Lemma E.2. *For all* $1 \leq k \leq (\log n)^{3/2}$ *we have* $\Pr_{T\in\mathcal{T}^U_{d,n}}[S = k] = 1/n^{\omega(1)}$.

Lemma E.3. *For* $d \geq \frac{1}{2}\log n$, $d = \Theta(\log n)$, $\Pr_{T\in\mathcal{T}^U_{d,n}}[S = 0 \mid x_1$ *is not a bottleneck*$] = 1/n^{\omega(1)}$.

(Note that bounding $\Pr[S = 0 \mid x_1$ is not a bottleneck$]$ by $2\Pr[S = 0]$ is a bad idea since $S = 0$ whenever $x_1$ is a bottleneck, and this occurs with probability roughly $1/n$; hence we use the above approach of handling $S = 0$ separately by bounding the conditional probability directly.)

*Proof of Lemma* E.2. We closely imitate the proof of Lemma 7.2. Let $p_{k,d,n}$ now denote $\Pr_{T\in\mathcal{T}^U_{d,n}}[S = k]$. For $k \geq 1$ and $d \geq 1$ we now have

$$p_{k,d,n} = q_{d,n} \cdot \frac{n-1}{n} \cdot \sum_{i=0}^{k} p_{i,d-1,n-1}p_{k-i,d-1,n-1}. \tag{E.2}$$

(The $q_{d,n} \cdot \frac{n-1}{n}$ is present because in order for $S$ to be nonzero it must be the case that $T$ is nontrivial and that the root is not $x_1$. If this is the case, then the left and right subtrees (which, under this conditioning, are drawn from $\mathcal{T}^U_{d-1,n-1}$) must have $i$ and $k-i$ $x_1$-free paths from their respective roots to preleaves at depth $d-1$ in those subtrees.) As before we have $p_{c,0,n} = 0$ for $c \geq 2$ since there cannot be two paths to preleaves in a depth-0 tree. We have $p_{1,0,n} = q_{0,n} \cdot \frac{n-1}{n}$ since there is one $x_1$-free path if and only if the tree is nontrivial and the root is not $x_1$. Moreover, we have $p_{0,0,n} = \frac{6}{4n+2}$ since the only trees of depth at most 0 which have $S = 0$ are the four trees with $x_1$ at the root and the two trivial trees.

Finally, if $k = 0$ and $d > 0$, then we have

$$p_{0,d,n} = (1 - q_{d,n}) + q_{d,n} \cdot \frac{1}{n} + q_{d,n} \cdot \frac{n-1}{n}(p_{0,d-1,n-1})^2. \tag{E.3}$$

(We have that $S = 0$ if $T$ is trivial, or if $T$ is nontrivial and $x_1$ is the root, or if $T$ is nontrivial, some other variable is the root, and both subtrees have no $x_1$-free paths to preleaves at depth $d-1$.) Equation (E.3), combined with the fact that $1 - q_{d,n} < \frac{1}{n}$ for $d \geq 0$, implies that for $d \geq 1$ we have

$$p_{0,d,n} \leq \frac{2}{n} + \frac{n-1}{n}(p_{0,d-1,n-1})^2.$$

A straightforward analysis of this recurrence shows that $p_{0,d,n} < \frac{3}{n}$ for all $d = O(\log n)$.

Now let $\tilde{p}_{k,d,n}$ be defined by the same base case conditions (for $k = 0$ or $d = 0$) that we have just given, but be defined for $k \geq 1, d \geq 1$ by the rule from section C, i.e.,

$$\tilde{p}_{k,d,n} = \frac{n-1}{n}\sum_{i=0}^{k}\tilde{p}_{i,d-1,n-1}\tilde{p}_{k-i,d-1,n-1}.$$

(Note that these base conditions differ only slightly from the base conditions on $p_{k,d,n}$ in section C; the bound $\frac{3}{n}$ which we have on $\tilde{p}_{0,d,n}$ is slightly weaker than the $\frac{2}{n}$ bound we used in the earlier proof, and the $\tilde{p}_{0,0,n}$ bound of $\frac{6}{4n+2}$ is slightly weaker than the old bound of $\frac{1}{n}$.) A proof entirely similar to that of Lemma 7.2 now establishes that $\tilde{p}_{k,d,n} = 1/n^{\omega(1)}$ for $1 \leq k \leq (\log n)^{3/2}$ and $d \geq \frac{1}{2}\log n$, $d = \Theta(\log n)$. We now observe that the recurrence for $\tilde{p}_{k,d,n}$ dominates the recurrence which we have in this section for $p_{k,d,n}$, and hence $p_{k,d,n} \leq \tilde{p}_{k,d,n} = 1/n^{\omega(1)}$ as well. (Note that we cannot argue directly that the old $p_{k,d,n}$ recurrence dominates the new one, since some initial values of the new recurrence are as noted earlier slightly higher than the old values.) This proves Lemma E.2. ▯

It remains to prove Lemma E.3.

*Proof of Lemma* E.3. We have that

$$\Pr_{T \in \mathcal{T}^U_{d,n}}[S = 0 \mid x_1 \text{ is not a bottleneck}] = \frac{\Pr[S = 0 \text{ \& } x_1 \text{ is not a bottleneck}]}{\Pr[x_1 \text{ is not a bottleneck}]}$$
$$< 2\Pr[S = 0 \text{ \& } x_1 \text{ is not a bottleneck}]$$

since $\Pr[x_1 \text{ is not a bottleneck}] = 1 - p_{d,n} \geq \frac{1}{2}$ by Lemma E.1. Since $S = 0$ whenever $x_1$ is a bottleneck, we have that

$$\Pr[S = 0 \text{ \& } x_1 \text{ is not a bottleneck}] = \Pr[S = 0] - \Pr[x_1 \text{ is a bottleneck}].$$

Thus it suffices to bound $\epsilon_{d,n} \equiv p_{0,d,n} - p_{d,n}$. Combining (E.1) and (E.3) we have

$$\begin{aligned}
\epsilon_{d,n} &= (1 - q_{d,n}) + q_{d,n} \cdot \frac{n-1}{n}\left[(p_{0,d-1,n-1})^2 - (p_{d-1,n-1})^2\right] \\
&= (1 - q_{d,n}) + q_{d,n} \cdot \frac{n-1}{n}\left[(p_{0,d-1,n-1} - p_{d-1,n-1})(p_{0,d-1,n-1} + p_{d-1,n-1})\right] \\
&= (1 - q_{d,n}) + q_{d,n} \cdot \frac{n-1}{n}\left[\epsilon_{d-1,n-1}(p_{0,d-1,n-1} + p_{d-1,n-1})\right].
\end{aligned}$$

Our bounds on $p_{0,d,n}$ and $p_{d,n}$ imply that $p_{0,d-1,n-1} + p_{d-1,n-1} \leq \frac{5}{n-1}$. The above thus implies

$$\epsilon_{d,n} \leq (1 - q_{d,n}) + \epsilon_{d-1,n-1} \cdot \frac{5}{n-1}.$$

It is clear that for $\ell \geq \frac{1}{4}\log n$, we have $1-q_{\ell,n} = \frac{2}{C_{\ell,n}} = 1/2^{n^{\Omega(1)}}$. Since $\epsilon_{\frac{1}{4}\log n, n-d+\frac{1}{4}\log n}$ is clearly at most 1, expanding out the above recurrence we thus have

$$\epsilon_{d,n} < \frac{d-\frac{1}{4}\log n}{2^{n^{\Omega(1)}}} + \left(\frac{10}{n}\right)^{d-\frac{1}{4}\log n}.$$

Since $d \geq \frac{1}{2}\log n, d = \Theta(\log n)$ this is $\frac{1}{n^{\omega(1)}}$, and the lemma is proved. ◻

Finally, we can also now prove two lemmas used in section 5.

*Proof of Lemma* 5.7. It is easy to see that $C_{t,\Omega(n)} = 2^{n^{\Omega(1)}}$ for $t \geq \frac{1}{4}\log n$. Also, there are only poly($n$) chances for `MakeTree` to output a trivial tree down to depth $d - \frac{1}{4}\log n$. Therefore, the chance of any leaf being output before depth $\frac{1}{4}\log n$ is at most $2^{n^{\Omega(1)}}$. ◻

*Proof of Lemma* 5.5. In all three models we have that if $d = O(\log n)$, then $p_{d,n} < 2/n$. If $T$ is drawn according to $\mathcal{T}_{d,n}$ and has a bottleneck variable $x_1$ labeling node $v$ at depth $k \geq \frac{1}{8}\log n$, then the sibling of $v$ and the sibling of each of $v$'s nonroot ancestors must have $x_1$ as a bottleneck. These probabilities are all independent, and each is at most $(2/n)$. ◻

# A NEW MULTILAYERED PCP AND THE HARDNESS OF HYPERGRAPH VERTEX COVER[*]

IRIT DINUR[†], VENKATESAN GURUSWAMI[‡], SUBHASH KHOT[§], AND ODED REGEV[¶]

**Abstract.** Given a $k$-uniform hypergraph, the E$k$-Vertex-Cover problem is to find the smallest subset of vertices that intersects every hyperedge. We present a new multilayered probabilistically checkable proof (PCP) construction that extends the Raz verifier. This enables us to prove that E$k$-Vertex-Cover is NP-hard to approximate within a factor of $(k-1-\varepsilon)$ for arbitrary constants $\varepsilon > 0$ and $k \geq 3$. The result is nearly tight as this problem can be easily approximated within factor $k$. Our construction makes use of the biased long-code and is analyzed using combinatorial properties of $s$-wise $t$-intersecting families of subsets.

We also give a different proof that shows an inapproximability factor of $\lfloor \frac{k}{2} \rfloor - \varepsilon$. In addition to being simpler, this proof also works for superconstant values of $k$ up to $(\log N)^{1/c}$, where $c > 1$ is a fixed constant and $N$ is the number of hyperedges.

**Key words.** hypergraph vertex cover, hardness of approximation, probabilistically checkable proof, multilayered outer verifier, long-code

## 1. Introduction.

A $k$-uniform hypergraph $H = (V, E)$ consists of a set of vertices $V$ and a collection $E$ of $k$-element subsets of $V$ called hyperedges. A *vertex cover* of $H$ is a subset $S \subseteq V$ such that every hyperedge in $E$ intersects $S$; i.e., $e \cap S \neq \emptyset$ for each $e \in E$. An *independent set* in $G$ is a subset whose complement is a vertex cover or, in other words, a subset of vertices that contains no hyperedge entirely within it. The E$k$-Vertex-Cover problem is the problem of finding a minimum size vertex cover in a $k$-uniform hypergraph. This problem is alternatively called the minimum hitting set problem with sets of size $k$ (and is equivalent to the set cover problem where each element of the universe occurs in exactly $k$ sets).

The E$k$-Vertex-Cover problem is a fundamental NP-hard optimization problem. For $k = 2$, it is just the famous vertex cover problem on graphs. Owing to its NP-hardness, one is interested in how well it can be approximated in polynomial time. A very simple algorithm that is often taught in an undergraduate algorithms class is the following: greedily pick a maximal set of pairwise disjoint hyperedges and then

include all vertices in the chosen hyperedges in the vertex cover. It is easy to show that this gives a factor $k$ approximation algorithm for E$k$-Vertex-Cover. State-of-the-art techniques yield only a tiny improvement, achieving a $k - o(1)$ approximation ratio [14]. This raises the question of whether achieving an approximation factor of $k - \varepsilon$ for any constant $\varepsilon > 0$ could be NP-hard. In this paper, we prove a nearly tight hardness result for E$k$-Vertex-Cover, as described in the following theorem.

THEOREM 1.1 (main theorem). *For every integer $k \geq 3$ and every $\varepsilon > 0$, it is NP-hard to approximate Ek-Vertex-Cover within a factor of $(k - 1 - \varepsilon)$.*

**Previous hardness results.** The vertex cover problem on hypergraphs where the size of the hyperedges is unbounded is nothing but the set cover problem. For this problem there is a $\ln n$ approximation algorithm [23, 20] and a matching hardness factor of $(1 - o(1)) \ln n$ due to Feige [10]. Feige showed that an approximation algorithm achieving a factor of $(1 - o(1)) \ln n$ would imply NP $\subseteq$ DTIME($n^{O(\log \log n)}$), where $n$ is the number of hyperedges. The best NP-hardness result (where the reduction is polynomial time) is due to Raz and Safra [25], who showed that it is NP-hard to approximate set cover to within $c \cdot \log n$ for some small $c > 0$. The first explicit hardness result shown for E$k$-Vertex-Cover was due to Trevisan [27], who considered the approximability of bounded degree instances of several combinatorial problems and specifically showed an inapproximability factor of $\Omega(k^{1/19})$ for E$k$-Vertex-Cover. Holmerin [18] showed that E4-Vertex-Cover is NP-hard to approximate within $(2-\varepsilon)$. Independently, Goldreich [12] showed a direct "FGLSS"-type [11] reduction (involving no use of the long-code, a crucial component in most recent probabilistically checkable proof (PCP) constructions) attaining a hardness factor of $(2-\varepsilon)$ for E$k$-Vertex-Cover for some constant $k$. Later, Holmerin [19] showed that E$k$-Vertex-Cover is NP-hard to approximate within a factor of $\Omega(k^{1-\varepsilon})$, and also that it is NP-hard to approximate E3-Vertex-Cover within factor $(3/2 - \varepsilon)$.

More recently Dinur, Guruswami, and Khot [7] gave a fairly simple proof of an $\alpha \cdot k$ hardness result for E$k$-Vertex-Cover for some $\alpha > \frac{1}{3}$. The proof takes a combinatorial view of Holmerin's construction and instead of Fourier analysis uses some properties concerning intersecting families of finite sets. The authors also give a more complicated reduction that shows a factor $(k - 3 - \varepsilon)$ hardness for E$k$-Vertex-Cover. The crucial impetus for that work came from the recent result of Dinur and Safra [9] on the hardness of approximating vertex cover (on graphs), and, as in [9], the notion of biased long-codes and some extremal combinatorics relating to intersecting families of sets play an important role. In addition to ideas from [9], the factor $(k - 3 - \varepsilon)$ hardness result also exploits the notion of covering complexity introduced by Guruswami, Håstad, and Sudan [13]. Neither the $\alpha \cdot k$ result nor the $k - 3 - \varepsilon$ result has been published (an ECCC manuscript exists [7]) since they have been subsumed by the work presented herein.

**Our result and techniques.** In this paper we improve upon all the above hardness results by proving a factor $(k-1-\varepsilon)$ inapproximability result for E$k$-Vertex-Cover. Already for $k = 3$, this is an improvement from $3/2 - \varepsilon$ to $2 - \varepsilon$. Improving our hardness factor from $(k - 1 - \varepsilon)$ to $(k - \varepsilon)$ appears highly nontrivial (although it was recently proved under a certain conjecture [22]). Note that such a bound would imply a factor $2 - \varepsilon$ hardness for vertex cover on graphs, a problem that is notoriously difficult. While our proof shares some of the extremal combinatorics flavor of [9] and [7], it draws its strength mainly from a new multilayered outer verifier system for NP languages. This multilayered system is constructed using the Raz verifier [24] as a building block.

The Raz verifier, which serves as the starting point or "outer verifier" in most (if not all) recent hardness results, can be described as follows. There are two sets of (non-Boolean) variables $Y$ and $Z$, and for certain pairs of $y \in Y$ and $z \in Z$, a constraint $\pi_{y\to z}$. The constraints are projections; i.e., for each assignment to $y$ there exists exactly one assignment to $z$ such that the constraint $\pi_{y\to z}$ is satisfied. The goal is to find an assignment $A$ to the variables so that a maximum number of constraints $\pi_{y\to z}$ are satisfied, i.e., have the property $\pi_{y\to z}(A(y)) = A(z)$. By the PCP theorem [2, 1] together with the parallel repetition theorem [24], we know that for every $\varepsilon > 0$ it is NP-hard to distinguish between the case where all the constraints can be satisfied and the case where no more than a fraction $\varepsilon$ of the constraints can be satisfied.

In [7], the $\alpha \cdot k$ hardness result is obtained by replacing every $Y$-variable by a block of vertices (representing its long-code). Hyperedges connect $y_1$-vertices to $y_2$-vertices only if there is some $z \in Z$ such that $\pi_{y_1\to z}, \pi_{y_2\to z}$ are constraints in the system. This construction has an inherent symmetry between blocks which deteriorates the projection property of the constraints, limiting the hardness factor one can prove to at most $k/2$. Since this is a relatively simple reduction, we include a proof showing a hardness of approximation factor of $(\lfloor k/2 \rfloor - \varepsilon)$. The improvement over the factor $k/3$ in [7] is obtained using a better result on $s$-wise $t$-intersecting set families. We also remark that this result itself suffices for the recent reduction from E$k$-Vertex-Cover to asymmetric $K$-center [5]. Moreover, this result has the advantage of working for much larger superconstant values of $k$ (up to $(\log N)^{1/c}$ for some absolute constant $c$, where $N$ is the number of hyperedges).

Another way of reducing the Raz verifier to E$k$-Vertex-Cover is by maintaining the asymmetry between $Y$ and $Z$, introducing a block of vertices for each variable in $Y$ and in $Z$ (representing their long-code). Each constraint $\pi_{y\to z}$ can be emulated by a set of hyperedges, where each hyperedge consists of both $y$-vertices and $z$-vertices. The hyperedges can be chosen so that if the initial PCP instance were satisfiable, then taking a particular fraction $1/k$ of the vertices in each block would be a vertex cover. However, this reduction has a basic "bipartiteness" flaw: the underlying constraint graph, being bipartite with parts $Y$ and $Z$, has a vertex cover of size at most one-half of the number of vertices. Taking all the vertices of, say, the $Z$-variables will be a vertex cover for the hypergraph regardless of whether or not the initial PCP instance was satisfiable. This, once again, limits the gap to no more than $k/2$.

We remark that this "bipartiteness" flaw naturally arises in other settings as well. One example is approximate hypergraph coloring, where indeed our multilayered PCP construction has been successfully used for showing hardness; see [8, 21].

*The multilayered PCP.* We overcome the $k/2$ limit by presenting a new, multilayered PCP. In this construction we maintain the projection property of the constraints that is a strong feature of the Raz verifier, while overcoming the "bipartiteness" flaw. In the usual Raz verifier we have two "layers," the first containing the $Y$-variables and the second containing the $Z$-variables. In the multilayered PCP, we have $\ell$ layers containing variables $X_1, X_2, \dots, X_\ell$, respectively. Between every pair of layers $i_1$ and $i_2$, we have a set of projection constraints that represent an instance of the Raz verifier. In the multilayered PCP, it is NP-hard to distinguish between (i) the case where there exists an assignment that satisfies *all* the constraints, between *every* pair of layers, and (ii) the case where for *every* $i_1, i_2$ it is impossible to satisfy more than a fraction $\varepsilon$ of the constraints between $X_{i_1}$ and $X_{i_2}$.

In addition, we prove that the underlying constraint graph no longer has the "bipartiteness" obstacle; i.e., it no longer has a small vertex cover, and hence it has no large independent set. Indeed we show that the multilayered PCP has a certain "weak-density" property: for any set containing an $\varepsilon$ fraction of the variables there are many constraints between variables of this set. This guarantees that "fake" independent sets in the hypergraph (i.e., independent sets that occur because there are no constraints between the variables of the set) contain at most an $\varepsilon$ fraction of the vertices.

We mention that the PCP presented by Feige in [10] has a few structural similarities with ours. Most notably, both have more than two types of variables. However, while in our construction the types are layered with decreasing domain sizes, in Feige's construction the different types are all symmetric. Furthermore, and more importantly, the constraints tested by the verifier in Feige's construction are not projections, while this is a key feature of our multilayered PCP, crucially exploited in our analysis.

We view the construction of the multilayered PCP as a central contribution of our paper and believe that it could be a powerful starting point for other hardness of approximation results as well. In fact, as mentioned above, our multilayered construction has already been used in obtaining strong hardness results for coloring 3-uniform hypergraphs [8, 21] (namely, the hardness of coloring a 2-colorable 3-uniform hypergraph using an arbitrary constant number of colors), a problem for which no nontrivial inapproximability results are known using other techniques. We anticipate that this new outer verifier will also find other applications besides the ones in this paper and in [8, 21].

*The biased long-code.* Our hypergraph construction relies on the long-code that was introduced in [3] and, more specifically, on the biased long-code defined in [9]. Thus, each PCP-variable is represented by a block of vertices, one for each "bit" of the biased long-code. More specifically, in $x$'s block we have one vertex for each subset of $R$, where $R$ is the set of assignments for the variable $x$. However, rather than taking all vertices in a block with equal weight, we attach weights to the vertices according to the $p$-biased long-code. The weight of a subset $F$ is set to $p^{|F|}(1-p)^{|R\setminus F|}$, highlighting subsets of cardinality $p \cdot |R|$. Thus we actually construct a weighted hypergraph; we will later describe how it can be translated to a nonweighted one.

The vertex cover in the hypergraph is shown to have relative size of either $1-p$ in the good case or almost 1 in the bad case. Choosing large $p = 1 - \frac{1}{k-1-\varepsilon}$ yields the desired gap of $\frac{1}{1-p} \approx k-1-\varepsilon$ between the good and bad cases. The reduction uses the following combinatorial property: *a family of subsets of a set $R$, where each subset has size $p\,|R|$, either contains very few subsets, or it contains some $k-1$ subsets whose common intersection is very small.* We will later show that this property holds for $p < 1 - \frac{1}{k-1}$, and hence we obtain a gap of $k-1-\varepsilon$. As can be seen, this property does not hold for $p > 1 - \frac{1}{k-1}$, and hence one cannot improve the $k-1-\varepsilon$ result by simply increasing $p$.

**Weighted versus unweighted.** As mentioned above, our construction yields a weighted hypergraph: each vertex is associated with a weight, and the goal is to minimize the weight of the vertex cover. By appropriately duplicating vertices, we can obtain an unweighted hypergraph (for more detail, see [6, 9]). We note that in all of our constructions, duplicating vertices does not change the asymptotic size of the hypergraph, and hence all of our results carry over to the unweighted case.

**Location of the gap.** All of our hardness results have the gap between sizes of the vertex cover at the "strongest" location. Specifically, to prove a factor $(k-1-\varepsilon)$

hardness we show that it is hard to distinguish between $k$-uniform hypergraphs that have a vertex cover of weight $\frac{1}{k-1} + \varepsilon$ and those whose minimum vertex cover has weight at least $(1 - \varepsilon)$. This result is stronger than a gap of about $(k - 1)$ achieved, for example, between vertex covers of weight $\frac{1}{(k-1)^2}$ and $\frac{1}{k-1}$. In fact, by adding dummy vertices, our result implies that for any $c < 1$ it is NP-hard to distinguish between hypergraphs whose minimum vertex cover has weight at least $c$ and those which have a vertex cover of weight at most $\left(\frac{c}{k-1} + \varepsilon\right)$. Put another way, our result shows that for any $k \geq 3$ there exists an $\alpha = \alpha(k) > 0$ such that for arbitrarily small $\varepsilon > 0$, it is NP-hard to find an independent set consisting of a fraction $\varepsilon$ of the vertices in a given $k$-uniform hypergraph, even if the hypergraph is promised to contain an independent set comprising a fraction $\alpha$ of the vertices. We remark that such a result is not known for graphs and seems out of the reach of current techniques. (The 1.36 hardness result for vertex cover on graphs due to Dinur and Safra [9], for example, shows that it is NP-hard to distinguish between cases when the graph has an independent set of size $0.38 \cdot n$ and cases when no independent set has more than $0.16 \cdot n$ vertices.) This gap location feature was crucial to the recent tight $\Omega(\log^* n)$ inapproximability result for asymmetric $K$-center [5].

**Organization.** We begin in section 2.1 by developing the machinery from extremal combinatorics concerning intersecting families of sets that will play a crucial role in our proof. This is followed by a statement of the starting point of our reduction, which is the standard gap instance obtained by combining the PCP theorem with Raz's parallel repetition theorem. In section 3, we present a relatively simple reduction that shows an inapproximability factor of $\lfloor k/2 \rfloor - \varepsilon$ for arbitrary $\varepsilon > 0$. As explained earlier, this is as far as we can go using just the "bipartite" Raz outer verifier. In section 4, we present the multilayered PCP construction, which offers hope of breaking the $k/2$ barrier. In section 5, we present our reduction to a gap version of E$k$-Vertex-Cover which allows us to prove a factor $(k-1-\varepsilon)$ inapproximability result for this problem. Finally, we discuss the case when $k$ is not a constant but instead is a growing function of the number of hyperedges in section 6.

## 2. Preliminaries.

### 2.1. Intersecting families.

In this section we define the notion of an $s$-wise $t$-intersecting family and prove an important property of such families. For a comprehensive survey, see [15]. Denote $[n] = \{1, \ldots, n\}$ and $2^{[n]} = \{F \mid F \subseteq [n]\}$. We start with the following definition.

Definition 2.1. *A family $\mathcal{F} \subseteq 2^{[n]}$ is called* $s$-wise $t$-intersecting *if for every $s$ sets $F_1, \ldots, F_s \in \mathcal{F}$, we have $|F_1 \cap \cdots \cap F_s| \geq t$.*

For example, the family of all sets $F \in 2^{[n]}$ such that $[t] \subseteq F$ is an $s$-wise $t$-intersecting family. A more interesting example is given by the family of all sets $F \in 2^{[n]}$ such that $|F \cap [t+s]| \geq t + s - 1$. Each set in this family has at most one "hole" in $[t+s]$. Therefore, any intersection of $s$ sets of this family contains at least $t + s - s = t$ elements from the range $[t+s]$. More generally, for any $j \geq 0$, we can define the family of all sets $F \in 2^{[n]}$ such that $|F \cap [t + js]| \geq t + (s-1)j$; it is easy to see that this is an $s$-wise $t$-intersecting family.

We need another important definition.

Definition 2.2. *For a bias parameter $0 < p < 1$ and a ground set $R$, the weight of a set $F \subseteq R$ is*

$$\mu_p^R(F) \overset{def}{=} p^{|F|} \cdot (1-p)^{|R \setminus F|}.$$

*When $R$ is clear from the context we write $\mu_p$ for $\mu_p^R$. The weight of a family $\mathcal{F} \subseteq 2^R$ is $\mu_p(\mathcal{F}) = \sum_{F \in \mathcal{F}} \mu_p(F)$.*

The weight of a subset is precisely the probability of obtaining this subset when one picks every element in $R$ independently with probability $p$.

The following is the main lemma of this section. It shows that for any $p < \frac{s-1}{s}$, a family of nonnegligible $\mu_p$-weight (i.e., $\mu_p(\mathcal{F}) \geq \varepsilon$) cannot be $s$-wise $t$-intersecting for sufficiently large $t$.

LEMMA 2.3. *For arbitrary $\varepsilon, \delta > 0$, and integer $s \geq 2$, let $p = 1 - \frac{1}{s} - \delta$. Then, there exists $t = t(\varepsilon, s, \delta)$ such that for any $s$-wise $t$-intersecting family $\mathcal{F} \subseteq 2^{[n]}$, $\mu_p(\mathcal{F}) < \varepsilon$. Moreover, it is enough to choose $t(\varepsilon, s, \delta) = \Omega(\frac{1}{\delta^2}(\log \frac{1}{\varepsilon} + \log(1 + \frac{1}{s\delta^2})))$.*

*Proof.* In order to prove this lemma, we need to introduce the notion of a left-shifted family. Performing an $(i,j)$-shift on a family consists of replacing the element $j$ with the element $i$ in all sets $F \in \mathcal{F}$ such that $j \in F$, $i \notin F$, and $(F \setminus \{j\}) \cup \{i\} \notin \mathcal{F}$. A left-shifted family is a family which is invariant with respect to $(i,j)$-shifts for any $1 \leq i < j \leq n$. For any family $\mathcal{F}$, by iterating the $(i,j)$-shift for all $1 \leq i < j \leq n$ we eventually get a left-shifted family which we denote by $S(\mathcal{F})$. The following simple lemma summarizes the properties of the left-shift operation.

LEMMA 2.4 (see [15, Lemma 4.2, p. 1298]). *For any family $\mathcal{F} \subseteq 2^{[n]}$, there exists a one-to-one and onto mapping $\tau$ from $\mathcal{F}$ to $S(\mathcal{F})$ such that $|F| = |\tau(F)|$ for every $F \in \mathcal{F}$. In other words, left-shifting a family maintains its size and the size of the sets in the family. Moreover, if $\mathcal{F}$ is an $s$-wise $t$-intersecting family, then so is $S(\mathcal{F})$.*

It can be easily checked that the examples given after Definition 2.1 are all left-shifted. As the next lemma shows, those examples essentially represent all possible sets in any left-shifted $s$-wise $t$-intersecting family.

LEMMA 2.5 (see [15, Lemma 8.3, p. 1311]). *Let $\mathcal{F} \subseteq 2^{[n]}$ be a left-shifted $s$-wise $t$-intersecting family. Then, for every $F \in \mathcal{F}$, there exists a $j \geq 0$ with $|F \cap [t+sj]| \geq t + (s-1)j$.*

*Proof.* For completeness, we sketch the proof of the lemma. For two equally sized sets $A = \{a_1, \ldots, a_l\}$, $1 \leq a_1 < \cdots < a_l \leq n$, and $B = \{b_1, \ldots, b_l\}$, $1 \leq b_1 < \cdots < b_l \leq n$, we say that $A \preceq B$ if $a_i \leq b_i$ for all $i = 1, \ldots, l$. Then, we claim that for such $A, B$, if $[n] \setminus A \in \mathcal{F}$, then also $[n] \setminus B \in \mathcal{F}$. We prove this by induction: for $i = 0, \ldots, l$ define the set $F_i = [n] \setminus \{a_1, \ldots, a_i, b_{i+1}, \ldots, b_l\}$. Notice that $F_l = [n] \setminus A$ and therefore $F_l \in \mathcal{F}$. Next, we show that $F_i \in \mathcal{F}$ implies that $F_{i-1} \in \mathcal{F}$. If $a_i = b_i$, then the claim is obvious. Otherwise, $a_i < b_i$ and hence $b_i \in F_i$. Since $\mathcal{F}$ is left-shifted and $a_i \notin F_i$, it follows that $F_i \setminus \{b_i\} \cup \{a_i\} = F_{i-1}$ is in $\mathcal{F}$. This proves our claim since $F_0 = [n] \setminus B$.

Let us now complete the proof of the lemma. Assume on the contrary that there exists $F \in \mathcal{F}$ such that for all $j \geq 0$, $|F \cap [t+sj]| < t + (s-1)j$. Let $A = \{a_1, \ldots, a_l\}$ be such that $F = [n] \setminus A$ and assume that $a_1 < \cdots < a_l$. The above condition implies that $F$ contains at least $i$ "holes" in $[t + (i-1)s]$ and therefore $a_i \leq t + (i-1)s$. It also implies that $l \geq \lfloor (n-t)/s \rfloor + 1$.

For $k = 0, \ldots, s-1$, define the set $B_k = \{b_{k,1}, \ldots, b_{k,l}\}$ by $b_{k,i} = \min\{t + k + (i-1)s, n - (l-i)\}$. Since $a_i \leq t + (i-1)s$ and $a_i \leq n - (l-i)$ (just because $a_i < a_{i+1} < \cdots < a_l \leq n$ are all integers), we obtain that $a_i \leq b_{0,i}$. In other words, $A \preceq B_0$. Moreover, since $b_{k,i} \leq b_{k+1,i}$, we see that $A \preceq B_0 \preceq B_1 \preceq \cdots \preceq B_{s-1}$. Using the claim we proved before, we obtain that for all $k = 0, \ldots, s-1$, $[n] \setminus B_k \in \mathcal{F}$. But this is a contradiction since $([n] \setminus B_0) \cap \cdots \cap ([n] \setminus B_{s-1}) \subseteq [t-1]$ and in particular its size is less than $t$. ☐

We now complete the proof of Lemma 2.3. We follow the general outline of the proof of Theorem 8.4 in [15, p. 1311]. Let $\mathcal{F}$ be an $s$-wise $t$-intersecting family where

$t$ will be determined later. According to Lemma 2.4, $S(\mathcal{F})$ is also $s$-wise $t$-intersecting and $\mu_p(S(\mathcal{F})) = \mu_p(\mathcal{F})$. By Lemma 2.5, for every $F \in S(\mathcal{F})$ there exists a $j \geq 0$ such that $|F \cap [t+sj]| \geq t+(s-1)j$. We can therefore bound $\mu_p(S(\mathcal{F}))$ from above by the probability that such a $j$ exists for a random set chosen according to the distribution $\mu_p$. We now prove an upper bound on this probability, which will give the desired bound on $\mu_p(S(\mathcal{F}))$ and hence also on $\mu_p(\mathcal{F})$.

The Chernoff bound [4] says that for a sequence of $m$ independent random variables $X_1, \dots, X_m$ on $\{0,1\}$ such that for all $i$, $\Pr[X_i = 1] = p$ for some $p$,

$$\Pr\left[\sum X_i > (p+\tau)m\right] \leq e^{-2m\tau^2}.$$

Hence, for any $j \geq 0$, $\Pr[\ |F \cap [t+sj]| \geq t+(s-1)j\ ]$ is at most

$$\Pr[\ |F \cap [t+sj]| - p(t+sj) \geq \delta(t+sj)\ ] \leq e^{-2(t+sj)\delta^2}.$$

Summing over all $j \geq 0$ we get

$$\mu_p(S(\mathcal{F})) \leq \sum_{j\geq 0} e^{-2(t+sj)\delta^2} = \frac{e^{-2t\delta^2}}{(1-e^{-2s\delta^2})} \leq e^{-2t\delta^2}\left(1+\frac{1}{2s\delta^2}\right),$$

which is smaller than $\varepsilon$ for $t = \Omega(\frac{1}{\delta^2}(\log\frac{1}{\varepsilon} + \log(1+\frac{1}{s\delta^2})))$. $\square$

**2.2. The PCP theorem and the parallel repetition theorem.** As is the case with many inapproximability results (e.g., [3, 16, 17, 26]), we begin our reduction from the Raz verifier described next. Let $R$ be some parameter and let $\Psi$ be a collection of two-variable constraints, where the variables are of two types, denoted $Y$ and $Z$. Let $R_Y$ denote the range of the $Y$-variables and $R_Z$ the range of the $Z$-variables,[1] where $|R_Z| \leq |R_Y|$ and both are at most $R^{O(1)}$. Assume that each constraint $\pi \in \Psi$ depends on exactly one $y \in Y$ and one $z \in Z$ and furthermore, that for every value $a_y \in R_Y$ assigned to $y$ there is exactly one value $a_z \in R_Z$ to $z$ such that the constraint $\pi$ is satisfied. Therefore, we can write each constraint $\pi \in \Psi$ as a function from $R_Y$ to $R_Z$ and use notation $\pi_{y\to z} : R_Y \to R_Z$. Furthermore, we assume that the underlying constraint graph is biregular; i.e., every $Y$-variable appears in the same number of constraints in $\Psi$, and every $Z$-variable appears in the same number of constraints in $\Psi$. Both of these numbers are assumed to be at most $R^{O(1)}$.

The following theorem follows by combining the PCP theorem with Raz's parallel repetition theorem. The PCP given by this theorem will henceforth be called the Raz verifier.

THEOREM 2.6 (PCP theorem [1, 2] and Raz's parallel repetition theorem [24]). *Let $\Psi$ be as above. There exists a universal constant $\gamma > 0$ such that for every (large enough) constant $R$ it is NP-hard to distinguish between the following two cases:*

- *Yes. There is an assignment $A : Y \to R_Y$, $A : Z \to R_Z$ such that all $\pi \in \Psi$ are satisfied by $A$, i.e., for all $\pi_{y\to z} \in \Psi$, $\pi_{y\to z}(A(y)) = A(z)$.*
- *No. No assignment can satisfy more than a fraction $\frac{1}{R^\gamma}$ of the constraints in $\Psi$.*

*Remark.* The reduction, from 3SAT say, proving the above hardness can be assumed to run in time $n^{O(\log R)}$, where $n$ is the size of the 3SAT instance. Also recall that the constraint graph of $\Psi$ is biregular with $Y$ and $Z$ degrees $d_l$ and $d_r$, where both $d_l, d_r \leq R^{O(1)}$.

[1]Readers familiar with the Raz verifier may prefer to think concretely of $R_Y = [7^u]$ and $R_Z = [2^u]$ for some number $u$ of repetitions.

**3. A factor $k/2$ inapproximability result.** In this section, we prove the factor $(\lfloor k/2 \rfloor - \varepsilon)$ hardness result for E$k$-Vertex-Cover for $k \geq 4$. We will show this by proving a factor $(k/2 - \varepsilon)$ hardness for even $k \geq 4$ (the result for odd $k$ follows by a trivial reduction that adds a new vertex to every hyperedge of a hard instance of the $(k-1)$-uniform hypergraph).

Let $IS(G)$ denote the weight of vertices contained in the largest independent set of the hypergraph $G$.

THEOREM 3.1. *Let $k \geq 4$ be an arbitrary even integer. Then for every $\varepsilon > 0$, it is NP-hard to approximate Ek-Vertex-Cover within a factor of $(k/2 - \varepsilon)$. More specifically, for every $\varepsilon, \delta > 0$, it is NP-hard to distinguish, given a k-uniform hypergraph G, between the following two cases:*
- $IS(G) \geq 1 - \frac{2}{k} - \delta$.
- $IS(G) \leq \varepsilon$.

*Proof.* Start with a PCP instance, as given in Theorem 2.6, namely, a set of local constraints $\Psi$ over variables $Y \cup Z$, whose respective ranges are $R_Y, R_Z$. For parameters, we pick $t$ to be larger than $t(\frac{\varepsilon}{2}, \frac{k}{2}, \delta)$ in Lemma 2.3, say, $t = O(\frac{1}{\delta^3} \log \frac{1}{\varepsilon})$ with some large enough constant. Moreover, take $R > (\frac{2t^2}{\varepsilon})^{1/\gamma}$, where $\gamma > 0$ is the universal constant from Theorem 2.6. From $\Psi$, we now construct a (weighted) $k$-uniform hypergraph $G$ whose minimum vertex cover has weight $\approx 2/k$ or $\approx 1$ depending on whether $\Psi$ is satisfiable or not.

For a set $R$ we denote by $2^R$ the power set of $R$. The vertex set of $G$ is

$$V \overset{def}{=} Y \times 2^{R_Y};$$

i.e., for each $y \in Y$ we construct a block of vertices denoted $V[y] = \{y\} \times 2^{R_Y}$ corresponding to all possible subsets of $R_Y$. The weight of each vertex $\langle y, F \rangle \in V$ is

$$\Lambda(\langle y, F \rangle) \overset{def}{=} \frac{1}{|Y|} \cdot \mu_{1-\frac{2}{k}-\delta}(F).$$

The hyperedges are defined as follows. For every pair of local constraints $\pi_{y_1 \to z}, \pi_{y_2 \to z} \in \Psi$ sharing a common variable $z \in Z$, we add the hyperedge

$$\{\langle y_1, F_1^1 \rangle, \langle y_1, F_2^1 \rangle, \ldots, \langle y_1, F_{k/2}^1 \rangle\} \bigcup \{\langle y_2, F_1^2 \rangle, \langle y_2, F_2^2 \rangle, \ldots, \langle y_2, F_{k/2}^2 \rangle\}$$

if and only if there is no $r_1 \in \bigcap_{1 \leq j \leq k/2} F_j^1$ and $r_2 \in \bigcap_{1 \leq j \leq k/2} F_j^2$ such that $\pi_{y_1 \to z}(r_1) = \pi_{y_2 \to z}(r_2)$. Formally,

$$E \overset{def}{=} \bigcup_{\pi_{y_1 \to z}, \pi_{y_2 \to z} \in \Phi} \Big\{ \{\langle y_1, F_1^1 \rangle, \ldots, \langle y_1, F_{k/2}^1 \rangle, \langle y_2, F_1^2 \rangle, \ldots, \langle y_2, F_{k/2}^2 \rangle\} \Big| \quad \pi_{y_1 \to z}(F_1^1 \cap \cdots \cap F_{k/2}^1) \cap \pi_{y_2 \to z}(F_1^2 \cap \cdots \cap F_{k/2}^2) = \emptyset \Big\},$$

where the union is taken over all pairs of local constraints with a common variable $z$.

LEMMA 3.2 (completeness). *If $\Psi$ is satisfiable, then $IS(G) \geq 1 - \frac{2}{k} - \delta$.*

*Proof.* Assume a satisfying assignment $A : Y \cup Z \to R_Y \cup R_Z$ for $\Psi$. The following set is an independent set of $G$:

$$\mathcal{I} = \{\langle y, F \rangle \in V[y] \mid y \in Y,\ A(y) \in F\}. \qquad (1)$$

For every hyperedge $e = \{\langle y_1, F_1^1 \rangle, \ldots, \langle y_1, F_{k/2}^1 \rangle, \langle y_2, F_1^2 \rangle, \ldots, \langle y_2, F_{k/2}^2 \rangle\}$ either $A(y_1) \notin F_1^1 \cap \cdots \cap F_{k/2}^1$ or $A(y_2) \notin F_1^2 \cap \cdots \cap F_{k/2}^2$; otherwise since $A(y_1), A(y_2)$ agree on every common $Z$-variable, we have $\pi_{y_1\to z}(F^1_1 \cap \cdots \cap F^1_{k/2}) \cap \pi_{y_2\to z}(F^2_1 \cap \cdots \cap F^2_{k/2}) \neq \emptyset$, and $e$ would not have been a hyperedge.

Now note that the weight of the family $\{F \mid A(y) \in F\}$ with respect to the bias parameter $(1 - 2/k - \delta)$ is $(1 - 2/k - \delta)$. Hence the weight of the independent set $\mathcal{I}$ in (1) is $1 - 2/k - \delta$. $\square$

LEMMA 3.3 (soundness). *If $IS(G) \geq \varepsilon$, then there exists an assignment $A : Y \cup Z \to R_Y \cup R_Z$ that satisfies more than a fraction $1/R^\gamma$ of the constraints in $\Psi$.*

*Proof.* Let $S \subset V$ be such an independent set of weight at least $\varepsilon$. We consider the set $Y' \subseteq Y$ of all variables $y$ for which the weight (under $\Lambda$) of $S \cap V[y]$ in $V[y]$ is at least $\varepsilon/2$. A simple averaging argument shows that $|Y'| \geq |Y|\varepsilon/2$.

For each $y \in Y'$, define

$$\mathcal{F}_y = \{F \in 2^{R_Y} \mid \langle y, F\rangle \in S\}.$$

Thus we have for all $y \in Y'$, $\mu_{1-\frac{2}{k}-\delta}(\mathcal{F}_y) \geq \frac{\varepsilon}{2}$. By Lemma 2.3, applied with the choice $s = k/2$ and $\varepsilon/2$ in place of $\varepsilon$, there must exist $F^y_1, F^y_2, \ldots, F^y_{k/2} \in \mathcal{F}_y$ such that $|F^y_1 \cap F^y_2 \cap \cdots \cap F^y_{k/2}| \leq t$, where $t$ is as defined before. Let us denote by $B(y)$ the intersection $F^y_1 \cap F^y_2 \cap \cdots \cap F^y_{k/2}$; we will refer to $B(y)$ as the *core* of assignments for $y$. Intuitively, for any $y$ for which the independent set $S$ has large intersection with $V[y]$, we can decode a small collection of potential values from $R_Y$, specifically the core $B(y)$, that may be assigned to $y$.

We next translate these cores into an assignment satisfying more than a fraction $\frac{1}{R^\gamma}$ of the constraints in $\Psi$. Observe that for every $z \in Z$ and $y_1, y_2 \in Y'$, $y_1 \neq y_2$, such that $\pi_{y_1\to z}, \pi_{y_2\to z} \in \Psi$, we must have

$$\pi_{y_1\to z}(B(y_1)) \cap \pi_{y_2\to z}(B(y_2)) \neq \emptyset. \tag{2}$$

Indeed, otherwise the set $\{\langle y_1, F^{y_1}_1\rangle, \ldots, \langle y_1, F^{y_1}_{k/2}\rangle, \langle y_2, F^{y_2}_1\rangle, \ldots, \langle y_2, F^{y_2}_{k/2}\rangle\}$ would be a hyperedge whose vertices all lie in $S$, contradicting the assumption that $S$ is an independent set. Let us now slightly modify the definition of $B(y)$: for any $y$ such that $B(y)$ is empty, we add to $B(y)$ some arbitrary element of $R_Y$. Notice that (2) still holds; moreover, it also holds in the case that $y_1$ and $y_2$ are equal.

Let $Z' \subseteq Z$ denote the set of all $Z$-variables of the instance $\Psi$ that participate in some constraint with some $y \in Y'$. Formally, $Z' \overset{def}{=} \{z \mid \pi_{y\to z} \in \Psi \text{ for some } y \in Y'\}$. Associate each such $z \in Z'$ with an arbitrary $y \in Y'$ for which $\pi_{y\to z} \in \Psi$, and let $B(z) \overset{def}{=} \pi_{y\to z}(B(y)) \subseteq R_Z$. Now define a random assignment $A$ by independently selecting for each $y \in Y', z \in Z'$ a random value from $B(y), B(z)$, respectively. Assign the rest of the variables $(Y \setminus Y') \cup (Z \setminus Z')$ with any arbitrary value. To complete the proof, we prove

$$E_A\big[\big|\{\pi_{y\to z} \in \Psi \mid \pi_{y\to z} \text{ is satisfied by } A\}\big|\big] \geq \frac{\varepsilon}{2t^2} \cdot |\Psi|\,. \tag{3}$$

Here the expectation is taken over the choice of the random assignment $A$. We will show that for every $y \in Y'$, each constraint $\pi_{y\to z} \in \Psi$ is satisfied by $A$ with probability $\geq \frac{1}{t^2}$; thus the expected number of local constraints satisfied by $A$ is $\frac{|Y'|}{|Y|} \cdot \frac{1}{t^2}|\Psi| \geq \frac{\varepsilon}{2t^2} \cdot |\Psi|$ (because each $y \in Y$ appears in the same number of local constraints).

So, let $\pi_{y\to z} \in \Psi$ for arbitrary $y \in Y'$. Assume $z$ is associated with some $y' \in Y'$ possibly equal to $y$. By (2), we have

$$\pi_{y\to z}(B(y)) \cap B(z) \;=\; \pi_{y\to z}(B(y)) \cap \pi_{y'\to z}(B(y')) \;\neq \emptyset.$$

Therefore, there is at least one value $a_y \in B(y)$ such that $\pi_{y\to z}(a_y) \in B(z)$. Since for every $y \in Y'$, $|B(y)| \leq t$, there is at least a $\frac{1}{t^2}$ probability of having $\pi_{y\to z}(A(y)) = A(z)$, thereby showing (3).

Thus, there exists some assignment $A$ that meets the expectation, which means it satisfies at least $\frac{\varepsilon}{2t^2} > \frac{1}{R^\gamma}$ (by our choice of $R$) of the local constraints in $\Psi$. This completes the proof of the soundness Lemma 3.3. $\square$

Theorem 3.1 now follows from Lemmas 3.2 and 3.3 and Theorem 2.6. $\square$

Let us compute some parameters of the reduction, which will be useful in section 6 where we will consider the case with superconstant values of $k$. First, let us compute $R$. The condition $R \geq (2t^2/\varepsilon)^{1/\gamma}$, together with our choice of $t$, implies that it suffices if

$$R = \left(\frac{1}{\varepsilon\delta}\right)^{O(1)}.$$

By the remark following Theorem 2.6, the number of variables in the PCP instance is at most $n^{O(\log R)} = n^{O(\log(1/\varepsilon\delta))}$, where $n$ is the size of the original 3SAT instance. Since there is a block of $2^{R^{O(1)}}$ vertices corresponding to all subsets of $R_y$ for each of these variables, the number of vertices in the hypergraph produced by the reduction is at most

$$n^{O(\log(1/\varepsilon\delta))} 2^{R^{O(1)}} \leq n^{O(\log(1/\varepsilon\delta))} 2^{(1/\varepsilon\delta)^{O(1)}}. \tag{4}$$

The degree of the hypergraph, i.e., the maximum number of hyperedges in which each vertex appears, is at most $2^{R^{O(1)}k} \cdot R^{O(1)}$, since each variable in the PCP instance appears in at most $R^{O(1)}$ constraints. Hence, the degree is at most

$$2^{k/(\varepsilon\delta)^{O(1)}}.$$

Finally, the running time of the reduction is polynomial in the number of hyperedges. A bound on the latter can be obtained by combining the two previous bounds:

$$n^{O(\log(1/\varepsilon\delta))} 2^{(1/\varepsilon\delta)^{O(1)}} \cdot 2^{k/(\varepsilon\delta)^{O(1)}} \leq n^{O(\log(1/\varepsilon\delta))} 2^{k/(\varepsilon\delta)^{O(1)}}. \tag{5}$$

## 4. The multilayered PCP.

As discussed in the introduction, a natural approach to build a hypergraph from the PCP $\Psi$ is to have a block of vertices for every variable $y$ or $z$ and define hyperedges of the hypergraph so as to enforce the constraints $\pi_{y\to z}$. For every constraint $\pi_{y\to z}$, there will be hyperedges containing vertices from the block of $y$ and the block of $z$. However, this approach is limited by the fact that the constraint graph underlying the PCP has a small vertex cover. Since each hyperedge contains vertices from both the $Y$ and $Z$ "sides," the subset of all vertices on the $Y$ (resp., $Z$) "side" already covers all of the hyperedges regardless of whether the initial PCP system was satisfiable or not.

This difficulty motivates our construction of a multilayered PCP where we have many types of variables (rather than only $Y$ and $Z$) and the resulting hypergraph is *multipartite*. The multilayered PCP is able to maintain the properties of Theorem 2.6 between *every* pair of layers. Moreover, the underlying constraint graph has a special "weak-density" property that, roughly speaking, guarantees it will have only tiny independent sets (thus any vertex cover for it must contain almost all of the vertices).

**4.1. Layering the variables.** Let $\ell, R > 0$. Let us begin by defining an $\ell$-layered PCP. In an $\ell$-layered PCP there are $\ell$ sets of variables denoted by $X_1, \ldots, X_\ell$. The range of variables in $X_i$ is denoted $R_i$, with $|R_i| = R^{O(\ell)}$. For every $1 \le i < j \le \ell$ there is a set of constraints $\Phi_{ij}$ where each constraint $\pi \in \Phi_{ij}$ depends on exactly one $x \in X_i$ and one $x' \in X_j$. For any two variables we denote by $\pi_{x \to x'}$ the constraint between them if such a constraint exists. Moreover, the constraints in $\Phi_{ij}$ are projections from $x$ to $x'$; that is, for every assignment to $x$ there is exactly one assignment to $x'$ such that the constraint is satisfied.

In addition, as mentioned in the introduction, we would like to show a certain "weak-density" property of our multilayered PCP. This property is defined in the following definition.

DEFINITION 4.1. *An $\ell$-layered PCP is said to be* weakly-dense *if for any $\delta$, $2/\ell < \delta < 1$, given $m \ge \lceil \frac{2}{\delta} \rceil$ layers $i_1 < \cdots < i_m$, and given any sets $S_j \subseteq X_{i_j}$ for $j \in [m]$ such that $S_j \ge \delta |X_{i_j}|$, there always exist two sets $S_j$ and $S_{j'}$ such that the number of constraints between them is at least a $\frac{\delta^2}{4}$ fraction of the constraints between the layers $X_{i_j}$ and $X_{i_{j'}}$.*

THEOREM 4.2. *There exists a universal constant $\gamma > 0$ such that for any parameters $\ell, R$, there is a weakly-dense $\ell$-layered PCP $\Phi = \cup \Phi_{ij}$ such that it is NP-hard to distinguish between the following two cases:*

- *Yes. There exists an assignment that satisfies all the constraints.*
- *No. For every $i < j$, not more than $1/R^\gamma$ of the constraints in $\Phi_{ij}$ can be satisfied by an assignment.*

*Moreover, the theorem holds even if every variable participates in $R^{O(\ell)}$ constraints.*

*Proof.* Let $\Psi$ be a constraint system as in Theorem 2.6. We construct $\Phi = \cup \Phi_{ij}$ as follows. The variables $X_i$ of layer $i \in [\ell]$ are the elements of the set $Z^i \times Y^{\ell - i}$, i.e., all $\ell$-tuples where the first $i$ elements are $Z$-variables and the last $\ell - i$ elements are $Y$-variables. The variables in layer $i$ have assignments from the set $R_i = (R_Z)^i \times (R_Y)^{\ell - i}$ corresponding to an assignment to each variable of $\Psi$ in the $\ell$-tuple. It is easy to see that $|R_i| \le R^{O(\ell)}$ for any $i \in [\ell]$ and that the total number of variables is no more than $|\Psi|^{O(\ell)}$. For any $1 \le i < j \le \ell$ we define the constraints in $\Phi_{ij}$ as follows. A constraint exists between a variable $x_i \in X_i$ and a variable $x_j \in X_j$ if they contain the same $\Psi$ variables in the first $i$ and the last $\ell - j$ elements of their $\ell$-tuples. Moreover, for any $i < k \le j$ there should be a constraint in $\Psi$ between $x_{i,k}$ and $x_{j,k}$. More formally, denoting $x_i = (x_{i,1}, \ldots, x_{i,\ell})$ for $x_i \in X_i = Z^i \times Y^{\ell - i}$,

$$\Phi_{ij} = \left\{ \pi_{x_i, x_j} \;\middle|\; \begin{array}{l} x_i \in X_i, x_j \in X_j \\ \forall k \in [\ell] \setminus \{i+1, \ldots, j\}, x_{i,k} = x_{j,k}, \\ \forall k \in \{i+1, \ldots, j\}, \pi_{x_{i,k} \to x_{j,k}} \in \Psi \end{array} \right\}.$$

As promised, the constraints $\pi_{x_i \to x_j}$ are projections. Given an assignment $a = (a_1, \ldots, a_\ell) \in R_i$ to $x_i$, we define the consistent assignment $b = (b_1, \ldots, b_\ell) \in R_j$ to $x_j$ as $b_k = \pi_{x_{i,k} \to x_{j,k}}(a_k)$ for $k \in \{i+1, \ldots, j\}$ and $b_k = a_k$ for all other $k$.

In how many constraints does a variable $x$ participate? Let $x \in X_i$ for some $i \in [\ell]$. Then $x = (x_1, \ldots, x_\ell)$ has a constraint with $x' = (x'_1, \ldots, x'_\ell) \in X_j$ if $i < j$ and on each coordinate $k \in \{i+1, \ldots, j\}$, $\Psi$ contains a constraint between $x'_k$ and $x_k$. For each $k$ there are at most $R^{O(1)}$ constraints in $\Psi$ that touch $x_k$, so altogether there are $R^{O(j-i)}$ such constraints that touch $x$. This is similar for the case where

$j < i$, and summing these together there are at most $\ell \cdot R^{O(\ell)} = R^{O(\ell)}$ constraints that touch any given $x$.

The completeness of $\Phi$ follows easily from the completeness of $\Psi$. That is, assume we are given an assignment $A : Y \cup Z \to R_Y \cup R_Z$ that satisfies all the constraints of $\Psi$. Then, the assignment $B : \bigcup X_i \to \bigcup R_i$ defined by $B(x_1, \dots, x_\ell) = (A(x_1), \dots, A(x_\ell))$ is a satisfying assignment.

For the soundness part, assume that there exist two layers $i < j$ and an assignment $B$ that satisfies more than a $1/R^\gamma$ fraction of the constraints in $\Phi_{ij}$. We partition $X_i$ into classes such that two variables in $X_i$ are in the same class if and only if they are identical except possibly on coordinate $j$. The variables in $X_j$ are also partitioned according to coordinate $j$. Since more than $1/R^\gamma$ of the constraints in $\Phi_{ij}$ are satisfied, it must be the case that there exist a class $x_{i,1}, \dots, x_{i,j-1}, x_{i,j+1}, \dots, x_{i,\ell}$ in the partition of $X_i$ and a class $x_{j,1}, \dots, x_{j,j-1}, x_{j,j+1}, \dots, x_{j,\ell}$ in the partition of $X_j$ between which there exist constraints and the fraction of satisfied constraints is more than $1/R^\gamma$. We define an assignment to $\Psi$ as

$$A(y) = (B(x_{i,1}, \dots, x_{i,j-1}, y, x_{i,j+1}, \dots, x_{i,\ell}))_j$$

for $y \in Y$ and as

$$A(z) = (B(x_{j,1}, \dots, x_{j,j-1}, z, x_{j,j+1}, \dots, x_{j,\ell}))_j$$

for $z \in Z$. Notice that there is a one-to-one and onto correspondence between the constraints in $\Psi$ and the constraints between the two chosen classes in $\Phi$. Moreover, if the constraint in $\Phi$ is satisfied, then the constraint in $\Psi$ is also satisfied. Therefore, $A$ is an assignment to $\Psi$ that satisfies more than $1/R^\gamma$ of the constraints.

To prove that this multilayered PCP is *weakly-dense*, we recall the biregularity property mentioned above; i.e., each variable $y \in Y$ appears in the same number of constraints, and also each $z \in Z$ appears in the same number of constraints. Therefore, the distribution obtained by uniformly choosing a variable $y \in Y$ and then uniformly choosing one of the variables in $z \in Z$ with which it has a constraint is a uniform distribution on $Z$.

Take any $m = \lceil \frac{2}{\delta} \rceil$ layers $i_1 < \cdots < i_m$ and sets $S_j \subseteq X_{i_j}$ for $j \in [m]$ such that $S_j \geq \delta |X_{i_j}|$. Consider a random walk beginning from a uniformly chosen variable $x_1 \in X_1$ and proceeding to a variable $x_2 \in X_2$ chosen uniformly among the variables with which $x_1$ has a constraint. The random walk continues in a similar way to a variable $x_3 \in X_3$ chosen uniformly among the variables with which $x_2$ has a constraint and so on up to a variable in $X_\ell$. Denote by $E_j$ the indicator variable of the event that the random walk hits an $S_j$-variable when in layer $X_{i_j}$. From the uniformity of $\Psi$ it follows that for every $j$, $\Pr[E_j] \geq \delta$. Moreover, using the inclusion-exclusion principle, we get

$$\begin{aligned} 1 \geq \Pr\left[\bigvee E_j\right] &\geq \sum_j \Pr[E_j] - \sum_{j<k} \Pr[E_j \wedge E_k] \\ &\geq \left\lceil \frac{2}{\delta} \right\rceil \cdot \delta - \binom{m}{2} \max_{j<k} \Pr[E_j \wedge E_k] \\ &\geq 2 - \binom{m}{2} \max_{j<k} \Pr[E_j \wedge E_k], \end{aligned}$$

which implies

$$\max_{j<k} \Pr[E_j \wedge E_k] \geq 1 / \binom{m}{2} \geq \frac{\delta^2}{4}.$$

Fix $j$ and $k$ such that $\Pr[E_j \wedge E_k] \geq \frac{\delta^2}{4}$ and consider a shorter random walk beginning from a random variable in $X_{i_j}$ and proceeding to the next layer and so on until hitting layer $i_k$. Since $E_j$ is uniform on $X_{i_j}$ we still have that $\Pr[E_j \wedge E_k] \geq \frac{\delta^2}{4}$ where the probability is taken over the random walks between $X_{i_j}$ and $X_{i_k}$. Also, notice that there is a one-to-one and onto mapping from the set of all random walks between $X_{i_j}$ and $X_{i_k}$ to the set $\Phi_{i_j,i_k}$. Therefore, at least a fraction $\frac{\delta^2}{4}$ of the constraints between $X_{i_j}$ and $X_{i_k}$ are between $S_j$ and $S_k$, which completes the proof of the weak-density property. ▯

## 5. A factor $(k-1-\varepsilon)$ inapproximability result.

THEOREM 1.1 (main theorem). *For any $k \geq 3$, it is NP-hard to approximate Ek-Vertex-Cover within any factor less than $k-1$. More specifically, for every $\varepsilon, \delta > 0$, it is NP-hard to distinguish, given a $k$-uniform hypergraph $G$, between the following two cases:*

- *$IS(G) \geq 1 - \frac{1}{k-1} - \delta$.*
- *$IS(G) \leq \varepsilon$.*

*Proof.* Fix $k \geq 3$ and arbitrarily small $\varepsilon, \delta > 0$. Define $p = 1 - \frac{1}{k-1} - \delta$. Let $\Phi$ be a PCP instance with layers $X_1, \ldots, X_\ell$, as described in Theorem 4.2, with parameters $\ell = 33\varepsilon^{-2}$ and $R$ large enough to be chosen later. We present a construction of a $k$-uniform hypergraph $G = (V, E)$. We use the long-code introduced by Bellare, Goldreich, and Sudan [3]. A long-code over domain $R$ has one bit for every subset $v \subseteq R$. An encoding of element $x \in R$ assigns bit-value 1 to the sets $v$ such that $x \in v$ and assigns 0 to the sets which do not contain $x$. In the following, the bits in the long-code will be vertices of the hypergraph. The vertices that correspond to a bit-value 0 are (supposedly) the vertices of a vertex cover.

*Vertices.* For each variable $x$ in layer $X_i$ we construct a block of vertices $V[x]$. This block contains a vertex for each subset of $R_i$. Throughout this section we slightly abuse notation by writing a vertex rather than the set it represents. The weight of each vertex in the block $V[x]$ is set according to $\mu_p^{R_i}$; i.e., the weight of a subset $v \subseteq R_i$ is proportional to $\mu_p^{R_i}(v) = p^{|v|}(1-p)^{|R_i \setminus v|}$ as in Definition 2.2. All blocks in the same layer have the same total weight, and the total weight of each layer is $\frac{1}{\ell}$. Formally, the weight of a vertex $v \in V[x]$, where $x \in X_i$, is given by

$$\frac{1}{\ell|X_i|}\mu_p^{R_i}(v).$$

*Hyperedges.* We construct hyperedges between blocks $V[x]$ and $V[y]$ such that there exists a constraint $\pi_{x\to y}$. We connect a hyperedge between any $v_1, \ldots, v_{k-1} \in V[x]$ and $u \in V[y]$ whenever $\pi_{x\to y}(\bigcap_{i=1}^{k-1} v_i) \cap u = \emptyset$.

The intuition for the hyperedges comes from the proof of completeness. In fact, the hypergraph is constructed by first deciding how to map a satisfying assignment for $\Phi$ into a subset of $G$'s vertices. Then, we construct the hyperedges so as to ensure that such subsets are independent sets in $G$.

Let $IS(G)$ denote the weight of vertices contained in the largest independent set of the hypergraph $G$.

LEMMA 5.1 (completeness). *If $\Phi$ is satisfiable, then $IS(G) \geq p = 1 - \frac{1}{k-1} - \delta$.*

*Proof.* Let $A$ be a satisfying assignment for $\Phi$; i.e., $A$ maps each $i \in [\ell]$ and $x \in X_i$ to an assignment in $R_i$ such that all the constraints are satisfied. Let $\mathcal{I} \subseteq V$ contain in the block $V[x]$ all the vertices that contain the assignment $A(x)$:

$$\mathcal{I} = \bigcup_x \{v \in V[x] \mid v \ni A(x)\} \ .$$

We claim that $\mathcal{I}$ is an independent set. Take any $v_1, \ldots, v_{k-1}$ in $\mathcal{I} \cap V[x]$ and a vertex $u$ in $\mathcal{I} \cap V[y]$. The vertices $v_1, \ldots, v_{k-1}$ intersect on $A(x)$ and therefore the projection of their intersection contains $\pi_{x\to y}(A(x)) = A(y)$. Since $u$ is in $\mathcal{I} \cap V[y]$ it must contain $A(y)$. The proof is completed by noting that inside each block, the weight of the set of all vertices that contain a specific assignment is exactly $p$. ∎

We now turn to the soundness of the construction.

LEMMA 5.2 (soundness). *If $IS(G) \geq \varepsilon$, then $\Phi$ is satisfiable.*

*Proof.* Let $\mathcal{I}$ be an independent set of weight $\varepsilon$. We consider the set $X'$ of all variables $x$ for which the weight of $\mathcal{I} \cap V[x]$ in $V[x]$ is at least $\varepsilon/2$. A simple averaging argument shows that the weight of $\bigcup_{x\in X'} V[x]$ is at least $\frac{\varepsilon}{2}$. Another averaging argument shows that in at least $\frac{\varepsilon}{4}\ell > \frac{8}{\varepsilon}$ layers, $X'$ contains at least an $\frac{\varepsilon}{4}$ fraction of the variables. Using the weak-density property of the PCP (see Definition 4.1) with the choice $\delta = \varepsilon/4$, we conclude that there exist two layers $X_i$ and $X_j$ such that an $\frac{\varepsilon^2}{64}$ fraction of the constraints between them are constraints between variables in $X'$. Let us denote by $X$ the variables in $X_i \cap X'$ and by $Y$ the variables in $X_j \cap X'$.

We first find, for each variable $x \in X$, a short list $B(x)$ of values that are "assigned" to it by $\mathcal{I}$. Indeed consider the vertices in $\mathcal{I} \cap V[x]$. Define $t$ to be $O(\frac{1}{\delta^3} \log \frac{1}{\varepsilon})$ with some large enough constant. Then, since $t \geq t(\frac{\varepsilon}{2}, k-1, \delta)$, Lemma 2.3 implies that there exist $k-1$ vertices in $\mathcal{I} \cap V[x]$ that intersect in at most $t$ assignments. We denote these vertices by $v_{x,1}, \ldots, v_{x,k-1}$ and their intersection by $B(x)$, where $|B(x)| \leq t$.

In the following we define an assignment to the variables in $X$ and $Y$ such that many of the constraints between them are satisfied. For a variable $y \in Y$ we choose the assignment that is contained in the largest number of projections of $B(x)$:

$$A(y) = \underset{a\in R_Y}{\mathrm{maxvar}} \, |\{x \in X \mid a \in \pi_{x\to y}(B(x))\}|.$$

For a variable $x \in X$ we simply choose $A(x)$ to be a random assignment from the set $B(x)$ (or some arbitrary assignment in case $B(x)$ is empty). We will prove that indeed $A(y)$ occurs in many of the projections of $B(x)$.

CLAIM 5.3. *Let $y \in Y$, and let $X(y)$ be the set of all variables $x \in X$ that have a constraint with $y$. Then,*

$$\Pr_{x\in X(y)} [A(y) \in \pi_{x\to y}(B(x))] > \varepsilon_1 \overset{def}{=} \frac{1}{t \log\left(\frac{\varepsilon}{4}\right) / \log(1 - 1/(k-1)^t)} \ .$$

Before we prove the claim let us see how it concludes the proof. Indeed, the fraction of constraints between $Y$ and $X$ satisfied by $A$ is, in expectation, at least $\varepsilon_1/t$. This is because for every $y$, the fraction of $x \in X(y)$ for which $A(y) \in \pi_{x\to y}(B(x))$ is by Claim 5.3 at least $\varepsilon_1$. For such $x$, the probability that $A(x)$ was randomly chosen so that $\pi_{x\to y}(A(x)) = A(y)$ is at least $\frac{1}{|B(x)|} \geq \frac{1}{t}$.

Thus, there must be some assignment $A$ that attains the expectation and satisfies at least $\frac{\varepsilon_1}{t}$ of the constraints between $X$ and $Y$. This amounts to an $\frac{\varepsilon_1}{t} \cdot \frac{\varepsilon^2}{64}$ fraction of the total constraints, which would imply that $\Phi$ is satisfiable, as long as

$$\frac{1}{t \log(\frac{\varepsilon}{4}) / \log(1 - 1/(k-1)^t)} \cdot \frac{1}{t} \cdot \frac{\varepsilon^2}{64} \geq \frac{1}{R^\gamma} \ . \tag{6}$$

*Proof of Claim* 5.3. Let $y \in Y$, $x \in X(y)$. By definition, there are no hyperedges of the form $(v_{x,1}, \ldots, v_{x,k-1}, u)$ for any vertex $u \in \mathcal{I} \cap V[y]$. In other words, every vertex $u \in \mathcal{I} \cap V[y]$ must intersect $\pi_{x\to y}(B(x))$. Let $x_{i_1}, \ldots, x_{i_N}$ be the variables in $X$ such that the constraint $\pi_{x_{i_j}\to y}$ exists, and consider the collection of sets $A_j = \pi_{x_{i_j}\to y}(B(x_{i_j}))$ for $j = 1, \ldots, N$. Clearly $|A_j| \leq t$, and let $D$ denote the maximum number of disjoint sets inside this family. We will show that $D$ cannot be too large by estimating the maximum possible weight of the vertices in $\mathcal{I} \cap V[y]$. Indeed the vertices in $\mathcal{I} \cap V[y]$ must intersect every $A_j$. The constraint imposed by one $A_j$ in isolation reduces the maximum possible weight of the vertices in $\mathcal{I} \cap V[y]$ by a factor of $1 - (1-p)^{|A_j|} \leq 1 - (1-p)^t$. Moreover, for disjoint $A_j$'s, these constraints are independent, so the total weight becomes at most $(1 - (1-p)^t)^D$. Since the weight of $\mathcal{I} \cap V[y]$ is at least $\frac{\varepsilon}{4}$, we have

$$\frac{\varepsilon}{4} \leq (1 - (1-p)^t)^D < \left(1 - \frac{1}{(k-1)^t}\right)^D$$

so

$$D < \log\left(\frac{\varepsilon}{4}\right) / \log(1 - 1/(k-1)^t)\,.$$

To finish, we need the following simple claim.

Claim 5.4. *Let $A_1, \ldots, A_N$ be a collection of $N$ sets, each of size at most $T \geq 1$. If there are not more than $D$ pairwise disjoint sets in this collection, then there is an element that is contained in at least $\frac{N}{TD}$ sets.*

*Proof.* Take any maximal collection of pairwise disjoint sets and let $A'$ denote their union. Notice that $|A'| \leq TD$ and that any set not in this collection must contain one of the elements of $A'$. Hence, there must exist an element of $A'$ that is contained in at least $1 + \frac{N-D}{TD} \geq N/TD$ sets. □

Claim 5.4 implies that there exists an assignment for $y$ that is contained in at least

$$\frac{N}{t \cdot \log(\frac{\varepsilon}{4}) / \log(1 - 1/(k-1)^t)}$$

of the $A_j$'s. □

This completes the soundness proof (Lemma 5.2). □

Theorem 1.1 now follows from Lemmas 5.1 and 5.2, since the ratio between the sizes of the vertex cover in the yes and no cases is at least $\frac{1-\varepsilon}{1-p} = (1-\varepsilon)/(\frac{1}{k-1} + \delta)$, which can be made arbitrarily close to $k-1$. □

As before, let us compute some parameters of the reduction, which will be useful in the next section. We start by choosing $R$ so that (6) is satisfied. Since $\frac{1}{(k-1)^t}$ is small, we estimate $\log(1-x) \approx -x$ and get

$$R \geq \Omega\left(\frac{1}{\varepsilon^2} \log\frac{1}{\varepsilon} \cdot t^2 \cdot (k-1)^t\right)^{1/\gamma}. \tag{7}$$

By plugging in the value for $t$, we obtain that choosing

$$R = 2^{O(\delta^{-3} \log k \log \frac{1}{\varepsilon})}$$

suffices. The number of variables in the multilayered PCP is $n^{O(\ell \log R)}$, which, using $\ell = O(1/\varepsilon^2)$, is at most

$$n^{\left(\frac{\log k}{\varepsilon\delta}\right)^{O(1)}}.$$

Hence, the number of vertices in the hypergraph is at most

$$n^{\left(\frac{\log k}{\varepsilon\delta}\right)^{O(1)}} \cdot 2^{R^{O(l)}} \leq n^{\left(\frac{\log k}{\varepsilon\delta}\right)^{O(1)}} \cdot 2^{2^{\left(\frac{\log k}{\varepsilon\delta}\right)^{O(1)}}}.$$

Since the number of constraints in which each variable participates is at most $R^{O(\ell)}$, the degree of the hypergraph is at most

$$R^{O(\ell)} \cdot 2^{O(kR^{O(\ell)})} \leq 2^{2^{\left(\frac{\log k}{\varepsilon\delta}\right)^{O(1)}}}.$$

Finally, the running time of the reduction is polynomial in the number of hyperedges, which is at most

$$2^{2^{\left(\frac{\log k}{\varepsilon\delta}\right)^{O(1)}}} \cdot n^{\left(\frac{\log k}{\varepsilon\delta}\right)^{O(1)}}. \tag{8}$$

**6. Nonconstant values of *k*.** In this section we outline what happens to our construction when we increase $k$ beyond a constant. This should be contrasted with the general hypergraph vertex cover problem in which $k$ is unbounded (i.e., the set cover problem). It is well known that if $N$ is the number of hyperedges, the greedy algorithm achieves a factor $\ln N$ approximation, and no polynomial time algorithm can achieve an approximation factor of $(1-o(1))\ln N$, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log\log n)})$ [10].

Below, we discuss in turn the extension of both the $k-1$ and $k/2$ hardness bounds from sections 5 and 3, respectively, to the case when $k$ is superconstant. We note that in this context the $k/2$ result is not subsumed by the $(k-1)$ result since it works for much larger values of $k$ (as a function of the number of hyperedges in the hypergraph). We discuss the $(k-1)$ result first since this reduction and the calculations at the end of section 5 are, we hope, fresh in the reader's mind at this point of reading.

**6.1. The $(k-1-\varepsilon)$ inapproximability bound.**

THEOREM 6.1. *There exists some $c > 0$ such that unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log\log n)})$, there is no polynomial time algorithm for approximating Ek-Vertex-Cover for $k \leq (\log\log N)^{1/c}$ to within a factor of $k-1.01$, where $N$ is the number of hyperedges in the $k$-uniform hypergraph.*

*Proof.* Recall the calculation at the end of section 5, specifically the bound on the number of hyperedges from (8). The produced hypergraph $G$ has

$$N = 2^{2^{\left(\frac{\log k}{\varepsilon\delta}\right)^{O(1)}}} \cdot n^{\left(\frac{\log k}{\varepsilon\delta}\right)^{O(1)}}$$

hyperedges, when starting from a 3SAT instance of size $n$. Furthermore, the reduction runs in time polynomial in the number of hyperedges.

The gap in vertex cover sizes equals

$$\frac{1-\varepsilon}{1/(k-1)+\delta} \geq (k-1)(1-\varepsilon)(1-k\delta) \geq (k-1.01)$$

if we set $\varepsilon = 1/(200k)$ and $\delta = 1/(200k^2)$. For these choices of $\varepsilon, \delta$, the number of hyperedges $N$ is at least $2^{2^{k^{O(1)}}}$, so the largest value of $k$ we can set is $k = (\log\log n)^{1/c'}$ for a large enough constant $c'$. For this choice of $k$, the number of hyperedges $N$ and the runtime of the reduction can both be bounded above by $n^{O(\log\log n)}$. For large enough $n$, $\log\log N \leq 2\log\log n$ for this choice of parameters, so we get a result that works for $k \leq (\log\log N)^{1/c}$ for some fixed constant $c$. $\square$

**6.2. The $(k/2-\varepsilon)$ inapproximability bound.** We can obtain a similar result corresponding to the factor $k/2$ hardness result, as stated below. Note that this result works for $k$ up to $(\log N)^{1/b}$ for some fixed constant $b > 0$.

THEOREM 6.2. *There exists some $b > 0$ such that unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log\log n)})$, there is no polynomial time algorithm for approximating Ek-Vertex-Cover for $k \le (\log N)^{1/b}$ to within a factor of $\lfloor \frac{k}{2} \rfloor - 0.01$, where $N$ is the number of hyperedges in the $k$-uniform hypergraph.*

*Proof.* Recall the calculation at the end of section 3, specifically (4) and (5). The produced hypergraph $G$ has $n_0 \le n^{O(\log(1/\varepsilon\delta))} 2^{(1/\varepsilon\delta)^{O(1)}}$ vertices and $N = n_0 2^{k/(\varepsilon\delta)^{O(1)}}$ hyperedges, when starting from a 3SAT instance of size $n$. Furthermore, the reduction runs in time polynomial in the number of hyperedges.

By plugging in $k = (\log n)^{1/b'}$ for a large enough constant $b' > 0$, $\varepsilon = 1/(100k)$ and $\delta = 1/(100k^2)$, we get $\log(1/\varepsilon\delta) \le \log\log n$, and $2^{k/(\varepsilon\delta)^{O(1)}} \le n$. Thus, the reduction runs in time $n^{O(\log\log n)}$ and produces a hypergraph with $N = n^{O(\log\log n)}$ hyperedges, with a gap in vertex cover sizes (assuming $k$ is even for convenience) of

$$\frac{1-\varepsilon}{2/k+\delta} \ge \frac{k}{2}(1-\varepsilon)(1-k\delta) \ge \frac{k}{2} - \frac{1}{100}$$

by our choices of $\varepsilon, \delta$. Since for large enough $n$, $\log n \ge \sqrt{\log N}$ for the above choice of parameters, we get a result that works for $k \le (\log N)^{1/b}$ for some fixed constant $b$. ∎

**Acknowledgments.** We would like to thank Noga Alon for his help with $s$-wise $t$-intersecting families. We would also like to thank Luca Trevisan and the anonymous referees for useful comments.

# THE DIFFICULTY OF TESTING FOR ISOMORPHISM AGAINST A GRAPH THAT IS GIVEN IN ADVANCE[*]

ELDAR FISCHER[†]

**Abstract.** Motivated by a question from [E. Fischer, G. Kindler, D. Ron, S. Safra, and A. Samorodnitsky, *J. Comput. System Sci.*, 68 (2004), pp. 753–787], we investigate the number of queries required for testing that an input graph $G$ is isomorphic to a fixed graph $H$ that is given in advance. We correlate this number with a measure of the "complexity" of $H$ that we define here, by proving both an upper bound and a lower bound on the number of queries that depends on this new measure. As far as we know this is the first characterization of this type for graphs.

**Key words.** property testing, graph isomorphism, regularity lemma

## 1. Introduction.

Combinatorial property testing deals with the following task: For a fixed $\epsilon > 0$ and a fixed property $P$, distinguish using as few queries as possible (and with probability at least $\frac{2}{3}$) between the case that an input of length $m$ satisfies $P$, and the case that the input is $\epsilon$-far (with respect to an appropriate metric) from satisfying $P$. In our context the inputs are boolean functions, and the distance from $P$ is measured by the minimum number of bits that have to be modified in the input in order to make it satisfy $P$, divided by the input length $m$. Many cases of interest involve tests that have a number of queries that depends only on the approximation parameter $\epsilon$ and is independent of the input length. In this paper we define a measure of complexity for the properties we consider and use it to bound the number of queries required for the test.

We start with some historical background: The first time a question formulated in terms of property testing was considered was in the work of Blum, Luby, and Rubinfeld [3], and the general notion of property testing was first formally defined by Rubinfeld and Sudan [12], mainly for the context of the algebraic properties (such as linearity) of functions over finite fields and vector spaces. The first investigation in the combinatorial context was that of Goldreich, Goldwasser, and Ron [9], where the testing of combinatorial graph properties was first formalized; their framework will also be the one used here. In recent years the field of property testing has enjoyed rapid growth, as witnessed in the surveys [11] and [5].

In the context of boolean functions, it was proved in [6] that for a fixed $k$ and $\epsilon$ one can $\epsilon$-test a boolean function $f : \{0,1\}^n \to \{0,1\}$ for the property of depending on only $k$ of its variables, where the number of queries depends on only $\epsilon$ and $k$. As a corollary, it was then shown that if a function $h : \{0,1\}^n \to \{0,1\}$ is "simple," in the sense that it depends on only $k$ of its variables, then one can $\epsilon$-test an input function

$f$, for the property of being identical to $h$ up to a permutation of its variables, using a number of queries that depends on only $k$ and $\epsilon$.

In [6] there were also examples of functions $h : \{0,1\}^n \to \{0,1\}$, depending on $k$ variables, for which the number of required queries is *at least* a function of $k$. However, not all functions that are far from depending on a few variables require many queries. The question of finding a complexity measure for which both upper and lower bounds hold for *every* function $h$ was posed in [6] and to our knowledge is still open.

Here we consider an analogous question for graphs: Given a graph $H$, how many queries are required to test an input graph $G$ for the property of being isomorphic to $H$? Here too, one would assume that the answer depends on some measure of the "complexity" of $H$.

First we need a criterion for simplicity, similar in spirit to that of depending on few variables in the case of boolean functions. Such a natural criterion is that the graph $H$ is the result of only a few basic operations (defined below), taken over a constant number of subsets of its vertices. Alternatively, one can formulate the criterion of $H$ having a partition of its vertex set into a constant number of subsets $W_1, \dots, W_k$, such that for every $1 \leq i \leq j \leq k$ the pair $W_i, W_j$ either contains no edge at all or contains all possible edges (the gap between the first and the second approach turns out to be not more than an exponent, which is irrelevant for the purpose here).

Our main result shows both an upper bound and a lower bound on the number of queries required for the test that a graph is isomorphic to $H$, given in terms of the complexity parameter of $H$. We thus obtain that a simple graph (or a graph that is close enough to simple) admits an easy isomorphism test, while a graph far from all simple graphs does not admit such a test. In contrast, the result from [6] about boolean functions provides only an upper bound.

The rest of the paper is organized as follows. Some preliminaries, the definition of our complexity measure for $H$, and the formal statement of the main result are all in section 2. The upper bound part of the main result is proved in section 3. Section 4 introduces Szemerédi's regularity lemma and other tools used in the proofs following it, and section 5 proves the lower bound part of our main result. All positive results here deal with 2-sided tests, which is not a coincidence as section 6 contains a simple proof of a nonconstant lower bound for 1-sided testing for isomorphism, even against a graph comprised of just one clique and an additional set of isolated vertices. Finally, section 7 contains some discussion and concluding comments.

We note here that the upper bound part of the main result is rather easy, using the results of [9]. The lower bound, however, uses Szemerédi's regularity lemma, known usually for its strength in proving *upper* bounds about graph property testing. This lemma, which enables us to find random-like structures in any graph, is used here to construct a "rerandomization" of $H$ that provides a graph $H'$ that is far from being isomorphic to $H$ and yet is not distinguishable from it by any testing algorithm using too few queries.

## 2. Preliminaries and statement of the main result.

The most central notion to property testing is that of the distance between inputs and properties. We deal with the "dense" model of graph property testing, first defined in [9], as per the following definition.

DEFINITION 1. *Given two (labeled) graphs $G$ and $G'$ on the same vertex set $V$, the* distance *between $G$ and $G'$ is the size of the symmetric difference between the edge sets of $G$ and $G'$, divided by $\binom{|V|}{2}$.*

*Given a graph $G$ and a graph property (a set of graphs that is closed under graph isomorphisms) $P$, the* distance *between $G$ and $P$ is the minimum distance between $G$ and any graph $G'$ on the same vertex set which satisfies $P$.*

Using this definition of the distance, we give a formal definition of a graph testing algorithm.

Definition 2. *An* $\epsilon$-testing algorithm with $q$ queries *for a property $P$ is a probabilistic algorithm that for any input graph $G$ makes up to $q$ queries (a query consisting of finding whether two vertices $u, v$ of $G$ form an edge of $G$ or not) and satisfies the following.*

1. *If $G$ satisfies $P$, then the algorithm accepts $G$ with probability at least $\frac{2}{3}$.*
2. *If $G$ is $\epsilon$-far from $P$, that is, the distance of $G$ from $P$ is more than $\epsilon$, then the algorithm rejects $G$ with probability at least $\frac{2}{3}$.*

The measure of the complexity of a graph $H$ is formalized in the following. We also formulate an approximate notion, of only being close to a simple graph. We need this technicality because such graphs also admit an efficient isomorphism test, as one can just test the input graph for isomorphism with the simple graph close to $H$, instead of testing for isomorphism with $H$ itself.

Definition 3. *The* algebra number *of a graph $H$, denoted by* $\mathrm{Algnum}(H)$*, is the minimal number $k$ for which there exist cliques $H_1, \dots, H_k$ over subsets of the vertex set of $H$, such that $H$ is in the boolean algebra generated by $H_1, \dots, H_k$ (that is, the edge set of $H$ can be generated from the edge sets of $H_1, \dots, H_k$ by the appropriate set operations).*

*The* $\epsilon$-approximate algebra number*, denoted by* $\mathrm{Algnum}_\epsilon(H)$*, is the minimal $k$ such that $H$ is $\epsilon$-close (i.e., has distance at most $\epsilon$) to some graph whose algebra number is $k$.*

For stating the main result, it is convenient to define the number of queries required for $\epsilon$-testing a graph for the property of being isomorphic to $H$ as a parameter of $H$.

Definition 4. *The* $\epsilon$-testing number *of a graph $H$, denoted by* $\mathrm{Testnum}_\epsilon(H)$*, is the minimum $q$ for which there exists an $\epsilon$-testing algorithm with $q$ queries for the property of being isomorphic to $H$.*

We are now ready for the formal statement of the main result.

Theorem 2.1. *For every $\epsilon$ there exists a pair of functions $L_\epsilon(t)$ and $U_\epsilon(t)$, with $\lim_{t\to\infty} L_\epsilon(t) = \infty$, such that for every graph $H$ we have* $L_\epsilon(\mathrm{Algnum}_{3\epsilon}(H)) \leq \mathrm{Testnum}_\epsilon(H) \leq U_\epsilon(\mathrm{Algnum}_{\epsilon/3}(H))$.

As a final note, it is not a coincidence that our results provide 2-sided algorithms, that is, algorithms that may err with some small probability on both sides. Section 6 contains a proof that 1-sided algorithms (algorithms that accept a graph that is isomorphic to $H$ with probability 1) require an unbounded number of queries even for a graph $H$ for which $\mathrm{Algnum}(H) = 1$.

## 3. Isomorphism testing against a simple graph.

To prove that it is easy to test an input graph for isomorphism against a simple graph that is given in advance, we use the result of [9] about the efficiency of testing for properties defined by the existence of a partition with prescribed densities, as stated in the following.

Definition 5. *For two disjoint sets $U, W$ of vertices of a graph $G$ we define $d(U, W)$ as the number of edges between $U$ and $W$, divided by $|U||W|$. In addition we define $d(U, U)$ for every $U$ as the number of edges of $G$ internal to $U$, divided by $\binom{|U|}{2}$.*

*Suppose we are given parameters $m$, $(\alpha_i)_{1\le i\le m}$, $(\alpha'_i)_{1\le i\le m}$, $(\beta_{i,j})_{1\le i\le j\le m}$, and $(\beta'_{i,j})_{1\le i\le j\le m}$ satisfying $0 \le \alpha_i < \alpha'_i \le 1$ and $0 \le \beta_{i,j} < \beta'_{i,j} \le 1$. We say that a graph $G$ satisfies the* partition property *with respect to these parameters if there exists a partition $V_1,\dots,V_m$ of the vertex set of $G$ such that $\alpha_i \le \frac{1}{n}|V_i| \le \alpha'_i$ for every $1 \le i \le m$, and $\beta_{i,j} \le d(V_i,V_j) \le \beta'_{i,j}$ for every $1 \le i \le j \le m$.*

Lemma 3.1 (partition testing [9]). *Given parameters $m$, $(\alpha_i)_{1\le i\le m}$, $(\alpha'_i)_{1\le i\le m}$, $(\beta_{i,j})_{1\le i\le j\le m}$, and $(\beta'_{i,j})_{1\le i\le j\le m}$ satisfying $0 \le \alpha_i < \alpha'_i \le 1$ and $0 \le \beta_{i,j} < \beta'_{i,j} \le 1$, the partition property with respect to these parameters is testable with $\epsilon^{-\mathrm{poly}(m)}$ queries, a number that depends on only $m$ and the distance parameter $\epsilon$.*

We first prove as a warm-up that if $H$ has a small algebra number (and not just a small approximated algebra number), then there is a test for being an isomorphism of $H$ that uses few queries. The following lemma shows in essence that a graph with a small algebra number can be approximated by a partition property (in fact if we were allowed to choose $\alpha_i = \alpha'_i$ and $\beta_{i,j} = \beta'_{i,j}$, then there would be a partition property *identical* to the property of being an isomorphism of $H$).

Lemma 3.2. *If* $\mathrm{Algnum}(H) = k$, *then for every $\epsilon$, there exist for some $m \le 2^k$ parameters for the partition property (as it appears in Lemma 3.1) satisfying the following.*

*$H$ satisfies the partition property with respect to the parameters, and, moreover, every graph $G$ that satisfies it is $\frac{1}{2}\epsilon$-close to being isomorphic to $H$.*

*Proof.* We look at the construction of $H$ from the cliques $H_1,\dots,H_k$, and let $W_1,\dots,W_m$ be the atoms of the boolean algebra generated from the vertex sets of $H$ and $H_1,\dots,H_k$ (in other words, $W_1,\dots,W_m$ are the smallest nonempty vertex sets that can be constructed from the vertices of $H$ and $H_1,\dots,H_k$ by set operations). Note that $m \le 2^k$. We now note that for this partition, for every $1 \le i \le j \le m$ the graph $H$ either has all possible edges between $W_i$ and $W_j$, or it has no such edge. From this it is not hard to see that the following parameters will satisfy the assertions of the lemma: $\alpha_i = \max\{0, \frac{1}{n}|W_i| - \frac{1}{8m}\epsilon\}$, $\alpha'_i = \min\{1, \frac{1}{n}|W_i| + \frac{1}{8m}\epsilon\}$, $\beta_{i,j} = \max\{0, d(W_i,W_j) - \frac{1}{4}\epsilon\}$, and $\beta'_{i,j} = \min\{1, d(W_i,W_j) + \frac{1}{4}\epsilon\}$ (note that here there are only two possible values for $\beta_{i,j}$ and $\beta'_{i,j}$, as $d(W_i,W_j)$ is either 1 or 0). □

From Lemma 3.2 it is not hard to construct an $\epsilon$-test for the property of being an isomorphism of an $H$ with a small algebra number—we just apply a $\frac{1}{2}\epsilon$-test as guaranteed by Lemma 3.1 for the property given by Lemma 3.2. Such a test uses for a fixed $\epsilon$ a number of queries that is exponential in some power of $m \le 2^{\mathrm{Algnum}(H)}$.

The following is a strengthening of Lemma 3.2, in that it holds also for graphs with a small *approximated* algebra number.

Lemma 3.3. *If* $\mathrm{Algnum}_{\epsilon/3}(H) = k$, *then there exist partition parameters as in the formulation of Lemma 3.1, where $m \le 2^k$, such that the partition property with respect to these parameters satisfies the following.*

*$H$ satisfies the partition property, and, moreover, every graph that satisfies it is $\frac{8}{9}\epsilon$-close to being isomorphic to $H$.*

*Proof.* We again construct $W_1,\dots,W_m$ as the smallest nonempty vertex sets that can be generated from the vertex sets of the appropriate cliques, but instead of doing this for $H$ we do it for a graph $H'$ that is $\frac{1}{3}\epsilon$-close to $H$ and whose algebra number is $k$. We then set $\alpha_i = \max\{0, \frac{1}{n}|W_i| - \frac{1}{18m}\epsilon\}$, $\alpha'_i = \min\{1, \frac{1}{n}|W_i| + \frac{1}{18m}\epsilon\}$, $\beta_{i,j} = \max\{0, d(W_i,W_j) - \frac{1}{9}\epsilon\}$, and $\beta'_{i,j} = \min\{1, d(W_i,W_j) + \frac{1}{9}\epsilon\}$, where $d(W_i,W_j)$ denotes the density of the respective pair in the graph $H$ and not in $H'$ (this is important).

Again it is easy to see that $H$ satisfies the partition property. On the other hand, any graph that satisfies the partition property is $\frac{2}{9}\epsilon$-close to some graph that has a partition into $W_1, \ldots, W_m$ with exactly the same set sizes as $H$ and exactly the same pair densities as $H$.

A graph $\tilde{H}$ having the same densities as $H$ is $\frac{2}{3}\epsilon$-close to it because $H$ is $\frac{1}{3}\epsilon$ close to $H'$: For every $W_i, W_j$, the number of vertex pairs between $W_i$ and $W_j$ for which $H$ and $\tilde{H}$ differ is clearly bounded by $2\min\{d(W_i, W_j), 1 - d(W_i, W_j)\}$ times the total number of vertex pairs ($|W_i||W_j|$ if $i < j$ and $\binom{|W_i|}{2}$ if $i = j$), and by the information on $H$ the sum of these differences when taken over all $1 \le i \le j \le m$ is bounded by $\frac{2}{3}\epsilon\binom{n}{2}$. From this we conclude that a graph that satisfies the partition property is $\frac{8}{9}\epsilon$-close to being isomorphic to $H$. $\square$

PROPOSITION 3.4 (part 1 of Theorem 2.1). *For every fixed $\epsilon$ there exists a function $U_\epsilon(t)$ such that* $\text{Testnum}_\epsilon(H) \le U_\epsilon(\text{Algnum}_{\epsilon/3}(H))$ *for every graph $H$.*

*Proof.* If $\text{Algnum}_{\epsilon/3}(H) \le k$, then we construct a test whose number of queries depends on only $\epsilon$ and $k$ as follows. We take the partition property provided for $H$ by Lemma 3.3 and $\frac{1}{9}\epsilon$-test for it using the testing algorithm provided by Lemma 3.1. It is clear why this algorithm accepts (with probability at least $\frac{2}{3}$) a graph that is isomorphic to $H$ (and hence satisfies the partition property); on the other hand, if the input graph $G$ is $\epsilon$-far from being isomorphic to $H$, then by Lemma 3.3 and the triangle inequality it is at least $\frac{1}{9}\epsilon$-far from the partition property, and so it is rejected by the algorithm. $\square$

We close this section with some remarks about the running time of the testing algorithm. In general, the partition testing algorithm provided in [9] consists of choosing a uniformly random set $U$ of vertices of $G$, with a constant number of vertices (this number is a polynomial in $\epsilon$ whose coefficients and degree depend on $m$), and then checking all possible partitions of the subgraph induced by $U$ for certain properties. The running time of such a test is thus exponential in the number of queries.

Given a bound on $\text{Algnum}(H)$ (and not just on the approximated algebra number), it seems that by the methods of [9] one can devise a test in which only partitions of the induced subgraph into $m$ sets, for which all set pairs are either full (of density 1) or edgeless (of density 0), need be considered. These partitions can be calculated in only a polynomial time in the number of queries, by sorting the vertices according to their sets of neighbors, yielding a corresponding reduction in the running time of the test.

## 4. Further preliminaries and Szemerédi's regularity lemma.

The most common use of Szemerédi's regularity lemma in graph property testing is in proving upper bounds such as, e.g., those in [1] and [4]. Here it will be used for proving a lower bound—the existence of regular pairs (as defined below) will be used in constructing a graph that is far from the original $H$, but in a way that is not detectable by a testing algorithm. First we define the regularity of pairs.

DEFINITION 6. *For two nonempty disjoint vertex sets $A$ and $B$ of a graph $H$, we say that the pair $A, B$ is* $\gamma$-regular *if, for any two subsets $A'$ of $A$ and $B'$ of $B$ satisfying $|A'| \ge \gamma|A|$ and $|B'| \ge \gamma|B|$, the edge densities satisfy $|d(A', B') - d(A, B)| < \gamma$.*

A first observation about regular pairs is the following well-known fact that regularity is somewhat preserved when considering large enough subsets of the original pair.

*Observation* 4.1. If $A, B$ is a $\gamma$-regular pair with density $\eta$ and $A' \subset A$ and $B' \subset B$ satisfy $|A'| \ge \delta|A|$ and $|B'| \ge \delta|B|$ for some $\delta \ge \gamma$, then $A', B'$ is a $\max\{2, \delta^{-1}\}\gamma$-regular pair, with density at least $\eta - \gamma$ and at most $\eta + \gamma$. $\square$

The following lemma shows how much regular pairs have in common with random bipartite graphs. Its proof is not new (similar lemmas have been used extensively in the literature), but it is given here for completeness. To clarify the presentation of the mathematical formulas in the following, functions that are defined in a statement of a lemma are indexed with the lemma's number.

Lemma 4.2. *For every fixed $t$ and $\epsilon > 0$ there exists $\gamma = \gamma_{4.2}(\epsilon, t)$ with the following property.*

*Suppose that $I$ is a graph with vertices $v_1, \dots, v_t$ and that $V_1, \dots, V_t$ is a $t$-tuple of disjoint vertex sets of $H$ such that for every $1 \le i < j \le t$ the pair $V_i, V_j$ is $\gamma$-regular. Define $\eta_{i,j}$ to be $d(V_i, V_j)$ if $v_i v_j$ is an edge of $I$ and $1 - d(V_i, V_j)$ if $v_i v_j$ is not an edge of $I$. Then, the number of $t$-tuples $w_1 \in V_1, \dots, w_t \in V_t$ that span induced copies of $I$, where each $w_i$ plays the role of $v_i$, is between $(\prod_{1 \le i < j \le t} \eta_{i,j} - \epsilon) \prod_{l=1}^{t} |V_l|$ and $(\prod_{1 \le i < j \le t} \eta_{i,j} + \epsilon) \prod_{l=1}^{t} |V_l|$.*

*Proof.* We will prove here the existence of $\gamma' = \gamma'(\epsilon, t)$ such that the number of copies of $I$ as per the assertion of the lemma is at least $(\prod_{1 \le i < j \le t} \eta_{i,j} - \epsilon) \prod_{l=1}^{t} |V_l|$. We can then set $\gamma = \gamma'(2^{-\binom{t}{2}}\epsilon, t)$, because then the full assertion of the lemma (both upper and lower bounds) follows from the correctness of the above for every one of the $2^{\binom{t}{2}}$ possible graphs $I$.

In proving the existence of $\gamma'$ we assume without loss of generality that $I$ is the clique with $t$ vertices. In this case we may also assume that $\eta_{i,j} = d(V_i, V_j) > \epsilon$ for every $1 \le i < j \le t$, as otherwise the above assertion is trivial. The proof is by induction on $t$, where the case $t = 2$ is trivial.

We set $\gamma' = \min\{\epsilon/4\binom{t-1}{2}, \epsilon/4(t-1), \frac{3}{4}\epsilon\gamma'(\frac{1}{4}\epsilon, t-1)\}$. We look at the vertices of $V_t$. Because of the regularity property, for every $1 \le i < t$ there are at least $(1 - \epsilon/4(t-1))|V_t|$ vertices of $V_t$ that have at least $(\eta_{i,t} - \epsilon/4(t-1))|V_i|$ neighbors in $V_i$, as otherwise the set $V_t'$ of vertices that do not satisfy this with the set $V_i$ will contradict the regularity of the pair $V_i, V_t$. Thus there are at least $(1 - \frac{1}{4}\epsilon)|V_t|$ vertices of $V_t$ for which the degree condition is true for *every* $1 \le i < t$.

For every vertex $v$ of $V_t$ satisfying the above, let $V_i'$ be the set of neighbors of $v$ in $V_i$ for $1 \le i \le t-1$, and accordingly set $\eta_{i,j}' = d(V_i', V_j')$ for every $1 \le i < j \le t-1$. We note that $|V_i'| \ge (\eta_{i,t} - \epsilon/4(t-1))|V_i|$ (and in particular $|V_i'| \ge \frac{3}{4}\epsilon|V_i|$) for every $i$, that $\eta_{i,j}' \ge \eta_{i,j} - \epsilon/4\binom{t-1}{2}$ for every $i < j$, and that every pair $V_i', V_j'$ is in particular $\gamma'(\frac{1}{4}\epsilon, t-1)$-regular by Observation 4.1. We now use the induction hypothesis to obtain that $V_1', \dots, V_{t-1}'$ admit sufficiently many cliques with $t-1$ vertices, one from every $V_i'$, where each such clique makes a copy of $I$ with $v \in V_t$ added. Specifically, the number of such cliques is at least

$$\left(\prod_{1 \le i < j \le t-1} \eta_{i,j}' - \frac{1}{4}\epsilon\right) \prod_{l=1}^{t-1} |V_l'| \ge \left(\prod_{1 \le i < j \le t-1} \eta_{i,j} - \frac{2}{4}\epsilon\right) \prod_{l=1}^{t-1} |V_l'|$$
$$\ge \left(\prod_{1 \le i < j \le t} \eta_{i,j} - \frac{3}{4}\epsilon\right) \prod_{l=1}^{t-1} |V_l|.$$

Multiplying this by the number of vertices $v \in V_t$ for which the analysis holds, we obtain the required number of copies of $I$. □

In our lower bound proof we construct a graph that is hard to distinguish from $H$ by a testing algorithm. We construct it by replacing some of the regular pairs of $H$ with actual random subgraphs. But to find these regular pairs, we need Szemerédi's regularity lemma.

DEFINITION 7. *An* equipartition *of a graph $H$ is a partition of its vertex set into sets whose sizes differ from each other by no more than* 1. *A $\gamma$*-regular partition *is an equipartition of $H$ into $k$ sets such that all $\binom{k}{2}$ set pairs but at most $\gamma\binom{k}{2}$ of them are $\gamma$-regular.*

LEMMA 4.3 (Szemerédi's regularity lemma [13]). *For every $m$ and $\gamma > 0$ there exists $T = T_{4.3}(m, \gamma)$ with the following property.*

*If $H$ is a graph with $n \geq T$ vertices, and $\mathcal{A}$ is an equipartition of the vertex set of $H$ into $m$ sets, then there exists an equipartition $\mathcal{B}$ that is a refinement of $\mathcal{A}$ into $k$ sets, where $m \leq k \leq T$, and such that $\mathcal{B}$ is a $\gamma$-regular partition.*

For the proof of the lower bound we will need an equipartition of the vertices of $H$ so that many of its pairs, apart from being regular, also have densities that are not too close to 0 or 1. A high approximate algebra number guarantees this.

LEMMA 4.4. *For every $\epsilon > 0$, $\gamma > 0$, and $m$ there exists $T = T_{4.4}(\epsilon, \gamma, m)$ such that if $H$ is a graph with $\mathrm{Algnum}_{3\epsilon}(H) > T$, then there exists a $\gamma$-regular partition $\mathcal{B} = \{V_1, \ldots, V_k\}$ of $H$ with $m \leq k \leq T$, for which*

$$\binom{k}{2}^{-1} \sum_{1 \leq i < j \leq k} \min\{d(V_i, V_j), 1 - d(V_i, V_j)\} > 2\epsilon.$$

*Proof.* We set $T = \binom{T_{4.3}(\max\{m, 2/\epsilon\}, \gamma) + 1}{2}$. We first use Lemma 4.3 to find the appropriate $\gamma$-regular partition $\mathcal{B}$ with $k$ sets, where $k \leq T_{4.3}(\max\{m, 2/\epsilon\}, \gamma)$ (we let $\mathcal{A}$ be an arbitrary equipartition with $\max\{m, 2/\epsilon\}$ sets), and then prove that $\mathrm{Algnum}_{3\epsilon}(H) \leq \binom{k+1}{2}$ unless $\mathcal{B}$ satisfies the assertion of the lemma.

We let $H'$ be the graph obtained from $H$ by the following modifications: For every $i$ we add all possible edges inside $V_i$, and in addition for every pair $V_i, V_j$, if $d(V_i, V_j) > \frac{1}{2}$, then we add all possible edges between $V_i$ and $V_j$, and if $d(V_i, V_j) \leq \frac{1}{2}$, then we remove all edges between these sets.

The distance between $H'$ and $H$ is bounded by

$$\epsilon + \binom{k}{2}^{-1} \sum_{1 \leq i < j \leq k} \min\{d(V_i, V_j), 1 - d(V_i, V_j)\}.$$

On the other hand, the algebra number of $H'$ is no more than $\binom{k+1}{2}$, because its edge set is the union of the edge sets of the following cliques: the clique on $V_i$ for every $1 \leq i \leq k$ and the clique on $V_i \cup V_j$ for every $1 \leq i < j \leq k$ for which $d(V_i, V_j) > \frac{1}{2}$. This means that if the assertion of the lemma does not hold, then $\mathrm{Algnum}_{3\epsilon}(H) \leq \binom{k+1}{2}$, a contradiction. $\square$

To prove lower bounds it is best if we can restrict ourselves to relatively simple algorithms. In the context of graph properties, this can be done with the following.

LEMMA 4.5 (from [10]). *If there exists an $\epsilon$-testing algorithm for a graph property that makes $q$ queries, then there exists an $\epsilon$-testing algorithm that makes its queries by uniformly and randomly choosing a set of $2q$ vertices and querying all their pairs. In particular, it is a nonadaptive $\epsilon$-test making $\binom{2q}{2}$ queries.*

## 5. Isomorphism testing against a complex graph.

Given a graph $H$, we would like to construct a graph $H'$ that is far from being isomorphic to $H$, but in a way that cannot be detected by a testing algorithm of the type depicted in Lemma 4.5. The way to do this is to replace regular pairs in $H$ with alternative regular pairs. We would like to construct them at random; for such considerations the following well-known large deviation inequality comes in handy.

LEMMA 5.1 (see, e.g., [2, Appendix A]). *Suppose that we are given $m$ independent random variables $X_1, \dots, X_m$, each of which receiving a value of 1 with probability $p_i$ and a value of 0 with probability $1 - p_i$. The probability that $|\frac{1}{m}\sum_{i=1}^m X_i - \frac{1}{m}\sum_{i=1}^m p_i| > \delta$ is bounded by $2e^{-2\delta^2 m}$.*

The following lemma now allows us to construct regular pairs at random.

LEMMA 5.2. *For every $\gamma > 0$ and $\epsilon > 0$ there exists $\alpha = \alpha_{5.2}(\gamma, \epsilon) > 0$ and $N = N_{5.2}(\gamma, \epsilon)$ with the following property: If $I$ is a random bipartite graph with color classes $A$ and $B$ where $|A| \ge N$ and $|B| \ge N$, in which every pair of vertices is taken to be an edge independently with probability $\eta$, then with probability at least $1 - 2^{-\alpha|A||B|}$ the pair $A, B$ will be a $\gamma$-regular pair (with respect to $I$) whose density is between $\eta - \epsilon$ and $\eta + \epsilon$.*

*Proof.* For proving the required regularity and density properties, it is not hard to see that it is enough to prove that with the asserted probability, every $A' \subset A$ with $|A'| = \gamma|A|$ and $B' \subset B$ with $|B'| = \gamma|B|$ satisfy $|d(A', B') - \eta| \le \min\{\frac{1}{2}\gamma, \epsilon\}$. For every fixed $A'$ and $B'$, using Lemma 5.1 (where the variables $X_1, \dots, X_m$ are defined as the indicator variables for the edges between $|A'|$ and $|B'|$) implies that the probability that the above is not satisfied is at most $2e^{-2(\min\{\gamma/2,\epsilon\})^2|A'||B'|} \le 2^{-\beta|A'||B'|} = 2^{-\beta'|A||B|}$ for the appropriate $\beta$ and $\beta' = \gamma^2\beta$. To bound the probability that the above is not satisfied for any of the possible pairs $|A'|, |B'|$, whose number is no more than $2^{|A|+|B|}$, we set $\alpha = \frac{1}{2}\beta'$ and $N = 4/\beta'$ (for which $|A| + |B| \le \frac{1}{2}\beta'|A||B|$ holds). $\square$

We also need the following rather trivial observation about distance of random graphs.

*Observation* 5.3. For every $\epsilon$ there exists $\alpha = \alpha_{5.3}(\epsilon) > 0$ such that if $J$ is any fixed bipartite graph with vertex classes $A$ and $B$, and $I$ is a random bipartite graph with the same vertex classes, where every pair of vertices is taken to be an edge independently with probability $\eta$, then with probability at least $1 - 2^{-\alpha|A||B|}$, the number of pairs that belong to the symmetric difference between the edges of $I$ and $J$ is at least $(\min\{\eta, 1-\eta\} - \epsilon)|A||B|$.

*Proof sketch.* Assume without loss of generality that $\eta \le \frac{1}{2}$, and define the random variables $X_1, \dots, X_m$ as the indicator variables, each for the event that a specific vertex pair belongs to the symmetric difference between the edges of $I$ and those of the original graph $J$. One can easily see that regardless of the original graph, $\frac{1}{m}\sum_{i=1}^m p_i \ge \eta$, and then use Lemma 5.1. $\square$

We now formalize which features of an input graph a testing algorithm of the type depicted in Lemma 4.5 can detect.

DEFINITION 8. *The* $t$-statistic *of a graph $H$ is the distribution over labeled graphs with $t$ vertices that results from choosing uniformly an ordered set (with no repetitions) of $t$ vertices of $H$, and looking at the appropriate induced subgraph.*

*The* variation distance *between the $t$-statistics of a graph $H$ and a graph $H'$ is defined as the usual variation distance between the corresponding distributions. That is, if we denote by $\mu$ the $t$-statistic of $H$ and by $\mu'$ the $t$-statistic of $H'$, then the variation distance is equal to $\frac{1}{2}\sum_K |\mathrm{Pr}_\mu[K] - \mathrm{Pr}_{\mu'}[K]|$, where the index $K$ runs over possible labeled graphs with a fixed set of $t$ vertices.*

The following lemma is then immediate from Lemma 4.5.

LEMMA 5.4. *If $H$ and $H'$ have $2q$-statistics which differ by less than $\frac{1}{3}$ in the variation distance and $H'$ is $\epsilon$-far from being isomorphic to $H$, then* $\mathrm{Testnum}_\epsilon(H) > q$.

*Proof.* If there exists an $\epsilon$-test for the property of being isomorphic to $H$ that makes at most $q$ queries, then by Lemma 4.5 there exists such a test that chooses a uniformly random set of $2q$ vertices and bases its decision solely on the subgraph induced on this set. However, if such an algorithm accepts $H$ with probability at least $\frac{2}{3}$, then the variation distance between the $2q$-statistics of $H$ and $H'$ implies that the algorithm accepts $H'$ with probability more than $\frac{1}{3}$, a contradiction. ∎

The main lemma is the following. It shows how, given a regular partition of a graph in which many pairs have densities that are not close to 0 or 1, one can construct a graph $H'$ that is the one we need for a lower bound on the testing number.

LEMMA 5.5. *For every $t$ and $\epsilon$ there exist $m = m_{5.5}(t, \epsilon)$ and $\gamma = \gamma_{5.5}(t, \epsilon)$, such that for every $T \geq m$ there exists $N = N_{5.5}(t, \epsilon, T)$ with the following property. Suppose that for a graph $H$ with $n > N$ vertices there exists a $\gamma$-regular partition $V_1, \dots, V_k$ with $m \leq k \leq T$ that also satisfies $\binom{k}{2}^{-1} \sum_{1 \leq i < j \leq k} \min\{d(V_i, V_j), 1 - d(V_i, V_j)\} > 2\epsilon$. Then there exists a graph $H'$ that is $\epsilon$-far from being isomorphic to $H$, and such that the $t$-statistics of the two graphs have variation distance less than $\frac{1}{3}$ between them.*

*Proof.* We choose

$$\gamma = \min\left\{2^{-\binom{t}{2}}/15\binom{t}{2}, \gamma_{4.2}\left(2^{-\binom{t}{2}}/15\binom{t}{2}, t\right), \frac{1}{3}\epsilon\right\}$$

and

$$m = \max\left\{15\binom{t}{2}, 3/\epsilon\right\}.$$

$H'$ is constructed from $H$ as follows: For every $\gamma$-regular pair $V_i, V_j$ in the equipartition of $H$, we let the edges of $H'$ between $V_i$ and $V_j$ be randomly and independently taken with probability $\eta_{i,j} = d(V_i, V_j)$ each. For every $i, j$ such that $i = j$ or $V_i, V_j$ is not a regular pair, we just let the corresponding edges of $H'$ be identical to those of $H$ (this is an arbitrary choice, and any other choice for such a pair will also do here).

To analyze the $t$-statistics we consider a uniformly random ordered set of vertices (with no repetitions), $v_1, \dots, v_t$. For $1 \leq j \leq t$ we define $i_j$ to be such that $v_j \in V_{i_j}$; with probability at least $\frac{14}{15}$ the indexes $i_1, \dots, i_t$ will be all different, because $m \geq 15\binom{t}{2}$. Given this event, with probability at least $\frac{14}{15}$ (for the choice of $v_1, \dots, v_t$) all the pairs in $V_{i_1}, \dots, V_{i_t}$ are $\gamma$-regular with respect to $H$, because $\gamma \leq 1/30\binom{t}{2}$.

We assume that $N$ is, in particular, chosen to be large enough so that with probability at least $\frac{3}{4}$ over the choice of $H'$, the following holds: Every pair $V_i, V_j$ that was $\gamma$-regular with respect to $H$ will also be $\gamma$-regular with respect to $H'$, and its density will be between $\eta_{i,j} - 2^{-\binom{t}{2}}/15\binom{t}{2}$ and $\eta_{i,j} + 2^{-\binom{t}{2}}/15\binom{t}{2}$, on account of Lemma 5.2 (we choose $N$ so that the probability for every such pair to be otherwise is bounded by $1/4\binom{T}{2}$).

The above choices guarantee that with probability at least $\frac{3}{4}$ over the choice of $H'$, the graphs $H$ and $H'$ have $t$-statistics that differ by less than $\frac{1}{3}$. This is because when we condition the choice of $v_1, \dots, v_t$ on a particular outcome of $i_1, \dots, i_t$ that are all different and for which all pairs are $\gamma$-regular (in both graphs), Lemma 4.2 guarantees that the two conditioned distributions on the induced subgraphs differ from each other by no more than 3/15, because for every fixed labeled graph with $t$ vertices the respective probabilities for its occurrence differ by no more than $3 \cdot 2^{-\binom{t}{2}}/15$. The bound on the difference is because Lemma 4.2 is invoked once for $H$ and once for $H'$ (accounting for a possible $2^{-\binom{t}{2}}/15$ difference from the corresponding product of pair densities in each invocation), while there may be up to an additional $2^{-\binom{t}{2}}/15$ difference between the products of the pair densities for $H$ and $H'$.

To make sure that $H$ and $H'$ are also $\epsilon$-far from being isomorphic, in addition to the choice of the parameters above, we assume that $N$ is chosen to be large enough so that with probability at least $\frac{3}{4}$ over the choice of $H'$, the following occurs: For every pair $V_i, V_j$ of $H'$ that corresponds to a $\gamma$-regular pair of $H$, when its edges are compared to the edges of $H$ between any two disjoint labeled vertex sets $U_1, U_2$ of the same sizes as $V_i, V_j$, the number of vertex pairs in the symmetric difference will be at least $(\min\{\eta_{i,j}, 1-\eta_{i,j}\} - \frac{1}{3}\epsilon)|V_i||V_j|$. A large enough $N$ will satisfy this, because the number of all possibilities for choosing $U_1$ and $U_2$ and labeling them for correspondence with $V_i$ and $V_j$, respectively, is clearly bounded by $n!$, while the bound on the probability for a lesser difference between the edges of $H'$ over $V_i, V_j$ and the edges of $H$ over $U_1, U_2$ is $2^{-\Theta(n^2)}$ by Observation 5.3, which decreases more rapidly than $1/n!$.

When this occurs, there is at least a $\binom{k}{2}^{-1}\big(\sum_{1\le i<j\le k}\min\{\eta_{i,j}, 1-\eta_{i,j}\}\big) - \epsilon \ge \epsilon$ distance between $H$ and $H'$, so with probability at least $\frac{1}{2}$ the graph $H'$ has all the required properties. ∎

Proposition 5.6 (part 2 of Theorem 2.1). *For every fixed $\epsilon$ there exists a function $L_\epsilon(t)$, with $\lim_{t\to\infty} L_\epsilon(t) = \infty$, such that $L_\epsilon(\mathrm{Algnum}_{3\epsilon}(H)) \le \mathrm{Testnum}_\epsilon(H)$ for every graph $H$.*

*Proof.* We construct the inverse function of $L_\epsilon(t)$, that is, we prove that for every $q$ there exists $A = A_\epsilon(q)$ such that if $\mathrm{Algnum}_{3\epsilon}(H) > A$, then $\mathrm{Testnum}_\epsilon(H) > q$. We will first prove the above only for graphs with $n > N$ vertices for some $N = N_\epsilon(q)$. From this we can conclude the proof, as we can use $A' = \max\{A, \binom{N}{2}\}$ instead of $A$ and then remove the condition that $n > N$, because clearly $\mathrm{Algnum}(G) \le \binom{n}{2}$ for any graph $G$ with $n$ vertices. We now choose $A = T_{4.4}(\epsilon, \gamma_{5.5}(2q,\epsilon), m_{5.5}(2q,\epsilon))$ and $N = N_{5.5}(2q, \epsilon, A)$.

If $H$ has $n > N$ vertices and satisfies $\mathrm{Algnum}_{3\epsilon}(H) > A$, we construct an $H'$ that is $\epsilon$-far from being isomorphic to $H$, and such that the $2q$-statistics of $H$ and $H'$ differ by less than $\frac{1}{3}$, which by Lemma 5.4 implies that $\mathrm{Testnum}_\epsilon(H) > q$. For this we use Lemma 4.4 to find a partition satisfying the conditions of Lemma 5.5, through which we construct $H'$. ∎

## 6. The difficulty of 1-sided testing for isomorphism against H.

The test constructed in section 3 for graphs with a small approximate algebra number has a 2-sided error, and the lower bounds for graphs with a large approximate algebra number hold for the general 2-sided error algorithms as well. If one insists on the more restricted framework of a 1-sided testing algorithm, where the testing algorithm must accept a graph that is isomorphic to $H$ with probability 1, then the situation is much worse, as a bounded $\mathrm{Algnum}(H)$ does not guarantee any bound on the testing number of $H$.

*Observation* 6.1. Let $H$ be a graph with $n$ vertices, constructed by taking a clique with $\frac{1}{2}n$ vertices and adding to it $\frac{1}{2}n$ additional isolated vertices (note that in particular $\mathrm{Algnum}(H) = 1$). A 1-sided $\frac{1}{4}$-test for being isomorphic to $H$ requires at least $\frac{1}{4}n$ queries.

*Proof.* If $G$ is a random permutation of $H$, then any test making fewer than $\frac{1}{4}n$ queries will, with some positive (albeit small) probability, fail to find any edge of $G$. This is because the $\frac{1}{4}n$ queries of the algorithm cannot involve more than $\frac{1}{2}n$ vertices, and with some (small but positive) probability none of these vertices will belong to the clique. If the algorithm has 1-sided error, then it must accept $G$ with probability 1 even when encountering this small probability case. But this means that the algorithm will also accept the null (edgeless) graph with $n$ vertices with probability 1, which is a contradiction. $\square$

In fact, *any* graph $H$ with $n$ vertices that admits a 1-sided $\epsilon$-test for isomorphism making $o(\log n)$ queries is either $\epsilon$-close to being a clique or $\epsilon$-close to being edgeless for $n$ large enough. To prove this, one can use Ramsey's theorem to find in $H$ either a clique with $\Omega(\log n)$ vertices or an edgeless set of this size, and then proceed similarly to the proof above to show that the 1-sided $\epsilon$-testing algorithm must also accept either the clique with $n$ vertices or the edgeless graph with $n$ vertices with probability 1.

## 7. Concluding comments.

**The question of a combinatorial characterization of all testable graph properties.** The question of a logical characterization of the testable graph properties seems very hard. Just as this work provides a combinatorial characterization for a graph admitting an easy isomorphism test, one could hope for a combinatorial characterization of whole properties for admitting an easy test, which motivated a joint work with Newman [8]. It is hinted there that a testable graph property may be characterized as being approximable by properties concerning regular graph partitions.

The resulting "characterization" is, however, convoluted and not really a characterization in the strictest sense of the word. However, for the purpose of [8] it was used to prove that for every testable graph property, one can actually approximate the distance of any graph from satisfying it using a number of queries that depends only on the (additive) tolerance.

**Worst cases and unknown graphs.** After showing that the testing number of a graph depends on a measure of its complexity, there is still the question of the worst case. In other words, there is the question of estimating the maximum for $\text{Testnum}_\epsilon(H)$ where $\epsilon$ is fixed and $H$ ranges over all graphs with $n$ vertices.

If we disregard running time, then it is not hard to construct an $\epsilon$-testing algorithm that uses $\tilde{O}(n)$ queries for any graph $H$ that is given in advance, where the tilde notation here and in the following is used to hide polylogarithmic factors in $n$. This holds because, for an input graph $G$ and a graph $H$ that is given in advance, and for a particular labeling of the vertices of $G$, it takes $\tilde{O}(n)$ queries to detect with probability at least $1 - \frac{1}{3n!}$ whether $G$ differs from $H$ in at least $\epsilon\binom{n}{2}$ labeled pairs. By using a union bound over all $n!$ possible labelings of the vertices of $G$, one set of $\tilde{O}(n)$ queries is sufficient to completely test $G$ for having any labeling that can serve as an isomorphism function with $H$. A joint work with A. Matzliah [7] suggests that the true bound for 2-sided error algorithms is in fact a smaller power of $n$.

Another problem is deciding whether two graphs $G$ and $H$ that are both given as input (with only the number of vertices $n$ being given in advance) are isomorphic. This property, used in [1] to prove the existence of a first-order graph property that is hard to test, is also investigated in [7]. Ignoring again the running time and concentrating on the number of queries, there seem to be an $\tilde{\Omega}(n)$ lower bound and an upper bound of $n^\alpha$ queries for some $1 \leq \alpha < 2$ for this problem.

**Narrowing the gap between $U_\epsilon$ and $L_\epsilon$.** There is a huge gap between the lower bound function and the upper bound function, on account of the lower bound proof using Szemerédi's regularity lemma. In fact, $U_\epsilon(t)$ is a tower in a polynomial of

$L_\epsilon(t)$ (when comparing their values for the same $t$). It would be interesting to prove a better lower bound using a weaker version of Szemerédi's regularity lemma.

**The gap between the approximation parameters.** In Theorem 2.1, the $\epsilon$-testing number is compared from above with the $\epsilon/3$-approximate algebra number, and from below it is compared with the $3\epsilon$-approximate algebra number. In the upper bound the approximation parameter can be made closer to $\epsilon/2$, and in the lower bound it can be made closer to $\epsilon$, but it would still be interesting to be able to make all approximation parameters arbitrarily close to each other (with the closeness parameter being an additional parameter of the bounding functions).

**Back to boolean functions.** The main question treated in this paper was motivated by a question about boolean functions, so now the original question motivates the following: Is there any analogue of Szemerédi's regularity lemma that can be used to prove lower bounds on testing that a function $f : \{0,1\}^n \to \{0,1\}$ is identical to a given function $g$ up to a permutation of the variables?

There are indications that this question is rather hard. For example, it is not yet entirely clear what the complexity measure for boolean functions should be. Being dependent on a small number of variables cannot be the sole parameter of simplicity, because functions like the parity function on all $n$ variables admit an efficient test despite not being close to any function depending on a small number of variables.

**Acknowledgment.** I wish to thank an anonymous referee for many useful suggestions and comments.

# FAIR SIMULATION RELATIONS, PARITY GAMES, AND STATE SPACE REDUCTION FOR BÜCHI AUTOMATA*

KOUSHA ETESSAMI†, THOMAS WILKE‡, AND REBECCA A. SCHULLER§

**Abstract.** We give efficient algorithms, improving optimal known bounds, for computing a variety of simulation relations on the state space of a Büchi automaton. Our algorithms are derived via a unified and simple parity-game framework. This framework incorporates previously studied notions like *fair* and *direct* simulation, but also a new natural notion of simulation called *delayed* simulation, which we introduce for the purpose of state space reduction. We show that delayed simulation—unlike fair simulation—preserves the automaton language upon quotienting and allows substantially better state space reduction than direct simulation.

Using our parity-game approach, which relies on an algorithm by Jurdziński, we give efficient algorithms for computing all of the above simulations. In particular, we obtain an $O(mn^3)$-time and $O(mn)$-space algorithm for computing both the delayed and the fair simulation relations. The best prior algorithm for fair simulation requires time and space $O(n^6)$. Our framework also allows one to compute bisimulations: we compute the fair bisimulation relation in $O(mn^3)$ time and $O(mn)$ space, whereas the best prior algorithm for fair bisimulation requires time and space $O(n^{10})$.

## 1. Introduction.

There are at least two distinct purposes for which it is useful to compute simulation relationships between the states of automata: (1) to efficiently establish language containment among nondeterministic automata; and (2) to reduce the state space of an automaton by obtaining its quotient with respect to the equivalence relation underlying the simulation preorder.

For state machines without acceptance conditions, there is a well-understood notion of simulation with a long history (see, e.g., [20, 16]), mainly aimed at comparing the branching behavior of such machines (rather than just their sets of traces). For $\omega$-automata, where acceptance (fairness) conditions are present, there are a variety of different simulation notions (see, e.g., [14, 11]). At a minimum, for such a simulation to be of use for purpose (1), it must have the following property:

(*) whenever state $q'$ "simulates" state $q$, the language of the automaton with start state $q'$ contains the language of the automaton with start state $q$.

As we will see in section 5, however, this property alone is not sufficient to assure usefulness for purpose (2), which requires the following stronger property:

(**) the "simulation quotient" preserves the language of the automaton.

We will state precisely what is meant by a simulation quotient later.

In [14], a number of different simulation notions for $\omega$-automata were studied using a game-theoretic framework. The authors also introduced a new natural notion of simulation, titled *fair* simulation. They showed how to compute fair simulations for both Büchi and, more generally, Streett automata. For Büchi automata, their algorithm requires $O(n^6)$ time to determine, for one pair of states $(q, q')$, whether $q'$

fairly simulates $q$. Their algorithm relies on an algorithm for tree automaton emptiness testing developed in [19]. In this paper, we present a new comparatively simple algorithm for Büchi automata. Our algorithm reduces the problem to a parity game computation, for which we use a recent elegant algorithm by Jurdziński [17], along with some added enhancements to achieve our bounds. Our algorithm determines in time $O(mn^3)$ and space $O(mn)$ *all* such pairs $(q, q')$ of states in an input automaton $A$ where $q'$ simulates $q$. Here $m$ denotes the number of transitions and $n$ the number of states of $A$. In other words, our algorithm computes the entire maximal fair simulation relation on the state space in the stated time and space bound.

In [14], the authors were interested in using fair simulation for purpose (1) and thus did not consider quotients with respect to fair simulation. The question arises whether fair simulation can be used for purpose (2), i.e., whether it satisfies property (**). The answer is no: we show that quotienting with respect to fair simulation fails badly at preserving the underlying language, under any reasonable definition of a quotient. (Closely related observations were also made in [15].) On the other hand, there is an obvious and well-known way to define simulation so that quotients do preserve the underlying language: *direct* simulation[1] [6] simply accommodates acceptance into the standard definition of simulation [20] by asserting that only an accept state can simulate another accept state. Direct simulation has already been used extensively (see, e.g., [8, 22]) to reduce the state space of automata. See also [5], where simulation minimization for ordinary Kripke structures was studied. Both [8] and [22] describe tools for optimized translations from linear temporal logic to automata, where one of the key optimizations is simulation reduction. However, as noted in [8], direct simulation alone is not able to reduce many obviously redundant state spaces. Recall that, in general, it is PSPACE-hard to find the minimum equivalent automaton for a given nondeterministic automaton. Thus, there is a need for efficient algorithms and heuristics that reduce the state space substantially.

We introduce a natural intermediate notion between direct and fair simulation, called *delayed* simulation, which satisfies property (**). We show that delayed simulation can yield substantially greater reduction—by an arbitrarily large factor—than direct simulation. We provide an algorithm for computing the entire delayed simulation relation which arises from precisely the same parity-game framework and has the same complexity as our algorithm for fair simulation.

Last, our parity-game framework also easily accommodates computation of bisimulation relations (which are generally less coarse than simulation). In particular, we show that the fair bisimulation relation on Büchi automata can be computed in time $O(mn^3)$ and space $O(mn)$. Fair bisimulation was studied in [15] for Büchi and Streett automata, where for Büchi automata they gave an $O(n^{10})$–time and space algorithm to compute whether one state is fair bisimilar to another.

This paper is based on the conference paper [9]. Several papers have since appeared that build on and/or use our work: [13, 10, 7, 4]. Independent of [9], in [3] Bustan and Grumberg obtained an algorithm for computing fair simulation which, while it did not improve the $O(n^6)$-time complexity of [14], improved the space complexity to $O(mn)$. The algorithms described here have been implemented in the TMP tool, available for download at http://www1.bell-labs.com/project/TMP/.

The paper is organized as follows: in section 2, we define all (bi)simulation notions used in the paper. In section 3 we show how for each simulation notion (and fair bisimulation), given a Büchi automaton, we can define a parity game that captures

[1] Direct simulation is called *strong* simulation in [8].

the (bi)simulation. In section 4, we use our variant of Jurdziński's algorithm for parity games to give efficient algorithms for computing several such (bi)simulation relations. In section 5, we prove that the delayed simulation quotient can be used to reduce automaton size, and yields better reduction than direct simulation, but that the fair simulation quotient cannot be so used. We conclude in section 6.

For background on simulation and its versions incorporating acceptance, see, e.g., [20, 16] and [14], respectively. For background on Büchi automata and automata on infinite words in general, see [23, 24, 12].

We thank an anonymous referee for pointing out that an earlier version of the algorithm in Figure 2 was too complicated.

**2. Simulation and bisimulation relations.** We now define various notions of simulation, including fair and the new delayed simulation, in terms of appropriate games.

**2.1. Büchi automata.** As usual, a *Büchi automaton* $A = \langle \Sigma, Q, q_I, \Delta, F \rangle$ has an alphabet $\Sigma$, a state set $Q$, an initial state $q_I \in Q$, a transition relation $\Delta \subseteq Q \times \Sigma \times Q$, and a set of final states $F \subseteq Q$. We will henceforth assume that the automaton has no *dead ends*; i.e., from each state of $A$ there is a path of length at least 1 to *some* state in $F$. Unless the automaton is trivial (i.e., has an empty $\omega$-language), it is easy to make sure this property holds without changing the accepting runs from any state, using a simple search to eliminate unnecessary states and transitions. (Also, it is easy to check nontriviality while doing the same search. The running time of the search is linear in the size of the automaton.)

Recall that a *run* of $A$ is a sequence $\pi = q_0 a_0 q_1 a_1 q_2 \ldots$ of states alternating with letters such that for all $i$, $(q_i, a_i, q_{i+1}) \in \Delta$. The $\omega$-word associated with $\pi$ is $w_\pi = a_0 a_1 a_2 \ldots$ The run $\pi$ is *initial* if it starts with $q_I$; it is *accepting* if there exist infinitely many $i$ with $q_i \in F$. The language defined by $A$ is $L(A) = \{w_\pi \in \Sigma^\omega \mid \pi \text{ is an initial, accepting run of } A\}$. We may want to change the start state of $A$ to a different state $q$; the revised automaton is denoted by $A[q]$.

**2.2. Simulation relations.** As in [14], we define simulation game-theoretically. We will focus on simulations between distinct states of the same automaton ("autosimulations"), because we are primarily interested in state space reduction. Simulations between different automata can be treated by considering autosimulations between the states of the automaton consisting of their disjoint union. In [14], the authors presented their work in terms of Kripke structures with fairness constraints. We use Büchi automata directly, where labels are on transitions instead of states. This difference is inconsequential for our results.

We will consider four kinds of simulations: ordinary simulation, which ignores acceptance, as well as three variants which incorporate acceptance conditions of the given automaton, in particular, our new delayed simulation. All four simulations are based on the same game, which is described first. They differ only in the winning condition.

Let $A$ be a Büchi automaton as above and $q_0$ and $q'_0$ arbitrary states of $A$. The *basic game* $G_A(q_0, q'_0)$ is played by two players, *Spoiler* and *Duplicator,* in rounds, where, at the beginning and at the end of each round, two pebbles, *Red* and *Blue*, are placed on two states (possibly the same). At the start, round 0, Red and Blue are placed on $q_0$ and $q'_0$, respectively. Assume that, at the beginning of round $i$, Red is on state $q_i$ and Blue is on $q'_i$. Then:

1. Spoiler chooses a transition $(q_i, a, q_{i+1}) \in \Delta$ and moves Red to $q_{i+1}$.

2. Duplicator, responding, must choose a transition $(q'_i, a, q'_{i+1}) \in \Delta$ and moves Blue to $q'_{i+1}$. If no $a$-transition starting from $q'_i$ exists, then the game halts and Spoiler wins.

Either the game halts, in which case Spoiler wins, or the game produces two infinite runs, $\pi = q_0 a_0 q_1 a_1 q_2 \dots$ and $\pi' = q'_0 a_0 q'_1 a_1 q'_2 \dots$, built from the transitions visited by the two pebbles (and such that the same word is associated with them). The pair $(\pi, \pi')$ is called an *outcome* of the game. Given such an outcome, the following rules are used to determine the winner.

DEFINITION 1 (simulation games). *Let $A$ be a Büchi automaton, let $(q_0, q'_0) \in Q^2$, and let $(\pi, \pi')$ be an outcome of $G_A(q_0, q'_0)$ with $\pi = q_0 a_0 q_1 a_1 q_2 \dots$ and $\pi' = q'_0 a_0 q'_1 a_1 q'_2 \dots$*

1. *The* ordinary simulation game, *denoted by $G^o_A(q_0, q'_0)$, is the basic game $G_A(q_0, q'_0)$ extended by the rule that the outcome $(\pi, \pi')$ is winning for Duplicator (i.e., as long as the game does not halt, Duplicator wins).*

2. *The* direct (strong) simulation game, *denoted by $G^{di}_A(q_0, q'_0)$, is the basic game $G_A(q_0, q'_0)$ extended by the rule that the outcome $(\pi, \pi')$ is winning for Duplicator iff, for all $i$, if $q_i \in F$, then also $q'_i \in F$.*

3. *The* delayed simulation game, *denoted by $G^{de}_A(q_0, q'_0)$, is the basic game $G_A(q_0, q'_0)$ extended by the rule that the outcome $(\pi, \pi')$ is winning for Duplicator iff, for all $i$, if $q_i \in F$, then there exists $j \geq i$ such that $q'_j \in F$.*

4. *The* fair simulation game, *denoted by $G^f_A(q_0, q'_0)$, is the basic game $G_A(q_0, q'_0)$ extended by the rule that the outcome $(\pi, \pi')$ is winning for Duplicator iff there are infinitely many $j$ such that $q'_j \in F$ or there are only finitely many $i$ such that $q_i \in F$. In all other cases, Spoiler wins.*

In other words, in ordinary simulation games, fairness conditions are ignored; Duplicator wins as long as the game does not halt. And in fair simulation games, Duplicator's winning condition is as follows: if there are infinitely many $i$ such that $q_i \in F$, then there are also infinitely many $j$ such that $q'_j \in F$.

*Remark* 1. Let $A$ be a Büchi automaton and $\star \in \{di, de, f\}$. If $(\pi, \pi')$ is the outcome of a play of $G^\star_A(q, q')$ which Duplicator wins, then $\pi'$ is accepting if $\pi$ is.

Let $\star \in \{o, di, de, f\}$. A *strategy* for Duplicator in game $G^\star_A(q_0, q'_0)$ is a partial function $f\colon Q(Q\Sigma Q)^* \to Q$ which, given the history of the game up to a certain point, determines the next move of Duplicator. Formally, $f$ is a strategy for Duplicator if $f(q_0) = q'_0$ and $(q'_i, a_i, q'_{i+1}) \in \Delta$ holds for every sequence $q_0 q'_0 a_0 q_1 q'_1 a_1 \dots a_i q_{i+1}$ with $(q_j, a_j, q_{j+1}) \in \Delta$ and $q'_j = f(q_0 q'_0 a_0 \dots a_j q_j)$ for $j \leq i$. Observe that the existence of a strategy implies that Duplicator has a way of playing such that the game does not halt. A strategy $f$ for Duplicator is a *winning* strategy if, no matter how Spoiler plays, Duplicator always wins. Formally, a strategy $f$ for Duplicator is winning if whenever $\pi = q_0 a_0 q_1 a_1 \dots$ is a run through $A$ and $\pi' = q'_0 a_0 q'_1 a_1 q'_2 \dots$ is the run defined by

$$q'_{i+1} = f(q_0 q'_0 a_0 q_1 q'_1 a_1 \dots q_{i+1}), \tag{1}$$

then $(\pi, \pi')$ is winning for Duplicator (as specified in Definition 1). Observe that $\pi'$ is well-defined.

DEFINITION 2 (simulation relations). *Let $A$ be a Büchi automaton. A state $q'$* ordinary, direct, delayed, fair simulates *a state $q$ if there is a winning strategy for Duplicator in $G^\star_A(q, q')$ where $\star = o$, $di$, $de$, or $f$, respectively. We denote such a relationship by $q \preceq_\star q'$ (where $A$ is implicit).*

Our game definition of fair simulation deviates very slightly from that given in [14], but is equivalent since we consider only automata with no dead ends.

We first prove fundamental properties of the defined simulation relations.

PROPOSITION 3. *Let $A$ be a Büchi automaton.*

1. *For $\star \in \{o, di, de, f\}$, $\preceq_\star$ is a reflexive, transitive relation (also called* pre-order *or* quasi-order*) on the state set $Q$.*
2. *The relations are ordered by containment: $\preceq_{di} \subseteq \preceq_{de} \subseteq \preceq_f \subseteq \preceq_o$.*
3. *For $\star \in \{di, de, f\}$, if $q \preceq_\star q'$, then $L(A[q]) \subseteq L(A[q'])$.*

*Proof.* Reflexivity is obvious, as is part 2. To prove transitivity, suppose that $q_0 \preceq_\star q'_0 \preceq_\star q''_0$ for some $\star \in \{o, di, de, f\}$. Then, by definition, Duplicator has winning strategies in both $G^\star_A(q_0, q'_0)$ and $G^\star_A(q'_0, q''_0)$, say $f$ and $f'$. We combine these to get a winning strategy $f''$ for Duplicator in the game $G^\star_A(q_0, q''_0)$ as follows. If $f(q_0q'_0a_0q_1q'_1a_1 \dots q_{i+1}) = q'_{i+1}$ and $f'(q'_0q''_0a_0q'_1q''_1a_1 \dots q'_{i+1}) = q''_{i+1}$, we set $f(q_0q''_0a_0q_1q''_1a_1 \dots q_{i+1}) = q''_{i+1}$. It is easy to see that this defines a strategy for Duplicator. To see that $f''$ is in fact winning, let $\pi = q_0a_0q_1a_1 \dots$ be a run through $A$ and let $\pi'' = q''_0a_0q''_1a_1 \dots$ be the run defined by

$$q''_{i+1} = f''(q_0q''_0a_0q_1q''_1a_1 \dots q_{i+1}). \tag{2}$$

We need to argue that $(\pi, \pi'')$ is winning for Duplicator. By induction, one easily proves that if $\pi' = q'_0a_0q'_1a_1 \dots$ is defined by (1), then

$$q''_{i+1} = f'(q'_0q''_0a_0q'_1q''_1a_1 \dots q'_{i+1}). \tag{3}$$

This means that $(\pi, \pi')$ is winning for Duplicator in $G^\star_A(q_0, q'_0)$ and $(\pi', \pi'')$ is winning for Duplicator in $G^\star_A(q'_0, q''_0)$. For instance, when $\star = de$, this implies the following: if $q_i \in F$, there exists $j \geq i$ such that $q'_j \in F$, which, in turn, means there exists $k \geq j$ such that $q''_k \in F$. That is, $(\pi, \pi'')$ is winning for Duplicator in $G^{de}_A(q_0, q''_0)$. Similar arguments apply in the other cases.

To prove part 3, assume $\star \in \{di, de, f\}$, $q_0 \preceq_\star q'_0$, and $w \in L(A[q_0])$ with $w = a_0a_1 \dots$. Then there exists a winning strategy $f$ for Duplicator in $G^\star_A(q_0, q'_0)$ and an accepting run $\pi = q_0a_0q_1a_1 \dots$ of $A$ starting with $q_0$. Imagine Spoiler plays in $G^\star_A(q_0, q'_0)$ just as $\pi$ prescribes this and Duplicator replies according to $f$. Then a run $\pi' = q'_0a_0q'_1a_1 \dots$ of $A$ is built up according to (1). Since $\pi$ is accepting and $f$ is winning, $\pi'$ will also be accepting; see Remark 1. ◻

Thus, delayed simulation is a new notion of intermediate "coarseness" between direct and fair simulation. We will see in section 5 why it is more useful for state space reduction.

**2.3. Bisimulation relations.** For all the mentioned simulations there are corresponding notions of bisimulation, defined via a modification of the game. We will not provide detailed definitions for bisimulation; instead we describe intuitively the simple needed modifications.

The bisimulation game differs from the simulation game in that Spoiler gets to choose in each round which of the two pebbles, Red or Blue, to move, and Duplicator has to respond with a move of the other pebble.

The winner of the game is determined very similarly: if the game comes to a halt, Spoiler wins. If not, the winning condition for *fair* bisimulation (see [15]) is as follows: "if an accept state appears infinitely often on one of the two runs $\pi$ and $\pi'$, then an accept state must appear infinitely often on the other as well." The winning condition for *delayed* bisimulation is as follows: "if an accept state is seen at position $i$ of either run, then an accept state must be seen thereafter at some position $j \geq i$ of the other run." The winning condition for *direct* bisimulation becomes "if an accept state is seen at position $i$ of either run, it must be seen at position $i$ of both runs."

Strategies and winning strategies for the bisimulation games are defined similarly. Note, however, that the definitions have to take into account that Spoiler may choose his pebble.

Bisimulations define an equivalence relation $\approx_\star^{bi}$ (not only a preorder) on the state space, and the following containments hold: $\approx_{di}^{bi} \subseteq \approx_{de}^{bi} \subseteq \approx_f^{bi} \subseteq \approx_o^{bi}$. Generally, bisimulation is less coarse than the equivalence derived from the simulation preorder, which we describe in section 5, i.e., $\approx_\star^{bi} \subseteq \approx_\star$.

## 3. Reformulating simulations and bisimulations as parity games.

**3.1. Simulation.** We now show how, given a Büchi automaton $A$ and $\star \in \{o, di, de, f\}$, we can obtain in a straightforward way a parity-game graph $G_A^\star$ such that the winning vertices in $G_A^\star$ for Even (a.k.a. Player 0) in the parity game determine precisely the pairs of states $(q, q')$ of $A$ where $q'$ $\star$-simulates $q$. Importantly, the size of these parity-game graphs will be $O(|Q||\Delta|)$, and the nodes of the game graphs will be labeled by at most three distinct "priorities." In fact, only one priority will suffice for $G_A^o$ and $G_A^{di}$, while $G_A^{de}$ and $G_A^f$ will use three priorities.

We briefly review here the basic formulation of a parity game. A parity-game graph $G = \langle V_0, V_1, E, p\rangle$ has two disjoint sets of vertices, $V_0$ and $V_1$, whose union is denoted $V$. There is an edge set $E \subseteq V \times V$, and $p\colon V \to \{0, \ldots, d-1\}$ is a mapping that assigns a *priority* to each vertex.

A parity game on $G$, starting at vertex $v_0 \in V$, is denoted $\mathrm{P}(G, v_0)$, and is played by two players, *Even* and *Odd*. The play starts by placing a pebble on vertex $v_0$. Thereafter, the pebble is moved according to the following rule: with the pebble currently on a vertex $v_i$, and $v_i \in V_0$ ($V_1$), Even (Odd, respectively) plays and moves the pebble to a neighbor $v_{i+1}$, that is, such that $(v_i, v_{i+1}) \in E$.

If ever the above rule cannot be applied, i.e., someone can't move because there are no outgoing edges, the game ends, and the player who cannot move loses. Otherwise, the game goes on forever and defines a path $\pi = v_0 v_1 v_2 \ldots$ in $G$, called a *play* of the game. The winner of the play is determined as follows. Let $k_\pi$ be the minimum priority that occurs infinitely often in the play $\pi$, i.e., so that for infinitely many $i$, $p(v_i) = k_\pi$ and $k_\pi$ is the least number with this property. Even wins if $k_\pi$ is even, whereas Odd wins if $k_\pi$ is odd.

We now show how to build the game graphs $G_A^\star$. All the game graphs are built following the same general pattern, with some minor alterations. We start with $G_A^f$. The game graph $G_A^f = \langle V_0^f, V_1^f, E_A^f, p_A^f\rangle$ will have three priorities (i.e., the range of $p_A^f$ will be $\{0, 1, 2\}$). For each pair of states $(q, q') \in Q^2$, there will be a vertex $v_{(q,q')} \in V_0^f$ such that Even has a winning strategy from $v_{(q,q')}$ iff $q'$ fair simulates $q$. Formally, $G_A^f$ is defined by

$$V_0^f = \{v_{(q,q',a)} \mid q, q' \in Q \wedge \exists q''((q'', a, q) \in \Delta)\}, \tag{4}$$

$$V_1^f = \{v_{(q,q')} \mid q, q' \in Q\}, \tag{5}$$

$$\begin{aligned} E_A^f = {} & \{(v_{(q_1,q_1',a)}, v_{(q_1,q_2')}) \mid (q_1', a, q_2') \in \Delta\} \\ & \cup \{(v_{(q_1,q_1')}, v_{(q_2,q_1',a)}) \mid (q_1, a, q_2) \in \Delta\}, \end{aligned} \tag{6}$$

$$p_A^f(v) = \begin{cases} 0 & \text{if } v = v_{(q,q')} \text{ and } q' \in F, \\ 1 & \text{if } v = v_{(q,q')},\ q \in F, \text{ and } q' \notin F, \\ 2 & \text{otherwise.} \end{cases} \tag{7}$$

Let's first explain the underlying idea. The parity game mimics the simulation game. Even takes over the role of Duplicator and Odd takes over the role of Spoiler: when in the parity game the current position is node $v_{(q,q')}$, it denotes the situation in the simulation game when the red pebble is on $q$, the blue pebble is on $q'$, and it is Spoiler's turn to move; $v_{(q,q',a)}$ denotes the situation where the red pebble is on $q$, the blue pebble is on $q'$, it is Duplicator's turn to move, and the last transition taken by Spoiler was labeled by $a$. The priority function is defined in such a way that every time Duplicator visits a final state, the priority function returns 0. It returns only 1 if Spoiler visits a final state, but Duplicator does not. In all other cases, 2 is returned. That is, Spoiler wins iff he visits an accept state infinitely often but Duplicator does not. This is exactly what is needed.

We now describe how $G_A^f$ can be modified to obtain $G_A^o$ and $G_A^{di}$, both of which require only trivial modification to $G_A^f$. The parity-game graph $G_A^o$ is exactly the same as $G_A^f$, except that all nodes will receive priority 0, i.e., $p_A^o(v) = 0$ for all $v$. This reflects the winning condition of the ordinary simulation game.

The parity-game graph $G_A^{di}$ is just like $G_A^o$, meaning every vertex has priority 0, but some edges (the ones into and out of states of the form $v_{(q,q')}$ where $q \in F$ but $q' \notin F$) are eliminated in order to take care of the winning condition of the direct simulation game:

$$E_A^{di} = E_A^f \setminus (\{(v, v_{(q,q')}) \mid q \in F \wedge q' \notin F\} \cup \{(v_{(q,q')}, w) \mid q \in F \wedge q' \notin F\}). \tag{8}$$

Finally, to define $G_A^{de}$ we need to modify the game graph somewhat more. For each vertex of $G_A^f$ there will be at most two corresponding vertices in $G_A^{de}$:

$$V_0^{de} = \{v_{(b,q,q',a)} \mid q, q' \in Q \wedge b \in \{0,1\} \wedge \exists q''((q'', a, q) \in \Delta)\}, \tag{9}$$

$$V_1^{de} = \{v_{(b,q,q')} \mid q, q' \in Q \wedge b \in \{0,1\} \wedge (q' \in F \rightarrow b = 0)\}. \tag{10}$$

The extra bit $b$ encodes whether or not, thus far in the simulation game, the red pebble has witnessed an accept state without the blue pebble having witnessed one since then. The edges of $G_A^{de}$ are as follows:

$$\begin{aligned} E_A^{de} = \{&(v_{(b,q_1,q_1',a)}, v_{(b,q_1,q_2')}) \mid (q_1', a, q_2') \in \Delta \wedge q_2' \notin F\} \\ \cup \{&(v_{(b,q_1,q_1',a)}, v_{(0,q_1,q_2')}) \mid (q_1', a, q_2') \in \Delta \wedge q_2' \in F\} \\ \cup \{&(v_{(b,q_1,q_1')}, v_{(b,q_2,q_1',a)}) \mid (q_1, a, q_2) \in \Delta \wedge q_2 \notin F\} \\ \cup \{&(v_{(b,q_1,q_1')}, v_{(1,q_2,q_1',a)}) \mid (q_1, a, q_2) \in \Delta \wedge q_2 \in F\}. \end{aligned} \tag{11}$$

Last, we describe the priority function of $G_A^{de}$:

$$p_A^{de}(v) = \begin{cases} b & \text{if } v = v_{(b,q,q')}, \\ 2 & \text{if } v \in V_0^{de}. \end{cases} \tag{12}$$

In other words, we will assign priority 1 to only those vertices in $V_1$ that signify that an "unmatched" accept has been visited by the red pebble.[2] The priority function

[2]Note that it is possible to use only two priorities in $p_A^{de}$ by assigning a vertex $v$ the priority $b$, where $b$ is the indicator bit of $v$. However, it turns out that using two priorities is a disadvantage over three because the encoding would not have property 3 of Lemma 4, which we need for our complexity bounds.

makes sure that the smallest number occurring infinitely often is 1 iff from some point onwards the bit in the first component is 1. Now observe that this bit is 1 iff a final state has been visited by Spoiler but not yet matched by Duplicator. In this way the winning condition of the delayed simulation game is transferred to the parity game.

The following lemma gathers a collection of facts we will need.

LEMMA 4. *Let $A$ be a Büchi automaton.*

1. *For $\star \in \{o, di, f\}$, Even has a winning strategy in $\mathrm{P}(G^{\star}_A, v_{(q_0,q_0')})$ iff $q_0'$ $\star$-simulates $q_0$ in $A$.*
*For $\star = de$, this statement holds if $v_{(q_0,q_0')}$ is replaced by $v_{(b,q_0,q_0')}$, letting $b = 1$ if $q_0 \in F$ and $q_0' \notin F$, and $b = 0$ otherwise.*
2. *For $\star \in \{o, di, de, f\}$, $|G^{\star}_A| \in O(|\Delta||Q|)$, i.e., the number of vertices and the number of edges is $O(|\Delta||Q|)$.*
3. *For $\star \in \{f, de\}$, $|\{v \in V^{\star}_A \mid p^{\star}_A(v) = 1\}| \in O(|Q|^2)$.*

*Proof.* Part 1 is obvious from the explanations given above.

To prove part 2, first consider the case where $\star \in \{f, o\}$. In this case, $V^{\star}_1$ contains exactly $|Q|^2$ vertices, and since by assumption every state of $A$ has a transition leaving it, $|Q|^2 \leq |\Delta||Q|$. Similarly, $V^{\star}_0$ has, for every $q'$, a state $v_{(q,q',a)}$ iff there is a transition to $q$ labeled by $a$. Thus $|V_0| \leq |\Delta||Q|$.

As far as $|E^f_A|$, for every transition $(q, a, q') \in \Delta$, and every $q'' \in Q$, there is an edge $(v_{(q,q'')}, v_{(q',q'',a)}) \in E^{\star}$. There are $|\Delta||Q|$ such edges. Likewise, there are $\leq |\Delta||Q|$ edges from $V^{\star}_0$ to $V^{\star}_1$. So $|E^f_A| \in O(|\Delta||Q|)$. Thus, the size of $G^{\star}_A$ is $O(|\Delta||Q|)$. Now observe that if $\star = o$, the vertices do not change and the edge set is a subset, and if $\star = de$, the number of vertices and edges is larger by at most a factor of 2.

Last, since the vertices labeled by priority 1 in both $G^f$ and $G^{de}$ are a subset of $V_0$, clearly $|p^{-1}(1)| \in O(|Q|^2)$. □

Since vertices of $G^o_A$ and $G^{di}_A$ only get assigned a single priority, we can dispense with algorithms for computing ordinary and direct simulation right away, matching the best known upper bounds:

PROPOSITION 5 (see [16, 2]). *Given a Büchi automaton $A$, with $n$ states and $m$ transitions, both $\preceq_o$ and $\preceq_{di}$ can be computed in time and space $O(mn)$.*

*Proof.* $G^{\star}_A$ here has size $O(|\Delta||Q|)$ and only one priority. For such game graphs, we can compute the winning set for Even using a variant of AND/OR graph accessibility, which can be computed in linear time (see, e.g., [1]). The only vertices in the game graph that have no outgoing edges are in $V_0$. These are losing positions for Even, as are any other vertices from which these are accessible in the and/or sense (vertices from $V_0$ are considered "and nodes" and vertices from $V_1$ are considered "or nodes"). All the remaining vertices are winning positions for Even. □

Algorithms for computing the other simulation relations will be presented in section 4.

## 3.2. Bisimulation.

For $\star \in \{o, di, de, f\}$, $\star$-bisimulations can also be reformulated as parity games. For improving the complexity, such a reformulation helps only for fair bisimulation. Ordinary and direct bisimulation have known $O(m \log n)$-time algorithms (see [21]), and we will see that delayed bisimulation corresponds to direct bisimulation after some linear-time preprocessing on accept states of the Büchi automaton.

We formulate fair bisimulation with a parity-game graph $G^{f\,bi}_A$ as follows. The vertex sets of $G_A^{f\,bi}$ are

$$V_0^{f\,bi} = \{v_{(q,q',a,b_1,b_2)} \mid q, q' \in Q \wedge b_1, b_2 \in \{0,1\} \wedge \exists q''((q'', a, q) \in \Delta)\}, \tag{13}$$

$$V_1^{f\,bi} = \{v_{(q_0,q_1,b_2)} \mid q, q' \in Q \wedge b_2 \in \{0,1\}\}. \tag{14}$$

The two bits $b_1$ and $b_2$ will encode (1) which pebble was moved by Spoiler in this round, and (2) which of the two pebbles was latest to visit an accept state (prior to this round and with precedence for the red pebble, with 0 encoding the red pebble). For $q_0, q_1 \in Q$ and $b_2 \in \{0,1\}$, let

$$\text{new}(q_0, q_1, b_2) = \begin{cases} 0 & \text{if } q_0 \in F, \\ 1 & \text{if } q_0 \notin F \text{ and } q_1 \in F, \\ b_2 & \text{otherwise.} \end{cases} \tag{15}$$

The edge set $E_A^{f\,bi}$ is the union of

$$\{(v_{(q_0,q_1,b_2)}, v_{(q'_0,q'_1,a,b_1,\text{new}(q_0,q_1,b_2))}) \mid (q_{b_1}, a, q'_{b_1}) \in \Delta \wedge q_{1-b_1} = q'_{1-b_1}\} \tag{16}$$

and

$$\{(v_{(q_0,q_1,a,b_1,b_2)}, v_{(q'_0,q'_1,b_2)}) \mid (q_{1-b_1}, a, q'_{1-b_1}) \in \Delta \wedge q_{b_1} = q'_{b_1}\}. \tag{17}$$

The priority of a vertex is determined using the following function. For $q_0, q_1, b$ let

$$\text{pr}(q_0, q_1, b) = \begin{cases} 0 & \text{if } q_{1-b} \in F, \\ 1 & \text{if } q_{1-b} \notin F \text{ and } q_b \in F, \\ 2 & \text{otherwise.} \end{cases} \tag{18}$$

For $v \in V_0$, $p_A^{f\,bi}(v) = 2$, and for $v_{(q_0,q_1,b_2)} \in V_1$,

$$p_A^{f\,bi}(v_{(q_0,q_1,b_2)}) = \text{pr}(q_0, q_1, b_2). \tag{19}$$

The correspondence of this parity game and fair bisimulation is as follows, similar to Lemma 4.

LEMMA 6. *Let $A$ be a Büchi automaton.*

1. *Even has a winning strategy in* $\text{P}(G_A^{f\,bi}, v_{(q_0,q_1,0)})$ *iff $q_0$ and $q_1$ are fair-bisimilar in $A$.*
2. $|G_A^{f\,bi}| \in O(|\Delta||Q|)$ *and* $|\{v \in V_A^{f\,bi} \mid p_A^{f\,bi}(v) = 1\}| \in O(|Q|^2)$.

*Proof.* It is clear that the parity game models the bisimulation game in a straightforward way as far as the sequence of the visited positions is concerned. We show that the winning condition is also taken care of.

Assume $\pi = q_0a_0q_1a_1\ldots$ and $\pi' = q'_0a_0q'_1a_1\ldots$ are two runs. Let $b_0b_1\ldots$ be the sequence of bits defined by $b_0 = 0$ and $b_{i+1} = \text{new}(q_i, q'_i, b_i)$. Finally, let $p_i$ be defined by $p_i = \text{pr}(q_i, q'_i, b_i)$. This describes exactly what happens in the game. We proceed by a case distinction.

Clearly, if $\pi$ and $\pi'$ are not accepting, then $p_j = 2$ for all $j$ large enough and Even wins, which is required. Next, assume $\pi$ is accepting, and $\pi'$ is not. Then there exists $i$ such that $q'_j \notin F$ for $j \geq i$ and $q_j \in F$ for infinitely many $j$, say $i_0 < i_1 < i_2 < \cdots$ are such that $q_{i_j} \in F$ for every $j$. Assume $i_k > i$. According to the definition of *new*, $b_{i_j} = 0$ for $j > k$. Thus, by definition of *pr*, for every $j > i_k$, $p_j = 1$ if $j = i_l$ for some $l > k$ and $p_j = 2$ otherwise—Even loses. The same argument applies if $\pi$ is not accepting but $\pi'$ is. (The precedence for red does not play any role here.) Finally, assume $\pi$ and $\pi'$ are accepting. Let $i_0 < i_1 < \cdots$ be an infinite sequence such that $q_{i_j} \in F$ for all $j$. For $j$, let $i'_j$ be the least $k > i_j$ such that $q'_k \in F$. We will have $b_k = 0$ for $i_j < k \leq i'_j$, which means $p_{i'_j} = 0$ for every $j$—Even wins.

The claim about the size of $G_A^{f\,bi}$ and the number of its vertices of priority 1 can be proved along the same lines as Lemma 4. □

This enables us to give an efficient algorithm for computing fair bisimulation in section 4.

To compute delayed bisimulation efficiently, we show that the delayed bisimulation relation corresponds to the direct bisimulation relation after some linear-time preprocessing on the accept states of the Büchi automaton. Consider the following closure operation on the set of accept states. Let $\mathrm{cl}(A)$ be the Büchi automaton obtained from $A$ by repeating the following until a fixed point is reached: while there is a state $q$ such that all of its successors are in $F$, put $q$ in $F$. Call the revised set of accept states $F'$. Clearly, $\mathrm{cl}(A)$ can be computed in linear time and $L(A) = L(\mathrm{cl}(A))$.

Proposition 7. *Let $A$ be a Büchi automaton. For any two states $q$ and $q'$, $q \approx_{de}^{bi} q'$ in $A$ iff $q \approx_{di}^{bi} q'$ in* $\mathrm{cl}(A)$.

*Proof.* We show that for every pair $(q, q')$ of states, a winning strategy for Duplicator in the delayed bisimulation game on $(q, q')$ in $A$ is a winning strategy for Duplicator in the direct bisimulation game on $(q, q')$ in $\mathrm{cl}(A)$, and vice versa. By definition of the bisimulation relations, this proves the proposition.

First, let $f$ be a winning strategy for Duplicator in the delayed bisimulation game on $(q_0, q'_0)$ in $A$. Suppose that with Duplicator playing according to strategy $f$ the direct bisimulation game reaches $(q_i, q'_i)$ after $i$ rounds. We have to show that $q_i \in F'$ iff $q'_i \in F'$. Suppose, for contradiction, that $q_i \notin F'$, while $q'_i \in F'$ (the other situation is symmetric). We will show how Spoiler can win the delayed bisimulation game. Since $q_i \notin F'$, there is an infinite path leaving $q_i$ such that no state on this path is an accepting state. Spoiler's strategy is to play this path. Since $q'_i \in F'$, there is no such path (without an accept state on it) starting at $q'_i$. Therefore, regardless of how Duplicator plays, when $(q_0 a_0 q_1 a_1 \ldots, q'_0 a_0 q'_1 a_1 \ldots)$ is the outcome of the play, then $q'_i \in F'$, but $q_j \notin F'$ for all $j \geq i$—Spoiler wins the delayed bisimulation game.

Second, let $f$ be a winning strategy for Duplicator in the direct bisimulation game on $(q, q')$ in $\mathrm{cl}(A)$ and suppose Duplicator plays according to $f$ in the delayed bisimulation game. Let $(q_0 a_0 q_1 a_1 \ldots, q'_0 a_0 q'_1 a_1 \ldots)$ be any outcome of such a play. We have to show that it satisfies Duplicator's winning condition. So let $i$ be any index such that $q_i \in F$. Then, by definition of $F'$, $q_i \in F'$. But since $f$ is a winning strategy in the direct bisimulation game, this implies $q'_i \in F'$. As every infinite path out of $q'_i$ contains an accept state, there must be a $j \geq i$ such that $q'_j \in F$. Symmetrically, if $q'_i \in F$, then there exists $j \geq i$ such that $q_j \in F$. □

Taking into account that direct bisimulation can be computed in time $O(m \log n)$ (see [21]), we conclude with the following result.

Corollary 8. *Delayed bisimulation can be computed in time $O(m \log n)$.*

## 4. Fast parity-game algorithm to compute simulations (and bisimulations) efficiently.

Using the parity-game graphs $G_A^f$, $G_A^{f\,bi}$, and $G_A^{de}$, we give fast algorithms for computing the relations $\preceq_f$, $\approx_f^{bi}$, and $\preceq_{de}$. To this effect, we describe an efficient implementation of an algorithm for solving parity games presented by Jurdziński in [17]. This algorithm uses progress measures (see also [18, 25]) to compute the set of vertices in a parity game from which Even has a winning strategy.

Henceforth, we assume all parity-game graphs have neither self loops nor dead ends. (We can always obtain an "equivalent" such graph in linear time.) We start with some terminology, closely following the notation of [17]. Let $G$ be a parity-game graph as before, $n'$ its number of vertices, $m'$ its number of edges. For computing simulations, we only need assume there are only three priorities, that is, $p\colon V \to \{0,1,2\}$. However, we will present the algorithm in its full generality, i.e., $p\colon V \to \{0,1,\dots,d-1\}$, since the algorithm is of much broader interest.

Let $[n] = \{0,\dots,n-1\}$, and let $n_i = |p^{-1}(i)|$. The algorithm assigns to each vertex a "progress measure" from $M_G^\infty = M_G \cup \{\infty\}$, where

$$(20) \quad M_G = \begin{cases} [1]\times[n_1+1]\times[1]\times[n_3+1]\times\cdots[1]\times[n_{d-1}+1] & \text{if } d \text{ is even,}\\ [1]\times[n_1+1]\times[1]\times[n_3+1]\times\cdots[1]\times[n_{d-2}+1] & \text{if } d \text{ is odd.}\end{cases}$$

In other words, a progress measures is either $\infty$ or a length $d$ vector which at even index positions is 0, and at odd index positions $i$ ranges over $\{0,\dots,n_i\}$.

Initially, every vertex is assigned 0, the all-zero vector. The measures are repeatedly "incremented" in a certain fashion until a fixed point is reached.

We first explain the increment operation, which is at the heart of Jurdziński's algorithm. For $i < d$ and $x \in M_G^\infty$ we define $\langle x\rangle_i$ as follows. For $x = (l_0,\dots,l_{d-1})$, $\langle x\rangle_i = (l_0,\dots,l_i,0,0,\dots,0)$. In other words, we set positions indexed $> i$ to 0. Moreover, $\langle\infty\rangle_i = \infty$. We define a lexicographic total order on $M_G^\infty$, denoted $>$. Here, index 0 is the most significant position, and $\infty$ is greater than all other vectors. In addition, for $d$-vectors $x$ and $y$, we write $x >_i y$ iff $\langle x\rangle_i > \langle y\rangle_i$ according to the above ordering. For example, $(0,3,0,1) >_1 (0,2,0,3)$. Note that $x > y$ iff $x >_{d-1} y$. Now, we can say what it means to "increment" a progress measure. For each $i \in [d]$, let

$$(21) \qquad \mathrm{incr}_i(x) = \begin{cases} \langle x\rangle_i & \text{if } i \text{ is even } x \neq \infty,\\ \min\{y \in M_G^\infty \mid y >_i x\} & \text{if } i \text{ is odd, } x \neq \infty,\\ \infty & \text{if } x = \infty.\end{cases}$$

Observe that, for a fixed $i$, the operation $\mathrm{incr}_i(\cdot)$ is monotone with respect to the ordering $<$; that is, if $x \le x'$, then $\mathrm{incr}_i(x) \le \mathrm{incr}_i(x')$.

For simplicity in notation, if $v \in V$, we write $\langle x\rangle_v$ and $\mathrm{incr}_v(x)$ for $\langle x\rangle_{p(v)}$ and $\mathrm{incr}_{p(v)}(x)$, respectively. For every assignment $\rho\colon V \to M_G^\infty$ of progress measures to the vertices of a game graph, which we call an *assignment* for short, and for $v \in V$, let

$$(22) \qquad \text{best-nghb-ms}(\rho,v) = \begin{cases} \langle \min(\{\rho(w) \mid (v,w)\in E\})\rangle_v & \text{if } v \in V_0,\\ \langle \max(\{\rho(w) \mid (v,w)\in E\})\rangle_v & \text{if } v \in V_1.\end{cases}$$

Here, best-nghb-ms$(\rho,v)$ stands for the set of *best neighbors* of $v$ with respect to the *measure* we have defined. Jurdziński defines a "lifting" operator, which, given an assignment $\rho$ and $v \in V$, gives a new assignment. In order to define it, he first defines how an individual vertex's measure is "updated" with respect to those of its neighbors:

$$(23) \qquad \mathrm{update}(\rho,v) = \mathrm{incr}_v(\text{best-nghb-ms}(\rho,v)).$$

The "lifted" assignment, $\mathrm{lift}(\rho,v)\colon V \to D$, is then defined as follows:

$$(24) \qquad \mathrm{lift}(\rho,v)(u) = \begin{cases} \mathrm{update}(\rho,v) & \text{if } u = v,\\ \rho(u) & \text{otherwise.}\end{cases}$$

```
1 for $v \in V$ do
2   $\rho(v) := 0$
3 endfor
4 while there exists a $v$ such that update$(\rho, v) \neq \rho(v)$ do
5   $\rho := \text{lift}(\rho, v)$
6 endwhile
```

FIG. 1. *Jurdziński's lifting algorithm.*

Observe that for every $v$, the operator $\text{lift}(\cdot, v)$ is a monotone operator with respect to the complete partial ordering where $\rho \leq \rho'$ if $\rho(v) \leq \rho'(v)$ for all $v \in V$.

Jurdziński's algorithm is depicted in Figure 1. The outcome determines the winning set of vertices for each player as follows.

THEOREM 9 (see [17]). *Let $G$ be a parity game. Even has a winning strategy from precisely the vertices $v$ such that, after the lifting algorithm depicted in Figure* 1 *halts, $\rho(v) < \infty$.*

Jurdziński's algorithm needs at most $n' N_G$ iterations of the while loop where

$$N_G = |M_G^\infty| = 1 + \prod_{i:\ 0<2i+1\leq d-1} n_{2i+1}. \tag{25}$$

More precisely, Jurdziński argues as follows. Each vertex can only be lifted $N_G$ times. A lifting operation at $v$ can be performed in time $O(|\text{Sucs}(v)|)$, where $\text{Sucs}(v)$ denotes the set of successors of $v$. So, overall, he concludes, the running time is $O(m' N_G d)$. In this analysis, it is implicitly assumed that one can, in constant time, decide if there is a vertex $v$ such that update$(\rho, v) \neq \rho(v)$, and find such a vertex. We provide an implementation of Jurdziński's algorithm that achieves this.

Our algorithm, depicted in Figure 2, maintains a set $L$ of "pending" vertices $v$ whose measure needs to be considered for lifting, because a successor has recently been updated resulting in a requirement to update $\rho(v)$. This set $L$ is implemented as a list together with a bit array; extracting an element, adding an element, and membership test can then be carried out in constant time. Further, we maintain arrays $B$ and $C$ that store, for each vertex $v$, the value best-nghb-ms$(\rho, v)$ and the number of successors $u$ of $v$ with $\langle \rho(u) \rangle_v =$ best-nghb-ms$(\rho, v)$, denoted cnt$(\rho, v)$.

Whether a vertex $w$ needs to be placed on $L$ is determined in constant time by maintaining, for each vertex $w$, the current "best measure" $B(w)$ of any of its successors, as well as the count $C(w)$ of how many such neighbors there are with the "best measure." This is only necessary for $w \in V_0$, because if this is the case we need to be able to realize when all neighbors with the current minimum value have "died out," while for $w \in V_1$ we look at the maximum of all neighbors.

LEMMA 10. *The lifting algorithm depicted in Figure* 2 *computes the function $\rho$ from Jurdziński's algorithm in time $O(m' N_G d)$ and space $O(dm')$.*

*Proof.* The correctness follows from the above explanation. The running time follows because each vertex can enter $L$ at most $n_1 + 1$ times, and the time taken by the body of the while loop is proportional to the number of edges incident on the vertex.

The bound on the running time can be explained as follows. The initialization (lines 1–4) takes time $O(m'd)$. If a vertex enters $L$ in the body of the while loop, then its $\rho$-value will be incremented next time the vertex is removed from $L$. That means every vertex enters $L$ at most $N_G$ times. The time it takes to process a vertex $v$ taken

```
 1  foreach $v \in V$ do
 2    $B(v) := 0$; $C(v) := |\{w \mid (v,w) \in E\}|$; $\rho(v) := 0$;
 3  endfor
 4  $L := \{v \in V \mid p(v)$ is odd$\}$;
 5  while $L \neq \emptyset$ do
 6    let $v \in L$; $L := L \setminus \{v\}$;
 7    $t := \rho(v)$;
 8    $B(v) :=$ best-nghb-ms$(\rho, v)$; $C(v) :=$ cnt$(\rho, v)$; $\rho(v) := \mathrm{incr}_v(B(v))$;
 9    $P := \{w \in V \mid (w,v) \in E\}$;
10    foreach $w \in P$ such that $w \notin L$ do
11      if $w \in V_0$, $\langle t \rangle_w = B(w)$, and $\langle \rho(v) \rangle_w > B(w)$ then
12        if $C(w) = 1$ then $L := L \cup \{w\}$;
13        if $C(w) > 1$ then $C(w) := C(w) - 1$;
14      if $w \in V_1$ and $\langle \rho(v) \rangle_w > B(w)$ then
15        $L := L \cup \{w\}$;
16    endfor
17  endwhile
```

FIG. 2. *Efficient implementation of the lifting algorithm.*

from the loop is $O(\#$ vertices incident on $v)$. This means that lines 5–17 take time $O(m' N_G d)$. This proves the claim. ∎

We can now state one of our main theorems.

THEOREM 11. *For a Büchi automaton $A$, the relations $\preceq_f$, $\approx_f^{bi}$, and $\preceq_{de}$ can all be computed in time $O(|\Delta||Q|^3)$ and space $O(|Q||\Delta|)$.*

*Proof.* The theorem follows from Lemmas 4 and 10. Observe that in the (bi)simulation games involved we have $N_G = n_1 + 1 = O(|Q|^2)$. ∎

As mentioned, in prior work $O(|Q|^6)$–time and space [14], and $O(|Q|^{10})$–time and space [15] algorithms were given for deciding whether $q \preceq_f q'$, and, respectively, $q \approx_f^{bi} q'$, hold for a *single* pair of states $(q, q')$.

## 5. Reducing state spaces by quotienting: Delayed simulation is better.

In this section, we show that (1) quotienting with respect to delayed simulation preserves the recognized language; (2) this is not true with fair simulation; and (3) quotients with respect to delayed simulation can indeed be substantially smaller than quotients with respect to direct simulation, even when the latter is computed on the "accept closure" cl$(A)$ (unlike what we saw with delayed bisimulation). We first define quotients.

DEFINITION 12. For a Büchi automaton $A$, and an equivalence relation $\approx$ on the states of $A$, let $[q]$ denote the equivalence class of $q \in Q$ with respect to $\approx$. The *quotient* of $A$ with respect to $\approx$ is the automaton

$$A/\!\approx\; = \langle \Sigma, Q/\!\approx, \Delta_\approx, [q_I], F/\!\approx \rangle, \tag{26}$$

where

$$\Delta_\approx = \{([q], a, [q']) \mid \exists\, q_0 \in [q],\ q_0' \in [q'] \text{ such that } (q_0, a, q_0') \in \Delta\}. \tag{27}$$

In order to apply our simulation relations, we define, corresponding to each simulation preorder, an equivalence relation $\approx_o$, $\approx_{di}$, $\approx_{de}$, and $\approx_f$, where $q \approx_\star q'$ iff $q \preceq_\star q'$ and $q' \preceq_\star q$. Note that both $\approx_\star$ and $A/\!\approx_\star$ can be computed from $\preceq_\star$ requiring no more time (asymptotically) than that needed to compute $\preceq_\star$ on $A$. The quotient with respect to $\approx_{di}$ preserves the language of any automaton, while this is obviously not true for $\approx_o$. We will later see that this is not true for $\approx_f$ either. But first we show that this is true for $\approx_{de}$.

We start with a lemma.

LEMMA 13. *Let $A$ be a Büchi automaton.*

1. *If $q_0 \preceq_{de} q_0'$ and $(q_0, a, q_1) \in \Delta$, then there exists $q_1'$ with $q_1 \preceq_{de} q_1'$ and $(q_0', a, q_1') \in \Delta$.*

2. *If $q_0 \preceq_{de} q_0'$ and $[q_0]_{de}\, a_0\, [q_1]_{de}\, a_1 \dots$ is a finite or infinite run of $A/{\approx_{de}}$, then there exists a run $q_0' a_0 q_1' a_1 \dots$ of $A$ of the same length such that $q_i \preceq_{de} q_i'$ for every $i$.*

3. *If $q_0 \preceq_{de} q_0''$ and $[q_0]_{de}\, a_0\, [q_1]_{de}\, a_1 \dots$ is an infinite run of $A/{\approx_{de}}$ with $q_0 \in F$, then there exists a finite run $q_0'' a_0 \dots a_{r-1} q_r''$ of $A$ such that $q_j \preceq_{de} q_j''$ for $j \le r$ and $q_r'' \in F$.*

*Proof.* For the first part, recall that by definition of $\preceq_{de}$, we know Duplicator wins $G_A^{de}(q_0, q_0')$. Let $f$ be a winning strategy for him, and let $q_1' = f(q_0 q_0' a q_1)$. Then, by definition, $(q_0', a, q_1') \in \delta$. Also, it is easy to see that $f'$ defined by $f'(\rho) = f(q_0 q_0' a \rho)$ is a winning strategy for Duplicator in $G_A^{de}(q_1, q_1')$. Therefore, the claim holds.

For the second part, observe that by definition of $A/{\approx_{de}}$ there exist $\hat{q}_0$ and $\hat{q}_1$ such that (i) $q_0 \approx_{de} \hat{q}_0$, (ii) $q_1 \approx_{de} \hat{q}_1$, and (iii) $(\hat{q}_0, a_0, \hat{q}_1) \in \Delta$. From (i), we obtain $\hat{q}_0 \preceq_{de} q_0'$ by transitivity of $\preceq_{de}$. So, from (iii) and the first part of the lemma, we can conclude there exists $(q_0', a, q_1') \in \Delta$ such that $\hat{q}_1 \preceq_{de} q_1'$. From (ii), we obtain $q_1 \preceq_{de} q_1'$. Hence, we have constructed the first transition of the desired run and are in a completely analogous situation. The rest follows by induction.

For the third part, first set $q_0' = q_0$. Let $q_0' a_0 q_1' a_1 \dots$ be the infinite run which we know exists by the second part. Next, let $f$ be a winning strategy of Duplicator in $G_A^{de}(q_0', q_0'')$. Consider $q_0'' a_0 q_1'' a_1 \dots$ defined by $q_{i+1}'' = f(q_0' q_0'' a_0 \dots q_i')$. Just as in the proof of the first part, it can be argued that $q_j \preceq_{de} q_j' \preceq_{de} q_j''$ holds for every $j$. Because of $q_0' = q_0 \in F$, we conclude there exists $r$ such that $q_r'' \in F$, which completes the proof. ∎

THEOREM 14. *For any Büchi automaton $A$, $L(A) = L(A/{\approx_{de}})$.*

*Proof.* To see that $L(A) \subseteq L(A/{\approx_{de}})$, consider any accepting run $\pi = q_0 a_0 q_1 a_1 \dots$ of $A$. By definition of $A/{\approx_{de}}$, $[q_0]a_0[q_1]a_1 \dots$ is an accepting run of $A/{\approx_{de}}$. This holds for any of our simulation notions.

To show $L(A/{\approx_{de}}) \subseteq L(A)$, consider an accepting run $[q_0]a_0[q_1]a_1 \dots$ of $A/{\approx_{de}}$. Although we cannot guarantee that $q_0 a_0 q_1 a_1 \dots$ is a run of $A$, we can construct another accepting run over the same word.

We may assume that $q_0 = q_I$ and that there are infinitely many $i$ such that $q_i \in F$. We construct a sequence $\rho_0$, $\rho_1$, ... of finite runs of $A$ on prefixes of $a_0 a_1 \dots$ where $\rho_{l+1}$ strictly extends $\rho_l$ and contains at least $l+1$ elements from $F$. So the limit of the $\rho_i$'s will be the run we are looking for.

We start with $\rho_0 = q_0$. Assume $\rho_l = q_0' a_0 \dots q_i'$ has already been constructed in such a way that $q_i \preceq_{de} q_i'$. There exists $j > i$ such that $q_j \in F$. So, by the second part of the previous lemma, we know there exists a run $q_i' a_i \dots q_j'$ such that $q_j \preceq_{de} q_j'$. By the third part of the lemma, we know there exists $k \ge j$ and a run $q_j' a_j \dots q_k'$ such that $q_k \preceq_{de} q_k'$ and $q_k' \in F$. We set $\rho_{l+1} = \rho a_i q_{i+1}' \dots q_k'$. ∎

We can thus use $A/{\approx_{de}}$ to reduce the size of $A$, just as with direct simulation. In fact, $A/{\approx_{de}}$ can be smaller than $A/{\approx_{di}}$ (as well as $\mathrm{cl}(A)/{\approx_{di}}$) by an arbitrarily large factor.

PROPOSITION 15. *For $n \ge 2$, there is a Büchi automaton $A_n$ with $n+1$ states*

FIG. 4. *Family of automata $B_n$.*

*such that $A_n/{\approx_{de}}$ has 2 states but $A_n/{\approx_{di}}$ has $n + 1$ states (and $A_n = \mathrm{cl}(A_n)$).*

*Proof.* Consider automaton $A_n$ in Figure 3. It is not hard to establish that in $A_n$ each outer state delayed simulates each other outer state. Thus $A_n/{\approx_{de}}$ has 2 states. On the other hand, $A_n = \mathrm{cl}(A_n)$, and no state of $A_n$ direct simulates any other state of $A_n$. Thus $A_n/{\approx_{di}} = A_n$ and has $n + 1$ states. ▯

Next we see that Theorem 14 fails badly for fair simulation and bisimulation; that is, fair (bi)simulation cannot be used for state space reduction via quotienting under any reasonable definition of quotient. [15] already makes a very closely related observation, showing an automaton whose fair bisimulation quotient is not fair bisimilar to itself.

PROPOSITION 16. *For $n \geq 2$, there is a Büchi automaton $B_n$ with $n$ states, each of which fairly (bi)simulates every other state, but such that no Büchi automaton with fewer than $n$ states accepts $L(B_n)$. In particular, $L(B_n) \neq L(B_n/{\approx_f^{bi}})$.*

*Proof.* Consider the automaton $B_n$ shown in Figure 4. It has $n$ states and an alphabet $\Sigma = \{a_1, \ldots, a_{n-1}\}$. To see that every state of $B_n$ fair simulates (and fair bisimulates) every other state, first note that because the automaton is deterministic Duplicator has no choice in her strategy. A run (played by Spoiler) goes through the accept state infinitely often iff each $a_i$ is encountered infinitely often. But this statement holds no matter which state the run begins from. Thus Duplicator's unique strategy from the initial state pair will be a winning strategy. The language $L(B_n)$ contains precisely those $\omega$-words where each $a_i$ occurs infinitely often. It is not hard to show that there are no Büchi automata recognizing $L(B_n)$ with fewer than $n$ states. $\square$

**6. Conclusions.** We have presented a unified parity-game framework in which to understand optimal known algorithms for a variety of simulation notions for Büchi automata. In particular, we have improved upon the best bounds for fair simulation (and fair bisimulation), matched the best bound for ordinary simulation, and presented an algorithm for the new notion of delayed simulation. Our algorithms employ a relatively simple fixed point computation, an implementation of an algorithm by Jurdziński for parity games, and should perform well in practice.

Our own main aim in using simulations is efficient state space reduction, as in [8]. We introduced delayed simulation and showed that, unlike fair simulation, delayed simulation quotients can be used for state space reduction, and allow greater reduction than direct (strong) simulation, which has been used in the past. Optimization of property automata prior to model checking is an ingredient in making explicit state model checkers such as SPIN more efficient. Preliminary results indicate that in practice delayed simulation does outperform direct simulation on many inputs; further studies need to be carried out to get a clearer picture of the relative advantages of delayed simulation.

# THE COMPLEXITY OF FINDING PATHS IN GRAPHS WITH BOUNDED INDEPENDENCE NUMBER[*]

ARFST NICKELSEN[†] AND TILL TANTAU[†]

**Abstract.** We study the problem of finding a path between two vertices in finite directed graphs whose independence number is bounded by some constant $k$. The independence number of a graph is the largest number of vertices that can be picked such that there is no edge between any two of them. The complexity of this problem depends on the exact question we ask: Do we wish only to tell whether a path exists? Do we also wish to construct such a path? Are we required to construct the shortest one? Concerning the first question, we show that the reachability problem is first-order definable for all $k$ and that its succinct version is $\Pi_2^{\mathrm{P}}$-complete for all $k$. In contrast, the reachability problems for many other types of finite graphs, including dags and trees, are not first-order definable, and their succinct versions are PSPACE-complete. Concerning the second question, we show not only that we can construct paths in logarithmic space, but that there even exists a logspace approximation scheme for this problem. The scheme gets a ratio $r > 1$ as additional input and outputs a path that is at most $r$ times as long as the shortest path. Concerning the third question, we show that even telling whether the shortest path has a certain length is NL-complete and thus is as difficult as for arbitrary directed graphs.

## 1. Introduction.

Finding paths in graphs is one of the most fundamental problems in graph theory and has both practical and theoretical applications in many different areas. For this problem we are given a graph $G$ and two vertices $s$ and $t$, the *source* and the *target*, and we are asked to find a path from $s$ to $t$. The problem comes in different versions: The most basic is the *reachability problem*, which just asks whether such a path *exists*. This problem is also known as the "graph accessibility problem" or "s-t-connectivity problem." The *construction problem* asks us to *construct* a path, provided one exists. The *optimization problem* asks us to construct not just any path, but a *shortest* one. Closely related to the optimization problem is the *distance problem*, which asks us to decide whether the distance of $s$ and $t$ is bounded by a given number. If the optimization problem is difficult to solve, we can consider the *approximation problem*, which asks us to construct a path that is not necessarily a shortest path, but that is no longer than the distance of $s$ and $t$ times a constant factor.

In this paper we show that for directed graphs whose independence number is bounded by some constant $k$, the reachability problem, the construction problem,

and the optimization problem have fundamentally different computational complexities. The *independence number* $\alpha(G)$ of an (undirected or directed) graph $G$ is the maximum number of vertices that can be picked from $G$ such that there is no edge between any two of these vertices. Our main results are the following:

1. The reachability problem for finite graphs with independence number at most $k$ is first-order definable for all $k$. This does not hold for infinite graphs for any $k$.
2. The reachability problem for succinctly represented graphs with independence number at most $k$ is $\Pi_2^{\mathrm{P}}$-complete for all $k$.
3. There exists an algorithm that needs space $O\big((\alpha(G) + \log m) \log n\big)$ on $n$-vertex graphs to compute a path between two given connected vertices whose length is at most $1 + 1/m$ times their distance.
4. The distance problem for graphs with independence number at most $k$ is NL-complete for all $k$.

The most prominent examples of graphs with bounded independence number are *tournaments* [21, 24], which are directed graphs with exactly one edge between any two vertices. Their independence number is 1. The reachability problem for tournaments arises naturally if we try to rank or sort objects according to a comparison relation that for any two objects tells us which one "beats" the other, but which is not necessarily acyclic. A different example of graphs with bounded independence number, studied in [7], are directed graphs $G = (V, E)$ whose underlying undirected graph is claw-free, i.e., does not contain the graph $K_{1,m}$ for some constant $m$, and whose minimum degree is at least $|V|/3$. Their independence number is at most $3m - 3$.

To gain some understanding of the behavior of the independence number function, first note that independence is a monotone graph property: adding edges to a graph can only decrease the independence number, and deleting edges can only increase it. Given two graphs with the same vertex set and independence numbers $\alpha$ and $\alpha'$, the independence number of their union is at most the minimum of $\alpha$ and $\alpha'$, and the independence number of their disjoint union is $\alpha + \alpha'$. Thus if a graph consists of, say, four disjoint tournaments with arbitrary additional edges connecting these tournaments, its independence number is at most 4. Intuitively, a graph with a low independence number must have numerous edges, and, indeed, at least $\binom{n}{2} \,/\, \binom{\alpha(G)+1}{2}$ edges must be present in any $n$-vertex graph $G$. This abundance of edges might suggest that if paths between two given vertices exist, there should also exist a short path between them. While this is true for the undirected case, in the directed case (which interests us in this paper) the distance between two vertices can become as large as $n - 1$, even in $n$-vertex tournaments.

**1.1. How difficult is it to tell whether a path exists?** The reachability problem for finite directed graphs, which will be denoted REACH in the following, is well known to be NL-complete [16, 17] and thus "easy" from a computational point of view. The complexity of the reachability problem drops if we restrict the type of graphs for which we try to solve it. The reachability problem $\text{REACH}_{\text{u}}$ for finite undirected graphs is SL-complete [19] and thus presumably easier to solve. The even more restricted problem $\text{REACH}_{\text{forest}}$ for directed forests and the problem $\text{REACH}_{\text{out}\le 1}$ for directed graphs in which all vertices have out-degree at most 1 are L-complete [4]. Here and in the following, "completeness" is meant with respect to first-order reductions ($\le_{\text{fo}}$-reductions) in the sense of Immerman [15], where ordering and the bit predicate are available. Barrington, Immerman, and Straubing [2] have shown that first-order reductions are the same as DLOGTIME-uniform many-one $\mathrm{AC}^0$-reductions.

The complexity of the reachability problem for finite directed graphs whose independence number is bounded by a constant $k$ is much lower: Somewhat surprisingly, this problem is first-order definable for all $k$. Formally, for each $k$ the language $\text{REACH}_{\alpha \leq k} := \text{REACH} \cap \{\langle G, s, t\rangle \mid \alpha(G) \leq k\}$ is first-order definable, where $\langle\,\rangle$ denotes a standard binary encoding. First-order definability means the following: Let $\tau = (\mathrm{E}^2, \mathrm{s}, \mathrm{t})$ be the signature of directed graphs with two distinguished vertices. The binary relation symbol E represents an edge relation, and the constant symbols s and t represent a source and a target vertex. We show that for each $k$ there exists a first-order formula $\phi_{\text{reach},\alpha\leq k}$ over the signature $\tau$ for which the following holds: For all *finite* directed graphs $G = (V, E)$ and all $s, t \in V$ the $\tau$-structure $(V, E, s, t)$ is a model of $\phi_{\text{reach},\alpha\leq k}$ if

1. $\alpha(G) \leq k$ and
2. there is path from $s$ to $t$ in $G$.

The formulas will require neither an ordering on the universe nor the bit predicate; see [15] for a discussion of the importance of these predicates. Note, however, that we implicitly use these predicates in the first-order reductions that we present.

Languages whose descriptive complexity is first-order are known to be very simple from a computational point of view. They can be decided by a family of DLOGTIME-uniform $\mathrm{AC}^0$-circuits [2], in constant parallel time on concurrent-read, concurrent-write parallel random access machines [14], and they constitute a small subclass of the class L of logarithmic space. Since it is known that L-hard sets cannot be first-order definable [1, 9], $\text{REACH}_{\alpha\leq k}$ is *unconditionally* easier to solve than REACH, $\text{REACH}_{\text{u}}$, and $\text{REACH}_{\text{forest}}$. It is even easier than the seemingly trivial reachability problem for graphs that are directed paths, which Etessami [6] has shown to be L-complete. For the special case of tournaments, conditions for strong connectedness (and thus, implicitly, for reachability) were proved in [12], but these conditions yield weaker bounds on the complexity of the reachability problem for tournaments than those shown in the present paper.

Our results on the first-order definability of $\text{REACH}_{\alpha\leq k}$ apply only to finite graphs. Let $\text{REACH}^{\infty}_{\alpha\leq k}$ denote the class of all triples $(G, s, t)$ such that $G$ is a (possibly infinite) directed graph with $\alpha(G) \leq k$ in which there is a path from $s$ to $t$. We show that no set of first-order formulas (not even an infinite one) has $\text{REACH}^{\infty}_{\alpha\leq k}$ as its class of models for any $k$.

When studying the complexity of a graph problem, one usually assumes (as we did above) that the input graph is encoded as a binary string "in some standardized way," for example, using adjacency lists. Which particular encoding method is chosen is of little or no concern for the computational complexity of the problem. This is no longer true if the input graphs are encoded *succinctly*, as is often the case, for instance, in hardware design. Succinctly represented graphs are given indirectly via a program or a circuit that decides the edge relation of the graph. For reachability problems, Papadimitriou and Yannakakis [23] and Wagner [35, 36] have shown that SUCCINCT-REACH, $\text{SUCCINCT-REACH}_{\text{u}}$, $\text{SUCCINCT-REACH}_{\text{forest}}$, and $\text{SUCCINCT-REACH}_{\text{out}\leq 1}$ are all PSPACE-complete. In contrast to this, we show that $\text{SUCCINCT-REACH}_{\alpha\leq k}$ is complete for the second level of the polynomial hierarchy, more precisely for $\Pi^{\mathrm{P}}_2$, for all $k$. Interestingly, the succinct version of the dominating set problem for tournaments is complete for $\Sigma^{\mathrm{P}}_2$, as shown by Umans [33].

**1.2. How difficult is it to construct a path?** The low complexity of the reachability problem seemingly settles the complexity of finding paths in graphs with bounded independence number. At first sight, the path construction problem appears to reduce to the reachability problem via a simple algorithm: Starting at the source vertex, for each successor of the current vertex check whether we can reach the target from it (for at least one successor this test will be true); make that successor the current vertex; and repeat until we have reached the target. Unfortunately, this algorithm is flawed since it can lead us around in endless cycles in graphs that are not acyclic. A correct algorithm does not move to an *arbitrary* successor, but to the successor that is *nearest* to the target. This corrected algorithm produces not only *some* path, but a shortest one. However, the algorithm now needs to compute the distance between vertices internally, which is conceptually a more difficult problem than deciding whether two vertices are connected.

Nevertheless, we show that a path between any two connected vertices can be constructed in logarithmic space in graphs with bounded independence number. There even exists a *logspace approximation scheme* for this problem. This means that for each $r > 1$ and each $k$ there exists a logspace-computable function that maps an input $\langle G, s, t\rangle$ with $\alpha(G) \leq k$ to a path from $s$ to $t$ of length at most $r$ times the distance of $s$ and $t$. If no path exists, the function outputs "no path exists."

**1.3. How difficult is it to construct a shortest path?** Our final result settles the complexity of constructing a *shortest* path in a graph with bounded independence number. We show that even for tournaments this problem is as difficult as constructing a shortest path in an arbitrary graph. As pointed out above, the complexity of constructing a shortest path hinges on the complexity of the *distance problem* $\text{DISTANCE}_{\text{tourn}} := \big\{\langle G, s, t, d\rangle \mid G \text{ is a tournament in which there is a path from } s \text{ to } t \text{ of length at most } d\big\}$. We prove that this problem is NL-complete. Thus DISTANCE and $\text{DISTANCE}_{\text{tourn}}$ are $\leq_{\text{fo}}$-equivalent, but REACH and $\text{REACH}_{\text{tourn}}$ are not. The succinct version of $\text{DISTANCE}_{\text{tourn}}$ is PSPACE-complete.

**1.4. Organization of this paper.** In section 2 we study graph-theoretic definitions and results. We prove a general theorem that relates the independence number of a graph to its different domination numbers. We believe this theorem to be of independent interest. In section 3 we study the reachability problem. We show that the problem $\text{REACH}_{\alpha\leq k}$ is first-order definable by explicitly giving a defining formula, that the infinite version is not first-order definable, and that the succinct version is $\Pi_2^{\text{P}}$-complete. In section 4 we present a logspace approximation scheme for constructing paths in graphs with bounded independence number. In section 5 we prove that the distance problem for tournaments is NL-complete and that its succinct version is PSPACE-complete.

## 2. Graph-theoretic definitions and results.

In this section we first fix the notation and terminology for basic graph-theoretic concepts. Then we prove a generalization of the so-called Lion King lemma; see Theorem 2.2. At the end of the section we prove Theorem 2.3, which will be the crucial building block of our first-order definition of $\text{REACH}_{\alpha\leq k}$.

A *directed graph* or just a *graph* is a nonempty set $V$ of *vertices* together with a set $E \subseteq V \times V$ of directed *edges*. A *tournament* is a graph with exactly one edge between any two different vertices and $(v, v) \notin E$ for all $v \in V$. A (rooted) *tree* is a graph in which there is a unique path from the root vertex to each vertex. A *forest* is the disjoint union of trees.

The *out-degree* of a vertex $u$ is the number of vertices $v$ with $(u, v) \in E$. A *path of length* $\ell$ in a graph $G = (V, E)$ is a sequence $(v_1, \dots, v_{\ell+1})$ of distinct vertices with $(v_i, v_{i+1}) \in E$ for $i \in \{1, \dots, \ell\}$. A vertex $t$ is *reachable* from a vertex $s$ if there is a path from $s$ to $t$. The *distance* $\mathrm{d}(s,t)$ of two vertices is the length of the shortest path between them or is undefined, if no path exists. For sets $U, U' \subseteq V$ let $\mathrm{d}(U,U') := \min\{\mathrm{d}(u,u') \mid u \in U, u' \in U'\}$. For $i \in \mathbb{N}$, a vertex $u \in V$ is said to *$i$-dominate* a vertex $v \in V$ if $\mathrm{d}(u,v) \le i$. Let $\mathrm{dom}_i(U)$ denote the set of all vertices that are $i$-dominated by vertices in $U$. A set $U \subseteq V$ is an *$i$-dominating set* for $G$ if $\mathrm{dom}_i(U) = V$. The *$i$-domination number* $\beta_i(G)$ is the minimum size of an $i$-dominating set for $G$. A set $U \subseteq V$ is *independent* if there is no edge in $E$ connecting vertices in $U$. The maximum size of independent sets in $G$ is its *independence number* $\alpha(G)$.

Turán [31], referenced in [32], gives an exact formula for the minimum number of edges in a graph as a function of the independence number. However, the simpler bound from the following lemma will be more appropriate for our purposes.

Lemma 2.1. *Let $G = (V,E)$ be a finite graph, $n := |V|$, $\alpha := \alpha(G) < n$. Then $G$ has at least $\binom{n}{2} \,/\, \binom{\alpha+1}{2}$ edges, and there exists a vertex with out-degree at least $(n-1) \,/\, 2\binom{\alpha+1}{2}$.*

*Proof.* The number of $(\alpha+1)$-element subsets of $V$ is $\binom{n}{\alpha+1}$ for $\alpha < n$. Every such set contains two vertices linked by an edge. Every such edge is in $\binom{n-2}{\alpha-1}$ different $(\alpha+1)$-element subsets of $V$. Therefore there are at least $\binom{n}{\alpha+1} \,/\, \binom{n-2}{\alpha-1} = \binom{n}{2} \,/\, \binom{\alpha+1}{2}$ edges in $G$. The average out-degree in $G$ hence must be at least

$$\frac{1}{n}\frac{\binom{n}{2}}{\binom{\alpha+1}{2}} = \frac{n-1}{2\binom{\alpha+1}{2}}.$$

Since this is a lower bound on the *average* out-degree, at least one vertex must have at least this out-degree. ∎

Theorem 2.2. *Let $G = (V,E)$ be a finite graph with at least two vertices, $n := |V|$, $\alpha := \alpha(G) < n$, and $c := (\alpha^2+\alpha)/(\alpha^2+\alpha-1)$. Then*

1. *$\beta_1(G) \le \lceil \log_c n \rceil$ and*
2. *$\beta_2(G) \le \alpha$.*

*Proof.* We greedily construct a 1-dominating set $D_1$ for $G$ of size at most $\lceil \log_c n \rceil$. In each step we put a vertex $v_i$ into $D_1$ that dominates as many vertices as possible of the subset $V_i \subseteq V$ not dominated so far. Formally, let $V_0 := V$ and for $i \ge 0$, as long as $V_i$ is not empty, choose a vertex $v_i \in V_i$ such that $V_{i+1} := V_i \setminus \mathrm{dom}_1\bigl(\{v_i\}\bigr)$ is as small as possible. Let $i_{\max}$ be the first $i$ such that $V_i$ is empty. By Lemma 2.1 the out-degree of each $v_i$ with $i \in \{0, \dots, i_{\max}-1\}$ is at least $\bigl(|V_i|-1\bigr) \,/\, 2\binom{\alpha+1}{2}$ and thus

$$\begin{aligned} |V_{i+1}| &\le |V_i| - 1 - \frac{|V_i|-1}{2\binom{\alpha+1}{2}} < |V_i| - \frac{|V_i|}{2\binom{\alpha+1}{2}} \\ &= |V_i|\left(1 - \frac{1}{2\binom{\alpha+1}{2}}\right) = |V_i|\left(\frac{\alpha^2+\alpha-1}{\alpha^2+\alpha}\right) = \frac{|V_i|}{c}. \end{aligned}$$

This shows that the size of $V_i$ decreases by at least the factor $c$ in each step. Thus after at most $\lceil \log_c n \rceil$ iterations the set $V_i$ is empty and $D_1 := \{v_0, \dots, v_{i_{\max}-1}\}$ is the desired 1-dominating set.

We next construct a 2-dominating set $D_2$ of size at most $\alpha$ by removing superfluous vertices from $D_1$. Formally, let $W_{i_{\max}} := \emptyset$ and

$$W_i := \begin{cases} W_{i+1} & \text{if } v_i \in \mathrm{dom}_1(W_{i+1}), \\ W_{i+1} \cup \{v_i\} & \text{otherwise.} \end{cases}$$

Clearly, $D_2 := W_0$ is a 2-dominating set. To prove $|D_2| \leq \alpha$, assume that $D_2$ contains at least $\alpha + 1$ vertices $v_{i_1}, \dots, v_{i_{\alpha+1}} \in D_1$. Since the set of these vertices cannot be independent, there must exist indices $i_r$ and $i_s$ such that $(v_{i_r}, v_{i_s}) \in E$. By construction of the set $D_1$, this can be the case only if $i_s > i_r$. But then $v_{i_r} \notin D_2$ by construction of $W_{i_r}$, a contradiction. ∎

For tournaments $G$, Theorem 2.2 yields $\beta_1(G) \leq \lceil \log_2 n \rceil$ and $\beta_2(G) = 1$. The first result was first proved by Megiddo and Vishkin in [20], where it was used to show that the dominating set problem for tournaments is not NP-complete, unless $\mathrm{NP} \subseteq \mathrm{DTIME}\bigl[n^{O(\log n)}\bigr]$. The second result is also known as the Lion King lemma, which was first noticed by Landau [18] in the study of animal societies, where the dominance relations in prides of lions form tournaments. It has applications in the study of P-selective sets [13] and many other fields.

THEOREM 2.3. *Let $G = (V, E)$ be a finite graph with at least two vertices, $n := |V|$, $\alpha := \alpha(G) < n$, $c := (\alpha^2 + \alpha)/(\alpha^2 + \alpha - 1)$, and $s, t \in V$. Then the following statements are equivalent:*

1. *There is no path from $s$ to $t$ in $G$.*
2. *There is a subset $D_1 \subseteq V$ with $|D_1| \leq \lceil \log_c n \rceil$ such that $\mathrm{dom}_1(D_1)$ is closed under reachability, $s \in \mathrm{dom}_1(D_1)$ and $t \notin \mathrm{dom}_1(D_1)$.*
3. *There is a subset $D_2 \subseteq V$ with $|D_2| \leq \alpha$ such that $\mathrm{dom}_2(D_2)$ is closed under reachability, $s \in \mathrm{dom}_2(D_2)$ and $t \notin \mathrm{dom}_2(D_2)$.*

*Proof.* The second and third statements imply the first since no path starting at a vertex $s$ inside a set that is closed under reachability can "leave" this set to arrive at a vertex $t$ outside this set. To show that the first statement implies the second, consider the set $S$ of vertices reachable from $s$ in $G$. Then $S$ is closed under reachability, $s \in S$ and $t \notin S$. The induced graph $G' := \bigl(S, E \cap (S \times S)\bigr)$ also has independence number at most $\alpha$. If $G'$ contains at least two vertices, Theorem 2.2 tells us that the graph $G'$ has a 1-dominating set $D_1$ of size at most $\lceil \log_c n \rceil$. If $G'$ contains only one vertex, it trivially has a 1-dominating set of size $1 \leq \lceil \log_c n \rceil$. To show that the first statement implies the third, consider the same graph $G'$ once more. By Theorem 2.2 it also has a 2-dominating set $D_2$ of size at most $\alpha$. ∎

## 3. Complexity of the reachability problem.

In this section we answer the following question: How difficult is it to tell whether there is a path between two vertices in a directed graph with bounded independence number? In the first subsection, we answer it for finite graphs, in the second for infinite ones, and in the third for succinctly represented graphs.

### 3.1. First-order definability of the reachability problem.

The reachability problem for graphs with bounded independence number is first-order definable. Before we prove this claim, let us review some basic notions from descriptive complexity theory.

*First-order definability* is a language property. It can be defined as follows for the special case of languages $A \subseteq \{\langle V, E, s, t\rangle \mid (V, E) \text{ is a finite graph}, s, t \in V\}$: Let $\tau = (\mathrm{E}^2, \mathrm{s}, \mathrm{t})$ be the *signature of graphs with two designated vertices.* A *first-order $\tau$-formula* is a first-order formula that contains, other than quantifiers, variables, and connectives, only the binary relation symbol E and the constant symbols s and t. An example is the formula $\exists x\bigl[\mathrm{E}(\mathrm{s}, x) \wedge \mathrm{E}(x, \mathrm{t})\bigr]$. A *$\tau$-structure* is a tuple $(V, E, s, t)$ consisting of a graph $(V, E)$ and two vertices $s, t \in V$. A $\tau$-structure is a *model* of a $\tau$-formula if the formula holds when we interpret the relation symbol E as the edge relation $E$ and the constant symbols s and t as the vertices $s$ and $t$. For example, the $\tau$-formula $\exists x\bigl[\mathrm{E}(\mathrm{s}, x) \wedge \mathrm{E}(x, \mathrm{t})\bigr]$ is a model of every $\tau$-structure $(V, E, s, t)$ in which there is a path (more precisely, a walk) from $s$ to $t$ in the graph $(V, E)$ of length exactly 2. The language $A$ is *first-order definable* if there exists a $\tau$-formula $\phi$ such that $\langle V, E, s, t\rangle \in A$ if and only if $(V, E, s, t)$ is a model of $\phi$.

THEOREM 3.1. *For each $k$,* $\text{REACH}_{\alpha\leq k}$ *is first-order definable.*

*Proof.* Let $k \geq 1$ be fixed. We give a stepwise construction of a formula $\phi_{\text{reach},\alpha\leq k}$ such that $(V, E, s, t) \models \phi_{\text{reach},\alpha\leq k}$ if and only if $\langle V, E, s, t\rangle \in \text{REACH}_{\alpha\leq k}$. Roughly, the formula $\phi_{\text{reach},\alpha\leq k}$ will say "$\alpha(G) \leq k$, and it is not the case that condition 3 of Theorem 2.3 holds for $s$ and $t$."

Let $\phi_{\text{distinct}}(v_1, \ldots, v_m) \equiv \bigwedge_{i\neq j}[v_i \neq v_j]$. This formula expresses that vertices are distinct. The property "$\alpha(G) \leq k$" can be expressed as

$$\phi_{\alpha\leq k} \equiv (\forall v_1, \ldots, v_{k+1})\Big[\phi_{\text{distinct}}(v_1, \ldots, v_{k+1}) \to \bigvee_{i\neq j} \mathrm{E}(v_i, v_j)\Big].$$

The next two formulas express that a vertex $v$ or a set $\{v_1, \ldots, v_m\}$ of vertices 2-dominates a vertex $u$:

$$\phi_{\text{2-dom}}(v, u) \equiv v = u \vee \mathrm{E}(v, u) \vee (\exists z)\big[\mathrm{E}(v, z) \wedge \mathrm{E}(z, u)\big],$$
$$\phi_{\text{2-dom}}(v_1, \ldots, v_m, u) \equiv \phi_{\text{2-dom}}(v_1, u) \vee \cdots \vee \phi_{\text{2-dom}}(v_m, u).$$

Since $\beta_2(G) \leq \alpha(G) \leq k$, condition 3 of Theorem 2.3 can be expressed as

$$\begin{aligned}\phi_{\text{condition}} \equiv\ & (\exists v_1, \ldots, v_k)\\ & \Big[\phi_{\text{2-dom}}(v_1, \ldots, v_k, \mathrm{s}) \wedge \neg\phi_{\text{2-dom}}(v_1, \ldots, v_k, \mathrm{t})\\ & \quad \wedge (\forall u, v)\big[\big(\phi_{\text{2-dom}}(v_1, \ldots, v_k, u) \wedge \mathrm{E}(u, v) \to \phi_{\text{2-dom}}(v_1, \ldots, v_k, v)\big)\big]\Big].\end{aligned}$$

The desired formula $\phi_{\text{reach},\alpha\leq k}$ is given by $\phi_{\alpha\leq k} \wedge \neg\phi_{\text{condition}}$. Note that its quantifier complexity (nesting depth) is $k + 3$ and that the number of quantifier alternations is three, beginning with a universal quantifier. ☐

COROLLARY 3.2. *The language* REACH *can be decided in space $O\big(\alpha(G)\log n\big)$.*

*Proof.* On input of a coded tuple $\langle G, s, t\rangle$ with $G = (V, E)$, $s, t \in V$, $n := |V|$, and $\alpha := \alpha(G)$, we can compute $\alpha$ in space $O(\alpha \log n)$ by iteratively testing for increasing values of $\alpha$ whether there exists a subset of $\alpha$ many vertices that is independent. Once we know $\alpha$, we check whether $(V, E, s, t) \models \phi_{\text{reach},\alpha\leq k}$ for $k := \alpha$. This check can also be performed in space $O(\alpha \log n)$, since we need $\log n$ bits to iterate over all possible assignments of a variable bound by a quantifier and since the number of nested quantifiers in $\phi_{\text{reach},\alpha\leq k}$ is $k + 3$. ☐

Theorem 3.1 can easily be extended to the following larger class of graphs: Define the *$q$-independence number* $\alpha_q(G)$ of a graph $G$ as the maximum size of a $q$-independent set in $G$, which is a vertex subset such that there is no path (in all of $G$) of length at most $q$ between any two vertices in this subset. Then reachability in graphs with $\alpha_q(G) \leq k$ is first-order definable for all $k, q \in \mathbb{N}$.

**3.2. Infinite version of the reachability problem.** In this subsection we study the class $\text{REACH}^{\infty}_{\alpha\leq k}$ and show that the first-order definability of $\text{REACH}_{\alpha\leq k}$ does not carry over to $\text{REACH}^{\infty}_{\alpha\leq k}$. This class contains all triples $(G, s, t)$ such that $G$ is a (possibly infinite) graph with $\alpha(G) \leq k$ in which there is a path from $s$ to $t$.

Let us fix the model-theoretic notations and terminology. Once more, we restrict our attention to the signature $\tau = (\mathrm{E}^2, \mathrm{s}, \mathrm{t})$ of graphs with two designated vertices. The notions of $\tau$-structures, first-order $\tau$-formulas, and models are defined as before. A class $K$ of $\tau$-structures, i.e., a class of possibly infinite graphs, each together with two designated vertices, is called *elementary (over finite structures)* if there exists a first-order $\tau$-formula $\phi$ such that for every (finite) $\tau$-structure $(V, E, s, t)$ we have $(V, E, s, t) \models \phi$ if and only if $(V, E, s, t) \in K$. A class $K$ of $\tau$-structures is $\Delta$-*elementary* if there exists a set $\Phi$ of first-order $\tau$-formulas such that for every $\tau$-structure $(V, E, s, t)$ we have $(V, E, s, t) \models \phi$ for all $\phi \in \Phi$ if and only if $(V, E, s, t) \in K$. Some authors use "finitely axiomatizable" instead of "elementary." With these definitions, Theorem 3.1 states that $\textsc{reach}^{\infty}_{\alpha \le k}$ is elementary over finite structures for all $k$. This is no longer true for infinite structures, as the following theorem shows.

Theorem 3.3. *$\textsc{reach}^{\infty}_{\alpha \le k}$ is not $\Delta$-elementary for any $k$.*

*Proof.* The proof follows the standard pattern of proofs applying the compactness theorem. Assume that there exist a set $\Phi$ of first-order $\tau$-formulas and a number $k \ge 1$ such that $(V, E, s, t) \models \Phi$ if and only if $(V, E, s, t) \in \textsc{reach}^{\infty}_{\alpha \le k}$. For each $n \in \mathbb{N}$ let $\psi_n$ be a formula that is satisfied by a graph if there is a path from $s$ to $t$ of length exactly $n$. Consider the set $\Psi := \Phi \cup \{\neg\psi_0, \neg\psi_1, \neg\psi_2, \neg\psi_3, \dots\}$. We claim that every finite $\Psi_0 \subseteq \Psi$ has a model $(V, E, s, t)$. To see this, let $n$ be large enough such that for all $i \ge n$ we have $\neg\psi_i \notin \Psi_0$ and define a tournament $G = (V, E)$ by $V := \{1, \dots, n+1\}$ and $(i, j) \in E$ if and only if $j \le i + 1$. Then $\alpha(G) = 1 \le k$ and the shortest path from $s := 1$ to $t := n + 1$ has length $n$. Thus $(V, E, s, t)$ is a model of $\Psi_0$. By the compactness theorem, $\Psi$ has a model $(V', E', s', t')$ since every finite subset of $\Psi$ has a model. Since this model satisfies $\neg\psi_n$ for all $n$, there cannot be a path of finite length from $s'$ to $t'$ in $G' = (V', E')$. Thus $\Phi \subseteq \Psi$ has a model that is not an element of $\textsc{reach}^{\infty}_{\alpha \le k}$. $\square$

**3.3. Succinct version of the reachability problem.** Up to now, we have not addressed the question of how we encode graphs. Varying the encoding method typically has no effect on the complexity of graph problems, but this is no longer true if we use *succinct graph representations.* In this subsection we show that the complexity of $\textsc{reach}_{\alpha \le k}$ jumps from first-order definable to $\Pi^{\mathrm{P}}_2$-complete if we use succinct representations instead of the usual ones (such as adjacency matrices).

Succinctly represented graphs are given implicitly via a description in some description language. Since succinct representations allow the encoding of large graphs by small codes, numerous graph properties are (provably) harder to check for succinctly represented graphs than for graphs coded in the usual way. Papadimitriou and Yannakakis [23] and Wagner [36] have shown that most interesting graph problems become PSPACE-complete or even NEXP-complete for succinctly represented graphs. For tournaments, Umans [33] has shown that the succinct version of the dominating set problem is $\Sigma^{\mathrm{P}}_2$-complete. There are other problems that become complete for levels of the polynomial hierarchy if the instances are succinctly represented by circuits. Schaefer has shown [26] that the problem of determining the Vapnik–Chervonenkis dimension of a succinctly represented family of subsets of a finite set is $\Sigma^{\mathrm{P}}_3$-complete. For an overview of results of this type, see the survey of Schaefer and Umans [27]. Succinct representations are known to be closely related to the concept of leaf languages; see Borchert and Lozano [3] and Veith [34].

The following formalization of succinct graph representations follows Galperin and Wigderson [10], but others are also possible [11, 36].

Definition 3.4. *A* succinct representation *of a graph $G = \big(\{0, 1\}^n, E\big)$ is a $2n$-input circuit $C$ such that for all $u, v \in \{0, 1\}^n$ we have $(u, v) \in E$ exactly if $C(uv) = 1$.*

The circuit tells us, for any two vertices of the graph, whether there is a directed edge between them or not. Note that $C$ will have size at least $2n$ since it has $2n$ input gates.

Having defined succinct versions of *graphs*, we can next define succinct versions of *languages*. Our definition is not the most general possible; we focus on succinct versions of languages that contain (the standard binary encoding of) graphs together with vertices or numbers (numbers are useful for the distance problem). We represent only the graphs succinctly; the vertex codes and numbers are left unchanged.

DEFINITION 3.5. *Let* $A \subseteq \bigl\{\langle G, b_1, \dots, b_m\rangle \mid G = (V, E)$ *is a finite graph,* $b_i \in V$ *or* $b_i \in \mathbb{N}$ *for all* $i\bigr\}$. *Then* SUCCINCT-$A$ *is the set of all* $\langle C, b_1, \dots, b_m\rangle$ *such that* $C$ *is a succinct representation of a graph* $G$ *with* $\langle G, b_1, \dots, b_m\rangle \in A$.

THEOREM 3.6. *For each* $k$, SUCCINCT-REACH$_{\alpha\le k}$ *is* $\Pi_2^{\mathrm{P}}$*-complete.*

*Proof.* Our first aim is to show SUCCINCT-REACH$_{\alpha\le k} \in \Pi_2^{\mathrm{P}}$. Let $\langle C, s, t\rangle$ be an input and let $C$ represent a graph $G = (V, E)$ with $V = \{0,1\}^n$. Note that $\log_2 |V| = n$. We first check whether $\alpha(G) \le k$ holds, which can easily be done using a coNP-machine. We then check whether there is a path from $s$ to $t$ in $G$. By Theorem 2.3 this is the case if *for all* sets $D_1 \subseteq \{0,1\}^n$ of size at most $\beta_1(G)$ either $s \notin \mathrm{dom}_1(D_1)$ or $t \in \mathrm{dom}_1(D_1)$ or $\mathrm{dom}_1(D_1)$ is not closed under reachability; i.e., *there exist* vertices $u \in \mathrm{dom}_1(D_1)$ and $v \in \{0,1\}^n \setminus \mathrm{dom}_1(D_1)$ such that $C(uv) = 1$. Since $\beta_1(G) \le \lceil \log_c 2^n\rceil = \lceil n \log_c 2\rceil$, the size of each $D_1$ that needs to be checked is linear in $n$, and testing for membership in $\mathrm{dom}_1(D_1)$ can be performed in polynomial time. Putting it all together, we see that the "for all... exists..."-test is a $\Pi_2^{\mathrm{P}}$-algorithm.

Our second aim is to prove that even the reachability problem for tournaments, SUCCINCT-REACH$_{\mathrm{tourn}}$, is $\le_{\mathrm{fo}}$-hard for $\Pi_2^{\mathrm{P}}$. Let $L \in \Pi_2^{\mathrm{P}}$ by any language. By the quantifier characterization of the polynomial hierarchy [37] there exists a polynomial-time-decidable ternary relation $R$ and a constant $d$ such that

$$L = \bigl\{x \mid \forall y \in \{0,1\}^{|x|^d}\ \exists z \in \{0,1\}^{|x|^d}\ R(x, y, z)\bigr\}.$$

To simplify the following presentation, we assume that for every $x$ there exists some $z \in \{0,1\}^{|x|^d}$ such that $R\bigl(x, 1^{|x|^d}, z\bigr)$ holds. In other words, we assume that the "last" $y$ is not important for deciding whether $x \in L$ holds.

The desired $\le_{\mathrm{fo}}$-reduction from $L$ to SUCCINCT-REACH$_{\mathrm{tourn}}$ is obtained in three steps.

1. We describe a mapping of inputs $x$ to exponentially large tournaments $G = (V, E)$ and vertices $s, t \in V$ such that $x \in L$ if and only if $(G, s, t) \in$ REACH$_{\mathrm{tourn}}$.
2. We explain how a succinct representation of the highly structured tournament $G$ can be computed in polynomial time.
3. We use an argument of Veith [34] to show that the polynomial-time computation can be replaced by a first-order query.

For the first step, the construction of the tournament $G$, let $n$ denote the length of $x$ and let $\ell := n^d$. The vertex set of $G$ is $V = \{0,1\}^{2\ell}$. The first $\ell$ bits of a vertex $v \in V$ will be called its *row*, and the last $\ell$ bits its *column*. In other words, the vertices are arranged in a big grid consisting of $2^\ell$ rows and $2^\ell$ columns. All vertices on the same row are connected such that they form a strongly connected subtournament of $G$. Let us say that the lexicographically smallest row is the topmost row and that the lexicographically largest row is the bottommost row.

Edges between different rows generally point "upward," i.e., from rows farther down to rows farther up. The only exception are edges between a vertex $v = yz$ on row $y$ and column $z$ and the vertex on the same column in the row directly below. Such an edge points "downward" if $R(x, y, z)$. The source $s$ is the upper-left corner of the grid, i.e., the vertex $s = 0^\ell 0^\ell$. The target $t$ is the lower-left corner, i.e., the

t \arrow[r] & y_8z_2 \arrow[r] & y_8z_3 \arrow[r] & y_8z_4 \arrow[r] & y_8z_5 \arrow[r] & y_8z_6 \arrow[r, thick] & y_8z_7 \arrow[r, thick] & y_8z_8 \arrow[lllllll, bend left, thick]
\end{tikzcd}$$

FIG. 3.1. *Example of a tournament $G$ constructed in the proof of Theorem* 3.6 *for $\ell = 3$. There are $2^\ell$ rows $y_1 = 000$, $y_2 = 001$, ..., $y_8 = 111$ and $2^\ell$ columns $z_1 = 000$, $z_2 = 001$, ..., $z_8 = 111$. Most arrows have been omitted for clarity; the missing arrows point upward for vertices on different rows and right for vertices on the same row. Downward arrows correspond to positions for which the predicate $R$ is true. For example, the downward arrow between the first two rows indicates that $R(x, y_1, z_3)$ holds. A path from $s$ to $t$, which is indicated in bold, exists since for each $y_i$ there exists some $z_j$ such that $R(x, y_i, z_j)$ holds.*

vertex $1^\ell 0^\ell$. An example of a tournament $G$ constructed in this way is depicted in Figure 3.1.

We claim that $(G, s, t) \in \text{REACH}_{\text{tourn}}$ if and only if $x \in L$. First, observe that $G$ is a tournament. Next, note that from each row $y$ one can go directly (at best) only one row down since all edges between nonneighboring rows point upward. Since all vertices on the same row are connected, if we can reach a vertex $v$ on row $y$, we can reach any vertex on the row directly below if and only if $R(x, y, z)$ holds for some $z \in \{0,1\}^\ell$. So we can "go all the way from the source down to the target" if for all $y \in \{0,1\}^\ell$ there exists a $z \in \{0,1\}^\ell$ such that $R(x, y, z)$. Recall that we assumed that for $y = 1^\ell$ there always exists some $z \in \{0,1\}^\ell$ with $R(x, y, z)$.

For the second step we argue that a succinct representation $C$ of $G$ can be computed in time polynomial in $n$. The circuit $C$ has $4\ell$ input gates. Through these gates two vertices $v, v' \in \{0,1\}^{2\ell}$ are fed into the circuit. In order to decide whether there is an edge pointing from $v$ to $v'$ in $G$, the circuit disassembles $v$ and $v'$ into their row parts $y$ and $y'$ and their column parts $z$ and $z'$. If the vertices lie on the same row, i.e., if $y = y'$, the circuit normally outputs 1 if $z$ is lexicographically smaller than $z'$ *except* for the edge from column $0^\ell$ to column $1^\ell$, which is turned around. This ensures that the vertices on each row form a strongly connected subtournament. If $y \neq y'$, the circuit normally outputs 1 if $y'$ is lexicographically smaller than $y$, which ensures that edges between different rows point "upward." The exception occurs when $z = z'$ and $y$ and $y'$ are only one row apart. In this case, the circuit outputs 1 if $R(x, y, z)$ and $y'$ is the lexicographic successor of $y$. For the check whether $R(x, y, z)$ holds, $C$ contains a subcircuit that evaluates $R$. Since $R$ is polynomial-time decidable, this subcircuit can be obtained in polynomial time. Hence, it takes only polynomial time to write down the code of a circuit $C$ that performs all of the above computations.

For the final step we invoke an observation of Veith [34], who showed that every polynomial-time many-one reduction to a succinctly represented problem can be turned into a $\leq_{\text{fo}}$-reduction to the same problem by "shifting" most of the computation done by the polynomial-time reduction machine into the circuit that succinctly represents a problem instance. However, Veith points out that this result is somewhat sensitive to the exact definition of succinctness and applies only if the polynomial-time reduction's output does not contain any parts that are not succinctly represented—such as the source and target in our definition or the length of the encoded bitstring in Borchert and Lozano's definition [3].

Although we cannot apply Veith's result directly, we can use the following key observation, which is implicit in Veith's paper: *Let $f$ be a polynomial-time computable function that outputs codes of circuits. Then there exists a first-order query $f'$ that also outputs codes of circuits such that for all $x$ the circuits encoded by $f(x)$ and $f'(x)$ compute the same function.* We can now assemble the desired $\leq_{\text{fo}}$-reduction from $L$ to $\textsc{succinct-reach}_{\text{tourn}}$ as follows: By the observation, there exists a first-order query that maps the input $x$ to a circuit $C'$ that, just like $C$, is a succinct representation of $G$. The source $s = 0^\ell 0^\ell$ and the target $t = 1^\ell 0^\ell$ can clearly be computed by first-order queries. Putting it all together, we get the desired reduction. $\square$

The tournament constructed in the above proof is a strong tournament (a strongly connected tournament) if and only if there is a path from $s$ to $t$. This proves the following corollary.

Corollary 3.7. $\textsc{succinct-strong-tournament}$ *is* $\Pi_2^{\text{P}}$*-complete.*

As mentioned earlier, succinct representations are closely related to leaf classes. Borchert and Lozano [3] and Veith [34] have shown that $\textsc{succinct-}A$ is complete for the balanced leaf class $\text{BLEAF}^{\text{P}}(A)$. The above completeness results can thus be stated equivalently as $\text{BLEAF}^{\text{P}}(\textsc{reach}_{\alpha \leq k}) = \Pi_2^{\text{P}}$ and $\text{BLEAF}^{\text{P}}(\textsc{strong-tournament}) = \Pi_2^{\text{P}}$.

## 4. Complexity of the construction problem.

In this section we show that for graphs with bounded independence number we not only can tell in logarithmic space whether a path exists between two vertices, but also can construct such a path. While it seems difficult to construct the *shortest* path in logarithmic space (by the results of the next section this is impossible unless $\text{L} = \text{NL}$), it is possible to find a path that is *approximately* as long as the shortest path. Even better, there exists a *logspace approximation scheme* for constructing paths whose lengths are as close to the length of the shortest path as we would like. This logspace approximation scheme can be obtained from the following theorem, which relates the space complexity of the reachability problem to the independence number $\alpha$ and to the desired approximation ratio $r = 1 + 1/m$, by fixing the maximum independence number and the ratio.

Theorem 4.1. *There exists a deterministic Turing machine $M$ with read-only access to the input tape and write-only access to the output tape with the following properties: On input $\langle G, s, t, m\rangle$, where $G = (V, E)$ is a graph, $s, t \in V$, $m \geq 1$, $n := |V|$, and $\alpha := \alpha(G)$,*

1. *if $\langle G, s, t\rangle \in \textsc{reach}$, then $M$ outputs a path from $s$ to $t$ of length at most*

$(1+1/m)\,\mathrm{d}(s,t)$ *and uses* $O\big((\alpha+\log m)\log n\big)$ *space on the work tape; and*

2. *if* $\langle G,s,t\rangle \notin$ REACH, *it outputs "no path exists" and uses* $O(\alpha\log n)$ *space on the work tape.*

The theorem's proof uses three lemmas. The first of these lemmas is a "constructive version" of Savitch's theorem [25]. Similarly to Theorem 4.1, the lemma relates the space complexity of the reachability problem to a graph parameter, namely, to the length of the shortest path.

LEMMA 4.2. *There exists a deterministic Turing machine* $M_{\text{Savitch}}$ *with read-only access to the input tape and write-only access to the output tape with the following properties: On input* $\langle G,s,t\rangle$, *where* $G=(V,E)$ *is a graph,* $s,t\in V$, *and* $n:=|V|$,

1. *if* $\langle G,s,t\rangle \in$ REACH, *then* $M_{\text{Savitch}}$ *outputs a shortest path from* $s$ *to* $t$ *and uses* $O\big(\log \mathrm{d}(s,t)\log n\big)$ *space on the work tape; and*

2. *if* $\langle G,s,t\rangle \notin$ REACH, *it outputs "no path exists" and uses* $O(\log^2 n)$ *space on the work tape.*

*Proof.* We augment Savitch's algorithm [25] by a construction procedure that outputs paths. The main difficulty is that if there are several shortest paths, then the procedure must "decide on one of them" and must do so "within the recursion." Since it will be useful later, the construction procedure outputs the list of edges on the shortest path, not only the vertices themselves.

Let *reachable*$(u,v,\ell)$ be Savitch's procedure for testing whether there is a path from $u$ to $v$ of length at most $\ell$: For $\ell=1$, it checks whether $(u,v)\in E$. For larger $\ell$, it checks whether for some vertex $z$ both the calls *reachable*$(u,z,\lfloor\ell/2\rfloor)$ and *reachable*$(z,v,\ell-\lfloor\ell/2\rfloor)$ succeed; see Figure 4.1 for pseudocode. As noted by Savitch, since we can reuse space, we can compute *reachable*$(u,v,\ell)$ in space $O(\log\ell\log n)$.

We next define a procedure *construct-path*$(u,v,\ell)$ that writes the edges of a path of length $\ell$ from $u$ to $v$ onto an output tape, provided *reachable*$(u,v,\ell)$ holds. For $\ell=1$, *construct-path* outputs $(u,v)$. For larger $\ell$, it finds the first vertex $z$ for which both the calls *reachable*$(u,z,\lfloor\ell/2\rfloor)$ and *reachable*$(z,v,\ell-\lfloor\ell/2\rfloor)$ succeed. For this vertex $z$ it first calls *construct-path*$(u,z,\lfloor\ell/2\rfloor)$ and then *construct-path*$(z,v,\ell-\lfloor\ell/2\rfloor)$; see Figure 4.1 once more.

The machine $M_{\text{Savitch}}$ iteratively calls *reachable*$(s,t,\ell)$ for increasing values of $\ell$. For the first value $\ell$ for which this test succeeds, it calls *construct-path*$(s,t,\ell)$ and quits. If the tests do not succeed for any $\ell\le n$, it outputs "no path exists." ∎

LEMMA 4.3. *Let* $G=(V,E)$ *be a graph and let* $u,v,v'\in V$ *be vertices with* $\mathrm{d}(u,v)=\mathrm{d}(u,v')$. *Let* $T$ *be the set of edges on the paths* $p$ *and* $p'$ *output by* $M_{\text{Savitch}}$ *on the inputs* $\langle G,u,v\rangle$ *and* $\langle G,u,v'\rangle$, *respectively. Then* $(V,T)$ *is a tree, i.e., the paths do not "split and join again."*

*Proof.* We prove the claim by induction on the distance $d=\mathrm{d}(u,v)=\mathrm{d}(u,v')$. The claim is true for distance 1. For the inductive step, consider the two vertices $z$ and $z'$ on the paths $p$ and $p'$ at distance $\lfloor d/2\rfloor$ from $u$. If $z=z'$, then the paths $p$ and $p'$ are identical up to $z$, and they form a tree after the vertex $z$ by the induction hypothesis applied to the three vertices $z$, $v$, and $v'$ for the distance $d-\lfloor d/2\rfloor<d$. If $z\ne z'$, then the parts of $p$ and $p'$ leading to $z$ and $z'$ form a tree by the induction hypothesis applied to $u$, $z$, and $z'$ for the distance $\lfloor d/2\rfloor<d$. Furthermore, $z\ne z'$ implies that the rest of the paths are completely disjoint since $v$ is not reachable from $z'$ and $v'$ is not reachable from $z$ (otherwise $M_{\text{Savitch}}$ would not have chosen two different midpoints $z$ and $z'$). ∎

LEMMA 4.4. *There exists a logspace-computable function that maps every input* $\langle G,s,t\rangle\in$ REACH$_{\text{forest}}$ *to the shortest path from* $s$ *to* $t$ *in* $G$ *and all other inputs to "no path exists."*

```
PROCEDURE reachable($u, v, \ell$)
INPUT: Vertices $u, v \in V$, a distance $\ell$
RETURN VALUE: Does a path exist?
1  if $\ell = 0$ then return yes if $u = v$ and no if $u \neq v$
2  else if $\ell = 1$ then return yes if $(u, v) \in E$ and no if $(u, v) \notin E$
3  else
4      for $i \leftarrow 1$ to $n$ do
5          if reachable($u, v_i, \lfloor \ell/2 \rfloor$) and reachable($v_i, v, \ell - \lfloor \ell/2 \rfloor$) then
6              return yes
7  return no
```

```
PROCEDURE construct-path($u, v, \ell$)
INPUT: Vertices $u, v \in V$, a distance $\ell$
OUTPUT: Edges on a path from $u$ to $v$
PRECONDITION: $1 \leq \mathrm{d}(u, v) \leq \ell$
1  if $\ell = 1$ then output "($u$,$v$)"; exit
2  else
3      for $i \leftarrow 1$ to $n$ do
4          if reachable($u, v_i, \lfloor \ell/2 \rfloor$) and reachable($v_i, v, \ell - \lfloor \ell/2 \rfloor$) then
5              call construct-path($u, v_i, \lfloor \ell/2 \rfloor$)
6              call construct-path($v_i, v, \ell - \lfloor \ell/2 \rfloor$)
7              exit
```

FIG. 4.1. *Savitch's algorithm reachable*$(u, v, \ell)$ *decides whether* $\mathrm{d}(u, v) \leq \ell$ *holds in some graph* $G = (V, E)$ *with* $V = \{v_1, \dots, v_n\}$. *Its "constructive" version construct-path*$(u, v, \ell)$ *outputs such a path, more precisely, the list of edges on this path. Here and in the following we do not explicitly list the immutable* $G$ *as an input parameter. Rather,* $G$ *is treated as a "global constant."*

*Proof.* The problem $\text{REACH}_{\text{forest}}$ is L-complete as shown in [4]. In order to compute the shortest path from $s$ to $t$ we iterate the following instructions, starting at $v = s$: For each successor $v'$ of the current vertex $v$, we check whether $t$ is reachable from $v'$. There is exactly one vertex $v'$ for which this test succeeds. We output this $v'$ or, if preferred, the edge $(v, v')$, make $v'$ the new current vertex, and repeat the procedure until we reach $t$. □

*Proof of Theorem* 4.1. Let an input $\langle G, s, t, m \rangle$ be given. Let $G = (V, E)$ and $n := |V|$. By Corollary 3.2 we can check in space $O(\alpha \log n)$ whether $\langle G, s, t \rangle \in \text{REACH}$ holds and output "no path exists" if this is not the case. Otherwise we proceed as follows.

Our algorithm is the composition of three functions. Each function takes the input of the previous function and maps it to an output, using space $O\big((\alpha + \log m) \log n\big)$ on the work tape. More precisely, the first two functions need space $O\big((\alpha + \log m) \log n\big)$, the last one only $O(\log n)$. Although the intermediate outputs are too large "to be written down" on the work tape of the composed machine, we can use the standard trick of composing logspace-computable functions: Whenever one of the functions needs a bit of the output of the previous function, we recalculate this bit "on the fly." This allows us to compute the composed function in space $O\big(2(\alpha + \log m) \log n + \log n\big) = O\big((\alpha + \log m) \log n\big)$.

*The first function: Construction of the* $U_i$. The first function takes the original input $\langle G, s, t, m \rangle$ and maps it to a sequence $U_1, U_2, \dots, U_\ell \subseteq V$ of vertex sets with $U_1 = \{s\}$ and $U_\ell = \{t\}$. For the construction of $U_i$ we access only $U_{i-1}$ and use space $O\big((\alpha + \log m) \log n\big)$. Once we have constructed $U_i$, we erase $U_{i-1}$ from the work tape and reuse the space it had occupied.

```
PROCEDURE compute-next-dominating-set($U_{i-1}$)
INPUT: Previous set $U_{i-1}$
RETURN VALUE: Next set $U_i$
1  foreach $U \subseteq V$ with $|U| \leq \alpha$ do
2      foreach $u \in U$ do
3          if not $\mathrm{d}(U_{i-1}, u) = 2m + 2$ then
4              continue with next $U$ on line 1
5      foreach $v \in V$ do
6          if $\mathrm{d}(U_{i-1}, v) = 2m + 2$ and not $\mathrm{d}(U, v) \leq 2$ then
7              continue with next $U$ on line 1
8      return $U$
```

```
PROCEDURE output-all-U
OUTPUT: The list $(U_1, \dots, U_\ell)$
PRECONDITION: $t$ is reachable from $s$
1  $i \leftarrow 1$
2  $U \leftarrow \{s\}$
3  output "$U_1 = \{s\}$"
4  while not $\mathrm{d}(U, t) \leq 2m + 2$ do
5      $U \leftarrow$ compute-next-dominating-set($U$)
6      $i \leftarrow i + 1$
7      output "$U_i = U$"
8  $\ell \leftarrow i + 1$
9  output "$U_\ell = \{t\}$"
```

FIG. 4.2. *Pseudocode for the computation of the sets $U_i$. To store $U$ and $U_{i-1}$, we need space $O(\alpha \log n)$. To perform the checks $\mathrm{d}(U_{i-1}, u) = 2m + 2$ and $\mathrm{d}(U, t) \leq 2m + 2$, we need extra space $O(\log m \log n)$. In total, the procedure outputs all $U_i$ using space $O\big((\alpha + \log m) \log n\big)$.*

The set $U_i$ is obtained from $U_{i-1}$ as follows: If $\mathrm{d}(U_{i-1}, t) \leq 2m+2$, let $U_i := \{t\}$. Otherwise let $S_i := \{v \in V \mid \mathrm{d}(U_{i-1}, v) = 2m + 2\}$ be the set of all vertices that have distance exactly $2m + 2$ from $U_{i-1}$. Choose $U_i \subseteq S_i$ as a 2-dominating vertex subset of size at most $\alpha$ of the graph $G' := \big(S_i, E \cap (S_i \times S_i)\big)$ induced on the vertices in $S_i$. Since $\alpha(G') \leq \alpha$, such a 2-dominating set $U_i$ exists by Theorem 2.2. We can obtain it in space $O\big((\alpha + \log m) \log n\big)$ as follows: For each subset $U \subseteq V$ of size at most $\alpha$ we check whether all $u \in U$ are in $S_i$—which can be checked in space $O(\log m \log n)$ for each $u$ using the procedure *reachable* from Lemma 4.2—and then check whether all elements of $S_i$ are 2-dominated by $U$. A set $U$ passing these checks can be used as $U_i$. Pseudocode for the computation of the $U_i$ is given in Figure 4.2.

The sets $U_i$ have the following properties for $i \in \{2, \dots, \ell - 1\}$:

1. All elements of $U_i$ are reachable from $s$.
2. $|U_i| \leq \alpha$.
3. $\mathrm{d}(U_{i-1}, u) = 2m + 2$ for all $u \in U_i$.
4. $\mathrm{d}(U_i, t) \leq \mathrm{d}(U_{i-1}, t) - 2m$ and hence $\mathrm{d}(U_i, t) \leq \mathrm{d}(s, t) - 2m(i - 1)$.

To see that the last property holds, note that $\mathrm{d}(U_i, t) \leq \mathrm{d}(S_i, t) + 2$ and that $\mathrm{d}(S_i, t) = \mathrm{d}(U_{i-1}, t) - 2m - 2$. For $i = \ell$, the first two properties are also true, and the third becomes $\mathrm{d}(U_{i-1}, t) \leq 2m + 2$.

Intuitively, in each iteration we reduce the distance between $U_i$ and $t$ by at least $2m$, and each $U_{i-1}$ can be connected to the next $U_i$ by a path of length $2m + 2$; see also Figure 4.3. It remains to explain how to connect the $U_i$'s correctly.

*The second function: Construction of the tree.* In order to output the desired path from $s$ to $t$ of length at most $(1 + 1/m)\,\mathrm{d}(s, t)$, we first construct a tree $T$ that

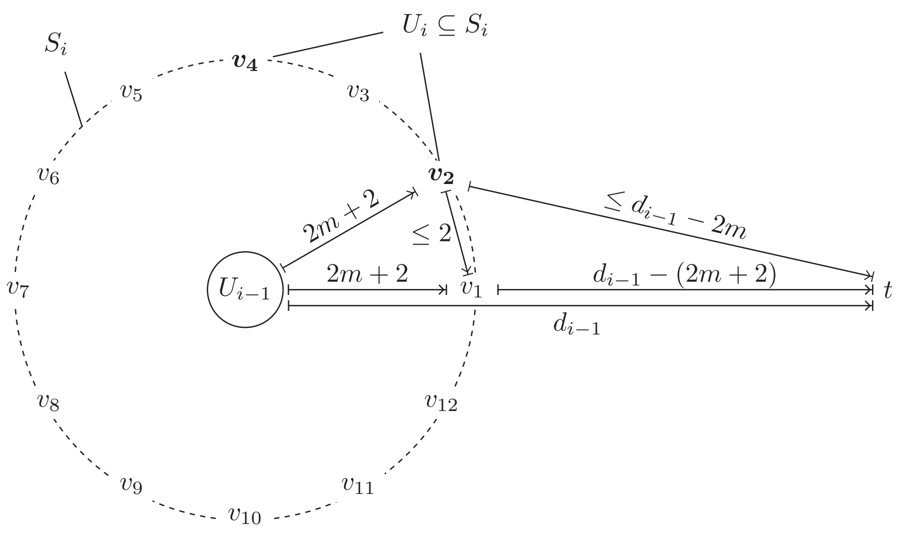

FIG. 4.3. *Visualization of the idea behind the construction of the set $U_i$, whose elements are shown in bold, based on the set $U_{i-1}$. The set $S_i = \{v_1, \dots, v_{12}\}$ contains all vertices at distance exactly $2m+2$ from $U_{i-1}$. The 2-dominating set $U_i$ for $S_i$ typically does not contain the vertex $v_1$ that is on the shortest path from $U_{i-1}$ to $t$. However, it will contain a vertex $v_2$ that is at most two steps removed from $v_1$. If the distance from $U_{i-1}$ to $t$ is $d_{i-1}$, then the distance from $v_2$ to $t$ is at most $d_{i-1} - 2m$. Thus, investing $2m+2$ steps to get to $v_2$ gets us $2m$ steps nearer to the target.*

contains this path. The shortest path in the tree will be the desired path. The second function takes the list of $U_i$'s computed by the first function as input and outputs the tree $T$.

The tree is the union of forests $F_i$ for $i \in \{2, \dots, \ell\}$. Each $F_i$ contains for each $u \in U_i$ the vertices and edges of a specific shortest path from $U_{i-1}$ to $u$. This path is constructed by calling the machine $M_{\text{Savitch}}$ from Lemma 4.2 on input $\langle G, u', u\rangle$ for the first vertex $u' \in U_{i-1}$ for which $\mathrm{d}(u', u) = \mathrm{d}(U_{i-1}, u)$ holds, i.e., for which $\mathrm{d}(u', u)$ is minimal. Since $\mathrm{d}(U_{i-1}, u) \leq 2m+2$, this call needs space $O(\log m \log n)$. Pseudocode for the construction of the $F_i$ is given in Figure 4.4. An example of a tree constructed in this way is depicted in Figure 4.5.

We claim that each graph $F_i$ is a forest. First, if the paths to two vertices $u_1, u_2 \in U_i$ start at two distinct vertices $u_1', u_2' \in U_{i-1}$, then these paths must be completely disjoint (otherwise we would have chosen the same starting vertex). Thus, $F_i$ can be partitioned into independent subgraphs, each containing exactly the paths originating at one vertex in $U_{i-1}$, and all these paths have the same length $\mathrm{d}(U_{i-1}, U_i)$. By Lemma 4.3 each of the subgraphs is a tree and thus the whole graph $F_i$ is a forest.

Let $T$ be the union of all the forests $F_i$ constructed during the run of the algorithm. This union is a tree since

1. every vertex in the union is reachable from the source by construction and
2. there cannot be two different paths to the same vertex $v$ in $T$ since they would induce, inside one of the forests $F_i$, two different paths to $v$ from different roots of $F_i$.

*The third function: Constructing the shortest path in the tree.* The final function outputs the shortest path from $s$ to $t$ in $T$, using the algorithm from Lemma 4.4. This path passes through all $U_i$. For $i \in \{1, \dots, \ell\}$ let $u_i \in U_i$ be the last vertex of $U_i$ on this path. The total length of the path is given by $\sum_{i=1}^{\ell-1} \mathrm{d}(u_i, u_{i+1})$. We have

```
PROCEDURE output-forest($U_{i-1}, U_i$)
INPUT: Pair $(U_{i-1}, U_i)$
OUTPUT: List of edges in the forest $F_i$
1    $d \leftarrow \mathrm{d}(U_{i-1}, U_i)$
2    foreach $u \in U_i$ do
3        foreach $u' \in U_{i-1}$ do
4            if $\mathrm{d}(u', u) = d$ then
5                call construct-path($u', u, d$)
6                continue with next $u$ on line 2
```

```
PROCEDURE output-tree($U_1, \dots, U_\ell$)
INPUT: The list $(U_1, \dots, U_\ell)$
OUTPUT: List of edges in the tree $T$
1    for $i \leftarrow 2$ to $\ell$ do
2        call output-forest($U_{i-1}, U_i$)
```

FIG. 4.4. *Procedures for computing the $F_i$ and the complete tree $T$. In the inner loop of output-forest, the vertices of $U_{i-1}$ are processed in the same order each time. Each call of the procedure construct-path will output edges of the forest $F_i$. Some edges might be output repeatedly, but this is not a problem for the subsequent computation.*

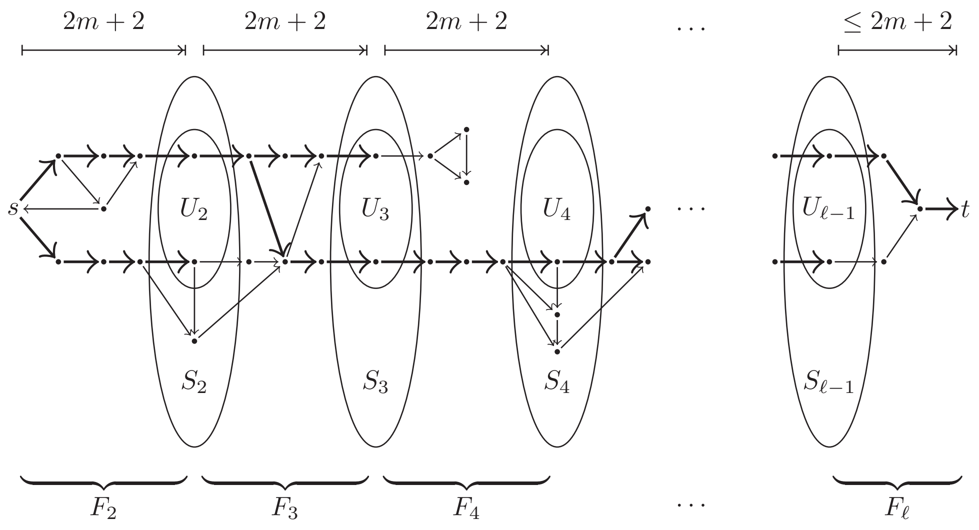

FIG. 4.5. *Example for the construction of the tree $T$, shown in bold, for $m = 1$. It is the union of the forests $F_i$, which connect the vertices from $U_i$ to $U_{i-1}$. For example, the forest $F_2$ consists of the two paths leading from $U_1 = \{s\}$ to the two vertices of $U_2$. The forest $F_3$ consists of the two paths from the top vertex of $U_2$ to the vertices in $U_3$. The approximation algorithm outputs the path from $s$ to $t$ inside the tree $T$. This path is not the shortest path, which follows the bottommost edges, but it is not much longer.*

$\mathrm{d}(u_i, u_{i+1}) = 2m + 2$ for $i \in \{1, \dots, \ell - 2\}$. Thus the total length is

$$\begin{aligned}(2m+2)(\ell-2) + \mathrm{d}(u_{\ell-1}, t) &= (2m+2)(\ell-2) + \mathrm{d}(U_{\ell-1}, t)\\ &\leq (2m+2)(\ell-2) + \mathrm{d}(s,t) - 2m(\ell-2)\\ &= \mathrm{d}(s,t) + 2(\ell-2)\\ &\leq \mathrm{d}(s,t) + \mathrm{d}(s,t)/m.\end{aligned}$$

For the two inequalities, both times we used the last property of $U_{\ell-1}$, by which $\mathrm{d}(U_{\ell-1},t) \leq \mathrm{d}(s,t) - 2m(\ell-2)$ and hence also $2(\ell-2) \leq \mathrm{d}(s,t)/m$. ∎

The space bound from Theorem 4.1 is optimal in the following sense: Suppose we could construct a machine $M'$ that uses space $O(\log^{1-\epsilon} m \log n)$ for some $\alpha$ and achieves the same as $M$ for that particular $\alpha$. This would imply $\text{DISTANCE}_{\text{tourn}} \in \text{DSPACE}[\log^{2-\epsilon} n]$, because $M'$ outputs the *shortest* path for $m = n+1$, and for tournaments we have $\alpha = 1$. The results of the next section show that this would imply $\text{NL} \subseteq \text{DSPACE}[\log^{2-\epsilon} n]$.

**5. Complexity of the distance problem.** In this section we study the complexity of the distance problem for graphs with bounded independence number. This problem asks us to decide whether the distance of two vertices in a graph is smaller than a given input number. We show that this problem is NL-complete even for tournaments and that the succinct version is PSPACE-complete.

The distance problem is closely linked to the problem of constructing a shortest path in a graph: As argued in the introduction, we can *construct* a shortest path in a graph if we have oracle access to the distance problem for this graph. The other way round, we can easily solve the distance problem if we have oracle access to an algorithm that constructs shortest paths. Because of this close relationship, the completeness result dashes any hope of finding a logspace algorithm for constructing shortest paths in tournaments unless L = NL.

THEOREM 5.1. *The problem* $\text{DISTANCE}_{\text{tourn}}$ *is* NL*-complete.*

*Proof.* We show $\text{REACH} \leq_{\text{fo}} \text{DISTANCE}_{\text{tourn}}$. Let an input $\langle G, s, t\rangle$ be given. Our first-order reduction maps this to an instance $\langle G', s', t', d\rangle$ for $\text{DISTANCE}_{\text{tourn}}$. Let $G = (V,E)$ and $n := |V|$. The tournament $G' = (V', E')$ is constructed as follows: The vertex set $V'$ is $\{1,\dots,n\} \times V$. We can think of this vertex set as a grid consisting of $n$ rows and $n$ columns. There is an edge in $G'$ from a vertex $(r_1, v_1)$ to a vertex $(r_2, v_2)$ if and only if one of the following conditions holds (see also Figure 5.1):

1. $r_2 = r_1 + 1$ and $(v_1, v_2) \in E$ or $v_1 = v_2$; i.e., if $v_1$ and $v_2$ are connected in $G$ or if they are the same, then there is an edge leading "downward" between them on adjacent rows.
2. $r_2 = r_1$ and $v_1 < v_2$; i.e., the vertices on the same row are ordered by the linear ordering to which the first-order reduction has access.
3. $r_2 = r_1 - 1$, $(v_1, v_2) \notin E$, and $v_1 \neq v_2$; i.e., if $v_1$ and $v_2$ are not connected in $G$ and if they are different, then there is an edge leading "upward" between them on adjacent rows.
4. $r_2 \leq r_1 - 2$, i.e., all edges spanning at least two rows point "upward."

Clearly, the above conditions for the edge relation $E'$ can be expressed by a first-order formula $\phi_{E'}(r_1, v_1, r_2, v_2)$. The new source $s' := (1, s)$, the new target $t' := (n, t)$, and the distance $d := n - 1$ are also first-order definable.

To see that this reduction works, first assume that there exists a path from $s$ to $t$ in $G$ of length $m \leq n-1$. Let $(s, v_2, \dots, v_m, t)$ be this path. Then $\bigl((1,s), (2,v_2), \dots, (m, v_m), (m+1, t), \dots, (n,t)\bigr)$ is a path in $G'$ of length $n-1$. Second, assume that there exists a path from $s'$ to $t'$ in $G'$ of length $m \leq n-1$. Then $m = n-1$ since any path from the first row to the last row must "brave all rows"—there are no edges that allow us to skip a row. Let $(v'_1, \dots, v'_n)$ be this path. Then $v'_i = (i, v_i)$ for some vertices $v_i \in V$. The sequence $(v_1, \dots, v_n)$ is "almost" a path from $s$ to $t$ in $G$: For each $i \in \{1, \dots, n-1\}$ we have either $v_i = v_{i+1}$ or $(v_i, v_{i+1}) \in E$. Thus, by removing consecutive duplicates and loops, we obtain a path from $s$ to $t$ in $G$. ∎

By the above theorem, DISTANCE and $\text{DISTANCE}_{\text{tourn}}$ are $\leq_{\text{fo}}$-equivalent, while

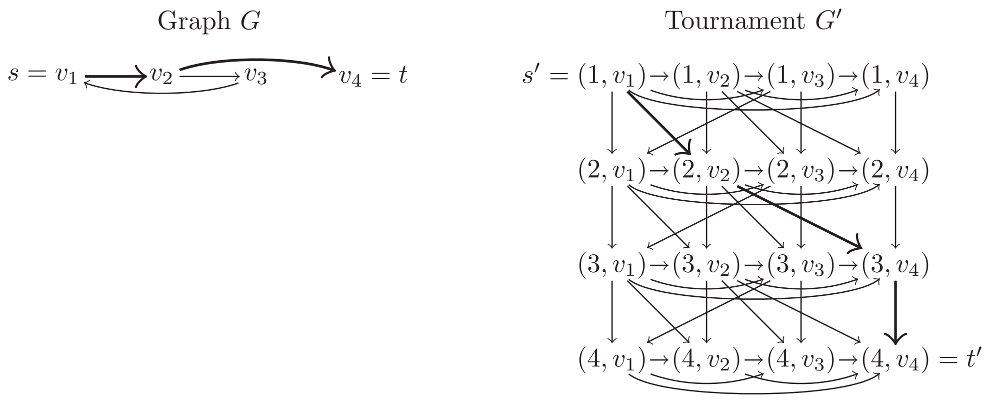

FIG. 5.1. *Example of the construction from Theorem* 5.1. *Arrows have been omitted on the right-hand side for clarity; all missing arrows point upward. The first-order reduction maps an input* $(G, s, t)$*, shown on the left-hand side, to the tournament on the right-hand side. There is a path from* $s$ *to* $t$ *in* $G$ *if and only if there is a path from* $s'$ *to* $t'$ *in* $G'$ *of length* $n - 1 = 3$*. Examples of such paths are shown in bold.*

REACH and REACH$_{\text{tourn}}$ are not. The "complexity jump" that occurs from REACH$_{\text{tourn}}$ to DISTANCE$_{\text{tourn}}$ is reflected by a similar jump for the succinct versions.

THEOREM 5.2. SUCCINCT-DISTANCE$_{\text{tourn}}$ *is* PSPACE-*complete.*

*Proof.* Since DISTANCE$_{\text{tourn}} \in$ NL, we have

$$\text{SUCCINCT-DISTANCE}_{\text{tourn}} \in \text{NPSPACE} = \text{PSPACE}.$$

For the hardness, let $A \in$ PSPACE be an arbitrary language and let $M$ be a polynomial-space machine that accepts $A$. We show $A \leq_{\text{fo}}$ SUCCINCT-DISTANCE$_{\text{tourn}}$. For an input $x$, let $G$ denote the configuration graph of $M$ on input $x$, let $s$ be the initial configuration, let $t$ be the (unique) accepting configuration, and let $n$ be the (exponential) size of $G$'s vertex set. Let $(G', s', t', n - 1)$ be the instance constructed in Theorem 5.1. Then $x \in A$ if and only if $\langle G', s', t', n - 1\rangle \in$ DISTANCE$_{\text{tourn}}$.

To finish the proof, we argue similarly as in the proof of Theorem 3.6: A succinct representation $C$ of $G'$ can be constructed in polynomial time. Invoking Veith's observation yields that a circuit $C'$ computing the same function as $C$ can even be obtained by a first-order query. Next, the source $s'$, the target $t'$, and the distance $d = n - 1$ can also be obtained from $x$ via first-order queries. Putting them together yields the desired first-order reduction from $A$ to SUCCINCT-DISTANCE$_{\text{tourn}}$. □

## 6. Conclusion.

How difficult is it to find paths in graphs with bounded independence number? Our results answer the question in three different ways, depending on exactly what is meant by this question. Checking only whether a path *exists* in a given graph can be done using AC$^0$-circuits. *Constructing* a path between two vertices can be done in logarithmic space. Constructing the *shortest* path in logarithmic space was shown to be impossible, unless L = NL.

These results settle the approximability of the (logspace) optimization problem "shortest paths in graphs with bounded independence number." We have shown that this minimization problem cannot be solved exactly in logarithmic space (unless L = NL), but it can be approximated well: There exists a logspace approximation scheme for it. We pointed out that the space dependency $O\big((\alpha + \log m) \log n\big)$ of our algorithm on the desired approximation ratio $1 + 1/m$ is essentially optimal—any approximation scheme that does substantially better could be used to show the unlikely inclusion

NL $\subseteq$ DSPACE[$\log^{2-\epsilon} n$]. It seems appropriate to call our scheme a "*fully* logspace approximation scheme" in analogy to "fully polynomial-time approximation schemes."

The shortest path problem for tournaments is not the only logspace optimization problem with surprising properties: The distance problem for *undirected* graphs is also NL-complete, while the reachability problem is SL-complete. The proof of the NL-completeness follows the same pattern as our completeness proof for tournaments, except that "upward" edges are omitted and "downward" edges are turned into undirected edges; detailed proofs are given in the technical reports of Toda [30] and Tantau [28]. On the other hand, the distance problem for directed graphs is just as hard as the reachability problem for directed graphs. This shows that, just as in the polynomial-time setting, logspace optimization problems can have different approximation properties, although their underlying decision problems have the same complexity.

The complexity of problems where some parameter—like the graph parameter "independence number"—is fixed is studied extensively in the theory of fixed parameter tractability. Our results can be interpreted as fixed parameter results, although they obviously do not fit directly into the classical framework of polynomial-time fixed parameter tractability.

We would like to recommend the following problems for further research:

1. We do not know whether the quantifier complexity $k + 3$ in the first-order formula for $\text{REACH}_{\alpha \leq k}$ is necessary but conjecture that this is the case. We were able to prove this conjecture for tournaments using an Ehrenfeucht–Fraïssé game played on two appropriate tournaments with 64 vertices. Ehrenfeucht–Fraïssé games [5, 8] seem particularly well-suited for proving matching lower bounds here, since we do not refer to an ordering relation in our first-order formula.

2. In the succinct setting we proved that the problem $\text{SUCCINCT-REACH}_{\alpha \leq k}$ is $\Pi_2^{\text{P}}$-complete for all $k$. In contrast to this, for $q > 1$ our arguments show only $\text{SUCCINCT-REACH}_{\alpha_q \leq k} \in \Pi_3^{\text{P}}$, where $\alpha_q$ is the $q$-independence number defined at the end of section 3.1. In particular, we would like to know the exact complexity of $\text{SUCCINCT-REACH}_{\alpha_2 \leq 1}$, i.e., the exact complexity of the reachability problem for succinctly represented graphs that become tournaments when squared.

**Acknowledgments.** We would like to thank Mitsu Ogihara, Ken Regan, Alan Selman, and Leen Torenvliet for helpful discussions. We are also grateful to the anonymous referees for pointing out mistakes in the references and for giving helpful criticism.

# SEPARATING THE POWER OF MONOTONE SPAN PROGRAMS OVER DIFFERENT FIELDS[*]

AMOS BEIMEL[†] AND ENAV WEINREB[†]

**Abstract.** Monotone span programs represent a linear-algebraic model of computation. They are equivalent to linear secret sharing schemes and have various applications in cryptography and complexity. A fundamental question regarding them is how the choice of the field in which the algebraic operations are performed affects the power of the span program. In this paper we prove that the power of monotone span programs over finite fields of different characteristics is incomparable; we show a superpolynomial separation between any two fields with different characteristics, solving an open problem of Pudlák and Sgall [*Algebraic models of computation and interpolation for algebraic proof systems*, in Proof Complexity and Feasible Arithmetic, DIMACS Ser. Discrete Math. Theoret. Comput. Sci. 39, P. W. Beame and S. Buss, eds., AMS, Providence, RI, 1998, pp. 279–296]. Using this result we prove a superpolynomial lower bound for monotone span programs for a function in uniform-$\mathcal{NC}^2$ (and therefore in $\mathcal{P}$), solving an open problem of Babai, Gál, and Wigderson [*Combinatorica*, 19 (1999), pp. 301–319]. (All previous superpolynomial lower bounds for monotone span programs were for functions not known to be in $\mathcal{P}$.) Finally, we show that quasi-linear secret sharing schemes, a generalization of linear secret sharing schemes introduced in Beimel and Ishai [*On the power of nonlinear secret-sharing*, in Proceedings of the 16th Annual IEEE Conference on Computational Complexity, 2001, pp. 188–202], are stronger than linear secret sharing schemes. In particular, this proves, without any assumptions, that nonlinear secret sharing schemes are more efficient than linear secret sharing schemes.

## 1. Introduction.

The relation between computational complexity and linear algebra is an important research direction with two main avenues. On one hand, algebraic techniques were used to prove lower bounds in combinatorics [1, 15, 18] and complexity; see, e.g., [21, 25, 28]. On the other hand, algebraic computational models, which capture the essence of linear algebra, were defined. Such models include, for example, arithmetic circuits, Boolean circuits with $MOD_p$ gates, and the Blum–Shub–Smale model of computation [9].

In this paper we discuss the algebraic computational model of span programs, introduced by Karchmer and Wigderson [19]. Intuitively, span programs capture the power of basic linear algebraic operations—the rank and dependency of a set of vectors. More specifically, a monotone span program is presented as a matrix over some field, with rows labeled by variables. The span program accepts an input if the rows whose variables are satisfied by the input span a fixed nonzero vector. The size of a span program is its number of rows. A detailed definition is given in section 2.

This paper deals with the role of the field in algebraic models of computation. Part of the specification of algebraic models of computation, in particular span programs, is the field in which the arithmetic operations are performed. A fundamental question is how the choice of the field, and especially its characteristic, affects the power of

the model. As different fields may differ substantially in their structures, especially when the characteristics of the fields are different, it would be natural to expect computational models defined over different fields to differ significantly in their power. A major result separating the power of algebraic models of computation over fields was the seminal paper by Smolensky for bounded depth circuits with $MOD_p$ gates [28]. Lower bounds related to the characteristic of the field are also known for polynomial calculus proofs [6]. However, the power of the field in algebraic models of computation is yet to be fully understood.

**Our results.** The main contribution of this paper is showing that the power of monotone span programs over finite fields of different characteristic is incomparable. Prior to this work, the best separation known for monotone span programs was a logarithmic separation for the threshold function [19].[1] In this paper we show a superpolynomial separation between any two fields with different characteristics, solving an open problem of [24]. That is, for every fixed prime number $p$, we describe a function, which has a small monotone span program over the field with $p$ elements, but requires a monotone span program of size $n^{\Omega(\sqrt{\log n})}$ over any field whose characteristic is not $p$ (including fields with characteristic 0).

Our second contribution concerns the functions for which lower bounds for monotone span programs have been proved. The best known lower bound for monotone span programs, proved by Gál [13], is $n^{\Omega(\log n)}$ (improving previous results of [3, 2]). However, all the known superpolynomial lower bounds [2, 13, 14] were for functions in $\mathcal{NP}$, not known to be in $\mathcal{P}$. We show a lower bound of $n^{\Omega(\sqrt{\log n})}$ for a function in uniform-$\mathcal{NC}^2$ (and therefore in $\mathcal{P}$), thus solving an open problem of [2].[2]

Our third contribution concerns secret sharing schemes, which are an important tool in cryptography, introduced by Blakley [8], Shamir [26], and Ito, Saito, and Nishizeki [16, 17]. A *secret sharing scheme* enables a dealer to share a secret among a set of parties, such that only some predefined authorized subsets will be able to reconstruct the secret from their shares. The authorized sets correspond to a monotone Boolean function $f : \{0,1\}^n \to \{0,1\}$, where $n$ is the number of parties and the authorized subsets are the subsets with their characteristic vectors in $f^{-1}(1)$. The efficiency of a secret sharing scheme is the overall size of the shares given to the parties. Monotone span programs are equivalent to a subclass of secret sharing schemes called *linear secret sharing schemes.* Monotone span programs were also used in other cryptographic applications; see, e.g., [23, 11]. Beimel and Ishai [4] showed functions that, under plausible assumptions, have no efficient linear secret sharing scheme but yet have an efficient nonlinear secret sharing scheme. Furthermore, they introduced the class of quasi-linear secret sharing schemes. In this paper we show that quasi-linear secret sharing schemes are stronger than linear schemes. In particular, this proves, without any assumptions, that nonlinear schemes are more efficient than linear schemes.

**Highlights of the techniques.** Proving a separation between the power of two models of computation requires a function with both a lower bound for one model and an upper bound for the other. To get the lower bound for monotone span programs over a certain field, we use the method of [13], which is based on [25]. In the center of Gál's method is a matrix whose rank over the field is much larger than

[1]It was known that span programs over finite fields with the same characteristics basically have the same power.

[2]We note that every function which has a polynomial size monotone $\mathcal{NC}^1$ circuit has a polynomial size monotone span program, and every function which has a polynomial size span program over a small field has a polynomial size $\mathcal{NC}^2$ circuit.

its combinatorial cover number. To get the upper bound for the same function for monotone span programs over another field, we require the cover to have an additional property, which is related to the characteristic of the field. As an example, for GF(2) we require that each entry of the matrix be covered by an odd number of rectangles. Our use of combinatorial covers and their properties is borrowed from communication complexity (see [20] for background on communication complexity). In particular, we use ideas similar to [12], which considered the model of counting communication complexity.

The main technical contribution of this paper is constructing such a matrix and proving that it satisfies the desired properties. In particular, the matrix we construct checks whether two linear subspaces over GF($p$) have a nontrivial intersection. Not surprisingly, the matrix reflects linear-algebraic computations over GF($p$), which are difficult to simulate over fields with characteristics different than $p$.

**Organization.** In section 2 we supply some preliminaries. In section 3 we give a general method for proving a separation between the power of monotone span programs over fields with different characteristics. In section 4 we apply this general method to achieve a separation of $n^{\Omega(\sqrt{\log n})}$ for an explicit function. Finally, in section 5, we use this separation to exhibit a monotone function in uniform-$\mathcal{NC}^2$ that has no polynomial size monotone span program, and to prove that there exist secret sharing schemes stronger than the linear secret sharing schemes.

## 2. Preliminaries.

We start with the definition of our main computational model, span programs.

DEFINITION 2.1 (span program [19]). *A* span program *over a field $F$ is a triplet $\widehat{M} = \langle M, \rho, \vec{v} \rangle$, where $M$ is a matrix over $F$, $\vec{v}$ is a nonzero row vector called the target vector (it has the same number of coordinates as the number of columns in $M$), and $\rho$ is a labeling of the rows of $M$ by literals from $\{x_1, \ldots, x_n, \overline{x}_1, \ldots, \overline{x}_n\}$ (every row is labeled by one literal, and the same literal can label many rows).*

*A span program accepts or rejects an input by the following criterion. For every input $u \in \{0,1\}^n$ define the submatrix $M_u$ of $M$ consisting of those rows whose labels are satisfied by the assignment $u$. The span program $\widehat{M}$* accepts *$u$ if and only if $\vec{v} \in \operatorname{span}(M_u)$, i.e., some linear combination of the rows of $M_u$ gives the target vector $\vec{v}$. A span program* computes *a Boolean function $f$ if it accepts exactly those inputs $u$, where $f(u) = 1$. The* size *of $\widehat{M}$ is the number of rows in $M$.*[3]

*A span program is called* monotone *if the labels of the rows are only positive literals $\{x_1, \ldots, x_n\}$. Monotone span programs compute only monotone functions, and every monotone Boolean function can be computed by a monotone span program. The size of the smallest monotone span program over $F$ that computes $f$ is denoted by* $\mathrm{mSP}_F(f)$.

*Example* 2.2. Consider the following monotone span program over GF(2):

| | | | | | |
|---|---|---|---|---|---|
| $x_2$ | 1 | 1 | 0 | 0 | 0 |
| $x_2$ | 0 | 1 | 1 | 1 | 0 |
| $x_1$ | 0 | 1 | 1 | 1 | 0 |
| $x_3$ | 0 | 1 | 0 | 1 | 1 |
| $x_4$ | 0 | 0 | 1 | 0 | 1 |

[3]The choice of the fixed nonzero vector $\vec{v}$ does not affect the size of the span program. It is always possible to replace $\vec{v}$ with another nonzero vector $\vec{v}'$ via a change of basis without changing the function computed and the size of the span program. Most often $\vec{v}$ is chosen to be the $\vec{1}$ vector (with all entries equal 1).

In this example, the target vector is $\vec{v} = \langle 1, 0, 0, 1, 1 \rangle$. There are 4 different variables labeling the rows of the matrix and the inputs are of size 4. Consider the input $\langle 0, 1, 0, 1 \rangle$. Since $x_2$ and $x_4$ are satisfied by the input, we consider the submatrix consisting of rows labeled by these variables:

$$\begin{array}{|c|c|c|c|c|c|}
\hline
x_2 & 1 & 1 & 0 & 0 & 0 \\
x_2 & 0 & 1 & 1 & 1 & 0 \\
x_4 & 0 & 0 & 1 & 0 & 1 \\
\hline
\end{array}$$

The question is whether the rows of this submatrix span the target vector $\langle 1, 0, 0, 1, 1 \rangle$. Since $\langle 1, 0, 0, 1, 1 \rangle$ is the sum, over GF(2), of the rows of the submatrix, the input is accepted by the program.

Now consider the input $\langle 1, 1, 0, 0 \rangle$. Again, we focus on the submatrix of rows labeled by $x_1$ and $x_2$, the variables satisfied by the input assignment:

$$\begin{array}{|c|c|c|c|c|c|}
\hline
x_2 & 1 & 1 & 0 & 0 & 0 \\
x_2 & 0 & 1 & 1 & 1 & 0 \\
x_1 & 0 & 1 & 1 & 1 & 0 \\
\hline
\end{array}$$

Looking at the rightmost coordinate, we see that all the submatrix entries in this column are 0, while in the target vector $\langle 1, 0, 0, 1, 1 \rangle$ the rightmost entry is 1. Hence, no linear combination of the rows of the submatrix gives the target vector. Therefore, the input is rejected by the program.

**Combinatorial rectangles and covers.** Combinatorial rectangles and covers are useful tools in communication complexity and are used in this work in a similar way. Let $X$ and $Y$ be arbitrary finite sets. A combinatorial rectangle is a set $X_0 \times Y_0$, where $X_0 \subseteq X$ and $Y_0 \subseteq Y$. A *cover* of $X \times Y$ is a set $\mathcal{R}$ of rectangles such that every pair $\langle x, y \rangle \in X \times Y$ belongs to at least one rectangle in $\mathcal{R}$.

Let $M$ be a Boolean $|X| \times |Y|$ matrix such that the rows of $M$ are indexed by the elements of $X$, and the columns of $M$ are indexed by the elements of $Y$. We say that a rectangle $R_0 = X_0 \times Y_0$, where $X_0 \subseteq X$ and $Y_0 \subseteq Y$, is a *monochromatic* rectangle if there exists a $b \in \{0, 1\}$ such that for every $x \in X_0$ and $y \in Y_0$ it holds that $M[x, y] = b$. If $b = 1$, we call $R_0$ a 1-*rectangle*, and if $b = 0$, we call $R_0$ a 0-*rectangle.* We say that a cover $\mathcal{R}$ is a *monochromatic* cover of $M$ if every rectangle $R \in \mathcal{R}$ is a monochromatic rectangle. If $\mathcal{R}$ is a set of 1-rectangles that covers all the 1-entries of $M$, then $\mathcal{R}$ is called a 1-*cover* of $M$. If $\mathcal{R}$ is a set of 0-rectangles that cover all the 0-entries of $M$, we call $\mathcal{R}$ a 0-*cover* of $M$.

**Linear subspaces.** We use basic linear algebra to find a function that is easy for span programs over one field and hard for span programs over another field. For a prime number $p$, we denote by GF$(p)$ the unique finite field with $p$ elements.

Let $k$ be a positive integer, and let $p$ be a prime. Denote by $V_k^{2k}(p)$ the set of all $k$-dimensional subspaces of GF$(p)^{2k}$, and denote by $v_k^{2k}(p)$ the number of such subspaces, that is, $v_k^{2k}(p) = \left|V_k^{2k}(p)\right|$. To prove our result, we count the number of subspaces satisfying a certain property. Toward this aim, we will use the following easy algebraic claim. We say that two linear spaces $U$ and $W$ are different if there exists a vector $\vec{v}$ such that $\vec{v} \in U$ and $\vec{v} \notin W$ or vice versa.

Claim 2.3. *Let $k$ be a positive integer, $F$ be a field, and $M$ be a matrix with $k$ rows such that* $\text{rank}_F(M) = k$. *Let $T_1, T_2$ be matrices with $k$ rows each, where $T_1 \neq T_2$. Define $M_1$ (respectively, $M_2$) to be the matrix resulting from concatenating* *the matrix $T_1$ (respectively, $T_2$) to $M$, that is, $M_i = (M|T_i)$ for $i \in \{1, 2\}$. Then, the linear spaces spanned by the rows of $M_1$ and $M_2$ are different.*

*Proof.* Since $T_1 \neq T_2$, there exists an index $j \in \{1, \ldots, k\}$, such that the rows $T_1[j]$ and $T_2[j]$ are different. Let $\vec{r} = M_1[j]$; that is, $\vec{r}$ is the $j$th row of $M_1$. We show that $\vec{r}$ is not spanned by the rows of $M_2$. Assume there exists a combination of the rows of $M_2$ that spans $\vec{r}$. That is, $\vec{r} = \sum_{i=1}^{k} \alpha_i M_2[i]$ for some $\alpha_1, \ldots, \alpha_k \in F$. Let $m$ be the number of columns in $M$, and consider the restriction of the above sum to the first $m$ coordinates. It holds that $M[j] = \sum_{i=1}^{k} \alpha_i M[i]$. Since $M$ has $k$ rows and $\operatorname{rank}_F(M) = k$, we get that $\alpha_j = 1$ and $\alpha_i = 0$ for every $i \neq j$. Thus, $\vec{r} = M_2[j]$; that is, $M_1[j] = M_2[j]$, contradicting the fact that $T_1[j] \neq T_2[j]$. $\square$

One application of Claim 2.3 is the following known corollary, which gives a lower bound on $v_k^{2k}(p)$.[4]

COROLLARY 2.4. *Let $k$ be a positive integer, and let $p$ be a prime. Then $v_k^{2k}(p) \geq p^{k^2}$.*

*Proof.* Let $I_k$ be the $k \times k$ unit matrix, $T$ be an arbitrary $k \times k$ matrix over $\mathrm{GF}(p)$, and $M_1$ be the $k \times 2k$ matrix that is a concatenation of $I_k$ and $T$. There are $p^{k^2}$ different choices of $T$, and therefore $p^{k^2}$ different ways to construct $M_1$. By Claim 2.3, each such $M_1$ represents a different element of $V_k^{2k}(p)$, and thus $v_k^{2k}(p) \geq p^{k^2}$. $\square$

It is easy to see that $v_k^{2k}(p) < p^{2k^2}$, since this is the number of ways to choose *any* $k$ vectors from $\mathrm{GF}(p)^{2k}$, and thus, we have $p^{k^2} \leq v_k^{2k}(p) < p^{2k^2}$.[5]

We will denote by $\vec{e}_j$ the $j$th unit vector, that is, the vector that is 1 in the $j$th coordinate and 0 in all the others. We say that a nonzero vector has a *leading* 1 if the first nonzero coordinate in the vector is 1. Let $p$ be a prime, $\ell$ be a positive integer, and $U$ be a subspace of dimension $\ell$ over $\mathrm{GF}(p)$. Then, the number of vectors with a leading 1 in $U$ is $\frac{p^\ell - 1}{p-1}$. We will denote by $\operatorname{char}(F)$ the characteristic of the field $F$. Finally, we denote by $[n]$ the set $\{1, \ldots, n\}$.

## 3. The general method for separation.

We want to construct a function that is hard for monotone span programs over fields with characteristic different than $p$ and easy for monotone span programs over $\mathrm{GF}(p)$, where $p$ is a prime. We use the method of [13] to get the lower bound for monotone span programs over fields with characteristic different than $p$. In the center of this method is a matrix with a large gap between its rank and the size of its monochromatic cover. To get a small upper bound for monotone span programs over $\mathrm{GF}(p)$, we shall require the cover to have an additional property, which we call 1-mod-$p$; that is, for every entry of the matrix, the number of rectangles covering it is equivalent to 1 modulo $p$. Generally speaking, the number of variables in $f$, the function for which we prove the separation, is equal to the number of rectangles in a cover. A detailed description is given below.

### 3.1. The lower bound.

Let $M$ be a matrix and $\mathcal{R}$ be a monochromatic cover of $M$. Recall that $\mathcal{R}$ is a set of rectangles. Denote $n = |\mathcal{R}|$, and $\mathcal{R} = \{R_1, \ldots, R_n\}$, where $R_i = X_i \times Y_i$. A vector in $\{0,1\}^n$ can be viewed as a characteristic vector of a subset of $\mathcal{R}$. Throughout the paper, we identify each such vector with its corresponding subset. We define two subsets of $\{0,1\}^n$, Acc and Rej. These are exactly the same sets defined by Razborov in [25], proving that a monotone function can be associated

[4]Corollary 2.4 can be proved by directly counting the elements of $V_k^{2k}$. However, since we need Claim 2.3 for other purposes, we use it to prove Corollary 2.4 as well.

[5]Actually, $v_k^{2k}(p) = O(p^{k^2})$.

with any cover. We will focus on functions that accept every $x \in \text{Acc}$ and reject every $y \in \text{Rej}$.

We first define a set Acc. For every row $x$ of $M$ we define a vector $\vec{z}_x \in \{0,1\}^n$. The $i$th coordinate in $\vec{z}_x$ indicates if the rectangle $R_i$ covers the row $x$ of $M$. That is, $\vec{z}_x[i] = 1$ if $x \in X_i$, and $\vec{z}_x[i] = 0$ otherwise. The set Acc contains the vectors $\vec{z}_x$ for every row $x$ of the matrix $M$. That is, $\text{Acc} = \{\vec{z}_x : x \in X\}$. An example for Acc is described in Figure 3.1. For example, the set in Acc corresponding to $x$ in the figure is $\{R_4, R_5, R_6\}$, the rectangles that cover the row $x$, and $\vec{z}_x = \langle 0,0,0,1,1,1\rangle$.

We now define a set Rej. For every column $y$ of $M$ we define a vector $\vec{w}_y \in \{0,1\}^n$. The $i$th coordinate of $\vec{w}_y$ indicates if the rectangle $R_i$ *does not* cover the column $y$ of the matrix $M$. That is, $\vec{w}_y[i] = 1$ if $y \notin Y_i$, and $\vec{w}_y[i] = 0$ otherwise. The set Rej contains the vectors $\vec{w}_y$ for every column $y$ of the matrix $M$. That is, $\text{Rej} = \{\vec{w}_y : y \in Y\}$. For example, the set in Rej corresponding to $y$ described in Figure 3.1 is $\{R_1, R_2, R_4\}$, the rectangles that *do not* cover the column $y$, and $\vec{w}_y = \langle 1,1,0,1,0,0\rangle$.

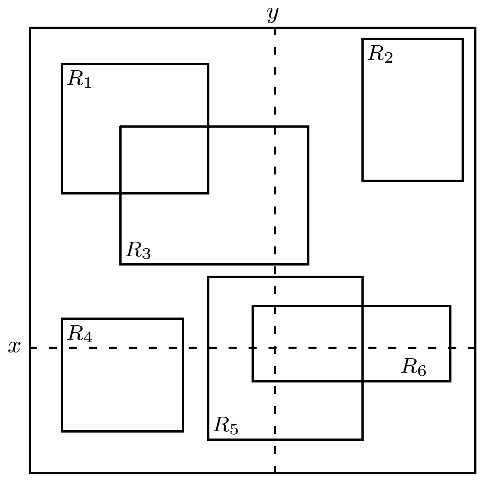

FIG. 3.1. *An illustration of elements in the sets* Acc *and* Rej. *Note that the rectangles in the figure* do not *form a cover.*

The lower bound on the size of monotone span programs is achieved using the following theorem, which is a (slightly different) restatement of Theorem 4.1 of [13].

THEOREM 3.1 (see [13]). *Let $M$ be a Boolean matrix, $\mathcal{R}$ be a monochromatic cover of $M$ of size $n$, and* Acc *and* Rej *be as defined above. If $f : \{0,1\}^n \to \{0,1\}$ is a monotone function such that $f(x) = 1$ for every $x \in$* Acc*, and $f(y) = 0$ for every $y \in$* Rej*, then* $\text{mSP}_F(f) \geq \text{rank}_F(M)$ *for every field $F$.*

That is, we get the lower bound for every function $f$ accepting Acc and rejecting Rej. Note that there are no requirements concerning inputs $t \notin (\text{Acc} \cup \text{Rej})$ (except for monotonicity). One can observe that such a function exists.

**3.2. The upper bound.** To prove a gap between the power of monotone span programs over the different fields, we need a function that has a small monotone span program over GF($p$). Toward this aim, we require the cover $\mathcal{R}$ to be a *monochromatic* 1-mod-$p$ *cover* according to the following definition.

DEFINITION 3.2. *Let $M$ be a Boolean matrix. A set $\mathcal{R}$ of combinatorial rectangles is called a* monochromatic 1-mod-$p$ cover *of $M$ if $\mathcal{R}$ is a monochromatic cover of $M$,* *and, for each entry of $M$, the number of rectangles covering it is equivalent to* 1 *modulo $p$.*

Given a small monochromatic 1-mod-$p$ cover of $M$, we construct a monotone span program over $\mathrm{GF}(p)$ that accepts Acc and rejects Rej. The gap will hold for the function computed by this span program.

Consider the following monotone span program $\widehat{P}$ over $\mathrm{GF}(p)$. The program $\widehat{P}$ associates a row with each rectangle of $\mathcal{R}$, and a column with each column of the matrix $M$. Therefore, the rectangle $R_j \in \mathcal{R}$ is represented by the variable $x_j$. The row associated with the rectangle $R_i = X_i \times Y_i$ is 1 in the column labeled $y$ if $y \in Y_i$, that is, if the rectangle $R_i$ covers the column $y$ in $M$. Otherwise, this entry in $\widehat{P}$ is 0. Note that $size(\widehat{P}) = n$; that is, there is exactly one row for each variable.

The following lemma is a simple special case of the upper bound part of Theorem 3.4 in [13]. In fact, the program $\widehat{P}$ considered here is exactly the program that one obtains by applying the construction from the proof of the upper bound in [13] to this simple special case.

LEMMA 3.3. *The program $\widehat{P}$ accepts every $\vec{z}_x \in$ Acc and rejects every $\vec{w}_y \in$ Rej.*

*Proof.* We first prove that $\widehat{P}$ accepts every $\vec{z}_x \in$ Acc. Specifically, we will show that since $\mathcal{R}$ is a 1-mod-$p$ cover, the sum of the rows labeled by the rectangles of $\vec{z}_x$ is the vector $\vec{1}$, and thus $\vec{z}_x$, is accepted by $\widehat{P}$. That is, we show that for every column of $\widehat{P}$, the rows labeled by variables satisfied by $\vec{z}_x$ sum to 1 in this column. Toward this goal, fix a column $y$. Since $\vec{z}_x \in$ Acc, it is the characteristic vector of the set of rectangles covering the row $x$ of $M$. According to the definition of $\widehat{P}$, for every rectangle $R_j$ such that $\vec{z}_x[j] = 1$, the entry $\langle R_j, y\rangle$ of $\widehat{P}$ is 1 if and only if $R_j$ covers the column $y$, that is, $y \in Y_j$. On the other hand, $\vec{z}_x[j] = 1$ if and only if $R_j$ covers the row $x$. Thus, the sum over the rows of $\widehat{P}$ associated with $\vec{z}_x$ in the column $y$ is exactly the number of rectangles covering both $y$ and $x$, that is, the number of rectangles covering the entry $\langle x, y\rangle$ in $M$. Since $\mathcal{R}$ is a 1-mod-$p$ cover, this number is 1 modulo $p$. To conclude, the sum of the rows labeled by variables that are satisfied by $\vec{z}_x$ is the vector $\vec{1}$, and $\vec{z}_x$ is accepted by $\widehat{P}$.

Let $\vec{w}_y \in$ Rej. We show that there is no linear combination of the rows labeled by the rectangles of $y$ that give the vector $\vec{1}$. Since $\vec{w}_y \in$ Rej, it is the characteristic vector of the subset of rectangles from $\mathcal{R}$ that *do not* cover the column $y$ of $M$. Hence, all the rows of $\widehat{P}$ corresponding to variables satisfied by $\vec{w}_y$ are 0 in the column associated with $y$. Therefore, every combination of the rows labeled by variables satisfied by $\vec{w}_y$ is 0 in this column. Thus, the vector $\vec{1}$ is not a linear combination of these rows, and $\vec{w}_y$ is rejected by $\widehat{P}$. ◻

Combining Theorem 3.1 and Lemma 3.3, we get the separation theorem.

THEOREM 3.4 (separation theorem). *Let $M$ be a Boolean matrix and $\mathcal{R}$ be a monochromatic* 1-mod-$p$ *cover of $M$ of size $n$. Then there exists a monotone function $f$, with $n$ variables, such that* $\mathrm{mSP}_{\mathrm{GF}(p)}(f) = n$ *and* $\mathrm{mSP}_F(f) \geq \mathrm{rank}_F(M)$ *for every field $F$.*

*Proof.* Denote by $f_{\widehat{P}}$ the function computed by $\widehat{P}$. By Lemma 3.3, $f_{\widehat{P}}$ accepts Acc and rejects Rej, and thus by Theorem 3.1 $\mathrm{mSP}_F(f_{\widehat{P}}) \geq \mathrm{rank}_F(M)$. On the other hand, $\mathrm{size}(\widehat{P}) = n$, and thus $\mathrm{mSP}_{\mathrm{GF}(p)}(f) = n$. The function $f_{\widehat{P}}$ is monotone, as it is computed by a monotone span program. ◻

## 4. The linear subspaces zero intersection function.

In this section we show an explicit matrix, with a high rank over fields with characteristic different than $p$, and a small monochromatic 1-mod-$p$ cover. Thus, by Theorem 3.4 we get a function

$f$ with a superpolynomial gap between $\mathrm{mSP}_{\mathrm{GF}(p)}(f)$ and $\mathrm{mSP}_F(f)$, where $F$ is any field such that $\mathrm{char}(F) \neq p$. We define the desired matrix in two steps: in the first step we define the matrix $M_{\mathrm{ZI}}$ and prove it has full rank over fields with $\mathrm{char}(F) \neq p$. In the second step we use $M_{\mathrm{ZI}}$ to define another matrix, $M_{\mathrm{LZI}}$, which has both a high rank over fields with char $\neq p$, and a small monochromatic 1-mod-$p$ cover.

Let $k$ be a positive integer and $p$ be a prime.[6] The *zero intersection* (ZI) function determines whether the intersection of two $k$-dimensional linear subspaces of $\mathrm{GF}(p)^{2k}$ is the subspace $\{\vec{0}\}$. More formally, define $\mathrm{ZI}_k^p : V_k^{2k}(p) \times V_k^{2k}(p) \to \{0,1\}$ as follows: $\mathrm{ZI}_k^p(U,W) = 1$, where $U$ and $W$ are subspaces in $V_k^{2k}(p)$, if and only if $\dim(U \cap W) = 0$. Recall that the intersection of any two linear subspaces is a linear subspace.

We represent $\mathrm{ZI}_k^p$ by a $v_k^{2k}(p) \times v_k^{2k}(p)$ matrix denoted $M_{\mathrm{ZI}_k^p}$. Each row and each column of $M_{\mathrm{ZI}_k^p}$ is labeled by a subspace $U \in V_k^{2k}(p)$, and each entry $M_{\mathrm{ZI}_k^p}[U,W]$ is equal to $\mathrm{ZI}_k^p(U,W)$. Denote by $r_U$ the row in $M_{\mathrm{ZI}_k^p}$ associated with the subspace $U \in V_k^{2k}(p)$. We will use ZI instead of $\mathrm{ZI}_k^p$, and $M_{\mathrm{ZI}}$ instead of $M_{\mathrm{ZI}_k^p}$, when $k$ and $p$ are clear from the context.

**4.1. Analyzing the rank of $M_{\mathrm{ZI}}$.** The next theorem shows that $M_{\mathrm{ZI}}$ has full rank over any field with char $\neq p$.

THEOREM 4.1. *Let $k$ be a positive integer, $p$ be a prime, and $F$ be a field such that* $\mathrm{char}(F) \neq p$. *Then, $M_{\mathrm{ZI}_k^p}$ has full rank over $F$.*

*Proof.* To prove that the matrix has full rank, it is sufficient to show that any unit vector is spanned by the rows of the matrix. Recall that the columns of the matrix are labeled by subspaces from $V_k^{2k}(p)$. For every $U \in V_k^{2k}(p)$ we consider the unit vector $\vec{e}_U \in \mathrm{GF}(p)^{v_k^{2k}(p)}$ and show that it is spanned by the rows of $M_{\mathrm{ZI}}$. Specifically, we show a combination of the rows of the matrix spanning $\vec{e}_U$ having a special structure: The coefficient of $\vec{r}_Z$, the row labeled $Z \in V_k^{2k}(p)$, depends only on the dimension of the subspace $U \cap Z$. More precisely, we show there are constants $\alpha_0, \dots, \alpha_k \in F$, such that

$$\vec{e}_U = \sum_{d=0}^{k} \alpha_d \sum_{\substack{Z \in V_k^{2k}(p) \\ \dim(Z \cap U) = d}} \vec{r}_Z. \tag{4.1}$$

Fix $W \in V_k^{2k}(p)$ and consider $\vec{c}_W$, the column of $M_{\mathrm{ZI}}$ associated with $W$. We have to show that with the appropriate constants $\alpha_0, \dots, \alpha_k \in F$, the above expression is 0 in this column if $W \neq U$ and is 1 if $W = U$. When computing the sum in the column $\vec{c}_W$, we add $\alpha_d$ for every subspace $Z$ such that $\mathrm{ZI}(Z,W) = 1$ (i.e., $\dim(Z \cap W) = 0$) and $\dim(Z \cap U) = d$. This motivates the following definition.

DEFINITION 4.2. *Let $U, W \in V_k^{2k}(p)$ be subspaces, and let $\ell$ be an integer such that* $\dim(U \cap W) = \ell$. *Define $H_k^p(\ell, d)$ to be the* number *of subspaces $Z \in V_k^{2k}(p)$ such that* $\dim(U \cap Z) = d$ *and* $\dim(W \cap Z) = 0$.

From symmetry arguments, the number $H_k^p(\ell, d)$ is independent of the choice of $U$ and $W$. We will write $H_k(\ell, d)$ instead of $H_k^p(\ell, d)$ when $p$ is clear from the context.

To summarize, we need to show that there are constants $\alpha_0, \dots, \alpha_k \in F$ such that the following hold:

1. For each $0 \leq \ell \leq k-1$, it holds that $\sum_{d=0}^{k} \alpha_d \cdot H_k(\ell, d) = 0$. That is, the sum over any column labeled with $W \neq U$ equals 0, where for a subspace $W \in V_k^{2k}(p)$ such that $\dim(U \cap W) = \ell$, the relevant equation is the $\ell$th equation.

[6]Throughout this section the reader should think of $k$ as small. That is, we construct a function with $n$ variables and $k \approx \sqrt{\log n}$.

2. $\sum_{d=0}^{k} \alpha_d \cdot H_k(k,d) = 1$. That is, the sum over the column associated with $U$ is 1.

Putting things differently, we view the numbers $H_k(\ell,d)$ for $\ell, d \in \{0,\dots,k\}$ as a $(k+1)\times(k+1)$ matrix over $F$.[7] According to the above conditions we have to prove there are $\alpha_0,\dots,\alpha_k \in F$ such that $H_k\langle\alpha_0,\alpha_1,\dots,\alpha_k\rangle^T = \langle 0,\dots,0,1\rangle^T$. We show that $H_k$ is invertible over $F$, and thus we can find $\alpha_0,\dots,\alpha_k$ using $H_k^{-1}$ as follows: $\langle\alpha_0,\alpha_1,\dots,\alpha_k\rangle^T = H_k^{-1}\langle 0,\dots,0,1\rangle^T$.

In the next two claims, we show that $H_k$ is upper-left triangular, where the numbers on the secondary diagonal are nonzero in $F$, and thus $H_k$ has full rank over $F$. The structure of $H_k$ is illustrated in Figure 4.1. In Claim 4.3 we show that the numbers below the secondary diagonal are all 0. In Claim 4.4 we show that the numbers on the secondary diagonal are all powers of $p$, which are nonzero since $\mathrm{char}(F) \neq p$. The numbers above the secondary diagonal may take any value from $F$.

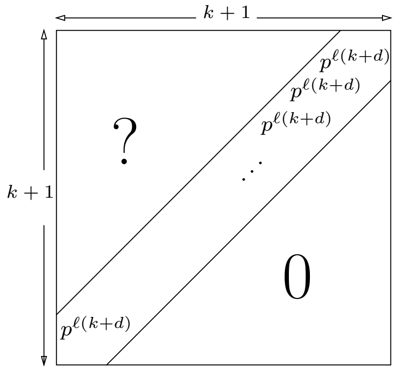

FIG. 4.1. *The structure of the matrix $H_k$.*

CLAIM 4.3. *Let $k$ be a positive integer, $\ell$ and $d$ be nonnegative integers, $p$ be a prime, and $H_k$ be as above. If $\ell + d > k$, then $H_k^p(\ell,d) = 0$.*

*Proof.* Let $U, W \in V_k^{2k}(p)$, where $\dim(U \cap W) = \ell$. We have to show that since $\ell + d > k$, there is no subspace $Z \in V_k^{2k}(p)$ such that $\dim(Z \cap U) = d$ and $\dim(Z \cap W) = 0$. Assume toward contradiction that there exists such $Z$. Let $B_{U\cap W} = \langle \vec{w}_1,\dots,\vec{w}_\ell\rangle$ be a basis of the subspace $U \cap W$. Let $B_{U\cap Z} = \langle \vec{z}_1,\dots,\vec{z}_d\rangle$ be a basis for $U \cap Z$. Consider the set of vectors $X = B_{U\cap W} \cup B_{U\cap Z}$. First note that $X \subseteq U$; that is, all the vectors in $X$ are in the subspace $U$. Since $\dim(U) = k$ and $|X| = \ell + d > k$, the set $X$ must be linearly dependent. Thus, there must be a nontrivial combination of the vectors of $X$, giving the vector $\vec{0}$, that is, $\sum_{i=1}^{\ell}\lambda_i\vec{w}_i + \sum_{i=1}^{d}\delta_i\vec{z}_i = \vec{0}$. Since both $B_{U\cap W}$ and $B_{U\cap Z}$ are linearly independent, the nonzero vector $\vec{v} = \sum_{i=1}^{\ell}\lambda_i\vec{w}_i$ is spanned by both $B_{U\cap W}$ and $B_{U\cap Z}$. Since $U \cap W \subseteq W$ and $U \cap Z \subseteq Z$, we get that $\vec{v} \in W \cap Z$, and thus $\dim(W \cap Z) > 0$, contradicting the assumption that $\dim(W \cap Z) = 0$. ▯

We need the following notation for the next claim: Let $B = \langle \vec{v}_1,\dots,\vec{v}_{2k}\rangle$ be a basis of $\mathrm{GF}(p)^{2k}$. Let $Z \in V_k^{2k}(p)$ and $B_Z = \langle \vec{z}_1,\dots,\vec{z}_k\rangle$ be a basis for $Z$. Thus there must be unique constants such that for every $i \in [k]$ we have $z_i = \sum_{j=1}^{2k}\beta_{i,j}\vec{v}_j$. Then we call the $k \times 2k$ matrix $(\beta_{i,j})$ the *representation matrix* of $B_Z$ *according to* $B$. Notice that for every basis $B$ of $Z$ we get a different representation.

[7]Since $H_k(\ell,d)$ may be a number not in $F$, we will replace it with $H_k(\ell,d) \bmod c$, where $c$ is the characteristic of $F$. If the characteristic of $F$ is 0, $H_k(\ell,d)$ will always be in $F$.

CLAIM 4.4. *Let $k$ be a positive integer, $\ell$ and $d$ be nonnegative integers, and $p$ be a prime. If $\ell + d = k$, then $H_k^p(\ell, d) = p^{\ell(k+d)}$.*

*Proof.* Let $U, W \in V_k^{2k}(p)$ be any subspaces such that $\dim(U \cap W) = \ell$. We must show that the number of subspaces $Z$ such that $\dim(Z \cap U) = d$ and $\dim(Z \cap W) = 0$ is $p^{\ell(k+d)}$. We will first define the term *canonical representation* of a subspace in $V_k^{2k}(p)$. Next, we will show that each subspace $Z$, such that $\dim(Z \cap U) = d$ and $\dim(Z \cap W) = 0$, has a canonical representation. Then we will show that every canonical representation is associated with a unique subspace $Z$ such that $\dim(Z \cap U) = d$ and $\dim(Z \cap W) = 0$. Thus, the number of such subspaces is equal to the number of different canonical representations. To complete the proof, we will show that the number of such canonical representations is $p^{\ell(k+d)}$. The canonical representation is defined according to a specific basis of $\mathrm{GF}(p)^{2k}$. Consider a basis $B_{U,W}$ of $\mathrm{GF}(p)^{2k}$ defined as follows:

$$B_{U,W} = \langle \vec{v}_1, \dots, \vec{v}_\ell, \vec{u}_1, \dots, \vec{u}_d, \vec{w}_1, \dots, \vec{w}_d, \vec{x}_1, \dots, \vec{x}_\ell \rangle,$$

where

(i) $\langle \vec{v}_1, \dots, \vec{v}_\ell \rangle$ is a basis of $U \cap W$. Recall that $\dim(U \cap W) = \ell$.

(ii) $\langle \vec{u}_1, \dots, \vec{u}_d \rangle$ is an expansion of $\langle \vec{v}_1, \dots, \vec{v}_\ell \rangle$ to a basis of $U$. Recall that $\dim(U) = k$ and $d + \ell = k$.

(iii) $\langle \vec{w}_1, \dots, \vec{w}_d \rangle$ is an expansion of $\langle \vec{v}_1, \dots, \vec{v}_\ell \rangle$ to a basis of $W$. Recall that $\dim(W) = k$ as well.

(iv) $\langle \vec{x}_1, \dots, \vec{x}_\ell \rangle$ is an expansion of $\langle \vec{v}_1, \dots, \vec{v}_\ell, \vec{u}_1, \dots, \vec{u}_{k-\ell}, \vec{w}_1, \dots, \vec{w}_{k-\ell} \rangle$ to a basis of $\mathrm{GF}(2)^{2k}$. Here there are $\ell$ vectors since $2k - (\ell + d + d) = \ell$.

We say that a subspace $Z \in V_k^{2k}(p)$ has a *canonical representation* according to $B_{U,W}$ if it has a basis whose representation matrix according to $B_{U,W}$ is as described in Figure 4.2. The matrix in Figure 4.2 is a $k \times 2k$ matrix. Each entry in zones $(b)$, $(g)$, and $(h)$ must be 0. The entries in zones $(d)$ and $(f)$ must form the unit matrices $I_\ell$ and $I_d$, respectively. Each entry in zones $(a)$, $(c)$, and $(e)$ can take any value from $\mathrm{GF}(p)$.

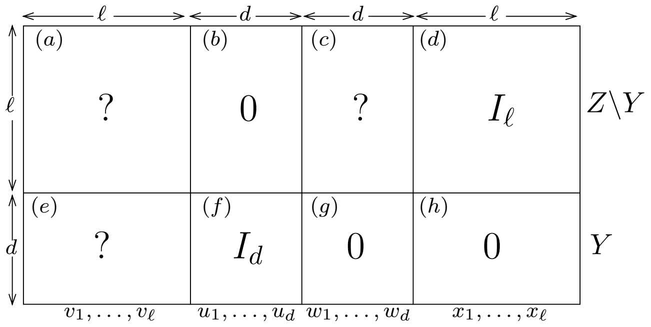

FIG. 4.2. *A canonical representation of a subspace $Z \in V_k^{2k}(p)$ with $\dim(U \cap Z) = d$ and $\dim(W \cap Z) = 0$.*

First, we show that every subspace $Z \in V_k^{2k}(p)$ such that $\dim(Z \cap U) = d$ and $\dim(Z \cap W) = 0$ has a canonical representation according to $B_{U,W}$. Let $Y = Z \cap U$. Note that $\dim(Y) = d$. Let $B_Y = \langle \vec{y}_1, \dots, \vec{y}_d \rangle$ be a basis of $Y$, and let $B_Z = \langle \vec{y}_1, \dots, \vec{y}_d, \vec{z}_1, \dots, \vec{z}_\ell \rangle$ be an expansion of $B_Y$ to a basis of $Z$. Consider $M_Z$, the representation matrix of $B_Z$ according to $B_{U,W}$. Since $Y \subseteq U$, all the entries in the zones $(g)$ and $(h)$ are 0 as required. We claim that we can perform elementary operations on the lower part of $M_Z$ so that we get the matrix $I_d$ in zone $(f)$. Otherwise, we would get a row $\vec{r}$ that is $\vec{0}$ in zone $(f)$, but this would leave all the nonzero entries of $\vec{r}$ in zone $(e)$. Since zone $(e)$ represents the basis vectors from $U \cap W$, this would mean $\dim(Z \cap W) > 0$, contradicting the properties of $Z$. It is left to set zone $(d)$ to $I_\ell$ and all the entries in zone $(b)$ to 0. Setting all the entries in zone $(b)$ to 0 can be done by elementary operations on the upper part of $M_Z$ using the rows from the lower part, which now form the unit matrix $I_d$ in zone $(f)$. (This would change the entries in zone $(a)$, but we have no constraints on this zone.) We claim that we can set zone $(d)$ to be $I_\ell$ by elementary operations on the upper part of $M_Z$. Otherwise we would get a row $\vec{r}$ that is all zero in zone $(d)$. Thus $\vec{r}$ has nonzero entries only in zones $(a)$ and $(c)$, but then it again implies that $\vec{r}$ represents a vector from $W$, contradicting the fact that $\dim(Z \cap W) = 0$.

Next we prove that *every* subspace $Z \in V_k^{2k}(p)$, which can be represented in the above canonical form, satisfies $\dim(Z \cap W) = 0$ and $\dim(Z \cap U) = d$. Let $M_Z$ be a canonical representation of $Z$ according to $B_{U,W}$. Since $M_Z$ has $I_\ell$ and $I_d$ as submatrices, we have $\text{rank}_{\text{GF}(p)}(M_Z) = k$, and thus $Z \in V_k^{2k}(p)$. Now suppose $\dim(Z \cap W) > 0$. Then we can span a vector $w \in W$ by the rows of $M_Z$. This vector has to be zero in the coordinates labeled by $\vec{u}_1, \dots, \vec{u}_d$, and by $\vec{x}_1, \dots, \vec{x}_\ell$, but this cannot be done by a nontrivial combination of the rows of $M_Z$. Thus, $\dim(W \cap Z) = 0$. The lower part of $M_Z$ is nonzero only in coordinates labeled by vectors from $U$, and since it has $I_d$ as a submatrix, we get that $\dim(Z \cap U) \geq d$. Now suppose that $\dim(Z \cap U) = d' > d$. Then we have $\dim(Z \cap U) = d'$, $\dim(Z \cap W) = 0$, and $\dim(U \cap W) = \ell$, where $\ell + d' > \ell + d = k$, which is impossible by Claim 4.3. Therefore, $\dim(U \cap Z) = d$.

To complete the proof, we show that any two subspaces having different canonical representations over $B_{U,W}$ are different. To see this, note that the matrix

$$S = \begin{pmatrix} 0 & I_\ell \\ I_d & 0 \end{pmatrix}$$

is a submatrix of any canonical representation. The matrix $S$ is clearly of rank $k$, and thus, by Claim 2.3 any two subspaces with different canonical representation are different.

Therefore, when constructing a subspace $Z$, with $\dim(Z \cap U) = d$ and $\dim(Z \cap W) = 0$, the freedom in exactly in the entries marked with "?" in Figure 4.2. Since there are $p$ possibilities for every such entry, and the number of such entries is $(k \cdot \ell) + (\ell \cdot d) = \ell(k + d)$, we conclude that $H_k(\ell, d) = p^{\ell(k+d)}$. □

Since the characteristic of $F$ is different than $p$, every power of $p$ is nonzero over $F$. Therefore, as argued above, we proved that $H_k$ has full rank over $F$, and the theorem follows. □

In Corollary 2.4 we proved that $v_k^{2k}(p) \geq p^{k^2}$. Since $M_{\text{ZI}_k}$ is a $v_k^{2k}(p) \times v_k^{2k}(p)$ matrix, $\text{rank}_F(M_{\text{ZI}_k}) \geq p^{k^2}$.

**4.2. A small 1-mod-$p$ cover for the zeros of $M_{\text{ZI}}$.** To apply Theorem 3.4 to an explicit matrix, we need this matrix to have a small monochromatic 1-mod-$p$ cover. We next show that there is a small 1-mod-$p$ cover for the 0's of $M_{\text{ZI}}$. We do not know if there exists a small 1-mod-$p$ cover for the 1's of $M_{\text{ZI}}$. Thus, we are not able to use $M_{\text{ZI}}$ directly, and we use it in section 4.3 to build the matrix $M_{\text{LZI}}$, which has a small 1-mod-$p$ cover for both the 1's and the 0's.

To gain some insight into the cover of $M_{\text{LZI}}$ we show a 1-mod-$p$ cover for the 0's of $M_{\text{ZI}}$ of size less than $p^{2k}$. This should be compared to the number of rows in

$M_{\mathrm{ZI}}$, which is $p^{\Theta(k^2)}$. Define the cover $\mathcal{R}$ as follows: Let $\vec{v} \in GF(p)^{2k}$ be a vector with a leading 1; that is, the first nonzero coordinate of $\vec{v}$ is 1. We add the rectangle $R_{\vec{v}} = X_{\vec{v}} \times Y_{\vec{v}}$ to the cover $\mathcal{R}$, where

$$X_{\vec{v}} = \left\{U \in V_k^{2k}(p) : \vec{v} \in U\right\} \text{ and } Y_{\vec{v}} = \left\{W \in V_k^{2k}(p) : \vec{v} \in W\right\}.$$

That is, $R_{\vec{v}}$ contains the rows and columns of $M_{\mathrm{ZI}}$ labeled by subspaces that contain the vector $\vec{v}$. The rectangle $R_{\vec{v}}$ is a 0-rectangle, since for each $U \in X_{\vec{v}}$ and $W \in Y_{\vec{v}}$ it holds that $\vec{v} \in U \cap W$, hence $\dim(U \cap W) \neq 0$, and thus $\mathrm{ZI}(U, W) = 0$. We claim $\mathcal{R}$ is a 1-mod-$p$ cover of the 0's of $M_{\mathrm{ZI}}$. Let $\langle U, W\rangle$ be an entry of $M_{\mathrm{ZI}}$ such that $\mathrm{ZI}(U, W) = 0$. Then $\dim(U \cap W) > 0$. Therefore, the entry $\langle U, W\rangle$ is covered by any rectangle $R_{\vec{v}}$ such that $\vec{v} \in U \cap W$, and $\vec{v}$ has a leading 1. Since $U \cap W$ is a linear subspace of $GF(p)^{2k}$, it has $\frac{p^\ell - 1}{p-1}$ vectors with a leading 1, where $\ell = \dim(U \cap W) \geq 1$. Since $\frac{p^\ell-1}{p-1} \equiv \frac{-1}{-1} \equiv 1 \pmod{p}$, the number of rectangles covering the entry $\langle U, W\rangle$ is equivalent to 1 modulo $p$. Since there are $\frac{p^{2k}-1}{p-1}$ different vectors with a leading 1 in $\mathrm{GF}(p)^{2k}$, the size of the 0-cover is $\frac{p^{2k}-1}{p-1}$.

**4.3. The list version of the zero intersection function.** To get a matrix with a high rank over fields with characteristic different than $p$, and a small monochromatic 1-mod-$p$ cover, we define the function LZI, the list version of the ZI function. The idea of using the list version of functions has been used in communication complexity [21] (see, e.g., [20]). Define $\mathrm{LZI}_k^p : (V_k^{2k}(p))^k \times (V_k^{2k}(p))^k \to \{0, 1\}$ as follows:

$$\mathrm{LZI}_k^p(\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle) = 1 \iff \exists i \in \{1 \ldots k\} \text{ such that } \mathrm{ZI}_k^p(A_i, B_i) = 1.$$

That is, $\mathrm{LZI}_k^p$ gets $k$ instances of $\mathrm{ZI}_k^p$, and outputs the value 1 if and only if $\mathrm{ZI}_k^p$ outputs 1 on at least one of the given instances. The matrix $M_{\mathrm{LZI}}$, representing LZI, is defined in a similar way to $M_{\mathrm{ZI}}$. The next two lemmas show that $M_{\mathrm{LZI}}$ has a small 1-mod-$p$ cover.

LEMMA 4.5. *There is a monochromatic* 1-mod-$p$ *cover of the* 0*'s of* $M_{\mathrm{LZI}}$ *of size smaller than* $p^{2k^2}$.

*Proof.* We build the 0-cover $\mathcal{R}_0$ of the 0's of $M_{\mathrm{LZI}}$ in a similar way to the 0-cover for $M_{\mathrm{ZI}}$ built in section 4.2. Let $\langle \vec{v}_1, \ldots, \vec{v}_k\rangle \in (\mathrm{GF}(p)^{2k})^k$ be a tuple of $k$ vectors from $\mathrm{GF}(p)^{2k}$, each with a leading 1. The rectangle in $\mathcal{R}_0$ corresponding to $\langle \vec{v}_1, \ldots, \vec{v}_k\rangle$ is $R = X \times Y$, where

$$X = \{\langle A_1, \ldots, A_k\rangle \in (V_k^{2k}(p))^k : \vec{v}_i \in A_i \text{ for each } i \in [k]\}, \text{ and}$$
$$Y = \{\langle B_1, \ldots, B_k\rangle \in (V_k^{2k}(p))^k : \vec{v}_i \in B_i \text{ for each } i \in [k]\}.$$

First we show $R$ is a 0-rectangle. If $\langle A_1, \ldots, A_k\rangle \in X$ and $\langle B_1, \ldots, B_k\rangle \in Y$, then $\vec{v}_i \in A_i \cap B_i$ for every $i \in [k]$, and thus $\mathrm{ZI}(A_i, B_i) = 0$ for every $i \in [k]$. Therefore, $\mathrm{LZI}(\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle) = 0$.

Next we show that for every 0-entry of $M_{\mathrm{LZI}}$, the number of rectangles covering it is equivalent to 1 modulo $p$. Let $\langle\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle\rangle \in (V_k^{2k}(p))^k \times (V_k^{2k}(p))^k$ such that $\mathrm{LZI}(\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle) = 0$. The entry $\langle\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle\rangle$ is covered by any rectangle associated with a tuple of $k$ nonzero vectors $\langle \vec{v}_1, \ldots, \vec{v}_k\rangle$, such that $\vec{v}_i \in A_i \cap B_i$, for every $i \in [k]$, and has a leading 1. Since $A_i \cap B_i$ is a linear subspace, the number of vectors with a leading 1 in $A_i \cap B_i$ is $\frac{p^{\ell_i}-1}{p-1}$, where $\ell_i = \dim(A_i \cap B_i) \geq 1$. Thus, the number of rectangles covering $\langle\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle\rangle$ is a product of numbers that are equivalent to 1 modulo $p$, and therefore is equivalent to 1 modulo $p$ itself.

The number of 0-rectangles in $\mathcal{R}_0$ is the number of tuples of $k$ vectors with a leading 1 from $\mathrm{GF}(p)^{2k}$, that is, $(\frac{p^{2k}-1}{p-1})^k < p^{2k^2}$. (This is much smaller than the number of rows in $M_{\mathrm{LZI}}$, which is $p^{\Omega(k^3)}$.) $\square$

Now we show a cover $\mathcal{R}_1$ for the 1's of $M_{\mathrm{LZI}}$. The natural way to do this is to associate a rectangle $R = X \times Y$ with each pair $\langle i, U\rangle$, such that $i \in [k]$, and $U \in V_k^{2k}(p)$, where

$$X = \left\{\langle A_1, \ldots, A_k\rangle \in (V_k^{2k}(p))^k : A_i = U\right\} \text{ and}$$

$$Y = \left\{\langle B_1, \ldots, B_k\rangle \in (V_k^{2k}(p))^k : \dim(U \cap B_i) = 0\right\}.$$

That is, any input pair having $ZI(A_i, B_i) = 1$ in the $i$th instance will be covered by the rectangle associated with $i$ and $A_i$.

The problem with this choice of $\mathcal{R}_1$ is that it is not a 1-mod-$p$ cover. For example, if $\langle A_1, \ldots, A_k\rangle$ and $\langle B_1, \ldots, B_k\rangle$ have exactly $p$ instances $\langle A_i, B_i\rangle$ such that $\mathrm{ZI}(A_i, B_i) = 1$, then the number of rectangles covering the entry

$$\langle\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle\rangle$$

will be equivalent to 0 modulo $p$. To solve this problem, we require $i$ to be the index of the *first* instance of ZI such that $\mathrm{ZI}(A_i, B_i) = 1$.

LEMMA 4.6. *There is a monochromatic* 1-mod-$p$ *cover for the* 1*'s of* $M_{\mathrm{LZI}}$ *of size smaller than* $p^{4k^2}$.[8]

*Proof.* Associate a rectangle $R = X \times Y$ with any pair $\langle\langle \vec{v}_1, \ldots, \vec{v}_{i-1}\rangle, U\rangle$, where $\langle \vec{v}_1, \ldots, \vec{v}_{i-1}\rangle$ is a tuple of $i-1$ vectors with a leading 1 from $\mathrm{GF}(p)^{2k}$, where $1 \le i \le k$, and $U \in V_k^{2k}(p)$ is a subspace. The sets $X$ and $Y$ are defined as follows:

$$X = \{\langle A_1, \ldots, A_k\rangle \in (V_k^{2k}(p))^k : \vec{v}_j \in A_j \text{ for each } j \in [i-1] \text{ and } A_i = U\} \text{ and}$$
$$Y = \{\langle B_1, \ldots, B_k\rangle \in (V_k^{2k}(p))^k : \vec{v}_j \in B_j \text{ for each } j \in [i-1] \text{ and } \dim(B_i \cap U) = 0\}.$$

To see that $R$ is a 1-rectangle, take $\langle A_1, \ldots, A_k\rangle \in X$ and $\langle B_1, \ldots, B_k\rangle \in Y$. Then, $\dim(A_i \cap B_i) = \dim(U \cap B_i) = 0$, and thus $\mathrm{ZI}(A_i, B_i) = 1$. Therefore, $\mathrm{LZI}(\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle) = 1$.

We next show that for every 1-entry of $M_{\mathrm{LZI}}$, the number of rectangles covering it is equivalent to 1 modulo $p$. Let $\langle\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle\rangle \in (V_k^{2k}(p))^k \times (V_k^{2k}(p))^k$ such that $\mathrm{LZI}(\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle) = 1$. Let $i$ be the smallest index such that $\dim(A_i \cap B_i) = 0$. Then the entry $\langle\langle A_1, \ldots, A_k\rangle, \langle B_1, \ldots, B_k\rangle\rangle$ is covered by a rectangle if and only if it is associated with a pair $\langle\langle \vec{v}_1, \ldots, \vec{v}_{i-1}\rangle, A_i\rangle$ such that $\vec{v}_j \in A_j \cap B_j$ for every $j \in \{1, \ldots, i-1\}$. Since the number of vectors with a leading 1 in $A_j \cap B_j$ for every $j \in [i]$ is equivalent to 1 modulo $p$, the number of such rectangles is equivalent to 1 modulo $p$ as well.

The size of $\mathcal{R}_1$ is smaller than the number of ways to choose $k$ vectors with a leading 1 from $\mathrm{GF}(p)^{2k}$, and a subspace from $V_k^{2k}(p)$, and thus is smaller than $p^{2k^2} \cdot v_k^{2k}(p) < p^{4k^2}$. $\square$

By taking the union of the 0-cover from Lemma 4.5 and the 1-cover from Lemma 4.6, we get the following corollary.

[8]It may seem that this number is too big, but this should be compared to the dimensions of $M_{LZI}$, which is $p^{\Omega(k^3)}$.

COROLLARY 4.7. *$M_{\text{LZI}}$ has a monochromatic* 1-mod-*p cover of size smaller than* $p^{5k^2}$.

We proved in Theorem 4.1 that $\operatorname{rank}_F(M_{\text{ZI}_k}) \geq p^{k^2}$. We use this to analyze the rank of $M_{\text{LZI}_k}$ over $F$. Let $A$ be an $m \times n$ matrix and $B$ be an $r \times s$ matrix. Then the *Kronecker product* of $A$ and $B$, denoted $A \otimes B$, is an $mr \times ns$ matrix formed by multiplying each element of $A$ by the entire matrix $B$ and putting it in the place of the element of $A$. For any field $F$, for every two matrices $A$ and $B$, it holds that $\operatorname{rank}_F(A \otimes B) = \operatorname{rank}_F(A) \operatorname{rank}_F(A)$. This property of the Kronecker product, together with the De Morgan laws, implies the following lemma.

LEMMA 4.8. *Let $k$ be a positive integer and let $p$ be a prime. Then*

$$\operatorname{rank}_F(M_{\text{LZI}_k^p}) = p^{\Omega(k^3)}.$$

We are ready to prove our main result.

THEOREM 4.9 (main result). *Let $p$ be a fixed prime. Then there exists a family of functions $\{f_n\}_{n\in\mathcal{N}}$ such that $\text{mSP}_{\text{GF}(p)}(f_n) = n$ and, for every field $F$ with characteristic different than $p$, it holds that $\text{mSP}_F(f_n) = n^{\Omega(\sqrt{\log n})}$.*

*Proof.* For a positive number $k$, denote by $n_k$ the size of the monochromatic 1-mod-$p$ cover for $M_{\text{LZI}}$ given by Corollary 4.7. We first show $f_n$ for each $n$ of the form $n = n_k$ for some positive $k$. According to Corollary 4.7, $M_{\text{LZI}_k}$ has a monochromatic 1-mod-$p$ cover of size $n$, which is smaller than $p^{5k^2}$. According to Lemma 4.8, we have that $\operatorname{rank}_F(M_{\text{LZI}_k}) = p^{\Omega(k^3)}$. In terms of $n$, we have

$$n^{\sqrt{\log_p n}} \leq (p^{5k^2})^{\sqrt{\log_p (p^{5k^2})}} = (p^{5k^2})^{\sqrt{5k^2}}.$$

By Theorem 3.4, there is a function $f_n$ in $n$ variables such that $\text{mSP}_{\text{GF}(p)}(f) = n$ and $\text{mSP}_F(f) \geq p^{\Omega(k^3)} = n^{\Omega(\sqrt{\log n})}$. The last equality holds since $p$ is a constant. By padding arguments, we find that the result holds for every value of $n$. ◻

## 5. A superpolynomial lower bound for a function in uniform-$\mathcal{NC}^2$.

In this section we show a monotone function that is computable by uniform-$\mathcal{NC}^2$ circuits and does not have a polynomial size monotone span program over any field.[9] For comparison, all the previous superpolynomial lower bounds were proved for functions not known to be in $\mathcal{P}$.

Denote by $f^2 = \{f_n^2\}_{n\in\mathcal{N}}$ and $f^3 = \{f_n^3\}_{n\in\mathcal{N}}$ the families of functions given by Theorem 4.9 for $p = 2$ and $p = 3$, respectively. Define the family of functions $f = \{f_{2n}\}_{n\in\mathcal{N}}$ as $f_{2n}(x_1, \ldots, x_n, y_1, \ldots, y_n) = f_n^2(x_1, \ldots, x_n) \wedge f_n^3(y_1, \ldots, y_n)$.

We show a uniform-$\mathcal{NC}^2$ family of circuits for $f$. Let $\widehat{P_2}$ be the monotone span program over GF(2) that computes $f^2$. Recall that $\text{size}(\widehat{P_2}) = n$. As mentioned in section 2, we can assume w.l.o.g. that the number of columns in $\widehat{P_2}$ is not larger than the number of rows, which is $n$. Therefore, since linear algebra over fixed finite fields is in log-space uniform-$\mathcal{NC}^2$ [7, 22, 10, 19], there exists an $\mathcal{NC}^2$ circuit $C_2$ that computes $f^2$. Similarly, there exists an $\mathcal{NC}^2$ circuit $C_3$ that computes $f^3$. Thus, the $\mathcal{NC}^2$ circuit $C = C_2 \wedge C_3$ computes $f$.

The problem with the circuit $C$, as described, is that it is not uniform. The mere *existence* of a monotone span program with a small number of columns does not yield a uniform-$\mathcal{NC}^2$ circuit. To get uniform circuits we have to show an *explicit*

[9]In this paper, *uniform* means log-space uniform.

monotone span program with a small number of columns that can be generated in space $O(\log n)$. We do this in section 5.1.

We next show that $f$ has no small monotone span program over any field. Assume there is a polynomial size monotone span program $\widehat{Q}$ that computes $f$ over some field $F$. Let $c$ be the characteristic of $F$. If $c \neq 2$, then the restriction of $\widehat{Q}$ to inputs of the form $x_1, \ldots, x_n \cdot 1^n$ gives a new monotone span program $\widehat{Q}_2$ of polynomial size over $F$ that computes $f^2$ (as any restriction of a function with a small monotone span program has a small monotone span program [19]), contradicting the fact that $f^2$ has no polynomial size monotone span program over fields with characteristic different than 2. If $c = 2$, then $c \neq 3$ and we get the contradiction for $f^3$ in a similar way. Thus, we have the following theorem.

THEOREM 5.1. *There exists a family of monotone functions* $\{f_n\}_{n\in\mathcal{N}}$ *that is computable by a uniform-*$\mathcal{NC}^2$ *family of circuits having* $\mathrm{mSP}_F(f_n) = n^{\Omega(\sqrt{\log n})}$ *for every field* $F$.

**5.1. Reducing the number of columns.** In Theorem 4.9 we introduced a function $f_{\widehat{P}}$ such that $\mathrm{mSP}_{\mathrm{GF}(p)}(f_n) = n$ and $\mathrm{mSP}_F(f_n) = n^{\Omega(\sqrt{\log n})}$. In this section we want to construct a family of uniform-$\mathcal{NC}^2$ circuits for a function that accepts Acc and rejects Rej.

It is known that any function that has a polynomial size monotone span program has a family of $\mathcal{NC}^2$ circuits. Since any monotone span program with $m$ rows that computes a function $f$ has an equivalent monotone span program with no more than $m$ columns, we can deduce the existence of a family of $\mathcal{NC}^2$ circuits that computes $f$. However, we want a uniform family of circuits. Since any transformation from a monotone span program with an arbitrary number of columns to an equivalent program with a smaller number of columns has to go over all the columns of the large original program, we cannot use the generic span program for $f_{\widehat{P}}$, as presented in section 3.4. In this section we show a monotone span program, with a linear number of both rows and columns, that accepts Acc and rejects Rej. We show that the span program can be generated in space $O(\log n)$, and we ensure the uniformity of the $\mathcal{NC}^2$ circuits.

Let $\mathcal{R}_{\mathrm{LZI}}$ be the monochromatic 1-mod-$p$ cover of $M_{\mathrm{LZI}}$ described in Corollary 4.7, and consider the following monotone span program $\widehat{S}$:[10] The program $\widehat{S}$ has a column for each $k$-tuple $\langle \vec{v}_1, \ldots, \vec{v}_k \rangle \in (\mathrm{GF}(p)^{2k})^k$, where each $\vec{v}_i$ is a vector with a leading 1 from $\mathrm{GF}(p)^{2k}$. Thus, the number of columns in $\widehat{S}$ is smaller than the number of rectangles in $\mathcal{R}_{\mathrm{LZI}}$, and hence is linear in the number of variables. Intuitively, the columns of $\widehat{S}$ form a basis of the columns of the program $\widehat{P}$ from section 4.

Recall that in $\mathcal{R}_{\mathrm{LZI}}$ there are two types of rectangles as follows:

- **0-rectangles.** We associated a 0-rectangle with every $k$-tuple of vectors $\langle \vec{v}_1, \ldots, \vec{v}_k \rangle \in (\mathrm{GF}(p)^{2k})^k$, each with a leading 1.
- **1-rectangles.** We associated a 1-rectangle $R = X \times Y$ with any pair $\langle \langle \vec{v}_1, \ldots, \vec{v}_{i-1} \rangle, U \rangle$ such that $\langle \vec{v}_1, \ldots, \vec{v}_{i-1} \rangle$ is a tuple of $i-1$ vectors with a leading 1 from $\mathrm{GF}(p)^{2k}$, where $1 \leq i \leq k$, and $U \in V_k^{2k}(p)$ is a subspace.

Every rectangle is assigned a row in $\widehat{S}$. Let $R$ be a rectangle in $\mathcal{R}_{\mathrm{LZI}}$, and let $c$ be a column in $\widehat{S}$ labeled with the tuple $\langle \vec{v}_1, \ldots, \vec{v}_k \rangle$. Then the value of the entry $\widehat{S}[R, c]$ is defined as follows:

[10]We do not know if the function computed by the monotone span program $\widehat{S}$ is the same as the function from Theorem 4.9.

- For a 0-rectangle $R$, let $\langle \vec{u}_1, \ldots, \vec{u}_k \rangle$ be the $k$-tuple of vectors associated with $R$. We set $\widehat{S}[R, c] = 1$ if $\vec{u}_j = \vec{v}_j$ for every $j \in [k]$. Otherwise, $\widehat{S}[R, c] = 0$.
- For a 1-rectangle $R$, let $\langle \langle \vec{u}_1, \ldots, \vec{u}_{i-1} \rangle, U_i \rangle$ be the $(i-1)$-tuple of vectors and the subspace associated with $R$. In this case set $\widehat{S}[R, c] = 1$ if $\vec{u}_j = \vec{v}_j$ for every $j \in [i-1]$ and $v_i \notin U_i$. Otherwise $\widehat{S}[R, c] = 0$.

By putting the rows corresponding to 0-rectangles in the upper part of $\widehat{S}$, the upper block of $\widehat{S}$ is in fact the unit matrix $I$. To compute an entry in the lower part of $\widehat{S}$, we need only check if a vector in $\mathrm{GF}(p)^{2k}$ belongs to a subspace, where $k = O(\sqrt{\log n})$. This can be easily done in space $O(\log n)$. Thus, $\widehat{S}$ can be generated in log-space. To construct a circuit that simulates the span program, we need a circuit that tests the rank of a matrix over $\mathrm{GF}(p)$. This can also be done in space $O(\log n)$ [7, 22, 10, 19]. We next prove that the function computed by $\widehat{S}$ can be used for obtaining our lower bounds. That is, the program $\widehat{S}$ accepts every $\vec{z}_x \in \mathrm{Acc}$ and rejects every $\vec{w}_y \in \mathrm{Rej}$. This fact is proved in the following two claims.

CLAIM 5.2. *The program $\widehat{S}$ accepts every $\vec{z}_x \in$* Acc.

*Proof.* Let $\vec{z}_x \in \mathrm{Acc}$. Throughout the proof we view the characteristic vector $\vec{z}_x$ as the set of rectangles it represents. We show that the vector $\vec{1}$ is the sum of the rows labeled by rectangles $R \in \vec{z}_x$, where the computations are done over $\mathrm{GF}(p)$.

Since $\vec{z}_x \in \mathrm{Acc}$, it is the characteristic vector of the set of all the rectangles in $\mathcal{R}_{\mathrm{LZI}}$ covering the row $x$ of $M_{\mathrm{LZI}}$. Let $\langle X_1, \ldots, X_k \rangle$ be the $k$-tuple of subspaces from $V_k^{2k}$ labeling the row $x$ in $M_{\mathrm{LZI}}$. Then the rectangles in $\vec{z}_x$ are of the following two types:

(i) 0-rectangles, labeled by $\langle \vec{x}_1, \ldots, \vec{x}_k \rangle$, where $\vec{x}_j \in X_j$ for every $j \in [k]$.

(ii) 1-rectangles, labeled by $\langle \langle \vec{x}_1, \ldots, \vec{x}_{i-1} \rangle, X_i \rangle$, where $\vec{x}_j \in X_j$ for every $j \in [i-1]$.

Let $c$ be a column in $\widehat{S}$. Assume that $c$ is labeled by $\langle \vec{v}_1, \ldots, \vec{v}_k \rangle$. We show that the sum of the rows labeled by rectangles from $\vec{z}_x$ in the column $c$ is 1. More specifically, we show that there is exactly one row labeled by $\vec{z}_x$ that is 1 in the column $c$. We consider the following two different cases:

(i) $\vec{v}_j \in X_j$ for every $j \in [k]$. We divide the rectangles in $\vec{z}_x$ into three as follows:

1. The unique 0-rectangle $R \in \vec{z}_x$ labeled by $\langle \vec{v}_1, \ldots, \vec{v}_k \rangle$. According to the definition of $\widehat{S}$, we have $\widehat{S}[R, c] = 1$.
2. Other 0-rectangles. Since the upper block of $\widehat{S}$ is the unit matrix $I$, we have $\widehat{S}[R, c] = 0$ for any such rectangle.
3. 1-rectangles. If $R$ is a 1-rectangle labeled by $\langle \langle \vec{x}_1, \ldots, \vec{x}_{i-1} \rangle, X_i \rangle$, then we have that $\widehat{S}[R, c] = 0$ since $\vec{v}_i \in X_i$.

Thus, there is exactly one rectangle $R \in \vec{z}_x$ such that $\widehat{S}[R, c] = 1$, and hence the sum of the rows labeled by rectangles from $\vec{z}_x$, in the column $c$ is 1.

(ii) If case (i) does not hold, there exists an index $\ell \in [k]$ such that $\vec{v}_j \in X_j$ for every $j \in [\ell - 1]$ and $\vec{v}_\ell \notin X_\ell$. In this case, for every 0-rectangle $R \in \vec{z}_x$, it holds that $\widehat{S}[R, c] = 0$, since for every such rectangle $\vec{x}_\ell \in X_\ell$, while $\vec{v}_\ell \notin X_\ell$, and thus $\vec{x}_\ell \neq \vec{v}_\ell$. Let $R \in \vec{z}_x$ be a 1-rectangle labeled by $\langle \langle \vec{x}_1, \ldots, \vec{x}_{i-1} \rangle, X_i \rangle$, for some $i \in [k]$, where $\vec{x}_j \in X_j$ for every $j \in [i-1]$. We have to check three cases.

*Case* I. $i < \ell$. In this case $\vec{v}_i \in X_i$, because $i \in [\ell - 1]$, and thus $\widehat{S}[R, c] = 0$.

*Case* II. $i > \ell$. In this case $\vec{x}_\ell \in X_\ell$, since $\ell \in [i-1]$. On the other hand, $\vec{v}_\ell \notin X_\ell$, and thus $\vec{v}_\ell \neq \vec{x}_\ell$, with $\ell \in [i-1]$, and so $\widehat{S}[R, c] = 0$.

*Case* III. $i = \ell$. In this case the only rectangle $R \in \vec{z}_x$ satisfying $\widehat{S}[R, c] = 1$ is the rectangle labeled by $\langle\langle\vec{v}_1, \ldots, \vec{v}_{i-1}\rangle, X_i\rangle$.

Therefore, again there is exactly one rectangle $R \in \vec{z}_x$ such that $\widehat{S}[R, c] = 1$, and the sum of the rows labeled by rectangles from $\vec{z}_x$, in the column $c$ is 1. Thus, $\widehat{S}$ accepts Acc. □

It is left to prove that $\widehat{S}$ rejects Rej. This part is a little more complicated than the generic case discussed in Lemma 3.3.

CLAIM 5.3. *The program* $\widehat{S}$ *rejects every* $\vec{w}_y \in \text{Rej}$.

*Proof.* Let $\vec{w}_y \in \text{Rej}$. Throughout the proof we view the characteristic vector $\vec{w}_y$ as the set of rectangles it represents. Then there exists a column labeled by $\langle Y_1, \ldots, Y_k\rangle$ in $M_{\text{LZI}}$, such that $\vec{w}_y$ is the set of all the rectangles in $\mathcal{R}_{\text{LZI}}$ that *do not* cover this column. The rectangles in $\vec{w}_y$, i.e., rectangles not covering the column labeled by $\langle Y_1, \ldots, Y_k\rangle$, are of the following types:

- **0-rectangles.** If $R$ is a 0-rectangle labeled by $\langle\vec{x}_1, \ldots, \vec{x}_k\rangle$ not covering the column $\langle Y_1, \ldots, Y_k\rangle$, then there exist an index $i \in [k]$ such that $\vec{x}_i \notin Y_i$.
- **1-rectangles.** If $R$ is a 1-rectangle labeled by $\langle\langle\vec{x}_1, \ldots, \vec{x}_{i-1}\rangle, X_i\rangle$ and not covering $\langle Y_1, \ldots, Y_k\rangle$, then either there exists an index $j \in [i-1]$ such that $\vec{x}_j \notin Y_j$ or $\dim(X_i \cap Y_i) > 0$.

Assume toward contradiction that the vector $\vec{1}$ is a linear combination of the rows labeled by rectangles from $\vec{w}_y$. Denote by $C_y$ the set of columns of $\widehat{S}$, labeled by a $k$-tuple of vectors $\langle\vec{y}_1, \ldots, \vec{y}_k\rangle$ such that $\vec{y}_i \in Y_i$, and $\vec{y}_i$ has a leading 1 for every $i \in [k]$. We will use the submatrix of $\widehat{S}$ defined by the rows of $\vec{w}_y$ and the columns $C_y$ to contradict the existence of the above linear combination. We claim that for every $R \in \vec{w}_y$, the sum of the entries in the row labeled by $R$, over the columns in $C_y$, is 0. See the following claim.

CLAIM 5.4. *For every* $R \in \vec{w}_y$,

$$\sum_{c \in C_y} \widehat{S}[R, c] = 0.$$

*Proof.* If $R \in \vec{w}_y$ is a 0-rectangle labeled by $\langle\vec{x}_1, \ldots, \vec{x}_k\rangle$, and $c$ is a column in $C_y$ labeled by $\langle\vec{y}_1, \ldots, \vec{y}_k\rangle$, then there is an index $i \in [k]$ such that $\vec{x}_i \notin Y_i$, and since $\vec{y}_j \in Y_j$ for every $j \in [k]$, we get that $\vec{x}_i \neq \vec{y}_i$ and thus $\widehat{S}[R, c] = 0$. Therefore, $\sum_{c \in C_y} \widehat{S}[R, c] = 0$.

If $R \in \vec{w}_y$ is a 1-rectangle labeled by $\langle\langle\vec{x}_1, \ldots, \vec{x}_{i-1}\rangle, X_i\rangle$, then either there exists an index $j \in [i-1]$ such that $\vec{x}_j \notin Y_j$ or $\dim(X_i \cap Y_i) > 0$. If the former is true, then for every column $c \in C_y$ labeled by $\langle\vec{y}_1, \ldots, \vec{y}_k\rangle$ we have $\vec{x}_j \notin Y_j$ and $\vec{y}_j \in Y_j$, and thus $\vec{x}_j \neq \vec{y}_j$. Since $j \in [i-1]$, this leads to $\widehat{S}[R, c] = 0$.

The only case left to discuss is that when $R \in \vec{w}_y$ is a 1-rectangle labeled by $\langle\langle\vec{x}_1, \ldots, \vec{x}_{i-1}\rangle, X_i\rangle$, such that $\vec{x}_j \in Y_j$ for every $j \in [i-1]$, and $\dim(X_i \cap Y_i) \neq 0$. We get that $\widehat{S}[R, c] = 1$ for every column $c \in C_y$ labeled by

$$\langle\vec{x}_1, \ldots, \vec{x}_{i-1}, \vec{y}_i, \ldots, \vec{y}_k\rangle,$$

where $\vec{y}_i \notin X_i$. The number of choices for a vector $\vec{y}_i$ with a leading 1 such that $\vec{y}_i \in Y_i$ and $\vec{y}_i \notin X_i$ is the number of vectors with a leading 1 in the set $Y_i \backslash X_i = Y_i \backslash (Y_i \cap X_i)$. Since both $Y_i$ and $Y_i \cap X_i$ are linear subspaces, the number of vectors with a leading 1 is equivalent to 1 modulo $p$ in both of them. Thus the number of choices for such $\vec{y}_i$ is equivalent to 0 modulo $p$. To get the number of columns $c \in C_y$ such that $\widehat{S}[R, c] = 1$, we have to multiply the number of ways to choose $\vec{y}_i$ by the number of ways to choose $\vec{y}_{i+1}, \dots, \vec{y}_k$, but the result is still equivalent to 0 modulo $p$. ∎

The number of columns in $C_y$ is the product of the number of vectors with a leading 1 in $Y_i$ for $i \in [k]$. Since each such number is 1 modulo $p$, the number of columns in $C_y$ is equivalent to 1 modulo $p$.

Recall that we assumed $\vec{1}$ is a linear combination of the rows corresponding to the rectangles in $\vec{w}_y$. Therefore, we can write

$$\sum_{R \in \vec{w}_y} \alpha_R \cdot \widehat{S}_R = \vec{1},$$

where for each $R \in \vec{w}_y$ the constant $\alpha_R$ is in GF($p$), and $\widehat{S}_R$ is the row in $\widehat{S}$ corresponding to $R$. We compute the sum

$$\sum_{R \in \vec{w}_y} \alpha_R \sum_{c \in C_y} \widehat{S}[R, c]$$

in two different ways. Since for every column $c$ it holds that

$$\sum_{R \in \vec{w}_y} \alpha_R \widehat{S}[R, c] = 1,$$

we get

$$\sum_{R \in \vec{w}_y} \alpha_R \sum_{c \in C_y} \widehat{S}[R, c] = \sum_{c \in C_y} \sum_{R \in \vec{w}_y} \alpha_R \widehat{S}[R, c] = \sum_{c \in C_y} 1 = |C_y| = 1 \bmod p.$$

On the other hand, according to Claim 5.4, the sum over any row $R \in \vec{w}_y$ of the entries in the columns of $C_y$ is equivalent to 0 modulo $p$, and we get that

$$\sum_{R \in \vec{w}_y} \alpha_R \sum_{c \in C_y} \widehat{S}[R, c] = \sum_{R \in \vec{w}_y} \alpha_R \cdot 0 = 0 \bmod p,$$

a contradiction. Thus $\vec{1}$ is not a linear combination of the rows of $\widehat{S}$ labeled by $\vec{w}_y$, and hence $\widehat{S}$ rejects $\vec{w}_y$. ∎

**5.2. Span programs and secret sharing schemes.** Secret sharing schemes, introduced by Blakley [8], Shamir [26], and Ito, Saito, and Nishizeki [16, 17], are a cryptographic tool allowing a dealer to share a secret between a set of parties such that only some predefined authorized subsets of parties can reconstruct the secret from their shares. The reader is referred to [27] and [29] for a more formal and detailed discussion on secret sharing schemes.

The authorized sets in a secret sharing scheme are described by a monotone Boolean function $f : \{0,1\}^n \to \{0,1\}$, where $n$ is the number of parties and the authorized subsets are the subsets with their characteristic vectors in $f^{-1}(1)$. Most of the known secret sharing schemes are linear schemes, that is, schemes in which the shares are a linear combination of the secret and some random field elements. Linear schemes are equivalent to monotone span programs, where the total size of the shares is the size of the corresponding monotone span program. Beimel and Ishai [4] showed functions that, under plausible assumptions, have no efficient linear secret sharing scheme but yet have an efficient nonlinear secret sharing scheme. However, prior to this work, no secret sharing schemes were proved more powerful than linear schemes, without any assumptions.

A quasi-linear secret sharing scheme [4] is obtained by composing linear secret sharing schemes, possibly over different fields. Beimel and Ishai [4] have shown that under the assumption that the power of monotone span programs over different fields is incomparable, quasi-linear schemes are superpolynomially stronger than linear schemes. Their proof is very similar to the proof of Theorem 5.1. That is, the functions described in Theorem 5.1 have, by definition, a small quasi-linear secret sharing scheme but cannot have a small linear scheme.

THEOREM 5.5. *There is an explicit family of functions* $\{f_n\}_{n\in\mathcal{N}}$ *such that the complexity of every linear secret sharing scheme for the family is* $n^{\Omega(\sqrt{\log n})}$*, and yet the family has a polynomial quasi-linear secret sharing scheme.*

# EFFICIENCY OF OBLIVIOUS VERSUS NONOBLIVIOUS SCHEDULERS FOR OPTIMISTIC, RATE-BASED FLOW CONTROL*

PANAGIOTA FATOUROU†, MARIOS MAVRONICOLAS‡, AND PAUL SPIRAKIS§

**Abstract.** Two important performance parameters of distributed, *rate-based flow control algorithms* are their *locality* and *convergence complexity.* The former is characterized by the amount of global knowledge that is available to their scheduling mechanisms, while the latter is defined as the number of *update operations* performed on rates of individual *sessions* until *max-min fairness* is reached. *Optimistic* algorithms allow any *session* to intermediately receive a rate larger than its max-min fair rate; *bottleneck* algorithms finalize the rate of a session only if it is restricted by a certain, highly congested link of the network. In this work, we present a comprehensive collection of lower and upper bounds on convergence complexity, under varying degrees of locality, for optimistic, bottleneck, rate-based flow control algorithms.

Say that an algorithm is *oblivious* if its scheduling mechanism uses no information of either the session rates or the network topology. We present a novel, combinatorial construction of a capacitated network, which we use to establish a fundamental lower bound of $\frac{dn}{4} + \frac{n}{2}$ on the convergence complexity of *any* oblivious algorithm, where $n$ is the number of sessions laid out on a network, and $d$, the *session dependency*, is a measure of topological dependencies among sessions. Moreover, we devise a novel *simulation proof* to establish that, perhaps surprisingly, the lower bound of $\frac{dn}{4} + \frac{n}{2}$ on convergence complexity still holds for any *partially oblivious* algorithm, in which the scheduling mechanism is allowed to use information about session rates, but is otherwise unaware of network topology.

On the positive side, we prove that the lower bounds for oblivious and partially oblivious algorithms are both *tight.* We do so by presenting *optimal* oblivious algorithms, which converge after $\frac{dn}{2} + \frac{n}{2}$ update operations are performed in the *worst* case. To complete the picture, we show that *linear* convergence complexity can indeed be achieved if information about both session rates and network topology is available to schedulers. We present a counterexample, *nonoblivious* algorithm, which converges within an *optimal* number of $n$ update operations.

Our results imply a surprising convergence complexity collapse of oblivious and partially oblivious algorithms, and a convergence complexity separation between (partially) oblivious and nonoblivious algorithms for optimistic, bottleneck rate-based flow control.

**Key words.** distributed algorithms; lower bounds; rate-based flow control; max-min fairness; convergence complexity; oblivious, partially oblivious, and nonoblivious algorithms; bottleneck algorithms

## 1. Introduction.

In many modern *communication networks*, a connection between different users is established by a *session*, a virtual circuit of infinite duration that involves a fixed path between a *source* and a *destination.* The role of *flow control algorithms* is to alleviate throughput degradation, unfairness, deadlocks, and failures by preventing buffer overflow from arising in situations where the externally injected load is larger than what can be accommodated even with optimal routing (see, e.g., [2, Chapter 6] or [3, 6, 12, 14, 15, 16, 17, 22]). In particular, *rate-based* flow control algorithms adjust transmission rates of different sessions in an end-to-end manner, with the objective to optimize network utilization while still maintaining fairness between different sessions (see, e.g., [1, 2, 4, 5, 11, 13, 16, 18]).

For a range of settings including both high-speed networks and Internet applications, *max-min fairness* [1, 2, 5, 6, 7, 13, 14, 15, 16, 17, 19] has emerged as a widely accepted formulation of fairness for flow control; roughly speaking, max-min fairness requires that it be impossible for any session to receive an infinitesimally larger rate on the account of a session with a smaller or equal rate [15, 16, 17, 21]. Call *max-min fair rates* those achieving max-min fairness.

Any rate-based flow control algorithm can be classified as one of two broad classes, *conservative* and *optimistic*, according to the way in which rates of sessions are adjusted. Conservative algorithms (see, e.g., [2, Chapter 6]) do not provide for decreases to the rates of sessions; in contrast, optimistic algorithms allow decreases, so that rates may go up and down and a session can intermediately receive a rate larger than its final. Afek, Mansour, and Ostfeld [1] introduced optimistic algorithms and advocated them as fitting better than the conservative ones into real dynamic networks; indeed, in such networks, new sessions may join in, so that it is desirable to incrementally adjust rates by decreasing the rates of some of them.

A crucial component of a rate-based flow control algorithm is its *scheduler*, the abstract mechanism it uses to decide which session's rate to adjust next. Apparently, it is desirable that the scheduler does not require *global* knowledge of either the session rates or the network topology. Clearly, no-knowledge schedulers are not only more efficient in terms of communication and computation, but they also adjust more easily to dynamic changes in network topology. So, one important performance parameter of a rate-based flow control algorithm is its *locality*, measured by the amount of global knowledge required by the scheduler.

Call a scheduler that uses no information of either the session rates or the network topology an *oblivious* scheduler. On the opposite extreme, a *nonoblivious* scheduler requires full knowledge of both session rates and network topology. There is, in addition, an important middle ground between oblivious and nonoblivious schedulers: schedulers which, although unaware of network topology, do have access to session rates; call these schedulers *partially oblivious.* Clearly, a partially oblivious scheduler is superior to a nonoblivious scheduler in terms of robustness to dynamic changes in network topology, while it is surpassed by an oblivious scheduler. Afek et al. [1, sections 4 and 5] presented two interesting, partially oblivious schedulers called GlobalMinSched and LocalMinSched, respectively; these schedulers always choose for an increase the session whose rate is the *globally* and *locally* smallest, respectively.

A second crucial component of a rate-based flow control algorithm is its *terminator*, the abstract mechanism it uses to decide which sessions to terminate at each specific instant.[1] *Bottleneck* terminators [16] finalize the rate of a session, thereby terminating the session, only if its rate is restricted on some particular network link that allows for the least possible share of bandwidth to each session traversing it; call such a link a *bottleneck edge* [16].

When a session is scheduled for an increase, its rate is increased by the minimum possible share of bandwidth along its path; this may involve possible decreases to the rates of crossing sessions (see, e.g., [5, 6, 7, 18, 19]). The *convergence complexity* of a rate-based flow control algorithm is the number of individual rate adjustments performed in the worst case until the algorithm terminates and rates have reached max-min fairness (so that they do not change any further). Thus, convergence complexity models the number of rounds of communication and local computation needed for convergence to max-min fairness, so that it is another significant performance parameter of such distributed algorithms.

We measure convergence complexity in terms of a particular, simple abstraction of rate adjustments, called an *update operation*, which was introduced in [1, section 2.1]. In essence, an `update` operation atomically adjusts the rates of a group of neighboring sessions in a fair and optimistic way.[2] We note that some of the essential intricacies encountered when designing practical, distributed flow-control algorithms [4, 5, 6, 7, 18, 19, 22] include scheduling the rate adjustments, minimizing the communication, and converging to fairness quickly. Although we do not address in this work implementation issues for the model used, we feel that it captures most of these intricacies. (For a discussion of such issues for this model, see [9].)

This work presents a comprehensive collection of bounds on convergence complexity under varying degrees of locality for optimistic, bottleneck, rate-based flow control algorithms; more specifically, we show upper and lower bounds (sections 5 and 7, resp.) on convergence complexity for oblivious, partially oblivious, and nonoblivious such algorithms. The lower bounds demonstrate that achieving oblivious, or even partially oblivious, scheduling, and therefore locality, necessarily imposes a nonconstant, multiplicative overhead on convergence complexity. These are the first general lower bounds ever shown on the convergence of rate-based flow control algorithms. In addition, our algorithms span a wide spectrum of convergence complexity bounds and locality properties, while they improve significantly upon all previous optimistic algorithms with respect to the combination of these two performance measures. To establish these upper bounds, we offer several new basic properties and tools for the design and analysis of optimistic, bottleneck, rate-based flow control algorithms (section 4); these properties significantly extend and strengthen the corresponding ones shown in [1].

Our bounds are expressed in terms of $n$, the total number of sessions laid out on the network, and a new parameter $d$, called *session dependency*, through which we derive more accurate bounds on convergence complexity. Specifically, $d$ is the maximum number of sessions that share an edge either directly or indirectly. In the rest of this paper, we will focus on optimistic and bottleneck algorithms; we sometimes refer to them simply as algorithms.

[1]In all of our discussion, a terminated session is meant to be one that has reached its final (max-min fair) rate, so that its rate value will not change any further.

[2]In more detail, an `update` operation increases, if possible, the rate of one session, so that it becomes the session with the maximum rate on some particular link that allows the minimum possible increase. The new value is a function of the link capacity and the rates of other sessions traversing the link. Conflicting sessions whose rates exceed the new value have their rates decreased to the new value, while rates of other sessions remain unchanged. These adjustments saturate that particular link.

Our first major result is a fundamental lower bound on the convergence complexity of oblivious algorithms. Its proof relies on constructing, given any arbitrary oblivious algorithm, a specific network, as a function of the algorithm's scheduler, so that if sessions are scheduled on this network according to the scheduler and the algorithm computes the max-min fair rates, then $\Omega(dn)$ `update` operations are required before convergence (section 6). The construction is novel, purely combinatorial, and of independent interest. We rely on the algorithm being optimistic and bottleneck to show that convergence is slow.

Although intuition may suggest that knowledge of session rates can be crucial to performance, we surprisingly establish that the lower bound of $\Omega(dn)$ that we show on the convergence complexity of oblivious algorithms applies also to partially oblivious algorithms. We use a powerful simulation proof to simulate any partially oblivious scheduler on some network by an oblivious scheduler on the same network. The simulation inherits the $\Omega(dn)$ lower bound shown for oblivious algorithms down to partially oblivious algorithms.

We show a matching upper bound on the convergence complexity of oblivious and partially oblivious algorithms. We present a class of oblivious algorithms, called $d$-Epoch, with convergence complexity $\Theta(dn)$; an example is algorithm RoundRobin, which uses the simple and natural idea of scheduling sessions in a round-robin order. We note that the partially oblivious algorithms GlobalMin and LocalMin from [1, sections 4 and 5] also achieve convergence complexity $\Theta(dn)$, which implies the tightness of our lower bound for partially oblivious algorithms; however, any $d$-Epoch algorithm improves over these two algorithms since it is oblivious.

At this point, it is only natural to ask whether it is possible to overcome the $\Theta(dn)$ barrier on convergence complexity achievable by oblivious or partially oblivious algorithms, possibly at the cost of sacrificing locality. Perhaps not very surprisingly, it turns out that the locality enjoyed by oblivious and partially oblivious algorithms comes at a multiplicative in $d$ overhead on convergence complexity. We present a counterexample, nonoblivious and optimistic algorithm called Linear that achieves an exact bound of $n$ on convergence complexity; Linear follows the earlier idea of selecting and conservatively increasing the rate of any session that traverses the most highly congested link in the network (see, e.g., [2, section 6.4.2] or [15]). We emphasize that Linear, although theoretically efficient, is clearly impractical.

Our work differs at first from earlier work on rate-based flow control carried out in the data networks community (see, e.g., [2, 3, 11, 12, 15, 16, 17, 22]) in adopting the optimistic approach introduced in [1]. We have been able to show that certain classical scheduling policies, such as round-robin [13, 14] or scheduling a session that traverses the most congested link [15], are correctly applicable in the optimistic framework. Most interestingly, we have shown the first general lower bounds on the convergence complexity of rate-based flow control algorithms; these imply that some scheduling policies are provably superior over some other policies, in terms of either convergence complexity or locality (or both), and even optimal.

**2. Model.** Many of our definitions formalize and refine those from [1] and [2, Chapter 6]. A *communication network* is a graph $G = (V, E)$, where vertices and edges represent switches and links, respectively. A set $\mathcal{S}$ of $n \geq 1$ *sessions* is laid out on $G$. Each session $S_i$ (also denoted as $i$) passes through a sequence of edges and has a *rate* $r(S_i)$. The vector $\mathbf{r} = \langle r(S_1), \ldots, r(S_n) \rangle$ is the *rate vector*. Each edge has a *capacity* $c(e) > 0$, which the sum of the rates of the sessions traversing it cannot exceed; when this sum equals the capacity, the edge is *saturated*. In a *max-min fair rate vector*

[15, 16, 17, 21], an increase to the rate of any session requires either exceeding an edge capacity or decreasing the rate of another session with equal or lower rate.

The communication network is abstracted as a state machine. Each state $Q = \langle \mathbf{r}_Q, \mathcal{A}_Q \rangle$ consists of a *rate vector* $\mathbf{r}_Q$ and a set $\mathcal{A}_Q \subseteq \mathcal{S}$ of *active sessions.* Intuitively, an active session is one that has not yet reached its max-min fair rate. Denote by $\mathcal{D}_Q = \mathcal{S} \setminus \mathcal{A}_Q$ the set of *done sessions* in state $Q$. In the *initial state* $Q^{in}$, all sessions are active and have zero rates. A state is *final* if all sessions have reached their max-min fair rates.

An operation defines a procedure to compute new rates for a set of sessions on the basis of their old rates. Formally, an *operation* is a function `operation` that takes as input a session $S_i$ and a state $Q$, and outputs new rates for $S_i$ and all sessions $S_j$ sharing edges with $S_i$. Say that `operation` is *conservative* if it decreases no individual rate; else `operation` is *optimistic.*

We will consider a specific optimistic operation, called `update`, which we describe below. For a state $Q$ and each edge $e$ traversed by $S_i$, $\Delta_Q(i, e)$ is the maximum amount by which $r_Q(S_i)$ can be increased (without exceeding the capacity of $e$) while decreasing down to the increased rate of $S_i$ the rates of other active sessions passing through $e$ and exceeding the increased rate. Notice that these rate adjustments saturate $e$. Intuitively, $\Delta_Q(i, e)$ is the maximum amount by which $r_Q(S_i)$ can be increased in a fair manner if edge $e$ were the only edge constraining $S_i$. Finally, $S_i$'s rate is increased by $\Delta_Q(i)$, called the *increase* for $S_i$ in $Q$, which is the minimum of these maximum amounts over all edges that $S_i$ passes through. In addition, each (active) session $S_j$ sharing an edge with $S_i$ has its rate decreased down to the new rate $r(S_i)$ (unless it is already less). We remark that the rates computed by `update` saturate the edge(s) realizing $\Delta_Q(i)$, but no other edges. Notice also that the `update` operation uses only local information with respect to session $S_i$ [17, section IV]. From now on, we will consider only optimistic algorithms that employ the `update` operation.

A scheduler decides the order of sessions on which to perform the `update` operation. Formally, a *scheduler* (cf. [1]) is a function $\mathsf{Sched}$ that maps a pair $\langle G, \mathcal{S} \rangle$, a state $Q$, and a state index $l \geq 1$ to a session $i = \mathsf{Sched}(\langle G, \mathcal{S} \rangle, Q, l)$. A *terminator* is a function $\mathsf{Term}$ that maps a pair $\langle G, \mathcal{S} \rangle$ and a state $Q$ to a set of sessions $\mathcal{T} = \mathsf{Term}(\langle G, \mathcal{S} \rangle, Q) \subseteq \mathcal{A}_Q$; intuitively, $\mathsf{Term}$ decides which active sessions will be *terminated* (and their rates will not change any further). An *algorithm* is a pair $\mathsf{Alg} = \langle \mathsf{Sched}, \mathsf{Term} \rangle$. The classification of operations into conservative and optimistic leads to the corresponding classification of algorithms in a natural way.

An *oblivious* scheduler uses no knowledge of either the topology of the network or the rates and *statuses* (active or done) of sessions. Thus, an oblivious scheduler is a (finite or infinite) sequence $\mathsf{Sched} = i_1, i_2, \ldots$, where for each $l \geq 1$, $i_l \in [n]$. A *partially oblivious* scheduler uses no knowledge of the topology of the network, while it may use knowledge of the rates (and statuses) of sessions. Notice that any oblivious scheduler is also partially oblivious, but not vice versa. A *nonoblivious* scheduler is a scheduler that is not partially oblivious. The classification of schedulers into oblivious, partially oblivious, and nonoblivious leads to the corresponding classification of algorithms in a natural way.

For any edge $e \in E$ and state $Q$, the *allotted capacity* of $e$ in $Q$ [1, section 2.1], denoted $allot_Q(e)$, is the total rate already allocated to done sessions passing through the edge. Clearly, $\sum_{S \in \mathcal{A}_Q | e} r_Q(S) \leq c(e) - allot_Q(e)$, where $\mathcal{A}_Q \mid e$ denotes the set of active sessions traversing $e$ in $Q$. For any state $Q$ and for any edge $e$ with $|\mathcal{A}_Q \mid e| > 0$ active sessions, the *fair share* of $e$ in state $Q$ [1, section 2.1], denoted $FS_Q(e)$, is defined to be $FS_Q(e) = \frac{c(e) - allot_Q(e)}{|\mathcal{A}_Q \mid e|}$; intuitively, $FS_Q(e)$ is the per-session share of the portion of the capacity of edge $e$ which has not yet been allocated to sessions done in state $Q$ that traverse the edge. For any state $Q$, a *bottleneck edge* for $Q$ [16] is an edge $e$ such that for each active session passing through $e$, $FS_Q(e)$ is the minimum fair share over all edges traversed by the session.

A terminator $\mathsf{Term}$ is *bottleneck* [16] if for any state $Q$ and session $S$, $S \in \mathsf{Term}(\langle G, \mathcal{S}\rangle, Q)$ if (and only if) there exists an edge $e$ traversed by $S$ such that (1) $e$ is a bottleneck edge for $Q$, and (2) $r_Q(S) = FS_Q(e)$. Whenever such an edge $e$ exists for state $Q$ and $\mathsf{Term}$ is bottleneck, we will say that $e$ causes the termination of session $S$ in $Q$. Say that an algorithm $\mathsf{Alg}$ is *bottleneck* if $\mathsf{Term}$ is.

The *execution* $\alpha$ of $\mathsf{Alg}$ on $\langle G, \mathcal{S}\rangle$ is an infinite sequence of alternating states and session indices $\alpha = Q_0, i_1, Q_1, \ldots, i_l, Q_l, \ldots$, satisfying the following conditions:

(1) $Q_0 = Q^{in}$ and $\mathcal{A}_{Q_0} = \mathcal{A}_{Q_1} = \mathcal{S}$;
(2) for each $l \geq 1$, $i_l = \mathsf{Sched}(\langle G, \mathcal{S}\rangle, Q_{l-1}, l-1)$;
(3) for each $l \geq 1$, if $i_l \in \mathcal{D}_{Q_l}$ or $\Delta_{Q_{l-1}}(i_l) = 0$, then $\mathbf{r}_{Q_l} = \mathbf{r}_{Q_{l-1}}$ and $\mathcal{A}_{Q_{l+1}} = \mathcal{A}_{Q_l}$; else
  (a) (i) $r_{Q_l}(i_l) := r_{Q_{l-1}}(i_l) + \Delta_{Q_{l-1}}(i_l)$;
    (ii) for each session $i \in \mathcal{A}_{Q_l}$, $i \neq i_l$, such that $S_i \cap S_{i_l} \neq \emptyset$,

$$r_{Q_l}(i) := \min\{r_{Q_{l-1}}(i), r_{Q_{l-1}}(i_l) + \Delta_{Q_{l-1}}(i_l)\};$$

  (b) $\mathcal{A}_{Q_{l+1}} = \mathcal{A}_{Q_l} \setminus \mathsf{Term}(\langle G, \mathcal{S}\rangle, Q_l)$.

Call each state $Q_l$ in an execution $\alpha$, where $l \geq 1$, a *reachable state.* Say that $\mathsf{Alg}$ *computes the max-min fair rate vector* if for each execution of $\mathsf{Alg}$ a final state $Q$ is reachable such that $\mathbf{r}_Q$ is a max-min fair rate vector.

The number of `update` operations in any execution $\alpha$ of $\mathsf{Alg}$ is the number of state indices $l \geq 1$ such that $i_l \in \mathcal{A}_{Q_{l-1}}$. The *convergence complexity* of $\mathsf{Alg}$ on network $G$ with session set $\mathcal{S}$, denoted $\mathcal{U}_{\mathsf{Alg}}(\langle G, \mathcal{S}\rangle)$, is the number of operations in the execution of $\mathsf{Alg}$ on $G$ with $\mathcal{S}$. The *convergence complexity of* $\mathsf{Alg}$, denoted $\mathcal{U}_{\mathsf{Alg}}$, is the maximum, over all pairs $\langle G, \mathcal{S}\rangle$, of the convergence complexity of $\mathsf{Alg}$ on $G$ with $\mathcal{S}$.

## 3. Notation.

We collect here some notation that will be used in most of the following sections. For each edge $e$ and for any set of sessions $\mathcal{S}' \subseteq \mathcal{S}$, denote $\mathcal{S}' \mid e$ to be the set of sessions in $\mathcal{S}'$ traversing $e$. We will sometimes treat a session $S_i$ as the set of its links; so, for any edge $e$ traversed by $S_i$, we will write $e \in S_i$. For an edge $e$ and for a rate vector $\mathbf{r}$, denote by $\mathbf{r} \mid e$ the restriction of $\mathbf{r}$ to sessions traversing $e$. We will sometimes abuse notation by writing $\mathbf{r}_{\mathcal{A}_Q}$ and $\mathbf{r}_{\mathcal{D}_Q}$ to denote the restriction of $\mathbf{r}_Q$ to active and done sessions, respectively, in $Q$.

Define the *share-an-edge* relation on $\mathcal{S}$, denoted $\|_{\mathcal{S}}$, as follows. For any pair of sessions $S_i, S_j \in \mathcal{S}$, $S_i \|_{\mathcal{S}} S_j$ if $S_i$ and $S_j$ traverse a common edge. The transitive closure of $\|_{\mathcal{S}}$ is an equivalence relation on $\mathcal{S}$, which partitions $\mathcal{S}$ into equivalence classes $\mathcal{S}_1, \ldots, \mathcal{S}_c$, called *clusters*, where $1 \leq c \leq n$. The *session dependency* $d$ is the maximum size of a cluster. Call a cluster $\mathcal{S}_j$ an *active cluster* in state $Q$ if it contains at least one session that remains active in $Q$.

The set of *active edges* of the cluster $\mathcal{S}_j$ in state $Q$, denoted $AE_Q(\mathcal{S}_j)$, contains all edges of the network traversed by at least one active session in $Q$ that belongs to $\mathcal{S}_j$. The set of *active edges* of the network in state $Q$, denoted $AE_Q$, contains all edges of the network traversed by at least one active session in $Q$. The *residual capacity* of edge $e$ in state $Q$, denoted $resid_Q(e)$, is the difference between the capacity of $e$ and the total rate of sessions traversing $e$ in $Q$.

The set of *edges with minimum fair share* for cluster $\mathcal{S}_j$ in state $Q$ is defined as $\mathit{MFSE}_Q(\mathcal{S}_j) = \{e \in \mathit{AE}_Q(\mathcal{S}_j) \mid \mathit{FS}_Q(e) \leq \mathit{FS}_Q(e') \text{ for each } e' \in \mathit{AE}_Q(\mathcal{S}_j)\}$. The set of *edges with minimum fair share* in state $Q$, denoted $\mathit{MFSE}_Q$, is defined to be $\mathit{MFSE}_Q = \bigcup_{1 \leq j \leq c} \mathit{MFSE}_Q(\mathcal{S}_j)$.

An *execution fragment* $\alpha$ of Alg is a contiguous subsequence of some execution of Alg starting with the state $\mathit{first}(\alpha)$; if $\alpha$ is finite, it ends with the state $\mathit{last}(\alpha)$. For each execution (resp., execution fragment) $\alpha$ of Alg, the *schedule* $\sigma(\alpha)$ is the sequence of session indices in $\alpha$. If $\alpha$ is a finite execution fragment and $\alpha'$ is any execution fragment such that $\mathit{first}(\alpha') = \mathit{last}(\alpha)$, then $\alpha \cdot \alpha'$ is the concatenation of $\alpha$ and $\alpha'$, eliminating the duplicate occurrence of $\mathit{last}(\alpha) = \mathit{first}(\alpha')$.

For any index $l \geq 1$, the *preceding state* of $Q_l$ in execution $\alpha$, denoted $\overleftarrow{Q_l}$, is the state $Q_{l-1}$; for any index $l \geq 0$, the *successor state* of $Q_l$ in $\alpha$, denoted $\overrightarrow{Q_l}$, is the state $Q_{l+1}$. For any indices $l$ and $l' > l$, write $Q_l \xrightarrow{\alpha} Q_{l'}$ to denote that $Q_l$ precedes $Q_{l'}$; moreover, write $Q_l \overset{\alpha}{\longmapsto} Q_{l'}$ if additionally $Q_l$ and $Q_{l'}$ may coincide. For any index $l \geq 1$, we will sometimes abuse language and say that session $l$ is *scheduled in front* of state $Q_l$. For any state $Q$, denote $i_Q$ the session scheduled in front of $Q$. The *least schedule* for $Q_l$ in $\alpha$, denoted $\widehat{l}$, is the index of the earliest state following $Q_l$ by which all sessions that remain active in $Q_l$ have been scheduled at least once, or infinite if no such state exists. Define $\widehat{l} \mid e$ in the natural way.

## 4. Bottleneck algorithms.

In this section, we present basic properties of bottleneck algorithms, which will be useful in what follows. These properties refer to an execution $\alpha = Q_0, i_1, Q_1, \ldots, i_l, Q_l, \ldots$ of any bottleneck algorithm. To prove these properties, some more general properties are also proved in section 4.1.

### 4.1. Preliminaries.

We study how several quantities of interest change during an execution. We first state an immediate consequence of the definitions of allotted capacity and execution; we then prove a similar simple fact that will be helpful in later proofs.

LEMMA 4.1. *For each integer $l \geq 1$, and for any edge $e$,*

$$\mathit{allot}_{Q_l}(e) = \mathit{allot}_{Q_{l-1}}(e) + \sum_{i \in (\mathcal{A}_{Q_{l-1}} \setminus \mathcal{A}_{Q_l}) \mid e} r_{Q_{l-1}}(i).$$

LEMMA 4.2. *For any integers $l_0$ and $l$, $0 \leq l_0 < l$, and for any edge $e$,*

$$\sum_{i \in (\mathcal{A}_{Q_{l_0}} \setminus \mathcal{A}_{Q_l}) \mid e} r_{Q_{l_0}}(i) = \mathit{allot}_{Q_l}(e) - \mathit{allot}_{Q_{l_0}}(e).$$

*Proof.* Clearly, $i \in (\mathcal{A}_{Q_{l_0}} \setminus \mathcal{A}_{Q_l}) \mid e$ if and only if $i \in (\mathcal{D}_{Q_l} \setminus \mathcal{D}_{Q_{l_0}}) \mid e$. Hence, it follows that

$$\begin{aligned}
&\sum_{i \in (\mathcal{A}_{Q_{l_0}} \setminus \mathcal{A}_{Q_l}) \mid e} r_{Q_l}(i) \\
&= \sum_{i \in (\mathcal{D}_{Q_l} \setminus \mathcal{D}_{Q_{l_0}}) \mid e} r_{Q_l}(i) \\
&= \sum_{i \in \mathcal{D}_{Q_l} \mid e} r_{Q_l}(i) - \sum_{i \in \mathcal{D}_{Q_{l_0}} \mid e} r_{Q_l}(i) \qquad (\text{since } \mathcal{D}_{Q_{l_0}} \subseteq \mathcal{D}_{Q_l}) \\
&= \mathit{allot}_{Q_l}(e) - \mathit{allot}_{Q_{l_0}}(e),
\end{aligned}$$

as needed. ∎

We continue to prove that the saturation of an edge depends in a critical way on how rates of sessions traversing the edge compare to each other.

LEMMA 4.3. *For any integer $l_0 \geq 0$, assume that edge $e$ is active in state $Q_{l_0}$. Then, for each integer $l \geq l_0$, the following hold:*

(1) *if for each session $i \in \mathcal{A}_{Q_{l_0}} \mid e$, $r_{Q_l}(i) = FS_{Q_{l_0}}(e)$, then $e$ is saturated in $Q_l$;*
(2) *if for each session $i \in \mathcal{A}_{Q_{l_0}} \mid e$, $r_{Q_l}(i) < FS_{Q_{l_0}}(e)$, then $e$ is not saturated in $Q_l$;*
(3) *there exists no session $k \in \mathcal{A}_{Q_{l_0}} \mid e$ such that $r_{Q_l}(k) > FS_{Q_{l_0}}(e)$, while for each session $i \in \mathcal{A}_{Q_{l_0}} \mid e$, $i \neq k$, $r_{Q_l}(i) \geq FS_{Q_{l_0}}(e)$.*

*Proof.* We start by proving (1). Clearly,

$$\begin{aligned}
&\sum_{i\in\mathcal{A}_{Q_l}|e} r_{Q_l}(i)\\
&= \sum_{i\in\mathcal{A}_{Q_{l_0}}|e} r_{Q_l}(i) - \sum_{i\in(\mathcal{A}_{Q_{l_0}}\setminus\mathcal{A}_{Q_l})|e} r_{Q_l}(i) &&(\text{since } \mathcal{A}_{Q_l} \mid e \subseteq \mathcal{A}_{Q_{l_0}} \mid e)\\
&= \sum_{i\in\mathcal{A}_{Q_{l_0}}|e} FS_{Q_{l_0}}(e) - \big(allot_{Q_l}(e) - allot_{Q_{l_0}}(e)\big) &&(\text{by assumption and Lemma 4.2})\\
&= \left|\mathcal{A}_{Q_{l_0}} \mid e\right| \cdot FS_{Q_{l_0}}(e) - (allot_{Q_l}(e) - allot_{Q_{l_0}}(e))\\
&= c(e) - allot_{Q_{l_0}}(e) - (allot_{Q_l}(e) - allot_{Q_{l_0}}(e)) &&(\text{by definition of fair share})\\
&= c(e) - allot_{Q_l}(e),
\end{aligned}$$

as needed to establish that $e$ is saturated in state $Q_l$.

Condition (2) is proved in an almost identical way. (The only difference is that now the assumption for (2) and Lemma 4.2 imply that $\sum_{i\in\mathcal{A}_{Q_{l_0}}|e} r_{Q_l}(i) - \sum_{i\in(\mathcal{A}_{Q_{l_0}}\setminus\mathcal{A}_{Q_l})|e} r_{Q_l}(i) < \sum_{i\in\mathcal{A}_{Q_{l_0}}|e} FS_{Q_{l_0}}(e) - (allot_{Q_l}(e) - allot_{Q_{l_0}}(e).)$

We finally prove (3). Assume otherwise; so, there exists some session $k \in \mathcal{A}_{Q_{l_0}} \mid e$ such that $r_{Q_l}(k) > FS_{Q_{l_0}}(e)$, while for each $i \in \mathcal{A}_{Q_{l_0}} \mid e$, $i \neq k$, $r_{Q_l}(i) \geq FS_{Q_{l_0}}(e)$. Then

$$\begin{aligned}
&\sum_{i\in\mathcal{A}_{Q_l}|e} r_{Q_l}(i)\\
&\quad= \sum_{i\in\mathcal{A}_{Q_{l_0}}|e} r_{Q_l}(i) - \sum_{i\in(\mathcal{A}_{Q_{l_0}}\setminus\mathcal{A}_{Q_l})|e} r_{Q_l}(i) &&(\text{since } \mathcal{A}_{Q_l}|e \subseteq \mathcal{A}_{Q_{l_0}} \mid e)\\
&\quad= \sum_{i\in\mathcal{A}_{Q_{l_0}}|e} r_{Q_l}(i) - (allot_{Q_l}(e) - allot_{Q_{l_0}}(e)) &&(\text{by Lemma 4.2})\\
&\quad= r_{Q_l}(k) + \sum_{i\in\mathcal{A}_{Q_{l_0}}|e,i\neq k} r_{Q_l}(i) - allot_{Q_l}(e) + allot_{Q_{l_0}}(e)\\
&\quad> FS_{Q_{l_0}}(e) + \sum_{i\in\mathcal{A}_{Q_{l_0}}|e,i\neq k} FS_{Q_{l_0}}(e) - allot_{Q_l}(e) + allot_{Q_{l_0}}(e) &&(\text{by assumption})
\end{aligned}$$

$$
\begin{aligned}
&= \sum_{i \in \mathcal{A}_{Q_{l_0}} | e} FS_{Q_{l_0}}(e) - allot_{Q_l}(e) + allot_{Q_{l_0}}(e)) \\
&= \left|\mathcal{A}_{Q_{l_0}} \mid e\right| \cdot FS_{Q_{l_0}}(e) - allot_{Q_l}(e) + allot_{Q_{l_0}}(e) \\
&= c(e) - allot_{Q_{l_0}}(e) - allot_{Q_l}(e) + allot_{Q_{l_0}}(e) \qquad \text{(by definition of fair share)} \\
&= c(e) - allot_{Q_l}(e),
\end{aligned}
$$

so that $\sum_{i \in \mathcal{A}_{Q_l} | e} r_{Q_l}(i) > c(e) - allot_{Q_l}(e)$. This is a contradiction. ∎

The next claim follows directly from the definitions of bottleneck edge and fair share.

LEMMA 4.4. *Let $e$ and $e'$ be bottleneck edges for state $Q$ such that $(\mathcal{A}_Q \mid e) \bigcap (\mathcal{A}_Q \mid e') \neq \emptyset$. Then $FS_Q(e) = FS_Q(e')$.*

The following (easy to prove) claim is a direct consequence of the definitions of a bottleneck edge and a minimum fair share edge for some particular cluster.

LEMMA 4.5. *For any state $Q$ and cluster $\mathcal{S}_j$, consider an edge $e \in MFSE_Q(\mathcal{S}_j)$. Then $e$ is a bottleneck edge for $Q$.*

We are interested in algorithms for which a final state is reachable for each possible execution. Bottleneck algorithms (whether conservative or optimistic) enjoy a related, interesting property [15].

PROPOSITION 4.6 (Hayden [15]). *Assume that* Alg *is a bottleneck algorithm. Then, for any reachable final state $Q$ of* Alg*, $\mathbf{r}_Q$ is a max-min fair rate vector.*

Proposition 4.6 implies that in order to show that any given bottleneck algorithm computes the max-min fair rate vector, it suffices to prove that it reaches a final state. We continue with an interesting monotonicity property of fair share.

LEMMA 4.7 (Afek, Mansour, and Ostfeld [1]). *Assume that* Alg *is a bottleneck algorithm. Then, for each integer $l \geq 1$ and for any edge $e \in AE_{Q_l}$, $FS_{Q_l}(e) \geq FS_{Q_{l-1}}(e)$.*

**4.2. Properties of bottleneck edges.** We strengthen Lemma 4.7 for the special case of bottleneck edges. We present a collection of invariant properties for any edge that becomes bottleneck in the course of an execution of a bottleneck algorithm (whether conservative or optimistic).

PROPOSITION 4.8 (invariants of bottleneck edge). *Assume that* Alg *is bottleneck. For any integer $l_0 \geq 0$, fix any edge $e$ that is a bottleneck edge for $Q_{l_0}$. Then, for any integer $l \geq l_0$ such that $e \in AE_{Q_l}$, the following hold:*

(1) *$FS_{Q_l}(e) = FS_{Q_{l_0}}(e)$;*
(2) *$e$ is a bottleneck edge for $Q_l$;*
(3) *for any session $i \in (\mathcal{A}_{Q_{l_0}} \setminus \mathcal{A}_{Q_{l+1}}) \mid e$, $r_{Q_l}(i) = FS_{Q_{l_0}}(e)$.*

Roughly speaking, Proposition 4.8 establishes that no change in the fair share of an active edge occurs once the edge has become bottleneck, so that the edge remains bottleneck; moreover, the final rate of any active session traversing it is equal to this constant fair share.

*Proof.* The proof is by induction on $l$. For the basis case where $l = l_0$, condition (1) holds trivially, condition (2) holds by assumption, and condition (3) holds by definition of a bottleneck algorithm. Assume inductively that for some integer $l \geq l_0$, the claims hold for any integer $l'$ where $l_0 \leq l' < l$. For the induction step, we show that the claims hold for integer $l$. We start by proving condition (1). Clearly,

$$\begin{aligned}
&FS_{Q_l}(e)\\
&= \frac{c(e) - allot_{Q_l}(e)}{|\mathcal{A}_{Q_l} \mid e|}\\
&= \frac{c(e) - allot_{Q_{l-1}}(e) - \sum_{i\in(\mathcal{A}_{Q_{l-1}}\setminus\mathcal{A}_{Q_l})|e} r_{Q_{l-1}}(i)}{|\mathcal{A}_{Q_l} \mid e|} \qquad \text{(by Lemma 4.1)}\\
&= \frac{\left|\mathcal{A}_{Q_{l-1}} \mid e\right| FS_{Q_{l-1}}(e) - \sum_{i\in(\mathcal{A}_{Q_{l-1}}\setminus\mathcal{A}_{Q_l})|e} r_{Q_{l-1}}(i)}{|\mathcal{A}_{Q_l} \mid e|} \qquad \text{(by definition of fair share).}
\end{aligned}$$

Consider any session $i \in (\mathcal{A}_{Q_{l-1}} \setminus \mathcal{A}_{Q_l}) \mid e$. Since $\mathcal{A}_{Q_{l-1}} \subseteq \mathcal{A}_{Q_{l_0}}$, this implies that $i \in (\mathcal{A}_{Q_{l_0}} \setminus \mathcal{A}_{Q_l}) \mid e$, so that by the induction hypothesis (condition (3)), $r_{Q_{l-1}}(i) = FS_{Q_{l_0}}(e)$. So,

$$\begin{aligned}
&FS_{Q_l}(e)\\
&= \frac{\left|\mathcal{A}_{Q_{l-1}} \mid e\right| FS_{Q_{l-1}}(e) - \sum_{i\in(\mathcal{A}_{Q_{l-1}}\setminus\mathcal{A}_{Q_l})|e} FS_{Q_{l_0}}(e)}{|\mathcal{A}_{Q_l} \mid e|}\\
&= \frac{\left|\mathcal{A}_{Q_{l-1}} \mid e\right| FS_{Q_{l_0}}(e) - \sum_{i\in(\mathcal{A}_{Q_{l-1}}\setminus\mathcal{A}_{Q_l})|e} FS_{Q_{l_0}}(e)}{|\mathcal{A}_{Q_l} \mid e|} \qquad \text{(by the induction hypothesis)}\\
&= \frac{\left|\mathcal{A}_{Q_{l-1}} \mid e\right| FS_{Q_{l_0}}(e) - \left|(\mathcal{A}_{Q_{l-1}} \setminus \mathcal{A}_{Q_l}) \mid e\right| FS_{Q_{l_0}}(e)}{|\mathcal{A}_{Q_l} \mid e|}\\
&= \frac{\left(\left|\mathcal{A}_{Q_{l-1}} \mid e\right| - \left|(\mathcal{A}_{Q_{l-1}} \setminus \mathcal{A}_{Q_l}) \mid e\right|\right) FS_{Q_{l_0}}(e)}{|\mathcal{A}_{Q_l} \mid e|}\\
&= \frac{|\mathcal{A}_{Q_l} \mid e| \; FS_{Q_{l_0}}(e)}{|\mathcal{A}_{Q_l} \mid e|}\\
&= FS_{Q_{l_0}}(e),
\end{aligned}$$

which completes the proof of condition (1).

We now prove condition (2). Take any session $i \in \mathcal{A}_{Q_l} \mid e$. Clearly, $i \in \mathcal{A}_{Q_{l_0}} \mid e$. Since $e$ is a bottleneck edge for $Q_{l_0}$, $FS_{Q_{l_0}}(e) = MFS_{Q_{l_0}}(i) = \min_{e'\in S_i} FS_{Q_{l_0}}(e')$. Consider any edge $e' \in S_i$. Since $i \in \mathcal{A}_{Q_l} \mid e$, it follows that $e' \in AE_{Q_l}$; thus, by Lemma 4.7, $FS_{Q_l}(e') \geq FS_{Q_{l_0}}(e')$. Since $e'$ was chosen arbitrarily, this implies that $\min_{e'\in S_i} FS_{Q_l}(e') \geq \min_{e'\in S_i} FS_{Q_{l_0}}(e')$. It follows that $\min_{e'\in S_i} FS_{Q_l}(e') \geq FS_{Q_{l_0}}(e)$. By condition (1) above, this implies that $\min_{e'\in S_i} FS_{Q_l}(e') \geq FS_{Q_l}(e)$. Since $e \in S_i$, $\min_{e'\in S_i} FS_{Q_l}(e') \leq FS_{Q_l}(e)$. It follows that $FS_{Q_l}(e) = \min_{e'\in S_i} FS_{Q_l}(e')$. Since $i$ was chosen arbitrarily, this implies that $e$ is a bottleneck edge for $Q_l$, which completes the proof of condition (2).

We finally prove condition (3). Take any session $i \in (\mathcal{A}_{Q_{l_0}} \setminus \mathcal{A}_{Q_{l+1}}) \mid e$. Since $i \notin \mathcal{A}_{Q_{l+1}}$, there exists some integer $l'$, $l_0 < l' \leq l$, such that $i \in \mathsf{Term}(Q_{l'})$. Since $\mathsf{Term}$ is bottleneck, there exists some edge $e' \in S_i$ such that $e'$ is a bottleneck edge for $Q_{l'}$, and $r_{Q_{l'}}(i) = FS_{Q_{l'}}(e')$.

Either $l_0 < l' < l$ or $l' = l$. If $l_0 < l' < l$, then the induction hypothesis (condition (2)) implies that $e$ is a bottleneck edge for $Q_{l'}$; if, on the other hand, $l' = l$, then condition (2) above implies that $e$ is a bottleneck edge for $Q_{l'}$. Thus, in either case, $e$ is a bottleneck edge for $Q_{l'}$. Since both $e$ and $e'$ are bottleneck edges for state $Q'_l$ and $S_i \in (\mathcal{A}_{Q_{l'}} \mid e) \bigcap (\mathcal{A}_{Q_{l'}} \mid e')$, Lemma 4.4 implies that $FS_{Q_{l'}}(e) = FS_{Q_{l'}}(e')$.

Since $r_{Q_{l'}}(i) = FS_{Q_{l'}}(e')$, this implies that $r_{Q_{l'}}(i) = FS_{Q_{l'}}(e)$. Since $l \geq l'$ and $i \in \mathsf{Term}(Q_{l'})$, $r_{Q_l}(i) = r_{Q_{l'}}(i)$. Either $l_0 < l' < l$ or $l' = l$. If $l_0 < l' < l$, then the induction hypothesis (condition (1)) implies that $FS_{Q_{l'}}(e) = FS_{Q_{l_0}}(e)$; if, on the other hand, $l' = l$, then condition (1) implies that $FS_{Q_{l'}}(e) = FS_{Q_{l_0}}(e)$. Thus, in either case, $FS_{Q_{l'}}(e) = FS_{Q_{l_0}}(e)$. Hence, it follows that $r_{Q_l}(i) = FS_{Q_{l_0}}(e)$, which completes the proof of condition (3). □

**4.3. Properties of minimum fair share edges.** We start by proving a simple invariant property for any edge that becomes a minimum fair share edge for any particular cluster in the course of an execution of a bottleneck algorithm. We establish that the edge remains a minimum fair share edge (as long as it is active).

PROPOSITION 4.9 (invariant of minimum fair share edge). *Assume that* Alg *is bottleneck. For any integer $l_0 \geq 0$, fix any edge $e \in MFSE_{Q_{l_0}}(\mathcal{S}_j)$ for some active cluster $\mathcal{S}_j$ in $Q_{l_0}$. Then, for any integer $l \geq l_0$ such that $e \in AE_{Q_l}$, $e \in MFSE_{Q_l}(\mathcal{S}_j)$.*

*Proof.* Consider any edge $e' \in AE_{Q_l}(\mathcal{S}_j)$; clearly, $e' \in AE_{Q_{l_0}}(\mathcal{S}_j)$. Since $e \in MFSE_{Q_{l_0}}(\mathcal{S}_j)$, it follows that $FS_{Q_{l_0}}(e) \leq FS_{Q_{l_0}}(e')$. By Lemma 4.5, $e$ is a bottleneck edge for $Q_{l_0}$; thus, by Proposition 4.8 (condition (2)), $FS_{Q_l}(e) = FS_{Q_{l_0}}(e)$. By Lemma 4.7, $FS_{Q_{l_0}}(e') \leq FS_{Q_l}(e')$. So, $FS_{Q_l}(e) \leq FS_{Q_l}(e')$. Since $e'$ is arbitrary, it follows that $e \in MFSE_{Q_l}(\mathcal{S}_j)$. □

Similarly to Proposition 4.8, Proposition 4.9 holds for any bottleneck algorithm (whether conservative or optimistic) as well. However, the rest of the properties established in this section require the assumption of optimistic, bottleneck algorithms. We first prove a safety property for any edge that becomes a minimum fair share edge for any particular cluster during the execution of an optimistic, bottleneck algorithm.

PROPOSITION 4.10 (safety property of minimum fair share edge). *Assume that* Alg *is optimistic and bottleneck. For any integer $l_0 \geq 0$, fix any edge $e \in MFSE_{Q_{l_0}}(\mathcal{S}_j)$ for some active cluster $\mathcal{S}_j$ in $Q_{l_0}$. Consider any session $i \in \mathcal{A}_{Q_{l_0}} \mid e$ such that $r_{Q_{l_0}}(i) \geq FS_{Q_{l_0}}(e)$. Then, for any integer $l \geq l_0$, $r_{Q_l}(i) \geq FS_{Q_{l_0}}(e)$.*

Proposition 4.10 considers any (active) session traversing a minimum fair share edge; roughly speaking, it establishes that no decrease to its rate below this particular minimum fair share is possible if the rate is initially no less than the minimum fair share.

*Proof.* The proof is by induction on $l$. For the basis case where $l = l_0$, the claim holds by our assumption. Assume inductively that for some integer $l > l_0$, $r_{Q_{l-1}}(i) \geq FS_{Q_{l_0}}(e)$. For the induction step, we show that $r_{Q_l}(i) \geq FS_{Q_{l_0}}(e)$.

Assume first that $r_{Q_l}(i) \geq r_{Q_{l-1}}(i)$. By the induction hypothesis, this implies that $r_{Q_l}(i) \geq FS_{Q_{l_0}}(e)$, as needed. So assume that $r_{Q_l}(i) < r_{Q_{l-1}}(i)$. By definition of execution and `update` operation, this implies that $S_i$ intersects the session $S_{i_l}$, scheduled in front of state $Q_l$; moreover, $r_{Q_l}(i) = r_{Q_l}(i_l)$. Let $e'$ be an edge such that $\Delta_{Q_{l-1}}(i_l) = \Delta_{Q_{l-1}}(i_l, e')$. We prove the following.

LEMMA 4.11. $r_{Q_l}(i_l) \geq FS_{Q_l}(e')$.

*Proof.* Assume otherwise; so, $r_{Q_l}(i_l) < FS_{Q_l}(e')$. By definition of the `update` operation, $e'$ is saturated in $Q_l$; moreover, for any session $k \in \mathcal{A}_{Q_{l_0}} \mid e'$, $r_{Q_l}(i_l) \geq r_{Q_l}(k)$. Thus, $FS_{Q_l}(e') > r_{Q_l}(k)$. Lemma 4.3 (condition (2)) implies that $e'$ is not saturated in $Q_l$. This is a contradiction. □

Since $r_{Q_l}(i) = r_{Q_l}(i_l)$, Lemma 4.11 implies that $r_{Q_l}(i) \geq FS_{Q_l}(e')$. Also, by Lemma 4.7, $FS_{Q_l}(e') \geq FS_{Q_{l_0}}(e')$, so that $r_{Q_l}(i) \geq FS_{Q_{l_0}}(e')$. Since $e \in MFSE_{Q_{l_0}}(\mathcal{S}_j)$, $FS_{Q_{l_0}}(e') \geq FS_{Q_{l_0}}(e)$. It follows that $r_{Q_l}(i) \geq FS_{Q_{l_0}}(e)$, as needed. □

The next claim complements Proposition 4.10 by giving a corresponding liveness property.

Proposition 4.12 (liveness property of minimum fair share edge). *Assume that* Alg *is optimistic and bottleneck. For any integer $l_0 \geq 0$, fix any edge $e \in \mathit{MFSE}_{Q_{l_0}}(\mathcal{S}_j)$ for some active cluster $\mathcal{S}_j$ in $Q_{l_0}$, such that $\widehat{l_0} \mid e < \infty$. Consider any session $i \in \mathcal{A}_{Q_{l_0}} \mid e$. Then, for any integer $l \geq \widehat{l_0} \mid e$, $r_{Q_l}(i) \geq FS_{Q_{l_0}}(e)$.*

Proposition 4.12 considers any active session traversing a minimum fair share edge; roughly speaking, it establishes that eventually, once all active sessions traversing this minimum fair share edge have been scheduled at least once, the rate of the session will be no less than this particular minimum fair share.

*Proof.* We start with an informal outline of the proof. We consider the point of the execution following state $Q_{l_0}$ where session $i$ is scheduled; clearly, that point comes no later than when all sessions have been scheduled at least once. We establish that at this point, the rate of $S_i$ is no less than the fair share of edge $e$ in state $Q_{l_0}$. We also argue that $e$ remains a minimum fair share edge beyond state $Q_{l_0}$; this allows us to exploit the safety property of minimum fair share edges in order to argue that the rate of $S_i$ will subsequently remain no less than the fair share of $e$ in state $Q_{l_0}$. We now present the details of the formal proof.

Since $e \in \mathit{MFSE}_{Q_{l_0}}(\mathcal{S}_j)$, Lemma 4.5 implies that $e$ is a bottleneck edge for state $Q_{l_0}$. Since $i \in \mathcal{A}_{Q_{l_0}} \mid e$, it follows by definition of $\widehat{l_0} \mid e$ that there exists a least index $l'$, $l_0 < l' \leq \widehat{l_0} \mid e$, such that $i$ is scheduled in front of state $Q_{l'}$. We proceed by case analysis.

1. Assume first that $i$ is not active in state $Q_{l'}$. Since $i \in \mathcal{A}_{Q_{l_0}}$, there exists an index $l''$, $l_0 \leq l'' < l'$, such that $i \in \mathsf{Term}(Q_{l''})$. Since $\mathsf{Term}$ is bottleneck, it follows that there exists some edge $e'$ traversed by session $i$ that is a bottleneck edge for state $Q_{l''}$, and $r_{Q_{l''}}(i) = FS_{Q_{l''}}(e')$. Since $i \in \mathcal{A}_{Q_{l''}}$ and $i$ traverses $e$, $e$ is an active edge at $Q_{l''}$. By Proposition 4.8 (conditions (1) and (2)), $FS_{Q_{l''}}(e) = FS_{Q_{l_0}}(e)$, and $e$ is a bottleneck edge for $Q_{l''}$. By Lemma 4.4, $FS_{Q_{l''}}(e') = FS_{Q_{l''}}(e)$, so that $FS_{Q_{l''}}(e') = FS_{Q_{l_0}}(e)$. It follows that $r_{Q_{l''}}(i) = FS_{Q_{l_0}}(e)$. Now take any integer $l \geq \widehat{l_0} \mid e$. Clearly, $l \geq l''$. Since $i \in \mathsf{Term}(Q_{l''})$, $r_{Q_l}(i) = r_{Q_{l''}}(i) = FS_{Q_{l_0}}(e)$, which establishes the claim in this case.
2. Assume now that $i$ is active in state $Q_{l'}$. Since $i$ traverses edge $e$, it follows that $e$ is active in state $Q_{l'}$. By Proposition 4.8 (conditions (1) and (2)), $FS_{Q_{l'}}(e) = FS_{Q_{l_0}}(e)$, and $e$ is a bottleneck edge for $Q_{l'}$. We prove the following.
   Lemma 4.13. $r_{Q_{l'}}(i) \geq FS_{Q_{l_0}}(e)$.
   *Proof.* Assume, by way of contradiction, that $r_{Q_{l'}}(i) < FS_{Q_{l_0}}(e)$. Let $e'$ be an edge such that $\Delta_{Q_{l'}}(i) = \Delta_{Q_{l'}}(i, e')$. By definition of the `update` operation, $e'$ is saturated in state $Q_{l'}$. Since $e$ is a bottleneck edge for state $Q_{l'}$, and $i$ traverses both $e$ and $e'$, $FS_{Q_{l'}}(e) \leq FS_{Q_{l'}}(e')$. Since $FS_{Q_{l'}}(e) = FS_{Q_{l_0}}(e)$, this implies that $FS_{Q_{l_0}}(e) \leq FS_{Q_{l'}}(e')$. Since $r_{Q_{l'}}(i) < FS_{Q_{l_0}}(e)$, it follows that $r_{Q_{l'}}(i) < FS_{Q_{l'}}(e')$. By definition of the `update` operation, for any session $k \in \mathcal{A}_{Q_{l'}} \mid e$, $r_{Q_{l'}}(k) \leq r_{Q_{l'}}(i)$, so that $r_{Q_{l'}}(k) < FS_{Q_{l'}}(e')$. It follows by Lemma 4.3 (condition (2)) that $e'$ is not saturated in state $Q_{l'}$. This is a contradiction. □
   Now take any integer $l \geq \widehat{l_0} \mid e$. Clearly, $l \geq l'$. Since $e$ is a minimum fair share edge for $Q_{l_0}$, Proposition 4.9 implies that $e$ is a minimum fair share edge for $Q_{l'}$ as well. Moreover, by Lemma 4.13, $r_{Q_{l'}}(i) \geq FS_{Q_{l_0}}(e)$. Since $FS_{Q_{l'}}(e) = FS_{Q_{l_0}}(e)$, this implies that $r_{Q_{l'}}(i) \geq FS_{Q_{l'}}(e)$. It follows by Proposition 4.10 (taking $l'$ for $l_0$) that $r_{Q_l}(i) \geq FS_{Q_{l_0}}(e)$, which establishes the claim in this case.

The proof of Proposition 4.12 is now complete. ∎

**4.4. Termination properties.** The first property considers active sessions in any particular cluster that traverse a minimum fair share edge; it is established that once each such session has been scheduled at least once, all of these sessions must have become done.

PROPOSITION 4.14 (termination of all sessions). *Assume that* Alg *is optimistic and bottleneck. For any integer $l_0 \geq 0$, fix any edge $e \in MFSE_{Q_{l_0}}(\mathcal{S}_j)$ for some active cluster $\mathcal{S}_j$ in $Q_{l_0}$ such that $\widehat{l_0} \mid e < \infty$. Then, for any session $i \in \mathcal{A}_{Q_{l_0}} \mid e$, $i \in \mathcal{D}_{\overrightarrow{Q_{\widehat{l_0}|e}}}$.*

*Proof.* We start with an informal outline of the proof. We consider any session active in state $Q_{l_0}$, and we argue that after all sessions have been scheduled at least once, the session will receive a rate equal to the fair share of $e$ in $Q_{l_0}$. We will exploit the fact that $e$ is a bottleneck edge for $Q_{l_0}$ in order to argue that $e$ remains bottleneck subsequently, and that its fair share does not change. Since Alg is a bottleneck algorithm, this will be sufficient for deducing that the session has reached its final rate. We now present the details of the formal proof.

Fix any session $i \in \mathcal{A}_{Q_{l_0}} \mid e$. We start by proving the following.

LEMMA 4.15. *$r_{Q_{\widehat{l_0}|e}}(i) = FS_{Q_{l_0}}(e)$.*

*Proof.* Assume, by way of contradiction, that $r_{Q_{\widehat{l_0}|e}}(i) \neq FS_{Q_{l_0}}(e)$. By Proposition 4.12, $r_{Q_{\widehat{l_0}|e}}(i) \geq FS_{Q_{l_0}}(e)$. It follows that $r_{Q_{\widehat{l_0}|e}}(i) > FS_{Q_{l_0}}(e)$. We proceed by case analysis.

Assume first that there exists no session $k \in \mathcal{A}_{Q_{l_0}} \mid e$ with $k \neq i$; thus, $\mathcal{A}_{Q_{l_0}} \mid e = \{i\}$. Denote by $Q_l$ the latest state in execution $\alpha$, such that $Q_{l_0} \xmapsto{\alpha} Q_l \xmapsto{\alpha} Q_{\widehat{l_0}|e}$, and $\mathcal{A}_{Q_l} \neq \emptyset$. Thus, $\mathcal{A}_{Q_l} \mid e = \mathcal{A}_{Q_{l_0}} \mid e$ and $allot_{Q_l}(e) = allot_{Q_{l_0}}(e)$. Clearly,

$$\begin{aligned}
&\sum_{k \in \mathcal{A}_{Q_l}|e} r_{Q_l}(k) \\
&\quad = r_{Q_l}(i) && (\text{since } \mathcal{A}_{Q_{l_0}} \mid e = \{i\}) \\
&\quad = r_{Q_{\widehat{l_0}|e}}(i) && (\text{by definition of state } Q_l) \\
&\quad > FS_{Q_{l_0}}(e) && (\text{by assumption}) \\
&\quad = c(e) - allot_{Q_{l_0}}(e) && (\text{by definition of fair share and since } \left|\mathcal{A}_{Q_{l_0}} \mid e\right| = 1) \\
&\quad = c(e) - allot_{Q_l}(e).
\end{aligned}$$

This is a contradiction.

Assume now that there exists some session $k \in \mathcal{A}_{Q_{l_0}} \mid e$ with $k \neq i$. By Proposition 4.12, $r_{Q_{\widehat{l_0}|e}}(k) \geq FS_{Q_{l_0}}(e)$. Together with $r_{Q_{\widehat{l_0}|e}}(i) > FS_{Q_{l_0}}(e)$, this implies a contradiction to Lemma 4.3 (condition (3)), and the proof is now complete. ∎

We continue with the proof of Proposition 4.14. In case $i \in \mathcal{D}_{Q_l}$ for some state $Q_l$ in $\alpha$ such that $Q_{l_0} \xrightarrow{\alpha} Q_l \xmapsto{\alpha} Q_{\widehat{l_0}|e}$, the definition of execution implies that $i \in \mathcal{D}_{\overrightarrow{Q_{\widehat{l_0}|e}}}$. So, assume that for each state $Q_l$ in execution $\alpha$ such that $Q_{l_0} \xrightarrow{\alpha} Q_l \xmapsto{\alpha} Q_{\widehat{l_0}|e}$, $i \in \mathcal{A}_{Q_l}$. Denote by $Q_l$ the latest state in execution $\alpha$ such that both $Q_{l_0} \xrightarrow{\alpha} Q_l \xmapsto{\alpha} Q_{\widehat{l_0}|e}$ and $r_{Q_l}(i) = r_{Q_{\widehat{l_0}|e}}(i)$.

Since $e \in MFSE_{Q_{l_0}}$, Lemma 4.5 implies that $e$ is a bottleneck edge for $Q_{l_0}$. Since $i \in \mathcal{A}_{Q_l}$ and $i$ traverses edge $e$, it follows that $\mathcal{A}_{Q_l} \mid e \neq \emptyset$. Hence, Proposition 4.8 (conditions (1) and (2)) implies that $FS_{Q_l}(e) = FS_{Q_{l_0}}(e)$, and $e$ is a bottleneck edge for $Q_l$. By Lemma 4.15, $r_{Q_{\widehat{l_0}|e}}(i) = FS_{Q_{l_0}}(e)$. It follows that $r_{Q_l}(i) = FS_{Q_l}(e)$.

In total, $e$ is a bottleneck edge for state $Q_l$, traversed by session $i$ for which $r_{Q_l}(i) = FS_{Q_l}(e)$. Since $\mathsf{Alg}$ is bottleneck, it follows that $i \in \mathcal{D}_{\overrightarrow{Q_l}}$. Since $Q_l \to \overrightarrow{Q_{\widehat{l_0}|e}}$, it follows that $i \in \mathcal{D}_{\overrightarrow{Q_{\widehat{l_0}|e}}}$. □

The final termination property is a direct consequence of Proposition 4.14. In essence, we establish that scheduling any sequence of sessions that includes all currently active ones must result in finalizing the rate of *at least one* active session per cluster.

PROPOSITION 4.16 (termination of at least one session per cluster). *Assume that* $\mathsf{Alg}$ *is optimistic and bottleneck. For any integer* $l_0 \geq 0$ *such that* $\mathcal{A}_{Q_{l_0}} \neq \emptyset$ *and* $\widehat{l_0} < \infty$*, fix any active cluster* $\mathcal{S}_j$ *in* $Q_{l_0}$*. Then there exists some session* $S_i \in \mathcal{S}_j \cap \mathcal{A}_{Q_{l_0}}$ *such that* $S_i \in \mathcal{D}_{\overrightarrow{Q_{\widehat{l_0}}}}$*.*

*Proof.* Since $\mathcal{S}_j$ is active in $Q_{\mathcal{A}_{Q_{l_0}}}$, it follows that $MFSE_{Q_{l_0}}(\mathcal{S}_j) \neq \emptyset$. Fix any edge $e \in MFSE_{Q_{l_0}}(\mathcal{S}_j)$, and consider any session $i \in \mathcal{A}_{Q_{l_0}} \mid e$. By Proposition 4.14, $i \in \mathcal{D}_{\overrightarrow{Q_{\widehat{l_0}}}}$. □

## 5. Upper bounds.

**5.1. Oblivious algorithms.** This section presents the algorithm $\mathsf{RoundRobin}$ and shows the following.

THEOREM 5.1 (upper bound for oblivious algorithms). $\mathsf{RoundRobin}$ *computes the max-min fair rate vector within* $\frac{dn}{2} + \frac{n}{2}$ `update` *operations.*

The scheduler of $\mathsf{RoundRobin}$ conducts scheduling rounds. In each round, each of the $n$ sessions is scheduled in round-robin order. Moreover, $\mathsf{RoundRobin}$ is bottleneck. By definition of $\mathsf{RoundRobin}$, each session is scheduled once in each round. Thus, Proposition 4.16 implies that at least one session per cluster becomes done in each round. Since each cluster contains at most $d$ sessions, all sessions are done after $d$ rounds, whence the network enters a final state. So, Proposition 4.6 immediately implies that $\mathsf{RoundRobin}$ computes the max-min fair rate vector.

We now establish an upper bound on the convergence complexity of $\mathsf{RoundRobin}$. Since at least one session per cluster becomes done in each round, at most $|\mathcal{S}_j| - l + 1$ `update` operations are executed in round $l$, $1 \leq l \leq |\mathcal{S}_j|$, on sessions in any cluster $\mathcal{S}_j$. Summing up over all clusters and rounds yields that

$$\begin{aligned}
\mathcal{U}_{\mathsf{RoundRobin}} &\leq \sum_{j\geq 1} \sum_{1\leq l\leq d} \max\{0, (|\mathcal{S}_j| - l + 1)\} \\
&\leq \sum_{j\geq 1} \sum_{1\leq l\leq |\mathcal{S}_j|} (|\mathcal{S}_j| - l + 1) \\
&= \sum_{j\geq 1} \frac{|\mathcal{S}_j|(\mathcal{S}_j + 1)}{2} \\
&\leq \frac{dn}{2} + \frac{n}{2}.
\end{aligned}$$

$\mathsf{RoundRobin}$ extends naturally to a class of bottleneck algorithms $d$-$\mathsf{Epoch}$. The scheduler $d$-$\mathsf{EpochSched} = d$-$\mathsf{EpochSched}_1 \ldots d$-$\mathsf{EpochSched}_d$ $d$-$\mathsf{EpochSched}'$ of algorithm $d$-$\mathsf{Epoch}$ is a sequence such that for each index $r$, $1 \leq r \leq d$, all sessions are included in $d$-$\mathsf{EpochSched}_r$. An argument identical to the one applied to $\mathsf{RoundRobin}$ immediately implies the following.

THEOREM 5.2 (upper bound for oblivious algorithms). $d$-$\mathsf{Epoch}$ *computes the max-min fair rate vector within* $\frac{dn}{2} + \frac{n}{2}$ `update` *operations.*

**5.2. Nonoblivious algorithms.** This section presents the algorithm $\mathsf{Linear}$ and shows the following.

THEOREM 5.3 (upper bound for nonoblivious algorithms). $\mathsf{Linear}$ *computes the max-min fair rate vector within exactly* $n$ `update` *operations.*

The scheduler of $\mathsf{Linear}$ maintains an active edge of minimum fair share and schedules all active sessions traversing it in any order. Once it finishes, it chooses any other (active) edge of minimum fair share, and so on. Moreover, $\mathsf{Linear}$ is bottleneck.

Consider any state $Q_{l_0}$ and an arbitrary edge $e \in \mathit{MFSE}_{Q_{l_0}}$. Clearly, $e \in \mathit{MFSE}_{Q_{l_0}}(\mathcal{S}_j)$ for some cluster $\mathcal{S}_j$. By definition of $\mathsf{Linear}$, each session traversing $e$ is scheduled exactly once, so that the state $Q_{\widehat{l_0|e}}$ is reached; by Proposition 4.14, each such session is done in state $Q_{\widehat{l_0|e}}$. It follows that all sessions eventually become done and a final state is reached. Hence, Proposition 4.6 immediately implies that $\mathsf{Linear}$ computes the max-min fair rate vector.

$\mathsf{Linear}$ incurs $n$ `update` operations. Recall that all rates are initially zero. Since all capacities exceed zero, all rates in a max-min fair rate vector exceed zero as well. Since each `update` increases the rate of exactly one session, it follows that at least $n$ `update` operations are needed, so that $\mathcal{U}_{\mathsf{Alg}} \geq n$ for every $\mathsf{Alg}$. Thus, $\mathsf{Linear}$ is optimal.

**6. Network construction.** We present a generic, combinatorial construction of a network associated with any sequence $\mathsf{Seq} = i_1, i_2, \ldots$, where for each $l \geq 1$, $i_l \in [n]$. For any sequence $\mathsf{Seq}$, denote $|\mathsf{Seq}|$ to be the *length* of $\mathsf{Seq}$; an infinite sequence has infinite length. For a sequence $\mathsf{Seq}$ of session indices, and for any set of sessions $\mathcal{S}' \subseteq \mathcal{S}$, denote by $\mathsf{Seq} \mid \mathcal{S}'$ the *restriction* of $\mathsf{Seq}$ to indices of sessions in $\mathcal{S}'$. Denote by $\mathsf{Seq} \uparrow \mathcal{S}'$ the shortest prefix of $\mathsf{Seq} \mid \mathcal{S}'$ that includes the indices of all sessions in $\mathcal{S}'$, in the order they appear in this prefix of $\mathsf{Seq} \mid \mathcal{S}'$ and with no repetitions; in case no such prefix exists, $\mathsf{Seq} \uparrow \mathcal{S}'$ results from $\mathsf{Seq} \mid \mathcal{S}'$ by removing repetitions, while, however, preserving the order of the indices. Denote by $\mathsf{Seq} \downarrow \mathcal{S}'$ the remaining suffix of $\mathsf{Seq} \mid \mathcal{S}'$. For example, if $\mathsf{Seq} = 1, 5, 4, 2, 1, 3, 3, 3, 5, 4$ and $\mathcal{S}' = \{1, 3, 4\} \subset \{1, 2, 3, 4, 5\}$, then $\mathsf{Seq} \mid \mathcal{S}' = 1, 4, 1, 3, 3, 3, 4$, $\mathsf{Seq} \uparrow \mathcal{S}' = 1, 4, 3$, and $\mathsf{Seq} \downarrow \mathcal{S}' = 3, 3, 4$.

Fix any even integer $d$, and choose any integer $n$ that is a multiple of $d$.[3] We construct a network $G = G(\mathsf{Seq}) = (V(\mathsf{Seq}), E(\mathsf{Seq}))$, as a function of $\mathsf{Seq}$, with a set of sessions $\mathcal{S} = \{S_1, S_2, \ldots, S_n\}$ laid out on $G$. For assigning capacities to network edges, we will use two (finite) sequences of real numbers, $b$ and $p$ (for *bottom* and *potential*, resp.), each of length $\frac{d}{2}$, defined recursively as follows.

- $b_0 = p_0 = 0$, $b_1 = 0$, and $p_1 = 2^p$ for some integer $p \geq d$;
- for each index $r$, $1 < r \leq \frac{d}{2}$, $b_r = b_{r-1} + \frac{p_{r-1}}{2}$ and $p_r = \frac{p_{r-1}}{4}$.

Partition $\mathcal{S}$ into $\frac{n}{d}$ clusters $\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_{n/d}$ so that for each $j$, $1 \leq j \leq \frac{n}{d}$, $\mathcal{S}_j$ contains sessions $S_{(j-1)d+1}, S_{(j-1)d+2}, \ldots, S_{(j-1)d+d}$; notice that $|\mathcal{S}_j| = d$. For each cluster $\mathcal{S}_j$, we construct a network $G_j = G_j(\mathsf{Seq} \mid \mathcal{S}_j) = (V_j(\mathsf{Seq} \mid \mathcal{S}_j), E_j(\mathsf{Seq} \mid \mathcal{S}_j))$, with $\mathcal{S}_j$ laid out on $G_j(\mathsf{Seq} \mid \mathcal{S}_j)$, so that

$$G(\mathsf{Seq}) = \left( \bigcup_{1 \leq j \leq n/d} V_j(\mathsf{Seq} \mid \mathcal{S}_j), \bigcup_{1 \leq j \leq n/d} E_j(\mathsf{Seq} \mid \mathcal{S}_j) \right);$$

thus, each individual network $G_j$ is a function of the sequence $\mathsf{Seq} \mid \mathcal{S}_j$, and the network $G$ is the resulting composition.

[3]Standard "padding" techniques can be used to handle the case where $n$ is not a multiple of $d$.

The construction of the network $G_j$ proceeds in a sequence of $\frac{d}{2}$ *epochs*; in epoch $r$, $1 \leq r \leq \frac{d}{2}$, the network $G_j^{(r)} = (V_j^{(r)}, E_j^{(r)})$ is constructed, so that $G_j = (\bigcup_{1\leq r\leq d/2} V_j^{(r)}, \bigcup_{1\leq r\leq d/2} E_j^{(r)})$; thus, the network $G_j$ is the composition of the individual networks $G_j^{(r)}$.

For each $r$, $1 \leq r \leq \frac{d}{2}$, the construction of $G_j^{(r)}$ uses $b_r$ and $p_r$ as parameters. It also uses the following sets and sequences:

- a set of indices $\mathcal{I}_j^{(r)} \subseteq \mathcal{S}_j$ such that $|\mathcal{I}_j^{(r)}| = d - 2(r-1)$;
- a sequence $\mathsf{Seq}_j^{(r)}$, which is a suffix of $\mathsf{Seq} \mid \mathcal{S}_j$;
- a set $\{i_f^{(r)}, i_l^{(r)}\} \subseteq \mathcal{I}_j^{(r)}$; roughly speaking, $i_f^{(r)}$ and $i_l^{(r)}$ will be defined to be the first and last indices, respectively, of $\mathsf{Seq}_j^{(r)} \uparrow \mathcal{I}_j^{(r)}$, or some of them will be set to arbitrary indices from $\mathcal{I}_j^{(r)}$ in case $|\mathsf{Seq}_j^{(r)} \uparrow \mathcal{I}_j^{(r)}| < 2$.

These sets and sequences are inductively defined as follows. For the basis case where $r = 1$, $\mathcal{I}_j^{(1)} := \mathcal{S}_j$, $\mathsf{Seq}_j^{(1)} := \mathsf{Seq} \mid \mathcal{S}_j$, and the set $\{i_f^{(1)}, i_l^{(1)}\}$ is defined as follows:

(1) First, assume that $\mathsf{Seq}_j^{(1)} = \lambda$, the *empty* sequence, so that $\mathsf{Seq}_j^{(1)} \uparrow \mathcal{I}_j^{(1)} = \lambda$; then fix $i_f^{(1)}$ and $i_l^{(1)}$ to be any arbitrary indices in $\mathcal{I}_j^{(1)}$.

(2) Now assume that $\mathsf{Seq}_j^{(1)} \neq \lambda$, so that $\mathsf{Seq}_j^{(1)} \uparrow \mathcal{I}_j^{(1)} \neq \lambda$; there are two cases to consider.

  (a) First, take $|\mathsf{Seq}_j^{(1)} \uparrow \mathcal{I}_j^{(1)}| = 1$; then $i_f^{(1)} := \mathsf{Seq}_j^{(1)} \uparrow \mathcal{I}_j^{(1)}$, and fix $i_l^{(1)}$ to be any arbitrary index in $\mathcal{I}_j^{(1)} \setminus \{i_f^{(1)}\}$.

  (b) Finally, take $|\mathsf{Seq}_j^{(1)} \uparrow \mathcal{I}_j^{(1)}| > 1$, so that $\mathsf{Seq}_j^{(1)} \uparrow \mathcal{I}_j^{(1)} = i_f, \ldots, i_l$; then $i_f^{(1)} := i_f$ and $i_l^{(1)} := i_l$.

Informally, $\mathcal{I}_j^{(1)}$ contains indices of all sessions in cluster $\mathcal{S}_j$, while $\mathsf{Seq}_j^{(1)}$ is the restriction of $\mathsf{Seq}$ to indices of sessions in cluster $\mathcal{S}_j$; moreover, $i_f^{(1)}$ and $i_l^{(1)}$ are the indices of sessions in cluster $\mathcal{S}_j$ appearing first and last, respectively, in $\mathsf{Seq}_j^{(1)} \uparrow \mathcal{I}_j^{(1)}$ or some of them will be set to be arbitrary indices if $\mathsf{Seq}_j^{(1)} \uparrow \mathcal{I}_j^{(1)}$ misses any such indices.

Assume inductively that we have defined $\mathcal{I}_j^{(r-1)}$, $\mathsf{Seq}_j^{(r-1)}$, and $\{i_f^{(r-1)}, i_l^{(r-1)}\}$ for some integer $r$, where $2 \leq r \leq \frac{d}{2}$. For the induction step, we show how to construct $\mathcal{I}_j^{(r)}$, $\mathsf{Seq}_j^{(r)}$, and $\{i_f^{(r)}, i_l^{(r)}\}$. Define $\mathcal{I}_j^{(r)} := \mathcal{I}_j^{(r-1)} \setminus \{i_f^{(r-1)}, i_l^{(r-1)}\}$, $\mathsf{Seq}_j^{(r)} := (\mathsf{Seq}_j^{(r-1)} \downarrow \mathcal{I}_j^{(r-1)}) \mid \mathcal{I}_j^{(r)}$, and the set $\{i_f^{(r)}, i_l^{(r)}\}$ is defined through a case analysis identical to the one for the basis case.

(1) Assume first that $\mathsf{Seq}_j^{(r)} = \lambda$, so that $\mathsf{Seq}_j^{(r)} \uparrow \mathcal{I}_j^{(r)} = \lambda$; then fix $i_f^{(r)}, i_l^{(r)}$ to be any arbitrary indices in $\mathcal{I}_j^{(r)}$.

(2) Now assume that $\mathsf{Seq}_j^{(r)} \neq \lambda$, so that $\mathsf{Seq}_j^{(r)} \uparrow \mathcal{I}_j^{(r)} \neq \lambda$; there are two cases to consider.

  (a) First, take $|\mathsf{Seq}_j^{(r)} \uparrow \mathcal{I}_j^{(r)}| = 1$; then $i_f^{(r)} := \mathsf{Seq}_j^{(r)} \uparrow \mathcal{I}_j^{(r)}$, and fix $i_l^{(r)}$ to be any arbitrary index in $\mathcal{I}_j^{(r)}$;

  (b) Finally, take $|\mathsf{Seq}_j^{(r)} \uparrow \mathcal{I}_j^{(r)}| > 1$, so that $\mathsf{Seq}_j^{(r)} \uparrow \mathcal{I}_j^{(r)} = i_f, \ldots, i_l$; then $i_f^{(r)} := i_f$ and $i_l^{(r)} := i_l$.

Informally, $\mathcal{I}_j^{(r)}$ is obtained by removing $i_f^{(r-1)}$ and $i_l^{(r-1)}$ from $\mathcal{I}_j^{(r-1)}$, while $\mathsf{Seq}_j^{(r)}$ results from $\mathsf{Seq}_j^{(r-1)}$ by chopping off its shortest prefix that includes all indices in

$\mathcal{I}_j^{(r-1)}$ and restricting the remaining suffix to indices in $\mathcal{I}_j^{(r)}$; moreover, $i_f^{(r)}$ and $i_l^{(r)}$ are the indices of sessions in $\mathcal{I}_j^{(r)}$ that appear first and last, respectively, in this suffix, or some of them will be set to arbitrary indices in case this suffix misses any such indices.

Since two different sessions are extracted from $\mathcal{S}_j$ in each of the $\frac{d}{2}$ epochs, all $d$ sessions in $\mathcal{S}_j$ will eventually be extracted. We now describe the construction of $G_j^{(r)}$, $1 \leq r \leq \frac{d}{2}$:

- sessions $i_f^{(r)}$ and $i_l^{(r)}$ traverse some edge $e_{i_l}^{(r)}$ with $c(e_{i_l}^{(r)}) = 2b_r + \frac{p_r}{2}$;
- for each $i \in \mathcal{I}_j^{(r)} \setminus \{i_f^{(r)}, i_l^{(r)}\}$, sessions $i_f^{(r)}$ and $i$ traverse some edge $e_i^{(r)}$ with $c(e_i^{(r)}) = 2b_r + p_r$.

Informally, $i_f^{(r)}$ shares an edge with every other session in $\mathcal{I}_j^{(r)}$; the capacity of the edge shared with $i_l^{(r)}$ is the smallest, while all other capacities are equal. All other sessions traverse only the edge shared with $i_f^{(r)}$. We finally state an easy to prove property of the construction.

LEMMA 6.1. *For each integer $r$, where $1 < r \leq \frac{d}{2}$, for each index $r'$ where $1 \leq r' < r$, let $e^{(r)}$ and $e^{(r')}$ be any edges in $E_j^{(r)}$ and $E_j^{(r')}$, respectively. Then $c(e^{(r)}) > c(e^{(r')})$.*

*Example.* Fix $d = 6$ and choose $n = 12$. Consider the (infinite) elevator sequence

$$\mathsf{ElevSched} = 1, 2, \ldots, 11, 12, 12, 11, \ldots, 2, 1, \ldots, 1, 2, \ldots, 11, 12, 12, 11, \ldots, 2, 1, \ldots .$$

We construct the network $G = G(\mathsf{ElevSched}) = (V(\mathsf{ElevSched}), E(\mathsf{ElevSched}))$ as a function of $\mathsf{ElevSched}$, with a set of sessions $\mathcal{S} = \{S_1, \ldots, S_{12}\}$ laid out on $G$. Partition $\mathcal{S}$ into $\frac{12}{6} = 2$ clusters $\mathcal{S}_1$ and $\mathcal{S}_2$, each containing six sessions, so that $\mathcal{S}_1 = \{S_1, \ldots, S_6\}$ and $\mathcal{S}_2 = \{S_7, \ldots, S_{12}\}$. Fix $p = 10$, so that $b_1 = 0$ and $p_1 = 2^{10} = 1024$.

For the basis case where $r = 1$, which corresponds to the first epoch, $\mathcal{I}_1^{(1)} = \mathcal{S}_1$, and

$$\begin{aligned}\mathsf{ElevSched}_1^{(1)} &= \mathsf{ElevSched} \mid \mathcal{S}_1 \\ &= 1, 2, \ldots, 6, 6, 5, \ldots, 1, \ldots, 1, 2, \ldots, 6, 6, 5, \ldots, 1, \ldots .\end{aligned}$$

Thus, $\mathsf{ElevSched}_1^{(1)} \uparrow \mathcal{S}_1^{(1)} = 1, 2, \ldots, 6$, so that $i_f^{(1)} = 1$ and $i_l^{(1)} = 6$. We continue to describe the construction of the network $G_1^{(1)}$:

- sessions 1 and 6 traverse edge $e_6^{(1)}$ with $c(e_6^{(1)}) = 2b_1 + \frac{p_1}{2} = 512$;
- for each $i \in \{2, 3, 4, 5\}$, sessions 1 and $i$ traverse $e_i^{(1)}$ with $c(e_i^{(1)}) = 2b_1 + p_1 = 1024$.

The construction of the network $G_2^{(1)}$ is similar; it can be found in Figure 1. We proceed to the case $r = 2$, corresponding to the second epoch, where $\mathcal{I}_1^{(2)} = \mathcal{I}_1^{(1)} \setminus \{1, 6\} = \{2, 3, 4, 5\}$ and

$$\begin{aligned}\mathsf{ElevSched}_1^{(2)} &= \left(\mathsf{ElevSched}_1^{(1)} \downarrow \mathcal{I}_1^{(1)}\right) \mid \mathcal{I}_1^{(2)} \\ &= 5, 4, 3, 2, 2, 3, 4, 5, \ldots, 5, 4, 3, 2, 2, 3, 4, 5, \ldots .\end{aligned}$$

Thus, $\mathsf{ElevSched}_1^{(2)} \uparrow \mathcal{I}_1^{(2)} = 5, 4, 3, 2$, so that $i_f^{(2)} = 5$ and $i_l^{(2)} = 2$. We continue to describe the construction of $G_1^{(2)}$:

- sessions 5 and 2 traverse edge $e_2^{(2)}$ with $c(e_2^{(2)}) = 2b_2 + \frac{p_2}{2} = 1152$;

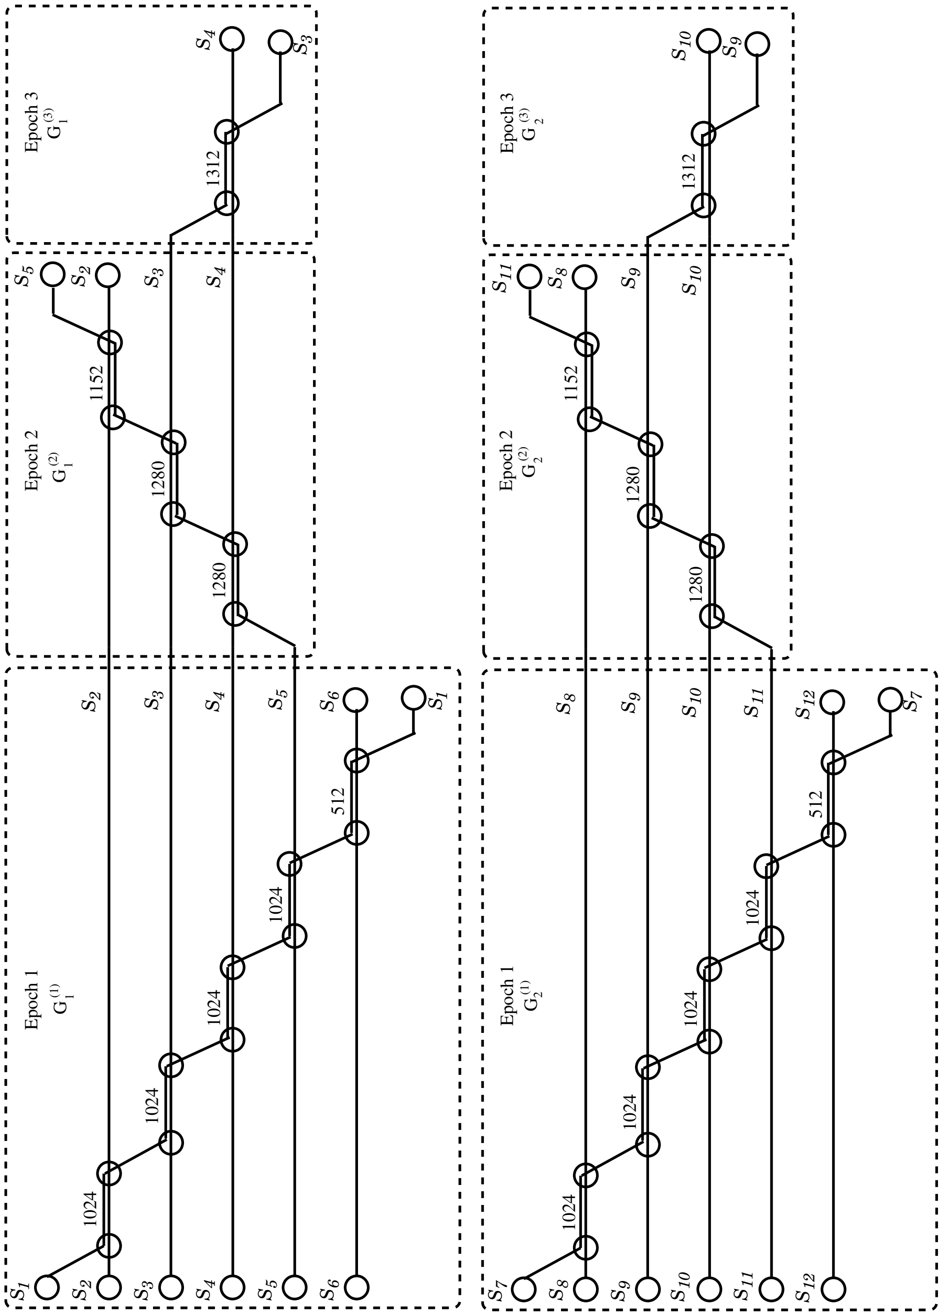

FIG. 1. *The network $G$(ElevSched).*

- for each $i \in \{3,4\}$, sessions 5 and $i$ traverse edge $e_i^{(2)}$ with $c(e_i^{(2)}) = 2b_2 + p_2 =$ 1280.

The construction of the network $G_2^{(2)}$ is similar; it can be found in Figure 1. We proceed to the case $r = 3$, corresponding to the third epoch, where $\mathcal{I}_1^{(3)} = \mathcal{I}_1^{(2)} \setminus$

$\{2,5\} = \{3,4\}$ and

$$\begin{aligned}\mathsf{ElevSched}_1^{(3)} &= \left(\mathsf{ElevSched}_1^{(2)} \downarrow \mathcal{I}_1^{(2)}\right) \mid \mathcal{I}_1^{(3)} \\ &= 3,4,4,3,\ldots,3,4,4,3,\ldots.\end{aligned}$$

Thus, $\mathsf{ElevSched}_1^{(3)} \uparrow \mathcal{I}_1^{(3)} = 3,4$, so that $i_f^{(3)} = 3$ and $i_l^{(3)} = 4$. We continue to describe the construction of $G_1^{(3)}$:

• sessions 3 and 4 traverse edge $e_4^{(3)}$ with $c(e_4^{(3)}) = 2b_3 + \frac{p_3}{2} = 2\cdot 640 + \frac{64}{2} = 1312$.

The construction of the network $G_2^{(3)}$ is similar; it can be found in Figure 1, which also depicts the complete network $G(\mathsf{ElevSched})$. $\square$

## 7. Lower bounds.

**7.1. Oblivious algorithms.** We present a lower bound of $\Omega(dn)$ on the convergence complexity of any optimistic, oblivious, and bottleneck algorithm $\mathsf{Alg} = \langle\mathsf{Sched}, \mathsf{Term}\rangle$ that computes the max-min fair rate vector. The proof uses the network $G\,(\mathsf{Sched})$ constructed in section 6. We start with two immediate technical lemmas that quantify $\Delta_Q(i,e)$ in case edge $e$ is traversed by only two sessions that remain active in state $Q$. (These lemmas will be used for Proposition 7.3.)

LEMMA 7.1. *For an edge e traversed only by sessions $i, i' \in \mathcal{A}_Q \mid e$, $\Delta_Q(i,e) = c(e) - r_Q(i) - \min\{\frac{c(e)}{2}, r_Q(i')\}$.*

Since in the setting of Claim 7.1, $c(e) - r_Q(i) - r_Q\,(i') = resid_Q(e)$, Lemma 7.2 follows.

LEMMA 7.2. *For an edge e traversed only by sessions $i, i' \in \mathcal{A}_Q \mid e$, $\Delta_Q(i,e) \geq resid_Q(e)$.*

We restrict our attention to the execution $\alpha$ of $\mathsf{Alg}$ on the network $G(\mathsf{Sched} \mid \mathcal{S}_j)$ with any particular cluster $\mathcal{S}_j$; for notational simplicity, we shall abuse notation and use $G\,(\mathsf{Sched})$ to denote $G(\mathsf{Sched} \mid \mathcal{S}_j)$ and $\mathcal{S}$ to denote $\mathcal{S}_j$.

For an execution $\alpha$, for any indices $l_1$ and $l_2$, $0 \leq l_1 \leq l_2$, define the set $\mathcal{S} \mid_\alpha (Q_{l_1}, Q_{l_2}] \subseteq \mathcal{S}$ to be $\mathcal{S} \mid_\alpha (Q_{l_1}, Q_{l_2}] = \left\{i_l \mid l_1 < l \leq l_2 \text{ and } i_l \in \mathcal{A}_{Q_{l_1}}\right\}$; roughly speaking, $\mathcal{S} \mid_\alpha (Q_{l_1}, Q_{l_2}]$ contains indices of all sessions active in $Q_{l_1}$ that are scheduled in front of any state following $Q_{l_1}$ and up to and including $Q_{l_2}$. Notice that if $l_1 = l_2$, $\mathcal{S} \mid_\alpha (Q_{l_1}, Q_{l_2}] = \emptyset$. For an execution $\alpha$, for any index $l_1 \geq 0$, define the set $\mathcal{S} \mid_\alpha (Q_{l_1}, \infty) \subseteq \mathcal{S}$ to be $\mathcal{S} \mid_\alpha (Q_{l_1}, \infty) = \left\{i_l \mid l_1 < l \text{ and } i_l \in \mathcal{A}_{Q_{l_1}}\right\}$; roughly speaking, $\mathcal{S} \mid_\alpha (Q_{l_1}, \infty)$ contains indices of all sessions active in $Q_{l_1}$ that are scheduled in front of any state following $Q_{l_1}$. Define $\mathcal{S} \mid_\alpha (Q_{l_1}, Q_{l_2}] \mid e$ and $\mathcal{S} \mid_\alpha (Q_{l_1}, \infty) \mid e$ in the natural way. Recall that for any state $Q_l$, $\widehat{l}$ is the least integer $l' \geq l$ such that $\mathcal{S} \mid_\alpha (Q_l, Q_{l'}] = \mathcal{A}_{Q_l}$, or infinite if no such integer exists.

Define inductively the index sequence $l_0, l_1, \ldots$ as follows. For the basis case, $l_0 = 0$. Assume inductively that for any integer $r \geq 1$, we have defined $l_1, \ldots, l_{r-1}$. For the induction step, define $l_r = \widehat{l_{r-1}}$. Define also the execution fragments $\alpha^{(1)}, \alpha^{(2)}, \ldots$, where for any integer $r \geq 1$, $\alpha^{(r)} = Q_{l_{r-1}}, \ldots, i_{l_r}, Q_{l_r}$. Call each $\alpha^{(r)}$, $r \geq 1$, an *execution epoch in* $\alpha$. Note that in case $l_r = \infty$, for any integer $r \geq 1$, $\alpha^{(r)}$ is the infinite suffix of $\alpha$ following state $Q_{l_{r-1}}$. Thus, write $\alpha = \alpha^{(1)} \cdot \alpha^{(2)} \ldots$. We remark that in case $\alpha$ is infinite, the number of execution epochs in $\alpha$ can still be finite if (and only if) there exists some integer $r \geq 0$ such that $l_r = \infty$. To simplify notation, denote each state $Q_{l_r}$, $r \geq 0$, as $Q^{(r)}$. Thus, $Q^{(r)}$ is the latest state in execution epoch $\alpha^{(r)}$ of $\alpha$. (Note that $Q^{(r)}$ exists if and only if $l_r < \infty$.)

The backbone of our analysis is a technical proposition (Proposition 7.3) that describes the states of execution $\alpha$. The first part of Proposition 7.3 (part (A)) deals with each state starting from $Q^{(r-1)}$, $1 \leq r \leq \frac{d}{2}$, such that not all active sessions in $\overrightarrow{Q^{(r-1)}}$ have yet been scheduled until this state. Thus, $Q^{(r)}$ would be the state immediately following this sequence of states; we will later show that $Q^{(r)}$ is well defined. Observe that the states considered in part (A) for any particular integer $r$, $1 \leq r \leq \frac{d}{2}$, are precisely the states in execution epoch $\alpha^{(r)}$ excluding state $Q^{(r)}$. Part (B) explores properties of state $Q^{(r)}$.

PROPOSITION 7.3 (properties of execution $\alpha$). *For each integer $r$, $1 \leq r \leq \frac{d}{2}$, the following hold for states in execution epoch $\alpha^{(r)}$:*

(A) (properties of states from $Q^{(r-1)}$ to $\overleftarrow{Q^{(r)}}$) *Consider any state $Q$ such that $Q^{(r-1)} \overset{\alpha}{\longmapsto} Q$ and $\mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \not\subseteq \mathcal{S} \mid_\alpha \left(Q^{(r-1)}, Q\right]$. Then the following conditions hold:*

(1) *for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$,*

$$r_Q(i) = \begin{cases} b_r + \frac{p_r}{2} & \text{if } i \in \mathcal{S} \mid_\alpha \left(Q^{(r-1)}, Q\right], \\ b_{r-1} + \frac{p_{r-1}}{2} & \text{otherwise}; \end{cases}$$

(2) *for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$,*

$$FS_Q(e_i^{(r)}) = \begin{cases} b_r + \frac{p_r}{2} & \text{if } i \notin \left\{i_f^{(r)}, i_l^{(r)}\right\}, \\ b_r + \frac{p_r}{4} & \text{if } i = i_l^{(r)}; \end{cases}$$

(3) *for the edges of $G(\mathsf{Sched})$, it holds, for $Q \neq Q^{(r-1)}$, that*

(a) *edge $e_{i_l^{(r)}}^{(r)}$ is a bottleneck edge for state $Q$;*

(b) *for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$,*

$$FS_Q(e_i^{(r)}) \neq MFS_Q(i_f^{(r)}),$$

*so that edge $e_i^{(r)}$ is not a bottleneck edge for state $Q$;*

(c) *for any integer $r'$, $1 \leq r' < r$, and for any edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ traversed by session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$,*

$$FS_Q(e^{(r')}) \neq MFS_Q(i),$$

*so that edge $e^{(r')}$ is not a bottleneck edge for state $Q$;*

(d) *for any integer $r'$, $r < r' \leq \frac{d}{2}$, and for any edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ traversed by session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$,*

$$FS_Q(e^{(r')}) \neq MFS_Q(i),$$

*so that $e^{(r')}$ is not a bottleneck edge for state $Q$;*

(4) *for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$, $i \notin \mathsf{Term}(Q)$;*

(5) *for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \mathcal{S} \mid_\alpha \left(Q^{(r-1)}, Q\right]$ scheduled in front of state $\overrightarrow{Q}$,*

$$\Delta_Q(i) = \begin{cases} \frac{p_r}{2} & \text{if } i \neq i_l^{(r)}, \\ \frac{p_r}{4} & \text{otherwise.} \end{cases}$$

(B) (properties of state $Q^{(r)}$) *The following conditions hold for state* $Q^{(r)}$*:*

(1) $l_r < \infty$*;*

(2) *for each session* $i \in \mathcal{A}_{Q^{\overrightarrow{(r-1)}}}$*,*

$$r_{Q^{(r)}}(i) = \begin{cases} b_r + \frac{p_r}{4} & \text{if } i \in \left\{i_f^{(r)}, i_l^{(r)}\right\}, \\ b_r + \frac{p_r}{2} & \text{if } i \in \mathcal{A}_{Q^{\overrightarrow{(r-1)}}} \setminus \left\{i_f^{(r)}, i_l^{(r)}\right\}; \end{cases}$$

(3) *for each session* $i \in \mathcal{A}_{Q^{\overrightarrow{(r-1)}}}$*,* $i \in \{i_f^{(r)}, i_l^{(r)}\}$ *if and only if* $i \in \mathsf{Term}(Q^{(r)})$*;*

(4) *for each session* $i \in \mathcal{A}_{Q^{\overrightarrow{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$ *and for any integer* $r'$*,* $1 \le r' \le r$*, for any edge* $e_i^{(r')}$*,*

(a) $resid_{Q^{(r)}}(e_i^{(r')}) \ge \frac{p_r}{4}$*;*

(b) $FS_{\overrightarrow{Q^{(r)}}}(e_i^{(r')}) \ge b_r + \frac{3\,p_r}{4}$.

Proposition 7.3 deals mainly with sessions active in state $Q^{\overrightarrow{(r-1)}}$ for any index $r$, $1 \le r \le \frac{d}{2}$. We start with an informal description of the conditions in part (A). Condition (A/1) determines rates of active sessions in state $Q$. Condition (A/2) determines the fair shares of all edges in epoch $r$; condition (A/3) establishes that edge $e_{i_l^{(r)}}^{(r)}$ is the only bottleneck edge for state $Q$. Condition (A/4) guarantees that no session is terminated in state $Q$. Finally, condition (A/5) determines the increase in state $Q$ for sessions active in $Q^{\overrightarrow{(r-1)}}$ that are not yet scheduled. We now continue with the conditions in part (B). Condition (B/1) asserts that all active sessions in state $Q^{\overrightarrow{(r-1)}}$ must be scheduled in execution epoch $\alpha^{(r)}$; condition (B/2) specifies their rates upon completion of $\alpha^{(r)}$. Moreover, condition (B/3) determines which of these sessions are terminated upon completion of $\alpha^{(r)}$. Condition (B/4) provides lower bounds on the residual capacity and fair share of some edges from previous epochs upon completion of $\alpha^{(r)}$.

We note that conditions (B/1) and (B/3) will suffice by themselves to imply the lower bound. However, the rather technical remaining conditions are necessary to assume inductively in the proof of conditions (B/1) and (B/3). To simplify notation, we will denote $e_{i_l^{(r)}}^{(r)}$ as $e_l^{(r)}$.

*Proof.* The proof is by induction on $r$. For the sake of shortening the proof, we merge the proof for the basis case (where $r = 1$) and the proof for the induction step; thus, the case $r = 1$ will be treated separately (where needed) along the proof of the induction step.

We assume, as our induction hypothesis, that the claims hold for all integers less than some fixed integer $r$, $1 \le r \le \frac{d}{2}$. Notice that if $r = 1$, the induction hypothesis is empty. We proceed to the induction step, where we prove the claims for $r$.

*Proof of part* (A). The proof is by induction on $Q$. For the sake of shortening the proof, we again merge the proof for the basis case (where $Q = Q^{(r-1)}$) and the proof for the induction step; thus, the case $Q = Q^{(r-1)}$ will be treated separately (where needed) along the proof for the induction step (on states).

Fix any state $Q$ such that $Q^{(r-1)} \stackrel{\alpha}{\longmapsto} Q$ and $\mathcal{A}_{Q^{\overrightarrow{(r-1)}}} \not\subseteq \mathcal{S} \mid_{\alpha} \left(Q^{(r-1)}, Q\right]$, and assume that for each state $Q'$ such that $Q^{(r-1)} \stackrel{\alpha}{\longmapsto} Q' \stackrel{\alpha}{\longrightarrow} Q$, the claims of part (A) hold for $Q'$; thus, we assume, as our induction hypothesis, that the claims of part (A) hold for all states from $Q^{(r-1)}$ through but not including state $Q$. Notice that if $Q = Q^{(r-1)}$, the induction hypothesis is empty. We now proceed with the induction step, where we prove the claims for $Q$.

*Proof of* (A/1). There are two cases to consider.

(1) Assume first that $Q = Q^{(r-1)}$. Then $\mathcal{S} \mid_\alpha \left(Q^{(r-1)}, Q\right] = \emptyset$. In case $r = 1$, $Q = Q_0$, and condition (A/1) holds trivially since all session rates are initially zero and $b_0 = p_0 = 0$. So assume $r > 1$. By the induction hypothesis of induction on $r$ (condition (B/3)), $\mathcal{A}_{\overrightarrow{Q^{(r-1)}}} = \mathcal{A}_{\overrightarrow{Q^{(r-2)}}} \setminus \{i_f^{(r-1)}, i_l^{(r-1)}\}$. Hence, condition (A/1) follows from the induction hypothesis of induction on $r$ (condition (B/2)).

(2) Now assume that $Q \neq Q^{(r-1)}$. We proceed by case analysis on $i_Q$ (the session scheduled in front of state $Q$).

(a) Assume first that $i_Q \notin \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$. (Notice that this case need not be considered when $r = 1$, since all sessions are active in $\overrightarrow{Q^{(0)}} = Q_1$.) Then $\mathcal{S} \mid_\alpha \left(Q^{(r-1)}, Q\right] = \mathcal{S} \mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}]$. Since, in addition, no session rates change from $\overleftarrow{Q}$ to $Q$, the claim follows inductively. So we proceed to the cases where $i_Q \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$.

(b) Next assume that $i_Q = i_f^{(r)}$. There are two subcases to consider.

(i) First, take $i_f^{(r)} \notin \mathcal{S} \mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}]$; that is, $i_f^{(r)}$ has not been scheduled in front of any state between $Q^{(r-1)}$ and $Q$. Recall that $i_f^{(r)}$ is the session scheduled first (following state $Q^{(r-1)}$) among active sessions in $\overrightarrow{Q^{(r-1)}}$; so, for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$, $i \notin \mathcal{S} \mid_\alpha (Q^{(r-1)}, Q]$. Thus, by the induction hypothesis of induction on states (condition (A/1)), $r_{\overleftarrow{Q}}(i) = b_{r-1} + \frac{p_{r-1}}{2} = b_r$ (by recursive definition of $b_r$). In particular, $r_{\overleftarrow{Q}}(i_f^{(r)}) = b_r$. By the induction hypothesis of induction on states (condition (A/5)), $\Delta_{\overleftarrow{Q}}(i_f^{(r)}) = \frac{p_r}{2}$. Thus, by the `update` operation, $r_Q(i_f^{(r)}) = r_{\overleftarrow{Q}}(i_f^{(r)}) + \Delta_{\overleftarrow{Q}}(i_f^{(r)}) = b_r + \frac{p_r}{2}$.
Since $p_r \neq 0$, it follows that for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}\}$, $r_{\overleftarrow{Q}}(i) < r_Q(i_f^{(r)})$. Thus, by the `update` operation, $r_Q(i) = r_{\overleftarrow{Q}}(i) = b_{r-1} + \frac{p_{r-1}}{2}$. Since $\mathcal{S} \mid_\alpha (Q^{(r-1)}, Q] = \{i_f^{(r)}\}$, it follows that for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$,

$$r_Q(i) = \begin{cases} b_r + \frac{p_r}{2} & \text{if } i \in \mathcal{S} \mid_\alpha \left(Q^{(r-1)}, Q\right], \\ b_{r-1} + \frac{p_{r-1}}{2} & \text{otherwise.} \end{cases}$$

(ii) Now take $i_f^{(r)} \in \mathcal{S} \mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}]$. Then $\mathcal{S} \mid_\alpha (Q^{(r-1)}, Q] = \mathcal{S} \mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}]$. Clearly, $i_l^{(r)} \notin \mathcal{S} \mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}]$, while $i_f^{(r)} \in \mathcal{S} \mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}]$. By construction of $G(\mathsf{Sched})$, session $i_f^{(r)}$ traverses edge $e_l^{(r)}$ with $c(e_l^{(r)}) = 2b_r + \frac{p_r}{2}$, as does session $i_l^{(r)}$. By the induction hypothesis of induction on states (condition (A/1)), $r_{\overleftarrow{Q}}(i_f^{(r)}) = b_r + \frac{p_r}{2}$, while $r_{\overleftarrow{Q}}(i_l^{(r)}) = b_{r-1} + \frac{p_{r-1}}{2} = b_r$. By Lemma 7.1,

$$\begin{aligned} &\Delta_{\overleftarrow{Q}}(i_f^{(r)}, e_l^{(r)}) \\ &= c(e_l^{(r)}) - r_{\overleftarrow{Q}}(i_f^{(r)}) - \min\left\{\frac{c(e_l^{(r)})}{2}, r_{\overleftarrow{Q}}(i_l^{(r)})\right\} \\ &= 2\,b_r + \frac{p_r}{2} - \left(b_r + \frac{p_r}{2}\right) - \min\left\{b_r + \frac{p_r}{2}, b_r\right\} \\ &= 0, \end{aligned}$$

so that $\Delta_{\overleftarrow{Q}}(i_f^{(r)}) = 0$. Thus, by the `update` operation, for each session $i \in \mathcal{A}_{\overleftarrow{Q}}$, $r_Q(i) = r_{\overleftarrow{Q}}(i)$. By the induction hypothesis of induction on states (condition (A/4)), it follows that $\mathcal{A}_{\overleftarrow{Q}} = \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$. Hence, the induction hypothesis of induction on states (condition (A/1)) implies that for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$,

$$r_Q(i) = \begin{cases} b_r + \frac{p_r}{2} & \text{if } i \in \mathcal{S}\mid_\alpha \left(Q^{(r-1)}, Q\right], \\ b_{r-1} + \frac{p_{r-1}}{2} & \text{otherwise.} \end{cases}$$

(c) Assume now that $i_Q \neq i_f^{(r)}$. There are two subcases to consider.

(i) First consider the case where $i_Q \notin \mathcal{S}\mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}]$. By the induction hypothesis of induction on states (condition (A/1)), it follows that $r_{\overleftarrow{Q}}(i_Q) = b_{r-1} + \frac{p_{r-1}}{2} = b_r$; moreover, by condition (A/5), $\Delta_{\overleftarrow{Q}}(i_Q) = \frac{p_r}{2}$. Thus, by the `update` operation, $r_Q(i_Q) = r_{\overleftarrow{Q}}(i_Q) + \Delta_{\overleftarrow{Q}}(i_Q) = b_r + \frac{p_r}{2}$.
By induction hypothesis of induction on states (condition (A/1)), it follows that for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_Q\}$, $r_{\overleftarrow{Q}}(i) \leq b_r + \frac{p_r}{2}$; hence, $r_{\overleftarrow{Q}}(i) \leq r_Q(i_Q)$. Thus, by the `update` operation, $r_Q(i) = r_{\overleftarrow{Q}}(i)$. Since $\mathcal{S}\mid_\alpha (Q^{(r-1)}, Q] = \mathcal{S}\mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}] \bigcup \{i_Q\}$, the induction hypothesis of induction on states (condition (A/1)) implies now that for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$,

$$r_Q(i) = \begin{cases} b_r + \frac{p_r}{2} & \text{if } i \in \mathcal{S}\mid_\alpha \left(Q^{(r-1)}, Q\right], \\ b_{r-1} + \frac{p_{r-1}}{2} & \text{otherwise.} \end{cases}$$

(ii) Finally, consider the case where $i_Q \in \mathcal{S}\mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}] \setminus \{i_f^{(r)}\}$. Then $\mathcal{S}\mid_\alpha (Q^{(r-1)}, Q] = \mathcal{S}\mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}]$. Clearly, both $i_Q, i_f^{(r)} \in \mathcal{S}\mid_\alpha (Q^{(r-1)}, \overleftarrow{Q}]$. Thus, by the induction hypothesis of induction on states (condition (A/1)), $r_{\overleftarrow{Q}}(i_Q) = r_{\overleftarrow{Q}}(i_f^{(r)}) = b_r + \frac{p_r}{2}$. By construction of $G(\mathsf{Sched})$, $c(e_{i_Q}^{(r)}) = 2\,b_r + p_r$. It follows that $r_{\overleftarrow{Q}}(i_Q) = r_{\overleftarrow{Q}}(i_f^{(r)}) = \frac{c(e_{i_Q}^{(r)})}{2}$. Hence, Lemma 7.1 implies that $\Delta_{\overleftarrow{Q}}(i_Q, e_{i_Q}^{(r)}) = 0$, so that $\Delta_{\overleftarrow{Q}}(i_Q) = 0$. Thus, by the `update` operation, for each session $i \in \mathcal{A}_{\overleftarrow{Q}}$, $r_Q(i) = r_{\overleftarrow{Q}}(i)$. By the induction hypothesis of induction on states (condition (A/4)), it follows that $\mathcal{A}_{\overleftarrow{Q}} = \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$. Hence, the induction hypothesis of induction on states (condition (A/1)) implies that for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$,

$$r_Q(i) = \begin{cases} b_r + \frac{p_r}{2} & \text{if } i \in \mathcal{S}\mid_\alpha \left(Q^{(r-1)}, Q\right], \\ b_{r-1} + \frac{p_{r-1}}{2} & \text{otherwise.} \quad \square \end{cases}$$

*Proof of* (A/2). First consider edge $e_i^{(r)}$ for any session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$, with capacity $c(e_i^{(r)}) = 2\,b_r + p_r$, which is traversed by sessions $i_f^{(r)}$ and $i$. Either by definition of $Q_0$ in case $Q = Q^{(r-1)}$ and $r = 1$, or by the induction hypothesis of induction on $r$ (condition (B/3)) in case $Q = Q^{(r-1)}$ and $r \neq 1$, or by the induction hypothesis of induction on states (condition (A/4)) in case $Q \neq Q^{(r-1)}$, it follows that both $i_f^{(r)}, i \in \mathcal{A}_Q$, so that $\mathcal{A}_Q \mid e_i^{(r)} = \{i_f^{(r)}, i\}$. Hence,

$$\begin{aligned} FS_Q(e_i^{(r)}) &= \frac{c(e_i^{(r)}) - \mathit{allot}_Q(e_i^{(r)})}{|\mathcal{A}_Q \mid e_i^{(r)}|} \\ &= \frac{c(e_i^{(r)})}{2} \\ &= b_r + \frac{p_r}{2}. \end{aligned}$$

Now consider edge $e_l^{(r)}$ with capacity $c(e_l^{(r)}) = 2b_r + \frac{p_r}{2}$, which is traversed by sessions $i_f^{(r)}$ and $i_l^{(r)}$. Either by definition of $Q_0$ in case $Q = Q^{(r-1)}$ and $r = 1$, or by the induction hypothesis of induction on $r$ (condition (B/3)) in case $Q = Q^{(r-1)}$ and $r \neq 1$, or by the induction hypothesis of induction on states (condition (A/4)) in case $Q \neq Q^{(r-1)}$, it follows that both $i_f^{(r)}, i_l^{(r)} \in \mathcal{A}_Q$, so that $\mathcal{A}_Q \mid e_l^{(r)} = \{i_f^{(r)}, i_l^{(r)}\}$. Hence,

$$\begin{aligned} FS_Q(e_l^{(r)}) &= \frac{c(e_l^{(r)}) - \mathit{allot}_Q(e_l^{(r)})}{\left|\mathcal{A}_Q \mid e_l^{(r)}\right|} \\ &= \frac{c(e_l^{(r)})}{2} \\ &= b_r + \frac{p_r}{4}. \qquad \Box \end{aligned}$$

*Proof of* (A/3/a). By construction of $G(\mathsf{Sched})$, edge $e_l^{(r)}$ is traversed by sessions $i_f^{(r)}$ and $i_l^{(r)}$. We prove that each of them receives its minimum fair share on edge $e_l^{(r)}$.

(1) First, take session $i_f^{(r)}$, which traverses the following edges.
- edge $e_l^{(r)}$; by condition (A/2) shown above, $FS_Q(e_l^{(r)}) = b_r + \frac{p_r}{4}$;
- edge $e_i^{(r)}$ for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$; by condition (A/2) shown above, $FS_Q(e_i^{(r)}) = b_r + \frac{p_r}{2}$;
- edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ for each integer $r'$, $1 \leq r' < r$, in case $r > 1$. By the induction hypothesis of induction on $r$ (condition (B/4/b)), $FS_{\overrightarrow{Q^{(r-1)}}}(e^{(r')}) \geq b_{r-1} + \frac{3\,p_{r-1}}{4} = b_r + p_r$ (by recursive definition of $b_r$ and $p_r$). Since $Q \neq Q^{(r-1)}$, the induction hypothesis of induction on states (condition (A/4)) is nonempty and implies that $\mathcal{A}_Q = \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$. It follows that $FS_Q(e^{(r')}) = FS_{\overrightarrow{Q^{(r-1)}}}(e^{(r')})$, so that $FS_Q(e^{(r')}) \geq b_r + p_r$.

Hence, $MFS_Q(i_f^{(r)}) = b_r + \frac{p_r}{4}$, so that $MFS_Q(i_f^{(r)}) = FS_Q(e_l^{(r)})$.

(2) Now take session $i_l^{(r)}$, which traverses the following edges.
- edge $e_l^{(r)}$; by condition (A/2) shown above, $FS_Q(e_l^{(r)}) = b_r + \frac{p_r}{4}$;
- edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ for each integer $r'$, $1 \leq r' < r$, in case $r > 1$. By the induction hypothesis of induction on $r$ (condition (B/4/b)), $FS_{\overrightarrow{Q^{(r-1)}}}(e^{(r')}) \geq b_{r-1} + \frac{3\,p_{r-1}}{4} = b_r + p_r$. Since $Q \neq Q^{(r-1)}$, the induction hypothesis of induction on states (condition (A/4)) implies that

$\mathcal{A}_Q = \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$. It follows that $FS_Q(e^{(r')}) = FS_{\overrightarrow{Q^{(r-1)}}}(e^{(r')})$, so that $FS_Q(e^{(r')}) \geq b_r + p_r$.

These imply that $MFS_Q(i_l^{(r)}) = b_r + \frac{p_r}{4}$, so that $MFS_Q(i_l^{(r)}) = FS_Q(e_l^{(r)})$. Hence $MFS_Q(i_f^{(r)}) = MFS_Q(i_l^{(r)}) = FS_Q(e_l^{(r)})$, so that $e_l^{(r)}$ is a bottleneck edge for $Q$. ◻

*Proof of* (A/3/b). Consider edge $e_i^{(r)}$ for any session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$, which is traversed by sessions $i_f^{(r)}$ and $i$. By condition (A/3/a) shown above, edge $e_l^{(r)}$, traversed by session $i_f^{(r)}$, is a bottleneck edge for state $Q$, so that $MFS_Q(i_f^{(r)}) = FS_Q(e_l^{(r)})$. By condition (A/2) shown above, $FS_Q(e_l^{(r)}) = b_r + \frac{p_r}{4}$ and $FS_Q(e_i^{(r)}) = b_r + \frac{p_r}{2}$. Since $p_r \neq 0$, it follows that $FS_Q(e_l^{(r)}) < FS_Q(e_i^{(r)})$, so that $MFS_Q(i_f^{(r)}) < FS_Q(e_i^{(r)})$. It follows that $e_i^{(r)}$ is not a bottleneck edge for $Q$. ◻

*Proof of* (A/3/c). The claim holds vacuously in case $r = 1$. So assume $r > 1$. Consider any edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ for any integer $r'$, $1 \leq r' < r$, traversed by some session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$. By the induction hypothesis of induction on $r$ (condition (B/4/b)), $FS_{\overrightarrow{Q^{(r-1)}}}(e^{(r')}) \geq b_{r-1} + \frac{3\,p_{r-1}}{4}$. Since $Q \neq Q^{(r-1)}$, the induction hypothesis of induction on states (condition (A/4)) is nonempty and implies that $\mathcal{A}_Q = \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$. It follows that $FS_Q(e^{(r')}) = FS_{\overrightarrow{Q^{(r-1)}}}(e^{(r')})$, so that $FS_Q(e^{(r')}) \geq p_{r-1} + \frac{3\,p_{r-1}}{4} = b_r + p_r$. Session $i$ also traverses edge $e_i^{(r)}$. By condition (A/2) shown above, $FS_Q(e_i^{(r)}) \leq b_r + \frac{p_r}{2}$.

Since $p_r \neq 0$, it follows that $FS_Q(e^{(r')}) > FS_Q(e_i^{(r)})$, so that $FS_Q(e^{(r')}) > MFS_Q(i)$. It follows that $e^{(r')}$ is not a bottleneck edge for $Q$. ◻

*Proof of* (A/3/d). Consider any edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ for any integer $r'$, $r < r' \leq \frac{d}{2}$. Take any session $i$ traversing $e^{(r')}$; by construction of $G(\mathsf{Sched})$, $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$, and $i$ traverses also $e_i^{(r)}$ with $c(e_i^{(r)}) = 2\,b_r + p_r$. By condition (A/2) shown above, $FS_Q(e_i^{(r)}) = b_r + \frac{p_r}{2} = \frac{c(e_i^{(r)})}{2}$. Since $Q \neq Q^{(r-1)}$, the induction hypothesis of induction on states (condition (A/4)) is nonempty and implies that both sessions traversing $e^{(r')}$ are active in $Q$. So, $FS_Q(e^{(r')}) = \frac{c(e^{(r')})}{2}$.

By Lemma 6.1, $c(e_i^{(r)}) < c(e^{(r')})$. So, $FS_Q(e_i^{(r)}) < FS_Q(e^{(r')})$. By definition of minimum fair share, $MFS_Q(i) < FS_Q(e^{(r')})$. Hence, $e^{(r')}$ is not a bottleneck edge for $Q$. ◻

*Proof of* (A/4). If $Q = Q^{(r-1)}$, the claim holds trivially. So assume $Q \neq Q^{(r-1)}$. By condition (A/3/b) shown above, any edge $e_i^{(r)}$ with $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$ is not a bottleneck edge for $Q$. Moreover, by conditions (A/3/c) and (A/3/d) shown above, neither is any edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ with $1 \leq r' < r$ or $r < r' \leq \frac{d}{2}$. Since $\mathsf{Alg}$ is bottleneck, none of these edges causes the termination of a session in $Q$. Thus, it remains to prove only that edge $e_{i_l^{(r)}}^{(r)}$ does not cause either the termination of any of the sessions $i_f^{(r)}$ and $i_l^{(r)}$ traversing it.

Since $p_r \neq 0$, conditions (A/1) and (A/2) shown above imply that $r_Q(i_f^{(r)}) \neq FS_Q(e_l^{(r)})$ and $r_Q(i_l^{(r)}) \neq FS_Q(e_l^{(r)})$. Since $\mathsf{Alg}$ is bottleneck, it follows that $i_f^{(r)}, i_l^{(r)} \notin \mathsf{Term}\,(Q)$. ◻

*Proof of* (A/5). The proof is obtained by case analysis on $i$.

1. Assume first that $i = i_f^{(r)}$. We first prove by case analysis on $Q$ that, in this case, for each session $k \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$, $r_Q(k) = b_r$. (This will be useful for some

later calculations.)

- First take $Q = Q^{(r-1)}$. In case $r = 1$ where $Q = Q_0$, all session rates are zero in $Q_0$. Since $b_0 = p_0 = 0$, it follows that $r_Q(k) = b_{r-1} + \frac{p_{r-1}}{2}$. Assume now that $r > 1$. Since $k \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$, by construction of $G(\mathsf{Sched})$ and by the induction hypothesis of induction on $r$ (condition (B/3)), $k \notin \{i_f^{(r-1)}, i_l^{(r-1)}\}$. Thus, the induction hypothesis of induction on $r$ (condition (B/2)) implies that $r_Q(k) = b_{r-1} + \frac{p_{r-1}}{2}$.
- Now take $Q \neq Q^{(r-1)}$. Since $i_f^{(r)} \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \mathcal{S} \mid_\alpha \big(Q^{(r-1)}, Q\big]$, $k \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \mathcal{S} \mid_\alpha \big(Q^{(r-1)}, Q\big]$ as well. So, by condition (A/1) shown above, $r_Q(k) = b_{r-1} + \frac{p_{r-1}}{2}$.

So, in all cases, $r_Q(k) = b_{r-1} + \frac{p_{r-1}}{2} = b_r$. By construction of $G(\mathsf{Sched})$, $i_f^{(r)}$ traverses the following edges.

- edge $e_l^{(r)}$ with $c(e_l^{(r)}) = 2b_r + \frac{p_r}{2}$;
- edge $e_k^{(r)}$ for each session $k \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$, with $c(e_k^{(r)}) = 2b_r + p_r$;
- edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ for each index $r'$, $1 \leq r' < r$, in case $r > 1$.

We next calculate separately the increases for $i_f^{(r)}$ in $Q$ allowed by these edges.

(a) First consider edge $e_l^{(r)}$, which is also traversed by $i_l^{(r)} \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$. By Lemma 7.1,

$$\begin{aligned}
\Delta_Q(i_f^{(r)}, e_l^{(r)}) &= c(e_l^{(r)}) - r_Q(i_f^{(r)}) - \min\left\{\frac{c((e_l^{(r)})}{2}, r_Q(i_l^{(r)})\right\} \\
&= 2b_r + \frac{p_r}{2} - b_r - \min\left\{b_r + \frac{p_r}{4}, b_r\right\} \\
&= \frac{p_r}{2}.
\end{aligned}$$

(b) Next consider any edge $e_k^{(r)}$ for any session $k \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$, which is also traversed by session $k$. By Lemma 7.1,

$$\begin{aligned}
\Delta_Q(i_f^{(r)}, e_k^{(r)}) &= c(e_k^{(r)}) - r_Q(i_f^{(r)}) - \min\{c(e_k^{(r)}), r_Q(k)\} \\
&= 2\,b_r + p_r - b_r - \min\left\{b_r + \frac{p_r}{2}, b_r\right\} \\
&= p_r.
\end{aligned}$$

(c) Finally, consider edge $e^{(r')}$ for any integer $r'$, $1 \leq r' < r$, in case $r > 1$. By the induction hypothesis of induction on $r$ (condition (B/4/a)), $resid_{Q^{(r-1)}}(e^{(r')}) \geq \frac{p_{r-1}}{4}$. Recall that $i_f^{(r)}$ is the session scheduled first (following state $Q^{(r-1)}$) among active sessions in $\overrightarrow{Q^{(r-1)}}$. Since $i_f^{(r)} \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \mathcal{S} \mid_\alpha \big(Q^{(r-1)}, Q\big]$, it follows that for each session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$, $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \mathcal{S} \mid_\alpha \big(Q^{(r-1)}, Q\big]$. Thus, rates of all sessions are preserved from state $Q^{(r-1)}$ to $Q$. Hence, $resid_Q(e^{(r')}) = resid_{Q^{(r-1)}}(e^{(r')}) \geq \frac{p_{r-1}}{4} = p_r$. By Lemma 7.2, it follows that $\Delta_Q(i_f^{(r)}, e^{(r')}) \geq resid_Q(e^{(r')}) \geq p_r$.

Thus, by definition of increase, it follows that $\Delta_Q(i_f^{(r)}) = \frac{p_r}{2}$.

2. Now assume that $i \notin \{i_f^{(r)}, i_l^{(r)}\}$. Since $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \mathcal{S} \mid_\alpha \big(Q^{(r-1)}, Q\big]$, by condition (A/1) shown above, we have that $r_Q(i) = b_{r-1} + \frac{p_{r-1}}{2}$. By construction of $G(\mathsf{Sched})$ $i$ traverses the following edges.

- edge $e_i^{(r)}$ with $c(e_i^{(r)}) = 2\,b_r + p_r$;
- edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ for each integer $r'$, $1 \leq r' < r$, in case $r > 1$;
- edge $e^{(r'')} \in E^{(r'')}(\mathsf{Sched})$ for any integer $r''$, $r < r'' \leq \frac{d}{2}$.

We next calculate separately the increases for $i$ in $Q$ allowed by these edges.

(a) First consider edge $e_i^{(r)}$, which is also traversed by $i_f^{(r)}$. Since $i$ is scheduled in front of state $\overrightarrow{Q}$, it follows that $i_f^{(r)} \in \mathcal{S}\,|_\alpha\,\big(Q^{(r-1)}, Q\big]$. Thus, condition (A/1) shown above implies that $r_Q(i_f^{(r)}) = b_r + \frac{p_r}{2} = \frac{c(e_i^{(r)})}{2}$. By Lemma 7.1,

$$\begin{aligned}\Delta_Q(i, e_i^{(r)}) &= c(e_i^{(r)}) - r_Q(i) - \min\left\{\frac{c(e_i^{(r)})}{2}, r_Q(i_f^{(r)})\right\}\\ &= c(e_i^{(r)}) - r_Q(i) - \frac{c(e_i^{(r)})}{2}\\ &= \frac{c(e_i^{(r)})}{2} - \Big(b_{r-1} + \frac{p_{r-1}}{2}\Big).\end{aligned}$$

Alternatively, we derive that $\Delta_Q(i, e_i^{(r)}) = b_r + \frac{p_r}{2} - (b_{r-1} + \frac{p_{r-1}}{2}) = \frac{p_r}{2}$.[4]

(b) Next consider edge $e_i^{(r')}$ for any integer $r'$, $1 \leq r' < r$, in case $r > 1$, which is also traversed by $i_f^{(r')} \notin \{i_f^{(r)}, i_l^{(r)}\}$. Induction hypothesis of induction on $r$ (condition (B/3)) implies that $i_f^{(r')} \notin \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$; hence, $i_f^{(r')} \notin \mathcal{A}_Q$. So, $r_{Q^{(r-1)}}(i_f^{(r')}) = r_Q(i_f^{(r')})$. Recall that $r_Q(i) = b_{r-1} + \frac{p_{r-1}}{2}$. On the other hand, by the induction hypothesis of induction on $r$ (condition (B/2)), $r_{Q^{(r-1)}}(i) = b_{r-1} + \frac{p_{r-1}}{2}$. Hence, $r_Q(i) = r_{Q^{(r-1)}}(i)$. It now follows that $\mathit{resid}_Q(e_i^{(r')}) = \mathit{resid}_{Q^{(r-1)}}(e_i^{(r')})$. By the induction hypothesis of induction on $r$ (condition (B/4/a)), $\mathit{resid}_{Q^{(r-1)}}(e_i^{(r')}) \geq \frac{p_{r-1}}{4}$, so that $\mathit{resid}_Q(e_i^{(r')}) \geq \frac{p_{r-1}}{4}$. By Lemma 7.2, $\Delta_Q(i, e_i^{(r')}) \geq \frac{p_{r-1}}{4} = p_r$.

(c) Finally, consider edge $e^{(r'')}$ for any integer $r''$, $r < r'' \leq \frac{d}{2}$, which is also traversed by some other session $k \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$. By condition (A/1) shown above and by recursive definition of $b_r$, $r_Q(k) \leq b_r + \frac{p_r}{2} = \frac{c(e_i^{(r)})}{2}$. By Lemma 6.1, $c(e^{(r'')}) > c(e_i^{(r)})$. By Lemma 7.1,

$$\begin{aligned}\Delta_Q(i, e^{(r'')}) &= c(e^{(r'')}) - r_Q(i) - \min\left\{\frac{c(e^{(r'')})}{2}, r_Q(k)\right\}\\ &\geq c(e^{(r'')}) - r_Q(i) - \min\left\{\frac{c(e^{(r'')})}{2}, \frac{c(e_i^{(r)})}{2}\right\}\\ &\geq c(e^{(r'')}) - r_Q(i) - \frac{c(e^{(r'')})}{2}\\ &= \frac{c(e^{(r'')})}{2} - \Big(b_{r-1} + \frac{p_{r-1}}{2}\Big).\end{aligned}$$

[4]Both expressions provided for $\Delta_Q(i, e_i^{(r)})$ will be needed in the rest of the proof.

Since $c(e^{(r'')}) > c(e_i^{(r)})$, comparing the first expression for $\Delta_Q(i, e_i^{(r)})$ to $\Delta_Q(i, e^{(r'')})$ implies that $\Delta_Q(i, e^{(r'')}) > \Delta_Q(i, e_i^{(r)})$.
Thus, by definition of increase, it follows that $\Delta_Q(i) = \frac{p_r}{2}$.

3. Finally, assume that $i = i_l^{(r)}$. Since $i_l^{(r)} \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \mathcal{S} \mid_\alpha \left(Q^{(r-1)}, Q\right]$, by condition (A/1) shown above, we have that $r_Q(i_l^{(r)}) = b_{r-1} + \frac{p_{r-1}}{2} = b_r$. By construction of $G(\mathsf{Sched})$, $i_l^{(r)}$ traverses the following edges.
   - edge $e_l^{(r)}$ with capacity $c(e_l^{(r)}) = 2\,b_r + \frac{p_r}{2}$;
   - edge $e^{(r')} \in E^{(r')}(\mathsf{Sched})$ for each integer $r'$, $1 \le r' < r$, in case $r > 1$.

   We next calculate separately the increases for $i_l^{(r)}$ in $Q$ allowed by these edges.
   (a) First consider edge $e_l^{(r)}$, which is also traversed by session $i_f^{(r)}$. Since $i_l^{(r)}$ is scheduled in front of $\overrightarrow{Q}$, it follows that $i_f^{(r)} \in \mathcal{S} \mid_\alpha \left(Q^{(r-1)}, Q\right]$. Thus, condition (A/1) shown above implies that $r_Q(i_f^{(r)}) = b_r + \frac{p_r}{2}$. By Lemma 7.1,

$$\begin{aligned}\Delta_Q(i_l^{(r)}, e_l^{(r)}) &= c(e_l^{(r)}) - r_Q(i_l^{(r)}) - \min\left\{\frac{c(e_l^{(r)})}{2}, r_Q(i_f^{(r)})\right\}\\ &= 2\,b_r + \frac{p_r}{2} - b_r - \min\left\{b_r + \frac{p_r}{4}, b_r + \frac{p_r}{2}\right\}\\ &= \frac{p_r}{4}.\end{aligned}$$

   (b) Finally, consider any edge $e^{(r')}$ for some integer $r'$, $1 \le r' < r$, in case $r > 1$, which is also traversed by session $i_f^{(r')} \notin \{i_f^{(r)}, i_l^{(r)}\}$. Induction hypothesis of induction on $r$ (condition (B/3)) implies that $i_f^{(r')} \notin \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$, so that $i_f^{(r')} \notin \mathcal{A}_Q$. It follows that $r_{Q^{(r-1)}}(i_f^{(r')}) = r_Q(i_f^{(r')})$. Recall that $r_Q(i_l^{(r)}) = b_{r-1} + \frac{p_{r-1}}{2}$. On the other hand, by the induction hypothesis of induction on $r$ (condition (B/2)), we have that $r_{Q^{(r-1)}}(i_l^{(r)}) = b_{r-1} + \frac{p_{r-1}}{2}$. Hence, $r_Q(i_l^{(r)}) = r_{Q^{(r-1)}}(i_l^{(r)})$. It now follows that $\mathit{resid}_Q(e^{(r')}) = \mathit{resid}_{Q^{(r-1)}}(e^{(r')})$. By the induction hypothesis of induction on $r$ (condition (B/4/a)), $\mathit{resid}_{Q^{(r-1)}}(e^{(r')}) \ge \frac{p_{r-1}}{4}$, so that $\mathit{resid}_Q(e^{(r')}) \ge \frac{p_{r-1}}{4}$ as well. By Lemma 7.2, it follows that $\Delta_Q(i_l^{(r)}, e^{(r')}) \ge \frac{p_{r-1}}{4} = p_r$.

   Thus, by definition of increase, it follows that $\Delta_Q(i_l^{(r)}) = \frac{p_r}{4}$. □

The proof of part (A) is now complete. We continue with the proof of part (B).

*Proof of part* (B).

*Proof of* (B/1). Assume, by way of contradiction, that $l_r = \infty$. Then there exists some session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$ which is not scheduled in front of any state following $Q^{(r-1)}$. By condition (A/5) shown above, it follows that for any state $Q$ such that $Q^{(r-1)} \overset{\alpha}{\longmapsto} Q$, $\Delta_Q(i) \ge \frac{p_r}{4} > 0$ (since $p_r > 0$). Thus, by the `update` operation, the rate of session $i$ can be increased without causing any decrease to the rate of any other session with smaller rate. This is in contradiction to max-min fairness. □

Condition (B/1) establishes that state $Q^{(r)}$ is well defined. Recall that in part (A) we considered all states from $Q^{(r-1)}$ through $\overleftarrow{Q^{(r)}}$. We now explore further properties of $Q^{(r)}$.

*Proof of* (B/2). Recall that session $i_l^{(r)}$ is scheduled in front of $Q^{(r)}$. By condition (A/1) shown above, $r_{\overleftarrow{Q^{(r)}}}(i_f^{(r)}) = b_r + \frac{p_r}{2}$, while $r_{\overleftarrow{Q^{(r)}}}(i_l^{(r)}) = b_{r-1} + \frac{p_{r-1}}{2} = b_r$. Moreover, by condition (A/5) shown above, $\Delta_{\overleftarrow{Q^{(r)}}}(i_l^{(r)}) = \frac{p_r}{4}$. Thus, by the `update` operation, $r_{Q^{(r)}}(i_l^{(r)}) = r_{\overleftarrow{Q^{(r)}}}(i_l^{(r)}) + \Delta_{\overleftarrow{Q^{(r)}}}(i_l^{(r)}) = b_r + \frac{p_r}{4}$; moreover, $r_{Q^{(r)}}(i_f^{(r)}) = \min\{r_{Q^{(r)}}(i_l^{(r)}), r_{\overleftarrow{Q^{(r)}}}(i_f^{(r)})\} = \min\left\{b_r + \frac{p_r}{4}, b_r + \frac{p_r}{2}\right\} = b_r + \frac{p_r}{4}$.

Consider now any session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$. By definition of $Q^{(r)}$, $i \in \mathcal{S}\,|_{\alpha}\,(Q^{(r-1)}, \overleftarrow{Q^{(r)}}]$. Thus, condition (A/1) shown above implies that $r_{\overleftarrow{Q^{(r)}}}(i) = b_r + \frac{p_r}{2}$. Since, by construction of $G(\mathsf{Sched})$, $i \cap i_l^{(r)} = \emptyset$, the `update` operation implies that $r_{Q^{(r)}}(i) = r_{\overleftarrow{Q^{(r)}}}(i) = b_r + \frac{p_r}{2}$. □

*Proof of* (B/3). By condition (A/4) shown above, it follows that fair shares of all active edges are preserved from $\overleftarrow{Q^{(r)}}$ to $Q^{(r)}$. Since $\mathsf{Alg}$ is bottleneck and the termination condition for bottleneck algorithms is a predicate on session rates and fair shares, it follows that the only sessions that are candidates to be terminated in state $Q^{(r)}$ are those whose rates are changed in $Q^{(r)}$; by conditions (A/1) and (B/1) shown above, these are sessions $i_f^{(r)}$ and $i_l^{(r)}$.

By condition (A/3/a) shown above, edge $e_l^{(r)}$ is a bottleneck edge for $\overleftarrow{Q^{(r)}}$. Condition (A/4) shown above implies that both $i_f^{(r)}, i_l^{(r)} \in \mathcal{A}_{Q^{(r)}}$, so that $e_l^{(r)} \in AE_{Q^{(r)}}$. Thus, Proposition 4.8 (condition (2)) implies that $e_l^{(r)}$ is a bottleneck edge for $Q^{(r)}$. Recall that $FS_{Q^{(r)}}(e_l^{(r)}) = FS_{\overleftarrow{Q^{(r)}}}(e_l^{(r)})$. Thus, by condition (A/2) shown above, it follows that $FS_{Q^{(r)}}(e_l^{(r)}) = b_r + \frac{p_r}{4}$. By condition (B/2) shown above, this implies that $r_{Q^{(r)}}(i_f^{(r)}) = r_{Q^{(r)}}(i_l^{(r)}) = FS_{Q^{(r)}}(e_l^{(r)})$. Since $\mathsf{Alg}$ is bottleneck, it follows that $i_f^{(r)}, i_l^{(r)} \in \mathsf{Term}\left(Q^{(r)}\right)$. □

*Proof of* (B/4). Take any session $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \setminus \{i_f^{(r)}, i_l^{(r)}\}$, and fix any integer $r'$, $1 \leq r' \leq r$. The proof is by case analysis on $r'$.

1. First consider the case where $r' = r$. By construction of $G(\mathsf{Sched})$, edge $e_i^{(r)}$ with capacity $c(e_i^{(r)}) = 2\,b_r + p_r$ is traversed by sessions $i_f^{(r)}$ and $i$. So,

$$\begin{aligned}
&\mathit{resid}_{Q^{(r)}}(e_i^{(r)})\\
&\quad = c(e_i^{(r)}) - r_{Q^{(r)}}(i_f^{(r)}) - r_{Q^{(r)}}(i)\\
&\quad = 2\,b_r + p_r - \left(b_r + \frac{p_r}{4}\right) - \left(b_r + \frac{p_r}{2}\right) \quad \text{(by condition (B/2) shown above)}\\
&\quad = \frac{p_r}{4},
\end{aligned}$$

which establishes condition (B/4/a) in this case.
We continue with condition (B/4/b). By condition (B/3) shown above, $i_f^{(r)} \notin$

$\mathcal{A}_{\overrightarrow{Q^{(r)}}}$, while $i \in \mathcal{A}_{\overrightarrow{Q^{(r)}}}$, so that $|\mathcal{A}_{\overrightarrow{Q^{(r)}}}|e_i^{(r)}| = 1$. Thus,

$$\begin{aligned}
&FS_{\overrightarrow{Q^{(r)}}}(e_i^{(r)})\\
&= \frac{c(e_i^{(r)}) - allot_{\overrightarrow{Q^{(r)}}}(e_i^{(r)})}{\left|\mathcal{A}_{\overrightarrow{Q^{(r-1)}}} \mid e_i^{(r)}\right|}\\
&= \frac{2b_r + p_r - (b_r + \frac{p_r}{4})}{1} \text{ (by conditions (B/1) and (B/3) shown above)}\\
&= b_r + \frac{3}{4}p_r,
\end{aligned}$$

which establishes condition (B/4/b) in this case.

2. Now consider the case where $r' < r$. Clearly, $r > 1$ in this case, so that the induction hypothesis of induction on $r$ is nonempty. Fix any edge $e_i^{(r')} \in E^{(r')}(\mathsf{Sched})$. Condition (B/3) shown above implies that $i_f^{(r')} \notin \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$, so that $r_{Q^{(r)}}(i_f^{(r')}) = r_{Q^{(r-1)}}(i_f^{(r')})$. By condition (B/2) shown above, $r_{Q^{(r)}}(i) = b_r + \frac{p_r}{2}$, while by the induction hypothesis of induction on $r$ (condition (B/2)), $r_{Q^{(r-1)}}(i) = b_{r-1} + \frac{p_{r-1}}{2} = b_r$. Thus,

$$\begin{aligned}
&resid_{Q^{(r-1)}}(e_i^{(r')}) - resid_{Q^{(r)}}(e_i^{(r')})\\
&= (c(e_i^{(r')}) - r_{Q^{(r-1)}}(i_f^{(r')}) - r_{Q^{(r-1)}}(i))\\
&\quad - (c(e_i^{(r')}) - r_{Q^{(r)}}(i_f^{(r')}) - r_{Q^{(r)}}(i))\\
&= (r_{Q^{(r)}}(i) - r_{Q^{(r-1)}}(i)) - (r_{Q^{(r)}}(i_f^{(r')}) - r_{Q^{(r-1)}}(i_f^{(r')}))\\
&= \left(b_r + \frac{p_r}{2}\right) - b_r - 0\\
&= \frac{p_r}{2}.
\end{aligned}$$

By the induction hypothesis of induction on $r$ (condition (B/4/a)), it follows that $resid_{Q^{(r-1)}}(e_i^{(r')}) \geq \frac{p_{r-1}}{4} = p_r$. Thus, $resid_{Q^{(r)}}(e_i^{(r')}) \geq p_r - \frac{p_r}{2} > \frac{p_r}{4}$, which establishes condition (B/4/a) in this case.

We continue with condition (B/4/b). Recall that $i_f^{(r')} \notin \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$, so that $i_f^{(r')} \notin \mathcal{A}_{\overrightarrow{Q^{(r)}}}$, and $r_{\overrightarrow{Q^{(r-1)}}}(i_f^{(r')}) = r_{\overrightarrow{Q^{(r)}}}(i_f^{(r')})$; on the other hand, $i \in \mathcal{A}_{\overrightarrow{Q^{(r)}}}$, so that $i \in \mathcal{A}_{\overrightarrow{Q^{(r-1)}}}$. It follows that $FS_{\overrightarrow{Q^{(r-1)}}}(e_i^{(r')}) = FS_{\overrightarrow{Q^{(r)}}}(e_i^{(r')})$. By the induction hypothesis of induction on $r$ (condition (B/4/b)), it follows that $FS_{\overrightarrow{Q^{(r-1)}}}(e_i^{(r')}) \geq b_{r-1} + \frac{3\,p_{r-1}}{4} = b_r + p_r$. Thus, $FS_{\overrightarrow{Q^{(r)}}}(e_i^{(r')}) \geq b_r + p_r > b_r + \frac{3\,p_r}{4}$, which establishes condition (B/4/b) in this case. □

The proof of Proposition 7.3 is now complete. □

We are now ready to prove the following.

THEOREM 7.4 (lower bound for oblivious algorithms). *Assume that* $\mathsf{Alg}$ *is optimistic, oblivious, and bottleneck, and that it computes the max-min fair rate vector. Then* $\mathcal{U}_{\mathsf{Alg}} \geq \frac{dn}{4} + \frac{n}{2}$.

*Proof.* We will show that $\mathcal{U}_{\mathsf{Alg}}(\langle G(\mathsf{Sched}), \mathcal{S}\rangle) = \frac{dn}{4} + \frac{n}{2}$, where $\mathsf{Alg} = \langle \mathsf{Sched}, \mathsf{Term}\rangle$ and $G(\mathsf{Sched})$ is the network constructed in section 6. To do so, we calculate

$\mathcal{U}_{\mathsf{Alg}}(\langle G\,(\mathsf{Sched})\,, \mathcal{S}_j\rangle)$ for any particular cluster $\mathcal{S}_j$, $j \geq 1$, and we add up over all $\frac{n}{d}$ clusters. By Proposition 7.3 (condition (B/1)), the execution of $\mathsf{Alg}$ on $G\,(\mathsf{Sched} \mid \mathcal{S}_j)$ is divided into $\frac{d}{2}$ execution epochs $\alpha^{(1)}, \ldots, \alpha^{(d/2)}$ such that all active sessions are scheduled at least once in each epoch; condition (B/3) implies that only two such sessions are terminated in each epoch. Thus, at least $d - 2\,(r-1)$ `update` operations are executed in $\alpha^{(r)}$, $1 \leq r \leq \frac{d}{2}$. Summing up over all clusters and execution epochs yields that $\mathcal{U}_{\mathsf{Alg}}\,(G, \mathcal{S}) \geq \sum_{j=1}^{n/d} \sum_{r=1}^{d/2} (d - 2(r-1)) = \frac{nd}{4} + \frac{n}{2}$, as needed. ∎

**7.2. Partially oblivious algorithms.** In this section, we present a lower bound of $\Omega(dn)$ on the convergence complexity of any optimistic, partially oblivious, and bottleneck algorithm that computes the max-min rate vector.

For the sake of clarity of presentation, we first consider the special case where $d = n$. (We remark that this is the case where the lower bound to be shown is maximum over all possible values of $d$, $1 \leq d \leq n$.) The backbone of our proof for this case will be a simulation lemma that establishes a correspondence between the executions of any partially oblivious algorithm and a suitable oblivious algorithm on the network constructed from the latter as in section 6 (assuming $d = n$). We will then use the simulation lemma to prove a lower bound of $\Omega(n^2)$ for this case. We finally consider the general case of arbitrary $d$; we state the $\Omega(dn)$ lower bound for it and discuss its proof, which relies on a generalization of the simulation lemma to general $d$. We start with the simulation lemma for the case $d = n$.

PROPOSITION 7.5 (simulation lemma). *Assume that* $\mathsf{Alg}$ *is optimistic, partially oblivious, and bottleneck, and that it computes the max-min fair rate vector. Then there exists some optimistic, oblivious, and bottleneck algorithm* $\mathsf{OAlg} = \langle \mathsf{OSched}, \mathsf{OTerm}\rangle$ *such that there exist execution prefixes* $\alpha = \alpha_1 \cdot \alpha_2 \cdot \ldots \cdot \alpha_{d/2}$ *of* $\mathsf{OAlg}$ *and* $\beta = \beta_1 \cdot \beta_2 \cdot \ldots \cdot \beta_{d/2}$ *of* $\mathsf{Alg}$*, on network* $G\,(\mathsf{OSched})$*, such that for each integer* $r$*,* $1 \leq r \leq \frac{d}{2}$*, the following conditions hold:*

(1) $\alpha_r$ *and* $\beta_r$ *are identical;*

(2) *all sessions active in* $\mathit{first}\,(\beta_r)$ *are scheduled at least once in* $\beta_r$ *and only two of them terminate in* $\beta_r$*.*

We first provide an informal, high-level outline of our proof. Given any partially oblivious algorithm, we derive some oblivious algorithm such that the executions of the two algorithms on the network constructed from the oblivious one in section 6 are identical. The execution of the oblivious algorithm is described by Proposition 7.3; since the two executions are shown to be identical, this will eventually imply the claimed lower bound for the partially oblivious algorithm. In order to derive the oblivious algorithm with the required properties, we start with the set of all $n$-epoch, oblivious algorithms; we inductively restrict this set until it contains only algorithms that are compatible with the partially oblivious algorithm (with respect to their schedulers) and perform sufficiently many `update` operations. All intermediate sets of oblivious algorithms contain only algorithms that induce executions identical to the partially oblivious algorithm up to each intermediate point. In more detail, the partial execution of each oblivious algorithm in any intermediate set on the network constructed from the algorithm in section 6 is identical to the partial execution of the partially oblivious algorithm on the same network. Each individual intermediate step is extended progressively by considering the session scheduled next by the partially oblivious algorithm and restricting the intermediate set of oblivious algorithms to those that schedule the same session next. (The construction follows an outer induction on execution epochs and an inner induction on states within each epoch.)

*Proof.* For each index $r$, $1 \leq r \leq \frac{d}{2}$, we will construct a set $\mathbf{A}^{(r)}$ of optimistic, oblivious, and bottleneck algorithms that compute the max-min fair rate vector such that for each algorithm $\mathsf{OAlg} \in \mathbf{A}^{(r)}$, there exist execution prefixes $\alpha(\mathsf{OAlg}) = \alpha_1(\mathsf{OAlg}) \dots \alpha_r(\mathsf{OAlg})$ of $\mathsf{OAlg}$ and $\beta(\mathsf{OAlg}) = \beta_1(\mathsf{OAlg}) \dots \beta_r(\mathsf{OAlg})$ of $\mathsf{Alg}$ on network $G(\mathsf{OSched})$ so that

(1) for each algorithm $\mathsf{OAlg} \in \mathbf{A}^{(r)}$ for each integer $r'$, $1 \leq r' \leq r$, $\alpha_{r'}(\mathsf{OAlg})$ and $\beta_{r'}(\mathsf{OAlg})$ are identical;
(2) $\alpha(\mathsf{OAlg})$ is identical over all algorithms $\mathsf{OAlg} \in \mathbf{A}^{(r)}$;
(3) $\beta(\mathsf{OAlg})$ is identical over all algorithms $\mathsf{OAlg} \in \mathbf{A}^{(r)}$;
(4) for each algorithm $\mathsf{OAlg} \in \mathbf{A}^{(r)}$ for each integer $r'$, $1 \leq r' \leq r$, all sessions active in state *first* $(\beta_{r'}(\mathsf{OAlg}))$ are scheduled at least once in $\beta_{r'}(\mathsf{OAlg})$, but only two of them terminate in $\beta_{r'}(\mathsf{OAlg})$.

Any algorithm $\mathsf{OAlg}$ in the final set $\mathbf{A}^{(d/2)}$ will satisfy the claim due to conditions (1) and (4) guaranteed by the construction.

The construction will be by induction on $r$, $1 \leq r \leq \frac{d}{2}$. The construction employs the set of all optimistic, oblivious, bottleneck, $n$-epoch algorithms, which we denote as $\mathbf{A}^{(0)}$. By Theorem 5.2, any algorithm from $\mathbf{A}^{(0)}$ computes the max-min fair rate vector. Our construction will progressively restrict the set $\mathbf{A}^{(0)}$ so that $\mathbf{A}^{(d/2)} \subseteq \cdots \subseteq \mathbf{A}^{(r)} \subseteq \cdots \subseteq \mathbf{A}^{(0)}$. Hence, for each integer $r$, $1 \leq r \leq \frac{d}{2}$, any algorithm from $\mathbf{A}^{(r)}$ computes the max-min fair rate vector. This property will be needed later, whenever we use Proposition 7.3, which assumes it. For each algorithm $\mathsf{OAlg} \in \mathbf{A}^{(0)}$, consider the initial state $Q_0(\mathsf{OAlg})$ of network $G(\mathsf{OSched})$ (with all rates zero and all sessions active). Set $\alpha_0(\mathsf{OAlg}) := Q_0(\mathsf{OAlg})$ and $\beta_0(\mathsf{OAlg}) := Q_0(\mathsf{OAlg})$. For the sake of shortening the construction, we merge the construction for the basis case (where $r = 1$) and the construction for the induction step. Thus, the case $r = 1$ will be treated separately (where needed) along the construction for the induction step.

Fix any integer $r$, $1 \leq r \leq \frac{d}{2}$, and assume inductively that we have constructed a set $\mathbf{A}^{(r-1)}$ with the required properties. Notice that if $r = 1$, then $\mathbf{A}^{(r-1)} = \mathbf{A}^{(0)}$ and the induction hypothesis is empty.

For the induction step, we construct a set $\mathbf{A}^{(r)} \subseteq \mathbf{A}^{(r-1)}$ with the required properties. This construction is progressive and uses induction on states, starting with *last* $(\beta(\mathsf{OAlg}))$ for any algorithm $\mathsf{OAlg} \in \mathbf{A}^{(r-1)}$. We will prove that conditions (1), (2), and (3) are preserved along the inductive construction on states, while (4) holds when the construction of $\mathbf{A}^{(r)}$ is complete.

For the basis case (of induction on states), take $\mathbf{A}^{(r)} := \mathbf{A}^{(r-1)}$; for any algorithm $\mathsf{OAlg} = \langle \mathsf{OSched}, \mathsf{OTerm} \rangle \in \mathbf{A}^{(r-1)}$, set $\alpha_r(\mathsf{OAlg}) = \mathit{last}(\alpha_{r-1}(\mathsf{OAlg}))$ and $\beta_r(\mathsf{OAlg}) = \mathit{last}(\beta_{r-1}(\mathsf{OAlg}))$. In case $r = 1$, by definition of initial state $(Q_0(\mathsf{OAlg}))$, $\alpha_1(\mathsf{OAlg})$ (resp., $\beta_1(\mathsf{OAlg})$) is identical for all algorithms $\mathsf{OAlg} \in \mathbf{A}^{(1)}$, implying (2) and (3). By construction, for each algorithm $\mathsf{OAlg} \in \mathbf{A}^{(1)}$, it trivially holds that $\alpha_1(\mathsf{OAlg})$ and $\beta_1(\mathsf{OAlg})$ are identical, which implies (1). In case $r > 1$, by the induction hypothesis of induction on $r$, conditions (1), (2), and (3) hold.

We now continue with the induction step (induction on states) of the inductive construction of $\mathbf{A}^{(r)}$. Take any algorithm $\mathsf{OAlg} \in \mathbf{A}^{(r)}$ and consider $\alpha(\mathsf{OAlg})$. (By the induction hypothesis of induction on states (condition (2)), the choice of $\mathsf{OAlg}$ does not matter.) In case $r = 1$, all sessions are active in state $\mathit{last}(\beta_{r-1}(\mathsf{OAlg})) = Q_0(\mathsf{OAlg})$. In case $r > 1$, since $r - 1 < \frac{d}{2}$, Proposition 7.3 (condition (B/3)) implies that the set of active sessions in state $\mathit{last}(\alpha_{r-1}(\mathsf{OAlg}))$ is nonempty; the induction hypothesis of induction on states (condition (1)) implies now that the set of active sessions in state $\mathit{last}(\beta_{r-1}(\mathsf{OAlg}))$ is nonempty as well. If all such sessions have been scheduled at least once in $\alpha_r(\mathsf{OAlg})$, then the inductive construction of $\mathbf{A}^{(r)}$ is complete and conditions (1), (2), and (3) hold by the induction hypothesis of induction on states. (Condition (4) will be shown later.) So assume that there exists at least one such active session $i\,(\mathsf{OAlg})$ that has not been scheduled in $\beta_r\,(\mathsf{OAlg})$. By the induction hypothesis of induction on states (condition (1)), $\alpha_r\,(\mathsf{OAlg})$ and $\beta_r\,(\mathsf{OAlg})$ are identical. It follows that $i\,(\mathsf{OAlg})$ has not been scheduled in $\alpha_r\,(\mathsf{OAlg})$ either. Proposition 7.3 (condition (A/5)) implies that the increase for session $i\,(\mathsf{OAlg})$ in state *last* $(\alpha_r\,(\mathsf{OAlg}))$ is nonzero. By the induction hypothesis of induction on states (condition (1)), it follows that the increase for session $i\,(\mathsf{OAlg})$ in state *last* $(\beta_r\,(\mathsf{OAlg}))$ is nonzero as well. By the `update` operation, it follows that an increase to the rate of $i\,(\mathsf{OAlg})$ in *last* $(\beta_r\,(\mathsf{OAlg}))$ is possible without decreasing the rate of any other session. So, max-min fairness has not been reached yet and some session rate must change. However, a session rate changes only when an active session is scheduled. Since $\mathsf{Alg}$ computes the max-min fair rate vector, it follows that at least one active session in *last* $(\beta_r\,(\mathsf{OAlg}))$ is scheduled after *last* $(\beta_r\,(\mathsf{OAlg}))$. An inductive application of this argument implies that all sessions active in *first* $(\beta_r\,(\mathsf{OAlg}))$ are scheduled at least once in $\beta_r\,(\mathsf{OAlg})$. It follows that the inductive construction of $\mathbf{A}^{(r)}$ eventually terminates.

Denote by $i'\,(\mathsf{OAlg})$ the session scheduled by $\mathsf{Alg}$ immediately after *last* $(\beta_r\,(\mathsf{OAlg}))$ on network $G\,(\mathsf{OSched})$. By the induction hypothesis of induction on states (condition (3)), it follows that *last* $(\beta_r\,(\mathsf{OAlg}))$ is identical for all $\mathsf{OAlg} \in \mathbf{A}^{(r)}$. Since $\mathsf{Alg}$ is partially oblivious, this implies that $i'\,(\mathsf{OAlg})$ is identical for all $\mathsf{OAlg} \in \mathbf{A}^{(r)}$ as well; so, denote it $i'$. Fix any algorithm $\mathsf{OAlg} \in \mathbf{A}^{(r)}$ and restrict $\mathbf{A}^{(r)}$ to the set of all optimistic, oblivious, bottleneck, $n$-epoch algorithms whose schedulers have prefix $\sigma\,(\alpha_r\,(\mathsf{OAlg}))\ i'$.

We now argue that $\mathbf{A}^{(r)}$ is nonempty and unique. Any sequence of sessions $\sigma\,(\beta_r\,(\mathsf{OAlg}))\,i'$ can be extended to an $n$-epoch scheduler (by appropriate padding). This implies that $\mathbf{A}^{(r)}$ is nonempty. By the induction hypothesis of induction on states (condition (3)), $\beta_r\,(\mathsf{OAlg})$ is identical over all algorithms $\mathsf{OAlg} \in \mathbf{A}^{(r)}$, so that $\sigma\,(\beta_r\,(\mathsf{OAlg}))\,i'$ is also identical over all $\mathsf{OAlg} \in \mathbf{A}^{(r)}$. It follows that the constructed $\mathbf{A}^{(r)}$ is unique.

Take any algorithm $\mathsf{OAlg} = \langle \mathsf{OSched}, \mathsf{OTerm} \rangle \in \mathbf{A}^{(r)}$.

- Define $Q\,(\mathsf{OAlg})$ to be the state that results when $\mathsf{Alg}$, starting from state *last* $(\beta_r\,(\mathsf{OAlg}))$ of the network $G\,(\mathsf{OSched})$, schedules session $i'$ on $G\,(\mathsf{OSched})$ and set $\beta_r\,(\mathsf{OAlg}) := \beta_r\,(\mathsf{OAlg}),\ i',\ Q\,(\mathsf{OAlg})$.
- Similarly, define $Q'\,(\mathsf{OAlg})$ to be the state that results when $\mathsf{OAlg}$, starting from *last* $(\alpha_r\,(\mathsf{OAlg}))$ of the network $G\,(\mathsf{OSched})$, schedules session $i'$ on $G\,(\mathsf{OSched})$ and set $\alpha_r\,(\mathsf{OAlg}) := \alpha_r\,(\mathsf{OAlg}),\ i',\ Q'\,(\mathsf{OAlg})$.

We now prove the required properties for the sets

$$\alpha\,(\mathsf{OAlg}) = \left\{ \alpha_1\,(\mathsf{OAlg}) \cdot \ldots \cdot \alpha_r\,(\mathsf{OAlg}) \ \mid\ \mathsf{OAlg} \in \mathbf{A}^{(r)} \right\}$$

and

$$\beta\,(\mathsf{OAlg}) = \left\{ \beta_1\,(\mathsf{OAlg}) \cdot \ldots \cdot \beta_r\,(\mathsf{OAlg}) \ \mid\ \mathsf{OAlg} \in \mathbf{A}^{(r)} \right\}$$

of execution prefixes.

We start by proving (1). Take any algorithm $\mathsf{OAlg} = \langle \mathsf{OSched}, \mathsf{OTerm} \rangle \in \mathbf{A}^{(r)}$. By the induction hypothesis of induction on states (condition (1)), $\mathsf{Alg}$ and $\mathsf{OAlg}$ start from identical states of the network $G\,(\mathsf{OSched})$; hence, scheduling the same session $(i')$ on the network $G\,(\mathsf{OSched})$ results in identical states, which inductively extends the claim.

We now treat (2) and (3). Since $i'(\mathsf{OAlg})$ is identical over all $\mathsf{OAlg} \in \mathbf{A}^{(r)}$, the induction hypothesis of induction on states (condition (2)) implies that the set of sessions scheduled in $\alpha_r(\mathsf{OAlg})$ is identical over all $\mathsf{OAlg} \in \mathbf{A}^{(r)}$. So, Proposition 7.3 (conditions (A/1) and (A/4)) implies that $Q'(\mathsf{OAlg})$ is identical over all $\mathsf{OAlg} \in \mathbf{A}^{(r)}$. Induction hypothesis of induction on states (condition (2)) and the fact that $i'(\mathsf{OAlg})$ is identical over all $\mathsf{OAlg} \in \mathbf{A}^{(1)}$ imply that $\alpha_r(\mathsf{OAlg})$ is identical over all $\mathsf{OAlg} \in \mathbf{A}^{(r)}$, which proves (2). Now (3) follows from (1) and (2).

We finally prove (4) for the set $\mathbf{A}^{(r)}$ constructed when the induction on states is complete. Fix any algorithm $\mathsf{OAlg} \in \mathbf{A}^{(r)}$. Recall that all sessions active in *first* $(\beta_r(\mathsf{OAlg}))$ are scheduled at least once in $\beta_r(\mathsf{OAlg})$; moreover, the termination condition used in the construction of $\mathbf{A}^{(r)}$ implies that $\beta_r(\mathsf{OAlg})$ is the shortest such fragment. By condition (1) shown above, this implies that $\alpha_r(\mathsf{OAlg})$ is the shortest execution fragment such that all sessions active in *first* $(\alpha_r(\mathsf{OAlg}))$ are scheduled at least once in $\alpha_r(\mathsf{OAlg})$. So, by Proposition 7.3 (condition (B/3)), only two sessions terminate in $\alpha_r(\mathsf{OAlg})$. Hence, the induction hypothesis of induction on states (condition (1)) implies that only two sessions terminate in $\beta_r(\mathsf{OAlg})$, as needed.

The proof of the simulation lemma is now complete. ☐

We are now ready to prove the lower bound for the case where $d = n$.

THEOREM 7.6 (lower bound for partially oblivious algorithms). *Assume that* $\mathsf{Alg}$ *is optimistic, partially oblivious, and bottleneck, and that it computes the max-min rate vector. Then* $\mathcal{U}_{\mathsf{Alg}} \geq \frac{n^2}{4} + \frac{n}{2}$.

*Proof.* Proposition 7.5 implies that there exists some optimistic, oblivious, and bottleneck algorithm $\mathsf{OAlg} = \langle \mathsf{OSched}, \mathsf{OTerm} \rangle$ such that there exists an execution prefix $\beta = \beta_1 \cdot \beta_2 \cdot \ldots \cdot \beta_{d/2}$ of $\mathsf{Alg}$ on network $G(\mathsf{OSched})$ such that for each integer $r$, $1 \leq r \leq \frac{d}{2}$, all sessions active in *first* $(\beta_r)$ are scheduled at least once in $\beta_r$ and only two of them terminate in $\beta_r$. Hence, at least $n - 2(r-1)$ `update` operations are executed in $\beta_r$, $1 \leq r \leq \frac{n}{2}$. Summing up over all $r$ epochs, $1 \leq r \leq \frac{n}{2}$, yields that $\mathcal{U}_{\mathsf{Alg}}(G(\mathsf{OSched}), \mathcal{S}) \geq \sum_{r=1}^{n/2}(n - 2(r-1)) = \frac{n^2}{4} + \frac{n}{2}$. ☐

As a direct generalization of the simulation lemma for the case $d = n$, we obtain the following.

PROPOSITION 7.7 (simulation lemma). *Assume that* $\mathsf{Alg}$ *is optimistic, partially oblivious, and bottleneck, and that it computes the max-min fair rate vector. Partition* $\mathcal{S}$ *into disjoint clusters* $\mathcal{S}_1, \ldots, \mathcal{S}_{n/d}$ *with* $d$ *sessions each. Then there exists some optimistic, oblivious, and bottleneck algorithm* $\mathsf{OAlg} = \langle \mathsf{OSched}, \mathsf{OTerm} \rangle$ *such that there exist execution prefixes* $\alpha$ *of* $\mathsf{OAlg}$ *and* $\beta$ *of* $\mathsf{Alg}$*, on network* $G(\mathsf{OSched})$*, such that for each cluster* $\mathcal{S}_j$*,* $1 \leq j \leq \frac{n}{d}$*,* $\alpha$ *and* $\beta$ *can be written as* $\alpha = \alpha_1 \cdot \alpha_2 \cdot \ldots \cdot \alpha_{\frac{d}{2}}$ *and* $\beta = \beta_1 \cdot \beta_2 \cdot \ldots \cdot \beta_{\frac{d}{2}}$ *so that for each integer* $r$*,* $1 \leq r \leq \frac{d}{2}$*, the following conditions hold:*

(1) $\alpha_r$ *and* $\beta_r$ *are identical;*

(2) *all sessions from* $\mathcal{S}_j$ *active in first* $(\beta_r)$ *are scheduled at least once in* $\beta_r$ *and only two of them terminate in* $\beta_r$.

The execution prefixes $\alpha$ and $\beta$ in Proposition 7.7 are constructed in a similar inductive manner to the corresponding prefixes in Proposition 7.5. The additional complications stem from the fact that the execution fragments $\alpha_r$ and $\beta_r$, $1 \leq r \leq \frac{d}{2}$, may now be different for each cluster; thus, the inductive construction in the proof of Proposition 7.5 needs to be adjusted in order to accommodate chopping off $\alpha$ and $\beta$ into the suitable execution fragments $\alpha_r$ and $\beta_r$, $1 \leq r \leq \frac{d}{2}$, for each particular cluster. We finally use Proposition 7.7 to show our final lower bound; its proof is similar to the one of Theorem 7.6 that used Proposition 7.5.

THEOREM 7.8 (lower bound for partially oblivious algorithms). *Assume that* Alg *is optimistic, partially oblivious, and bottleneck, and that it computes the max-min rate vector. Then* $\mathcal{U}_{\mathsf{Alg}} \geq \frac{dn}{4} + \frac{n}{2}$.

Consider the partially oblivious algorithm GlobalMinSched introduced by Afek, Mansour, and Ostfeld [1, section 4], whose scheduler chooses, for each state $Q$, the active session with the minimum rate. We note that [1, Theorem 4.3] implies an upper bound $\frac{|\mathcal{S}_j|\,(|\mathcal{S}_j|+1)}{2}$ on the number of `update` operations executed by GlobalMin on network $G$ with session set $\mathcal{S}_j$ for any particular cluster $\mathcal{S}_j$. So, $\mathcal{U}_{\mathsf{GlobalMin}} \leq \sum_{j\geq 1} \frac{|\mathcal{S}_j|\,(|\mathcal{S}_j|+1)}{2} \leq \frac{\max_{j\geq 1}|\mathcal{S}_j|+1}{2} \sum_{j\geq 1} |\mathcal{S}_j| = \frac{dn}{2} + \frac{n}{2}$. This implies that the lower bound established in Theorem 7.8 is tight (within a factor of 2).

## 8. Discussion and directions for further research.

We have presented a comprehensive collection of lower and upper bounds on the convergence complexity of optimistic, bottleneck, rate-based flow control algorithms, under varying degrees of the knowledge used by the scheduling component of the algorithms. In particular, we have defined and studied oblivious, partially oblivious, and nonoblivious algorithms. We have shown that, perhaps surprisingly, the classes of oblivious algorithms and partially oblivious algorithms collapse with respect to convergence complexity; we have also shown a convergence complexity separation between (partially) oblivious algorithms and nonoblivious algorithms. A more complete presentation of results for the model studied in this paper (and extensions of it) can be found in [8].

For the sake of completeness and comparison, we summarize in Table 1 all known lower and upper bounds on the convergence complexity of optimistic, bottleneck algorithms for rate-based flow control, established in this work and in the preceding work by Afek, Mansour, and Ostfeld [1]. We remark that RoundRobin represents an exponential improvement over the previous algorithm Arbitrary [1, section 6] for the class of oblivious algorithms we introduced. (The algorithm Arbitrary schedules sessions in any arbitrary way.)

TABLE 1
*Summary of known lower and upper bounds on convergence complexity for optimistic, bottleneck rate-based flow control algorithms.*

| Scheduler types | Lower bounds | Upper bounds |
|---|---|---|
| Oblivious | $\frac{dn}{4} + \frac{n}{2}$ | $\frac{dn}{2} + \frac{n}{2}$ (RoundRobin)<br>$\Theta(2^n)$ (Arbitrary [1]) |
| Partially oblivious | $\frac{dn}{4} + \frac{n}{2}$ | $\frac{dn}{2} + \frac{n}{2}$ (LocalMin or GlobalMin [1]) |
| Nonoblivious | $n$ | $n$ (Linear) |

Our work leaves open several important questions. The most obvious open question would be how to close the gap between the lower bound of $\frac{dn}{4} + \frac{n}{2}$ and the upper bound of $\frac{dn}{2} + \frac{n}{2}$ we have shown on the convergence complexity of oblivious algorithms.

The model considered in this work is simple and elegant, yet structured enough to capture several significant ingredients of distributed rate-based flow control; there remain, however, a number of significant practical issues untouched by our model and analysis. In the first place, we feel that the max-min fairness criterion may be undue in some realistic situations, where sessions have different demands. (Some results in this direction have been obtained in [10].) Second, the limitation to static sets of sessions is somehow restrictive; it would be significant to extend our model and techniques to handle set-up and take-down of sessions. Third, practical considerations may demand that rate-based flow control algorithms avoid too small or too large adjustments to session rates. Encompassing such practical considerations, and analyzing their impact on convergence complexity, into the framework of rate-based flow control algorithms is an interesting research problem.

Kleinberg, Rabani, and Tardos [20] formulated some natural approximations to max-min fairness and advocated them as suitable fairness conditions for certain routing and load balancing applications. It would be interesting to study the convergence complexity of such approximations within the framework of rate-based flow control algorithms.

# OPTIMAL TWO-STAGE ALGORITHMS FOR GROUP TESTING PROBLEMS[*]

ANNALISA DE BONIS[†], LESZEK GĄSIENIEC[‡], AND UGO VACCARO[†]

**Abstract.** Group testing refers to the situation in which one is given a set of objects $\mathcal{O}$, an unknown subset $\mathcal{P} \subseteq \mathcal{O}$, and the task of determining $\mathcal{P}$ by asking queries of the type "does $\mathcal{P}$ intersect $\mathcal{Q}$?", where $\mathcal{Q}$ is a subset of $\mathcal{O}$. Group testing is a basic search paradigm that occurs in a variety of situations such as quality control testing, searching in storage systems, multiple access communications, and data compression, among others. Group testing procedures have been recently applied in computational molecular biology, where they are used for screening libraries of clones with hybridization probes and sequencing by hybridization.

Motivated by particular features of group testing algorithms used in biological screening, we study the efficiency of two-stage group testing procedures. Our main result is the first optimal two-stage algorithm that uses a number of tests of the same order as the information-theoretic lower bound on the problem. We also provide efficient algorithms for the case in which there is a Bernoulli probability distribution on the possible sets $\mathcal{P}$, and an optimal algorithm for the case in which the outcome of tests may be unreliable because of the presence of "inhibitory" items in $\mathcal{O}$. Our results depend on a combinatorial structure introduced in this paper. We believe that it will prove useful in other contexts, too.

**Key words.** group testing, cover-free families

## 1. Introduction and contributions.

In group testing, the task is to determine the *positive* members of a set of objects $\mathcal{O}$ by asking subset queries of the form "does the subset $\mathcal{Q} \subseteq \mathcal{O}$ contain a positive object?" The answer to each query informs the tester whether or not the subset $\mathcal{Q}$ (in common parlance called a *pool*) has a nonempty intersection with the subset of positive members denoted by $\mathcal{P}$. A negative answer to this question informs the tester that all the items belonging to pool $\mathcal{Q}$ are negative, i.e., nonpositive. The aim of group testing is to identify the unknown subset $\mathcal{P}$ using as few queries as possible.

Group testing was originally introduced as a potential approach to economical mass blood testing [23]. However, due to its basic nature, it has been proven to be applicable in a surprising variety of situations, including quality control in product testing [52], searching files in storage systems [36], sequential screening of experimental variables [40], efficient contention resolution algorithms for multiple-access communication [36, 55], data compression [31], and computation in the data stream model [16]. Group testing has also exhibited strong relationships with several disciplines such as coding theory, information theory, complexity, computational geometry, and computational learning theory, among others.

Probably the most important modern applications of group testing are in the realm of computational molecular biology, where it is used for screening libraries of clones with hybridization probes [5, 10, 9] and sequencing by hybridization [45, 49]. We refer to [6, 24, 29, 32] for an account of the fervent development of the area. The applications of group testing to biological screening present some distinctive features that pose new and challenging research problems. For instance, in the biological setting, screening one pool at the time is far more expensive than screening many pools in parallel. This strongly encourages the use of nonadaptive procedures for screening, that is, procedures in which all tests must be specified in advance without the tester knowing the outcomes of other tests. Instead, in adaptive group testing algorithms the tests are performed one by one, and the outcomes of previous tests are assumed known at the time of determining the current test. Unfortunately, nonadaptive group testing strategies are inherently much more costly than adaptive algorithms. This can be seen by observing that nonadaptive group testing algorithms are essentially equivalent to *superimposed codes* [25, 28, 36] (equivalently, cover-free families) and by using known nonexistential results on the latter [30, 25, 51]. More precisely, any nonadaptive group testing algorithm must use a number of tests $\Omega((p^2/\log p)\log n)$, where $p$ is the maximum number of positives and $n = |\mathcal{O}|$, and the best known algorithms use a number of tests $O(p^2 \log n)$. Closing the gap between the above upper and lower bounds would also imply solving a major open problem in extremal combinatorics, that is, that of estimating the exact maximum size of $p$-cover-free families [28]. In contrast, adaptive algorithms that use an optimal number of tests $O(p \log n)$ are known [24].

A nearly nonadaptive algorithm that is of considerable interest for screening problems is the so called *trivial two-stage algorithm* [37]. Such an algorithm proceeds in two stages. In the first stage certain pools are tested in parallel; in the second stage individual objects may be tested separately, depending on the outcomes of the first stage. The following quotation from [37, p. 371] well emphasizes the importance of such an algorithm:

> It is generally feasible to construct a number of pools (much fewer than the number of clones) initially by exploiting parallelism, but adaptive construction of pools with many clones during the testing procedure is discouraged. The technicians who implement the pooling strategies generally dislike even the 3-stage strategies that are often used. Thus the most commonly used strategies for pooling libraries of clones rely on a fixed but reasonably small set on nonsingleton pools. The pools are either tested all at once or in a small number of stages (usually at most 2) where the previous stage determines which pools to test in the next stage. The potential positives are then inferred and confirmed by testing of individual clones. In most biological applications each positive clone must be confirmed even if the pool results unambiguously indicate that it is positive. This is to improve the confidence in the results, given that in practice the tests are prone to errors.

Our first result is rather surprising: we prove that the best trivial two-stage algorithms are asymptotically as efficient as the best *fully adaptive* group testing algorithms, that is, algorithms with arbitrarily many stages. More precisely, we prove that there are trivial two-stage algorithms that determine all positives using a worst-case number of tests equal to the information-theoretic lower bound on the problem.

The information-theoretic lower bound is evidently a lower bound on the number of tests required by any algorithm, and it is independent from the number of performed stages.

There is another feature that differentiates biologically motivated group testing problems from traditional ones. In the classical scenario it is assumed that the presence of a single positive object in a pool is sufficient for the test to produce a positive result. However, recent work [29, 56] suggests that classical group testing procedures should take into account the possibility of the existence of "inhibitory items," that is, objects whose presence in the tested set could render the outcome of the test meaningless, as far as the detection of positive objects is concerned. In other words, if during the execution of an algorithm we tested a subset $\mathcal{Q} \subseteq \mathcal{O}$ containing positive items *and* inhibitory items, we would get the same answer as if $\mathcal{Q}$ did not contain any positive object. Similar issues were considered in [20], where further motivations for the problem were given. Our contribution to the latter issue is an algorithm that determines all positives in a set of objects, containing also up to a certain number of inhibitory items, and that uses the optimal worst-case number of tests, considerably improving the results of [21] and [29]. An interesting feature of our algorithm is that it can be implemented to run in only four stages.

We also consider the important situation in which a trivial two-stage strategy is used to find the set of positives, given that some prior information about them has been provided in terms of a Bernoulli probability distribution; that is, it is assumed that each object has a fixed probability $q$ of being positive. Usually $q$ is a function $q(n)$ of $n = |\mathcal{O}|$. This situation has received much attention [7, 8, 9, 43], starting from the important work [37]. The relevant parameter in this scenario is the average number of tests necessary to determine all positives. We prove that trivial two-stage strategies can asymptotically attain the information-theoretic lower bound for a large class of probability functions $q(n)$. It should be remarked that for two-stage group testing algorithms there are values of $q(n)$ for which lower bounds on the average number of tests exist that are better than the information-theoretic lower bounds [7, 37].

Our results depend on a combinatorial structure we introduce in this paper: $(k, m, n)$-selectors, to be formally defined in section 2. Our definition of $(k, m, n)$-selectors includes, as particular cases, well-known combinatorial objects such as superimposed codes [36, 28] and $k$-selectors [13]. Superimposed codes and $k$-selectors are very basic combinatorial structures and find application in a variety of areas such as cryptography, data security [39, 54], computational molecular biology [6, 21, 24, 32], multiaccess communication [24, 36], database theory [36], pattern matching [34], distributed coloring [41], circuit complexity [12], broadcasting in radio networks [13, 15], and other areas in computer science. We believe that our $(k, m, n)$-selectors will prove useful in several different areas.

**1.1. Previous results.** We refer the reader to the excellent monographs [1, 2, 24] for a survey of the vast literature on group testing. The papers [32, 37, 29] include a very nice account of the most important results on biologically motivated group testing problems. To the best of our knowledge, our paper is the first to address the problem of estimating the worst-case complexity of trivial two-stage group testing algorithms. The problem of estimating the minimum expected number of tests of trivial two-stage group testing algorithms when it is known that any item has a probability $p = p(n)$ of being positive has been studied in [7, 8, 9, 37, 43]. The papers most closely related to our results are [37, 8]. In particular, the paper [37] proves that, for several classes of probability functions $p(n)$, trivial two-stage group testing procedures are inherently more costly than fully adaptive group testing procedures (interestingly, we prove that this is not so in the worst-case analysis). The paper [8], with a real tour de force of the probabilistic method, provides a sharp estimate of the minimum expected number of tests of trivial two-stage procedures for an ample class of probability functions $p(n)$. Our approach is simpler and still allows us to obtain the correct order of magnitude of the minimum expected number of tests of the trivial two-stage group testing procedure for several classes of probability functions. A more detailed comparison of our results with those of [8] will be given at the end of section 4. Finally, the study of group testing in the presence of inhibitory items, the subject of section 5, was initiated in [29], continued in [21] and, under different models, also appears in [22] and [20].

**1.2. Summary of the results and structure of the paper.** In section 2 we formally define our main combinatorial tool, $(k, m, n)$-selectors, and we give bounds on their sizes. These bounds will be crucial for all our subsequent results. In section 3 we present a two-stage group testing algorithm with asymptotically optimal worst-case complexity. In section 3 we also present some related results of independent interest. For instance, we prove an $\Omega(k \log n)$ lower bound on the size of $k$-selectors defined in [13], improving on the lower bound $\Omega(\frac{k}{\log k} \log n)$ mentioned in [35]. This bound shows that the construction in [13] is optimal. Also in section 3 we establish an interesting link between our findings and the problem of learning Boolean functions in a constant number of rounds, in the sense of [17]. In section 4 we present our results on two-stage group testing algorithms for the case when a probability distribution on the possible set of positives is assumed. Finally, in section 5 we present a worst-case optimal algorithm for group testing in the presence of inhibitory items, improving on the algorithms given in [21, 29, 33]. We conclude the paper with a discussion of our main findings and of possible future lines of research.

## 2. $(k, m, n)$-selectors and bounds on their sizes.

In this section we introduce our main combinatorial tools, $(k, m, n)$-selectors. We point out their relationships with other well-known combinatorial objects and provide upper and lower bounds on their sizes.

DEFINITION 1. *Given integers $k$, $m$, and $n$, with $1 \leq m \leq k \leq n$, we say that a Boolean matrix $M$ with $t$ rows and $n$ columns is a $(k, m, n)$-selector if* any *submatrix of $M$ obtained by choosing $k$ out of $n$ arbitrary columns of $M$ contains at least $m$ distinct rows of the identity matrix $I_k$. The integer $t$ is the* size *of the $(k, m, n)$-selector.*

One can prove that $k$-cover-free families [28], disjunctive codes [24], superimposed codes [36], and strongly selective families [15, 13] correspond to our notion of a $(k + 1, k + 1, n)$-selector. The $k$-selectors of [13] coincide with our definition of $(2k, 3k/2 + 1, n)$-selectors.

We are interested in providing upper and lower bounds on the minimum size $t = t(k, m, n)$ of $(k, m, n)$-selectors. Upper bounds will be obtained by translating the problem into the hypergraph language. Given a finite set $X$ and a family $\mathcal{F}$ of subsets of $X$, a hypergraph is a pair $\mathcal{H} = (X, \mathcal{F})$. Elements of $X$ will be called vertices of $\mathcal{H}$, and elements of $\mathcal{F}$ will be called hyperedges of $\mathcal{H}$. A *cover* of $\mathcal{H}$ is a subset $T \subseteq X$ such that for any hyperedge $E \in \mathcal{F}$ we have $T \cap E \neq \emptyset$. The minimum size of a cover of $\mathcal{H}$ will be denoted by $\tau(\mathcal{H})$. A fundamental result by Lovász [42] implies that

$$(1) \qquad \tau(\mathcal{H}) < \frac{|X|}{\min_{E \in \mathcal{F}} |E|}(1 + \ln \Delta),$$

where $\Delta = \max_{x \in X} |\{E\colon\ E \in \mathcal{F} \text{ and } x \in E\}|$.

Essentially, Lovász proves that, by greedily choosing vertices in $X$ that intersect the maximum number of yet nonintersected hyperedges of $\mathcal{H}$, one obtains a cover of a size smaller than the right-hand side of (1). Our aim is to show that $(k, m, n)$-selectors are covers of properly defined hypergraphs. Lovász's result (1) will then provide us with the desired upper bound on the minimum selector size.

We shall proceed as follows. Let $X$ be the set of all binary vectors $\mathbf{x} = (x_1, \dots, x_n)$ of length $n$ containing $n/k$ 1's (the value $n/k$ is a consequence of an optimized choice whose justification can be skipped here). For any integer $i$, $1 \le i \le k$, let us denote by $\mathbf{a}_i$ the binary vector of length $k$ having all components equal to zero with the exception of the component in position $i$, that is, $\mathbf{a}_1 = (1, 0, \dots, 0)$, $\mathbf{a}_2 = (0, 1, \dots, 0)$,$\dots$, $\mathbf{a}_k = (0, 0, \dots, 1)$. Moreover, for any set of indices $S = \{i_1, \dots, i_k\}$, with $1 \le i_1 \le i_2 < \cdots < i_k \le n$, and for any binary vector $\mathbf{a} = (a_1, \dots, a_k) \in \{\mathbf{a}_1, \dots, \mathbf{a}_k\}$, let us define the set of binary vectors $E_{\mathbf{a},S} = \{\mathbf{x} = (x_1, \dots, x_n) \in X : x_{i_1} = a_1, \dots, x_{i_k} = a_k\}$. For any set $A \subseteq \{\mathbf{a}_1, \dots, \mathbf{a}_k\}$ of size $r$, $r = 1, \dots, k$, and any set $S \subseteq \{1, \dots, n\}$, with $|S| = k$, let us define $E_{A,S} = \bigcup_{\mathbf{a} \in A} E_{\mathbf{a},S}$. For any $r = 1, \dots, k$ we define $\mathcal{F}_r = \{E_{A,S} : A \subset \{\mathbf{a}_1, \dots, \mathbf{a}_k\}, |A| = r, \text{ and } S \subseteq \{1, \dots, n\}, |S| = k\}$ and the hypergraph $\mathcal{H}_r = (X, \mathcal{F}_r)$. We claim that *any* cover $T$ of $\mathcal{H}_{k-m+1}$ is a $(k, m, n)$-selector; that is, any submatrix of $k$ arbitrary columns of $T$ contains at least $m$ distinct rows of the identity matrix $I_k$. The proof is done by contradiction. Assume that there exists a set of indices $S = \{i_1, \dots, i_k\}$ such that the submatrix of $T$ obtained by considering only the columns of $T$ with indices $i_1, \dots, i_k$ contains *at most* $m - 1$ distinct rows of $I_k$. Let such rows be $\mathbf{a}_{j_1}, \dots, \mathbf{a}_{j_s}$, with $s \le m-1$; let $A$ be *any* subset of $\{\mathbf{a}_1, \dots, \mathbf{a}_k\} \setminus \{\mathbf{a}_{j_1}, \dots, \mathbf{a}_{j_s}\}$ of cardinality $|A| = k - m + 1$; and let $E_{A,S}$ be the corresponding hyperedge of $\mathcal{H}_{k-m+1}$. By construction we have that $T \cap E_{A,S} = \emptyset$, contradicting the fact that $T$ is a cover for $\mathcal{H}_{k-m+1}$.

The above proof that $(k, m, n)$-selectors coincide with the covers of $\mathcal{H}_{k-m+1}$ allows us to use Lovász's result (1) to give upper bounds on the minimum size of selectors.

THEOREM 1. *For any integers $k$, $m$, and $n$, with $1 \le m \le k < n$, there exists a $(k, m, n)$-selector of size $t$, with*

$$t < \frac{ek^2}{k - m + 1} \ln \frac{n}{k} + \frac{ek(2k - 1)}{k - m + 1},$$

*where $e = 2.7182\dots$ is the base of the natural logarithm.*

*Proof.* From the arguments preceding the theorem and (1), in order to upper bound $t$ we need only evaluate the quantities

$$|X|, \quad \min\{|E| : E \in \mathcal{F}_{k-m+1}\} \quad \text{and} \quad \Delta$$

for the hypergraph $\mathcal{H}_{k-m+1}$. We shall do it here.

By definition $X = \binom{n}{n/k}$. Moreover, each hyperedge $E_{A,S}$ of $\mathcal{H}_{k-m+1}$ is the union of $k - m + 1$ disjoint sets $E_{\mathbf{a},S}$; therefore it has cardinality

$$|E_{A,S}| = (k - m + 1) \cdot |E_{\mathbf{a},S}| = (k - m + 1) \binom{n - k}{n/k - 1}.$$

To compute $\Delta$, observe that each $\mathbf{x} \in X$ belongs to $\binom{n/k}{1}\binom{n-n/k}{k-1}$ distinct sets $E_{\mathbf{a},S}$, and each $E_{\mathbf{a},S}$ belongs to $\binom{k-1}{k-m}$ distinct hyperedges $E_{A,S}$. Therefore, for $\mathcal{H}_{k-m+1}$ we have

$$\Delta = \binom{k - 1}{k - m}\binom{n/k}{1}\binom{n - n/k}{k - 1}.$$

Hence one has

$$t < \frac{\binom{n}{n/k}}{(k-m+1)\binom{n-k}{n/k-1}}\left[1+\ln\binom{k-1}{k-m}\binom{n/k}{1}\binom{n-n/k}{k-1}\right]. \tag{2}$$

For $k \in \{1,2\}$, it is $\frac{\binom{n}{n/k}}{\binom{n-k}{n/k-1}} < 2k$, whereas for $k \geq 3$ it is

$$\begin{aligned}
\frac{\binom{n}{n/k}}{\binom{n-k}{n/k-1}} &= k\frac{n-1}{n-n/k}\cdot\frac{n-2}{n-n/k-1}\times\cdots\times\frac{n-k+1}{n-k-n/k+2}\\
&\leq k\left(\frac{n-k+1}{n-k-n/k+2}\right)^{k-1}\\
&= k\left(\frac{k(n-k+1)}{k(n-k+1)-(n-k)}\right)^{k-1}\\
&= k\left(1+\frac{n-k}{k(n-k+1)-(n-k)}\right)^{k-1}\\
&\leq k\left(1+\frac{1}{k-1}\right)^{k-1}\\
&< ek.
\end{aligned}$$

Moreover, using the well-known inequality $\binom{a}{b} \leq (ea/b)^b$, one can conclude

$$\begin{aligned}
\binom{k-1}{k-m}\binom{n/k}{1}\binom{n-n/k}{k-1} &\leq \left(\frac{k-1}{k-m}\right)^{k-m} e^{k-m}\frac{n}{k}\left(\frac{n-n/k}{k-1}\right)^{k-1} e^{k-1}\\
&= e^{2k-m-1}\left(1+\frac{m-1}{k-m}\right)^{k-m}\left(\frac{n}{k}\right)^k\\
&\leq e^{2k-m-1}\left(1+\frac{m}{k-m}\right)^{k-m}\left(\frac{n}{k}\right)^k\\
&\leq e^{2k-m-1}e^m\left(\frac{n}{k}\right)^k.
\end{aligned}$$

The theorem now follows from (2) and the above inequalities. □

*Remark.* Applying the above theorem to $(k,k,n)$-selectors, that is, to $(k-1)$-cover-free-families, one recovers the usual upper bound of $O(k^2\log n)$ on their sizes [25, 28]. Applying the above theorem to $(2k, 3k/2+1, n)$-selectors (that is, to $k$-selectors in the sense of [13]), one gets the same upper bound of $O(k\log n)$ on their sizes, with a better constant (22 versus 87). By concatenating $(k,\alpha k,n)$-selectors, $\alpha < 1$, of suitably chosen parameter $k$, one gets in a simple way the important combinatorial structure of [38], with the same asymptotic upper bound given therein, but our constants are much better (44 versus $\sim 5\cdot 10^5$, according to [11]).

To present our first lower bound on the size of $(k,m,n)$-selectors, we need to recall the definition of $(p,q)$-superimposed codes [21, 25].

Definition 2. *Given integers $p,q$, and $n$, with $p+q\leq n$, we say that a Boolean matrix $M$ with $n$ columns and $t$ rows is a $(p,q)$-superimposed code if for any choice of two subsets $P$ and $Q$ of columns of $M$, where $P\cap Q=\emptyset$, $|P|=p$, and $|Q|=q$, there exists a row in $M$ in which entries corresponding to the columns in $P$ contain at least one nonzero value and all entries corresponding to the columns in $Q$ are set* *to zero. The integers $n$ and $t$ are the size and the length of the $(p, q)$-superimposed code, respectively. The minimum length of a $(p, q)$-superimposed code of size $n$ will be denoted by $t_s(p, q, n)$.*

It can be seen that $(k, m, n)$-selectors are $(k - m + 1, m - 1)$-superimposed codes with additional properties. Therefore, lower bounds on the length of $(p, q)$-superimposed codes translates into lower bounds on selectors. The following theorem provides a lower bound on the length of $(p, q)$-superimposed codes, and its proof uses the techniques developed in [3, 51] to lower bound the length of classical $(1, q)$-superimposed codes. The theorem improves the results of [25]. A similar result also has been obtained by Dyachkov [27].

THEOREM 2. *For any positive integers $p$, $q$, and $n$, with $n > q^2/(4p)$ the minimum length $t_s(p, q, n)$ of a $(p, q)$-superimposed code of size $n$ is bounded from below by*

$$t_s(p,q,n) > \begin{cases} q \log\left(\frac{n}{e(p+q-1)}\right) & \text{if } 1 \le q < 2p, \\ \frac{p(\lfloor q/(2p)\rfloor)^2}{\log(eq^2/(4p))} \log\left(\frac{4(n-2(p-1)-q/2)}{eq^2}\right) & \text{if } q \ge 2p. \end{cases}$$

*Proof.* For $q < 2p$ the stated bound immediately follows from Proposition 2 of [25], which implies $t_s(p, q, n) \ge \lceil \log \binom{n}{q} - \log \binom{p+q-1}{q} \rceil$, and from the well-known inequality

$$\binom{m}{k} \le 2^{k \log(em/k)}. \tag{3}$$

Let us consider the case when $q \ge 2p$ and assume for the moment that $q$ is a multiple of $2p$.

Let $\mathcal{F}$ be the family associated with a $(p, q)$-superimposed code $M$ of length $t$ and size $n$; that is, $\mathcal{F}$ is a family of subset of $\{1, \ldots, t\}$, $|\mathcal{F}| = n$, such that the column vectors of $M$ are the characteristic vectors of the subsets in $\mathcal{F}$. By Definition 2 we have that for any $p+q$ pairwise different members $F_1, \ldots, F_p, G_1, \ldots, G_q$ it holds that

$$F_1 \cup \cdots \cup F_p \not\subseteq G_1 \cup \cdots \cup G_q. \tag{4}$$

To prove our lower bound we first transform $\mathcal{F}$ into a family $\mathcal{F}'$ with members of size at most $\lfloor 2t/q \rfloor$. As long as $\mathcal{F}$ contains a set $H$ of size larger than $\lfloor 2t/q \rfloor$, we remove $H$ from $\mathcal{F}$ and replace any other set $G \in \mathcal{F}$ with $G' = G \setminus H$. Since the elements of $\mathcal{F}$ are subsets of $\{1, \ldots, t\}$, this process terminates after at most $\ell \le q/2$ steps. If for some $G \in \mathcal{F}$ it results in $G' = G \setminus (H_1 \cup \cdots \cup H_\ell) = \emptyset$, then we remove $G'$ from $\mathcal{F}$. Notice that there are no more than $p - 1$ such sets; otherwise there would be $p$ sets whose union is contained in $H_1 \cup \cdots \cup H_\ell$, thus violating (4). The resulting family $\mathcal{F}'$ therefore has size $|\mathcal{F}'| \ge |\mathcal{F}| - p + 1 - q/2$ and it results in $|F'| \le \lfloor 2t/q \rfloor$ for any $F' \in \mathcal{F}'$. It is possible to see that

$$F'_1 \cup \cdots \cup F'_p \not\subseteq G'_1 \cup \cdots \cup G'_{q/2} \tag{5}$$

for any choice of $p + q/2$ sets $F'_1, \ldots, F'_p, G'_1, \ldots, G'_{q/2} \in \mathcal{F}'$. Assume by contradiction that $\mathcal{F}'$ contains $F'_1, \ldots, F'_p, G'_1, \ldots, G'_{q/2}$ such that $F'_1 \cup \cdots \cup F'_p \subseteq G'_1 \cup \cdots \cup G'_{q/2}$; then the union of the $p$ sets of $\mathcal{F}$ from which $F'_1, \ldots, F'_p$ were obtained would be contained in the union of at most $q$ sets given by $G'_1, \ldots, G'_{q/2}$ and the $\ell$ removed sets, contradicting (4).

For each subfamily $\{F'_1,\ldots,F'_p\} \subset \mathcal{F}'$, there is a set $X_{\{F'_1,\ldots,F'_p\}}$ with $|X_{\{F'_1,\ldots,F'_p\}}| \leq \lceil 4tp/q^2 \rceil$ such that $X_{\{F'_1,\ldots,F'_p\}} \subseteq F'_j$ for some $F'_j \in \{F'_1,\ldots,F'_p\}$, and $X_{\{F'_1,\ldots,F'_p\}} \not\subseteq F'$ for any $F' \in \mathcal{F}' \setminus \{F'_1,\ldots,F'_p\}$. Suppose by contradiction that there exists no such set $X_{\{F'_1,\ldots,F'_p\}}$; then we can partition each $F'_1,\ldots,F'_p$ into $\frac{q}{2p}$ subsets of size at most $\lceil 4tp/q^2 \rceil$ such that each of those subsets is contained in some member of $\mathcal{F}' \setminus \{F'_1,\ldots,F'_p\}$. It follows that each $F'_1,\ldots,F'_p$ is contained in the union of at most $\frac{q}{2p}$ other members of $\mathcal{F}' \setminus \{F'_1,\ldots,F'_p\}$, and consequently the union $F'_1 \cup \cdots \cup F'_p$ is contained in the union of at most $q/2$ other members of $\mathcal{F}'$, which is a contradiction to (5). Let us now group all but at most $p-1$ members of $\mathcal{F}'$ into $\lfloor |\mathcal{F}'|/p \rfloor$ pairwise disjoint subfamilies of size $p$ and let $\mathcal{P}$ denote the set of those subfamilies. From the above argument, the family $\mathcal{G} = \{X_{\{F'_1,\ldots,F'_p\}} : \{F'_1,\ldots,F'_p\} \in \mathcal{P}\}$ is a Sperner family (i.e., an antichain) consisting of $|\mathcal{P}|$ sets of size at most $\lceil 4tp/q^2 \rceil$, and consequently it is $|\mathcal{P}| = |\mathcal{G}| \leq \binom{t'}{\lceil 4tp/q^2 \rceil}$, where $t' = \left|\bigcup_{F' \in \mathcal{F}'} F'\right| \leq t$. It follows that $|\mathcal{F}'| \leq p|\mathcal{P}| + p - 1 \leq p\binom{t}{\lceil 4tp/q^2 \rceil} + p - 1$, and consequently,

$$|\mathcal{F}| \leq |\mathcal{F}'| + p - 1 + q/2 \leq p\binom{t}{\lceil 4tp/q^2 \rceil} + 2(p-1) + q/2.$$

From the above inequality and from inequality (3) it follows

$$|\mathcal{F}| \leq p 2^{\lceil 4pt/q^2 \rceil \log(eq^2/(4p))} + 2(p-1) + q/2. \tag{6}$$

Inequality (6) implies

$$t > \frac{q^2}{4p \log(eq^2/(4p))} \log\left(\frac{4(n - 2(p-1) - q/2)}{eq^2}\right). \tag{7}$$

To obtain the lower bound in the theorem, we need to deal with the case when $q \geq 2p$ is not a multiple of $2p$. In this case, we observe that any $(p,q)$-superimposed code is a $(p, 2p\lfloor q/2p \rfloor)$-superimposed code and, exploiting lower bound (7), we get the following lower bound that holds for any $q \geq 2p$ and $n \geq q^2/4p$:

$$t > \frac{(2p\lfloor \frac{q}{2p} \rfloor)^2}{4p \log(ep(\lfloor \frac{q}{2p} \rfloor)^2)} \log\left(\frac{4(n - 2(p-1) - p\lfloor \frac{q}{2p} \rfloor)}{e(2p\lfloor \frac{q}{2p} \rfloor)^2}\right). \tag{8}$$

Inequalities (6) and (8) imply the stated lower bound on $t_s(p,q,n)$. ☐

By setting $p = k - m + 1$ and $q = m - 1$ in the above lower bound, one obtains the following lower bound on the size of $(k,m,n)$-selectors.

Corollary 1. *For any integers $k$, $m$, and $n$, with $1 \leq m \leq k \leq n$, $n > \frac{(m-1)^2}{4(k-m+1)}$, the minimum size $t(k,m,n)$ of a $(k,m,n)$-selector is at least*

$$t(k,m,n) \geq \frac{(m-1)^2}{16(k-m+1)\log(\frac{(m-1)^2+(k-m+1)^2}{k-m+1})} \log \frac{4(n-m+1)}{e((m-1)^2+k-m+1)}. \tag{9}$$

## 3. Application of $(k,m,n)$-selectors to optimal two-stage group testing.

We have a set of objects $\mathcal{O}$, $|\mathcal{O}| = n$ and a subset $\mathcal{P} \subseteq \mathcal{O}$ of positives $|\mathcal{P}| \leq p$. Our task is to determine the members of $\mathcal{P}$ by asking subset queries of the form "does the subset $\mathcal{Q} \subseteq \mathcal{O}$ contain a positive object?" We focus on the so-called trivial two-stage algorithms. Recall that these algorithms consist of two stages: in the first stage certain pools are tested in parallel and in the second stage only individual objects are tested (always in parallel). Which individual objects are tested may depend on the outcomes of the first stage.

In the following we provide a two-stage algorithm that uses an asymptotically optimal number of tests. We associate each item of the input set $\mathcal{O}$ with a distinct column of a $(k, p{+}1, n)$-selector $M = [M(i, j)]$. Let $t$ denote the size of the $(k, p{+}1, n)$-selector. For $i = 1, \dots, t$, we define $T_i = \{j \in \{1, \dots, n\} : M(i, j) = 1\}$. The first stage of the algorithm consists of testing the $t$ pools $T_1, \dots, T_t$ in parallel. Let $\mathbf{f}$ denote the binary vector collecting the answers of the $t$ tests (here a "yes" answer to test $T_i$ corresponds to a 1 entry in the $i$th position of $\mathbf{f}$, and a "no" answer corresponds to a 0 entry). If $\mathcal{O}$ contains $q \le p$ positive items, then $\mathbf{f}$ is the Boolean sum of the $q$ columns associated with the $q$ positives. It is easy to see that, in addition to the columns associated with the positives items, there are at most $k - q - 1$ columns "covered" by $\mathbf{f}$, that is, have the 1's in a subset of the positions in which the vector $\mathbf{f}$ also has 1's. Let $y_1, \dots, y_q$ denote the $q$ positives. Assume by contradiction that there are more than $k - q - 1$ columns, other than those associated with $y_1, \dots, y_q$, which are covered by $\mathbf{f}$. Let $z_1, \dots, z_{k-q}$ denote $k - q \ge k - p$ such columns and let us consider the submatrix of $M$ consisting of $y_1, \dots, y_q, z_1, \dots, z_{k-q}$. By Definition 1, this submatrix contains at least $p + 1$ rows of the identity matrix $I_k$. At least one of these $p + 1$ rows of $I_k$ has a 1 in one of the columns $z_1, \dots, z_{k-q}$. Let $\ell$ denote the index of such a row. Since the columns associated with $y_1, \dots, y_q$ have the $\ell$th entry equal to 0, then the $\ell$th entry of $\mathbf{f}$ is 0, thus contradicting the hypothesis that $\mathbf{f}$ covers all columns $z_1, \dots, z_{k-q}$. Using this argument, one concludes that if we discard all columns not covered by $\mathbf{f}$, then we are left with $k - 1$ columns, $q$ of which correspond to the $q$ positives. Stage 2 consists of individually probing these $k - 1$ elements. The following theorem holds.

THEOREM 3. *Let $t$ be the size of a $(k, p+1, n)$-selector. There exists a two-stage group testing algorithm for finding up to $p$ positives out of $n$ items and that uses a number of tests equal to $t + k - 1$.*

From Theorems 1 and 3 we get the following.

COROLLARY 2. *For any integers $k$, $p$, and $n$, with $1 \le p < k \le n$, there exists a two-stage group testing algorithm for finding up to $p$ positives using a number of tests less than*

$$\frac{ek^2}{k-p} \ln \frac{n}{k} + \frac{ek(2k-1)}{k-p} + k - 1. \tag{10}$$

By optimizing the choice of $k$ to $k = 2p$ in (10), we get the main result of this section.

COROLLARY 3. *For any integers $p$ and $n$, with $1 \le p \le n$, there exists a two-stage group testing algorithm for finding up to $p$ positives using a number of tests less than*

$$4ep \ln \frac{n}{2p} + p(8e + 2) - 2e - 1 < 7.54p \log_2 \frac{n}{p} + 16.21p - 2e - 1.$$

The two-stage algorithm of the above corollary is asymptotically optimal because of the information-theoretic lower bound on the number of tests given by

$$\log_2 \binom{n}{p} > p \log_2 \frac{n}{p}, \tag{11}$$

that holds also for fully adaptive group testing algorithms.

Corollaries 2 and 3 also can be used to solve the open problem, mentioned in [29], of providing estimates for the maximum size of a search space in which it is possible to successfully search for $p$ positives, using at most $v$ pools and no more than $h$ tests involving single elements. This problem is equivalent to fixing the cardinality of the search space and trying to minimize the number of constructed pools. This equivalent problem is solved by the above corollaries since in our algorithm the number of pools coincides with the number of performed tests.

**3.1. Deriving a lower bound on the size of $(k, m, n)$-selectors via two-stage group testing.** Let $g(p, n)$ denote the minimum number of tests needed to identify $p$ positive items out of $n$ items by a group testing strategy. Theorem 3 and the information-theoretic lower bound (11) give

$$\log_2 \binom{n}{p} \le g(n, p) \le t(k, p+1, n) + k - 1,$$

from which we get the following result that also provides a lower bound on the size of $(k, m, n)$-selectors for values of $k$ and $m$ not covered by (9).

THEOREM 4. *For any integers $k$, $m$, and $n$, with $1 \le m \le k < n$, the minimum size $t(k, m, n)$ of a $(k, m, n)$-selector satisfies*

$$t(k, m, n) \ge \log \binom{n}{m-1} - k + 1 \ge (m-1) \log \frac{n}{m-1} - k + 1.$$

The bound given in Theorem 4 improves on the bound given in Corollary 1 for all values of $k$ and $m$ such that $m = \alpha k$ for constant $\alpha$, $0 < \alpha < 1$. Theorem 4 also implies a lower bound of $\Omega(k \log \frac{n}{k})$ on the size of the $k$-selectors of [13] (that is, of our $(2k, 3k/2 + 1, n)$-selectors), improving on the lower bound of $\Omega(\frac{k}{\log k} \log \frac{n}{k})$ mentioned in [35]. Our lower bound is optimal since it matches the upper bound on the size of $k$-selectors given in [13].

**3.2. A remark on learning monotone Boolean functions.** We consider here the well-known problem of exact learning of an unknown Boolean function of $n$ variables by means of membership queries, provided that at most $k$ of the variables (attributes) are relevant. This is known as attribute-efficient learning. By *membership queries* we mean the following [4]: The learner chooses a 0-1 assignment $x$ of the $n$ variables and gets the value $f(x)$ of the function at $x$. The goal is to learn (identify) the unknown function $f$ exactly, using a small number of queries. Typically, one assumes that the learner knows in advance that $f$ belongs to a restricted class of Boolean functions, since the exact learning problem in the full generality admits only trivial solutions. In this scenario, the group testing problem is equivalent to the problem of exactly learning an unknown function $f$, where it is known that $f$ is an $OR$ of at most $p$ variables.

Recently, in a series of papers [17, 18, 19] Damaschke studied the power of adaptive versus nonadaptive attribute-efficient learning. In this framework he proved that adaptive learning algorithms are more powerful than nonadaptive ones. More precisely, he proved that in general it is impossible to learn monotone Boolean functions with $k$ relevant variables in less than $\Omega(k)$ stages, if one insists that the total number of queries be of the same order as that used by the best fully adaptive algorithm (i.e., an algorithm that may use an arbitrary number of stages; see [17, 18] for details). In view of Damaschke's results, we believe it worthwhile to state our Corollary 3 in the following form.

COROLLARY 4. *Boolean functions made by the disjunction of at most $p$ variables are exactly learnable in only* two stages *by using a number of queries of the same order as that of the best fully adaptive learning algorithm.*

The above remark raises the interesting problem of how to characterize monotone Boolean functions which are "optimally" learnable in a constant number of stages. Another example of a class of functions optimally learnable in a constant number of stages will be given at the end of section 5.

## 4. Two-stage algorithms for probabilistic group testing.

In this section we assume that objects in $\mathcal{O}$, $|\mathcal{O}| = n$, independently of each other, have some probability $q = q(n)$ of being positive. This means that the probability distribution on the possible subsets of positives is a binomial distribution, which is a standard assumption in the area of probabilistic group testing (see, e.g., [7, 8, 37]). In this scenario one is interested in minimizing the average number of queries necessary to identify all positives. Shannon's source coding theorem implies that the minimum average number of queries is lower bounded by the entropy

$$n(-q(n)\log q(n) - (1-q(n))\log(1-q(n))). \tag{12}$$

It is also known [7, 37] that for two-stage group testing algorithms there are values of the probability $q(n)$ for which the lower bound (12) is not reachable, in the sense that better lower bounds exist. Our algorithm for the probabilistic case is very simple and is based on the following idea. Given the probability $q = q(n)$ that a single object in $\mathcal{O}$ is positive, we estimate the expected number of positives $\mu = nq(n)$. We now run the two-stage algorithm described in section 3, using a $(k, m, n)$-selector with parameters $m = (1+\delta)\mu + 1$, with $\delta > 0$, and $k = 2(1+\delta)\mu$. Denote by $X$ the random variable taking the value $i$ if and only if the number of positives in $\mathcal{O}$ is exactly $i$. $X$ is distributed according to a binomial distribution with parameter $q$ and mean value $\mu$. If the number of positives is at most $(1+\delta)\mu$, and this happens with probability $Pr[X \leq (1+\delta)\mu]$, then by the result of section 3 the execution of the queries of Stage 1 will restrict our search to $2(1+\delta)\mu - 1$ elements, which will be individually probed during Stage 2. Stage 1 requires $O(m \log \frac{n}{m})$ queries. If, on the contrary, the number of positives is larger than $(1+\delta)\mu$, then the feedback vector $\mathbf{f}$ might cover more than $2(1+\delta)\mu - 1$ columns of the selector. Consequently a larger number of elements, potentially *all* $n$ elements, must be individually probed in Stage 2. The crucial observation is that this latter unfavorable event happens with probability $Pr[X > (1+\delta)\mu]$. Altogether, the above algorithm uses an average number of queries $E$ given by

$$E = O\left(m \log \frac{n}{m}\right) + nPr[X > (1+\delta)\mu]. \tag{13}$$

Choosing $\delta \geq 2e$ and by recalling that $m = (1+\delta)\mu + 1$, we get from (13) and by the Chernoff bound (see [46, p. 72]) that

$$E = O\left(nq(n) \log \frac{1}{q(n)}\right) + n2^{-(1+\delta)nq(n)}. \tag{14}$$

A similar idea was used in [8]. However, the authors of [8] used classical superimposed codes in the first stage of their algorithm, and since these codes have sizes much larger than our selectors, their results are worse than ours. Recalling now the information-theoretic lower bound (12) on the expected number of queries, we get from (14) that our algorithm is provably asymptotically optimal whenever the probability function $q(n)$ satisfies the condition

$$q(n) \geq \frac{1}{n}\left(\log\frac{1}{q(n)} - \log\log\frac{1}{q(n)} - O(1)\right). \tag{15}$$

For instance, $q(n) = c\frac{\log n}{n}$ for any positive constant $c$ or $q(n)$ such that $\frac{q(n)n}{\log n} \to \infty$ satisfy (15). The previous two cases were explicitly considered in [7], where the authors obtained results similar to ours, with better constants. Nevertheless, our condition (15) is more general. Also, our method is rather flexible since one can "tune" the choice of $m$ to some value $f(n)\delta\mu$, for a suitably chosen function $f(n)$, in order to get good performances also when $q(n)$ does not satisfy (15).

The main difference between our results and those of [7] consists of the following. Here we estimate the average number of queries of our explicitly defined algorithm. Instead, the authors of [7] estimate the average number of queries performed by a two-stage algorithm, where the Boolean matrix used in the first stage is randomly chosen among all $m \times n$ binary matrices, where the choice of $m$ depends on $q(n)$. Using a very complex yet accurate analysis, they probabilistically show the *existence* of two-stage algorithms with good performances. For several classes of probability functions $q(n)$, they are able to give asymptotic upper and lower bounds on the minimum average number of queries that differ in several cases only by a multiplicative constant.

## 5. An optimal four-stage group testing algorithm for the GTI model.

In this section we consider the group testing with inhibitors (GTI) model introduced in [29]. We recall that, in this model, in addition to positive items and regular items, there is also a category of items called inhibitors. The inhibitors are the items that interfere with the test by hiding the presence of positive items. As a consequence, a test yields a positive feedback if and only if the tested pool contains one or more positives and no inhibitors. We present an optimal worst-case four-stage group testing algorithm to find $p$ positives in the presence of up to $r$ inhibitors.

**Stage 1.** The goal of this stage is to find a pool $Q \subseteq \mathcal{O}$ which tests positive. To this aim, we associate each item with a distinct column of a $(p, r)$-superimposed code $M = [M(i, j)]$. Let $t$ be the length of the code. For $i = 1, \ldots, t$ we construct the pool $T_i = \{j \in \{1, \ldots, n\} : M(i, j) = 1\}$. If we test pools $T_1, \ldots, T_t$, then the feedback vector has the $i$th entry equal to 1 if and only if at least one the columns associated with the $p$ positives has the $i$th entry equal to 1, whereas none of the columns associated with the inhibitors has the $i$th entry equal to 1. It is easy to prove that such an entry $i$ exists by using the fact that the code $M$ is $(p, r)$-superimposed. Stage 1 returns $Q = T_i$.

**Stage 2.** The goal of this stage is to remove all inhibitors from the set $\mathcal{O}$. To this aim we associate each item not in $Q$ with a distinct column of a $(k', r + 1, n - |Q|)$-selector $M'$. Let $t'$ be the size of the selector. For $i = 1, \ldots, t'$ we construct the pool $T'_i = \{j \in \{1, \ldots, n\} : M'(i, j) = 1\}$. Let $s \leq r$ denote the number of inhibitors in $\mathcal{O}$. If we test pools $T'_1 \cup Q, \ldots, T'_{t'} \cup Q$, then the feedback vector $\mathbf{f}'$ has the $i$th entry equal to 0 if and only if $T'_i$ contains one or more inhibitors. Hence, the feedback vector $\mathbf{f}'$ is equal to the intersection (Boolean product) of the bitwise complement of the $s$ columns associated with the inhibitors. Let $\overline{\mathbf{f}}'$ be the bitwise complement of $\mathbf{f}'$. The column $\overline{\mathbf{f}}'$ is equal to the Boolean sum of the $s$ columns associated with the $s$ inhibitors. Using an argument similar to that used for the two-stage group testing algorithm of section 3, one has that $\overline{\mathbf{f}}'$ covers at most $k' - s - 1$ columns in addition to those associated with the $s$ inhibitor items. We set apart all $k'-1$ items covered by $\overline{\mathbf{f}}'$. These $k'-1$ items will be individually probed in Stage 4 since some of them might be defective.

**Stage 3.** The goal of this stage is to discard a "large" number of regular items from the set of $n-k'$ items remaining after Stage 2. The present stage is similar to Stage 1 of our two-stage algorithm of section 3. We associate each of the $n-k'$ items with a distinct column of a $(k'', p+1, n-k')$-selector $M''$. Let $t''$ be the size of the selector. For $i=1,\dots,t''$ we construct the pool $T''_i = \{j \in \{1,\dots,n\} : M''(i,j)=1\}$ and test pools $T''_1,\dots,T''_{t''}$. Notice that after Stage 2 there is no inhibitor among the searched set of items and, consequently, the feedback vector $\mathbf{f}''$ is equal to the Boolean sum of the columns associated with the positive items in the set (those which have not been set apart in Stage 2). After these $t''$ tests we discard all items but those corresponding to columns covered by the feedback vector $\mathbf{f}''$. Hence, we are left with $k''-1$ items.

**Stage 4.** We individually probe the $k'-1$ items returned by Stage 2 and the $k''-1$ items returned by Stage 3.

The above algorithm provides the following general result.

THEOREM 5. *Let $k'$, $k''$, $n$, $p$, and $r$ be integers with $1 \le r < k' < n$ and $1 \le p < k'' < n-k'$. There exists a four-stage group testing algorithm for finding $p$ positives in the presence of up to $r$ inhibitors by*

$$t_s(p,r,n) + t(k', r+1, n-|Q|) + t(k'', p+1, n-k') + k' + k'' - 2$$

*tests.*

The following main corollary of Theorem 5 holds.

COROLLARY 5. *Let $p$ and $r$ be integers with $1 \le r < n$ and $1 \le p < n-2r$. There exists a four-stage group testing algorithm for finding $p$ positives in the presence of up to $r$ inhibitors by*

$$t_s(p,r,n) + O\left(r\log\frac{n}{r} + p\log\frac{n-r}{p}\right) \tag{16}$$

*tests, and this upper bound is asymptotically optimal.*

*Proof.* By setting $k'=2r$ and $k''=2p$ in Theorem 5 and using the bound of Theorem 1 on the size of selectors, one gets the following upper bound on the number of tests performed by the four-stage algorithm:

$$t_s(p,r,n) + 4er\ln\frac{n-|Q|}{2r} + 2e(4r-1) + 4ep\ln\frac{n-2r}{2p} + 2e(4p-1) + 2r + 2p. \tag{17}$$

We now prove that the above upper bound is asymptotically optimal. In [21] the authors proved the following lower bound of

$$\Omega\left(t_s(p,r,n-p-1) + \ln\binom{n}{p}\right) \tag{18}$$

on the number of tests required by *any* algorithm (using any number of stages) to find $p$ defectives in the presence of $r$ inhibitors. It is easy to see that any $(p,r)$-superimposed code of size $n-p-1$ and length $t$ can be transformed into a $(p,r)$-superimposed code of size $n$ and length $t+p+1$. Indeed, let $M$ be a $(p,r)$-superimposed code of size $n-p-1$ and length $t$, and let $c_j$, $j=1,\dots,p+1$, denote the binary column of length $t+p+1$ with all entries, except that in position $t+j$, equal to zero. If we add $p+1$ entries equal to zero at the end of each column of $M$ and introduce the columns $c_1, \dots, c_{p+1}$ in the resulting code, then we obtain a $(p,r)$-superimposed code of size $n$ and length $t+p+1$. It follows that $t_s(p,r,n-p-1)+p+1 = \Omega(t_s(p,r,n))$ and, consequently, the lower bound (18) is

$$\Omega\left(t_s(p,r,n) + \ln\binom{n}{p}\right). \tag{19}$$

It is possible to see that expression (19) is $\Omega(t_s(p,r,n) + r\log\frac{n}{r} + p\log\frac{n}{p})$. If $p > r$, this is immediate. If $p \le r$, Theorem 2 implies that

$$t_s(p,r,n) = \Omega\left(r\log\frac{n}{r}\right). \tag{20}$$

Therefore expression (19) is $\Omega(t_s(p,r,n) + r\log\frac{n}{r} + p\log\frac{n}{p})$. It follows that the upper bound (17) on the number of tests performed by the four-stage algorithm is tight with lower bound (18). $\square$

We can employ a $(p+r, r+1, n)$-selector in Stage 1 of the four-stage algorithm and use the bound of Theorem 1 on the size of selectors to estimate the number of tests performed by this stage. Notice that the weight of the rows of the $(p+r, r+1, n)$-selector corresponds to the size of the pools tested during Stage 1 and, consequently, to that of the set $Q$ returned by this stage. By using the construction of Theorem 1 one has that the size of $Q$ is $\frac{n}{r+p}$. Hence, the following result holds.

Corollary 6. *For any integers $p, r$, and $n$, with $p \ge 1$, $r \ge 0$ and $p + r \le n$, there exists a four-stage group testing algorithm for finding $p$ positives in a set of $n$ elements, up to $r$ of which can be inhibitors, using a number of tests at most*

$$\frac{e(p+r)^2}{p}\ln\frac{n}{p+r} + 4er\ln\frac{n(r+p-1)}{2r(r+p)} + 4ep\ln\frac{n-2r}{2p}$$
$$+ (10e+2)p + (12e+2)r - 5e + \frac{er(2r-1)}{p} - 2.$$

It is remarkable that for $r = O(p)$ Corollary 6 implies that our deterministic algorithm attains the same asymptotic complexity $O((r+p)\log n)$ of the randomized algorithm presented in [29].

Notice that the algorithm presented in this section actually discovers both the positives *and* the inhibitors. Therefore, in the same spirit of section 3.2, we observe that the problem of finding $p$ positives and $r$ inhibitors is equivalent to the problem of learning an unknown Boolean function of the form $(x_1 \vee \cdots \vee x_p) \wedge \overline{(y_1 \vee \cdots \vee y_r)}$. Hence, the above results can be rephrased as follows.

Corollary 7. *For any $p$ and $r$, Boolean functions of the form $(x_1 \vee \cdots \vee x_p) \wedge \overline{(y_1 \vee \cdots \vee y_s)}$, $s \le r$, are exactly learnable in only* four stages *by using a number of queries of the same order as that of the best fully adaptive learning algorithm.*

## 6. Final discussion.

The main result obtained in this paper is the first two-stage group testing algorithm that uses a number of tests of the same order as the information-theoretic lower bound on the problem. In retrospect, it could be useful to see how we have reached our goal. The first stage of our algorithm is conceptually similar to a classical totally nonadaptive group testing algorithm that first encodes the items of the search space $\mathcal{O}$ with the column vectors of a superimposed code and then performs tests according to the subsets of $\mathcal{O}$ specified by the rows of the matrix constituting the code (recall section 3). Unfortunately, any matrix that represents a superimposed code has $\Omega((p^2/\log p)\log n)$ number of rows, where $p$ is the known upper bound on the number of positive elements, and therefore the number of performed tests is well above the information-theoretic lower bound $\log\binom{n}{p}$. Hence, we are lead to look for combinatorial objects satisfying weaker conditions and having a number of rows at most $O(p\log n)$ so that, by using them to specify the tests of the first stage, we would remain close to the information-theoretic lower bound. Of course, if we used such objects, whatever they are, at the end of the first stage we would necessarily have unclassified items (recall the lower bound of $\Omega((p^2/\log p)\log n)$ on the number of tests for one-stage algorithms that correctly discriminate all items in positives and negatives). Luckily, by using our selectors of length $O(\log\binom{n}{p})$, at the end of the first stage the number of unclassified items is very small, at most $2p-1$, and by testing them one by one we find all positives, and we remain asymptotically within the border of the information-theoretic lower bound. We recall that our algorithm uses an overall number of tests that is less than $7p\log\frac{n}{p}+O(p)$; therefore the relevant constant in $O(p\log(n/p))$ is also reasonably small.

It would be interesting to see whether this approach of "weakening" combinatorial structures that are used in totally nonadaptive search procedures could be used also for other problems to obtain "few-stages" algorithms, with the same asymptotic performances of totally adaptive algorithms. The general approach should be the following: since it may be too expensive to determine in a totally nonadaptive fashion the exact solution to the problem, one first nonadaptively individuates an "approximate" solution to the problem, that is, a small set of potential solutions, and thereafter one searches for the exact solution in this small set.

There are numerous problems that are possible candidates for such an investigation; potentially, many of the search problems mentioned in [2, 24], for which there exists a gap between the complexity of adaptive and nonadaptive algorithms, could be studied in this light. A particularly interesting one is the so-called "group testing for complexes" [26, 44]. Here the elements of $\mathcal{O}$ are positive or negative not by themselves, but only in conjunction with some others (imagine some chemical substances that react with others and therefore cannot be mixed with them, but yet are nonreacting with other, different substances). The problem is to identify all positive subsets, that is, to remain in the chemical scenario, to identify all groups of mutually reacting substances. The best nonadaptive algorithm for the above problem has huge complexity [26], and an interesting open problem would be to see whether our approach could lead to efficient "few-stage" algorithms.

In general, our study raises the following question: How much adaptiveness is really needed in search procedures to obtain the optimal performances of fully adaptive algorithms? Our results show that in group testing one needs to use adaptiveness only once. There are other situations in which this phenomenon occurs. For instance, for the well-known Renyi–Ulam game [48, 50, 53], in which one looks for an unknown number by asking arbitrary yes/no questions, at most a fixed number of which can receive an erroneous answer, the authors of [14] have shown that there exist two-stage search strategies using a number of questions exactly equal to the information-theoretic lower bound, and that one-stage search strategies cannot reach this lower bound. Conversely, it is also known that there are natural search problems for which fully adaptive algorithms are better than any $k$-stage algorithm (see, e.g., [47]). A better understanding of the above issues is worth pursuing.

# STRICTLY NONBLOCKING MULTIRATE $\log_d(N, m, p)$ NETWORKS*

FRANK K. HWANG†, YONG HE‡, AND YANG WANG‡

**Abstract.** We give necessary and sufficient conditions for the $d$-nary multilog network to be strictly nonblocking under the discrete multirate model, and we give sufficient conditions for the same under the continuous multirate model.

**Key words.** strictly nonblocking network, multirate model, multilog network, Cantor network

**AMS subject classifications.** 68M10, 90B18

**DOI.** 10.1137/S0097539703433158

## 1. Introduction.

In a multirate network, each link has a (normalized) capacity 1 and each request for connection is associated with a weight (bandwidth requirement) $w$. Many paths can go through a link simultaneously as long as their total weight has not exceeded unity. In particular, an input or output (link) can generate or receive many requests as long as their total weight does not exceed unity. Often, the weight of a request is bounded in the range $[b, B]$. A more general model is to assume that an input or output link has capacity $\beta \leq 1$ to reflect the reality that many networks need an internal-to-external speed-up to be more efficient. In the discrete case (the channel model), we assume that each internal link has $f_1$ channels, each input or output has $f_0 \leq f_1$ channels, and a request is associated with a positive integer number $q, 1 \leq q \leq Q$, where $Q \leq f_0$ is an upper bound of the number of channels a request can demand.

A network state is a set of paths connecting a set of requests $\{(i_x, o_y, w)\}$ such that no link carries a load exceeding 1 (or $f_1$), where $i_x$ is an input, $o_y$ is an output, and $w$ is the associated weight. Given a state, a new request $(i, o, w)$ must satisfy the condition that $i$ has not generated and $o$ has not received requests whose total weight exceeds $1 - w$ (or $f_0 - w$). A network is strictly nonblocking if, at any state, a new request can always be connected without having any links carrying a load exceeding 1 (or $f_1$).

Strictly nonblocking multirate networks have been studied for the 3-stage Clos network [3] and the $d$-nary Cantor network [1], $d \geq 2$. In this paper, we extend the results of the Cantor network to the more general $\log_d(N, m, p)$ network (also called the $d$-nary multilog network), where the Cantor network is the special case with $m = n - 1$. In particular, we give necessary and sufficient conditions for $\log_d(N, m, p)$ to be multirate strictly nonblocking.

**2. The channel model.** The $\log_d(N, m, p)$ network was first proposed by Shyy and Lea [6], extending the $\log_d(N, 0, p)$ network proposed by Lea [4]. The $\log_d(N, m, p)$ network has an input (output) stage consisting of $N = d^n$ $1 \times p$ ($p \times 1$) crossbars and $p$ copies of the $d$-nary $m$-extra-stage, $0 \leq m \leq n-1$, inverse banyan network $BY_d^{-1}(n, m)$, where each input and output crossbar is connected to every copy of $BY_d^{-1}(n, m)$. We will label the $n + m + 2$ stages by $0, 1, \dots, n + m + 1$. Figure 1 illustrates an example of $\log_d(N, m, p)$.

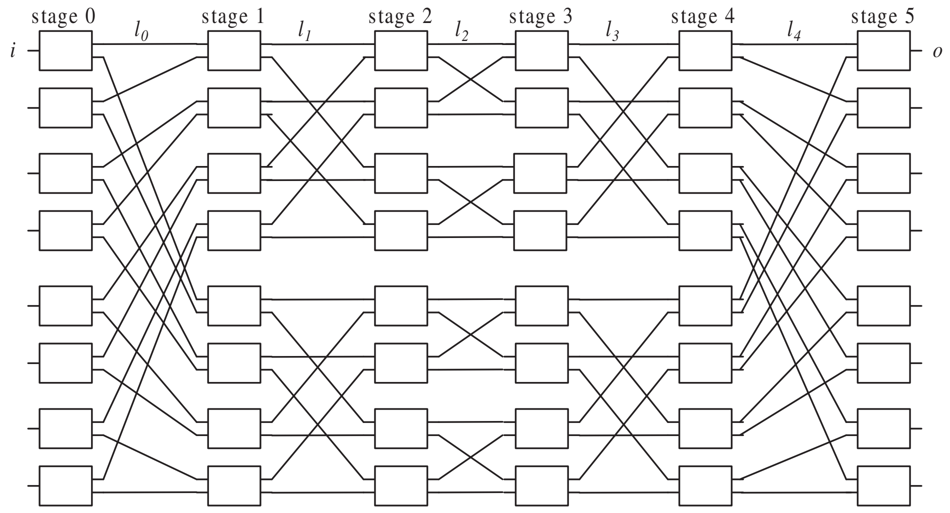

Fig. 1. *A* $\log_2(8, 1, 2)$ *network.*

Next we study the channel model in this section.

Theorem 2.1. *Consider the* $(Q, f_0, f_1)$ *channel model with* $d^{\lfloor \frac{n-1}{2} \rfloor} f_0 \geq f_1 + 1$. *Then* $\log_d(N, 0, p)$ *is multirate strictly nonblocking if and only if*

$$p \geq \left\lfloor \frac{d^{\lfloor \frac{n-1}{2} \rfloor} f_0 - Q}{f_1 - Q + 1} \right\rfloor + \left\lfloor \frac{d^{\lceil \frac{n-1}{2} \rceil} f_0 - Q}{f_1 - Q + 1} \right\rfloor + 1.$$

*Proof.* Suppose the new request is $(i, o, q)$. Call an internal link *$q$-saturated* if it carries a load exceeding $f_1 - q + 1$ (and hence cannot carry a new $q$-request). Note that the channel graph between $i$ and $o$ is just a single path $l$. An intersecting path is a path $p$ from input $i' \neq i$ to output $o' \neq o$ such that $p$ shares a link with $l$. In particular, let $l_j$ denote the stage-$j$ link (a link between stage $j$ and stage $j + 1$) in $l$ (see Figure 1). Then a $j$-intersecting path is one which intersects $l$ at $l_j$. Note that a $j$-intersecting path can also be a $j'$-intersecting path for $j \neq j'$. Further, $l_0$ ($l_n$) cannot be saturated since its load is from $i$ ($o$). Therefore we need only look inside the $BY_d^{-1}(n, 0)$ for saturated links.

*Sufficiency.* The new request cannot be carried in a copy of $BY_d^{-1}(n, 0)$ if and only if there exists an $l_j$ which is $q$-saturated by $j$-intersecting paths. We divide $l$ into two disjoint halves:

$$H_1 = \{l_j : 1 \leq j \leq \lfloor (n-1)/2 \rfloor\},$$

$$H_2 = \{l_j : \lfloor (n+1)/2 \rfloor \leq j \leq n-1\}.$$

Note that only $d^{\lfloor (n-1)/2 \rfloor}$ inputs can generate $j$-intersecting paths over all $j$ in $H_1$. The total weight of these paths is bounded by $d^{\lfloor (n-1)/2 \rfloor} f_0 - q$ since the weight of the new request must be excluded. In the right-hand side of the inequality in Theorem 2.1, the first term is an upper bound of the number of $q$-saturated $l_j$ over all $j$ in $H_1$. Similarly, only $d^{\lceil (n-1)/2 \rceil}$ outputs can generate $j$-intersecting paths for $j$ in $H_2$, and the second term in the inequality is an upper bound of the number of $q$-saturated $l_j$ over all $j$ in $H_2$. Thus their sum is an upper bound of the number of saturated links in $l$, and hence an upper bound of the number of blocked copies of $BY_d^{-1}(n,0)$. One more copy suffices to route the new request.

*Necessity.* It suffices to construct a set of connections intersecting the $(i,o,Q)$ request with total weights of $\lfloor \frac{d^{\lfloor \frac{n-1}{2} \rfloor} f_0 - Q}{f_1 - Q + 1} \rfloor$ and $\lfloor \frac{d^{\lceil \frac{n-1}{2} \rceil} f_0 - Q}{f_1 - Q + 1} \rfloor$. With respect to $l$, an input (output) is called *$j$-marginal*, $1 \le j \le n-1$, if it can generate a $j$-intersecting path but not a $(j-1)$-intersecting ($(j+1)$-intersecting) path. Let $WI_j$ ($WO_j$) denote the total weight of requests which can be generated by $j$-marginal inputs (outputs). Then

$$WI_1 = df_0 - q, \quad WI_j = (d^j - d^{j-1}) f_0 \quad \text{for} \ \ 2 \le j \le n-1,$$

$$WO_j = WI_{n-j} \quad \text{for} \ \ 1 \le j \le n-1.$$

Note that

$$WI_j < WO_j \quad \text{for} \ \ j \in H_1$$

and

$$WI_j > WO_j \quad \text{for} \ \ j \in H_2.$$

Compute the maximum number $b_1$ of $Q$-saturated links generated by 1-marginal inputs. Assign a total weight of $b_1(f_1 - Q + 1)$ of requests to 1-marginal outputs (doable by the above inequalities), and mix the remaining requests of weight $df_0 - Q - b_1(f_1 - Q + 1)$ with requests generated by 2-marginal inputs. Again, compute the maximum number $b_2$ of $Q$-saturated links generated by this mixture of requests. Assign requests with a total weight $b_2(f_1 - Q + 1)$ to 2-marginal outputs, and mix the rest with requests from 3-marginal inputs. Proceed like this until the last step $s = \lfloor (n-1)/2 \rfloor$. At step $s$, assign requests with a total weight of $b_s(f_1 - Q + 1)$ to $s$-marginal outputs and ignore unassigned requests. It is straightforward to verify that the number of saturated $l_j$ for $j$ in $H_1$ constructed by this assignment is the first term in the inequality of Theorem 2.1. Similarly, the corresponding number for $j$ in $H_2$ is the second term. Thus their sum plus one copy is the necessary number of copies needed to route the new request. $\square$

Next we consider the general $m$ case. Define

$$g_m(q) = \sum_{j=1}^{m} \frac{1}{d^j} \left\{ \left\lfloor \frac{d^j f_0 - q}{f_1 - q + 1} \right\rfloor - \left\lfloor \frac{d^{j-1} f_0 - q}{f_1 - q + 1} \right\rfloor \right\} \qquad \text{for} \quad 0 \le m \le n-1.$$

THEOREM 2.2. *Consider the $(Q, f_0, f_1)$ channel model with $d^{\lfloor \frac{n-1}{2} \rfloor} f_0 \ge f_1 + 1$. Then $\log_d(N,m,p)$ is multirate strictly nonblocking for $0 \le m \le n-1$ if and only if*

$$p \geq \left\lfloor 2g_m(Q) + \left\lfloor \frac{d^{\lfloor \frac{n+m-1}{2} \rfloor} f_0 - Q - \lfloor \frac{d^m f_0 - Q}{f_1 - Q + 1} \rfloor (f_1 - Q + 1)}{f_1 - Q + 1} \right\rfloor \frac{1}{d^m} \right.$$

$$\left. + \left\lfloor \frac{d^{\lceil \frac{n+m-1}{2} \rceil} f_0 - Q - \lfloor \frac{d^m f_0 - Q}{f_1 - Q + 1} \rfloor (f_1 - Q + 1)}{f_1 - Q + 1} \right\rfloor \frac{1}{d^m} \right\rfloor + 1.$$

*Proof.* Our strategy is to partition the $BY_d^{-1}(n, m)$ stages into two parts as follows: the outer part consists of $m + 1$ outer stages from the input side and $m + 1$ outer stages from the output side; and the inner part consists of $n - m$ inner stages, i.e., stage $m + 1$ to stage $n$, composed of $d^m$ copies of $BY_d^{-1}(n - m, 0)$. (Note that stage $m + 1$ ($n$) is in both parts.) For the outer part, we adopt (and extend) the approach of Chung and Ross [2] given for the special case of the Cantor network. For the inner part we apply Theorem 2.1.

More specifically, for the outer part, we compute the total weight of requests which can reach a stage-$j$ link, $1 \leq j \leq m$, in the $(i, o)$ channel graph that is $d^j f_0 - q$, while a $q$-saturated link carries a load of at least $f_1 - q + 1$. Thus, at most

$$\left\lfloor \frac{d^j f_0 - q}{f_1 - q + 1} \right\rfloor$$

links in the channel graph at or before stage $j$ can be saturated. The worst case is to assign the saturated links to as early a stage as possible since links in the early stages have more blocking power. This results in assigning

$$\left\lfloor \frac{d^j f_0 - q}{f_1 - q + 1} \right\rfloor$$

saturated links to stage $j$, each of which blocks $1/d^j$ copies of $BY_d^{-1}(n, m)$. Thus $\lfloor g_m(q) \rfloor$ is the number of copies of $BY_d^{-1}(n, m)$ blocked by paths intersecting the links of the $(i, o)$ channel graph in the first or last $m$ stages.

The total weight of requests which can reach a stage-$\lfloor (n + m - 1)/2 \rfloor$ link is

$$d^{\lfloor (n+m-1)/2 \rfloor} f_0 - q.$$

But a total weight of

$$\left\lfloor \frac{d^m f_0 - q}{f_1 - q + 1} \right\rfloor (f_1 - q + 1)$$

was already connected in the first $m$ stages. Therefore only the difference of these two weights can be used to saturate stage-$j$ links for $m+1 < j \leq \lfloor (n+m-1)/2 \rfloor$. Since the $\log_d(N, m, p)$ network between these stages consists of $d^m$ copies of $BY_d^{-1}(n - m, 0)$, we apply Theorem 2.1 (only the input side) to the number of copies of $BY_d^{-1}(n - m, 0)$ blocked, which must be divided by $d^m$ to convert to the number of copies of $BY_d^{-1}(n, m)$ blocked.

The argument for the output side is analogous. One extra channel then guarantees the routing of the current request. Therefore

$$p \geq \max_{1 \leq q \leq Q} \left\{ \lfloor 2g_m(q) + \left\lfloor \frac{d^{\lfloor \frac{n+m-1}{2} \rfloor} f_0 - q - \lfloor \frac{d^m f_0 - q}{f_1 - q + 1} \rfloor (f_1 - q + 1)}{f_1 - q + 1} \right\rfloor \frac{1}{d^m} \right.$$

$$\left. \left\lfloor \frac{d^{\lceil \frac{n+m-1}{2} \rceil} f_0 - q - \lfloor \frac{d^m f_0 - q}{f_1 - q + 1} \rfloor (f_1 - q + 1)}{f_1 - q + 1} \right\rfloor \frac{1}{d^m} \rfloor \right\} + 1 \tag{1}$$

is a sufficient condition for $\log_d(N,m,p)$ to be multirate strictly nonblocking for $0 \leq m \leq n-1$. We show that the maximum is achieved at $q = Q$. To see this, define

$$A_j = \left\lfloor \frac{d^j f_0 - q}{f_1 - q + 1} \right\rfloor, \qquad j = 0, 1, \ldots, \left\lfloor \frac{n+m-1}{2} \right\rfloor$$

for simplicity. Then, trivially, $A_0 = \lfloor \frac{f_0 - q}{f_1 - q + 1} \rfloor = 0$ and $A_j \geq 0$ is nondecreasing in $q$ for every $j = 0, 1, \ldots, \lfloor \frac{n+m-1}{2} \rfloor$. We have

$$\begin{aligned}
&g_m(q) + \left\lfloor \frac{d^{\lfloor \frac{n+m-1}{2} \rfloor} f_0 - q - \lfloor \frac{d^m f_0 - q}{f_1 - q + 1} \rfloor (f_1 - q + 1)}{f_1 - q + 1} \right\rfloor \frac{1}{d^m} \\
&= g_m(q) + \left( \left\lfloor \frac{d^{\lfloor \frac{n+m-1}{2} \rfloor} f_0 - q}{f_1 - q + 1} \right\rfloor - \left\lfloor \frac{d^m f_0 - q}{f_1 - q + 1} \right\rfloor \right) \frac{1}{d^m} \\
&= \frac{1}{d}(A_1 - A_0) + \frac{1}{d^2}(A_2 - A_1) + \cdots + \frac{1}{d^m}(A_m - A_{m-1}) + \frac{1}{d^m}(A_{\lfloor \frac{n+m-1}{2} \rfloor} - A_m) \\
&= \left( \frac{1}{d} - \frac{1}{d^2} \right) A_1 + \left( \frac{1}{d^2} - \frac{1}{d^3} \right) A_2 + \cdots + \left( \frac{1}{d^{m-1}} - \frac{1}{d^m} \right) A_{m-1} + \frac{1}{d^m} A_{\lfloor \frac{n+m-1}{2} \rfloor}.
\end{aligned}$$

Since every term is positive and nondecreasing in $q$, we conclude that

$$g_m(q) + \left\lfloor \frac{d^{\lfloor \frac{n+m-1}{2} \rfloor} f_0 - q - \lfloor \frac{d^m f_0 - q}{f_1 - q + 1} \rfloor (f_1 - q + 1)}{f_1 - q + 1} \right\rfloor \frac{1}{d^m}$$

is maximized at $Q$. A similar conclusion holds for the term

$$g_m(q) + \left\lfloor \frac{d^{\lceil \frac{n+m-1}{2} \rceil} f_0 - q - \lfloor \frac{d^m f_0 - q}{f_1 - q + 1} \rfloor (f_1 - q + 1)}{f_1 - q + 1} \right\rfloor \frac{1}{d^m}.$$

It follows that (1) is maximized at $Q$.

The necessity part follows from the fact that both the conditions of Chung and Ross and those of Theorem 2.1 are necessary. However, the $j$-marginal input is defined only for $1 \leq j \leq n$ since they use up all inputs. Similarly, the $j$-marginal output is defined only for $n \leq j \leq n+m-1$, and $WO_j = WI_{n+m-j}$. Therefore we need to slightly modify the assignment of requests from $j$-marginal inputs and outputs. It is easily verified as follows:

$$\sum_{j=1}^{m} WI_j < WO_m \quad \text{and} \quad \sum_{j=n}^{n+m-1} WO_j < WI_n.$$

The modification is to assign requests from $j$-marginal inputs for all $1 \leq j \leq m$ to $m$-marginal outputs and requests for $j$-marginal outputs for all $n \leq j \leq n+m-1$ to $n$-marginal inputs. The above inequalities ensure that such assignments are doable. $\square$

Note that for $m = 0$, $g_m(Q) = 0$, and $\lfloor \frac{d^m f_0 - Q}{f_1 - Q + 1} \rfloor = 0$, Theorem 2.2 is reduced to Theorem 2.1. For $m = n-1$, the terms

$$\left\lfloor \frac{d^{\lfloor \frac{n+m-1}{2} \rfloor} f_0 - Q - \lfloor \frac{d^m f_0 - Q}{f_1 - Q + 1} \rfloor (f_1 - Q + 1)}{f_1 - Q + 1} \right\rfloor$$

and

$$\left\lfloor \frac{d^{\lceil \frac{n+m-1}{2} \rceil} f_0 - Q - \lfloor \frac{d^m f_0 - Q}{f_1 - Q + 1} \rfloor (f_1 - Q + 1)}{f_1 - Q + 1} \right\rfloor$$

equal 0. Theorem 2.2 is reduced to the result on the Cantor network in [2].

We further study the situation when the internal links have different capacities. Suppose the input and output have capacity $f_0$, the stage-$j$ links and stage-$(n-j)$ links have capacity $f_j$, $j = 1, 2, \ldots, \lceil \frac{n+m-1}{2} \rceil$, and $f_{j-1} \le f_j$.

We define

$$l_k(q) = \left\lfloor \frac{d^k f_0 - q - \sum_{i=1}^{k-1} (f_i - q + 1) l_i(q)}{f_k - q + 1} \right\rfloor \qquad \text{for} \quad 1 \le k \le \left\lceil \frac{n+m-1}{2} \right\rceil,$$

and

$$g_m(q) = \sum_{j=1}^{m} \frac{1}{d^k} l_k(q) \qquad \text{for} \quad 0 \le m \le n-1.$$

THEOREM 2.3. *Consider the* $(Q, f_0, f_1, \ldots, f_{\lceil \frac{n+m-1}{2} \rceil})$ *channel model with* $d^{\lfloor \frac{n-1}{2} \rfloor} f_0 \ge f_1 + 1$. *Then* $\log_d(N, m, p)$ *is multirate strictly nonblocking for* $0 \le m \le n-1$ *if and only if*

$$p \ge \max_{1 \le q \le Q} \left\{ \left\lfloor 2 g_m(q) + \frac{1}{d^m} \sum_{m+1}^{\lfloor \frac{n+m-1}{2} \rfloor} l_k(q) + \frac{1}{d^m} \sum_{m+1}^{\lceil \frac{n+m-1}{2} \rceil} l_k(q) \right\rfloor \right\} + 1.$$

*Proof.* The proof is analogous to the proof of Theorem 2.2. The assumption $f_{j-1} \le f_j$ for $j = 1, 2, \ldots, \lceil \frac{n+m-1}{2} \rceil$ is needed to guarantee

$$\frac{f_0}{f_k - q + 1} \cdot \frac{1}{d^k} > \frac{f_0}{f_{k+1} - q + 1} \cdot \frac{1}{d^{k+1}} \qquad \text{for} \quad 1 \le k \le m,$$

$$\frac{f_0}{f_k - q + 1} \cdot \frac{1}{d^m} > \frac{f_0}{f_{k+1} - q + 1} \cdot \frac{1}{d^m} \qquad \text{for} \quad 1 \le k \le \left\lfloor \frac{n+m-1}{2} \right\rfloor,$$

such that if an intersecting path intersects at several stages, the blocking effect is always greatest at the outmost stage, justifying our assigning it to that stage. ∎

**3. The continuous model.** We first quote a lemma proved by Melen and Turner [5].

LEMMA 3.1. $\lfloor \frac{a-w}{b-w+\epsilon} \rfloor = \lceil \frac{a-w}{b-w} \rceil - 1$ *if* $a \ge b$, *where* $\epsilon$ *is positive and tends to* 0.

THEOREM 3.2. *Consider the* $(b, B, \beta)$ *continuous model satisfying* $b + B \le 1$. *Then* $\log_d(N, 0, p)$ *is strictly nonblocking if*

$$p \ge \left\lceil \frac{d^{\lfloor \frac{n-1}{2} \rfloor} \beta - B}{1 - B} \right\rceil + \left\lceil \frac{d^{\lceil \frac{n-1}{2} \rceil} \beta - B}{1 - B} \right\rceil - 1,$$

*and the condition is necessary if* $b = 0$.

*Proof.* With an argument analogous to the proof of Theorem 2.1, we obtain the sufficient condition to route an $(i, o, w)$ new request to be

$$\begin{aligned}&\left\lfloor \frac{d^{\lfloor \frac{n-1}{2} \rfloor}\beta - w}{1-w+\epsilon} \right\rfloor + \left\lfloor \frac{d^{\lceil \frac{n-1}{2} \rceil}\beta - w}{1-w+\epsilon} \right\rfloor + 1 \\ &= \left\lceil \frac{d^{\lfloor \frac{n-1}{2} \rfloor}\beta - w}{1-w} \right\rceil + \left\lceil \frac{d^{\lceil \frac{n-1}{2} \rceil}\beta - w}{1-w} \right\rceil - 1,\end{aligned}$$

which is maximized at $w = B$.

To prove the necessity, note that for $b = 0$ we can always generate requests with suitable weights such that every saturated link carries a load of $1 - w - \epsilon$. □

THEOREM 3.3. *Consider the $(b, B, \beta)$ continuous model satisfying $b + B > 1$. Then $\log_d(N, 0, p)$ is strictly nonblocking if and only if*

$$p \geq \left\lfloor \frac{\beta}{b} \right\rfloor (d^{\lfloor \frac{n-1}{2} \rfloor} - 1) + \left\lfloor \frac{\beta}{b} \right\rfloor (d^{\lceil \frac{n-1}{2} \rceil} - 1) + 1.$$

*Proof.* Let the new request be $(i, o, w)$. Note that the channel graph between $i$ and $o$ is just a single path $l$. Similar to the proof of Theorem 2.1, $d^{\lfloor (n-1)/2 \rfloor} - 1$ inputs other than $i$ can generate $j$-intersecting paths for $j$ in $H_1$, and $d^{\lceil (n-1)/2 \rceil} - 1$ outputs can generate $j$-intersecting paths for $j$ in $H_2$. Since either an input or an output can generate at most $\lfloor \beta/b \rfloor$ requests, then

$$\left\lfloor \frac{\beta}{b} \right\rfloor (d^{\lfloor \frac{n-1}{2} \rfloor} - 1) + \left\lfloor \frac{\beta}{b} \right\rfloor (d^{\lceil \frac{n-1}{2} \rceil} - 1)$$

is an upper bound of the number of intersecting paths, and hence an upper bound of the number of blocked copies. Thus one extra copy suffices to carry the new request. Note that whether the extra copy carries any load from $i$ or $o$ is immaterial since the load cannot exceed $\beta - w$.

On the other hand, suppose $w = B$. Then, analogous to Theorem 2.1, the worst case described above can occur and the new request cannot be routed through any link already carrying a load $b$. Hence the sufficient condition is also necessary. □

Next we consider $m > 0$ case. Define

$$g_m(w) = \sum_{j=1}^{m} \frac{1}{d^j} \left\{ \left\lceil \frac{d^j\beta - w}{1-w} \right\rceil - \left\lceil \frac{d^{j-1}\beta - w}{1-w} \right\rceil \right\} \qquad \text{for} \quad 1 \leq m \leq n-1.$$

THEOREM 3.4. *Consider the $(b, B, \beta)$ continuous model satisfying $b + B \leq 1$. Then $\log_d(N, m, p)$ is strictly nonblocking if*

$$\begin{aligned}p \geq \Bigg\lfloor 2g_m(B) &+ \left\lceil \frac{d^{\lfloor \frac{n+m-1}{2} \rfloor}\beta - B - (\lceil \frac{d^m\beta - B}{1-B} \rceil - 1)(1-B)}{(1-B)} \right\rceil \frac{1}{d^m} \\ &+ \left\lceil \frac{d^{\lceil \frac{n+m-1}{2} \rceil}\beta - B - (\lceil \frac{d^m\beta - B}{1-B} \rceil - 1)(1-B)}{(1-B)} \right\rceil \frac{1}{d^m} \Bigg\rfloor - 1,\end{aligned}$$

*and the condition is necessary if $b = 0$.*

*Proof.* The proof is analogous to the proof of Theorem 2.2. □

THEOREM 3.5. *Consider the $(b, B, \beta)$ continuous model satisfying $b + B > 1$. Then $\log_d(N, m, p)$ is strictly nonblocking if and only if*

$$p \geq 2\left\lfloor \frac{m(d-1)\lfloor \beta/b \rfloor}{d} \right\rfloor + \left\lfloor \frac{(d^{\lfloor \frac{n+m-1}{2} \rfloor} - d^m)\lfloor \beta/b \rfloor}{d^m} \right\rfloor + \left\lfloor \frac{(d^{\lceil \frac{n+m-1}{2} \rceil} - d^m)\lfloor \beta/b \rfloor}{d^m} \right\rfloor + 1.$$

*Proof.* Each input can generate at most $\lfloor \beta/b \rfloor$ requests. Let each internal link carry at most one request. Then there are $d^j - d^{j-1}$ inputs generating $(d^j - d^{j-1})\lfloor \beta/b \rfloor$ requests to intersect a stage-$j$ link in the $(i, o)$ channel graph for $1 \leq j \leq m$. Since each such intersecting path blocks $1/d^j$ copies of $BY_d^{-1}(n, m)$, a total of

$$\left\lfloor \sum_{j=1}^{m} \frac{(d^j - d^{j-1})\lfloor \beta/b \rfloor}{d^j} \right\rfloor = \left\lfloor \frac{m(d-1)\lfloor \beta/b \rfloor}{d} \right\rfloor$$

copies is blocked. Similarly, the output side blocks the same number of copies. Finally, stage $m + 1$ to stage $n - m - 1$ consists of $d^m$ copies of $BY_d^{-1}(n - m, 0)$. We use an argument analogous to the proof of Theorem 2.2 to compute the number of copies blocked in these stages to be

$$\left\lfloor \frac{(d^{\lfloor \frac{n+m-1}{2} \rfloor} - d^m)\lfloor \beta/b \rfloor}{d^m} \right\rfloor + \left\lfloor \frac{(d^{\lceil \frac{n+m-1}{2} \rceil} - d^m)\lfloor \beta/b \rfloor}{d^m} \right\rfloor.$$

So one extra copy suffices to route the new request.

To prove the necessity, let $w = B$. Then the worst case discussed above can occur. ◻

# SRT DIVISION ALGORITHMS AS DYNAMICAL SYSTEMS[*]

MARK MCCANN[†] AND NICHOLAS PIPPENGER[†]

**Abstract.** Sweeney–Robertson–Tocher (SRT) division, as it was discovered in the late 1950s, represented an important improvement in the speed of division algorithms for computers at the time. A variant of SRT division is still commonly implemented in computers today. Although some bounds on the performance of the original SRT division method were obtained, a great many questions remained unanswered. In this paper, the original version of SRT division is described as a dynamical system. This enables us to bring modern dynamical systems theory, a relatively new development in mathematics, to bear on an older problem. In doing so, we are able to show that SRT division is ergodic, and is even Bernoulli, for all real divisors and dividends. With the Bernoulli property, we are able to use entropy to prove that the natural extensions of SRT division are isomorphic by way of the Kolmogorov–Ornstein theorem. We demonstrate how our methods and results can be applied to a much larger class of division algorithms.

**Key words.** SRT division, ergodic, Bernoulli, dynamical systems, entropy

## 1. Introduction.

Since the discovery of the first radix-2 Sweeney–Robertson–Tocher (SRT) division algorithm, the use of the term "SRT division" has expanded to include a wide variety of higher radix nonrestoring division algorithms that are loosely based on the original. For example, there is the infamous implementation of a radix-4 SRT division algorithm in the first release of the Pentium CPU that has become widely known as the "Pentium Bug." One major difference between this implementation of radix-4 SRT division and the original radix-2 SRT division is that the former produces a constant number of quotient bits per step, while the latter produces a variable number. Modern implementations of SRT division use carry-save adders to perform additions and subtractions in constant time. Earlier implementations, however, used carry-propagate adders with delays that grow with the word length. Therefore, the primary goal of the early investigators was to reduce the number of uses of the costly adder. In the late 1950s, Sweeney [3], Robertson [17], and Tocher [21] independently made the observation that whenever a partial remainder is in the range $(-\frac{1}{2}, \frac{1}{2})$, there will be one or more leading zeros that can be shifted through in a very short amount of time (usually one cycle) thereby reducing the use of the adder. Although the aforementioned have received most of the credit for the algorithm named after them, it can be argued that Nadler described an equivalent algorithm in a 1956 paper [13]. The description of higher radix SRT division, which is the basis for modern SRT division, is generally attributed to Atkins [1], but this is not the version of division that we will be concerned with in this paper.

The research of the second author was supported by an NSERC research grant and by a Canada Research Chair. It was conducted while the author was at the University of British Columbia.

Although what is considered to be "costly" for a division algorithm has changed, it is still interesting to study and important to understand the behavior of successive partial remainders on average for a given divisor. Surprisingly, some of the most basic questions that one might have concerning the behavior of partial remainders for even simple radix-2 SRT division have remained unanswered for over 40 years. The difficulty that early investigators experienced in answering such questions was mainly due to a lack of necessary mathematical tools and results. During that past 30 years, the field of "dynamical systems theory" or "ergodic theory" has come into existence in mathematics and has been greatly developed. In this paper we show how to apply some of what is now known in dynamical systems theory to the earliest version of SRT division. In doing so, we are able to prove several previously unknown properties for simple SRT division. The results are quite general and can be adapted to other division algorithms. We view the value of these results as lying in the establishment of a connection between a well-developed area of mathematics and digital division, rather than in any practical consequences for division algorithms. For the remainder of this paper, the term SRT division will refer to the original algorithm unless otherwise stated.

The SRT division algorithms analyzed by Freiman [5] and Shively [20] are the same, but the authors differ in what they take to be a step of the algorithm: Freiman defines a step to be the operations from one use of the adder to the next, while Shively defines it to be the operations from one normalizing shift (of a single place) to the next. The following definitions are consistent with Shively's:

1. $n$ represents the number of iterations performed in the algorithm.
2. $p_0$ is the dividend (or initial partial remainder) normalized so that $p_0 \in [\frac{1}{2}, 1)$.
3. $p_i \in (-1, 1)$, $i \in \mathbb{N}$, is the partial remainder after the $i$th step.
4. $D$ is the divisor normalized to $[\frac{1}{2}, 1)$.
5. $q_i \in \{-1, 0, 1\}$ $(i \in \{0, \ldots, n-1\})$ is the quotient digit generated by the $i$th step.
6. $Q_n = \sum_{i=0}^{n-1} \frac{q_i}{2^i}$ is the "rounded off" quotient generated after $n$ steps of the algorithm.

Given the above definitions, after $n$ steps of the division algorithm, we would like it to be true that

$$p_0 = DQ_n + \varepsilon(n),$$

where $\varepsilon(n)$ is a term that goes to zero as $n$ goes to infinity.

A recurrence relation for the SRT division algorithm can be stated as

$$(p_{i+1},\ q_i) = \begin{cases} (2p_i, & 0) & : & |p_i| < \frac{1}{2}, \\ (2(p_i - D), & 1) & : & |p_i| \geq \frac{1}{2} \text{ and } p_i \geq 0, \\ (2(p_i + D), & -1) & : & |p_i| \geq \frac{1}{2} \text{ and } p_i < 0. \end{cases}$$

By observing that

$$p_{i+1} = \begin{cases} 2(p_i - (0)D) & : & |p_i| < \frac{1}{2}, \\ 2(p_i - (1)D) & : & |p_i| \geq \frac{1}{2} \text{ and } p_i \geq 0, \\ 2(p_i - (-1)D) & : & |p_i| \geq \frac{1}{2} \text{ and } p_i < 0, \end{cases}$$

we can rewrite the definition of $p_{i+1}$ as

$$p_{i+1} = 2(p_i - q_i D)\,.$$

After $n$ steps have been completed, we have

$$p_n = 2^n p_0 - 2^n q_0 D - 2^{n-1} q_1 D - \cdots - 2^1 q_{n-1} D \,,$$

and then after dividing by $2^n$ and solving for $p_0$ we find that

$$\begin{aligned} p_0 &= \frac{p_n}{2^n} + \frac{q_0 D}{2^0} + \frac{q_1 D}{2^1} + \cdots + \frac{q_{n-1} D}{2^{n-1}} \\ &= D \sum_{i=0}^{n-1} \frac{q_i}{2^i} + \frac{p_n}{2^n} = D Q_n + \frac{p_n}{2^n} \,. \end{aligned}$$

Now let $\varepsilon(n) = p_n / 2^n$ and let $Q^* = \lim_{n\to\infty} Q_n$. Since $|p_n| < 1$, in the limit as $n$ goes to infinity,

$$p_0 = D Q^* \,.$$

The generated quotient bits ($-1$, 0, $+1$ valued) are not in a standard binary representation, but it is a simple matter to convert the answer back to standard binary without using any expensive operations. Table 1 shows an example of using the SRT division algorithm to divide 0.67 by 0.75. The steps that produce nonzero quotient bits have been shown. In this example, after six uses of the adder, the quotient ($0.89\overline{3}$) has been determined to four digits of precision.

Table 1
*SRT division where* $p_0 = 0.67$ *and* $D = 0.75$.

| | | | |
|---|---|---|---|
| $p_0 = 0.67$ | $= \phantom{-}0.67$ | | |
| $p_1 = 2(0.67 - D)$ | $= -0.16$ | $q_0 = 1$ | $Q_0 = 1$ |
| $p_4 = 2(2^2(-0.16) + D)$ | $= \phantom{-}0.22$ | $q_3 = -1$ | $Q_3 = 0.875$ |
| $p_7 = 2(2^2(0.22) - D)$ | $= \phantom{-}0.26$ | $q_6 = 1$ | $Q_6 = 0.890625$ |
| $p_9 = 2(2^1(0.26) - D)$ | $= -0.46$ | $q_8 = 1$ | $Q_8 = 0.89453125$ |
| $p_{11} = 2(2^1(-0.46) + D)$ | $= -0.34$ | $q_{10} = -1$ | $Q_{10} = 0.8935546875$ |
| $p_{13} = 2(2^1(-0.34) + D)$ | $= \phantom{-}0.14$ | $q_{12} = -1$ | $Q_{12} \doteq 0.8933105469$ |

Now, with this simple system of division in hand, we might want to ask certain questions about its performance. For example, we could ask, "How many bits of precision are generated per iteration of the algorithm on average?" To answer this question, we must look at the magnitude of $|Q^* - Q_n| = |p_n/2^n|$. The number of bits of precision on the $n$th step is then $n - \log_2 p_n$. In the worst case, $p_n$ is close to 1, and therefore we get at least one bit of precision per iteration of the algorithm, regardless of the values of $D$ or $p_0$. Of course, a designer of actual floating-point hardware probably wants to know the expected performance based on the expected values of $p_n$. To answer the many variants of this type of question, it is clear that we must know something about the distribution of partial remainders over time. The remainder of this paper is devoted to extending what is known about the answer to this type of question as it relates to SRT division and its variants.

**2. SRT division as a dynamical system.** The example in Table 1 makes it clear that keeping track of the signs of successive partial remainders is irrelevant in determining how many times the adder will be used for a particular calculation. For this reason, we need only consider the magnitudes of successive partial remainders. We now give a reformulation of SRT division that will allow us to look at division as a dynamical system.

DEFINITION 1 (SRT division transformation). *For $D \in [\frac{1}{2}, 1)$, we define the function $T_D : [0,1) \to [0,1)$ as*

$$T_D(x) = \begin{cases} 2x & : \quad 0 \le x < \frac{1}{2}, \\ 2(D - x) & : \quad \frac{1}{2} \le x < D, \\ 2(x - D) & : \quad D \le x < 1. \end{cases}$$

*This transformation of the unit interval represents the successive partial remainders that arise as SRT division is carried out by a divisor $D$ on a dividend $x$. $D$ is normalized to $[\frac{1}{2}, 1)$. The dividend $x$ is normalized to $[\frac{1}{2}, 1)$ initially, while each of the successive partial remainders $T_D^n(x)$ ($n \in \mathbb{N}$) subsequently ranges through $[0, 1)$.*

By using the characteristic function for a set $\Delta$ defined as

$$1_\Delta(x) = \begin{cases} 1 & : \quad x \in \Delta, \\ 0 & : \quad x \notin \Delta, \end{cases}$$

we can rewrite $T_D$ as

$$T_D(x) = 2x \cdot 1_{[0,\frac{1}{2})}(x) \, + \, 2(D - x) \cdot 1_{[\frac{1}{2},D)}(x) \, + \, 2(x - D) \cdot 1_{[D,1)}(x) \; . \tag{1}$$

If we plot (1) on the unit interval, we obtain a very useful visualization of our transformation. Figure 1 shows the plot of $T_{0.75}(x)$ combined with a plot of the successive partial remainders that arise while dividing 0.67 by 0.75. This is the same system that was presented earlier in Table 1. Notice that a vertical line in the interval $[\frac{1}{2}, D)$ corresponds to a subsequent flip in the sign of the next partial remainder.

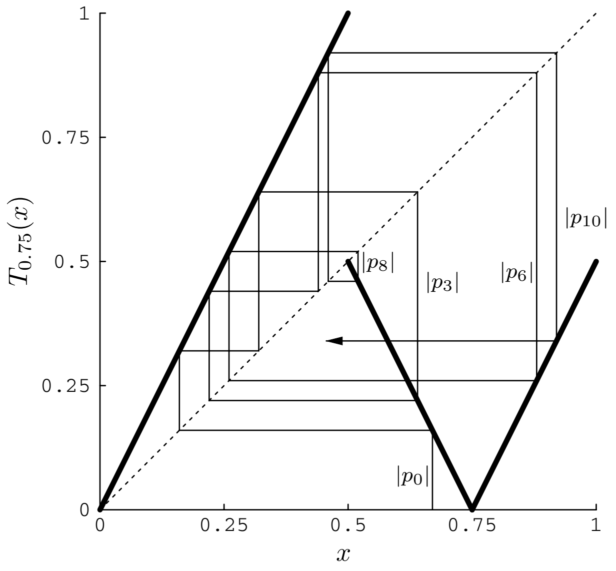

FIG. 1. *Graphic representation of partial remainder magnitudes for $D = 0.75$ and $p_0 = 0.67$.*

Figure 1 shows an example of following the trajectory of a single partial remainder for a particular divisor. In this figure, the heavy solid lines represent the transformation $T_{0.75}$, while the abscissa of the thin vertical lines represents successive partial remainder magnitudes. After 10 applications of the $T_{0.75}$, there is not any obvious regular pattern, although we expect to see one eventually since the quotient is rational in this case.[1] Of course, most numbers are not rational and we can deduce that for most numbers, the transformation will never exhibit a repeating pattern. In Figures 2 and 3, we see that a very small change in the value of the initial partial remainder quickly produces large differences in the observed behavior of the subsequent partial remainders. As we show in the appendix, our system is actually chaotic, and therefore we will gain little understanding by studying the trajectories of individual partial remainders. The logical next step is to study the behavior of distributions of points over the whole interval.

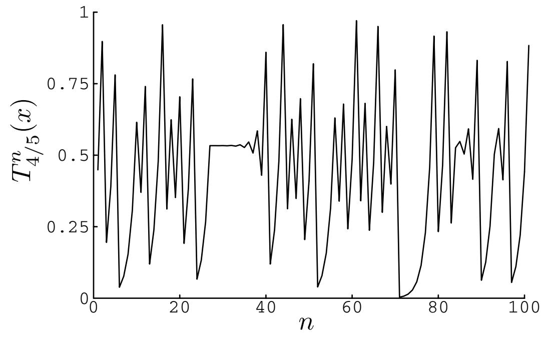

FIG. 2. *The result of applying $T_{4/5}$ to $x = \frac{\pi}{7}$ one hundred times.*

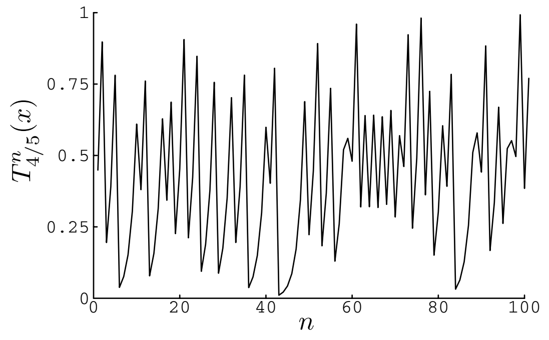

FIG. 3. *The result of applying $T_{4/5}$ to $x = \frac{\pi}{7} + 0.00001$ one hundred times.*

Understanding the behavior of ensembles of points under repeated transformation is in the realm of dynamical systems theory. For the remainder of this paper, we assume a certain amount of familiarity with the fundamentals of dynamical systems theory (or ergodic theory), which requires some basic understanding of measure theory. We will include a few helpful background material definitions as they are needed, but mostly we will provide references. A very good introduction to the study of chaotic systems is Lasota and Mackey's book [8]. For a more detailed introduction to ergodic theory (along with the necessary measure theory needed to understand this paper), Walters's book [22] and Petersen's book [16] are highly recommended.

[1]With redundant representations, rational numbers can have aperiodic representations, though we do not expect this to happen.

Definition 2 (probability space). *If $\mathcal{B}$ is a $\sigma$-algebra on subsets of a set $X$ and if $m$ is a measure on $\mathcal{B}$, where $m(X) = 1$, then the triple $(X, \mathcal{B}, m)$ is called a probability space.* (*See* [22, *pp.* 3–9] *and* [8, *pp.* 19–31] *for a good overview of basic measure theory and Lebesgue integration.*)

Definition 3 (Perron–Frobenius operator). *For a probability space $(X, \mathcal{B}, m)$,*[2] *the Perron–Frobenius operator $P : L^1 \to L^1$ associated with a nonsingular transformation $T : X \to X$ is defined by*

$$\int_B Pf(x)\,\mathrm{d}m = \int_{T^{-1}(B)} f(x)\,\mathrm{d}m \quad \textit{for } B \in \mathcal{B}\ .$$

For a piecewise monotonic $C^2$ transformation[3] $T$ with $n$ monotonic pieces, we can give an explicit formula for the Perron–Frobenius operator. Let $A = \{A_1, A_2, \dots, A_n\}$ be the partition of $X$ which separates $T$ into $n$ pieces. For $i \in \{1, \dots, n\}$, let $t_i(x)$ represent the natural extension of the $i$th $C^2$ function $T(x)|_{A_i}$. The Perron–Frobenius operator for $T$ is then

$$Pf(x) = \sum_{i=1}^{n} \left| \frac{\mathrm{d}}{\mathrm{d}x} t_i^{-1}(x) \right| f(t_i^{-1}(x)) \cdot 1_{t_i(A_i)}(x)\ .$$

In particular, for $T_D$ (as in (1)),

$$Pf(x) = \tfrac{1}{2} f(\tfrac{1}{2}x) \cdot 1_{[0,1)}(x) \;+\; \tfrac{1}{2} f(D - \tfrac{1}{2}x) \cdot 1_{(0,2D-1]}(x) \;+\; \tfrac{1}{2} f(D + \tfrac{1}{2}x) \cdot 1_{[0,2-2D)}(x). \tag{2}$$

With (2) we can show precisely what happens to an initial distribution of points (described by an integrable function) after they are repeatedly transformed under $T_D$. Figures 4 and 5 show what happens to two different initial distributions of points after five applications of the Perron–Frobenius operator associated with $T_{3/5}(x)$. By the fifth application, the distributions look remarkably similar. One might guess that they are both approaching the same final distribution. This situation is in marked contrast to chaotic behavior observed in Figures 2 and 3.

Definition 4 (stationary distribution). *Let $(X, \mathcal{B}, m)$ be a probability space, let $P$ be the Perron–Frobenius operator associated with a nonsingular transformation $T : X \to X$, and let $L^1$ denote the $L^1$ space of $(X, \mathcal{B}, m)$. If $f \in L^1$ is such that $Pf = f$ a.e.,*[4] *then $f$ is called a stationary distribution of $T$.*

A practical use of the Perron–Frobenius operator is in deriving and verifying the equations of stationary distributions for given divisors. As an example of this, we verify the correctness of a previously known stationary distribution for $D \in [\frac{3}{4}, 1)$. An exact equation was first given by Freiman [5] and is restated by Shively [20] as

$$f(x) = \frac{1}{D} 1_{[0,2D-1)}(x) + \frac{1}{2D} 1_{[2D-1,1)}(x)\,. \tag{3}$$

This relation can be verified by applying the Perron–Frobenius operator as given in (2) to (3). Such exact equations are not known in general for all $D \in [\frac{1}{2}, \frac{3}{4})$. This issue is discussed further in the conclusion.

[2]For a probability space $(X, \mathcal{B}, m)$, the $L^1$ space of $(X, \mathcal{B}, m)$ is the set of $f : X \to \mathbb{R}$ satisfying $\int_X |f(x)|\,\mathrm{d}m < \infty$.

[3]$C^2$ denotes the set of all functions with two continuous derivatives.

[4]a.e. indicates that the given relation holds *almost everywhere*, that is, everywhere except possibly on a set of measure zero.

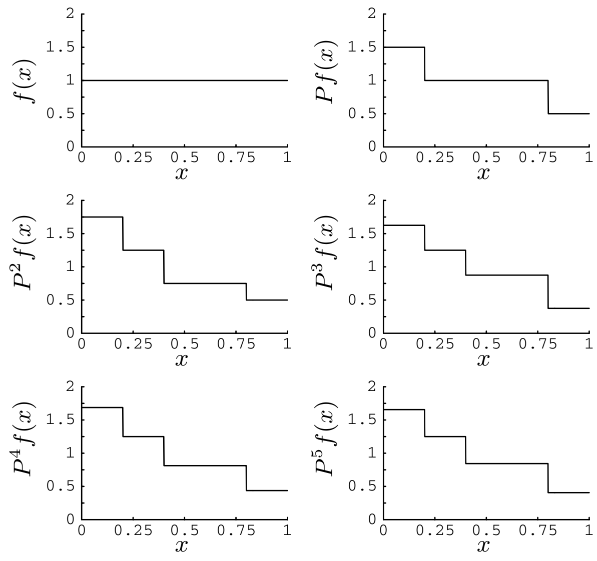

FIG. 4. *The result of applying the Perron–Frobenius operator $P$ associated with $T_{3/5}$ to $f(x) = 1$ six times.*

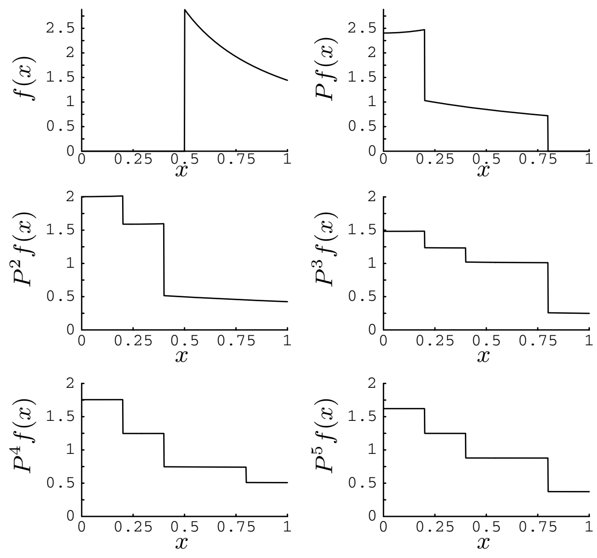

FIG. 5. *The result of applying the Perron–Frobenius operator $P$ associated with $T_{3/5}$ to $f(x) = (1/x \log_e 2) \cdot 1_{[\frac{1}{2},1)}(x)$ six times.*

In the case of variable quotient-bits-per-cycle algorithms such as the original SRT division, one of the primary uses of a formula for the distribution of partial remainders is for calculating the *shift average* for a given divisor. (Note that higher shift averages are desirable.) The shift average is the average number of uses of the shift register (single shift or multiplication by two) between uses of the adder. Under the assumption that a register shift is a much faster operation than using the adder, the shift average gives a useful characterization of the expected performance of our algorithm for a given divisor. With (3), we know the fraction of bits which require the use of the adder. To calculate the average number of zero bits generated between nonzero bits (bits requiring use of the adder), we take the reciprocal of the fraction of bits which do not require the adder. For $D \in [\frac{3}{4}, 1)$, the shift average function is

$$s(D) = \left(1 - \frac{1}{2D}\right)^{-1} = \frac{2D}{2D-1}\,. \tag{4}$$

Unfortunately, since we have not proven that the stationary distributions from SRT division are unique, we have no way of knowing whether or not a shift average calculation in (4) is correct for all initial probability distributions. To prove that all stationary distributions are unique, we need to show that $T_D$ is ergodic for all $D \in [\frac{1}{2}, 1)$.

Definition 5 (ergodic; see [8]). *Let $(X, \mathcal{B}, m)$ be a probability space and let a nonsingular transformation $T : X \to X$ be given. Then $T$ is ergodic if for every set $B \in \mathcal{B}$ such that $T^{-1}(B) = B$, either $m(B) = 0$ or $m(X \setminus B) = 0$.*

Freiman [5] shows that $T_D$ is ergodic for rational $D$, but we extend this result to real $D$. In the next section we show that all $T_D$ are Bernoulli and it is known that having the Bernoulli property implies ergodicity.

## 3. Bernoulli property.

Our central result, which we present in this section, is that the class of transformations of the interval that characterizes SRT division for all real divisors $D$ has the property that each transformation $T_D$ is Bernoulli. Although the basic concept of a Bernoulli shift (the things to which transformations having the Bernoulli property are isomorphic) is not difficult, a complete definition requires enough auxiliary concepts from measure theory (concepts not used anywhere else in this paper) that we refer the interested reader to [15, 16, 19, 22]. Neither an understanding of Bernoulli shifts nor a formal definition of what it means to be Bernoulli is required to follow the proofs in this section. Having said this, we should mention informally the connection between Bernoulli shifts and transformations having the Bernoulli property.

The transformation $T_D$ is a noninvertible endomorphism of the unit interval. This means that from a given partial remainder we can predict all future partial remainders, but we cannot uniquely predict past partial remainders. There is a natural way (called the natural extension) to make our transformation invertible (an automorphism) on a larger space. Specifically, each noninvertible transformation $T_D$ having the Bernoulli property has an extension to an automorphic transformation, isomorphic to a two-sided Bernoulli shift [16, pp. 13, 276]. From the way that entropy for a transformation is defined, the entropy for an automorphic Bernoulli transformation associated with a noninvertible Bernoulli transformation is the same as the entropy for the noninvertible Bernoulli transformation. By proving that all transformations $T_D$ are Bernoulli, and by proving that the entropy of each $T_D$ is the same, we will be able to conclude that the natural extensions of SRT division algorithms are isomorphic to each other for all divisors.

Definition 6 (expanding; see Bowen [2]). *We will say that a transformation $T$ on an interval is expanding if it has the property that $\sup_{n>0} \mu(T^n U) = 1$ for all open intervals $U$ with $\mu(U) > 0$, where $\mu$ is any normalized measure that is absolutely continuous with respect to Lebesgue measure.*

Definition 7 (straddle). *Let $U$ be an interval of reals (either open, closed, or half open) and let $p \in \mathbb{R}^+$. If $p \in U^\circ$,*[5] *then we say that $U$ straddles $p$.*

Theorem 8. *The SRT division transformation is expanding for all real divisors.*

*Proof.* Let $(X, \mathcal{B}, m)$ be a probability space, where $X = [0,1)$, $\mathcal{B}$ is the Borel $\sigma$-algebra on $X$, and $m$ is the Lebesgue measure on $\mathcal{B}$.[6] Let $T_D : X \to X$ be the SRT division transformation for a given normalized divisor $D$ as defined in (1).

Let us define an infinite sequence of intervals $\mathcal{U} = \{U_i\}_{i\in\mathbb{N}}$ as

$$U_1 = U \quad \text{and}$$
$$U_{i+1} = \begin{cases} T_D(U_i) & : \quad U_i^\circ \subseteq [0, \frac{1}{2}) \qquad \text{or } U_i^\circ \subseteq [\frac{1}{2}, 1), \\ T_D(U_i \cap [0, \frac{1}{2})) & : \quad U_i^\circ \not\subseteq [0, \frac{1}{2}) \text{ and } U_i^\circ \not\subseteq [\frac{1}{2}, 1) \text{ and} \\ & \qquad\qquad m(U_i \cap [0, \frac{1}{2})) \geq m(U_i \cap [\frac{1}{2}, 1)), \\ T_D(U_i \cap [\frac{1}{2}, 1)) & : \quad U_i^\circ \not\subseteq [0, \frac{1}{2}) \text{ and } U_i^\circ \not\subseteq [\frac{1}{2}, 1) \text{ and} \\ & \qquad\qquad m(U_i \cap [0, \frac{1}{2})) < m(U_i \cap [\frac{1}{2}, 1)). \end{cases}$$

Property 1. *For all $U_i$ such that $\frac{1}{2} \notin U_i^\circ$ and $D \notin U_i^\circ$, $m(U_{i+1}) = 2m(U_i)$.*

*Proof.* If a $U_i^\circ$ is a subset of either $[0, \frac{1}{2})$, $[\frac{1}{2}, D)$, or $[D, 1)$, then we are in the first case of the $\mathcal{U}$ definition and we apply $T_D$ directly. Since each of the three cases of the $T_D$ expands an interval by a factor of two, it is clear that $m(T_D(U_i)) = m(U_{i+1}) = 2m(U_i)$.

Property 2. *For all $U_i$ where $D \notin U_i$, $m(U_{i+1}) \geq m(U_i)$.*

*Proof.* Assume that $D \notin U_i$. If $\frac{1}{2} \notin U_i$, then according to Property 1, $U_{i+1}$ doubles. Otherwise, $\frac{1}{2} \in U_i$, and therefore, to find $U_{i+1}$, we must consider the second and third cases of the $\mathcal{U}$ sequence. In the worst case, $m(U_i \cap [0, \frac{1}{2})) = m(U_i \cap [\frac{1}{2}, D))$, and regardless of which half we choose, $m(U_i \cap [0, \frac{1}{2})) = m(U_i \cap [\frac{1}{2}, D)) = \frac{1}{2}m(U_i)$. By applying $T_D$ to this truncated interval, we double what we halved so that $m(U_i) = m(U_{i+1})$.

By way of contradiction, let us assume that there exists an initial $U$ such that the sequence $\mathcal{U}$ never expands to fill $X$. Such a sequence can never include the point $D$; if it did, there would be a small interval about $D$ that would be mapped to $[0, \varepsilon)^\circ$, and this interval would quickly expand to fill the whole interval. We can show that the following property will hold.

Property 3. *There exists $N$ such that for all $i \geq N$,*

(a) $m(U_i \cap [0, \frac{1}{2})), m(U_i \cap [\frac{1}{2}, 1)) > 0$ *(in other words, all subsequent intervals must straddle $\frac{1}{2}$), and*

(b) $m(U_i \cap [0, \frac{1}{2})) < m(U_i \cap [\frac{1}{2}, 1))$ *(in other words, all subsequent $U_i$ must be such that the right half of $U_i$ is not discarded by the definition of $\mathcal{U}$).*

*Proof of Property* 3(a). Property 1 says that the only way not to double is to straddle $\frac{1}{2}$. Therefore, at a minimum, it must be the case that $\frac{1}{2}$ is eventually included every time or else the interval will double a sufficient number of times to include $D$, which would be a contradiction.

*Proof of Property* 3(b). If $m(U_i \cap [0, \frac{1}{2})) \geq m(U_i \cap [\frac{1}{2}, 1))$, then we have $U_i = (\frac{1}{2} - \varepsilon, \frac{1}{2} + \varepsilon')$, where $\varepsilon > \varepsilon'$. Now $U_{i+1} = T_D(U_i) = T_D(\frac{1}{2} - \varepsilon, \frac{1}{2}) = (1 - 2\varepsilon, 1)$. But,

[5]The symbol $\circ$ as the exponent of an interval denotes an open version of the interval.

[6]For an interval $[a, b]$, the Lebesgue measure is defined as $m([a, b]) = b - a$.

since $D$ is not in $U_{i+1}$, $\frac{1}{2}$ cannot be in $U_{i+1}$ and Property 3(a) fails, resulting in a contradiction.

By Property 3(a), we will eventually be in a situation where $U_i = (\frac{1}{2} - \varepsilon', \frac{1}{2} + \varepsilon)$, $\varepsilon' < \varepsilon$, and Property 3(a) will hold for every subsequent interval. So then

$$U_{i+1} = T_D(\tfrac{1}{2} - \varepsilon', \tfrac{1}{2} + \varepsilon) = T_D[\tfrac{1}{2}, \tfrac{1}{2} + \varepsilon) = (2D - 1 - 2\varepsilon, 2D - 1]$$

by Property 3(b). But again by Property 3(a),

$$U_{i+2} = T_D(2D - 1 - 2\varepsilon, 2D - 1] = T_D[\tfrac{1}{2}, 2D - 1] = [2 - 2D, 2D - 1]\,.$$

It is now clear that $\frac{1}{2}$ is at the midpoint of $U_{i+2}$ and that we must now pick the left half of the interval, which contradicts Property 3(b). Therefore, $D$ will eventually be included in an interval and the sequence will expand to fill all of $X$. ∎

We can now prove that the SRT division process is weak-mixing, and therefore Bernoulli, by two theorems of Bowen [2].

THEOREM 9 (see Bowen [2]). *Let $T$ be a piecewise $C^2$ map of $[0,1]$, $\mu$ be a smooth $T$-invariant probability measure, and $\lambda = \inf_{0\le x\le 1} |f'(x)| > 1$. If the dynamical system $(T,\mu)$ is weak-mixing, then the natural extension of $(T,\mu)$ is Bernoulli.*

We mention here that the *natural extension* of $(T,\mu)$ is the associated automorphic transformation that we alluded to at the beginning of this section. See Petersen [16, p. 13] for an exact definition.

THEOREM 10 (see Bowen [2]). *With $T$ and $\mu$ as in Theorem 9, $(T,\mu)$ will be weak-mixing if $T$ is expanding.*

THEOREM 11 (see Lasota and Yorke [9]). *Let $(X, \mathcal{B}, m)$ be a probability space and let $T : X \to X$ be a piecewise $C^2$ function such that $\inf |T'| > 1$. If $P$ is the Perron–Frobenius operator associated with $T$, then for any $f \in L^1$, the sequence $(\frac{1}{n}\sum_{k=0}^{n-1} P^k f)_{n=1}^{\infty}$ is convergent in norm to a function $f^* \in L_1$. The limit function $f^*$ has the property that $Pf^* = f^*$ and, consequently, the measure $\mathrm{d}\mu^* = f^*\,\mathrm{d}m$ is invariant under $T$.*

Having established that $T_D$ is expanding, we now use the above three theorems to prove the central result of this paper.

THEOREM 12. *$T_D$ is Bernoulli.*

*Proof.* From the definition of $T_D$, we see that $T_D$ is $C^2$ and that

$$\inf_{0\le x\le 1} \left|{T_D}'(x)\right| = 2 > 1$$

since $\left|{T_D}'(x)\right| = 2$ for all $x$, for which the derivative is defined. Since

$$\inf_{0\le x\le 1} \left|{T_D}'(x)\right| > 1,$$

by Theorem 11 there exists at least one $\mu$ such that $\mu$ is a smooth $T_D$-invariant probability measure. By Theorem 8, we see that Theorem 10 holds. Hence, $(T_D,\mu)$ is weak-mixing, and by Theorem 9 $(T_D,\mu)$ is Bernoulli. ∎

That all $T_D$ are Bernoulli is a very useful property because we can use entropy as a complete invariant to show isomorphism among the two-sided Bernoulli shifts associated with $T_D$ that have the same entropy. This comes from the contribution of Ornstein to the Kolmogorov–Ornstein theorem.

THEOREM 13 (see Kolmogorov [6, 7] and Ornstein [14]). *Two Bernoulli shifts are isomorphic if and only if they have the same entropy.*

Before we calculate the entropy, we review the definition of entropy for a transformation along with some supporting definitions that follow the development presented by Walters [22, pp. 75–87].

DEFINITION 14 (partition). *A partition of $(X, \mathcal{B}, m)$ is a disjoint collection of nonempty elements of $\mathcal{B}$ whose union is $X$.*

DEFINITION 15 (join). *Let $\mathcal{P}$ and $\mathcal{Q}$ be finite partitions of $(X, \mathcal{B}, m)$. Then $\mathcal{P} \vee \mathcal{Q} = \{P \cap Q : P \in \mathcal{P} \text{ and } Q \in \mathcal{Q}\} \setminus \{\emptyset\}$ is called the join of $\mathcal{P}$ and $\mathcal{Q}$. Note that $\mathcal{P} \vee \mathcal{Q}$ is also a finite partition of $(X, \mathcal{B}, m)$.*

DEFINITION 16 (entropy of a partition). *Let $(X, \mathcal{B}, m)$ be a probability space and let $\mathcal{P} = \{P_1, \ldots, P_k\}$ be a finite partition of $(X, \mathcal{B}, m)$. The entropy of the partition is defined as*

$$H(\mathcal{P}) = -\sum_{i=1}^{k} m(P_i) \log m(P_i) \, .$$

DEFINITION 17 (entropy of a transformation with respect to a partition). *Suppose $T : X \to X$ is a measure-preserving transformation of the probability space $(X, \mathcal{B}, m)$. If $\mathcal{P}$ is a finite partition of $(X, \mathcal{B}, m)$, then*

$$h(T, \mathcal{P}) = \lim_{n \to \infty} \frac{1}{n} H\left( \bigvee_{i=0}^{n-1} T^{-i}\mathcal{P} \right)$$

*is called the entropy of $T$ with respect to partition $\mathcal{P}$.*

DEFINITION 18 (entropy of a transformation). *Let $T : X \to X$ be a measure-preserving transformation of the probability space $(X, \mathcal{B}, m)$ and suppose $h(T) = \sup h(T, \mathcal{P})$, where the supremum is taken over all finite partitions $\mathcal{P}$ of $(X, \mathcal{B}, m)$. Then $h(T)$ is called the entropy of $T$.*

In general it can be very difficult to calculate the entropy for a class of transformations directly from the definition of entropy. Even with the many standard formulas that have been derived for calculating entropy, a great number of systems found in practice are not covered. Simple SRT division is one such dynamical system for which it is not easy to calculate the entropy from results found in standard textbooks on ergodic theory. Fortunately, a result by Ledrappier does allow us to calculate the entropy for simple SRT division.

The following definitions and theorems involving C-maps and PC-maps are taken from a paper of Ledrappier [10] and have been streamlined for our argument.

DEFINITION 19 (C-map; see Ledrappier [10]). *A real function $f$ defined on an interval $[a, b]$ is said to be a* C*-map if $f$ is continuously differentiable and its derivative $f'$ has the following properties:*

(a) *$f'$ satisfies a Hölder condition*[7] *of order $\varepsilon > 0$.*

(b) *There are only a finite number of points $x \in [a, b]$ where $f'(x) = 0$. We denote them by $a \le a_1 < a_2 \cdots < a_n \le b$ with $f'(a_i) = 0$ for $0 < i \le n$.*

(c) *There exist positive numbers $k_i^-$ ($k_i^+$) such that*

$$\left| \log \frac{|f'(x)|}{|x - a|^{k_i^{-(+)}}} \right|$$

*is bounded in a left (right) neighborhood of $a_i$.*

[7]A function $f(x)$ defined on an interval $[a, b]$ satisfies a Hölder condition of order $\varepsilon \in \mathbb{R}^+$ if there exists $c \in \mathbb{R}^+$ such that for any two points $p_1, p_2 \in [a, b]$, $|f(p_1) - f(p_2)| \le c\,|p_1 - p_2|^{\varepsilon}$.

Definition 20 (PC-map; see Ledrappier [10]). *A map $f : [0,1) \to [0,1)$ is called a* PC*-map if there exists a finite partition $0 < b_1 < b_2 \cdots < b_m < 1$ such that $f$ is a* C*-map from $[b_j, b_{j+1}]$ into $[0,1)$ for any $j$.*

Theorem 21 (see Ledrappier [10]). *Let $f$ be a* PC*-map. If $\mu$ is an a.c.i.m. (absolutely continuous invariant measure), then*

$$h(f) = \int \log |f'| \, \mathrm{d}\mu. \tag{5}$$

This formula was shown by Rohlin [18] to hold for a smaller class of transformations, which does not include the $T_D$ associated with SRT division.

Theorem 22. *The entropy $h(T_D)$ of $T_D$ for $D \in [\frac{1}{2}, 1)$ is equal to $\int \log \left|T_D{}'\right| \, \mathrm{d}\mu = \log 2$.*

*Proof.* By the definition of a PC-map, $T_D$ is a PC-map if each of the three functions $T_D|_{[0,\frac{1}{2})}$, $T_D|_{[\frac{1}{2},D)}$, and $T_D|_{[D,1)}$ is a C-map.

Trivially, each $T_D$ restricted to any of the three domains $[0, \frac{1}{2})$, $[\frac{1}{2}, D)$, and $[D, 1)$ satisfies a Hölder condition of order $\varepsilon = 1$ because each piece of $T_D$ is just a line of slope two. Thus condition (a) of Definition 19 is satisfied. Conditions (b) and (c) are satisfied because there are no points for which the derivative is equal to zero within a given line segment. Thus each of the three segments of $T_D$ are C-maps and, by Definition 20, $T_D$ is a PC-map.

Now, since each $T_D$ is Bernoulli, there exists a unique a.c.i.m. (call it $\mu$) for each $T_D$. By Theorem 21, we can use (5) to calculate the entropy:

$$h(T_D) = \int \log \left|T_D{}'\right| \mathrm{d}\mu = \log 2 \int \mathrm{d}\mu = \log 2. \qquad \square$$

With the proof of Theorem 22 we have established isomorphism among the automorphic transformations (or natural extensions) associated with simple SRT division transformations by an application of the Kolmogorov–Ornstein theorem. The key to obtaining this result was being able to show that $T_D$ has Bowen's expanding property. In the following section, we extend these results to a more general type of SRT division.

## 4. Multithreshold SRT division.

A simple optimization to the original SRT division algorithm, at least with the historical concern of avoiding additions and subtractions in mind, is the inclusion of additional divisors to increase the shift average. In this section, we prove that all such division algorithms with reasonable assumptions on the separation of the divisor multiples have the expanding property. It will be useful to precisely define a class of "multithreshold" SRT transformations.

Definition 23. *Let $\boldsymbol{\alpha} \in \mathbb{R}^n$ be such that*

(a) $0 < \alpha_1 < \alpha_2 < \cdots < \alpha_n$*, and*

(b) *for all $x, D \in [\frac{1}{2}, 1)$, there exists $i \in \{1, \ldots, n\}$ such that $|\alpha_i D - x| < \frac{1}{2}$.*

*We define $\mathfrak{A}_n$ to be the set of all $\boldsymbol{\alpha} \in \mathbb{R}^n$ satisfying conditions* (a) *and* (b)*. Also, $\mathfrak{A} = \bigcup_{n \in \mathbb{N}} \mathfrak{A}_n$.*

Definition 24 (peaks and valleys). *Given an $\boldsymbol{\alpha} \in \mathfrak{A}_{n \geq 2}$, the point of intersection between two lines $f(x) = 2(x - \alpha_i D)$ and $g(x) = 2(\alpha_{i+1} D - x)$ will be called a peak and is denoted by $\boldsymbol{\psi_i} = (\frac{1}{2} D(\alpha_{i+1} + \alpha_i), D(\alpha_{i+1} - \alpha_i))$. For convenience, we will refer to the abscissa as $\psi_i^x = \frac{1}{2} D(\alpha_{i+1} + \alpha_i)$ and to the ordinate as $\psi_i^y = D(\alpha_{i+1} - \alpha_i)$. The point of intersection of the two lines $f(x) = 2(\alpha_i D - x)$ and $g(x) = 2(x - \alpha_i D)$ is $(\alpha_i D, 0)$ and will be called a valley.*

Definition 25. *For a $D \in [\frac{1}{2}, 1)$ and an $\boldsymbol{\alpha} \in \mathfrak{A}$, define the transformation $T_{D,\boldsymbol{\alpha}}(x) : [0,1) \to [0,1)$. For $\boldsymbol{\alpha} \in \mathfrak{A}_1$, we get the familiar transformation*

$$T_{D,\boldsymbol{\alpha}}(x) = \begin{cases} 2x & : \quad 0 \le x < \frac{1}{2}, \\ |2(D-x)| & : \quad \frac{1}{2} \le x < 1\,. \end{cases}$$

*For $\boldsymbol{\alpha} \in \mathfrak{A}_2$,*

$$T_{D,\boldsymbol{\alpha}}(x) = \begin{cases} 2x & : \quad 0 \le x < \frac{1}{2}, \\ |2(\alpha_1 D - x)| & : \quad \frac{1}{2} \le x < \psi_1^x, \\ |2(\alpha_2 D - x)| & : \quad \frac{1}{2} \le x \text{ and } \psi_1^x \le x < 1\,. \end{cases}$$

*For $\boldsymbol{\alpha} \in \mathfrak{A}_{n\ge 3}$,*

$$T_{D,\boldsymbol{\alpha}}(x) = \begin{cases} 2x & : \quad 0 \le x < \frac{1}{2}, \\ |2(\alpha_1 D - x)| & : \quad \frac{1}{2} \le x < \psi_1^x, \\ |2(\alpha_i D - x)| & : \quad \frac{1}{2} \le x \text{ and } \psi_i^x \le x < \psi_{i+1}^x, \\ |2(\alpha_n D - x)| & : \quad \frac{1}{2} \le x \text{ and } \psi_{n-1}^x \le x < 1\,. \end{cases}$$

Definition 26. *Define $\mathfrak{M}_n = \{T_{D,\boldsymbol{\alpha}} : D \in (\frac{1}{2}, 1], \boldsymbol{\alpha} \in \mathfrak{A}_n\}$ and define $\mathfrak{M} = \bigcup_{n\in\mathbb{N}} \mathfrak{M}_n$. We call $\mathfrak{M}_n$ the set of all $n$-threshold SRT division transformations and call $\mathfrak{M}$ the set of multithreshold SRT division transformations.*

Table 2 shows an example of dividing 0.67 by 0.75 using multithreshold SRT division with $\boldsymbol{\alpha} = (0.75, 1, 1.25)$. This is the same example calculation as in Table 1, but here the dividend has been computed to twice as many digits of precision with the same effective number of uses of the adders. We say "effective" because in multithreshold SRT division, there are several adders working in parallel. In a real implementation of multithreshold SRT division, the values for $\boldsymbol{\alpha}$ must be carefully chosen so that not too much overhead is required to select a good partial remainder. There is also a tradeoff between the amount of overhead in choosing a good partial remainder and the precision to which a good partial remainder is selected.

Table 2
*An example of multithreshold SRT division.*

| | | |
|---|---|---|
| $p_0 = 0.67 = 0.67$ | | |
| $p_1 = 2(0.67 - \alpha_2 D) = -0.16$ | $q_0 = \alpha_2$ | $Q_0 = 1$ |
| $p_4 = 2(2^2(-0.16) + \alpha_1 D) = -0.155$ | $q_3 = -\alpha_1$ | $Q_3 = 0.90625$ |
| $p_7 = 2(2^2(-0.155) + \alpha_1 D) = -0.115$ | $q_6 = -\alpha_1$ | $Q_6 = 0.89453125$ |
| $p_{11} = 2(2^3(-0.115) + \alpha_3 D) = 0.035$ | $q_{10} = -\alpha_3$ | $Q_{10} \doteq 0.8933105469$ |
| $p_{16} = 2(2^4(0.035) - \alpha_1 D) = -0.005$ | $q_{15} = \alpha_1$ | $Q_{15} \doteq 0.8933334351$ |
| $p_{24} = 2(2^7(0.005) + \alpha_1 D) = -0.155$ | $q_{23} = -\alpha_1$ | $Q_{23} \doteq 0.8933333456$ |

Condition (b) in Definition 23 guarantees that the division algorithm generates a new quotient bit at every step. Although the condition makes sense intuitively, it is not immediately obvious just by inspection if an $\boldsymbol{\alpha}$ satisfies the condition. Lemma 28 below provides an easier way to check.

Lemma 27. *If $\boldsymbol{\alpha} = (\alpha_1)$, then condition* (b) *of Definition* 23 *is satisfied if and only if $\alpha_1 = 1$.*

*Proof.* If $\alpha_1 = 1$, then $\max_{D,x\in[1/2,1)} |\alpha_1 D - x| < \frac{1}{2}$. Now consider the cases when $\alpha_1 \ne 1$ and $\varepsilon \in \mathbb{R}^+$. If $\alpha_1 = 1 + \varepsilon$, then when $D = \frac{1}{1+\varepsilon}$ and $x = \frac{1}{2}$, $|\alpha_1 D - x| =$

$1 - \frac{1}{2} = \frac{1}{2} \not< \frac{1}{2}$. On the other hand, if $\alpha_1 = 1 - \varepsilon$, then when $D = \frac{1}{2}$ and $x = 1 - \frac{\varepsilon}{2}$, $|\alpha_1 D - x| = 1 - \frac{\varepsilon}{2} - (1-\varepsilon)\frac{1}{2} = \frac{1}{2} \not< \frac{1}{2}$. ◻

Lemma 28. *An $\boldsymbol{\alpha} \in \mathfrak{A}_n$ that satisfies condition* (a) *of Definition* 23 *also satisfies condition* (b) *if and only if for some $i, j \in \{1, \ldots, n\}$ (possibly $i = j$) either*

(i) $\alpha_i \in (0, \frac{1}{2}]$ *and* $\alpha_j \in [1, 1 + \alpha_i]$, *or*

(ii) $\alpha_i \in [\frac{1}{2}, 1]$ *and* $\alpha_j \in [1, 3\alpha_i]$.

*Proof* (sketch). Lemma 27 has shown that a single component $\alpha$ of $\boldsymbol{\alpha}$ with $\alpha = 1$ is sufficient to ensure that the range of $f(x) = 2\,|\alpha D - x|$ is equal to $[0, 1)$ as $x$ and $D$ range over $[\frac{1}{2}, 1)$. It is easy to see, based on the proof of Lemma 27, that if there does not exist $i \in \{1, \ldots, n\}$ such that $\alpha_i = 1$, then there must exist $i, j \in \{1, \ldots, n\}$ $(i < j)$, where $\alpha_i < 1$ and $\alpha_j > 1$.

Let us assume that $i$ is the largest value, where $\alpha_i < 1$, and let us assume that $j$ is the smallest value, where $\alpha_j > 1$ (therefore $j = i + 1$). We make these assumptions because no other scalars of $D$ will have an influence on whether or not condition (b) is satisfied. Consider the case when $\alpha_i \in (0, \frac{1}{2}]$. In this case, when $D$ is close enough to 1, some of the line $f(x) = 2(x - \alpha_i D)$ appears in the region (denoted $R$), when $\frac{1}{2} \le x < 1$, $0 \le T_{\boldsymbol{\alpha}}(x) < 1$. When a portion of the line $f(x)$ appears in region $R$, we must put restrictions on $\alpha_j$ in terms of $\alpha_i$ so that the peak $\boldsymbol{\psi}_1$ is always in $R$. $\psi_i^y$ is greatest when $D = 1$. We find the maximum allowable value of $\alpha_j$ by setting $D = 1$ and solving $\psi_i^y = 1$ for $\alpha_j$:

$$\psi_i^y = 1 \quad \Rightarrow \quad D(\alpha_j - \alpha_i) = 1 \quad \Rightarrow \quad \alpha_j = \alpha_i + 1\,.$$

Therefore, if $\alpha_i \in (0, \frac{1}{2}]$, then $\alpha_j \in [1, 1 + \alpha_i]$.

In the case when $\alpha_i \in [\frac{1}{2}, 1]$, for large enough values of $D$, the line $f(x) = 2(x - D\alpha_i)$ crosses the line $x = 1$ in the range $[0, 1)$. Because of this, we must loosen the restriction that $\alpha_j \in [1, 1 + \alpha_j]$. It is straightforward to calculate that $f(x)$ begins to cross the line $x = 1$ in the range $[0, 1)$ when $D = \frac{1}{2\alpha_i}$. By solving $\psi_i^y = 1$ for $\alpha_j$ when $D = \frac{1}{2\alpha_i}$ we can ensure that as $D$ becomes smaller, the peak $\boldsymbol{\psi_i}$ will always be in region $R$:

$$\psi_i^y = 1 \quad \Rightarrow \quad D(\alpha_j - \alpha_i) = 1 \quad \Rightarrow \quad \frac{1}{2\alpha_i}(\alpha_j - \alpha_i) = 1 \quad \Rightarrow \quad \alpha_j = 3\alpha_i\,.$$

Therefore, if $\alpha_i \in [\frac{1}{2}, 1]$, then $\alpha_j \in [1, 3\alpha_i]$. ◻

Definition 29 (separation). *For $\boldsymbol{\alpha} \in \mathfrak{A}_n$, we define the separation in $\boldsymbol{\alpha}$ as*

$$sep(\boldsymbol{\alpha}) = \max_{i \in \{1, \ldots, n-1\}} \frac{\alpha_{i+1}}{\alpha_i}\,.$$

*Limiting the separation is a convenient way to restrict the subset of $\mathfrak{A}$ being considered. If $sep(\boldsymbol{\alpha}) = r$, we say that "the divisor multiples in $\boldsymbol{\alpha}$ are separated by at most a factor of $r$."*

We are now ready to show that all multithreshold SRT division transformations are Bernoulli, given a necessary restriction on the multiples of the divisor. As in the case for a single divisor, it will be useful to define a sequence of intervals that are subsets of the sequence of sets that would arise from repeatedly applying $T_{D,\boldsymbol{\alpha}}$ to an initial open interval. Unless otherwise noted, assume that the function $m$ denotes the Lebesgue measure.

Definition 30. *Given an initial open interval $U \subset [0, 1)$ and $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}$, we* *define the infinite sequence of intervals* $\mathcal{U} = \{U_i\}_{i\in\mathbb{N}}$ *as*

$$U_1 = U \quad \textit{and}$$

$$U_{i+1} = \begin{cases} T_{D,\boldsymbol{\alpha}}(U_i) & : \quad U_i^\circ \subseteq [0,\frac{1}{2}) \qquad\qquad \textit{or } U_i^\circ \subseteq [\frac{1}{2},1), \\ T_{D,\boldsymbol{\alpha}}(U_i \cap [0,\frac{1}{2})) & : \quad U_i^\circ \not\subseteq [0,\frac{1}{2}) \textit{ and } U_i^\circ \not\subseteq [\frac{1}{2},1) \textit{ and} \\ & \qquad\qquad m(U_i \cap [0,\frac{1}{2})) \geq m(U_i \cap [\frac{1}{2},1)), \\ T_{D,\boldsymbol{\alpha}}(U_i \cap [\frac{1}{2},1)) & : \quad U_i^\circ \not\subseteq [0,\frac{1}{2}) \textit{ and } U_i^\circ \not\subseteq [\frac{1}{2},1) \textit{ and} \\ & \qquad\qquad m(U_i \cap [0,\frac{1}{2})) < m(U_i \cap [\frac{1}{2},1)). \end{cases}$$

DEFINITION 31 (critical points). *For a given* $T_{D,\boldsymbol{\alpha}}$ *where* $\boldsymbol{\alpha} \in \mathfrak{A}_n$*, define the set*

$$C = \{c_i \,:\, i \in \{1,\dots,m\}, c_i \in B \cup \{0,\tfrac{1}{2},1\}\}$$

*where* $B = \{b \,:\, \frac{1}{2} < b < 1$ *and* $b \in \{\alpha_1 D,\dots,\alpha_n D\} \cup \{\psi_1^x,\dots,\psi_{n-1}^x\}\}$ *and* $c_1 < c_2 < \dots < 1$. $C$ *is called the set of critical points for* $T_{D,\boldsymbol{\alpha}}$.

LEMMA 32 (doubling). *Given* $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}$*, let the sequence of intervals* $\mathcal{U}$ *be defined as in Definition* 30 *and let* $U_i$ *be some interval in the sequence. Furthermore, let* $C = \{c_1,\dots,c_m\}$ *be the set of critical points for* $T_{D,\boldsymbol{\alpha}}$. *If* $U_i \subseteq [c_j, c_{j+1}]$ *for some* $j \in \{1,\dots,m-1\}$*, then* $m(U_{i+1}) = 2m(U_i)$.

*Proof.* Since $U_i \subseteq [c_j, c_{j+1}]$ for some $j \in \{1,\dots,m-1\}$, because we are in the first case of the definition of $\mathcal{U}$, either $U_i^\circ \subseteq [0,\frac{1}{2})$ or $U_i^\circ \subseteq [\frac{1}{2},1)$. By simple inspection of the individual cases that define $T_{D,\boldsymbol{\alpha}}$, it is apparent that all of $U_i$, except possibly the points $c_j$ and $c_{j+1}$, fall within the same case of $T_{D,\boldsymbol{\alpha}}$. Therefore, the resulting interval $U_{i+1}$ will be double the length of $U_i$. □

DEFINITION 33 (active valleys). *Given* $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_n$*, define*

$$V = \{\alpha_i D \,:\, i \in \{1,\dots,n\} \textit{ and } \tfrac{1}{2} < \alpha_i D < 1\}.$$

$V$ *is called the set of active valleys for* $T_{D,\boldsymbol{\alpha}}$.

DEFINITION 34 (active peaks). *Given* $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_n$*, define*

$$P = \{\psi_i^x \,:\, i \in \{1,\dots,n-1\} \textit{ and } \tfrac{1}{2} < \psi_i^x < 1\}.$$

$P$ *is called the set of active peaks for* $T_{D,\boldsymbol{\alpha}}$.

LEMMA 35 (nonshrinking). *Given* $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_n$ *with* $sep(\boldsymbol{\alpha}) \leq \frac{5}{3}$*, let the sequence of intervals* $\{U_i\}_{i\in\mathbb{N}}$ *be defined as above and let* $V$ *denote the set of active valleys for* $T_{D,\boldsymbol{\alpha}}$. *For any interval* $U_i \in \mathcal{U}$ *such that* $V \cap U_i = \varnothing$*, either* $m(U_{i+1}) \geq m(U_i)$ *or* $m(U_{i+2}) \geq m(U_i)$.

*Proof.* $sep(\boldsymbol{\alpha}) \leq \frac{5}{3}$ implies that $\alpha_{i+1} \leq \frac{5}{3}\alpha_i$. For a given separation, the value of $\psi_i^y$ is maximized when $\psi_i^x = 1$. This implies that $\alpha_i = \frac{3}{4D}$. We calculate the value of $\psi_i^y$ with the assumption that $\psi_i^x = 1$ to get a bound on $\psi_i^y$ for $D < 1$:

$$\psi_i^y \leq D(\tfrac{5}{3}\alpha_i - \alpha_i) = D(\tfrac{2}{3}\alpha_i) = D(\tfrac{2}{3}\tfrac{3}{4D}) = \tfrac{1}{2}.$$

*Case* 1. Consider when $U_i \subseteq [0,\frac{1}{2}]$. In this case, $m(U_{i+1}) = 2m(U_i)$.

*Case* 2. Consider when $U_i \subseteq [\frac{1}{2},1)$. The interval $U_i$ can span at most one peak. Therefore, $m(U_{i+1}) \geq m(U_i)$. A further observation is that since $U_{i+1} \subseteq [0,\frac{1}{2}]$, $m(U_{i+2}) = 2m(U_i)$.

*Case* 3. Consider when $U_i \not\subseteq [0, \frac{1}{2}]$ and $U_i \not\subseteq [\frac{1}{2}, 1)$. In this case, $U_i$ straddles $\frac{1}{2}$. From the definition of $\mathcal{U}$, we see that in the worst case we might throw away up to half of $U_i$. Call the part not thrown away $U_i{}'$ and observe that $m(U_i{}') \geq \frac{1}{2}m(U_i)$. Now, either $U_i{}' \subseteq [0, \frac{1}{2}]$ or $U_i{}' \subseteq [\frac{1}{2}, 1)$. If $U_i{}' \subseteq [0, \frac{1}{2}]$, then $m(U_{i+1}) = 2m(U_i{}') \geq m(U_i)$. If $U_i{}' \subseteq [\frac{1}{2}, 1)$, then $m(U_{i+2}) = 2m(U_i{}') \geq m(U_i)$. $\square$

LEMMA 36. *A multithreshold SRT division transformation $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}$ is expanding when sep$(\boldsymbol{\alpha}) \leq \frac{5}{3}$.*

*Proof.* Let $V$ be the set of active valleys (as defined in Definition 33) for a $T_{D,\boldsymbol{\alpha}}$. Let $P$ be the set of active peaks (as defined in Definition 34) for a $T_{D,\boldsymbol{\alpha}}$. Let $\mathcal{U} = \{U_i\}_{i \in \mathbb{N}}$ be the sequence of intervals associated with a $T_{D,\boldsymbol{\alpha}}$ and an initial interval $U$.

By way of contradiction, assume that a $T_{D,\boldsymbol{\alpha}}$ is not expanding. This means that for some $T_{D,\boldsymbol{\alpha}}$, there does not exist an interval $U_i$ where any of the points in $V$ are contained in $U_i$. This is true because if any of the valley points are in $U_i$, then $U_{i+1} = [0, \varepsilon)$ or $U_{i+1} = [0, \varepsilon]$, and after a finite number of steps, $U_i$ will have grown to include all of $[0, 1)$.

If there is a sequence $\mathcal{U}$ that avoids all points in $V$, then by Lemma 35 it must be true that the intervals in the sequence can double only a finite number of times. Let $i \in \mathbb{N}$ be the first index for which there is no $j > i$ such that $m(U_j) \geq 2m(U_i)$. It now follows that $U_i$ straddles $\frac{1}{2}$. The proof for Lemma 35 reveals that this is the only situation where it is not necessarily the case that either $m(U_{i+1}) = 2m(U_i)$ or $m(U_{i+2}) = 2m(U_i)$. In fact, $U_i$ must straddle both $\frac{1}{2}$ and $\min P$. If $\min P$ is not straddled and $m(U_i \cap [0, \frac{1}{2})) < m(U_i \cap [\frac{1}{2}, 1))$, then either $m(U_{i+2}) \geq 2m(U_i)$ or $m(U_{i+3}) \geq 2m(U_i)$. In the other possibility, where $\min P$ is not straddled and $m(U_i \cap [0, \frac{1}{2})) \geq m(U_i \cap [\frac{1}{2}, 1))$, we find that $m(U_{i+2}) \geq 2m(U_i)$.

Assuming that $U_i$ straddles both $\frac{1}{2}$ and $\min P$, we also observe that there can be no $j > i$ such that $m(U_j \cap [0, \frac{1}{2})) \geq m(U_j \cap [\frac{1}{2}, 1))$ because this quickly leads to doubling. In other words, the right side must be larger than the left side whenever we straddle $\frac{1}{2}$. Therefore, we must be in the situation where

$$\begin{aligned}
& U_i = (\tfrac{1}{2} - \varepsilon', \tfrac{1}{2} + \varepsilon),\ \varepsilon' < \varepsilon \\
\Rightarrow\quad & U_{i+1} = (\min\{2(\tfrac{1}{2} - \alpha_i D), 2(\alpha_{i+1} D - (\tfrac{1}{2} + \varepsilon))\}, \psi_i^y) \\
\Rightarrow\quad & U_{i+2} = (2\min\{2(\tfrac{1}{2} - \alpha_i D), 2(\alpha_{i+1} D - (\tfrac{1}{2} + \varepsilon))\}, 2\psi_i^y) \\
\Rightarrow\quad & U_{i+3} = (\min\{2(\tfrac{1}{2} - \alpha_i D), 2(\alpha_{i+1} D - 2\psi_i^y)\}, \psi_i^y) \\
\Rightarrow\quad & U_{i+4} = (2\min\{2(\tfrac{1}{2} - \alpha_i D), 2(\alpha_{i+1} D - 2\psi_i^y)\}, 2\psi_i^y) \\
\Rightarrow\quad & U_{i+5} = (\min\{2(\tfrac{1}{2} - \alpha_i D), 2(\alpha_{i+1} D - 2\psi_i^y)\}, \psi_i^y) = U_{i+3}\,.
\end{aligned}$$

It is apparent that the interval represented by $U_{i+4}$ will re-occur every other interval ad infinitum. We now use this interval to show that in fact such a sequence of nonexpanding intervals is not possible.

Since $U_{i+4}$ straddles $\frac{1}{2}$, we can compare the length of the left and right sides of $U_{i+4}$. Let $R = [\frac{1}{2}, 2\psi_i^y)$ denote the right side and let $L = (4(\frac{1}{2} - \alpha_i D), \frac{1}{2})$ and $L' = (4(\alpha_{i+1} D - 2\psi_i^y), \frac{1}{2})$ denote the two possibilities for the left side. The length of the right side is

$$m(R) = 2\psi_i^y - \tfrac{1}{2},$$

while the length of the left side is the larger of two possible lengths

$$m(L) = \tfrac{1}{2} - 4(\tfrac{1}{2} - \alpha_i D)$$

and

$$m(L') = \tfrac{1}{2} - 4(\alpha_{i+1}D - 2\psi_i^y) \ .$$

We then compare the differences between the right side and each of the two possible left sides. The first possibility is

$$\begin{aligned} m(R) - m(L) &= 2\psi_i^y - \tfrac{1}{2} - (\tfrac{1}{2} - 4(\tfrac{1}{2} - \alpha_i D)) \\ &= 2D(\alpha_{i+1} - \alpha_i) - 1 + 2 - 4\alpha_i D \\ &= 2\alpha_{i+1}D - 6\alpha_i D + 1 \ , \end{aligned}$$

while the second possibility is

$$\begin{aligned} m(R) - m(L') &= 2\psi_i^y - \tfrac{1}{2} - (\tfrac{1}{2} - 4(\alpha_{i+1} - 2\psi_i^y)) \\ &= 2D(\alpha_{i+1} - \alpha_i) - 1 + 4(\alpha_{i+1}D - 2D(\alpha_{i+1} - \alpha_i)) \\ &= -2\alpha_{i+1}D + 6\alpha_i D - 1 \, . \end{aligned}$$

It is now clear that

$$m(R) - m(L) = -\left(m(R) - m(L')\right) \ .$$

But this means that the length of the left side is always greater than or equal to the length of the right side, which contradicts our assumption that the right side must be bigger than the left side whenever the interval straddles $\frac{1}{2}$. □

THEOREM 37. *$T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}$ is Bernoulli when sep$(\boldsymbol{\alpha}) \leq \frac{5}{3}$.*

*Proof.* Let $T = T_{D,\boldsymbol{\alpha}}$. From the definition of $T$, we see that $T_{D,\boldsymbol{\alpha}}$ is $C^2$ and that $\inf_{0 \leq x \leq 1} |T'(x)| = 2 > 1$ since $|T'(x)| = 2$ for all $x$ for which the derivative is defined. Since $\inf_{0 \leq x \leq 1} |T'(x)| > 1$, by Theorem 11, there exists at least one $\mu$ such that $\mu$ is a smooth $T$-invariant probability measure. By Lemma 36 we see that Theorem 10 holds when *sep*$(\boldsymbol{\alpha}) \leq \frac{5}{3}$. Hence, $(T, \mu)$ is weak-mixing and, by Theorem 9, $(T, \mu)$ is Bernoulli when *sep*$(\boldsymbol{\alpha}) \leq \frac{5}{3}$. □

The calculation for entropy in multithreshold SRT division follows the same method used for single divisor SRT division. We begin by showing that $T_{D,\boldsymbol{\alpha}}$ is a PC-map.

LEMMA 38. *$T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}$ is a PC-map (as defined in Definition* 20*).*

*Proof.* By inspection, each $T_{D,\boldsymbol{\alpha}}$ is a finite collection of line segments, each with slope 2. Each of these line segments is a C-map by the same argument used in the proof for Theorem 22. Therefore, by definition, each $T_{D,\boldsymbol{\alpha}}$ is a PC-map. □

THEOREM 39. *The entropy of any $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}$ with sep$(\boldsymbol{\alpha}) \leq \frac{5}{3}$ is* $\log 2$.

*Proof.* By Lemma 38, all $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}$ are PC-maps. By Theorem 37, $T_{D,\boldsymbol{\alpha}}$ is Bernoulli when *sep*$(\boldsymbol{\alpha}) \leq \frac{5}{3}$, and hence there exists a unique a.c.i.m. $\mu$. Theorem 21 says that Rohlin's formula for the entropy is true, and therefore

$$h(T_{D,\boldsymbol{\alpha}}) = \int \log \left|T_{D,\boldsymbol{\alpha}}{}'\right| \mathrm{d}\mu = \log 2 \int \mathrm{d}\mu = \log 2. \qquad \square$$

**5. Some restrictions on $\boldsymbol{\alpha}$ for multithreshold division.** In section 4, we showed that for all $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}$, if *sep*$(\alpha) \leq \frac{5}{3}$, then $T_{D,\boldsymbol{\alpha}}$ is Bernoulli. In this section, we construct examples of $T \in \mathfrak{M}_n$, for every $n$, that fail to be Bernoulli when the restriction that *sep*$(\boldsymbol{\alpha}) \leq \frac{5}{3}$ is relaxed.

THEOREM 40. *For $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_{n \geq 4}$, if sep$(\boldsymbol{\alpha}) > \frac{5}{3}$, then for each $D \in [\frac{1}{2}, 1)$, there exist uncountably many $\boldsymbol{\alpha}$ for which $T_{D,\boldsymbol{\alpha}}$ is not ergodic.*

*Proof.* We begin this proof by considering $T \in \mathfrak{M}_{n=4}$.

Assume that we relax the restrictions on $\boldsymbol{\alpha}$ by $\varepsilon > 0$. This means that $sep(\boldsymbol{\alpha}) \leq \frac{5}{3} + \varepsilon$ and that no peak can be above the line $f(x) = \frac{4+6\varepsilon x}{8+3\varepsilon}$. With this relaxation, we can define $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \alpha_3, \alpha_4)$ with respect to a given $D$ so that a subset of $[0, 1)$ is nonexpanding. We let $\alpha_1 = \frac{30+27\varepsilon}{80D+48D\varepsilon}$, $\alpha_2 = \frac{50+57\varepsilon}{80D+48D\varepsilon}$, $\alpha_3 = \frac{30-9\varepsilon}{40D+24D\varepsilon}$, and $\alpha_4 = \frac{50+21\varepsilon}{40D+24D\varepsilon}$. For our constructed $\boldsymbol{\alpha}$ to be valid, we must be careful that conditions (a) and (b) of Definition 23 hold. Condition (a) requires that the components of $\boldsymbol{\alpha}$ remain in ascending order. This is satisfied when $\varepsilon \in (0, \frac{2}{15}]$. Since ordering is maintained, $sep(\boldsymbol{\alpha}) < 3$, and $\min_{D\in[1/2,1),\, \varepsilon\in(0,2/15]} \alpha_4 = 1.\overline{2} \geq 1$, to verify that condition (b) of Definition 23 holds, it is sufficient to show (by Lemma 28) that for all values of $D$ and $\varepsilon$, either $\alpha_1$, $\alpha_2$, or $\alpha_3 \in [\frac{1}{2}, 1]$. By maximizing and minimizing over $\varepsilon$ and $D$, we find that $\alpha_1 \in [0.375, 0.\overline{7}]$ and $\alpha_2 \in [0.625, 1.\overline{3}]$. Figure 6 provides a visual proof that as $\varepsilon$ is varied over $[0, \frac{2}{15}]$ and $D$ is varied over $[\frac{1}{2}, 1]$, it is never the case that both $\alpha_1 \leq \frac{1}{2}$ and $\alpha_2 \geq 1$. Therefore, it is always the case that either $\alpha_1$ or $\alpha_2 \in [\frac{1}{2}, 1]$.

Having verified that our defined $\boldsymbol{\alpha}$ satisfies Definition 23, we calculate that peak $\boldsymbol{\psi}_1 = (\frac{20+21\varepsilon}{40+24\varepsilon}, \frac{10+15\varepsilon}{40+24\varepsilon})$ and peak $\boldsymbol{\psi}_3 = (\frac{20+3\varepsilon}{20+12\varepsilon}, \frac{10+15\varepsilon}{20+12\varepsilon})$. With this definition for $\boldsymbol{\alpha}$, and our assumption that $\varepsilon \in [0, \frac{2}{15})$, the point $\boldsymbol{\psi}_3$ will always touch the line $f(x)$ while remaining above the line $g(x) = \frac{1}{2}$, and the point $\boldsymbol{\psi}_1$ will always be slightly below $f(x)$ while remaining above the line $g(x) = \frac{1}{4}$. All of the definitions have been chosen so that $1 - \psi_3^x = \psi_3^y - \frac{1}{2} = 2(\psi_1^x - \frac{1}{2}) = 2(\psi_1^y - \frac{1}{4})$. Another important feature in this construction is the interval between $\alpha_2 D$ and $\alpha_3 D$. Since $\boldsymbol{\psi}_2$ is not used in our construction, it is possible to insert an arbitrary number of divisor multiples between $\alpha_2 D$ and $\alpha_3 D$. Thus, the results in this proof apply to $T \in \mathfrak{M}_n$ for arbitrarily large $n$.

We are now in a position to show that there exists a set of points $A$ with $0 < m(A) < 1$, for which $T_{D,\boldsymbol{\alpha}}(A) = A$. This is the definition of a transformation being nonergodic [8, p. 59]. Define $A = A_1 \cup A_2 \cup A_3$, where $A_1 = [\frac{1}{4} - (\psi_1^x - \frac{1}{2}), \frac{1}{4} + (\psi_1^x - \frac{1}{2})]$, $A_2 = [\frac{1}{2} - 2(\psi_1^x - \frac{1}{2}), \frac{1}{2} + 2(\psi_1^x - \frac{1}{2})]$, and $A_3 = [1 - 2(1 - \psi_3^x), 1]$. It can be shown by calculation that $T_{D,\boldsymbol{\alpha}}(A_1) = A_2$, $T_{D,\boldsymbol{\alpha}}(A_2) = A_1 \cup A_3$, and $T_{D,\boldsymbol{\alpha}}(A_3) = A_2$. Therefore, $T_{D,\boldsymbol{\alpha}}(A) = A$, and by definition, $T_{D,\boldsymbol{\alpha}}$ is nonergodic or nonexpanding. ∎

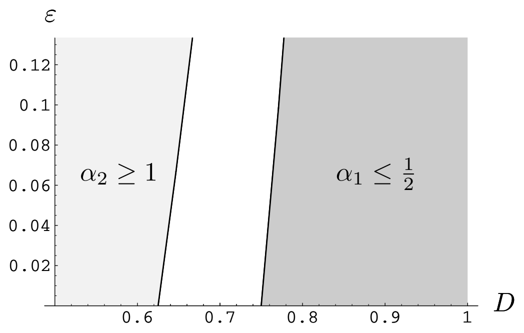

FIG. 6. *Combined plot of the regions where* $\alpha_1 \leq \frac{1}{2}$ *and* $\alpha_2 \geq 1$.

Figure 7 illustrates the type of transformation that we have constructed in the proof of Theorem 40. In this figure, $n = 4$, $D = \frac{11}{16}$, $\boldsymbol{\alpha} = (\frac{37}{66}, \frac{21}{22}, 1, \frac{59}{33})$, and $sep(\boldsymbol{\alpha}) = \frac{5}{3} + \frac{5}{51}$. The thick lines represent $T_{D,\boldsymbol{\alpha}}$. The coarse dashed line represents the necessary separation restriction on $\boldsymbol{\alpha}$ to guarantee that $T_{D,\boldsymbol{\alpha}}$ is ergodic. In this case, partial remainders in the set $A = [\frac{11}{48}, \frac{13}{48}] \cup [\frac{22}{48}, \frac{26}{48}] \cup [\frac{44}{48}, 1)$ are mapped back to $A$ by $T_{D,\boldsymbol{\alpha}}$.

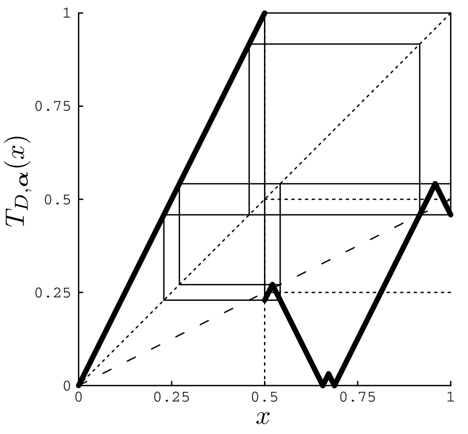

FIG. 7. *An example of a nonergodic system for $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_{n\geq 4}$.*

THEOREM 41. *For $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_3$, if $sep(\boldsymbol{\alpha}) \geq \frac{9}{5}$, then for each $D \in [\frac{1}{2}, 1)$, there exists an $\boldsymbol{\alpha}$ for which $T_{D,\boldsymbol{\alpha}}$ is not ergodic.*

*Proof.* The proof for this theorem comes as a special case from the proof for Theorem 40. Consider $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \alpha_3, \alpha_4)$ as defined in the proof for Theorem 40. When $sep(\boldsymbol{\alpha}) = \frac{9}{5} = \frac{5}{3} + \frac{2}{15}$, we are in the special situation where $\alpha_2 = \alpha_3$. Since all of the results for the proof of Theorem 40 still hold, we now have an example transformation $T$ with only three unique multiples of $D$, and this $T$ has been proven to be nonergodic. $\square$

Figure 8 gives an example of a nonergodic transformation for $D = \frac{7}{12}$ and $\boldsymbol{\alpha} = (\frac{2}{3}, \frac{8}{7}, \frac{44}{21})$. In this case, partial remainders in the set $A = [\frac{4}{18}, \frac{5}{18}] \cup [\frac{8}{18}, \frac{10}{18}] \cup [\frac{16}{18}, 1)$ are mapped back to $A$ by $T_{D,\boldsymbol{\alpha}}$.

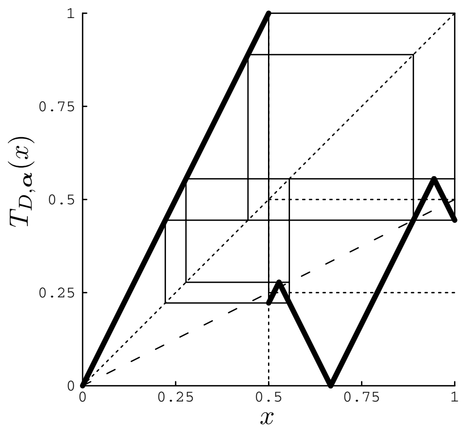

FIG. 8. *An example of a nonergodic system for $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_3$.*

THEOREM 42. *For $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_2$, if $sep(\boldsymbol{\alpha}) > 3$, then for some $D \in (\frac{1}{2}, 1)$, there exist uncountably many $\boldsymbol{\alpha}$ for which $T_{D,\boldsymbol{\alpha}}$ is not ergodic.*

*Proof.* Assume that $sep(\boldsymbol{\alpha}) \leq 3 + \varepsilon$ and $D \in (\frac{1}{2}, \frac{2+\varepsilon}{4})$. First, we choose $\alpha_1 = \frac{1}{4D}$ so that $\alpha_1 D = \frac{1}{4}$ and $\alpha_2 = 1 + \alpha_1$. Our restriction on $D$ in terms of $\varepsilon$ has been chosen so that $\alpha_2/\alpha_1 < 3 + \varepsilon$ when $\alpha_2 = 1 + \alpha_1$. Since $\alpha_2 > \alpha_1$, condition (a) of Definition

23 is satisfied. Since $\alpha_1 \in (\frac{1}{4}, \frac{1}{2})$ and $\alpha_2 \in (1, 1 + \alpha_1]$ by Lemma 28, condition (b) of Definition 23 is satisfied. Thus, our defined $\boldsymbol{\alpha}$ is always valid. Define $A = [\frac{1}{2}, D]$. We now apply $T = T_{D,\boldsymbol{\alpha}}$ to $A$:

$$\begin{aligned} T[\tfrac{1}{2}, D] &= [\min\{2(\tfrac{1}{2} - \alpha_1 D), 2(\alpha_2 D - D)\}, \psi_1^y] \\ &= [\min\{2(\tfrac{1}{2} - \tfrac{D}{4D}), 2(D + \tfrac{1}{4} - D)\}, D(\alpha_2 - \alpha_1)] \\ &= [\min\{\tfrac{1}{2}, \tfrac{1}{2}\}, D(1 + \tfrac{1}{4D} - \tfrac{1}{4D})] \\ &= [\tfrac{1}{2}, D]\,. \end{aligned}$$

Now, since $\frac{1}{2} < D < 1$, $0 < m(A) < 1$, and $T_{D,\boldsymbol{\alpha}}A = A$, by definition $T_{D,\boldsymbol{\alpha}}$ is not ergodic. ◻

Figure 9 shows an example of a nonergodic system for $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_2$. In this example, $D = \frac{3}{5}$ and $\boldsymbol{\alpha} = (\frac{5}{12}, \frac{17}{12})$. Partial remainders within the interval $[\frac{1}{2}, \frac{3}{5}]$ map back to $[\frac{1}{2}, \frac{3}{5}]$.

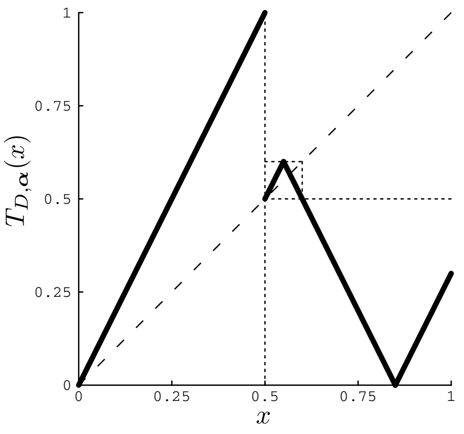

FIG. 9. *An example of a nonergodic system for* $T_{D,\boldsymbol{\alpha}} \in \mathfrak{M}_2$.

**6. Conclusions.** The original question that inspired this paper was, "Is simple SRT division ergodic for all real divisors?" In pursuing the solution to this problem, we discovered that not only is simple SRT division ergodic for all divisors, but it is also Bernoulli. Having established a Bernoulli property, and having calculated the entropy for our transformations, we were able to use the Kolmogorov–Ornstein theorem to conclude that our transformations are equivalent to each other in the sense that their natural extensions are isomorphic. In proving these important properties for simple SRT division, we made extensive use of more general results from dynamical systems theory. Consequently, our results were shown to be easily extensible to more general division systems. In general, it is difficult to prove that a particular class of transformations is ergodic or Bernoulli. Our results have provided an effective means of proving both of these properties for a large class of SRT-like division algorithms.

From the standpoint of understanding an algorithm's expected performance, it is necessary to know that when a stationary distribution is found, it is unique. Having established the uniqueness of stationary distributions, the next step is to find the actual stationary distribution for as wide a class of transformations as possible. In section 2, we gave the stationary distribution function for $T_D$, where $D \in [\frac{3}{4}, 1)$. Many of the stationary distribution functions have been classified by Shively and Freiman for $D \in [\frac{3}{5}, \frac{3}{4}]$, although the derivations are not nearly as simple as for $D \in [\frac{3}{4}, 1)$. It turns out that things become very complicated when $D \in [\frac{1}{2}, \frac{3}{5}]$. In his thesis [20], Shively shows many interesting properties for the stationary distribution functions in this region. For example, he shows that there are many different intervals of $D$, where there are an infinite number of different stationary distribution equations. As such, the graph of the shift average for $D \in [\frac{1}{2}, \frac{3}{5}]$ is far from complete and appears to have a complex pattern (from the few points that have been plotted in this region). This is surprising, considering the simplicity of the underlying transformation. A better understanding of this final region of simple SRT division would be an interesting goal to pursue.

In the work of Freiman [5], it was first shown that the shift average for $D \in [\frac{3}{5}, \frac{3}{4}]$ is constantly 3, which can be easily shown to be the maximum possible shift average. This property was then used by Metze [12] to obtain a version of SRT division that has an expected shift average of 3 for all divisors. Another area to pursue would be to explore shift averages for multithreshold SRT division and, if other plateaus are found, they could possibly be used to obtain higher expected shift averages for all possible divisors. Undoubtedly, obtaining a complete understanding of the stationary distribution functions for multithreshold division would be even more difficult than it is for simple SRT division. It is possible that such results in this area could lead to improvements in modern SRT division. Related to this, it would be interesting to attempt to extend the results of this paper to modern SRT division.

**Appendix. SRT division is chaotic.** In section 2 we mentioned that SRT division is chaotic, and we prove this fact here for SRT division with the expansion property (see Definition 6). Simple SRT division was shown to be expanding for all divisors (see Theorem 8). Multithreshold SRT division, of which simple SRT division is a special case, was shown to be expanding when there is a restriction on the separation of the divisor multiples (see Lemma 36).

Although there are several definitions for what it means to be "chaotic," the one given by Devaney [4] is commonly used. The following definitions are taken from [4, pp. 49, 50].

DEFINITION 43 (sensitivity). *A transformation $f : X \to X$ has sensitive dependence on initial conditions if there exists $\delta > 0$ such that, for any $x \in X$ and any neighborhood $N$ about $x$, there exists $y \in X$ and $n \geq 0$ such that $|f^n(x) - f^n(y) > \delta|$.*

DEFINITION 44 (topological transitivity). *A transformation $f : X \to X$ is topologically transitive on $X$ if, for any pair of open sets $U$, $V \subset X$, there exists $n$ such that $f^n(U) \cap V \neq \emptyset$.*

DEFINITION 45 (chaotic). *Let $f : X \to X$ be a transformation of the set $X$. $f$ is said to be chaotic on $X$ if*

(a) *$f$ has sensitive dependence on initial conditions;*

(b) *$f$ is topologically transitive;*

(c) *periodic points are dense in $X$.*

THEOREM 46. *Every multithreshold SRT division transformation with the expansion property is chaotic.*

*Proof.* Let $T$ be a multithreshold SRT division transformation on $[0, 1)$ having the expansion property.

To prove sensitivity to initial conditions, we notice, by the expansion property, that for any open neighborhood $N$ about a point $x$, the successive images of $N$ under $T$ expand to be arbitrarily close to filling the entire interval densely after a finite number $n$ of steps. In particular, since $f^n(x)$ must be at least distance $\frac{1}{2}$ away from either 0 or 1, for any $\frac{1}{2} > \delta > 0$, there is $y \in N$ such $|f^n(x) - f^n(y)| > \delta$. Therefore, $T$ is sensitive to initial conditions on $[0, 1)$.

Again, by the expansion property of $T$, the successive images of any two open intervals will intersect within a finite number of steps. Therefore, $T$ is topologically transitive on $[0, 1)$.

The expansion property alone is not sufficient to ensure that periodic points are dense. However, the existence of a particular sequence $\mathcal{U}$ of nonempty subintervals as given in Definition 30 is sufficient, in general, for dense periodic points.

Let $V_1$ be an open interval on part of the domain where $T$ is continuous. In the proof of Lemma 36, we showed that sequence $\{T^i(V_1)\}_{i=1}^{\infty}$ necessarily expands after a finite number of steps to fill the unit interval by proving that another sequence $\mathcal{U} = \{U_i\}$ of intervals expands to fill the unit interval where $U_i \subseteq V_i$ for $i \geq 0$. For a given $U_i$, $U_{i+1}$ is chosen to be the largest subinterval of $T(U_i)$ on a continuous part of $T$'s domain. In the event of equal-length subintervals, we choose the left half to be $U_i$'s successor. $\mathcal{U}$ induces another (possibly not unique) sequence of intervals $\{I_i\}$, where $I_i$ is any subinterval of $U_i$, where $T(I_i) = U_{i+1}$. In any situation where part of $T(U_i)$ is discarded, there exists at least one interval $I_i \subset U_i$, where $T(I_i) = U_{i+1}$ because $U_i$ is chosen such that $T$ is continuous on $U_i$. Note that $T|_{I_i} : I_i \to U_{i+1}$ is a continuous onto map. Eventually, by the expansion property, it must be true that $U_n \supseteq U_1 = V_1$ for some $n$. We now have a sequence of continuous onto maps $T|_{U_1} : I_1 \to U_2$, $T|_{U_2} : I_2 \to U_3$, $\ldots$, $T|_{U_{n-1}} : I_{n-1} \to U_n$ and it follows that there is a nonempty interval $U' \subseteq U_1$ such that $T^{n-1}(U') = T|_{U_{n-1}} \circ T|_{U_{n-2}} \circ \cdots \circ T|_{U_1} (U') = U_n$. Since $T^{n-1}|_{U'}$ is continuous, there exists $x \in V_1$ such that $T^{n-1}(x) = x$. $\square$

# POLYNOMIAL-TIME APPROXIMATION SCHEMES FOR GEOMETRIC INTERSECTION GRAPHS[*]

THOMAS ERLEBACH[†], KLAUS JANSEN[‡], AND EIKE SEIDEL[‡]

**Abstract.** A disk graph is the intersection graph of a set of disks with arbitrary diameters in the plane. For the case that the disk representation is given, we present polynomial-time approximation schemes (PTASs) for the maximum weight independent set problem (selecting disjoint disks of maximum total weight) and for the minimum weight vertex cover problem in disk graphs. These are the first known PTASs for $\mathcal{NP}$-hard optimization problems on disk graphs. They are based on a novel recursive subdivision of the plane that allows applying a shifting strategy on different levels simultaneously, so that a dynamic programming approach becomes feasible. The PTASs for disk graphs represent a common generalization of previous results for planar graphs and unit disk graphs. They can be extended to intersection graphs of other "disk-like" geometric objects (such as squares or regular polygons), also in higher dimensions.

**Key words.** independent set, vertex cover, shifting strategy, disk graph

**AMS subject classifications.** 68Q25, 68R10

**DOI.** 10.1137/S0097539702402676

## 1. Introduction.

Intersection graphs are graphs whose vertices are represented by sets such that two vertices are adjacent if and only if the corresponding sets have a nonempty intersection. They have been studied by many authors [12, 6, 24]. We are interested in approximation algorithms for $\mathcal{NP}$-hard optimization problems on intersection graphs of geometric objects, in particular approximation algorithms for independent set and vertex cover. Two prominent applications of geometric intersection graphs are frequency assignment in cellular networks [13, 22] and map labeling [1].

The goal of the *maximum weight independent set* problem (MWIS) is to compute, for a given set of geometric objects with certain weights, a subset of disjoint (nonoverlapping) objects with maximum total weight. The goal of the *minimum weight vertex cover* problem (MWVC) is to compute a subset of the given objects with minimum total weight such that, for any two intersecting objects, at least one of the objects is contained in the subset. MIS and MVC refer to the unweighted versions of these problems. We obtain polynomial-time approximation schemes for MWIS and MWVC in the intersection graphs of disks, squares, or other "disk-like" objects, also in higher dimensions.

### 1.1. Preliminaries.

For a set $V$ of geometric objects, the corresponding *intersection graph* is the undirected graph with vertex set $V$ and an edge between two

vertices if the corresponding objects intersect.

Assume that we are given a set $\mathcal{D} = \{D_1, \ldots, D_n\}$ of $n$ (topologically closed) disks in the plane, where $D_i$ has diameter $d_i$, center $c_i = (x_i, y_i)$, and weight $w_i$. For a subset $U \subseteq \mathcal{D}$, $w(U)$ denotes the sum of the weights of the disks in $U$. Disks $D_i$ and $D_j$ *intersect* if $dist(c_i, c_j) \leq (d_i + d_j)/2$, where $dist(p_1, p_2)$ denotes the Euclidean distance between two points $p_1$ and $p_2$ in the plane. A *disk graph* is the intersection graph of a set of disks. We assume that the input to our algorithms is the set $\mathcal{D}$ of disks, not only the corresponding intersection graph. This is an important distinction, because determining for a given graph whether it is a disk graph is known to be $\mathcal{NP}$-hard [16], and hence no efficient method is known for computing a disk representation if only the intersection graph is given.

Interestingly, every planar graph is a *coin graph*, i.e., the intersection graph of a set of interior-disjoint disks [21]. Therefore, the class of disk graphs properly contains the class of planar graphs.

For a given set $\mathcal{D}$ of disks in the plane, we let $OPT_{IS}(\mathcal{D})$ and $OPT_{VC}(\mathcal{D})$ denote the total weight of an optimal solution for MWIS and MWVC, respectively. An algorithm is a $\rho$-approximation algorithm for MWIS if it runs in polynomial time and always computes an independent set of total weight at least $\frac{1}{\rho} OPT_{IS}(\mathcal{D})$. An algorithm is a $\rho$-approximation algorithm for MWVC if it runs in polynomial time and always computes a vertex cover of total weight at most $\rho OPT_{VC}(\mathcal{D})$. An algorithm is a *polynomial-time approximation scheme* (PTAS) for MWIS if it takes an additional parameter $\varepsilon > 0$ and always computes an independent set of total weight at least $\frac{1}{1+\varepsilon} OPT_{IS}(\mathcal{D})$, where the running-time is polynomial in the size of the representation of $\mathcal{D}$ for fixed $\varepsilon > 0$. A PTAS for MWVC is defined analogously. If an algorithm is a $\rho$-approximation algorithm, the algorithm is also said to have approximation ratio $\rho$.

Note that the complement of an independent set is a vertex cover, and vice versa. Therefore, we have $OPT_{IS}(\mathcal{D}) = w(\mathcal{D}) - OPT_{VC}(\mathcal{D})$. Nevertheless, taking the complement of the solution output by a $\rho$-approximation algorithm for MWIS does in general not provide a $\rho$-approximation for MWVC, and vice versa.

In general graphs with $n$ vertices, there cannot be a polynomial-time approximation algorithm for MWIS with approximation ratio $n^{1-\varepsilon}$ for any $\varepsilon > 0$ unless $\mathcal{NP} = \text{co-}RP$ [14]. MWVC is MAX SNP-hard in general graphs and cannot be approximated within a constant smaller than 7/6 unless $\mathcal{P} = \mathcal{NP}$ [15]. For MWVC in general graphs, a 2-approximation algorithm is known [3]. For intersection graphs of geometric objects, better approximation ratios are often possible.

**1.2. Related work on disk graphs.** For unit disk graphs (intersection graphs of disks with equal diameter), MWIS and MWVC remain $\mathcal{NP}$-hard [9], but PTASs exist for MWIS, MWVC, and the minimum dominating set problem if the disk representation is given as part of the input [18]. For intersection graphs of disks with arbitrary diameters, the best previously known approximation algorithms achieve approximation ratio 5 for MIS [23] and $\frac{3}{2}$ for MWVC [22]. In [18] and [22], the question was raised whether a PTAS exists for disk graphs. As the class of disk graphs contains the class of unit disk graphs and the class of planar graphs, a PTAS for disk graphs would generalize the results for unit disk graphs due to Hunt et al. [18] and the results for planar graphs due to Baker [2]. This paper resolves this question by presenting PTASs for MWIS and MWVC in disk graphs (with given representation).

A PTAS for the fractional chromatic number problem on disk graphs, using our PTAS for MWIS as a subroutine, was obtained in [20, 19].

**1.3. Related work on map labeling.** Map labeling refers to a family of tasks concerning the placement of labels on a map. Often it is assumed that the features to be labeled are points and that the labels can be modeled as rectangles (just take the bounding box of the label text). For each feature, there are certain admissible positions of the labeling rectangle: for example, the rectangle must be placed so that the feature coincides with a corner of the rectangle. Rectangles can be assigned weights that represent the importance of including that label on the map. Then it is meaningful to study the problem of maximizing the total weight of labeled features subject to the constraint that different labels must not overlap. This is just MWIS in the intersection graph of a set of (topologically closed) axis-aligned rectangles.

Agarwal, van Kreveld, and Suri [1] give an $O(\log n)$-approximation algorithm for MIS in an intersection graph of $n$ axis-aligned rectangles. Their algorithm can be adapted to the weighted case in a straightforward way, thus yielding an approximation ratio of $O(\log n)$ also for MWIS. For the special case that all rectangles have the same height (which is meaningful if the labels are text labels of a certain font size), they obtain a PTAS.

Doddi et al. [10] consider *sliding labels* (a point can lie anywhere on the boundary of its label) and assume that labels may be placed in any orientation. They provide constant-factor approximation algorithms for maximizing the size of the labels (assuming that all features must be labeled and that all labels are circles or squares with identical size). These were recently improved in [11]. In [10], bicriteria approximation algorithms that label a $(1-\varepsilon)$-fraction of all features with labels whose size is at least a $\frac{1}{1+\varepsilon}$-fraction of the optimal size are also discussed. These algorithms use a PTAS for MWIS as a subroutine. In [10], it is mentioned that their algorithms can be extended to the case of nonuniform squares if the ratio between the size of the largest square and the smallest square is bounded by a constant. Using our new PTAS for MWIS in the intersection graphs of squares, their algorithms can now be extended to labeling with nonuniform squares where this ratio is arbitrary.

Van Kreveld, Strijk, and Wolff [27] investigate the question of how many features in a map can be labeled with rectangular labels if different restrictions on the labeling model are enforced (feature must be at a corner of the rectangle versus sliding rectangles). They present a practical 2-approximation algorithm and a PTAS for maximizing the number of labeled features in the case of sliding rectangular labels of equal height.

An up-to-date bibliography of publications on map labeling can be found on the Web [28].

**1.4. Our results.** In this paper we present PTASs for MWIS and MWVC in the intersection graphs of "disk-like" objects. In sections 2 and 3, we present the details of the PTASs for MWIS and MWVC in disk graphs. In section 4, we discuss how our approach can be extended to other geometric objects (such as squares or regular polygons) and to higher dimensions. We give our conclusions and mention some open problems in section 5.

Our PTASs are based on a sophisticated use of the *shifting strategy* [2, 17] that was previously employed, among other results, for obtaining PTASs for various optimization problems in planar graphs [2] and unit disk graphs [18]. We partition the given disks into levels according to their diameters and use a novel recursive subdivision of the plane that allows us to apply the shifting strategy on all levels simultaneously.

We outline the basic idea of the PTAS for MWIS. The plane is partitioned into squares on each level, and some of the disks are removed from the input so that different squares on the same level yield independent subproblems with respect to all disks that are on this level or on a level with disks of smaller diameter. Furthermore, at most a constant number of disks with larger diameter can be disjoint and intersect a square on the current level. Hence, all such sets of disks can be enumerated in polynomial time for each square, and a dynamic programming approach becomes feasible. The details are given in the next section.

**2. A PTAS for independent set in disk graphs.** Let $k > 1$ be a fixed positive integer. Scale all disks so that the largest disk has diameter 1. Let $d_{\min}$ be the diameter of the smallest disk. Let $\ell = \lfloor \log_{k+1}(1/d_{\min}) \rfloor$. We partition the given set $\mathcal{D}$ of disks into $\ell + 1$ levels. For $0 \leq j \leq \ell$, level $j$ consists of all disks $D_i$ with diameter $d_i$ satisfying $(k+1)^{-j} \geq d_i > (k+1)^{-(j+1)}$. Note that the disk with diameter $d_{\min}$ is on level $\ell$.

An example with three levels is sketched in Figure 2.1.

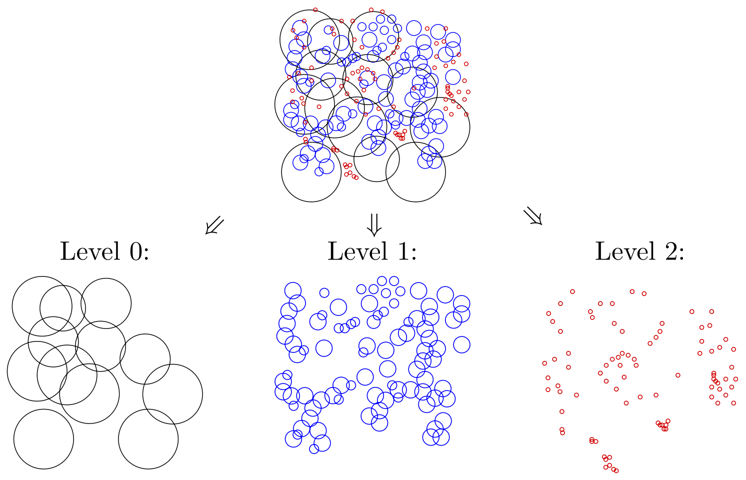

FIG. 2.1. *Partitioning the disks into levels ($k = 2$).*

**2.1. Subdividing the plane.** For each level $j$, $0 \leq j \leq \ell$, we impose a grid on the plane that consists of lines that are $(k+1)^{-j}$ apart from each other. The $v$th vertical line, $v \in \mathbb{Z}$, is at $x = v(k+1)^{-j}$. The $h$th horizontal line, $h \in \mathbb{Z}$, is at $y = h(k+1)^{-j}$. We say that the $v$th vertical line has index $v$ and that the $h$th horizontal line has index $h$. Furthermore, we say that a disk $D_i$ with center $(x_i, y_i)$ and diameter $d_i$ *hits* a vertical line at $x = a$ if $a - d_i/2 < x_i \leq a + d_i/2$. Similarly, we say that $D_i$ hits a horizontal line at $y = b$ if $b - d_i/2 < y_i \leq b + d_i/2$. Intuitively, a disk hits a line if it intersects that line, except if it only touches the line from the left or from below. Note that every disk can hit at most one horizontal line and at most one vertical line on its level.

Let $0 \leq r, s < k$ and consider the vertical lines whose index modulo $k$ equals $r$ and the horizontal lines whose index modulo $k$ equals $s$. We say that these lines are *active* for $(r, s)$. Figure 2.2 illustrates the horizontal grid lines and active lines on two consecutive levels.

Define $\mathcal{D}(r, s)$ to be the set of disks that is obtained from $\mathcal{D}$ by deleting all disks that hit a line that is on the same level as the disk and that is active for $(r, s)$. See Figure 2.3 for an example.

In the following, we write $OPT$ as shorthand for $OPT_{IS}$.

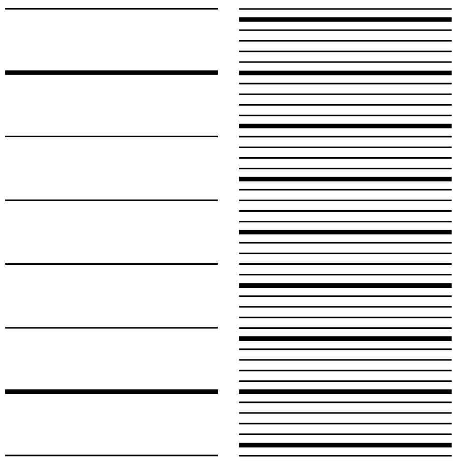

FIG. 2.2. *Horizontal grid lines on level $j$ (left-hand side) and level $j+1$ (right-hand side) for $k=5$. Active lines are drawn bold.*

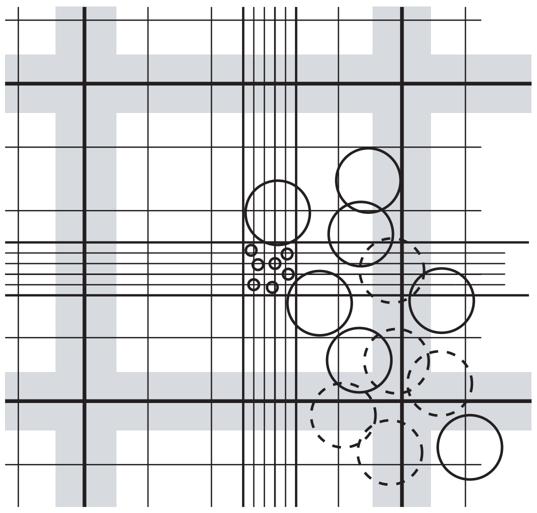

FIG. 2.3. *Example of grid and active lines on level $j$ (coarse grid) and on level $j+1$ (fine grid) for $k=5$. The big disks have level $j$, and the small disks have level $j+1$. All disks shown have the maximum possible diameter on their level. Active lines are drawn bold. Disks that hit active lines are drawn dashed. Note that a disk on level $j$ can hit an active line only if its center is in the shaded strip along that active line.*

LEMMA 2.1. *For at least one pair $(r,s)$, $0 \le r,s < k$, we have $OPT(\mathcal{D}(r,s)) \ge (1-\frac{1}{k})^2 OPT(\mathcal{D})$.*

*Proof.* Let $S^* \subseteq \mathcal{D}$ be any set of disjoint disks with total weight $OPT(\mathcal{D})$.

For $0 \le r < k$, let $S_r^*$ be the set of all disks in $S^*$ that hit a vertical line on their level whose index modulo $k$ is $r$. As the sets $S_r^*$ are disjoint, the weight of at least one of them must be at most a $\frac{1}{k}$-fraction of the weight of $S^*$. For this set $S_r^*$, let $T^* = S^* \setminus S_r^*$ and note that the weight of $T^*$ is at least $(1-\frac{1}{k})OPT(\mathcal{D})$.

For $0 \le s < k$, let $T_s^*$ be the set of all disks in $T^*$ that hit a horizontal line on their level whose index modulo $k$ is $s$. The weight of at least one of these sets $T_s^*$

must be at most a $\frac{1}{k}$-fraction of the weight of $T^*$. For this set $T^*_s$, let $U^* = T^* \setminus T^*_s$. Note that $U^* \subseteq \mathcal{D}(r,s)$ and the weight of $U^*$ is at least $(1-\frac{1}{k})^2 OPT(\mathcal{D})$. ◻

The algorithm considers all $k^2$ possible values for $r$ and $s$ such that $0 \le r,s < k$. For each possibility, an optimal independent set in $\mathcal{D}(r,s)$ is computed using dynamic programming. Among the $k^2$ sets obtained in this way, the one with largest weight is output. By Lemma 2.1, this set has total weight at least $(1-\frac{1}{k})^2 OPT(\mathcal{D})$. Therefore, the algorithm achieves approximation ratio $(1+\frac{1}{k-1})^2$. As $k$ gets larger, the approximation ratio gets arbitrarily close to 1.

It remains to show how an optimal independent set in $\mathcal{D}(r,s)$ can be computed using dynamic programming and that the running-time of the algorithm is polynomial in the size of the input for a fixed value of $k$.

**2.2. Dynamic programming.** Let $0 \le r,s < k$. In this section we discuss the dynamic programming algorithm for computing an optimal independent set in $\mathcal{D}(r,s)$.

Consider one particular level $j$, $0 \le j \le \ell$. The lines on level $j$ that are active for $(r,s)$ partition the plane into squares. More precisely, for consecutive active vertical lines at $x = a_1$ and $x = a_2$ and consecutive active horizontal lines at $y = b_1$ and $y = b_2$, one square $\{(x,y) \mid a_1 < x \le a_2, b_1 < y \le b_2\}$ is obtained. We refer to these squares on level $j$ as *$j$-squares.*

By definition of $\mathcal{D}(r,s)$, every disk in $\mathcal{D}(r,s)$ that is on level $j$ is completely contained in some $j$-square. Furthermore, we have the following lemma about the relationship between squares on different levels.

LEMMA 2.2. *For any $j$, $0 \le j < \ell$, every $(j+1)$-square is completely contained in some $j$-square.*

*Proof.* We prove the lemma by showing that every line that is active for $(r,s)$ on level $j$ is also active for $(r,s)$ on level $j+1$. Figure 2.2 illustrates this claim for the horizontal lines: note that the active lines on level $j$ are active on level $j+1$ also after the active lines are "shifted" up or down on their respective levels.

Without loss of generality, consider only the horizontal lines. Let $y = h(k+1)^{-j}$ be an active horizontal line on level $j$. This means that $h \bmod k = s$. This line is identical to the line $y = h(k+1)(k+1)^{-(j+1)}$, which is on level $j+1$ and has index $h(k+1)$. Obviously, $h(k+1) \bmod k = h \bmod k = s$. Hence, the line is also active on level $j+1$. ◻

COROLLARY 2.3. *Every $j$-square is the union of $(k+1)^2$ $(j+1)$-squares.*

Call a $j$-square $S$ *relevant* if $\mathcal{D}(r,s)$ contains at least one disk of level $j$ that is contained in $S$. For a relevant $j$-square $S$ and a relevant $j'$-square $S'$, $j' > j$, we say that $S'$ is a *child* or *child square* of $S$ (and $S$ is a *parent* of $S'$) if $S'$ is contained in $S$ and if there is no relevant $j''$-square $S''$, $j' > j'' > j$, such that $S'$ is contained in $S''$ and $S''$ is contained in $S$.

The algorithm processes all relevant squares in order of nonincreasing levels. When a $j$-square $S$ is processed, a table $T_S$ is computed. For every set $I$ of disjoint disks of level smaller than $j$ that intersect $S$, the table entry $T_S(I)$ is a maximum weight set of disjoint disks of level at least $j$ that are contained in $S$ and disjoint from the disks in $I$. To formalize this property, we introduce the following definition.

DEFINITION 2.4. *Let $S$ be a relevant $j$-square and let $I$ be a set of disjoint disks of level less than $j$ that intersect $S$. Then the table entry $T_S(I)$ is called* good *if it satisfies the following properties:*

(a) *$T_S(I) \subseteq \mathcal{D}(r,s)$ consists of disks that are contained in $S$ and have level at least $j$.*

(b) *$I \cup T_S(I)$ is an independent set.*

(c) *$w(T_S(I))$ is maximum among all sets that satisfy* (a) *and* (b).

Provided that tables with good entries have been computed for all relevant squares, it is clear that the algorithm can output a maximum weight independent set in $\mathcal{D}(r, s)$ by taking the union of the sets $T_S(\emptyset)$ for all relevant squares $S$ that do not have a parent. In the next section, we give an algorithm to efficiently compute the table $T_S$ for a $j$-square $S$ provided that the tables $T_{S'}$ have already been computed for all child squares $S'$ of $S$.

**2.3. Computing the table for a relevant square.** Consider some relevant $j$-square $S$. First, we give a bound on the number of sets $I$ for which a table entry $T_S(I)$ needs to be computed. For this purpose, we show that the number of disjoint disks of level smaller than $j$ that can intersect a $j$-square is bounded by $O(k^2)$. Figure 2.3 can serve as an illustration of this fact: only $O(k^2)$ disjoint disks whose diameter is larger than that of the big disks can intersect the $j$-square shown in the figure.

LEMMA 2.5. *Let $S$ be some $j$-square and let $I \subseteq \mathcal{D}$ be a set of disjoint disks such that each disk in $I$ has level at most $j - 1$ and intersects $S$. Then there is a constant $C$ such that $|I| \leq Ck^2$.*

*Proof.* Let $\bar{S}$ be a square that consists of $S$ and a strip of width $(k + 1)^{-j}$ surrounding $S$. As the disks in $I$ have level at most $j - 1$, they have diameter larger than $(k + 1)^{-j}$ and, therefore, area larger than $\pi((k + 1)^{-j}/2)^2$. Furthermore, each disk in $I$ occupies an area larger than $\pi((k + 1)^{-j}/2)^2$ within $\bar{S}$: a disk of diameter $(k + 1)^{-j}$ that intersects $S$ would have to be completely contained in $\bar{S}$, and larger disks that intersect $S$ would have to occupy an area of $\bar{S}$ that is even larger. The area of $\bar{S}$ is $((k + 2)(k + 1)^{-j})^2$. Therefore, we must have

$$|I| \leq \frac{((k + 2)(k + 1)^{-j})^2}{\pi((k + 1)^{-j}/2)^2} = \frac{4}{\pi}(k + 2)^2 < 6k^2.$$

Hence, we can choose $C = 6$. ∎

By Lemma 2.5, the algorithm can enumerate all independent sets $I$ of disks that have level smaller than $j$ and that intersect $S$ as follows: It simply enumerates all subsets of at most $Ck^2$ disks of level smaller than $j$ that intersect $S$ and checks for each of them whether it is an independent set. This enumeration can be performed in time $n^{O(k^2)}$.

We consider one such set $I$ and show how $T_S(I)$ is computed. Assume for now that the $j$-square $S$ has either no child square at all or exactly $(k + 1)^2$ child squares on level $j + 1$. Denote the child squares by $S'_{g,h}$, where $g$ is the row index and $h$ is the column index, $0 \leq g, h \leq k$. Thus, $S'_{0,0}$ is the bottom left child square of $S$, and $S'_{k,k}$ is the top right child square. We will show later how to deal with the case that some child squares of $S$ are at a level larger than $j + 1$.

We can assume that $T_{S'_{g,h}}$ has already been computed for each such child square $S'_{g,h}$. A first approach to computing $T_S(I)$, which we have used in an earlier version of our result, is to enumerate all sets $I'$ of disjoint disks of level $j$ that intersect $S$ and that are disjoint from the disks in $I$, and to look up, for each such set $I'$, the table entries $T_{S'_{g,h}}(I'_{g,h})$, where $I'_{g,h}$ is the set of disks in $I \cup I'$ that intersect $S'_{g,h}$. The union of $I'$ and all sets of the form $T_{S'_{g,h}}(I'_{g,h})$ forms a candidate set, and the candidate set of largest weight yields $T_S(I)$. The cardinality of $I'$ can be bounded by $O(k^4)$, and so this approach leads to a running-time of $n^{O(k^4)}$. In the following, we present an improved algorithm based on dynamic programming that allows us to reduce the running-time to $n^{O(k^2)}$.

By $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$, where $0 \le g_1 \le g_2 \le k$ and $0 \le h_1 \le h_2 \le k$, we denote the union of all child squares $S'_{g,h}$ with $g_1 \le g \le g_2$ and $h_1 \le h \le h_2$. We call such a union of child squares a *rectangle*. We say that a disk $D$ *intersects the boundary* of a rectangle $R$ if $D \cap R$ and $D \setminus R$ are both nonempty.

In order to determine $T_S(I)$, the algorithm computes an auxiliary table $AT_{S,I}$ with entries $AT_{S,I}(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, J)$ for certain values of $g_1, g_2, h_1, h_2$, where $J$ is a set of disks of level $j$ that intersect the boundary of $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$ and have the property that $I \cup J$ is an independent set. The table entry $AT_{S,I}(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, J)$ is a maximum weight set $J'$ of disks that have level at least $j$, are contained in $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$, and have the property that $I \cup J \cup J'$ is an independent set. This property is captured formally in the following definition.

DEFINITION 2.6. *Let $S$ be a relevant $j$-square and let $I$ be a set of disjoint disks of level less than $j$ that intersect $S$. Let $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$ be a rectangle of child squares of $S$, and let $J$ be a set of disks of level $j$ that intersect the boundary of $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$ and have the property that $I \cup J$ is an independent set.*

*Then the table entry $AT_{S,I}(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, J)$ is called* good *if it satisfies the following properties:*

(a) *$AT_{S,I}(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, J) \subseteq \mathcal{D}(r,s)$ consists of disks that are contained in $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$ and have level at least $j$.*

(b) *$I \cup J \cup AT_{S,I}(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, J)$ is an independent set.*

(c) *$w(AT_{S,I}(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, J))$ is maximum among all sets that satisfy* (a) *and* (b).

Once a good table entry $AT_{S,I}(S'_{0\cdot\cdot k,0\cdot\cdot k}, \emptyset)$ is computed, it immediately yields $T_S(I)$.

Table entries $AT_{S,I}(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, J)$ are again computed by dynamic programming. First, we bound the number of different sets $J$ that must be considered as table index for a rectangle $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$.

LEMMA 2.7. *Let $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$ be a rectangle and let $J$ be a set of disjoint disks of level $j$ such that all disks in $J$ intersect the boundary of $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$. Then there is a constant $C'$ such that $|J| \le C'k^2$.*

*Proof.* Let $R = S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$. The boundary $B$ of $R$ consists of line segments with total length at most $4k(k+1)^{-j}$. Let $\bar{B}$ be obtained by extending $B$ by a strip of width $(k+1)^{-(j+1)}$ on the inside of $B$ and on the outside of $B$. The total area of $\bar{B}$ is at most $8k(k+1)^{-2j-1}$. Each disk of level $j$ that intersects $B$ occupies an area at least $\pi(k+1)^{-2(j+1)}/4$ of $\bar{B}$. Therefore, $J$ can contain at most

$$\frac{8k(k+1)^{-2j-1}}{\frac{\pi}{4}(k+1)^{-2(j+1)}} = \frac{32}{\pi}k(k+1) \le 16k^2$$

disjoint disks. So we can take $C' = 16$. ∎

Lemma 2.7 shows that for each rectangle $S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}$, there are at most $n^{O(k^2)}$ different sets $J$ that need to be considered as table index with respect to $AT_{S,I}$ $(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, J)$.

Here and in the following, we use $AT_{S,I}(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, *)$ as a shorthand notation to refer to the table entries $AT_{S,I}(S'_{g_1\cdot\cdot g_2,h_1\cdot\cdot h_2}, J)$ for all relevant values of $J$.

As the basis of the dynamic programming, the table entries $AT_{S,I}(S'_{g\cdot\cdot g,h\cdot\cdot h}, *)$ are computed for $0 \le g, h \le k$ as shown in Figure 2.4. Note that $S'_{g\cdot\cdot g,h\cdot\cdot h} = S'_{g,h}$. For each child square $S'_{g,h}$, all independent sets $U$ of disks of level $j$ intersecting $S'_{g,h}$ are enumerated. This can be done in time $n^{O(k^2)}$ by Lemma 2.5. If $I \cup U$ is

FIG. 2.4. *Computing the auxiliary table $AT_{S,I}(S'_{g,h}, *)$.*

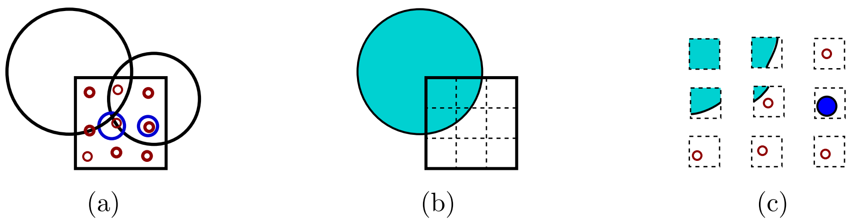

FIG. 2.5. *Example of table lookups for a square $S$ at level $j$ in case $k = 2$.* (a) *shows* 13 *disks in $\mathcal{D}(r,s)$ that intersect $S$:* 2 *disks of level less than $j$,* 2 *disks on level $j$, and* 9 *disks on level $j+1$.* (b) *displays an independent set $I$ consisting of* 1 *disk of level less than $j$.* (c) *illustrates that lookups are performed in* 9 *tables $T_{S'_{g,h}}$ during the computation of the table entries $AT_{S,I}(S'_{g,h}, *)$.*

an independent set, the optimal way of extending the set $I \cup U$ to a larger weight independent set by adding disks of larger levels that are contained in $S'_{g,h}$ is computed by looking up $T_{S'_{g,h}}(I' \cup U)$, where $I' = \{D \in I \mid D$ intersects $S'_{g,h}\}$. (If $S$ does not have any relevant child squares, all lookups in tables $T_{S'_{g,h}}$ are taken to return the empty set.) Let $J = \{D \in U \mid D$ intersects the boundary of $S'_{g,h}\}$. If the independent set obtained in this way has larger weight than the previous set stored in table entry $AT_{S,I}(S'_{g,h}, J)$, the entry is updated to store the new set. An example of the table lookups performed for a relevant $j$-square $S$ in the tables $T_{S'_{g,h}}$ of subsquares at level $j+1$ is sketched in Figure 2.5.

Next, we show how to combine the information from the table entries of two rectangles to obtain the table entries for the rectangle representing the union of the two rectangles. Without loss of generality, we discuss only the case where the two rectangles share a horizontal edge and have the same width. The combination of rectangles that share a vertical edge and have the same height is analogous. It is clear that $(k+1)^2-1$ such combinations suffice to obtain the table entry $AT_{S,I}(S'_{0\cdot\cdot k,0\cdot\cdot k}, \emptyset)$,

FIG. 2.7. *Computing the auxiliary table* $AT_{S,I}(S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, *)$.

which then gives $T_S(I)$. See Figure 2.6 for an example with $k = 4$ in which first the horizontally adjacent rectangles within each row are combined and then the vertically adjacent row rectangles are combined.

The algorithm for computing the table entries $AT_{S,I}(S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, *)$ from the table entries $AT_{S,I}(S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}, *)$ and $AT_{S,I}(S'_{g_2+1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, *)$ for some $g_1 \le g_2 < g_3, h_1 \le h_2$ is shown in Figure 2.7. Let $R_1 = S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}$ and $R_2 = S'_{g_2+1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}$. The algorithm enumerates all independent sets $U$ of disks of level $j$ that intersect the boundary of $R_1$ or $R_2$. As each such set has cardinality at most $2C'k^2$, where $C'$ is the constant from Lemma 2.7, there are at most $n^{O(k^2)}$ such sets. If $I \cup U$ is an independent set, the optimal way of extending the set to a larger weight independent set by adding disks of level at least $j$ that are contained in $R_1$ or $R_2$ is computed by looking up $AT_{S,I}(R_1, U_1)$ and $AT_{S,I}(R_2, U_2)$, where $U_i$ for $i = 1, 2$ is the set of disks in $U$ that intersect the boundary of $R_i$. Then the table entry $AT_{S,I}(S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, J)$ is updated for the appropriate choice of $J$ provided that the new set is better than the previously stored entry. When all sets $U$ have been processed in this way, the table entries $AT_{S,I}(S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, *)$ have their final values.

So far we have assumed that the current $j$-square $S$ has either no child squares or exactly $(k+1)^2$ child squares on level $j+1$. It is easy to handle the case that $S$ has fewer than $(k+1)^2$ child squares on level $j+1$ and possibly some child squares on levels larger than $j+1$: Just before the computation of $T_S$, we compute the tables $T_{S'_{g,h}}$ for all $(k+1)^2$ $(j+1)$-squares $S'_{g,h}$ contained in $S$. For the $(j+1)$-squares that are relevant, the tables are already computed. For every $(j+1)$-square $S'_{g,h}$ that is not relevant, we can enumerate all $n^{O(k^2)}$ sets $I$ of disjoint disks of level at most $j$ that intersect $S'_{g,h}$ and compute $T_{S'_{g,h}}(I)$ by taking the union of the sets $T_{S''}(I^{S''})$ for all child squares $S''$ of $S$ that are contained in $S'_{g,h}$. Here, $I^{S''} = \{D \in I \mid D \text{ intersects } S''\}$. It is clear that the table entries $T_{S'_{g,h}}(I)$ computed in this way are good provided that good entries of the tables $T_{S''}$ have been computed previously.

This completes the description of the algorithm. In summary, the optimal independent set in $\mathcal{D}(r,s)$ is computed by dynamic programming on the relevant squares using table entries $T_S(I)$, while each such entry is computed by dynamic programming on rectangles within the current square using auxiliary table entries $AT_{S,I}(S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}, J)$.

## 2.4. Running-time of the algorithm.

LEMMA 2.8. *The running-time of the algorithm is $n^{O(k^2)}$ and hence polynomial for any fixed $k > 1$.*

*Proof.* There are $k^2$ sets $\mathcal{D}(r,s)$ that have to be considered. As there are at most $n$ disks in $\mathcal{D}(r,s)$, there can be at most $n$ relevant squares. The relevant squares and their forest structure (the links between every relevant square and its children) can be computed easily in time polynomial in $n$.

For each relevant square $S$, the algorithm first computes the missing tables $T_{S'_{g,h}}$ for $(j+1)$-squares $S'_{g,h}$ that are contained in $S$, as discussed at the end of section 2.3. Each of the $O(k^2)$ such $(j+1)$-squares can be handled in time $n^{O(k^2)}$. Then the algorithm enumerates $n^{O(k^2)}$ sets $I$ for which a table entry $T_S(I)$ has to be computed. Each such entry is determined by using dynamic programming to fill the table $AT_{S,I}$. Table entries $AT_{S,I}(S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}, J)$ are computed for $O(k^2)$ different rectangles $S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}$, and for each rectangle the computation takes time $n^{O(k^2)}$, as can be seen from the pseudocode in Figures 2.4 and 2.7.

Thus, the total running-time can be bounded by

$$k^2 \cdot n^{O(1)} \cdot \left( O(k^2) \cdot n^{O(k^2)} + n^{O(k^2)} \cdot O(k^2) \cdot n^{O(k^2)} \right) = n^{O(k^2)}. \qquad \square$$

## 2.5. Correctness of the algorithm.

LEMMA 2.9. *The entries of all the tables $T_S$ and $AT_{S,I}$ computed by the algorithm are good.*

*Proof.* First, it is clear that the table entries computed by the algorithm satisfy properties (a) and (b) of Definitions 2.4 and 2.6. It remains to show that the sets stored in the tables are indeed of maximum weight.

The proof is by induction on the number of squares processed by the algorithm. Initially, the claim of the lemma holds vacuously. Now assume that the algorithm processes a relevant $j$-square $S$ and that good entries for the tables $T_{S'}$ have been computed for all relevant squares $S'$ that were processed before $S$. Let $I$ be a set of disjoint disks of level smaller than $j$ that intersect $S$.

Consider the computation of the table entries $AT_{S,I}(S'_{g,h}, J)$ as shown in Figure 2.4. Fix some set $J$ of disks at level $j$ intersecting the boundary of $S'_{g,h}$ such that $I \cup J$ is an independent set. Let $X^*$ be a maximum weight set of disks at level at least $j$ that are contained in $S'_{g,h}$ such that $I \cup J \cup X^*$ is an independent set. Let $X^*_{=j}$ be the set of disks at level $j$ in $X^*$ and let $U^* = J \cup X^*_{=j}$. Then $U^*$ is one of the sets $U$ enumerated by the algorithm, and we consider the iteration of the for-loop when this set is processed. Since the entries of $T_{S'_{g,h}}$ are good, the lookup in $T_{S'_{g,h}}(I' \cup U)$ returns a set of weight at least $w(X^* \setminus X^*_{=j})$. Then the set

$$\begin{aligned} X &= T_{S'_{g,h}}(I' \cup U) \cup \{D \in U \mid D \text{ is contained in } S'_{g,h}\} \\ &= T_{S'_{g,h}}(I' \cup U) \cup X^*_{=j} \end{aligned}$$

computed by the algorithm has weight at least $w(X^* \setminus X^*_{=j}) + w(X^*_{=j}) = w(X^*)$. Hence, the table entry $AT_{S,I}(S'_{g,h}, J)$ contains a set $X$ of weight at least $w(X^*)$ when the algorithm of Figure 2.4 terminates. Since $AT_{S,I}(S'_{g,h}, J)$ satisfies properties (a) and (b) of Definition 2.6 and $X^*$ is a maximum weight set with this property, we get that $w(AT_{S,I}(S'_{g,h}, J)) = w(X^*)$. Hence, the computed table entry $AT_{S,I}(S'_{g,h}, J)$ is good.

Consider the computation of a table entry $AT_{S,I}(S'_{g_1\cdot\cdot g_3, h_1\cdot\cdot h_2}, J)$ as shown in Figure 2.7. Assume that the previously computed entries $AT_{S,I}(S'_{g_1\cdot\cdot g_2, h_1\cdot\cdot h_2}, *)$ and $AT_{S,I}(S'_{g_2+1\cdot\cdot g_3, h_1\cdot\cdot h_2}, *)$ are good. Let $R_1 = S'_{g_1\cdot\cdot g_2, h_1\cdot\cdot h_2}$ and $R_2 = S'_{g_2+1\cdot\cdot g_3, h_1\cdot\cdot h_2}$.

Fix some set $J$ of disks at level $j$ intersecting the boundary of $S'_{g_1\cdot\cdot g_3, h_1\cdot\cdot h_2} = R_1 \cup R_2$ such that $I \cup J$ is an independent set. Let $X^*$ be a maximum weight set of disks at level at least $j$ that are contained in $R_1 \cup R_2$ such that $I \cup J \cup X^*$ is an independent set. Let $X^*_{1,2}$ be the set of disks at level $j$ in $X^*$ that intersect the boundary of $R_1$ and the boundary of $R_2$. Let $X^*_1$ and $X^*_2$ be the set of disks in $X^*$ that are contained in $R_1$ and in $R_2$, respectively.

Let $U^* = J \cup X^*_{1,2}$. Then $U^*$ is one of the sets $U$ enumerated by the algorithm. For this set $U^*$, the table lookups $AT_{S,I}(R_i, U_i)$ for $i = 1, 2$, with $U_i$ calculated as shown in Figure 2.7, yield disjoint sets $X_1$ and $X_2$ of weight at least $w(X^*_1)$ and $w(X^*_2)$, respectively. Then the set

$$\begin{aligned} X &= X_1 \cup X_2 \cup \{D \in U \mid D \text{ does not intersect the boundary of } S'_{g_1\cdot\cdot g_3, h_1\cdot\cdot h_2}\} \\ &= X_1 \cup X_2 \cup X^*_{1,2} \end{aligned}$$

calculated by the algorithm has weight at least $w(X^*_1) + w(X^*_2) + w(X^*_{1,2}) = w(X^*)$. Hence, the table entry $AT_{S,I}(R_1 \cup R_2, J)$ contains a set $X$ of weight at least $w(X^*)$ when the algorithm of Figure 2.7 terminates, and is thus a good entry.

So we see that the computed auxiliary table entries $AT_{S,I}(S'_{g_1\cdot\cdot g_2, h_1\cdot\cdot h_2}, *)$ are indeed good for the rectangles $S'_{g_1\cdot\cdot g_2, h_1\cdot\cdot h_2}$. Since the algorithm then sets $T_S(I)$ equal to $AT_{S,I}(S, \emptyset)$, this shows that the computed entries of $T_S(I)$ are good as well. $\square$

We observe that all disks in $\mathcal{D}(r, s)$ are contained in some relevant square without parent, and that all relevant squares without parent are disjoint. By Lemma 2.9, the computed table entries $T_S(\emptyset)$ are good for all relevant squares without parent, and this shows that the algorithm indeed computes an optimal independent set in $\mathcal{D}(r, s)$. Together with the discussion in section 2.1, we have that the algorithm achieves approximation ratio $(1 + \frac{1}{k-1})^2 \leq 1 + \frac{3}{k-1}$. In order to achieve approximation ratio

$1+\varepsilon$, we can set $k = \lceil 3/\varepsilon \rceil + 1$. The running-time is $n^{O(k^2)}$ and hence polynomial for any fixed $k > 1$. So the algorithm indeed constitutes a PTAS. We summarize our result in the following theorem.

THEOREM 2.10. *There is a PTAS for MWIS in disk graphs, provided that a disk representation of the graph is given. The running-time for achieving approximation ratio* $1+\varepsilon$ *is* $n^{O(1/\varepsilon^2)}$ *for a disk graph with* $n$ *disks.*

## 3. A PTAS for vertex cover in disk graphs.

In this section we describe a PTAS for MWVC. The basic approach is similar to the PTAS for MWIS of the previous section, but a number of details cause additional technical difficulties and require a different treatment. One problem is that the size of a vertex cover cannot be bounded by area arguments as the size of an independent set can. The main idea to circumvent this problem is to work with the complements of vertex covers, which are independent sets.

The partitioning of the disks into levels and the subdivision of the plane into squares at each level is the same as for MWIS. Again, all values of $r$ and $s$ such that $0 \leq r, s < k$ are considered in turn. Note that the definition of the squares on each level depends on $r$ and $s$. Contrary to the PTAS for MWIS, disks that are not completely contained in some square on their level are not removed; instead, these disks are considered in all squares on their level that they intersect (there are at most four such squares). Now a $j$-square $S$ is called relevant if $\mathcal{D}$ contains a disk of level $j$ that intersects $S$.

Consider some $j$-square $S$ and let $\mathcal{D}^S$ denote the set of all disks in $\mathcal{D}$ that intersect $S$. Let $\mathcal{D}^S_{<j}$ be the set of disks in $\mathcal{D}^S$ that have level smaller than $j$. Define $\mathcal{D}^S_{\leq j}$, $\mathcal{D}^S_{=j}$, $\mathcal{D}^S_{\geq j}$, and $\mathcal{D}^S_{>j}$ analogously.

We say that a set $Z \subseteq \mathcal{D}$ is a *pseudocover* of $S$ if, for any two disks $D_1, D_2 \in \mathcal{D}^S$ that intersect in $S$ (i.e., $D_1 \cap D_2 \cap S \neq \emptyset$), $Z$ contains $D_1$ or $D_2$ (or both). Note that a pseudocover of $S$ need not contain $D_1$ or $D_2$ if the only intersection of $D_1$ with $D_2$ is outside $S$. We observe that, for any two disks in $\mathcal{D}$ that intersect, there exists a relevant square in which they intersect.

For any pseudocover $Z$ of $S$, call $\mathcal{D}^S_{<j} \cap Z$ the *projection* of $Z$ onto $\mathcal{D}^S_{<j}$. While processing $S$, the algorithm considers only pseudocovers $Z$ of $S$ for which the projection of $Z$ onto $\mathcal{D}^S_{<j}$ equals $\mathcal{D}^S_{<j} \setminus I$ for some independent set $I \subseteq \mathcal{D}^S_{<j}$. As the number of independent sets in $\mathcal{D}^S_{<j}$ is bounded by $n^{O(k^2)}$ by Lemma 2.5, we can enumerate all of them and thus, by taking the complements, also the corresponding projections of pseudocovers of $S$ onto $\mathcal{D}^S_{<j}$ in time $n^{O(k^2)}$.

As in the PTAS for MWIS, all relevant squares are processed in a bottom-up fashion, and for each square $S$ a table $T_S$ is computed. For a relevant $j$-square $S$ and a set $I$ of disjoint disks in $\mathcal{D}^S_{<j}$, the table entry $T_S(I)$ has the following property.

PROPERTY 1. *For every relevant $j$-square $S$ and every set $I$ of disjoint disks in $\mathcal{D}^S_{<j}$, the table entry $T_S(I)$ is a subset of $\mathcal{D}^S_{\geq j}$ such that the set*

$$(\mathcal{D}^S_{<j} \setminus I) \cup T_S(I)$$

*is a pseudocover of $S$.*

Unlike in the PTAS for MWIS, the entries $T_S(I)$ will not be optimal (minimum weight) sets with the stated property, but will still be good enough to achieve the desired approximation ratio. It is clear that we cannot expect to compute minimum weight entries $T_S(I)$, as in that case the entry $T_S(\emptyset)$ of a relevant square $S$ without parent would represent an optimal vertex cover of all disks contained in $S$, thus solving an $\mathcal{NP}$-hard problem optimally. (Note that we do not delete any disks from the given instance of MWVC in disk graphs before we compute the table entries, contrary to our algorithm for MWIS.)

In the end, the algorithm outputs the union of the sets $T_S(\emptyset)$ for all relevant squares $S$ without parent. By the definition of pseudocovers, this union is a vertex cover of $\mathcal{D}$.

At a relevant $j$-square $S$, all independent sets $I$ in $\mathcal{D}^S_{<j}$ are enumerated in time $n^{O(k^2)}$. The computation of the table entry $T_S(I)$ for one such set $I$ is described in the following.

Assume again that the $j$-square $S$ has $(k+1)^2$ child squares on level $j+1$ (with the same justification as in the case of MWIS) and denote these child squares by $S'_{g,h}$, where $g$ is the row index and $h$ is the column index, $0 \le g, h \le k$. Since the algorithm processes the relevant squares in order of nonincreasing levels, the table $T_{S'_{g,h}}$ has already been computed for each such child square $S'_{g,h}$.

In order to determine $T_S(I)$, the algorithm computes an auxiliary table $AT_{S,I}$ with entries $AT_{S,I}(S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}, J)$ for certain values of $g_1, g_2, h_1, h_2$, where $J$ is a set of disks that are on level $j$ and intersect the boundary of $S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}$ such that $I \cup J$ is an independent set. For a rectangle $R$, let $\mathcal{D}^{\partial R}$ be the set of all disks in $\mathcal{D}$ that intersect the boundary of $R$.

PROPERTY 2. *Let $S$ be a relevant $j$-square and $I$ an independent set in $\mathcal{D}^S_{<j}$. Let $R = S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}$ be a rectangle of child squares of $S$ and $J$ a set of disks of level $j$ intersecting the boundary of $R$ such that $I \cup J$ is an independent set. The table entry $AT_{S,I}(R, J)$ is a set of disks in $\mathcal{D}$ that*

- *either have level $j$ and are contained in $R$ or*
- *have level at least $j+1$ and intersect $R$*

*such that*

$$(\mathcal{D}^S_{<j} \setminus I) \cup (\mathcal{D}^{\partial R}_{=j} \setminus J) \cup AT_{S,I}(R, J)$$

*is a pseudocover of $R$.*

Once the table entries $AT_{S,I}(S'_{0 \cdot\cdot k, 0 \cdot\cdot k}, J) = AT_{S,I}(S, J)$ for all $J$ are computed, $T_S(I)$ is obtained by taking the set $AT_{S,I}(S, J) \cup (\mathcal{D}^{\partial S}_{=j} \setminus J)$ of minimum weight (over all $J$).

The table entries $AT_{S,I}(S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}, J)$ are again computed by dynamic programming. By Lemma 2.7, for each rectangle $S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}$ there are at most $n^{O(k^2)}$ different sets that are relevant as table index $J$ for $AT_{S,I}(S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}, J)$.

As the basis of the dynamic programming, the table entries $AT_{S,I}(S'_{g \cdot\cdot g, h \cdot\cdot h}, J)$ are computed for $0 \le g, h \le k$ as shown in Figure 3.1. For each child square $S'_{g,h}$, all independent sets $U$ of disks of level $j$ intersecting $S'_{g,h}$ are enumerated in time $n^{O(k^2)}$ (by Lemma 2.5). If $I \cup U$ is an independent set, the table entry $T_{S'_{g,h}}(I' \cup U)$ is looked up, where $I' = \{D \in I \mid D \text{ intersects } S'_{g,h}\}$, in order to obtain the pseudocover of $S'_{g,h}$ given by the set

$$(\mathcal{D}^S_{<j} \setminus I) \cup (\mathcal{D}^{S'_{g,h}}_{=j} \setminus U) \cup T_{S'_{g,h}}(I' \cup U).$$

Then $J$ is taken to be the set of disks in $U$ intersecting the boundary of $S'_{g,h}$, and the table entry $AT_{S,I}(S'_{g,h}, J)$ is updated appropriately if the current pseudocover has smaller weight than the one previously stored. (Of course, if $S$ does not have any child squares, the table lookups $T_{S'_{g,h}}(I' \cup U)$ are taken to return the empty set.)

```

FIG. 3.1. *Computing the auxiliary table $AT_{S,I}(S'_{g,h}, *)$ for MWVC.*

Next, the information from the tables of two rectangles is combined to obtain the table for the rectangle representing the union of the two rectangles. Again, we discuss only the case where the two rectangles share a horizontal edge and have the same width. The algorithm for computing the table $AT_{S,I}(S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, *)$ from the tables $AT_{S,I}(S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}, *)$ and $AT_{S,I}(S'_{g_2+1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, *)$ for some $g_1 \leq g_2 < g_3, h_1 \leq h_2$ is shown in Figure 3.2. Let $R_1 = S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}$ and $R_2 = S'_{g_2+1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}$. The algorithm enumerates all independent sets $U$ of disks of level $j$ that intersect the boundary of $R_1$ or $R_2$. As each such set has cardinality at most $2C'k^2$, where $C'$ is the constant from Lemma 2.7, there are at most $n^{O(k^2)}$ such sets. If $I \cup U$ is an independent set, the table entries $X_1 = AT_{S,I}(R_1, U_1)$ and $X_2 = AT_{S,I}(R_2, U_2)$, where $U_1$ and $U_2$ are calculated as shown in Figure 3.2, are looked up to obtain the pseudocover of $R_1 \cup R_2 = S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}$ given by the set

$$(\mathcal{D}_{<j}^{S} \setminus I) \cup ((\mathcal{D}_{=j}^{\partial R_1} \cup \mathcal{D}_{=j}^{\partial R_2}) \setminus U) \cup X_1 \cup X_2.$$

Then the table entry $AT_{S,I}(S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, J)$ for

$$J = \{D \in U \mid D \text{ intersects the boundary of } S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}\}$$

is updated appropriately if this pseudocover has smaller weight than the one previously stored.

In the end, the algorithm outputs the union of the sets $T_S(\emptyset)$, taken over all relevant squares $S$ that do not have a parent. We will see that this is a $(1 + \frac{6}{k})$-approximation of the minimum weight vertex cover.

### 3.1. The algorithm outputs a vertex cover.

LEMMA 3.1. *The algorithm outputs a vertex cover of $\mathcal{D}$.*

*Proof.* We prove by induction on the number of processed squares that Properties 1 and 2 hold for all computed table entries. Let $S$ be some $j$-square. Recall that

```
Input: square $S$ on level $j$,
        set $I$ of disjoint disks of level $< j$ intersecting $S$,
        integers $g_1, g_2, g_3$ with $0 \leq g_1 \leq g_2 < g_3 \leq k$,
        integers $h_1, h_2$ with $0 \leq h_1 \leq h_2 \leq k$,
        previously computed table entries $AT_{S,I}(S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}, *)$ and
            $AT_{S,I}(S'_{g_2+1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, *)$
Output: table entries $AT_{S,I}(S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, J)$ for all $J$
$R_1 \leftarrow S'_{g_1 \cdot\cdot g_2, h_1 \cdot\cdot h_2}$;
$R_2 \leftarrow S'_{g_2+1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}$;
$AT_{S,I}(S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, *) \leftarrow$ undefined;
$Q \leftarrow$ all disks in $\mathcal{D}$ of level $j$ intersecting the boundary of $R_1$ or $R_2$, i.e.,
    $\mathcal{D}^{\partial R_1}_{=j} \cup \mathcal{D}^{\partial R_2}_{=j}$;

    fi
od
```

FIG. 3.2. *Computing the auxiliary table $AT_{S,I}(S'_{g_1 \cdot\cdot g_3, h_1 \cdot\cdot h_2}, *)$ for MWVC.*

$\mathcal{D}^S$ is the set of all disks in $\mathcal{D}$ that intersect $S$ and that $\mathcal{D}^S_{<j}$ denotes the set of disks in $\mathcal{D}^S$ whose level is smaller than $j$, and similarly for $\mathcal{D}^S_{\leq j}$, $\mathcal{D}^S_{=j}$, $\mathcal{D}^S_{\geq j}$, and $\mathcal{D}^S_{>j}$. Let $I$ be a set of disjoint disks in $\mathcal{D}^S_{<j}$.

Assume that the entries of all tables $T_{S'}$ computed for previously processed squares $S'$ satisfy Property 1. Then each set $T_{S'_{g,h}}(I' \cup U)$ that is looked up by the algorithm of Figure 3.1 is such that

$$(\mathcal{D}^{S'_{g,h}}_{\leq j} \setminus (I' \cup U)) \cup T_{S'_{g,h}}(I' \cup U)$$

is a pseudocover of $S'_{g,h}$. Therefore, the set stored in $AT_{S,I}(S'_{g,h}, J)$ for $J = \{D \in U \mid D$ intersects the boundary of $S'_{g,h}\}$ satisfies Property 2.

Now assume that the information from table entries $AT_{S,I}(R_1, *)$ and $AT_{S,I}(R_2, *)$ is combined to obtain the table entries $AT_{S,I}(R_1 \cup R_2, *)$ using the algorithm of Figure 3.2. Consider some iteration of the algorithm of Figure 3.2 and let $U_1$ and $U_2$ be defined as calculated by the algorithm. Note that $U_1 \cup U_2 = U$ but $U_1 \cap U_2$ can be nonempty. Since table entries $AT_{S,I}(R_i, U_i)$ for $i = 1, 2$ satisfy Property 2, we have that the set

$$(\mathcal{D}^S_{<j} \setminus I) \cup ((\mathcal{D}^{\partial R_1}_{=j} \cup \mathcal{D}^{\partial R_2}_{=j}) \setminus (U_1 \cup U_2)) \cup AT_{S,I}(R_1, U_1) \cup AT_{S,I}(R_2, U_2)$$

is indeed a pseudocover of $R_1$ and $R_2$ and thus also of $R_1 \cup R_2$. Therefore, the set stored in $AT_{S,I}(R_1 \cup R_2, J)$ for $J = \{D \in U \mid D \text{ intersects the boundary of } R_1 \cup R_2\}$ satisfies Property 2 as well.

When the auxiliary table entries $AT_{S,I}(S, *)$ have been computed, the algorithm obtains $T_S(I)$ by taking the minimum weight set obtainable as $AT_{S,I}(S, J) \cup (\mathcal{D}^{\partial S}_{=j} \setminus J)$. Since the table entry $AT_{S,I}(S, J)$ leading to the minimum satisfies Property 2, the resulting table entry $T_S(I)$ satisfies Property 1.

In the end, the algorithm outputs a union of pseudocovers $T_S(\emptyset)$ in all relevant squares $S$ without parent. As every intersection of two disks is contained in some relevant square without parent, the algorithm always outputs a vertex cover of $\mathcal{D}$. □

**3.2. Analysis of approximation ratio.** Let $\mathcal{C}$ be any optimal vertex cover of $\mathcal{D}$. Every disk hits at most one vertical line on its level and at most one horizontal line on its level. For any pair of values $r$ and $s$, $0 \le r, s < k$, let $\mathcal{C}(r, s)$ be the set of all disks in $\mathcal{C}$ that hit a vertical line on their level whose index modulo $k$ equals $r$ or a horizontal line on their level whose index modulo $k$ equals $s$. Note that there must be a value of $r$ such that the total weight of disks in $\mathcal{C}$ that hit a vertical line on their level whose index modulo $k$ equals $r$ is at most $\frac{1}{k}w(\mathcal{C})$. An analogous argument shows that there is a value of $s$ with the corresponding property for horizontal lines. Therefore, there exist values of $r$ and $s$ such that the total weight of $\mathcal{C}(r, s)$ is at most $\frac{2}{k}$ times the weight of $\mathcal{C}$. Consider the subdivision of the plane that results from this choice of $r$ and $s$.

Let $\mathcal{R}$ be the set of all relevant squares. For any $j$-square $S$, let $\mathcal{C}(S)$ denote the disks in $\mathcal{C}$ that intersect $S$ and that are on level $j$. Note that $\mathcal{C} = \bigcup_{S \in \mathcal{R}} \mathcal{C}(S)$ but the sets $\mathcal{C}(S)$ and $\mathcal{C}(S')$ for $S \ne S'$ need not be disjoint.

LEMMA 3.2. *We have* $\sum_{S \in \mathcal{R}} w(\mathcal{C}(S)) \le (1 + \frac{6}{k})w(\mathcal{C})$.

*Proof.* The only disks in $\mathcal{C}$ that are counted more than once in the sum on the left-hand side are those that intersect several squares on their level. However, any disk can intersect at most 4 squares on its level. Furthermore, only disks in $\mathcal{C}(r, s)$ can intersect more than 1 square on their level. Thus, only disks of total weight $w(\mathcal{C}(r, s)) \le \frac{2}{k}w(\mathcal{C})$ are counted multiple times, and each disk is counted at most four times on the left-hand side, while it is counted once in $w(\mathcal{C})$. Thus $\sum_{S \in \mathcal{R}} w(\mathcal{C}(S))$ can exceed $w(\mathcal{C})$ by at most $3 \cdot \frac{2}{k}w(\mathcal{C})$, establishing the claimed inequality. □

Lemma 3.2 shows that the sum of the weights of the sets $\mathcal{C}(S)$ is only slightly larger than the weight of $\mathcal{C}$, although certain disks are counted several times in this sum. The following lemma shows that the weight of the vertex cover output by our algorithm does not exceed this sum. Intuitively, the lemma means that, on average, for each square $S$ on some level $j$ the weight of the set of disks from $\mathcal{D}^S_{=j}$ chosen by the algorithm does not exceed the weight of the disks chosen from $\mathcal{D}^S_{=j}$ in the optimal solution.

LEMMA 3.3. *Let $A$ be the vertex cover output by the algorithm. Then* $w(A) \le \sum_{S \in \mathcal{R}} w(\mathcal{C}(S))$.

*Proof.* For any relevant $j$-square $S$ or any rectangle $R$ of child squares of $S$, let $\mathcal{C}^S$ and $\mathcal{C}^R$ be the set of all disks in $\mathcal{C}$ that intersect $S$ and $R$, respectively. Define $\mathcal{C}^S_{<j}$, $\mathcal{C}^S_{\le j}$, $\mathcal{C}^S_{=j}$, etc. as usual. Observe that $\mathcal{C}(S) = \mathcal{C}^S_{=j}$. We claim that, after $T_S$ has been computed, we have

$$w(T_S(\mathcal{D}^S_{<j} \setminus \mathcal{C}^S_{<j})) \le \sum_{S' : S' \prec S} w(\mathcal{C}(S')) , \tag{3.1}$$

where $S' \prec S$ means that $S'$ is a relevant square that is contained in $S$. Note that $S \prec S$.

The proof is by induction on the number of relevant squares that have been processed by the algorithm. Assume that the algorithm is about to process the relevant square $S$ and that (3.1) holds for all squares that have been processed before $S$. One of the independent sets $I$ in $\mathcal{D}^S_{<j}$ enumerated by the algorithm is equal to $\mathcal{D}^S_{<j} \setminus \mathcal{C}^S_{<j}$. Consider that set $I$ in the following.

We turn to the computation of the auxiliary table entries $AT_{S,I}(R, J)$, where $R = S'_{g_1\cdots g_2,h_1\cdots h_2}$ is a rectangle of subsquares of $S$. We claim that when the table entries $AT_{S,I}(R, *)$ are computed, we have

$$w(AT_{S,I}(R,J)) \ \le \ w(\{D \in \mathcal{C}^R_{=j} \mid D \text{ is contained in } R\}) + \textstyle\sum_{S':S'\prec R, S'\neq S} w(\mathcal{C}(S'))$$
$$\text{for } J = \{D \in \mathcal{D}^R_{=j} \setminus \mathcal{C} \mid D \text{ intersects the boundary of } R\} = \mathcal{D}^{\partial R}_{=j} \setminus \mathcal{C}. \tag{3.2}$$

Note that the sum in (3.2) is over all relevant $j'$-squares, $j' > j$, that are contained in $R$, and that the sum does *not* include the term $w(\mathcal{C}(S))$ even if $R = S$.

First, consider the computation of $AT_{S,I}(S'_{g,h}, *)$ by the algorithm of Figure 3.1. In one of the iterations of the for-loop, the set $U$ is equal to $Q \setminus \mathcal{C} = \mathcal{D}^{S'_{g,h}}_{=j} \setminus \mathcal{C}$. For this set $U$, the table entry $T_{S'_{g,h}}(I' \cup U) = T_{S'_{g,h}}(\mathcal{D}^{S'_{g,h}}_{\le j} \setminus \mathcal{C}^{S'_{g,h}}_{\le j})$ is looked up. Since (3.1) holds for $T_{S'_{g,h}}$, we get that $w(T_{S'_{g,h}}(I' \cup U)) \le \sum_{S':S'\prec S'_{g,h}} w(\mathcal{C}(S'))$. Hence, the set

$$X = T_{S'_{g,h}}(I' \cup U) \cup \{D \in \mathcal{D}^{S'_{g,h}}_{=j} \setminus U \mid D \text{ is contained in } S'_{g,h}\}$$

stored in $AT_{S,I}(S'_{g,h}, J)$ for

$$\begin{aligned} J &= \{D \in U \mid D \text{ intersects the boundary of } S'_{g,h}\} \\ &= \{D \in \mathcal{D}^{S'_{g,h}}_{=j} \setminus \mathcal{C} \mid D \text{ intersects the boundary of } S'_{g,h}\} \end{aligned}$$

has weight at most

$$\begin{aligned} &\sum_{S':S'\prec S'_{g,h}} w(\mathcal{C}(S')) + w(\{D \in \mathcal{D}^{S'_{g,h}}_{=j} \setminus U \mid D \text{ is contained in } S'_{g,h}\}) \\ = &\sum_{S':S'\prec S'_{g,h}} w(\mathcal{C}(S')) + w(\{D \in \mathcal{C}^{S'_{g,h}}_{=j} \mid D \text{ is contained in } S'_{g,h}\}). \end{aligned}$$

From this we see that (3.2) is satisfied for $R = S'_{g,h}$.

Next, consider the combination of table entries $AT_{S,I}(R_1, *)$ and $AT_{S,I}(R_2, *)$ to obtain table entries $AT_{S,I}(R_1 \cup R_2, *)$ using the algorithm of Figure 3.2. In one of the iterations of the for-loop, the set $U$ is equal to the set

$$Q\setminus\mathcal{C} = \{D \in \mathcal{D}^{R_1\cup R_2}_{=j}\setminus\mathcal{C} \mid D \text{ intersects the boundary of } R_1 \text{ or } R_2\} = (\mathcal{D}^{\partial R_1}_{=j} \cup \mathcal{D}^{\partial R_2}_{=j})\setminus\mathcal{C}.$$

For this set $U$, the table entries $AT_{S,I}(R_i, U_i)$ are looked up for $i = 1, 2$, where $U_i = \{D \in U \mid D \text{ intersects the boundary of } R_i\}$. Thus, we have $U_i = \mathcal{D}^{\partial R_i}_{=j} \setminus \mathcal{C}$ and we know that (3.2) holds for table entries $AT_{S,I}(R_i, U_i)$. Then the weight of the set

$$\begin{aligned}X &= AT_{S,I}(R_1,U_1)\cup AT_{S,I}(R_2,U_2)\cup\{D\in(\mathcal{D}^{\partial R_1}_{=j}\cup\mathcal{D}^{\partial R_2}_{=j})\setminus U \mid D \text{ is contained}\\ &\qquad \text{in } R_1\cup R_2\}\\ &= AT_{S,I}(R_1,U_1)\cup AT_{S,I}(R_2,U_2)\cup\{D\in\mathcal{C}\cap(\mathcal{D}^{\partial R_1}_{=j}\cup\mathcal{D}^{\partial R_2}_{=j}) \mid D \text{ is contained}\\ &\qquad \text{in } R_1\cup R_2\}\\ &= AT_{S,I}(R_1,U_1)\cup AT_{S,I}(R_2,U_2)\cup\{D\in\mathcal{C}^{\partial R_1}_{=j}\cup\mathcal{C}^{\partial R_2}_{=j} \mid D \text{ is contained in } R_1\cup R_2\}\\ &= AT_{S,I}(R_1,U_1)\cup AT_{S,I}(R_2,U_2)\cup\{D\in\mathcal{C}^{\partial R_1}_{=j}\cap\mathcal{C}^{\partial R_2}_{=j} \mid D \text{ is contained in } R_1\cup R_2\}\\ &= AT_{S,I}(R_1,U_1)\cup AT_{S,I}(R_2,U_2)\cup\{D\in\mathcal{C}^{\partial R_1\cap\partial R_2}_{=j} \mid D \text{ is contained in } R_1\cup R_2\}\end{aligned}$$

is at most

$$\begin{aligned}&w(\{D\in\mathcal{C}^{R_1}_{=j}\mid D \text{ is contained in } R_1\})+\sum_{S':S'\prec R_1}w(\mathcal{C}(S'))\\ &\quad+w(\{D\in\mathcal{C}^{R_2}_{=j}\mid D \text{ is contained in } R_2\})+\sum_{S':S'\prec R_2}w(\mathcal{C}(S'))\\ &\quad+w(\{D\in\mathcal{C}^{\partial R_1\cap\partial R_2}_{=j}\mid D \text{ is contained in } R_1\cup R_2\})\\ &=\left(\sum_{S':S'\prec(R_1\cup R_2),S'\neq S}w(\mathcal{C}(S'))\right)+w(\{D\in\mathcal{C}^{R_1\cup R_2}_{=j}\mid D \text{ is contained in } R_1\cup R_2\}).\end{aligned}$$

The set $X$ is stored in $AT_{S,I}(R_1\cup R_2,J)$ for $J=\{D\in U\mid D$ intersects the boundary of $R_1\cup R_2\}=\{D\in\mathcal{D}^{R_1\cup R_2}_{=j}\setminus\mathcal{C}\mid D$ intersects the boundary of $R_1\cup R_2\}$ provided its weight is smaller than that of the previously stored set. This shows that (3.2) holds for $R=R_1\cup R_2$ when the algorithm of Figure 3.2 terminates. Thus, by induction we see that all table entries $AT_{S,I}(R,J)$ satisfy (3.2).

This implies that for $J=\mathcal{D}^{\partial S}_{=j}\setminus\mathcal{C}$, the table entry $AT_{S,I}(S,J)$ has weight at most $w(\{D\in\mathcal{C}^S_{=j}\mid D$ is contained in $S\})+\sum_{S':S'\prec S,S'\neq S}w(\mathcal{C}(S'))$. Note that $\mathcal{D}^{\partial S}_{=j}\setminus J=\mathcal{C}^{\partial S}_{=j}$. The set $AT_{S,I}(S,J)\cup(\mathcal{D}^{\partial S}_{=j}\setminus J)$, which is one of the candidates for the table entry $T_S(I)$, has weight at most $w(\mathcal{C}(S))+\sum_{S':S'\prec S,S'\neq S}w(\mathcal{C}(S'))$. Thus, we get that (3.1) holds for $T_S$ as well, and the inductive step with respect to the tables $T_S$ is established.

Finally, let $\mathcal{R}_0$ be the set of all relevant squares without parent. The algorithm outputs $\bigcup_{S\in\mathcal{R}_0}T_S(\emptyset)$ as a solution. For any relevant $j$-square $S\in\mathcal{R}_0$, we have $\mathcal{C}^S_{<j}=\emptyset$. Thus we get from (3.1) that $\sum_{S\in\mathcal{R}_0}w(T_S(\emptyset))\leq\sum_{S\in\mathcal{R}}w(\mathcal{C}(S))$. ☐

Combining these lemmas, we get that the algorithm outputs a vertex cover whose weight is at most a factor of $1+\frac{6}{k}$ larger than the weight of the optimal vertex cover. Furthermore, by a similar analysis as in the case of MWIS, the running-time of the algorithm is bounded by $n^{O(k^2)}$. Thus we obtain our second main theorem.

THEOREM 3.4. *There is a PTAS for MWVC in disk graphs, provided that a disk representation of the graph is given. The running-time for achieving approximation ratio* $1+\varepsilon$ *is* $n^{O(1/\varepsilon^2)}$ *for a disk graph with* $n$ *disks.*

## 4. Extension to other geometric intersection graphs.

In the previous sections we have presented PTASs for MWIS and MWVC in the intersection graphs of disks with arbitrary diameters. Our approach does not make use of any specific properties of disks; it is required only that the given geometric objects can be partitioned into levels such that only a constant number (for fixed $k$) of disjoint objects of level smaller than $j$ can intersect a square on level $j$. Therefore, the same approach can be used for other geometric objects such as squares or regular polygons. We can also deal with rectangles if the ratio between the height and the width does not differ by more than a constant factor between different rectangles, because it suffices to scale the input along one axis so that the resulting rectangles are approximately squares.

Furthermore, the approach works for geometric objects in any $d$-dimensional space provided that $d$ is a constant. The space is partitioned into $d$-dimensional cubes on each level, and instead of removing objects (in the case of MWIS) that hit certain horizontal or vertical lines, we remove objects that hit certain hyperplanes.

More specifically, to obtain PTASs for MWIS and MWVC in the intersection graphs of geometric objects in $d$ dimensions, the following conditions are sufficient:

(i) $d$ is a constant.

(ii) For each object $i$, a $d$-dimensional ball $B_i$ that contains $i$ can be determined in polynomial time.

(iii) Let level $j$ contain all given objects whose balls $B_i$ have diameter $d_i$ satisfying $(k+1)^{-j} \geq d_i > (k+1)^{-(j+1)}$. Then the number of disjoint objects of level smaller than $j$ that can intersect a $d$-dimensional cube with side length $k(k+1)^{-j}$ must be bounded by a constant (for fixed $k$), and the number of disjoint objects of level $j$ that can intersect the boundary of a $d$-dimensional hyperrectangle with sides of length at most $k(k+1)^{-j}$ must be bounded by a constant (for fixed $k$).

(iv) One can decide in polynomial time whether two of the given objects intersect and whether an object intersects an arbitrary cube.

For example, our approach yields a PTAS for MWIS or MWVC in the intersection graphs of $n$ balls in $d$-dimensional space with running-time $n^{O(1/\varepsilon^{2d-2})}$ for any constant $d$.

## 5. Conclusion and open problems.

We have presented the first known PTASs for MWIS and MWVC in the intersection graphs of disks. Our algorithms partition the given disks into levels and apply a shifting strategy on all levels simultaneously. The PTASs can be generalized to other "disk-like" geometric objects in $d$ dimensions, achieving running-time $n^{O(1/\varepsilon^{2d-2})}$ for any constant $d$. Another PTAS for MWIS in disk graphs, based on ideas similar to ours but using shifted quadtrees in the recursive subdivision strategy, was discovered recently by Chan [8]. Chan's algorithm achieves running-time $n^{O(1/\varepsilon)}$ for MWIS in disk graphs and $n^{O(1/\varepsilon^{d-1})}$ for the $d$-dimensional generalization. MWVC is not considered in Chan's paper.

Our approximation schemes use a partitioning of the plane into squares on each level, and this works only if the ratio of the height to the width is roughly the same for all given geometric objects. It is not clear whether the approach can be extended to the intersection graphs of arbitrary axis-parallel rectangles, for example. For computing a maximum independent set among $n$ given rectangles, an $O(\log n)$-approximation algorithm was presented by Agarwal, van Kreveld, and Suri [1]. Berman et al. [4] improved upon this result and gave a family of approximation algorithms with approximation ratio $1 + \frac{\log n}{c}$ for *any* positive constant $c$. It is an open problem to devise an approximation algorithm with constant approximation ratio or even a PTAS for this problem, or to provide evidence that MWIS in intersection graphs of arbitrary rectangles is substantially harder to approximate than in intersection graphs of squares or disks.

Concerning disk graphs, it would be interesting to see whether one can also find a PTAS for the minimum dominating set problem, where the goal is to select a minimum number of disks such that each given disk is either selected or intersects a disk that is selected. For planar graphs and for unit disk graphs, PTASs for the minimum dominating set problem have been found using the shifting strategy [2, 18], but we have not yet been able to adapt the approach of the present paper to the minimum dominating set problem.

The PTASs for disk graphs require that the disk representation of the graph is given as part of the input. It would be interesting to determine whether a PTAS can be obtained even in the case without given representation. In this context we note that for the maximum clique problem in unit disk graphs, which can be solved in polynomial time [9], an exact algorithm that does not need the representation has recently been found by Raghavan and Spinrad [26]. This is somewhat surprising since it is $\mathcal{NP}$-hard to determine whether a given graph is a unit disk graph [7]. In fact, the algorithm by Raghavan and Spinrad is *robust* in the sense that for any given graph $G$, the algorithm either finds a maximum clique in $G$ or asserts correctly that $G$ is not a unit disk graph. Robust algorithms solving MWIS optimally in certain classes of graphs that are characterized by forbidden subgraphs have been presented by Brandstädt [5]. The concept of robustness can be applied to approximation algorithms for graph problems by calling an algorithm a *robust $\rho$-approximation algorithm* for a graph class $\mathcal{C}$ if, for any input graph $G$, the algorithm either outputs a solution that is within a factor $\rho$ of the optimal solution or asserts correctly that $G$ is not a member of $\mathcal{C}$. Recently, a robust PTAS that does not require the disk representation as part of the input has been obtained for MWIS in unit disk graphs by Nieberg, Hurink, and Kern [25].

# QUANTUM ALGORITHMS FOR ELEMENT DISTINCTNESS*

HARRY BUHRMAN†, CHRISTOPH DÜRR‡, MARK HEILIGMAN§, PETER HØYER¶, FRÉDÉRIC MAGNIEZ‖, MIKLOS SANTHA‖, AND RONALD DE WOLF†

**Abstract.** We present several applications of quantum amplitude amplification for deciding whether all elements in the image of a given function are distinct, for finding an intersection of two sorted tables, and for finding a triangle in a graph. Our techniques generalize and improve those of Brassard, Høyer, and Tapp [*ACM SIGACT News*, 28 (1997), pp. 14–19]. This shows that in the quantum world element distinctness is significantly easier than sorting, in contrast to the classical world.

**Key words.** quantum query complexity, element distinctness, collision problem

**AMS subject classification.** 68Q25

**DOI.** 10.1137/S0097539702402780

**1. Introduction.** In the last decade, quantum computing has become a prominent and promising area of theoretical computer science. Realizing this promise will require two things: actually building a quantum computer and discovering tasks where a quantum computer is significantly faster than a classical computer. Here we are concerned with the second issue. Few good quantum algorithms are known to date. The two main examples are Shor's algorithm for factoring [23], which achieves an exponential speed-up over the best known classical factoring algorithms, and Grover's search algorithm [15], which achieves a quadratic speed-up over classical search algorithms. Whereas the first so far has remained a seminal but somewhat isolated result, the second has been applied as a building block in quite a few other quantum algorithms [6, 8, 9, 10, 21, 20, 7, 12].

The security of the widely used cryptosystem RSA is based on the assumption that it is hard to factor integers. Shor's algorithm solves precisely this task. In the same vein, the security of digital signatures is based on the assumption that it is difficult to find two items that map to the same value for some particular function. This motivates the research on the quantum complexity of this task. We define different variants of this problem. Though we do not improve the bounds for the following problem, we define it first to start our explanation. We use $[N]$ to denote $\{1, \ldots, N\}$.

Collision Problem

**input** $f : [N] \to [M]$ which is 2-to-1, i.e., $\forall i \in [N] \exists! j \in [N],\ i \neq j : f(i) = f(j)$

**output** $i, j \in [N]$ with $i \neq j$ and $f(i) = f(j)$

**complexity** Classically, the bounded-error query complexity is $\Theta(N^{1/2})$. For a quantum computer the bounded-error query complexity is $\Theta(N^{1/3})$: In 1997 Brassard, Høyer, and Tapp [8] gave a bounded-error quantum algorithm using $O(N^{1/3})$ queries to $f$, and in 2002 Aaronson and Shi [1] showed the matching lower bound.

In the following problem we remove the assumption about the input. The birthday paradox gives a simple relation between both problems. A random subset of size $\sqrt{N}$ of the domain of any 2-to-1 function contains with high probability a collision pair. Therefore any bounded-error algorithm for Element Distinctness using $O(N^{\alpha})$ queries implies a bounded-error algorithm for the Collision Problem using $O(N^{\alpha/2})$ queries.

Element Distinctness

**input** $f : [N] \to [M]$

**output** $i, j \in [N]$ with $i \neq j$ and $f(i) = f(j)$, or "all distinct" if $f$ is injective

**complexity** We present a bounded-error quantum algorithm which makes $O(N^{3/4})$ queries. It dates from early 2000 and first appeared in [11]. However, recently the bounded-error quantum query complexity was shown to be $\Theta(N^{2/3})$: The lower bound follows from Aaronson and Shi [1] by the observation above, and an algorithm matching this bound was found in 2003 by Ambainis [3] using a quantum walk. The classical bounded-error query complexity is $\Theta(N)$ by a trivial reduction from the OR-problem: For an OR-instance $x \in \{0,1\}^N$ we define the function $f : [N+1] \to [N+1]$, where $f(N+1) = 0$ and for all $i \in [N]$ $f(i) = (1 - x_i)i$. Now $\mathrm{OR}(x) = 1$ if and only if $f$ contains a collision pair.

The element distinctness problem has been well studied classically [24, 18, 14, 5]. It is particularly interesting because its classical complexity is related to that of sorting, which is well known to require $N \log N + \Theta(N)$ comparisons in the classical world. If we sort $f$, we can decide element distinctness by going through the sorted list once, which gives a classical upper bound of $N \log N + O(N)$ comparisons. Conversely, element distinctness requires $\Omega(N \log N)$ comparisons in the case of classical bounded-error algorithms (even in a much stronger model [14]), so sorting and element distinctness are essentially equally hard classically. On a quantum computer, the best known upper bound for sorting is $0.53\, N \log N$ comparisons [13], and such a linear speed-up is best possible: quantum sorting requires $\Omega(N \log N)$ comparisons, even if one allows a small probability of error [16]. Accordingly, our $O(N^{3/4} \log N)$ upper bound shows that element distinctness is significantly easier than sorting for a quantum computer, in contrast to the classical case.

In this paper we also give algorithms for related problems. Typically, web search engines like Google associate to every word a list of pages containing it (sorted in order of its page rank) and when the query is "Rolling Stones," for example, then the search engine must output the intersection of the lists associated to the words "Rolling" and "Stones." Now imagine a search engine implemented on a quantum computer. This motivates the following problem.

List Intersection

**input** $f, g : [N] \to [M]$ each is monotone increasing

**output** $i, j \in [N]$ with $i \neq j$ and $f(i) = f(j)$, or "lists disjoint" if the images of $f$ and $g$ are disjoint

**complexity** We present a bounded-error quantum algorithm which makes $O(\sqrt{N} c^{\log^* N})$ queries to $f$ for some constant $c > 1$. A trivial lower bound $\Omega(\sqrt{N})$ can be obtained by a reduction from the OR-problem: given an OR-instance $x \in \{0,1\}^N$, define $f, g : [N] \to [2N+1]$ by $f(i) = 2i + 1$ and $g(i) = 2i + x_i$ for all $i \in [N]$. Then $f$ and $g$ are ordered, and $\mathrm{OR}(x) = 1$ iff the List Intersection problem has a solution. The same reduction shows that the classical bounded-error query complexity is $\Theta(N)$.

The function $\log^\star(N)$ is defined as the minimum number of iterated applications of the logarithm function necessary to obtain a number less than or equal to 1: $\log^\star(N) = \min\{i \geq 0 \mid \log^{(i)}(N) \leq 1\}$, where $\log^{(i)} = \log \circ \log^{(i-1)}$ denotes the $i$th iterated application of log, and $\log^{(0)}$ is the identity function. Even though $c^{\log^\star(N)}$ is exponential in $\log^\star(N)$, it is still very small in $N$, in particular $c^{\log^\star(N)} \in o(\log^{(i)}(N))$ for any constant $i \geq 1$.

To a function $f : [N] \to [M]$ we can associate a *collision graph* $G(V, E)$ with $V = [N]$ and $(i, j) \in E$ if $i \neq j$ and $f(i) = f(j)$. The Element Distinctness problem simply consists of finding an edge in $G$. An interesting problem is to ask whether $G$ contains some fixed subgraph. A simple, yet nontrivial subgraph is the triangle, i.e., the complete graph on three vertices.

Triangle Finding

**input** the symmetric adjacency matrix $M : [n] \times [n] \to \{0,1\}$ of a graph with $m$ edges

**output** $u, v, w \in [N]$ such that $M(u,v) = M(v,w) = M(w,u) = 1$, or "failure" if the graph contains no triangle

**complexity** We present a bounded-error quantum algorithm which needs $O(n + \sqrt{nm})$ queries. A better algorithm has been found in 2003, with $O(n^{1.3})$ bounded-error query quantum complexity [19], while Yao [25] showed a lower bound of $\Omega(n^{2/3} \log^{1/6} n)$. Classically a simple reduction from the OR-problem shows that the bounded-error query complexity is $\Theta(n^2)$, even if $m = O(n)$.

## 2. Preliminaries.

We assume the reader is familiar with the formalism of quantum computing; otherwise we refer to [22]. The quantum ingredient of our algorithms is *amplitude amplification* [7], which generalizes quantum search [15]. The essence of amplitude amplification can be summarized by the following theorem.

Theorem 2.1 (amplitude amplification). *There exists a quantum algorithm QSearch with the following property. Let $\mathcal{A}$ be any quantum algorithm that uses no measurements and that maps $|0\rangle$ to a superposition $\sum_{x \in X} \alpha_x |x\rangle$ for some set $X$. Let $g : X \to \{0,1\}$ be a function testing whether a basis state represents a* solution *or not. Let $p$ be the success probability of $\mathcal{A}$, i.e., $p^2 = \sum_{x : g(x)=1} |\alpha_x|^2$. Let $S_g$ be an operator implementing $g$ such that $S_g|x\rangle = (-1)^{g(x)}|x\rangle$ for every $x \in X$. Then algorithm QSearch finds a solution using an expected number of $O(1/\sqrt{p})$ applications of $\mathcal{A}$, $\mathcal{A}^{-1}$, and $S_g$ if $p > 0$, and otherwise runs forever.*

Note that when an algorithm $\mathcal{A}$ does make measurements during its computation there is a standard trick that transforms it into an equivalent algorithm $\mathcal{A}'$ that does not. We replace every measurement with an operator writing the value, which would be the result of the measurement, in a new register, which initially is all zero. In the rest of the computation, every computation depending on the result of the measurement will depend rather on the content of this register.

QSearch works by iterating the unitary transformation $Q = -\mathcal{A}S_0\mathcal{A}^{-1}S_g$ a number of times, starting with initial state $\mathcal{A}|0\rangle$. The operator $S_0$ is defined as $S_0|0\rangle = -|0\rangle$ and $S_0|x\rangle = |x\rangle$ for all $x \neq 0$. The analysis of [7] shows that a measurement after $\Theta(1/\sqrt{p})$ iterations of $Q$ yields a solution with probability close to 1. The algorithm QSearch does not need to know the value of $p$ in advance, but if $p$ is known, then a slight modification finds a solution *with certainty* using $O(1/\sqrt{p})$ applications of $\mathcal{A}$, $\mathcal{A}^{-1}$, and $S_g$.

Grover's algorithm for searching a space of $N$ items is a special case of amplitude amplification, where $\mathcal{A}$ is the Hadamard transform on each qubit. This $\mathcal{A}$ has probability $p \geq 1/N$ of finding a solution (if there is at least one), so amplitude amplification implies an $O(\sqrt{N})$ quantum algorithm for searching the space. We refer to this process as "quantum searching."

## 3. Element distinctness.

```
ALGORITHM: FIND A COLLISION PAIR IN $f : [N] \to [M]$
  1. Partition the domain of $f$ into disjoint sets $S_1, \dots, S_{\sqrt{N}}$ of size $O(\sqrt{N})$ each.
  2. Apply amplitude amplification to the following inner block:
     (a) Select a random subset $S_k$ of the partition.
     (b) Query all values $f(i)$ for $i \in S_k$, and build a binary search tree over the
         set $f(S_k) := \{f(i) : i \in S_k\}$. If $S_k$ contains a collision pair, output it.
     (c) Otherwise search $j \in [N]\backslash S_k$ such that $f(j) \in f(S_k)$. Use the quantum
         search procedure which succeeds with probability at least 1/2 provided
         $S_k$ contains one element of a collision pair. In case of success, output
         the collision pair.
```

THEOREM 3.1. *If $f$ has a collision pair $i, j$, then the previous algorithm finds it after an expected number of $O(N^{3/4})$ queries to $f$.*

*Proof.* With probability at least $1/\sqrt{N}$, step 2(a) selects a subset containing $i$ or $j$. Suppose this is the case. Then either the set contains a collision pair or it does not. If it does, then step 2(b) finds it, and if it does not, then with probability at least 1/2, step 2(c) finds a collision pair. Therefore amplitude amplification will iterate the inner loop $O(N^{1/4})$ expected times until it succeeds. Steps 2(b) and 2(c) each use $O(\sqrt{N})$ queries, from which we conclude the claimed complexity. ∎

A weaker model is the comparison model, where we are allowed to ask query $f(i) \leq f(j)$ only for given indices $i, j$, rather than for the actual values $f(i), f(j)$. The previous algorithm can be adapted to that model with the price of an $O(\log N)$ factor in steps 2(b) and 2(c). In contrast, for classical (exact or bounded-error) algorithms, element distinctness is as hard as sorting and requires $\Theta(N \log N)$ comparisons.

## 4. List intersection.

We are given two monotone increasing functions $f, g : [N] \to [M]$ and search for $i, j \in [N]$ such that $f(i) = g(j)$. A simple algorithm would be to make a quantum search for $i \in [N]$ such that there exists $j \in [N]$ with $f(i) = g(j)$. The quantum search of $i$ will need $O(\sqrt{N})$ iterations, and the binary search of $j$ will need $O(\log N)$ queries. This gives a bounded-error quantum algorithm using $O(\sqrt{N} \log N)$ queries. We now show how to get rid of most of the log factor by exploiting the fact that both functions are monotone increasing.

Our quantum algorithm solves the problem using $O\big(\sqrt{N} c^{\log^\star(N)}\big)$ comparisons for some constant $c > 0$. We define a set of subproblems such that the original problem

$(f, g)$ contains a collision pair if and only if at least one of the subproblems contains one. We then solve the original problem by running the subproblems in quantum parallel and applying amplitude amplification.

Let $1 \leq r < N$ be an integer. For the purpose of defining subproblems we extend the functions $f$ and $g$ to the domain $[1, N+r]$, mapping $f(N+i) = \max\{f(N), g(N)\}+i$ and $g(N+i) = f(N+i)+r$ for all $1 \leq i \leq r$ and extending at the same time the range of $f$ and $g$ to $[M+2r]$. We also define the *insertion point* of some integer $x < h(N+1)$ in a monotone increasing function $h : [N+r] \rightarrow [M+2r]$ as the smallest index $i$ such that $h(i) \geq x$.

We define $2\left\lceil \frac{N}{r} \right\rceil$ subproblems as follows. For each $0 \leq i \leq \lceil N/r \rceil - 1$, consider the subproblem $(f_i, g_i')$, where $f_i$ denotes the restriction of $f$ to subdomain $[ir+1, (i+1)r]$ and $g_i'$ denotes the restriction of $g$ to $[j, j+r-1]$, where $j$ is the insertion point of $f(ir+1)$ in $g$.

Similarly, for each $0 \leq j \leq \lceil N/r \rceil - 1$, consider the subproblem $(f_j', g_j)$, where $g_j$ denotes the restriction of $g$ to $[jr+1, (j+1)r]$ and $f_j'$ denotes the restriction of $f$ to $[i, i+r-1]$, where $i$ is the insertion point of $g(jr+1)$ in $f$.

Lemma 4.1. *If $i, j \in [N]$ is a collision pair for $(f, g)$, then it is also a collision pair for one of the subproblems.*

*Proof.* Let $k = \lfloor i/r \rfloor + 1$ and let $k'$ be the insertion point of $f(k)$ in $g$. If $j \in [k', k'+r-1]$, then $(i, j)$ is also a collision pair for the subproblem $(f_k, g_k')$. However, if $j \notin [k', k'+r-1]$, then let $\ell = \lfloor j/r \rfloor + 1$. We have $f(k) \leq g(\ell) \leq f(i)$. Therefore the insertion point $\ell'$ of $g(\ell)$ in $f$ satisfies $i \in [\ell', \ell'+r-1]$, from which we conclude that $(i, j)$ is a collision pair for the subproblem $(f_{\ell}', g_{\ell})$. $\square$

Theorem 4.2. *There exists a quantum algorithm that outputs a collision pair between $f$ and $g$ with probability at least $\frac{2}{3}$ provided one exists, using $O\left(\sqrt{N} c^{\log^\star(N)}\right)$ queries, for some constant $c > 1$.*

*Proof.* Let $T(N)$ denote the worst-case number of queries required if $f$ and $g$ have domain of size $N$. We show that

$$T(N) \leq c' \sqrt{\frac{N}{r}} \left(\lceil \log(N+1) \rceil + T(r)\right) \tag{4.1}$$

for some (small) constant $c'$. Let $0 \leq i \leq \lceil N/r \rceil - 1$ and consider the subproblem $(f_i, g_i')$. To find the insertion point of $f(\lfloor i/r \rfloor + 1)$ in $g$ we need $\lceil \log(N+1) \rceil$ queries by using binary search. Then we need at most $T(r)$ additional queries to find a collision pair for $(f_i, g_i')$. There are $2\left\lceil \frac{N}{r} \right\rceil$ subproblems, so by applying amplitude amplification we can find a collision pair among any one of them with probability at least $\frac{2}{3}$, provided there is one, using the number of queries claimed in (4.1).

We pick $r = \lceil \log^2(N) \rceil$. Since $T(r) \geq \Omega(\sqrt{r}) = \Omega(\log N)$, (4.1) implies

$$T(N) \leq c'' \sqrt{\frac{N}{r}} T(r) \tag{4.2}$$

for some constant $c''$. Furthermore, our choice of $r$ implies that the depth of the recursion defined by (4.2) is on the order of $\log^\star(N)$, so unfolding the recursion gives the theorem. $\square$

**5. Triangle finding.** Finally we consider a related search problem. Consider an undirected graph $G = (V, E)$ on $|V| = n$ nodes with $|E| = m$ edges. There are $N = \binom{n}{2}$ edge slots in $E$, which we can query in a black box fashion (see also [10, section 7]). The goal is now to find distinct vertices $a, b, c \in V$ such that $(a, b)$, $(a, c)$,

$(b,c) \in E$. Since there are $\binom{n}{3}$ triples $a,b,c$, and we can decide whether a given triple is a triangle using three queries, we can use Grover's algorithm to find a triangle in $O(n^{3/2})$ queries. Below we give an algorithm that has the same complexity for dense graphs $m = O(n^2)$ but is more efficient for sparse graphs. In particular when $m = O(n)$, then the algorithm uses only $O(n)$ queries, while any classical bounded-error algorithm needs $\Omega(n^2)$ queries by a sensitivity argument for distinguishing the star graph, with the same graph augmented by a single edge.

```
ALGORITHM: FIND A TRIANGLE
  1. Use the bounded-error quantum counting procedure from [7, Theorem 18] to
     get a factor-2 estimation $m'$ of the number of edges $m$, with $O(n)$ expected
     queries.
  2. Apply amplitude amplification to the following inner block, interrupting it
     after $O(\sqrt{m'})$ calls to the inner block.
     (a) Use quantum search to find an edge $(a,b) \in E$ among all $\binom{n}{2}$ potential
         edges, using at most $O(n/\sqrt{m'})$ queries.
     (b) Use quantum search to find a node $c \in V$ such that $a,b,c$ is a triangle,
         using at most $(n)$ queries.
  3. Repeat until a triangle is found.
```

Quantum search of an edge $(a,b) \in E$ succeeds after $O(n/\sqrt{m})$ expected queries. Since amplitude amplification forbids any observation in the inner block, we need step 2 to get an estimation of $m$, which determines the number of queries after which step 2(a) will be interrupted.

THEOREM 5.1. *If the graph contains a triangle, then the previous algorithm finds one after $O(n + \sqrt{nm})$ expected queries.*

*Proof.* Suppose the graph contains a triangle. Let an edge be *good* if it is part of a triangle. Then step 2(a) finds one with probability at least $1/2m$. Given this event, step 2(b) finds a triangle with probability at least $1/2$. Now suppose that step 1 found the correct estimation of $m$. Therefore due to the amplitude amplification step 2 succeeds with probability at least $1/2$.

Finally the expected number of repetitions generated by step 3 is constant.

Each iteration costs $O(n + \sqrt{nm'})$ queries, where $m'$ is the random outcome of step 2 with expectation $m$. This establishes the claimed complexity. ∎

## 6. Concluding remarks.

An interesting related problem that is still wide open is the issue of *time-space tradeoffs* for element distinctness. Such tradeoffs have been studied for classical algorithms by Yao [24], Ajtai [2], Beame, Saks, Sun, and Vee [5], and others. In particular, Yao shows that the time-space product of any classical deterministic comparison-based branching program solving element distinctness satisfies $TS \geq \Omega(N^{2-\varepsilon(N)})$, where $\varepsilon(N) = 5/\sqrt{\ln N}$. An upper bound $TS = O((N \log N)^2)$ is achievable classically.

Ignoring logarithmic factors, the quantum algorithm presented here uses time $T = N^{3/4}$ and space $S = N^{1/2}$. An alternative quantum algorithm is to search the space of all $\binom{N}{2}$ $(x,y)$-pairs to try to find a collision. This algorithm has roughly $T = N$ and $S = \log N$. Third, Ambainis's new algorithm has $T = N^{2/3}$ and $S = N^{2/3}$. All these algorithms satisfy $T^2 S \approx N^2$. In fact, for every space bound $S$ less than $N^{2/3}$, one can find an algorithm whose time (or query) complexity $T$ satisfies $T^2 S \approx N^2$. We conjecture that this is close to optimal. Proving this would be very interesting, since no nontrivial quantum time-space tradeoff lower bounds are known for any decision problem (some tradeoffs for multiple-output problems may be found in [17]).

# OUTPUT-SENSITIVE CONSTRUCTION OF THE UNION OF TRIANGLES*

ESTHER EZRA† AND MICHA SHARIR†

**Abstract.** We present an efficient algorithm for the following problem: Given a collection $T = \{\Delta_1, \dots, \Delta_n\}$ of $n$ triangles in the plane, such that there exists a subset $S \subset T$ (unknown to us) of $\xi \ll n$ triangles, such that $\bigcup_{\Delta \in S} \Delta = \bigcup_{\Delta \in T} \Delta$, construct efficiently the union of the triangles in $T$. We show that this problem can be solved in randomized expected time $O(n^{4/3} \log n + n\xi \log^2 n)$, which is subquadratic for $\xi = o(n/\log^2 n)$. In our solution, we use a variant of the method of Brönnimann and Goodrich [*Discrete Comput. Geom.*, 14 (1995), pp. 463–479] for finding a set cover in a set system of finite VC-dimension. We present a detailed implementation of this variant, which makes it run within the asserted time bound. Our approach is fairly general, and we show that it can be extended to compute efficiently the union of simply shaped bodies of constant description complexity in $\mathbb{R}^d$, when the union is determined by a small subset of the bodies.

## 1. Introduction.

Many problems in computational geometry involve the task of constructing the boundary of the union of $n$ geometric objects in the plane or in higher dimensions. Problems of this kind include motion planning [26], where we wish to construct the forbidden portions of the configuration space; hidden surface removal for visibility problems in three dimensions [32]; finding the minimal Hausdorff distance between two sets of points (or of segments) in $\mathbb{R}^2$ [23]; applications in geographic information systems [15]; and many others. In this paper, we focus mainly on the problem of constructing the union of $n$ triangles in $\mathbb{R}^2$, but we also show that our algorithm can be extended to other geometric objects in the plane and in higher dimensions.

Computing the union by constructing the full arrangement of the $n$ input triangles requires $\Theta(n^2)$ time in the worst case, which, in many instances, is wasteful, since the combinatorial complexity of the union boundary might be considerably smaller. Nevertheless, an algorithm for this problem that runs in subquadratic time when the boundary of the union has subquadratic complexity[1] is unlikely to exist, since this problem belongs to the family of 3*SUM-hard* problems [21], which are problems that are very likely to require $\Omega(n^2)$ time in the worst case; see below for more details.

However, subquadratic algorithms exist in several special cases, such as the case of *fat* triangles (namely, every angle of each triangle is at least some constant positive

[1]This is one variant of *output sensitivity* that one may wish to attain. In this paper we use a different notion of output sensitivity, described later in the introduction.

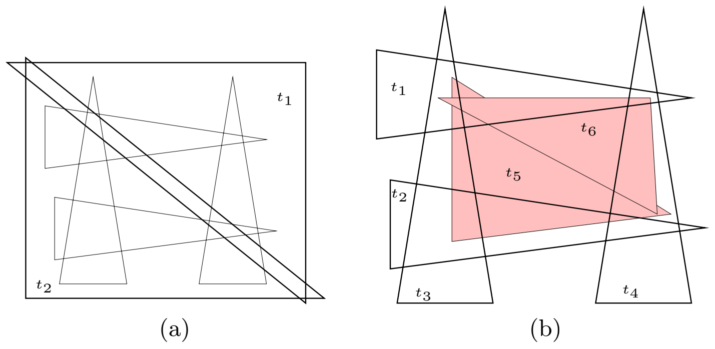

FIG. 1. (a) *An arrangement of six triangles, illustrating the first measure of output sensitivity. The triangles* $t_1$ *and* $t_2$ *cover the entire union, so the output size is* 2. (b) *Illustrating the second measure of output sensitivity. The union boundary is determined only by the triangles* $t_1, \ldots, t_4$*, even though the triangles* $t_5$ *and* $t_6$ *cover the hole created by* $\bigcup_{i\le 4} t_i$*. The output size is* 4 *according to the second measure and* 6 *according to the first.*

angle) or of triangles that arise in the union of Minkowski sums of a fixed convex polygon with a set of pairwise disjoint convex polygons (which is the problem one faces in translational motion planning of a *convex* polygon). In these cases, the union has only linear or near-linear complexity [24, 28, 29], and more efficient algorithms, based on either deterministic divide-and-conquer or on randomized incremental construction, can be devised and are presented in the above-cited papers.

If the input consists of general triangles, then the complexity of the union can be $\Theta(n^2)$ in the worst case. If it happens to be smaller, one can attempt to compute the union by employing the randomized incremental construction (RIC) of Agarwal and Har-Peled [1], whose analysis is based on Mulmuley's *theta series* [32]. Briefly, the algorithm inserts the triangles one at a time in a random order and maintains the union incrementally, updating it after each insertion. As is well known (and discussed in [18]), the RIC algorithm has good performance, even when the size of the arrangement is quadratic, provided that the *depth* $d(v)$ (i.e., the number of input triangles containing $v$ in their interior) of most of the vertices $v$ in the arrangement induced by the $n$ input triangles is large enough. We refer to such vertices as being *deep*. Otherwise, when most of the vertices in the arrangement are *shallow*, the RIC algorithm performs poorly. In this case, one can employ the *disjoint cover* (DC) algorithm proposed in [18], which has good performance in practice. This algorithm also inserts the triangles one at a time, but it computes an insertion order that attempts to cover as many shallow vertices as possible in each insertion step. However, from a theoretical point of view (and in view of certain pathological examples presented in [18]), the DC algorithm can produce $\Omega(n^2)$ vertices of the arrangement, even if the size of the output (i.e., the number of vertices on the boundary of the union) is only linear or constant, and it can be beaten by the RIC algorithm in such cases.

*Output sensitivity.* In this paper we present an efficient algorithm that computes the union in an "output-sensitive" manner. There are two obvious ways to define output sensitivity. The first is to measure the output size in terms of the size of the smallest subset $S \subset T$ that satisfies $\bigcup S = \bigcup T$, where $\bigcup S$ (resp., $\bigcup T$) denotes the union of the triangles in $S$ (resp., in $T$). The second measure is in terms of the size of the smallest subset $S'$ such that $\partial \bigcup T \subseteq \partial \bigcup S'$. See Figure 1 for an illustration of the two measures. Note that if the output size is $\xi$, according to either measure, the actual complexity of the union may be as large as $\Theta(\xi^2)$ (but not larger).

The second measure of output size is likely to be too weak. Indeed, consider the reduction, as presented in [21], of an instance of 3SUM (namely, the problem of determining whether there exist $a \in A$, $b \in B$, $c \in C$ satisfying $a + b + c = 0$ for three given sets $A$, $B$, $C$ of real numbers) to an instance of the problem of determining whether the union of a given set of triangles fully covers the unit square. We can further reduce this latter problem to our problem, as follows. Let $A$ denote an algorithm that efficiently computes the union of $n$ triangles in the plane in terms of the second measure, and let $T_A(n, \xi)$ denote its running time, expressed as a function of $n$ and of the "output size" $\xi$. We assume that $T_A(n, \xi) = o(n^2)$ when $\xi = o(n)$. In order to determine efficiently whether the given triangles fully cover the unit square, we consider only the portions of the triangles that are contained in the unit square and retriangulate them if necessary. In addition, we add four thin and narrow triangles that cover the boundary of the unit square. We now run $A$ on the newly constructed instance. Clearly, there are no holes in the union of the newly created triangles if and only if the original union contains the unit square. In this case, the boundary of the new union consists of only four triangles, and thus $A$ will terminate in a predictable subquadratic time. We thus run $A$. If it terminates within the anticipated (subquadratic) time, we can determine, at no extra cost, whether the union covers the unit square. Otherwise, we stop $A$ and correctly report that the union of the original triangles does not cover the unit square. Hence an efficient output-sensitive solution, under the second measure, would have yielded a subquadratic solution to 3SUM and is thus unlikely to exist.

In contrast, the first measure does lend itself to an efficient output-sensitive solution, which is the main result of this paper.

*Our results.* Specifically, we present an efficient algorithm to construct the boundary of the union of a set $T = \{\Delta_1, \ldots, \Delta_n\}$ of $n$ triangles in the plane, under the assumption that there exists a subset $S \subset T$ of $\xi \ll n$ triangles (unknown to us) such that $\bigcup S = \bigcup T$. We present an algorithm whose running time is $O(n^{4/3} \log n + n\xi \log^2 n)$, which is subquadratic when $\xi = o(n/\log^2 n)$. Our approach is a randomized algorithm based on the method of Brönnimann and Goodrich for finding a set cover or a hitting set in a set system of finite VC-dimension, as presented in [10]. Their method is based on a randomized *natural selection* technique used by Clarkson [12, 13], Littlestone [27], and Welzl [35]; see section 2.1 for a brief review of this method. In our case, the objects are the triangles of $T$, and any point $v$ in the plane defines a set $T_v = \{\Delta \in T \mid v \in int(\Delta)\}$. The collection $\{T_v\}_{v \in \mathbb{R}^2}$ forms a set system for which a *hitting set* $H \subset T$ is a subset satisfying $\bigcup H = \bigcup T$, and thus a minimum-size hitting set is the object that we wish to compute. (It is well known, and easy to verify, that this set system has finite VC-dimension; see below for details.) Note that this set system is the same as the one generated by sampling one point $v$ in the interior of each cell of the arrangement $\mathcal{A}(T)$. In general, the Brönnimann–Goodrich technique is not efficient enough for our purposes, but we use a variant of the algorithm which can be implemented efficiently. Specifically, we apply the algorithm of Brönnimann and Goodrich in an "approximate setting," fine-tuning it (using randomization) so that it constructs a subset $T'$ of $O(\xi \log \xi)$ triangles of $T$, whose union covers the overwhelming majority of the vertices (of positive depth) in the arrangement $\mathcal{A}(T)$. This allows us, with some care, to compute the portion of $\bigcup T$ that lies outside $\bigcup T'$ in an efficient explicit manner. We note that when measuring the expected number of vertices generated by the algorithm, it suffices (and is appropriate) to consider only vertices at positive depth, since vertices at depth 0 are the vertices of the union, and they have to be constructed by any algorithm that computes the union. We call the latter quantity, namely, the number of positive-depth vertices generated by the algorithm, the *residual cost* of the algorithm.

In section 2.1 we briefly recall the algorithm of Brönnimann and Goodrich and present our approximate version of it. Then we derive an upper bound on the expected residual cost of the algorithm in its approximate version. Section 3 describes a detailed implementation of our algorithm. In this implementation, we use generic and simple techniques that can be easily extended to other geometric objects of constant description complexity[2] in the plane and in $\mathbb{R}^d$. These extensions are discussed in section 4. We give concluding remarks and suggestions for further research in section 5.

## 2. The union construction as a set cover problem.

**2.1. An overview of the Brönnimann–Goodrich technique.** A technique for finding a set cover of a set system of finite VC-dimension is described in detail by Brönnimann and Goodrich [10]; for the sake of completeness, we provide a brief overview of this approach, in the context of the union construction problem. Very recently, Even, Rawitz, and Shahar [17] have proposed an alternative technique, based on a linear programming formulation of the problem, that appears to be somewhat simpler and more efficient.

We denote by $V$ the set of vertices of the arrangement $\mathcal{A}(T)$ at positive depth (considering only intersection points of the triangle boundaries and ignoring triangle vertices). A hitting set for the set system induced by $\{T_v\}_{v \in V}$, where $T_v$ consists of all the triangles $\Delta \in T$ that contain $v$ in their interior, is a subset of triangles $H \subset T$ such that $\bigcup H$ covers all the vertices in $V$. It need not necessarily cover $\bigcup T$ entirely, but the pieces left uncovered are easily computable and will be computed in the final stages of the algorithm. Thus we consider the set system $(T, V^*)$, where

$$V^* = \{T_v : v \in V\}.$$

Since this set system is dual to $(V, T)$, which has some finite VC-dimension $d$ (see, e.g., [6]), it follows that the VC-dimension of $(T, V^*)$ is also finite; as a matter of fact, it does not exceed $2^{d+1}$ [8]. As already mentioned, our goal is to find a *hitting set* for $(T, V^*)$, that is, a subset $H \subseteq T$ that has a nonempty intersection with every set $T_v \in V^*$, $v \in V$.

The algorithm of Brönnimann and Goodrich finds a hitting set whose size is $O(h^* \log h^*)$, where $h^*$ is the smallest size of any hitting set. Note that the reported hitting set is actually a *set cover* for the primal set system $(V, T)$, where a set cover, in this case, is a collection $\mathcal{C} \subseteq T$ of triangles whose union covers the entire set $V$. (For technical reasons, the method of Brönnimann and Goodrich computes a set cover via a hitting set of the dual set system, which is why we also work with the dual system; see [10] for further details.) Since, by definition, the size of the optimal cover is assumed to be $\xi$, it follows that the size of the set cover reported by the algorithm is at most $O(\xi \log \xi)$.

We first describe the algorithm of Brönnimann and Goodrich in its "ideal setting," where the entire set $V$ is given, and then show how to modify this setting, so that it suffices to consider only a small subset of vertices.

[2]A set in $\mathbb{R}^d$ is said to have *constant description complexity* if it is a semialgebraic set defined as a Boolean combination of a constant number of polynomial equalities and inequalities of constant maximum degree in a constant number of variables.

The Brönnimann–Goodrich algorithm has two key subroutines: (i) a *net finder* $\mathcal{F}$ for $(T, V^*)$, which is an algorithm that, given a parameter $r \geq 1$ and a weight distribution $w$ on $T$, computes a $(1/r)$-*net* for the weighted system $(T, V^*)$ [6]. A $(1/r)$-net is a subset $N \subseteq T$, which has a nonempty intersection with each set in $V^*$ whose total weight is at least $1/r$ of the total weight of $T$; (ii) a *verifier* $\mathcal{V}$ that, given a subset $H \subseteq T$, either states (correctly) that $H$ is a hitting set, or returns a nonempty "witness" set $T_v \in V^*$, for some $v$, such that $T_v \cap H = \emptyset$. In our context, $\mathcal{V}$ simply has to output a vertex $v \in V$ that is not contained in the interior of $\bigcup H$.

The Brönnimann–Goodrich algorithm then proceeds as follows. We guess the value of $\xi$ (homing in on the right value using an exponential search). We assign weights to the triangles in $T$. Initially, all weights are 1. We then use the net finder $\mathcal{F}$ to construct a $(1/2\xi)$-net $N$ for $(T, V^*)$. If the verifier $\mathcal{V}$ outputs some set $T_v$ that $N$ does not hit, we double the weights of the triangles in $T_v$ and repeat the process with the new weights. As shown in [10], a hitting set is found after at most $4\xi \log (n/\xi)$ iterations.

The problem with this ideal setting is that it requires the construction of all the (positive-depth) vertices of $\mathcal{A}(T)$, which is much too much to ask for, since it can be too expensive ($V$ can be quadratic in the worst case, while $\xi$ can still be very small). Instead, we use a smaller randomly sampled subset $R \subseteq V$ of $r$ elements, whose actual computation is presented in section 3. We then feed the verifier $\mathcal{V}$ with $R$ instead of the entire set $V$. We show that once the verifier $\mathcal{V}$ announces that the subset $H$, reported by the net finder $\mathcal{F}$, covers $R$ (actually, it suffices that $H$ covers most of $R$—see below), the actual number of vertices of $V$ that remain uncovered is relatively small, with high probability. We then compute the uncovered vertices in an explicit manner and thereby complete the construction of $\bigcup T$.

**2.2. A subquadratic residual cost via sampling.** We begin the analysis of our implementation of the Brönnimann–Goodrich technique with the following lemma, which provides a lower bound for the size of the sample $R$, which is sufficient to guarantee the property asserted at the end of the preceding subsection.

In what follows, we say that an event occurs *with overwhelming probability* (or w.o.p., for short) if the probability that it does not occur is at most $\frac{1}{n^c}$ for some constant $c \geq 1$.

LEMMA 2.1. *Let $T = \{\Delta_1, \ldots, \Delta_n\}$ be a given collection of $n$ triangles in the plane, let $V$ denote the set of vertices of the arrangement $\mathcal{A}(T)$ at positive depth, let $\kappa$ denote the size of $V$, and suppose that there are only $\xi$ triangles of $T$ whose union is equal to $\bigcup T$. Let $S \subseteq T$ denote a subset of triangles, and let $R \subseteq V$ be a random sample of $r = \Omega(t \log n)$ positive-depth vertices, sampled after $S$ has been fixed for some prespecified parameter $t \geq 1$ and with a sufficiently large constant of proportionality. If $S$ covers all but $r_S < r$ vertices of $R$, then, w.o.p., the actual number $\kappa_S$ of vertices of $V$ that are not covered by the elements of $S$ satisfies*

$$\kappa_S \leq \max\left\{\frac{\kappa}{t}, \beta\frac{\kappa}{r} r_S\right\} \tag{2.1}$$

*for some absolute constant $\beta > 1$.*

*Proof.* For simplicity of exposition, we present the analysis under the model where $R$ is obtained by drawing each point of $V$ independently with probability $p = \frac{r}{\kappa}$. Nevertheless, the assertion of the lemma also holds for other models of sampling $R$, in particular, for the model we use in the actual implementation of the algorithm; see section 3 and Appendix A for details. Since each point in $V \setminus \bigcup S$ is chosen independently with probability $\frac{r}{\kappa}$, the expected number of vertices of $R$ that are not covered by $S$ is $\frac{r}{\kappa}\kappa_S$.

It suffices to consider the case $\kappa_S > \frac{\kappa}{t}$, for otherwise (2.1) clearly holds.

Since $R$ is sampled *after* $S$ has been fixed, the number $r_S$ of vertices of $R$ that are not covered by $\bigcup S$ is a random variable, which can be expressed as the sum of $\kappa_S$ mutually independent indicator variables, $X_1, \ldots, X_{\kappa_S}$, each satisfying

$$Pr[X_i = 1] = p, \qquad Pr[X_i = 0] = 1 - p \quad \text{for } i = 1, \ldots, \kappa_S.$$

Fix a parameter $r_0 > 0$ and consider the event

$$A_S : \quad r_S - \frac{r}{\kappa}\kappa_S < -r_0.$$

Using a large deviation bound given in [6, Theorem A.13], it follows that

$$Pr[A_S] < e^{-\frac{{r_0}^2}{2\frac{r}{\kappa}\kappa_S}}. \tag{2.2}$$

Putting $r_0 = \sqrt{2c_0\frac{r}{\kappa}\kappa_S \log n}$ for some constant $c_0 \geq 1$, (2.2) implies that the probability that the event $A_S$ does not occur is at most $\frac{1}{n^{c_0}}$. Hence, w.o.p.,

$$r_S - \frac{r}{\kappa}\kappa_S \geq -\sqrt{2c_0\frac{r}{\kappa}\kappa_S \log n},$$

or

$$r_S \geq \sqrt{\frac{r}{\kappa}\kappa_S}\left[\sqrt{\frac{r}{\kappa}\kappa_S} - \sqrt{2c_0 \log n}\right].$$

Since we have assumed that $\kappa_S > \frac{\kappa}{t}$ and that $r = \Omega(t \log n)$, with a sufficiently large constant of proportionality, it follows that, w.o.p.,

$$\sqrt{\frac{r}{\kappa}\kappa_S} - \sqrt{2c_0 \log n} > \alpha\sqrt{\frac{r}{\kappa}\kappa_S} \tag{2.3}$$

for some absolute constant $0 < \alpha < 1$, which implies that

$$\kappa_S \leq \frac{\kappa}{\alpha r} r_S,$$

and thus the lemma follows. □

*Remarks.* (1) Note that Lemma 2.1, as well as its variant discussed in Appendix A, deals with abstract sets, and does not exploit any special property of vertices in arrangements of triangles. We will therefore be able to use the lemma, more or less verbatim, in the extensions presented in section 4.

(2) We reemphasize that Lemma 2.1 relies on the assumption that $R$ is sampled *after* $S$ has been chosen (in our implementation, this choice will also be random). In particular, for the lemma to be applicable at each iteration of the Brönnimann–Goodrich algorithm, $R$ should be redrawn from scratch before applying the verifier $\mathcal{V}$. (See section 3 for further details.)

Lemma 2.1 implies that if the triangles in $S$ cover all but at most $\frac{r}{t}$ of the elements of $R$ (and thus $r_S = O\left(\frac{r}{t}\right)$), then, w.o.p., $\kappa_S \leq \frac{\kappa}{t}$. We thus construct the union of the input triangles in two steps: in the first we find a set $H$ of $O(\xi \log \xi)$ triangles that covers all but at most $\frac{\kappa}{t}$ vertices of $V$ and compute the union $\bigcup H$, and in the second step we handle efficiently all the remaining vertices of $V$ that $H$ does not cover; see below for details. It thus follows that the overall expected number of positive-depth vertices generated by the algorithm is $O(\xi^2 \log^2 \xi)$ (which is the number of vertices of the arrangement of the triangles in $H$) in the first part, and at most $\frac{\kappa}{t}$ in the second part.

We have established the following theorem.

THEOREM 2.2. *Let $T = \{\Delta_1, \ldots, \Delta_n\}$ be a given collection of $n$ triangles in the plane, and assume that there exists a subset $H \subset T$ of $\xi \ll n$ triangles (unknown to us) such that $\bigcup H = \bigcup T$. Let $V$, $\kappa$, and $t$ be as in Lemma* 2.1*. Then one can implement the Brönnimann–Goodrich algorithm, so that its residual cost is $O(\xi^2 \log^2 \xi + \frac{\kappa}{t})$, w.o.p. In particular, for $t = \max\{\frac{\kappa}{\xi^2}, 1\}$ the residual cost is $O(\xi^2 \log^2 \xi)$.*

*Discussion.* Clearly, if our only concern is to have the algorithm generate as few positive-depth vertices as possible, we should choose $t$ as large as possible, thereby making $R$ larger and the set of vertices of $V$ not covered by $H$ smaller. For example, as noted, if we choose $t = \max\{\frac{\kappa}{\xi^2}, 1\}$, then the residual cost of the algorithm is at most $O(\xi^2 \log^2 \xi)$, w.o.p. Since there are only $\xi$ triangles that define the union, the combinatorial complexity of the boundary of the union is only $O(\xi^2)$. This implies that for the above choice of $t$, the overall number of vertices that the algorithm generates is $O(\xi^2 \log^2 \xi)$, which is subquadratic for $\xi = o(n/\log n)$. However, if we are concerned with the actual running time, large values of $t$ will slow down the algorithm, because sampling the sets $R$ will be more expensive. Hence, in the actual implementation of the algorithm, presented in section 3 below, we will choose a smaller value for $t$ in order to optimize the bound on the actual running time of the algorithm. This will also affect the bound on the residual cost.

We also note that the bound $O(\xi^2 \log^2 \xi)$ on the complexity of the union of the triangles computed in the first part of the algorithm may be too pessimistic in practice. If the complexity of the union $\bigcup H$ turns out to be smaller, the residual cost will be smaller too.

## 3. Implementation of the algorithm.

The actual cost of the algorithm depends on the cost of several support routines (in addition to the cost of the actual generation of positive-depth vertices), such as (i) constructing the random samples $R$; (ii) finding a $(1/2\xi)$-net for the set system $(T, V^*)$; (iii) implementing the verifier $\mathcal{V}$, which in our case is an algorithm that efficiently decides whether a given subset $S$ of triangles covers (most of the elements of) another given subset $R$ of positive-depth vertices; and (iv) the actual construction of the union of the input triangles after an approximate hitting set has been found. We present here an implementation that uses generic and simple techniques and yields a subquadratic output-sensitive algorithm for constructing the union.

In the following description, we denote by $h$ the size of the set $H$ computed in the first stage of the algorithm.

**Sampling *R*.** The task at hand is to construct, at each iteration of the algorithm, a random sample of (an expected number of) $r = ct \log n$ positive-depth vertices of $\mathcal{A}(T)$, for appropriate values of the parameter $t$ and the constant $c$. (As already mentioned and to be discussed below, we have to draw a new subset $R$ in each iteration of the algorithm in order to eliminate any dependence between the present subset of triangles reported by the net finder $\mathcal{F}$ and the (current) sample $R$.)

We sample $R$ using the following simple approach. Suppose that we have a guess for the values of $\xi$ and $\kappa$ (see below for details concerning these guesses). Let $\kappa^*$ denote the number of vertices on the boundary of $\bigcup T$. If $\kappa = O(\kappa^*)$, then the entire arrangement has only $O(\kappa^*) = O(\xi^2)$ vertices and can thus be constructed in time $O(n \log n + \xi^2)$, using any of the standard techniques [32]. We may thus assume that $\kappa > \beta\kappa^*$ for some absolute constant $\beta > 1$. We also may assume that $\kappa > \beta \max\{\xi^2, n^{4/3}\}$ for the same constant. Otherwise, we construct the entire arrangement in time $O((n + \xi^2 + n^{4/3}) \log n) = O((\xi^2 + n^{4/3}) \log n)$.

We now perform $\frac{9c'r\binom{n}{2}}{\kappa}$ sampling steps, where in each step we choose, uniformly and independently, a pair of edges of distinct triangles in $T$ for an appropriate constant $c' > 1$ (we first select a random pair of triangles and then randomly choose a pair of triangle edges out of the nine triangle edge pairs induced by the two chosen triangles). Clearly, a real vertex of the arrangement $\mathcal{A}(T)$ (that is formed by a pair of intersecting triangle edges) is chosen in a single step with probability $\frac{\kappa+\kappa^*}{9\binom{n}{2}}$, and thus the expectation of the number $r'$ of pairs of edges that actually intersect is

$$\frac{\kappa + \kappa^*}{9\binom{n}{2}} \cdot \frac{9c'r\binom{n}{2}}{\kappa} = \Theta(r).$$

Applying the same deviation bound used in Lemma 2.1, it can be shown that, w.o.p., the actual number of such pairs satisfies

$$r' \geq \mathbf{E}(r') - \sqrt{\gamma \frac{\kappa}{9\binom{n}{2}} \frac{9c'r\binom{n}{2}}{\kappa} \log n} = \mathbf{E}(r') - \sqrt{\gamma c' r \log n}$$

for some constant $\gamma \geq 1$. Since $\sqrt{\gamma c' r \log n} = o(r)$ (by the choice of $\gamma$, $c'$, and $r$), there is a constant $0 < \alpha < 1$, which can be made arbitrarily small (for a proper choice of $\gamma$) such that, w.o.p.,

$$r' \geq (1 - \alpha)\mathbf{E}(r') = \Theta(r)$$

for a sufficiently large constant of proportionality that depends on $c'$ and $\gamma$.

Not all sampled vertices have positive depth. However, since $\kappa > \beta\kappa^*$, the overwhelming majority of the sampled vertices will have positive depth. By choosing $c'$ to be sufficiently large, at least $r$ of these vertices will have positive depth, w.o.p.

**Implementing a net finder $\mathcal{F}$ and a verifier $\mathcal{V}$.** As already described in the preceding section, we assign weights to the elements of $T$ (initially, each triangle gets the weight 1) and use a net finder $\mathcal{F}$ to construct a $(1/2\xi)$-net for the weighted dual system $(T, V^*)$. We then apply the verifier $\mathcal{V}$ in order to decide whether $H$ covers (most of the elements of the newly resampled subset) $R$. If it does, the first part of the algorithm terminates, and we proceed to the actual construction of the union; otherwise, $\mathcal{V}$ returns a particular witness subset $T_v \in V^*$, for some $v \in R$, such that $T_v \cap H = \emptyset$. We then double the weights of the triangles in $T_v$, construct a new $(1/2\xi)$-net and a new sample $R$, and repeat this process until we find a subset of triangles that covers all but at most $\frac{r}{t}$ elements of $R$. The analysis in [10] can be modified to show that the number of iterations that this algorithm performs is $O(\xi \log(n/\xi))$. Indeed, as long as there exists some vertex of the new sample $R$ that is not covered by the set $H$ constructed by $\mathcal{F}$, we keep on doubling the weights of the triangles covering this vertex, and, according to the analysis in [10], the overall number of such iterations does not exceed $4\xi \log(n/\xi)$.

We start with the description of the net finder $\mathcal{F}$. We use a simple method, presented by Matoušek [30] and briefly reviewed in [10], for reducing the weighted case to the unweighted one. In this method, we scale all weights of the triangles in $T$ such that the sum $w(T)$ of the weights of all the elements of $T$ satisfies $w(T) = n$. We then take $\lfloor w(\Delta) + 1 \rfloor$ copies of each element $\Delta \in T$ (where $w(\Delta)$ is the scaled weight of $\Delta$). Note that the multiset $T'$ that we have constructed contains all the elements of $T$ and has at most $2n$ elements. It is shown in [30] that an $\varepsilon$-net for (the unweighted set) $T'$ is also an $\varepsilon$-net for the weighted set $T$. Finding a $(1/2\xi)$-net for $T'$ can be done by drawing $O(\xi \log \xi)$ random elements of $T'$. As shown, e.g., in [6], an appropriate choice of the constant of proportionality ensures that such a random sample is a $(1/2\xi)$-net, w.o.p. Clearly, creating the multiset $T'$ takes $O(n)$ time, and drawing $O(\xi \log \xi)$ random elements of $T'$ takes an additional time of $O(\xi \log \xi)$. Thus the overall running time of the net finder is $O(n)$, for a total time of $O(n\xi \log(n/\xi))$ over all iterations of the algorithm. Note that if the random sample is not a $(1/2\xi)$-net (which may happen with an overwhelmingly small probability for any $\xi \geq \log n$; see, e.g., [22]), the number of iterations of the algorithm may exceed $4\xi \log(n/\xi)$, and, in this case, we may stop the whole process and restart it from scratch. The fact that the process fails with an overwhelmingly small probability ensures that, w.o.p., the number of such trials is not larger than some constant. (When $\xi < \log n$, the number of trials that guarantees success, w.o.p., is at most $O(\log n)$. However, this does not affect the asymptotic running time of the algorithm; see section 3 for the specific bound on the running time of the algorithm.)

In the implementation of the verifier $\mathcal{V}$, we use brute force and iterate over all the vertices of $R$ and the triangles of $H$ in $O(r\xi \log \xi)$ time, to determine whether there exists a vertex in $R$ that is not covered by the triangles of $H$. We denote the set of all such vertices of $R$ by $R_H$. Suppose $R_H$ contains at least $\frac{r}{t}$ vertices (otherwise, the first part of the algorithm terminates). Rather than just picking any $v \in R_H$, we sample a random vertex $v$ from $R_H$, obtain, by brute force, the set $T_v$ of all triangles in $T$ that contain $v$ in their interior (clearly, $T_v \cap H = \emptyset$), and if $T_v \neq \emptyset$, double their weights. The reason for sampling is that $R$ may in general also contain zero-depth vertices, and $T_v$ will be empty for such vertices $v$. To accommodate this case, we use the sampling technique and stop when we find a positive-depth vertex in $R_H$. Since (i) $|R_H| \geq \frac{r}{t} = \Omega(\log n)$, (ii) $\kappa > \beta\kappa^*$, and (iii) $R$ is sampled after $H$ has been constructed, it follows that a constant positive fraction of the elements of $R_H$ have positive depth, and that, w.o.p., such an element will be found after at most $O(\log n)$ samplings. Hence, w.o.p., the total cost of this substep is $O(n \log n)$. Since we repeat this procedure for $O(\xi \log(n/\xi))$ steps, the overall cost of this stage is, w.o.p.,

$$O(\xi \log(n/\xi)(r\xi \log \xi + n \log n)) = O(r\xi^2 \log \xi \log(n/\xi) + n\xi \log(n/\xi) \log n),$$

and this bounds the overall running time, for both the net finder $\mathcal{F}$ and the verifier $\mathcal{V}$, over all iterations of the first part of the algorithm.

**The actual construction of the union.** The implementation of the actual construction of the union proceeds through two stages. We first construct the union of the triangles in the set $H$ and then compute the portion of $\mathcal{A}(T)$ outside this union. As argued earlier, this portion contains, w.o.p., at most $\frac{\kappa}{t}$ positive-depth vertices of $\mathcal{A}(T)$.

We first construct the union of the $h$ triangles of $H$ in $O(h^2) = O(\xi^2 \log^2 \xi)$ time (using, e.g., randomized incremental construction [32]). Next, we efficiently find the intersections of the boundary of each of the remaining triangles $\Delta$ with the boundary

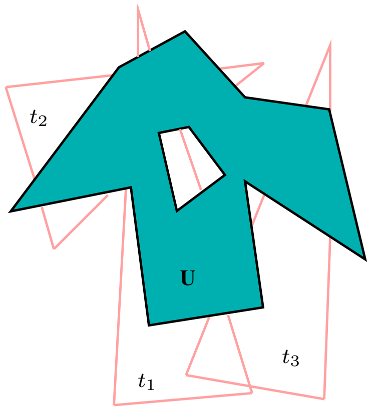

FIG. 2. *The second stage of the actual construction of the union. $U$ denotes the union of the $h$ triangles in the hitting set $H$ and $t_1, t_2$, and $t_3$ denote the remaining triangles to be inserted into the union. Only the portions of $t_1, t_2$, and $t_3$ that lie outside $U$ are relevant.*

of $\bigcup H$ in order to collect all the portions of $\partial\Delta$ lying outside $\bigcup H$. We denote the set of all such portions, over all the remaining triangles, by $\mathcal{C}$. (See Figure 2 for an illustration.)

In order to find those portions efficiently, we use the algorithm of Bentley and Ottmann [9] (see also [16]) for reporting all $k$ intersections in a set of $n$ simply shaped Jordan arcs in $O(n \log n + k \log n)$ time. We partition the set of the remaining triangles into $\lceil \frac{n}{\xi \log \xi} \rceil$ subsets, each containing $O(\xi \log \xi)$ triangles. We denote the collection of all these subsets by $\mathcal{S} = \{S_1, \ldots, S_{\lceil \frac{n}{\xi \log \xi} \rceil}\}$. Next, we compute, for every subset $S \in \mathcal{S}$, the arrangement $\mathcal{A}(S)$ induced by the triangles in $S$ and then run the Bentley–Ottmann algorithm on the combined collection of the edges of $\mathcal{A}(S)$ and the $O(h^2)$ edges of $\bigcup H$. Since the edges of $\mathcal{A}(S)$ are pairwise openly disjoint, as are the edges of $\bigcup H$, the algorithm will report only intersections between the boundary of $\bigcup H$ and the remaining triangles. Since the overall number of such intersections over all subsets in $\mathcal{S}$ is at most $\frac{\kappa}{t}$, the overall cost of reporting all intersections is

$$O\left(\left(\frac{n}{\xi \log \xi} \cdot \xi^2 \log^2 \xi\right) \log n + \frac{\kappa}{t} \log n\right) = O\left(n\xi \log \xi \log n + \frac{\kappa}{t} \log n\right).$$

Next, we trim the edges of the remaining triangles to their portions outside $\bigcup H$ and then construct the entire union using another line-sweeping procedure on these exterior edge portions and the boundary edges of $\bigcup H$ [9]. Since there are at most $\frac{\kappa}{t}$ positive-depth vertices that are constructed during this process, the algorithm takes $O((n + \xi^2 \log^2 \xi + \frac{\kappa}{t}) \log n)$ time.

This completes the detailed description of our algorithm, which is summarized in the following procedure for which $\xi$ is an input parameter. Since $\xi$ is not known a priori, we run this procedure with the values $\xi = 1, 2, 4, \ldots, 2^i, \ldots$ (where $i < \log n$), thereby guaranteeing a constant approximation of the actual value of $\xi$. The choice of $r$ (that is, of the parameter $t$) in this procedure will be specified later.

**Procedure** CONSTRUCTUNION($T$, $\xi$)

```
1. Construct $\bigcup T$ by a line-sweeping procedure on the triangles in $T$. Stop the
   procedure as soon as it constructs more than $\max\{\xi^2, n^{4/3}\}$ vertices.
   If it terminates **goto** 16.
```

```
2.    Initialize all weights of the triangles in $T$ to 1.
3.    **repeat**
4.      $H \leftarrow (1/2\xi)$-net of size $O(\xi \log \xi)$ for the weighted system $(T, V^*)$.
5.      Construct a new random sample $R$ of $r$ vertices out of the vertices of $\mathcal{A}(T)$.
6.      Apply the verifier $\mathcal{V}$ to $H$ and $R$.
7.      **if** $H$ covers all but at most $\frac{r}{t}$ vertices of $R$ **goto** 11.
8.      **else**
9.        Double the weights of all the triangles in the subset $T_v$ reported by $\mathcal{V}$.
10.   **endrepeat**
11.   Construct the union of the triangles in $H$.
12.   Partition $T$ into subsets $S_1, \ldots, S_{\lceil \frac{n}{\xi \log \xi} \rceil}$ of size $O(\xi \log \xi)$ each.
13.   For each $S_i$, compute $\mathcal{A}(S_i)$ and find all intersections between its edges and
      $\partial \bigcup H$, using a line-sweeping procedure.
14.   Trim the edges of the remaining triangles to their portions outside $\bigcup H$.
      Denote the set of the resulting segments by $\mathcal{C}$.
15.   Construct $\bigcup T$ by a line-sweeping procedure on $\mathcal{C}$ and the boundary edges of
      $\bigcup H$.
16. **end**
```

We substitute $r = ct \log n$ for some absolute constant $c$ and for the parameter $t$ that we still need to fix. Since the size $h$ of $H$ is $O(\xi \log \xi)$ and since the algorithm terminates after $O(\xi \log (n/\xi))$ iterations, the overall cost of the algorithm (including the exponential search of the actual value of $\xi$) is

$$\min \left\{ \begin{array}{l} O((n+\kappa)\log n), \\ O\Big(\frac{n^2}{\kappa} r\xi \log(n/\xi) + n\xi \log(n/\xi)\log n + hr\xi \log(n/\xi) \\ \qquad + nh \log n + \frac{\kappa}{t}\log n + h^2 \log n\Big) \end{array} \right\}$$

$$= \min \left\{ \begin{array}{l} O((n+\kappa)\log n), \\ O\Big(\frac{n^2}{\kappa} t\xi \log n \log(n/\xi) + n\xi(\log(n/\xi) + \log \xi)\log n \\ \qquad + \xi^2 t \log \xi \log n \log(n/\xi) + \frac{\kappa}{t}\log n\Big) \end{array} \right\}.$$

Choosing

$$t = \max\left\{ \frac{\sqrt{\kappa}}{\xi \log n}, 1 \right\},$$

the running time bound becomes

$$\min\left\{ O((n+\kappa)\log n), O\left( \frac{n^2}{\sqrt{\kappa}} \log(n/\xi) + \xi\sqrt{\kappa}\log^2 n + n\xi(\log(n/\xi) + \log \xi)\log n \right) \right\}.$$

Since $\kappa = O(n^2)$ and $\xi \le n$, this is upper bounded by

$$\min\left\{ O((n+\kappa)\log n), O\left( \frac{n^2}{\sqrt{\kappa}}\log n + n\xi \log^2 n \right) \right\}.$$

The two terms involving $\kappa$ are equal when $\kappa = n^{4/3}$. Hence the running time is always bounded by $O(n^{4/3}\log n + n\xi \log^2 n)$.

We have established the following theorem.

Theorem 3.1. *Let $T$ be a set of $n$ triangles in the plane whose union is equal to the union of an unknown subset of $\xi \ll n$ triangles. Then the union can be constructed in randomized expected time $O(n^{4/3} \log n + n\xi \log^2 n)$, which is subquadratic for any $\xi = o(\frac{n}{\log^2 n})$.*

## 4. Extensions.

In this section we show how to extend our algorithm to compute the union of other planar shapes, as well as unions of simply shaped bodies in three and higher dimensions.

The analysis of the algorithm of [10] holds for any range space of finite VC-dimension. Consider an input set $S$ of bodies in $\mathbb{R}^d$, and let $V$ denote the set of positive-depth vertices of $\mathcal{A}(S)$. It is well known that the range space $(S, V^*)$ has finite VC-dimension if the objects have constant description complexity. This can be shown, for instance, by the linearization technique (see, e.g., [31]). In this case, the number of vertices that the objects in the set $H$, reported by the net finder $\mathcal{F}$, can generate, among themselves, is $O(\xi^d \log^d \xi)$. In addition, Lemma 2.1 continues to hold in this case, since it does not make any assumptions on the input shapes. It thus follows that Theorem 2.2 can be easily extended to bodies in $\mathbb{R}^d$ of constant description complexity, and that the residual cost of the algorithm, in this case, is $O(\xi^d \log^d \xi + \frac{\kappa}{t})$, w.o.p.

The actual implementation of the various stages of the algorithm can also be easily extended to bodies in $\mathbb{R}^d$ of constant description complexity. We begin with the planar case, and then discuss in section 4.1 the extension to higher dimensions.

In the case of simply shaped planar regions, we apply similar subroutines, which run within the same time bounds as stated in section 3. In the sampling procedure, each pair of region boundaries intersect in a constant number of points, and we collect all these intersections to form $R$. Since our system has finite VC-dimension, we can construct a $(1/2\xi)$-net for this system in much the same way as in section 3. In addition, the verifier $\mathcal{V}$ can still detect whether a given vertex $v$ is contained in the interior of another given region in $O(1)$ time, and thus these two subroutines will run within the same asymptotic time bounds as in the case of triangles. (In fact, these properties hold for bodies of constant description complexity in higher dimensions as well, and thus the net finder $\mathcal{F}$ and the verifier $\mathcal{V}$ will run within the same asymptotic time bounds in these cases too.) In the actual construction of the union, we use the algorithm of Bentley and Ottmann [9], which can be applied for any set of Jordan arcs of constant description complexity, with the same asymptotic time bound, as stated in section 3.

We can thus easily derive the following theorem.

Theorem 4.1. *Let $S$ be a set of $n$ planar regions of constant description complexity, whose union is equal to the union of an unknown subset of $\xi \ll n$ regions. Then the union can be constructed in randomized expected time $O(n^{4/3} \log n + n\xi \log^2 n)$, which is subquadratic for any $\xi = o(\frac{n}{\log^2 n})$.*

### 4.1. The union of simply shaped bodies in $\mathbb{R}^d$.

We begin with the extension of our algorithm to the case of bodies of constant description complexity in three dimensions and then describe the generalization to higher dimensions.

In 3-space, we may assume in the sampling procedure that $\kappa > \beta \max\{\xi^3, n^2\}$ for some absolute constant $\beta > 1$. Otherwise, we construct the union in time $O((n^2 + \xi^3) \log n)$, as follows. We fix a body $B \in S$ and intersect its boundary $F$ with each object $B' \in S \setminus \{B\}$. We obtain a collection of $n-1$ Jordan regions of constant description complexity on $F$. The complement of their union is the portion of $F$ that appears on $\partial \bigcup S$. Computing this complement can be done in time $O(n \log n + \kappa_B \log n)$, where $\kappa_B$ is the number of vertices of $\mathcal{A}(S)$ that lie on $F$, using an appropriate variant of the line-sweeping algorithm of Bentley and Ottmann [9]. Repeating this procedure for each boundary $F$, the total cost is $O((n^2 + \kappa) \log n) = O((n^2 + \xi^3) \log n)$, as claimed.

The main part of the algorithm then proceeds in much the same way as before. For example, when we construct a sample $R$ of vertices, we perform, in analogy with the two-dimensional procedure, $\frac{c' r \binom{n}{3}}{\kappa}$ sampling steps, for an appropriate constant $c' > 1$, where in each step we choose, uniformly and independently, a triple of distinct input bodies in $S$ and collect all resulting boundary intersections to form $R$. An analysis similar to that described in section 3 shows that with an appropriate choice of the constant $c'$, at least $r$ of the chosen triples generate real vertices that have positive depth, w.o.p.

As noted above, the net finder $\mathcal{F}$ and the verifier $\mathcal{V}$ can be implemented in a manner similar to that described in section 3 and run within the same asymptotic time bounds (and this holds in higher dimensions as well). It follows that, choosing $t = \max\{\frac{\sqrt{\kappa}}{\xi \log n}, 1\}$, the first part of the algorithm computes a subset $H$ of $S$ of size $h = O(\xi \log \xi)$, in time $O(r\xi^2 \log \xi \log(n/\xi) + n\xi \log(n/\xi) \log n)$, such that at most $\frac{\kappa}{t}$ positive-depth vertices of $\mathcal{A}(S)$ lie outside the (interior of the) union $\bigcup H$.

After constructing $\bigcup H$, we need to compute all the intersections between the remaining bodies and the boundary of $\bigcup H$. This is done as follows. For each body $B \in S$ (particularly, $B$ may belong to $H$), we take its boundary $F$ and compute the set of its exposed portions that lie outside $\bigcup H \setminus \{B\}$. This is done by constructing the intersections $B'_F = B' \bigcap F$ for each $B' \in H \setminus \{B\}$, and then we compute the complement of their union within $F$. Since the regions $B'_F$ are bounded by curves of constant description complexity, their arrangement has $O(h^2)$ complexity and can be constructed in $O(h^2 \log n)$ time. We denote by $E_F$ the set of edges of the arrangement that appear on the boundary of the union of the regions $B'_F$. Clearly $|E_F| = O(h^2)$. We then intersect $F$ with all the remaining $n - h$ input bodies, obtaining a set of curves $\mathcal{S}_F$ bounding the intersection regions. Our goal is to find the portions of the curves in $\mathcal{S}_F$ that are not contained in the interior of $\bigcup H$; see Figure 3 for an illustration. We first report the intersections between the curves in $\mathcal{S}_F$ and $E_F$ in $O(nh \log n + I_F \log n)$ time, where $I_F$ is the number of such intersections, in a manner similar to that described in the two-dimensional case. Since the overall number of these intersections, over all boundaries $F$, is less than $\frac{\kappa}{t}$, the overall time needed to report all these intersections, over all these boundaries, is

$$O\left(n^2 h \log n + \frac{\kappa}{t} \log n\right).$$

We now trim, on each boundary $F$, the edges of the cross sections of the remaining input bodies, to their portions outside $\bigcup H$, and continue in a similar manner to that described in the two-dimensional case; that is, we run a line-sweeping procedure on these portions and the curves in $E_F$. This constructs the entire two-dimensional arrangements that these portions induce, from which the complete union boundary is easy to extract. The running time of this procedure over all boundaries $F$ is $O((n^2 + nh^2 + \frac{\kappa}{t}) \log n)$.

The overall running time of the algorithm in this case is thus

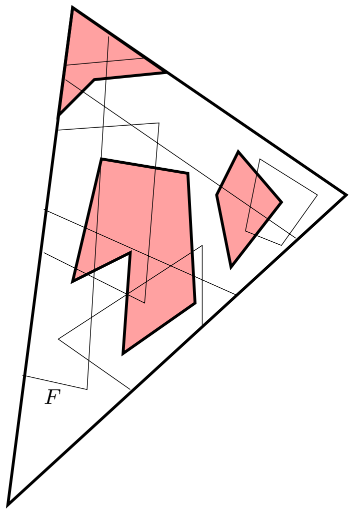

FIG. 3. *The case where the input bodies are simplices in three dimensions. The facet $F$ belongs to one of the $h$ simplices in $H$. The thick lines are the boundaries of $\bigcup H$ on $F$. The thin lines are the intersections of the $n-h$ remaining simplex boundaries with $F$. The intersections appearing in the shaded regions lie in the interior of the union of the $n$ simplices and need not be computed explicitly.*

$$\min\left\{\begin{array}{l} O((n^2+\kappa)\log n), \\ O\left(\frac{n^3}{\kappa}r\xi\log(n/\xi)+n\xi\log(n/\xi)\log n+hr\xi\log(n/\xi)+n^2h\log n+\frac{\kappa}{t}\log n\right)\end{array}\right\}$$

$$=\min\left\{\begin{array}{l} O((n^2+\kappa)\log n), \\ O\left(\frac{n^3}{\kappa}t\xi\log n\log(n/\xi)+\xi^2t\log\xi\log n\log(n/\xi)+n^2\xi\log\xi\log n+\frac{\kappa}{t}\log n\right)\end{array}\right\}.$$

Choosing, as above,

$$t=\max\left\{\frac{\sqrt{\kappa}}{\xi\log n},1\right\},$$

the running time bound becomes

$$\min\left\{O((n^2+\kappa)\log n), O\left(\frac{n^3}{\sqrt{\kappa}}\log(n/\xi)+\xi\sqrt{\kappa}\log^2 n+n^2\xi\log\xi\log n\right)\right\}.$$

Since $\kappa=O(n^3)$ and $\xi\le n$, this is upper bounded by

$$\min\left\{O((n^2+\kappa)\log n), O\left(\frac{n^3}{\sqrt{\kappa}}\log n+n^2\xi\log^2 n\right)\right\}.$$

The two terms involving $\kappa$ are equal when $\kappa=n^2$. Hence the running time is always bounded by

$$O(n^2\log n+n^2\xi\log^2 n)=O(n^2\xi\log^2 n),$$

which is subcubic for $\xi=o(\frac{n}{\log^2 n})$.

Consider next the union problem in $d \geq 4$ dimensions. Let $\mathcal{B}$ be a set of $n$ bodies of constant description complexity in $\mathbb{R}^d$, and let $\mathcal{S} \subset \mathcal{B}$ be the (unknown) subset of $\xi$ bodies whose union is equal to $\bigcup \mathcal{B}$. We compute the union by recursing on the dimension. That is, we fix a body $B \in \mathcal{B}$, take its boundary $F$, and intersect it with each body $B' \in \mathcal{B} \setminus \{B\}$. We then compute the union of these intersection bodies and construct its component within $F$. The union of all these components over all boundaries $F$ yields the boundary of $\partial \mathcal{B}$. Note that if $B \in \mathcal{B} \setminus \mathcal{S}$, then the union of the intersection bodies along $\partial B$ covers the entire boundary of $B$. In fact, the union of the intersections with the bodies of $\mathcal{S}$ already covers the boundary. Similarly, if $B \in \mathcal{S}$, then the union of the intersection bodies along $\partial B$ is equal to the union of the intersections with the bodies of $\mathcal{S}$. In either case, with an appropriate parametrization of the boundaries, we obtain $n$ $(d-1)$-dimensional instances of the union construction problem, each with output size $\leq \xi$, according to our measure. We thus compute these $(d-1)$-dimensional unions recursively and stop the recursion when $d = 3$. This leads to an overall algorithm that runs in randomized expected time $O(n^{d-1}\xi \log^2 n)$. That is, we have the following theorem.

THEOREM 4.2. *Let $S$ be a set of $n$ bodies of constant description complexity in $\mathbb{R}^d$, whose union is equal to the union of an unknown subset of $\xi \ll n$ bodies. Then the union can be constructed in randomized expected time $O(n^{d-1}\xi \log^2 n)$, which is asymptotically smaller than $n^d$ for any $\xi = o(\frac{n}{\log^2 n})$.*

## 5. Concluding remarks.

We have presented an output-sensitive algorithm for the problem of constructing efficiently the union of $n$ triangles in the plane, whose running time is expressed in terms of the smallest size $\xi$ of an unknown subset of the triangles whose union is equal to the union of the entire set. We have used a variant of the technique of Brönnimann and Goodrich [10] for finding an approximate set cover in a set system of finite VC-dimension. We have also presented a detailed and fairly generic implementation of this method, showing that the above problem can be solved in randomized expected time $O(n^{4/3} \log n + n\xi \log^2 n)$, which is subquadratic for $\xi = o(\frac{n}{\log^2 n})$. Derandomization of our implementation seems nontrivial, and an open problem that thus arises is to make the worst-case running time of the algorithm subquadratic and deterministic. The algorithm does not have to know the value of $\xi$ in advance. Instead, it runs an exponential search on $\xi$, which approximates well the correct value of $\xi$, up to a constant factor. However, this approximation concerns only the size $h$ of the subset $H$ computed in the first stage of the algorithm, whereas the number of the remaining triangles whose union covers $\bigcup T \setminus \bigcup H$ may be much larger than $h$. An open problem that this paper raises is to compute (in subquadratic time) a subset $H' \subset T$ such that $\bigcup H' = \bigcup T$ and $|H'|$ is within a constant (or even $O(\log n)$) factor off the optimum size $\xi$, or, alternatively, to show that this problem is *3SUM-hard*.

In addition, the subset $H$ of triangles that the algorithm computes is not a hitting set for the weighted system $(T, V^*)$ but is rather a $(1/2\xi)$-net for that system. Thus another question that arises is whether the Brönnimann–Goodrich algorithm can be transformed to an algorithm that finds a small $\varepsilon$-net in a general setting (with finite VC-dimension), as it is believed that finding the smallest $\varepsilon$-net is NP-complete. This might lead to an approximation algorithm for finding minimum-size $\varepsilon$-nets.

We showed that our approach can be easily extended to simply shaped bodies of constant description complexity in $\mathbb{R}^d$ for $d \geq 2$, where the union is determined by $\xi$ bodies. In the planar case, the running time remains $O(n^{4/3} \log n + n\xi \log^2 n)$. In $d \geq 3$, the union can be constructed in randomized expected time $O(n^{d-1}\xi \log^2 n)$, which is asymptotically smaller than $n^d$ for $\xi = o(\frac{n}{\log^2 n})$. For $d > 3$, we computed the union recursively on $d$ by constructing the union along each object boundary separately. However, this recursion had to stop at $d = 3$. Indeed, for $d = 3$, applying the two-dimensional algorithm on the boundary of each input body yields an overall $O(n^{7/3} \log n + n^2 \xi \log^2 n)$ expected running time, which is worse than the bound that we have obtained when $\xi = o(\frac{n^{1/3}}{\log n})$. (Note, however, that the two-dimensional approach is used in the actual construction of the union, because a global approach, in this case, would yield an inefficient solution, since it involves the vertical decomposition of simply shaped bodies in three dimensions, which may become quadratic in the number of bodies in the worst case [14, 25, 34].)

A direction for further research is to determine whether there exist simpler efficient approaches to the union construction problem studied in this paper. We note that the standard RIC of [32] may fail in the case that we have considered. In fact, the standard bad example for the RIC, consisting of $n$ triangles that form $\Theta(n^2)$ shallow vertices that are all covered by one large triangle (or, more generally, sparsely covered by $\xi = o(n)$ triangles), shows that the RIC may fail to construct the union in an output-sensitive manner.

Another direction for further research is to extend our approach to instances involving unions in three dimensions where the worst-case complexity of the union is only quadratic or near-quadratic (see [4, 7, 33] for known instances of this kind). Our approach runs in *subcubic* time, when $\xi$ is small, but does not improve upon standard, output-insensitive techniques when the union complexity is always near-quadratic. The simplest instance of such a problem would be the following: Given a collection of $n$ balls in $\mathbb{R}^3$ whose union is equal to the union of some $\xi = o(n)$ of the balls, can the union be constructed in subquadratic time?

Finally, we note that in an earlier version of the algorithm [20], we used a different approach, based on a careful implementation of the DC algorithm of [18]. The previous approach is more complicated, yields a somewhat less efficient solution (which is subquadratic for only a smaller range of the values of the parameter $\xi$), and is more difficult to extend to other geometric shapes and to higher dimensions (in this previous approach, the implementation was based on the techniques of [2, 3, 5, 11, 19]. Our new approach, based on the technique of Brönnimann and Goodrich, is simpler and more generic, improves our previous result, and extends to other shapes and to higher dimensions.

## Appendix A. The actual model for sampling $R$.

In this appendix we show that Lemma 2.1 continues to hold under the actual model of sampling $R$.

As described in section 3, we draw the elements of $R$ by randomly making $\frac{9c'r\binom{n}{2}}{\kappa}$ independent selections of a vertex out of $V^+$ for some constant $c' \geq 1$, where in each trial, each vertex (or more precisely, each pair of triangle edges from distinct triangles) is chosen with probability $\frac{1}{9\binom{n}{2}}$ (thus the same vertex may be sampled more than once). The probability $p$ that a vertex $v \in V^+$ is chosen (at least once) is equal to

$$p = 1 - \left(1 - \frac{1}{9\binom{n}{2}}\right)^{9c'r\frac{\binom{n}{2}}{\kappa}}. \tag{A.1}$$

It is easily checked that $p$ is smaller than $c' \frac{r}{\kappa}$. Moreover, one can also easily show that

$$p > c' \frac{r}{\kappa} - \frac{(c'r)^2}{\kappa^2}. \tag{A.2}$$

In this model, the variables $X_1, \ldots, X_{\kappa_S}$ (as defined in Lemma 2.1) are no longer independent. Nevertheless, examining the proof of the deviation bound given in [6, Theorem A.13], we note that the only place where it uses the assumption that these variables are independent is in the derivation of the equality

$$\mathbf{E}\left[e^{\sum_{i=1}^{\kappa_S} \lambda X_i}\right] = \prod_{i=1}^{\kappa_S} \mathbf{E}\left[e^{\lambda X_i}\right]$$

for any $\lambda$. Moreover, the analysis in [6] uses only the value $\lambda = \frac{r_0}{p\kappa_S}$, where $r_0$ is defined as in Lemma 2.1. An inspection of the derivation of these bounds in [6] shows that they continue to hold when

$$\mathbf{E}\left[e^{\sum_{i=1}^{\kappa_S} \lambda X_i}\right] \le \prod_{i=1}^{\kappa_S} \mathbf{E}\left[e^{\lambda X_i}\right].$$

Furthermore, Lemma 2.1 continues to hold when the weaker inequality

$$\mathbf{E}\left[e^{\sum_{i=1}^{\kappa_S} \lambda X_i}\right] \le \gamma \prod_{i=1}^{\kappa_S} \mathbf{E}\left[e^{\lambda X_i}\right] \tag{A.3}$$

holds for some positive constant $\gamma$. This has the effect of multiplying the probability that (2.1) fails by $\gamma$, which implies that (2.1) still holds, w.o.p. Hence, it suffices to show that (A.3) holds for the above value of $\lambda$. More precisely, as in the original proof of Lemma 2.1, it suffices to establish this under the assumption that $\kappa_S > \frac{\kappa}{t}$.

In our model,

$$\prod_{i=1}^{\kappa_S} \mathbf{E}\left[e^{\lambda X_i}\right] = \left(e^{\lambda} p + (1-p)\right)^{\kappa_S} = \left(1 + p(e^{\lambda} - 1)\right)^{\kappa_S}, \tag{A.4}$$

and

$$\mathbf{E}\left[e^{\sum_{i=1}^{\kappa_S} \lambda X_i}\right] = \sum_{m=0}^{r^*} Pr\left[r_S = m\right] e^{\lambda m}, \tag{A.5}$$

where $r^* = \min\{\frac{9c'r\binom{n}{2}}{\kappa}, \kappa_S\}$. (Note that $Pr[r_S = m] = 0$ for any $m > r^*$.)

In each of the $\frac{9c'r\binom{n}{2}}{\kappa}$ drawing trials, the probability that we have selected a vertex $v$, and that it is not covered by $S$, is $q = \frac{\kappa}{9\binom{n}{2}} \cdot \frac{\kappa_S}{\kappa} = \frac{\kappa_S}{9\binom{n}{2}}$. Since these trials are independent, we have

$$Pr\left[r_S = m\right] = \binom{r^*}{m} q^m (1-q)^{r^*-m}.$$

Hence the expression in (A.5) becomes

$$\sum_{m=0}^{r^*} \binom{r^*}{m} q^m (1-q)^{r^*-m} e^{\lambda m} = \left(e^\lambda q + 1 - q\right)^{r^*} = \left(1 + q\left(e^\lambda - 1\right)\right)^{r^*}.$$

In other words, putting $e^\lambda - 1 = \lambda_0$, we need to show that

$$\left(1+\lambda_0 q\right)^{r^*} \leq \gamma\left(1+\lambda_0 p\right)^{\kappa_S}$$

for some constant $\gamma > 0$. We will show that

$$\left(1+\lambda_0 q\right)^{r^*} \leq \left(1+\lambda_0 p\right)^{2c'r}\left(1+\lambda_0 p\right)^{\kappa_S},$$

which implies the preceding inequality because $(1+\lambda_0 p)^{2c'r} = O(1)$. Indeed, $(1+\lambda_0 p)^{2c'r} < e^{2c'\lambda_0 pr}$. Using the fact that $e^\lambda \leq 1+2\lambda$ for $0 \leq \lambda \leq 1$ and substituting $\lambda = \frac{r_0}{p\kappa_S}$ (which is indeed $\leq 1$ when $r_0$ is chosen as in Lemma 2.1 and $c'$ is sufficiently large, as is easily verified) and $\lambda_0 = e^\lambda - 1$, we have $\lambda_0 \leq 2\lambda$, and thus

$$e^{2c'\lambda_0 pr} \leq e^{4c'\frac{rr_0}{\kappa_S}}.$$

Since we choose $r_0 = \sqrt{2c_0\frac{r}{\kappa}\kappa_S \log n}$ in Lemma 2.1, for some constant $c_0 \geq 1$, the latter expression is smaller than

$$e^{4c'\frac{r}{\kappa_S}\sqrt{2c_0\frac{r}{\kappa}\kappa_S\log n}} = e^{O\left(r\sqrt{\frac{r\log n}{\kappa\kappa_S}}\right)},$$

which, since we assume that $\kappa_S > \frac{\kappa}{t}$, is upper bounded by

$$e^{O\left(\frac{r}{\kappa}\sqrt{tr\log n}\right)}.$$

Substituting $r = ct\log n$, for some constant $c$, and $t = \max\{\frac{\sqrt{\kappa}}{\xi\log n}, 1\}$, as above, and using the assumption that $\kappa > \beta\max\{\xi^2, n^{4/3}\}$, for an absolute constant $\beta > 1$ (see section 3), we have

$$e^{2c'\lambda_0 pr} < \max\left\{e^{O\left(\frac{1}{\xi^2}\right)}, e^{O\left(\frac{\log^2 n}{\kappa}\right)}\right\} = O(1).$$

It thus remains to show that

$$\left(1+\lambda_0 q\right)^{r^*} \leq \left(1+\lambda_0 p\right)^{2c'r+\kappa_S}. \tag{A.6}$$

Let us first assume that $\frac{9c'r\binom{n}{2}}{\kappa} \leq \kappa_S$. We thus need to show that

$$\left(1+\lambda_0\frac{\kappa_S}{9\binom{n}{2}}\right)^{\frac{9c'r\binom{n}{2}}{\kappa}} \leq \left(1+\lambda_0 p\right)^{2c'r+\kappa_S}$$

or that

$$\left(1+\lambda_0\frac{\kappa_S}{9\binom{n}{2}}\right)^{\frac{9\binom{n}{2}}{\kappa_S}} \leq \left(1+\lambda_0 p\right)^{\frac{\kappa(2c'r+\kappa_S)}{c'r\kappa_S}}.$$

Note that the function $(1+\lambda_0 x)^{\frac{1}{x}}$ is monotone decreasing, and since we have assumed that $\frac{9c'r\binom{n}{2}}{\kappa} \le \kappa_S$, it follows that $\frac{\kappa_S}{9\binom{n}{2}} \ge \frac{c'r}{\kappa} > p$. We thus have

$$\left(1+\lambda_0\frac{\kappa_S}{9\binom{n}{2}}\right)^{\frac{9\binom{n}{2}}{\kappa_S}} \le (1+\lambda_0 p)^{\frac{1}{p}}.$$

It therefore suffices to show that $\frac{1}{p} \le \frac{\kappa(2c'r+\kappa_S)}{c'r\kappa_S}$. Using (A.2), $p > c'\frac{r}{\kappa} - \frac{(c'r)^2}{\kappa^2}$, and thus it suffices to show that $\frac{c'r}{\kappa}(1-\frac{c'r}{\kappa}) \ge \frac{c'r\kappa_S}{\kappa(2c'r+\kappa_S)}$, or that

$$1-\frac{c'r}{\kappa} \ge 1-\frac{2c'r}{2c'r+\kappa_S}, \tag{A.7}$$

or that

$$\kappa \ge c'r+\frac{\kappa_S}{2},$$

which clearly holds, since $\kappa_S \le \kappa$ and $r = o(\kappa)$.

We next assume that $\frac{9c'r\binom{n}{2}}{\kappa} > \kappa_S$. We thus need to show that

$$\left(1+\lambda_0\frac{\kappa_S}{9\binom{n}{2}}\right) \le (1+\lambda_0 p)^{\frac{2c'r+\kappa_S}{\kappa_S}}.$$

Using the facts that $(1+\lambda_0 p)^{\frac{2c'r+\kappa_S}{\kappa_S}} \ge 1+\lambda_0 p\,(\frac{2c'r+\kappa_S}{\kappa_S})$ and $\frac{\kappa_S}{9\binom{n}{2}} < \frac{c'r}{\kappa}$, as well as (A.2), it is sufficient to show that

$$\frac{c'r}{\kappa} \le c'\frac{r}{\kappa}\left(1-\frac{c'r}{\kappa}\right)\left(1+\frac{2c'r}{\kappa_S}\right)$$

or that $(1-\frac{c'r}{\kappa})(1+\frac{2c'r}{\kappa_S}) \ge 1$, which is identical to (A.7), as is easily checked, and thus follows by the preceding argument.

We note that (A.6) holds for any value of $\lambda_0 > 0$, and the assumption on $\lambda$ is used only when showing that $(1+\lambda_0 p)^{2c'r} = O(1)$. This completes the proof of (A.3) for the value of $\lambda$ that we use and therefore shows that Lemma 2.1 also holds for the sampling model used by our algorithm.

**Acknowledgments.** The authors wish to thank Ken Clarkson, Alon Efrat, and Sariel Har-Peled for useful discussions on this problem. In particular, Sariel's insistence that we use the Brönnimann–Goodrich technique (instead of the DC algorithm in the earlier version [20]) has finally led to the improved algorithm presented in this paper. The authors also wish to thank two anonymous referees for useful comments.

# EXTENDING DOWNWARD COLLAPSE FROM 1-VERSUS-2 QUERIES TO $m$-VERSUS-$m$+1 QUERIES*

EDITH HEMASPAANDRA†, LANE A. HEMASPAANDRA‡, AND HARALD HEMPEL§

**Abstract.** The top part of Figure 1.1 shows some classes from the (truth-table) bounded-query and boolean hierarchies. It is well known that if either of these hierarchies collapses at a given level, then all higher levels of that hierarchy collapse to that same level. This is a standard "upward translation of equality" that has been known for over a decade. The issue of whether these hierarchies can translate equality *downwards* has proven vastly more challenging. In particular, with regard to Figure 1.1, consider the following claim:

$$\mathrm{P}^{\Sigma_k^p}_{m\text{-tt}} = \mathrm{P}^{\Sigma_k^p}_{m+1\text{-tt}} \Rightarrow \mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p) = \mathrm{BH}(\Sigma_k^p). \qquad (*)$$

This claim, if true, says that equality translates downwards between levels of the bounded-query hierarchy and the boolean hierarchy levels that (before the fact) are immediately below them.

Until recently, it was not known whether (*) *ever* held, except for the degenerate cases $m = 0$ and $k = 0$. Then Hemaspaandra, Hemaspaandra, and Hempel [*SIAM J. Comput.,* 28 (1999), pp. 383–393] proved that (*) holds for all $m$, for $k > 2$. Buhrman and Fortnow [*J. Comput. System Sci.,* 59 (1999), pp. 182–199] then showed that, when $k = 2$, $(*)$ holds for the case $m = 1$. In this paper, we prove that for the case $k = 2$, $(*)$ holds for all values of $m$. Since there is an oracle relative to which "for $k = 1$, $(*)$ holds for all $m$"fails (see Buhrman and Fortnow), our achievement of the $k = 2$ case cannot be strengthened to $k = 1$ by any relativizable proof technique. The new downward translation we obtain also tightens the collapse in the polynomial hierarchy implied by a collapse in the bounded-query hierarchy of the second level of the polynomial hierarchy.

**Key words.** computational complexity theory, no-search easy-hard technique, downward collapse, upward separation, downward translation of equality, boolean hierarchy, polynomial hierarchy

## 1. Introduction.

Does the equality of low-complexity classes imply the equality of higher-complexity classes? Does the equality of high-complexity classes imply the equality of lower-complexity classes? These questions—known, respectively, as upward and downward translation of equality—have long been central topics in computational complexity theory. For example, in the seminal paper on the polynomial

hierarchy, Meyer and Stockmeyer [20] proved that the polynomial hierarchy displays upward translation of equality (e.g., $\mathrm{P} = \mathrm{NP} \Rightarrow \mathrm{P} = \mathrm{PH}$).

The issue of whether the polynomial hierarchy—its levels and/or bounded access to its levels—ever displays *downward* translation of equality has proven more difficult. The first such result regarding bounded access to polynomial hierarchy levels was recently obtained by Hemaspaandra, Hemaspaandra, and Hempel [14], who proved that if for some high level of the polynomial hierarchy one query equals two queries, then the hierarchy collapses down not just to one query to that level, but rather to that level itself. That is, they proved the following result (note: the levels of the polynomial hierarchy [20, 27] are denoted in the standard way, namely, $\Sigma_0^p = \mathrm{P}$, $\Sigma_1^p = \mathrm{NP}$, $\Sigma_k^p = \mathrm{NP}^{\Sigma_{k-1}^p}$ for each $k > 1$, and $\Pi_k^p = \{L \mid \overline{L} \in \Sigma_k^p\}$ for each $k \geq 0$).

THEOREM 1.1 (see [14]). *For each $k > 2$: If $\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{P}^{\Sigma_k^p[2]}$, then $\Sigma_k^p = \Pi_k^p = \mathrm{PH}$.*

There are two clear directions in which one might hope to strengthen Theorem 1.1. First, one might ask not just about 1-versus-2 queries but rather about $m$-versus-$m+1$ queries. Second, one might ask if the $k > 2$ can be improved to $k > 1$. Both of these have been achieved. The first strengthening was achieved in a more technical section of the same paper by Hemaspaandra, Hemaspaandra, and Hempel [14]. They showed that Theorem 1.1 was just a special case of a more general downward translation result they established, for $k > 2$, between bounded access to $\Sigma_k^p$ and the boolean hierarchy over $\Sigma_k^p$. The second type of strengthening was achieved by Buhrman and Fortnow [4], who showed that Theorem 1.1 holds even for $k = 2$, but who also showed that no relativizable technique can establish Theorem 1.1 for $k = 1$.

Neither of the results or proofs just mentioned is broad enough to achieve both strengthenings simultaneously. In this paper we derive new theorems strong enough to achieve this. In particular, we unify and extend all the above claims, and from our more general results it easily follows that (see Corollary 5.1)

For each $m > 0$ and each $k > 1$;

$$\mathrm{P}^{\Sigma_k^p}_{m\text{-tt}} = \mathrm{P}^{\Sigma_k^p}_{m+1\text{-tt}} \Rightarrow \mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p).$$

Prior to the work of this paper, the cases $(k = 2 \wedge m = 2)$, $(k = 2 \wedge m = 3)$, $(k = 2 \wedge m = 4)$, and so on were open. As shown near the end of section 5, the stronger downward translation we obtain yields a strengthened collapse of the polynomial hierarchy under the assumption of a collapse in the bounded-query hierarchy over $\mathrm{NP}^{\mathrm{NP}}$. (Throughout this paper, we mean the *truth-table* bounded-query hierarchy when we say bounded-query hierarchy. However, as mentioned in section 5, our results equally well strengthen the collapse of the polynomial hierarchy under the assumption of a collapse in the *Turing* bounded-query hierarchy over $\mathrm{NP}^{\mathrm{NP}}$.)

The results that lead to the result mentioned above (i.e., Corollary 5.1) are themselves examples of downward translation of equality. Those intermediate results that are of interest in their own right are proven in sections 3 and 4.

We conclude this section with some comments and pointers to the literature. As to techniques, to study *upward* translations of equality resulting from collapses of the boolean hierarchy, Kadin [17] introduced what is known as the "easy-hard technique," and that technique was employed and strengthened in a long series of papers by many authors (see the survey [13]). In particular, Hemaspaandra, Hemaspaandra, and Hempel [14] achieved Theorem 1.1 by introducing what can be called the *no-search easy-hard technique*—basically, they show that a complexity-raising search seemingly central in the easy-hard technique can in fact be eliminated, and this stronger technique opens the door to stronger results, namely, *downward* translation of equality results for bounded-query classes. The present paper builds on the no-search easy-hard technique and on a variation on that used by Buhrman and Fortnow to prove the 1-versus-2-queries case at the second level of the polynomial hierarchy. However, these approaches seem not to be strong enough to yield our result, and so we also must combine with these techniques a new approach extending beyond 1-versus-2 queries.[1] We mention that Chang has obtained exciting applications of easy-hard-type arguments in the context of the study of approximation [7]. We also mention that there is a body of literature showing that equality of exponential-time classes translates downwards in a limited sense: Relationships are obtained connecting such equalities to whether *sparse* sets within lower time classes are unexpectedly simple (see [9, 10], see also [6, 21, 22]; limitations of this line are presented in [1, 2, 16]). Other than being an interesting restricted type of downward translation of equality, that work has no close connection with the present paper due to that body of literature being applicable only to sparse sets. Finally, we mention that the study of downward collapse results is closely related to the formal study of the power of query order—whether the order in which databases are accessed matters—an area recently introduced by Hemaspaandra, Hempel, and Wechsung [15]. In particular, downward collapse techniques have been used to understand the power of query order within the polynomial hierarchy (see [12], the survey [11], and the references therein, especially [31]).

## 2. Preliminaries.

To explain exactly what we do and how it extends previous results, we now state the previous results in the more general forms in which they were

[1] Regarding this new approach (and this footnote is aimed primarily at those already familiar with the techniques of the previous papers on the no-search easy-hard technique): In the previous work extending Theorem 1.1 to the boolean hierarchy (part 1 of Theorem 2.4), the "coordination" difficulties presented by the fact that boolean hierarchy sets are in effect handled via collections of machines were resolved via using certain lexicographically extreme objects as clear signposts to signal machines with (see [14, section 3]). In the current stronger context that approach fails. Instead, we integrate into the structure of no-search easy-hard-technique proofs (especially those of [14, 4]) the so-called "telescoping" normal form possessed by the boolean hierarchy over $\Sigma_k^p$ (for each $k$, see [18, 5]). (The telescoping normal form guarantees that if $L \in \mathrm{DIFF}_m(\Sigma_k^p)$, then there are sets $L_1, L_2, \ldots, L_m \in \Sigma_k^p$ such that $L = L_1 - (L_2 - (L_3 - \cdots (L_{m-1} - L_m)\cdots))$ and $L_1 \supseteq L_2 \supseteq \cdots \supseteq L_{m-1} \supseteq L_m$.) This normal form has in different contexts proven useful in the study of boolean hierarchies (see, e.g., [5, 6, 18]) and has been used by Rohatgi in the context of a paper using the original (i.e., the with-search version of the) easy-hard technique [24].

actually established, though in some cases with different notation or statements (see, e.g., the interesting paper by Wagner [31] regarding the relationship between truth-table classes and what in the present paper is $\bigoplus$ notation). Before stating the results, we very briefly remind the reader of some definitions and notations, namely the $\Delta$ levels of the polynomial hierarchy, truth-table access, symmetric difference classes, and boolean hierarchies. A detailed introduction to the boolean hierarchy, including its motivation and applications, can be found in [5, 6].

DEFINITION 2.1.

1. *For each* $k \geq 1$, $\Delta_k^p$ *denotes* $\mathrm{P}^{\Sigma_{k-1}^p}$ [20]. *For each* $m \geq 0$ *and each set* $A$, $\mathrm{P}_{m\text{-tt}}^A$ *denotes the class of languages accepted by deterministic polynomial-time machines allowed* $m$ *truth-table (i.e., nonadaptive) queries to* $A$ *(see* [19]*). For each* $m \geq 0$ *and each complexity class* $\mathcal{C}$, $\mathrm{P}_{m\text{-tt}}^{\mathcal{C}}$ *is defined as* $\bigcup_{A \in \mathcal{C}} \mathrm{P}_{m\text{-tt}}^A$. *For each* $m \geq 0$ *and each set* $A$, $\mathrm{P}^{A[m]}$ *denotes the class of languages accepted by deterministic polynomial-time machines allowed* $m$ *Turing (i.e., adaptive) queries to* $A$ *(see* [19]*). For each* $m \geq 0$ *and each complexity class* $\mathcal{C}$, $\mathrm{P}^{\mathcal{C}[m]}$ *is defined as* $\bigcup_{A \in \mathcal{C}} \mathrm{P}^{A[m]}$.
2. *For any sets* $C$ *and* $D$, $C \oplus D = (C - D) \cup (D - C)$. *For any classes* $\mathcal{C}$ *and* $\mathcal{D}$, $\mathcal{C} \bigoplus \mathcal{D} = \{L \mid (\exists C \in \mathcal{C})(\exists D \in \mathcal{D})[L = C \oplus D]\}$. *We will refer to classes defined via* $\bigoplus$ *as* symmetric difference classes.
3. [5, 6] *Let* $\mathcal{C}$ *be any complexity class. The levels of the boolean hierarchy are defined as follows.*
   (a) $\mathrm{DIFF}_1(\mathcal{C}) = \mathcal{C}$.
   (b) *For all* $m \geq 1$, $\mathrm{DIFF}_{m+1}(\mathcal{C}) = \{L \mid (\exists L_1 \in \mathcal{C})(\exists L_2 \in \mathrm{DIFF}_m(\mathcal{C}))[L = L_1 - L_2]\}$.
   (c) *For all* $m \geq 1$, $\mathrm{coDIFF}_m(\mathcal{C}) = \{L \mid \overline{L} \in \mathrm{DIFF}_m(\mathcal{C})\}$.
   (d) $\mathrm{BH}(\mathcal{C})$, *the boolean hierarchy over* $\mathcal{C}$, *is* $\bigcup_{m \geq 1} \mathrm{DIFF}_m(\mathcal{C})$.

As is standard, for any set $A$ and any natural number $n$, $A^{\leq n}$ denotes the set of all strings in $A$ of length less than or equal to $n$. As is standard, for any set $A$ and any natural number $n$, $A^{=n}$ denotes the set of all strings in $A$ of length exactly $n$. For example, note that "$|x| = n$," "$x \in (\Sigma^*)^{=n}$," and "$x \in \Sigma^n$" are all ways of saying that the length of string $x$ equals $n$. This notation should not be confused with the notation $\Sigma_n^p$, which denotes the $n$th level of the polynomial hierarchy [20].

The relationship between the levels of the boolean hierarchy over $\Sigma_k^p$, bounded access to $\Sigma_k^p$, and various symmetric difference classes is as follows.

PROPOSITION 2.2.

1. [30] *For each* $k \geq 1$ *and each* $m \geq 1$, $\mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} \subseteq \mathrm{DIFF}_{m+1}(\Sigma_k^p) \subseteq \mathrm{P}_{m+1\text{-tt}}^{\Sigma_k^p}$ *and* $\mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} \subseteq \mathrm{coDIFF}_{m+1}(\Sigma_k^p) \subseteq \mathrm{P}_{m+1\text{-tt}}^{\Sigma_k^p}$.
2. [18] *For all* $k \geq 1$ *and all* $m \geq 1$,
$$\mathrm{DIFF}_m(\Sigma_k^p) = \underbrace{\Sigma_k^p \bigoplus \Sigma_k^p \bigoplus \cdots \bigoplus \Sigma_k^p}_{m \text{ times}}.$$
3. [31] *For all* $k \geq 1$ *and all* $m \geq 1$,
$$\mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} = \mathrm{P} \bigoplus \mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{P} \bigoplus \underbrace{\Sigma_k^p \bigoplus \Sigma_k^p \bigoplus \cdots \bigoplus \Sigma_k^p}_{m \text{ times}}.$$

We will use the following easy fact about symmetric difference classes.

*Observation* 2.3. Let $\mathcal{C}_1$, $\mathcal{C}_2$, and $\mathcal{D}$ be complexity classes. If $\mathcal{C}_1 \subseteq \mathcal{C}_2$, then $\mathcal{C}_1 \bigoplus \mathcal{D} \subseteq \mathcal{C}_2 \bigoplus \mathcal{D}$.

Now we can state what the earlier papers achieved. (In achieving these results, those papers obtained as corollaries the results attributed to them in the Introduction.)

THEOREM 2.4.

1. [14] *Let $m > 0$, $0 \leq i < j < k$, and $i < k-2$. If* $\mathrm{P}_{1\text{-tt}}^{\Sigma_i^p} \bigoplus \mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{P}_{1\text{-tt}}^{\Sigma_j^p} \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$, *then* $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$.
2. [4] *If* $\mathrm{P} \bigoplus \Sigma_2^p = \mathrm{NP} \bigoplus \Sigma_2^p$, *then* $\Sigma_2^p = \Pi_2^p = \mathrm{PH}$.

In this paper, we unify both of the above results—and achieve the strengthened corollary alluded to in the Introduction regarding the relative power of $m$ and $m+1$ queries to $\Sigma_k^p$ (namely Corollary 5.1: For each $m > 0$ and each $k > 1$, $\mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} = \mathrm{P}_{m+1\text{-tt}}^{\Sigma_k^p} \Rightarrow \mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$)—by proving the following downward translation of equality result, which will be our Theorem 3.3:

Let $m > 0$ and $0 < i < k$. If $\Delta_i^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p) = \Sigma_i^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$, then $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$.

## 3. A new downward translation of equality.

We first need a definition and a useful lemma.

DEFINITION 3.1. *For any sets $C$ and $D$,* $C \tilde{\oplus} D = \{\langle x, y\rangle \mid x \in C \Leftrightarrow y \notin D\}$.

LEMMA 3.2. *If $C$ is $\leq_{\mathrm{m}}^p$-complete for $\mathcal{C}$ and $D$ is $\leq_{\mathrm{m}}^p$-complete for $\mathcal{D}$, then $C \tilde{\oplus} D$ is $\leq_{\mathrm{m}}^p$-hard for $\mathcal{C} \bigoplus \mathcal{D}$.*

*Proof.* Let $L \in \mathcal{C} \bigoplus \mathcal{D}$. We need to show that $L \leq_{\mathrm{m}}^p C \tilde{\oplus} D$. Let $\widehat{C} \in \mathcal{C}$ and $\widehat{D} \in \mathcal{D}$ be such that $L = \widehat{C} \oplus \widehat{D}$. Let $\widehat{C} \leq_{\mathrm{m}}^p C$ by $f_C$, and $\widehat{D} \leq_{\mathrm{m}}^p D$ by $f_D$. Then $x \in L$ if and only if $x \in \widehat{C} \oplus \widehat{D}$, and $x \in \widehat{C} \oplus \widehat{D}$ if and only if $(x \in \widehat{C} \Leftrightarrow x \notin \widehat{D})$, and $(x \in \widehat{C} \Leftrightarrow x \notin \widehat{D})$ if and only if $(f_C(x) \in C \Leftrightarrow f_D(x) \notin D)$, and $(f_C(x) \in C \Leftrightarrow f_D(x) \notin D)$ if and only if $\langle f_C(x), f_D(x)\rangle \in C \tilde{\oplus} D$. It follows that $x \in L$ if and only if $\langle f_C(x), f_D(x)\rangle \in C \tilde{\oplus} D$. □

We now state our main result. (Note that as both $\Delta_i^p$ and $\Sigma_i^p$ contain both $\emptyset$ and $\Sigma^*$, it is clear that the classes involved in the first equality below are at least as large as the classes involved in the second equality below.)

THEOREM 3.3. *Let $m > 0$ and $0 < i < k$. If* $\Delta_i^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p) = \Sigma_i^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$, *then* $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$.

This result almost follows from the forthcoming Theorem 4.1 (which states that if $s, m > 0$, $0 < i < k-1$, and $\mathrm{DIFF}_s(\Sigma_i^p) \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$ is closed under complementation, then $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$)—or, to be more accurate, most of its cases are easy corollaries of Theorem 4.1. The $s = 1$ case of Theorem 4.1 states that for all $m > 0$ and all $i$ and $k$ such that $0 < i < k-1$, if $\Sigma_i^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$ is closed under complementation, then $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$. Since $\Delta_i^p \bigoplus \mathcal{C}$ is closed under complementation for all $\mathcal{C}$ and all $i \geq 0$, we have that if $\Delta_i^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p) = \Sigma_i^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$, then $\Sigma_i^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$ is closed under complementation. Thus, Theorem 4.1 certainly implies Theorem 3.3 for all $m > 0$ and all $i$ and $k$ such that $0 < i < k-1$. It remains for us to establish the missing cases, and Theorem 3.4 below does exactly that.

THEOREM 3.4. *Let $m > 0$ and $k > 1$. If* $\Delta_{k-1}^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p) = \Sigma_{k-1}^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$, *then* $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$.

Before proving Theorem 3.4, we fix some complete languages that will be useful, and establish names that we will use globally for these fixed, complete languages. (In light of the standard quantifier characterization of the polynomial hierarchy's levels [32] and the legality of padding sets to get new sets for which linear-bounded quantification suffices, it is not hard to see that there exist complete languages having the properties stated in Fact 3.5.) Throughout the paper we will use the names introduced in this fact for these sets (or more specifically, let us consider sets of the form guaranteed by the fact to be fixed, and let us attach to them the names used in the fact).

FACT 3.5. *For each $k > 1$, there exist a set $L'_{\Sigma_k^p}$ that is $\leq_{\mathrm{m}}^p$-complete for $\Sigma_k^p$, a set $\widehat{L}_{\Sigma_{k-1}^p}$ that is $\leq_{\mathrm{m}}^p$-complete for $\Sigma_{k-1}^p$, and a set $L''_{\Sigma_{k-2}^p}$ that is $\leq_{\mathrm{m}}^p$-complete for $\Sigma_{k-2}^p$, such that these sets satisfy*

$$L'_{\Sigma_k^p} = \{x \mid (\exists y \in \Sigma^{|x|})(\forall z \in \Sigma^{|x|})[\langle x, y, z\rangle \in L''_{\Sigma_{k-2}^p}]\}$$

*and*

$$\widehat{L}_{\Sigma_{k-1}^p} = \{\langle x, y, z\rangle \mid |x| = |y| \wedge (\exists z')[(|x| = |zz'|) \wedge \langle x, y, zz'\rangle \notin L''_{\Sigma_{k-2}^p}]\}.$$

*Proof of Theorem* 3.4. Let $m > 0$ and $k > 1$. Let $\widehat{L}_{\Sigma_{k-1}^p} \in \Sigma_{k-1}^p$ be as fixed in Fact 3.5, and let $L_{\Delta_{k-1}^p}$ and $L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ be any fixed $\leq_{\mathrm{m}}^p$-complete sets for $\Delta_{k-1}^p$ and $\mathrm{DIFF}_m(\Sigma_k^p)$, respectively; such languages exist, e.g., via the standard type of canonical-complete-set constructions involving padding and enumerations of clocked machines. From Lemma 3.2 it follows that $L_{\Delta_{k-1}^p} \tilde{\oplus} L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ is $\leq_{\mathrm{m}}^p$-hard for $\Delta_{k-1}^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$. Since $\widehat{L}_{\Sigma_{k-1}^p} \tilde{\oplus} L_{\mathrm{DIFF}_m(\Sigma_k^p)} \in \Sigma_{k-1}^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$ and by assumption $\Delta_{k-1}^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p) = \Sigma_{k-1}^p \bigoplus \mathrm{DIFF}_m(\Sigma_k^p)$, there exists a (polynomial-time) many-one reduction $h$ from $\widehat{L}_{\Sigma_{k-1}^p} \tilde{\oplus} L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ to $L_{\Delta_{k-1}^p} \tilde{\oplus} L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ (in light of the latter's $\leq_{\mathrm{m}}^p$-hardness). So, for all $x_1, x_2, y_1, y_2 \in \Sigma^*$: If $h(\langle x_1, x_2\rangle) = \langle y_1, y_2\rangle$, then $((x_1 \in \widehat{L}_{\Sigma_{k-1}^p} \Leftrightarrow x_2 \notin L_{\mathrm{DIFF}_m(\Sigma_k^p)})$ iff $(y_1 \in L_{\Delta_{k-1}^p} \Leftrightarrow y_2 \notin L_{\mathrm{DIFF}_m(\Sigma_k^p)}))$. Equivalently, for all $x_1, x_2, y_1, y_2 \in \Sigma^*$: If $h(\langle x_1, x_2\rangle) = \langle y_1, y_2\rangle$, then

$$(3.1)\quad (x_1 \in \widehat{L}_{\Sigma_{k-1}^p} \Leftrightarrow x_2 \in L_{\mathrm{DIFF}_m(\Sigma_k^p)}) \text{ iff } (y_1 \in L_{\Delta_{k-1}^p} \Leftrightarrow y_2 \in L_{\mathrm{DIFF}_m(\Sigma_k^p)}).$$

We can use $h$ to recognize some of $\overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ by a $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm. In particular, we say that a string $x$ is *easy for length* $n$ if there exists a string $x_1$ such that $|x_1| \leq n$ and $(x_1 \in \widehat{L}_{\Sigma_{k-1}^p} \Leftrightarrow y_1 \notin L_{\Delta_{k-1}^p})$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$.

Let $p$ be a fixed polynomial, which will be exactly specified later in the proof. We have the following algorithm to test whether $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ in the case that (our input) $x$ is an easy string for length $p(|x|)$. Guess $x_1$ with $|x_1| \leq p(|x|)$, let $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$, and accept if and only if $((x_1 \in \widehat{L}_{\Sigma_{k-1}^p} \Leftrightarrow y_1 \notin L_{\Delta_{k-1}^p}) \wedge y_2 \in L_{\mathrm{DIFF}_m(\Sigma_k^p)})$. (To understand what is going on here, simply note that if $(x_1 \in \widehat{L}_{\Sigma_{k-1}^p} \Leftrightarrow y_1 \notin L_{\Delta_{k-1}^p})$ holds, then by (3.1) we have $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}} \Leftrightarrow y_2 \in L_{\mathrm{DIFF}_m(\Sigma_k^p)}$. Note also that both $x_1 \in \widehat{L}_{\Sigma_{k-1}^p}$ and $y_1 \notin L_{\Delta_{k-1}^p}$ can be very easily tested by a machine that has a $\Sigma_{k-1}^p$ oracle.) This algorithm is not necessarily a $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm, but it does inspire the following $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm to test whether $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ in the case that $x$ is an easy string for length $p(|x|)$. For clarity, we will attempt to telegraph the complexity issues as we work to develop the algorithm.

Let $L_1, L_2, \ldots, L_m$ be languages in $\Sigma_k^p$ such that $L_{\mathrm{DIFF}_m(\Sigma_k^p)} = L_1 - (L_2 - (L_3 - \cdots (L_{m-1} - L_m) \cdots))$ and $L_1 \supseteq L_2 \supseteq \cdots \supseteq L_{m-1} \supseteq L_m$ (this can be done as this is simply the "telescoping" normal form of the levels of the boolean hierarchy over $\Sigma_k^p$; see [5]). For $1 \leq \ell \leq m$, define $L'_\ell$ as the language accepted by the following $\Sigma_k^p$

machine: On input $x$, guess $x_1$ with $|x_1| \leq p(|x|)$, let $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$, and accept if and only if $((x_1 \in \widehat{L}_{\Sigma^p_{k-1}} \Leftrightarrow y_1 \notin L_{\Delta^p_{k-1}}) \wedge y_2 \in L_\ell)$.

Note that $L'_\ell \in \Sigma^p_k$ for each $\ell$, and that $L'_1 \supseteq L'_2 \supseteq \cdots \supseteq L'_{m-1} \supseteq L'_m$. We will show that if $x$ is an easy string for length $p(|x|)$, then $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma^p_k)}}$ if and only if $x \in L'_1 - (L'_2 - \cdots (L'_{m-1} - L'_m)\cdots)$.

So suppose that $x$ is an easy string for length $p(|x|)$. Define $\ell'$ to be the unique integer such that (a) $0 \leq \ell' \leq m$, (b) $x \in L'_s$ for $1 \leq s \leq \ell'$, and (c) $x \notin L'_s$ for $s > \ell'$. It is immediate that $x \in L'_1 - (L'_2 - \cdots (L'_{m-1} - L'_m)\cdots)$ if and only if $\ell'$ is odd.

Let $w$ be some string such that

$$(\exists x_1 \in (\Sigma^*)^{\leq p(|x|)})(\exists y_1)[h(\langle x_1, x\rangle) = \langle y_1, w\rangle \wedge (x_1 \in \widehat{L}_{\Sigma^p_{k-1}} \Leftrightarrow y_1 \notin L_{\Delta^p_{k-1}})],$$

and $w \in L_{\ell'}$ if $\ell' > 0$ ($\ell'$ here is the $\ell'$ already set in the previous paragraph). Note that such a $w$ exists, since $x$ is easy for length $p(|x|)$ and, by our definition of $\ell'$, $x \in L'_{\ell'}$. By the definition of $\ell'$ (namely, since $x \notin L'_s$ for $s > \ell'$), $w \notin L_s$ for all $s > \ell'$. It follows that $w \in L_{\mathrm{DIFF}_m(\Sigma^p_k)}$ if and only if $\ell'$ is odd. It is clear, keeping in mind the definition of $h$, that $(x \in \overline{L_{\mathrm{DIFF}_m(\Sigma^p_k)}} \Leftrightarrow w \in L_{\mathrm{DIFF}_m(\Sigma^p_k)})$, $(w \in L_{\mathrm{DIFF}_m(\Sigma^p_k)} \Leftrightarrow \ell'$ is odd), and ($\ell'$ is odd $\Leftrightarrow x \in L'_1 - (L'_2 - \cdots (L'_{m-1} - L'_m)\cdots)$). So $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma^p_k)}} \Leftrightarrow x \in L'_1 - (L'_2 - \cdots (L'_{m-1} - L'_m)\cdots))$.

This completes the case where $x$ is easy, as $L'_1 - (L'_2 - \cdots (L'_{m-1} - L'_m)\cdots)$ in effect specifies a $\mathrm{DIFF}_m(\Sigma^p_k)$ algorithm.

We say that $x$ is *hard for length* $n$ if $|x| \leq n$ and $x$ is not easy for length $n$, i.e., if $|x| \leq n$ and for all $x_1$ with $|x_1| \leq n$, $(x_1 \in \widehat{L}_{\Sigma^p_{k-1}} \Leftrightarrow y_1 \in L_{\Delta^p_{k-1}})$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$. Note that if $x$ is hard for $p(|x|)$, then $x \notin L'_1$.

If $x$ is a hard string for length $p(|x|)$, then $x$ induces a many-one reduction from $(\widehat{L}_{\Sigma^p_{k-1}})^{\leq p(|x|)}$ to $L_{\Delta^p_{k-1}}$, namely, $\lambda x_1.f(x, x_1)$, where $f(x, x_1) = y_1$, where $y_1$ is the unique string such that $(\exists y_2)[h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle]$. We will write $f_x$ for $\lambda x_1.f(x, x_1)$. Note that $f$ is computable in polynomial time. (This in turn certainly implies the true but not too relevant fact that, for each fixed $x$, $f_x$ is computable in polynomial time.)

So it is not hard to see that if we choose $p$ appropriately large, then a hard string $x$ for length $p(|x|)$ induces $\Sigma^p_{k-1}$ algorithms for $(L_1)^{=|x|}, (L_2)^{=|x|}, \ldots, (L_m)^{=|x|}$ (essentially since each is in $\Sigma^p_k = \mathrm{NP}^{\Sigma^p_{k-1}}$, $\widehat{L}_{\Sigma^p_{k-1}}$ is $\leq^p_{\mathrm{m}}$-complete for $\Sigma^p_{k-1}$, and $\mathrm{NP}^{\Delta^p_{k-1}} = \Sigma^p_{k-1}$), which we can use to obtain a $\mathrm{DIFF}_m(\Sigma^p_{k-1})$ algorithm for $(L_{\mathrm{DIFF}_m(\Sigma^p_k)})^{=|x|}$ and thus certainly a $\mathrm{DIFF}_m(\Sigma^p_k)$ algorithm for $\left(\overline{L_{\mathrm{DIFF}_m(\Sigma^p_k)}}\right)^{=|x|}$.

However, there is a problem. The problem is that we cannot combine the $\mathrm{DIFF}_m(\Sigma^p_k)$ algorithms for easy and hard strings into one $\mathrm{DIFF}_m(\Sigma^p_k)$ algorithm for $\overline{L_{\mathrm{DIFF}_m(\Sigma^p_k)}}$ that works for all strings. The reason why is that it is too difficult to decide whether a string is easy or hard: To decide this deterministically takes one query to $\Sigma^p_k$, and we cannot do that in a $\mathrm{DIFF}_m(\Sigma^p_k)$ algorithm. This is also the reason why the methods from [14] failed to prove that if $\mathrm{P} \bigoplus \Sigma^p_2 = \mathrm{NP} \bigoplus \Sigma^p_2$, then $\Sigma^p_2 = \Pi^p_2$. Recall from the introduction that the latter theorem was proven by Buhrman and Fortnow [4, p. 184]. We will generalize their technique at this point. In particular, the following lemma, which we will prove after we have finished the proof of this theorem, establishes a generalized version of the technique from [4]. It has been extended to deal with arbitrary levels of the polynomial hierarchy and to be useful in settings involving boolean hierarchies.

LEMMA 3.6. *Let $k > 1$. For all $L \in \Sigma_k^p$, there exist a polynomial $q$ and a set $\widehat{L} \in \Pi_{k-1}^p$ such that*

1. *for each natural number $n'$, $q(n') \geq n'$,*
2. *$\widehat{L} \subseteq \overline{L}$, and*
3. *if $x$ is hard for length $q(|x|)$, then $(x \in \overline{L} \Leftrightarrow x \in \widehat{L})$.*

We defer the proof of Lemma 3.6 and first finish the current proof. From Lemma 3.6, it follows that there exist sets $\widehat{L_1}, \widehat{L_2}, \ldots, \widehat{L_m} \in \Pi_{k-1}^p$ and polynomials $q_1, q_2, \ldots, q_m$ with the following properties for all $1 \leq \ell \leq m$:

1. $\widehat{L_\ell} \subseteq \overline{L_\ell}$, and
2. if $x$ is hard for length $q_\ell(|x|)$, then $(x \in \overline{L_\ell} \Leftrightarrow x \in \widehat{L_\ell})$.

Take $p$ to be an (easy-to-compute—we may without loss of generality require that there is a $t$ such that it is of the form $n^t + t$) polynomial such that $p$ is at least as large as all the $q_\ell$s, i.e., such that, for each natural number $n'$, we have $p(n') \geq \max\{q_1(n'), \ldots, q_m(n')\}$. By the definition of hardness and condition 1 of Lemma 3.6, if $x$ is hard for length $p(|x|)$, then $x$ is hard for length $q_\ell(|x|)$ for all $1 \leq \ell \leq m$. As promised earlier, we have now specified $p$. Define $\widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)}$ as follows: On input $x$, guess $\ell$, $\ell$ even, $0 \leq \ell \leq m$, and accept if and only if both (a) $x \in L_\ell$ or $\ell = 0$, and (b) if $\ell < m$, then $x \in \widehat{L_{\ell+1}}$. Clearly, $\widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)} \in \Sigma_k^p$. In addition, this set inherits certain properties from the $\widehat{L_\ell}$s. In particular, in light of the definition of $\widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)}$, the definitions of the $\widehat{L_\ell}$s, and the fact that

$$x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}} \Leftrightarrow (\exists \ell, 0 \leq \ell \leq m, \ell \text{ even})[(\ell \neq 0 \Rightarrow x \in L_\ell) \wedge (\ell \neq m \Rightarrow x \in \overline{L_{\ell+1}})],$$

we have that the following properties hold:

1. $\widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)} \subseteq \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$, and
2. if $x$ is hard for length $p(|x|)$, then $(x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}} \Leftrightarrow x \in \widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)})$.

Finally, we are ready to give the algorithm. Recall that $L'_1, L'_2, \ldots, L'_m$ are sets in $\Sigma_k^p$ such that (1) $L'_1 \supseteq L'_2 \supseteq \cdots \supseteq L'_{m-1} \supseteq L'_m$, and (2) if $x$ is easy for length $p(|x|)$, then $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ if and only if $x \in L'_1 - (L'_2 - (L'_3 - \cdots (L'_{m-1} - L'_m) \cdots))$, and (3) if $x$ is hard for length $p(|x|)$, then $x \notin L'_1$. We claim that for all $x$, $(x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}} \Leftrightarrow x \in (L'_1 \cup \widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)}) - (L'_2 - (L'_3 - \cdots (L'_{m-1} - L'_m) \cdots)))$, which completes the proof of Theorem 3.4, as $\Sigma_k^p$ is closed under union.

($\Rightarrow$): Let $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$. If $x$ is easy for length $p(|x|)$, then $x \in L'_1 - (L'_2 - (L'_3 - \cdots (L'_{m-1} - L'_m) \cdots))$, and so certainly $x \in (L'_1 \cup \widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)}) - (L'_2 - (L'_3 - \cdots (L'_{m-1} - L'_m) \cdots))$. If $x$ is hard for length $p(|x|)$, then $x \in \widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)}$ and $x \notin L'_\ell$ for all $\ell$ (since $x \notin L'_1$ and $L'_1 \supseteq L'_2 \supseteq \cdots \supseteq L'_m$). Thus, $x \in (L'_1 \cup \widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)}) - (L'_2 - (L'_3 - \cdots (L'_{m-1} - L'_m) \cdots))$.

($\Leftarrow$): Suppose $x \in (L'_1 \cup \widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)}) - (L'_2 - (L'_3 - \cdots (L'_{m-1} - L'_m) \cdots))$. If $x \in \widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)}$, then $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$. If $x \notin \widehat{L}_{\mathrm{DIFF}_m(\Sigma_k^p)}$, then $x \in L'_1 - (L'_2 - (L'_3 - \cdots (L'_{m-1} - L'_m) \cdots))$ and so $x$ must be easy for length $p(|x|)$ (as $x \in L'_1$, and this is possible only if $x$ is easy for length $p(|x|)$). However, this says that $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$. $\square$

Having completed the proof of Theorem 3.4, we now return to the deferred proof of the lemma used within that theorem's proof.

*Proof of Lemma* 3.6. Let $L \in \Sigma_k^p$. We need to show that there exist a polynomial $q$ and a set $\widehat{L} \in \Pi_{k-1}^p$ such that

1. for each natural number $n'$, $q(n') \geq n'$,
2. $\widehat{L} \subseteq \overline{L}$, and
3. if $x$ is hard for length $q(|x|)$, then $(x \in \overline{L} \Leftrightarrow x \in \widehat{L})$.

From Fact 3.5, we know that $L'_{\Sigma_k^p}$ is $\leq_{\rm m}^p$-complete for $\Sigma_k^p$, $\widehat{L}_{\Sigma_{k-1}^p} \in \Sigma_{k-1}^p$, $L''_{\Sigma_{k-2}^p} \in \Sigma_{k-2}^p$, and

1. $L'_{\Sigma_k^p} = \{x \mid (\exists y \in \Sigma^{|x|})(\forall z \in \Sigma^{|x|})[\langle x, y, z\rangle \in L''_{\Sigma_{k-2}^p}]\}$, and
2. $\widehat{L}_{\Sigma_{k-1}^p} = \{\langle x, y, z\rangle \mid |x| = |y| \wedge (\exists z')[(|x| = |zz'|) \wedge \langle x, y, zz'\rangle \notin L''_{\Sigma_{k-2}^p}]\}$.

Note that $\overline{L'_{\Sigma_k^p}} = \{x \mid (\forall y \in \Sigma^{|x|})(\exists z \in \Sigma^{|x|})[\langle x, y, z\rangle \notin L''_{\Sigma_{k-2}^p}]\}$.

Since $L \in \Sigma_k^p$, and $L'_{\Sigma_k^p}$ is $\leq_{\rm m}^p$-complete for $\Sigma_k^p$, there exists a polynomial-time computable function $g$ such that, for all $x$, $(x \in L \Leftrightarrow g(x) \in L'_{\Sigma_k^p})$.

Let $q$ be such that (a) $(\forall x \in \Sigma^n)(\forall y \in \Sigma^{|g(x)|})(\forall z \in (\Sigma^*)^{\leq |g(x)|})[q(n) \geq |\langle g(x), y, z\rangle|]$ and (b) $(\forall \widehat{m} \geq 0)[q(\widehat{m}+1) > q(\widehat{m}) > 0]$. Note that we have ensured that for each natural number $n'$, $q(n') \geq n'$.

If $x$ is a hard string for length $p(|x|)$, then $x$ induces a many-one reduction from $(\widehat{L}_{\Sigma_{k-1}^p})^{\leq p(|x|)}$ to $L_{\Delta_{k-1}^p}$, namely, $\lambda x_1.f(x, x_1)$, where $f(x, x_1) = y_1$, where $y_1$ is the unique string such that $(\exists y_2)[h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle]$. (This is the $h$ from the proof of Theorem 3.4. One should treat the current proof as if it occurs immediately after the statement of Lemma 3.6.) We will write $f_x$ for $\lambda x_1.f(x, x_1)$. Note that $f$ is computable in polynomial time. (This in turn certainly implies the true but not too relevant fact that, for each fixed $x$, $f_x$ is computable in polynomial time.)

Let $\widehat{L}$ be the language accepted by the following $\Pi_{k-1}^p$ machine.[2]

```
On input $x$:
        Compute $g(x)$
        Guess $y$ such that $|y| = |g(x)|$
        Set $w = \epsilon$ (i.e., the empty string)
        While $|w| < |g(x)|$
              if the $\Delta_{k-1}^p$ algorithm for $\widehat{L}_{\Sigma_{k-1}^p}$ induced by $x$ accepts $\langle g(x), y, w0\rangle$
              (that is, if $f_x(\langle g(x), y, w0\rangle) \in L_{\Delta_{k-1}^p}$),
              then $w = w0$
              else $w = w1$
        Accept if and only if $\langle g(x), y, w\rangle \notin L''_{\Sigma_{k-2}^p}$.
```

It remains to show that $\widehat{L}$ thus defined fulfills the properties of Lemma 3.6. First, note that the machine described above is clearly a $\Pi_{k-1}^p$ machine. To show that $\widehat{L} \subseteq \overline{L}$, suppose that $x \in \widehat{L}$. Then (keeping in mind the comments of footnote 2) for every $y \in \Sigma^{|g(x)|}$, there exists a string $w \in \Sigma^{|g(x)|}$ such that $\langle g(x), y, w\rangle \notin L''_{\Sigma_{k-2}^p}$. This implies that $g(x) \in \overline{L'_{\Sigma_k^p}}$ and thus that $x \in \overline{L}$.

Finally, suppose that $x$ is hard for length $q(|x|)$ and that $x \in \overline{L}$. We have to show that $x \in \widehat{L}$. Since $x \in \overline{L}$, $g(x) \in \overline{L'_{\Sigma_k^p}}$. So, $(\forall y \in \Sigma^{|g(x)|})(\exists z \in \Sigma^{|g(x)|})[\langle g(x), y, z\rangle \notin L''_{\Sigma_{k-2}^p}]$. Since $x$ is hard for length $q(|x|)$, $(\forall y \in \Sigma^{|g(x)|})(\forall w \in (\Sigma^*)^{\leq |g(x)|})[\langle g(x), y, w\rangle \in \widehat{L}_{\Sigma_{k-1}^p} \Leftrightarrow f_x(\langle g(x), y, w\rangle) \in L_{\Delta_{k-1}^p}]$. It follows that the algorithm above will find, for

[2]For $k > 1$, $\Pi_{k-1}^p = \mathrm{coNP}^{\Sigma_{k-2}^p}$, and by a $\Pi_{k-1}^p$ machine we mean, for the duration of this proof, a co-nondeterministic machine with a $\Sigma_{k-2}^p$ oracle. A co-nondeterministic machine by definition accepts if and only if *all* of its computation paths are accepting paths.

every $y \in \Sigma^{|g(x)|}$, a witness $w$ such that $\langle g(x), y, w\rangle \notin L''_{\Sigma^p_{k-2}}$, and thus the algorithm will accept $x$. $\square$

**4. Downward collapse from closure under complementation.** This section's main result is the following theorem.

THEOREM 4.1. *Let $s, m > 0$ and $0 < i < k-1$. If $\mathrm{DIFF}_s(\Sigma^p_i) \bigoplus \mathrm{DIFF}_m(\Sigma^p_k)$ is closed under complementation, then $\mathrm{DIFF}_m(\Sigma^p_k) = \mathrm{coDIFF}_m(\Sigma^p_k)$.*

The $s = 1$ case of Theorem 4.1 is as follows: If $m > 0$, $0 < i < k-1$, and $\Sigma^p_i \bigoplus \mathrm{DIFF}_m(\Sigma^p_k)$ is closed under complementation, then $\mathrm{DIFF}_m(\Sigma^p_k) = \mathrm{coDIFF}_m(\Sigma^p_k)$. In the present paper, this $s = 1$ case is used, along with Theorem 3.4, to establish Theorem 3.3.

Theorem 4.1 is also of interest in its own right as a reflection of how closure under complementation of even quite general symmetric difference classes implies a downward collapse. Selivanov [25, 26] shows that if certain symmetric difference classes are closed under complementation, then the polynomial hierarchy collapses. His result is, however, very different than this section's main result, Theorem 4.1, as Selivanov collapses the polynomial hierarchy to a higher level, and thus shows merely an upward translation of equality. In contrast, our Theorem 4.1 collapses the difference hierarchy over $\Sigma^p_k$ to a level that is contained in the classes of its complementation hypothesis—thus obtaining a *downward* translation of equality. Also, we note that Theorem 4.1 implies a collapse of the polynomial hierarchy to a class a full level lower in the difference hierarchy over $\Sigma^p_{k+1}$ than could be concluded without our downward collapse result (namely a collapse to $\mathrm{DIFF}_m(\Sigma^p_k) \bigoplus \mathrm{DIFF}_{m-1}(\Sigma^p_{k+1})$, in light of the strongest known "Boolean Hierarchy/Polynomial Hierarchy-collapse connection," see [13, Theorem 5.1], [23, Corollary 27], and the related discussion in section 5).

Before proving Theorem 4.1, we fix some useful complete languages. Throughout the paper we will use the names introduced in this fact for these sets (or more specifically, let us consider, for each $i$, the three "Sigma"-type sets of the form guaranteed by the fact to be fixed, and let us attach to them the names used in the fact for those sets, and then based on those apply the second half of the fact to assign fixed sets to be the $L_{\Pi^p_i}$'s and other "Pi"-type sets).

FACT 4.2. *For each $i \geq 1$, there exist a set $L_{\Sigma^p_i}$ that is $\leq^p_{\mathrm{m}}$-complete for $\Sigma^p_i$, a set $\widetilde{L}_{\Sigma^p_{i+1}}$ that is $\leq^p_{\mathrm{m}}$-complete for $\Sigma^p_{i+1}$, and a set $L^\dagger_{\Sigma^p_{i+2}}$ that is $\leq^p_{\mathrm{m}}$-complete for $\Sigma^p_{i+2}$, such that these sets satisfy*

$$\widetilde{L}_{\Sigma^p_{i+1}} = \{x \mid (\exists y \in \Sigma^{|x|})[\langle x, y\rangle \notin L_{\Sigma^p_i}]\}$$

*and*

$$L^\dagger_{\Sigma^p_{i+2}} = \{x \mid (\exists y \in \Sigma^{|x|})[\langle x, y\rangle \notin \widetilde{L}_{\Sigma^p_{i+1}}]\}.$$

*For each $i \geq 1$, let $L_{\Pi^p_i} = \overline{L_{\Sigma^p_i}}$ and define $L_{\mathrm{DIFF}_1(\Pi^p_i)} = L_{\Pi^p_i}$ and for all $j \geq 2$, $L_{\mathrm{DIFF}_j(\Pi^p_i)} = \{\langle x, y\rangle \mid x \in L_{\Pi^p_i} \wedge y \notin L_{\mathrm{DIFF}_{j-1}(\Pi^p_i)}\}$. It is not hard to see that $L_{\mathrm{DIFF}_j(\Pi^p_i)}$ is many-one complete for $\mathrm{DIFF}_j(\Pi^p_i)$ for all $j \geq 1$. Note also that $\mathrm{DIFF}_j(\Pi^p_i) = \mathrm{DIFF}_j(\Sigma^p_i)$ if $j$ is even and $\mathrm{DIFF}_j(\Pi^p_i) = \mathrm{co}\overline{\mathrm{DIFF}_j(\Sigma^p_i)}$ if $j$ is odd. Let $L_{\mathrm{DIFF}_s(\Sigma^p_i)} = L_{\mathrm{DIFF}_s(\Pi^p_i)}$ if $s$ is even and $L_{\mathrm{DIFF}_s(\Sigma^p_i)} = \overline{L_{\mathrm{DIFF}_s(\Pi^p_i)}}$ if $s$ is odd. Then $L_{\mathrm{DIFF}_s(\Sigma^p_i)}$ is $\leq^p_{\mathrm{m}}$-complete for $\mathrm{DIFF}_s(\Sigma^p_i)$.*

The reason these sets exist is similar to the reason that the sets of Fact 3.5 exist, but may at first seem a bit confusing, due to the fact that in Fact 4.2 $\widetilde{L}_{\Sigma^p_{i+1}}$ is being treated as a set of strings in its own definition but as a set of pairs of strings in the definition of $L^{\dagger}_{\Sigma^p_{i+2}}$. However, since the pairing function maps strings to strings, this isn't a problem; it merely requires some pairing in forming the sets. For example, to give the intuition of what is going on, consider the following sets:

- $A_{\Sigma^p_0} = \{\langle\langle F, v\rangle, w\rangle \mid v$ specifies assignments to the first half of $F$'s variables and $w$ specifies assignments to the second half of $F$'s variables and $F$ under the (complete) assignment specified by $v$ and $w$ evaluates to false$\}$.
- $A_{\Sigma^p_1} = \{\langle F, v\rangle \mid$ $v$ specifies assignments to the first half of $F$'s variables and there exists a $w$ specifying assignments to the second half of $F$'s variables such that $\langle\langle F, v\rangle, w\rangle \notin A_{\Sigma^p_0}\}$.
- $A_{\Sigma^p_2} = \{F \mid$ there exists a $v$ specifying assignments to the first half of $F$'s variables such that $\langle F, v\rangle \notin A_{\Sigma^p_1}\}$.

These sets are easily seen to be, respectively, $\leq^p_m$-complete for $\Sigma^p_0$ (trivial, in this case), $\Sigma^p_1$, and $\Sigma^p_2$. Caveat: These are not exactly the sets of Fact 4.2, as here we have not been careful to make sure the quantified lengths are exactly the same length as the input, and we have been sloppy about what "half" means when the number of variables is odd; however, this example should make it clearer that sets satisfying Fact 4.2 exist.

*Proof of Theorem* 4.1. Let $s, m > 0$ and $0 < i < k-1$. $L_{\mathrm{DIFF}_s(\Sigma^p_i)} \tilde{\oplus} L_{\mathrm{DIFF}_m(\Sigma^p_k)}$ is $\leq^p_m$-hard for $\mathrm{DIFF}_s(\Sigma^p_i) \bigoplus \mathrm{DIFF}_m(\Sigma^p_k)$ by Lemma 3.2 and $L_{\mathrm{DIFF}_s(\Sigma^p_i)} \tilde{\oplus} L_{\mathrm{DIFF}_m(\Sigma^p_k)}$ is clearly in $\mathrm{DIFF}_s(\Sigma^p_i) \bigoplus \mathrm{DIFF}_m(\Sigma^p_k)$. Since by assumption $\mathrm{DIFF}_s(\Sigma^p_i) \bigoplus \mathrm{DIFF}_m(\Sigma^p_k)$ is closed under complementation, there exists a (polynomial-time) many-one reduction $h$ from $L_{\mathrm{DIFF}_s(\Sigma^p_i)} \tilde{\oplus} L_{\mathrm{DIFF}_m(\Sigma^p_k)}$ to its complement. That is, for all $x_1, x_2, y_1, y_2 \in \Sigma^*$: If $h(\langle x_1, x_2\rangle) = \langle y_1, y_2\rangle$, then $(\langle x_1, x_2\rangle \in L_{\mathrm{DIFF}_s(\Sigma^p_i)} \tilde{\oplus} L_{\mathrm{DIFF}_m(\Sigma^p_k)} \Leftrightarrow \langle y_1, y_2\rangle \notin L_{\mathrm{DIFF}_s(\Sigma^p_i)} \tilde{\oplus} L_{\mathrm{DIFF}_m(\Sigma^p_k)})$. Equivalently, for all $x_1, x_2, y_1, y_2 \in \Sigma^*$:

FACT 1: *If* $h(\langle x_1, x_2\rangle) = \langle y_1, y_2\rangle$, *then*: $(x_1 \in L_{\mathrm{DIFF}_s(\Sigma^p_i)} \Leftrightarrow x_2 \notin L_{\mathrm{DIFF}_m(\Sigma^p_k)})$ *if and only if* $(y_1 \in L_{\mathrm{DIFF}_s(\Sigma^p_i)} \Leftrightarrow y_2 \in L_{\mathrm{DIFF}_m(\Sigma^p_k)})$.

We can use $h$ to recognize some of $\overline{L_{\mathrm{DIFF}_m(\Sigma^p_k)}}$ by a $\mathrm{DIFF}_m(\Sigma^p_k)$ algorithm. In particular, we say that a string $x$ is *easy for length* $n$ if there exists a string $x_1$ such that $|x_1| \leq n$ and $(x_1 \in L_{\mathrm{DIFF}_s(\Sigma^p_i)} \Leftrightarrow y_1 \in L_{\mathrm{DIFF}_s(\Sigma^p_i)})$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$.

Let $p$ be a fixed polynomial, which will be exactly specified later in the proof. We have the following algorithm to test whether $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma^p_k)}}$ in the case that (our input) $x$ is an easy string for length $p(|x|)$. On input $x$, guess $x_1$ with $|x_1| \leq p(|x|)$, let $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$, and accept if and only if $((x_1 \in L_{\mathrm{DIFF}_s(\Sigma^p_i)} \Leftrightarrow y_1 \in L_{\mathrm{DIFF}_s(\Sigma^p_i)}) \wedge y_2 \in L_{\mathrm{DIFF}_m(\Sigma^p_k)})$. This algorithm is not necessarily a $\mathrm{DIFF}_m(\Sigma^p_k)$ algorithm, but in the same way as in the proof of Theorem 3.4, we can construct sets $L'_1, L'_2, \ldots, L'_m \in \Sigma^p_k$ such that if $x$ is an easy string for length $p(|x|)$, then $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma^p_k)}}$ if and only if $x \in L'_1 - (L'_2 - (L'_3 - \cdots (L'_{m-1} - L'_m)\cdots))$.

We say that $x$ is *hard for length* $n$ if $|x| \leq n$ and $x$ is not easy for length $n$, i.e., if $|x| \leq n$ and, for all $x_1$ with $|x_1| \leq n$, $(x_1 \in L_{\mathrm{DIFF}_s(\Sigma^p_i)} \Leftrightarrow y_1 \notin L_{\mathrm{DIFF}_s(\Sigma^p_i)})$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$.

If $x$ is a hard string for length $n$, then $x$ induces a many-one reduction from $(L_{\mathrm{DIFF}_s(\Sigma^p_i)})^{\leq n}$ to $\overline{L_{\mathrm{DIFF}_s(\Sigma^p_i)}}$, namely, $\lambda x_1.f(x, x_1)$, where $f(x, x_1) = y_1$, where $y_1$ is the unique string such that $(\exists y_2)[h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle]$. We will write $f_x$ for $\lambda x_1.f(x, x_1)$. Note that $f$ is computable in polynomial time. (This in turn certainly implies the true but not too relevant fact that, for each fixed $x$, $f_x$ is computable in polynomial time.)

It is known that a collapse of the boolean hierarchy over $\Sigma_i^p$ implies a collapse of the polynomial hierarchy. A long series of papers studied the question to what level the polynomial hierarchy collapses in that case. The best known results (e.g., [8, 3, 14, 23, 13], see, especially, the strongest such connection, which is that obtained independently in [23] and [13]) conclude a collapse of the polynomial hierarchy to a level within the boolean hierarchy over $\Sigma_{i+1}^p$. Though a hard string for length $n$ only induces a many-one reduction between initial segments of $L_{\mathrm{DIFF}_s(\Sigma_i^p)}$ and $\overline{L_{\mathrm{DIFF}_s(\Sigma_i^p)}}$, we would nevertheless like to derive at least a $\mathrm{P}^{\Sigma_{k-1}^p}$ algorithm for some of $L^{\dagger}_{\Sigma_{i+2}^p}$. The following lemma does exactly that.

LEMMA 4.3. *Let $s, m > 0$ and $0 < i < k-1$, and suppose that* $\mathrm{DIFF}_s(\Sigma_i^p) \bigoplus \mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{co}(\mathrm{DIFF}_s(\Sigma_i^p) \bigoplus \mathrm{DIFF}_m(\Sigma_k^p))$. *There exist a set $D \in \mathrm{P}^{\Sigma_{i+1}^p}$ and a polynomial $r$ such that for all $n$,* (a) *$r(n+1) > r(n) > 0$ and* (b) *for all $x \in \Sigma^*$, if $x$ is a hard string for length $r(n)$ then for all $y \in (\Sigma^*)^{\leq n}$,*

$$y \in L^{\dagger}_{\Sigma_{i+2}^p} \Leftrightarrow \langle x, 1^n, y\rangle \in D.$$

We defer the proof of Lemma 4.3 and first finish the proof of the current theorem.

We will use the result of Lemma 4.3 to obtain a $\mathrm{P}^{\Sigma_{k-1}^p}$ algorithm that for any string $x$ that is hard for length $p(|x|)$ will determine whether $x \in L_{\mathrm{DIFF}_m(\Sigma_k^p)}$.

Let $L_1, L_2, \ldots, L_m$ be languages in $\Sigma_k^p$ such that $L_{\mathrm{DIFF}_m(\Sigma_k^p)} = L_1 - (L_2 - (L_3 - \cdots (L_{m-1} - L_m) \cdots))$. Since $L_{\Sigma_k^p}$ is complete for $\Sigma_k^p$, there exist functions $g_1, \ldots, g_m$ that many-one reduce $L_1, \ldots, L_m$ to $L_{\Sigma_k^p}$, respectively. Let the output sizes of all the $g_j$'s be bounded by the polynomial $p'$, which without loss of generality satisfies $(\forall \widehat{m} \geq 0)[p'(\widehat{m}+1) > p'(\widehat{m}) > 0]$. So there exists a polynomial-time machine that queries strings of length at most $p'(n)$ on inputs of length $n$ to $L_{\Sigma_k^p}$ and that accepts $L_{\mathrm{DIFF}_m(\Sigma_k^p)}$.

A $\Sigma_0^p$ machine is an oracle P machine; for $z \geq 1$, a $\Sigma_z^p$ machine is a polynomial-time-bounded $z$-alternation-block-bounded oracle machine with the first alternation block existential. For example, the class of languages accepted by $\Sigma_2^p$ machines allowed $\Sigma_3^p$ oracles is $\Sigma_5^p$. Let $M$ be a $\Sigma_{k-(i+2)}^p$ machine recognizing $L_{\Sigma_k^p}$ with oracle queries to $L^{\dagger}_{\Sigma_{i+2}^p}$ and running in time $q'$ for some polynomial $q'$ satisfying $(\forall \widehat{m} \geq 0)[q'(\widehat{m}+1) > q'(\widehat{m}) > 0]$. Let $p$ be an easily computable polynomial satisfying $(\forall \widehat{m} \geq 0)[p(\widehat{m}+1) > p(\widehat{m}) > 0]$ and for all $n$, $p(n) \geq r(q'(p'(n)))$, where $r$ is the polynomial of Lemma 4.3. As promised, we now have specified $p$.

If $x$ is a hard string for length $p(|x|)$, then $x$ is also a hard string for length $r(q'(p'(|x|)))$. So, by Lemma 4.3, for all $y \in (\Sigma^*)^{\leq q'(p'(|x|))}$, $y \in L^{\dagger}_{\Sigma_{i+2}^p} \Leftrightarrow \langle x, 1^n, y\rangle \in D$. Define the following $\mathrm{P}^{\Sigma_{k-1}^p}$ set $E$: On input $\langle x, z\rangle$, simulate $M$ on input $z$ and replace every query $y$ to $L^{\dagger}_{\Sigma_{i+2}^p}$ by query $\langle x, 1^n, y\rangle$ to $D$. (Note that if $i < k-2$, $E$ is even in $\Sigma_{k-1}^p$.) Clearly, for all $x \in \Sigma^*$, if $x$ is a hard string for length $p(|x|)$, then for all $z \in (\Sigma^*)^{\leq p'(|x|)}$, $\langle x, z\rangle \in E$ if and only if $z \in L_{\Sigma_k^p}$.

Recall that there exists a polynomial-time machine that determines whether $x \in L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ with oracle queries of length at most $p'(|x|)$ to $L_{\Sigma_k^p}$. If $x$ is a hard string for length $p(|x|)$, we can replace every query $z$ to $L_{\Sigma_k^p}$ by query $\langle x, z\rangle$ to $E$. We have now defined a $\mathrm{P}^{\mathrm{P}^{\Sigma_{k-1}^p}} = \mathrm{P}^{\Sigma_{k-1}^p}$ algorithm that for any string $x$ that is hard for length $p(|x|)$ will determine whether $x \in L_{\mathrm{DIFF}_m(\Sigma_k^p)}$.

However, now we have an outright $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm for $\overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$: For $1 \leq \ell \leq m$ define an $\mathrm{NP}^{\Sigma_{k-1}^p}$ machine $N_\ell$ as follows: On input $x$, the NP base machine of $N_\ell$ executes the following algorithm:

1. Using its $\Sigma_{k-1}^p$ oracle, it deterministically determines whether the input $x$ is an easy string for length $p(|x|)$. This can be done, as checking whether the input is an easy string for length $p(|x|)$ can be done by one query to $\Sigma_{i+1}^p$, and $i+1 \leq k-1$ by our $i < k-1$ hypothesis.
2. If the previous step determined that the input is not an easy string, then the input must be a hard string for length $p(|x|)$. If $\ell = 1$, then simulate the $\mathrm{P}^{\Sigma_{k-1}^p}$ algorithm for hard strings to determine whether $x \in L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ and accept if and only if $x \notin L_{\mathrm{DIFF}_m(\Sigma_k^p)}$. If $\ell > 1$, then reject.
3. If the first step determined that the input $x$ is easy for length $p(|x|)$, then our NP machine simulates (using itself and its oracle) the $\Sigma_k^p$ algorithm for $L'_\ell$ on input $x$.

Note that the $\Sigma_{k-1}^p$ oracle in the above algorithm is being used for a number of different sets. However, as $\Sigma_{k-1}^p$ is closed under disjoint union, this presents no problem as we can use the disjoint union of the sets, while modifying the queries so they address the appropriate part of the disjoint union.

It follows that, for all $x$, $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ if and only if $x \in L(N_1) - (L(N_2) - (L(N_3) - \cdots (L(N_{m-1}) - L(N_m)) \cdots))$. Since $\overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ is complete for $\mathrm{coDIFF}_m(\Sigma_k^p)$, it follows that $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$. ☐

We now give the proof of Lemma 4.3. This proof should be seen in the context of the proof of Theorem 4.1 and Fact 4.2 as some notations we are going to use are defined there.

*Proof of Lemma* 4.3. Our proof generalizes a proof from [3]. Let $\langle \cdots \rangle$ be a pairing function that maps sequences of up to $2s+2$ of strings over $\Sigma^*$ to $\Sigma^*$ having the standard properties such as polynomial-time computability and invertibility, etc. Let $t$ be a polynomial such that $|\langle x_1, x_2, \ldots, x_j \rangle| \leq t(\max\{|x_1|, |x_2|, \ldots, |x_j|\})$ for all $1 \leq j \leq 2s+2$ and all $x_1, x_2, \ldots, x_j \in \Sigma^*$. Without loss of generality let $t$ be such that $t(n+1) > t(n) > 0$ for all $n$. Define

$$t^{(0)}(n) = n \text{ and } t^{(j)}(n) = \underbrace{t(t(\cdots t}_{j\ times}(n)\cdots))$$

for all $n$ and all $j \geq 1$.

Define $r'$ to be a polynomial such that $r'(n+1) > r'(n) > 0$ and $r'(n) \geq t^{(s-1)}(n)$ for all $n$. Let $n$ be an integer. Suppose that $x$ is a hard string for length $r'(n)$, where hardness is defined as in the proof of Theorem 4.1. Then (recall the sets fixed/named in Fact 4.2), for all $y$ such that $|y| \leq r'(n)$,

$$y \in L_{\mathrm{DIFF}_s(\Sigma_i^p)} \Leftrightarrow f_x(y) \notin L_{\mathrm{DIFF}_s(\Sigma_i^p)},$$

or equivalently

$$y \in L_{\mathrm{DIFF}_s(\Pi_i^p)} \Leftrightarrow f_x(y) \notin L_{\mathrm{DIFF}_s(\Pi_i^p)}.$$

Recall that $f_x = \lambda y.f(x,y)$ and that $f$ can be computed in polynomial time. If $s > 1$, let $y = \langle y_1, y_2 \rangle$ and let $f_x(y) = \langle z_1, z_2 \rangle$. Then, for all $y_1, y_2 \in \Sigma^*$ such that $|y_1| \leq n$ and $|y_2| \leq t^{(s-2)}(n)$,

$$y_1 \in L_{\Pi_i^p} \wedge y_2 \notin L_{\mathrm{DIFF}_{s-1}(\Pi_i^p)} \Leftrightarrow z_1 \notin L_{\Pi_i^p} \vee z_2 \in L_{\mathrm{DIFF}_{s-1}(\Pi_i^p)}. \tag{4.1}$$

If $s > 1$, we say that $y_1$ is $s$-easy for length $n$ if and only if $|y_1| \le n$ and $(\exists y_2\ |y_2| \le t^{(s-2)}(n))[z_1 \notin L_{\Pi_i^p}]$. $y_1$ is said to be $s$-hard for length $n$ if and only if $|y_1| \le n$, $y_1 \in L_{\Pi_i^p}$, and $(\forall y_2\ |y_2| \le t^{(s-2)}(n))[z_1 \in L_{\Pi_i^p}]$. Observe that the above notions are defined with respect to our hard string $x$, since $z_1$ depends on $x$, $y_1$, and $y_2$. Furthermore, according to (4.1), if $y_1$ is $s$-easy for length $n$ then $y_1 \in L_{\Pi_i^p}$.

Suppose there exists an $s$-hard string $\omega_s$ for length $n$. Let $f_{(x,\omega_s)}$ be the function defined by $f_x(\langle \omega_s, y\rangle) = \langle z_1, f_{(x,\omega_s)}(y)\rangle$. Note that there exists a polynomial-time computable function $f_2$ such that $f_{(x,\omega_s)} = \lambda y.f_2(x, \omega_s, y)$. If $s-1 > 1$, we define $(s-1)$-easy and $(s-1)$-hard strings in analogy to the above. If an $(s-1)$-hard string exists we can repeat the process and define $(s-2)$-easy and $(s-2)$-hard strings and so on. Note that the definition of $j$-easy and $j$-hard strings can only be made with respect to our hard string $x$, some fixed $s$-hard string $\omega_s$, some fixed $(s-1)$-hard string $\omega_{s-1}$, ..., some fixed $(j+1)$-hard string $\omega_{j+1}$. If we have found a sequence of strings $(\omega_s, \omega_{s-1}, \dots, \omega_2)$ (note that if $s = 1$, $(\omega_s, \omega_{s-1}, \dots, \omega_2)$ is the empty sequence) such that every $\omega_j$ is $j$-hard with respect to $(x, \omega_s, \omega_{s-1}, \dots, \omega_{j+1})$, then we have for all $y$, $|y| \le n$,

$$y \in L_{\Pi_i^p} \Leftrightarrow f_{(x,\omega_s,\omega_{s-1},\dots,\omega_2)}(y) \notin L_{\Pi_i^p}.$$

We say that a string $y$ is 1-easy for length $n$ if and only if it holds that $|y| \le n$ and $f_{(x,\omega_s,\omega_{s-1},\dots,\omega_2)}(y) \notin L_{\Pi_i^p}$. We define that no string is 1-hard for length $n$.

$(x)$ is called a hard sequence for length $n$ if and only if $x$ is hard for length $r'(n)$. A sequence $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$ of strings is called a hard sequence for length $n$ if and only if $x$ is hard for length $r'(n)$ and for all $\ell$, $j \le \ell \le s$, $\omega_\ell$ is $\ell$-hard for length $n$ with respect to $(x, \omega_s, \omega_{s-1}, \dots, \omega_{\ell+1})$. Note that given a hard sequence $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$ for length $n$, the strings in $(L_{\Pi_i^p})^{\le n}$ divide into $(j-1)$-easy and $(j-1)$-hard strings (with respect to $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$) for length $n$.

$(x)$ is called a maximal hard sequence for length $n$ if and only if $(x)$ is a hard sequence for length $n$ and there exists no $s$-hard string for length $n$. A hard sequence $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$ for length $n$ is called a maximal hard sequence for length $n$ if and only if there exists no $(j-1)$-hard string for length $n$ with respect to $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$. When in what follows we denote a maximal hard sequence by $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$, we implicitly include the case that the maximal hard sequence might be $(x)$ or $(x, \omega_s)$ or ....

*Claim* 1. There exists a set $A \in \Sigma_i^p$ such that if $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$ is a maximal hard sequence for length $n$, then for all $y$ and $n$ satisfying $|y| \le n$,

$$y \in L_{\Pi_i^p} \Leftrightarrow \langle x, 1^n, \omega_s, \omega_{s-1}, \dots, \omega_j, y\rangle \in A.$$

*Proof of Claim* 1. Let $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$ be a maximal hard sequence for length $n$. If $(x, \omega_s, \omega_{s-1}, \dots, \omega_j) = (x)$, we let $j = s+1$. Note that $j \ge 2$ and that the strings in $(L_{\Pi_i^p})^{\le n}$ are exactly the strings of length at most $n$ that are $(j-1)$-easy with respect to $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$. It is immediate from the definition that testing whether a string $y$ is $(j-1)$-easy for length $n$ with respect to $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$ can be done by a $\Sigma_i^p$ algorithm running in time polynomial in $n$: If $j \ge 3$, check that $|y| \le n$, guess $y_2$, $|y_2| \le t^{(j-3)}(n)$, compute $f_{(x,\omega_s,\omega_{s-1},\dots,\omega_j)}(\langle y, y_2\rangle) = \langle z_1, z_2\rangle$, and accept if and only if $z_1 \notin L_{\Pi_i^p}$. If $j = 2$, check $|y| \le n$, and accept if and only if $f_{(x,\omega_s,\omega_{s-1},\dots,\omega_2)}(y) \notin L_{\Pi_i^p}$.

*Claim* 2. There exist a set $B \in \Sigma_i^p$ and a polynomial $\widehat{p}$ such that $(\forall n \ge 0)[\widehat{p}(n+1) > \widehat{p}(n) > 0]$ and if $(x, \omega_s, \omega_{s-1}, \dots, \omega_j)$ is a maximal hard sequence for length $\widehat{p}(n)$, then for all $y$ and $n$ satisfying $|y| \leq n$,

$$y \in \widetilde{L}_{\Sigma^p_{i+1}} \Leftrightarrow \langle x, 1^{\widehat{p}(n)}, \omega_s, \omega_{s-1}, \ldots, \omega_j, y\rangle \in B.$$

*Proof of Claim* 2. Let $A \in \Sigma^p_i$ as in Claim 1. Let $y$ be a string such that $|y| \leq n$. According to the definition of $\widetilde{L}_{\Sigma^p_{i+1}}$,

$$y \in \widetilde{L}_{\Sigma^p_{i+1}} \Leftrightarrow (\exists z \in \Sigma^{|y|})[\langle y, z\rangle \notin L_{\Sigma^p_i}].$$

Recall that $L_{\Pi^p_i} = \overline{L_{\Sigma^p_i}}$ from Fact 4.2. Define $\widehat{p}$ to be a polynomial such that $\widehat{p}(n+1) > \widehat{p}(n) > 0$ and $\widehat{p}(n) \geq t(n)$ for all $n$. Applying Claim 1 we obtain that if $(x, \omega_s, \omega_{s-1}, \ldots, \omega_j)$ is a maximal hard sequence for length $\widehat{p}(n)$, then

$$y \in \widetilde{L}_{\Sigma^p_{i+1}} \Leftrightarrow (\exists z \in \Sigma^{|y|})[\langle x, 1^{\widehat{p}(n)}, \omega_s, \omega_{s-1}, \ldots, \omega_j, \langle y, z\rangle\rangle \in A].$$

We define $B$ to be the set $B = \{\langle x, 1^{\widehat{p}(n)}, \omega_s, \omega_{s-1}, \ldots, \omega_j, y\rangle \mid (\exists z \in \Sigma^{|y|})[\langle x, 1^{\widehat{p}(n)}, \omega_s, \omega_{s-1}, \ldots, \omega_j, \langle y, z\rangle\rangle \in A]\}$. Clearly $B \in \Sigma^p_i$. This proves Claim 2.

*Claim* 3. There exist a set $C \in \Sigma^p_{i+1}$ and a polynomial $\widehat{p}_1$ such that $(\forall n \geq 0)[\widehat{p}_1(n+1) > \widehat{p}_1(n) > 0]$ and if $(x, \omega_s, \omega_{s-1}, \ldots, \omega_\ell)$ is a maximal hard sequence for length $\widehat{p}_1(n)$, then for all $y$ and $n$ satisfying $|y| \leq n$,

$$y \in L^{\dagger}_{\Sigma^p_{i+2}} \Leftrightarrow \langle x, 1^n, \omega_s, \omega_{s-1}, \ldots, \omega_\ell, y\rangle \in C.$$

*Proof of Claim* 3. Let $B \in \Sigma^p_i$ and $\widehat{p}$ be a polynomial, both as defined in Claim 2. Let $y$ be a string such that $|y| \leq n$. According to the definition of $L^{\dagger}_{\Sigma^p_{i+2}}$,

$$y \in L^{\dagger}_{\Sigma^p_{i+2}} \Leftrightarrow (\exists z \in \Sigma^{|y|})[\langle y, z\rangle \notin \widetilde{L}_{\Sigma^p_{i+1}}].$$

Define $\widehat{p}_1$ to be a polynomial such that $\widehat{p}_1(n+1) > \widehat{p}_1(n) > 0$ and $\widehat{p}_1(n) \geq \widehat{p}(t(n))$ for all $n$. Applying Claim 2, we obtain that if $(x, \omega_s, \omega_{s-1}, \ldots, \omega_\ell)$ is a maximal hard sequence for length $\widehat{p}_1(n)$, then

$$y \in L^{\dagger}_{\Sigma^p_{i+2}} \Leftrightarrow (\exists z \in \Sigma^{|y|})[\langle x, 1^{\widehat{p_1}(n)}, \omega_s, \omega_{s-1}, \ldots, \omega_\ell, \langle y, z\rangle\rangle \notin B].$$

Let $C = \{\langle x, 1^n, \omega_s, \omega_{s-1}, \ldots, \omega_j, y\rangle \mid (\exists z \in \Sigma^{|y|})[\langle x, 1^{\widehat{p_1}(n)}, \omega_s, \omega_{s-1}, \ldots, \omega_j, \langle y, z\rangle\rangle \notin B]\}$. Clearly $C \in \Sigma^p_{i+1}$. This concludes the proof of Claim 3.

We are now ready to prove the claim of Lemma 4.3. Note that the set

$$\begin{aligned} E = \{\langle x, 1^n, \omega_s, \omega_{s-1}, \ldots, \omega_j\rangle \mid\ & \text{for all } \ell, j \leq \ell \leq s, \\ & \omega_\ell \text{ is } \ell\text{-hard for length } n \text{ with respect to } (x, \omega_s, \omega_{s-1}, \ldots, \omega_{\ell+1})\} \end{aligned}$$

is in $\Pi^p_i$. Consequently, the set

$$F = \{\langle x, 1^n, k\rangle \mid (\exists\ \omega_s, \omega_{s-1}, \ldots, \omega_{s-k+2})[\langle x, 1^n, \omega_s, \omega_{s-1}, \ldots, \omega_{s-k+2}\rangle \in E]\}$$

is in $\Sigma^p_{i+1}$. Observe that if $x$ is a hard string for length $r'(\widehat{p}_1(n))$, then it is the case that $\langle x, 1^n, \omega_s, \omega_{s-1}, \ldots, \omega_j\rangle \in E$ if and only if $(x, \omega_s, \omega_{s-1}, \ldots, \omega_j)$ is a hard sequence for length $\widehat{p}_1(n)$. Similarly, if $x$ is a hard string for length $r'(\widehat{p}_1(n))$, then $\langle x, 1^n, k\rangle \in F$ if and only if there exists a hard sequence (starting with $(x, \ldots)$) *of length* $k$ for length $\widehat{p}_1(n)$.

It follows from those observations and the above proven claims that if $x$ is a hard string for length $r'(\widehat{p}_1(n))$, then the following algorithm will accept $\langle x, 1^n, y\rangle$ if and only if $y \in L^{\dagger}_{\Sigma^p_{i+2}}$. On input $\langle x, 1^n, y\rangle$ the algorithm proceeds as follows:

1. Using $F$ as an oracle, compute the largest $k$, call it $\widehat{k}$, such that $\langle x, 1^n, k\rangle \in F$.
2. Then, by making one oracle query, check the following: Do there exist strings $\omega_s, \omega_{s-1}, \ldots, \omega_{s-\widehat{k}+2}$ such that $\langle x, 1^n, \omega_s, \omega_{s-1}, \ldots, \omega_{s-\widehat{k}+2}\rangle \in E$ and $\langle x, 1^n, \omega_s, \omega_{s-1}, \ldots, \omega_{s-\widehat{k}+2}, y\rangle \in C$? Though we actually are allowed as many queries as we like (within our time bound), we note that it is not hard to see that this checking can be done by making one query to an appropriately chosen $\Sigma^p_{i+1}$ oracle.
3. Accept if and only if the final query returned the answer "yes."

Though the above algorithm queries two different $\Sigma^p_{i+1}$ oracles it is clearly a $\mathrm{P}^{\Sigma^p_{i+1}}$ algorithm, since $\Sigma^p_{i+1}$ is closed under disjoint union. Let $D$ be the set accepted by this algorithm. Define $r$ to be the polynomial such that $r(n) = r'(\widehat{p}_1(n))$ for all $n$. Note that due to the definitions of $r'$ and $\widehat{p}_1$, $r$ satisfies $r(n+1) > r(n) > 0$ for all $n$. This completes the proof of Lemma 4.3. $\square$

## 5. Conclusions.

We have proven a general downward translation of equality, Theorem 3.3, sufficient to yield, as a corollary, the following.

COROLLARY 5.1. *For each $m > 0$ and each $k > 1$,*

$$\mathrm{P}^{\Sigma^p_k}_{m\text{-tt}} = \mathrm{P}^{\Sigma^p_k}_{m+1\text{-tt}} \Rightarrow \mathrm{DIFF}_m(\Sigma^p_k) = \mathrm{coDIFF}_m(\Sigma^p_k).$$

The corollary follows immediately from Theorem 3.3, Proposition 2.2, and Observation 2.3. Corollary 5.1 itself has an interesting further consequence. From this corollary, it follows that for a number of previously missing cases (namely, when $m > 1$ and $k = 2$), the hypothesis $\mathrm{P}^{\Sigma^p_k}_{m\text{-tt}} = \mathrm{P}^{\Sigma^p_k}_{m+1\text{-tt}}$ implies that the polynomial hierarchy collapses to about one level lower in the boolean hierarchy over $\Sigma^p_{k+1}$ than could be concluded from previous papers. This is because we can, thanks to Corollary 5.1, when given $\mathrm{P}^{\Sigma^p_k}_{m\text{-tt}} = \mathrm{P}^{\Sigma^p_k}_{m+1\text{-tt}}$, invoke the powerful collapses of the polynomial hierarchy that are known to follow from $\mathrm{DIFF}_m(\Sigma^p_k) = \mathrm{coDIFF}_m(\Sigma^p_k)$. In particular, a long line of research started by Kadin [17] and Wagner [28, 29] over a decade ago has studied what collapses follow from $\mathrm{DIFF}_m(\Sigma^p_k) = \mathrm{coDIFF}_m(\Sigma^p_k)$. The strongest currently known connection was recently obtained, independently, by Hemaspaandra, Hemaspaandra, and Hempel [13, Theorem 5.1] and by Reith and Wagner [23, Corollary 27], namely: For all $m > 0$ and all $k > 0$, if $\mathrm{DIFF}_m(\Sigma^p_k) = \mathrm{coDIFF}_m(\Sigma^p_k)$, then $\mathrm{PH} = \mathrm{DIFF}_m(\Sigma^p_k) \bigoplus \mathrm{DIFF}_{m-1}(\Sigma^p_{k+1})$. Putting all the above together, one sees that, for all cases where $m > 1$ and $k > 1$, $\mathrm{P}^{\Sigma^p_k}_{m\text{-tt}} = \mathrm{P}^{\Sigma^p_k}_{m+1\text{-tt}}$ implies that the polynomial hierarchy collapses to $\mathrm{DIFF}_m(\Sigma^p_k) \bigoplus \mathrm{DIFF}_{m-1}(\Sigma^p_{k+1})$. This also yields that, for all cases where $m > 1$ and $k > 1$, $\mathrm{P}^{\Sigma^p_k[m]} = \mathrm{P}^{\Sigma^p_k[m+1]}$ implies that the polynomial hierarchy collapses to $\mathrm{DIFF}_{2^m-1}(\Sigma^p_k) \bigoplus \mathrm{DIFF}_{2^m-2}(\Sigma^p_{k+1})$. Of course, for the case $m = 1$, we already know [14, 4] that, for $k > 1$, if $\mathrm{P}^{\Sigma^p_k[1]} = \mathrm{P}^{\Sigma^p_k[2]}$ (equivalently, if $\mathrm{P}^{\Sigma^p_k}_{1\text{-tt}} = \mathrm{P}^{\Sigma^p_k}_{2\text{-tt}}$), then $\Sigma^p_k = \Pi^p_k = \mathrm{PH}$.

**Acknowledgments.** We thank the anonymous conference and journal referees for helpful comments and suggestions, and we thank the students of CSC486 at the University of Rochester for their proofreading help.

# APPROXIMATING THE MINIMUM SPANNING TREE WEIGHT IN SUBLINEAR TIME[*]

BERNARD CHAZELLE[†], RONITT RUBINFELD[‡], AND LUCA TREVISAN[§]

**Abstract.** We present a probabilistic algorithm that, given a connected graph $G$ (represented by adjacency lists) of average degree $d$, with edge weights in the set $\{1, \ldots, w\}$, and given a parameter $0 < \varepsilon < 1/2$, estimates in time $O(dw\varepsilon^{-2} \log \frac{dw}{\varepsilon})$ the weight of the minimum spanning tree (MST) of $G$ with a relative error of at most $\varepsilon$. Note that the running time does *not* depend on the number of vertices in $G$. We also prove a nearly matching lower bound of $\Omega(dw\varepsilon^{-2})$ on the probe and time complexity of any approximation algorithm for MST weight.

The essential component of our algorithm is a procedure for estimating in time $O(d\varepsilon^{-2} \log \frac{d}{\varepsilon})$ the number of connected components of an unweighted graph to within an additive error of $\varepsilon n$. (This becomes $O(\varepsilon^{-2} \log \frac{1}{\varepsilon})$ for $d = O(1)$.) The time bound is shown to be tight up to within the $\log \frac{d}{\varepsilon}$ factor. Our connected-components algorithm picks $O(1/\varepsilon^2)$ vertices in the graph and then grows "local spanning trees" whose sizes are specified by a stochastic process. From the local information collected in this way, the algorithm is able to infer, with high confidence, an estimate of the number of connected components. We then show how estimates on the number of components in various subgraphs of $G$ can be used to estimate the weight of its MST.

## 1. Introduction.

Traditionally, a linear time algorithm has been held as the gold standard of efficiency. In a wide variety of settings, however, large data sets have become increasingly common, and it is often desirable and sometimes necessary to find very fast algorithms which can assert nontrivial properties of the data in *sublinear* time.

One direction of research that has been suggested is that of property testing [16, 8], which relaxes the standard notion of a decision problem. Property testing algorithms distinguish between inputs that have a certain property and those that are far (in terms of Hamming distance or some other natural distance) from having the property. Sublinear and even constant time algorithms have been designed for testing various algebraic and combinatorial properties (see [15] for a survey). Property testing can be viewed as a natural type of approximation problem, and, in fact, many of the property testers have led to very fast, even constant time, approximation schemes for the associated problem (cf. [8, 5, 6, 1]). For example, one can approximate the

value of a maximum cut in a dense graph in time $2^{O(\varepsilon^{-3}\log 1/\varepsilon)}$, with relative error at most $\varepsilon$, by looking at only $O(\varepsilon^{-7}\log 1/\varepsilon)$ locations in the adjacency matrix [8]. Other sublinear time approximation schemes have been applied to dense instances of graph bisection, general partitioning problems, quadratic assignment, minimum linear arrangement, and maximum acyclic subgraph and constraint satisfaction [8, 5], as well as clustering [1, 14]. Note that typically such schemes approximate the value of the optimal solution, for example, the size of a maxcut, without computing the structure that achieves it, i.e., the actual cut. Sometimes, however, a solution can also be constructed in linear or near-linear time.

In this paper, we consider the problem of finding the weight of the minimum spanning tree (MST) of a graph. Finding the MST of a graph has a long, distinguished history [3, 10, 12]. Currently the best known deterministic algorithm of Chazelle [2] runs in $O(m\alpha(m,n))$ time, where $n$ (resp., $m$) is the number of vertices (resp., edges) and $\alpha$ is inverse-Ackermann. The randomized algorithm of Karger, Klein, and Tarjan [11] runs in linear expected time (see also [4, 13] for alternative models).

In this paper, we show that there are conditions under which it is possible to approximate the weight of the MST of a connected graph in time sublinear in the number of edges. We give an algorithm which approximates the MST of a graph $G$ to within a multiplicative factor of $1+\varepsilon$ and runs in time $O(dw\varepsilon^{-2}\log\frac{dw}{\varepsilon})$ for any $G$ with average degree $d$ and edge weights in the set $\{1,\ldots,w\}$. The algorithm requires no prior information about the graph besides $w$ and $n$; in particular, the average degree is assumed to be unknown. The relative error $\varepsilon$ $(0<\varepsilon<1/2)$ is specified as an input parameter. Note that if $d$ and $\varepsilon$ are constant and the ratios of the edge weights are bounded, then the algorithm runs in constant time. We also extend our algorithm to the case where $G$ has nonintegral weights in the range $[1,w]$, achieving a comparable running time with a somewhat worse dependence on $\varepsilon$.

Our algorithm considers several auxiliary graphs: If $G$ is the weighted graph, let us denote by $G^{(i)}$ the subgraph of $G$ that contains only edges of weight at most $i$. We estimate the number of connected components in each $G^{(i)}$. To do so, we sample uniformly at random $O(1/\varepsilon^2)$ vertices in $G^{(i)}$ and then estimate the size of the component that contains each sampled vertex by constructing "local trees" of some appropriate size defined by a random process. Based on information about these local trees, we can in turn produce a good approximation for the weight of the MST of $G$. Our algorithm for estimating the number of connected components in a graph runs in time $O(d\varepsilon^{-2}\log\frac{d}{\varepsilon})$—or $O(\varepsilon^{-2}\log\frac{1}{\varepsilon})$ for $d=O(1)$—and produces an estimate that is within an additive error of $\varepsilon n$ of the true count. The method is based on a similar principle as the property tester for graph connectivity given by Goldreich and Ron [9].

We give a lower bound of $\Omega(dw/\varepsilon^2)$ on the time complexity of any algorithm which approximates the MST weight. In order to prove the lower bound, we give two distributions on weighted graphs, where the support set of one distribution contains graphs with MST weight at least $1+\varepsilon$ times the MST weight of the graphs in the support of the other distribution. We show that any algorithm that reads $o(dw/\varepsilon^2)$ weights from the input graph is unlikely to distinguish between graphs from the two distributions. We also prove a lower bound of $\Omega(d/\varepsilon^2)$ on the running time of any approximation algorithm for counting connected components. The above lower bounds apply to the class of graphs which may contain self-loops and multiple edges.

## 2. Estimating the number of connected components.

We begin with the problem of estimating the number of components in an arbitrary graph $G$. For no-

```
approx-number-connected-components($G, \varepsilon, W, d^*$)
  uniformly choose $r = O(1/\varepsilon^2)$ vertices $u_1, \ldots, u_r$
  for each vertex $u_i$,
    set $\beta_i = 0$
    take the first step of a BFS from $u_i$
    (*) flip a coin
    if (heads) & (# vertices visited in BFS $< W$)
              & (no visited vertex has degree $> d^*$)
      then {resume BFS to double number of visited edges
            if this allows BFS to complete
              then {if $m_{u_i} = 0$ set $\beta_i = 2$
                    else set $\beta_i = d_{u_i} 2^{\#\text{coin flips}} / \#\text{edges}$ visited in BFS }
              else go to (*) }
  output $\hat{c} = \frac{n}{2r} \sum_{i=1}^{r} \beta_i$
```

FIG. 1. *Estimating the number of connected components; see main text for precise definition of BFS.*

tational convenience, we may assume that $d \geq 1$: This can always be achieved by implicitly adding a fictitious self-loop to each vertex, which does not change the number of connected components. We present an algorithm that gives an additive estimate of the number of components in $G$ to within $\varepsilon n$ in $O(d\varepsilon^{-2} \log \frac{d}{\varepsilon})$ time for any $0 < \varepsilon < 1/2$. We later show how to use the ideas from our algorithm to aid in estimating the weight of the MST of a graph. We use the following notation: Given a vertex $u$, $d_u$ is the number of edges incident upon it (including self-loops), and $m_u$ is the number of edges in $u$'s component in $G$. Finally, $c$ denotes the number of connected components. Our algorithm is built around the following simple observation.

FACT 1. *Given a graph with vertex set $V$, for every connected component $I \subseteq V$, $\sum_{u \in I} \frac{1}{2} d_u / m_u = 1$ and $\sum_{u \in V} \frac{1}{2} d_u / m_u = c$.*

To handle isolated vertices, we must make the convention that $d_u/m_u = 2$ if $m_u = 0$. Our strategy is to estimate $c$ by approximating each $d_u/m_u$. Computing them directly could take linear time, so we construct an estimator of the quantity $d_u/m_u$ that has the same expected value. We approximate the number of connected components via the algorithm given in Figure 1. The parameter $W$ is a threshold value which is set to $4/\varepsilon$ for counting connected components and somewhat higher for MST weight estimation. We also use an estimate $d^*$ of the average degree $d$, which we compute separately in $O(d/\varepsilon)$ expected time (see Lemma 4). This approximation ensures that $d^* = O(d/\varepsilon)$ and that at most $\varepsilon n/4$ vertices have degree higher than $d^*$.

In the algorithm, doubling the number of edges does not include duplicate visits to the same edges; in other words, at each phase the number of new edges visited is supposed to match the number of distinct edges already visited. In our terminology, the first step of the BFS (shorthand for breadth first search) involves the visit of the single vertex $u_i$ and all its $d_{u_i}$ incident edges. That is, unless $d_{u_i} > d^*$, in which case we abort the BFS.

We now bound the expectation and variance of the estimator $\beta_i$ for a fixed $i$. If the BFS from $u_i$ completes, the number of coin flips associated with it is $\lceil \log(m_{u_i}/d_{u_i}) \rceil$, and the number of distinct edges visited is $m_{u_i}$. Let $S$ denote the set of vertices that lie in components with fewer than $W$ vertices all of which are of degree at most $d^*$. If $u_i \notin S$, then $\beta_i = 0$; otherwise, it is $2^{\lceil \log(m_{u_i}/d_{u_i}) \rceil} d_{u_i}/m_{u_i}$ with probability

$2^{-\lceil \log(m_{u_i}/d_{u_i})\rceil}$ (and 2 if $m_{u_i} = 0$) and 0 otherwise. Since $\beta_i \leq 2$, the variance of $\beta_i$ is

$$\mathbf{var}\,\beta_i \leq \mathbf{E}\,\beta_i^2 \leq 2\mathbf{E}\,\beta_i = \frac{2}{n}\sum_{u\in S}\frac{d_u}{m_u} \leq \frac{4c}{n}\,.$$

Then the variance of $\hat{c}$ is bounded by

$$\mathbf{var}\,\hat{c} = \mathbf{var}\left(\frac{n}{2r}\sum_i \beta_i\right) = \frac{n^2}{4r^2}\cdot r\cdot \mathbf{var}\,\beta_i \leq \frac{nc}{r}. \tag{1}$$

By our choice of $W = 4/\varepsilon$ and $d^*$, there are at most $\varepsilon n/2$ components with vertices not in $S$, and so

$$c - \frac{\varepsilon n}{2} \leq \mathbf{E}\,\hat{c} \leq c\,. \tag{2}$$

Furthermore, by Chebyshev,

$$\text{Prob}[\,|\hat{c} - \mathbf{E}\,\hat{c}| > \varepsilon n/2\,] < \frac{\mathbf{var}\,\hat{c}}{(\varepsilon n/2)^2} \leq \frac{4c}{\varepsilon^2 rn}\,. \tag{3}$$

Choosing $r = O(1/\varepsilon^2)$ ensures that, with constant probability arbitrarily close to 1, our estimate $\hat{c}$ of the number of connected components deviates from the actual value by at most $\varepsilon n$.

The expected number of edges visited in a given iteration of the "for loop" is $O(d_{u_i}\log M)$, where $M$ is the maximum number of edges visited, which is at most $Wd^* = O(d/\varepsilon^2)$. Therefore, the expected running time of the entire algorithm is

$$\frac{O(r)}{n}\sum_{u\in V} d_u \log(Wd^*) = O(dr\log(Wd^*)) = O\left(d\varepsilon^{-2}\log\frac{d}{\varepsilon}\right)\,, \tag{4}$$

not counting the $O(d/\varepsilon)$ time needed for computing $d^*$.

As stated, the algorithm's running time is randomized. If $d$ is known, however, we can get a deterministic running time bound by stopping the algorithm after $Cd\varepsilon^{-2}\log\frac{d}{\varepsilon}$ steps and outputting 0 if the algorithm has not yet terminated. This event occurs with probability at most $O(1/C)$, which is a negligible addition to the error probability. Thus we have the following theorem.

THEOREM 2. *Let $c$ be the number of components in a graph with $n$ vertices. Then Algorithm* approx-number-connected-components *runs in time $O(d\varepsilon^{-2}\log\frac{d}{\varepsilon})$ and with probability at least $3/4$ outputs $\hat{c}$ such that $|c - \hat{c}| \leq \varepsilon n$.*

*Finetuning the algorithm.* If we proceed in two stages, first estimating $c$ within a constant factor, and then in a second pass using this value to optimize the size of the sample, we can lower the running time to $O((\varepsilon + c/n)d\varepsilon^{-2}\log\frac{d}{\varepsilon})$. This is a substantial improvement for small values of $c$. First, run the algorithm for $r = O(1/\varepsilon)$. By Chebyshev and (1, 2),

$$\text{Prob}\left[\,|\hat{c} - \mathbf{E}\,\hat{c}| > \frac{\mathbf{E}\,\hat{c} + \varepsilon n}{2}\,\right] < \frac{4nc}{r(c+\varepsilon n/2)^2} \leq \frac{4n}{r(c+\varepsilon n/2)},$$

which is arbitrarily small for $r\varepsilon$ large enough. Next, we use this approximation $\hat{c}$ to "improve" the value of $r$. We set $r = A/\varepsilon + A\hat{c}/(\varepsilon^2 n)$ for some large enough constant

$A$ and we run the algorithm again, with the effect of producing a second estimate $c^*$. By (2, 3),

$$\text{Prob}[\,|c^* - \mathbf{E}\,c^*| > \varepsilon n/2\,] < \frac{4c}{\varepsilon^2 rn} \leq \frac{8c}{A\varepsilon n + A\mathbf{E}\,\hat{c}} \leq \frac{8}{A},$$

and so, with overwhelming probability, our second estimate $c^*$ of the number of connected components deviates from $c$ by at most $\varepsilon n$. So we have the following theorem.

THEOREM 3. *Let $c$ be the number of components in a graph with $n$ vertices. Then there is an algorithm that runs in time $O(d\varepsilon^{-2} \log \frac{d}{\varepsilon})$ and with probability at least $3/4$ outputs $\hat{c}$ such that $|c - \hat{c}| \leq \varepsilon n$.*

*Approximating the degree.* We show how to compute the desired estimate $d^*$ of the average degree $d$. Pick $C/\varepsilon$ vertices of $G$ at random, for some large constant $C$, and set $d^*$ to be the maximum degree among them. To find the degree of any one of them takes $O(d)$ time on average, and so the expected running time is $O(d/\varepsilon)$. Imagine the vertex degrees sorted in nonincreasing order, and let $\rho$ be the rank of $d^*$. With high probability, $\rho = \Theta(\varepsilon n)$. To see why, we easily bound the probability that $\rho$ exceeds $\varepsilon n$ by $(1-\varepsilon)^{C/\varepsilon} \leq e^{-C}$. On the other hand, observe that the probability that $\rho > \varepsilon n/C^2$ is at least $(1-\varepsilon/C^2)^{C/\varepsilon} \geq e^{-2/C} > 1 - 2/C$.

LEMMA 4. *In $O(d/\varepsilon)$ expected time, we can compute a vertex degree $d^*$ that, with high probability, is the $k$th largest vertex degree for some $k = \Theta(\varepsilon n)$.*

Note that $k = \Omega(\varepsilon n)$ alone implies that $d^* = O(d/\varepsilon)$, and so, if we scale $\varepsilon$ by the proper constant, we can ensure that at most $\varepsilon n/4$ vertices have degree higher than $d^*$, and thus conform to the requirements of approx-number-connected-components.

## 3. Approximating the weight of an MST.

In this section we present an algorithm for approximating the value of the MST in bounded weight graphs. We are given a connected graph $G$ with average degree $d$ and with each edge assigned an integer weight between 1 and $w$. We assume that $G$ is represented by adjacency lists or, for that matter, any representation that allows one to access all edges incident to a given vertex in $O(d)$ time. We show how to approximate the weight of the MST of $G$ with a relative error of at most $\varepsilon$.

In section 3.1 we give a new way to characterize the weight of the MST in terms of the number of connected components in subgraphs of $G$. In section 3.2 we give the main algorithm and its analysis. Finally, section 3.3 addresses how to extend the algorithm to the case where $G$ has nonintegral weights.

### 3.1. MST weight and connected components.

We reduce the computation of the MST weight to counting connected components in various subgraphs of $G$. To motivate the new characterization, consider the special case when $G$ has only edges of weight 1 or 2 (i.e., $w = 2$). Let $G^{(1)}$ be the subgraph of $G$ consisting precisely of the edges of weight 1, and let $n_1$ be its number of connected components. Then, any MST in $G$ must contain exactly $n_1 - 1$ edges of weight 2, with all the others being of weight 1. Thus, the weight of the MST is exactly $n - 2 + n_1$. We easily generalize this derivation to any $w$.

For each $0 \leq \ell \leq w$, let $G^{(\ell)}$ denote the subgraph of $G$ consisting of all the edges of weight at most $\ell$. Define $c^{(\ell)}$ to be the number of connected components in $G^{(\ell)}$ (with $c^{(0)}$ defined to be $n$). By our assumption on the weights, $c^{(w)} = 1$. Let $M(G)$ be the weight of the MST of $G$. Using the above quantities, we give an alternate way of computing the value of $M(G)$ in the following claim.

```
approx-MST-weight($G, \varepsilon$)
  For $i = 1, \dots, w-1$
    $\hat{c}^{(i)} =$ approx-number-connected-components($G^{(i)}, \varepsilon, 4w/\varepsilon, d^*$)
  output $\hat{v} = n - w + \sum_{i=1}^{w-1} \hat{c}^{(i)}$
```

FIG. 2. *Approximating the weight of the MST.*

CLAIM 5. *For integer $w \geq 2$,*

$$M(G) = n - w + \sum_{i=1}^{w-1} c^{(i)} .$$

*Proof.* Let $\alpha_i$ be the number of edges of weight $i$ in an MST of $G$. (Note that $\alpha_i$ is independent of which MST we choose [7].) Observe that for all $0 \leq \ell \leq w-1$, $\sum_{i>\ell} \alpha_i = c^{(\ell)} - 1$; therefore

$$M(G) = \sum_{i=1}^{w} i\alpha_i = \sum_{\ell=0}^{w-1} \sum_{i=\ell+1}^{w} \alpha_i = -w + \sum_{\ell=0}^{w-1} c^{(\ell)} = n - w + \sum_{i=1}^{w-1} c^{(i)}. \qquad \square$$

Thus, computing the number of connected components allows us to compute the weight of the MST of $G$.

**3.2. The main algorithm.** Our algorithm approximates the value of the MST by estimating each of the $c^{(\ell)}$'s. The algorithm is given in Figure 2. Note that we do not set $W = 4/\varepsilon$ in the call to the connected-components algorithm. For the same reason (to be explained below) we need a different estimate of the degree $d^*$. We use Lemma 4 just once to compute, in $O(dw/\varepsilon)$ time, an estimate $d^* = O(dw/\varepsilon)$ such that at most $\varepsilon n/4w$ vertices have degree higher than $d^*$.

In the following, we assume that $w/n < 1/2$, since otherwise we might as well compute the MST explicitly, which can be done in $O(dn)$ time with high probability [11].

THEOREM 6. *Let $w/n < 1/2$. Let $v$ be the weight of the MST of $G$. Algorithm* approx-MST-weight *runs in time $O(dw\varepsilon^{-2} \log \frac{dw}{\varepsilon})$ and outputs a value $\hat{v}$ that, with probability at least $3/4$, differs from $v$ by at most $\varepsilon v$.*

*Proof.* Let $c = \sum_{i=1}^{w-1} c^{(i)}$. Repeating the previous analysis, we find that (1), (2) become

$$c^{(i)} - \frac{\varepsilon n}{2w} \leq \mathbf{E}\, \hat{c}^{(i)} \leq c^{(i)} \qquad \text{and} \qquad \mathbf{var}\, \hat{c}^{(i)} \leq \frac{nc^{(i)}}{r} .$$

By summing over $i$, it follows that $c - \varepsilon n/2 \leq \mathbf{E}\, \hat{c} \leq c$ and $\mathbf{var}\, \hat{c} \leq nc/r$, where $\hat{c} = \sum_{i=1}^{w-1} \hat{c}^{(i)}$. Choosing $r\varepsilon^2$ large enough, by Chebyshev we have

$$\text{Prob}[\, |\hat{c} - \mathbf{E}\, \hat{c}| > (n - w + c)\varepsilon/3\,] < \frac{9nc}{r\varepsilon^2 (n - w + c)^2},$$

which is arbitrarily small. It follows that, with high probability, the error on the estimate satisfies

$$|v - \hat{v}| = |c - \hat{c}| \leq \frac{\varepsilon n}{2} + \frac{\varepsilon(n - w + c)}{3} \leq \varepsilon v.$$

Since, by (4), the expected running time of each call to approx-number-connected-components is $O(dr\log(Wd^*))$, the total expected running time is $O(dw\varepsilon^{-2}\log\frac{dw}{\varepsilon})$. As before, if we know $d$, then the running time can be made deterministic by stopping execution of the algorithm after $Cdw\varepsilon^{-2}\log\frac{dw}{\varepsilon}$ steps for some appropriately chosen constant $C$. $\square$

**3.3. Nonintegral weights.** Suppose the weights of $G$ are all in the range $[1, w]$, but are not necessarily integral. To extend the algorithm to this case, one can multiply all the weights by $1/\varepsilon$ and round each weight to the nearest integer. Then one can run the above algorithm with error parameter $\varepsilon/2$ and with a new range of weights $[1, \lceil w/\varepsilon\rceil]$ to get a value $v$. Finally, output $\varepsilon v$. The relative error introduced by the rounding is at most $\varepsilon/2$ per edge in the MST and hence $\varepsilon/2$ for the whole MST, which gives a total relative error of at most $\varepsilon$. The running time of the above algorithm is $O(dw\varepsilon^{-3}\log\frac{w}{\varepsilon})$.

## 4. Lower bounds.

We prove that our algorithms for estimating the MST weight and counting connected components are essentially optimal. Our lower bounds apply to graphs that may contain self-loops and multiple edges.

THEOREM 7. *Any probabilistic algorithm for approximating, with relative error $\varepsilon$, the MST weight of a connected graph with average degree $d$ and weights in $\{1, \dots, w\}$ requires $\Omega(dw\varepsilon^{-2})$ edge weight lookups on average. It is assumed that $w > 1$ and $C\sqrt{w/n} < \varepsilon < 1/2$, for some large enough constant $C$.*

We can obviously assume that $w > 1$; otherwise the MST weight is always $n-1$ and no work is required. The lower bound on $\varepsilon$ might seem restrictive, but it is not at all. Indeed, by monotonicity on $\varepsilon$, the theorem implies a lower bound of $\Omega(dw(C\sqrt{w/n})^{-2})$ for any $\varepsilon \le C\sqrt{w/n}$. But this is $\Omega(dn)$, which we know is tight. Therefore, the case $C\sqrt{w/n} < \varepsilon$ is the only one that deserves attention.

THEOREM 8. *Given a graph with $n$ vertices and average degree $d$, any probabilistic algorithm for approximating the number of connected components with an additive error of $\varepsilon n$ requires $\Omega(d\varepsilon^{-2})$ edge lookups on average. It is assumed that $C/\sqrt{n} < \varepsilon < 1/2$, for some large enough constant $C$.*

Again, note that the lower bound on $\varepsilon$ is nonrestrictive since we can always solve the problem exactly in $O(dn)$ time. (For technical reasons, we allow graphs to have self-loops.)

Both proofs revolve around the difficulty of distinguishing between two nearby distributions. For any $0 < q \le 1/2$ and $s = 0, 1$, let $\mathcal{D}_q^s$ denote the distribution induced by setting a 0/1 random variable to 1 with probability $q_s = q(1 + (-1)^s\varepsilon)$. We define a distribution $\mathcal{D}$ on $n$-bit strings as follows: (1) pick $s = 1$ with probability 1/2 (and 0 else); (2) then draw a random string from $\{0,1\}^n$ (by choosing each $b_i$ from $\mathcal{D}_q^s$ independently). Consider a probabilistic algorithm that, given access to such a random bit string, outputs an estimate on the value of $s$. How well can it do?

LEMMA 9. *Any probabilistic algorithm that can guess the value of $s$ with a probability of error below $1/4$ requires $\Omega(\varepsilon^{-2}/q)$ bit lookups on average.*

*Proof.* By Yao's minimax principle, we may assume that the algorithm is deterministic and that the input is distributed according to $\mathcal{D}$. It is intuitively obvious that any algorithm might as well scan $b_1 b_2 \cdots$ until it decides it has seen enough to produce an estimate of $s$. In other words, there is no need to be adaptive in the choice of bit indices to probe (but the running time itself can be adaptive). To see why is easy. An algorithm can be modeled as a binary tree with a bit index at each node and a 0/1 label at each edge. An adaptive algorithm may have an arbitrary set of bit indices at the nodes, although we can assume that the same index does not appear twice along any path. Each leaf is naturally associated with a probability, which is that of a random input from $\mathcal{D}$ following the path to that leaf. The performance of the algorithm is entirely determined by these probabilities and the corresponding estimates of $s$. Because of the independence of the random $b_i$'s, we can relabel the tree so that each path is a prefix of the same sequence of bit probes $b_1 b_2 \cdots$. This oblivious algorithm has the same performance as the adaptive one.

We can go one step further and assume that the running time is the same for all inputs. Let $t^*$ be the expected number of probes, and let $0 < \alpha < 1$ be a small constant. With probability at most $\alpha$, a random input takes time $\geq t \overset{\text{def}}{=} t^*/\alpha$. Suppose that the prefix of bits examined by the algorithm is $b_1 \cdots b_u$. If $u < t$, simply go on probing $b_{u+1} \cdots b_t$ without changing the outcome. If $u > t$, then stop at $b_t$ and output $s = 1$. Thus, by adding $\alpha$ to the probability of error, we can assume that the algorithm consists of looking up $b_1 \cdots b_t$ regardless of the input string.

Let $p_s(b_1 \cdots b_t)$ be the probability that a random $t$-bit string chosen from $\mathcal{D}_q^s$ is equal to $b_1 \cdots b_t$. The probability of error satisfies

$$p_{\text{err}} \geq \frac{1}{2} \sum_{b_1 \cdots b_t} \min_s p_s(b_1 \cdots b_t).$$

Obviously, $p_s(b_1 \cdots b_t)$ depends only on the number of ones in the string, so if $p_s(k)$ denotes the probability that $b_1 + \cdots + b_t = k$, then

$$p_{\text{err}} \geq \frac{1}{2} \sum_{k=0}^{t} \min_s p_s(k). \tag{5}$$

By the normal approximation of the binomial distribution,

$$p_s(k) \to \frac{1}{\sqrt{2\pi t q_s(1-q_s)}}\, e^{-\frac{(k-tq_s)^2}{2tq_s(1-q_s)}}$$

as $t \to \infty$. This shows that $p_s(k) = \Omega(1/\sqrt{qt}\,)$ over an interval $I_s$ of length $\Omega(\sqrt{qt}\,)$ centered at $tq_s$. If $qt\varepsilon^2$ is smaller than a suitable constant $\gamma_0$, then $|tq_0 - tq_1|$ is small enough that $I_0 \cap I_1$ is itself an interval of length $\Omega(\sqrt{qt}\,)$; therefore $p_{\text{err}} = \Omega(1)$. This shows that if the algorithm runs in expected time $\gamma_0 \varepsilon^{-2}/q$, for some constant $\gamma_0 > 0$ small enough, then it will fail with probability at least some absolute constant. By setting $\alpha$ small enough, we can make that constant larger than $2\alpha$. This means that, prior to uniformizing the running time, the algorithm must still fail with probability $\alpha$.

Note that by choosing $\gamma_0$ small enough, we can always assume that $\alpha > 1/4$. Indeed, suppose by contradiction that even for an extremely small $\gamma_1$, there is an algorithm that runs in time at most $\gamma_1 \varepsilon^{-2}/q$ and fails with probability $\leq 1/4$. Then run the algorithm many times and take a majority vote. In this way we can bring the failure probability below $\alpha$ for a suitable $\gamma_1 = \gamma_1(\alpha, \gamma_0) < \gamma_0$ and therefore reach a contradiction. This means that an expected time lower than $\varepsilon^{-2}/q$ by a large enough constant factor causes a probability of error at least $1/4$. $\square$

*Proof of Theorem* 8. Consider the graph $G$ consisting of a simple cycle of $n$ vertices $v_1, \ldots, v_n$. Pick $s \in \{0, 1\}$ at random and take a random $n$-bit string $b_1 \cdots b_n$ with bits drawn independently from $\mathcal{D}_{1/2}^s$. Next, remove from $G$ any edge $(v_i, v_{i+1 \bmod n})$ if $b_i = 0$. Because $\varepsilon > C/\sqrt{n}$, the standard deviation of the number of components, which is $\Theta(\sqrt{n})$, is sufficiently smaller than $\varepsilon n$ so that with overwhelming probability any two graphs derived from $\mathcal{D}^0_{1/2}$ and $\mathcal{D}^1_{1/2}$ differ by more than $\varepsilon n/2$ in their numbers of connected components. That means that any probabilistic algorithm that estimates the number of connected components with an additive error of $\varepsilon n/2$ can be used to identify the correct $s$. By Lemma 9, this requires $\Omega(\varepsilon^{-2})$ edge probes into $G$ on average. Replacing $\varepsilon$ by $2\varepsilon$ proves Theorem 8 for graphs of average degree about 1.

For values of $d$ smaller than one, we may simply build a graph of the previous type on a fraction $d$ of the $n$ vertices and leave the others isolated. The same lower bound still holds as long as $d\varepsilon^2 n$ is bigger than a suitable constant. If $d > 1$, then we may simply add $d \pm O(1)$ self-loops to each vertex in order to bring the average degree up to $d$. Each linked list thus consists of two "cycle" pointers and about $d$ "loop" pointers. If we place the cycle pointers at random among the loop pointers, then it takes $\Omega(d)$ probes on average to hit a cycle pointer. If we single out the probes involving cycle pointers, it is not hard to argue that the probes involving cycle pointers are alone sufficient to solve the connected-components problem on the graph deprived of its loops: One expects at most $O(T/d)$ such probes, and therefore $T = \Omega(d\varepsilon^{-2})$. $\square$

*Proof of Theorem* 7. The input graph $G$ is a simple path of $n$ vertices. Pick $s \in \{0, 1\}$ at random and take a random $(n-1)$-bit string $b_1 \cdots b_{n-1}$ with bits drawn independently from $\mathcal{D}^s_q$, where $q = 1/w$. Assign weight $w$ (resp., 1) to the $i$th edge along the path if $b_i = 1$ (resp., 0). The MST of $G$ has weight $n - 1 + (w-1)\sum b_i$, and so its expectation is $\Theta(n)$. Also, note that the difference $\Delta$ in expectations between drawing from $\mathcal{D}^0_q$ or $\mathcal{D}^1_q$ is $\Theta(\varepsilon n)$.

Because $\varepsilon > C\sqrt{w/n}$, the standard deviation of the MST weight, which is $\Theta(\sqrt{nw})$, is sufficiently smaller than $\Delta$ that with overwhelming probability any two graphs derived from $\mathcal{D}^0_q$ and $\mathcal{D}^1_q$ differ by more than $\Delta/2$ in MST weight. Therefore, any probabilistic algorithm that estimates the weight with a relative error of $\varepsilon/D$, for some large enough constant $D$, can be used to identify the correct $s$. By Lemma 9, this means that $\Omega(w\varepsilon^{-2})$ probes into $G$ are required on average.

In this construction, $d = 2 - 2/n$ (the smallest possible value for a connected graph). For higher values of $d$, we join each vertex in the cycle to about $d-2$ others (say, at distance $> 2$ to avoid introducing multiple edges) to drive the degree up to $d$. Also, as usual, we randomize the ordering in each linked list. Assign weight $w+1$ to the new edges. (Allowing the maximum weight to be $w+1$ instead of $w$ has no influence on the lower bound for which we are aiming.) Clearly none of the new edges are used in the MST, so the problem is the same as before, except that we now have to find our way amidst $d-2$ spurious edges, which takes the complexity to $\Omega(dw\varepsilon^{-2})$. $\square$

## 5. Open questions.

Our algorithm for the case of nonintegral weights requires extra time. Is this necessary? Can the ideas in this paper be extended to finding maximum weighted independent sets in general matroids? There are now a small number of examples of approximation problems that can be solved in sublinear time; what other problems lend themselves to sublinear approximation schemes? More generally, it would be interesting to gain a more global understanding of what can and cannot be approximated in sublinear time.

**Acknowledgments.** We wish to thank David Silver for his helpful comments about the paper and for implementing the MST algorithm and showing that it works well in practice. We also thank the referees for many useful suggestions.

# BINARY SPACE PARTITIONS OF ORTHOGONAL SUBDIVISIONS*

JOHN HERSHBERGER†, SUBHASH SURI‡, AND CSABA D. TÓTH§

**Abstract.** We consider the problem of constructing binary space partitions (BSPs) for orthogonal subdivisions (space-filling packings of boxes) in $d$-space. We show that a subdivision with $n$ boxes can be refined into a BSP of size $O(n^{(d+1)/3})$ for all $d \geq 3$ and that such a partition can be computed in time $O(K \log n)$, where $K$ is the size of the BSP produced. Our upper bound on the BSP size is tight for 3-dimensional subdivisions; in higher dimensions, this is the first nontrivial result for general full-dimensional boxes. We also present a lower bound construction for a subdivision of $n$ boxes in $d$-space for which every axis-aligned BSP has $\Omega(n^{\beta(d)})$ size, where $\beta(d)$ converges to $(1+\sqrt{5})/2$ as $d \to \infty$.

## 1. Introduction.

Many algorithms in computational geometry, robotics, and computer graphics decompose a set of objects and the ambient space for efficient processing of certain queries. A binary space partition (BSP) is a popular scheme for constructing such decompositions. Given an open convex region of space containing a set of pairwise disjoint objects $S$, a BSP partitions the region and objects with a cutting hyperplane, then recursively partitions the two resulting subproblems. The process stops when each open partition region intersects at most one object of $S$. See Figure 1 in section 2 for an example in two dimensions. In the ideal case, the number of regions in the final BSP would be at most $n$, the number of input objects. In general, however, the recursive partitioning may fracture input objects many times, and the size of the partition can be much larger than $n$.

BSPs were introduced in the computer graphics community [10, 16] to solve hidden surface removal problems. But they are now used for a wide variety of applications, including set operations in solid modeling, visibility preprocessing for interactive walkthroughs, shadow generation, and cell decomposition methods in robotics, to name only a representative sample [2, 6, 7, 12, 13, 17]. The *size* of a BSP is the total number of pieces the input objects are partitioned into by the BSP, and it is a measure of the *fragmentation* caused by the partition. Because BSPs are often used to decompose large data sets, their size can be crucial to the performance of the applications that rely on them. Theoretical analyses have therefore focused primarily

on BSP algorithms that produce small size partitions.

A theoretical study of BSPs began in earnest with two influential papers by Paterson and Yao [14, 15]. In two dimensions, Paterson and Yao gave an $O(n)$ size BSP construction for orthogonal (axis-parallel rectangular) objects, and an $O(n \log n)$ size construction for general polygons with a total of $n$ edges. Recently, Tóth [18] showed an almost-matching lower bound of $\Omega(n \log n / \log \log n)$ for arbitrary polygons in the plane. In three dimensions, Paterson and Yao gave an $O(n^{3/2})$ size BSP construction for orthogonal boxes, and an $O(n^2)$ size construction for arbitrarily oriented polyhedra with a total of $n$ edges. They also gave lower bound constructions matching these upper bounds.

The results of Paterson and Yao have been extended and improved in several important directions, yet the complexity of BSPs in three and higher dimensions is still not fully understood. We briefly review the previous research most relevant to our work. De Berg shows that any *uncluttered* scene of $n$ objects in $d$-space admits a linear size BSP [4]; informally, "uncluttered" means that any cubical region intersecting more than a constant number of objects must include a vertex of the bounding box of one of the objects. For instance, a collection of hypercubes (or, more generally, of *fat* objects) is uncluttered. Such an assumption may be practical in some situations, but it seems quite restrictive in general.

Paterson and Yao [14] consider the complexity of BSPs for 1-dimensional objects (line segments) in $d$-space, and show that a worst-case set of $n$ axis-aligned line segments requires a BSP of size $\Theta(n^{d/(d-1)})$ for $d > 2$. Dumitrescu, Mitchell, and Sharir [8] give an upper bound of $O(n^{d/(d-k)})$ for the BSP size of disjoint $k$-dimensional orthogonal objects in $d$-space for $1 \leq k < d$. This bound is asymptotically tight for $k < d/2$. The only known tight bound for orthogonal $k$-flats in $d$-space with $k \geq d/2$ is the case $d = 4$ and $k = 2$, where a $\Theta(n^{5/3})$ bound has been shown [8].

The general $O(n^{d/(d-k)})$ upper bound does not say anything about full-dimensional boxes. Berman, DasGupta, and Muthukrishnan [5] show that every set of $n$ axis-aligned rectangles in the plane has a BSP of size at most $3n$. The best known lower bound, $\frac{7}{3}n - o(n)$, is due to Dumitrescu, Mitchell, and Sharir [8]. If the rectangles tile the plane, however, Berman, DasGupta, and Muthukrishnan [5] prove an upper bound of $2n - 1$, matching a lower bound of $2n - o(n)$ by Dumitrescu, Mitchell, and Sharir [8] (originally designed for axis-parallel line segments). For full-dimensional axis-aligned boxes in $d$-space, $d \geq 2$, one can obtain an upper bound of $O(n^{d/2})$ by using the result of [8] in conjunction with an observation of Paterson and Yao [15] that a set of $n$ full-dimensional boxes in $d$-space has the same BSP complexity in certain cases as the set of their $(d-2)$-dimensional faces.

Agarwal et al. [1] consider BSPs of 2-dimensional *fat rectangles* in 3-space—each rectangle has sides parallel to the axes and a constant aspect ratio. Agarwal et al. [1] show that a collection of $n$ such rectangles admits a BSP of size $n2^{O(\sqrt{\log n})}$. This bound was recently improved to $O(n \log^8 n)$ by Tóth [19].

**Our results.** In an attempt to understand the true complexity of $d$-dimensional BSPs, we consider a natural but restricted setting: *orthogonal subdivisions.* An orthogonal subdivision is a collection of interior-disjoint rectilinear boxes that fill their containing space. (That is, a subdivision is a space-filling packing of boxes.) Our interest in subdivisions is motivated by the observation that all the known lower bound constructions involve intertwined rod-like objects that create many "holes." This raises the following natural question: What is the complexity of the BSP for polygonal scenes in which the complement space can be "tiled" with few boxes, say, a linear number? Our main result is the following theorem.

Theorem 1.1. *Given an orthogonal subdivision with $n$ boxes in $d$-space, we can construct a BSP for it of size $O(n^{(d+1)/3})$ for any $d \geq 2$.*

Thus, for collections of orthogonal objects that fill their containing space, we are able to improve the worst-case bound on the BSP size from $O(n^{d/2})$ to $O(n^{(d+1)/3})$. As a corollary, for any collection of $n$ orthogonal boxes whose complement space can be tiled with $m$ boxes, there exists a BSP of size $O((n+m)^{(d+1)/3})$. Our subdivision BSP can be constructed in time $O(K \log n)$, where $K$ is the output size. We also exhibit a lower bound construction for an important class of BSPs: An *axis-aligned BSP* is a BSP in which every cutting hyperplane is orthogonal to one of the axes. We describe a subdivision that requires an axis-aligned BSP of size $\Omega(n^{\beta(d)})$ in $\mathbb{R}^d$, where $\beta(d)$ converges to $(1+\sqrt{5})/2$ as $d$ goes to infinity. The value of $\beta(d)$ is $4/3$ for $d = 3$, and thus our upper bound is tight in 3-space.

Our BSP algorithms are quite simple and therefore easy to implement. Their key component is a round robin partitioning scheme (in which cutting hyperplanes orthogonal to the coordinate axes are selected in a round robin order). They follow a conventional scheme—a round robin partitioning phase followed by efficient BSP construction in the terminal regions. Such a two-phase partitioning framework has been used earlier in several papers [1, 8], but in each case it requires problem-specific insights to find the right stopping rule for the round robin phase as well as an analysis for the terminal case. In our case, we show that "round robin cutting until no interior $(d-3)$-dimensional face remains" is a good stopping rule. One tricky part of analyzing this round robin scheme is that each cut may also *increase* the number of $(d-3)$-faces. The second phase requires efficient BSPs for regions that do not contain a $(d-3)$-face. To this end, we prove the following theorem, which may have independent appeal.

Theorem 1.2. *Consider a box $R$ in $d$-space and a subdivision of $R$ into $n$ boxes such that no $(d-3)$-dimensional face of any box intersects the interior of $R$. Then there is a BSP of size $O(n)$ for this subdivision.*

## 2. Geometric preliminaries.

A *$d$-dimensional box $B$* is the cross product of $d$ real-valued intervals. Given a box $R$ and a set of boxes $S = \{B_1, \dots, B_n\}$, we say that $S$ is a *subdivision* of $R$ if each $B_i$ lies in $R$, the union of the $B_i$'s covers $R$, and the $B_i$'s have pairwise disjoint interiors. Thus, an orthogonal subdivision of $R$ is a packing by boxes that completely fills $R$. In this paper, we consider BSPs for $d$-dimensional box subdivisions only.

A BSP for a problem instance $(R, S)$ partitions $R$ with a hyperplane into subboxes $R_1$ and $R_2$ and recursively solves the problems $(R_1, S_1)$ and $(R_2, S_2)$, where $S_i = S \cap R_i$ is the set of fragments of the input objects contained in $R_i$ for $i = 1, 2$. The partitioning stops when every subproblem contains at most one object (fragment). A BSP is naturally modeled as a binary tree: the root corresponds to the problem $(R, S)$, and its two children correspond to the subproblems $(R_1, S_1)$ and $(R_2, S_2)$. Every internal node stores the splitting hyperplane for the corresponding problem; the leaf nodes correspond to the regions in the final partition. See Figure 1 for a simple example in two dimensions. For ease of reference, we will often call $R$ the *container box* for the problem instance. Thus, $R_i$ is the container box for the $i$th subproblem, for $i = 1, 2$, produced at the root.

*Free cuts* are important for the construction of small BSPs. A free cut is a hyperplane that separates the object set without splitting any object. When a subproblem $(R, S)$ has a free cut, it is always worth splitting the subproblem with the free cut, since the split does necessary work—separating objects that must be separated by

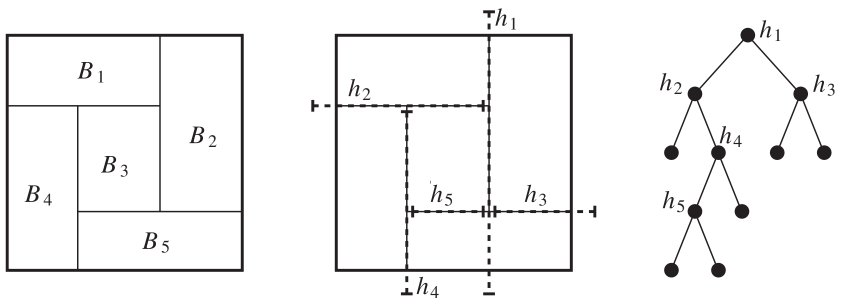

FIG. 1. *An orthogonal subdivision $S$ (left), a BSP for $S$ (middle), and the corresponding binary tree (right).*

the BSP—without increasing the complexity of the subproblems (and hence the final BSP size). In Figure 1, the cuts along $h_2$, $h_3$, $h_4$, and $h_5$ are free cuts.

A $d$-dimensional box $B$ has $2^d$ vertices, $d2^{d-1}$ edges, and $2d$ facets. $B$ also has many faces of intermediate dimensions $j$ for $2 \leq j \leq d-2$. A *$k$-face* of $B$ is a $k$-dimensional box, and it can be characterized as follows: a $k$-face of $B$ is obtained from the cross product $B$ by fixing $(d-k)$ coordinates at one of the two extremes of the corresponding intervals; the remaining $k$ coordinates maintain the same extent as $B$. Thus, vertices are the 0-faces, edges are the 1-faces, and facets are the $(d-1)$-faces of $B$. It is easy to see that every $k$-face of the box $B$, for $0 \leq k < d$, lies on the boundary of $B$. Our algorithm exploits the structure of boxes whose extents in certain dimensions match those of the container box. We therefore introduce the notions of *pass-through* and *$k$-rod*.[1]

Consider a container box $R$ and a box $B$ in a subdivision of $R$. We say that $B$ is *pass-through* for $R$ in dimension $j$ if the extent of $B$ in dimension $j$ equals that of $R$. We say that box $B$ is a *$k$-rod* in $R$ if $B$ is pass-through in exactly $k$ dimensions. If $B$ is a $k$-rod in $R$, then its *orientation* $\sigma(B)$ is the set of the $k$ dimensions in which $B$ is pass-through for $R$. Whenever the container box $R$ is clear from the context, we will simply say that $B$ is a $k$-rod, without mentioning $R$. Figure 2 illustrates $k$-rods in three dimensions, for $k = 1, 2$.

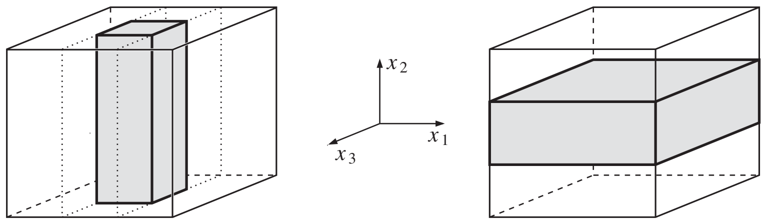

FIG. 2. *A 1-rod of orientation $\{x_2\}$ on the left and a 2-rod of orientation $\{x_1, x_3\}$ on the right.*

Suppose $B$ is a rod in a box subdivision of some container $R$. If $B$ is a $d$-rod, then, of course, $B$ fills up $R$, and it is the only box in $R$. If $B$ is a $(d-1)$-rod, with orientation $\sigma(B) = \{x_1, x_2, \ldots, x_{d-1}\}$, then at least one of the two facets of $B$ orthogonal to the $x_d$-axis intersects the interior of $R$, separating it into two parts. A

[1]The notion of pass-through also appears in [8]. Our analysis, however, requires a more detailed investigation into the properties of rods.

cut along this facet is a free cut for the subdivision of $R$. For instance, in the right half of Figure 2, the box $B$ is a 2-rod in 3-space, and there are free cuts along its top and bottom faces. We summarize this fact for future reference.

LEMMA 2.1. *If a box subdivision contains a $(d-1)$-rod, then there is a free cut along one of the facets of that rod.*

We next establish an elementary but useful characterization of $k$-rods: a box $B$ is a $k$-rod in a container $R$ *if and only if* every $j$-face of $B$ is disjoint from the interior of $R$, for all $j < k$. For instance, in Figure 2 (right), $B$ is a 2-rod, and all of its vertices and edges (0- and 1-faces) lie on the boundary of the container box. We call a face an *interior face* if it intersects the interior of the container box.

LEMMA 2.2. *Suppose $B$ is a box in the subdivision of $R$. Then $B$ is a $k$-rod if and only if $B$ has no interior $j$-faces for $j < k$ and at least one interior $j$-face for every $j$ such that $k \leq j \leq d$.*

*Proof.* Consider a $k$-rod $B$. Let $F$ be one of its $j$-faces, where $j < k$. By definition, $F$ has a fixed coordinate in $(d-j)$ dimensions and the same extent as $B$ in the remaining $j$ dimensions. Because $B$ is a $k$-rod, it is pass-through for $R$ in $k$ dimensions, and $k \geq j+1$. Thus, at least one of the fixed coordinates of $F$ is at one of the extremes of a pass-through dimension of $B$, and so $F$ lies on the boundary of $R$. Now consider $j$ such that $k \leq j \leq d$. Choose $F$ to be a $j$-face whose varying coordinates include all the pass-through directions of the $k$-rod $B$, and whose fixed coordinates are chosen inside the corresponding intervals of the cross product of the container box $R$ (possible because $B$ is pass-through in none of those $d-j \leq d-k$ dimensions). By construction, this $j$-face $F$ intersects the interior of $R$. ∎

## 3. An upper bound in $\mathbb{R}^3$.

Our first result is an optimal BSP for 3-dimensional subdivisions. Our BSP has worst-case size $O(n^{4/3})$, which is optimal because a modified Paterson–Yao construction gives a matching lower bound for orthogonal subdivisions (see section 6). The 3-dimensional bound is central to our main result because our algorithm for constructing the $d$-dimensional BSP uses projection of the $d$-dimensional subdivision onto an appropriate 3-space (after a suitable number of round robin cuts).

Our algorithm (Algorithm 3-BSP) is a round robin partitioning scheme that iteratively slices the subdivision by planes passing through interior box vertices, producing a collection of smaller subdivisions, each of which ultimately contains only $j$-rods, for $j \geq 1$. A similar round robin scheme is also used by Murali [11] in his construction of BSPs for fat axis-aligned rectangles in $\mathbb{R}^3$. Interestingly, while Murali also achieves an $O(n^{4/3})$ size BSP, that complexity is suboptimal for his problem. In our case, the round robin algorithm produces an optimal BSP.

The partition tree $T$ created by Algorithm 3-BSP is *not* a BSP—the cells output by the algorithm may contain multiple boxes. These terminal regions, however, do not contain any vertices of the subdivision. We can refine each such box into a proper BSP, with only a constant factor increase in complexity, and append the tree associated with this refinement to each leaf of $T$. Therefore, the key to efficiency is bounding the total complexity of all the regions produced by the slicing procedure.

Suppose we have a container box $R$ and its subdivision $S = \{B_1, B_2, \ldots, B_n\}$ into $n$ boxes, so that there are $m$ vertices in the interior of $R$; clearly, $m \leq 8n$. Our partitioning scheme cuts the subdivision using planes normal to each of the three axes in turn, cycling through the three possible orientations in a round robin fashion. In the following pseudocode description of our algorithm, we use the term *median $x_j$ plane* of a point set to denote the plane normal to the $x_j$-axis and passing through the median $x_j$ coordinate of the point set.

ALGORITHM 3-BSP.

```
• Input is the box subdivision $S = \{B_1, B_2, \dots, B_n\}$ of a container box $R$.
• Initialize $i = 0$, and $\mathcal{C}_0 = \{R\}$.
• While there is a container box $C \in \mathcal{C}_i$ with a subdivision vertex in its interior, do
    1. For each container box $C \in \mathcal{C}_i$ with at least one vertex of the subdivision
       in its interior, split $C$ by the median $x_p$ plane of the vertices in the
       interior of $C$, where $p = 1 + (i \bmod 3)$.
    2. Apply all possible free cuts.
    3. Let $\mathcal{C}_{i+1}$ be the set of all container boxes resulting from these cuts, and
       set $i := i + 1$.
• Return $\mathcal{C}_i$.
```

Using an argument similar to one of Paterson and Yao [15] and Murali [11], we derive an upper bound on the total number of box fragments generated by our algorithm by considering how many times the edges of the original subdivision $S$ are cut.

LEMMA 3.1. *Consider the partition tree $T$ generated by Algorithm 3-BSP. At depth $i$ in $T$, there are $O(n2^{i/3})$ fragments of the original edges of $S$.*

*Proof.* Each edge is parallel to one of the three directions $x_1$, $x_2$, and $x_3$. It can be cut only by planes orthogonal to its direction. Since our splitting planes cycle through the three directions, an edge can be cut at every third level of $T$. Thus, the number of fragments of a given original edge at most doubles at every third level. Since the number of edges in the subdivision at the root of $T$ is $O(n)$, the total number of edge fragments at depth $i$ is $O(n2^{i/3})$. $\square$

LEMMA 3.2. *Suppose $S$ is a 3-dimensional box subdivision with $n$ boxes, and $m = O(n)$ vertices lie in the interior of the container box. Then the partition created by Algorithm 3-BSP produces $O(nm^{1/3}) = O(n^{4/3})$ fragments of the input boxes.*

*Proof.* We analyze the algorithm in *rounds* of three consecutive steps: round $j$ corresponds to the steps $i = 3j, 3j+1, 3j+2$. In one round, cuts are made in all three directions, and a box of a subproblem can be split into at most eight pieces.

We observe that if a box is split into a subproblem, then at least one edge of the box must be interior to the container box for this subproblem. This is because only a 3-rod or a 2-rod can have all its edges on the boundary of the container box (Lemma 2.2), but no 3-rods are ever split and all 2-rods are eliminated in step 2 by free cuts. Lemma 3.1 implies that $O(n2^j)$ box fragments can be further partitioned at round $j$. Since there is no vertex in the interior of any container cell after $\lceil \log m \rceil$ steps, the algorithm terminates in $\lceil \frac{1}{3} \log m \rceil$ rounds. The number of box fragments produced is

$$O\left(n \cdot \sum_{j \le \lceil \frac{1}{3} \log m \rceil} 2^j\right) = O\left(n \cdot 2^{(\log m)/3}\right) = O\left(nm^{1/3}\right) = O\left(n^{4/3}\right). \qquad \square$$

All that remains now is to show that the terminal cells output by Algorithm 3-BSP can be refined into linear size BSPs. The interior of each of these terminal cells is empty of subdivision vertices and, by Lemma 2.2, every box restricted to these containers is a $k$-rod, $k \ge 1$. We first establish a useful technical lemma for the case where all subdivision boxes are 1-rods.

Lemma 3.3. *If all boxes in a* 3*-dimensional subdivision are* 1*-rods, then taken together the* 1*-rods have at most two distinct orientations.*

*Proof.* Suppose to the contrary that $A$, $B$, and $C$ are three 1-rods with three distinct orientations. Let $\ell_A$, $\ell_B$, and $\ell_C$ be lines running down the centers of $A$, $B$, and $C$, respectively, parallel to their rods' orientations. These are three axis-parallel skew lines. Let $P_{AB}$ be the axis-aligned plane containing $\ell_A$ and intersecting $\ell_B$ (see Figure 3). Define $P_{BC}$ and $P_{CA}$ similarly. Note that $P_{AB}$ does not intersect $\ell_C$ because it is parallel to it. The point $P_{AB} \cap \ell_B$ lies in the interior of $B$—$P_{AB}$ lies between the planes supporting the two opposite faces of the container box that $\ell_B$ pierces. Now $P_{AB} \cap P_{BC}$ is a line parallel to $\ell_A$ that intersects $\ell_B$. It follows that $P_{AB} \cap P_{BC}$ is disjoint from $A$ and intersects $B$. Similar claims hold for $P_{BC} \cap P_{CA}$ and $P_{CA} \cap P_{AB}$.

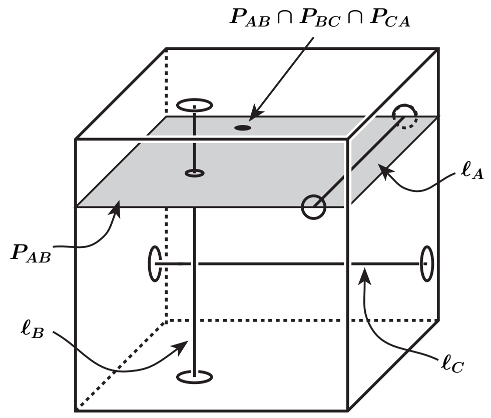

Fig. 3. 1*-rods with three different orientations imply the existence of an interior vertex.*

Let $p$ be the point $P_{AB} \cap P_{BC} \cap P_{CA}$. Point $p$ is disjoint from $A \cup B \cup C$, and $p$ also lies in the interior of the container box, since it is connected by three axis-parallel lines to the points $P_{AB} \cap \ell_B$, $P_{BC} \cap \ell_C$, and $P_{CA} \cap \ell_A$, all of which lie in the interior of the container box. Now we claim that the box containing $p$ cannot be a 1-rod in this subdivision: for each of the axis-parallel directions there is a line (e.g., $P_{AB} \cap P_{BC}$) that intersects one of $A$, $B$, and $C$, and hence the box containing $p$ cannot touch any pair of opposite faces of the container box. This completes the proof. $\square$

Lemma 3.4. *Consider a set of boxes $S = \{B_1, B_2, \ldots, B_n\}$ that forms a subdivision of a* 3*-dimensional container box $R$. If none of the vertices of any box $B_i$ is in the interior of $R$, then there is a BSP of size at most $2n - 1$ for $S$.*

*Proof.* We proceed by induction on $n$. The base case, $n = 1$, is trivial. Now suppose that Lemma 3.4 holds for every $n'$, $1 \leq n' < n$. If no 0-face of any box $B$ lies in the interior of $R$, then every box is a rod by Lemma 2.2. A 3-rod completely fills the container, and thus $n = 1$ and no BSP cuts are needed. If there is a 2-rod, then there is a free cut by Lemma 2.1: We split $R$ into two subdivisions along the free cut such that each has fewer than $n$ boxes, and induction completes the proof. We may assume, therefore, that all boxes are 1-rods. By Lemma 3.3, all rods in the subdivision have at most two different orientations. We handle the two cases below separately.

If the rods in the subdivision have two different orientations, we show that there is a free cut, and the proof then follows by induction, since each subproblem produced by the free cut is strictly smaller than $n$. Suppose, without loss of generality, that the orientation of every rod is either $\{x_1\}$ or $\{x_2\}$. Observe that all the 1-rods properly intersecting a hyperplane $H$ orthogonal to $x_3$ must have the same orientation, or else two rods with different orientations would intersect on $H$. (This observation is equivalent to applying Lemma 4.1 to the 2-dimensional subdivision on $H$.) Now consider a point $p$ on the common boundary of two 1-rods of different orientations, and let $H$ be a hyperplane passing through $p$ and orthogonal to $x_3$. Any (closed) box of $S$ intersecting $H$ lies on one side of $H$ because there are 1-rods of different orientations on the two sides of $H$. Every box intersecting $H$ has a face along $H$, and therefore $H$ is a free cut (see Figure 4).

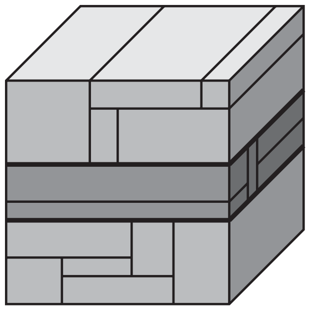

FIG. 4. 1-*rods with two different orientations imply the existence of a free cut.*

If all the 1-rods in the container have the same orientation, then we project them onto the plane orthogonal to their orientation. This gives a 2-dimensional subdivision, which has a 2-dimensional BSP of size at most $2n-1$ by a result of Berman, DasGupta, and Muthukrishnan [5]. Extending each linear cut of the 2-dimensional BSP into a planar cut parallel to the rod orientation, we obtain a BSP for $S_A$ of size at most $2n-1$. $\square$

Thus, combining Lemmas 3.2 and 3.4, we get the main result of this section.

THEOREM 3.5. *A 3-dimensional box subdivision with $n$ boxes and $m$ interior vertices has a BSP of size $O(nm^{1/3}) = O(n^{4/3})$. We can construct such a BSP in time $O(\min(nm^{1/3}, K \log n))$, where $K$ is the size of the final BSP.*

The implementation that achieves the $O(\min(nm^{1/3}, K \log n))$ construction time is quite simple. We maintain all the extents of all the boxes in all containers. It is easy to determine from the extents which boxes are split into two, where the median planes lie, and which faces are free cuts. If we sort the extents initially in all dimensions, we can find medians trivially in linear time and can create sorted extent lists for the child containers in the same time. We spend $O(n \log n)$ time for the initial sorting and $O(K)$ time for each of the $O(\log n)$ steps. Because $K \geq n$, this gives a running time of $O(K \log n)$.

The same implementation also has a running time of $O(nm^{1/3})$—without a logarithmic factor. By Lemma 3.1, the number of box fragments at step $i$ is $O(n2^{i/3})$. The time for step $i$ is therefore $O(n2^{i/3})$ as well. Because the time per step increases geometrically, the last step dominates the running time, giving a bound of $O(nm^{1/3})$.

The size upper bound of $O(n^{4/3})$ in Theorem 3.5 is tight in the worst case: In section 6, we exhibit a 3-dimensional subdivision requiring a BSP of size $\Omega(n^{4/3})$.

**4. The structure of rods in $\mathbb{R}^d$.** In order to extend our 3-dimensional BSP algorithm to higher dimensions, we need two key ingredients: (1) a suitable stopping rule for our round robin algorithm, that is, one that does not result in too much fragmentation, and (2) a linear size BSP construction for the cells obtained when the round robin phase ends. In three dimensions, the correct stopping rule was the elimination of interior vertices. In $d$ dimensions, we show that the *elimination of interior* $(d-3)$*-dimensional faces* is a good stopping rule. The analysis of the total fragmentation caused by this stopping rule as well as the construction of BSPs in terminal cells requires a better understanding of higher-dimensional geometry. In this section, we establish two key facts about the $d$-dimensional subdivisions that are central to our analysis.

LEMMA 4.1. *Consider two boxes $B_1, B_2$ that are rods for their container box $R$ in d-space. Let $D_1, D_2 \subset \{1,2,\dots,d\}$ be the sets of dimensions in which $B_1$ and $B_2$, respectively, are pass-through. If $D_1 \cup D_2 = \{1,2,\dots,d\}$, then $B_1$ and $B_2$ have intersecting interiors.*

*Proof.* Let $\ell_i$ be the extent of dimension $x_i$ *common* to $B_1$ and $B_2$. Since in each dimension at least one of the rods is pass-through, $\ell_i$ is nonempty for every $i$. Thus a full-dimensional box defined by the cross product $\ell_1 \times \cdots \times \ell_d$ lies in the common interior of $B_1$ and $B_2$. □

This lemma implies that, for any two boxes $B_i, B_j$ in a subdivision, there is at least one direction in which neither is a rod. With this basic property, we next classify the set system of all possible orientations of $(d-2)$-rods in a box subdivision. The $(d-2)$-rods are especially important to us because our ultimate goal is to consider subdivisions without any interior $(d-3)$-faces. Recall that a set system is a pair $(X, \mathcal{F})$, where $X$ is a ground set, and $\mathcal{F}$ is a family of subsets of $X$. We consider the set system $(D, \mathcal{F})$, where $D = \{1,2,\dots,d\}$, and $|F| = d-2$ for all $F \in \mathcal{F}$. We are interested in the following two configurations:

- **Cycle configuration:** $\mathcal{F}$ is a *cycle configuration* if $\mathcal{F}$ has at least three sets and there is some $x \in D$ that is not an element of any set of $\mathcal{F}$.
- **Star configuration:** $\mathcal{F}$ is a *star configuration* if $\mathcal{F}$ has at most three sets and they all share a common $(d-3)$ element subset of $D$.

LEMMA 4.2. *Consider a set system $(D, \mathcal{F})$ with $D = \{1,2,\dots,d\}$ and $|F| = d-2$ for every $F \in \mathcal{F}$. If every two sets $F_1, F_2 \in \mathcal{F}$ have $F_1 \cup F_2 \neq D$, then $\mathcal{F}$ is either a star or a cycle configuration.*

*Proof.* Consider the set system $G = (D, E)$, $E = \{D \setminus F : F \in \mathcal{F}\}$. Every $e \in E$ has two elements, and so $G$ is a graph with vertex set $D$ and edge set $E$. The condition that $F_1 \cup F_2 \neq D$ for any $F_1, F_2 \in \mathcal{F}$ is equivalent to saying that any two distinct edges of $E$ are adjacent. $\mathcal{F}$ is a cycle configuration if and only if $G$ is a star graph (all edges are incident to a common vertex) with at least three edges. $\mathcal{F}$ is a star configuration if and only if $G$ is a subgraph of a triangle.

To prove that $\mathcal{F}$ is either a cycle or a star configuration, it suffices to show that every graph with pairwise adjacent edges is either a triangle or a star graph. Elementary graph theory completes the proof: If $|E| < 3$, then $G$ is trivially a star graph, so let us assume that $|E| \geq 3$. If there is a triangle in $G$, then $|E| = 3$, and $E$ forms a triangle because any fourth edge would be nonadjacent to at least one edge of the triangle. Now assume that $G$ is triangle-free and consider two adjacent edges, $e_1 = \{a, b\}$ and $e_2 = \{a, c\}$, $b \neq c$. Since any $e_3 \in E \setminus \{e_1, e_2\}$ is adjacent to both $e_1$ and $e_2$, but $e_3 \neq \{b, c\}$, $e_3$ must be incident to $a$. So every edge is incident to $a$, and $G$ is a star graph. □

This lemma turns out to be a critical technical piece in constructing linear size BSPs in higher dimensions whenever the subdivision is free of $(d-3)$-dimensional faces. A 4-dimensional version of our star-cycle property was observed by Dumitrescu, Mitchell, and Sharir [8].

## 5. An upper bound in $\mathbb{R}^d$.

We begin by showing that if a $d$-dimensional subdivision is free of all interior $(d-3)$-faces, then it admits a linear size BSP. This fact ensures that if we use the stopping rule "recurse until no interior $(d-3)$-dimensional faces remain," the second phase of the algorithm incurs only a linear additional fragmentation.

LEMMA 5.1. *Consider a set of boxes $S = \{B_1, B_2, \ldots, B_n\}$ that forms a subdivision of a $d$-dimensional container box $R$. If none of the $(d-3)$-faces of any box $B_i$ is in the interior of $R$, then there is a BSP of size at most $2n-1$ for $S$.*

*Proof.* Our proof is by induction on $n$. The base case is $n = 1$, for which there is nothing to prove. If any of the boxes of $S$ is a $(d-1)$-rod, then we can make a free cut along a facet of this box by Lemma 2.1; each of the subproblems on either side of the cut contains strictly fewer than $n$ boxes, so our lemma follows by induction. Lemma 2.2 tells us that all boxes of $S$ are $(d-2)$-rods. By Lemmas 4.1 and 4.2, the orientations of these $(d-2)$-rods form either a star or a cycle configuration. We handle these two cases separately.

First, suppose that the orientations of the rods form a cycle configuration. Without loss of generality, let us assume that none of the $(d-2)$-rods is pass-through in direction $x_d$. We will show that there is a free cut orthogonal to the $x_d$-axis, and the rest of the proof then follows by induction. We observe that all the $(d-2)$-rods properly intersecting a hyperplane $H$ orthogonal to $x_d$ must have the same orientation; otherwise Lemma 4.1 is violated for the $(d-1)$-dimensional subdivision on $H$. Now consider a point $p$ on the common boundary of two $(d-2)$-rods of different orientations, and let $H$ be a hyperplane passing through $p$ and orthogonal to $x_d$. Any (closed) box of $S$ intersecting $H$ lies on one side of $H$ because there are $(d-2)$-rods of different orientations on the two sides of $H$. Every box intersecting $H$ has a facet along $H$, and therefore $H$ is a free cut.

Next, suppose that the orientations of the rods form a star configuration. Without loss of generality, assume that all boxes are pass-through in $(d-3)$ dimensions $x_4, x_5, \ldots, x_d$. We project the boxes of $S$ onto the subspace spanned by the remaining three axes, using the map $\pi : (x_1, x_2, \ldots, x_d) \to (x_1, x_2, x_3)$. Any BSP for the projection corresponds to a BSP of equal size for $S$, since the preimage of a plane $h$ in the projection is a hyperplane $H$ in $\mathbb{R}^d$, and $H$ cuts only those $(d-2)$-rods that are the preimages of the 3-dimensional boxes cut by $h$. Observe that the subdivision $\pi(S)$ does not have any interior vertices (interior in $\mathbb{R}^3$), because an interior vertex $v$ corresponds to an interior $(d-3)$-face in $S$, namely, $\pi^{-1}(v)$. By Lemma 3.4, there is a BSP of size at most $2n-1$ for the projected subdivision which, when lifted to $\mathbb{R}^d$, gives a BSP of the same size for $S$. □

We are now ready to describe our BSP algorithm for $d$-dimensional subdivisions. In three dimensions, our round robin cuts were made along planes that evenly partition the set of interior vertices. In $d$ dimensions, we choose hyperplanes that "evenly split" the interior $(d-3)$-dimensional faces. Unfortunately, these median hyperplanes can also introduce new $(d-3)$-dimensional faces by splitting some old ones. For instance, in 4-space, a cutting hyperplane can split many 1-faces (line segments). Our fragmentation lemma (Lemma 5.2) below will bound the total number of box fragments created in the round robin phase. We need to introduce a bit of notation first to discuss the objects used in the algorithm.

Given a $d$-dimensional box $B$, let $f_k(B)$ denote the set of $k$-faces of $B$, where $0 \le k \le d$. We use the notation $f_k(S)$ to refer to the (multi) set of $k$-faces in all the boxes of $S = \{B_1, B_2, \ldots, B_n\}$; that is, $f_k(S)$ contains multiple copies of a face if that face is incident to multiple boxes. Finally, given a container box $R$, we use the notation $f_k(R, S)$ to denote the (fragments of) interior $k$-faces of $f_k(S)$ (faces that intersect the interior of $R$). In our $d$-dimensional BSP scheme, the elements of the set $f_{d-3}(R, S)$ will play the role that vertices played in Algorithm 3-BSP.

Algorithm $d$-BSP.

```
• Input is a $d$-dimensional box subdivision $S = \{B_1, B_2, \ldots, B_n\}$ of a container
  box $R$.
• Initialize $j = 0$, and $\mathcal{C}_0 = \{R\}$.
• While there is a container box $C \in \mathcal{C}_j$ with nonempty $f_{d-3}(C, S)$, do
    1. For each container box $C \in \mathcal{C}_j$ with nonempty $f_{d-3}(C, S)$, do
        (a) Set $\mathcal{D}_1 = \{C\}$ and let $V$ be the multiset of vertices of all faces in
            $f_{d-3}(C, S)$.
        (b) For $i = 1$ to $d$, do
              i. Split every $D \in \mathcal{D}_i$ by the median $x_i$ hyperplane of the multiset
                 $V \cap D$.
             ii. Apply all possible free cuts.
            iii. Let $\mathcal{D}_{i+1}$ be the set of all container boxes resulting from these
                 cuts.
             iv. Remove from $V$ all vertices on the splitting planes used in the
                 first two steps.
    2. Let $\mathcal{C}_{j+1}$ be the set of all container boxes resulting from these cuts, and
       set $j := j + 1$.
• Return $\mathcal{C}_j$.
```

Algorithm $d$-BSP constructs a partition tree $T$ whose leaves correspond to regions that do not contain any fragment of a $(d-3)$-face of the subdivision $S$. By Lemma 5.1, each of these regions can be refined into a BSP of size linear in the number of box fragments contained in it. Thus, it suffices to bound the total complexity of all the box fragments produced by Algorithm $d$-BSP.

Lemma 5.2. *Given a $d$-dimensional box subdivision with $n$ boxes, Algorithm $d$-BSP produces $O(n^{(d+1)/3})$ box fragments.*

*Proof.* Let us define $m = |f_{d-3}(R, S)|$. We call a *round* of the algorithm the work done between increments of $j$. First we show that Algorithm $d$-BSP terminates in $\lceil (\log m)/3 \rceil$ rounds, and then we bound the number of box fragments produced in $\lceil (\log m)/3 \rceil$ rounds.

During a round, every $(d-3)$-face $F$ of a subproblem $(C, S)$ can be cut into at most $2^{d-3}$ fragments—it is cut at most once for each of the $(d-3)$ directions orthogonal to $F$. We focus on the fragments of $F$ that are not contained in any splitting hyperplane of the round. We argue that at least one vertex of every fragment of $F$ is a vertex of $F$ that does not lie on any of the splitting hyperplanes of the round. A fragment is itself a $(d-3)$-face, and so it is the cross product of three fixed coordinates and $(d-3)$ nontrivial intervals. Each nontrivial interval contains at least one of the two endpoints of the corresponding original interval of $F$ (because there is at most one cut orthogonal to the interval's direction). The cross product of the three fixed coordinates and the $(d-3)$ original interval endpoints is a vertex of $F$ but does not lie on any splitting hyperplane of the round.

The container box $C$ is divided into subboxes during the round, each containing at most $2^{d-3} \cdot |f_{d-3}(C,S)|/2^d = |f_{d-3}(C,S)|/8$ vertices of $V$. As noted, each face fragment produced by the round is incident to a vertex from $V$, and so $|f_{d-3}(C',S)| \le |f_{d-3}(C,S)|/8$ for each subcontainer $C'$ produced. By induction, the number of interior $(d-3)$-faces at the beginning of round $j$ is at most $m/8^j$. Therefore, after $\lceil \log_8 m \rceil = \lceil (\log m)/3 \rceil$ rounds, no $(d-3)$-face intersects the interior of any subproblem's container box, and the algorithm terminates.

Now consider a $(d-2)$-dimensional face of a box $B$. During a round of the algorithm, it can be cut recursively in $(d-2)$ steps. Thus, the total number of fragments of $(d-2)$-faces of $f_{d-2}(R,S)$ at round $j$ is $O(n2^{(d-2)j})$.

Finally, in each round $j$ when a box fragment $B$ in some subproblem is split, the container box for the subproblem must have a fragment of a $(d-2)$-face of $B$ in its interior. This is because only a $d$-rod or a $(d-1)$-rod can have all its $(d-2)$-faces on the boundary of the container by Lemma 2.2. But a $d$-rod is never split and step 1(b)ii eliminates all $(d-1)$-rods. This implies that $O(n2^{(d-2)j})$ box fragments can be further split in round $j$. The algorithm terminates in $\lceil (\log m)/3 \rceil$ rounds, and so the number of box fragments produced by the algorithm is

$$O\left(n \cdot \sum_{j \le \lceil \log m/3 \rceil} 2^{(d-2)j}\right) = O\left(n \cdot 2^{(d-2)(\log m)/3}\right)$$
$$= O\left(nm^{(d-2)/3}\right) = O\left(n^{(d+1)/3}\right). \qquad \square$$

Since $m$ is at most $2^3\binom{d}{3}\cdot n$, our bound in terms of both $n$ and $d$ is $O(d^{d-2}\cdot n^{(d+1)/3})$.

Finally, this result, combined with Lemma 5.1 and standard implementation techniques similar to those used for Algorithm 3-BSP, yields our main theorem.

THEOREM 5.3. *A box subdivision of $n$ boxes in $d$-space, $d \ge 2$, has a BSP of size $O(n^{(d+1)/3})$. The BSP can be constructed in time $O(\min(n^{(d+1)/3}, K \log n))$, where $K$ is the size of the BSP.*

A simple but practical corollary of this theorem is the following: Any collection of $n$ disjoint boxes in $d$-space whose complement space can be tiled with $m$ additional boxes admits a BSP of size $O((n+m)^{(d+1)/3})$.

If we perform Algorithm $d$-BSP with $(d-2)$-faces instead of $(d-3)$-faces (i.e., replacing $f_{d-3}(C,S)$ by $f_{d-2}(C,S)$ everywhere in the algorithm description), then we obtain a BSP for general nonoverlapping boxes in $d$-space: in the resulting partition, no $(d-2)$-face of any input box intersects the interior of any container box, so every such container can be refined to a proper BSP by free cuts. Repeating Lemma 5.2 using $(d-2)$-faces instead of $(d-3)$-faces implies that the modified algorithm terminates in $\lceil (\log m)/2 \rceil$ rounds, where $m = |f_{d-2}(R,S)| \le 2^2\binom{d}{2} \cdot n$. By analogous computation, the total number of box fragments is $O\left(n \cdot 2^{(d-2)(\log m)/2}\right) = O\left(nm^{(d-2)/2}\right) = O\left(n^{d/2}\right)$. This is the best currently known upper bound on the size of a BSP for $n$ nonoverlapping general boxes in $\mathbb{R}^d$. We can summarize this argument in the following theorem.

THEOREM 5.4. *Every set of $n$ nonoverlapping boxes in $d$-space, $d \ge 2$, has a BSP of size $O(n^{d/2})$.*

One interpretation of our results suggests that for a set $S$ of general axis-aligned boxes in $\mathbb{R}^d$, a round robin BSP for their $(d-2)$-dimensional faces is also a BSP for $S$; while for a $d$-dimensional box subdivision $S$, a round robin BSP for only the $(d-3)$-dimensional faces gives a BSP for the input $S$.

**6. Lower bounds.** Paterson and Yao gave a configuration of $3n$ (non–space-filling) axis-aligned rods such that any BSP for the configuration cuts the rods into $\Omega(n^{3/2})$ subcells [15]. (According to Eppstein [9], "Paterson and Yao credit this application of the shape to a personal communication by W. P. Thurston, but the shape itself has been seen before, e.g., in Alan Holden's book *Shapes, Space, and Symmetry* (Columbia Univ. Press 1971), p. 161.") We describe a variant of the Paterson–Yao construction in some detail, because it is the basis of our lower bound for box subdivisions.

The rods of the Paterson–Yao construction belong to three families, each parallel to one of the coordinate axes, and form an interlocking grid. See Figure 5. Without loss of generality, assume that $n = \ell^2$ for some integer $\ell$. The $x$-, $y$-, and $z$-parallel families consist of boxes indexed by $1 \le i, j, k \le \ell$:

$$R_1 = \{r_1(j,k) = [0, 2\ell] \times [2j, 2j+1] \times [2k, 2k+1] : j, k = 0, 1, \dots, \ell - 1\},$$
$$R_2 = \{r_2(i,k) = [2i, 2i+1] \times [0, 2\ell] \times [2k+1, 2k+2] : i, k = 0, 1, \dots, \ell - 1\},$$
$$R_3 = \{r_3(i,j) = [2i+1, 2i+2] \times [2j+1, 2j+2] \times [0, 2\ell] : i, j = 0, 1, \dots, \ell - 1\}.$$

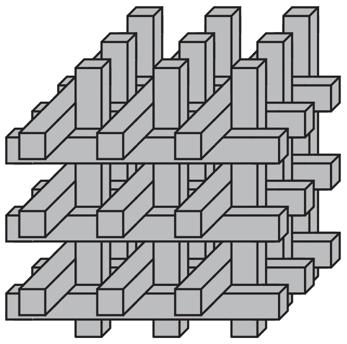

FIG. 5. *The Paterson–Yao lower bound construction, with the rods slightly separated and lengthened to make them easier to see.*

It is straightforward to observe that the rods in each family are disjoint. Furthermore, rods in different families are disjoint, because for each pair of families there is one of the three dimensions ($x$, $y$, or $z$) in which the two families lie in disjoint ranges: for one family, any rod's coordinates lie in the range $[2A, 2A+1]$, for some integer $A$; for the other family, any rod's coordinates lie in $[2B+1, 2B+2]$, for integral $B$. Note also that each grid point $(2i+1, 2j+1, 2k+1)$, for $1 \le i, j, k \le \ell$, is incident to one rod from each of the three families.

For every $i, j, k = 0, 1, \dots, \ell - 1$, consider the box

$$[2i, 2i+2] \times [2j, 2j+2] \times [2k, 2k+2].$$

We call these boxes *junctions*. The junctions are interior-disjoint boxes, and each must be cut by a BSP plane passing through its center, since the BSP must separate the three rods in the neighborhood of the center $(2i+1, 2j+1, 2k+1)$. The first plane that passes through the junction must cut at least one of the three rods incident to the center. Since all the junctions are disjoint, the total number of rod cuts is at least $\ell^3 = n^{3/2}$.

The Paterson–Yao construction is *opaque*, in the sense that every axis-parallel line passing through the container cube

$$[0, 2\ell] \times [0, 2\ell] \times [0, 2\ell]$$

intersects the closure of at least one rod. However, the configuration of rods is not a subdivision: the rods do not fill space. This is easy to prove by observing that the total volume of the container cube is $8\ell^3$, and the total volume of each rod inside is $2\ell$. There are $3\ell^2$ rods, for a total rod volume inside the container cube of $6\ell^3$, which is less than $8\ell^3$. The empty space is distributed in $2\ell^3$ unit cubes. In particular, for each junction for $i, j, k$, the unit cubes

$$[2i, 2i + 1] \times [2j + 1, 2j + 2] \times [2k, 2k + 1]$$

and

$$[2i + 1, 2i + 2] \times [2j, 2j + 1] \times [2k + 1, 2k + 2]$$

are empty. See Figure 6.

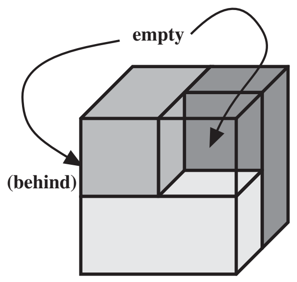

FIG. 6. *A unit cube centered on a grid point in the Paterson–Yao construction.*

**6.1. Lower bound construction for 3-dimensional subdivisions.** Converting the Paterson–Yao configuration into a subdivision requires adding $\Theta(\ell^3)$ new cells—two unit cubes for each junction. Thus the $\Omega(\ell^3)$ lower bound on the BSP complexity becomes trivial—it is linear in the input size. However, with a little more work, we can extend the construction to give a nontrivial lower bound.

THEOREM 6.1. *There is a 3-dimensional subdivision of space into $n$ axis-aligned boxes such that any axis-aligned BSP for the subdivision cuts the boxes into $\Omega(n^{4/3})$ subcells.*

*Proof.* We begin with a Paterson–Yao construction consisting of $3\ell^2$ rods, and then extend it to a subdivision of the container cube $[0, 2\ell]^3$ by adding the $2\ell^3$ unit cubes needed to fill in the empty space between the rods. We then subdivide each rod longitudinally into $\ell$ parallel subrods.

As in the original Paterson–Yao argument, each of the $\ell^3$ junctions must be cut by at least one BSP plane, since the BSP must separate the cells incident to $(2i + 1, 2j + 1, 2k + 1)$. The first plane that cuts a junction must completely cross one of the original rods, and hence it cuts at least $\ell$ subrods. The total number of rod cuts is at least $\ell^3 \times \ell = \ell^4$. The total number of cells in our subdivision is $n = 3\ell^2 \times \ell + 2\ell^3 = 5\ell^3$, and hence the number of subcells produced by the BSP is $\Omega(n^{4/3})$. ☐

**6.2. Constructions for multidimensional subdivisions.** Our multidimensional construction is similar in spirit to the previous construction. This construction is recursive—we use the lower bound construction in $(d-1)$-space to build the subdivision in $d$ dimensions. We begin with an informal description, then formally describe the construction in four dimensions. The construction in $d$ dimensions is a straightforward extension of this construction.

We partition the container box in a grid-like fashion into disjoint regions that we call *junctions* and give a lower bound for the BSP complexity for the fragments of objects within each region. Then we bound the complexity of a BSP for all objects by the sum of complexities over all the regions.

We have $(d-1)$ families of congruent $(d-2)$-rods, whose orientations form a cycle configuration, and a family of 1-rods whose orientation is the complement of the orientations of the $(d-2)$-rods. The rods ensure our complexity bound in each region. (Intuitively, it is efficient to use rods of larger orientations, because a $k$-rod of the container box is a $k$-rod in each junction it intersects.) On the other hand, rods of such orientations cannot fill the container box, and therefore we need to add a number of filler boxes to obtain a box subdivision.

In order to balance the number of rods and the number of filler boxes, we allocate the rods in *bundles* so that the union of a bundle of rods is again a rod with the same orientation. The $(d-2)$-rods in a bundle are all congruent; the $\mathbb{R}^{d-1}$-projection of a bundle of 1-rods, however, is the worst-case box subdivision we obtain in $\mathbb{R}^{d-1}$.

THEOREM 6.2. *There is a* 4*-dimensional box subdivision with n boxes such that the size of any axis-aligned BSP is* $\Omega(n^{13/9})$.

*Proof.* First, we describe an auxiliary construction of $\Theta(\ell^{9/2})$ boxes such that all vertices of the boxes lie on a $2\ell \times 2\ell \times 2\ell \times 3\ell^{3/2}$ grid. The rods of the auxiliary subdivision correspond to the bundles of rods in the final subdivision.

We have $\ell^3$ long 1-rods that are pass-through in $x_4$:

$$R_1 = \{r_1(i,j,k) = [2i, 2i+1] \times [2j, 2j+1] \times [2k, 2k+1] \times [0, 3\ell^{3/2}] : \\ i,j,k = 0, \ldots, \ell-1\}.$$

We also have three families of boxes, each containing $\ell^{5/2}$ 2-rods with orientations $\{x_1, x_2\}$, $\{x_1, x_3\}$, and $\{x_2, x_3\}$, respectively:

$$R_{1,2} = \{r_{1,2}(k,t) = [0, 2\ell] \times [0, 2\ell] \times [2k+1, 2k+2] \times [3t, 3t+1] : \\ k = 0, 1, \ldots, \ell-1;\ t = 0, \ldots, \ell^{3/2}-1\},$$

$$R_{1,3} = \{r_{1,3}(j,t) = [0, 2\ell] \times [2j+1, 2j+2] \times [0, 2\ell] \times [3t+1, 3t+2] : \\ j = 0, \ldots, \ell-1;\ t = 0, \ldots, \ell^{3/2}-1\},$$

$$R_{2,3} = \{r_{2,3}(i,t) = [2i+1, 2i+2] \times [0, 2\ell] \times [0, 2\ell] \times [3t+2, 3t+3] : \\ i = 0, \ldots, \ell-1;\ t = 0, \ldots, \ell^{3/2}-1\}.$$

Figure 7 illustrates the intersection of our auxiliary construction with three (3-dimensional) hyperplanes orthogonal to $x_4$. The intersection of the 1-rods in $R_1$ with every hyperplane consists of $\ell^3$ unit cubes in a grid. The 2-rods of three distinct orientations appear in three different slices. In each slice, congruent 2-rods fill $\ell$ slots between the grid of unit cubes.

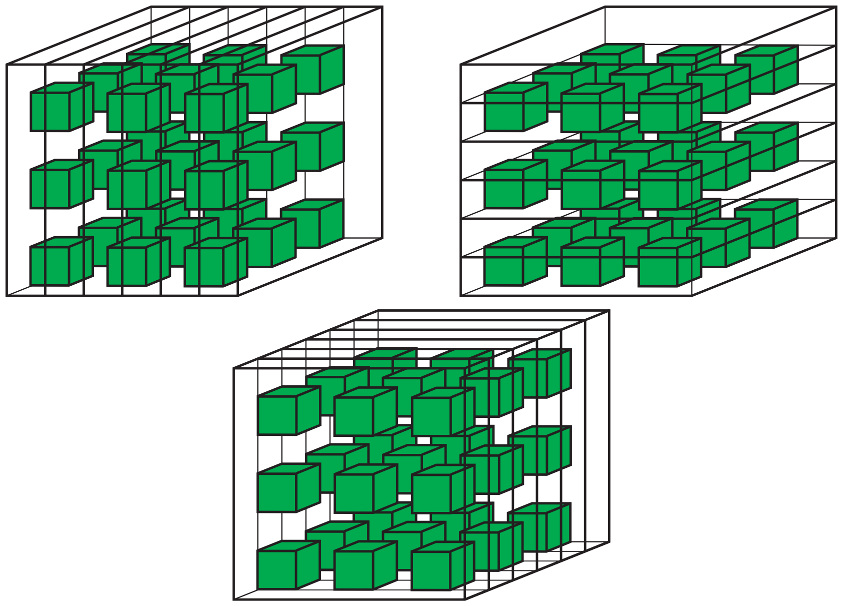

FIG. 7. *Three different* 3*-dimensional slices of the subdivision along three hyperplanes orthogonal to* $x_4$.

Since all the rods have pairwise disjoint interiors, we can obtain an orthogonal subdivision of the container box $R = [0, 2\ell] \times [0, 2\ell] \times [0, 2\ell] \times [0, 3\ell^{3/2}]$ by filling up the space between the rods with $9\ell^{9/2}$ unit cubes. This completes the description of our auxiliary construction of $\Theta(\ell^{9/2})$ boxes. We obtain a subdivision $S$ of $n = \Theta(\ell^{9/2})$ boxes in the following way: Partition each 2-rod into $\ell^2$ congruent 2-rods with the same orientation, and replace each 1-rod by $\ell^{3/2}$ pairwise disjoint 1-rods whose projection to the $(x_2, x_3, x_4)$ hyperplane is the worst-case construction for a subdivision in $\mathbb{R}^3$.

Consider the $\ell^{9/2}$ boxes $\Pi(i, j, k, t) = [2i, 2i+2] \times [2j, 2j+2] \times [2k, 2k+2] \times [3t, 3t+3]$, where $i, j, k = 0, 1, \ldots, \ell - 1$ and $t = 0, 1, \ldots, \ell^{3/2} - 1$. These are the *junction* regions. Note that the junctions have pairwise disjoint interiors. We show that any axis-aligned BSP for $S$ dissects the rods of $S$ such that pieces of rods have at least $\ell^2$ vertices in the interior of every junction. This implies that the total number of pieces is $\Omega(\ell^{9/2} \cdot \ell^2) = \Omega(\ell^{13/2}) = \Omega(n^{13/9})$.

First, suppose that each of the $\ell^{3/2}$ 1-rods in $r_1(i, j, k) \in R_1$ is cut by some hyperplane $x_4 = c$ for $c \in (3t, 3t + 3)$. (Not all 1-rods may be cut by the same hyperplane, though.) Consider an intersection of the bundle of 1-rods with a hyperplane $x_4 = c_0$ such that each 1-rod has a vertex in the interior of $\Pi(i, j, k, t)$ below $x_4 = c_0$. A BSP for $S$, restricted to the intersection of the bundle with $x_4 = c_0$, must be a BSP for the 3-dimensional subdivision to which the bundle projects. Hence the intersection BSP must have $\Omega((\ell^{3/2})^{4/3}) = \Omega(\ell^2)$ vertices, by the previous lower bound. Each vertex corresponds to a vertex in the interior of $\Pi(i, j, k, t)$—in fact, it is connected to its corresponding vertex by an edge of the BSP parallel to the $x_4$-axis.

Otherwise, let $r$ be a rod in $R_1(i, j, k)$ that is not cut by any hyperplane $x_4 = c$, for $c \in (3t, 3t + 3)$. Let $e$ be a segment in the interior of $r$ such that $e$ is pass-through in $x_4$ within $\Pi(i, j, k, t)$ and does not lie on any hyperplane of the BSP. Since $e$ is not cut by the BSP, one subproblem contains $e$ all through the partitioning procedure. Notice that the container box for $e$ cannot be separated from all the other original boxes by hyperplanes orthogonal to only one axis. Let $H_1$ and $H_2$ be hyperplanes orthogonal to, say, $x_1$ and $x_2$, on the boundary of the final container box of $e$. The 2-face $F = H_1 \cap H_2$ is pass-through in $x_3$ and $x_4$ and lies in the interior of $\Pi(i, j, k, t)$. Therefore $F$ has a common vertex with all $\ell^2$ 2-rods in $r_{1,2}(k, t)$ in the interior of $\Pi(i, j, k, t)$. ◻

Generalizing this recursive construction, we obtain a recursive formula for the exponent of the lower bound $\beta(d)$ we can reach for a box subdivision in $\mathbb{R}^d$.

THEOREM 6.3. *There is a $d$-dimensional box subdivision $S$ with $n$ boxes such that the size of any axis-aligned BSP for $S$ is $\Omega(n^{\beta(d)})$, where $\beta(3) = 4/3$, $\beta(4) = 13/9$, and $\beta(d)$ converges to $(1 + \sqrt{5})/2$ as $d \to \infty$.*

*Proof.* In $\mathbb{R}^d$, our auxiliary construction consists of $\ell^{d-1}$ 1-rods that are pass-through in $x_d$, and $(d-1)$ families of $\ell^{1+\alpha(d)}$ $(d-2)$-rods such that each slice $x_d = c$ intersects $\ell$ $(d-2)$-rods and there are $\ell^{\alpha(d)}$ levels in the $x_d$ extent ($\alpha(d)$ is a parameter to be specified later). We need $\Theta(\ell^{(d-1)+\alpha(d)})$ unit cubes to convert this configuration into a subdivision.

We balance the number of filler unit cubes and rods by replacing each auxiliary $(d-2)$-rod with a bundle of $\ell^{d-2}$ congruent $(d-2)$-rods and each auxiliary 1-rod by a bundle of $\ell^{\alpha(d)}$ 1-rods. We arrange the 1-rods in each bundle such that their $(d-1)$-dimensional projection gives the $\mathbb{R}^{d-1}$ subdivision for which any BSP has size $\Omega((\ell^{\alpha(d)})^{\beta(d-1)})$.

We define $\ell^{(d-1)+\alpha(d)}$ junctions, arranged in a grid. Each junction contains either $\Omega(\ell^{d-2})$ vertices on fragments of $(d-2)$-rods or $\Omega((\ell^{\alpha(d)})^{\beta(d-1)})$ vertices on fragments of 1-rods. To achieve our bound, we set $\alpha(d) = (d-2)/\beta(d-1)$, implying that any BSP for our subdivision has at least $\ell^{(d-1)+\alpha(d)} \cdot \ell^{d-2} = \ell^{2d-3+\alpha(d)}$ vertices. That gives a lower bound of

$$\Omega\left(n^{\frac{2d-3+\alpha(d)}{d-1+\alpha(d)}}\right) = \Omega\left(n^{\frac{2d-3+(d-2)/\beta(d-1)}{d-1+(d-2)/\beta(d-1)}}\right).$$

The exponent in this bound is

$$\beta(d) = \frac{2d-3+(d-2)/\beta(d-1)}{d-1+(d-2)/\beta(d-1)} = 1 + \frac{d-2}{d-1+(d-2)/\beta(d-1)}.$$

The first values of this sequence are $\beta(4) = 13/9 = 1.444$, $\beta(5) = 118/79 = 1.494$, $\beta(6) = 689/453 = 1.521$, and $\beta(7) = 9844/6399 = 1.538$. The sequence converges to $\lim_{d\to\infty} \beta(d) = (1 + \sqrt{5})/2 = 1.618$.

Note that the $d$-dimensional lower bound subsumes the lower bound for three dimensions. If $d = 3$, then $\beta(d-1) = \beta(2) = 1$, and $\alpha(3) = (3-2)/\beta(2) = 1$. The lower bound we obtain is

$$\Omega\left(n^{\frac{2\cdot 3-3+\alpha(3)}{3-1+\alpha(3)}}\right) = \Omega(n^{4/3}),$$

matching Theorem 6.1. ◻

## 7. Concluding remarks.

The BSP is a popular space decomposition method in computational geometry, computer graphics, and other fields dealing with geometric shapes. However, its worst-case complexity remains poorly understood in dimensions three and higher. Even for the BSP of $n$ orthogonal boxes in $d$ dimensions, the best upper bound known is $O(n^{d/2})$, while no lower bound better than $\Omega(n^2)$ is known.

In an attempt to understand the complexity of higher-dimensional BSPs, we considered a natural special case: orthogonal subdivisions. We showed that every

$d$-dimensional subdivision with $n$ boxes admits a BSP of size $O(n^{(d+1)/3})$. We also exhibited subdivisions in $d$ dimensions for which every axis-aligned BSP must have size $\Omega(n^{\beta(d)})$, where $\beta(d)$ converges to $(1+\sqrt{5})/2$ as $d \to \infty$. Our result shows that if the objects do not fracture the complement space too badly, then their BSP size can be significantly smaller than the current worst-case bounds indicate.

Clearly, the most interesting open problem suggested by this paper is to close the gap between the upper and lower bounds. The absence of superquadratic lower bounds is intriguing. Can it really be the case that, in any dimension $d$, a set of $n$ boxes (forming a subdivision, or not) admits a quadratic size BSP? If not, then what is the true complexity of the BSP of $n$ $d$-dimensional boxes? Is this bound necessarily worse than that for $n$ boxes forming a subdivision in higher dimensions?

# A SHORTEST PATH ALGORITHM FOR REAL-WEIGHTED UNDIRECTED GRAPHS[*]

SETH PETTIE[†] AND VIJAYA RAMACHANDRAN[‡]

**Abstract.** We present a new scheme for computing shortest paths on real-weighted undirected graphs in the fundamental *comparison-addition model*. In an efficient preprocessing phase our algorithm creates a linear-size structure that facilitates single-source shortest path computations in $O(m \log \alpha)$ time, where $\alpha = \alpha(m, n)$ is the very slowly growing inverse-Ackermann function, $m$ the number of edges, and $n$ the number of vertices. As special cases our algorithm implies new bounds on both the all-pairs and single-source shortest paths problems. We solve the all-pairs problem in $O(mn \log \alpha(m, n))$ time and, if the ratio between the maximum and minimum edge lengths is bounded by $n^{(\log n)^{O(1)}}$, we can solve the single-source problem in $O(m + n \log \log n)$ time. Both these results are theoretical improvements over Dijkstra's algorithm, which was the previous best for real weighted undirected graphs. Our algorithm takes the hierarchy-based approach invented by Thorup.

## 1. Introduction.

The problem of computing shortest paths is indisputably one of the most well-studied problems in computer science. It is thoroughly surprising that in the setting of *real*-weighted graphs, many basic shortest path problems have seen little or no progress since the early work by Dijkstra, Bellman and Ford, Floyd and Warshall, and others [CLRS01]. For instance, no algorithm for computing single-source shortest paths (SSSPs) in arbitrarily weighted graphs has yet to improve the Bellman–Ford $O(mn)$ time bound, where $m$ and $n$ are the number of edges and vertices, respectively. The fastest uniform all-pairs shortest path (APSP) algorithm for dense graphs [Z04, F76] requires time $O(n^3\sqrt{\log \log n}/\log n)$, which is just a slight improvement over the $O(n^3)$ bound of the Floyd–Warshall algorithm. Similarly, Dijkstra's $O(m + n \log n)$ time algorithm [Dij59, FT87] remains the best for computing SSSPs on nonnegatively weighted graphs, and until the recent algorithms of Pettie [Pet04, Pet02b, Pet03], Dijkstra's algorithm was also the best for computing APSPs on sparse graphs [Dij59, J77, FT87].

In order to improve these bounds most shortest path algorithms depend on a restricted type of input. There are algorithms for geometric inputs (see Mitchell's survey [Mit00]), planar graphs [F91, HKRS97, FR01], and graphs with randomly chosen edge weights [Spi73, FG85, MT87, KKP93, KS98, M01, G01, Hag04]. In recent years there

has also been a focus on computing approximate shortest paths—see Zwick's recent survey [Z01]. One common assumption is that the graph is *integer*-weighted, though structurally unrestricted, and that the machine model is able to manipulate the integer representation of weights. Shortest path algorithms based on scaling [G85b, GT89, G95] and fast matrix multiplication [Sei95, GM97, AGM97, Tak98, SZ99, Z02] have running times that depend on the magnitude of the integer edge weights, and therefore yield improved algorithms only for sufficiently small edge weights. In the case of the matrix multiplication–based algorithms the critical threshold is rather low: even edge weights sublinear in $n$ can be too large. Dijkstra's algorithm can be sped up in the integer-weight model by using an integer priority queue.[1] The best bounds on Dijkstra's algorithm to date are $O(m\sqrt{\log\log n})$ (expected) [HT02] and $O(m + n\log\log n)$ [Tho03]. Both of these algorithms use multiplication, a non-$AC^0$ operation; see [Tho03] for bounds in the $AC^0$ model. Thorup [Tho99] considered the restricted case of integer-weighted undirected graphs and showed that on an $AC^0$ random access machine (RAM), shortest paths could be computed in linear time. Thorup invented what we call in this paper the *hierarchy-based* approach to shortest paths.

The techniques developed for integer-weighted graphs (scaling, matrix multiplication, integer sorting, and Thorup's hierarchy-based approach) *seem* to depend crucially on the graph being integer-weighted. This state of affairs is not unique to the shortest path problem. In the weighted matching [G85b, GT89, GT91] and maximum flow problems [GR98], for instance, the best algorithms for real- and integer-weighted graphs have running times differing by a *polynomial* factor. For the shortest path problem on positively weighted graphs the integer/real gap is only logarithmic. It is of great interest whether an integer-based approach is inherently so, or whether it can yield a faster algorithm for general, real-weighted inputs. In this paper we generalize Thorup's hierarchy-based approach to the comparison-addition model (see section 2.1) and, as a corollary, to real-weighted input graphs. For the undirected APSP problem we nearly eliminate the existing integer/real gap, reducing it from $\log n$ to $\log\alpha(m,n)$, where $\alpha$ is the incomprehensibly slowly growing inverse-Ackermann function. Before stating our results in detail, we first give an overview of the hierarchy-based approach and discuss the recent hierarchy-based shortest path algorithms [Tho99, Hag00, Pet04, Pet02b].

Hierarchy-based algorithms should be thought of as preprocessing schemes for answering SSSP queries in nonnegatively weighted graphs. The idea is to compute a small non–source-specific structure that encodes useful information about all the shortest paths in the graph. We measure the running time of a hierarchy-based algorithm with two quantities: $\mathcal{P}$, the worst case preprocessing cost on the given graph, and $\mathcal{M}$, the marginal cost of one SSSP computation after preprocessing. Therefore, solving the $s$-sources shortest path problem requires $s\cdot\mathcal{M}+\mathcal{P}$ time. If $s = n$, that is, if we are solving APSP, then for all known hierarchy algorithms the $\mathcal{P}$ term becomes negligible. However, $\mathcal{P}$ may be dominant (in either the asymptotic or real-world sense) for smaller values of $s$. In Thorup's original algorithm [Tho99], $\mathcal{P}$ and $\mathcal{M}$ are both $O(m)$; recall that his algorithm works on integer-weighted undirected graphs. Hagerup [Hag00] adapted Thorup's algorithm to integer-weighted *directed* graphs, incurring a slight loss of efficiency in the process. In [Hag00], $\mathcal{P} = O(\min\{m\log\log C, m\log n\})$,[2]

[1]It can also be sped up using an integer sorting algorithm in conjunction with Thorup's reduction [Tho00] from priority queues to sorting.

[2]Hagerup actually proved $\mathcal{P} = O(\min\{m\log\log C, mn\})$; see [Pet04] for the $O(m\log n)$ bound.

where $C$ is the maximum edge weight and $\mathcal{M} = O(m + n \log\log n)$. After the initial publication of our results [PR02a], Pettie [Pet04, Pet02b] gave an adaptation of the hierarchy-based approach to *real*-weighted directed graphs. The main result of [Pet04] is an APSP algorithm running in time $O(mn + n^2 \log\log n)$, which improved upon the $O(mn + n^2 \log n)$ bound derived from multiple runs of Dijkstra's algorithm [Dij59, J77, FT87]. The result of [Pet04] is stated in terms of the APSP problem because its preprocessing cost $\mathcal{P}$ is $O(mn)$, making it efficient only if $s$ is very close to $n$. In [Pet02b] (see also [Pet03]) the *nonuniform* complexity of APSP is considered; the main result of [Pet02b] is an algorithm performing $O(mn \log \alpha(m, n))$ comparison and addition operations. This bound is essentially optimal when $m = O(n)$ due to the trivial $\Omega(n^2)$ lower bound on APSP.

In this paper we give new bounds on computing *undirected* shortest paths in real-weighted graphs. For our algorithm, the preprocessing cost $\mathcal{P}$ is $O(\textsc{mst}(m, n) + \min\{n \log n, n \log\log r\})$, where $\textsc{mst}(m, n)$ is the complexity of the minimum spanning tree problem and $r$ is the ratio of the maximum-to-minimum edge weight. This bound on $\mathcal{P}$ is never worse than $O(m + n \log n)$, though if $r$ is not excessively large, say less than $n^{(\log n)^{O(1)}}$, $\mathcal{P}$ is $O(m + n \log\log n)$. We show that the marginal cost $\mathcal{M}$ of our algorithm is asymptotically equivalent to $\textsc{split-findmin}(m, n)$, which is the decision-tree complexity of a certain data structuring problem of the same name. It was known that $\textsc{split-findmin}(m, n) = O(m\alpha(m, n))$ [G85a]; we improve this bound to $O(m \log \alpha(m, n))$. Therefore, the marginal cost of our algorithm is essentially (but perhaps not precisely) linear. Theorem 1.1 gives our general result, and Corollaries 1.2 and 1.3 relate it to the canonical APSP and SSSP problems, respectively.

THEOREM 1.1. *Let $\mathcal{P} = \textsc{mst}(m, n) + \min\{n \log n, n \log\log r\}$, where $m$ and $n$ are the number of edges and vertices in a given undirected graph, $r$ bounds the ratio of any two edge lengths, and $\textsc{mst}(m, n)$ is the cost of computing the graph's minimum spanning tree. In $O(\mathcal{P})$ time an $O(n)$-space structure can be built that allows the computation of SSSPs in $O(\textsc{split-findmin}(m, n))$ time, where $\textsc{split-findmin}(m, n) = O(m \log \alpha(m, n))$ represents the decision-tree complexity of the split-findmin problem and $\alpha$ is the inverse-Ackermann function.*

COROLLARY 1.2. *The undirected APSP problem can be solved on a real-weighted graph in $O(n \cdot \textsc{split-findmin}(m, n)) = O(mn \log \alpha(m, n))$ time.*

COROLLARY 1.3. *The undirected SSSP problem can be solved on a real-weighted graph in $O(\textsc{split-findmin}(m, n) + \textsc{mst}(m, n) + \min\{n \log n, n \log\log r\}) = O(m\alpha(m, n) + \min\{n \log n, n \log\log r\})$ time.*

The running time of our SSSP algorithm (Corollary 1.3) is rather unusual. It consists of three terms, where the first two are unknown (but bounded by $O(m\alpha(m, n))$) and the third depends on a nonstandard parameter: the maximum ratio of any two edge lengths.[3] A natural question is whether our SSSP algorithm can be substantially improved. In section 6 we formally define the class of "hierarchy-based" SSSP algorithms and show that any comparison-based undirected SSSP algorithm in this class must take time $\Omega(m + \min\{n \log n, n \log\log r\})$. This implies that our SSSP algorithm is optimal for this class, up to an inverse-Ackermann factor, and that no hierarchy-based SSSP algorithm can improve on Dijkstra's algorithm, for $r$ unbounded.

Pettie, Ramachandran, and Sridhar [PRS02] implemented a simplified version of our algorithm. The observed marginal cost of the [PRS02] implementation is nearly linear, which is in line with our asymptotic analysis. Although it is a little slower

[3]Dinic's implementation [Din78, Din03] of Dijkstra's algorithm also depends on $r$, in both time and space consumption.

than Dijkstra's algorithm in solving SSSP, it is faster in solving the $s$-sources shortest path problem, in some cases for $s$ as small as 3. In many practical situations it is the $s$-sources problem, not SSSP, that needs to be solved. For instance, if the graph represents a physical network, such as a network of roads or computers, it is unlikely to change very often. Therefore, in these situations a nearly linear preprocessing cost is a small price to pay for more efficient shortest path computations.

**1.1. An overview.** In section 2 we define the SSSP and APSP problems and review the comparison-addition model and Dijkstra's algorithm [Dij59]. In section 3 we generalize the hierarchy approach to real-weighted graphs and give a simple proof of its correctness. In section 4 we propose two implementations of the general hierarchy-based algorithm, one for proving the asymptotic bounds of Theorem 1.1 and one that is simpler and uses more standard data structures. The running times of our implementations depend heavily on having a *well-balanced* hierarchy. In section 5 we give an efficient method for constructing balanced hierarchies; it is based on a hierarchical clustering of the graph's minimum spanning tree. In section 6 we prove a lower bound on the class of hierarchy-based undirected SSSP algorithms. In section 7 we discuss avenues for further research.

## 2. Preliminaries.

The input is a weighted, undirected graph $G = (V, E, \ell)$, where $V = V(G)$ and $E = E(G)$ are the sets of $n$ vertices and $m$ edges, respectively, and $\ell : E \to \mathbb{R}$ assigns a real length to each edge. The *distance* from vertex $u$ to vertex $v$, denoted $d(u, v)$, is the length of the minimum length path from $u$ to $v$, or $\infty$ if there is no such path from $u$ to $v$, or $-\infty$ if there is no such path of minimum length. The APSP problem is to compute $d(u, v)$, for $(u, v) \in V \times V$, and the SSSP problem is to compute $d(u, v)$ for some specified *source* $u$ and all $v \in V$.

If, in an undirected graph, some connected component contains an edge of negative length, say $e$, then the distance between two vertices $u$ and $v$ in that component is $-\infty$: one can always construct a path of arbitrarily small length by concatenating a path from $u$ to $e$, followed by the repetition of $e$ a sufficient number of times, followed by a path from $e$ to $v$. Without loss of generality we will assume that $\ell : E \to \mathbb{R}^+$ assigns only positive edge lengths. A slightly restricted problem (which forbids the types of paths described above) is the shortest *simple* path problem. This problem is NP-hard as it generalizes the Hamiltonian path problem. However, Edmonds showed that when there is no negative weight simple cycle, the problem is solvable in polynomial time by a reduction to weighted matching—see [AMO93, p. 496] and [G85a].

### 2.1. The comparison-addition model.

We use the term *comparison-addition model* to mean any uniform model in which real numbers are subject to only comparison and addition operations. The term *comparison-addition complexity* refers to the number of comparison and addition operations, ignoring other computational costs. In the comparison-addition model we leave unspecified the machine model used for all data structuring tasks. Our results as stated hold when that machine model is a RAM. If instead we assume a pointer machine [Tar79], our algorithms slow down by at most an inverse-Ackermann factor.[4]

The comparison-addition model has some aesthetic appeal because it is the simplest model appropriate to computing shortest paths and many other network opti-

[4]The only structure we use whose complexity changes between the RAM and pointer machine models is the split-findmin structure. On a pointer machine there are matching upper and lower bounds of $\Theta(m\alpha)$ [G85a, LaP96], whereas on the RAM the complexity is somewhere between $\Omega(m)$ and $O(m \log \alpha)$—see Appendix B.

mization problems. A common belief is that simplicity is necessarily gained at the price of practicality; however, this is not true. In the setting of an algorithms library, such as LEDA [MN00], it is important—and practical—that *data types* be fully separated from *algorithms* and that the interface between the two be as generic as possible. There is always room for fast algorithms specialized to integers or floats. However, even under these assumptions, the gains in speed can be surprisingly minor; see [PRS02] for one example.

**2.1.1. Techniques.** In our algorithm we sometimes use subtraction on real numbers, an operation that is not directly available in the comparison-addition model. Lemma 2.1, given below, shows that simulating subtraction incurs at most a constant factor loss in efficiency.

LEMMA 2.1. *$C$ comparisons and $A$ additions and subtractions can be simulated in the comparison-addition model with $C$ comparisons and $2(A+C)$ additions.*

*Proof.* We represent each real $x_i = a_i - b_i$ as two reals $a_i, b_i$. An addition $x_i + x_j = (a_i + a_j) - (b_i + b_j)$ or a subtraction $x_i - x_j = (a_i + b_j) - (b_i + a_j)$ can be simulated with two actual additions. A comparison $x_i : x_j$ is equivalent to the comparison $a_i + b_j : a_j + b_i$, which involves two actual additions and a comparison. □

At a key point in our algorithm we need to approximate the ratio of two numbers. Division is clearly not available for real numbers in the comparison-addition model, and with a little thought one can see that it cannot be simulated exactly. Lemma 2.2, given below, bounds the time to find certain *approximate* ratios in the comparison-addition model, which will be sufficient for our purposes.

LEMMA 2.2. *Let $p_1, \dots, p_k$ be real numbers, where $p_1$ and $p_k$ are the smallest and largest, respectively. We can find the set of integers $\{q_i\}$ such that $2^{q_i} \le \frac{p_i}{p_1} < 2^{q_i+1}$ in $\Theta(\log \frac{p_k}{p_1} + k \log\log \frac{p_k}{p_1})$ time.*

*Proof.* We generate the set $\mathcal{L} = \{p_1, 2 \cdot p_1, 4 \cdot p_1, \dots, 2^{\lceil \log \frac{p_k}{p_1} \rceil} \cdot p_1\}$ with $\log \frac{p_k}{p_1}$ additions; then for each $p_i$ we find $q_i$ in $\log |\mathcal{L}| = O(\log\log \frac{p_k}{p_1})$ time with a binary search over $\mathcal{L}$. □

In our algorithm the $\{p_i\}$ correspond to certain edge lengths, and $k = \Theta(n)$. Our need to approximate ratios, as in Lemma 2.2, is the source of the peculiar $n \log\log r$ term in the running time of Theorem 1.1. We note here that the bound stated in Lemma 2.2 is pessimistic in the following sense. If we randomly select the $\{p_i\}$ from a uniform distribution (or other natural distribution), then the time to find approximate ratios can be reduced to $O(k)$ (with high probability) using a linear search rather than a binary search.

**2.1.2. Lower bounds.** There are many lower bounds for shortest path problems in the comparison-addition model, though none are truly startling. Spira and Pan [SP75] showed that even if additions are free, $\Omega(n^2)$ comparisons are necessary to solve SSSP on the complete graph. Karger, Koller, and Phillips [KKP93] proved that directed APSP requires $\Omega(mn)$ comparisons if each summation corresponds to a path in the graph.[5] Kerr [K70] showed that any oblivious APSP algorithm performs $\Omega(n^3)$ comparisons, and Kolliopoulos and Stein [KS98] proved that any fixed sequence of edge relaxations solving SSSP must have length $\Omega(mn)$. By "fixed sequence" they mean one that depends only on $m$ and $n$ but not on the graph structure. Ahuja et al. [AMOT90] observed that any implementation of Dijkstra's algorithm requires $\Omega(m + n \log n)$ comparison and addition operations. Pettie [Pet04] gave an $\Omega(m +$

[5]However, it is not true that all shortest path algorithms satisfy this condition. For example, our algorithm does not, and neither do [F76, Tak92, Han04, Z04, Pet04, Pet02b].

$\min\{n \log r, n \log n\})$ lower bound on computing directed SSSP with a "hierarchy-type" algorithm, where $r$ bounds the ratio of any two edge lengths. In section 6 we prove a lower bound of $\Omega(m + \min\{n \log\log r, n \log n\})$ on hierarchy-type algorithms for *undirected* SSSP. These last two lower bounds are essentially tight for hierarchy-type algorithms, on directed and undirected graphs, respectively.

Graham, Yao, and Yao [GYY80] proved that the information-theoretic argument cannot prove a nontrivial $\omega(n^2)$ lower bound on the *comparison*-complexity of APSP, where additions are granted for free. It is also simple to see that there can be no nontrivial information-theoretic lower bound on SSSP.

**2.2. Dijkstra's algorithm.** Our algorithm, like [Tho99, Hag00], is best understood as circumventing the limitations of Dijkstra's algorithm. We give a brief description of Dijkstra's algorithm in order to illustrate its complexity and introduce some vocabulary.

For a vertex set $S \subseteq V(G)$, let $d_S(u, v)$ denote the distance from $u$ to $v$ in the subgraph induced by $S \cup \{v\}$. Dijkstra's algorithm maintains a *tentative* distance function $D(v)$ and a set of *visited* vertices $S$ satisfying Invariant 2.1. Henceforth, $s$ denotes the source vertex.

INVARIANT 2.1. *Let $s$ be the source vertex and $v$ be an arbitrary vertex:*

$$D(v) = \begin{cases} d(s, v) & \text{if } v \in S, \\ d_S(s, v) & \text{if } v \notin S. \end{cases}$$

Choosing an initial assignment of $S = \emptyset$, $D(s) = 0$, and $D(v) = \infty$ for $v \neq s$ clearly satisfies the invariant. Dijkstra's algorithm consists of repeating the following step $n$ times: choose a vertex $v \in V(G) \backslash S$ such that $D(v)$ is minimized, set $S := S \cup \{v\}$, and finally, update tentative distances to restore Invariant 2.1. This last part involves *relaxing* each edge $(v, w)$ by setting $D(w) = \min\{D(w), D(v) + \ell(v, w)\}$. Invariant 2.1 and the positive-weight assumption imply $D(v) = d(s, v)$ when $v$ is selected. It is also simple to prove that relaxing outgoing edges of $v$ restores Invariant 2.1.

The problem with Dijkstra's algorithm is that vertices are selected in increasing distance from the source, a task that is at least as hard as sorting $n$ numbers. Maintaining Invariant 2.1, however, does not demand such a particular ordering. In fact, it can be seen that selecting *any* vertex $v \notin S$ for which $D(v) = d(s, v)$ will maintain Invariant 2.1. All hierarchy-type algorithms [Tho99, Hag00, Pet04, Pet02b] maintain Invariant 2.1 by generating a weaker certificate for $D(v) = d(s, v)$ than "$D(v)$ is minimal." Any such certificate must show that for all $u \notin S$, $D(u) + d(u, v) \geq D(v)$. For example, Dijkstra's algorithm presumes there are no negative length edges, hence $d(u, v) \geq 0$, and by choice of $v$ ensures $D(u) \geq D(v)$. This is clearly a sufficient certificate. In Dinic's version [Din78] of Dijkstra's algorithm the lower bound $d(u, v) \geq \ell_{\min}$ is used, where $\ell_{\min}$ is the minimum edge length. Thus Dinic is free to visit any $v \notin S$ for which $\lfloor D(v)/\ell_{\min} \rfloor$ is minimal. All hierarchy-type algorithms [Tho99, Hag00, Pet04, Pet02b], ours included, precompute a much stronger lower bound on $d(u, v)$ than $d(u, v) \geq \ell_{\min}$.

## 3. The hierarchy approach and its correctness.

In this section we generalize the hierarchy-based approach of [Tho99] to real-weighted graphs. Because the algorithm follows directly from its proof of correctness, we will actually give a kind of correctness proof first.

Below, $X \subseteq V(G)$ denotes any set of vertices, and $s$ always denotes the source vertex. Let $I$ be a real interval. The notation $X^I$ refers to the subset of $X$ whose distance from the source lies in the interval $I$, i.e.,

$$X^I = \{ v \in X \ : \ d(s,v) \in I \}.$$

DEFINITION 3.1. *A vertex set $X$ is $(S, [a,b))$-SAFE if* (i) $X^{[0,a)} \subseteq S$,
(ii) *for* $v \in X^{[a,b)}$, $d_{S \cup X}(s,v) = d(s,v)$.

In other words, if a subgraph is $(S, I)$-SAFE, we can determine the distances that lie in interval $I$ without looking at parts of the graph outside the subgraph and $S$. Clearly, finding safe subgraphs has the potential to let us compute distances cheaply.

DEFINITION 3.2. *A set $\{X_i\}_i$ is a $t$-partition of $X$ if the $\{X_i\}_i$ partition $X$ and for every edge $(u,v)$ with $u \in X_i$, $v \in X_j$, and $i \neq j$, we have $\ell(u,v) \geq t$.*

Note that a $t$-partition need not be maximal; that is, if $\{X_1, X_2, \ldots, X_k\}$ is a $t$-partition, then $\{X_1 \cup X_2, X_3, \ldots, X_k\}$ is as well.

LEMMA 3.3. *Suppose that $X$ is $(S, [a,b))$-SAFE. Let $\{X_i\}_i$ be a $t$-partition of $X$ and let $S'$ be such that $S \cup X^{[a, \min\{a+t,b\})} \subseteq S'$. Then*
(i) *for $X_i$ in the $t$-partition, $X_i$ is $(S, [a, \min\{a+t, b\}))$-SAFE;*
(ii) *$X$ is $(S', [\min\{a+t,b\}, b))$-SAFE.*

*Proof.* We prove part (i) first. Let $v \in X_i^{[a,\min\{a+t,b\})}$ and suppose that the lemma is false, that $d(s,v) \neq d_{S \cup X_i}(s,v)$. From the assumed safeness of $X$ we know that $d(s,v) = d_{S \cup X}(s,v)$. This means that the shortest path to $v$ must pass through $X \backslash (X_i \cup S)$. Let $w$ be the last vertex in $X \backslash (X_i \cup S)$ on the shortest $s$–$v$ path. By Definition 3.2, the edge from $w$ to $X_i$ has length $\geq t$. Since $d(s,v) < \min\{a+t, b\}$, $d(s,w) < \min\{a+t,b\} - t \leq a$. Since, by Definition 3.1(i), $X^{[0,a)} \in S$, it must be that $w \in S$, contradicting our selection of $w$ from $X \backslash (X_i \cup S)$. Part (ii) claims that $X$ is $(S', [\min\{a+t,b\}, b))$-SAFE. Consider first Definition 3.1(i) regarding safeness. By the assumption that $X$ is $(S, [a,b))$-SAFE we have $X^{[0,a)} \subseteq S$, and by definition of $S'$ we have $S \cup X^{[a,\min\{a+t,b\})} \subseteq S'$; therefore $X^{[0,\min\{a+t,b\})} \subseteq S'$, satisfying Definition 3.1(i). By the assumption that $X$ is $(S,[a,b))$-SAFE we have that for $v \in X^{[a,b)}$, $d_{S\cup X}(s,v) = d(s,v)$; this implies the weaker statement that for $v \in X^{[\min\{a+t,b\},b)}$, $d_{S' \cup X}(s,v) = d_{S \cup X}(s,v) = d(s,v)$. □

As Thorup noted [Tho99], Lemma 3.3 alone leads to a simple recursive procedure for computing SSSP; however, it makes no guarantee as to efficiency. The input to the procedure is an $(S, I)$-SAFE subgraph $X$; its only task is to compute the set $X^I$, which it performs with recursive calls (corresponding to Lemma 3.3(i) and (ii)) or directly if $X$ consists of a single vertex. There are essentially three major obstacles to making this general algorithm efficient: bounding the number of recursive calls, bounding the *time* to decide what those recursive calls are, and computing good $t$-partitions. Thorup gave a simple way to choose the $t$-partitions in integer-weighted graphs so that the number of recursive calls is $O(n)$. However, if adapted directly to the comparison-addition model, the time to decide which calls to make becomes $\Omega(n \log n)$; it amounts to the problem of implementing a general priority queue. We reduce the overhead for deciding which recursive calls to make to linear by using a "well balanced" hierarchy and a specialized priority queue for exploiting this kind of balance. Our techniques rely heavily on the graph being undirected and do not seem to generalize to directed graphs in any way.

As in other hierarchy-type algorithms, we generalize the distance and tentative distance notation from Dijkstra's algorithm to include not just single vertices but sets of vertices. If $X$ is a set of vertices (or associated with a set of vertices), then

$$(1) \qquad D(X) \overset{\mathbf{def}}{=} \min_{v \in X} D(v) \qquad \text{and} \qquad d(u,X) \overset{\mathbf{def}}{=} \min_{v \in X} d(u,v).$$

The procedure Generalized-Visit, given below, takes a vertex set $X$ that is $(S, I)$-safe and computes the distances to all vertices in $X^I$, placing these vertices in the set $S$ as their distances become known. We maintain Invariant 2.1 at all times. By Definition 3.1 we can compute the set $X^I$ without looking at parts of the graph outside of $S \cup X$. If $X = \{v\}$ happens to contain a single vertex, we can compute $X^I$ directly: if $D(v) \in I$, then $X^I = \{v\}$; otherwise it is $\emptyset$. For the general case, Lemma 3.3 says that we can compute $X^I$ by first finding a $t$-partition $\chi$ of $X$, then computing $X^I$ in phases. Let $I = I_1 \cup I_2 \cup \cdots \cup I_k$, where each subinterval is disjoint from the others and has width $t$, except perhaps $I_k$, which may be a leftover interval of width less than $t$. Let $S_i = S \cup X^{I_1} \cup \cdots \cup X^{I_i}$ and let $S_0 = S$. By the assumption that $X$ is $(S, I)$-safe and Lemma 3.3, each set in $\chi$ is $(S_i, I_{i+1})$-safe. Therefore, we can compute $S_1, S_2, \ldots, S_k = S \cup X^I$ with a series of recursive calls as follows. Assume that the current set of visited vertices is $S_i$. We determine $X^{I_{i+1}} = \bigcup_{Y \in \chi} Y^{I_{i+1}}$ with recursive calls of the form Generalized-Visit$(Y, I_{i+1})$, for every $Y \in \chi$ such that $Y^{I_{i+1}} \neq \emptyset$.

To start things off, we initialize the set $S$ to be empty, set the $D$-values (tentative distances) according to Invariant 2.1, and call Generalized-Visit$(V(G), [0, \infty))$. By the definition of safeness, $V(G)$ is clearly $(\emptyset, [0, \infty))$-safe. If Generalized-Visit works according to specification, when it completes $S = V(G)$ and Invariant 2.1 is satisfied, implying that $D(v) = d(s, v)$ for all vertices $v \in V(G)$.

```
Generalized-Visit($X$, $[a, b)$): A generalized hierarchy-type algorithm for real-weighted graphs.
        Input guarantee: $X$ is $(S, [a, b))$-safe and Invariant 2.1 is satisfied.

        Output guarantee: Invariant 2.1 is satisfied and $S_{post} = S_{pre} \cup X^{[a,b)}$,
        where $S_{pre}$ and $S_{post}$ are the set $S$ before and after the call.

    1. If $X$ contains one vertex, $X = \{v\}$, and $D(v) \in [a, b)$, then $D(v) =
       d_S(s, v) = d(s, v)$, where the first equality is by Invariant 2.1 and the
       second by the assumption that $X$ is $(S, [a, b))$-safe. Let $S := S \cup \{v\}$.
       Relax all edges incident on $v$, restoring Invariant 2.1, and return.
    2. Let $a' := a$
       While $a' < b$ and $X \not\subseteq S$
           Let $t > 0$ be any positive real
           Let $\chi = \{X_1, X_2, \ldots, X_k\}$ be an arbitrary $t$-partition of $X$
           Let $\chi' = \{X_i \in \chi \ :\ D(X_i) < \min\{a' + t, b\}$ and $X_i \not\subseteq S\}$
           For each $X_i \in \chi'$, Generalized-Visit($X_i$, $[a', \min\{a' + t, b\})$)
           $a' := \min\{a' + t, b\}$
```

Lemma 3.4. *If the input guarantees of* Generalized-Visit *are met, then after a call to* Generalized-Visit$(X, I)$*, Invariant* 2.1 *remains satisfied and* $X^I$ *is a subset of the visited vertices* $S$.

*Proof* (sketch). The base case, when $X$ is a single vertex, is simple to handle. Turning to the general case, we prove that each time the while statement is examined in step 2, $X$ is $(S, [a', b))$-safe for the *current* value of $S$ and $a'$; in what follows we will treat $S$ as a variable, not a specific vertex set. The first time through the while-loop in step 2, it follows from the input guarantee to Generalized-Visit that $X$ is $(S, [a', b))$-safe. Similarly, the input guarantee for all recursive calls holds by Lemma 3.3. However, to show that $X$ is $(S, [a', b))$-safe at the assignment $a' := \min\{a' + t, b\}$, by Definition 3.1 we must show $X^{[0, \min\{a'+t, b\})} \subseteq S$. We assume inductively that the output guarantee of any recursive call to Generalized-Visit is fulfilled; that is, upon the completion of Generalized-Visit$(X_i, [a', \min\{a' + t, b\}])$, $S$ includes the set $X_i^{[a', \min\{a'+t,b\})}$. Each time through the while-loop in step 2 Generalized-Visit makes recursive calls to all $Y \in \chi'$. To complete the proof we must show that for $Y \in \chi \backslash \chi'$, $Y^{[a', \min\{a'+t,b\})} \backslash S = \emptyset$. If $Y \in \chi \backslash \chi'$, it was because $D(Y) \geq \min\{a' + t, b\}$ or because $Y \subseteq S$, both of which clearly imply $Y^{[a', \min\{a'+t,b\})} \backslash S = \emptyset$. The output guarantee for Generalized-Visit is clearly satisfied if step 1 is executed; if step 2 is executed, then when the while-loop finishes, $X$ is either $(S, [b, b))$-safe or $X \subseteq S$, both implying $X^{[0,b)} \in S$. □

Generalized-Visit can be simplified in a few minor ways. It can be seen that in step 1 we do not need to check whether $D(v) \in [a, b)$; the recursive call would not have taken place were this not the case. In step 2 the final line can be shortened to $a' := a' + t$. However, we cannot change all occurrences of $\min\{a' + t, b\}$ to $a' + t$ because this is crucial to the procedure's correctness. It is not assumed (nor can it be guaranteed) that $t$ divides $(b - a)$, so the procedure must be prepared to deal with fractional intervals of width less than $t$. In section 4 we show that for a *proper* hierarchy this fractional interval problem does not arise.

## 4. Efficient implementations of Generalized-Visit.

We propose two implementations of the Generalized-Visit algorithm, called Visit and Visit-B. The time bound claimed in Theorem 1.1 is proved by analyzing Visit, given later in this section. Although Visit is asymptotically fast, it seems too impractical for a real-world implementation. In section 4.5 we give the Visit-B implementation of Generalized-Visit, which uses fewer specialized data structures. The asymptotic running time of Visit-B is just a little slower than that of Visit.

Visit and Visit-B differ from Generalized-Visit in their input/output specification only slightly. Rather than accepting a set of vertices, as Generalized-Visit does, our implementations (like [Tho99, Hag00, Pet04, Pet02b]) accept a *hierarchy node* $x$, which represents a set of vertices. Both of our implementations work correctly for any *proper* hierarchy $\mathcal{H}$, defined below. We prove bounds on their running times as a function of $m, n$, and a certain function of $\mathcal{H}$ (which is different for Visit and Visit-B). In order to compute SSSP in near-linear time the proper hierarchy $\mathcal{H}$ must satisfy certain *balance* conditions, which are the same for Visit and Visit-B. In section 5 we give the requisite properties of a balanced hierarchy and show how to construct a balanced proper hierarchy in $O(\textsc{mst}(m, n) + \min\{n \log n,\ n \log \log r\})$ time. Definition 4.1, given next, describes exactly what is meant by hierarchy and proper hierarchy.

Definition 4.1. *A* hierarchy *is a rooted tree whose leaf nodes correspond to graph vertices. If $x$ is a hierarchy node, then $p(x)$ is its parent, $\textsc{deg}(x)$ is the number of children of $x$, $V(x)$ is the set of descendant leaves (or the equivalent graph vertices), and $\textsc{diam}(x)$ is an upper bound on the diameter of $V(x)$ (where the diameter of $V(x)$ is defined to be $\max_{u,v \in V(x)} d(u, v)$). Each node $x$ is given a value $\textsc{norm}(x)$. A hierarchy is* proper *if the following hold:*

(i) $\textsc{norm}(x) \leq \textsc{norm}(p(x))$,

(ii) *either* $\textsc{norm}(p(x))/\textsc{norm}(x)$ *is an integer or* $\textsc{diam}(x) < \textsc{norm}(p(x))$,

(iii) $\textsc{deg}(x) \neq 1$,

(iv) *if $x_1, \ldots, x_{\textsc{deg}(x)}$ are the children of $x$, then $\{V(x_i)\}_i$ is a $\textsc{norm}(x)$-partition of $V(x)$. (Refer to Definition 3.2 for the meaning of "$\textsc{norm}(x)$-partition.")*

Part (iv) of Definition 4.1 is the crucial one for computing shortest paths. Part (iii) guarantees that a proper hierarchy has $O(n)$ nodes. The second part of (ii) is admittedly a little strange. It allows us to replace all occurrences of $\min\{a + t, b\}$

in GENERALIZED-VISIT with just $a + t$, which greatly simplifies the analysis of our algorithms. Part (i) will be useful when bounding the total number of recursive calls to our algorithms.

**4.1.** VISIT**.** Consider the VISIT procedure given below. We prove that VISIT correctly computes SSSPs by demonstrating that it is an implementation of GENERALIZED-VISIT, which was already proved correct.

```
VISIT($x$, $[a, b)$).

    Input: $x$ is a node in a proper hierarchy $\mathcal{H}$; $V(x)$ is $(S, [a, b))$-SAFE and
    Invariant 2.1 is satisfied.

    Output guarantee: Invariant 2.1 is satisfied and $S_{post} = S_{pre} \cup V(x)^{[a,b)}$,
    where $S_{pre}$ and $S_{post}$ are the set $S$ before and after the call.

 1. If $x$ is a leaf and $D(x) \in [a, b)$, then let $S := S \cup \{x\}$, relax all edges
    incident on $x$, restoring Invariant 2.1, and return.
 2. If VISIT$(x, \cdot)$ is being called for the first time, create a bucket array of
    $\lceil \text{DIAM}(x)/\text{NORM}(x) \rceil + 1$ buckets. Bucket $i$ represents the interval

        $[a_x + i \cdot \text{NORM}(x),\ a_x + (i + 1) \cdot \text{NORM}(x)),$

    where  $a_x = \begin{cases} D(x) & \text{if } D(x) + \text{DIAM}(x) < b, \\ b - \lceil \frac{b - D(x)}{\text{NORM}(x)} \rceil \text{NORM}(x) & \text{otherwise.} \end{cases}$

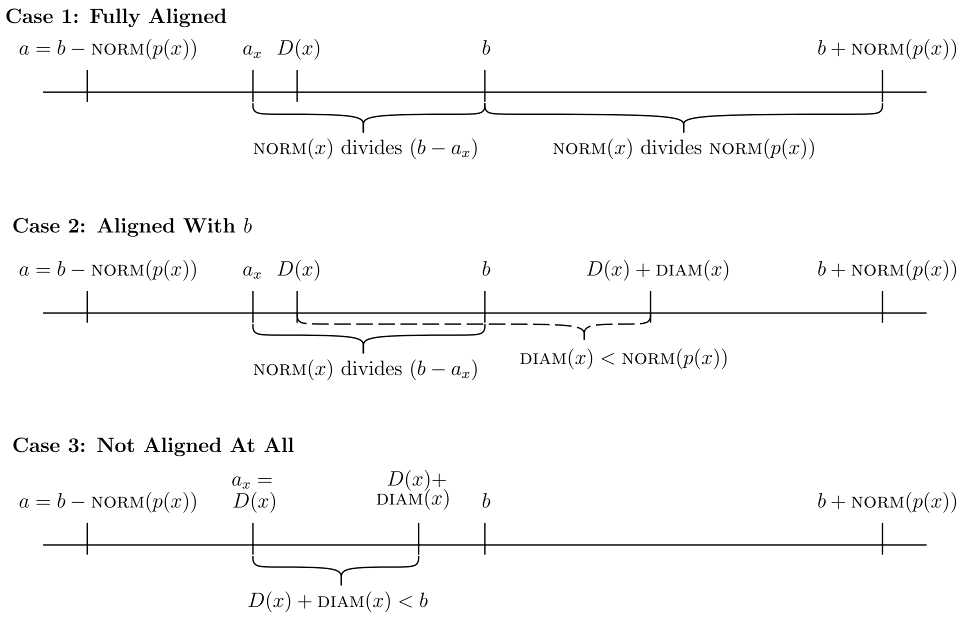
    We initialize $a' := a_x$ and insert all the children of $x$ in $\mathcal{H}$ into the bucket
    array.

    The bucket invariant: A node $y \in \mathcal{H}$ in $x$'s bucket array appears (log-
    ically) in the bucket whose interval spans $D(y)$. If $\{x_i\}$ are the set of
    bucketed nodes, then $\{V(x_i)\}$ is a NORM$(x)$-partition of $V(x)$.

 3. While $a' < b$ and $V(x) \not\subseteq S$
        While $\exists y$ in bucket $[a',\ a' + \text{NORM}(x))$ s.t. $\text{NORM}(y) = \text{NORM}(x)$
            Remove $y$ from the bucket array
            Insert $y$'s children in $\mathcal{H}$ in the bucket array
        For each $y$ in bucket $[a', a' + \text{NORM}(x))$
        and each $y$ such that $D(y) < a'$ and $V(y) \not\subseteq S$
            VISIT$(y, [a', a' + \text{NORM}(x)))$
        $a' := a' + \text{NORM}(x)$
```

In step 2 of GENERALIZED-VISIT we let $\chi$ be any arbitrary $t$-partition of the subset of vertices given as input. In VISIT the input is a hierarchy node $x$, and the associated vertex set is $V(x)$. We represent the $t$-partition of $V(x)$ (where $t = \text{NORM}(x)$) by the set of bucketed $\mathcal{H}$-nodes $\{x_i\}_i$ (see step 2), where the sets $\{V(x_i)\}_i$ partition $V(x)$. Clearly the $\{x_i\}_i$ are descendants of $x$. The set $\{x_i\}_i$ will begin as $x$'s children, though later on $\{x_i\}_i$ may contain a mixture of children of $x$, grandchildren of $x$, and so on.

Consider the inner while-loop in step 3. Assuming inductively that the bucketed $\mathcal{H}$-nodes represent a NORM$(x)$-partition of $V(x)$, if $y$ is a bucketed node and $\text{NORM}(y) = \text{NORM}(x)$, then replacing $y$ by its children in the bucket array produces a new NORM$(x)$-partition. This follows from the definitions of $t$-partitions and proper



Case 1: Fully Aligned
$a = b - \text{NORM}(p(x))$
$a_x$
$D(x)$
$b$
$b + \text{NORM}(p(x))$
NORM($x$) divides $(b - a_x)$
NORM($x$) divides NORM($p(x)$)
Case 2: Aligned With $b$
$a = b - \text{NORM}(p(x))$
$a_x$
$D(x)$
$b$
$D(x) + \text{DIAM}(x)$
$b + \text{NORM}(p(x))$
NORM($x$) divides $(b - a_x)$
$\text{DIAM}(x) < \text{NORM}(p(x))$
Case 3: Not Aligned At All
$a = b - \text{NORM}(p(x))$
$a_x = D(x)$
$D(x)+\text{DIAM}(x)$
$b$
$b + \text{NORM}(p(x))$
$D(x) + \text{DIAM}(x) < b$

FIG. 1. *First observe that when $a_x$ is initialized we have $D(x) \geq a_x \geq a$, as in the figure. If $a_x$ is chosen such that* NORM($x$) *divides $(b - a_x)$, then by Definition* 4.1(ii) *either* NORM($x$) *divides* NORM($p(x)$) *(which puts us in Case* 1*) or* $\text{DIAM}(x) < \text{NORM}(p(x))$ *(putting us in Case* 2*); that is,* NORM($x$) *does not divide $(b + \text{NORM}(p(x)) - a_x)$, but it does not matter since we'll never reach $b + \text{NORM}(p(x))$ anyway. If $a_x$ is chosen so that* NORM($x$) *does not divide $(b - a_x)$, then $a_x = D(x)$ and $D(x) + \text{DIAM}(x) < b$ (putting us in Case* 3*), meaning we will never reach $b$. Note that by the definition of* DIAM($x$) *(Definition* 4.1*) and Invariant* 2.1*, for any vertex in $u \in V(x)$ we have $d(s, u) \leq d(s, x) + \text{DIAM}(x) \leq D(x) + \text{DIAM}(x)$.*

hierarchies (Definitions 3.2 and 4.1). Since the bucketed nodes form a NORM($x$)-partition, one can easily see that the recursive calls in step 3 of VISIT correspond to the recursive calls in GENERALIZED-VISIT. However, their interval arguments are different. We sketch below why this change does not affect correctness.

In GENERALIZED-VISIT the intervals passed to recursive calls are of the form $[a', \min\{a' + t, b\})$, whereas in VISIT they are $[a', a' + t) = [a', a' + \text{NORM}(x))$. We will argue why $a' + t = a' + \text{NORM}(x)$ is never more than $b$. The main idea is to show that we are always in one of the three cases portrayed in Figure 1.

If NORM($x$) divides NORM($p(x)$) and $a_x$ is chosen in step 2 so that $t = \text{NORM}(x)$ divides $(b - a_x)$, then we can freely substitute the interval $[a', a' + t)$ for $[a', \min\{a' + t, b\})$ since they will be identical. Note that in our algorithm $(b - a) = \text{NORM}(p(x))$.[6] The problems arise when NORM($x$) does not divide either NORM($p(x)$) or $(b - a_x)$. In order to prove the correctness of VISIT we must show that the input guarantee (regarding SAFE-ness) is satisfied for each recursive call. We consider two cases: when we are in the first recursive call to VISIT($x, \cdot$) and any subsequent call. Suppose we are in the first recursive call to VISIT($x, \cdot$). By our choice of $a_x$ in step 2, either $b = a_x + q \cdot \text{NORM}(x)$ for some integer $q$, or $b > D(x) + \text{DIAM}(x) = a_x + \text{DIAM}(x)$. If it is the first case, each time the outer while-loop is entered we have $a' < b$, which,

[6]Strictly speaking, this does not hold for the initial call because in this case, $x = \text{ROOT}(\mathcal{H})$ is the root of the hierarchy $\mathcal{H}$ and there is no such node $p(x)$. The argument goes through just fine if we let $p(\text{ROOT}(\mathcal{H}))$ denote a dummy node such that $\text{NORM}(p(\text{ROOT}(\mathcal{H}))) = \infty$.

since $q$ is integral, implies $\min\{a' + \textsc{norm}(x), b\} = a' + \textsc{norm}(x)$. Now consider the second case, where $b > D(x) + \textsc{diam}(x) = a_x + \textsc{diam}(x)$, and one of the recursive calls $\textsc{Visit}(y, [a', a' + \textsc{norm}(x)))$ made in step 3. By Lemma 3.3, $V(y)$ is $(S, [a', \min\{a' + \textsc{norm}(x), b\}))$-SAFE, and it is actually $(S, [a', a' + \textsc{norm}(x)))$-SAFE as well because $b > D(x) + \textsc{diam}(x)$, implying $V(y)^{[b,\infty)} \subseteq V(x)^{[b,\infty)} = \emptyset$. (Recall from Definition 4.1 that for any $u \in V(x)$, $\textsc{diam}(x)$ satisfies $d(s, x) \leq d(s, u) \leq d(s, x) + \textsc{diam}(x) \leq D(x) + \textsc{diam}(x)$.) Now consider a recursive call $\textsc{Visit}(x, [a, b))$ that is *not* the first call to $\textsc{Visit}(x, \cdot)$. Then by Definition 4.1(ii), either $(b - a) = \textsc{norm}(p(x))$ is a multiple of $\textsc{norm}(x)$ or $a + \textsc{diam}(x) < b$; these are identical to the two cases treated above.

There are two data structural problems that need to be solved in order to efficiently implement VISIT. First, we need a way to compute the tentative distances of hierarchy nodes, i.e., the $D$-values as defined in (1) in section 3. For this problem we use an improved version of Gabow's split-findmin structure [G85a]. The other problem is efficiently implementing the various bucket arrays, which we solve with a new structure called the *bucket-heap.* The specifications for these two structures are discussed below, in sections 4.2 and 4.3, respectively. The interested reader can refer to Appendices A and B for details about our implementations of split-findmin and the bucket-heap, and for proofs of their respective complexities.

**4.2. The split-findmin structure.** The split-findmin structure operates on a collection of disjoint sequences, consisting in total of $n$ elements, each with an associated key. The idea is to maintain the smallest key in each sequence under the following operations.

| | |
|---|---|
| split($x$): | Split the sequence containing $x$ into two sequences: the elements up to and including $x$, and the rest. |
| decrease-key($x, \kappa$): | Set key($x$) $= \min\{\text{key}(x), \kappa\}$. |
| findmin($x$): | Return the element with minimum key in $x$'s sequence. |

Theorem 4.2, given below, establishes some new bounds on the problem that are just slightly better than Gabow's original data structure [G85a]. Refer to Appendix B for a proof. Thorup [Tho99] gave a similar data structure for integer keys in the RAM model that runs in linear time. It relies on the RAM's ability to sort small sets of integers in linear time [FW93].

THEOREM 4.2. *The split-findmin problem can be solved on a pointer machine in $O(n+m\alpha)$ time while making only $O(n+m\log\alpha)$ comparisons, where $\alpha = \alpha(m, n)$ is the inverse-Ackermann function. Alternatively, split-findmin can be solved on a RAM in time $\Theta(\textsc{split-findmin}(m, n))$, where $\textsc{split-findmin}(m, n) = O(n+m\log\alpha)$ is the decision-tree complexity of the problem.*

We use the split-findmin structure to maintain $D$-values as follows. In the beginning there is one sequence consisting of the $n$ leaves of $\mathcal{H}$ in an order consistent with some depth-first search traversal of $\mathcal{H}$. For any leaf $v$ in $\mathcal{H}$ we maintain, by appropriate decrease-key operations, that key($v$) $= D(v)$. During execution of VISIT we will say an $\mathcal{H}$-node is *unresolved* if it lies in another node's bucket array but its tentative distance ($D$-value) is not yet finalized. The $D$-value of an $\mathcal{H}$-node becomes finalized, in the sense that it never decreases again, during step 3 of VISIT, either by being removed from some bucket array or passed, for the first time, to a recursive call of VISIT. (It follows from Definition 3.1 and Invariant 2.1 that $D(y) = d(s, y)$ at the first recursive call to $y$.) One can verify a couple properties of the unresolved nodes.

First, each unvisited leaf has exactly one unresolved ancestor. Second, to implement Visit we need only query the $D$-values of unresolved nodes. Therefore, we maintain that for each unresolved node $y$, there is some sequence in the split-findmin structure corresponding to $V(y)$, the descendants of $y$. Now suppose that a previously unresolved node $y$ is *resolved* in step 3 of Visit. The $\mathrm{DEG}(y)$ children of $y$ will immediately become unresolved, so to maintain our correspondence between sequences and unresolved nodes, we perform $\mathrm{DEG}(y) - 1$ split operations on $y$'s sequence, so that the resulting subsequences correspond to $y$'s children.

We remark that the split-findmin structure we use can be simplified slightly because we know in advance where the splits will occur. However, this knowledge does not seem to affect the asymptotic complexity of the problem.

## 4.3. The bucket-heap.

We now turn to the problem of efficiently implementing the bucket array used in Visit. Because of the information-theoretic bottleneck built into the comparison-addition model, we cannot always bucket nodes in constant time: each comparison extracts at most one bit of information, whereas properly bucketing a node in $x$'s bucket array requires us to extract up to $\log(\mathrm{DIAM}(x)/\mathrm{NORM}(x))$ bits of information. Thorup [Tho99] and Hagerup [Hag00] assume integer edge lengths and the RAM model and therefore do not face this limitation. We now give the specification for the *bucket-heap*, a structure that supports the bucketing operations of Visit. This structure logically operates on a sequence of buckets; however, our implementation is really a simulation of the logical structure. Lemma 4.3, proved in Appendix A, bounds the complexity of our implementation of the bucket-heap.

| | |
|---|---|
| create$(\mu, \delta)$: | Create a new bucket-heap whose buckets are associated with intervals $[\delta, \delta + \mu), [\delta + \mu, \delta + 2\mu), [\delta + 2\mu, \delta + 3\mu), \ldots$. An item $x$ lies in the bucket whose interval spans key$(x)$. All buckets are initially *open*. |
| insert$(x, \kappa)$: | Insert a new item $x$ with key$(x) = \kappa$. |
| decrease-key$(x, \kappa)$: | Set key$(x) = \min\{\text{key}(x), \kappa\}$. It is guaranteed that $x$ is not moved to a closed bucket. |
| enumerate: | Close the first open bucket and enumerate its contents. |

Lemma 4.3. *Let $\Delta_x \geq 1$ denote the number of buckets between the first open bucket at the time of $x$'s insertion and the bucket from which $x$ was enumerated. The bucket-heap can be implemented on a pointer machine to run in $O(N + \sum_x \log \Delta_x)$ time, where $N$ is the number of operations.*

When $\mathrm{Visit}(x, \cdot)$ is called for the first time, we initialize the bucket-heap at $x$ with a call to create$(\mathrm{NORM}(x),\ a_x)$, followed by a number of insert operations for each of $x$'s children, where the key of a child is its $D$-value. Here $a_x$ is the beginning of the real interval represented by the bucket array, and $\mathrm{NORM}(x)$ the width of each bucket. Every time the $D$-value of a bucketed node decreases, which can easily be detected with the split-findmin structure, we perform a decrease-key on the corresponding item in the bucket-heap. We usually refer to buckets not by their cardinal number but by their associated real interval, e.g., bucket $[a_x, a_x + \mathrm{NORM}(x))$.

## 4.4. Analysis of Visit.

In this section we bound the time required to compute SSSP with Visit as a function of $m$, $n$, and the given hierarchy $\mathcal{H}$. We will see later that the dominant term in this running time corresponds to the split-findmin structure, whose complexity is no more than $O(m \log \alpha)$ but could turn out to be linear.

LEMMA 4.4. *Let $\mathcal{H}$ be a proper hierarchy. Computing SSSPs with* VISIT *on $\mathcal{H}$ takes time $O(\text{SPLIT-FINDMIN}(m,n) + \phi(\mathcal{H}))$, where $\text{SPLIT-FINDMIN}(m,n)$ is the complexity of the split-findmin problem and*

$$\phi(\mathcal{H}) = \sum_{\substack{x\in\mathcal{H} \text{ such that} \\ \text{NORM}(x)\neq\text{NORM}(p(x))}} \frac{\text{DIAM}(x)}{\text{NORM}(x)} + \sum_{x\in\mathcal{H}} \log\left(\frac{\text{DIAM}(p(x))}{\text{NORM}(p(x))} + 1\right).$$

*Proof.* The $\text{SPLIT-FINDMIN}(m,n)$ term represents the time to relax edges (in step 1) and update the relevant $D$-values of $\mathcal{H}$-nodes, as described in section 4.2. Except for the costs associated with updating $D$-values, the overall time of VISIT is linear in the number of recursive calls and the bucketing costs. The two terms of $\phi(\mathcal{H})$ represent these costs. Consider the number of calls to $\text{VISIT}(x, I)$ for a particular $\mathcal{H}$-node $x$. According to step 3 of VISIT, there will be *zero* calls to $x$ unless $\text{NORM}(x) \neq \text{NORM}(p(x))$. If it is the case that $\text{NORM}(x) \neq \text{NORM}(p(x))$, then for all recursive calls on $x$, the given interval $I$ will have the same width: $\text{NORM}(z)$ for some ancestor $z$ of $x$. By Definition 4.1(i), $\text{NORM}(z) \geq \text{NORM}(x)$, and therefore the number of such recursive calls on $x$ is $\leq \text{DIAM}(x)/\text{NORM}(x) + 2$; the extra 2 counts the first and last recursive calls, which may cover negligible parts of the interval $[d(s,x), d(s,x) + \text{DIAM}(x)]$. By Definition 4.1(iii), $|\mathcal{H}| < 2n$, and therefore the total number of recursive calls is bounded by $4n + \sum_x \text{DIAM}(x)/\text{NORM}(x)$, where the summation is over $\mathcal{H}$ nodes whose NORM-values differ from their parents' NORM-values.

Now consider the bucketing costs of VISIT if implemented with the bucket-heap. According to steps 2 and 3, a node $y$ is bucketed either because $\text{VISIT}(p(y), \cdot)$ was called for the first time, or its parent $p(y)$ was removed from the first open bucket (of some bucket array), say bucket $[a, a + \text{NORM}(p(y)))$. In either case, this means that $d(s, p(y)) \in [a, a + \text{NORM}(p(y)))$ and that $d(s, y) \in [a, a + \text{NORM}(p(y)) + \text{DIAM}(p(y)))$. To use the terminology of Lemma 4.3, $\Delta_y \leq \lceil \text{DIAM}(p(y))/\text{NORM}(p(y)) \rceil$, and the total bucketing costs would be #(buckets scanned) + #(insertions) + #(dec-keys) + $\sum_x \log(\text{DIAM}(p(x))/\text{NORM}(p(x)) + 1)$, which is $O(\phi(\mathcal{H}) + m + n)$. ☐

In section 5 we give a method for constructing a proper hierarchy $\mathcal{H}$ such that $\phi(\mathcal{H}) = O(n)$. This bound together with Lemma 4.4 shows that we can compute SSSP in $O(\text{SPLIT-FINDMIN}(m,n))$ time, given a suitable hierarchy. Asymptotically speaking, this bound is the best we are able to achieve. However, the promising experimental results of a simplified version of our algorithm [PRS02] have led us to design an alternate implementation of GENERALIZED-VISIT that is both theoretically fast and easier to code.

### 4.5. A practical implementation of GENERALIZED-VISIT.

In this section we present another implementation of GENERALIZED-VISIT, called VISIT-B. Although VISIT-B is a bit slower than VISIT in the asymptotic sense, it has other advantages. Unlike VISIT, VISIT-B treats all internal hierarchy nodes in the same way and is generally more streamlined. VISIT-B also works with any optimal off-the-shelf priority queue, such as a Fibonacci heap [FT87]. We will prove later that the asymptotic running time of VISIT-B is $O(m + n\log^* n)$. Therefore, if $m/n = \Omega(\log^* n)$, both VISIT and VISIT-B run in optimal $O(m)$ time.

The pseudocode for VISIT-B is given as follows.

```
Visit-B($x$, $[a,b)$).

        Input: $x$ is a node in a proper hierarchy $\mathcal{H}$; $V(x)$ is $(S,[a,b))$-safe and
        Invariant 2.1 is satisfied.

        Output guarantee: Invariant 2.1 is satisfied and $S_{post} = S_{pre} \cup V(x)^{[a,b)}$,
        where $S_{pre}$ and $S_{post}$ are the set $S$ before and after the call.

    1. If $x$ is a leaf and $D(x) \in [a,b)$, then let $S := S \cup \{x\}$, relax all edges
       incident on $x$, restoring Invariant 2.1, and return.
    2. If Visit-B$(x,\cdot)$ is being called for the first time, put $x$'s children in $\mathcal{H}$
       in a heap associated with $x$, where the key of a node is its $D$-value.
       Choose $a_x$ as in Visit and initialize $a' := a_x$ and $\chi := \emptyset$.
    3. While $a' < b$ and either $\chi$ or $x$'s heap is nonempty,
           While there exists a $y$ in $x$'s heap with $D(y) \in [a', a' + \text{norm}(x))$
               Remove $y$ from the heap
               $\chi := \chi \cup \{y\}$
           For each $y \in \chi$
               Visit-B$(y, [a', a' + \text{norm}(x)))$
               If $V(y) \subseteq S$, then set $\chi := \chi \backslash \{y\}$
           $a' := a' + \text{norm}(x)$
```

The proof of correctness for Visit-B follows the same lines as that for Visit. It is easy to establish that before the for-loop in step 3 is executed, $\chi = \{y : p(y) = x, D(y) < a' + \text{norm}(x), \text{ and } V(y) \not\subseteq S\}$, so Visit-B is actually a more straightforward implementation of Generalized-Visit than Visit. In Visit-B the norm$(x)$-partition for $x$ corresponds to $x$'s children, whereas in Visit the partition begins with $x$'s children but is decomposed progressively.

Lemma 4.5. *Let $\mathcal{H}$ be a proper hierarchy. Computing SSSPs with* Visit-B *on $\mathcal{H}$ takes time $O(\text{split-findmin}(m,n) + \psi(\mathcal{H}))$, where split-findmin$(m,n)$ is the complexity of the split-findmin problem and*

$$\psi(\mathcal{H}) \;=\; \sum_{x \in \mathcal{H}} \left( \frac{\text{diam}(x)}{\text{norm}(x)} + \text{deg}(x) \log \text{deg}(x) \right).$$

*Proof.* The split-findmin term plays the same role in Visit-B as in Visit. Visit-B is different than Visit in that it makes recursive calls on *all* hierarchy nodes, not just those with different norm-values than their parents. Using the same argument as in Lemma 4.5, we can bound the number of recursive calls of the form Visit-B$(x,\cdot)$ as diam$(x)$/norm$(x) + 2$; this gives the first summation in $\psi(\mathcal{H})$. Assuming an optimal heap is used (for example, a Fibonacci heap [FT87]), all decrease-keys take $O(m)$ time, and all deletions take $\sum_x \text{deg}(x) \log \text{deg}(x)$ time. The bound on deletions follows since each of the deg$(x)$ children of $x$ is inserted into and deleted from $x$'s heap at most once. ∎

In section 5 we construct a hierarchy $\mathcal{H}$ such that $\psi(\mathcal{H}) = \Theta(n\log^* n)$, implying an overall bound on Visit-B of $O(m + n\log^* n)$, since split-findmin$(m,n) = O(m\alpha(m,n)) = O(m + n\log^* n)$. Even though $\psi(\mathcal{H}) = \Omega(n\log^* n)$ in the worst case, we are only able to construct very contrived graphs for which this lower bound is tight.

**5. Efficient construction of balanced hierarchies.** In this section we construct a hierarchy that works well for both Visit and Visit-B. The construction procedure has three distinct phases. In phase 1 we find the graph's minimum spanning tree, denoted $M$, and classify its edges by length. This classification immediately induces a coarse hierarchy, denoted $\mathcal{H}_0$, which is analogous to the *component hierarchy* defined by Thorup [Tho99] for integer-weighted graphs. Although $\mathcal{H}_0$ is proper, using it to run Visit or Visit-B may result in a slow SSSP algorithm. In particular, $\phi(\mathcal{H}_0)$ and $\psi(\mathcal{H}_0)$ can easily be $\Theta(n \log n)$, giving no improvement over Dijkstra's algorithm. Phase 2 facilitates phase 3, in which we produce a *refinement* of $\mathcal{H}_0$, called $\mathcal{H}$; this is the "well balanced" hierarchy we referred to earlier. The refined hierarchy $\mathcal{H}$ is constructed so as to minimize the $\phi(\mathcal{H})$ and $\psi(\mathcal{H})$ terms in the running times of Visit and Visit-B. In particular, $\phi(\mathcal{H})$ will be $O(n)$, and $\psi(\mathcal{H})$ will be $O(n\log^* n)$. Although $\mathcal{H}$ could be constructed directly from $M$ (the graph's minimum spanning tree), we would not be able to prove the time bound of Theorem 1.1 using this method. The purpose of phase 2 is to generate a collection of small auxiliary graphs that—loosely speaking—capture the structure and edge lengths of certain subtrees of the minimum spanning tree. Using the auxiliary graphs in lieu of $M$, we are able to construct $\mathcal{H}$ in phase 3 in $O(n)$ time.

In section 5.1 we define all the notation and properties used in phases 1, 2, and 3 (sections 5.2, 5.3, and 5.4, respectively). In section 5.5 we prove that $\phi(\mathcal{H}) = O(n)$ and $\psi(\mathcal{H}) = O(n\log^* n)$.

## 5.1. Some definitions and properties.

**5.1.1. The coarse hierarchy.** Our refined hierarchy $\mathcal{H}$ is derived from a *coarse hierarchy* $\mathcal{H}_0$, which is defined here and in section 5.2. Although $\mathcal{H}_0$ is typically very simple to describe, the general definition of $\mathcal{H}_0$ is rather complicated since it must take into account certain extreme circumstances. $\mathcal{H}_0$ is defined w.r.t. an increasing sequence of norm-values: $\text{NORM}_1, \text{NORM}_2, \ldots$, where all edge lengths are at least as large as $\text{NORM}_1$. (Typically $\text{NORM}_{i+1} = 2 \cdot \text{NORM}_i$; however, this is not true in general.) We will say that an edge $e$ is at level $i$ if $\ell(e) \in [\text{NORM}_i, \text{NORM}_{i+1})$, or alternatively, we may write $\text{NORM}(e) = \text{NORM}_i$ to express that $e$ is at level $i$. A level $i$ subgraph is a maximal connected subgraph restricted to edges with level $i$ or less, that is, with length strictly less than $\text{NORM}_{i+1}$. Therefore, the level zero subgraphs consist of single vertices. A level $i$ node in $\mathcal{H}_0$ corresponds to a nonredundant level $i$ subgraph, where a level $i$ subgraph is redundant if it is also a level $i-1$ subgraph. This nonredundancy property guarantees that all nonleaf $\mathcal{H}_0$-nodes have at least two children. The ancestor relationship in $\mathcal{H}_0$ should be clear: $x$ is an ancestor of $y$ if and only if the subgraph of $y$ is contained in the subgraph of $x$, i.e., $V(y) \subseteq V(x)$. The leaves of $\mathcal{H}_0$ naturally correspond to graph vertices, and the internal nodes to subgraphs. The coarse hierarchy $\mathcal{H}_0$ clearly satisfies Definition 4.1(i), (iii), (iv); however, we have to be careful in choosing the norm-values if we want it to be a *proper* hierarchy, that is, for it to satisfy Definition 4.1(ii) as well. Our method for choosing the norm-values is deferred to section 5.2.

**5.1.2. The minimum spanning tree.** By the *cut property* of minimum spanning trees (see [CLRS01, PR02c]) the $\mathcal{H}_0$ w.r.t. $G$ is identical to the $\mathcal{H}_0$ w.r.t. $M$, the minimum spanning tree (MST) of $G$. Therefore, the remainder of this section is mainly concerned with $M$, not the graph itself. If $X \subseteq V(G)$ is a set of vertices, we let $M(X)$ be the minimal connected subtree of $M$ containing $X$. Notice that $M(X)$ can include vertices outside of $X$. Later on we will need $M$ to be a rooted tree in order to talk coherently about a vertex's parent, ancestors, children, and so on. Assume that $M$ is rooted at an arbitrary vertex. The notation $\text{ROOT}(M(X))$ refers to the root of the subtree $M(X)$.

**5.1.3. Mass and diameter.** The MASS of a vertex set $X \subseteq V(G)$ is defined as

$$\textsc{mass}(X) \overset{\mathbf{def}}{=} \sum_{e \in E(M(X))} \ell(e).$$

Extending this notation, we let $M(x) = M(V(x))$ and $\textsc{mass}(x) = \textsc{mass}(V(x))$, where $x$ is a node in *any* hierarchy. Since the MST path between two vertices in $M(x)$ is an upper bound on the shortest path between them, $\textsc{mass}(x)$ is an upper bound on the diameter of $V(x)$. Recall from Definition 4.1 that $\textsc{diam}(x)$ denoted any upper bound on the diameter of $V(x)$; henceforth, we will freely substitute $\textsc{mass}(x)$ for $\textsc{diam}(x)$.

**5.1.4. Refinement of the coarse hierarchy.** We will say that $\mathcal{H}$ is a *refinement* of $\mathcal{H}_0$ if all nodes in $\mathcal{H}_0$ are also represented in $\mathcal{H}$. An equivalent definition, which provides us with better imagery, is that $\mathcal{H}$ is derived from $\mathcal{H}_0$ by *replacing* each node $x \in \mathcal{H}_0$ with a rooted subhierarchy $H(x)$, where the root of $H(x)$ corresponds to (and is also referred to as) $x$ and the leaves of $H(x)$ correspond to the children of $x$ in $\mathcal{H}_0$. Consider a refinement $\mathcal{H}$ of $\mathcal{H}_0$ where each internal node $y$ in $H(x)$ satisfies $\textsc{deg}(y) \neq 1$ and $\textsc{norm}(y) = \textsc{norm}(x)$. One can easily verify from Definitions 3.2 and 4.1 that if $\mathcal{H}_0$ is a proper hierarchy, so too is $\mathcal{H}$. Of course, in order for $\phi(\mathcal{H})$ and $\psi(\mathcal{H})$ to be linear or near-linear, $H(x)$ must satisfy certain properties. In particular, it must be sufficiently short and balanced. By balanced we mean that a node's mass should not be *too* much smaller than its parent's mass.

**5.1.5. Lambda values.** We will use the following $\lambda$-values in order to quantify precisely our notion of balance:

$$\lambda_0 = 0, \quad \lambda_1 = 12 \quad \text{and} \quad \lambda_{q+1} = 2^{\lambda_q \cdot 2^{-q}}.$$

Lemma 5.1 gives a lower bound on the growth of the $\lambda$-values; we give a short proof before moving on.

LEMMA 5.1. $\min\{q : \lambda_q \geq n\} \leq 2\log^* n$.

*Proof.* Let $\mathcal{S}_q$ be a stack of $q$ twos; for example, $\mathcal{S}_3 = 2^{2^2} = 16$. We will prove that $\lambda_q \geq \mathcal{S}_{\lfloor q/2 \rfloor}$, giving the lemma. One can verify that this statement holds for $q \leq 9$. Assume that it holds for all $q' \leq q$.

$$\begin{aligned}
\lambda_{q+1} &= 2^{2^{\lambda_{q-1} \cdot 2^{-(q-1)}} 2^{-q}} && \{\text{definition of } \lambda_{q+1}\} \\
&\geq 2^{2^{\mathcal{S}_{\lfloor (q-1)/2 \rfloor} \cdot 2^{-(q-1)} - q}} && \{\text{inductive assumption}\} \\
&\geq 2^{2^{\mathcal{S}_{\lfloor (q-1)/2 \rfloor - 1}}} = \mathcal{S}_{\lfloor (q+1)/2 \rfloor} && \{\text{holds for } q \geq 9\}.
\end{aligned}$$

The third line follows from the inequality $\mathcal{S}_{\lfloor (q-1)/2 \rfloor} \cdot 2^{-(q-1)} - q \geq \mathcal{S}_{\lfloor (q-1)/2 \rfloor - 1}$, which holds for $q \geq 9$. $\square$

**5.1.6. Ranks.** Recall from section 5.1.4 that our refined hierarchy $\mathcal{H}$ is derived from $\mathcal{H}_0$ by replacing each node $x \in \mathcal{H}_0$ with a subhierarchy $H(x)$. We assign to all nodes in $H(x)$ a nonnegative integer *rank*. The analysis of our construction would become very simple if for every rank $j$ node $y$ in $H(x)$, $\textsc{mass}(y) = \lambda_j \cdot \textsc{norm}(x)$. Although this is our ideal situation, the nature of our construction does not allow us to place any nontrivial lower or upper bounds on the mass of $y$. We will assign ranks in order to satisfy Property 5.1, given below, which ensures us a sufficiently good approximation to the ideal. It is mainly the internal nodes of $H(x)$ that can have subideal ranks; we assign ranks to the leaves of $H(x)$ (representing children of $x$ in $\mathcal{H}_0$) to be as close to the ideal as possible.

We should point out that the assignment of ranks is mostly for the purpose of analysis. Rank information is never stored explicitly in the hierarchy nodes, nor is rank information used, implicitly or explicitly, in the computation of shortest paths. We only refer to ranks in the construction of $\mathcal{H}$ and when analyzing their effect on the $\phi$ and $\psi$ functions.

PROPERTY 5.1. *Let $x \in \mathcal{H}_0$ and $y, z \in H(x) \subseteq \mathcal{H}$.*

(a) *If $y$ is an internal node of $H(x)$, then* $\textsc{norm}(y) = \textsc{norm}(x)$ *and* $\textsc{deg}(y) > 1$.

(b) *If $y$ is a leaf of $H(x)$ (i.e., a child of $x$ in $\mathcal{H}_0$), then $y$ has rank $j$, where $j$ is maximal s.t.* $\textsc{mass}(y)/\textsc{norm}(x) \geq \lambda_j$.

(c) *Let $y$ be a child of a rank $j$ node. We call $y$ stunted if* $\textsc{mass}(y)/\textsc{norm}(x) < \lambda_{j-1}/2$. *Each node has at most one stunted child.*

(d) *Let $y$ be of rank $j$. The children of $y$ can be divided into three sets: $Y_1$, $Y_2$, and a singleton $\{z\}$ such that* $(\textsc{mass}(Y_1) + \textsc{mass}(Y_2))/\textsc{norm}(x) < (2 + o(1)) \cdot \lambda_j$.

(e) *Let $\mathcal{X}$ be the nodes of $H(x)$ of some specific rank. Then* $\sum_{y \in \mathcal{X}} \textsc{mass}(y) \leq 2 \cdot \textsc{mass}(x)$.

Before moving on, let us examine some features of Property 5.1. Part (a) is asserted to guarantee that $\mathcal{H}$ is proper. Part (b) shows how we set the rank of leaves of $H(x)$. Part (c) says that at most one child of any node is less than half its ideal mass. Part (d) is a little technical but basically says that for a rank $j$ node $y$, although $\textsc{mass}(y)$ may be huge, the children of $y$ can be divided into sets $Y_1, Y_2, \{z\}$ such that $Y_1$ and $Y_2$ are of reasonable mass—around $\lambda_j \cdot \textsc{norm}(x)$. However, no bound is placed on the mass contributed by $z$. Part (e) says that if we restrict our attention to the nodes of a particular rank, their subgraphs do not overlap in too many places. To see how two subgraphs might overlap, consider $\{x_i\}$, the set of nodes of some rank in $H(x)$. By our construction it will always be the case that the vertex sets $\{V(x_i)\}$ are disjoint; however, this does not imply that the subtrees $\{M(x_i)\}$ are edge-disjoint because $M(x_i)$ can, in general, be much larger than $V(x_i)$.

We show in section 5.5 that if $\mathcal{H}$ is a refinement of $\mathcal{H}_0$ and $\mathcal{H}$ satisfies Property 5.1, then $\phi(\mathcal{H}) = O(n)$ and $\psi(\mathcal{H}) = O(n\log^* n)$. Recall from Lemmas 4.4 and 4.5 that $\phi(\mathcal{H})$ and $\psi(\mathcal{H})$ are terms in the running times of VISIT and VISIT-B, respectively.

**5.2. Phase 1: The MST and the coarse hierarchy.** Pettie and Ramachandran [PR02c] recently gave an MST algorithm that runs in time proportional to the decision-tree complexity of the MST problem. As the complexity of MST is trivially $\Omega(m)$ and only known to be $O(m\alpha(m, n))$ [Chaz00], it is unknown whether this cost will dominate or be dominated by the $\textsc{split-findmin}(m, n)$ term. (This issue is mainly of theoretical interest.) In the analysis we use $\textsc{mst}(m, n)$ to denote the cost of computing the MST. This may be interpreted as the decision-tree complexity of MST [PR02c] or the randomized complexity of MST, which is known to be linear [KKT95, PR02b].

Recall from section 5.1.1 that $\mathcal{H}_0$ was defined w.r.t. an arbitrary increasing sequence of $\textsc{norm}$-values. We describe below exactly how the $\textsc{norm}$-values are chosen, then prove that $\mathcal{H}_0$ is a proper hierarchy. Our method depends on how large $r$ is, which is the ratio of the maximum-to-minimum edge length in the minimum spanning tree. If $r < 2^n$, which can easily be determined in $O(n)$ time, then the possible $\textsc{norm}$-values are $\{\ell_{\min} \cdot 2^i \;:\; 0 \leq i \leq \log r + 1\}$, where $\ell_{\min}$ is the minimum edge length in the graph. If $r \geq 2^n$, then let $e_1, \ldots, e_{n-1}$ be the edges in $M$ in nondecreasing order by length and let $J = \{1\} \cup \{j : \ell(e_j) > n \cdot \ell(e_{j-1})\}$ be the indices that mark large separations in the $(\ell(e_i))_{1\leq i<n}$ sequence. The possible NORM-values are then $\{\ell(e_j) \cdot 2^i \ : \ i \geq 0,\ j \in J \text{ and } \ell(e_j) \cdot 2^i < \ell(e_{j+1})\}$.

Under either definition, $\textsc{norm}_i$ is the $i$th largest NORM-value, and for an edge $e \in E(M)$, $\textsc{norm}(e) = \textsc{norm}_i$ if $\ell(e) \in [\textsc{norm}_i, \textsc{norm}_{i+1})$. Notice that if no edge length falls within the interval $[\textsc{norm}_i, \textsc{norm}_{i+1})$, then $\textsc{norm}_i$ is an unused NORM-value. We only need to keep track of the NORM-values in use, of which there are no more than $n-1$.

LEMMA 5.2. *The coarse hierarchy $\mathcal{H}_0$ is a proper hierarchy.*

*Proof.* As we observed before, parts (i), (iii), and (iv) of Definition 4.1 are satisfied for any monotonically increasing sequence of NORM-values. Definition 4.1(ii) states that if $x$ is a hierarchy node, either $\textsc{norm}(p(x))/\textsc{norm}(x)$ is an integer or $\textsc{diam}(x)/\textsc{norm}(p(x)) < 1$. Suppose that $x$ is a hierarchy node and $\textsc{norm}(p(x))/\textsc{norm}(x)$ is not integral; then $\textsc{norm}(x) = \ell(e_{j_1}) \cdot 2^{i_1}$ and $\textsc{norm}(p(x)) = \ell(e_{j_2}) \cdot 2^{i_2}$, where $j_2 > j_1$. By our method for choosing the NORM-values, the lengths of all MST edges are either at least $\ell(e_{j_2})$ or less than $\ell(e_{j_2})/n$. Since edges in $M(x)$ have length less than $\ell(e_{j_2})$, and hence less than $\ell(e_{j_2})/n$, $\textsc{diam}(x) < (|V(x)|-1) \cdot \ell(e_{j_2})/n < \ell(e_{j_2}) \leq \textsc{norm}(p(x))$. ∎

LEMMA 5.3. *We can compute the minimum spanning tree $M$, and* $\textsc{norm}(e)$ *for all $e \in E(M)$, in $O(\textsc{mst}(m,n) + \min\{n \log\log r,\ n \log n\})$ time.*

*Proof.* $\textsc{mst}(m,n)$ represents the time to find $M$. If $r < 2^n$, then by Lemma 2.2 we can find $\textsc{norm}(e)$ for all $e \in M$ in $O(\log r + n \log\log r) = O(n \log\log r)$ time. If $r \geq 2^n$, then $n \log\log r = \Omega(n \log n)$, so we simply sort the edges of $M$ and determine the indices $J$ in $O(n \log n)$ time. Suppose there are $n_j$ edges $e$ s.t. $\textsc{norm}(e)$ is of the form $\ell(e_j) \cdot 2^i$. Since $\ell(e)/\ell(e_j) \leq n^{n_j}$, we need only generate $n_j \log n$ values of the form $\ell(e_j) \cdot 2^i$. A list of the $\sum_j n_j \log n = n \log n$ possible NORM-values can easily be generated in sorted order. By merging this list with the list of MST edge lengths, we can determine $\textsc{norm}(e)$ for all $e \in M$ in $O(n \log n)$ time. ∎

Lemma 5.4, given below, will come in handy in bounding the running time of our preprocessing and SSSP algorithms. It says that the total normalized mass in $\mathcal{H}_0$ is linear in $n$. Variations of Lemma 5.4 are at the core of the hierarchy approach [Tho99, Hag00, Pet04, Pet02b].

LEMMA 5.4.

$$\sum_{x \in \mathcal{H}_0} \frac{\textsc{mass}(x)}{\textsc{norm}(x)} < 4(n-1).$$

*Proof.* Recall that the notation $\textsc{norm}(e) = \textsc{norm}_i$ stands for $\ell(e) \in [\textsc{norm}_i, \textsc{norm}_{i+1})$, where $\textsc{norm}_i$, is the $i$th largest NORM-value. Observe that if $e \in M$ is an MST edge with $\textsc{norm}(e) = \textsc{norm}_i$, $e$ can be included in $\textsc{mass}(x)$ for no more than one $x$ at levels $i, i+1, \ldots$ in $\mathcal{H}_0$. Also, it follows from our definitions that for every $\textsc{norm}_i$ in use, $\textsc{norm}_{i+1}/\textsc{norm}_i \geq 2$, and for any MST edge, $\ell(e)/\textsc{norm}(e) < 2$. Therefore, we can bound the normalized mass in $\mathcal{H}_0$ as

$$\begin{aligned}\sum_{x \in \mathcal{H}_0} \frac{\textsc{mass}(x)}{\textsc{norm}(x)} &\leq \sum_{\substack{e \in M \\ \textsc{norm}(e)=\textsc{norm}_i}} \sum_{j=i}^{\infty} \frac{\ell(e)}{\textsc{norm}_j} \\ &\leq \sum_{\substack{e \in M \\ \textsc{norm}(e)=\textsc{norm}_i}} \sum_{j=i}^{\infty} \frac{\ell(e)}{2^{j-i} \cdot \textsc{norm}_i} < 4(n-1). \qquad \blacksquare\end{aligned}$$

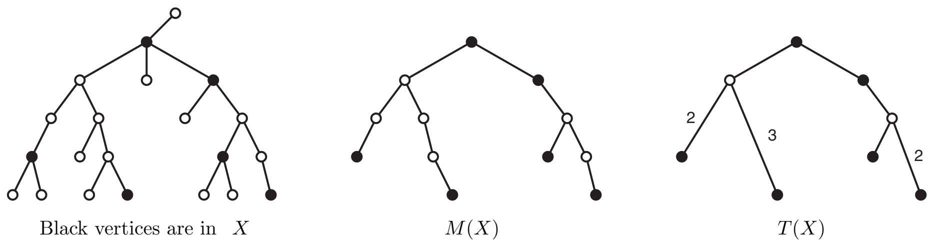


FIG. 2. *On the left is a subtree of $M$, the MST, where $X$ is the set of blackened vertices. In the center is $M(X)$, the minimal subtree of $M$ connecting $X$, and on the right is $T(X)$, derived from $M(X)$ by splicing out unblackened degree 2 nodes in $M(X)$ and adjusting edge lengths appropriately. Unless otherwise marked, all edges in this example are of length* 1.

Implicit in Lemma 5.4 is a simple accounting scheme where we treat mass, or more accurately normalized mass, as a currency equivalent to computational work. A hierarchy node $x$ "owns" $\text{MASS}(x)/\text{NORM}(x)$ units of currency. If we can then show that the share of some computation relating to $x$ is bounded by $k$ times its currency, the total time for this computation is $O(kn)$, that is, of course, if all computation is attributable to some hierarchy node. Although simple, this accounting scheme is very powerful and can become quite involved [Pet04, Pet02b, Pet03].

**5.3. Phase 2: Constructing $\boldsymbol{T(x)}$ trees.** Although it is possible to construct an $H(x)$ that satisfies Property 5.1 by working directly with the subtree $M(x)$, we are unable to efficiently compute $H(x)$ in this way. The problem is that we have time roughly proportional to the size of $H(x)$ to construct $H(x)$, whereas $M(x)$ could be significantly larger than $H(x)$. Our solution is to construct a *succinct tree* $T(x)$ that preserves the essential structure of $M(x)$ while having size roughly the same as $H(x)$.

For $X \subseteq V(G)$, let $T(X)$ be the subtree derived from $M(X)$ by *splicing* out all single-child vertices in $V(M(X)) - X$. That is, we replace each chain of vertices in $M(X)$, where only the end vertices are potentially in $X$, with a single edge; the length of this edge is the sum of its corresponding edge lengths in $M(X)$. Since there is a correspondence between vertices in $T(X)$ and $M$, we will refer to $T(X)$ vertices by their names in $M$. Figure 2 gives examples of $M(X)$ and $T(X)$ trees, where $X$ is the set of blackened vertices.

If $x \in \mathcal{H}_0$ and $\{x_j\}_j$ is the set of children of $x$, then let $T(x)$ be the tree $T(\{\text{ROOT}(M(x_j))\}_j)$; note that $\text{ROOT}(M(x))$ is included in $\{\text{ROOT}(M(x_j))\}_j$. Since only some of the edges of $M(x)$ are represented in $T(x)$, it is possible that the total length of $T(x)$ is significantly less than the total length of $M(x)$ (the MASS of $M(x)$); however, we will require that any subgraph of $T(x)$ have roughly the same mass as an equivalent subgraph in $M(x)$. In order to accomplish this we attribute certain amounts of mass to the *vertices* of $T(x)$ as follows. Suppose that $y$ is a child of $x$ in $\mathcal{H}_0$ and $v = \text{ROOT}(y)$ is the corresponding root vertex in $T(x)$. We let $\text{MASS}(v) = \text{MASS}(y)$. All other vertices in $T(x)$ have zero mass. The mass of a subtree of $T(x)$ is then the sum of its edge lengths plus the collective mass of its vertices.

We will think of a subtree of $T(x)$ as corresponding to a subtree of $M(x)$. Each edge in $T(x)$ corresponds naturally to a path in $M(x)$, and each vertex in $T(x)$ with nonzero mass corresponds to a subtree of $M(x)$.

LEMMA 5.5. *For $x \in \mathcal{H}_0$,*

(i) $\text{DEG}(x) \leq |V(T(x))| < 2 \cdot \text{DEG}(x)$;

(ii) *let $T_1$ be a subtree of $T(x)$ and $T_2$ be the corresponding tree in $M(x)$. Then*

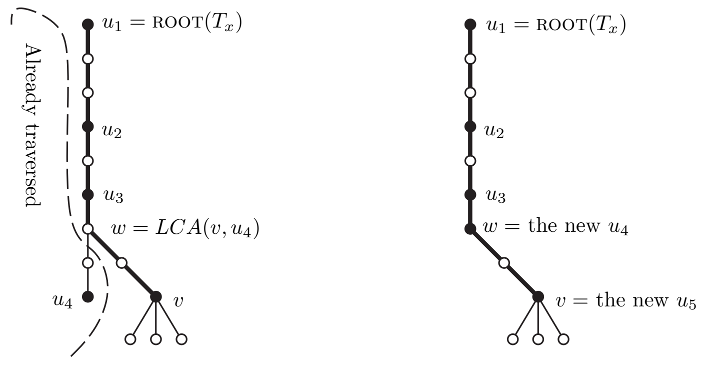

FIG. 3. *The blackened vertices represent those known to be in $T(x)$. The active path of the traversal is shown in bold edges. Before $v$ is processed (left) the stack consists of $\langle u_1, u_2, u_3, u_4\rangle$, where $u_4$ is the last vertex in the traversal known to be in $T(x)$ and $w = LCA(v, u_4)$, which implies $w \in T(x)$. After $v$ is processed (right) the stack is set to $\langle u_1, u_2, u_3, w, v\rangle$ and $w$ is blackened.*

$\text{MASS}(T_2) \le \text{MASS}(T_1) \le 2 \cdot \text{MASS}(T_2)$.

*Proof.* Part (i) follows from two observations. First, $T(x)$ has no degree two vertices. Second, there are at most $\text{DEG}(x)$ leaves of $T(x)$ since each such leaf corresponds to a vertex $\text{ROOT}(M(y))$ for some child $y$ of $x$ in $\mathcal{H}_0$. Part (ii) follows since all mass in $T_2$ is represented in $T_1$, and each edge in $T_2$ contributes to the mass of at most one edge and one vertex in $T_1$. ☐

We construct $T(x)$ with a kind of depth first traversal of the minimum spanning tree, using the procedure SUCCINCT-TREE, given below. SUCCINCT-TREE focuses on some fixed $\mathcal{H}_0$-node $x$. We will explain how SUCCINCT-TREE works with the aid of the diagram in Figure 3. At every point in the traversal we maintain a stack of vertices $\langle u_1, \ldots, u_q\rangle$ consisting of all vertices known to be in $T(x)$, whose parents in $T(x)$ are not yet fixed. The stack has the following properties: $u_i$ is ancestral to $u_{i+1}$, $\langle u_1, \ldots, u_{q-1}\rangle$ are on the *active path* of the traversal, and $u_q$ is the last vertex known to be in $T(x)$ encountered in the traversal.

In Figure 3 the stack consists of $\langle u_1, \ldots, u_4\rangle$, where $\langle u_1, u_2, u_3\rangle$ are on the active path of the traversal, marked in bold edges. The preprocessing of $v$ (before making recursive calls) is to do nothing if $v \notin \{\text{ROOT}(M(x_j))\}_j$. Otherwise, we update the stack to reflect our new knowledge about the edges and vertices of $T(x)$. The vertex $w = LCA(u_q, v) = LCA(u_4, v)$ must be in $T(x)$. There are three cases: either $w$ is the ultimate or penultimate vertex in the stack ($u_q$ or $u_{q-1}$), that is, we already know $w \in T(x)$, or $w$ lies somewhere on the path between $u_q$ and $u_{q-1}$. Figure 3 diagrams the third situation. Because no $T(x)$ vertices were encountered in the traversal between $u_q = u_4$ and $v$, there can be no new $T(x)$ vertices discovered on the path between $u_q$ and $w$. Therefore, we can pop $u_q$ off the stack, designating its parent in $T(x)$ to be $w$, and push $w$ and $v$ onto the stack. The other two situations, when $w = u_q$ or $w = u_{q-1}$, are simpler. If $w = u_q$, then we simply push $v$ onto the stack, and if $w = u_{q-1}$, we pop $u_q$ off the stack and push $v$ on. Now consider the postprocessing of $v$ (performed after all recursive calls), and let $u_{q-1}, u_q$ be the last two vertices in the stack. Suppose that $v = u_{q-1}$. We cannot simply do nothing, because when the active path retracts there will be two stack vertices ($v = u_{q-1}$ and $u_q$) outside of the active path, contrary to the stack properties. However, because no $T(x)$ vertices were discovered between $u_q$ and $u_{q-1}$, we can safely say that $u_{q-1}$ is the parent of $u_q$ in $T(x)$. So, to maintain the stack properties, we pop off $u_q$ and add the edge $(u_q, u_{q-1})$ to $T(x)$.

```
SUCCINCT-TREE($v$): A procedure for constructing $T(x)$, for a given $x \in \mathcal{H}_0$.
        The argument $v$ is a vertex in the MST $M$.
        The stack for $T(x)$ consists of vertices $\langle u_1, \ldots, u_q \rangle$, which
        are known to be in $T(x)$ but whose parents in $T(x)$ are
        not yet known. All but $u_q$ are on the active path of the
        DFS traversal. Initially the stack for $T(x)$ is empty.

1.    If $v = \text{ROOT}(y)$, where $y$ is a child of $x$ in $\mathcal{H}_0$, then
2.        Let $w = LCA(v, u_q)$
3.        If $w \neq u_q$
4.            POP $u_q$ off the stack
5.            Designate $(u_q, w)$ an edge in $T(x)$
6.            If $w \neq u_{q-1}$
7.                PUSH $w$ on the stack
8.        PUSH $v$ on the stack
9.    Call SUCCINCT-TREE on all the children of $v$ in $M$
10.   Let $u_{q-1}, u_q$ refer to the last two elements in the current stack
11.   If $v = u_{q-1}$
12.       POP $u_q$ off the stack
13.       Designate $(u_q, u_{q-1}) = (u_q, v)$ an edge in $T(x)$
```

LEMMA 5.6. *Given the MST and a list of its edges ordered by level, $\mathcal{H}_0$ and $\{T(x)\}_x$ can be constructed in $O(n)$ time.*

*Proof.* We construct $\mathcal{H}_0$ with a union-find structure and mark all vertices in $M$ as roots of $M(x)$ for (one or more) $x \in \mathcal{H}_0$. It is easy to see that we can construct all $T(x)$ for $x \in \mathcal{H}_0$, with one tree traversal given in procedure SUCCINCT-TREE. We simply maintain a different stack for each $T_x$ under construction. Thus if $v$ is the root of several $M(y_1), M(y_2), \ldots$, where $y_i \in \mathcal{H}_0$, we simply reexecute lines 1–8 and 10–13 of SUCCINCT-TREE for each of $v$'s roles. Using a well-known union-find–based least common ancestors (LCA) algorithm [AHU76, Tar79b], we can compute the LCAs in line 2 in $O(n\alpha(n))$ time, since the number of finds is linear in the number of nodes in $\mathcal{H}_0$. If we use the scheme of Buchsbaum et al. [BKRW98] instead, the cost of finding LCAs is linear; however, since this algorithm is offline (it does not handle LCA queries in the middle of a tree traversal, unlike [AHU76, Tar79b]), we would need to determine what the LCA queries are with an initial pass over the tree. Finally, we compute the length function in $T(x)$ as follows. If $(u, v) \in E(T(x))$ and $v$ is ancestral to $u$ in $M$, then $\ell(u, v) = d_M(u, \text{ROOT}(M)) - d_M(v, \text{ROOT}(M))$, where $d_M$ is the distance function for $M$. Clearly the $d_M(\cdot, \text{ROOT}(M))$ function can be computed in $O(n)$ time. See Lemma 2.1 for a simulation of subtraction in the comparison-addition model. ∎

## 5.4. Phase 3: Constructing the refined hierarchy.

We show in this section how to construct an $H(x)$ from $T(x)$ that is consistent with Property 5.1.

The REFINE-HIERARCHY procedure, given as pseudocode below, constructs $H(x)$ in a bottom-up fashion by traversing the tree $T(x)$. A call to REFINE-HIERARCHY($v$), where $v \in T(x)$, will produce an array of sets $v[\cdot]$ whose elements are nodes in $H(x)$ that represent (collectively) the subtree of $T(x)$ rooted at $v$. The set $v[j]$ holds rank $j$ nodes, which, taken together, are not yet massive enough to become a rank $j+1$ node. We extend the mass notation to sets $v[\cdot]$ as follows. Bear in mind that this mass is w.r.t. the tree $T(x)$, not $M(x)$. By Lemma 5.5(ii), mass w.r.t. $T(x)$ is a good approximation to the mass of the equivalent subtree in $M(x)$:

$$\textsc{mass}(v[j]) \;=\; \textsc{mass}\left(\bigcup_{j' \le j} \; \bigcup_{y \in v[j']} V(y)\right).$$

```
REFINE-HIERARCHY($v$): Constructing $H(x)$, for a given $x \in \mathcal{H}_0$,
        where $v$ is a vertex in $T(x)$.
1.      Initialize $v[j] := \emptyset$ for all $j$.
2.      If $v = \textsc{root}(M(y))$ for some child $y$ of $x$ in $\mathcal{H}_0$
3.              Let $j$ be maximal s.t. $\textsc{mass}(y)/\textsc{norm}(x) \ge \lambda_j$
4.              $v[j] := \{y\}$    (i.e., $y$ is implicitly designated a rank $j$ node)
5.      For each child $w$ of $v$ in $T(x)$:
6.              REFINE-HIERARCHY($w$)
7.              For all $i$,  $v[i] := v[i] \cup w[i]$
8.              Let $j$ be maximal such that $\textsc{mass}(v[j])/\textsc{norm}(x) \ge \lambda_{j+1}$
9.              Promote $v[0], \ldots, v[j]$      (see Definition 5.7)
10.     If $v$ is the root of $T(x)$, promote $v[0], v[1], \ldots$ until one node remains.
        (This final node is the root of $H(x)$.)
```

The structure of Refine-Hierarchy is fairly simple. To begin with, we initialize $v[\cdot]$ to be an array of empty sets. Then, if $v$ is a root vertex of a child $y$ of $x$ in $\mathcal{H}_0$, we create a node representing $y$ and put it in the proper set in $v[\cdot]$; which set receives $y$ depends only on $\textsc{mass}(y)$. Next we process the children of $v$. On each pass through the loop, we pick an as yet unprocessed child $w$ of $v$; recurse on $w$, producing sets $w[\cdot]$ representing the subtree rooted at $w$; and then merge the sets $w[\cdot]$ into their counterparts in $v[\cdot]$. At this point, the mass of some sets may be beyond a critical threshold: the threshold for $v[j]$ is $\lambda_{j+1} \cdot \textsc{norm}(x)$. In order to restore a quiescent state in the sets $v[\cdot]$ we perform *promotions* until no set's mass is above threshold.

Definition 5.7. *Promoting the set $v[j]$ involves removing the nodes from $v[j]$, making them the children of a new rank $j+1$ node, and then placing this node in $v[j+1]$. There is one exception: if $|v[j]| = 1$, then to comply with Definition* 4.1(iii), *we simply move the node from $v[j]$ to $v[j+1]$. Promoting the sets $v[0], v[1], \ldots, v[j]$ means promoting $v[0]$, then $v[1]$, up to $v[j]$, in that order.*

Suppose that after merging $w[\cdot]$ into $v[\cdot]$, $j$ is maximal such that $\textsc{mass}(v[j])$ is beyond its threshold of $\lambda_{j+1} \cdot \textsc{norm}(x)$ (there need not be such a $j$). We promote the sets $v[0], \ldots, v[j]$, which has the effect of emptying $v[0], \ldots, v[j]$ and adding a new node to $v[j+1]$ representing the nodes formerly in $v[0], \ldots, v[j]$. Lemma 5.8, given below, shows that we can compute the $H(x)$ trees in linear time.

Lemma 5.8. *Given $\{T(x)\}_x$, $\{H(x)\}_x$ can be constructed to satisfy Property* 5.1 *in $O(n)$ time.*

*Proof.* We first argue that Refine-Hierarchy produces a refinement $\mathcal{H}$ of $\mathcal{H}_0$ that satisfies Property 5.1. We then look at how to implement it in linear time.

Property 5.1(a) states that internal nodes in $H(x)$ must have $\textsc{norm}$-values equal to that of $x$, which we satisfy by simply assigning them the proper $\textsc{norm}$-values, and that no node of $H(x)$ has one child. By our treatment of one-element sets in the promotion procedure of Definition 5.7, it is simply impossible to create a one-child node in $H(x)$. Property 5.1(e) follows from Lemma 5.5(ii) and the observation that the mass (in $T(x)$) represented by nodes of the same rank is disjoint. Now consider Property 5.1(c), regarding stunted nodes. We show that whenever a set $v[j]$ accepts a new node $z$, either $v[j]$ is immediately promoted, or $z$ is not stunted, or the promotion of $z$ into $v[j]$ represents the *last* promotion in the construction of $H(x)$. Consider the pattern of promotions in line 9. We promote the sets $v[0], \ldots, v[j]$ in a cascading fashion: $v[0]$ to $v[1]$, $v[1]$ to $v[2]$, and so on. The only set accepting a new node that is not immediately promoted is $v[j+1]$, so in order to prove Property 5.1(c) we must show that the node derived from promoting $v[0], \ldots, v[j]$ is not stunted. By choice of $j$, $\textsc{mass}(v[j]) \geq \lambda_{j+1} \cdot \textsc{norm}(x)$, where mass is w.r.t. the tree $T(x)$. By Lemma 5.5(ii) the mass of the equivalent tree in $M(x)$ is at least $\lambda_{j+1} \cdot \textsc{norm}(x)/2$, which is exactly the threshold for this node being stunted. Finally, consider Property 5.1(d). Before the merging step in line 7, none of the sets in $v[\cdot]$ or $w[\cdot]$ is massive enough to be promoted. Let $v[\cdot]$ and $w[\cdot]$ denote the sets associated with $v$ and $w$ before the merging in step 7, and let $v'[\cdot]$ denote the set associated with $v$ after step 7. By the definition of $\textsc{mass}$ we have

$$\textsc{mass}(v'[j]) = \textsc{mass}(v[j]) + \textsc{mass}(w[j]) + \ell(v,w) < 2 \cdot \lambda_{j+1} \cdot \textsc{norm}(x) + \ell(v,w).$$

Since $(v,w)$ is an edge in $T(x)$, it can be arbitrarily large compared to $\textsc{norm}(x)$, meaning we cannot place any reasonable bound on $\textsc{mass}(v'[j])$ after the merging step. Let us consider how Property 5.1(d) is maintained. Suppose that $v'[j]$ is promoted in lines 9 or 10, and let $y$ be the resulting rank $j+1$ node. Using the terminology from Property 5.1(d), let $Y_1 = v[j], Y_2 = w[j]$ and let $z$ be the node derived by promoting $v'[0], \ldots, v'[j-1]$. Since neither $v[j]$ nor $w[j]$ was sufficiently massive to be promoted before they were merged, we have $(\textsc{mass}(Y_1) + \textsc{mass}(Y_2))/\textsc{norm}(x) < 2\lambda_{j+1}$. This is slightly stronger than what Property 5.1(d) calls for, which is the inequality $< (2 + o(1))\lambda_{j+1}$. We'll see why the $(2 + o(1))$ is needed below.

Suppose that we implemented Refine-Hierarchy in a straightforward manner. Let $L$ be the (known) maximum possible index of any nonempty set $v[\cdot]$ during the course of Refine-Hierarchy. One can easily see that the initialization in lines 1–4 takes $O(L+1)$ time and that, exclusive of recursive calls, each time through the for-loop in line 5 takes $O(L+1)$ amortized time. (The bound on line 5 is *amortized* since promoting a set $v[j]$ takes worst case $O(|v[j]|+1)$ time but only constant amortized time.) The only hidden costs in this procedure are updating the $\textsc{mass}$ of sets, which is done as follows. After the merging step in line 7, we simply set $\textsc{mass}(v[j]) := \textsc{mass}(v[j]) + \ell(v,w) + \textsc{mass}(w[j])$ for each $j \leq L$. Therefore the total cost of computing $H(x)$ from $T(x)$ is $O((L+1) \cdot |T(x)|)$. We can bound $L$ as $L \leq 2\log^*(4n)$ as follows. The first node placed in any previously empty set is unstunted; therefore, by Lemma 5.1, the maximum nonempty set has rank at most $2\log^*(\textsc{mass}(T(x))/\textsc{norm}(x))$. By Lemma 5.5(ii) and the construction of $\mathcal{H}_0$, $\textsc{mass}(T(x)) \leq 2 \cdot \textsc{mass}(M(x)) < 4(n-1) \cdot \textsc{norm}(x)$.

In order to reduce the cost to linear we make a couple adjustments to the Refine-Hierarchy procedure. First, $v[\cdot]$ is represented as a linked list of nonempty sets. Second, we update the mass variables in a lazy fashion. The time for steps 1–4 is dominated by the time to find the appropriate $j$ in step 3, which takes time $t_1$—see below. The time for merging the $v[\cdot]$ and $w[\cdot]$ sets in line 7 is only proportional to the shorter list; this time bound is given by expression $t_2$ below.

$$t_1 = O\left(1 + \log^* \frac{\textsc{mass}(v)}{\textsc{norm}(x)}\right),$$

$$t_2 = O\left(1 + \log^* \frac{\min\{\textsc{mass}(v[\cdot]), \textsc{mass}(w[\cdot])\}}{\textsc{norm}(x)}\right),$$

where $\textsc{mass}(v[\cdot])$ is just the total mass represented by the $v[\cdot]$ sets. We update the mass of only the first $t_1 + t_2$ sets in $v[\cdot]$, and, as a rule, we update $v[j+1]$ half as often as $v[j]$. It is routine to show that Refine-Hierarchy will have a lower bound on the mass of $v[j]$ that is off by a 1+o(1) factor, where the $o(1)$ is a function of $j$.[7] This leads to the conspicuous $2 + o(1)$ in Property 5.1(d). To bound the cost of Refine-Hierarchy we model its computation as a binary tree: leaves represent the creation of nodes in lines 1–4, and internal nodes represent the merging events in line 7. The cost of a leaf $f$ is $\log^*(\textsc{mass}(f)/\textsc{norm}(x))$, and the cost of an internal node $f$ with children $f_1$ and $f_2$ is $1 + \log^*(\min\{\textsc{mass}(f_1)/\textsc{norm}(x), \textsc{mass}(f_2)/\textsc{norm}(x)\})$. We can think of charging the cost of $f$ collectively to the mass in the subtree of $f_1$ or $f_2$, whichever is smaller. Therefore, no unit of mass can be charged for two nodes $f$ and $g$ if the total mass under $f$ is within twice the total mass under $g$. The total cost is then

$$\sum_f cost(f) = O\left(|T(x)| + \frac{\textsc{mass}(T(x))}{\textsc{norm}(x)} \cdot \sum_{i=0}^{\infty} \frac{\log^*(2^i)}{2^i}\right) = O\left(\frac{\textsc{mass}(x)}{\textsc{norm}(x)}\right).$$

The last equality follows because $|T(x)| = O(\textsc{mass}(T(x))/\textsc{norm}(x)) = O(\textsc{mass}(M(x))/\textsc{norm}(x))$. Summing over all $x \in \mathcal{H}_0$, the total cost of constructing $\{H(x)\}_{x\in\mathcal{H}_0}$ is, by Lemma 5.4, $O(n)$. ◻

Lemma 5.9. *In $O(\textsc{mst}(m,n) + \min\{n \log\log r, n \log n\})$ time we can construct both the coarse hierarchy $\mathcal{H}_0$ and a refinement $\mathcal{H}$ of $\mathcal{H}_0$ satisfying Property* 5.1.

*Proof.* The proof follows from Lemmas 5.3, 5.6, and 5.8. ◻

**5.5. Analysis.** In this section we prove bounds on the running times of Visit and Visit-B, given an appropriate refined hierarchy such as the one constructed in section 5.4. Theorem 1.1 follows directly from Lemma 5.10, given below, and Lemma 5.9.

Lemma 5.10. *Let $\mathcal{H}$ be any refinement of $\mathcal{H}_0$ satisfying Property* 5.1*. Using $\mathcal{H}$,* Visit *computes SSSP in $O(\textsc{split-findmin}(m,n))$ time, and* Visit-B *computes SSSP in $O(m + n\log^* n)$ time.*

*Proof.* We prove that $\phi(\mathcal{H}) = O(n)$ and $\psi(\mathcal{H}) = O(n\log^* n)$. Together with Lemmas 4.4 and 4.5, this will complete the proof.

With the observation that $\textsc{mass}(x)$ is an upper bound on the diameter of $V(x)$, we will substitute $\textsc{mass}(x)$ for $\textsc{diam}(x)$ in the functions $\phi$ and $\psi$. By Lemma 5.4, the first sum in $\phi$ is $O(n)$. The first sum of $\psi(\mathcal{H})$ is much like that in $\phi$, except we sum over *all* nodes in $\mathcal{H}$, not just those nodes that also appear in $\mathcal{H}_0$. By Property 5.1(a), (c), and (d) and Lemma 5.1, the maximum rank of any node in $H(x)$ is

[7]The proof of this is somewhat tedious. Basically one shows that for $i < j$ the mass of $v[i]$ can be updated at most $2^{j-i} - 1$ times before the mass of $v[j]$ is updated. Since $2^{j-1} - 1 \cdot \lambda_i \ll \lambda_j$, our neglecting to update the mass of $v[j]$ causes a negligible error.

$2\log^*(\textsc{mass}(x)/\textsc{norm}(x)) \leq 2\log^* n$. By Property 5.1(e) the total mass of nodes of one rank in $H(x)$ is bounded by $2 \cdot \textsc{mass}(x)$. Therefore, we can bound the first sum in $\psi(\mathcal{H})$ as $\sum_x \textsc{mass}(x)/\textsc{norm}(x) \leq 4\log^* n \cdot \sum_{x \in \mathcal{H}_0} \textsc{mass}(x)/\textsc{norm}(x)$, which is $O(n\log^* n)$ by Lemma 5.4.

We now turn to the second summations in $\phi(\mathcal{H})$ and $\psi(\mathcal{H})$, which can be written as $\sum_x \textsc{deg}(x) \log(\textsc{mass}(x)/\textsc{norm}(x))$ and $\sum_x \textsc{deg}(x) \log \textsc{deg}(x)$, respectively. Since $\textsc{deg}(x) \leq 1 + \textsc{mass}(x)/\textsc{norm}(x)$, any bound established on the first summation will extend to the second.

Let $y$ be a rank $j$ node. Using the terms from Property 5.1(d), let $\alpha = (\textsc{mass}(Y_1)+ \textsc{mass}(Y_2))/\textsc{norm}(y)$ and $\beta = \textsc{mass}(y)/\textsc{norm}(y) - \alpha$. Property 5.1(c), (d) imply that $\alpha < (2 + o(1)) \cdot \lambda_j$ and that $\textsc{deg}(y) \leq 2\alpha/\lambda_{j-1} + 2$, where the $+2$ represents the stunted child and the child $z$ exempted from Property 5.1(d):

$$\begin{aligned}
\textsc{deg}(y) \log \frac{\textsc{mass}(y)}{\textsc{norm}(y)} &\leq \left(\frac{2\alpha}{\lambda_{j-1}} + 2\right) \log(\alpha + \beta) \qquad \{\text{see explanations below}\} \\
&= O\left(\frac{\max\{\alpha \log(2\lambda_j), \beta\}}{\lambda_{j-1}}\right) \\
&= O\left(\frac{\alpha + \beta}{2^{j-1}}\right) \;=\; O\left(\frac{\textsc{mass}(y)}{\textsc{norm}(y) \cdot 2^{j-1}}\right).
\end{aligned}$$

The first line follows from our bound on $\textsc{deg}(y)$ and the definitions of $\alpha$ and $\beta$. The second line follows since $\alpha < (2+o(1))\lambda_j$ and $\alpha \log(\alpha+\beta) = O(\max\{\alpha \log \alpha, \beta\})$. The last line follows since $\log \lambda_j = \lambda_{j-1}/2^{j-1} > 1$. By the above bound and Property 5.1(e), $\sum_{y \in H(x)} \textsc{deg}(y) \log(\textsc{mass}(y)/\textsc{norm}(y)) = O(\textsc{mass}(x)/\textsc{norm}(x))$. Therefore, by Lemma 5.4, the second summations in both $\phi(\mathcal{H})$ and $\psi(\mathcal{H})$ are bounded by $O(n)$. ☐

## 6. Limits of hierarchy-type algorithms.

In this section we state a simple property (Property 6.1) of all hierarchy-type algorithms and give a lower bound on any undirected SSSP algorithm satisfying that property. The upshot is that our SSSP algorithm is optimal (up to an inverse-Ackermann factor) for a fairly large class of SSSP algorithms, which includes all hierarchy-type algorithms, variations on Dijkstra's algorithm, and even a heuristic SSSP algorithm [G01].

We will state Property 6.1 in terms of directed graphs. Let $\textsc{cycles}(u, v)$ denote the set of all cycles, including nonsimple cycles, that pass through both $u$ and $v$, and let $\textsc{sep}(u, v) = \min_{C \in \textsc{cycles}(u,v)} \max_{e \in C} \ell(e)$. Note that in undirected graphs $\textsc{sep}(u, v)$ corresponds exactly to the longest edge on the MST path between $u$ and $v$.

Property 6.1. *An SSSP algorithm with the* hierarchy property *computes, aside from shortest paths, a permutation $\pi_s : V(G) \to V(G)$ such that for any vertices $u, v$, we find $d(s, u) \geq d(s, v) + \textsc{sep}(u, v) \implies \pi_s(u) > \pi_s(v)$, where $s$ is the source and $d$ the distance function.*

The permutation $\pi_s$ corresponds to the order in which vertices are visited when the source is $s$. Property 6.1 says that $\pi_s$ is loosely sorted by distance, but may invert pairs of vertices if their relative distance is less than their $\textsc{sep}$-value. To see that our hierarchy-based algorithm satisfies Property 6.1, consider two vertices $u$ and $v$. Let $x$ be the LCA of $u$ and $v$ in $\mathcal{H}$, and let $u'$ and $v'$ be the ancestors of $u$ and $v$, respectively, which are children of $x$. By our construction of $\mathcal{H}$, $\textsc{norm}(x) \leq \textsc{sep}(u, v)$. If $d(s, u) \geq d(s, v) + \textsc{sep}(u, v)$, then $d(s, u) \geq d(s, v) + \textsc{norm}(x)$, and therefore the recursive calls on $u'$ and $v'$ that cause $u$ and $v$ to be visited are not passed the same interval argument, since both intervals have width $\textsc{norm}(x)$. The recursive call on $u'$

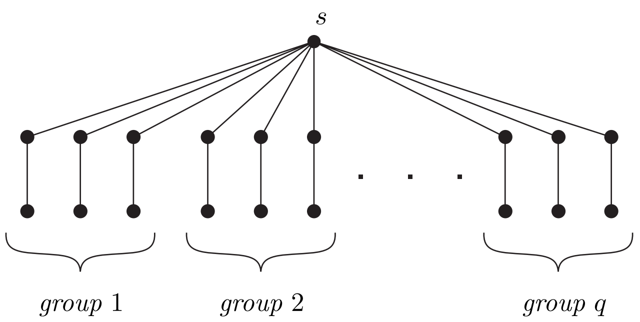

FIG. 4. *The minimum spanning tree of the graph.*

must, therefore, precede the recursive call on $v'$, and $u$ must be visited before $v$.

THEOREM 6.1. *Suppose that our computational model allows any set of functions from $\mathbb{R}^{O(1)} \to \mathbb{R}$ and comparison between two reals. Any SSSP algorithm for real-weighted graphs satisfying Property* 6.1 *makes $\Omega(m + \min\{n \log\log r,\, n \log n\})$ operations in the worst case, where $r$ is the ratio of the maximum to minimum edge length.*

*Proof.* Let $q$ be an integer. Assume without loss of generality that $2q$ divides $n-1$. The MST of the input graph is as depicted in Figure 4. It consists of the source vertex $s$, which is connected to $p = (n-1)/2$ vertices in the top row, each of which is paired with one vertex in the bottom row. All the vertices (except $s$) are divided into disjoint *groups*, where group $i$ consists of exactly $p/q$ randomly chosen pairs of vertices. There are exactly $p!/(p/q)!^q = q^{\Omega(p)}$ possible group arrangements. We will show that any algorithm satisfying Property 6.1 must be able to distinguish them.

We choose edge lengths as follows. All edges in group $i$ have length $2^i$. This includes edges from $s$ to the group's top row and between the two rows. Other non-MST edges are chosen so that shortest paths from $s$ correspond to paths in the MST. Let $v_i$ denote any vertex in the bottom row of group $i$. Then $d(s, v_i) = 2 \cdot 2^i$ and $\text{SEP}(v_i, v_j) = 2^{max\{i,j\}}$. By Property 6.1, $v_i$ must be visited before $v_j$ if $d(s, v_i) + \text{SEP}(v_i, v_j) \leq d(s, v_j)$, which is true for $i < j$ since $2 \cdot 2^i + 2^j \leq 2 \cdot 2^j$. Therefore, any algorithm satisfying Property 6.1 must be prepared to visit vertices in $q^{\Omega(p)}$ distinct permutations and make at least $\Omega(p \log q) = \Omega(n \log\log r)$ comparisons in the worst case. It also must include every non-MST edge in at least one operation, which gives the lower bound. $\square$

Theorem 6.1 shows that our SSSP algorithm is optimal among hierarchy-type algorithms, to within a tiny inverse-Ackermann factor. A lower bound on *directed* SSSP algorithms satisfying Property 6.1 is given in [Pet04]. Theorem 6.1 differs from that lower bound in two respects. First, the [Pet04] bound is $\Omega(m + \min\{n \log r,\, n \log n\})$, which is $\Omega(m + n \log n)$ for even reasonably small values of $r$. Second, the [Pet04] bound holds even if the algorithm is allowed to compute the SEP function (and sort the values) for free. Contrast this with our SSSP algorithm, where the main obstacle to achieving linear time is the need to sort the SEP-values.

## 7. Discussion.

We have shown that with a near-linear time investment in preprocessing, SSSP queries can be answered in very close to linear time. Furthermore, among a natural class of SSSP algorithms captured by Property 5.1, our SSSP algorithm is optimal, aside from a tiny inverse-Ackermann factor. We can imagine several avenues for further research, the most interesting of which is developing a feasible alternative to Property 5.1 that does not have an intrinsic sorting bottleneck. This would be a backward approach to algorithm design: first we define a desirable property, then we hunt about for algorithms with that property. Another avenue, which might have some real-world impact, is to reduce the preprocessing cost of the *directed* shortest path algorithm in [Pet04] from $O(mn)$ to near-linear, as it is in our algorithm.

The marginal cost of computing SSSP with our algorithm may or may not be linear; it all depends on the complexity of the split-findmin structure. This data structure, invented first by Gabow [G85a] for use in a weighted matching algorithm, actually has connections with other fundamental problems. For instance, it can be used to solve both the minimum spanning tree and shortest path tree sensitivity analysis problems [Pet03]. (The sensitivity analysis problem is to decide how much each edge's length can be perturbed without changing the solution tree.) Therefore, by Theorem 4.2 both these problems have complexity $O(m \log \alpha(m,n))$, an $\alpha / \log \alpha$ improvement over Tarjan's path-compression–based algorithm [Tar82]. If we consider the *offline* version of the split-findmin problem, where all splits and decrease-keys are given in advance, one can show that it is reducible to *both* the MST problem and the MST sensitivity analysis problem. None of these reductions proves whether $\textsc{mst}(m,n)$ dominates $\textsc{split-findmin}(m,n)$ or vice versa; however, they do suggest that we have no hope of solving the MST problem [PR02b, PR02c] without first solving the manifestly simpler split-findmin and MST sensitivity analysis problems.

The experimental study of Pettie, Ramachandran, and Sridhar [PRS02] shows that our algorithm is very efficient in practice. However, the [PRS02] study did not explore all possible implementation choices, such as the proper heap to use, the best preprocessing algorithm, or different implementations of the split-findmin structure. To our knowledge no one has investigated whether the other hierarchy-type algorithms [Tho99, Hag00, Pet04] are competitive in real-world scenarios.

An outstanding research problem in parallel computing is to bound the time-work complexity of SSSP. There are several published algorithms on the subject [BTZ98, CMMS98, KS97, M02, TZ96], though none runs in worst-case polylogarithmic time using work comparable to Dijkstra's algorithm. There is clearly a lot of parallelism in the hierarchy-based algorithms. Whether this approach can be effectively parallelized is an intriguing question.

**Appendix A. The bucket-heap.** The bucket-heap structure consists of an array of buckets, where the $i$th bucket spans the interval $[\delta + i\mu, \delta + (i+1)\mu)$, for fixed reals $\delta$ and $\mu$. Logically speaking, a heap item with key $\kappa$ appears in the bucket whose interval spans $\kappa$. We are never concerned about the relative order of items within the same bucket.

*Proof of Lemma* 4.3. Our structure simulates the logical specification given earlier; it actually consists of *levels* of bucket arrays. The level zero buckets are the ones referred to in the bucket-heap's specification, and the level $i$ buckets preside over disjoint intervals of $2^i$ level zero buckets. The interval represented by a higher-level bucket is the union of its component level zero buckets. Only one bucket at each level is *active*: it is the first one that presides over no closed level zero buckets; see Figure 5. Suppose that an item $x$ should *logically* be in the level zero bucket $B$. We maintain the invariant that $x$ is either *descending* and in the lowest active bucket presiding over $B$, or *ascending* and in some active bucket presiding over level zero buckets before $B$.

To insert a node we put it in the first open level zero bucket and label it as ascending. This clearly satisfies the invariant. The result of a decrease-key depends

FIG. 5. *Active buckets are shaded.*

on whether the node $x$ is ascending or descending. Suppose $x$ is ascending and in a bucket (at some level) spanning the interval $[a, b)$. If $\text{key}(x) < b$, we relabel it as descending; otherwise we do nothing. If $x$ is descending (or was just relabeled as descending), we move it to the lowest level active bucket consistent with the invariant. If $x$ drops $i \geq 0$ levels, we assume that this is accomplished in $O(i + 1)$ time; i.e., we search from its current level down, not from the bottom up.

Suppose that we close the first open level zero bucket $B$. According to the invariant all items that are logically in $B$ are descending and actually in $B$, so enumerating them is no problem; there will, in general, be ascending items in $B$ that do not logically belong there. In order to maintain the invariant we must deactivate all active buckets that preside over $B$ (including $B$). Consider one such bucket at level $i$. If $i > 0$, we move each descending node in it to the level $i - 1$ active bucket. For each ascending node (at level $i \geq 0$), depending on its key, we either move it to the level $i + 1$ active bucket and keep it ascending, or relabel it descending and move it to the proper active bucket at level $\leq i + 1$.

From the invariant it follows that no node $x$ appears in more than $2 \log \Delta_x + 1$ distinct buckets: $\log \Delta_x + 1$ buckets as an ascending node and another $\log \Delta_x$ as a descending node. Aside from this cost of moving nodes around, the other costs are clearly $O(N)$. ◻

We remark that the bucket-heap need not actually label the items. Whether an item is ascending or descending can be inferred from context.

**Appendix B. The split-findmin problem.** The split-findmin problem is to maintain a collection of sequences of weighted elements under the following operations:

| | |
|---|---|
| split($x$): | Split the sequence containing $x$ into two sequences: the elements up to and including $x$ and the rest. |
| decrease-key($x, \kappa$): | Set $\text{key}(x) = \min\{\text{key}(x), \kappa\}$. |
| findmin($x$): | Return the element in $x$'s sequence with minimum key. |

Gabow [G85a] gave an elegant algorithm for this problem that is nearly optimal. On an initial sequence of $n$ elements, it handles up to $n - 1$ splits and $m$ decrease-keys in $O((m + n)\alpha(m, n))$ time. Gabow's algorithm runs on a pointer machine [Tar79]. We now prove Theorem 4.2 from section 4.2.

*Proof of Theorem* 4.2. In Gabow's decrease-key routine a sequence of roughly $\alpha$ variables needs to be updated, although it is already known that their values are monotonically decreasing. We observe that, on a pointer machine, the same task can be accomplished in $O(\alpha)$ time using $O(\log\alpha)$ comparisons for a binary search. Using a simple two-level scheme, one can easily reduce the $n\alpha$ term in the running time to $n$. This gives the split-findmin algorithm that performs $O(m\log\alpha(m,n)+n)$ comparisons.

To get a potentially faster algorithm on the RAM model we construct all possible split-findmin solvers on inputs with at most $q=\log\log n$ elements and choose one that is close to optimal for all problem sizes. We then show how to compose this optimal split-findmin solver on $q$ elements with Gabow's structure to get an optimal solver on $n$ elements.

We consider only instances with $m'<q^2$ decrease-keys. If more decrease-keys are actually encountered, we can revert to Gabow's algorithm [G85a] or a trivial one that runs in $O(m')$ time.

We represent the state of the solver with three components: a bit-vector with length $q-1$, representing where the splits are; a directed graph $H$ on no more than $q+m'<q(q+1)$ vertices, representing known inequalities between current keys *and* older keys retired by decrease-key operations; and finally, a mapping from elements to vertices in $H$. One may easily confirm that the state can be represented in no more than $3q^4=o(\log n)$ bits. One may also confirm that a split or decrease-key can update the state in $O(1)$ time. We now turn to the findmin operation. Consider the *findmin-action* function, which determines the next step in the findmin procedure. It can be represented as

$$\text{findmin-action} \;:\; \text{state}\times\{1,\ldots,q\} \;\rightarrow\; \big(V(H)\times V(H)\big)\cup\{1,\ldots,q\},$$

where the first $\{1,\ldots,q\}$ represents the argument to the findmin query. The findmin-action function can either perform a comparison (represented by $V(H)\times V(H)$) which, if performed, will alter the state, or return an answer to the findmin query, represented by the second $\{1,\ldots,q\}$. One simply applies the findmin-action function until it produces an answer. We will represent the findmin-action function as a table. Since the state is represented in $o(\log n)$ bits, we can keep it in one machine word; therefore, computing the findmin-action function (and updating the state) takes constant time on a RAM.

One can see that any split-findmin solver can be converted, without loss of efficiency, into one that performs comparisons only during calls to findmin. Therefore, finding the optimal findmin-action function is tantamount to finding the optimal split-findmin solver.

We have now reduced the split-findmin problem to a brute force search over the findmin-action function. There are less than $F=2^{3q^4}\cdot q\cdot(q^4+q)<2^{4q^4}$ distinct findmin-action functions, most of which do not produce correct answers. There are less than $I=(2q+q^2(q+1))^{q^2+3q}$ distinct instances of the problem, because the number of decrease-keys is $<q^2$, findmins $<2q$, and splits $<q$. Furthermore, each operation can be a split or findmin, giving the $2q$ term, or a decrease-key, which requires us to choose an element and where to fit its new key into the permutation, giving the $q^2(q+1)$ term. Each findmin-action/problem instance pair can be tested for correctness in $V=O(q^2)$ time, and therefore all correct findmin-action functions can be chosen in time $F\cdot I\cdot V=2^{\Omega(q^4)}$. For $q=\log\log n$ this is $o(n)$, meaning the time for this brute force search does not affect the other constant factors involved.

How do we choose the optimal split-findmin solver? This is actually not a trivial question because of the possibility of there not being one solver that dominates all others on all input sizes. Consider charting the worst-case complexity of a solver $\mathcal{S}$ as a function $g_{\mathcal{S}}$ of the number of operations $p$ in the input sequence. It is plausible that certain solvers are optimal for only certain densities $p/q$. We need to show that for some solver $\mathcal{S}^*$, $g_{\mathcal{S}^*}$ is within a constant factor of the lower envelope of $\{g_{\mathcal{S}}\}_{\mathcal{S}}$, where $\mathcal{S}$ ranges over all correct solvers. Let $\mathcal{S}_k$ be the optimal solver for $2^k$ operations. We let $\mathcal{S}^*$ be the solver that mimics $\mathcal{S}_k$ from operations $2^{k-1}+1$ to $2^k$. At operation $2^k$ it resets its state, reexecutes all $2^k$ operations under $\mathcal{S}_{k+1}$, and continues using $\mathcal{S}_{k+1}$ until operation $2^{k+1}$. Since $g_{\mathcal{S}_{k+1}}(2^{k+1}) \leq 2 \cdot g_{\mathcal{S}_k}(2^k)$, it follows that $g_{\mathcal{S}^*}(p) \leq 4 \cdot \min_{\mathcal{S}}\{g_{\mathcal{S}}(p)\}$.

Our overall algorithm is very simple. We divide the $n$ elements into $n' = n/q$ superelements, each representing a contiguous block of $q$ elements. Each unsplit sequence then consists of three parts: two subsequences in the leftmost and rightmost superelements and a third subsequence consisting of unsplit superelements. We use Gabow's algorithm on the unsplit superelements, where the key of a superelement is the minimum over constituent elements. For the superelements already split, we use the $\mathcal{S}^*$ split-findmin solver constructed as above. The cost of Gabow's algorithm is $O((m + n/q)\alpha(m, n/q)) = O(m + n)$, and the cost of using $\mathcal{S}^*$ on each superelement is $\Theta(\text{SPLIT-FINDMIN}(m, n))$ by construction; therefore the overall cost is $\Theta(\text{SPLIT-FINDMIN}(m, n))$.

One can easily extend the proof to randomized split-findmin solvers by defining the findmin-action as selecting a distribution over actions. $\square$

We note that the *time* bound of Theorem 4.2 on pointer machines is provably optimal. La Poutré [LaP96] gave a lower bound on the pointer machine complexity of the split-find problem, which is subsumed by the split-findmin problem. The results in this section address the RAM complexity and decision-tree complexity of split-findmin, which are unrelated to La Poutré's result.

# ON THE BOUNDED SUM-OF-DIGITS DISCRETE LOGARITHM PROBLEM IN FINITE FIELDS*

QI CHENG†

**Abstract.** In this paper, we study the bounded sum-of-digits discrete logarithm problem in finite fields. Our results are concerned primarily with fields $\mathbf{F}_{q^n}$, where $n|q-1$. The fields are called Kummer extensions of $\mathbf{F}_q$. It is known that we can efficiently construct an element $g$ with order exponential in $n$. Let $S_q(\bullet)$ be the function from integers to the sum of digits in their $q$-ary expansions. We first present an algorithm that, given $g^e$ $(0 \le e < q^n)$, finds $e$ in random polynomial time, provided that $S_q(e) < n$. We then show that the problem is solvable in random polynomial time for most of the exponent $e$ with $S_q(e) < 1.32n$ by exploring an interesting connection between the discrete logarithm problem and the problem of list decoding of Reed–Solomon codes and applying the Guruswami–Sudan algorithm. As far as we are aware, our algorithm is the first one which can solve discrete logarithms of $2^{\log^{1-\epsilon} q^n}$ many instances in polynomial time for infinite many constant characteristic fields $\mathbf{F}_{q^n}$. Furthermore, since every finite field has an extension of reasonable degree, which is a Kummer extension, our result reveals an unexpected property of the discrete logarithm problem, namely, the bounded sum-of-digits discrete logarithm problem in any given finite field becomes polynomial-time solvable in certain low degree extensions.

As a side result, we obtain a sharper lower bound on the number of congruent polynomials generated by linear factors than the one based on the Stothers–Mason ABC-theorem. We also prove that, in the field $\mathbf{F}_{q^{q-1}}$, the bounded sum-of-digits discrete logarithm with respect to $g$ can be computed in random time $O(f(w)\log^4(q^{q-1}))$, where $f$ is a subexponential function and $w$ is the bound on the $q$-ary sum-of-digits of the exponent; hence the problem is fixed parameter tractable. These results are shown to be generalized to Artin–Schreier extension $\mathbf{F}_{p^p}$, where $p$ is a prime.

## 1. Introduction and motivation.

Most practical public key cryptosystems base their security on the hardness of solving the integer factorization problem or the discrete logarithm problem in finite fields. Both problems admit subexponential algorithms; thus we have to use long parameters, which make the encryption/decryption costly if the parameters are randomly chosen. Parameters of low Hamming weight, or more generally, of small sum-of-digits, offer some remedy. Another popular approach is to use a small multiplicative subgroup of a large field [16]. Both methods speed up the system while seeming to keep the security intact. In particular, in the cryptosystem based on the discrete logarithm problem in finite fields of small characteristic, using small sum-of-digits exponents is very attractive, due to the existence of normal bases [2]. It is proposed and implemented for smart cards and mobile devices, where the computing power is severely limited. Although attacks exploring the specialty were proposed [17], none of them have polynomial-time complexity.

Let $\mathbf{F}_{q^n}$ be a finite field. For $\beta \in \mathbf{F}_{q^n}$, if $\beta, \beta^q, \beta^{q^2}, \dots, \beta^{q^{n-1}}$ form a linear basis of $\mathbf{F}_{q^n}$ over $\mathbf{F}_q$, we call them, collectively, *a normal basis.* It is known that a normal

basis exists for every pair of prime power $q$ and a positive integer $n$ [12, p. 29]. Every element $\alpha$ in $\mathbf{F}_{q^n}$ can be represented as

$$\alpha = a_0\beta + a_1\beta^q + \cdots + a_{n-1}\beta^{q^{n-1}},$$

where $a_i \in \mathbf{F}_q$ for $0 \le i \le n-1$. The power of $q$ is a linear operation; thus

$$\alpha^q = a_0\beta^q + \cdots + a_{n-2}\beta^{q^{n-1}} + a_{n-1}\beta.$$

Hence to compute the $q$th power, we need only rotate the digits, which can be done very quicky, possibly on the hardware level. Let $e$ be an integer with $q$-ary expansion

$$e = e_0 + e_1 q + e_2 q^2 + \cdots + e_{n-1}q^{n-1} \qquad (0 \le e_i < q \text{ for } 0 \le i \le n-1). \tag{1.1}$$

The sum-of-digits of $e$ in the $q$-ary expansion is defined as $S_q(e) = \sum_{i=0}^{n-1} e_i$. When $q = 2$, the sum-of-digits becomes the famous Hamming weight. To compute $\alpha^e$, we need only do at most $S_q(e)$ many multiplications in addition to cyclic shiftings. Furthermore, the exponentiation algorithm can be parallelized, which is a property not enjoyed by the large characteristic fields. It was proved in [19] that the size of the arithmetic circuit computing the $e$th exponentiation is about $S_q(e)$, and the depth is about $\log_2 S_q(e)$.

The discrete logarithm problem in finite field $\mathbf{F}_{q^n}$ is to compute an integer $e$ such that $t = g^e$, given a generator $g$ of a subgroup of $\mathbf{F}_{q^n}^*$ and $t$ in the subgroup. The general purpose algorithms for solving the discrete logarithm problem are the number field sieve and the function field sieve (for a survey, see [14]). They have conjectured time complexity

$$\exp(c(\log q^n)^{1/3}(\log\log q^n)^{2/3})$$

for some constant $c$, when $q$ is small or $n$ is small.

**1.1. Related work.** Suppose we want to compute the discrete logarithm of $t = g^e$ with respect to base $g$ in the finite field $\mathbf{F}_{q^n}$. An algorithm proposed by Coppersmith (described in [17]) works well when the Hamming weight of $e$, denoted by $w$, is very small. It is a clever adaptation of the baby-step giant-step idea and runs in random time $O(\sqrt{w}\binom{\lfloor \log q^n/2\rfloor}{\lfloor w/2\rfloor})$. It is proved in [17] that the average-case complexity achieves only a constant factor speed-up over the worst case. As an interesting comparison, the fastest method for solving the subgroup discrete logarithm problem is either to solve it in the large field or to use the Pollard rho algorithm in the subgroup, which obtains a square root speed-up over the trivial exhaustive search algorithm.

It is not clear how Coppersmith's idea can be generalized when the exponent has small sum-of-digits in the base $q > 2$. However, we can consider the very special case when $e_i \in \{0, 1\}$ for $0 \le i \le n-1$ and $\sum_{0\le i\le n-1} e_i = \lfloor \frac{n}{2} \rfloor$. Recall that $e_i$'s are the digits of $e$ in the $q$-ary expansion. It can be verified that Coppersmith's algorithm can be applied in this case. The time complexity becomes $O(\sqrt{n}\binom{\lfloor n/2\rfloor}{\lfloor n/4\rfloor})$. If $q < n^{O(1)}$, it is much worse than the time complexity of the function field sieve on a general exponent.

If the $q$-ary sum-of-digits of the exponent is bounded by $w$, is there an algorithm which runs in time $f(w)\log^c(q^n)$ and solves the discrete logarithm problem in $\mathbf{F}_{q^n}$ for some function $f$ and a constant $c$? A similar problem has been proposed from the parametric point of view by Fellows and Koblitz in [11], where they consider the prime finite fields and the bounded Hamming weight exponents. Their problem is listed among the most important open problems in the theory of parameterized complexity [10]. From the above discussions, it is certainly more relevant to cryptography to treat the finite fields with small characteristic and exponents with bounded sum-of-digits.

Unlike the case of the integer factorization, where many special purpose algorithms exist, the discrete logarithm problem is considered more intractable in general. As an example, one should not use the RSA (Rivest–Shamir–Adleman) algorithm modulus of approximately 1000 bits with one prime factor of 160 bits. It would be vulnerable to the elliptic curve factorization attack. However, in the Digital Signature Standard, adopted by the U.S. Government, the finite field has cardinality of approximately $2^{1024}$ or larger, while the encryption/decryption is done in a subgroup of cardinality of approximately $2^{160}$. As another example, one should search for a secret prime as random as possible in the RSA algorithm, while in the case of the discrete logarithm problem, one may use a finite field of small characteristic; hence the group of very special order. It is believed that no trapdoor can be placed in the group order, as long as it has a large prime factor (see the panel report on this issue in the Proceeding of Eurocrypt 1992 [15]). In order to have an efficient algorithm for solving the discrete logarithm, we need every prime factor of the group order to be bounding by a polynomial function on the logarithm of the cardinality of the field. Given the current state of analytic number theory, it is very hard, if not impossible, to decide whether there exists *infinitely* many finite fields of even (or constant) characteristic, where the discrete logarithm can be solved in polynomial time.

In summary, there are several common assumptions about the discrete logarithm problem in finite fields as follows:

1. As long as the group order has a large prime factor, the discrete logarithm problem is hard. We may use exponents with small sum-of-digits, since the discrete logarithm problem in that case seems to be fixed-parameter intractable. We gain advantage in speed by using bounded sum-of-digits exponents, while at the same time we keep the problem as infeasible as when using the general exponents.
2. If computing discrete logarithm is difficult, it should be difficult for any generator of the group. The discrete logarithm problem with respect to one generator can be reduced to the discrete logarithm problem with respect to any generator. Even though a reduction is not available in the small sum-of-digits case, it is not known that changing the generator of the group affects the hardness of the discrete logarithm problem.

**1.2. Our results.** In this paper, we show that the above assumptions taken in combination are incorrect. We study the discrete logarithm problem in large multiplicative subgroups of the Kummer and Artin–Schreier extensions with a prescribed base and prove that the bounded sum-of-digits discrete logarithm is easy in those groups. More precisely, we prove constructively the following theorem.

THEOREM 1.1 (main). *There exists a random algorithm for finding the integer $e$ given $g$ and $g^e$ in $\mathbf{F}_{q^n}$ in polynomial time in $\log(q^n)$ under the following conditions:*

1. $n|q-1$;
2. $0 \le e < q^n$ *and* $S_q(e) \le n$;
3. $g = \alpha + b$, *where* $\mathbf{F}_q(\alpha) = \mathbf{F}_{q^n}$, $b \in \mathbf{F}_q^*$, *and* $\alpha^n \in \mathbf{F}_q$.

*Moreover, there does not exist an integer $e' \ne e$ satisfying that* $0 \le e' < q^n$, $S_q(e') \le n$ *and* $g^{e'} = g^e$.

The theorem leads directly to a parameterized complexity result concerning the bounded sum-of-digits discrete logarithm, which answers an important open question for many special yet nonnegligible cases.

COROLLARY 1.2. *There exists an element $g$ of order greater than $2^q$ in $\mathbf{F}^*_{q^{q-1}}$ such that the discrete logarithm problem with respect to the generator $g$ can be solved in time $f(w)\log^4(q^{q-1})$, where $f$ is a subexponential function and $w$ is the bound of the sum-of-digits of the exponent in $q$-ary expansion.*

The following few comments are in order:

- For a finite field $\mathbf{F}_{q^n}$, if $n|q-1$, then there exists $g \in \mathbf{F}_{q^n}$ satisfying the condition in the theorem; in other words, there exists an irreducible polynomial of form $x^n - a$ $(a \in \mathbf{F}_q)$ over $\mathbf{F}_q$; vice versa, if there exists $\alpha$ such that $\mathbf{F}_q(\alpha) = \mathbf{F}_{q^n}$ and $\alpha^n \in \mathbf{F}_q$, then $n|q-1$.
- As a comparison, Coppersmith's algorithm runs in exponential time in the case when $e_i \in \{0,1\}$ for $0 \le i \le n-1$, $S_q(e) = \frac{n}{2}$, and $q < n^{O(1)}$, while our algorithm runs in polynomial time in that case. On the other hand, Coppersmith's algorithm works for every finite field, while our algorithm works only in Kummer and Artin–Schreier extensions.
- Usually, we can increase the strength of the cryptosystem based on a finite field discrete logarithm problem by moving the problem to extension fields. Our result shows that we need to be careful here. As an example, suppose that to replace $\mathbf{F}_{q^n}$, where $gcd(n,q) = 1$ and $n$ does not divide $q-1$, we decide to use the field $\mathbf{F}_{q^{nl}}$, where $l$ is the order of $q$ in $(\mathbf{Z}/n\mathbf{Z})^*$. The field $\mathbf{F}_{q^{nl}} = \mathbf{F}_{(q^l)^n}$ is a Kummer extension of $\mathbf{F}_{q^l}$ since $n|q^l-1$. According to Theorem 1.1, there is a polynomial-time algorithm that computes the discrete logarithm to some element $g$ in $\mathbf{F}_{q^{ln}}$, provided that the sum-of-digits of the exponent in the $q^l$-ary expansion is less than $n$. Hence, the bounded sum-of-digits discrete logarithm problem over $\mathbf{F}_{(q^l)^n}$ is much easier than the problem over $\mathbf{F}_{q^n}$. Our result reveals the following unexpected property of the discrete logarithm problem in finite fields: the difficulty of the bounded sum-of-digits discrete logarithm problem may decrease dramatically if we move up to extensions.
- Even though we cannot bound from below the largest prime factor of the order of $g$, it seems, as supported by numerical evidence, that the order of $g$, which is a factor of $q^n - 1$ larger than $2^n$, is rarely smooth. For instance, in $\mathbf{F}_{2^{889}} = \mathbf{F}_{128^{127}}$, any $g$ generates the whole group $\mathbf{F}^*_{2^{889}}$. The order $2^{889} - 1$ contains a prime factor of 749 bits. One should not attempt to apply the Silver–Pohlig–Hellman algorithm here.

The following natural question arises: Can the restriction on the sum-of-digits in Theorem 1.1 be relaxed? Clearly, if we can solve the problem under condition $S_q(e) \le (q-1)n$ in polynomial time, then the discrete logarithm problem in the subgroup generated by $g$ is broken. If $g$ is a generator of $\mathbf{F}^*_{q^n}$, which is true in many cases, then the discrete logarithm problem in $\mathbf{F}_{q^n}$ and any of its subfields to any base are broken. We find a surprising relationship between the relaxed problem and the list decoding problem for Reed–Solomon codes. We are able to prove the following theorem.

THEOREM 1.3. *Suppose $e$ is chosen randomly from the set*

$$\{0 \le e < q^n - 1 | S_q(e) < 1.32n\}.$$

*There exists an algorithm, given $g$ and $g^e$ in $\mathbf{F}_{q^n}$, for finding $e$ in polynomial time in $\log(q^n)$, with probability greater than $1 - c^{-n}$ for some constant $c$ greater than 1, under the following conditions:*

1. $n|q-1$;
2. $g = \alpha + b$, *where* $\mathbf{F}_q(\alpha) = \mathbf{F}_{q^n}$, $b \in \mathbf{F}_q^*$, *and* $\alpha^n \in \mathbf{F}_q$.

Given a polynomial ring $\mathbf{F}_q[x]/(h(x))$, it is an important problem to determine the size of the multiplicative subgroup generated by $x - s_1, x - s_2, \ldots, x - s_n$, where $(s_1, s_2, \ldots, s_n) = S$ is a list of distinct elements in $\mathbf{F}_q$ and for all $i$, $h(s_i) \neq 0$. The lower bound of the order directly affects the time complexity of an AKS (Agrawal–Kayal–Saxena)-style primality-proving algorithm. In that context, the degree of $h(x)$ divides $n$. Assume that deg $h(x) = n$. For a list of integers $E = (e_1, e_2, \ldots, e_n)$, we denote

$$(x-s_1)^{e_1}(x-s_2)^{e_2}\cdots(x-s_n)^{e_n}$$

by $(x-S)^E$. One can estimate the number of distinct congruent polynomials of the form $(x-S)^E$ modulo $h(x)$ for $E$ in a certain set. It is obvious that if $E \in \{(e_1, e_2, \ldots, e_n) | \sum e_i < n-1, e_i \geq 0\}$, then all the polynomials are in different congruent classes. This gives a lower bound of approximately $4^n$. Through a clever use of the Stothers–Mason ABC-theorem, Voloch [18] and Bernstein [5] proved that if $\sum e_i < 1.1n$, then at most four such polynomials can fall into the same congruent class; hence a lower bound of $4.27689^n$ is obtained. We improve their result and obtain a lower bound of $5.17736^n$.

Theorem 1.4. *Use the above notation. Let $C$ be*

$$\left\{(e_1, e_2, \ldots, e_n) | e_i \geq 0 \text{ for } 1 \leq i \leq n, \sum_{i=1}^{n} e_i < 1.5501n, |\{i | e_i \neq 0\}| = \lfloor 0.7416n \rfloor\right\}.$$

*If there exist pairwise different elements $E_1, E_2, \ldots, E_m \in C$ such that*

$$(x-S)^{E_1} \equiv (x-S)^{E_2} \equiv \cdots \equiv (x-S)^{E_m} \pmod{h(x)},$$

*then $m = O(n^2)$. Note that $|C| = 5.17736^n n^{\Theta(1)}$.*

By allowing negative exponents, Voloch [18] obtained a bound of $5.828^n$. Our bound is smaller than his. However, starting from $|S| = 2\deg h(x)$, our method gives slightly better bounds [9]. A distinct feature of our bound is that it relates to the list decoding problem for Reed–Solomon codes. If a better list decoding algorithm is found, then our bound can be improved accordingly.

### 1.3. Organization of the paper.

The paper is organized as follows. In section 2, we list some results of counting numbers with small sum-of-digits. In section 3, we present the basic idea and the algorithm, and we prove Theorem 1.1 and Corollary 1.2. In section 4, we prove Theorems 1.3 and 1.4. In section 5, we extend our results to Artin–Schreier extensions. We conclude our paper with discussions of open problems.

## 2. Numbers with small sum-of-digits.

Suppose that the $q$-ary expansion of a positive integer $e$ is

$$e = e_0 + e_1 q + e_2 q^2 + \cdots + e_{n-1} q^{n-1},$$

where $0 \leq e_i \leq q-1$ for all $0 \leq i \leq n-1$. How many nonnegative integers $e$ less than $q^n$ satisfy $S_q(e) = w$? Denote the number by $N(w, n, q)$. Then $N(w, n, q)$ equals the number of nonnegative integral solutions of

$$\sum_{i=0}^{n-1} e_i = w$$

under the conditions that $0 \le e_i \le q-1$ for all $0 \le i \le n-1$. The generating function for $N(w,n,q)$ is

$$(1+x+\cdots+x^{q-1})^n = \sum_i N(i,n,q)x^i.$$

If $w \le q-1$, then the conditions $e_i \le q-1$ can be removed, and we have that $N(w,n,q) = \binom{w+n-1}{n-1}$. It is easy to see that if $q=2$, we have that $N(w,n,2) = \binom{n}{w}$. Later, we will need to estimate $N(w,n,q)$, where $w$ is $n$ times a small constant less than 2. Since

$$\begin{aligned}(1+&\ x +\cdots+x^{q-1})^n \\ &= \left(\frac{1-x^q}{1-x}\right)^n \\ &= (1-x^q)^n \sum_{i=0}^{\infty} \binom{i+n-1}{n-1} x^i \\ &\equiv (1-nx^q) \sum_{i=0}^{2q-1} \binom{i+n-1}{n-1} x^i \pmod{x^{2q}} \\ &\equiv \sum_{i=0}^{q-1} \binom{i+n-1}{n-1} x^i + \sum_{i=q}^{2q-1} \left( \binom{i+n-1}{n-1} - n\binom{i-q+n-1}{n-1} \right) x^i \pmod{x^{2q}},\end{aligned}$$

we have $N(w,n,q) = \binom{w+n-1}{n-1} - n\binom{w-q+n-1}{n-1}$ if $q \le w < 2q$.

## 3. The algorithm and the proof of the main theorem.

The basic idea of our algorithm is adopted from the index calculus algorithm. The idea of index calculus computing a discrete logarithm over finite fields was developed by Western and Miller [20] and Adleman [1]. To start the algorithm, we select a small set of elements called *the factor base*. It usually consists of prime numbers less than a chosen bound or of polynomials of low degrees. In the preprocessing part, we try to compute the discrete logarithm of elements in the factor base with respect to the base (denoted by $g$). We do this by randomly selecting an exponent $e$ and computing $g^e$, taking the result as an integer or a polynomial, and factoring it over $\mathbf{Z}$ or $\mathbf{F}[x]$. If it can be factored into elements in the factor base, i.e., if it is smooth, we obtain a linear relation between the discrete logarithms of the elements in the factor base. We repeat the step a number of times and complete the preprocessing part by solving the linear system after we accumulate enough relations. The next step is selecting random exponents $e$ and evaluating $tg^e$, where $t$ is the element whose discrete logarithm is sought. Hopefully it becomes smooth after a number of trials, in which case we obtain the discrete logarithm of $t$. For the algorithm to be efficient, we would like to have a small factor base and a high probability of a random element being smooth. These two goals contradict each other and we need to make a compromise; the resultant algorithm usually has subexponential time complexity.

Let $\mathbf{F}_{q^n}$ be a Kummer extension of $\mathbf{F}_q$, namely, $n | q-1$. Assume that $q = p^d$, where $p$ is the characteristic of the field. The field $\mathbf{F}_{q^n}$ is usually given as $\mathbf{F}_p[x]/(u(x))$, where $u(x)$ is an irreducible polynomial of degree $dn$ over $\mathbf{F}_p$. If $g$ satisfies the condition in Theorem 1.1, then $x^n - \alpha^n$ must be an irreducible polynomial over $\mathbf{F}_q$. Denote $\alpha^n$ by $a$. To implement our algorithm, it is necessary that we work in another model of $\mathbf{F}_{q^n}$, namely, $\mathbf{F}_q[x]/(x^n-a)$. Fortunately the isomorphism

$$\psi : \mathbf{F}_p[y]/(u(y)) \to \mathbf{F}_{q^n} = \mathbf{F}_q[x]/(x^n-a)$$

can be efficiently computed. To compute $\psi(v(y))$, where $v(y)$ is a polynomial of degree at most $dn-1$ over $\mathbf{F}_p$, all we have to do is factor $u(y)$ over $\mathbf{F}_q[x]/(x^n-a)$ and evaluate $v(y)$ at one of the roots. Factoring polynomials over finite fields is a well-studied problem in computational number theory; see [3] for a complete survey. The random algorithm runs in expected time $O(dn(dn+\log q^n)(dn\log q^n)^2)$, and the deterministic algorithm runs in time $O(dn(dn+q)(dn\log q^n)^2)$. From now on we assume the model $\mathbf{F}_q[x]/(x^n-a)$.

Consider the subgroup generated by $g=\alpha+b$ in $(\mathbf{F}_q[x]/(x^n-a))^*$ and recall that $b\in\mathbf{F}_q^*$ and $\alpha=x \pmod{x^n-a}$. The generator $g$ has an order greater than $4^n$ [8] and has a very nice property as follows. Denoting $a^{\frac{q-1}{n}}$ by $h$, we have

$$g^q=(\alpha+b)^q=\alpha^q+b=a^{\frac{q-1}{n}}\alpha+b=h\alpha+b;$$

more generally,

$$(\alpha+b)^{q^i}=\alpha^{q^i}+b=h^i\alpha+b.$$

In other words, we obtain a set of relations $\log_{\alpha+b}(h^i\alpha+b)=q^i$ for $0\le i\le n-1$. This corresponds to the precomputation stage of the index calculus. The difference is that, in our case, this stage finishes in polynomial time, while generally it requires subexponential time. For a general exponent $e$,

$$\begin{aligned}(\alpha+b)^e&=(\alpha+b)^{e_0+e_1q+\cdots+e_{n-1}q^{n-1}}\\&=(\alpha+b)^{e_0}(h\alpha+b)^{e_1}\cdots(h^i\alpha+b)^{e_i}\cdots(h^{n-1}\alpha+b)^{e_{n-1}}.\end{aligned}$$

If $f(\alpha)$ is an element in $\mathbf{F}_{q^n}$, where $f\in\mathbf{F}_q[x]$ is a polynomial of degree less than $n$, and $f(\alpha)=(\alpha+b)^e$ and $S_q(e)<n$, then, due to unique factorization in $\mathbf{F}_q[x]$, $f(x)$ can be completely split into linear factors over $\mathbf{F}_q$. We can read the discrete logarithm from the factorizations after the coefficients are normalized. The algorithm is described as follows.

Algorithm 1.

*Input: $g$, $g^e$ in $\mathbf{F}_{q^n}=\mathbf{F}_q[x]/(x^n-a)$ satisfying the conditions in Theorem* 1.1.

*Output: $e$.*

1. *Define an order in $\mathbf{F}_q$ (for example, use the lexicographic order). Compute and sort the list $(1,h,h^2,h^3,\ldots,h^{n-1})$.*
2. *Suppose that $g^e$ is represented by $f(\alpha)$, where $f\in\mathbf{F}_q[x]$ has degree less than $n$. Factoring $f(x)$ over $\mathbf{F}_q$, let $f(x)=c(x+d_1)^{e_1}\cdots(x+d_k)^{e_k}$, where $c,d_1,\ldots,d_k$ are in $\mathbf{F}_q$.*
3. *(Normalization.) Normalize the coefficients and reorder the factors of $f(x)$ such that their constant coefficients are $b$ and $f(x)=(x+b)^{e_1}\cdots(h_{n-1}x+b)^{e_{n-1}}$, where $h_i=h^i$.*
4. *Output $e_0+e_1q+\cdots+e_{n-1}q^{n-1}$.*

Step 1 takes time $O(n\log^2q\log n+n\log n\log q)=O(n\log n\log^2q)$. The most time-consuming part is factoring a polynomial over $\mathbf{F}_q$ with degree at most $n$. The random algorithm runs in expected time $O(n(n+\log q)(n\log q)^2)$ and the deterministic algorithm runs in time $O(n(n+q)(n\log q)^2)=O(n^3q\log^2q)$. Normalization and reordering can be done in time $O(n\log n\log q)$, since we have a sorted list of $(1,h,h^2,h^3,\ldots,h^{n-1})$. Thus, the algorithm can be finished in random time $O(n(n+\log q)(n\log q)^2)$ and in deterministic time $O(n^3q\log^2q)$. This concludes the proof of the main theorem.

Now we are ready to prove Corollary 1.2. Any $f(x)$, where $f(\alpha) = (\alpha + b)^e \in \, <\alpha + b> \subseteq \mathbf{F}_{q^{q-1}}$, is congruent to a product of at most $w = S_q(e)$ linear factors modulo $x^{q-1} - a$. If $w < q - 1$, we have an algorithm running in time $O(q^4 \log^2 q)$ and solving the discrete logarithm, according to Theorem 1.1. So we need only consider the case when $w \geq q - 1$. The general purpose algorithm will run in random time $f(\log q^{q-1})$, where $f$ is a subexponential function. Theorem 1.2 follows from the fact that $\log q^{q-1} \leq w \log w$ when $w \geq q - 1$.

There are approximately $2^{\log^{1-\epsilon} q^{q-1}}$ many nonnegative solutions of $e_0 + e_1 + \cdots + e_{q-2} < q-1$; hence our algorithm can efficiently solve discrete logarithms of $2^{\log^{1-\epsilon} q^{q-1}}$ many instances for fields $\mathbf{F}_{q^{q-1}}$.

**4. The application of the list decoding algorithm of Reed–Solomon codes.** The following natural question arises: Can we relax the bound on the sum-of-digits and still obtain a polynomial-time algorithm? Solving the problem under the condition $S_q(e) \leq (q - 1)n$ basically renders the discrete logarithm problems in $\mathbf{F}_{q^n}$ and any of its subfields easy. Suppose that $g^e = f(\alpha)$, where $f(x) \in \mathbf{F}_q[x]$ has degree less than $n$. Using the same notation as in the previous section, we have

$$f(\alpha) = (\alpha + b)^{e_0}(h\alpha + b)^{e_2} \cdots (h^{n-1}\alpha + b)^{e_{n-1}}.$$

Note that $f(x)$ may be irreducible. For example, let $\alpha = x \pmod{x^5 - 2}$ in $\mathbf{F}_{11}$,

$$(\alpha + 1)^{2+11+2*11^2+11^4} = 7\alpha^4 + 9\alpha^3 + 10\alpha^2 + 3\alpha + 9,$$

and $7x^4 + 9x^3 + 10x^2 + 3x + 9$ is irreducible over $\mathbf{F}_{11}$. In any case, there exists a polynomial $t(x)$ with degree $\sum_{i=0}^{n-1} e_i - n$ such that

$$f(x) + (x^n - a)t(x) = (x + b)^{e_0}(hx + b)^{e_1} \cdots (h^{n-1}x + b)^{e_{n-1}}.$$

We call the polynomial $t(x)$ a *smoothing polynomial* for $f(x)$. If the cardinality of $\{i | e_i \neq 0\}$ is greater than $k$, then the curve $y = t(x)$ will pass at least $k$ points in the set

$$\left\{ \left( i, -\frac{f(i)}{i^{q-1} - a} \right) \middle| i \in \left\{ -b, -\frac{b}{h}, \ldots, -\frac{b}{h^{n-1}} \right\} \right\}.$$

To find all the polynomials of degree $d = \sum_{i=0}^{n-1} e_i - n$ that pass at least $k$ points in a given set of $n$ points, we use the list decoding problem for Reed–Solomon codes. It turns out that there are only a few such polynomials, and they can be found efficiently as long as $k \geq \sqrt{nd}$.

PROPOSITION 4.1 (Guruswami–Sudan [13]). *Given $n$ distinct elements $x_0, x_1, \ldots, x_{n-1} \in \mathbf{F}_q$, $n$ values $y_0, y_1, \ldots, y_{n-1} \in \mathbf{F}_q$ and a natural number $d$, there are at most $O(\sqrt{n^3 d})$ many univariate polynomials $t(x) \in \mathbf{F}_q[x]$ of degree at most $d$ such that $y_i = t(x_i)$ for at least $\sqrt{nd}$ many points. Moreover, these polynomials can be found in random polynomial time.*

For each $t(x)$, we use the Cantor–Zassenhaus algorithm [3] to factor $f(x) + (x^n - a)t(x)$. There must exist a $t(x)$ such that the polynomial $f(x) + (x^n - a) * t(x)$ can be completely factored into a product of linear factors in $\{h^i x + b | 0 \leq i \leq n - 1\}$, and $e$ is computed as a consequence.

**4.1. The proof of Theorem 1.3.** In this section, we consider the case when $S_q(e) \leq 1.32n$. If there are at least $0.5657n \geq \sqrt{0.32n \cdot n}$ number of nonzero $e_i$'s, then we can apply the Guruswami–Sudan algorithm to find all the smoothing polynomials. In order to prove Theorem 1.3, it remains to show the following lemma.

LEMMA 4.2. *Define* $A_{n,q}$ *as*

$$\{(e_1, e_2, \ldots, e_n) \mid e_1+e_2+\cdots+e_n \leq 1.32n, e_i \in \mathbf{Z}, \text{ and } 0 \leq e_i \leq q-1 \text{ for } 1 \leq i \leq n\}$$

*and* $B_n$ *as*

$$\{(e_1, e_2, \ldots, e_n) \mid |\{i | e_i \neq 0\}| < 0.5657n\}.$$

*We have*

$$\frac{|A_{n,q} \cap B_n|}{|A_{n,q}|} < c^{-n}$$

*for some constant* $c > 1$ *when* $n$ *is sufficiently large.*

*Proof.* The cardinality of $A_{n,q}$ is $\sum_{i=0}^{\lfloor 1.32n \rfloor} N(i, n, q) > \binom{2.32n}{n} > 4.883987, \ldots^n$. The cardinality of $A_{n,q} \cap B_n$ is less than $\sum_{v=\lceil 0.5657n \rceil}^{n} \binom{n}{v}\binom{1.32n}{n-v-1}$. The summands maximize at $v = 0.5657n$ if $v \geq 0.5657n$. Hence we have

$$\begin{aligned} &\sum_{v=\lceil 0.5657n \rceil}^{n} \binom{n}{v}\binom{\lfloor 1.32n \rfloor}{n-v-1} \\ &\qquad < 0.4343n \binom{n}{\lceil 0.5657n \rceil}\binom{\lfloor 1.32n \rfloor}{\lfloor 0.4343n \rfloor} \\ &\qquad < 4.883799, \ldots^n. \end{aligned}$$

This proves the lemma with $c = 4.883987, \ldots / 4.883799, \ldots > 1$. ◻

**4.2. The proof of Theorem 1.4.**

*Proof.* Let $\tau$ be a positive real number less than 1. Define

$$C_{n,q,\tau} = \left\{ (e_1, e_2, \ldots, e_n) \left| \begin{array}{l} e_1 + e_2 + \cdots + e_n = \lfloor (1+\tau)n \rfloor, e_i \in \mathbf{Z} \\ \text{and } 0 \leq e_i \leq q-1 \text{ for } 1 \leq i \leq n \\ \text{and } |\{i | e_i \neq 0\}| = \lfloor \sqrt{\tau} n \rfloor \end{array} \right. \right\}.$$

Given $f(x) \in \mathbf{F}_q[x]$, if there exists $E \in C_{n,q,\tau}$, such that $(x-S)^E \equiv f(x) \pmod{h(x)}$, there must exist a polynomial $t(x)$ such that $(x-S)^E = t(x)h(x) + f(x)$, and $t(x)$ is a solution for the list decoding problem with input $\{(s, -\frac{f(s)}{h(s)}) | s \in S\}$. According to Proposition 4.1, there are at most $O(n^2)$ solutions. Thus the number of congruent classes modulo $h(x)$ that $\{(x-S)^E | E \in C_{n,q,\tau}\}$ has is $\Omega(|C_{n,q,\tau}|/n^2)$. We have

$$|C_{n,q,\tau}| = \binom{n}{\sqrt{\tau} n}\binom{(1+\tau)n}{\sqrt{\tau} n} = n^{\Theta(1)} \left( \frac{(1+\tau)^{1+\tau}}{\tau^{\sqrt{\tau}}(1-\sqrt{\tau})^{1-\sqrt{\tau}}(1+\tau-\sqrt{\tau})^{1+\tau-\sqrt{\tau}}} \right)^n.$$

It takes the maximum value $n^{\Theta(1)} 5.17736, \ldots^n$ at $\tau = 0.5501$. ◻

**5. Artin–Schreier extensions.** Let $p$ be a prime. The Artin–Schreier extension of a finite field $\mathbf{F}_p$ is $\mathbf{F}_{p^p}$. The polynomial $x^p - x - a = 0$ is irreducible in $\mathbf{F}_p$

for any $a \in \mathbf{F}_p^*$, since $\alpha, \alpha^p, \ldots, \alpha^{p^{p-1}}$ are all different and $\alpha^{p^p} = \alpha$, where $\alpha = x \pmod{x^p - x - a}$. So we may take $\mathbf{F}_{p^p} = \mathbf{F}_p[x]/(x^p - x - a)$. For any $b \in \mathbf{F}_p$, we have

$$(\alpha + b)^p = \alpha^p + b = \alpha + b + a,$$

and similarly

$$(\alpha + b)^{p^i} = \alpha^{p^i} + b = \alpha + b + ia.$$

Hence the results for Kummer extensions can be adopted to Artin–Schreier extensions. For the subgroup generated by $\alpha + b$, we have a polynomial algorithm for solving the discrete logarithm if the exponent has $p$-ary sum-of-digits less than $p$. Note that $b$ may be 0 in this case.

THEOREM 5.1. *There exists an algorithm for finding the integer $e$ given $g$ and $g^e$ in $\mathbf{F}_{p^p}$ in polynomial time in $\log p^p$ under the following conditions:*

1. $0 \le e < p^p$ *and* $S_q(e) \le p - 1$;
2. $g = \alpha + b$, *where* $\mathbf{F}_p(\alpha) = \mathbf{F}_{p^p}$, $b \in \mathbf{F}_p$, *and* $\alpha^p + \alpha \in \mathbf{F}_p^*$.

*Moreover, there does not exist an integer $e' \neq e$ satisfying that $0 \le e' < p^p$, $S_q(e') \le n$ and $g^{e'} = g^e$.*

THEOREM 5.2. *There exists an element $g$ of order greater than $2^p$ in $\mathbf{F}_{p^p}^*$ such that the discrete logarithm problem with respect to $g$ can be solved in time $O(f(w)(\log p^p)^4)$, where $f$ is a subexponential function and $w$ is the bound of the sum-of-digits of the exponent in the $p$-ary expansion.*

THEOREM 5.3. *Suppose that $g = \alpha + b$, where $\mathbf{F}_p(\alpha) = \mathbf{F}_{p^p}$, $b \in \mathbf{F}_p$, and $\alpha^p + \alpha \in \mathbf{F}_p^*$. Suppose $e$ is chosen in random from the set*

$$\{0 \le e < q^n - 1 | S_q(e) < 1.32n\}.$$

*There exists an algorithm given $g$ and $g^e$ in $\mathbf{F}_{p^p}$ for finding $e$ in polynomial time in $\log(p^p)$, with probability greater than $1 - c^{-n}$ for some constant $c$ greater than* 1.

## 6. Concluding remarks.

A novel idea in the celebrated AKS primality testing algorithm is to construct a subgroup of large cardinality through linear elements in finite fields. The subsequent improvements [6, 7, 4] rely on constructing a single element of large order. It is speculated that these ideas will be useful in attacking the integer factorization problem. In this paper, we show that they do affect the discrete logarithm problem in finite fields. We give an efficient algorithm that computes the bounded sum-of-digits discrete logarithm with respect to prescribed bases in Kummer extensions. We also show that the problem is related to an important problem in coding theory. The most interesting open problem is to further relax the restriction on the sum-of-digits of the exponent.

**Acknowledgment.** We thank Professor Pedro Berrizbeitia for very helpful discussions.

# DUALITY BETWEEN PREFETCHING AND QUEUED WRITING WITH PARALLEL DISKS[*]

DAVID A. HUTCHINSON[†], PETER SANDERS[‡], AND JEFFREY SCOTT VITTER[§]

**Abstract.** Parallel disks promise to be a cost effective means for achieving high bandwidth in applications involving massive data sets, but algorithms for parallel disks can be difficult to devise. To combat this problem, we define a useful and natural duality between writing to parallel disks and the seemingly more difficult problem of prefetching. We first explore this duality for applications involving read-once accesses using parallel disks. We get a simple linear time algorithm for computing optimal prefetch schedules and analyze the efficiency of the resulting schedules for randomly placed data and for arbitrary interleaved accesses to striped sequences. Duality also provides an optimal schedule for prefetching plus caching, where blocks can be accessed multiple times. Another application of this duality gives us the first parallel disk sorting algorithms that are provably optimal up to lower-order terms. One of these algorithms is a simple and practical variant of multiway mergesort, addressing a question that had been open for some time.

**Key words.** caching, external memory sorting, load balancing, lower bound, prefetching, randomized algorithm

## 1. Introduction.

External memory (EM) algorithms are those for which the problem data set is too large to fit into the high-speed random access memory (RAM) of a computer and therefore must reside on external devices such as disk drives [23]. In order to cope with the high latency of accessing data on disks, efficient EM algorithms exploit locality in their design. In the *I/O model*, EM algorithms access a large *block* of $B$ contiguous data elements in one *I/O step* and perform the necessary algorithmic operations on the elements in the block while in the high-speed memory. The speedup can be significant. However, even with blocked access, a single disk provides much less bandwidth than the internal memory. This problem can be mitigated by using multiple disks in parallel. For each input/output operation, one block is transferred between a fast memory of size $M$ and each of the $D$ disks. The algorithm therefore transfers $D$ blocks at the cost of a single-disk access delay.

A simple approach to algorithm design for parallel disks is to employ large logical blocks, or *superblocks*, of size $B \cdot D$ in the algorithm. This reduces the problem to designing an EM algorithm for one disk with logical block size $BD$. A superblock is split into $D$ physical blocks—one on each disk. All $D$ physical blocks are accessed

simultaneously whenever the superblock is accessed. We refer to this technique as *superblock striping*. Unfortunately, this approach is suboptimal for em algorithms like sorting that deal with many blocks at the same time. For sorting and many related EM problems, an optimal algorithm requires *independent access* to the $D$ disks, in which each of the $D$ blocks in a parallel I/O operation can reside at a different position on its disk [25, 23]. Designing algorithms for independent parallel disks has been surprisingly difficult [25, 21, 20, 10, 11, 5, 6, 23, 22, 24]. In this paper we consider parallel disk output and parallel disk input separately, in particular as the parallel *output scheduling problem* and the parallel *prefetch scheduling problem*, respectively.

The (online) *output scheduling (or queued writing) problem* takes as input a fixed size pool of $m$ (initially empty) memory buffers each capable of storing a block, and the sequence $\langle w_0, w_1, \ldots, w_{L-1}\rangle$ of $L$ block *write requests* as they are issued. Each write request is prelabeled with the disk it will use. The solution of the output scheduling problem is a schedule that specifies when the blocks are output (i.e., the contents of each parallel output operation). The buffer pool can be used to reorder the outputs with respect to the logical writing order given by $\langle w_0, w_1, \ldots, w_{L-1}\rangle$ so that the total number of parallel output steps is minimized.

We use the term *write* for the logical process of moving a block from the responsibility of the application to the responsibility of the scheduling algorithm. The scheduling algorithm orchestrates the physical *output* of these blocks to disks.

The (offline) *prefetch scheduling problem* takes as input a fixed size pool of $m$ (empty) memory buffers for storing blocks, and the sequence $\langle r_0, r_1, \ldots, r_{L-1}\rangle$ of $L$ distinct block *read requests* that will be issued. Each read request is prelabeled with the disk it will use. The resulting *prefetch schedule* specifies when the blocks should be fetched so that they can be consumed by the application in the right order.

By the term *read*, we mean the logical process of moving a block from the responsibility of the scheduling algorithm to the application. We use the term *fetch* (or *prefetch*) to refer to the physical disk access.

The central theme in this paper is the *duality* between these two problems. Roughly speaking, an output schedule corresponds to a prefetch schedule with reversed time axis, and vice versa. The power of this idea is that computations in one domain can be analyzed via duality with respect to computations in the other domain.

In section 2, we formally introduce the duality principle for the case of distinct blocks to be written or read (*write-once* and *read-once* scheduling). In section 3, we derive an optimal write-once output scheduling algorithm and apply the duality principle to obtain an optimal read-once prefetch scheduling algorithm. In section 4, we modify the previous algorithm so that blocks are fetched as early as possible, so as to be more robust against delays in practical implementations.

For difficult input sequences, an optimal schedule might use parallel disks very inefficiently because most disks might still be idle most of the time. In section 5, we therefore give performance guarantees for two particular classes of input sequences: randomly placed data and arbitrarily interleaved data streams. A data stream is a sequence of blocks that is read or written sequentially by the application. Many algorithms access several such streams in an interleaved manner, and the order of accesses to the streams is not predictable at the time the streams are allocated. Nevertheless, we obtain performance guarantees for the following allocation strategies of the data streams:

**Fully randomized (FR):** Each block is allocated to a random disk.

**Striping (S):** Consecutive blocks of a data stream are allocated to consecutive disks

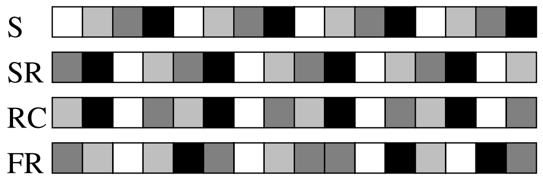

FIG. 1.1. *A sequence of* 16 *blocks allocated to* 4 *disks (*1 = *white,* 2 = *light grey,* 3 = *dark grey,* 4 = *black) using different allocation strategies.*

in a simple, round-robin manner.

**Simple randomized (SR):** For each data stream, this strategy follows a striping allocation, where the disk selected for the first block is chosen randomly and independently of the other data streams.

**Randomized cycling (RC):** Each data stream $i$ chooses a random (and independent) permutation $\pi_i$ of disk numbers and allocates the $j$th block of stream $i$ on disk $\pi_i(j \bmod D)$.

Figure 1.1 gives an example.

In section 6, we relax the restriction that blocks are accessed only once and allow caching of blocks and repeated block requests (*write-many* and *read-many* scheduling). Again we derive a simple optimal algorithm for the writing case and obtain an optimal algorithm for the reading case using the duality principle. A similar result has been obtained by Kallahalla and Varman [16, 17] using more complicated arguments.

In section 7, we apply the results from sections 3 and 5 to parallel disk sorting. Results on online writing translate into improved sorting algorithms using the distribution paradigm. Results on offline reading translate into improved sorting algorithms based on multiway merging. By appending a "D" for distribution sort or an "M" for mergesort to an allocation strategy (FR, S, SR, RC) we obtain a descriptor for a sorting algorithm (FRD, FRM, SD, SM, SRD, SRM, RCD, RCM). This notation is an extension of the notation used in [24]. RCD and RCM turn out to be particularly efficient. Let

$$\mathrm{Sort}(N) = \frac{N}{DB}\left(1 + \log_{M/B}\frac{N}{M}\right).$$

In section 8, we show that $2 \cdot \mathrm{Sort}(N)$ is the lower bound for sorting $N$ elements on $D$ disks. Our versions of RCD and RCM are the first algorithms that provably match this bound up to a lower-order term if $M = \omega(DB)$. The good performance of RCM is particularly interesting. The question of whether there is a simple variant of mergesort that is asymptotically optimal for multiple disks has been open since the model was formalized in [25]. A summary of the notation used in this paper is included in the appendix.

**Related work.** An announcement [14] and a preliminary version [13] of this paper have appeared in conference volumes. The problems of prefetching and caching have been intensively studied and can be quite difficult. We begin our overview with offline algorithms for the I/O model. Belady [7] solved the caching problem for a single disk. Kallahalla and Varman [15, 17] developed an optimal parallel disk prefetching algorithm for read-once sequences. Besides a simpler algorithm and analysis, our contribution is a linear time algorithm (which is, however, also implicit in [16], which was published simultaneously with the first announcement of our result [14].) Moreover, the concept of duality allows us to translate performance guarantees for writing into performance guarantees for reading. The main contribution in [16] is an optimal result for prefetching plus caching. Again, the concept of duality yields a simpler algorithm and proof.

Cao et al. [9] and Kimbrel and Karlin [18] have introduced a model that allows us to study integrated prefetching and caching with overlapping of I/O and computation. In this *penalty model*, internal computation is linked to I/Os by a penalty of $F$ time units for an I/O step. For $F \rightarrow \infty$, the penalty model becomes equivalent to the I/O model since the internal computations become insignificant. Kimbrel and Karlin [18] already introduced the idea of time reversal and the *reverse aggressive* algorithm that has our algorithm as a special case. They also defined a similar kind of duality, namely between fetches and evictions of a caching algorithm. The analysis in the penalty model predicts that the performance ratio between reverse aggressive and the optimal algorithm goes to infinity as $F \rightarrow \infty$. Hence it is a bit surprising that the algorithm turns out to be *optimal* in the I/O model.

The prudent prefetching algorithm introduced in section 4 is similar to the *conservative* algorithm described in [9]. The main difference is that it applies to the optimal parallel disk prefetching algorithm rather than to the optimal schedule in a sequential system.

Albers, Garg, and Leonardi [4] gave an optimal polynomial time offline algorithm for the single-disk case in the penalty model, but it does not generalize well to multiple disks. Albers and Büttner [3] overcame this problem by requiring synchronized parallel disk access (as in the I/O model) and by postulating $\mathcal{O}(D)$ additional buffer blocks not available to the optimal algorithm. Both these algorithms are based on linear programming and hence are quite complicated and time consuming.

There has also been intensive work on online integrated prefetching and caching. Albers [2] showed for a single disk that a lookahead for the next $\Omega(M/B)$ *different* blocks is needed to get good competitiveness. For parallel disks, Kallahalla and Varman [15, 17] showed that another factor of $\Omega(D)$ lookahead is needed even for the read-once problem. Applying the optimal offline algorithm to the lookahead matches this lower bound for read-once sequences.

There are deterministic algorithms for parallel disk external sorting [21, 20] that are optimal up to a constant factor, but the constant factors are not ideal. The first optimal (up to a constant factor independent of the parameters $N$, $M$, $B$, and $D$) sorting algorithm was a randomized one by Vitter and Shriver [25]. Barve, Grove, and Vitter [5] and Barve and Vitter [6] introduced a simple and efficient randomized sorting algorithm called *simple randomized mergesort (SRM)*. For each run, SRM allocates blocks to disks using the SR allocation discipline. For $\gamma < 1$, SRM comes within an additive term of about $\gamma\text{Sort}(N)$ of the sorting lower bound if $M/B = \Omega(D\log(D)/\gamma^2)$, but for $M/B = o(D\log D)$, the bound proven is not asymptotically optimal. It is an open problem whether SRM or another variant of striped mergesort could be asymptotically optimal for small internal memory. Knuth [19, Exercise 5.4.9–31] gives the question of a tight analysis of SR a difficulty rating of 48 on a scale between 1 and 50.

Sanders, Egner, and Korst [22] analyzed a (slightly) suboptimal output scheduling algorithm for FR allocation that would yield a good parallel disk distribution sorting algorithm (FRD) yet has the disadvantage that reading cannot be done in a striped fashion. To overcome the apparent difficulty of analyzing SR, Vitter and Hutchinson [24] analyzed RC allocation, which provides more randomness but retains the advantages of striping. RCD is an asymptotically optimal distribution sort algorithm that allocates successive blocks of a bucket to the disks according to the RC discipline. The present paper uses the concept of duality to apply these results to external mergesort.

The lower bound in section 8 is a refinement of the analysis by Aggarwal and Vitter [1]. In particular, our analysis gives the precise constant factor in the leading term, and it applies to algorithms that do not necessarily use the same number of inputs and outputs. The remaining gap between the upper and lower bound is only a lower-order term if $M = \omega(DB)$.

Building on the results in the present paper, Dementiev and Sanders [12] develop a parallel disk external sorting algorithm that perfectly overlaps I/O and computation. This algorithms works independently of the failure penalty $F$ and need not know how much internal work is done between I/O requests. (These times are far from constant and not easy to predict so that previous results on prefetching in the penalty model are inapplicable for sorting.)

**2. The duality principle.** Duality is a quite simple yet powerful concept once the model is properly defined. Therefore, we start with a more formal description of the model.

Our machine model is the (independent parallel disk) I/O model of Vitter and Shriver [25] with a single[1] processor, $D$ disks, and an internal memory of size $M$. All blocks have the same size $B$. In one *I/O step*, one block on each disk can be accessed in a synchronized fashion. We consider either a queued writing or a buffered prefetching arrangement, where a pool of $m$ block buffers is available to the algorithm (see Figure 2.1).

DEFINITION 2.1. *A* write-once output scheduling problem *is defined by a sequence $\Sigma = \langle b_0, \ldots, b_{L-1} \rangle$ of distinct blocks which are to be output using parallel output operations. Let* $\text{disk}(b_i)$ *denote the disk on which block $b_i$ is to be located. An application* writes *these blocks in the order specified by $\Sigma$. We use the term* write *for the logical process of moving a block from the responsibility of the application to the responsibility of the scheduling algorithm. The scheduling algorithm orchestrates the physical* output *of these blocks to disks. Time is measured in I/O steps actually performed. In particular, in each time step at least one block is output.*

*An output schedule is specified by giving a function* $\text{oStep} : \{b_0, \ldots, b_{L-1}\} \to \mathbb{N}$ *that specifies for each disk block $b_i \in \Sigma$ the time step when it will be output. An output schedule is* correct *if the following conditions hold:*

(i) *No disk is referenced more than once in a single time step. That is, if $i \neq j$ and* $\text{disk}(b_i) = \text{disk}(b_j)$, *then* $\text{oStep}(b_i) \neq \text{oStep}(b_j)$.

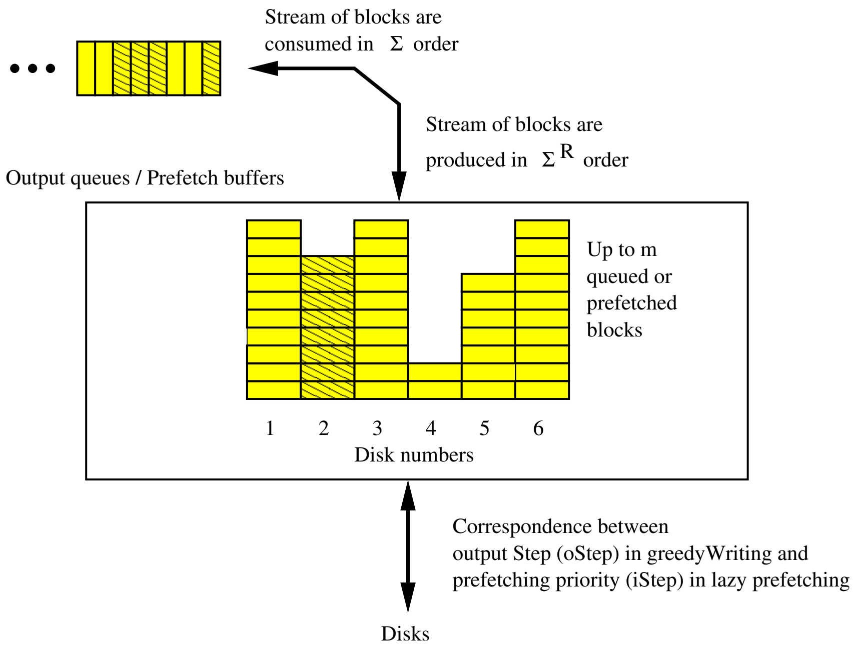
(ii) *The buffer pool is large enough that it does not overflow. That is, if we define*

$$\text{o}\mathcal{B}\text{acklog}(b_i) = |\{j < i : \text{oStep}(b_j) \geq \text{oStep}(b_i)\}|$$

*to be the number of blocks $b_j$ that are written before block $b_i$ but not output before $b_i$, then we require for all $0 \leq i \leq L$ that* $\text{o}\mathcal{B}\text{acklog}(b_i) < m$.

*The blocks are output in increasing order of* oStep. *The number of steps needed by an output schedule is $T = \max_{0 \leq i < L} \text{oStep}(b_i)$. An output schedule is* optimal *if it minimizes $T$ among all correct schedules.*

[1]Our results generalize to multiple processors as long as data exchange between processors is much faster than disk access.



Stream of blocks are consumed in Σ order
Stream of blocks are produced in Σ R order
Output queues / Prefetch buffers
Up to m queued or prefetched blocks
1 2 3 4 5 6

Correspondence between output Step (oStep) in greedyWriting and prefetching priority (iStep) in lazy prefetching
Disks

FIG. 2.1. *Duality between the prefetching priority and the output step. The hashed blocks illustrate how the blocks of disk* 2 *might be distributed.*

It will turn out that our write-once output scheduling algorithms work optimally even if they are given the blocks *online*, that is, one at a time without specifying $\Sigma$ explicitly.

DEFINITION 2.2. *Analogously to a write-once output scheduling problem, a* read-once prefetch scheduling problem *is defined by a sequence* $\Sigma$ *of blocks to be read. By the term* reading, *we mean the logical process of moving a block from the responsibility of the scheduling algorithm to the application. We use the term* fetching *(or* prefetching*) to refer to the physical disk access.*

*A prefetch schedule is defined using a function* $\text{iStep} : \{b_0, \ldots, b_{L-1}\} \to \mathbb{N}$. *The blocks are prefetched in increasing order of* iStep. *Let us define*

$$\text{i}\mathcal{B}\text{acklog}(b_i) = |\{j > i : \text{iStep}(b_j) \leq \text{iStep}(b_i)\}|$$

*to be the number of blocks* $b_j$ *that are fetched no later than block* $b_i$ *but are read after* $b_i$. *All blocks in* $\text{i}\mathcal{B}\text{acklog}(b_i)$ *must be buffered. The limited buffer pool size requires the correctness condition* $\text{i}\mathcal{B}\text{acklog}(b_i) < m$. *The number of steps needed by a prefetch schedule is* $T = \max_{0 \leq i < L} \text{iStep}(b_i)$. *A prefetch schedule is* optimal *if it minimizes* $T$ *among all correct schedules.*

It will turn out that our prefetch scheduling algorithms work *offline*; that is, they need to know $\Sigma$ in advance. We explain in section 7 how this is sufficient for sorting applications.

The following theorem shows that reading and writing not only have similar models but are equivalent to each other in a quite interesting sense.

THEOREM 2.3 (duality principle). *Consider any sequence* $\Sigma = \langle b_0, \ldots, b_{L-1} \rangle$ *of distinct write requests. Let* oStep *denote a correct output schedule for* $\Sigma$ *that uses* $T$ *output steps. Then we get a correct prefetch schedule* iStep *for* $\Sigma^R = \langle b_{L-1}, \ldots, b_0 \rangle$

*that uses $T$ fetch steps by setting* $\mathrm{iStep}(b_i) = T - \mathrm{oStep}(b_i) + 1$.

*Vice versa, every correct prefetch schedule* iStep *for $\Sigma^R$ that uses $T$ fetch steps yields a correct output schedule* $\mathrm{oStep}(b_i) = T - \mathrm{iStep}(b_i) + 1$ *for $\Sigma$, using $T$ output steps.*

*Proof.* For the first part, consider the schedule $\mathrm{iStep}(b_i) = T - \mathrm{oStep}(b_i) + 1$. The resulting fetch steps are between 1 and $T$ and all blocks on the same disk get different fetch steps. It remains to be shown that $\mathrm{i}\mathcal{B}\mathrm{acklog}(b_i) < m$ for $0 \leq i < L$. With respect to $\Sigma^R$, we have

$$\begin{aligned}\mathrm{i}\mathcal{B}\mathrm{acklog}(b_i) &= |\{j > i : \mathrm{iStep}(b_j) \leq \mathrm{iStep}(b_i)\}| \\ &= |\{j > i : T - \mathrm{oStep}(b_j) + 1 \leq T - \mathrm{oStep}(b_i) + 1\}| \\ &= |\{j > i : \mathrm{oStep}(b_j) \geq \mathrm{oStep}(b_i)\}|\,.\end{aligned}$$

The latter value is $\mathrm{o}\mathcal{B}\mathrm{acklog}(b_i)$ with respect to $\Sigma$. It is smaller than $m$ because oStep is a correct schedule.

The proof for the converse case is completely analogous. ∎

## 3. Optimal write-once and read-once scheduling.

We now give an optimal algorithm for writing a write-once sequence, prove its optimality, and then apply the duality principle to transform it into a read-once prefetching algorithm.

Consider the algorithm *greedyWriting* for writing a sequence $\Sigma = \langle b_0, \ldots, b_{L-1}\rangle$ of distinct blocks. Let $Q$ denote the set of blocks in the buffer pool so, initially, $Q = \emptyset$. Let $Q_d = \{b \in Q : \mathrm{disk}(b) = d\}$ denote the blocks queued for disk $d$. Write the blocks $b_i$ in sequence as follows:

1. If $|Q| < m$, then simply insert $b_i$ into $Q$.
2. Otherwise, each disk $d$ with $Q_d \neq \emptyset$ outputs the block of $Q_d$ that appears first in $\Sigma$. The blocks so output are then removed from $Q$ and $b_i$ is inserted into $Q$.
3. Once all blocks are written, the queues are flushed; that is, additional output steps are performed until $Q$ is empty.

Figure 3.1 gives an example.

A schedule is called a *FIFO schedule* if blocks are output in arrival order on each disk. For the write-once case, the following lemma tells us that when we look for optimal schedules, it is sufficient to consider FIFO schedules. On real disks, FIFO schedules are not necessarily optimal, since they do not optimize seek times and rotational delays, but in our synchronous model, using FIFO suffices and simplifies subsequent proofs.

LEMMA 3.1. *For any sequence of blocks $\Sigma$ and every correct output schedule* oStep *there is a FIFO output schedule* oStep$'$ *consisting of at most the same number of output steps.*

*Proof.* The proof of the lemma is based on transforming a non-FIFO schedule into a FIFO schedule by exchanging blocks in the schedule of a disk that are output out of order. Consider a non-FIFO schedule that services two block requests $b_i$ and $b_j$ for the same disk "out of order"; that is, we have $i < j$ but $\mathrm{oStep}(b_i) > \mathrm{oStep}(b_j)$. If we swap the output order of $b_i$ and $b_j$, then the buffer pool consumption between output steps $\mathrm{oStep}(b_j)$ and $\mathrm{oStep}(b_i)$ can only decrease or remain the same. Such swapping operations can be repeated as necessary until a FIFO schedule is obtained. ∎

Algorithm greedyWriting is one way to compute a FIFO schedule. The following lemma shows that greedyWriting outputs every block as early as possible.

LEMMA 3.2. *For any sequence of blocks* $\Sigma$ *and any FIFO output schedule* $\mathrm{oStep}'$ *for* $|\Sigma|$*, let* oStep *denote the schedule produced by algorithm greedyWriting. Then for all* $b_i \in \Sigma$*, we have* $\mathrm{oStep}(b_i) \le \mathrm{oStep}'(b_i)$.

*Proof.* The proof is by induction on $|\Sigma|$.

**Base case for induction.** $|\Sigma| = 0$. The claim is vacuously true for $|\Sigma| = 0$.

**Induction hypothesis.** Assume that the claim is true for $|\Sigma| = L - 1$.

**Induction step** $|\Sigma| = L-1 \rightsquigarrow |\Sigma| = L$. Consider the state of *greedyWriting* when the last block $b_L$ is scheduled. Let $d = \mathrm{disk}(b_L)$. Using the induction hypothesis, it suffices to prove that $\mathrm{oStep}(b_L) \le \mathrm{oStep}'(b_L)$.

*Case* 1. $\mathrm{oStep}(b_L) = 1$. This case is trivial since 1 is the smallest possible output step.

*Case* 2. $\mathrm{oStep}(b_L) = \mathrm{oStep}(b_l) + 1$ for some other block $b_l$ with $\mathrm{disk}(b_l) = d$. Applying the induction hypothesis to $|\Sigma| = \langle b_1, \ldots, b_{L-1}\rangle$, we have $\mathrm{oStep}(b_l) \le \mathrm{oStep}'(b_l)$. By the definition of FIFO output schedules, we have $\mathrm{oStep}'(b_l) < \mathrm{oStep}'(b_L)$; that is, $\mathrm{oStep}'(b_l) + 1 \le \mathrm{oStep}'(b_L)$. All in all, we get

$$\mathrm{oStep}(b_L) = \mathrm{oStep}(b_l) + 1 \le \mathrm{oStep}'(b_l) + 1 \le \mathrm{oStep}'(b_L).$$

**All remaining cases.** Let $t = \mathrm{oStep}(b_L) > 1$. Disk $d$ is idle during step $t-1$, and we have to explain why this is unavoidable. Let $C = \{b_l : \mathrm{oStep}(b_l) \ge t-1\}$ denote the set of blocks that are queued during step $t-1$. We must have $|C| \ge m$, since otherwise greedyWriting would have queued and output $b_L$ already during step $t-1$ or earlier. Assume that $\mathrm{oStep}(b_L) > \mathrm{oStep}'(b_L)$; that is, $\mathrm{oStep}(b_L) - 1 \ge \mathrm{oStep}'(b_L)$. By the induction hypothesis, $\mathrm{oStep}'(b_l) \ge \mathrm{oStep}(b_l)$ for all $b_l \in C$. In other words,

$$\mathrm{oStep}'(b_l) \ge \mathrm{oStep}(b_l) \ge \mathrm{oStep}(b_L) - 1 \ge \mathrm{oStep}'(b_L).$$

Hence, if the schedule defined by $\mathrm{oStep}'$ is used, all blocks in $C$ are written no earlier than $b_L$, which requires that more than $m$ blocks have to be buffered at the same time, contradicting the assumption that $\mathrm{oStep}'$ is correct. □

Combining Lemmas 3.1 and 3.2 we see that greedyWriting gives us optimal schedules for write-once sequences.

THEOREM 3.3. *Algorithm greedyWriting gives a correct, minimum length output schedule for any write-once reference sequence* $\Sigma$.

Combining the duality principle and the optimality of greedyWriting, we get an optimal algorithm for read-once prefetching that we call *lazy prefetching.*

COROLLARY 3.4. *An optimal prefetch schedule* iStep *for a sequence* $\Sigma$ *can be obtained by using greedyWriting to get an output schedule* oStep *for* $\Sigma^R$ *and setting* $\mathrm{iStep}(b_i) = T - \mathrm{oStep}(b_i) + 1$.

The schedule can be computed in time $\mathcal{O}(L + D)$ using very simple data structures. Figure 3.1 (top) gives an example. We refer to this approach as *lazy prefetching.*

## 4. Prudent prefetching.

Although the lazy prefetching approach in the previous section allows us to obtain a prefetch schedule with a minimal number of steps by means of reversing time, it has the practical disadvantage that blocks are accessed as late as possible even if most blocks could be fetched earlier. For example, in Figure 3.1 (top) only the bottom-most disk fetches a block in Step 1. This policy may result in unnecessary delays in real implementations where the access times to the blocks fluctuate. Many of these delays might be avoidable if some blocks were fetched earlier. One might instead use "eager prefetching" [6, 15], i.e., always accessing the

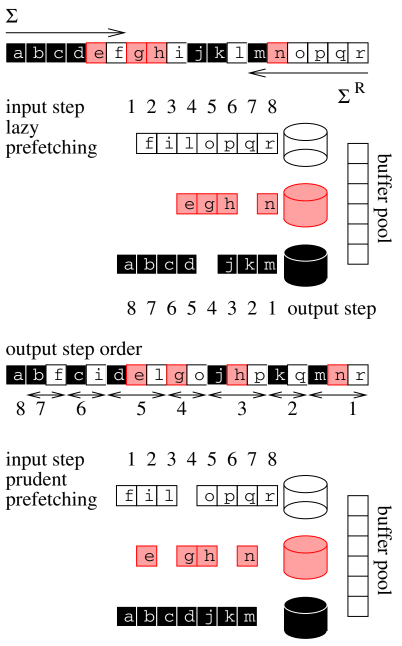

FIG. 3.1. *Duality between prefetching and output for a sequence* $\Sigma = \langle \texttt{a}, \texttt{b}, \ldots, \texttt{r} \rangle$ *of* $L = 18$ *blocks to be read using* $D = 3$ *disks and* $m = 6$ *buffers. Top part: A lazy prefetch schedule for* $\Sigma$ *as the dual of an output schedule for* $\Sigma^R$*. The shading of the blocks indicates the disks where the blocks are located. Before output Step* 2*, the eight blocks* `hijklopq` *would have to be buffered in order to output block* `h` *in Step* 2*. But since only six blocks can be buffered, the middle disk has to remain idle in Step* 2*. Similarly, before output Step* 4*, the seven blocks* `defgilo` *would have to be buffered to output block* `d`*. Bottom part: The resulting schedule for prudent prefetching. For example, before Step* 3*, blocks* `a` *and* `b` *are fetched and buffers for blocks* `fcidel` *are reserved. Block* `g` *cannot be fetched because no buffer is reserved for it. Prudent prefetching using the reading order as a priority instead of the priorities based on the optimal lazy schedule would need one more I/O step.*

highest priority block on each disk. But eager prefetching sometimes has to discard and refetch blocks, causing complications and inefficiencies.

Here we propose *prudent prefetching*, a prefetching strategy that avoids both problems. It maintains optimal schedule length, but attempts to fetch blocks as early as possible. The idea is to use the oStep obtained by greedyWriting as a priority rather than as a direct indication of the input step for fetching a block. Algorithm prudent prefetching allows blocks to be fetched before blocks with higher priority are fetched but only if buffers have been reserved for them. This way, otherwise idle disks can prefetch low priority blocks without hindering any fetches of higher priority blocks in later steps.

This strategy is easy to implement. Prudent prefetching works with a sequence $\langle l_0, \ldots, l_{L-1} \rangle$ of block requests sorted by nonincreasing priority (and hence by nondecreasing iStep of lazy prefetching). Blocks $l_0, \ldots, l_{j-1}$ have either been fetched or have a reserved buffer while blocks $l_j, \ldots, l_{L-1}$ are neither fetched nor have a reserved buffer.

Before each fetch step, all empty buffers are reserved for the next blocks in the priority sequence, and $j$ is advanced by the number of buffers so reserved. The highest priority block from each disk is then fetched if a buffer has been reserved for it. Then from each disk the highest priority block is fetched if a buffer has been reserved for it.

As before, blocks are delivered to the application in the order prescribed by $\Sigma$. When a block is delivered to the application, its buffer becomes empty and is available.

An example of the algorithm is shown in Figure 3.1. We cannot expect algorithm *prudent prefetching* to be better than lazy prefetching as long as we only count I/O steps, but we can show that it is not worse.

THEOREM 4.1. *For any correct output schedule* oStep*,* prudent prefetching *takes no more I/O steps than* lazy prefetching*.*

*Proof.* We have already observed that fetching a reserved block can never hinder a higher priority block from being fetched. Hence, in the $i$th step, all unfetched blocks with iStep $i$ will be fetched. We omit a trivial, more detailed proof by induction over the number of steps. $\square$

Another advantage of *prudent prefetching* is that it can be implemented in an event driven manner, and the fetch steps for each disk need not be synchronized. When the next block from $\Sigma$ is delivered to the application, its buffer can immediately be used for advancing $j$. When a disk finishes fetching a block, it waits (if necessary) until the next highest priority block on this disk has a reserved buffer and then starts to fetch this block. Thus there is never a need to synchronize the disks, the system can adapt to variances in access times, and the load of the interconnections between disks and processors is better balanced than for synchronous access.

## 5. How good is optimal?

When we have complex data access patterns, the knowledge that we have an optimal prefetching algorithm is often of little help. We also want to know "how good is optimal?". In the worst case, all requests may go to the same disk and no prefetching algorithm can cure the dreadful performance caused by this bottleneck. However, the situation is different if an appropriate block allocation strategy is used; for example, if blocks are allocated to disks using striping, randomization,[2] or both.

THEOREM 5.1. *Consider a sequence of $L$ block requests, and a buffer pool of size $m \geq D$ blocks. The number of I/O steps needed by greedyWriting or lazy prefetching is given by the following bounds, depending on the block allocation strategy. For striping and randomized cycling, an arbitrary interleaving of sequential accesses to $S$ sequences is allowed:*

$$
\begin{aligned}
&\textit{S:}\left\lfloor \frac{L}{D} \right\rfloor + S \quad \textit{if } m > S(D-1);\\
&\textit{FR:}\left(1+\mathcal{O}\left(\frac{D}{m}\right)\right)\frac{L}{D}+\mathcal{O}\left(\frac{m}{D}\log m\right) \qquad \textit{(expected)};\\
&\textit{RC:}\left(1+\mathcal{O}\left(\frac{D}{m}\right)\right)\frac{L}{D}+\min\left\{S+\frac{L}{D},\mathcal{O}\left(\frac{m}{D}\log m\right)\right\} \textit{ (expected).}
\end{aligned}
$$

*For the case of writing, the second term can be dropped if we are only interested in the number of steps needed to write (but not necessarily output) all blocks.*

*Proof.* Due to our result on duality, it suffices to prove the bounds for writing.

**Striping (S).** Since greedyWriting is optimal, it suffices to analyze the following specialized algorithm: Each sequence gets an exclusive allotment of $D-1$ buffer blocks. When a block from sequence $k$ is written there are two possible cases. If the pool for $k$ has a free buffer block, the block is buffered there. Otherwise, we have

[2] In practice, this will be done using simple hash functions. However, for the analysis we assume that we have a perfect source of randomness.

exactly $D$ consecutive blocks from the striped sequence $k$ so that we can output one block from sequence $k$ to each disk. There can be at most $\lfloor L/D \rfloor$ of these output steps. When all blocks are written, one additional output step for each sequence suffices to empty all buffers.

**Fully random allocation (FR).** Since *greedyWriting* is optimal, it dominates the algorithm analyzed in [22]. This algorithm admits $(1-\epsilon)D$ blocks into the buffer pool before each output step. It is shown that with this regime the buffer pool size remains in $\mathcal{O}(D/\epsilon)$ most of the time. More precisely, the probability that the required pool size exceeds $qD$ is less than $e^{(\ln 2-\epsilon q)D}$ [22, Lemma 3]. By setting $\epsilon = \Theta(D/m)$ we can make sure that the pool size is exceeded so rarely that we could afford to flush the queues whenever this happens. We omit the straightforward calculations with the tail bound showing that after an expected number of $(1+\mathcal{O}(D/m))L/D$ output steps all blocks have been written. The number of output steps needed to flush the buffers at the end is the maximum number of blocks queued at a disk. In [22] it is shown that the probability that the queue length at a particular disk exceeds $q$ is bounded by $2e^{-\epsilon q}$. Setting $q = \ln(2Dm)/\epsilon$ and multiplying by $D$, we can see that the probability $p_{\text{fail}}$ that some disk has a final load of more than $\ln(2Dm)/\epsilon$ is bounded by $D \cdot 2e^{-\epsilon \ln(2Dm)/\epsilon} = 1/m$. Since the load cannot exceed $L$, the expected maximum load is bounded by $\ln(2Dm)/\epsilon + L/m = \mathcal{O}\big(\frac{m}{D}\log m + L/m\big)$. The term $L/m$ can be absorbed into $\big(1+\mathcal{O}\big(\frac{D}{m}\big)\big)\frac{L}{D}$.

**Randomized cycling (RC).** Vitter and Hutchinson [24] show that the algorithm from [22] performs at least as well on RC-streams as it does for fully random allocation. This extends to *greedyWriting* by Theorem 3.3. Furthermore, the reverse of a sequence accessing RC-streams is indistinguishable from a sequence accessing RC-streams in the forward direction. Theorem 2.3 therefore extends the result to prefetching. Hence, the bound

$$\left(1+\mathcal{O}\left(\frac{D}{m}\right)\right)\frac{L}{D}+\mathcal{O}\left(\frac{m}{D}\log m\right)$$

transfers from the fully random allocation case.

For small $L$ and $m$ this bound can be improved using the observation that the maximum number of blocks queued at a disk at the end cannot exceed the total number of blocks allocated to it. The bound for striping shows that this load cannot exceed $L/D + S$. ◻

## 6. Prefetching with caching.

We now relax the condition that the read requests in $\Sigma$ are for distinct blocks, permitting the possibility of saving disk accesses by keeping previously accessed blocks in memory. For this *read-many* problem, we get a tradeoff for the use of the buffer pool because it has to serve the double purposes of keeping blocks that are accessed multiple times, and decoupling physical and logical accesses to equalize transient load imbalance of the disks. We define the *write-many* problem in such a way that the duality principle from Theorem 2.3 transfers: *The latest instance of each block must be kept either on its assigned disk, or in the buffer pool. The final instance of each block must be output to its assigned disk.*[3]

We prove that the following offline algorithm *manyWriting* minimizes the number of output operations for the write-many problem: Let $Q$ denote the set of blocks in

[3]The requirement that the latest versions have to be kept might seem odd in an offline setting. However, this makes sense if there is a possibility that there are reads at unknown times that need an up-to-date version of a block.

the buffer pool, so initially $Q = \emptyset$. Let $Q_d = \{b \in Q : \text{disk}(b) = d\}$ denote the blocks queued for disk $d$. To write block $b_i$, if $b_i \in Q$, the old version is overwritten in its existing buffer. Otherwise, if $|Q| < m$, $b_i$ is inserted into $Q$. If this also fails, an output step is performed before $b_i$ is inserted into $Q$. The output analogue of Belady's MIN rule [7] is used on each disk; that is, each disk with $Q_d \neq \emptyset$ outputs the block in $Q_d$ that is written again farthest in the future.

THEOREM 6.1. *Algorithm manyWriting solves the* write-many problem *with the fewest number of output steps.*

Applying duality, we also get an optimal algorithm for prefetching plus caching of a sequence $\Sigma$; using the same construction as in Corollary 3.4 we get an optimal prefetching and caching schedule.

COROLLARY 6.2. *The dual of manyWriting solves the* read-many problem *with the fewest number of input steps.*

It remains to prove Theorem 6.1.

*Proof of Theorem* 6.1. We generalize the proof of Belady's algorithm by Borodin and El-Yaniv [8] to the case of writing and multiple disks. Let $\Sigma = \langle b_0, \ldots, b_{L-1} \rangle$ be any sequence of blocks to be written. The proof is based on the following claim.

*Claim.* Let ALG be any algorithm for the write-many problem. Let $d$ denote a fixed disk. For any $0 \leq i < L$ it is possible to construct an offline algorithm $\text{ALG}_i$ that satisfies the following properties:

(i) $\text{ALG}_i$ processes the first $i - 1$ writes exactly as ALG does.

(ii) If block $b_i$ is the first block written after output step $s$, then immediately before output step $s$ there was no free buffer slot.

(iii) If $b_i$ is the first block written after output step $s$, then $\text{ALG}_i$ performs this output according to the MIN rule on disk $d$.

(iv) $\text{ALG}_i$ takes no more steps than ALG.

Once this claim is established, the theorem can be proven as follows: Starting with an optimal offline algorithm OPT, we apply the claim with $i = 0$ and $d = 0$ to obtain another optimal algorithm $\text{OPT}_0$, then apply the claim with $i = 1$ and $d = 0$ to obtain $\text{OPT}_1$ and so on. By induction over $i$, it can be seen that $\text{OPT}_{L-1}$ never leaves unused buffer slots before an output step and uses MIN for deciding which blocks to output on disk 0. Subsequently, we apply this sequence of $L$ transformations for each disk. Since these transformations do not undo property (iii) for other disks, we arrive at an optimal algorithm that works like manyWriting on all disks.

It remains to prove the claim. We initialize $\text{ALG}_i$ to ALG and transform $\text{ALG}_i$ until it fulfills all four properties. Note that this initialization automatically fulfills properties (i) and (iv). If properties (ii) and (iii) also hold, we are done.

If property (ii) is violated by $\text{ALG}_i$, then $b_i$ is the first block written by $\text{ALG}_i$ *after* some output step $s$, and before output step $s$ a free buffer slot was available. In this case, $\text{ALG}_i$ is modified so that $b_i$ is now the last block written *before* output step $s$. Note that this transformation preserves the order in which blocks are written and properties (i) and (iv). This transformation is repeated until $\text{ALG}_i$ also satisfies property (ii).

If properties (i), (ii), and (iv) hold but property (iii) is violated, there must be a write step $s$ so that $b_{i-1}$ is the last block written before output step $s$, and $b_i$ is the first block written after output step $s$ in $\text{ALG}_i$. Now we define a modified algorithm $\text{ALG}'_i$ that mimics $\text{ALG}_i$ (and hence ALG) until $b_{i-1}$ is written but uses the MIN rule in step $s$ so that properties (i)–(iii) hold for $\text{ALG}'_i$.

It remains to define the behavior of $\text{ALG}'_i$ after step $s$ so that property (iv) is also maintained. We use $\mathcal{X} + b$ as a shorthand for $\mathcal{X} + \{b\}$ for a set of blocks $\mathcal{X}$ and a block $b$. Immediately after output step $s$, the buffer pool of $\text{ALG}_i$ can be written as $\mathcal{M} = \mathcal{X} + b$ whereas $\text{ALG}'_i$ has buffer pool $\mathcal{M}' = \mathcal{X} + b'$ where $b$ is the block on disk $d$ whose next access is farthest in the future. $\text{ALG}'_i$ mimics $\text{ALG}_i$ as far as possible; that is, it performs output steps at the same time as $\text{ALG}_i$ and outputs the same blocks. As long as neither $b$ nor $b'$ is written or output by $\text{ALG}_i$, these two blocks remain the only difference between $\mathcal{M}$ and $\mathcal{M}'$. There are only three types of events that require special treatment.

**Event 1.** $\text{ALG}_i$ outputs $b$. In that case, $\text{ALG}'_i$ outputs $b'$. Afterwards we have $\mathcal{M} = \mathcal{M}'$, and from now on $\text{ALG}'_i$ can completely mimic $\text{ALG}_i$.

**Event 2.** Block $b'$ is rewritten. By definition of $b$, this situation happens before block $b$ is rewritten. After $b'$ is rewritten, we have $\mathcal{M} = \mathcal{Y} + b + b'$ and $\mathcal{M}' = \mathcal{Y} + b'$ for some common set $\mathcal{Y}$ of blocks. In particular, $\mathcal{M}'$ has one unused buffer slot. If $\text{ALG}_i$ outputs $b$ in this situation, $\text{ALG}'_i$ can again unify the states $\mathcal{M}$ and $\mathcal{M}'$ by *not* outputting anything on disk $d$.

**Event 3.** Block $b$ is rewritten. As discussed above, if $\mathcal{M} \neq \mathcal{M}'$, we must have $\mathcal{M} = \mathcal{Y} + b + b'$ and $\mathcal{M}' = \mathcal{Y} + b'$ before $b$ is rewritten. Now $\text{ALG}'_i$ uses its free buffer slot to accommodate $b$. We get $\mathcal{M} = \mathcal{M}' = \mathcal{Y} + b + b'$.

We end up with an algorithm $\text{ALG}'_i$ that fulfills properties (i)–(iv) and hence set $\text{ALG}_i{=}\text{ALG}'_i$. $\square$

**7. Application to sorting.** In this section we extend the duality between prefetching and queued writing to apply to problems of merging and distribution. In the merging phase of mergesort, there are several sorted runs on the disk, and the problem is to merge them together into a single sorted run. We assume that each run is striped across the disks using any given striping discipline, such as RC or FR, as described in the introduction. How to lay out the runs so as to permit fully parallel I/O is a challenging problem; recent work is surveyed in [23].

A big problem is that the input order $\Sigma$ for the blocks, namely the order in which the blocks need to be accessed, is highly data-dependent. The key to duality is to characterize $\Sigma$ in a simple and easily implementable way. If we examine the process of merging, as illustrated in Figure 7.1 from the bottom to top, we see that the merging buffer contains a partially filled block from each run (not yet expired). When the block empties all its items into the merged output stream, the next block from that run is inserted into the merging buffer. The merging buffer is pictured in the upper rectangle in Figure 7.1, which is distinct from the space reserved for the prefetch buffers (lower rectangle in Figure 7.1).

The first moment, therefore, that a block absolutely must be in memory is when the smallest key value of the block is merged into the output stream. We therefore define the *trigger* of a block to be its smallest key value. We say that a block is read when it is moved from the prefetch buffer to the merging buffer, where it stays until its items are exhausted by the merging process. Thus, the read order $\Sigma$ of the blocks is given by the sorted order of the triggers.

We have now reduced the merging problem to that of prefetching for the input sequence $\Sigma$. The dual problem to merging is distribution. To solve it via the duality principle, we need to process $\Sigma$ in reverse order. We equate the notion of bucket in distribution with that of run-in merging, so each block therefore has a bucket assigned to it. Since each bucket uses a fixed striping discipline, the blocks can then be assigned to disks. The dual distribution problem is thus well defined, and we get an optimal algorithm for merging by applying the algorithm of section 3.

FIG. 7.1. *The relationship between merging and distribution. Buffer space is required both "privately" within the application (for storing the lead block of each run in merging, and for storing the next block being formed for each bucket in distribution), and for the Output queues / Prefetch buffers required for the techniques proposed in this paper. During distribution, the priorities of blocks correspond to their output step. For merging, blocks are read in the order given by the triggers. When an appropriate allocation discipline is used to allocate blocks of a stream to the parallel disks, the queued I/O techniques of this paper permit I/O complexity results for distribution sort to be applied to mergesort (and vice versa if desired).*

**Mergesort with randomized cycling (RCM).** How the blocks of each run are striped depends on the particular allocation discipline used. We start by discussing multiway mergesort using randomized cycling allocation (RCM) in some detail and then survey a number of additional results. Originally, the $N$ input elements are stored as a single data stream using any kind of striping. During *run formation* the input is read in chunks of size $M$ that are sorted internally and then written out in runs allocated using RC allocation. Neglecting trivial rounding issues, run formation is easy to do using $2N/(DB)$ I/O steps. For example, we need $\mathcal{O}\big(N/(DB^2)\big)$ additional I/Os for writing the trigger values to separate files. Then we set aside a buffer pool of size $m = D/\gamma$ for some parameter $\gamma$ and perform $\lceil \log_{M/B-\mathcal{O}(D/\gamma)} \frac{N}{M} \rceil$ *merge phases.* In a merge phase, groups of $k = \frac{M}{B} - \mathcal{O}(D/\gamma)$ runs are merged into new sorted runs; that is, after the last merge phase, only one sorted run is left. Merging $k$ runs of total size $sB$ can be performed using $s$ block reads by keeping one block of each run in the internal memory of the sorting application. The I/O schedule for a merging phase is found by sorting the triggers for groups of $k$ runs each. These sorted trigger sequences are then concatenated, yielding the order in which the blocks are to be read. At this point we can apply duality.

The overhead for this precomputation of $\Sigma$ (trigger values) is $\mathcal{O}\big(N/B^2\big)$ I/Os even for a single disk [6]. The triggers allow us to do optimal prefetching so that Theorem 5.1 gives an upper bound of

$$(1+\mathcal{O}(\gamma))\,\frac{N}{BD} + \min\left\{k + \frac{N}{BD}, \mathcal{O}(\log(D/\gamma)/\gamma)\right\}$$

for the expected number of fetch steps of a phase. The number of output steps for a phase is $N/(BD)$ if we have an additional output buffer of $D$ blocks. The final result

TABLE 7.1

*Summary of the I/O complexity for parallel disk sorting algorithms. Each algorithm's I/O complexity is given by* $\mathrm{Sort}_{\Delta}^{a,f}(N)$ *when the parameters are set according to the algorithm's entry in the table. Algorithms with* **boldface** *names are asymptotically optimal: M = Mergesort. SM/SD = Merge / Distribution sort with any S allocation. SRM and SRD use SR. RCD, RCD+, and RCM use RC allocation.*

| $\mathrm{Sort}_{\Delta}^{a,f}(N)$ I/Os | | | Algorithm | Source |
|---|---|---|---|---|
| $a$ | $f$ | $\Delta$ | | |
| 2 | 0 | 0 | Lower bound | |
| Deterministic algorithms | | | | |
| 2 | 0 | 0 | M, $D = 1$ | [1] |
| $\mathcal{O}(1)$ | 0 | 0 | **Greed sort** | [21] |
| $2+\gamma$ | 0 | $\Theta\left((2D)^{1+\frac{2}{\gamma}}\right)$ | M, superblock striping | |
| $2+\gamma$ | 0 | $\Theta\left((2D)^{1+\frac{2}{\gamma}}\right)$ | SM | here |
| $2+\gamma$ | 0 | $\Theta\left((2D)^{1+\frac{2}{\gamma}}\right)$ | SD | here |
| Randomized algorithms | | | | |
| $2+\gamma$ | 0 | $\Theta(D\log(D)/\gamma^2)$ | SRM | [6] |
| $2+\gamma$ | 0 | $\Theta(D\log(D)/\gamma^2)$ | SRD | here |
| $3+\gamma$ | 0 | $\Theta(D/\gamma)$ | **RCD** | [24] |
| $2+\gamma$ | $\min(\frac{N}{BD}, \log(D)/\mathcal{O}(\gamma))$ | $\Theta(D/\gamma)$ | **RCM** | here |
| $2+\gamma$ | 0 | $\Theta(D/\gamma)$ | **RCD+** | here |

is written using any striped allocation strategy; the application calling the sorting routine need not be able to handle RC allocation. For any constant $\gamma > 0$, we can write the resulting total number of I/O steps as $\mathrm{Sort}_{m+D}^{2+\mathcal{O}(\gamma),\min(\frac{N}{BD},\frac{\log D}{\mathcal{O}(\gamma)})}(N)$, where

$$\mathrm{Sort}_{\Delta}^{a,f}(N) = \frac{2N}{DB} + a \cdot \frac{N}{DB} \cdot \left\lceil \log_{\frac{M}{B}-\Delta} \frac{N}{M} \right\rceil + f + o\left(\frac{N}{DB}\right).$$

Table 7.1 compares a selection of sorting algorithms using this generalized form of the I/O bound for parallel disk sorting. The term $\frac{2N}{DB}$ represents the reading and writing of the input and the final output, respectively. The factor $a$ is decisive for the I/O complexity for large inputs. Note that for $a = 2$ and $f = \Delta = 0$ this expression is the lower bound for sorting. The additive offset $f$ may dominate for small inputs. The reduction of the memory by $\Delta$ blocks in the base of the logarithm is due to memory that is used for output or prefetching buffer pools outside the merging or distribution routines, and hence reduces the number of data streams that can be handled concurrently. One way to interpret $\Delta$ is to view it as the amount of *additional* memory needed to match the performance of the algorithm on the multihead I/O model [1] where load balancing disk accesses is not an issue.

Note that the RCM algorithm outlined above is the first asymptotically optimal parallel disk sorting algorithm that approaches the optimal constant factor 2 for $M/B \gg D$. The first two rows of Table 7.1 show that single disk sorting (e.g., multiway mergesort) is optimal. Greed sort [21] is an optimal (up to a constant factor) deterministic sorting method based on mergesort; it does it an approximate merge and then finalizes the merge using columnsort. Balance sort [20] is an equally optimal but more practical deterministic sorting algorithm that uses distribution sorting together with adaptive allocation of blocks. An algorithm frequently used in practice is a single disk algorithm together with superblock striping (i.e., using logical blocks of size $BD$). This algorithm is quite good if the input is sufficiently small that we can still sort in two passes despite the much larger block size. Using Theorem 5.1, we get the same asymptotic bounds if we use the parallel disk mergesort outlined above together with any deterministic striping discipline (SM); that is, even as a deterministic algorithm, our algorithm has performance comparable to algorithms used in practice.

Mergesort using SRM was analyzed in [6]. Although our optimal prefetching result simplifies and improves the prefetching algorithms given there, we do not get improved asymptotic bounds.

**Distribution sort with randomized cycling (RCD+).** Using random sampling and the duality between reading and writing, as shown in Figure 7.1, we can transfer the results for mergesort to results using distribution-based sorting algorithms. We obtain a new distribution sort using deterministic striping (RD) or simple randomized striping (SRD). We can also improve the analysis of the variant with RC [24] reducing the constant factor from three to two. Furthermore, an additional optimization can be used to remove the additive term $\min(\frac{N}{BD}, \log(D)/\mathcal{O}(\gamma))$ in the complexity of RCM. Below we describe the resulting algorithm RCD+ in more detail since it currently represents the parallel disk sorting algorithm with the best known bounds. The same algorithm underlies the results for the other allocation strategies SD and SRD.

The basic idea behind distribution sort is to use a generalization of quicksort where elements are classified into $k = \mathcal{O}(M/B)$ classes based on $k-1$ splitter elements. The splitters are chosen in such a way that each class has size $\mathcal{O}(N/k)$. These classes are then sorted recursively and the results are appended to form the final output.

As in mergesort, we start with an input that is striped over the disks using some arbitrary allocation strategy. We set $k = \min(N/(M - cBD), M/B - cBD)$ for an appropriate parameter $c$. To find the splitter elements we take $dk - 1$ random sample elements for an appropriate integer $d$. The sample is sorted and every $d$th element in the sorted sample is used as a splitter. Standard calculations using Chernoff bounds indicate that $d = \mathcal{O}(\log k)$ is sufficient to ensure that with high probability at most $\mathcal{O}(N/k)$ elements lie between two splitters. It can be seen that the number of I/Os needed for obtaining the sample is only a lower-order term compared to the number of I/Os needed to scan the input.

Now the input is classified into $k$ classes by scanning the input and putting each element in the appropriate class. For each class we use an output stream allocated using RC. For each class, an output buffer block is maintained that is written to an RC allocated output stream when the buffer is completely filled. Writing uses greedyWriting. Here it is useful that the algorithm is an online algorithm since it is not known in advance in what order blocks have to be written out.

The additive term in the I/O bound for RCM mergesort can be avoided in RCD+ using the simple observation that the write buffers need not be flushed—blocks that are logically written but still in the output queue when the distribution finishes, are not flushed to disk but kept in the queues; see also the last sentence in Theorem 5.1. When we read a block in the subsequent recursive sorting phases, we therefore have to check whether this block is still in the output queue and should be taken from there.

Recursive sorting of the classes proceeds depth first, from left to right. As soon as a class fits into internal memory, it is loaded and sorted internally, then it is output using any kind of striping. No randomization is needed for the final output because there is only a single data stream. It suffices to keep $D$ output buffer blocks for the final output. Since the output is generated in sorted order, these output buffers need not be flushed when we are finished with a class which would lead to load imbalance for writing and partially filled blocks. Rather these buffer blocks are kept until they are filled by the sorting of subsequent classes. This way the output is produced in a perfectly striped fashion without partially filled blocks.

**8. A tight lower bound for external sorting.** Our main result for parallel disk sorting is that we close the gap between the upper and lower bounds up to lower-order terms. However, the lower bound from [1] leaves open the constant factors. In particular, it is not clear there what happens if the number of output steps and input steps differ. Therefore we now strengthen the lower bound to obtain the right constant factor.

THEOREM 8.1. *Assuming that $M/B$ is an increasing function, the number of I/Os required to sort or permute $n$ items, up to lower-order terms, is at least*

$$\frac{2N}{D}\frac{\log(N/B)}{B\log(M/B)+2\log N} \sim \begin{cases} \dfrac{2N}{DB}\dfrac{\log(N/B)}{\log(M/B)} & \textit{if } B\log\dfrac{M}{B}=\omega(\log N), \\ \dfrac{N}{D} & \textit{if } B\log\dfrac{M}{B}=o(\log N). \end{cases}$$

The second case in the theorem is the pathological case in which the block size $B$ and internal memory size $M$ are so small that the optimal way to permute the items is to move them one at a time in the naive manner, not making use of blocking.

The rest of this section is devoted to a proof of Theorem 8.1.

For the lower bound calculation, we can assume without loss of generality that there is only one disk, namely, $D = 1$. The I/O lower bound for general $D$ follows by dividing the lower bound for one disk by a factor of $D$.

DEFINITION 8.2. *We call an input operation* simple *if each item that is transferred from the disk gets removed from the disk and deposited into an empty location in internal memory; similarly, an output is* simple *if the transferred items are removed from internal memory and deposited into empty locations on disk.*

LEMMA 8.3 (Aggarwal and Vitter [1]). *For each computation that implements a permutation of the $N$ items, there is a corresponding computation strategy involving only simple I/Os such that the total number of I/Os is no greater.*

*Proof.* It is easy to construct the simple computation strategy by working backwards. We cancel the transfer of an item if its transfer is not needed for the final result. The resulting I/O strategy is simple. ☐

For the lower bound, we use the approach of Aggarwal and Vitter [1] and bound the maximum number of permutations that can be produced by at most $t$ I/Os. If we take the value of $t$ for which the bound first reaches $N!$, we get a lower bound on the worst-case number of I/Os. We can get a lower bound on the average case in a similar way.

DEFINITION 8.4. *We say that a permutation $p_1, p_2, \ldots, p_N$ of the $N$ items can be* produced after $t_I$ input operations and $t_O$ output operations *if there is some intermixed sequence of $t_I$ input operations and $t_O$ output operations so that the items end up in the permuted order $p_1, p_2, \ldots, p_N$ in extended memory. (By extended memory we mean the memory locations of internal memory followed by the memory locations on disk in sequential order.) The items do not have to be in contiguous positions in internal memory or on disk; there can be arbitrarily many empty locations between adjacent items.*

As mentioned above, we assume that I/Os are simple. Each I/O transfers exactly $B$ items, although some of the items may be *nil*. In addition, the I/Os obey block boundaries, in that all the non-*nil* items in a given I/O come from or go to the same block on disk.

Initially, the number of producible permutations is 1. Let us consider the effect of an output. There can be at most $N/B + o - 1$ nonempty blocks before the $o$th output operation, and thus the items in the $o$th output can go into one of $N/B + o$ places relative to the other blocks. Hence, the $o$th output boosts the number of producible permutations by a factor of at most $N/B + o$, which can be bounded trivially by

$$N(1 + \log N). \tag{8.1}$$

For the case of an input operation, we first consider a read I/O from a specific block on disk. If the $b$ items involved in the read I/O were together in internal memory at some previous time (e.g., if the block was created by an earlier output operation), then the items could have been arranged in an arbitrary order by the algorithm while in internal memory. Thus, the $b!$ possible ordering of the $b$ inputted items relative to themselves could already have been produced before the input operation. This implies in a subtle way that rearranging the newly inputted items among the other $M - b$ items in internal memory can boost the number of producible permutations by a factor of at most $\binom{M}{b}$, which is the number of ways to intersperse $b$ indistinguishable items within a group of size $M$.

The above analysis applies to input from a specific block. If the input was preceded by a total of $o$ output operations, there are at most $N/B + o \leq N(1 + \log N)$ blocks to choose from for the I/O, so the number of producible permutations is boosted further by at most $N(1 + \log N)$. Therefore, assuming that at some point the $b$ inputted items were previously together in internal memory, an input operation can boost the number of producible permutations by at most

$$N(1 + \log N)\binom{M}{b}. \tag{8.2}$$

Now let us consider an input operation in which some of the inputted items were not together previously in internal memory (e.g., the first time a block is read). By rearranging the relative order of the items in internal memory, we can increase the number of producible permutations. Given that there are $N/B$ full blocks initially, we get the maximum increase when the $N/B$ blocks are read in full, which boosts the number of producible permutations by a factor of

$$(B!)^{N/B}. \tag{8.3}$$

Let $I$ be the total number of input operations. In the $i$th input operation, let $b_i$ be the number of items brought into internal memory. By the simplicity property, some of the items in the block being accessed may not be brought into internal memory, but rather may be left on disk. In this case, $b_i$ counts only the number of items that are removed from disk and left in internal memory. In particular, we have $0 \leq b_i \leq B$.

By the simplicity property, we need to make room in internal memory for the new items arriving, and in the end all items are stored back on disk. Therefore we get the following lower bound on the number $O$ of output operations:

$$O \geq \frac{1}{B}\left(\sum_{1 \leq i \leq I} b_i\right). \tag{8.4}$$

Combining (8.1), (8.2), and (8.3), we find that

$$\big(N(1+\log N)\big)^{I+O} \prod_{1\le i\le I} \binom{M}{b_i} \ge \frac{N!}{(B!)^{N/B}}, \tag{8.5}$$

where $O$ satisfies (8.4).

Let $\bar{B}$ be the average number of items read during the $I$ input operations. By a convexity argument, the left-hand side of (8.5) is maximized when each $b_i$ has the same value, namely, $\bar{B}$. From (8.5) and (8.4), we get

$$\big(N(1+\log N)\big)^{I+O} \binom{M}{\bar{B}}^{I} \ge \frac{N!}{(B!)^{N/B}}, \tag{8.6}$$

$$\big(N(1+\log N)\big)^{I+O} \binom{M}{\bar{B}}^{(I+O)/(1+\bar{B}/B)} \ge \frac{N!}{(B!)^{N/B}}. \tag{8.7}$$

The left-hand side of (8.7) is maximized when $\bar{B} = B$, so we get

$$\big(N(1+\log N)\big)^{I+O} \binom{M}{B}^{(I+O)/2} \ge \frac{N!}{(B!)^{N/B}}. \tag{8.8}$$

The theorem follows by taking logarithms of both sides of (8.8) and using Stirling's formula and the fact that $M/B$ is an increasing function.

## 9. Conclusions.

In this paper we have exploited a natural duality between prefetching (read problem) and outputting (write problem). We have shown that an optimal schedule for one problem is the reverse of an optimal schedule for the other. We have generalized our approach to the read-many case in which frequently accessed blocks can be cached in memory. We have further reduced the problem of mergesorting and distribution sorting to the read and write problems, and by duality we have given practical yet asymptotically optimal (up to lower-order terms) em algorithms for mergesort and distribution sort. The algorithms are practical [12] and have very low overheads, thus making them desirable in practice.

## Appendix. Summary of notation.

$B$: Block size.
$b_i$: The $i$th block in a sequence of blocks.
$D$: Number of disks. In an acronym it stands for a sorting algorithm based on data Distribution.
$d$: Index of some disk.
disk($b_i$): The disk where block $b_i$ is allocated.
**FR**: Fully random allocation.
iStep($b_i$): The input step when block $b_i$ is fetched.
i$\mathcal{B}$acklog($b_i$): $|\{j > i : \text{iStep}(b_j) \le \text{iStep}(b_i)\}|$.
$L$: Number of blocks in the access sequence $\Sigma$.
$M$: Size of the fast internal memory. In an acronym it stands for a sorting algorithm based on Merging.
$m$: Number of buffer blocks in the buffer pool. Note that $m \le M/B$. In the sorting algorithms $m = \Theta(M/B)$.
$N$: The number of elements to be sorted.
oStep($b_i$): The output step when block $b_i$ is fetched.
o$\mathcal{B}$acklog($b_i$): $|\{j < i : \text{oStep}(b_j) \ge \text{oStep}(b_i)\}|$.

**RC**: Randomized Cycling allocation.
$\pi_i$: In RC allocation the random permutation used to allocate sequence $i$.
**S**: Stands for Striping in an allocation strategy or sorting algorithm.
**SR**: Simple randomized Striping using a random rotation.
Sort($N$): $\frac{N}{DB}(1 + \log_{M/B} \frac{N}{M})$ the I/O complexity of sorting $N$ elements "without the constant factor."
$\Sigma$: The sequence of blocks to be read or written.
$\Sigma^R$: The reverse of sequence $\Sigma$.

**Acknowledgments.** We would like to thank Jeffrey Chase, Andreas Crauser, S. Mitra, Nitin Rajput, Erhard Rahm, and Berthold Vöcking for valuable discussions. Anonymous referees have given detailed feedback that helped to improve the readability of the paper.

# DECIDABLE AND UNDECIDABLE PROBLEMS ABOUT QUANTUM AUTOMATA[*]

VINCENT D. BLONDEL[†], EMMANUEL JEANDEL[‡], PASCAL KOIRAN[‡], AND NATACHA PORTIER[‡]

**Abstract.** We study the following decision problem: is the language recognized by a quantum finite automaton empty or nonempty? We prove that this problem is decidable or undecidable depending on whether recognition is defined by strict or nonstrict thresholds. This result is in contrast with the corresponding situation for probabilistic finite automata, for which it is known that strict and nonstrict thresholds both lead to undecidable problems.

**Key words.** quantum automata, probabilistic automata, undecidable problems, algebraic groups

**DOI.** 10.1137/S0097539703425861

## 1. Introduction.

In this paper, we provide decidability and undecidability proofs for two problems associated with quantum finite automata. Quantum finite automata (QFA) were introduced by Moore and Crutchfield [MC00]; they are to quantum computers what finite automata are to Turing machines. Quantum automata are also analogous to the probabilistic finite automata introduced in the 1960s by Rabin that accept words with a certain probability (see [Rab63], [Rab67]; see also [Paz71] for a book-length treatment). A quantum automaton $A$ assigns real values $\mathrm{Val}_A(w)$ to input words $w$ (see below for a precise description of how these values are computed). $\mathrm{Val}_A(w)$ can be interpreted as the probability that on any given run of $A$ on the input word $w$, $w$ is accepted by $A$. Nonisolated cut-point recognition will be considered in this article: we do not ask for a gap between the set of $\mathrm{Val}_A(w)$ for accepted words $w$ and the set of $\mathrm{Val}_A(w)$ for rejected words $w$. Associated to a real threshold $\lambda$, the languages recognized by the automaton $A$ with nonstrict and strict threshold $\lambda$ are

$$L_{\geq} = \{w : \mathrm{Val}_A(w) \geq \lambda\} \quad \text{and} \quad L_{>} = \{w : \mathrm{Val}_A(w) > \lambda\}.$$

Many properties of these languages are known in the case of probabilistic and quantum automata. For instance, it is known that the class of languages recognized by quantum automata is strictly contained in the class of languages recognized by probabilistic finite automata [BP02]. For probabilistic automata it is also known that the problem of determining if $L_{\geq}$ is empty and the problem of determining if $L_{>}$ is empty are undecidable (see [Paz71, Thm. 6.17, p. 90]). This is true even for automata of fixed dimensions [BC03]. Decidability problems on QFA were first studied in the paper by Amano and Iwama [AI99]: is the language recognized by a 1.5-way quantum automaton empty? The undecidability of this problem was proven, even in the case of isolated cut-point.

Table 1
*Decidable and undecidable problems for probabilistic and quantum automata.*

| | $L_{\geq} = \emptyset$ | $L_{>} = \emptyset$ | $L_{\leq} = \emptyset$ | $L_{<} = \emptyset$ |
|---|---|---|---|---|
| PFA | undecidable | undecidable | undecidable | undecidable |
| QFA | undecidable | decidable | undecidable | decidable |

In this contribution, we consider the problem of determining for a quantum automaton $A$ and threshold $\lambda$ if there exists a word $w$ for which $\mathrm{Val}_A(w) \geq \lambda$ and if there exists a word $w$ for which $\mathrm{Val}_A(w) > \lambda$. We prove in Theorem 2.1 and Corollary 2.2 that the first problem is undecidable, and in Theorem 3.1 that the second problem is decidable. For quantum automata it thus makes a difference to consider strict or nonstrict thresholds. This result is in contrast with probabilistic automata, for which both problems are undecidable.

Similarly to the languages $L_{\geq}$ and $L_{>}$, one can define the languages $L_{\leq}$ and $L_{<}$ and ask whether or not they are empty (of course, emptiness of $L_{\leq}$ is equivalent to $L_{>}$ being equal to $\Sigma^*$). These two problems are known [Paz71] to be undecidable for probabilistic automata. For quantum automata our decidability results do again differ depending on whether we consider strict or nonstrict inequalities. Our results are summarized in Table 1.

Before we proceed with the proofs, we first define what we mean by a QFA. A number of different quantum automata models have been proposed in the literature and not all models are computationally equivalent. For the "measure-many" model of quantum automata introduced by Kondacs and Watrous [KW97] the four problems of Table 1 are proven undecidable in [Jea02]. The model we consider here is the so-called measure once quantum finite automaton introduced by Moore and Crutchfield [MC00]. These automata operate as follows. Let $\Sigma$ be a finite set of input letters and let $\Sigma^*$ denote the set of finite input words (including the empty word); typical elements of $\Sigma^*$ will be denoted $w = w_1 \cdots w_{|w|}$, where $w_i \in \Sigma$ and $|w|$ denotes the length of $w$. The QFA $A$ is given by a finite set of $n$ states, $n \times n$ unitary transition matrices $X_\alpha$ (one for each symbol $\alpha$ in $\Sigma$), a (row) vector of unit norm $s$ (the initial configuration), and an $n \times n$ orthogonal projection matrix $P$. Given a word $w \in \Sigma^*$, the value of $w$, denoted $\mathrm{Val}_A(w)$, is defined by

$$\mathrm{Val}_A(w) = \|sX_wP\|^2.$$

In this expression, $\|\cdot\|$ is the euclidean vector norm, and we use the notation $X_w$ for the product $X_{w_1} \cdots X_{w_{|w|}}$. For a vector $v$, the value $\|vP\|^2$ is the probability for the quantum state $v$ to be observed in acceptance space. The value $\mathrm{Val}_A(w)$ can thus be interpreted as the probability of observing the quantum state in acceptance space after having applied the operator sequence $X_{w_1}$ to $X_{w_{|w|}}$ to the initial quantum state $s$.

The rest of the paper is organized as follows. In section 2, we reduce Post's correspondence problem to the problem of determining if a quantum automata has a word of value larger than or equal to a given threshold. Post's correspondence problem is undecidable, and this therefore proves our first result. Our reduction uses an encoding of words in three-dimensional space. In section 3, we prove decidability of the same problem for strict inequality. For the proof we use the fact that any compact matrix group is algebraic, and the group we consider can be given an effective description.

**Complex versus real entries.** Throughout the paper we will assume that the initial state, the unitary matrices $X_\alpha$, and the projection matrix $P$ have real rather than complex entries (i.e., these matrices are actually orthogonal). This is not a significant restriction since any quantum automaton $A$ (with possibly complex entries) can be simulated by another quantum automaton $A'$ with real entries by doubling the number of states. More precisely, let $Q$ be the set of states of $A$. We replace each element $q_j$ of $Q$ by two states $q_j^1$ and $q_j^2$. Let $\phi : \mathbb{C}^n \to \mathbb{R}^{2n}$ be the $\mathbb{R}$-linear map which sends a configuration $x = \sum_{j=1}^n (\alpha_j + i\beta_j) q_j$ to $\phi(x) = \sum_{j=1}^n \alpha_j q_j^1 + \sum_{j=1}^n \beta_j q_j^2$. We replace the initial configuration $s$ by $s' = \phi(s)$. Let $X$ be one of the matrices of $A$. The rows and columns of $A$ are indexed by elements of $Q$. Let $x_{jk} + iy_{jk}$ be the entry at row $q_j$ and column $q_k$. Recall that a complex number $x + iy$ can be identified to the 2 × 2 matrix

$$\begin{pmatrix} x & -y \\ y & x \end{pmatrix} .$$

It is therefore natural to replace this entry by the 2 × 2 matrix

$$\begin{pmatrix} x_{jk} & -y_{jk} \\ y_{jk} & x_{jk} \end{pmatrix} .$$

The two rows and two columns of this matrix are indexed, respectively, by $q_j^1, q_j^2, q_k^1$, and $q_k^2$. By abuse of notation we also denote by $\phi$ the map which sends $X$ to $X'$. It is easy but instructive to check that for any $v \in \mathbb{C}^n$ and for any $n \times n$ complex matrices $A$ and $B$ the following relations hold: $\phi(Av) = \phi(A)\phi(v)$, $\phi(AB) = \phi(A)\phi(B)$, $\phi(A^*) = \phi(A)^T$, and $v^*v = \phi(v)^T\phi(v)$. Now recall that unitary matrices, orthogonal matrices, complex matrices of orthogonal projection, and real matrices of orthogonal projection are, respectively, characterized by the following relations: $AA^* = I$, $AA^T = I$, $A = A^* = A^2$, and $A = A^T = A^2$. It follows that $\phi$ sends unitary matrices to orthogonal matrices, and complex matrices of orthogonal projection to real matrices of orthogonal projection. The quantum automaton $A'$ defined by the orthogonal matrices $X'_a = \phi(X_a)$, the projection matrix $P' = \phi(P)$, and the initial configuration $s'$ satisfies $\phi(sX_wP) = s'X'_wP'$ for any word $w$. Hence $\mathrm{Val}_A(w) = \mathrm{Val}_{A'}(w)$ for any word $w$.

## 2. Undecidability for nonstrict inequality.

We prove in this section that the problem of determining if a quantum automata has a word of value larger than or equal to some threshold is undecidable. The proof is by reduction from Post's correspondence problem (PCP), a well-known undecidable problem. An instance of PCP is given by a finite alphabet $\Sigma$ and $k$ pairs of words $(u_i, v_i) \in \Sigma^* \times \Sigma^*$ for $i = 1, \dots, k$. A solution to the correspondence is any nonempty word $w = w_1 \cdots w_n$ over the alphabet $\{1, \dots, k\}$ such that $u_w = v_w$, where $u_w = u_{w_1} \dots u_{w_n}$. This correspondence problem is known to be undecidable: there is no algorithm that decides if a given instance has a solution [Pos46]. It is easy to see that the problem remains undecidable when the alphabet $\Sigma$ contains only two letters. The problem is also known to be undecidable for $k = 7$ pairs [MS05] but is decidable for $k = 2$ pairs; the decidability of the cases $2 < k < 7$ is not yet known. We are now ready to state our first result.

THEOREM 2.1. *There is no algorithm that decides for a given automaton $A$ if there exists a nonempty word $w$ for which $\mathrm{Val}_A(w) \le 0$, or if there exists one for which $\mathrm{Val}_A(w) \ge 1$. These two problems remain undecidable even if the automaton is given by 7 orthogonal matrices in dimension 6.*

*Proof.* We proceed by reduction from PCP. For our reduction we need to encode words by orthogonal matrices. We will take matrices that represent rotations of angle arccos(3/5) on, respectively, the first and third axes:

$$X_a = \frac{1}{5}\begin{pmatrix}3 & -4 & 0\\ 4 & 3 & 0\\ 0 & 0 & 5\end{pmatrix}, \quad X_b = \frac{1}{5}\begin{pmatrix}5 & 0 & 0\\ 0 & 3 & -4\\ 0 & 4 & 3\end{pmatrix}.$$

These matrices are orthogonal, $X_a X_a^T = I = X_b X_b^T$, and they generate a free group since a result from Swierczkowski [Sw58, Sw94] ensures that if $\cos\phi \in \mathbb{Q}$, two rotations of angle $\phi$ on orthogonal axes in $\mathbb{R}^3$ generate a free group if and only if $\cos\phi \notin \{0, \pm\frac{1}{2}, \pm 1\}$.

In addition to that, we now prove that there exists a vector $t$ such that $tX_u = tX_w$ implies $u = w$.

We will use here a method from [Su90]. One can show by induction that for any reduced matrix product $M$ of $k$ matrices[1] taken from the set $\{X_a, X_b, X_a^{-1}, X_b^{-1}\}$, we have

$$(3\ 0\ 4)M = (x_1\ x_2\ x_3)/5^k$$

with $x_1, x_2, x_3 \in \mathbb{Z}$, and 5 divides $x_2$ if and only if $k = 0$ (and then $M = I$).

The result is obviously true for $k = 0, 1$. Now, if $M = M' X_a X_b$, then $(3\ 0\ 4)M = (x_1\ x_2\ x_3)/5^k X_a X_b = (x_4\ x_5\ 5x_3)/5^{k+1} X_b$ for some $x_4, x_5$, and by induction hypothesis, 5 does not divide $x_5$. Now $(3\ 0\ 4)M = (x_6\ 3x_5 + 20x_3\ x_7)/5^{k+2}$ so that 5 does not divide the second term. The proofs for all the other cases are similar.

We will now call $t$ the row vector $(3\ 0\ 4)$. If $tX_u = tX_v$, then $tX_u X_v^{-1} = t$. As the second component of $t$ is equal to 0, the product must be trivial, and so $u = v$.

Given an instance $(u_i, v_i)_{1 \le i \le k}$ of PCP over the alphabet $\{a, b\}$ and a word $w \in \{1, \ldots, k\}^*$, we construct the matrix

$$Y_w = \frac{1}{2}\begin{pmatrix}X_{u_w} + X_{v_w} & X_{u_w} - X_{v_w}\\ X_{u_w} - X_{v_w} & X_{v_w} + X_{u_w}\end{pmatrix}.$$

These matrices are orthogonal and verify $Y_{w\nu} = Y_w Y_\nu$.

A solution of the original PCP problem is a nonempty word $w \in \{1, \ldots, k\}^*$ such that the upper-right block of the matrix $Y_w$ is equal to zero. We may use the previously introduced vector $t = (3\ 0\ 4)$ to test this condition. We have

$$\begin{pmatrix}t & 0\end{pmatrix} Y_w = \frac{1}{2}\begin{pmatrix}tX_{u_w} + tX_{v_w} & tX_{u_w} - tX_{v_w}\end{pmatrix},$$

and thus a solution of the PCP problem is a word $w$ such that the last three coordinates of $yY_w$ are equal to zero, where $y = \begin{pmatrix}t & 0\end{pmatrix}$. This condition can be tested with a projection matrix. Defining

$$P = \begin{pmatrix}0_3 & 0\\ 0 & I_3\end{pmatrix}$$

[1]A product is said to be *reduced* if no two consecutive matrices in the product are inverse from each other.

we have that the solutions of the original PCP problem are the words $w$ for which $y\ Y_w\ P = 0$, which is equivalent to

$$\mathrm{Val}_A(w) = \|yY_wP\|^2 = 0.$$

The values taken by $\mathrm{Val}_A(w)$ are nonnegative and so the problem of determining if there exists a nonempty word $w$ such that $\mathrm{Val}_A(w) \leq 0$ is undecidable. Notice also that $\|yY_wI\|^2 = 1$ and so

$$\|yY_w(I-P)\|^2 \leq 1$$

with equality only for $yY_wP = 0$. Thus, the problem of determining if there exists a nonempty word $w$ such that $\mathrm{Val}_A(w) \geq 1$ is undecidable too. ∎

Theorem 2.1 deals only with nonempty words. We remove this restriction in the next result, and we reduce the number of matrices from 7 to 2.

COROLLARY 2.2. *There is no algorithm that decides for a given automaton $A$ if there exists a word $w$ for which $\mathrm{Val}_A(w) \leq 0$, or if there exists one for which $\mathrm{Val}_A(w) \geq 1$. These problems remain undecidable even if the automaton is given by 7 orthogonal matrices in dimension 6, or by 2 orthogonal matrices in dimension 42.*

*Proof.* As in the proof of Theorem 2.1, the undecidability results for the condition $\mathrm{Val}_A(w) \geq 1$ follow from those for the condition $\mathrm{Val}_A(w) \leq 0$. Hence we supply the proofs for the latter condition only. We proceed by reduction from the problem $\exists w\ \mathrm{Val}_A(w) \leq 0$ for 7 matrices in dimension 6, which is undecidable for nonempty words $w$ as shown in Theorem 2.1. Note that the language of the nonempty $w$'s such that $\mathrm{Val}_A(w) \leq 0$ is the union of the seven languages defined by the conditions $\mathrm{Val}_A(iw) \leq 0$ for possibly empty words $w$ and $i \in \{1, \ldots, 7\}$. Hence the emptiness of one of these languages (say, the first one) must be undecidable. Thus, the problem of determining if there exists a word $w$ such that $\mathrm{Val}_A(1w) \leq 0$ is undecidable.[2] For each automaton $A = ((Y_i)_{i\in\{1,\ldots,7\}}, s, P)$ we can now construct the quantum automaton $B = ((Y_i)_{i\in\{1,\ldots,7\}}, y, P)$, where $y = sY_1$. Then $\mathrm{Val}_A(1w) \leq 0$ if and only if $\mathrm{Val}_B(w) \leq 0$.

The following problem is therefore undecidable: given a quantum automaton $A$ defined by 7 orthogonal matrices in dimension 6, is there a (possibly empty) word $w$ such that $\mathrm{Val}_A(w) \leq 0$?

Finally, we show how to reduce the number of matrices to 2. We use a construction from Blondel and Tsitsiklis [BT97] and Blondel and Caterini [BC03]. Given the above matrices $Y_i$ and the projection matrix $P$, we define

$$Z_0 = \begin{pmatrix} Y_1 & 0 & \ldots & 0 \\ 0 & Y_2 & \ddots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & Y_7 \end{pmatrix} \quad \text{and} \quad Z_1 = \begin{pmatrix} 0 & I & 0 & 0 \\ 0 & \ddots & \ddots & 0 \\ \vdots & \vdots & \ddots & I \\ I & 0 & \ldots & 0 \end{pmatrix}.$$

When taking products of these two matrices the matrix $Z_1$ acts as a "selecting matrix" on the blocks of $Z_0$. Let us define $x = \begin{pmatrix} y & 0 \end{pmatrix}$ and

$$Q = \begin{pmatrix} P & 0 & \ldots & 0 \\ 0 & P & \ddots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & P \end{pmatrix}.$$

[2]It is not difficult to show that the 6 other problems must be undecidable as well.

We claim that there exists a word $w$ over the alphabet $\{1,\dots,7\}$ such that $\|yY_wP\| = 0$ if and only if there exists a word $\nu$ over $\{0,1\}$ such that $\|xZ_\nu Q\| = 0$. Indeed, for any word $\nu$ over $\{0,1\}$, $xZ_\nu$ is a row vector of block form $(0\cdots 0\ yY_w\ 0\cdots 0)$ for some word $w$ over $\{1,\dots,7\}$ (the length of $w$ is equal to the number of 0's in $\nu$). Therefore $\|xZ_\nu Q\| = \|yY_wP\|$. Conversely, for any word $w$ over $\{1,\dots,7\}$ there exists a word $\nu$ over $\{0,1\}$ such that $xZ_\nu$ is a row vector of block form $(yY_w\ 0\cdots 0)$, and we therefore have again the equality $\|xZ_\nu Q\| = \|yY_wP\|$. To obtain $Z_\nu$ from $Y_w$, one can for instance replace as in [BT97] each matrix $Y_i$ in the product $Y_w$ by $Z_1^{-(8-i)}Z_0Z_1^{(8-i)} = Z_1^{i-1}Z_0Z_1^{8-i}$. ∎

Theorem 2.1 and its corollary deal only with 0/1 thresholds. We prove below that, whichever threshold $0 < \lambda \leq 1$ is used, the problem of determining if there exists a word for which $\mathrm{Val}_A(w) \geq \lambda$ is undecidable. This result follows as a corollary to the following lemma.

LEMMA 2.3. *Associated to every QFA $A$ and threshold $0 < \lambda \leq 1$ we can effectively construct a QFA $B$ such that the language recognized with threshold $\lambda$ by $B$ is the language recognized with threshold 1 by $A$. Moreover, if $\lambda \in \mathbb{Q}$ and $A$ has only rational entries, then $B$ can be chosen with rational entries.*

*Proof.* The idea is to construct $B$ by adding a state to $A$. Let $A$ be given by the orthogonal matrices $X_i^A$, the projection matrix $P^A$, and the initial vector $s^A$. Let

$$X_i^B = \begin{pmatrix} X_i^A & 0 \\ 0 & 1 \end{pmatrix},$$

and define $s^B = \begin{pmatrix} \sqrt{\lambda}\, s^A & \sqrt{1-\lambda} \end{pmatrix}$. If we choose

$$P^B = \begin{pmatrix} P^A & 0 \\ 0 & 0 \end{pmatrix},$$

we immediately have $\mathrm{Val}_B(w) = \lambda\ \mathrm{Val}_A(w)$ and the first part of lemma is proven. The entries $\sqrt{\lambda}$ and $\sqrt{1-\lambda}$ in general do not need to be rational. It remains to show how the parameters of $B$ can be chosen rational when those of $A$ are. We therefore use Lagrange's theorem to write $\lambda$ and $1-\lambda$ as the sum of the squares of four rational numbers, say $\lambda = a_1^2 + a_2^2 + a_3^2 + a_4^2$ and $1 - \lambda = b_1^2 + b_2^2 + b_3^2 + b_4^2$.

Now, if we define

$$s^B = \begin{pmatrix} a_1 s^A & a_2 \cdots a_4 & b_1 \cdots b_4 \end{pmatrix}\ X_i^B = \begin{pmatrix} X_i^A & 0 \\ 0 & I_7 \end{pmatrix}\ P^B = \begin{pmatrix} P^A & 0 & 0 \\ 0 & I_3 & 0 \\ 0 & 0 & 0_4 \end{pmatrix},$$

we immediately have $\mathrm{Val}_B(w) = a_1^2\mathrm{Val}_A(w) + a_2^2 + a_3^2 + a_4^2$, $\|s^B\|^2 = 1$ and the lemma is proven. ∎

Combining Lemma 2.3 with Corollary 2.2, we immediately obtain the following.

COROLLARY 2.4. *For any rational $\lambda$, $0 < \lambda \leq 1$, there is no algorithm that decides if a given quantum automata has a word $w$ for which* $\mathrm{Val}(w) \geq \lambda$.

## 3. Decidability for strict inequality.

We now prove that the problem of determining if a quantum automata has a word of value *strictly* larger than some threshold is decidable. This result points to a difference between quantum and probabilistic automata since for probabilistic automata this problem is known to be undecidable.

Once an automaton is given, one can of course always enumerate all possible words $w$ and halt as soon as one is found for which $\mathrm{Val}_A(w) > \lambda$, and so the problem is clearly semidecidable. In order to show that it is decidable, it remains to exhibit a procedure that halts when $\mathrm{Val}_A(w) \leq \lambda$ for all $w$.

Let a quantum automata $A$ be given by a finite set of $n \times n$ orthogonal transition matrices $X_i$, an initial configuration $s$ of unit norm, and a projection matrix $P$. The value of the word $w$ is given by $\mathrm{Val}_A(w) = \|sX_wP\|^2$. Let $\mathcal{X}$ be the semigroup generated by the matrices $X_i$, $\mathcal{X} = \{X_w : w \in \Sigma^*\}$, and let $f : \mathbb{R}^{n\times n} \mapsto \mathbb{R}$ be the function defined by $f(X) = \|sXP\|^2$. We have that

$$\mathrm{Val}_A(w) = f(X_w),$$

and the problem is now that of determining if $f(X) \leq \lambda$ for all $X \in \mathcal{X}$. The function $f$ is a (continuous) polynomial map and so this condition is equivalent to $f(X) \leq \lambda$ for all $X \in \overline{\mathcal{X}}$, where $\overline{\mathcal{X}}$ is the closure of $\mathcal{X}$ in $\mathbb{R}^{n\times n}$. The set $\overline{\mathcal{X}}$ has the interesting property that it is algebraic (see below for a proof), and so there exist polynomial mappings $f_1, \dots, f_p : \mathbb{R}^{n\times n} \mapsto \mathbb{R}$, such that $\overline{\mathcal{X}}$ is exactly the set of common zeros of $f_1, \dots, f_p$. If the polynomials $f_1, \dots, f_p$ are known, the problem of determining whether $f(X) \leq \lambda$ for all $X \in \overline{\mathcal{X}}$ can be written as a quantifier elimination problem

$$\forall X \big[ (f_1(X) = 0 \wedge \cdots \wedge f_p(X) = 0) \implies f(X) \leq \lambda \big]. \tag{3.1}$$

This is a first-order formula over the reals and can be decided effectively by Tarski–Seidenberg elimination methods (see [Ren92a, Ren92b, Ren92c, BPR96] for a survey of known algorithms). If we knew how to effectively compute the polynomials $f_1, \dots, f_p$ from the matrices $X_i$, a decision algorithm would therefore follow immediately. In the following we solve a simpler problem: we effectively compute a sequence of polynomials whose zeros describe the same set $\overline{\mathcal{X}}$ after finitely many terms (but we may never know how many). It turns out that this is sufficient for our purposes. We will use some basic algebraic geometry. In particular, we will use the Noether (or "descending chain") property: in any field, the set of common zeros of a set of $n$-variate polynomials is equal to the set of common zeros of a *finite* subset of these polynomials (see any textbook on algebraic geometry, for instance, [CLO92, Prop. 1, sect. 4.6]).

THEOREM 3.1. *Let $(X_i)_{i\in\Sigma}$ be orthogonal matrices of dimension $n$ and let $\overline{\mathcal{X}}$ be the closure of the semigroup $\{X_w : w \in \Sigma^*\}$. The set $\overline{\mathcal{X}}$ is algebraic, and if the $X_i$ have rational entries, we can effectively compute a sequence of polynomials $f_1, \dots, f_i, \dots$ such that*

1. *if $X \in \overline{\mathcal{X}}$, $f_i(X) = 0$ for all $i$;*
2. *there exists some $k$ such that $\overline{\mathcal{X}} = \{X : f_i(X) = 0, i = 1, \dots, k\}$.*

*Proof.* We first prove that $\overline{\mathcal{X}}$ is algebraic. It is known (see, e.g., [OV90]) that every compact group of real matrices is algebraic. In fact, the proof of algebraicity in [OV90] reveals that any compact group $G$ of real matrices of size $n$ is the zero set of

$$\mathbb{R}[X]^G = \{f \in \mathbb{R}[X] : f(I) = 0 \text{ and } f(gX) = f(X)\, \forall\, g \text{ in } G\};$$

i.e., $G$ is the zero set of the polynomials in $n \times n$ variables which vanish at the identity and are invariant under the action of $G$. We will use this property later in the proof.

To show that $\overline{\mathcal{X}}$ is algebraic, it suffices to show that $\overline{\mathcal{X}}$ is compact and is a group. The set $\overline{\mathcal{X}}$ is obviously compact (bounded and closed in a normed vector space of finite dimension). Let us show that it is a group. It is in fact known that every compact subsemigroup of a topological group is a subgroup. Here is a self-contained proof in our setting: For every matrix $X$, the sequence $X^k$ admits a subsequence that is a

Cauchy sequence, by compactness. Hence for every $\epsilon$ there exists $k > 0$ and $l > k+1$ such that $\|X^k - X^l\| \leq \epsilon$, that is, $\|X^{-1} - X^{l-k-1}\| \leq \epsilon$ (recall that $\|AB\| = \|B\|$ if $A$ is orthogonal and if $\|.\|$ is the operator norm associated to the euclidean norm). Hence, $X^{-1}$ is in the set and the first part of the theorem is proven. For notational convenience, we will denote the group $\overline{\mathcal{X}}$ by $G$ in the remainder of the proof.

For the second part of the theorem, we will prove that we can take

$$\{f_i\} = \{f \in \mathbb{Q}[X] : f(I) = 0 \text{ and } f(X_j X) = f(X)\, \forall j \text{ in } \Sigma\}.$$

In other words, this is the set $\mathbb{Q}[X]^G$ of rational polynomials which vanish at the identity and are invariant under the action of each matrix $X_j$. It is clear that this set is recursively enumerable. We claim that $G$ is the zero set of the $f_i$'s. By Noetherianity the zero set of the $f_i$'s is equal to the zero set of a finite subset of the $f_i$'s, so that the theorem follows immediately from this claim. To prove the claim, we will use the fact that $G$ is the zero set of $\mathbb{R}[X]^G$. Note that

$$\mathbb{R}[X]^G = \{f \in \mathbb{R}[X] : f(I) = 0 \text{ and } f(X_j X) = f(X)\, \forall j \text{ in } \Sigma\}.$$

(A polynomial is invariant under the action of $G$ if and only if it is invariant under the action of all the $X_j$.) This observation implies immediately that each $f_i$ is in $\mathbb{R}[X]^G$, so that the zero set of the $f_i$'s contains the zero set of $\mathbb{R}[X]^G$. The converse inclusion follows from the fact that any element $P$ of $\mathbb{R}[X]^G$ can be written as a linear combination of some $f_i$'s. Indeed, let $d$ be the degree of $P$ and let $E_d$ be the set of real polynomials in $n \times n$ variables of degree at most $d$. The set $V_d = E_d \cap \mathbb{R}[X]^G$ is a linear subspace of $E_d$ defined by a system of linear equations with rational coefficients (those equations are $f(I) = 0$ and $f(X_j X) = f(X)$ for all $j \in \Sigma$). Hence there exists a basis of $V_d$ made up of polynomials with rational coefficients, that is, of elements of $\{f_i\}$. This completes the proof of the claim, and of the theorem. $\square$

We may now apply this result to quantum automata.

THEOREM 3.2. *The two following problems are decidable:*

(i) *Given a quantum automaton $A$ and a threshold $\lambda$, decide whether there exists a word $w$ such that* $\mathrm{Val}_A(w) > \lambda$.

(ii) *Given a quantum automaton $A$ and a threshold $\lambda$, decide whether there exists a word $w$ such that* $\mathrm{Val}_A(w) < \lambda$.

*Proof.* We show only that problem (i) is decidable. The argument for problem (ii) is essentially the same.

As pointed out at the beginning of this section, it suffices to exhibit an algorithm which halts if and only if $\mathrm{Val}_A(w) \leq \lambda$ for every word $w$. Consider the following algorithm:

- enumerate the $f_i$'s;
- for every initial segment $f_1, \ldots, f_p$, decide whether (3.1) holds, and halt if it does.

It follows from property (1) in Theorem 3.1 that $\mathrm{Val}_A(w) \leq \lambda$ for every word $w$ if the algorithm halts. The converse follows from property (2). $\square$

In Theorems 3.1 and 3.2 we have assumed that our orthogonal matrices have rational entries, mostly because the undecidability results of section 2 already hold for rational entries. It is not hard to relax this hypothesis. For instance, it is clear from the proofs that Theorems 3.1 and 3.2 can be generalized to matrices with real algebraic entries. Even more generally, one may allow "arbitrary" real entries by proceeding as follows. Let $K$ be the subfield of $\mathbb{R}$ generated by the entries of our matrices. We may give a transcendence basis $\mathcal{B}$ of $K$ and represent the entries as algebraic numbers over $\mathcal{B}$. This purely algebraic information is sufficient to compute the sequence of polynomials $(f_i)$ in Theorem 3.1. We also need to decide for every initial segment whether (3.1) holds. After quantifier elimination, this amounts to computing the sign of a finite number of polynomial functions of the elements of $\mathcal{B}$. In order to do this we need only assume that we have access to an oracle which for any element $x$ of $\mathcal{B}$ and any $\epsilon > 0$ outputs a rational number $q$ such that $|x - q| < \epsilon$ (such an oracle can be effectively implemented if the entries are computable real numbers). We use the algebraic information to determine whether a polynomial takes the value zero, and if not we use approximations to determine its sign.

In the proof of Theorem 3.2 we have bypassed the problem of explicitly computing a finite set of polynomials defining $\overline{\mathcal{X}}$. It is in fact possible to show that this problem is algorithmically solvable [DJK03]. This implies in particular that the following two problems are decidable:

(i) Decide whether a given threshold is isolated.

(ii) Decide whether a given QFA has an isolated threshold.

A threshold $\lambda$ is said to be isolated if

$$\exists \epsilon > 0 \; \forall w \in \Sigma^* \; |\mathrm{Val}_A(w) - \lambda| > \epsilon.$$

It is known that these two problems are undecidable for probabilistic automata [Ber75, BMT77, BC03].

The algorithm of [DJK03] for computing $\overline{\mathcal{X}}$ also has applications to quantum circuits: this algorithm can be used to decide whether a given set of quantum gates is complete (*complete* means that any orthogonal transformation can be approximated to any desired accuracy by a quantum circuit made up of gates from the set). Much effort has been devoted to the construction of specific complete sets of gates [DBE95, BBC+95], but no general algorithm for deciding whether a given set is complete was known.

Finally, we note that the proof of Theorem 3.2 does not yield any bound on the complexity of problems (i) and (ii). We hope to investigate this question in future work.

**Acknowledgment.** P.K. would like to thank Etienne Ghys for pointing out reference [OV90]. We are also grateful to the anonymous referee for his very careful reading of the manuscript.

# NOVEL TRANSFORMATION TECHNIQUES USING Q-HEAPS WITH APPLICATIONS TO COMPUTATIONAL GEOMETRY[*]

QINGMIN SHI[†] AND JOSEPH JAJA[†]

**Abstract.** Using the notions of Q-heaps and fusion trees developed by Fredman and Willard, we develop general transformation techniques to reduce a number of computational geometry problems to their special versions in partially ranked spaces. In particular, we develop a fast fractional cascading technique, which uses linear space and enables sublogarithmic iterative search on catalog trees in the case when the degree of each node is bounded by $O(\log^\epsilon n)$ for some constant $\epsilon > 0$, where $n$ is the total size of all the lists stored in the tree. We apply the fast fractional cascading technique in combination with the other techniques to derive the first linear-space sublogarithmic time algorithms for two fundamental geometric retrieval problems: orthogonal segment intersection and rectangular point enclosure.

**1. Introduction.** Q-heaps and fusion trees [10, 11] are data structures that achieve sublogarithmic search time on one-dimensional (1-D) data. In particular, a Q-heap supports constant time *insertion*, *deletion,* and *predecessor* search on very "small" subsets of a larger set using linear space. In [30], Willard illustrated how upper bounds for several search problems can be improved using the Q-heap. In this paper, we further explore the Q-heap technique in the context of computational geometry by using it to develop several general techniques, which lead to faster algorithms for a number of geometric retrieval problems.

A geometric retrieval problem is to preprocess a set $S$ of $n$ geometric objects so that, when given a query specifying a set of geometric constraints, the subset $Q$ of $S$ consisting of the objects that satisfy these constraints can be reported quickly. Examples of geometric retrieval problems include orthogonal segment intersection [26, 3], rectangular point enclosure [19, 27, 3], and orthogonal range queries [2, 29, 20, 3, 4, 21, 25] and their special cases [19, 30, 5, 18]. A typical data structure for handling such a problem often involves a primary constant-degree search tree $T$ whose nodes are each equipped with secondary structures, which are built on a subset of $S$ and are capable of handling special versions of the original query very quickly. There are two main ideas behind such a typical data structure. First, the objects in $S$ are distributed among the nodes of $T$ in such a way that the number of nodes of $T$ visited during a search process is bounded by the depth of $T$ or the output size. Second, for each node $v$ visited, the search query on the set $S(v)$ of objects stored there can be performed very quickly. The first idea is often realized by ensuring that either a nonroot node $v$ is visited only if it is on a specific path from the root of $T$

to a leaf node (for example, in handling the segment intersection and rectangle point enclosure problems [3]), or the time spent at $v$ can be compensated by the time spent at reporting $Q \cap S(parent(v))$, in case searching $S(v)$ is not fruitful; i.e., we visit $v$ only if $S(parent(v)) \cap Q \neq \emptyset$ (for example, in handling the three-sided three-dimensional (3-D) range queries [19] and the 3-D dominance queries [5]). The second idea is often implemented by (i) making sure that we can perform certain types of *rank* operations on $S(v)$ in constant time (typically using the fractional cascading technique), or (ii) constructing a constant number of secondary data structures on $S(v)$ such that each can be chosen to handle a special version of the original query, which is derived based on the additional information provided by the discriminator associated with $v$ and which has less constraints.

The fusion tree technique makes it possible to further reduce the search complexity of some of these structures by increasing the degree of the primary search trees to $\log^\epsilon n$, so that the height of the tree is reduced to $O(\log n / \log\log n)$. The *branch* operation at each node can be performed in constant time by making direct use of the Q-heaps. However, the fact that the degree of the tree is now dependent on $n$ introduces at least the following three problems. First, the standard fractional cascading technique would take a nonconstant amount of time at each node. In fact, a search operation performed on the list associated with a tree node would require $O(\log\log n)$ time, which negates the effect of a “fattened” primary search tree. Second, the number of discriminators at a node $v$ is no longer a constant, which makes it very difficult to use only a constant number of secondary structures for the quick handling of special versions of the original query. Finally, a nonempty output at a node no longer ensures that we can afford to search each of its children, since none of them may contain an output object. Doing so would result in an $O(f \log^\epsilon n)$ term in the overall search complexity, where $f$ is the output size.

In this paper, we develop several techniques to handle the first two problems by making strong use of the Q-heap technique. In particular, we show that, under the RAM model used by Fredman and Willard, if $T$ is a tree whose degree $c$ is bounded by a logarithmic function of $n$, i.e., $c = \log^\epsilon n$ for some constant $\epsilon$, then it is possible to improve the performance of the standard fractional cascading structure so that *rank* operations on $S(v)$ for each node $v$ except the root can be performed in constant time (independent of $n$) without asymptotically increasing the storage cost. We call this new fractional cascading technique *fast fractional cascading*. This is a general technique and is of independent interest. We also show how to perform search operations on a set $S(v)$ very quickly by transforming the problem to the partially ranked space $[1, 2, \ldots, c] \times \mathcal{N}$, where very fast search operations are possible using Q-heaps and table look-ups. This transformation can also be used to handle the so-called *lookahead* problem [30], deciding whether or not searching a substructure will be fruitful before it is actually searched, which is crucial in overcoming the third obstacle mentioned at the end of the last paragraph.

We believe that these techniques have the potential to improve the asymptotic upper bounds of a wide range of geometrical retrieval problems. In this paper we apply our techniques to two fundamental geometric retrieval problems: *orthogonal segment intersection* and *rectangular point enclosure*. Each of our algorithms achieves $O(n)$ space and $O(\log n / \log\log n + f)$ query time. The best previous results require $O(\log n + f)$ query time when using linear space [3, 18]. In a separate paper [14], we show how to apply these techniques to obtain the first linear-space sublogarithmic algorithm for the 3-D dominance reporting problem.

We now formally define the two geometric retrieval problems to be tackled in this paper. To facilitate our explanation, we will denote a horizontal (resp., vertical) segment in a 2-D space as $(x_1, x_2; y)$ (resp., $(x; y_1, y_2)$), where $(x_1, y)$ and $(x_2, y)$ (resp., $(x, y_1)$ and $(x, y_2)$) are its two endpoints and $x_1 \leq x_2$ (resp., $y_1 \leq y_2$)).

1. *Orthogonal segment intersection.* Given a set $S$ of $n$ horizontal segments, report the subset $Q$ of segments that intersect a given vertical segment. We say a horizontal segment $(x_1, x_2; y)$ *intersects* a vertical segment $(x; y_1, y_2)$ if and only if $x_1 \leq x \leq x_2$ and $y_1 \leq y \leq y_2$. We call the segments in $Q$ *proper segments* relative to the given query.

2. *Rectangular point enclosure.* Let $(x_1, x_2; y_1, y_2)$ denote a rectangle in a 2-D space with edges parallel to the axes, where the intervals $[x_1, x_2]$ and $[y_1, y_2]$ are the projections of this rectangle to the $x$-axis and $y$-axis, respectively. Given a set $S$ of rectangles, report the subset $Q$ of *proper rectangles* such that each rectangle $(x_1, x_2; y_1, y_2)$ in $Q$ contains a query point $(x, y)$, i.e., $x_1 \leq x \leq x_2$ and $y_1 \leq y \leq y_2$.

In this paper, we use the RAM model as described in [10]. In this model, it is assumed that each word contains $w$ bits, and the size of a data set never exceeds $2^w$, i.e., $w \geq \log_2 n$. In addition to arithmetic operations, bitwise logical operations are also assumed to take constant time.

The next section introduces some well-known techniques that will be heavily utilized in the rest of the paper. In section 3, we present the fast fractional cascading structure, while sections 4 and 5 present the improved algorithms for, respectively, orthogonal segment intersection and rectangular enclosure.

## 2. Preliminaries.

Given a set $S$ of multidimensional points $(x_1, x_2, \ldots, x_d)$, a point with the largest $x_i$-coordinate smaller than or equal to a real number $\alpha$ is called the $x_i$-*predecessor* of $\alpha$, and the one with the smallest $x_i$-coordinate larger than or equal to $\alpha$ is called the $x_i$-*successor* of $\alpha$.

The notion of a *Cartesian* tree was first introduced by Vuillemin [28] (and rediscovered by Seidel and Aragon [23]). A Cartesian tree is a binary tree defined over a finite set of 2-D points sorted by their $x$-coordinates, say $(p_1, \ldots, p_n)$. Let $p_i$ be the point with the largest $y$-coordinate. Then $p_i$ is associated with the root $w$ of $C$. The two children are, respectively, the root of the Cartesian trees built on $p_1, \ldots, p_{i-1}$ and $p_{i+1}, \ldots, p_n$. Note that the left (resp., right) child of $w$ does not exist if $i = 1$ (resp., $i = n$). Figure 2.1 shows an example of the Cartesian tree.

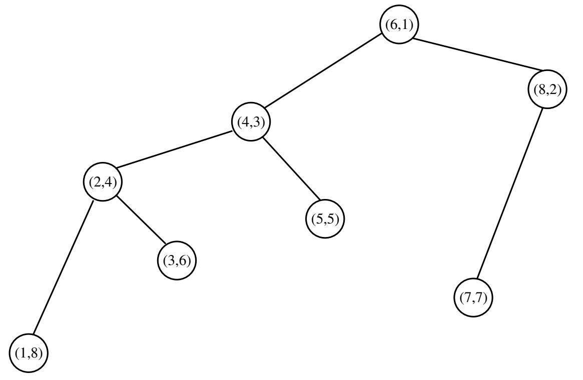

FIG. 2.1. *Cartesian tree.*

**2.1. Cartesian trees.** An important property of the Cartesian tree is given by the following observation [12].

OBSERVATION 2.1. *Consider a set $S$ of 2-D points and the corresponding $(x, y)$-Cartesian tree $C$. Let $x_1 \leq x_2$ be the x-coordinates of two points in $S$, and let $\alpha$ and $\beta$ be their respective nodes in $C$. Then the point with the largest y-coordinate among those points whose x-coordinates are between $x_1$ and $x_2$ is stored in the nearest common ancestor of $\alpha$ and $\beta$.*

Using Observation 2.1, combined with the techniques for computing the nearest common ancestors [13] (see also [1]) in constant time, we have shown in [24] that we can handle the so-called *three-sided* 2-D *range queries* efficiently. Briefly, a point $(a, b)$ satisfies the three-sided query $(x_1, x_2, y)$, with $x_1 \leq x_2$, if $x_1 \leq a \leq x_2$ and $b \geq y$.

LEMMA 2.1. *By preprocessing a set of $n$ 2-D points to construct an $(x, y)$-Cartesian tree $C$, we can handle any three-sided 2-D range query given as $(x_1, x_2, y)$, with $x_1 \leq x_2$, in $O(t(n) + f)$ time, where $t(n)$ is the time it takes to find in $C$ the leftmost and rightmost nodes whose x-coordinates fall within the range $[x_1, x_2]$, and $f$ is the number of points reported.*

Note that $C$ should be transformed into a suitable form to enable the computation of nearest common ancestors in constant time.

**2.2. Q-heaps and fusion trees.** *Q-heaps* and *fusion trees*, developed by Fredman and Willard [10, 11], achieve sublogarithmic search time on 1-D data. While the Q-heap data structure was proposed later than the fusion tree, it can be used as a building block for the fusion tree [30]. Using Q-heaps and fusion trees, Willard demonstrated in [30] theoretical improvements for a number of range search problems.

The Q-heap [11] supports insert, delete, and search operations in constant time for small subsets of a large data set of size $n$. Its main properties are given in the following lemma (the version presented here is taken from [30]).

LEMMA 2.2. *Suppose $S$ is a subset with cardinality $m < \log^{1/5} n$ lying in a larger database consisting of $n$ elements. Then there exists a Q-heap data structure of size $O(m)$ that enables insertion, deletion, member, and predecessor queries on $S$ to run in constant worst-case time, provided that access is available to a precomputed table of size $o(n)$.*

Note that the look-up table of size $o(n)$ referred to above is shared by all the Q-heaps built on subsets of this larger database.

The fusion tree built on the Q-heap achieves linear space and sublogarithmic search time. The following lemma is a simplified version of Corollary 3.2 from [30].

LEMMA 2.3. *Assume that in a database of $n$ elements we have available the use of precomputed tables of size $o(n)$. Then it is possible to construct a data structure of size $O(n)$ space, which has a worst-case time $O(\log n / \log \log n)$ for performing member, predecessor, and rank operations.*

Notice that the assumptions of the RAM model introduced in section 1 are critical to achieving the bounds claimed in the above lemmas.

**2.3. Adjacency map and hive graph.** The notion of the *adjacency map* was first introduced by Lipski and Preparata [16]. Given a set $S$ of $n$ horizontal segments, the *vertical adjacency map* $G(S)$ is constructed by interconnecting the horizontal segments in $S$ using vertical (infinite, semi-infinite, or finite) segments as follows: from each endpoint of the segments in $S$, draw two rays shooting upward and downward, respectively, until they meet other segments in $S$ except possibly at an endpoint. This creates a planar subdivision $G(S)$ with $O(n)$ vertices, which are the joints of

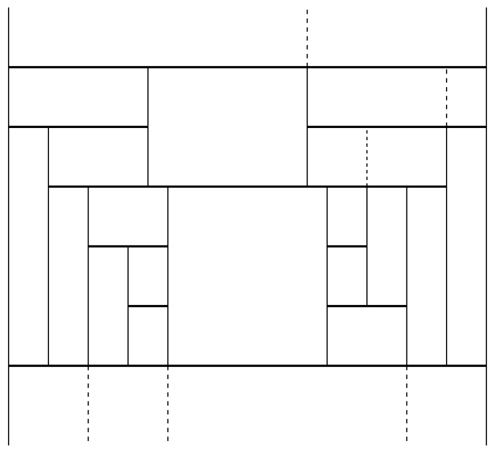

FIG. 2.2. *A hive graph.*

the horizontal and vertical segments. $G(S)$ can be represented in $O(n)$ space using the adjacency lists associated with the vertices. We call the edges supported by the horizontal segments *horizontal* edges and those supported by the vertical segments *vertical* edges.

Chazelle noticed in [3] that the adjacency map is a useful tool which, when modified appropriately, can be used to handle the orthogonal segment intersection problem efficiently. His modification of the vertical adjacency map is called the *hive graph.* A hive graph $H(S)$ is derived from $G(S)$ by adding only vertical segments to $G(S)$ while maintaining $O(n)$ vertices and $O(n)$ space representation. However, it has the important property that each face may have, in addition to its four (or fewer) corners, at most two extra vertices, one on each horizontal edge. Figure 2.2 shows a vertical adjacency map and its corresponding hive graph, in which the additional vertical edges are depicted as dashed lines. By assuming that the endpoints of the segments in $S$ all have distinct $x$- and $y$-coordinates, as [3] did, one can conclude that each face of $H(S)$ has $O(1)$ vertices on its boundary. Given a query segment $(x; y_1, y_2)$, the segment intersection query can be handled as follows. We first find the face in $H(S)$ that contains the endpoint $(x, y_1)$ in $O(\log n)$ time by using one of the well-known planar point location algorithms [8, 9, 15, 17, 22]. Then we traverse a portion of $H(S)$ from bottom up, following the direction from $(x, y_1)$ to $(x, y_2)$. Only a constant number of vertices are visited between two consecutive encounters of the horizontal edges that intersect the query segment.

Note that the vertical boundary of a face of the hive graph corresponding to a vertical adjacency map will not necessarily contain a constant number of vertices if the assumption that the endpoints of the segments in $S$ have distinct $x$-coordinates does not hold. Since we will need to deal later with such a case, we get around this problem by associating with each vertex pointers to the upper-right or upper-left corner in the same face, as follows. We modify $H(S)$ by associating with each vertex $\beta$ two additional pointers $p(\beta)$ and $q(\beta)$. Let $\beta = \delta_1, \delta_2, \ldots, \delta_l = \gamma$ be the maximal chain of vertices such that each pair of consecutive vertices $\delta_i$ and $\delta_{i+1}$ is connected by a vertical edge $e_i$ and $\delta_{i+1}$ is above $\delta_i$, for $i = 1, \ldots, l-1$. Note that this chain can be empty ($l = 1$), in which case both $p(\beta)$ and $q(\beta)$ are null. If there exists a vertex in $\{\delta_2, \delta_3, \ldots, \delta_l\}$ which has a horizontal edge connecting it to a

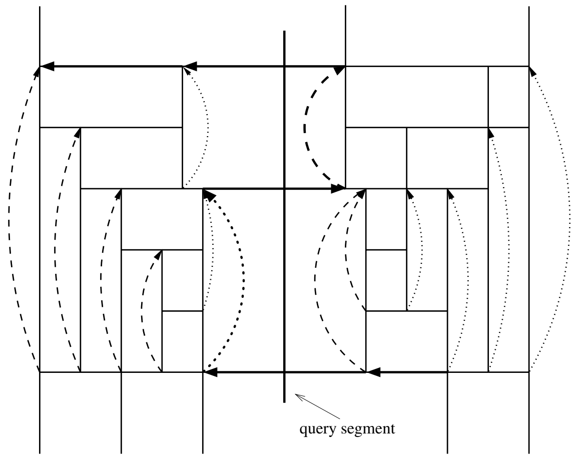

FIG. 2.3. *Modified hive graph.*

vertex to the left of it, then $p(\beta)$ points to the lowest such vertex. Otherwise, $p(\beta)$ is null. Similarly, if there exists a vertex that has a horizontal edge connecting it to a vertex to the right of it, then $q(\beta)$ points to the lowest such vertex. Otherwise, $q(\beta)$ is null. It is easy to see that, using these additional pointers, we can in constant time reach the next proper segment without the distinct $x$-coordinates assumption. Figure 2.3 shows such a modified hive graph. The additional pointers $p(\beta)$ and $q(\beta)$ are depicted, respectively, as dashed and dotted arrows. To simplify the drawing, we omit the pointer $\alpha = p(\beta)$ or $\alpha = q(\beta)$ if $\alpha$ is null or $(\alpha, \beta)$ is an edge in $H(s)$. This figure also illustrates the search path of an exemplary segment intersection query by highlighting the pointers involved.

As noted in [3], when the query segment is semi-infinite, that is, consists of a ray $(x; -\infty, y_2)$ shooting downward, there is no need to perform the initial planar point location query. Instead, we can, during preprocessing, sort the $x$-coordinates of the vertical edges of the faces unbounded from below, and perform as the first step at query time a search on the sorted $x$-coordinates to locate the face that contains the point $(x, -\infty)$. The following lemma is a restatement of Corollary 1 in [3].

LEMMA 2.4. *Given a set $S$ of $n$ horizontal segments in the plane, an $O(n)$ space hive graph can be used to determine all the intersections of the horizontal segments with a semi-infinite vertical query segment $s = (x; -\infty, y_2)$ in $O(t(n)+f)$ time, where $f$ is the number of intersections, and $t(n)$ is the time it takes to search the sorted list of $x$-coordinates.*

Combining Lemmas 2.3 and 2.4, we have the following corollary.

COROLLARY 2.5. *Given a set $S$ of $n$ horizontal segments in the plane and a vertical query segment in the form of $(x; -\infty, y_2)$, it is possible to report all $f$ proper segments of $S$ in $O(\log n/\log\log n + f)$ time using $O(n)$ space.*

Clearly, by rotating the hive graph 90° clockwise (resp., counterclockwise), the same type of techniques will yield a solution for handling any orthogonal segment intersection query that involves a set $S$ of vertical segments and a horizontal query segment of the form $(-\infty, x_2; y)$ (resp., $(x_1, +\infty; y)$). We will denote this rotated hive graph HL(S) (resp., $HR(S)$).

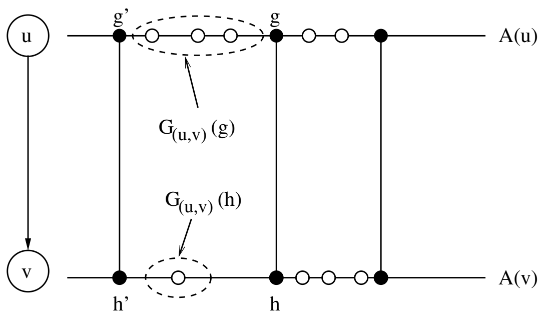

FIG. 3.1. *Fractional cascading.*

**3. Fast fractional cascading.** Suppose we have a tree $T = (V, E)$ rooted at $w$ such that each node $v$ has a degree bounded by $c$ and contains a catalog $L(v)$ of sorted elements. Let $n$ denote the total number of elements in these catalogs. A key value $k(g)$ from $\mathcal{N} \cup \{-\infty, +\infty\}$ is associated with each element $g$ in $L(v)$. The elements in $L(v)$ do not need to have distinct key values. We call such a tree a *catalog tree.* Let $x$ be a real number and $F$ be an arbitrary forest with $p$ nodes consisting of subtrees of $T$ determined by some of the children of $w$. Both $x$ and $F$ can be specified online, i.e., not necessarily at preprocessing time. Let $\sigma_L(x)$ denote the successor of $x$ in a catalog $L$. The *iterative search problem* is defined as follows [6]: report $\sigma_{L(v)}(x)$ for each $v$ in $F$. This problem (in a somewhat less general form) was first discussed by Willard in the context of handling 2-D orthogonal range queries [29]. A technique called *fractional cascading* was later proposed by Chazelle and Guibas [6, 7] to deal with the general problem. We now briefly introduce their approach.

**3.1. Fractional cascading.** The following lemma is a direct derivation from the one given by Chazelle and Guibas for identifying the successor of a value $x$ in each of the catalogs in $F$ [6].

LEMMA 3.1. *There exists a linear size fractional cascading data structure that can be used to determine the successors of a given value $x$ in the catalogs associated with $F$ in $O(p \log c + t(n))$ time, where $t(n)$ is the time it takes to identify the successor of $x$ in $L(w)$.*

The main component of a fractional cascading structure is the notion of the *augmented catalogs.* At each node $v$ in $T$, in addition to the original catalog $L(v)$, we store another augmented catalog $A(v)$, which is a superset of $L(v)$ and contains additional copies of elements from the augmented lists associated with its parent and children. With each element $h$ in $A(v)$, we associate a pointer to its successor $\sigma_{L(v)}(h)$ in $L(v)$. Since $A(v)$ is a superset of $L(v)$, we have $\sigma_{L(v)}(g) = \sigma_{L(v)}(\sigma_{A(v)}(g))$. Note that the elements in an augmented list $A(v)$ form a multiset $S(v)$; that is, a single element can appear multiple times in an augmented list. The elements in an augmented list are chained together to form a doubly linked list.

As illustrated in Figure 3.1, let $u$ and $v$ be two neighboring nodes in $T$, $u$ being $v$'s parent. There exists a subset $B(u, v)$ of $A(u) \times A(v)$ such that, for each pair of elements $(g, h) \in B(u, v)$, $k(g) = k(h)$. The pair of elements $(g, h)$ are called a *bridge.* There is a pointer to $h$ associated with the element $g$, and similarly a pointer to $g$ is associated with $h$. We will call $g$ a *down-bridge*, and $h$ an *up-bridge*, associated with the edge $(u, v)$. It is important to point out that each element in an augmented list can serve as at most one up-bridge or one down-bridge, but not both. Bridges respect the ordering of equal-valued elements and thus do not "cross." This guarantees that $B(u, v)$ can be ordered and the concept of *gap* presented next is well defined. In this ordered set $B(u, v)$, the bridge $(g, h)$ appears after the $(g', h')$ if and only if $g$ appears after $g'$ in $A(u)$. A *gap* $G_{(u,v)}(g, h)$ of bridge $(g, h)$ is defined as the multiset of elements from both $A(u)$ and $A(v)$ which are strictly between two bridges $(g, h)$ and $(g', h')$, where $(g', h')$ is the bridge that appears immediately before $(g, h)$ in $B(u, v)$. Accordingly, we define the *up-gap* (resp., *down-gap*) $G_{(u,v)}(g)$ (resp., $G_{(u,v)}(h)$) as the subset of $G_{(u,v)}(g, h)$ containing elements from $A(u)$ (resp., $A(v)$), preserving their orders in the respective augmented catalogs.

The fractional cascading structure maintains the invariant that the size of any gap cannot exceed $6c - 1$. Chazelle and Guibas provided in [6] an algorithm that can construct such a data structure in $O(n)$ time, and they prove that it requires $O(n)$ space.

Given a parent-child pair $(u, v) \in E$, suppose we know the successor $\sigma_{A(u)}(x)$ of a value $x$ in $A(u)$. We follow $A(u)$ along the direction of increasing values to the next down-bridge $g$ connecting $u$ and $v$ (it could be $\sigma_{A(u)}(x)$ itself if it is a down-bridge), cross it to its corresponding up-bridge $h$, and scan $A(v)$ in the opposite position until the successor of $x$ in $A(v)$ is encountered. Clearly, $\sigma_{A(v)}(x)$ is guaranteed to be found by this process. The constraint on the gap size ensures that the number of comparisons required is $O(c)$.

When $c$ is a constant, the above result is optimal. When $c$ is large, Chazelle and Guibas used the so-called *star tree* to achieve $O(\log c)$ search time on each catalog except the one stored at the root.

**3.2. Fast fractional cascading.** The fractional cascading structure described above is strictly list-based, and hence all the related algorithms can run on a pointer machine within the complexity bounds stated. Using the variation of the RAM model introduced in section 1 and the Q-heap technique of Fredman and Willard [11], summarized in section 2.2, we can achieve constant search time (independent of $c$) per node for the class of catalog trees whose degree is bounded by $c = \log^{\epsilon} n$, while simultaneously maintaining a linear size data structure. We call this version *fast fractional cascading*. This result improves over our previous result in [24], which achieves the same search complexity but requires nonlinear space. We will first revisit the nonlinear space solution and then explain how to reduce the storage cost to linear.

**3.2.1. Fast fractional cascading with nonlinear space.** We augment the fractional cascading structure described in section 3.1 by adding two types of components to each augmented catalog $A(v)$. First, we associate $c$ additional pointers $p_1(g), p_2(g), \ldots, p_c(g)$ with each element $g$ in $A(v)$ such that $p_i(g)$ points to the next down-bridge (possibly $g$ itself) connecting $v$ to $w_i$, where $w_i$ is the $i$th child of $v$ from the left. Second, we build for each up-gap $G_{(u,v)}(h)$ a Q-heap $Q(h)$, containing elements in $G_{(u,v)}(h)$ with distinct values (choosing the first one if multiple elements have the same value). For large enough $n$ we have $6c - 1 < \log^{1/5} n$, and therefore Lemma 2.2 is applicable. We have added $c$ pointers for each of the elements in the augmented catalogs, whose overall size cannot exceed $O(n)$. In addition, a global look-up table of size $O(n)$ is used to serve all the Q-heaps. Finally, no two up-gaps in an augmented catalog overlap, as they correspond to the same edge in $T$ (which is not true for a general graph). Hence the Q-heaps cannot consume more than $O(n)$ space.

Now suppose we have found $g = \sigma_{A(u)}(x)$ in $A(u)$. Let $v$ be the $i$th child of $u$.

By following the pointer $p_i(g)$, we can reach in constant time the next down-bridge in $u$ and then its companion up-bridge $h$ in $v$. Using $Q(h)$, we can find the successor of $x$ in $G_{(u,v)}(h)$ in constant time.

LEMMA 3.2. *Let $c = O(\log^\epsilon n)$. The fast fractional cascading structure described above allows the identification of the successors of a given value $x$ in the catalogs associated with $F$ in $O(p + t(n))$ time, where $t(n)$ is the time it takes to identify the successor of $x$ in $L(w)$. This structure requires $O(cn)$ space.*

**3.2.2. Fast fractional cascading with linear space.** We partition each augmented catalog $A(u)$ into $p = \lceil |A(u)|/c \rceil$ blocks $B_1, B_2, \ldots, B_p$, each, except possibly the last one, containing $c$ elements. For each block $B_i$ starting from the $l$th element of $A(u)$, we construct a set $C_i$ of $t \le 7c - 1$ records as follows. For each down-bridge $g$ that is the $d$th element in $A(u)$, where $l \le d \le l + 7c - 2$, we include in $C_i$ a record $r$ that contains two entries *r.ptr* and *r.key*. The entry *r.ptr* is a pointer to $g$, and *r.key* is the key of $r$ whose value is defined as $r.key = j * (7c - 1) + (d - l)$ if $g$ is associated with the edge connecting $u$ and its $(j + 1)$th child (note that *r.key* can fit in a word). The records in $C_i$ are sorted in increasing order by their key values. Now let $g$ be the successor of a value $x$ in $A(u)$ and suppose we want to find the successor of $x$ in the augmented catalog associated with the $(j + 1)$th child $v$ of $u$. It is easy to determine in constant time the block $B_i$ to which $g$ belongs and its position $f$ relative to the starting position of $B_i$ ($f = 0$ if $g$ is the first element in $B_i$). If $g$ is itself a down-bridge associated with $(u, v)$, then we are done. Otherwise, due to the invariant regarding the gap size, the next down-bridge $h$ associated with $(u, v)$ must have a corresponding record in $C_i$. The following lemma transforms the problem of finding $h$ to a successor search in $C_i$.

LEMMA 3.3. *The record in $C_i$ that corresponds to $h$ is the successor of the value $y = j \cdot (7c - 1) + f$.*

*Proof.* First we notice the fact that all the keys of the records in $C_i$ are distinct. Let $y' = j \cdot (7c - 1) + f'$ be the key of the record in $C_i$ that corresponds to $h$. It is obvious that $y < y'$. Now let $y'' = j'' \cdot (7c + 1) + f''$ be the key of a record $r$ in $C_i$ such that $y \le y''$. We need to show only that $y' \le y''$. Since both $f''$ and $f$ are nonnegative integers less than $7c - 1$, the fact that $y \le y''$ leads to either $j < j''$, or $j = j''$ and $f \le f''$. If $j < j''$, we immediately have $y' < y''$. On the other hand, if $j = j''$, then the record $r$ also corresponds to a down-bridge associated with the edge $(u, v)$. Since $h$ is the leftmost down-bridge closest to $g$, we have $f' \le f''$. Thus $y' \le y''$. ☐

The problem of finding the successor of an integer value in a small set $C_i$ can be solved, again using the Q-heap data structure. The following straightforward observations ensure the applicability of Lemma 2.2:

1. $|C_i| < \log^{1/5} n$ for $n$ large enough; and
2. the total number of distinct keys created for all the augmented catalogs is bounded by $O(n)$.

Finally, it is easy to see that the overall additional space introduced by the new Q-heaps is $O(n)$, and thus we have the following theorem.

THEOREM 3.4. *For $c = O(\log^\epsilon n)$ for some $\epsilon < \frac{1}{5}$, our fast fractional cascading structure allows the identification of the successors of a given value $x$ in the catalogs associated with $F$ in $O(p + t(n))$ time, where $t(n)$ is the time it takes to identify the successor of $x$ in $L(w)$. This structure requires $O(n)$ space.*

**4. Orthogonal segment intersection.** Before tackling the general orthogonal segment intersection problem, we develop a linear size data structure to handle a special case in which the $x$-coordinates of the endpoints of the segments and the query segment can take integer values only over a small range of values. We will later show how to use the solution of the special case to derive a solution to the general problem.

**4.1. Modified vertical adjacency map.** Assume that the $x$-coordinates of the endpoints of each segment $(k_1, k_2; y)$ in the given set $R$ of $n$ horizontal segments can take values from the set of integers $\{1, 2, \ldots, c\}$, where $c = \log^{\epsilon} n$ is an integer, and furthermore, assume that the $x$-coordinate $k$ of the query segment $r = (k; z_1, z_2)$ is an integer between 1 and $c$. Let $Y(R) = (y_1(R), y_2(R), \ldots, y_{n'}(R))$ be the list of distinct $y$-coordinates of the segments in $R$ sorted in increasing order.

Our overall strategy consists of augmenting the vertical adjacency map with auxiliary structures so that we will be able to identify the lowest segment in $R$ intersecting $r$ very quickly, followed by progressively determining the next sequence of lowest segments, each in $O(1)$ time. The details of this strategy are described next.

Our indexing structure $D(R)$ consists of two major components: $H(R)$ and $M(R)$. $H(R)$ is a *directed* vertical adjacency map with auxiliary information attached to it. We define the direction of the horizontal edges to be from right to left, and that of the vertical edges to be from bottom up. Note that we do not require that each face of $H(R)$ have a constant number of vertices on its boundary.

Each vertex of $H(R)$ is naturally associated with a pair of $x$, $y$-coordinates. We call the vertex with an outgoing horizontal edge a *tail*. We augment $H(R)$ with three types of components as follows.

1. For each distinct $y$-coordinate $y_j(R)$ of $Y(R)$, we create a Q-heap $Q_j(R)$ to index the $x$-coordinates of the vertices whose $y$-coordinates are equal to $y_j(R)$.

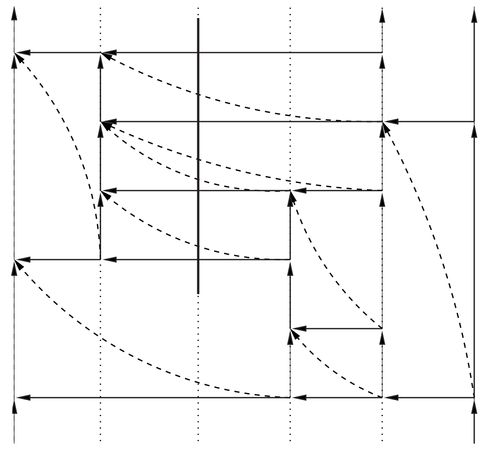
2. For each integer $1 \leq i \leq c$ that serves as the $x$-coordinate of at least one tail, we create a list $P_i(R)$ of records. Each record $g$ corresponds to a tail $\alpha$ whose $x$-coordinate is $i$ and contains two elements: $g.key$, which is the $y$-coordinate of $\alpha$, and $g.ptr$, which is a pointer to $\alpha$. This list is sorted in increasing order by the key values.

3. With each vertex $\beta$ we associate two pointers $p(\beta)$ and $q(\beta)$. Let $y_j(R)$ be the $y$-coordinate of $\beta$. Then $p(\beta)$ points to the Q-heap $Q_j(R)$. If $\beta$ is not a tail, $q(\beta)$ is null. Otherwise, there is at least one vertex with the same $y$-coordinate as $\beta$ that has an outgoing vertical edge and is to the strict left of $\beta$. Let $\gamma$ be the rightmost such vertex, and $e_1, e_2, \ldots, e_l$ be the shortest chain of vertical edges starting from $\gamma$ such that the head $\xi$ of $e_l$ has an incoming horizontal edge. If such a chain exists, then $q(\beta)$ points to $\xi$. If not, $q(\beta)$ is null. Note that intuitively $q(\beta)$ is the top left corner (if it exists) of a face containing $\beta$.

It is clear that $H(R)$ is of size $O(n)$.

In addition to $H(R)$, we have a bitmap $M(R)$ consisting of a list of bit-vectors. Each vector $V_j(R)$ corresponds to a distinct $y$-coordinate $y_j(R)$ and contains $c$ bits. The $i$th bit, starting from the most significant one, is set to 1 if there is a vertical edge in $H(R)$ passing through the point $(i, y_j(R))$ and 0 otherwise. Each vector can easily fit in a single word, and thus the storage cost of $M(R)$ is $O(n)$. These vectors are aligned with the lower end of the words and are stored in increasing order by the values of the corresponding $y$-coordinates.

As an example, Figures 4.1(a) and (b) illustrate the structures $H(R)$ and $M(R)$. In Figure 4.1(a), the dotted lines depict the $c$ possible $x$-coordinates, the dashed pointers are the $q$-pointers that are not null, and the thick line represents the query segment.



(a)

|  | 6 | 5 | 4 | 3 | 2 | 1 |
|---|---|---|---|---|---|---|
| $V_6(R)$ | 1 | 1 | 0 | 0 | 1 | 1 |
| $V_5(R)$ | 1 | 1 | 0 | 0 | 1 | 1 |
| $V_4(R)$ | 1 | 1 | 0 | 1 | 1 | 1 |
| $V_3(R)$ | 1 | 1 | 0 | 1 | 1 | 1 |
| $V_2(R)$ | 1 | 0 | 0 | 1 | 1 | 1 |
| $V_1(R)$ | 1 | 0 | 0 | 1 | 1 | 1 |

(b)

FIG. 4.1. (a) $H(R)$ *and* (b) $M(R)$.

Given a vertical segment $r = (k; z_1, z_2)$, we first identify the lowest segment that intersects $r$ and then report each of the remaining proper segments in the direction of increasing $y$-coordinates.

Locating the lowest segment that intersects $r$ is performed using $M(R)$. Let $y_j(R)$ be the smallest $y$-coordinate greater than or equal to $z_1$. If no such $y$ exists, then there is no segment in $R$ which intersects $r$. Otherwise, we find the largest value $i \leq k$ such that the $i$th bit in $V_j(R)$ is 1. (This number always exists because the vertical edges whose $x$-coordinates are equal to $c$ form a infinite line, and therefore the lowest bits of all the vectors are set to 1.) This can be accomplished by first masking out the highest $w - k$ bits of $V_j(R)$, $w$ being the number of bits in a word, and then locating its most significant bit. In [10], Fredman and Willard describe how to compute the most significant bit of a word in constant time.

After identifying $i$, we use $P_i(R)$ to determine the record $g$ with the smallest key larger than or equal to $z_1$. We can then immediately obtain the vertex $\alpha$ pointed to by *g.ptr*.

LEMMA 4.1. *Let* $(k_\alpha, y_\alpha)$ *be the coordinates of* $\alpha$. *Then for any segment* $(k_1, k_2; y)$ *in* $R$ *such that* $k_1 \leq k$ *and* $y_\alpha > y \geq y_1$, *we have* $k_2 < k$. *That is, any horizontal segment between* $y_\alpha$ *and* $y$ *which starts to the left of* $r$ *ends before meeting* $r$.

*Proof.* The proof is by contradiction. Suppose $k_2 \geq k$. We then have $k_2 < k_\alpha$, because otherwise the vertical line passing through $\alpha$ would have had at least one vertex $\alpha'$ lying on it with its coordinates $(k_{\alpha'}, y_{\alpha'})$ satisfying $k_{\alpha'} = k_\alpha = i$ and $y_{\alpha'} < y_\alpha$, which contradicts the way we chose $\alpha$. Now consider the vertical line passing through the endpoint $(k_2, y)$. Either it passes through the point $(k_2, y_j(R))$ or intersects a horizontal segment whose left endpoint is to the left of $\alpha$ and whose $y$-coordinate is strictly between $y$ and $y_j(R)$. In the first case, we have a contradiction because there would have been a more significant one-bit than $i$ in $V_j(R)$. In the second case, the right endpoint of that horizontal segment has to be to the strict left of $\alpha$, following the same argument for the segment $(k_1, k_2; y)$. By repeatedly applying this argument, we can show that either there is a one-bit in $V_j(R)$ more significant than the $i$, or there is a record in $P_i(R)$ whose key is smaller than $y_\alpha$ but larger than $y_1$, each leading to a contradiction. ∎

LEMMA 4.2. *If $y_\alpha \le y_2$, then the horizontal segment $t = (k_1, k_2; y)$ on which $\alpha$ lies intersects $r$.*

*Proof.* The only possible scenario in which $t$ does not intersect $r$ is when $k_1 > k$. If this is the case, then there has to be a vertical segment $(k_1; y_1', y_2')$ consisting of several edges in $H$ and passing through the point $(k_1, y)$. This segment cannot cross the horizontal line corresponding to $V_j(R)$ because otherwise there would have been a more significant one-bit than the $i$th in $V_j(R)$. Therefore there has to be a horizontal segment $t' = (k_1', k_2'; y_1')$ with $k_2' > k_1 > k$. Lemma 4.1 implies that $k_1' > k$. Repeating this argument will ultimately lead to a contradiction. $\square$

Lemmas 4.1 and 4.2 show that the horizontal segment $t$ on which $\alpha$ lies is the lowest segment that intersects $r$. Using the Q-heap pointed to by $p(\alpha)$, we can find the vertex $\beta$ with the same $y$-coordinate as $\alpha$ and the smallest $x$-coordinate greater than or equal to $k$. Since $t$ intersects $r$, we are sure that $\beta$ is also on $t$. The following lemma explains how to iteratively find the remaining segments that intersect $r$.

LEMMA 4.3. *Let $t$ be a horizontal segment that intersects $r$ and suppose we know the vertex $\beta$ of $H(R)$ on $t$ with the smallest $x$-coordinate $k_\beta$ larger than or equal to $k$. We can in constant time decide whether there is another segment $t'$ above $t$ that intersects $r$, and furthermore, if there is one, identify in constant time such a $t'$ having the smallest $y$-coordinate larger than that of $t$.*

*Proof.* We first give the algorithm to compute the vertex $\beta'$ on $t'$ with the smallest $x$-coordinate $k_{\beta'}$ larger than or equal to $k$. Consider the following cases.

Case 1: $\beta$ has an outgoing vertical edge $e$ and $k = k_\beta$.

Case 1.1: $e$ is an infinite edge, i.e., $e$ is a ray shooting upwards. Then there are no other segments intersecting $r$.

Case 1.2: The edge $e$ is finite. In this case, the vertex $\beta'$ is the head of $e$, and $t'$ is the horizontal segment on which $\beta'$ lies.

Case 2: $\beta$ does not have an outgoing vertical edge $e$ or $k \ne k_\beta$.

Case 2.1: $q(\beta)$ is null. There are no other segments intersecting $r$.

Case 2.2: $q(\beta)$ is not null. $\beta'$ corresponds to the successor of $k$ in the Q-heap pointed to by $p(q(\beta))$, and $t'$ is the horizontal segment on which $\beta'$ lies.

We now show the correctness of this algorithm. We only discuss Case 2, as the correctness of our algorithm for Case 1 is obvious. First consider the case when $q(\beta)$ is null. Since $\beta$ has to be a tail, the vertical ray starting from $\gamma$ (introduced in the definition of $q(\beta)$) shooting upward does not contain a vertex with an incoming horizontal edge. Hence if there were a horizontal segment above $t$ that intersected $r$, $\gamma$ would not be the rightmost vertex to the left of $\beta$ that has an outgoing vertical edge. Hence no segment above $t$ intersects $r$.

We now consider Case 2.2. In this case, $\gamma$ and the chain starting from it always exist. Let $e_1, e_2, \ldots, e_l$ be the chain of vertical edges used to define $q(\beta)$; $\gamma = \delta_1, \delta_2, \ldots, \delta_{l+1} = \xi$ be the sequence of vertices such that for each $1 \le j \le l$, $e_j = (\delta_j, \delta_{j+1})$; and $(k', y_\gamma)$ and $(k', y_\xi)$ be the respective coordinates of $\gamma$ and $\xi$. We claim that (i) no horizontal segment whose $y$-coordinates are strictly between those of $t$ and $t'$ intersects $r$; (ii) the horizontal segment $t'$ on which $\xi$ lies does intersect $r$; and (iii) the successor $\beta'$ of $k$ in the Q-heap pointed to by $p(q(\beta))$ always exists.

To see why the first claim is true, suppose there is a horizontal segment $(k_1', k_2'; y')$ intersecting $r$ that satisfies $y_\gamma < y < y_\xi$. Then it has to be true that $k' < k_1' \le k$. Since we are discussing Case 2, there has to be another horizontal segment $(k_1'', k_2''; y'')$ such that $k' < k_1'' < k$ and $y_\gamma < y'' < y_\xi$. Following similar arguments as in the proof of Lemma 4.1, we can show that either there exists a vertex on $t$ between $\beta$ and $\gamma$ with an outgoing vertical edge, or there exists a vertex $\xi'$ with an incoming horizontal edge such that its coordinate $(k_{\xi'}, y_{\xi'})$ satisfies $k_{\xi'} = k'$ and $y_\gamma < y_{\xi'} < y_\xi$. Either case leads to a contradiction.

To show that $t'$ indeed intersects $r$, we notice that the right endpoint of the horizontal segment of which the horizontal incoming edge of $\xi$ is a part cannot be to the (strict) left of $s$, because otherwise either there would be a chain of vertical edges closer to $\beta$ than the one we have, or there would be a horizontal segment lying vertically between $t$ and $t'$ that intersects $r$, each leading to a contradiction. This also justifies the last claim (iii), and the proof of the lemma is complete. $\square$

LEMMA 4.4. *Given a set $R$ of $n$ horizontal segments in the plane, whose endpoints can only have $c = \log^\epsilon n$ possible x-coordinates $\{1, 2, \ldots, c\}$, it is possible to report using $O(n)$ space all $f$ proper segments of $R$ which satisfy a query $r = (k; y_1, y_2)$, where $k = 1, 2, \ldots, c$, in $O(t(n) + f)$ time, where $t(n)$ is the time it takes to compute the successor of $y_1$ in $Y(R)$ and $P_i(R)$ for some $i = 1, 2, \ldots, c$.*

Note that we can apply the fusion tree to index the distinct $y$-coordinates using linear space so that $t(n) = O(\log n/ \log\log n)$. In the next section, we will show how to use the algorithm of Lemma 4.4 to solve the general orthogonal segment intersection problem. By applying the fast fractional cascading technique, the time $t(n)$ in Lemma 4.4 can be reduced to $O(1)$ except for the initial search, in which $t(n) = O(\log n/ \log\log n)$.

## 4.2. Handling the general orthogonal segment intersection problem.

In this section we consider the general orthogonal segment intersection problem involving a set $S$ of $n$ horizontal segments. To simplify the presentation, we assume that the endpoints of the segments in $S$ have distinct $x$-coordinates. The primary data structure is a tree $T$ of degree $c = \log^\epsilon n$, built on the endpoints of the $n$ segments sorted in increasing order of the $x$-coordinates. Each leaf node $v$ is associated with $c$ endpoints. Let $x_{\mathrm{l}}$ and $x_{\mathrm{r}}$ be the $x$-coordinates of, respectively, the leftmost endpoints associated with $v$ and the leaf node to its immediate right ($x_{\mathrm{r}} = +\infty$ if $v$ is the rightmost leaf node); then the *x-range* of $v$ is defined as $[x_{\mathrm{l}}, x_{\mathrm{r}})$. For an internal node $u$ with $c$ children $v_0, v_1, \ldots, v_{c-1}$, whose corresponding $x$-ranges are $[x_0, x_1), [x_1, x_2), \ldots, [x_{c-1}, x_c)$, its $x$-range is $[x_0, x_c)$. The set of $c-1$ infinite horizontal lines $b_1(u), b_2(u), \ldots, b_{c-1}(u)$, whose $x$-coordinates are $x_1, x_2, \ldots, x_{c-1}$, respectively, are called the *boundaries* of $u$. When the context is clear, we will use $b_i(u)$ to represent its corresponding $x$-coordinate as well.

The segments in $S$ are distributed among the nodes of $T$ as follows. A horizontal segment is associated with an internal node $u$ if it intersects one of the boundaries of $u$ but none of the boundaries of $u$'s ancestors. A segment is associated with a leaf node $v$ if its endpoints both lie within the $x$-range of $v$.

The set $S(v)$ of segments associated with an internal node $v$ is organized into several secondary data structures, as described below and illustrated in Figure 4.2.

1. The $c-1$ boundaries of each node $v$ are indexed by a Q-heap so that, given an arbitrary value $x$, the leftmost boundary $b_i(v)$ that satisfies $x \leq b_i(v)$ can be identified in constant time.

2. With each boundary $b_i(v)$ with $1 \leq i \leq c-1$, we associate two Cartesian trees $L_i(v)$ and $R_i(v)$. The Cartesian tree $L_i(v)$ contains the endpoints of those segments $(x_1, x_2; y)$ in $S(v)$ which satisfy $b_{i-1}(v) < x_1 \leq b_i(v)$ ($b_0(v) = -\infty$) and $x_2 \geq b_i(v)$, and is used to answer the three-sided range query of the form $(x_1 \leq a, b \leq y \leq d)$; $R_i(v)$ contains the endpoints of those segments that satisfy $b_i(v) \leq x_2 < b_{i+1}(v)$

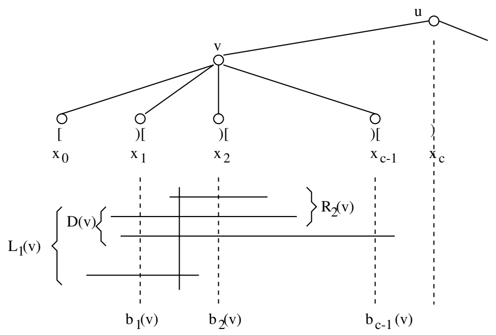


FIG. 4.2. *Data structures for the segments associated with node $v$.*

($b_{i+1}(v) = +\infty$ for $i = c-1$) and $x_1 \le b_i(v)$, and is used to answer the three-sided range query of the form $(x_2 \ge a, b \le y \le d)$. Each Cartesian tree thus created has its nodes doubly linked in order of increasing $y$-coordinates.

3. Let $S'(v)$ be a subset of $S(v)$ containing segments that each intersect at least two boundaries of $v$. We organize these segments using the data structure $D(v)$ discussed in section 4.1. We will later explain how to transform the problem corresponding to $S'(v)$ into the one discussed in section 4.1.

The number of horizontal segments associated with a leaf node is at most $c/2$ since there are only $c$ different endpoints associated with a leaf node, which are simply stored in a list.

We analyze the storage cost of the structures involved in our overall data structure. Obviously, each segment in $S$ is associated with exactly one node $v$ of $T$. For any segment associated with an internal node $v$, it appears in at most three secondary structures, once in $L_i(v)$ associated with the leftmost boundary that $b_i(v)$ it intersects, once in $R_j(v)$ associated with the rightmost boundary $b_j(v)$ that it intersects, and possibly once in $D(v)$. Any segment associated with a leaf node is stored exactly once. Note that all these data structures are linear-space. Hence the total amount of space used by these structures is $O(n)$.

We next outline our search algorithm and then fill in the details as we go along. Let $s = (a; b, d)$ be a vertical segment. To avoid the tedious but not difficult task of treating special cases, we make the assumption that the endpoints of $s$ are different from any of the endpoints of the segments in $S$. To compute the set of proper segments in $Q$, we recursively search the tree $T$, starting from the root. Let $v$ be the node we are currently visiting. We search $v$ as follows.

1. If $v$ is a leaf node, check each segment associated with $v$ and report those that intersect $s$, after which the algorithm terminates.
2. If $x$ lies outside the $x$-range of $v$, then no segment in $S$ intersect $s$, and the algorithm terminates. (This can happen only at the root, when $s$ is to the left of all the segments in $S$.)
3. Otherwise do the following:
   3.1. Find the pair of consecutive boundaries $b_i(v)$ and $b_{i+1}(v)$ of $v$ such that $b_i(v) < a < b_{i+1}(v)$. (The boundary $b_i(v)$ does not exist if $x < b_1(v)$; and $b_{i+1}(v)$ does not exist if $a > b_{c-1}(v)$.)
   3.2. If $b_i(v)$ exist, use $R_i(v)$ to report segments $(x_1, x_2; y)$ that satisfy $x_2 \ge a$ and $b \le y \le d$.
   3.3. If $b_{i+1}(v)$ exist, use $L_{i+1}(v)$ to report those segments $(x_1, x_2; y)$ that

satisfy $x_1 \le a$ and $b \le y \le d$.

3.4. If both $b_i(v)$ and $b_{i+1}(v)$ exist, use $D(v)$ to report those proper segments with no endpoints in the interval $(b_i(v), b_{i+1}(v))$.

3.5. Recursively visit the $(i+1)$th child of $v$ (the first child being the leftmost).

The correctness of the algorithm is obvious, provided that step 3.4 can be performed correctly, a fact we will show shortly. First we note that step 3.1 can be done in constant time using the Q-heap. Furthermore, the access of the Cartesian trees in steps 3.2 and 3.3 can be done in time proportional to the number of segments reported if the successor of $b$ and the predecessor of $d$ in the list of nodes for each Cartesian tree can be identified in constant time. We will show later that we can indeed achieve this goal by applying the fast fractional cascading structure. Finally, it is clear that only one node is visited at each level of $T$, which consists of $O(\log n/\log\log n)$ levels.

Now we focus on step 3.4. The difficulty is to keep the size of $D(v)$ linear and at the same time be able to execute this step in time proportional to the number of segments reported. Let $n'$ be the size of $S'(v)$. One obvious choice is to keep $D(v)$ as $O(c^2)$ lists of segments. Each list corresponds to a pair of boundaries and consists of segments sorted by their $y$-coordinates that cross both boundaries. The storage cost is obviously $O(n')$. However, we will have to visit each list to report the proper segments, since there is no obvious way to decide beforehand which lists contain at least one proper segment (as Willard cleverly did in the design of the fusion priority tree [30]). At least $\Omega(\log^{2\epsilon} n)$ time seems to be required as a result. On the other hand, we can associate with each pair of consecutive boundaries the sorted list of segments that crosses both of them. This approach satisfies the requirement on the query complexity but increases the storage cost by a factor of $\log^{\epsilon} n$.

We now present our solution to handle these segments. We first transform the $x$-coordinates $x_1$ and $x_2$ of the endpoints of each segment $s$ into two integers $k_1$ and $k_2$ between 1 and $c-1$. More specifically, $k_1$ and $k_2$ are the indices of the leftmost and rightmost boundaries of $v$ crossed by $s$. By doing this, we transform $S'(v)$ into another set $W(v)$, in which the segments have their $y$-coordinates unchanged but their $x$-coordinates replaced by the indices of the boundaries. At query time, we also transform the query segment $s = (x; y_1, y_2)$ into another segment $r$ by replacing its $x$-coordinate with the index $k$ of the boundary to its immediate right. It is straightforward to see that a segment in $S'(v)$ is proper if and only if its corresponding segment $(k_1, k_2; y)$ in $W(v)$ satisfies $k_1 < k \le k_2$ and $y_1 \le y \le y_2$. (In the case where $k_1 = k$, the original segment corresponding to $(k_1, k_2; y)$ is already found using $L_{k_1}(v)$ and thus need not be reported here.) We now have exactly the problem we tackled in section 4.1. Hence by Lemma 4.4, we can find the $f'$ proper segments in $W(v)$ in $O(f')$ time, provided that we can in constant time identify the successor of $b$ in the various sorted lists of $y$-coordinates associated with $H(v)$.

To complete the description of our algorithm, we show how to apply the fast fractional cascading structure to search the sorted lists at different levels of the tree. The sorted lists stored at each node $v$ consist of the $2(c-1)$ lists $R_i(v)$ and $L_i(v)$ for $i = 1, \ldots, c-1$; the list of vectors in $M(v)$; and up to $c-1$ lists of $P_i(v)$. Note that during the query time, we need to search only $O(1)$ such lists at each level. Using the fusion tree, we can search the relevant list at the root of $T$ in $O(\log n/\log\log n)$ time.

To see how the various lists are linked through fast fractional cascading, we can imagine a virtual forest $F$ consisting of $c$ "virtual" trees $T_1, T_2, \ldots, T_c$ of degree $3c-2$, such that the lists stored at the roots are $L_1(v), L_2(v), \ldots, L_{c-1}(v), R_{c-1}(v)$, respectively, where $v$ is the root of our search tree. The children of the root storing $L_i(v)$ contain the lists of the $i$th children of $v$ from the left; and the children of the root

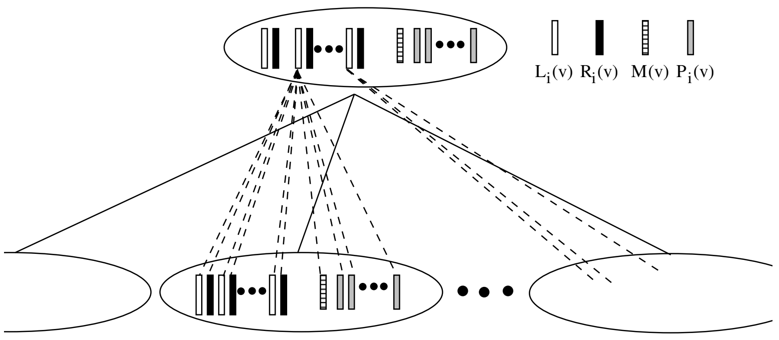

FIG. 4.3. *The virtual forest.*

storing $R_{c-1}(v)$ contain the lists of the $c$th children of $v$. Figure 4.3 illustrates the concept of the virtual forest. It is straightforward to see that a node in $F$ is searched only if its parent is searched. Since $c = \log^\epsilon n$ with $\epsilon < 1/5$, $3c-2 < \log^{1/5} n$ for large enough $n$. Therefore we can apply the fast fractional cascading technique to interconnect the lists according to the topology of the virtual forest so that we can search each list in constant time after the initial search at the root of $F$ without increasing the space requirements.

In summary, handling a query consists of processing the nodes on a path from the root to a leaf node. Processing the root $w$ of $T$ takes $O(\log n/\log\log n + f(w))$ time. The time spent processing any other internal node $u$ is $O(f(u))$. To search the leaf node $w$, we simply check each segment stored there. Since there are at most $O(c)$ such segments and $c = \log^\epsilon n < \log n/\log\log n$ for large enough $n$, the overall query time is $O(\log n/\log\log n)$, and therefore we have the following theorem.

THEOREM 4.5. *There exists a linear-space algorithm to handle the orthogonal segment intersection problem in $O(\log n/\log\log n + f)$ query time, where $f$ is the number of segments reported.*

## 5. Rectangle point enclosure.

To simplify our presentation, we assume that the corners of the rectangles in $S$ all have distinct $x$- and $y$-coordinates. As in the case of the segment intersection problem, the primary data structure consists of a tree $T$ of degree $c = \log^\epsilon n$. Let $v$ be the root of $T$ and $b_1(v), b_2(v), \ldots, b_{c-1}(v)$ be a set of infinite vertical lines, called the *boundaries* of $v$, which partition the set of $2n$ vertical edges of the rectangles in $S$ into $c$ subsets of equal size, thereby creating $c$ stripes $P_1(v), P_2(v), \ldots, P_c(v)$. We define the $c$ subtrees rooted at the children of $v$ recursively, each with respect to the vertical edges that fall into the same stripe. If the number of vertical edges is less than $\log^\epsilon n$ in a stripe, the child node corresponding to this stripe becomes a leaf node. Clearly the height of this tree is $O(\log n/\log\log n)$. A Q-heap $Q(v)$ holding the boundaries of $v$ is built for each node $v$, which will enable a constant time identification of the stripe of $v$ to which the query point belongs. In addition, for each node $v$, except for the root, we define its *x-range* as the stripe $P_i(u)$ of its parent $u$, assuming $v$ is the $i$th child of $u$ from the left.

We associate with each internal node $v$ the rectangles that intersect at least one of its boundaries but none of the boundaries of its ancestors. Each leaf node contains the set of rectangles both of whose vertical edges lie within its $x$-range. Hence at most $O(\log^\epsilon n) = O(\log n/\log\log n)$ rectangles are associated with a leaf node, and no preprocessing will be required for these rectangles.

Now consider the set $S(v)$ of rectangles associated with an internal node $v$. As in [3], we build two hive-graphs $HL_i(v)$ and $HR_i(v)$, as defined in section 2.3, for each boundary $b_i(v)$, $i = 1, \ldots, c-1$. The hive-graph $HL_i(v)$ is built on left vertical edges lying inside stripe $P_i$ and is used to answer the semi-infinite segment intersection queries of the form $(x_1 \leq x, y_1 \leq y \leq y_2)$; $HR_i(v)$ is built on the right vertical edges lying inside stripe $P_{i+1}$ and is used to answer the semi-infinite segment intersection queries of the form $(x_2 \geq x, y_1 \leq y \leq y_2)$. In addition, let $S'(v)$ be a subset of $S(v)$ such that each rectangle in $S'(v)$ crosses at least two boundaries. We transform the coordinates of $S'(v)$ from the space $\mathcal{N} \times \mathcal{N}$ to $W(v)$ in the space $[1, 2, \ldots, c-1] \times \mathcal{N}$ as follows. We transform each rectangle $[x_1, x_2; y_1, y_2]$ in $S'(v)$ into the rectangle $[k_1, k_2; y_1, y_2]$ in $W(v)$, where $b_{k_1}(v)$ and $b_{k_2}(v)$ are the leftmost and rightmost boundaries it crosses.

We now turn our attention to the query algorithm and postpone the description of the data structure for $W(v)$ until the end of this section. Using the Q-heaps stored at the internal nodes, we can in $O(\log n/\log\log n)$ determine the path from the root to the leaf node whose $x$-range contains the query point $p = (x, y)$. (We assume for simplicity that the $x$- and $y$-coordinates of $p$ are different from those of the corners of the rectangles in $S$.) It is clear that only the rectangles associated with the nodes on this path can possibly contain the query point.

Consider a node $v$ on this path. If $v$ is a leaf node, we simply examine each rectangle associated with it, a process that takes $O(\log n/\log\log n + f(v))$ time, where $f(v)$ denotes the number of rectangles reported at node $v$.

If $v$ is an internal node, we first decide which stripe of $v$ the query point $p$ belongs to, a task that can be done in $O(1)$ time; say it belongs to $P_i(v)$. The rectangles stored at node $v$ and which contain $p$ can be classified into three groups: (i) the set $L(v)$ that contains the rectangles whose left vertical edges lie inside $P_i(v)$; (ii) the set $R(v)$ that contains the rectangles whose right vertical edges lie inside $P_i(v)$; and (iii) the set $F(v)$ consisting of those rectangles whose horizontal edges cross $P_i(v)$ entirely. If $i = 1$, $R(v)$ and $F(v)$ do not exist. Similarly, if $i = c$, $L(v)$ and $F(v)$ do not exist.

By Lemma 2.4, the rectangles that belong to the first two groups can be identified in $O(1)$ time per rectangle reported if we apply the fast fractional cascading technique on the lists of the sorted $y$-coordinates of the vertices of the corresponding hive-graph. For example, we know that each rectangle $(x_1, x_2; y_2, y_2)$ associated with the hive-graph $HL_i(v)$ satisfies $x_2 \geq x$. Therefore, to find rectangles in $L(v)$, we only need to check the criteria: $x_1 \leq x$ and $y_1 \leq y \leq y$. Also note that a proper rectangle can be reported at most once in this process.

The remaining task is to determine the rectangles in group $F(v)$, which requires an additional data structure. We start from the set $W(v)$ consisting of rectangles of the form $(k_1, k_2; y_1, y_2)$, where $k_1$ and $k_2$ are integers between 1 and $c-1$. For each pair of different integers $i < j$ between 1 and $c-1$, we construct a Cartesian tree $C_{i,j}(v)$ consisting of rectangles $(i, j; y_1, y_2)$ in $W(v)$ to answer the two-sided range queries in the form $y_1 \leq y \leq y_2$. Note that the total space is still linear, and the use of the fast fractional cascading technique will enable us to access the appropriate nodes in time proportional to the number of rectangles reported.

However, we still need to resolve the problem of identifying which of these Cartesian trees should be accessed when handling a query. We cannot afford to access such a tree unless we are guaranteed to find at least one proper rectangle. To address this problem, we do the following.

We construct a look-up table $M(v)$ with $n'$ rows, each corresponding to a distinct $y$-coordinate of the horizontal edges of the rectangles in $W(v)$ and occupying one word (of $\log n$ bits). The rows are sorted by increasing order of the $y$-coordinates. Let $y_1(v) < y_2(v) < \cdots < y_{n'}(v)$ be the set of distinct $y$-coordinates of the horizontal edges. Let $V_j(v) = (b_{c^3}, b_{c^3-1}, \ldots, b_1)$ be a sequence of $c^3$ bits, where $b_i$ is the $i$th bit from the lower end of the word representing the $j$th row of $M(v)$ (note that $c^3 < \log n$). The word $V_j(v)$ is evenly divided into $c$ sections, each corresponding to a stripe of $v$ (actually we only use $c-2$ of them which correspond to $P_2(v), \ldots, P_{c-1}(v)$). Let $(b_{l+c^2} b_{l+c^2-1} \cdots b_{l+1})$ be one of them that corresponds to $P_i(v)$, $i = 2, \ldots, c-1$. For each pair of integers $k_1 < i \leq k_2$ between 1 and $c-1$, we set the bit $b_{l+k_1 \cdot c+k_2}$ to 1 if there is a rectangle $(k_1, k_2; y_1, y_2)$ in $R$ such that $y_1 < y_j(v) \leq y_2$. All the other bits are set to 0.

To find the proper rectangles in $S'(v)$, we first transform in $O(1)$ time using $Q(v)$ the query point $(x, y)$ to the point $(k, y)$ in the same space as $W(v)$. Let $b_k(v)$ be the leftmost boundary of $v$ whose $x$-coordinate is greater than or equal to $x$. It is clear that a rectangle $(x_1, x_2; y_1, y_2)$ in $S'(v)$ contains $(x, y)$ if and only if its corresponding rectangle $(k_1, k_2; y_1, y_2)$ in $W(v)$ contains $(k, y)$. Let $y_j(v) = \min\{y_l(v) | 1 \leq l \leq n', y_l(v) \geq y\}$. We have the following lemma.

LEMMA 5.1. *Let $(b_{l+c^2} b_{l+c^2-1} \cdots b_{l+1})$ be the section of $V_j(v)$ which corresponds to $P_k(v)$. Then for each pair of integers $1 \leq k_1 < k_2 \leq c-1$ such that $k_1 < k \leq k_2$, $b_{l+k_1 \cdot c+k_2} = 1$ if and only if there exists a rectangle $(k_1, k_2; y_1, y_2) \in W(v)$ which contains $(k, y)$.*

*Proof.* By the definition of $V_j(v)$, $b_{l+k_1 \cdot c+k_2} = 1$ if and only if there exists a rectangle $(k_1, k_2; y_1, y_2)$ such that $y_1 < y_j(v) \leq y_2$. If this rectangle indeed exists, we have $k_1 \leq k \leq k_2$ and $y_2 \geq y_j(v) \geq y$. The definition of $y_j(v)$ ensures that $y \geq y_1$. Therefore $(k_1, k_2; y_1, y_2)$ contains $(k, y)$. Now suppose there is a $(k_1, k_2; y_1, y_2)$ in $W(v)$ which satisfies $k_1 \leq k \leq k_2$ and contains $(k, y)$. The only scenario in which $(k_1, k_2; y_1, y_2)$ does not satisfy $y_1 < y_j(v) \leq y_2$ is $y_j(v) = y = y_1$. This is not possible, given the assumption that $y$ can not be the $y$-coordinate of any horizontal edge.[1] $\square$

Lemma 5.1 shows that the section $B$ of $V_j(v)$ which corresponds to the stripe containing $(k, y)$ indicates correctly the Cartesian trees in $\{C_{i,j} | 2 \leq i < j \leq c-1\}$ which should be visited. Using a look-up table of size $O(n)$, similar to the one described in [24], we can transform $B$ into a list of integers $(m, I_1, I_2, \ldots, I_m)$, where $m$ is the number of 1-bits in $B$ and $I_l$ is the index of a unique Cartesian $C_{i,j}(v)$, for $l = 1, 2, \ldots, m$. Then we simply visit these Cartesian trees one by one.

Searching the sorted lists associated with nonroot nodes can be done using fast fractional cascading. The correctness proof and complexity analysis for this part is similar to that in section 4 and thus is omitted here.

THEOREM 5.2. *There exists a linear-space algorithm to handle the rectangle point enclosure queries in $O(\log n / \log\log n + f)$ time, where $f$ is the number of segments reported.*

[1]This assumption might seem to be crucial to the correctness of the lemma. However, without this assumption, the only case that needs a special care is when $(k, y)$ is contained in no rectangle of the form of $(k_1, k_2; y_1, y_2)$ except those satisfying $y_2 = y$. This can be fixed by modifying $L(v)$ to make sure that this special case is not missed.

# COMPLEXITIES FOR GENERALIZED MODELS OF SELF-ASSEMBLY[*]

GAGAN AGGARWAL[†], QI CHENG[‡], MICHAEL H. GOLDWASSER[§], MING-YANG KAO[¶], PABLO MOISSET DE ESPANES[||], AND ROBERT T. SCHWELLER[¶]

**Abstract.** In this paper, we study the complexity of self-assembly under models that are natural generalizations of the tile self-assembly model. In particular, we extend Rothemund and Winfree's study of the tile complexity of tile self-assembly [*Proceedings of the* 32*nd Annual ACM Symposium on Theory of Computing*, Portland, OR, 2000, pp. 459–468]. They provided a lower bound of $\Omega(\frac{\log N}{\log\log N})$ on the tile complexity of assembling an $N \times N$ square for almost all $N$. Adleman et al. [*Proceedings of the* 33*rd Annual ACM Symposium on Theory of Computing*, Heraklion, Greece, 2001, pp. 740–748] gave a construction which achieves this bound. We consider whether the tile complexity for self-assembly can be reduced through several natural generalizations of the model. One of our results is a tile set of size $O(\sqrt{\log N})$ which assembles an $N \times N$ square in a model which allows flexible glue strength between nonequal glues. This result is matched for almost all $N$ by a lower bound dictated by Kolmogorov complexity. For three other generalizations, we show that the $\Omega(\frac{\log N}{\log\log N})$ lower bound applies to $N \times N$ squares. At the same time, we demonstrate that there are some other shapes for which these generalizations allow reduced tile sets. Specifically, for thin rectangles with length $N$ and width $k$, we provide a tighter lower bound of $\Omega(\frac{N^{1/k}}{k})$ for the standard model, yet we also give a construction which achieves $O(\frac{\log N}{\log\log N})$ complexity in a model in which the temperature of the tile system is adjusted during assembly. We also investigate the problem of verifying whether a given tile system uniquely assembles into a given shape; we show that this problem is NP-hard for three of the generalized models.

**Key words.** Kolmogorov complexity, polyominoes, self-assembly, tile complexity, tilings, Wang tiles

## 1. Introduction.

Self-assembly is the ubiquitous process by which objects autonomously assemble into complexes. This phenomenon is common in nature and yet is poorly understood from a mathematical perspective. It is believed that self-assembly technology will ultimately permit the precise fabrication of complex nanostructures. Of particular interest is DNA self-assembly. Double and triple crossover DNA molecules have been designed that can act as four-sided building blocks for

DNA self-assembly [4, 5]. Experimental work has been done to show the effectiveness of using these building blocks to assemble DNA crystals and perform DNA computation [6, 8, 12, 13]. With these building blocks (tiles) in mind, researchers have considered the power of the *tile* self-assembly model.

The tile assembly model extends the theory of Wang tilings of the plane [10] by adding a natural mechanism for growth. Informally, the model consists of a set of four-sided Wang tiles whose sides are each associated with a type of glue. The bonding strength between any two glues is determined by a *glue function.* A special tile in the tile set is called the *seed* tile. Assembly takes place by starting with the seed tile and attaching copies of tiles from the tile set one-by-one to the growing seed whenever the total strength of attraction from the glue function meets or exceeds a fixed parameter called the *temperature.*

In this paper we focus on two fundamental complexities relating to this model. The first is the *tile complexity* of self-assembled shapes, defined as the minimum number of distinct Wang tiles required to assemble the shape. Rothemund and Winfree [9] introduced this concept and considered the tile complexity of self-assembled squares. The second is the complexity of verifying whether or not a system of tiles uniquely assembles into a given shape. This problem is considered by Adleman et al. [2] and shown to have a polynomial time solution for the standard tile assembly model.

We extend these studies of tile complexity and shape verification by considering the removal of various restrictions the standard model places on the assembly process. From this we obtain four natural generalizations of the tile assembly model that exhibit significant differences in tile complexity and the complexity of shape verification from that of the standard model. This suggests that some previously derived bounds on tile self-assembly are artifacts of artificial restrictions placed on the standard tile assembly model, rather than bounds on the actual process of self-assembly. Our results are summarized in Table 1.1. Informally, the generalized models are defined as follows.

In the *flexible glue* model, the restriction imposed by Rothemund and Winfree [9], that differing glue types have bonding strength of zero, is removed. In the *multiple temperature* model, the temperature of the system is permitted to change during the assembly process. In the *multiple tile* model, tiles may cooperate by assembling into supertiles before being added to the growing result. In the *unique shape* model, a system *uniquely assembles* a shape if the shape of its resultant supertiles is unique, though its produced supertile may not be unique.

In the standard tile assembly model, Kolmogorov complexity dictates a lower bound of $\Omega(\frac{\log N}{\log\log N})$ on the tile complexity of self-assembling $N \times N$ squares for almost all values of $N$ [9]. Adleman et al. [1] showed how to reach this bound for all $N$. We show (in Theorem 6.1) that this lower bound also applies to each of the generalized models except for the flexible glue model. For this model, Kolmogorov complexity dictates only an $\Omega(\sqrt{\log N})$ lower bound for almost all $N$ (as shown in Theorem 6.2). We show how to achieve this bound for all $N$ by encoding an arbitrary $(\log N)$-bit binary number into the glue function (Theorem 5.1).

Additionally, for some of the models we provide a lower bound of $\Omega(\frac{N^{\frac{1}{k}}}{k})$ (see Theorem 3.1) for assembling *thin* width $k$ length $N$ rectangles (a $k \times N$ rectangle is *thin* if $k < \frac{\log N}{\log\log N - \log\log\log N}$). These lower bounds show that it can require significantly larger tile sets to assemble thinner rectangles than thicker rectangles. With this in mind, we utilize the multiple temperature model to construct a thin rectangle by first constructing a thicker rectangle using a small tile set. We then raise the temperature of the system so that portions of the larger rectangle fall apart,

Table 1.1

*This table gives the general flavor of our results regarding upper and lower asymptotic bounds on tile complexity under the generalized models for $k \times N$ rectangles, as well as the complexity of the* Unq-Shape *problem, but the reader should reference precise details in the stated theorems. A rectangle is* thin *when $k < \frac{\log N}{\log\log N - \log\log\log N}$ and* thick *otherwise. NP-X denotes the class of decision problems not in NP or co-NP unless P = NP.*

| Complexity of self-assembling $k \times N$ rectangles, $k \le N$, and shape verification | | | | | |
|---|---|---|---|---|---|
| | Thin rectangles LB | Thin rectangles UB | Thick rectangles LB | Thick rectangles UB | Unq-Shape |
| Standard | $\frac{N^{\frac{1}{k}}}{k}$ (Thm. 3.1) | $N^{\frac{1}{k}}$ (Thm. 3.2) | $\frac{\log N}{\log\log N}$ (see [9]) | (see [1]) | P (see [2]) |
| Flexible glue | $\frac{N^{\frac{1}{k}}}{k}$ (Thm. 3.1) | $N^{\frac{1}{k}}$ (Thm. 3.2) | $\sqrt{\log N}$ (Thm. 6.2) | (Thm. 5.1) | P (see [2]) |
| Multiple temperature | $\frac{\log N}{\log\log N}$ (Thm. 6.1) | (Thm. 4.1) | $\frac{\log N}{\log\log N}$ (Thm. 6.1) | (see [1]) | NP-X (Thm. 7.6) |
| Multiple tile | $\frac{\log N}{\log\log N}$ (Thm. 6.1) | $N^{\frac{1}{k}}$ (Thm. 3.2) | $\frac{\log N}{\log\log N}$ (Thm. 6.1) | (see [1]) | NP-X (Thm. 7.7) |
| Unique shape | $\frac{N^{\frac{1}{k}}}{k}$ (Thm. 3.1) | $N^{\frac{1}{k}}$ (Thm. 3.2) | $\frac{\log N}{\log\log N}$ (Thm. 6.1) | (see [1]) | Co-NPC (Thm. 7.1) |

leaving the desired rectangle (Theorem 4.1).

Given a tile system, Adleman et al. [2] give an algorithm to verify whether the tile system uniquely assembles into a given supertile. However, in the unique shape model, a tile system could uniquely assemble into a shape even if it does not produce a unique supertile. We investigate the problem of verifying whether a given tile system uniquely assembles into a given shape in the unique shape model, and show that this problem is co-NP-complete (Theorem 7.1). We also show that the problem of determining whether a tile system uniquely assembles into a given supertile is not in NP or co-NP for the multiple temperature model (Theorem 7.6) or the multiple tile model (Theorem 7.7) unless P = NP. These results are in contrast to the polynomial-time verification algorithm for the standard model [2].

*Paper layout.* In section 2 the standard tile model is defined, as well as the generalized models. In section 3 we introduce a construction for assembling $k \times N$ rectangles and provide a lower bound on the tile complexity of such rectangles. In section 4 we use this construction to show how the multiple temperature model can reduce tile complexity when $k \ll N$. In section 5 we use the flexible glue model to reduce the tile complexity of assembling $N \times N$ squares from $\Theta(\frac{\log N}{\log\log N})$ to $\Theta(\sqrt{\log N})$. In section 6 we discuss the lower bounds for assembling shapes of extent $N$ for the generalized models as dictated by Kolmogorov complexity. Finally, in section 7, we show that shape verification is co-NP-complete in the unique shape model and not in NP or co-NP unless P = NP for the multiple temperature and multiple tile models.

## 2. Basics.

**2.1. The standard model.** For alternate descriptions of the tile assembly model, see [1, 2, 9, 11]. Briefly, a tile $t$ in the model is a four-sided Wang tile denoted by the ordered quadruple $(\text{north}(t), \text{east}(t), \text{south}(t), \text{west}(t))$. The entries of the quadruples are glue types taken from an alphabet $\Sigma$ representing the north, east, south, and west edges, respectively, of the Wang tile. A *tile system* is an ordered quadruple $\langle T, s, G, \tau \rangle$, where $T$ is a set of tiles called the *tileset* of the system, $\tau$ is a positive integer called the *temperature* of the system, $s \in T$ is a single tile called the *seed* tile, and $G$ is a function from $\Sigma^2$ to $\{0, 1, \ldots, \tau\}$ called the *glue function* of the system. It is assumed that $G(x, y) = G(y, x)$, and there exists a $\texttt{null}$ in $\Sigma$ such that $\forall x \in \Sigma$, $G(\texttt{null}, \texttt{x}) = \texttt{0}$. In the standard tile assembly model [1, 2, 9], the glue function is such that $G(x, y) = 0$ when $x \neq y$. When dealing with the standard glue model, denote $G(x, x)$ by $G(x)$.

Define a *configuration* to be a mapping from $\mathbb{Z}^2$ to $T \bigcup \{\texttt{empty}\}$, where $\texttt{empty}$ is a special tile that has the $\texttt{null}$ glue on each of its four edges. The *shape* of a configuration is defined as the set of positions $(i, j)$ that do not map to the empty tile. For a configuration $C$ a tile $t \in T$ is said to be *attachable* at the position $(i, j)$ if $C(i, j) = \texttt{empty}$ and $G(\text{north}(t), \text{south}(C(i, j+1))) + G(\text{east}(t), \text{west}(C(i+1, j))) + G(\text{south}(t), \text{north}(C(i, j-1))) + G(\text{west}(t), \text{east}(C(i-1, j))) \geq \tau$. For configurations $C$ and $C'$ such that $C(x, y) = \texttt{empty}$, $C'(i, j) = C(i, j)\ \forall (i, j) \neq (x, y)$ and $C'(x, y) = t$ for some $t \in T$ define the act of *attaching* tile $t$ to $C$ at position $(x, y)$ as the transformation from configuration $C$ to $C'$.

Define the *adjacency graph* of a configuration $C$ as follows. Let the set of vertices be the set of coordinates $(i, j)$ such that $C(i, j)$ is not empty. Let there be an edge between vertices $(x_1, y_1)$ and $(x_2, y_2)$ iff $|x_1 - x_2| + |y_1 - y_2| = 1$. We refer to a configuration whose adjacency graph is finite and connected as a *supertile*. For a supertile $S$, denote the number of nonempty positions (tiles) in the supertile by $\text{size}(S)$. We also note that each tile $t \in T$ can be thought of as denoting the unique supertile that maps position $(0, 0)$ to $t$ and all other positions to $\texttt{empty}$. Throughout this paper we will informally refer to tiles as being supertiles.

A *cut* of a supertile is a cut of the adjacency graph of the supertile. In addition, for each edge $e_i$ in a cut define the *edge strength* $s_i$ of $e_i$ to be the glue strength (from the glue function) of the glues on the abutting edges of the adjacent tiles corresponding to $e_i$. Now define the *cut strength* of a cut $c$ to be $\sum s_i$ for each edge $e_i$ in the cut.

In the standard model, assembly takes place by *growing* a supertile starting with tile $s$ at position $(0, 0)$. Any $t \in T$ that is attachable at some position $(i, j)$ may attach and thus increase the size of the supertile. For a given tile system, any supertile that can be obtained by starting with the seed and attaching arbitrary attachable tiles is said to be *produced*. If this process comes to a point at which no tiles in $T$ can be added, the resultant supertile is said to be *terminally* produced. For a given shape $\Upsilon$, a tile system $\Gamma$ *uniquely produces* shape $\Upsilon$ if there exists a terminal supertile $S$ of shape $\Upsilon$ such that every supertile derived from the seed can be grown into $S$. The *tile complexity* of a shape $\Upsilon$ is the minimum tile set size required to uniquely assemble $\Upsilon$ under a given assembly model. While the definition of unique shape production provided here is the same as in [1, 2, 9], we note that it is somewhat unnatural in that it requires unique production of supertiles. In section 2.2 we introduce a model that utilizes a more natural definition of unique shape production.

**2.2. Four generalized models.**

*The multiple temperature model.* In the *multiple temperature* model, the integer temperature $\tau$ in the tile system description is replaced with a sequence of integers

$\{\tau_i\}_{i=1}^{k}$ called the *temperature sequence* of the system. A system with $k$ temperatures in its temperature sequence is said to be a *$k$-temperature* system.

In a $k$-temperature system, assembly takes place in $k$ phases. In the first phase, assembly takes place as in the standard model under temperature $\tau_1$. Phase 1 continues until no tiles can be added. In phase two, tiles can be added or removed under $\tau_2$. Specifically, at any point during phase 2 if there exists a cut of the resultant supertile with cut strength less than $\tau_2$, the portion of the supertile occurring on the side of the cut not containing the seed tile may be removed. Also, at any point in the second phase any tile in $T$ may be added to the supertile if the tile is attachable at a given position under temperature $\tau_2$. The second phase of this assembly continues until no tiles can be added or removed. We then go to phase 3 in which tiles may be added and removed under temperature $\tau_3$. The process is continued up through $\tau_k$. For any given choice of additions and removals such that each of the $k$ phases finishes, the tile system *terminally* produces the corresponding shape assembled after phase $k$. If the $k$ phases always finish regardless of the choice of additions and removals, and the terminally produced supertile $R$ is unique, the tile system *uniquely assembles* the shape of $R$ under the $k$-temperature model.

*The flexible glue model.* In the *flexible glue* model, the restriction that $G(x, y) = 0$ for $x \neq y$ is removed.

*The unique shape model.* In the *unique shape* model, we redefine what it means for a system to uniquely produce a shape $S$. In this model, a tile system uniquely produces a shape $S$ iff all producible supertiles can be grown into a terminal supertile with shape $S$. Thus, the system may produce many different terminal supertiles as long as they all have the desired shape.

*The multiple tile model.* In the *multiple tile* model with parameter $q$, tiles can combine into supertiles of size at most $q$ before being added to the growing seed supertile. Attaching a supertile is much like attaching a singleton tile. Intuitively, two supertiles attach to one another by abutting together and sticking if the total edge strength of the abutting edges meets or exceeds the temperature $\tau$. However, the formal definition of a supertile is a connected configuration of tiles on $\mathbb{Z}^2$. This definition makes a distinction between two supertiles that are equal up to translation. However, we actually wish to think of two such supertiles as the same supertile. We therefore use the following formal definition of supertile attachment, which generalizes the notion of singleton tile attachment.

For any two supertiles $A$ and $B$, define $A \oplus B$ to be the configuration obtained by setting all empty positions $A(i, j)$ equal to $B(i, j)$. Further, we say $A \oplus B$ is *valid* if it is a supertile (i.e., it is connected), and if $\forall\,(i, j)$ either $A(i, j) = \texttt{empty}$ or $B(i, j) = \texttt{empty}$. For a valid supertile $A \oplus B$, denote the cut defined by separating all the tile positions initially in $A$ from all the tile positions initially in $B$ as the *border* cut. For a supertile $A$ and integers $x$ and $y$, let $A_{x,y}$ denote the configuration obtained by translating $A$ by $x$ units along the $x$-axis and $y$ units along the $y$-axis. Finally, for a given temperature $\tau$, supertile $B$ can be attached to supertile $A$ to form supertile $A \oplus B_{x,y}$ if $A \oplus B_{x,y}$ is valid and the cut strength of the border of $A \oplus B_{x,y}$ is at least $\tau$.

Having defined how to attach supertiles, we now define multiple tile systems. A tile system in the multiple tile model is a quintuple $\langle T, s, G, \tau, q \rangle$. Intuitively, in a multiple tile system any supertile of size at most $q$ that can be obtained by combining two smaller addable supertiles is also an addable supertile. The assembly process then permits any addable supertile to attach to the growing seed supertile if the tile can be placed so that the abutting edges of the two supertiles have a total strength that meets or exceeds the temperature $\tau$. For such a system define a set of *addable* supertiles $W_T$ as follows. First, $T \subseteq W_T$. Second, if there exist $A, B \in W_T$ such that $\text{size}(A) + \text{size}(B) \leq q$ and $B$ can be attached to $A$ under temperature $\tau$ to obtain $A \oplus B_{x,y}$, then $A \oplus B_{x,y}$ is also in $W_T$. In the multiple tile assembly model, supertiles from the set $W_T$ as well as from $T$ may be added. Specifically, any supertile that is in the set of addable supertiles $W_T$ that is attachable to the seed supertile under temperature $\tau$ can attach and increase the size of the seed supertile. For $q = 1$, we have $W_T = T$, which gives us the standard model of assembly.

**3. The assembly of $k \times N$ rectangles.** In this section, we present both an upper and a lower bound for assembling $k \times N$ rectangles for arbitrary $k$ and $N$. The upper bound comes from a simple construction which constitutes a $k$-digit base-$N^{\frac{1}{k}}$ counter and has tile complexity $\Theta(N^{\frac{1}{k}} + k)$. In later sections, we use modifications of this counter to show how both the two-temperature and flexible glue model can reduce tile complexity of certain shapes. Additionally, for the case of $k = \log N$, this construction constitutes a $\log N$-bit base-2 counter which assembles a $\log N \times N$ block. The tile set created by this special case is used in [3] to assemble a $\log N \times N$ block in optimal *time complexity* (as defined in [1]) of $\Theta(N)$. This permits the assembly of $N \times N$ squares in optimal tile complexity and optimal time complexity as in [1], but does so in a much simpler fashion and uses only temperature $\tau = 2$.

THEOREM 3.1. *The tile complexity of self-assembling a $k \times N$ rectangle is $\Omega(\frac{N^{\frac{1}{k}}}{k})$ for the standard model, the unique shape model, and the flexible glue model.*

*Proof.* Suppose there exists a tile system with fewer than $(\frac{N}{2(k!)})^{\frac{1}{k}}$ distinct tile types, which uniquely assembles a $k \times N$ rectangle. Then there must be fewer than $\frac{N}{2(k!)}$ distinct $k$-tile columns consisting of these tiles. So in a $k \times N$ configuration, there must exist some $k$-tile sequence which is repeated for more than $2(k!)$ of the columns. And under the standard, unique shape, and flexible glue models, for each of these identical columns we can assign an ordering on the $k$ tiles that corresponds to a possible relative order in which the $k$ tiles of the given column could be attached. (In the multiple tile model, groups of tiles may be attached simultaneously, and thus this ordering is not sufficient.) Since there are at most $k!$ orderings possible, we get that at least three of the identical columns must also have an identical order of attachment. From this we derive a contradiction as follows. Wherever the seed tile of the construction occurs, it lies to either the west or east of two of the identically placed columns. And if the seed tile occurs to the west (respectively, east) of a column, then all tiles east (respectively, west) of the column are determined by (1) the tiles and their positions in the column, and (2) the relative attachment order of the tiles in the column. That is, if a rectangle has fewer than $(\frac{N}{2(k!)})^{\frac{1}{k}} = \Omega(\frac{N^{\frac{1}{k}}}{k})$ distinct tile types, there necessarily are at least two identical columns east (respectively, west) of the seed tile whose order of attachment is the same. When attaching only a single tile at a time, this guarantees the possibility of producing an infinite repeating loop of tiles. Thus, no finite shape can be uniquely produced. $\square$

*Remark.* We also point out that the argument for Theorem 3.1 applies to any length $N$ shape whose height at each column is bounded by a value $k$.

THEOREM 3.2. *The tile complexity of self-assembling a $k \times N$ rectangle is $O(N^{\frac{1}{k}} + k)$ for the standard model, the unique shape model, and the multiple tile model.*

We show this by first providing a construction for the standard model and then arguing that the construction works for the unique shape model and the multiple tile model as well.

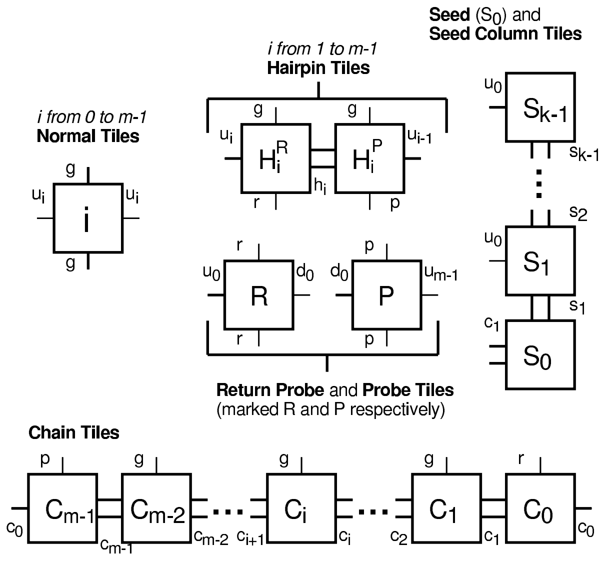

FIG. 1. *This tile set assembles a $k \times m^k$ rectangle in $\Theta(k+m)$ tile complexity under the standard assembly model.*

*Proof for the standard model.* For a given $N$, let $m = \lceil N^{\frac{1}{k}} \rceil$. To show this bound, we give a general tile set for assembling a $k \times m^k$ rectangle in $O(N^{\frac{1}{k}} + k)$ tiles under the standard model. We then show how to adjust the tile set so it produces a $k \times N$ rectangle. The tile system we use constitutes a $k$-digit base-$m$ counter. The system has temperature $\tau = 2$, and the tile set and glue strength function are given in Figure 1.

The assembly takes place as follows. The north edge of the seed tile produces a length $k$ *seed column* from the seed column tiles. The west edge of the seed produces a length $m$ *chain* from the chain tiles. The 0-normal tile can then fill in all the rows and columns up until column $m-1$. In this column the $H_1^P$ hairpin tile must be placed. This causes a *hairpin* growth, which causes another length $m$ chain of chain tiles to be placed in the first row. The next section of $m$ columns are then filled with the 0-normal tile in all rows but the second, which will contain the 1-normal tile or a hairpin tile. In general, when the $C_{m-1}$ chain tile is placed, probe tiles are added on top of each other until a row is found that does not consist of the $(m-1)$-normal tile. In such a row the appropriate pair of hairpin tiles are placed, and a downward growing column of return probe tiles are placed until the bottom row is encountered, at which point the $C_0$ chain tile is placed to start the length $m$ chain growth over again in the first row. If no such row is encountered, the assembly finishes. The idea here is that the bottom *chain* row represents the least significant digit of the counter, thus incrementing every column. After each block of $m$ we need to find the most significant digit that requires incrementation, as well as rollover all the trailing digits displaying $m-1$ to 0. The hairpin tiles perform the incrementation, while the probe and return probe tiles perform the rollover.

It is easy to see that for a given $k$ and $m$, this construction assembles into a $k \times m^k$ block. In addition, we can adjust the glue types of the west edges of the seed column and seed tiles to represent any $k$-digit base-$m$ number. By doing this the counter can be made to start at any number between 0 and $m^k - 1$. Thus, we can designate the length of the constructed shape to be any number between 1 and $m^k$. Therefore, to assemble a $k \times N$ block, we use the above tile set with $m = \lceil N^{\frac{1}{k}} \rceil$ and the west edges of the seed and seed columns tiles set to represent the number $m^k - N$. Thus, we can construct a $k \times N$ block in $4m + k = O(N^{\frac{1}{k}} + k)$ tiles. □

*Proof for the unique shape model.* This follows from the construction for the standard model. □

*Proof for the multiple tile model.* Now we argue that the tile set given for the standard model uniquely assembles a $k \times N$ rectangle for the multiple tile model as well. Let $A$ denote the uniquely produced $k \times N$ supertile from the tile set of Figure 1 under the standard model. From the proof for the standard model we have that $A$ is produced under the multiple tile model as well. We thus need to show that the multiple tile model will not produce any shape other than $A$. Denote any produced supertile under the standard model to be a *substructure* of $A$. We thus want to show that any supertile produced by a multiple tile model is a substructure of $A$.

To show this, consider a multiple tile system with tile set given in Figure 1. Consider the set $W$ of addable supertiles and the set $X \subset W$ of supertiles that do not contain the seed tile. For a given $x \in X$, denote $x$ as a *column* if it consists of only a column of seed column tiles, a *chain* if it consists of only a chain of chain tiles, a *hairpin* if it consists of exactly two hairpin tiles, and a *singleton* if $x \in T$. For our argument we show the following three claims.

*Claim* 1. Every supertile in the set $X$ is either a column, chain, hairpin, or singleton.

*Claim* 2. Attaching a column, chain, hairpin, or singleton to a substructure yields a new substructure.

*Claim* 3. Two substructures cannot be attached to one another.

From this we have that by starting off with a single seed tile, which is a substructure, only supertiles that preserve the substructure property may be added. Thus, the multiple tile model can only produce substructures and thus cannot produce anything that the standard model cannot produce. □

*Proof of Claim* 1. Clearly all supertiles in $X$ of size 1 can be classified as either a chain, column, hairpin, or singleton. (They are all singletons, some are chains, some are columns, none are hairpins.) Inductively, suppose all supertiles in $X$ of size less than $k$ can be classified into the above categories. Consider an arbitrary size $k$ supertile in $X$. By definition of $W$ the supertile must be composed of two smaller supertiles. However, we cannot combine a chain with a column, nor a chain with a hairpin, nor a column with a hairpin. And clearly, if a singleton can be added to some other chain, column, hairpin, or singleton, it must yield a column, chain, or hairpin. Similarly, when two chains are combined, they yield another chain, and when two columns are combined, they yield another column. Thus, the size $k$ supertile is either a chain, column, or hairpin. □

*Proof of Claim* 2. If a column is attachable to a substructure, it is attachable solely due to the glue strength of the south glue on the southernmost tile of the column. Instead of placing the column as a single chunk, each tile can be placed one by one under the standard model, starting with the southernmost tile. Thus, the end result is a substructure. The same type of argument applies to chains and hairpins. □

*Proof of Claim* 3. Among the tiles in an arbitrary substructure, no tile is farther north than the northern most tile in the eastmost column. Similarly, no tile is farther west than the westmost tile in the southernmost row, except for possibly a single hairpin tile. Now, since the eastern edges of all tiles in the first column and the southern edges of all tiles in the first row have bonding strength of 0, the only possible way for two substructures to bond together is for there to be an attraction between the north edge of some tile in the first column of one substructure with the south edge of a hairpin tile of the other substructure. But there is no attraction strength between the northern edges of seed column tiles and the southern edges of hairpin tiles, so this is not possible. ∎

## 4. Reducing tile complexity with the two-temperature model.

Now we show how a multiple temperature model can reduce tile complexity for assembling thin rectangles. For a given $k$ and $N$ with $k \ll N$, the idea is to use a modification of the construction from section 3 to build a $j \times N$ rectangle for optimal (bigger than $k$) $j$ such that the top $j-k$ rows are less stable than the bottom $k$. The temperature of the system is then raised to cause all but the bottom $k$ rows to fall apart. We then compare the complexity of this construction with the lower bound for the standard model given in section 3 to show that the 2-temperature model can beat a lower bound for the standard model.

*Minimizing the complexity.* For a given $j$ and $N$, assembling a $j \times N$ rectangle using the construction of Theorem 3.2 yields an upper bound that is a function of $j$. If we are only interested in constructing a rectangle of length $N$ but do not care about the width, we can choose $j$ as a function of $N$ such that the tile complexity is minimized. To do this we choose a value for $j$ that balances the size of $N^{\frac{1}{j}}$ and $j$. For $j = \frac{\log N}{\log\log N - \log\log\log N} = \Theta(\frac{\log N}{\log\log N})$, the term $N^{\frac{1}{j}}$ is $\frac{\log N}{\log\log N}$. Thus, the number of tiles used in the construction for building a $j \times N$ block for such a $j$ is $j + N^{\frac{1}{j}} = \Theta(\frac{\log N}{\log\log N})$, which meets the lower bound dictated by Kolmogorov complexity for almost all $N$ [9]. We use this result in the following theorem.

THEOREM 4.1. *Under the two-temperature model, the tile complexity of self-assembling a $k \times N$ rectangle for an arbitrary integer $k \geq 2$ is $O(\frac{\log N}{\log\log N})$.*

*Proof.* In the case that $k$ exceeds $\lceil \frac{\log N}{\log\log N - \log\log\log N} \rceil$, we can simply use a single-temperature model to build the two perpendicular axes of the rectangle in optimal $O(\frac{\log N}{\log\log N})$ complexity. The addition of a constant number of tiles can then fill in the rest of the rectangle. Otherwise, to reach the bound we use a tile system that assembles a $j \times N$ block for optimal value $j = \lceil \frac{\log N}{\log\log N - \log\log\log N} \rceil$ under temperature $\tau_1$ and breaks down to a smaller $k \times N$ block in the second phase of the two-temperature assembly process. As in the construction from Theorem 3.2, let $m = \lceil N^{\frac{1}{j}} \rceil$. Consider the two-temperature tile system with $\tau_1 = 4$ and $\tau_2 = 6$ and the tile set and glue strength function given in Figure 2.

Under temperature $\tau_1$, this tile system assembles a $j \times N$ block in exactly the same fashion as the single-temperature system from Theorem 3.2. See Figure 3 for an example of the construction. However, for each tile in the top $j-k$ rows other than the seed column tiles, the north and south edges have glue strength 1. Therefore, since no glue in the system exceeds strength 4, we are assured that any cut consisting of one north-south edge and one east-west edge has cut strength less than $\tau_2 = 6$. Therefore, under the two-temperature model each tile in the top $j-k$ rows can be removed one at a time, starting at the northwest corner of the $j \times N$ block. We are then left with the bottom $k$ rows. Since our design ensures that each edge in the bottom $k$ rows has strength 3 or greater, no cut of the bottom $k \times N$ supertile can have cut strength less than 6. Thus, no cut can break up the remaining $k \times N$ block. And since any alternate choice of cuts would only expedite the process to this end, this construction uniquely assembles a $k \times N$ block in $10m + j = O(N^{\frac{1}{j}} + j) = O(\frac{\log N}{\log\log N})$

FIG. 2. *A tile set to assemble a $k \times N$ rectangle in $\Theta(j+m)$ tile complexity for $m = \lceil N^{\frac{1}{j}} \rceil$ under the two-temperature model with $\tau_1 = 4$ and $\tau_2 = 6$. At temperature $\tau_1$ the shaded tiles fill in the bottom $k$ rows of a $j \times N$ rectangle, while the clear tiles fill the top $j-k$ rows. At temperature $\tau_2$ the clear tiles fall off.*

tile complexity under the two-temperature assembly model. □

For small values of $k$, this beats the lower bound for the standard model. Consider $k = \frac{\log N}{2 \log \log N}$. For such $k$ the value of $N^{\frac{1}{k}}$ is

$$N^{\frac{2 \log \log N}{\log N}} = (\log N)^2.$$

Thus, from Theorem 3.1, the lower bound for the standard model is

$$\Omega\left(\frac{N^{\frac{1}{k}}}{k}\right) = \Omega((\log N)(\log \log N)).$$

Since this bound only gets higher for smaller values of $k$, the two-temperature model yields an asymptotically smaller tile complexity for all $k$ between 2 and $\frac{\log N}{2 \log \log N}$.

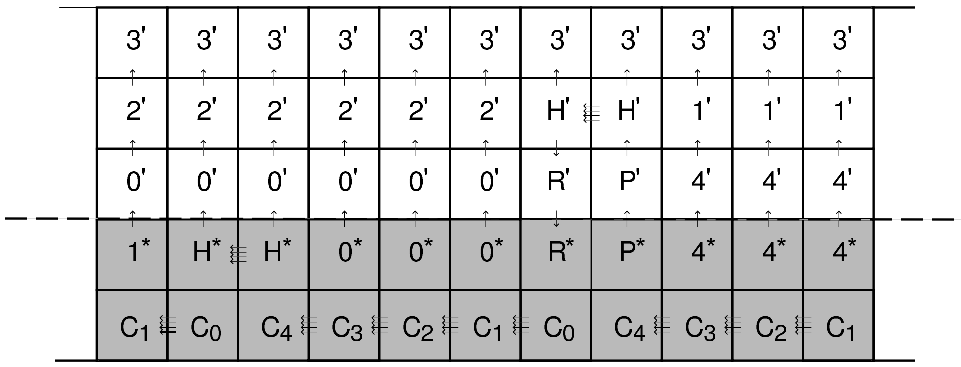

FIG. 3. *Here is a typical section of a self-assembled* $5 \times N$ *block from the tile set in Figure* 2 *that will break down to a* $2 \times N$ *block under temperature* 6*. Edges with strength* 4 *are marked by four adjacent arrows, while edges with strength* 1 *are marked with one. All remaining edges have strength* 3.

**5. Assembling $N \times N$ squares in $O(\sqrt{\log N})$ tiles.** Kolmogorov complexity dictates an $\Omega(\frac{\log N}{\log \log N})$ lower bound for almost all $N$ on the tile complexity of self-assembling $N \times N$ squares for the standard model in which the glue function is limited so that $G(x, y) = 0$ for $x \neq y$. However, if this restriction is lifted, the bound no longer applies. In this section, we show that the tile complexity of self-assembling $N \times N$ squares is $\Theta(\sqrt{\log N})$ under the flexible glue model for almost all $N$.

THEOREM 5.1. *The tile complexity of self-assembling $N \times N$ squares is $O(\sqrt{\log N})$ under the flexible glue model.*

*Proof.* The trick as introduced in [9] is to be able to initialize a fixed length binary counter to any arbitrary $(\log N)$-bit binary number. This can be done trivially in $O(\log N)$ tile complexity. By simulating base conversion, it can be done in $O(\frac{\log N}{\log \log N})$ [1]. Here we provide a tile system that assembles a $2 \times \log N$ block in $O(\sqrt{\log N})$ tiles such that the top row of the block encodes a given binary number $b$. This is accomplished by taking advantage of the flexible glue function and encoding $b$ into the glue function. Let $n = \lfloor \log N \rfloor + 1$ and $m = \lceil \sqrt{n}\, \rceil$. Let $b$ be a given $n$-bit binary number. Let $b_{ij}$ be the bit in position $im + j$ in $b$. We use the tile set and glue function from Figure 4 to construct a $2 \times n$ block such that the top row of the block represents the number $b$. For convenience we denote some glues by the symbols 0 and 1. See Figure 5 for an example of the construction.

To simplify the illustration, the tile set in Figure 4 assumes that $m^2 = n$. If this is not the case, we can do as before in Theorem 3.2 and initialize the 2-digit counter to an arbitrary value $c$ so that a block of length exactly $n$ is assembled. At any rate, the construction uses $5\lceil \sqrt{n}\, \rceil + 1$ tiles and constructs a $2 \times n$ block in the same fashion as the general $k \times n$ assembly. Additionally, the glue function assures us that for the $(i, j)$ digit of $b$, the corresponding position in the top row of the construction can only be tiled with either a hairpin, seed column, or normal tile with north edge glue equal to $b_{ij}$.

To complete the $N \times N$ square we need to create a fixed length binary counter that is initialized to the given binary number $b$ and grows north, incrementing row-by-row, until $2^n$ is reached. The addition of a constant number of stairstep tiles can then finish off the square, as shown in [9]. The fixed length binary counter can also be implemented in a constant number of tiles, as is done in [1, 9]. Alternatively, we

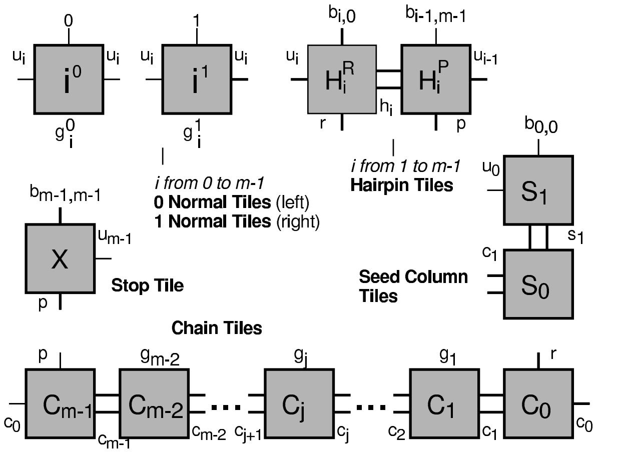

FIG. 4. *This tile set creates a $2 \times n$ block whose top row represents a given $n$-bit binary number $b$. Here $b_{ij}$ is the value of the bit in position $im + j$ in $b$. The glue function for glues $g_i^1$ and $g_j$ for $i$ from $0$ to $m - 1$ and $j$ from $1$ to $m - 2$ is $G(g_i^1, g_j) = b_{ij}$. All other pairs of nonequal glues have strength $0$.*

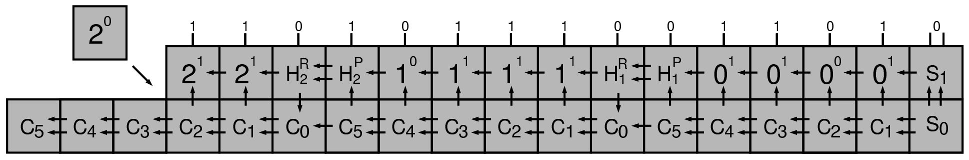

FIG. 5. *Assembling an arbitrary $n$-bit binary number in $O(\sqrt{n})$ tiles. Here we show the construction for $n = 36$ and binary number $b = \ldots 0110101110011010$.*

can use the construction from section 3 for building a $k \times N$ block for $k = \log N$. This yields a binary counter consisting of eight tiles plus $\log N$ seed column tiles. However, since we already have a "seed column" via the $2 \times n$ *seed block*, we can omit the seed column tiles. Thus, the total number of tiles used for the assembly of an $N \times N$ square is only a constant greater than the $\Theta(\sqrt{\log N})$ tiles used to build the $2 \times n$ seed block. $\square$

**6. Kolmogorov lower bounds.** Rothemund and Winfree [9] showed that Kolmogorov complexity dictates an $\Omega(\frac{\log N}{\log \log N})$ lower bound on the tile complexity for self-assembling $N \times N$ squares for almost all $N$. We show that their proof generalizes to the multiple temperature model, the unique shape model, and the multiple tile model. For the flexible glue model, we modify their argument to get an $\Omega(\sqrt{\log N})$ lower bound from Kolmogorov complexity, making the construction in Theorem 5.1 tight for almost all $N$.

THEOREM 6.1. *For almost all $N$ the tile complexity of self-assembling an $N \times N$ square is $\Omega(\frac{\log N}{\log \log N})$ for the multiple tile model, the multiple temperature model, and the unique shape model.*

*Proof.* The Kolmogorov complexity of an integer $N$ with respect to a universal Turing machine $U$ is $K_U(N) = \min|p|$ s.t $U(p) = b_N$, where $b_N$ is the binary representation of $N$. A straightforward application of the pigeonhole principle yields that $K_U(N) \geq \lceil \log N \rceil - \Delta$ for at least $1 - (\frac{1}{2})^{\Delta}$ of all $N$. (See [7] for results on Kolmogorov complexity.) Thus, for any $\epsilon > 0$, $K_U(N) \geq (1 - \epsilon) \log N = \Omega(\log N)$ for almost all $N$.

This tells us that if we have a Turing machine that takes as input a tile system and outputs the maximum length of the shape produced by the given tile system, then the total size in bits of the machine plus the size in bits of a tile system that uniquely assembles an $N \times N$ square is $\Omega(\log N)$.

For a given assembly model, if there exists a finite size Turing machine that takes as input a tile system and outputs the maximum extent (i.e., width or length) of the shape uniquely produced by the system, then the $\Omega(\log N)$ bound applies to the number of bits required to represent the tile system. For each of the nonflexible glue models, let $\tau$ be the maximal temperature of the system and $n$ the size of the tile set. Such tile sets can be represented by $4n \log 4n + 4n \log \tau$ bits as follows. For each of the $4n$ edges in the system assign an index to represent one of the at most $4n$ glues of the system. Also record a mapping from each glue to an index from 0 to $\tau$ representing the corresponding strength of the given glue. Thus, for $\tau$ bounded by a constant, the number of bits required to represent a tile system is $O(n \log n)$, which implies that $n = \Omega(\frac{\log N}{\log \log N})$ for almost all $N$ for any system that self-assembles a shape with maximum extent $N$ [9].

To finish this argument, we explicitly give algorithms for each model, which output the maximum extent of the shape uniquely produced by a given system. For the standard model, the multiple tile model, and the unique shape model, the following algorithm can output the maximum extent of the shape produced by a given tile system.

```
PRODUCED-EXTENT($\mathbf{\Gamma}$).
  1. Set $D_1 = T$. In general, $D_i$ denotes the set of all supertiles of size $i$ which
     consist of tiles in $T$.
  2. Mark each $t \in D_1$ as FEASIBLE.
  3. Set $i = 2$.
  4. Create $D_i$, the set of all supertiles of size $i$. Mark each $t \in D_i$ as FEASIBLE
     if $t$ can be constructed from two smaller FEASIBLE supertiles from
     the set $\bigcup_{r=1}^{i-1} D_r$. If $t$ is FEASIBLE and contains the seed tile, mark $t$ as
     PRODUCED.
  5. Increment $i$ and repeat step 4 unless $\bigcup_{r=\frac{i}{2}}^{i} D_r$ contains no FEASIBLE super-
     tile.
  6. Mark each PRODUCED supertile in $\bigcup_{r=1}^{i} D_r$ as TERMINAL if no FEASI-
     BLE supertile can be attached.
  7. Output the maximum extent (width or length) of any smallest TERMINAL
     supertile in $\bigcup_{r=1}^{i} D_r$.
```

Under the multiple tile model, if there are no addable supertiles of size between $\frac{i}{2}$ and $i$, then we know that there are no addable supertiles of size greater than $i$, since such a tile would need to be assembled from at least one smaller supertile of size at least $\frac{i}{2}$. Thus, in the case where each addable supertile is finite, this algorithm will finish and output the correct result. We also note that the algorithm outputs the extent of the smallest terminally produced supertile for the system. This tells us that the Kolmogorov bound applies to models with even more general definitions of uniqueness than what we consider. For the multiple temperature model we have the following.

```
$k$-TEMPERATURE-PRODUCED-EXTENT($\Gamma$).
  1. Initialize the *current supertile* to be the seed tile.
  2. For $i = 1$ to $k$ do the following. If there exists a cut $c$ in the current supertile
     with strength($c$) $< \tau_i$, remove the tiles on the side of the cut not containing
```

the seed. If there exists some $x \in T$ such that $x$ is addable under $\tau_i$, add $x$. Continue adding and removing until nothing can be added or removed at temperature $\tau_i$.

3. Output the maximum extent of the resultant shape.

Since the definition of the $k$-temperature model requires that a system that uniquely produces a shape must, regardless of the sequence of additions and removals, finish each phase, we are assured that each iteration of the for-loop will finish, thus giving the end result. ∎

Theorem 6.2. *For almost all $N$ the tile complexity of self-assembling an $N \times N$ square is $\Omega(\sqrt{\log N})$ under the flexible glue model.*

*Proof.* The Produced-extent algorithm given in Theorem 6.1 for the standard assembly model works just as well for the flexible glue model. Thus, as discussed in Theorem 6.1, the number of binary digits required to represent a flexible glue tile system that self-assembles an $N \times N$ square is bounded below by $\Omega(\log N)$ for almost all $N$. We can represent a flexible glue tile system of size $n$ tiles and temperature $\tau$ bounded by a constant with $f(n) = 4n\log(4n) + (4n)^2 \log\tau = O(n^2)$ bits as follows. For each tile there are four sides for which we must denote a glue. We need at most $4n$ distinct glues, and for each glue we need to store the bonding strength with every other glue in the model. This can be stored in a $4n \times 4n$ matrix. Now for a given $N$, let $\beta(N)$ be the cardinality of the minimum tile set for assembling an $N \times N$ square under the flexible glue model. Then, there exist constants $C_1$ and $C_2$ such that for almost all $N$,

$$C_1 \log N \leq f(\beta(N)) \leq C_2 \beta(N)^2.$$

Thus $\beta(N) = \Omega(\sqrt{\log N})$ for almost all $N$. ∎

## 7. Shape verification.

Given a shape, Adleman et al. [2] studied the problem of finding the minimum set of tiles which uniquely produces a supertile $A$ such that $A$ has the given shape. To show that the decision version of the problem is in NP, they gave an algorithm to verify whether a given set of tiles uniquely produces a supertile which has the given shape. In contrast, in this section we show that for the unique shape, multiple tile, and multiple temperature models this problem is NP-hard. The problem of shape verification is defined as follows.

Unq-Shape$(\Gamma, M)$ is the problem of deciding whether the tile system $\Gamma$ uniquely assembles into the shape $M$.

### 7.1. Unique shape model.

The algorithm of [2] to verify whether a given set of tiles uniquely produces a given shape insists that the tile system should assemble into a unique terminal supertile. Under the *unique shape* model, a tile system $\mathbb{T}$ uniquely produces a shape if all terminal supertiles of $\mathbb{T}$ (henceforth called $Term(\mathbb{T})$) have the given shape, and no larger supertiles are produced. We note that this definition automatically implies that if a tile system uniquely produces a shape, then $Term(\mathbb{T})$ is nonempty. In this section, we show that the unique shape problem is co-NP-complete under the unique shape model, in contrast to the standard model.

Theorem 7.1. Unq-Shape *is co-NP-complete under the unique shape model. It remains NP-hard even when the temperature $\tau = 2$.*

We begin by showing that Unq-Shape is in co-NP, and then show that it is NP-hard (and thus co-NP-hard).

Lemma 7.2. Unq-Shape *is in co-NP under the unique shape model.*

*Proof.* For this, we need to show that if an instance of Unq-Shape is false, i.e., if the tile system in the instance does not assemble uniquely into the given shape, then there is a short proof of the fact. By definition, a given tile system $\mathbb{T} = \langle T, \mathcal{S}, G, \tau \rangle$ does not uniquely assemble into the given shape $M$ iff one of the following occurs:

1. A terminal supertile of a shape different from $M$ can be assembled. In this case, $Term(\mathbb{T})$ contains a supertile $A$ with a shape different from $M$. Then $A$, along with the order in which the tiles join to assemble $A$, would suffice as a proof. In order to check this proof, we first verify that $A$ can indeed be assembled by adding the tiles in the order specified. Then we check that $A$ is a terminal supertile by simply testing whether any tile is attachable at any of the empty sites adjacent to it.
2. A supertile $C$ of size larger than the given shape can be assembled. Note that this supertile need not be terminal. We note that if any such $C$ exists, then there exists such a $C$ with size one larger than $M$. Such a $C$, along with the order in which tiles are added to assemble $C$, would suffice as a proof. We verify this proof by checking that $C$ can indeed be assembled by adding the tiles in the order specified, and that the size of the supertile is larger than the shape.

In both cases, the size of the proof is linear in the instance size, and the verification algorithm runs in time quadratic in the instance size. □

Lemma 7.3. Unq-Shape *is NP-hard under the unique shape model.*

*Proof.* The proof uses a construction proposed by Lagoudakis and LaBean [6] to solve the 3-SAT problem by exploiting the massive parallelism possible in DNA operations to emulate a nondeterministic device that solves 3-SAT.

We reduce 3-SAT to Unq-Shape using their construction. Given any instance of 3-SAT with $m$ clauses and $n$ different variables, we construct an instance of Unq-Shape, $(\langle T, \mathcal{S}, G, 2\rangle, M)$ with $|T| = O(m+n)$, and the size of the shape $M$ of order $O(mn)$. There is a one-to-one correspondence between variable assignments for the 3-SAT instance and the supertiles in $Term(\mathbb{T})$; i.e., every possible assignment to variables is associated with a distinct terminal supertile. If the assignment satisfies the formula, the terminal supertile associated with it has the shape of an $(n+2) \times (m+3)$ rectangle; else the shape associated with the assignment has the shape of an $(n+2) \times (m+3)$ rectangle with its top-right corner missing. Thus, if the tile system uniquely assembles into a rectangle with its top-right corner missing, then no assignment satisfies the 3-SAT formula; on the other hand, if the tile system does not uniquely assemble into this corner-missing rectangle, then there is at least one assignment which satisfies the 3-SAT formula. Thus, a polynomial time algorithm to decide Unq-Shape will result in a polynomial time algorithm for 3-SAT.

The idea of the reduction is to have the bottom row of the rectangle encode the clauses, have the left column encode the variables, and let the second column correspond to a possible assignment of values to the variables. The rest of the assembly evaluates the formula at that assignment, and the row below the top row encodes which of the clauses get satisfied by the assignment. A tile gets added to the top-right corner iff the assignment satisfies all the clauses.

Take any 3-SAT formula with $n$ variables, $x_1, x_2, \ldots, x_n$, appearing in $m$ clauses $C_1, C_2, \ldots, C_m$. We define a tile system as shown in Figure 6, where the temperature is fixed at 2. In addition to the seed tile, there are $n$ *variable tiles* which attach on top of the seed tile to give the first column. The east side of these tiles provides a strength-2 glue to the *assignment tiles.* Besides, there are $m$ *clause tiles* that attach to the east of the seed tile to form the bottom row. For any clause-variable pair, $C_j$ and $x_i$, the following *computation tiles* are present:

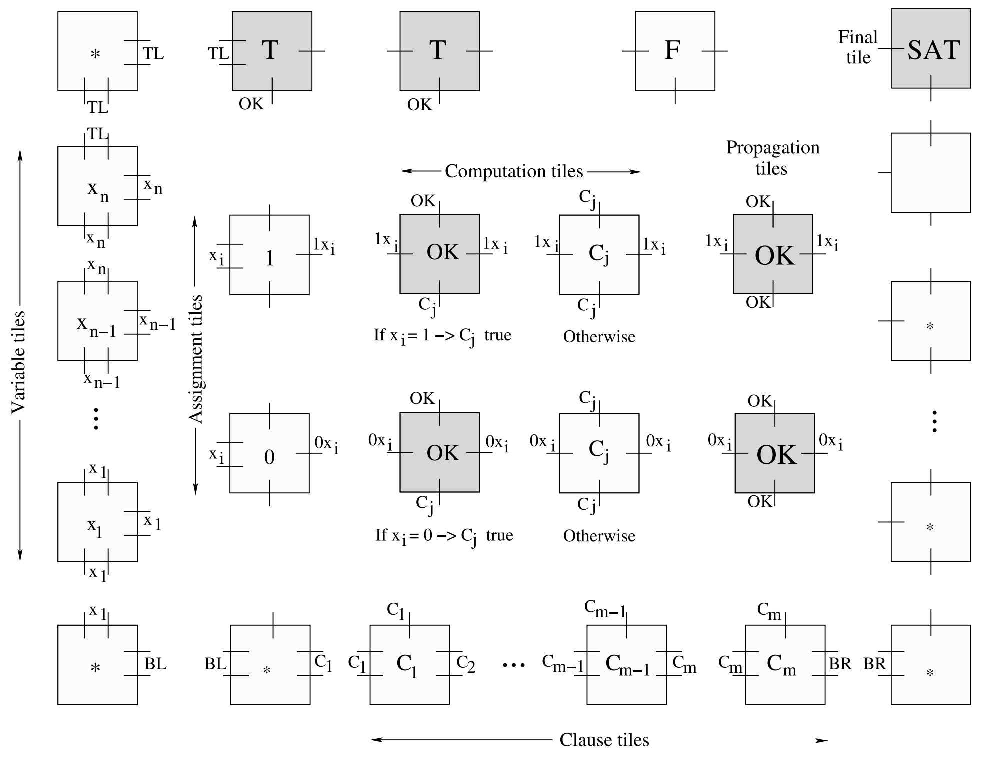

FIG. 6. *Tile system for evaluation of a* 3-*SAT formula.*

1. If $x_i$ set to 1 makes the clause $C_j$ true, then the upper-left computation tile shown in the figure is present; otherwise, the upper right one is present.
2. Similarly, if $x_i$ set to 0 makes the clause $C_j$ true, then the lower-left computation tile in the figure is present; otherwise, the lower right one is present.

In addition, there are $2n$ tiles to propagate $OK$ upwards. The tile labeled $SAT$ attaches to the top-right corner only if the formula is satisfied by the assignment in the second column of the supertile.

Figures 7(a) and (b) show two of the terminal supertiles of a tile system corresponding to the formula $(x_1 + x_2 + \overline{x_3})(x_1 + \overline{x_2} + x_3)(\overline{x_1} + x_2 + \overline{x_3})$. Note that since the assignment $x_1 = 0$, $x_2 = 1$, $x_3 = 1$ satisfies the formula, a tile gets attached in the top-right corner in Figure 7(a). Also, since the assignment $x_1 = 0$, $x_2 = 1$, $x_3 = 0$ does not satisfy the formula, the rectangle in Figure 7(b) is missing a tile in the top-right corner. $\square$

**7.2. Multiple tile and multiple temperature models.** The algorithm of [2] to determine whether a tile system uniquely assembles a given shape does not work if the self-assembly model allows preassembled supertiles to be added to the growing seed supertile. The algorithm therefore does not apply to the multiple tile model. The algorithm also assumes that once a tile is placed, it can never be removed. This is not the case in the multiple temperature model. In this section we consider the complexity of the unique shape problem under the multiple tile model and the multiple temperature model. We first show that for both models the problem is NP-hard. We then generalize the proofs of this fact to show that the problem for both models is neither in NP nor co-NP unless P = NP.

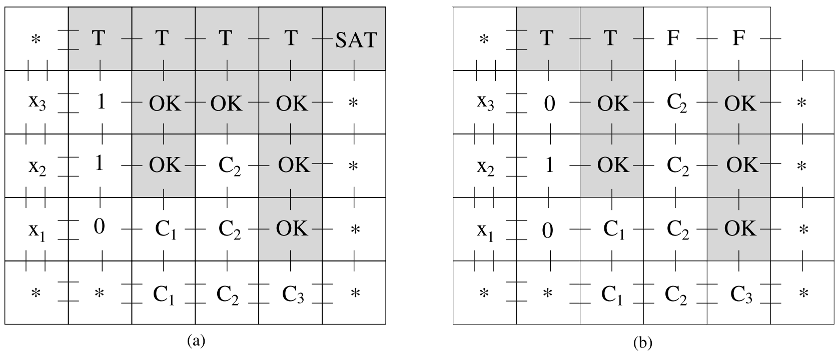

FIG. 7. *Two terminal supertiles for the formula* $(x_1 + x_2 + \overline{x_3})(x_1 + \overline{x_2} + x_3)(\overline{x_1} + x_2 + \overline{x_3})$.

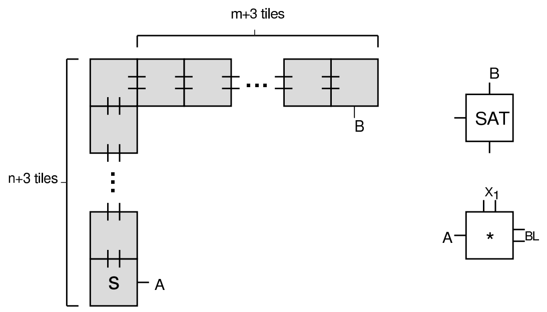

FIG. 8. *To show that the* UNQ-SHAPE *problem is NP-hard for the multiple tile model we modify the tile set of Theorem* 7.1. *We add the tiles given above as well as change the seed tile to be S, add glue A to the west edge of the old seed tile, and add glue B to the north edge of the final SAT tile.*

THEOREM 7.4. UNQ-SHAPE *is NP-hard under the multiple tile model. It remains NP-hard even when the temperature* $\tau = 2$ *and q is polynomial in the number of tiles in the system.*

*Proof.* The proof is a reduction from 3-SAT similar in spirit to the reduction in Theorem 7.1. For a given instance of 3-SAT with $n$ variables and $m$ clauses, consider a multiple tile system $\langle T, s, G, 2, q = (n+2)(m+3)\rangle$ given as follows. The tile set includes the tiles given in Figure 8, as well as the tiles for solving 3-SAT as given in Theorem 7.1, with the following adjustment. The seed tile is no longer the seed, but just a tile in the set, and it is given a west glue $A$ with glue strength 1. Also, the SAT tile from the construction is given a north glue $B$ with strength 1.

This tile set assembles a single-width chain of tiles that grows north for $n+2$ tiles and then turns east and grows for $m+3$ tiles. The east glue of the first tile in this chain (the seed tile) has east glue $A$, and the last tile in the chain has south glue $B$. Denote the shape of this supertile as $M$. Now in the case that the corresponding 3-SAT formula is not satisfiable, nothing else can be attached, and $M$ is uniquely assembled. However, if there exists a satisfying assignment to the 3-SAT formula, an $(n+2) \times (m+3)$ rectangle whose northeast-most tile has north glue $B$ and southwest-most tile has west glue $A$ is in the system's addable supertile set $W$. Thus, a supertile of the shape of an $(n+3) \times (m+4)$ rectangle can be produced. Thus, in this case $M$ is not uniquely produced. So the output of UNQ-SHAPE when given this tile system and shape $M$ as input is yes iff the corresponding 3-SAT formula is not satisfiable. Thus, UNQ-SHAPE is NP-hard under the multiple tile model. See Figure 9 for an example

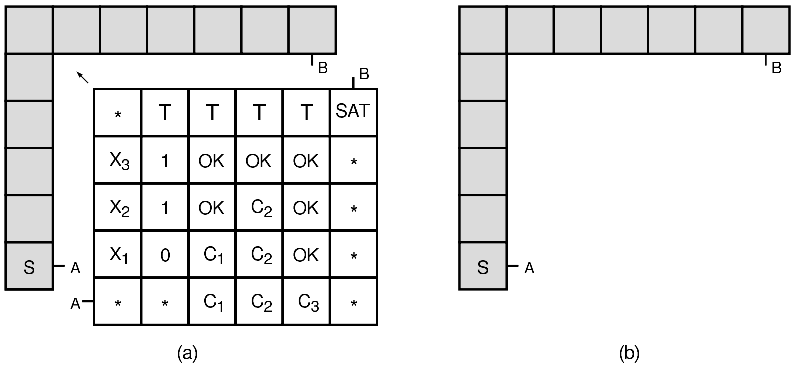

FIG. 9. *Two terminal supertiles for the formula* $(x_1 + x_2 + \overline{x_3})(x_1 + \overline{x_2} + x_3)(\overline{x_1} + x_2 + \overline{x_3})$. *In the case that a given* 3*-SAT formula is not satisfiable, the tree on the right is uniquely assembled.*

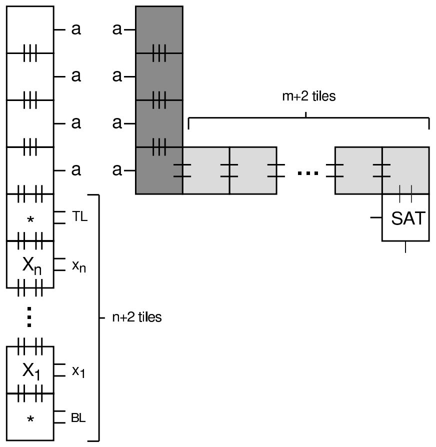

FIG. 10. *This tile set in addition to the tile set of Theorem* 7.1 *under the two-temperature model with* $\tau_1 = 2$ *and* $\tau_2 = 4$ *uniquely assembles an* $(n+6) \times 1$ *column iff the corresponding* 3*-SAT formula is unsatisfiable.*

of the construction. □

*Proof.* We again use a reduction from 3-SAT similar in spirit to the reduction in Theorem 7.1. For a given 3-SAT formula with $n$ variables and $m$ clauses, consider the two-temperature tile system with temperatures $\tau_1 = 2, \tau_2 = 4$, and tile set given by the construction in Theorem 7.1, with the additions and modifications given in Figure 10. The modifications increase the north/south glue strengths of the tiles that occur in the first column of the $(n + 2) \times (m + 3)$ construction from strength 2 to strength 4. Additionally, four tiles are added such that the length of the first column in the construction grows to height $n + 6$ rather than $n + 2$. Another modification is made to the final SAT tile such that it has a strength-2 glue on its north edge. This, in combination with other added tiles, allows a new chain of tiles to be added in the case that a satisfying set of variable assignments are given. The new tiles grow westward back to the first column of the construction. Here four tiles are placed, growing northward now, adjacent to the four *extra* tiles in the first column. These four tiles are connected to one another by strength-3 bonds. In addition, each has a west glue of strength-1. See Figure 11 for an example of the construction.

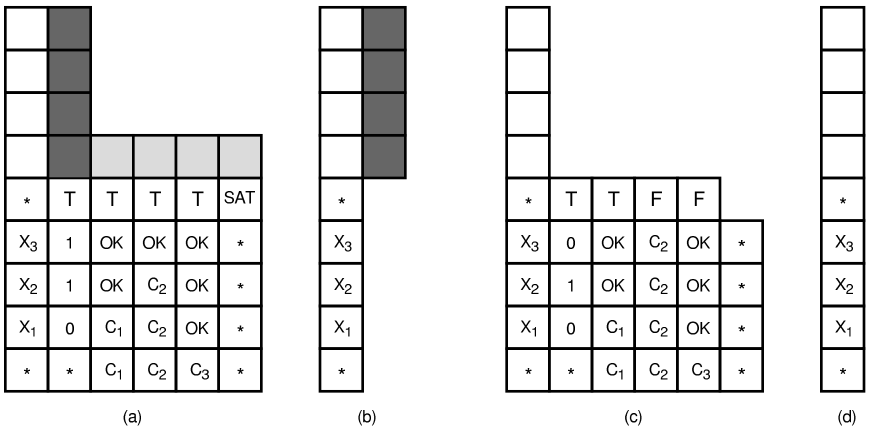

FIG. 11. *At the initial temperature $\tau_1 = 2$, a supertile of the shape given in* (a) *is formed if a satisfying assignment to the* 3*-SAT variables is given. Otherwise, a supertile of the shape given in* (c) *is constructed. At temperature $\tau_2 = 4$, supertiles like* (a) *are broken down to the supertile in* (b). *Supertiles of form* (c) *are broken down into the supertile in* (d). *The supertile in* (d) *is uniquely assembled iff the corresponding* 3*-SAT formula is unsatisfiable.*

THEOREM 7.5. UNQ-SHAPE *is NP-hard under the multiple temperature model. It remains NP-hard even when the temperature is raised only once.*

The idea is that now the temperature of the system is raised from 2 to 4. At temperature 4, each tile between column 2 and column $m + 3$, row 1 to $n + 2$, can be removed, going from bottom to top, right to left. All tiles in row $n + 3$ from column 3 to $m + 3$ can also be removed, leaving a height $n + 6$ column with four extra tiles attached at the end. Nothing within this supertile can be removed, and clearly nothing can be added, so this structure is terminal. However, in the case that no satisfying arrangement exists, the four extra tiles can never get added in the first phase of the two-temperature assembly process. Thus in this case the shape $M$ equal to an $(n + 6) \times 1$ column is uniquely assembled. Thus, when given this tile set and shape $M$ as input, the UNQ-SHAPE problem outputs yes iff the corresponding 3-SAT formula is not satisfiable. So the UNQ-SHAPE problem is NP-hard for the two-temperature model. ▯

THEOREM 7.6. UNQ-SHAPE *is not in NP or co-NP under the multiple temperature model unless $P = NP$. This remains true even when the temperature is raised only once.*

*Proof.* To show this we generalize the reduction from co-SAT given in Theorem 7.5. Our construction yields, depending on the input shape, a reduction from either SAT or co-SAT to the problem of deciding whether a given tile set assembles the given shape. The "not in co-NP" part of the theorem follows from the SAT reduction, and the "not in NP" part from the co-SAT reduction.

The reduction is as follows. Given a 3-SAT formula with $n$ variables and $m$ clauses, we create a tile set at temperature $\tau_1 = 2$ in the fashion of Theorem 3.2 that assembles an $n$-bit binary counter growing from west to east, which counts from 0 to $2^n - 1$. In this case, however, at each incrementation of the counter the given 3-SAT formula is evaluated for the variable assignment corresponding to the current value of the binary counter. After the final iteration of the counter, a string of tiles grows back to the initial column of tiles and *latches on* by creating a second vertical column that is attached adjacent to the first. However, this growth is disrupted if any occurrence

FIG. 12. *To show that the* UNQ-SHAPE *problem is not in NP or co-NP unless P=NP under the multiple temperature model, we combine a binary counter with the SAT solving tiles of section* 7.1 *to evaluate a given SAT formula for every possible assignment to the variables. Some tiles or glues of the construction are omitted in this figure as they are unchanged from the construction in section* 7.1.

of an SAT tile is encountered. Thus, such a latch is created iff there is no satisfying assignment to the variables.

The temperature of the system is then raised to $\tau_2 = 4$. This eliminates any tile occurring east of the initial variable column. What is left is a single column supertile in the case that there exists a satisfying assignment, and a pair of adjacent columns in the case that there is no satisfying assignment. The tile set for this construction is given in Figure 12. Let shape $M$ be the single column, and shape $W$ be the double column. Thus, when given this tile set and shape $M$ as input, the UNQ-SHAPE problem outputs yes iff the corresponding 3-SAT formula is satisfiable. If shape $W$ is given as input, the UNQ-SHAPE problem outputs yes iff the corresponding 3-SAT formula is not satisfiable. The first input exhibits the reduction from SAT, the second from co-SAT. See Figure 13 for an example. □

THEOREM 7.7. UNQ-SHAPE *is not in NP or co-NP under the multiple tile model unless $P = NP$. This remains true even when the temperature $\tau = 2$.*

*Proof.* The proof is again a reduction from 3-SAT and very similar to the proof for Theorem 7.6. Consider a given instance of 3-SAT with $n$ variables and $m$ clauses. Let the size of the addable supertiles be $q = 2^n(n+3)(m+2)+2(n+3)$. The tile set for the reduction is essentially that from Figure 12 except we remove all but one of the clamping tiles, reduce all glue strengths greater than 2 down to 2, and add tiles $S_1$ and $S_2$ given in Figure 14, with $S_1$ being set as the seed tile.

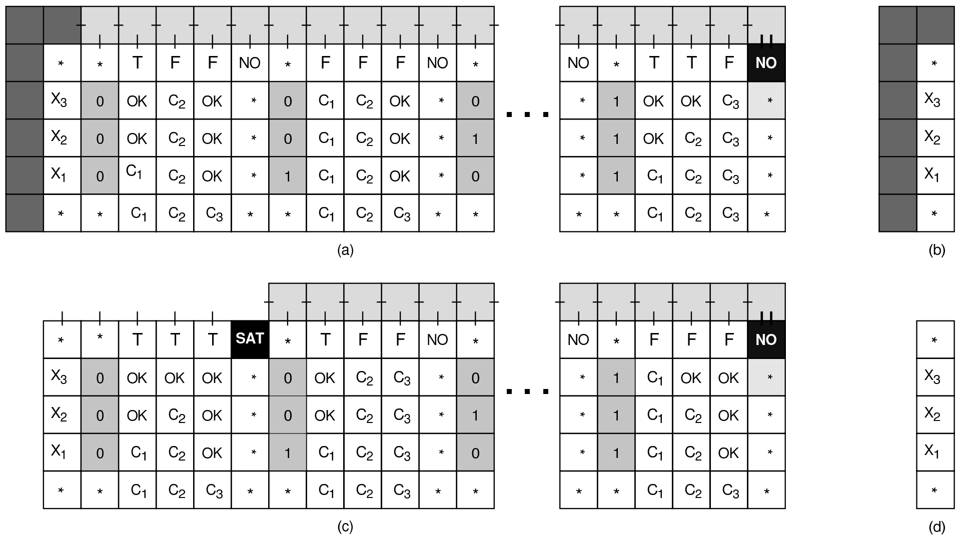

FIG. 13. *At temperature $\tau = 2$, if the corresponding SAT formula has no satisfying assignment, then a growth of tiles, starting at the final NO tile, is started and reaches back to the initial column of variable tiles and clamps on. In the case that there are one or more satisfying assignments, the growth is stopped, and a shape like* (c) *is formed. After raising the temperature to $\tau = 4$, shape* (b) *is uniquely produced in the first case and shape* (d) *in the second. Thus, the* UNQ-SHAPE *problem with the tile set of Figure* 12 *yields a reduction from co-SAT with input shape* (b) *and a reduction from SAT with input shape* (d).

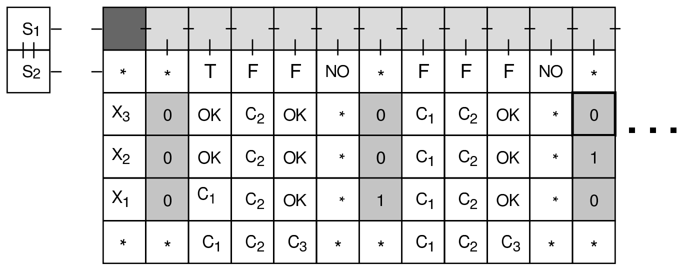

FIG. 14. *Under the multiple tile model with $q = 2^n(n+3)(m+2) + 2(n+3)$, the large $(2^n(m+2)+2) \times (n+3)$ rectangle can be attached to the two S tiles iff the corresponding* 3*-SAT formula is satisfied.*

Clearly this tile set uniquely assembles a two-tile supertile consisting only of $S_1$ and $S_2$ in the case that the 3-SAT formula is satisfiable. On the other hand, if there is no satisfying arrangement, the complete size $(2^n(m+2)+2) \times (n+3)(m+2)$ rectangle from the tiles of Figure 12 is in the set of addable supertiles. The resultant uniquely assembled shape is then the rectangle with the tiles $S_1$ and $S_2$ attached to the side. Thus, the unique shape problem with the size-2 shape given as input gives a reduction from SAT, while the rectangle with the two $S$ tiles attached gives a reduction from co-SAT. ∎

## 8. Conclusions.

We have considered various natural generalizations of the self-assembly model in an attempt to reduce the tile complexity of certain shapes. In doing so, we have produced a construction for building arbitrary-sized rectangles, which is particularly useful for the assembly of thin rectangles (a $k \times N$ rectangle is thin if $k < \frac{\log N}{\log\log N - \log\log\log N}$). This construction also yields a simple way to assemble thicker rectangles while achieving the same optimal tile and time complexity achieved in [1]. We use modifications of this construction to show how two of the models, the multitemperature model and the flexible glue model, can reduce tile complexity below theoretical lower bounds for the standard model for certain shapes. In particular, the multitemperature model assembles thin $k \times N$ rectangles in optimal $\Theta(\frac{\log N}{\log\log N})$, while the flexible glue model reduces the complexity of $\Theta(\frac{\log N}{\log\log N})$ for the assembly of $N \times N$ squares to the tight bound of $\Theta(\sqrt{\log N})$. For the remaining models, we have extended Kolmogorov lower bound proofs from [9] to show that, for many shapes, the new models do not improve tile complexity. We have also shown that the problem of verifying whether a given tile set assembles into a given shape is co-NPC under the unique shape model and not in NP or co-NP unless P = NP under the multiple tile and multiple temperature models, in contrast to the polynomial time solution for the standard and flexible glue models.

There are a number of open questions remaining, some of which are as follows. First, there are some questions as to how the parameter $q$ in the multiple tile model affects complexity. The proof of the Kolmogorov lower bound for $N \times N$ squares does not hold if the bound of $q$ on the size of the addable supertiles is removed. Also, to show that the Unq-Shape problem under the multiple tile model is neither in NP nor co-NP we required that $q$ be exponential in the size of the tile set. To show NP-hardness, we needed $q$ to grow linearly in the size of the tile set. For polynomial sized $q$, is the problem in NP or co-NP, and for constant $q$, is the problem in P?

Second, can new examples be found showing that the generalized models can reduce tile complexity? For example, are there shapes for which the multiple tile or the unique shape models reduce complexity? And for the multiple temperature model, can it help to use more than two temperatures? If so, does the temperature need only be monotonically increasing or can it help to raise and lower the temperature? Also, the construction for the flexible glue model shows how to create rectangles with width at least logarithmic in their length, but does not work for thinner rectangles. However, for *medium* rectangles (width less than $\log N$ but not thin) we can combine the flexible glue model with the two-temperature model to attain the tight $\Theta(\sqrt{\log N})$ tile complexity. Is it possible to assemble such a rectangle using only the flexible glue model? And finally, even in the case of the standard model, the Kolmogorov lower bounds for the assembly of $N \times N$ squares (Theorems 6.1, 6.2) do not apply if the temperature of the system is a large exponential function of $N$. If this is allowed, is it possible to reduce the tile complexity of assembling $N \times N$ squares?

**Acknowledgment.** We would like to thank the anonymous reviewer of this paper for the extremely detailed and helpful comments.

# CONVERGENCE PROPERTIES OF THE GRAVITATIONAL ALGORITHM IN ASYNCHRONOUS ROBOT SYSTEMS[*]

REUVEN COHEN[†] AND DAVID PELEG[†]

**Abstract.** This paper considers the convergence problem in autonomous mobile robot systems. A natural algorithm for the problem requires the robots to move towards their center of gravity. This paper proves the correctness of the gravitational algorithm in the fully asynchronous model. It also analyzes its convergence rate and establishes its convergence in the presence of crash faults.

**Key words.** robot swarms, autonomous mobile robots, convergence

**AMS subject classifications.** 68Q22, 70B15

**DOI.** 10.1137/S0097539704446475

## 1. Introduction.

### 1.1. Background and motivation.

Swarms of low cost robots provide an attractive alternative when facing various large-scale tasks in hazardous or hostile environments. Such systems can be made cheaper, more flexible, and potentially resilient to malfunction. Indeed, interest in autonomous mobile robot systems arose in a variety of contexts (see [4, 5, 13, 14, 15, 16, 17, 18, 19, 20, 27] and the survey in [6, 7]).

Along with developments related to the physical engineering aspects of such robot systems, there have been recent research attempts geared at developing suitable algorithmics, particularly for handling the distributed coordination of multiple robots [3, 8, 9, 21, 23, 25, 26]. A number of computational models were proposed in the literature for multiple robot systems. In this paper we consider the fully asynchronous model of [8, 9, 11, 22]. In this model, the robots are assumed to be identical and indistinguishable, lack means of communication, and operate in Look-Compute-Move cycles. Each robot wakes up at unspecified times, observes its environment using its sensors (capable of identifying the locations of the other robots), performs a local computation determining its next move, and moves accordingly.

Much of the literature on distributed control algorithms for autonomous mobile robots has concentrated on two basic tasks, called *gathering* and *convergence*. Gathering requires the robots to occupy a single point within finite time, regardless of their initial configuration. Convergence is the closely related task in which the robots are required to converge to a single point, rather than reach it. More precisely, for every $\epsilon > 0$ there must be a time $t_\epsilon$ from which all robots are within a distance of at most $\epsilon$ of each other.

A common and straightforward approach to these tasks relies on the robots in the swarm calculating some median position and moving towards it. Arguably, the most natural variant of this approach is the one based on using the *center of gravity* (sometimes called the *center of mass*, the *barycenter*, or the average) of the robot swarm. This approach is easy to analyze in the synchronous model. In the asynchronous

model, analyzing the process becomes more involved, since the robots operate at different rates and may take measurements at different times, including while other robots are in movement. The inherent asynchrony in operation might therefore cause various oscillatory effects on the centers of gravity calculated by the robots, preventing them from moving towards each other and possibly even causing them to diverge and stray away from each other in certain scenarios.

Several alternative, more involved, algorithms have been proposed in the literature for the gathering and convergence problems. The gathering problem was first discussed in [25, 26] in a semisynchronous model, where the robots operate in cycles but not all robots are active in every cycle. It was proven therein that it is impossible to gather *two* oblivious autonomous mobile robots without a common orientation under the semisynchronous model (although 2-robot convergence is easy to achieve in this setting). On the other hand, there is an algorithm for gathering $N \geq 3$ robots in the semisynchronous model [26]. In the asynchronous model, an algorithm for gathering $N = 3, 4$ robots is presented in [9, 22], and an algorithm for gathering $N \geq 5$ robots has recently been described in [8]. The gathering problem was also studied in a system where the robots have limited visibility [2, 12]. Fault-tolerant algorithms for gathering were studied in [1]. In a failure-prone system, a gathering algorithm is required to successfully gather the nonfaulty robots, independently of the behavior of the faulty ones. The paper presents an algorithm tolerant against a single crash failure in the asynchronous model. For Byzantine faults, it is shown therein that in the asynchronous model it is impossible to gather a 3-robot system, even in the presence of a single Byzantine fault. In the fully synchronous model, an algorithm is provided for gathering $N$ robots with up to $f$ faults, where $N \geq 3f + 1$.

Despite the existence of these elaborate gathering algorithms, the gravitational approach is still very attractive for a number of reasons. To begin with, it requires only very simple and efficient calculations, which can be performed on simple hardware with minimal computational efforts. It can be applied equally easily to any number of dimensions and to any swarm size. Moreover, the errors it incurs due to rounding are bounded and simple to calculate. In addition, it is oblivious (i.e., it does not require the robots to store any information on their previous operations or on past system configurations). This makes the method both memory-efficient and self-stabilizing (meaning that following a finite number of transient errors that change the states of some of the robots into other (possibly illegal) states, the system returns to a legal state and achieves eventual convergence). Finally, the method avoids deadlocks, in the sense that every robot can move at any given position (unless it has already reached the center of gravity). These advantages may well make the gravitational algorithm the method of choice in many practical situations.

Subsequently, it is interesting to study the correctness and complexity properties of the gravitational approach to convergence. This study is the focus of the current paper. We prove the convergence of the center of gravity algorithm in the fully asynchronous model. We also analyze the convergence rate of the algorithm. Finally, we establish convergence in the crash fault model. Specifically, we show that in the presence of $f$ crash faults, $1 \leq f \leq N - 2$, the $N - f$ nonfaulty robots will converge to the center of gravity of the crashed robots.

### 1.2. The model.

The basic model studied in [3, 8, 9, 21, 23, 25, 26] can be summarized as follows. The $N$ robots execute a given algorithm in order to achieve a prespecified task. Each robot $i$ in the system operates individually, repeatedly going through simple cycles consisting of three steps:

- *Look*: Identify the locations of all robots in $i$'s private coordinate system and obtain (instantaneously) a multiset of points $P = \{p_1, \dots, p_N\}$ defining the current *configuration*. The robots are indistinguishable, so $i$ knows its own location $p_i$ but does not know the identity of the robots at each of the other points. This model allows robots to detect multiplicities; i.e., when two or more robots reside at the same point, all robots will detect this fact. Note that this model is stronger than, e.g., the one of [8].
- *Compute*: Execute the given algorithm, resulting in a goal point $p_G$.
- *Move*: Move on a straight line towards the point $p_G$. The robot might stop before reaching its goal point $p_G$ but is guaranteed to traverse a distance of at least $S$ (unless it has reached the goal). The value of $S$ is not assumed to be known to the robots, and they cannot use it in their calculations.

This model, which allows the robot to suddenly stop short of reaching its goal point, is henceforth referred to as the *sudden-stop* model. The simpler model where the robot always reaches $p_G$ is henceforth called the *undisturbed-motion* model. For simplicity of presentation, we will prove some of our claims first in the undisturbed-motion model and then extend the proof to the full (sudden-stop) model.

The Look and Move operations are identical in every cycle, and the differences between various algorithms are in the Compute step. The procedure carried out in the Compute step is identical for all robots.

In most papers in this area (cf. [9, 12, 24, 25]), the robots are assumed to be rather limited. To begin with, the robots are assumed to have no means of directly communicating with each other. Moreover, they are assumed to be *oblivious* (or memoryless); namely, they cannot remember their previous states, their previous actions, or the previous positions of the other robots. Hence the algorithm used in the Compute step cannot rely on information from previous cycles, and its only input is the current configuration. While this is admittedly an overrestrictive and unrealistic assumption, developing algorithms for the oblivious model still makes sense in various settings for two reasons. First, solutions that rely on nonobliviousness do not necessarily work in a dynamic environment where the robots are activated in different cycles, or robots might be added to or removed from the system dynamically. Second, any algorithm that works correctly for oblivious robots is inherently self-stabilizing; i.e., it withstands transient errors that alter the robots' local states into other (possibly illegal) states.

We consider mainly the *fully asynchronous* ($\mathcal{ASYNC}$) timing model (cf. [8, 9]). In this model, robots operate on their own (time-varying) rates, and no assumptions are made regarding the relative speeds of different robots. In particular, robots may remain inactive for arbitrarily long periods between consecutive operation cycles (subject to some "fairness" assumption that ensures that each robot is activated infinitely often in an infinite execution). This feature is sometimes modeled by incorporating a *Wait* phase in each operation cycle of the robots.

We find it instructive to compare the performance of the gravitational algorithm in this model with its performance in two alternative models studied in the literature, namely, the *semisynchronous* ($\mathcal{SSYNC}$) model (cf. [25]) and the *fully synchronous* ($\mathcal{FSYNC}$) model (cf. [26]). In the fully synchronous model, all robots operate at fixed time cycles, and the Look phase of all robots is simultaneous. In the commonly studied intermediate semisynchronous model, it is again assumed that there are fixed time cycles, and the Look phase of the robots is simultaneous. However, now only a subset of the robots may wake up at every cycle.

To describe the center of gravity algorithm, hereafter named Algorithm Go_to_COG, we use the following notation. Denote by $\bar{r}_i[t]$ the location of robot $i$ at time $t$. Denote the true center of gravity at time $t$ by $\bar{c}[t] = \frac{1}{N}\sum_{i=1}^{N}\bar{r}_i[t]$. Denote by $\bar{c}_i[t]$ the center of gravity as last calculated by the robot $i$ before or at time $t$; i.e., if the last calculation by $i$ was done at time $t' \leq t$, then $\bar{c}_i[t] = \bar{c}[t']$. Note that, as mentioned before, robot $i$ calculates this location in its own private coordinate system; however, for the purpose of describing the algorithm and its analysis, it is convenient to represent these locations in a unified global coordinate system (which, of course, is unknown to the robots themselves). This is justified by the linearity of the center of gravity calculation, which renders it invariant under any linear transformation. By convention, $\bar{c}_i[0] = \bar{r}_i[0]$ for all $i$.

Algorithm Go_to_COG is very simple. After measuring the current configuration at some time $t$, the robot $i$ computes as its goal point the average location of all robot positions (including its own), $\bar{c}_i[t] = \sum_j \bar{r}_j[t]/N$, and then proceeds to move towards the calculated goal point $\bar{c}_i[t]$. A formal definition of this algorithm follows.

```
Algorithm Go_to_COG (code for robot $i$ at time $t$):
    1. Calculate the center of gravity, $\bar{c}_i[t] = \frac{1}{N}\sum_j \bar{r}_j[t]$.
    2. Move to the point $\bar{c}_i[t]$.
```

As mentioned earlier, the move may terminate before the robot $i$ actually reaches the point $\bar{c}_i[t]$. The point at which the robot does stop its movement is henceforth referred to as its *destination point.* More formally, define the destination point $\bar{\gamma}_i[t]$ of robot $i$ to be the final point of the movement made by $i$ following the last Look performed by $i$ before or at time $t$. Note that at time $t$, robot $i$ may not have computed its goal point $\bar{c}_i[t]$ yet, and, even if it had, it has no knowledge of the possibility of sudden stops; hence it is unaware of its destination point $\bar{\gamma}_i[t]$. Nevertheless, for the analysis we may treat this point as given at the moment of the Look action. Recall also that even in case the robot $i$ has not reached $\bar{c}_i[t]$, it must have traversed a distance of at least $S$.

## 2. Asynchronous convergence.

This section proves our main result, namely, that Algorithm Go_to_COG guarantees the convergence of $N$ robots for any $N \geq 2$ in the asynchronous model. Notice that in the $\mathcal{ASYNC}$ model, since no guarantees are given as to the behavior of the robot's location and velocity at the duration of the Move phase, the Compute and Wait phases may be assimilated into the Move phase and treated as time periods during the Move phase in which the robot progresses with zero velocity. Hence in the analysis we may consider only the Look and Move phases.

LEMMA 2.1. *If for some time $t_0$, $\bar{r}_i[t_0]$ and $\bar{\gamma}_i[t_0]$ for all $i$ reside in the interior of a closed convex curve, $\mathcal{P}$, then for every time $t > t_0$, $\bar{r}_i[t]$ and $\bar{\gamma}_i[t]$ also reside in the interior of $\mathcal{P}$ for every $1 \leq i \leq N$.*

*Proof.* For the Move operation, it is clear that if for some $i$, $\bar{r}_i[t_0]$ and $\bar{\gamma}_i[t_0]$ both reside in the interior of a convex $\mathcal{P}$, then for the rest of the Move operation $\bar{\gamma}_i[t] = \bar{\gamma}_i[t_0]$ does not change and $\bar{r}_i[t]$ remains on the segment $[\bar{r}_i[t_0], \bar{\gamma}_i[t_0]]$, which is inside $\mathcal{P}$.

For the Look step, the claim is obvious for the $\bar{r}_i[t]$ values. We first argue that the calculated centers of gravity $\bar{c}_i[t]$, for every $i$, also reside in the interior of $\mathcal{P}$. If $N = 2$, then the calculated center of gravity is on the line segment connecting both robots and therefore respects convexity. For $N > 2$ robots, the center of gravity is on the line connecting the center of gravity of $N - 1$ robots and the $N$th robot, and the claim follows by induction. The lemma now follows since the destination $\bar{\gamma}_i[t]$ of robot $i$ is on the line segment connecting the robot location $\bar{r}_i[t]$ and its calculated center of gravity $\bar{c}_i[t]$ and therefore also respects convexity. $\square$

Hereafter we assume, for the time being, that the configuration is one-dimensional; i.e., the robots reside on the $x$-axis. Later on, we extend the convergence proof to $d$ dimensions by applying the result to each dimension separately.

For every time $t$, let $H[t]$ denote the convex hull of the points $\{\bar{r}_i[t] \mid 1 \le i \le N\} \cup \{\bar{\gamma}_i[t] \mid 1 \le i \le N\}$, namely, the smallest closed interval containing all $2N$ points. Lemma 2.1 yields the following.

COROLLARY 2.2. *For $N \ge 2$ robots and times $t_1, t_0$, if $t_1 > t_0$, then $H[t_1] \subseteq H[t_0]$.*

Unfortunately, it is hard to prove convergence on the basis of the size of $H$ alone, since it is hard to show that it strictly decreases. Other potentially promising measures, such as $\phi_1$ and $\phi_2$ defined next, also prove problematic, as they might sometimes increase in certain scenarios. Subsequently, the measure $\psi$ we use in what follows to prove strict convergence is defined as a combination of a number of different measures. Formally, let us define the following quantities:

$$\begin{aligned}
\phi_1[t] &= \sum_{i=1}^{N} |\bar{c}[t] - \bar{\gamma}_i[t]| \ , \\
\phi_2[t] &= \sum_{i=1}^{N} |\bar{\gamma}_i[t] - \bar{r}_i[t]| \ , \\
\phi[t] &= \phi_1[t] + \phi_2[t] \ , \\
h[t] &= |H[t]| \ , \\
\psi[t] &= \frac{\phi[t]}{2N} + h[t] \ .
\end{aligned}$$

We now claim that $\phi$, $h$, and $\psi$ are nonincreasing functions of time.

LEMMA 2.3. *For every $t_1 > t_0$, $\phi[t_1] \le \phi[t_0]$.*

*Proof.* Examine the change in $\phi$ due to the various robot actions. Suppose a Look operation is performed by robot $i$ at time $t$. (If two or more robots perform a Look operation simultaneously, then we serialize these operations for the sake of analysis and consider their sequential effects.) Denote with a superscript $^b$ (respectively, $^a$) the values of the robot locations and centers of gravity and the above quantities just before (resp., after) the (instantaneous) Look operation. Then $\bar{\gamma}_i^b[t] = \bar{r}_i^b[t] = \bar{r}_i^a[t]$. Moreover, $\bar{r}_j^a[t] = \bar{r}_j^b[t]$ and $\bar{\gamma}_j^a[t] = \bar{\gamma}_j^b[t]$ for every $j \ne i$; hence also $\bar{c}^a[t] = \bar{c}^b[t]$. These equalities imply the following. First, denoting the contributions of the robots $j \ne i$ to $\phi_1$ and $\phi_2$ by $\tilde{\phi}_1[t] = \sum_{j \ne i} |\bar{c}[t] - \bar{\gamma}_j[t]|$ and $\tilde{\phi}_2[t] = \sum_{j \ne i} |\bar{\gamma}_j[t] - \bar{r}_j[t]|$, respectively, these contributions do not change; namely, $\tilde{\phi}_1^a[t] = \tilde{\phi}_1^b[t]$ and $\tilde{\phi}_2^a[t] = \tilde{\phi}_2^b[t]$. Also, the contributions of robot $i$ to $\phi_1^b$ and $\phi_2^b$ are $|\bar{c}^b[t] - \bar{\gamma}_i^b[t]| = |\bar{c}^b[t] - \bar{r}_i^b[t]|$ and $\bar{\gamma}_i^b[t] - \bar{r}_i^b[t] = 0$, respectively. Finally, the contributions of robot $i$ to $\phi_1^a$ and $\phi_2^a$ are $|\bar{r}_i^a[t] - \bar{\gamma}_i^a[t]|$ and $|\bar{\gamma}_i^a[t] - \bar{c}^a[t]|$. Hence the total contribution of robot $i$ to $\phi^a$ is the same as its contribution to $\phi^b$, since the point $\bar{\gamma}_i^a[t]$ occurs on the segment $[\bar{r}_i^b[t], \bar{c}^b[t]] = [\bar{r}_i^a[t], \bar{c}^a[t]]$. (In the undisturbed-motion case the situation is even simpler, as the robot always reaches its calculated destination and therefore $\bar{\gamma}_i^a[t] = \bar{c}^b[t]$.) Therefore, $\phi$ is unchanged by the Look performed.

Now consider some time interval $[t_0', t_1'] \subseteq [t_0, t_1]$, such that no Look operations were performed during $[t_0', t_1']$. Suppose that during this interval each robot $i$ moved a distance $\Delta_i$ (where some of these distances may be 0). Then $\phi_2$ decreased by $\sum_i \Delta_i$, the maximum change in the center of gravity is $|\bar{c}[t'_1] - \bar{c}[t'_0]| \leq \sum_i \Delta_i / N$, and the robots' calculated centers of gravity have not changed. Therefore, the change in $\phi_1$ is at most $\phi_1[t'_1] - \phi_1[t'_0] \leq \sum_i \Delta_i$. Hence the sum $\phi = \phi_1 + \phi_2$ cannot increase. $\square$

LEMMA 2.4. *$\psi$ is a nonincreasing function of time.*

*Proof.* By Lemma 2.3, $\phi$ is nonincreasing. By Corollary 2.2, $h$ is nonincreasing. Therefore their sum is also nonincreasing. $\square$

LEMMA 2.5. *For all $t$, $h[t] \leq \psi[t] \leq 2h[t]$.*

*Proof.* The lower bound is trivial. For the upper bound, notice that $\phi[t]$ is the sum of $2N$ summands, each of which is at most $h[t]$ (since they all reside in the segment).

We now state a lemma which allows the analysis of the change in $\phi[t]$ (and therefore also $\psi[t]$) in terms of the contributions of individual robots. It is, in general, impossible to separate the change in $\phi[t]$ to contributions of individual robots. However, it is possible to bound the minimum decrease in $\phi[t]$ by the decrease caused by the motion of a single robot.

LEMMA 2.6. *If $H[t_0] = [0,1]$ and at some time $t \geq t_0$ all robots are in the interval $[0, 1/2]$ (i.e., $\bar{r}_i[t] \in [0, 1/2]$ for all $i$), then there exists a time $t_1 \geq t$, such that $\psi[t_1] \leq \left(1 - \frac{1}{8N^2}\right) \psi[t_0]$.*

*Proof.* We split the situation into two subcases:

1. At time $t$ all destination points $\bar{\gamma}_i[t]$ resided in the interval $[0, \frac{3}{4}]$. In this case, take $t_1$ to be the time when each robot has completed at least one cycle. All robots and destinations are now in the interval $[0, \frac{3}{4}]$, and therefore $h \leq \frac{3}{4}$. Now $h[t_1] \leq \frac{3}{4} \leq \frac{3}{4} h[t_0]$, and therefore

$$\psi[t_1] = h[t_1] + \frac{\phi[t_1]}{2N} \leq \frac{3}{4} h[t_0] + \frac{\phi[t_0]}{2N} \leq \frac{7}{8} h[t_0] + \frac{7}{8} \frac{\phi[t_0]}{2N} = \frac{7}{8} \psi[t_0],$$

where the last inequality is due to the fact that $\frac{\phi[t_0]}{2N} \leq h[t_0]$ as argued in the proof of Lemma 2.5. The lemma immediately follows in this case.

2. At time $t$ there existed robots with $\bar{\gamma}_i[t] > \frac{3}{4}$. In this case, take $k$ to be the robot with the highest destination point (or one of them) and take $t_1$ to be the time robot $k$ completes its next Move. Its Move size is at least $\Delta_k \geq \frac{1}{4}$. Suppose at some time interval $[t', t''] \subseteq [t, t_1]$ no Look was performed by any robot and that every robot, $i$, moved in this time interval by the vector $\bar{\delta}_i$. Now, all robots approached their destinations, so $\phi_2[t''] = \phi_2[t] - \frac{1}{N} \sum_i \delta_i$. The center of gravity was changed by the robots' motions to $\bar{c}[t''] = \bar{c}[t'] + \frac{1}{N} \sum_i \bar{\delta}_i$ and therefore also $\bar{c}[t''] - \bar{c}[t'] \leq \frac{1}{N} \sum_i \delta_i$. Since no Look operations occur in the time interval $[t', t'']$, no $\bar{\gamma}_i$ is changed, and for every $i$, $|\bar{c}[t''] - \bar{\gamma}_i[t'']| \leq |\bar{c}[t''] - \bar{\gamma}_i[t'']| + \frac{1}{N} \sum_i \delta_i$. For $i = k$,

$$\begin{aligned} |\bar{c}[t''] - \bar{\gamma}_k[t'']| &= \left| \bar{c}[t'] + \frac{\bar{\delta}_k}{N} + \frac{1}{N} \sum_{i \neq k} \bar{\delta}_i - \bar{\gamma}_k[t'] \right| \\ &\leq \left| \bar{c}[t'] + \frac{\bar{\delta}_k}{N} - \bar{\gamma}_k[t'] \right| + \frac{1}{N} \sum_{i \neq k} \delta_j . \end{aligned}$$

Since robot $k$ is approaching $\bar{\gamma}_k$ from the left, it follows that $\bar{r}_k + \bar{\delta}_k \leq \bar{\gamma}_k$. Since by its maximality all robots are to the left of $\bar{\gamma}_k$ at all times, it follows that $\bar{c} = \frac{1}{N}(\sum_{i \neq k} \bar{r}_i + \bar{r}_k) \leq \bar{\gamma}_k - \frac{\delta_k}{N}$. Therefore,

$$|\bar{c}[t''] - \bar{\gamma}_k[t'']| \leq |\bar{c}[t'] - \bar{\gamma}_k[t']| + \frac{1}{N}\left(\sum_i \delta_i - 2\delta_k\right).$$

Look operations do not change $\psi$, and the total movement of robot $k$ is $\Delta_k \geq \frac{1}{4}$. Therefore, $\phi$ decreased by at least $2\Delta_k/N$, and the term $\frac{\phi}{2N}$ in $\psi$ decreased by at least $\frac{2\Delta_k/N}{2N} = \frac{\Delta_k}{N^2} \geq \frac{1}{4N^2}$. As $\psi[t_0] \leq 2$ and $h$ is nonincreasing, $\psi$ decreased by at least $\frac{1}{4N^2} \geq \frac{\psi[t_0]}{8N^2}$. The lemma follows. $\square$

We now give our main lemma. First, we treat the undisturbed-motion model. Note that in this case, the destination points are always the calculated centers of gravity.

LEMMA 2.7. *In the undisturbed-motion model, for every time $t_0$, there exists some time $\hat{t} > t_0$ such that*

$$\psi[\hat{t}] \leq \left(1 - \frac{1}{8N^2}\right)\psi[t_0].$$

*Proof.* Assume, without loss of generality, that at time $t_0$, the robots and their destination points resided in the interval $H[t_0] = [0, 1]$ (and thus $h[t_0] = 1$ and $\psi[t_0] \leq 2$). Take $t^*$ to be the earliest time after $t_0$ when each robot has completed at least one entire Look-Compute-Move cycle. There are now two possibilities.

*Case* (1). Every destination point $\bar{\gamma}_i[t']$ that was calculated at any time $t' \in [t_0, t^*]$ resided in the segment $(\frac{1}{2N}, 1]$. In this case, at time $t^*$ no robot can reside in the segment $[0, \frac{1}{2N}]$, since every robot has completed at least one cycle operation, where it has arrived at its calculated center of gravity outside the segment $[0, \frac{1}{2N}]$, and from then on it may have moved a few more times to its newly calculated centers of gravity, which were also outside this segment, by Corollary 2.2. Hence at time $\hat{t} = t^*$ all robots and centers of gravity reside in $H[\hat{t}] \subseteq [\frac{1}{2N}, 1]$, so $h[\hat{t}] \leq 1 - \frac{1}{2N}$, and $\phi[\hat{t}] \leq \phi[t_0]$. Therefore,

$$\psi[\hat{t}] \;=\; \frac{\phi[\hat{t}]}{2N} + h[\hat{t}] \;\leq\; \frac{\phi[t_0]}{2N} + 1 - \frac{1}{2N} \;=\; \psi[t_0] - \frac{1}{2N}\;.$$

Also, by Lemma 2.5, $\psi[t] \leq 2$, and hence $\frac{1}{2N} \geq \frac{1}{4N}\psi[t_0]$. Combined, we get $\psi[\hat{t}] \leq \left(1 - \frac{1}{4N}\right)\psi[t_0]$.

*Case* (2). For some $t_1 \in [t_0, t^*]$, the destination point (or center of gravity) $\bar{\gamma}_i[t_1] = \bar{c}_i[t_1] = \frac{1}{N}\sum_{j=1}^{N} \bar{r}_j[t_1]$ calculated by some robot $i$ at time $t_1$ resided in $[0, \frac{1}{2N}]$. Therefore, at time $t_1$ all robots resided in the segment $[0, \frac{1}{2}]$. The lemma then follows by applying Lemma 2.6. $\square$

To prove the convergence of the gravitational algorithm in the undisturbed-motion model in $d$-dimensional Euclidean space, we apply Lemma 2.7 to each dimension separately. Observe that by Lemmas 2.7 and 2.5, for every $\epsilon > 0$ there is a time $t_\epsilon$ by which $h[t_\epsilon] \leq \psi[t_\epsilon] \leq \epsilon$; hence the robots have converged to an $\epsilon$-neighborhood. This proves that in the undisturbed-motion model in $d$-dimensional Euclidean space, for any $N \geq 2$, $N$ robots performing Algorithm `Go_to_COG` will converge.

We now turn to the full (sudden-stop) model. In this case the following lemma replaces Lemma 2.7.

LEMMA 2.8. *In the full (sudden-stop) model in $d$ dimensions, for every time $t_0$, there exists some time $\hat{t} > t_0$ such that*

$$\psi[\hat{t}] \le \max\left\{ \left(1 - \frac{1}{8N^2}\right)\psi[t_0] \ , \ \psi[t_0] - \frac{S}{4N\sqrt{d}} \right\}.$$

*Proof.* The proof is similar to the proof of Lemma 2.7 with the following changes.

- In each round we treat only the dimension for which $h$ is largest (or one such dimension if there exist more than one). We refer to this dimension as the $x$-dimension and denote quantities in this dimension by ${}^{(x)}$.
- In Case (1), the moving robots may not complete their move and therefore may not leave the segment $[0, \frac{1}{2N}]$ even if no center of gravity was calculated in this segment. We split this case into two cases. If at the time of the last Look no robot resided in the segment $[0, \frac{1}{4N}]$, then no robot will reside there also at the end of the Move, and $h$ must have decreased by at least $\frac{1}{4N}$. Otherwise, the distance between each of the robots in the segment $[0, \frac{1}{4N}]$ to its observed center of gravity in the $x$-dimension is at least $\frac{1}{4N}$, since by assumption $\bar{c}[t] \ge \frac{1}{2N}$ for all $t \in [t_0, \hat{t}]$. Recalling that $d$ is the number of dimensions, we conclude that the total distance from these robots to the center of gravity is at most $\sqrt{d}$, since by the maximality of $h$ in dimension $x$ over every other dimension $\nu$, $h^{(\nu)}[t_0] \le h^{(x)}[t_0] = 1$. Thus, the ratio of the $x$-component of the vector $\bar{r}_i[t] - \bar{c}[t]$ to the vector size is at least $\frac{1}{4N\sqrt{d}}$. Therefore, the projection of a vector of length at least $S$ in this direction on the $x$-axis is at least $\frac{S}{4N\sqrt{d}}$, and $h^{(x)}$ decreases by at least this amount.
- Case (2) still holds, since Lemma 2.6 is true even with sudden stops. $\square$

Lemma 2.8 yields the following.

THEOREM 2.9. *In the full (sudden-stop) $\mathcal{ASYNC}$ model for any $N \ge 2$, in $d$-dimensional Euclidean space, $N$ robots performing Algorithm* `Go_to_COG` *will converge.*

*Proof.* Denote $\Psi[t] = \sum_{\nu=1}^{d} \psi^{(\nu)}[t]$. Then

$$\Psi[t_0] \ \le \ 2\sum_{\nu=1}^{d} h^{(\nu)}[t_0] \ \le \ 2dh^{(x)}[t_0] \ \le \ 2d\psi^{(x)}[t_0].$$

Therefore, the value of $\psi$ for the largest dimension is $\psi^{(x)}[t_0] \ge \Psi[t_0]/2d$. By Lemma 2.8 the value of $\psi$ for the largest dimension decreases after every two complete cycles of the robot swarm by an additive or multiplicative constant. The theorem follows. $\square$

## 3. Convergence rate.

**3. Convergence rate.** To bound the rate of convergence in the fully asynchronous model, one should make some normalizing assumption on the operational speed of the robots. A standard type of assumption is based on defining the maximum length of a robot cycle during the execution (i.e., the maximum time interval between two consecutive Look steps of the same robot) as one time unit. For our purposes it is more convenient to make the slightly modified assumption that for every time $t$, during the time interval $[t, t+1]$ every robot has completed at least one cycle. Note that the two assumptions are equivalent up to a constant factor of 2. Note also that this assumption is used only for the purpose of complexity analysis and was not used in our correctness proof.

**3.1. The undisturbed-motion model.** First, we discuss the convergence rate in the undisturbed-motion model.

LEMMA 3.1. *In the undisturbed-motion model, for every time interval* $[t_0, t_1]$,

$$\psi[t_1] \;\le\; \left(1-\frac{1}{8N^2}\right)^{\left\lfloor\frac{t_1-t_0}{2}\right\rfloor}\psi[t_0].$$

*Proof.* Consider the different cases analyzed in the proof of Lemma 2.7. By our timing assumption, we can take $t^* = t_0+1$. In Case (1), $\psi$ is decreased by a factor of $1-\frac{1}{4N}$ by time $\hat{t}=t^*$, i.e., within one time unit. In Case (2), we have two possibilities. If Case (1) of Lemma 2.6 holds, then $\psi$ is decreased by a factor of $\frac{7}{8}$ by time $\hat{t}=t^*$, i.e., within one time unit again. The slowest convergence rate is obtained in Case (2) of Lemma 2.6. Here we can take $\hat{t}=t^*+1=t_0+2$ and conclude that $\psi$ is decreased by a factor of $1-\frac{1}{8N^2}$ after two time units. The lemma follows by assuming a worst-case scenario in which during the time interval $[t_0,t_1]$, the "slow" Case (2) is repeated for $\lfloor\frac{t_1-t_0}{2}\rfloor$ times. ∎

By the two inequalities of Lemma 2.5 we have that $h[t_1]\le\psi[t_1]$ and $\psi[t_0]\le 2h[t_0]$, respectively. Lemma 3.1 now yields the following lemma.

LEMMA 3.2. *In the undisturbed-motion* $\mathcal{ASYNC}$ *model, for every time interval* $[t_0,t_1]$,

$$h[t_1] \;\le\; 2\left(1-\frac{1}{8N^2}\right)^{\left\lfloor\frac{t_1-t_0}{2}\right\rfloor}h[t_0]\;.$$

COROLLARY 3.3. *In any execution of the gravitational algorithm in the undisturbed-motion* $\mathcal{ASYNC}$ *model, over every interval of* $O(N^2)$ *time units, the size of the d-dimensional convex hull of the robot locations and centers of gravity is halved in each dimension separately.*

An example for slow convergence is given by the following lemma.

LEMMA 3.4. *There exist executions of the gravitational algorithm in which* $\Omega(N)$ *time is required to halve the convex hull of* $N$ *robots in each dimension.*

*Proof.* Initially, and throughout the execution, the $N$ robots are organized on the $x$-axis. The execution consists of phases of the following structure. Each phase takes exactly one time unit, from time $t$ to time $t+1$. At each (integral) time $t$, robot 1 is at one endpoint of the bounding segment $H[t]$, while the other $N-1$ robots are at the other endpoint of the segment. Robot 1 performs a Look at time $t$ and determines its perceived center of gravity $\bar{\gamma}_i[t]$ to reside at a distance $\frac{h[t]}{N-1}$ from the distant endpoint. Next, the other $N-1$ robots perform a long sequence of (fast) cycles, bringing them to within a distance $\epsilon$ of robot 1, for arbitrarily small $\epsilon$. Robot 1 then performs its movement to its perceived center of gravity $\bar{\gamma}_i[t]$. Hence the decrease in the size of the bounding interval during the phase is $h[t]-h[t+1]=\frac{h[t]}{N-1}+\epsilon$, or, in other words, at the end of the phase, $h[t+1]\approx(1-\frac{1}{N-1})h[t]$. It follows that $O(N)$ steps are needed to reduce the interval size to half of its original size. ∎

Note that there is still a linear gap between the upper and lower bounds on the convergence rate of the gravitational algorithm as stated in Corollary 3.3 and Lemma 3.4.

It is interesting to compare these bounds with what happens in the fully synchronous ($\mathcal{FSYNC}$) model. Here all robots operate at fixed time cycles, and the Look phase of all robots is simultaneous. In this model, after the first step all robots are at the center of gravity. Therefore, we have the following.

LEMMA 3.5. *In any execution of the gravitational algorithm in the undisturbed-motion $\mathcal{FSYNC}$ model, the robots gather after a single step.*

We now turn to the intermediate semisynchronous ($\mathcal{SSYNC}$) model. In this model there are fixed time cycles, and the Look phase of the robots is simultaneous, but only a subset of the robots may wake up at every cycle. We define, for the sake of time analysis, the notion of a (possibly long) time unit so that at every time unit, every robot is awakened at least once. (Here a "time unit" may compose of many cycles.)

LEMMA 3.6. *In any execution of the gravitational algorithm in the undisturbed-motion $\mathcal{SSYNC}$ model, over every interval of $O(N)$ time units, the size of the $d$-dimensional convex hull of the robot locations and centers of gravity is halved in each dimension separately.*

*Proof.* Again, we appeal to the proof of Lemma 2.7. However, in the semisynchronous model we have the advantage that at the beginning of the Look phase, each of the robots resides at the location of its last calculated center of gravity. This implies that Case (2) of the analysis of Lemma 2.6 is impossible. Thus, it is guaranteed that at every time step $t$, $h[t]$ is decreased by at least $\frac{h[t]}{2N}$. Therefore, we conclude that, over every interval of $O(N)$ time units, the size of the $d$-dimensional convex hull of the robot locations and centers of gravity is halved in each dimension separately. $\square$

**3.2. The full (sudden-stop) model.** We now discuss the full (sudden-stop) model. We give the analogues of the above theorems in this case.

First, we discuss the fully synchronous model $\mathcal{FSYNC}$. In the following, $H[0]$ is the convex hull of the $N$ robots at time 0 and $h[0]$ is the maximum width of $H[0]$ in any of the $d$ dimensions. We have the following lemma.

LEMMA 3.7. *In any execution of the gravitational algorithm in the full (sudden-stop) $\mathcal{FSYNC}$ model, the robots achieve gathering in at most $\lceil 4h[0]d^{3/2}/S \rceil$ time.*

*Proof.* If the distance of each robot from the center of gravity is at most $S$, then at the next step they will all gather. Suppose now that there exists at least one robot whose distance from the center of gravity is greater than $S$. Since the center of gravity is within the convex hull, the largest dimension is at least $h[0] \geq S/\sqrt{d}$. Without loss of generality, assume that the projection of the hull on the maximum width dimension is on the interval $[0, a]$ and that the projection of the center of gravity $\bar{c}[0]$ is in the interval $[\frac{a}{2}, a]$. Then in each step, $t$, every robot moves by a vector $\min\{\bar{r}_i[t] - \bar{c}[t], S' \frac{\bar{r}_i[t]-\bar{c}[t]}{|\bar{r}_i[t]-\bar{c}[t]|}\}$ for some $S' \geq S$. By assumption, $a$ is the width of the largest dimension, and therefore $a \geq |\bar{r}_i[t] - \bar{c}[t]|/\sqrt{d}$. For every robot in the interval $[0, \frac{a}{4}]$, the distance to the current center of gravity will decrease in the next step by at least $\min\{\frac{a}{4}, S\frac{a/4}{a\sqrt{d}}\} \geq \frac{S}{4\sqrt{d}}$. Thus, the width of at least one dimension decreases by at least $\frac{S}{4\sqrt{d}}$ in each step. Therefore, gathering is achieved after at most $\lceil 4h[0]d^{3/2}/S \rceil$ cycles, independently of $N$. $\square$

LEMMA 3.8. *In any execution of the gravitational algorithm in the full (sudden-stop) $\mathcal{SSYNC}$ model, over every interval of $O\left(N\left\lceil \frac{h}{S}\right\rceil\right)$ time units, the size of the $d$-dimensional convex hull of the robot locations and centers of gravity is halved in each dimension separately.*

*Proof.* As in the proof of Lemma 3.6, Case (2) of the analysis of Lemma 2.6 is impossible here. This guarantees that at every time step $t$, $h[t]$ is decreased by at least $\min\{\frac{S}{4N\sqrt{d}}, \frac{h[t]}{2N}\}$. Therefore, over every interval of $O(N\left\lceil \frac{h}{S}\right\rceil)$ time units, the size of the $d$-dimensional convex hull of the robot locations and centers of gravity is halved in each dimension separately. $\square$

Finally, we present the result for the $\mathcal{ASYNC}$ model. The proof is similar to Corollary 3.3, with the additional option of sudden stops, as discussed in the proof of Lemma 2.8. We obtain the following.

THEOREM 3.9. *In any execution of the gravitational algorithm in the full (sudden-stop) $\mathcal{ASYNC}$ model, over every interval of $O\left(N^2 + \frac{Nh}{S}\right)$ time units, the size of the d-dimensional convex hull of the robot locations and centers of gravity is halved in each dimension separately.*

## 4. Fault tolerance.

In this section we consider the behavior of the gravitational algorithm in the presence of possible robot failures.

Let us first observe that the gravitational algorithm achieves *self-stabilization* (cf. [10]) in a model allowing only *transient* failures. Such a failure causes a change in the states of some robots, possibly into illegal states. That is, a measurement, calculation, or movement error may occur, causing the robot to move to a location other than the center of gravity. In essence, self-stabilization is the requirement that if the system *quiets* at some time $t_0$ (namely, no more transient errors occur), then from time $t_0$ on, the algorithm will achieve convergence, despite starting from a potentially illegal state. Notice that Theorem 2.9 makes no assumptions about the initial positions and centers of gravity, other than that they are restricted to some finite region. It follows that, due to the oblivious nature of the robots (and hence the algorithm), the robots will converge regardless of any finite number of transient errors occurring in the early stages of the execution.

We now turn to consider the *crash* fault model. This model, presented in [1], follows the common crash (or "fail-stop") fault model in distributed computing and assumes that a robot may fail by halting. This may happen at any point in time during the robot's cycle, i.e., either during the movement towards the goal point or before it has started. Once a robot has crashed, it will remain stationary indefinitely.

In [1], it is shown that in the presence of a single crash fault, it is possible to *gather* the remaining (functioning) robots to a common point. Here we avoid the gathering requirement and settle for the weaker goal of convergence. We show that the `Go_to_COG` algorithm converges for every number of crashed robots. In fact, in a sense, convergence is easier in this setting since the crashed robots determine the final convergence point for the nonfaulty robots. We have the following.

THEOREM 4.1. *In the full (sudden-stop) $\mathcal{ASYNC}$ model, consider a swarm of $N$ robots that execute Algorithm `Go_to_COG`. If $1 \leq M \leq N-2$ robots crash during the execution, then the remaining $N-M$ robots will converge to the center of gravity of the crashed robots. Moreover, the size of the robots' convex hull is halved every $O\left(N\left\lceil\frac{h}{S}\right\rceil\right)$ time units.*

*Proof.* Let us first consider an execution of the gravitational algorithm by a swarm of $N$ robots in one dimension. Without loss of generality, assume that the crashed robots were $1, \ldots, M$ and their crashing times were $t_1 \leq \cdots \leq t_M$, respectively. Consider the behavior of the algorithm starting from time $t_M$. For the analysis, a setting in which the $M$ robots crashed at general positions $\bar{r}_1, \ldots, \bar{r}_M$ is equivalent to one in which all $M$ crashed robots are concentrated in their center of gravity $\frac{1}{M}\sum_{i=1}^{M}\bar{r}_i$. Assume, without loss of generality, that this center of gravity is at 0.

Now consider some time $t_0 \geq t_M$. Let $H[t_0] = [a, b]$ for some $a \leq 0 \leq b$. By Corollary 2.2, the robots will remain in the segment $[a, b]$ at all times $t \geq t_0$. The center of gravity calculated by any nonfaulty robot $M+1 \leq j \leq N$ at time $t \geq t_0$

will then be

$$\bar{\gamma}_j[t] \;=\; \frac{1}{N}\sum_{i=1}^{N}\bar{r}_i \;=\; \frac{1}{N}\left(M\cdot 0+\sum_{i=M+1}^{N}\bar{r}_i[t]\right).$$

Hence all centers of gravity calculated hereafter will be restricted to the segment $[a', b']$, where $a' = \frac{N-M}{N}\cdot a$ and $b' = \frac{N-M}{N}\cdot b$. Consequently, denoting by $\hat{t}$ the time by which every nonfaulty robot has completed a Look-Compute-Move cycle and no sudden stops occur, we have that $H[\hat{t}] \subseteq [a', b']$, and hence $h[\hat{t}] \le \frac{N-M}{N}\cdot h[t_0]$.

Again, the argument can be extended to any number of dimensions by considering each dimension separately. It follows that the robots converge to the point 0, namely, the center of gravity of the crashed robots.

If sudden stops do occur, then the robots are not guaranteed to reach their destination. However, they are guaranteed to travel a distance of at least $S$. Therefore, using arguments similar to the proof of Lemma 2.8, if sudden stops occur, then the size of the hull in the largest dimension is decreased by at least $\frac{S}{4N\sqrt{d}}$, leading to the theorem. $\square$

**5. Conclusions.** We have considered the properties of the gravitational algorithm for convergence of mobile robot swarms. We have shown that the algorithm guarantees convergence to a point for any number of robots $N$ and in any dimension $d$. We have shown that an appropriate quantity is halved every $O(N^2)$ steps and have shown a case where $O(N)$ steps are needed for halving the invariant. Thus, a gap still exists between our bounds on the convergence rate, which is left as an open question. We have shown analogous (and somewhat stronger) results for the simpler synchronous and semisynchronous models. We have also shown that the algorithm is resilient to crash failures of any number of robots.

**Acknowledgment.** We are grateful to the anonymous reviewers, whose comments helped clarify and improve the presentation of our results.
