = 0.4$ if $i \equiv 1,2 \pmod 4$, and $a_{ij} = 0.6$ if $i \equiv 3,4 \pmod 4$. Then $E(d(A,B)) = 0.3|\mathcal{R}| + d(A,B^*)$, where $B^*$ is an optimal rounding of $A$.

The large deviation bound (iii) displays one disadvantage of nonindependent randomized rounding. Due to the dependencies, the rounding error cannot be written as the sum of $\Omega(|\mathcal{R}|)$ independent random variables. One might think that this problem could be overcome by replacing the Chernoff bound by martingale inequalities. The following example shows that the problem of the errors $d(A_{R_{ij}}, B_{R_{ij}})$ not being independent is "real."

Let $A \in \{0, \frac{1}{2}\}^{4 \times n}$ such that $a_{ij} = 0$ if and only if $i \in \{2,3\}$ and $j$ is even. Let $B$ be a continuous block randomized rounding of $A$. Then $B$ is completely determined by $b_{11}$ and $b_{41}$. In particular, we have $d(A,B) = \frac{2}{3}|\mathcal{R}|$ if $b_{11} = b_{41}$, and $d(A,B) = \frac{1}{3}|\mathcal{R}|$ if $b_{11} \ne b_{41}$. Note that both events occur with probability $\frac{1}{2}$ each.

**3.3. Algorithmic properties of continuous block randomized rounding.** Computing matrix roundings with the randomized approach above has some noteworthy advantages.

First, it is fast. Computing $(b_{i,j+1}, b_{i+1,j+1})$ in Lemma 3.7 takes constant time. Therefore the whole matrix rounding can be done in linear time. The problem of computing time can be further addressed with parallel computing (and this is actually an issue when discussing digital halftoning algorithms). Since the roundings of the $2 \times n$ double-rows are independent, it is no problem to assign them to different processors. From the viewpoint of application to digital halftoning, these points are crucial improvements over the algorithm of [2], which has roughly quadratic time complexity (ignoring a polylogarithmic factor). As stated in [2], this is too slow for high-resolution images.

Our algorithm can be derandomized with the method of conditional probabilities. Since the arising conditional probabilities can be computed efficiently, we do not need pessimistic estimators. The computation of the conditional probabilities can be arranged in such a way that the resulting algorithm has linear time complexity. We refer to Srivastav [31] for a recent survey on derandomization issues.

Another advantage is diversity. Suppose that we do not want to find a good rounding with respect to the $2 \times 2$ boxes, but instead with respect to $3 \times 3$ boxes (or with respect to both). We currently have no hint of whether the error with respect to these sets is a better measure for the visual quality of the resulting digital halftoning, but it seems plausible to try this experimentally. Hence we need an algorithm to compute such roundings.

The algorithm of Asano et al. seems not to work very well for this problem. The roundings computed by their algorithm may have error up to $(1.5-9\varepsilon)|\mathcal{R}|$ with respect to the $3 \times 3$ boxes. This is shown by a matrix $A$ with entries $\frac{1}{6} - \varepsilon$ only, which may be rounded to the all-zero matrix. We are also pessimistic that their approach, in general, can be extended to $3 \times 3$ boxes or other larger structures.

In contrast to these difficulties, nonindependent rounding does very well: We may even use a similar rounding as before: Assuming $m, n$ even for simplicity, compute $B$ from $A$ by letting $B_{R_{ij}}$ be a block randomized rounding of $A_{R_{ij}}$ independently for all odd $i \in [m-1]$ and odd $j \in [n-1]$. We call such an $A$ an independent block randomized rounding. Now each $3 \times 3$ box contains exactly one block randomized rounding, two joint randomized roundings, and one single randomized rounding. Since the four values of the block randomized rounding in total behave like a single randomized rounding, as do the two values of each joint randomized rounding, the expected error of a $3 \times 3$ box is just given by Theorem 2.1. We have the following result.

THEOREM 3.10. *With respect to the family $\mathcal{R}_3$ of $3 \times 3$ boxes, an independent block randomized rounding $B$ of $A$ has expected error $d_{\mathcal{R}_3}(A, B) \leq 0.82944|\mathcal{R}_3|$.*

We presented Theorem 3.10 to demonstrate how easily the ideas of this section can be applied to other rounding problems as well. There are different nonindependent randomized roundings achieving slightly better bounds. The reader is encouraged to try to find some on his own. The following characterization might be helpful for this purpose.

## 4. Proof of the characterization.

In this section we put the results presented previously into a more general framework and prove the characterization proposed in the introduction. As should be clear by now, we are looking for randomized roundings that are also "good" with respect to some sets (i.e., sums) of variables. It is convenient to describe such structures through hypergraphs: A *hypergraph* is a pair $\mathcal{H} = (V, \mathcal{E})$ such that $V$ is a finite set and $\mathcal{E} \subseteq 2^V$. The elements of $V$ are called *vertices*, and those of $\mathcal{E}$ *hyperedges* or *edges* for short. In our setting, $V$ will always be some index set for the variables, and $\mathcal{E}$ contains those sets of variables on which we want our roundings to be "good."

DEFINITION 4.1. *Let $\mathcal{H} = (I, \mathcal{E})$ be a hypergraph. Let $x_i \in \mathbb{R}$ for $i \in I$. Let $y_i, i \in I$, be random variables. For $E \subseteq I$ set $x_E := \sum_{i \in E} x_i$ and $y_E := \sum_{i \in E} y_i$. We call $y_E$ a randomized rounding of $x_E$ if*

$$\begin{aligned} \Pr(y_E = \lfloor x_E \rfloor + 1) &= \{x_E\}, \\ \Pr(y_E = \lfloor x_E \rfloor) &= 1 - \{x_E\} \end{aligned}$$

*holds. We say that $(y_i)_{i \in I}$ is a randomized rounding of $(x_i)_{i \in I}$ with respect to the dependency hypergraph $\mathcal{H}$ (or a randomized $\mathcal{H}$-rounding) if $y_E$ is a randomized rounding of $x_E$ for all $E \in \mathcal{E}$ and $y_i$ is a randomized rounding of $x_i$ for all $i \in I$.*

In this language, continuous block randomized roundings are randomized roundings with respect to the hypergraph $\mathcal{H} = ([m] \times [n], \mathcal{E})$ and

$$\begin{aligned} \mathcal{E} = &\{R_{ij} \mid i \in [m-1] \text{ odd}, j \in [n-1]\} \\ &\cup \{\{(i,j), (i,j+1)\} \mid i \in [m], j \in [n-1]\} \\ &\cup \{\{(i,j), (i+1,j)\} \mid i \in [m-1] \text{ odd}, j \in [n]\}. \end{aligned}$$

A hypergraph is said to be *totally unimodular* if its incidence matrix is totally unimodular. Recall that a matrix is totally unimodular if each square submatrix has determinant $-1$, 0, or 1. There is a rather complicated recursive characterization for totally unimodular matrices and hypergraphs due to Seymour [26, 27]. For our purposes, the following easier, though fundamental, result is sufficient.

THEOREM 4.2 (see Ghouila-Houri [12]). *A hypergraph $\mathcal{H} = (V, \mathcal{E})$ is totally unimodular if and only if for each subset $V_0$ of vertices there is a partition $V_1 \dot\cup V_2 = V_0$ such that any hyperedge $E$ satisfies $\big||E \cap V_1| - |E \cap V_2|\big| \le 1$.*

Let us give some intuition to this result. For $V_0 \subseteq V$, $\mathcal{H}_{|V_0} = (V_0, \{E \cap V_0 \mid E \in \mathcal{E}\})$ is an induced subhypergraph of $\mathcal{H}$. We call a hypergraph $\mathcal{H} = (V, \mathcal{E})$ perfectly balanced if there is a partition $V_1 \dot\cup V_2 = V$ of its vertex set such that $\big||E \cap V_1| - |E \cap V_2|\big| \le 1$ holds for all $E \in \mathcal{E}$, i.e., apart from single vertices of odd cardinality hyperedges, each hyperedge contains the same number of vertices in $V_1$ and $V_2$. In this language, the Ghouila-Houri theorem states that $\mathcal{H}$ is totally unimodular if and only if each induced subhypergraph is perfectly balanced. Both from the definition and (easier) from Ghouila-Houri's characterization, one can deduce that $\mathcal{H}$ is totally unimodular if and only if $(V, \mathcal{E} \cup \{\{v\} \mid v \in V\})$ is totally unimodular. A second result we use is the following well-known theorem of Hoffman and Kruskal.

THEOREM 4.3 (see Hoffman and Kruskal [14]). *Let $A \in \mathbb{R}^{m \times n}$ be a totally unimodular matrix. Let $b, b' \in \mathbb{Z}^m$ and $c, c' \in \mathbb{Z}^n$. Then*

$$\{x \in \mathbb{R}^n \mid b \le Ax \le b', c \le x \le c'\}$$

*is an integral polyhedron.*

Hoffman and Kruskal also showed a converse result: An integral matrix $A$ is totally unimodular if the polyhedron $\{x \in \mathbb{R}^n \mid x \ge 0, Ax \le b\}$ is integral for all $b \in \mathbb{Z}^m$. However, we shall not need that much understanding of integral polyhedra. Basically, it suffices to know the above theorem and the fact that any bounded polyhedron is the convex hull of its extremal points. Thus for any $x \in P$ there are $k \le n+1$, $w^{(1)}, \dots, w^{(k)} \in \operatorname{ex}(P)$, $\lambda_1, \dots, \lambda_k \in [0,1]$ such that $\sum_{\ell \in [k]} \lambda_\ell = 1$ and $x = \sum_{\ell \in [k]} \lambda_\ell w^{(\ell)}$. This is the well-known Carathéodory theorem (see Eckhoff [10] for a survey).

THEOREM 4.4. *Let $\mathcal{H} = (I, \mathcal{E})$ be a hypergraph. The following two properties are equivalent:*

(i) *for all $(x_i)_{i \in I}$ there is a randomized $\mathcal{H}$-rounding $(y_i)_{i \in I}$;*

(ii) *$\mathcal{H}$ is totally unimodular.*

*Proof.* Since the vertex set of $\mathcal{H}$ is not relevant, we may conveniently assume that $I = [n]$. Let $\mathcal{H}$ be totally unimodular and $x_1, \dots, x_n \in \mathbb{R}$. Without loss of generality (cf. the remark following Theorem 4.2), we may assume that $\{j\} \in \mathcal{E}$ for all $j \in [n]$. Let $A$ be an incidence matrix of $\mathcal{H}$; i.e., fix an enumeration $\mathcal{E} = \{E_1, \dots, E_m\}$ of the hyperedges and define $A = (a_{ij})$ by $a_{ij} = 1$ if $j \in E_i$, and $a_{ij} = 0$ otherwise. Set $P = \{w \in \mathbb{R}^n \mid \lfloor Ax \rfloor \le Aw \le \lceil Ax \rceil\}$. By definition, $x \in P$. Since the $n \times n$ identity matrix is a submatrix of $A$, $P$ is bounded.

Thus, $x$ is a convex combination of the extremal point of $P$: There are $w^{(1)}, \dots, w^{(k)} \in \operatorname{ex}(P)$, $\lambda_1, \dots, \lambda_k \in [0,1]$ such that $\sum_{\ell \in [k]} \lambda_\ell = 1$ and $x = \sum_{\ell \in [k]} \lambda_\ell w^{(\ell)}$. By Theorem 4.3, all $w^{(\ell)}$ are integral, and in our case we even have $w_j^{(\ell)} \in \{\lfloor x_j \rfloor, \lceil x_j \rceil\}$. Define the random variables $y_1, \dots, y_n$ by setting $y = w^{(\ell)}$ with probability $\lambda_\ell$.

We compute that $y_1, \dots, y_n$ is a randomized rounding of $x_1, \dots, x_n$ with respect to $\mathcal{H}$: Let $E = E_i \in \mathcal{E}$. If $x_E$ is integral, then $(Aw^{(\ell)})_i = x_E$ for all $\ell \in [k]$ by definition

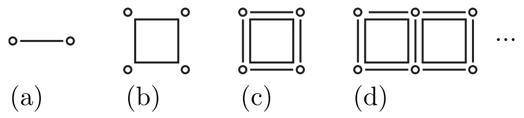

FIG. 1. *Sample diagrams.*

of $P$. Hence $y_E = (Ay)_i$ is trivially a randomized rounding of $x_E$. Assume that $x_E$ is nonintegral. We have $x_E = \sum_{\ell \in [k]} \lambda_\ell (Aw^{(l)})_i$. Set $L_E^+ = \{\ell \in [k] \,|\, (Aw^{(\ell)})_i = \lceil x_E \rceil\}$. Since $(Aw^{(\ell)})_i \in \{\lfloor x_E \rfloor, \lceil x_E \rceil\}$ for all $\ell \in [k]$, we conclude that $\{x_E\} = \sum_{\ell \in L_E^+} \lambda_\ell$. Thus $\Pr(y_E = \lceil x_E \rceil) = \sum_{\ell \in L_E^+} \lambda_\ell = \{x_E\}$. As $y_E$ takes only the two values $\lfloor x_E \rfloor$ and $\lceil x_E \rceil$, we also have $\Pr(y_E = \lfloor x_E \rfloor) = 1 - \{x_E\}$. This shows that $y_1, \ldots, y_n$ is a randomized $\mathcal{H}$-rounding of $x_1, \ldots, x_n$.

Now assume that $\mathcal{H}$ is not totally unimodular. By Theorem 4.2, some induced subhypergraph of $\mathcal{H}$ has discrepancy at least two; i.e., there is a $V_0 \subseteq [n]$ such that for any 2-partition $V_1 \dot\cup V_2 = V_0$ there is an $E \in \mathcal{E}$ such that $\big||E \cap V_1| - |E \cap V_2|\big| \geq 2$. Set $x_j = 0$ for all $j \in [n] \setminus V_0$ and $x_j = \frac{1}{2}$ for all $j \in V_0$. Let $y_1, \ldots, y_n$ be a randomized $\mathcal{H}$-rounding of $x_1, \ldots, x_n$. Then $y_j = 0$ holds with probability one for all $j \in [n] \setminus V_0$ by the definition of randomized $\mathcal{H}$-rounding. For $j \in V_0$, $y_j$ may take only the values 0 and 1. Let $\tilde{y}$ be a possible outcome of the underlying random experiment, that is, an image of the random variable $y$ having probability greater than zero. Let $V_1 = \{j \in V_0 \,|\, \tilde{y}_j = 0\}$ and $V_2 = \{j \in V_0 \,|\, \tilde{y}_j = 1\}$. Let $E \in \mathcal{E}$ such that $\big||E \cap V_1| - |E \cap V_2|\big| \geq 2$. Then $\tilde{y}_E = |E \cap V_2|$, whereas $x_E = \frac{1}{2}|E \cap V_0|$. Thus we have $|x_E - \tilde{y}_E| \geq 1$. Since $|x_E - y_E| \geq 1$ holds with nonzero probability, $y_E$ is not a randomized rounding of $x_E$. This is a contradiction of our assumption that $y_1, \ldots, y_n$ is a randomized $\mathcal{H}$-rounding of $x_1, \ldots, x_n$. $\square$

The use of linear programming ideas to deal with dependencies resembles the work of Koller and Megiddo [18] and Karger and Koller [15]. However, these results are of a completely different nature. There, the aim is to cope with dependencies, since they can lead to smaller sample spaces, whereas we try to use dependencies. There, linear programming ideas are used to transform a given sample space satisfying some dependencies into a smaller one where the dependencies still hold, whereas we construct a sample space directly from a set of given dependencies. Nevertheless, all results indicate that linear programming is a useful framework when dealing with probabilistic constraints.

## 5. Alternative randomized $\mathcal{H}$-roundings.

In this section we investigate what can be achieved by using different randomized $\mathcal{H}$-roundings for the approximation problem of Asano et al. [2]. We omit the proofs for reasons of space, but let us stress that these results depend heavily on Theorem 4.4: It allows us to decide whether a randomized $\mathcal{H}$-rounding exists or not by simply checking whether $\mathcal{H}$ is totally unimodular or not. Thus we may postpone the work of designing a rounding algorithm (and the proof of Lemma 3.7 indicates that this might be quite tedious) until we have found a dependency hypergraph $\mathcal{H}$ yielding suitable bounds.

We denote the hypergraphs considered through simple diagrams. We assume that all variables are randomized roundings. If two variables form a joint randomized rounding, we denote this by connecting the respective nodes by an edge (see Figure 1(a)). If four variables are rounded together (i.e., they form a hyperedge in $\mathcal{H}$), we connect them by a square (Figure 1(b)). Thus a single block randomized rounding is depicted by the diagram in Figure 1(c).

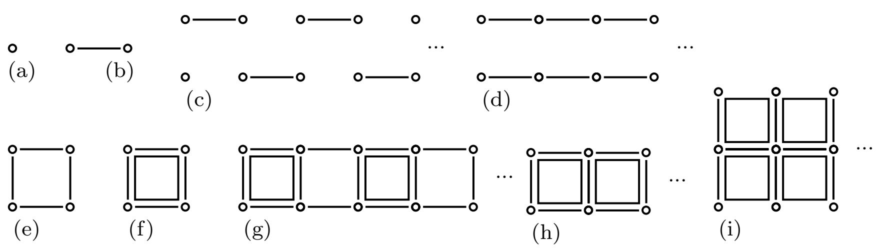

FIG. 2. *Totally unimodular hypergraphs.*

TABLE 1
*Error bounds of the $\mathcal{H}$-roundings depicted in Figure 2.*

| | Absolute | Relative |
|---|---|---|
| (a) | 0.8295 | 0.75 |
| (b) | 0.7111 | 0.625 |
| (c) | 0.75 | 0.5926 |
| (d) | 0.5926 | 0.5 |
| (e) | 0.6518 | 0.5625 |
| (f) | 0.6287 | 0.4688 |
| (g) | 0.5695 | 0.4063 |
| (h) | 0.5493 | 0.3125 |
| (i) | 0.5617 | 0.4166 |

We shall always assume that the grid is plastered with the pattern, and further, that nodes not connected through a series of hyperedges are rounded independently. Hence Figure 1(c) also denotes the independent block randomized rounding investigated in Theorem 3.10. Repeated overlapping patterns will be indicated through (ellipsis) dots. Figure 1(d) thus describes the hypergraph used in section 3.

In Figure 2 we show some totally unimodular hypergraphs. In Table 1 we give upper bounds for the errors inflicted by applying the corresponding $\mathcal{H}$-roundings to Asano's approximation problem. The middle column contains an upper bound for the expected absolute error $E(d(A,B))$, and the right column an upper bound for the expected loss $E(d(A,B)) - d(A,B^*)$ compared to an optimal rounding $B^*$. These upper bounds are derived using the methods of section 3. They are either sharp or close to the optimum.

Table 1 shows several interesting facts. We see that already simple dependencies yield a significant improvement over the independent case (a). Nevertheless, the right choice of dependencies is important: While (b) and (c) look almost identical—plastering the grid with independent joint randomized roundings—the resulting error bounds are not the same. Better bounds can be achieved by larger structures than just independent joint randomized roundings. On the other hand, structures larger than (h) either yield worse bounds, as in (i), or cannot be realized, since the corresponding hypergraph is not totally unimodular. Some examples of the latter type are shown in Figure 3. As Figure 3(c) shows, the dependencies that all boxes are already randomized roundings are not realizable. Thus a nonindependent randomized rounding having $E(d(A,B)) \le \frac{1}{2}|\mathcal{R}|$ seems not to exist. Currently we cannot determine the precise value between our upper bound of $0.5463|\mathcal{R}|$ and the lower one of $\frac{1}{2}|\mathcal{R}|$.

There is some caution necessary in viewing rows (e), (g), and (i). These three patterns generate $\mathcal{R}$-boxes that are not sums of independent randomized roundings. In (e) the error inflicted in the box containing the four nodes connected in a cyclic

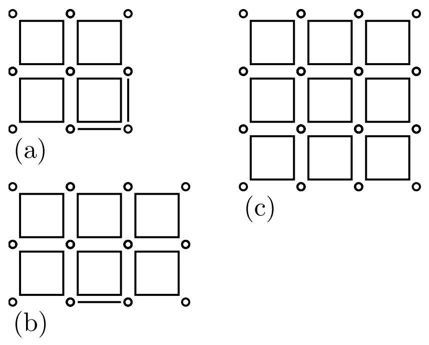

Fig. 3. *Hypergraphs that are not totally unimodular.*

manner depends on the precise way that this rounding is generated. For our estimate we assumed that the nonintersecting joint randomized roundings display neither a positive nor a negative correlation. This is justified by the fact that a rounding exists in which the errors are in fact likely to cancel (namely, (f)). An analogous statement holds for (g) but not for (i). Here Figure 3 tells us that further restrictions on the random process are not possible. Therefore our upper bound here assumes that we have a bad correlation among the horizontally adjacent nodes that do not form a joint randomized rounding.

Note that such negative correlation can indeed occur: Assume three nodes 1, 2, and 3 such that 1 and 2 as well as 2 and 3 form a joint randomized rounding. Let $x_1 = 1 - x_2 = x_3$. Then any nonindependent randomized rounding with respect to these dependencies has $y_1 = y_3$. Thus the error $|(x_1 + x_3) - (y_1 + y_3)|$ does not have the distribution of two independent randomized roundings, but a worse one, namely, twice that of a single randomized rounding.

## 6. Summary and outlook.

This paper describes a new approach in randomized rounding. By imposing suitable dependencies, we improve the expected rounding error significantly. For a problem arising in digital halftoning, this improves previous algorithms with respect to both run-time and rounding error. In particular, we presented the first algorithm that solves this problem fast enough for practical application, namely, in linear time.

On the methodological side, this paper shows that nonindependent randomized rounding can be very effective if one succeeds in finding the right dependencies. To this end, we give a complete characterization of realizable dependencies.

From this work, some open questions arise:

- What is the true approximability of the matrix rounding problem suggested by Asano et al., i.e., can we close the gap between the lower bound of $0.5|\mathcal{R}|$ and the upper bound stemming from our methods?
- For which further rounding problems is it possible to translate part of the structure of the problem into suitable dependencies for the random experiment?
- Engineering aspects: How do the roundings computed by our algorithm look to the human eye? Asano et al. proposed the idea that low error roundings with respect to $2 \times 2$ boxes look nice, but of course they could check this only with their algorithm. Therefore, theoretically, our roundings might even look worse. Coming from the other end, one might (and actually should)

investigate other error measures. Using the ideas of this paper, one may also design rounding algorithms that optimize different error measures stemming from larger boxes or even completely different geometric structures. It could well be that such error measures are better suited to distinguishing good halftonings from poor ones.

**Appendix.** This paper is intended to be of a theoretical nature. Since one of the referees felt that readers from a more applied background would severely miss images and experimental data, we do our best to provide some in this appendix.

We applied the three classical algorithms mentioned in the introduction, together with independent randomized rounding and our algorithm, to several images. All image data used 1 byte per pixel, resulting in an integer value between 0 and 255. We used two types of input data: Real-world images taken with a digital camera (not shown in this paper) and artificial images produced with commercial imaging software. Naturally, the first type is more suitable to estimating how well the algorithm performs in real-world applications, whereas the second is better suited to demonstrating the particular strengths and weaknesses of an algorithm.

The images displayed in Figure 4 are obtained from halftoning an artificially generated image of size $160 \times 160$ pixels with the standard algorithms of error diffusion, ordered dither, dot diffusion, random dither (independent randomized rounding), and our nonindependent randomized rounding algorithm. In all cases, the standard form of the algorithms has been used. It is known that some algorithms produce better outputs if the inputs are subject to some preprocessing. Since such data is mainly available for the algorithms of error diffusion and ordered dither, we believe that an unbiased comparison might be easier without any preprocessings. As indicated in the first paragraph, the intention of this appendix is merely to give the interested reader an idea of how our ideas could work in practice rather than giving evidence that they are competitive with previous algorithms.

Figure 4 shows that the randomized nature of our algorithm has a positive effect on the generation of unwanted structures and grains. Unwanted structures include all kinds of regular patterns like snakes, crosses, or labyrinths that attract objectionable attention. In particular, the error diffusion and ordered dither algorithms tend to produce those.

Grains emerge if in dark (respectively, light) parts of the picture two or more white (respectively, black) pixels touch and thus build a recognizable block. Randomized rounding is very vulnerable to this problem, which is why it is not used in practice for digital halftoning. On the other end, we find error diffusion, which hardly produces any grains. It seems that algorithms that are good concerning graininess tend to produce unwanted structures and vice versa. In this sense, nonindependent randomized rounding could be a fair compromise: Being by far less grainy than independent randomized rounding, it is unlikely to produce unwanted structures.

We also computed the actual errors generated by the algorithms on several input images (on roughly 300,000 pixels). The averages values are given in Table A.1. The error measures considered are the following:

*Total error:* The absolute difference in the average intensity of input and output image $\frac{1}{mn}|\sum_{i,j}(a_{ij} - b_{ij})|$.

$2 \times 2$ *error:* The average error in the $2 \times 2$ boxes, that is, $\frac{1}{|\mathcal{R}|}d(A, B)$, where $d(A, B)$ is the error measure proposed by Asano et al.

$3 \times 3$ *error:* The average error in the $3 \times 3$ boxes.

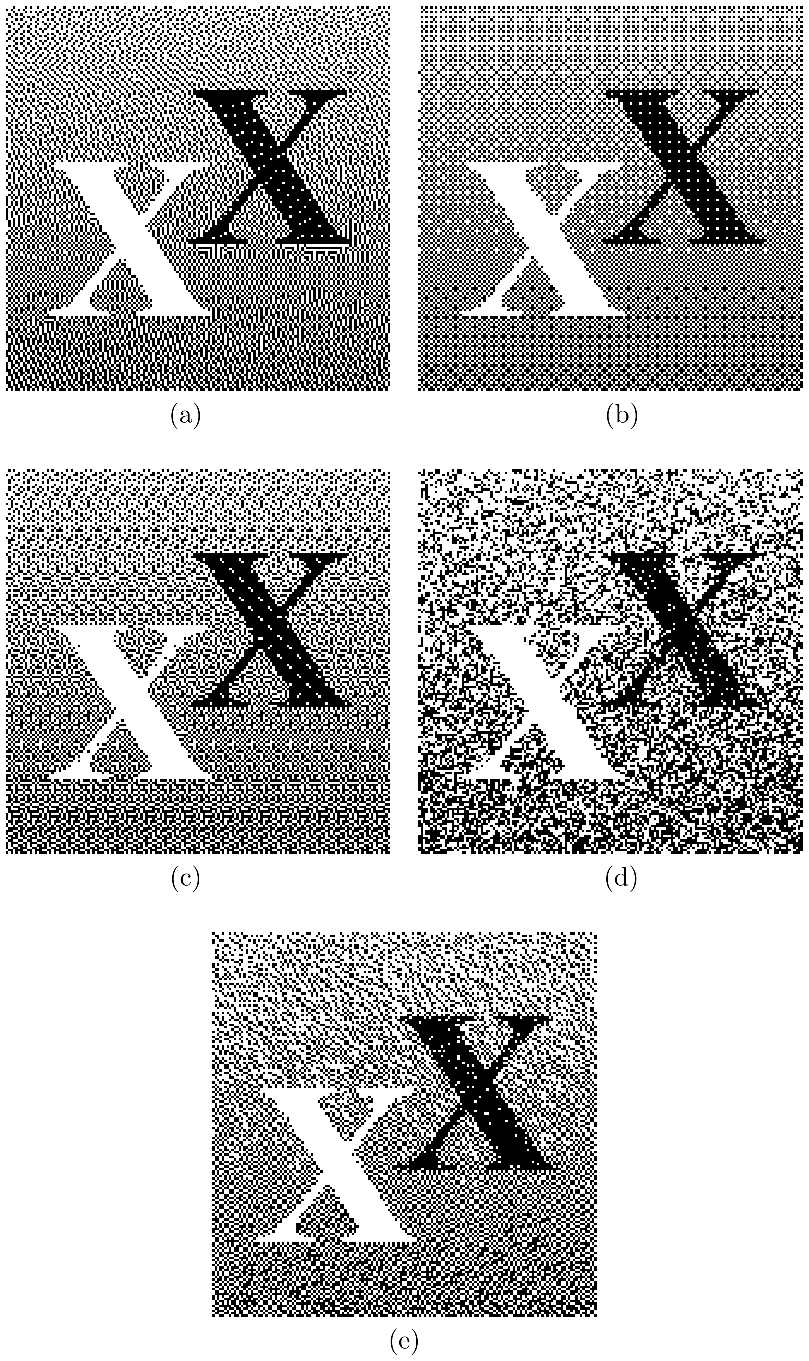

FIG. 4. *Halftoning results of different standard algorithms and our own:* (a) *error diffusion,* (b) *ordered dither,* (c) *dot diffusion,* (d) *random dither (randomized rounding),* (e) *nonindependent randomized rounding.*

Table A.1
*Experimental average errors of the algorithms.*

| Method | Total | $3 \times 3$ | $2 \times 2$ |
|---|---|---|---|
| Error diffusion | 0.00027 | 0.45 | 0.35 |
| Ordered dither | 0.00052 | 0.65 | 0.34 |
| Dot diffusion | 0.00024 | 0.65 | 0.43 |
| Randomized rounding | 0.00056 | 0.96 | 0.64 |
| Nonindependent RR | 0.00034 | 0.60 | 0.40 |

As can be seen, all algorithms change the average intensity only minimally. Concerning the errors in the $2 \times 2$ and $3 \times 3$ boxes, the case is more interesting. Whereas for the $2 \times 2$ boxes error diffusion is slightly, and nonindependent randomized rounding is significantly, worse than the best performer ordered dither, things change for $3 \times 3$ boxes. Here error diffusion takes the lead, followed by nonindependent randomized rounding. Together with the visual quality of the output images, this poses the question of whether larger boxes might yield a better similarity measure. The fact that error diffusion performs relatively well also asks for theoretical bounds for the errors generated with respect to the $2 \times 2$ boxes. Here the inherently sequential nature of this algorithm seems to impose some difficulties.

**Acknowledgments.** I would like to thank Tetsuo Asano, Naoki Katoh, Koji Obokata, and Takeshi Tokuyama for providing me with a preprint of their SODA 2002 paper and some useful discussion on the topic. I am also grateful that Henning Schnieder gave his kind permission for me to use some of his numerical results and sample images in the appendix of this paper.

# INSTABILITY OF FIFO AT ARBITRARILY LOW RATES IN THE ADVERSARIAL QUEUEING MODEL[*]

RAJAT BHATTACHARJEE[†], ASHISH GOEL[‡], AND ZVI LOTKER[§]

**Abstract.** We study the stability of the commonly used packet forwarding protocol, FIFO (first in first out), in the adversarial queueing model. We prove that FIFO can become unstable, i.e., lead to unbounded buffer-occupancies and queueing delays, at arbitrarily low injection rates. In order to demonstrate instability at rate $r$, we use a network of size $\tilde{O}(1/r)$.

**Key words.** FIFO, stability, adversarial queueing model

**AMS subject classifications.** 68M12, 68M20

**DOI.** 10.1137/S0097539703426805

## 1. Introduction.

In traditional queueing theory, the source which generates network traffic and the processing times are typically assumed to be stochastic. However, the growing complexity of network traffic makes it increasingly unrealistic to model traffic as, say, a Poisson stream. Adversarial queueing theory is a robust and elegant framework developed by Borodin et al. [9] to address this problem. In this model, packets are injected into the network by an adversary rather than by a stochastic process. To keep things simple, it is assumed that the route of each packet is given along with the packet itself. Each edge in the network can forward at most one packet in one time step. If there are multiple packets waiting to cross the same edge, then we need a contention resolution protocol to decide which packet goes across and which packets wait in the queue. The adversary is limited in the following way: over any window of $T$ consecutive time steps, the adversary can inject at most $w + rT$ packets that need to traverse any edge in the network. The parameter $r$ is called the injection rate and must be less than 1. The parameter $w$ is called the burst-size. Such an adversary is called a $(w, r)$-adversary. Once injected, packets follow their routes one edge at a time until they reach their destination.

Intuitively, the adversary is not allowed to introduce more traffic on average than $r$ times the capacity of any edge. Thus, there can be no identifiable "hot-spots" in the system. This model finds the fine middle ground between stochastic arrivals on the one hand (as in traditional queueing theory), where packet arrival is too predictable, and completely unconstrained adversaries on the other (as in competitive analysis), where the adversary is allowed to overload the system.

A packet forwarding protocol is said to be *stable* against a given adversary and for a given network if the maximum queue size, as well as the maximum delay experienced

[*]Received by the editors April 28, 2003; accepted for publication (in revised form) April 30, 2004; published electronically December 1, 2004. The instability of FIFO at arbitrarily low rates using polynomial sized networks was first obtained by [8] and the reduction in diameter was obtained by [27]. This paper combines the two results.

by a packet, remain bounded. A packet forwarding protocol is said to be stable at rate $r$ (or, $r$-stable) if it is stable against all $(w, r)$-adversaries and for all networks. It is said to be *universally stable* if it is $r$-stable for all $r < 1$. Studying the stability of protocols was the main motivation behind the adversarial queueing theory model. In a seminal paper, Andrews et al. [5] showed that several natural protocols are universally stable, but surprisingly, FIFO (first in first out) is not. This is an important observation since FIFO is by far the most widely used scheduling protocol. It also leaves the following question open:

> Is FIFO $r$-stable at some rate $r > 0$, or is FIFO unstable at arbitrarily low rates?

This is an important question, given the prominence of FIFO as the packet forwarding protocol for the Internet and other networks, and has been the subject of much study over the last few years [12, 10, 11, 5, 4, 23, 25, 28]. For several natural protocols other than FIFO, the corresponding question about the stability threshold in the adversarial model has already been answered [31]. The problem for FIFO is particularly intriguing since there is some intuitive evidence for both the existence and the nonexistence of a stability threshold, due to Bramson [11, 12], arising from two somewhat unrelated models (more details are given in the related work section). Diaz et al. [23] improved the threshold of instability for FIFO to 0.83. (The original proof of Andrews et al. [5] showed instability of FIFO at rate 0.85.) This was further improved by Koukopoulos, Nikoletseas, and Spirakis [25] to 0.749, and recently Lotker, Patt-Shamir, and Rosen [28] further improved it to 0.5.

In this paper, we will assume that packet paths are required to be simple.[1]

**1.1. Our result.** In this paper, we prove that FIFO can become unstable at arbitrarily low rates in the adversarial model. This was one of the major remaining open problems in the field of adversarial queueing theory. In particular, for an arbitrarily low injection rate $r$, we construct a network (with size polynomial in $1/r$) and determine adversarial injections so that FIFO becomes unstable. We then tighten the size of the network to $\tilde{O}(1/r)$. This is quite strong since it even excludes the possibility that FIFO might be stable at rate $O(1/\log^c m)$, where $m$ is the size of the network and $c$ is a constant.[2]

The main idea is the construction of a gadget which, assuming certain initial conditions, allows only a small fraction of packets to pass through it for a long duration. In particular, the fraction of packets which escape is bounded by $k/(1+r)^k$, where $k$ is a parameter of the gadget and can be increased arbitrarily. The network is constructed using this gadget. The adversary works in phases. At the beginning of a phase, we assume that there are some packets waiting to pass through a column of gadgets. Using each gadget in the column, more packets are generated, which want to ultimately traverse a second column. Additional copies of the gadget mentioned above are used to delay and synchronize these new packets so that, at the end of the phase, there are more packets waiting to traverse the second column than were waiting at the first column at the beginning of the phase. Applying this inductively leads to instability.

While the idea of concatenating gadgets to prove instability has been used before (most recently by Lotker, Patt-Shamir, and Rosen [28], for example), our gadget and

[1]Since we will demonstrate the instability of FIFO, any restriction we place on the adversary can only make our results stronger.

[2]It is trivial to see that FIFO (in fact, any greedy protocol) is stable at rate $1/m$.

network are quite different from those used in earlier works [11, 5, 31, 28] to prove instability results. A review of related work is presented below.

**1.2. Related work.** Andrews et al. [5] proved that rings and DAGs (directed acyclic graphs) are universally stable networks (i.e., networks for which all greedy protocols are stable at all rates $r < 1$). They showed that longest in system (LIS) and shortest in system (SIS) are universally stable protocols and that FIFO is not universally stable. In fact, they showed that FIFO can become unstable at rates greater than 0.85. Several natural protocols such as NTG (nearest to go) and LIFO (last in first out) have been shown to be unstable at arbitrarily low rates [31]. Goel [22], Gamarnik [20], and Alvarez, Blesa, and Serna [3] gave a simple and complete characterization of universally stable networks. Diaz et al. [23] improved the threshold of instability for FIFO to 0.83, and Koukopoulos, Nikoletseas, and Spirakis [25] improved it to 0.749. Lotker, Patt-Shamir, and Rosen [28] further improved the instability threshold to all rates above 0.5. Like our construction, they used a network obtained by concatenating parameterized gadgets; of course, their gadget and network are quite different from ours. They also proved that a network with diameter $d$ is stable at all rates below $1/d$.

For the case when routes are not given by the adversary, Aiello et al. [1] and Andrews et al. [6] studied routing algorithms which ensure that no edge gets overloaded, assuming that the adversary injects packets for which this is feasible. Aiello et al. [2] have recently initiated the study of stability in the presence of fixed size buffers. Gamarnik [21] showed that it is undecidable whether a given protocol is universally stable, for an interesting class of protocols. Feige [18] and Dumas [17] demonstrated nonmonotonic phenomena in packet and queueing networks, respectively. Andrews [4] demonstrated the instability of FIFO in session-oriented networks [13, 14].[3]

Stability of networks has also been studied from a more queueing theoretic viewpoint in stochastic networks, where the packets are injected and serviced according to a stochastic process. Instability in stochastic networks was first demonstrated by Rybko and Stolyar [30], building on the work of Lu and Kumar [29] and Kumar and Seidman [26]. The fluid model involves taking the fluid limit of a stochastic process. Dai [15] related stability in the fluid model to that in the stochastic model. Gamarnik [19] proved an analogue of Dai's result for adversarial networks. Dai and Prabhakar [16] studied the stability of a scheduling protocol for data switches with speed-up in the fluid model. Bennett et al. [7] study the bounds on the worst case delay in a network implementing aggregate scheduling, assuming stochastic arrivals.

Bramson studied the stability of FIFO in two different stochastic models. Building on earlier work by Kelly [24] and others, Bramson showed that FIFO is stable at all rates $r < 1$ under a large class of stationary arrival processes, assuming that the time for a packet to traverse an edge is an i.i.d. (independently and identically distributed) exponential random variable [12]. As pointed out in [12], the last assumption is not critical, and the result also holds for generalized Kelly networks. Quite interestingly, Bramson [11] also showed that FIFO can become unstable at arbitrarily low rates in a job-shop scheduling model. Superficially, it would seem that a minor modification of Bramson's techniques could imply our result. However, in Bramson's construction, the same job can visit the same machine multiple times, and have a *different mean processing time* on each visit. In trying to adapt his result to the networking case,

[3]Whether FIFO is unstable at arbitrarily low rates in the session-oriented model remains an interesting open problem.

we run into the problem that different packets queued up at the same link can have different traversal times. Thus the same link appears to be of different length to different packets in a queue. To implement this construction directly requires injecting extra packets to make the link appear "long" to some packets; these extra packets result in a violation of the rate threshold. Hence, a gadget that can delay packets for arbitrarily long durations (like ours) seems inevitable. Even given our gadget, it is not obvious to us how to use a network similar to Bramson's.

Section 2 describes and analyzes our basic gadget. Section 3 gives the construction of a network which is unstable at arbitrarily low injection rates. The adversarial injection patterns are described in section 4. For ease of exposition, we present the proof in two stages. First, we show a family of networks that can be made unstable at all rates $r > 0$. The proof of instability for these networks is simpler to understand, and is presented in section 5. However, in order to achieve instability at rate $r$, the diameter of a network from this family must be $\tilde{O}(1/r^7)$. We then show (section 6) another family of networks, which is more involved but which has a tighter diameter of $\tilde{O}(1/r)$.

**2. The basic gadget.** Section 2.1 describes the topology of the gadget. Section 2.2 talks about a special kind of flow. Finally, in section 2.3 an upper bound on the number of packets that escape the gadget for this flow is proved.

**2.1. The topology of the gadget.** The gadget has a parameter $k$. A $k$-gadget has $2k$ vertices: $v_1, \dots, v_k, w_1, \dots, w_k$. There are four groups of edges:

- input edges, $g_1, \dots, g_k$, pointing into $v_1, \dots, v_k$, respectively;
- output edges, $h_1, \dots, h_k$, pointing out from $w_1, \dots, w_k$, respectively;
- load edges, $e_1, \dots, e_k$, pointing from $v_i$ to $w_i$;
- helper edges, $f_1, \dots, f_k$, pointing from $w_i$ to $v_{i+1}$. The $i$'s wrap around $k$.

Note that the load and helper edges form a ring with the input and output edges pointing in and out from alternate nodes. Figure 1 shows an example gadget.

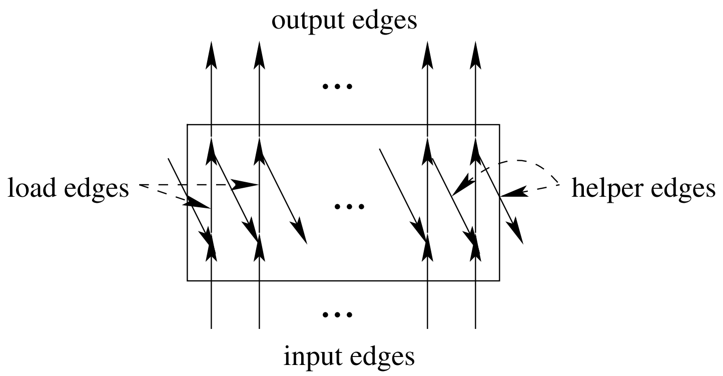

FIG. 1. *A gadget.*

**2.2. A special flow.** There are two kind of packets in this flow:

1. For each $i \in 1, \dots, k$, packets enter the gadget through $g_i$ at rate 1. The route of a particular packet is

$$g_i, e_i, f_i, e_{i+1}, f_{i+1}, e_{i+2}, \dots, f_{i+k-2}, e_{i+k-1}, h_{i+k-1}.$$

Hence, each packet traverses all the load edges in the gadget. These packets are referred to as the *gadget-traversing* packets.

2. For each load edge $e_i$, single edge packets are introduced at a rate $r$. These packets are referred to as the *internal-gadget* packets.

**2.3. Upper bound on the leak.** We are working here in the discrete model. However, we will use the notion of the rate at which packets of a particular kind $X$ arrive at a node, which essentially comes from the fluid model. We can view the rate as the average number of packets arriving at a node per unit time. Also, whenever we use the notion of a rate, we clearly specify the time period on which it is applicable. Rate of leak from a gadget, $R$, is the sum of the rates at which the gadget-traversing packets arrive at the source node of an output edge. In the following, we prove an upper bound for $R$, assuming the flows mentioned in section 2.2. For proving the upper bound we use the following property of FIFO.

*Remark* 2.1. Let $e$ be an edge in the network, and $X_1, X_2, \dots, X_n$ be $n$ different types of packets which arrive at the source node of $e$ at rates $R_1, R_2, \dots, R_n$, respectively. Then the rate at which packets of type $X_i$ traverse $e$ is given by the expression

$$\min\left\{R_i, \frac{R_i}{\sum_{j=1}^{n} R_j}\right\}.$$

LEMMA 2.2. *During the time when the special flow is maintained,* $R \le \frac{k}{(1+r)^k}$.

*Proof.* By symmetry, the total rate of arrival of packets at the source node of the load edges is the same. Let that rate be $T$:

$$T = 1 + r + r_1 + \cdots + r_{k-1},$$

where $r_i$ is the rate of arrival of packets which have traversed $i$ of the $k$ load edges. Using Remark 2.1, we obtain $r_1 = 1/T$. Similarly, for all $2 \le i \le k$,

$$r_i = \frac{r_{i-1}}{T} = \frac{1}{T^i}.$$

Since $T \ge 1 + r$ at all times, it follows that $r_k \le 1/(1+r)^k$. Therefore at all times,

$$R = kr_k \le \frac{k}{(1+r)^k}. \qquad \square$$

Although the above lemma assumes the fluid model, the same bounds can be achieved for the discrete model using slightly higher rates. Also the adversarial injection pattern in this paper is similar to that in the fluid model.

**3. The network topology.** The network contains three components; the columns, the connectors, and the shortcuts. We describe each of these in turn, after first describing the concept of concatenation of gadgets, which is required for each of these components. In this section and all others, all gadgets would have the same parameter, $k$.

**3.1. Concatenating gadgets.** A gadget $G_2$ is said to be concatenated to a gadget $G_1$ if

1. the output edges of $G_1$ act as the load edges of $G_2$, and
2. the load edges of $G_1$ act as the input edges of $G_2$.

Note that more than one gadget can be concatenated to a gadget, and also a single gadget can be concatenated to more than one other gadget. A *chain* $C = \langle H_1, H_2, \ldots, H_n \rangle$, of length $n$, is produced by the concatenation of the gadget $H_{i+1}$ to the gadget $H_i$, for $1 \leq i < n$. A *bridge* $B$ of length $l$ is said to exist between gadgets $G_1$ and $G_2$ if there exists a chain $\langle G_1, H_1, H_2, \ldots, H_l, G_2 \rangle$.

**3.2. Columns.** The network has two separate columns, $C_1, C_2$. A column is a chain of length $\alpha$, where $\alpha$ is a parameter which will be specified later.

$$C_1 = \langle C_{1,1}, C_{1,2}, \ldots, C_{1,\alpha} \rangle,$$

$$C_2 = \langle C_{2,1}, C_{2,2}, \ldots, C_{2,\alpha} \rangle.$$

**3.3. Connectors.** There are two sets of connectors, one from $C_1$ to $C_2$ and the other from $C_2$ to $C_1$. Connectors are bridges of length $\beta$ between each gadget of a column and the first gadget of the other column, where $\beta$ is a parameter which will be specified later. So, for each $C_{1,i}$, we have the following bridge:

$$\langle C_{1,i}, D_{1,i,1}, D_{1,i,2}, \ldots, D_{1,i,\beta}, C_{2,1} \rangle.$$

Similarly, for each $C_{2,i}$, we have the following bridge:

$$\langle C_{2,i}, D_{2,i,1}, D_{2,i,2}, \ldots, D_{2,i,\beta}, C_{1,1} \rangle.$$

**3.4. Shortcuts.** Shortcuts are bridges of length 1 from each connector gadget $D_{1,i,j}$ to $C_{2,1}$. We refer to the respective shortcut gadgets as $E_{1,i,j}$. Similar shortcuts exist between the other set of connector gadgets and $C_{2,1}$. Figure 2 shows the schematic of the network topology.

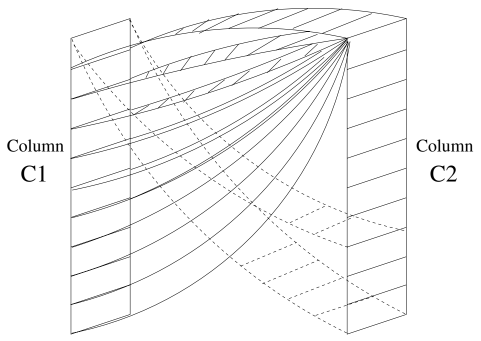

FIG. 2. *Topology of the network; shortcuts are not shown.*

**4. The adversarial injection pattern.** The adversary introduces two kinds of flows of packets (in addition to the internal gadget packets): flow through the columns and flow through the connectors. The description of both assumes the concept of activation of a gadget and sequential activation of gadgets in a chain, which are

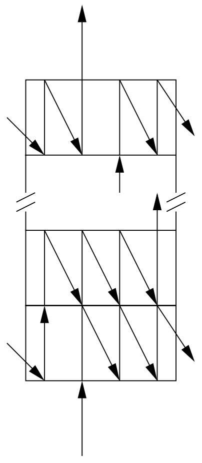

FIG. 3. *Route of a chain-traversing packet.*

described next. We will assume that there is a chain $\langle G_1, G_2, \ldots, G_p \rangle$. These gadgets will be activated one after the other.

A packet is considered to be a *chain-traversing* packet for a chain $\langle G_1, G_2, \ldots, G_p \rangle$ if the route of the packet is gadget-traversing for each $G_i$ in the chain (see Figure 3 for an illustration).

## 4.1. Activation of a gadget.

*Precondition.* There are $t$ gadget-traversing packets in the queue of each input edge of the gadget $G_i$. Also, there is no other packet in any other gadget in the chain. Moreover, the packets are chain-traversing for the chain $\langle G_i, G_{i+1}, \ldots, G_p \rangle$. (We will slightly modify this condition later.)

*Activation.* During the activation phase, the adversary introduces internal-gadget packets at rate $r$ in the gadget $G_i$. The activation phase lasts for $t$ time steps. Note that during this phase the internal-gadget packets and the gadget-traversing packets compete with each other to traverse the load edges of the gadget.

*Postcondition.* There are $t' < t$ packets in the queue of each load edge of the gadget $G_i$, and there are no other packets in any other gadget. Each packet is chain-traversing for the chain $\langle G_{i+1}, G_{i+2}, \ldots, G_p \rangle$. Later a lower bound for the quantity $t'$ will be presented. In order to ensure that these conditions are met, we modify the injection in the following way (we essentially use the fact that the routes of all the packets are predetermined). (1) In order to get rid of internal-gadget packets which might be interleaved with the chain-traversing packets in the queue (after $t$ time steps), we make sure that these particular internal-gadget packets are never introduced. (2) To avoid the case when packets in the queue of the load edges have other edges, within the gadget $G_i$, to traverse, we modify the routes of the packets such that after $t$ time steps, they are simply queued in one of the load edges of $G_i$, and the next edge on their route is a load edge of gadget $G_{i+1}$. This can be done since it amounts to merely taking away some of the edges from the path of the packets and can only reduce the injection rate. (3) We will assume that the routes of all the packets which escaped the gadget during the $t$ time steps end at gadget $G_i$ itself. This ensures that there are no packets in the other gadgets. Note that these changes have no effect on the number of packets queued on a load edge.

*Sequential activation of gadgets.* In a chain of gadgets, the postcondition of the activation of a gadget acts as the precondition for the activation of the concatenated gadget. Sequential activation of gadgets is the cascading activation of gadgets starting from some initial chain-traversing packets waiting in the queue of the input edges of the first gadget.

**4.2. Flow through the columns.** Time steps are grouped into phases. It is assumed that at the beginning of an even phase there are $s$ chain-traversing (for column $C_1$) packets in the queue of each of the input edges of the gadget $C_{1,1}$. We show that at the end of the phase there are more than $s$ chain-traversing (for column $C_2$) packets waiting on each of the input edges of the gadget, $C_{2,1}$. Similarly, at the beginning of an odd phase, there are $s'$ chain-traversing packets in the queue of each of the input edges of the gadget, $C_{2,1}$, and at the end of the phase there are more than $s'$ chain-traversing packets in the queue of each of the input edges of the gadget, $C_{1,1}$. We show packet injections only for the even phases; packet injections for the odd phases are similar. Applying the above repeatedly leads to instability.

*Subphases.* Each phase is divided into $\alpha$ subphases. During the $i$th subphase the gadget $C_{1,i}$ is activated.

**4.3. Flow through the connectors.** At the end of subphase $i$, let there be $s_i$ packets in the queue of each of the input edges of $C_{1,i+1}$. These packets are chain-traversing for column $C_1$. During the next $s_i$ time steps (i.e., the subphase $i+1$), $rs_i/k$ packets each are introduced into the queue of each input edge of $C_{1,i+1}$. These packets are introduced behind the $s_i$ packets mentioned above. The routes of these packets are chosen such that they are chain-traversing for the chain

$$\langle D_{1,i,1}, D_{1,i,2}, \ldots, D_{1,i,j}, E_{1,i,j}, C_{2,1}, C_{2,2}, \ldots, C_{2,\alpha}\rangle$$

for some $j < \beta$. After $s_i$ time steps, these packets form the precondition for the sequential activation of the gadgets in the chain mentioned above. This is because there are $s_i$ packets present in the queue of each input edge of $C_{1,i}$ ahead of the newly injected packets. The routes of the packets are such that at the end of the phase, i.e., at time $\sum_{i=1}^{\alpha} s_i$, they are all queued at the input edges of the the gadget, $C_{2,1}$. This can be achieved using the shortcut gadgets and the fact that the route of each packet is determined in advance ($j < \beta$ can be chosen arbitrarily). Observe that the routes of the chain-traversing packets and the internal-gadget packets introduced during a subphase are mutually exclusive. Moreover, the injection rate of each type of packet is less than $r$ for any edge.

## 5. Proof of instability.

This section shows that at the end of a phase there are more packets queued at the input edges of $C_{2,1}$, than were queued at the input edges of $C_{1,1}$. To initially generate a constant number of packets to start phase 0, we can attach large acyclic graphs to the input edges of $C_{1,1}$, where the acyclic portion is used to generate the initial packets (for details, please refer to [5]).

Analogously to our description of the flow, the analysis can be broken down into two parts: flow through the columns and flow through the connectors.

**5.1. Flow through the columns.** First we set the values of the various parameters. Let $k$ be such that $(1+r)^k > 64k^3/r^2$, $\alpha = 4k/r$, $\beta = 16k^2/r^2$.

LEMMA 5.1. *Let $s_i$ be the duration for which the gadget $C_{1,i}$ remains activated during the ith subphase. For $1 \le i \le \alpha$, the number of packets in the queue of each of the input edges of the gadget $C_{1,i}$ at time $\sum_{j=1}^{i-1} s_j$, i.e., the beginning of the ith subphase, is lower bounded by $s/2$.*

*Proof.* Recall that the duration for which a gadget remains activated is the same as the number of packets waiting at each input edge when the gadget gets activated. Observe that $s_1 = s$. Lemma 2.2 implies that, for a gadget activated for $s_i$ time steps, the total number of packets which leak through in the $s_i$ steps is at most

$$\left\lceil \frac{s_i k}{(1+r)^k} \right\rceil \leq 2s_i \frac{k}{(1+r)^k}.$$

By our choice of $\alpha$ and $k$, it follows that $\alpha\frac{k}{(1+r)^k} < \frac{\alpha r^2}{64k^2} = \frac{r}{16k} < \frac{1}{2}$. We now have

$$\begin{aligned} s_i &\geq s_{i-1}\left(1 - \frac{2k}{(1+r)^k}\right) \\ &\geq s\left(1 - \frac{2k}{(1+r)^k}\right)^{\alpha} \qquad [\text{since } i \leq \alpha] \\ &> s\left(1 - \alpha\frac{2k}{(1+r)^k}\right) \\ &\geq s\left(1 - \frac{1}{2}\right) \\ &= \frac{s}{2}. \end{aligned}$$

Hence, the lemma follows. ◻

**5.2. Flow through the connectors.** Recall that, for each $1 \leq i < \alpha$, a set of $rs_i/k$ (for each edge) chain-traversing packets for the chain

$$\langle C_{1,i}, D_{1,i,1}, D_{1,i,2}, \ldots, C_{2,1}, \ldots, C_{2,\alpha}\rangle$$

is introduced during the subphase $i + 1$.

LEMMA 5.2. *After the packets have activated $j - 1$ gadgets in a connector, the number of packets queued at each input edge of the connector gadget $D_{1,i,j}$ is lower bounded by $rs/4k$.*

*Proof.* Using arguments similar to that used in Lemma 5.1, we can conclude that the number of packets queued at each input edge of the gadget $D_{1,i,j}$ (after $j - 1$ gadgets have been activated) is at least

$$\frac{rs_i}{k}\left(1 - \frac{2k}{(1+r)^k}\right)^{\beta}.$$

By the choice of $\beta$ and $k$, $\beta\frac{2k}{(1+r)^k} < \frac{1}{2}$, and since $s_i > \frac{s}{2}$, the number of packets is more than

$$\frac{rs}{2k}\left(1 - \beta\frac{2k}{(1+r)^k}\right) \geq \frac{rs}{2k}\left(1 - \frac{1}{2}\right) = \frac{rs}{4k}.$$

Hence, the lemma follows. ◻

LEMMA 5.3. *At time $\sum_{i=1}^{\alpha} s_i$, i.e., at the end of all subphases, the number of packets queued at the input edges of $C_{2,1}$ is greater than $s$.*

*Proof.* We first show that $\beta$ is large enough to allow the different sets of chain-traversing packets injected during each of the $\alpha$ subphases to simultaneously arrive at the input edges of $C_{2,1}$. This can be accomplished if the time step at which $D_{1,i,\beta}$

(for all $1 \leq i \leq \alpha$) is activated is greater than $\sum s_i$. By Lemma 5.2, the time step at which $D_{1,i,\beta}$ is activated is more than

$$\frac{rs}{4k}\beta = \frac{rs}{4k}\alpha^2 = \alpha s \geq \sum s_i.$$

Using Lemma 5.2, the number of packets on the queue of each input edge is more than

$$\frac{\alpha rs}{4k} = s.$$

Hence we obtain the lemma. □

We now state the main theorem of our paper.

THEOREM 5.4. *FIFO is unstable for arbitrarily low injection rates.*

*Proof.* In light of Lemma 5.3, we need to show only that the rate of injection is always less than $r$. The latter is true because the gadget-traversing packets and the internal-gadget packets are always injected for mutually exclusive sets of edges and these packets themselves respect the injection rate $r$. (See section 4 for details.) □

**5.3. The size of the network.** We show that the size of the network is polynomial in $\frac{1}{r}$. Let $k$ be $c\frac{1}{r}\log(\frac{1}{r})$ for a large enough $c$. We use the fact that $(1+r)^{\frac{1}{r}} > 2$ when $r < 1$, and obtain.

$$(1+r)^k > 2^{c\log(\frac{1}{r})} \geq \frac{64k^3}{r^2}.$$

Therefore, $k = O(\frac{1}{r}\log(\frac{1}{r}))$. Now, the size of the network is $O(\alpha\beta k) = O(\frac{k^4}{r^3})$, which is polynomial in $\frac{1}{r}$. This is quite strong since it even excludes the possibility that FIFO might be stable at rate $O(\frac{1}{\log^c m})$, where $m$ is the size of the network and $c$ is a constant.

## 6. Reducing the diameter of the network to $\tilde{O}(\frac{1}{r})$.

In this section, we present a variant of our construction in which we prove instability at an arbitrary rate $r > 0$ in a graph of diameter $\tilde{O}(\frac{1}{r})$. (The graph used in the previous section has diameter $\tilde{O}(\frac{1}{r^7})$.) The idea is to combine the gadget in the previous section with results from [28].

**6.1. The topology of the gadget.** We add to our basic $k$-gadget $k$ new edges; we call those edges bypass edges, $b_1, b_2, \ldots, b_k$, pointing from the nodes $v_i$ to the nodes $w_i$, respectively. Note that edges $b_i, e_i$ have the same source (the node $v_i$) and the same target (the node $w_i$). Figure 4 shows two concatenating gadgets.

**6.2. The adversary in two concatenating gadgets.** We use a daisy chain of many gadgets in our construction. However, we start by considering two chained gadgets (Figure 4). We will construct an adversary that maintains the following *gadget invariant*; this condition is similar to Definition 5 in [28]. Let $\alpha = \frac{2r}{2k-r}$.

DEFINITION 6.1. *Let $1 \leq j \leq N$. We say that condition State$(S, \langle H^j, H^{j+1}, \ldots, H^{N+1}\rangle)$ is true at a given time if the following hold at that time on the gadget chain $\langle H^j, H^{j+1}, \ldots, H^{N+1}\rangle$:*

1. *$H^j, H^{j+1}, \ldots, H^{N+1}$ are $k$-gadgets.*
2. *For each $i = 1, \ldots, k$, the number of packets in the buffer of $g_i^j$ is $\alpha \cdot S$, and all those packets in $g_i^j$ have remaining routes $g_i^j, b^j, h_i^j$.*

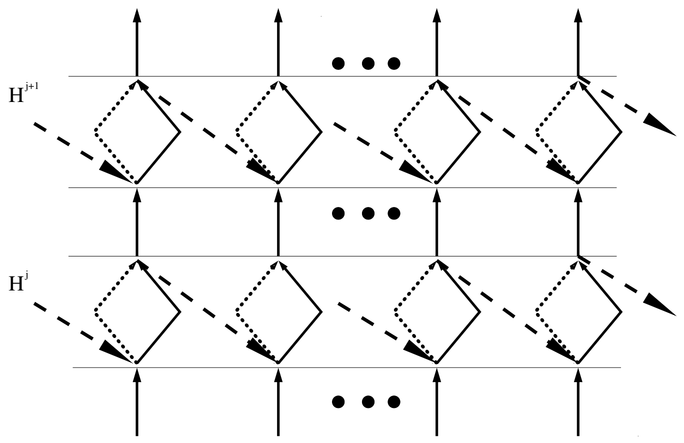

FIG. 4. *A chain of two connected gadgets glued together. The upper gadget is $H^{j+1}$, the lower gadget is $H^j$. Both are $G_k$ gadgets. The twisted dot arrows are the bypass edges $b_i^j, b_i^{j+1}$; the strong twisted arrows are the load edges $e_i^j, e_i^{j+1}$.*

3. *For each $i = 1, \ldots, k$, the number of packets in the buffer of $e_i^j$ is $S$, and all packets in $e_i^j$ have remaining routes $e_i^j, h_i^j$.*
4. *There are no other packets in $H^j, H^{j+1}, \ldots, H^{N+1}$.*
5. *All the packets that are in $H^j$, $H^{j+1}$ can be rerouted in the gadgets $H^{j+2}, H^{j+3}, \ldots, H^{N+1}$ arbitrarily.*

The next lemma shows that if at a time $\tau$ condition $State(S, \langle H^j, H^{j+1}, \ldots, H^{N+1}\rangle)$ holds, then at time $\tau + (1+\alpha)S$ condition $State(S_1, \langle H^{j+1}, \ldots, H^{N+1}\rangle)$ holds, where $\frac{S_1}{S} > 1$. Note that this lemma enables us to use the $k$-gadgets as amplifiers.

LEMMA 6.1. *Let $r > 0$. There exist numbers $k$ and $S_0$ that depend on $r$ such that, for any $S > S_0$, if at some time $\tau$ all the $S$ packets in the gadget $H^j$ were injected after certain time $\tau_0$, and $State(S, \langle H^j, H^{j+1}, \ldots, H^{N+1}\rangle)$ holds at time $\tau$, then there exists a rate $r$ adversary such that, at time $\tau + (1+\alpha)S$, condition $State(S_1, \langle H^{j+1}, \ldots, H^{N+1}\rangle)$ holds for some $S_1 = S(1 + \frac{r}{2k})$.*

*Proof.* For sake of simplicity of presentation we make two facilitating assumptions:

1. $\tau = 0$ and $\tau_0 = \frac{-1}{r}$. This assumption can lead to an additive error of one packet in each load edge of the gadget $H^{j+1}$, and an additional packet from among the packets injected in the load edge of the gadget $H^j$: all together, we get $(k+1)$ fewer packets in the calculation of the number of packets.
2. We ignore floors and ceilings. This is a common assumption in proving instability results (cf. [3, 23, 25]).

We remark that carrying these assumptions throughout the computations would add only additive terms, which can be compensated for by using a larger $S_0$ value (cf. [3, 23, 25, 28]). We now specify the adversary that will create a situation where $State(S_1, \langle H^{j+1}, \ldots, H^{N+1}\rangle)$ holds, as follows.

DEFINITION 6.2. *For each $i = 1, \ldots, k$ the adversary does the following:*

1. *extends the routes of all the packets that enter the gadget $H^{j+1}$ stored in the buffers $g_i^j, e_i^j$ at time 0 by adding the path*

$$e_i^{j+1}, f_i^{j+1}, e_{i+1}^{j+1}, f_{i+1}^{j+1}, e_{i+2}^{j+1}, \ldots, f_{i+k-2}^{j+1}, e_{i+k-1}^{j+1}, h_{i+k-1}^{j+1}$$

*to the path of those packets. Note that the routes of all those packets end in* *the edge $h_i^j$, and therefore we get a legal path. We call these packets* old long *packets.*

2. *injects packets at rate $r$ in time steps $1, 2, \dots, t$. The route of each of these packets is the single edge $e_i^{j+1}$; we call those packets* new short *packets. We set $t$ to be the maximal number such that at time $(1+\alpha)S$ there are no short packets at the edges $e_i^{j+1}$.*
3. (a) *injects packets at rate $\frac{r}{k}$ in the time interval $[1, S]$, with route $e_i^j, h_i^j, b_i^{j+1}, h_i^{j+1}$, for all $i = 1, \dots, k$. We call those packets* new long *packets of the first kind.*
   (b) *injects packets at rate $\frac{r}{k}$ in the time interval $[S+1, (1+\alpha)S]$, with route $h_i^j, b_i^{j+1}, h_i^{j+1}$, for all $i = 1, \dots, k$. We call those packets* new long *packets of the second kind.*

First, note that this is a rate-$r$ adversary: Definition 6.2.1 is justified by Definition 6.1.5. Edges $e_1^{j+1}, \dots, e_k^{j+1}$ are used only by Definition 6.2.2 at rate $r$. Edges $e_i^j, h_i^j, b_i^{j+1}, h_i^{j+1}$ are used only by parts 3(a) and 3(b) of Definition 6.2 at rate $\frac{r}{k}$. Since the time intervals of Definition 6.2 parts 3(a) and 3(b) are disjoint, we get a legal $r$ adversary.

Next we prove that condition $State(S_1, \langle H^{j+1}, \dots, H^{N+1}\rangle)$ holds.

1. Since condition $State(S, \langle H^j, H^{j+1}, \dots, H^{N+1}\rangle)$ holds at time $\tau$, we get that for every $i$, $H^i$ is a $G_k$-gadget.
2. All the new long packets of the first kind leave the edge $e_i^j$ after the last old long packets have left this edge. Since $\frac{r}{k} < \alpha$, all the new long packets of the first kind leave the edge $e_i^j$ by the time $(1+\alpha)S$. Since the number of old long packets is $S \cdot (1+\alpha)$ and all of them arrive at the edge $h_i^j$ before the first new long packet arrives to this edge, no new long packets pass through the edge $h_i^j$ in the time interval $[0, S \cdot (1+\alpha)]$. From Definition 6.2, parts 3(a) and 3(b), the number of new long packets is $S \cdot (1+\alpha) \cdot \frac{r}{k} = S_1 \cdot \alpha$, and all of them are in the edge $h_i^j$. Therefore, Definition 6.1.2 holds.
3. We will see condition 3 of Definition 6.1 in the next subsection.
4. To see that condition 4 of Definition 6.1 holds, we use the idea from [28]. Briefly, this holds because packet routes are predetermined. We can define the destination of long packets that depart from the gadget $H^j$ to be the last node in the gadget $H^j$. To get rid of the short packets at time $(1+\alpha)S$ we simply stop injecting short packets at the right time.
5. To see that Definition 6.1.5 holds, note that the total injection rate of the new long packets is $r$. Therefore we can reroute the path of those packets arbitrarily in the next gadgets. Since the old packets were injected to the graph before time $\frac{-1}{r}$ and the new packets were injected to the graph after time 0, we can reroute the path of all the long packets arbitrarily in the next gadgets. $\square$

**6.3. Upper bound on the leak.** Next we analyze the leak rate from a $k$-gadget $G_k$ in a manner similar to what we did in subsection 2.3. We use a strong version of Lemma 2.2. Let $\phi = \frac{1+\sqrt{5}}{2}$.

LEMMA 6.2. *Assume that we are using the adversary described in Definition* 6.2. *Let $k > 2$; during the time* 0 *to* $(1+\alpha)S$, $R \leq \frac{k}{\phi^k}$.

*Proof.* The proof is similar to the proof of Lemma 2.2 except that, using the fact that $k > 2$ in this case, we can get that $T \geq 1 + r + \frac{1}{T}$ at all times. Solving this inequality, we get that $T > \phi$. From this it follows that $r_k \leq \frac{1}{(\phi)^k}$. Therefore at all

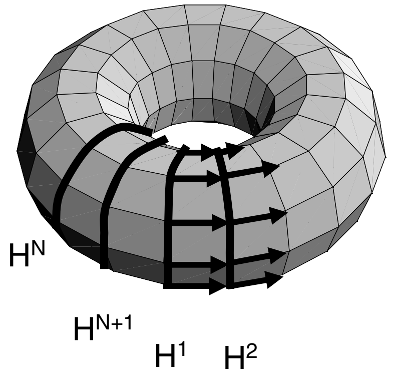

Fig. 5. *The big picture. Every $H^1, H^2, \ldots, H^{N+1}$ is a $G_k$-gadget. In each $G_k$-gadget we have $2k$ nodes that don't appear in this schematic diagram; for accurate description of $G_k$, see subsection 6.1. The marked arrows demonstrate the general direction of packet movement in the networks. The last gadget $H^{N+1}$ serves as a gluing component.*

times, $R = kr_k \leq \frac{k}{\phi^k}$. ◻

The next corollary states that if $k > 4\log_\phi(\frac{1}{r})$ and $\frac{1}{2\sqrt{2}} > r > 0$, we can use the basic gadget $G_k$ as an amplifier.

Lemma 6.3. *Assume that we are using the adversary mentioned in Definition 6.2. Let $\frac{1}{2\sqrt{2}} > r > 0$ and $k > 4\log_\phi(\frac{1}{r})$; then the number of packets in $e_i^{j+1}$ at time $(1+\alpha)S$ is greater than or equal to $S(1+\frac{r}{2k})$.*

*Proof.* Using Lemma 6.2, we get that the total number of packets in $e_i^{j+1}$ at time $(1+\alpha)S$ is $S_1 \geq S \cdot (1+\alpha) \cdot (1-\phi^{-k})$. Using $\frac{1}{2\sqrt{2}} > r > 0$ and $k > 4\log_\phi(\frac{1}{r})$, we get that $\frac{r}{2k} > \frac{1}{\phi^k}$. Now using the definition of $\alpha$, we get that $S_1 \geq S \cdot (\frac{2k+r}{2k-r}) \cdot (\frac{2k-r}{2k}) = S(1+\frac{r}{2k})$. ◻

**6.4. The network topology.** Our networks can be embedded in the torus (see Figure 5). The network contains a chain of gadgets $\langle H^1, \ldots, H^{N+1}\rangle$, and each of these gadgets is a $G_k$-gadget. We use the $H^1, \ldots, H^N$ as amplifiers. We also concatenate the last gadget $H^{N+1}$ to the first gadget $H^1$. We denote this graph by $T_k$. The last gadget acts as gluing component. Now we can repeat exactly what is done in section 3.3 of [28]. Following similar steps, we concatenate a sequence of basic gadgets $H^j$, that is, $1, 2, \ldots, N$, each of which amplifies the number of packets by a multiplicative factor $(1+\frac{r}{2k})$. After this we close the $k$ cycles for each $i = 1, \ldots, k$ exactly as described in Lemma 3.12 of [28]. For completeness we quote Lemma 3.12 from [28], which describes how to close a single cycle. We use this construction for every cycle; i.e., we close $k$ cycles. We consider a path of three edges, called $a_0, a_1$, and $a_2$; we can think of $g_i^{N+1}$ as $a_0$, $e_i^{N+1}$ as $a_1$, and $h_i^{N+1}$ as $a_2$. The routes that will be traversed by old packets will all end at $a_0$, and the fresh packets all start at the tail of $a_2$.

Lemma 6.4. *Suppose that at time $\tau$ there are $S$ packets stored in the buffer of $a_0$ with remaining routes of length 1. Then for any $r > 0$ there exists a rate-$r$ adversary such that at time $\tau + S + rS + r^2S$ there are $r^3S$ packets stored in the buffer of $a_2$ and there are no other packets in the network. Moreover, all the packets stored in the buffer of $a_2$ were injected at the tail of $a_2$ after time $\tau + S$.*

Since the above lemma needs a path of length 3, we can use one gadget $G_k$ in the end. We call this gadget a gluing component. By doing this we lose a fraction of $r^3$ from the total number of packets. The outcome of these two mechanisms is described in Theorem 3.13 of [28]. Finally we get that the total number of packets after traversing all the gadgets $(S_1)$ is $\frac{r}{k(1+\alpha)} \cdot S \cdot (\frac{r}{k})^3 \cdot (1+\frac{r}{2k})^{N-1}$. We show that $S_1 > 10S$. Since $\alpha < 0.5$ and $\frac{1}{k} > r$, we get that $S_1 > \frac{2}{3}S \cdot r^8 \cdot (1+\frac{r}{2k})^{N-1}$. If we take $N = \frac{4k}{r}\log(\frac{4}{r^4}) + 1$, we get that the number of packets in $e_i^1$ at time $t' + S \cdot (\frac{r}{k})^3 \cdot (1+\frac{r}{2k})^{N-1}$ is

$$\begin{aligned} S_1 &> \frac{2}{3} \cdot S \cdot r^8 \cdot \left(1+\frac{r}{2k}\right)^{N-1} \\ &= \frac{2}{3} \cdot S \cdot r^8 \cdot \left(1+\frac{r}{2k}\right)^{\frac{4k}{r}\log\left(\frac{4}{r^4}\right)} \\ &\geq \frac{2}{3} \cdot S \cdot r^8 \cdot 4^{\log\left(\frac{4}{r^4}\right)} \\ &> 10S. \end{aligned}$$

Let $d$ be the diameter of the graph. It is easy to see that $d = O(N \cdot k) = O(\frac{1}{r} \cdot \log^3(\frac{1}{r}))$. In section 4 of Theorem 4.1 in [28] it was proved that FIFO is stable for an injection rate less than $r = \frac{1}{d}$. In this construction we prove that FIFO is unstable for rates bigger than $d = O(\frac{1}{r}\log(\frac{1}{r})^3)$. This leaves a gap of polylog factor.

THEOREM 6.5. *For every $1 > r > 0$ there exists a graph $T_k$, a rate-$r$ adversary, and an initial configuration such that FIFO is unstable on $T_k$ and the diameter of the graph $T_k$ is $O(1/r\log(1/r)^3)$.*

# GENERALIZED IRREDUCIBILITY OF CONSENSUS AND THE EQUIVALENCE OF $t$-RESILIENT AND WAIT-FREE IMPLEMENTATIONS OF CONSENSUS*

TUSHAR CHANDRA†, VASSOS HADZILACOS‡, PRASAD JAYANTI§, AND SAM TOUEG‡

**Abstract.** We study the consensus problem, which requires multiple processes with different input values to agree on one of these values, in the context of asynchronous shared memory systems. Prior research focussed either on $t$-resilient solutions of this problem (which must be correct even if up to $t$ processes crash) or on wait-free solutions (which must be correct despite the crash of any number of processes). In this paper, we show that these two forms of solvability are closely related. Specifically, for all $n > t \geq 2$ and all sets $\mathcal{S}$ of shared object types (that include simple read/write registers), there is a $t$-resilient solution to $n$-process consensus using objects of types in $\mathcal{S}$ if and only if there is a wait-free solution to $(t + 1)$-process consensus using objects of types in $\mathcal{S}$.

Our proof of this equivalence uses another result derived in this paper, which is of independent interest. Roughly speaking, this result states that a wait-free solution to $(n - 1)$-process consensus is never necessary in designing a wait-free solution to $n$-process consensus, regardless of the types of objects available. More precisely, for all $n \geq 2$ and all sets $\mathcal{S}$ of shared object types (that include simple read/write registers), if there is a wait-free solution to $n$-process consensus that uses a wait-free solution to $(n-1)$-process consensus and objects of types in $\mathcal{S}$, then there is a wait-free solution to $n$-process consensus that uses only objects of types in $\mathcal{S}$.

## 1. Introduction.

We consider concurrent systems in which asynchronous processes communicate via typed shared objects. Informally, an object's type specifies (i) the number of ports, which represents the maximum number of processes that may access the object *simultaneously*; (ii) the set of states of the object; (iii) the set of operations that processes may apply to the object through its ports; and (iv) the behavior of the object, described by the effect of each operation on the object's state and the value the operation returns, assuming no other operation is accessing the object at that time. Every object is *linearizable* [14]: when operations are invoked concurrently at different ports, the object behaves *as if* each operation had occurred instantaneously, with no interference from other operations, at some point between the time it was invoked and the time it returned its response. An object that belongs to a type with $n$ ports is called *$n$-ported*.

In such systems, some shared objects, such as registers and test&set objects, are

supported in hardware, while other objects, such as queues and stacks, are implemented in software. Objects used in the implementation of another object (registers and test&set objects, in our example) are called *base* objects with respect to that implementation. We consider two forms of implementations: wait-free and $t$-resilient. An implementation is *wait-free* if every process can complete every operation on the implemented object in a finite number of its own steps, regardless of whether other processes are fast, slow, or have crashed [18, 28, 12]. Wait-free implementations provide an extreme degree of fault-tolerance. They assure that even if just one process survives, it will be able to complete its operations on the implemented object. In contrast, *$t$-resilient* implementations support a more modest degree of fault-tolerance [11, 10, 24]. They guarantee that nonfaulty processes will complete their operations, as long as no more than $t$ processes fail, where $t$ is a specified parameter. It is immediate from the definitions that wait-freedom is equivalent to $(n-1)$-resilience, where $n$ is the number of processes in the system.

This paper concerns $t$-resilient and wait-free implementations of a particular type of object, known as $n$-consensus. Informally, an $n$-consensus object allows each of $n$ processes to access it by proposing a value; the object returns the same value to all accesses, where the value returned is the value proposed by some process. The following are two reasons why it is important to implement $n$-consensus objects:

- It is possible to design a wait-free implementation of an object of *any* type, shared by $n$ processes, using only $n$-consensus objects and registers [12].[1]
- In an asynchronous system, since processes progress at independent and arbitrarily varying speeds, the view that a process holds of the global state of the computation does not necessarily coincide either with the reality or with the views of other processes. However, processes can reconcile their differences and arrive at a mutually acceptable common view if they have access to consensus objects.

A lot of research was aimed at determining the feasibility of implementing $n$-consensus objects from other types of objects. Some of this research studied the feasibility of $t$-resilient implementations [11, 10, 24], while some studied the feasibility of wait-free implementations [24, 12, 9]. To a large degree, the two questions, namely, the feasibility of $t$-resilient implementations and the feasibility of wait-free implementations, were treated separately, as if they had no particular relationship with each other (see section 1.1 for an exception). The main contribution of this paper is to show that the two questions are closely related, as we explain below.

Consider the task of devising a $t$-resilient implementation of an $n$-consensus object. As $n$ decreases, the fraction of nonfaulty processes on which the implementation can rely gets smaller, and the task therefore seems to become progressively more difficult. For example, a $t$-resilient implementation that works only when a majority of processes are nonfaulty cannot be used when $n$ becomes smaller than $2t+1$. In the limit, when $n$ becomes $t+1$, the task amounts to providing a *wait-free* implementation of the object. Thus, *prima faciae*, it seems that the ability of objects belonging to

[1]A register is an object that allows processes to access it (only) through write operations, each of which stores a new value into the register, and read operations, which return the current value of the register. It is possible to implement $k$-ported registers, for any $k$, from just 2-ported registers. This is a consequence of the well-known fact that arbitrary multireader, multiwriter atomic registers (hence, $k$-ported registers, for any $k$) can be implemented from single-reader, single-writer (hence, 2-ported) atomic registers. (For more information on register constructions see, for example, [19, 20, 15].) Because of this, whenever we mention registers we do not bother to explicitly specify the number of ports: it is understood that any number of ports greater than one suffices.

a set $\mathcal{S}$ of types to support a $t$-resilient implementation of an $n$-consensus object is greater than their ability to support a wait-free implementation of a $(t+1)$-consensus object. We show that this is not the case. Specifically, our result is the following.

Equivalence theorem. *For all $n > t \geq 2$ and all sets $\mathcal{S}$ of types that include* `register` *($\mathcal{S}$ may include nondeterministic types), there is a $t$-resilient implementation of an $n$-consensus object from objects of types in $\mathcal{S}$ if and only if there is a wait-free implementation of a $(t+1)$-consensus object from objects of types in $\mathcal{S}$.*

One use of our theorem stems from the observation that proofs of impossibility of $t$-resilient implementations of consensus tend to be generally much harder than proofs of impossibility of wait-free implementations of consensus.[2] Our theorem allows one to conclude the impossibility of $t$-resilient implementations of $n$-consensus simply by establishing the impossibility of wait-free implementations of $(t+1)$-consensus. For instance, since there is no wait-free implementation of 3-consensus from queues and registers [12], our theorem implies that there is no 2-resilient implementation of $n$-consensus from queues and registers (for all $n \geq 3$). We present several other such applications of our theorem.

A key ingredient in our proof of the equivalence theorem discussed above is another result of this paper that is of interest in its own right. Roughly speaking, this result states that $(n-1)$-consensus objects are not necessary for a wait-free implementation of $n$-consensus, *no matter what other base objects may be available for the implementation*. Specifically, our result is as follows.

Generalized irreducibility theorem for consensus. *For all $n \geq 2$ and all sets $\mathcal{S}$ of types that include* `register` *($\mathcal{S}$ may include nondeterministic types), if there is a wait-free implementation of an $n$-consensus object from $(n-1)$-consensus objects and objects of types in $\mathcal{S}$, then there is a wait-free implementation of an $n$-consensus object from objects of types in $\mathcal{S}$.*

*In other words, the $(n-1)$-consensus base objects can be eliminated from the implementation.*

The above theorem is more general (and has a more complex proof) than the well-known irreducibility of consensus, stated as follows: for all $n \geq 2$, there is no wait-free implementation of an $n$-consensus object from $(n-1)$-consensus objects and registers [12, 17]. To illustrate the difference between the two results, we consider the following question: Is there a wait-free implementation of a 4-consensus object from 3-consensus objects, 4-ported queues, and registers? The irreducibility of consensus does not help answer this question, but our result does. Specifically, since there is no wait-free implementation of a 4-consensus object from 4-ported queues and registers [12], our result implies that the answer to the above question is no.

**1.1. Related work.** As stated earlier, this paper has two main results: the generalized irreducibility theorem and the equivalence theorem. We discuss below prior research related to each of these results.

Our generalized irreducibility theorem is related to the following robustness question, posed in [16]: Suppose that (a) there is no wait-free implementation of an $n$-consensus object from registers and objects of type $T$, and (b) there is no wait-free implementation of an $n$-consensus object from registers and objects of type $T'$. Does

[2]The difference in difficulty can be appreciated by comparing the proof that there is no wait-free implementation of a 3-consensus object from registers and 1-bit read-modify-write objects to the proof that there is no 2-resilient implementation of an $n$-consensus object from the same objects [24]. The latter proof is much longer (three pages versus one page) and the arguments are more involved.

it then follow that there is no wait-free implementation of an $n$-consensus object from registers, objects of type $T$, and objects of type $T'$?

For the special case when one of $T$ and $T'$ is $m$-`consensus`, for any $m$, and the other type is arbitrary (it may even be nondeterministic), our generalized irreducibility theorem states that the answer to the robustness question is yes. For the case when both $T$ and $T'$ are deterministic, Borowsky, Gafni, and Afek [5] and Peterson, Bazzi, and Neiger [27] prove that the answer is yes. Neither result is strictly stronger than the other: our result restricts one of the types to be $m$-`consensus`, while theirs restricts both types to be deterministic. It is significant that our result applies to *all* types, not just deterministic ones, because nondeterministic types sometimes exhibit dramatically different properties. For instance, in sharp contrast to the results in [5, 27] stated above, Lo and Hadzilacos prove that the answer to the robustness question is no if types may be nondeterministic [21]. For different models, Chandra et al. [7], Moran and Rappoport [26], and Schenk [30] also prove that the answer to the robustness question is no.

We now describe prior work related to our equivalence theorem. To our knowledge, Borowsky and Gafni are the first to relate $t$-resilient and wait-free implementations of tasks. To state their result, we need to introduce a new object type, called $n$-ported $k$-set consensus. Informally, an object of this type allows each of $n$ processes to access it by proposing a value. Each access returns some value that has been proposed to the object, subject to the requirement that the number of *different* values returned by all the accesses does not exceed $k$. Thus, an $n$-consensus object is the special case of this object where $k = 1$. Borowsky and Gafni's result is that, for all $n > t$, if there is a $t$-resilient implementation of $n$-ported $t$-set consensus from registers, then there is a wait-free implementation of $(t + 1)$-ported $t$-set consensus from registers [3]. It was also shown (independently, in [3, 13, 29]) that there is no wait-free implementation of $(t + 1)$-ported $t$-set consensus from registers. In conjunction with this, Borowsky and Gafni's result implies that, for *all* $n > t$, there is also no $t$-resilient implementation of $n$-ported $t$-set consensus from registers.

Our equivalence theorem differs from Borowsky and Gafni's result in fundamental ways. First, our result concerns $t$-resilient implementations of consensus, while theirs concerns $t$-resilient implementations of $t$-set consensus. Second, our result applies regardless of the types of objects used in the implementation, while their result requires the objects to be registers. The two results are independent in that neither implies the other.

The proofs of both results are based on simulation techniques whereby a small number of processes simulate a $t$-resilient algorithm originally designed for a larger number of processes, in a manner that preserves the resilience of the original algorithm. The two simulation techniques bear some superficial resemblance, but they differ in substance, reflecting the differences between the results noted in the previous paragraph. The simulation we use to obtain the generalized irreducibility theorem (cf. proof of Lemma 5.1) applies only to consensus algorithms, while Borowsky and Gafni's simulation [3, 6] (as well as the simulation we use to obtain the equivalence theorem—cf. proof of Lemma 6.2) applies to a wider class of algorithms that is formally characterized in [6]. Also, the simulations we use to obtain the generalized irreducibility theorem and the equivalence theorem apply to algorithms that use arbitrary base objects, while Borowsky and Gafni's simulation applies only to algorithms that use registers. There is a variant of Borowsky and Gafni's simulation [4, 8] that applies to algorithms that use registers and $k$-set consensus objects. This variant, however, cannot be used to obtain our equivalence theorem because the algorithm that results from the simulation has lower resilience than the original, simulated algorithm.

Our equivalence theorem requires that $t \geq 2$. A result by Lo, strengthened further by Lo and Hadzilacos, proves that the "only if" direction of our theorem does not hold for $t = 1$: There exist nondeterministic [23] and even deterministic [22] object types which, together with registers, can provide a 1-resilient implementation of 3-consensus, but cannot provide a wait-free implementation of 2-consensus.

**1.2. Organization.** In section 2, we describe the model. In sections 3 and 4, we present the intermediate results needed to prove the generalized irreducibility theorem. This theorem and the equivalence theorem are then proved in sections 5 and 6, respectively.

## 2. Model and definitions.

Our description of the model is somewhat informal. Herlihy [12] has shown how to formalize a similar model using I/O automata [25]. We use the following notation for sets of natural numbers: for any $i, j \in \mathbb{N}$, $[i..j] = \{k \in \mathbb{N} : i \leq k \leq j\}$.

**2.1. Types.** A *type* is a tuple $T = (n, OP, RES, Q, \delta)$, where $n$ is a positive integer denoting the number of ports, $OP$ is a set of operations, $RES$ is a set of responses, $Q$ is a set of states, and $\delta \subseteq Q \times OP \times [1..n] \times Q \times RES$ is the type's *sequential specification*. The number of ports corresponds to the maximum number of processes that can concurrently access an object of this type. The sequential specification describes the behavior of an object of this type in the absence of concurrency: If operation $op$ is applied to port $i$ of an object of type $T$ when the object is in state $q$, the object can enter state $q'$ and return response $res$ if and only if $(q, op, i, q', res) \in \delta$. If, for each $(q, op, i) \in Q \times OP \times [1..n]$, the set $\{(q', res) : (q, op, i, q', res) \in \delta\}$ has at most one element, $T$ is deterministic. In this paper we allow types to be nondeterministic, but we require that they exhibit *finite nondeterminism*: each of the above sets must be finite.

For example, the $n$-ported consensus type $n$-`consensus`[3] informally described in section 1 can be formally defined as the tuple $(n, OP, RES, Q, \delta)$, where $OP = \{propose\ u : u \in \mathbb{N}\}$, $RES = \mathbb{N}$, $Q = \mathbb{N} \cup \{\perp\}$, and for each $i \in [1..n]$ and $u, v \in \mathbb{N}$, $\delta$ contains exactly the following tuples: $(\perp, propose\ u, i, u, u)$ and $(v, propose\ u, i, v, v)$. Clearly, this is a deterministic type.

**2.2. Objects and linearizability.** An object $O$ is an instance of a type initialized to a specified state. For each operation $op$ and port $i$ of its type, $O$ provides an access procedure $\text{Apply}(op, i, O)$. This is the sole means by which operation $op$ can be applied to port $i$ of $O$. As explained above, the sequential specification of $O$'s type describes the behavior of $O$ when access procedures are applied sequentially. In general, however, access procedures *at different ports* of an object can be applied concurrently. Usually, the behavior of the object in this case is constrained by the assumption that the object is *linearizable* [14]. This means that if there are no concurrent accesses to the *same* port, then the object behaves *as if* it had been initialized to the specified state and each access procedure occurred instantaneously at some point between its invocation and its response.[4] Occasionally it will be convenient to consider objects

[3] Throughout the paper we use the `typewriter font` for type names.

[4] We emphasize that the linearizability assumption constrains the behavior of an object only if access procedures at the same port are applied sequentially. No assurances are given about what the object does if access procedures are applied concurrently to one of its ports. The object may fail to respond, or it may return arbitrary responses in that case.

that are linearizable only if used in restricted ways. When discussing such objects we will explicitly state the conditions under which they are linearizable.

In general, when we talk about an object we need to specify both its type and its initial state. However, in the case of consensus objects (i.e., objects of type $n$-`consensus` for some $n$) we will assume, without explicitly saying so, that the initial state is $\perp$. This is because a consensus object initialized to any state other than $\perp$ is trivial: it remains in that state forever, returning it to each invocation.

**2.3. Implementation of consensus.** We now explain what an *implementation* of a *target* object $\mathcal{O}$ of type $T$ from a set $A$ of *base* objects is. The concept of implementation can be defined in a general way for target objects of any type. In this paper, however, we are concerned exclusively with implementations of $n$-consensus objects. For simplicity and brevity we tailor our definitions specifically to such objects.

An *implementation of an $n$-consensus object $\mathcal{O}$ from a set $A$ of objects* consists of a specification of access procedures $\text{Apply}(\textit{propose}\ u, i, \mathcal{O})$ for each $u \in \mathbb{N}$ and $i \in [1..n]$. These access procedures can store and manipulate values in private variables using ordinary programming language constructs; in addition they can apply operations (only) to objects in $A$ through the access procedures provided by those objects. To apply operation *op* to port $i$ of a base object $O \in A$, an access procedure of the target object $\mathcal{O}$ invokes $\text{Apply}(op, i, O)$; when this operation finishes it returns a response. A *step* of the target object $\mathcal{O}$'s access procedure refers to the invocation of an operation at some port of a base object, the receipt of that operation's response, and (if relevant) the assignment of that response to a private variable of $\mathcal{O}$'s access procedure. We do not assume a step to be atomic: the invocation of an operation and its response may be separated in time and, during this interval, steps may be performed at other ports of the base object and/or at other base objects. We do, however, assume that a step terminates or, equivalently, that base objects are responsive: once an operation is invoked at a port of a base object, a response is eventually returned.

The implementation must satisfy certain safety properties (typically linearizability) and liveness properties (typically wait-freedom or $t$-resilience). We will state the properties that must be satisfied by (concurrent) executions of $\mathcal{O}$'s access procedures. Before doing so, we need to clarify certain points about such executions.

First, we assume that at most one operation is applied to each port of $\mathcal{O}$. This assumption can be made without loss of generality because $\mathcal{O}$ is a consensus object: If multiple operations could be applied to a port, the response given by a port to the first *propose* operation applied to it can be stored in a private variable associated with the port and returned to any subsequent operation without involving accesses to any other shared objects (recall that operations to the same port must be applied sequentially).

Second, the concurrent executions we consider may contain one or more access procedures of $\mathcal{O}$ that have *not* run to completion. Taking such executions into account is necessary since we are interested in executions where some of the processes that invoke access procedures may crash. Therefore, given an execution, there are four mutually exclusive possibilities for an access procedure $P$ (note that, in view of the previous paragraph, there can be at most one instance of $P$ in an execution):

(a) $P$ does not appear in the execution. This could be because in this execution no process had an interest in invoking $P$, or because the process that has an interest in invoking $P$ has not gotten around to it yet (and perhaps never will because it has crashed).

(b) $P$ is finite and incomplete in the execution, meaning that it has been invoked but has not returned a response. This could be because the process invoking $P$ has not had a chance to run long enough or because it has crashed.

(c) $P$ is complete (and, of course, finite) in the execution, meaning that $P$ has returned a response.

(d) $P$ is infinite (and, of course, incomplete). In this case the process invoking $P$ does not crash (since $P$ has infinitely many steps in the execution), yet the access procedure does not terminate. A typical reason for this behavior is that processes that invoked other procedures crashed at inopportune moments, making it impossible for $P$ to terminate. In this case we will say that the nonterminating access procedure is *blocked* in this execution.

With these comments in mind, consider a concurrent execution $\mathcal{E}$ of a consensus object $\mathcal{O}$'s access procedures. First we will define the safety properties that should hold in $\mathcal{E}$. We say that $\mathcal{O}$

- *satisfies validity in* $\mathcal{E}$ if any value returned by any access procedure in $\mathcal{E}$ was proposed by some access procedure in $\mathcal{E}$;
- *satisfies agreement in* $\mathcal{E}$ if no two values returned by access procedures in $\mathcal{E}$ are different.

Recall that an $n$-consensus object $\mathcal{O}$ is linearizable in $\mathcal{E}$ if the values returned by the access procedures in $\mathcal{E}$ are in accordance with the sequential specification of $n$-`consensus`, when $\mathcal{O}$ is initialized to state $\perp$ and each access procedure in $\mathcal{E}$ takes effect atomically at some point after it is invoked and before it completes. It is easy to see that $\mathcal{O}$ satisfies validity and agreement in $\mathcal{E}$ if and only if it is linearizable in $\mathcal{E}$. Thus, instead of proving that an implementation of $n$-consensus is linearizable, we will prove that it satisfies validity and agreement.

Next we discuss the liveness properties of the implementation. Intuitively, wait-freedom requires that if a process that invokes an access procedure of the target object $\mathcal{O}$ does not crash, then it will receive a response, no matter how many processes invoking access procedures at other ports of $\mathcal{O}$ crash. The property of $t$-resilience requires that if a process that invokes an access procedure of the target object $\mathcal{O}$ does not crash, then it will receive a response, as long as at most $t$ processes invoking access procedures at other ports of $\mathcal{O}$ crash. Actually, there are two slightly different formulations of $t$-resilience. The weaker formulation assumes that all of $\mathcal{O}$'s ports must be accessed in an execution. Thus, if an access procedure does not appear in $\mathcal{E}$, the process that was supposed to invoke it is considered to have crashed. The stronger formulation of $t$-resilience does not make this assumption; here, an access procedure may not appear in $\mathcal{E}$ just because no process had an interest in invoking it in this execution. The difference between these two formulations lies in what counts as one of the up to $t$ crashes that the implementation is supposed to tolerate. With respect to the four aforementioned possibilities (a)–(d) for an access procedure in an execution, in the weaker formulation, access procedures in cases (a) and (b) count as crashes, while in the stronger formulation, only access procedures in case (b) count as crashes. It turns out that our equivalence theorem holds under both definitions of $t$-resilience.

We now state the liveness properties that should hold in $\mathcal{E}$. We say that $\mathcal{O}$

- *is wait-free for port $i$ in* $\mathcal{E}$ if for every $u \in \mathbb{N}$, $\textsc{Apply}(\textit{propose } u, i, \mathcal{O})$ is finite in $\mathcal{E}$;
- *is wait-free in* $\mathcal{E}$ if it is wait-free for each port in $\mathcal{E}$;
- *is weakly $t$-resilient in* $\mathcal{E}$ if the access procedure at some port is infinite only if the access procedures in more than $t$ other ports do not appear or are finite and incomplete in $\mathcal{E}$;

- *is strongly $t$-resilient in $\mathcal{E}$* if the access procedure at some port is infinite only if the access procedures in more than $t$ other ports are finite, nonempty, and incomplete in $\mathcal{E}$.

For each of the safety and liveness properties defined above, we omit the qualifier "in $\mathcal{E}$" if the property holds in every concurrent execution of the target object's access procedures in which the base objects are linearizable.

**2.4. Binding schemes.** The *binding scheme* of an implementation refers to the rules that govern how each access procedure of the implementation's target object can apply operations to ports of the base objects—specifically, the number of ports of a base object to which it can apply operations, and the length of time during which it is permitted to apply operations to these ports. Under the most permissive binding scheme, called *softwired* binding [5], an access procedure can apply operations to any number of ports of a base object, and it "owns" the port only for the duration of each operation. In this binding scheme, different access procedures of the target object may apply (at different times) operations to the same port. Under the more restrictive *one-to-one static binding scheme*, for each access procedure $P$ and each base object $O$ there is at most one port of $O$ to which $P$ can apply operations, in all executions of the implementation; moreover no other access procedure can apply operations to that port of $O$. With one-to-one static binding, we can think of each port of a base object as being "owned" by an access procedure of the target object, namely, the one that is allowed to apply operations to that port.

Unless otherwise specified, in this paper we assume softwired binding.

**2.5. A remark on composing implementations.** An implementation $\mathcal{I}'$ may depend on another implementation $\mathcal{I}$. For instance, suppose that $\mathcal{I}'$ implements an object $\mathcal{O}'$ and this implementation uses, among others, an object $\mathcal{O}$ implemented by $\mathcal{I}$. In this case, an access procedure $P'$ of $\mathcal{O}'$ might include a call to an access procedure $P$ of $\mathcal{O}$. We note that the execution of $P$ should not be viewed as a single step (because a step is required to terminate, but the termination of $P$ may not be necessarily guaranteed by the design of $\mathcal{O}$). The correct view is that $\mathcal{O}$ is implemented from base objects and, hence, the execution of $P$ amounts to performing a sequence of steps on these (responsive) base objects, as dictated by the implementation $\mathcal{I}$. Thus, $\mathcal{O}$ is not viewed as a base object of $\mathcal{O}'$; instead, the base objects of $\mathcal{O}$ are viewed as also belonging to the set of base objects of $\mathcal{O}'$.

## 3. Achieving one-to-one static binding with base consensus objects.

In this section, we prove a result that we will later use in our proof of the generalized irreducibility theorem (section 5). In general, the binding of a target object $\mathcal{O}$ with its base objects is not one-to-one static. The main result of this section is that, if $\mathcal{O}$ has some base consensus objects, then it is possible to transform the implementation so that, in the new implementation, the binding of $\mathcal{O}$ with all its base consensus objects is one-to-one static. We begin by describing an intermediate implementation needed to prove this result.

For any $m > n$, we describe how to implement an $m$-consensus object $\mathcal{O}$ from $n$-consensus objects. The binding of $\mathcal{O}$ with its base objects is one-to-one static, but our implementation is only conditionally correct: It is always wait-free, and it satisfies validity and agreement *provided that* no more than $n$ of the $m$ access procedures of $\mathcal{O}$ take steps.

Consider the $n$-element subsets of $[1..m]$. Let $S_1, S_2, \dots, S_\ell$ be a listing of these subsets, where $\ell = \binom{m}{n}$. For all $i \in S_j$, define $\text{pos}(i, S_j) = k$ if $i$ is the $k$th smallest element in $S_j$.

```
$O_1, O_2, \ldots, O_\ell$: $n$-consensus objects, initialized to $\bot$

$\underline{\textsc{Apply}(\textit{propose } u, i, \mathcal{O})}$;  $u \in \mathbb{N}, i \in [1..m]$

$est_i := u$
for $j := 1$ to $\ell$ do
    if $i \in S_j$ then
        $est_i := \textsc{Apply}(\textit{propose } est_i, \mathrm{pos}(i, S_j), O_j)$
return $est_i$
```

FIG. 1. *Implementation of $m$-consensus object $\mathcal{O}$ from $n$-consensus objects.*

Our implementation of an $m$-consensus object $\mathcal{O}$, described in Figure 1, employs $\ell$ base $n$-consensus objects, denoted $O_1, O_2, \ldots, O_\ell$. The access procedure $\textsc{Apply}(\textit{propose } v, i, \mathcal{O})$ is implemented as follows. For brevity, let $P$ denote this access procedure. $P$ keeps a running estimate of the eventual return value in a local variable $est_i$. Initially, this estimate is $v$, the value that $P$ wants to propose. $P$ considers the base objects $O_1, \ldots, O_\ell$ in sequence and performs the following actions. For each base object $O_j$, $P$ checks whether $i \in S_j$. If $i \notin S_j$, $P$ does not access $O_j$. Otherwise, it proposes its current estimate to $O_j$ (at port $\mathrm{pos}(i, S_j)$ of $O_j$) and regards the return value as its new estimate. After considering all base objects, $P$ regards the estimate as the response of $\mathcal{O}$.

LEMMA 3.1. *The implementation of $m$-consensus object $\mathcal{O}$ in Figure* 1 *has the following properties:*

1. *The binding of $\mathcal{O}$ (with all its base objects) is one-to-one static.*
2. *$\mathcal{O}$ is wait-free.*
3. *$\mathcal{O}$ satisfies validity and agreement in all executions in which at most $n$ access procedures take steps.*

*Proof.* Part 1 follows from the observation that port $i$ of $\mathcal{O}$ applies an operation to port $p$ of base object $O_j$ if and only if $i \in S_j$ and $\mathrm{pos}(i, S_j) = p$. Part 2 follows from the fact that the implementation has no unbounded loops.

For part 3, consider an execution $\mathcal{E}$ where $i_1, i_2, \ldots, i_n$ are all the ports of $\mathcal{O}$ at which access procedures are invoked. (We may assume, without loss of generality, that access procedures in exactly $n$ ports are invoked: if there is an execution that violates validity or agreement and involves access procedures in $n'$ ports, where $n' \leq n$, then there is also an execution that violates validity or agreement, respectively, and involves access procedures in exactly $n$ ports.) Specifically, let $\textsc{Apply}(\textit{propose } u_k, i_k, \mathcal{O})$ be the access procedure executed at port $i_k$; for brevity, let $P_{i_k}$ denote this access procedure. We argue below that $\mathcal{O}$ satisfies validity and agreement in $\mathcal{E}$.

*$\mathcal{O}$ satisfies validity.* Using the fact that the base objects $O_1, \ldots, O_\ell$ satisfy validity, it follows by an easy induction that $\mathcal{O}$ satisfies validity.

*$\mathcal{O}$ satisfies agreement.* Consider the object $O_j$ such that $S_j = \{i_1, i_2, \ldots, i_n\}$. For each $k \in [1..n]$, $P_{i_k}$ accesses $O_j$ in its $j$th iteration of the for-loop. Since $O_j$ returns the same response $u$ to every access procedure that applies a propose operation to it, it follows that all access procedures have the same estimate $u$ at the end of $j$ iterations of the for-loop. That is, for all $k \in [1..n]$, $est_{i_k} = u$ just after $P_{i_k}$ completes the $j$th iteration of the for-loop. Since $O_{j+1}, \ldots, O_\ell$ satisfy validity, it follows from the implementation that the estimate of an access procedure never changes from the $(j+1)$th iteration onward. Thus, for every $k \in [1..n]$, $P_{i_k}$ returns $u$.

This completes the proof of the lemma. □

LEMMA 3.2. *Let $m > n$ and $\mathcal{S}$ be any set of types. Consider a wait-free implementation of an $m$-consensus object $\mathcal{O}$ from objects belonging to types in $\mathcal{S}$. Suppose that $\mathcal{O}$ has an $n$-consensus base object $O$. If the binding of $\mathcal{O}$ with $O$ is not one-to-one static, it is possible to modify the implementation of $\mathcal{O}$ by replacing $O$ with a bounded number of $n$-consensus objects, in such a way that the new implementation satisfies validity and agreement, is wait-free, and the binding of $\mathcal{O}$ with each of the newly introduced $n$-consensus base objects is one-to-one static.*

*Proof.* Suppose that the binding of $\mathcal{O}$ with $O$ is not one-to-one static. Consider the following modifications to the implementation of $\mathcal{O}$:

1. The base objects of the new implementation are the same as in the original implementation with one exception: The base object $O$ is replaced with $O'$, where $O'$ is implemented as in Figure 1. (Thus, $O'$ is an $m$-consensus object, but it is implemented entirely from $n$-consensus objects.)
2. The access procedures of the new implementation are the same as in the original implementation with one exception: Each time an access procedure APPLY(*propose* $v, i, \mathcal{O}$) performs, in the original implementation, an operation (say, *propose* $u$) at some port $j$ of $O$, the new implementation requires the access procedure to perform the same operation (namely, *propose* $u$) at port $i$ of $O'$.

It is obvious from the above modifications that, in the new implementation, port $i$ of $O'$ is used only by the access procedures for port $i$ of $\mathcal{O}$. This, together with the fact that the binding between $O'$ and its base objects is one-to-one static (by part 1 of Lemma 3.1), implies that the binding between $\mathcal{O}$ and the newly introduced $n$-consensus base objects (i.e., the base objects of $O'$) is one-to-one static.

The fact that the new implementation satisfies validity and agreement follows from two facts: (i) $O$, the base object of the old implementation, has only $n$ ports, and (ii) $O'$, which replaces $O$, satisfies validity and agreement if it is accessed at no more than $n$ of its $m$ ports (by part 3 of Lemma 3.1).

That the new implementation is wait-free follows again from two facts: (i) the old implementation is wait-free, and (ii) the implementation of $O'$ is wait-free (by part 2 of Lemma 3.1). This completes the proof of the lemma. □

## 4. The building blocks.

In this section we present three implementations of $n$-consensus objects from $(n-1)$-consensus objects. These implementations are only conditionally correct: each ensures wait-freedom, validity, and agreement only in executions that satisfy certain conditions. Yet they have certain nice properties that make them useful in the proof of the generalized irreducibility theorem, presented in the next section.

### 4.1. Nonconcurrent implementation.

Figure 2 shows an implementation of $n$-consensus object $\mathcal{O}$ from two $(n-1)$-consensus objects $O$ and $O'$ and a register *DEC*. This implementation is wait-free and, if the access procedures for ports $n-1$ and $n$ are not executed concurrently, the implementation satisfies validity and agreement.

The implementation is informally described as follows. For $i \in [1..n]$, let $P_i$ denote the access procedure APPLY(*propose* $u_i, i, \mathcal{O}$), where $u_i \in \mathbb{N}$. $P_1, \ldots, P_{n-2}$ share $\mathcal{O}$'s base objects $O$ and $O'$ with $P_{n-1}$ and $P_n$, respectively. For each $i \in [1..n-2]$, $P_i$ proposes its value $u_i$ to $O$, proposes the return value from $O$ to $O'$, writes the return value from $O'$ in register *DEC* (for "decision"), and returns it. Each of $P_{n-1}$ and $P_n$ first checks whether the return value is already available in *DEC*. If not, it proposes

```
$O, O'$: $(n-1)$-consensus objects, initialized to $\bot$
$DEC$: register, initialized to $\bot$

$\underline{\text{Apply}(propose\ u, i, \mathcal{O})}$; $u \in \mathbb{N}$, $i \in [1..n-2]$

$v_i := \text{Apply}(propose\ u, i, O)$
$DEC := \text{Apply}(propose\ v_i, i, O')$
return $DEC$

$\underline{\text{Apply}(propose\ u, n-1, \mathcal{O})}$; $u \in \mathbb{N}$

if $DEC = \bot$ then
    $DEC := \text{Apply}(propose\ u, n-1, O)$
return $DEC$

$\underline{\text{Apply}(propose\ u, n, \mathcal{O})}$; $u \in \mathbb{N}$

if $DEC = \bot$ then
    $DEC := \text{Apply}(propose\ u, n-1, O')$
return $DEC$
```

FIG. 2. *Nonconcurrent implementation of $n$-consensus object $\mathcal{O}$ from $(n-1)$-consensus objects.*

its value to the appropriate base consensus object (namely, $O$ for $P_{n-1}$ and $O'$ for $P_n$), writes the return value from the base consensus object in *DEC*, and returns it.

We now explain intuitively why this implementation works. Since the implementation needs to be correct only if the steps of $P_{n-1}$ and $P_n$ do not overlap, there are two cases: either $P_{n-1}$ is before $P_n$ or $P_n$ is before $P_{n-1}$. In the former case, $P_1, \ldots, P_{n-2}$ and $P_{n-1}$ agree on a return value using the object $O$, and $P_n$ learns this value simply by reading *DEC*, where the value is made available by $P_{n-1}$. In the latter case, $O'$ serves as the object that brings about agreement on the return value among $P_1, \ldots, P_{n-2}$ and $P_n$, and $P_{n-1}$ learns this value by reading *DEC*.

LEMMA 4.1. *The implementation, shown in Figure 2, of the $n$-consensus object $\mathcal{O}$ from $(n-1)$-consensus objects and a register has the following properties:*

1. *$\mathcal{O}$ is wait-free.*
2. *$\mathcal{O}$ satisfies validity and agreement in all executions in which the access procedures at ports $n-1$ and $n$ of $\mathcal{O}$ are not concurrent.*

*Proof.* Part 1 is obvious. For part 2, let $\mathcal{E}$ be any execution of the implementation; for each $i \in [1..n]$, let $P_i$ be the access procedure at port $i$ of $\mathcal{O}$ that appears in $\mathcal{E}$. (We may assume, without loss of generality, that access procedures at all ports appear in $\mathcal{E}$: If there is any execution that violates validity or agreement, then there is also one that violates validity or agreement, respectively, and involves the access procedures at all ports.)

*$\mathcal{O}$ satisfies validity.* This follows easily by induction and the fact that the base objects $O$ and $O'$ satisfy validity.

*$\mathcal{O}$ satisfies agreement if $P_{n-1}$ and $P_n$ are not concurrent.* Suppose $P_{n-1}$ and $P_n$ are not concurrent in $\mathcal{E}$. We observe that each of $O$ and $O'$ satisfies agreement. Let $d$ and $d'$ denote the (unique) return values from $O$ and $O'$, respectively, in $\mathcal{E}$.

If the first of $P_{n-1}$ and $P_n$ to read *DEC* finds that $DEC \neq \bot$, it is clear from the implementation that some $P_i$, $i \in [1..n-2]$, had previously written $d$ into *DEC*. Since $O$ and $O'$ satisfy agreement, it is easy to see that, in this case, all access procedures return $d$ and so $\mathcal{O}$ satisfies agreement. If the first of $P_{n-1}$ and $P_n$ to read *DEC* finds that $DEC = \bot$, we consider two cases, depending on which of the two access

```
                         $O, O'$: $(n-1)$-consensus objects, initialized to $\bot$
                         $GP$, $SP$, $DEC$: registers, initialized to $\bot$

    APPLY($propose\ u, i, \mathcal{O}$); $u \in \mathbb{N}$,            APPLY($propose\ u, n, \mathcal{O}$); $u \in \mathbb{N}$
                             $i \in [1..n-1]$

1.  $GP :=$ APPLY($propose\ u, i, O$)           $SP := u$
2.  if $SP = \bot$ then                         if $GP = \bot$ then
3.      $vote_i := GP$                              $DEC := u$
4.  else $vote_i := SP$                         else busy-wait until $DEC \neq \bot$
5.  $DEC :=$ APPLY($propose\ vote_i, i, O'$)
6.  return $DEC$                                return $DEC$
```

FIG. 3. *Group-solo implementation of $n$-consensus object $\mathcal{O}$ from $(n-1)$-consensus objects.*

procedures was executed first (recall that $P_{n-1}$ and $P_n$ are not concurrent in $\mathcal{E}$).

If $P_{n-1}$ was executed first, it is clear from the implementation that $P_{n-1}$ writes $d$ (the return value from $O$) in *DEC* and returns it. $P_n$, which begins after $P_{n-1}$ finishes, reads $d$ from *DEC* and returns it. $P_1, \ldots, P_{n-2}$ propose $d$ to $O'$. Since $O'$ satisfies validity, and $d$ is the only value proposed to it, it returns $d$ to all, and all of $P_1, \ldots, P_{n-2}$ therefore return $d$. Thus, $\mathcal{O}$ satisfies agreement.

If $P_n$ was executed first, it is clear from the implementation that $P_1, \ldots, P_{n-2}$ and $P_n$ return $d'$ (the return value from $O'$). $P_n$ also writes $d'$ in *DEC*. $P_{n-1}$, which begins after $P_n$ finishes, reads $d'$ from *DEC*, and returns it. Thus, $\mathcal{O}$ satisfies agreement.

This completes the proof of the lemma. ☐

**4.2. Group-solo implementation.** Figure 3 shows an implementation of an $n$-consensus object $\mathcal{O}$ from two $(n-1)$-consensus objects $O$ and $O'$, and three registers *GP*, *SP*, and *DEC*. This implementation is wait-free for all ports except port $n$. It is also wait-free for port $n$ unless both of the following hold: (i) an operation is invoked on a port other than $n$, and (ii) no such operation completes. (Note that since ports $1, \ldots, n-1$ are wait-free, an operation that has been invoked on these ports can fail to complete only because of a crash.)

We now informally describe how this implementation works. For $i \in [1..n]$, let $P_i$ denote the access procedure at port $i$ of $\mathcal{O}$. $P_1, \ldots, P_{n-1}$ act as one group, while $P_n$ acts as a solo outsider. $P_1, \ldots, P_{n-1}$ reach consensus on their initial proposals by accessing $O$. Each $P_i$ in the group regards the response of $O$ as the group's proposal for consensus with $P_n$ and writes this value into register *GP* (see line 1). (*GP* and *SP* are acronyms for "group's proposal" and "solo proposal," respectively, and *DEC* stands for "decision.") $P_i$ then reads *SP* to check whether the solo access procedure $P_n$ has published its proposal yet. If *SP* is blank, $P_i$ attempts to promote the group's proposal as the consensus value between $P_n$ and the group. Otherwise, $P_i$ attempts to promote the value in *SP* (which is the proposal of the solo access procedure $P_n$) as the consensus value. Lines 2, 3, and 4, in which $P_i$ sets the local variable $vote_i$ to either *GP* or *SP*, implement this strategy. It is possible, however, that some access procedures in the group find *SP* blank and consequently promote the group's proposal, while others find in *SP* a nonblank value that they promote. To reconcile such differences, access procedures in the group reach consensus on their votes by accessing $O'$. The response of $O'$ is regarded as the final outcome of consensus between $P_n$ and the group.

The solo access procedure $P_n$, on the other hand, begins by publishing its proposal in register *SP*. It then reads *GP*, the register where the group's proposal is published. If *GP* is blank, $P_n$ concludes that it is ahead of all access procedures in the group and that access procedures in the group will all vote for its ($P_n$'s) proposal. Thus, $P_n$ regards its proposal as the outcome of its consensus with the group. On the other hand, if $P_n$ finds *GP* nonblank, then $P_n$ is uncertain of the views of the access procedures in the group (because some members of the group might promote $P_n$'s proposal, while the others promote the group's proposal). $P_n$ therefore blocks itself until the consensus value is published in the register *DEC* by (some $P_i$ in) the group.

LEMMA 4.2. *The implementation, shown in Figure* 3*, of the* $n$*-consensus object* $\mathcal{O}$ *from* $(n-1)$*-consensus objects and registers has the following properties:*

1. $\mathcal{O}$ *satisfies validity and agreement.*
2. $\mathcal{O}$ *is wait-free for all ports except port* $n$*.*
3. $\mathcal{O}$ *is wait-free for port* $n$ *in every execution where either no operation is applied to other ports or an operation applied to some port returns a response.*

*Proof.* For part 1, let $\mathcal{E}$ be any execution of the implementation; for each $i \in [1..n]$, let $P_i$ denote the access procedure at port $i$ of $\mathcal{O}$ that appears in $\mathcal{E}$. (As in the proof of Lemma 4.1, we may assume, without loss of generality, that access procedures at all ports appear in $\mathcal{E}$.)

$\mathcal{O}$ *satisfies validity.* This follows easily by induction and the fact that the base objects $O$ and $O'$ satisfy validity.

$\mathcal{O}$ *satisfies agreement.* There are two cases, based on whether the if-condition in line 2 of $P_n$ evaluates to true or to false. Below we consider these cases in turn.

Suppose that the if-condition (in $P_n$'s access procedure) evaluates to true. Then two facts are obvious from the implementation: (i) $P_n$ finished writing its proposal $u$ in *SP* before any of $P_1, \ldots, P_{n-1}$ completed line 1 of its access procedure, and (ii) $P_n$ writes $u$ in *DEC* and returns it. Fact (i) implies that, for each $i \in [1..n-1]$, the if-condition on line 2 of $P_i$ evaluates to false, thus causing $P_i$ to set $vote_i$ to $u$, the value in *SP*. Thus, all of $P_1, \ldots, P_{n-1}$ propose $u$ to $O'$; since $O'$ satisfies validity, $O'$ returns $u$ to all. Thus, all of $P_1, \ldots, P_{n-1}$ return $u$. Since $P_n$ also returns $u$, we have agreement.

Suppose that the if-condition in $P_n$ evaluates to false. Then two facts are obvious from the implementation: (i) $P_n$ waits until it reads a non-$\perp$ value in *DEC* and returns it, and (ii) the only writes performed on *DEC* are by $P_1, \ldots, P_{n-1}$ in line 5, when they write the return value of $O'$ in *DEC*. Since $O'$ satisfies validity and agreement, it returns the same non-$\perp$ value, say $d$, to all of $P_1, \ldots, P_{n-1}$. Thus, each of $P_1, \ldots, P_{n-1}$ writes $d$ in *DEC* and returns it. $P_n$ eventually reads $d$ in *DEC* and returns it. Hence we have agreement.

Parts 2 and 3 are obvious from the implementation. ◻

**4.3. 1-blocking array implementation.** We now use the group-solo implementation of $n$-consensus to implement, for any constant $c$, an array $\mathcal{O}[1..c]$ of $n$-consensus objects from $(n-1)$-consensus objects and registers. To access the $i$th port of the $j$th object in the array, where $i \in [1..n]$ and $j \in [1..c]$, the implementation provides the access procedure APPLY(*propose* $u, i, \mathcal{O}[j]$). The implementation guarantees some nice properties, but only in certain restricted executions. The implementation treats port $n$ of the array elements differently from ports $1, \ldots, n-1$ in two respects: the restrictions it places on how the port may be used, and the wait-free properties it guarantees for the port.

Specifically, the implementation imposes the following restriction for all ports $i \in [1..n-1]$: port $i$ of two different array elements must not be accessed concurrently.

More precisely, the execution of access procedures at port $i$ of any two array elements $\mathcal{O}[j]$ and $\mathcal{O}[k]$ must not be concurrent. Concurrent execution of access procedures at port $n$ of distinct array elements is, however, permitted.

In executions that satisfy the above restriction, the implementation satisfies validity and agreement and, in addition, guarantees the following two properties: (i) All of $\mathcal{O}[1], \dots, \mathcal{O}[c]$ are wait-free for ports $1, \dots, n-1$, and (ii) all but one of $\mathcal{O}[1], \dots, \mathcal{O}[c]$ are wait-free for port $n$. By property (ii), if access procedures at port $n$ of two different objects in the array are executing concurrently, they do not *both* block. This property will be crucial to the proof of the generalized irreducibility theorem of the next section.

Below we develop the ideas behind the implementation in two stages. In the first stage, we propose an obvious implementation and point out its drawbacks. We fix these drawbacks in the second stage.

*Stage* 1: *Obvious implementation.* Let $GS_1, \dots, GS_c$ be $n$-consensus objects implemented using the group-solo implementation of Figure 3. Access procedure $\text{APPLY}(\textit{propose } u, i, \mathcal{O}[j])$ simply makes a call to $\text{APPLY}(\textit{propose } u, i, GS_j)$.

The drawback is that this implementation fails to satisfy property (ii), stated above. To see this, consider an execution of $\text{APPLY}(\textit{propose } v_1, i_1, \mathcal{O}[1])$, for some $v_1$ and $i_1 \in [1..n-1]$, up to the point where register *GP* of $GS_1$ has been written but before register *DEC* of $GS_1$ has been written (see lines 1 and 5 in Figure 3). Thus, port $n$ of $GS_1$ is now blocked: an access procedure that invokes an operation on port $n$ of $GS_1$ will have to wait until register *DEC* of $GS_1$ is written (see the busy-wait statement in Figure 3). Suppose that, at this point, the access procedure $\text{APPLY}(\textit{propose } v_2, i_2, \mathcal{O}[2])$, for some $v_2$ and $i_2 \in [1..n-1]$ such that $i_2 \neq i_1$, is executed, again up to the point where register *GP* of $GS_2$ has been written but before register *DEC* of $GS_2$ has been written. Thus, port $n$ of $GS_2$ is now blocked as well. If access procedures are now called at port $n$ of $\mathcal{O}[1]$ and $\mathcal{O}[2]$, they will *both* have to wait indefinitely, violating property (ii).

*Stage* 2: *Refined implementation.* We observe that the failure of the above implementation to satisfy property (ii) is due to the fact that it permits port $n$ of more than one *GS* object to become blocked. We now describe a mechanism which ensures that, at all times, port $n$ of at most one *GS* object can be blocked. The basic idea is as follows: When an access procedure $P$ wants to apply *propose* $u$ at port $i \in [1..n-1]$ of $\mathcal{O}[j]$, as in the obvious implementation $P$ applies *propose* $u$ at port $i$ of $GS_j$, but it does so only after completing any propose operations that have already been initiated by other access procedures at ports $1, \dots, n-1$ of $GS_1, \dots, GS_c$. In this way, before $P$ accesses $GS_j$ to perform its own operation (thereby potentially causing port $n$ of that object to become blocked) it ensures that port $n$ of every other object is not blocked.

This idea is implemented as follows. We use $(n-1)$-consensus objects $O_1, \dots, O_c$ (in addition to $GS_1, \dots, GS_c$). When an access procedure $P$ wants to apply an operation *propose* $u$ at a port $i \in [1..n-1]$ of $\mathcal{O}[j]$, $P$ seeks to "obtain permission" to apply *propose* $u$ at port $i$ of $GS_j$. To obtain this permission, $P$ accesses $O_1, \dots, O_c$, in that order, as described below. $P$ proposes the tuple $\langle j, u \rangle$ to $O_1$.[5] Let $\langle k, v \rangle$ be $O_1$'s response. There are two cases: $j \neq k$ or $j = k$. Below, we handle the two cases in turn.

If $j \neq k$, it means that some access procedure has already obtained permission

[5]Strictly speaking, it is natural numbers, and not pairs of natural numbers, that can be proposed to consensus objects. It is well known, however, that pairs of natural number can be "coded" by natural numbers, so this is not a problem.

```
$O_1, \ldots, O_c$: $(n-1)$-consensus objects, initialized to $\perp$
$GS_1, \ldots, GS_c$: $n$-consensus objects, implemented from $(n-1)$-consensus objects and
        registers using the Group-Solo implementation in Figure 3

APPLY(propose $u, i, \mathcal{O}[j]$);  $u \in \mathbb{N}, j \in [1..c]$
                                        $i \in [1..n-1]$
$\ell := 1$
repeat
    $\langle k, v\rangle :=$ APPLY(propose $\langle j, u\rangle, i, O_\ell$)
    $res :=$ APPLY(propose $v, i, GS_k$)
    $\ell := \ell + 1$
until $j = k$
return $res$

APPLY(propose $u, n, \mathcal{O}[j]$);  $u \in \mathbb{N}$,
                                        $j \in [1..c]$
$res :=$ APPLY(propose $u, n, GS_j$)
return $res$
```

FIG. 4. *Implementation of* 1*-blocking array* $\mathcal{O}[1..c]$ *of* $n$*-consensus objects from* $(n-1)$*-consensus objects.*

(from $O_1$) to apply *propose* $v$ to $GS_k$ (at one of its first $n-1$ ports). This operation on $GS_k$ may not have completed, and thus it is possible that port $n$ of $GS_k$ is blocked. $P$ therefore helps complete that operation by applying *propose* $v$ on $GS_k$. $P$ then accesses $O_2$ for permission to apply *propose* $u$ on $GS_j$. It does this by proposing $\langle j, u\rangle$ to $O_2$ and proceeds as above.

If $j = k$, it means that $P$ has the permission to apply a propose operation to $GS_j$. At this point, $P$ can propose either $u$ or $v$ ($u$ is justified since it is $P$'s proposal to $\mathcal{O}[j]$, and $v$ is justified since some access procedure wants to propose it to $\mathcal{O}[j]$). In our implementation, $P$ proposes $v$ to $GS_j$, and regards the response of $GS_j$ as the response of $\mathcal{O}[j]$ to its *propose* $u$ operation.

LEMMA 4.3. *Consider the implementation of array* $\mathcal{O}[1..c]$ *of* $n$*-consensus objects, shown in Figure* 4. *Let* $\mathcal{E}$ *be any execution of this implementation that satisfies the following property:*

(A) *For all ports* $i \in [1..n-1]$ *and all* $j, j' \in [1..c]$ *such that* $j \neq j'$, *the access procedures at port* $i$ *of* $\mathcal{O}[j]$ *and port* $i$ *of* $\mathcal{O}[j']$ *are not concurrent in* $\mathcal{E}$.

*Then, the following hold in* $\mathcal{E}$:

1. *All of* $\mathcal{O}[1], \ldots, \mathcal{O}[c]$ *are wait-free for ports* $1, \ldots, n-1$.
2. *All but one of* $\mathcal{O}[1], \ldots, \mathcal{O}[c]$ *are wait-free for port* $n$.
3. *All of* $\mathcal{O}[1], \ldots, \mathcal{O}[c]$ *satisfy validity and agreement.*

*Proof.* We prove the lemma through a series of claims. The first two claims state that the base objects are accessed as required to ensure they behave properly. As a result, these objects satisfy their safety and liveness properties.

CLAIM 4.3.1. *For each* $i \in [1..n-1]$ *and* $\ell \in [1..c]$ *there are no concurrent operations applied to port* $i$ *of* $O_\ell$ *in* $\mathcal{E}$.

*Proof of Claim* 4.3.1. The claim follows immediately from the following two facts: (i) port $i$ of $O_\ell$ is accessed only by access procedures invoked at port $i$ of $\mathcal{O}[1], \ldots, \mathcal{O}[c]$, and (ii) by (A), access procedures at port $i$ of different objects $\mathcal{O}[j]$ and $\mathcal{O}[j']$ are not concurrent. $\square$

CLAIM 4.3.2. *For each* $i \in [1..n]$ *and* $k \in [1..c]$, *there are no concurrent operations applied to port* $i$ *of* $GS_k$ *in* $\mathcal{E}$.

*Proof of Claim* 4.3.2. For $i \in [1..n-1]$, the claim is immediate from the following two facts: (i) port $i$ of $GS_k$ is accessed only by access procedures invoked at port $i$ of $\mathcal{O}[1], \ldots, \mathcal{O}[c]$, and (ii) by (A), access procedures are not executed concurrently at port $i$ of different objects $\mathcal{O}[j]$ and $\mathcal{O}[j']$. For $i = n$, the claim follows from the observation that port $n$ of $GS_k$ is accessed only by the access procedure at port $n$ of $\mathcal{O}[k]$. ☐

Notice that each proposal to (and hence each response of) $O_\ell$ is of the form $\langle j, u\rangle$. The next claim states that the first components of the responses returned by different objects among $O_1, \ldots, O_c$ are different.

CLAIM 4.3.3. *Let $\langle j, u\rangle$ and $\langle j', u'\rangle$ be the values returned by operations applied to objects $O_\ell$ and $O_{\ell'}$. If $\ell \neq \ell'$, then $j \neq j'$.*

*Proof of Claim* 4.3.3. Suppose $\ell \neq \ell'$. Without loss of generality, we can assume that $\ell' < \ell$. By Claim 4.3.1, $O_\ell$ satisfies validity, and so some access procedure $P$ proposed $\langle j, u\rangle$ to $O_\ell$. By the implementation it is clear that $P$ is an access procedure of the form APPLY(*propose* $u, *, \mathcal{O}[j]$).[6] An inspection of this access procedure shows that before $P$ proposed $\langle j, u\rangle$ to $O_\ell$, it proposed $\langle j, u\rangle$ to $O_{\ell'}$ and received a response $\langle k, v\rangle$, where $k \neq j$. By Claim 4.3.1, $O_{\ell'}$ satisfies agreement, and so $\langle k, v\rangle = \langle j', u'\rangle$. Therefore, $j \neq j'$, as wanted. ☐

CLAIM 4.3.4. *For each $i \in [1..n-1]$ and $j \in [1..c]$, $\mathcal{O}[j]$ is wait-free for port $i$ in $\mathcal{E}$.*

*Proof of Claim* 4.3.4. For each $\ell \in [1..c]$, $O_\ell$ is wait-free for port $i$ since, by Claim 4.3.1, it is accessed properly. By part 2 of Lemma 4.2, $GS_j$ is wait-free for port $i$. Thus, it remains to show that the repeat-loop of access procedure APPLY(*propose* $u$, $i, \mathcal{O}[j]$) in Figure 4 terminates. If that loop does not terminate after $\ell$ iterations, then the propose operations applied to $O_1, \ldots, O_\ell$ return pairs whose first components are different from each other (by Claim 4.3.3) and from $j$. Recall that the first components of propose operations applied to $O_1, \ldots, O_c$ are integers in $[1..c]$, and that these objects satisfy validity since, by Claim 4.3.1, they are accessed properly. Therefore, the loop terminates after at most $c$ iterations. ☐

CLAIM 4.3.5. *All but one of $\mathcal{O}[1], \ldots, \mathcal{O}[c]$ are wait-free for port $n$ in $\mathcal{E}$.*

*Proof of Claim* 4.3.5. Suppose, for contradiction, that there exist $k, k' \in [1..c]$ such that $k \neq k'$ and neither of $\mathcal{O}[k], \mathcal{O}[k']$ is wait-free for port $n$ in $\mathcal{E}$. It follows that neither of $GS_k, GS_{k'}$ is wait-free for port $n$ in $\mathcal{E}$. By part 3 of Lemma 4.2, the following holds for both $GS_k$ and $GS_{k'}$ in $\mathcal{E}$: An operation has been applied to some port other than $n$ and no operation applied to any port returns a response.

Let $P_k$ and $P_{k'}$ denote access procedures that applied, respectively, an operation to a port other than $n$ of $GS_k$ and $GS_{k'}$. From the implementation, it is clear that $P_k$ obtained a response of $\langle k, *\rangle$ from some $O_\ell$ (otherwise $P_k$ would not have applied an operation to $GS_k$). Similarly, $P_{k'}$ obtained a response of $\langle k', *\rangle$ from some $O_{\ell'}$. Since the responses of $O_\ell$ and $O_{\ell'}$ to $P_k$ and $P_{k'}$, respectively, are different (recall that $k \neq k'$), and since each of $O_\ell$ and $O_{\ell'}$ satisfies agreement (recall that, by Claim 4.3.1, these objects are accessed properly), it follows that $\ell \neq \ell'$. Without loss of generality, assume $\ell' < \ell$. From the implementation it is clear that $P_k$ accessed $O_{\ell'}$ before accessing $\mathcal{O}_\ell$. Since $O_{\ell'}$ satisfies agreement, its response to $P_k$ was $\langle k', *\rangle$. It is again clear from the implementation that upon obtaining this response $P_k$ invoked an operation APPLY(*propose* $*, *, GS_{k'}$) and received the corresponding response before proceeding to access $O_{\ell'+1}$. But this contradicts the fact that no operation applied to any port of $GS_{k'}$ returns a response. ☐

CLAIM 4.3.6. *For each $j \in [1..c]$, $\mathcal{O}[j]$ satisfies validity and agreement in $\mathcal{E}$.*

*Proof of Claim* 4.3.6. We observe that the value returned in $\mathcal{E}$ by any of $\mathcal{O}[j]$'s access procedures (namely, APPLY(*propose* $*, *, \mathcal{O}[j]$)) is a response received from

[6]We use an $*$ to denote a quantity whose value is immaterial for the argument at hand.

$GS_j$. By Claim 4.3.2 and Lemma 4.2, $GS_j$ satisfies agreement in $\mathcal{E}$. Therefore, $\mathcal{O}[j]$ also satisfies agreement in $\mathcal{E}$.

Consider any access procedure $P$ of $\mathcal{O}[j]$ that returns $v$ in $\mathcal{E}$. To prove that $\mathcal{O}[j]$ satisfies validity in $\mathcal{E}$ it suffices to show that some access procedure proposed $v$ to $\mathcal{O}[j]$. Since $P$ returns $v$, it is clear from the implementation that $GS_j$ returned $v$ to $P$. By Claim 4.3.2 and Lemma 4.2, $GS_j$ satisfies validity in $\mathcal{E}$. Thus, $v$ was proposed to $GS_j$ by some access procedure $P'$. By the implementation, this implies that one of the following two cases applies:

(i) $P'$ is the access procedure Apply(*propose* $v, n, \mathcal{O}[j]$) and proposes $v$ to $GS_j$.

(ii) $P'$ is an access procedure Apply(*propose* $*, i', \mathcal{O}[j']$), for some $i' \in [1..n-1]$ and $j' \in [1..c]$, and proposes $v$ to $GS_j$ after receiving $\langle j, v\rangle$ from some object $O_\ell$. This means that some access procedure $P''$ proposed $\langle j, v\rangle$ to $O_\ell$, and so $P''$ is an access procedure Apply(*propose* $v, *, \mathcal{O}[j]$).

In either case, some access procedure proposed $v$ to $\mathcal{O}[j]$, as wanted. □

The three parts of Lemma 4.3 are immediate from Claims 4.3.4, 4.3.5, and 4.3.6, respectively. □

## 5. Generalized irreducibility theorem for consensus.

In this section, we prove the generalized irreducibility theorem for consensus, stated as follows. For all $n \geq 2$ and all sets $\mathcal{S}$ of types that include `register`, if there is a wait-free implementation of an $n$-consensus object from $(n-1)$-consensus objects and objects of types in $\mathcal{S}$, then there is a wait-free implementation of an $n$-consensus object just from objects of types in $\mathcal{S}$. In other words, the base $(n-1)$-consensus objects can be eliminated from the implementation. Thus, $(n-1)$-consensus objects are not necessary to implement a wait-free $n$-consensus object, regardless of the base objects that are available for such an implementation.

We obtain this result by repeated application of a lemma stating that if $n$-consensus objects are helpful in implementing $(n+1)$-consensus objects, then $(n-1)$-consensus objects are helpful in implementing $n$-consensus objects.

Lemma 5.1. *For all $n \geq 2$ and all sets $\mathcal{S}$ of types that include* `register`*, if there is a wait-free implementation of an $(n+1)$-consensus object from $n$-consensus objects and objects of types in $\mathcal{S}$, then there is a wait-free implementation of an $n$-consensus object from $(n-1)$-consensus objects and objects of types in $\mathcal{S}$.*

*Proof.* Consider a wait-free implementation of an $(n+1)$-consensus object $\mathcal{O}$ from $n$-consensus objects and objects of types in $\mathcal{S}$. By König's lemma, the number of base objects of $\mathcal{O}$ is finite [2].[7]

Consider any $n$-consensus base object $O$ of $\mathcal{O}$. By Lemma 3.2, we can assume that the binding of $\mathcal{O}$ with $O$ is one-to-one static. Since $\mathcal{O}$ has $n+1$ ports and $O$ has $n$ ports, some port of $\mathcal{O}$, say $p$, does not use any port of $O$. Let $i_1, i_2, \ldots, i_n$ be the remaining ports of $\mathcal{O}$ (i.e., the elements of $[1..n+1] - \{p\}$) listed in ascending order. We may assume without loss of generality (by renaming ports of $O$, if necessary) that ports $i_1, i_2, \ldots, i_n$ of $\mathcal{O}$ are bound, respectively, to ports $1, 2, \ldots, n$ of $O$. We may therefore classify the base objects of $\mathcal{O}$ into four categories:

(a) $A_1, \ldots, A_a$ are the $n$-consensus base objects that are not accessed by port $n+1$ of $\mathcal{O}$. Thus, ports $n-1$ and $n$ of $A_1, \ldots, A_a$ are bound, respectively, to ports $n-1$ and $n$ of $\mathcal{O}$.

(b) $B_1, \ldots, B_b$ are the $n$-consensus base objects that are not accessed by port $n$ of $\mathcal{O}$. Thus, ports $n-1$ and $n$ of $B_1, \ldots, B_b$ are bound, respectively, to ports

[7]It is here that we make use of the assumption that types exhibit finite nondeterminism.

$n-1$ and $n+1$ of $\mathcal{O}$.

(c) $C_1, \ldots, C_c$ are the $n$-consensus base objects that are not accessed by one of the first $n-1$ ports of $\mathcal{O}$. Thus, ports $n-1$ and $n$ of $C_1, \ldots, C_c$ are bound, respectively, to ports $n$ and $n+1$ of $\mathcal{O}$.

(d) $D_1, \ldots, D_d$ are the remaining base objects of $\mathcal{O}$ (these belong to the types in $\mathcal{S}$).

Modify the implementation of $\mathcal{O}$ as follows:

- Replace the base objects $A_1, \ldots, A_a$ and $B_1, \ldots, B_b$ with a 1-blocking array $O[1..a+b]$, implemented as in Figure 4. Objects $O[1..a]$ of the array are used in the place of $A_1, \ldots, A_a$ and $O[a+1..a+b]$ are used in the place of $B_1, \ldots, B_b$.
- Replace the base objects $C_1, \ldots, C_c$ with $NC_1, \ldots, NC_c$, where each $NC_i$ is implemented using the nonconcurrent implementation in Figure 2.
- The access procedures of the new implementation are the same as in the original implementation with the following exception: Each time any access procedure Apply(*propose* $*, *, \mathcal{O}$) applies, in the original implementation, a *propose* $u$ operation to port $i$ of $A_j$, $B_j$, or $C_j$, the new implementation requires the access procedure instead to apply *propose* $u$ to port $i$ of $O[j]$, $O[a+j]$, or $NC_j$, respectively.

Claim 5.1.1. *The* $(n+1)$*-consensus object* $\mathcal{O}$ *in the new implementation described above has the following properties:*

1. *All base consensus objects of* $\mathcal{O}$ *are* $(n-1)$*-consensus objects and all other base objects of* $\mathcal{O}$ *belong to types in* $\mathcal{S}$.
2. $\mathcal{O}$ *satisfies validity and agreement in all executions in which operations are not executed concurrently at ports* $n-1$ *and* $n$ *of* $NC_i$ *for all* $i \in [1..c]$.
3. $\mathcal{O}$ *is wait-free for ports* $1, \ldots, n-1$.
4. $\mathcal{O}$ *is wait-free for one of ports* $n$ *and* $n+1$.

*Proof of Claim* 5.1.1. Part 1 follows from the fact that $O[1..a+b]$ and $NC_1, \ldots, NC_c$ are implemented from $(n-1)$-consensus objects and registers, the latter being in $\mathcal{S}$ by assumption.

To prove part 2, consider any execution $\mathcal{E}$ of the new implementation of $\mathcal{O}$ in which operations are not executed concurrently at ports $n-1$ and $n$ of any $NC_i$, $i \in [1..c]$. The following three facts imply that $\mathcal{O}$ satisfies validity and agreement in $\mathcal{E}$:

- The original implementation of $\mathcal{O}$ satisfies validity and agreement in all executions.
- By part 3 of Lemma 4.3, $O[1], \ldots, O[a+b]$ (which have replaced $A_1, \ldots, A_a$ and $B_1, \ldots, B_b$ of the original implementation) satisfy validity and agreement in all executions that satisfy the following proviso: there are no concurrent invocations at the *same* port $p \in [1..n-1]$ of two *distinct* objects $O[j]$ and $O[k]$, where $j, k \in [1..a+b]$. This proviso is satisfied in $\mathcal{E}$ because (i) the first $n-1$ ports of each object $O[1], \ldots, O[a+b]$ are bound to the first $n-1$ ports of $\mathcal{O}$, respectively; and (ii) in the original implementation of $\mathcal{O}$, no access procedure invokes concurrent operations on distinct base objects—and, in particular, on the $n$-consensus base objects $A_1, \ldots, A_a$ and $B_1, \ldots, B_b$ that were replaced by $O[1], \ldots, O[a+b]$.
- By part 2 of Lemma 4.1, $NC_1, \ldots, NC_c$ (which have replaced $C_1, \ldots, C_c$ of the original implementation) satisfy validity and agreement in $\mathcal{E}$.

Part 3 follows from the following facts: (i) $NC_1, \ldots, NC_c$ are wait-free (by part 1 of Lemma 4.1), (ii) $O[1], \dots, O[a+b]$ are wait-free for ports $1, \dots, n-1$ (by part 1 of Lemma 4.3), and (iii) none of the first $n-1$ ports of $\mathcal{O}$ use port $n$ of any of $O[1], \dots, O[a+b]$.

Part 4 follows from the following facts: (i) all but one of $O[1], \dots, O[a+b]$ are wait-free for port $n$ (by part 2 of Lemma 4.3), and (ii) port $n$ of each of $O[1], \dots, O[a]$ is used only by port $n$ of $\mathcal{O}$, and port $n$ of each of $O[a+1], \dots, O[a+b]$ is used only by port $n+1$ of $\mathcal{O}$ (thus, port $n$ of each $O[i]$ is used either by port $n$ of $\mathcal{O}$ or by port $n+1$ of $\mathcal{O}$, but not by both). $\square$

Next we describe how to transform the new implementation of $\mathcal{O}$, the $(n+1)$-consensus object satisfying the properties in Claim 5.1.1, into an implementation of an $n$-consensus object $\mathcal{O}'$. Informally, the access procedure for each of the first $n-1$ ports of $\mathcal{O}'$ simply calls the access procedure at the corresponding port of $\mathcal{O}$ and returns that procedure's response. For port $n$, the access procedure of $\mathcal{O}'$ executes the access procedures of *both* ports $n$ and $n+1$ of $\mathcal{O}$, alternating between the two in such a manner that one of them is guaranteed to terminate and return a value; that value then becomes the response of the access procedure of port $n$ of $\mathcal{O}'$.

To explain more precisely how $\mathcal{O}'$ works, we need to make some observations and introduce some terminology. Recall (see Figure 4) that to propose a value to port $n$ of an object $O[j]$ in a 1-blocking array, we simply propose the same value to port $n$ of an object $GS_j$ in the group-solo implementation. If, in some execution, the latter enters the busy-wait statement (see Figure 3), we say that object $O[j]$ is *blocked*.

Here, now, is how the access procedure APPLY(*propose* $u, i, \mathcal{O}'$) works:

- For all $i \in [1..n-1]$, APPLY(*propose* $u, i, \mathcal{O}'$) executes APPLY(*propose* $u, i, \mathcal{O}$).
- APPLY(*propose* $u, n, \mathcal{O}'$), the access procedure at port $n$ of $\mathcal{O}'$, interleaves the execution of APPLY(*propose* $u, n, \mathcal{O}$) and APPLY(*propose* $u, n+1, \mathcal{O}$), using the rules below. For convenience, we let PROC$_n$ and PROC$_{n+1}$ denote APPLY(*propose* $u, n, \mathcal{O}$) and APPLY(*propose* $u, n+1, \mathcal{O}$), respectively. Note that, by construction of $\mathcal{O}$, PROC$_n$ applies operations to port $n$ of $O[1], \dots, O[a]$ (as well as to port $n-1$ of $NC_1, \dots, NC_c$, and possibly to ports of $D_1, \dots, D_d$). Similarly, PROC$_{n+1}$ applies operations to port $n$ of $O[a+1], \dots, O[a+b]$ (as well as to port $n$ of $NC_1, \dots, NC_c$, and possibly to ports of $D_1, \dots, D_d$).
  - (a) Begin by executing PROC$_n$.
  - (b) Suspend PROC$_n$ and resume PROC$_{n+1}$ if and only if PROC$_n$ accesses an object $O[j]$ that is blocked (for some $j \in [1..a]$). Similarly, suspend PROC$_{n+1}$ and resume PROC$_n$ if and only if PROC$_{n+1}$ accesses an object $O[a+j]$ that is blocked (for some $j \in [1..b]$).
  - (c) As soon as either PROC$_n$ or PROC$_{n+1}$ terminates and returns some value $v$, terminate APPLY(*propose* $u, n, \mathcal{O}'$) and return $v$.

CLAIM 5.1.2. *The $n$-consensus object $\mathcal{O}'$, in the implementation described above, has the following properties:*

1. *All base consensus objects of $\mathcal{O}'$ are $(n-1)$-consensus objects, and all other base objects belong to types in $\mathcal{S}$.*
2. *$\mathcal{O}'$ satisfies validity and agreement.*
3. *$\mathcal{O}'$ is wait-free.*

*Proof of Claim* 5.1.2. Part 1 follows directly from part 1 of Claim 5.1.1.

Each access procedure of $\mathcal{O}'$ merely returns the value of a corresponding access procedure of $\mathcal{O}$. By part 2 of Claim 5.1.1, $\mathcal{O}$ satisfies validity and agreement as long as there are no concurrent operations at ports $n-1$ and $n$ of each $NC_i$ for $i \in [1..c]$.

Thus, to prove part 2 of the present claim, it suffices to prove that, for every $i \in [1..c]$, the access procedures of $\mathcal{O}'$ do not apply concurrent operations to ports $n-1$ and $n$ of $NC_i$. To see why this is the case, recall that ports $n-1$ and $n$ of each $NC_i$ are accessed only by $\text{PROC}_n$ and $\text{PROC}_{n+1}$, respectively. By construction of $\mathcal{O}'$, only the access procedure of port $n$ of $\mathcal{O}'$ executes $\text{PROC}_n$ and $\text{PROC}_{n+1}$. Furthermore, while the access procedure of port $n$ of $\mathcal{O}'$ is executing one of $\text{PROC}_n$ or $\text{PROC}_{n+1}$, it has suspended execution of the other. Therefore, no concurrent operations are executed at ports $n-1$ and $n$ of $NC_i$, as wanted.

Part 3 of Claim 5.1.1 implies that $\mathcal{O}'$ is wait-free for ports $1, \ldots, n-1$, and part 4 of Claim 5.1.1 implies that $\mathcal{O}'$ is wait-free for port $n$. Thus, $\mathcal{O}'$ is wait-free for all its $n$ ports. □

This completes the proof of Lemma 5.1. □

THEOREM 5.2 (generalized irreducibility theorem for consensus). *For all $n \geq 2$ and all sets $\mathcal{S}$ of types that include* `register`*, if there is a wait-free implementation of an $n$-consensus object from $(n-1)$-consensus objects and objects of types in $\mathcal{S}$, then there is a wait-free implementation of an $n$-consensus object from objects of types in $\mathcal{S}$.*

*Proof.* Suppose there is a wait-free implementation of an $n$-consensus object from $(n-1)$-consensus objects and objects of types in $\mathcal{S}$. By repeated application of Lemma 5.1 we have that for all $k \in [2..n]$, there is a wait-free implementation of a $k$-consensus object from $(k-1)$-consensus objects and objects of types in $\mathcal{S}$. Composing all these implementations, we obtain a wait-free implementation of an $n$-consensus object from 1-consensus objects and objects of types in $\mathcal{S}$. Since 1-consensus objects have a trivial implementation,[8] we have a wait-free implementation of an $n$-consensus object from objects of types in $\mathcal{S}$. □

**6. Equivalence of $t$-resilient and wait-free implementations of consensus.** In this section, we prove that the three versions of fault-tolerant consensus—wait-free consensus, weak $t$-tolerant consensus, and strong $t$-tolerant consensus—are equivalent: if any of them can be implemented from certain types of shared objects, the other two can also be implemented from the same types of shared objects. More precisely, we have the following.

THEOREM 6.1 (equivalence of $t$-resilient and wait-free consensus). *For all $n > t \geq 2$ and all sets $\mathcal{S}$ of types that include* `register`*, the following three statements are equivalent:*

S1. *There is an implementation of a weakly $t$-resilient $n$-consensus object from objects of types in $\mathcal{S}$.*

S2. *There is a wait-free implementation of a $(t+1)$-consensus object from objects of types in $\mathcal{S}$.*

S3. *There is an implementation of a strongly $t$-resilient $n$-consensus object from objects of types in $\mathcal{S}$.*

We prove the theorem by showing that S1 implies S2, S2 implies S3, and S3 implies S1. As we will see, the generalized irreducibility theorem of the previous section is used to prove the first of these three claims.

LEMMA 6.2. S1 *implies* S2*, where statements* S1 *and* S2 *are as in Theorem* 6.1.

*Proof.* Let $\mathcal{O}$ be a $t$-resilient implementation of an $n$-consensus object from objects of types in $\mathcal{S}$. Using $\mathcal{O}$ (and a few other base objects) we implement a wait-free $(t+1)$-consensus object $\mathcal{O}'$. Roughly speaking, the access procedures of $\mathcal{O}'$ coordinate with

[8] A *propose $u$* operation on a 1-consensus object simply returns $u$.

each other to simulate an execution of $\mathcal{O}$. The simulation is done in such a way that each access procedure of $\mathcal{O}'$ that crashes can prevent *at most one* access procedure of $\mathcal{O}$ in the simulated execution from making progress. Thus, if access procedures in at most $t$ ports of $\mathcal{O}'$ crash, then access procedures of at most $t$ ports of $\mathcal{O}$ will stop making progress in the simulated execution. Since $\mathcal{O}$ is $t$-resilient, the access procedures in the remaining $n - t$ ports of $\mathcal{O}$ eventually terminate and return the same value. This value is adopted as the return value of $\mathcal{O}'$.

We implement the above idea as follows:

- We employ registers $U_1, \ldots, U_n$ and $R_1, \ldots, R_n$. For each $i \in [1..n]$, $U_i$ stores the value proposed at port $i$ of $\mathcal{O}$, and $R_i$ stores the current state of that port's access procedure. (The state of an access procedure consists of the values of all its private variables and of its "program counter.")
- We employ $(t+1)$-ported test&set objects $TS_1, \ldots, TS_n$. (The test&set object type has two states—*win* and *lose*—and supports two operations: *test&set* and *reset*. The *test&set* operation returns the current state of the object and sets the state to *lose*. The *reset* sets the state to *win* and returns an acknowledgment as a response.)
  We use $TS_j$ to ensure that at any time at most one of $\mathcal{O}'$'s access procedures simulates steps of the access procedure at port $j$ of $\mathcal{O}$.
- For brevity, let $P_i$ denote the access procedure Apply(*propose* $u, i, \mathcal{O}'$) for each $i \in [1..t+1]$. $P_i$ considers the $n$ ports of $\mathcal{O}$ in round-robin fashion. When $P_i$ considers port $j$ of $\mathcal{O}$, it applies a *test&set* operation to $TS_j$. If $TS_j$ returns *lose*, $P_i$ moves on to consider the next port of $\mathcal{O}$, $\big((j+1) \mod n\big)+1$. If $TS_j$ returns *win*, $P_i$ advances the simulation of the access procedure at port $j$ of $\mathcal{O}$ by performing the following actions:
  (1) $P_i$ reads $R_j$ to determine the current state of that procedure.
  (2) If no step of port $j$ has been simulated before, $P_i$ writes its proposal $u$ into $U_j$ and sets $R_j$ to the initial state of Apply(*propose* $U_j, j, \mathcal{O}$).
  (3) $P_i$ performs a single step of Apply(*propose* $U_j, j, \mathcal{O}$) and writes the resulting state of that procedure in $R_j$.
  (4) $P_i$ performs a reset operation on $TS_j$ (so that some $P_{i'}$, $i' \in [1..t+1]$, may execute the next step of the access procedure at $\mathcal{O}$'s port $j$).
  (5) If the step that $P_i$ simulated caused the access procedure of port $j$ of $\mathcal{O}$ to terminate and return $v$, $P_i$ writes $v$ in a register *DEC* and terminates; otherwise, $P_i$ moves on to consider the next port of $\mathcal{O}$.

The implementation of $\mathcal{O}'$, described informally above, is shown in Figure 5. The following claim states the desired properties of $\mathcal{O}'$.

Claim 6.2.1. *The* $(t+1)$*-consensus object* $\mathcal{O}'$*, shown in Figure* 5*, satisfies validity and agreement and is wait-free.*

*Proof of Claim* 6.2.1. Let $\mathcal{E}'$ be an arbitrary concurrent execution of $\mathcal{O}'$'s access procedures, and let $\mathcal{E}$ be the subexecution of $\mathcal{E}'$ consisting of the operations applied to $\mathcal{O}$ (see line 8 in Figure 5). Thus $\mathcal{E}$ is a concurrent execution of $\mathcal{O}$'s access procedures. To prove the claim it suffices to show that $\mathcal{O}'$ satisfies validity and agreement and is wait-free in $\mathcal{E}'$.

It is clear from the implementation that the values returned by access procedures of $\mathcal{O}'$ in $\mathcal{E}'$ are values returned by access procedures of $\mathcal{O}$ in $\mathcal{E}$. In addition, any value proposed by an access procedure of $\mathcal{O}$ in $\mathcal{E}$ is a value proposed by some access procedure of $\mathcal{O}'$ in $\mathcal{E}'$ (see line 6). From these two observations, and the fact that $\mathcal{O}$ satisfies validity and agreement in $\mathcal{E}$, it follows that $\mathcal{O}'$ satisfies validity and agreement in $\mathcal{E}'$.

```
        $\mathcal{O}$: $t$-resilient implementation of $n$-consensus object, initialized to $\bot$
        $TS_1, \ldots, TS_n$: $(t+1)$-ported test&set objects, initialized to $win$
        $R_1, \ldots, R_n$: registers, initialized to $\bot$
        $U_1, \ldots, U_n$: registers, initialized arbitrarily
        $DEC$: register, initialized to $\bot$
        $\underline{\text{APPLY}(propose\ u, i, \mathcal{O}')}$; $u \in \mathbb{N}, i \in [1..t+1]$

1.      $j := 1$
2.      repeat
3.          if APPLY($test\&set, i, TS_j$) = $win$ then
4.              read $R_j$ to determine the state of PROC$_j$
5.              if $R_j = \bot$ then
6.                  $U_j := u$
7.                  $R_j :=$ initial state of APPLY($propose\ U_j, j, \mathcal{O}$)
8.              execute one step of APPLY($propose\ U_j, j, \mathcal{O}$)
9.              write in $R_j$ the new state of APPLY($propose\ U_j, j, \mathcal{O}$)
10.             if APPLY($propose\ U_j, j, \mathcal{O}$) terminated and returned $v$ then $DEC := v$
11.             APPLY($reset, i, TS_j$)
12.         if $DEC \neq \bot$ then return $DEC$
13.         $j := \big((j+1) \mod n\big) + 1$
14.     forever
```

FIG. 5. *Wait-free implementation of a $(t+1)$-consensus object $\mathcal{O}'$ from t-resilient implementation of n-consensus object $\mathcal{O}$.*

It remains to show that $\mathcal{O}'$ is wait-free in $\mathcal{E}'$. Suppose, for contradiction, that there is an access procedure, say $P$, of $\mathcal{O}'$ that is infinite in $\mathcal{E}'$. For $i \in [1..t+1]$ let $P_i$ denote the access procedure at port $i$ of $\mathcal{O}'$ in $\mathcal{E}'$, and for $j \in [1..n]$ let $Q_j$ denote the access procedure at port $j$ of $\mathcal{O}$ in $\mathcal{E}$. We make a subclaim that, for each finite $Q_j$ in $\mathcal{E}$ ($j \in [1..n]$), there is a $P_i$ ($i \in [1..t+1]$) such that $P_i$ applies only finitely many operations to $TS_j$ in $\mathcal{E}'$, the last of which is a *test&set* that returns *win*. We prove this subclaim by contradiction: suppose that every $P_i$ that receives *win* from $TS_j$ at line 3 subsequently resets it at line 11. Then, since $P$ applies infinitely many *test&set* operations to $TS_j$ in $\mathcal{E}'$, there would be infinitely many *test&set* operations to $TS_j$ that return *win* in $\mathcal{E}'$. As a result, either infinitely many steps of $Q_j$ are performed in $\mathcal{E}$ or $Q_j$ completes in $\mathcal{E}$ and returns some response $v$. The former case contradicts the premise that $Q_j$ is finite in $\mathcal{E}$. In the latter case, whichever $P_k$ simulated the last step of $Q_j$ would write $v$ in *DEC* (at line 10) before resetting $TS_j$. After this writing in *DEC*, when $P$ reads *DEC* at line 12, it finds $v$ in *DEC* and therefore completes, which contradicts the premise that $P$ is infinite. This completes the proof of the subclaim. It is clear from Figure 5 that if $Q_j$ and $Q_{j'}$ are distinct access procedures of $\mathcal{O}$ that are finite in $\mathcal{E}$, then the corresponding access procedures of $\mathcal{O}'$ that executed the last *test&set* operation on $TS_j$ and $TS_{j'}$, respectively, are also distinct. Thus, it is immediate from the subclaim that if at most $m$ of $P_1, P_2, \ldots, P_{t+1}$ are finite, then at most $m$ of $Q_1, \ldots, Q_n$ are finite. Since, by our supposition, $P$ is infinite (and $P$ is one of $P_1, \ldots, P_{t+1}$), it follows that at most $t$ of $Q_1, \ldots, Q_n$ are finite, which implies that at least $n-t$ of $Q_1, \ldots, Q_n$ are infinite. This conclusion contradicts the fact that $\mathcal{O}$ is $t$-resilient. Hence, we conclude that $\mathcal{O}'$ is wait-free in $\mathcal{E}'$. ∎

Afek, Weisberger, and Weisman showed that there is a wait-free implementation of a $k$-ported test&set object from 2-consensus objects and registers for all $k \geq 2$ [1].

This, together with Claim 6.2.1, implies the following.

CLAIM 6.2.2. *There is a wait-free implementation of a* $(t+1)$*-consensus object from* 2*-consensus objects and objects of types in* $\mathcal{S}$*.*

We now have all the ingredients needed to complete the proof of Lemma 6.2. Since $t \geq 2$, Claim 6.2.2 implies that there is a wait-free implementation of a $(t+1)$-consensus object from $t$-consensus objects and objects of types in $\mathcal{S}$. This, together with Theorem 5.2, implies that there is a wait-free implementation of a $(t+1)$-consensus object from just objects of types in $\mathcal{S}$. This completes the proof of Lemma 6.2. ◻

The next lemma has a similar proof, so we provide only an informal sketch.

LEMMA 6.3. S2 *implies* S3*, where statements* S2 *and* S3 *are as in Theorem* 6.1*.*

*Proof.* The proof is based on a simulation of a strong $t$-resilient $n$-consensus object $\mathcal{O}'$ using a wait-free $(t+1)$-consensus object $\mathcal{O}$. This simulation is similar to that in the proof of Lemma 6.2 (see Figure 5). The only difference is that now a larger number $n$ of access procedures simulate the steps of a wait-free implementation for a smaller number $t+1$ of access procedures (in Figure 5 it is the other way around: a smaller number $t+1$ of access procedures simulate the steps of a $t$-resilient implementation for a larger number $n$ of access procedures). In this way, even if only a few access procedures of the $t$-resilient implementation are active, they will nevertheless simulate an execution of the wait-free implementation and reach a decision that satisfies validity and agreement. As before, the simulation uses a register *DEC* (to publish the decision value) and test&set objects to ensure that the simulation is done correctly. (One test&set object is used at each port $i$ of $\mathcal{O}$ to ensure that at most one access procedure of $\mathcal{O}'$ simulates port $i$ of $\mathcal{O}$ at any time.)

The above argument shows that a strong $t$-resilient $n$-consensus object $\mathcal{O}'$ can be simulated using a wait-free $(t+1)$-consensus object $\mathcal{O}$, $t+1$ $n$-ported test&set objects, and the register *DEC*. We show next that the test&set objects can be eliminated from the simulation. As mentioned earlier, an $n$-ported test&set object can be implemented wait-free from 2-consensus objects and registers [1]. Since $t \geq 2$, it follows that $n$-ported test&set objects used in the simulation can be substituted by their implementations from $(t+1)$-consensus objects and registers. With this substitution, we have a simulation of a strong $t$-resilient $n$-consensus object $\mathcal{O}$ from registers and a set of wait-free $(t+1)$-consensus objects. By the premise of the lemma (i.e., statement S2), we have that (1) a wait-free $(t+1)$-consensus object can be implemented from objects that belong to the types in $\mathcal{S}$, and (2) $\mathcal{S}$ includes the register type. It follows that a strong $t$-resilient $n$-consensus object can be simulated using only objects whose types are in $\mathcal{S}$. ◻

The next lemma trivially holds since strong $t$-resilience implies weak $t$-resilience.

LEMMA 6.4. S3 *implies* S1*, where statements* S3 *and* S1 *are as in Theorem* 6.1*.*

Theorem 6.1 is immediate from Lemmas 6.2, 6.3, and 6.4.

Notice that the equivalence of statements S1, S2, and S3 in the theorem is proved for $t \geq 2$. As shown by Lo and Hadzilacos, the implication S1 $\implies$ S2 breaks down for $t = 1$ [22]. The other implications, however, continue to hold for $t = 1$: S2 implies S3 (the proof is the same as in Lemma 6.3) and S3 implies both S1 and S2 (by definition).

Finally, we present some corollaries of the equivalence theorem. Herlihy proved that there is no wait-free implementation of 3-consensus from objects belonging to any of the following sets of types [12]: $\{\texttt{queue}, \texttt{register}\}$, $\{\texttt{stack}, \texttt{register}\}$, $\{\texttt{fetch\&add}, \texttt{register}\}$, $\{\texttt{swap}, \texttt{register}\}$. (Here, the types `register`, `queue`, `stack`, `fetch&add`, and `swap` can have *any* number of ports; the impossibility result holds regardless.) This, together with Theorem 6.1, implies the following.

COROLLARY 6.5. *For all $n \geq 3$, there is no 2-resilient implementation of an n-consensus object from objects belonging to any of the following sets of types:* {`queue`, `register`}, {`stack`, `register`}, {`fetch&add`, `register`}, {`swap`, `register`}.

Consider a MEM($m$) object that corresponds to Herlihy's $m$-register assignment memory [12]. Informally, MEM($m$) consists of an infinite array of cells; it supports the *read* $i$ operation, which returns the value in the $i$th cell, and the *write*$(i_1, v_1, \ldots, i_m, v_m)$ operation, which (atomically) writes $v_j$ in cell $i_j$ for all $j \in [1..m]$. For $m \geq 2$, Herlihy proved that there is no wait-free implementation of a $(2m-1)$-consensus object from MEM($m$) objects (regardless of the number of ports the MEM($m$) objects may have). This, together with Theorem 6.1, implies the following.

COROLLARY 6.6. *For all $m \geq 2$ and $n \geq 2m-1$, there is no $(2m-2)$-resilient implementation of an n-consensus object from* MEM($m$) *objects.*

**Acknowledgments.** We thank Michael Merritt for many helpful suggestions and the anonymous referees for their comments on an earlier draft of this paper.

# APPROXIMATION ALGORITHMS FOR THE 0-EXTENSION PROBLEM*

GRUIA CALINESCU†, HOWARD KARLOFF‡, AND YUVAL RABANI§

**Abstract.** In the 0-*extension problem*, we are given a weighted graph with some nodes marked as *terminals* and a semimetric on the set of terminals. Our goal is to assign the rest of the nodes to terminals so as to minimize the sum, over all edges, of the product of the edge's weight and the distance between the terminals to which its endpoints are assigned. This problem generalizes the multiway cut problem of Dahlhaus et al. [*SIAM J. Comput.*, 23 (1994), pp. 864–894] and is closely related to the metric labeling problem introduced by Kleinberg and Tardos [*Proceedings of the* 40*th IEEE Annual Symposium on Foundations of Computer Science*, New York, 1999, pp. 14–23].

We present approximation algorithms for 0-EXTENSION. In arbitrary graphs, we present a $O(\log k)$-approximation algorithm, $k$ being the number of terminals. We also give $O(1)$-approximation guarantees for weighted planar graphs. Our results are based on a natural *metric relaxation* of the problem previously considered by Karzanov [*European J. Combin.*, 19 (1998), pp. 71–101]. It is similar in flavor to the linear programming relaxation of Garg, Vazirani, and Yannakakis [*SIAM J. Comput.*, 25 (1996), pp. 235–251] for the multicut problem, and similar to relaxations for other graph partitioning problems. We prove that the integrality ratio of the metric relaxation is at least $c\sqrt{\lg k}$ for a positive $c$ for infinitely many $k$. Our results improve some of the results of Kleinberg and Tardos, and they further our understanding on how to use metric relaxations.

## 1. Introduction.

Let $V$ be a finite set, let $T \subseteq V$, and let $d$ be a semimetric on $T$.[1] Then a semimetric $\delta$ on $V$ is an *extension of $d$ to $V$* iff for every $i, j \in T$, $\delta(i,j) = d(i,j)$. If, in addition, for every $i \in V$ there exists $j \in T$ such that $\delta(i,j) = 0$, then $\delta$ is a 0-*extension of $d$ to $V$*.

We consider the following optimization problem, denoted 0-EXTENSION and posed by Karzanov [13]: Given a clique $V$ with a nonnegative edge weight $c(e)$ for every edge $e$, a subset $T$ of the nodes, and a semimetric $d$ on $T$, find a 0-extension $\delta$ of $d$ to $V$ that minimizes $\sum_{uv\in E} c(u,v)\delta(u,v)$.

Before doing anything else, we give an alternate formulation of 0-EXTENSION: Given the input above, find a function $f : V \to T$ such that $f(t) = t$ for all $t \in T$ which

[1]A function $d : T \times T \to \mathbb{R}$ is a *semimetric* on $T$ iff for every $i_1, i_2, i_3 \in T$, $d(i_1, i_1) = 0$, $d(i_1, i_2) \geq 0$, $d(i_1, i_2) = d(i_2, i_1)$, and $d(i_1, i_2) + d(i_2, i_3) \geq d(i_1, i_3)$. If, in addition, $d(i_1, i_2) = 0$ implies $i_1 = i_2$, then $d$ is a *metric*.

minimizes $\sum_{uv\in E} c(u,v)d(f(u),f(v))$. It is easy to see that the two formulations are equivalent. For given a feasible solution of the first kind, we can define $f(u)$ to be some terminal $i$ such that $\delta(u,i)=0$, choosing $f(u)=u$ if $u\in T$, and given a feasible solution of the second kind, we can define $\delta(u,v)=d(f(u),f(v))$ for all $u,v\in V$; the costs of the two solutions are identical because if $u,v\in V$, $i,j\in T$, and $\delta(u,i)=\delta(v,j)=0$, then $\delta(u,v)=\delta(i,j)=d(i,j)$. Often, instead of defining the edge weights on *all* edges of a clique on $V$, we will define $c(u,v)$ for each edge $uv$ in a given graph $G=(V,E)$, where $c(u,v)=0$ for $uv\notin E$ is assumed. That way, we can exploit the structure of $G$ if, say, $G$ is planar.

It helps to compare 0-Extension to the multiway cut problem of Dahlhaus et al. [7, 8]. Multiway Cut is the following problem: Given a graph $G=(V,E)$ with nonnegative edge weights $c:E\to\mathbb{R}$, and a subset $T\subseteq V$ of terminals, find a mapping $f:V\to T$, such that $f(t)=t$ for all $t\in T$, so as to minimize

$$\sum_{uv\in E, f(u)\neq f(v)} c(u,v).$$

In other words, find a set of edges of minimum total weight whose removal disconnects all terminal pairs. If we define $d$ to be the uniform metric on $T$, i.e., $d(i,j)=1$ if $i\neq j$ and $d(i,i)=0$, then Multiway Cut is exactly this problem: Find $f:V\to T$, with $f(t)=t$ for all $t\in T$, so as to minimize

$$\sum_{uv\in E} c(u,v)\cdot d(f(u),f(v)),$$

as $d(f(u),f(v))=1$ if $f(u)\neq f(v)$ and $d(f(u),f(v))=0$ otherwise. Now 0-Extension is the natural generalization of Multiway Cut in which, instead of being the uniform metric, $d$ is an arbitrary semimetric on $T$. In other words, we must find an $f:V\to T$, with $f(t)=t$ for all $t\in V$, so as to minimize

$$\sum_{uv\in E} c(u,v)\cdot d(f(u),f(v)).$$

Dahlhaus et al. [8] show that Multiway Cut (and therefore 0-Extension) is APX-hard. Thus there exists a constant $\alpha>1$ such that no polynomial-time algorithm can find a solution within a factor of $\alpha$ of the optimum, unless P=NP.

In this paper we develop approximation algorithms for the 0-extension problem. We study what seems to us to be the most natural linear programming relaxation for the 0-extension problem: Find a minimum weight extension of $d$ to $V$; specifically, given the semimetric $d$ on $T$, extend $d$ to a semimetric $\delta$ on the larger set $V$ so as to minimize $\sum_{uv\in E} c(u,v)\delta(u,v)$. (We call this the *metric relaxation.*) Obviously, the set of feasible extensions $\delta$ is defined by $O(|V|^3)$ linear constraints, and the objective function is linear. Thus finding the best extension is a linear programming problem, and thus it can be solved in polynomial time. We derive approximation algorithms using the metric relaxation, thus bounding also the integrality ratio for the relaxation. For arbitrary graphs we give a randomized $O(\log|T|)$-approximation algorithm. We show that the integrality ratio is at least a constant times $\sqrt{\log|T|}$ for infinitely many $|T|$. We improve the upper bounds to $O(1)$ for (weighted) planar graphs (or, in fact, for any family of graphs that excludes a $K_{r,r}$-minor for some fixed $r$).

Karzanov [13] considers the metric relaxation for the 0-extension problem and characterizes some of the cases in which the relaxation gives the optimal solution. For the multiway cut problem, it was known that the metric relaxation has integrality ratio exactly $2 - 2/|T|$ [5, Theorem 3.1]. Indeed, this observation uses the same idea underlying the combinatorial algorithm of Dahlhaus et al. [8] that has the same performance guarantee. For the general case, the quality of the metric relaxation was not known prior to our work. For multiway cut, a different relaxation gives better approximations, with an asymptotic ratio significantly below 2 (see Calinescu, Karloff, and Rabani [2] and the improved bounds of Cunningham and Tang [6] and of Karger et al. [12]). It is not clear whether the Calinescu, Karloff, and Rabani relaxation can be extended to handle the general case of 0-Extension.

In a recent paper, Kleinberg and Tardos [16] give approximation algorithms for a similar problem of classification with pairwise relations, which they call Metric Labeling. In their problem, the terminals are distinct from the vertices and are called *labels*. There is a semimetric on the labels, and for each node of the graph there is a vector of assignment costs to each of the labels. The goal is to minimize the total assignment cost plus the sum of weighted edge lengths. More formally, given a graph $G = (V, E)$ with nonnegative edge weights $c : E \to \mathbb{R}$, a set $T$ of labels, a semimetric $d$ on $T$, and a nonnegative assignment cost function $a : V \times T \to \mathbb{R} \cup \{\infty\}$, Metric Labeling is the problem of finding a mapping $f : V \to T$ so as to minimize

$$\sum_{u \in V} a(u, f(u)) + \sum_{uv \in E} c(u, v) \cdot d(f(u), f(v)).$$

For the case in which $d$ is the uniform metric, Kleinberg and Tardos give a 2-approximation algorithm, based on a relaxation similar to the Calinescu et al. relaxation for Multiway Cut. The integrality ratio for the relaxation here, as opposed to the relaxation for the multiway cut problem, is at least $2 - 2/|T|$. Chuzhoy [4] improves their result for three and four labels (achieving a tight 4/3 bound for three labels). Kleinberg and Tardos further give a constant approximation algorithm for a class of tree metrics, the so-called hierarchically well-separated tree metrics (HST metrics). Following Bartal's small distortion embeddings of metrics into HST metrics [1], they use a constant-ratio approximation algorithm for HST metrics to give an $O(\log |T| \log \log |T|)$-approximation algorithm for arbitrary metrics. Gupta and Tardos [11] later give a local search-based 4-approximation algorithm for the case that $d$ is a truncated linear metric (i.e., $T = \{1, 2, \ldots, k\}$ and for some value $m$, $d(i, j) = \min\{|i - j|, m\}$). Recently, Chekuri et al. [3] introduced a new linear programming relaxation for the metric labeling problem, and using it, obtained another $O(\log |T| \log \log |T|)$-approximation algorithm for arbitrary metrics and a $2 + \sqrt{2}$-approximation algorithm for the truncated linear metric.

The authors of [16] and [11] motivate their work by several applications, mostly concerning computer vision, such as image restoration and visual correspondence. In these applications the nodes of the graph are pixels in a raster image, and the edges model adjacency (in fact, the graph is a two-dimensional mesh). In image restoration applications, the labels model pixel intensities or colors. Assigning a label to a pixel amounts to determining the "true" intensity (or color) of the pixel from the observed values. The assignment cost penalizes for the difference between the observed and assigned intensity. In visual correspondence applications, the labels model possible shifts between two images. Assigning a label to a pixel amounts to determining the shift of that pixel between the two images. The assignment cost penalizes for the difference between the values of the supposedly matching pixels. In both types of applications, the structure of the graph arises from assuming that the a priori distribution of "true" labels is generated by a Markov random field (where the distribution of a pixel depends only on the distribution of its neighbors).

Note that 0-Extension is a special case of Metric Labeling: Given an instance of 0-Extension with $T \subseteq V$, define $a : V \times T \to \mathbb{R} \cup \{\infty\}$ by

- if $u \in T$, then $a(u,u) = 0$ and $a(u,t) = \infty$ for all $t \in T \setminus \{u\}$;
- if $u \notin T$, then $a(u,t) = 0$ for all $t \in T$.

The feasible solutions to Metric Labeling of finite cost then correspond to functions $f : V \to T$, which are arbitrary except for the constraint that $f(t) = t$ for all terminals t, and the objective function value corresponding to $f$ is $\sum c(u,v)d(f(u), f(v))$, the value of the objective function of 0-Extension.

Thus, our results improve upon the results in [16] for this case. We note that the 0-extension formulation seems appropriate for many of the computer vision applications mentioned in [16, 11]. For example, if we connect each pixel by a weighted edge to the label corresponding to its observed intensity, we get an assignment cost proportional to the distance between the observed and assigned value. Our algorithm for weighted planar graphs actually assumes only that $V \setminus T$ induces a planar graph. Thus we get a constant-ratio approximation algorithm for some of these computer vision problems, for an arbitrary metric on the labels $T$.

Another problem related to ours is the multicut problem, first considered in the context of approximation algorithms in two papers by Garg, Vazirani, and Yannakakis [9, 10] (and implicitly in Klein et al. [14]). In this problem, we are given a (weighted) graph and $k$ *pairs* of terminals (nodes in the graph), and the goal is to find a minimum weight set of edges whose removal disconnects every pair of terminals. This is a different generalization of multiway cut (the latter can be viewed as the multicut problem for all $\binom{k}{2}$ pairs of terminals). It is not comparable to the 0-extension problem, in the sense that neither problem is a special case of the other. In [10], Garg et al. give an $O(\log |T|)$ approximation algorithm for the multicut problem, based on a metric relaxation which assigns lengths to edges so that the distance between every specified pair of terminals is at least 1. Their result is tight for the relaxation. The example achieving (asymptotically) the integrality ratio is an expander. For their upper bounds, they use a region-growing technique similar to that used by Leighton and Rao [17] for approximating the minimum flux (edge expansion) of a graph. Klein, Plotkin, and Rao [15] improve the Leighton and Rao technique for planar graphs (and more generally for graphs that exclude a $K_{r,r}$-minor) to get a constant factor approximation for the minimum flux. Using their technique, Tardos and Vazirani [18] exhibit a constant-factor approximation algorithm for the multicut problem on planar graphs (and $K_{r,r}$-minor free graphs).

Our result can be seen as a counterpart to the Garg et al. and the Tardos and Vazirani results. The region-growing technique does not give a good approximation in the case of 0-extension. However, our results can be viewed as a form of (randomized) region growing after the application of a scaling function to the distances. This is implicit in the general case algorithm, and explicit in the planar graphs algorithm, where we use the Klein et al. technique on the scaled distances. It is worth noting that, in contrast with the situation of [10], expanders are *not* a particularly bad case for our relaxation (see section 4).

The rest of the paper is organized as follows. In section 2 we present the algorithm for the general case. Section 3 has the improved bounds for planar graphs. In section 4 we discuss the quality of the linear programming relaxation underlying our approximation algorithms. Throughout the rest of the paper we use $k$ to denote the number $|T|$ of terminals. We call the vertices in $V \setminus T$ *nonterminals*.

## 2. An $O(\log k)$-approximation algorithm.

In this section we present the randomized algorithm which finds a 0-extension of weight at most $O(\log k)$ times the optimum. We begin by computing an optimal solution to the following natural linear programming relaxation, which we denote by (MET):

$$\text{Minimize } \sum_{uv \in E} c(u,v)\delta(u,v) \quad \text{subject to}$$

$$(V,\delta) \text{ is a semimetric,} \tag{2.1}$$

$$\delta(i,j) = d(i,j) \qquad \forall i,j \in T. \tag{2.2}$$

If an assignment $f : V \to T$ defines an optimal solution to the 0-extension problem, then setting $\delta(u,v) = d(f(u), f(v))$ defines a feasible solution of (MET) of the same weight as the optimal solution. Therefore, the optimal value $Z^*$ of (MET) is a lower bound on the minimum weight 0-extension. We exhibit a rounding procedure that takes any feasible solution $\delta$ of (MET) of value $Z$ and constructs a 0-extension assignment $f : V \to T$ whose weight is $O(Z \log k)$.

Our rounding procedure works as follows. Pick uniformly at random a permutation $\sigma$ of $T$ and independently choose, uniformly at random in the interval $[1,2)$, a real number $\alpha$. The rounding algorithm iteratively assigns some nodes to terminal $\sigma_1$, then some of the remaining nodes to terminal $\sigma_2$, and so on. For every $u \in V$, set $A_u = \min_{i \in T} \delta(u,i)$. The rounding procedure is given below.

Rounding Procedure.

```
Set $f(t) = t$ for all terminals $t$.
Pick a random permutation $\sigma = \langle \sigma_1, \sigma_2, \ldots, \sigma_k \rangle$ of the terminals.
Pick $\alpha$ uniformly at random in the interval $[1,2)$.
for $j = 1$ to $k$ do
    for all unassigned nonterminals $u$ such that $\delta(u,\sigma_j) \le \alpha A_u$, do
        Set $f(u) = \sigma_j$ (i.e., assign $u$ to $\sigma_j$).
    endfor
endfor
```

We first show that the rounding procedure produces a 0-extension, as follows.

Claim 2.1. *The rounding procedure assigns every nonterminal to a terminal.*

*Proof.* Consider a nonterminal $v$, and let $t \in T$ be a terminal with $\delta(v,t) = A_u$. Choose $j$ such that $t = \sigma_j$. Then if $v$ is not assigned to a terminal in iterations $1, 2, \ldots, j-1$, it must be assigned to $t$ in iteration $j$, because $\alpha \ge 1$. ☐

For any pair of nodes $u, v \in V$, define a random variable $s(u,v) = d(f(u), f(v))$. We say that $u, v \in V$ are *separated* if $f(u) \ne f(v)$. Note that if $u, v$ are not separated, then $s(u,v) = 0$. Our goal is to bound the expectation $E[s(u,v)]$. We first state a bound on the probability that $u, v$ are separated.

Lemma 2.2. *Fix $u, v \in V$ and let $\delta = \delta(u,v)$. If $0 < \delta \le \frac{1}{4}\min\{A_u, A_v\}$, then*

$$\Pr[u, v \textit{ are separated}] \le 4\mathcal{H}_k \left( \frac{\delta}{A_u} + \frac{\delta}{A_v} \right),$$

*where $\mathcal{H}_k = 1 + \frac{1}{2} + \cdots + \frac{1}{k}$ is the kth harmonic number.*

Before we prove this bound, we state and prove its consequence, a bound for $E[s(u,v)]$, which is the core of the analysis of our algorithm.

LEMMA 2.3. *For any pair of distinct vertices $u, v \in V$, $E[s(u,v)] \le 38\mathcal{H}_k\delta(u,v)$.*[2]

*Proof.* Fix $u \neq v$ and set $\delta = \delta(u,v)$. By the triangle inequality, $A_v \le A_u + \delta$ and $A_u \le A_v + \delta$. We have $s(u,v) = d(f(u), f(v)) = \delta(f(u), f(v)) \le \delta(f(u), u) + \delta(u,v) + \delta(v, f(v))$. As $\alpha \in [1,2)$, we obtain

$$s(u,v) \le 2A_u + \delta + 2A_v. \tag{2.3}$$

If $u$ is a terminal, then $A_u = 0$ and $A_v \le \delta$. Therefore, by inequality (2.3), $s(u,v) \le 3\delta$, regardless of the choice of $\sigma$ and $\alpha$. If both $u$ and $v$ are nonterminals and $\delta = 0$, then by the triangle inequality, for any terminal $j \in T$, $\delta(u,j) = \delta(v,j)$. Therefore, $u$ and $v$ are assigned to the same terminal, regardless of the choice of $\sigma$ and $\alpha$, so $s(u,v) = 0 = \delta$.

Thus we may assume that both $u$ and $v$ are nonterminals, and that $\delta > 0$. We consider two cases, depending on whether or not $\delta$ is small compared to $A_u$ or $A_v$. If $A_u < 4\delta$, then $A_v < 5\delta$, and by inequality (2.3), $s(u,v) < 2(4+5)\delta + \delta = 19\delta$. Similarly, if $A_v < 4\delta$, then $s(u,v) < 19\delta$. Therefore, if $A_u < 4\delta$ or $A_v < 4\delta$, the lemma holds.

Assume, therefore, that $\delta \le \frac{1}{4}\min\{A_u, A_v\}$. (Recall that we also assume that $\delta > 0$.) We have

$$\begin{aligned} E[s(u,v)] &\le 4\mathcal{H}_k\left(\frac{\delta}{A_u} + \frac{\delta}{A_v}\right)(2A_u + 2A_v + \delta) \\ &\le 4\mathcal{H}_k\delta\left(\frac{4A_u + 3\delta}{A_u} + \frac{4A_v + 3\delta}{A_v}\right) \\ &\le 4\mathcal{H}_k\delta\left(4 + \frac{3}{4} + 4 + \frac{3}{4}\right) = 38\mathcal{H}_k\delta, \end{aligned}$$

where the first inequality follows from Lemma 2.2 and inequality (2.3). ◻

We conclude with the following result.

THEOREM 2.4. *There is a randomized polynomial-time $O(\log k)$-approximation algorithm for* 0-EXTENSION.

*Proof.* Let $\delta^*$ be an optimal solution of (MET) of cost $Z^*$. By Lemma 2.3, the expected weight of the 0-extension obtained by the rounding procedure is $O(Z^* \log k)$. Therefore, there exists a choice of $\sigma$ and of $\alpha$ that produces a solution of weight $O(Z^* \log k)$. To obtain a polynomial-time algorithm, notice that for a given permutation $\sigma$, two different values of $\alpha$, $\alpha_1 > \alpha_2$, produce combinatorially distinct solutions only if there is a terminal $j$ and a node $u$ such that $\delta^*(u,j) \le \alpha_1 A_u$ but $\delta^*(u,j) > \alpha_2 A_u$. Thus we can enumerate over at most $k|V|$ "interesting" values of $\alpha$. We can determine these values by sorting the fractions $\delta^*(u,j)/A_u$, over all nodes $u$ with $A_u > 0$ and over all $j \in T$. ◻

*Proof of Lemma* 2.2. Let $\mathcal{E}(u,v)$ denote the event that there is a terminal $j$ such that when $j$ is processed $u$ is assigned to $j$ whereas $v$ remains unassigned; define $\mathcal{E}(v,u)$ similarly. We will show that

$$\Pr[\mathcal{E}(u,v)] \le \frac{4\mathcal{H}_k\delta}{A_u}. \tag{2.4}$$

By symmetry, $\Pr[\mathcal{E}(v,u)] \le 4\mathcal{H}_k\delta/A_v$. Therefore, the lemma follows from inequality (2.4).

[2]The constant 38 is somewhat arbitrary, and definitely could be improved.

Label the $k$ terminals so that $\delta(u,1) \leq \delta(u,2) \leq \cdots \leq \delta(u,k)$. For $j = 1,2,\ldots,k$, let $l_j = \delta(u,j)/A_u$; $1 = l_1 \leq l_2 \leq l_3 \leq \cdots \leq l_k$. Let $r_j = \delta(v,j)/A_v \geq 1$.

For $\gamma \geq 1$, let

$$M(\gamma) = \{j \in T \mid l_j \leq \gamma < r_j\},$$

and let

$$S(\gamma) = \{j \in T \mid \gamma \geq r_j\}.$$

Note that $M(\gamma)$ and $S(\gamma)$ are disjoint subsets of terminals. Set $m(\gamma) = |M(\gamma)|$ and $s(\gamma) = |S(\gamma)|$.

Let $\alpha \in [1,2)$ be the value used by the rounding procedure. Then $v$ must be assigned to a terminal in $S(\alpha)$, because $\delta(v,j) \leq \alpha A_v$ is equivalent to $r_j \leq \alpha$. Similarly, $u$ cannot be assigned to a terminal which is not in $M(\alpha) \cup S(\alpha)$. Indeed, $u$ can only be assigned to a terminal $j$ with $l_j \leq \alpha$, and based on whether $r_j \leq \alpha$ or not, $j$ is either in $S(\alpha)$ or in $M(\alpha)$. Moreover, $\mathcal{E}(u,v)$ happens iff the first terminal in $M(\alpha) \cup S(\alpha)$ to be processed is in $M(\alpha)$. Indeed, if the first such terminal is $j \in S(\alpha)$, then $v$ (and possibly also $u$) will be assigned to $j$. Thus

$$\Pr[\mathcal{E}(u,v) \mid \alpha] = \frac{m(\alpha)}{m(\alpha)+s(\alpha)}.$$

(Note that there exists a $j$ for which $r_j = 1$, and thus $S(\alpha)$ is never empty.) As $\alpha$ is distributed uniformly in $[1,2)$, we get

$$\Pr[\mathcal{E}(u,v)] = \int_1^2 \frac{m(\alpha)}{m(\alpha)+s(\alpha)} d\alpha. \tag{2.5}$$

We need the following claim.

CLAIM 2.5. *Fix a positive integer $k$ and a nonnegative real $\beta$. Let $(\langle l_1,l_2,\ldots,l_k\rangle, \langle r_1,r_2,\ldots,r_k\rangle)$ be a pair of real sequences such that $1 = l_1 \leq l_2 \leq l_3 \leq \cdots \leq l_k$, $r_j \geq 1$ for all $j$, some $r_j = 1$, and (either $r_j - l_j \leq \beta$ or $l_j > 2$) for all $j$. Define functions $m : [1,\infty) \to \mathbb{Z}$ and $s : [1,\infty) \to \mathbb{Z}$ as follows: $m(\alpha) = |\{j \mid l_j \leq \alpha < r_j\}|$ and $s(\alpha) = |\{j \mid \alpha \geq r_j\}|$. Then*

$$\int_1^2 \frac{m(\alpha)}{m(\alpha)+s(\alpha)} d\alpha \leq \mathcal{H}_k \beta.$$

*Proof.* Note that $s(\alpha) \geq 1$ for all $\alpha$ (because some $r_j = 1$), so the function we are integrating is well defined. Let $t$ be the largest index for which $l_t \leq 2$. We prove by induction on $t$ that the value of the integral is at most $\mathcal{H}_t\beta \leq \mathcal{H}_k\beta$. For $t = 1$ the claim holds, because for $\alpha \in [r_1, 2]$, $m(\alpha) = 0$. As $r_1 - 1 = r_1 - l_1 \leq \beta$, we get

$$\int_1^2 \frac{m(\alpha)}{m(\alpha)+s(\alpha)} d\alpha \leq \int_1^{\min\{r_1,2\}} 1 d\alpha \leq r_1 - 1 \leq \beta = \mathcal{H}_1\beta.$$

Assume that the claim is true for the case in which exactly $t-1$ $j$'s satisfy $l_j \leq 2$ for some $t \geq 2$, and consider pairs $(\langle l_1,l_2,\ldots,l_k\rangle, \langle r_1,r_2,\ldots,r_k\rangle)$ in which exactly $t$ $j$'s are such that $l_j \leq 2$. We compare the value $I$ of the integral in this case to the value $I'$ of the integral for the pair in which the $t$th coordinate of the first sequence is replaced by $l_{t+1}$, except that if $t = k$, the $t$th coordinate is replaced by 3. We use

$m'(\alpha)$ and $s'(\alpha)$ for the latter pair, where clearly $s'(\alpha) = s(\alpha)$ for all $\alpha$. Note that the latter pair satisfies the hypotheses of the claim, and, furthermore, only $t-1$ $j$'s are such that $l_j \le 2$. Therefore, by the inductive hypothesis, $I' \le \mathcal{H}_{t-1}\beta$.

If $l_t \ge r_t$, then for every $\alpha \in (1,2)$, $m'(\alpha) = m(\alpha)$, and therefore $I = I'$, thus establishing the claim in this case. Thus we may assume that $l_t < r_t$. Clearly $m(\alpha) \in \{m'(\alpha), m'(\alpha)+1\}$ for any $\alpha$. Therefore, for any $\alpha \in (1,2)$,

$$\begin{aligned}\frac{m(\alpha)}{m(\alpha)+s(\alpha)} - \frac{m'(\alpha)}{m'(\alpha)+s'(\alpha)} &\le \frac{m'(\alpha)+1}{m'(\alpha)+1+s'(\alpha)} - \frac{m'(\alpha)}{m'(\alpha)+s'(\alpha)}\\ &\le \frac{1}{m'(\alpha)+s'(\alpha)+1}.\end{aligned}$$

Now $m(\alpha) \ne m'(\alpha)$ implies $\alpha \in [l_t, r_t]$, and $\alpha \in [l_t, r_t]$ implies $l_j \le l_t \le \alpha$ for all $j \le t-1$. However, every $j \le t-1$ satisfying $l_j \le \alpha$ satisfies either $l_j \le \alpha < r_j$ or $\alpha \ge r_j$, and hence each such $j$ contributes to at least one of $m'(\alpha)$ and $s'(\alpha)$. Hence $\alpha \in [l_t, r_t]$ implies $m'(\alpha)+s'(\alpha) \ge t-1$ and $1/(m'(\alpha)+s'(\alpha)+1) \le 1/t$.

Therefore $I - I' \le (r_t - l_t)(1/t)$. Because $l_t \le 2$, $r_t - l_t \le \beta$. Hence, $I \le I' + \beta/t \le \mathcal{H}_{t-1}\beta + \beta/t = \mathcal{H}_t\beta$. This completes the proof of Claim 2.5. ∎

We now proceed with the proof of Lemma 2.2. Note that if $l_j \le 2$, then $\delta(u,j) \le 2A_u$. Using the assumption that $\delta \le \frac{1}{4}A_u$, we have, for such $j$,

$$\begin{aligned} r_j - l_j &\le \frac{\delta(u,j)+\delta}{A_v} - \frac{\delta(u,j)}{A_u}\\ &\le \frac{\delta(u,j)+\delta}{A_u-\delta} - \frac{\delta(u,j)}{A_u} = \frac{\delta(\delta(u,j)+A_u)}{A_u(A_u-\delta)}\\ &\le \frac{3\delta}{A_u-\delta}\\ &\le \frac{4\delta}{A_u}.\end{aligned}$$

Hence, using Claim 2.5 with $\beta = 4\delta/A_u$, we have

$$\int_1^2 \frac{m(\alpha)}{m(\alpha)+s(\alpha)}d\alpha \le \mathcal{H}_k \cdot \frac{4\delta}{A_u}. \tag{2.6}$$

Combining (2.5) and inequality (2.6), we get $\Pr[\mathcal{E}(u,v)] \le 4\mathcal{H}_k\delta/A_u$, which proves inequality (2.4) and thus the lemma. ∎

## 3. An $O(1)$-approximation algorithm for planar graphs.

In this section we use the linear programming relaxation (MET) to get improved bounds for planar graphs. To achieve the improved bounds, we present a different rounding procedure. We show that if the input graph $G = (V,E)$ does not have a $K_{r,r}$-minor, then the rounding procedure presented in this section guarantees an $O(r^3)$ approximation ratio. As planar graphs are $K_{3,3}$-minor free, this gives a polynomial-time $O(1)$-approximation algorithm for planar graphs (and, more generally, for $K_{r,r}$-minor free graphs, for every fixed $r$).

The main tool that we use is the following theorem of Klein, Plotkin, and Rao [15] (the extension to the weighted case was stated by Tardos and Vazirani [18]).

THEOREM 3.1 (see Klein, Plotkin, and Rao). *There are constants $\kappa$ and $\lambda$ and a polynomial-time algorithm $KPR(H,\delta,c,\gamma,r)$ which takes as input a graph $H = (V_H, E_H)$ with nonnegative integral edge lengths $\delta : E_H \to \mathbb{Z}$ and nonnegative edge* *costs $c : E_H \to \mathbb{Q}$, a positive rational $\gamma$, and a positive integer $r$, and which finds either (1) a $K_{r,r}$-minor in $H$ or (2) a set of edges of total $c$-cost at most $\kappa \frac{r}{\gamma} \sum_{e \in E_H} \delta(e)c(e)$ whose removal decomposes $H$ into connected components called* clusters *such that the shortest path (in $H$, using edge lengths $\delta$) between any two nodes in the same component is at most $\lambda r^2 \gamma$.* □

Let $r$ be a positive integer. Let $\delta : V \times V \to \mathbb{R}$ be a feasible solution of (MET) of weight $Z$. Using Theorem 3.1, we exhibit a deterministic rounding procedure that obtains a 0-extension of weight $O(Z)$, assuming that the input graph $G$ is $K_{r,r}$-minor–free.

The main idea of the rounding procedure is to partition the nonterminals into clusters such that, for any two nodes $u$ and $v$ in the same cluster, $A_u$ is at most twice $A_v$. We then assign all the nodes in a cluster to a terminal closest to one of the nodes in the cluster. More formally, the rounding procedure computes a 0-extension $f : V \to T$ as follows.

Second Rounding Procedure.

```
Set $f(t) = t$ for every terminal $t$.
**for** every nonterminal $u \in V$ such that $A_u = 0$, **do**
    Set $f(u) \leftarrow i$ for some $i \in T$ with $\delta(u,i) = 0$.
**endfor**
Let $\bar{G} = (\bar{V}, \bar{E})$ be the subgraph of $G$ induced by the remaining nonterminals.
$\bar{\delta}_{\min} \leftarrow \min\{\delta(u,v)/\max\{A_u, A_v\} \mid uv \in \bar{E},\ \delta(u,v) > 0\}$.
**for** every edge $uv \in \bar{E}$, **do**
    $\tilde{\delta}(uv) \leftarrow \lceil \delta(u,v)/(\bar{\delta}_{\min} \cdot \max\{A_u, A_v\}) \rceil$,
    $\tilde{c}(uv) \leftarrow c(u,v) \cdot \max\{A_u, A_v\}$,
**endfor**
Execute KPR$(\bar{G}, \tilde{\delta}, \tilde{c}, 1/(2\lambda r^2 \bar{\delta}_{\min}), r)$.
**for** each resulting cluster $C \subseteq \bar{V}$, **do**
    Choose $x \in C$ to minimize $A_x$.
    Choose $i \in T$ such that $\delta(x,i) = A_x$.
    Set $f(u) \leftarrow i$ for all $u \in C$.
**endfor**
```

We first establish a few simple facts about this rounding procedure. Let $\tilde{Z} = \sum_{uv \in \bar{E}} \tilde{\delta}(uv)\tilde{c}(uv)$.

Claim 3.2. $\tilde{Z} \le 2Z/\bar{\delta}_{\min}$.

*Proof.* Note that if $\delta(u,v) > 0$, then $\delta(u,v)/(\bar{\delta}_{\min} \cdot \max\{A_u, A_v\}) \ge 1$; hence $\tilde{\delta}(uv) = \lceil \delta(u,v)/(\bar{\delta}_{\min} \cdot \max\{A_u, A_v\}) \rceil \le 2\delta(u,v)/(\bar{\delta}_{\min} \cdot \max\{A_u, A_v\})$. We have

$$\begin{aligned}
\sum_{uv \in \bar{E}} \tilde{\delta}(uv)\tilde{c}(uv) &= \sum_{uv \in \bar{E}} \left\lceil \frac{\delta(u,v)}{\bar{\delta}_{\min} \cdot \max\{A_u, A_v\}} \right\rceil \cdot (c(u,v) \cdot \max\{A_u, A_v\}) \\
&\le \frac{2}{\bar{\delta}_{\min}} \sum_{uv \in \bar{E}} \delta(u,v)c(u,v) \\
&\le \frac{2}{\bar{\delta}_{\min}} \sum_{uv \in E} \delta(u,v)c(u,v) \\
&= 2Z/\bar{\delta}_{\min}. \qquad \square
\end{aligned}$$

Claim 3.3. *The total $\tilde{c}$-cost of the edges removed by KPR$(\bar{G}, \tilde{\delta}, \tilde{c}, 1/(2\lambda r^2 \bar{\delta}_{\min}), r)$ is at most $4\kappa\lambda r^3 Z$, where $\kappa$ and $\lambda$ are the constants from Theorem* 3.1*. Moreover, each of the resulting clusters $C$ has $\tilde{\delta}$-diameter at most $1/(2\bar{\delta}_{\min})$.*

*Proof.* By Theorem 3.1, the sum of $\tilde{c}(uv)$ over edges $uv$ with $u, v$ in different clusters is at most $(\kappa r/\gamma)\tilde{Z}$. By Claim 3.2, this is at most $4\kappa\lambda r^3 Z$ (since $\gamma = 1/(2\lambda r^2 \bar{\delta}_{\min})$). Also, by Theorem 3.1, the $\tilde{\delta}$-diameter of each resulting cluster $C$ is at most $1/(2\bar{\delta}_{\min})$. ◻

We now relate the $\tilde{\delta}$-distances to the original $\delta$-distances.

LEMMA 3.4. *Let $u, v \in \bar{V}$. If the length of a shortest path in $\bar{G}$ between $u$ and $v$ with respect to edge lengths $\tilde{\delta}$ is at most $1/(2\bar{\delta}_{\min})$, then $\delta(u,v) \le A_u$.*

*Proof.* Let $\langle u = x_0, x_1, \ldots, x_j = v\rangle$ be a shortest path in $\bar{G}$ between $u$ and $v$ with respect to the edge lengths $\tilde{\delta}$. For $1 \le t \le j$, let $s_t = \sum_{i=1}^{t} \delta(x_{i-1}, x_i)$. By the triangle inequality, $A_{x_t} \le A_u + \sum_{i=1}^{t} \delta(x_{i-1}, x_i) = A_u + s_t$. Note that $s_1 \le s_2 \le \cdots \le s_j$. Therefore, for $i \le j$, $\delta(x_{i-1}, x_i)/\max\{A_{x_{i-1}}, A_{x_i}\} \ge \delta(x_{i-1}, x_i)/(A_u + s_i) \ge \delta(x_{i-1}, x_i)/(A_u + s_j)$. Also, $\tilde{\delta}(x_{i-1}, x_i) \ge \delta(x_{i-1}, x_i)/(\max\{A_{x_{i-1}}, A_{x_i}\}\bar{\delta}_{\min})$, and therefore $\delta(x_{i-1}, x_i)/\max\{A_{x_{i-1}}, A_{x_i}\} \le \bar{\delta}_{\min}\tilde{\delta}(x_{i-1}, x_i)$. Using this, we have $s_j/(A_u + s_j) = \sum_{i=1}^{j} \delta(x_{i-1}, x_i)/(A_u + s_j) \le \bar{\delta}_{\min} \sum_{i=1}^{j} \tilde{\delta}(x_{i-1}, x_i) \le \bar{\delta}_{\min}/(2\bar{\delta}_{\min}) = 1/2$, where the last inequality follows from the hypothesis that the length of $\langle x_0, x_1, \ldots, x_j\rangle$ is at most $1/(2\bar{\delta}_{\min})$. We conclude that $s_j \le A_u$. Finally, notice that, by the triangle inequality, $\delta(u,v) \le s_j$. ◻

We are ready to analyze the performance of the rounding procedure.

LEMMA 3.5. *Let $r > 0$ be an integer. Then for every input graph $G$ which is $K_{r,r}$-minor–free, for every feasible solution to (MET) of weight $Z$, the above rounding procedure produces a 0-extension of weight at most $(4 + 16\kappa\lambda r^3)Z$, where $\kappa$ and $\lambda$ are the constants from Theorem* 3.1.

*Proof.* Let $uv \in E$ be an edge of $G$. If both endpoints $u, v \notin \bar{V}$, then each endpoint is either a terminal or a node at distance 0 from some terminal; hence $d(f(u), f(v)) = \delta(u,v)$.

If $u \notin \bar{V}$ and $v \in \bar{V}$, then $\delta(f(u), u) = 0$, and $v$, together with the cluster $C$ that contains it, is assigned to some terminal $i$. By the definition of the rounding procedure, there is a node $x \in C$ such that $\delta(x, i) = A_x \le A_v$. Combining Claim 3.3 and Lemma 3.4, we have $\delta(v, x) \le A_v$. Therefore, using the triangle inequality, $\delta(v, i) \le 2A_v$. Using the triangle inequality again, $d(f(u), f(v)) = \delta(f(u), f(v)) \le \delta(f(u), v) + \delta(v, i) \le \delta(f(u), v) + 2A_v$. However, $\delta(u,v) = \delta(f(u), v) \ge A_v$. Therefore, for any $u \notin \bar{V}$ and $v \in \bar{V}$

$$d(f(u), f(v)) \le 3\delta(u,v). \tag{3.1}$$

We are left with the edges $uv \in \bar{E}$. For $u \in \bar{V}$, let $C(u)$ denote the cluster containing $u$. Then

$$\sum_{uv \in \bar{E}} d(f(u), f(v))c(u,v) = \sum_{uv \in \bar{E}:\ C(u) \ne C(v)} d(f(u), f(v))c(u,v).$$

However, $d(f(u), f(v)) = \delta(f(u), f(v)) \le \delta(f(u), u) + \delta(u,v) + \delta(v, f(v)) \le \delta(u,v) + 2A_u + 2A_v \le \delta(u,v) + 4\max\{A_u, A_v\}$. The second inequality follows from the fact that, by the definition of the algorithm, for every nonterminal $u$, $f(u)$ is a terminal closest to some $x \in C(u)$ with $\delta(f(u), x) = A_x \le A_u$. As argued in the previous case, $\delta(x, u) \le A_u$. The inequality follows because, by the triangle inequality, $\delta(f(u), u) \le \delta(f(u), x) + \delta(x, u)$. Therefore,

$$\sum_{uv \in \bar{E}:\ C(u) \ne C(v)} d(f(u), f(v))c(u,v) \le \sum_{uv \in \bar{E}:\ C(u) \ne C(v)} \delta(u,v)c(u,v) + 4 \sum_{uv \in \bar{E}:\ C(u) \ne C(v)} \tilde{c}(uv)$$

$$\leq Z + 4 \sum_{uv \in \bar{E}:\ C(u) \neq C(v)} \tilde{c}(uv).$$

Now Claim 3.3 states that $\sum_{uv \in \bar{E}:\ C(u) \neq C(v)} \tilde{c}(uv) \leq 4\kappa\lambda r^3 Z$, and using this together with (3.1), we finish the proof of Lemma 3.5. ◻

We conclude with the main result of this section.

THEOREM 3.6. *Let $r > 0$ be a fixed integer. There is a deterministic polynomial-time $(4 + 16\kappa\lambda r^3)$-approximation algorithm for* 0-EXTENSION *in $K_{r,r}$-minor–free weighted graphs, where $\kappa$ and $\lambda$ are the constants from Theorem* 3.1.

*Proof.* Solve (MET) optimally and then use the rounding procedure from this section, which clearly can be implemented in polynomial time. Lemma 3.5 establishes the performance guarantee of this algorithm. ◻

**4. The integrality ratio.** In this section we use the max flow-min cut theorem to prove the following lower bound on the integrality ratio of the natural relaxation.

THEOREM 4.1. *There are $c > 0$ and infinitely many positive integers $k$ such that there is an instance of* 0-EXTENSION *with $k$ terminals for which the optimal value of the objective function is at least $c\sqrt{\lg k}$ times the optimal value of the relaxation.*

*Proof.* There are fixed positive $\Delta$ and $\alpha$ such that there is an infinite family of expanders of maximum degree at most $\Delta$ having expansion at least $\alpha$, i.e., graphs $G$ of maximum degree at most $\Delta$ such that, for any subset $S$ of at most $|V(G)|/2$ nodes, there are at least $\alpha|S|$ nodes not in $S$ which are adjacent to at least one node of $S$. For any expander $G$ with $n = |V(G)|$ sufficiently large, define $l = \lceil \sqrt{\lceil \lg n \rceil} \rceil \leq n$ and $k = \lceil n/l \rceil$. Choose any $k$ distinct nodes $h_1, h_2, \ldots, h_k$ in $V$. For $i = 1$ to $k$, add $l$ new nodes and $l$ new edges to the current graph, forming a new path $P_i$ starting at $h_i$ and ending at some new node; label that new node $i$. Let the new graph be $G' = (V', E')$. Now $n' = |V'| = n + kl \leq n + (1 + n/l) \cdot l \leq n + (n + l) \leq n + 2n = 3n$ vertices. $|E'| = |E| + kl \leq n(\Delta/2 + 2)$.

Now define an instance $I$ of 0-EXTENSION as follows. The vertex set is $V'$. The set $T$ of terminals is $\{1, 2, 3, \ldots, k\}$. Define $d(i,j)$, for terminals $1 \leq i, j \leq k$, to be the distance in $G'$ between $i$ and $j$. Define $c(u,v)$ to be 1 if $uv \in E'$, and $c(u,v) = 0$ otherwise.

We now show that the integrality ratio for this instance $I$ is large. First, we study the relaxation. Define $\delta(u,v)$ to be the distance in $G'$ between $u$ and $v$. It is clear that $\delta(i,j) = d(i,j)$ if $i, j$ in $T$. It is also clear that $\delta$ is a semimetric on $G'$. It follows that $\sum_{u<v} c(u,v)\delta(u,v) = |E'| \leq (\Delta/2 + 2)n$ (since adjacent vertices in $G'$ are at distance 1).

Now we prove that there is a universal $c > 0$ such that any feasible solution to $I$, i.e., any function $f : V' \to T$ with $f(t) = t$ for all terminals $t \in T$, satisfies $\sum_{u<v} c(u,v)d(f(u), f(v)) \geq cn\sqrt{\lg n}$. Note first of all that the minimum distance between two distinct terminals $i, j$ is at least $2l \geq 2\sqrt{\lg n}$. We will see in Lemma 4.2, however, that there are at least $k/2$ terminals for which the distance to terminal $i^*$ is at least $\epsilon \lg n$, $\epsilon$ a fixed positive constant, not just $\sqrt{\lg n}$, for any $i^* \in T$.

LEMMA 4.2. *For any $i^* \in T$, there are at least $k/2$ vertices $h_i$ in $G$ whose distance from $h_{i^*}$ exceeds $a = \lceil \frac{\lg k}{2 \lg \Delta} \rceil$.*

*Proof.* For a contradiction, assume that there are more than $k/2$ vertices of $G$ at distance at most $a$ from $h_{i^*}$. By the degree bound, the number of vertices in $G$ at distance at most $a$ from $h_{i^*}$ is at most $1 + \Delta^1 + \Delta^2 + \cdots + \Delta^a < \Delta^{a+1}$. Hence $k/2 < \Delta^{a+1}$. Hence $-1 + \frac{-1 + \lg k}{\lg \Delta} < a$, $\lg k < 2 + 4 \lg \Delta$, and $k < 4\Delta^4$. Require that $n$ be large enough that $k$, which goes to $\infty$ with $n$, is at least $4\Delta^4$, giving us a contradiction. $\square$

Let $R_i = \{v \in V \subseteq V' | f(v) = i\}$. We have two cases.

*Case* 1. $|R_i| \leq n/2$ for all $i$. If $uv \in E$, $u \in R_i$, $v \in R_j$, $i \neq j$, then $d(f(u), f(v)) = d(i,j) = \delta(i,j) \geq 2\sqrt{\lg n}$. Because $G$ is an expander and $|R_i| \leq n/2$ for all $i$, for each $i$ the number of edges $uv$, $u \in R_i$, $v \notin R_i$, is at least $\alpha|R_i|$. Hence $\sum_{u<v,u,v\in V} c(u,v)d(f(u),f(v)) \geq (1/2) \times \sum_{i=1}^{k} \alpha|R_i|(2\sqrt{\lg n}) = \alpha \cdot n\sqrt{\lg n}$. (Each "cross edge" is counted twice.)

*Case* 2. Some $R_i$, say $R_1$, has size exceeding $n/2$. We will use expansion and the max flow-min cut theorem to prove our theorem.

Choose any $\lceil k/2 \rceil$ terminals $i$ such that the distance in $G$ between $h_i$ and $h_1$ is at least $a = \lceil \frac{\lg k}{2 \lg \Delta} \rceil$; by Lemma 4.2, such terminals exist. Let $F$ be the set of chosen terminals. Insist that $n \geq 16$, so that $a \geq \frac{\lg n}{4 \lg \Delta}$.

Let $V^* = V \cup (\cup_{i\in F} P_i)$. Build a (directed) network $N$ on $V^* \cup \{s,t\}$, $s,t$ being new nodes, as follows. Start with the subgraph of $G'$ induced by $V^*$, and replace each edge by a pair of antiparallel arcs, each of capacity one. Add arcs $(u,t)$ for all $u \in R_1$, each of capacity $\infty$. Add arcs $(s,i)$ for all $i \in F$, each of capacity $\infty$. Because $R_1 \subseteq V$ and, for all $i \in F$, $i \notin V$, $N$ has a finite capacity $s \to t$ cut defined by $\{s\} \cup F$.

Now choose any finite capacity $s \to t$ cut $C^* = (S^*, \bar{S^*})$ in $N$, $s \in S^*$, $t \notin S^*$. $S^* \supseteq F$ and $S^* \cap R_1 = \emptyset$. Let $S = S^* \cap V$ (possibly $S = \emptyset$). Because $|R_1| \geq n/2$, $|S| \leq n/2$. Let $C$ be the set of arcs $(u,v)$ with $u \in S, v \in V - S$. By the expansion of $G$, $|C| \geq \alpha|S|$. Let $M = \{i | i \in F, h_i \notin S\}$. Corresponding to each $i \in F$ such that $h_i \notin S$ there is at least one an arc of $P_i$ in $C^* - C$, $|M|$ in total. Thus the total number of arcs in $C^*$ is at least $\alpha|S| + |M| \geq \alpha(|S| + |M|) \geq \alpha|F| \geq \alpha k/2$, the penultimate inequality following from the fact that either $h_i \in S$ or $i \in M$, for all $i \in F$. It follows that the minimum capacity of an $s \to t$ cut in $N$ is at least $\alpha k/2$.

By the max flow-min cut theorem, there are at least $\alpha k/2$ arc-disjoint paths from an $i \in F$ to some vertex in $R_1$. If $Q = \langle i = v_{i0}, v_{i1}, v_{i2}, v_{i3}, \ldots, v_{is} \in R_1 \rangle$ is such a path, then, using $f(i) = i$, $f(v_{is}) = 1$, we have $\sum_{j=0}^{s-1} d(f(v_{ij}), f(v_{i,j+1})) \geq d(f(i), f(v_{is})) = d(i,1) \geq a$, $a$ being at least $\frac{\lg n}{4 \lg \Delta}$. Since the paths are arc-disjoint and there are at least $\frac{\alpha k}{2}$ of them, we infer that $\sum_{u<v:u,v\in V'} c(u,v)d(f(u),f(v)) \geq \frac{\alpha k}{2} \frac{\lg n}{4 \lg \Delta}$.

Using the definition of $k$, this last sum is at least $(\alpha/(16 \lg \Delta)) \cdot n\sqrt{\lg n}$. Since we have a feasible solution to (MET) of value at most $|E'| \leq (\Delta/2 + 2)n$, the ratio between the two is at least

$$\frac{\alpha}{(8 \lg \Delta)(\Delta + 4)} \sqrt{\lg n} \geq \frac{\alpha}{(8 \lg \Delta)(\Delta + 4)} \sqrt{\lg k}.$$

Choose $c = \alpha/((8 \lg \Delta)(\Delta + 4))$, and the proof of Theorem 4.1 is complete. $\square$

The following theorem shows that the above analysis is asymptotically tight. It also suggests an alternative rounding procedure that for some instances performs better than the results in section 2 (though in general it is far worse).

THEOREM 4.3. *There is a polynomial-time algorithm that takes as input a connected graph $G = (V,E)$ and a subset $T \subseteq V$ of terminals and computes a function $f : V \to T$ with $f(i) = i$ for all $i \in T$ such that*

$$\sum_{uv\in E} d(f(u), f(v)) \leq 3\sqrt{d_{\max}}|E|,$$

*where $d(u,v)$ is the minimum number of edges in a path between $u$ and $v$ and $d_{\max} = \max_{uv} d(u,v)$.*

*Proof.* Add a new vertex $s$ to $G$ and connect $s$ to all the terminals. Run a breadth-first search starting at $s$, computing for every node $v \in V$ its distance $l(v)$ from $s$. Note that for every $v \in V$, $1 \le l(v) \le d_{\max} + 1$. Partition $E$ into classes $C_i$, for $i = 1, 2, \ldots, d_{\max}+1$: Place edge $uv \in E$ in $C_i$ for $i = \min\{l(u), l(v)\}$. Let $r$ be the smallest positive integer such that $|C_r| \le |E|/\sqrt{d_{\max}}$. As $\sum_i |C_i| = |E|$, $r \le \sqrt{d_{\max}}$. We now define $f$. Let $t$ be an arbitrary terminal. For every $v \in V$ with $l(v) > r$, set $f(v) = t$. For every $v \in V$ with $l(v) \le r$, set $f(v) = t_v$, where $t_v$ is a terminal closest to $v$ in $G$.

If $uv \in C_i$, then $d(u, t_u) \le i$ and $d(v, t_v) \le i$, and at least one of the inequalities is strict. Therefore $d(t_u, t_v) \le d(t_u, u) + 1 + d(v, t_v) \le 2i$. Consider an edge $uv \in C_i$. If $i \le r - 1$, then both $l(u), l(v) \le r$, so $d(f(u), f(v)) = d(t_u, t_v) \le 2i \le 2r - 2$. If $i > r$, then both $l(u), l(v) > r$, so $d(f(u), f(v)) = d(t, t) = 0$. For the remaining case of $i = r$ we use the trivial bound $d(f(u), f(v)) \le d_{\max}$. Using the bounds on $r$ and on $|C_r|$, we have

$$\sum_{uv\in E} d(f(u), f(v)) \le \sum_{i<r} \sum_{uv\in C_i} (2r-2) + \sum_{uv\in C_r} d_{\max} + \sum_{i>r} \sum_{uv\in C_i} 0 < 3\sqrt{d_{\max}}\ |E|. \qquad \square$$

It is interesting to note that for bounded degree expanders the bounds are much better. Using arguments similar to those of the proofs of Theorems 4.1 and 4.3, we can prove the following result.

THEOREM 4.4.

1. *There are a positive integer $\Delta$ and a constant $\kappa > 0$ such that for infinitely many $k$ there is an expander $G = (V, E)$ with maximum degree at most $\Delta$, $|V|$ being $O(k \log k / \log\log k)$, and a set $T \subseteq V$ of size $k$, such that the integrality ratio of* (MET) *on the* 0*-extension instance defined by $G$, $T$, and the $G$-path metric on $T$ is at least $\kappa \log\log k$.*
2. *For all positive constants $\Delta$ and $\alpha$, there is a $\lambda$ such that if $n$ is sufficiently large, the optimal cost of* 0-EXTENSION *on the* 0*-extension instance defined by any $n$-node expander $G$ of maximum degree at most $\Delta$, with expansion constant at least $\alpha$, any set $T \subseteq V$ of terminals, and the $G$-path metric on $T$, is at most $\lambda n \lg\lg n$ (and there is a polynomial-time algorithm which computes a solution to the* 0*-extension problem of cost at most $\lambda n \lg\lg n$).*

*Proof sketch.* For the first part, choose a family of expanders of maximum degree at most $\Delta$. Given $k$, choose an $n$ and an $n$-node expander from the family such that $k$ is approximately equal to $n(\lg\lg n)/\lg n$. Now we modify the proof of Theorem 4.1. Instead of choosing $h_1, h_2, \ldots, h_k$ to be any $k$ nodes, choose $k$ nodes with minimum pairwise distance $\Omega(\lg\lg n)$, as follows. Choose the first node arbitrarily and choose the $j$th node to be at distance $\Omega(\lg\lg n)$ from the $j - 1$ previously chosen nodes. The iterative choices are possible since, for some suitable constant $c$, the number of nodes within distance at most $c \lg\lg n$ from $j - 1$ given points is at most $j\Delta^{1+c\lg\lg n} < n$. Call the $k$ nodes $1, 2, \ldots, k$, and make them the terminals. The 0-extension instance is now defined on this graph $G$, relative to its shortest path metric. It is clear that the optimal value of (MET) is $O(n)$.

Given any vertex $v$ of $G$, arguing as in the proof of Lemma 4.2, there are at least $k/2$ terminals in $G$ whose distance from $v$ is at least $a$, with $a$ being $\Omega(\log n)$.

Now we study Cases 1 and 2 from the proof of Theorem 4.1. In Case 1, we have $d(f(u), f(v)) = d(i, j)$, which is $\Omega(\log\log n)$, so the total cost is $\Omega(n \log\log n)$.

The argument of Case 2 applies as before: There are at least $\alpha k/2$ (which is $\Omega(n(\log\log n)/\log n)$) paths, each contributing at least $a$ (which is $\Omega(\log n)$), or $\Omega(n \log\log n)$ in total.

For the second part of Theorem 4.4, let $\Delta, \alpha$ be positive and let $G = (V, E)$ be an $n$-node expander of maximum degree at most $\Delta$ and expansion constant at least $\alpha$. Let $T = \{1, 2, \ldots, k\} \subseteq V$ be the set of terminals. Note that there is a constant $C = C(\Delta, \alpha)$ such that $C \lg n$ bounds the diameter from above.

Consider the 0-extension instance defined by $G$, $T$, and the $G$-path metric on $T$. There are two cases.

*Case* 1. If $k \leq n/\lg n$, set $f(v) = 1$ for all $v \in V - T$. The number of edges $\{u, v\}$ that are cut is at most $\Delta \cdot k$, and for each, $d(f(u), f(v)) \leq C \lg n$. Hence the total cost is at most $C\Delta k \lg n \leq C\Delta n$.

*Case* 2. If $k > n/\lg n$, add a dummy source $s$ which is adjacent to all (and only) the terminals. Do a breadth-first search starting from $s$ until there are no more than $n/\lg n$ unreached vertices. Since $\Delta, \alpha$ are constant, the number of reached nodes increases by a constant factor in each BFS step, until the number of reached nodes exceeds $n/2$. Afterward, the number of unreached nodes drops by a constant factor in each BFS step. Altogether, where $d$ is the number of BFS steps needed, $d$ is $O(\lg \lg n)$ (because $\Delta, \alpha$ are constant). Now assign $f(v)$ for nonterminals $v$ as follows. If $v$ is unreached, set $f(v) = 1$. Otherwise, set $f(v)$ equal to the terminal nearest to $v$. Now consider $\sum c(u, v)d(f(u), f(v))$. If $u, v$ are both reached, the contribution $c(u, v)d(f(u), f(v)) \leq d + 1 + d$, which is $O(\lg \lg n)$. If $u, v$ are both unreached, the contribution is 0. There are at most $\Delta n/\lg n$ edges $\{u, v\}$ with $u$ reached and $v$ not, and each contributes at most $C \lg n$, or at most $\Delta C n$ in total for these edges. Hence the overall total is $O(n \lg \lg n)$. $\square$

# AN OPTIMAL ALGORITHM FOR THE MAXIMUM-DENSITY SEGMENT PROBLEM*

KAI-MIN CHUNG† AND HSUEH-I LU‡

**Abstract.** We address a fundamental problem arising from analysis of biomolecular sequences. The input consists of two numbers $w_{\min}$ and $w_{\max}$ and a sequence $S$ of $n$ number pairs $(a_i, w_i)$ with $w_i > 0$. Let *segment* $S(i,j)$ of $S$ be the consecutive subsequence of $S$ between indices $i$ and $j$. The *density* of $S(i,j)$ is $d(i,j) = (a_i + a_{i+1} + \cdots + a_j)/(w_i + w_{i+1} + \cdots + w_j)$. The *maximum-density segment problem* is to find a maximum-density segment over all segments $S(i,j)$ with $w_{\min} \le w_i + w_{i+1} + \cdots + w_j \le w_{\max}$. The best previously known algorithm for the problem, due to Goldwasser, Kao, and Lu [*Proceedings of the Second International Workshop on Algorithms in Bioinformatics*, R. Guigó and D. Gusfield, eds., Lecture Notes in Comput. Sci. 2452, Springer-Verlag, New York, 2002, pp. 157–171], runs in $O(n \log(w_{\max} - w_{\min} + 1))$ time. In the present paper, we solve the problem in $O(n)$ time. Our approach bypasses the complicated *right-skew decomposition*, introduced by Lin, Jiang, and Chao [*J. Comput. System Sci.*, 65 (2002), pp. 570–586]. As a result, our algorithm has the capability to process the input sequence in an online manner, which is an important feature for dealing with genome-scale sequences. Moreover, for a type of input sequences $S$ representable in $O(m)$ space, we show how to exploit the sparsity of $S$ and solve the maximum-density segment problem for $S$ in $O(m)$ time.

## 1. Introduction.

We address the following fundamental problem: The input consists of two numbers $w_{\min}$ and $w_{\max}$ and a sequence $S$ of number pairs $(a_i, w_i)$ with $w_i > 0$ for $i = 1, \ldots, n$. A *segment* $S(i,j)$ is a consecutive subsequence of $S$ from position $i$ to position $j$. The *width* $w(i,j)$ of $S(i,j)$ is $w_i + w_{i+1} + \cdots + w_j$. The *density* $d(i,j)$ of $S(i,j)$ is $(a_i + a_{i+1} + \cdots + a_j)/w(i,j)$. It is not difficult to see that with an $O(n)$-time preprocessing to compute all $O(n)$ prefix sums $a_1 + a_2 + \cdots + a_j$ and $w_1 + w_2 + \cdots + w_j$, the density of any segment can be computed in $O(1)$ time. $S(i,j)$ is *feasible* if $w_{\min} \le w(i,j) \le w_{\max}$. The *maximum-density segment* problem is to find a maximum-density segment over all $O(n(w_{\max} - w_{\min} + 1))$ feasible segments.

This problem arises from the investigation of the nonuniformity of nucleotide composition within genomic sequences, which was first revealed through thermal melting and gradient centrifugation experiments [21, 28]. The GC content of the DNA sequences in all organisms varies from 25% to 75%. GC-ratios have the greatest variation among bacterial DNA sequences, while the typical GC-ratios of mammalian

genomes stay in the range 45–50%. Despite intensive research effort in the past two decades, the underlying causes of the observed heterogeneity remain debatable [2, 3, 5, 8, 9, 10, 11, 18, 40, 42]. Researchers [32, 39] observed that the extent of the compositional heterogeneity in a genomic sequence strongly correlates with its GC content regardless of genome size. Other investigations showed that gene length [7], gene density [44], patterns of codon usage [37], distribution of different classes of repetitive elements [7, 38], number of isochores [2], lengths of isochores [32], and recombination rate within chromosomes [12] are all correlated with GC content. More research related to GC-rich segments can be found in [16, 17, 20, 23, 29, 31, 35, 41, 43] and references therein.

In the most basic form of the maximum-density segment problem, the sequence $S$ corresponds to the given DNA sequence, where $a_i = 1$ if the corresponding nucleotide in the DNA sequence is a G or C, and $a_i = 0$ otherwise. In the work of Huang [19], sequence entries took on values of $p$ and $1 - p$ for some real number $0 \le p \le 1$. More generally, we can look for regions where a given set of patterns occurs very often. In such applications, $a_i$ could be the relative frequency with which the corresponding DNA segments appear in the given patterns. Further natural applications of this problem can be designed for sophisticated sequence analysis such as mismatch density [36], ungapped local alignments [1], annotated multiple sequence alignments [39], promoter mapping [22], and promoter recognition [33].

For the *uniform* case, i.e., $w_i = 1$ for all indices $i$, Nekrutenko and Li [32] and Rice, Longden, and Bleasby [34] employed algorithms for the case $w_{\min} = w_{\max}$, which is trivially solvable in $O(n)$ time. More generally, when $w_{\min} \ne w_{\max}$, the problem is also easily solvable in $O(n(w_{\max} - w_{\min} + 1))$ time, linear in the number of feasible segments. Huang [19] studied the case where $w_{\max} = n$, i.e., there is effectively no upper bound on the width of the desired maximum-density segments. He observed that an optimal segment exists with width at most $2w_{\min} - 1$. Therefore, this case is equivalent to the case with $w_{\max} = 2w_{\min} - 1$ and can be solved in $O(nw_{\min})$ time in a straightforward manner. Lin, Jiang, and Chao [27] gave an $O(n \log w_{\min})$-time algorithm for this case based on right-skew decompositions of a sequence. (See [26] for related software.) The case with general $w_{\max}$ was first investigated by Goldwasser, Kao, and Lu [13, 14], who gave an $O(n)$-time algorithm for the uniform case. Recently, Kim [25] showed an alternative algorithm based upon a geometric interpretation of the problem, which basically relates the maximum-density segment problem to the fundamental *slope selection problem* in computational geometry [4, 6, 24, 30]. Unfortunately, Kim's analysis of time complexity has a flaw which seems difficult to fix.[1] For the general (i.e., *nonuniform*) case, Goldwasser, Kao, and Lu [13] also gave an $O(n \log(w_{\max} - w_{\min} + 1))$-time algorithm. By bypassing the complicated preprocessing step required in [13], we successfully reduce the time required for the general case down to $O(n)$. Our result is based upon the following set of equations, stating that the order of $d(x, y)$, $d(y + 1, z)$, and $d(x, z)$ with $x \le y < z$ can be determined by the

[1]Kim claims that all the progressive updates of the lower convex hulls $L_j \cup R_j$ can be done in overall linear time. The paper only sketches how to obtain $L_{j+1} \cup R_{j+1}$ from $L_j \cup R_j$. (See the fourth-to-last paragraph of p. 340 in [25].) Unfortunately, Kim seems to overlook the marginal cases when the upper bound $w_{\max}$ forces the $p_z$ of $L_j \cup R_j$ to be deleted from $L_{j+1} \cup R_{j+1}$. As a result, obtaining $L_{j+1} \cup R_{j+1}$ from $L_j \cup R_j$ could be much more complicated than Kim's sketch. A naive implementation of Kim's algorithm still takes $\Omega(n(w_{\max} - w_{\min} + 1))$ time in the worst case. We believe that any correct implementation of Kim's algorithm requires $\Omega(n \log(w_{\max} - w_{\min} + 1))$ time in the worse case.

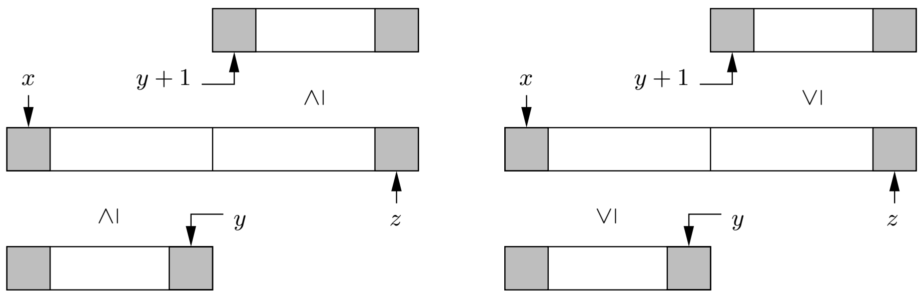

FIG. 1.1. *An illustration for* (1.1)*: There exist only two possibilities for the order among* $d(x,y), d(x,z), d(y+1,z)$.

order of any two of them:

$$\begin{aligned} d(x,y) \le d(y+1,z) \Leftrightarrow d(x,y) \le d(x,z) \Leftrightarrow d(x,z) \le d(y+1,z),\\ d(x,y) \ge d(y+1,z) \Leftrightarrow d(x,y) \ge d(x,z) \Leftrightarrow d(x,z) \ge d(y+1,z). \end{aligned} \tag{1.1}$$

(Both equations can be easily verified by observing the existence of some number $\rho$ with $0 < \rho < 1$ and $d(x,z) = \rho \cdot d(x,y) + (1-\rho) \cdot d(y+1,z)$. See Figure 1.1.) Our algorithm is capable of processing the input sequence in an online manner, which is an important feature for dealing with genome-scale sequences.

For bioinformatics applications, e.g., in [1, 22, 33, 36, 39], the input sequence $S$ is usually very *sparse*. That is, $S$ can be represented by $m = o(n)$ triples

$$(a'_1, w'_1, n_1), (a'_2, w'_2, n_2), \ldots, (a'_m, w'_m, n_m)$$

with $0 = n_0 < n_1 < n_2 < \cdots < n_m = n$ to signify that $(a_i, w_i) = (a'_j, w'_j)$ holds for all indices $i$ and $j$ with $n_{j-1} < i \le n_j$ and $1 \le j \le m$. If $w'_j = 1$ holds for all $1 \le j \le m$, we show how to exploit the sparsity of $S$ and solve the maximum-density problem for $S$ given in the above compact representation in $O(m)$ time.

The remainder of the paper is organized as follows. Section 2 shows the main algorithm. Section 3 explains how to cope with the simple case that the width upper bound $w_{\max}$ is ineffective. Section 4 takes care of the more complicated case that $w_{\max}$ is effective. Section 5 explains how to exploit the sparsity of the input sequence for the uniform case.

**2. The main algorithm.** For any integers $x$ and $y$, let $[x, y]$ denote the set $\{x, x+1, \ldots, y\}$. Without loss of generality, we may assume that $w_1 + w_2 + \cdots + w_n \ge w_{\min}$ and $w_i \le w_{\max}$ holds for each $i = 1, 2, \ldots, n$. Throughout the paper, we need the following definitions and notation with respect to the input length-$n$ sequence $S$ and width bounds $w_{\min}$ and $w_{\max}$. Define $\phi(x, y)$ to be the largest index $z \in [x, y]$ that minimizes $d(x, z)$. That is, $S(x, \phi(x, y))$ is the longest minimum-density prefix of $S(x, y)$. Let $j_0$ be the smallest index with $w(1, j_0) \ge w_{\min}$. Let $J = [j_0, n]$. For each $j \in J$, let $\ell_j$ be the smallest index $i$ with $w(i, j) \le w_{\max}$, and let $r_j$ be the largest index $i$ with $w(i, j) \ge w_{\min}$. That is, $S(i, j)$ is feasible if and only if $i \in [\ell_j, r_j]$. (Figure 2.1 is an illustration for the definitions of $\ell_j$ and $r_j$.) Clearly, for the uniform case, we have $\ell_{i+1} = \ell_i + 1$ and $r_{i+1} = r_i + 1$. As for the general case, we know only that $\ell_j$ and $r_j$ are both (not necessarily strictly) increasing. One can easily compute all $\ell_j$ and $r_j$ in $O(n)$ time.

Let $i^*_j$ be the largest index $k \in [\ell_j, r_j]$ with $d(k, j) = \max\{d(i, j) \mid i \in [\ell_j, r_j]\}$. There must be an index $j^*$ such that $S(i^*_{j^*}, j^*)$ is a maximum-density segment of

FIG. 2.2. *Our main algorithm.*

$S$. Therefore, a natural but seemingly difficult possibility for solving the maximum-density segment problem would be to compute $i_j^*$ for all indices $j \in J$ in $O(n)$ time. Instead, our approach is to compute a pair $(i_j, j)$ of indices with $i_j \in [\ell_j, r_j]$ for each index $j \in J$ by the algorithm shown in Figure 2.2. More specifically, each iteration of our algorithm, based upon (1.1), keeps chopping off the lowest-density prefix without affecting the feasibility of the remaining segment until its density does not go any higher. For brevity of presentation, each algorithm throughout the paper outputs a linear number of index pairs $(i, j)$. (See, e.g., step 4 of algorithm MAIN shown in Figure 2.2.) Clearly, it takes a linear-time postprocessing for the produced index pairs to obtain one that maximizes $d(i, j)$. The rest of the section ensures the correctness of our algorithm by showing $i_{j^*} = i_{j^*}^*$, and thus reduces the maximum-density segment problem to implementing our algorithm to run in $O(n)$ time.

LEMMA 2.1. *The index returned by function call* BEST$(\ell, r, j)$ *is the largest index* $i \in [\ell, r]$ *that maximizes* $d(i, j)$.

*Proof.* Let $i^*$ be the largest index in $[\ell, r]$ that maximizes $d(i, j)$, i.e., $d(i^*, j) = \max_{i \in [\ell, r]} d(i, j)$. Let $i_j$ be the index returned by function call BEST$(\ell, r, j)$. We show $i_j = i^*$ as follows. If $i_j < i^*$, then $i_j < r$. By the condition of the while-loop at step 2 of BEST, we know $d(i_j, \phi(i_j, r-1)) > d(i_j, j)$. By $d(i_j, j) \leq d(i^*, j)$ and (1.1), we have $d(i_j, i^*-1) \leq d(i_j, j)$. It follows that $d(i_j, i^*-1) < d(i_j, \phi(i_j, r-1))$, contradicting the definition of $\phi(i_j, r-1)$.

On the other hand, suppose that $i_j > i^*$. By definition of BEST, there must be an index $i \in [\ell, r]$ with $i < r$, $d(i, \phi(i, r-1)) \leq d(i, j)$, and $i \leq i^* < \phi(i, r-1) + 1$. If $i = i^*$, by (1.1) we have $d(i^*, \phi(i^*, r-1)) \leq d(i^*, j) \leq d(\phi(i^*, r-1) + 1, j)$, where the last inequality contradicts the definition of $i^*$. Now that $i < i^*$, we have $d(i^*, j) \geq d(i, j) \geq d(i, i^*-1) \geq d(i, \phi(i, r-1)) \geq d(i^*, \phi(i, r-1))$, where (a) the first inequality is by definition of $i^*$, (b) the second inequality is by (1.1) and the first inequality, (c) the third inequality is by $i^* \le \phi(i, r-1)$ and the definition of $\phi(i, r-1)$, and (d) the last inequality is by (1.1) and the third inequality. It follows from $d(i^*, j) \ge d(i^*, \phi(i, r-1))$ and (1.1) that $d(\phi(i, r-1)+1, j) \ge d(i^*, j)$, contradicting the definition of $i^*$ by $i^* < \phi(i, r-1)+1$. ∎

THEOREM 2.2. *Algorithm* MAIN *correctly solves the maximum-density segment problem.*

*Proof.* We prove the theorem by showing $i_{j^*} = i^*_{j^*}$. By $\ell_{j_0} = i_{j_0-1} = 1$ and Lemma 2.1, the equality holds if $j^* = j_0$. The rest of the proof assumes $j^* > j_0$. By Lemma 2.1 and $\ell_{j^*} \le i^*_{j^*}$, it suffices to ensure $i_{j^*-1} \le i^*_{j^*}$. Assume for contradiction that there is an index $j \in [j_0, j^*-1]$ with $i_{j-1} \le i^*_{j^*} < i_j$. By $j < j^*$, we know $\ell_j \le i^*_{j^*}$. By Lemma 2.1 and $\max(\ell_j, i_{j-1}) \le i^*_{j^*} < i_j \le r_j$, we have $d(i_j, j) \ge d(i^*_{j^*}, j)$. It follows from (1.1) and $i^*_{j^*} < i_j$ that $d(i^*_{j^*}, j) \ge d(i^*_{j^*}, i_j - 1)$. By $\ell_{j^*} \le i^*_{j^*} < i_j \le r_{j^*}$ and the definition of $j^*$, we know $d(i^*_{j^*}, j^*) > d(i_j, j^*)$. It follows from $i^*_{j^*} < i_j$ and (1.1) that $d(i^*_{j^*}, i_j - 1) > d(i^*_{j^*}, j^*)$. Therefore, $d(i_j, j) \ge d(i^*_{j^*}, j) \ge d(i^*_{j^*}, i_j - 1) > d(i^*_{j^*}, j^*)$, contradicting the definition of $j^*$. ∎

One can verify that the value of $i$ increases by at least 1 each time step 3 of BEST is executed. Therefore, to implement the algorithm to run in $O(n)$ time, it suffices to maintain a data structure to support an $O(1)$-time query for each $\phi(i, r_j - 1)$ in step 2 of BEST.

## 3. Coping with ineffective width upper bound.

When $w_{\max}$ is ineffective, i.e., $w_{\max} \ge w(1, n)$, we have $\ell_j = 1$ for all $j \in J$. Therefore, the function call in step 3 of MAIN is exactly BEST$(i_{j-1}, r_j, j)$. Moreover, during the execution of the function call BEST$(i_{j-1}, r_j, j)$, the value of $i$ can only be $i_{j-1}$, $\phi(i_{j-1}, r_j - 1) + 1$, $\phi(\phi(i_{j-1}, r_j - 1) + 1, r_j - 1) + 1, \ldots, r_j$. Suppose that a subroutine call to UPDATE$(j)$ yields an array $\Phi$ of indices and two indices $p$ and $q$ of $\Phi$ with $p \le q$ and $\Phi[p] = i_{j-1}$ such that the following condition holds.

*Condition $C_j$* : $\Phi[q] = r_j$ and $\Phi[t] = \phi(\Phi[t-1], r_j - 1) + 1$ holds for each index $t \in [p+1, q]$. (See Figure 3.1 for an illustration.)

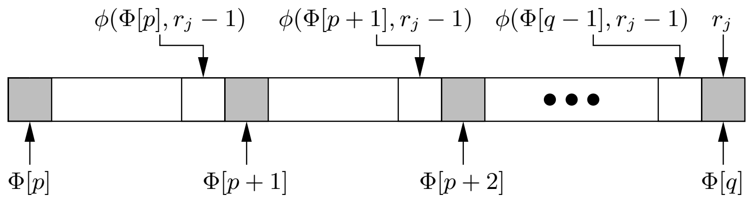

FIG. 3.1. *An illustration for Condition $C_j$.*

Then, the subroutine call to BEST$(i_{j-1}, r_j, j)$ can clearly be replaced by LBEST$(j)$, as defined in Figure 3.2. That is, LBEST$(j)$ can access the value of each $\phi(i, r_j - 1)$ by looking up $\Phi$ in $O(1)$ time. It remains to show how to implement UPDATE$(j)$ such that all $O(n)$ subroutine calls to UPDATE from step 3 of LMAIN run in overall $O(n)$ time. With the initialization of letting $p = q = r_{j_0-1} = \Phi[1] = 1$, as described at step 1 of algorithm LMAIN, Condition $C_{j_0-1}$ clearly holds before the subroutine call to UPDATE$(j_0)$. The following lemma is crucial in ensuring the correctness and efficiency of our implementation shown in Figure 3.2.

LEMMA 3.1. *For each index $j \in J$, the following statements hold:*

1. *If Condition $C_{j-1}$ holds right before calling* UPDATE$(j)$*, then Condition $C_j$ holds right after the subroutine call.*

```
ALGORITHM LMAIN.
1   let $p = q = r_{j_0-1} = \Phi[1] = 1$;
2   for $j = j_0$ to $n$ do {
3       call UPDATE($j$);
4       let $i_j =$ LBEST($j$);
5       output $(i_j, j)$;
6   }

FUNCTION LBEST($j$).
1   while $p < q$ and $d(\Phi[p], \Phi[p+1]-1) \le d(\Phi[p], j)$ do
2       let $p = p + 1$;
3   return $\Phi[p]$;

SUBROUTINE UPDATE($j$).
1   for $r = r_{j-1} + 1$ to $r_j$ do {
2       while $p < q$ and $d(\Phi[q-1], \Phi[q]-1) \ge d(\Phi[q-1], r-1)$ do
3           let $q = q - 1$;
4       let $q = q + 1$;
5       let $\Phi[q] = r$;
6   }
```

FIG. 3.2. *An efficient implementation for the case that $w_{\max}$ is ineffective.*

2. *If Condition $C_j$ holds right before calling* LBEST($j$)*, then the index returned by the function call is exactly that returned by* BEST($\Phi[p], \Phi[q], j$)*.*

*Proof.* Statement 1. We need the following condition.

*Condition $D_r$* : $\Phi[q] = r$ and $\Phi[t] = \phi(\Phi[t-1], r-1) + 1$ holds for each index $t \in [p+1, q]$.

Clearly, Condition $C_j$ is exactly Condition $D_{r_j}$. To prove the statement, we show that if Condition $D_{r-1}$ holds, then Condition $D_r$ holds right after executing steps 2–5 of UPDATE (i.e., an iteration of the for-loop of UPDATE), although the value of $q$ may change.

Consider the moment when step 4 of UPDATE is about to be executed. We first show that if $p < q$, then $\Phi[t] = \phi(\Phi[t-1], r-1) + 1$ holds for each $t \in [p+1, q]$. By the definition of $\phi$, we have

$$\phi(\ell, r-1) = \begin{cases} r-1 & \text{if } d(\ell, \phi(\ell, r-2)) \ge d(\ell, r-1), \\ \phi(\ell, r-2) & \text{otherwise.} \end{cases} \tag{3.1}$$

By Condition $D_{r-1}$, we know $\phi(\Phi[q-1], r-2) = \Phi[q]-1$. With $\ell = \Phi[q-1]$ plugged into (3.1), we know that if $d(\Phi[q-1], \Phi[q]-1) < d(\Phi[q-1], r-1)$, then $\phi(\Phi[q-1], r-1) = \phi(\Phi[q-1], r-2)$. It follows from the condition of step 2 of UPDATE that $\phi(\Phi[q-1], r-1) = \phi(\Phi[q-1], r-2)$. Furthermore, if $\phi(\ell, r-2) < r-2$, then one can prove as follows that $\phi(\phi(\ell, r-2)+1, r-1) = \phi(\phi(\ell, r-2)+1, r-2)$ implies $\phi(\ell, r-1) = \phi(\ell, r-2)$.

Let $m = \phi(\ell, r-2)$. By $\phi(m+1, r-1) = \phi(m+1, r-2)$, we have $d(m+1, \phi(m+1, r-1)) < d(m+1, r-1)$. By definition of $\phi$ and (1.1), we have $d(\ell, m) < d(\ell, \phi(m+1, r-1)) < d(m+1, \phi(m+1, r-1))$. As a result, we have $d(\ell, m) < d(m+1, r-1)$, which by (1.1) implies $d(\ell, m) < d(\ell, r-1)$. Thus $\phi(\ell, r-1) = \phi(\ell, r-2)$.

Therefore, $\phi(\Phi[t], r-1) = \phi(\Phi[t], r-2)$ implies $\phi(\Phi[t-1], r-1) = \phi(\Phi[t-1], r-2)$. As a result, $\phi(\Phi[t], r-1) = \phi(\Phi[t], r-2)$ holds for each $t \in [p, q-1]$. By Condition $D_{r-1}$, we know $\Phi[t] = \phi(\Phi[t-1], r-1) + 1$ holds for each $t \in [p+1, q]$.

Since the value of $q$ will be incremented by 1 after executing step 4 of UPDATE and $\Phi[q+1]$ will equal $r$ after executing step 5 of UPDATE, it remains to show $\phi(\Phi[q], r-1) = r-1$. Clearly, the equality holds if $\Phi[q] = r-1$, i.e., step 3 was not executed. If step 3 was executed at least once, then we know $d(\Phi[q], \Phi[q+1]-1) \geq d(\Phi[q], r-1)$, i.e., $d(\Phi[q], \phi(\Phi[q], r-2)) \geq d(\Phi[q], r-1)$. By plugging $\ell = \Phi[q]$ into (3.1), we know $\phi(\Phi[q], r-1) = r-1$.

Statement 2. By Condition $C_j$, one can easily verify that LBEST$(j)$ is a faithful implementation of BEST$(\Phi[p], \Phi[q], j)$. Therefore, the statement holds. ∎

LEMMA 3.2. *The implementation* LMAIN *solves the maximum-density problem for the case with ineffective* $w_{\max}$ *in* $O(n)$ *time.*

*Proof.* By Lemma 3.1(1) and the definitions of UPDATE and LBEST, both Condition $C_j$ and $\Phi[p] = i_{j-1}$ hold right after the subroutine call to UPDATE$(j)$. By Condition $C_j$ and Lemma 3.1(2), LBEST$(j)$ is a faithful implementation of BEST$(\Phi[p], \Phi[q], j)$. Therefore, the correctness of LMAIN follows from $\Phi[p] = i_{j-1}$, $\Phi[q] = r_j$, and Theorem 2.2.

As for the efficiency of LMAIN, observe that $q - p \geq 0$ holds throughout the execution of LMAIN. Note that each iteration of the while-loops of LBEST and UPDATE decreases the value of $q - p$ by one. Since step 4 of UPDATE, which is the only place that increases the value of $q - p$, increases the value of $q - p$ by one for $O(n)$ times, the overall running time of LMAIN is $O(n)$. ∎

## 4. Coping with effective width upper bound.

In contrast to the previous simple case, when $w_{\max}$ is arbitrary, $\ell_j$ may not always be 1. Therefore, the first argument of the function call in step 3 of MAIN could be $\ell_j$ with $\ell_j > i_{j-1}$. It seems quite difficult to update the corresponding data structure $\Phi$ in overall linear time such that both $\Phi[p] = \max(i_{j-1}, \ell_j)$ and Condition $C_j$ hold throughout the execution of our algorithm. To overcome this difficulty, our algorithm sticks with Condition $C_j$ but allows $\Phi[p] > \max(i_{j-1}, \ell_j)$. As a result, $\max_{j\in J} d(i_j, j)$ may be less than $\max_{j\in J} d(i_j^*, j)$. Fortunately, this potential problem can be resolved if we simultaneously solve a series of variant versions of the maximum-density segment problem.

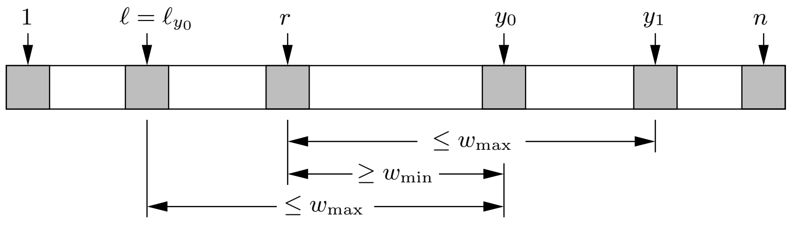

FIG. 4.1. *An illustration for the relation among* $\ell, r, y_0, y_1$.

### 4.1. A variant version of the maximum-density segment problem.

Suppose that we are given two indices $r$ and $y_0$ with $w(r, y_0) \geq w_{\min}$. Let $X = [\ell, r]$ and $Y = [y_0, y_1]$ be two intervals such that $\ell = \ell_{y_0}$ and $y_1$ is the largest index in $J$ with $w(r, y_1) \leq w_{\max}$. See Figure 4.1 for an illustration. The *variant version* of the maximum-density segment problem is to look for a maximum-density segment over

```
ALGORITHM VMAIN($r, y_0$).
    let $\ell$ be the smallest index in $[1, n]$ with $w(\ell, y_0) \leq w_{\max}$;
    let $y_1$ be the largest index in $[1, n]$ with $w(r, y_1) \leq w_{\max}$;
    let $x_{y_0-1} = \ell$;
    for $y = y_0$ to $y_1$ do {
        let $x_y$ = BEST($\max(x_{y-1}, \ell_y), r, y$);
        output $(x_y, y)$;
    }
```

FIG. 4.2. *Our algorithm for the variant version of the maximum-density segment problem, where function* BEST *is as defined in Figure* 2.2.

all feasible segments $S(x, y)$ with $x \in X$, $y \in Y$, and $w_{\min} \leq w(x, y) \leq w_{\max}$ such that $d(x, y)$ is maximized.

For each $y \in Y$, let $x^*_y$ be the largest index $x \in X$ with $w_{\min} \leq w(x, y) \leq w_{\max}$ that maximizes $d(x, y)$. Let $y^*$ be an index in $Y$ with $d(x^*_{y^*}, y^*) = \max_{y \in Y} d(x^*_y, y)$. Although solving the variant version can naturally be reduced to computing the index $x^*_y$ for each index $y \in Y$, the required running time is more than what we can afford. Instead, we compute an index $x_y \in X$ with $w_{\min} \leq w(x_y, y) \leq w_{\max}$ for each index $y \in Y$ such that $x_{y^*} = x^*_{y^*}$. By $w(r, y_0) \geq w_{\min}$ and $w(r, y_1) \leq w_{\max}$, one can easily see that, for each $y \in Y$, $r$ is always the largest index $x \in X$ with $w_{\min} \leq w(x, y) \leq w_{\max}$. Our algorithm for solving the variant problem is as shown in Figure 4.2, presented in a way to emphasize the analogy between VMAIN and MAIN. For example, the index $x_y$ in VMAIN is the counterpart of the index $i_j$ in MAIN. Also, the index $r$ in VMAIN plays the role of the index $r_j$ in MAIN. We have the following lemma whose proof is very similar to that of Theorem 2.2.

LEMMA 4.1. *Algorithm* VMAIN *solves the variant version of the maximum-density problem correctly.*

*Proof.* We prove the theorem by showing $x_{y^*} = x^*_{y^*}$. By $\ell_{y_0} = x_{y_0-1} = \ell$ and Lemma 2.1, the equality holds if $y^* = y_0$. The rest of the proof assumes $y^* > y_0$. By Lemma 2.1 and $\ell_{y^*} \leq x^*_{y^*}$, it suffices to ensure $x_{y^*-1} \leq x^*_{y^*}$. Assume for contradiction that there is an index $y \in [y_0, y^* - 1]$ with $x_{y-1} \leq x^*_{y^*} < x_y$. By $y < y^*$, we know $\ell_y \leq x^*_{y^*}$. By Lemma 2.1 and $\max(\ell_y, x_{y-1}) \leq x^*_{y^*} < x_y \leq r$, we have $d(x_y, y) \geq d(x^*_{y^*}, y)$. It follows from (1.1) and $x^*_{y^*} < x_y$ that $d(x^*_{y^*}, y) \geq d(x^*_{y^*}, x_y - 1)$. By $\ell_{y^*} \leq x^*_{y^*} < x_y \leq r$ and the definition of $y^*$, we know $d(x^*_{y^*}, y^*) > d(x_y, y^*)$. It follows from $x^*_{y^*} < x_y$ and (1.1) that $d(x^*_{y^*}, x_y - 1) > d(x^*_{y^*}, y^*)$. Therefore, $d(x_y, y) \geq d(x^*_{y^*}, y) \geq d(x^*_{y^*}, x_y - 1) > d(x^*_{y^*}, y^*)$, contradicting the definition of $y^*$. ∎

Again, the challenge lies in supporting each query to $\phi(i, r-1)$ of BEST in $O(1)$ time during the execution of VMAIN. Fortunately, unlike during the execution of MAIN, where both parameters of $\phi(i, r-1)$ may change, the second parameter $r - 1$ is now fixed. Therefore, to support each query to $\phi(i, r-1)$ in $O(1)$ time, we can actually afford $O(r - \ell + 1)$ time to compute a data structure $\Psi$ such that $\Psi[i] = \phi(i, r-1)$ for each $i \in [\ell, r-1]$. As a result, the function BEST can be implemented as the function VBEST shown in Figure 4.3. The following lemma ensures the correctness and efficiency of our implementation VARIANT shown in Figure 4.3.

LEMMA 4.2. *The implementation* VARIANT *correctly solves the variant version of the maximum-density segment problem in* $O(r - \ell + y_1 - y_0 + 1)$ *time.*

*Proof.* One can easily verify that if $\Psi[i] = \phi(i, r-1)$ holds for each index $i \in$

```
   ALGORITHM VARIANT($r, y_0$).
1      let $\ell$ be the smallest index in $[1, n]$ with $w(\ell, y_0) \le w_{\max}$;
2      let $y_1$ be the largest index in $[1, n]$ with $w(r, y_1) \le w_{\max}$;
3      call INIT($\ell, r - 1$);
4      let $x_{y_0 - 1} = \ell$;
5      for $y = y_0$ to $y_1$ do {
6          let $x_y$ = VBEST($\max(x_{y-1}, \ell_y), r, y$);
7          output $(x_y, y)$;
8      }

   FUNCTION VBEST($\ell, r, y$).
1      let $x = \ell$;
2      while $x < r$ and $d(x, \Psi[x]) \le d(x, y)$ do
3          let $x = \Psi[x] + 1$;
4      return $x$;

   SUBROUTINE INIT($\ell, r$)
1      let $\Psi[r] = r$;
2      for $s = r - 1$ downto $\ell$ do {
3          let $t = s$;
4          while $t < r$ and $d(s, t) \ge d(s, \Psi[t + 1])$ do
5              let $t = \Psi[t + 1]$;
6          let $\Psi[s] = t$;
7      }
```

FIG. 4.3. *An efficient implementation for the algorithm* VMAIN.

$[\ell, r-1]$, then VBEST is a faithful implementation of BEST. Therefore, by Lemma 4.1, the correctness of VARIANT can be ensured by showing that after calling INIT$(\ell, r-1)$ at step 3 of algorithm VARIANT , $\Psi[i] = \phi(i, r-1)$ holds for each index $i \in [\ell, r-1]$. Note that for brevity of the following proof, we slightly abuse the notation $r$ in Figure 4.3. That is, although the subroutine call at step 3 of algorithm VARIANT is INIT$(\ell, r-1)$, the second parameter in the definition of subroutine INIT in Figure 4.3 becomes $r$. Let us make it clear that the rest of the proof (i) lets $r$ denote the one in the definition of subroutine INIT$(\ell, r)$, and (ii) proves that $\Psi[i] = \phi(i, r)$ holds for each index $i \in [\ell, r]$ at the end of the subroutine call to subroutine INIT$(\ell, r)$.

By step 1 of INIT, we have $\Psi[r] = r = \phi(r, r)$. Now suppose that $\Psi[i] = \phi(i, r)$ holds for each index $i \in [x+1, r]$ right before INIT is about to execute the iteration for index $x \in [\ell, r]$. It suffices to show $\Psi[x] = \phi(x, r)$ after the iteration. Let

$$Z_x = \{x, \Psi[x+1], \Psi[\Psi[x+1]+1], \Psi[\Psi[\Psi[x+1]+1]+1], \ldots, r\}.$$

Let $|Z_x|$ denote the cardinality of $Z_x$. We first show $\phi(x, r) \in Z_x$ as follows.

Assume for contradiction that $\phi(x, r) \notin Z_x$, i.e., there is an index $z \in Z_x$ with $z < \phi(x, r) < \Psi[z+1] = \phi(z+1, r)$. By definition of $\phi$ and (1.1), we have $d(z+1, \phi(x, r)) > d(z+1, \phi(z+1, r)) > d(\phi(x, r)+1, \phi(z+1, r))$ and $d(\phi(x, r)+1, \phi(z+1, r)) \ge d(x, \phi(z+1, r)) \ge d(x, \phi(x, r))$. By $d(z+1, \phi(x, r)) > d(x, \phi(x, r))$ and (1.1), we have $d(x, \phi(x, r)) > d(x, z)$, contradicting the definition of $\phi(x, r)$.

For any index $z \in Z_x$ with $z < \phi(x, r)$, we know $z < r$ and $\phi(z+1, r) = \Psi[z+1] \le$

```
ALGORITHM GENERAL.
1      let $p = q = r_{j_0-1} = \Phi[1] = 1$;
2      for $j = j_0$ to $n$ do {
3          call UPDATE($j$);
4          while $\Phi[p] < \ell_j$ do
5              let $p = p + 1$;
6          if $i_{j-1} < \Phi[p]$ then
7              call VARIANT($\Phi[p], j$);
8          let $i_j$ = LBEST($j$);
9          output $(i_j, j)$;
10     }
```

FIG. 4.4. *Our algorithm for the general case, where* UPDATE *and* LBEST *are defined in Figure* 3.2 *and* VARIANT *is defined in Figure* 4.3.

$\phi(x, r)$. By $\phi(z + 1, r) \le \phi(x, r) \le r$ and the definition of $\phi(z + 1, r)$, we have $d(z + 1, \phi(x, r)) \ge d(z + 1, \phi(z + 1, r))$. By definition of $\phi(x, r)$ and (1.1), we have $d(x, z) \ge d(x, \phi(x, r)) \ge d(z + 1, \phi(x, r))$. By $d(x, z) \ge d(z + 1, \phi(z + 1, r))$ and (1.1), we have $d(x, z) \ge d(x, \phi(z + 1, r))$. Therefore, if $z < \phi(x, r)$, then step 5 of INIT will be executed to increase the value of $z$. Observe that $\phi(x, r) = z < r$ and $\Psi[z + 1] > z$ imply $d(x, z) < d(x, \Phi[z + 1])$. It follows that as soon as $z = \phi(x, r)$ holds, whether $\phi(x, r) = r$ or not, the value of $\Psi[x]$ will immediately be set to $z$ at step 6 of INIT.

As for the time complexity, we first observe that $\ell$ and $y_1$ can be found from $r$ and $y_0$ in $O(r - \ell + y_1 - y_0 + 1)$ time:

- Let $\ell = r$, and then repeatedly decrease $\ell$ by 1 as long as $w(\ell - 1, y_0) \le w_{\max}$ holds.
- Let $y_1 = y_0$, and then repeatedly increase $y_1$ by 1 as long as $w(r, y_1 + 1) \le w_{\max}$ holds.

Secondly, one can see that the rest of the implementation also runs in $O(r - \ell + y_1 - y_0 + 1)$ time by verifying that throughout the execution of the implementation (a) the while-loop of VBEST runs for $O(r - \ell + y_1 - y_0 + 1)$ iterations, and (b) the while-loop of INIT runs for $O(r - \ell + 1)$ iterations. To see statement (a), just observe that the value of index $x$ (i) never decreases, (ii) stays in $[\ell, r]$, and (iii) increases by at least one each time step 3 of VBEST is executed. As for statement (b), consider the iteration with index $s$ of the for-loop of INIT. Note that if step 6 of INIT executes $t_s$ times in this iteration, then $|Z_s| = |Z_{s+1}| - t_s + 1$. Since $|Z_s| \ge 1$ holds for each $s \in X$, we have $\sum_{s \in X} t_s = O(r - \ell + 1)$, and thus statement (b) holds. □

**4.2. Our algorithm for the general case.** With the help of VARIANT, we have a linear-time algorithm for solving the original maximum-density segment problem as shown in Figure 4.4. Algorithm GENERAL is obtained by inserting four lines of code (i.e., steps 4–7 of GENERAL) between steps 3 and 4 of LMAIN in order to handle the case $i_{j-1} < \ell_j$. Specifically, when $i_{j-1} < \ell_j$, we cannot afford to appropriately update the data structure $\Phi$. Therefore, instead of moving $i$ to $\ell_j$, steps 4 and 5 move $i$ to $\Phi[p]$, where $p$ is the smallest index with $\ell_j \le \Phi[p]$. Of course, these two steps may cause our algorithm to overlook the possibility of $i_j \in [i_{j-1}, \Phi[p] - 1]$, as illustrated in Figure 4.5. This is when the variant version comes in: As shown in the next theorem, we can remedy the problem by calling VARIANT($\Phi[p], j$).

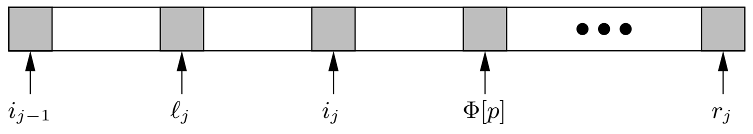

FIG. 4.5. *An illustration for the situation when Steps* 6 *and* 7 *of* GENERAL *are needed.*

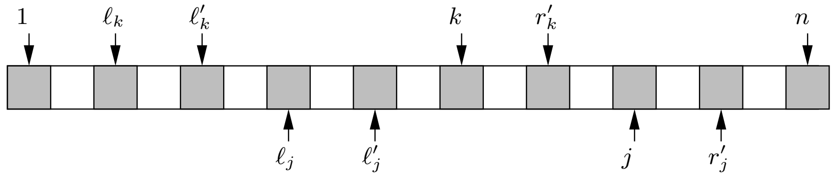

FIG. 4.6. *An illustration showing that the overall running time of all subroutine calls to* VARIANT$(\ell'_j, j)$ *in* GENERAL *is* $O(n)$.

THEOREM 4.3. *Algorithm* GENERAL *solves the maximum-density segment problem in an online manner in linear time.*

*Proof.* We prove the correctness of GENERAL by showing that $i^*_{j^*} \neq i_{j^*}$ implies $i^*_{j^*} = x_{j^*}$. By Lemma 3.1(1), Condition $C_j$ holds after the subroutine call UPDATE$(j)$ at step 3 of GENERAL. Observe that steps 4 and 5 of GENERAL, which may increase the value of $p$, do not affect the validity of Condition $C_j$. Also, steps 6 and 7 do not modify $p$, $q$, and $\Phi$. Let $\ell'_j$ be the value of $\Phi[p]$ right before executing step 8 of GENERAL. By Lemma 3.1(2), the index $i_j$ returned by LBEST$(j)$ is the largest index in $[\ell'_j, r_j]$ that maximizes $d(i_j, j)$. Clearly, $i_{j^*} = i^*_{j^*}$ implies the correctness of GENERAL. If $i_{j^*} \neq i^*_{j^*}$, there must be an index $j \in [j_0, j^*]$ with $i_{j-1} \leq i^*_{j^*} < i_j$. It can be proved as follows that $i^*_{j^*} \leq \ell'_j - 1$.

> Assume $\ell'_j \leq i^*_{j^*}$ for contradiction. It follows from Lemma 3.1(2) and (1.1) that $d(i_j, j) \geq d(i^*_{j^*}, j) \geq d(i^*_{j^*}, i_j - 1)$. By the definition of $j^*$, we have $d(i^*_{j^*}, j^*) > d(i_j, j^*)$, which by (1.1) implies $d(i^*_{j^*}, i_j - 1) > d(i^*_{j^*}, j^*)$. Therefore, $d(i_j, j) > d(i^*_{j^*}, j^*)$, contradicting the definition of $j^*$.

Since $i_{j-1} \leq i^*_{j^*} \leq \ell'_j - 1$, we know $w(\ell'_j - 1, j^*) \leq w(i^*_{j^*}, j^*) \leq w_{\max}$. Thus, $S(i^*_{j^*}, j^*)$ is a feasible segment in the variant version of the maximum-density segment problem for $S$ with respect to indices $r = \ell'_j$ and $y_0 = j$. By Lemma 4.2, the subroutine call VARIANT$(\ell'_j, j)$ at step 7 of algorithm GENERAL has to output an index pair $(x, y)$ with $w_{\min} \leq w(x, y) \leq w_{\max}$ and $d(x, y) = d(i^*_{j^*}, j^*)$.

As for the running time, observe that $q - p \geq 0$ holds throughout the execution of GENERAL. Step 4 of UPDATE, which is the only place that increases the value of $q - p$, increases the value of $q - p$ by 1 for $O(n)$ times. Note that each iteration of the while-loops of GENERAL, LBEST, and UPDATE decreases the value of $q - p$ by 1. Therefore, to show that the overall running time of GENERAL is $O(n)$, it remains to ensure that all those subroutine calls to VARIANT at step 7 of GENERAL take overall $O(n)$ time. Suppose that $j$ and $k$ are two arbitrary indices with $k < j$ such that GENERAL makes subroutine calls to VARIANT$(\ell'_k, k)$ and VARIANT$(\ell'_j, j)$. Let $r'_k$ be the largest index in $[1, n]$ with $w(\ell'_k, r'_k) \leq w_{\max}$. By Lemma 4.2, it suffices to show $\ell'_k < \ell_j$ and $r'_k < j$ as follows. (See Figure 4.6.) By the definition of GENERAL, we know that $i_{j-1} < \ell_j$, which is ensured by the situation illustrated in Figure 4.5. By $k < j$, we have $\ell'_k \leq i_{j-1}$, implying $\ell'_k < \ell_j$. Moreover, by the definitions of $\ell_j$ and

$r'_k$, one can easily verify that $\ell'_k < \ell_j$ implies $r'_k < j$.

It is not difficult to see that our algorithm shown in Figure 4.4 is already capable of processing the input sequence in an online manner, since the only preprocessing required is to obtain $\ell_j$, $r_j$, and the prefix sums of $a_1, a_2, \dots, a_j$ and $w_1, w_2, \dots, w_j$ (for the purpose of evaluating the density of any segment in $O(1)$ time), which can easily be computed on the fly. ∎

## 5. Exploiting sparsity for the uniform case.

In this section, we assume that the input sequence $S = (a_1, w_1), (a_2, w_2), \dots, (a_n, w_n)$ is run-length encoded [15], i.e., represented by $m$ pairs $(a'_1, n_1), (a'_2, n_2), \dots, (a'_m, n_m)$ with $0 = n_0 < n_1 < n_2 < \cdots < n_m = n$ to signify that $w_1 = w_2 = \cdots = w_n = 1$ and that $a_i = a'_j$ holds for all indices $i$ and $j$ with $n_{j-1} < i \le n_j$ and $1 \le j \le m$. Our algorithm for solving the maximum-density problem for the $O(m)$-space representable sequence $S$ is shown in Figure 5.1.

```
Algorithm sparse.
1    for $k = 1$ to $m$ do
2        let $n'_k = n_k - n_{k-1}$;
3    let $S'$ be the length-$m$ sequence $(n'_1 a'_1, n'_1), (n'_2 a'_2, n'_2), \dots, (n'_m a'_m, n'_m)$;
4    let $(i', j')$ be an optimal output of general$(w_{\min}, w_{\max}, S')$;
5    output $(n_{i'-1} + 1, n_{j'})$;

Fig. 5.1. *Our algorithm that handles sparse input sequence for the uniform case, where* general *is defined in Figure* 4.4.

Theorem 5.1. *Algorithm* sparse *solves the maximum-density problem for the above $O(m)$-space representable sequence in $O(m)$ time.*

*Proof.* By Theorem 4.3, sparse runs in $O(m)$ time. Let $S(i^*, j^*)$ be a feasible segment with maximum density. We first show that without loss of generality $i^* - 1 \in \{n_0, n_1, \dots, n_{m-1}\}$ or $j^* \in \{n_1, n_2, \dots, n_m\}$ holds. More specifically, we show as follows that if $i^* - 1 \notin \{n_0, n_1, \dots, n_{m-1}\}$ and $j^* \notin \{n_1, n_2, \dots, n_m\}$, then $S(i^* + 1, j^* + 1)$ is also a feasible segment with maximum density.

> By $i^* - 1 \notin \{n_0, n_1, \dots, n_{m-1}\}$, we know $a_{i^*-1} = a_{i^*}$. By $j^* \notin \{n_1, n_2, \dots, n_m\}$, we know $a_{j^*} = a_{j^*+1}$. It follows from the optimality of $S(i^*, j^*)$ that $a_{i^*} \ge a_{j^*+1}$ and $a_{i^*-1} \le a_{j^*}$, implying $a_{i^*-1} = a_{i^*} = a_{j^*} = a_{j^*+1}$. Therefore, $S(i^* + 1, j^* + 1)$ is also a maximum-density segment.

It remains to show that our algorithm works correctly for each possible case.

- Case 1: $i^* - 1 \in \{n_0, n_1, \dots, n_{m-1}\}$ and $j^* \in \{n_1, n_2, \dots, n_m\}$. Clearly, steps 1–5 of sparse take care of this case.
- Case 2: $i^* - 1 \notin \{n_0, n_1, \dots, n_{m-1}\}$ and $j^* \in \{n_1, n_2, \dots, n_m\}$. Clearly, if $i^* \in \{\ell_{j^*}, r_{j^*}\}$, $S(i^*, j^*)$ can be discovered by steps 7 and 8 of sparse. Since $i^* - 1 \notin \{n_0, n_1, \dots, n_{m-1}\}$, we have $a_{i^*-1} = a_{i^*}$. If $a_{i^*-1} = a_{i^*} \ne d(i^*, j^*)$, then by (1.1) we have either $d(i^*-1, j^*) > d(i^*, j^*)$ or $d(i^*+1, j^*) > d(i^*, j^*)$,

which implies that either $S(i^*-1,j^*)$ or $S(i^*+1,j^*)$ is infeasible, and thus $i^* \in \{\ell_{j^*}, r_{j^*}\}$. On the other hand, if $a_{i^*-1} = a_{i^*} = d(i^*,j^*)$ and $i^* \neq \ell_j^*$, then $S(i^*-1,j^*)$ is also a feasible segment with maximum density. We can continue the same argument until we have a maximum-density segment $S(i,j^*)$ such that either $i-1 \in \{n_0, n_1, \ldots, n_{m-1}\}$, which is handled in Case 1, or $i = \ell_{j^*}$, which is handled by steps 7 and 8 of SPARSE.

- Case 3: $i^*-1 \in \{n_0, n_1, \ldots, n_{m-1}\}$ and $j^* \notin \{n_1, n_2, \ldots, n_m\}$. The proof of this case, omitted for brevity, is very similar to that of Case 2.

The theorem is proved. □

# NEW APPROXIMATION TECHNIQUES FOR SOME LINEAR ORDERING PROBLEMS*

SATISH RAO† AND ANDRÉA W. RICHA‡

**Abstract.** We describe logarithmic approximation algorithms for the NP-hard graph optimization problems of minimum linear arrangement, minimum containing interval graph, and minimum storage–time product. This improves upon the best previous approximation bounds of Even, Naor, Rao, and Schieber [*J. ACM*, 47 (2000), pp. 585–616] for these problems by a factor of $\Omega(\log\log n)$.

We use the lower bound provided by the volume $W$ of a spreading metric for each of the ordering problems above (as defined by Even et al.) in order to find a solution with cost at most a *logarithmic factor times* $W$ for these problems. We develop a divide-and-conquer strategy where the cost of a solution to a problem at a recursive level is $C$ plus the cost of a solution to the subproblems at this level, *and* where the spreading metric volume on the subproblems is less than the original volume by $\Omega(C/\log n)$, ensuring that the resulting solution has cost $O(\log n)$ times the original spreading metric volume. We note that this is an existentially tight bound on the relationship between the spreading metric volume and the true optimal values for these problems.

For planar graphs, we combine a structural theorem of Klein, Plotkin, and Rao [*Proceedings of the* 25th *ACM Symposium on Theory of Computing*, 1993, pp. 682–690] with our new recursion technique to show that the spreading metric cost volumes are within an $O(\log\log n)$ factor of the cost of an optimal solution for the minimum linear arrangement, and the minimum containing interval graph problems.

## 1. Introduction.

We describe the approximation algorithms that apply to the NP-hard graph optimization problems of finding a minimum linear arrangement, a minimum containing interval graph, and a minimum storage–time product [5]. All these problems can be viewed as linear ordering problems. In a linear ordering problem on a graph $G$, the nodes of $G$ need to be ordered linearly—i.e., from $1, \ldots, n$—so as to minimize (or maximize) some given function of the ordering. An $\alpha$-*approximation algorithm* is an algorithm that finds a solution to the respective problem whose cost is at most $\alpha$ times the cost of an optimal solution to the problem.

All the ideas that we use for approximating the minimum containing interval graph and the minimum storage–time product problems can be illustrated by the algorithms for the minimum linear arrangement problem. Thus, we restrict our exposition primarily to the minimum linear arrangement problem, which we define as follows: Let $G$ be a graph with associated edge weights. Informally, a minimum linear arrangement (MLA) of $G$ is an embedding[1] of $G$ in the linear array such that (i) we

[1]An *embedding* of a graph $G$ into a graph $H$ maps nodes of $G$ to nodes of $H$, and edges of $G$ to paths in $H$. Typically, a guest network $G$ is emulated by a host network $H$ by embedding $G$ into $H$. (For a more complete discussion of emulations and embeddings, see [9].)

FIG. 1. *A graph $G$ and an MLA $\sigma$ of $G$.*

have a one-to-one mapping from the nodes of $G$ to the nodes of the linear array, and (ii) the weighted sum of the lengths of the edges of $G$—that is, the *cost* of the linear arrangement—is minimum. The length of an edge of $G$ in the embedding is given by the distance between its two endpoints on the linear array. In Figure 1, we show a linear arrangement $\sigma$ for the graph $G$ with cost 28 (in fact this linear arrangement is an MLA of $G$).

Finding an MLA is NP-hard, even for the case when all the edges have unit weight. We present a polynomial time $O(\log n)$-approximation algorithm for the MLA problem on a graph with $n$ nodes. This improves the best previous approximation bound of Even, Naor, Rao, and Schieber [3] for this problem by a factor of $O(\log \log n)$.

We extend our approximation techniques (and bounds) to two other problems that involve finding a linear ordering of the nodes of a graph: the minimum containing interval graph and the minimum storage–time product problems. Using techniques from [14], we can view the minimum containing interval graph problem as a "node version" of the MLA (see [3]). Thus, we also obtain an $O(\log n)$-approximation algorithm for the minimum containing interval graph problem on general graphs. This improves on the previous best-known bound of $O(\log n \log \log n)$ [3].

We can also use techniques from [14] to extend our ideas to produce an $O(\log T)$-approximation for the minimum storage–time product problem (where $T$ is the sum of the processing times of all tasks), improving on a previous approximation bound of $O(\log T \log \log T)$ in [3]. The minimum storage–time product problem can be viewed as a generalization of the MLA, as explained in section 4.

If the graph is planar (or, more generally, if it excludes $K_{r,r}$ as a minor, for fixed $r$, where $K_{r,r}$ is the $r \times r$ complete bipartite graph), we obtain an $O(\log \log n)$-approximation factor for the MLA problem—improving upon the best-known bound of $O(\log n)$ for these graphs—using a variation of the algorithm presented for the general case. We obtain this improvement by combining the techniques used for the general case with the algorithm presented by Klein, Plotkin, and Rao [8] for finding separators in graphs that exclude fixed $K_{r,r}$-minors.

Since we view the minimum containing interval graph problem as a "node variation" of the MLA problem, we are also able to obtain the same improved approximation bound of $O(\log \log n)$ for the minimum containing interval graph problem for graphs that exclude fixed $K_{r,r}$-minors, improving on the previous bound of $O(\log n)$. Note that the decomposition techniques of Klein, Plotkin, and Rao do not apply for directed graphs, and therefore do not yield a better approximation factor for the minimum storage–time product when restricted to the class of $K_{r,r}$-excluded minor graphs.

A small variation of our algorithm (as presented in [1]) can match the best-known existing approximation algorithms for two other related problems: Namely, a small variation of the algorithms presented in section 3 provides $O(\log^2 n)$-approximation for the minimum-cut linear arrangement and the minimum pathwidth problems.

Our approximation techniques rely on a lower bound $W$ on the cost of an optimal solution provided by a *spreading metric* (to be defined soon) for each of the problems considered: We find a solution to the general problem that has cost $O(W \log n)$ ($O(W \log T)$ for the minimum storage–time product problem). In [15], Seymour credits Alon with proving that there exists a logarithmic gap between the spreading metric cost volume and the true optimal cost for certain instances of the problem of finding a minimum feedback arc set. Alon's proof can be translated to prove analogous logarithmic gap bounds for the problems of MLA, minimum containing interval graph, and minimum storage–time product. Thus we provide an existentially tight bound on the relationship between the spreading metric cost volumes and the true optimal values for these problems. We briefly describe the approach for obtaining this lower bound in section 2.

**1.1. Previous work.** Leighton and Rao [10] presented an $O(\log n)$-approximation algorithm for balanced partitions of graphs. Among other applications, this provided $O(\log^2 n)$-approximation algorithms for the minimum feedback arc set and for the minimum-cut linear arrangement problem. Hansen [6] used the ideas in [10] to present $O(\log^2 n)$-approximation algorithms for the minimum linear arrangement problem and for the more general problem of graph embeddings in $d$-dimensional meshes. Ravi, Agrawal, and Klein [14] presented polynomial time approximation algorithms that deliver a solution with cost within an $O(\log n \log T)$ factor from optimal for the minimum storage–time product problem, where $T$ is the sum of the processing times of all tasks, and within an $O(\log^2 n)$ factor from optimal for the minimum containing interval graph.

Seymour [15] was the first to present a directed graph decomposition divide-and-conquer approach that does not rely on balanced cuts. He presented a polynomial time $O(\log n \log\log n)$-approximation algorithm for the minimum feedback arc set problem. Even et al. [3] extended the recursive decomposition technique used by Seymour to obtain polynomial time $O(\log n \log\log n)$-approximation algorithms for the MLA and the minimum containing interval graph problems, and an $O(\log T \log\log T)$-approximation algorithm for the minimum storage–time product problem. Even et al. actually showed similar approximation results for a broader class of graph optimization problems, namely, the ones that satisfy their "approximation paradigm": A graph optimization problem where their divide-and-conquer approach is applicable, and for which a spreading metric exists, satisfies this paradigm. They presented polynomial time $O(\min\{\log W \log\log W, \log k \log\log k\})$-approximation algorithms for these problems, where $k$ denotes the number of "interesting" nodes in the problem instance (clearly $k \leq n$), and $W$ is a lower bound on the cost of an optimal solution for the optimization problem provided by a spreading metric. Examples of such problems, besides the ones already mentioned, are graph embeddings in $d$-dimensional meshes, symmetric multicuts in directed networks, and multiway separators and $\rho$-separators (for small values of $\rho$) in directed graphs. For a detailed description of each of those problems, see [3].

Even et al. [2] extended the spreading metric techniques to graph partitioning problems. They used simpler recursions that yield a logarithmic approximation factor for balanced cuts and multiway separators. However, they were not able to extend this simpler technique to obtain a logarithmic approximation bound for the other problems considered in [3].

Recently, Bornstein and Vempala [1] proposed an alternative unified approach for obtaining lower bounds for the problems considered in this work. They present a unified linear program framework which defines "flow metrics" for each of the problems considered. Flow metrics are approximately equivalent to spreading metrics, in the sense that the spreading polyhedron is a projection of the flow distance polyhedron. While spreading metrics have exponentially many constraints, the definition of flow metrics uses more variables but only polynomially many constraints. By simply varying the objective function of the linear program, they obtain lower bounds for each of the problems, which they use in conjunction with the divide-and-conquer algorithm presented in this work (and its preliminary version in [13]) to match our approximation factors for the three problems considered. They also present a minor variation of our algorithm which can be used to obtain $O(\log^2 n)$-approximations for the minimum-cut linear arrangement and minimum pathwidth problems.

**1.2. Spreading metrics and our recursion.** Our algorithms use an approach that relies on *spreading metrics*. Spreading metrics have been used in recent divide-and-conquer techniques to obtain improved approximation algorithms for several graph optimization problems that are NP-hard [3]. These techniques perform the divide step according to the *cost* of a solution to the subproblems generated, rather than according to the *size* of such subproblems.

A spreading metric on a graph is an assignment of lengths to the edges or nodes of the graph that has the property of "spreading apart" (with respect to the metric lengths) all the nontrivial connected subgraphs. The *volume* of the spreading metric is the sum, taken over all edges (resp., nodes), of the length of each edge (resp., node) multiplied by its weight. For each of the optimization problems considered in this paper, Even et al. [3] showed how to find a spreading metric of volume $W$ such that $W$ is a lower bound on the cost of a solution to the problem. Our techniques are based on showing that a spreading metric of volume $W$ can be used to find a solution to the respective problem with cost $O(W \log n)$ ($O(W \log T)$ for the minimum storage–time product problem).

All of the spreading metrics used in this paper can be viewed as *one-dimensional spreadings metrics.* The main idea of a one-dimensional spreading metric is that the sum of the pairwise distances of any subset of $k$ nodes in the graph is at least the sum of the pairwise distances in a linear metric for $k$ uniformly spaced points on the line.

In this paper, we develop a recursion where at each level we identify cost which, if incurred, yields subproblems with reduced spreading metric volume. Specifically, we present a divide-and-conquer strategy where the cost of a solution to a problem at a recursive level is $C$ plus the cost of a solution to the subproblems, *and* where the spreading metric volume on the subproblems generated is less than the original volume by $\Omega(C/\log n)$ (resp., $\Omega(C/\log T)$ for the minimum storage–time product problem). We will show that this ensures that the resulting solution has cost $O(\log n)$ (resp., $O(\log T)$) times the original spreading metric volume.

The recursion is based on divide-and-conquer—that is, we find an edge or node set whose removal divides the graphs into subgraphs, and then recursively order the subgraphs. The cost of a recursive level is the cost associated with the edges (or nodes) in the cut selected at this level. Previous recursive methods and analyses proceeded by finding a small cutset where the maximum spreading metric volumes of the subproblems were quickly reduced. We proceed by finding a *sequence* of cutsets whose total cost can be upper bounded, say by a quantity $C$, and whose total spreading metric volume is $\Omega(C/\log n)$ (resp., $\Omega(C/\log T)$), as stated above. The crux of the argument is that the cost associated with an edge (or node) in a cutset can be bounded by the number of nodes between the previous and the next cutset in the sequence.

We point out that the methods in [3] applied to more problems, including the $d$-dimensional graph embedding problem and the minimum feedback arc set problem [15]. We could not extend our methods to these other problems, since we were unable to find a suitable bound on the cost of a sequence of cutsets associated with any of these problems.

Finally, for planar graphs and other undirected graphs that exclude some fixed minors, we combine a structural theorem of Klein, Plotkin, and Rao [8] with our new recursion techniques to show that the spreading metric cost volumes are within an $O(\log\log n)$ factor of the cost of the optimal solution for the MLA and the minimum containing interval graph problems.

**1.3. Overview.** In section 2, we present a formal definition of the MLA problem and define the spreading metric used for this problem. In section 3, we present a polynomial time $O(\log n)$-approximation algorithm for the MLA problem on an arbitrary graph with $n$ nodes and nonnegative edge weights. In sections 4 and 5, we define and briefly discuss the algorithms for approximating the minimum storage–time product problem and minimum containing interval graph problem, respectively. In section 6, we show how to improve the approximation factor for the MLA and the minimum containing interval problems to $O(\log\log n)$, in case the graph has no fixed $K_{r,r}$-minors—e.g., the graph is planar.

## 2. The MLA problem.

The *minimum linear arrangement* (MLA) *problem* is defined as follows: Given an undirected graph $G(V,E)$, with $n$ nodes, and nonnegative edge weights $w(e)$, for all $e$ in $E$, we would like to find a linear arrangement of the nodes $\sigma : V \rightarrow \{1,\dots,n\}$ that minimizes the sum, over all $(i,j) \in E$, of the weighted edge lengths $|\sigma(i)-\sigma(j)|$. In other words, we would like to minimize the *cost*

$$\sum_{(i,j)\in E} w(i,j)\,|\sigma(i)-\sigma(j)|$$

of a linear arrangement $\sigma$. In the context of VLSI layout, $|\sigma(i)-\sigma(j)|$ represents the length of the interconnection between $i$ and $j$.

We now define the spreading metric used in the algorithms for the MLA problem presented in sections 3 and 6. Analogous functions are used when approximating the minimum storage–time product problem (as presented in section 4) and the minimum containing interval graph problem (see section 5). Here we present the concept of spreading metrics in the context of the MLA problem (see [3] for a more general definition).

A *spreading metric* is a function $\ell : E \rightarrow Q$ that assigns rational lengths to every edge in $E$ and that can be computed in polynomial time. It also satisfies the two properties below. The *volume* of a spreading metric $\ell$ is given by $\sum_{e\in E} w(e)\ell(e)$.

1. *Diameter guarantee.* Let the distances be measured with respect to the lengths $\ell(e)$. The distances induced by the spreading metric "spread" the graph and all its nontrivial subgraphs. In this application, this translates to, "The diameter of every nontrivial connected subgraph $U$ of $V$ is $\Omega(|U|)$."

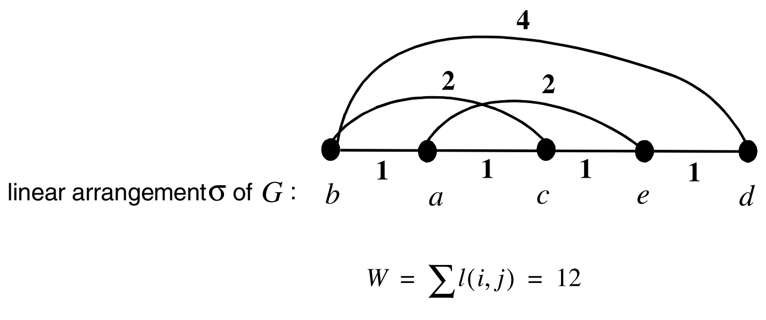

FIG. 2. *An assignment of lengths to the edges of G.*

2. *Lower bound.* The minimum volume of a spreading metric is a lower bound on the cost of an MLA of $G$.

A solution $\ell$ to (1)–(3) is a spreading metric for the MLA problem (see [3]). Let $\mathcal{V}$ denote the set of all nontrivial connected subgraphs of $V$.

$$W = \min_{e \in E} w(e)\ell'(e) \tag{1}$$

$$\text{s.t. } \frac{\left(\sum_{u \in U} \mathbf{dist}\ (u,v)\right)}{|U|} \geq \frac{|U|}{4} \quad \forall v \in U, \ \ \forall U \in \mathcal{V}, \tag{2}$$

$$\ell'(e) \geq 0 \qquad \forall e \in E, \tag{3}$$

where **dist** $(u,v)$ is the length of a shortest path from $u$ to $v$ according to the lengths $\ell'(e)$. The metric $\ell$ can be computed in polynomial time (see [3]) using, e.g., the ellipsoid method (there may be an exponential number of constraints in (2)). Note that (2) actually implies that $\ell(e) \geq 1$ for all $e$ in $E$—simply consider the subsets $U$ that consist of a single edge and its endpoints.

A solution $\ell$ to (1)–(3) is a *lower bound* on the cost of an MLA, since for any linear ordering $\sigma$ of the nodes of $G$, the assignment of lengths to the edges of $G$ given by $\ell'(i,j) = |\sigma(i) - \sigma(j)|$ satisfies (2)–(3). The volume of such an assignment is exactly the cost of $\sigma$. In particular this is true for an MLA $\sigma$. Hence $W = \sum_{e \in E} w(e)\ell(e)$ is less than or equal to the cost of an MLA. (Note that this lower bound is existentially tight, since there exist instances of this problem such that $\ell(i,j) = |\sigma(i) - \sigma(j)|$, where $\sigma$ is an MLA of $G$, as, for example, when $G$ is a linear array.) We will use this fact later, when proving Theorems 3.2 and 6.3. Figure 2 illustrates an assignment of lengths for the linear arrangement $\sigma$ given by the ordering of the nodes of $G$ from left to right (the lengths $\ell'(i,j)$ are the numbers associated with the edges in that picture; w.l.o.g.,[2] assume that all the edge weights are 1).

Let $\ell$ be a spreading metric of volume $W = \sum_{e \in E} w(e)\ell(e)$ that satisfies (1)–(3). In the remainder of this paper, all the distances in $G$ are measured with respect to $\ell$.

In [15], Seymour presents a lower bound (which he attributes to Noga Alon) on the gap between the volume of a spreading metric and an optimal integral solution for the minimum feedback arc set problem. In a nutshell, we can describe this lower bound when translated to the MLA problem as follows. Consider a bounded degree expander on $n$ nodes. An optimal solution of the spreading metric on this expander graph will assign a length of $O(n/\log n)$ to each edge (since, for any node $u$ in the

[2]Without loss of generality.

graph, there are roughly $n/2$ nodes at distance $\Theta(\log n)$ from $u$), incurring a volume of $O(n^2/\log n)$. Any integral solution to the minimum linear arrangement problem must stretch $\Omega(n)$ edges by $\Omega(n)$, leading to a lower bound of $\Omega(\log n)$ on the gap.

## 3. The algorithm.

We now present our $O(\log n)$-approximation algorithm for the MLA problem on general graphs. Let $G(V, E)$ be a graph with nonnegative edge weights $w(e)$. Assume w.l.o.g. that $G$ is connected (otherwise consider each connected component of $G$ separately), and that all the edge weights $w(e)$ are greater than or equal to 1.

In this paragraph, we introduce the notion of a *level* according to $\ell$. Fix a node $v$ in $V$. An edge $(x, y)$ belongs to *level* $i$ with respect to $v$ if and only if $\mathbf{dist}\ (v, x) \leq i$ and $\mathbf{dist}\ (v, y) > i$ for any $i \in N$. Note that an edge may belong to more than one level, and that there may be edges that do not belong to any level. Let the *weight of level* $i$, denoted by $\rho_i$, be the sum of the weights of the edges at level $i$.

We will partition the levels according to their weights. For ease of notation, we assume that $\log W$ is an integer (otherwise, simply use $\lceil \log W \rceil$ instead of $\log W$ below). We partition the levels into $\log W$ groups, according to the indices assigned to the levels. Let $\alpha_k = 2^k$ for all $k$ in $[(\log W) + 1]$.[3] Level $i$ has *index* $k$, $k$ in $[\log W]$, if and only if $\rho_i$ belongs to the interval $I_k = (\alpha_k, \alpha_{k+1}]$.

It follows from (2) that we must have at least $n/4$ distinct levels with nonzero weight. Note that since $w(e) \geq 1$ and $\ell(e) \geq 1$ for all $e$, any level with nonzero weight must have weight at least 1. Since there are $\log W$ distinct level indices, there must be at least $n/(4 \log W)$ levels with same index $k$, for some $k$. Let $\kappa$ be the exact number of levels of index $k$.

In a recursive step of the algorithm, we cut along the sequence of $\kappa$ levels of index $k$—i.e., we remove all of the edges that belong to at least one of these levels, even if they also belong to some other levels of an index different from $k$. A more detailed, stepwise description of the algorithm follows:

1. Select any node $v$ in the graph.
2. *Assign edges to levels.* An edge $(x, y)$ belongs to level $i$ with respect to $v$ if and only if $\mathbf{dist}\ (v, x) \leq i$ and $\mathbf{dist}\ (v, y) > i$ for any $i \in N$.
3. *Partition levels according to their indices.* Level $i$ has index $k$, $k$ in $[\log W]$, if and only if the weight of level $i$ (given by the sum of the weights of the edges at this level), $\rho_i$, belongs to the interval $I_k = (\alpha_k, \alpha_{k+1}]$, where $\alpha_k = 2^k$ for all $k$ in $[(\log W) + 1]$. Select an index $k$ such that there are $\kappa \geq n/(4 \log W)$ levels with this index.
4. *Cut along selected levels.* For all $i$, let level $a_i$ be the $i$th level of index $k$, in increasing order of distances to $v$. Let $H_i$ be the subgraph induced by the nodes that are at distance greater than $a_i$ and at most $a_{i+1}$ from $v$; let $H_0$ (resp., $H_\kappa$) be the subgraph induced by the nodes that are at distance at most $a_1$ (resp., greater than $a_\kappa$) from $v$. Let $n_i$ denote the number of nodes in $H_i$.
5. *Recursive step.* Recursively call the algorithm on each $H_i$, obtaining a linear arrangement $\sigma_i$ for the $n_i$ nodes in this subgraph.
6. *Combine.* Combine the linear arrangements obtained for the $H_i$'s, obtaining a linear arrangement $\sigma$ for $G$, as follows:

$$(\sigma(1), \ldots, \sigma(n)) = (\sigma_0(1), \ldots, \sigma_0(n_0), \sigma_1(1), \ldots, \sigma_1(n_1), \ldots, \sigma_\kappa(1), \ldots, \sigma_\kappa(n_\kappa)).$$

[3]For integer $x$ we use the notation $[x]$ to denote the set $\{0, \ldots, x - 1\}$.

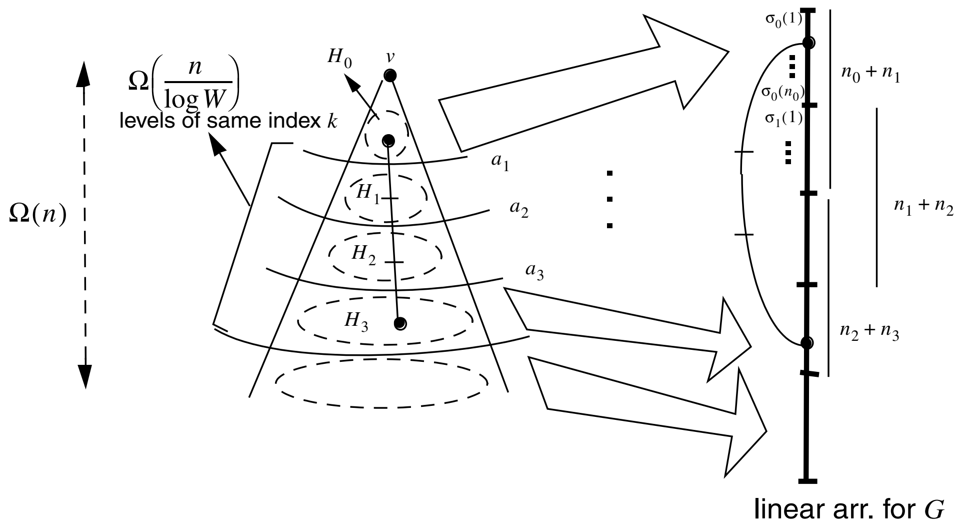

FIG. 3. *The algorithm and charging scheme.*

Each recursive step runs in polynomial time; at each recursive step, we decompose a connected component into at least two connected components. Hence the algorithm runs in polynomial time.

We use a *charging scheme* to account for the length of an edge $e$ in the linear arrangement for $G$ obtained by our algorithm (note that we will account for the *length of the edge in the linear arrangement*, rather than for the spreading metric length of the edge). If some edge $e$ in level $a_i$ belongs to some other level of index $k$, say level $a_j$, then this edge also belongs to every level of index $k$ between $a_i$ and $a_j$. W.l.o.g. assume that $i < j$. Edge $e$ will be "stretched over" all the nodes in $H_i \cup \cdots \cup H_{j-1}$ and may be "stretched over" some of the nodes in $H_{i-1}$ and $H_j$ in the linear arrangement produced by our algorithm. Hence the length of such an edge in the final linear arrangement will be at most $n_{i-1} + \cdots + n_j$. Suppose we charge $n_{p-1} + n_p$ for the portion of the edge that is stretched over the nodes in $H_{p-1} \cup H_p$, when considering level $a_p$, for all $i \leq p \leq j$. Then the total charge associated with edge $e$ is equal to $n_{i-1} + 2(n_i + \cdots + n_{j-1}) + n_j$—that is, edge $e$ will be charged at least as much as its length in a final linear arrangement.

Figure 3 illustrates the algorithm and charging scheme described above. On the left, we illustrate the selected levels $a_i$ along which we cut, resulting in the subgraphs $H_i$. After recursively calling the algorithm on these subgraphs, we obtain linear arrangements $\sigma_i$ for each $H_i$, which are concatenated—according to the distances from $v$ to each $H_i$—to form a linear arrangement of the original graph (illustrated on the right). The figure on the right also illustrates the charging scheme for one edge of the graph, which belongs to levels $a_1, a_2$, and $a_3$ in this example.

We will now compute an upper bound on the cost of a linear arrangement obtained by our algorithm. Let $C(Z)$ be the maximum cost of a linear arrangement obtained by our algorithm for a subgraph of $G$ whose volume of the spreading metric $\ell$ is at most $Z$. Since the sum of the weights of all edges in level $a_i$ is $\rho_{a_i}$, and since the quantity $w(e)\ell(e)$ for an edge $e$ which belongs to levels $a_i, \ldots, a_j$, $i \leq j$, satisfies $w(e)\ell(e) \geq w(e)(j - i + 1)/2$, we have that the sum of the weights of all edges that belong to some level of index $k$ is at least $\sum_{i=1}^{\kappa} \rho_{a_i}/2$. Note that this lower bound on the total sum of the weights of the edges removed in this cut step is tight: Suppose there are two consecutive levels $i$ and $i+1$ of index $k$, and suppose there is an edge $e$ which belongs to both of these levels such that $\ell(e) = 1 + \epsilon$ for some arbitrarily small $\epsilon > 0$; the quantity $w(e)\ell(e)$ is equal to $w(e)(1+\epsilon)$, which tends to $w(e)[(i+1) - i + 1]/2 = w(e)$ as $\epsilon$ tends to zero. We charge for the length of an edge as described in the preceding paragraph, and thus derive the following recurrence relation for $C(W)$:

$$C(W) \leq C\left(W - \sum_{i=1}^{\kappa} \frac{\rho_{a_i}}{2}\right) + \sum_{i=1}^{\kappa} [\rho_{a_i}(n_{i-1} + n_i)].$$

We now show that $C(W) = O(W \log n)$. We first prove the following lemma.[4]

LEMMA 3.1. *$C(W) \leq 32W \log(W+1)$.*

*Proof.* We will use induction on $W$. The base case $W = 0$ corresponds to a totally disconnected graph (a graph with no edges), and therefore $C(W) = 0$ in this case.

We can use induction on $W$ here since, for any subgraph of $G$ on $x$ nodes whose volume of the spreading metric $\ell$ is at most $Z$ ($Z \leq W$),

$$\sum_{i=1}^{\kappa} \frac{\rho_{a_i}}{2} \geq \frac{\alpha_k x}{8 \log Z} \geq \frac{\alpha_k x}{8 \log W} \geq \frac{1}{8 \log W}$$

since $\rho_{a_i} > \alpha_k$ and $\kappa \geq x/(4 \log W)$. Thus, the recurrence relation above will converge to the base case in at most $8W \log W$ steps.

Combining the recurrence relation for $C(W)$ with $\alpha_k < \rho_{a_i} \leq \alpha_{k+1}$ for all $i$, we obtain

$$\begin{aligned} C(W) &\leq C\left(W - \frac{\alpha_k n}{8 \log W}\right) + \alpha_{k+1} \sum_i (n_{i-1} + n_i) \\ &\leq 32 \left[W - \frac{\alpha_k n}{8 \log W}\right] \log\left[W - \frac{\alpha_k n}{8 \log W} + 1\right] + 2\alpha_{k+1} n \\ &\leq 32 \left[W - \frac{\alpha_k n}{8 \log W}\right] \log(W+1) + 2\alpha_{k+1} n \\ &\leq 32W \log(W+1) + \alpha_{k+1} n \left[2 - \frac{32}{16}\right] \\ &\leq 32W \log(W+1). \end{aligned}$$

The second inequality follows from the induction hypothesis; the fourth inequality follows since $\alpha_{k+1} = 2\alpha_k$. ☐

We still need to show how to bring the approximation factor down from $O(\log W)$ to $O(\log n)$. We will do this by using standard techniques of rescaling and rounding down the edge weights (as in [4]).

Our goal will be to reduce, by rescaling and rounding down weights, our original input graph $G$ to an "equivalent" input graph $G'$ whose spreading metric volume is a polynomial in $n$. Consider the set $E'$ of edges $e$ such that $w(e) \leq W/(mn)$. Since an edge has length at most $n$ in any linear arrangement for $G$, the contribution of the

[4] All the logarithms in this paper are base 2.

edges in $E'$ to an MLA of $G$ is at most $W$. Suppose we delete all those edges and apply a $\rho$-approximation algorithm to the resulting graph.

We now round down each weight $w(e)$, for all $e$ in $E \setminus E'$, to its nearest multiple of $W/(mn)$. The error incurred by this rounding procedure is again at most $W$. Furthermore, we scale the rounded weights by $W/(mn)$, obtaining new weights for the edges that are all integers in the interval $[0, mn]$. Note that we have only changed the units in which the weights are expressed.

The volume $W'$ of the spreading metric for solving the MLA problem on $G' = G \setminus E'$ with integral weights that belong to $[0, mn]$ is at most a polynomial on $n$ (since $W' \leq m^2n^2$). By Lemma 3.1, we have $C(W') \leq cW' \log(W') = c'W' \log n$ for some constant $c'$. Rescaling the edge weights back by multiplying $C(W')$ by $W/(mn)$, we obtain a linear arrangement for the original weights on $G'$ with cost at most $c'W \log n$. Putting back the edges in $E'$ into the linear arrangement obtained for $G'$, we obtain a linear arrangement for $G$ with cost at most $(c' \log n + 1)W$.

Since $W = w(e)\ell(e)$ is a lower bound on the cost of an MLA, by Lemma 3.1 and the considerations above, we have proved the following theorem.

THEOREM 3.2. *The cost of a solution to the MLA problem, obtained by our algorithm, is within an $O(\log n)$ factor of the cost of an MLA of $G$.*

## 4. Storage–time product.

In this section, we sketch our approach for approximating the minimum storage–time product problem on a directed acyclic graph $G(V, E)$. The minimum storage–time product problem arises in a manufacturing or computational process, in which the goal is to minimize the total storage–time product of the process: We want to minimize the use of storage over time, assuming storage is an expensive resource. Let $G(V, E)$ be an acyclic directed graph on $n$ nodes with edge weights $w(e)$ for all $e \in E$ and node weights $\tau(v)$ for all $v \in V$. The nodes of $G$ represent tasks to be scheduled on a single processor. The time required to process task $v$ is given by $\tau(v)$. The weight on edge $(u, v)$, $w(u, v)$ represents the number of units of storage required to save intermediate results generated by task $u$ until they are consumed at task $v$. The *minimum storage–time product problem* consists of finding a topological ordering[5] of the nodes $\sigma : V \to \{1, \ldots, n\}$ that minimizes

$$\sum_{(i,j)\in E, \sigma(i)<\sigma(j)} \left\{ w(i,j) \left[ \sum_{k \;:\; \sigma(i)\leq\sigma(k)\leq\sigma(j)} \tau(\sigma(k)) \right] \right\}.$$

Figure 4 illustrates a topological ordering of the nodes of $G$ (given from left to right on the rightmost representation of the graph) with minimum storage–time product of 177.

This problem generalizes the MLA problem: When all tasks have unit execution time, it becomes a directed version of the MLA problem. It is also a generalization of the single-processor scheduling problem, if we are minimizing the weighted sum of completion times (this problem is NP-complete [5, problem SS13, p. 240]).

For the storage–time product problem, we use a spreading metric $\ell$ defined as follows. Let $E^R = \{(u, v) | (v, u) \in E\}$. We define $G' = (V, E \cup E^R)$. Let $\mathcal{V}$ denote the set of all nontrivial strongly connected subgraphs of $G'$. The spreading metric $\ell$ is a

[5]An ordering $\sigma$ of the nodes of $G$ (where $G$ is an acyclic directed graph) is said to be *topological* if and only if for every $(i, j) \in E$, $\sigma(i) < \sigma(j)$.

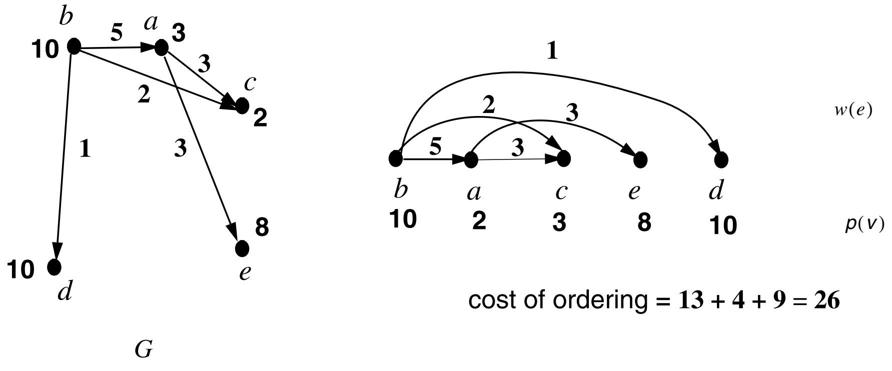

FIG. 4. *A minimum storage–time product of G.*

solution to

$$\begin{aligned} &W = \min w(e)\ell'(e) \\ \text{s.t.}\quad &\frac{\sum_{u\in U}\tau(u)\delta(u,v)}{|U|} \geq \frac{\sum_{u\in U}\tau(u)}{4} && \forall U \in \mathcal{V},\ \ \forall v \in U, \\ &\ell'(i,j) \geq \tau(i)+\tau(j) && \forall (i,j) \in E, \\ &\ell'(i,j) = 0 && \forall (i,j) \in E^R, \end{aligned}$$

where $\delta(u,v)$ is equal to $(\mathbf{dist}\ (u,v) + \mathbf{dist}\ (v,u))$. Here we define $\mathbf{dist}\ (u,v)$ to be the length of a shortest path from $u$ to $v$ in $G'$ according to the lengths $\ell'(e)$ for $e \in E \cup E^R$. (Note that each $e \in E^R$ has length zero.)

For any linear ordering $\sigma$ of $V$, the assignment of lengths to the edges given by $\ell'(i,j) = \sum_{k\ :\ \sigma(i)\leq\sigma(k)\leq\sigma(j)} \tau(\sigma(k))$, for all $(i,j)$ in $E$, satisfies the constraints above. Thus the volume $W$ of the spreading metric $\ell$ is a lower bound on the optimal cost of a solution to the storage–time product problem.

We can adapt the algorithm of section 3 to this problem as follows. Let $T = \sum_{v\in V}\tau(v)$. There is a node $v$ such that the out-tree rooted at $v$ or the in-tree rooted at $v$ has depth $\Omega(T)$. Thus, we can find a sequence $a_1,\ldots,a_\kappa$ of $\kappa = \Omega(T/\log W)$ levels whose weights $\rho_{a_1},\ldots,\rho_{a_\kappa}$ are within a factor of two of each other (as in section 3).

Laying out the resulting pieces successively, we obtain a solution where the cost is bounded by

$$C(W) \leq C\left(W - \sum_{i=1}^{\kappa}\frac{\rho_{a_i}}{2}\right) + \sum_{i=1}^{\kappa}[\rho_{a_i}(\tau_{i-1}+\tau_i)],$$

where $\tau_i$ is the sum of $\tau(v)$ over all nodes $v$ that lie between levels $a_{i-1}$ and $a_i$ ($\tau_0$ and $\tau_\kappa$ are defined accordingly).

This recursion can be upper bounded by $O(W\log W)$, as in section 3. This cost can be reduced to $O(W\log T)$ using the standard techniques that were used in section 3 to reduce $O(\log W)$ to $O(\log n)$.

**5. Minimum containing interval graph.** In this section, we sketch our approach to approximating the cost of a minimum containing interval graph of a graph $G(V,E)$.

We first introduce interval graphs. An *interval graph* is a graph whose nodes can be mapped to distinct intervals in the real line such that two nodes in the graph have an edge between them if and only if their corresponding intervals overlap. A completion of a graph $G$ into an interval graph results in an interval graph with the same node set as $G$ that contains $G$ as a subgraph.

We use the following characterization of interval graphs, due to [12]. An undirected graph $G(V, E)$ on $n$ nodes is an interval graph if and only if there exists a linear ordering $\sigma : V \to \{1, \ldots, n\}$ of the nodes in $V$ such that if an edge $(u, v) \in E$, where $\sigma(u) < \sigma(v)$, then every edge $(u, w)$, for $w$ such that $\sigma(u) < \sigma(w) < \sigma(v)$, also belongs to $E$. This characterization implies that, for any given ordering $\sigma$ of the nodes in $G$, there exists a *unique* way of completing $G$ into an interval graph $\overline{G}$ by adding as few edges to $G$ as possible.

The *minimum containing interval graph problem* seeks a completion of a graph $G$ into an interval graph $\overline{G}$ with *minimum total number of edges.* Thus, in this problem, the cost of a completed graph is given by the *total* number of edges in the graph. This cost can be viewed as the sum over nodes of the maximum backward stretch of the node—i.e., of the distance to the farthest lower-numbered node to which the node is connected. This is very similar to the MLA problem, except that the nodes are stretched along the order rather than the edges (see [3]). Thus, our techniques in sections 3 and 6 also apply to this problem. The containing interval graph problem arises in several areas, from computer science, to biology (see [11]), to archaeology (e.g., when finding a consistent chronological model for tool use while making as few assumptions as possible [7]).

The spreading metric $\ell$ that we use (due to [3]) assigns lengths to the nodes of the graph, rather than to its edges, as in the minimum linear arrangement and in the minimum storage–time product problems. Let $\mathcal{V}$ denote the set of all nontrivial connected subgraphs of $G$. The metric $\ell$ is a solution to

$$\begin{aligned} W = \min\ & \frac{1}{2}\left(\sum_{v \in V} \ell'(v)\right) \\ \text{s.t. } & \sum_{v \in U} \mathbf{dist}\,(u, v) \geq \frac{1}{4}(|U|^2 - 1) \qquad \forall u \in U,\ \forall U \in \mathcal{V}, \\ & \ell'(v) \geq 0 \qquad\qquad \forall v \in V, \end{aligned}$$

where $\mathbf{dist}\,(u, v)$ is the shortest length—given by $[\ell'(u) + \sum_{i=0}^{p} \ell'(x_i) + \ell'(v)]$—of a path $u, x_0, \ldots, x_p, v$, $x_i \in V$, from $u$ to $v$ in $G$.

Let $\overline{G}(V, \overline{E})$ be a completion of $G$ into an interval graph. If we let $\ell'(v)$ be the degree of node $v$ in $\overline{G}$, the cost $(\sum_{v \in V} \ell'(v))/2$ clearly gives the number of edges in $\overline{E}$. Also this assignment of lengths to the nodes satisfies the constraints above. Hence the volume $W$ of the metric $\ell$ is a lower bound on the number of edges in a minimum containing interval graph of $G$.

The recurrence relations that bound the cost of a solution obtained for the minimum containing interval graph problem are analogous to the ones for the MLA problem, both for the general case and for the excluded $K_{r,r}$-minors case (to be addressed in section 6).

A closely related problem to the minimum containing interval graph problem is that of the *minimum interval graph completion problem.* In this problem, the cost of a completion of a graph $G$ into an interval graph $\overline{G}$ is given by the number of edges in $\overline{G} - G$. While an optimal solution to the minimum containing interval graph problem on a graph $G$ is also an optimal solution to the minimum interval graph completion problem on $G$, an $\alpha$-approximate solution $\overline{G}$ to the minimum containing interval graph completion problem on $G$ is not enough to guarantee the existence of a solution to the minimum interval graph completion problem on $G$ with an $\alpha$-approximation factor.

**6. Graphs with excluded minors.** In this section we show how to obtain, in polynomial time, an $O(\log \log n)$-approximation for the MLA problem on a graph $G$ with no fixed $K_{r,r}$-minors—e.g., on a planar graph $G$. We denote the $r \times r$ complete bipartite graph by $K_{r,r}$.

DEFINITION 6.1. *Let $H$ and $G$ be graphs. Suppose that* (i) *$G$ contains disjoint connected subgraphs $A_v$ for each node $v$ of $H$; and* (ii) *for every edge $(u, v)$ in $H$, there is a path $P_{(u,v)}$ in $G$ with endpoints in $A_u$ and $A_v$, such that any node in $P_{(u,v)}$ other than its endpoints does not belong to any $A_w$, $w$ in $H$, nor to any $P_{(i,j)}$, $(i, j)$ in $H \setminus (u, v)$. Then $\cup_v A_v$ is said to be an $H$*-minor *of $G$.*

Klein, Plotkin, and Rao [8] showed how to decompose (in polynomial time) an undirected graph with no $K_{r,r}$-minors into connected components of small diameter. In our application, this implies that each connected component has at most a constant fraction of the nodes in $G$, as shown below.

The algorithm presented in this section also implies an $O(\log \log n)$-approximation for the minimum containing interval problem in excluded $K_{r,r}$-minor graphs, since this problem can be viewed as a "node version" of the MLA problem. Since the minimum storage–time problem is defined on a directed graph $G$, the decomposition techniques from Klein, Plotkin, and Rao [8] cannot be applied to $G$. Thus the results in this section do not translate into a better approximation factor for the minimum storage–time problem on graphs with no $K_{r,r}$-minors.

**6.1. The algorithm.** We recursively solve the problem, as we do in the general case. We combine the partial solutions returned by each recursive step, and we charge for each edge removed at a cut step in the same way as in the algorithm of section 3. It is in the way we decompose the graph before a recursive step (steps 2–4) that the algorithm of section 3 differs considerably from the one presented in this section. Before each recursive step, we will perform a series of *shortest path levelings*, to be defined soon, on each induced connected subgraph, until we can guarantee that the original graph has been decomposed into subgraphs that contain at most a fixed fraction (strictly less than one) of the nodes each. In the algorithm of section 3, we perform only one shortest path leveling before each recursive step.

The algorithm proceeds in rounds. In each round we have a *cut step*, which corresponds to the series of cuts performed during the round, and a *recursive step*, which consists of recursively calling the algorithm on the connected components that result from the cut step. Let $G(V, E)$ be a graph on $n$ nodes that excludes $K_{r,r}$ as a minor for some fixed $r > 0$. Let $\ell$ be a spreading metric for $G$ of volume $W$ that satisfies constraints (2)–(3).

A single *cut step* in $G$ will produce a series of subgraphs of $G$, $G = G_0, \ldots, G_t$, $t \leq r$, where each $G_{i+1}$ results from cutting according to a shortest path leveling of $G_i$. Fix a node $v$ in $G_i$. A *shortest path leveling* (SPL) of $G_i$ rooted at $v$ consists of an assignment of levels to the edges of $G_i$ as follows: An edge $(x, y)$ is at *level* $j$ of this SPL if and only if **dist** $(v, x)$ (in $G_i$) is at most $j$ and **dist** $(v, y)$ (in $G_i$) is greater than $j$, for all $j \in N$. (An edge may be at more than one level.)

We group the levels of this SPL into *bands* of $2s$ consecutive levels as follows: *Band* $i$, for $i \in N$, of the SPL consists of levels $2si$ through $2s(i + 1) - 1$, where $s = n/b$, and $b$ is a constant. Let $n(G_i)$ denote the number of nodes in $G_i$. The spreading metric diameter guarantee implies that this SPL has at least $n(G_i)/4$ levels. We will see later that $n(G_i) = \Theta(n)$, and that we can choose $b$ such that $n(G_i)/4 \geq 2s$ (we need $b \geq 8$). Alternate coloring the bands "blue" and "red" in increasing order of the levels.

We will cut along a sequence of levels of the SPL; one of the connected components resulting from this cutting procedure will be $G_{i+1}$. W.l.o.g., assume that the subgraph induced by the blue bands has at least $n(G_i)/2$ nodes. We have $2s$ cuts of the following type: For $0 \leq j \leq 2s-1$, a *leveled cut* $j$ consists of all the edges in the $j$th level (with respect to distance from $v$) of every red band. For example, if the band consisting of the first $2s$ levels is colored blue, then the leveled cut $j$ consists of the levels $2s+j, 6s+j, \dots$ for all $j$.

We group the leveled cuts according to their indices, which we define below (the definition of an index in this context is slightly different from that in section 3). We will see that there must exist at least an $\Omega(1/\log\log n)$ fraction of the leveled cuts with the same index $k_i$. Let $\beta_k = W2^k/(s\log n)$ for all $k$ in $[1, 2\log\log n]$. Let $\beta_0 = 0$ and $\beta_{(2\log\log n)} = W$. The *weight* of leveled cut $j$ is the sum of the weights of the levels in the cut (the weight of a level being the sum of the weights of the edges at that level). Leveled cut $j$ has *index* $k$, $k$ in $[2\log\log n]$, if and only if the weight of leveled cut $j$ belongs to the interval $I_k = (\beta_k, \beta_{k+1}]$. Thus there must exist at least $s/\log\log n$ leveled cuts in $G_i$ with same index $k_i$, since there are at least $2s$ distinct leveled cuts.

We summarize the steps above and conclude the description of the algorithm in the stepwise format below.

1. Let $i = 0$ and let $G_0 = G$.
2. Select a node $v$ in $G_i$.
3. *Assign edges to the leveled cuts of an SPL.* Assign the edges of $G_i$ to levels (we use the same definition of a level as in section 3), forming an SPL of $G_i$. We group the levels of the SPL into *bands* of $2s$ consecutive levels as described above. Alternate coloring the bands "blue" and "red" in increasing order of the levels. Assume, w.l.o.g., that the subgraph induced by the blue bands has at least $n(G_i)/2$ nodes. For $0 \leq j \leq 2s-1$, the $j$th *leveled cut* consists of all the edges in the $j$th level (with respect to distance from $v$) of every red band.
4. *Partition the leveled cuts of the SPL according to their indices.* Leveled cut $j$ has *index* $k$, $k$ in $[2\log\log n]$, if and only if the weight of leveled cut $j$ belongs to the interval $I_k = (\beta_k, \beta_{k+1}]$, where $\beta_k = W2^k/(s\log n)$ for all $k$ in $[1, 2\log\log n]$, $\beta_0 = 0$, and $\beta_{(2\log\log n)} = W$. Choose $k_i$ to be the index $k$ such that there exists at least $s/\log\log n$ leveled cuts in $G_i$ with same index $k$.
5. *Cut along selected leveled cuts.* If $i = r-1$, we let $t = i$ and go to step 6. If $i < r-1$, we proceed as described below.
   If $k_i > 0$, then we cut along these at least $s/\log\log n$ leveled cuts of index $k_i$ and weight at least $W/(s\log n)$. We recursively call the algorithm on the resulting connected components. In this case, we let $t = i$ and go to step 6.
   Otherwise, we first cut along only one of the leveled cuts of index $k_i = 0$ (chosen arbitrarily). Then we check whether there exists a resulting connected component $G_{i+1}$ of $G_i$ with at least $n(G_i)/2$ nodes. In case no such component exists, we let $t = i$ and go to step 6. If a component $G_{i+1}$ with at least $n(G_i)/2$ nodes exist, we proceed by going back to step 2 with $i = i+1$, thus performing an SPL on $G_{i+1}$.
6. *Recursive step.* The cut step is complete and we recursively call the algorithm on each of the resulting connected components $H_0, \dots, H_p$ of $G$. Let $n_i$ be

the number of nodes on component $H_i$, and let $\sigma_i$ be the linear arrangement obtained for $H_i$ for all $i$.

7. *Combine.* Assume the connected components $H_i$'s are ordered in nondecreasing order of distances from $v$ (i.e., $v$ is no closer to the nodes in $H_{i+1}$ than to the nodes in $H_i$). Combine the linear arrangements obtained for the $H_i$'s, obtaining a linear arrangement $\sigma$ for $G$, as follows:

$$(\sigma(1), \ldots, \sigma(n)) = (\sigma_0(1), \ldots, \sigma_0(n_0), \sigma_1(1), \ldots, \sigma_1(n_1), \ldots, \sigma_p(1), \ldots, \sigma_p(n_p)).$$

The number of nodes in $G_i$, $n(G_i)$, is proportional to $n$ for all $i$ in $[t]$. This follows since $n(G_{i+1}) \geq n(G_i)/2$, by the choice of $G_{i+1}$, and since $t$ $(\leq r)$ is a constant.

Suppose we just performed a series of $t$ SPLs and corresponding cut procedures. The last cut performed, on $G_{t-1}$, generated a collection of connected components of $G_{t-1}$. Klein, Plotkin, and Rao [8] proved that the distance in $G$ between any pair of nodes in any such component is $O(s)$ (where the constant in the $O(\cdot)$ notation depends only on $r$). Thus, for a large enough constant $b$, $b \geq 8$, we can ensure that the distance between any pair of nodes is at most $n/6$ in any such component.

We now show that it follows from the result by Klein, Plotkin, and Rao that any connected component that results from this cut step has at most $2n/3$ nodes. Fix any node $u$ in $G$. It follows from (2) that any subgraph of $G$ on $(n-x)$ nodes that contains $u$ has a node at distance at least $(n-x)/4$ from $u$. Suppose we start with the graph $G$ and proceed by removing one node at a time, choosing always a node that has maximum distance to $u$ among the remaining nodes. Thus, we need to remove at least one-third of the nodes before we are left only with nodes that are within distance $n/6$ from $u$ in $G$. This implies that any resulting connected component of $G_{t-1}$ has at most $2n/3$ nodes. Any other resulting connected component (of $G \setminus G_{t-1}$) has at most $n/2$ nodes, by the choice of the $G_i$'s.

We distinguish between two types of cut steps: If $k_{t-1}$ is equal to 0, then we have a cut step of *type I* in this round; otherwise $k_{t-1}$ is not zero, and the cut step in this round is of *type II*. Note that in either type of cut step, $k_j = 0$ for all $j$ in $[t-1]$.

Let $C(Z, x)$ denote the maximum cost of a linear arrangement obtained by our algorithm for a subgraph of $G$ with $x$ nodes, whose volume of the spreading metric $\ell$ is at most $Z$. Any graph with less than two nodes has no edges. Thus the cost of an MLA obtained by our algorithm and the volume of the corresponding spreading metric for a graph with $n < 2$ are both equal to zero. Hence it is sufficient to prove the claim below for $n \geq 2$ (note that $\log \log n$ is undefined for $n < 2$).

LEMMA 6.2. *$C(W, n) \leq cW \log \log n$ for $n \geq 2$ and some constant $c$.*

*Proof.* We use induction on $W$ and $n$ (a similar argument to that in Lemma 3.1 shows that induction converges to the base case here in a finite number of steps). The base cases for $W = 0$ or $n = 2$ are trivial. Suppose we perform a cut step of type I. Thus, we perform a sequence of at most $r$ cuts along a single leveled cut of each SPL in this step, and each of these leveled cuts has weight at most $2W/(s \log n)$. Let the connected components resulting from this cut step be $H_0, \ldots, H_p$. Then

$$\begin{aligned} C(W, n) &\leq \sum_{i=0}^{p} C(W_i, n_i) + r \frac{2W}{s \log n} n \\ &\leq \sum_i cW_i \log \log(2n/3) + \frac{2brW}{\log n} \\ &\leq cW \log \log n - \frac{cW}{3 \log n} + \frac{2brW}{\log n} \\ &\leq cW \log \log n, \end{aligned}$$

where $W_i$ and $n_i$ are the volume and number of nodes, respectively, associated with component $H_i$. We have shown that every $n_i$ is at most $2n/3$. The second inequality above follows by induction. Note that $\log\log(2n/3) \leq \log\log n - 1/(3\log n)$: Thus the third inequality follows. The last inequality follows for a sufficiently large constant $c$ ($c \geq 6br$).

If the cut step performed was of type II, then we performed a series of $t \leq r$ SPLs and respective cut procedures. The last term on the right-hand side of the first inequality below accounts for the first $(t-1)$th leveled cuts of index $k_i = 0$ used, one for each $G_i$, $0 \leq i < t-1$. The second term on the right-hand side of that inequality accounts for the $t$th group of leveled cuts of index $k_{t-1} > 0$ used for $G_{t-1}$. The charging scheme for the edges removed in the $t$th set of leveled cuts used in this cut step and the lower bound on how much those edges contributed to the spreading metric volume $W$ are analogous to the ones used in section 3.

$$\begin{aligned} C(W,n) &\leq C\left(W - \frac{\beta_k}{2}\frac{s}{\log\log n}, n\right) + 2\beta_{k+1}n \\ &\quad +(r-1)\frac{2W}{s\log n}n \\ &\leq C\left(W - \frac{\beta_k s}{2\log\log n}, n\right) + (r+3)\beta_k n \\ &\leq c\left(W - \frac{\beta_k s}{2\log\log n}\right)\log\log n + (r+3)\beta_k n \\ &\leq cW\log\log n + \beta_k n\left(r+3-\frac{c}{2b}\right) \\ &\leq cW\log\log n \end{aligned}$$

when $c \geq 2b(r+3)$. The second inequality above follows from $\beta_k \geq 2W/(s\log n)$, and from $\beta_{k+1} = 2\beta_k$, $0 < k < 2\log\log n - 1$; the fourth inequality follows since $s = n/b$. ∎

Since the volume $W$ of the spreading metric $\ell$ is a lower bound on the cost of an MLA, by Lemma 6.2, we obtain the following theorem.

THEOREM 6.3. *Given a graph $G$ on $n$ nodes that excludes fixed $K_{r,r}$-minors, the cost of a solution to the MLA problem obtained by the algorithm presented in this section is within an $O(\log\log n)$ factor of the cost of an MLA of $G$.*

## 7. Conclusion.

We provided an existentially tight bound on the relationship between the spreading metric cost volumes and the true optimal values for the problems of minimum linear arrangement, minimum containing interval graph, and minimum storage–time product.

It would be interesting to extend the techniques presented in this paper to obtain $O(\log n)$-approximation algorithms for other problems. In particular, it seems natural to extend our techniques to improve the best-known approximation factors for other problems that satisfy the "approximation paradigm" of [3], including the $d$-dimensional graph embedding problem and the minimum feedback arc set problem [15]. We would then provide an existentially tight bound—on the ratio between the value of an optimal solution and the spreading metric volume—for any such problem.

However, it is unclear whether the techniques presented in this paper could be directly extended to other problems in [3], since we heavily rely on the linear ordering properties of the solutions for the problems considered when finding a suitable bound on the cost of the sequence of cutsets used. It is unclear how to find a sequence of cutsets whose cost is $O(\log n)$ times the corresponding spreading metric volume due to the edges in the sequence of cutsets for the other problems in [3].

Another interesting problem would be to extend the ideas used for approximating the minimum containing interval graph problem to obtain better approximations for the minimum containing chordal graph problem (interval graphs are a particular subclass of chordal graphs). The minimum containing chordal graph problem has not been addressed in [3].

# QUICK $k$-MEDIAN, $k$-CENTER, AND FACILITY LOCATION FOR SPARSE GRAPHS*

MIKKEL THORUP†

**Abstract.** We present $\tilde{O}(m)$ time and space constant factor approximation algorithms for the $k$-median, $k$-center, and facility location problems with assignment costs being shortest path distances in a weighted undirected graph with $n$ vertices and $m$ edges.

For all of these location problems, $\tilde{O}(n^2)$ time and space algorithms were already known, but here we are addressing large sparse graphs. An application could be placement of content distributing servers on the Internet. The Internet is large and changes so frequently that an $\tilde{O}(n^2)$ time solution would likely be outdated long before completion.

**Key words.** efficient approximation algorithms, shortest paths, location problems, $k$-median, $k$-center, facility location

## 1. Introduction.

We present efficient algorithms for several classical location problems defined in terms of a metric $(P, \text{dist})$, $|P| = n$. We want to pick a set $S \subseteq P$ of *facilities* subject to different objectives. By $\text{dist}(x, S)$ we mean the distance from $x$ to the nearest facility in $S$, that is, $\text{dist}(x, S) = \min_{f \in S} \text{dist}(x, f)$. In the *$k$-median* and *$k$-center problems* we require $|S| = k$, and our goal is to minimize $\sum_{x \in P} \text{dist}(x, S)$ and $\max_{x \in P} \text{dist}(x, S)$, respectively. In the *facility location problem*, there is no limit $k$ on the number of facilities, but we are further given a facility cost function f-cost, $P \rightarrow \mathbb{N}_0$, and our goal is to minimize $\sum_{a \in S} \text{f-cost}(a) + \sum_{x \in P} \text{dist}(x, S)$. Often one is really interested in an *augmentation version* of the problems, where one is given a set of existing facilities for free. For simplicity, we do not touch this issue, but it is straightforward to generalize the presented algorithms to deal with such augmentations.

In this paper, we are interested in the *graph setting* where the metric is the shortest path metric of a weighted undirected graph $G = (V, E, \ell : E \rightarrow \mathbb{N})$, $|V| = n$, $|E| = m$; that is, $\text{dist}(x, y)$ is the length of the shortest path from $x$ to $y$ in $G$. This setting is the basis for many of the classical applications of facility location. For example, a 1983 survey [26] describes applications of the $k$-median and $k$-center problems in mostly sparse networks using shortest path distances as cost metric (as in this paper) and mentions about 100 related references. A typical example is the placement of shopping centers on a road network with driving distance to the nearest shopping center being the consumer cost. A more contemporary example could be the placement of content distribution servers on the Internet (see [20, 21, 25] for more details on Internet-related applications). Both examples may concern large sparse graphs. Also, in both cases $k$ may be large; e.g., McDonald's has more than 28,000 fast-food restaurants on the US road network which has millions of road intersections.

Similarly, Akamai has thousands of servers on the Internet which is heading towards a million routers. For Internet-related applications, we further note that the Internet changes frequently, and thus an algorithm has to be fast in order to produce up-to-date answers.

For all of the above location problems, we present $\tilde{O}(m)$ time and space constant factor approximation algorithms. Here $\tilde{}$ means that we ignore log-factors, including a log in the maximal edge weight. The concrete approximation factors are $12 + o(1)$ for $k$-median, 2 for $k$-center, and $3 + o(1)$ for facility location. The approximation factor for the $k$-median problem may be reduced to around 9, but this is complicated and beyond the scope of the current paper. Also, using much more complicated techniques, the author has recently shown that the approximation factor for facility location can be reduced to 1.62 while preserving the near-linear time and space [28]. We note that a constant factor approximation is the best we can hope for in polynomial time for each of these location problems. More precisely, for $k$-median a factor of 1.36 is the best possible unless $NP = P$ [10]; for $k$-center, a factor of 2 is the best possible unless $NP = P$ [14]; and for facility location, a factor of 1.46 is the best possible unless $NP \subseteq DTIME(n^{\log \log n})$ [11]. Our focus here, however, is on reasonable running times rather than on the concrete constant in the approximation factor.

Most previous theoretical work on the above location problems has been focused on finding the best approximation factors in polynomial time (see, e.g., [2] and references therein). A notable exception is the work of Jain and Vazirani [19]. They considered a *distance oracle* setting where, given any pair of points $(x, y) \in P^2$, one can compute $\text{dist}(x, y)$ in constant time. The distance oracle setting is interesting in its own right, e.g., interpreting the location problems as clustering problems for large data bases [12]. For the $k$-median and facility location problems, Jain and Vazirani achieved approximation factors of 6 and 3, respectively, in $\tilde{O}(n^2)$ time,[1] improving for the $k$-median the LP-based factor $6\frac{2}{3}$ from [2]. They noted, "The distinguishing feature of our algorithms is their low running time." In their final discussion they ask whether improved running times can be obtained for the graph setting in the case of sparse graphs. To run their distance oracle algorithm on a graph, one would first have to compute all pairs of shortest paths in $\tilde{O}(mn)$ time. (Some other alternatives will be discussed in section 1.3.) Our positive answer to Jain and Vazirani's question is that constant factor approximations can be achieved with high probablility (w.h.p.) in $\tilde{O}(m)$ time.

The central result of this paper is the near-linear time solution to the $k$-median problem, the difficulty being the sharp bound on the number of facilities. Facility location is comparatively easy because we can use approximate facility costs; it is considered here for completeness because it was part of Jain and Vazirani's open problem. The $k$-center solution comes in for free as a warm-up for our solution to the facility location problem. Also, by covering $k$-median, $k$-center, and facility location, we develop a quite general toolbox for basic location problems in networks [26].

**1.1. Efficient algorithms for NP-hard problems.** For this paper, we have adopted the standard target in the algorithms field of minimizing the asymptotic time and space efficiency [6]. We make this point because within approximation algorithms there has been a tendency towards putting more emphasis on whether a polynomial time algorithm is "combinatorial," "primal-dual," "greedy," or "local search."

[1]Actually, they get $\tilde{O}(fn)$ time if only $f$ points are potential facilities, but here we generally assume that all points are potential facilities.

Obviously efficient algorithms are as important for NP-hard problems as for problems in P, especially since most important combinatorial optimization problems are NP-hard [7]. Of course, the design of efficient algorithms for NP-hard problems has to await an understanding of approximability of such problems in polynomial time. Fortunately, this understanding is emerging for many NP-hard optimization problems, thus opening many new challenges for the design of efficient algorithms. As the design of efficient approximation algorithms for NP-hard problems blossoms, it is expected that many new ideas will emerge due to the difference in nature between NP-hard problems and problems in P. In particular, it is very natural to trade approximation for efficiency, as approximation has already been traded for polynomial time. Some recent examples of this line of research may be found in [5, 15]. One way of thinking about the trade-off between time and approximation factor is that one should go for the best approximation factor that can be obtained within the time available. Thus, if one has $O(mn)$ time available for solving the $k$-median problem in a network, Jain and Vazirani's algorithm is superior to ours. However, with $o(mn)$ time available, our $\tilde{O}(m)$ time solution is the right choice.

To appreciate our improved running time, consider placing shopping centers on a U.S. map with several million intersections/vertices. Computing all pairwise shortest paths for a distance oracle algorithm would take several months, if not years. Of course, one might be able to reduce the problem by hand, but our goal here is to construct algorithms not relying on human preprocessing. An even worse problem would be the placement of servers on the full Internet graph, which is changing so rapidly that the input graph would be outdated long before an all-pairs shortest path computation finished. For contrast, our algorithm runs in time close to that of a single source shortest path algorithm. In addition to speed problems, even if we don't count the space needed to represent the pair-wise distances, it is not obvious how to implement Jain and Vazirani's algorithm in subquadratic space, unless we substantially increase the running time. Our algorithm needs only $\tilde{O}(m)$ space, which could be crucial in avoiding external memory problems. We note that we cannot expect future faster computers to solve our problems, for as computers grow faster, the problems grow bigger, and hence so does the need for near-linear time algorithms.

**1.2. The distance oracle version.** Our work was strongly inspired by Indyk's [15] work on finding "sublinear" $o(n^2)$ time algorithms in the distance oracle setting, saving time by only querying $o(n^2)$ distances. Our basic question was whether similar savings were possible in the graph setting, where individual distance queries take linear time.

For the $k$-median problem, Indyk [15] presented a randomized reduction that, together with the $\tilde{O}(fn)$ time factor 6 approximation algorithm of Jain and Vazirani [19], implies a $\tilde{O}(k^3n)$ time factor $(3 + o(1))(2 + 6) = 24 + o(1)$ bicriteria approximation using $2k$ facilities. Thus Indyk's solution may use up to $2k$ facilities, and it has a cost that is at most a factor $24 + o(1)$ from the optimal solution using only $k$ facilities. Later, based on Indyk's construction [15], Guha et al. [12] presented a $\tilde{O}(kn)$ time factor $6 \times 2 \times (24 + o(1) + 1) = 300 + o(1)$ approximation algorithm using only $k$ facilities, as required for the $k$-median problem. Their algorithm works for a special streaming version of the problem that we shall return to later in section 5.3. Their approximation factor can be reduced to $80 + o(1)$ if $k = \tilde{O}(\sqrt{n})$ [Guha, personal communication]. An $\tilde{O}(kn)$ time constant factor approximation is also announced by Mettu and Plaxton [23], but with no specification of the constant. They also pointed out that $\Omega(kn)$ time is necessary for any approximation guarantee even for randomized algorithms.

Some of our initial developments actually imply an $\tilde{O}(kn)$ time factor $12 + o(1)$ approximation for the distance oracle version of the $k$-median problem, thus doing 25 times better than the previous $\tilde{O}(kn)$ time algorithm for unbounded $k$. Clearly some of the previous approximation factors could have been improved somewhat, but our vast improvement is due to some new simple and powerful sampling techniques.

For the $k$-center algorithm, the standard factor 2 approximation [9, 13] uses only $\tilde{O}(kn)$ distance queries, and $\Omega(kn)$ queries are needed for any approximation guarantee. For facility location, $\Omega(n^2)$ distance queries are needed, and that is matched by Mettu and Plaxton's $O(n^2)$ time factor 3 approximation [23].

**1.3. The graph version.** The problem in the graph setting is that a single distance query is answered by a single source shortest path computation, computing the distance from a source to all other points. Thus, answering just $n$ distance queries independently is as slow computing all pairwise shortest paths.

Nevertheless, the previous work on the distance oracle version does have some applications for the graph version. Taking the $k$-median problem as the main example, first we can apply the all pairs small-stretch path algorithm of Cohen and Zwick [4]. In $\tilde{O}(n^2)$ time, this gives us all distances in the graph within a factor 3. Next, we can apply Jain and Vazirani's algorithm [19] in $\tilde{O}(n^2)$ time to get a factor $3 \times 6 = 18$ approximation algorithm. In order to exploit the $\tilde{O}(kn)$ time distance oracle algorithm of Guha et al. [12], we can first apply Thorup and Zwick's [29] approximate distance oracle algorithm: for any positive integer $t$, after $O(tmn^{1/t})$ preprocessing time, we can answer distance queries within a factor $2t - 1$ in $O(t)$ time. Setting $t = 2$ and combining it with [12], we get an $\tilde{O}(m\sqrt{n} + nk)$ time algorithm with approximation factor $3(300 + o(1)) = 900 + o(1)$, or $3(80 + o(1)) = 240 + o(1)$ if $k = O(\sqrt{n})$.

Our $\tilde{O}(m)$ time bound is near-optimal and breaks the $\Omega(kn)$ lower bound for distance oracles if $k \gg m/n$. Further, our approximation factor is only $12 + o(1)$, which is better than that of any previous $o(nm)$ algorithm.

Our algorithm is easily generalized to work for weighted points. One application of this arises if only a subset of the points are potential facilities. Then we first assign each point to its nearest potential facility. Second we solve the $k$-median problem over the potential facilities, each weighted by the number of assigned original points. The resulting solution can be seen to be a factor $2(12+o(1))+1 = 25+o(1)$ approximation.

**1.4. All points nearest marked neighbor.** What makes fast location algorithms possible for graphs is that we can quickly find the nearest facility of each point. More abstractly, the *all points nearest marked neighbor problem* concerns a metric $(P, \text{dist})$ with a set $S \subseteq P$ of marked points. The task is for each $x \in P$ to find a nearest marked point $x^S \in S$ as well as its distance $\text{dist}(x, x^S) = \text{dist}(x, S)$ from $x$. If $S$ is a set of facilities, having solved the all points nearest marked neighbor problem, we can easily compute the $k$-median, $k$-center, or facility location cost of $S$ in $O(n)$ time.

With a distance oracle, we need $\Theta(n|S|)$ time to find all points nearest neighbor in $S$. However, when $P$ is the vertex set of a graph and dist the shortest path distances, we can find all points nearest neighbor in $S$ in near-linear time with a single source shortest path computation, no matter the size of $S$. More precisely, we have the following.

Observation 1. *In a weighted connected graph with $m$ edges, we can solve the all points nearest marked neighbor problem in $\tilde{O}(m)$ time.*

*Proof.* Introduce a source $s$ with zero length edges to all $a \in S$, and compute the shortest path tree to all vertices in $\tilde{O}(m)$ time. For each $x$, $\mathrm{dist}(x, S)$ is the found distance from $s$. Also, for each $x$ in the subtree of $a \in S$, we set $x^S = a$. We note that the same construction works for directed graphs if we first reverse the direction of all edges. ∎

All our results are achieved by a polylogarithmic number of all points nearest marked neighbor computations, hence by a polylogarithmic number of single source shortest paths computations.

Our solution to the $k$-median problem via a small number of all points nearest marked neighbor computations is also useful in Hamming space, where it gives a constant factor approximation in $\tilde{O}(nk^{\varepsilon})$ time for $\varepsilon > 0$, thus beating that $\Omega(kn)$ lower bound for general distance oracles if $k = \log^{\omega(1)} n$.

**1.5. Contents.** After some preliminaries in section 2, we present our solutions to the $k$-center, facility location, and $k$-median problem in sections 3, 4, and 5. Our solution to the $k$-median problem is by far the hardest result in the paper, taking up most of the space.

## 2. Preliminaries.

Unless otherwise stated, logarithms are base 2; e.g., $\log n = \log_2 n$.

When we say *w.h.p.*, we mean with probability $\geq 1 - 1/n^{\omega(1)}$. The advantage of an error probability of $1/n^{\omega(1)}$ is that even if we multiply it by $n$, it remains $1/n^{\omega(1)}$.

Let $S$ be a set of facilities. We will generally use $x^S$ to denote the facility that a point $x$ is assigned to. Typically $x^S$ is the nearest point in $S$ as found by an all points nearest marked neighbor computation. By the $S$-cluster of $a \in S$ we mean the set $\{x \in P : x^S = a\}$, denoted $\mathrm{cluster}(a, S)$.

Generally, we will use a subscript to indicate that measurements are done in a metric different from the one currently understood. For example, if $H$ is a graph, $\mathrm{dist}_H(x, y)$ is the distance from $x$ to $y$ in $H$.

In our stated running times for graphs, we will assume that there are no isolated vertices, and hence that $m + n = O(m)$. Isolated vertices are trivially dealt with, in that each of them has to be a facility; otherwise the cost is $\infty$.

The results presented here are not intended to be of immediate practical value. The focus is on running times and approximation factors for arbitrary input instances, and for the running times we will be sloppy with log-factors in order to facilitate the simplest possible analysis.

## 3. $k$-center.

We want to pick $S \subseteq V$, $|S| = k$ minimizing $\max_{v \in V} \mathrm{dist}(v, S)$. A factor 2 approximation is classical [9, 13] and best possible [14], but the natural algorithm takes $\tilde{O}(km)$ time. We get down to $\tilde{O}(m)$ expected time, and our methods will be reused for facility location. Here, for the $k$-center problem, the $\tilde{O}$-notation includes a log-factor in the maximal edge weight.

The classical factor 2 approximation is the following greedy algorithm: Guess the optimal distance $d^*$, and then return any maximal dist-$2d^*$ independent set. Here, for any $d$, a subset $U \subseteq V$ is dist-$d$ *independent* if no two vertices of $U$ are within distance $d$ of each other. We know we have an adequate value of $d$ if it gives rise to $\leq k$ facilities whereas $d - 1$ gives rise to $> k$ facilities, so $d$ may be found with a binary search. If $N$ is the maximal edge weight, the maximal distance is less than $nN$, so the depth of the binary search is less than $\log_2 nN$.

The obvious greedy way of finding a maximal dist-$d$ independent set $U$ is as follows: set $U = \emptyset$ and $W = V$. While $W \neq \emptyset$, add an arbitrary vertex $v \in W$ to $U$

and remove all vertices within distance $d$ from $W$. The complexity of this algorithm is $\tilde{O}(|U|m)$. Here we show how to find a maximal dist-$d$ independent set in near-linear time. Including the binary search for $d$, this will give us a near-linear time solution to the $k$-center problem.

Let $\Gamma_{\leq d}(v)$ denote the neighborhood of vertices within distance $d$ of $v$. We shall use the following result of Cohen [3].

LEMMA 2 (Cohen). *Let $\varepsilon > 0$. For any $W \subseteq V$, after preprocessing in $\tilde{O}(m/\varepsilon)$ time and space, w.h.p, for every vertex $v$ and $d$, in $O(\log\log n - \log\varepsilon)$ time, we can estimate the size of $\Gamma_{\leq d}(v) \cap W$ within a factor $1 \pm \varepsilon$.*

In applications, we will typically use $\varepsilon = 1/\log n$ so that $\tilde{O}(m/\varepsilon) = \tilde{O}(m)$, $O(\log\log n - \log\varepsilon) = O(\log\log n)$, and $1 \pm \varepsilon = 1 \pm o(1)$. We now have the following maximal dist-$d$ independent set algorithm.

ALGORITHM A. Finds a maximal dist-$d$ independent set $U \subseteq W$ for a given $W \subseteq V$.

```
A.1.     set $U = \emptyset$
A.2.     while $W \neq \emptyset$,
A.2.1.       using Lemma 2, compute $\delta = (1 \pm o(1)) \max_{v \in W} |\Gamma_{\leq d}(v) \cap W|$
A.2.2.       pick a random subset $R$ of $W$ of size $|W|/\delta$
A.2.3.       let $T = \{v \in R | \Gamma_{\leq d}(v) \cap R = \{v\}\}$—see implementation comments below
A.2.4.       add $T$ to $U$
A.2.5.       using Observation 1, find dist$(v, U)$ for each $v \in W$, removing those with
             dist$(v, U) \leq d$
```

To identify the set $T$ in step A.2.3, we construct a family $\{R_i\}_{i \leq 2\log_2 |R|}$ of subsets of $R$ such that for all $v, w \in R$ there is a set $R_i$ containing $v$ but not $w$. These sets may be constructed by associating different $\log_2 |R|$ bit vectors to the vertices in $R$ and then characterizing each set by the value of a certain bit position. Now, $\Gamma_{\leq d}(v) \cap R = \{v\}$ if and only if dist$(v, R_i) > d$ for each $R_i$ not containing $v$. For each $R_i$, using Observation 1, we find dist$(v, R_i)$ for all $v$ in near-linear time. Hence, we can implement step A.2.3 in near-linear time.

PROPOSITION 3. *Algorithm* A *finds a maximal* dist-$d$ *independent subset of a given set $W \subseteq V$ in $\tilde{O}(m)$ expected time.*

*Proof.* It follows directly from the construction that we get a maximal dist-$d$ independent subset $U \subseteq W$. Also, it is clear that each iteration of the while-loop takes near-linear time. We want to show that we expect

$$\delta^* = \max_{v \in W} |\Gamma_{\leq d}(v) \cap W|$$

to be reduced by a constant factor within $O(\log n)$ iterations. This will imply that the total expected number of iterations is $O(\log^2 n)$.

Consider a specific iteration. We assume that $\delta = (1 \pm o(1))\delta^*$, as is the case w.h.p. Consider any vertex $v \in W$ with $|\Gamma_{\leq d}(v) \cap W| \geq 0.6\,\delta^* \geq \delta/2$. We will show that the iteration eliminates $v$ from $W$ with constant probability. The condition $|\Gamma_{\leq d}(v) \cap W| \geq \delta/2$ implies that some vertex $u \in \Gamma_{\leq d}(v) \cap W$ is picked for $R$ with constant probability. On the other hand, $|\Gamma_{\leq d}(u) \cap W| \leq \delta^* \leq (1 + o(1))\delta$, and thus with constant probability no other vertex from $\Gamma_{\leq d}(u)$ is picked for $R$. By definition, this means that $u$ ends in $T$, and since $u \in \Gamma_{\leq d}(v)$, this eliminates $v$ from $W$. Thus we conclude that if a vertex $v$ has $|\Gamma_{\leq d}(v) \cap W| \geq 0.6\,\delta^*$, then the iteration eliminates $v$ with constant probability.

Consider a specific value of $\delta^*$. There are at most $n$ vertices $v$ with $|\Gamma_{\leq d}(v) \cap W| \geq 0.6\,\delta^*$, and each such $v$ is eliminated with constant probability in each of the following iterations. Thus, we expect all of them to be eliminated within $O(\log n)$ iterations, thereby reducing $\delta^*$ by a factor 0.6. We can have only $O(\log n)$ such reductions of $\delta^*$, and so we conclude that the total expected number of iterations is $O(\log^2 n)$, and hence that the total expected running time of Algorithm A is near-linear. ∎

We note that the above proof has some similarities to the randomized parallel independent set algorithm in [22]. However, the algorithm in [22] accesses all edges, whereas we do not want to consider the $O(n^2)$ pairs of distance $\leq d$.

THEOREM 4. *In $\tilde{O}(m)$ expected time, we can find a factor 2 approximation to the $k$-center problem.*

*Proof.* As discussed earlier, we make a binary search over $\{1, \dots, nN\}$ for a value of $d$ such that the set $U_d$ returned by Algorithm A has at most $k$ elements, whereas the set $U_{d-1}$ returned for $d-1$ has more than $k$ elements. Then $U_d$ is our factor 2 approximate solution to the $k$-center problem. ∎

In [13] several similar problems are mentioned that can be improved with similar methods.

We note that the above algorithms, including those of Cohen [3], are based on a polylogarithmic number of all points nearest marked neighbor computations plus an $\tilde{O}(n)$ time overhead.

## 4. Facility location.

In the *facility location problem* for a metric $(P, \text{dist})$, there is a facility cost f-cost$(x)$ associated with each $x \in P$, and then the cost of $S \subseteq P$ is $\sum_{f \in S} \text{f-cost}(f) + \sum_{x \in P} \text{dist}(x, S)$. First we note that in the distance oracle version of the facility location problem, even if all facility costs are uniform, no constant factor approximation is possible with $o(n^2)$ queries, not even if we allow randomization. For a negative example, divide into clusters of size $t$ with intra- and inter-cluster distance 0 and $\infty$, respectively. Then we expect to need $\Omega(n^2/t)$ queries for an approximation factor substantially below $t$. It follows that Mettu and Plaxton's [23] $O(n^2)$ time bound is optimal for facility location with distance oracles, even with uniform facility costs.

However, in [8] (see also [16, p. 73]), it is shown that Jain and Vazirani's facility location algorithm [19] can be implemented with $\tilde{O}(n)$ nearest neighbor queries, leading to a more efficient solution in Hamming space [17]. We note that [8] does not give anything for the $k$-median problem, as it is based on approximate counting and hence approximate payment of facilities, and then Jain and Vazirani's rounding trick [19, section 3.2] from facility location to $k$-medians does not work.

In a graph, we have no efficient way of supporting individual nearest neighbor queries, but we can solve them efficiently for all points together as the all points nearest marked neighbor problem. Essentially, we show below that facility location can be solved within a factor 3 from optimality with a polylogarithmic number of solutions to the all points nearest neighbor problem. We note that whereas "phase 2" of Jain and Vazirani's algorithm [19] is trivial to implement with efficient individual nearest neighbor queries [8], it needs something like Proposition 3 for graphs.

Instead of using Jain and Vazirani's algorithm [19], we use the one of Mettu and Plaxton [23]. The factor 3 approximation algorithm of Mettu and Plaxton for facility location is very simple and elegant. As for the algorithm in [19], it has two phases.

*Phase* 1. For each $x \in P$, we find $r_x$ such that value$(x, r_x) =$ f-cost$(x)$, where value$(x, r) = \sum_{y \in P, \text{dist}(x,y) \leq r} (r - \text{dist}(x, y))$.

*Phase* 2. Starting with $S = \emptyset$, we visit $x \in P$ in order of increasing $r_x$, adding $x$ to $S$ if $\text{dist}(x, S) > 2r_x$.

Lemma 5 (see Mettu and Plaxton [23]). *The above set $S$ is at most a factor 3 from the optimal solution to the facility location problem.*

For an efficient implementation of the above algorithm, let $\varepsilon = \Theta(1/\log n)$ be such that 2 is an integral power of $(1+\varepsilon)$ for some integer $i$. Increasing assignment costs just a little, we will view all distances as rounded up to the nearest integral power of $(1+\varepsilon)$. We use $\text{dist}^{\uparrow}$ to denote this distance function, and let $\text{value}^{\uparrow}$ denote the corresponding change in value, that is, $\text{value}^{\uparrow}(x,r) = \sum_{y\in P, \text{dist}^{\uparrow}(x,y)\le r}(r - \text{dist}^{\uparrow}(x,y))$.

Note that when we use $r_x$ in Phase 2, all we care about is which vertices are within distance $2r_x$ from $x$. Let $i$ be such that $(1+\varepsilon)^i \le r_x < (1+\varepsilon)^{i+1}$. Since 2 is an integral power of $(1+\varepsilon)$, there are no rounded distances between $2(1+\varepsilon)^i$ and $2(1+\varepsilon)^{i+1}$. Thus, we can round $r_x$ down to the nearest power of $(1+\varepsilon)$, even if this implies $\text{value}^{\uparrow}(x, r_x) \ll \text{f-cost}(x)$. The rounded down value of $r_x$ is denoted $r_x^{\downarrow}$.

Algorithm B. Implements an approximate version of Phase 1, finding an $r_v^{\downarrow}$ for each $v \in V$.

```
B.1.        for all $v \in V$, set $f_v = 0$
B.2.        set $U = V$
B.3.        for $i = 1, 2, \dots$ while $U \neq \emptyset$,
B.3.1.          using Lemma 2 with $W = V$, estimate for each $u \in U$ the number $q_u$ of
                vertices $v$ within distance $(1+\varepsilon)^i$ from $u$, that is, $\text{dist}(u,v) \le (1+\varepsilon)^i$,
                or equivalently, $\text{dist}^{\uparrow}(u,v) \le (1+\varepsilon)^i$.
B.3.2.          for each $u \in U$,
B.3.2.1.            $f_u = f_u + ((1+\varepsilon)^i - (1+\varepsilon)^{i-1})q_u$
B.3.2.2.            if $f_u > \text{f-cost}(u)$,
B.3.2.2.1.              set $r_u^{\downarrow} = (1+\varepsilon)^{i-1}$
B.3.2.2.2.              remove $u$ from $U$
```

The following lemma states that Algorithm B performs an approximate implementation of Phase 1.

Lemma 6. *For each $v$, there is an $\text{f-cost}^{\approx}(v) = \text{f-cost}(v)/(1\pm\varepsilon)$ and an $r_v^{\approx}$ with $\text{value}^{\uparrow}(v, r_v^{\approx}) = \text{f-cost}^{\approx}(v)$ such that $r_v^{\downarrow}$ is $r_v^{\approx}$ rounded down to the nearest power of $(1+\varepsilon)$.*

*Proof.* First, suppose that the numbers $q_u$ counted the number of vertices within distance $(1+\varepsilon)^i$ exactly. Then, after step B.3.2.1, we would have $f_u = \text{value}^{\uparrow}(v, (1+\varepsilon)^i)$. However, each $q_u$ may be off by a factor $(1\pm\varepsilon)$, and hence so is $((1+\varepsilon)^i - (1+\varepsilon)^i)q_u$. Since $f_u$ is a sum of such approximate terms, we conclude that $f_u = (1\pm\varepsilon)\text{value}^{\uparrow}(v,(1+\varepsilon)^i)$.

Suppose we set $r_u^{\downarrow} = (1+\varepsilon)^{i-1}$ in step B.3.2.2.1. In the last iteration $i-1$, we had $f_u \le \text{f-cost}(u)$, and hence $(1-\varepsilon)\text{value}^{\uparrow}(v,(1+\varepsilon)^{i-1}) \le \text{f-cost}(u)$. However, in the current iteration $i$, we have $f_u > \text{f-cost}(u)$, and hence $(1+\varepsilon)\text{value}^{\uparrow}(u,(1+\varepsilon)^i) > \text{f-cost}(u)$. It follows that there is a value $\text{f-cost}^{\approx}(u) = (1\pm\varepsilon)\text{f-cost}(u)$ and an $r_u^{\approx} \in [(1+\varepsilon)^{i-1}, (1+\varepsilon)^i)$ such that $\text{value}^{\uparrow}(v, r_u^{\approx}) = \text{f-cost}^{\approx}(u)$. ∎

For any solution $T$, using the $r_v^{\approx}$ from Lemma 6, we define

$$\text{cost}^{\uparrow\approx}(T) = \sum_{v\in V}\text{dist}^{\uparrow}(v,T) + \sum_{f\in T}\text{f-cost}^{\approx}(f).$$

Since $\varepsilon = \Theta(1/\log n)$, we get the following.

Observation 7. *For any solution $T$, we have $\text{cost}^{\uparrow\approx}(T) = (1\pm O(\varepsilon))\text{cost}(T) = (1\pm o(1))\text{cost}(T)$.*

Algorithm C. Implements an approximate version of Phase 2, constructing the solution $S$.

```
C.1.     set $S = \emptyset$
C.2.     for $i = 0, 1, 2 \dots,$
C.2.1.       let $W$ be the set of vertices $w \in V$ with $r^{\downarrow}_w = (1+\varepsilon)^i$
C.2.2.       remove from $W$ all vertices $w$ within distance $2(1+\varepsilon)^i$ from $S$, that is,
             with $\mathrm{dist}^{\uparrow}(w, S) \le 2(1+\varepsilon)^i$
C.2.3.       using Proposition 3, construct a maximal dist-$2(1+\varepsilon)^i$ independent set
             $I$ from $W$
C.2.4.       add $I$ to $S$
C.3.     return $S$
```

The following lemma states that Algorithm C implements Phase 2 but using $r^{\downarrow}_v$ instead of $r_v$ or $r^{\approx}_v$.

LEMMA 8. *There exists a total ordering $\prec$ of the vertices in $V$ such that $u \prec v \Rightarrow r^{\downarrow}_v \ge r^{\downarrow}_u$ and such that $v$ is added to $S$ if and only if there is no previous $u \prec v$ in $S$ with* $\mathrm{dist}(u, v) \le 2r^{\downarrow}_v$.

*Proof.* The ordering is obtained if each iteration first lists the vertices in $I$ that we pick for $S$ and second lists the rest of the vertices in $W$. ∎

Using Lemmas 6 and 8, we will argue that Algorithms B and C are good approximations of Mettu and Plaxton's Phases 1 and 2. Unfortunately, we cannot just apply Lemma 5 in conjunction with Observation 7. We have two basic problems. One is that the algorithms use $r^{\downarrow}_v$ instead of $r^{\approx}_v$, and we may have $\mathrm{value}^{\uparrow}(v, r_v) \ll \text{f-cost}^{\approx}(v)$. The other problem is that $\mathrm{dist}^{\uparrow}$ does not satisfy the triangle inequality. To deal with these problems, we have to redo the analysis from [23] so as to prove the following claim.

THEOREM 9. *In near-linear expected time, w.h.p., Algorithms* B *and* C *find a factor $3 + o(1)$ approximate solution $S$ to the facility location problem.*

*Proof.* Recall that $\varepsilon = \theta(1/\log n)$. First, there are at most $\log_{1+1/\varepsilon} nN = O((\log n)(\log nN))$ possible values of $i$, and hence at most that many iterations in each algorithm. Since each iteration takes near-linear expected time, we conclude that the overall expected running time is near-linear.

The rest of the proof is a modified version of the one of Lemma 5 in [23]. The proof is divided into several local claims. In the proof, we will carefully switch between $\mathrm{dist}^{\uparrow}$ and dist, where only the latter supports triangle inequality. In particular, this concerns the proof of Claim 9.5 below.

From Lemma 8, we immediately get our first local claim.

CLAIM 9.1. *For any vertex $v \in V$, there is a vertex $u \in S$ such that $u \preceq v$ and* $\mathrm{dist}(u, v) \le 2r^{\downarrow}_v$. ∎

CLAIM 9.2. *For any distinct vertices $u, v \in S$, we have* $\mathrm{dist}(u, v) > 2\max\{r^{\downarrow}_u, r^{\downarrow}_v\}$.

*Proof.* By symmetry, we may assume that $u \prec v$. By Lemma 8, we have $\mathrm{dist}(u, v) > 2r^{\downarrow}_v \ge 2r^{\downarrow}_u$. ∎

For any solution $T$ and vertex $v \in V$, we define

$$\mathrm{charge}(v, T) = \mathrm{dist}^{\uparrow}(v, T) + \sum_{u \in T} \max\{0, r^{\approx}_u - \mathrm{dist}^{\uparrow}(u, v)\}.$$

CLAIM 9.3. *For any solution $T$,* $\sum_{v \in V} \mathrm{charge}(v, T) = \mathrm{cost}^{\uparrow\approx}(T)$.

*Proof.* We have

$$\sum_{v \in V} \mathrm{charge}(v, T) = \sum_{v \in V} \mathrm{dist}^{\uparrow}(v, T) + \sum_{u \in T} \left( \sum_{v \in V, \mathrm{dist}^{\uparrow}(u,v) \le r^{\approx}_u} (r^{\approx}_u - \mathrm{dist}^{\uparrow}(u, v)) \right)$$

$$= \sum_{v \in V} \operatorname{dist}^{\uparrow}(v, T) + \sum_{u \in T} \operatorname{value}^{\uparrow}(u, r_u^{\approx}),$$

which equals $\operatorname{cost}^{\uparrow\approx}(T)$ since $\operatorname{value}^{\uparrow}(u, r_u^{\approx}) = \text{f-cost}^{\approx}(u)$ by Lemma 6. ∎

CLAIM 9.4. *Let $v$ be a vertex and $u$ be nearest to $v$ in a solution $T$. Then* $\operatorname{charge}(v, T) \geq \max\{r_u^{\approx}, \operatorname{dist}^{\uparrow}(u, v)\}$.

*Proof.* Since $\operatorname{charge}(v, T) \geq \operatorname{dist}^{\uparrow}(v, T) = \operatorname{dist}^{\uparrow}(u, v)$, the statement is trivial if $\operatorname{dist}^{\uparrow}(u, v) \geq r_u^{\approx}$. Otherwise, $\operatorname{charge}(x, T) \geq \operatorname{dist}^{\uparrow}(u, v) + (r_u^{\approx} - \operatorname{dist}^{\uparrow}(u, v)) = r_u^{\approx} \geq \operatorname{dist}^{\uparrow}(u, v)$. ∎

CLAIM 9.5. *If $v \in V$ and $u \in S$, we have* $\operatorname{charge}(v, S) \leq \max\{r_u^{\approx}, \operatorname{dist}^{\uparrow}(v, u)\}$.

*Proof.* If there is no vertex $u' \in S$ with $\operatorname{dist}^{\uparrow}(v, u') \leq r_{u'}^{\approx}$, then $\operatorname{charge}(v, S) = \operatorname{dist}^{\uparrow}(v, S) \leq \operatorname{dist}^{\uparrow}(v, u)$. Hence, we may assume that there is a $u' \in S$ with $\operatorname{dist}^{\uparrow}(v, u') \leq r_{u'}^{\approx}$, or equivalently, with $\operatorname{dist}(v, u') \leq r_{u'}^{\downarrow}$.

Consider a vertex $w \in S$ which is different from $u'$. By Claim 9.2, we have that $\operatorname{dist}(u', w) > 2\max\{r_{u'}^{\downarrow}, r_w^{\downarrow}\}$. Hence $\operatorname{dist}(v, w) \geq \operatorname{dist}(u', w) - \operatorname{dist}(v, u') > 2\max\{r_{u'}^{\downarrow}, r_w^{\downarrow}\} - r_{u'}^{\downarrow} \geq \max\{r_{u'}^{\downarrow}, r_w^{\downarrow}\}$, but this implies that $\operatorname{dist}^{\uparrow}(v, w) > \max\{r_{u'}^{\approx}, r_w^{\approx}\}$.

We conclude that $\operatorname{charge}(v, S) = \operatorname{dist}^{\uparrow}(v, S) + r_{u'}^{\approx} - \operatorname{dist}^{\uparrow}(v, u') \leq r_{u'}^{\approx}$ and that $u = u'$ if $\operatorname{dist}^{\uparrow}(v, u) \leq r_{u'}^{\approx}$. ∎

CLAIM 9.6. *For any $v \in V$ and solution $T$,* $\operatorname{charge}(v, S) \leq 3(1 + \varepsilon)\operatorname{charge}(v, T)$.

*Proof.* Let $u \in T$ be such that $\operatorname{dist}^{\uparrow}(x, u) = \operatorname{dist}^{\uparrow}(x, T)$. By Claim 9.1, there exists a vertex $u' \in S$ with $u' \preceq u$ and $\operatorname{dist}(u, u') \leq 2r_u^{\downarrow}$.

If $\operatorname{dist}^{\uparrow}(v, u') \leq r_{u'}^{\approx}$, then $\operatorname{charge}(v, S) \leq r_{u'}^{\approx}$, by Claim 9.5. The statement now follows, since $u' \preceq u$ implies $r_{u'}^{\downarrow} \leq r_u^{\downarrow}$ and Claim 9.4 implies that $\operatorname{charge}(v, T) \geq r_u^{\approx}$.

Suppose instead that $\operatorname{dist}^{\uparrow}(v, u') > r_{u'}^{\approx}$. By Claim 9.5, we have $\operatorname{charge}(v, S) \leq \operatorname{dist}^{\uparrow}(v, u') < (1 + \varepsilon)\operatorname{dist}(v, u')$. Moreover, $\operatorname{dist}(v, u') \leq \operatorname{dist}(v, u) + \operatorname{dist}(u, u') \leq \operatorname{dist}(v, u) + 2r_u^{\downarrow}$. The result now follows from Claim 9.4 since the ratio of $\operatorname{dist}(v, u) + 2r_u^{\downarrow}$ over $\max\{r_u^{\approx}, \operatorname{dist}^{\uparrow}(x, u)\}$ is at most 3. ∎

Now Theorem 9 follows from Observation 7 in conjunction with Claims 9.3 and 9.6. ∎

Currently our solutions to the $k$-center or facility location problem are found in near-linear expected time (cf. Theorems 4 and 9). To get a solution in worst-case near-linear time, we can search $\Theta(\log^2 n)$ solutions in parallel, returning the first solution found, and give up if no search terminates within twice the expected time. Since the solutions of the original searches were "good" w.h.p., our parallel search finds a good solution w.h.p. in near-linear worst-case time.

## 5. *k*-median.

In the *k-median problem* for a metric $(P, \operatorname{dist})$, we want to find a set $S \subseteq P$ of $k$ facilities minimizing $\sum_{x \in P} \operatorname{dist}(x, S)$. The main result of this paper is that we can get a constant factor approximation in $\tilde{O}(m)$ time when the metric is the shortest path metric for a graph with $m$ edges (and $n$ vertices).

Our $\tilde{O}(m)$ solution to the $k$-median problem in graphs is rather complicated and hence unlikely to be of direct practical relevance. However, in our developments we present some theoretically weaker algorithms that are simple and easy to implement, yet provide stronger bounds than were previously known.

First, in section 5.2, we present a simple fast randomized algorithm for selecting a set of $\tilde{O}(k)$ potential facilities, guaranteed to contain a solution with $k$ facilities with at most twice the cost of the optimal solution. Using this as a preprocessing step for Jain and Vazirani's algorithm, we find a factor $12 + o(1)$ approximation in $\tilde{O}(kn)$ time for distance oracles, with efficient implementations for external memory and the streaming model, and in $\tilde{O}(km)$ time for graphs. This part is considered very practical, "perfect" for distance oracles, and good for graphs if $k$ is not too large.

Next, in section 5.4, we show that it can be meaningful to apply the algorithm from [19] to a sparse graph whose weights do not satisfy the triangle inequality, and construct a graph for which this makes sense. In $\tilde{O}(m)$ time, this process leads to a factor $12+o(1)$ approximation to the $k$-median problem but cheating using $k+k/\log^2 n$ facilities. This part is still simple enough to be of practical use, and good enough if the bound on the number of facilities is not sharp.

The true difficulty in the $k$-median problem is the sharp bound on the facilities. In section 5.5, we present a rather convoluted recursion for getting rid of the last $k/\log^2 n$ extra facilities. It is based on structural theorems showing that if we cannot easily get rid of the $k/\log^2 n$ extra facilities, it is because our current solution is very similar to any optimal solution. This similarity allows us to fix most of the facilities and recurse on a $o(k)$-median problem. As described, this last step is considered too complicated to be of practical interest, but it takes us to our theoretical goal: a near-linear time constant factor approximation to the $k$-median problem.

**5.1. Notation and terminology.** For $S \subseteq P$, define $\text{cost}(S) = \sum_{x\in P} \text{dist}(x, S)$. Then the *k-median problem* is the problem of finding $S \subseteq P$, $|S| \leq k$, minimizing $\text{cost}(S)$. Define $k\text{-mediancost}^{\subseteq F} = \min\{\text{cost}(S) : S \subseteq F, |S| = k\}$ and $k\text{-mediancost} = k\text{-mediancost}^{\subseteq P}$. By a factor $c$ approximation to the $k$-median problem, we mean a solution $S \subseteq P$, $|S| = k$, with $\text{cost}(S) \leq c \times k\text{-mediancost}$.

**5.2. Sampling $k \log^{O(1)} n$ facilities.** In this section, we will show how to sample a set $F$ of $k \log^{O(1)} n$ facilities, which we expect to contain a factor $2 + o(1)$ approximation to the $k$-median problem. The set $F$ is found by the following simple algorithm.

ALGORITHM D. Given a metric $(P, \text{dist})$ and a parameter $\varepsilon$, $0 < \varepsilon < 0.5$, with probability at least $1/2$, the algorithm constructs a set $F$ of $O(k \log^2 n/\varepsilon)$ facilities which contains a factor $2 + \varepsilon$ approximation to the $k$-median problem.

```
D.1.     $R := P$; $F := \emptyset$;
D.2.     while $R \neq \emptyset$ but for at most $3 \log n$ iterations, do
D.2.1.       add $21k(\log n)/\varepsilon$ random points from $R$ to $F$, or the rest of $R$ if $|R| \leq$
             $21k(\log n)/\varepsilon$
D.2.2.       for each point $x \in R$, compute the distance $\text{dist}(x, F)$ to the nearest
             neighbor in $F$
D.2.3.       pick a random $t \in R$, and remove from $R$ all those $x$ with $\text{dist}(x, F) \leq$
             $\text{dist}(t, F)$.
D.3.     return $F$
```

The following theorem states the significant properties of Algorithm D.

THEOREM 10. *Algorithm* D *computes a set $F$ of size $O(k(\log^2 n)/\varepsilon)$ by computing all points nearest neighbors in $O(\log n)$ subsets of $P$, each of size $O(k(\log n)/\varepsilon)$. With probability at least $1/2$, we get $k\text{-mediancost}^{\subseteq F} \leq (2+\varepsilon) \times k\text{-mediancost}$, and the $2+\varepsilon$ approximation factor holds even if the optimal solution is allowed to place facilities outside $P$.*

Note here that when comparing our solution with an optimal solution using facilities outside $P$, we may lose a factor of 2 just by restricting ourselves to $P$. For a concrete worst-case example, just take the 1-median problem where all points in $P$ are at distance 2 from each other, whereas the optimal solution is allowed to use an extra center of distance 1 to all points in $P$. It follows that our factor $2 + \varepsilon$ is close to the best possible. Allowing the optimal solution to use facilities outside $P$ is crucial to a later reduction in the proof of Lemma 13.

*Proof of Theorem* 10. The statements concerning the size of $F$ and the all points nearest neighbor computations follow directly from the description of Algorithm D as it performs at most $3\log n$ iterations of the while loop D.2. The hard part is to prove that with probability at least 1/2, $k$-mediancost$^{\subseteq F} \leq (2+\varepsilon) \times k$-mediancost.

For the analysis, we define $R_0$ and $F_0$ to be the initial values of $R$ and $F$. Also, we let $R_i$ and $F_i$ be the values after the $i$th iteration. Finally, we let $P_i$ be the points removed from $R = R_{i-1}$ in the $i$th iteration, that is, $R_i = R_{i-1} \setminus P_i$. Let $\ell$ be the final iteration. Then $F_\ell$ is the final set returned by the algorithm.

First we will argue that we expect $R = R_\ell$ to be empty when done with the while loop. In this case, all points in $P$ end in some $P_i$, so the $P_i$ partition $P$.

CLAIM 10.1. *The probability that $R_\ell \neq \emptyset$ is $o(1)$.*

*Proof.* In proving this claim, we think of Algorithm D as always performing $\ell^* = 3\log n$ iterations. However, pseudoiterations $i > \ell$ with $R_{i-1} = \emptyset$ have no effect. For a real iteration $i \leq t$, there is a probability of at least 1/2 that the iteration removes half the points in $R$. Also, all pseudoiterations reduce the size of $R$ by a factor 2 since $0/2 = 0$. Hence, for each iteration $i \leq \ell^*$, there is a probability of at least 1/2 that $|R_i| \leq |R_{i-1}|/2$. Consequently, the expected number of such iterations is at least $1.5\log n$.

On the other hand, if $R_\ell \neq \emptyset$, we have $\ell^* = \ell$ and $|R_{\ell^*}| \geq 1$. Hence there can be at most $\log|R_0| = \log n$ iterations $i$ with $|R_i| \leq |R_{i-1}|/2$, that is, only 2/3 of the expected number of such iterations. Using a standard Chernoff bound (see, e.g., [24, Theorem 4.2]), we get that the probability of this event is at most $\exp(-(1.5\log n)(1/3)^2/2) = \exp(-(\log n)/12) < n^{-0.12}$. ∎

Let $OPT$ be an optimal solution to the $k$-median problem. Our claimed good solution inside $F$ will be $OPT^F$ denoting $\{a^F\}_{a\in OPT}$. Recall there that $a^F$ is a facility $f \in F$ which is nearest to $a$. Trivially $|OPT^F| \leq |OPT| \leq k$. For our analysis, we will assign each $x \in P$ to $(x^{OPT})^F$. The cost assigned to $x$ will be

$$\mathrm{dist}(x, x^{OPT}) + \mathrm{dist}(x^{OPT}, (x^{OPT})^F).$$

We refer to $\mathrm{dist}(x^{OPT}, (x^{OPT})^F)$ as the "extra cost" of $x$. This extra cost can only decrease as $F$ grows. Our goal is to show that, with probability at least 1/2,

$$(1) \qquad \sum_{x\in P} \mathrm{dist}(x^{OPT}, (x^{OPT})^F) \leq \sum_{x\in P}((1+\varepsilon)\mathrm{dist}(x, x^{OPT})) = (1+\varepsilon)\mathrm{cost}(OPT).$$

All points in $P$ start off "unhappy." A point $x \in P$ will be defined as "happy" from the moment that a point $a$ with $\mathrm{dist}(a, x^{OPT}) \leq \mathrm{dist}(x, x^{OPT})$ is picked for $F$. From that moment, $\mathrm{dist}(x^{OPT}, (x^{OPT})^F) \leq \mathrm{dist}(x^{OPT}, a) \leq \mathrm{dist}(x, x^{OPT})$. Hence, if all points ended up happy, we would get (1) satisfied with $\varepsilon = 0$. Unfortunately, we cannot hope to make all points happy, but we will find a way to pay for the unhappy ones.

Consider an unhappy point $x$. The extra cost of $x$ is $\mathrm{dist}(x^{OPT}, (x^{OPT})^F) \leq \mathrm{dist}(x^{OPT}, x^F) \leq \mathrm{dist}(x^{OPT}, x) + \mathrm{dist}(x, x^F) \leq \mathrm{dist}(x, OPT) + \mathrm{dist}(x, F)$. Thus, to prove (1) it suffices to show that the sum over $\mathrm{dist}(x, F)$ over all unhappy $x$ is bounded by $\varepsilon\,\mathrm{cost}(OPT)$.

We say an iteration $i$ "ends well" if the following equation is satisfied at the end of iteration $i$:

$$\sum_{\text{unhappy } x\in P_i} \text{dist}(x, F_i) \;\leq\; \varepsilon \sum_{\text{happy } x\in P_i} \frac{\text{dist}(x, F_i)}{2}. \tag{2}$$

As part of our proof of Theorem 10, we will prove a series of local claims concerning individual iterations. The first states that if an iteration $i$ ends well, the extra cost of points in $P_i$ satisfies (1). Later we will argue that we expect all iterations to end well.

CLAIM 10.2. *If iteration $i$ ends well, $\sum_{x\in P_i} \text{dist}(x^{OPT}, (x^{OPT})^{F_i}) \leq \sum_{x\in P_i}((1+\varepsilon)\text{dist}(x, OPT))$.*

*Proof.* Following our discussion of happy and unhappy points, it suffices to show that

$$\sum_{\text{unhappy } x\in P_i} \text{dist}(x, F_i) \;\leq\; \varepsilon \sum_{x\in P_i} \text{dist}(x, OPT).$$

However, if $x$ is happy, we have

$$\text{dist}(x, F_i) \leq \text{dist}(x, x^{OPT}) + \text{dist}(x^{OPT}, (x^{OPT})^F) \leq 2\,\text{dist}(x, OPT).$$

Thus from (2) we get

$$\begin{aligned}\sum_{\text{unhappy } x\in P_i} \text{dist}(x, F_i) &\leq \varepsilon \sum_{\text{happy } x\in P_i} \frac{\text{dist}(x, F_i)}{2}\\ &\leq \varepsilon \sum_{\text{happy } x\in P_i} \text{dist}(x, OPT)\\ &\leq \varepsilon \sum_{x\in P_i} \text{dist}(x, OPT),\end{aligned}$$

as desired. □

The next two claims concern the probability that an iteration $i$ ends well.

CLAIM 10.3. *The expected fraction of unhappy points in $R_{i-1}$ after step* D.2.1 *is $\leq \varepsilon/(21\log n)$.*

*Proof.* Consider a point $x \in R_{i-1}$ which was not happy before step D.2.1, and let $C$ be the remaining part of the $OPT$-cluster containing $x$; that is, $C = \text{cluster}(x^{OPT}, OPT) \cap R_{i-1}$.

Suppose there are $q$ points in $C$, including $x$, that are as close to $x^{OPT}$ as $x$. Now, the probability that $x$ is not turned happy by step D.2.1 is $(1 - q/|R_i|)^{21k(\log n)/\varepsilon} < e^{-q21k(\log n)/(\varepsilon|R_{i-1}|)}$. Thus, no matter the size of $C$, the expected number of unhappy points in $C$ is at most $\sum_{q=1}^{\infty} e^{-q21k(\log n)/(\varepsilon|R|)} < \int_{x=0}^{\infty} e^{-x21k(\log n)/(\varepsilon|R_{i-1}|)}dx < \varepsilon|R_{i-1}|/(21k(\log n))$, so with $k$ clusters, the expected fraction of unhappy elements in $R_{i-1}$ is at most $\varepsilon/(21\log n)$. □

CLAIM 10.4. *Let $u$ be the fraction of unhappy points in $R_{i-1}$ after step* D.2.1. *Then the probability that iteration $i$ does not end well is at most $u(2 + 2/\varepsilon)$.*

*Proof.* Let the points in $R_{i-1}$ be sorted in order of increasing distance to $F$, resolving ties so that unhappy points come before happy points. Traverse $R_{i-1}$ and let each unhappy point grab the next $\lceil 2/\varepsilon\rceil$ happy points, if any, that are not grabbed yet. Now, if point $t$ from step D.2.3 is neither unhappy nor grabbed, then each unhappy point in $P_i$ has all its $\lceil 2/\varepsilon\rceil$ grabbed points in $P_i$, and hence (2) is satisfied.

The fraction of points that are unhappy or grabbed by an unhappy point is at most $u(\lceil 2/\varepsilon \rceil + 1)$. ∎

Claim 10.5. *The probability that iteration $i$ does not end well is at most* $1/(7 \log n)$.

*Proof.* By Claim 10.4, the probability that iteration $i$ does not end well is at most the sum over each possible fraction $u$ of unhappy points in $R_i$ of $u(2 + 2/\varepsilon)$ times the probability of the fraction $u$, but this equals $\mathsf{E}[u](2 + 2/\varepsilon)$. Moreover, by Claim 10.3, $\mathsf{E}[u] \le \varepsilon/(21 \log n)$, so we conclude that the probability of not ending well is bounded by $(\varepsilon/(21 \log n))(2 + 2/\varepsilon) \le (2 + 2\varepsilon)/(21 \log n) < 1/(7 \log n)$. The last inequality used the fact that $\varepsilon < 0.5$. ∎

We have at most $3 \log n$ iterations, and so by Claim 10.5, the probability that all iterations end well is at least

$$1 - \frac{(3 \log n)}{(7 \log n)} = \frac{4}{7}.$$

Combining this with Claim 10.1, we conclude that the probability that all iterations end well and that we finish with $R = R_\ell = \emptyset$ is at least $4/7 - o(1) > 1/2$. We now assume this combination of events.

Since we finish with $R = R_\ell = \emptyset$, the $P_i$ partition $P$. Then (1) follows directly from Claim 10.2. This completes the proof of Theorem 10. ∎

Often we prefer a high probability result, as obtained by the following algorithm.

Algorithm E. Given a metric $(P, \mathrm{dist})$, the algorithm constructs a set $F$ of $O(k \log^4 n)$ facilities which, w.h.p., contains a factor $2 + o(1)$ approximation to the $k$-median problem.

```
E.1.    for $i = 1, \ldots, \lceil \log^{3/2} n \rceil$,
E.1.1.      with $\varepsilon = 1/\sqrt{\log n}$, apply Algorithm D to $(P, \mathrm{dist})$, obtaining a set $F_i$
E.2.    return $F = \bigcup_i F_i$
```

Theorem 11. *Algorithm* E *involves $O(\log^{2.5} n)$ computations of nearest neighbors in sets of size $O(k \log^{1.5} n)$, and the final set $F$ has size $O(k \log^4 n)$. Moreover, w.h.p., $k$-mediancost$^{\subseteq F} \le (2 + o(1)) \times k$-mediancost. The $2 + o(1)$ approximation factor holds even if the optimal solution is allowed to place facilities outside $P$.*

*Proof.* By Theorem 10, with probability at least $1 - 1/2^{\log^{3/2} n} = 1 - 1/n^{\omega(1)}$, there is some set $F_i$ with $k$-mediancost$^{\subseteq F_i} \le (2 + 1/\sqrt{\log n}) \times k$-mediancost. Now the result follows because $k$-mediancost$^{\subseteq F} \le k$-mediancost$^{\subseteq F_i}$ for all $i$. ∎

## 5.3. Distance oracles, external memory, and the streaming model.

The simple sampling above has several interesting consequences for distance oracles, with or without memory restrictions.

Proposition 12. *For a metric $(P, \mathrm{dist})$, w.h.p. we can find a factor $(12 + o(1))$ approximation to the $k$-median problem, using $\tilde{O}(kn)$ distance queries and computation time, and $\tilde{O}(n)$ space. The $12 + o(1)$ approximation factor holds even if the optimal solution is allowed to place facilities outside $P$.*

*Proof.* By Theorem 11, we spend $\tilde{O}(kn)$ distance queries on finding a set of $\tilde{O}(k)$ relevant facility locations, and then the algorithm from [19] allows us to solve the $k$-median problem in $\tilde{O}(kn)$ time and space. To get the $\tilde{O}(n)$ space, we actually need the full power of the techniques presented in this paper, as stated in Theorem 32. ∎

The previous $\tilde{O}(kn)$ algorithm by Guha et al. [12] had an approximation factor of $300 + o(1)$ for unbounded $k$ and $80 + o(1)$ if $k = O(\sqrt{n})$.

We will now demonstrate that our techniques give interesting results for various kinds of restricted memory, including the streaming model which was the target of [12]. We will use the following generic algorithm.

ALGORITHM F. Generic $k$-median algorithm for metric $(P, \mathrm{dist})$, which provides a factor $38 + o(1)$ approximation w.h.p.

```
F.1.    Compute the set $F$ using Algorithm E.
F.2.    Construct the multiset $P^F = \{x^F\}_{x \in P}$.
F.3.    Apply Proposition 12 to $P^F$ and return the found solution $S$.
```

Above $P^F$ is the set $F$, but where each $f \in F$ has a multiplicity or weight equal to the number of points $x \in P$ with $x^F = f$. We do not remember which points in $P$ gave rise to the multiplicities, so $P^F$ is stored in $O(|F|) = \tilde{O}(k)$ space. The set $F$ will be computed using some variant of Algorithm D. We place $F$ in internal memory, and then we compute $P^F$ by a linear scan of $P$, taking each point $x \in P$, an identifying $x^F$ in $O(|F|) = \tilde{O}(k)$ time. Hence, given $F$, the construction of $P^F$ takes $\tilde{O}(kn)$ time and $\tilde{O}(k)$ space. Finally Proposition 12 computes $S$ for $P^F$ internally in $\tilde{O}(k^2)$ time and $\tilde{O}(k)$ space.

LEMMA 13. *Algorithm* F *is a factor* $38 + o(1)$ *approximation to the k-median problem for P.*

*Proof.* Let $OPT$ be the optimal solution to the original $k$-median problem over $P$. Now, considering $OPT$ as a solution for $P^F$, the cost is $\mathrm{cost}_{P^F}(OPT) \le \sum_{x\in P} \mathrm{dist}(x^F, x^{OPT}) \le \sum_{x\in P} \mathrm{dist}(x^F, x) + \sum_{x \in P} \mathrm{dist}(x, x^{OPT}) \le k\text{-mediancost}_P^{\subseteq F} + \mathrm{cost}_P(OPT) \le (3 + o(1))\mathrm{cost}_P(OPT)$. We now apply Proposition 12 to $P^F$, getting a solution $S$ with $\mathrm{cost}_{P^F}(S) \le (12 + o(1))\mathrm{cost}_{P^F}(OPT) \le (36 + o(1))\mathrm{cost}(OPT)$. Finally, $\mathrm{cost}_P(S) \le \sum_{x\in P} \mathrm{dist}(x, x^F) + \sum_{x \in P} \mathrm{dist}(x^F, (x^F)^S) = \mathrm{cost}_P(F) + \mathrm{cost}_{P^F}(S) \le (38 + o(1))\mathrm{cost}(OPT)$.

Note even if $OPT \subseteq P$, we may have $OPT \not\subseteq F$, and hence it is important that Proposition 12 does not require that $OPT$ be a subset of the point set. □

Our first restricted memory model is external memory which is divided into blocks. Instead of counting individual accesses to external memory cells, we count the number of read and writes of blocks.

PROPOSITION 14. *W.h.p., in the external memory model with block-size B and access to a distance oracle, if n points are stored in n/B blocks, we can find a factor* $38 + o(1)$ *approximation to the k-median problem using* $\tilde{O}(kn)$ *time and distance queries,* $\tilde{O}(k)$ *internal space, and* $\tilde{O}(n/B)$ *blocks and block operations.*

*Proof.* We simply note that Algorithm D fits perfectly with external memory. In each iteration, we first scan the current set $R$, picking out the new points for $S$ and the point $t$. Both $S$ and $t$ are stored in internal memory. We now make another scan creating the new set $R'$ with the points from $R$ further from $S$ than $t$. Here both $R$ and $R'$ are packed in blocks, so the iteration takes $O(|R|/B)$ block operations. In expectation $R$ decreases by a constant factor in each iteration, and w.h.p., the total number of blocks and block operations is $O(n/B)$. □

Next, we consider a model where we can modify only our internal space, but where we have arbitrary access to the input. This is the model in which log-space is defined as having logarithmic internal space.

PROPOSITION 15. *In Proposition* 12*, the internal space can be reduced to* $\tilde{O}(k)$ *at the expense of increasing the approximation factor to* $38 + o(1)$.

*Proof.* First, we assume that we have access to a random permutation of the points in $P$. We can then implement Algorithm D in a single scan of $P$. From each iteration $j$, we will store the set $T_j$ of new points picked for $S$, the threshold point $t_j$, and the distance $\delta_j$ from $t_j$ to $S_j = \bigcup_{i \le j} T_i$. Now, iteration $j$ is implemented as follows. We continue our scanning of the points from $P$ from where we stopped in the last iteration. A point $x$ is *distant* if for each $i < j$, $\mathrm{dist}(x, S_i) \le \delta_i$. We now build $T_j$ from the next $k/\varepsilon \log^2 n$ distant points, and the following distant point is our new threshold point $t_j$. Finally, we compute $\delta_j = \operatorname{dist}(t_j, S_j)$. The distant points are exactly the points removed from $R$ by Algorithm D, so this is just a new implementation.

To check whether a point $x$ is distant, we do as follows. First we set $d := 0$. Then, for : $i = 1, \ldots, j-1$, we set $d := \min\{d, \operatorname{dist}(x, T_i)\}$, and if $d \leq \delta_i$, we conclude that $x$ is not distant.

In case we do not have access to a random permutation, then we pick $O(n \log n)$ points randomly from $P$, thus making sure that all points are picked eventually. We note that a point will not be distant the second time it is picked, so we do not need to worry about the repetitions. □

In [12], the focus was on the streaming model, where points are stored in a read-only stream that can only be read sequentially from one end to the other, having only limited internal memory. The stream could, for example, be a tape. The main performance measure is the number of times we read over the tape. The main result of [12] is that with $\tilde{O}(kn^{1/\ell})$ internal memory, we can find a $2^{O(\ell)}$ approximation for the $k$-median problem reading the stream once using $\tilde{O}(kn)$ distance queries and internal computation time. Our sampling can directly improve and simplify the techniques from [12]. Their essential step is that they take a set $X \subseteq P$, $|X| \gg k$, points and find a set $F$ of roughly $k$ facilities such that if $OPT$ is the optimal $k$-median solution, the cost of assigning the points in $X$ to $F$ is a constant factor from the cost of assigning the points in $X$ to $OPT$. For this step they use a combination of techniques from [1, 15, 19], and the exact approximation factor is unclear but appears to be large. However, the sampling technique of Theorem 11 does this job directly, with a near-optimal approximation factor of $2 + o(1)$.

More interestingly, we can replace the exponential factor $2^{O(\ell)}$ with a constant, and instead just pay a linear factor $O(\ell)$ in time.

PROPOSITION 16. *W.h.p., in the distance oracle streaming model, with $O(kn^{1/\ell})$ internal memory, we can find a $38 + o(1)$ approximation for the $k$-median problem reading the stream $O(\ell)$ times using $\tilde{O}(kn)$ distance queries and internal computation time.*

*Proof.* We are going to emulate the proof of Proposition 15. Each "streaming round" will correspond to a number of iterations of Algorithm D. In each streaming round we first pick a random set $X$ of $O(kn^{1/\ell})$ points from $P$ that are still distant. To do this, we first make one scan to count the number of distant points. We then select $O(kn^{1/\ell})$ random indices of distant points, and finally, we scan $P$ again, picking out the indexed points. We now continue with the iterations of Algorithm D, as described in the proof of Proposition 15 but taking the random points from $X$. Since we know that we end up picking only $\tilde{O}(k)$ facilities for $S$, in order to run out of points in $X$, we must be skipping all but a fraction $\tilde{O}(k)/O(kn^{1/\ell}) = \tilde{O}(1/n^{\ell})$ of the points. Since $X$ is randomly chosen from points distant at the start of the streaming round, we conclude w.h.p. that the fraction of distant points has dropped by a factor $\tilde{\Omega}(n^{\ell})$. Hence there are only $O(\ell)$ streaming rounds. □

## 5.4. Reducing to $k + k/\log^2 n$ facilities.

In this section, we will show that we can get down from the $k \log^{O(1)} n$ potential facilities from Theorem 11 to a solution $S$ with $k + k/\log^2 n$ facilities. We wish to apply the techniques of Jain and Vazirani [19], but these techniques are quoted only as working with graphs satisfying the triangle inequality. More precisely, let $F$ be the set of potential facilities. They assume all edges in $F \times P$, and that each edge $(a, x) \in F \times P$ has length $\ell(a, x) = \operatorname{dist}(a, x)$. If

$|F| = \log^{\omega(1)} n$, this is too much for our time bounds.

We will now consider what happens when the algorithm from [19] is applied when $G$ does not satisfy the triangle inequality. Define $\ell\text{-cost}(S) = \sum_{x \in P} \ell(x, x^S)$. Here $\ell(x, x^S) = \infty$ if $(x, x^S)$ is not an edge in $G$. What the algorithm from [19] really finds is a $k$-median $S \subseteq F$ with $\text{cost}(S) \le 6 \times k\text{-median-}\ell\text{-cost}^{\subseteq F}$. The point is that the dual variables providing the lower bound in [19] do not require the triangle inequality. The triangle inequality is used only in bounding the gap between the primal solution and the dual variables.

Concerning speed, the algorithm in [19] works in $\tilde{O}(m)$ time. Here we use the randomized rounding from [19, section 3.2]. For that rounding, we have two sets $A$ and $B$ of facilities, and for each $a \in A$, we need to find a nearest facility $a^B \in B$, but by Observation 1, this is done in $\tilde{O}(m)$ time. Because of the randomization, the cost is only expected.

THEOREM 17. *In $\tilde{O}(m)$ time, we can find $S \subseteq F$, $|S| = k$, with an expected cost of* $\text{cost}(S) \le 6 \times k\text{-median-}\ell\text{-cost}^{\subseteq F}$.

To apply this theorem, we construct a graph $G^\ell$ with $\tilde{O}(n)$ edges $(v, w)$, each with $\ell(v, w) = \text{dist}(v, w)$, and with $k^\ell\text{-median-}\ell\text{-cost}_{G^\ell}^{\subseteq F} = O(k\text{-mediancost}^{\subseteq F})$, where $k^\ell = k + k \log^2 n$. Applying Theorem 17 then gives us a $k^\ell$-median $S \subseteq F$ with $\text{cost}(S) \le \text{cost}_{G^\ell}(S) = O(k\text{-mediancost}^{\subseteq F})$.

The construction of $G^\ell$ based on $F$ is rather simple. Set $d = \log^3 n |F|/k = \log^{O(1)} n$. For each point $x \in P$, we include an edge to each of the $d$ nearest neighbors in $F$.

LEMMA 18. *The graph $G^\ell$ has $(k + k/\log^2 n)$-median $S \subseteq F$ with* $\ell\text{-cost}(S) \le k\text{-mediancost}^{\subseteq F}$.

*Proof.* All we need is to show the existence of a set $D \subseteq F$ of size $k/\log^2 n$ which dominates in the sense that each $x$, $x^D$ is one of its $d$ nearest neighbors. We then set $S = OPT \cup D$, where $OPT$ is the optimal solution. If $x^{OPT}$ is one of the $d$ nearest neighbors in $F$, $x^S = x^{OPT}$. Otherwise, $x^S = x^D$ and then $\ell(x, x^D) \le \text{dist}(x, OPT)$, so $\ell\text{-cost}(S) \le \text{cost}(OPT)$.

To show the existence of $D$, we just pick $D$ randomly. For each $x \in P$, the probability that none of its $d$ nearest neighbors are picked is $\le (1 - |D|/|F|)^d < e^{-\log n} < 1/n$, so there is a positive probability that this does not happen for any $x$. ◻

For the construction of $G$, we need the following result.

LEMMA 19. *W.h.p., using $O(d \log n)$ all points nearest marked neighbor computations, we can find the $d$ nearest neighbors in $F$ to each point $x$.*

*Proof.* We pick each $a \in F$ with probability $1/(2d)$ for a set $Q$ of marked neighbors. For each $x \in P$ and each $i \le d$, the probability that $x^Q$ is the $i$th nearest neighbor in $F$ is $\ge (1 - 1/(2d))^{i-1}/2d \ge 1/(4d)$. Hence, in $O(d \log n)$ all points nearest marked neighbor computations, we can find the $d$ nearest neighbors of all $x$ w.h.p. ◻

THEOREM 20. *With probability $1 - O(1/n)$, in $\tilde{O}(m)$ time, we can construct a $k + k/\log^2 n$-median $S$ with* $\text{cost}(S) \le (12 + o(1)) \times k\text{-mediancost}$.

*Proof.* First using Theorem 11, with probability at least $1/2$, we identify a set $F$ of size $k \log^{O(1)} n$ with $k\text{-mediancost}^{\subseteq F} \le (2 + o(1))k\text{-mediancost}$. Then, using the above lemmas, we construct $G^\ell$ with $(k + k/\log^2 n)\text{-median-}\ell\text{-cost}_{G^\ell} \le k\text{-mediancost}^{\subseteq F}$ and finally, we apply Theorem 17 to $G^\ell$ to get a set $S$, $|S| = k + k/\log^2 n$, with an expected cost of $(12 + o(1)) \times k\text{-mediancost}$. ◻

**5.5. Recursing down to $k$ facilities.** Let $OPT$ denote some optimal solution to the $k$-median problem. Our starting point is a solution $S$, as from Theorem 20, of satisfactory cost, that is, $\mathrm{cost}(S) = O(OPT)$, but which uses $q = k/\log^2 n$ too many facilities. We will then first try greedily to remove $q$ facilities from $S$. If this cannot be done at cost $o(\mathrm{cost}(S))$, we will be able to fix many universally good facilities and then recurse.

**5.6. Some basic definitions.** We will use $\alpha = \omega(1) \cup \log^{o(1)}(n)$ to denote a value that grows slowly with $n$, e.g., like an inverse of Ackermann's function.

For our presentation, it is useful for each $a \in S$ to define $\mathrm{clustercost}(a, S) = \sum_{x\in \mathrm{cluster}(a,S)} \mathrm{dist}(x, a)$. Thus, $\mathrm{cost}(S) = \sum_{a\in S} \mathrm{clustercost}(a, S)$. Also, we define $\delta_{a,S} = \mathrm{dist}(a, S \setminus \{a\})$ and $\mathrm{shiftcost}(a, S) = |\mathrm{cluster}(a, S)| \times \delta_{a,S}$. Note that if $b$ is nearest to $a$ in $S$, $\mathrm{shiftcost}(a, S)$ is a trivial upper-bound on the increase in cost encountered by reassigning all $x \in \mathrm{cluster}(x, S)$ to $b$; that is, for $x \in \mathrm{cluster}(a, S)$, $\mathrm{dist}(x, b) - \mathrm{dist}(x, a) \leq \mathrm{dist}(a, b) = \delta_{a,S}$.

Let $a_1, \ldots , a_{|S|}$ be an enumeration of the facilities in $S$ in order of nondecreasing $\mathrm{shiftcost}(\cdot, S)$.

**5.7. Greedy elimination of facilities.** We will now present the following routine.

Greedy$(q, S)$ eliminates $q$ terminals from $S$, increasing the cost by $\mathrm{greedycost}(q, S) \leq \sum_{i\leq 2q} \mathrm{shiftcost}(a_i, S)$.

We consider Greedy successful if $\mathrm{greedycost}(q, S) \leq \mathrm{cost}(S)/\alpha$. Then $\mathrm{cost}(\mathrm{Greedy}(q, S)) = (1 + o(1))\mathrm{cost}(S)$, and we return Greedy$(q, S)$.

To implement Greedy, we will use the following claim.

Lemma 21. *Suppose that each element $a$ in $A$ has at most one successor $s(a) \in A$. Then, in $O(|A|)$ time, we can mark at least $|A|/2$ elements so that if $a$ is marked, $s(a)$ is unmarked.*

*Proof.* Let $P(a) = \{b \in A : s(b) = a\}$. First, we mark all $a$ with $P(a) = \emptyset$. Next, repeatedly, we mark facilities $a \in A$ such that $|P(a)| = 1$, protecting $|P(a)|$ from being marked in a later round. To see that we do not run out of elements, note that on the average, $|P(a)| \leq 1$. Thus, if there are $i$ elements with $P(a) = \emptyset$, there are at most $i$ elements with $|P(a)| > 1$. Each marking of an element $a$ with $|P(a)| = 1$ protects one element from being marked, so we will mark at least half of these elements, leading to a total marking of at least $i + (|A| - 2i)/2 = |A|/2$ elements. □

To implement Greedy, we apply Lemma 21 with $A = \{a_1, \ldots , a_{2q}\}$ and $s(a)$ denoting the facility in $A$ nearest to $a$. We can then eliminate any $q$ marked facilities.

**5.8. When Greedy does not work.** We will now start studying properties of our solution when Greedy does not report success, that is, when $\mathrm{greedycost}(q, S) > \mathrm{cost}(S)/\alpha$. We say that $a \in S$ is *concentrated* if $\mathrm{clustercost}(a, S) \leq \mathrm{shiftcost}(a, S)/\alpha$.

Lemma 22. *If there are $2\alpha^2 q$ facilities in $S$ that are not concentrated, Greedy$(q, S)$ reports success.*

*Proof.* Let $A$ be the set of facilities in $S$ that are not concentrated. Then $\mathrm{greedycost}(q, S) \leq \sum_{i\leq 2q} \mathrm{shiftcost}(a_i, S) \leq \frac{2q}{|A|} \sum_{a\in A} \mathrm{shiftcost}(a, S) < \alpha^{-2} \sum_{a\in A}(\alpha \mathrm{clustercost}(a, S)) \leq \mathrm{cost}(S)/\alpha$. □

Note that if $y \in P \setminus \mathrm{cluster}(a, S)$, $\mathrm{dist}(y, a) \geq 0.5\, \delta_{a,S}$. Define $\Delta(a, S) = \{x \in P : \mathrm{dist}(x, a) \leq (0.25 - 1/\alpha)\delta_{a,S}\}$. It is easy to see that if $a$ is concentrated, most facilities in $\mathrm{cluster}(a, S)$ are inside $\Delta(a, S)$.

We say that a solution $T$ *hits* $a \in S$ if $T \cap \Delta(a, S) \neq \emptyset$; otherwise $T$ *misses* $a$.

Observation 23. *If $T$ misses $a \in S$, then* $\sum_{x\in \mathrm{cluster}(a,S)} \mathrm{dist}(x, T) \geq \sum_{x\in \mathrm{cluster}(a,S)}(\mathrm{dist}(a, T) - \mathrm{dist}(x, a)) \geq (0.25 - 1/\alpha)\, \mathrm{shiftcost}(a, S) - \mathrm{clustercost}(a, S)$, *which is* $\geq (0.25 - 2/\alpha)\mathrm{shiftcost}(a, S)$ *if $a$ is concentrated.*

As a consequence of Observation 23, if $a$ is concentrated but missed by $T$ and we add $a$ to $T$, we reduce the cost by $(0.25 - 3/\alpha)\,\mathrm{shiftcost}(a, S)$.

LEMMA 24. *If $T$ is a solution with $\mathrm{cost}(T) = O(\mathrm{cost}(OPT))$ and $T$ misses $3\alpha^2 q$ facilities in $S$, Greedy$(q, S)$ reports success.*

*Proof.* Among the $3\alpha^2 q$ misses, we may assume that there are $\geq \alpha^2 q$ concentrated facilities, for otherwise Greedy$(S)$ reports success by Lemma 22.

Let $M \subseteq S$ be the set of $\geq \alpha^2 q$ concentrated facilities missed by $T$. By Observation 23, $\mathrm{cost}(T) \geq \sum_{a\in M} \sum_{x\in \mathrm{cluster}(a,S)} \mathrm{dist}(x, T) = \sum_{a\in M} (0.25-2/\alpha)\,\mathrm{shiftcost}(a, S)$ $\geq \frac{(0.25-2/\alpha)|M|}{2q} \sum_{i\leq 2q} \mathrm{shiftcost}(a_i, S) \geq \Omega(\alpha^2)\mathrm{greedycost}(q, S)$. Now, $\mathrm{cost}(OPT) \leq \mathrm{cost}(S) + \mathrm{greedycost}(q, S) = \mathrm{cost}(S) + o(\mathrm{cost}(T)/\alpha) = \mathrm{cost}(S) + o(OPT/\alpha)$, and thus $\mathrm{greedycost}(q, S) = o(\mathrm{cost}(S)/\alpha)$. ∎

**5.9. The basic recursion.** As hinted at by Lemma 24, if Greedy$(q, S)$ is not successful, no good solution can be too far away from our current solution $S$. We will exploit this recursively by fixing most of the facilities with high shiftcost.

In order to code the fixing of facilities, we introduce the notion of a *free facility*, which is a facility which is automatically included in any $k$-median solution, but which does not count as one of the $k$ medians. In addition, we want to encode a penalty for not using a fixed facility anyway. This is done by introducing a *single* point $s$ whose only link is to a free facility $f$. Thus the assignment cost of $s$ is $\ell(s, f)$ if $s$ is not picked as a facility, and 0 otherwise.

We are now ready to describe the basic mechanics of our general recursion, but ignoring that we may have free facilities and singles in our own input.

ALGORITHM G. Solves $k$-median problem assuming no free facilities or singles in input.

```
G.1.    Construct $S \subseteq P$, $|S| \leq k + q$, $q = k/\log^2 n$ with $\mathrm{cost}(S) = O(k\text{-mediancost})$
        (cf. sections 5.2 and 5.4).
G.2.    Let $a_1, \ldots, a_{|S|}$ be the facilities in $S$ in order of increasing shiftcost (cf. sec-
        tion 5.7).
G.3.    If $\mathrm{greedycost}(q, S) \leq \mathrm{cost}(S)/\alpha$ (cf. section 5.7), return Greedy$(q, S)$ and exit
        the recursion.
G.4.    Produce a modified graph $G'$, fixing more than half the facilities as follows.
G.4.1.      Set $U = S \setminus (NOTCONC \cup SMALLSHIFT \cup LARGE)$, where
            $NOTCONC$ is the set of nonconcentrated facilities, $SMALLSHIFT =$
            $\{a_1, \ldots, a_r\}$ with $r = \alpha^4 q \log n$, and $LARGE = \{a \in S : \mathrm{clustercost}(a, S)$
            $\geq \frac{\mathrm{cost}(S)}{(\alpha^3 q \log n)}\}$.
            Define smallshiftcost = $\mathrm{shiftcost}(a_r, S)$.
G.4.2.      Using the technique from [18] (cf. the appendix), for each $a \in U$ find a
            factor $(1 + 1/\alpha)$ approximate 1-median $a'$ for $\Delta(a, S)$. If $a$ is a better
            1-median for $\Delta(a, S)$ than $a'$, set $a' := a$. We are going to use $a'$ in our
            final solution.
            Note that for distances over $\Delta(a, S)$ we need to consider only paths
            inside cluster$(a, S)$. Hence our approximate 1-medians are found based
            on disjoint induced subgraphs, so the total running time is $\tilde{O}(m)$.
G.4.3.      Create a free facility $f$ with a zero length edge to each $a'$, $a \in U$. Reduce
            all distances from $f$ by a factor 2; that is, first compute all shortest paths
            from $f$, and second add an edge to each vertex of length half the found
            distance.
G.4.4.      Introduce a set $AUX$ of $p_{\max} = 3\alpha^2 q$ singles, each connected to $f$ by an
```

```
            edge of length $(0.25 - 2.5/\alpha)$smallshiftcost.
G.4.5.      Set $k' := k - |U| + p_{\max}$. Since $q = k/\log^2 n$, $k' = q\alpha^{O(1)} \log n = o(k)$.
        In section 5.10 it will be shown that the modified graph $G'$ admits a $k'$-median
        at cost $(1 + o(1/\log n))$ times the minimal cost of a $k$-median for $G$.
G.5.    Recursively, find a $k'$-median $S'$ for the modified graph.
G.6.    Using the knowledge of $S$, we modify $S'$ into a $k$-median solution $S^*$ for the
        original graph $G$, as follows.
G.6.1.      Set $S'' = (S' \cup \{a'\}_{a\in U}) \setminus (\{f\} \cup AUX)$. All points that were assigned
            to $f$ are now assigned to their nearest facility $a'$.
            Then $S'' \subseteq P$ and $|S''| = k + p$, where $p = |AUX \setminus S'|$.
G.6.2.      Reduce $S''$ to $S^*$ by removal of $p$ facilities from $\bigcup_{a\in SMALLSHIFT} \Delta(a, S)$
            as described in section 5.11, at cost $p(2.5 - 2/\alpha)$ smallshiftcost+
            $o(\text{cost}(S)/\log n)$.
G.7.    Return $S^*$.
```

To understand the basics of the above algorithm, first note that we lose a factor $(1+o(1/\log n))$ both in step G.4 and in step G.6.2. However, the recursion has depth $o(\log k)$, so the total loss due to these factors is $(1 + o(1/\log n))^{o(\log k)} = (1 + o(1))$.

Now, since we end up using all the facilities $a'$, the reader may wonder why we even bother introducing the singles in $AUX$ that we eliminate anyway. The direct reason is that if we did not have any singles in $AUX$ and just sought a $k-|U|$ median recursively, then an optimal solution for the modified solution could be a constant factor worse than that of the original optimal solution, and hence we would lose a constant factor in each recursive step. Another obstacle is that for step G.6.2 we actually use the knowledge of $S$ to deal with the singles, and there is no obvious way of including this knowledge recursively.

As the recursion stands, our main loss is when we return from the recursion and modify $S'$ into $S^*$. In step G.6.1, each $x$ previously assigned to $f$ gets assigned to a facility $a'$ that is twice as far away. However, for each point $x$, such a reassignment will happen only once throughout the recursion. Similarly, for the singles, we lose a factor $\phi = (2.5 - 2/\alpha)/(0.25 - 2.5/\alpha) = 10 + o(1)$ in cost when they get eliminated, and again this happens only once for each single.

## 5.10. Cheap fixing of facilities.

In this section, we will show the following.

THEOREM 25. *For step* G.4*, there is a $k'$-median $OPT'$ for $G'$ with* $\text{cost}_{G'}(OPT') \leq (1 + o(1/(\alpha \log n)))\text{cost}(OPT)$*, where $OPT$ is an optimal $k$-median for $G$.*

*Proof.* Let $p$ be the number of facilities in $S$ not hit by $OPT$. By Lemma 24 with $T = OPT$, $OPT$ misses at most $3\alpha^2 q = p_{\max}$ facilities. We then obtain $OPT'$ from $OPT$ by first deleting all facilities in $\bigcup_{a\in U} \Delta(a, S)$, thus deleting at least $|U|-p$ facilities from $OPT'$. Second we add $|AUX| - p$ facilities from $AUX$. As a result, $OPT'$ gets at most $k - (|U| - p) + |AUX| - p = k'$ nonfree facilities, as desired.

We will now reassign points from $OPT$ to $OPT'$, attributing the reassignments, and their costs, to the different $a \in U$:

- If $a$ is not hit by $OPT$, we reassign each $x \in \Delta(a, S)$ to $f$. Further, we assign one point $a^s$ in $AUX \setminus OPT'$ to $f$, at cost $(0.25 - 2.5/\alpha)$smallshiftcost.
- If $a$ is hit by $OPT$, all points $x$ with $x^{OPT} \in \Delta(a, S)$ or $x \in \Delta(a, S)$ are reassigned to $f$.

Before analyzing the cost of the reassignments, we need some simple observations. (This is all part of our proof of Theorem 25.) First, as a general strengthening of Observation 23, we have the next claim.

CLAIM 25.1. *If* $\text{dist}(a, T) \geq \beta\, \delta_{a,S}$ *and* $\beta \leq 0.25 - 1/\alpha$, $\sum_{x\in\Delta(a,S)} \text{dist}(x, T) \geq$

$\beta\,\text{shiftcost}(a,S) - \text{clustercost}(a,S)$.

*Proof.* We see $\sum_{x\in\Delta(a,S)} \text{dist}(x,T) \ge \sum_{x\in\Delta(a,S)}(\text{dist}(a,T) - \text{dist}(a,x)) \ge \sum_{x\in\Delta(a,S)}(\beta\,\delta_{a,S} - \text{dist}(a,x)) \ge \sum_{x\in\text{cluster}(a,S)}(\beta\,\delta_{a,S} - \text{dist}(a,x)) \ge \beta\,\text{shiftcost}(a,S) - \text{clustercost}(a,S)$. In the third inequality above we used that $\beta\,\delta_{a,S} - \text{dist}(a,x)$ is negative for $x \notin \Delta(a,S)$. ∎

CLAIM 25.2. $\text{dist}(a,a') \le 2\delta_{a,S}/\alpha$.

*Proof.* If $\text{dist}(a,a') > 2\delta_{a,S}/\alpha$, by Claim 25.1, with $\beta = \frac{2}{\alpha}$, $\sum_{x\in\Delta(a,S)} \text{dist}(x,a') > 2\,\text{shiftcost}(a,S)/\alpha - \text{clustercost}(a,S) \ge \text{clustercost}(a,S) \ge \sum_{x\in\Delta(a,S)} \text{dist}(x,a)$, contradicting that $a'$ is at least as good a median for $\Delta(a,S)$ as $a$. ∎

CLAIM 25.3. $\sum_{x\in\text{cluster}(a,S)} \text{dist}_{G'}(x,f) \le \text{clustercost}(a,S)/(2-o(1))$.

*Proof.* First note that $\sum_{x\in\Delta(a,S)} \text{dist}_{G'}(x,f) = \sum_{x\in\Delta(a,S)} \text{dist}(x,a')/2 \le \sum_{x\in\Delta(a,S)} \text{dist}(x,a)/2$. However, if $x \in \text{cluster}(a,S) \setminus \Delta(a,S)$, using Claim 25.2, $\text{dist}(x,a') \le \text{dist}(x,a) + \text{dist}(a,a') \le \text{dist}(x,a) + 2\delta_{a,S}/\alpha \le (1+o(1))\text{dist}(x,a)$. Hence $\text{dist}_{G'}(x,f) \le \text{dist}(x,a')/2 \le \text{dist}(x,a)/(2-o(1))$. ∎

We are now ready to account for the change in cost due to the reassignments in connection with each $a \in U$.

*Suppose that OPT did not hit a.* First we have an added increase of $(0.25 - 2.5/\alpha)$ smallshiftcost for assigning $a^s$ to $f$. The only other points that get reassigned are points in $\Delta(a,S)$. By Claim 25.1 with $\beta = 0.25 - 1/\alpha$, $OPT$ paid $\sum_{x\in\Delta(a,S)} \text{dist}(x,OPT) \ge (0.25-1/\alpha)\,\text{shiftcost}(a,S) - \text{clustercost}(a,S)$. However, we only pay $\sum_{x\in\Delta(a,S)} \text{dist}_{G'}(x,f) \le \sum_{x\in\Delta(a,S)} \text{dist}(x,a)/2 \le \text{clustercost}(a,S)/2$, so the reassignments to $f$ buys us at least $(0.25-1/\alpha)\,\text{shiftcost}(a,S) - 1.5\text{clustercost}(a,S) \ge (0.25-2.5/\alpha)\,\text{shiftcost}(a,S) \ge (0.25-2.5/\alpha)$ smallshiftcost, matching the new assignment cost for $a^s$.

*Suppose that OPT did hit a.* First, we argue that if $x \notin \text{cluster}(a,S)$, the assignment cost for $x$ can only go down. We are reassigning $x \notin \text{cluster}(a,S)$ only if $x^{OPT} \in \Delta(a,S)$.

CLAIM 25.4. *If* $x \notin \text{cluster}(a,S)$ *and* $x^{OPT} \in \Delta(a,S)$, $\text{dist}_{G'}(x,f) \le \text{dist}(x,OPT)$.

*Proof.* Define $\gamma \ge 0$ by $\text{dist}(x,a) = (0.5+\gamma)\delta_{a,S}$. Then $\text{dist}(x,OPT) \ge \text{dist}(x,a) - \text{dist}(a,x^{OPT}) \ge (0.25+\gamma+1/\alpha)\delta_{a,S}$, and using Claim 25.2, $\text{dist}(x,a') \le \text{dist}(x,a) + \text{dist}(a,a') \le (0.5+\gamma+2/\alpha)\delta_{a,S}$. Hence $\text{dist}(x,f) = \text{dist}(x,a')/2 \le \text{dist}(x,a)$. ∎

Thus we do well on all $x \notin \text{cluster}(a,S)$. To complete the proof, we further divide in cases depending on whether or not $OPT$ has exactly one facility in $\text{cluster}(a,S)$.

*Suppose that OPT has* one *facility in* $\text{cluster}(a,S)$. Since $OPT$ hits $a$, this facility is $a^{OPT} \in \Delta(a,S)$. Having dealt with $x \notin \text{cluster}(a,S)$, it suffices to demonstrate an improvement over $x \in \text{cluster}(a,S)$. First we show we are done if $a^{OPT}$ is not close to $a$.

CLAIM 25.5. *If* $\text{dist}(a,a^{OPT}) > 2\delta_{a,S}/\alpha$, *then* $\sum_{x\in\text{cluster}(a,S)} \text{dist}_{G'}(x,f) < \sum_{x\in\text{cluster}(a,S)} \text{dist}(x,OPT)$.

*Proof.* By Claim 25.1 with $\beta = 2/\alpha$, we have $\sum_{x\in\text{cluster}(a,S)} \text{dist}(x,OPT) \ge \sum_{x\in\Delta(a,S)} \text{dist}(x,OPT) > 2\,\text{shiftcost}(a,S)/\alpha - \text{clustercost}(a,S)$. However, by Claim 25.3, our cost is $\sum_{x\in\text{cluster}(a,S)} \text{dist}_{G'}(x,OPT) < \text{clustercost}(a,S)$, and since $a$ is concentrated, $\text{shiftcost}(a,S)/\alpha \ge \text{clustercost}(a,S)$. ∎

CLAIM 25.6. *If* $\text{dist}(a,a^{OPT}) \le 2\delta_{a,S}/\alpha$, $x \notin \Delta(a,S)$, *and* $x^{OPT} = a^{OPT}$, *then* $\text{dist}_{G'}((x,f) \le \text{dist}(x,a^{OPT})/(2-o(1))$.

*Proof.* $\text{dist}(x,a^{OPT}) \ge \text{dist}(x,a) - \text{dist}(a,a^{OPT}) \ge \text{dist}(x,a) - 2\delta_{a,S}/\alpha$. On the other hand, by Claim 25.2, $\text{dist}_{G'}(x,f) \le (\text{dist}(x,a) + \text{dist}(a,a'))/2 \le \text{dist}(x,a)/2 + \delta_{a,S}/\alpha$. Since $\text{dist}(x,a) = \Omega(\delta_{a,S})$, the claim follows. ∎

In order to deal with $x \in \Delta(a, S)$, we first prove the next claim.

CLAIM 25.7. *If* $\operatorname{dist}(a, a^{OPT}) \le 2\delta_{a,S}/\alpha$ *and* $x \in \Delta(a, S)$, *then* $\operatorname{dist}(x, OPT) \ge \operatorname{dist}(x, a^{OPT})$.

*Proof.* If $x^{OPT} \ne a^{OPT}$, $x^{OPT} \notin \operatorname{cluster}(a, S)$, so $\operatorname{dist}(x, OPT) \ge (0.25+1/\alpha)\delta_{a,S}$. On the other hand, $\operatorname{dist}(x, a^{OPT}) \le \operatorname{dist}(x, a) + \operatorname{dist}(a, a^{OPT}) \le (0.25 - 1/\alpha + 2/\alpha)\delta_{a,S}$. □

CLAIM 25.8. *If* $\operatorname{dist}(a, a^{OPT}) \le 2\delta_{a,S}/\alpha$, *then* $\sum_{x\in\Delta(a,S)} \operatorname{dist}_{G'}(x, f) \le \sum_{x\in\Delta(a,S)} \operatorname{dist}(x, OPT)$.

*Proof.* By Claim 25.7, $\sum_{x\in\Delta(a,S)} \operatorname{dist}(x, OPT) \ge \sum_{x\in\Delta(a,S)} \operatorname{dist}(x, a^{OPT}) \ge$ 1-mediancost$_{\Delta(a,S)} \ge (\sum_{x\in\Delta(a,S)} \operatorname{dist}(x, a'))/(1 + 1/\alpha) \ge (2 - o(1)) \cdot \sum_{x\in\Delta(a,S)} \operatorname{dist}_{G'}(x, f)$. □

Thus, if $|OPT \cap \Delta(a, S)| = 1$, the reassignments decrease the cost, by Claims 25.4, 25.5, 25.6, and 25.8.

*Finally, suppose that* $|OPT \cap \operatorname{cluster}(a, S)| > 1$. By Claim 25.4 we can restrict our attention to $x \in \operatorname{cluster}(a, S)$. By Claim 25.3, $\sum_{x\in\operatorname{cluster}(a,S)} \operatorname{dist}_{G'}(x, f) < \operatorname{clustercost}(a, S)$. Since $a \notin LARGE$, this cost is bounded by $\operatorname{cost}(S)/(q\alpha^3 \log n)$. However, by Lemma 24, $OPT$ misses $\le 3\alpha^2 q$ facilities in $S$, and hence $OPT$ can make multiple hits of at most $(3\alpha^2 q - q)$ facilities in $S$, so our total cost encountered in this case is $o(\operatorname{cost}(S)/(\alpha \log n))$, as claimed. This completes the proof of Theorem 25. □

## 5.11. Eliminating facilities with small shiftcost.

THEOREM 26. *Assume that Greedy$(q, S)$ is not successful and that we are given a $k$-median with* $\operatorname{cost}(T) = O(k\text{-mediancost})$. *We can then free* $p \le p_{\max}$ *facilities from* $T \cap \bigcup_{a\in SMALLSHIFT} \Delta(a, S)$, *increasing the cost of $T$ by at most* $(2.5 - 2/\alpha)p\,\text{smallshiftcost} + o(\operatorname{cost}(T)/(\alpha \log n))$.

*Proof.* We will identify a set $D \subseteq SMALLSHIFT$, $|D| = p$, of facilities from $S$ that are all hit by $T$, and let the modified set be $T' = T \setminus \bigcup_{a\in D} \Delta(a, S)$. Then $|T'| \le |T| - p$, as desired.

For the analysis of the cost increase, for each $a \in D$, we will reassign all $x$ with $x^T \in \Delta(a, S)$ to $x^{T'} = b^T$, where $b$ is the nearest facility in $S$ to $a$. Hence $D$ needs to be selected so that $b^T \notin \Delta(c, S)$ for any $c \in D$. We will then prove Theorem 26 by showing that the reassignment cost over all $x$ with $x^T \in \Delta(a, S)$ is $(2.5 - 2/\alpha)\operatorname{shiftcost}(a, S) + o(\operatorname{cost}(T)/(\alpha p \log n))$.

More precisely, the set $D$ will be selected subject to the following conditions:

(i) $c \notin D$ if there is a $b \in S$ not hit by $T$ with $b^T \in \Delta(c, S)$. By Lemma 24, there are $\le 3\alpha^2 q$ facilities $b \in S$ not hit by $T$, so this prevents only $\le 3\alpha^2 q$ facilities from entering $D$.

(ii) $a \notin D$ if $\sum_{x^T\in\Delta(a,S), x\notin\operatorname{cluster}(b,x)} \operatorname{dist}(x, T) \ge 4\operatorname{cost}(T)/(\alpha^2 p \log n)$. For each $x$, there is at most one $a \in S$ with $x^T \in \Delta(a, S)$, and thus $\sum_{a\in S} \sum_{x^T\in\Delta(a,S), x\notin\operatorname{cluster}(a,S)} \operatorname{dist}(x, T) \le \operatorname{cost}(T)$. This prevents at most $\alpha^2 p \log n/4 \le \frac{3}{4}\alpha^4 q \log n$ facilities from entering $D$.

(iii) $b \notin D$ if $b$ is hit by $T$ and $b$ is nearest in $S$ to some $a \in D$.

Consider some $a \in D$ with $b$ nearest to $a$ in $S$. We want to argue that $b^T \in T'$, and hence that $b^T \notin \Delta(c, S)$ for any $c \in D$. If $b$ is not hit by $T$, this follows immediately from (i). However, if $b$ is hit, $b^T \in \Delta(b, S)$, and by (iii), $b \notin D$.

As mentioned above, we are going to reassign all $x$ with $x^T \in \Delta(a, S)$ to $b^T$. Then the cost increase for $x$ is bounded by $\operatorname{dist}(x^T, b^T) \le 2\operatorname{dist}(x^T, b) \le 2\,(\operatorname{dist}(x^T, a) +$

$\operatorname{dist}(a,b)) \leq (2.5 - 2/\alpha)\,\delta_{a,S}$. Hence, the cost increase over all $x \in \operatorname{cluster}(a,S)$ is at most $\sum_{x\in\operatorname{cluster}(a,S)}((2.5-2/\alpha)\,\delta_{a,S}) \leq (2.5-2/\alpha)\operatorname{shiftcost}(a,S)$.

Now, consider $x \notin \operatorname{cluster}(a,S)$. Then $\operatorname{dist}(x,x^T) \geq \delta_{a,S}/4$, so the cost increase is $\geq (2.5-2/\alpha)\,\delta_{a,S} > 10\operatorname{dist}(x,x^T)$. Hence by (ii), for each $a \in D$, the cost increase over all $x$ with $x^T \in \Delta(a,S)$ and $x \notin \operatorname{cluster}(a,x)$ is at most $40\operatorname{cost}(T)/(\alpha^2 p\log n) = o(\operatorname{cost}(T)/(\alpha p\log n)$.

Thus, the total reassignment cost over all $x$ with $x^T \in \Delta(a,S)$ is at most $(2.5 - 2/\alpha)\operatorname{shiftcost}(a,S) + o(\operatorname{cost}(T)/(\alpha p\log n))$, as desired.

Our last problem is to construct the set $D$. As mentioned above, (i) and (ii) rule out at most $3\alpha^2 q + \frac{3}{4}\alpha^4\log n$ facilities. Since $|SMALLSHIFT| = \alpha^4 q\log n$, this leaves us with a subset $A \subseteq SMALLSHIFT$ of $\Omega(\alpha^4 q\log n)$ facilities satisfying (i) and (ii). By Lemma 21, we can mark at least half the facilities in $A$ so that $a$ is not marked if it is nearest in $S$ to some marked facility $b$. Then (iii) is trivially satisfied by picking $D$ as any set of $p \leq p_{max} = 3\alpha^2 q = o(\alpha^4 q\log n)$ marked facilities from $A$. ∎

**5.12. The true recursion.** In order to deal formally with the loss factors mentioned at the end of section 5.9, we need to consider graphs of the type $G^{c(d)}$, denoting the graph obtained from $G$ by multiplying the lengths of edges from free facilities by $c$ if they are to nonsingles and by $d$ if they are to singles. Also, define $G^c = G^{c(c)}$.

Our recursive solution $S$ to the $k$-median problem for $G$ with free facilities and singles will, with probability $(1 - O(1/n))$, satisfy

$$\operatorname{cost}_{G^{2(\phi)}}(S) \leq \left(1 + \frac{1}{(\alpha\log n)}\right)^{\log k}(1+\varepsilon)12 \times k\text{-mediancost}, \tag{3}$$

where $\phi = (2.5 - 2/\alpha)/(0.25 - 2.5/\alpha) = 10 + o(1)$ and $\varepsilon = o(1)$ is to be determined. Then the right-hand side reduces to $(12+o(1))k$-mediancost, and by definition, $\operatorname{cost}(S) \leq \operatorname{cost}_{G^{2(\phi)}}(S)$, so (3) implies $\operatorname{cost}(S) \leq (12 + o(1))k$-mediancost.

We now have to modify our basic recursion (cf. Algorithm G) so as to deal with free facilities and singletons so that we can formally prove (3).

As a very first preliminary step, if there are several free facilities in our input graph, we contract them into a single free facility $f_{in}$, where $\ell(f_{in}, x)$ is the shortest length of an edge from a free facility to $x$, and $\infty$ otherwise.

To implement step G.1, we modify the material from sections 5.2 and 5.4 to prove the next result.

Theorem 27. *In $\tilde{O}(m)$ time, with probability $1 - O(1/n)$, we can construct a $k + k/\log^2 n$-median $S$ with* $\operatorname{cost}_{G^{2(\phi)}}(S) \leq (12 + o(1)) \times k$-mediancost.

*Proof.* Concerning the sampling in section 5.2, we simply start Algorithm D by setting $S := \{f_{in}\}$. The algorithm is then run as before except that distances are computed in $G^2$. For the analysis, we consider all points assigned $f_{in}$ to be happy from the beginning. We then preserve that $\operatorname{dist}_{G^2}(x,S) \leq 2\operatorname{dist}(x,OPT)$ for all happy $x$. Consequently, the final sampled $F$ will satisfy $k$-mediancost$^{\subseteq F}_{G^2} \leq (2+o(1))\operatorname{cost}(OPT)$, as in Theorem 11.

Taking $H = G^2$ as starting point for the techniques in section 5.4, the first step is to include all links from $f_{in}$ in the graph $H^\ell$ to which we apply the algorithm from [19]. For the facility location in [19, section 2], we set the cost of $f_{in}$ to 0, whereas the cost is $z$ for all other points. To prove Theorem 27, we need to show that singles can be included optimally. For a given $z$ it is optimal to include a single $s$ linked to free facility $f$ if and only if $z \geq \operatorname{dist}(s,f)$. Hence, we do not pay the factor 3 from [19, Lemma 6]. Also, we avoid paying the factor 2 for rounding in [19, sections 3.3–5] if we make sure that $A$ and $B$ pick the same free facilities. To achieve this with $z_1 \geq z_2$ as in [19, section 3.3], we note that we can freely choose whether to include $s$ if $\text{dist}(a^p, f) \in [z_2, z_1]$, and hence we just need to make the same choices for $A$ and $B$. Thus we avoid any penalty for singles. Consequently, with $k^\ell = k + k/\log^2 n$, we end up with a $k^\ell$-median $S$ for $H$ with $\text{cost}_{H^{1(\phi/2)}}(S) = (1+o(1)) \max\{6, \phi/2\} k\text{-mediancost}_H^{\subseteq F} = (6+o(1))k\text{-mediancost}_H^{\subseteq F}$. Since $H^{1(\phi/2)} = G^{2(\phi)}$, we get $\text{cost}_{G^{2(\phi)}}(S) = (2+o(1))\text{cost}_{H^{1(\phi/2)}}(S) \leq (12+o(1))k\text{-mediancost}$, as desired. $\square$

Concerning shiftcost, we define $\text{shiftcost}(f_{in}, S) = \infty$, coding that $f_{in}$ may not be eliminated. For each input single facility $s$, we define $\text{shiftcost}(s, S) = \text{dist}(s, f_{in})/(0.25 - 2.5/\alpha)$, thus reversing the effect of step G.4.4 from when $s$ was created. Step G.2 uses this definition of shiftcost for the ordering.

The application of $\text{Greedy}(q, S)$ in step G.3 is unchanged, and our success criterion is still that the cost increase is bounded by $\text{cost}(S)/\alpha$. Then $\text{cost}_{G^{2(\phi)}}(\text{Greedy}(q, S)) \leq (1+\phi/\alpha)\text{cost}_{G^{2(\phi)}}(S) \leq (12+\varepsilon)k\text{-mediancost}$ with $\varepsilon = o(1)$. This defines the $\varepsilon$ in (3), which is hence satisfied if Greedy is successful.

If Greedy was not successful, we need to argue that the analysis from section 5.8 is still valid. All measures are still done in $G$. The free facility $f_{in}$ does not cause any problems. For a single facility $s$, we have $\text{cluster}(s, S) = \Delta(s, S) = \{s\}$, $\text{cost}(s, S) = 0$, and $\text{shiftcost}(s, S) = \text{dist}(s, f_{in})/(0.25 - 2.5/\alpha)$, so $s$ is concentrated. The cost of eliminating $s$ is $\text{dist}(s, f_{in})$. Observation 23 still holds for nonsingles, and for a single $s$, we note that if $T$ misses $s$, $\sum_{x \in \text{cluster}(s,S)} \text{dist}(x, T) = \text{dist}(s, f_{in}) = (0.25 - 2.5/\alpha)\text{shiftcost}(s, S)$. This bound suffices for our application of Observation 23 in Lemma 24, giving us our $3\alpha^2 q$ bound on the maximal number of missed facilities.

In step G.4.1 we remove $f_{in}$ from $U$, and in step G.4.3 we only set $\ell(x, f) = \text{dist}(x, a')/2$ if $f_{in}$ is not on all shortest paths from $x$ to $a'$. Our purpose here is to avoid reducing previously reduced distances. To see what happens with a single $s \in U$, first note that step G.4.2 sets $s' = s$. Also, since $f_{in}$ is the only neighbor $s$, step G.4.3 has no effect. Finally, a new single $t \in AUX$ from step G.4.4 has $\text{dist}_{G'}(t, f) = (0.25 - 2.5/\alpha)\text{smallshiftcost} \leq \text{dist}(s, f_{in})$.

For step G.4, we need to establish that Theorem 25 remains true, that is there is a $k'$-median $OPT'$ for $G'$ with $\text{cost}_{G'}(OPT') \leq (1 + o(1/(\alpha \log n)))\text{cost}(OPT)$. The construction of $OPT'$ is unchanged. Our reasoning above about singles implies that the cost over $\text{cluster}(s, S) = \{s\}$ goes down from $\text{dist}(s, f_{in})$ to $\text{dist}(s^s, f) \leq \text{dist}(s, f_{in})$ if $s \notin OPT$, and otherwise it stays 0.

For a nonsingle $a \in U$, we need to argue that our analysis is preserved despite the constraint that we do not set $\ell(x, f) \leq \text{dist}(x, a')/2$ if all shortest paths from $x$ to $a'$ go through $f_{in}$. However, a point $x$ is only affected by changes around $a$ if $x \in \Delta(a, S)$ or $x^{OPT} \in \Delta(a, S)$. Hence our analysis is preserved if we can prove the next results.

LEMMA 28. *If $x \in \Delta(a, S)$ or $x^{OPT} \in \Delta(a, S)$, no shortest path from $x$ to $a'$ passes $f_{in}$.*

*Proof.* By Claim 25.2, $\text{dist}(a, a') \leq 2\delta_{a,S}/\alpha$.

Now, if $x \in \Delta(a, S)$, $\text{dist}(x, a') \leq (0.25 - 1/\alpha)\delta_{a,S} + 2\delta_{a,S}/\alpha = (0.25 + o(1))\delta_{a,S}$, whereas $\text{dist}(x, f_{in}) \geq 0.75\,\delta_a$, so clearly $f_{in}$ cannot be on a shortest path from $x$ to $a'$.

Suppose $x^{OPT} \in \Delta(a, S)$ and that a shortest path from $x$ to $a'$ passs $f_{in}$. Then $\text{dist}(x, x^{OPT}) \geq \text{dist}(x, a') - (\text{dist}(a', a) + \text{dist}(a, x^{OPT}) \geq \text{dist}(x, a') - (2/\alpha + 0.25 - 1/\alpha)\delta_{a,S} = \text{dist}(x, a') - (0.25 + o(1))\delta_{a,S}$. However, $\text{dist}(x, f_{in}) \leq \text{dist}(x, a') - \text{dist}(a', f_{in}) \leq \text{dist}(x, a') - (\text{dist}(a, f_{in}) - \text{dist}(a, a')) \leq \text{dist}(x, a') - (1 - 2/\alpha)\delta_{a,S}$.

Since $f_{in} \in OPT$, this contradicts $x^{OPT}$ nearest to $x$ in $OPT$. ◻

Thus Theorem 25 remains true, and $k'$-mediancost$(G') \le (1 + o(1/(\alpha \log n))) \times$ $k$-mediancost$(G)$.

We now apply the recursive step G.5. Using (3) inductively, we get a $k'$-median $S'$ for $G'$ with $\mathrm{cost}_{G'^{2(\phi)}}(S') \le (1 + 1/(\alpha \log n))^{\log k'}(1 + \varepsilon)12 \times k\text{-mediancost}(G')$, which since $k' = o(k) < k/4$, is bounded by $(1 + 1/(\alpha \log n))^{(\log k)-1}(1 + \varepsilon)12 \times$ $k$-mediancost$(G)$.

Concerning step G.6.1, we want to argue as follows.

LEMMA 29. $\mathrm{cost}_{G^{2(\phi)}}(S'') \le \mathrm{cost}_{G'^{2(\phi)}}(S') - p(2.5 - 2/\alpha)\,\mathrm{smallshiftcost}$.

*Proof.* First note that when we delete $AUX$ from $G'$ and $S'$, for each of the $p$ facilities in $S' \setminus AUX$, we save $\phi(0.25 - 2.5/\alpha)$smallshiftcost $> (2.5 - 2/\alpha)$ smallshiftcost, as desired.

It remains to show that the deletion of $f_{in}$ with incident edges and the inclusion of $\{a'\}_{a \in U}$ does not increase our cost. Consider any $x$. The assignment cost of $x$ is affected only if either (a) $x^{S'} = f$ or (b) a shortest path from $x$ to $x^{S'}$ uses an edge incident to $f$. However, the two cases coincide, for clearly (a) implies (b), and (b) implies that $f$ is as near to $x$ as $x^{S'}$, and hence we can assume (a).

By (a), $x$ is not a single, since all singles linked to $f$ have been deleted. On a shortest path from $x$ to $f$ in $G'$ it is only the last edge $(y, f)$ that is incident to $f$. Then the assignment cost for $x$ was $\mathrm{dist}_{G'^{2(\phi)}}(x, y) + 2\ell(y, f)$, and $\mathrm{dist}_{G'^{2(\phi)}}(x, y) = \mathrm{dist}_{G^{2(\phi)}}(x, y)$. If $x$ is now assigned to $a'$, we know that $\ell(y, f) = \mathrm{dist}(y, f)/2$. Further, the edge $(y, f)$ was created only because a shortest path from $x$ to $a'$ did not contain $f$, and hence $\mathrm{dist}(y, f) = \mathrm{dist}_{G^{2(\phi)}}(y, f)$. Thus, the assignment cost for $x$ is unchanged. ◻

For the final step G.6.2, we want to prove the following version of Theorem 26 dealing with free facilities and singles.

THEOREM 30. *Assume that Greedy$(q, S)$ is not successful and that we are given a $k$-median with* $\mathrm{cost}(T) = O(k\text{-mediancost})$. *We can then free $p \le p_{\max}$ facilities from $T \cap \bigcup_{a \in SMALLSHIFT} \Delta(a, S)$, increasing the cost of $T$ in $G^{2(\phi)}$ by at most* $(2.5 - 2/\alpha)p\,\mathrm{smallshiftcost} + o(\mathrm{cost}(T)/(\alpha \log n))$.

*Proof.* Our proof consists of small modifications to the proof of Theorem 26. In particular, we will try to avoid the high cost of reassigning points to $f_{in}$ in $G^{2(\phi)}$.

As in Theorem 26, we will identify a set $D \subseteq SMALLSHIFT$, $|D| = p$, of facilities from $S$ that are all hit by $T$, and let the modified set be $T' = T \setminus \bigcup_{a \in D} \Delta(a, S)$.

Let $a \in D$, and let $b$ be the nearest facility to $a$ in $S$. If $b = f_{in}$, we will reassign all $x$ with $x^T \in \Delta(a, S)$ to $b^T = f_{in}$, as in Theorem 26. However, if $b \ne f_{in}$, we will reassign all $x$ with $x^T \in \Delta(a, S)$ to $b^{T \setminus \{f_{in}\}}$. For the latter case, we need to make sure that $b^{T \setminus \{f_{in}\}}$ is not deleted. This is done simply by changing (i) to

(i)$'$ $c \notin D$ if there is a $b \in S$ not hit by $T$ with $b^{T \setminus \{f_{in}\}}$.

Consider some $a \in D$ with $b$ nearest to $a$ in $S$. If $b \ne f_{in}$, we need to argue that $b^{T \setminus \{f_{in}\}} \in T'$, and hence that $b^{T \setminus \{f_{in}\}} \notin \Delta(c, S)$ for any $c \in D$. If $b$ is not hit by $T$, this follows immediately from (i)$'$. However, if $b$ is hit, then $b^{T \setminus \{f_{in}\}} \in \Delta(b, S)$, and by (iii), $b \notin D$.

Concerning the reassignment costs for points $x$ with $x^T \in \Delta(a, S)$, if $a \in D$ is single, the only such point is $a$ itself, and $a$ will be reassigned to $a^{T'} = f_{in}$ at cost $\mathrm{dist}_{G^{2(\phi)}}(a, f_{in}) = \phi\,\mathrm{dist}(a, f_{in}) = \phi(0.25 - 2.5/\alpha)\,\mathrm{shiftcost}(a, S) = (2.5 - 2/\alpha)\,\mathrm{smallshiftcost}$.

Now consider a nonsingle $a \in D$, and let $x \in \Delta(a, S)$. As in the analysis from Theorem 26, we want to argue that the reassignment cost is at most $2\,\mathrm{dist}(x^T, b)$, where

$b$ is nearest to $a$ in $S$. If $b = f_{in}$, $x$ is reassigned to $b$ at cost $\leq \text{dist}_{G^{2(\phi)}}\text{dist}(x^T, b) \leq 2\,\text{dist}(x^T, b)$, as desired. However, if $b \neq f_{in}$, $\text{dist}(b, b^{T\setminus\{f_{in}\}}) \leq \text{dist}(b, x^T)$ since $x^T \neq f_{in}$. Hence the reassignment cost for $b \neq f_{in}$ is $\leq \text{dist}(x^T, b^{T\setminus\{f_{in}\}}) \leq 2\,\text{dist}(x^T, b)$.

Having established that the reassignment cost is at most $2\,\text{dist}(x^T, b)$, we can directly apply the rest of the analysis from Theorem 26, thus showing that our total cost increase over all $x$ with $x^T \in \Delta(a, S)$ is $\leq (2.5 - 2/\alpha)\,\text{shiftcost}(a, S) + o(\text{cost}(T)/(\alpha p \log n)$, as desired.

The set $D$ is picked as in Theorem 26, noting that singles can always be added to $D$ since they are never nearest to any other facility than $f_{in}$. ∎

By Lemma 29 and Theorem 30—with $T = S''$ and $S^*$ the result of the modification—$\text{cost}_{G^{2(\phi)}}(S^*) \leq o(\text{cost}(S'')/(\alpha \log n)) + \text{cost}_{G'^{2(\phi)}}(S')$, where $\text{cost}(S'') < \text{cost}_{G'^{2(\phi)}}(S')$. Further we saw that $\text{cost}_{G'^{2(\phi)}}(S') \leq (1+1/(\alpha \log n))^{(\log k)-1}(1+\varepsilon)12\times k\text{-mediancost}(G)$, so we conclude that $\text{cost}_{G^{2(\phi)}}(S^*) \leq (1+1/(\alpha \log n))^{\log k}(1+\varepsilon)12 \times k\text{-mediancost}(G)$, thus establishing (3).

As mentioned just below the introduction of (3), it directly implies our main result, which is the following.

THEOREM 31. *W.h.p., in $\tilde{O}(m)$ time and space, we can find a $k$-median solution $S$ with* $\text{cost}(S) \leq (12 + o(1))k\text{-mediancost}$.

## 5.13. The *k*-median for other metrics.

So far, we have considered solving the $k$-median problem only for graphs, but our technique is really much more general. The only way we use the input graph is to compute all points nearest point in sets $F$ of potential facilities; otherwise, we work internally on auxiliary graphs of size $\tilde{O}(n)$. Thus, we have really proved the following more general result.

THEOREM 32. *W.h.p., using a polylogarithmic number of all points nearest point in sets of facilities $F \subseteq P$ of size $\tilde{O}(k)$ as well as $\tilde{O}(n)$ internal computation time and space, we can find a $k$-median solution $S$ with* $\text{cost}(S) \leq (12 + o(1))k\text{-mediancost}$.

Clearly Theorem 32 implies Theorem 31 since an all points nearest marked neighbor computation on a graph can be done in linear time using a single source shortest path computation (cf. Observation 1). However, with a distance oracle, the marked neighbor computation is trivially done by comparing the distances from each $x \in P$ to each $f \in F$, hence with $\tilde{O}(kn)$ distance queries total. Thus Theorem 32 implies our $\tilde{O}(kn)$ time bound with linear space for general distance oracles, as stated earlier in Proposition 12. However, in, say, Hamming space, we can do better using approximate nearest neighbor queries.

COROLLARY 33. *For points in Hamming space of arbitrary dimension, for $0 < \varepsilon \leq 1$, w.h.p., we can solve the $k$-median problem within a factor $(12 + o(1))/\varepsilon$ in $\tilde{O}(nk^{\varepsilon})$ time.*

*Proof.* For $0 < \varepsilon \leq 1$, Indyk and Motwani [17], [16, p. 22] have shown that we can in $\tilde{O}(|F|^{1+\varepsilon})$ time and space build a data structure that for an arbitrary point finds its $1/\varepsilon$-approximate nearest neighbor in $\tilde{O}(F|^{\varepsilon})$ time with constant probability. The dimension of the space does not matter, as long as we can access each coordinate of a point in constant time. Using $O(\log n)$ such structures, all points in $P$ will find an $(1/\varepsilon)$-approximate nearest neighbor $x^F$ in $F$ w.h.p. Our total running time is then $\tilde{O}(nk^{\varepsilon})$. With these $(1/\varepsilon)$-approximate nearest neighbors, we can perform at least as well as with exact neighbors with all distances multiplied by $(1/\varepsilon)$, so our approximation factor becomes $(12 + o(1))/\varepsilon$. ∎

Since $\varepsilon = \Theta(1)$, our Hamming space approximation factor is constant, and for $\varepsilon < 1$, we beat $\Omega(kn)$ lower-bound on the time needed for any approximation factor in the general distance oracle model.

**Appendix. 1-median.** We need a result from [18] on approximating 1-medians. Since [18] may never be published, we present here the relevant result. We prove that we can find a factor $(1+\varepsilon)$ approximate 1-median by computing all distances from $O((\log n)/\varepsilon^2)$ random points as follows.

THEOREM 34. *Let $\varepsilon \leq 1$. Let $Q$ be a random multisubset of $P$. Let $a \in P$ minimize $\sum_{x\in Q} \mathrm{dist}(a,x)$. Then* $\Pr(\mathrm{cost}(\{a\}) \geq (1+\varepsilon) \times \text{1-mediancost}) \leq ne^{-\varepsilon^2|Q|/16}$.

*Proof.* Let *opt* be the optimal 1-median for $P$, and let $b$ be an arbitrary point in $P$ with $\mathrm{cost}(\{b\}) > (1+\varepsilon)\mathrm{cost}(\{opt\})$. There are at most $n-1$ such choices of $b$, and thus the theorem follows if

$$\Pr\left(\sum_{x\in Q} \mathrm{dist}(opt,x) \geq \sum_{x\in Q} \mathrm{dist}(b,x)\right) < e^{-\varepsilon^2|Q|/64}. \tag{4}$$

To prove (4), we study the random variable $X = \sum_{x\in Q} \frac{\mathrm{dist}(b,x)-\mathrm{dist}(opt,x)+\mathrm{dist}(opt,b)}{2\mathrm{dist}(opt,b)}$. By the triangle inequality, this is the sum of random variables between 0 and 1. Our bad event is that $X \leq |Q|/2$. On the other hand,

$$E(X) = \frac{|Q|}{|P|}\sum_{x\in P} \frac{\mathrm{dist}(b,x)-\mathrm{dist}(opt,x)+\mathrm{dist}(opt,b)}{2\mathrm{dist}(opt,b)}.$$

Since $\mathrm{dist}(b,x)+\mathrm{dist}(opt,x) \geq \mathrm{dist}(opt,b)$ and $\sum_{x\in P}\mathrm{dist}(x,b) > (1+\varepsilon)\sum_{x\in P}\mathrm{dist}(x,opt)$, $\sum_{x\in P}(\mathrm{dist}(b,x)-\mathrm{dist}(opt,x)) \geq \sum_{x\in P}\frac{\varepsilon}{2+\varepsilon}\mathrm{dist}(opt,b)$, so $E(X) \geq |Q|(1+\frac{\varepsilon}{2+\varepsilon})/2$. Consequently, $|Q|/2 \leq (1-\delta)E(X)$ with $\delta = \frac{\varepsilon}{2+\varepsilon}/(1+\frac{\varepsilon}{2+\varepsilon}) \geq \varepsilon/4$ for $\varepsilon \leq 1$. Applying a Chernoff bound from [24, Theorem 4.2], $\Pr(X \leq |Q/2|) \leq \Pr(X \leq (1-\delta)E(X)) < e^{-\delta^2 E(X)/2} < e^{-\varepsilon^2|Q|/64}$. This completes the proof of (4). □

# ONLINE SCHEDULING TO MINIMIZE AVERAGE STRETCH[*]

S. MUTHUKRISHNAN[†], RAJMOHAN RAJARAMAN[‡], ANTHONY SHAHEEN[§], AND JOHANNES E. GEHRKE[¶]

**Abstract.** We consider the classical problem of online job scheduling on uniprocessor and multiprocessor machines. For a given job, we measure the quality of service provided by an algorithm by the *stretch* of the job, which is defined as the ratio of the amount of time that the job spends in the system to the processing time of the job. For a given sequence of jobs, we measure the performance of an algorithm by the *average stretch* achieved by the algorithm over all the jobs in the sequence. The average stretch metric has been used to evaluate the performance of scheduling algorithms in many applications arising in databases, networks, and systems.

The main contribution of this paper is to show that the *shortest remaining processing time* (SRPT) algorithm is $O(1)$-competitive with respect to average stretch for both uniprocessors and multiprocessors. For uniprocessors, we prove that SRPT is 2-competitive; we also establish an essentially matching lower bound on the competitive ratio of SRPT. For multiprocessors, we show that the competitive ratio of SRPT is at most $9 + 2\sqrt{6} \leq 14$. Furthermore, we establish constant-factor lower bounds on the competitive ratio of any online algorithm for both uniprocessors and multiprocessors.

**Key words.** scheduling, online algorithms, competitive ratio, shortest remaining processing time (SRPT), stretch, slowdown

## 1. Introduction.

Many servers, such as web and database servers, receive a continuous stream of requests with processing times that vary over several orders of magnitude. The main challenge in such a scenario is to schedule the stream of requests so as to provide various service guarantees such as response time, throughput, and fairness. In the combinatorial scheduling literature, this problem is typically abstracted as one of optimizing a suitably defined performance measure. Two classical performance measures are the *makespan*, which is the maximum completion time of any job, and the *total completion time*, which is the sum of the completion times of all the jobs; these are suitable for applications where the jobs are executed in batches. For jobs arriving continuously, a relevant parameter is the time that a job spends in the system, namely, the *response time* (also sometimes referred to as the *flow time*) of the job, which can be defined as the difference between the completion time and release time of the job. For over two decades, the *average response time* has been a popular performance measure in online scheduling research.

Recently, alternative performance measures have been considered. The premise

underlying these studies is that an important parameter of performance for a job is the *factor by which it is slowed down relative to the time it takes on a unloaded system*. Formally, the *stretch* (also known as the *slowdown*) of a job is the ratio of the response time of the job to the processing time of the job. Intuitively, the stretch measure relates the users' waiting times to their demands, since it measures the quality of service provided to a job in proportion to its demand. It may also reflect users' psychological expectation that, in a system with highly variable job sizes, users are willing to wait longer for larger requests. Thus it is a reasonably fair measure of the service that an individual job gets in the system.

The stretch measure, more precisely, the *average stretch* (or equivalently, the *total stretch*), has been used to empirically study the performance of several applications, e.g., in databases [19], operating systems [15], and parallel systems [13]. Average stretch is used for measuring the performance of scheduling algorithms in the context of web servers or clusters thereof [14, 23], which process requests for downloading files of different sizes and types. The average stretch is also a good indicator of the total load of the system. A schedule with large average stretch is likely to have a majority of jobs waiting in queue for large periods of time, while a schedule may have small average queue size and yet a large average response time simply because one of the jobs has a large processing time.

To summarize, average stretch is a natural measure that fits many applications, and is a better indicator of system performance than the traditional average response time measure. Surprisingly, very little is known about scheduling algorithms that optimize (minimize) average stretch; in fact, the rather basic problem of minimizing average stretch on a single processor has not been studied.

In this paper, we study the problem of online scheduling to minimize average stretch on both single and multiprocessor systems. We focus on the *preemptive clairvoyant* version of the scheduling problem: by preemptive, we mean that jobs may be stopped before their completion and resumed later after processing other jobs in the interim; by clairvoyant, we mean that the processing time of each job is known at the time of its arrival. The aforementioned application of web server scheduling is an important example where preemptive clairvoyant schedules are useful.

Our main contribution is to show that the *shortest remaining processing time* (SRPT) heuristic is $O(1)$-competitive with respect to average stretch for both uniprocessors and multiprocessors. Our results show that the problem of optimizing the average stretch is fundamentally different from that of optimizing the average response time in the uniprocessor as well as in the multiprocessor case, although, interestingly, the difference is contrasting. (See section 1.2.) Our results, taken together with previous work on analyzing average response time [3, 18], imply that SRPT simultaneously optimizes the average response time and average stretch measures, up to constant factors, for both uniprocessors and multiprocessors.

**1.1. Problem and definitions.** We consider the following online scheduling scenario. A sequence of jobs arrives online, and the processing time of each job is known at the time of its arrival. Our goal is to produce a schedule to process the continuously arriving stream of such jobs. The quality of service we consider is the *stretch* of a job, which is defined as the ratio of the amount of time that the job spends in the system to the processing time of the job. Thus, if a job $j$ with processing time $p(j)$ arrives at time $r(j)$ and is completed at time $C(j)$, then the stretch of the job is given by $s(j) = (C(j) - r(j))/p(j)$. We seek to minimize the total stretch of the jobs in a given instance.

We study the problem of minimizing total stretch for both uniprocessor as well as multiprocessor scheduling. In the case of multiprocessor scheduling, we assume that all of the processors are identical. Thus, in the standard 3-field scheduling notation [17], the problems that we study may be listed as $1 \mid pmtn, r_j \mid \sum_j (C_j - r_j)/p_j$ and $Pm \mid pmtn, r_j \mid \sum_j (C_j - r_j)/p_j$, respectively.

Since our focus is on online algorithms, we perform a competitive analysis [22] of the algorithms under consideration. An online algorithm $\mathcal{A}$ is *r-competitive* if for every instance $\mathcal{J}$, $S(\mathcal{J})$ is at most $rS^*(\mathcal{J})$, where $S(\mathcal{J})$ and $S^*(\mathcal{J})$ represent the total stretch achieved by $\mathcal{A}$ and an optimal offline algorithm, respectively, on instance $\mathcal{J}$. The *competitive ratio* of an algorithm $\mathcal{A}$ is the infimum over all $r$ such that $\mathcal{A}$ is $r$-competitive.

Much of our work concerns the analysis of the well-known SRPT algorithm. For uniprocessors, SRPT is simply defined as follows: In each time step, process a job with the shortest remaining processing time among all the unfinished jobs. For an $m$-processor machine each time step consists of the following operation: If there are at least $m$ unfinished jobs, a set of $m$ jobs that have the $m$ shortest remaining processing times are processed, where we break ties arbitrarily; otherwise, every unfinished job is processed. (Since the processors are assumed to be identical, the particular assignment of an unfinished job to a processor at any step is irrelevant.[1])

**1.2. Our results.** Our main results are threefold:

- *Uniprocessor* SRPT. We show that for any instance $\mathcal{J}$ on a uniprocessor machine, the total stretch $S(\mathcal{J})$ achieved by SRPT is at most $S^*(\mathcal{J}) + |\mathcal{J}|$; since $S^*(\mathcal{J}) \geq |\mathcal{J}|$, this implies that SRPT is 2-competitive. We also establish an essentially matching lower bound on SRPT for uniprocessors. These results appear in section 2.
  Our upper bound for SRPT makes it an attractive algorithm for uniprocessor scheduling since it is nearly optimal with respect to total stretch while it is known to be truly optimal with respect to average response time. Indeed, recent experimental and analytical studies on scheduling algorithms for web servers [4, 14] have shown that SRPT outperforms several other scheduling policies currently used in web servers on real-world workloads; the analyses in the preceding studies adopt a Poisson model for the job arrival process, and general as well as heavy-tailed distributions for job service times.
- *Multiprocessor* SRPT. For multiprocessors, we show that for any instance $\mathcal{J}$ the total stretch $S(\mathcal{J})$ achieved by SRPT is at most $3S^*(\mathcal{J}) + (6 + 2\sqrt{6})|\mathcal{J}|$, which implies an upper bound of $9 + 2\sqrt{6} \leq 14$ on the competitive ratio, independent of the number of processors $m \geq 2$. These results appear in section 3.
  Our constant-factor competitiveness result for multiprocessors provides a surprising contrast to the recent lower bound established on the competitive ratio of any online algorithm with respect to average response time. It is shown in [18] that the best competitive ratio achievable for average response time on an $m$-processor machine is $\Omega(\max\{\log P, \log(n/m)\})$, where $P$ is the ratio of the maximum to the minimum processing time of any job and $n$ is the number of jobs. In [18], it is also shown that the competitive ratio of SRPT with respect to average response time on multiprocessors is optimal to within a constant factor. This indicates that SRPT is a compelling algorithm for

[1]A job may be preempted at one processor and later resumed at a different processor.

multiprocessor scheduling as well since it matches the best competitive ratio up to constant factors for both total stretch as well as average response time.
- *Lower bounds.* We show that there exists no online algorithm that minimizes average stretch for every instance; specifically, we show that the competitive ratio of every online algorithm is at least 1.04. We also show a lower bound of at least 7/6 on the competitive ratio for minimizing total stretch on any $2m$-processor machine, for any positive integer $m$. These results appear in section 4.

The average response time and total stretch metrics have the following interesting contrasting characteristics. For uniprocessors, while average response time can be optimized by an on-line algorithm, the best competitive ratio achievable for total stretch is strictly greater than 1. On the other hand, for multiprocessors, while a constant-factor competitive online algorithm exists for total stretch, the best competitive ratio for average response time grows logarithmically with the number of jobs.

**1.3. Related work.** While average response time has been studied extensively in the literature [3, 16, 21], the analytical study of stretch as a performance measure was initiated only recently [6]. All of the results presented in [6], however, concern the metric of *maximum stretch* (that is, $\max_i S_i$) and do not yield any useful bounds for total stretch. Recently, max-stretch was also studied in the context of performing file transfers over a network with given bandwidth constraints on the underlying links [11].

Two measures closely related to total stretch are weighted completion time and weighted flow time, each of which associate a weight with each job $i$. If we set the weight of job $i$ to the reciprocal of flow time, completion time also optimizes total stretch. From the point of view of approximation, however, the two metrics are different. A randomized online algorithm that achieves a competitive ratio of 4/3 with respect to weighted completion time is given in [20]; this result, however, does not directly yield any useful upper bound on the competitive ratio for total stretch. In fact, it is easy to construct schedules that have a constant-factor approximation ratio with respect to weighted completion time, with $w_i = 1/p_i$, and yet have a linear approximation ratio with respect to total stretch. For other results on the online and offline complexity of weighted completion time, see [12].

The weighted flow time with weights given by the reciprocal of processing times is identical to the total stretch metric. The best known approximation result for weighted flow time is the recent approximation scheme of [8], which takes time super-polynomial, but subexponential, in the input size. In a subsequent study [9], it has been shown that a quasi-polynomial approximation scheme (quasi-PTAS) is achievable for weighted flow time when $\Delta$ and the ratio of the maximum weight to minimum weight are both polynomially bounded. When applied to the special case of the total stretch metric, the techniques of [9] yield a PTAS. A PTAS for total stretch is also given in [7].

For multiprocessors, the work most closely related to our study is that of [18], which is discussed in section 1.2. In recent work [1], a polynomial-time approximation scheme is derived for the weighted completion time problem on multiprocessors.

**1.4. Overview of our analyses.** Our analysis of SRPT relies on a careful comparison of the queue of unfinished jobs in SRPT with the corresponding queue associated with any other scheduling algorithm at every time step. For the case of uniprocessors, we derive a tight bound on the total stretch of SRPT by placing a separate bound, for *every* unfinished job at *every* time step, on the contribution of the job to the total stretch of SRPT. A key component behind this approach is to appropriately map the jobs in SRPT's queue to the jobs in the queue associated with an arbitrary scheduling algorithm at every time step. The particular mapping enables us to analyze the total stretch of SRPT time step by time step. The relevant property of this mapping is illustrated in Figure 1 of section 2 and formally established in Lemma 2.8.

Our analysis for multiprocessors is more involved. The difficulty in the analysis arises due to the following observation made in [18]: there exist multiprocessor scheduling instances that may force SRPT to have many more unfinished jobs at certain time steps than an alternative schedule has at that time. As a result, the contribution to the total stretch corresponding to such time steps may be disproportionately larger for SRPT than for the other schedule. We overcome this hurdle by showing the existence of an appropriate partial mapping from the jobs in SRPT's queue to the jobs in the queue associated with the other schedule. In addition to placing an upper bound on the contribution of the mapped jobs in each step, the particular mapping enables us to place an upper bound on the exact or amortized contribution of the unmapped jobs in SRPT's queue at each time step. The mapping is illustrated in Figure 2 of section 3 and formally established in Lemma 3.5.

## 2. Analysis of SRPT for uniprocessor scheduling.

In this section, we analyze the competitiveness of SRPT on uniprocessors with respect to total stretch. An instance $\mathcal{J}$ of our scheduling problem consists of a set of jobs with arbitrary release times and processing times. For job $j \in \mathcal{J}$, let $r(j)$ and $p(j)$ denote the release time and processing time, respectively, of $j$. The performance of a schedule is measured by the total stretch achieved. Recall that the total stretch of a schedule for a given instance is the sum, taken over all jobs $j \in \mathcal{J}$, of the stretch of $j$ under the schedule, where the stretch of a job is the ratio of the response time of the job to the processing time of the job. Let $S(\mathcal{J})$ and $S^*(\mathcal{J})$ denote the total stretch of SRPT and the optimal total stretch, respectively, for instance $\mathcal{J}$. The main result of this section is the following theorem that places an upper bound on the total stretch achieved by SRPT.

THEOREM 2.1. *For any instance $\mathcal{J}$, $S(\mathcal{J})$ is at most $S^*(\mathcal{J}) + |\mathcal{J}|$.*

The proof of Theorem 2.1 is given in section 2.1. In terms of competitive ratio, Theorem 2.1 implies the following result.

COROLLARY 2.2. SRPT *is 2-competitive with respect to average stretch.*

*Proof.* For any scheduling algorithm, the stretch of any job is at least 1. Therefore $S^*(\mathcal{J})$ is at least $|\mathcal{J}|$. It thus follows from Theorem 2.1 that $S(\mathcal{J}) \leq 2S^*(\mathcal{J})$. ∎

We also show an essentially matching lower bound in Theorem 2.3, which is proved in section 2.2.

THEOREM 2.3. *For any real $\varepsilon > 0$ and any positive integer $n \geq 3$, there exists an instance $\mathcal{J}$ with $n$ jobs such that $S(\mathcal{J})$ is at least $S^*(\mathcal{J}) + n - 1 - \varepsilon$.*

### 2.1. Upper bound.

In this section, we prove Theorem 2.1. We begin by introducing some notation to characterize the execution of SRPT on a given instance $\mathcal{J}$. For any job $j$ in $\mathcal{J}$ and time $t \geq r(j)$, let $\rho_t(j)$ denote the remaining processing time of job $j$ at time $t$ under SRPT. For any time $t$, let $Q_t$ denote the set of all jobs in $\mathcal{J}$ that have been released at some time less than or equal to $t$ and have not been completed by SRPT; that is, $Q_t$ is the set of all jobs $j$ for which $r(j) \leq t$ and $\rho_t(j) > 0$. We rank all of the jobs in $Q_t$ in nondecreasing order of their remaining processing times, breaking ties according to an arbitrary ordering of the job IDs whenever necessary. For $i \geq 1$, let $q_{t,i}$ denote the job of rank $i$ in $Q_t$; if the job of rank $i$ is not defined, we set $q_{t,i}$ to be a job with processing time $\infty$. We refer to a job as *active* (resp., *waiting*) at time $t$ if the rank of the job is equal to 1 (resp., greater than 1). Note that in time step $t$, SRPT processes one unit of the job that is active at that time. Let $U_t$ denote the set of waiting jobs at time $t$.

We now express the total stretch $S(\mathcal{J})$ in SRPT as a sum, taken over all time steps $t$ and over all jobs in $Q_t$, of the reciprocal of the processing time of the job:

$$S(\mathcal{J}) = \sum_{j \in \mathcal{J}} \sum_{t : j \in Q_t} \frac{1}{p(j)} = \sum_{t} \sum_{j \in Q_t} \frac{1}{p(j)}.$$

We now introduce two new variables for notational convenience. Let $\alpha_t$ denote the sum of the reciprocals of the processing times of the jobs in $Q_t$. Thus, the total stretch $S(\mathcal{J})$ is simply $\sum_t \alpha_t$. Finally, let $\beta_t$ denote the sum of the reciprocals of the remaining processing times of the jobs in $Q_t$. Since the remaining processing time of a job at any time is at most its processing time, we obtain that $\alpha_t \leq \beta_t$ for all $t$.

We split the total stretch $S(\mathcal{J})$ into two parts $S_1(\mathcal{J})$ and $S_2(\mathcal{J})$, which represent the total contribution of the active jobs and the waiting jobs, respectively, in SRPT:

$$S_1(\mathcal{J}) = \sum_t \frac{1}{p(q_{t,1})} \quad \text{and}$$
$$S_2(\mathcal{J}) = \sum_t \sum_{j \in U_t} \frac{1}{p(j)}.$$

The total contribution of the active jobs can be calculated easily. Whenever a job $j$ is active, it contributes $1/p(j)$ to the term $S_1(\mathcal{J})$. Since an active job is always processed by SRPT, there are exactly $p(j)$ time steps when $j$ is active. Thus, $j$ contributes $p(j)/p(j) = 1$ to $S_1(\mathcal{J})$. We thus obtain the following lemma.

LEMMA 2.4. *For any instance $\mathcal{J}$, $S_1(\mathcal{J}) = |\mathcal{J}|$.* □

We place an upper bound on the contribution of the waiting jobs by means of a careful comparison of SRPT's queue $Q_t$ with the corresponding queue of an arbitrary scheduling algorithm $\mathcal{A}$. Just as we have characterized the execution of SRPT for a given instance $\mathcal{J}$ using the variables $\rho_t$, $Q_t$, and $q_t$, we can characterize the execution of $\mathcal{A}$ for $\mathcal{J}$. Let $\widetilde{Q}_t$, $\widetilde{\rho}_t$, $\widetilde{\alpha}_t$, and $\widetilde{\beta}_t$ denote the equivalent of $Q_t$, $\rho_t$, $\alpha_t$, and $\beta_t$, respectively, for the execution of $\mathcal{A}$. Furthermore, whenever we henceforth introduce a new notation for a variable associated with SRPT, it is implicit that the "tilde" version of the notation denotes the corresponding variable for $\mathcal{A}$.

We obtain the desired upper bound on $S_2(\mathcal{J})$ by showing the following key lemma that relates $\beta_t$ and $\widetilde{\alpha}_t$.

LEMMA 2.5. *For any time $t$, we have $\beta_t \leq \widetilde{\alpha}_t + \frac{1}{\rho_t(q_{t,1})}$.*

COROLLARY 2.6. *For any instance $\mathcal{J}$, $S_2(\mathcal{J}) \leq S^*(\mathcal{J})$.*

*Proof.* Since $1/p(j)$ is at most $1/\rho_t(j)$ for any job $j$, it follows that

$$S_2(\mathcal{J}) \leq \sum_t \left( \beta_t - \frac{1}{\rho_t(q_{t,1})} \right)$$
$$\leq \sum_t \widetilde{\alpha}_t \leq \widetilde{S}(\mathcal{J}),$$

where the last step is obtained by invoking Lemma 2.5. Since the above inequality holds for every scheduling algorithm $\mathcal{A}$, the desired claim follows. □

Theorem 2.1 follows directly from Lemma 2.4 and Corollary 2.6. Thus all that remains to prove is Lemma 2.5. A crucial component of our proof of Lemma 2.5 is

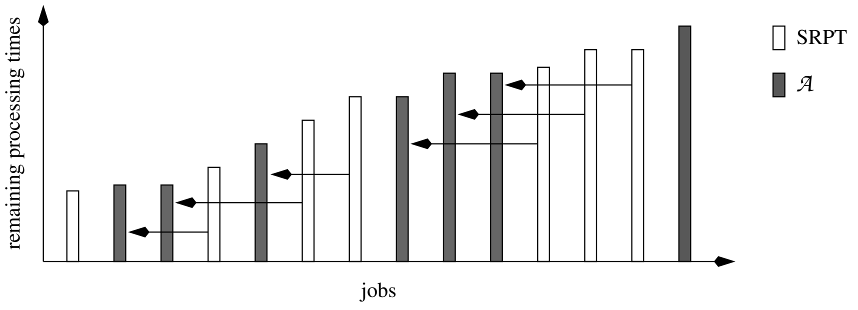

FIG. 1. *The remaining processing times of the jobs in the queues of* SRPT *and* $\mathcal{A}$ *at time* $t$. *The shaded jobs belong to* $\mathcal{A}$*'s queue* $\widetilde{Q}_t$*, while the unshaded jobs belong to* SRPT*'s queue* $Q_t$. *The arrows indicate that for any* $i > 1$ *the remaining processing time of the job of rank* $i$ *in* $Q_t$ *is at least that of the job of rank* $i-1$ *in* $\widetilde{Q}_t$.

to establish the following relationship between the queues of SRPT and $\mathcal{A}$: for any $i > 1$, the remaining processing time of the job of rank $i$ in $Q_t$ is *at least* the remaining processing time of the job of rank $i-1$ in $\widetilde{Q}_t$. The preceding claim is formally stated in Lemma 2.8 and illustrated in Figure 1.

We establish Lemma 2.8 by relating appropriately defined "prefixes" of the two queues $Q_t$ and $\widetilde{Q}_t$. For any time $t$ and positive integer $i$, let $P_t(i)$ denote the set of jobs in $Q_t$ with remaining processing time at most $i$. For any time $t$ and positive integer $i$, let $V_t(i)$ denote the sum of the remaining processing times of all jobs in $P_t(i)$. We call $V_t(i)$ the *volume* of jobs in $Q_t$ with remaining processing time at most $i$.

LEMMA 2.7. *For any time* $t$ *and any positive integer* $i$, $V_t(i)$ *is at most* $\widetilde{V}_t(i)+i$.

*Proof.* The proof is by induction on $t$. The induction basis holds trivially since for all $i$, $V_0(i) = \widetilde{V}_0(i)$. For the induction hypothesis, we assume that the claim is true at the end of step $t-1$. We now establish the induction step for time step $t$. Let $i$ be any positive integer. We first note that the release of new jobs at the start of step $t$ does not change $V_t(i) - \widetilde{V}_t(i)$ for any $i$. Now let $X$ denote the union of the set $P_{t-1}(i)$ and the set of jobs with processing time at most $i$ that are released at time $t$.

We consider two cases, depending on whether $X$ is empty. In the case where $X$ is nonempty, SRPT executes one job from $X$. Since $\mathcal{A}$ performs at most one unit of work, we can invoke the induction hypothesis and obtain that $V_t(i) \le \widetilde{V}_t(i) + i$. We now consider the case where $X$ is empty. In this case, at most one job in $Q_t$ can have remaining processing time at most $i$ at the end of step $t$; this happens when a job with remaining processing time $i+1$ gets processed and enters $P_t(i)$. Therefore, we have $V_t(i) \le i \le \widetilde{V}_t(i) + i$. This completes the proof of the desired claim. ∎

LEMMA 2.8. *For any time* $t$ *and any integer* $k > 1$, *we have* $\rho_t(q_{t,k}) \ge \widetilde{\rho}_t(\widetilde{q}_{t,k-1})$.

*Proof.* We first prove that for all $k > 1$, $\rho_t(q_{t,k}) \ge \widetilde{\rho}_t(\widetilde{q}_{t,k-1})$. The proof is by contradiction. Let, if possible, $k > 1$ be the smallest integer such that $\rho_t(q_{t,k}) < \widetilde{\rho}_t(\widetilde{q}_{t,k-1})$. Let $b$ denote $\rho_t(q_{t,k})$. It follows that $|P_t(b)| \ge k$, while $|\widetilde{P}_t(b)| = k-2$. We thus have the following inequality:

$$\begin{aligned} V_t(b) &\ge \sum_{1\le i\le k} \rho_t(q_{t,i}) \\ &= \rho_t(q_{t,1}) + \rho_t(q_{t,k}) + \sum_{2\le i<k} \rho_t(q_{t,i}) \end{aligned}$$

$$\begin{aligned}&\geq \rho_t(q_{t,1}) + b + \sum_{1\leq i<k-1} \widetilde{\rho}_t(\widetilde{q}_{t,i})\\ &= \rho_t(q_{t,1}) + b + \widetilde{V}_t(b)\\ &> b + \widetilde{V}_t(b),\end{aligned}$$

thus contradicting Lemma 2.7. (In the third step, we use the assumption that for $1 < i < k$, $\rho_t(q_{t,i}) \geq \widetilde{\rho}_t(\widetilde{q}_{t,i-1})$. In the final step, we use the fact that $\rho_t(q_{t,1})$ is positive.) □

Corollary 2.9. *For any time $t$, we have $\beta_t \leq \widetilde{\beta}_t + \frac{1}{\rho_t(q_{t,1})}$.*

*Proof.* The desired claim follows from Lemma 2.8:

$$\begin{aligned}\beta_t - \widetilde{\beta}_t &= \sum_{k\geq 1}\left(\frac{1}{\rho_t(q_{t,k})} - \frac{1}{\widetilde{\rho}_t(\widetilde{q}_{t,k})}\right)\\ &\leq \frac{1}{\rho_t(q_{t,1})} + \sum_{k\geq 2}\left(\frac{1}{\rho_t(q_{t,k})} - \frac{1}{\widetilde{\rho}_t(\widetilde{q}_{t,k-1})}\right)\\ &\leq \frac{1}{\rho_t(q_{t,1})},\end{aligned}$$

since $\rho_t(q_{t,k}) \geq \widetilde{\rho}_t(\widetilde{q}_{t,k-1})$ for all $k \geq 2$. □

We are now ready to prove Lemma 2.5.

*Proof of Lemma* 2.5. Consider an arbitrary time step $t$. Let $\mathcal{B}$ be a scheduling algorithm that minimizes the sum of the reciprocals of the processing times of the jobs in the queue at time $t$. Let $\alpha'_t$ denote the sum of the reciprocals of the processing times of the jobs in $\mathcal{B}$'s queue at time $t$.

We now argue that $\mathcal{B}$ can be chosen such that for every job $j$ in $\mathcal{B}$'s queue, the remaining processing time at time $t$ is the same as the processing time $p(j)$. If not, we can define a schedule $\mathcal{C}$ that mimics $\mathcal{B}$ except that $\mathcal{C}$ never processes any of the jobs that remain in $\mathcal{B}$'s queue at time $t$. Clearly, $\mathcal{C}$'s queue at time $t$ contains exactly the same jobs as $\mathcal{B}$'s. Moreover, none of the jobs in $\mathcal{C}$'s queue at time $t$ have been processed prior to time $t$. Since the remaining processing time of every job in $\mathcal{C}$'s queue is the same as the actual processing time, we obtain the desired inequality from Corollary 2.9:

$$\beta_t \leq \alpha'_t + \frac{1}{\rho_t(q_{t,1})} \leq \widetilde{\alpha}_t + \frac{1}{\rho_t(q_{t,1})}. \qquad \square$$

**2.2. Lower bound.** In this section, we prove Theorem 2.3. Consider an instance in which a job of size $\ell_1$ arrives in time step 0 and a job of size $\ell_2 \ll \ell_1$ arrives in time steps $\ell_1 + \ell_2(i-1) + 1$ for $0 \leq i < n-1$. An SRPT schedule will process the large job until time $\ell_1 - \ell_2 + 1$ when the first small job arrives. Since the remaining processing time of the large job $(\ell_2 - 1)$ is smaller than the size of the small job, SRPT continues processing the large job until it is finished. Thereafter, the $n-1$ small jobs are processed one after another. The total stretch of the SRPT schedule is $n + (n-1)(\ell_2-1)/\ell_2 = 2n - 1 - (n-1)/\ell_2$. Given $\varepsilon > 0$, we set $\ell_2 > 2(n-1)/\varepsilon$ so that the total stretch of SRPT is at least $2n - 1 - \varepsilon/2$.

An alternative schedule is to complete the small jobs immediately upon their arrival, and complete the large job at time $\ell_1 + (n-1)\ell_2$. This yields a total stretch of $n + (n-1)\ell_2/\ell_1$. We set $\ell_1 > 2(n-1)\ell_2/\varepsilon$ so that the preceding schedule has total stretch at most $n + \varepsilon/2$.

Thus, we have $S(\mathcal{J}) \geq S^*(\mathcal{J}) + n - 1 - \varepsilon$. This completes the proof of Theorem 2.3.

**3. Analysis of SRPT for multiprocessor scheduling.** This section analyzes the competitiveness of SRPT on an $m$-processor machine, where $m$ is any integer greater than 1. For any instance $\mathcal{J}$, let $S(\mathcal{J})$ and $S^*(\mathcal{J})$ denote the total stretch of SRPT and an optimal schedule, respectively. The main result of this section is the following upper bound on the total stretch achieved by SRPT, which is proved in section 3.1.

THEOREM 3.1. *For any instance $\mathcal{J}$ on multiprocessors, $S(\mathcal{J})$ is at most $3S^*(\mathcal{J})+(6+2\sqrt{6})|\mathcal{J}|$. Thus, the competitive ratio of* SRPT *for multiprocessors is at most $9+2\sqrt{6} \leq 14$.*

We can also show a constant-factor lower bound on the competitive ratio of SRPT for multiprocessors. The lower bound is proved in section 3.2.

THEOREM 3.2. *For any even integer $m > 1$ and any positive real $\varepsilon$, there exists a scheduling instance $\mathcal{J}$ for an $m$-processor machine such that $S(\mathcal{J})$ is at least $(2.5-\varepsilon)S^*(\mathcal{J})$.*

**3.1. Upper bound.** A crucial component of our upper bound proof for uniprocessors in section 2 is the property of SRPT's queue established in Lemma 2.8. Lemma 2.8 implies that, given any scheduling algorithm $\mathcal{A}$ and any time $t$, we can map each job $j$ in SRPT's queue except the one with the smallest remaining processing time to a unique job in $\mathcal{A}$'s queue at time $t$ that has remaining processing time at most that of $j$. For multiprocessors, however, a similar claim does not hold. In fact, even for a two-processor system, one can construct an instance for every positive integer $k$ such that the following claim holds: there exists a time step $t$ when the number of jobs in SRPT's queue at time $t$ is $k$ while the queue in the optimal schedule at time $t$ is empty. A nice example of such an instance is presented in [18], where it is used to derive a lower bound on the competitive ratio of SRPT with respect to total flow time.

While establishing an upper bound on the total flow time of SRPT, [18] provides a characterization of the queue of SRPT that implies an upper bound on the *number of jobs* in the queue of SRPT at each step. We note that the total flow time of a schedule is the sum, taken over every time step $t$, of the number of jobs in the queue at time $t$. The analysis of [18] does not suffice for our purposes, however, because the total stretch takes into account the sum of the *reciprocals of the processing times* of the jobs in the queue at any time step. In our analysis of SRPT that follows, we perform a more careful comparison between SRPT and an optimal schedule in terms of the relative distribution of the remaining processing times of the jobs in the two queues at each time step. We are able to establish a *partial* mapping from the jobs in SRPT's queue to the jobs in another schedule such that the following property of the mapping holds: the remaining processing time of a mapped job in SRPT's queue is at least that of the job to which it is mapped. This mapping, together with an appropriate characterization of the unmapped jobs in SRPT's queue, then enables us to place an upper bound on the exact or "amortized" contribution of the jobs in the queue at each time step.

As in the case of uniprocessor scheduling, we rank all of the jobs in $Q_t$ in nondecreasing order of their remaining processing times, breaking ties according to an arbitrary ordering of the job IDs whenever necessary. Let $F_t$ denote the set of jobs in $Q_t$ ranked at most $m$. Let $U_t$ denote the set $Q_t \setminus F_t$.

Analogous to the uniprocessor case, we split the sum $S(\mathcal{J})$ into two parts $S_1(\mathcal{J})$ and $S_2(\mathcal{J})$:

$$S_1(\mathcal{J}) = \sum_t \sum_{j \in F_t} \frac{1}{p(j)} \quad \text{and}$$

$$S_2(\mathcal{J}) = \sum_t \sum_{j \in U_t} \frac{1}{p(j)}.$$

By invoking the same argument used in proving Lemma 2.4, we show that $S_1(\mathcal{J})$ equals $|\mathcal{J}|$.

LEMMA 3.3. *For any instance $\mathcal{J}$, $S_1(\mathcal{J}) = |\mathcal{J}|$.*

*Proof.* Since each job in $F_t$ is processed at time $t$, a job $j$ is in $F_t$ for exactly $p(j)$ steps. The desired claim follows. ∎

We now consider the jobs in $U_t$. For any time $t$ and positive integer $i$, let $P_t(i)$ denote the set of jobs in $Q_t$ with remaining processing time at most $i$. We define the *volume* of any subset $X$ of $Q_t$ as the sum of the remaining processing time of the jobs in $X$ at time $t$. For any time $t$ and positive integer $i$, let $V_t(i)$ denote the volume of $P_t(i)$.

The following lemma is an easy generalization of Lemma 2.7. (As in section 2, we follow the notational convention that the "tilde" version of a variable defined for SRPT denotes the corresponding variable for $\mathcal{A}$.)

LEMMA 3.4. *For any time $t$ and any positive integer $i$, $V_t(i)$ is at most $\widetilde{V}_t(i)+mi$.*

*Proof.* The proof is by induction on $t$. The induction basis holds trivially since, for all $i$, $V_0(i) = \widetilde{V}_0(i)$. For the induction hypothesis, we assume that the claim is true at the end of step $t-1$. We now establish the induction step for time step $t$. Let $i$ be any positive integer. We first note that the release of new jobs at the start of a step does not change $V_t(i) - \widetilde{V}_t(i)$ for any $i$. Let $X$ denote the union of the set $P_{t-1}(i)$ and the set of jobs with processing time at most $i$ that are released at time $t$.

We consider two cases, depending on whether $|X|$ is at least $m$. In the case where $|X|$ is at least $m$, all of the jobs processed by SRPT are in $X$. Since $\mathcal{A}$ can perform at most $m$ units of work, we invoke the induction hypothesis and obtain that $V_t(i) \le \widetilde{V}_t(i) + mi$. We now consider the case where $|X|$ is less than $m$. In this case, the number of jobs not in $X$ that are processed in step $t$ is at most $m-|X|$. Therefore, at most $m-|X|$ jobs outside of $X$ may have remaining processing time at most $i$ after time step $t$. We thus obtain that $V_t(i) \le mi \le \widetilde{V}_t(i) + mi$. ∎

Given any schedule $\mathcal{A}$ and any time $t$, we define a partial mapping $f_t$ from $U_t$ to $\widetilde{Q}_t$ that satisfies properties (P1) and (P2) defined below. Let $\text{MPD}_t$ (resp., $\text{UMPD}_t$) denote the set of jobs in $U_t$ that are mapped (resp., unmapped) by $f_t$.

(P1) For each job $j$ in $\text{MPD}_t$, $\widetilde{\rho}_t(f_t(j)) \le \rho_t(j)$.

(P2) For any $i > 0$, the total volume of the jobs in $\text{UMPD}_t \cap P_t(i)$ is at most $mi$.

LEMMA 3.5 (partial mapping). *For any schedule $\mathcal{A}$ and any time $t$, there exists an injective mapping $f_t$ from $U_t$ to $\widetilde{Q}_t$ that satisfies properties* (P1) *and* (P2).

*Proof.* We describe a procedure for defining the mapping $f_t$. This procedure runs in phases, starting from phase 1. Let $X$ denote the set of jobs in $U_t \cap P_t(i)$ with remaining processing time equal to $i$. Let $Y$ denote the set of jobs in $\widetilde{P}_t(i)$ to which no job in $U_t$ has been mapped at the start of phase $i$. (At the start of phase 1, $Y$ is $\emptyset$.) In phase $i$, we map as many jobs as possible in $X$ to jobs in $Y$. The mapping is illustrated in Figure 2.

We now argue that for every $i$ the following two properties hold at the start of phase $i$: (i) for each job $j$ in $U_t$ that has been mapped, $\widetilde{\rho}_t(f_t(j)) \le \rho_t(j)$; (ii) for $0 < k < i$, the total volume of the unmapped jobs in $U_t \cap P_t(k)$ is at most $mk$.

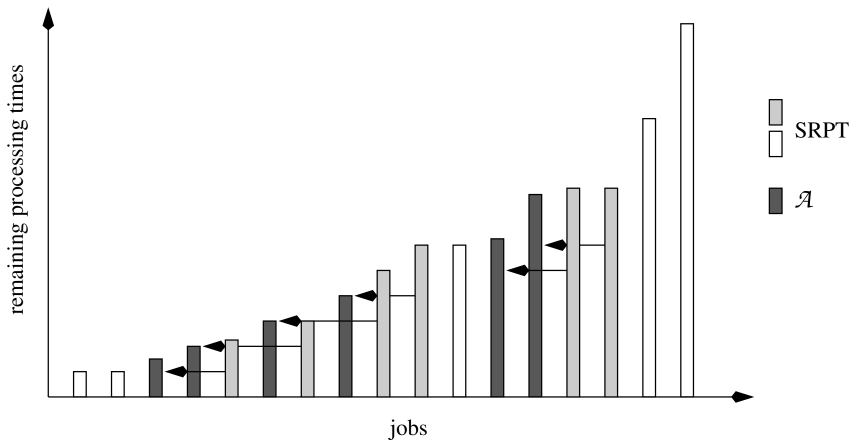

FIG. 2. *The remaining processing times of the jobs in the queues of* SRPT *and $\mathcal{A}$ at time $t$. The arrows depict the mapping $f_t$. The darkly shaded jobs belong to $\mathcal{A}$'s queue, while the lightly shaded and unshaded jobs belong to* SRPT*'s queue. The lightly shaded jobs are the mapped jobs in* SRPT*'s queue.*

Clearly, if the two properties hold at the end of the procedure when all of the jobs in $U_t$ have been considered, then the desired claim follows.

By the definition of the mapping, it is evident that property (i) holds at the start of every phase. We now prove property (ii). The proof is by induction on $i$. For the induction basis, $i = 1$ and property (ii) holds vacuously. We now assume that property (ii) holds at the start of phase $i$ and consider the effect of phase $i$.

By property (ii) of the induction hypothesis, it follows that for $0 < k < i$ the total volume of the unmapped jobs in $U_t \cap P_t(k)$ is at most $mk$. Thus, it suffices to prove that at the start of phase $i+1$, the total volume of the unmapped jobs in $U_t \cap P_t(i)$ is at most $mi$. We consider two cases. The first case is when every job in $\widetilde{P}_t(i)$ is the image of some job after phase $i$. By property (i), each job in $\text{MPD}_t$ is mapped to a job in $\widetilde{Q}_t$ with no larger remaining processing time. Therefore, it follows from Lemma 3.4 that the volume of unmapped jobs in $U_t \cap P_t(i)$ is at most $mi$. The second case is when there exists a job in $\widetilde{P}_t(i)$ to which no job is mapped at the end of phase $i$. In this case, we note that every job in $U_t$ with remaining processing time equal to $i$ is mapped in phase $i$. Therefore, we invoke property (ii) of the induction hypothesis to obtain that the total volume of the jobs in $U_t \cap P_t(i)$ that are unmapped at the end of phase $i$ is at most $m(i-1) \leq mi$. This completes the induction step and the proof of the lemma. □

Properties (P1) and (P2) help in placing upper bounds on the contribution of the mapped jobs and unmapped jobs, respectively, to $S_2(\mathcal{J})$. While Lemma 3.5 holds for any schedule $\mathcal{A}$, the particular mapping $f_t$ that we employ for the remainder of this proof is with respect to a schedule $\mathcal{B}$ that minimizes the sum of the reciprocals of the processing times of the jobs in the queue at time $t$. Let $\alpha'_t$ denote the sum of the reciprocals of the processing times of the jobs in $\mathcal{B}$'s queue at time $t$. As in Lemma 2.5, we can assume without loss of generality that none of the jobs that belong to $\mathcal{B}$'s queue at time $t$ have been processed until time $t$. Therefore, for each job $j$ in $\mathcal{B}$'s queue at time $t$, the remaining processing time equals $p(j)$. By property (P1) of Lemma 3.5, we know that $\rho_t(j) \geq p(f_t(j))$. Since $f$ is injective, we obtain the following lemma about the mapped jobs in $Q_t$.

LEMMA 3.6 (mapped jobs). *For any time $t$, we have $\sum_{j \in \mathrm{MPD}_t} \frac{1}{\rho_t(j)} \le \alpha'_t$.* □

We now consider the unmapped jobs. We begin by establishing a technical lemma that is helpful in placing an upper bound on the contribution of the unmapped jobs. (The reader may choose to skip the proof of this lemma on their first pass through this section.)

LEMMA 3.7. *Let $m$ be a positive integer. Let $X$ be a multiset of positive reals that satisfies the following condition.*

(C) *For any positive real $x$ the sum of the elements in $X$ with value at most $x$ is at most $mx$.*

*Then the following inequality holds true for any positive real $z$:*

$$\sum_{x \in X, x \ge z} \frac{1}{x} \le \frac{2m-1}{z}.$$

*Proof.* We first consider the case $m = 1$. By condition (C), this case implies that $X$ has at most one element. Therefore, the desired inequality follows trivially.

In the remainder of the proof, we assume that $m > 1$. Let $v(X)$ denote the term $\sum_{x \in X, x \ge z} \frac{1}{x}$. Consider the following greedy algorithm for constructing $X$ with the goal of maximizing $v(X)$. Initially set $X$ to $\emptyset$. Iteratively, add to $X$ the smallest element greater than or equal to $z$ that can be added without violating the condition on $X$ as stated in the lemma. Let $x_i$ be the $i$th element added to $X$. We claim that $x_i$ may be defined as follows:

$$x_i = \begin{cases} z & \text{if } 1 \le i \le m, \\ \frac{\sum_{1 \le j < i} x_j}{m-1} & \text{otherwise.} \end{cases}$$

We first prove the following two claims by induction on $i$: (i) $x_i \ge x_j$ for $1 \le j < i$, and (ii) the multiset $\{x_j : 1 \le j \le i\}$ is a valid solution for $X$. For the base case, we consider $1 \le i \le m$. Since $x_i = z$, the desired claim holds trivially for the base case. We now assume that the desired claim holds for $i-1$. Consider iteration $i$. The element $x_i$ equals $(\sum_{1 \le j < i} x_j)/(m-1)$, which is at least $(\sum_{1 \le j < i-1} x_j)/(m-1)$ and hence at least $x_{i-1}$, thus establishing part (i) of the induction step. For part (ii) of the induction step, we note that part (i) implies that we only need to check whether $\sum_{1 \le j \le i} x_j \le m x_i$. By the definition of $x_i$ it follows that $\sum_{1 \le j \le i} x_j = m x_i$, thus ensuring that the multiset $\{x_j : 1 \le j \le i\}$ is a valid solution for $X$. This completes the proofs of claims (i) and (ii).

We next show that $X^* = \{x_j : j \ge 1\}$ is an optimal choice for $X$. If possible, let $Y$ be a different optimal solution. Let $y_i$ denote the $i$th smallest element of $Y$, where we break ties arbitrarily. Let $i$ be the smallest integer such that $y_i \ne x_i$. We now derive a contradiction in each of the following two cases: $y_i > x_i$ and $y_i < x_i$. If $y_i > x_i$, we can replace the element $y_i$ in $Y$ by the element $x_i$ and obtain a valid solution yielding a value strictly larger than $v(Y)$, thus contradicting the assumption that $v(Y)$ is optimal. If $y_i < x_i$, then since $Y$ is a valid solution, so is the multiset $\{y_j : 1 \le j \le i\}$. This implies the following inequality:

$$\begin{aligned} \sum_{1 \le j \le i} y_j &= y_i + \sum_{1 \le j < i} x_j \\ &= y_i + (m-1)x_i \\ &> y_i + (m-1)y_i \\ &= m y_i, \end{aligned}$$

thus violating the condition stated in the lemma. (The argument for the second step is the following: since all of the elements in $Y$ are at least $z$, we have $i > m$, implying that $(m-1)x_i = \sum_{1 \le j < i} x_j$.)

To complete the proof of the lemma, we now compute $v(X^*)$. We first note that for $i > m$, $x_i$ is equal to $z(m/m-1)^{i-m}$. Therefore, we can calculate $v(X^*)$ as follows:

$$\begin{aligned} v(X^*) &= \frac{m}{z} + \sum_{i>m} \frac{1}{z}\left(\frac{m-1}{m}\right)^{i-m} \\ &= \frac{m}{z} + \sum_{j>0} \frac{1}{z}\left(\frac{m-1}{m}\right)^{j} \\ &= \frac{2m-1}{z}. \qquad \square \end{aligned}$$

In the following lemma, we invoke the inequality established above to place an upper bound on the sum of the reciprocals of the remaining processing times of certain subsets of unmapped jobs.

LEMMA 3.8. *For any positive integer $i$ and any step $t$, we have*

$$\sum_{j \in \mathrm{UMPD}_t, \rho_t(j) \ge i} \frac{1}{\rho_t(j)} \le \frac{2m-1}{i}.$$

*Proof.* We invoke Lemma 3.7, with $X$ equal to the set $\{j \in \mathrm{UMPD}_t : \rho_t(j) \ge i\}$, to prove the desired claim. We note that condition (C) of Lemma 3.7 holds due to property (P2) of Lemma 3.4. The claim of Lemma 3.7 is the desired inequality. $\square$

Lemma 3.8 indicates that if the rank of every unmapped job exceeds the rank of $\Omega(m)$ mapped jobs at any time step $t$, then the total stretch contribution of the unmapped jobs at $t$ can be upper bounded by a constant factor times the sum of the reciprocals of the remaining processing times of the mapped jobs, which in turn is bounded by Lemma 3.6. This suggests classifying the unmapped jobs at any time $t$ into two groups as follows. A job $j$ is *marked at time $t$* if $j \in \mathrm{UMPD}_t$ and the number of mapped jobs in $P_t(\rho_t(j))$ is at most $m$. Note that whether a job is marked depends on the particular time $t$; thus, for instance, a job may be marked at one time step and may be unmarked at a subsequent step. We call the first time when a job gets marked the *marking time* of the job; the marking time of a job that is never marked may be set to $\infty$. Let $\mathrm{MKD}_t$ and $\mathrm{UMKD}_t$ denote the sets of marked and unmarked jobs, respectively, at time $t$. We first account for the contribution of unmarked jobs by relating it to the contribution of mapped jobs of lesser rank.

LEMMA 3.9 (unmarked jobs). *For any time $t$, we have*

$$\sum_{j \in \mathrm{UMKD}_t} \frac{1}{p(j)} \le \sum_{j \in \mathrm{MPD}_t} \frac{2}{\rho_t(j)}.$$

*Proof.* For any mapped job $j$ in $Q_t$, let $X(j)$ denote the set of unmarked jobs in $Q_t$ that have rank greater than that of $j$. Since each job in $X(j)$ is unmapped, the following inequality follows from Lemma 3.8:

$$\sum_{j_1 \in X(j)} \frac{1}{\rho_t(j_1)} \le \frac{2m-1}{\rho_t(j)}. \tag{3.1}$$

By definition, for each unmarked job $j_1$, there exist at least $m$ jobs $j$ such that $j_1$ is in $X(j)$. Therefore, we obtain the following inequality:

$$\begin{aligned}\sum_{j_1 \in \mathrm{UMKD}_t} \frac{1}{p(j_1)} &\le \sum_{j_1 \in \mathrm{UMKD}_t} \frac{1}{\rho_t(j_1)} \\ &\le \frac{1}{m} \sum_{j \in \mathrm{MPD}_t} \sum_{j_1 \in X(j)} \frac{1}{\rho_t(j_1)} \\ &\le \frac{1}{m} \sum_{j \in \mathrm{MPD}_t} \frac{2m-1}{\rho_t(j)} \\ &\le \sum_{j \in \mathrm{MPD}_t} \frac{2}{\rho_t(j)}.\end{aligned}$$

(The third inequality is derived by adding (3.1) over all the mapped jobs.) □

We now consider the marked jobs. We call a marked job $j$ *dependent* at time $t$ if the number of jobs in $F_t$ with release time of at least the marking time of $j$ is greater than $\gamma m$, where $\gamma$ is a constant in $(0, 1)$ to be specified later. A marked job that is not dependent at time $t$ is said to be *independent*. Let $\mathrm{DEP}_t$ and $\mathrm{IND}_t$ denote the set of dependent and independent jobs, respectively, at time $t$. We account for the contributions of the jobs in $\mathrm{IND}_t$ and $\mathrm{DEP}_t$ in the following manner. In Lemma 3.10, we show that any job $j$ is independent during $O(p(j))$ steps only. This implies that the total contribution of the independent jobs during the execution of SRPT is $O(|\mathcal{J}|)$. Next, in Lemma 3.11, we show that the total contribution of the marked dependent jobs is within a constant factor of the contribution of the jobs in $F_t$, which we have already shown in Lemma 3.3 to be equal to $|\mathcal{J}|$.

LEMMA 3.10 (independent jobs). *Any job $j$ is independent during at most $2p(j)/(1-\gamma)$ time steps.*

*Proof.* Since any job $j$ is independent only when it is marked, we only need to consider time steps beginning from the marking time of $j$. Let $t$ denote the marking time of $j$. Let $X$ denote the set of jobs in $Q_t$ that have rank less than that of $j$. Since $j$ is marked at time $t$, it follows that the number of mapped jobs in $X$ is at most $m$. Moreover, by property (P2) of Lemma 3.5, the volume of all of the unmapped jobs in $X$ at time $t$ is at most $m\rho_t(j) \le mp(j)$. Therefore, the volume of all the jobs in $X$ is at most $2mp(j)$.

Consider any time step $t' \ge t$ when $j$ is independent. It follows from the definition of independence that there are at most $\gamma m$ jobs in $F_{t'}$ with release time at least $t$. Since $j$ is not in $F_{t'}$, it follows that there are at least $(1-\gamma)m$ jobs in $X$ that are in $F_{t'}$. Thus, the volume of the jobs in $X$ decreases by at least $(1-\gamma)m$ in time step $t_1$. Once all of the jobs in $X$ are completed, $j$ can be never be independent. Since the total volume of $X$ at time $t$ is at most $2mp(j)$, the number of time steps when $j$ is independent is at most $2p(j)/(1-\gamma)$. □

We next consider the dependent jobs.

LEMMA 3.11 (dependent jobs). *For any time $t$, we have*

$$\sum_{j \in \mathrm{DEP}_t} \frac{1}{p(j)} \le \frac{3}{\gamma} \sum_{j \in F_t} \frac{1}{p(j)}.$$

*Proof.* Consider a job $j$ in $F_t$. Let $X(j)$ be the set of jobs in $\mathrm{DEP}_t$ whose marking time is at most the release time of $j$. Since every job in $X(j)$ has rank greater than

$m$ and hence greater than that of $j$, it follows that at the time of the release of $j$ the remaining processing time of every job in $X(j)$ is at least $p(j)$; that is, for any $j_1$ in $X(j)$, we have $\rho_{r(j)}(j_1) \geq p(j)$. Moreover, if $Y(j)$ denotes the set of jobs in $X(j)$ that have been processed at any time during the time interval $[r(j), t]$, then $|Y(j)|$ is at most $m - 1$ because every job in $X(j)$ has rank greater than that of $j$.

Consider the jobs in $X(j) \setminus Y(j)$. For every job $j_1$ in $X(j) \setminus Y(j)$, we have $\rho_t(j_1) = \rho_{r(j)}(j_1) \geq p(j)$. Moreover, since every job in $X(j)$ is unmapped, we obtain the following inequality from Lemma 3.8:

$$\sum_{j_1 \in X(j) \setminus Y(j)} \frac{1}{p(j_1)} \leq \frac{2m}{p(j)}. \tag{3.2}$$

We now consider the jobs in $Y(j)$. Since there are at most $m - 1$ jobs in $Y(j)$, each with processing time at least $p(j)$, we have the following inequality:

$$\sum_{j_1 \in Y(j)} \frac{1}{p(j_1)} \leq \frac{m-1}{p(j)}. \tag{3.3}$$

Equations 3.2 and 3.3 together yield the following inequality for each job $j$ in $F_t$:

$$\sum_{j_1 \in X(j)} \frac{1}{p(j_1)} \leq \frac{3m}{p(j)}. \tag{3.4}$$

Now consider a job $j_1$ in $\text{DEP}_t$. Since $j_1$ is dependent, there are more than $\gamma m$ jobs $j$ in $F_t$ such that $j_1$ is in $X(j)$. Thus, if we add up both the left-hand and right-hand sides of (3.4) over all jobs in $F_t$, $j_1$ appears at least $\lceil \gamma m \rceil$ times on the left-hand side. Therefore, we obtain the following inequality, that establishes the desired claim:

$$\sum_{j_1 \in \text{DEP}_t} \frac{1}{p(j_1)} \leq \frac{3}{\gamma} \sum_{j \in F_t} \frac{1}{p(j)}. \qquad \square$$

Putting Lemmas 3.6, 3.9, 3.10, and 3.11 together, we obtain the following main lemma.

LEMMA 3.12. *For any instance $\mathcal{J}$, we have*

$$\sum_t \sum_{j \in U_t} \frac{1}{p(j)} \leq 3S^*(\mathcal{J}) + \left(\frac{2}{1-\gamma} + \frac{3}{\gamma}\right) |\mathcal{J}|.$$

*Proof.* We establish the desired inequality as follows:

$$\begin{aligned}
\sum_t \sum_{j \in U_t} \frac{1}{p(j)} &= \sum_t \left( \sum_{j \in \text{MPD}_t} \frac{1}{p(j)} + \sum_{j \in \text{IND}_t} \frac{1}{p(j)} + \sum_{j \in \text{DEP}_t} \frac{1}{p(j)} + \sum_{j \in \text{UMKD}_t} \frac{1}{p(j)} \right) \\
&\leq \sum_t \sum_{j \in \text{MPD}_t} \frac{3}{\rho_t(j)} + \sum_j \sum_{t: j \in \text{IND}_t} \frac{1}{p(j)} + \frac{3}{\gamma} \sum_t \sum_{j \in F_t} \frac{1}{p(j)} \\
&\leq \sum_t 3\alpha'_t + \frac{2|\mathcal{J}|}{1-\gamma} + \frac{3}{\gamma} \sum_t \sum_{j \in F_t} \frac{1}{p(j)} \\
&\leq 3S^*(\mathcal{J}) + \left(\frac{2}{1-\gamma} + \frac{3}{\gamma}\right) |\mathcal{J}|.
\end{aligned}$$

(In the second step, we invoke Lemmas 3.9 and 3.11. In the third step, we invoke Lemmas 3.6 and 3.10. The final step follows from Lemma 3.3.) ∎

The term $2/(1-\gamma)+3/\gamma$ attains a minimum value of $5+2\sqrt{6} \leq 10$ when $\gamma = 3-\sqrt{6}$. The main theorem now directly follows from Lemmas 3.3 and 3.12.

**3.2. Lower bound.** We now prove Theorem 3.2. We consider the case of two processors only; the argument can be easily extended to the case of $2m$ processors for any positive integer $m$. The main idea in the argument is similar to that used in [18]. Consider an instance that starts with three jobs, one of size $2^n$ and two of size $2^{n-1}$, all of which arrive at time 0. At time $2^n$, one job of size $2^{n-1}$ and two jobs of size $2^{n-2}$ are released. In general, for $1 \leq i \leq n$, at time $\sum_{i<j\leq n} 2^j$, one job of size $2^i$ and two jobs of size $2^{i-1}$ are released. Finally, at each of the $p$ steps of the interval $[2^{n+1}-2, 2^{n+1}+p-3]$, a pair of unit-size jobs are released. (Here $p$ is an integer that is specified below.) The optimal total stretch equals $4n+2p$. The total stretch achieved by SRPT is at least $3n+4p+p(1/2^{n-2}+1/2^{n-1}+\cdots+1/2)$, which is $3n+(5-1/2^{n-2})p$. For any constant $\varepsilon > 0$, we can choose $p$ sufficiently larger than $n$ so as to make the competitive ratio at least $2.5-\varepsilon$.

## 4. Lower bounds.

This section contains lower bounds on the competitive ratio of arbitrary online algorithms for uniprocessor and multiprocessor scheduling. Section 4.1 concerns uniprocessor scheduling, while section 4.2 concerns multiprocessor scheduling.

**4.1. Uniprocessor scheduling.** Our main result for lower bounds on online uniprocessor scheduling is the following.

THEOREM 4.1. *If there are only two distinct job sizes, there exists an optimal online algorithm for minimizing average stretch. If there are three or more distinct job sizes, the competitive ratio of any online algorithm is at least* 1.04.

*Proof.* Consider the case when there are only two distinct job sizes. We first observe that there is an optimal schedule in which all large (resp., small) jobs are processed in first-in-first-out (FIFO) order. Thus, at any time $t$, there is at most one partially processed job in each category, and that is the job at the head of the FIFO order in that category at that time; let $\ell$ and $s$ denote the job at the head of the FIFO order in the large and small categories, respectively. We need to decide which one of these two jobs must be processed. Suppose we complete the large job $\ell$ first, and follow it by processing the small job $s$; then the total stretch contributed by the two jobs is

$$\frac{t+\rho_t(\ell)-r(\ell)}{p(\ell)} + \frac{t+\rho_t(\ell)+\rho_t(s)-r(s)}{p(s)}.$$

On the other hand, if we complete the small job first, followed by the the large job, then the stretch contributed by the two jobs is

$$\frac{t+\rho_t(s)-r(s)}{p(s)} + \frac{t+\rho_t(\ell)+\rho_t(s)-r(\ell)}{p(\ell)}.$$

The former is desirable when $\rho_t(\ell)/p(s) \leq \rho_t(s)/p(\ell)$, that is, when $\rho_t(\ell)p(\ell) \leq \rho_t(s)p(s)$.

We now argue that the following online algorithm is optimal: at each time step $t$, process a job $i$ with the smallest $\rho_t(i)p(i)$. The proof is by contradiction. Suppose that there exists an optimal schedule in which there is a time step $t$ at which a job $i$

with the smallest $\rho_t(i)p(i)$ is not processed. Let $t$ be the earliest such time step. Let $s$ and $\ell$ denote the jobs at the head of the FIFO order in the small and large categories, respectively, at time $t$. Let us consider the case that $\rho_t(\ell)p(\ell) < \rho_t(s)p(s)$, yet job $s$ is processed at time $t$. Let $t'$ denote the completion time of job $\ell$ in the schedule. It then follows that the set of jobs that complete during the interval $[t, t')$ are all small jobs (this set is nonempty since $s$ belongs to it). Let $j$ denote the last small job to complete in the interval $[t, t')$. Consider the schedule in which we swap the order of jobs $j$ and $\ell$ and complete $\ell$ before $j$; thus, the completion time of $\ell$ is decreased by at least $\rho_t(s)$, and the completion time of $j$ is increased by at most $\rho_t(\ell)$. As a result, the decrease in total stretch is at least

$$\frac{\rho_t(s)}{p(\ell)} - \frac{\rho_t(\ell)}{p(s)} > 0,$$

which contradicts the assumption that the given schedule is optimal. The analysis for the other case is symmetric, thus completing the proof of the first claim of the theorem.

We next consider the lower bound when there are three or more distinct job sizes. We give the proof of a weaker lower bound first. Consider three jobs $j_1$, $j_2$, and $j_3$, with release times 0, 4, and 5, respectively, and processing times 5, 2, and 1, respectively. Let instance $\mathcal{J}_1$ be the set $\{j_1, j_2\}$ and instance $\mathcal{J}_2$ be the set $\{j_1, j_2, j_3\}$. For $\mathcal{J}_1$, the optimal solution is to process $j_1$ for 4 steps, then process $j_2$ for 2 steps and then complete $j_1$. The optimal total stretch is $1 + 7/5 = 2.4$. For $\mathcal{J}_2$, the optimal solution is to process $j_1$ for 5 steps and thus complete it, then process $j_3$ for 1 step, and finally, process $j_2$. The optimal stretch value for this instance is 4. For instance $\mathcal{J}_1$, if the given online algorithm completes $j_1$ before $j_2$, then its stretch is at least 2.5, implying a competitive ratio of at least 1.04. If, on the other hand, the algorithm preempts $j_1$ at time 4 (i.e., at the start of the fifth step), then the best scenario for the algorithm with regard to instance $\mathcal{J}_2$ is to finish the jobs in one of the following orders: (i) $j_2$, $j_3$, $j_1$ or (ii) $j_3$, $j_2$, $j_1$. The stretch for case (i) is 4.6 and for case (ii) is 4.1. Therefore, the competitive ratio is at least 1.025.

We can generalize the above example as follows. Let $\ell$, $m$, and $s$ be the jobs with processing times $p(\ell)$, $p(m)$, and $p(s)$, respectively, where $p(\ell) > p(m) > p(s)$. Consider the instance in which $\ell$ arrives at time 0 and $m$ arrives at the end of time step $p(\ell) - k$, where $k \leq p(m)$. If the algorithm does not preempt the first job when the second job arrives, the competitive ratio is at least $(2 + (k/p(m)))/(2 + (p(m)/p(\ell)))$. Otherwise, job $s$ is presented at the end of time step $p(\ell)$. Then we can argue as above that any such algorithm has average stretch at least $\min\{3 + p(s)/p(m) + (p(m) + p(s))/p(\ell), 3 + (p(m) + p(s))/p(\ell) + (p(m) - k)/p(s)\}$, while the optimum average stretch is at most $3 + (k + p(s))/p_m$. The lower bound on the competitive ratio, thus obtained, is nearly maximized by setting $p(s) = 54$, $p(m) = 100$, $p(\ell) = 200$, and $k = 60$; this setting of parameters yields that the average stretch is at least 1.04. $\square$

**4.2. Multiprocessor scheduling.** For multiprocessors, we can establish a slightly stronger lower bound on the competitive ratio of any online algorithm.

THEOREM 4.2. *For any positive integer $m$, the competitive ratio of any online algorithm for any $2m$-processor machine is at least $7/6$.*

*Proof.* We first consider the case of a 2-processor machine. We consider two instances of the scheduling problem. One instance consists of three jobs, two of size 1 and one of size $\ell > 1$, all of which are released at time 0. The parameter $\ell$ is an integer, whose value is specified below. The optimal schedule for this instance is to schedule the two size-1 jobs in parallel and then schedule the size-$\ell$ job, thus yielding a total stretch of $3 + 1/\ell$. If the given online algorithm schedules the two unit-size jobs in sequential order on one of the processors, then it achieves a total stretch of 4, thus yielding a competitive ratio of $4\ell/(3\ell + 1)$.

If the online algorithm instead schedules the above instance optimally, then we consider its performance on another scheduling instance which consists of the same set of three jobs as above, together with a sequence of unit-size jobs, arriving in pairs at times $\ell$, $\ell+1$, ..., $\ell+n-1$. Since the incomplete size-$\ell$ job has at least one unit of processing time remaining, the online algorithm will be forced to delay the size-$\ell$ job until all of the size-1 jobs complete, thus leading to a total stretch of $2n+3+(n+1)/\ell$. (Note that we are making use of our assumption that time is discrete; thus, job arrivals and preemptions occur at integer time steps.) An alternative schedule for this instance is to schedule the first two unit-size jobs in sequence on one of the processors and the size-$\ell$ job on the other processor so that the sequence of pairs of unit-size jobs that are released from time $\ell$ onwards can be scheduled immediately upon arrival without delaying the size-$\ell$ job. The total stretch of this schedule is $2n + 4$. Therefore, the competitive ratio of the given online algorithm is at least $(2n\ell+3\ell+n+1)/(2n\ell+4\ell)$, which tends to $(2\ell + 1)/(2\ell)$ as $n$ tends to infinity.

We now choose integer $\ell$ so as to maximize the minimum of $4\ell/(3\ell + 1)$ and $(2\ell + 1)/(2\ell)$. A maximum of 7/6 is achieved at $\ell = 3$.

We next generalize the above proof to $2m$-processor machines, for $m > 1$. Again, we consider two instances of the scheduling problem. One instance consists of $3m$ jobs, $2m$ jobs of size 1 and $m$ jobs of size $\ell > 1$, all of which are released at time 0. The parameter $\ell$ is an integer, whose value is specified below. The optimal schedule for this instance is to schedule the $2m$ unit-size jobs in parallel on each of the $2m$ processors and then schedule the size-$\ell$ jobs on any $m$ of the processors, thus yielding a total stretch of $3m + m/\ell$. Let $k$ denote the number of size-$\ell$ jobs that the given online algorithm completes by time $\ell$. It follows that at least $k$ of the $2m$ unit-size jobs are delayed by a time unit and incur a stretch of 2. Furthermore, at least $m - k$ size-$\ell$ jobs are delayed by unit time. Thus the total stretch of the online algorithm is at least $3m + k + (m - k)/\ell$.

The second instance for which we evaluate the given online algorithm consists of the same set of $3m$ jobs as in the first instance, together with a sequence of $2nm$ unit-size jobs, arriving in groups of $2m$ jobs at each of the steps $\ell$, $\ell$+1, ..., $\ell$+$n$−1. For this instance, the total stretch objective forces the given online algorithm to schedule all of the $2nm$ jobs ahead of the $m-k$ size-$\ell$ incomplete jobs at time $\ell$. The total stretch of the online algorithm for the second instance is at least $2nm+3m+k+n(m-k)/\ell$. On the other hand, an alternative (optimal) schedule completes the first set of $3m$ jobs (that arrive at time 0) within time $\ell$ and then schedules the remaining $2nm$ unit-size jobs as they arrive. This schedule has a total stretch of $2nm + 4m$. As $n$ tends to infinity, the ratio $(2nm+3m+k+n(m-k)/\ell)/(2nm+4m)$ tends to $1+(m-k)/(2m\ell)$.

The competitive ratio of the online algorithm is thus at least

$$\begin{aligned}
&\min_k \max\left\{\frac{3m + k + (m-k)/\ell}{3m + m/\ell}, 1 + \frac{m-k}{2m\ell}\right\}\\
&\quad = \min_k \max\left\{1 + \frac{k - k/\ell}{3m + m/\ell}, 1 + \frac{m-k}{2m\ell}\right\}\\
&\quad = 1 + \min_k \max\left\{\frac{k - k/\ell}{3m + m/\ell}, \frac{m-k}{2m\ell}\right\}
\end{aligned}$$

$$\geq 1 + \frac{1}{2} \min_k \left[ \frac{1}{2\ell} + \frac{k}{m} \left( \frac{\ell - 1}{3\ell + 1} - \frac{1}{2\ell} \right) \right]$$
$$\geq 1 + \frac{\ell - 1}{6\ell + 2}.$$

(The penultimate step holds since the maximum of two numbers is at least the average of the two. The last step uses the inequality $(\ell - 1)/(3\ell + 1) \leq 1/2\ell$.) The term $1 + (\ell - 1)/(6\ell + 2)$ tends to 7/6 as $\ell$ tends to infinity. $\square$

**5. Discussion.** We have studied the online complexity of minimizing average stretch. Our results show that SRPT is attractive for both uniprocessor and multiprocessor cases since it simultaneously achieves optimal performance (up to constant factors) for average response time as well as average stretch. In general, any algorithm aimed at optimizing average response time or average stretch, and SRPT in particular, may starve jobs on worst case inputs. However, for certain applications such as serving web traffic, it appears that the adverse effect of starvations in SRPT is limited [4, 14]. In multiprocessors, a potential drawback of SRPT is the overhead it incurs due to migrations. Recall that SRPT may preempt a job at one processor and later resume the job at a different processor. A natural variant of SRPT that does not perform any migrations has been proposed in [2]. In recent work [5], it has been shown that the "migrationless" scheduling algorithm of [2] also achieves a constant-factor competitive ratio with respect to average stretch.

Many interesting problems remain open. In particular, the lower bounds may quite possibly be strengthened. Also, it will be of interest to analyze the algorithm that schedules the job $i$ with the smallest $p(i)\rho_t(i)$ at time $t$; for the special case of two job sizes, this algorithm is optimal, as we showed (see section 4). The average stretch metric may also be studied in other models, such as when preemption is not allowed.

In this paper, we have focused on online scheduling. The complexity of optimizing average stretch offline is open for both uniprocessors and multiprocessors. For uniprocessors, a PTAS is achievable, as shown recently in [7, 9]. For multiprocessors, the online constant-factor upper bounds that we have shown yield the best known approximations offline. Whether the offline problem is NP-hard is open, even for the multiprocessor case. The reduction used in the NP-completeness proof for minimizing average response time on 2-processors [10] may be helpful in this regard.

# TRAVELING WITH A PEZ DISPENSER (OR, ROUTING ISSUES IN MPLS)[*]

ANUPAM GUPTA[†], AMIT KUMAR[‡], AND RAJEEV RASTOGI[§]

**Abstract.** A new packet routing model proposed by the Internet Engineering Task Force is *MultiProtocol Label Switching*, or MPLS [B. Davie and Y. Rekhter, *MPLS: Technology and Applications*, Morgan Kaufmann (Elsevier), New York, 2000]. Instead of each router's parsing the packet network layer header and doing its lookups based on that analysis (as in much of conventional packet routing), MPLS ensures that the analysis of the header is performed just once. The packet is then assigned a *stack of labels*, where the labels are usually much smaller than the packet headers themselves. When a router receives a packet, it examines the label at the *top* of the label stack and makes the decision of where the packet is forwarded based solely on that label. It can pop the top label off the stack if it so desires, and can also push some new labels onto the stack, before forwarding the packet. This scheme has several advantages over conventional routing protocols, the two primary ones being (a) reduced amount of header analysis at intermediate routers, which allows for faster switching times, and (b) better traffic engineering capabilities and hence easier handling of quality of service issues. However, essentially nothing is known at a theoretical level about the performance one can achieve with this protocol, or about the intrinsic trade-offs in its use of resources.

This paper initiates a theoretical study of MPLS protocols, and routing algorithms and lower bounds are given for a variety of situations. We first study the routing problem on the line, a case which is already nontrivial, and give routing protocols whose trade-offs are close to optimality. We then extend our results for paths to trees, and thence onto more general graphs. These routing algorithms on general graphs are obtained by finding a *tree cover* of a graph, i.e., a small family of subtrees of the graph such that, for each pair of vertices, one of the trees in the family contains an (almost-)shortest path between them. Our results show tree covers of logarithmic size for planar graphs and graphs with bounded separators, which may be of independent interest.

## 1. Introduction.

In most conventional network routing protocols, a packet makes its way from source to destination in essentially the following way: when a packet reaches the router, the router analyzes the packet's header (which contains the destination address) and uses the results of this analysis to decide the next hop for the packet. These routing decisions are made locally and independently of other routers, based solely on the identity of the incoming edge and the analysis of the packet header. For example, routers using conventional IP forwarding typically look for a longest-prefix match between the destination address and the entries in the

routing table to decide the next hop for the packet. In general, *each* router has to extract the information relevant to it from the (much longer) packet header. Furthermore, conventional routers are not designed to use information about the source of the packets from these headers.

An alternative to this routing model was proposed by the Internet Engineering Task Force (IETF) and is called *MultiProtocol Label Switching* (MPLS) [11, 20]. In MPLS, the analysis of the packet's network layer header is performed just once; this is done by the first router that receives the packet, called the *ingress router*. This analysis causes the packet to be assigned a *stack* of *labels*, where these labels are usually much smaller than the packet headers themselves [31, 30]. Each subsequent router now examines only the label at the *top* of the label stack, and makes its routing decision (i.e., the next hop) based solely on that label. It can then pop this label off the stack, if it so desires, and push some labels (maybe none) onto the stack, before sending the packet on its merry way. Note that, apart from looking at the top label, none of the subsequent routers perform any further analysis of the network layer header.

There are a number of advantages of MPLS over conventional network layer forwarding protocols. The first one, already alluded to above, is the elimination of header analysis at each hop. This allows the replacement of routers by simpler and faster switches, which merely perform the basic operations of label lookup and replacement. Furthermore, since the packet headers are analyzed by the ingress router when packets enter the system, the ingress router can possibly use additional information about packets to route different packets along different paths. This enables the routing of packets according to their desired quality of service. For example, packets corresponding to time-sensitive applications may be sent along different channels from regular data, which may be faster but more expensive. The ingress router may also use information about the source of the data, in addition to the destination address; this is something that is not possible in conventional routing protocols. In addition to these factors, traffic engineering and network control are important reasons for using MPLS rather than conventional routing schemes [3, 24, 12]. This is for two reasons: first, the time savings achieved by one-time analyses of packet headers allows us to perform fine-grained routing of packets; second, this fine-grained routing allows the entire route for the packet to be encoded very naturally on the stack. These features have made MPLS very popular among network providers and router designers, and companies like Cisco, Juniper, Lucent, and Nortel have been producing routers which support MPLS protocols [9, 25].

However, despite this popularity of MPLS, and the fact that it is becoming more widespread on the Internet, essentially nothing is known at a theoretical level about the performance achievable by MPLS, or about the intrinsic trade-offs in its use of resources. The basic question that this paper addresses is the following: what is the depth of the stack that is sufficient for routing in an $n$-node network, and how does this stack depth interact with the label size?

Note that a small number of labels is desirable, since the bandwidth reservation in networks is often done by creating a (virtual) channel for each label; a small number of labels thus ensures that traffic is not split too much, which usually implies a better bandwidth utilization. Furthermore, having a small set of labels causes the forwarding tables to be small, and makes the forwarding procedures simpler and faster. On the other hand, the size of the label stack translates directly to the size of the packet header, and hence small stacks are desirable as well. These goals naturally oppose each other, and the trade-offs between these resources are nontrivial. If the label size is $L$ and the stack depth is $s$, a simple counting argument indicates that $L^s \geq n$, the size of the network; it is not clear whether MPLS routing protocols can get close to this information theoretic bound.

Previous papers on distributed routing do not address such questions. Indeed, the idea of using a stack of labels is novel to MPLS, as is the all-important restriction that the routers can look only at the top of the stack when deciding the next hop for a packet. As a simple example, consider the question of routing on a path with 2 labels; with each intermediate router getting only one bit of information from the stack (instead of the entire $\log n$ bit destination address), is it possible to achieve a stack depth of $O(\log n)$? While we show in section 2 that this is indeed possible, the solution is not trivial and illustrates the issues that arise from this restricted model of access to the network header.

This paper initiates a theoretical study of the MPLS protocol. We give routing algorithms and lower bounds in a variety of situations. We first study the routing problem on a path, and give near-optimal protocols for this basic case. When combined with a suitable decomposition of trees into paths, these protocols then yield routing algorithms for trees. These results are then extended to more general classes of graphs by the use of *tree covers*. A tree cover is a set of subtrees of the graph such that for each pair of vertices one of the trees in the cover contains an (almost-)shortest path between the two vertices.

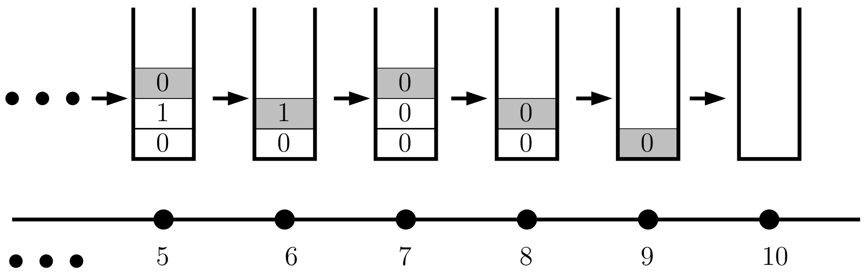
**1.1. The model.** The header of each *packet* consists of a *stack $S$* of *labels*. The labels are drawn from a set $\Sigma$ of size $L$, which is usually identified with the set $\{1, 2, \ldots, L\}$. The two quantities of interest are (a) the number of labels $L$ and (b) the maximum stack depths required for routing between any two vertices.

The network is represented by an undirected graph $G = (V, E)$, each node representing a *router* and running some routing protocol. A *routing protocol $\mathcal{A}$* has two components: a suite of *stack-making functions* $\{g_v\}_{v \in V}$ and a suite of *forwarding functions* $\{f_v\}$, one each for every node $v$ in the network.

Let $E_v$ be the set of edges adjacent to the node $v$. The stack-making function $g_v : V \to (E_v \times \Sigma^*)$ is evaluated at each ingress router $v$: it takes the destination address $u$ of the packet and outputs the outgoing edge $e = (v, w) \in E_v$ to which $v$ should send the packet. Further, it outputs a stack $g_v(u)$ that subsequently would take the packet from $w$ to $u$. The forwarding function $f_v : E_v \times \Sigma \to (E_v \times \Sigma^*)$, where $E_v$ is the set of edges incident to $v$, prescribes the behavior of the router. On obtaining a packet with stack $S$, the router $v$ performs the following actions:

- The router first pops the top label off the top of the stack; this label is denoted by $\ell$. A correct protocol must ensure that if the stack is empty, then $v$ is the packet's destination.
- If the packet arrived on edge $e$, let $f_v(e, \ell) = (e', \sigma)$ for $e' \in E_v$, $\sigma \in \Sigma^*$. The router now pushes $\sigma$ on top of the stack and sends the packet out on the edge $e'$.

If there is a single function $f$ such that $f_v = f$ for all $v$, the protocol $\mathcal{A}$ is called *uniform*; otherwise it is *nonuniform*. A protocol $\mathcal{A}$ is an $(L, s)$-protocol for a graph $G$ if it uses $L$ labels and has a maximum stack depth of $s$. We will mostly consider protocols that route on shortest paths, and this is implicitly assumed in our results. We will explicitly specify the cases in which packets may travel on nonshortest paths; a routing protocol has stretch $D$ if, given any pair $u, v \in V$, the protocol routes from $u$ to $v$ on a path with length at most $D$ times the length of the shortest path between $u$ and $v$.



$$\text{\textit{For all} } v\text{:}\quad f_v(\textit{left}, 0) = (\textit{right}, \langle\,\rangle)$$
$$f_v(\textit{left}, 1) = (\textit{right}, \langle 0\,0\rangle)$$

FIG. 1.1. *An example of MPLS routing.*

A simple example is given in Figure 1.1 with $\Sigma = \{0, 1\}$. All functions $f_v$ are the same, and only the relevant subset of the actions is shown here. The packet in the example is destined for the vertex labeled 10. Each node bases its decision on the top (shaded) label and the incoming edge.

**1.2. Our results.** The first routing problem that we consider is on the path $P_n$; here we show a substantial gap between uniform and nonuniform protocols. In particular, we show that while uniform protocols on the line with $L$ labels require a stack depth of $s = \Theta(Ln^{1/L})$, there are nonuniform protocols using $L$ labels that require a stack depth of just $O(\log_L n)$. Recall that there is an information-theoretic lower bound of $\log_L n$ on the stack depth, and hence the latter result is within a constant factor of the optimum.

The protocol for the path serves as our basic building-block when we consider arbitrary trees; we use it in conjunction with the so-called *caterpillar decomposition* [23] of trees into paths to get a $(\Delta + k, kn^{1/k}\log n)$ uniform protocol and a $\left(\Delta + k, \frac{\log^2 n}{\log k}\right)$ nonuniform protocol. (The additive $\Delta$ in the number of labels is unavoidable while routing on trees; if the maximum degree of a tree is $\Delta$, then we require at least $\Delta - 1$ distinct labels to achieve shortest path routing.) We also show that our uniform protocol is close to the best uniform protocol by give an almost matching lower bound when $k$ is $O(\log n)$. Furthermore, note that setting $k = \log n$ in the above nonuniform protocol gives a stack depth of $O(\log^2 n/\log\log n)$ with $\Delta + O(\log n)$ labels; we go on to refine the protocol and give a nonuniform $(\Delta + \log\log n, \log n)$ protocol as well.

The protocols developed for trees are then used to give routing protocols for general graphs. To this end, a *tree cover* of a graph $G = (V, E)$ is defined to be a family of subtrees $\mathcal{F}$ of the graph such that for each pair of vertices $u, v \in V$ there exists a tree $T \in \mathcal{F}$ which contains an (almost-)shortest path between $u$ and $v$. (See Definition 4.1 for a formal definition.) If the network has a tree cover with $t$ trees and we want to route a packet from $u$ to $v$, we can identify the appropriate tree for this pair of vertices and use the tree routing protocol to route on it; note that this causes the number of labels to increase by a factor of $t$, since the label has to encode the identity of the tree.

A simple argument can show that general graphs do not have $(\log n)$-sized tree covers unless the trees are allowed to stretch distances by $\Omega(\log n)$. Since a nonconstant stretch is often inadmissible in routing applications, we restrict our attention to important special classes of graphs. Our first result in this realm shows that graph families with $r(n)$-sized balanced vertex separators have $O(r(n)\log n)$-sized tree covers (without any stretch); using the same idea and the fact that planar graphs have balanced separators of size $O(\sqrt{n})$, we can get $O(\sqrt{n})$-sized tree covers for planar graphs. We then show a matching lower bound of $\Omega(\sqrt{n})$ for tree covers of planar graphs.

Though these matching results seem disheartening, we show that allowing tree covers to have a small stretch (of 3) makes them very powerful: we show that all planar graphs have $O(\log n)$-sized tree covers with stretch 3. The proof of this result uses the planar separator theorem of Lipton and Tarjan [21] in a novel way.

As the above discussion indicates, our protocols are extremely modular in nature; hence improvements in MPLS routing strategies for (say) trees will result in improvements for trees and graphs (see the paper of Gupta, Kumar, and Thorup [19] for such an improvement). Finally, we would like to emphasize that the constants involved in our protocols are small (and perhaps can be improved), which makes these useful in practice.

## 1.3. Previous work.

*Distributed packet routing protocols.* These protocols have been widely studied in the theoretical computer science community; see, e.g., [13, 14, 29, 28, 10] or the survey by Gavoille [15] on some of the issues and techniques. The results in these works are incomparable to our results, since the objectives of the two lines of research are quite different. Much of the conventional packet routing literature focuses on reducing the sizes of the routing tables and the sizes of the packet headers while performing near-shortest path routing. On the other hand, our work on MPLS routing may require more memory for setting up the initial stack than conventional routing protocols; however, once the stack is set up, the memory needed by each router just to forward the packets is very small. As a concrete example, the best result known for minimizing the total memory (i.e., summed over all the routers) on planar networks in traditional routing is $\tilde{O}(n^{4/3})$ due to Frederickson and Janardan [14]; in contrast, setting up the stack in our protocols requires more memory, but the total memory required for implementing the packet forwarding functions $f_v$ is $\tilde{O}(n)$.

Another difference with previous packet routing results is that our algorithms are name-independent; while many of the previous results require that the routing protocol be allowed to assign the names to the nodes in some convenient fashion, we do not make any such assumptions. (See the papers [4] and [2] for two other conventional routing schemes which are name-independent.)

*Spanners.* There is considerable literature on finding sparse *spanners* of graphs [1, 8]; these are sparse subgraphs that preserve distances well. However, results about spanners are interesting only when the original graph is not sparse, whereas the routing problems we address are nontrivial even for bounded degree graphs.

*Distance labeling schemes.* Another related corpus of work studies the problem of distance labeling of graphs [34, 26, 16]. The *distance labeling problem* requires assigning "short" labels to vertices so that the distance between two vertices can be inferred from their labels alone, without any additional information about the graph. The techniques used in many papers on distance labeling problems are similar to those we use, and involve finding good separators of graphs. However, the scope of the two problems are quite different. Indeed, the distance labeling problem precludes any knowledge of the global structure of the graph, and hence the label sizes are usually in the range of $\Theta(\log n)$. In contrast, MPLS routing schemes assume that the graph structure is known; the challenge in this case is in devising routing algorithms that base their routing decisions on a sublogarithmic (even possibly a constant) number of bits. As an example, MPLS routing for the path graph is quite nontrivial, whereas the distance labeling problem is trivial for the path. On the other hand, the similarity in the techniques allows us to use some of the results on MPLS routing to improve known results on distance labeling schemes. In section 5.2, we exhibit stretch-3 distance labeling schemes for planar graphs that use labels with $O(\log^2 n)$ bits; previous labeling schemes for planar graphs used a polynomial number of bits, even when a constant stretch was allowed [16].

*Tree covers.* The notion of tree covers was introduced in the papers of Awerbuch and Peleg [6] and Awerbuch, Kutten, and Peleg [5], though it had a slightly different definition. In those papers, the trees were not required to be spanning trees, and there was no explicit bound placed on the number of trees in the cover; however, the number of trees that contained any particular vertex had to be small. The objective was the same as in this paper: to construct a family of trees such that for every pair of vertices there was a tree containing an almost-shortest path between them. The best known constructions are due to Thorup and Zwick [33]; their algorithms find stretch $2k-1$ tree covers for general graphs, where each vertex lies in $\tilde{O}(n^{1/k})$ trees. This can be used to give stretch $2k-1$ MPLS routing schemes for arbitrary graphs with $\tilde{O}(n^{1/k})$ labels and polylogarithmic stack depth. In contrast to these results, the focus of our paper is on cases where constant stretch routing can be achieved with both stack depth and labels being $(\log n)^{O(1)}$.

**1.4. Organization.** The organization of the rest of the paper follows the above discussions: in section 2, we give MPLS routing protocols for the line, which highlight the difference in power between uniform and nonuniform routing. Section 3 gives the routing protocols for trees using the results for the line. Constructions of tree covers for graphs with small separators are given in section 4, which imply routing protocols for these graphs. Finally, constructions of stretch-3 tree covers for planar graphs, as well as their application to distance labeling schemes, appear in section 5.

## 2. Routing on the line.

In this section, we give uniform and nonuniform shortest path MPLS routing schemes for the path graph $P_n$; these will be used as basic building blocks for tree routing schemes in the next section. For our uniform scheme, we show that the maximum stack depth is $O(Ln^{1/L})$ when $L$ labels are used; our nonuniform scheme uses a maximum stack depth of $s = O(\log_L n)$. We also show that both these bounds on the stack depth are within constant factors of optimum.

**2.1. Uniform protocols.** The upper bound of $O(Ln^{1/L})$ is achieved by the following simple strategy. Suppose we wish to send a packet from a node $v$ to a node $u$ which is at distance $D$ from it. Suppose that $D-1$ can be written as $d_L d_{L-1} \dots d_1$ in base $n^{1/L}$. We push $d_i$ copies of $i$ onto the stack for $i$ going down from $L$ to 1. Now the forwarding function is trivial: nothing is pushed onto the stack when a 1 is seen; seeing an $i > 1$ causes $n^{1/L}$ copies of $(i-1)$ to be pushed onto the stack. In all cases, the outgoing edge is the one opposite the incoming edge.

A simple inductive argument can be used to prove that this forwarding function maintains the following invariant—when the packet is at a vertex $w$ at distance $D'$ from the destination $u$, the stack encodes $D'$ in the fashion described above. This immediately implies that the maximum stack depth is at most $Ln^{1/L}$; it also proves the correctness of the protocol, since the stack being empty implies $D' = 0$ and that the packet is indeed at the destination $u$. The following theorem follows from the discussions above.

THEOREM 2.1. *There is a uniform routing protocol for the $n$-vertex path with a maximum stack depth of $Ln^{1/L}$.*

This construction is indeed tight up to constant factors, as the following theorem shows.

THEOREM 2.2. *Any uniform routing protocol for the $n$-vertex path requires a stack depth of $\Omega(Ln^{1/L})$.*

*Proof.* We will show the above lower bound for the special case where all packets are forwarded on the path from left to right. Consider a directed auxiliary graph $H$ with the $L$ labels as its vertices, with an arc $(j, i)$ in the graph if the function $f$, on seeing $i$ on top of the stack, causes $j$ (among others) to be pushed on the stack. Note that any label that lies on a directed cycle in $H$ can never be used in the routing protocol, since the stack can never empty if this label appears on the stack. Hence we can assume that $H$ is a directed acyclic graph, and hence defines a partial order on the nodes.

Consider a total order consistent with the partial order implied by $H$; w.l.o.g., this is the order $1, 2, \dots, L$. Hence each label $i$ just corresponds to placing some number of labels $1, \dots, i-1$ on the stack. Therefore, the ordering of the labels on the stack does not matter—two stacks which have the same number of copies of label $i$ for all possible values of $i$ will reach the same destination.

Let $k_i$ be the number of copies of label $i$ on the stack, and hence $k_1+k_2+\cdots+k_L \leq s$. The number of solutions to this equation (and hence the number of distinct stacks) is $\binom{s+L}{L}$, which must be at least $n$, the number of possible destinations. Some simple algebra implies that $s = \Omega(Ln^{1/L})$, completing the proof. ∎

**2.2. Nonuniform protocols.** Interestingly, in the case for nonuniform protocols, the relationship between $s$ and $L$ almost achieves the information-theoretic bound of $s \geq \log_L n$. Since the direction of travel of the packet is decided by the edge at which it enters the vertex, it suffices to give a procedure to send packets from left to right.

For simplicity, consider the case when $L = 2$. Let the vertices on the path $P_n$ be numbered $0, 1, \dots, n-1$; this is only for ease of exposition, and the protocol does not depend on this labeling. We direct all edges in $P_n$ from left to right, and assign label 1 to these edges. We then add some (virtual) arcs $E'$ to this graph, also directed from left to right, and assign label 2 to these edges. It can be shown that these edges can be added so that the following properties are satisfied:

- *Single outgoing edge property*: Each vertex $v$ has at most one edge in $E'$ out of it.
- *Low-diameter property*: For any two vertices $u < v$, there is a directed path in $P_n \cup E'$ from $u$ to $v$ of length at most $3 \log n$.
- *Nesting property*: Let $u < u' < u''$ be three distinct vertices on the line. If $(u, u'')$ and $(u', v')$ are two directed edges in $E'$, then $v'$ does not lie to the right of $u''$; i.e., $v' \leq u''$. Essentially, no two edges in $E'$ *cross* each other; either they span disjoint portions of the line, or the span of one is contained within the span of the other.

One way to get such graphs is recursive: to build a graph $G_{2^k}$ on $2^k$ nodes, we take 2 copies of $G_{2^{k-1}}$ on $2^{k-1}$ nodes and attach them in series, giving a graph on $2^k - 1$ vertices. (A graph on 2 nodes is just a single arc.) A new vertex is now attached to the leftmost vertex by an arc labeled 1, and to the rightmost vertex by an arc labeled 2. This new vertex becomes vertex 0 in the new graph $G_{2^k}$, and the other vertices get suitably renumbered. In general, a graph $G_n$ on $n$ nodes is obtained by

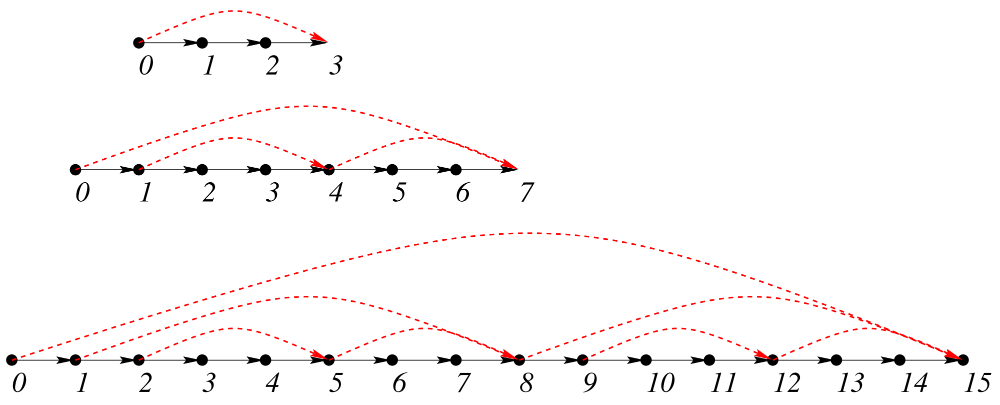


FIG. 2.1. *Specifying the routing protocol for the path $P_{16}$.*

taking a graph on $2^{\lceil \log_2 n \rceil}$ nodes and retaining only the leftmost $n$ nodes. An example for $n = 16$ is shown in Figure 2.1, where the solid edges are labeled 1 and the dotted edges are labeled 2.

The nesting property implies the following property for shortest paths in $P_n \cup E'$ (measured in terms of the number of hops).

LEMMA 2.3. *Let $u < u' < v' < v$ be four distinct nodes on the line $P_n$. If the shortest path $P$ from $u$ to $v$ in $P_n \cup E'$ contains $v'$, then the shortest path from $u'$ to $v$ contains $v'$.*

*Proof.* Suppose that the shortest path $P'$ from $u'$ to $v$ does not contain $v'$. Let $e = (w, w')$ be an edge in $P'$ such that $w < v' < w'$; clearly, such an edge must exist. We claim that $P$ must contain $w$. If not, since $u < w < v$, $P$ must contain an edge $e' = (x, x')$ such that $x < w < x'$; furthermore, $x' < v'$ since $P$ contains $v'$. But now $e$ and $e'$ violate the nesting property, a contradiction; hence $w \in P$.

Also, the portion of $P$ from $w$ to $v$ must be the shortest path from $w$ to $v$. Since we know that $P'$ contains $w$, replacing the portion of $P'$ after $w$ by the corresponding portion of $P$, we again get a shortest path $P''$ from $u'$ to $v$ which contains $v'$. Noting that there is a unique shortest path between any two vertices in $P \cup E'$ gives us a contradiction and proves the lemma. ◻

We can now describe the routing protocol. Given a node $u$ and a stack of labels $l_0, \ldots, l_r$ ($l_0$ being on the top), we define the *path defined by the stack* to be the sequence of edges obtained by starting from $u$ and following the edges labeled $l_0, \ldots, l_r$ in $P_n \cup E'$. If $u$ wants to send a packet to node $v$ ($u < v$), the stack is initialized so that the path defined by the stack is the shortest path from $u + 1$ to $v$, and the packet is sent to $u + 1$. The protocol will maintain the invariant that when a node $u'$ receives the packet, the path defined by the stack at that point is the shortest path from $u'$ to $v$. The low-diameter property thus ensures that the stack depth is at most $3 \log n$.

Let us see how to maintain the invariant. Let the packet be at $u'$, and let the edges labeled 1 and 2 originating from $u'$ be $e_1 = (u', u_1) \in P_n$ and $e_2 = (u', u_2) \in E'$, respectively. (If there is no label 2 edge from $u'$, the argument gets even simpler.) Since the edges in $E'$ do not exist, a packet can be forwarded along $e_1$ but not along $e_2$. If the top of the stack contains label 1, then $u'$ simply pops this label and sends the packet to $u_1$, the next vertex on $P_n$. Since the path defined by the stack was inductively the shortest path from $u'$ to $v$ and contained $u_1$, the new stack must define the shortest path from $u_1$ to $v$.

In the other case, the top of the stack has a 2: in this case, $u'$ pops it and pushes a set of labels which encode a shortest path from $u_1$ to $u_2$. Lemma 2.3 ensures that the shortest path from $u_1$ to $v$ contains $u_2$ as an intermediate node, and hence the path defined by the stack when it reaches $u_1$ is also a shortest path from $u_1$ to $v$, maintaining the invariant.

For the graph $G_n$ defined above, implementing the above protocol is extremely simple. As mentioned above, each router pops off a 1 if it sees one on top of the stack; the difference is in the handling of the 2's. If the router has outdegree 1, it just pops off the 2 (in fact, such a vertex will never see a 2); if it has outdegree 2, it replaces the 2 by two 2's. The following theorem follows from the above discussion.

THEOREM 2.4. *There is a nonuniform protocol for routing on the $n$-vertex path which uses* 2 *labels and stack depth at most* $3 \log n$.

It is trivial to encode $O(\log L)$ successive labels on the stack in a single label of size $L$, and hence we can use the above protocol to get the following theorem.

THEOREM 2.5. *There is a nonuniform protocol for routing on the $n$-vertex path which uses $L$ labels and stack depth at most $O(\log_L n)$. This is within a constant factor of the information-theoretic bound.*

**3. An algorithm for trees.** In this section, we consider the problem of routing on trees. Since we already have developed protocols for the line that are within constants of the best possible, we first show how to use them in a modular way to get protocols for trees; these are then refined to get better trade-offs.

Let the tree be $T$, and let it be rooted at $r$. All the algorithms use the so-called caterpillar decomposition of a tree into edge-disjoint paths. The *caterpillar dimension* [23] of a rooted tree $T$, henceforth denoted by $\kappa(T)$, is defined thus: for a tree with a single vertex, $\kappa(T) = 0$. Else, $\kappa(T) \leq k+1$ if there exist paths $P_1, P_2, \ldots, P_t$ beginning at the root and pairwise edge-disjoint such that each component $T_j$ of $T - E(P_1) - E(P_2) - \cdots - E(P_t)$ has $\kappa(T_j) \leq k$, where $T - E(P_1) - E(P_2) - \cdots - E(P_t)$ denotes the tree $T$ with the edges of the $P_i$'s removed, and the components $T_j$ are rooted at the unique vertex lying on some $P_i$. The collection of edge-disjoint paths in the above recursive definition form a partition of $E$, and are called the *caterpillar decomposition* of $T$.

By the very definition of caterpillar decompositions, it follows that the unique path between any two vertices of $T$ intersects no more than $2\kappa(T)$ of the paths in the decomposition. It can also be shown that $\kappa(T)$ is at most $\log n$ (see, e.g., [23]).

Now given a packet that has to traverse $k \leq 2 \log n$ paths, the stack just specifies the $k$ different stacks for routing on these paths, with each consecutive pair of stacks separated by one of $\Delta - 1$ special labels that specify the path to switch to. Hence, given an $(L, s)$ routing protocol for the line, we get a $(\Delta(T) + L - 1, s \times 2\kappa(T))$ protocol for the tree. Plugging in the values from the Theorems 2.1 and 2.5, we get the following result.

THEOREM 3.1. *Given a tree $T$ with maximum degree $\Delta$, there exists a $(\Delta + k - 1, 2\, k\, n^{1/k}\, \kappa(T))$ uniform routing protocol and a $(\Delta + k - 1, 6\, \log_k n\, \kappa(T))$ nonuniform routing protocol for $T$.*

Note that for $k = 2$ we have a $(\Delta + 1, 6 \log^2 n)$ nonuniform protocol, and for $k = \log n$ and constant $\Delta$ the worst-case guarantees for both these algorithms are approximately $(\log n + O(1), O(\log^2 n))$. The results of section 3.2 will show how to improve on this result in the nonuniform case. But before that, let us prove some lower bounds on uniform protocols for trees.

**3.1. A lower bound for uniform protocols on trees.** Before proving the lower bound, let us pin down what uniform protocols mean in the context of trees; since vertices may have varying degrees, they cannot have exactly the same actions. Hence, let us assume that there are $\Delta$ special labels belonging to the set $\Sigma_\Delta \subseteq \Sigma$, which are used only to travel a distance of one hop from a vertex, essentially by specifying which of the outgoing edges to take. Let $\Sigma' = \Sigma \setminus \Sigma_\Delta$ be the remaining labels. For each edge $e = \{u, v\}$, the vertex $v$ specifies another edge $e' = \{v, w\}$, called the *exit edge* for $v$ along edge $e$, such that any packet arriving at $v$ on edge $e$ having a label from $\Sigma'$ on top of the stack is forwarded only along $e'$. Furthermore, the action of all vertices on seeing a label from $\Sigma'$ is identical: i.e., an identical sequence of labels is placed on top of the stack, and then the packet is sent along the exit edge for the current vertex.

For such protocols, we now prove a lower bound that almost matches the result of Theorem 3.1 for the case of $k = \log n$.

THEOREM 3.2. *There exists a binary tree $\widehat{T}$ for which any uniform routing protocol that routes along shortest paths with $L = O(\log n)$ labels requires a stack depth of $\Omega(\log^2 n/\log\log n)$.*

*Proof.* Let us study some of the properties of uniform routing protocols on binary trees before we give the concrete instance for the lower bound. Look at any binary tree $T$; since each vertex has degree at most 3, it is easy to see that $\Sigma_\Delta$ needs to only contain a single label $\{l_\Delta\}$. Indeed, when a node $v$ receives a packet along an edge $e$, it can only send it on one of the other two edges, or else the routing would not be along a shortest path. One of these edges is the exit edge for $v$ along edge $e$, and hence we need only one label in $\Sigma_\Delta$.

Two vertices $u, v$ in $T$ are said to be connected by a *straight path* if all the internal vertices in the unique path connecting $u$ and $v$ have degree 2. Given two nodes $u, v \in T$, let $S[u, v]$ denote the stack depth needed to route a packet from $u$ to $v$. Given a label $l$, define $S_l[u, v]$ as the stack depth needed to route a packet from $u$ to $v$ such that when the packet reaches $v$, the top of the stack contains the label $l$. Since we may refer to several different protocols, we will use the notation $S_l[u, v](\mathcal{A})$ and $S[u, v](\mathcal{A})$ when talking about the protocol $\mathcal{A}$. The following lemma follows from the definition of a uniform protocol.

LEMMA 3.3. *Let $v \in T$ be a node of degree 3 and let $C_1, C_2, C_3$ be the components of $T \setminus \{v\}$. Let $v_i$ be the neighbor of $v$ in $C_i$. Then there exists a $j \in \{2, 3\}$ such that given any $x_1 \in C_1$ and $x_j \in C_j$, $S[x_1, x_j] \geq S_{l_\Delta}[x_1, v] + S[v, x_j] - 1$.*

*Proof.* Consider the edge $e = \{v_1, v\}$. Suppose the exit edge for the vertex $v$ along edge $e$ is the edge $\{v, v_2\}$. Now if we want to send a packet from $x_1$ to $x_3$, it must contain $l_\Delta$ on top of stack when it reaches $v$. Hence the part of this stack which takes the packet from $x_1$ to $v$ contributes to $S_{l_\Delta}[x_1, v]$. The part of the stack below $l_\Delta$ can actually route from $v_3$ to $x_3$, and hence $S[v, x_3] \leq S[v_3, x_3] + 1$. Since $S[x_1, x_3] = S_{l_\Delta}[x_1, v] + S[v_3, x_3]$, the lemma follows. ◻

Given two protocols $\mathcal{A}''$ and $\mathcal{A}'$, we say that $\mathcal{A}'$ *strictly dominates* $\mathcal{A}''$ if for every pair of vertices $u, v$ and label $l \in \Sigma$, the following hold true: (i) $S_l[u, v](\mathcal{A}') \leq S_l[u, v](\mathcal{A}'')$, (ii) $S[u, v](\mathcal{A}') \leq S[u, v](\mathcal{A}'')$, and (iii) there is a pair $u, v$ of vertices, and some label $l$ such that $S_l[u, v](\mathcal{A}') < S_l[u, v](\mathcal{A}'')$. Fix a uniform routing protocol $\mathcal{A}$ that is not strictly dominated by any other $\mathcal{A}'$.

LEMMA 3.4. *Let $T$ contain a straight path of length $n'$ joining vertices $u$ and $v$. There exists a value $x$ with $n'/2 \leq x \leq n'$, such that if $u', v'$ are any two vertices in $T$ connected by a straight path of length $x$, then $S_{l_\Delta}[u', v']$ is $\Omega(\log n'/\log\log n')$.*

*Proof.* Let $P$ be the path joining $u$ and $v$, and let $V'$ be the vertices in $P$ whose distance from $u$ lies between $n'/2$ and $n'$. We claim that there is a vertex $w \in V'$ such that $S_{l_\Delta}[u, w]$ is $s' = \Omega(\log n'/\log\log n)$. Indeed, if we are allowed a stack depth of $s'$, the number of different stacks possible is $L^{s'}$. Since this must be at least $n'/2$, it follows that $s'$ is at least $\Omega(\log_L n') = \Omega(\log n'/\log\log n)$.

Let the distance between $u$ and $w$ be $x$, suppose that $u'$ and $v'$ are two vertices with a straight path of length $x$ between them, and suppose $S_{l_\Delta}[u', v'] < s'$. Then the uniformity of $\mathcal{A}$ implies that, keeping other things the same, we can make $S_{l_\Delta}[u, w] < s'$ and get a protocol that strictly dominates $\mathcal{A}$, a contradiction. This proves the lemma. ∎

For each integer $x = n^{1/3}, \ldots, 2n^{1/3}$, let $T_x$ denote the complete binary tree of depth $1/6 \log n$ and having $x$ subdivisions on each edge. Let $\widehat{F} = \cup T_x$ be the forest formed by the union of all these trees; this is the lower bound instance. (We can extend $\widehat{F}$ to a single binary tree $\widehat{T}$ by adding suitable edges; the bound clearly holds for $\widehat{T}$ as well.) Let us define a *branching node* in $T_x$ to be a node of degree 3.

Note that $\widehat{F}$ (and thus $\widehat{T}$) has a straight path of length $2n^{1/3}$ between two vertices. Hence, by Lemma 3.4, there is a value $x$ satisfying $n^{1/3} \le x \le 2n^{1/3}$ such that if $u, v$ are two *branching* nodes in $T_x$ joined by a straight path, then $S_{l_\Delta}[u, v]$ is $\Omega(\log n'/\log\log n) = \Omega(\log n/\log\log n)$. Now, using Lemma 3.3 repeatedly, we can demonstrate a path from the root to a leaf $y$ of $T_x$ such that routing from the root of $T_x$ to $y$ requires stack depth $\Omega(\log^2 n/\log\log n)$. ∎

**3.2. Improved nonuniform protocols.** In this section, we show how to obtain nonuniform routing protocols which require a stack depth of only $O(\log n)$ (as in the case of the path graph), but with $\Delta + O(\log\log n)$ labels.

THEOREM 3.5. *There exists a* $(\Delta + 2\log\log n, 21\log n)$ *nonuniform routing protocol for trees.*

*Proof.* For any vertex $w \in T$, let $T_w$ be the subtree rooted at $w$. To prove the theorem, we will need the following claim, which will be proved by induction on $|T_w|$.

CLAIM 3.6. *There exists a nonuniform protocol to route a packet from any vertex* $w$ *to a descendant* $x$ *in* $T_w$ *using* $2\log k + (\Delta - 1)$ *labels and a stack of depth at most* $18\,k$*, where* $k = \lceil \log_2 |T_w| \rceil$.

To use this protocol to route packets from any vertex $u$ to any other vertex $x$, we first route it to $w$, the least common ancestor of $u$ and $x$, and then use the protocol from Claim 3.6 to route from $w$ to $x$. Sending the packet from $u$ to $w$ is very simple; indeed, the problem of routing a packet from a vertex to some ancestor in a tree is isomorphic to the problem of routing on the line. This can be done by the protocol in Theorem 2.5 with 2 labels and a stack depth of $3\log n$; Claim 3.6 then ensures that the stack depth to route from $w$ to $x$ is at most $18\log_2 n$. ∎

*Proof of Claim* 3.6. Let $P'_1, \ldots, P'_t$ be the paths in the caterpillar decomposition that contain the vertex $w$, and let $P_i$ be the subpath of $P'_i$ that contains $w$ and its descendants; i.e., $P_i = P'_i \cap T_w$.

We make an additional requirement on the caterpillar decomposition for the tree $T$, which is the following *halving* property: we demand that for a vertex $v \in P_i$, any connected component of $T_w - \{v\}$ not containing a node of $P_i$ has at most $\lfloor |T_w|/2 \rfloor$ nodes. It can be shown that such a caterpillar decomposition exists (see, e.g., [23]).

The basic idea is similar to the one used in section 3; we will route on a series of paths, using the protocol for the line given in Theorem 2.5 as the basic building block. As before, when we switch between paths, a special subset of $\Delta - 1$ of the

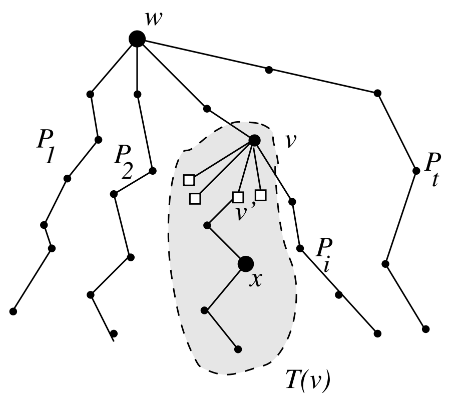

FIG. 3.1. *The tree $T_w$ in the proof of Claim* 3.6. *Vertices marked by squares belong to $V'$.*

labels will be used to indicate which of the new paths to continue on. The rest of the proof indicates how the other $2\log k$ labels can be used for the rest of the routing.

The base case of $|T_w| = 1$ is trivial. We now show how to route a packet from $w$ to $x$, where $x$ is a descendant of some node in $P_i - \{w\}$; the lemma follows from the fact that the paths $P_1, \ldots, P_t$ intersect only at the origin node $w$.

Consider a vertex $v \in P_i - \{w\}$, and let $V'$ be the immediate children of $v$ which do not lie on $P_i$ itself (for an illustration, see Figure 3.1). Define $T(v)$ be a subtree rooted at $v$ containing $v$, the subset of $v$'s children $V'$ that do not lie on $P_i$, and all the descendants of $V'$. Observe that if $v_1 \neq v_2 \in P_i$, then $T(v_1)$ and $T(v_2)$ are disjoint. We define $t(v)$, the *index* of a node $v$, to be $\lceil \log_2 |T(v)| \rceil$. Let the *group* $I(j)$ be the set of nodes in $P_i - \{w\}$ with index $j$. Note that if $t(v) = j$, then $|T(v)| \geq 2^{j-1}$; since all the trees $T(v)$ are disjoint and their union contains at most $|T_w| \leq 2^k$ nodes, there can be at most $2^{k-j+1}$ nodes in $I(j)$.

We now define $\log k$ *supergroups*, with each supergroup being the union of several groups $I(j)$. For each $p = 0, \ldots, \log k$, define

$$\mathcal{I}(p) = \bigcup_{q=2^p}^{2^{p+1}-1} I(k-q+1).$$

Since the size of $\mathcal{I}(p)$ is maximized when all nodes in it come from the group $I(k - 2^{p+1} + 2)$, the supergroup $\mathcal{I}(p)$ can contain at most $2^{2^{p+1}-1}$ nodes. We divide the $2\log k$ labels we have into $\log k$ sets $L_1, \ldots, L_{\log k}$, with each $L_i$ containing two labels. The labels in $L_p$ are used to route from $w$ to nodes that lie in $\mathcal{I}(p)$. If a node in $P_i$ that does not belong the supergroup $\mathcal{I}(p)$ sees a label in $L_p$ on top of the stack, it merely forwards the packet on to its unique child lying in $P_i$. Theorem 2.5 implies that we can use the labels in $L_p$ to route from $w$ to all nodes in $\mathcal{I}(p)$ using a stack depth of at most $3(2^{p+1} - 1)$.

Suppose that $w$ wants to send a packet to $x \in T(v)$, with $v \in I(j)$ and $I(j) \subseteq \mathcal{I}(p)$. The top of the stack contains the labels (belonging to $L_p$) which specify how to send the packet from $w$ to $v$; this requires a depth of at most $3(2^{p+1} - 1)$. Let $v' \in V'$ be the child of $v$ such that $x \in T_{v'}$; hence, the next label on the stack is one of the $\Delta - 1$ labels and causes $v$ to forward the packet to $v'$. The remaining part of the stack specifies how to route the packet from $v'$ to $u$; by induction, this part has depth at most $18\lceil \log |T_{v'}| \rceil$.

By the facts that $v \in \mathcal{I}(p)$ and $|T_{v'}| \le |T(v)|$, it must be the case that $\lceil \log |T_{v'}| \rceil \le k - 2^p + 1$. Furthermore, the halving property of the caterpillar decomposition ensures that $|T_{v'}| \le |T_w|/2 \le 2^{k-1}$. Hence the total stack depth to route from $w$ to $x$ is at most

$$\begin{aligned} & 3\,(2^{p+1}-1) + 1 + 18\,\lceil \log T_{v'} \rceil \\ \le\ & 3\,(2^{p+1}-1) + 1 + 6\,(k - 2^p + 1) + 12\,(k-1) \\ \le\ & 18\,k. \end{aligned}$$

This shows that we can achieve a stack depth of at most $18\,k$ using only $\Delta + 2\,k - 1$ labels, proving the claim. $\square$

**4. Covering graphs by trees.** Several problems arise in trying to extend the approach of decomposing arbitrary graphs into paths, and then using the path routing schemes on them: the shortest paths between vertices in general graphs are not unique, and they intersect in nontrivial ways, making it difficult to arrive at a useful notion of a path decomposition. On the other hand, if we find a family of $t$ subtrees, such that for each pair of vertices there was a tree in this family that maintained the shortest path distance between them, we could use this for routing. Indeed, we could use the tree routing scheme of the previous section, with the labels also specifying which of these $t$ trees we were routing on; this would cause the number of labels to increase by a factor of $t$. We could, in fact, relax the distance preservation condition and allow distances to be stretched by a small factor even in the best tree. Motivated by this, we define a *tree cover* of a graph, as follows.

DEFINITION 4.1. *Given a graph $G = (V, E)$, a* tree cover *(with* stretch *$D$) of $G$ is a family $\mathcal{F}$ of subtrees $\{T_1, T_2, \ldots, T_k\}$ of $G$ such that for every $u, v \in V$ there is a tree $T_i \in \mathcal{F}$ such that $d_{T_i}(u, v) \le D\, d_G(u, v)$.*

Note that, since the trees $T_i$ are subtrees of $G$, it immediately follows that $d_{T_i}(u, v) \ge d_G(u, v)$ for all $u, v \in V$ and $T_i \in \mathcal{F}$. The following theorem formalizes the discussion above.

THEOREM 4.2. *Given an $(L, s)$ protocol for routing on trees, and a tree cover $\mathcal{F}$ of $G$ with stretch $D$, there exists an $(L\,|\mathcal{F}|, s)$ protocol (with stretch $D$) for $G$.*

Tree covers have been previously defined and used for conventional routing applications in [6, 5] (see also [27, Chapter 15]). Note that our tree covers, as defined in Definition 4.1, are slightly different from those in the previous literature; we do not place a restriction on the number of trees in which a vertex appears, instead placing a uniform restriction on the number of trees in the family.

**4.1. Some lower bounds.** It is easy to see that the size of a tree cover may necessarily be large: if we require a stretch-1 tree cover for the complete graph $K_n$, the union of the trees $T_i$ in the cover must cover every edge, and hence $\Omega(n)$ trees are required in this case.

Even allowing stretch-$D$ tree covers does not help much: there are constructions of $n$-vertex graphs with $\Omega(n^{1+4/(3g-6)})$ edges which have girth $g$ [22]. For such a graph, desiring a stretch of at most $g - 2$ forces the union of $T_i$ to contain every edge of the graph. This gives a lower bound of $\Omega(n^{4/3D})$ on the size of tree covers having stretch $D$. For the special case of stretch 3, note that any stretch-3 tree cover for the complete bipartite graph must also require $\Omega(n)$ trees.

While the graphs considered above are not sparse, these lower bounds can be strengthened to obtain the following theorem.

THEOREM 4.3. *There are $n$-vertex graphs with maximum degree 3 for which any stretch-$D$ tree cover must contain $n^{\Omega(1/D)}$ trees.*

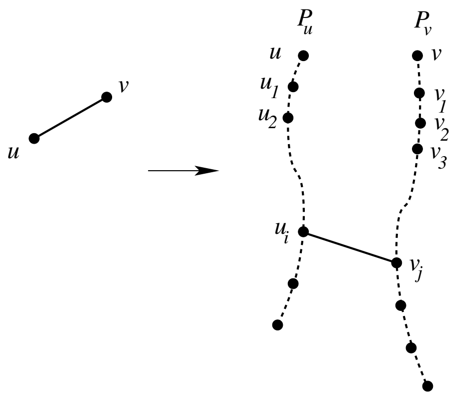

FIG. 4.1. *Mapping an edge of $G$ into an edge of $H$. The dotted edges have length* 0.

*Proof.* Let us consider an $\hat{n}$-vertex graph $G = (V, E)$ with girth $D + 2$ and $\hat{m} = |E| = \Omega(\hat{n}^{1+4/3D})$ edges given by Margulis [22], and create an $n$-vertex degree-3 graph $H = (V', E')$ from it as follows. Initially $V' = E' = \emptyset$. For each vertex $v \in V$ of degree $\delta(v)$, we create a path $P_v$ with $\delta(v)$ vertices, with $v$ as one of its endpoints, and consisting of $\delta(v) - 1$ other (new) vertices. We set the length of all these edges to be 0 and add all these vertices and edges to $H$. We now add some more edges to $E'$: for an edge $(u, v) \in E$, we add an edge (of length 1) between some vertex of $P_u$ and some vertex of $P_v$ such that the degree of all vertices stays at most 3. (Since there are $\delta(v)$ vertices in $P_v$ and $\delta(v)$ such edges are added, this is trivially possible.) It is easy to check that $n = |V'| = 2|E|$ and $|E'| \leq \frac{3}{2}|V'| = 3|E'|$. Furthermore, since $G$ is the minor of $H$ obtained by contracting all the 0-length edges, and the 0-length edges themselves induce a forest in $H$, it can be verified that each cycle on $H$ contains at least $(D + 2)$ edges of unit length.

Let $\mathcal{F}_H = \{T'_1, T'_2, \ldots, T'_t\}$ be a stretch-$D$ tree cover for $H$; we want to infer that $t = n^{\Omega(1/D)}$. To this end, we will use $\mathcal{F}_H$ to define a family $\mathcal{F}_G$ of $t$ forests in $G$ such that every edge in $G$ must be contained in some forest in $\mathcal{F}_G$. This would imply that $t \geq \hat{n}^{4/3D} \leq n^{\Omega(1/D)}$.

Given a tree $T'_i \in \mathcal{F}_H$, let us define the forest $F_i$ of $G$ as follows: consider an edge $(u, v) \in E$. Due to the construction above, this edge corresponds to an edge $(u_i, v_j) \in E'$ with $u_i \in P_u$ and $v_j \in P_v$. (See Figure 4.1 for an illustration.) We add $(u, v)$ to $F_i$ if the entire path $\langle u, u_1, u_2, \ldots, u_i, v_j, v_{j-1}, \ldots, v_1, v\rangle$ lies in $T'_i$. It is easily verified that $F_i$ is a forest.

Let us now prove that every edge in $G$ must be contained by some forest $F_j \in \mathcal{F}_G$ if $\mathcal{F}_H$ is a stretch-$D$ tree cover. Consider an $(u, v) \in E$ as above; we claim that one of these trees $T'_i \in \mathcal{F}_H$ must contain the entire path $\langle u, u_1, u_2, \ldots, u_i, v_j, v_{j-1}, \ldots, v_1, v\rangle$. Indeed, since every cycle in $H$ contains $(D + 2)$ edges of unit length, the absence of this path in $T'_i$ would imply that the alternative path between $u$ and $v$ in $T'_i$ would incur a stretch of at least $D + 1$. Let $T'_j$ contain this path; by the mapping above, $F_j$ now contains the edge $(u, v) \in E$. Hence each edge in $E$ is contained in some forest in $\mathcal{F}_G$, implying that $t \geq n^{4/(4+3D)}$ and proving the theorem. $\square$

In view of these negative results, we will focus our attention on some natural important families of graphs, like planar graphs and those with small separators. In this section, we consider tree covers with stretch 1 and show that graphs which have small separators (and whose subgraphs also have this property) have good tree covers.

This result also shows that planar graphs have $O(\sqrt{n})$-sized tree covers; we then show that this bound is tight.

**4.2. Unit-weighted grid.** To warm up, let us give the following simple result, which illustrates some of the ideas used later in the section.

PROPOSITION 4.4. *The unit-weighted $n$-vertex grid $G$ has tree covers of size $O(\log n)$.*

*Proof.* Let the vertex set of $G$ be $V = \{(i,j) \mid 1 \le i,j \le \sqrt{n}\}$. Consider the tree $T$ defined by taking the center vertical path $P = \{(\sqrt{n}/2, j) | 1 \le j \le \sqrt{n})\}$ and the horizontal paths $P_j = \{(i,j) | 1 \le i \le \sqrt{n})\}$ for all $j$. It is easy to check that, for any two vertices that lie in different halves of the grid defined by the vertical path $P$, the shortest path lies in $T$.

To maintain distances between vertices which lie on the same side of the vertical path, we can recurse on both the smaller grids $G_L$ and $G_R$ induced by $\{(i,j) \in V \mid i < \sqrt{n}/2\}$ and $\{(i,j) \mid i > \sqrt{n}/2\}$, respectively. (A construction identical to the one for the square grid works for rectangular grids as well, and so the recursion is well defined.) Inductively, we get two families of at most $t = \log(n/2)$ forests, one for each subgrid $G_L$ and $G_R$; let them be $\mathcal{F}_L = \{F_1', F_2', \ldots, F_t'\}$ and $\mathcal{F}_R = \{F_1'', F_2'', \ldots, F_t''\}$, respectively. Note that defining $F_i = F_i' \cup F_i''$ gives us $t$ forests of the original graph $G$ (since $F_i'$ and $F_i''$ are vertex disjoint), and each of these can be extended to a spanning tree by adding some more edges. Finally, adding the tree $T$ to these $\log n - 1$ trees gives us the desired $\log n$-sized tree cover. ∎

Combining this result for the grid with Theorems 4.2 and 3.5 gives us an $(O(\log n \log\log n), O(\log n))$ routing protocol. While it is not clear how to improve the tree cover of Proposition 4.4, it is indeed possible to get a better routing scheme for the unweighted grid. Given two vertices $u = (i,j)$ and $v = (i',j')$, there is a shortest path between them that goes from $u$ to $w = (i,j')$ and then from $w$ to $v$. The protocol specifies how much distance to go without changing the first coordinate, and then how far to go without changing the second coordinate; this gives us an $(O(1), O(\log n))$ routing scheme for the grid.

**4.3. Graphs with small separators.** We say that a graph $G$ on $n$ vertices admits *$r(n)$-sized hierarchical separators* if it can be separated into pieces of size at most $2n/3$ by removing at most $r(n)$ vertices, and any connected component $G_i$ thus obtained has a separator of size $r(|G_i|)$, and so on. Using some of the ideas from the construction above, we give tree covers of size $O(r(n) \log n)$ for families of graphs which admit $r(n)$-sized hierarchical separators. It is well known that for planar graphs, $r(n) = O(\sqrt{n})$ [21], and for treewidth-$k$ graphs, $r(n) = k$ (see, e.g., [7]). (We shall assume that $r(n)$ is a monotonically increasing function of $n$.)

The basic idea is simple: we first find a separator $S$ of $G$ of size at most $r(n)$. For each of the vertices $s \in S$, we take the shortest-path tree $T_s$ rooted at $S$. Lemma 4.5 now shows that the distance between a vertex in any component $C$ of $G - S$ and another vertex in $G - C$ is maintained by the tree $T_s$ for some $s \in S$.

LEMMA 4.5. *For any pair of vertices $u, v \in T$ for which the shortest path $P$ connecting them intersects $S$, there is a tree $T_s$ which contains the shortest path between $u$ and $v$.*

*Proof.* Let us assume, for the sake of convenience, that $P$ is the unique shortest path between $u$ and $v$. Let $P \cap S$ contain the vertex $s$. Then $P$ must be the concatenation of the shortest path from $s$ to $u$ and that from $s$ to $v$. Since both these paths lie in $T_s$, the claim is proved. ∎

We now have to maintain distances between vertices lying in some component of $G-S$. However, each of these components has size at most $2n/3$; recursively, for each component, we can find a tree cover of size $r(2n/3)\log_{3/2}(2n/3) \leq r(n)(\log_{3/2} n - 1)$. Finally, pairing them up and adding the set of $r(n)$ trees created at the top level, we get a tree cover with $r(n)\log_{3/2} n$ subtrees, proving the following theorem.

THEOREM 4.6. *Given a graph which admits $r(n)$-sized hierarchical separators, we can find a tree cover of size $O(r(n)\log n)$.*

## 4.4. Lower bounds.

For planar graphs, we can obtain tree covers of size $O(\sqrt{n})$; this requires using the existence of separators of size $r(n) = O(\sqrt{n})$ and being slightly more careful in the above analysis. We now show that this result for planar graphs is tight.

The lower bound is achieved on a reweighted grid: let $G = (V, E)$ be the $n = t \times t$ square grid, where the vertices are $V = \{(i, j) \,|\, 1 \leq i, j \leq t\}$. Since there may be several shortest paths between two vertices, let us break the symmetry. Define a partial order on the edges by declaring all vertical edges in the grid to be less than the horizontal edges; the lexicographically least shortest path between two vertices in the grid is now defined to be the (unique) shortest path between them. (It can be verified that there is a setting of edge weights that achieves this as well; e.g., set the length of an edge $e$ joining vertices $(i, j)$ and $(i', j')$ to be $1 + \epsilon\,(\min(i, i') + (1+\epsilon)\min(j, j'))$ for $\epsilon = 1/n$.) Defining this total order ensures that the lexicographically least path between two vertices consists of all the vertical edges followed by the horizontal edges. The following lemma then follows immediately.

LEMMA 4.7. *Given any two vertices in $G$, there is a unique shortest path between them. Furthermore, this shortest path has at most one bend.*

Let $T$ be any spanning tree of $G$, and let $\mathcal{S}_T$ be the set of pairs of vertices $(u, v) \in V \times V$ such that $T$ contains a shortest path between $u$ and $v$ as defined above. The following key lemma shows that $\mathcal{S}_T$ cannot be too large.

LEMMA 4.8. *For any spanning tree $T$ of $G$, the number of vertex pairs whose shortest paths lie in $T$ is $O(t^3)$; i.e., $|\mathcal{S}_T| = O(t^3)$.*

Before we prove the lemma, let us see what it implies: since there are $\binom{n}{2} = \Omega(t^4)$ pairs of vertices, this shows that we need $\Omega(t) = \Omega(\sqrt{n})$ trees in the cover, proving the following theorem.

THEOREM 4.9 (lower bound theorem). *There exist length assignments to the edges of the $n$-vertex grid so that any tree cover (with stretch 1) is of size $\Omega(\sqrt{n})$.*

*Proof of Lemma* 4.8. A connected path $P \subseteq T$ is called *straight* if it does not have any bends and is of maximal length; i.e., adding any other edge of $T$ to $P$ results in a bend. Let $\{P_1, \ldots, P_k\}$ be the set of all straight paths in $T$, and let $V_i = V(P_i)$. Clearly, each straight path has at most $t$ vertices, i.e., $|V_i| \leq t$. Furthermore, the paths must cover the entire tree, and hence $\cup_{i=1}^{k} V_i = V$. The maximality of these straight paths ensures that for any $i \neq j$, $|V_i \cap V_j| \leq 1$.

Construct the intersection graph $T' = (V', E')$ for these paths, where $V'$ has a vertex $p_i$ for each path $P_i$ and $E'$ contains an edge joining $p_i$ and $p_j$ if and only if $V_i \cap V_j \neq \emptyset$. Since a cycle in $T'$ would imply a cycle in $T$, it follows that $T'$ is a tree.

CLAIM 4.10. *Let $u \in V_i$, $v \in V_j$ be two vertices. The tree $T$ preserves the shortest path between $u$ and $v$ only if either $i = j$ or $(p_i, p_j)$ is an edge in $T'$.*

*Proof.* By Lemma 4.7, the shortest path $P$ between $u$ and $v$ has at most one bend. Suppose $E(P) \subseteq E(T)$; then $P$ either lies within some straight path $P_l$ (and hence $i = j = l$), or lies in the union of two straight paths which intersect (and hence $(p_i, p_j) \in E'$). $\square$

Let $t_i = |V_i| \leq t$, and define the *weight* of the tree $T'$ to be

$$f(T') = \sum_{p_i \in V'} t_i^2 + \sum_{(p_i,p_j)\in E'} (t_i - 1)(t_j - 1). \tag{4.1}$$

Claim 4.10 implies that $|\mathcal{S}_T| \leq f(T')$, and hence it suffices to show that $f(T')$ is $O(t^3)$.

For the rest of the proof, we will not look at the semantics of the sets again. Instead we will consider an arbitrary set system on $t^2$ vertices satisfying the following properties: (a) each set $V_i$ has size $t_i \leq t$, (b) two sets intersect in at most one element, and (c) the intersection graph of the subsets is a tree. For such an intersection tree $T'$, we assign weight $t_i^2$ to each node and $(t_i - 1)(t_j - 1)$ to each edge $(p_i, p_j)$ in $T'$; hence $f(T')$ is the total weight of vertices and edges in $T'$. The following claim now suffices.

CLAIM 4.11. *For an intersection tree $T'$ satisfying conditions* (a)–(c) *above, the total weight $f(T')$ of vertices and edges is $O(t^3)$.*

*Proof.* Let us root $T'$ at any vertex, and record the following useful lemma.

LEMMA 4.12. *Suppose $(p_i, p_j) \in E'$ with $t_i + t_j \leq t$. Then deleting the two sets $V_i$ and $V_j$ and adding $V_i \cup V_j$ to the set system maintains properties* (a)–(c) *and does not cause the weight to decrease.*

*Proof.* Clearly, the size of the new set $|V_i \cup V_j| = t_i + t_j - 1 \leq t$, satisfying property (a). Furthermore, since the intersection graph was initially a tree, no $V_l$ (for $l \notin \{i, j\}$) can intersect both of $V_i$ and $V_j$, and hence $|V_l \cap (V_i \cup V_j)| \leq 1$, satisfying (b). Also, the new intersection graph is obtained by contracting the edge $(p_i, p_j)$ in $T'$. Finally, the increase in weight of the tree is at least

$$\begin{aligned}(t_i + t_j - 1)^2 - t_i^2 - t_j^2 - (t_i - 1)(t_j - 1) &= 2t_it_j - 2t_i - 2t_j - t_it_j + t_i + t_j \\ &= (t_i - 1)(t_j - 1) - 1 \ \geq \ 0,\end{aligned}$$

hence proving the lemma. ☐

We can perform the above operation on the tree $T'$ up to the point at which every edge $(p_i, p_j) \in E'$ has $t_i + t_j \geq t + 1$. We call a leaf $p_i$ in the resulting tree $T'$ *bad* if $t_i < t/2$, and we delete all these leaves from $T'$ to get a new tree $T''$. Since the parent vertices of the deleted leaves must be of size at least $t/2$, all leaves in $T''$ (which are either surviving leaves of $T'$ or parents of leaves deleted from $T'$) have size at least $t/2$.

We claim that $T''$ has $4t$ nodes. Indeed, let us root $T''$ at some vertex and greedily match nodes in $T''$: we start at the root, which we match to one of its children. At the $i$th step, we look at the unmatched nodes at depth $i$ in $T''$, and match them to one of their children. At the end of the process, all nodes except some leaves of $T''$ would be matched. Note that, for each edge $(p_i, p_j)$ in the matching, $t_i + t_j \geq t + 1$, and hence there are at most $2 \cdot t^2/(t + 1) < 2t$ matched nodes. Furthermore each leaf of $T''$ that is unmatched has at least $t/2$ nodes, and hence $T''$ has at most $2t$ unmatched nodes; this proves the claim.

Let us now bound $f(T')$. The contribution of the edges of $T''$ is at most $t^2(4t-1)$, since each edge can contribute only $t^2$. The edges connecting the deleted bad nodes to their parents contribute $O(t^3)$; this is because the bad leaves are all disjoint, and hence $\sum t_i$ (summed over the bad leaves) is at most $t^2$. For the vertex contributions, note that $T''$ has $4t$ nodes, each having at most $t$ elements, and hence the contribution of these nodes is at most $O(t^3)$. Finally, the bad leaves are all disjoint with $\sum t_i \leq t^2$, and $\max_i t_i \leq t$; hence $\sum_i t_i^2 \leq (\sum_i t_i) \times (\max_i t_i) \leq t^3$. Summing up all these terms shows that $f(T') = O(t^3)$. ☐

Since $f(T')$ gave a bound on the number of pairs of vertices in the grid whose distances could be maintained by a single tree, we need at least $\Omega(t) = \Omega(\sqrt{n})$ trees in the cover, thus proving the theorem. ☐

## 5. Tree covers for planar graphs.

In the previous section, we saw that planar graphs may require polynomially sized tree covers if we allow no stretch. The results of this section show that all planar graphs have stretch-3 tree covers of size $O(\log n)$. For this result, we use the planar separator theorem of Lipton and Tarjan [21] in an unusual way.

### 5.1. Isometric separators.

We can refine the ideas in section 4.3 to get an $O(\log n)$-sized stretch-3 tree cover for all planar graphs. Given a graph $G = (V, E)$, define a *k-part isometric separator* to be a family $\mathcal{S}$ of $k$ subtrees $S_1 = (V_1, E_1), \ldots, S_k = (V_k, E_k)$ of $G$ such that the following two conditions hold:

- $S = \cup_i V_i$ is a $\frac{1}{3}$–$\frac{2}{3}$ separator of $G$; i.e., each component in $G \setminus S$ has at most $\frac{2n}{3}$ vertices, where $n$ is the number of vertices in $G$.
- For each $i$ and each pair of vertices $u, v \in S_i$, $d_{S_i}(u, v) = d_G(u, v)$; i.e., each of the subtrees $S_i$ contains the shortest paths between its constituent vertices, and hence the tree metric on $S_i$ is isometric to the restriction of the shortest path metric of $G$ to $V_i$.

Note that the parameter of interest is not the total number of vertices in $S$, but only the number of isometric subtrees. Trivially, any graph having a $\frac{1}{3}$–$\frac{2}{3}$ separator of size $r(n)$ has an $r(n)$-part isometric separator, with each $S_i$ having just a single vertex. Isometric separators can also be used to give small-stretch routing; a simple extension of the ideas in the previous sections demonstrates the following theorem.

THEOREM 5.1. *Given a graph $G = (V, E)$ with $r(n)$-part isometric separators, there exists a stretch-3 tree cover with $O(r(n) \log n)$ trees.*

*Proof.* The algorithm is very similar to that of Theorem 4.6. Let $S_1, S_2, \ldots, S_{r(n)}$ be the subtrees for $G$. For each $i$, we construct a tree $T_i$ as follows: we contract the edges of $S_i$ to a new node $s_i$ and find a shortest-path tree from $s_i$ in the resulting graph. We then expand back the contracted edges in this tree, and call the resulting tree $T_i$. Note that $T_i$ contains $S_i$, as well as a shortest path from every vertex in $V - V_i$ to the subtree $S_i$. We claim that if the shortest path between any two vertices in $V$ intersects the separator vertices $\cup_i V_i$, then one of these trees approximately maintains the distance between them.

Indeed, consider vertices $u, v$ such that the shortest path $P$ between $u$ and $v$ intersects some $S_i$ (at point $b$, say). The path $P'$ between $u$ and $v$ in $T_i$ can be divided into three sections $P'_1, P'_2, P'_3$, where $P'_1$ is the shortest path from $u$ to $S_i$, $P'_3$ is the shortest path from $v$ to $S_i$, and $P'_2$ is the unique path in $S_i$ connecting the points $a$ and $c$ at which $P'_1$ and $P'_3$ meet $S_i$. (See Figure 5.1 for an illustration.) For nodes $x, y$, let $[x, y]$ denote the shortest path between $x$ and $y$ in $G$. Now since $[u, a]$ and $[v, b]$ are the shortest paths to $S_i$, $d_G(u, a) \leq d_G(u, b)$ and $d_G(v, c) \leq d_G(v, b)$. Furthermore, by the fact that $[a, c]$ is the shortest path, $d_G(a, c) \le d_G(a, u) + d_G(u, v) + d_G(v, c)$. However, the length of the path

$$\begin{aligned} d_{T_i}(u, v) &= d_G(u, a) + d_G(a, c) + d_G(c, v) \\ &\le d_G(u, a) + (d_G(a, u) + d_G(u, v) + d_G(v, c)) + d_G(c, v) \\ &\le 2(d_G(u, b) + d_G(v, b)) + d_G(u, v) = 3d_G(u, v), \end{aligned}$$

which proves the claim.

This gives us $r(n)$ trees $\{T_i\}$; it now remains to maintain distances lying within the connected components of $G - \cup_i S_i$, and hence we build tree covers for these subgraphs recursively. Since the components have size at most $\frac{2n}{3}$, we would again get at most $r(n)(\log_{3/2} n - 1)$ trees from each component; pairing them up and adding the $r(n)$ trees from the top level would give us the desired tree cover with at most $r(n) \log_{3/2} n$ trees. $\square$

A close examination of the proof of the planar separator theorem of Lipton and Tarjan [21] shows us that all planar graphs have 2-part isometric separators. Indeed, their proof first fixes an arbitrary tree $T$ in the planar graph $G$ and triangulates the graph while maintaining the planarity; it then considers cycles formed by a nontree edge $(u, v)$ and the path between $u$ and $v$ in the tree, and shows that the vertices of one such cycle form a good balanced separator.

Let us take $T$ to be the shortest-path tree from some (arbitrary) vertex $x$, and let the separator be the vertices of the fundamental cycle formed by adding the nontree $E = \{u, v\}$ to $T$. Since $T$ is a shortest-path tree rooted at $x$, there is a natural relationship between vertices in $G$, and let $\text{lca}(u, v)$ be the least common ancestor of $u$ and $v$ in $T$. The claimed 2-part isometric separator consists of the two paths from $\text{lca}(u, v)$ to $u$ and $v$.

Using this fact that planar graphs have 2-part isometric separators in conjunction with Theorem 5.1 gives us the following theorem.

THEOREM 5.2. *There exists a stretch-*3 *tree cover of size* $O(\log n)$ *for all planar graphs.*

Combining this result with Theorems 4.2 and 3.5, we immediately obtain good routing schemes for planar graphs.

COROLLARY 5.3. *There is an* $(\Delta + O(\log n \log \log n), O(\log n))$ *routing scheme for planar graphs with stretch at most* 3.

Proving such a result for broader classes of graphs, say for graphs with bounded treewidth or other graphs with small excluded minors, still remains an open problem.

**5.2. An application to small distance labelings.** In this section, we give another application of isometric separators. A *distance labeling* scheme specifies a way to label each vertex $v$ of an input graph $G$ with a label $l(v)$ drawn from a set of labels $\Sigma$, and also a uniform function $f : \Sigma \times \Sigma \to \mathbb{R}^+$ (independent of the input) which takes two labels and outputs a distance value. A *stretch-D distance labeling scheme* ensures that, given a graph $G$, the estimate given by $f$ is within a factor $D$ of the actual distance; i.e., $1 \le f(l(u), l(v))/d_G(u, v) \le D$ for all pairs of vertices $u, v \in G$. These labeling schemes have been well studied (see, e.g., [34, 26, 16]).

THEOREM 5.4. *For any planar graph* $G = (V, E)$ *with diameter* $\text{diam}(G)$*, there is a stretch-*3 *distance labeling scheme with labels of size* $O(\log n \log \text{diam}(G))$ *bits.*

The result of Theorem 5.4 should be contrasted with the result of Gavoille et al. [16], which says that planar graphs require labels of length $\Omega(n^{1/3})$ bits if no stretch is allowed. We should point out that it is possible to get a simpler $O(\log^3 n)$ bit result, by taking the $O(\log n)$ tree cover of Theorem 5.2 and using the distance labeling scheme of Peleg [26] to embed each tree with $O(\log^2 n)$ bits.

*Proof of Theorem* 5.4. For each vertex $v$, we generate $5 \log n$ coordinates $\phi_i(v)$, with each of these coordinates using $\log \operatorname{diam}(G)$ bits; these coordinates are generated in groups of five. Let us fix a hierarchical decomposition of $G$ using isometric separators.

To generate the first group for $v$, consider the 2-part isometric separator $S_0$ of $G_0 = G$. This has two shortest paths, say $P_0$ and $P_0'$, and let $a_0$ and $a_0'$ be arbitrary endpoints of $P_0$ and $P_0'$, respectively. The first two coordinates encode distances from these paths; i.e., $\phi_1(v) = d_{G_0}(v, P_0)$ and $\phi_2(v) = d_{G_0}(v, P_0')$. For the next two coordinates, let $v_0$ and $v_0'$ be the closest vertices from $v$ on $P_0$ and $P_0'$, and set $\phi_3(v) = d_{G_0}(v, a_0)$ and $\phi_4(v) = d_{G_0}(v, a_0')$. Finally, look at the graph $G \setminus S_0$, and record in the fifth coordinate the connected component in which $v$ lies, where we have numbered the components by some consistent canonical order. Set $G_1$ to be the component of $G \setminus S_0$ containing $v$, and recurse on $G_1$ to create the next set of coordinates. Note that if $v$ was in the separator, the rest of the labels would be set to $\infty$.

For the decoding function $f(u, v)$, we find the highest level of recursion $k$ in which the two vertices lie in different components (which is indicated by a difference in their values in the corresponding fifth coordinate $\phi_{5k+k}$). For each level of recursion $i$ till that level $k$, let the graph containing $u$ and $v$ be denoted by $G_i$. Now we obtain an estimate of the distance between $u$ and $v$ in $G$ by summing $d_{G_i}(v, P_i)$ and $d_{G_i}(v, P_i')$, and then adding $|d_{G_i}(v, a_i) - d_{G_i}(v, a_i')|$ to it. (All these values can be obtained from the coordinates $\phi_{5i+j}$ for $1 \leq j \leq 4$.) Finally, we take the minimum among all these estimates $0 \leq i \leq k$.

Using an argument similar to the one used in Theorem 5.2, it can be shown that if the shortest path between $u$ and $v$ intersected $S_i$, then the estimate for level $i$ would be within a factor of 3 of $d_G(u, v)$; all other estimates would be at least as large as $d_G(u, v)$. This proves the theorem. □

**6. Conclusions.** Let us conclude by mentioning some of the results that have appeared since the announcement of these results. Simultaneously and independent of our work, Thorup has used the planar separator theorem of Lipton and Tarjan in a manner similar to an approach in section 5.1 to obtain compact distance oracles for planar digraphs [32]. In fact, he uses these techniques to give a stretch-$(1 + \epsilon)$ distance labeling scheme of size $O(\log^2 n)$ for planar graphs.

Subsequently, the paper of Gupta, Kumar, and Thorup [19] has given asymptotically optimal $(\Delta + k, O(\log_k n))$ MPLS routing schemes for trees, combining these with the results of [32] to obtain $(1+\epsilon)$ stretch $(\Delta + O(\log n), O(\log n))$ MPLS routing schemes for planar graphs. Some experimental results have been given by the authors in [18], where the question of approximating the minimum label size for a given stack depth is also considered.

**Acknowledgments.** We would like to thank Jon Kleinberg, Bruce Shepherd, Éva Tardos, Peter Winkler, and Francis Zane for discussions and helpful comments.

# THE SIMPLEX ALGORITHM IN DIMENSION THREE*

VOLKER KAIBEL[†], RAFAEL MECHTEL[‡], MICHA SHARIR[§], AND GÜNTER M. ZIEGLER[‡]

**Abstract.** We investigate the worst-case behavior of the simplex algorithm on linear programs with three variables, that is, on 3-dimensional simple polytopes. Among the pivot rules that we consider, the "random edge" rule yields the best asymptotic behavior as well as the most complicated analysis. All other rules turn out to be much easier to study, but also produce worse results: Most of them show essentially worst-possible behavior; this includes both Kalai's "random-facet" rule, which without dimension restriction is known to be subexponential, and Zadeh's deterministic history-dependent rule, for which no nonpolynomial instances in general dimensions have been found so far.

**Key words.** linear programming, random edge, pivot rule, linearity coefficient

**AMS subject classifications.** 65K05, 90C05, 90C35

**DOI.** 10.1137/S0097539703434978

## 1. Introduction.

The simplex algorithm is a fascinating method for at least three reasons: For computational purposes it is still the most efficient general tool for solving linear programs; from a complexity point of view it is the most promising candidate for a strongly polynomial time linear programming algorithm; and last but not least, geometers are pleased by its inherent use of the structure of convex polytopes.

The essence of the method can be described geometrically: Given a convex polytope $P$ by means of inequalities, a linear functional $\varphi$ "in general position," and some vertex $v_{\text{start}}$, the simplex algorithm chooses an edge to a neighboring vertex along which $\varphi$ decreases strictly. Iterating this yields a $\varphi$-monotone edge-path. Such a path can never get stuck, and will end at the unique $\varphi$-minimal ("optimal") vertex of $P$.

Besides implementational challenges, a crucial question with respect to efficiency asks for a suitable *pivot rule* that prescribes how to proceed with the monotone path at any vertex. Since Dantzig invented the simplex algorithm in the late 1940's [4], a great variety of pivot rules have been proposed. Most of them (including Dantzig's original "largest coefficient rule") have subsequently been shown to lead to exponentially long paths in the worst case. (See [1] for a survey.) Prominent exceptions are Zadeh's

history-dependent "least entered" rule and several randomized pivot rules. Particularly remarkable is the "random facet" rule proposed by Kalai [9]; its expected path length for all instances is bounded subexponentially in the number of facets. See also Matoušek, Sharir, and Welzl [14].

In this paper, we analyze the worst-case behavior of the simplex method on 3-dimensional simple polytopes for some well-known pivot rules. At first glance, the 3-dimensional case may seem trivial, since by Euler's formula a 3-polytope with $n$ facets has at most $2n-4$ vertices (with equality if and only if the polytope is simple), and there are examples where $n-3$ steps are needed for any monotone path to the optimum (see, e.g., Figure 2.1). Therefore, for *any* pivot rule the simplex algorithm is linear, with at least $n-3$ and at most $2n-5$ steps in the worst case. However, no pivot rule is known that would work with at most $n-3$ steps.

In order to summarize our results, we define the following measure of quality. Fix a pivot rule $\mathcal{R}$. For every 3-dimensional polytope $P \subset \mathbb{R}^3$ and for every linear functional $\varphi : \mathbb{R}^3 \longrightarrow \mathbb{R}$ *in general position* with respect to $P$ (i.e., no two vertices of $P$ have the same $\varphi$-value), denote by $\lambda_{\mathcal{R}}(P, v_{\text{start}})$ the path length (expected path length, if $\mathcal{R}$ is randomized) produced by the simplex algorithm with the pivot rule $\mathcal{R}$, when started at vertex $v_{\text{start}}$. The *linearity coefficient* of $\mathcal{R}$ is

$$\Lambda(\mathcal{R}) \; := \; \limsup_{n(P)\to\infty} \left\{ \frac{\lambda_{\mathcal{R}}(P, v_{\text{start}})}{n(P)} \; : \; P, \varphi, v_{\text{start}} \text{ as above} \right\},$$

where $n(P)$ is the number of facets of $P$. With the usual simplifications for a geometric analysis (cf. [13], [20, Lecture 3], [1]), we may restrict our attention to *simple* 3-dimensional polytopes $P$ (where each vertex is contained in precisely three facets). Thus we consider only 3-dimensional polytopes $P$, with $n = n(P)$ facets, $3n-6$ edges, and $2n-4$ vertices. By the discussion above, the linearity coefficient satisfies $1 \le \Lambda(\mathcal{R}) \le 2$ for every pivot rule $\mathcal{R}$.

The most remarkable aspect of the picture that we obtain, in section 3, is that the "random edge" rule ("RE" for short) performs quite well (as it is conjectured for general dimensions), but it is quite tedious to analyze (as has already been observed for general dimensions). The following bounds for the random edge rule,

$$1.3473 \quad \le \quad \Lambda(\text{RE}) \quad \le \quad 1.4943,$$

are our main results. Thus we manage to separate $\Lambda(\text{RE})$ from the rather easily achieved lower bound of $\frac{4}{3}$, as well as from the already nontrivial upper bound of $\frac{3}{2}$.

On the other hand, in section 4 we prove that the linearity coefficient for the "greatest decrease" pivot rule is $\Lambda(\text{GD}) = \frac{3}{2}$, while many other well-known rules have linearity coefficient $\Lambda = 2$, including the largest coefficient, least index, steepest decrease, and the shadow vertex rules, as well as Zadeh's history-dependent least entered rule (not known to be superpolynomial in general), and Kalai's random facet rule (known to be subexponential in general).

## 2. Basics.

Klee [12] proved in 1965 that the "monotone Hirsch conjecture" is true for 3-dimensional polytopes; that is, whenever the graph of a 3-dimensional polytope $P$ with $n$ facets is oriented by means of a linear functional in general position, there is a monotone path of length at most $n-3$ from any vertex to the sink $v_{\min}$. (See Klee and Kleinschmidt [13] for a survey of the Hirsch conjecture and its ramifications.) Unfortunately, Klee's proof is not based on a pivot rule.

THEOREM 2.1 (Klee [12]). *For any simple 3-polytope $P \subset \mathbb{R}^3$, a linear functional $\varphi : \mathbb{R}^3 \longrightarrow \mathbb{R}$ in general position for $P$, and any vertex $v_{start}$ of $P$, there is a $\varphi$-monotone path from $v_{start}$ to the $\varphi$-minimal vertex $v_{\min}$ of $P$ that does not revisit any facet.*

*In particular, there is a $\varphi$-monotone path from $v_{start}$ to $v_{\min}$ of length at most $n - 3$.*

It is not too hard to come up with examples showing that the bound provided by Theorem 2.1 is best possible. One of the constructions will be important for our treatment later on, so we describe it below in Figure 2.1.

A particularly useful tool for constructing LP-oriented 3-polytopes is the following result due to Mihalisin and Klee. It is stated in a slightly weaker version in their paper, but their proof actually shows the following.

THEOREM 2.2 (Mihalisin and Klee [17]). *Let $G = (V, E)$ be a planar 3-connected graph, $f : V \longrightarrow \mathbb{R}$ any injective function, and denote by $\vec{G}$ the acyclic oriented graph obtained from $G$ by directing each edge to its endnode with the smaller $f$-value. Then the following are equivalent:*

1. *There exist a polytope $P \subset \mathbb{R}^3$ and a linear functional $\varphi : \mathbb{R}^3 \longrightarrow \mathbb{R}$ in general position for $P$ such that $G$ is isomorphic to the graph of $P$ and, for every $v \in V$, $f(v)$ agrees with the $\varphi$-value of the vertex of $P$ corresponding to $v$.*
2. *Both* (a) *and* (b) *hold:*
   (a) *$\vec{G}$ has a unique sink in every facet (induced nonseparating cycle) of $G$, and*
   (b) *there are three node-disjoint monotone paths joining the (unique) source to the (unique) sink of $\vec{G}$.*

Here the fact that the source and the sink of $\vec{G}$ are unique (referred to in condition (b)) follows from (a); cf. Joswig, Kaibel, and Körner [8]. Equipped with Theorem 2.2, one readily verifies that the family of directed graphs indicated in Figure 2.1 ($n \geq 4$) can be realized as convex 3-polytopes, with associated linear functionals, demonstrating that Klee's bound of $n - 3$ on the length of a shortest monotone path cannot be improved.

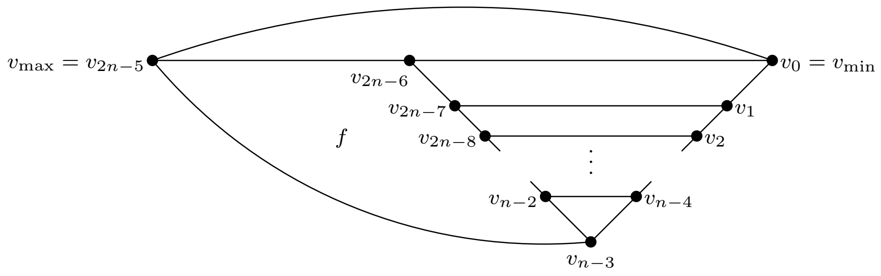

FIG. 2.1. *A worst case example for Klee's theorem, starting at $v_{n-3}$ (and for Bland's rule, starting at $v_{2n-6}$; see section 4.1). All edges are oriented from left to right.*

**3. The random edge rule.** At any nonoptimal vertex, the *random edge* pivot rule takes a step to one of its improving neighbors, chosen uniformly at random. Thus the expected number $\mathbf{E}(v)$ of steps that the random edge rule would take from a given vertex $v$ to the optimal one $v_{\min}$ may be computed recursively as

$$\mathbf{E}(v) \;=\; 1 + \frac{1}{|\,\delta^{\text{out}}(v)|} \sum_{u:(v,u)\in\delta^{\text{out}}(v)} \mathbf{E}(u), \tag{3.1}$$

where $\delta^{\text{out}}(v)$ denotes the set of edges that leave $v$ (that is, lead to *better* vertices), so that $|\,\delta^{\text{out}}(v)|$ is the number of neighbors of $v$ whose $\varphi$-value is smaller than that of $v$.

Despite its simplicity and its (deceptively) simple recursion, this rule has by now resisted several attempts to analyze its worst-case behavior, with a few exceptions for special cases, namely linear assignment problems (Tovey [19]), the Klee–Minty cubes (Kelly [11] and Gärtner, Henk, and Ziegler [6]), and $d$-dimensional linear programs with at most $d+2$ inequalities (Gärtner et al. [7]). All known results leave open the possibility that the expected number of steps taken by the random edge rule on a $d$-dimensional linear program with $n$ inequalities could be bounded by a polynomial, perhaps even by $O(n^2)$ or $O(dn)$, where $n$ is the number of facets.

However, Matoušek and Szabó [15] recently showed that the random edge rule does not have a polynomially bounded running time on the larger class of *acyclic unique sink orientations* (*AUSO*'s), i.e., acyclic orientations of the graph of a polytope that induce unique sinks in all nonempty faces (cf. condition 2(a) in Theorem 2.2). They exhibited particular AUSO's on $d$-dimensional cubes for which random edge needs at least $\text{const}\cdot 2^{\text{const}\cdot d^{1/3}}$ steps.

**3.1. Lower bounds.** The lower bound calculations appear to be much simpler if we do not use the recursion given above but instead use a "flow model." For this, fix a starting vertex $v_{\text{start}}$, and denote by $p(v)$ the probability that the vertex $v$ will be visited by a random edge path from $v_{\text{start}}$ to $v_{\min}$, and similarly by $p(e)$ the probability that a directed edge $e$ will be traversed. Then the probability that a vertex $v$ is visited is the sum of the probabilities that the edges leading into $v$ are traversed,

$$p(v) = \sum_{e\in\delta^{\text{in}}(v)} p(e),$$

if $v$ is not the starting vertex. (Here $\delta^{\text{in}}(v)$ denotes the set of edges that enter $v$.) Furthermore, by definition of the random edge rule we have

$$p(e) \;=\; \frac{1}{|\,\delta^{\text{out}}(v)|}p(v) \qquad \text{for all } e\in\delta^{\text{out}}(v) \tag{3.2}$$

at each nonoptimal vertex. The random edge rule thus induces a flow $(p(e))_{e\in E}$ of value 1 from $v_{\text{start}}$ to $v_{\min}$. The expected path length $\mathbf{E}(v_{\text{start}})$ is then given by

$$\mathbf{E}(v_{\text{start}}) \;=\; \sum_{e\in E} p(e), \tag{3.3}$$

and we refer to it as the *cost* of the flow $(p(e))_{e\in E}$.

THEOREM 3.1. *The linearity coefficient of the random edge rule satisfies*

$$\Lambda(\text{RE}) \;\geq\; \frac{1897}{1408} \;>\; 1.3473.$$

*Proof.* We describe a family of linear programs (LPs) which show the above lower bound on the linearity coefficient. We start with the graph of the dual-cyclic polytope

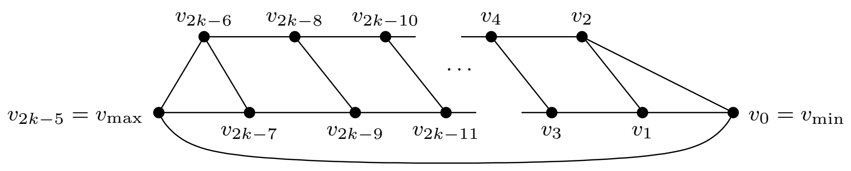

FIG. 3.1. *Lower bound construction for the random edge rule: the backbone polytope. All edges are oriented from left to right.*

$C_3(k)^\Delta$ with the orientation depicted in Figure 3.1, and refer to this as the *backbone* of the construction.

Starting at the vertex $v_{2k-7}$, the simplex algorithm will take the path along the $k-2$ vertices $v_{2k-7}, v_{2k-9}, \ldots, v_3, v_1, v_0$. Replacing each vertex in the path by a copy of the digraph depicted in Figure 3.2—called a *configuration* in the following—yields the desired LP. The corresponding feasible polytope can be constructed explicitly by applying ten suitable successive vertex cuts at each vertex $v_i$ of the backbone. Alternatively, one can check that the orientations we get satisfy the conditions of Theorem 2.2.

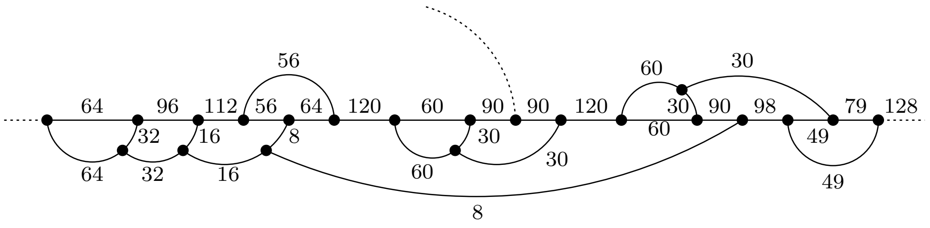

FIG. 3.2. *Lower bound construction for the random edge rule: the configuration. All edges are oriented from left to right. The target of the rightmost edge (not shown) is the starting node of the next configuration. The middle dotted edge enters the configuration from the corresponding vertex of the top backbone row. The actual flow at each edge is* 1/128 *times the number written next to the edge.*

The maximal and minimal vertex of each configuration is visited with probability 1. We send 128 units of flow (each of value $\frac{1}{128}$) through each configuration according to (3.2); see Figure 3.2. This yields the flow-cost of $\frac{1897}{128}$ for each of the $k-2$ configurations. (The last configuration produces a flow-cost of $\frac{1897}{128} - 1$ only, as it does not have a leaving edge.)

We take the maximal vertex of the configuration at $v_{2k-7}$ as the starting vertex $v_{\text{start}}$. Using (3.3), we obtain for the expected cost $\mathbf{E}(v_{\text{start}})$

$$\mathbf{E}(v_{\text{start}}) = (k-2)\frac{1897}{128} - 1.$$

With $n = k + 10(k-2)$, this yields

$$\mathbf{E}(v_{\text{start}}) \;=\; \frac{n-2}{11} \cdot \frac{1897}{128} - 1 \;=\; \frac{1897}{1408}n - \frac{5202}{1408},$$

which proves the lower bound. $\square$

The configuration depicted in Figure 3.2 was found by complete enumeration of the acyclic orientations satisfying condition (a) of Theorem 2.2 (AUSOs) on 3-polytopes with $n \leq 12$ facets. In particular, our proof of Theorem 3.1 includes a worst-possible example for $n = 12$. We refer to Mechtel [16] for more details of the search procedure, as well as for a detailed analysis of the properties of worst-case examples for the random edge rule.

**3.2. Upper bounds.**

THEOREM 3.2. *The linearity coefficient of the random edge rule satisfies*

$$\Lambda(\mathrm{RE}) \ \le\ \frac{130}{87} < 1.4943.$$

*Proof.* Consider any linear program on a simple 3-polytope with $n$ facets, with a linear objective function $\varphi$ in general position. We will refer to the $\varphi$-value of a vertex as its "height." A 1-*vertex* will denote a vertex with exactly one neighbor that is lower with respect to $\varphi$. Similarly, a 2-*vertex* has exactly two lower neighbors. Consequently, from any 1-vertex the random edge rule proceeds deterministically to the unique improving neighbor, and from any 2-vertex it proceeds to one of the two improving neighbors, each with probability $\frac{1}{2}$.

Basic counting yields that our LP has exactly $(n-3)$ 1-vertices and $(n-3)$ 2-vertices in addition to the unique maximal vertex $v_{\max}$ and the unique minimal vertex $v_{\min}$, which have 3 and 0 lower neighbors, respectively. For the following, we also assume that the vertices are sorted and labelled $v_{2n-5}, \dots, v_1, v_0$ in decreasing order of their objective function values, with $v_{\max} = v_{2n-5}$ and $v_{\min} = v_0$.

For any vertex $v$, let $N_1(v)$ (resp., $N_2(v)$) denote the number of 1-vertices (resp., 2-vertices) that are not higher than $v$ (including $v$ itself). Set $N(v) = N_1(v) + N_2(v)$. For all vertices $v$ other than the maximal one, this is the number of vertices lower than $v$; that is, $N(v_i) = i$ for all $i \neq 2n-5$.

We will establish the following generic inequality for all $v \neq v_{\max}$ by induction on $N(v)$:

$$\mathbf{E}(v) \ \le\ \alpha N_1(v) + \beta N(v) + \gamma. \tag{3.4}$$

Here, $\alpha$ and $\beta$ are constants whose values will be fixed later in the induction step, and $\gamma$ is a constant whose value will be fixed in the induction base case. The inductive step will be subdivided into 24 distinct cases. Each case depends on a linear inequality on $\alpha$ and $\beta$ that, when satisfied, justifies the induction step in that case. Since our case analysis is complete, we have a proof of (3.4) for any pair $(\alpha, \beta)$ that satisfies all the 24 inequalities.

Because we always have $N_1(v), N_2(v) \le n-3$, we obtain

$$\begin{aligned}\mathbf{E}(v) &\le\ \alpha N_1(v) + \beta(N_1(v) + N_2(v)) + \gamma = (\alpha+\beta)N_1(v) + \beta N_2(v) + \gamma \\ &\le\ (\alpha + 2\beta)(n-3) + \gamma\end{aligned}$$

for $v \neq v_{\max}$. The single vertex $v_{\max}$ is irrelevant for the asymptotic considerations. Thus we minimize $\alpha + 2\beta$ subject to the linear constraints posed by the various cases; this leads to an LP in two variables with 24 constraints, whose optimal solution is $(\alpha, \beta) = (\frac{46}{87}, \frac{42}{87})$, of value $\frac{130}{87} < 1.4943$. This yields the upper bound on $\Lambda(\mathrm{RE})$ stated in the theorem.

Before starting the inductive proof, we modify the original polytope to a new one $P'$ (with $v'_{\min}$ being the new sink) by cutting off the sink of the given simple 3-polytope ten times in succession, in the following way: (1) For all original vertices $v \neq v_{\min}$, the expected number of vertices on a path to $v'_{\min}$ is larger than the expected number of vertices on a path to $v_{\min}$ in $P$; (2) every original vertex lies at distance at least five from $v'_{\min}$; (3) the newly generated 20 vertices, together with the sink, are the 21 lowest vertices of $P'$.

By choosing the constant $\gamma$ sufficiently large, we ensure that $\mathbf{E}(v) \le \gamma$ holds for all vertices $v$ of $P'$ with $N(v) \le 20$.

We prove Theorem 3.2 for the new polytope $P'$. Since the expected path lengths only increase, this also implies the theorem for the original polytope. The preceding analysis implies that (3.4) holds for all $v$ satisfying $N(v) \le 20$, which establishes the base case of the induction.

Suppose now that (3.4) holds for all vertices lower than some vertex $v$ with $N(v) > 20$. By an appropriate unwinding of the recursion (3.1), we express $\mathbf{E}(v)$ in terms of the expected cost $\mathbf{E}(w_i)$ of certain vertices $w_i$ that are reachable from $v$ via a few downward edges. The general form of such a recursive expression will be

$$\mathbf{E}(v) \;=\; c + \sum_{i=1}^{k} \lambda_i \mathbf{E}(w_i),$$

where $\lambda_i > 0$ for $i = 1, \dots, k$, and $\sum_i \lambda_i = 1$.

Since we assume by induction that $\mathbf{E}(w_i) \le \alpha N_1(w_i) + \beta N(w_i) + \gamma$, for each $i$, it suffices to show that

$$\sum_{i=1}^{k} \alpha\lambda_i \left(N_1(v) - N_1(w_i)\right) + \sum_{i=1}^{k} \beta\lambda_i \left(N(v) - N(w_i)\right) \;\ge\; c.$$

In our analysis, we will need to classify some of the vertices $w_i$ as being either 1-vertices or 2-vertices, for which we need to make sure that they are not the sink. By inspecting all 24 cases, we see that this will be the case if $v$ lies at distance at least five from $v'_{\min}$. Since we assume that $N(v) > 20$, the vertex $v$ must be an original one; thus it has distance at least five from $v'_{\min}$.

Write

$$\Delta_1(w_i) := N_1(v) - N_1(w_i), \qquad \Delta(w_i) := N(v) - N(w_i),$$

for $i = 1, \dots, k$. (These terms are defined with respect to the vertex $v$ that is currently considered.) Here $\Delta(w_i)$ is the *distance* between $v$ and $w_i$, that is, one plus the number of vertices between $v$ and $w_i$ in the numbering of the vertices $(v_{2n-5}, \dots, v_0)$ detailed above. Clearly $\Delta(w_i) \ge \Delta_1(w_i)$.

We thus need to show that for each vertex $v$,

$$\alpha \sum_{i=1}^{k} \lambda_i \Delta_1(w_i) + \beta \sum_{i=1}^{k} \lambda_i \Delta(w_i) \ge c. \tag{3.5}$$

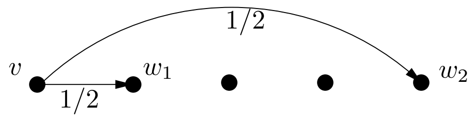
At this point we start our case analysis.

*Case* 1: $v$ is a 1-vertex. Let $w_1$ denote the target of the unique downward edge emanating from $v$, as in the following figure, where (here and in all subsequent figures) each edge is labelled by the probability of reaching it from $v$.

In this case, $\mathbf{E}(v) = 1 + \mathbf{E}(w_1)$. In the setup presented above, we have $\lambda_1 = 1$, $c = 1$, $\Delta_1(w_1) \ge 1$, and $\Delta(w_1) \ge 1$; thus (3.5) is implied by

$$\alpha + \beta \ge 1. \tag{3.6}$$

*Case* 2: $v$ is a 2-vertex. Let $w_1$ and $w_2$ denote the targets of the two downward edges emanating from $v$, where $w_2$ is lower than $w_1$.



We have

$$\mathbf{E}(v) \ = \ 1 + \frac{1}{2}\mathbf{E}(w_1) + \frac{1}{2}\mathbf{E}(w_2),$$

and hence we need to require that

$$\frac{\alpha}{2}\Delta_1(w_1) + \frac{\alpha}{2}\Delta_1(w_2) + \frac{\beta}{2}\Delta(w_1) + \frac{\beta}{2}\Delta(w_2) \ \geq \ 1.$$

Note that $\Delta(w_2) > \Delta(w_1) \geq 1$.

*Case* 2.a: $\Delta(w_2) \geq 4$ (as in the preceding figure). Ignoring the effect of the $\Delta_1(w_j)$'s, it suffices to require that

$$\frac{\beta}{2}\Delta(w_1) + \frac{\beta}{2}\Delta(w_2) \geq 1,$$

which will follow if

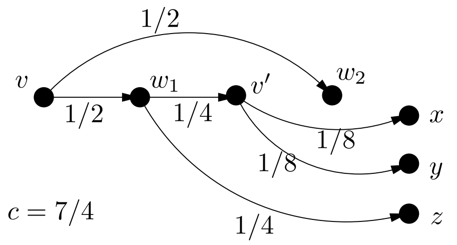
$$\beta \geq \frac{2}{5}. \tag{3.7}$$

*Case* 2.b.i: $\Delta(w_2) = 3$ and one of the two vertices above $w_2$ and below $v$ is a 1-vertex. In this case $\Delta_1(w_2) \geq 1$ and $\Delta(w_1) + \Delta(w_2) \geq 4$, so (3.5) is implied by

$$\frac{1}{2}\alpha + 2\beta \geq 1. \tag{3.8}$$

*Case* 2.b.ii: $\Delta(w_2) = 3$ and the two vertices between $v$ and $w_2$ are 2-vertices. Denote the second intermediate vertex as $v'$. We may assume that $v'$ is reachable from $v$ (that is, from $w_1$); otherwise we can ignore it and reduce the situation to Case 2.c treated below (by choosing another ordering of the vertices producing the same oriented graph). Three subcases can arise.

First, assume that none of the three edges that emanate from $w_1$ and $v'$ further down reaches $w_2$. Denote by $x, y$ the two downward neighbors of $v'$, and by $z$ the downward neighbor of $w_1$ other than $v'$. The vertices $x, y, z$ need not be distinct (except that $x \neq y$), but none of them coincides with $w_2$.



We have here $c = 7/4$.

To make the analysis simpler to follow visually, we present it in a table. Each row denotes one of the target vertices $w_2, x, y, z$, "multiplied" by the probability of reaching it from $v$. The left (resp., right) column denotes a lower bound on the corresponding quantities $\Delta_1(\cdot)$ (resp., $\Delta(\cdot)$). To obtain an inequality that implies (3.5), one has to multiply each entry in the left (resp., right) column by the row probability times $\alpha$ (resp., times $\beta$), and require that the sum of all these terms be $\geq c$.

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/2w_2$ | 0 | 3 |
| $1/8x$ | 0 | 4 |
| $1/8y$ | 0 | 5 |
| $1/4z$ | 0 | 4 |

Note the following: (a) We do not assume that the rows represent distinct vertices (in fact, $x = z$ is implicit in the table); this does not cause any problem in applying the rule for deriving an inequality from the table. (b) We have to squeeze the vertices so as to make the resulting inequality as sharp (and difficult to satisfy) as possible; thus we made one of $x, y$ the farthest vertex, because making $z$ the farthest vertex would have made the inequality easier to satisfy.

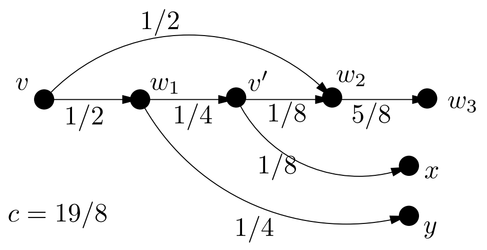
We thus obtain

$$\left(\frac{3}{2} + \frac{4}{8} + \frac{5}{8} + \frac{4}{4}\right)\beta \geq \frac{7}{4},$$

or

$$\beta \geq \frac{14}{29}. \tag{3.9}$$

Next, assume that $w_2$ is connected to $v'$. In this case $w_2$ is a 1-vertex, and we extend the configuration to include its unique downward neighbor $w_3$.



Let $x$ denote the other downward neighbor of $v'$, and let $y$ denote the other downward neighbor of $w_1$. In the following table, the "worst" case is to make $w_3$ and $y$ coincide, and make $x$ the farthest vertex.

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $5/8w_3$ | 1 | 4 |
| $1/8x$ | 1 | 5 |
| $1/4y$ | 1 | 4 |

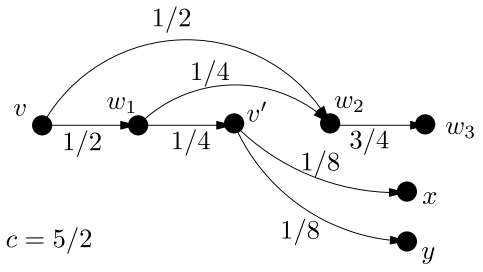
We then obtain

$$\alpha + \left(\frac{20}{8} + \frac{5}{8} + \frac{4}{4}\right)\beta \geq \frac{19}{8},$$

or

$$\alpha + \frac{33}{8}\beta \geq \frac{19}{8}. \tag{3.10}$$

Finally, assume that $w_2$ is connected to $w_1$. Here too $w_2$ is a 1-vertex, and we extend the configuration to include its unique downward neighbor $w_3$.



Denoting by $x, y$ the two downward neighbors of $v'$, our table and resulting inequality become

(3.11)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $3/4w_3$ | 1 | 4 |
| $1/8x$ | 1 | 4 |
| $1/8y$ | 1 | 5 |

$$\alpha + \frac{33}{8}\beta \geq \frac{5}{2},$$

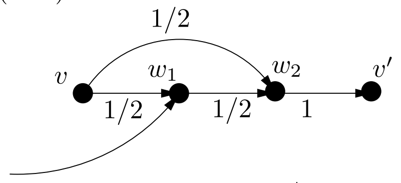
which, by the way, is stronger than (3.10).

*Case* 2.c: $\Delta(w_2) = 2$. Hence, the only remaining case is that $w_1$ and $w_2$ are the two vertices immediately following $v$.

*Case* 2.c.i: $w_1$ is a 1-vertex (whose other upward neighbor lies above $v$). Its unique downward edge ends at some vertex which is either $w_2$ or lies below $w_2$.

Assume first that this vertex coincides with $w_2$, which makes $w_2$ a 1-vertex, whose unique downward neighbor is denoted as $v'$. The local structure, table, and inequality are

(3.12)



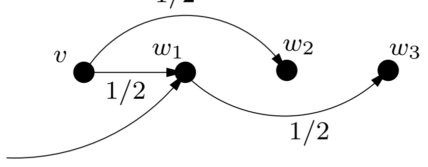
$c = 5/2$

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $v'$ | 2 | 3 |

$$2\alpha + 3\beta \geq \frac{5}{2}.$$

Suppose next that the downward neighbor $w_3$ of $w_1$ lies below $w_2$. We get

(3.13)

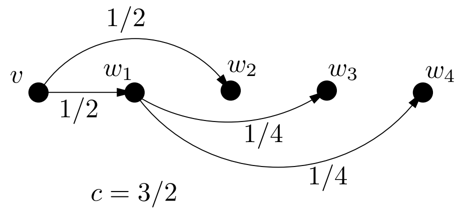


$c = 3/2$

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/2w_2$ | 1 | 2 |
| $1/2w_3$ | 1 | 3 |

$$\alpha + \frac{5}{2}\beta \geq \frac{3}{2}.$$

*Case* 2.c.ii: $w_1$ is a 2-vertex, both of whose downward neighbors lie strictly below $w_2$. Denote these neighbors as $w_3, w_4$, with $w_3$ lying above $w_4$.



We may assume that $\Delta(w_3) = 3$ (i.e., there is no vertex between $w_2$ and $w_3$), since the case $\Delta(w_3) \geq 4$ is already covered by (3.9).

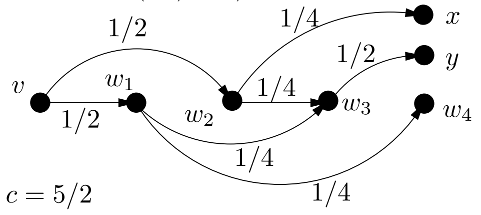
*Case* 2.c.ii.1: $w_2$ is a 1-vertex. Then the table and inequality become

(3.14)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/2w_2$ | 0 | 2 |
| $1/4w_3$ | 1 | 3 |
| $1/4w_4$ | 1 | 4 |

$$\frac{1}{2}\alpha + \frac{11}{4}\beta \geq \frac{3}{2}.$$

*Case* 2.c.ii.2: $w_2$ is a 2-vertex but $w_3$ is a 1-vertex. Then $w_3$ (which satisfies $\Delta(w_3) = 3$) is connected either to $w_2$ or to a vertex above $v$. In the former case, let $x$ denote the other downward neighbor of $w_2$, and let $y$ denote the unique downward neighbor of $w_3$. The local structure looks like this (with $x, y, w_4$ not necessarily distinct but all below $w_3$ due to $\Delta(w_3) = 3$):



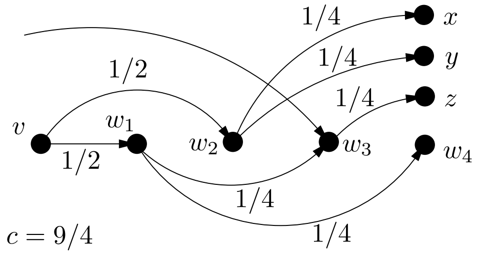
The (worst) table and inequality are

(3.15)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/4x$ | 1 | 4 |
| $1/2y$ | 1 | 4 |
| $1/4w_4$ | 1 | 5 |

$$\alpha + \frac{17}{4}\beta \geq \frac{5}{2}.$$

The next case is where the other upward neighbor of $w_3$ lies above $v$. Let $x, y$ denote the two downward neighbors of $w_2$, and let $z$ denote the unique downward neighbor of $w_3$. (Again, $x, y, z, w_4$ need not be distinct, but $x \neq y$ and they are all below $w_3$ due to $\Delta(w_3) = 3$.) The local structure is



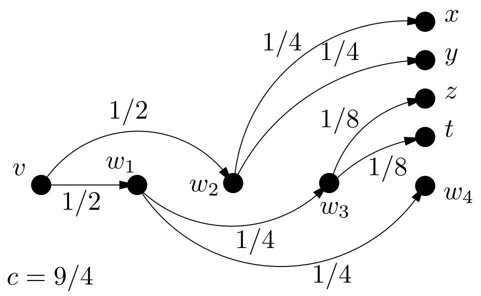
The (worst) table and inequality become

(3.16)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/4x$ | 1 | 4 |
| $1/4y$ | 1 | 5 |
| $1/4z$ | 1 | 4 |
| $1/4w_4$ | 1 | 5 |

$$\alpha + \frac{9}{2}\beta \geq \frac{9}{4}.$$

*Case* 2.c.ii.3: Both $w_2$ and $w_3$ are 2-vertices. We have to consider the following type of configuration (where $x, y, z, t, w_4$ need not all be distinct, but $x \neq y$ and $z \neq t$, and we may assume $x \neq t$, $y \neq z$; also, because $\Delta(w_3) = 3$, both $x$ and $y$ are lower than $w_3$):



Intuitively, a worst table is obtained by "squeezing" $x$, $y$, $z$, $t$, and $w_4$ as much to the left as possible, placing two of them at distance 4 from $v$, two at distance 5, and one at distance 6. However, squeezing them this way will make some pairs of them coincide and form 1-vertices, which will affect the resulting tables and inequalities.

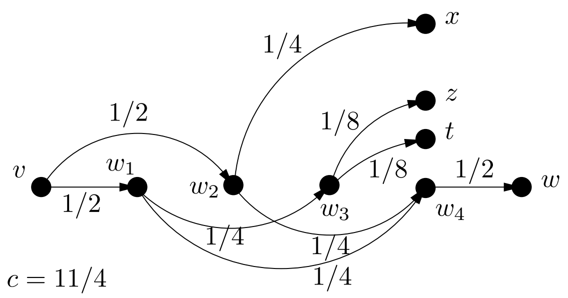
Suppose first that among the three "heavier" targets $x, y, w_4$, at most one lies at distance 4 from $v$. The worst table and the associated inequality are (recall that $x \neq y$):

(3.17)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/4x$ | 0 | 4 |
| $1/4y$ | 0 | 5 |
| $1/8z$ | 0 | 4 |
| $1/8t$ | 0 | 6 |
| $1/4w_4$ | 0 | 5 |

$$\frac{19}{4}\beta \geq \frac{9}{4}.$$

Suppose then that among $\{w_4, x, y\}$, two are at distance 4 from $v$, say $w_4$ and $y$. Then $w_4 = y$ is a 1-vertex, and we denote by $w$ its unique downward neighbor. The local structure is



Two equally worst tables, and the resulting common inequality, are

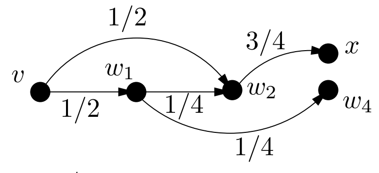
(3.18)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/4x$ | 1 | 5 |
| $1/8z$ | 1 | 6 |
| $1/8t$ | 1 | 7 |
| $1/2w$ | 1 | 5 |

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/4x$ | 1 | 6 |
| $1/8z$ | 1 | 6 |
| $1/8t$ | 1 | 5 |
| $1/2w$ | 1 | 5 |

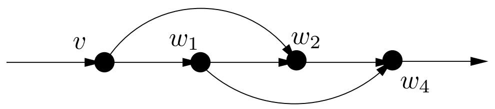
$$\alpha + \frac{43}{8}\beta \geq \frac{11}{4}\ .$$

*Case* 2.c.iii: $w_1$ is a 2-vertex that reaches $w_2$; that is, one of its downward neighbors, say $w_3$, coincides with $w_2$. Then $w_2$ is a 1-vertex, and we denote by $x$ its unique downward neighbor.



$c = 9/4$

A crucial observation is that $x$ cannot be equal to $w_4$. Indeed, if they were equal, then $w_4$ would be a 1-vertex.



In this case, cutting the edge graph $G$ of $P$ at the downward edge emanating from $w_4$ and at the edge entering $v$ would have disconnected $G$, contradicting the fact that $G$ is 3-connected.

We first dispose of the case where $x$ lies lower than $w_4$. The table and inequality are

(3.19)

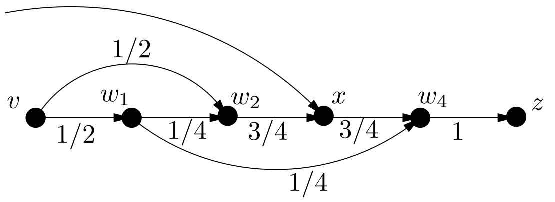
| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $3/4x$ | 1 | 4 |
| $1/4w_4$ | 1 | 3 |

$$\alpha + \frac{15}{4}\beta \geq \frac{9}{4}.$$

In what follows we thus assume that $x$ lies above $w_4$.

*Case* 2.c.iii.1: $x$ is a 1-vertex that precedes $w_4$. Suppose first that $w_4$ is the unique downward neighbor of $x$. Then $w_4$ is a 1-vertex, and we denote its unique downward neighbor by $z$. The local structure, table, and inequality are

(3.20)



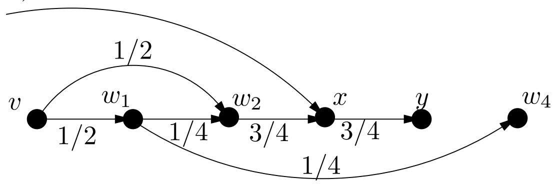
$c = 4$

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $z$ | 3 | 5 |

$$3\alpha + 5\beta \geq 4.$$

Suppose next that the unique downward neighbor $y$ of $x$ is not $w_4$. The local structure, table, and inequality look like this ($y$ is drawn above $w_4$ because this yields a sharper inequality):

(3.21)



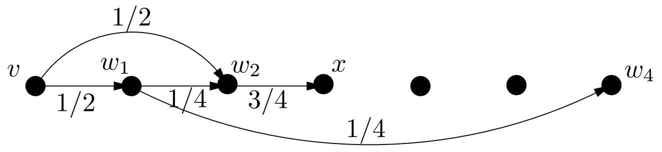
$c = 3$

$$2\alpha + \frac{17}{4}\beta \geq 3.$$

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $3/4y$ | 2 | 4 |
| $1/4w_4$ | 2 | 5 |

*Case* 2.c.iii.2: $x$ is a 2-vertex that precedes $w_4$. This subcase splits into several subcases, where we assume, respectively, that $\Delta(w_4) \geq 6$, $\Delta(w_4) = 4$, and $\Delta(w_4) = 5$.

*Case* 2.c.iii.2(a): Suppose first that $\Delta(w_4) \geq 6$. The configuration looks like this:



$c = 9/4$

The table and inequality are

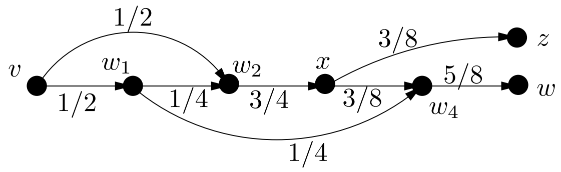
(3.22)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $3/4x$ | 1 | 3 |
| $1/4w_4$ | 1 | 6 |

$$\alpha + \frac{15}{4}\beta \geq \frac{9}{4}.$$

Note that this is the same inequality as in (3.19).

*Case* 2.c.iii.2(b): Suppose next that $\Delta(w_4) = 4$, and that one of the downward neighbors of $x$ is $w_4$. Let $z$ denote the other downward neighbor. $w_4$ is a 1-vertex, and we denote by $w$ its unique downward neighbor.



$c = 29/8$

The 3-connectivity of the edge graph of $P$ implies, as above, that $w \neq z$. Since we assume that $\Delta(w_4) = 4$, $z$ also lies below $w_4$, and the table and inequality are

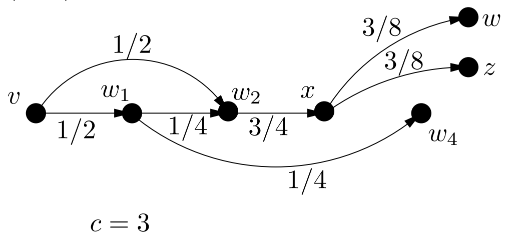
(3.23)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $5/8w$ | 2 | 5 |
| $3/8z$ | 2 | 6 |

$$2\alpha + \frac{43}{8}\beta \geq \frac{29}{8}.$$

Suppose next that $\Delta(w_4) = 4$ and $w_4$ is not a downward neighbor of $x$. Denote those two neighbors as $w$ and $z$, both of which lie lower than $w_4$, by assumption, and are clearly distinct. The configuration, table, and inequality look like this:

(3.24)

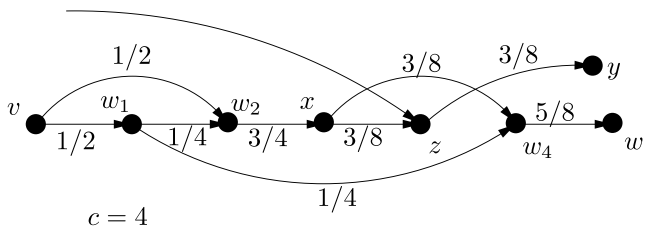


| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/4w_4$ | 1 | 4 |
| $3/8w$ | 1 | 5 |
| $3/8z$ | 1 | 6 |

$$\alpha + \frac{41}{8}\beta \geq 3.$$

*Case* 2.c.iii.2(c): It remains to consider the case $\Delta(w_4) = 5$. Let $z$ denote the unique vertex lying between $x$ and $w_4$. We may assume that $z$ is connected to $x$, for otherwise $z$ is not reachable from $v$, and we might as well reduce this case to the case $\Delta(w_4) = 4$ just treated.

Consider first the subcase where the other downward neighbor of $x$ is $w_4$ itself. Then $w_4$ is a 1-vertex, and we denote by $w$ its unique downward neighbor. This subcase splits further into two subcases: First, assume that $z$ is a 1-vertex, and let $y$ denote its unique downward neighbor. Clearly, $y$ must lie below $w_4$ (it may coincide with or precede $w$). The configuration looks like this:



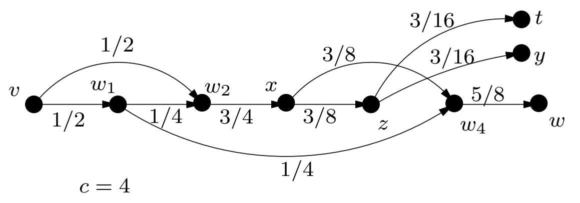
The table and inequality are

(3.25)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $3/8y$ | 3 | 6 |
| $5/8w$ | 3 | 6 |

$$3\alpha + 6\beta \geq 4.$$

In the other subcase, $z$ is a 2-vertex; we denote its two downward neighbors as $y$ and $t$. The vertices $w, y, t$ all lie below $w_4$ and may appear there in any order (except that $w \neq t$). The configuration looks like this:



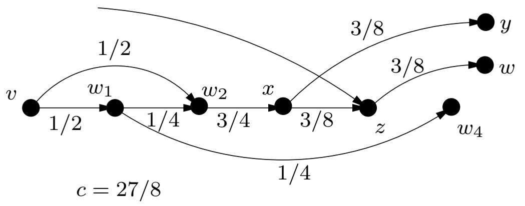
The table and inequality are

(3.26)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $3/16y$ | 2 | 6 |
| $3/16t$ | 2 | 7 |
| $5/8w$ | 2 | 6 |

$$2\alpha + \frac{99}{16}\beta \geq 4.$$

Consider next the subcase where $w_4$ is not a downward neighbor of $x$. Denote the other downward neighbor of $x$ as $y$, which lies strictly below $w_4$. This subcase splits into three subcases. First, assume that $z$ is a 1-vertex, and denote its unique downward neighbor as $w$. The configuration looks like this:



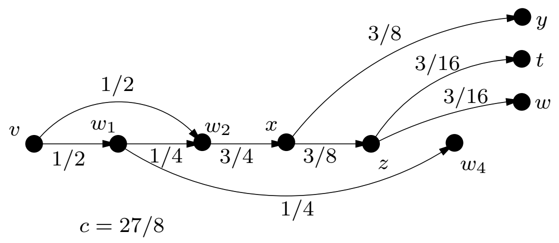
The table and inequality are

(3.27)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/4w_4$ | 2 | 5 |
| $3/8y$ | 2 | 6 |
| $3/8w$ | 2 | 5 |

$$2\alpha + \frac{43}{8}\beta \geq \frac{27}{8}.$$

Second, assume that $z$ is a 2-vertex, so that none of its two downward neighbors is $w_4$. Denote these neighbors as $w$ and $t$. All three vertices $y, t, w$ lie strictly below $w_4$, and $w \neq t$. The configuration looks like this:



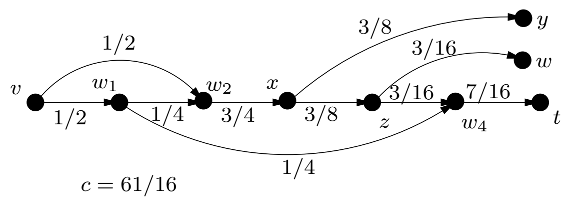
The table and inequality are

(3.28)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $1/4w_4$ | 1 | 5 |
| $3/8y$ | 1 | 6 |
| $3/16w$ | 1 | 6 |
| $3/16t$ | 1 | 7 |

$$\alpha + \frac{95}{16}\beta \geq \frac{27}{8}.$$

Finally, assume that $z$ is a 2-vertex, so that one of its two downward neighbors is $w_4$. Denote the other neighbor as $w$. In this case $w_4$ is a 1-vertex, and we denote its unique downward neighbor as $t$. All three vertices $y, t, w$ lie strictly below $w_4$. The configuration looks like this:



The table and inequality are

(3.29)

| | $\alpha\Delta_1$ | $\beta\Delta$ |
|---|---|---|
| $3/8y$ | 2 | 6 |
| $3/16w$ | 2 | 7 |
| $7/16t$ | 2 | 6 |

$$2\alpha + \frac{99}{16}\beta \geq \frac{61}{16},$$

which, by the way, is weaker than (3.26).

This completes the case distinction. Thus (3.4) holds for every pair $(\alpha, \beta)$ that satisfies (3.6)–(3.29). In particular, it holds for the pair $(\alpha, \beta) = (\frac{46}{87}, \frac{42}{87})$, which (as discussed at the beginning of the proof) yields the upper bound $\frac{130}{87} < 1.4943$ on the linearity coefficient of random edge. $\square$

**3.3. Discussion.** (1) The analysis has used (twice) the fact that $G$ is a 3-connected graph. Without this assumption, the linearity coefficient becomes 13/8: A lower bound construction can be derived from the figure shown in Case 2.c.iii, and an upper bound can be obtained along the same lines of the preceding proof, using a much shorter case analysis. It is interesting that the proof did not use at all the planarity of the polytope graph $G$.

(2) In an earlier phase of our work, we obtained the upper bound of 3/2 on the linearity coefficient, using a similar but considerably shorter case analysis. Unfortunately, the lengthier case distinction presented in the proof above is not just a refinement of that shorter one (which is the reason for presenting only the lengthier proof). The proof indicates that the problem probably is far from admitting a clean and simple solution—at least using this approach. Of course, it would be interesting to find an alternative simpler way of attacking the problem.

(3) The solution $(\alpha, \beta) = (\frac{46}{87}, \frac{42}{87})$ satisfies (3.9) and (3.20) with equality. If we examine the configuration corresponding to (3.9) and expand it further, we can replace (3.9) by better inequalities, which result in a (slightly) improved bound on the linearity coefficient, at the cost of lengthening further our case analysis. This refinement process can continue for a few more steps, as we have verified. We have no idea whether this iterative refinement process ever converges to some critical configuration, whose further expansion does not improve the bound, and which is then likely to yield a tight bound on the linearity coefficient.

## 4. Other pivot rules.

**4.1. Bland's rule.** For Bland's *least index* pivot rule [2] the facets (inequalities) are numbered. At every nonminimal vertex the rule then dictates choosing the edge that leaves the facet with the smallest number. (A special feature of Bland's rule is that it does not admit cycling even on degenerate programs/nonsimple polytopes, when our geometric description of the rule is, however, not applicable.)

PROPOSITION 4.1. *The linearity coefficient of Bland's rule is* 2.

*Proof.* Figure 2.1 illustrates a family of 3-dimensional LPs on which Bland's rule, started at $v_{\text{start}} = v_{2n-6}$, visits all but one of the vertices. (As we have already

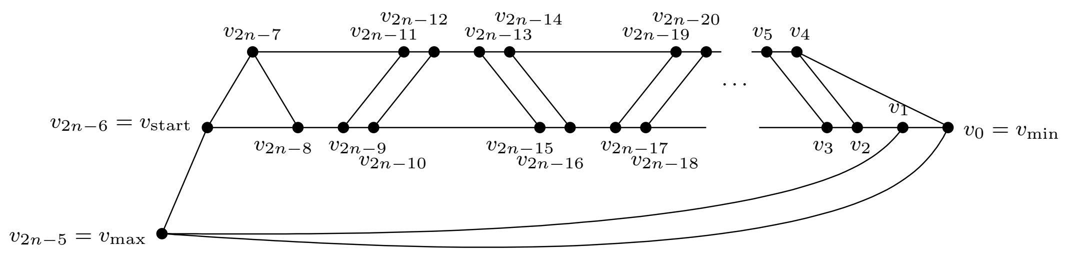


FIG. 4.1. *Lower bound for the greatest decrease rule. All edges are oriented from left to right.*

noted, the directed graph in the figure is readily verified to satisfy the conditions of Theorem 2.2.) Specifically, choose an initial numbering of the facets, where the largest index is assigned to facet $f$. When starting at the vertex $v_{\text{start}} = v_{2n-6}$, the simplex algorithm with Bland's rule visits the $2n-5$ vertices $v_{2n-6}, \dots, v_0$. ☐

**4.2. Dantzig's rule.** *Dantzig's rule* is the original rule proposed by Dantzig when he invented the simplex algorithm. In his setting of a maximization problem formulated in the language of simplex tableaus, the rule requires pivoting into the basis the variable that has the largest reduced cost coefficient (if no variable has positive reduced cost, the current tableau is optimal).

By suitably scaling the inequalities of the LP, Dantzig's rule follows the same path as Bland's rule; see Amenta and Ziegler [1, Observation 2.6]. Thus Dantzig's rule cannot be faster than Bland's rule, and Proposition 4.1 thus implies the following.

PROPOSITION 4.2. *The linearity coefficient of Dantzig's rule is* 2.

**4.3. Greatest decrease rule.** The *greatest decrease* rule moves from any non-optimal vertex to the neighbor with the smallest objective function value. We assume that the objective function is generic, so the vertex is unique. However, the greatest decrease rule may compare nonadjacent neighbors, so the information given by the directed graph is not sufficient to implement it; we rather need explicit objective function values.

PROPOSITION 4.3. *The linearity coefficient of the greatest decrease rule is* $\frac{3}{2}$.

*Proof.* First we show that $\Lambda(\text{GD}) \geq \frac{3}{2}$. Figure 4.1 indicates a family of 3-dimensional LPs. By Theorem 2.2, there is a realization of these LPs with the objective function linear ordering on the vertices given by the left-to-right ordering in our figure. Started at $v_{\text{start}} = v_{2n-6}$, the greatest decrease rule visits all 1-vertices, the global sink, and half of the 2-vertices. Thus it needs $\frac{3}{2}(n-3)$ pivot steps to reach $v_{\min} = v_0$.

For the proof of $\Lambda(\text{GD}) \leq \frac{3}{2}$, we consider an arbitrary instance with $n$, $P$, $\varphi$, and $v_{\text{start}}$ as above. Denote by $n_1$ and $n_2$ the number of visited 1- and 2-vertices, respectively. Thus there are $n-3-n_1$ and $n-3-n_2$ unvisited 1-vertices and 2-vertices, respectively. For every visited 2-vertex $v$ only one of the two direct successors $v'$ and $v''$ is visited. Assuming that $\varphi(v') > \varphi(v'')$, the greatest decrease rule will proceed directly from $v$ to $v''$ and thus skip $v'$, whose objective function value satisfies $\varphi(v) > \varphi(v') > \varphi(v'')$. Thus there is an unvisited vertex uniquely associated with every visited 2-vertex. Thus $n_2 \leq 2n-6-n_1-n_2$, which is equivalent to $n_1 + 2n_2 \leq 2n-6$. We get

$$n_1 + n_2 \;=\; \frac{1}{2}n_1 + \frac{1}{2}(n_1 + 2n_2) \;\leq\; \frac{1}{2}(n-3) + \frac{1}{2}(2n-6) \;\leq\; \frac{3}{2}(n-3).$$

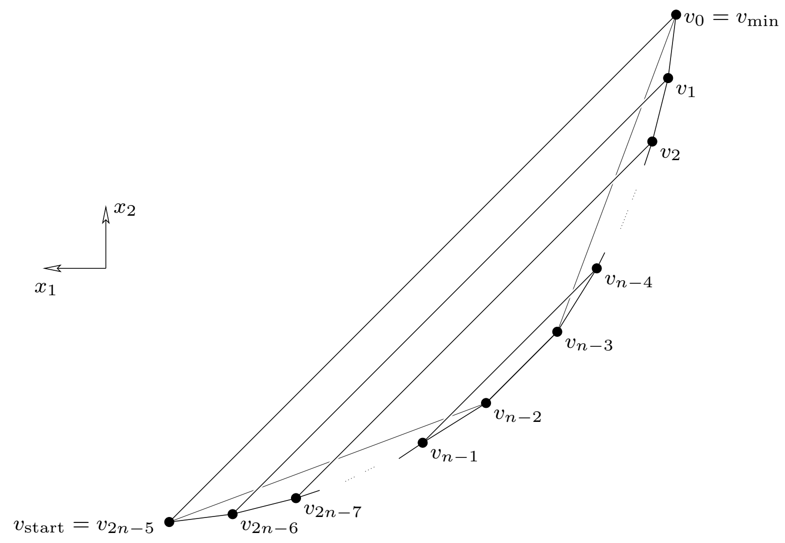

FIG. 4.2. *Lower bounds for the steepest decrease and shadow vertex rules. Planar projection of the polytope: The objective function is $x_1$; it directs all edges from left to right.*

This yields $\Lambda(\text{GD}) \le \frac{3}{2}$ and completes the proof. ∎

**4.4. Steepest decrease rule.** At any nonminimal vertex $v$ the *steepest decrease* pivot rule moves to the neighbor $w$ with $vw$ being the steepest decreasing edge, that is, such that $\frac{\langle c, w-v\rangle}{\|w-v\|\,\|c\|}$ is minimal (where $\langle c, x\rangle$ is the objective function).

PROPOSITION 4.4. *The linearity coefficient of the steepest decrease rule is* 2.

*Proof.* Figure 4.2 depicts a planar projection onto the $(x_1, x_2)$-plane of an LP that is easily constructed either "by hand" or as a deformed product (see Amenta and Ziegler [1]). If the polytope is scaled to be very flat in the $x_3$-direction, then steepest decrease tells the simplex algorithm to use the edge that in the projection has the smallest slope (in absolute value). Thus starting at $v_{\text{start}} = v_{2n-5}$, the steepest decrease rule visits *all* the vertices. ∎

**4.5. Shadow vertex rule.** The *shadow vertex* pivot rule chooses a sequence of edges that lie on the boundary of the 2-dimensional projection of the polytope given by $x \mapsto (\langle c, x\rangle, \langle d, x\rangle)$, where $\langle c, x\rangle$ is the given objective function and $\langle d, x\rangle$ is an objective function that is constructed to be optimal at the starting vertex $v_{\text{start}}$. The vertices that are visited on the path from $v_{\text{start}}$ to $v_{\min}$ are then optimal for objective functions that interpolate between $\langle d, x\rangle$ and $\langle c, x\rangle$. (This pivot rule is known to be polynomial on "random linear programs" in specific models; cf. Borgwardt [3], Ziegler [21], and Spielman and Teng [18].)

PROPOSITION 4.5. *The linearity coefficient of the shadow vertex rule is* 2.

*Proof.* We reuse the LPs of Proposition 4.4/Figure 4.2. Here $v_{2n-5} = v_{\max}$ is optimal for the starting objective function $\langle d, x\rangle = x_2$, while $v_0$ is optimal for $\langle c, x\rangle = x_1$. On the way from $v_{2n-5}$ to $v_{\min} = v_0$ the shadow vertex rule visits *all* the vertices. ∎

**4.6. Random facet.** The *random facet* pivot rule, due to Kalai [10, p. 228], is as follows:

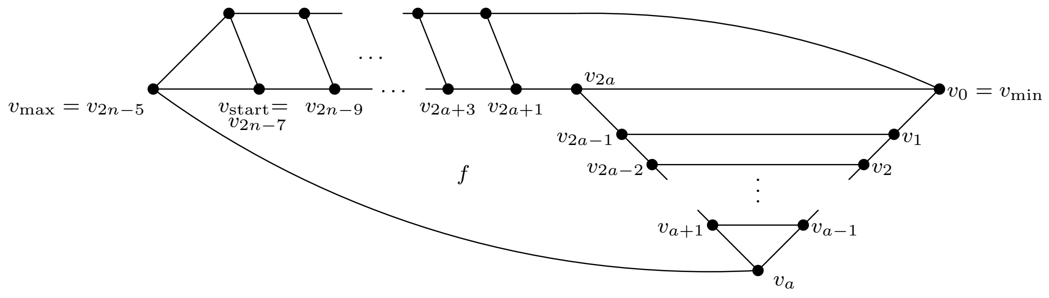

FIG. 4.3. *Lower bound for the random facet rule* (RF). *All edges are oriented from left to right.*

(RF) At any nonoptimal vertex $v$ choose one facet $f$ containing $v$ uniformly at random, and solve the problem restricted to $f$ by applying (RF) recursively. The recursion will eventually restrict to a 1-dimensional subproblem (that is, an edge), which is solved by following the edge.

The 1-dimensional base case singled out here is only implicit in Kalai's work. This is probably the reason why there are different versions of this rule in the literature, which unfortunately were not distinguished. They all differ in the way that 1-vertices are treated. Since the (unique) out-edge of a 1-vertex is always taken with probability one (regardless of which facets we restrict to) we could use the following alternative formulations of the random facet rule:

(RF1) At each nonoptimal vertex $v$ follow the (unique) outgoing edge if $v$ is a 1-vertex. Otherwise choose one facet $f$ uniformly at random containing $v$, and solve the problem restricted to $f$ by applying (RF1) recursively.

(RF2) At any nonoptimal vertex $v$ choose one facet $f$ containing $v$ uniformly at random, and solve the problem restricted to $f$ by applying (RF2) recursively. The minimal vertex opt$(f)$ of $f$ is a 1-vertex, and we follow the (unique) outgoing edge of the vertex opt$(f)$.

The variant (RF1) appears in Gärtner, Henk, and Ziegler [6, p. 350], while the version (RF2) is from Gärtner [5], who, however, formulated this variant of the random facet rule for combinatorial cubes, where the formulations above are equivalent.

Note that (RF) uses randomness at every vertex, and (RF1) would follow a path of 1-vertices deterministically, while (RF2) takes at most one deterministic step in a row. This results in distinct pivot rules, with different worst case examples.

PROPOSITION 4.6. *For each version* (RF), (RF1), *and* (RF2) *of the random facet rule, the linearity coefficient is* 2.

*Proof.* Figure 4.3 depicts a family of LPs with $2n - 4 = 2a + 2b + 2$ vertices and $n = a + b + 3$ facets. For each of the $b$ 1-vertices $v_{\text{start}} = v_{2n-7}, v_{2n-9}, \ldots, v_{2a+1}$, the probability of leaving it via choosing facet $f$ is $\frac{1}{2}$. After choosing facet $f$, (RF) "sticks" to facet $f$ until $v_a$ is reached.

Choosing $a = k^2$ and $b = k$, we obtain a family of LPs with $n = k^2 + k + 3$ facets. Then (RF) sticks to facet $f$ with probability $p \geq 1 - (\frac{1}{2})^k$. Thus the expected number of visited vertices is at least

$$\left(1 - \left(\frac{1}{2}\right)^k\right) (2a + b) \;\geq\; 2k^2 - \frac{2k^2}{2^k}.$$

Since there are $n = k^2 + k + 3$ facets, the linearity coefficient is 2.

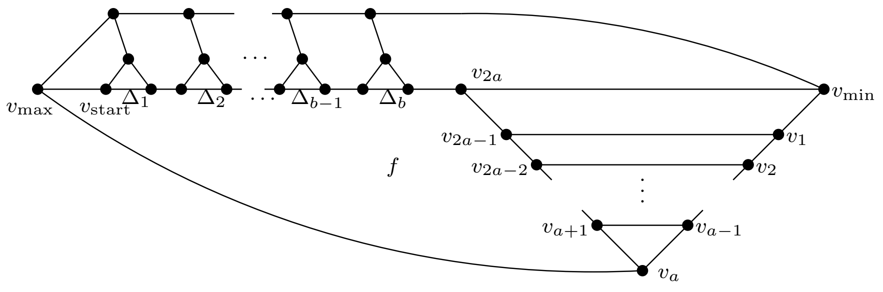

FIG. 4.4. *Lower bounds for the* (RF1) *and* (RF2) *variants of the random facet rule, and for the least entered rule with random edge as the tie-breaking rule. All edges are oriented from left to right.*

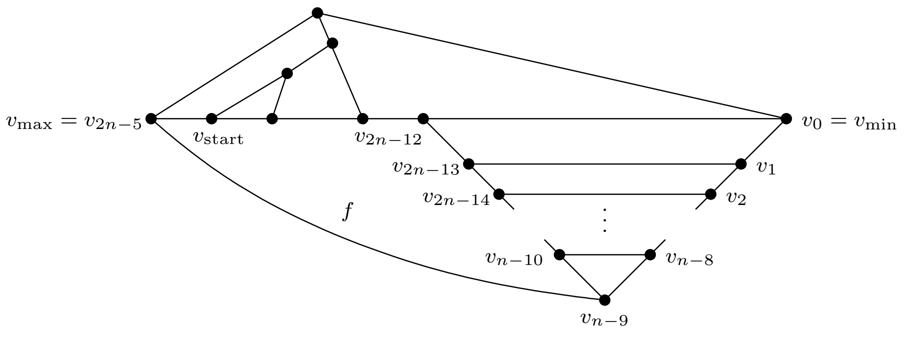

FIG. 4.5. *Lower bound for the least entered rule with greatest decrease as the tie-breaking rule. All edges are oriented from left to right.*

The version (RF1) of the random facet rule follows the path of 1-vertices $v_{\text{start}} = v_{2n-7}, v_{2n-9}, \dots, v_{2a+1}$ deterministically. We can cut off each of these vertices. This yields the graphs depicted in Figure 4.4. At each source of the new facets $\Delta_1, \dots, \Delta_b$, the facet $f$ is chosen with probability $\frac{1}{3}$. If any of the other two facets is chosen, we end up at the sink vertex of the respective facet $\Delta_i$. Thus the linearity coefficient remains 2, and only the rate of convergence decreases. The same works for (RF2) as well. ▯

**4.7. Least entered rule.** At any nonoptimal vertex, the *least entered* pivot rule chooses the decreasing edge that leaves the facet that has been left least often in the previous moves. In case of ties, a tie-breaking rule is used to determine the decreasing edge to be taken. Any other pivot rule can be used as a tie-breaking rule.

The least entered rule was first formulated by Norman Zadeh around 1980 (see [13] and [21]). It has still not been determined whether Zadeh's rule is polynomial if the dimension is part of the input. Zadeh has offered $1000 for solving this problem.

PROPOSITION 4.7. *The linearity coefficient of the least entered rule with greatest decrease as tie-breaking rule is* 2.

*Proof.* Figure 4.5 describes a family of 3-dimensional LPs, where the left-to-right ordering of the vertices suggested by the figure can be realized, according to the Mihalisin–Klee theorem (Theorem 2.2). Starting at $v_{\text{start}} = v_{2n-6}$, the greatest decrease rule decides to leave the facet $f$. Following two 1-vertices, the facet $f$ is entered again. All upcoming facets have not been visited before. Thus the least entered rule "sticks" to the facet $f$, and $2n - 7$ vertices (that is, all but 3 vertices) are visited. ∎

PROPOSITION 4.8. *The linearity coefficient of the least entered rule with random edge as the tie-breaking rule is* 2.

*Proof.* Figure 4.4 describes LPs with $2n-4 = 2a+4b+2$ vertices and $n = a+2b+3$ facets. At the sources of the facets, $\Delta_i$, the random edge rule leaves the facet $f$ with probability $\frac{1}{2}$. As soon as $f$ is left once, it will be revisited, and the least entered rule will "stick" to the facet $f$. (Thus the only way not to "stick" to $f$ is that the random edge rule chooses to continue along $f$ until it reaches the vertex $v_{2a}$.) When the least entered rule "sticks" to the facet $f$, all of the $2a$ vertices $v_{2a-1}, v_{2a-2}, \ldots, v_1, v_0$ are visited.

Now the analysis is exactly the same as in the proof of Proposition 4.6. Thus choosing $a = k^2$ and $b = k$ yields that the linearity coefficient is 2. ∎

**Acknowledgments.** We are grateful to Emo Welzl and Günter Rote for inspiring discussions and helpful comments, and to Gabriel Nivasch for pointing out an error in an earlier version of the proof of Theorem 3.2.

# TEMPORAL REASONING ABOUT TWO CONCURRENT SEQUENCES OF EVENTS[*]

YASUNORI ISHIHARA[†], SHIN ISHII[‡], HIROYUKI SEKI[‡], AND MINORU ITO[‡]

**Abstract.** This paper discusses temporal reasoning with respect to constraints on two concurrent sequences of events. If two given sequences of events can be mapped into one sequence that satisfies a given constraint, then the constraint is said to be consistent. First, we mention that the consistency of such constraints is NP-complete. Then we introduce the notion of graph representations of constraints. If a graph representation of a given constraint $c$ can be constructed in polynomial time, then the consistency of $c$ is decidable in polynomial time. However, it is shown that the graph representability of a given $c$ is coNP-complete. Next, we propose a subclass CDC$^{\neq}$ of constraints such that for each constraint $c$ in CDC$^{\neq}$, a graph representation of $c$ can be constructed in polynomial time. The expressive power of CDC$^{\neq}$ is incomparable to any other subclasses of constraints for which the consistency problem is known to be tractable.

**Key words.** temporal reasoning, temporal constraint, consistency, complexity

**AMS subject classifications.** 68Q25, 68Q20

## 1. Introduction.

In many practical information systems, each fragment of data has temporal information. For example, in relational databases, relations are often augmented by temporal attributes (such databases are called temporal databases [1]). It is often desirable for information systems to manage such temporal information in an intelligent way. For example, suppose that a knowledge base system has the following information:

- Last night, the people in the restaurant heard two shots.
- The electricity was off at least between the first and second shots.
- After the electric power resumed, the people found all the money in the restaurant had been stolen.

We want the knowledge base system to infer that the people found all the money stolen *after* the second shot. This is a trivial but typical example of *temporal reasoning*.

In this paper, temporal reasoning about two concurrent sequences of events is considered. Two sets of time variables $S = \{s_0, s_1, \dots, s_m\}$ and $T = \{t_0, t_1, \dots, t_n\}$ are used for describing temporal constraints, where $s_0, s_1, \dots, s_m$ represent time points of one local clock and $t_0, t_1, \dots, t_n$ represent time points of the other clock. A temporal constraint consists of expressions of the forms $s_i < t_j$, $s_i > t_j$, $s_i \leq t_j$, $s_i \geq t_j$, $s_i = t_j$, and $s_i \neq t_j$, and Boolean operators $\neg$, $\vee$, and $\wedge$. One of the applications of temporal reasoning about such constraints is belief revision [4] in a multiagent environment, as shown in the next example. As far as we know, no paper has focused on the class of constraints such that the number of local clocks is fixed.

*Example* 1.1. Consider the following multiagent environment: Each agent has its own local clock and records its observations, each of which is a pair consisting

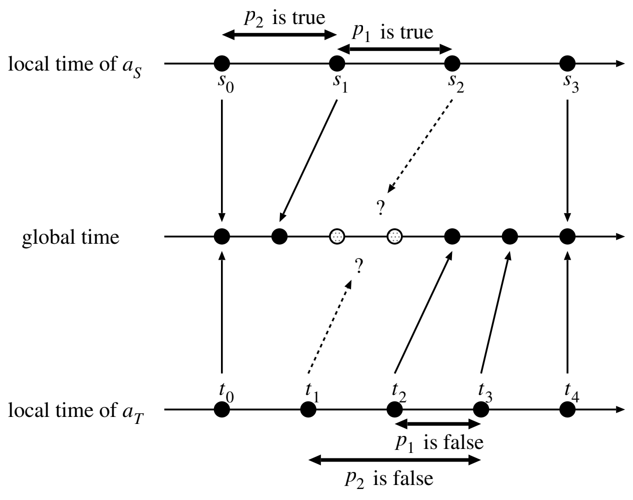

FIG. 1. *Example of temporal reasoning about two concurrent sequences of events.*

of a proposition and an observation time. The agents sometimes meet together and exchange their observations in order to revise and refine their information on the observation times.

See Figure 1. $s_0, \ldots, s_3$ represent local time points of agent $a_S$ with $s_0 < \cdots < s_3$, and $t_0, \ldots, t_4$ represent local time points of agent $a_T$ with $t_0 < \cdots < t_4$. The agents met together at $s_0 = t_0$ and $s_3 = t_4$. Suppose that $a_S$ observed that a proposition $p_1$ was true during its local time interval $[s_1, s_2]$. Also suppose that $a_T$ observed that $p_1$ was false during $[t_2, t_3]$. Then the agents can conclude that intervals $[s_1, s_2]$ and $[t_2, t_3]$ are disjoint, i.e., $(s_1 \geq t_3) \vee (s_2 \leq t_2)$. In this paper, a constraint of this form is called a *disjointness constraint* and is denoted by $[s_1, s_2] \not\cap [t_2, t_3]$. The agents also obtain $[s_0, s_1] \not\cap [t_1, t_3]$ from the observations of $p_2$.

Now, several facts can be inferred from the obtained constraint $c = ([s_1, s_2] \not\cap [t_2, t_3]) \wedge ([s_0, s_1] \not\cap [t_1, t_3])$. For example, $s_1 \leq t_1$ can be concluded since $c \wedge (s_1 > t_1)$ is inconsistent (i.e., unsatisfiable). On the other hand, the order between $s_2$ and $t_1$ cannot be determined since all of $c \wedge (s_2 < t_1)$, $c \wedge (s_2 = t_1)$, and $c \wedge (s_2 > t_1)$ are consistent.

Another possible application is job scheduling for two processors, where each job is denoted by a time interval and each pair of mutually exclusive jobs is specified by a disjointness constraint.

The contribution of this paper is as follows. We first mention that the consistency of constraints on two local clocks is NP-complete when both conjunction and disjunction are freely used. Next, we introduce the notion of *graph representations* of constraints. A graph representation of a constraint $c$ is a directed graph representing all the valuations that satisfy $c$. If $c$ has a graph representation $G_c$, and $G_c$ can be constructed in polynomial time, then the consistency of $c$ is also decidable in polynomial time. However, it is shown that the graph representability of a given $c$ is coNP-complete (and therefore constructing $G_c$ is coNP-hard). Next, we propose a new tractable subclass CDC$^{\neq}$ of constraints. CDC$^{\neq}$ stands for conjunctive disjointness constraints with inequalities, and it can express conjunctions of constraints in the form of $[s_i, s_{i'}] \not\cap [t_j, t_{j'}]$ or $s_i \,\Theta\, t_j$, where $\Theta \in \{<, >, \leq, \geq, =, \neq\}$. All the constraints appearing in Example 1.1 are expressible in CDC$^{\neq}$. We show that for each constraint $c$ in CDC$^{\neq}$, a graph representation of $c$ can be constructed in polynomial time. Let $m$ be the number of time variables of one of the two local clocks, and $n$ the other clock. The consistency of $c \in$ CDC$^{\neq}$ is decidable in $O(|c|mn)$ time, where $|c|$ is the size of $c$. Lastly, we show the intractability of constraints generated by disjointness constraints and conjunction and disjunction operators. For such general disjointness constraints, the consistency is NP-complete and the graph representability is coNP-complete.

The rest of the paper is organized as follows. Constraints on two clocks are formulated in section 2. In section 3, graph representations are introduced. It is also shown that the graph representability of a given constraint is coNP-complete. In section 4, a tractable subclass CDC$^{\neq}$ of constraints is proposed. In section 5, the intractability of general disjointness constraints is shown. Section 6 compares the expressive powers of the classes of constraints. Section 7 summarizes the paper.

## 2. Constraints on two clocks.

Let $R$ be an infinite set of *global time points.* Suppose that a total order $\leq$ is defined on $R$. $r \leq r'$ means that point $r$ precedes or is equal to $r'$. When $r \leq r'$ and $r \neq r'$, we write $r < r'$.

Let $S = \{s_0, s_1, \ldots, s_m\}$ and $T = \{t_0, t_1, \ldots, t_n\}$ $(m,\ n \geq 1)$ be sets of *variables.* We write $s_i \leq_S s_j$ and $t_i \leq_T t_j$ if $i \leq j$, and we write $s_i <_S s_j$ and $t_i <_T t_j$ if $i < j$. Intuitively, $S$ and $T$ are sets of *local time points.*

Let $\Sigma_{ST}$ be the family of all the *valuations* $\sigma : S \cup T \to R$ satisfying the following conditions:

- $\sigma(s_0) = \sigma(t_0)$;
- $\sigma(s_m) = \sigma(t_n)$;
- if $s <_S s'$, then $\sigma(s) < \sigma(s')$;
- if $t <_T t'$, then $\sigma(t) < \sigma(t')$.

The first two conditions are introduced merely for theoretical simplicity. Namely, instead of the first condition, we can put dummy variables $s_{-\infty}$ and $t_{-\infty}$ such that $s_{-\infty} <_S s_0$, $t_{-\infty} <_T t_0$, and $\sigma(s_{-\infty}) = \sigma(t_{-\infty})$. On the other hand, the last two conditions are essential. $\sigma$ must preserve the temporal orders of local time points.

Hereafter, we do not distinguish isomorphic valuations with respect to $<$ and $=$. In other words, we are interested in only the quotient sets of $\Sigma_{ST}$ under $<$ and $=$. Therefore, $\sigma$ will be regarded as a permutation of $S \cup T$ which is consistent with both $<_S$ and $<_T$ (although it may hold that $\sigma(s) = \sigma(t)$ for some $s \in S$ and $t \in T$), and $\Sigma_{ST}$ will be regarded as the family of such permutations.

An *atomic constraint* is an expression with one of the following forms: $s < t$, $s > t$, $s \leq t$, $s \geq t$, $s = t$, and $s \neq t$. A *constraint* is generated from atomic constraints and Boolean operators $\neg$, $\vee$, and $\wedge$. For readability, we may use notation such as $t < s < t'$ to mean $(s > t) \wedge (s < t')$. The *satisfaction relation* is defined in an ordinary way, and we write $\sigma \models c$ (read as $\sigma$ *satisfies* $c$) if $c$ is true under valuation $\sigma$. If $\sigma \models c$ for some $\sigma$, then $c$ is *consistent* (or *satisfiable*). By $c \models c'$, we mean that every valuation $\sigma \in \Sigma_{ST}$ satisfying $c$ also satisfies $c'$. We say that $c$ is *equivalent* to $c'$, denoted $c \equiv c'$, if both $c \models c'$ and $c' \models c$ hold.

The *consistency problem* is to determine whether, given sets $S$ and $T$ of variables and constraint $c$, $c$ is consistent or not. The *implication problem* is to determine whether $c \models c'$ holds or not for given sets $S$ and $T$ of variables and constraints $c$ and $c'$. Since $c \models c'$ if and only if $\neg c \wedge c'$ is inconsistent, we mainly focus on the consistency problem in this paper.

Define the size of $S$ and $T$ as $m$ and $n$, respectively. Also define the size of $c$ as the number of atomic constraints in $c$.

THEOREM 2.1. *The consistency of an arbitrary constraint is in NP. The consistency of a constraint in conjunctive normal form (CNF) is NP-hard.*

*Proof.* The consistency problem is obviously in NP. The NP-hardness is shown by reducing the satisfiability problem of CNF logical formulas to this problem. In the reduction, each logical variable $x_i$ in a given logical formula is replaced with an atomic constraint $s_i < t_i$. Whether $s_i < t_i$ holds or not can be determined independently of other atomic constraints $s_j < t_j$. Thus, the obtained constraint is consistent if and only if the original logical formula is satisfiable. □

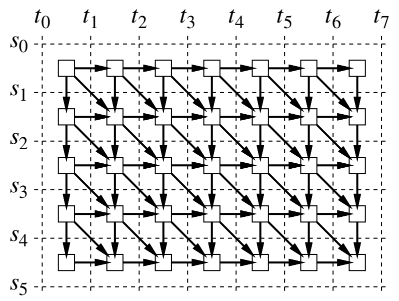

FIG. 2. $G_{ST}$.

## 3. Consistency and graph representability.

**3.1. Graph representations of constraints.** First, we define the graph $G_{ST}$.

DEFINITION 3.1. *Let $S = \{s_0, \ldots, s_m\}$ and $T = \{t_0, \ldots, t_n\}$. Define $G_{ST}$ as a directed acyclic graph consisting of $mn$ nodes arranged in $m$ rows and $n$ columns, with each node having outgoing arcs to the right, lower, and lower-right nodes (if existing). The node at the $i$th row of the $j$th column is denoted by $(i, j)$.*

$G_{ST}$ for $S = \{s_0, \ldots, s_5\}$ and $T = \{t_0, \ldots, t_7\}$ is shown in Figure 2. The $m + 1$ dotted horizontal lines (labeled $s_0, \ldots, s_m$) and $n + 1$ dotted vertical lines (labeled $t_0, \ldots, t_n$) are auxiliary lines explained below.

A *complete path* on $G_{ST}$ is a path from $(1, 1)$ to $(m, n)$. Let $W_{ST}$ denote the set of all the complete paths on $G_{ST}$. There is a one-to-one correspondence between $W_{ST}$ and $\Sigma_{ST}$. To see this, define a mapping $\rho : W_{ST} \to \Sigma_{ST}$ as follows. Let $w \in W_{ST}$.

- $\rho(w)(s_0) = \rho(w)(t_0)$ and $\rho(w)(s_m) = \rho(w)(t_n)$.
- If $w$ crosses line $s_i$ before line $t_j$, then $\rho(w)(s_i) < \rho(w)(t_j)$.
- If $w$ crosses line $t_j$ before line $s_i$, then $\rho(w)(s_i) > \rho(w)(t_j)$.
- If $w$ crosses lines $s_i$ and $t_j$ at the same time, then $\rho(w)(s_i) = \rho(w)(t_j)$.

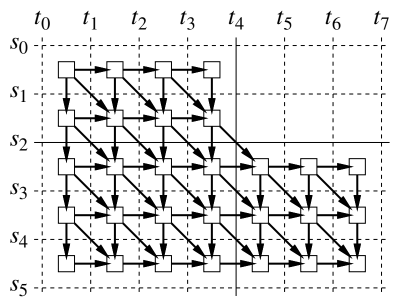
It can be shown that $\rho$ is a bijection. Let $\rho^{-1}$ denote the inverse of $\rho$.

If $G$ is a subgraph of $G'$, we write $G \subseteq G'$. The union $\cup$ (resp., intersection $\cap$) of subgraphs of $G_{ST}$ is defined as the least upper bound (resp., greatest lower bound) of the subgraphs with respect to $\subseteq$.

The notion of complete paths is extended to subgraphs of $G_{ST}$. That is, for a subgraph $G$ of $G_{ST}$, if there is a path from $(1, 1)$ to $(m, n)$ on $G$, then the path is called a complete path on $G$.

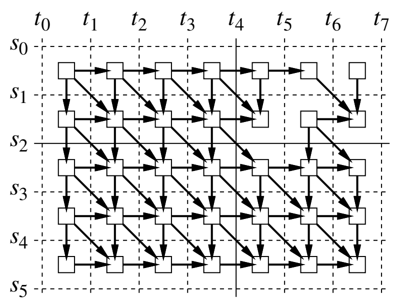
DEFINITION 3.2. *Let $c$ be a constraint and let $G$ be a subgraph of $G_{ST}$. If the following two conditions hold, then $G$ is a* graph representation *of $c$:*

- *$\rho(w) \models c$ for every complete path $w$ on $G$; and*
- *$\rho^{-1}(\sigma)$ is a complete path on $G$ for every valuation $\sigma$ such that $\sigma \models c$.*



$t_0$ $t_1$ $t_2$ $t_3$ $t_4$ $t_5$ $t_6$ $t_7$
$s_0$ $s_1$ $s_2$ $s_3$ $s_4$ $s_5$

FIG. 3. *Minimum graph representation of $s_2 \leq t_4$.*



$t_0$ $t_1$ $t_2$ $t_3$ $t_4$ $t_5$ $t_6$ $t_7$
$s_0$ $s_1$ $s_2$ $s_3$ $s_4$ $s_5$

FIG. 4. *Another graph representation of $s_2 \leq t_4$.*

*If $c$ has a graph representation, then $c$ is* graph representable.

Some constraints have more than one graph representation, while some constraints have no graph representation. For example, both Figures 3 and 4 are graph representations of $s_2 \leq t_4$. On the other hand, as will be shown later, $(s_2 \leq t_4) \vee (s_4 \leq t_6)$ has no graph representation. Note that false has a graph representation (e.g., the empty graph).

For a graph-representable constraint $c$, let $G_c$ denote an arbitrary graph representation of $c$.

LEMMA 3.3. *Let $c$ and $c'$ be graph-representable constraints. Then $G_c \cap G_{c'}$ is a graph representation of $c \wedge c'$.*

*Proof.* Any complete path $w$ on $G_c \cap G_{c'}$ is contained in both $G_c$ and $G_{c'}$. Therefore $\rho(w) \models c \wedge c'$. Conversely, consider any valuation $\sigma$ such that $\sigma \models c \wedge c'$. Then $\rho^{-1}(\sigma)$ must be contained in both $G_c$ and $G_{c'}$. Therefore, $\rho^{-1}(\sigma)$ is contained in $G_c \cap G_{c'}$. ☐

Suppose that $c$ has a graph representation $G_c$. By Definition 3.2, $c$ is consistent if and only if $(m, n)$ is reachable from $(1, 1)$ on $G_c$. Since the reachability is decidable in $O(mn)$ time, we obtain the following lemma.

LEMMA 3.4. *Let $c = c_1 \vee \cdots \vee c_l$ be a disjunction of graph-representable constraints $c_1, \ldots, c_l$. Suppose that each $G_{c_i}$ can be constructed in $O(f(c_i, m, n))$ time. Then the consistency of $c$ is decidable in $O(f(c_1, m, n) + \cdots + f(c_l, m, n) + lmn)$ time.*

*Proof.* $c$ is consistent if and only if some $c_i$ is consistent. For each $i$, the consistency of $c_i$ is decidable in $O(f(c_i, m, n) + mn)$ time. Therefore, the consistency of $c$ is decidable in $O(f(c_1, m, n) + \cdots + f(c_l, m, n) + lmn)$ time. ☐

**3.2. Minimum graph representations.** A graph representation may contain redundant nodes and arcs. The following lemma states the existence of the simplest graph representation.

LEMMA 3.5. *Among all the graph representations of $c$, there is a unique minimum graph representation $G^*_c$ with respect to $\subseteq$.*

*Proof.* The number of all the graph representations of $c$ is finite since $G_{ST}$ is a finite graph. Therefore, the intersection of all the graph representations of $c$ can be defined. We show that the intersection $G^*_c$ is the unique minimum graph representation of $c$. By Lemma 3.3, $G^*_c$ is a graph representation of $c$ $(= c \wedge c \wedge \cdots \wedge c)$. Clearly, $G^*_c \subseteq G_c$ for any graph representation $G_c$ of $c$. Hence, $G^*_c$ satisfies the lemma. $\square$

LEMMA 3.6. *Let $c$ be a graph-representable constraint. The minimum graph representation $G^*_c$ of $c$ can be constructed in $O(f(c,m,n)+mn)$ time, where $f(c,m,n)$ is the time complexity of constructing some graph representation of $c$.*

*Proof.* Suppose that a graph representation $G_c$ of $c$ is obtained. Then $G^*_c$ can be constructed by the following algorithm:

1. Mark all the nodes and arcs that are reachable from $(1,1)$ in $G_c$. This can be done in $O(mn)$ time by performing depth first search from $(1,1)$.
2. Mark all the nodes and arcs from which $(m,n)$ is reachable in $G_c$. This can be done in $O(mn)$ time by performing depth first search from $(m,n)$, exploring the arcs in the opposite direction.
3. Excepting the nodes and arcs which are marked both in steps 1 and 2 above, remove the other nodes and arcs.

This algorithm is correct since the resultant graph contains only the nodes and arcs that are contained by a complete path on $G_c$. $\square$

By Lemma 3.3, $G_c \cap G_{c'}$ is a graph representation of $c \wedge c'$. However, $G^*_c \cap G^*_{c'}$ is not necessarily the minimum graph representation of $c \wedge c'$. For example, consider $G^*_c$ and $G^*_{c'}$ which have no common complete paths. Then $G^*_{c \wedge c'}$ is the empty graph, but $G^*_c \cap G^*_{c'}$ is not necessarily empty.

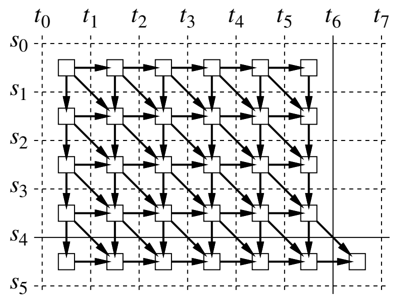
**3.3. Complexity of deciding graph representability.** We are interested in the complexity $f(c,m,n)$ of constructing $G_c$. Unfortunately, the graph representability of a given $c$ with disjunction is coNP-complete (and therefore constructing $G_c$ is coNP-hard), even if $c$ is in disjunctive normal form (DNF). First, we characterize the graph representability.

LEMMA 3.7. *The following properties are equivalent:*

1. *$c$ has no graph representation.*
2. *There is a complete path $w$ on $G_{ST}$ such that*
   - *$\rho(w) \not\models c$, and*
   - *for every arc $a$ contained in $w$, there is another complete path $w_a$ on $G_{ST}$ containing the arc $a$ such that $\rho(w_a) \models c$.*

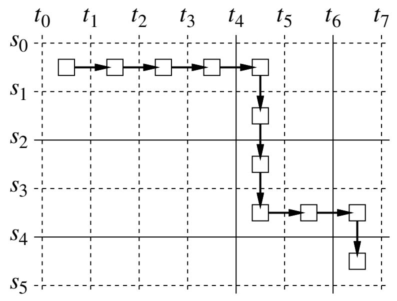
*Proof.* Suppose that $c$ has no graph representation. Let $G$ be the minimum graph that contains all the complete paths satisfying $c$. Since $c$ has no graph representation, there is a complete path $w$ on $G$ such that $\rho(w) \not\models c$. By the definition of $G$, for every arc $a$ contained in $w$, there is another complete path $w_a$ containing the arc $a$ such that $\rho(w_a) \models c$. Thus the second property holds.

Conversely, suppose that the second property holds. Also assume that $c$ has a graph representation $G_c$. Then $G_c$ does not contain $w$ of the second property, since $G_c$ contains only the complete paths $w'$ such that $\rho(w') \models c$. However, by the second property, for every arc $a$ in $w$, there is $w_a$ containing the arc $a$ such that $\rho(w_a) \models c$. By definition, $G_c$ contains $w_a$. This implies that all the arcs in $w$ must be contained



$t_0$ $t_1$ $t_2$ $t_3$ $t_4$ $t_5$ $t_6$ $t_7$
$s_0$ $s_1$ $s_2$ $s_3$ $s_4$ $s_5$

FIG. 5. *Minimum graph representation of* $s_4 \leq t_6$.



$t_0$ $t_1$ $t_2$ $t_3$ $t_4$ $t_5$ $t_6$ $t_7$
$s_0$ $s_1$ $s_2$ $s_3$ $s_4$ $s_5$

FIG. 6. *A complete path not satisfying* $(s_2 \leq t_4) \vee (s_4 \leq t_6)$.

in $G_c$, and contradicts the assumption that $w$ is not a complete path on $G_c$. Thus, the second property implies the first one. □

We show that $c = (s_2 \leq t_4) \vee (s_4 \leq t_6)$ has no graph representation. The minimum graph representation of $s_4 \leq t_6$ is shown in Figure 5. Consider the complete path $w$ shown in Figure 6. $w$ does not satisfy $c$ since $w$ crosses line $t_4$ before line $s_2$, and crosses line $t_6$ before line $s_4$. However, for each arc $a$ in $w$, there is another complete path $w_a$ containing $a$ such that $\rho(w_a) \models c$ (see Figures 3 and 5). By Lemma 3.7, $c$ has no graph representation.

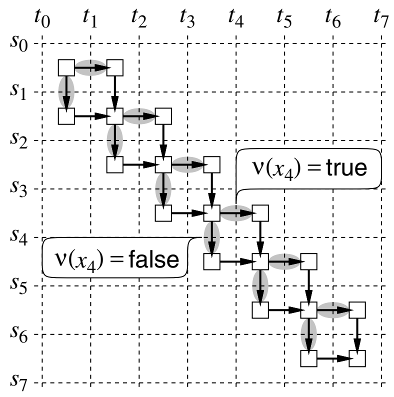
Before showing the coNP-completeness of the graph representability, we introduce a coNP-complete problem. Let $F$ be a logical formula in DNF such that both $\nu_{\text{true}}$ and $\nu_{\text{false}}$ satisfy $F$, where $\nu_{\text{true}}$ (resp., $\nu_{\text{false}}$) is the interpretation that maps every logical variable to true (resp., false). The *modified tautology problem* is to decide whether such a given logical formula $F$ is a tautology (i.e., $F$ is satisfied by all the interpretations). It is easily shown that the modified tautology problem is coNP-complete.

THEOREM 3.8. *The graph representability of an arbitrary constraint is in coNP. The graph representability of a constraint $c$ with disjunction is coNP-hard, even if $c$ is in DNF.*

*Proof.* The second property of Lemma 3.7 is decidable by an NP algorithm as follows. First, guess a complete path $w$ and verify that $\rho(w) \not\models c$. Then, for every arc $a$ contained in $w$, guess a complete path $w_a$ containing $a$ and verify that $\rho(w_a) \models c$.

To see the coNP-hardness, we reduce the modified tautology problem to the graph representability problem. Let $F = F_1 \vee \cdots \vee F_k$ be a DNF formula with $n$ variables $x_1, \ldots, x_n$ such that both $\nu_{\text{true}}$ and $\nu_{\text{false}}$ satisfy $F$. Let

$$S = \{s_0, \ldots, s_{n+1}\}, \quad T = \{t_0, \ldots, t_{n+1}\}.$$



$t_0$ $t_1$ $t_2$ $t_3$ $t_4$ $t_5$ $t_6$ $t_7$
$s_0$ $s_1$ $s_2$ $s_3$ $s_4$ $s_5$ $s_6$ $s_7$
$\nu(x_4) = \text{true}$
$\nu(x_4) = \text{false}$

FIG. 7. *Graph representation of* $c'$ *(*$n = 6$*).*

Let $F_l'$ be the constraint obtained by replacing $x_i$ in $F_l$ by $s_i > t_i$, and $\neg x_i$ by $s_i < t_i$. Define $c_l = F_l' \wedge c'$, where

$$c' = \bigwedge_{i=1}^{n} ((t_{i-1} < s_i < t_{i+1}) \wedge (s_i \neq t_i)).$$

The minimum graph representation $G_{c'}^*$ of $c'$ is shown in Figure 7. Lastly, define $c = c_1 \vee \cdots \vee c_k$. Note that only the complete paths on $G_{c'}^*$ can satisfy $c$.

First, we show that $F$ is a tautology if and only if all the complete paths on $G_{c'}^*$ satisfy $c$. With each interpretation $\nu$ of $F$, associate the following complete path $w_\nu$ on $G_{c'}^*$ (see Figure 7 again):

- $w_\nu$ contains $((i,i),(i,i+1))$ if $\nu(x_i) = $ true;
- $w_\nu$ contains $((i,i),(i+1,i))$ if $\nu(x_i) = $ false.

It is not difficult to see that $\nu$ satisfies $F$ if and only if $\rho(w_\nu) \models c$. Note that $\rho(w_{\nu_{\text{true}}}) \models c$ and $\rho(w_{\nu_{\text{false}}}) \models c$ since both $\nu_{\text{true}}$ and $\nu_{\text{false}}$ satisfy $F$.

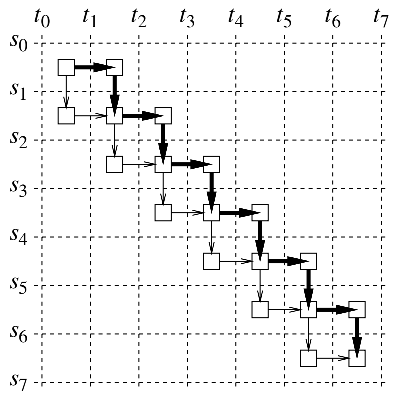
To complete the proof, we show that all the complete paths on $G_{c'}^*$ satisfy $c$ if and only if $c$ has a graph representation. For the *only if* part, suppose that all the complete paths on $G_{c'}^*$ satisfy $c$. Then, immediately from Definition 3.2, $G_{c'}^*$ is a graph representation of $c$. For the *if* part, suppose that $\rho(w) \not\models c$, where $w$ is a complete path on $G_{c'}^*$. Then, for every arc $a$ contained in $w$, there is another complete path $w_a$ (namely, $w_{\nu_{\text{true}}}$ or $w_{\nu_{\text{false}}}$; see Figure 8) that contains $a$ and $\rho(w_a) \models c$. Therefore, by Lemma 3.7, $c$ has no graph representation. $\square$

**4. A tractable subclass of graph-representable constraints.** We define a subclass CDC$^{\neq}$ of constraints such that for each constraint $c$ in CDC$^{\neq}$, a graph representation of $c$ can be constructed in $O(|c|mn)$ time.

DEFINITION 4.1. *A constraint in* CDC$^{\neq}$ *is a conjunction such that each conjunct is in the form of either* $s \neq t$ *or* $(s \geq t') \vee (s' \leq t)$*, where* $s <_S s'$ *and* $t <_T t'$*.*

CDC$^{\neq}$ can express any constraints in the form of $s_i \,\Theta\, t_j$, where $\Theta \in \{<, >, \leq, \geq, =, \neq\}$. For example,

$$(s_i \leq t_j) \equiv (s_0 \geq t_n) \vee (s_i \leq t_j),$$
$$(s_i < t_j) \equiv ((s_0 \geq t_n) \vee (s_i \leq t_j)) \wedge (s_i \neq t_j).$$



$t_0$ $t_1$ $t_2$ $t_3$ $t_4$ $t_5$ $t_6$ $t_7$
$s_0$ $s_1$ $s_2$ $s_3$ $s_4$ $s_5$ $s_6$ $s_7$

FIG. 8. $w_{\nu_{\mathrm{true}}}$ *(thick arcs) and* $w_{\nu_{\mathrm{false}}}$ *(thin arcs) in Theorem* 3.8 *(*$n = 6$*).*

Also, constraints in the form of $(s > t')\vee(s' \le t)$, $(s \ge t')\vee(s' < t)$, or $(s > t')\vee(s' < t)$ are expressible in CDC$^{\neq}$. For example,

$$(s > t') \vee (s' \le t) \equiv ((s \ge t') \vee (s' \le t)) \wedge (s \ne t').$$

As stated in section 1, constraint $(s \ge t')\vee(s' \le t)$ $(s <_S s'$ and $t <_T t')$ represents that time intervals $[s, s']$ and $[t, t']$ are disjoint. Therefore, we call the constraint a *disjointness constraint*, and we write $[s, s'] \not\pitchfork [t, t']$ to mean $(s \ge t') \vee (s' \le t)$. The class of conjunctive disjointness constraints is denoted by CDC.

Now we show that constructing a graph representation of every constraint in CDC$^{\neq}$ is tractable. By Lemma 3.3, it suffices to show that each of the two forms in Definition 4.1 has a graph representation.

LEMMA 4.2. *The following two properties hold:*

1. *Let* $c = (s_i \ne t_j)$*. A graph representation of* $c$ *is obtained by removing the arc* $((i, j), (i + 1, j + 1))$ *from* $G_{ST}$*. See Figure* 9*, for example.*
2. *Let* $c = ([s_i, s_{i'}] \not\pitchfork [t_j, t_{j'}])$*. Let* $N = \{(i'', j'') \mid i + 1 \le i'' \le i'$ *and* $j + 1 \le j'' \le j'\}$*. A graph representation of* $c$ *is obtained by removing* $N$ *and the adjacent arcs from* $G_{ST}$*. See Figure* 10*, for example.*

*Proof.* Since the first property is obvious, we consider only the case that $c = ([s_i, s_{i'}] \not\pitchfork [t_j, t_{j'}])$. Let $G$ be the graph obtained by this lemma. We show that $G$ is a graph representation of $c$. That is, $\sigma \models c$ if and only if $\rho^{-1}(\sigma)$ is a complete path on $G$.

Suppose that $\sigma \not\models c$. Then $\sigma \models (s_i < t_{j'}) \wedge (s_{i'} > t_j)$. This means that $\rho^{-1}(\sigma)$ contains some $(i'', j'')$ such that $i + 1 \le i'' \le i'$ and $j + 1 \le j'' \le j'$. Since $G$ does not contain $(i'', j'')$ by definition, $\rho^{-1}(\sigma)$ is not a complete path on $G$.

Conversely, consider a complete path $\rho^{-1}(\sigma)$ on $G_{ST}$ which is not contained in $G$. Then there is a node $(i'', j'')$ $(i + 1 \le i'' \le i'$ and $j + 1 \le j'' \le j')$ in $\rho^{-1}(\sigma)$ which is contained in $G_{ST}$ but not in $G$. Therefore, we conclude that $\sigma \models (s_i < t_{j'})\wedge(s_{i'} > t_j)$. That is, $\sigma \not\models c$. □

THEOREM 4.3. *Let* $c \in$ CDC$^{\neq}$*. A graph representation of* $c$ *can be constructed in* $O(|c|mn)$ *time. The minimum graph representation can also be constructed in* $O(|c|mn)$ *time.*

*Proof.* The proof is immediate from Lemmas 3.3, 3.6, and 4.2. □

FIG. 10. *Minimum graph representation of* $[s_2, s_4] \not\cap [t_4, t_6]$.

THEOREM 4.4. *Let c be a disjunction of constraints in* $\mathrm{CDC}^{\neq}$. *The consistency of c is decidable in* $O(|c|mn)$ *time.*

*Proof.* The proof is immediate from Theorem 4.3 and Lemma 3.4. □

**5. Intractability of general disjointness constraints.** Recall the explanation of disjointness constraints in Example 1.1. Now we consider the case in which observations may contain uncertainty. For example, suppose that $a_S$ observed that $p$ or $p'$ was true during time interval $[s, s']$. Also suppose that $a_T$ observed that $p$ was false during $[t, t']$, and $p'$ was false during $[u, u']$. Then we obtain $([s, s'] \not\cap [t, t']) \vee ([s, s'] \not\cap [u, u'])$.

As stated above, observations with uncertainty bring disjunction into disjointness constraints. In this section, we show that both the consistency and the graph representability for disjointness constraints with disjunction are intractable.

**5.1. Consistency of general disjointness constraints.** We show that the consistency of general disjointness constraints is NP-complete.

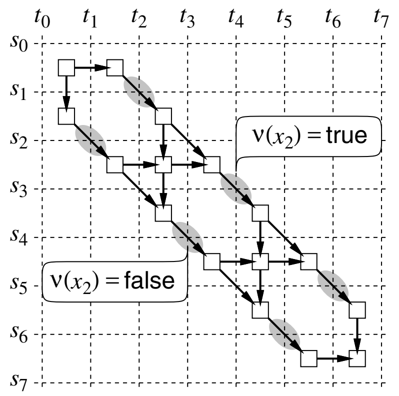
THEOREM 5.1. *Let d be a constraint in CNF with respect to disjointness constraints; i.e., d is in the form of* $d_1 \wedge \cdots \wedge d_n$, *where each* $d_i$ *is a disjunction of disjointness constraints. Then the consistency of d is NP-complete.*

*Proof.* By Theorem 2.1, the problem is in NP. To see the NP-hardness, we reduce the satisfiability of CNF logical formulas to the consistency problem.

Let $F$ be a CNF formula with $n$ variables $x_1, \ldots, x_n$. Let

$$S = \{s_0, \ldots, s_{2n+1}\}, \quad T = \{t_0, \ldots, t_{2n+1}\},$$

and let $F'$ be the constraint obtained by replacing $x_i$ in $F$ by $[s_{2i}, s_{2i+1}] \not\cap [t_{2i-1}, t_{2i}]$,



$t_0$ $t_1$ $t_2$ $t_3$ $t_4$ $t_5$ $t_6$ $t_7$
$s_0$ $s_1$ $s_2$ $s_3$ $s_4$ $s_5$ $s_6$ $s_7$
$\nu(x_2) = \text{true}$
$\nu(x_2) = \text{false}$

FIG. 11. *Graph representation of* $d'$ $(n = 3)$.

and $\neg x_i$ by $[s_{2i-1}, s_{2i}] \not\cap [t_{2i}, t_{2i+1}]$. Also define

$$d' = \bigwedge_{i=1}^{n} ([s_{2i-1}, s_{2i}] \not\cap [t_{2i-1}, t_{2i}])$$
$$\wedge \bigwedge_{j=1}^{2n-1} ([s_{j-1}, s_j] \not\cap [t_{j+1}, t_{j+2}])$$
$$\wedge \bigwedge_{j=1}^{2n-1} ([s_{j+1}, s_{j+2}] \not\cap [t_{j-1}, t_j]).$$

The minimum graph representation $G^*_{d'}$ of $d'$ is shown in Figure 11. Last, define $d = F' \wedge d'$. Note that only the complete paths on $G^*_{d'}$ can satisfy $d$.

We show that $d$ is consistent if and only if $F$ is satisfiable. With each interpretation $\nu$ of $F$, associate a complete path $w_\nu$ on $G^*_{d'}$ satisfying the following conditions (see Figure 11 again):

- $w_\nu$ contains $((2i-1, 2i), (2i, 2i+1))$ if $\nu(x_i) = \text{true}$; and
- $w_\nu$ contains $((2i, 2i-1), (2i+1, 2i))$ if $\nu(x_i) = \text{false}$.

Such $w_\nu$ always exists. On the other hand, for every complete path $w$ on $G^*_{d'}$, there is $\nu$ such that $w = w_\nu$.

Suppose that $\nu(x_i) = \text{true}$. Then $w_\nu$ contains $((2i-1, 2i), (2i, 2i+1))$, and therefore $\rho(w_\nu)(s_{2i-1}) = \rho(w_\nu)(t_{2i})$. This means that $\rho(w_\nu)$ satisfies $[s_{2i}, s_{2i+1}] \not\cap [t_{2i-1}, t_{2i}]$ but not $[s_{2i-1}, s_{2i}] \not\cap [t_{2i}, t_{2i+1}]$. Similarly, suppose that $\nu(x_i) = \text{false}$. Then $w_\nu$ contains $((2i, 2i-1), (2i+1, 2i))$, and therefore $\rho(w_\nu)(s_{2i}) = \rho(w_\nu)(t_{2i-1})$. This means that $\rho(w_\nu)$ satisfies $[s_{2i-1}, s_{2i}] \not\cap [t_{2i}, t_{2i+1}]$ but not $[s_{2i}, s_{2i+1}] \not\cap [t_{2i-1}, t_{2i}]$. Thus $\nu$ satisfies $F$ if and only if $\rho(w_\nu) \models d$. □

**5.2. Graph representability of general disjointness constraints.** We show that the graph representability of general disjointness constraints is coNP-complete.

THEOREM 5.2. *Let $d$ be a constraint in DNF with respect to disjointness constraints; i.e., $d$ is in the form of $d_1 \vee \cdots \vee d_n$, where each $d_i$ is a conjunction of disjointness constraints. Then the graph representability of $d$ is coNP-complete.*

*Proof.* By Theorem 3.8, the problem is in coNP. To see the coNP-hardness, we reduce the modified tautology problem to the graph representability problem.

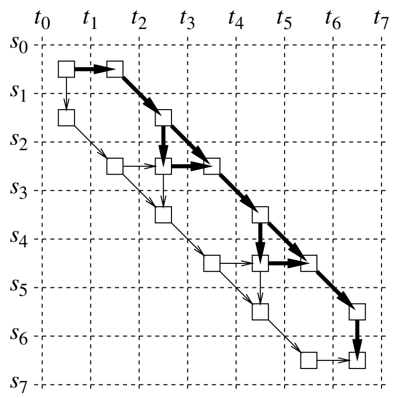


FIG. 12. $w_{\nu_{\text{true}}}$ *(thick arcs) and* $w_{\nu_{\text{false}}}$ *(thin arcs) in Theorem* 5.2 *(*$n = 3$*).*

Let $F = F_1 \vee \cdots \vee F_k$ be a DNF formula with $n$ variables $x_1, \ldots, x_n$ such that both $\nu_{\text{true}}$ and $\nu_{\text{false}}$ satisfy $F$. Let

$$S = \{s_0, \ldots, s_{2n+1}\}, \quad T = \{t_0, \ldots, t_{2n+1}\}.$$

Let $F'_l$ be the constraint obtained by replacing $x_i$ in $F_l$ by $[s_{2i}, s_{2i+1}] \not\pitchfork [t_{2i-1}, t_{2i}]$, and $\neg x_i$ by $[s_{2i-1}, s_{2i}] \not\pitchfork [t_{2i}, t_{2i+1}]$. Then define $d_l = F'_l \wedge d'$, where $d'$ is the same as the proof of Theorem 5.1. Last, define $d = d_1 \vee \cdots \vee d_k$.

In the same way as Theorem 5.1, associate a complete path $w_\nu$ on $G^*_{d'}$ with each interpretation $\nu$ of $F$. Then $\nu$ satisfies $F$ if and only if $\rho(w_\nu) \models d$. Therefore, $F$ is a tautology if and only if all the complete paths on $G^*_{d'}$ satisfy $d$. Note that $\rho(w_{\nu_{\text{true}}}) \models d$ and $\rho(w_{\nu_{\text{false}}}) \models d$ since both $\nu_{\text{true}}$ and $\nu_{\text{false}}$ satisfy $F$.

To complete the proof, we show that all the complete paths on $G^*_{d'}$ satisfy $d$ if and only if $d$ has a graph representation. For the *only if* part, suppose that all the complete paths on $G^*_{d'}$ satisfy $d$. Then, immediately from Definition 3.2, $G^*_{d'}$ is a graph representation of $d$. For the *if* part, suppose that $\rho(w) \not\models d$, where $w$ is a complete path on $G^*_{d'}$. Then, for every arc $a$ contained in $w$, there is another complete path $w_a$ (namely, $w_{\nu_{\text{true}}}$ or $w_{\nu_{\text{false}}}$; see Figure 12) that contains $a$ and $\rho(w_a) \models d$. Therefore, by Lemma 3.7, $d$ has no graph representation. $\square$

## 6. Comparison to the related works.

**6.1. Related works.** Temporal reasoning has been extensively studied mainly in the field of artificial intelligence. Allen [2] proposed the *interval algebra*, which can express the conjunction of any relation between two time intervals. Table 1 shows the 13 basic operators of the interval algebra. Every relation between two time intervals is represented by a disjunctive combination of some of these basic operators. For example, the disjointness of two intervals $I$ and $J$ is represented by $I(\mathsf{pp}^{-1}\mathsf{mm}^{-1})J$, i.e., either $I$ precedes $J$, $I$ is preceded by $J$, $I$ meets $J$, or $I$ is met by $J$. Unfortunately, many of the basic problems including the consistency (i.e., satisfiability) for the interval algebra are NP-hard [12]. Therefore, most of the researches aim to find tractable classes of temporal constraints.

One of the research directions is to weaken the expressive power of the interval algebra. Vilain and Kautz [12] proposed the *point algebra*, which can express the conjunction of any relationship between two time points. The point algebra is strictly

Table 1

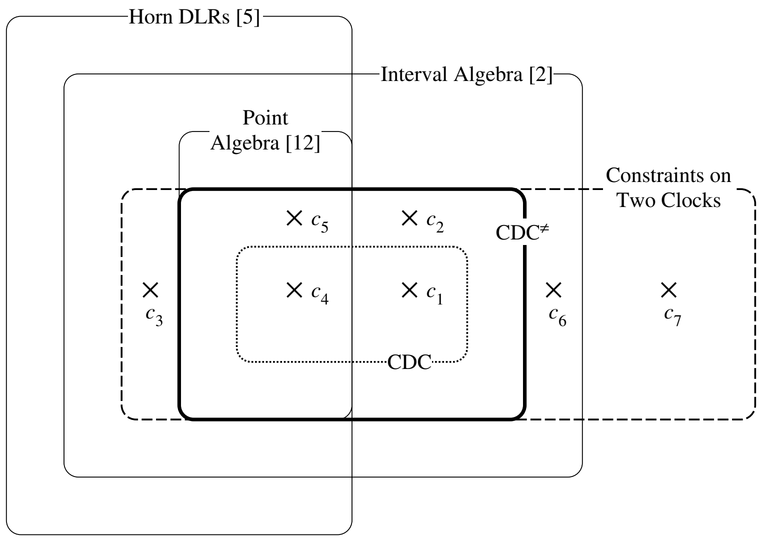
less expressive than the interval algebra, and the consistency of a given constraint $c$ is decidable in $O(|c|^2)$ time [13]. Golumbic and Shamir [3] investigated several subalgebras of the interval algebra for which the consistency is decidable in polynomial time. Nebel and Bürckert [9] proposed a subalgebra of the interval algebra called ORD-Horn, which contains the point algebra. They showed that ORD-Horn is a maximal tractable subalgebra. More precisely, the consistency of a given ORD-Horn constraint $c$ is decidable in $O(|c|^3)$ time, while the consistency for any subalgebra of the interval algebra which strictly contains ORD-Horn is NP-complete. Recently, all the tractable subalgebras of the interval algebra were discovered by Krokhin, Jeavons, and Jonsson [6].

On the other hand, some researches focus on classes incomparable to the interval algebra. Jonsson and Bäckström [5] proposed a class of temporal constraints called Horn DLRs. The class of Horn DLRs is a superclass of ORD-Horn and includes quantitative constraints (and therefore Horn DLRs are incomparable to the interval algebra). The consistency of Horn DLRs is decidable in polynomial time using a fast algorithm for the linear programming problem. Van der Meyden [11] studied the complexity of determining whether a conjunction of given constraints in the form of $s \leq t$ or $s' < t$ implies a given negation-free existentially quantified constraint.

**6.2. Comparison of the expressive power.** The relationship among classes of constraints is shown in Figure 13.

First of all, note that ORD-Horn and CDC$^{\neq}$ are incomparable. In a constraint of ORD-Horn, every relation between intervals must be expressed by a conjunction of *ORD-Horn clauses*. An ORD-Horn clause is a disjunction of at most one positive atomic constraint (i.e., $s \leq t$ or $s = t$) and an arbitrary number of negative atomic constraints (i.e., $s \neq t$). Since a disjointness constraint $c_1 = [s_1, s_2] \not\cap [t_1, t_2]$ is a disjunction of two positive atomic constraints, it is not in ORD-Horn. Also, $c_2 = (s_1 \neq t_1) \wedge ([s_1, s_2] \not\cap [t_1, t_2])$ is in CDC$^{\neq}$, but in neither CDC nor ORD-Horn. On the other hand, ORD-Horn includes constraints that are not in CDC$^{\neq}$. For example, $c_3 = (s_1 \neq t_1) \vee (s_2 \neq t_2)$ is in ORD-Horn but not in CDC$^{\neq}$. Also, ORD-Horn includes some of the constraints on more than two clocks, but CDC$^{\neq}$ never includes them.

Next, note that CDC$^{\neq}$ $\cap$ "ORD-Horn" = CDC$^{\neq}$ $\cap$ "point algebra". Any clause of a constraint in CDC$^{\neq}$ consists of one atomic constraint or two positive atomic constraints. Therefore, any clause of a constraint in CDC$^{\neq}$ $\cap$ "ORD-Horn" consists



"ORD-Horn" [9] = "Horn DLRs" ∩ "Interval Algebra"

FIG. 13. *Comparison of the expressive power of the classes of constraints.*

of one atomic constraint, and hence is expressible in the point algebra.

Class CDC and the point algebra have a nonempty intersection since it contains $c_4 = ([s_0, s_i] \not\pitchfork [t_j, t_n]) \equiv (s_i \leq t_j)$ as stated in section 4. On the other hand, $c_5 = (s_2 \neq t_4)$ is not in CDC because the minimum graph representation of $c_5$ (Figure 9) cannot be a subgraph of an intersection of graph representations of disjointness constraints (Figure 10).

Let $c_6 = ([s_0, s_2] \not\pitchfork [t_4, t_5]) \vee ([s_0, s_4] \not\pitchfork [t_6, t_7])$. Then

$$\begin{aligned} c_6 &\equiv (s_0 \geq t_5) \vee (s_2 \leq t_4) \vee (s_0 \geq t_7) \vee (s_4 \leq t_6) \\ &\equiv (s_2 \leq t_4) \vee (s_4 \leq t_6). \end{aligned}$$

This is not in CDC$^{\neq}$ because $c_6$ has no graph representation as shown in section 3. On the other hand, $c_6$ is in the interval algebra, i.e., $c_6 \equiv [s_2, s_4](\mathsf{pmodd}^{-1}\mathsf{ss}^{-1}\mathsf{ff}^{-1}\equiv)[t_4, t_6]$.

Last, $c_7 = ([s_1, s_2] \not\pitchfork [t_1, t_2]) \vee ([s_3, s_4] \not\pitchfork [t_3, t_4])$ is a constraint on two clocks but not in the interval algebra, because in the interval algebra, disjunction of relations of distinct pairs of intervals is not expressible.

After the first submission of this paper, all the maximal tractable subalgebras of the interval algebra were identified by Krokhin, Jeavons, and Jonsson [6]. CDC$^{\neq}$ is incomparable to any of the tractable subalgebras. The outline of the proof is as follows. Let $A$ be a subalgebra of the interval algebra that can express all the constraints in CDC$^{\neq}$. $A$ must contain $(\mathsf{pp}^{-1}\mathsf{mm}^{-1})$ in order to express $\not\pitchfork$. Also $A$ must contain $(\mathsf{m})$ or $(\mathsf{m}^{-1})$ in order to express adjacency of intervals (e.g., $[s_0, s_1]$ and $[s_1, s_2]$ in Example 1.1). Then, from the definitions of the discovered tractable subalgebras (Table 3 of [6]), it is immediate that $A$ is not contained in any of the tractable subalgebras.

Recently, Krokhin and Jonsson [7] also found maximal tractable subclasses of Meiri's qualitative algebra [8]. The qualitative algebra contains all the relational

Table 2
*Basic point-interval operators.*

| | | |

| | | `  III` |
| p finishes I | `f` | `    p` |
| | | `  III` |
| p after I | `a` | `      p` |
| | | `  III` |

operators between points, between intervals, and between a point and an interval (see Table 2). CDC$^{\neq}$ is also incomparable with any of the known tractable subclasses of the qualitative algebra. The outline of the proof is as follows. Let $A'$ be a subclass of the qualitative algebra that can express all the constraints in CDC$^{\neq}$. First, it can be shown that $\not\cap$ is not expressible by using only point-point and point-interval operators. Therefore, $A'$ must contain $(\mathsf{pp}^{-1}\mathsf{mm}^{-1})$. Next, we can conclude that in order to express adjacency of intervals, either (1) $A'$ must contain either $(\mathsf{m})$ or $(\mathsf{m}^{-1})$; or (2) $A'$ must contain both $(\mathsf{s})$ and $(\mathsf{f})$. Then it is not difficult to see that $A'$ is not contained in any of the known tractable subclasses.

**7. Conclusions.** In this paper, we have studied temporal reasoning with respect to constraints on two concurrent sequences of events. We have introduced the notion of graph representations of constraints. If a graph representation of a given constraint $c$ can be constructed in polynomial time, then the consistency of $c$ is also decidable in polynomial time. We have proposed a subclass CDC$^{\neq}$ of constraints such that a graph representation of a constraint in CDC$^{\neq}$ can be constructed in polynomial time.

We have considered only the case in which the number of local clocks is *two*. However, this assumption is for simplicity. If the number of local clocks is an *arbitrary* constant, then the idea of graph representability is applicable and the consistency is decidable in polynomial time.

As future work, constraints on durations [10] and/or quantitative constraints on two concurrent sequences of events should be studied. First-order constraints on two concurrent sequences of events also remain to be investigated.

**Acknowledgments.** The authors would like to thank Mr. Tetsuya Murakami of Furukawa Electric Co., Ltd. for his helpful discussions. The authors are also grateful to the anonymous referees for their valuable suggestions and comments.

# TOP-DOWN ANALYSIS OF PATH COMPRESSION*

RAIMUND SEIDEL† AND MICHA SHARIR‡

**Abstract.** We present a new analysis of the worst-case cost of path compression, which is an operation that is used in various well-known "union-find" algorithms. In contrast to previous analyses which are essentially based on bottom-up approaches, our method proceeds top-down, yielding recurrence relations from which the various bounds arise naturally. In particular the famous quasi-linear bound involving the inverse Ackermann function can be derived without having to introduce the Ackermann function itself.

**Key words.** union-find problem, disjoint sets data structure, path compression, inverse Ackermann function

**AMS subject classifications.** 68P05, 68W40

**DOI.** 10.1137/S0097539703439088

**1. Introduction.** Path compression is used in a number of algorithms, most notably in various very natural solutions to the so-called union-find problem. This problem is basic enough to be covered in most introductory texts on algorithms; however, the performance analysis of the solutions is more often than not at best incomplete, if not omitted altogether. Already the definition of the function $\alpha$, the interesting constituent of the time bound, as a quasi inverse of the Ackermann function is complicated.

Let us briefly recall the union-find problem. It asks for the maintenance of a partition of a finite set $X$ and a representative element $\rho(A) \in A$ for each set $A$ participating in the partition. There are two operations: For $x \in X$ the query FIND$(x)$ is to determine the representative element $\rho(A_x)$, where $A_x$ is the set in the partition that contains $x$. For two sets $A$ and $B$ in the current partition the operation UNION$(\rho(A), \rho(B))$ is to change the partition, replacing $A$ and $B$ by their union and providing the new representative element $\rho(A \cup B)$.

A very natural solution of this union-find problem is to represent the partition as a forest of rooted trees on the node set $X$, where each tree represents a set of the partition and its root is the representative element of that set. The operation FIND$(x)$ is realized by traversing the path from $x$ to the root $\rho$ of its containing tree (just follow parent pointers) and reporting $\rho$. The operation UNION$(\rho(A), \rho(B))$ is realized by making $\rho(A)$ the parent of $\rho(B)$, or vice versa, thus combining the two trees. Note that a single parent pointer per node suffices to implement such forests.

The time thus necessary for a UNION-operation is constant, whereas for a FIND-operation it is proportional to the length of the path traversed. Thus it is advantageous to keep paths short. To this end it makes sense to be judicious in the UNION-operation

when deciding which of the two involved roots to make the new root. Choosing the one whose tree has the larger number of nodes is known as the *linking-by-weight* strategy; choosing the one with larger *rank* is known as the *linking-by-rank* strategy. Here "rank" is an integer associated with node $x$ that is initially 0 and that is increased by 1 whenever $x$ is made a parent to a node of equal rank.[1] In both strategies ties are broken arbitrarily.

Both strategies produce trees of at most logarithmic height. Thus a sequence of UNION- and $m$ FIND-operations takes at most $O(n+m\log n)$ time. Here $n=|X|$ and the initial partition consists of all singleton subsets of $X$. Note that at most $n-1$ UNION-operations can occur.

Another way of producing short find-paths is by so-called *path compression*: When performing a FIND-operation, make all nodes of the traversed path children of the root. This increases the running time of the FIND-operation only by a constant factor but may make the find-paths of subsequent operations shorter.

Analyzing the performance of algorithms employing path compression in combination with various linking strategies has a long history.

Fischer [2] showed a bound of $O(m\log\log n)$. Hopcroft and Ullman [5] proved an $O(m\log^* n)$ bound. Their approach was refined by Tarjan [7] to the so-called "multiple partition method" leading to a bound of $O(m\alpha_T(m,n))$, where

$$\alpha_T(m,n)=\min\{i\geq 1 \mid A(i,\lfloor m/n\rfloor)>\lceil\log_2 n\rceil\}$$

and $A$ is the "Ackermann function" defined by

$$\begin{aligned} A(1,j) &= 2^j && \text{for } j\geq 1,\\ A(i,1) &= A(i-1,2) && \text{for } i\geq 2,\\ A(i,j) &= A(i-1,A(i,j-1)) && \text{for } i,j\geq 2. \end{aligned}$$

Tarjan [8] also showed that this slightly superlinear bound was best possible for a reasonable, pointer-based model of computation. Later Fredman and Saks [3] proved the optimality of this bound also for the so-called cell probe model of computation. Kozen [6] simplified Tarjan's analysis of the upper bound. Later Tarjan [10] and also Harfst and Reingold [4] cast the existing analyses in terms of potential functions, a standard tool for the amortized analysis of algorithm performance. This type of analysis was taken into [1].

All the analyses so far have proceeded by low-level accounting and charging individual parent pointer changes to operations or nodes and bounding the grand total of those charges. In this paper we present an analysis that is based on a radically different approach. We proceed top-down and employ divide-and-conquer to derive recurrence relations from which the bounds follow. Our analysis yields rather precise bounds. For example, if $n=|X|<2^{66}$ and linking-by-rank and path compression are used, then any sequence of $m$ FIND-operations causes at most $\min\{m+4n, 2m+2n\}$ parent pointer changes.

## 2. The main lemma.

Let $\mathcal{F}$ be a forest of disjoint rooted trees on a finite node set $X$. Here we consider only paths $p$ in $\mathcal{F}$ that lead from some node $x$ to some ancestor $y$ of $x$. If $y$ is a root in $\mathcal{F}$, we refer to $p$ as a *rootpath*; otherwise we call it a *nonrootpath* and denote the parent of $y$ by $a(p)$.

[1] In other words the rank of $x$ is nothing but the height (number of edges on longest leaf-root path) of the tree rooted at $x$ *if no path compression had occurred.*

*Compressing a nonrootpath* $p$ means minimally changing $\mathcal{F}$ so that every node on $p$ has $a(p)$ as its parent. *Compressing a rootpath* $p$ means minimally changing $\mathcal{F}$ so that every node on $p$ becomes a root. We define the cost of such an operation to be the number of nodes that get a new parent; i.e., if $p$ is a nonrootpath with $d$ nodes, the cost is $d-1$, and if $p$ is a rootpath, the cost is 0. It is also convenient to allow empty paths involving no nodes. We classify them as rootpaths, and "compressing" them has cost 0.

Let $C = \left(p^{(i)}\right)_{1\le i\le M}$ be a sequence of paths along which compressions are performed starting with the initial forest $\mathcal{F}$; i.e., $\mathcal{F}_0 = \mathcal{F}$ and for $1 \le i \le M$ the path $p_i$ is in $\mathcal{F}_{i-1}$ and $\mathcal{F}_i$ is obtained from $\mathcal{F}_{i-1}$ by compressing $p_i$. Let $cost(C)$ denote the cumulative cost of $C$, i.e., the total number of times that some node gets a new parent. Finally we define the length of sequence $C$, $|C|$ for short, in a somewhat unorthodox way: We define $|C|$ to be the number of nonrootpaths in $C$.

Compared to the path compressions that arise in FIND-operations, the notion of path compression that we just defined is more general in two ways: First, we allow rootpath compressions. They make the presentation of our proofs simpler and play no other role. Second, we allow compressions of paths $p$ where $a(p)$ is not a root. This makes the union-find problem more static in the sense that the forest changes caused by UNION-operations can be ignored. This was already noted in [5] and [7] and is captured in the following lemma.

LEMMA 2.1. *Let $S$ be some sequence of* UNION- *and $m$* FIND-*operations on an initial partition of an $n$-element set $X$ into singletons. Let $T$ be the time necessary to execute $S$.*

*There is a forest $\mathcal{F}$ on $X$ and a sequence $C$ of $m$ path compressions, all involving nonrootpaths, so that $T = O(m + n + cost(C))$.*

*Proof.* (Sketch) For $\mathcal{F}$ consider the forest that is generated by performing just the UNION-operations of the sequence. The sequence of FIND-operations then defines a sequence of nonrootpaths in the corresponding forest. □

Thus we are interested in upper bounds for $cost(C)$ measured in terms of $|X|$ and $|C|$, the number of nonrootpath compressions in $C$.

Let us create a setup for divide-and-conquer. Consider a partition of the node set $X$ of $\mathcal{F}$ into a "bottom set" $X_b$ and a "top set" $X_t$. We call the pair $(X_b, X_t)$ a *dissection for* $\mathcal{F}$ iff $X_t$ is upwards closed in $\mathcal{F}$; i.e., if some node $x$ is in $X_t$, then every ancestor of $x$ in $\mathcal{F}$ must be in $X_t$ also. Note that a dissection $(X_b, X_t)$ cuts every path into two contiguous subpaths $p_b$ and $p_t$ consisting of the nodes on $p$ that are in $X_b$ and $X_t$, respectively. Either subpath may be empty. Also note that upward-closedness and hence also dissections are preserved under path compression. Let $\mathcal{F}(X_b)$ and $\mathcal{F}(X_t)$ be the subforests of $\mathcal{F}$ induced by the sets $X_b$ and $X_t$.

All our analyses hinge on the following main lemma.

LEMMA 2.2. *Let $C$ be a sequence of $|C|$ compress operations in a forest $\mathcal{F}$ with node set $X$. Let $(X_b, X_t)$ be an arbitrary dissection for $\mathcal{F}$.*

*There are sequences $C_b$ and $C_t$ of compress operations for $\mathcal{F}(X_b)$ and $\mathcal{F}(X_t)$, respectively, with $|C_b| + |C_t| \le |C|$ and*

$$cost(C) \le cost(C_b) + cost(C_t) + |X_b| + |C_t| .$$

*Proof.* Let $C = \left(p^{(i)}\right)_{1\le i\le M}$ be the sequence of paths to be compressed and let $\left(\mathcal{F}^{(i)}\right)_{0\le i\le M}$ be the resulting sequence of forests.

Let $(X_b, X_t)$ be a dissection of $\mathcal{F} = \mathcal{F}^{(0)}$ and let $\mathcal{F}_b = \mathcal{F}(X_b)$ and $\mathcal{F}_t = \mathcal{F}(X_t)$ be the induced bottom and top forests.

First, we define the postulated path sequences $C_b$ and $C_t$. Intuitively they are what one gets when recording the compression sequence $C$ executed with the nodes in $X_t$ (resp., $X_b$) hidden. More formally, define $C_b = \big(p_b^{(i)}\big)_{1\le i\le M}$ and $C_t = \big(p_t^{(i)}\big)_{1\le i\le M}$. It is easy to check inductively that for each $1 \le i \le M$ the path $p_b^{(i)}$ occurs in $\mathcal{F}^{(i-1)}(X_b)$, and compressing it produces $\mathcal{F}^{(i)}(X_b)$. Thus $C_b$ is a compression sequence for $\mathcal{F}_b$. Analogously $C_t$ is a compression sequence for $\mathcal{F}_t$.

Next we establish the required bound $|C_b|+|C_t| \le |C|$. If $p^{(i)}$ is a nonrootpath in $\mathcal{F}^{(i-1)}$, then at most one of $p_b^{(i)}$ and $p_t^{(i)}$ is a nonrootpath in its respective forest. If $p^{(i)}$ is a rootpath in $\mathcal{F}^{(i-1)}$, then both $p_b^{(i)}$ and $p_t^{(i)}$ are rootpaths. Thus $|C_b|+|C_t| \le |C|$. Note that here it is crucial that only nonrootpaths contribute to the length of a sequence.

Finally we show the postulated cost inequality. If a node from $X_t$ gets a new parent (necessarily from $X_t$) when compressing path $p^{(i)}$, then exactly the same thing happens when compressing $p_t^{(i)}$. Thus the number of those types of parent changes is given by $\mathit{cost}(C_t)$. Likewise the number of times that a node from $X_b$ gets a new parent from $X_b$ is given by $\mathit{cost}(C_b)$.

A node from $X_b$ getting a new parent which is in $X_t$ can happen only when compressing a nonrootpath $p^{(i)}$ for which $p_b^{(i)}$ is a nonempty rootpath in the bottom forest. In this case all but the topmost node on $p_b^{(i)}$ get a parent from $X_t$ for the first time, which can happen to each node in $X_b$ at most once. The topmost node gets a new parent again from $X_t$ only if $p_t^{(i)}$ is nonempty, which means $p_t^{(i)}$ is a nonrootpath (since $p^{(i)}$ is a nonrootpath). So this type of event can happen at most $|C_t|$ times. (Here it is crucial that only nonrootpaths contribute to the length of a sequence.) Since $X_t$ is upwards closed, no node in $X_t$ can get a parent from $X_b$, and thus the total number of parent changes, i.e., $\mathit{cost}(C)$, is bounded by

$$\mathit{cost}(C_b) + \mathit{cost}(C_t) + |X_b| + |C_t|\,. \qquad \square$$

**3. Arbitrary linking.** Let $f(m,n)$ denote the maximum possible cost for a path compression sequence of length $m$ in a forest of $n$ nodes. By Lemma 2.1 the value $f(m,n)$ yields an asymptotic upper bound for the running time of $m$ union-find operations in a universe of $n$ elements if path compression and *arbitrary* linking is used.

Using our main lemma it is straightforward to give a rough argument that something like $f(m,n) \le (m+n/2)\log_2 n$ must hold: For a given compression sequence $C$ of length $m$, choose a dissection $(X_b, X_t)$, where both $X_b$ and $X_t$ have size about $n/2$. Using induction, the inequality of the main lemma then yields

$$\begin{aligned}\mathit{cost}(C) &\le (|C_b| + n/4)\log_2(n/2) + (|C_t| + n/4)\log_2(n/2) + n/2 + |C_t|\\ &\le (m+n/2)\log_2(n/2) + n/2 + m\\ &\le (m+n/2)\log_2 n\,.\end{aligned}$$

This argument ignores rounding issues. It can be made precise by setting $|X_b| = \lfloor n/2\rfloor$ and $|X_t| = \lceil n/2\rceil$, replacing $\log_2()$ by $\lceil\log_2()\rceil$, and noting that $\lceil\log_2\lceil n/2\rceil\rceil \le \lceil\log_2 n\rceil - 1$ for integers $n > 1$.

For large $m$ this bound can be improved to

$$f(m,n) \le (2m+n)\log_{\lceil m/n\rceil+1} n\,,$$

which is achieved by setting $k = \lceil m/n\rceil + 1$ in the following claim.

CLAIM 3.1. *For any integer $k > 1$ we have $f(m,n) \le (m + (k-1)n)\lceil \log_k n \rceil$.*

*Proof.* The bound clearly holds if $n \le k$, since each node can get a new parent at most $n-2$ times. So assume $n > k$ and let $C$ be some sequence of $m$ compress operations in a forest with $n$ nodes. Let $(X_b, X_t)$ be a dissection with $n_t = |X_t| = \lceil n/k \rceil$ and $n_b = |X_b|$. Let $C_t$ and $C_b$ be the compression sequences asserted in the main lemma and let $m_t$ and $m_b$ be their respective sizes. Then, using induction, the inequality of the main lemma implies

$$\begin{aligned} cost(C) &\le (m_b + (k-1)n_b)\underbrace{\lceil \log_k n_b \rceil}_{\le \lceil \log_k n \rceil} + (m_t + (k-1)n_t)\underbrace{\lceil \log_k n_t \rceil}_{= \lceil \log_k n \rceil - 1} + n_b + m_t \\ &= (m_t + m_b + (k-1)(n_t + n_b))\lceil \log_k n \rceil - m_t - (k-1)n_t + n_b + m_t \\ &\le (m + (k-1)n)\lceil \log_k n \rceil , \end{aligned}$$

where the last inequality follows from the fact that $n_b \le (k-1)n_t$ by construction. ◻

A bound of this form was first proved by Tarjan and van Leeuwen in [9].

**4. Linking by rank.** For every node $x$ in a forest $\mathcal{F}$, define its rank rank$(x)$ to be the height of the subtree rooted at $x$, where the height of a one-node tree is 0. We call $\mathcal{F}$ a *rank-balanced forest*, or simply *rank forest*, if for each node $x$ in $\mathcal{F}$ the following property holds: For each $i$ with $0 \le i <$ rank$(x)$ node $x$ has at least one child $y_i$ with rank$(y_i) = i$.

Rank forests arise in union-find algorithms that employ the linking-by-rank strategy. It is easy to prove by induction that in such a forest every node of rank $k$ must be the root of a subtree of size at least $2^k$. Thus the maximum rank that occurs is at most $\lfloor \log_2 n \rfloor$, where $n$ is the number of nodes. The following inheritance lemma is important for our purposes. Its straightforward proof is left to the reader.

LEMMA 4.1. *Let $\mathcal{F}$ be a rank forest with node set $X$ and maximum rank $r$. Let $s$ be some integer, let $X_{\le s}$ be the set of nodes with rank at most $s$, and let $X_{>s}$ be the set of nodes with rank exceeding $s$. Then*

(i) *$(X_{\le s}, X_{>s})$ is a dissection;*
(ii) *$\mathcal{F}(X_{\le s})$ is a rank forest with maximum rank at most $s$;*
(iii) *$\mathcal{F}(X_{>s})$ is a rank forest with maximum rank at most $r - s - 1$;*
(iv) *$|X_{>s}| \le |X|/2^{s+1}$.*

Let $f(m,n,r)$ be the maximum cost for a sequence of path compressions of length $m$ in a rank forest with $n$ nodes and maximum rank $r$. By Lemma 2.1 $f(m,n,\lfloor \log_2 n \rfloor)$ yields an asymptotic upper bound for the running time of $m$ union-find operations in a universe of $n$ elements if path compression and linking-by-rank are used.

Before we prove the best possible bound for $f(m,n,r)$, let us first show how even very simple applications of our main lemma already yield surprisingly good bounds. We mainly want to convey some intuition here, so for the sake of clarity we will be imprecise and ignore rounding issues. The formal proofs in the second part of this section will be precise.

First of all note that trivially the bound $f(m,n,r) \le (r-1)n < rn =: P(r,n)$ holds, since every node can get a new parent at most $r-1$ times, as the new parent has larger rank than the previous parent.

Now consider a compression sequence $C$ of length $m$ in a rank forest with $n$ nodes and maximum rank $r$. Apply the main lemma to the dissection $(X_{\le s}, X_{>s})$ with $s = \log_2 r$. With this choice of $s$ the top forest contains so few nodes that the trivial

$P(r,n)$ bound already yields that the cost of the top sequence $C_t$ is at most $n$:

$$\begin{aligned}\mathit{cost}(C_t) &\le f(|C_t|, |X_{>s}|, r-s-1) \le P(r-s-1, |X_{>s}|)\\ &= (r-s-1)\cdot|X_{>s}| \le r\cdot n/2^{s+1} \le r\cdot n/2^{\log_2 r} = n\,.\end{aligned}$$

From the main lemma we now get

$$\mathit{cost}(C) \le \mathit{cost}(C_b) + \underbrace{\mathit{cost}(C_t)}_{\le n} + \underbrace{|X_b|}_{\le n} + \underbrace{|C_t|}_{\le |C|-|C_b|}\quad,$$

yielding

(*) $$\mathit{cost}(C) \le \mathit{cost}(C_b) - |C_b| + 2n + |C|\,,$$

where $C_b$ is a compression sequence in a rank forest with fewer than $n$ nodes and of maximum rank $s = \log_2 r$.

Using the trivial bound $P(n,s) = n\cdot s = n\log_2 r$ to bound $\mathit{cost}(C_b)$ in (*) then yields that $\mathit{cost}(C) \le m + 2n + n\log_2 r$.

Note that since $r \le \log_2 n$ this already implies an $O(m + n\log\log n)$ bound for union-find with path compression and linking-by-rank. But of course the natural and better thing to do is to apply the inequality (*) itself to bound $\mathit{cost}(C_b)$, which yields

$$\begin{aligned}\mathit{cost}(C) &\le (\mathit{cost}(C_{bb}) - |C_{bb}| + 2n + |C_b|) - |C_b| + 2n + |C|\\ &= \mathit{cost}(C_{bb}) - |C_{bb}| + 4n + |C|\,,\end{aligned}$$

where $C_{bb}$ is now a compression sequence in a rank forest with fewer than $n$ nodes and of maximum rank $\log_2 s = \log_2\log_2 r$. Of course inequality (*) can now be used to bound $\mathit{cost}(C_{bb})$, and this can be done again and again, yielding bounds of the form

$$\mathit{cost}(C) \le \mathit{cost}(C') - |C'| + 2jn + |C|\,,$$

where $C'$ is a compression sequence in a rank forest with fewer than $n$ nodes and of maximum rank

$$\underbrace{\log\cdots\log}_{j\text{ times}} r = \log^{(j)} r.$$

By definition, for $j = \log^* r$ we have $\log^{(j)} r \le 1$ and we are dealing with a rank forest of maximum rank 1. In such a forest any compression sequence has cost 0, and thus we get

$$\mathit{cost}(C) \le 2n\log^* r + |C|\,,$$

which already implies an $O(m+n\log^* n)$ bound for union-find with path compression and linking-by-rank.

But this is not the end of the story. We now know the bound $f(m,n,r) \le m + 2n\log^* r$. Knowing this bound, we can start over to bound the cost of $C$ and apply the main lemma to the dissection $(X_{\le s}, X_{>s})$ with $s = \log\log^* r$. Again with this choice of $s$ the top forest contains so few nodes that the bound already yields that the cost of the top sequence $C_t$ is at most $n + |C_t|$, yielding a bound analogous to (*) of the form

(**) $$\mathit{cost}(C) \le \mathit{cost}(C_b) - 2|C_b| + 2n + 2|C|\,,$$

where $C_b$ is a compression sequence in a rank forest with fewer than $n$ nodes and of maximum rank $s = \log\log^* r$. Inequality (**) can then be iterated again, yielding the bound

$$\mathit{cost}(C) \leq 2nL(r) + 2|C|\,,$$

where $L(r)$ counts how often $\log\log^*$ can be applied to $r$ until it is reduced to at most 1. This gives a new bound for $f(m,n,r)$ and the whole process can be repeated again and again.

To formalize this we need two definitions involving integer functions, the first of which is standard. Let $g : \mathbb{N} \to \mathbb{N}$ be a function with $g(n) < n$ for $n > 0$. Define the functions $g^* : \mathbb{N} \to \mathbb{N}$ and $g^\diamond : \mathbb{N} \to \mathbb{N}$ as follows:

$$g^*(r) = \begin{cases} 0 & \text{if } r \leq 1, \\ 1 + g^*(g(r)) & \text{if } r > 1, \end{cases}$$

$$g^\diamond(r) = \begin{cases} g(r) & \text{if } g(r) \leq 1, \\ 1 + g^\diamond(\lceil \log_2 g(r) \rceil) & \text{if } g(r) > 1. \end{cases}$$

Note that $g^\diamond$ is essentially $(\log \circ g)^*$.

With these definitions we can state and prove the following shifting lemma.

LEMMA 4.2. *Assume there is some $k \geq 0$ and some nondecreasing function $g : \mathbb{N} \to \mathbb{N}$ with $g(r) < r$ for $r > 0$ so that*

$$f(m,n,r) \leq km + 2ng(r)$$

*holds for all $m,n,r$. Then the following bound also holds for all $m,n,r$:*

$$f(m,n,r) \leq (k+1)m + 2ng^\diamond(r)\,.$$

*Proof.* We proceed by induction on $r$. The statement clearly holds if $g(r) \leq 1$, since in these cases we have $g^\diamond(r) = g(r) = 0$.

So assume $r$ is such that $g(r) > 1$ and let $C$ be some compression sequence of length $m$ in a rank forest $\mathcal{F}$ with $n$ nodes and maximum rank $r$. Let $s = \lceil \log_2 g(r) \rceil$ and let $(X_{\leq s}, X_{>s})$ be the dissection described in Lemma 4.1. Note that $s < r$ since $g(r) < r$. Put $n_b = |X_{\leq s}|$ and $n_t = |X_{>s}|$. Let $C_b$ and $C_t$ be the compression sequences asserted in the main lemma and put $m_b = |C_b|$ and $m_t = |C_t|$. By the main lemma we have

$$\mathit{cost}(C) \leq \mathit{cost}(C_b) + \mathit{cost}(C_t) + n_b + m_t\,.$$

The bottom forest $\mathcal{F}(X_{\leq s})$ is a rank forest of maximum rank $s < r$. Using the inductive assumption we get

$$\begin{aligned} \mathit{cost}(C_b) &\leq (k+1)m_b + 2n_b g^\diamond(s) \\ &\leq (k+1)m_b + 2n\,\underbrace{g^\diamond(\lceil \log_2 g(r) \rceil)}_{g^\diamond(r)-1} \\ &= (k+1)m_b + 2ng^\diamond(r) - 2n\,. \end{aligned}$$

The top forest $\mathcal{F}(X_{>s})$ is a rank forest of maximum rank $r - s - 1$ with

$$n_t \leq n/2^{s+1} = n/2^{1+\lceil \log_2 g(r) \rceil} \leq n/(2g(r))$$

nodes. Using the assumption of the lemma and the fact that $g$ is nondecreasing, we therefore get

$$cost(C_t) \le km_t + 2n_t g(r-s-1) \le km_t + n\,.$$

Putting things together, we get

$$\begin{aligned} cost(C) &\le \Big((k+1)m_b + 2ng^{\diamond}(r) - 2n\Big) + \Big(km_t + n\Big) + n_b + m_t \\ &\le (k+1)(m_b+m_t) + 2ng^{\diamond}(r) \\ &= (k+1)m + 2ng^{\diamond}(r)\,. \end{aligned}$$

Since this is true for any sequence $C$ of length $m$ in a rank forest with $n$ nodes and maximum rank $r$, we get the desired bound

$$f(m,n,r) \le (k+1)m + 2ng^{\diamond}(r)\,. \qquad \square$$

The shifting lemma makes it possible to take a simple but loose bound for $f(m,n,r)$ and derive from it a whole sequence of valid bounds. From these bounds we then choose a particularly good one.

COROLLARY 4.3. *Let the integer functions $J_k$ with $k \in \mathbb{N}$ be defined as*

$$J_0(r) = \lceil (r-1)/2 \rceil \quad \textit{and} \quad J_k(r) = J^{\diamond}_{k-1}(r) \textit{ for } k > 0.$$

*Then for each $k \in \mathbb{N}$ we have*

$$f(m,n,r) \le km + 2nJ_k(r)\,.$$

*Proof.* It is easy to show by induction that for each $k$ the function $J_k$ is nondecreasing and satisfies $J_k(r) < r$ for all $r > 0$.

Since a node in a rank forest of maximum rank $r$ has at most $r$ ancestors (one of which is its initial parent) it can get a new parent at most $r-1$ times. Therefore

$$f(m,n,r) \le n \cdot (r-1) \le 2nJ_0(r)$$

holds. For $k > 0$ the stated bound now follows by induction using the shifting lemma. $\square$

The $J_k$'s are very slowly growing functions even for small $k$'s. The reader may check that $J_1(r) \le 2$ and $J_2(r) \le 1$ for $r \le 65$. Since in a rank forest with $n$ nodes and of maximum rank $r$ we have $r \le \lfloor \log_2 n \rfloor$, we therefore get for $n < 2^{66}$ a bound of

$$f(m,n,r) \le \min\{m + 4n, 2m + 2n\}\,.$$

For general $m$ and $n$ we now want to choose from the infinitely many bounds provided by the $J_k$'s one that is particularly good. To this end define

$$\alpha_S(m,n) = \min\{k \in \mathbb{N} | J_k(\lfloor \log_2 n \rfloor) \le 1 + m/n\}\,.$$

Using the corollary we then get the following.

THEOREM 4.4. *For all $m, n, r$ we have $f(m,n,r) \le (\alpha_S(m,n) + 2)m + 2n$.*

Invoking Lemma 2.1 we immediately get the following.

THEOREM 4.5. *Performing a sequence of* UNION-*operations and* $m$ FIND-*operations on a set of size* $n$ *using union-by-rank and path compression requires at most* $O(n + m\alpha_S(m, n))$ *time.*

The reader may wonder how the function $\alpha_S(m, n)$ defined here relates to Tarjan's initial definition of the inverse Ackermann function $\alpha_T(m, n)$. In analogy to the formalism used in this paper, $\alpha_T$ can be defined as follows:

$$\alpha_T(m, n) = \min\{k \geq 1 \mid T_k(\lfloor \log_2 n \rfloor) < m/n\},$$

where

$$T_1(r) = \lfloor \log_2 r \rfloor \quad \text{and} \quad T_k(r) = T^{\bullet}_{k-1}(r) \text{ for } k > 1,$$

and

$$g^{\bullet}(r) = \begin{cases} 0 & \text{if } r \leq 2 \quad \text{(in contrast to 1 in the definition of } g^*\text{)}, \\ 1 + g^{\bullet}(g(r)) & \text{if } r > 2. \end{cases}$$

One can see that the differences between $\alpha_S$ and $\alpha_T$ are minor, and one can show that asymptotically they are equivalent.

## 5. Linking by weight.

Besides linking-by-rank, the method of linking-by-weight is another standard strategy in union-find algorithms. Applying our top-down approach to its analysis is a bit less straightforward than in the case of linking by rank that we just saw. The main technical issue is to create a setting where some analogue of Lemma 4.1 holds.

Let $\mathcal{F}$ be a forest, and for each node $x$ in $\mathcal{F}$ let $T_x$ be the subtree rooted at $x$, let $h_x$ be the height of $T_x$, and let $w(x)$ be some positive integer weight function on the nodes $x$ of $\mathcal{F}$. For each node $x$ define $W(x) = \sum_{y \text{ node in } T_x} w(y)$. We call $\mathcal{F}$ a *weight-balanced forest* iff for every node $x$ in $\mathcal{F}$ with parent $y$ we have $W(y) \geq 2W(x)$. We say such a forest is of type $(\mu, h, W)$ iff

(i) $w(x) \geq 2^\mu$ for every leaf $x$,

(ii) $h_x \leq h$ for each node $x$,

(iii) $\sum_{y \text{ node in } \mathcal{F}} w(y) \leq W$.

Note that any forest created by linking-by-weight with $n$ initial nodes, each of weight 1, is a weight-balanced forest of type $(0, \lfloor \log_2 n \rfloor, n)$.

LEMMA 5.1. *Let* $\mathcal{F}$ *be a weight-balanced forest with node set* $X$ *and node weight function* $w$ *and let* $\mathcal{F}$ *be of type* $(\mu, h, W)$. *Let* $s$ *be some integer, let* $X_{\leq s}$ *be the set of the nodes* $x$ *with* $h_x \leq s$, *and let* $X_{>s}$ *be the set of nodes with* $h_x > s$. *Define a new weight function*

$$w'(x) = \begin{cases} w(x) & \textit{if } x \in X_{\leq s}, \\ w(x) + \sum_{y \in X_{\leq s} \textit{ child of } x} W(y) & \textit{if } x \in X_{>s}. \end{cases}$$

*The following hold:*

(i) $(X_{\leq s}, X_{>s})$ *is a dissection.*

(ii) $\mathcal{F}(X_{\leq s})$ *with weight function* $w'$ *is a weight-balanced forest of type* $(\mu, s, W)$.

(iii) $\mathcal{F}(X_{>s})$ *with weight function* $w'$ *is a weight-balanced forest of type* $(\mu + s + 1, h - s - 1, W)$.

(iv) $|X_{\leq s}| \leq |X| < 2W/2^\mu$ *and* $|X_{>s}| < 2W/2^{\mu+s+1}$.

*Proof.* Points (i) and (ii) are trivial. Point (iii) follows from the property $W(\textit{parent}(x)) \geq 2W(x)$ and from the fact that the definition of the new weights

$w'()$ implies that for each node $x \in X_t$ the value $W'(x)$, defined with respect to $\mathcal{F}(X_{>s})$, coincides with $W(x)$ defined with respect to $\mathcal{F}$.

For point (iv) it suffices to show that the number of nodes in a weight-balanced forest $\mathcal{F}$ of type $(\mu, h, W)$ is less than $2W/2^{\mu}$. For each $i \in \mathbb{N}$ let $N_i = \{x \text{ node in } \mathcal{F} | h_x = i\}$ and let $W_i = \sum_{x \in N_i} W(x)$. Note that $W_i \leq W$ for each $i$. Since for each $x \in N_i$ we have $W(x) \geq 2^{\mu+i}$ (a consequence of the property $W(\mathit{parent}(x)) \geq 2W(x)$), we get

$$|N_i| \leq W_i/2^{\mu+i} \leq W/2^{\mu+i}.$$

Summing over all $i$ yields the desired bound on the number of nodes in $\mathcal{F}$. $\square$

Let $f(m, \mu, h, W)$ denote the maximum cost for a sequence of $m$ path compressions in a weight-balanced forest of type $(\mu, h, W)$. Again a shifting lemma holds.

Lemma 5.2. *Assume there is some $k \geq 0$ and some nondecreasing function $g : \mathbb{N} \to \mathbb{N}$ with $g(h) < h$ for $h > 0$ so that*

$$f(m, \mu, h, W) \leq km + 4(W/2^{\mu})g(h)$$

*holds for all $m, \mu, h, W$. Then also the following bound holds for all $m, \mu, h, W$:*

$$f(m, \mu, h, W) \leq (k+1)m + 4(W/2^{\mu})g^{\diamond}(h).$$

The proof proceeds in the same way as the proof of Lemma 4.2, using the dissection properties described in Lemma 5.1 instead of the ones described in Lemma 4.1, and with $h$ playing the role of $r$.

We can now conclude that

$$f(m, \mu, h, W) \leq km + 4(W/2^{\mu})J_k(h)$$

for every $k \in \mathbb{N}$.

As already noted, in forests as they arise in union-find algorithms with linking-by-weight, we have $w(x) = 1$ for each of the $n$ nodes, and hence $\mu = 0$, $W = n$, and $h \leq \log_2 n$. Thus we get the following.

Theorem 5.3. *A sequence of $m$ path compressions in a forest of $n$ nodes as it arises in union-find algorithms with linking-by-weight has cost at most*

$$(\alpha_S(m, n) + 4)m + 4n.$$

Again invoking Lemma 2.1 we immediately get the following.

Theorem 5.4. *Performing a sequence of* Union*-operations and $m$* Find*-operations on a set of size $n$ using union-by-weight and path compression requires at most $O(n + m\alpha_S(m, n))$ time.*

## 6. Open problems.

Can this top-down analysis method be made to work also for variants of path compression such as path compaction (see [9])? Most likely this will require some additional ideas, because, in contrast to compression, the compaction of rootpaths is nontrivial and can incur costs.

Another question is whether such a top-down approach be used to prove lower bounds involving the inverse Ackermann function.

# PSEUDO-LINE ARRANGEMENTS: DUALITY, ALGORITHMS, AND APPLICATIONS[*]

PANKAJ K. AGARWAL[†] AND MICHA SHARIR[‡]

**Abstract.** A finite collection of $x$-monotone unbounded Jordan curves in the plane is called a family of *pseudo-lines* if every pair of curves intersect in at most one point, and the two curves cross each other there. Let $L$ be such a collection of $n$ pseudo-lines, and let $P$ be a set of $m$ points in $\mathbb{R}^2$. Extending a result of Goodman [*Discrete Math.*, 32 (1980), pp. 27–35], we define a *duality* transform that maps $L$ to a set $L^*$ of points in $\mathbb{R}^2$ and $P$ to a set $P^*$ of ($x$-monotone) pseudo-lines in $\mathbb{R}^2$, so that the incidence and the "above-below" relations between the points and the pseudo-lines are preserved. We present an efficient algorithm for computing the dual arrangement $\mathcal{A}(P^*)$ under an appropriate model of computation.

We also present a dynamic data structure for reporting, in $O(m^\varepsilon + k)$ time, all $k$ points of $P$ that lie below a query arc, which is either a circular arc or a portion of the graph of a polynomial of fixed degree. This result is needed for computing the dual arrangement for certain classes of pseudo-lines arising in several applications, but is also interesting in its own right. We present a few applications of our dual arrangement algorithm, such as computing incidences between points and pseudo-lines and computing a subset of faces in a pseudo-line arrangement.

Next, we present an efficient algorithm for cutting a set of circles into arcs so that every pair of arcs intersect in at most one point, i.e., the resulting arcs constitute a collection of *pseudo-segments*. By combining this algorithm with our algorithm for computing the dual arrangement of pseudo-lines, we obtain efficient algorithms for several problems involving arrangements of circles or circular arcs, such as reporting or counting incidences between points and circles and computing a set of marked faces in arrangements of circles.

## 1. Introduction.

The *arrangement* of a finite collection $\Gamma$ of geometric curves or surfaces in $\mathbb{R}^d$, denoted as $\mathcal{A}(\Gamma)$, is the decomposition of the space into relatively open connected cells of dimensions $0, \ldots, d$ induced by $\Gamma$, where each cell is a maximal connected set of points lying in the intersection of a fixed subset of $\Gamma$ and avoiding all other elements of $\Gamma$. Besides being interesting in their own right due to the rich geometric, combinatorial, algebraic, and topological structures that they possess, arrangements also lie at the heart of numerous geometric problems arising in a wide range of applications, including robotics, computer graphics, molecular modeling, and computer vision. The study of arrangements of lines and hyperplanes has a long, rich

history. A summary of early work on arrangements can be found in [27, 28]. Although hyperplane arrangements already possess a rich structure, many applications (e.g., motion-planning in robotics and molecular modeling) call for a systematic study of arrangements of curved arcs in the plane and of curved surface patches in higher dimensions. There has been considerable progress in this area in the last two decades; see [10] for a review of recent results.

A collection $L$ of $n$ unbounded Jordan curves is called a family of *pseudo-lines* if every pair of curves intersect in at most one point and the two curves cross each other there. Arrangements of pseudo-lines were probably first studied by Levi [32]; see [23, 26, 28] for known results on pseudo-line arrangements. The work by Goodman and Pollack on allowable sequences [26] shows that any arrangement of pseudo-lines can be transformed into an arrangement of $x$-monotone pseudo-lines that is isomorphic to the original one. Such a transformation, however, is not efficient for the algorithms that we seek to develop, and we will thus confine our analysis to a priori given $x$-monotone pseudo-lines. For such pseudo-lines, the above-below relation between points and pseudo-lines, which will be used a lot in our analysis, is naturally defined. Many of the combinatorial results related to arrangements of lines (e.g., complexity of a single face, complexity of many faces, complexity of a level, incidences with a given set of points, etc.) hold for arrangements of pseudo-lines as well.

It has been shown [9, 11, 15, 16, 42] that various families of arcs (e.g., circular, parabolic, or graphs of polynomials of fixed degree) can be converted into a family of *pseudo-segments*, that is, subarcs with the property that each pair intersect at most once, by cutting the original arcs into a subquadratic number of pieces. Achieving this property with a quadratic number of cuts is trivial. Chan [15] has also shown that a collection of $N$ $x$-monotone pseudo-segments can be cut further into $O(N \log N)$ subarcs, each of which can be extended into an unbounded $x$-monotone curve, so that these curves constitute a family of pseudo-lines; the resulting subarcs are referred to as *extendible pseudo-segments*. One can then use the close relationship between line and pseudo-line arrangements to solve a variety of problems involving arrangements of arcs; see [2, 9, 11, 15, 42].

In this paper, we focus on algorithmic problems involving arrangements of pseudo-lines in the plane. These problems are much less studied than the corresponding combinatorial problems. Of course, one has to assume a reasonable representation of the given pseudo-lines in order to develop efficient algorithms for their manipulation. We therefore assume, for example, that the given pseudo-lines are algebraic (or semi-algebraic) curves of fixed maximum degree, and that our model of computation allows us to perform, in constant time, exact computations involving any constant number of such curves, such as computing the intersection point of a pair of pseudo-lines. However, even with these assumptions, several algorithms for line arrangements do not extend routinely to pseudo-line arrangements. A stumbling block in many of these algorithms, when we try to extend them to the case of pseudo-lines, is that they rely on some kind of a *duality* transform that maps lines to points and points to lines. Typically, one uses the duality that maps a line $\ell : y = ax + b$ to a point $\ell^* = (a, b)$ and a point $p = (\alpha, \beta)$ to the line $p^* : y = -\alpha x + \beta$ [20]. Note that $\ell$ passes above (resp., below, through) $p$ if and only if $\ell^*$ lies above (resp., below, on) $p^*$.

Burr, Grünbaum, and Sloane [14] had raised the question of whether a similar dual transform exists for pseudo-lines. Goodman [22], based on his work with Pollack on allowable sequences [24, 25, 26], defined a dual transform for (not necessarily $x$-monotone) pseudo-lines in the projective plane that preserves the incidence relation. That is, given a set $L$ of $n$ pseudo-lines and a set $P$ of $m$ points in $\mathbb{R}^2$, the transform yields a set $L^*$ of $n$ points and a set $P^*$ of $m$ pseudo-lines, so that a point $p$ of $P$ lies on a pseudo-line $\ell \in L$ if and only if the dual point $\ell^*$ lies on the dual pseudo-line $p^*$. Goodman's construction has several disadvantages from an algorithmic point of view. First, his construction is defined in the projective plane, and, consequently, it does not (and cannot, without considerable modifications) handle the above-below relation. A more significant problem, from the algorithmic point of view, is that his construction requires that for each pair of the given points, there exists an input pseudo-line passing through this pair. Although the existence of such a pseudo-line follows from the classical result of Levi [32], known as the *Levi enlargement lemma*, computing all these connecting pseudo-lines seems to be a highly nontrivial (and certainly inefficient) task.

We define a different dual transform, which may be regarded as an extension of Goodman's construction, and which overcomes the technical problems mentioned above. Suppose we have a data structure for storing the $m$ points of $P$ that supports the following operations, each in at most $f(m)$ (amortized) time: (i) determining whether any point of $P$ lies below (or above) a query pseudo-line $\ell$, and (ii) inserting a point into $P$ or deleting a point from $P$. Using this data structure as a "black box," we present a sweep-line algorithm for constructing the dual arrangement $\mathcal{A}(P^*)$ that runs in time $O((n + \chi)f(m) \log m)$, where $\chi$ is the number of vertices in $\mathcal{A}(P^*)$. We note that if $f(m)$ is small, say polylogarithmic in $m$ or of the form $O(m^\varepsilon)$, for any $\varepsilon > 0$, then this bound is nearly optimal. It is a bound of this kind that was missing so far in the algorithmic applications alluded to above.

Next, we describe a data structure for preprocessing a set $P$ of $m$ points in the plane so that all $k$ points of $P$ lying below the graph of a query fixed-degree polynomial can be reported in $O(m^\varepsilon + k)$ time.[1] It can also determine, in $O(m^\varepsilon)$ time, whether any point of $P$ lies below a query curve. A point can be inserted into or deleted from $P$ in $O(\log^2 m)$ time. Although our approach is closely based on Matoušek's algorithm [34] for reporting points that lie below a query line, a few technical difficulties must be overcome to extend this algorithm to the case of graphs of fixed-degree polynomials. A similar data structure also works for circular arcs.

Using our dual-arrangement algorithm, we show that all incidences between a set $P$ of $m$ points and a set $L$ of $n$ pseudo-lines can be reported in time $O(m^{2/3-\varepsilon}n^{2/3+2\varepsilon} + n^{1+\varepsilon} + m^{1+\varepsilon})$, provided the pseudo-lines in $L$ are extensions of bounded-degree polynomial arcs or of circular arcs, or for any other family of arcs for which a data structure with the above properties can be constructed. More precisely, we assume that all of our arcs have the same $x$-projection, and that they can be extended to pseudo-lines in some simple manner, e.g., by horizontal rays. If the arcs in $L$ intersect at $\chi$ points, the running time of the algorithm is $O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + n^{1+\varepsilon} + m^{1+\varepsilon})$. We also describe an algorithm, with the same running time, for computing the faces of $\mathcal{A}(L)$ that have a nonempty intersection with a set $P$ of $m$ "marking points," none of which lies on any arc of $L$. It has been shown in [18, 41] that the maximum number of incidences between $m$ points and $n$ pseudo-lines is $\Theta(m^{2/3}n^{2/3} + m + n)$, and that the same holds for the complexity of $m$ marked faces in an arrangement of $n$ pseudo-lines. Hence both of our algorithms are nearly optimal in the worst case.

Let $L$ be a family of $n$ *pseudo-circles* in the plane, which is a collection of closed Jordan curves, each pair intersecting at most twice. Recently, considerable progress has been made on the problem of splitting the curves in such a family $L$ into

[1]We follow the convention that an upper bound of the form $O(g(n, \varepsilon))$ means that for each $\varepsilon > 0$ there is a constant $c_\varepsilon$ such that the actual bound is $c_\varepsilon g(n, \varepsilon)$.

pseudo-segment arcs. This work started with the paper of Tamaki and Tokuyama [42], and has continued with recent papers of Aronov and Sharir [11], Chan [15, 16], Agarwal et al. [9], and Marcus and Tardos [33]. Since the resulting set of arcs is a collection of pseudo-segments, one can obtain bounds on the complexity of various substructures in arrangements of pseudo-circles by applying the known results for pseudo-segment arrangements. This approach has recently been used to obtain, among other results, nontrivial upper bounds on the complexity of a level in an arrangement of pseudo-circles [9, 15, 16, 33, 42], on the number of incidences between points and circles or parabolas [9, 11, 33], and on the complexity of many faces in an arrangement of circles or parabolas [2, 9, 33]. Specifically, the cited papers show that the number of incidences between $m$ points and $n$ circles or parabolas is $O(m^{2/3}n^{2/3} + m^{6/11}n^{9/11}\log^{2/11}(m^3/n) + m + n)$ (see [9, 11, 33]), and that the complexity of $m$ marked faces in an arrangement of $n$ circles or parabolas is $O(m^{2/3}n^{2/3} + m^{6/11}n^{9/11}\log^{6/11}(m^3/n) + n\log n)$ (see [2, 9, 33]). However, none of the preceding results were algorithmic. The only exception is an efficient algorithm for computing incidences between points and congruent circles. By adapting Matoušek's algorithm [35] for reporting point-line incidences, the incidences between $m$ points and $n$ unit circles can be computed in time $O(m^{2/3}n^{2/3}2^{O(\log^* n)} + (m+n)\log(m+n))$. Moreover, if there are only $\chi$ intersecting pairs among the circles, the running time reduces to $O(m^{2/3}\chi^{1/3}\log n + m\log n + n^{1+\varepsilon}(m/\chi)^{2\varepsilon/3})$.

In this paper we present an $O(n^{3/2+\varepsilon})$-time algorithm for splitting $n$ circles into $O(n^{3/2+\varepsilon})$ pseudo-segment arcs. The recent algorithms of Solan [40] and of Har-Peled and Sharir [30] can also be used or adapted for this task, but the running time of the resulting solutions would be close to $O(n^{7/4})$. Our algorithm follows the general approach of these algorithms, but it uses additional tools and a more refined analysis to obtain the bound stated above. Combining this algorithm with our new algorithms for handling arrangements of pseudo-lines, we obtain algorithms that report (or count) all incidences between $m$ points and $n$ circles in time

$$O(m^{2/3-\varepsilon}n^{2/3+2\varepsilon} + m^{6/11+3\varepsilon}n^{9/11-\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon}). \tag{1.1}$$

One can also refine the bound so that it depends on the number $\chi$ of intersecting pairs among the given circles. The bound then becomes

$$O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + m^{6/11+3\varepsilon}\chi^{4/11+2\varepsilon}n^{1/11-5\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon}), \tag{1.2}$$

where $\chi$ is the number of intersecting pairs of circles.

We also describe an algorithm for computing the faces in an arrangement of $n$ circles that contain at least one of $m$ given points, whose running time is

$$O(m^{2/3-\varepsilon}n^{2/3+2\varepsilon} + m^{6/11+3\varepsilon}n^{9/11-\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon}).$$

Moreover, as in the case of incidences, we can also adapt the algorithm so that its running time is sensitive to $\chi$, the number of intersecting pairs of circles. If all circles have the same radius, then the running time can be improved to $O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon})$. These bounds are therefore close to the best known upper bounds for the corresponding combinatorial problems (as provided in [2, 9, 11, 33] and reviewed above). The previously best known algorithm for computing $m$ distinct faces in an arrangement of $n$ circles (even for congruent circles) required $O(n\sqrt{m}\log n)$ randomized expected time [38].

Finally, another application of our duality is found in [39], where it is shown that graphs drawn in the plane with their edges drawn as a collection of extendible pseudo-segments are equivalent to *pseudo-line graphs*, whose vertex set is a family $L$ of pseudo-lines, and whose edge set corresponds to some subset of the vertices of $\mathcal{A}(L)$ (where each vertex represents the edge that connects the two incident pseudo-lines). The equivalence means that two edges in the original graph cross each other if and only if the two corresponding arrangement vertices form a *diamond* (each lying between the two pseudo-lines incident to the other vertex). This property was originally observed by Tamaki and Tokuyama [43]. Many applications of this correspondence are presented in [39].

**2. Duality between points and pseudo-lines.** Let $L$ be a set of $n$ $x$-monotone pseudo-lines and $P$ a set of $m$ points in the plane. Let $W$ be a vertical strip that contains $P$ and all vertices of $\mathcal{A}(L)$. Let $\lambda$ and $\rho$ be, respectively, the left and right boundary lines of $W$. We clip the pseudo-lines of $L$ to within $W$ and thus assume that $L$ is a set of $x$-monotone arcs whose left and right endpoints lie on $\lambda$ and on $\rho$, respectively; see Figure 1 (i). Given such a family of arcs, we can apply an inverse transformation that extends each arc $\ell$ in $L$ to an unbounded $x$-monotone Jordan curve $\bar{\ell}$ by drawing leftward and rightward horizontal rays from its left and right endpoints, respectively; the resulting curves form a family of $x$-monotone pseudo-lines. We refer to $\bar{\ell}$ as the *extension* of $\ell$. An $x$-monotone Jordan arc that crosses $W$ completely splits $W$ into two regions. We will refer to each of these regions as a *pseudo-halfplane*. See Figure 1 (ii).

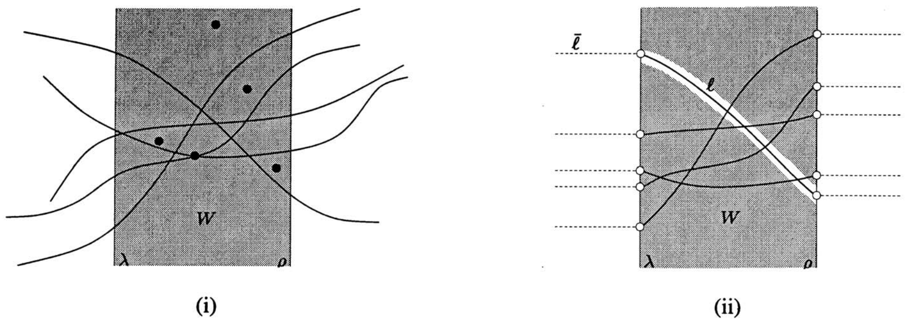

FIG. 1. (i) *A family of pseudo-lines and a set of points.* (ii) *Clipped pseudo-lines within a vertical strip $W$, extensions of the clipped arcs to Jordan curves, and two pseudo-halfplanes within $W$, bounded by a clipped pseudo-line $\ell$.*

We now present a duality transform that maps $L$ to a set $L^*$ of $n$ points and $P$ to a set $P^*$ of $m$ $x$-monotone pseudo-lines so that the incidences and the above-below relations between the points and pseudo-lines are preserved. We first describe the duality in a manner that, albeit being constructive, is not concerned with real algorithmic efficiency. We then show how to implement the construction in an efficient manner.

We sort the pseudo-lines of $L$ in increasing order of their intercepts with $\lambda$. Map each pseudo-line $\ell \in L$ to the point $\ell^* = (i_\ell, 0)$, where $i_\ell$ is the rank of the intercept $\ell \cap \lambda$ along $\lambda$. We refer to $i_\ell$ as the *index* of $\ell$. In other words, the dual points all lie on the $x$-axis and appear there from left to right in the same order as the $y$-order of the intercepts of the corresponding curves with $\lambda$. Since we are dealing with ($x$-monotone unbounded) pseudo-lines, the $y$-coordinates of the dual points, as well as the exact spacings between their $x$-coordinates, are not important. One can always move any dual point up or down (arbitrarily) or left or right (without passing over another dual point) and deform the dual pseudo-lines (that we will define shortly) accordingly, so that the incidences, the above-below relations, the $x$-monotonicity, and the pseudo-line property are all preserved. See Figure 2 for an illustration.

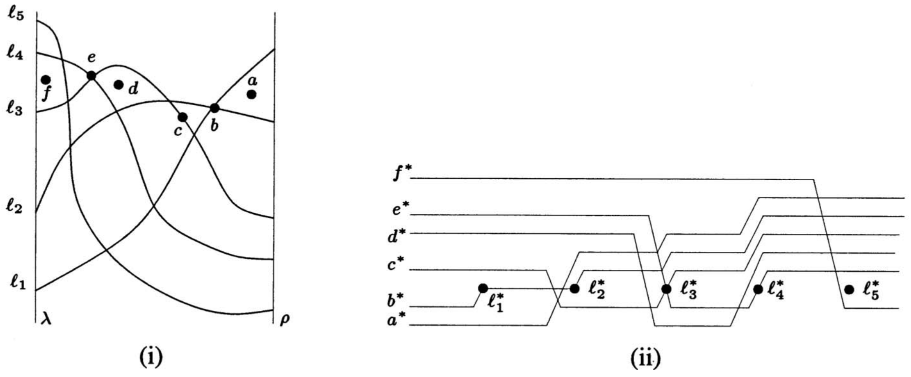

FIG. 2. *The duality transform:* (i) *The primal setting.* (ii) *The dual representation.*

Each point $p \in P$ is mapped to an $x$-monotone curve $p^*$ that is constructed so as to obey the following (necessary) rule: For each pseudo-line $\ell \in L$, if $p$ lies above (resp., below, on) $\ell$, draw $p^*$ to pass above (resp., below, through) the point $\ell^*$. This rule does not fully specify the curves $p^*$, but as we will see next, with some additional care, it yields a drawing of these curves as a collection of pseudo-lines. In order to fully specify the curves we first need to define the ordering of the dual curves $p^*$, for $p \in P$, at $x = -\infty$. Let us first assume that no pair of points of $P$ lie in the same edge or face of $\mathcal{A}(L)$. In the present course of analysis, we have no way of distinguishing between any two points that lie in the same face, and we simply regard such a pair as identical. For two points $p, q \in P$, we say that $p \prec q$ if either $x(p) < x(q)$ or $x(p) = x(q)$ and $y(p) < y(q)$. For two lines $\ell_1, \ell_2 \in L$, we say that $\ell_1 \prec \ell_2$ if the left endpoint of $\ell_1$ (on $\lambda$) lies below that of $\ell_2$.

We sort the dual curves by the order $\prec$ on the original points, and draw them at $x = -\infty$ in this order *from top to bottom*, i.e., if $p \prec q$, then $p^*$ lies above $q^*$ at $x = -\infty$. (For example, $e^*$ lies above $d^*$ at $x = -\infty$ in Figure 2 because $e \prec d$.) We draw the curves from left to right as horizontal, parallel curves until we are about to sweep past a dual point $\ell^*$. We compute the sets $P^+(\ell^*)$ (resp., $P^-(\ell^*)$, $P^\circ(\ell^*)$) consisting of those points that lie above (resp., below, on) $\ell$. This allows us to find all *inversions* enforced by $\ell^*$, namely, all pairs $(p, q)$, such that $p^*$ passes above $q^*$ to the left of $\ell^*$, but $p^*$ has to pass below or through $\ell^*$ whereas $q^*$ has to pass above or through $\ell^*$, forcing their order to reverse before we reach $\ell^*$ or at $\ell^*$ itself. We then draw the curves past $\ell^*$ so that exactly those inverted pairs cross each other just to the left of, or at $\ell^*$. To achieve this, we take all the curves in $P^+(\ell^*)$ (that have to pass above $\ell^*$) and bend them simultaneously upward, keeping them parallel to each other, so that they do not intersect among themselves, and pass above $\ell^*$. We apply a symmetric deformation downward to the curves in $P^-(\ell^*)$. Finally, we bend all curves of $P^\circ(\ell^*)$ into straight segments that pass through $\ell^*$, so that their ordering reverses after passing through $\ell^*$. (For example, $P^\circ(\ell_3^*) = \{c^*, e^*\}$, so the ordering of $c^*$ and $e^*$ reverses after they pass through $\ell_3^*$.) All these bends start at the same $x$-coordinate slightly to the left of $\ell^*$, end at the same $x$-coordinate slightly to its right (where all dual curves turn to become horizontal), and continue in this direction in parallel. In this way, it is clear that intersections in the vicinity of $\ell^*$ arise exactly between the inverted pairs. See Figure 2(ii); for simplicity we have added only those bends to the dual curves which were necessary and have omitted the others. We now prove that this procedure does indeed produce an arrangement of pseudo-lines.

LEMMA 2.1. *There do not exist two points $p, q \in P$ and two pseudo-lines $\ell_1, \ell_2 \in L$ such that*

(C1) $p \prec q$,
(C2) *$\ell_1^*$ lies to the left of $\ell_2^*$,*
(C3) *$\ell_1^*$ lies above (or on) $p^*$ and below (or on) $q^*$, and*
(C4) *$\ell_2^*$ lies below (or on) $p^*$ and above (or on) $q^*$.*

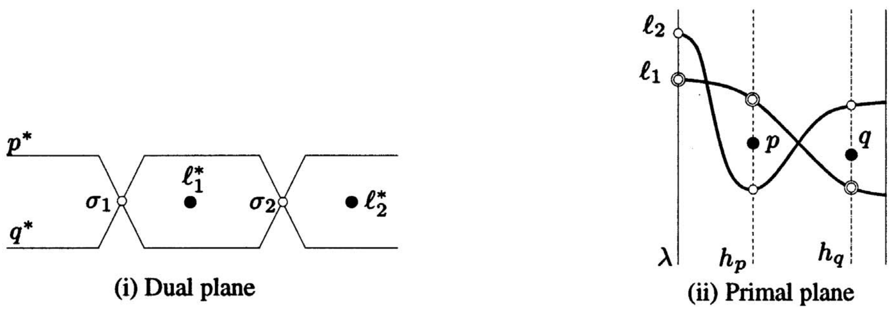

FIG. 3. *Two points $p, q$ and two curves $\ell_1, \ell_2$, satisfying* (C1)–(C4)*, in the dual and primal settings.*

*Proof.* Suppose to the contrary that there exist $p_1, p_2 \in P$ and $\ell_1, \ell_2 \in L$ that satisfy (C1)–(C4). Let $h_p$ (resp., $h_q$) be the vertical line passing through $p$ (resp., $q$). We first claim that $x(p) < x(q)$. Indeed, if $p \prec q$ and $x(p) \not< x(q)$, then $x(p) = x(q)$ and $y(p) < y(q)$. Since $\ell_2$ is $x$-monotone, it intersects the vertical line $h_p = h_q$ at a single point. Therefore $\ell_2$ cannot pass through both $p$ and $q$ if $x(p) = x(q)$. Assume that $q \notin \ell_2$. Then condition (C4) in conjunction with our construction implies that $\ell_2$ lies above $q$ but does not lie above $p$. However, both of these conditions cannot be satisfied simultaneously since $y(p) < y(q)$. The case $p \notin \ell_2$ is handled symmetrically. Hence, we can assume that $x(p) < x(q)$.

It is impossible for both $p^*$ and $q^*$ to pass through both $\ell_1^*$ and $\ell_2^*$, as this would imply that $\ell_1$ and $\ell_2$ cross twice, contradicting the fact that they are pseudo-lines. So assume that $\ell_1^* \notin q^*$; any of the symmetric cases $\ell_1^* \notin p^*$, $\ell_2^* \notin q^*$, or $\ell_2^* \notin p^*$ is handled in exactly the same manner. This in turn implies that $q \notin \ell_1$. We will consider the ordering of $\ell_1$ and $\ell_2$ along the lines $\lambda$, $h_p$, and $h_q$. Since $\ell_1^*$ lies to the left of $\ell_2^*$, $\ell_1$ lies below $\ell_2$ along $\lambda$. If $p \in \ell_1 \cap \ell_2$, then by the definition of pseudo-lines, $p$ is the only point at which $\ell_1$ and $\ell_2$ cross and $\ell_1$ lies above $\ell_2$ to the right of $h_p$. Otherwise, suppose $p \notin \ell_1$. Then by (C3) and (C4), $\ell_1$ lies above $p$ and $\ell_2$ does not lie above $p$, so $\ell_1$ lies above $\ell_2$ at $h_p$ and they cross at a point between $\lambda$ and $h_p$. See Figure 3. Once again, by (C3) and (C4) and the assumption that $q \notin \ell_1$, we can argue that $\ell_2$ lies above $\ell_1$ at the line $h_q$. Hence, $\ell_1$ and $\ell_2$ cross again between the lines $h_p$ and $h_q$. But this contradicts the assumption that $\ell_1$ and $\ell_2$ are pseudo-lines. This contradiction completes the proof of the lemma. $\square$

COROLLARY 2.2. *$P^*$ is a family of pseudo-lines.*

*Proof.* If $P^*$ were not a family of pseudo-lines, then there would exist two dual curves $p^*$ and $q^*$ that cross at least twice, say, at points $\sigma_1$ and $\sigma_2$, with $\sigma_1$ lying to the left of $\sigma_2$. Without loss of generality, assume that $p \prec q$. Then $p^*$ lies above $q^*$ at $x = -\infty$. Since $p^*$ and $q^*$ cross at $\sigma_1$, then by construction, there is an $\ell_1 \in L$ such that $p^*$ passes below or through $\ell_1^*$, $q^*$ passes above or through $\ell_1^*$, and $\ell_1^*$ lies slightly to the right of $\sigma_1$ or is equal to $\sigma_1$, but in either case it lies to the left of $\sigma_2$. The pseudo-line $p^*$ lies below $q^*$ to the right of $\sigma_1$ until their second intersection point $\sigma_2$. Again, our construction forces $p^*$ and $q^*$ to cross at $\sigma_2$ only if there is another $\ell_2 \in L$ such that $\ell_2^*$ lies to the right of $\ell_1^*$, $q^*$ passes below or through $\ell_2^*$, and $p^*$ passes above or through $\ell_2^*$. These conditions, however, yield a configuration satisfying (C1)–(C4), which contradicts Lemma 2.1. $\square$

We thus obtain the first main result of the paper.

THEOREM 2.3. *For a finite set $P$ of points and a finite set $L$ of $x$-monotone pseudo-lines in the plane, there is a duality transformation that maps $L$ into a set of points and $P$ into a set of $x$-monotone pseudo-lines so that the incidence and the above-below relations between $P$ and $L$ and between their duals are the same, i.e., $p \in P$ lies above (resp., below, on) $\ell \in L$ if and only if the pseudo-line dual to $p$ passes above (resp., below, through) the point dual to $\ell$.*

## 3. Constructing the dual arrangement.

Let $L^*$ denote the set of points dual to the pseudo-lines of $L$, and let $P^*$ denote the set of pseudo-lines dual to the points of $P$, as defined in the preceding section. We describe an efficient algorithm for computing the arrangement $\mathcal{A}(P^*)$. The output consists of a representation of $\mathcal{A}(P^*)$ as a planar map, using, e.g., the standard DCEL structure [19], which records the adjacencies between vertices and edges and between edges and faces of $\mathcal{A}(P^*)$, as well as the order of incident edges and faces about a vertex, the order of incident vertices and edges along the boundary of a face, and the order of vertices and edges along each curve of $P^*$. Moreover, the output also records, for each $\ell^* \in L^*$, the vertex, edge, or 2-face of $\mathcal{A}(P^*)$ that contains $\ell^*$.

We construct $\mathcal{A}(P^*)$ by sweeping a vertical line from left to right that stops at every point of $L^*$. We maintain the following two structures during the sweep:

(i) the ordering of curves in $P^*$ along the sweep line;
(ii) the planar map representation of $\mathcal{A}(P^*)$ restricted to the (closed) halfplane lying to the left of the sweep line.

Let $\Pi_i$ be the ordering of $P^*$ (from bottom to top) along any vertical line $\Lambda_i$ lying immediately to the right of $\ell_i^*$ (and to the left of the portion of the plane where we bend pseudo-lines of $P^*$ toward their interaction around $\ell_{i+1}^*$), let $\mathcal{A}_i$ be the arrangement of $P^*$ restricted to the (closed) halfplane lying to the left of $\Lambda_i$, and let $\mathcal{G}_i$ be the DCEL representation of $\mathcal{A}_i$. $\Pi_0$ is the ordering of $P^*$ at $x = -\infty$, as defined in section 2. $\Pi_0$ can be computed in $O(m \log m)$ time by sorting the points in $P$ in lexicographical order. $\mathcal{A}_0$, the arrangement of $P^*$ lying to the left of the "bending region" preceding $\ell_1^*$, is a planar subdivision induced by a family of $m$ horizontal segments. After having computed $\Pi_0$, $\mathcal{G}_0$ can be computed in $O(m)$ time.

When the sweep line stops at $\ell_i^*$, we compute $\Pi_i$ and $\mathcal{G}_i$ from $\Pi_{i-1}$ and $\mathcal{G}_{i-1}$. In order to expedite the computation, we maintain $\Pi_i$ in a minimum-height balanced tree $\mathcal{T}$ whose $j$th leftmost leaf stores the $j$th lowest curve in $\Pi_i$. For each node $v \in \mathcal{T}$, let $P_v \subseteq P$ denote the set of points stored at the leaves of the subtree rooted at $v$; if $v$ is a leaf, we denote the singleton point of $p$ stored at $v$ by $p_v$. At each node $v \in \mathcal{T}$, we maintain a data structure $\mathcal{D}_v = \mathcal{D}(P_v)$ that supports the following operations on $P_v$:

EMPTY($\ell$, $v$): For a pseudo-line $\ell \in L$, which of the (open) pseudo-halfplanes bounded by $\ell$, if any, contains a point of $P_v$? If neither pseudo-halfplane contains a point of $P_v$, then $P_v \subset \ell$.

INSERT$(p,\ v)$: Insert a point $p$ into $P_v$.

DELETE$(p,\ v)$: Delete a point $p$ from $P_v$.

We describe in the next section a data structure that supports these operations efficiently for certain classes of pseudo-lines. For now, assume that each of these operations can be performed in $O(f(m))$ (amortized) time.

Using this data structure, the algorithm computes $\Pi_i$ and $\mathcal{G}_i$ from $\Pi_{i-1}$ and $\mathcal{G}_{i-1}$, respectively, as follows. We visit $\mathcal{T}$ in a top-down manner. Suppose we are at a node $v \in \mathcal{T}$. We execute EMPTY$(\ell_i,\ v)$. If neither pseudo-halfplane bounded by $\ell_i$ contains a point of $P_v$, we mark $v$ by "$\circ$." If the pseudo-halfplane lying below (resp., above) $\ell_i$ does not contain a point of $P_v$ (but the complementary halfplane contains such a point), then we mark $v$ by "$+$" (resp., "$-$"). If points of $P_v$ lie on both sides of $\ell_i$, then we recursively visit the two children of $v$. Let $V^- = \langle \alpha_1, \ldots, \alpha_a \rangle$, $V^\circ = \langle \beta_1, \ldots, \beta_b \rangle$, and $V^+ = \langle \gamma_1, \ldots, \gamma_g \rangle$ be the combined sequences of leaves, sorted from left to right, lying in the subtrees rooted at the nodes marked by $-$, $\circ$, and $+$, respectively. Let $\Pi_i^- = \langle p^*_{\alpha_1}, \ldots, p^*_{\alpha_a} \rangle$, $\Pi_i^\circ = \langle p^*_{\beta_1}, \ldots, p^*_{\beta_b} \rangle$, and $\Pi_i^+ = \langle p^*_{\gamma_1}, \ldots, p^*_{\gamma_g} \rangle$. We do not compute $V^-$, $V^\circ$, $V^+$, $\Pi_i^-, \Pi_i^+, \Pi_i^\circ$ explicitly. Instead we represent them implicitly, using the roots of the subtrees where our search terminates (the nodes of $\mathcal{T}$ that were marked).

We rearrange the curves stored at the leaves of $\mathcal{T}$ so that their resulting ordering becomes $\Pi_i = \Pi_i^- \,\|\, \mathrm{rev}(\Pi_i^\circ) \| \Pi_i^+$, where $\|$ denotes concatenation and $\mathrm{rev}(\cdot)$ reverses the ordering of a list. We accomplish this in three stages, by repeatedly swapping pairs of curves stored in adjacent leaves (strictly speaking, the leaves store points of $P$, but we will not distinguish between points and their dual curves), so that:

- After the first stage all curves in $\Pi_i^-$ appear to the left of those in $\Pi_i^\circ \cup \Pi_i^+$.
- After the second stage all curves in $\Pi_i^+$ appear to the right of $\Pi_i^\circ$.
- After the third stage the ordering of curves in $\Pi_i^\circ$ is reversed.

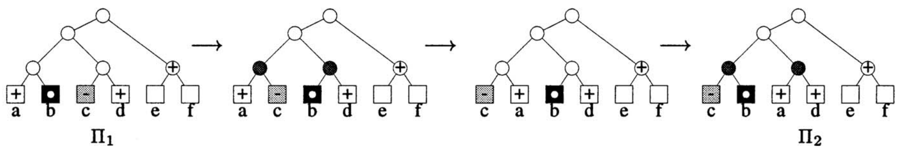

FIG. 4. *Processing $\ell_2^*$ in the dual arrangement of* Figure 2. *$\Pi_2$ is computed from $\Pi_1$ by performing the swaps $(b,c)$, $(a,c)$, and $(a,b)$. Nodes are marked $+$, $-$, and $\circ$ by the algorithm; secondary structures at the shaded interior nodes are updated.*

See Figure 4. At the end of the third stage, the curves are stored in the desired order. Whenever we swap two adjacent curves, their ordering along the sweep line gets reversed and a new vertex, along with some new faces and edges in $\mathcal{A}(P^*)$, gets created; some of the existing edges terminate at this new vertex. We update $\mathcal{A}_{i-1}, \mathcal{G}_{i-1}$ accordingly. Conceptually, while rearranging the leaves of $\mathcal{T}$, we are sweeping the vertical line from (slightly to the right of) $\ell_{i-1}^*$ to (slightly to the right of) $\ell_i^*$, swapping two curves and creating a new vertex at each step, and updating the arrangement and its planar map representation as we sweep. It is important to verify (as will be done below) that the order in which we swap the curves is topologically valid: Every pair of curves is vertically adjacent just before the curves get swapped. We call a (0-, 1-, or 2-dimensional) face of $\mathcal{A}_i$ *active* if it intersects the sweep line. At least one boundary subface of each active face lies to the right of the sweep line.

We now describe the first stage in detail. Let $\alpha_t$ be the leftmost leaf in $V^-$ that lies to the right of a leaf in $\Pi_i^\circ \cup \Pi_i^+$. Then $p^*_{\alpha_1}, \ldots, p^*_{\alpha_{t-1}}$ are in correct positions, and we move $p^*_{\alpha_t}, \ldots, p^*_{\alpha_a}$, one by one, in increasing order of their indices, to their correct positions. Suppose we have already moved $p^*_{\alpha_1}, \ldots, p^*_{\alpha_{t-1}}, p^*_{\alpha_t}, \ldots, p^*_{\alpha_{k-1}}$ to their correct positions and we now wish to bring $p^*_{\alpha_k}$ to its correct position. We repeat the following steps until $p^*_{\alpha_k}$ becomes adjacent to $p^*_{\alpha_{k-1}}$: Suppose $p^*_{\alpha_k}$ is currently stored at a leaf $w$ of $\mathcal{T}$, and $p^*_h$ is the left predecessor of $p^*_{\alpha_k}$, stored at a leaf $z$. Let $u$ be the nearest common ancestor of $w$ and $z$. We first swap the two curves stored at $w$ and $z$, that is, $w$ now stores $p^*_h$ and $z$ stores $p^*_{\alpha_k}$. Next, we delete $p^*_{\alpha_k}$ (resp., $p^*_h$) from the secondary structures $\mathcal{D}_v$ at each of the nodes $v$ on the path from $u$ to $w$ (resp., to $z$), excluding $u$, and insert $p^*_h$ (resp., $p^*_{\alpha_k}$) at $v$, using the DELETE and INSERT operations mentioned above. See Figure 5 (i).

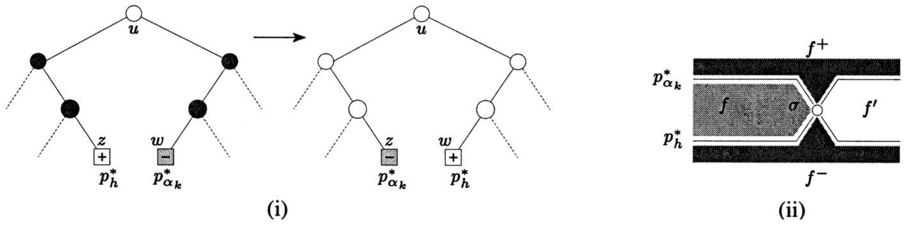

FIG. 5. (i) *Swapping two adjacent leaves $w$ and $z$ of $\mathcal{T}$.* (ii) *Swapping two curves $p^*_{\alpha_k}$ and $p^*_h$ and creating a new vertex $\sigma$, two new edges, and a 2-face; two edges and a face terminate at $\sigma$.*

Next, we create a new vertex $\sigma = p^*_{\alpha_k} \cap p^*_h$, move the sweep line over $\sigma$, and update the arrangement of $P^*$. That is, the current active edges of $p^*_h$ and $p^*_{\alpha_k}$ end at $\sigma$, with $\sigma$ being their right endpoint, and we create a new edge on each of $p^*_h$ and $p^*_{\alpha_k}$, with $\sigma$ as their left endpoint. The 2-face $f$ lying between $p^*_h$ and $p^*_{\alpha_k}$ also ends at $\sigma$, and a new 2-face $f'$ is created, with $\sigma_h$ as its leftmost endpoint and $p^*_h$ (resp., $p^*_{\alpha_k}$) as its top (resp., bottom) edge. Moreover, $p^*_h$ (resp., $p^*_{\alpha_k}$) becomes the new bottom (resp., top) edge of the 2-face $f^+$ (resp., $f^-$) that lies above $p^*_{\alpha_k}$ (resp., below $p^*_h$) to the left of $\sigma$. See Figure 5 (ii). We now update the DCEL structure to reflect these changes. Since we perform insertions and deletions in $O(\log m)$ different secondary structures, the total time spent in swapping $p^*_h$ and $p^*_{\alpha_k}$ is $O(f(m)\log m)$. The local update of $\mathcal{A}(P^*)$ and its DCEL representation take only $O(1)$ time.

After we have performed the above steps for $p^*_{\alpha_t}, \ldots, p^*_{\alpha_a}$, all curves in $\Pi_i^-$ appear to the left of $\Pi_i^\circ \cup \Pi_i^+$. Note also that all the swaps that we perform are topologically valid: They process the curves $p^*_{\alpha_t}, \ldots, p^*_{\alpha_a}$ in increasing height, effectively "bending downward" each in turn and forcing it to intersect exactly those curves that lie below it but have to pass through $\ell_i^*$ or above it, and these intersections occur in the right order. Next, we perform the same procedure on the curves in $\Pi_i^+$ that appear to the left of a curve in $\Pi_i^\circ$, in decreasing order of their indices, so that all curves in $\Pi_i^+$ appear to the right of those in $\Pi_i^\circ$. Finally, we reverse the ordering of the curves in $\Pi_i^\circ$, by once again performing swaps and updating the arrangement. Unlike the previous two stages, in which each swap created a new vertex, we create only one new vertex, namely, $\ell_i^*$, and all curves in $\Pi_i^\circ$ pass through $\ell_i^*$. Again, all the changes in $\mathcal{A}(P^*)$ that correspond to these swaps occur in a topologically valid manner.

If the algorithm performs $\mu_i$ swaps while processing $\ell_i^*$, we spend $O(\mu_i f(m)\log m)$ time in rearranging the leaves of $\mathcal{T}$ and constructing $\mathcal{G}_i$ from $\mathcal{G}_{i-1}$. If $\Pi_{i-1}$ consists of $\nu_i$ maximal contiguous subsequences such that all curves within the same subsequence lie in $\Pi_i^-$ (or $\Pi_i^+, \Pi_i^\circ$), then the algorithm marks $O(\nu_i \log m)$ nodes—$O(\log m)$ nodes for each such subsequence—and spends $O(f(m))$ time at each such node. Moreover, if any of $\Pi_i^-, \Pi_i^+, \Pi_i^\circ$ is composed of more than one contiguous subsequence in $\Pi_{i-1}$, then the curves in all subsequences, or in all but one such subsequence, are swapped, so $\nu_i \le \mu_i + 3$. Hence, the total time spent by the algorithm in processing $\ell_i^*$ is $O((\mu_i + 3)f(m)\log m)$. However, each swap introduces a new crossing between a pair of curves in $P^*$; therefore the overall running time of the algorithm is $O((n+\chi)f(m)\log m)$, where $\chi = O(m^2)$ is the number of pairs of curves in $P^*$ that cross each other.

If many curves of $P^*$ pass through a single point of $L^*$, then the number of crossing pairs could be much larger than the number of vertices in $\mathcal{A}(P^*)$. The algorithm can be modified so that $\chi$ is the number of vertices instead of the number of crossing pairs. Roughly speaking, we do not explicitly swap the curves of $\Pi_i^\circ$ in the third stage. Instead at each node $v$ of $\mathcal{T}$, we store a bit that is 0 (resp., 1) if the curves in the subtree rooted at $v$ are ordered from bottom to top (resp., top to bottom). If a node $v$ is marked $\circ$, we flip this bit at $v$. This information is needed to determine the order in which the swaps are performed. We skip the straightforward details, which are very similar to the standard sweep-line algorithm for computing the intersection points in a family of segments [12]. In summary, we have shown the following.

THEOREM 3.1. *Let $L$ be a set of $n$ $x$-monotone pseudo-lines in $\mathbb{R}^2$ and $P$ a set of $m$ points in $\mathbb{R}^2$. Suppose we have a data structure that supports each of the three operations* EMPTY, INSERT, *and* DELETE *described above, in $f(m)$ amortized time. Then we can construct $\mathcal{A}(P^*)$ (in the sense prescribed in the beginning of this section) in $O((n+\chi)f(m)\log m)$ time, where $\chi$ is the number of vertices in $\mathcal{A}(P^*)$.*

We show in the next section that if $L$ is a set of circular arcs or bounded-degree polynomial arcs (with a common $x$-projection), then $f(m) = O(m^\varepsilon)$, for any $\varepsilon > 0$, so we obtain the following corollary. The last statement in the corollary is an easy consequence of the way the algorithm is implemented.

COROLLARY 3.2. *Let $L$ be a set of $n$ circular arcs or bounded-degree polynomial arcs in $\mathbb{R}^2$ with a common $x$-projection, each pair of which intersects at most once, and let $P$ be a set of $m$ points in $\mathbb{R}^2$. Then we can construct $\mathcal{A}(P^*)$ (with respect to an extension of the arcs of $L$ into pseudo-lines) in $O((n+\chi)m^\varepsilon)$ time, where $\chi$ is the number of vertices in $\mathcal{A}(P^*)$ and $\varepsilon > 0$ is an arbitrarily small constant. Moreover, for each point $p \in P$, the above algorithm can also return, within the same overall asymptotic time bound, the set of arcs in $L$ that contain $p$, as well as the arcs that lie immediately above and below $p$.*

## 4. Pseudo-halfplane range reporting.

Let $W$ be a vertical strip, and let $\Gamma$ be a (possibly infinite) collection of $x$-monotone arcs whose endpoints lie on the left and right boundaries of $W$. Each arc $\gamma \in \Gamma$ splits $W$ into two (closed) regions. As above, we call each of these regions a *pseudo-halfplane* bounded by $\gamma$. Let $P$ be a set of $m$ points lying inside the strip $W$. We wish to preprocess $P$ into a data structure that efficiently supports the three operations described in the previous section—EMPTY, INSERT, and DELETE—with respect to arcs $\gamma \in \Gamma$. We present such a data structure for two special cases: (i) $\Gamma$ is a set of circular arcs, and (ii) $\Gamma$ is a set of (portions of the) graphs of polynomials of bounded degree.

### 4.1. Querying with circular arcs.

Let $\Gamma$ be the set of $x$-monotone circular arcs whose endpoints lie on the left and right boundaries of $W$. Let $P$ be a set of $m$ points lying inside $W$. We construct a weight-balanced binary tree $\mathcal{T}$ on the points in $P$, sorted by their $y$-coordinates [37]. For a node $v \in \mathcal{T}$, let $P_v \subseteq P$ be the set of points whose $y$-coordinates are stored at the leaves of the subtree rooted at $v$, and put $m_v = |P_v|$. We map each point $p = (x_p, y_p) \in P_v$ to the point $\bar{p} = (x_p, y_p, x_p^2 + y_p^2)$

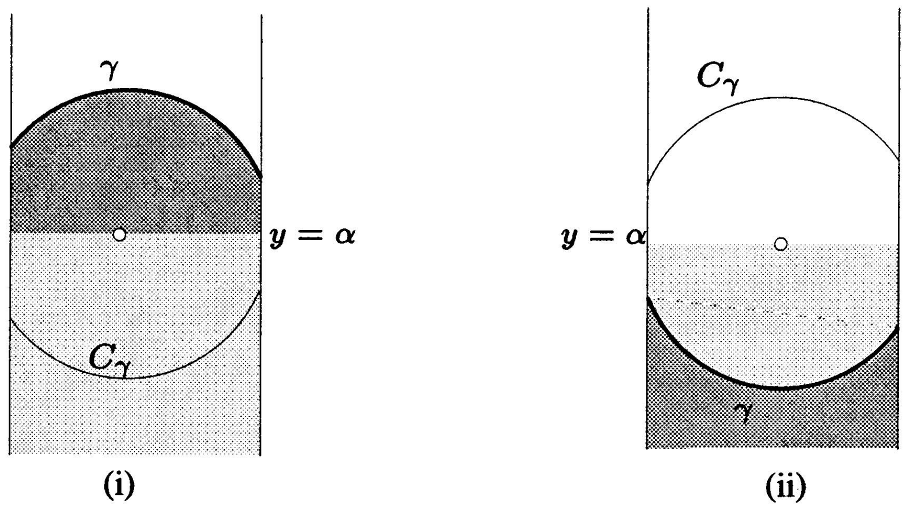

FIG. 6. *Querying with a pseudo-halfplane lying below a query arc:* (i) *The case where the arc lies in the upper semi-circle,* (ii) *The case where the arc lies in the lower semicircle.*

in $\mathbb{R}^3$. As is well known [20], if we map any circle $C$, centered at $(a, b)$ and having radius $r$, to the plane

$$\bar{C}: \; z = 2ax + 2by + (r^2 - a^2 - b^2),$$

then a point $p$ lies inside (resp., on, outside) a circle $C$ if and only if the point $\bar{p}$ lies below (resp., on, above) the plane $\bar{C}$. Let $\bar{P}_v = \{\bar{p} \mid p \in P_v\}$. We preprocess each of the sets $\bar{P}_v$ into a dynamic halfspace-emptiness data structure of size $O(m_v)$ that supports halfspace-emptiness queries (in $\mathbb{R}^3$) in time $O(m_v^\varepsilon)$ and insert/delete operations in $O(\log m_v)$ (amortized) time. See [8] for details.

Consider the halfplane-emptiness query associated with the region $g$ lying below an arc $\gamma \in \Gamma$. First, let us assume that $\gamma$ lies in the upper semicircle of its circle, denoted $C_\gamma$; let $\alpha$ denote the $y$-coordinate of the center of $C_\gamma$. We first test in $O(\log m)$ time, by checking the $y$-coordinate of the point stored in the leftmost leaf of $\mathcal{T}$, whether there exists a point of $P$ whose $y$-coordinate is at most $\alpha$. If the answer is yes, then $g \cap P \neq \emptyset$, and we terminate the query. If no such point exists, then $g \cap P \neq \emptyset$ if and only if there exists a point of $P$ inside the circle $C_\gamma$ (see Figure 6 (i)), which is equivalent to the existence of a point of $\bar{P}$ below the plane $\bar{C}_\gamma$. Using the halfspace-emptiness data structure stored at the root of $\mathcal{T}$, we determine in $O(m^\varepsilon)$ time whether any point of $P$ lies inside $C_\gamma$.

Next, assume that $\gamma$ lies on the lower semicircle of its circle $C_\gamma$. Then a point $p \in P$ lies in $g$ if and only if the $y$-coordinate of $p$ is less than $\alpha$ and $p$ lies outside the circle $C_\gamma$. We first identify in $O(\log m)$ time the $O(\log m)$ nodes $v_1, \ldots, v_s$ of $\mathcal{T}$ such that $\bigcup_{i=1}^{s} P_{v_i}$ is the set of points in $P$ whose $y$-coordinates are at most $\alpha$. For each $v_i$, we check in $O(m_{v_i}^\varepsilon)$ time whether any point of $P_{v_i}$ lies outside the circle $C_\gamma$. If the answer is yes for any $i$, then $g \cap P \neq \emptyset$; otherwise we conclude that $g \cap P = \emptyset$.

The case in which $g$ is the pseudo-halfplane lying above the arc $\gamma \in \Gamma$ can be handled in a fully symmetric manner. Using the standard partial-rebuilding technique [37], a point can be inserted into or deleted from the overall structure in $O(\log^2 m)$ amortized time. Hence, we obtain the following result (in which amortization is needed only for insertions and deletions).

THEOREM 4.1. *Let $\Gamma$ and $P$ be as above. Then each of the operations* EMPTY, INSERT*, and* DELETE *can be performed in $O(m^{\varepsilon})$ amortized time for any $\varepsilon > 0$.*

**4.2. Querying with fixed-degree polynomial arcs.** Let $\Gamma$ be the set of all arcs that are intersections with a fixed vertical strip $W$ of graphs of polynomials of degree at most $d$. We describe a dynamic data structure that determines whether any point of $P$ lies below an arc in $\Gamma$. The case of points lying above an arc is handled in a fully symmetric manner. The data structure is similar to the one proposed by Matoušek for answering halfspace-reporting queries [34]. However, we need to adapt his structure, using the results by Agarwal, Efrat, and Sharir [4] and Agarwal and Matoušek [7], to extend it to pseudo-halfplanes bounded by polynomial arcs.

We call an arc $\gamma \in \Gamma$ *$k$-shallow* if at most $k$ points of $P$ lie below $\gamma$. We call a simply connected region with at most four edges a *pseudo-trapezoid* if its top and bottom edges are portions of arcs in $\Gamma$ and its left and right edges are vertical segments. We allow pseudo-trapezoids to be degenerate, i.e., they can be unbounded or lower dimensional. A 1-dimensional pseudo-trapezoid is a portion of a curve in $\Gamma$ or a vertical segment, and a 0-dimensional pseudo-trapezoid is a point. An *elementary partition* of $P$ is a family $\Pi = \{(P_1, \triangle_1), \ldots, (P_u, \triangle_u)\}$, where $P_1, \ldots, P_u$ form a partition of $P$, and, for each $i \le u$, $\triangle_i$ is a pseudo-trapezoid, and $P_i \subseteq \triangle_i$. The pseudo-trapezoids $\Delta_i$ may intersect each other, and $\Delta_i$ may contain a point of $P_j$ for some $j \ne i$. We say that an arc $\gamma \in \Gamma$ *crosses* a cell $\triangle_i$ of $\Pi$ if $\gamma \cap \triangle_i \ne \emptyset$ and $\triangle_i \not\subseteq \gamma$. Let $\chi(\Pi, \gamma)$ be the number of cells of $\Pi$ that $\gamma$ crosses, and for any subset $Q \subseteq \Gamma$, let $\chi(\Pi, Q) = \max_{\gamma \in Q} \chi(\Pi, \gamma)$.

LEMMA 4.2. *Let $P$ be a set of $m$ points in $\mathbb{R}^2$, and let $r > 1$ be a parameter. There exists a set $Q \subseteq \Gamma$ of $O(r^{\lceil d/2 \rceil})$ $(2m/r)$-shallow curves (with respect to $P$) such that for any elementary partition $\Pi$ in which each class has at least $\lceil m/r \rceil$ points, $\chi(\Pi, \Gamma) \le (d+2)\chi(\Pi, Q)$.*

*Proof*. Let $\varphi : \mathbb{R} \to \mathbb{R}^d$ be the map $\varphi(x) = (x, x^2, \ldots, x^d)$. Then any univariate polynomial $\gamma : y = a_0 + a_1 x + \cdots + a_d x^d$ of degree $d$ maps to a $d$-variate linear function $h_\gamma : x_{d+1} = a_0 + a_1 x_1 + \cdots + a_d x_d$, in the sense that $\gamma(x) = h_\gamma(\varphi(x))$ for all $x \in \mathbb{R}$. Conversely, for any $d$-variate linear function $h : x_{d+1} = \alpha_0 + \sum_{i=1}^{d} \alpha_i x_i$, let $\gamma_h$ be the polynomial $y = \sum_{i=0}^{d} \alpha_i x^i$. Let $P^* = \{(\varphi(x), y) \mid (x, y) \in P\} \subset \mathbb{R}^{d+1}$. The notion of $k$-shallowness is extended naturally to hyperplanes in $\mathbb{R}^{d+1}$: Such a hyperplane $h$ is *$k$-shallow* with respect to $P^*$ if at most $k$ points of $P^*$ lie below $h$.

Let $H$ be a finite set of hyperplanes in $\mathbb{R}^{d+1}$. The *zone* of a hyperplane $h \notin H$ with respect to $H$, denoted as $\mathcal{Z}(H, h)$, is (the closure of) the set of points that can be reached from $h$ without intersecting any hyperplane in $H$ (it is the closure of the union of all cells crossed by $h$). We call $H$ a *$t$-guarding set* of $h$ (with respect to $P^*$) if $|\mathcal{Z}(H, h) \cap P^*| < t$. Matoušek [34, Lemma 3.3] has shown that, given a set $P^*$ of $m$ points in $\mathbb{R}^{d+1}$ and a parameter $r > 1$, there exists a family $H$ of $O(r^{\lceil d/2 \rceil})$ $(2m/r)$-shallow hyperplanes in $\mathbb{R}^{d+1}$ such that for any $(m/r)$-shallow hyperplane in $\mathbb{R}^{d+1}$, there is an $(m/r)$-guarding set $G \subseteq H$ of size at most $d+2$.

We claim that $Q = \{\gamma_h \mid h \in H\}$ is the desired set of polynomial curves. Indeed, a point $p$ lies below a curve $\gamma \in \Gamma$ if and only if $\varphi(p)$ lies below the hyperplane $h_\gamma$, so $Q$ is a set of $(2m/r)$-shallow curves. Let $\Pi = \{(P_1, \triangle_1), \ldots, (P_u, \triangle_u)\}$ be an elementary partition such that $|P_i| \ge \lceil n/r \rceil$, for any $1 \le i \le u$, and let $\eta \in \Gamma$ be a polynomial curve. If $\eta \in Q$, then obviously $\chi(\Pi, \eta) \le \chi(\Pi, Q)$. Otherwise, let $G_\eta \subseteq G$ be the guarding set of size at most $d+2$ for the hyperplane $h_\eta$. Suppose $\eta$ crosses a cell $\triangle_i$ of $\Pi$. Then $h_\eta$ crosses $\varphi(\triangle_i)$. If $\triangle_i$ is not crossed by any curve of $Q_\eta = \{\gamma_h \mid h \in G_\eta\}$, then $\varphi(\triangle_i)$ does not intersect any hyperplane of $G_\eta$ and thus lies in a single cell of $\mathcal{A}(G_\eta)$. On the other hand, $\eta$ crosses $\triangle_i$, so $h_\eta$ crosses $\varphi(\triangle_i)$, thereby implying that $\mathcal{Z}(G_\eta, h_\eta) \supset \varphi(\triangle_i) \supset \varphi(P_i)$. However, $G_\eta$ is an $(m/r)$-guarding set of $h_\eta$, so $|\mathcal{Z}(G_\eta, h_\eta) \cap \varphi(P)| < m/r$, which contradicts the fact that $\varphi(P_i) \subset \mathcal{Z}(G_\eta, h_\eta)$, as $|P_i| \geq m/r$. Hence, $\triangle_i$ is crossed by one of the curves in $Q_\eta$. Since $|Q_\eta| \leq d+2$, the lemma follows. □

The next lemma follows from a result of Matoušek [34, Lemma 3.2]. The only difference is that we use the result by Agarwal, Efrat, and Sharir [4] on "shallow-cuttings" for algebraic arcs. We omit the proof, which can be trivially adapted from the proof in the original paper.

Lemma 4.3. *Let $P$ and $\Gamma$ be as defined above, let $Q \subset \Gamma$ be a set of $r^{O(1)}$ $(2m/r)$-shallow curves, and let $r$ be a parameter. Then there exists an elementary partition $\Pi = \{(P_1, \triangle_1), \ldots, (P_u, \triangle_u)\}$ of $P$ such that $m/r \leq |P_i| \leq 2m/r$, for each $i$ (so $u \leq r$), and $\chi(\Pi, Q) = O(\log r)$. If $r$ is a constant, then $\Pi$ can be computed in $O(m)$ time.*

The following is an immediate corollary of Lemmas 4.2 and 4.3.

Lemma 4.4. *Let $P$ and $\Gamma$ be as defined above, and let $r$ be a parameter. Then there exists an elementary partition $\Pi = \{(P_1, \triangle_1), \ldots, (P_u, \triangle_u)\}$ of $P$ such that $m/r \leq |P_i| \leq 2m/r$, for each $i$ (so $u \leq r$), and $\chi(\Pi, \Gamma) = O(\log r)$. If $r$ is a constant, $\Pi$ can be computed in $O(m)$ time.*

As in [7, 34], choosing $r$ to be a sufficiently large constant and applying Lemma 4.4 recursively, we can construct, in $O(m \log m)$ time, a "partition tree" of size $O(m)$. This tree can be used for answering pseudo-halfplane-emptiness queries in $O(m^\varepsilon)$ time; see [34] for details. A point can be inserted or deleted in $O(\log^2 m)$ amortized time using the standard partial-rebuilding technique [37]. Hence, we obtain the following result.

Theorem 4.5. *Let $P$ be a set of $m$ points in some vertical strip $W$, and let $\Gamma$ be a set of fixed-degree polynomial arcs clipped to $W$. Then each of the operations* Empty, Insert, *and* Delete *can be performed in $O(m^\varepsilon)$ amortized time.*

*Remark* 4.6. As in [34], by combining the above data structure with the data structure in [7], we can report, in $O(m^\varepsilon + k)$ time, all $k$ points lying in a pseudo-halfplane bounded by a query arc in $\Gamma$. The asymptotic running time of the insertion and deletion operations remains the same.

**5. Incidences in pseudo-line arrangements.** Let $P$ be a set of $m$ points in a fixed vertical strip $W \subseteq \mathbb{R}^2$, let $L$ be a set of $n$ pseudo-lines in $\mathbb{R}^2$ that are extensions of circular or fixed-degree polynomial arcs that traverse $W$, and let $\mathcal{I}(L, P)$ denote the set of pairs $(\ell, p) \in L \times P$ such that $p$ lies on $\ell$. We wish to report $\mathcal{I}(L, P)$, compute $|\mathcal{I}(L, P)|$, or just determine whether $\mathcal{I}(L, P)$ is nonempty. The latter problem is an extension of *Hopcroft's problem* to the case of pseudo-lines. For simplicity, we focus on the first subproblem. We follow the same approach as in [6, 17]. Corollary 3.2, combined with the analysis in section 4, implies that $\mathcal{I}(L, P)$ can be computed in $O((m^2 + n)m^\varepsilon)$ time. By partitioning $P$ into $\lceil m/\sqrt{n}\ \rceil$ subsets $P_1, \ldots, P_s$, each of size at most $\sqrt{n}$, and computing $\mathcal{I}(L, P_i)$ for each subset separately, $\mathcal{I}(L, P)$ can be reported in $O(mn^{1/2+\varepsilon} + n^{1+\varepsilon})$ time, which is near optimal for $m \leq \sqrt{n}$. We now describe an algorithm that is efficient for all values of $m$ and $n$.

*Cuttings.* We first need to introduce the notion of $(1/r)$-*cuttings*. Since we will be using $(1/r)$-cuttings in the subsequent sections as well, we define them in a more general setting than needed here. Let $H$ be a set of $m$ hyperplanes in $\mathbb{R}^d$, $1 \leq r \leq m$ a parameter, and $\Delta$ a simplex. A simplicial subdivision $\Xi$ of $\Delta$ is called a $(1/r)$-*cutting* of $H$ (with respect to, or within, $\Delta$) if at most $m/r$ hyperplanes of $H$ cross any simplex of $\Xi$. We will use Chazelle's *hierarchical cuttings* [17] to construct a $(1/r)$-cutting $\Xi$ of $H$. In this approach, one chooses a sufficiently large constant $r_0$ and sets $\nu = \lceil \log_{r_0} r \rceil$. One then constructs a sequence of cuttings $\Xi_0, \Xi_1, \ldots, \Xi_\nu = \Xi$, where $\Xi_i$ is a $(1/r_0^i)$-cutting of $H$ within $\Delta$. The initial cutting $\Xi_0$ is simply $\Delta$ itself. The cutting $\Xi_i$ is obtained from $\Xi_{i-1}$ by computing, for each $\tau \in \Xi_{i-1}$, a $(1/r_0)$-cutting $\Xi_i^\tau$ of $H_\tau$ within $\tau$. It is shown in [17] that this can be done so that $|\Xi_i| \le c r_0^{di}$ for each $i$ and for some common constant $c > 0$ that depends only on $d$. Hence, $|\Xi| = O(r^d)$. If we are also given a set $P$ of $n$ points, then we can guarantee, by further partitioning simplices if needed, that each simplex in $\Xi_i$ contains at most $n/r_0^{di}$ points of $P$. The reasons for using hierarchical cuttings will become clearer in the later sections. One such reason is that it facilitates an efficient construction of $(1/r)$-cuttings in optimal $O(nr^{d-1})$ time. Chazelle's technique is presented only for the case of hyperplanes, but it admits several extensions. In the planar case, for example, it also applies to many other families of curves. In particular, we can compute in $O(mr)$ time a $(1/r)$-cutting of size $O(r^2)$ for a family $\Gamma$ of $m$ pseudo-lines (or circular arcs), in an appropriate model of computation. The only technical difference is that, instead of simplices (i.e., triangles), one needs to use vertical pseudo-trapezoids (see, e.g., [1] for details). Finally, the cutting produced by Chazelle's method can be fine-tuned, so that its size depends on the actual complexity of the arrangement of the given hyperplanes or curves. For example, in the planar case, if there are $\chi$ intersecting pairs of curves in $\Gamma$, then the size of the cutting is $O(r^{1+\varepsilon} + \chi r^2/n^2)$, for any $\varepsilon > 0$, and it can be computed in time $O(n^{1+\varepsilon} + \chi r/n)$.

Returning to the computation of $\mathcal{I}(L,P)$, we choose a parameter $r < n$ and construct a $(1/r)$-cutting $\Xi$ of $L$ of size $O(r^2)$. For a cell $\tau \in \Xi$, let $L_\tau \subseteq L$ be the set of pseudo-lines that intersect the interior of $\tau$, and let $P_\tau \subseteq P$ be the set of points that either lie in the interior of $\tau$ or lie on (the relative interior of) an edge of $\tau$. Set $n_\tau = |L_\tau|$ and $m_\tau = |P_\tau|$. Then $\sum_\tau m_\tau \le 2m$ and $n_\tau \le n/r$. At most one pseudo-line $\ell_e$ of $L$ can contain an edge $e$ of $\Xi$. If there is such a pseudo-line, we report all incidences between $e$ and the points that lie on $e$, over all edges $e$, in a total time of $O(r^2 + m)$. We compute $\mathcal{I}(L_\tau, P_\tau)$ in time $O(m_\tau n_\tau^{1/2+\varepsilon} + n_\tau^{1+\varepsilon})$ using the algorithm outlined above and repeat this for each cell $\tau$ of $\Xi$. The remaining incidences, between the pseudo-lines of $L$ and those points of $P$ that lie at the vertices of $\Xi$, are reported as follows: If an input point $p$ lies on a vertex of a cell $\tau \in \Xi$, we report in $O(n/r)$ time, using brute force, all curves of $L_\tau$ that pass through $p$. Since there are $O(r^2)$ cells in $\Xi$, the total time spent in this step is $O(nr)$. Hence, the overall running time is

$$\sum_\tau O\left(m_\tau (n/r)^{1/2+\varepsilon} + (n/r)^{1+\varepsilon}\right) + O(nr) = O\left(m(n/r)^{1/2+\varepsilon} + n^{1+\varepsilon} r^{1-\varepsilon}\right).$$

Choosing $r = \lceil m^{2/3}/n^{1/3} \rceil$ and replacing $\varepsilon$ by an appropriate constant multiple of $\varepsilon$, we obtain the following theorem.

THEOREM 5.1. *The incidences between $m$ points in a vertical strip $W$ and $n$ pseudo-lines that are extensions of circular or fixed-degree polynomial arcs that traverse $W$ can be detected, counted, or reported in time $O(m^{2/3-\varepsilon} n^{2/3+2\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon})$ for any $\varepsilon > 0$.*

If $\mathcal{A}(L)$ has $\chi$ vertices, then, using a $(1/r)$-cutting whose size depends on $\chi$ (see above) and choosing $r = \lceil m^{2/3} n/\chi^{2/3} \rceil$, we obtain the following theorem.

THEOREM 5.2. *The incidences between $m$ points in a vertical strip $W$ and $n$ pseudo-lines with $\chi$ crossing pairs that are extensions of circular or fixed-degree polyno-*

*mial arcs that traverse W can be detected, counted, or reported in time* $O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon}+m^{1+\varepsilon}+n^{1+\varepsilon})$ *for any* $\varepsilon > 0$.

**6. Many faces in pseudo-line arrangements.** Let $L$ be a set of $n$ pseudo-lines in $\mathbb{R}^2$ that are extensions of circular or polynomial arcs, and let $P$ be a set of $m$ points in the plane, none lying on any pseudo-line of $L$. Let $\mathcal{F}(L,P)$ denote the set of faces in $\mathcal{A}(L)$ that contain at least one point of $P$. We can compute $\mathcal{F}(L,P)$ by following an approach similar to the one for computing $\mathcal{I}(L,P)$. We first describe an $O((m^2+n)n^{\varepsilon})$ algorithm for computing $\mathcal{F}(L,P)$.

We compute the arrangement $\mathcal{A}(P^*)$ of the pseudo-lines dual to the points of $P$ (with respect to $L$) and then construct its vertical decomposition $\mathcal{A}^{||}(P^*)$. For each face $\varphi \in \mathcal{A}^{||}(P^*)$, we compute the subset $L_\varphi \subseteq L$ of pseudo-lines whose dual points lie inside $\varphi$. This step takes $O((m^2+n)n^{\varepsilon})$ time. Next, we compute an Eulerian tour $\Pi$ of the planar graph dual to $\mathcal{A}^{||}(P^*)$ so that each face of $\mathcal{A}^{||}(P^*)$ is visited $O(1)$ times; see [3]. If an edge $e$ of $\Pi$ crosses two adjacent faces of $\mathcal{A}(P^*)$, we set $\pi(e)$ to be the point of $P$ whose dual pseudo-line separates these two faces (it is the dual of the curve of $P^*$ that $e$ crosses). Otherwise, $e$ connects two faces of $\mathcal{A}^{||}(P^*)$ separated by a vertical line, and we set $\pi(e) = \emptyset$. Next, we construct a minimum-height binary tree $\mathcal{T}$ on $\Pi$. Each leaf of $\mathcal{T}$ is associated with a node of $\Pi$, i.e., with a face of $\mathcal{A}^{||}(P^*)$, and each internal node $v$ of $\mathcal{T}$ is associated with the subpath $\Pi_v$ of $\Pi$ that connects the leaves of the subtree rooted at $v$. For each node $v$ of $\mathcal{T}$, we set $L_v = \bigcup_\varphi L_\varphi$, where the union is taken over all faces $\varphi$ of $\mathcal{A}^{||}(P^*)$ associated with the leaves of $\Pi_v$. Similarly, we define $P_v \subseteq P$ to be the set of points (taken without repetition) associated with the edges in $\Pi_v$. Set $m_v = |P_v|$ and $n_v = |L_v|$. At any level of $\mathcal{T}$,

$$\sum_v m_v = O(m^2) \qquad \text{and} \qquad \sum_v n_v = O(n). \tag{6.1}$$

By construction, any point in $P \setminus P_v$ lies either above or below all pseudo-lines in $L_v$. We therefore add two points, one at $y = +\infty$ and another at $y = -\infty$, to each $P_v$ and compute $\mathcal{F}(L_v, P_v)$ at each node $v$ of $\mathcal{T}$, in a bottom-up manner. Let $\kappa_v$ be the complexity of $\mathcal{F}(L_v, P_v)$. For each leaf $w \in \mathcal{T}$, we compute the lower and upper envelopes of $L_w$ in $O(n_w \log n_w)$ time. (Clearly, any of our marked faces must lie above the upper envelope or below the lower envelope.) For each internal node $v \in \mathcal{T}$, with children $w$ and $z$, we compute $\mathcal{F}(L_v, P_v)$ from $\mathcal{F}(L_w, P_w)$ and $\mathcal{F}(L_z, P_z)$ in $O((\kappa_v + \kappa_w + \kappa_z + m_v + n_v)\log n)$ time, using the "red-blue-merge" algorithm proposed by Edelsbrunner, Guibas, and Sharir [21] (and adapted by Guibas, Sharir, and Sifrony [29] for curves). Let $H$ be the height of $\mathcal{T}$, and let $h(v)$ denote the height of a node $v$ in $\mathcal{T}$ (i.e., the length of the longest path from $v$ to a leaf in its subtree). The time spent by the red-blue-merge algorithm over all nodes of $\mathcal{T}$ is

$$\sum_{v\in\mathcal{T}} O((\kappa_v + m_v + n_v)\log n) = \sum_{i=1}^{H} \sum_{v\in\mathcal{T},\, h(v)=i} O((\kappa_v + m_v + n_v)\log n). \tag{6.2}$$

The combination lemma of [21] implies that, for a node $v$ with children $w, z$, one has

$$\kappa_v \le \kappa_w + \kappa_z + 4m_v + 6n_v.$$

Therefore, if $\mathcal{T}_v$ (resp., $\Lambda_v$) is the set of nodes (resp., leaves) in the subtree rooted at

$v$, then

$$\kappa_v \leq \sum_{u \in \Lambda_v} \kappa_u + \sum_{z \in \mathcal{T}_v} O(m_z + n_z). \tag{6.3}$$

Since we compute only the upper and lower envelopes of $L_u$ at each leaf $u$ of $\mathcal{T}$, $\kappa_u = O(n_u)$. Using (6.1), (6.3), and the bound on $\kappa_u$, we obtain

$$\begin{aligned}\sum_{v \in \mathcal{T},\, h(v)=i} \kappa_v + m_v + n_v &= \sum_{v \in \mathcal{T},\, h(v)=i} O\left(\sum_{u \in \Lambda_v} n_u + \sum_{z \in \mathcal{T}_v} (m_z + n_z)\right) \\ &= \sum_{j \leq i} \sum_{\substack{z \in \mathcal{T} \\ h(z)=j}} O(m_z + n_z) \\ &= O((m^2 + n)i).\end{aligned}$$

Hence, (6.2) can now be rewritten as

$$\sum_{i=1}^{H} O((m^2+n)i \log n) = O((m^2+n)\log^3 n).$$

Together with the time spent in computing $\mathcal{A}(P^*)$, the overall running time of the algorithm is $O(m^{2+\varepsilon} + n^{1+\varepsilon})$. As in section 5, using the batching technique, the running time can be reduced to $O(mn^{1/2+\varepsilon} + n^{1+\varepsilon})$.

Next, we use $(1/r)$-cuttings to obtain an algorithm for computing $\mathcal{F}(L, P)$, which is efficient for all values of $m$ and $n$, as in [6], and in the general spirit of the preceding section. That is, we choose a parameter $r < n$ and compute a $(1/r)$-cutting $\Xi$ of $L$, as described in section 5. For each cell $\tau \in \Xi$, we compute $\mathcal{F}(L_\tau, P_\tau)$ in $O((m_\tau\sqrt{n_\tau} + n_\tau)n_\tau^{\varepsilon})$ time, using the algorithm just described. In addition, we also compute, in $O(n_\tau \log^2 n_\tau)$ time [29], the unbounded face of the arcs obtained by clipping $L_\tau$ within $\tau$. After having computed this for all cells of $\Xi$, we stitch the faces together to obtain $\mathcal{F}(L, P)$ in a straightforward manner; see [6] for details. The time spent in computing $\Xi$ and computing $\mathcal{F}(L_\tau, P)$ for each cell $\tau \in \Xi$ is

$$\sum_{\tau} O\left(m_\tau (n/r)^{1/2+\varepsilon} + (n/r)^{1+\varepsilon}\right) + O(nr).$$

Again, choosing an appropriate value of $r$ and following the same analysis as in section 5, we obtain the following result.

THEOREM 6.1. *Let $L$ be a set of $n$ pseudo-lines that are extensions of circular or polynomial arcs of bounded degree that traverse a fixed vertical strip $W$ in the plane, and let $P$ be a set of $m$ points in $W$, none lying on any pseudo-line. One can compute $\mathcal{F}(L, P)$ in time $O(m^{2/3-\varepsilon}n^{2/3+2\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon})$. If there are $\chi$ crossing pairs of curves in $L$, $\mathcal{F}(L, P)$ can be computed in time $O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon})$ for any $\varepsilon > 0$.*

**7. Cutting lenses.** Among our main motivations for studying arrangements of pseudo-lines were the problems of computing incidences between points and circles and computing marked faces in an arrangement of circles. The recent analysis of Marcus and Tardos [33], following those of Aronov and Sharir [11] and Agarwal et al. [9], shows that a collection of $n$ circles can be cut into $O(n^{3/2}\log n)$ pseudo-segment arcs, meaning that any pair of arcs intersect at most once. One can then apply known bounds for incidences between points and pseudo-segments to obtain the bound $O(m^{2/3}n^{2/3} + n^{3/2}\log n)$ on the number of incidences between $m$ points and $n$ circles. (As already noted, this bound can then be further refined for small values of $m$; see [9, 11] for details.) Our goal is to make this combinatorial analysis constructive, so as to obtain a comparably efficient algorithm for detecting, counting, or reporting these incidences. The first task that we face is to find, in time $O(n^{3/2+\varepsilon})$, a set of $O(n^{3/2+\varepsilon})$ points that cut the given circles into pseudo-segments. If two circles $\gamma, \gamma' \in C$ intersect, then the boundary of each of the three bounded faces of $\mathcal{A}(\{\gamma, \gamma'\})$ is called a *lens*. Our goal is thus to cut the circles in $C$ so that all lenses will be cut, i.e., a cut is made on at least one of the two edges of every lens.

The algorithm proceeds in two stages. In the first stage, we use standard range-searching techniques [5] to decompose the intersection graph of the circles in $C$ into a union of complete bipartite subgraphs $\{A_i \times B_i\}_i$ such that (see also [11])[2]

$$\sum_i (|A_i| + |B_i|)^{3/2} = O(n^{3/2+\varepsilon}). \tag{7.1}$$

In the second stage, we cut circles in each bipartite subgraph independently. Let $A$ be a set of "red" circles and $B$ a set of "blue" circles so that every red circle intersects every blue circle; set $m = |A| + |B|$. We cut circles in $A$ and $B$ into circular arcs such that all *bichromatic* lenses, i.e., lenses formed by a red circle and a blue circle, are cut. We describe a recursive algorithm, which uses cutting-based decompositions of $\mathbb{R}^2$ into pseudo-trapezoids, for making these cuts. We first cut each circle in $A \cup B$ at its leftmost and rightmost points, yielding $2m$ $x$-monotone semicircles. At each step, we have a pseudo-trapezoid $\tau$ and two sets $\Gamma$, $\Gamma'$ of $x$-monotone circular arcs clipped to within $\tau$. The arcs in $\Gamma$ and $\Gamma'$ lie on the circles in $A$ and $B$, respectively. Initially, $\Gamma$ (resp., $\Gamma'$) is the set of upper and lower semicircles in $A$ (resp., $B$), and $\tau$ is the entire plane.

LEMMA 7.1. *If the endpoints of all arcs in $\Gamma$ and $\Gamma'$ lie on $\partial\tau$, then we can determine, in $O((|\Gamma| + |\Gamma'|)\log^3 m)$ time, whether $\Gamma$ and $\Gamma'$ induce at least one bichromatic lens that lies entirely in the interior of $\tau$.*

*Proof.* We use a two-level divide-and-conquer algorithm to determine whether a lens of the desired form exists. We choose a point, say, the topmost point $\xi$, on $\partial\tau$, and cut $\partial\tau$ at $\xi$. This induces a linear ordering on the endpoints of the arcs in $\Gamma \cup \Gamma'$, obtained by sorting the endpoints along $\partial\tau \setminus \{\xi\}$ in counterclockwise direction. For each arc $\gamma \in \Gamma \cup \Gamma'$, we refer to its first endpoint (in this ordering) as the *birth* point and to the second point as the *death* point of $\gamma$. See Figure 7 (i). We denote these points by $\beta_\gamma$ and $\delta_\gamma$, respectively.

Let $\lambda$ be a lens formed between an arc $\gamma \in \Gamma$ and an arc $\gamma' \in \Gamma'$, and lying fully in the interior of $\tau$. Then the four points $\beta_\gamma$, $\delta_\gamma$, $\beta_{\gamma'}$, $\delta_{\gamma'}$ must appear along $\partial\tau \setminus \{\xi\}$ either in the order $\beta_\gamma$, $\beta_{\gamma'}$, $\delta_{\gamma'}$, $\delta_\gamma$, or in the order $\beta_{\gamma'}$, $\beta_\gamma$, $\delta_\gamma$, $\delta_{\gamma'}$. We describe an algorithm that tests for the existence of a lens of the first kind; lenses of the second kind are handled in a fully symmetric manner.

We construct a 2-level range-tree data structure. The first-level structure $\mathcal{T}$ is a minimum-height binary tree that stores at its leaves the arcs of $\Gamma$ in increasing counterclockwise order of their birth points along $\partial\tau \setminus \{\xi\}$. For each node $v$ of $\mathcal{T}$,

[2]The same bound $O(n^{3/2+\varepsilon})$ also holds for the smaller sum $\sum_i (|A_i| + |B_i|)$. See remark (iv) in the concluding section for the implications of this fact for potential improvements of the algorithm.

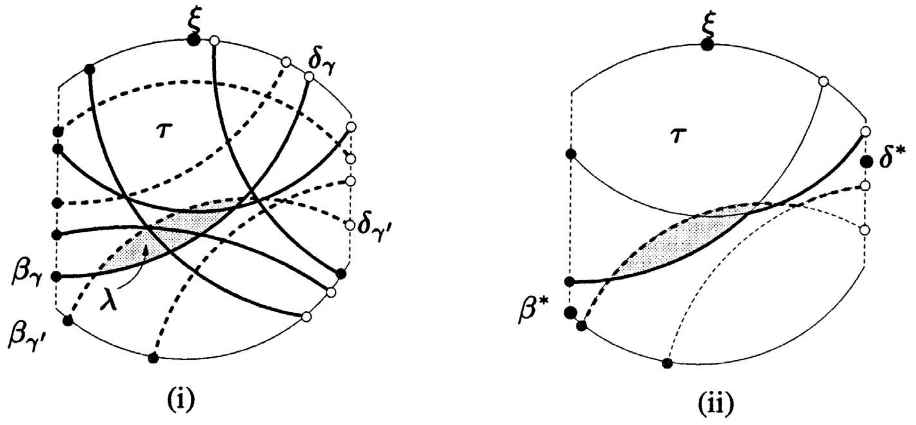

FIG. 7. (i) *All endpoints of* $\Gamma$ *(solid arcs) and* $\Gamma'$ *(dashed arcs) lie on* $\partial\tau$*; endpoints drawn as filled (resp., hollow) circles are birth (resp., death) points.* (ii) *A recursive subproblem: The arcs of* $\Gamma_{\mathcal{T}^*}$ *are drawn as solid and those of* $\Gamma'_{\mathcal{T}^*}$ *are drawn as dashed. The boundaries of the faces of* $\mathcal{A}(\Gamma_{\mathcal{T}^*})$ *and of* $\mathcal{A}(\Gamma'_{\mathcal{T}^*})$ *that contain* $\beta^*$ *and* $\delta^*$ *are drawn as bold. Since their overlay separates* $\beta^*$ *and* $\delta^*$*, this subproblem yields a bichromatic lens (two, as a matter of fact) fully contained in* $\tau$.

we construct a secondary tree $\mathcal{T}'_v$ on the set of all arcs that are stored at the leaves of the subtree rooted at $v$, and store them at the leaves of $\mathcal{T}'_v$, sorted in increasing counterclockwise order of their death points along $\partial\tau \setminus \{\xi\}$. We query with each arc $\gamma' \in \Gamma'$ in this data structure, as follows. We search in the primary tree for all arcs of $\gamma$ whose birth points precede the birth point of $\gamma'$ and obtain them as a collection of $O(\log m)$ disjoint subtrees. For each such subtree rooted at some node $v$, we go to the secondary structure $\mathcal{T}'_v$ and search for all arcs of $\Gamma$ that are stored there, whose death points succeed the death point of $\gamma'$, again obtaining them as a collection of $O(\log m)$ disjoint subtrees. Thus the query output consists of $O(\log^2 m)$ pairwise disjoint subtrees of secondary trees. We repeat this procedure for each arc $\gamma' \in \Gamma'$. This produces $O(m \log m)$ subproblems, where each subproblem is associated with a subtree $\mathcal{T}^*$ of some secondary tree $\mathcal{T}'_v$, and involves the set $\Gamma_{\mathcal{T}^*}$ of the arcs of $\Gamma$ stored at $\mathcal{T}^*$, and the set $\Gamma'_{\mathcal{T}^*}$ of those arcs of $\Gamma'$ for which $\mathcal{T}^*$ is one of their query output subtrees. The overall size $\sum_{\mathcal{T}^*}(|\Gamma'_{\mathcal{T}^*}| + |\Gamma'_{\mathcal{T}^*}|)$ of all subproblems is $O(m \log^2 m)$. Clearly, for any lens of the kind under consideration, formed by some $\gamma \in \Gamma$, $\gamma' \in \Gamma'$, there exists a (unique) subproblem involving both $\gamma$ and $\gamma'$.

Consider the subproblem associated with $\mathcal{T}^*$. By construction, there exist points $\beta^*, \delta^* \in \partial\tau$, such that all birth points of arcs in $\Gamma_{\mathcal{T}^*}$ lie between $\xi$ and $\beta^*$ (in counterclockwise direction), all birth and death points of arcs in $\Gamma'_{\mathcal{T}^*}$ lie between $\beta^*$ and $\delta^*$, and all death points of arcs in $\Gamma_{\mathcal{T}^*}$ lie between $\delta^*$ and $\xi$. It is easy to see that $\beta^*$ and $\delta^*$ lie below the lower envelope of $\Gamma_{\mathcal{T}^*}$ and above the upper envelope of $\Gamma'_{\mathcal{T}^*}$. Hence the subproblem of $\mathcal{T}^*$ induces a lens of the desired kind if and only if $\beta^*$ and $\delta^*$ lie in different connected components of the sandwich region formed by the lower envelope of $\Gamma_{\mathcal{T}^*}$ and the upper envelope of $\Gamma'_{\mathcal{T}^*}$, clipped to within $\tau$. See Figure 7 (ii). We can compute this sandwich region in $O((|\Gamma_{\mathcal{T}^*}| + |\Gamma'_{\mathcal{T}^*}|) \log m)$ time, using the fact that all arcs are $x$-monotone and circular [38]. Summing this bound over all subtrees $\mathcal{T}^*$, the lemma follows. □

If the endpoints of all arcs in $\Gamma$ and $\Gamma'$ lie on $\partial\tau$ and $\Gamma$ and $\Gamma'$ do not induce a lens that lies completely inside $\tau$, we stop. Otherwise (i.e., either an endpoint lies inside $\tau$, or there is a bichromatic lens lying fully inside $\tau$), we choose a sufficiently large constant $r$ and compute, within $\tau$, a $(1/r)$-cutting $\Xi$ of $\Gamma \cup \Gamma'$, of size $cr^2$, for a constant $c > 0$, as described in section 5. For every arc $\gamma \in \Gamma \cup \Gamma'$ and for every cell $\Delta \in \Xi$ that is crossed by $\gamma$, we cut $\gamma$ at its intersection points with $\partial\Delta$. The total number of cuts made is $O(mr)$. After this step, all lenses that lie in more than one cell of $\Xi$ have been cut, so we recursively solve the problem within each cell $\Delta$ of $\Xi$, with the sets $\Gamma_\Delta$ and $\Gamma'_\Delta$, where $\Gamma_\Delta$ is the set of the connected components of the intersections $\gamma \cap \Delta$, for $\gamma \in \Gamma$, and where $\Gamma'_\Delta$ is similarly defined.

It is clear that the algorithm cuts all bichromatic lenses inside $\tau$. (Initially, $\tau$ is the whole plane.) In order to analyze its performance, we need the following result, proven in [9, Lemma 3.2] and stated here in a slightly different manner.

Lemma 7.2 (see [9]). *Let $C = \Gamma \cup \Gamma'$ be a family of $n$ pseudo-circles, where each pseudo-circle in $\Gamma$ intersects every pseudo-circle in $\Gamma'$ twice. Then the maximum size of a family of pairwise-nonoverlapping bichromatic lenses in $\mathcal{A}(C)$ with pairwise disjoint interiors is $O(n)$.*

Returning to the subproblem inside the trapezoid $\tau$, let $m = |\Gamma| + |\Gamma'|$, let $k$ be the number of endpoints of arcs in $\Gamma \cup \Gamma'$ that lie in the interior of $\tau$ plus the maximum size of a family of pairwise-nonoverlapping bichromatic lenses in $\mathcal{A}(C)$ with pairwise disjoint interiors that are fully contained in the interior of $\tau$,[3] and let $N(m, k)$ denote the maximum number of cuts that the above algorithm performs, for sets $\Gamma, \Gamma'$ with parameters $m$ and $k$. Since the algorithm does not make any cuts if neither an endpoint nor a bichromatic lens lies inside $\tau$, we have $N(m, 0) = 0$. For $k > 0$, $N(m, k)$ satisfies the recurrence

$$N(m,k) \le \sum_{\Delta \in \Xi} N(m/r, k_\Delta) + amr,$$

where $a$ is a constant and $k_\Delta$ is the number of endpoints of $\Gamma \cup \Gamma'$ that lie in the interior of a cell $\Delta$ plus the maximum size of a family of pairwise-nonoverlapping bichromatic lenses in $\mathcal{A}(C)$ with pairwise disjoint interiors that are fully contained in the interior of $\Delta$. By definition, we have $\sum_\Delta k_\Delta \le k$. We claim that

$$N(m,k) \le Am^{1+\varepsilon}\sqrt{k}$$

for some constant $A$ that depends on $\varepsilon$. Indeed, the bound trivially holds if either $m$ or $k$ is 0. For larger values of $m$ and $k$, we have, by induction hypothesis (here $c$ is the constant defined above so that $cr^2$ is an upper bound on the size of $\Xi$),

$$\begin{aligned} N(m,k) &\le \sum_{\Delta \in \Xi} A\left(\frac{m}{r}\right)^{1+\varepsilon}\sqrt{k_\Delta} + amr \\ &\le Am^{1+\varepsilon}\frac{\sqrt{\sum_\Delta k_\Delta}\sqrt{|\Xi|}}{r^{1+\varepsilon}} + amr \\ &\le Am^{1+\varepsilon}\sqrt{k}\left(\frac{\sqrt{c}}{r^\varepsilon} + \frac{ar}{Am^\varepsilon\sqrt{k}}\right) \\ &\le Am^{1+\varepsilon}\sqrt{k}, \end{aligned}$$

provided that $r > (2\sqrt{c})^{1/\varepsilon}$ and $A \ge 2ar$. By Lemma 7.2, we have $k = O(m)$. Hence, the algorithm makes $O(m^{3/2+\varepsilon})$ cuts.

[3]Note that $k$ is not known to the algorithm and is used only for the purpose of the analysis of its performance.

Finally, let $T(m,k)$ denote the maximum running time of the above algorithm for sets $\Gamma, \Gamma'$ that have parameters $m$ and $k$. Then, by Lemma 7.1, $T(m,0) = O(m \log^3 m)$. As in the analysis of $N(m,k)$, we obtain the following recurrence for $T(m,k)$:

$$T(m,k) = \sum_{\Delta \in \Xi} T(m/r, k_\Delta) + O(m \log^3 m).$$

The same analysis as for $N(m,k)$ implies that

$$T(m,k) = O(m^{1+\varepsilon}\sqrt{k}).$$

Substituting $k = O(m)$, the maximum running time of the algorithm is $O(m^{3/2+\varepsilon})$.

Repeating this procedure to all bipartite graphs $A_i \times B_i$ and adding up the resulting complexity bounds, using (7.1), we obtain the following theorem.

THEOREM 7.3. *A collection of $n$ circles in $\mathbb{R}^2$ can be cut into $O(n^{3/2+\varepsilon})$ pseudo-segments, in time $O(n^{3/2+\varepsilon})$, for any $\varepsilon > 0$.*

**8. Circle arrangements.** Let $\mathcal{C}$ be a set of $n$ circles and $P$ a set of $m$ points in $\mathbb{R}^2$, and let $\chi$ be the number of intersection points between the circles of $\mathcal{C}$. We combine the algorithm described in section 7 with those in sections 5 and 6 to obtain efficient algorithms for computing $\mathcal{I}(\mathcal{C}, P)$ and $\mathcal{F}(\mathcal{C}, P)$. This is done as follows.

Using Theorem 7.3, we cut $\mathcal{C}$ into a set $L$ of $N = O(n^{3/2+\varepsilon})$ pseudo-segments for any $\varepsilon > 0$. Each pair of arcs in $L$ intersect at most once, but the endpoints of these arcs do not lie on the boundary of a common vertical strip. To adapt the algorithms of sections 5 and 6, we construct a segment tree $\mathcal{T}$ on the $x$-projections of the arcs in $L$. Each node $v$ of $\mathcal{T}$ is associated with a vertical strip $W_v$. Let $L_v$ be the subset of arcs in $L$, clipped within $W_v$, that are stored at $v$ (these arcs cross $W_v$ from left to right, but have an endpoint inside the parent strip), and let $\bar{L}_v$ be the set of arcs that are stored at the descendants of $v$ (including $v$ itself), again clipped within $W_v$ (each of these arcs that is stored at a proper descendant has an endpoint in the interior of $W_v$). Let $P_v = W_v \cap P$. Set $N_v = |L_v|, \bar{N}_v = |\bar{L}_v|$, and $m_v = |P_v|$. Let $\chi_v$ (resp., $\bar{\chi}_v$) be the number of intersections between the arcs of $L_v$ (resp., of $\bar{L}_v$). We construct $\mathcal{I}(L,P)$ and $\mathcal{F}(L,P)$ by visiting the nodes of $\mathcal{T}$ in a bottom-up manner and computing $\mathcal{I}(\bar{L}_v, P_v)$ and $\mathcal{F}(\bar{L}_v, P_v)$ at each node $v \in \mathcal{T}$. If $\xi$ is the root of $\mathcal{T}$, then $\mathcal{I}(L,P) = \mathcal{I}(\bar{L}_\xi, P_\xi)$ and $\mathcal{F}(L,P) = \mathcal{F}(\bar{L}_\xi, P_\xi)$.

*Computing incidences.* Let $w$ and $z$ be the two children of a node $v$ in $\mathcal{T}$. Then

$$\mathcal{I}(\bar{L}_v, P_v) = \mathcal{I}(L_v \cup \bar{L}_w \cup \bar{L}_z, P_v) = \mathcal{I}(L_v, P_v) \cup \mathcal{I}(\bar{L}_w, P_w) \cup \mathcal{I}(\bar{L}_z, P_z).$$

The last equality holds because $P_w \cap W_z = P_z \cap W_w = \emptyset$. The sets $\mathcal{I}(\bar{L}_w, P_w)$ and $\mathcal{I}(\bar{L}_z, P_z)$ are computed recursively, so we need only to compute $\mathcal{I}(L_v, P_v)$ at $v$. Since the endpoints of all arcs in $L_v$ lie on the boundary of $W_v$, we can compute $\mathcal{I}(L_v, P_v)$ in time $O(m_v^{2/3-\varepsilon}\chi_v^{1/3+\varepsilon} + m_v^{1+\varepsilon} + N_v^{1+\varepsilon})$, for any $\varepsilon > 0$, using Theorem 5.2. Using the fact that $\sum_v m_v = O(m \log m)$, $\sum_v N_v = O(N \log N)$, and $\sum_v \chi_v \le \chi$, the overall running time, summed over all nodes of $\mathcal{T}$, is

$$O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + m^{1+\varepsilon} + n^{3/2+\varepsilon})$$

for any $\varepsilon > 0$, which has to be chosen larger than the preceding $\varepsilon$ but can still be arbitrarily small.

This bound is nearly worst-case optimal for $m \geq n^{5/4}$. For smaller values of $m$, we can improve the algorithm, following the decomposition technique of [9, 11]. Specifically, we map each circle $C \in \mathcal{C}$ to a point $C^* \in \mathbb{R}^3$ and each point $p \in \mathbb{R}^2$ to a plane $p^*$ in $\mathbb{R}^3$, so that $p$ lies inside (resp., on, outside) $C$ if and only if $C^*$ lies above (resp., on, below) $p^*$. Let $\mathcal{C}^* = \{C^* \mid C \in \mathcal{C}\}$ and $P^* = \{p^* \mid p \in P\}$. We choose the parameter $r = \min\left\{\lceil n^{5/11}/m^{4/11}\rceil, m\right\}$ and compute, in $O(mr^2)$ time, a hierarchical $(1/r)$-cutting $\Xi$ of $P^*$, as mentioned in section 5. For each cell $\Delta \in \Xi$, let $\mathcal{C}^*_\Delta = \mathcal{C}^* \cap \Delta$, let $P^*_\Delta \subseteq P^*$ be the set of planes that cross $\Delta$, and let $\bar{P}^*_\Delta$ be the set of planes that contain $\Delta$. Chazelle's technique computes $\mathcal{C}^*_\Delta$ and $P^*_\Delta$ explicitly, for all cells $\Delta$, in time $O(n \log r + mr^2)$ [17]. Moreover, for any cell $\Delta$, $\bar{P}^*_\Delta$ can be computed in time $O(\log m + |\bar{P}^*_\Delta|)$ by traversing the ancestors of $\Delta$ (i.e., the cells in the intermediate cuttings that contain $\Delta$). Let $C_\Delta$, $P_\Delta$, $\bar{P}_\Delta$ denote the corresponding primal sets of circles and points. We compute $\mathcal{I}(\mathcal{C}_\Delta, P_\Delta)$ in time

$$O(m_\Delta^{2/3-\varepsilon}\chi_\Delta^{1/3+\varepsilon} + m_\Delta^{1+\varepsilon} + n_\Delta^{3/2+\varepsilon})$$

using the algorithm just outlined, where $m_\Delta = |P_\Delta|$, $n_\Delta = |\mathcal{C}_\Delta|$, and $\chi_\Delta$ is the number of intersection points between the circles of $\mathcal{C}_\Delta$. We also report all pairs in $\bar{P}_\Delta \times \mathcal{C}_\Delta$. Since $m_\Delta \leq m/r$ for each $\Delta$, $\sum_\Delta n_\Delta = n$, and $\sum_\Delta \chi_\Delta \leq \chi$, we obtain the following result by a straightforward calculation (see also [9, 11]).

THEOREM 8.1. *Let $\mathcal{C}$ be a set of $n$ circles in $\mathbb{R}^2$ and $P$ a set of $m$ points in $\mathbb{R}^2$, and let $\chi$ be the number of intersection points between the circles of $\mathcal{C}$. Then the incidences between $\mathcal{C}$ and $P$ can be detected, counted, or reported, in time $O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + m^{6/11+3\varepsilon}\chi^{4/11+2\varepsilon}n^{1/11-5\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon})$, for any $\varepsilon > 0$.*

*Computing marked faces.* Here the points of $P$ do not lie on any circle of $\mathcal{C}$ and are used to mark faces of $\mathcal{A}(\mathcal{C})$ that we wish to construct. To do so, we follow the same approach as for computing $\mathcal{I}(L, P)$, but we need to be a little more careful. Consider the processing of a node $v$ of $T$. For a subset $X \subseteq \bar{L}_v$ and a set $A$ of points, let $\bar{\mathcal{F}}(X, A)$ denote $\mathcal{F}(X, A)$ together with the unbounded face of $\mathcal{A}(X)$. (Since the arcs in $\bar{L}_v$ are clipped to within $W_v$, there is a single unbounded face.) Let $w$ and $z$ be the children of $v$. Then we have $\bar{\mathcal{F}}(\bar{L}_w, P_v) = \bar{\mathcal{F}}(\bar{L}_w, P_w)$ and $\bar{\mathcal{F}}(\bar{L}_z, P_v) = \bar{\mathcal{F}}(\bar{L}_z, P_z)$. Moreover, $\bar{\mathcal{F}}(\bar{L}_w \cup \bar{L}_z, P_v)$ can be obtained from $\bar{\mathcal{F}}(\bar{L}_w, P_w)$ and $\bar{\mathcal{F}}(\bar{L}_z, P_z)$ by simply stitching together the common endpoints of the clipped arcs that they share at the common boundary of $W_w$ and $W_z$, updating the representation and the global structure of the faces as this stitching takes place.

We recursively compute $\bar{\mathcal{F}}(\bar{L}_w, P_w)$ and $\bar{\mathcal{F}}(\bar{L}_z, P_z)$ and merge them into $\bar{\mathcal{F}}(\bar{L}_w \cup \bar{L}_z, P_v)$ by stitching the subarcs as just described. We then compute $\bar{\mathcal{F}}(L_v, P_v)$ using Theorem 6.1, and merge the two collections of faces, $\bar{\mathcal{F}}(L_v, P_v)$ and $\bar{\mathcal{F}}(\bar{L}_w \cup \bar{L}_z, P_v)$, using the red-blue-merge algorithm mentioned in section 6, to obtain $\bar{\mathcal{F}}(\bar{L}_v, P_v)$. The total time spent at $v$ is $O(m_v^{2/3-\varepsilon}\chi_v^{1/3+\varepsilon} + m_v^{1+\varepsilon} + N_v^{1+\varepsilon})$. Summing up this cost over all nodes of $\mathcal{T}$, the total time spent in computing $\mathcal{F}(L, P)$ is

$$O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + m^{1+\varepsilon} + n^{3/2+\varepsilon}).$$

Note that at the root $\xi$ we also obtain the unbounded face of $\mathcal{A}(C)$, regardless of whether it is one of the marked faces.

For small values of $m$, as in the case of incidences, we compute the sets $\mathcal{C}^*$ and $P^*$, choose the parameter $r = \lceil n^{5/11}/m^{4/11}\rceil$, construct a hierarchical $(1/r)$-cutting $\Xi$ of $\mathcal{A}(P^*)$ in $\mathbb{R}^3$, and obtain the subsets $P_\Delta$, $\mathcal{C}_\Delta$, for each cell $\Delta \in \Xi$, as defined above (because of the generic locations of the points in $P$, the sets $\bar{P}_\Delta$ are not needed in the case of marked faces). For each $\Delta \in \Xi$, any point in $P \setminus P_\Delta$ lies either in the common interior of all the circles in $\mathcal{C}_\Delta$ or in their common exterior. For each $\Delta$, we compute $\mathcal{F}(\mathcal{C}_\Delta, P_\Delta)$ in time

$$O(m_\Delta^{2/3-\varepsilon}\chi_\Delta^{1/3+\varepsilon} + m_\Delta^{1+\varepsilon} + n_\Delta^{3/2+\varepsilon}).$$

We next compute the common interior and the common exterior of $\mathcal{C}_\Delta$. These additional faces have a combined complexity of only $O(n_\Delta)$ [31], and they can be constructed in randomized expected time $O(n_\Delta \log n_\Delta)$ [36] or in deterministic time $O(n_\Delta \log^2 n_\Delta)$ [31]. Adding these faces to $\mathcal{F}(\mathcal{C}_\Delta, P_\Delta)$, we thus obtain $\bar{\mathcal{F}}(\mathcal{C}_\Delta, P_\Delta) \supseteq \mathcal{F}(\mathcal{C}_\Delta, P)$. Plugging in the value of $r$ and using the fact that $m_\Delta \le m/r$ and $n_\Delta \le n/r^3$, we obtain that the total time spent so far is

$$O(m^{2/3-\varepsilon}n^{2/3+2\varepsilon} + m^{6/11+3\varepsilon}n^{9/11-\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon}).$$

Recall (cf. section 5) that a hierarchical cutting consists of a sequence of cuttings $\Xi_0, \Xi_1, \ldots, \Xi_\nu = \Xi$, where $\Xi_i$ is a $(1/r_0^i)$-cutting of $P^*$ for some constant $r_0$ and $\nu = \lceil \log_{r_0} r \rceil$. We extend the notation $P_\tau$ and $\mathcal{C}_\tau$ to the cells $\tau$ of the intermediate cuttings $\Xi_i$. If $\tau \in \Xi_i$, then $m_\tau = |P_\tau| \le m/r_0^i$, $n_\tau = |\mathcal{C}_\tau| \le n/r_0^{3i}$, and $\sum_{\tau\in\Xi_i} n_\tau \le n$. For each $\tau \in \Xi_i$, the next cutting $\Xi_{i+1}$ contains a $(1/r_0)$-cutting $\Xi^{(\tau)}$ of $P_\tau^*$ (with respect to $\tau$) of size at most $O(r_0^3)$. By proceeding in decreasing order of $i$, we compute $\mathcal{F}(\mathcal{C}_\tau, P)$, for each $\tau \in \Xi_i$, as follows: If $i = \nu$, we have already computed the collections of faces $\mathcal{F}(\mathcal{C}_\tau, P)$. If $i < \nu$, let $\tau_1, \ldots, \tau_s$ be the simplices in $\Xi^{(\tau)}$. We compute $\mathcal{F}(\mathcal{C}_\tau, P)$ from $\mathcal{F}(\mathcal{C}_{\tau_1}, P_{\tau_1}), \ldots, \mathcal{F}(\mathcal{C}_{\tau_s}, P_{\tau_s})$, which we have already computed, by using the red-blue-merge algorithm repeatedly. Let $\kappa_\tau$ be the complexity of $\mathcal{F}(\mathcal{C}_\tau, P)$. Since all points in $P \setminus P_\tau$ lie either in the common exterior or in the common interior of all circles of $C_\tau$, the total time spent in computing $\mathcal{F}(\mathcal{C}_\tau, P)$ is

$$O\left(\left(\kappa_\tau + \sum_{i=1}^{s} \kappa_{\tau_i} + m_\tau + n_\tau\right)\log n\right),$$

where the constant of proportionality depends on $r_0$.[4] Since $\Xi_0$ consists of a single cell, namely, the entire $\mathbb{R}^3$, we have $\mathcal{F}(\mathcal{C}, P)$ at our disposal after we have processed the unique cell of $\Xi_0$.

Summing the cost over all cells of the intermediate cuttings, the total running time is

$$\begin{aligned}
&\sum_{i=0}^{\nu}\sum_{\tau\in\Xi_i} O\left(\left(\kappa_\tau + \sum_{\tau'\in\Xi^{(\tau)}} \kappa_{\tau'} + m_\tau + n_\tau\right)\log n\right)\\
&= \sum_{i=0}^{\nu}\sum_{\tau\in\Xi_i} O(\kappa_\tau \log n) + \sum_{i=0}^{\nu} O((m r_0^{2i} + n)\log n)\\
&= \sum_{i=0}^{\nu}\sum_{\tau\in\Xi_i} O(\kappa_\tau \log n) + O((mr^2 + n\log r)\log n). \qquad (8.1)
\end{aligned}$$

[4]This is the main reason for using hierarchical cuttings here: Applying the red-blue-merge for a single-level cutting, with a nonconstant value of $r$, would result in a constant of proportionality that is a high power of $r$, and would thus be too expensive.

As mentioned in the introduction, the recent result of Agarwal, Aronov, and Sharir [2], enhanced by the more recent result of Marcus and Tardos [33], implies that

$$\kappa_\tau = O(m_\tau^{2/3}n_\tau^{2/3} + m_\tau^{6/11}n_\tau^{9/11}\log^{6/11}(m_\tau^3/n_\tau) + n_\tau \log n_\tau).$$

Substituting the individual bounds on $m_\tau$ and $n_\tau$, we obtain

$$\begin{aligned}\sum_{i=0}^{\nu}\sum_{\tau\in\Xi_i}\kappa_\tau &= \sum_{i=0}^{\nu}\sum_{\tau\in\Xi_i} O(m_\tau^{2/3}n_\tau^{2/3} + m_\tau^{6/11}n_\tau^{9/11}\log^{6/11}(m_\tau^3/n_\tau) + n_\tau\log n_\tau)\\ &= \sum_{i=0}^{\nu} O(m^{2/3}n^{2/3}r_0^{i/3} + m^{6/11}n^{9/11}\log^{6/11}(m) + n\log n)\\ &= O(m^{2/3}n^{2/3}r^{1/3} + m^{6/11}n^{9/11}\log^{6/11}(m) + n\log^2 n). \qquad (8.2)\end{aligned}$$

Plugging (8.2) and the value of $r$ into (8.1), the total running time is

$$O((m^{2/3}n^{2/3} + m^{6/11}n^{9/11}\log^{6/11}(m)\log n + n\log^2 n)\log n).$$

Adding the time spent in computing $\mathcal{F}(\mathcal{C}_\Delta, P)$ for all cells $\Delta$ in the final cutting $\Xi$, we obtain the following result.

THEOREM 8.2. *Given a set $\mathcal{C}$ of $n$ circles and a set $P$ of $m$ points in $\mathbb{R}^2$, we can compute $\mathcal{F}(\mathcal{C}, P)$ in time $O(m^{2/3-\varepsilon}n^{2/3+2\varepsilon} + m^{6/11+3\varepsilon}n^{9/11-\varepsilon} + n^{1+\varepsilon})$ for any $\varepsilon > 0$.*

As for the case of incidences, we can obtain a bound that is sensitive to the number of intersecting pairs of circles in $\Xi$. Omitting the details, we obtain the following result.

THEOREM 8.3. *Given a set $\mathcal{C}$ of $n$ circles with $\chi$ intersecting pairs and a set $P$ of $m$ points in $\mathbb{R}^2$, we can compute $\mathcal{F}(\mathcal{C}, P)$ in time*

$$O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + m^{6/11+3\varepsilon}\chi^{4/11+2\varepsilon}n^{1/11-5\varepsilon} + n^{1+\varepsilon})$$

*for any $\varepsilon > 0$.*

*Remark* 8.4. Theorems 8.1–8.3 do not extend to pseudo-circles for small values of $m$ because we map $\mathcal{C}$, the family of input circles, to a set $P^*$ of points in $\mathbb{R}^3$ by using the so-called lifting transform, which we do not know how to extend to pseudo-circles. See an expanded remark in the next section.

*Handling congruent circles.* If $\mathcal{C}$ is a set of congruent circles, then the algorithm for computing $\mathcal{F}(\mathcal{C}, P)$ can be improved and simplified. We partition each circle in $\mathcal{C}$ into two semicircles by splitting it at its leftmost and rightmost points. Let $U$ and $L$ denote the sets of resulting upper and lower semicircles, respectively. Each pair of arcs within $U$ (or within $L$) intersect in at most one point. We use the segment-tree based algorithm just described to compute $\mathcal{F}(L, P)$ and $\mathcal{F}(U, P)$, in time $O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon})$. We can then compute $\mathcal{F}(\mathcal{C}, P) = \mathcal{F}(U \cup L, P)$ from $\mathcal{F}(L, P)$ and $\mathcal{F}(U, P)$ in time $O(\kappa \log n)$ using, as above, the red-blue-merge algorithm of [21], where $\kappa$ is the total number of vertices in $\mathcal{F}(L, P)$, $\mathcal{F}(U, P)$, and $\mathcal{F}(\mathcal{C}, P)$. Hence we obtain the following result.

THEOREM 8.5. *Let $P$ be a set of $m$ points and $\mathcal{C}$ a set of $n$ congruent circles with $\chi$ intersecting pairs in $\mathbb{R}^2$. We can compute $\mathcal{F}(\mathcal{C}, P)$ in time $O(m^{2/3-\varepsilon}\chi^{1/3+\varepsilon} + m^{1+\varepsilon} + n^{1+\varepsilon})$ for any $\varepsilon > 0$.*

## 9. Conclusion.

In this paper we define a duality transform for pseudo-lines and present an efficient algorithm for constructing the dual arrangement for the case when the pseudo-lines are defined by circular arcs or graphs of polynomials of bounded degree, clipped to within some vertical strip. Our algorithm relies on a dynamic pseudo-halfplane-emptiness data structure, an extension of the halfspace-emptiness data structure of Matoušek [34], and is therefore interesting in its own right. Finally, we present various applications of our duality algorithm. Roughly speaking, our algorithm extends algorithms for many problems involving arrangements of lines to arrangements of pseudo-lines, which in turn leads to faster algorithms for problems involving arrangements of circles and of other arcs. We conclude by mentioning a few open problems.

(i) It is known [13, 23] that there does not exist a duality transform between points and pseudo-hyperplanes in higher dimensions that preserves the above-below relation. However it is not known whether the *lifting transform*, used in section 8, can be extended to pseudo-circles. That is, given a set $\mathcal{C}$ of pseduo-circles and a set $P$ of points in the plane, can we map each $C \in \mathcal{C}$ to a point $C^*$ in $\mathbb{R}^3$ and each point $p \in P$ to a pseudo-plane $p^*$ in $\mathbb{R}^3$ so that $p$ lies outside $C$ if and only if $C^*$ lies below $p^*$? Such a transform, and an efficient algorithm for computing it, will allow us to extend several known algorithms for circle arrangements (e.g., computing incidences and computing a family of marked faces) to pseudo-circle arrangements.

(ii) Currently our pseudo-halfplane-emptiness data structure, and thus our algorithm for constructing the dual arrangement, does not work efficiently for algebraic arcs defined by implicit equations, e.g., a family of $x$-monotone elliptic arcs whose endpoints lie on the boundary of a fixed vertical strip. We need to extend Lemma 4.2 to such arcs in order to answer pseudo-halfplane-emptiness queries efficiently.

(iii) Since our lens-cutting algorithm uses a circle-range-searching structure in its first step, it does not extend to pseudo-circles. It would be useful to develop an efficient algorithm that bypasses the range-searching step.

(iv) The current combinatorial bound on point-circle incidences is not believed to be optimal for smaller point sets. Should that bound be improved, the current method would still need a more efficient algorithm that cuts circles into fewer pseudo-segments. The current approach, based on complete bipartite decomposition of the intersection graph of circles, is "stuck" with near-$n^{3/2}$ running time.

# LAYOUT OF GRAPHS WITH BOUNDED TREE-WIDTH[*]

VIDA DUJMOVIĆ[†], PAT MORIN[‡], AND DAVID R. WOOD[†]

**Abstract.** A *queue layout* of a graph consists of a total order of the vertices, and a partition of the edges into *queues*, such that no two edges in the same queue are nested. The minimum number of queues in a queue layout of a graph is its *queue-number*. A *three-dimensional* (*straight-line grid*) *drawing* of a graph represents the vertices by points in $\mathbb{Z}^3$ and the edges by noncrossing line-segments. This paper contributes three main results:

(1) It is proved that the minimum volume of a certain type of three-dimensional drawing of a graph $G$ is closely related to the queue-number of $G$. In particular, if $G$ is an $n$-vertex member of a proper minor-closed family of graphs (such as a planar graph), then $G$ has a $\mathcal{O}(1) \times \mathcal{O}(1) \times \mathcal{O}(n)$ drawing if and only if $G$ has a $\mathcal{O}(1)$ queue-number.

(2) It is proved that the queue-number is bounded by the tree-width, thus resolving an open problem due to Ganley and Heath [*Discrete Appl. Math.*, 109 (2001), pp. 215–221] and disproving a conjecture of Pemmaraju [*Exploring the Powers of Stacks and Queues via Graph Layouts*, Ph. D. thesis, Virginia Polytechnic Institute and State University, Blacksburg, VA, 1992]. This result provides renewed hope for the positive resolution of a number of open problems in the theory of queue layouts.

(3) It is proved that graphs of bounded tree-width have three-dimensional drawings with $\mathcal{O}(n)$ volume. This is the most general family of graphs known to admit three-dimensional drawings with $\mathcal{O}(n)$ volume.

The proofs depend upon our results regarding *track layouts* and *tree-partitions* of graphs, which may be of independent interest.

**Key words.** queue layout, queue-number, three-dimensional graph drawing, tree-partition, tree-partition-width, tree-width, $k$-tree, track layout, track-number, acyclic coloring, acyclic chromatic number

## 1. Introduction.

A *queue layout* of a graph consists of a total order of the vertices, and a partition of the edges into *queues*, such that no two edges in the same queue are nested. The dual concept of a *stack layout*, introduced by Ollmann [71] and commonly called a *book embedding*, is defined similarly, except that no two edges in the same *stack* may cross. The minimum number of queues (respectively, stacks) in a queue (stack) layout of a graph is its *queue-number* (*stack-number*). Queue layouts have been extensively studied [41, 53, 54, 58, 74, 78, 84, 86] with applications in parallel process scheduling, fault-tolerant processing, matrix computations, and sorting networks (see [74] for a survey). Queue layouts of directed acyclic graphs [9, 56, 57, 74] and posets [55, 74] have also been investigated. Our motivation for studying queue layouts is a connection with three-dimensional graph drawing.

Graph drawing is concerned with the automatic generation of aesthetically pleasing geometric representations of graphs. Graph drawing in the plane is well studied

(see [23, 64]). Motivated by experimental evidence suggesting that displaying a graph in three dimensions is better than in two [88, 89], and applications including information visualisation [88], VLSI circuit design [66], and software engineering [90], there is a growing body of research in three-dimensional graph drawing. In this paper we study *three-dimensional straight-line grid drawings*, or *three-dimensional drawings* for short. In this model, vertices are positioned at grid-points in $\mathbb{Z}^3$, and edges are drawn as straight line-segments with no crossings [16, 20, 24, 26, 27, 42, 53, 76, 73]. We focus on the problem of producing three-dimensional drawings with small volume. Three-dimensional drawings with vertices in $\mathbb{R}^3$ have also been studied [39, 47, 18, 15, 17, 61, 21, 63, 60, 62, 68, 72]. Aesthetic criteria besides volume that have been considered include symmetry [60, 61, 62, 63], aspect ratio [18, 47], angular resolution [47, 18], edge-separation [18, 47], and convexity [17, 18, 39, 85].

The first main result of this paper (Theorem 2.10) reduces the question of whether a graph has a three-dimensional drawing with small volume to a question regarding queue layouts. In particular, we prove that every $n$-vertex graph from a proper minor-closed graph family $\mathcal{G}$ has a $\mathcal{O}(1) \times \mathcal{O}(1) \times \mathcal{O}(n)$ drawing if and only if $\mathcal{G}$ has a $\mathcal{O}(1)$ queue-number, and this result holds true when replacing $\mathcal{O}(1)$ by $\mathcal{O}(\operatorname{polylog} n)$. Consider the family of planar graphs, which are minor-closed. (In the conference version of their paper) Felsner, Liotta, and Wismath [42] asked whether every planar graph has a three-dimensional drawing with $\mathcal{O}(n)$ volume. Heath and Rosenberg [58] and Heath Leighton, and Rosenberg [54] asked whether every planar graph has a $\mathcal{O}(1)$ queue-number. By our result, these two open problems are almost equivalent in the following sense. If every planar graph has $\mathcal{O}(1)$ queue-number, then every planar graph has a three-dimensional drawing with $\mathcal{O}(n)$ volume. Conversely, if every planar graph has a $\mathcal{O}(1) \times \mathcal{O}(1) \times \mathcal{O}(n)$ drawing, then every planar graph has $\mathcal{O}(1)$ queue-number. It is possible, however, that planar graphs have unbounded queue-number, yet have, say, $\mathcal{O}(n^{1/3}) \times \mathcal{O}(n^{1/3}) \times \mathcal{O}(n^{1/3})$ drawings.

Our other main results regard three-dimensional drawings and queue layouts of graphs with bounded tree-width. Tree-width, first defined by Halin [50], although largely unnoticed until independently rediscovered by Robertson and Seymour [79] and Arnborg and Proskurowski [7], is a measure of the similarity of a graph to a tree (see section 2.1 for the definition). Tree-width (or its special case, path-width) has been previously used in the context of graph drawing by Dujmović et al. [32], Hliněný [59], and Peng [75], for example.

The second main result (Corollary 2.8) is that the queue-number of a graph is bounded by its tree-width. This solves an open problem due to Ganley and Heath [45], who proved that stack-number is bounded by tree-width and asked whether a similar relationship holds for queue-number. This result has significant implications for the above open problem (does every planar graph have $\mathcal{O}(1)$ queue-number), and the more general question (since planar graphs have stack-number at most four [93]) of whether queue-number is bounded by stack-number. Heath and colleagues [58, 54] originally conjectured that both of these questions have an affirmative answer. More recently, however, Pemmaraju [74] conjectured that the "stellated $K_3$," a planar 3-tree, has $\Theta(\log n)$ queue-number, and provided evidence to support this conjecture (also see [45]). This suggested that the answer to both of the above questions was negative. In particular, Pemmaraju [74] and Heath [private communication, 2002] conjectured that planar graphs have $\mathcal{O}(\log n)$ queue-number. However, our result provides a queue layout of *any* 3-tree, and thus the stellated $K_3$, with $\mathcal{O}(1)$ queues. Hence our result disproves the first conjecture of Pemmaraju [74] mentioned above and renews hope in an affirmative answer to the above open problems.

The third main result is that every graph of bounded tree-width has a three-dimensional drawing with $\mathcal{O}(n)$ volume. The family of graphs of bounded tree-width includes most of the graphs previously known to admit three-dimensional drawings with $\mathcal{O}(n)$ volume (for example, outerplanar graphs), and also includes many graph families for which the previous best volume bound was $\mathcal{O}(n^2)$ (for example, series-parallel graphs). Many graphs arising in applications of graph drawing do have small tree-width. Outerplanar and series-parallel graphs are the obvious examples. Another example arises in software engineering applications. Thorup [87] proved that the control-flow graphs of go-to free programs in many programming languages have tree-width bounded by a small constant; in particular, 3 for Pascal and 6 for C. Other families of graphs having bounded tree-width (for constant $k$) include almost trees with parameter $k$, graphs with a feedback vertex set of size $k$, band-width $k$ graphs, cut-width $k$ graphs, planar graphs of radius $k$, and $k$-outerplanar graphs. If the size of a maximum clique is a constant $k$, then chordal, interval, and circular arc graphs also have bounded tree-width. Thus, by our result, all of these graphs have three-dimensional drawings with $\mathcal{O}(n)$ volume, and $\mathcal{O}(1)$ queue-number.

To prove our results for graphs of bounded tree-width, we employ a related structure called a tree-partition, introduced independently by Seese [83] and Halin [51]. A *tree-partition* of a graph is a partition of its vertices into "bags" such that contracting each bag to a single vertex gives a forest (after deleting loops and replacing parallel edges by a single edge). In a result of independent interest, we prove that every $k$-tree has a tree-partition such that each bag induces a connected $(k-1)$-tree, amongst other properties. The second tool that we use is a *track layout*, which consists of a vertex-coloring and a total order of each color class, such that between any two color classes no two edges cross.

The remainder of the paper is organized as follows. In section 2 we introduce the required background material, state our results regarding three-dimensional drawings and queue layouts, and compare these with results in the literature. In section 3 we establish a number of results concerning track layouts. That three-dimensional drawings and queue-layouts are closely related stems from the fact that three-dimensional drawings and queue layouts are both closely related to track layouts, as proved in section 4 and section 5, respectively. In section 6 we prove the above-mentioned theorem for tree-partitions of $k$-trees, which is used in section 7 to construct track layouts of graphs with bounded tree-width. We conclude in section 8 with a number of open problems.

## 2. Background and results.

Throughout this paper all graphs $G$ are undirected, simple, and finite with vertex set $V(G)$ and edge set $E(G)$. The number of vertices and the maximum degree of $G$ are respectively denoted by $n = |V(G)|$ and $\Delta(G)$. The subgraph induced by a set of vertices $A \subseteq V(G)$ is denoted by $G[A]$. For all disjoint subsets $A, B \subseteq V(G)$, the bipartite subgraph of $G$ with vertex set $A \cup B$ and edge set $\{vw \in E(G) : v \in A, w \in B\}$ is denoted by $G[A, B]$.

A graph $H$ is a *minor* of a graph $G$ if $H$ is isomorphic to a graph obtained from a subgraph of $G$ by contracting edges. A family of graphs closed under taking minors is *proper* if it is not the class of all graphs.

A *graph parameter* is a function $\alpha$ that assigns to every graph $G$ a nonnegative integer $\alpha(G)$. Let $\mathcal{G}$ be a family of graphs. By $\alpha(\mathcal{G})$ we denote the function $f : \mathbb{N} \to \mathbb{N}$, where $f(n)$ is the maximum of $\alpha(G)$ taken over all $n$-vertex graphs $G \in \mathcal{G}$. We say that $\mathcal{G}$ has *bounded* $\alpha$ if $\alpha(\mathcal{G}) \in \mathcal{O}(1)$. A graph parameter $\alpha$ is *bounded by* a graph parameter $\beta$ (for some graph family $\mathcal{G}$), if there exists a function $g$ such that $\alpha(G) \leq g(\beta(G))$ for every graph $G$ (in $\mathcal{G}$).

**2.1. Tree-width.** Let $G$ be a graph and let $T$ be a tree. An element of $V(T)$ is called a *node*. Let $\{T_x \subseteq V(G) : x \in V(T)\}$ be a set of subsets of $V(G)$ indexed by the nodes of $T$. Each $T_x$ is called a *bag*. The pair $(T, \{T_x : x \in V(T)\})$ is a *tree-decomposition* of $G$ if

1. $\bigcup_{x \in V(T)} T_x = V(G)$ (that is, every vertex of $G$ is in at least one bag),
2. $\forall$ edges $vw$ of $G$, $\exists$ node $x$ of $T$ such that $v \in T_x$ and $w \in T_x$, and
3. $\forall$ nodes $x, y, z$ of $T$, if $y$ is on the path from $x$ to $z$ in $T$, then $T_x \cap T_z \subseteq T_y$.

The *width* of a tree-decomposition is one less than the maximum cardinality of a bag. A *path-decomposition* is a tree-decomposition where the tree $T$ is a path $T = (x_1, x_2, \dots, x_m)$, which is simply identified by the sequence of bags $T_1, T_2, \dots, T_m$ where each $T_i = T_{x_i}$. The *path-width* (respectively, *tree-width*) of a graph $G$, denoted by $\mathsf{pw}(G)$ ($\mathsf{tw}(G)$), is the minimum width of a path- (tree-) decomposition of $G$. Graphs with tree-width at most one are precisely the forests. Graphs with tree-width at most two are called *series-parallel*,[1] and are characterized as those graphs with no $K_4$ minor (see [10]).

A *k-tree* for some $k \in \mathbb{N}$ is defined recursively as follows. The empty graph is a $k$-tree, and the graph obtained from a $k$-tree by adding a new vertex adjacent to each vertex of a clique with at most $k$ vertices is also a $k$-tree. This definition of a $k$-tree is by Reed [77]. The following more restrictive definition of a $k$-tree, which we call "strict," was introduced by Arnborg and Proskurowski [7], and is more often used in the literature. A $k$-clique is a *strict k-tree*, and the graph obtained from a strict $k$-tree by adding a new vertex adjacent to each vertex of a $k$-clique is also a strict $k$-tree. Obviously the strict $k$-trees are a proper subclass of the $k$-trees. A subgraph of a $k$-tree is called a *partial k-tree*, and a subgraph of a strict $k$-tree is called a *partial strict k-tree*. The following result is well known (see, for example, [10, 77]). A *chord* of a cycle $C$ is an edge not in $C$ whose end-vertices are both in $C$. A graph is *chordal* if every cycle on at least four vertices has a chord.

LEMMA 2.1. *Let $G$ be a graph. The following are equivalent:*

1. *$G$ has tree-width $\mathsf{tw}(G) \leq k$,*
2. *$G$ is a partial $k$-tree,*
3. *$G$ is a partial strict $k$-tree,*
4. *$G$ is a subgraph of a chordal graph that has no clique on $k + 2$ vertices.*

*Proof.* Scheffler [81] proved that (1) and (3) are equivalent. That (1) and (4) are equivalent is due to Robertson and Seymour [79]. That (2) and (4) are equivalent is the characterization of chordal graphs in terms of "perfect elimination" vertex-orderings due to Fulkerson and Gross [44]. $\square$

**2.2. Tree-partitions.** As in the definition of a tree-decomposition, let $G$ be a graph and let $\{T_x \subseteq V(G) : x \in V(T)\}$ be a set of subsets of $V(G)$ (called *bags*) indexed by the nodes of a tree $T$. The pair $(T, \{T_x : x \in V(T)\})$ is a *tree-partition* of $G$ if

1. $\forall$ distinct nodes $x$ and $y$ of $T$, $T_x \cap T_y = \emptyset$, and
2. $\forall$ edges $vw$ of $G$, either
   (i) $\exists$ node $x$ of $T$ with $v \in T_x$ and $w \in T_x$ ($vw$ is called an *intrabag* edge), or

[1] "Series-parallel digraphs" are often defined in terms of certain "series" and "parallel" composition operations. The underlying undirected graph of such a digraph has tree-width at most two (see [10]).

(ii) $\exists$ edge $xy$ of $T$ with $v \in T_x$ and $w \in T_y$ ($vw$ is called an *interbag* edge).

The main property of tree-partitions that has been studied in the literature is the maximum cardinality of a bag, called the *width* of the tree-partition [11, 51, 83, 30, 31]. The minimum width over all tree-partitions of a graph $G$ is the *tree-partition-width*[2] of $G$, denoted by $\mathsf{tpw}(G)$. A graph with bounded degree has bounded tree-partition-width if and only if it has bounded tree-width [31]. In particular, for every graph $G$, Ding and Oporowski [30] proved that $\mathsf{tpw}(G) \leq 24\,\mathsf{tw}(G)\,\Delta(G)$ (assuming $\Delta(G) \geq 1$), and Seese [83] proved that $\mathsf{tw}(G) \leq 2\,\mathsf{tpw}(G) - 1$.

Theorem 6.1 provides a tree-partition of a $k$-tree $G$ with additional features besides small width. First, the subgraph induced by each bag is a connected $(k-1)$-tree. This allows us to perform induction on $k$. Second, in each nonroot bag $T_x$ the set of vertices in the parent bag of $x$ with a neighbor in $T_x$ form a clique. This feature is crucial in the intended application (Theorem 7.3). Finally the tree-partition has width at most $\max\{1, k(\Delta(G) - 1)\}$, which represents a constant-factor improvement over the above result by Ding and Oporowski [30] in the case of $k$-trees.

**2.3. Track layouts.** Let $G$ be a graph. A *coloring* of $G$ is a partition $\{V_i : i \in I\}$ of $V(G)$, where $I$ is a set of *colors*, such that for every edge $vw$ of $G$, if $v \in V_i$ and $w \in V_j$, then $i \neq j$. Each set $V_i$ is called a *color class*. A coloring of $G$ with $c$ colors is a *$c$-coloring*, and we say that $G$ is *$c$-colorable*. The *chromatic number* of $G$, denoted by $\chi(G)$, is the minimum $c$ such that $G$ is $c$-colorable.

If $<_i$ is a total order of a color class $V_i$, then we call the pair $(V_i, <_i)$ a *track*. If $\{V_i : i \in I\}$ is a coloring of $G$ and $(V_i, <_i)$ is a track for each color $i \in I$, then we say $\{(V_i, <_i) : i \in I\}$ is a *track assignment* of $G$ *indexed by* $I$. Note that at times it will be convenient to also refer to a color $i \in I$ and the color class $V_i$ as a *track*. The precise meaning will always be clear from the context. A *$t$-track assignment* is a track assignment with $t$ tracks.

As illustrated in Figure 2.1, an *X-crossing* in a track assignment consists of two edges $vw$ and $xy$ such that $v <_i x$ and $y <_j w$ for distinct tracks $V_i$ and $V_j$. A $t$-track assignment with no X-crossing is called a *$t$-track layout*. The *track-number* of a graph $G$, denoted by $\mathsf{tn}(G)$, is the minimum $t$ such that $G$ has a $t$-track layout.

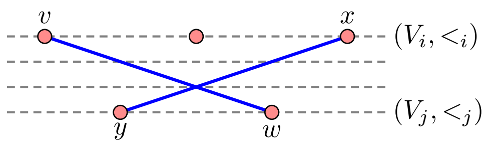

FIG. 2.1. *An example of an X-crossing in a track assignment.*

Let $\{(V_i, <_i) : i \in I\}$ be a $t$-track layout of a graph $G$. The *span* of an edge $vw$ of $G$, with respect to a numbering of the tracks $I = \{1, 2, \ldots, t\}$, is defined to be $|i - j|$, where $v \in V_i$ and $w \in V_j$.

Track layouts will be central in most of our proofs. To enable comparison of our results to those in the literature we now introduce the notion of an "improper" track layout. A *improper coloring* of a graph $G$ is simply a partition $\{V_i : i \in I\}$ of $V(G)$. Here adjacent vertices may be in the same color class. A track of an improper coloring is defined as above. Suppose $\{V_i : i \in I\}$ is an improper coloring of $G$ and $(V_i, <_i)$ is a track for each color $i \in I$. An edge with both end-vertices in the same

[2]Tree-partition-width has also been called *strong tree-width* [83, 11].

track is called an *intratrack* edge; otherwise it is called an *intertrack* edge. We say that $\{(V_i, <_i) : i \in I\}$ is an *improper track assignment* of $G$ if, for all intratrack edges $vw \in E(G)$ with $v \in V_i$ and $w \in V_i$ for some $i \in I$, there is no vertex $x$ with $v <_i x <_i w$. That is, adjacent vertices in the same track are consecutive in that track. An improper $t$-track assignment with no X-crossing is called an *improper $t$-track layout.*[3]

LEMMA 2.2. *If a graph $G$ has an improper $t$-track layout, then $G$ has a $2t$-track layout.*

*Proof.* For every track $V_i$ of an improper $t$-track layout of $G$, let $V_i'$ be a new track. Move every second vertex from $V_i$ to $V_i'$ such that $V_i'$ inherits its total order from the original $V_i$. Clearly there is no intratrack edge and no X-crossing. Thus we obtain a $2t$-track layout of $G$. $\square$

Hence the track-number of a graph is at most twice its "improper track-number." The following lemma, which was jointly discovered with Giuseppe Liotta, gives a compelling reason to only consider proper track layouts. Similar ideas can be found in [42, 26]. Let $vw$ be an edge of a graph $G$. Let $G'$ be the graph obtained from $G$ by adding a new vertex $x$ only adjacent to $v$ and $w$. We say $x$ is an *ear*, and $G'$ is obtained from $G$ by *adding an ear to $vw$*.

LEMMA 2.3. *Let $\mathcal{G}$ be a class of graphs closed under the addition of ears (for example, series-parallel graphs or planar graphs). If every graph in $\mathcal{G}$ has an improper $t$-track layout for some constant $t$, then every graph in $\mathcal{G}$ has a (proper) $t$-track layout.*
