*Proof.* For any graph $G \in \mathcal{G}$, let $G'$ be the graph obtained from $G$ by adding $t$ ears to every edge of $G$. By assumption, $G'$ has an improper $t$-track layout. Suppose that there is an edge $vw$ of $G$ such that $v$ and $w$ are in the same track. None of the ears added to $vw$ are on the same track, as otherwise adjacent vertices would not be consecutive in that track. Thus there is a track containing at least two of the ears added to $vw$. However, this implies that there is an X-crossing, which is a contradiction. Thus the end-vertices of every edge of $G$ are in distinct tracks. Hence the improper $t$-track layout of $G'$ contains a $t$-track layout of $G$. $\square$

Lemmas 2.2 and 2.3 imply that only for relatively small classes of graphs will the distinction between track layouts and improper track layouts be significant. We therefore chose to work with the less cumbersome notion of a track layout. The following theorem summarizes our bounds on the track-number of a graph.

THEOREM 2.4. *Let $G$ be a graph with maximum degree $\Delta(G)$, path-width $\mathsf{pw}(G)$, tree-partition-width $\mathsf{tpw}(G)$, and tree-width $\mathsf{tw}(G)$. The track-number of $G$ satisfies*

(a) $\mathsf{tn}(G) \leq \mathsf{pw}(G) + 1 \leq 1 + (\mathsf{tw}(G) + 1)\log n$,

(b) $\mathsf{tn}(G) \leq 3\,\mathsf{tpw}(G) \leq 72\,\mathsf{tw}(G)\,\Delta(G)$ (*assuming* $\Delta(G) \geq 1$),

(c) $\mathsf{tn}(G) \leq 3^{\mathsf{tw}(G)} \cdot 6^{(4^{\mathsf{tw}(G)} - 3\,\mathsf{tw}(G) - 1)/9}$.

*Proof.* Part (a) follows from Lemma 3.2 and the fact that $\mathsf{pw}(G) \leq (\mathsf{tw}(G) + 1)\log n$ (see [10]). Note that $\mathsf{tn}(G) \leq 1 + (\mathsf{tw}(G)+1)\log n$ can be proved directly using a separator-based approach similar to that used to prove $\mathsf{pw}(G) \leq (\mathsf{tw}(G) + 1)\log n$. Part (b) follows from Lemma 3.3 in section 3 and the result of Ding and Oporowski [30] discussed in section 2.2. Part (c) is Theorem 7.3. $\square$

## 2.4. Vertex-orderings.

Let $G$ be a graph. A total order $\sigma = (v_1, v_2, \ldots, v_n)$ of $V(G)$ is called a *vertex-ordering* of $G$. Suppose that $G$ is connected. The *depth* of a vertex $v_i$ in $\sigma$ is the graph-theoretic distance between $v_1$ and $v_i$ in $G$. We say that

[3]In [33, 35, 91] we called a track layout an *ordered layering with no X-crossing and no intralayer edges*, and an improper track layout was called an *ordered layering with no X-crossing.*

$\sigma$ is a *breadth-first* vertex-ordering if for all vertices $v$ and $w$ with $v <_\sigma w$ the depth of $v$ in $\sigma$ is no more than the depth of $w$ in $\sigma$. Vertex-orderings, and in particular, vertex-orderings of trees, will be used extensively in this paper. Consider a breadth-first vertex-ordering $\sigma$ of a tree $T$ such that vertices at depth $d \geq 1$ are ordered with respect to the ordering of vertices at depth $d-1$. In particular, if $v$ and $x$ are vertices at depth $d$ with respective parents $w$ and $y$ at depth $d-1$ with $w <_\sigma y$, then $v <_\sigma x$. Such a vertex-ordering is called a *lexicographical* breadth-first vertex-ordering of $T$, and is illustrated in Figure 2.2.

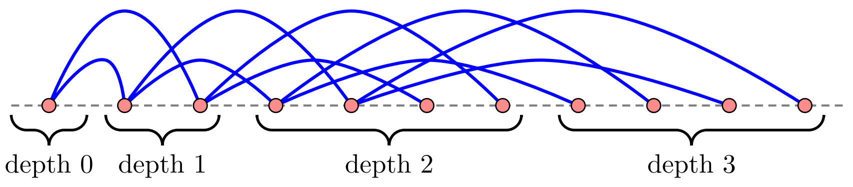

FIG. 2.2. *A lexicographical breadth-first vertex-ordering of a tree.*

**2.5. Queue layouts.** A *queue layout* of a graph $G$ consists of a vertex-ordering $\sigma$ of $G$ and a partition of $E(G)$ into *queues* such that no two edges in the same queue are *nested* with respect to $\sigma$. That is, there are no edges $vw$ and $xy$ in a single queue with $v <_\sigma x <_\sigma y <_\sigma w$. The minimum number of queues in a queue layout of $G$ is called the *queue-number* of $G$ and is denoted by $\mathsf{qn}(G)$. A similar concept is that of a *stack layout* (or *book embedding*), which consists of a vertex-ordering $\sigma$ of $G$ and a partition of $E(G)$ into *stacks* (or *pages*) such that there are no edges $vw$ and $xy$ in a single stack with $v <_\sigma x <_\sigma w <_\sigma y$. The minimum number of stacks in a stack layout of $G$ is called the *stack-number* (or *page-number* or *book-thickness*) of $G$ and is denoted by $\mathsf{sn}(G)$. A queue (respectively, stack) layout with $k$ queues (stacks) is called a *$k$-queue* (*$k$-stack*) *layout*, and a graph that admits a $k$-queue ($k$-stack) layout is called a *$k$-queue* (*$k$-stack*) *graph*.

Heath and Rosenberg [58] characterized 1-queue graphs as the "arched levelled planar" graphs, and proved that it is $\mathcal{NP}$-complete to recognize such graphs. This result is in contrast to the situation for stack layouts—1-stack graphs are precisely the outerplanar graphs [8], which can be recognized in polynomial time. Heath, Leighton, and Rosenberg [54] proved that 1-stack graphs are 2-queue graphs (rediscovered by Rengarajan and Veni Madhavan [78]), and that 1-queue graphs are 2-stack graphs.

While it is $\mathcal{NP}$-hard to minimize the number of stacks in a stack layout given a fixed vertex-ordering [46], the analogous problem for queue layouts can be solved as follows. A *$k$-rainbow* in a vertex-ordering $\sigma$ consists of a matching $\{v_i w_i : 1 \leq i \leq k\}$ such that $v_1 <_\sigma v_2 <_\sigma \cdots <_\sigma v_k <_\sigma w_k <_\sigma w_{k-1} <_\sigma \cdots <_\sigma w_1$, as illustrated in Figure 2.3.

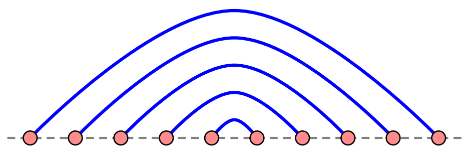

FIG. 2.3. *A rainbow of five edges in a vertex-ordering.*

A vertex-ordering containing a $k$-rainbow needs at least $k$ queues. A straightforward application of Dilworth's Theorem [29] proves the converse. That is, a fixed vertex-ordering admits a $k$-queue layout, where $k$ is the size of the largest rainbow. (Heath and Rosenberg [58] describe a $\mathcal{O}(m \log\log n)$ time algorithm to compute the queue assignment.) Thus determining $\mathsf{qn}(G)$ can be viewed as the following vertex-ordering problem.

LEMMA 2.5 (see [58]). *The queue-number* $\mathsf{qn}(G)$ *of a graph* $G$ *is the minimum, taken over all vertex-orderings* $\sigma$ *of* $G$*, of the maximum size of a rainbow in* $\sigma$. □

Stack and/or queue layouts of $k$-trees have previously been investigated in [19, 78, 45]. A 1-tree is a 1-queue graph, since in a lexicographical breadth-first vertex-ordering of a tree no two edges are nested (see Figure 2.2). Chung, Leighton, and Rosenberg [19] proved that in a depth-first vertex-ordering of a tree no two edges cross. Thus 1-trees are 1-stack graphs. Rengarajan and Veni Madhavan [78] proved that graphs with tree-width at most two (the series parallel graphs) are 2-stack and 3-queue graphs.[4] Improper track layouts are implicit in the work of Heath, Leighton, and Rosenberg [54] and Rengarajan and Veni Madhavan [78]. In section 5 we prove the following fundamental relationship between queue and track layouts.

THEOREM 2.6. *For every graph* $G$*,* $\mathsf{qn}(G) \leq \mathsf{tn}(G) - 1$*. Moreover, if* $\mathcal{G}$ *is any proper minor-closed graph family, then* $\mathcal{G}$ *has queue-number* $\mathsf{qn}(\mathcal{G}) \in \mathcal{F}(n)$ *if and only if* $\mathcal{G}$ *has track-number* $\mathsf{tn}(\mathcal{G}) \in \mathcal{F}(n)$*, where* $\mathcal{F}(n)$ *is any family of functions closed under multiplication* (*such as* $\mathcal{O}(1)$ *or* $\mathcal{O}(\operatorname{polylog} n)$).

Ganley and Heath [45] proved that every graph $G$ has stack-number $\mathsf{sn}(G) \leq \mathsf{tw}(G) + 1$ (using a depth-first traversal of a tree-decomposition), and asked whether queue-number is bounded by tree-width. One of the principal results of this paper is to solve this question in the affirmative. Applying Theorems 2.4 and 2.6, we have the following.

THEOREM 2.7. *Let* $G$ *be a graph with maximum degree* $\Delta(G)$*, path-width* $\mathsf{pw}(G)$*, tree-partition-width* $\mathsf{tpw}(G)$*, and tree-width* $\mathsf{tw}(G)$*. The queue-number* $\mathsf{qn}(G)$ *satisfies*[5]

(a) $\mathsf{qn}(G) \leq \mathsf{pw}(G) \leq (\mathsf{tw}(G)+1)\log n$,

(b) $\mathsf{qn}(G) \leq 3\,\mathsf{tpw}(G) - 1 \leq 72\,\mathsf{tw}(G)\,\Delta(G) - 1$ (*assuming* $\Delta(G) \geq 1$),

(c) $\mathsf{qn}(G) \leq 3^{\mathsf{tw}(G)} \cdot 6^{(4^{\mathsf{tw}(G)} - 3\,\mathsf{tw}(G) - 1)/9} - 1$. □

A similar upper bound to Theorem 2.7(a) was obtained by Heath and Rosenberg [58], who proved that every graph $G$ has $\mathsf{qn}(G) \leq \lceil \frac{1}{2}\mathsf{bw}(G) \rceil$, where $\mathsf{bw}(G)$ is the band-width of $G$. In many cases this result is weaker than Theorem 2.7(a) since $\mathsf{pw}(G) \leq \mathsf{bw}(G)$ (see [28]). More importantly, we have the following corollary of Theorem 2.7(c).

COROLLARY 2.8. *Queue-number is bounded by tree-width, and hence graphs with bounded tree-width have bounded queue-number.* □

**2.6. Three-dimensional drawings.** A *three-dimensional straight-line grid drawing* of a graph, henceforth called a *three-dimensional drawing*, represents the vertices by distinct points in $\mathbb{Z}^3$ (called *grid-points*) and represents each edge as a line-segment between its end-vertices, such that edges intersect only at common end-vertices, and an edge only intersects a vertex that is an end-vertex of that edge.

In contrast to the case in the plane, a folklore result states that every graph has a three-dimensional drawing. Such a drawing can be constructed using the "moment

[4]In [35] we give a simple proof based on Theorem 6.1 for the result by Rengarajan and Veni Madhavan [78] that every series-parallel graph has a 3-queue layout.

[5]In [91] we obtained an alternative proof that $\mathsf{qn}(G) \leq \mathsf{pw}(G)$ using the "vertex separation number" of a graph (which equals its path-width); applying Lemma 2.5 directly, we proved that $\mathsf{qn}(G) \leq \frac{3}{2}\,\mathsf{tpw}(G)$, and thus $\mathsf{qn}(G) \leq 36\,\Delta(G)\,\mathsf{tw}(G)$.

curve" algorithm in which vertex $v_i$, $1 \leq i \leq n$, is represented by the grid-point $(i, i^2, i^3)$. It is easily seen—compare with Lemma 4.2—that no two edges cross. (Two edges *cross* if they intersect at some point other than a common end-vertex.)

Since every graph has a three-dimensional drawing, we are interested in optimizing certain measures of the aesthetic quality of a drawing. If a three-dimensional drawing is contained in an axis-aligned box with side lengths $X-1$, $Y-1$, and $Z-1$, then we speak of an $X \times Y \times Z$ drawing with *volume* $X \cdot Y \cdot Z$ and *aspect ratio* $\max\{X,Y,Z\}/\min\{X,Y,Z\}$. This paper considers the problem of producing a three-dimensional drawing of a given graph with small volume, and with small aspect ratio as a secondary criterion.

Observe that the drawings produced by the moment curve algorithm have $\mathcal{O}(n^6)$ volume. Cohen et al. [20] improved this bound by proving that if $p$ is a prime with $n < p \leq 2n$, and each vertex $v_i$ is represented by the grid-point $(i, i^2 \bmod p, i^3 \bmod p)$, then there is still no crossing. This construction is a generalization of an analogous two-dimensional technique due to Erdős [40]. Furthermore, Cohen et al. [20] proved that the resulting $\mathcal{O}(n^3)$ volume bound is asymptotically optimal in the case of the complete graph $K_n$. It is therefore of interest to identify fixed graph parameters that allow for three-dimensional drawings with small volume.

The first such parameter to be studied was the chromatic number [16, 73]. Calamoneri and Sterbini [16] proved that every 4-colorable graph has a three-dimensional drawing with $\mathcal{O}(n^2)$ volume. Generalizing this result, Pach, Thiele, and Tóth [73] proved that graphs of bounded chromatic number have three-dimensional drawings with $\mathcal{O}(n^2)$ volume, and that this bound is asymptotically optimal for the complete bipartite graph with equal sized bipartitions. If $p$ is a suitably chosen prime, the main step of this algorithm represents the vertices in the $i$th color class by grid-points in the set $\{(i, t, it) : t \equiv i^2 \pmod{p}\}$. It follows that the volume bound is $\mathcal{O}(k^2 n^2)$ for $k$-colorable graphs.

The lower bound of Pach, Thiele, and Tóth [73] for the complete bipartite graph was generalized by Bose et al. [14] for all graphs. They proved that every three-dimensional drawing with $n$ vertices and $m$ edges has volume at least $\frac{1}{8}(n+m)$. In particular, the maximum number of edges in an $X \times Y \times Z$ drawing is exactly $(2X-1)(2Y-1)(2Z-1) - XYZ$. For example, graphs admitting three-dimensional drawings with $\mathcal{O}(n)$ volume have $\mathcal{O}(n)$ edges.

The first nontrivial $\mathcal{O}(n)$ volume bound was established by Felsner, Liotta, and Wismath [42] for outerplanar graphs. Their elegant algorithm "wraps" a two-dimensional drawing around a triangular prism to obtain an improper 3-track layout (see Lemmas 3.1 and 3.4 for more on this method). Poranen [76] proved that series-parallel digraphs have upward three-dimensional drawings with $\mathcal{O}(n^3)$ volume, and that this bound can be improved to $\mathcal{O}(n^2)$ and $\mathcal{O}(n)$ in certain special cases. Di Giacomo, Liotta, and Wismath [26] proved that series-parallel graphs with maximum degree three have three-dimensional drawings with $\mathcal{O}(n)$ volume.

In section 4 we prove the following intrinsic relationship between three-dimensional drawings and track layouts.

THEOREM 2.9. *Every graph $G$ has a $\mathcal{O}(\mathsf{tn}(G)) \times \mathcal{O}(\mathsf{tn}(G)) \times \mathcal{O}(n)$ drawing. Moreover, $G$ has an $\mathcal{F}(n) \times \mathcal{F}(n) \times \mathcal{O}(n)$ drawing if and only if $G$ has track-number $\mathsf{tn}(G) \in \mathcal{F}(n)$, where $\mathcal{F}(n)$ is a family of functions closed under multiplication.*

Of course, every graph has an $n$-track layout—simply place a single vertex on each track. Thus Theorem 2.9 matches the $\mathcal{O}(n^3)$ volume bound discussed in section 2.6. In fact, the drawings of $K_n$ produced by our algorithm, with each vertex in a distinct track, are identical to those produced by the algorithm of Cohen et al. [20].

Theorems 2.6 and 2.9 immediately imply the following result, which reduces the problem of producing a three-dimensional drawing with small volume to that of producing a queue layout of the same graph with few queues.

THEOREM 2.10. *Let $\mathcal{G}$ be a proper minor-closed family of graphs, and let $\mathcal{F}(n)$ be a family of functions closed under multiplication. The following are equivalent:*

(a) *every $n$-vertex graph in $\mathcal{G}$ has an $\mathcal{F}(n) \times \mathcal{F}(n) \times \mathcal{O}(n)$ drawing,*

(b) *$\mathcal{G}$ has track-number $\mathsf{tn}(\mathcal{G}) \in \mathcal{F}(n)$, and*

(c) *$\mathcal{G}$ has queue-number $\mathsf{qn}(\mathcal{G}) \in \mathcal{F}(n)$.* □

Graphs with constant queue-number include de Bruijn graphs, FFT, and Beneš network graphs [58]. By Theorem 2.10, these graphs have three-dimensional drawings with $\mathcal{O}(n)$ volume. Applying Theorems 2.4 and 2.9, we have the following result.

THEOREM 2.11. *Let $G$ be a graph with maximum degree $\Delta(G)$, path-width $\mathsf{pw}(G)$, tree-partition-width $\mathsf{tpw}(G)$, and tree-width $\mathsf{tw}(G)$. Then $G$ has a three-dimensional drawing with the following dimensions:*

(a) $\mathcal{O}(\mathsf{pw}(G)) \times \mathcal{O}(\mathsf{pw}(G)) \times \mathcal{O}(n)$*, which is* $\mathcal{O}(\mathsf{tw}(G) \log n) \times \mathcal{O}(\mathsf{tw}(G) \log n) \times \mathcal{O}(n)$*,*

(b) $\mathcal{O}(\mathsf{tpw}(G)) \times \mathcal{O}(\mathsf{tpw}(G)) \times \mathcal{O}(n)$*, which is* $\mathcal{O}(\Delta(G)\,\mathsf{tw}(G)) \times \mathcal{O}(\Delta(G)\,\mathsf{tw}(G)) \times \mathcal{O}(n)$*,*

(c) $\mathcal{O}(3^{\mathsf{tw}(G)} \cdot 6^{(4^{\mathsf{tw}(G)} - 3\,\mathsf{tw}(G) - 1)/9}) \times \mathcal{O}(3^{\mathsf{tw}(G)} \cdot 6^{(4^{\mathsf{tw}(G)} - 3\,\mathsf{tw}(G) - 1)/9}) \times \mathcal{O}(n)$. □

Most importantly, we have the following corollary of Theorem 2.11(c).

COROLLARY 2.12. *Every graph with bounded tree-width has a three-dimensional drawing with $\mathcal{O}(n)$ volume.* □

Note that bounded tree-width is not necessary for a graph to have a three-dimensional drawing with $\mathcal{O}(n)$ volume. The $\sqrt{n} \times \sqrt{n}$ plane grid graph has $\Theta(\sqrt{n})$ tree-width, and has a $\sqrt{n} \times \sqrt{n} \times 1$ drawing with $n$ volume. It also has a 3-track layout, and thus, by Lemma 4.2, has a $\mathcal{O}(1) \times \mathcal{O}(1) \times \mathcal{O}(n)$ drawing.

Since a planar graph is 4-colorable, by the results of Calamoneri and Sterbini [16] and Pach, Thiele, and Tóth [73] discussed above, every planar graph has a three-dimensional drawing with $\mathcal{O}(n^2)$ volume. This result also follows from the classical algorithms of de Fraysseix, Pach, and Pollack [22] and Schnyder [82] for producing $\mathcal{O}(n) \times \mathcal{O}(n)$ plane grid drawings. All of these methods produce $\mathcal{O}(n) \times \mathcal{O}(n) \times \mathcal{O}(1)$ drawings, which have $\Theta(n)$ aspect ratio. Since every planar graph $G$ has $\mathsf{pw}(G) \in \mathcal{O}(\sqrt{n})$ [10], we have the following corollary of Theorem 2.11(a).

COROLLARY 2.13. *Every planar graph has a three-dimensional drawing with $\mathcal{O}(n^2)$ volume and $\Theta(\sqrt{n})$ aspect ratio.* □

This result matches the above $\mathcal{O}(n^2)$ volume bounds with an improvement in the aspect ratio by a factor of $\Theta(\sqrt{n})$. Our final result regarding three-dimensional drawings, which is proved in section 4, examines the apparent trade-off between aspect ratio and volume.

THEOREM 2.14. *For every graph $G$ and for every $r$, $1 \leq r \leq n/\mathsf{tn}(G)$, $G$ has a three-dimensional drawing with $\mathcal{O}(n^3/r^2)$ volume and aspect ratio $2r$.*

## 3. Track layouts.

In this section we describe a number of methods for producing and manipulating track layouts. The following result is implicit in the proof by Felsner, Liotta, and Wismath [42] that every outerplanar graph has an improper 3-track layout.

LEMMA 3.1 (see [42]). *Every tree $T$ has a 3-track layout.*

*Proof.* Root $T$ at an arbitrary node $r$. Let $\sigma$ be a lexicographical breadth-first vertex-ordering of $T$ starting at $r$, as described in section 2.4. For $i \in \{0, 1, 2\}$, let $V_i$ be the set of nodes of $T$ with depth $d \equiv i \pmod 3$ in $\sigma$. With each $V_i$ ordered by $\sigma$, we have a 3-track assignment of $T$. Clearly adjacent vertices are on distinct tracks. Since no two edges are nested in $\sigma$, there is no X-crossing (see Figure 3.1). $\square$

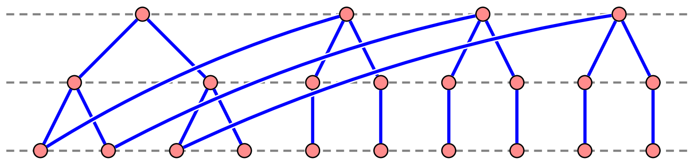

FIG. 3.1. *A* 3*-track layout of a tree.*

LEMMA 3.2. *Every graph $G$ with path-width* $\mathsf{pw}(G)$ *has track-number* $\mathsf{tn}(G) \leq \mathsf{pw}(G) + 1$.

*Proof.* Let $k = \mathsf{pw}(G)+1$. It is well known that $G$ is the subgraph of a $k$-colorable interval graph [10, 48]. That is, there is a set of intervals $\{[\ell(v), r(v)] \subseteq \mathbb{R} : v \in V(G)\}$ such that $[\ell(v), r(v)] \cap [\ell(w), r(w)] \neq \emptyset$ for every edge $vw$ of $G$. Let $\{V_i : 1 \leq i \leq k\}$ be a $k$-coloring of $G$. Consider each color class $V_i$ to be an ordered track $(v_1, v_2, \dots, v_p)$, where $\ell(v_1) < r(v_1) < \ell(v_2) < r(v_2) < \cdots < \ell(v_p) < r(v_p)$, as illustrated in Figure 3.2. Suppose there is an X-crossing between edges $vw$ and $xy$ with $v, x \in V_i$ and $w, y \in V_j$ for some pair of tracks $V_i$ and $V_j$. Without loss of generality, $r(v) < \ell(x)$ and $r(y) < \ell(w)$. Since $vw$ is an edge, $\ell(w) \leq r(v)$. Thus $r(y) < \ell(w) \leq r(v) < \ell(x)$, which implies that $xy$ is not an edge of $G$. This contradiction proves that there is no X-crossing, and $G$ has a $k$-track layout. $\square$

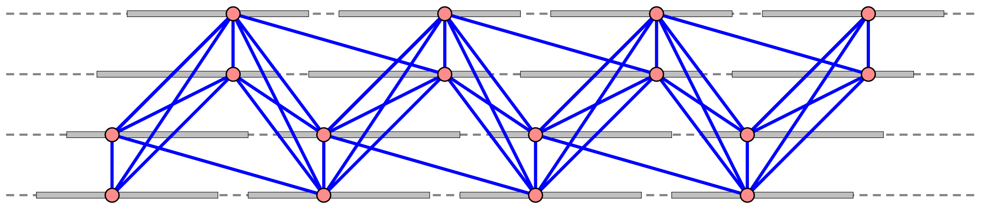

FIG. 3.2. *A* 4*-track layout of a* 4*-colorable interval graph.*

The next lemma uses a tree-partition to construct a track layout.

LEMMA 3.3. *Every graph $G$ with maximum degree $\Delta(G) \geq 1$, tree-width* $\mathsf{tw}(G)$*, and tree-partition-width* $\mathsf{tpw}(G)$*, has track-number* $\mathsf{tn}(G) \leq 3\,\mathsf{tpw}(G) \leq 72\,\Delta(G)\mathsf{tw}(G)$.

*Proof.* Let $(T, \{T_x : x \in V(T)\})$ be a tree-partition of $G$ with width $\mathsf{tpw}(G)$. By Lemma 3.1, $T$ has a 3-track layout. Replace each track by $\mathsf{tpw}(G)$ "subtracks," and for each node $x$ in $T$ place the vertices in bag $T_x$ on the subtracks replacing the track containing $x$, with at most one vertex in $T_x$ in a single track. For all nodes $x$ and $y$ of $T$, if $x < y$ in a single track of the 3-track layout of $T$, then for all vertices $v \in T_x$ and $w \in T_y$, $v < w$ whenever $v$ and $w$ are assigned to the same track. There is no X-crossing, since in the track layout of $T$, adjacent nodes are on distinct tracks and there is no X-crossing. Thus we have a track layout of $G$. The number of tracks is $3\,\mathsf{tpw}(G)$, which is at most $72\,\Delta(G)\mathsf{tw}(G)$ by the theorem of Ding and Oporowski [30] discussed in section 2.2. $\square$

In the remainder of this section, we prove two results that show how track layouts can be manipulated without introducing an X-crossing. The first is a generalization of the "wrapping" algorithm of Felsner, Liotta, and Wismath [42], who implicitly proved the case $s = 1$.

LEMMA 3.4. *If a graph $G$ has an (improper) track layout $\{(V_i, <_i) : 1 \leq i \leq t\}$ with maximum edge span $s$, then $G$ has an (improper) $(2s+1)$-track layout.*

*Proof.* Let $\ell = 2s + 1$. Construct an $\ell$-track assignment of $G$ by merging the tracks $\{V_i : i \equiv j \pmod{t}\}$ for each $j$, $0 \leq j \leq t-1$, with vertices in $V_\alpha$ appearing before vertices in $V_\beta$ in the new track $j$ for all $\alpha, \beta \equiv j \pmod{t}$ with $\alpha < \beta$. The given order of each $V_i$ is preserved in the new tracks. It remains to prove that there is no X-crossing. Consider two edges $vw$ and $xy$. Let $i_1$ and $i_2$, $1 \leq i_1 < i_2 \leq t$, be the minimum and maximum tracks containing $v$, $w$, $x$, or $y$ in the given $t$-track layout of $G$.

First consider the case that $i_2 - i_1 > 2s$. Then without loss of generality $v$ is in track $i_2$ and $y$ is in track $i_1$. Thus $w$ is in a greater track than $x$, and even if $x$ (or $y$) appear on the same track as $v$ (or $w$) in the new $\ell$-track assignment, $x$ (or $y$) will be to the left of $v$ (or $w$). Thus these edges do not form an X-crossing in the $\ell$-track assignment. Otherwise $i_2 - i_1 \leq 2s$. Thus any two of $v$, $w$, $x$, or $y$ will appear on the same track in the $\ell$-track assignment if and only if they are on the same track in the given $t$-track layout (since $\ell > 2s$). Hence the only way for these four vertices to appear on exactly two tracks in the $\ell$-track assignment is if they were on exactly two layers in the given $t$-track layout, in which case, by assumption, $vw$ and $xy$ do not form an X-crossing. Therefore there is no X-crossing, and we have an $\ell$-track layout of $G$. ∎

The next result shows that the number of vertices in different tracks of a track layout can be balanced without introducing an X-crossing. The proof is based on an idea due to Pach, Thiele, and Tóth [73] for balancing the size of the color classes in a coloring.

LEMMA 3.5. *If a graph $G$ has an (improper) $t$-track layout, then for every $t' > 0$, $G$ has an (improper) $\lfloor t + t' \rfloor$-track layout with at most $\lceil \frac{n}{t'} \rceil$ vertices in each track.*

*Proof.* For each track with $q > \lceil \frac{n}{t'} \rceil$ vertices, replace it by $\lceil q / \lceil \frac{n}{t'} \rceil \rceil$ "subtracks" each with exactly $\lceil \frac{n}{t'} \rceil$ vertices except for at most one subtrack with $q \bmod \lceil \frac{n}{t'} \rceil$ vertices, such that the vertices in each subtrack are consecutive in the original track and the original order is maintained. There is no X-crossing between subtracks from the same original track as there is at most one edge between such subtracks. There is no X-crossing between subtracks from different original tracks as otherwise there would be an X-crossing in the original. There are at most $\lfloor t' \rfloor$ tracks with $\lceil \frac{n}{t'} \rceil$ vertices. Since there are at most $t$ tracks with less than $\lceil \frac{n}{t'} \rceil$ vertices, one for each of the original tracks, there is a total of at most $\lfloor t + t' \rfloor$ tracks. ∎

## 4. Three-dimensional drawings and track layouts.

In this section we prove Theorem 2.9, which states that three-dimensional drawings with small volume are closely related to track layouts with few tracks.

LEMMA 4.1. *If a graph $G$ has an $A \times B \times C$ drawing, then $G$ has an improper $AB$-track layout, and $G$ has a $2AB$-track layout.*

*Proof.* Let $V_{x,y}$ be the set of vertices of $G$ with an $X$-coordinate of $x$ and a $Y$-coordinate of $y$, where without loss of generality $1 \leq x \leq A$ and $1 \leq y \leq Y$. With each set $V_{x,y}$ ordered by the $Z$-coordinates of its elements, $\{V_{x,y} : 1 \leq x \leq A, 1 \leq y \leq Y\}$ is an improper $AB$-track assignment. There is no X-crossing, as otherwise there would be a crossing in the original drawing, and hence we have an improper $AB$-track layout. By Lemma 2.2, $G$ has a $2AB$-track layout. ∎

We now prove the converse of Lemma 4.1. The proof is inspired by the generalizations of the moment curve algorithm by Cohen et al. [20] and Pach, Thiele, and Tóth [73], described in section 2.6. Loosely speaking, Cohen et al. [20] allow three "free" dimensions, whereas Pach, Thiele, and Tóth [73] use the assignment of vertices to color classes to "fix" one dimension with two dimensions free. We use an assignment of vertices to tracks to fix two dimensions with one dimension free. The style of three-dimensional drawing produced by our algorithm, where tracks are drawn vertically, is illustrated in Figure 4.1.

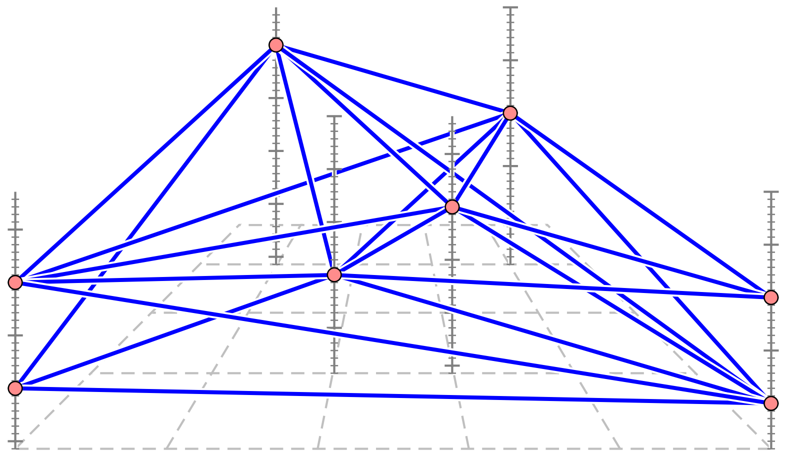

FIG. 4.1. *A three-dimensional drawing produced from a track layout.*

LEMMA 4.2. *If a graph $G$ has a (possibly) improper $k$-track layout, then $G$ has a $k \times 2k \times 2k \cdot n'$ three-dimensional drawing, where $n'$ is the maximum number of vertices in a track.*

*Proof.* Suppose that $\{(V_i, <_i) : 1 \leq i \leq k\}$ is the given improper $k$-track layout. Let $p$ be the smallest prime such that $p > k$. Then $p \leq 2k$ by Bertrand's postulate. For each $i$, $1 \leq i \leq k$, represent the vertices in $V_i$ by the grid-points

$$\{(i, i^2 \bmod p, t) : 1 \leq t \leq p \cdot |V_i|, t \equiv i^3 \pmod p\}$$

such that the $Z$-coordinates respect the given total order $<_i$. Draw each edge as a line-segment between its end-vertices. Suppose that two edges $e$ and $e'$ cross such that their end-vertices are at distinct points $(i_\alpha, i_\alpha^2 \bmod p, t_\alpha)$, $1 \leq \alpha \leq 4$. Then these points are coplanar, and if $M$ is the matrix

$$M = \begin{pmatrix} 1 & i_1 & i_1^2 \bmod p & t_1 \\ 1 & i_2 & i_2^2 \bmod p & t_2 \\ 1 & i_3 & i_3^2 \bmod p & t_3 \\ 1 & i_4 & i_4^2 \bmod p & t_4 \end{pmatrix},$$

then the determinant $\det(M) = 0$. We proceed by considering the number of distinct tracks $N = |\{i_1, i_2, i_3, i_4\}|$.

• $N = 1$: By the definition of an improper track layout, $e$ and $e'$ do not cross.

• $N = 2$: If either edge is intratrack, then $e$ and $e'$ do not cross. Otherwise neither edge is intratrack, and since there is no X-crossing, $e$ and $e'$ do not cross.

• $N = 3$: Without loss of generality $i_1 = i_2$. It follows that $\det(M) = (t_2 - t_1) \cdot \det(M')$, where

$$M' = \begin{pmatrix} 1 & i_2 & i_2^2 \bmod p \\ 1 & i_3 & i_3^2 \bmod p \\ 1 & i_4 & i_4^2 \bmod p \end{pmatrix}.$$

Since $t_1 \neq t_2$, $\det(M') = 0$. However, $M'$ is a Vandermonde matrix modulo $p$, and thus

$$\det(M') \equiv (i_2 - i_3)(i_2 - i_4)(i_3 - i_4) \pmod{p},$$

which is nonzero since $i_2$, $i_3$, and $i_4$ are distinct and $p$ is a prime, a contradiction.

• $N = 4$: Let $M'$ be the matrix obtained from $M$ by taking each entry modulo $p$. Then $\det(M') = 0$. Since $t_\alpha \equiv i_\alpha^3 \pmod{p}$, $1 \leq \alpha \leq 4$,

$$M' \equiv \begin{pmatrix} 1 & i_1 & i_1^2 & i_1^3 \\ 1 & i_2 & i_2^2 & i_2^3 \\ 1 & i_3 & i_3^2 & i_3^3 \\ 1 & i_4 & i_4^2 & i_4^3 \end{pmatrix} \pmod{p}.$$

Since each $i_\alpha < p$, $M'$ is a Vandermonde matrix modulo $p$, and thus

$$\det(M') \equiv (i_1 - i_2)(i_1 - i_3)(i_1 - i_4)(i_2 - i_3)(i_2 - i_4)(i_3 - i_4) \pmod{p},$$

which is nonzero since $i_\alpha \neq i_\beta$ and $p$ is a prime. This contradiction proves there are no edge crossings. The produced drawing is at most $k \times 2k \times 2k \cdot n'$. $\square$

*Proof of Theorem* 2.9. Let $\mathcal{F}(n)$ be a family of functions closed under multiplication. Let $G$ be an $n$-vertex graph with a $t$-track layout, where $t \in \mathcal{F}(n)$. By Lemma 3.5 with $t' = t$, $G$ has a $2t$-track layout with at most $\lceil \frac{n}{t} \rceil$ vertices in each track. By Lemma 4.2, $G$ has a $2t \times 4t \times 4t \cdot \lceil \frac{n}{t} \rceil$ drawing, which is $\mathcal{O}(t) \times \mathcal{O}(t) \times \mathcal{O}(n)$. Conversely, suppose that an $n$-vertex graph $G$ has an $A \times B \times \mathcal{O}(n)$ drawing, where $A, B \in \mathcal{F}(n)$. By Lemma 4.1, $G$ has a track layout with $2AB \in \mathcal{F}(n)$ tracks. $\square$

*Proof of Theorem* 2.14. Let $t = \mathsf{tn}(G)$, and suppose $1 \leq r \leq n/t$. By Lemma 3.5 with $t' = \frac{n}{r}$, $G$ has a $\lfloor \frac{n}{r} + t \rfloor$-track layout with at most $r$ vertices in each track. By assumption $t \leq \frac{n}{r}$, and the number of tracks is at most $\frac{2n}{r}$. By Lemma 4.2, $G$ has a $\frac{2n}{r} \times \frac{4n}{r} \times 4n$ three-dimensional drawing, which has volume $32n^3/r^2$ and aspect ratio $2r$. $\square$

## 5. Queue layouts and track layouts.

In this section we prove Theorem 2.6, which states that track and queue layouts are closely related. Our first lemma highlights this fact—its proof follows immediately from the definitions (see Figure 5.1).

LEMMA 5.1. *A bipartite graph $G = (A, B; E)$ has a 2-track layout with tracks $A$ and $B$ if and only if $G$ has a 1-queue layout such that in the corresponding vertex-ordering, the vertices in $A$ appear before the vertices in $B$.* $\square$

We now show that a queue layout can be obtained from a track layout. This result can be viewed as a generalization of the construction of a 2-queue layout of an outerplanar graph by Heath, Leighton, and Rosenberg [54] and Rengarajan and Veni Madhavan [78] (with $s = 1$).

LEMMA 5.2. *If a graph $G$ has a (possibly) improper $t$-track layout $\{(V_i, <_i) : 1 \leq i \leq t\}$ with maximum edge span $s$ $(\leq t-1)$, then $\mathsf{qn}(G) \leq s+1$, and if the given track layout is not improper, then $\mathsf{qn}(G) \leq s$.*

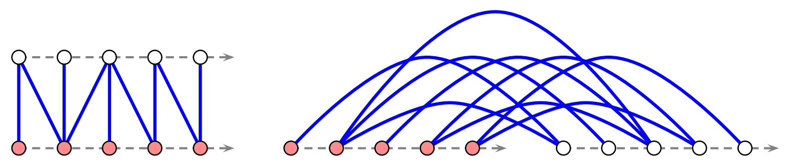

FIG. 5.1. *A 2-track layout and a 1-queue layout of a bipartite graph.*

*Proof.* First suppose that there are no intratrack edges. Let $\sigma$ be the vertex ordering $(V_1, V_2, \dots, V_t)$ of $G$. Let $E_\alpha$ be the set of edges with span $\alpha$ in the given track layout. As in Lemma 5.1, two edges from the same pair of tracks are nested in $\sigma$ if and only if they form an X-crossing in the track layout. Since no two edges form an X-crossing in the track layout, no two edges that are between the same pair of tracks are nested in $\sigma$. If two edges not from the same pair of tracks have the same span, then they are not nested in $\sigma$. (This idea is due to Heath and Rosenberg [58].) Thus no two edges are nested in each $E_\alpha$, and we have an $s$-queue layout of $G$. If there are intra-track edges, then they all form one additional queue in $\sigma$. $\square$

We now set out to prove the converse of Lemma 5.2. It is well known that the subgraph induced by any two tracks of a track layout is a forest of caterpillars [52]. A coloring of a graph is *acyclic* if every bichromatic subgraph is a forest; that is, every cycle receives at least three distinct colors. Thus a $t$-track layout of a graph $G$ defines an acyclic $t$-coloring of $G$. The minimum number of colors in an acyclic coloring of $G$ is the *acyclic chromatic number* of $G$, denoted by $\chi_{\mathrm{a}}(G)$. Thus,

$$\chi_{\mathrm{a}}(G) \leq \mathsf{tn}(G).$$

Acyclic colorings were introduced by Grünbaum [49], who proved that every planar graph is acyclically 9-colorable. This result was steadily improved [1, 65, 67] until Borodin [12] proved that every planar graph is acyclically 5-colorable, which is the best possible bound. Many other graph families have bounded acyclic chromatic number, including graphs embeddable on a fixed surface [2, 3, 6], 1-planar graphs [13], graphs with bounded maximum degree [5], and graphs with bounded tree-width. A folklore result states that $\chi_{\mathrm{a}}(G) \leq \mathsf{tw}(G) + 1$ (see [43]). More generally, Nešetřil and Ossona de Mendez [69] proved that every proper minor-closed graph family has bounded acyclic chromatic number. In fact, they proved that every graph $G$ has a *star* $k$-coloring (every bichromatic subgraph is a forest of stars), where $k$ is a (small) quadratic function of the maximum chromatic number of a minor of $G$.

LEMMA 5.3. *Every graph $G$ with acyclic chromatic number $\chi_{\mathrm{a}}(G) \leq c$ and queue-number $\mathsf{qn}(G) \leq q$ has track-number $\mathsf{tn}(G) \leq c\,(2q)^{c-1}$.*

*Proof.* Let $\{V_i : 1 \leq i \leq c\}$ be an acyclic coloring of $G$. Let $\sigma$ be the vertex-ordering in a $q$-queue layout of $G$. Consider an edge $vw$ with $v \in V_i$, $w \in V_j$, and $i < j$. If $v <_\sigma w$, then $vw$ is *forward*, and if $w <_\sigma v$, then $vw$ is *backward*. Consider the edges to be colored with $2q$ colors, where each color class consists of the forward edges in a single queue, or the backward edges in a single queue.

Alon and Marshall [4] proved that given a (not necessarily proper) edge $k$-coloring of a graph $G$, any acyclic $c$-coloring of $G$ can be refined to a $ck^{c-1}$-coloring so that the edges between any pair of (vertex) color classes are monochromatic, and each (vertex) color class is contained in some original color class. (Nešetřil and Raspaud [70] generalized this result for colored mixed graphs.) Apply this result with the given acyclic $c$-coloring of $G$ and the edge $2q$-coloring discussed above. Consider the resulting $c(2q)^{c-1}$ color classes to be tracks ordered by $\sigma$. The edges between any two tracks are from a single queue, and are all forward or all backward.

Suppose that there are edges $vw$ and $xy$ that form an X-crossing. Since each track is a subset of some $V_i$, we can assume that $v, x \in V_i$, $w, y \in V_j$, and $i < j$. Suppose that $vw$ and $xy$ are both forward. The case in which $vw$ and $xy$ are both backward is symmetric. Thus $v <_\sigma w$ and $x <_\sigma y$. Since $vw$ and $xy$ form an X-crossing, and the tracks are ordered by $\sigma$, we have $v <_\sigma x$ and $y <_\sigma w$. Hence $v <_\sigma x <_\sigma y <_\sigma w$. That is, $vw$ and $xy$ are nested. This is the desired contradiction, since edges between any pair of tracks are from a single queue. Thus we have a $c(2q)^{c-1}$-track layout of $G$. $\square$

*Proof of Theorem* 2.6. Let $\mathcal{F}(n)$ be a family of functions closed under multiplication. Let $G$ be an $n$-vertex graph from a proper minor-closed graph family $\mathcal{G}$. First, suppose that $G$ has a $t$-track layout, where $t \in \mathcal{F}(n)$. By Lemma 5.2, $G$ has queue-number $\mathsf{qn}(G) \leq t - 1 \in \mathcal{F}(n)$. Conversely, suppose $G$ has queue-number $\mathsf{qn}(G) = q \in \mathcal{F}(n)$. By the above-mentioned result of Nešetřil and Ossona de Mendez [69], $G$ has bounded acyclic chromatic number $\chi_{\mathrm{a}}(G) \leq c \in \mathcal{O}(1)$. By Lemma 5.3, $G$ has a $t$-track layout, where $t \leq c(2q)^{c-1} \in \mathcal{F}(n)$. $\square$

## 6. Tree-partitions of *k*-trees.

In this section we prove our theorem mentioned in section 2.2 regarding tree-partitions of $k$-trees. This result forms the cornerstone of the proof of Theorem 7.3.

THEOREM 6.1. *Let $G$ be a $k$-tree with maximum degree $\Delta$. Then $G$ has a rooted tree-partition $(T, \{T_x : x \in V(T)\})$ such that for all nodes $x$ of $T$,*

(a) *if $x$ is a nonroot node of $T$ and $y$ is the parent node of $x$, then the set of vertices in $T_y$ with a neighbor in $T_x$ forms a clique $C_x$ of $G$, and*

(b) *the induced subgraph $G[T_x]$ is a connected $(k-1)$-tree.*

*Furthermore the width of $(T, \{T_x : x \in V(T)\})$ is at most* $\max\{1, k(\Delta - 1)\}$.

*Proof.* We assume that $G$ is connected, since if $G$ is not connected, then a tree-partition of $G$ that satisfies the theorem can be determined by adding a new root node with an empty bag, adjacent to the root node of a tree-partition of each connected component of $G$.

It is well known that $G$ is a connected $k$-tree if and only if $G$ has a vertex-ordering $\sigma = (v_1, v_2, \ldots, v_n)$, such that for all $i \in \{1, 2, \ldots, n\}$,

(i) if $G^i$ is the induced subgraph $G[\{v_1, v_2, \ldots, v_i\}]$, then $G^i$ is connected and the vertex-ordering of $G^i$ induced by $\sigma$ is a breadth-first vertex-ordering of $G^i$, and

(ii) the neighbors of $v_i$ in $G^i$ form a clique $C_i = \{v_j : v_i v_j \in E(G), j < i\}$ with $1 \leq |C_i| \leq k$ (unless $i = 1$, in which case $C_i = \emptyset$).

In the language of chordal graphs, $\sigma$ is a (reverse) "perfect elimination" vertex-ordering and can be determined, for example, by the Lex-BFS algorithm by Rose, Tarjan, and Leuker [80] (also see [48]). Moreover, we can choose $v_1$ to be any vertex in $G$.

Let $r$ be a vertex of minimum degree[6] in $G$. Then $\deg(r) \leq k$. Let $\sigma = (v_1, v_2, \ldots, v_n)$ be a vertex-ordering of $G$ with $v_1 = r$ and satisfying (i) and (ii). By (i), the depth of each vertex $v_i$ in $\sigma$ is the same as the depth of $v_i$ in the vertex-ordering of $G^j$ induced by $\sigma$ for all $j \geq i$. We therefore simply speak of *the* depth of $v_i$. Let $V_d$ be the set of vertices of $G$ at depth $d$.

[6]We choose $r$ to have minimum degree to obtain a slightly improved bound on the width of the tree-partition. If we choose $r$ to be an arbitrary vertex, then the width is at most $\max\{1, \Delta, k(\Delta-1)\}$, and the remainder of Theorem 6.1 holds.

CLAIM 1. *For all $d \geq 1$, and for every connected component $Z$ of $G[V_d]$, the set of vertices at depth $d-1$ with a neighbor in $Z$ form a clique of $G$.*

*Proof.* The claim is trivial for $d = 1$ or $d = 2$. Now suppose that $d \geq 3$. Assume for the sake of contradiction that there are two nonadjacent vertices $x$ and $y$ at depth $d-1$ such that $x$ has a neighbor in $Z$ and $y$ has a neighbor in $Z$. Let $P_1$ be a shortest path between $x$ and $y$ with its interior vertices in $Z$. Let $P_2$ be a shortest path between $x$ and $y$ with its interior vertices at depth at most $d-2$. Since the interior vertices of $P_1$ are at depth $d$, there is no edge between an interior vertex of $P_1$ and an interior vertex of $P_2$. Thus $P_1 \cup P_2$ is a chordless cycle of length at least four, contradicting the fact that $G$ is chordal (by Lemma 2.1). $\square$

Define a graph $T$ and a partition $\{T_x : x \in V(T)\}$ of $V(G)$ indexed by the nodes of $T$ as follows. There is one node $x$ in $T$ for every connected component of each $G[V_d]$, whose bag $T_x$ is the vertex-set of the corresponding connected component. We say $x$ and $T_x$ are at *depth* $d$. Clearly a vertex in a depth-$d$ bag is also at depth $d$. The (unique) node of $T$ at depth zero is called the *root* node. Let two nodes $x$ and $y$ of $T$ be connected by an edge if there is an edge $vw$ of $G$ with $v \in T_x$ and $w \in T_y$. Thus $(T, \{T_x : x \in V(T)\})$ is a "graph-partition."

We now prove that in fact $T$ is a tree. First observe that $T$ is connected since $G$ is connected. By definition, nodes of $T$ at the same depth $d$ are not adjacent. Moreover, nodes of $T$ can be adjacent only if their depths differ by one. Thus $T$ has a cycle only if there is a node $x$ in $T$ at some depth $d$ such that $x$ has at least two distinct neighbors in $T$ at depth $d-1$. However this is impossible since, by Claim 1, the set of vertices at depth $d-1$ with a neighbor in $T_x$ form a clique (which we call $C_x$) and are hence in a single bag at depth $d-1$. Thus $T$ is a tree, and $(T, \{T_x : x \in V(T)\})$ is a tree-partition of $G$ (see Figure 6.1).

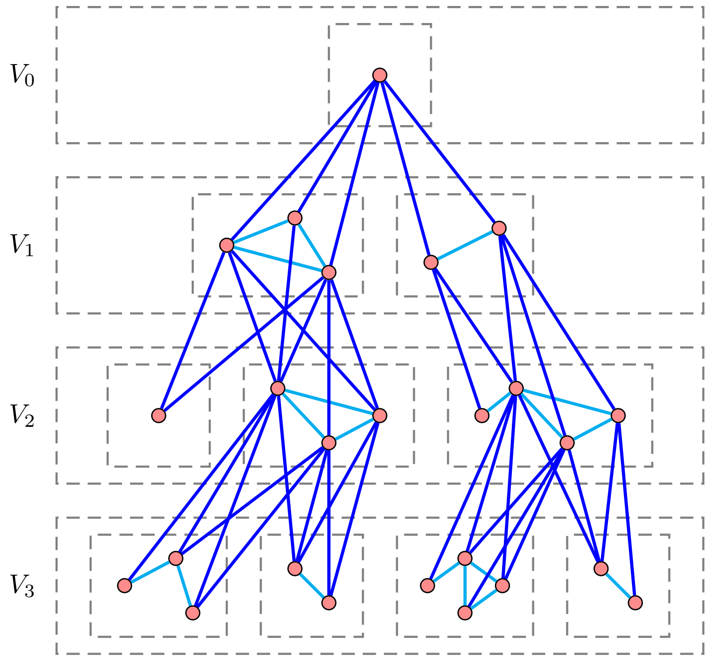

FIG. 6.1. *Illustration for Theorem* 6.1 *in the case of* $k = 3$.

We now prove that each bag $T_x$ induces a connected $(k-1)$-tree. This is true for the root node which only has one vertex. Suppose $x$ is a nonroot node of $T$ at depth $d$. Each vertex in $T_x$ has at least one neighbor at depth $d-1$. Thus in the vertex-ordering of $T_x$ induced by $\sigma$, each vertex $v_i \in T_x$ has at most $k-1$ neighbors $v_j \in T_x$ with $j < i$. Thus the vertex-ordering of $T_x$ induced by $\sigma$ satisfies (i) and (ii) for $k-1$, and $G[T_x]$ is $(k-1)$-tree. By definition, each $G[T_x]$ is connected.

Finally, consider the cardinality of a bag in $T$. We claim that each bag contains at most $\max\{1, k(\Delta-1)\}$ vertices. The root bag has one vertex. Let $x$ be a nonroot node of $T$ with parent node $y$. Suppose that $y$ is the root node. Then $T_y = \{r\}$, and thus $|T_x| \leq \deg(r) \leq k \leq k(\Delta-1)$, assuming $\Delta \geq 2$. If $\Delta \leq 1$, then all bags have one vertex. Now assume that $y$ is a nonroot node. The set of vertices in $T_y$ with a neighbor in $T_x$ forms the clique $C_x$. Let $k' = |C_x|$. Thus $k' \geq 1$, and since $C_x \subseteq T_y$ and $G[T_y]$ is a $(k-1)$-tree, $k' \leq k$. A vertex $v \in C_x$ has $k'-1$ neighbors in $C_x$ and at least one neighbor in the parent bag of $y$. Thus $v$ has at most $\Delta - k'$ neighbors in $T_x$. Hence the number of edges between $C_x$ and $T_x$ is at most $k'(\Delta-k')$. Every vertex in $T_x$ is adjacent to a vertex in $C_x$. Thus $|T_x| \leq k'(\Delta-k') \leq k(\Delta-1)$. This completes the proof. ∎

**7. Tree-width and track layouts.** In this section we prove that track-number is bounded by tree-width. Let $\{(V_i, <_i) : i \in I\}$ be a track layout of a graph $G$. We say a clique $C$ of $G$ *covers* the set of tracks $\{i \in I : C \cap V_i \neq \emptyset\}$. Let $S$ be a set of cliques of $G$. Suppose that there exists a total order $\preceq$ on $S$ such that for all cliques $C_1, C_2 \in S$, if there exists a track $i \in I$, and vertices $v \in V_i \cap C_1$ and $w \in V_i \cap C_2$ with $v <_i w$, then $C_1 \prec C_2$. In this case, we say $\preceq$ is *nice*, and $S$ is *nicely ordered* by the track layout.

LEMMA 7.1. *Let $L \subseteq I$ be a set of tracks in a track layout $\{(V_i, <_i) : i \in I\}$ of a graph $G$. If $S$ is a set of cliques each of which covers $L$, then $S$ is nicely ordered by the given track layout.*

*Proof.* Define a relation $\preceq$ on $S$ as follows. For every pair of cliques $C_1, C_2 \in S$, define $C_1 \preceq C_2$ if $C_1 = C_2$ or there exists a track $i \in L$ and vertices $v \in C_1$ and $w \in C_2$ with $v <_i w$. Clearly all cliques in $S$ are comparable.

Suppose that $\preceq$ is not antisymmetric; that is, there exist distinct cliques $C_1, C_2 \in S$, distinct tracks $i, j \in L$, and distinct vertices $v_1, w_1 \in C_1$ and $v_2, w_2 \in C_2$ such that $v_1 <_i v_2$ and $w_2 <_j w_1$. Since $C_1$ and $C_2$ are cliques, the edges $v_1w_1$ and $v_2w_2$ form an X-crossing, which is a contradiction. Thus $\preceq$ is antisymmetric.

We claim that $\preceq$ is transitive. Suppose that there exist cliques $C_1, C_2, C_3 \in S$ such that $C_1 \preceq C_2$ and $C_2 \preceq C_3$. We can assume that $C_1$, $C_2$, and $C_3$ are pairwise distinct. Thus there are vertices $u_1 \in C_1$, $u_2 \in C_2$, $v_2 \in C_2$, and $v_3 \in C_3$ such that $u_1 <_i u_2$ and $v_2 <_j v_3$ for some pair of (not necessarily distinct) tracks $i, j \in L$. Since $C_3$ has a vertex in $V_i$ and since $C_3 \not\preceq C_2$, there is a vertex $u_3 \in C_3$ with $u_2 \leq_i u_3$. Thus $u_1 <_i u_3$, which implies that $C_1 \preceq C_3$. Thus $\preceq$ is transitive.

Hence $\preceq$ is a total order on $S$, which by definition is nice. ∎

Consider the problem of partitioning the cliques of a graph into sets such that each set is nicely ordered by a given track layout. The following immediate corollary of Lemma 7.1 says that there exists such a partition where the number of sets does not depend upon the size of the graph.

COROLLARY 7.2. *Let $G$ be a graph with maximum clique size $k$. Given a $t$-track layout of $G$, there is a partition of the cliques of $G$ into $\sum_{i=1}^{k} \binom{t}{i}$ sets, each of which is nicely ordered by the given track layout.* ∎

We do not actually use Corollary 7.2 in the following result, but the idea of partitioning the cliques into nicely ordered sets is central to its proof.

THEOREM 7.3. *For every integer $k \geq 0$, there is a constant $t_k = 3^k \cdot 6^{(4^k-3k-1)/9}$ such that every graph $G$ with tree-width $\mathsf{tw}(G) \leq k$ has a $t_k$-track layout.*

*Proof.* If the input graph $G$ is not a $k$-tree, then add edges to $G$ to obtain a $k$-tree containing $G$ as a subgraph. It is well known that a graph with tree-width at most $k$ is a *spanning* subgraph of a $k$-tree. These extra edges can be deleted once we are done. We proceed by induction on $k$ with the following hypothesis:

*For all $k \in \mathbb{N}$, there exists a constant $s_k$ and sets $\mathcal{I}_k$ and $\mathcal{S}_k$ such that*

1. *$|\mathcal{I}_k| = t_k$ and $|\mathcal{S}_k| = s_k$,*
2. *each element of $\mathcal{S}_k$ is a subset of $\mathcal{I}_k$, and*
3. *every $k$-tree $G$ has a $t_k$-track layout indexed by $\mathcal{I}_k$, such that for every clique $C$ of $G$, the set of tracks that $C$ covers is in $\mathcal{S}_k$.*

Consider the base case with $k = 0$. A 0-tree $G$ has no edges and thus has a 1-track layout. Let $\mathcal{I}_0 = \{1\}$, and order $V_1 = V(G)$ arbitrarily. Thus $t_0 = 1$, $s_0 = 1$, and $\mathcal{S}_0 = \{\{1\}\}$ satisfy the hypothesis for every 0-tree. Now suppose that the result holds for $k-1$, and $G$ is a $k$-tree.

Let $(T, \{T_x : x \in V(T)\})$ be a tree-partition of $G$ described in Theorem 6.1, where $T$ is rooted at $r$. Each induced subgraph $G[T_x]$ is a $(k-1)$-tree. Thus, by induction, there are sets $\mathcal{I}_{k-1}$ and $\mathcal{S}_{k-1}$ with $|\mathcal{I}_{k-1}| = t_{k-1}$ and $|\mathcal{S}_{k-1}| = s_{k-1}$ such that for every node $x$ of $T$ the induced subgraph $G[T_x]$ has a $t_{k-1}$-track layout indexed by $\mathcal{I}_{k-1}$. For every clique $C$ of $G[T_x]$, if $C$ covers $L \subseteq \mathcal{I}_{k-1}$, then $L \in \mathcal{S}_{k-1}$. Assume $\mathcal{I}_{k-1} = \{1, 2, \ldots, t_{k-1}\}$ and $\mathcal{S}_{k-1} = \{X_1, X_2, \ldots, X_{s_{k-1}}\}$. By Theorem 6.1, for each nonroot node $x$ of $T$, if $p$ is the parent node of $x$, then the set of vertices in $T_p$ with a neighbor in $T_x$ form a clique $C_x$. Let $\alpha(x) = i$, where $C_x$ covers $X_i$. For the root node $r$ of $T$, let $\alpha(r) = 1$.

**Track layout of $T$.** To construct a track layout of $G$ we first construct a track layout of the tree $T$ indexed by the set $\{(d, i) : d \geq 0, 1 \leq i \leq s_{k-1}\}$, where the track $L_{d,i}$ consists of nodes $x$ of $T$ at depth $d$ with $\alpha(x) = i$. Here the *depth* of a node $x$ is the distance in $T$ from the root node $r$ to $x$. We order the nodes of $T$ within the tracks by increasing depth. There is only one node at depth $d = 0$. Suppose that we have determined the orders of the nodes up to depth $d-1$ for some $d \geq 1$.

Let $i \in \{1, 2, \ldots, s_{k-1}\}$. The nodes in $L_{d,i}$ are ordered primarily with respect to the relative positions of their parent nodes (at depth $d-1$). More precisely, let $\rho(x)$ denote the parent node of each node $x \in L_{d,i}$. For all nodes $x$ and $y$ in $L_{d,i}$, if $\rho(x)$ and $\rho(y)$ are in the same track and $\rho(x) < \rho(y)$ in that track, then $x < y$ in $L_{d,i}$. For $x$ and $y$ with $\rho(x)$ and $\rho(y)$ on distinct tracks, the relative order of $x$ and $y$ is not important. It remains to specify the order of nodes in $L_{d,i}$ with a common parent.

Suppose that $P$ is a set of nodes in $L_{d,i}$ with a common parent node $p$. By construction, for every node $x \in P$, the parent clique $C_x$ covers $X_i$ in the track layout of $G[T_p]$. By Lemma 7.1 the cliques $\{C_x : x \in P\}$ are nicely ordered by the track layout of $G[T_p]$. Let the order of $P$ in track $L_{d,i}$ be specified by a nice ordering of $\{C_x : x \in P\}$, as illustrated in Figure 7.1.

This construction defines a partial order on the nodes in track $L_{d,i}$, which can be arbitrarily extended to a total order. Hence we have a track assignment of $T$. Since the nodes in each track are ordered primarily with respect to the relative positions of their parent nodes in the previous tracks, there is no X-crossing, and hence we have a track layout of $T$.

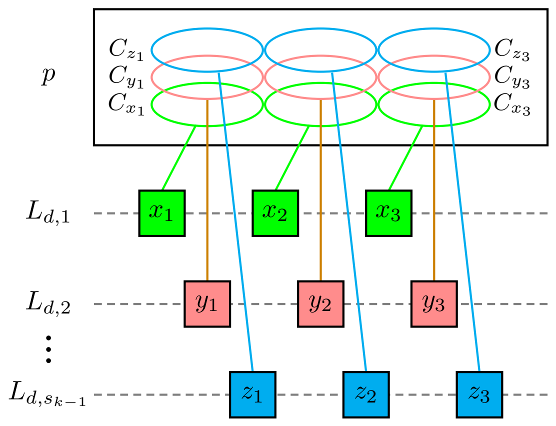

FIG. 7.1. *Track layout of nodes with a common parent $p$.*

**Track layout of $G$.** To construct a track assignment of $G$ from the track layout of $T$, replace each track $L_{d,i}$ by $t_{k-1}$ subtracks, and for each node $x$ of $T$ insert the track layout of $G[T_x]$ in place of $x$ on the subtracks corresponding to the track containing $x$ in the track layout of $T$. More formally, the track layout of $G$ is indexed by the set

$$\{(d, i, j) : d \geq 0, 1 \leq i \leq s_{k-1}, 1 \leq j \leq t_{k-1}\}.$$

Each track $V_{d,i,j}$ consists of those vertices $v$ of $G$ such that, if $T_x$ is the bag containing $v$, then $x$ is at depth $d$ in $T$, $\alpha(x) = i$, and $v$ is in track $j$ in the track layout of $G[T_x]$. If $x$ and $y$ are distinct nodes of $T$ with $x < y$ in $L_{d,i}$, then $v < w$ in $V_{d,i,j}$ for all vertices $v \in T_x$ and $w \in T_y$ in track $j$. If $v$ and $w$ are vertices of $G$ in track $j$ in bag $T_x$ at depth $d$, then the relative order of $v$ and $w$ in $V_{d,\alpha(x),j}$ is the same as in the track layout of $G[T_x]$.

Clearly adjacent vertices of $G$ are in distinct tracks. Thus we have defined a track assignment of $G$. We claim there is no X-crossing. Clearly an intrabag edge of $G$ is not in an X-crossing with an edge not in the same bag. By induction, there is no X-crossing between intrabag edges in a common bag. Since there is no X-crossing in the track layout of $T$, interbag edges of $G$ which are mapped to edges of $T$ without a common parent node are not involved in an X-crossing.

Consider a parent node $p$ in $T$. For each child node $x$ of $p$, the set of vertices in $T_p$ adjacent to a vertex in $T_x$ forms the clique $C_x$. Thus there is no X-crossing between a pair of edges both from $C_x$ to $T_x$, since the vertices of $C_x$ are on distinct tracks. Consider two child nodes $x$ and $y$ of $p$. For there to be an X-crossing between an edge from $T_p$ to $T_x$ and an edge from $T_p$ to $T_y$, the nodes $x$ and $y$ must be on the same track in the track layout of $T$. Suppose $x < y$ in this track. By construction, $C_x$ and $C_y$ cover the same set of tracks, and $C_x \preceq C_y$ in the corresponding nice ordering. Thus for any track containing vertices $v \in C_x$ and $w \in C_y$, $v \leq w$ in that track. Since all the vertices in $T_x$ are to the left of the vertices in $T_y$ (in a common track), there is no X-crossing between an edge from $T_p$ to $T_x$ and an edge from $T_p$ to $T_y$. Therefore there is no X-crossing, and hence we have a track layout of $G$.

**Wrapped track layout of $G$.** 0As illustrated in Figure 7.2, we now "wrap" the track layout of $G$ in the spirit of Lemma 3.1. In particular, define a track assignment

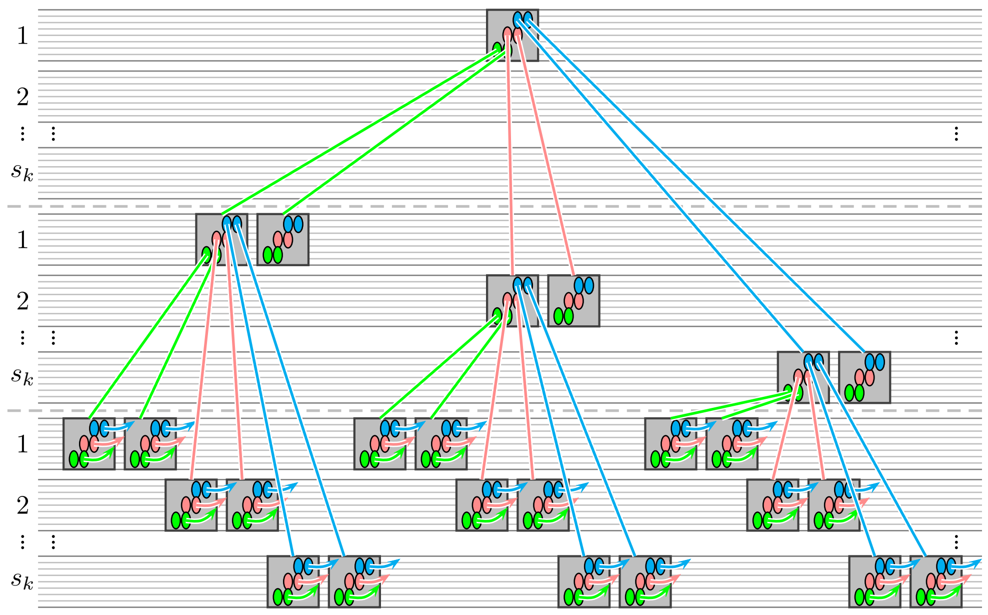

FIG. 7.2. *Wrapped track layout in Theorem* 7.3.

of $G$ indexed by

$$\{(d',i,j) : d' \in \{0,1,2\}, 1 \leq i \leq s_{k-1}, 1 \leq j \leq t_{k-1}\},$$

where each track

$$W_{d',i,j} = \bigcup\{V_{d,i,j} : d \equiv d' \pmod 3\}.$$

If $v \in V_{d,i,j}$ and $w \in V_{d+3,i,j}$, then $v < w$ in the order of $W_{d',i,j}$ (where $d' = d \bmod 3$). The order of each $V_{d,i,j}$ is preserved in $W_{d',i,j}$. The set of tracks $\{W_{d',i,j} : d' \in \{0,1,2\}, 1 \leq i \leq s_{k-1}, 1 \leq j \leq t_{k-1}\}$ forms a track assignment of $G$.

For every edge $vw$ of $G$, the depths of the bags in $T$ containing $v$ and $w$ differ by at most one. Thus in the wrapped track assignment of $G$, adjacent vertices remain on distinct tracks, and there is no X-crossing. The number of tracks is $3 \cdot s_{k-1} \cdot t_{k-1}$.

Every clique $C$ of $G$ is either contained in a single bag of the tree-partition or is contained in two adjacent bags. Let

$$\mathcal{S}' = \{\{(d',i,h) : h \in X_j\} : d' \in \{0,1,2\}, 1 \leq i,j \leq s_{k-1}\}.$$

For every clique $C$ of $G$ contained in a single bag, the set of tracks containing $C$ is in $\mathcal{S}'$. Let

$$\mathcal{S}'' = \{\{(d',i,\ell) : \ell \in X_j\} \cup \{((d'+1) \bmod 3, p, h) : h \in X_q\} : \\ d' \in \{0,1,2\}, 1 \leq i,j,p,q \leq s_{k-1}\}.$$

For every clique $C$ of $G$ contained in two bags, the set of tracks containing $C$ is in $\mathcal{S}''$. Observe that $\mathcal{S}' \cup \mathcal{S}''$ is independent of $G$. Hence $\mathcal{S}_k = \mathcal{S}' \cup \mathcal{S}''$ satisfies the hypothesis for $k$.

Now $|\mathcal{S}'| = 3s_{k-1}^2$ and $|\mathcal{S}''| = 3s_{k-1}^4$, and thus $|\mathcal{S}' \cup \mathcal{S}''| = 3s_{k-1}^2(s_{k-1}^2 + 1)$. Therefore any solution to the following set of recurrences satisfies the theorem:

$$s_0 \ \geq\ 1, \quad t_0 \ \geq\ 1, \quad s_k \ \geq\ 3s_{k-1}^2(s_{k-1}^2+1), \quad t_k \ \geq\ 3s_{k-1}\cdot t_{k-1}. \tag{7.1}$$

We claim that

$$s_k = 6^{(4^k-1)/3} \quad \text{and} \quad t_k = 3^k \cdot 6^{(4^k-3k-1)/9}$$

is a solution to (7.1). Observe that $s_0 = 1$ and $t_0 = 1$. Now

$$3s_{k-1}^2(s_{k-1}^2+1) \ \leq\ 6s_{k-1}^4$$

and

$$6(6^{(4^{k-1}-1)/3})^4 \ =\ 6^{1+4(4^{k-1}-1)/3} \ =\ 6^{(4^k-1)/3} \ =\ s_k.$$

Thus the recurrence for $s_k$ is satisfied. Now

$$\begin{aligned} 3\cdot s_{k-1}\cdot t_{k-1} &= 3\cdot 6^{(4^{k-1}-1)/3}\cdot 3^{k-1}\cdot 6^{(4^{k-1}-3(k-1)-1)/9}\\ &= 3^k\cdot 6^{(3\cdot 4^{k-1}-3+4^{k-1}-3k+3-1)/9}\\ &= 3^k\cdot 6^{(4^k-3k-1)/9}\\ &= t_k. \end{aligned}$$

Thus the recurrence for $t_k$ is satisfied. This completes the proof. □

In the proof of Theorem 7.3 we have made little effort to reduce the bound on $t_k$, beyond that it is a doubly exponential function of $k$. In [35] we describe a number of refinements that result in improved bounds on $t_k$. One such refinement uses strict $k$-trees. From an algorithmic point of view, the disadvantage of using strict $k$-trees is that at each recursive step, extra edges must be added to enlarge the graph from a partial strict $k$-tree into a strict $k$-tree, whereas when using (nonstrict) $k$-trees, extra edges need be added only at the beginning of the algorithm.

For small values of $k$, much-improved results can be obtained. For example, we prove that every series-parallel graph (that is, with tree-width at most two) has an 18-track layout [35], whereas $t_2 = 54$. This bound has recently been improved to 15 by Di Giacomo, Liotta, and Meijer [25]. Their method is based on Theorems 6.1 and 7.3, and in the general case still gives a doubly exponential upper bound on the track-number of graphs with tree-width $k$. For other particular classes of graphs, Di Giacomo [24] and Di Giacomo and Meijer [27] recently improved the constants in our results.

Our doubly exponential upper bound is probably not best possible. Di Giacomo, Liotta, and Meijer [25] constructed graphs with tree-width $k$ and track-number at least $2k+1$. The following construction establishes a quadratic lower bound. It is similar to a graph due to Albertson et al. [3], which gives a tight lower bound on the star chromatic number of graphs with tree-width $k$.

THEOREM 7.4. *For all $k \geq 0$, there is a graph $G_k$ with tree-width at most $k$ and track-number* $\mathsf{tn}(G_k) = \frac{1}{2}(k+1)(k+2)$.

*Proof.* Let $G_0 = K_1$. Obviously $G_0$ has tree-width 0. Construct $G_k$ from $G_{k-1}$ as follows. Start with a $k$-clique $\{v_1, v_2, \dots, v_k\}$. Let $n = 2(\frac{1}{2}(k+1)(k+2) - 1 - k) + 1$. Add $n$ vertices $\{w_1, w_2, \dots, w_n\}$, each adjacent to every $v_i$. Let $H_1, H_2, \dots, H_n$ be

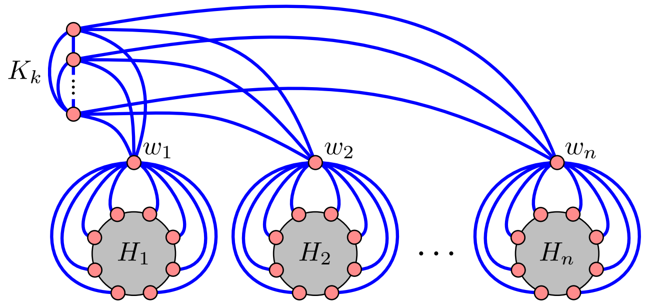

FIG. 7.3. *The graph $G_k$.*

copies of $G_{k-1}$. For all $1 \le j \le n$, add an edge between $w_j$ and each vertex of $H_j$, as illustrated in Figure 7.3. It is easily seen that from a tree decomposition of $G_{k-1}$ of width $k-1$ we can construct a tree decomposition of $G_k$ of width $k$. Thus $G_k$ has tree-width at most $k$.

To prove that $\mathtt{tn}(G_k) \ge \frac{1}{2}(k+1)(k+2)$, we proceed by induction on $k \ge 0$. Obviously $\mathtt{tn}(G_0) = 1$. Suppose that $\mathtt{tn}(G_{k-1}) \ge \frac{1}{2}k(k+1)$ but $\mathtt{tn}(G_k) \le \frac{1}{2}(k+1)(k+2)-1$. Since $\{v_1, v_2, \dots, v_k\}$ is a clique, we can assume that $v_i$ is in track $i$. Since each vertex $w_j$ is adjacent to each $v_i$, no $w_j$ is in tracks $\{1, 2, \dots, k\}$. There are $\frac{1}{2}(k+1)(k+2)-1-k$ remaining tracks. Since $n$ is more than twice this number, there are at least three $w_j$ vertices in a single track. Without loss of generality, $w_1 < w_2 < w_3$ in track $k+1$. No vertex $x$ of $H_2$ is in track $i \in \{1, 2, \dots, k\}$, as otherwise $xw_2$ would form an X-crossing with $v_iw_1$ or $v_iw_3$. No vertex $x$ of $H_2$ is in track $k+1$, since $x$ and $w_2$ are adjacent, and $w_2$ is in track $k+1$. Thus all the vertices of $H_2$ are in tracks $\{k+2, k+3, \dots, \frac{1}{2}(k+1)(k+2)-1\}$. There are $\frac{1}{2}(k+1)(k+2)-1-(k+1) = \frac{1}{2}k(k+1)-1$ such tracks. This contradicts the assumption that $\mathtt{tn}(G_{k-1}) \ge \frac{1}{2}k(k+1)$. Therefore $\mathtt{tn}(G_k) \ge \frac{1}{2}(k+1)(k+2)$.

It remains to prove that $\mathtt{tn}(G_k) \le \frac{1}{2}(k+1)(k+2)$. Suppose we have a $\frac{1}{2}k(k+1)$-track layout of $G_{k-1}$. Thus each $H_j$ has a $\frac{1}{2}k(k+1)$-track layout. Put each vertex $v_i$ of $G_k$ in track $i$. Put the vertices $\{w_1, w_2, \dots, w_n\}$ in track $k+1$ in this order. Put the track layout of each $H_j$ in tracks $k+2, k+3, \dots, \frac{1}{2}(k+1)(k+2)$ such that the vertices of $H_j$ precede the vertices of $H_{j+1}$. Clearly there are no X-crossings. ∎

Also note that Theorem 7.4 (for $k \ge 2$) can be extended using the proof technique of Lemma 2.3 to give the same lower bound for improper track layouts.

## 8. Open problems.

1. (In the conference version of their paper) Felsner, Liotta, and Wismath [42] asked whether every planar graph has a three-dimensional drawing with $\mathcal{O}(n)$ volume. By Theorem 2.9, this question has an affirmative answer if every planar graph has a $\mathcal{O}(1)$ track-number. Whether every planar graph has $\mathcal{O}(1)$ track-number is an open problem due to H. de Fraysseix [private communication, 2000] and, by Theorem 2.6, is equivalent to the following question.

2. Heath and colleagues [58, 54] asked whether every planar graph has a $\mathcal{O}(1)$ queue-number. The best known upper bound on the queue-number of a planar graph is $\mathcal{O}(\sqrt{n})$. In general, Dujmović and Wood [37] proved that every $m$-edge graph has queue-number at most $\boldsymbol{e}\sqrt{m}$, where $\boldsymbol{e}$ is the base of the natural logarithm.

3. Heath and colleagues [58, 54] also asked whether stack-number is bounded by queue-number (and vice-versa). Note that there is a family of graphs $\mathcal{G}$ with

$\mathsf{sn}(G) \in \Omega(3^{\Omega(\mathsf{qn}(G))-\epsilon})$ for all $G \in \mathcal{G}$ [54].

4. Is the queue-number of a graph bounded by a polynomial (or even singly exponential) function of its tree-width?

**Note added in proof.** Subsequent to this research, Dujmović and Wood [38] proved that graphs excluding a fixed graph as a minor, such as planar graphs, have three-dimensional drawings with $\mathcal{O}(n^{3/2})$ volume, as do graphs with bounded degree; Dujmović, Pór, and Wood [34] proved that track-number and queue-number are tied for all graphs; and Theorem 6.1 has been generalized (with a different proof) by Wood [92].

**Acknowledgments.** The authors are grateful for stimulating discussions with Prosenjit Bose, Jurek Czyzowicz, Hubert de Fraysseix, Stefan Langerman, Giuseppe Liotta, Patrice Ossona de Mendez, and Matthew Suderman. Thanks also to an anonymous referee for many helpful comments.

# ABSTRACT COMBINATORIAL PROGRAMS AND EFFICIENT PROPERTY TESTERS*

ARTUR CZUMAJ† AND CHRISTIAN SOHLER‡

**Abstract.** Property testing is a relaxation of classical decision problems which aims at distinguishing between functions having a predetermined property and functions being far from any function having the property. In this paper we present a novel framework for analyzing property testing algorithms. Our framework is based on a connection of property testing and a new class of problems which we call *abstract combinatorial programs*. We show that if the problem of testing a property can be reduced to an *abstract combinatorial program* of *small dimension*, then the property has an efficient tester.

We apply our framework to a variety of problems. We present efficient property testing algorithms for *geometric clustering* problems, for the *reversal distance* problem, and for *graph* and *hypergraph coloring* problems. We also prove that, informally, any *hereditary graph property* can be efficiently tested if and only if it can be reduced to an abstract combinatorial program of small size.

Our framework allows us to analyze all our testers in a unified way, and the obtained complexity bounds either match or improve the previously known bounds. Furthermore, even if the asymptotic complexity of the testers is not improved, the obtained proofs are significantly simpler than the previous ones. We believe that our framework will help to understand the structure of efficiently testable properties.

## 1. Introduction.

In this paper, we consider *property testing* problems, that is, problems of determining whether a given function has a predetermined property or is "far" from any function having the property. A notion of property testing was first explicitly formulated by Rubinfeld and Sudan [69], where it was motivated mainly by its connection to program checking. The notion of property testing arises naturally in the context of program verification [15, 69], learning theory, and, in a more theoretical setting, probabilistically checkable proofs [9, 70], and it has been further developed in many follow-up works.

In [43], Goldreich, Goldwasser, and Ron initiated the study of property testing for *combinatorial objects*. They investigated several classical properties of labeled graphs and showed, for example, that $k$-colorability of graphs is testable in time independent of the input size. In this and other more recent papers (see, e.g., the excellent surveys in [34, 42, 68]), various algorithms have been proposed for testing graph and hypergraph properties [2, 4, 5, 7, 8, 23, 35, 43, 45, 46, 47, 56]; for testing geometric properties

[3, 24, 27, 28]; for testing properties of metrics [62] and matrices [37]; for testing properties of regular languages and branching problems [6, 38, 61]; for testing monotonicity [29, 36, 44], etc. (see, e.g., the result about quantum property testing [17]).

In all these algorithms the goal is to verify whether an input function (or an object) has a predetermined property or is "far" from having the property. Since the exact and deterministic solution to this problem may still be very hard to obtain, a property testing algorithm (*tester*) may have a one-sided error,[1] i.e., the tester must *accept* every function that has the property and must *reject* with probability at least $\frac{2}{3}$ every function that is "far" from having the property. To specify the notion of being "far" from having a property, we define a *distance* measure between functions. For a given parameter $\epsilon$, we say a *function is $\epsilon$-far from having a property if it has distance bigger than $\epsilon$ from any function having the property.*

Property testing may be seen as some kind of approximation algorithm for decision problems. Since we only want to "approximately decide" problems, it is often possible to obtain algorithms that are much more efficient than their exact counterparts. Many property testers have indeed a query complexity and running time that is sublinear in the input size. For some problems it is even possible to obtain property testers whose query complexity and running time is *independent* of the input size (see, e.g., the surveys [34, 42, 68]). This, in turn, resulted in the development of *sublinear*-time approximation algorithms for many classical combinatorial problems, including dense max-cut, clustering problems, and estimating the cost of the minimum spanning tree (see, e.g., [19, 20, 25, 26, 33, 39, 43, 52, 53]).

Even if there are known many very efficient testing algorithms, most of them have been analyzed using ad hoc techniques, designed specially for the problem at hand. There is still insufficient methodology and few tools that could help in the analysis of efficient testers for new problems. One such general approach has been developed by Goldreich, Goldwasser, and Ron [43], where a close relationship between property testing and PAC learning was investigated. In particular, it is shown that (in the two-sided error model) testing is not harder than (proper) learning, and thus known algorithms for learning can be applied in the context of property testing. Goldreich et al. [43] (see also Theorem 4.3 in [34]) presented also a fairly general framework (in the two-sided error model; see [47] for a characterization in a one-sided error model) of studying testing of certain graph partitioning problems. They were able to apply this framework to some graph problems, including graph coloring, clique, cut, and bisection. Another general approach, which uses the Szemerédi regularity lemma, has been proposed for studying graph problems and problems on matrices [4, 28, 39, 40, 56]. Even if this method is very powerful and has been shown to be very successful (for example, it allowed to prove that all first order graph properties without a quantifier alternation of type $\forall\exists$ have property testers whose complexity is independent of the size of the input graph), there are still many limitations of this approach. Furthermore, even though the bounds obtained by using the regularity lemma lead to the complexity bounds that are often independent from the input size, their dependence on the approximation parameter $\epsilon$ is often enormous (see the "tower" bounds in [4] and superpolynomial lower bounds in [2]).

**1.1. Framework for property testing.** The main contribution of this paper is a novel framework to analyze property testing algorithms. We consider *one-sided*

[1]In the literature a *two-sided error* model for property testing has also been investigated. In this paper we focus on the one-sided error model only.

*error* testers for properties of functions $f$ from a finite domain $\mathcal{D}$ to range $\mathcal{R}$. We denote by $f_{|X}$ the function $f$ restricted to $X$. We denote the tested property with $\Pi$. We consider property testing algorithms that choose a random sample of the domain $\mathcal{S} \subseteq \mathcal{D}$ and then verify whether $f$ agrees on $\mathcal{S}$ with some function $g$ having property $\Pi$. If this is the case, our sampling property tester accepts; otherwise, it rejects.

```
SAMPLING PROPERTY TESTER FOR PROPERTY $\Pi$.
    Sample a set $\mathcal{S}$ of $s$ objects from $\mathcal{D}$ uniformly at random
    **if** $f_{|\mathcal{S}} = g_{|\mathcal{S}}$ for some function $g$ with property $\Pi$ **then** *accept*
    **else** *reject*
```

Sampling property testers are simple to implement. The main difficulty with their use is the estimation of the sample size—what is the right sample size $s$ (the *query complexity* of the tester) so that the algorithm is a correct property tester? It is easy to see that if $f$ has the required property, then the algorithm will always accept $f$. Thus, the challenging part of the analysis is to estimate the value of $s$ such that if $f$ is far from having the property, then $f$ will be rejected with probability at least $\frac{2}{3}$. Our framework is designed to help in the analysis needed in this step.

In order to define our framework, we first introduce a notion of an *abstract combinatorial program* (ACP). An ACP is a triplet that consists of a *ground set*, which is typically a set of basic objects underlying the property testing problem; a set of *bases*, where each basis is a configuration of a subset of the ground set; and a *violation function* that verifies the input constraints and determines whether an element violates a given basis or not. We call a basis *feasible* if it is not violated by any object from the ground set. We investigate a generic problem of *testing feasibility of an ACP*. That is, for a given ACP, we want to distinguish whether the ACP has a feasible basis or any basis is violated by at least an $\epsilon$ fraction of objects from the ground set. Our main technical result is a theorem that gives a bound for the size of the random sample used in the sampling property tester for feasibility of ACPs. We show that if a certain monotonicity property is satisfied by an ACP, then the sample size $s$ can be chosen to be of size depending only on the maximum size of any basis in the ACP. Thus, the sample size is independent of the size of the ground set.

The main idea behind introducing ACPs is that for many properties ACPs capture the structure essential for testing the property. Therefore, in our framework we reduce property testing of a given property $\Pi$ to the problem of testing feasibility of related ACPs. We show that property $\Pi$ can be tested efficiently if there is a *reduction* to ACPs that satisfies two properties:

- the reduction is *distance preserving*, that is, any function that is far away from $\Pi$ is mapped to an ACP in which each basis is violated by many objects from the ground set; and
- the reduction is *feasibility preserving*, that is, if the function restricted to a sample set $S$ can be extended to a function with property $\Pi$, then there is a feasible basis for the subset of the ground set corresponding to $S$ in the ACP.

What are the advantages of our framework? We believe that our framework can be used as one of the first general tools to estimate the sample size for many tested properties. Our approach of using ACPs introduces/enforces a very important structure in the analysis of the properties and gives rather clear guidelines on how to perform the analysis. For many problems, our framework allows us to abstract the most important features of the problem at hand and to focus only on the combinatorial structures/properties of the problem. As a result, as we demonstrate in this paper,

Table 1.1
*Summary of specific results.*

| Problem | Source | Query complexity | Comments |
|---|---|---|---|
| $k$-radius clustering in $\mathbb{R}^d$ | Alon et al. [3] | $\widetilde{\mathcal{O}}(d \cdot k/\epsilon)$ | in any $L_p$ metric, $p \geq 1$ |
| | *this paper* | $\widetilde{\mathcal{O}}(d \cdot k/\epsilon)$ | in any $L_p$ metric, $p \geq 1$ |
| $k$-diameter clustering in $\mathbb{R}^d$ | Alon et al. [3] | $\Omega((1/\beta)^{(d-1)/4})$ | $\Omega(\sqrt{n})$ for $\beta = 0$ |
| | Alon et al. [3] | $\widetilde{\mathcal{O}}(k^2 \cdot d \cdot \epsilon^{-1} \cdot (2/\beta)^{2\,d})$ | in $L_2$ metric |
| | *this paper* | $\widetilde{\mathcal{O}}(k \cdot \epsilon^{-1} \cdot (1 + 2/\beta)^d)$ | in any $L_p$ metric, $p \geq 1$ |
| sorting by reversals | *this paper* | $\mathcal{O}(k/\epsilon)$ | |
| graph $k$-coloring | Goldreich et al. [43] | $\widetilde{\mathcal{O}}(k^4/\epsilon^6)$ | |
| | Alon and Krivelevich [7] | $\widetilde{\mathcal{O}}(k^2/\epsilon^4)$ | |
| | *this paper* | $\widetilde{\mathcal{O}}(k^2/\epsilon^4)$ | |
| $k$-coloring of $\ell$-uniform hypergraphs | Czumaj and Sohler [23] | $(\widetilde{\mathcal{O}}(k^2\,\ell^2/\epsilon^2))^\ell$ | |
| | Alon and Shapira [8] | $(\widetilde{\mathcal{O}}(k^{\ell-1}/\epsilon^2))^\ell$ | claimed $(\widetilde{\mathcal{O}}(k\,\ell/\epsilon^2))^\ell$ |
| | *this paper* | $(\widetilde{\mathcal{O}}(k\,\ell/\epsilon^2))^\ell$ | |

the use of this method often allows us to obtain short and elegant proofs.

Finally, we would like to mention that the notion of ACPs and the approach to correlate the algorithmic question of testing to the existence of a certain combinatorial structure is similar to the framework of LP-type problems introduced in [60].

**1.2. Applications of new framework: Specific results.** We demonstrate our framework on a variety of classical problems in computational geometry, graph algorithms, and computational biology (see Table 1.1 for a summary). We begin with two classical geometric clustering problems: *radius clustering* and *diameter clustering.* Then we discuss a standard problem in computational biology of *sorting by reversals*; we provide the first property tester for this problem. Next, we study labeled graph and hypergraph problems (in the adjacency matrix model). We first apply our approach to the *graph and hypergraph $k$-coloring problems.* Next, we consider testability of *hereditary graph properties* (that is, graph properties that are closed under taking induced subgraphs). We prove that any hereditary graph property can be tested with query complexity independent of the size of the input graph if and only if it can be reduced to an ACP in which each basis is of size independent of the size of the input graph. This result shows that for this specific and very important class of properties our framework captures the essence of property testing.

All our analyses of property testers listed above use our new framework of ACPs. All the obtained property testers have a *query complexity independent of the input size.* Furthermore, all our results either match or improve upon the best previously known query complexity of the problems; our tester for sorting by reversals is the first tester for this problem, and our result for hereditary graph properties is a new general tool to analyze graph properties. We will discuss now our specific results in more detail.

**1.2.1. Clustering.** We apply our framework to study two classical geometric clustering problems in $\mathbb{R}^d$: *radius clustering* [1, 3, 32], [51, p. 325] (also called the Euclidean $k$-center problem) and *diameter clustering* [3], [10, problem ND54], [41, problem MS9], [51, p. 326]. For a given point set $X$ in $\mathbb{R}^d$, the *radius* of $X$ is the radius of the smallest ball containing $X$, and the *diameter* of $X$ is the maximum distance between any two points in $X$. In this paper, we consider the problem under an arbitrary $L_p$ metric, $p \geq 1$. The (decision version of the) *radius clustering* problem is to decide if an input point set $P$ in $\mathbb{R}^d$ can be partitioned into $k$ clusters such that the radius of each cluster is bounded from above by a given real number $r$; the (decision version of the) *diameter clustering* problem is to decide if an input point set $P$ in $\mathbb{R}^d$ can be partitioned into $k$ clusters such that the diameter of each cluster is bounded from above by a given real number $b$.

It is well known that both the radius and the diameter clustering problems are $\mathcal{NP}$-complete and that it is $\mathcal{NP}$-hard to find a $(1+c)$-approximation algorithm for these two problems for certain positive constant $c$ [32] (for recent positive approximation results, see, e.g., [11, 49]). In the context of property testing, both radius and diameter clustering have been recently investigated by Alon et al. [3].

*Radius clustering.* For radius clustering under the $L_2$ metric, Alon et al. designed an $\epsilon$-tester having a query complexity of $\widetilde{\mathcal{O}}(d \cdot k/\epsilon)$. Given a positive real $r$, this tester accepts any point set $P$ in $\mathbb{R}^d$ that can be partitioned into $k$ clusters such that in each cluster all points can be enclosed by a ball of radius $r$. If $P$ cannot be partitioned in that way even if any $\epsilon$ fraction of the points is removed from $P$, then the tester rejects $P$ with probability at least $\frac{2}{3}$. Alon et al. [3] pointed out that their analysis can be extended to deal with the problem in arbitrary $L_p$ metrics, $p \geq 1$.

We apply our framework to design an $\epsilon$-tester for the radius clustering problem under any $L_p$ metric, $p \geq 1$. The query complexity of our tester is asymptotically the same as the query complexity of the tester from [3]. The main advantage of our approach is that it follows easily from our general framework (though the analysis from [3] is also relatively simple). We discuss our tester in detail here mostly to demonstrate our approach to a relatively simple but nontrivial problem.

*Diameter clustering.* For diameter clustering under the $L_2$ metric, Alon et al. [3] designed a so-called $(\epsilon, \beta)$*-tester* having a query complexity of $\widetilde{\mathcal{O}}(k^2 \cdot d \cdot \epsilon^{-1} \cdot (2/\beta)^{2\,d})$. Given $b > 0$, this tester accepts any point set $P$ in $\mathbb{R}^d$ that can be partitioned into $k$ clusters such that the diameter of every cluster is upper bounded by $b$. If, however, after removal of any $\epsilon$ fraction of the points in $P$ the obtained set cannot be partitioned into $k$ clusters so that the diameter of each cluster is upper bounded by $b \cdot (1+\beta)$, then the tester rejects $P$ with probability at least $\frac{2}{3}$. Alon et al. [3] also gave a lower bound for the query complexity of $(\epsilon, \beta)$-testers for diameter clustering, which is $\Omega(\sqrt{n})$ for $\beta = 0$ and $\Omega((1/\beta)^{(d-1)/4})$ for $\beta > 0$; these bounds hold for constant $\epsilon$ and $k = 1$.

Unlike in the radius clustering problem, Alon et al. [3] did not extend their results with arbitrarily small positive $\beta$ for testing diameter clustering to any other metric than $L_2$. For the values of $\beta$ around 1, they discussed the diameter clustering problem under an *arbitrary metric* (not necessarily $L_p$). On one hand, Alon et al. showed that there is an $(\epsilon, 1)$-tester having a query complexity of $\widetilde{\mathcal{O}}(k^2 \log k/\epsilon)$, and on the other hand, they showed that for any $\beta < 1$ every $(\epsilon, \beta)$-tester must have a query complexity of $\Omega(\sqrt{n/\epsilon})$.

For diameter clustering under the $L_2$ metric, we apply our framework to improve upon the result of Alon et al. [3] and design an $(\epsilon, \beta)$-tester having the query complexity of $\widetilde{\mathcal{O}}(k \cdot \epsilon^{-1} \cdot (1 + 2/\beta)^d)$. If $\beta \leq 1/d$, then we can obtain even a better bound for the query complexity of $\widetilde{\mathcal{O}}(k \cdot d \cdot \epsilon^{-1} \cdot (2/\beta)^{d-1})$. And so, in the most classical version of the diameter clustering problem on the plane, we improve the bound for the query complexity of Alon et al. [3] from $\widetilde{\mathcal{O}}(k^2\,(2/\beta)^4/\epsilon)$ to $\widetilde{\mathcal{O}}(k/(\beta\,\epsilon))$. Besides the improvement in the complexity of the property tester (quadratic with respect to $k$ and $1/\beta$), our analysis is significantly simpler than that in [3]. Moreover, unlike the method of Alon et al., our approach can be easily extended to deal with the diameter clustering problem under an arbitrary $L_p$ metric, $p \geq 1$.

**1.2.2. Reversals distance.** The study of genome comparisons and rearrangements is one of the major topics in modern molecular biology. Mathematical analysis of genome rearrangements was initiated by Sankoff, who introduced the *sorting by reversals problem* (see, e.g., [63, Chapter 10]). In sorting by reversals, one asks to compute the *reversal distance* of a given permutation, which is the minimum number of *reversals* (inversions of segments) needed to be performed to transform the permutation into the identity permutation. Because of its applications in computational biology, sorting by reversals has been widely studied in recent years (see, e.g., [12, 13, 18, 54, 63, 64]). For example, Pevzner and Waterman [64], in their collection of open problems in computational biology, mentioned algorithmic issues of the sorting by reversals problem as one of the most important problems in genome rearrangements. It is known that sorting by reversals is $\mathcal{NP}$-hard [18], that its optimization version is MAX-SNP-hard [14], and that there exits a polynomial-time 1.375-approximation algorithm [13] (see also [12, 54]).

In this paper, we introduce the notion of property testing in the context of sorting by reversals. We design a property testing algorithm that verifies whether a given permutation has reversal distance at most $k$ or is $\epsilon$-far from having reversal distance at most $k$. We apply our framework to show that this property tester has the query complexity of $\widetilde{\mathcal{O}}(k/\epsilon)$.

**1.2.3. Graphs and hypergraphs.** Our framework can be also successfully applied to test graph and hypergraph properties in the adjacency matrix representation model. We discuss here its applications to graph and hypergraph coloring and to testing arbitrary hereditary properties.

*Graph coloring.* The graph $k$-coloring problem is a classical problem in algorithmic graph theory. It is known that for $k \geq 3$ the problem of verifying whether an input graph is $k$-colorable is $\mathcal{NP}$-complete (see, e.g., [41, problem GT4] or [10, problem GT5]). It is also well known that this problem is very hard to approximate, and so, for example, it is $\mathcal{NP}$-hard to 4-color 3-colorable graphs, and it is hard to color $k$-colorable graphs with approximation within $n^{1-\epsilon}$, and even within $n^{1-\mathcal{O}(1/\sqrt{\log\log n})}$ [31]; here and in what follows, $n$ denotes the number of vertices in the graph. The best known approximation bound for arbitrary $k$ is of $\mathcal{O}(n\,(\log\log n)^2/\log^3 n)$ [10, problem GT5].

The problem of testing graph $k$-coloring has been first investigated in the seminal work of Goldreich et al. [43]. We say a graph is *$\epsilon$-far from $k$-colorable* if one has to remove more than $\epsilon\, n^2$ of its edges to obtain a $k$-colorable graph. Goldreich et al. [43] showed that it is possible to test with the query complexity of $\widetilde{\mathcal{O}}(k^4/\epsilon^6)$ whether a given graph has a $k$-coloring or is $\epsilon$-far from being $k$-colorable. This result has been improved to the query complexity of $\widetilde{\mathcal{O}}(k^2/\epsilon^4)$ by Alon and Krivelevich [7]. In the current paper, we present a simple analysis of a property tester based on our framework that matches the best known bounds from Alon and Krivelevich [7].

*Hypergraph coloring.* The simple structure of our framework allows us to extend relatively easily our analysis for graph coloring to obtain a very efficient *property tester for testing hypergraph coloring.* Let us recall that a *hypergraph* is a pair $\mathcal{H} = (V, E)$ with a finite vertex set $V$ and the edge set $E \subseteq 2^V$; we let $n$ denote the size of the vertex set $V$. A hypergraph $\mathcal{H}$ is *$\ell$-uniform* if $|e| = \ell$ for all $e \in E$; a 2-uniform hypergraph is a graph. A *$k$-coloring* of a hypergraph $\mathcal{H}$ is an assignment $\chi : V \to \{1, \ldots, k\}$. A coloring is *proper* if no edge in $E$ is *monochromatic*, that is, if for every edge $e \in E$, there are $v, u \in e$ with $\chi(v) \neq \chi(u)$. If $\mathcal{H}$ has a proper $k$-coloring, then $\mathcal{H}$

is *$k$-colorable*. The $k$-coloring problem for hypergraphs is to decide whether a given hypergraph is $k$-colorable. We say an $\ell$-uniform hypergraph is *$\epsilon$-far from $k$-colorable* if one has to remove more than $\epsilon n^\ell$ of its edges to obtain a $k$-colorable hypergraph.

Hypergraph coloring is a well-studied problem in the literature of discrete mathematics, combinatorics, and computer science. In contrast to graphs, where one can decide in linear time if a graph is 2-colorable (or, equivalently, bipartite), testing whether a given hypergraph is 2-colorable is $\mathcal{NP}$-complete even for 3-uniform hypergraphs [59]. In [57], it is shown that unless $\mathcal{NP} \subseteq \mathcal{ZPP}$, for any fixed $\ell \geq 3$, it is impossible to approximate in polynomial time the chromatic number of $\ell$-uniform hypergraphs within a factor $n^{1-\varepsilon}$ for any constant $\varepsilon > 0$. See also [48, 55] for further inapproximability results. The property of hypergraph 2-colorability has also been extensively studied in combinatorics (see, e.g., [21, 22, 30, 66]), and, for example, the study of this problem led to the discovery of the celebrated Lovász Local lemma [30].

In the context of property testing, Czumaj and Sohler [23] were the first to design efficient property testers for hypergraph coloring. They presented an $\epsilon$-tester for $k$-coloring $\ell$-uniform hypergraphs with the query complexity of $(\mathcal{O}(k^2\,\ell^2\,\log k/\epsilon^2))^\ell$. Alon and Shapira [8] applied a novel framework based on testing satisfiability of boolean formulas to design property testers for coloring uniform hypergraphs. The complexity of that tester is $\mathcal{O}((k^{\ell-1}\,\log k/\epsilon^2)^\ell)$, which is worse than that of Czumaj and Sohler. However, Alon and Shapira claimed they could modify the proof due to Czumaj and Sohler [23] to obtain an improvement in the query complexity to $\mathcal{O}((\ell\,k\,\log k/\epsilon^2)^\ell)$. In this paper, we show how our framework can be applied to test hypergraph coloring. The obtained property tester has asymptotically the same query complexity as the one claimed by Alon and Shapira [8] (both of these results have been obtained independently).

The generic results for testing hypergraph properties presented in [5] and [56] imply also new property testing algorithms for $k$-coloring $\ell$-uniform hypergraphs that achieve query complexity independent of the hypergraph size (that is, their query complexity is a function of $k$, $\ell$, and $\epsilon$ only). However, in these papers the dependence on $k$, $\ell$, and $\epsilon$ is significantly higher than in our paper.

*Hereditary graph properties.* Many interesting graph properties are *hereditary*; i.e., they are closed under taking induced graphs. And so, for example, being acyclic, stable (independent set), planar, perfect, bipartite, $k$-colorable, chordal, perfect, and having no induced predefined subgraph $K$ are all hereditary graph properties.

Hereditary graph properties have been extensively investigated in combinatorics, graph theory (see, e.g., [16] for a recent survey), and theoretical computer science (see, e.g., the classical hardness result in [58]). The class of hereditary graph properties contains also trivially all (decreasing) monotone graph properties (these are properties closed under edge removal). Monotone graph properties have been studied extensively in the literature, most notably in the context of the celebrated Aanderaa–Rosenberg conjecture (proven in [67]).

There are known hereditary graph properties (e.g., the graph $k$-coloring discussed above) being testable with the query complexity independent of the input graph size; such properties are often called *testable*. On the other hand, Goldreich and Trevisan [47] prove that there exist monotone (and thus hereditary) graph properties for which testing requires one to examine a constant fraction of the entries in the input graph adjacency matrix. It is a major problem in property testing to characterize graph properties, and in particular hereditary graph properties, that are testable. In this paper we prove that any hereditary graph property is testable with the query complexity independent of the input graph size if and only if it can be reduced to an ACP of constant size. This result implies that for hereditary graph properties our framework captures the entire essential structure of the property.

**1.3. Organization.** In section 2, we describe formally the property testing problem and then, in section 3, we introduce the concept of *abstract combinatorial programs.* In section 4, we discuss a (simple) version of our framework that reduces property testing to testing ACPs. In section 5, we apply our framework of testing ACPs to testing two classical *geometric clustering problems*: radius clustering and diameter clustering. Next, in section 6, we apply this framework to test the *reversal distances of permutations.* In section 7, we generalize our framework presented in section 4 and give a *full description of our framework.* In section 8, we apply this general framework to design a property tester for *$k$-coloring of graphs.* In section 9, we extend our testing analysis for graph coloring to design a property tester for *$k$-coloring of uniform hypergraphs.* Then, in section 10, we give a new *characterization of hereditary graph properties* and show that, essentially, any such property is efficiently testable if and only if it is efficiently testable in our framework. Finally, in section 11, we *summarize* the results obtained in the paper and provide final *conclusions.*

## 2. Preliminaries.

We begin with some basic notation and definitions. We use the $\widetilde{\mathcal{O}}$-notation to hide polylogarithmic factors; i.e., we have $\widetilde{\mathcal{O}}(n) = n \cdot \log^{\mathcal{O}(1)} n$. We write $[n] = \{1, \ldots, n\}$ to denote the set of integer numbers between 1 and $n$. Throughout this paper, we let $\mathcal{D}$ denote a finite set called *domain* and $\mathcal{R}$ a (possibly infinite) set called *range.* Next, let $\mathcal{F}$ denote a set of functions from $\mathcal{D}$ to $\mathcal{R}$. For a subset $S \subseteq \mathcal{D}$ and a function $f \in \mathcal{F}$ let $f_{|\,S}$ denote the *restriction* of $f$ to $S$. That is, $f_{|\,S} : S \to \mathcal{D}$ with $f_{|\,S}(x) = f(x)$ for all $x \in S$. Now we define a property of $\mathcal{F}$ as a set of functions from $\mathcal{F}$.

DEFINITION 2.1. *A set* $\Pi \subseteq \mathcal{F}$ *is called a* property.

As already mentioned in the introduction we also need a distance measure between functions in $\mathcal{F}$ to define a property testing problem. In general, such a distance measure can be an arbitrary function $\varsigma : \mathcal{F} \times \mathcal{F} \to [0, 1]$.

DEFINITION 2.2. *Given a distance measure $\varsigma$ between functions in $\mathcal{F}$ and a real number $\epsilon$, $0 \le \epsilon < 1$, we say a function $f \in \mathcal{F}$ is* $\epsilon$-far from (having a property) $\Pi$ *if $\varsigma(f, g) > \epsilon$ for every function $g \in \Pi$.*

Typically, we define the distance between two functions $f, g \in \mathcal{F}$ as the fraction of domain elements on which the two functions differ (see, for example, [43]). Therefore, we denote this distance measure as the *standard distance measure.*

DEFINITION 2.3. *Given two functions $f, g \in \mathcal{F}$ we define* the standard distance measure $\varsigma_1$ *for functions in $\mathcal{F}$ as*

$$\varsigma_1(f, g) \;=\; \frac{|\{x \in \mathcal{D} : f(x) \neq g(x)\}|}{|\mathcal{D}|} \quad .$$

The goal of property testing is to design efficient *property testers.* A property tester for $\Pi$ is an algorithm that takes as input a distance parameter $\epsilon$ and a (possibly implicit) description of $\mathcal{D}$. The property tester has *oracle access* to the input function $f$ (for each $x \in \mathcal{D}$ it may ask queries of the form, "What is the value of $f(x)$?"). A property tester must

- accept every function $f \in \Pi$; and
- reject every function $f$ that is $\epsilon$-far from $\Pi$ with probability at least $\frac{2}{3}$.[2]

[2]We consider a *one-sided error* model, though in the literature a *two-sided error* model has also

Notice that *if $f \notin \Pi$ and $f$ is not $\epsilon$-far from $\Pi$, then the outcome of the algorithm can go either way.*

*Complexity of property testers.* There are two types of possible complexity measures for property testers: the *query complexity* and the *running time.* In this paper we focus our attention on the query complexity, which measures the number of queries asked by a property testing algorithm.

DEFINITION 2.4. *The number of queries to the oracle is the* query complexity *of the property tester.*

## 3. Abstract combinatorial programs.

In this section we introduce *abstract combinatorial programs* (ACPs). An ACP is a combinatorial structure defined over a *ground set* of *atom items.* Some subsets of the ground set can describe possible "basic" configurations, and they are called the *bases* of the abstract combinatorial program. Furthermore, there is a relationship between atom items and bases: Each atom item is either *consistent* with a given basis or *violates* it; this relation is described by a *violation function.*

ACPs can be used to highlight combinatorial features of property testing problems. In typical applications the *ground set* depends on the problem under consideration and corresponds in a natural way to the basic items of the considered problem. For example, when we want to apply ACPs to graph problems, then the ground set might be the set of vertices of the graph, and when we consider properties of point sets, the ground set might be the set of points.

The set of *bases* describes possible "basic" configurations of the corresponding problem. If we consider a graph coloring problem, then a basis might correspond to a subset of vertices $W$ together with an associated coloring of $W$. For technical reasons we define every basis as a pair $(W, \ell)$, where $W$ is a subset of the ground set and $\ell$ is an index describing a configuration of $W$ (for example, in the graph coloring example above, it might encode a coloring of vertices in $W$).

The *violation function* describes for each basis $b$ and each atom item $x$ whether $x$ is consistent with $b$ or not. If $x$ is not consistent with $b$, then we say *$x$ violates $b$.* If every atom item is consistent with a basis, then we call this basis *feasible.* Normally, the violation function depends on the input instance. For the graph coloring example above one could define the violation function such that a vertex $v$ violates a basis (colored vertex set $W$) if and only if in the input graph the $k$-coloring of $W$ cannot be extended to a proper $k$-coloring of $W \cup \{v\}$.

Formally, we define an ACP in the following way.

DEFINITION 3.1. *An ACP is a triple $(\mathcal{C}, \mathcal{B}, \varpi)$, where*

- *$\mathcal{C}$ is a finite set called* ground set*;*
- *$\mathcal{B} \subseteq \{(W, \ell) : W \subseteq \mathcal{C}, \ell \in \mathbb{N}\}$ is a set of* bases*; and*
- *$\varpi : \mathcal{B} \to 2^{\mathcal{C}}$ is a* violation function.

*For each basis $b \in \mathcal{B}$ the set $\varpi(b)$ is the set of atom items violating $b$. A basis $b$ is* feasible *if $\varpi(b) = \emptyset$. An ACP is* feasible *if it has a feasible basis.*

Before we introduce some further definitions we give an example of how problem instances can be formulated as ACPs.

*Example* 1. We consider the problem of testing if a function $f : \mathbb{F} \to \mathbb{F}$ over a finite field $\mathbb{F}$ is a polynomial of degree at most $d$. We use the standard distance measure: a function is $\epsilon$-far from being a polynomial of degree at most $d$ if one has

been considered. In the two-sided error model the goal is to distinguish with probability at least $\frac{2}{3}$ between the case $f \in \Pi$ and the case of $f$ being $\epsilon$-far from $\Pi$.

to change more than $\epsilon \cdot |\mathbb{F}|$ function values to obtain a polynomial of degree no more than $d$.

In many cases (as in this example) one can formulate a problem instance as an ACP by using the domain of the tested functions as the ground set of the ACP. Consequently, in this example we have $\mathcal{C} = \mathbb{F}$. Bases typically correspond to "solutions" of the problem under consideration. In our example a basis should therefore correspond to a polynomial of degree at most $d$. By the fundamental theorem of algebra which states that a degree $d$ polynomial is uniquely defined by $d+1$ function values, we define the bases to be the set of $(d+1)$-tuples from $\mathcal{C}$. Thus, the set of bases is defined as

$$\mathcal{B} = \{(W, 1) : W \in \mathbb{F}^{d+1}\} \ .$$

We associate with each basis $(W, 1)$ the unique polynomial $p : \mathbb{F} \to \mathbb{F}$ with $p_{|W} = f_{|W}$. Then we define the violation function in a straightforward way: A basis $b = (W, 1)$ is violated by an atom item $c \in \mathcal{C}$ if $f(c) \neq p_b(c)$, where $p_b$ is the polynomial associated with $b$. Thus we get

$$\varpi(b) = \{c \in \mathcal{C} : f(c) \neq p_b(c)\} \ .$$

In this example we did not use the second parameter of the bases. This parameter comes into play when a single set of input constraints might correspond to multiple solutions of the problem. One such example can be found in section 5, where we consider clustering problems.

It is easy to see that the ACP in our example is feasible if and only if the corresponding function is a polynomial of degree at most $d$. Furthermore, if $f$ is $\epsilon$-far from being a polynomial of degree at most $d$, then every basis in the ACP is violated by more than $\epsilon \cdot |\mathbb{F}|$ atom items.

We are now interested in the problem of testing the feasibility of ACPs. Our property testing algorithm will explore properties of ACPs for subsets of the ground set, and for this we need further definitions.

DEFINITION 3.2 (ACP dimension and width). *Let $\mathcal{P}$ be an ACP. The* dimension *of $\mathcal{P}$,* $\dim(\mathcal{P})$, *is defined as* $\max\{|W| : (W, \ell) \in \mathcal{B}\}$. *The* width *of $\mathcal{P}$, width($\mathcal{P}$), is defined as* $\max\{\ell : (W, \ell) \in \mathcal{B}\}$.

DEFINITION 3.3 (self-feasible bases). *Let $\mathcal{P} = (\mathcal{C}, \mathcal{B}, \varpi)$ be an ACP. We say a basis $b = (W, \ell) \in \mathcal{B}$ is* covered *by a subset $C^* \subseteq \mathcal{C}$ if $W \subseteq C^*$. We say that a basis $b$ is* feasible *for a subset $C^* \subseteq \mathcal{C}$ if no $c \in C^*$ violates $b$. We say a subset $C^* \subseteq \mathcal{C}$* contains a self-feasible basis *if there is a basis $b$ that is covered by $C^*$ and that is feasible for $C^*$.*

In the next section, we design a property tester for feasibility of ACPs. We assume that the algorithm can determine for a set $S \subseteq \mathcal{C}$ if $S$ has a self-feasible basis or not. The size of the set $S$ should be as small as possible (the size of this set could be seen as the query complexity of the algorithm). To ensure that our property tester has a one-sided error, we consider only *monotone* ACPs.

DEFINITION 3.4 (monotonicity). *Let $\mathcal{P} = (\mathcal{C}, \mathcal{B}, \varpi)$ be an ACP with dimension* $\dim(\mathcal{P})$. *$\mathcal{P}$ is called* monotone *if it is either not feasible or if (it is feasible and) every subset $S \subseteq \mathcal{C}$ with $|S| \geq \dim(\mathcal{P})$ contains a self-feasible basis.*

## 3.1. Testing ACPs.

**3.1. Testing ACPs.** In this section we design a property tester for monotone ACPs. We first have to define when an ACP is far from feasible. We do this directly without specifying a distance measure between ACPs.

Definition 3.5. *An ACP is* $\epsilon$-far from feasible *if every basis is violated by more than $\epsilon \cdot |\mathcal{C}|$ objects from the ground set $\mathcal{C}$.*

A property tester for ACPs is an algorithm that (i) accepts every feasible ACP and (ii) rejects with probability at least $\frac{2}{3}$ every ACP that is $\epsilon$-far from feasible. The following is our main theorem, which establishes the quality of a simple property tester for ACPs.

Theorem 3.6 (testing ACPs). *Let $\mathcal{P} = (\mathcal{C}, \mathcal{B}, \varpi)$ be an ACP with dimension at most $\delta$ and width at most $\varrho$. Then there exists $s$ with*

$$s = \Theta(\epsilon^{-1} \cdot (\delta \cdot \ln(\delta/\epsilon) + \ln \varrho)) \ ,$$

*such that the algorithm*

```
ACP-TESTER(P, ε).
    Sample a set S of s objects from C uniformly at random
    **if** S contains a self-feasible basis **then** accept P
    **else** reject P
```

1. *accepts $\mathcal{P}$ if $\mathcal{P}$ is monotone and feasible, and*
2. *rejects $\mathcal{P}$ with probability at least $2/3$ if $\mathcal{P}$ is $\epsilon$-far from feasible.*

*Proof.* Let $\mathcal{P} = (\mathcal{C}, \mathcal{B}, \varpi)$ be an ACP that is $\epsilon$-far from feasible. Let $\mathcal{P}$ have dimension at most $\delta$ and width at most $\varrho$. For a basis $b = (W, \ell)$, let $\mathcal{E}_b$ be the random event (with respect to the random choice of $S$) that $W \subseteq S$ and that none of the elements from $\varpi(b)$ is in $S$. Now, in order to prove the theorem it is sufficient to show that with the probability larger than or equal to $\frac{2}{3}$ for none of $b \in \mathcal{B}$ the event $\mathcal{E}_b$ holds.

For every $r$, $0 \le r \le \delta$, let $\Delta_r$ be the set of all $b = (W, \ell) \in \mathcal{B}$ with $|W| = r$. Let us fix an arbitrary $b \in \Delta_r$. Then we have

$$\mathbf{Pr}[\mathcal{E}_b] \ = \ \frac{\binom{n-r-|\varpi(b)|}{s-r}}{\binom{n}{s}} \ \le \ \frac{\binom{(1-\epsilon)\,n-r}{s-r}}{\binom{n}{s}} \ .$$

Since $\mathcal{P}$ has dimension at most $\delta$ and width at most $\varrho$, we have $|\Delta_r| \le \varrho \cdot \binom{n}{r}$ for every $r \ge 0$. Furthermore, we have $|\Delta_r| = 0$ for all $r > \delta$. Therefore, by the union bound we obtain

$$\begin{aligned}
\mathbf{Pr}[\exists b \in \mathcal{B} : \mathcal{E}_b] \le \sum_{b \in \mathcal{B}} \mathbf{Pr}[\mathcal{E}_b] \ &= \ \sum_{r=0}^{\delta} \sum_{b \in \Delta_r} \mathbf{Pr}[\mathcal{E}_b] \ \le \ \varrho \cdot \sum_{r=0}^{\delta} \binom{n}{r} \cdot \frac{\binom{(1-\epsilon)\,n-r}{s-r}}{\binom{n}{s}} \\
&= \varrho \cdot \sum_{r=0}^{\delta} \binom{s}{r} \cdot \frac{((1-\epsilon)n - r) \cdots ((1-\epsilon)n - s + 1)}{(n-r) \cdots (n-s+1)} \\
&\le \varrho \cdot \sum_{r=0}^{\delta} s^r \cdot (1-\epsilon)^{s-r} \ \le \ \varrho \cdot \sum_{r=0}^{\delta} s^r \cdot e^{-\epsilon(s-r)} \\
&\le \varrho \cdot \delta \cdot s^{\delta} \cdot e^{-\epsilon(s-\delta)} \ \le \ \varrho \cdot \delta \cdot s^{\delta} \cdot e^{-\epsilon(s-s/2)} \ ,
\end{aligned}$$

where we assume in the last inequality that $s \ge 2\delta$. Then we set $s' = (\delta\, \epsilon^{-1}\, \ln(3\,\delta\,\varrho))^3$ and

$$s = 2\,\epsilon^{-1}\,(\delta\, \ln s' + \ln(3\,\delta\,\varrho)) \ .$$

With these choices, we have

$$\begin{aligned} s &= 2\,\epsilon^{-1}\cdot(\delta\,\ln s' + \ln(3\,\delta\,\varrho)) \;\le\; 2\,\epsilon^{-1}\,\delta\,\ln s'\,\ln(3\,\delta\,\varrho) \\ &\le 2\,(\epsilon^{-1}\,\delta\,\ln(3\,\delta\,\varrho))^2 \;\le\; (\delta\,\epsilon^{-1}\,\ln(3\,\delta\,\varrho))^3 \;=\; s' \enspace . \end{aligned}$$

We conclude that

$$\varrho\cdot\delta\cdot s^{\delta}\cdot e^{-\epsilon(s-s/2)} \;\le\; \varrho\cdot\delta\cdot s^{\delta}\cdot(s')^{-\delta}\cdot(3\delta\cdot\varrho)^{-1} \;\le\; 1/3 \enspace .$$

Hence, with probability at least $\frac{2}{3}$ all $b = (W, \ell) \in \mathcal{B}$ with $W \subseteq S$ are violated by $S$, which completes the proof of the first part of the theorem. If $\mathcal{P}$ is monotone and feasible, then every set $X \subseteq \mathcal{C}$ of size at least $\dim(\mathcal{P})$ contains a self-feasible basis. Therefore, $S$ must contain a self-feasible basis because $s \ge \dim(\mathcal{P})$. Hence the tester accepts the input. It remains to show that

$$s = \Theta(\epsilon^{-1}\cdot(\delta\cdot\ln(\delta/\epsilon) + \ln\varrho)) \enspace .$$

We have

$$\begin{aligned} s &= 2\,\epsilon^{-1}\,(\delta\,\ln s' + \ln(3\,\delta\,\varrho)) \;=\; \Theta(\epsilon^{-1}\,(\delta\,(\ln(\delta\,\epsilon^{-1}) + \ln\ln(\delta\,\varrho)) + \ln(\delta\,\varrho))) \\ &= \Theta(\epsilon^{-1}\,(\delta\,(\ln(\delta\,\epsilon^{-1}) + \ln\ln\varrho) + \ln\varrho)) \;=\; \Theta(\epsilon^{-1}\,(\delta\,\ln(\delta/\epsilon) + \ln\varrho)) \end{aligned}$$

by the observation that for $\delta \ge \sqrt{\ln\varrho}$ we have $\delta\ln\ln\varrho = \mathcal{O}(\delta\ln(\delta/\epsilon))$ and for $\delta < \sqrt{\ln\varrho}$ we have $\delta\ln\ln\varrho = o(\ln\varrho)$. □

COROLLARY 3.7. *Algorithm* ACP-TESTER *is a property tester for monotone ACPs.*

*Proof.* The proof follows immediately from Theorem 3.6. □

## 4. Property testing vs. testing ACPs.

Our motivation to introduce ACPs was to study their relation to property testing problems. We now prove a theorem that shows how we can use ACPs to prove for certain properties that there is an efficient property tester. Roughly speaking, a property can be tested with small query complexity if for every problem instance there is an equivalent (in the sense of property testing) ACP of small dimension and width.

We now present a first (simple) variant of Theorem 3.6. Then we give some examples and discuss in detail how our theorem can be used to prove the existence of a property tester with small query complexity. In most examples the obtained algorithm also has a small running time.

Our approach of using the framework of ACPs to study property testers of functions $f \in \mathcal{F}$ is to reduce testing of $f$ to testing certain ACPs. *In this section we consider only ACPs whose ground set $\mathcal{C}$ is the domain $\mathcal{D}$ of the function $f$.* Later, in section 7, we show how to deal with other, more general cases.

THEOREM 4.1. *Let $\mathcal{F}$ be a set of functions from a finite set $\mathcal{D}$ to a set $\mathcal{R}$ and let $\Pi$ be a property of $\mathcal{F}$. Let $0 < \epsilon < 1$ and let $\delta, \varrho \in \mathbb{N}$. If for every $f \in \mathcal{F}$ there exists an ACP $\mathcal{P}_f$ with $\dim(\mathcal{P}_f) \le \delta$ and width$(\mathcal{P}_f) \le \varrho$ such that*

- (distance preserving) *if $f$ is $\epsilon$-far from $\Pi$, then $\mathcal{P}_f$ is $\epsilon$-far from feasible; and*
- (feasibility preserving) *for every $X \subseteq \mathcal{C}$ with $|X| \ge \delta$: If there exists $g \in \Pi$ with $f_{|X} = g_{|X}$, then $X$ contains a self-feasible basis;*

*then there exists $s = \Theta(\epsilon^{-1}\cdot(\delta\cdot\ln(\delta/\epsilon) + \ln\varrho))$ such that the following algorithm is a property tester for property $\Pi$:*

```
TESTER($f, \epsilon$).
    Sample a set $S$ of $s$ elements in $\mathcal{D}$ uniformly at random
    if $f_{|S} = g_{|S}$ for some $g \in \Pi$ then accept $f$
    else reject $f$
```

*Proof.* In order to show that $\text{Tester}(f, \epsilon)$ is a property tester for $\Pi$, we have to prove that every function having property $\Pi$ is accepted by the tester, and every function that is $\epsilon$-far from having property $\Pi$ is rejected with probability at least $\frac{2}{3}$. If $f \in \Pi$, then for every $X \subseteq \mathcal{C}$ we have $f_{|X} = g_{|X}$ with $g = f \in \Pi$. This immediately implies that every $f \in \Pi$ is accepted by $\text{Tester}(f, \epsilon)$. Therefore, it remains to prove that if $f$ is $\epsilon$-far from $\Pi$, then the algorithm rejects the input with probability greater than or equal to $\frac{2}{3}$. We prove this by relating ACP-$\text{tester}(\mathcal{P}, \epsilon)$ to $\text{Tester}(f, \epsilon)$ and by applying Theorem 3.6.

By the distance preserving property, if $f$ is $\epsilon$-far from $\Pi$, then $\mathcal{P}_f$ is $\epsilon$-far from feasible. Furthermore, by Theorem 3.6, if $\mathcal{P}_f$ is $\epsilon$-far from feasible, then ACP-$\text{tester}(\mathcal{P}_f, \epsilon)$ rejects $\mathcal{P}_f$ with probability greater than or equal to $\frac{2}{3}$. $\mathcal{P}_f$ is rejected by ACP-$\text{Tester}(\mathcal{P}_f, \epsilon)$ only if the chosen sample set $S$ contains no self-feasible basis. But the feasibility preserving property implies that if there is $g \in \Pi$ that agrees with $f$ on the sample set, then every set $X \subseteq \mathcal{C}$ with $|X| \geq \delta \geq \dim(\mathcal{P}_f)$ contains a self-feasible basis. By the fact that $|S| \geq \delta$ we can conclude that $S$ contains a self-feasible basis if there exists a $g \in \Pi$ that agrees with $f$ on the sample set $S$. Therefore, we can conclude that if $f$ is $\epsilon$-far from $\Pi$, then with probability at least $\frac{2}{3}$ there is no such $g \in \Pi$ with $f_{|S} = g_{|S}$. Hence, $f$ is rejected by $\text{Tester}(f, \epsilon)$ with probability at least $\frac{2}{3}$. This implies that $\text{Tester}(f, \epsilon)$ is a property tester for $\Pi$. ☐

## 5. Clustering problems.

In this section, we apply our framework of testing ACPs to test two classical clustering problems. Clustering deals with the problem of partitioning a set of items into different groups called *clusters* such that a given optimization function is minimized. If we consider the corresponding decision problem, we want to know if a clustering with a given optimization value exists.

We consider two clustering problems of point sets in the $\mathbb{R}^d$: the *radius $k$-clustering* and the *diameter $k$-clustering.* Both problems have been analyzed in the context of property testing, and it is known that they possess efficient property testers [3]. Our goal is to show that these two problems can also be analyzed using our framework; in the case of the diameter clustering problem we also significantly improve the query complexity.

### 5.1. Radius clustering.

The decision version of the *radius $k$-clustering* problem in the Euclidean space $\mathbb{R}^d$ [3, 32], [51, p. 325] (sometimes also called the Euclidean $k$-center problem) consists of verifying whether a given set $P$ of $n$ points in $\mathbb{R}^d$ can be partitioned into $k$ sets such that the points in each set are contained in a unit ball. If such a partition exists, we say that $P$ is *$k$-clusterable.* We assume that $P$ is in a general position and that $P$ is represented as a function $f : [n] \to \mathbb{R}^d$, where $f(i)$ describes the location of the $i$th input point. Let $\mathcal{F}$ denote the set of functions representing point sets of size $n$ and let $\Pi \subseteq \mathcal{F}$ denote the set of functions representing point sets that are $k$-clusterable. The distance between two point sets is given by the standard distance measure between functions (see Definition 2.3), which is consistent with the following definition.

DEFINITION 5.1. *A set $P$ of $n$ points in $\mathbb{R}^d$ is* $\epsilon$-far from being $k$-clusterable *if more than $\epsilon n$ points must be deleted from $P$ to obtain a point set that is $k$-clusterable.*

In order to use our framework from Theorem 4.1 we have to describe for every input point set $P$ in $\mathbb{R}^d$ an ACP $\mathcal{P} = (\mathcal{C}, \mathcal{B}, \varpi)$ with $\mathcal{C} = [n]$ that satisfies the two conditions of the theorem. Let us first observe that the radius $k$-clustering property is a combinatorial property, that is, the identifiers of the points in the representation are irrelevant for the property. Thus, we can identify the ground set $\mathcal{C}$ of the ACP with the point set $P$. Hence, a basis of such ACP consists of a small set of points from $P$ (formally, of their corresponding indices) and some additional information (formally encoded as an integer).

We define the bases to specify all possible representations of feasible $k$-clusterings. For simplicity, let us first consider the radius 1-clustering problem. If the point set $P$ is 1-clusterable, then it is contained in some unit ball. Conversely, we can implicitly describe every "possible solution" of the problem by the position of such a unit ball. In a similar way, we can consider every ball with radius at most 1 as a possible solution. Our goal is to describe a subset of these balls implicitly in terms of atom items (points). If $P$ is 1-clusterable, then this subset must contain a ball that contains every point in $P$.

It is known that every finite point set $X$ is contained in a unique (closed) ball of smallest radius (see, e.g., [72]). We denote this ball by $\mathit{sball}(X)$. With every subset $W \subseteq P$ we associate its smallest enclosing ball $\mathit{sball}(W)$. If the radius of $\mathit{sball}(W)$ is at most 1, then this ball can be interpreted as a "possible solution" of the problem and $W$ (formally, the pair $(W, 1)$) as a basis. So we could say that for each $W \subseteq P$ the pair $(W, 1)$ is a basis if and only if the radius of $\mathit{sball}(W)$ is at most 1. But to obtain a query complexity independent of $n$ we need to reduce the number of atoms involved in a basis. To do this, we use the fact that there is always a subset $W \subseteq P$ of cardinality at most $d+1$ such that $\mathit{sball}(W) = \mathit{sball}(P)$ [72]. This motivates us to define $(W, 1)$ as a basis if the following two conditions are satisfied:

- $|W| \le d + 1$; and
- the radius of $\mathit{sball}(W)$ is at most 1.

We can now define a natural violation function in the following way: A basis $(W, 1)$ is violated by all points that are not contained in $\mathit{sball}(W)$. Using this definition we notice two important properties of our construction: (a) if $P$ is 1-clusterable, then $\mathcal{P}$ has a feasible basis, and (b) if $P$ is $\epsilon$-far from 1-clusterable, then every basis in $\mathcal{P}$ is violated by more than $\epsilon\, n$ points.

We can easily extend this definition of a basis to $k$ clusters: A basis for the radius $k$-clustering problem consists of $k$ bases for single clusters. Formally, a basis consists of at most $k\,(d+1)$ points from $P$ and an integer encoding a partition of the $k\,(d+1)$ points into $k$ sets (of size at most $d+1$). The violation function is defined in a straightforward way: a point violates a basis if it is not contained in any of the smallest enclosing balls defined by the bases.

*Bases for radius clustering.* We define the set of bases $\mathcal{B} = \{(W, \ell) : W \subseteq [n], |W| \le (d+1)\,k, 1 \le \ell \le k^{(d+1)\,k}\}$, where the pair $(W, \ell) \in \mathcal{B}$ should be interpreted as follows:

- $W$ is the set of points defining $k$ smallest enclosing balls (clusters); and
- $\ell$ is represented as a vector $\langle \nu_1, \dots, \nu_{(d+1)\,k} \rangle$ of length $(d+1)\,k$, where for $1 \le i \le k$, the $i$th point in $W$ is one of the points defining the smallest enclosing ball containing cluster number $\nu_i \in [k]$.

We say a basis $b \in \mathcal{B}$ is *valid* if, for every set $W'$ of points defining one of the $k$ smallest enclosing balls in $b$, the radius of $\mathit{sball}(W')$ is at most 1.

It is easy to see that with such a definition of the bases, the ACP designed for the radius clustering problem has $\dim(\mathcal{P}) = (d+1)\,k$ and $width(\mathcal{P}) = k^{(d+1)\,k}$.

*Violation function for radius clustering.* We say $p \in \mathcal{C} = [n]$ *violates a basis* $b \in \mathcal{B}$ if $b$ is not valid or the point $p$ (located at $f(p)$) is not contained in any of the $k$ balls defined by $b$. (Notice that all nonvalid bases are violated by all ground set elements.)

Once we have defined formally the ACP $\mathcal{P}$ for every instance of the radius clustering problem, we have to verify the prerequisites of Theorem 4.1: the distance preserving and the feasibility preserving properties.

*Distance preserving property.* If $P$ is $\epsilon$-far from being $k$-clusterable, then for every set of $k$ unit balls in $\mathbb{R}^d$ there is always a set of more than $\epsilon\, n$ points in $P$ that are not contained in any of the balls. By definition every basis corresponds to such a set of unit balls and the violation function is defined according to these balls. Thus every basis $b \in \mathcal{B}$ must be violated by more than $\epsilon\, n$ elements from $\mathcal{C}$. This implies the distance preserving property.

*Feasibility preserving property.* Every set $S$, $|S| \geq \delta$, that is $k$-clusterable is contained in $k$ unit balls. Thus we can partition $S$ into $k$ clusters $S_1, \dots, S_k$, each of which is contained in a unit ball. Furthermore, there exist sets $W_i \subseteq S_i$ with $sball(W_i) = sball(S_i)$ and $|W_i| \leq d+1$. The sets $W_i$ define a basis in $\mathcal{B}$ which is covered by $S$ and is feasible for $S$. This implies the feasibility preserving property.

*$L_p$ metrics.* We remark that the proof of [72] can be generalized to any $L_p$ metric. Hence, our analysis holds for any $L_p$ metric as well.

To summarize our discussion in this section, using our framework we can apply Theorem 4.1 to obtain a property tester for the radius clustering problem with a query complexity of $\widetilde{\mathcal{O}}(d\,k/\epsilon)$.

THEOREM 5.2. *There is a property tester for the radius clustering problem (in any $L_p$ metric) with query complexity of*

$$\mathcal{O}(d\,k\,\epsilon^{-1}\,\ln(d\,k/\epsilon)) = \widetilde{\mathcal{O}}(d\,k/\epsilon)\ .$$

**5.2. Diameter clustering.** The decision version of the diameter $k$-clustering problem (see [3], [10, problem ND54], [41, problem MS9], [51, p. 326]) is defined as follows: Given a point set $P$ in $\mathbb{R}^d$ and a positive integer $k$, can $P$ be partitioned into $k$ disjoint sets (clusters) $C_1, \dots, C_k$ such that for every $i$, $1 \leq i \leq k$, and every $x, y \in C_i$ it holds that $dist(x,y) \leq 1$? If such a partition exists, we say that $P$ is $k$-clusterable. As before, we assume in the property testing setting that the point set is represented by a function $f : [n] \to \mathbb{R}^d$.

Unlike for the radius clustering problem (and for all other problems discussed in this paper) we *do not use* the standard distance measure. This is because under the standard distance measure every property tester must have a query complexity of $\Omega(\sqrt{n})$ [3]. Therefore, we use instead the bicriteria distance measure that was proposed first in [3] and which is defined in the following way.

DEFINITION 5.3 (see [3]). *Let $P$ be a point set in $\mathbb{R}^d$ and $k$ a positive integer. We say $P$ is* $(\epsilon, \beta)$-far from being $k$-clusterable *if, for every partition of $P$ into sets $C_0, C_1, \dots, C_k$ satisfying $dist(x,y) \leq 1+\beta$ for all $1 \leq i \leq k$ and $x, y \in C_i$, it holds that $C_0 > \epsilon \cdot |P|$.*

It is known that under this distance measure there is a property tester with query complexity $\widetilde{\mathcal{O}}(k^2/\epsilon \cdot (2/\beta)^{2\,d})$ for the diameter $k$-clustering problem [3]. In this section we improve this result using our framework and decrease the query complexity to $\widetilde{\mathcal{O}}(k/\epsilon \cdot (2/\beta)^d)$. Our proof uses combinatorial arguments similar to those that appear implicitly in the proof presented in [3], but the use of our framework allows us to obtain a significant improvement in the complexity. Our goal is to design an efficient property tester that for given $k$, $\epsilon$ and $\beta > 0$, (i) accepts every point set that is $k$-clusterable and (ii) rejects with probability at least $\frac{2}{3}$ every input that is $(\epsilon, \beta)$-far from being $k$-clusterable. As in our analysis for the radius clustering problem, we denote by $\mathcal{F}$ all functions representing point sets of size $n$ and by $\Pi \subseteq \mathcal{F}$ all functions representing point sets that are $k$-clusterable.

We begin our discussion with the construction of bases for a single cluster. We use the following notation: A *cluster* is a nonempty set of points $C$ in $\mathbb{R}^d$ with $dist(x, y) \leq 1$ for every $x, y \in C$.

DEFINITION 5.4. *Let $C$ be a cluster. The* kernel $kern(C)$ of $C$ *is defined as the intersection of unit balls with centers at the points in $C$.*

We use the following simple properties of a kernel.

CLAIM 5.5. *Let $C$ be a cluster. Then we have the following:*

1. *$C \subseteq kern(C)$;*
2. *there exists a unit ball containing all the points in $C$; and*
3. *if $p \in kern(C)$, then $dist(x, y) \leq 1$ for every $x, y \in C \cup \{p\}$.*

*Proof.* (1) Since $dist(x, y) \leq 1$ for every $x, y \in C$, each point $x \in C$ is contained in every unit ball with the center at any other point $y \in C$, and hence $x$ is contained in $kern(C)$. (2) Since $C \neq \emptyset$, from the previous property we get $kern(C) \neq \emptyset$. Let us pick any point $x \in kern(C)$. Since $x$ is contained in all unit balls with centers at the points in $C$, it is at the distance at most 1 from every point in $C$. Therefore all points in $C$ are contained in the unit ball with the center at $x$. (3) If $p \in kern(C)$, then $p$ is contained in all unit balls with centers at the points in $C$, and thus its distance to every point in $X$ is at most 1. ◻

Now, in order to use our framework, from Theorem 4.1 we describe for every input set $P$ of $n$ points in $\mathbb{R}^d$ an ACP $\mathcal{P} = (\mathcal{C}, \mathcal{B}, \varpi)$ with $\mathcal{C} = [n]$ that satisfies the preconditions of the theorem. Following the arguments from the radius clustering case we identify the ground set $\mathcal{C}$ of the ACP with the input point set $P$. We first consider the case $k = 1$.

We start by making an observation about the kernel of a cluster $C$: for any point $p$, $C \cup \{p\}$ is a cluster if and only if $p$ is in the kernel of $C$. Thus we would like a good basis to contain exactly those elements from $C$ that define the "boundary" of $kern(C)$. Unfortunately, it might be that almost every element of $C$ defines the boundary of $C$, in which case the bases would be too large. Therefore, instead we find a small set of points $W$ in $C$ that approximates the kernel of $C$. We choose a basis for a cluster $C$ to be any maximal subset $W \subseteq C$ with the property that all points in $W$ have a mutual pairwise distance of at least $\beta$. In this way, we ensure that (a) the kernel is well approximated and (b) the number of points defining the kernel of a cluster is small.

Our first result shows that every basis for a single cluster is defined by at most $(1 + \frac{2}{\beta})^d$ points.

LEMMA 5.6. *Let $C$ be a cluster and let $W$ be a subset of $C$ such that for every $p, q \in W$ we have $dist(p, q) \geq \beta > 0$. Then $|W| \leq (1 + 2/\beta)^d$.*

*Proof.* Let $C$ and $W$ be as stated in the lemma. If we draw balls of radius $\beta/2$ centered at every point in $W$, then all these balls are pairwise disjoint. By property 2 in Claim 5.5, all points in $W$ are contained in some unit ball because $W \subseteq C$ and $C$ is a cluster. Therefore, if we draw balls of radius $\beta/2$ centered at every point in $W$, then all these balls are contained in a ball of radius $1 + \beta/2$. Since all these small balls are disjoint, we have the following upper bound for the size of $W$, where $Vol()$

denotes the volume of the object:

$$|W| \cdot Vol(\text{ball of radius } \beta/2) \ \le \ Vol(\text{ball of radius } 1+\beta/2) \ .$$

Since the volume of a $d$-dimensional ball of radius $r$ is equal to[3] $\frac{r^d \cdot \pi^{d/2}}{\Gamma(1+d/2)}$, we obtain an upper bound of $(1+(2/\beta))^d$ for the size of $W$. ◻

To formalize our definition of bases we need the following.

DEFINITION 5.7. *Let $P$ be a point set in $\mathbb{R}^d$, and let $\beta$ be a positive real. Let $C$ be a cluster. We say a point $p \in P$ is* $\beta$-covered *by $C$ if $p \in kern(C)$, and there is $q \in C$ such that $dist(p,q) \le \beta$.*

We say a pair $b = (W, \ell)$ is a *basis* for the diameter 1-clustering problem if $W$ is a subset of $P$ of size at most $(1+\frac{2}{\beta})^d$ and $\ell = 1$. We say a basis $(W,\ell)$ is *valid* if for all $p, q \in W$ we have $\beta < dist(p,q) \le 1$. It remains to define the violation function. If a basis is not valid, it is violated by every point in $P$. If a basis is valid, we have two different types of violation: First, a point $p$ violates a basis $b = (W,1)$ if $p \notin kern(W)$. This is the straightforward type of violation. If a point is not in the kernel of $W$, then it cannot belong to the same cluster. The second type of violation is different. A point $p \in kern(W)$ violates $b$ if $p$ is not $\beta$-covered by $W$. The intuition behind this definition is such that a point violates a basis if it is consistent with the current basis of the cluster, but it changes the kernel significantly, and hence it is no longer a good implicit description of the solution of the clustering problem.

*Bases for diameter clustering.* We can extend our definition of bases for the diameter 1-clustering problem to arbitrary $k$ in the following way: A basis for the diameter $k$-clustering problem is an encoding of $k$ sets $W_1, \dots, W_k \subseteq P$ each of size at most $(1+\frac{2}{\beta})^d$. A basis is *valid* if for every $p, q \in W_i$, $1 \le i \le k$, it holds that $\beta < dist(p,q) \le 1$. Formally, a basis is a set $W = \bigcup_i W_i$ with an integer encoding the partition of $W$ in the sets $W_i$.

LEMMA 5.8. *For any point set in $\mathbb{R}^d$, the ACP $\mathcal{P}$ for the diameter $k$-clustering problem has dimension at most $k \cdot (1+2/\beta)^d$ and width at most $k^{k\cdot(1+2/\beta)^d}$.*

*Proof.* The dimension of the ACP follows immediately from the definition of the bases. The width follows from the fact that every point of a basis can belong to one of $k$ sets; that is, we have (at most) $k$ choices for each point of the basis. ◻

*Violation function for diameter clustering.* A basis $b$ that is an encoding of the sets $W_1, \dots, W_k$ is violated by a point $p \in P$ if $b$ is not valid or if $p$ violates every $W_i$ (seen as a basis for the 1-clustering problem), $1 \le i \le k$.

*Feasibility preserving property.* In order to show the feasibility preserving property we have to show that every $k$-clusterable set $S \subseteq P$ of size at least $\delta = k \cdot (1+2/\beta)^d \ge \dim(\mathcal{P})$ has a self-feasible basis. If $S$ is $k$-clusterable, then there exists a partition of $S$ into $k$ clusters $C_1, \dots, C_k$. Since for every $W_i \subseteq C_i$ it holds that $kern(C_i) \subseteq kern(W_i)$, we know that there exist sets $W_i$ with the property that for each $p, q \in W_i$ we have $\beta < dist(p,q) \le 1$ and for each $p \in C_i$ and $q \in W_i$ we have $dist(p,q) \le \beta$. By Lemma 5.6 and the bound of the size of the bases, the feasibility preserving property follows.

*Distance preserving property.* We prove the distance preserving property by contradiction. Let us assume $P$ is $(\epsilon,\beta)$-far from being $k$-clusterable, and suppose there is a basis $b$ encoding the sets $W_1, \dots, W_k$ that is violated by less than $\epsilon\, n$ points. We

[3]Here, $\Gamma()$ is Euler's Gamma (factorial) function, defined as $\Gamma(x) = \int_0^\infty t^{x-1}\, e^{-t}\, dt$ for all positive $x$. It is well known that $\Gamma(x+1) = x\,\Gamma(x)$ and that for integer $x \ge 0$ we have $\Gamma(x+1) = x!$ and $\Gamma(x+\frac{1}{2})! = \sqrt{\pi} \cdot ((2\,x)!)/(x! \cdot 4^x)$.

delete all points in $P$ that violate $b$ and let $P^*$ be the remaining point set. Since all the points in $P^*$ are $\beta$-covered by some $W_i$, for each point $p \in P^*$ there is a $W_i$ with $p \in kern(W_i)$ and for which there exists $q_p \in W_i$ with $dist(p, q_p) \leq \beta$. We assign each such point $p$ to the cluster corresponding to $W_i$. Observe that all points in the cluster are contained in $kern(W_i)$. Furthermore, for every point $r \in kern(W_i)$ the distance between $p$ and $r$ is not larger than the distance from $p$ to $q_p$ plus the distance from $q_p$ to $r$. Hence, we can conclude that the distance between two points in the cluster (both of which must be contained in $kern(W_i)$) is at most $1 + \beta$. This implies that $P^*$ can be partitioned into $k$ clusters of diameter at most $1 + \beta$ each, which is a contradiction.

**5.2.1. Generalization to $L_p$ metrics.** It is not hard to see that our entire analysis carries over to arbitrary $L_p$ metrics. Indeed, all our arguments but the volume argument in the proof of Lemma 5.6 are independent of the metric space. The volume arguments in the proof of Lemma 5.6 can be easily extended to an arbitrary $L_p$ metric by observing that the volume of a ball with radius $r$ in the $d$-dimensional $L_p$ space is equal to $r^d \cdot (2\,\Gamma(1 + 1/p))^d / \Gamma(1 + d/p)$; see, e.g., [65, p. 11]. Using this bound in the proof of Lemma 5.6, one can easily see that also that the lemma is true for arbitrary $L_p$ metrics.

Now, we can summarize our discussion above and apply Theorem 4.1 to obtain the following result.

THEOREM 5.9. *There is a property tester for the diameter $k$-clustering problem in an arbitrary $L_p$ metric with the query complexity of*

$$\widetilde{\mathcal{O}}(k \cdot \epsilon^{-1} \cdot (1 + (2/\beta))^d) \ .$$

**6. Reversal distance.** In this section we consider the *reversal distance problem.* In sorting by reversals one is asked to compute the shortest sequence of (interval) *reversals* that transforms a given permutation $\pi$ into the identity permutation. The number of reversals that are necessary is called the *reversal distance* between $\pi$ and the identity permutation.

We now introduce the problem formally. Let $\mathbb{S}_n$ denote the set of all permutations of $[n]$.

DEFINITION 6.1. *A reversal $\varrho\langle i, j\rangle$ of an interval $[i, j]$, $1 \leq i \leq j \leq n$, is the permutation*

$$\begin{pmatrix} 1 & 2 & \dots & i-1 & i & i+1 & \dots & j-1 & j & j+1 & \dots & n \\ 1 & 2 & \dots & i-1 & j & j-1 & \dots & i+1 & i & j+1 & \dots & n \end{pmatrix}.$$

*That is, for a permutation $\pi = (\pi_1, \dots, \pi_n) \in \mathbb{S}_n$, $\varrho\langle i, j\rangle$ has the effect of reversing the order of $(\pi_i, \pi_{i+1}, \dots, \pi_j)$ and transforming $\pi$ into*

$$\pi \cdot \varrho\langle i, j\rangle \ = \ (\pi_1, \dots, \pi_{i-1}, \pi_j, \pi_{j-1}, \dots, \pi_i, \pi_{j+1}, \dots, \pi_n) \ .$$

We now define the reversal distance between two permutations.

DEFINITION 6.2. *Given a pair of permutations $\pi = (\pi_1, \dots, \pi_n), \sigma = (\sigma_1, \dots, \sigma_n) \in \mathbb{S}_n$, the* reversal distance *$d_{rev}(\pi, \sigma)$ between $\pi$ and $\sigma$ is the minimum number of reversals needed to transform $\pi$ into $\sigma$ (that is, the minimum number $k$ such that there exists a sequence of reversals $\varrho_1, \varrho_2, \dots, \varrho_k$ with $\pi \cdot \varrho_1 \cdot \varrho_2 \cdots \varrho_k = \sigma$).*

Equivalently, we can compute the number of reversals necessary to transform $\sigma^{-1}\pi$ into the identity permutation $id$. Therefore, we are interested in the reversal distance between a given permutation $\pi$ and the identity permutation. We consider the decision version of the reversal distance problem.

DEFINITION 6.3. *The* reversal distance *problem consists of determining, for a given permutation $\pi \in \mathbb{S}_n$ and an integer $k$, whether the reversal distance $d_{rev}(\pi, id)$ between $\pi$ and the identity permutation $id$ is at most $k$.*

We now formulate the problem as a property testing problem that fits into our framework. The set of functions $\mathcal{F}$ we want to consider is the set of permutations of $[n]$, that is, $\mathcal{F} = \mathbb{S}_n$. We are interested in all permutations that have a reversal distance of at most $k$ to the identity permutation. We can write this as a property $\Pi$ as follows:

$$\Pi = \{\pi \in \mathbb{S}_n : d_{rev}(\pi, id) \le k\} \ .$$

We use the standard distance measure from Definition 2.3, which is equivalent to the following.

DEFINITION 6.4. *A permutation $\pi \in \mathbb{S}_n$ is $\epsilon$-far from having reversal distance smaller than or equal to $k$ if for every sequence of $k$ reversals $\varrho_1, \varrho_2, \ldots, \varrho_k$ the permutation $\pi \cdot \varrho_1 \cdot \varrho_2 \cdots \varrho_k$ disagrees with the identity permutation on more than $\epsilon \cdot n$ places; that is, if $\pi \cdot \varrho_1 \cdot \varrho_2 \cdots \varrho_k = (\sigma_1, \ldots, \sigma_n)$, then $|\{i \in \{1, 2, \ldots, n\} : \sigma_i \ne i\}| > \epsilon \cdot n$.*

In contrast to the clustering problems, the reversal distance property is not combinatorial. Therefore, we have to take the domain of the function into account. For a permutation $\pi = (\pi_1, \ldots, \pi_n)$ we denote atom items by $\pi_i$. This notion covers the fact that the value of domain element $i$ is $\pi_i = \pi(i)$. Hence it captures also the domain of a value of $f$.

Let us notice that we can encode an interval $[i, j]$ by the two domain elements $\pi_i$ and $\pi_j$ (using the fact that $\pi^{-1}(\pi_i) = i$ and $\pi^{-1}(\pi_j) = j$). If we apply a reversal $\varrho$ to $\pi$, then $\pi_i$ and $\pi_j$ *induce* the interval $\big[((\pi \cdot \varrho)^{-1})(\pi_i), ((\pi \cdot \varrho)^{-1})(\pi_j)\big]$ (for this reason we want to work with $\pi_i$ rather than with $i$). We denote the interval induced by two elements $\pi_i$ and $\pi_j$ by $[\pi_i, \pi_j]$.

We say a reversal $\varrho\langle r, s\rangle$ *splits* an interval $[\pi_i, \pi_j]$ if $i < r \le j$ or $i \le s < j$ (or both).

DEFINITION 6.5. *Let $\pi = (\pi_1, \ldots, \pi_n)$ be a permutation and let $[\pi_i, \pi_j]$ denote an interval. We say that a reversal $\varrho\langle k, \ell\rangle$* splits *an interval $[\pi_i, \pi_j]$ if $i < k \le j$ or if $i \le \ell < j$.*

We generalize this notion to $k$-reversals.

DEFINITION 6.6. *Let $\pi = (\pi_1, \ldots, \pi_n)$ be a permutation. A $k$-reversal $\varrho = \varrho_1 \cdot \varrho_2 \cdots \varrho_k$* splits *an interval $[\pi_i, \pi_j]$ if there exists $\ell$, $0 \le \ell < k$, such that $\varrho_{\ell+1}$ splits*

$$[(\pi \cdot \varrho_1 \cdots \varrho_\ell)^{-1}(\pi_i), (\pi \cdot \varrho_1 \cdots \varrho_\ell)^{-1}(\pi_j)] \ .$$

*If $\varrho$ does not split $[\pi_i, \pi_j]$, then we say $\varrho$ is* safe *for $[\pi_i, \pi_j]$.*

Notice that if $\varrho_1, \ldots, \varrho_k$ is *safe* for $[\pi_i, \pi_j]$, then each of the reversals $\varrho_1, \ldots, \varrho_k$ either entirely contains $[\pi_i, \pi_j]$ or it does not contain any $\pi_\ell \in [\pi_i, \pi_j]$. Therefore, in this case, after applying $\varrho_1, \ldots, \varrho_k$ the positions of $\pi_{i+1}, \ldots, \pi_{j-1}$ are determined by the position of $\pi_i$ and $\pi_j$.

*Bases for the $k$-reversal problem.* We define a basis as a set of $2k + 1$ intervals induced by pairs of the atom items of the basis. For each such set we consider only reversals that are safe for these intervals. We say a set of $2k + 1$ intervals is a basis if there exists a sequence of $k$ reversals $\varrho_1, \ldots, \varrho_k$ such that for each atom item $\pi_i$ of the basis $(\pi \cdot \varrho_1 \cdots \varrho_k)^{-1}(\pi_i) = \pi_i$ and if $\varrho_1, \ldots, \varrho_k$ is safe for all intervals induced by the elements involved in the basis.

DEFINITION 6.7. *Let $\pi = (\pi_1, \dots, \pi_n) \in \mathbb{S}_n$. A set $\mathcal{I}$ of $2k+1$ intervals is a valid basis for the reversal distance problem if there is a sequence $\varrho_1, \dots, \varrho_k$ of $k$ reversals such that*

- *$(\pi \cdot \varrho_1 \cdots \varrho_k)^{-1}(\pi_i) = \pi_i$ and $(\pi \cdot \varrho_1 \cdots \varrho_k)^{-1}(\pi_j) = \pi_j$ for each interval $[\pi_i, \pi_j] \in \mathcal{I}$; and*
- *no interval $[\pi_i, \pi_j] \in I$ is split by $\varrho_1, \dots, \varrho_k$.*

*If the set of intervals is a basis $b$, then we associate with it the $k$-reversal $\varrho_b = \varrho_1 \cdots \varrho_k$. (In case that there are different sequences that witness the basis property we choose an arbitrary one.)*

Formally, a basis consists of $4k+2$ atom items and an integer number encoding the $2k+1$ pairs of atom items (an atom item may be paired with itself). The integer number can be seen as a vector of length $2k+1$ having entries with values from $[4k+2] \times [4k+2]$ to specify each of the $2k+1$ pairs.

LEMMA 6.8. *For each instance of the reversal distance problem the corresponding ACP $\mathcal{P}$ has $\dim(\mathcal{P}) \leq 4k+2$ and $width(\mathcal{P}) \leq (4k+2)^{4k+2}$.*

*Proof.* By definition, a basis consists of $4k+2$ atom items. Thus we have $\dim(\mathcal{P}) \leq 4k+2$. Each vector of length $2k+1$ with values from $[4k+2] \times [4k+2]$ can be encoded as an integer number between 1 and $(4k+2)^{4k+2}$. Thus we have $width(\mathcal{P}) \leq (4k+2)^{4k+2}$. ◻

*Violation function for k-reversal distance.* Let $b$ be a basis and let $\varrho_b = \varrho_1 \cdots \varrho_k$ be the $k$-reversal associated with basis $b$. We say $b$ is violated by $\pi_i \in \mathcal{C}$ if $(\pi \cdot \varrho_b)^{-1}(\pi_i) \neq \pi_i$; that is, $\pi_i$ is not moved to position $\pi_i$ when $\varrho_b$ is applied to $\pi$.

*Distance preserving property.* We have associated a $k$-reversal $\varrho_b$ to each basis. An atom item violates a basis if it is not at the correct position when $\varrho_b$ is applied to $\pi$. If a permutation is $\epsilon$-far from having reversal distance smaller than or equal to $k$, then every $k$-reversal puts more than $\epsilon n$ elements to the wrong position. Hence every basis is violated by more than $\epsilon\, n$ elements. Therefore, the distance preserving property is satisfied.

*Feasibility preserving property.* Let $S \subseteq \mathcal{C}$ be a set of atom items and let $\varrho = \varrho_1 \cdots \varrho_k$ be a $k$-reversal with $(\pi \cdot \varrho)^{-1}(\pi_i) = \pi_i$ for each $\pi_i \in S$. We show that in this case $S$ has a self-feasible basis. First we want to construct a set of $2k+1$ intervals that are safe for $\varrho_1, \dots, \varrho_k$. We start with the set of $s-1$ intervals induced by $S$. Now we observe that each reversal $\varrho_i$ can split at most 2 of these intervals. We conclude that at most $2k$ of these intervals are split by $\varrho_1, \dots, \varrho_k$. We can merge adjacent intervals not split by $\varrho_1, \dots, \varrho_k$ and obtain a set of $2k+1$ intervals that are not split by $\varrho_1, \dots, \varrho_k$. Hence there exists a sequence of $k$ reversals that is safe for each of our intervals. Thus these intervals form a basis $b$. It remains to prove that this basis is not violated (the $k$-reversal associated with the basis must not be the $k$-reversal $\varrho$). By our construction of the intervals each $\pi_i \in S$ is contained in a safe interval. Therefore, its position after applying the reversal is uniquely determined by the positions of the endpoints of the interval. Let $S_I \subseteq S$ denote the set of endpoints of intervals of the basis $b$. Since $b$ is a basis there is a $k$-reversal $\varrho_b$ with

$$(\pi \cdot \varrho_b)^{-1}(\pi_i) \;=\; \pi_i \;=\; (\pi \cdot \varrho)^{-1}(\pi_i) \text{ for each } \pi_i \in S_I \;\;.$$

Since the endpoints are mapped to the same places when $\varrho_b$ and $\varrho$ are applied to $\pi$, we can conclude that each other point in $S$ is also mapped to the same place. Hence no $\pi_i \in S$ violates $b$, and we have shown the feasibility preserving property.

Once we have proven the distance and the feasibility preserving properties, Lemma 6.8 and Theorem 4.1 allow us to conclude with the following theorem.

Theorem 6.9. *There exists a property tester for the $k$-reversal distance property with query complexity $\widetilde{\mathcal{O}}(k/\epsilon)$.*

## 7. Property testing vs. testing ACPs: General case.

In section 4, we described a framework for testing problems via testing ACPs. We only considered ACPs whose ground set is identical to the domain of the tested function. Although we showed that this framework can be applied to various problems, it is not always powerful enough to deal with a larger spectrum of problems. In some cases it is necessary to consider ground sets different from the domain of the tested function. For example, if we consider the adjacency matrix model using the approach from section 4 and represent a graph by a function $f : V \times V \to \{0,1\}$, then the ground set would be a set of entries in the adjacency matrix. But sampling entries of the adjacency matrix results in a disconnected set of edges if the size of the sample set is $o(\sqrt{n})$ [43]. For graph problems, typically a better approach would be to identify the ground set with the set of vertices of the graph and then analyze the subgraph induced by these vertices. To make a more flexible model in order to deal with problems more complex than this one, we introduce *interpretations.*

*Interpretations.* Interpretations are functions that map each subset of the ground set of the ACP to a subset of the domain of the tested function. Given a sample set $S$ of ground set items, we use the interpretation to determine a set of domain elements $\mathcal{D}_S$. Then we query for the value $f(x)$ for each $x \in \mathcal{D}_S$.

Definition 7.1. *An* interpretation *of $\mathcal{C}$ in $\mathcal{D}$ is a function $I : 2^{\mathcal{C}} \to 2^{\mathcal{D}}$.*

To investigate quantitative properties of the reduction, we need the following definition.

Definition 7.2. *For a function $h : \mathbb{N} \to \mathbb{N}$, we say an interpretation $I$ of $\mathcal{C}$ in $\mathcal{D}$ is $h$-*bounded *if for every $X \subseteq \mathcal{C}$ it holds that $|I(X)| \le h(|X|)$. (We write in that case that $I$ is $h(N)$-bounded, with $N$ being the formal input variable.)*

The main idea behind introducing these notions is to allow a more general analysis of algorithm Tester$(f,\epsilon)$ from section 4. Similarly to the proof of Theorem 4.1, we want to test an input function $f \in \mathcal{F}$ via testing a related ACP $\mathcal{P} = (\mathcal{C}, \mathcal{B}, \varpi)$. Since $\mathcal{P}$ is now allowed to be an ACP with an arbitrary ground set $\mathcal{C}$, we use the interpretation $I$ of $\mathcal{C}$ in $\mathcal{D}$ to link the domains of $f$ and $\mathcal{P}$ in the reduction. The notion of $h$-bounded functions in Definition 7.2 is used to describe the size of the random sample in the tester. That is, if the interpretation $I$ is $h(N)$-bounded and if our algorithm samples a set $S \subseteq \mathcal{C}$, then we query for the value of $f(x)$ for every $x \in I(S) \subset \mathcal{D}$, and the restriction $|I(S)| \le h(s)$ yields an upper bound on the query complexity.

*Distance preserving property.* In Theorem 4.1 we used the distance preserving property that requires that if a function $f$ is $\epsilon$-far from property $\Pi$, then the ACP is $\epsilon$-far from feasible. In general, however, one can parameterize this property and require the *$(\epsilon,\lambda)$-distance preserving* property: *if $f$ is $\epsilon$-far from property* $\Pi$*, then the ACP is $\lambda$-far from feasible.*

Now, in the framework defined above, it is easy to see that Theorem 4.1 can be generalized to the following theorem, which describes our framework in its full generality.

Theorem 7.3. *Let $\mathcal{F}$ be a set of functions from a finite set $\mathcal{D}$ to a set $\mathcal{R}$, and let $\Pi$ be a property of $\mathcal{F}$. Let $0 < \epsilon, \lambda < 1$ and let $I : 2^{\mathcal{C}} \to 2^{\mathcal{D}}$ be an $h$-bounded interpretation of $\mathcal{C}$ in $\mathcal{D}$. If for every $f \in \mathcal{F}$ there exists an ACP $\mathcal{P}_f$ with $\dim(\mathcal{P}_f) \le \delta$ and width$(\mathcal{P}_f) \le \varrho$ such that*

- ($(\epsilon,\lambda)$-distance preserving) *if $f$ is $\epsilon$-far from $\Pi$, then every basis in $\mathcal{P}_f$ is $\lambda$-far from feasible; and*

- (feasibility preserving) *for every $X \subseteq \mathcal{C}$ with $|X| \geq \delta$: If there exists $g \in \Pi$ with $f_{|I(X)} = g_{|I(X)}$, then $X$ contains a self-feasible basis;*

*then there exists $s = \Theta(\lambda^{-1} \cdot (\delta \cdot \ln(\delta/\lambda) + \ln \varrho))$ such that the following algorithm is a property tester for $\Pi$ with query complexity $h(s)$:*

```
TESTER($f, \epsilon$).
    Sample a set $S$ of $s$ elements in $\mathcal{C}$ uniformly at random
    if $f_{|I(S)} = g_{I(S)}$ for some $g \in \Pi$ then accept $f$
    else reject $f$
```

*Proof.* In order to show that $\text{Tester}(f, \epsilon)$ is a property tester for $\Pi$, we have to prove that every function having property $\Pi$ is accepted by the tester, and every function that is $\epsilon$-far from having property $\Pi$ is rejected with probability at least $\frac{2}{3}$. If $f \in \Pi$, then for every $X \subseteq \mathcal{C}$ we have $f_{|I(X)} = g_{|I(X)}$ with $g = f \in \Pi$. This immediately implies that every $f \in \Pi$ is accepted by $\text{Tester}(f, \epsilon)$. Therefore, it remains to prove that if $f$ is $\epsilon$-far from $\Pi$, then the algorithm rejects the input with probability greater than or equal to $\frac{2}{3}$. We prove this by relating ACP-tester$(\mathcal{P}, \lambda)$ to $\text{Tester}(f, \epsilon)$ and by applying Theorem 3.6.

By the distance preserving property, if $f$ is $\epsilon$-far from $\Pi$, then $\mathcal{P}_f$ is $\lambda$-far from feasible. Furthermore, by Theorem 3.6, if $\mathcal{P}_f$ is $\lambda$-far from feasible, then ACP-tester$(\mathcal{P}_f, \lambda)$ rejects $\mathcal{P}_f$ with probability greater than or equal to $\frac{2}{3}$. $\mathcal{P}_f$ is rejected by ACP-tester$(\mathcal{P}_f, \lambda)$ only if the chosen sample set $S$ contains no self-feasible basis. But now the feasibility preserving property implies that if there is $g \in \Pi$ that agrees with $f$ on the interpretation of the sample set, then every set $X \subseteq \mathcal{C}$ with $|X| \geq \delta \geq \dim(\mathcal{P}_f)$ contains a self-feasible basis. By the fact that $|S| \geq \delta$ we can conclude that $S$ contains a self-feasible basis if there exists a $g \in \Pi$ that agrees with $f$ on the sample set $S$. Therefore, we can conclude that if $f$ is $\epsilon$-far from $\Pi$, then with probability at least $\frac{2}{3}$ there is no such $g \in \Pi$ with $f_{|I(S)} = g_{|I(S)}$. Hence, $f$ is rejected by $\text{Tester}(f, \epsilon)$ with probability at least $\frac{2}{3}$. This implies that $\text{Tester}(f, \epsilon)$ is a property tester for $\Pi$. □

## 8. Graph coloring.

In this section we apply Theorem 7.3 to graph coloring. A $k$-coloring of a graph $G = (V, E)$ is an assignment $\chi : V \to \{1, \ldots, k\}$ of colors to the vertices of the graph. A coloring is *proper* if there is no edge $e = (v, u) \in E$ such that $\chi(v) = \chi(u)$. If $G$ has a proper $k$-coloring, then $G$ is *$k$-colorable.* The graph $k$-coloring problem consists of determining whether a given graph is $k$-colorable.

We consider the graph coloring problem in the *adjacency matrix model.* That is, the input graph $G = (V, E)$ is given as a function $V \times V \to \{0, 1\}$ representing the adjacency matrix of the graph. Therefore we have $f(u, v) = 1$ if and only if $(u, v) \in E$. Without loss of generality, we assume that $V = [n]$. Let $\Pi$ denote all $n$-vertex graphs that have a proper $k$-coloring. We use the standard distance measure between graphs (see Definition 2.3), which is equivalent to the following definition.

Definition 8.1. *A graph $G$ is* $\epsilon$-far from being $k$-colorable *if in order to transform $G$ into a $k$-colorable graph one has to modify more than $\epsilon n^2$ entries in the adjacency matrix of $G$.*

It is known that graph coloring in the adjacency model can be tested efficiently [43]. The main contribution of our framework is a clear and elegant proof that highlights the combinatorial aspects of the problem and a slight improvement in the query complexity that matches for $k > 2$ the bounds from [7] in the $\widetilde{\mathcal{O}}$-notation.

For the $k$-coloring problem, we identify the ground set $\mathcal{C}$ with the set of vertices $V$ of the input graph $G = (V, E)$. Since in our framework $G$ can be viewed as given by its adjacency matrix representation, we define the interpretation $I$ to map each set of vertices to the submatrix induced by these vertices. That is, for every $W \subseteq V$, we have $I(W) = W \times W$. Clearly, the interpretation is $N^2$-bounded.

The bases of the coloring problem are formed by some properly colored sets of vertices. That is, every basis corresponds to a pair $(W, \chi^*)$, where $W \subseteq V = \mathcal{C}$ and $\chi^*$ is an encoding of a proper $k$-coloring of $W$ (here, one can think that a $k$-coloring of $W$ is represented by a vector of length $|W|$ with values in $k^W$). Notice that with this definition, if for each $(W, \chi^*) \in \mathcal{B}$ we have $|W| \leq \delta$, then the so-defined ACP $\mathcal{P}$ has $\dim(\mathcal{P}) \leq \delta$ and $\mathit{width}(\mathcal{P}) \leq k^{\delta}$.

Before we define the bases formally, we need some more definitions.

Definition 8.2. *Let $S \subseteq V$ be a set of vertices and let $\chi$ be a proper $k$-coloring of $S$. Let*

$$V_i \;=\; \bigl\{v \in V : \exists u \in S \textit{ with } \chi(u) = i \textit{ and } (v,u) \in E\bigr\}$$

*be the set of vertices that cannot be properly colored in color $i$ using any extension of $\chi$ to $V$. We call a vertex $v \in V \setminus S$* heavy *for $\langle S, \chi\rangle$ if there is a proper extension of $\chi$ to $S \cup \{v\}$, but every extension increases the number of vertices in certain $V_i$, $1 \leq i \leq k$, by at least $\epsilon n/3$ (that is,* (i) *there exists $1 \leq j \leq k$, with $v \notin V_j$, and* (ii) *$\forall_{1\leq j\leq k}$ if $v \notin V_j$, then $\bigl|\{w \notin V_j : (v,w) \in E\}\bigr| \geq \epsilon n/3$).*

*A vertex $v \in V \setminus S$ that cannot be properly colored by any extension of the coloring $\chi$ (that is, $v \in \bigcap_{i=1}^{k} V_i$) is called a* conflict *vertex for $\langle S, \chi\rangle$.*

*Bases for $k$-coloring.* For the graph coloring problem we define the bases inductively.

- $\{\emptyset, 1\}$ is a basis (where 1 is the encoding of the coloring of the empty set of vertices).
- If $b = (K, \chi)$ is a basis, $v$ is a *heavy* vertex for $b$, and $\chi^*$ is an encoding of the previous coloring $\chi$ of $K$ extended by a proper coloring of $v$, then $(K \cup \{v\}, \chi^*)$ is a basis.

Our next step is to show that the ACP has small dimension and width.

Lemma 8.3. *For every input instance of the graph coloring problem the corresponding ACP $\mathcal{P}$ has* $\dim(\mathcal{P}) \leq 3k/\epsilon$ *and* $\mathit{width}(\mathcal{P}) \leq k^{3k/\epsilon}$.

*Proof.* Since every $k$-coloring of a set of $r$ vertices can be encoded using an integer number between 1 and $k^r$, it is enough to show that $|K| \leq 3k/\epsilon$ for every basis $b = (K, \chi)$.

Let $b = (K, \chi)$ be a basis with $|K| = r$. Since $b$ is a basis, there must exist a sequence of bases $(K_0, \chi_0)$, $(K_1, \chi_1)$, $\dots$, $(K_r, \chi_r)$ with $(K_0, \chi_0) = (\emptyset, 1)$, $(K_r, \chi_r) = (K, \chi)$, and such that for every $1 \leq i \leq r$ we have $|K_i| = i$ and the only vertex in $K_i \setminus K_{i-1}$ is heavy for $\langle K_{i-1}, \chi_{i-1}\rangle$.

Let $V_1^{(i)}, V_2^{(i)}, \dots, V_k^{(i)}$, $0 \leq i \leq r$, be the sets of vertices such that each vertex $v \in V_j^{(i)}$ cannot be properly colored in color $j$ if we want to extend coloring $\chi_i$ to the set $K_i \cup \{v\}$. That is,

$$V_j^{(i)} \;=\; \bigl\{v \in V : \exists u \in K_i \text{ with } \chi_i(u) = j \text{ and } (v,u) \in E\bigr\}\ .$$

It is easy to see that for every $i, j$ we have $V_j^{(i)} \subseteq V_j^{(i+1)}$. Furthermore, by the definition of heavy vertices, we know that for every $i$, $1 \leq i \leq r$, there is certain $j$, $1 \leq j \leq k$, such that $|V_j^{(i)}| \geq |V_j^{(i-1)}| + \epsilon n/3$. Therefore, since we have $V_j^{(0)} = \emptyset$ for every $j$, $1 \leq j \leq k$, it must hold that $\sum_{j=1}^{k} |V_j^{(i)}| \geq i\,\epsilon n/3$ for every $i$, $1 \leq i \leq r$. Finally, since $|V_j^{(r)}| \leq n$ for every $j$, $1 \leq j \leq k$, we conclude that $r \leq 3k/\epsilon$. ◻

*Violation function for $k$-coloring. A basis $b = (K, \chi)$ is* violated *by a vertex $v \in V$ if either* (i) *$v$ is a heavy vertex for $\langle K, \chi \rangle$ or* (ii) *$v$ is a conflict vertex for $\langle K, \chi \rangle$.*

Once we have described $k$-coloring in our framework, in order to apply Theorem 7.3, we must show that the $(\epsilon, \lambda)$-distance preserving and the feasibility preserving properties hold. We begin with the proof of the following lemma that implies the $(\epsilon, \lambda)$-distance preserving property with $\lambda = \epsilon/3$.

LEMMA 8.4 ($(\epsilon, \epsilon/3)$-distance preserving property). *Let $G = (V, E)$ be a graph that is $\epsilon$-far from being $k$-colorable and let $S \subseteq V$ be any set of properly $k$-colored vertices with a proper coloring $\chi$. Then $V$ contains more than $\epsilon n/3$ conflict vertices for $\langle S, \chi \rangle$ or $V$ has more than $\epsilon n/3$ heavy vertices for $\langle S, \chi \rangle$.*

*Proof.* Our proof is by contradiction. Assume $G$ is $\epsilon$-far from having a proper $k$-coloring and there are less than $\epsilon n/3$ conflict vertices for $\langle S, \chi \rangle$ and less than $\epsilon n/3$ heavy vertices for $\langle S, \chi \rangle$. Then we show that there is a $k$-colorable graph $G^*$ that is obtained from $G$ by removing less than $\epsilon n^2$ edges. This would yield a contradiction and hence would conclude the proof.

Let $X$ be the set of all conflict vertices for $\langle S, \chi \rangle$, let $Y$ be the set of all heavy vertices for $\langle S, \chi \rangle$, and let $Z$ be the set of remaining uncolored vertices (i.e., $Z = V \setminus (S \cup X \cup Y)$). For every $i$, $1 \le i \le k$, let $V_i$ be the set of vertices in $V$ such that for every $v \in V_i$ the extension of $\chi$ by coloring $v$ with color $i$ is not a proper coloring (cf. Definition 8.2).

We first construct a graph $G'$ by removing all edges incident to the vertices in $X \cup Y$ and extend the coloring $\chi$ of $S$ to a $k$-coloring of $S \cup X \cup Y$ by coloring the vertices in $X \cup Y$ arbitrarily. Since $|X \cup Y| < 2\epsilon n/3$, less than $2\epsilon n^2/3$ edges are removed from $G$ in this way. Furthermore, since all vertices in $X \cup Y$ are isolated, the obtained coloring $\chi'$ is a proper $k$-coloring of $S \cup X \cup Y$.

Now, we modify $G'$ to extend the coloring $\chi'$ to all vertices in $Z$. For each $v \in Z$, let $\tau(v)$ be a color that satisfies the following two constraints:

- If we extend $\chi'$ to $S \cup \{v\}$ and we color $v$ with $\tau(v)$, then the resulting $k$-coloring is proper.
- If we extend $\chi'$ to $S \cup \{v\}$ and we color $v$ with $\tau(v)$, then the absolute increase in the size of $V_{\tau(v)}$ is minimal (among all possible choices that satisfy the first constraint).

In other words, $v \notin V_{\tau(v)}$ and for every $i$, $1 \le i \le k$, if $v \notin V_i$, then $|\{w \notin V_i : (v, w) \in E\}| \ge |\{w \notin V_{\tau(v)} : (v, w) \in E\}|$. Since $v$ is not a conflict vertex for $\langle S, \chi \rangle$, such a color $\tau(v)$ always exists (but is possibly not unique). By the fact that $v$ is not a heavy vertex for $\langle S, \chi \rangle$, we know that $|\{w \notin V_{\tau(v)} : (v, w) \in E\}| < \epsilon n/3$. Therefore, if we remove from $G'$ for every $v \in Z$ all edges $(v, w) \in E$ with $w \notin V_{\tau(v)}$, then the resulting graph $G^*$ is obtained from $G$ by removal of less than $\epsilon n^2$ edges. It remains to show that the following coloring of $G^*$ is proper: We color each vertex $v \in S \cup X \cup Y$ with color $\chi'(v)$. Each vertex $v \in Z$ is colored with color $\tau(v)$. Now assume that this coloring is not proper. Then there must be an edge $(v, u)$ such that $v$ and $u$ are colored in the same color. Since $\chi$ is proper, all vertices in $X$ and $Y$ are isolated, and by the definition of $\tau(v)$ it is immediate that such an edge can only be between vertices in $Z$. But then we have that $u \notin V_{\tau(v)}$, and this implies that $(v, u)$ has been removed from $G'$. This yields a contradiction. $\square$

It remains to prove the feasibility preserving property.

LEMMA 8.5 (feasibility preserving property). *If for some $S \subseteq V$ every basis covered by $S$ is violated by certain $v \in S$, then the subgraph of $G$ induced by vertices in $S$ cannot be properly $k$-colored.*

*Proof.* The proof is by contradiction. Let us suppose there is a proper $k$-coloring $\chi$ of the subgraph of $G$ induced by the vertices in $S$. For every $U \subseteq S$, let $\chi_U$ denote the coloring $\chi$ restricted to vertex set $U$.

Let us observe that the set of bases covered by $S$ is not empty because it contains the "empty set" basis $(\emptyset, \chi_\emptyset)$. Therefore, there exists a basis (possibly one of many) $b = (U, \chi_U)$ covered by $S$ having the maximum size of set $U$. Since $b$ is violated by certain $v \in S$, either $v$ is a conflict vertex for $\langle U, \chi_U \rangle$ or $v$ is a heavy vertex for $\langle U, \chi_U \rangle$. Furthermore, since $\chi$ was assumed to be a proper $k$-coloring of $S$, $v$ cannot be a conflict vertex for $\langle U, \chi_U \rangle$ and therefore it must be a heavy vertex for $\langle U, \chi_U \rangle$. But this implies that $(U \cup \{v\}, \chi_{U \cup \{v\}})$ is a basis that is moreover covered by $S$. This yields a contradiction, because we assumed that there is no basis $(K, \chi_K)$ covered by $S$ having $|K| > |U|$. $\square$

Therefore, we summarize our discussion in this section with the following theorem that follows directly from Theorem 7.3 and Lemmas 8.4 and 8.5.

THEOREM 8.6. *There is a property tester for the graph $k$-coloring property with a query complexity of*

$$\mathcal{O}\left((k\,\epsilon^{-2}\,\ln(k/\epsilon^2))^2\right) = \widetilde{\mathcal{O}}(k^2/\epsilon^4)\ .$$

## 9. Hypergraph coloring.

We now want to extend the analysis from section 8 to obtain an efficient *property tester for hypergraph coloring*. A *hypergraph* is a pair $\mathcal{H} = (V, E)$ with a finite vertex set $V$ and the edge set $E \subseteq 2^V$. A hypergraph $\mathcal{H}$ is *$\ell$-uniform* if $|e| = \ell$ for all $e \in E$. (Notice that a 2-uniform hypergraph is a graph.) A *$k$-coloring* of a hypergraph $\mathcal{H}$ is an assignment $\chi : V \to \{1, \ldots, k\}$ of colors to the vertices of the hypergraph. A coloring is *proper* if no edge in $E$ is *monochromatic*, that is, if for every edge $e \in E$ there are $v, u \in e$ with $\chi(v) \neq \chi(u)$. If $\mathcal{H}$ has a proper $k$-coloring, then $\mathcal{H}$ is *$k$-colorable.* The $k$-coloring problem for hypergraphs consists of determining whether a given hypergraph is $k$-colorable.

We want to design a property tester for the $k$-coloring problem in $\ell$-uniform hypergraphs. An $\ell$-uniform hypergraph can be represented by a function $f : V^\ell \to \{0, 1\}$ that encodes its adjacency matrix. We use the standard distance measure (Definition 2.3) to measure the distance between hypergraphs. In terms of hypergraphs we can express this distance measure as follows.

DEFINITION 9.1. *An $\ell$-uniform hypergraph $\mathcal{H} = (V, E)$ is $\epsilon$-far from having a proper $k$-coloring if one has to remove more than $\epsilon n^\ell$ edges from $\mathcal{H}$ to obtain a hypergraph that has a proper $k$-coloring.*

Now, we discuss how to apply our framework to hypergraph coloring. Similarly to the graph coloring problem, we identify the ground set $\mathcal{C}$ with the set of vertices $V$ of the input hypergraph $\mathcal{H} = (V, E)$. Since in our representation $\mathcal{H}$ can be viewed as given by its adjacency matrix representation, we define the interpretation $I$ to map each set of vertices to the submatrix induced by these vertices. That is, for every $S \subseteq V$, we have $I(S) = S \times S \times \cdots \times S$. Clearly, the interpretation is $N^\ell$-bounded. Let $\langle S, \chi \rangle$ be a pair with $S \subseteq V$ and $\chi$ a proper $k$-coloring of vertices in $S$.

DEFINITION 9.2. *We say a vertex $v$ is* $i$-colorable *with respect to $\langle S, \chi \rangle$ if for every $e \in E$ with $v \in e$, either* (i) *there exists a vertex $u \in (S \cap e)$ with $\chi(u) \neq i$ or* (ii) *there exists a vertex $w \in e \setminus (S \cup \{v\})$.*

We want to extend our approach for graph coloring to hypergraphs. Again we use a recursive definition of bases that is based on *heavy* vertices and *conflict* vertices. In order to define heavy vertices we introduce a potential function. A vertex is a heavy vertex if its coloring increases the potential significantly, very much in the spirit of graph coloring; further motivation behind the definition of the potential function can be found in the proof of Lemma 9.7.

DEFINITION 9.3. *Let $\mathcal{H} = (V, E)$ be a hypergraph. Let $S \subseteq V$ and let $\chi$ be a proper $k$-coloring of vertices in $S$. The* potential *of $\langle S, \chi \rangle$ is defined as*

$$\Phi_{\mathcal{H}}(\langle S, \chi \rangle) \;=\; \sum_{i=1}^{k} \sum_{j=1}^{\ell-1} n^{j-1} \cdot |\varphi(\langle S, \chi \rangle, i, j)| \;\;,$$

*where*

$$\varphi(\langle S, \chi \rangle, i, j) \;=\; \big\{ W \subseteq V \;:\; |W| = \ell - j \;\;\&\;\; \exists e \in E \; (W \subseteq e \;\;\&\;\; \forall_{v \in e \setminus W} \;\; \chi(v) = i) \big\} \;.$$

Hence, if $W \in \varphi(\langle S, \chi \rangle, i, j)$, then coloring all vertices in $W$ with color $i$ creates a monochromatic edge. Our next step is to extend the notion of heavy and conflict vertices to hypergraphs.

DEFINITION 9.4. *A vertex $v \in V \setminus S$ is* heavy *with respect to $\langle S, \chi \rangle$ if* (i) *there is an $i$, $1 \le i \le k$, such that $v$ is $i$-colorable and* (ii) *for every $i$, $1 \le i \le k$, if $v$ is $i$-colorable and $\chi'$ is the extension of $\chi$ to $S \cup \{v\}$ by coloring $v$ with color $i$, then*

$$\Delta\Phi_{\mathcal{H}}(\langle S, \chi \rangle, v, i) \;=\; \Phi_{\mathcal{H}}(\langle S \cup \{v\}, \chi' \rangle) - \Phi_{\mathcal{H}}(\langle S, \chi \rangle) \;>\; \frac{\epsilon n^{\ell-1}}{3} \;\;.$$

DEFINITION 9.5. *A vertex $v \in V \setminus S$ is a* conflict vertex *with respect to $\langle S, \chi \rangle$ if for every $i$, $1 \le i \le k$, $v$ is* not *$i$-colorable.*

The bases and the violation function are defined in the same way as for graph coloring.

*Bases for $k$-coloring.*

- $\{\emptyset, 1\}$ is a basis (where 1 is the encoding of the coloring of the empty set of vertices).
- If $b = (K, \chi)$ is a basis, $v$ is a *heavy* vertex for $b$ and $\chi'$ is an encoding of the previous coloring $\chi$ of $K$ extended by a proper coloring of $v$, then $(K \cup \{v\}, \chi')$ is a basis.

*Violation function for $k$-coloring. A basis $b = (K, \chi)$ is* violated *by a vertex $v \in V$ if either* (i) *$v$ is a heavy vertex for $\langle K, \chi \rangle$ or* (ii) *$v$ is a conflict vertex for $\langle K, \chi \rangle$.*

In a manner similar to that for the graph coloring problem, we can give an upper bound for the dimension of the constructed ACP.

LEMMA 9.6. *For every problem instance of the hypergraph $k$-coloring problem the corresponding ACP $\mathcal{P}$ has* $\dim(\mathcal{P}) \le 3k\ell/\epsilon$ *and width$(\mathcal{P}) \le k^{3k\ell/\epsilon}$.*

*Proof.* Since every $k$-coloring of a set of $r$ vertices can be encoded using an integer in the range between 1 and $k^r$, it is enough to show that $|K| \le 3\,k\,\ell/\epsilon$ for every basis $b = (K, \chi)$. To show this, let us recall that the bases are defined inductively by adding a heavy vertex to another basis. By definition, a heavy vertex increases the potential of the corresponding basis by more than $\frac{1}{3}\,\epsilon\, n^{\ell-1}$. The maximum potential of every basis is less than $k\,\ell\, n^{\ell-1}$ and the starting potential is 0. Thus, it follows for every basis $b = (K, \chi)$ that $|K| \le 3\,k\,\ell/\epsilon$. $\square$

Our next step is to prove the distance preserving property.

LEMMA 9.7 (($\epsilon, \epsilon/3$)-distance preserving property). *Let $\mathcal{H} = (V, E)$ be a hypergraph that is $\epsilon$-far from being $k$-colorable, and let $S \subseteq V$ be an arbitrary set of vertices colored according to a proper $k$-coloring $\chi$. Then either $V$ contains more than $\epsilon\, n/3$ conflict vertices with respect to $\langle S, \chi \rangle$ or $V$ has more than $\epsilon\, n/3$ heavy vertices for $\langle S, \chi \rangle$.*

*Proof.* Our arguments are similar to those used in the proof of Lemma 8.4. The proof is by contradiction. Let us assume there are less than or equal to $\epsilon\, n/3$ heavy vertices and less than or equal to $\epsilon\, n/3$ conflict vertices with respect to $\langle S, \chi\rangle$. Then we show that it is possible to extend coloring $\chi$ of $S$ to a coloring $\chi^*$ of $V$ that has at most $\epsilon\, n^\ell$ monochromatic (violating) edges in $\mathcal{H}$. This would yield a contradiction.

We define $\chi^*$ as follows:

$$\chi^*(v) = \begin{cases} \chi(v) & \text{for every } v \in S;\\ 1 & \text{if } v \in V \setminus S \text{ and } v \text{ is a heavy vertex or a conflict vertex with} \\ & \quad \text{respect to } \langle S,\chi\rangle;\\ i & \text{if } v \in V\setminus S \text{ is } i\text{-colorable with respect to } \langle S,\chi\rangle \text{ and } i \text{ minimizes} \\ & \quad \text{(over all possible choices of proper coloring } i\text{) the increase in} \\ & \quad \text{the potential, that is, } \Delta\Phi_{\mathcal{H}}(\langle S,\chi\rangle, v, i) \le \Delta\Phi_{\mathcal{H}}(\langle S,\chi\rangle, v, j) \\ & \quad \text{for every proper coloring } j \text{ of } v. \end{cases}$$

Now, we give an upper bound on the number of monochromatic edges in coloring $\chi^*$ of $\mathcal{H}$. Let us first consider heavy and conflict vertices. By our assumption, the number of such vertices is upper bounded by $\frac{2}{3}\,\epsilon\, n$. Therefore, the number of edges incident to these vertices is upper bounded by $\frac{2}{3}\,\epsilon\, n^\ell$. Hence, it is sufficient to show that there are at most $\frac{1}{3}\,\epsilon\, n^\ell$ monochromatic edges in $\mathcal{H}$ that are not incident to heavy or conflict vertices. We show this indirectly by defining a set $E_D \subseteq E$ of at most $\frac{1}{3}\,\epsilon\, n^\ell$ edges. Then we prove that this set contains all monochromatic edges for the coloring $\chi^*$. Let $V_{light}$ denote the set of all vertices in $V \setminus S$ that are neither heavy nor conflict vertices for $\langle S, \chi\rangle$.

For a vertex $v \in V_{light}$ let us define

$$\Delta\varphi(\langle S,\chi\rangle, v, i, j) \;=\; \varphi(\langle S\cup\{v\}, \chi'\rangle, i, j) \setminus \varphi(\langle S,\chi\rangle, i, j) \enspace ,$$

where $\chi'$ is the extension of $\chi$ to $S \cup \{v\}$ by coloring vertex $v$ with color $i$. We further denote by $E(X, v) = \{e \in E : v \in e \;\&\; X \subseteq e\}$ all edges of the hypergraph that contain $X \cup \{v\}$. Now we make a simple but important observation.

Claim 9.8. *If $E(X,v) = \emptyset$, then $X \notin \Delta\varphi(\langle S,\chi\rangle, v, \chi^*(v), j)$.*

*Proof.* The proof follows immediately from the definition of $\Delta\varphi(\langle S,\chi\rangle, v, \chi^*(v), j)$. ☐

We define the set

$$E_D \;=\; \bigcup_{v\in V_{light}} \; \bigcup_{j\in[\ell-1]} E^{(v)}_{D,j}$$

using sets $E^{(v)}_{D,j}$ that determine for each vertex $v$ a set of edges that is responsible for the sets in $\Delta\varphi(\langle S,\chi\rangle, v, \chi^*(v), j)$. As we will see later, these edges are the only edges that may possibly be monochromatic in $\chi^*$. We define the set $E^{(v)}_{D,j}$ as follows:

$$E^{(v)}_{D,j} \;=\; \bigcup_{X\in\Delta\varphi(\langle S,\chi\rangle, v, \chi^*(v), j)} E(X, v) \enspace .$$

Claim 9.9. *Let $e \in E$ be a monochromatic edge in the coloring $\langle V, \chi^*\rangle$. Then $e \in E_D$.*

*Proof.* If $e$ is monochromatic, then there is $i \in [k]$ such that $\chi^*(u) = i$ for all $u \in e$. Furthermore, we conclude that for each $u \in e$ we have $\{u\} \in \varphi(\langle V,\chi\rangle, i, \ell - 1)$. Now we distinguish between two cases. First let us consider the case when there is a

$u \in e$ with $\{u\} \in \varphi(\langle S, \chi\rangle, i, \ell - 1)$. In this case $\chi^*(u) \neq i$ by the definition of $\chi^*$. In the second case such a $u$ does not exists, but we have $\{u\} \in \varphi(\langle V, \chi\rangle, i, \ell - 1)$. But as can be seen from Claim 9.8, we defined $E_D$ in such a way that there cannot be an $X \in \varphi(\langle V, \chi\rangle, i, \ell - 1)$ that is not contained in $\varphi(\langle S, \chi\rangle, i, \ell - 1)$. Hence, if $e$ is not in $E_D$, it cannot be monochromatic. ∎

It remains to show that the size of $E_D$ is small enough. By definition we have

$$\left|E_D\right| \; = \sum_{v \in V_{light}} \sum_{j=1}^{\ell-1} \left|E_{D,j}^{(v)}\right| \; ,$$

and it is easy to see that for the $E_{D,j}^{(v)}$ it holds that

$$\left|E_{D,j}^{(v)}\right| \; \leq \; \left|\Delta\varphi(\langle S, \chi\rangle, v, \chi^*(v), j)\right| \cdot n^{j-1}$$

because of the fact that $|E(X, v)| \leq n^{\ell-(|X|+1)}$. We conclude that we have

$$\left|E_D\right| \; \leq \sum_{v \in V_{light}} \sum_{j=1}^{\ell-1} \left|\Delta\varphi(\langle S, \chi\rangle, v, \chi^*(v), j)\right| \cdot n^{j-1} \; .$$

Since all considered vertices are light we also have, for every $v \in V_{light}$,

$$\Delta\Phi_{\mathcal{H}}(\langle S, \chi\rangle, v, \chi^*(v)) \; = \sum_{j=1}^{\ell-1} \left|\Delta\varphi(\langle S, \chi\rangle, v, \chi^*(v), j)\right| \cdot n^{j-1} \; \leq \; \frac{1}{3}\epsilon n^{\ell-1} \; .$$

This finally gives us

$$\left|E_D\right| \; \leq \; \frac{1}{3}\epsilon n^{\ell} \; .$$

Together with Claim 9.9 we get a contradiction to the fact that $\mathcal{H}$ is $\epsilon$-far from being $k$-colorable. This proves the lemma. ∎

The proof of the following lemma is essentially the same as the proof of Lemma 8.5, and we present it here for the sake of completeness only.

LEMMA 9.10 (feasibility preserving property). *If for some $S \subseteq V$ every basis covered by $S$ is violated by certain $v \in S$, then the subhypergraph of $\mathcal{H}$ induced by vertices in $S$ cannot be properly $k$-colored.*

*Proof.* The proof is by contradiction. Let us suppose there is a proper $k$-coloring $\chi$ of the subgraph of $\mathcal{H}$ induced by the vertices in $S$. For every $U \subseteq S$, let $\chi_{|U}$ denote the coloring $\chi$ restricted to vertex set $U$.

Let us observe that the set of bases covered by $S$ is not empty, because it contains the "empty set" basis $(\emptyset, \chi_{\emptyset})$. Therefore, there exists a basis (possibly one of many) $b = (U, \chi_{|U})$ covered by $S$ having the maximum size of set $U$. Since $b$ is violated by certain $v \in S$, either $v$ is a conflict vertex for $\langle U, \chi_{|U}\rangle$ or $v$ is a heavy vertex for $\langle U, \chi_{|U}\rangle$. Furthermore, since $\chi$ was assumed to be a proper $k$-coloring of $S$, $v$ cannot be a conflict vertex for $\langle U, \chi_U\rangle$, and therefore it must be a heavy vertex for $\langle U, \chi_{|U}\rangle$. But this implies that $(U \cup \{v\}, \chi_{|U\cup\{v\}})$ is a basis that is moreover covered by $S$. This yields a contradiction, because we assumed that there is no basis $(K, \chi_{|K})$ covered by $S$ having the size of $K$ greater than $|U|$. ∎

The three lemmas above combined with our framework from Theorem 7.3 imply the following result.

Theorem 9.11. *There is a property tester for the hypergraph $k$-colorability with the query complexity*

$$\mathcal{O}\left((k\,\ell\,\epsilon^{-2}\,\ln(k/\epsilon))^{\ell}\right) = \widetilde{\mathcal{O}}((k\,\ell/\epsilon^2)^{\ell}) \ .$$

**10. Testable hereditary graph properties.** In this section we consider arbitrary *hereditary graph properties.* A *graph property* $\Pi$ is a family of graphs that is preserved under graph isomorphism (that is, if $G$ satisfies property $\Pi$ and $G'$ is a graph isomorphic to $G$, then $G'$ has property $\Pi$, too). A graph property $\Pi$ is *hereditary* if it is closed under taking induced subgraphs; that is, if graph $G = (V, E)$ has $\Pi$, then every subgraph $G_S$ induced by a set $S \subseteq V$ has property $\Pi$ (see, e.g., [16]). Similarly as in section 8, we consider undirected graphs that are represented by a function $f : V \times V \to \{0, 1\}$ that encodes the adjacency matrix of the graph. We assume without loss of generality that $V = [n]$. When we talk about graph properties we have to observe that in our framework a property is defined as a subset of the set of $n$-vertex graphs. When no confusion can arise we use $\Pi$ to denote the graph property $\Pi$ as well as the corresponding set of $n$-vertex graphs (which is the formal definition of a property in this paper). Our main result is that a hereditary graph property is efficiently testable if and only if it can be reduced to an ACP of dimension that is independent of the size of the input graph.

For every graph $G = (V, E)$ and every subset $U \subseteq V$ we denote by $G_U$ the subgraph of $G$ induced by $U$.

We use the standard distance measure from Definition 2.3 for testing graph properties.

Definition 10.1. *Let* $\Pi$ *be an arbitrary graph property. A graph* $G$ *is* $\epsilon$-far from (satisfying) $\Pi$ *if in order to transform* $G$ *into a graph satisfying* $\Pi$ *one has to modify more than* $\epsilon\, n^2$ *entries in the adjacency matrix of* $G$.

Now, we can formally state the main result of this section.

Theorem 10.2. *Let* $\Pi$ *be a hereditary graph property. Let* $0 < \epsilon < 1$. *Let* $\mathcal{G}$ *be the set of all graphs on the vertex set* $V = [n]$. *Then* $\Pi$ *is efficiently testable* if and only if *there are* $\delta = \delta(\epsilon)$, $\varrho = \varrho(\epsilon)$, *and* $\lambda = \lambda(\epsilon)$, *such that every* $G \in \mathcal{G}$ *can be mapped to an ACP* $\mathcal{P}_G = ([n], \mathcal{B}, \varpi)$ *with* $\dim(\mathcal{P}_G) \le \delta(\epsilon)$ *and width*$(\mathcal{P}_G) \le \varrho(\epsilon)$ *satisfying the following two properties:*

- $((\epsilon, \lambda)$-distance preserving) *if* $G$ *is* $\epsilon$*-far from* $\Pi$, *then every basis in* $\mathcal{P}_G$ *is* $\lambda$*-far from feasible; and*
- (feasibility preserving) *for every* $S \subseteq V$ *with* $|S| \ge \delta(\epsilon)$*: If there is* $G' \in \Pi$ *with* $G_S = G'_S$, *then there is a self-feasible basis for* $S$ *in* $\mathcal{P}_G$.

The remaining part of this section is devoted to the proof of Theorem 10.2. We begin with the following lemma, which simplifies the analysis of property testers for graph properties. By this lemma, if a hereditary graph property $\Pi$ has a property tester with a query complexity of $q(\epsilon)$, then it has a property tester that samples a set $S$ of $r(q(\epsilon)) = \mathcal{O}(q(\epsilon))$ vertices and accepts if and only if the subgraph induced by $S$ has $\Pi$.

Lemma 10.3 (Alon; see [47, Proposition D.2]). *Let* $\Pi$ *be a hereditary graph property. Suppose there is a property tester for property* $\Pi$ *with query complexity* $q(\epsilon)$. *Then there is a property tester for property* $\Pi$ *that selects uniformly at random a set of* $r(q(\epsilon)) = \mathcal{O}(q(\epsilon))$ *vertices and accepts the input graph if and only if the corresponding induced subgraph satisfies property* $\Pi$.

In order to prove Theorem 10.2, we must prove that our condition is both necessary and sufficient for efficient testability of any property $\Pi$. We first observe that our proof of Theorem 7.3 with the interpretation $I$ as defined in section 8 implies directly the sufficiency of our conditions. Now, we prove the necessity of our condition (Lemma 10.4 uses the identical function $r()$ as in Lemma 10.3).

LEMMA 10.4 (necessary condition). *Let $\Pi$ be a hereditary graph property. Let $0 < \epsilon < 1$. Suppose there is a property tester for property $\Pi$ with query complexity $q(\epsilon) \le \frac{1}{4}n$, and let us set $r = r(q(\epsilon))$. Let $\mathcal{G}$ be the set of all graphs on the vertex set $V = \{1, \ldots, n\}$. Let $\lambda = \lambda(\epsilon) = \frac{1}{3 \cdot 2^r}$. Then for every $G \in \mathcal{G}$ there exists an ACP $\mathcal{P}_G = ([n], \mathcal{B}, \varpi)$ with $\dim(\mathcal{P}_G) \le 2r$ and width$(\mathcal{P}_G) = 1$ satisfying the $(\epsilon, \lambda)$-distance preserving and the feasibility preserving properties.*

*Proof.* Let us fix an arbitrary graph $G = (V, E)$ for which we describe ACP $\mathcal{P}_G$ satisfying the required properties.

*Bases for graph properties.* We define the bases of $\mathcal{P}_G$ to be of the form $(K, 1)$, where $K \subseteq V$. We first give a set of basis candidates $\mathcal{BC}$ and then show how to obtain the set of bases from this set of candidates.

We define the set of *basis candidates* $\mathcal{BC}$ as follows:
- $(\emptyset, 1)$ *is a basis candidate*;
- if $K$ is a set of vertices of size $r$ and $G_K$ (the subgraph induced by $K$) does not satisfies $\Pi$, then $(K, 1)$ *is a basis candidate*; and
- if $(K, 1)$ is a basis and $K' \subseteq K$, then $(K', 1)$ *is a basis candidate.*

We also define the notion of *violators* and *light* bases.

DEFINITION 10.5. *Let $\mathcal{BC}$ be a set of basis candidates and let $b = (K, 1) \in \mathcal{BC}$. The set of* violators *$Viol^{\mathcal{BC}}(b)$ of $b$ with respect to $\mathcal{BC}$ is defined as follows:*
- *if $|K| = r$, then $Viol^{\mathcal{BC}}(b) = V \setminus K$; and*
- *if $|K| < r$, then $Viol^{\mathcal{BC}}(b) = \{v \in V \setminus K :$ there exists a basis candidate $b' = (K \cup \{v\}, 1)\}$.*

DEFINITION 10.6. *Let $\mathcal{BC}$ be a set of basis candidates and let $b \in \mathcal{BC}$. We call $b$* light *(with respect to $\mathcal{BC}$) if $|Viol^{\mathcal{BC}}(b)| \le \frac{3}{2}\lambda n$. If $b$ is not light, then it is* heavy.

Now, we define the *set of bases* $\mathcal{B}$ as the output of the following algorithm COMPUTEBASES.

```
COMPUTEBASES (set of candidates $\mathcal{BC}$).
    while there is a light basis $b$ (with respect to the current $\mathcal{BC}$) do
        $\mathcal{BC} = \mathcal{BC} \setminus \{b\}$
    return $\mathcal{B} = \mathcal{BC} \cup \{(\emptyset, 1)\}$
```

*Violation function for graph properties. A basis $b \in \mathcal{B}$ is violated by its violators, that is, by all vertices contained in $Viol^{\mathcal{B}}(b)$.*

Notice that our construction of bases and the definition of the violation function implies that every basis $b \in \mathcal{B}$ is heavy; that is, it is violated by more than $\frac{3}{2}\lambda n$ vertices in $V$.

Now, the following claim follows trivially from our construction.

CLAIM 10.7. *$\mathcal{P}_G$ has dimension $(r, 1)$.*

*$(\epsilon, \lambda)$-distance preserving property.* We prove now that the ACP $\mathcal{P}_G$ defined above satisfies the $(\epsilon, \lambda)$-distance preserving property; that is, we prove that if $G$ is $\epsilon$-far from $\Pi$, then every basis in $\mathcal{P}_G$ is $\lambda$-far from feasible, where $\lambda = \lambda(\epsilon) = \frac{1}{3 \cdot 2^r}$. Notice that by the definition of bases, every basis except for $(\emptyset, 1)$ is violated by more than $\lambda n$ ground set elements. Therefore, what remains to be proved is that the basis $(\emptyset, 1)$ is also violated by more than $\lambda n$ ground set elements. Our proof of this fact is via a sequence of claims that top-down establish lower bounds for the number of bases of given size.

For a basis $b = (K, 1)$, let $|K|$ be called its *size.* We begin with the following simple claim about bases of size $r$.

CLAIM 10.8. *Suppose $r < (1 - \frac{2}{3}\lambda)\, n$. If $G$ is $\epsilon$-far from $\Pi$, then the number of bases of size $r$ in $\mathcal{B}$ is bigger than $\frac{2}{3} \cdot \binom{n}{r}$.*

*Proof.* The proof follows directly from the definition of the bases and from Lemma 10.3. Indeed, Lemma 10.3 implies that for a graph that is $\epsilon$-far from $\Pi$, if one picks at random a set of $r$ vertices in $V$, then with probability at least $\frac{2}{3}$ the subgraph induced by these vertices does not satisfy $\Pi$. This is equivalent to saying that the number of subsets of $V$ of size $r$ for which the induced subgraph does not satisfy $\Pi$ is bigger than $\frac{2}{3} \cdot \binom{n}{r}$. By the definition of the basis candidates, for every set $K \subseteq V$ of size $r$, $(K, 1) \in \mathcal{BC}$. Moreover, the set $V \setminus K$ is the set of violators of $K$. Hence $(K, 1)$ is a basis that is violated by $n - r$ violators, and thus $(K, 1)$ is heavy. Thus, $(K, 1)$ belongs to $\mathcal{B}$. Therefore, the number of bases of size $r$ in $\mathcal{B}$ is bigger than $\frac{2}{3} \cdot \binom{n}{r}$. □

The next claim deals with the relation between the number of bases of size $k$ and of size $k - 1$.

CLAIM 10.9. *Suppose that $n \geq 2\,r$. Let $\zeta$, $0 \leq \zeta \leq 1$, and let $k$, $1 \leq k \leq r$, be an integer. If there are more than $\zeta \cdot \binom{n}{k}$ bases of size $k$ in $\mathcal{B}$, then the number of bases in $\mathcal{B}$ of size $k - 1$ is bigger than $\frac{\zeta - 3 \cdot \lambda}{2} \cdot \binom{n}{k-1}$.*

*Proof.* Recall that $\mathcal{B}$ contains only heavy bases. Furthermore, if $(K, 1)$ is a basis, then our construction of bases ensures that for every $u \in K$, $(K \setminus \{u\}, 1)$ is a basis (in the following, "basis" also refers to basis candidates) and that this basis is violated by $u$. Thus, every basis of size $k$ defines $k$ violators for bases for size $k - 1$. We conclude that overall, there are more than

$$k \cdot \zeta \cdot \binom{n}{k} = (n - k + 1) \cdot \zeta \cdot \binom{n}{k-1} > \frac{1}{2} \cdot n \cdot \zeta \cdot \binom{n}{k-1}$$

violators for bases of size $k - 1$. Observe that every light basis has at most $\frac{3}{2}\,\lambda\, n$ violators. Therefore, the number of violators of all light bases of size $k - 1$ is at most $\frac{3}{2}\,\lambda\, n\, \binom{n}{k-1}$. It follows that the number of violators of heavy bases of that size is bigger than

$$\frac{1}{2} \cdot n \cdot \zeta \cdot \binom{n}{k-1} - \frac{3}{2} \cdot \lambda \cdot n \cdot \binom{n}{k-1} = \frac{1}{2} \cdot (\zeta - 3\,\lambda) \cdot n \cdot \binom{n}{k-1} \ .$$

Since each basis has at most $n$ violators it follows that the number of heavy bases is larger than

$$\frac{1}{2} \cdot (\zeta - 3\,\lambda) \cdot \binom{n}{k-1} \ ,$$

which completes the proof of our claim. □

The next claim gives a lower bound for the number of bases of given size (bigger than 0).

CLAIM 10.10. *Let $1 \leq k \leq r$ be an integer. Then the number of bases of size $r - k$ is bigger than*

$$\left( \frac{1}{3 \cdot 2^{k-1}} - \frac{3}{2}\,\lambda \left( 2 - \frac{1}{2^{k-1}} \right) \right) \cdot \binom{n}{r-k} \ .$$

*Proof.* The proof is by induction on $k$. For $k = 1$ the claim follows directly from Claims 10.8 and 10.9. Now, let us assume the claim is true for $k = k'$, for certain

$1 \le k' < r$, and we show that this implies that the claim is true also for $k = k' + 1$. By induction, this will yield the claim.

By the induction hypothesis, the number of bases in $\mathcal{B}$ of size $r - k'$ is bigger than

$$\begin{aligned}&\left(\frac{1}{3 \cdot 2^{k'-1}} - \frac{3}{2}\,\lambda\,(2 - \frac{1}{2^{k'-1}})\right) \cdot \binom{n}{r-k'}\\ &= \left(\frac{1}{3 \cdot 2^{k-2}} - \frac{3}{2}\,\lambda\left(2 - \frac{1}{2^{k-2}}\right)\right) \cdot \binom{n}{r-k+1}\ .\end{aligned}$$

Therefore, by Claim 10.9, the number of bases in $\mathcal{B}$ of size $r - k = (r - k') - 1$ is bigger than

$$\frac{\left(\frac{1}{3 \cdot 2^{k-2}} - \frac{3}{2}\lambda\left(2 - \frac{1}{2^{k-2}}\right)\right) - 3\,\lambda}{2} \cdot \binom{n}{r-k} = \left(\frac{1}{3 \cdot 2^{k-1}} - \frac{3}{2}\,\lambda\left(2 - \frac{1}{2^{k-1}}\right)\right) \cdot \binom{n}{r-k},$$

and the claim follows. $\square$

Now, we are ready to complete the proof of the $(\epsilon, \lambda)$-distance preserving property for $\mathcal{P}_G$. By our discussion above, we must show only that the basis $(\emptyset, 1)$ is violated by more than $\lambda\, n$ ground set elements. By Claim 10.10, the number of bases in $\mathcal{B}$ of size 1 is bigger than

$$\left(\frac{1}{3 \cdot 2^{r-2}} - 3 \cdot \lambda\right) \cdot \binom{n}{1} \;=\; \left(\frac{4}{3 \cdot 2^{r}} - 3 \cdot \lambda\right) \cdot n \;\ge\; \lambda \cdot n$$

by our assumption that $\lambda = \frac{1}{3 \cdot 2^r}$. Each of the bases of size 1 is of the form $(\{u\}, 1)$ for some $u \in V$, and by the definition of violation, such a vertex $u$ violates $(\emptyset, 1)$. Since the number of such vertices $u$ is bigger than $\lambda \cdot n$, this completes the proof of the $(\epsilon, \lambda)$-distance preserving property for $\mathcal{P}_G$.

*Feasibility preserving property.* We prove now that the ACP $\mathcal{P}_G$ satisfies the feasibility preserving property. We prove that for every $S \subseteq V$, $|S| \ge 2\,r$, if the subgraph $G_S$ satisfies $\Pi$, then there is a self-feasible basis for $S$ in $\mathcal{P}_G$. This implies the feasibility preserving property because $\Pi$ is hereditary, and so if $G_S$ does not have property $\Pi$, then $G$ cannot have $\Pi$, as well.

Our arguments are roughly the same as those in the proof of Lemma 8.5. The proof is by contradiction. Let us suppose that the subgraph $G_S$ satisfies $\Pi$, but every basis in $S$ is violated. Observe that the set of bases covered by $S$ is not empty, because it contains the "empty set" basis $(\emptyset, 1)$. Therefore, there exists a basis $b = (K, 1)$ covered by $S$ maximizing the size of set $K$. Since $b$ is violated by certain $v \in S$ and since $K$ is of maximum size, we conclude that $|K| = r$. It follows that the subgraph $G_K$ induced by $K$ does not have property $\Pi$. Since $\Pi$ is hereditary, it is closed under taking induced subgraphs, and hence we conclude that $G_S$ does not have property $\Pi$.

If $n < 2r$, then we use the following simple ACP: The ACP has a single basis $(V, 1)$ which is violated by all ground set elements if $G$ is $\epsilon$-far from $\Pi$, and which is not violated otherwise. This completes the proof of Lemma 10.4. $\square$

Now, we can conclude our discussion to complete the proof of Theorem 10.2.

*Proof.* The "only if" part follows from Lemma 10.4, and the "if" part follows from Theorem 7.3 with the interpretation $I$ as defined in section 8. $\square$

## 11. Conclusions.

In this paper we introduced a novel framework that provides a sufficient condition for property testing in the one-sided error model. We demonstrated how to apply our framework on several problems from different areas, including computational geometry, graph theory, and computational biology. For some of these problems we presented the first property tester. For others, we improved existing bounds on the query complexity of property testers for these problems. We also proved that for hereditary graph properties our framework provides a sufficient and necessary condition for testability: we showed that any hereditary graph property is testable with query complexity independent of the input graph if and only if this can be proven using our framework.

Perhaps one of the most interesting open problems left in the paper concerns extending our framework to the two-sided error model. Another exciting problem is to design a similar framework for the sparse graph model. Compared to our framework, one difficulty with testing properties of sparse graphs is the fact that property testers use adaptive sampling techniques, e.g., random walks or graph traversals starting from random vertices, rather than uniform sampling. Consequently, one would have to find a randomized process that covers most of these adaptive sampling techniques.

**Acknowledgments.** We would like to thank Emo Welzl and an anonymous referee for their helpful comments on this work.

# LOAD BALANCING IN ARBITRARY NETWORK TOPOLOGIES WITH STOCHASTIC ADVERSARIAL INPUT[*]

ARIS ANAGNOSTOPOULOS[†], ADAM KIRSCH[‡], AND ELI UPFAL[†]

**Abstract.** We study the long-term (steady state) performance of a simple, randomized, local load balancing technique under a broad range of input conditions. We assume a system of $n$ processors connected by an arbitrary network topology. Jobs are placed in the processors by a deterministic or randomized adversary. The adversary knows the current and past load distribution in the network and can use this information to place the new tasks in the processors. A node can execute one job per step, and can also participate in one load balancing operation in which it can move tasks to a direct neighbor in the network. In the protocol we analyze here, a node equalizes its load with a random neighbor in the graph.

Our analysis of the protocol does not assume any particular input distribution. The input is generated by an arbitrary deterministic or probabilistic adversary subject only to some weak statistical properties. For stability and expected performance of the system we adopt the stochastic adversary model of [Borodin et al., *J. ACM*, 48 (2001), pp. 13–38]. For high-probability bounds we introduce a more restricted input model, the *strongly bounded* adversary.

Assuming the stochastic adversarial input model, we show that if the adversary does not trivially overload the network (i.e., there is an integer $w \geq 1$ such that the expected number of new jobs in any interval of length $w$ is bounded by $\lambda n w$ for some $\lambda < 1$), then the system is stable for any connected network topology, regardless of how the adversary allocates the new jobs between the processors.

When the system is stable, the next performance parameter of interest is the waiting time of jobs. We develop expected and high probability bounds on the total load in the system and the waiting time of jobs in terms of the network topology. In particular, in the above stochastic adversary model, if the network is an expander graph, the expected wait of a task is $O(w + \log n)$, and in the strongly bounded adversary model the waiting time of a task is $O(w + \log n)$ with high probability.

We contrast these results with the work stealing load balancing protocol, where we show that in sparse networks, the load in the system and the waiting time can be exponential in the network size.

**Key words.** dynamic load balancing, stochastic adversary, stability, efficiency, steady state analysis

## 1. Introduction.

Efficient utilization of parallel and distributed systems can often depend on dynamic load balancing of individual tasks between processors. In the dynamic load balancing problem, we consider a system that is designed to run indefinitely. New jobs arrive during the run of the system, and existing jobs are executed by the processors and leave the system. The arrival of new jobs may not be evenly distributed between the processors. The task of the load balancing protocol is to maintain approximately uniform job load between the processors, and in particular to keep all processors working as long as there are jobs in the system waiting for execution.

We assume a simple combinatorial model of load balancing following a number of earlier studies. The computing system is represented by a connected, undirected,

$n$-node graph. Jobs (represented by tokens) have equal execution time. The load of a node is the number of tokens in its queue. A processor can execute (or consume) one token per step, and we assume that it executes the oldest job in its queue. In each step a processor can also move a number of jobs from its queue to the queue of an adjacent node in the network. This abstraction models the case where the execution time of a job is significantly longer than the time required to move a job to an adjacent node. The assumption that all jobs have equal execution time simplifies the analysis while still capturing the combinatorial complexity of the load balancing problem in networks.

Dynamic load balancing algorithms have been studied extensively in experimental settings, demonstrating significant run-time improvements obtained by relatively simple load balancing techniques [20, 21]. Rigorous, theoretical study of load balancing in the past has focused mainly on static analysis [1, 7, 8, 11, 16, 18], where a set of jobs is initially placed in the processors and the algorithm needs to distribute the jobs almost evenly between the processors in a minimum number of parallel rounds. A number of important techniques have been developed in this line of work, and in particular our work here builds on the static analysis in [8].

Load balancing, however, is best analyzed in a dynamic setting that captures the actual application of such protocols. An important step in that direction was taken in [4], where the work stealing model was shown to be stable on the complete network. The main tool used in that work was the stability conditions for ergodic Markov chains, and consequently their stability result holds only for Markovian adversaries. In addition, a number of other works have studied dynamic load balancing under the assumptions that jobs are generated by a randomized process that is oblivious to the current state of the system [10, 13, 14, 19]. Finally, [3, 15] proved stability results for load balancing on a general network assuming the deterministic adversarial model. The computational model there is different, assuming that only one job can traverse an edge per step.

## 2. Model and main results.

In this work we address both the stability and the efficiency (waiting time) of the load balancing task. We present a simple local randomized protocol and analyze its performance on a general $n$-node network, and under several adversarial models for the arrival of jobs into the system. Since we do not use Markov chain techniques in the analysis, our results are not restricted to Markovian adversaries. That is, the process that injects new jobs into the system can use information about all previous steps.

In particular, we consider the type of adversaries proposed by Borodin et al. in [5]. Following that work we define a $(w, \lambda n)$ input adversary as a process that inserts jobs in the system subject to the condition that for every sequence of $w$ consecutive time steps, the total inserted load is at most $\lambda n w$. This allows the adversary to insert more jobs at some time steps, as long as the total load in windows of size $w$ is bounded. An extension is a $(w, \lambda n)$ stochastic adversary, whose input load is a random variable, with the property that the expected injected load during any sequence of $w$ consecutive time steps is bounded by $\lambda n w$, and additionally, for some $p > 2$, the $p$th moment of the new load is bounded (see [5] for a detailed discussion).

For these adversaries, we derive asymptotic (with respect to the network size) bounds on both the expected total load and the waiting time of a job in the system. However, it is still reasonable to seek stronger guarantees than bounds on expected performance can provide. In particular, one might wish to augment the expected performance results with high-probability bounds. In this case, the stochastic adversarial model is too powerful, since it allows for large bursts of load to occur in certain time steps with decent probability. Therefore we need to place additional restrictions on the adversary if we wish to derive high-probability results. To this end, we introduce a constrained version of the stochastic adversary by enforcing a large-deviation–type bound for the incoming load, similar to a Chernoff bound. We call these adversaries *strongly bounded.*

Formally, let $\mathcal{A}$ be an adversary that is injecting load into the system. Let $I_t$ be the load injected by the adversary during time step $t$.

DEFINITION 2.1. *We say that $\mathcal{A}$ is a $(\lambda, w, p, M)$* stochastic adversary *(where we assume that $w$ is a positive integer) if the following conditions hold for any time $t$ and any event $\mathcal{H}$ determined entirely by information about the system at or before time $t$.*

1. $\mathbf{E}\left[\sum_{i=1}^{w} I_{t+i} \,|\, \mathcal{H}\right] \le \lambda n w$.
2. $\mathbf{E}\left[\left(\sum_{i=1}^{w} I_{t+i}\right)^p \,|\, \mathcal{H}\right] \le M n^p w^p$.

*In addition, we say that $\mathcal{A}$ is* strongly bounded *if it also satisfies the following condition.*

3. *There is a constant $\alpha > 0$ and a constant $\beta \ge 1$ such that for any $\epsilon > 0$*

$$\mathbf{Pr}\left(\sum_{i=1}^{w} I_{t+i} > (1+\epsilon)\lambda n w \,|\, \mathcal{H}\right) \le e^{-\alpha\lambda n w \epsilon^{\beta}}.$$

Throughout the paper, we always assume that $\lambda$ and $p$ do not depend on $n$, while $w$ and $M$ may be functions of $n$.

We give a high-level description of the protocol here, deferring the details to section 3. After the generation of new load, the nodes execute a particular distributed randomized algorithm for choosing a random matching. The matching is not necessarily perfect, nor is it necessarily chosen uniformly from all possible matchings, although it does have some important properties that we will exploit later. Once the matching is chosen, every two matched nodes equalize their load (up to one token). For simplicity, we refer to this protocol as $\mathcal{P}$.

We first show that the system (using $\mathcal{P}$) is stable under the stochastic adversary model (for $\lambda < 1$ and $p > 2$). That is, the expected total load in the system is bounded with respect to time. The following theorem, proven in sections 5.1 and 5.3, relates the load in the system to the network topology and establishes the stability of the system. We assume a connected network $G = (V, E)$ that has $n$ nodes, maximum degree at most $\Delta$, and whose Laplacian[1] has smallest nontrivial eigenvalue $\Lambda$. For convenience, we define the quantity $\gamma = \Lambda/16\Delta$.

THEOREM 2.2. *Suppose that we run the system with a $(\lambda, w, p, M)$ adversary, where $\lambda < 1$ and $p > 2$, using protocol $\mathcal{P}$ (described in section 3). Let $L_t$ be the load of the system at time $t$. Then the system is stable and*

$$\limsup_{t\to\infty} \mathbf{E}[L_t \,|\, L_0] = O(\gamma^{-1} n (w + \ln n)(1+M)^{3p}) \qquad \textit{as } n \to \infty.$$

*In addition, if the adversary is strongly bounded, then for any constant $c > 0$ there is a constant $\kappa = \kappa(c)$, such that for sufficiently large $n$,*

$$\liminf_{t\to\infty} \mathbf{Pr}(L_t \le \kappa\gamma^{-1} n (w + \ln n)) \ge 1 - n^{-c}.$$

*The above bounds hold without the limits if the system starts with no load.*

[1]Let $A$ denote the adjacency matrix of a graph $G$, and let $D = (d_{ij})$, where $d_{ij}$ is the degree of node $i$ if $i = j$, and is 0 otherwise. The Laplacian of $G$ is the matrix $L = D - A$. The eigenvalues of $L$ are $0 = \Lambda_1 \le \Lambda_2 \le \cdots \le \Lambda_n$, and $\Lambda_2 = \Omega(n^{-2})$ if $G$ is connected.

Next we address the efficiency of the load balancing protocol, an important performance parameter that was not addressed in most previous work. That is, we relate the waiting time of jobs to the topology of the network. Since protocol $\mathcal{P}$ treats all tokens equally regardless of their ages, it cannot guarantee efficient delivery time for individual packets. To bound the waiting time of jobs in the system, we augment the protocol with a distributed version of the *first-in-first-out* queueing discipline, requiring that a node always respect the ages of its tokens in the load balancing step, and always consume its oldest token in the load consumption step (see section 3 for details). We denote this version of $\mathcal{P}$ by $\mathcal{P}^*$.

THEOREM 2.3. *Suppose that we run the system with a $(\lambda, w, p, M)$ adversary, where $\lambda < 1$ and $p > 2$, using protocol $\mathcal{P}^*$ (described in section 3). Let $W_t$ be the wait of a job that arrived at time $t$. Then*

$$\limsup_{t\to\infty} \mathbf{E}[W_t \mid L_0] = O(\gamma^{-1}(w + \ln n)(1+M)^{3p}) \qquad \text{as } n \to \infty.$$

*In addition, if the adversary is strongly bounded, then for any constant $c > 0$ there is a constant $\kappa = \kappa(c)$, such that for sufficiently large $n$,*

$$\liminf_{t\to\infty} \mathbf{Pr}(W_t \le \kappa\gamma^{-1}(w + \ln n)) \ge 1 - n^{-c}.$$

*The above bounds hold without the limits if the system starts with no load.*

In particular, for bounded degree regular expanders, $\gamma = \Theta(1)$, and the diameter of the graph is $\Theta(\ln n)$, so for these graphs the above result is optimal.

As a special case of a strongly bounded adversary, we consider the generator model that appeared in [4]. We contrast our results with the work stealing load balancing protocol that is analyzed there and show that in sparse networks, both the load in the system and the waiting time of a job can be exponential in the network size.

Notice that both Theorems 2.2 and 2.3 are concerned with the long-term behavior of the system. In both cases, we show that if certain restrictions are placed on the adversary, then the system behaves well most of the time. Since we focus on the asymptotic behavior of the system, every valid system state will occur infinitely often. Therefore the analysis must ensure that the system rarely enters undesirable states and quickly recovers from them when it does. Simple probabilistic techniques (e.g., estimating the probability of rare events for every time point and using a union bound over all time steps) are not sufficient to achieve these goals. We require more sophisticated arguments.

There is a substantial class of results, based on modeling the system's evolution as a Markov chain, that is frequently employed in these sorts of analyses—the proof of stability for the work stealing protocol in [4] is one example. Furthermore, for this Markov chain setting, there are additional tools for proving rapid convergence to a stationary distribution (see Meyn and Tweedie [12]), as well as for deriving properties of the stationary distribution (see [4] and the references therein). However, many of these results are qualitative and not quantitative. More importantly, they restrict the class of problems that they can model. In the particular context of adversarial load balancing that is the focus of this work, any straightforward application of such tools will only yield results for Markovian adversaries (i.e., adversaries whose usage allows for the system to be modeled as a time-homogeneous Markov chain)—the analysis in [4] is an example. While it is not obvious whether this restricted class of adversaries is really any weaker than the general class presented earlier, it is clear that results in the general adversarial model serve as a compelling argument for the efficacy of the load balancing protocol under a wide range of input conditions.

Since we seek greater generality than Markov chain results are known to provide, we need more elaborate tools. In the conference version of this paper [2], we apply results from renewal theory to show that the system has efficient long-term behavior under a particular non-Markovian adversary. In the current work, we generalize the results presented there by analyzing the behavior under the more general adversaries of Definition 2.1. To this end, we show that the load in the system behaves like a supermartingale above some threshold and then employ a result of Pemantle and Rosenthal [17] for the analysis of such processes. Finally, in section 5.3, we derive stronger, high-probability results for the more restricted adversaries.

**3. Protocol.** If we were simply interested in a stability result we could use the protocol studied in [8]: in each step nodes are matched randomly with adjacent neighbors in the network, and if node $v$ is matched with node $u$, they equalize their load subject to integer rounding. The details of the protocol (which we call protocol $\mathcal{P}$) are given below.

```
1. Matching phase:
   • For each node $i$
      – Node $i$ inserts each incident edge $(i,j)$ into a set $S$ with probability $\frac{1}{8\max(d_i,d_j)}$, where
        $d_i$ is the degree of node $i$.
      – Node $i$ removes edge $(i,j)$ from $S$ if some edge $(i,k)$ or $(j,k)$ is in $S$, with $k \neq i,j$.
   • Let the matching $M$ consist of the remaining edges in $S$.
2. Transfer phase:
   • If $(i,j) \in M$
      – $i$ and $j$ equalize their loads so that, say, $i$ gets load $\lceil(\ell_t(i)+\ell_t(j))/2\rceil$ and $j$ gets load
        $\lfloor(\ell_t(i)+\ell_t(j))/2\rfloor$, where $\ell_t(i)$ is the load of processor $i$ in the beginning of the step.
```

To bound the waiting time of jobs in the system we need to augment the above protocol with a distributed version of the *first-in-first-out* queueing discipline. It is not enough to require that a node consume the oldest job in its queue; we also need to consider the jobs' ages in the load balancing procedure. In particular, when $u$ and $v$ are matched they should not only equalize their total load but also equalize (up to rounding) the load that they have above any given age. A simple method to maintain this property is given by protocol $\mathcal{P}^*$ below. Note that protocol $\mathcal{P}^*$ is a special case of protocol $\mathcal{P}$.

```
1. Matching phase:
   • For each node $i$
      – Node $i$ inserts each incident edge $(i,j)$ into a set $S$ with probability $\frac{1}{8\max(d_i,d_j)}$, where
        $d_i$ is the degree of node $i$.
      – Node $i$ removes edge $(i,j)$ from $S$ if some edge $(i,k)$ or $(j,k)$ is in $S$, with $k \neq i,j$.
   • Let the matching $M$ consist of the remaining edges in $S$.
2. Transfer phase:
   • If $(i,j) \in M$
      – Let $J^i_1, J^i_2, \ldots, J^i_{\ell_t(i)}$ (where $\ell_t(i)$ is the load of processor $i$ in the beginning of the step),
        and let $J^j_1, J^j_2, \ldots, J^j_{\ell_t(j)}$ be the jobs in the queues of nodes $i$ and $j$, respectively, sorted
        from oldest to newest.
      – Node $i$ sends jobs $J^i_2, J^i_4, \ldots, J^i_{2\lfloor \ell_t(i)/2\rfloor}$ to node $j$. Similarly, node $j$ sends jobs
        $J^j_2, J^j_4, \ldots, J^j_{2\lfloor \ell_t(i)/2\rfloor}$ to node $i$.
      – Node $i$ merges jobs $J^i_1, J^i_3, J^i_5, \ldots$ with $J^j_2, J^j_4, J^j_6, \ldots$ in its queue, so that, finally, if a
        job $J$ is older than a job $J'$, then job $J$ is in the queue before job $J'$.
      – Similarly, node $j$ merges jobs $J^j_1, J^j_3, J^j_5, \ldots$ with $J^i_2, J^i_4, J^i_6, \ldots$ in its queue, so that,
        finally, if a job $J$ is older than a job $J'$, then job $J$ is in the queue before job $J'$.
```

**4. Analysis of the static case.** We first analyze our load balancing protocol in a static setting in which some initial load is placed on the $n$ processors, and load is moved between processors until the loads in all the processors are approximately equal. No new load is added to or removed from the system throughout the execution of the protocol.

Our analysis of the static case is based on coupling the execution of our protocol with the nonintegral protocol studied in [8]. The only difference between the two protocols is that in the nonintegral protocol the load is equally distributed between the two matched processors with no rounding. We consider two copies of the network starting with the same initial distribution, one using our protocol and the other using the nonintegral protocol. The two processes are coupled so that they use the same matching at every time step.

Fix any initial distribution of $K$ tokens to the nodes in $V$, and let $\bar{\ell} = K/n$. For each time step $t \geq 0$ and $u \in V$, let $\ell_t(u)$ be the number of tokens at $u$ at the end of step $t$ of the original, integral protocol, and let $\ell'_t(u)$ be the number of tokens at $u$ at the end of step $t$ in the nonintegral copy of the protocol. Also, for each time step $t \geq 0$, let $\Phi'_t = \sum_{v \in V}(\ell'_t(v) - \bar{\ell})^2$. Note that if the total load in the system is $K$, then for any $t \geq 0$, $\Phi'_t \leq K^2$. Notice that $\Phi'_t$ corresponds to the variance of the load on the nodes, and it is easy to see that it is nonincreasing with time, which, intuitively, means that successive applications of the load balancing protocol even out the distribution of the tokens to the nodes.

Recall that $\gamma = \Lambda/16\Delta$. The performance of the nonintegral protocol was analyzed in terms of $\gamma$ in [8]. The relevant result is the following lemma, which follows immediately from Theorem 1 in that work.

LEMMA 4.1. *For any $t \geq 0$,*

$$\mathbf{E}[\Phi'_{t+1} \,|\, \Phi'_t] \leq (1-\gamma)\Phi'_t.$$

Adapting the technique in [8] we can prove the following static load balancing result for the nonintegral copy.

LEMMA 4.2. *If $t \geq \gamma^{-1}(2\ln K + c\ln n)$, then the probability that there is some $v \in V$ with $|\ell'_t(v) - \bar{\ell}| > 1$ is at most $1/n^c$.*

*Proof.* By Lemma 4.1 we get

$$\mathbf{E}[\Phi'_t] = \mathbf{E}[\,\mathbf{E}[\Phi'_t \,|\, \Phi'_{t-1}]\,] \leq (1-\gamma)\mathbf{E}[\Phi'_{t-1}].$$

By applying the same argument $t$ times we get

$$\begin{aligned}\mathbf{E}[\Phi'_t] &= (1-\gamma)^t \Phi'_0 \\ &\leq \Phi'_0 e^{-\gamma t} \\ &\leq e^{-c\ln n},\end{aligned}$$

where in the last inequality we used the facts that $\Phi'_0 \leq K^2$ and $t \geq \gamma^{-1}(2\ln K + c\ln n)$. Applying Markov's inequality yields $\mathbf{Pr}(\Phi'_t > 1) < n^{-c}$. □

We will now tie the performance of our protocol to the performance of the nonintegral copy.

LEMMA 4.3. *For any $t \geq 0$ and any $v \in V$, $|\ell_t(v) - \ell'_t(v)| \leq t/2$, regardless of the chosen matchings and the rounding decisions in the original protocol.*

*Proof.* The proof is by induction on $t \geq 0$. If $t = 0$, then $\ell_t(v) = \ell'_t(v)$ for every $v \in V$, because no randomness has been introduced into the process yet. For the induction step, suppose that the lemma holds for time $t$. Choose any $v \in V$. If $v$ is not matched at time $t+1$, then $\ell_{t+1}(v) = \ell_t(v)$ and $\ell'_{t+1}(v) = \ell'_t(v)$, so the lemma holds by the induction hypothesis. Otherwise, $v$ is matched to some vertex $u$ at time $t+1$. In this case, for any rounding choice, $(\ell_t(u)+\ell_t(v)-1)/2 \le \ell_{t+1}(v) \le (\ell_t(u)+\ell_t(v)+1)/2$. Also, $\ell'_{t+1}(v) = (\ell'_t(u) + \ell'_t(v))/2$. These observations give

$$\begin{aligned}
|\ell_{t+1}(v) - \ell'_{t+1}(v)| &\overset{(a)}{\le} \frac{1}{2} + \left| \frac{\ell_t(u)+\ell_t(v)}{2} - \frac{\ell'_t(u)+\ell'_t(v)}{2} \right| \\
&\overset{(b)}{\le} \frac{1}{2} + \frac{1}{2}|\ell_t(u) - \ell'_t(u)| + \frac{1}{2}|\ell_t(v) - \ell'_t(v)| \\
&\overset{(c)}{\le} \frac{1}{2}\cdot\frac{t}{2} + \frac{1}{2}\cdot\frac{t}{2} + \frac{1}{2} \\
&= \frac{t+1}{2},
\end{aligned}$$

where (a) follows from previous observations, (b) follows from the triangle inequality, and (c) follows from the induction hypothesis. □

Putting Lemmas 4.2 and 4.3 together yields the following theorem.

THEOREM 4.4. *Let $\hat{t} = \gamma^{-1}(2\ln K + c\ln n)$. Then, for any $t \ge \hat{t}$, the probability that there is some $v \in V$ with $|\ell_t(v) - \bar{\ell}| > 1 + \frac{\hat{t}}{2}$ is at most $n^{-c}$.*

*Proof.* We first prove the theorem for the case $t = \hat{t}$. Regardless of the matchings generated in the first $\hat{t}$ steps, $|\ell_{\hat{t}}(v) - \ell'_{\hat{t}}(v)| \le \hat{t}/2$ for every $v \in V$ by Lemma 4.3. With probability at least $1 - 1/n^c$, $|\ell'_{\hat{t}}(v) - \bar{\ell}| \le 1$ for all $v \in V$ by Lemma 4.2. Adding these inequalities proves the theorem for the case $t = \hat{t}$. To extend the result for the case $t > \hat{t}$, notice that the sequence $\{\max_{v\in V}|\ell_t(v) - \bar{\ell}|\}_{t\ge\hat{t}}$ is nonincreasing. □

**5. Analysis of the dynamic case.** In order to analyze the long-term performance of the system, we split the time into *epochs* of a fixed length $T_E$ (to be defined later). We analyze each epoch in Theorem 5.1, which is the key ingredient in showing the stability and waiting-time properties of the system. Notice that the first part of the theorem, which we will apply for the stability result, holds for any protocol obeying the rules of $\mathcal{P}$, while the second part, which will be applied for the waiting-time guarantees, uses protocol $\mathcal{P}^*$.

THEOREM 5.1. *For any constant $c > 0$ and load $\Theta = \Theta_n > 0$, consider an epoch of length $T_E = T_D + T_C$, such that*

$$T_D \ge \gamma^{-1}(2\ln\Theta + c\ln n) \qquad \textit{and} \qquad T_C \ge \frac{\Theta}{n} + \frac{T_D}{2} + 1.$$

1. *Running protocol $\mathcal{P}$, if at time $\tau$ the load is $L_\tau$, then the system consumes at least $\min\{L_\tau, \Theta\}$ tokens in the next $T_E$ steps with probability at least $1 - n^{-c}$.*
2. *Running protocol $\mathcal{P}^*$, if at time $\tau$ the load is bounded by $\Theta$, then with probability at least $1 - n^{-c}$, all the jobs that exist in the system at time $\tau$ will be consumed by time $\tau + T_E$.*

*Proof.* For the purpose of the analysis we split the epoch into two parts. In the first $T_D$ steps we focus on the distribution of load between the processors, and in the remaining $T_C$ steps we focus on the consumption of load by the processors (although load is consumed throughout the whole execution by processors that have load).

We start by proving the first part of the theorem; a modification of that argument gives the second part. To analyze the distribution of load between the processors, we couple the actual execution of the protocol in the first $T_D$ steps with an execution of the protocol in a static setting that starts with a total load of exactly $\Theta$ and does not generate or consume any jobs. We refer to the actual execution of the protocol as the *dynamic copy* and the static execution as the *static copy*.

To formulate the coupling we color all the tokens (jobs) in the dynamic copy at time $\tau$ by red and blue. A subset of $M = \min\{L_\tau, \Theta\}$ tokens in the system at time $\tau$ is colored red, and the rest are colored blue. We now place $\Theta$ tokens in the static copy so that each node in the static copy starts the process with at least as many tokens as the number of red tokens in the corresponding node of the dynamic copy. New tokens that arrive through the execution of the dynamic copy are colored blue.

The executions of the two copies are coupled so that they use the same matching in each step and the same rounding decisions. When we equalize (up to one) the load between two vertices in the dynamic execution, we also equalize (up to one, using the same rounding rule) the number of red tokens in the two nodes, keeping the total number of red tokens in the two nodes as before (this can be achieved by recoloring some tokens). Finally, after each matching we recolor the tokens in the nodes again, preserving the total number of red tokens in each queue, but putting all the red tokens in a queue ahead of all the blue tokens.

LEMMA 5.2. *At any time $\tau \le t \le \tau + T_D$ the number of red tokens in each node of the dynamic copy is bounded by the number of tokens in the corresponding node in the static copy.*

*Proof.* We begin with some intuition. Initially the coloring of the tokens in the dynamic copy is such that the claim holds. New tokens that enter the system in the dynamic copy are colored blue, while no tokens in the static copy are removed. Furthermore, the matching operations in both copies are coupled, so we expect that if one node in the static copy gives half of its tokens to a neighbor, the same node in the dynamic copy will do the same with its red tokens. Therefore, we expect that the claim will hold at the next step. By induction, the lemma follows.

We now proceed formally by induction on $t$. The claim is true for $t = \tau$ by the construction of the static copy. Assume that the claim holds after the execution of step $t - 1$, and consider the load of node $u$ after the execution of step $t$. If $u$ was not part of a matching in step $t$, then the load of the static copy did not change. The number of red tokens of the dynamic copy either did not change or was reduced by 1 if a red token was consumed. In both cases, using the induction hypothesis, the number of red tokens in the dynamic copy after the execution of step $t$ is bounded by the number of tokens in the static copy of $u$.

Assume now that node $u$ was matched with node $v$ during step $t$. Recall that every time step in the process can be decomposed into three substeps: the insertion substep (where new load is created in the dynamic copy), the balancing substep (where the matching is chosen and the nodes in both copies equalize their loads), and the consumption substep (where the nonempty nodes in the dynamic copy consume a job). With this in mind, we define some new variables:

- $\ell_t^i(u)$, $\ell_t^b(u)$, $\ell_t^c(u)$ are the total number of tokens at node $u$ in the dynamic copy immediately following the insertion, balancing, and consumption substeps of time step $t$, respectively.
- $r_t^i(u)$, $r_t^b(u)$, $r_t^c(u)$ are the number of red tokens at node $u$ in the dynamic copy at that time.
- $s_t^i(u)$, $s_t^b(u)$, $s_t^c(u)$ are the number of tokens at node $u$ in the static copy at that time.

We analyze each substep separately.

• Initially, by the induction hypothesis, we have

$$r^c_{t-1}(u) \le s^c_{t-1}(u), \qquad r^c_{t-1}(v) \le s^c_{t-1}(v). \tag{5.1}$$

• After the insertion substep, we color the new tokens blue so the number of red tokens remains the same:

$$r^i_t(u) = r^c_{t-1}(u), \qquad r^i_t(v) = r^c_{t-1}(v). \tag{5.2}$$

The static copy does not accept new tokens, so

$$s^i_t(u) = s^c_{t-1}(u), \qquad s^i_t(v) = s^c_{t-1}(v). \tag{5.3}$$

So from relations (5.1), (5.2), and (5.3) we get that

$$r^i_t(u) \le s^i_t(u), \qquad r^i_t(v) \le s^i_t(v). \tag{5.4}$$

Notice also that the number of red tokens is bounded by the total number of tokens, so

$$r^i_t(u) \le \ell^i_t(u), \qquad r^i_t(v) \le \ell^i_t(v). \tag{5.5}$$

• After the balancing substep, we assume, without loss of generality, that the rounding is such that

$$\ell^b_t(u) = \left\lceil \frac{1}{2}(\ell^i_t(u) + \ell^i_t(v)) \right\rceil, \qquad \ell^b_t(v) = \left\lfloor \frac{1}{2}(\ell^i_t(u) + \ell^i_t(v)) \right\rfloor. \tag{5.6}$$

The results of the analysis of the static case in section 4 hold for an arbitrary rounding procedure. Thus, in the static copy we perform the rounding so that

$$s^b_t(u) = \left\lceil \frac{1}{2}(s^i_t(u) + s^i_t(v)) \right\rceil, \qquad s^b_t(v) = \left\lfloor \frac{1}{2}(s^i_t(u) + s^i_t(v)) \right\rfloor. \tag{5.7}$$

Finally, we recolor the tokens in the dynamic copy (we swap colors between some tokens), so that

$$r^b_t(u) = \left\lceil \frac{1}{2}(r^i_t(u) + r^i_t(v)) \right\rceil, \qquad r^b_t(v) = \left\lfloor \frac{1}{2}(r^i_t(u) + r^i_t(v)) \right\rfloor. \tag{5.8}$$

Then, using relation (5.4), we get

$$r^b_t(u) = \left\lceil \frac{1}{2}(r^i_t(u) + r^i_t(v)) \right\rceil \le \left\lceil \frac{1}{2}(s^i_t(u) + s^i_t(v)) \right\rceil = s^b_t(u) \tag{5.9}$$

and

$$r^b_t(v) = \left\lfloor \frac{1}{2}(r^i_t(u) + r^i_t(v)) \right\rfloor \le \left\lfloor \frac{1}{2}(s^i_t(u) + s^i_t(v)) \right\rfloor = s^b_t(v). \tag{5.10}$$

Notice that

$$r^b_t(u) + r^b_t(v) = \left\lceil \frac{1}{2}(r^i_t(u) + r^i_t(v)) \right\rceil + \left\lfloor \frac{1}{2}(r^i_t(u) + r^i_t(v)) \right\rfloor = r^i_t(u) + r^i_t(v),$$

which means that we haven't changed the number of red tokens, and notice also that by using relation (5.5) we get that

$$r_t^b(u) = \left\lceil \frac{1}{2}(r_t^i(u) + r_t^i(v)) \right\rceil \leq \left\lceil \frac{1}{2}(\ell_t^i(u) + \ell_t^i(v)) \right\rceil = \ell_t^b(u)$$

and

$$r_t^b(v) = \left\lfloor \frac{1}{2}(r_t^i(u) + r_t^i(v)) \right\rfloor \leq \left\lfloor \frac{1}{2}(\ell_t^i(u) + \ell_t^i(v)) \right\rfloor = \ell_t^b(v),$$

which ensure that the recoloring is valid (i.e., for both $u$ and $v$, the number of the red tokens is not more than the total number of tokens).

Finally, we recolor the tokens again (preserving the number of red tokens at each node), so that every red token in a queue is ahead of every blue token in that queue.

• After the consumption substep, since some red tokens may be consumed, we get that

$$r_t^c(u) \leq r_t^b(u), \qquad r_t^c(v) \leq r_t^b(v). \tag{5.11}$$

In the static copy there are no tokens being consumed, so

$$s_t^c(u) = s_t^b(u), \qquad s_t^c(v) = s_t^b(v). \tag{5.12}$$

Hence, from relations (5.9), (5.10), (5.11), and (5.12) we can finally prove the induction hypothesis for step $t$:

$$r_t^c(u) \leq s_t^c(u), \qquad r_t^c(v) \leq s_t^c(v). \qquad \square$$

We now turn to studying the consumption phase. Applying Theorem 4.4 to the execution of the static copy, we see that at time $\tau + T_D$ (the reader can verify that the condition of Theorem 4.4 holds for $t = T_D$ and $K = \Theta$), with probability at least $1 - n^{-c}$ no node of the static copy has more than $T_D/2 + \Theta/n + 1 \leq T_C$ tokens. Thus, by Lemma 5.2, with the same probability, no node in the dynamic copy has more than $T_C$ red tokens.

We continue to run the coupling from time $\tau + T_D$ with this new coloring. When balancing between two nodes, we recolor the tokens in exactly the same way as in the distribution phase (see Lemma 5.2), so that, in particular, if a node has some red tokens in its queue, then these tokens are at the front of the node's queue, before the blue tokens. In this case, notice that after a balancing substep, the maximum (over all the nodes in the graph) number of tokens does not increase. In the consumption substep the maximum (again, over all the nodes in the graph) number of red tokens decreases by 1, since the red tokens are at the front of their queues. Since initially at most $T_C$ red tokens are at a node with probability at least $1 - n^{-c}$, we conclude that with probability $1 - n^{-c}$, all the red tokens (which means at least $M = \min\{L_\tau, \Theta\}$ tokens) are consumed in this epoch. This completes the proof of the first part of the theorem.

The proof of the second part of the theorem is almost identical to the first one. We color initially all the $L_\tau \leq \Theta$ tokens of the dynamic copy at time $\tau$ red, while all the subsequent ones are colored blue, and again we consider the coupled static copy. Since now we are interested in the identities of the jobs that are being consumed, we do not allow recolorings of the tokens.

Notice though that protocol $\mathcal{P}^*$ ensures that during the whole epoch, if a node has both red and blue tokens in its queue, the red tokens are before the blue ones. Moreover, the transfer phase of $\mathcal{P}^*$ ensures that when node $u$ is matched with node $v$, they balance their red tokens (up to a difference of 1). Without loss of generality, we assume that the rounding is such that if the ensemble of the red tokens in the two nodes is odd, then node $u$ ends up with one more red token. Hence equations (5.8) remain true. We then perform the rounding in the static copy to ensure that equations (5.7) remain true as well.

As an aside, notice that it may be the case that after the balancing substep, node $v$'s *total* load is exactly one larger than $u$'s total load, in which case equations (5.6) may become

$$\ell_t^b(u) = \left\lfloor \frac{1}{2}(\ell_t^i(u) + \ell_t^i(v)) \right\rfloor, \qquad \ell_t^b(v) = \left\lceil \frac{1}{2}(\ell_t^i(u) + \ell_t^i(v)) \right\rceil.$$

Here, however, we analyze only the distribution of the red tokens, so the analysis is not affected by this fact.

Everything else is identical to the first part, and by the same reasoning we conclude that by the end of the distribution phase, for every node $u$, the number of red tokens in the dynamic copy is bounded by the number of tokens in the static copy, with probability at least $1 - n^{-c}$, which, by applying Theorem 4.4, implies that every node has at most $T_C$ red tokens.

Then, as in the first part, we can conclude that by the end of the consumption phase all the red tokens—which are exactly the tokens that were in the system in the beginning of the epoch—are consumed. ∎

An immediate consequence of the analysis of the second part of Theorem 5.1 is the following lemma, which gives a bound on the expected time needed until the initial load is distributed. We make use of the lemma in order to bound the expected waiting time.

LEMMA 5.3. *Assume that we are given $c, \Theta, T_D, T_C$, satisfying the conditions of Theorem 5.1, and assume that we balance according to protocol $\mathcal{P}^*$. If at time $\tau$ the load is bounded by $\Theta$, then the expected time needed until every node in the system has at most $T_C$ of the initial jobs is bounded by $2T_D$ for sufficiently large $n$. At every time, when a node has some of the initial load, this is at the head of its queue.*

*Proof.* The analysis is an extension of the proof of the second part of Theorem 5.1. We color the initial load at time $\tau$ red, all the new incoming load blue, and we let $T$ be the time until every node in the network has at most $T_C$ red tokens. We perform the same coupling as in Theorem 5.1 from time $\tau$ until time $\tau + T$. During this whole period the number of red tokens in the dynamic copy is bounded by the number of tokens in the static copy. Since the red tokens are the oldest tokens in the system, protocol $\mathcal{P}^*$ ensures that if a node has some red tokens and some blue tokens, the red tokens are always in front of the blue ones.

Thus, by the proof of Theorem 5.1, part 2, we get that $T \le T_C$ with probability at least $1 - n^{-c}$. It follows that $\lceil T/T_D \rceil$ is stochastically dominated by a geometric random variable with parameter $1 - n^{-c}$, so

$$\mathbf{E}[T] \le \frac{1}{1 - n^{-c}} T_D \le 2T_D$$

for sufficiently large $n$. ∎

**5.1. Stability.** In this section we prove the stability of the system under a $(\lambda < 1, w, p > 2, M)$ stochastic adversary. The main technical tool that we use is the following theorem, which follows immediately from [17, Corollary 2].

THEOREM 5.4. *Let $X_1, X_2, \ldots$ be a sequence of nonnegative random variables satisfying the following conditions:*

1. *There exist positive numbers $\alpha = \alpha_n$ and $\Theta = \Theta_n$ such that for all $x_1, \ldots, x_i$ with $x_i > \Theta$,*

$$\mathbf{E}[X_{i+1} - X_i \,|\, X_1 = x_1, \ldots, X_i = x_i] \le -\alpha.$$

2. *There exists a positive number $\xi = \xi_n$ and a $p = p_n > 2$ such that for all $x_1, \ldots, x_i$*

$$\mathbf{E}[|X_{i+1} - X_i|^p \,|\, X_1 = x_1, \ldots, X_i = x_i] \le \xi.$$

*Then there exists $\Xi = \Xi(X_0, \alpha, \Theta, \xi)$ and $t_0$ such that for all $t \ge t_0$,*

$$\mathbf{E}[X_t \,|\, X_0] \le \Xi + \max(0, X_0 - \Theta).$$

*Furthermore, assuming that $p$ is a constant with respect to $n$,*

$$\Xi = O\left(\Theta + \alpha\left(1 + \frac{\xi}{\alpha^p}\right)^{3p}\right) \qquad \textit{as } n \to \infty.$$

Our stability result is summarized in the following theorem.

THEOREM 5.5. *Suppose that we run protocol $\mathcal{P}$ with a $(\lambda, w, p, M)$ adversary, where $\lambda < 1$ and $p > 2$. Then*

$$\sup_{t \ge 0} \mathbf{E}[L_t \,|\, L_0] = O(\max(\gamma^{-1} n(w + \ln n)(1 + M)^{3p}, L_0)) \qquad \textit{as } n \to \infty.$$

*Proof.* We first present the high-level idea of the proof. Recall that $L_t$ is the load of the system at time $t$. We partition the time into *epochs* of some length $d$ and apply Theorem 5.4 to the subsequence $\{L_{di} \mid i \ge 0\}$. Using Theorem 5.1, we show that if the load at the beginning of an epoch is above some threshold $\Theta$, then the expected load at the end of that epoch is strictly smaller by a significant amount, proving condition 1 of Theorem 5.4. We then derive the required bound on the $p$th moment $L_{(i+1)d} - L_{id}$, establishing condition 2 of Theorem 5.4. Applying Theorem 5.4 then gives the desired bound on the maximum expected load at the end of epochs. Finally, we generalize to steps that are not multiples of $d$.

Let us now formalize the above argument. The two conditions that we want to satisfy are

$$\mathbf{E}[L_{(i+1)d} - L_{id} \,|\, L_0 = l_0, L_d = l_d, \ldots, L_{(i-1)d} = l_{(i-1)d}, L_{id} = \ell_{id} > \Theta] \le -\alpha,$$
$$\mathbf{E}[|L_{(i+1)d} - L_{id}|^p \,|\, L_0 = l_0, L_d = l_d, \ldots, L_{(i-1)d} = l_{(i-1)d}, L_{id} = \ell_{id}] \le \xi$$

for all $(l_0, l_1, \ldots, l_{id})$. In order to simplify the notation we denote

$$\mathcal{L}_{i-1} = \{L_0 = l_0, L_d = l_d, \ldots, L_{(i-1)d} = l_{(i-1)d}\},$$

so the conditions become

$$\mathbf{E}[L_{(i+1)d} - L_{id} \,|\, \mathcal{L}_{i-1}, L_{id} = \ell_{id} > \Theta] \le -\alpha, \tag{5.13}$$

$$\mathbf{E}[|L_{(i+1)d} - L_{id}|^p \,|\, \mathcal{L}_{i-1}, L_{id}] \le \xi. \tag{5.14}$$

Let

$$\Theta = \sigma\gamma^{-1}n(w + \ln n) \tag{5.15}$$

for some constant $\sigma$ that we will fix later. Also let

$$T_D = \gamma^{-1}(2\ln\Theta + \ln n) \qquad \text{and} \qquad T_C = \frac{\Theta}{n} + \frac{T_D}{2} + 1,$$

so that

$$\begin{aligned} T_E &= T_D + T_C \\ &= \frac{\Theta}{n} + 3\gamma^{-1}\ln\Theta + \frac{3}{2}\gamma^{-1}\ln n + 1 \\ &= \sigma\gamma^{-1}(w + \ln n) + 3\gamma^{-1}\ln\sigma + 3\gamma^{-1}\ln\gamma^{-1} + 3\gamma^{-1}\ln(w + \ln n) + \frac{9}{2}\gamma^{-1}\ln n + 1. \end{aligned} \tag{5.16}$$

We let $\sigma$ be such that $T_E/w$ is an integer, say $k$ (we show later that such a $\sigma$ exists), so that $T_E$ is a multiple of the window size $w$, and define the epoch length

$$d = kw = T_E. \tag{5.17}$$

Notice that $d = O(\gamma^{-1}(w + \ln n))$, a fact that we use later. Fix some time $t = id$ and consider what happens in the case that $L_t > \Theta$. By Theorem 5.1, part 1 (for $c = 1$), we get that within $d = T_E$ steps the system consumes at least $\Theta$ units of load, with probability at least $1 - 1/n$. Thus, the expected number of tokens consumed between steps $id$ and $(i+1)d$ is at least

$$\left(1 - \frac{1}{n}\right) \cdot \Theta = \sigma\gamma^{-1}n(w + \ln n) - \sigma\gamma^{-1}(w + \ln n), \tag{5.18}$$

independently of the past, and of any of the adversary's decisions.

Since an epoch consists of $k$ windows, by the definition of the adversary, the expected injected new load in the system from time $id$ until $(i+1)d$, conditioned on $\mathcal{L}_{i-1}$, is bounded by

$$k\lambda nw = \lambda nd.$$

Using (5.16) and (5.17) we can conclude that the expected new load injected by the adversary, conditioned on the history, is bounded by

$$\begin{aligned} \lambda nd &= \lambda\sigma\gamma^{-1}n(w + \ln n) + 3\lambda\gamma^{-1}n\ln\sigma \\ &\quad + 3\lambda\gamma^{-1}n\ln\gamma^{-1} + 3\lambda\gamma^{-1}n\ln(w + \ln n) + \frac{9}{2}\lambda\gamma^{-1}n\ln n + \lambda n \\ &\le \lambda\sigma\gamma^{-1}n(w + \ln n) + 3\lambda\gamma^{-1}n\ln\sigma \\ &\quad + 9\lambda\gamma^{-1}n\ln(c'n) + 3\lambda\gamma^{-1}n\ln(w + \ln n) + \frac{9}{2}\lambda\gamma^{-1}n\ln n + \lambda n \qquad (5.19) \\ &= \gamma^{-1}n(w + \ln n)\left[\lambda\sigma + \frac{3\lambda\ln\sigma}{w + \ln n} + \frac{9\lambda\ln(c'n)}{w + \ln n} + \frac{3\lambda\ln(w + \ln n)}{w + \ln n}\right. \\ &\qquad \left. + \frac{9\lambda\ln n}{2(w + \ln n)} + \frac{\lambda}{\gamma^{-1}(w + \ln n)}\right], \end{aligned}$$

where the inequality follows from the fact that $\gamma^{-1} \leq c'n^3$ for some constant $c'$, since $\Lambda = \Omega(n^{-2})$ for any connected graph. Therefore, from relations (5.18) and (5.19) we get

$$\begin{aligned}\mathbf{E}[L_{(i+1)d} - L_{id} \,|\, \mathcal{L}_{i-1}] &\leq -\sigma\gamma^{-1}n(w+\ln n) + \gamma^{-1}n(w+\ln n)\\ &\qquad \left[\lambda\sigma + \frac{3\lambda\ln\sigma}{w+\ln n} + \frac{9\lambda\ln(c'n)}{w+\ln n} + \frac{3\lambda\ln(w+\ln n)}{w+\ln n}\right.\\ &\qquad \left. + \frac{9\lambda\ln n}{2(w+\ln n)} + \frac{\lambda}{\gamma^{-1}(w+\ln n)} + \frac{\sigma}{n}\right]\\ &\leq -\sigma\gamma^{-1}n(w+\ln n) + \gamma^{-1}n(w+\ln n)(\lambda\sigma + Q),\end{aligned}$$

for sufficiently large $n$, where $Q$ is a constant independent of $\sigma$. Hence,

$$\mathbf{E}[L_{(i+1)d} - L_{id} \,|\, \mathcal{L}_{i-1}] \leq -\gamma^{-1}n(w+\ln n)(\sigma - \lambda\sigma - Q).$$

If

$$\sigma > \frac{Q}{1-\lambda},$$

then relation (5.13) is satisfied for sufficiently large $n$. We therefore let $\sigma$ be the smallest number that is greater than $Q/(1-\lambda)$ that ensures that $d = T_E$ is a multiple of the window size $w$. Notice that the fact that $d$ is a continuous function of $\sigma$ ensures that such a value of $\sigma$ exists and satisfies

$$\sigma \leq \frac{2Q}{1-\lambda}.$$

Thus condition 1 is satisfied for $\alpha = O(\gamma^{-1}n(w+\ln n))$.

We now turn our attention to relation (5.14). Let $J_i$ and $Z_i$ be the number of tokens injected by the adversary and consumed by the processors, respectively, during the $i$th epoch. We note that

$$\begin{aligned}|L_{(i+1)d} - L_{id}|^p &= |J_i - Z_i|^p\\ &\leq J_i^p + Z_i^p\\ &\leq J_i^p + d^p n^p,\end{aligned} \tag{5.20}$$

where the last inequality follows from the fact that the system (deterministically) consumes at most $n$ tokens in every step.

We now bound $\mathbf{E}[J_i^p \,|\, \mathcal{L}_{i-1}, L_{id}]$. Write $J_i = \sum_{j=0}^{k-1} Y_j$, where

$$Y_j = \sum_{t=0}^{w-1} I_{id+jw+t}$$

is the number of tokens injected by the adversary during the window $[id+jw,\, id+(j+1)w-1]$.

The second condition on the stochastic adversary gives, for all $j$,

$$\mathbf{E}[Y_j^p] \leq Mn^p w^p.$$

Applying Hölder's inequality gives

$$J_i^p = \left(\sum_{j=0}^{k-1} Y_j\right)^p \leq \left(\sum_{j=0}^{k-1} 1\right)^{p\left(1-\frac{1}{p}\right)} \left(\sum_{j=0}^{k-1} Y_j^p\right) = k^{p-1}\sum_{j=0}^{k-1} Y_j^p,$$

and therefore we get

$$\mathbf{E}[J_i^p \mid \mathcal{L}_{i-1}, L_{id}] \leq k^p M n^p w^p. \tag{5.21}$$

Therefore, relations (5.20) and (5.21) imply that relation (5.14) is satisfied with

$$\xi = k^p M n^p w^p + d^p n^p = (M+1) d^p n^p,$$

and by Theorem 5.4 we deduce that

$$\sup_{i \geq 0} \mathbf{E}[L_{id} \mid L_0] = O(\max(\gamma^{-1} n (w + \ln n)(1+M)^{3p}, L_0)).$$

We have now proven the theorem for $t$ corresponding to the beginning of an epoch. To finish the proof, we have for any $t \geq 0$

$$\begin{aligned}
\mathbf{E}[L_t \mid L_0] &= \mathbf{E}[L_{\lfloor t/d \rfloor d + (t - \lfloor t/d \rfloor d)} \mid L_0] \\
&\leq \mathbf{E}[L_{\lfloor t/d \rfloor d} \mid L_0] + \mathbf{E}\left[ \sum_{j = \lfloor t/d \rfloor d}^{t} I_j \,\middle|\, L_0 \right] \\
&\leq \sup_{i \geq 0} \mathbf{E}[L_{id} \mid L_0] + \lambda n d \\
&= O(\max(\gamma^{-1} n (w + \ln n)(1+M)^{3p}, L_0)). \qquad \square
\end{aligned}$$

THEOREM 5.6. *Given any initial load $L_0$, with probability 1 there is an $i \geq 0$, such that $L_{id} \leq \Theta$ for $\Theta$ defined as in (5.15).*

*Proof.* For intuition, assume that the initial load $L_0$ is above $\Theta$. Then by relation (5.13), we expect it to decrease below $\Theta$ after a sufficiently long time period. In order to prove this fact, we use martingale techniques. Since the expected load decreases independently of the past, we can couple the load with a supermartingale until it drops below $\Theta$. Then we can apply a martingale convergence theorem to show that the supermartingale (and therefore the coupled system load) will eventually reach $\Theta$.

Proceeding formally, we define a supermartingale $\{Y_{id} \mid i \geq 0\}$ with respect to the sequence $\{L_{id} \mid i \geq 0\}$, where

$$Y_{id} = \begin{cases} \max(L_0, \Theta) & \text{for } i = 0, \\ L_{id} & \text{if } L_{(i-1)d} > \Theta, \\ \Theta & \text{if } L_{(i-1)d} \leq \Theta. \end{cases}$$

As long as $Y_{(i-1)d} > \Theta$ the two sequences of random variables are identical. The sequence $L_{id}$ assumes a value $\leq \Theta$ if and only if there is an index $j$ such that $Y_{jd} = \Theta$.

The (nonnegative) supermartingale $Y_{id}$ converges with probability 1 to a random variable $Y$ (see [9, Theorem 5.1]), and since

$$\mathbf{E}[Y_{(i+1)d} \mid Y_{id} > \Theta] \leq Y_{id} - \alpha$$

for some $\alpha > 0$ (defined in the proof of Theorem 5.5), we have $\lim_{i \to \infty} \mathbf{E}[Y_{id}] = \Theta$. By applying Fatou's lemma [6, p. 110] we get $\mathbf{E}[Y] \leq \liminf_{i \to \infty} \mathbf{E}[Y_{id}] = \Theta$. Thus, with probability 1 the sequence $\{L_{id}\}$ assumes at some time $jd$ a value less than or equal to $\Theta$. $\square$

Corollary 5.7.

1. *If the system starts with no load, then for sufficiently large $n$,*

$$\sup_{t\geq 0} \mathbf{E}[L_t] = O(\gamma^{-1} n(w + \ln n)(1 + M)^{3p}).$$

2. *For any starting conditions*

$$\limsup_{t\to\infty} \mathbf{E}[L_t \mid L_0] = O(\gamma^{-1} n(w + \ln n)(1 + M)^{3p}) \qquad \textit{as } n \to \infty.$$

*Proof.* The first part follows from Theorem 5.5, while the second part uses also Theorem 5.6. □

**5.2. Waiting time.** Having established that the system is stable, the next important performance parameter is the waiting time of a job from the time it enters the system until it is executed. For a given task that enters the system at time $t$, let $W_t$ be the number of steps until the task is executed. Following the discussion of section 3, throughout this section we assume that we perform protocol $\mathcal{P}^*$.

Theorem 5.8. *Suppose that we run protocol $\mathcal{P}^*$ with a $(\lambda, w, p, M)$ adversary, where $\lambda < 1$ and $p > 2$. Then*

$$\sup_{t\geq 0} \mathbf{E}[W_t \mid L_0] = O(\max(\gamma^{-1}(w + \ln n)(1 + M)^{3p}, L_0/n)) \qquad \textit{as } n \to \infty.$$

*Proof.* We begin with some intuition. By the results of section 5.1, we expect the load $L_t$ at time $t$ to be low, namely, bounded by $O(\max(\gamma^{-1}n(w+\ln n)(1+M)^{3p}, L_0))$. We also expect that the distribution protocol will rapidly distribute this load among the nodes (even if it is not already distributed, and regardless of any load that comes in after time $t$)—this is formalized by Lemma 5.3. Once this load is evenly distributed, it can be quickly consumed, since $\mathcal{P}^*$ ensures that every node consumes the oldest token in its queue at the end of every time step. Therefore, the expected time to consume all the load is $O(\mathbf{E}[L_t]/n)$.

We now proceed formally. Assume that at some time $t$ the load in the system is $L_t$. We apply Lemma 5.3 with $c = 1$, $\Theta = L_t$, $T_D = \gamma^{-1}(2 \ln L_t + \ln n)$ and

$$T_C = \frac{\Theta}{n} + \frac{T_D}{2} + 1,$$

and we get that the expected time, conditioned on any past event $\mathcal{H}$, until all the tokens that were present at time $t$ are consumed (measured from time $t$) is at most

$$2T_D + T_C \leq 4T_C + T_C = 5T_C$$

for $n \geq 2$. Thus for $n \geq 2$,

$$\mathbf{E}[W_t \mid L_t, \mathcal{H}] \leq 5T_C = \frac{5L_t}{n} + \frac{5\gamma^{-1}}{2}(2 \ln L_t + \ln n) + 5.$$

Consequently, for sufficiently large $n$, we have that for any $t \geq 0$,

$$\begin{aligned}
\mathbf{E}[W_t \mid L_0] &= \sum_{\ell_t} \mathbf{E}[W_t \mid L_0, L_t = \ell_t] \cdot \mathbf{Pr}(L_t = \ell_t \mid L_0) \\
&\leq \sum_{\ell_t} \left( \frac{5\ell_t}{n} + \frac{5\gamma^{-1}}{2}(2 \ln \ell_t + \ln n) + 5 \right) \cdot \mathbf{Pr}(L_t = \ell_t \mid L_0) \\
&= \mathbf{E}\left[ \frac{5L_t}{n} + \frac{5\gamma^{-1}}{2}(2 \ln L_t + \ln n) + 5 \,\middle|\, L_0 \right] \\
&= \frac{5\,\mathbf{E}[L_t \mid L_0]}{n} + \frac{5\gamma^{-1}}{2}(2\,\mathbf{E}[\ln L_t \mid L_0] + \ln n) + 5 \\
&\leq \frac{5\,\mathbf{E}[L_t \mid L_0]}{n} + \frac{5\gamma^{-1}}{2}(2\, \ln \mathbf{E}[L_t \mid L_0] + \ln n) + 5 \\
&= O(\max(\gamma^{-1}(w + \ln n)(1 + M)^{3p}, L_0/n)),
\end{aligned}$$

where the second-to-last step follows from Jensen's inequality applied to the concave function $f(x) = \ln x$, and the last step follows from Theorem 5.5. $\square$

Applying Theorem 5.6 we have the following.

Corollary 5.9.

1. *If the system starts with no load, then for sufficiently large $n$,*

$$\sup_{t \geq 0} \mathbf{E}[W_t] = O(\gamma^{-1}(w + \ln n)(1 + M)^{3p}).$$

2. *For any starting conditions,*

$$\limsup_{t \geq 0} \mathbf{E}[W_t \mid L_0] = O(\gamma^{-1}(w + \ln n)(1 + M)^{3p}) \qquad \textit{as } n \to \infty.$$

*Proof.* The first part follows from Theorem 5.8, while the second part uses also Theorem 5.6. $\square$

**5.3. Strongly bounded adversaries.** Recall that a strongly bounded adversary satisfies the additional requirement that for some constants $\alpha > 0$, $\beta \geq 1$, for any $\epsilon > 0$, the probability that the total number of new jobs that arrive in a given interval of length $w$ is greater than $(1 + \epsilon)\lambda n w$ is bounded by $e^{-\alpha \lambda n w \epsilon^{\beta}}$.

In this subsection we strengthen the preceding results for adversaries that are strongly bounded. The Chernoff-type restrictions on the input stream allow us to get high-probability results for the load and the waiting time.

**5.3.1. High-probability bound on load.** Our first result bounds the probability that at a given time point the load of the system is high.

Theorem 5.10. *Consider a system where load is injected by a strongly bounded adversary. Let $L_t$ be the load of the system at time $t$. Then for any sufficiently large constant $c_1$ there exists a constant $c' > 0$ such that*

$$\limsup_{t \to \infty} \mathbf{Pr}(L_t > c_1 \gamma^{-1} n(w + \ln n)) \leq 3n^{-c'}.$$

*The above holds without the limit if the system starts with no load.*

*Proof.* Let $\Theta = c_1 \gamma^{-1} n(w + \ln n)$. We observe the system at some time $t$, and we need to bound the probability that the load at time $t$ is above $\Theta$. Therefore, we assume that the load at time $t$ is above $\Theta$ and calculate the probability of the events that may have led to such a load. If the load at some time $t' < t$ were smaller than $\Theta$ (which holds with probability 1 as $t \to \infty$ by Theorem 5.6), then from time $t'$ up to $t$ some rare events have taken place and increased the load much more than expected. We bound the probability of those events, thus bounding the probability that the load at time $t$ is above $\Theta$.

Similarly to Theorem 5.5, we split time into epochs of length

$$T_E = c_2\gamma^{-1}(w + \ln n)$$

starting from time $t$ and going backwards. The constant $c_2$ (which depends on $c_1$) is chosen so that the epoch length is a multiple $k$ of the window size ($T_E = kw$). Let $\mathcal{B}$ be the event $\{L_t \geq \Theta\}$, and for $i \leq t/T_E$ let $\mathcal{B}_i$ be the event that the load of the system is above $\Theta$ for exactly the last $i$ epochs. More precisely,

$$\mathcal{B}_i = \{\forall j = 0, \ldots, i-1 : \ L_{t-jT_E} \geq \Theta, \quad L_{t-iT_E} < \Theta\}.$$

Let $\mathcal{C}_t$ be the event that the load in the system was not always above $\Theta$ before time $t$. Formally,

$$\mathcal{C}_t = \{\exists t' \leq t : \ L_{t'} \leq \Theta\}.$$

Then we have

$$\mathbf{Pr}(\mathcal{B} \,|\, \mathcal{C}_t) = \sum_{i=1}^{\lfloor t/T_E \rfloor} \mathbf{Pr}(\mathcal{B}_i \mid \mathcal{C}_t). \tag{5.22}$$

To estimate $\mathbf{Pr}(\mathcal{B}_i \,|\, \mathcal{C}_t)$ we distinguish between two cases, depending on the total load injected by the adversary during the $i$ epochs immediately before $t$. Either the adversary inserted a lot of new jobs during this time, or he inserted a reasonable number of new jobs and the protocol failed to reduce the total load. Both cases are intuitively unlikely: the first by the strong bound on the adversary, and the second by the efficacy of the protocol. We bound the two cases separately and then use a union bound. We fix a constant $\epsilon > 0$ (whose actual value will be determined later) and define $\mathcal{M}$ as the event that "the injected load during the $i$ epochs immediately preceding $t$ is less than $K = (1+\epsilon)i\lambda n T_E = (1+\epsilon)i\lambda nkw$." Then we have

$$\mathbf{Pr}(\mathcal{B}_i \,|\, \mathcal{C}_t) \leq \mathbf{Pr}(\overline{\mathcal{M}} \,|\, \mathcal{C}_t) + \mathbf{Pr}(\mathcal{B}_i \cap \mathcal{M} \,|\, \mathcal{C}_t). \tag{5.23}$$

We bound each term separately, starting with $\mathbf{Pr}(\overline{\mathcal{M}} \,|\, \mathcal{C}_t)$. The first $K$ jobs can be distributed in the $ik$ windows of the period in

$$\binom{K + ik - 1}{ik} \tag{5.24}$$

ways.

We now bound the probability of each such distribution of the inserted jobs $(K_1, K_2, \ldots, K_{ik})$ (so that $\sum_{j=1}^{ik} K_j = K$). Recall that the expected number of jobs during the $j$th time window is at most $\lambda nw$. Define $\epsilon_j$ as the deviation of $K_j$ above $\lambda nw$, namely,

$$\epsilon_j = \max\left(0, \frac{K}{\lambda nw} - 1\right).$$

In other words, $\epsilon_j$ is such that

$$K_j = (1+\epsilon_j)\lambda n w$$

if $K > \lambda n w$ and $\epsilon_j = 0$ otherwise. Since $\sum K_j = K$, we get that

$$\sum_{j=1}^{ik} \epsilon_j \geq ik\epsilon.$$

By using the definition of the strongly bounded adversary, we can bound the probability (conditioned on any past event) that in the $j$th window at least $K_j$ were generated by

$$e^{-\alpha\lambda n w \epsilon_j^\beta}.$$

Therefore, the probability of a particular distribution $(K_1, \dots, K_{id})$ of the first $K$ jobs is bounded by

$$\prod e^{-\alpha\lambda n w \epsilon_j^\beta} = e^{-\alpha\lambda n w \sum \epsilon_j^\beta}.$$

Since $\beta \geq 1$, and $\sum \epsilon_j \geq ik\epsilon$, we obtain $\sum \epsilon_j^\beta \geq ik\epsilon^\beta$ (by raising to the $\beta$th power and using Hölder's inequality as in relation (5.21)), and the aforementioned probability becomes

$$e^{-\alpha\lambda n w ik \epsilon^\beta}.$$

Together with (5.24) we get that

$$\begin{aligned}
\mathbf{Pr}(\overline{\mathcal{M}} \,|\, \mathcal{C}_t) &\leq \binom{K+ik-1}{ik} e^{-\alpha\lambda n w ik\epsilon^\beta} \\
&< \binom{K+ik}{ik} e^{-\alpha\lambda n w ik\epsilon^\beta} \\
&\leq \left(\frac{(K+ik)e}{ik}\right)^{ik} e^{-\alpha\lambda n w ik\epsilon^\beta} \\
&= e^{ik\ln(K+ik)+ik-\alpha\lambda n w ik\epsilon^\beta - ik\ln(ik)} \\
&\leq e^{ik\ln[ik((1+\epsilon)\lambda n w+1)]+ik-\alpha\lambda n w ik\epsilon^\beta - ik\ln(ik)} \\
&= e^{ik\ln[(1+\epsilon)\lambda n w+1]+ik-\alpha\lambda n w ik\epsilon^\beta} \\
&< n^{-\kappa i}
\end{aligned} \tag{5.25}$$

for any constant $\kappa$ and sufficiently large $n$.

Next we bound $\mathbf{Pr}(\mathcal{B}_i \cap \mathcal{M} \,|\, \mathcal{C}_t)$. By Theorem 5.1, part 1, if at the beginning of an epoch the load of the system is at least $\Theta$, then the load decreases by at least $\Theta$ with probability at least $1 - n^{-c}$. This is the case for the last $i-1$ epochs. However, at time $t - iT_E$ the load of the system is below $\Theta$, while at time $t$ the load is above $\Theta$. Moreover we have assumed that the total new load is at most $K = (1+\epsilon)i\lambda n T_E$. These facts imply that the consumed load is less than $K$, which in turn implies that in fewer than

$$\frac{K}{\Theta} = \frac{(1+\epsilon)\lambda c_2}{c_1} i \triangleq \mu i$$

epochs the consumed load was more than $\Theta$. By making $c_1$ sufficiently large and $\epsilon$ sufficiently small, we can guarantee that $\mu < 1$. In this case, the probability that, among the $i-1$ epochs, fewer than $\mu i$ consumed at least $\Theta$ load can be bounded by

$$\begin{aligned}\mathbf{Pr}(\mathcal{B}_i \cap \mathcal{M} \,|\, \mathcal{C}_t) &\leq \binom{i-1}{(1-\mu)i} \left(\frac{1}{n^c}\right)^{(1-\mu)i} \\ &\leq \left(\frac{e(i-1)}{(1-\mu)i}\right)^{(1-\mu)i} \left(\frac{1}{n^c}\right)^{(1-\mu)i} \\ &= \left(n^{-c} \cdot \frac{e}{1-\mu} \cdot \frac{i-1}{i}\right)^{(1-\mu)i} \\ &\leq n^{-(1-\mu)(c-1)i}.\end{aligned} \tag{5.26}$$

By combining (5.23), (5.25), and (5.26) we get that

$$\mathbf{Pr}(\mathcal{B}_i \,|\, \mathcal{C}_t) \leq 2n^{-(1-\mu)(c-1)i}.$$

Finally, we estimate the probability that the load is above $\Theta$ at time $t$ using (5.22). If we make $c$ and $c_1$ sufficiently large, we get that $(1-\mu)(c-1) > 0$, so the sum converges and we get

$$\mathbf{Pr}(\mathcal{B} \,|\, \mathcal{C}_t) = \sum_{i=1}^{\lfloor t/T_E \rfloor} 2n^{-(1-\mu)(c-1)i} \leq \sum_{i=1}^{\infty} 2n^{-(1-\mu)(c-1)i} \leq 3n^{-(1-\mu)(c-1)}.$$

From Theorem 5.6 we have $\lim_{t\to\infty} \mathbf{Pr}(\mathcal{C}_t) = 1$, which gives the result. □

**5.3.2. Waiting time.** By Theorem 5.1, part 2, we get that if the load of the system is bounded by $\Theta$ at some particular time, then with probability at least $1 - n^{-c} \geq 1 - n^{-c'}$ all the load that was in the system at that time is consumed during the next $T_E$ steps. The limiting probability that the load of the system is above $\Theta$ is bounded by $3n^{-c'}$. Summing the failure probabilities proves the following.

THEOREM 5.11. *Consider a system whose load is injected by a strongly bounded adversary. Let $W_t$ be the wait of a job that arrived at time $t$.*

$$\liminf_{t\to\infty} \mathbf{Pr}(W_t \leq c_2 \gamma^{-1}(w + \ln n)) \geq 1 - 4n^{-c'}.$$

*The above holds without the limit if the system starts with no load.*

**6. Work stealing and the generator models.** In this section we compare our results to the stochastic analysis of the *work stealing* load balancing protocol in [4]. In the work stealing protocol, nodes initiate load balancing steps only when their queues are empty. Concretely, after the new load generation, and before the load consumption, if a node $u$ is empty, it selects a random neighbor, say $v$. If the load of $v$ is $\ell_t(v)$, then $v$ transfers half of its load to $u$, so that eventually $u$ has load $\lfloor \ell_t(v) \rfloor$, while $v$ ends up with load $\lceil \ell_t(v) \rceil$. Finally the nonempty nodes execute one job from their queue. The advantage of the work stealing protocol is that the total load balancing work in the network at any given time is proportional to the number of processors with empty queues. In particular, as long as all the processors are working, the network does not perform any load balancing. However, in this section we show that the work stealing protocol is either unstable, or stable with expected load exponential in $n/d$, where $d$ is the minimum degree of the network. In contrast, protocol $\mathcal{P}$ is stable with expected load polynomial in $n$ for any connected network topology.

We prove the gap in performance between the two protocols in the job-generator model introduced in [4]. We distinguish between two versions of this input model. In the deterministic generator model, an adversary places $\lambda n$ job-generators in the processors in an arbitrary fashion at the beginning of every step (having full information of the history of the system), and each generator adds one new job to the processor on which it is placed. In the stochastic job-generator model an adversary places $n$ generators in the processors in an arbitrary fashion at the beginning of every time step (again having full information of the history), and each generator adds one new job to the processor on which it is placed with probability at most $\lambda < 1$, independently of the other generators.

Notice that both of these adversaries are special cases of a strongly bounded $(\lambda, w, p, M)$ adversary, with $w = 1$, $p = 3$ and corresponding $M$ being 0 for the deterministic and a constant for the stochastic. The deterministic model is clearly strongly bounded, while a standard Chernoff bound establishes the claim for the stochastic model. Then by Theorems 2.2 and 2.3, we get that, in both cases, the load and waiting time are bounded (both in expectation and with high probability) by $O(\gamma^{-1} n \ln n)$ and $O(\gamma^{-1} \ln n)$, respectively.

We contrast these results with the performance of the work stealing load balancing protocol on similar input. Consider first a deterministic job-generator adversary that adds, in each step, up to $\lambda n$ tokens to the $n$-node network. Let $v$ be a node in the network with degree $d = o(n)$ (the claim is trivial for $d = \Omega(n)$, since then $n/d = O(1)$). In each step, the adversary puts $\lambda n - d$ tokens in $v$ and one token in each of its neighbors. Since the queues of the $d$ neighbors of $v$ are never empty, $v$ never participates in a load balancing step, and so its load increases (unboundedly) by $\lambda n - d - 1$ in each step.

Consider now the stochastic job-generator adversarial input process. Assume again a node $v$ with minimal degree $d = o(n)$, and assume that in each step the adversary places exactly $m = \lfloor n/(d+1) \rfloor$ generators at $v$ and at least $m$ generators at each of its neighbors. Let $\ell_t(v)$ denote the load at $v$ at time $t$.

Define $p = (2 + \lambda m/(1-\lambda))e^{-\lambda m}$ and assume that $n$ is large, so that $p < 1$ (we use this fact later). Fix some time step $t \geq 1$. If node $v$'s load did not increase during this time step, then either $v$ did not produce many jobs (at most 1) or one of $v$'s neighbors (say $u_i$, with degree $d_{u_i} \geq d$) was empty and chose to try to steal work from $v$, so $v$ gave away load. For the latter to happen, $u_i$ must have had no load (and in particular must have not produced any load at time $t$) and must have randomly chosen $v$ out of its $d_{u_i}$ neighbors. Thus,

$$\begin{aligned}\mathbf{Pr}(\ell_t(v) - \ell_{t-1}(v) < 1) &\leq (1-\lambda)^m + \lambda m (1-\lambda)^{m-1} + \sum_{i=1}^{d} \frac{1}{d_{u_i}} (1-\lambda)^m \\ &\leq p,\end{aligned} \tag{6.1}$$

conditioned on all past events.

We now construct a random sequence $\{\ell'_t(v)\}_{t \geq 0}$, and we show that it is stochastically dominated by the sequence $\{\ell_t(v)\}$, as follows. We have $\ell'_0(v) = 0$, and for $t > 0$,

$$\ell'_t(v) = \begin{cases} \ell'_{t-1}(v)/2 & \text{with probability } p, \\ \ell'_{t-1}(v) + 1 & \text{with probability } 1-p, \end{cases}$$

with all the random choices being independent. Notice that by relation (6.1) the load of node $v$ decreases with probability at most $p$. Moreover, if the load of node $v$ decreases, the new load will be at least half of the old load, and hence each load $\ell_t(v)$ stochastically dominates the corresponding $\ell'_t(v)$. Therefore we have $\mathbf{E}[\ell_t(v)] \geq \mathbf{E}[\ell'_t(v)]$.

Using the recursion

$$\mathbf{E}[\ell'_t(v)] = \frac{p}{2}\mathbf{E}[\ell'_{t-1}(v)] + (1-p)(\mathbf{E}[\ell'_{t-1}(v)] + 1),$$

we compute

$$\mathbf{E}[\ell'_t(v)] = \frac{2(1-p)}{p}\left[1 - \left(1 - \frac{p}{2}\right)^t\right]$$

and

$$\begin{aligned}\mathbf{E}[L_t] &\geq \mathbf{E}[\ell_t(v)]\\ &\geq \mathbf{E}[\ell'_t(v)]\\ &= \frac{2(1-p)}{p}\left[1 - \left(1 - \frac{p}{2}\right)^t\right].\end{aligned}$$

Using the fact that $p < 1$, we get

$$\begin{aligned}\liminf_{t\to\infty} \mathbf{E}[L_t] &\geq \frac{2(1-p)}{p}\\ &= 2\left(\frac{1}{p} - 1\right)\\ &= \frac{2e^{\lambda\left\lfloor \frac{n}{d+1}\right\rfloor}}{2 + \frac{\lambda}{1-\lambda}\left\lfloor \frac{n}{d+1}\right\rfloor} - 2.\end{aligned}$$

Thus in the limit the expected total load in the system is at least exponential in $n/d$. In particular, if the network's minimum degree is constant, the expected total load in the system is exponential in the size of the network!

**7. Conclusion.** We analyze a simple load balancing system and show that it has many desirable steady state properties under a big variety of input conditions. In particular, we derive low-degree polynomial bounds on the asymptotic expected load and waiting times of jobs in the system, and we match these expected performance results with high-probability results in a very natural restriction of the general stochastic adversary model. While there are many stability results for similar systems in the literature, our analysis of waiting time, the strength of our bounds, and our high-probability results are novel. In addition, our application of the Pemantle–Rosenthal result reveals many of the challenges in using general adversaries and will likely provide good insight for other applications. Finally, unlike much of the related work, our results hold for arbitrary connected network topologies and are optimal for the extremely important expander topology.

Plenty of open problems remain. In particular, our analysis cannot be easily modified to handle the case $\lambda = 1$, since we do not count the load that is consumed during the distribution phase of an epoch. Thus that case remains open. In addition, it is unknown whether Markovian adversaries are weaker than the general adversaries that we analyze. A result along these lines would have important ramifications in future analyses of network processes, since it would answer the question of whether Markov chain techniques can fill the role of the more general Pemantle and Rosenthal stochastic process results. And, of course, any results in an extension of our model allowing for asynchronous communication between nodes, nonuniform job execution time, and/or a continuous timescale would be very interesting.

**Acknowledgments.** We would like to thank the anonymous referees, whose elaborate comments significantly improved the overall presentation of the paper.

# A SECOND-ORDER PERCEPTRON ALGORITHM*

NICOLÒ CESA-BIANCHI[†], ALEX CONCONI[†], AND CLAUDIO GENTILE[‡]

**Abstract.** Kernel-based linear-threshold algorithms, such as support vector machines and Perceptron-like algorithms, are among the best available techniques for solving pattern classification problems. In this paper, we describe an extension of the classical Perceptron algorithm, called second-order Perceptron, and analyze its performance within the mistake bound model of on-line learning. The bound achieved by our algorithm depends on the sensitivity to second-order data information and is the best known mistake bound for (efficient) kernel-based linear-threshold classifiers to date. This mistake bound, which strictly generalizes the well-known Perceptron bound, is expressed in terms of the eigenvalues of the empirical data correlation matrix and depends on a parameter controlling the sensitivity of the algorithm to the distribution of these eigenvalues. Since the optimal setting of this parameter is not known a priori, we also analyze two variants of the second-order Perceptron algorithm: one that adaptively sets the value of the parameter in terms of the number of mistakes made so far, and one that is parameterless, based on pseudoinverses.

## 1. Introduction.

Research in linear-threshold classifiers has been recently revamped by the popularity of kernel methods [1, 12, 36], a set of mathematical tools used to efficiently represent complex nonlinear decision surfaces in terms of linear classifiers in a high-dimensional feature space defined by kernel functions. To some extent, statistical learning theories have been able to explain why kernel methods do not suffer from the "curse of dimensionality"—that is, why they exhibit a remarkable predictive power despite the fact that the kernel-induced feature space has very many (possibly infinite) dimensions. However, these statistical results are often based on quantities, like the "margin," that provide only a superficial account of the way the predictive power is affected by the geometry of the feature space.

A different approach to the analysis of linear-threshold classifiers is the mistake bound model of on-line learning [28]. In this model, similarly to the framework of competitive analysis, the learning algorithm must be able to sequentially classify each sequence of data points making a number of mistakes not much bigger than those made by the best fixed linear-threshold classifier in hindsight (the reference predictor). The power of this approach resides in the fact that the excess loss of the learning algorithm with respect to the reference predictor can be nicely bounded in terms of the geometrical properties of any individual sequence on which the algorithm is run. Furthermore, as shown in [9], mistake bounds have corresponding statistical risk bounds that are not worse, and sometimes better, than those obtainable with a direct statistical approach.

So far, the best known mistake bound for kernel-based linear-threshold classifiers was essentially the one achieved by the classical[1] Perceptron algorithm [7, 32, 34]. In this paper we introduce an extension of the standard Perceptron algorithm, called *second-order Perceptron*.

The standard Perceptron algorithm is a popular greedy method for learning linear-threshold classifiers. Since the early sixties, it has been known that the performance of the Perceptron algorithm is governed by simple geometrical properties of the input data. As the Perceptron algorithm is essentially a gradient descent (first-order) method, we improve on it by introducing sensitivity to second-order data information. Our second-order algorithm combines the Perceptron's gradient with a sparse (and incrementally computed) version of the data correlation matrix. Our analysis shows that the second-order Perceptron algorithm is able to exploit certain geometrical properties of the data which are missed by the first-order algorithm. In particular, our bounds for the second-order algorithm depend on the distribution of the eigenvalues of the correlation matrix for the observed data sequence, as opposed to the bound for the first-order algorithm, relying only on trace information. A typical situation where the second-order bound is substantially smaller than the first-order bound is when the data lie on a flat ellipsoid, so that the eigenvalues of the correlation matrix have sharply different magnitudes, whereas the trace is dominated by the largest one.

In its basic form, the second-order Perceptron algorithm is parameterized by a constant $a > 0$, which rules the extent to which the algorithm adapts to the "warpedness" of the data. In the limit as $a$ goes to infinity our algorithm becomes the first-order Perceptron algorithm and, in that limit, the second-order bound reduces to the first-order one. The value of $a$ affects performance in a significant way. The best choice of $a$ depends on information about the learning task that is typically not available ahead of time. We develop two variants of our algorithm and prove corresponding mistake bounds. The first variant is an adaptive parameter version, while the second variant eliminates parameter $a$ and replaces standard matrix inversion with pseudo-inversion. Again, the bounds we prove are able to capture the spectral properties of the data.

In the next section, we take the classical Perceptron algorithm as a starting point for defining and motivating our second-order extension. Our description steps through an intermediate algorithm, called the *whitened Perceptron* algorithm, which serves as an illustration of the kind of spectral behavior we mean. The section is concluded with a precise definition of the learning model and with a description of the basic notation used throughout the paper.

## 2. Perceptron and whitened Perceptron.

The classical Perceptron algorithm processes a stream of examples $(\boldsymbol{x}_t, y_t)$ one at a time in trials. In trial $t$ the algorithm receives an instance vector $\boldsymbol{x}_t \in \mathbb{R}^n$ and predicts the value of the unknown label $y_t \in \{-1, +1\}$ associated with $\boldsymbol{x}_t$. The algorithm keeps a weight vector $\boldsymbol{w}_t \in \mathbb{R}^n$ representing its internal state, and its prediction at time $t$ is given by[2]

[1]Several kernel-based linear-threshold algorithms have been proposed and analyzed in recent years, including relaxation methods [14], ROMMA [27], Alma [17], and variants thereof. All these on-line algorithms are Perceptron-like, and their mistake bounds coincide with the one achieved by the standard Perceptron algorithm.

[2]Here and throughout, superscript $^\top$ denotes transposition. Also, SGN denotes the signum function $\text{SGN}(z) = 1$ if $z \ge 0$ and $\text{SGN}(z) = -1$ otherwise (we conventionally give a positive sign to zero).

$\widehat{y}_t = \textsc{sgn}(\boldsymbol{w}_t^\top \boldsymbol{x}_t) \in \{-1, 1\}$. We say that the algorithm has made a *mistake* at trial $t$ if the prediction $\widehat{y}_t$ and the label $y_t$ disagree. In such a case the algorithm updates its internal state according to the simple additive rule $\boldsymbol{w}_{t+1} = \boldsymbol{w}_t + y_t\,\boldsymbol{x}_t$, i.e., by moving the old weight vector along the direction of the instance $\boldsymbol{x}_t$ on which the algorithm turned out to be wrong (with the "right" orientation determined by $y_t = -\widehat{y}_t$). If $\widehat{y}_t = y_t$, no weight update is made (thus the number of mistakes is always equal to the number of weight updates).

A sequence of examples is linearly separable if the instance vectors $\boldsymbol{x}_t$ are consistently labeled according to whether they lie on the positive ($y_t = +1$) or the negative ($y_t = -1$) side of an unknown target hyperplane with normal vector $\boldsymbol{u} \in \mathbb{R}^n$ and passing through the origin. The well-known Perceptron convergence theorem [7, 32] states that the Perceptron algorithm is guaranteed to make at most $(R/\gamma)^2$ mistakes on any number $t$ of examples in a linearly separable sequence, where

$$\begin{aligned} R &= \max_{1\le s\le t} \|\boldsymbol{x}_s\|, \\ \gamma &= \min_{1\le s\le t} \left|\boldsymbol{u}^\top \boldsymbol{x}_t\right|. \end{aligned}$$

This implies that cycling through any sequence of linearly separable examples will eventually lead the Perceptron algorithm to compute a weight vector $\boldsymbol{w} \in \mathbb{R}^n$ classifying all examples correctly, i.e., such that $y_t = \textsc{sgn}(\boldsymbol{w}^\top \boldsymbol{x}_t)$ for all $t$ in the sequence. The convergence speed is thus critically influenced by the degree of linear separability of the examples, as expressed by the ratio $(R/\gamma)^2$. Hence, those vectors $\boldsymbol{x}_t$ which have both a small projection component over $\boldsymbol{u}$ (i.e., they are "almost" orthogonal to $\boldsymbol{u}$) and have a large norm $\|\boldsymbol{x}_t\|$ are the hardest ones for the Perceptron algorithm. The situation is illustrated in Figure 2.1. Consider the case when the algorithm observes instance vectors $\boldsymbol{x}_t$ lying in the dotted circles on opposite sides of that figure. Such vectors have small components along the direction of $\boldsymbol{u}$; hence they are intuitively irrelevant to the target vector. Still, such $\boldsymbol{x}_t$'s might significantly mislead the Perceptron algorithm (thereby slowing down its convergence). Trial $t$ depicted in Figure 2.1 is a mistaken trial for the algorithm, since $\textsc{sgn}(\boldsymbol{w}_t^\top \boldsymbol{x}_t) \neq \textsc{sgn}(\boldsymbol{u}^\top \boldsymbol{x}_t) = y_t = -1$. Now, the new weight vector $\boldsymbol{w}_{t+1}$ computed by the algorithm has a larger projection[3] onto $\boldsymbol{u}$ than the old vector $\boldsymbol{w}_t$. But the algorithm's prediction is based only upon the direction of its current weight vector. Hence the step $\boldsymbol{w}_t \to \boldsymbol{w}_{t+1}$ does not seem to make satisfactory progress toward $\boldsymbol{u}$.

Let us now turn to an algorithm which is related to both the first-order and the second-order Perceptron algorithm (described in section 3). We call this algorithm the *whitened Perceptron* algorithm. Strictly speaking, this is not an incremental algorithm. In fact, it assumes that all the instance vectors $\boldsymbol{x}_1, \boldsymbol{x}_2, \dots, \boldsymbol{x}_T \in \mathbb{R}^n$ are preliminarily available, and only the labels $y_1, y_2, \dots, y_T$ are hidden. For the sake of simplicity, assume that these vectors span $\mathbb{R}^n$. Therefore $T \ge n$, the correlation matrix $M = \sum_{t=1}^T \boldsymbol{x}_t\,\boldsymbol{x}_t^\top$ is full-rank, and $M^{-1}$ exists. Also, since $M$ is positive definite, $M^{-1/2}$ exists as well (see, e.g., [31, Chap. 3]). The whitened Perceptron algorithm is simply the standard Perceptron algorithm run on the transformed (whitened) sequence $(M^{-1/2}\boldsymbol{x}_1, y_1), (M^{-1/2}\boldsymbol{x}_2, y_2), \dots, (M^{-1/2}\boldsymbol{x}_T, y_T)$. The transformation $M^{-1/2}$ is called the whitening transform (see, e.g., [14]) and has the

[3]In its simplest form, the Perceptron convergence theorem exploits the measure of progress $\boldsymbol{u}^\top \boldsymbol{w}_t$ and is based on the fact that under linear separability assumptions this measure steadily increases through mistaken trials.

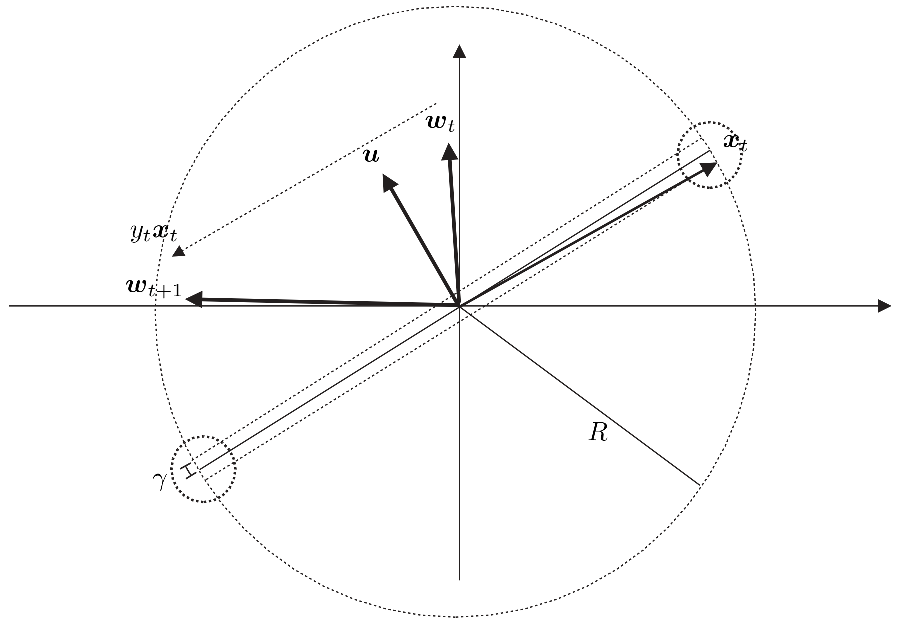

FIG. 2.1. *Behavior of the Perceptron algorithm on extreme (though linearly separable) cases. Here $\boldsymbol{u}$ denotes the hidden target vector, $\boldsymbol{w}_t$ is the weight vector maintained by the algorithm at the beginning of trial $t$, and $\boldsymbol{x}_t$ is the instance vector observed in that trial. We are assuming that all instances have bounded (Euclidean) length $R$ and that the examples are linearly separable with margin $\gamma > 0$ (so that no vector in the sequence of examples can lie within the two dotted lines running parallel to the decision boundary of $\boldsymbol{u}$). Since the angle between $\boldsymbol{u}$ and $\boldsymbol{x}_t$ is (slightly) larger than 90 degrees, the label $y_t$ is assigned the value $-1$. On the other hand, $\boldsymbol{w}_t^\top \boldsymbol{x}_t > 0$ holds; hence the algorithm makes a mistake. Now, $\boldsymbol{x}_t$ lies exactly on one of the two dotted lines and has maximal length $R$, but it has also a small projection along the direction of $\boldsymbol{u}$, meaning that the direction marked by $\boldsymbol{x}_t$ is (almost) irrelevant to $\boldsymbol{u}$. However, the simple additive rule of the Perceptron algorithm makes the new weight vector $\boldsymbol{w}_{t+1}$ farther from $\boldsymbol{u}$ than the old one.*

effect of reducing the correlation matrix of the transformed instances to the identity matrix $I_n$. In fact,

$$\begin{aligned}\sum_{t=1}^{T}\left(M^{-1/2}\boldsymbol{x}_t\right)\left(M^{-1/2}\boldsymbol{x}_t\right)^\top &= \sum_{t=1}^{T} M^{-1/2}\boldsymbol{x}_t\,\boldsymbol{x}_t^\top M^{-1/2}\\ &= M^{-1/2}M\,M^{-1/2}\\ &= I_n.\end{aligned}$$

Again for the sake of simplicity, suppose that the original sequence of examples is linearly separable: $\gamma = \min_t y_t\,\boldsymbol{u}^\top \boldsymbol{x}_t > 0$ for some unit norm vector $\boldsymbol{u}$. Then the whitened sequence is also linearly separable. In fact, hyperplane $\boldsymbol{z} = M^{1/2}\boldsymbol{u}$ separates the whitened sequence with margin $\gamma/\left\|M^{1/2}\boldsymbol{u}\right\|$. By the aforementioned convergence theorem, the number of mistakes made by the Perceptron algorithm on the whitened sequence is thus at most

$$(2.1)\qquad \frac{1}{\gamma^2}\left(\max_t \left\|M^{-1/2}\boldsymbol{x}_t\right\|^2\right)\left\|M^{1/2}\boldsymbol{u}\right\|^2 = \frac{1}{\gamma^2}\max_t\left(\boldsymbol{x}_t^\top M^{-1}\boldsymbol{x}_t\right)\left(\boldsymbol{u}^\top M\boldsymbol{u}\right).$$

To appreciate the potential advantage of whitening the data, note that when the instance vectors $\boldsymbol{x}_1,\dots,\boldsymbol{x}_T$ are very correlated the quadratic form $\boldsymbol{x}_t^\top M^{-1}\boldsymbol{x}_t$ tends

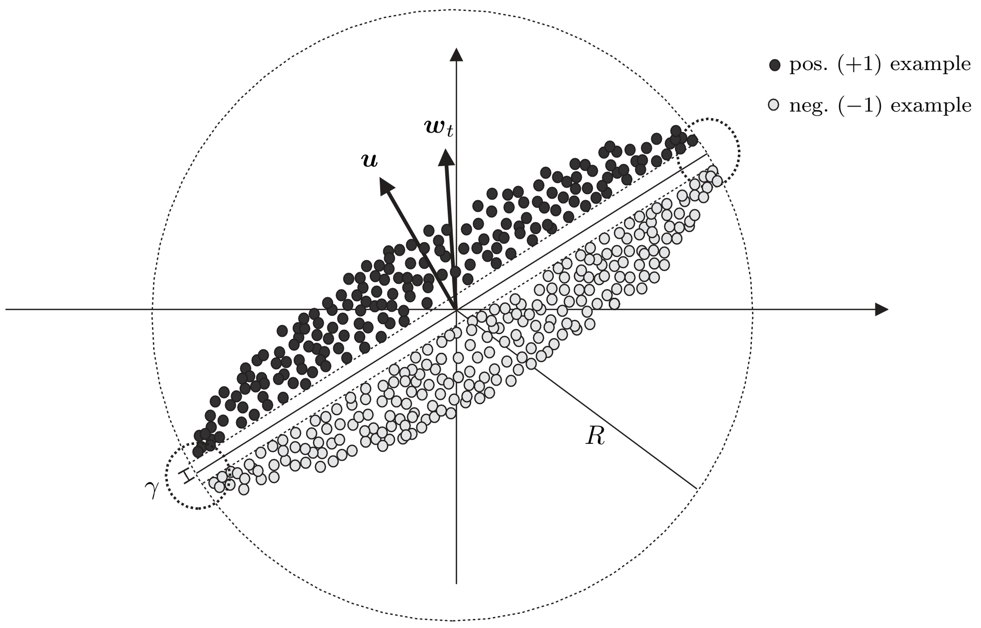

FIG. 2.2. *Scattering of data which the whitened (and the second-order) Perceptron algorithm can take advantage of. Here all instance vectors lie on a flat ellipsoid enclosed in a ball of radius $R$. The examples are linearly separable with margin $\gamma > 0$ via a hyperplane whose normal vector $\boldsymbol{u}$ is aligned with the small axis of the ellipse. Thus for any instance vector $\boldsymbol{x}_t$ the projection $|\boldsymbol{u}^\top \boldsymbol{x}_t|$ onto $\boldsymbol{u}$ is "small" (though not smaller than $\gamma$). This does not make any difference for the standard Perceptron algorithm, whose worst-case behavior is essentially ruled by the* norm *of the instances lying in the two dotted circles (recall Figure* 2.1*).*

to be quite small (the expression $\max_t \left(\boldsymbol{x}_t^\top M^{-1}\boldsymbol{x}_t\right)$ might actually be regarded as a measure of correlation of the instance vectors). Also, if the instances look like those displayed in Figure 2.2, where the separating hyperplane vector $\boldsymbol{u}$ is strongly correlated with a nondominant eigenvector of $M$ (i.e., if all instances have a small projected component onto $\boldsymbol{u}$), then the bound in the right-hand side of (2.1) can be significantly smaller than the corresponding mistake bound $\max_t \|\boldsymbol{x}_t\|^2/\gamma^2 = R^2/\gamma^2$ for the classical (nonwhitened) Perceptron algorithm.

For the sake of clarity, consider the degenerate case when all data points in Figure 2.2 are evenly spread over the two parallel lines at margin $\gamma$ (so that the ellipse sketched in that figure is maximally squashed along the direction of $\boldsymbol{u}$). It is not hard to argue that this symmetric scattering of data leads to the following eigenstructure of matrix $M$: Let $\lambda_{\min}$ and $\lambda_{\max}$ be the minimal and the maximal eigenvalues of $M$, respectively. We have that the first eigenvector of $M$ (the one associated with $\lambda_{\min}$) is aligned with $\boldsymbol{u}$, while the second eigenvector (associated with $\lambda_{\max}$) is orthogonal to $\boldsymbol{u}$ (i.e., it is parallel to the two lines mentioned above). Let us denote by $\boldsymbol{u}^\perp$ a unit norm vector orthogonal to $\boldsymbol{u}$. Now, since $\boldsymbol{u}$ has unit norm, we have

$$\lambda_{\min} = \boldsymbol{u}^\top M \boldsymbol{u} = \boldsymbol{u}^\top \left(\sum_{t=1}^{T} \boldsymbol{x}_t \boldsymbol{x}_t^\top\right) \boldsymbol{u} = \sum_{t=1}^{T} (\boldsymbol{u}^\top \boldsymbol{x}_t)^2 = \gamma^2 T. \tag{2.2}$$

Also, since $\lambda_{\min} + \lambda_{\max} = \sum_{t=1}^{T} \|\boldsymbol{x}_t\|^2$ (see, e.g., section 3.1) and since, for all $\boldsymbol{x} \in \mathbb{R}^n$,

$(\boldsymbol{u}^\top \boldsymbol{x})^2 + ((\boldsymbol{u}^\perp)^\top \boldsymbol{x})^2 = \|\boldsymbol{x}\|^2$, for each $t = 1, \dots, T$ we can write

$$\boldsymbol{x}_t M^{-1} \boldsymbol{x}_t = \frac{(\boldsymbol{u}^\top \boldsymbol{x}_t)^2}{\lambda_{\min}} + \frac{((\boldsymbol{u}^\perp)^\top \boldsymbol{x}_t)^2}{\lambda_{\max}} = \frac{\gamma^2}{\gamma^2 T} + \frac{\|\boldsymbol{x}_t\|^2 - \gamma^2}{\sum_{t=1}^T \|\boldsymbol{x}_t\|^2 - \gamma^2 T}, \tag{2.3}$$

where in the first step we used the singular value decomposition (SVD) of $M$ (see Appendix D). Hence, combining (2.2) and (2.3) as in (2.1) and simplifying, we conclude that in the extreme case we sketched, the number of mistakes made by the whitened Perceptron algorithm can be bounded by

$$\frac{1}{\gamma^2} \max_t \left(\boldsymbol{x}_t^\top M^{-1} \boldsymbol{x}_t\right) \left(\boldsymbol{u}^\top M \boldsymbol{u}\right) = 1 + \frac{R^2 T - \gamma^2 T}{\sum_{t=1}^T \|\boldsymbol{x}_t\|^2 - \gamma^2 T}.$$

Note that this bound approaches 2 as the norm of the instance vectors $\boldsymbol{x}_t$ approaches $R$ (which is just the hardest case for the standard Perceptron algorithm). Thus in this case, unlike the standard Perceptron bound $R^2/\gamma^2$, the whitened Perceptron bound tends to be a *constant*, independent of both the margin $\gamma$ and the radius $R$ of the ball containing the data.

**Learning model and notation.** In the last part of this section we precisely describe the learning model and introduce our notation (some of this notation has been used earlier). The formal model we consider is the well-known mistake bound model of incremental learning, introduced by Littlestone [28] (see also [2]) and further investigated by many authors (see, e.g., [4, 10, 11, 20, 21, 25, 26, 29, 30, 39] and the references therein).

In incremental or sequential models, learning proceeds in trials. In each trial $t = 1, 2, \dots$, the algorithm observes an *instance* vector $\boldsymbol{x}_t \in \mathbb{R}^n$ (all vectors here are understood to be column vectors) and then guesses a binary label $\widehat{y}_t \in \{-1, 1\}$. Before seeing the next vector $\boldsymbol{x}_{t+1}$, the true label $y_t \in \{-1, 1\}$ associated with $\boldsymbol{x}_t$ is revealed and the algorithm knows whether its guess $\widehat{y}_t$ for $y_t$ was correct or not. In the latter case we say that the algorithm has made a *mistake*, and we call $t$ a *mistaken trial*. Each pair $(\boldsymbol{x}_t, y_t)$ we call an *example*, and a *sequence of examples* is any sequence $\mathcal{S} = ((\boldsymbol{x}_1, y_1), (\boldsymbol{x}_2, y_2), \dots, (\boldsymbol{x}_T, y_T))$. No assumptions are made on the mechanism generating the sequence of examples. Similarly to competitive analyses of on-line algorithms [8], the goal of the learning algorithm is to minimize the amount by which its total number of mistakes on an arbitrary sequence $\mathcal{S}$ exceeds some measure of the performance of a fixed classifier (in a given *comparison class*) on the same sequence $\mathcal{S}$.

The comparison class we consider here is the set of linear-threshold classifiers parametrized by the unit norm vectors $\{\boldsymbol{u} \in \mathbb{R}^n : \|\boldsymbol{u}\| = 1\}$. Thus we speak of the linear-threshold classifier $\boldsymbol{u}$ to mean the classifier $h(\boldsymbol{x}) = \textsc{sgn}(\boldsymbol{u}^\top \boldsymbol{x})$. For technical reasons, the number of mistakes of the learning algorithm will be compared to the cumulative *hinge loss* (see, e.g., [19]) of the best linear-threshold classifier in the comparison class. For any $\gamma > 0$, the hinge loss of the linear-threshold classifier $\boldsymbol{u}$ on example $(\boldsymbol{x}, y)$ at margin $\gamma$ is $D_\gamma(\boldsymbol{u}; (\boldsymbol{x}, y)) = \max\{0, \gamma - y\,\boldsymbol{u}^\top \boldsymbol{x}\}$. Also, for a given sequence of examples $\mathcal{S} = ((\boldsymbol{x}_1, y_1), (\boldsymbol{x}_2, y_2), \dots, (\boldsymbol{x}_T, y_T))$, let $D_\gamma(\boldsymbol{u}; \mathcal{S}) = \sum_{t=1}^T D_\gamma(\boldsymbol{u}; (\boldsymbol{x}_t, y_t))$. Note that $D_\gamma(\boldsymbol{u}; \mathcal{S})/\gamma$ is a strict upper bound on the number of mistakes made by $\boldsymbol{u}$ on the same sequence $\mathcal{S}$. Moreover, if $\boldsymbol{u}$ linearly separates $\mathcal{S}$ with margin $\gamma$, i.e., if $y_t\,\boldsymbol{u}^\top \boldsymbol{x}_t \geq \gamma$ for $t = 1, \dots, T$, then $D_\gamma(\boldsymbol{u}; \mathcal{S}) = 0$.

We will prove bounds on the number of mistakes having the general form

$$\texttt{number of mistakes on } \mathcal{S} \quad \leq \quad \inf_{\gamma > 0} \inf_{\boldsymbol{u}} \left( \frac{D_\gamma(\boldsymbol{u}; \mathcal{S})}{\gamma} + \frac{\texttt{spectral}(\boldsymbol{u}; \mathcal{S})}{\gamma} \right),$$

where $\mathcal{S}$ is any sequence of examples and $\texttt{spectral}(\boldsymbol{u}; \mathcal{S})$ measures certain spectral properties arising from the interaction between $\boldsymbol{u}$ and $\mathcal{S}$. The mistake bound shown above reveals how the algorithm is able to optimally trade off between the terms $D_\gamma(\boldsymbol{u}; \mathcal{S})$ and $\texttt{spectral}(\boldsymbol{u}; \mathcal{S})$ using a *single* pass over an *arbitrary* data sequence. This aggressive adaptation can be successfully exploited in settings different from the mistake bound model. In fact, as mentioned in the conclusions, the linear-threshold classifiers generated by the second-order Perceptron algorithm can be easily shown to have a probability of mistake (risk) in the statistical model of pattern classification (see, e.g., [13]) which is tightly related to the algorithm's mistake bound. These risk bounds are actually among the best achievable by any algorithm for learning linear-threshold classifiers.

The rest of the paper is organized as follows. The next section describes and analyzes the basic form of the second-order Perceptron algorithm and also shows how to formulate the algorithm in dual form, thereby allowing the use of kernel functions. In section 4 we analyze two variants of the basic algorithm: the first variant has an adaptive parameter, and the second variant computes the pseudoinverse of the correlation matrix instead of the standard inverse. Some toy experiments are reported in section 5. Section 6 contains conclusions, final remarks, and open problems.

## 3. Second-order Perceptron, basic form.

The second-order Perceptron algorithm might be viewed as an incremental variant of the whitened Perceptron algorithm; this means that the instances in the data sequence are not assumed to be known beforehand. Besides, the second-order Perceptron algorithm is sparse; that is, the whitening transform applied to each new incoming instance is based only on a possibly very small subset of the instances observed so far.

In its basic form, the second-order Perceptron algorithm (described in Figure 3.1) takes an input parameter $a > 0$. To compute its prediction in trial $t$ the algorithm uses an $n$-row matrix $X_{k-1}$ and an $n$-dimensional weight vector $\boldsymbol{v}_{k-1}$, where subscript $k-1$ indicates the number of times matrix $X$ and vector $\boldsymbol{v}$ have been updated in the first $t-1$ trials. Initially, the algorithm sets $X_0 = \emptyset$ (the empty matrix) and $\boldsymbol{v}_0 = \mathbf{0}$. Upon receiving the $t$th instance $\boldsymbol{x}_t \in \mathbb{R}^n$, the algorithm builds the augmented matrix $S_t = [\, X_{k-1} \; \boldsymbol{x}_t \,]$ (where $\boldsymbol{x}_t$ is intended to be the last column of $S_t$) and predicts the label $y_t$ of $\boldsymbol{x}_t$ with $\widehat{y}_t = \text{SGN}\left(\boldsymbol{v}_{k-1}^\top \left(aI_n + S_t\, S_t^\top\right)^{-1} \boldsymbol{x}_t\right)$, with $I_n$ being the $n \times n$ identity matrix (the addition of $I_n$ guarantees that the above inverse always exists). If $\widehat{y}_t \neq y_t$, then a mistake occurs and the algorithm updates[4] both $\boldsymbol{v}_{k-1}$ and $X_{k-1}$. Vector $\boldsymbol{v}_{k-1}$ is updated using the Perceptron rule $\boldsymbol{v}_k = \boldsymbol{v}_{k-1} + y_t\, \boldsymbol{x}_t$, whereas matrix $X_{k-1}$ is updated using $X_k = S_t = [\, X_{k-1} \; \boldsymbol{x}_t \,]$. Note that this update implies $X_k X_k^\top = X_{k-1} X_{k-1}^\top + \boldsymbol{x}_t\, \boldsymbol{x}_t^\top$. The new matrix $X_k$ and the new vector $\boldsymbol{v}_k$ will be used in the next prediction. If $\widehat{y}_t = y_t$, no update takes place, and hence the algorithm is mistake driven [28]. Also, just after an update, matrix $X_k$ has as many columns as the number of mistakes made by the algorithm so far. Note that, unlike the Perceptron algorithm, here $\boldsymbol{w}_t$ does depend on $\boldsymbol{x}_t$ (through $S_t$). Therefore the second-order Perceptron algorithm, as described in Figure 3.1, is *not* a linear-threshold predictor.

Our algorithm might be viewed as an adaptation to on-line binary classification of the ridge regression [23] method. Indeed, our analysis is inspired by the analysis of a variant of ridge regression recently introduced by Vovk [40] and further studied by Azoury and Warmuth [5] and Forster and Warmuth [15]. This variant is an instance of Vovk's general *aggregating algorithm* and is called the "forward algorithm" in [5]. Both

[4]In the degenerate case when $\boldsymbol{x}_t = \mathbf{0}$ no update is performed.

```
**Parameter:** $a > 0$.
**Initialization:** $X_0 = \emptyset$; $\boldsymbol{v}_0 = \boldsymbol{0}$; $k = 1$.
**Repeat for** $t = 1, 2, \dots$ :
    1. get instance $\boldsymbol{x}_t \in \mathbb{R}^n$;
    2. set $S_t = [\, X_{k-1}\ \boldsymbol{x}_t \,]$;
    3. predict $\widehat{y}_t = \mathrm{SGN}(\boldsymbol{w}_t^\top \boldsymbol{x}_t) \in \{-1, +1\}$,
       where $\boldsymbol{w}_t = \left(aI_n + S_t\, S_t^\top\right)^{-1} \boldsymbol{v}_{k-1}$;
    4. get label $y_t \in \{-1, +1\}$;
    5. if $\widehat{y}_t \neq y_t$, then:
           $\boldsymbol{v}_k = \boldsymbol{v}_{k-1} + y_t\, \boldsymbol{x}_t$,
           $X_k = S_t$,
           $k \leftarrow k + 1$.
```

FIG. 3.1. *The second-order Perceptron algorithm with parameter $a > 0$.*

our algorithm and the forward algorithm predict with a weight vector $\boldsymbol{w}_t$ given by the product of the inverse correlation matrix from past trials and a linear combination of past instance vectors. In both cases the current instance $\boldsymbol{x}_t$ is incorporated into the current correlation matrix before prediction. However, unlike the forward algorithm, we only keep track of past trials where the algorithm made a mistake. To complete this qualitative analogy, we note that the analysis of our algorithm uses tools developed in [5] for the forward algorithm.

The reader might wonder whether this nonlinear dependence on the current instance is somehow necessary. As a matter of fact, if in Figure 3.1 we predicted using $X_{k-1}$ instead of the augmented matrix $S_t$, then the resulting algorithm would be a linear-threshold algorithm.[5] It is easy to show that the margin value $y_t\, \boldsymbol{w}_t^\top \boldsymbol{x}_t$ achieved by the latter algorithm is always equal to the margin value of the algorithm in Figure 3.1 multiplied by a *positive* quantity depending on all instances observed

[5]In this case, the weight vector $\boldsymbol{w}_t$ computed when the algorithm is run on a sequence of examples $((\boldsymbol{x}_1, y_1), \dots, (\boldsymbol{x}_{t-1}, y_{t-1}))$ can be defined by

$$\boldsymbol{w}_t = \operatorname*{argmin}_{\boldsymbol{v}} \left( \sum_{s \in \mathcal{M}_{t-1}} \left(\boldsymbol{v}^\top \boldsymbol{x}_s - y_s\right)^2 + a\, \|\boldsymbol{v}\|^2 \right),$$

where $\mathcal{M}_{t-1}$ is the set of all trials $s \leq t-1$ such that $y_s\, \boldsymbol{w}_s^\top \boldsymbol{x}_s < 0$, and $\boldsymbol{w}_0 = \boldsymbol{0}$. This way of writing the update rule shows that this version of the second-order Perceptron algorithm can also be viewed as a sparse variant of an on-line ridge regression algorithm, whose prediction rule is $\widehat{y}_t = \mathrm{SGN}(\boldsymbol{w}_t^\top \boldsymbol{x}_t)$, where the weight vector $\boldsymbol{w}_t$ is just

$$\boldsymbol{w}_t = \operatorname*{argmin}_{\boldsymbol{v}} \left( \sum_{s=1}^{t-1} \left(\boldsymbol{v}^\top \boldsymbol{x}_s - y_s\right)^2 + a\, \|\boldsymbol{v}\|^2 \right).$$

This is actually the approach to binary classification taken in [33], where it is called the regularized least-squares classification (RLSC) method. The reader might also want to check [37] for an approach having a similar flavor. This comparison also stresses the role played by the sparsity: First, our algorithm is more efficient than RLSC, as we have only to store a (potentially small) submatrix of the data correlation matrix—the algorithm becomes significantly more efficient on the "easy" sequences where it makes very few mistakes. Second, the mistake-driven property, which causes sparsity, is a key feature when deriving spectral bounds on the number of mistakes that hold for arbitrary data sequences: no such bounds are currently known for RLSC.

so far. Therefore, unlike the linear regression framework considered in [5, 40], for binary classification the inclusion of the current instance makes no difference: running the two algorithms on the same sequence of examples would produce the same sequence of predictions. This is true even for the second-order Perceptron algorithm with pseudoinverse described in Figure 4.2 (section 4.2).

Hence, the algorithms in Figures 3.1 and 4.2 can be equivalently viewed as generators of linear-threshold classifiers. The reason we did not formulate our algorithms directly in this way is threefold. First, the above equivalence does not hold in general when parameter $a$ changes with time, as in Figure 4.1 (section 4.1). Thus, in order to maintain a uniform style of exposition, we preferred to keep the difference between Figures 3.1, 4.2, and 4.1 as little as possible. Second, including the current instance for prediction seems to be naturally suggested by the way we analyzed the algorithms. Third, in scenarios where the margin plays a crucial role, such as the information filtering problems studied in [9], including the current instance in the margin computation seems to give a slight improvement in performance.

**3.1. Analysis.** We now claim the theoretical properties of our algorithm. The following theorem is proved in Appendix A.

THEOREM 3.1. *The number $m$ of mistakes made by the second-order Perceptron algorithm of Figure* 3.1*, run on any finite sequence $\mathcal{S} = ((\boldsymbol{x}_1, y_1), (\boldsymbol{x}_2, y_2), \dots)$ of examples, satisfies*

$$m \;\le\; \inf_{\gamma>0} \min_{\|\boldsymbol{u}\|=1} \left( \frac{D_\gamma(\boldsymbol{u};\mathcal{S})}{\gamma} + \frac{1}{\gamma}\sqrt{\left(a + \boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}\right) \sum_{i=1}^{n} \ln\left(1 + \lambda_i/a\right)} \right),$$

*where $\lambda_1, \dots, \lambda_n$ are the eigenvalues of $X_m\, X_m^\top$.*

Some remarks are in order.

First, observe that the quantity $\boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}$ in the above bound always lies between $\min_i \lambda_i$ and $\max_i \lambda_i$. In particular, $\boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u} = \lambda_i$ when $\boldsymbol{u}$ is aligned with the eigenvector associated with $\lambda_i$. This fact entails a trade-off between the hinge loss term and the square-root term in the bound.

Second, the larger $a$ gets, the more similar the "warping" matrix $(aI_n + S_t\, S_t^\top)^{-1}$ becomes to the diagonal matrix $a^{-1} I_n$. In fact, as the reader can see from Figure 3.1, in the limit as $a \to \infty$ the second-order Perceptron algorithm becomes the classical Perceptron algorithm, and the bound in Theorem 3.1 takes the form

$$m \le \inf_{\gamma>0} \min_{\|\boldsymbol{u}\|=1} \left( \frac{D_\gamma(\boldsymbol{u};\mathcal{S})}{\gamma} + \frac{1}{\gamma}\sqrt{\sum_{i=1}^{n} \lambda_i} \right).$$

Now, since the trace of a matrix equals the sum of its eigenvalues and the nonzero eigenvalues of $X_m\, X_m^\top$ coincide with the nonzero eigenvalues of $X_m^\top\, X_m$, we can immediately see that $\sum_{i=1}^n \lambda_i = \mathrm{trace}(X_m^\top\, X_m) = \sum_{t\in\mathcal{M}} \|\boldsymbol{x}_t\|^2 \le m\left(\max_{t\in\mathcal{M}} \|\boldsymbol{x}_t\|^2\right)$, where $\mathcal{M} \subseteq \{1, 2, \dots\}$ is the set of indices of mistaken trials. Thus, setting $R^2 = \max_{t\in\mathcal{M}} \|\boldsymbol{x}_t\|^2$, we can solve the resulting bound for $m$. This gives

$$m \le \inf_{\gamma>0} \min_{\|\boldsymbol{u}\|=1} \left( \frac{R^2}{2\,\gamma^2} + \frac{D_\gamma(\boldsymbol{u};\mathcal{S})}{\gamma} + \frac{R}{\gamma}\sqrt{\frac{D_\gamma(\boldsymbol{u};\mathcal{S})}{\gamma} + \frac{R^2}{4\,\gamma^2}} \right),$$

which is the Perceptron bound in the general nonseparable case [18]. This shows that, in a certain sense, the second-order Perceptron algorithm strictly generalizes the classical Perceptron algorithm by introducing an additional parameter $a$. In general, the larger $a$ becomes, the more the algorithm in Figure 3.1 resembles the Perceptron algorithm.

Third, in the linearly separable case the mistake bound for the Perceptron algorithm is $(R/\gamma)^2$. This bound is determined by the aforementioned trace inequality $\sum_{i=1}^n \lambda_i \le R^2\, m$. The second-order algorithm, on the other hand, has the bound $\sqrt{(a + \boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}) \sum_{i=1}^n \ln(1+\lambda_i/a)}\,/\,\gamma$, which is determined by the core spectral quantity $\left(a + \boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}\right) \sum_{i=1}^n \ln(1+\lambda_i/a)$. A quick comparison of the two bounds suggests that data sequences that are linearly separable by hyperplanes whose normal vectors are nearly aligned with eigenvectors having small eigenvalues should be advantageous for the second-order Perceptron algorithm (see Figure 2.2).

A more precise quantitative comparison between the two bounds might go as follows. We first note that in order to carry out this comparison, we need to somehow renounce the second-order dependence on the eigenvalues $\lambda_i$. Introduce the notation $\lambda_{\boldsymbol{u}} = \boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}$. We have

$$\begin{aligned}(a+\lambda_{\boldsymbol{u}}) \sum_{i=1}^n \ln(1+\lambda_i/a) &\le \max_{\lambda_1,\dots,\lambda_n\,:\,\sum_{i=1}^n \lambda_i \le R^2 m} (a+\lambda_{\boldsymbol{u}}) \sum_{i=1}^n \ln(1+\lambda_i/a)\\ &= (a+\lambda_{\boldsymbol{u}})\; n\, \ln\left(1+\frac{R^2 m}{n\,a}\right),\end{aligned}$$

since the maximum is achieved when all $\lambda_j$ are equal to $R^2 m/n$. Now, finding conditions on the data for which the second-order algorithm is advantageous is reduced to finding conditions on $a$, $\lambda_{\boldsymbol{u}}$, and $r = R^2 m/n$ such that

$$(a+\lambda_{\boldsymbol{u}}) \ln\left(1+\frac{r}{a}\right) \le r \tag{3.1}$$

is satisfied. The next lemma, proved in Appendix B through a simple derivative argument, shows that if $\lambda_{\boldsymbol{u}} < r/2$, then $a = r\lambda_{\boldsymbol{u}}/(r - 2\lambda_{\boldsymbol{u}})$ makes (3.1) a strict inequality. With this setting of $a$, the smaller $\lambda_{\boldsymbol{u}}$ is when compared to $r/2$, the smaller the left-hand side of (3.1) is when compared to the right-hand side, that is, the smaller the second-order bound is when compared to the first-order one. Thus, as we expected, if the data tend to be "flat" and $\boldsymbol{u}$ has irrelevant components along the direction of large instance vectors (as in Figure 2.2), then it is convenient to pick a small value of $a$. In particular, when $\lambda_{\boldsymbol{u}}$ is "small" the above setting of $a$ becomes $a \simeq \lambda_{\boldsymbol{u}}$ (independent of $r$). On the other hand, the lemma also shows that whenever $\lambda_{\boldsymbol{u}} \ge r/2$, then (3.1) is satisfied (as an equality) only for $a \to \infty$. Thus when $\lambda_{\boldsymbol{u}}$ is "not small" the best thing to do is to resort to the first-order algorithm.

LEMMA 3.2. *Let $f(a,\lambda,r) = (a+\lambda)\ln\left(1+\frac{r}{a}\right)$, where $a,\lambda,r > 0$. Then the following hold:*

1. *$\lim_{a\to\infty} f(a,\lambda,r) = r$; moreover, if $\lambda$ and $r$ are such that $\lambda \ge r/2$, then $f(a,\lambda,r) \ge r$ for all $a > 0$.*
2. *If $\lambda$ and $r$ are such that $\lambda < r/2$, then setting $a = a(\lambda,r) = \frac{r\lambda}{r-2\lambda}$ gets $f(a,\lambda,r) < r$ and $\lim_{2\lambda/r\to 0} f(a,\lambda,r)/r = 0$.*

We finally observe that the running time per trial of the second-order algorithm is $\Theta(n^2)$, since by the well-known Sherman–Morrison formula (see, e.g., [24, Chap. 0]) if $\boldsymbol{x}$ is a vector and $A$ is a positive definite matrix, then so is $B = A + \boldsymbol{x}\boldsymbol{x}^\top$ and

$$B^{-1} = A^{-1} - \frac{\left(A^{-1}\boldsymbol{x}\right)\left(A^{-1}\boldsymbol{x}\right)^\top}{1+\boldsymbol{x}^\top A^{-1}\boldsymbol{x}}. \tag{3.2}$$

This formula allows us to perform matrix inversion incrementally. In particular, since the $n \times n$ positive definite matrix $aI_n + S_t\, S_t^\top$ equals $aI_n + X_{k-1}\, X_{k-1}^\top + \boldsymbol{x}_t \boldsymbol{x}_t^\top$, one can compute in time $\Theta(n^2)$ the $n$-dimensional vector $\left(aI_n + X_{k-1}\, X_{k-1}^\top\right)^{-1} \boldsymbol{x}_t$ and use it along with the Sherman–Morrison formula to obtain $\left(aI_n + S_t\, S_t^\top\right)^{-1}$, again in time $\Theta(n^2)$.

**3.2. The algorithm in dual variables and the use of kernel functions.** In this section we show that the second-order Perceptron algorithm can be equivalently formulated in dual variables. This formulation allows us to run the algorithm efficiently in any given reproducing kernel Hilbert space. As a consequence, we are able to derive a kernel version of Theorem 3.1 where the mistake bound is expressed in terms of the eigenvalues of the kernel Gram matrix.

We recall that a *kernel* function (see, e.g., [12, 36, 38]) is a nonnegative function $K : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$ satisfying

$$\sum_{i=1}^{m} \sum_{j=1}^{m} \alpha_i\, \alpha_j\, K(\boldsymbol{x}_i, \boldsymbol{x}_j) \ge 0$$

for all $\alpha_1, \dots, \alpha_m \in \mathbb{R}$, $\boldsymbol{x}_1, \dots, \boldsymbol{x}_m \in \mathbb{R}^n$, and $m \in \mathbb{N}$ (such functions are also called positive definite). Given a kernel $K$, we can define the linear space

$$\mathcal{V}_K = \left\{ f(\cdot) = \sum_{i=1}^{m} \alpha_i\, K(\boldsymbol{x}_i, \cdot) \,:\, \alpha_i \in \mathbb{R},\, \boldsymbol{x}_i \in \mathbb{R}^n,\, i = 1, \dots, m,\, m \in \mathbb{N} \right\},$$

with norm defined by

$$\|f\|_K = \sqrt{\sum_{i=1}^{m} \sum_{j=1}^{m} \alpha_i\, \alpha_j\, K(\boldsymbol{x}_i, \boldsymbol{x}_j)}\ .$$

If this space is completed by adding all limit points of sequences $f_1, f_2, \ldots \in \mathcal{V}_K$ that are convergent in the norm $\|f\|_K$, the resulting space, denoted by $\mathcal{H}_K$, is called the *reproducing kernel Hilbert space* (induced by the kernel $K$). Classical examples of kernel functions include the so-called polynomial kernel $K(\boldsymbol{x}, \boldsymbol{y}) = (1 + \boldsymbol{x}^\top \boldsymbol{y})^d$, where $d$ is a positive integer, and the Gaussian kernel $K(\boldsymbol{x}, \boldsymbol{y}) = \exp(-\|\boldsymbol{x} - \boldsymbol{y}\|^2/2\sigma^2)$, $\sigma > 0$.

In practice, any algorithm depending on the instance vectors $\boldsymbol{x}_i$ only through inner products $\boldsymbol{x}_i^\top \boldsymbol{x}_j$ can be turned into a more general kernel version just by replacing the standard inner products $\boldsymbol{x}_i^\top \boldsymbol{x}_j$ throughout by the kernel inner products $K(\boldsymbol{x}_i, \boldsymbol{x}_j)$.

The following theorem is a slight modification of the dual formulation of the ridge regression algorithm derived in [35].

THEOREM 3.3. *With the notation of Figure* 3.1, *let $\widetilde{\boldsymbol{y}}_t$ be the $k$-component vector whose first $k-1$ components are the labels $y_i$ where the algorithm has made a mistake up to trial $t-1$ and whose last component is* 0. *Then, for all $\boldsymbol{x}_t \in \mathbb{R}^n$, we have*

$$\boldsymbol{v}_{k-1}^\top \left(aI_n + S_t\, S_t^\top\right)^{-1} \boldsymbol{x}_t = \widetilde{\boldsymbol{y}}_t^\top \left(aI_k + G_t\right)^{-1} \left(S_t^\top\, \boldsymbol{x}_t\right),$$

*where $G_t = S_t^\top S_t$ is a $k \times k$ (Gram) matrix and $I_k$ is the $k$-dimensional identity matrix.*

*Proof.* Recalling Figure 3.1, we have $\boldsymbol{v}_{k-1} = S_t\, \widetilde{\boldsymbol{y}}_t$. This implies

$$\boldsymbol{v}_{k-1}^\top \left(aI_n + S_t\, S_t^\top\right)^{-1} = \widetilde{\boldsymbol{y}}_t^\top S_t^\top \left(aI_n + S_t\, S_t^\top\right)^{-1}.$$

Thus we need only prove that

$$S_t^\top \left(aI_n + S_t\, S_t^\top\right)^{-1} = \left(aI_k + G_t\right)^{-1} S_t^\top$$

holds. But this follows from, e.g., part (d) of Exercise 17 in [6, Chap. 1]. $\square$

From a computational standpoint, we remark that the update rule of this algorithm can exploit a known adjustment formula for partitioned matrices (see, e.g., [24, Chap. 0]). This formula relates the inverse of a matrix to the inverses of some of its submatrices. In our simple case, given a $(k-1)\times(k-1)$ positive definite matrix $A$, a $(k-1)$-dimensional column vector $\boldsymbol{b}$, and a scalar $c$, we have

$$\begin{bmatrix} A & \boldsymbol{b} \\ \boldsymbol{b}^\top & c \end{bmatrix}^{-1} = \begin{bmatrix} A^{-1} + \boldsymbol{v}\boldsymbol{v}^\top/d & -\boldsymbol{v}/d \\ -\boldsymbol{v}^\top/d & 1/d \end{bmatrix},$$

where $\boldsymbol{v} = A^{-1}\boldsymbol{b}$ and[6] $d = c - \boldsymbol{b}^\top \boldsymbol{v}$ can be computed with $\Theta(k^2)$ multiplications. Using the notation of Theorem 3.3 it is easy to see that

$$aI_k + G_t = \begin{bmatrix} aI_{k-1} + X_{k-1}^\top X_{k-1} & X_{k-1}^\top \boldsymbol{x}_t \\ \boldsymbol{x}_t^\top X_{k-1} & a + \boldsymbol{x}_t^\top \boldsymbol{x}_t \end{bmatrix}.$$

Thus, using the above formula for the inverse of partitioned matrices, it follows that the $k$-dimensional matrix $\left(aI_k + G_t\right)^{-1}$ can be computed incrementally from the $(k-1)$-dimensional matrix $\left(aI_{k-1} + X_{k-1}^\top X_{k-1}\right)^{-1}$ with only $\Theta(k^2)$ extra dot products. Also, sweeping through a sequence of $T$ examples needs only $\Theta(m^2\, T)$ dot products, where $m$ is upper bounded as in Theorem 3.1.

The following result is a kernel version of Theorem 3.1. The hinge loss of any function $f \in \mathcal{H}_K$ is defined by $D_\gamma(f;(\boldsymbol{x},y)) = \max\{0, \gamma - y\, f(\boldsymbol{x})\}$.

COROLLARY 3.4. *The number $m$ of mistakes made by the dual second-order Perceptron algorithm with kernel $K$, run on any finite sequence $\mathcal{S} = ((\boldsymbol{x}_1,y_1),(\boldsymbol{x}_2,y_2),\dots)$ of examples, satisfies*

$$m \;\le\; \inf_{\gamma>0} \min_{\|f\|_K=1} \left( \frac{D_\gamma(f;\mathcal{S})}{\gamma} + \frac{1}{\gamma}\sqrt{\left(a + \sum_{t\in\mathcal{M}} f(\boldsymbol{x}_t)^2\right) \sum_i \ln\left(1 + \lambda_i/a\right)} \right).$$

*The numbers $\lambda_i$ are the nonzero eigenvalues of the kernel Gram matrix with entries $K(\boldsymbol{x}_i,\boldsymbol{x}_j)$, where $i,j \in \mathcal{M}$ and $\mathcal{M}$ is the set of indices of mistaken trials.*

Considerations similar to those made after the statement of Theorem 3.1 apply here as well. Note that the number of nonzero eigenvalues $\lambda_i$ of the kernel Gram matrix is, in general, equal to $m$, since the very nature of kernel functions makes the dimension of the space $\mathcal{H}_K$ very large, possibly infinite (hence the kernel Gram matrix is likely to be full-rank). Note also that if a linear kernel $K(\boldsymbol{x}_i,\boldsymbol{x}_j) = \boldsymbol{x}_i^\top \boldsymbol{x}_j$ is used in Corollary 3.4, then the mistake bound of Theorem 3.1 is recovered exactly. To see this observe that $\lambda_{\boldsymbol{u}} = \boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u} = \sum_{t\in\mathcal{M}} (\boldsymbol{u}^\top \boldsymbol{x}_t)^2$ and also that the nonzero eigenvalues of the matrix $X_m\, X_m^\top$ coincide with the nonzero eigenvalues of the Gram matrix $X_m^\top X_m$.

[6]The quantity $d$ is called the Schur complement of the augmented matrix $\left[\begin{smallmatrix} A & \boldsymbol{b} \\ \boldsymbol{b}^\top & c \end{smallmatrix}\right]$ with respect to matrix $A$. From the positive definiteness of both $A$ and $\left[\begin{smallmatrix} A & \boldsymbol{b} \\ \boldsymbol{b}^\top & c \end{smallmatrix}\right]$ it follows that $d > 0$ (see, e.g., [24, Chap. 7]).

## 4. Getting rid of parameter $a$.

A major drawback of the algorithm described in Figure 3.1 is that its input parameter $a$ is fixed ahead of time. It turns out that in any practical application the value of this parameter significantly affects performance. For instance, a bad choice of $a$ might make the second-order Perceptron algorithm similar to the first-order one, even in cases when the former should perform far better.

In this section we analyze two variants of the basic algorithm: The first variant (section 4.1) is an adaptive parameter version of the algorithm in Figure 3.1; the second variant (section 4.2) eliminates the need for the trade-off parameter $a$ by replacing the "warping" matrix $(aI_n + S_t\, S_t^\top)^{-1}$ with the matrix $(S_t\, S_t^\top)^+$, i.e., the *pseudoinverse* of $S_t\, S_t^\top$.

### 4.1. Second-order Perceptron with adaptive parameter.

In this section we refine the arguments of section 3.1 by motivating and analyzing an adaptive parameter version of the algorithm in Figure 3.1. Ideally, we would like the resulting algorithm to be able to learn on the fly the "best" $a$ for the given data sequence, such as the value of $a$ that minimizes the bound in Theorem 3.1. The optimal $a$ clearly depends on unknown quantities, like the spectral structure of data and the unknown target $\boldsymbol{u}$. This ideal choice of $a$ would be able to automatically turn the second-order algorithm into a first-order one when the actual scattering of data has, say, spherical symmetry. This is a typical eigenstructure of data which a second-order algorithm cannot take advantage of.

To make our argument, we first note that the value of $a$ in Theorem 3.1 affects the bound only through the quantity

$$(a + \lambda_{\boldsymbol{u}}) \sum_{i=1}^{n} \ln\left(1 + \lambda_i / a\right). \tag{4.1}$$

In turn, both $\lambda_{\boldsymbol{u}}$ and the $\lambda_i$'s depend only on the examples where the algorithm has made a mistake. Therefore it seems reasonable to let $a$ change only in mistaken trials (this keeps the algorithm mistake driven).

Our second-order algorithm with adaptive parameter is described in Figure 4.1. The algorithm is the same as the one in Figure 3.1, except that we now feed the algorithm with an *increasing* sequence of parameter values $\{a_k\}_{k=1,2,\ldots}$, indexed by the current number of mistakes $k$. The algorithm is analyzed in Theorem 4.1 below. From the proof of that theorem (given in Appendix C) the reader can see that any strictly increasing sequence $\{a_k\}$ results in a bound on the number of mistakes. In Theorem 4.1 we actually picked a sequence which grows *linearly* with $k$. This choice seems best according to the following simple upper bounding argument. Consider again (4.1). As we noted in section 3.1,

$$(4.1) \le (a + \lambda_{\boldsymbol{u}})\, n\, \ln\left(1 + \frac{R^2 m}{n\, a}\right), \tag{4.2}$$

where $R = \max_{t\in\mathcal{M}} \|\boldsymbol{x}_t\|$. Now, from the Cauchy–Schwarz inequality one gets $\lambda_{\boldsymbol{u}} = \sum_{t\in\mathcal{M}} (\boldsymbol{u}^\top \boldsymbol{x}_t)^2 \le R^2 m$. On the other hand, if the data sequence is linearly separable with margin $\gamma > 0$, then $\lambda_{\boldsymbol{u}} = \sum_{t\in\mathcal{M}} (\boldsymbol{u}^\top \boldsymbol{x}_t)^2 \ge \gamma^2 m$. Hence, in many interesting cases, $\lambda_{\boldsymbol{u}}$ is linear in $m$. A further glance at (4.2) allows us to conclude that, viewed as a function of $m$, the right-hand side of (4.2) cannot grow less than linearly. Moreover, this minimal growth speed is achieved when $a$ is a linear[7] function of $m$.

[7]The reader will note that if $a$ grows faster than linearly, then (4.2) is still linear in $m$. However, the resulting (multiplicative) constants in (4.2) would be larger.

```
**Parameter sequence:** $\{a_k\}_{k=1,2,\dots}$, $a_{k+1} > a_k > 0$, $k = 1, 2, \dots$.
**Initialization:** $X_0 = \emptyset$; $\boldsymbol{v}_0 = \mathbf{0}$; $k = 1$.
**Repeat for** $t = 1, 2, \dots$ :
    1. get instance $\boldsymbol{x}_t \in \mathbb{R}^n$;
    2. set $S_t = [\, X_{k-1}\ \boldsymbol{x}_t \,]$;
    3. predict $\widehat{y}_t = \mathrm{SGN}(\boldsymbol{w}_t^\top \boldsymbol{x}_t) \in \{-1, +1\}$,
       where $\boldsymbol{w}_t = \left(a_k I_n + S_t S_t^\top\right)^{-1} \boldsymbol{v}_{k-1}$;
    4. get label $y_t \in \{-1, +1\}$;
    5. if $\widehat{y}_t \neq y_t$, then
           $\boldsymbol{v}_k = \boldsymbol{v}_{k-1} + y_t \boldsymbol{x}_t$,
           $X_k = S_t$,
           $k \leftarrow k + 1$.
```

FIG. 4.1. *The second-order Perceptron algorithm with increasing parameter sequence* $\{a_k\}_{k=1,2,\dots}$.

It is important to point out that this qualitative argument does not depend on the number of nonzero eigenvalues of matrix $X_m X_m^\top$. For example, our conclusions would not change even if all instances $\boldsymbol{x}_1, \boldsymbol{x}_2, \dots$ lived in a small subspace of $\mathbb{R}^n$ or, alternatively, if we mapped the same instances into a high-dimensional feature space via a kernel function (see also the discussion after Corollary 3.4).

Theorem 4.1 below uses[8] $a_k = c\,R^2 k$, where $c$ is a small positive constant. This tuning captures the "right" order of growth of $a_k$, up to a multiplicative constant $c$, whose best choice depends again on unknown quantities.

THEOREM 4.1. *If the second-order Perceptron algorithm of Figure* 4.1 *is run with parameter sequence* $a_k = c\,R^2 k$, *where* $c > 0$, *on any finite sequence* $\mathcal{S} = ((\boldsymbol{x}_1, y_1), (\boldsymbol{x}_2, y_2), \dots)$ *of examples such that* $\|\boldsymbol{x}_t\| \le R$, *then the total number* $m$ *of mistakes satisfies*

$$m \le \inf_{\gamma>0} \min_{\|\boldsymbol{u}\|=1} \left[ \frac{D_\gamma(\boldsymbol{u};\mathcal{S})}{\gamma} + \frac{1}{\gamma}\sqrt{(a_m + \lambda_{\boldsymbol{u}}) \left( B(c,m) + \sum_{i=1}^{n} \ln\left(1 + \frac{\lambda_i}{a_m}\right)\right)} \right], \tag{4.3}$$

*where* $\lambda_1, \dots, \lambda_n$ *are the eigenvalues of* $X_m X_m^\top$, $a_m = c\,R^2 m$, *and*

$$B(c,m) = \frac{1}{c} \ln \frac{m + 1/c}{1 + 1/c}.$$

To see why the algorithm with adaptive parameter might be advantageous over the one with fixed parameter, recall the tuning argument around (3.1). There, it was shown that the second-order algorithm is able to exploit the spectral properties of data when $\lambda_{\boldsymbol{u}}$ is "small." In such a case, a good tuning of $a$ is $a = r\lambda_{\boldsymbol{u}}/(r - 2\lambda_{\boldsymbol{u}})$, which, for small values of $\lambda_{\boldsymbol{u}}$, becomes $a \simeq \lambda_{\boldsymbol{u}}$. Now, for the sake of concreteness, let us focus on the linearly separable case. We have already observed that in this case $\lambda_{\boldsymbol{u}} = c' R^2 m$, where $\gamma^2/R^2 \le c' \le 1$ and $\gamma \in (0, R]$ is the minimal margin on the data. We emphasize that the tuning $a \simeq \lambda_{\boldsymbol{u}} = c'\,R^2 m$ matches the one mentioned in Theorem 4.1 up to a scaling factor. In particular, after comparing the bounds in

[8]The presence of the scaling factor $R^2$ simplifies the analysis in Appendix C.

Theorems 3.1 and 4.1, we see that Theorem 4.1 replaces $a$ with $a_m = c\,R^2 m$, i.e., with a function having a linear dependence on $m$. The price we pay for this substitution is a further additive term $B(c,m)$ which has a mild (logarithmic) dependence on $m$. The resulting bound has an inconvenient implicit form. An upper bound on an explicit solution can be clearly computed, but the calculations get overly complicated and do not add any new insights into the heart of the matter. Therefore we feel justified in omitting any further analytical detail.

As in section 3.2, one can derive a dual formulation of the algorithm in Figure 4.1 and prove a result similar to the one contained in Corollary 3.4.

In general, the total number of mistakes made by the algorithm conveys relevant information about the specific dataset at hand. Using a parameter that scales with this number allows one to partially exploit this information. Note, for instance, that if the second-order algorithm of Figure 4.1 is making "many" mistakes (and $c$ is not too small), then the algorithm tends to behave as a first-order algorithm, since $a_k$ is growing "fast." In other words, we might view the algorithm as being able to detect that its second-order structure is not suitable to the data it is processing, thereby trying to turn itself into a first-order algorithm. On the other hand, if the algorithm is making only a few mistakes, then $a_k$ tends to remain small, meaning that the current second-order structure of the algorithm appears to be the right one for the dataset at hand. This approach to parameter tuning is similar to the *self-confident* tuning adopted in [3].

We finally note that, unlike the algorithm with fixed $a$, here incremental matrix inversion looks a bit more troublesome. In fact, making $a$ change from trial to trial results in a matrix update which is no longer a low-rank adjustment. Therefore the algorithm in Figure 4.1 (as well as its dual version) does not seem to have an update rule requiring only a quadratic number of operations per trial.

## 4.2. Second-order Perceptron with pseudoinverse.

A more radical way of dealing with the trade-off parameter $a$ is to set it to zero and replace the inverse of $aI_n + S_t S_t^\top$ with the pseudoinverse $(S_t S_t^\top)^+$. This is done in the algorithm of Figure 4.2. The matrix $(S_t S_t^\top)^+$ does always exist and coincides with $(S_t S_t^\top)^{-1}$ in the case when $S_t S_t^\top$ is nonsingular. In Appendix D we collected some relevant information about pseudoinverses and their connection to the SVD. A classical reference in which to learn about them is [6].

The following result is proved in Appendix E.

THEOREM 4.2. *If the second-order Perceptron algorithm of Figure 4.2 is run on any finite sequence $\mathcal{S} = ((\boldsymbol{x}_1, y_1), (\boldsymbol{x}_2, y_2), \dots)$ of examples such that $\|\boldsymbol{x}_t\| \le R$, then the total number $m$ of mistakes satisfies*

(4.4)
$$m \le \inf_{\gamma>0} \min_{\|\boldsymbol{u}\|=1} \left[ \frac{D_\gamma(\boldsymbol{u};\mathcal{S})}{\gamma} + \frac{1}{\gamma}\sqrt{\lambda_{\boldsymbol{u}}\left(r + \frac{1}{2}r(r+1)\,\ln\left(1 + \frac{2\,R^2}{\lambda^*}\frac{m}{r(r+1)}\right)\right)}\,\right],$$

*where $r = \operatorname{rank}(X_m X_m^\top) \le n$ and $\lambda^*$ is the minimum among the* smallest *positive eigenvalues of the matrices $X_k X_k^\top$, $k = 1, \dots, m$, produced by the algorithm during its run.*

Inequality (4.4) depends on a lower bound on the positive eigenvalues of the correlation matrices produced by the algorithm. In a sense, this dependence substitutes the dependence on $a$ in the bound of Theorem 3.1. In fact, adding the matrix $aI_n$ to

```
Initialization: $X_0 = \emptyset$; $\boldsymbol{v}_0 = \mathbf{0}$; $k = 1$.
Repeat for $t = 1, 2, \ldots$ :
    1. get instance $\boldsymbol{x}_t \in \mathbb{R}^n$;
    2. set $S_t = [\, X_{k-1}\ \boldsymbol{x}_t \,]$;
    3. predict $\widehat{y}_t = \mathrm{SGN}(\boldsymbol{w}_t^\top \boldsymbol{x}_t) \in \{-1, +1\}$,
       where $\boldsymbol{w}_t = \left(S_t\, S_t^\top\right)^+ \boldsymbol{v}_{k-1}$;
    4. get label $y_t \in \{-1, +1\}$;
    5. if $\widehat{y}_t \neq y_t$, then:
           $\boldsymbol{v}_k = \boldsymbol{v}_{k-1} + y_t\, \boldsymbol{x}_t$,
           $X_k = S_t$,
           $k \leftarrow k + 1$.
```

FIG. 4.2. *The second-order Perceptron algorithm with pseudoinverse.*

the current correlation matrix of the data might be viewed as a way of setting a lower bound on the positive eigenvalues of the resulting matrix.

As we have observed in section 4.1, when the data are linearly separable with margin $\gamma > 0$ the quantity $\lambda_{\boldsymbol{u}}$ is linear in $m$. Thus, once we set $\lambda_{\boldsymbol{u}} = c' R^2 m$, with $\gamma^2/R^2 \le c' \le 1$, and simplify, bound (4.4) takes the form

$$m \le \frac{c' R^2}{\gamma^2}\left(r + \frac{1}{2} r(r+1)\,\ln\left(1 + \frac{2\,R^2}{\lambda^*}\frac{m}{r(r+1)}\right)\right). \tag{4.5}$$

As for Theorem 4.1, the two bounds (4.4) and (4.5) are in implicit form with respect to $m$. The bounds can be made explicit at the cost of adding a few logarithmic terms. Again, we decided not to carry out such calculations since they are not very insightful.

Comparing bounds (4.4) and (4.5) to the one in Theorem 3.1, one can see that the second-order algorithm with pseudoinverse might be advantageous over the basic version when the effective dimension $r$ of the data is relatively small. Also, the bounds (4.4) and (4.5) are nonvacuous only when $r < m$.

Actually, as for the algorithm in Figure 3.1, it is not hard to turn the algorithm in Figure 4.2 into an equivalent dual form. Again, one can exploit known methods to incrementally compute the pseudoinverse (see, e.g., the so-called Greville's method in [6]), reducing the computational cost per trial from cubic to quadratic.

Unfortunately, the bounds (4.4) and (4.5) are generally not useful in the presence of kernel functions[9] since the bounds have a linear[10] dependence on $r$ which cannot be avoided in the worst case. This is due to the simple fact that each time the new instance $\boldsymbol{x}_t$ lies outside the column space of the previous matrix $X_{k-1}$ the pseudoinverse $(S_t\, S_t^\top)^+$ maps $\boldsymbol{x}_t$ to the orthogonal space of this column space, so that the algorithm has a degenerate margin $\boldsymbol{w}_t^\top \boldsymbol{x}_t = 0$.

## 5. Simulations on a toy problem.

With the purpose of empirically verifying our theoretical results, we ran our second-order Perceptron algorithm on two sets of

[9]In the kernel case, $r$ is likely to be equal to $m$, giving rise to a vacuous bound.

[10]Note that the quadratic dependence on $r$ is essentially fictitious here since the $r(r+1)$ factor occurs both at the numerator and at the denominator inside the logarithm.

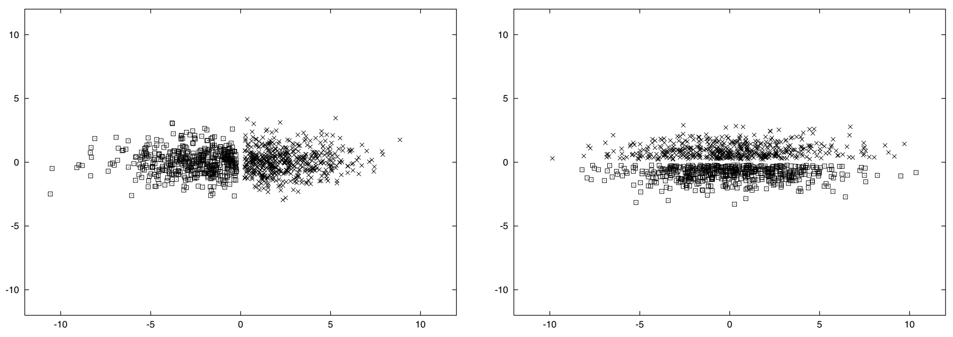

FIG. 5.1. *Projection on the two most relevant coordinates of the* 100*-dimensional datasets used in our simulations.*

TABLE 5.1

| Algorithm | Mistakes, 1st dataset | Mistakes, 2nd dataset |
|---|---|---|
| Perceptron | 30.20 (6.24) | 29.80 (8.16) |
| second-order Perceptron, $a = 1$ | 9.60 (2.94) | 5.60 (2.80) |
| second-order Perceptron, $a = 10$ | 10.60 (2.58) | 3.20 (1.47) |
| second-order Perceptron, $a = 50$ | 14.00 (4.36) | 10.40 (6.05) |

linearly separable data with 100 attributes. The two datasets are generated by sampling a Gaussian distribution whose correlation matrix has a single dominant eigenvalue, the remaining eigenvalues having the same size (in the sample realizations, the dominant eigenvalue is about eight times bigger than the others). In the first dataset (leftmost plot in Figure 5.1), labels are assigned so that the separating hyperplane is orthogonal to the eigenvector associated with the dominant eigenvalue. In the second dataset (rightmost plot in Figure 5.1), labels are assigned so that the separating hyperplane is orthogonal to the eigenvector associated with the first nondominant eigenvalue in the natural ordering of the coordinates.

According to the remarks following Theorem 3.1, we expect the Perceptron algorithm to perform similarly on both datasets (as the radius of the enclosing ball and the margin do not change between datasets), whereas the second-order Perceptron algorithm is expected to outperform the Perceptron algorithm on the second dataset. This conjecture is supported by the results in Table 5.1. These results were obtained by running the Perceptron algorithm and the second-order Perceptron algorithm (for different values of parameter $a$) for two epochs on a training set of 9000 examples, and then saving the final classifier generated by each algorithm after its last training mistake. The numbers in the table are the average number of mistakes made by these classifiers on a test set of 3000 examples, where the averages are computed over 5 random permutations of the training set (standard deviations are shown in parentheses). Normalizing the instances did not alter significantly Perceptron's performance.

To offer a familiar context for the reader experienced in empirical comparisons of learning algorithms, the predictive performance in our experiments has been evaluated using the standard test error measure. However, we could have drawn the same conclusions using, instead of the test error, the number of mistakes made by the two algorithms during training. This quantity, which is the one we bound in our theoretical results, is different from the standard training error, since in the on-line model each new mistake is made by a different classifier. A theory accounting for the relationship between the fraction of mistakes in the on-line model and the test error is developed in [9].

## 6. Conclusions and open problems.

We have introduced a second-order Perceptron algorithm, a new on-line binary classification algorithm for learning linear-threshold functions. The algorithm is able to exploit certain spectral properties of the data sequence, expressed as an interaction between the underlying target vector and the eigenvalues of the correlation matrix of the data.

The second-order Perceptron algorithm retains the standard Perceptron's key properties of sparsity and efficient dual variable representation. This allows us to efficiently run the algorithm in any reproducing kernel Hilbert space. We have proved for this algorithm the best known mistake bound for efficient kernel-based linear-threshold classifiers to date.

Since the performance of our algorithm is critically influenced by an input parameter $a$, whose optimal setting depends on the whole training set, we have developed two variants of our basic algorithm. The first variant increases the parameter $a$ as a function of the number of mistakes made. The second variant avoids altogether the parameter $a$ by replacing the inverse correlation matrix $(aI + X\,X^\top)^{-1}$ with the pseudoinverse $(X\,X^\top)^+$.

We have also run a simple experiment on synthetic data to give some evidence of the theoretical properties of our algorithm (in its basic form).

Our second-order Perceptron algorithm might be seen as a new on-line classification technique. As such, this technique could be combined with previous techniques, such as the shifting target technique [4, 22] and the approximate on-line large margin technique (see, e.g., [17, 27]).

As shown in [9], our analysis can be used to derive linear-threshold classifiers whose statistical risk can be bounded, in probability, by quantities directly related to the mistake bounds of Theorems 3.1, 4.1, and 4.2. The resulting data-dependent generalization bounds are similar in spirit, though not readily comparable, to the bounds given in [41, Thm. 5.2]. In fact, the results in [41] are derived, via involved covering numbers arguments, in terms of the correlation matrix $X\,X^\top$ of the *whole* sequence of examples. More precisely, these results are expressed in terms of all the "large" eigenvalues of $X\,X^\top$, taken in decreasing order of magnitude up to the "effective number of dimensions."[11] In contrast to that, our bounds are in terms of all the eigenvalues of the submatrix of $X\,X^\top$ made up of instances where the algorithm has made a mistake. In this sense, the sparsity of the solution produced by our algorithm is directly reflected by the magnitude of the eigenvalues of the above submatrix. To see this, go back to the primal variable form of Theorem 3.1 and observe that adding rank-one matrices of type $\boldsymbol{x}\,\boldsymbol{x}^\top$ to a correlation matrix $X\,X^\top$ results in a new correlation matrix whose eigenvalues can only be larger. Hence few mistakes are equivalent to high sparsity, which, in turn, is equivalent to small eigenvalues.

We also observe that the application of mistake bounds to the statistical learning setting is not straightforward for the whitened Perceptron algorithm described in section 2. Since the whitening matrix $M^{-1/2}$ depends on the whole training data, the whitening transformation $\boldsymbol{x} \to M^{-1/2}\boldsymbol{x}$ does not preserve stochastic independence among the (whitened) instance vectors $M^{-1/2}\boldsymbol{x}_1, \ldots, M^{-1/2}\boldsymbol{x}_T$.

There are several directions in which this work can be extended. In the following we briefly mention three of them.

[11]The "effective number of dimensions" depends, for instance, on the margin of the data.

First, it might be possible to refine the analysis of the second-order Perceptron algorithm with adaptive parameter (Theorem 4.1). The linear growth of $a_k$ is certainly a first step toward on-line parameter adaptation, though somewhat unsatisfactory since it leaves the leading coefficient of $a_k$ unspecified. Moreover, we are not aware of any incremental updating scheme for this algorithm (neither in primal nor in dual form). Second, it might be possible to refine the analysis of the second-order Perceptron with the pseudoinverse (Theorem 4.2) so as to eliminate the dependence on $\lambda^*$. Third, we would like to combine the second-order classification technology with dual-norm algorithms such as the $p$-norm algorithms [18, 20] and the Winnow/weighted majority algorithms [28, 29, 30]. This would probably give rise to new attractive algorithms for learning sparse linear-threshold functions.

**Appendix A. Proof of Theorem 3.1.** Fix an arbitrary finite sequence $\mathcal{S} = ((\boldsymbol{x}_1, y_1), (\boldsymbol{x}_2, y_2), \dots)$, and let $\mathcal{M} \subseteq \{1, 2, \dots\}$ be the set of trials where the algorithm of Figure 3.1 made a mistake. Let $A_0 = aI_n$ and $A_k = aI_n + X_k X_k^\top$. We study the evolution of $\boldsymbol{v}_k^\top A_k^{-1} \boldsymbol{v}_k$ over mistaken trials. Let $t = t_k$ be the trial where the $k$th mistake occurred. We have

$$\begin{aligned}
\boldsymbol{v}_k^\top A_k^{-1} \boldsymbol{v}_k &= (\boldsymbol{v}_{k-1} + y_t\, \boldsymbol{x}_t)^\top A_k^{-1} (\boldsymbol{v}_{k-1} + y_t\, \boldsymbol{x}_t) \\
&\qquad (\text{since } \widehat{y}_t \neq y_t \text{ implies } \boldsymbol{v}_k = \boldsymbol{v}_{k-1} + y_t\, \boldsymbol{x}_t) \\
&= \boldsymbol{v}_{k-1}^\top A_k^{-1} \boldsymbol{v}_{k-1} + 2y_t \left(A_k^{-1} \boldsymbol{v}_{k-1}\right)^\top \boldsymbol{x}_t + \boldsymbol{x}_t^\top A_k^{-1} \boldsymbol{x}_t \\
&= \boldsymbol{v}_{k-1}^\top A_k^{-1} \boldsymbol{v}_{k-1} + 2y_t\, \boldsymbol{w}_t^\top \boldsymbol{x}_t + \boldsymbol{x}_t^\top A_k^{-1} \boldsymbol{x}_t \\
&\qquad (\text{since } \widehat{y}_t \neq y_t \text{ implies } X_k = S_t \text{ and } A_k^{-1} \boldsymbol{v}_{k-1} = \boldsymbol{w}_t) \\
&\leq \boldsymbol{v}_{k-1}^\top A_k^{-1} \boldsymbol{v}_{k-1} + \boldsymbol{x}_t^\top A_k^{-1} \boldsymbol{x}_t \\
&\qquad (\text{since } \widehat{y}_t \neq y_t \text{ implies } y_t\, \boldsymbol{w}_t^\top \boldsymbol{x}_t \leq 0).
\end{aligned}$$

Now, note that $A_k$ can be recursively defined using $A_k = A_{k-1} + \boldsymbol{x}_t \boldsymbol{x}_t^\top$. Hence, applying the Sherman–Morrison formula (3.2), we get

$$\boldsymbol{v}_{k-1}^\top A_k^{-1} \boldsymbol{v}_{k-1} = \boldsymbol{v}_{k-1}^\top A_{k-1}^{-1} \boldsymbol{v}_{k-1} - \frac{\left(\boldsymbol{v}_{k-1}^\top A_{k-1}^{-1} \boldsymbol{x}_t\right)^2}{1 + \boldsymbol{x}_t^\top A_{k-1}^{-1} \boldsymbol{x}_t} \leq \boldsymbol{v}_{k-1}^\top A_{k-1}^{-1} \boldsymbol{v}_{k-1},$$

where the inequality holds since $A_{k-1}^{-1}$ is the inverse of a positive definite matrix (and so $A_{k-1}^{-1}$ is positive definite). Thus we get

$$\boldsymbol{v}_k^\top A_k^{-1} \boldsymbol{v}_k \leq \boldsymbol{v}_{k-1}^\top A_{k-1}^{-1} \boldsymbol{v}_{k-1} + \boldsymbol{x}_t^\top A_k^{-1} \boldsymbol{x}_t,$$

holding for all $k = 1, \dots, m = |\mathcal{M}|$. Summing the last inequality over $k$ (or, equivalently, over $t \in \mathcal{M}$) and using $\boldsymbol{v}_0 = \boldsymbol{0}$ yields

$$\begin{aligned}
\boldsymbol{v}_m^\top A_m^{-1} \boldsymbol{v}_m &\leq \sum_{k=1}^m \boldsymbol{x}_t^\top A_k^{-1} \boldsymbol{x}_t \\
&= \sum_{k=1}^m \left(1 - \frac{\det(A_{k-1})}{\det(A_k)}\right) \\
&\qquad (\text{using Lemma A.1 from [5] or Lemma D.1 in Appendix D}) \\
&\leq \sum_{k=1}^m \ln \frac{\det(A_k)}{\det(A_{k-1})} \qquad (\text{since } 1 - x \leq -\ln x \text{ for all } x > 0)
\end{aligned}$$

$$
\begin{aligned}
&= \ln \frac{\det(A_m)}{\det(A_0)} \\
&= \ln \frac{\det(aI_n + X_m X_m^\top)}{\det(aI_n)} \\
&= \sum_{i=1}^{n} \ln\left(1 + \frac{\lambda_i}{a}\right), \qquad \text{(A.1)}
\end{aligned}
$$

where $\lambda_1, \ldots, \lambda_n$ are the eigenvalues of $X_m\, X_m^\top$.

To conclude the proof, note that $A_m^{1/2}$ does exist since $A_m$ is positive definite (see, e.g., [31, Chap. 3]). Pick any unit norm vector $\boldsymbol{u} \in \mathbb{R}^n$ and let $\boldsymbol{z} = A_m^{1/2}\boldsymbol{u}$. Then, using the Cauchy–Schwarz inequality, we have

$$
\begin{aligned}
\sqrt{\boldsymbol{v}_m^\top A_m^{-1} \boldsymbol{v}_m} &= \left\| A_m^{-1/2} \boldsymbol{v}_m \right\| \\
&\ge \frac{\left(A_m^{-1/2}\boldsymbol{v}_m\right)^\top \boldsymbol{z}}{\|\boldsymbol{z}\|} \\
&= \frac{\boldsymbol{v}_m^\top \boldsymbol{u}}{\sqrt{\boldsymbol{u}^\top A_m \boldsymbol{u}}} \\
&= \frac{\boldsymbol{v}_m^\top \boldsymbol{u}}{\sqrt{a + \boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}}} \\
&\ge \frac{\gamma\, m - D_\gamma(\boldsymbol{u}; \mathcal{S})}{\sqrt{a + \boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}}}, \qquad \text{(A.2)}
\end{aligned}
$$

where the last inequality follows from the very definition of $D_\gamma(\boldsymbol{u}; \mathcal{S})$ and holds for any $\gamma > 0$. Putting together (A.1) and (A.2) and solving for $m$ gives the statement of the theorem.

**Appendix B. Proof of Lemma 3.2.** We first check the limiting behavior of $f$ as a function of $a$: we have $f(a, \lambda, r) \to \infty$ as $a \to 0$ and $f(a, \lambda, r) \to r$ as $a \to \infty$ for any fixed $\lambda, r > 0$. To prove the remainder of part 1, note that since $\partial^2 f / \partial a^2$ has the same sign as

$$
2\, a\, \lambda + r\, \lambda - a\, r, \qquad \text{(B.1)}
$$

it follows that when $\lambda \ge r/2$, no choice of $a > 0$ exists, which makes (B.1) negative. In this case, $f(a, \lambda, r)$, viewed as a function of $a$, is convex and decreasing. Hence its minimal value $r$ is achieved only asymptotically ($a \to \infty$).

When $\lambda < r/2$ a finite value of $a$ exists which minimizes $f$. However, computing the minimizing $a$ analytically does not seem to be easy. Therefore we resort to the approximation $a = \frac{r\lambda}{r - 2\lambda}$, which is actually the value of $a$ where (B.1) vanishes, i.e., where $f$ changes concavity. To prove part 2 we set $\beta = r/(2\lambda) > 1$ and $g(\beta) = \frac{2\beta - 1}{2\beta(\beta - 1)} \ln(2\beta - 1) = f(\frac{r\lambda}{r - 2\lambda}, \lambda, r)/r$. It thus suffices to show that $g(\beta) < 1$ for all $\beta > 1$ and $\lim_{\beta \to \infty} g(\beta) = 0$. The first statement can be proved by showing that $\lim_{\beta \to 1} g(\beta) = 1$ and that for any $\beta > 1$ the first derivative of $\ln(2\beta - 1)$ is always smaller than the first derivative of $\frac{2\beta(\beta - 1)}{2\beta - 1}$. We omit the details of these easy calculations. The second statement trivially follows from $g(\beta) = O(\ln \beta / \beta)$, as $\beta \to \infty$.

**Appendix C. Proof of Theorem 4.1.** The proof is a more refined version of the proof of Theorem 3.1 and proceeds along the same lines.

Again, we assume that the $k$th mistake occurs when processing example $(\boldsymbol{x}_t, y_t)$, $t = t_k$, and we let $\mathcal{M} \subseteq \{1, 2, \dots\}$ be the set of trials where a mistake occurred. Let $A_k = a_k I_n + X_k X_k^\top$, $k = 1, 2, \dots$, and $A_0 = a_1 I_n$. We have

$$A_k = A_{k-1} + (a_k - a_{k-1}) I_n + \boldsymbol{x}_t \boldsymbol{x}_t^\top, \quad k = 1, 2, \dots, \tag{C.1}$$

where $a_0 = a_1$. We study the evolution of the quantity $\boldsymbol{v}_k^\top A_k^{-1} \boldsymbol{v}_k$ over mistaken trials. As in the proof of Theorem 3.1, we have

$$\boldsymbol{v}_k^\top A_k^{-1} \boldsymbol{v}_k \le \boldsymbol{v}_{k-1}^\top A_k^{-1} \boldsymbol{v}_{k-1} + \boldsymbol{x}_t^\top A_k^{-1} \boldsymbol{x}_t. \tag{C.2}$$

We need to bound $\boldsymbol{v}_{k-1}^\top A_k^{-1} \boldsymbol{v}_{k-1}$ from above. From (C.1) we see that when $k \ge 2$ the matrix $A_k$ is the sum of the nonsingular matrices $A_{k-1}$ and $(a_k - a_{k-1}) I_n + \boldsymbol{x}_t \boldsymbol{x}_t^\top$ (the latter is nonsingular since $a_k > a_{k-1}$). Thus, when $k \ge 2$, computing $A_k^{-1}$ can be done through the general inversion formula

$$(B + C)^{-1} = B^{-1} - B^{-1}(B^{-1} + C^{-1})^{-1} B^{-1}$$

with $B = A_{k-1}$ and $C = (a_k - a_{k-1}) I_n + \boldsymbol{x}_t \boldsymbol{x}_t^\top$. Now, since both $B$ and $C$ are positive definite, so is the matrix $B^{-1}(B^{-1} + C^{-1})^{-1} B^{-1}$ (this easily follows from the fact that the inverse of a positive definite matrix is again positive definite and that both the sum and the product of two positive definite matrices give rise to positive definite matrices). Hence if $k \ge 2$, we can write

$$\begin{aligned}
\boldsymbol{v}_{k-1}^\top A_k^{-1} \boldsymbol{v}_{k-1} &= \boldsymbol{v}_{k-1}^\top (B + C)^{-1} \boldsymbol{v}_{k-1} \\
&= \boldsymbol{v}_{k-1}^\top \left( B^{-1} - B^{-1}(B^{-1} + C^{-1})^{-1} B^{-1} \right) \boldsymbol{v}_{k-1} \\
&\le \boldsymbol{v}_{k-1}^\top B^{-1} \boldsymbol{v}_{k-1} \\
&= \boldsymbol{v}_{k-1}^\top A_{k-1}^{-1} \boldsymbol{v}_{k-1}. \qquad \text{(C.3)}
\end{aligned}$$

On the other hand, when $k = 1$, inequality (C.3) is trivially true since $\boldsymbol{v}_0 = \boldsymbol{0}$. Thus the inequality holds for all $k \ge 1$. We plug (C.3) back into (C.2), sum over $k = 1, \dots, m = |\mathcal{M}|$, and take into account that $\boldsymbol{v}_0 = \boldsymbol{0}$. We obtain

$$\begin{aligned}
\boldsymbol{v}_m^\top A_m^{-1} \boldsymbol{v}_m &\le \sum_{k=1}^m \boldsymbol{x}_t^\top A_k^{-1} \boldsymbol{x}_t \\
&= \sum_{k=1}^m \left( 1 - \frac{\det(A_{k-1} + (a_k - a_{k-1}) I_n)}{\det(A_k)} \right) \\
&\qquad \text{(applying Lemma A.1 in [5] or Lemma D.1 in Appendix D to (C.1))} \\
&\le \sum_{k=1}^m \ln \frac{\det(A_k)}{\det(A_{k-1} + (a_k - a_{k-1}) I_n)}. \qquad \text{(C.4)}
\end{aligned}$$

The presence of matrix term $(a_k - a_{k-1}) I_n$ makes the rest of the proof a bit more involved than the proof of Theorem 3.1. Since we want to obtain bounds in terms of eigenvalues of matrices, we rewrite the rightmost side of (C.4) as a function of the eigenvalues of matrices $X_k X_k^\top$. Let $\lambda_{k,i}$ be the $i$th eigenvalue of matrix $X_k X_k^\top$, with $\lambda_{0,i} = 0$. We can write

$$\ln \frac{\det(A_k)}{\det(A_{k-1} + (a_k - a_{k-1}) I_n)} = \sum_{i=1}^n \ln \frac{a_k + \lambda_{k,i}}{a_k + \lambda_{k-1,i}}.$$

Now, simple manipulations yield

$$\begin{aligned}\sum_{k=1}^{m}\sum_{i=1}^{n}\ln\frac{a_k+\lambda_{k,i}}{a_k+\lambda_{k-1,i}} &= \sum_{k=1}^{m}\sum_{i=1}^{n}\ln\left(\frac{a_k}{a_{k-1}}\,\frac{a_{k-1}+\lambda_{k-1,i}}{a_k+\lambda_{k,i}}\right) \quad \text{(recall that } a_0=a_1\text{)}\\ &\quad+\sum_{k=1}^{m}\sum_{i=1}^{n}\ln\left(\frac{a_k+\lambda_{k,i}}{a_k+\lambda_{k-1,i}}\right)\\ &\quad+\sum_{i=1}^{n}\ln\left(\frac{a_m+\lambda_{m,i}}{a_m}\right)\\ &=\sum_{k=1}^{m}\sum_{i=1}^{n}\ln\left(\frac{a_k}{a_{k-1}}\,\frac{a_{k-1}+\lambda_{k-1,i}}{a_k+\lambda_{k-1,i}}\right)+\sum_{i=1}^{n}\ln\left(1+\frac{\lambda_{m,i}}{a_m}\right).\end{aligned}$$

Hence from (C.4) we have obtained

$$\boldsymbol{v}_m^\top A_m^{-1}\boldsymbol{v}_m \le \sum_{k=1}^{m}\sum_{i=1}^{n}\ln\left(\frac{a_k}{a_{k-1}}\,\frac{a_{k-1}+\lambda_{k-1,i}}{a_k+\lambda_{k-1,i}}\right)+\sum_{i=1}^{n}\ln\left(1+\frac{\lambda_{m,i}}{a_m}\right). \tag{C.5}$$

The reader can see that (C.5) is analogous to (A.1) but for the presence of a spurious double sum term.

We turn to upper bounding the double sum in (C.5) as a function of $m$. We proceed as follows. We first note that for $k=1$ the inner sum is zero. Therefore we continue by assuming $k\ge 2$ in the inner sum. Since $X_{k-1}\,X_{k-1}^\top$ has size $n\times n$ and has rank at most $k-1$, only $\min\{k-1,n\}$ among the eigenvalues $\lambda_{k-1,1},\dots,\lambda_{k-1,n}$ can be nonzero. Also, as we have observed elsewhere, $X_{k-1}\,X_{k-1}^\top$ has the same nonzero eigenvalues as the (Gram) matrix $X_{k-1}^\top X_{k-1}$. Since the trace of a matrix equals the sum of its eigenvalues and the trace of $X_{k-1}^\top X_{k-1}$ is at most $(k-1)\,R^2$, we have, for $k=2,\dots,m$,

$$\begin{aligned}&\sum_{i=1}^{n}\ln\left(\frac{a_k}{a_{k-1}}\,\frac{a_{k-1}+\lambda_{k-1,i}}{a_k+\lambda_{k-1,i}}\right)\\ &\le \max\left\{\sum_{j=1}^{k'}\ln\left(\frac{a_k}{a_{k-1}}\,\frac{a_{k-1}+\mu_j}{a_k+\mu_j}\right)\ :\ \mu_1,\dots,\mu_{k'}\ge 0,\ \sum_{j=1}^{k'}\mu_j\le (k-1)\,R^2\right\},\end{aligned}$$

where $k'=\min\{k-1,n\}$. The maximum is achieved when all $\mu_j$ equal $(k-1)\,R^2/k'$. Thus

$$\begin{aligned}\sum_{i=1}^{n}\ln\left(\frac{a_k}{a_{k-1}}\,\frac{a_{k-1}+\lambda_{k-1,i}}{a_k+\lambda_{k-1,i}}\right) &\le k'\,\ln\left(\frac{a_k}{a_{k-1}}\,\frac{a_{k-1}+(k-1)\,R^2/k'}{a_k+(k-1)\,R^2/k'}\right)\\ &= k'\,\ln\left(\frac{k'\,a_k\,a_{k-1}+a_k\,(k-1)\,R^2}{k'\,a_k\,a_{k-1}+a_{k-1}\,(k-1)\,R^2}\right)\end{aligned} \tag{C.6}$$

for $k=2,3,\dots,m$. Now, a derivative argument shows that the function $f(x;\alpha,\beta)=$

$x \ln\left(\frac{x+\alpha}{x+\beta}\right)$ is increasing in $x > 0$ whenever $\alpha > \beta \geq 0$. Therefore we see that

$$\begin{aligned}
\text{(C.6)} &= \frac{1}{a_k\, a_{k-1}} f\big(a_k\, a_{k-1} k';\; a_k(k-1)\, R^2,\; a_{k-1}(k-1)\, R^2\big) \\
&\leq \frac{1}{a_k\, a_{k-1}} f\big(a_k\, a_{k-1}(k-1);\; a_k(k-1)\, R^2,\; a_{k-1}(k-1)\, R^2\big) \\
&= (k-1)\, \ln\left(\frac{a_k}{a_{k-1}}\, \frac{a_{k-1}+R^2}{a_k+R^2}\right).
\end{aligned}$$

Hence we can write

$$\begin{aligned}
\sum_{k=1}^{m}\sum_{i=1}^{n} \ln\left(\frac{a_k}{a_{k-1}}\, \frac{a_{k-1}+\lambda_{k-1,i}}{a_k+\lambda_{k-1,i}}\right) &\leq \sum_{k=2}^{m}(k-1)\, \ln\left(\frac{a_k}{a_{k-1}}\, \frac{a_{k-1}+R^2}{a_k+R^2}\right) \\
&= \sum_{k=1}^{m-1} k\, \ln\left(\frac{k+1}{k}\, \frac{c\,R^2 k + R^2}{c\,R^2(k+1)+R^2}\right) \\
&\quad \text{(using } a_k = c\,R^2 k\text{)} \\
&= \sum_{k=1}^{m-1} k\, \ln\left(1 + \frac{1}{c\,k^2 + c\,k + k}\right) \\
&\leq \sum_{k=1}^{m-1} \frac{1}{c\,k + c + 1} \qquad \text{(using } \ln(1+x) \leq x\text{)} \\
&\leq \frac{1}{c}\int_{1+1/c}^{m+1/c} \frac{dx}{x} \\
&= \frac{1}{c}\, \ln\frac{m+1/c}{1+1/c} \\
&= B(c,m).
\end{aligned}$$

To bound $\sqrt{\boldsymbol{v}_m^\top A_m^{-1}\boldsymbol{v}_m}$ from below, one can proceed as in the proof of Theorem 3.1, yielding

$$\sqrt{\boldsymbol{v}_m^\top A_m^{-1}\boldsymbol{v}_m} \geq \frac{\gamma\, m - D_\gamma(\boldsymbol{u}; \mathcal{S})}{\sqrt{a_m + \boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}}},$$

where $a_m = c\,R^2 m$. We plug this lower bound back into (C.5) together with the previous upper bound. After rearranging we obtain

$$\left(\frac{\gamma\, m - D_\gamma(\boldsymbol{u}; \mathcal{S})}{\sqrt{a_m + \boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}}}\right)^2 \leq B(c,m) + \sum_{i=1}^{n} \ln\left(1 + \frac{\lambda_{m,i}}{a_m}\right).$$

Solving for $m$ occurring in the numerator of the left-hand side gives the desired bound.

**Appendix D. Pseudoinverse and SVD of a matrix.** In this section we recall basic facts about the pseudoinverse and the SVD of a matrix. This background material can be found, e.g., in [6]. We then exploit these facts to prove two technical lemmas which will be used in the subsequent sections. These lemmas build on ancillary results proven, e.g., in [5, 15, 16].

The pseudoinverse of an $n \times n$ real matrix $A$ is the (unique) $n \times n$ matrix $A^+$ satisfying the following four conditions:

$$\begin{aligned} A\,A^+A &= A, \\ A^+A\,A^+ &= A^+, \\ (A^+A)^\top &= (A^+\,A), \\ (A\,A^+)^\top &= (A\,A^+). \end{aligned}$$

If the matrix is nonsingular, then the pseudoinverse coincides with the usual inverse, i.e., $A^+ = A^{-1}$.

In order to state the properties of the pseudoinverse that we need, we exploit the well-known connection between the pseudoinverse of a matrix and its SVD. In what follows we will focus only on (symmetric) positive semidefinite matrices. This allows us to simplify the exposition and replace the notion of singular value with the more familiar notion of eigenvalue.

Let $r \le n$ be the rank of $A$. An SVD of a matrix $A$ takes the form $A = U\,D\,U^\top$, where $U$ is an orthogonal matrix (i.e., such that $U\,U^\top = U^\top U = I_n$), and $D$ is a diagonal matrix whose first $r$ diagonal entries are the positive eigenvalues $\lambda_1, \dots, \lambda_r$ of $A$, and the remaining entries are zero. The first $r$ columns of $U$ form an orthonormal basis for span$(A)$, the space spanned by the columns of $A$, whereas the remaining $n-r$ columns of $U$ form an orthonormal basis for the orthogonal complement span$^\perp(A)$. Recall that in the case under consideration, span$^\perp(A)$ coincides with null$(A)$, the null space of $A$.

A more convenient form of an SVD is one in which only the eigenvectors corresponding to positive eigenvalues are shown. Let $U_r$ be the $n \times r$ matrix made up of the first $r$ columns of $U$ and let $D_r$ be the $r \times r$ diagonal matrix whose diagonal entries are the positive eigenvalues of $A$. Then one immediately sees that the finer SVD holds:

(D.1) $$A = U_r\,D_r\,U_r^\top.$$

Every positive semidefinite matrix admits an SVD like (D.1).

Given an SVD of a matrix, computing its pseudoinverse is a rather simple matter. In particular, given (D.1), one can easily show that

(D.2) $$A^+ = U_r\,D_r^{-1}\,U_r^\top,$$

where $D_r^{-1}$ is the inverse of the (nonsingular) matrix $D_r$.

Many properties of pseudoinverses which are relevant to this paper can be derived from (D.1) and (D.2). For instance, one can immediately see that, viewed as linear transformations from $\mathbb{R}^n$ to $\mathbb{R}^n$, both $A^+A$ and $A\,A^+$ are the identical transformation onto span$(A)$ and the null transformation on span$^\perp(A)$, i.e.,

(D.3) $$A^+A\,\boldsymbol{x} = A\,A^+\boldsymbol{x} = \begin{cases} \boldsymbol{x} & \text{if } \boldsymbol{x} \in \text{span}(A), \\ 0 & \text{if } \boldsymbol{x} \in \text{span}^\perp(A). \end{cases}$$

This property easily follows from the matrix identity

(D.4) $$A^+A = A\,A^+ = U_r\,U_r^\top.$$

We are now ready to prove the following lemma, which generalizes the valuable Lemma A.1 in [5] to positive *semi*definite matrices.

Lemma D.1. *Let $A$ be an arbitrary $n \times n$ positive semidefinite matrix, let $\boldsymbol{x}$ be an arbitrary vector in $\mathbb{R}^n$, and let $B = A - \boldsymbol{x}\,\boldsymbol{x}^\top$. Then*

$$\boldsymbol{x}\,A^+\,\boldsymbol{x} = \begin{cases} 1 & \text{if } \boldsymbol{x} \notin \operatorname{span}(B), \\ 1 - \frac{\det_{\neq 0}(B)}{\det_{\neq 0}(A)} < 1 & \text{if } \boldsymbol{x} \in \operatorname{span}(B), \end{cases} \tag{D.5}$$

*where* $\det_{\neq 0}(M)$ *denotes the product of the nonzero eigenvalues of matrix $M$. Note that* $\det_{\neq 0}(M) = \det(M)$ *when $M$ is nonsingular.*

*Proof.* If $\boldsymbol{x} = 0$, the lemma is trivially verified. Hence we continue by assuming $\boldsymbol{x} \neq 0$. We first prove that $\boldsymbol{x}^\top A^+ \boldsymbol{x} = 1$ if and only if $\boldsymbol{x} \notin \operatorname{span}(B)$. From Lemma A.3 in [16] it follows that $B\,A^+\boldsymbol{x} = 0$ when $\boldsymbol{x} \notin \operatorname{span}(B)$. Hence, using (D.3) we can write

$$0 = B\,A^+\boldsymbol{x} = (A - \boldsymbol{x}\boldsymbol{x}^\top)A^+\boldsymbol{x} = \boldsymbol{x} - \boldsymbol{x}\,\boldsymbol{x}^\top A^+\boldsymbol{x},$$

which implies $\boldsymbol{x}^\top A^+ \boldsymbol{x} = 1$. On the other hand, if $\boldsymbol{x} \in \operatorname{span}(B)$, we can always apply the Sherman–Morrison formula (3.2) and conclude that

$$\boldsymbol{x}^\top A^+ \boldsymbol{x} = \boldsymbol{x}^\top (B + \boldsymbol{x}\,\boldsymbol{x}^\top)^+ \boldsymbol{x} = \frac{\boldsymbol{x}^\top B^+ \boldsymbol{x}}{1 + \boldsymbol{x}^\top B^+ \boldsymbol{x}} < 1.$$

Let us now continue by assuming $\boldsymbol{x} \in \operatorname{span}(B)$. Let $A = U_r D_r U_r^\top$ be an SVD for $A$, in the sense of (D.1). Since $U_r\,U_r^\top \boldsymbol{x} = \boldsymbol{x}$ we can write

$$B = A - \boldsymbol{x}\boldsymbol{x}^\top = U_r M U_r^\top,$$

where $M$ is the $r \times r$ symmetric matrix $M = D_r - U_r^\top \boldsymbol{x}\boldsymbol{x}^\top U_r$. We now claim that $B$ and $M$ have the same nonzero eigenvalues, so that $\det_{\neq 0}(B) = \det_{\neq 0}(M)$. Let $\mu_1, \mu_2, \ldots, \mu_k$, $k \leq r$, be the nonzero eigenvalues of $M$ and let $\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_k$ be the corresponding orthonormal eigenvectors. It is then easy to verify that $\mu_1, \mu_2, \ldots, \mu_k$ are also eigenvalues of $B$ with corresponding orthonormal eigenvectors $U_r\boldsymbol{e}_1, U_r\boldsymbol{e}_2, \ldots, U_r\boldsymbol{e}_k$. Let $E_k$ be the orthonormal matrix whose columns are $\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_k$, let $M = E_k S_k E_k^\top$ be an SVD of $M$, and let $\boldsymbol{v} \in \operatorname{span}^\perp(U_r E_k)$. We have

$$B\boldsymbol{v} = U_r M U_r^\top \boldsymbol{v} = U_r E_k S_k E_k^\top U_r^\top \boldsymbol{v} = 0,$$

where the last equality follows from the orthogonality $\boldsymbol{v}^\top U_r E_k = 0$. Thus $\boldsymbol{v} \in \operatorname{null}(B)$, $\operatorname{rank}(B) = \operatorname{rank}(M)$, and the only nonzero eigenvalues of $B$ are $\mu_1, \mu_2, \ldots, \mu_k$.

Computing the nonzero eigenvalues of $M$ is actually fairly straightforward. We have

$$M = D_r - U_r^\top \boldsymbol{x}\boldsymbol{x}^\top U_r = D_r(I_r - D_r^{-1} U_r^\top \boldsymbol{x}\boldsymbol{x}^\top U_r).$$

Now, $\det_{\neq 0}(D_r) = \det(D_r) = \det_{\neq 0}(A)$, while it is easy to verify by direct inspection that the matrix $I_r - D_r^{-1} U_r^\top \boldsymbol{x}\boldsymbol{x}^\top U_r$ has eigenvalue 1 with multiplicity $r-1$ corresponding to $r-1$ eigenvectors forming an orthogonal basis for $\operatorname{span}^\perp(D_r^{-1} U_r^\top \boldsymbol{x})$, and eigenvalue $1 - \boldsymbol{x}^\top U_r D_r^{-1} U_r^\top \boldsymbol{x} = 1 - \boldsymbol{x}^\top A^+ \boldsymbol{x}$ corresponding to eigenvector $D_r^{-1} U_r^\top \boldsymbol{x}$. Since $\boldsymbol{x} \in \operatorname{span}(B)$ we already know that $1 - \boldsymbol{x}^\top A^+ \boldsymbol{x} > 0$. Therefore we have obtained

$$\det_{\neq 0}(B) = \det_{\neq 0}(M) = \det(D_r) \det_{\neq 0}(I_r - D_r^{-1} U_r^\top \boldsymbol{x}\boldsymbol{x}^\top U_r) = \det_{\neq 0}(A)(1 - \boldsymbol{x}^\top A^+ \boldsymbol{x}).$$

Rearranging gives the desired result. ∎

LEMMA D.2. *Let $A$ be an arbitrary $n \times n$ positive semidefinite matrix. Set $B = A - \boldsymbol{x}\boldsymbol{x}^\top$, where $\boldsymbol{x} \notin \operatorname{span}(B)$. Then for any $\boldsymbol{v}, \boldsymbol{w} \in \operatorname{span}(B)$ we have $\boldsymbol{v}^\top A^+ \boldsymbol{w} = \boldsymbol{v}^\top B^+ \boldsymbol{w}$.*

*Proof.* We have

$$\begin{aligned}
\boldsymbol{v}^\top A^+ \boldsymbol{w} &= \boldsymbol{v}^\top B^+ B A^+ \boldsymbol{w} \\
&\qquad \text{(by (D.3) and the fact that } \boldsymbol{v} \in \operatorname{span}(B)) \\
&= \boldsymbol{v}^\top B^+ (A - \boldsymbol{x}\boldsymbol{x}^\top) A^+ \boldsymbol{w} \\
&= \boldsymbol{v}^\top B^+ A A^+ \boldsymbol{w} - \boldsymbol{v}^\top B^+ \boldsymbol{x}\boldsymbol{x}^\top A^+ \boldsymbol{w} \\
&= \boldsymbol{v}^\top B^+ \boldsymbol{w} - \boldsymbol{v}^\top B^+ \boldsymbol{x}\boldsymbol{x}^\top A^+ \boldsymbol{w} \\

\end{aligned}$$

**Appendix E. Proof of Theorem 4.2.** The proof is again similar to the proof of Theorem 3.1.

Let $\mathcal{M} \subseteq \{1, 2, \dots\}$ be the set of trials where the algorithm in Figure 4.2 made a mistake, and let $A_k = X_k X_k^\top$, $k = 1, \dots, m = |\mathcal{M}|$. We investigate how the quadratic form $\boldsymbol{v}_k^\top A_k^+ \boldsymbol{v}_k$ changes over mistaken trials. Suppose the $k$th mistake occurred in trial $t = t_k$. Proceeding as in the proof of Theorem 3.1, one can show that

$$\boldsymbol{v}_k^\top A_k^+ \boldsymbol{v}_k \le \boldsymbol{v}_{k-1}^\top A_k^+ \boldsymbol{v}_{k-1} + \boldsymbol{x}_t^\top A_k^+ \boldsymbol{x}_t. \tag{E.1}$$

Now, as in the proof of Theorem 3.1, if $\boldsymbol{x}_t \in \operatorname{span}(A_k)$, we can apply the Sherman–Morrison formula (3.2) and obtain $\boldsymbol{v}_{k-1}^\top A_k^+ \boldsymbol{v}_{k-1} \le \boldsymbol{v}_{k-1}^\top A_{k-1}^+ \boldsymbol{v}_{k-1}$. On the other hand, in the case when $\boldsymbol{x}_t \notin \operatorname{span}(A_k)$ we can apply Lemma D.2 and conclude that $\boldsymbol{v}_{k-1}^\top A_k^+ \boldsymbol{v}_{k-1} = \boldsymbol{v}_{k-1}^\top A_{k-1}^+ \boldsymbol{v}_{k-1}$. Thus in both cases $\boldsymbol{v}_{k-1}^\top A_k^+ \boldsymbol{v}_{k-1} \le \boldsymbol{v}_{k-1}^\top A_{k-1}^+ \boldsymbol{v}_{k-1}$. Combining with (E.1) we obtain

$$\boldsymbol{v}_k^\top A_k^+ \boldsymbol{v}_k \le \boldsymbol{v}_{k-1}^\top A_{k-1}^+ \boldsymbol{v}_{k-1} + \boldsymbol{x}_t^\top A_k^+ \boldsymbol{x}_t,$$

holding for all $k = 1, \dots, m$. We now sum over $k = 1, \dots, m$ using $\boldsymbol{v}_0 = \boldsymbol{0}$. We get

$$\boldsymbol{v}_m^\top A_m^+ \boldsymbol{v}_m \le \sum_{k=1}^{m} \boldsymbol{x}_t^\top A_k^+ \boldsymbol{x}_t. \tag{E.2}$$

In order to upper bound the right-hand side of (E.2), we proceed as follows. We separate the mistaken trials $k$ such that $\boldsymbol{x}_t \in \operatorname{span}(A_{k-1})$ (i.e., the trials such that $\operatorname{rank}(A_k) = \operatorname{rank}(A_{k-1})$) from the mistaken trials $k$ such that $\boldsymbol{x}_t \notin \operatorname{span}(A_{k-1})$ (i.e., the trials such that $\operatorname{rank}(A_k) = \operatorname{rank}(A_{k-1}) + 1$). Then, in applying Lemma D.1, we count $1 - \frac{\det_{\neq 0}(A_{k-1})}{\det_{\neq 0}(A_k)}$ for the first kind of trials and 1 for the second kind. Finally, we upper bound taking the worst possible case of arranging the two kinds of trials within the sequence $\mathcal{M}$, taking into account that the number of trials of the second kind is equal to $r = \operatorname{rank}(A_m)$.

We assume the following general scenario:

$$\operatorname{rank}(A_k) = \begin{cases} 1, & k = 1, 2, \dots, 1 + i_1, \\ 2, & k = 2 + i_1, 3 + i_1, \dots, 2 + i_2, \\ 3, & k = 3 + i_2, 4 + i_2, \dots, 3 + i_3, \\ \vdots & \\ r, & k = r + i_{r-1}, r + i_{r-1} + 1, \dots, r + i_r, \end{cases}$$

where $0 \le i_1 \le i_2 \le \cdots \le i_r = m - r$. With this notation the right-hand side of (E.2) can be rewritten as follows (here and in what follows we assume $i_0 = 0$):

$$\begin{aligned}
\sum_{k=1}^{m} \boldsymbol{x}_t^\top A_k^+ \boldsymbol{x}_t &= \sum_{\ell=1}^{r} \left( \boldsymbol{x}_t^\top A_{\ell+i_{\ell-1}}^+ \boldsymbol{x}_t + \sum_{k=\ell+i_{\ell-1}+1}^{\ell+i_\ell} \boldsymbol{x}_t^\top A_k^+ \boldsymbol{x}_t \right) \\
&= \sum_{\ell=1}^{r} \left( 1 + \sum_{k=\ell+i_{\ell-1}+1}^{\ell+i_\ell} \left( 1 - \frac{\det_{\neq 0}(A_{k-1})}{\det_{\neq 0}(A_k)} \right) \right) \qquad \text{(using Lemma D.1)} \\
&= r + \sum_{\ell=1}^{r} \sum_{k=\ell+i_{\ell-1}+1}^{\ell+i_\ell} \left( 1 - \frac{\det_{\neq 0}(A_{k-1})}{\det_{\neq 0}(A_k)} \right) \\
&\le r + \sum_{\ell=1}^{r} \sum_{k=\ell+i_{\ell-1}+1}^{\ell+i_\ell} \ln \frac{\det_{\neq 0}(A_k)}{\det_{\neq 0}(A_{k-1})} \\
&= r + \sum_{\ell=1}^{r} \ln \frac{\det_{\neq 0}(A_{\ell+i_\ell})}{\det_{\neq 0}(A_{\ell+i_{\ell-1}})}. \qquad \text{(E.3)}
\end{aligned}$$

We now proceed by bounding from above the logarithmic terms in (E.3). By construction we have $\operatorname{rank}(A_{\ell+i_\ell}) = \operatorname{rank}(A_{\ell+i_{\ell-1}}) = \ell$, which is also equal to the number of nonzero eigenvalues of the two matrices. Let $\lambda_i$, $i = 1, \dots, \ell$, denote the positive eigenvalues of $A_{\ell+i_{\ell-1}}$. Since $A_{\ell+i_\ell} - A_{\ell+i_{\ell-1}}$ is positive semidefinite, the positive eigenvalues of $A_{\ell+i_\ell}$ can be expressed as $\lambda_i + \mu_i$, $i = 1, \dots, \ell$, for some nonnegative values $\mu_i$, such that $\sum_{i=1}^{\ell} \mu_i \le d_\ell R^2$, where $d_\ell = i_\ell - i_{\ell-1}$ is the number of rank-one matrices of the form $\boldsymbol{x}_t \boldsymbol{x}_t^\top$ which have been added to $A_{\ell+i_{\ell-1}}$ in order to obtain $A_{\ell+i_\ell}$. We have

$$\begin{aligned}
\ln \frac{\det_{\neq 0}(A_{\ell+i_\ell})}{\det_{\neq 0}(A_{\ell+i_{\ell-1}})} &= \ln \prod_{i=1}^{\ell} \frac{\lambda_i + \mu_i}{\lambda_i} \\
&\le \sum_{i=1}^{\ell} \ln \left( 1 + \frac{\mu_i}{\lambda^*} \right) \qquad (\text{recall that } \lambda^* \le \lambda_i,\ i = 1, \dots, \ell) \\
&\le \max_{\mu_1,\dots,\mu_\ell \,:\, \sum_{i=1}^{\ell} \mu_i \le R^2 d_\ell} \sum_{i=1}^{\ell} \ln \left( 1 + \frac{\mu_i}{\lambda^*} \right) \\
&= \ell \ln \left( 1 + \frac{R^2 d_\ell}{\lambda^* \ell} \right)
\end{aligned}$$

since the maximum is achieved when $\mu_i = R^2 d_\ell / \ell$, $i = 1, \dots, \ell$. Now, since $\sum_{\ell=1}^{r} d_\ell = m - r \le m$, we can plug back into (E.3) and maximize over $d_1, \dots, d_r$ such that $\sum_{\ell=1}^{r} d_\ell \le m$. We have

$$\begin{aligned}
\sum_{t \in \mathcal{M}} \boldsymbol{x}_t^\top A_k^+ \boldsymbol{x}_t &\le r + \sum_{\ell=1}^{r} \ell \ln \left( 1 + \frac{R^2 d_\ell}{\lambda^* \ell} \right) \\
&\le r + \max_{d_1,\dots,d_r \,:\, \sum_{\ell=1}^{r} d_\ell \le m} \sum_{\ell=1}^{r} \ell \ln \left( 1 + \frac{R^2 d_\ell}{\lambda^* \ell} \right)
\end{aligned}$$

$$= r + \frac{r(r+1)}{2} \ln\left(1 + \frac{2R^2}{\lambda^*}\frac{m}{r(r+1)}\right) \tag{E.4}$$

(since the maximum is achieved when $d_\ell = \frac{2\ell m}{r(r+1)}$, $\ell = 1, \ldots, r$),

which is the required upper bound on the right-hand side of (E.2).

When $\boldsymbol{u} \notin \mathrm{span}^\perp(A_m)$ we can bound $\sqrt{\boldsymbol{v}_m^\top A_m^+ \boldsymbol{v}_m}$ from below as in the proof of Theorem 3.1. This yields

$$\sqrt{\boldsymbol{v}_m^\top A_m^+ \boldsymbol{v}_m} \ge \frac{\gamma\, m - D_\gamma(\boldsymbol{u}; \mathcal{S})}{\sqrt{\boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}}}.$$

Plugging back into (E.2) and combining with (E.4) gives

$$\left(\frac{\gamma\, m - D_\gamma(\boldsymbol{u}; \mathcal{S})}{\sqrt{\boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u}}}\right)^2 \le r + \frac{r(r+1)}{2} \ln\left(1 + \frac{2R^2}{\lambda^*}\frac{m}{r(r+1)}\right).$$

Solving for $m$ occurring in the numerator of the left-hand side gives (4.4). On the other hand, when $\boldsymbol{u} \in \mathrm{span}^\perp(A_m)$ we have $\frac{D_\gamma(\boldsymbol{u};\mathcal{S})}{\gamma} = m$ and $\boldsymbol{u}^\top X_m\, X_m^\top \boldsymbol{u} = 0$, and thus (4.4) is vacuously verified as an equality.

# NONMIGRATORY ONLINE DEADLINE SCHEDULING ON MULTIPROCESSORS[*]

HO-LEUNG CHAN[†], TAK-WAH LAM[†], AND KAR-KEUNG TO[†]

**Abstract.** In this paper we consider multiprocessor scheduling with hard deadlines and investigate the cost of eliminating migration in the online setting. Let $I$ be any set of jobs that can be completed by some migratory offline schedule on $m$ processors. We show that $I$ can also be completed by a nonmigratory online schedule using $m$ speed-5.828 processors (i.e., processors 5.828 times faster). This result supplements the previous results that $I$ can also be completed by a nonmigratory offline schedule using $6m$ unit-speed processors [B. Kalyanasundaram and K. R. Pruhs, *J. Algorithms*, 38 (2001), pp. 2–24] or a migratory online schedule using $m$ speed-2 processors [C. A. Phillips et al., *Algorithmica*, 32 (2002), pp. 163–200]. Our result is based on a simple conservative scheduling algorithm called PARK, which commits a processor to a job only when the processor has zero commitment before its deadline. A careful analysis of PARK further shows that the processor speed can be reduced arbitrarily close to 1 by exploiting more processors (say, using $16m$ speed-1.8 processors). PARK also finds application in overloaded systems; it gives the first online nonmigratory algorithm that can exploit moderately faster processors to match the performance of any migratory offline algorithm.

## 1. Introduction.

In this paper we consider the online hard-deadline scheduling problem on multiprocessors; our focus is on eliminating migration among the processors. The hard-deadline scheduling problem is defined as follows: There are $m$ identical processors. Given a set of jobs, each characterized by its release time, deadline, and processing time (work), the objective is to schedule all the jobs on the processors so that each job can be completed by its deadline. Note that each job can be scheduled on at most one processor at any time. Preemption is allowed and a preempted job can resume later from the point of preemption. If migration is allowed, a job can resume on a different processor. From a practical point of view, nonmigratory schedules are preferable since migration may incur significant overhead. Yet allowing migration simplifies the design of scheduling algorithms.

Let $I$ be a set of jobs that can be completed by an offline schedule that allows migration. Kalyanasundaram and Pruhs [8] showed that migration is actually of limited power in offline scheduling; given a migratory offline schedule on $m$ processors, it is always possible to construct a nonmigratory offline schedule on $6m-5$ processors.[1] On the other hand, scheduling $I$ online (i.e., the information about a job is known only when it is released) is very difficult even if migration is allowed. In fact, $I$ does

[1]The construction runs in pseudopolynomial time but can be improved to run in polynomial time if the processor bound is raised from $6m-5$ to $12m-5$.

not admit any online schedule on $m$ processors if $m \geq 2$ [5].[2] Nevertheless, Phillips et al. showed that $I$ can be completed by a migratory online schedule on $m$ processors that are two times faster [13]. Migration seems to be a necessary tool in all online algorithms that are known to be able to complete $I$ on $m$ moderately faster processors (e.g., EDF (earliest deadline first), LLF (least laxity first), FR [13, 11]).

**Main result.** In this paper we devise a conservative online algorithm to show that $I$ can be completed by a nonmigratory online schedule on $m$ speed-5.828 processors. This result supplements the result of Kalyanasundaram and Pruhs [8], as it illustrates that allowing migration in the online setting also gives limited power. A careful analysis of the new algorithm further shows that the speed requirement of 5.828 can also be reduced arbitrarily close to 1 by exploiting more processors (say, using $16m$ speed-1.8 processors). More precisely, we show that for any $\epsilon > 0$, $I$ can be completed by a nonmigratory online schedule on $\lceil (1+\frac{1}{\epsilon})^2 \rceil\, m$ speed-$(1+\epsilon)^2$ processors.

**Laxity assumption.** It is widely believed that jobs with very tight deadlines or very small laxity (i.e., deadline minus release time minus work) make online scheduling difficult. Our nonmigratory online scheduling is no exception; in this paper we show that advance knowledge of the laxity of jobs in $I$ can reduce the speed or processor requirement for a nonmigratory online schedule. For example, if the work requested for every job in $I$ is at most one-eighth of its span (i.e., deadline minus release time), then we can have a nonmigratory online schedule for $I$ on $m$ speed-2.5 processors or on $4m$ unit-speed processors. Note that the latter result does not demand the presence of faster processors. In general, if the work-span ratio is at most $w$, then $I$ can be completed by a nonmigratory online schedule on $m$ speed-$(4w+2)$ processors or $\lceil 2/(1-4w) \rceil\, m$ unit-speed processors. (The latter result holds only for $w < 1/4$.)

**PARK.** The core of our results is a simple conservative online scheduling algorithm called PARK; it does not commit a processor to any job unless the processor has zero commitment before its deadline. This algorithm often lets a job wait for a while before admitting it to a processor. The conservative nature of PARK keeps any processor from being overcrowded and being tricked by the offline adversary. Like many other online algorithms, PARK is very simple but the analysis of its performance is relatively complicated. In this paper we present two different analyses of PARK showing different dimensions of its performance.

**Firm-deadline scheduling.** PARK also finds applications in scheduling overloaded systems, in which there may be too many jobs to be completed and the deadlines are firm (instead of hard) in the sense that failing to complete a job by its deadline causes only a loss in value due to that job and does not cause a system failure. Given a set $I$ of such jobs, the objective of a scheduler is to maximize the value obtained from completing the jobs. For any $c \geq 1$, an online algorithm is said to be $c$-competitive if, for any job sequence, it can obtain at least a fraction of $1/c$ of the total value obtained by any offline schedule on $m$ speed-1 processors. Consider the special case when the value of a job is proportional to its processing time. The work of Koren and Shasha [10] gave a nonmigratory online algorithm on $m$ speed-1 processors that is 3-competitive. Lam and To [12] showed that, if migration is allowed, it is possible to devise an online algorithm on $m$ speed-3 processors that is 1-competitive. Based on the latter result, we can actually extend PARK to give a nonmigratory online algorithm on $m$ speed-10 processors that is 1-competitive.

In the context of offline scheduling, the study of the power of migration is centered on the notion $\omega_m$, which is defined as the maximum over all input $I$, the ratio of the

[2]When $m = 1$, the earliest deadline first (EDF) strategy guarantees the completion of $I$ [4].

value attained by the optimal migratory offline schedule for $I$ to the value attained by the optimal nonmigratory offline schedule for $I$ [9, 8]. For jobs with arbitrary values, the best upper bound of $\omega_m$ is $(6m-5)/m$ [8]. This paper contributes to the knowledge of $\omega_m$ for the case when jobs are assumed to have a certain laxity. More precisely, our work implies that $\omega_m \le \min(6, \lceil \frac{2}{1-4w} \rceil)$ if the work-span ratio is at most $w < 1/4$.

**Organization of the paper.** Section 2 presents the new online algorithm PARK and discusses several interesting properties of PARK. Section 3 gives the first analysis of PARK, showing how to obtain a nonmigratory online schedule on $m$ speed-5.828 processors. As a byproduct, we show how to improve the resource bounds when all jobs are assumed to have a certain laxity. Section 4 gives a slightly more complicated analysis of PARK, showing that the speed requirement of 5.828 can be reduced arbitrarily close to 1 when extra processors are used. Section 5 presents a simple lower bound result which shows that a nonmigratory schedule is not feasible on $m$ speed-$s$ processors if $s < 2m/(m+1)$. Also, the extension of PARK to firm-deadline scheduling is discussed.

**Notation.** Throughout this paper, we denote the release time, work (processing) time, and deadline of a job $J$ as $r(J)$, $p(J)$, and $d(J)$, respectively. We also assume that jobs have distinct deadlines (ties are broken using the job IDs). The laxity and span of $J$ are defined as $d(J) - r(J) - p(J)$ and $d(J) - r(J)$, respectively. For any $s \ge 1$, a speed-$s$ processor refers to a processor that can process $s$ units of work in one unit of time.

EDF refers to the strategy of scheduling jobs with earliest deadlines. Note that when a new job $J$ is released, the current job $J'$ on a processor will be preempted if $J'$ has a deadline later than $J$'s as well as the deadlines of the current jobs on all other processors. When we say an algorithm completes a job sequence, we mean that the algorithm completes all jobs in the sequence within their respective deadlines.

## 2. The PARK algorithm.

In this section, we describe a nonmigratory online algorithm called PARK and discuss several interesting properties of PARK. We will show in the next section that for any sequence $I$ of jobs that can be completed by a migratory offline schedule on $m$ unit-speed processors, $I$ can also be completed by PARK on $m$ speed-5.828 processors.

PARK is a very conservative algorithm. Roughly speaking, whenever PARK admits a job $J$ to a processor, it ensures that the processor has no commitment to other admitted jobs before the deadline of $J$. This concept of zero commitment is made formal through the following notion of *due*.

DEFINITION 1. *Let $t$ be the current time. Consider any job $J$.*

- *Denote $x_t(J)$ and $p_t(J)$ as the amount of work done on $J$ up to time $t$ and the remaining work, respectively (note that $p_t(J) = p(J) - x_t(J)$).*
- *Define the* latest processing interval (LPI) *of $J$ as the interval $[d(J) - p_t(J), d(J)]$. If $d(J) - p_t(J) < t$, we say that $J$* expires.
- *For any $t' > t$, define $due_t(J, t')$ as the minimum amount of $J$'s remaining work that a speed-1 processor needs to do by time $t'$ in order to complete $J$ by its deadline. More formally, $due_t(J, t') = \max\{0, t' - (d(J) - p_t(J))\}$ if $t' \le d(J)$, and $p_t(J)$ otherwise.*

PARK is a nonmigratory algorithm using $pm$ speed-$s$ processors, where $p$ and $m$ are positive integers and $s \ge 1$ is any real number. It maintains a central pool to store jobs that have been released but not yet admitted to any processor. PARK is nonmigratory and each processor has its own queue of admitted jobs. Before describing the algorithm, we have one more definition.

Definition 2. *Let $t$ be the current time. Consider any processor $P_i$ used by PARK. For any $t' > t$, we define $due_t(P_i, t')$ as the sum of $due_t(J, t')$ over each job $J$ in the queue of $P_i$ at time $t$.*

In the rest of the paper, we say that at time $t$, (i) a job $J$ has $w$ units of work due at time $t' > t$ if $due_t(J, t') = w$; (ii) a processor $P_i$ has $w$ units of work due at $t'$ if $due_t(P_i, t') = w$; (iii) a processor $P_i$ is doing some work due at $t'$ if $P_i$ is processing a job $J$ with $due_t(J, t') > 0$.

Algorithm 1 (PARK).

```
Job release: A job upon release is put into the pool if it cannot be admitted
to one of the processors.
Job admission: At any time $t$, let $S$ be the set of jobs in the pool plus possibly
the job just released at $t$. If $S$ is nonempty, we attempt to admit such jobs as
follows: Let $J \in S$ be the job with the earliest deadline.
• If $J$ expires, discard $J$.
• Else if there exists a processor $P_i$ such that $due_t(P_i, d(J)) = 0$, admit $J$ into
the queue of $P_i$.
Individual processor scheduling: Each processor schedules the jobs in its
queue using EDF.
```

It is worth mentioning that though PARK is using speed-$s$ processors, the definitions of $due_t(P_i, t')$ as well as LPI are based on a unit-speed processor. To understand the admission policy of PARK, we need to focus on the LPIs of the jobs. In general, the LPIs of jobs may overlap with each other. For example, if two jobs have the same deadline, their LPIs always share a common ending time. Yet the way PARK admits jobs aims to guarantee that, at any time, all jobs admitted to the same processor have nonoverlapping LPIs. This can be observed as follows. When a job $J$ is admitted by a processor $P_i$ at time $t$, all the previously admitted jobs have zero work due at $d(J)$. It means that at time $t$, the LPI of any previously admitted job starts no earlier than $d(J)$ and cannot overlap the LPI of $J$. As time passes, the LPI of each individual job might shrink (if $P_i$ has worked on it) but cannot get bigger; thus, the nonoverlapping property remains. The following is a precise statement about the nonoverlapping property. Figure 1 shows the LPIs of the jobs at different times when PARK is given a sequence of five jobs.

Property 1 (nonoverlapping property). *Let $t$ be the current time. Consider any processor $P_i$. Let $J_u$ and $J_v$ be two jobs in the queue of $P_i$. The LPIs of $J_u$ and $J_v$ do not overlap.*

The nonoverlapping property allows us to bound the commitment of each processor easily.

Property 2 (bounded-commitment property). *Let $t$ be the current time. Consider any processor $P_i$.*

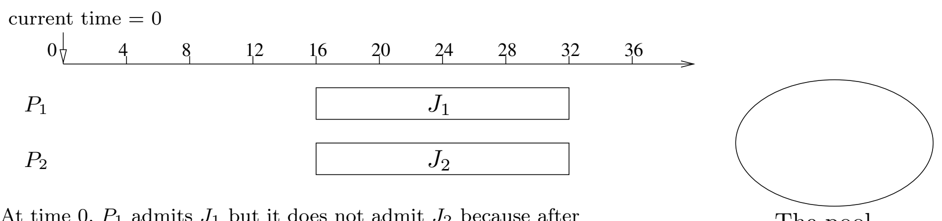
(a) *For every job in the queue of $P_i$, its LPI starts no earlier than $t$. That is, no job in the queue of $P_i$ expires.*

(b) *For any $t' > t$, $P_i$ has at most $(t' - t)$ units of work due at time $t'$.*

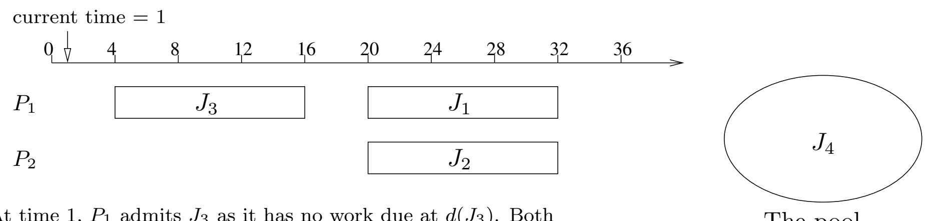
*Proof.* (a) For the sake of contradiction, assume that $J$ is the first job that expires in the queue of a processor $P_i$. When $J$ is admitted to $P_i$, $J$ has not yet expired. Let $t_0$ be the moment just before the first time $J$ is found to expire. That is, at $t_0$, the LPI of $J$ starts exactly at $t_0$; all other jobs in the queue of $P_i$ have not yet expired and their LPIs, due to the nonoverlapping property, must start after $J$'s LPI. In other

|  | Release time | Work | Deadline |
|---|---|---|---|
| $J_1$ | 0 | 16 | 32 |
| $J_2$ | 0 | 16 | 32 |
| $J_3$ | 1 | 12 | 16 |
| $J_4$ | 1 | 12 | 36 |
| $J_5$ | 2 | 12 | 28 |

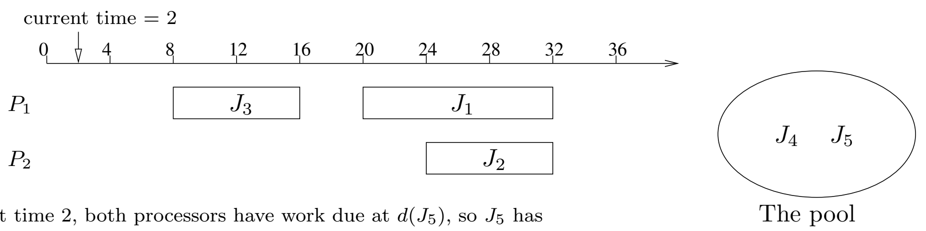
(a) Input job sequence



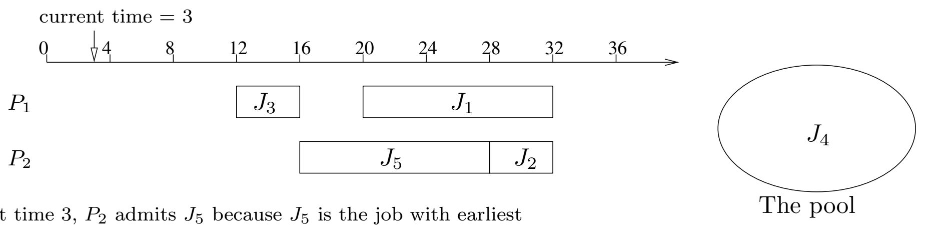
(b) At time 0, $P_1$ admits $J_1$ but it does not admit $J_2$ because after admitting $J_1$, $P_1$ has nonzero work due at $d(J_2)$. $P_2$ admits $J_2$.



(c) At time 1, $P_1$ admits $J_3$ as it has no work due at $d(J_3)$. Both processors have work due at $d(J_4)$, so $J_4$ has to wait in the pool.



(d) At time 2, both processors have work due at $d(J_5)$, so $J_5$ has to wait in the pool.



(e) At time 3, $P_2$ admits $J_5$ because $J_5$ is the job with earliest deadline in the pool, and $P_2$ has no work due at $d(J_5)$.

FIG. 1. *Figure* (a) *shows a sequence of five jobs to be scheduled by PARK on two speed-*4 *processors. Figures* (b)–(e) *show the LPIs (not the schedules) of the jobs in each processor at different times.*

words, all jobs except $J$ have deadlines later than $d(J)$. Recall that $P_i$ schedules jobs using EDF and its speed is $s \geq 1$. Thus, $J$ must be processed by $P_i$ at $t_0$ and cannot expire immediately after $t_0$. A contradiction occurs.

(b) At any time $t$, consider the LPIs of all the jobs in the queue of $P_i$. The LPIs are nonoverlapping and, by (a), the first LPI starts no earlier than $t$. For any $t' > t$, the amount of work due at $t'$ for $P_i$ is equal to the total length of each LPI (or its portion) that ends on or before $t'$. The latter is obviously upper bounded by $t' - t$. ∎

Since a job admitted by a processor $P_i$ never expires, it can be completed by $P_i$ by its deadline. In the next section, we will show that for a sequence of jobs that can be completed by some offline schedule, PARK will admit every job to a processor before they expire. PARK seems to be conservative in admitting jobs and often lets jobs wait in the pool. The next property shows that whenever a job is waiting, all processors are actually productive. In other words, such waiting is reasonable.

Property 3 (waiting property). *At any time $t$, if there is a job $J$ left in the pool, then*

- *all processors are busy, and*
- *all processors are doing some work due at $d(J)$.*

*Proof.* Suppose on the contrary that, at time $t$, there exists a processor $P_i$ that is idle. Then $P_i$ should admit $J$ or another job from the pool and become busy at $t$. A contradiction occurs. If $P_i$ at $t$ is working on a job $J_e$ that has no work due at $d(J)$, then the LPI of $J_e$ starts no earlier than $d(J)$. $P_i$ is using EDF and $J_e$ has the earliest deadline among all jobs in $P_i$. By the nonoverlapping property, at $t$, every job in $P_i$ has no work due at $d(J)$, and $P_i$ should admit $J$, or another job with a deadline earlier than $d(J)$, from the pool. This contradicts that at $t$, $P_i$ is working on $J_e$. ∎

## 3. Analysis of PARK.

In this section, we prove the main result that any job sequence that can be completed by some migratory offline schedule on $m$ speed-1 processors can also be completed by PARK on $m$ speed-$(3 + 2\sqrt{2})$ processors. Note that $3+2\sqrt{2} \approx 5.828$. We also show how to improve the resource bounds when jobs are assumed to have a certain laxity. For ease of discussion, this section will first present a lemma for the special case where every job has nonzero laxity, or equivalently, a work-span ratio strictly less than one. This is to illustrate the core idea of our analysis of PARK. Then we make use of a scaling technique to prove the general theorem, followed by two corollaries that capture the results stated earlier.

Lemma 3. *Let $I$ be any job sequence that can be completed by some migratory offline schedule on $m$ speed-1 processors. Let $0 < w < 1$. If all jobs in $I$ have a work-span ratio of at most $w$, then PARK can complete $I$ on $m$ speed-$(\frac{2}{1-w})$ processors.*

*Proof.* Note that the speed of the processors used by PARK is $\frac{2}{1-w} > 1$. As mentioned in the previous section, every job admitted by PARK to a processor can be completed by its deadline. To prove Lemma 3, it suffices to show that every job in $I$ is admitted rather than discarded in the admission step of PARK.

For the sake of contradiction, we assume that in the course of scheduling $I$ with PARK, some job expires in the pool and is discarded. Let $J$ be the first such job. Let $t_0 = d(J) - w(d(J) - r(J)) = r(J) + (1 - w)(d(J) - r(J))$. Since $J$ has a work-span ratio of at most $w$, $J$ cannot expire on or before $t_0$ and is in the pool during the time interval $[r(J), t_0]$.

Let $r(J) - l$ be the earliest time such that, at any time throughout the interval $[r(J) - l, t_0]$, there is at least one job in the pool with deadline on or before $d(J)$. Note that $l \geq 0$ is a real number. By the waiting property, during $[r(J) - l, t_0]$, all the $m$ processors of PARK are busy and the total work done by PARK is exactly

$$m \times \frac{2}{1-w} \times (t_0 - (r(J) - l)) = 2m(d(J) - r(J)) + \frac{2lm}{1-w}.$$

By the waiting property again, at any time in $[r(J) - l, t_0]$, PARK schedules all processors to do some work due at $d(J)$. Such work can be classified into two types:

1. Work owing to jobs that are admitted to processors before $r(J) - l$.
2. Work owing to jobs admitted during $[r(J) - l, t_0]$.

By the bounded-commitment property, at time $r(J) - l$, each processor has at most $d(J)-(r(J)-l)$ units of work due at $d(J)$, and hence the amount of type 1 work is at most $m \times (d(J) - (r(J) - l))$. Consider any job $J'$ admitted during $[r(J) - l, t_0]$. $J'$ has a deadline no later than $d(J)$ and, by definition of $l$, $J'$ must be released no earlier than $r(J) - l$. Note that the total work of jobs with release time at least $r(J)-l$ and deadline at most $d(J)$ cannot exceed $m(d(J)-(r(J)-l))$; otherwise such jobs cannot be completed by any offline schedule on $m$ unit-speed processors. On the other hand, $J$ is one of such jobs but is not admitted by PARK. The amount of type 2 work is at most $m \times (d(J) - (r(J) - l)) - p(J)$. In summary, the total amount of work done by PARK during $[r(J) - l, t_0]$ is at most

$$\begin{aligned}
&m(d(J) - (r(J) - l)) + m(d(J) - (r(J) - l)) - p(J) \\
&\quad < 2m(d(J) - r(J)) + 2lm \\
&\quad \leq 2m(d(J) - r(J)) + \frac{2lm}{1-w}.
\end{aligned}$$

This leads to a contradiction, and Lemma 3 follows. □

In the following, we present an extension to PARK so as to remove the assumption that the work-span ratio must be less than one. This extension also allows for a tradeoff between the processor speed and the number of processors used by PARK.

PARK($u$) is a scaled version of PARK characterized by a real number $u > 0$. Intuitively, PARK($u$) scales every job by a factor of $u$ and follows the schedules of PARK for the scaled jobs. When $u = 1$, PARK($u$) is identical to PARK. More specifically, to schedule a job sequence $I$ on $n$ speed-$s'$ processors, PARK($u$) simulates a copy of PARK that uses $n$ speed-$s$ processors, where $s = us'$. Whenever PARK($u$) receives a new job $J$, it releases a job $J'$ for PARK with $r(J') = r(J)$, $d(J') = d(J)$, and $p(J') = u \times p(J)$. Denote the processors used by PARK($u$) as $P_1, \ldots, P_n$ and those used by PARK as $P'_1, \ldots, P'_n$. At any time, PARK($u$) admits a job $J$ to a processor $P_i$ if PARK admits the corresponding job $J'$ to $P'_i$; PARK($u$) discards $J$ if PARK discards $J'$; and PARK($u$) runs a job $J$ on a processor $P_i$ if PARK runs $J'$ on $P'_i$.

We notice that PARK($u$) can always synchronize with the simulated copy of PARK because the amount of time for PARK($u$) to complete a job $J$ is exactly the same as that for PARK to complete the corresponding job $J'$. The following is the main theorem of this section.

THEOREM 4. *Let $I$ be any job sequence that can be completed by some migratory offline schedule on $m$ speed-1 processors. Let $0 < w \leq 1$. If all jobs in $I$ have a work-span ratio of at most $w$, then PARK($u$) can complete $I$ using $pm$ speed-$(\frac{p+u}{pu(1-wu)})$ processors, where $p$ is any positive integer and $u$ is any real number such that $0 < wu < 1$.*

Before proving Theorem 4, we illustrate how to choose the parameters in Theorem 4 so as to obtain the results claimed in the introduction. Consider the case where

$w = p = 1$. Choosing $u = \sqrt{2} - 1$ minimizes the speed requirement and gives the following corollary.

COROLLARY 5. *Let $I$ be any job sequence that can be completed by some migratory offline schedule on $m$ speed-1 processors. PARK$(u)$ with $u = \sqrt{2} - 1$ can complete $I$ using $m$ speed-$(3 + 2\sqrt{2})$ processors.*

Putting $u = 1/(2w)$ gives a more general corollary.

COROLLARY 6. *Let $I$ be any job sequence that can be completed by some migratory offline schedule on $m$ speed-1 processors. Let $0 < w \leq 1$. If all jobs in $I$ have a work-span ratio of at most $w$, then PARK$(u)$ with $u = 1/(2w)$ can complete $I$ using* (i) *$pm$ speed-$(4w + (2/p))$ processors for any positive integer $p$, or* (ii) *$\lceil 2/(s - 4w) \rceil m$ speed-$s$ processors for any $s > 4w$.*

*Proof of Theorem* 4. Recall that PARK$(u)$ uses $pm$ speed-$(\frac{p+u}{pu(1-wu)})$ processors. To schedule a job sequence $I$ as stated in the theorem, PARK$(u)$ simulates a copy of PARK that uses $pm$ speed-$(\frac{p+u}{p(1-wu)})$ processors. Let $I'$ be the sequence of the jobs created for PARK while PARK$(u)$ schedules $I$. As $I$ can be completed by some offline schedule on $m$ speed-1 processors, $I'$ can also be completed by some offline schedule on $m$ speed-$u$ processors. Each job in $I'$ has a work-span ratio of at most $wu$. To show that PARK$(u)$ can complete $I$, it suffices to show that PARK meets the deadlines of all jobs in $I'$. The proof is a straightforward generalization of Lemma 3.

First, note that $\frac{p+u}{p(1-wu)} > 1$, as both $u > 0$ and $1 > wu > 0$. Suppose, for the sake of contradiction, that PARK fails to complete a job in $I'$. This job must expire in the pool. Let $J$ be the first such job. Let $t_0 = r(J) + (1 - wu)(d(J) - r(J))$. As the work-span ratio of $J$ is at most $wu$, $J$ expires no earlier than $t_0$ and must have resided in the pool during the interval $[r(J), t_0]$. Again, let $l \geq 0$ be the largest number such that, at any time throughout the interval $[r(J) - l, t_0]$, there is at least one job in PARK's pool with deadline on or before $d(J)$. Note that $l \geq 0$. During $[r(J) - l, t_0]$, all $m$ processors are busy and the total work done by PARK is exactly

$$pm \times s \times (t_0 - (r(J) - l)) = (p + u)m(d(J) - r(J)) + \frac{(p + u)lm}{1 - wu}.$$

Furthermore, at any time in $[r(J) - l, t_0]$, every processor of PARK is always doing work due at $d(J)$ and such work belongs to either a job admitted before $r(J) - l$ or during $[r(J) - l, t_0]$. Thus, the total work done by PARK during $[r(J) - l, t_0]$ is at most

$$\begin{aligned} &pm(d(J) - (r(J) - l)) + mu(d(J) - (r(J) - l)) - p(J) \\ &\quad < (p + u)m(d(J) - r(J)) + l(p + u)m \\ &\quad \leq (p + u)m(d(J) - r(J)) + \frac{(p + u)lm}{1 - wu}. \end{aligned}$$

This leads to a contradiction, and PARK must be able to complete $I'$. Hence, the theorem follows. ☐

**4. Alternative analysis of PARK.** In this section, we show a more complicated analysis of PARK, resulting in the following theorem, which enables us to construct a nonmigratory online algorithm for hard-deadline scheduling that can exploit extra processors to reduce the speed requirement arbitrarily close to one (see Corollary 8).

THEOREM 7. *Let $0 < w < 1$ be a real number. Let $I$ be a job sequence that can be completed by some migratory offline schedule on $m$ speed-1 processors. If all jobs* *in $I$ have a work-span ratio of at most $w$, then $I$ can be completed by PARK using $pm$ speed-$s$ processors, where $p$ is any positive integer such that $p(1-w) > 1$ and $s = 1 + \frac{1}{p(1-w)-1}$.*

Using the scaling technique, we can remove the assumption of work-span ratios and extend Theorem 7 to any job sequence $I$. Recall that PARK($u$) scales every job of $I$ by a factor of $u$ and schedules the scaled jobs using PARK. Let $u = \frac{1}{1+\epsilon}$ for some $\epsilon > 0$, and denote the scaled version of $I$ as $I'$. Every job in $I'$ has a work-span ratio of at most $\frac{1}{1+\epsilon}$. By Theorem 7, $I'$ can be completed by PARK using $pm$ speed-$s$ processors where $s = 1 + \frac{1}{p(1-\frac{1}{1+\epsilon})-1}$. PARK($u$), using $pm$ speed-$s/u$ processors, can synchronize with PARK and complete $I$. In particular, choosing $p = \lceil (1+\frac{1}{\epsilon})^2 \rceil$, we have $s/u = (1 + \frac{1}{p(1-\frac{1}{1+\epsilon})-1})/u \le (1+\epsilon)^2$. This relationship is stated in the following corollary. Note that choosing a small $\epsilon$ means using more and slower processors.

COROLLARY 8. *Let $I$ be a job sequence that can be completed by some migratory offline schedule on $m$ speed-1 processors. Let $\epsilon > 0$ be any real number. PARK($u$) with $u = \frac{1}{1+\epsilon}$ can complete $I$ using $\lceil (1+\frac{1}{\epsilon})^2 \rceil \times m$ speed-$(1+\epsilon)^2$ processors.*

We are ready to prove Theorem 7. In the rest of this section, we assume that $I$ is a job sequence that can be completed by some migratory offline schedule OPT on $m$ speed-1 processors and all jobs in $I$ have a work-span ratio of at most $w < 1$. PARK is using $pm$ speed-$s$ processors, where $p$ is a positive integer such that $p(1-w) > 1$ and $s = 1 + \frac{1}{p(1-w)-1}$.

To prove Theorem 7, we need to compare the total amount of work due at any particular time in PARK and in OPT. At any time $t$, for any $t' > t$, we let $C(t, t')$ be the total amount of work due at $t'$ in PARK, and similarly $O(t, t')$ for OPT. Let $L(t, t') = C(t, t') - O(t, t')$. If $L(t, t') = \beta$, we say that at time $t$, PARK *lags behind* OPT by $\beta$ units of work due at $t'$. Furthermore, PARK is said to be *safe* at time $t$ if for any $t' > t$, $L(t, t')$ is proportional to the duration from $t$ to $t'$ (see the following definition).

DEFINITION 9. *In the course of scheduling $I$, at any time $t$, for any $t' > t$, PARK is $t'$*-safe *if $L(t, t') < \frac{m}{s-1}(t' - t)$. At any time $t$, PARK is* safe *if PARK is $t'$-safe for all $t' > t$.*

The most nontrivial observation in analyzing PARK is that at any time, PARK is safe (see Lemma 10). It is then relatively easy to see that, whenever a job $J$ is released to PARK, if PARK is safe at $r(J)$, then $J$ will be eventually admitted by PARK (see Lemma 11).

LEMMA 10. *In the course of scheduling $I$, at any time $t$, PARK is safe.*

LEMMA 11. *Let $J$ be any job in $I$. If PARK is safe at $r(J)$, then $J$ will be admitted by PARK on or before $t_0 = r(J) + (1-w)(d(J) - r(J))$.*

Lemmas 10 and 11 together guarantee that every job in $I$ must be admitted by PARK. As mentioned in section 2, PARK meets the deadlines of all admitted jobs. Thus, Theorem 7 follows. For ease of discussion, we will first present the proof for Lemma 11. We start with a more technical lemma, which will also be used in the proof of Lemma 10.

PROPOSITION 12. *Consider any time interval $[a, b]$ and any time $d > b$. Assume that PARK is $d$-safe at time $a$ and, at any time in $[a, b]$, there exists a job in PARK's pool with deadline no later than $d$. Then $b - a < \frac{1}{p(s-1)}(d - a)$. (Recall that $s$ is chosen as $1 + \frac{1}{p(1-w)-1}$; thus, $\frac{1}{p(s-1)} = 1 - w - \frac{1}{p}$.)*

*Proof.* Due to the waiting property, at any time in the interval $[a, b]$, all the $pm$ processors of PARK are busy and doing work due at $d$. The total work done by

PARK during $[a, b]$ is exactly

$$pm \times s \times (b - a). \tag{1}$$

PARK is $d$-safe at $a$ and $L(a, d) < \frac{m}{s-1}(d-a)$. At $a$, PARK and OPT have $C(a, d)$ and $O(a, d)$ units of work due at $d$, respectively. Consider all the jobs that are released from $a$ to $b$; the sum of their work due at $d$ is at most $m(d - a) - O(a, d)$ (otherwise, even OPT cannot complete these works by $d$). During the interval $[a, b]$, the total amount of work due at $d$ that PARK can possibly work on is at most

$$\begin{align} C(a, d) + m(d - a) - O(a, d) &= L(a, d) + m(d - a) \tag{2}\\ &< \frac{m}{s-1}(d - a) + m(d - a) \tag{3}\\ &= \frac{ms}{s-1}(d - a). \tag{4}\end{align}$$

Combining (1)–(4), we have $pms(b - a) < \frac{ms}{s-1}(d - a)$, or equivalently, $(b - a) < \frac{1}{p(s-1)}(d - a)$. ∎

Lemma 11 is in fact a corollary of Proposition 12. Details are as follows.

*Proof of Lemma* 11. Suppose on the contrary that at time $t_0 = r(J) + (1 - w)(d(J) - r(J))$, $J$ has not been admitted. As $J$ is assumed to have a work-span ratio of at most $w$, $J$ has not yet expired at $t_0$ and is in the pool during the interval $[r(J), t_0]$. Note that $t_0 - r(J) = (1 - w)(d(J) - r(J))$ and, by Proposition 12 (with $a = r(J)$, $b = t_0$, and $d = d(J)$), we have $(t_0 - r(J)) < (1 - w - \frac{1}{p})(d(J) - r(J))$. This implies that $\frac{1}{p} < 0$, contradicting that $p \geq 1$. ∎

The rest of this section is devoted to the proof of Lemma 10, which is further broken into two lemmas. We first state a simple fact about how the value of $L(t, t')$ changes over time.

FACT 1. *Let $[t_1, t_2]$ be a time interval before a certain time $t'$. Assume that during the interval $[t_1, t_2]$, PARK has done at least $x$ units of work due at $t'$ and OPT has done at most $y$ units of work due at $t'$. Then, $L(t_2, t') \leq L(t_1, t') - x + y$.*

Intuitively, we prove Lemma 10 inductively over time. Assume that PARK is safe at time $a$. We first consider two basic types of time intervals $[a, b]$ and show that, in either case, PARK is safe at time $b$. Precisely, for any $t' > b$, we call $[a, b]$

- a $t'$-quiet period if at any time in $[a, b]$ there is no job in PARK's pool with work due at $t'$, and
- a $t'$-hectic period if at any time in $[a, b]$ there is at least one job in PARK's pool with work due at $t'$.

During a $t'$-quiet period, any job with work due at $t'$ in PARK is admitted to some processor. Since PARK is using speed-$s$ processors, we can argue that PARK will not lag behind OPT too much on work due at $t'$ during a $t'$-quiet period (see Lemma 13). A hectic period is more complicated. In Lemma 14 we first show that with the extra speed and number of processors given to PARK, a $t'$-hectic period cannot last for too long. Then we notice that within such a short period, the amount of PARK's work due at $t'$ that lags behind OPT's cannot change too drastically and PARK is still $t'$-safe at $b$. Below we prove the above observations regarding quiet and hectic periods (see Lemmas 13 and 14). Then it is easy to show that PARK is safe at any time (i.e., Lemma 10).

LEMMA 13. *Consider a time interval $[a, b]$ and a certain time $t' > b$. Assume that at any time in the interval $[a, b]$ there is no job in PARK's pool with work due at $t'$. If PARK is safe at $a$, then PARK is $t'$-safe at $b$.*

*Proof.* We prove inductively that, at any time in $[a, b]$, PARK is $t'$-safe. Let $r > a$ be the first time a job is released; if no jobs are released on or before $b$, let $r = b$. Below we first show that PARK is $t'$-safe at time $r$, i.e., $L(r, t') \leq \frac{m}{s-1}(t' - r)$. Note that, at time $r$, if a job $J$ is released, it contributes exactly $p(J)$ to both $C(r, t')$ and $O(r, t')$ and does not affect the value of $L(r, t')$. To derive an upper bound of $L(r, t')$, it suffices to consider the amount of work released before $r$. In particular, we can tighten the trivial upper bound of $L(r, t')$ from $C(r, t')$ to $\hat{C}(r, t')$, where $\hat{C}(r, t')$ denotes, at time $r$, the amount of work in PARK that has been released before $r$ and due at $t'$.

Denote by $\Phi_r$ the set of PARK's processors which, at $r$, have work released before $r$ and due at $t'$. Then $\hat{C}(r, t') \leq |\Phi_r|(t' - r)$. If $|\Phi_r| < \frac{m}{s-1}$, then $L(r, t') \leq \hat{C}(r, t') < \frac{m}{s-1}(t' - r)$. Bound $L(r, t')$ for the case when $|\Phi_r| \geq \frac{m}{s-1}$ is more complicated. During $[a, r]$, the pool contains no job due at $t'$ and no job is released until $r$. Thus, at any time $t$ where $a \leq t < r$, if a processor of PARK does not have any work due at $t'$, this processor cannot be in $\Phi_r$. In other words, throughout the interval $[a, r]$, every processor in $\Phi_r$ has work due at $t'$ and PARK has done at least $|\Phi_r|s(r - a)$ units of work due at $t'$. Note that OPT achieves at most $m(r - a)$. Thus,

$$\begin{aligned} L(r, t') &\leq L(a, t') - |\Phi_r|s(r - a) + m(r - a) \\ &< \frac{m}{s-1}(t' - a) - \frac{m}{s-1}s(r - a) + m(r - a) \quad \text{(at time } a\text{, PARK is } t'\text{-safe)} \\ &= \frac{m}{s-1}(t' - r). \end{aligned}$$

In summary, we have proven that, at time $r$, PARK is $t'$-safe. If $r < b$, we can repeat the above argument to prove that PARK is $t'$-safe at each subsequent release time and eventually at time $b$. □

Next, we consider the case of hectic periods.

LEMMA 14. *Consider a time interval $[a, b]$ and a certain time $t' > b$. Assume that, just before $a$, there is no job in PARK's pool with work due at $t'$ and that, at any time in $[a, b]$, there is at least one job in PARK's pool with work due at $t'$. If PARK is safe at $a$, then*

(i) *$(b - a) < \frac{1}{s}(t' - a)$, and*

(ii) *PARK is $t'$-safe at $b$.*

*Proof.* (i) Due to the condition of Lemma 14, we know that, at any time in $[a, b]$, there is a job $J$ in the pool with work due at $t'$ and $J$ must be released on or after $a$. Due to the work-span ratio assumption, any job released after $a$ and with work due at $t'$ must have a deadline on or before $a + \frac{1}{1-w}(t' - a) \geq t'$. Let $d = a + \frac{1}{1-w}(t' - a)$. At time $a$, PARK is safe and, in particular, $d$-safe. By Proposition 12, $(b - a) < (1 - w - \frac{1}{p})(d - a) = (1 - w - \frac{1}{p})(t' - a)/(1 - w)$. Note that $s = 1 + \frac{1}{p(1-w)-1}$ and $\frac{1}{s} = \frac{p(1-w)-1}{p(1-w)} = (1 - w - \frac{1}{p})/(1 - w)$. Thus, $(b - a) < \frac{1}{s}(t' - a)$, and (i) follows.

(ii) Consider the $pm$ processors used by PARK. Let $\Psi$ be the set of PARK's processors which, at any time in the interval $[a, b]$, are doing work due at $t'$. Let $|\Psi| = \psi$. If $\psi \geq \frac{m}{s-1}$, then,

$$\begin{aligned} L(b, t') &\leq L(a, t') - \psi s(b - a) + m(b - a) \\ &< \frac{m}{s-1}(t' - a) - \frac{m}{s-1}s(b - a) + m(b - a) \\ &= \frac{m}{s-1}(t' - b). \end{aligned}$$

Next, we consider $\psi < \frac{m}{s-1}$. Label the processors in $\Psi$ as $P_1, P_2, \ldots, P_\psi$. At $a$, each of these processors has at most $t'-a$ units of work due at $t'$. Label the processors not in $\Psi$ as $P_{\psi+1}, \ldots, P_{pm}$. At $a$, for each processor $P_i$ not in $\Psi$, let $w_i$ be the amount of work due at $t'$. Let $W = \sum_{i=\psi+1}^{pm} w_i$. Then $L(a,t') \le C(a,t') \le \psi(t'-a) + W$.

From $a$ to $b$, each of $P_1, P_2, \ldots, P_\psi$, has done exactly $s(b-a)$ units of work due at $t'$. For each $P_i$, where $i = \psi+1, \ldots, pm$, $P_i$ at some point in $[a,b]$ is doing some work due at a time later than $t'$; thus $P_i$ has done at least $w_i$ units of work due at $t'$. In summary, during $[a,b]$, PARK, by time $b$, must have done at least $\psi \times s(b-a) + W$ units of work due at $t'$; note that OPT has done at most $m(b-a)$ units of work due at $t'$. Hence, we have the following conclusion:

$$\begin{aligned}
L(b,t') &\le L(a,t') - \Big(\psi s(b-a) + W\Big) + m(b-a) \\
&\le \psi(t'-a) + W - \Big(\psi s(b-a) + W\Big) + m(b-a) \\
&= \psi\Big(t' - a - s(b-a)\Big) + m(b-a) \\
&< \frac{m}{s-1}\Big(t' - a - s(b-a)\Big) + m(b-a) \\
&\qquad\qquad\qquad \text{(by Lemma 14(i), } (t'-a-s(b-a)) > 0) \\
&= \frac{m}{s-1}(t'-b).
\end{aligned}$$

In summary, no matter what the value of $\psi$ is, $L(b,t') < \frac{m}{s-1}(t'-b)$. Thus, PARK is $t'$-safe at time $b$. ◻

With the observations on the quiet and hectic periods, proving that PARK is safe at any time (i.e., Lemma 10) is straightforward.

*Proof of Lemma* 10. We first notice that, at time 0, $L(0,t')$ is equal to 0 for any $t' > 0$. Thus, PARK is safe at time 0. Let $\gamma_0 = 0$ and let $\gamma_1 = \min\{\gamma > \gamma_0 \mid$ at time $\gamma$, PARK switches from a $t'$-quiet period to a $t'$-hectic period for some $t' > \gamma\}$. Consider any time $t \le \gamma_1$. For any $t' > t$, $[\gamma_0, t]$ is a $t'$-quiet period and, by Lemma 13, PARK is $t'$-safe. Thus, PARK is safe at any time $t \le \gamma_1$. We can repeat the above argument to show inductively that PARK is safe at any time. In general, let $\gamma_{i+1} = \min\{\gamma > \gamma_i \mid$ at time $\gamma$, PARK switches from a $t'$-quiet period to a $t'$-hectic period for some $t' > \gamma$, or vice versa$\}$. Consider any time $t \le \gamma_{i+1}$. For any $t' > t$, let $j \le i$ be the smallest integer such that $[\gamma_j, t]$ is entirely a $t'$-quiet period or a $t'$-hectic period. By Lemma 13 and 14, PARK is $t'$-safe.

It is worth mentioning that, at any $\gamma_i$, a job is either released or admitted by PARK. Thus, in the course of scheduling $I$, there are only a finite number of $\gamma_i$'s. The above argument will complete eventually to show that PARK is safe at any time. ◻

## 5. Remarks.

**Lower bound.** Consider the following job sequence: $m+1$ identical jobs are released at time 0, each with $m$ units of work and deadline $m+1$. The set of jobs can be completed by a migratory schedule on $m$ speed-1 processors. For a nonmigratory (online or offline) schedule to complete the jobs on $m$ processors, some processor must admit at least two jobs, and thus the speed requirement is at least $\frac{2m}{m+1} = 2 - \frac{2}{m+1}$.

**Firm-deadline schedule.** Recall that in the firm-deadline scheduling problem, there may be too many jobs to be completed, and failing to complete a job causes only a loss in value due to that job and does not cause a system failure. Given a set $I$ of such jobs, the objective of a scheduler is to maximize the value obtained from completing the jobs. An online algorithm is said to be $c$-competitive for some $c \geq 1$ if, for any job sequence $I$, the algorithm can obtain at least a fraction of $1/c$ of the value obtained by the optimal offline schedule on $m$ speed-1 processors.

Consider the special case when the value of a job is proportional to its processing time. If migration is allowed, EDF-AC (EDF with admission control) using $m$ speed-3 processors is 1-competitive [12]. Since EDF-AC decides whether to complete or discard a job once the job is released, we can use it to select jobs for scheduling in PARK without migration. The actual operation is as follows. Whenever EDF-AC decides to complete a job $J$, we release $J$ to PARK with $p(J)$ scaled down to $p(J)/3$. The job sequence selected by EDF-AC can be completed by $m$ speed-3 processors, so the scaled job sequence can be completed by $m$ speed-1 processors and all jobs in the scaled sequence have work-span ratio of at most 1/3. By Corollary 6 with $p = 1$ and $w = 1/3$, the scaled job sequence can be completed by PARK using $m$ speed-$(\frac{10}{3})$ processors. As any job in the scaled sequence has only one-third of the original work, to complete the job actually selected by EDF-AC, we further increase the speed of the processors by a factor of 3. In summary, EDF-AC plus PARK gives a new algorithm which, using $m$ speed-10 processors, is 1-competitive nonmigratory for the firm-deadline scheduling problem.

**Effect of laxity on $\boldsymbol{\omega_m}$.** Consider the offline scheduling problem. Recall that $\omega_m$ is the maximum ratio, over all possible inputs, between the value attained by the optimal migratory schedule and that attained by the optimal nonmigratory schedule. The analysis of PARK reveals some information about the value of $\omega_m$ when all jobs are assumed to have a certain amount of laxity. More precisely, if all jobs have a work-span ratio no greater than $w$, where $w < \frac{1}{4}$, Corollary 6 shows that, for any job sequence, the subset of jobs that can be completed by the optimal offline migratory schedule on $m$ processors can also be completed by $\lceil 2/(1-4w) \rceil m$ (unit-speed) processors. By selecting the $m$ processors that achieve the highest values, we obtain a nonmigratory offline schedule attaining a value of at least $\frac{1}{\lceil 2/(1-4w) \rceil}$ of the value of the optimal migratory schedule. Hence, $\omega_m \leq \lceil 2/(1-4w) \rceil$.

**Implementation of PARK.** We notice that PARK admits a simple distributed implementation which does not require a centralized scheduler. Instead, each processor can monitor the pool and admit a job according to its own status, i.e., each processor does not need to inquire about the status of other processors. This is different from many other scheduling algorithms (e.g., EDF, LLF) in which the status of all processors is needed in order to make a scheduling decision. Thus, PARK is particularly useful when it is difficult to obtain complete information about all processors.

**Open problems.** Let $I$ be a job sequence that can be completed by some migratory offline schedule on $m$ speed-1 processors. Consider the processor speed required to obtain a nonmigratory online schedule for $I$. There is a gap between the upper bound of 5.828 and the lower bound of $2 - \frac{2}{m+1}$. The current analysis of PARK seems to be quite loose and we believe that a better analysis could possibly reduce the speed requirement to 4. We have shown that when extra processors are given, the speed requirement of PARK can be reduced arbitrarily close to 1. However, we do not know of any (migratory or nonmigratory) online algorithm that can guarantee the completion of $I$ using only $f(m)$ speed-1 processors, where $f(m)$ is a function of $m$. For the problem of firm-deadline scheduling, the current analysis depends on EDF-AC as the job selection module. In fact, we conjecture that PARK alone (say, with $m$ speed-9 processors) is sufficient to match the performance of any offline schedule.

# ON EVEN TRIANGULATIONS OF 2-CONNECTED EMBEDDED GRAPHS*

HUAMING ZHANG† AND XIN HE†

**Abstract.** Recently, Hoffmann and Kriegel proved an important combinatorial theorem [*SIAM J. Discrete Math.*, 9 (1996), pp. 210–224]: Every 2-connected bipartite plane multigraph $G$ without 2-cycle faces has a triangulation in which all vertices have even degree (this is called an *even triangulation*). Combined with the classical Whitney's theorem, this result implies that every such graph has a 3-colorable plane triangulation. Using this theorem, Hoffmann and Kriegel significantly improved the upper bounds of several art gallery and prison guard problems. A complicated $O(n^2)$ time algorithm was obtained in [*SIAM J. Discrete Math.*, 9 (1996), pp. 210–224] for constructing an even triangulation of $G$. Hoffmann and Kriegel conjectured that there is an $O(n^{3/2})$ time algorithm for solving this problem.

In this paper, we develop a simple proof of the above theorem. Our proof reveals and relies on a natural correspondence between even triangulations of $G$ and certain orientations of $G$. Based on this new proof, we obtain a very simple $O(n)$ time algorithm for finding an even triangulation of $G$. We also extend our proof to show the existence of even triangulations for similar graphs on high genus surface.

## 1. Introduction.

Let $G = (V, E)$ be a 2-connected bipartite plane multigraph without 2-cycle faces. A *triangulation* of $G$ is a plane graph obtained from $G$ by adding new edges into the faces of $G$ so that all of its faces are triangles. A triangulation $G'$ of $G$ is called *even* if all vertices of $G'$ have even degree. Recently, Hoffmann and Kriegel proved an important combinatorial theorem [3, 4].

THEOREM 1. *Every 2-connected bipartite plane multigraph without 2-cycle faces has an even triangulation.*

Combined with the following classical Whitney's theorem, Theorem 1 implies that every 2-connected bipartite plane multigraph has a 3-colorable plane triangulation.

THEOREM 2. *A plane triangulation is 3-colorable iff all of its vertices have even degree.*

An elegant proof of Theorem 2 can be found in [10].

Note: In the statement of Theorem 1 in [3, 4], the phrase "without 2-cycle faces" was not explicitly mentioned. It is implicitly used in their paper. However, without this condition, Theorem 1 is not true. To be precise, we explicitly mention this condition in Theorem 1.

In addition to its importance in graph theory, Hoffmann and Kriegel showed that, based on Theorem 1, the upper bounds of several *art gallery* and *prison guard* problems (a group of problems extensively studied in computational geometry; see [11, 12]) can be significantly improved [4]. Theorem 1 was proved in [4] by showing that a linear equation system derived from the input graph $G$ has a solution. An

†Department of Computer Science and Engineering, State University of New York at Buffalo, Buffalo, NY 14260 (huazhang@cse.buffalo.edu, xinhe@cse.buffalo.edu).

even triangulation of $G$ is found by solving this linear equation system. By using the *generalized nested dissection technique* of Lipton, Rose, and Tarjan [9], Hoffmann and Kriegel obtained a complicated algorithm with $O(n^2)$ runtime. This algorithm is the bottleneck of the algorithms for solving the art gallery and prison guard application problems discussed in [4]. By showing that another linear equation system derived from $G$ has a solution, Hoffmann and Kriegel discovered a relationship between all even triangulations of $G$ and certain closed walks in the dual graph of $G$.

It was conjectured in [4] that an even triangulation of $G$ can be found in $O(n^{1.5})$ time. In this paper, we give a very different proof of Theorem 1 without relying on the linear equation system derived in [4]. Our new proof is based on the discovery of a natural one-to-one correspondence between the set of all even triangulations of $G$ and the set of certain orientations of $G$ and its dual graph $G^*$. This new proof leads to a *very simple* $O(n)$ time algorithm for constructing an even triangulation of $G$. Thus, all algorithms for solving the art gallery and prison guard problems discussed in [4] can be uniformly improved to linear time. As a by-product, we also obtain a simple formula for calculating the number of distinct even triangulations of $G$.

A natural question is whether these theorems hold true for similar graphs on high genus surfaces. We show that our new proof of Theorem 1 and the algorithm for constructing even triangulations of 2-connected bipartite plane multigraphs without 2-cycle faces also apply to similar graphs on high genus surfaces. However, because a crucial property that is true for plane graphs does not hold for graphs on high genus surfaces, we can only prove a lower bound on the number of distinct even triangulations of such graphs. The problem of determining the exact value of this number remains an open problem.

The rest of the paper is organized as follows. In section 2, we introduce the definitions and preliminary results in [3, 4]. In section 3, we provide new proofs of Theorem 1 and another key theorem in [3, 4]. In section 4, we present our algorithm for finding even triangulations of plane graphs. In section 5, we investigate the problem for graphs on high genus surfaces.

**2. Preliminaries.** In this section, we give definitions and preliminary results. All definitions are standard and can be found in [1]. Let $G = (V, E)$ be a graph with $n = |V|$ vertices and $m = |E|$ edges. A *multigraph* is a graph where two edges can share the same pair of end vertices. We will restrict ourselves to multigraph without self loops in this paper, which will be simply called graph from now on, unless otherwise specified. The *degree* of a vertex $v \in V$, denoted by $deg_G(v)$, is the number of edges incident to $v$. If $G$ is clearly understood, we simply write $deg(v)$ for $deg_G(v)$. For a subset $V_1 \subseteq V$, $G - V_1$ denotes the graph obtained from $G$ by deleting the vertices in $V_1$ and their incident edges. A vertex $v$ of a connected graph $G$ is called a *cut vertex* if $G - \{v\}$ is disconnected. $G$ is 2-*connected* if it has no cut vertices. $G = (V, E)$ is *bipartite* if its vertex set $V$ can be partitioned into two subsets $V_1$ and $V_2$ such that no two vertices in $V_1$ are adjacent and no two vertices in $V_2$ are adjacent. A $k$-*coloring* of $G$ is a coloring of $V$ by $k$ colors so that no two vertices with the same color are adjacent to each other. Note that $G$ is bipartite iff it's 2-colorable.

A *cycle* $C$ of $G$ is a sequence of distinct vertices $u_1, u_2, \ldots, u_k$ such that $(u_i, u_{i+1}) \in E$ for $1 \leq i < k$ and $(u_k, u_1) \in E$. We also use $C$ to denote the set of the edges in it. If $C$ contains $k$ edges, it is called a $k$-cycle. A 3-cycle is also called a *triangle*. A *closed walk* is similarly defined except that it allows repeated vertices (but not repeated edges).

A *plane* graph $G$ is a graph embedded in the plane without edge crossings (i.e., an embedded planar graph). The embedding of a plane graph $G$ divides the plane into a number of regions. All regions are called *faces*. The unbounded region is called the *exterior face*. Other regions are called *interior faces*. The *degree* of a face is the number of edges on its boundary.

The dual graph $G^* = (V^*, E^*)$ of a plane graph $G$ is defined as follows: For each face $f$ of $G$, $V^*$ contains a vertex $v_f$. For each edge $e$ in $G$, $G^*$ has an edge $e^* = (v_{f_1}, v_{f_2})$, where $f_1$ and $f_2$ are the two faces of $G$ with $e$ on their common boundary. $e^*$ is called the *dual edge* of $e$. The mapping $e \Leftrightarrow e^*$ is a one-to-one correspondence between $E$ and $E^*$.

A *diagonal* of a plane graph $G$ is an edge which does not belong to $E$ and connects two vertices of a facial cycle. $G$ is *triangulated* if it has no diagonals. (Namely, all of its facial cycles, including the exterior face, are triangles.) A *triangulation* of $G$ is obtained from $G$ by adding a set of diagonals such that the resulting graph is plane and triangulated. An *even triangulation* is a triangulation in which all vertices have even degree. In this case, we also call the set of diagonals added into $G$ an even triangulation of $G$. The overloading of the term "even triangulation" makes our discussion easier. The meaning of "even triangulation" is always clear from context. Obviously, in order to triangulate a plane graph $G$, we cannot allow 2-cycle faces in $G$. Therefore, we will exclude the existence of 2-cycle faces in $G$ in this paper from now on. Thus, a plane graph really means a plane multigraph without 2-cycle faces.

For a 2-connected bipartite plane graph $G$, all of its facial cycles have even length. In order to triangulate $G$, we first add diagonals into the faces of $G$ so that all facial cycles of the resulting graph are 4-cycles. This can be easily done in linear time. Thus, without loss of generality, $G$ always denotes a 2-connected bipartite plane graph all of whose facial cycles have length 4. Such a graph will be called a 2-connected maximal bipartite plane graph (2MBP graph, for short). By Euler's formula, a 2MBP graph with $n$ vertices always has $n-2$ faces and $m = 2n-4$ edges. We denote the faces of $G$ by $Q(G) = \{q_1, q_2, \dots, q_{n-2}\}$. When $G$ is clearly understood, we simply use $Q$ to denote $Q(G)$.

Since $G$ is bipartite, we can fix a 2-coloring of $G$ with colors 0 and 1. For any face $q_i \in Q$, the set of the four vertices on the boundary of $q_i$ is denoted by $V_{q_i}$ and we set $Q_v = \{q_i \in Q | v \in V_{q_i}\}$. Since every facial cycle of $G$ is a 4-cycle, every face $q_i \in Q$ has two diagonals: the diagonal joining the two 0-colored (1-colored, respectively) vertices in $V_{q_i}$ is called the 0-diagonal (1-diagonal, respectively). Thus a triangulation of $G$ is nothing but choosing for each face $q_i$ either the 0-diagonal or the 1-diagonal and adding it into $q_i$. We associate each face $q_i \in Q$ with a $\{0,1\}$-valued variable $x_i$, and each triangulation $T$ of $G$ with a vector $\vec{x} = (x_1, x_2, \dots, x_{n-2}) \in GF(2)^{n-2}$, where

$$T \text{ contains the 0-diagonal of the face } q_i \Longleftrightarrow x_i = 1.$$

This mapping defines a one-to-one correspondence between the set of triangulations of $G$ and $GF(2)^{n-2}$. We choose $GF(2)$ because most calculations in this section are interpreted in $GF(2)$.

*Observation.* If $c(v)$ is the color of a vertex $v \in V_{q_i}$, then the term $x_i + c(v) \pmod 2$ describes the increase of the degree of $v$ after adding the diagonal of $q_i$ which corresponds to the value $x_i$ into the face $q_i$. Based on this observation, Hoffmann and Kriegel [3, 4] proved that a vector $\vec{x} = (x_i)_{1 \le i \le n-2} \in GF(2)^{n-2}$ represents an even triangulation of $G$ iff $\vec{x}$ is a solution of the following linear equation system (with $n$

equations and $n-2$ variables) over $GF(2)$:

$$\sum_{q_i \in Q_v} x_i = deg(v) + |Q_v|c(v) \pmod 2 \quad (\forall v \in V). \tag{1}$$

In [4], Hoffmann and Kriegel showed that (1) always has a solution, and hence proved Theorem 1. Therefore, the term "a vector $\vec{x}$ representing an even triangulation of $G$" and the term "a solution vector of (1)" can be used interchangeably.

To obtain all solutions of (1) (i.e., all even triangulations of $G$), [4] introduced the concept of *straight walk*. For a 2MBP graph $G$, its dual graph $G^*$ is 4-regular and connected. Consider a walk $S$ in $G^*$. Since $G^*$ is 4-regular, at every vertex of $S$, we have four possible choices to continue the walk: go back, turn left, go straight, or turn right. A closed walk of $G^*$ consisting of only straight steps at every vertex is called a *straight walk*, or *S-walk*. The edge set of $G^*$ can be uniquely partitioned into $S$-walks. We use $\mathcal{S}(G^*) = \{S_1, \ldots, S_k\}$ to denote this partition, where each $S_i$ $(1 \le i \le k)$ is an $S$-walk of $G^*$. Each vertex of $G^*$ (i.e., each face of $G$) occurs either twice on one $S$-walk or on two different $S$-walks. If a face $f$ occurs on one $S$-walk twice, it is called a 1-*walk face*. If $f$ occurs on two different $S$-walks, it is called a 2-*walk face*.

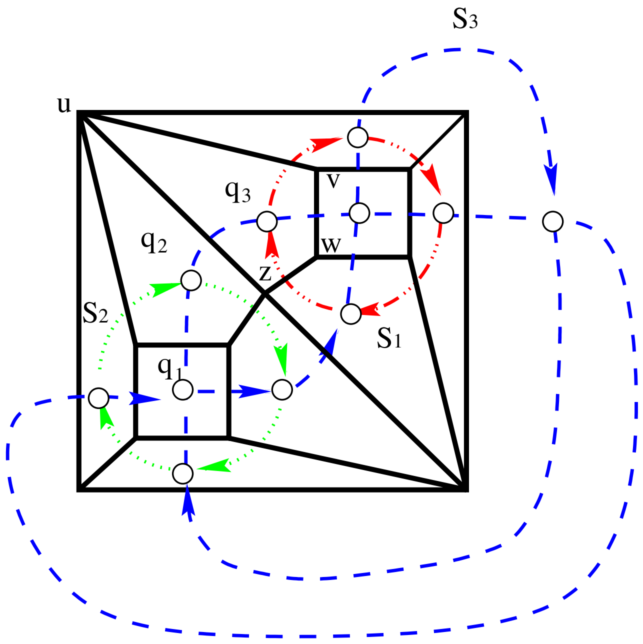

FIG. 1. *A 2MBP graph $G$, the dual graph $G^*$, and one of its $S$-orientation $\mathcal{O}$.*

Figure 1 shows a 2MBP graph and its dual graph $G^*$. The edges of $G$ are represented by solid lines. The edges of $G^*$ are represented by dotted lines. The vertices of $G^*$ (i.e., the faces of $G$) are represented by small circles. $\mathcal{S}(G^*)$ contains 3 $S$-walks $S_1$, $S_2$, and $S_3$. The face $q_1$ is a 1-walk face since it occurs on $S_3$ twice. The face $q_2$ is a 2-walk face since it occurs on both $S_2$ and $S_3$. (The $S$-walks in this figure are directed. Its meaning will be discussed in the next section.)

Let $S$ be an $S$-walk of $G^*$. Take an even triangulation of $G$. If we flip the diagonals of every face on $S$, it's easy to see that we get another even triangulation of $G$. (If a face $f$ occurs on $S$ twice, its diagonal is flipped twice and hence remains unchanged.)

THEOREM 3. *Let $G$ be a 2MBP graph and let $\mathcal{S}(G^*) = \{S_1, \ldots, S_k\}$ be the $S$-walks of $G^*$. The following statements hold:*

1. *If $T$ is an even triangulation of $G$ and the diagonals of $T$ are flipped along an $S$-walk $S_i$, we obtain another even triangulation of $G$.*
2. *If $T_1$ and $T_2$ are two even triangulations of $G$, there is a collection of $S$-walks such that by flipping the diagonals of $T_1$ along these $S$-walks we obtain $T_2$.*

Statement 1 of Theorem 3 was proved in [4]. Statement 2 of Theorem 3 was stated in [4]. Hoffmann and Kriegel mentioned that statement 2 can be proved by showing that another linear equation system derived from $G$ has a solution. However, since "the arguments are much more involved," its proof was omitted in [4] and was given in the technical report [3].

**3. Even triangulations of 2MBP graphs.** In this section, we provide new proofs of Theorems 1 and 3. First, we introduce a few definitions. An *orientation* of an undirected graph is an assignment of directions to its edges.

DEFINITION 1. *Let $G$ be a 2MBP graph.*

1. *A* $G$-orientation *of $G$ is an orientation of $G$ such that every facial cycle of $G$ is decomposed into two directed paths, one in a clockwise direction and another in a counterclockwise direction, each of length 2.*
2. *Let $\mathcal{G}_1, \mathcal{G}_2$ be two $G$-orientations of $G$. If every edge of $G$ has reverse direction in $\mathcal{G}_1$ and $\mathcal{G}_2$, we say $\mathcal{G}_2$ is the* reverse *of $\mathcal{G}_1$. In this case, $\mathcal{G}_1$ and $\mathcal{G}_2$ are called a* $G$-orientation pair *of $G$.*
3. *Fix a $G$-orientation $\mathcal{G}$ of $G$. For each face $q$ of $G$, the starting and the ending vertices of the two directed paths on the boundary of $q$ are called the* primary vertices *of $q$. The diagonal of $q$ connecting the two primary vertices is called its* primary diagonal *(with respect to $\mathcal{G}$). The other diagonal of $q$ is called its* secondary diagonal *(with respect to $\mathcal{G}$).*

It is worth mentioning that $G$-orientation should not be confused with the well-known *st-orientation*, which is widely used in graph theory and algorithms. (For its definition and applications, see, for example, [8, 13].) First of all, any *st*-orientation of a 2-connected plane graph has one and only one global source and sink, while this is not necessarily true in the case of $G$-orientation (although in $G$-orientation, each face has one source and one sink, which is similar to *st*-orientation). Second, in *st*-orientation, every facial cycle is also decomposed into two directed paths, but their source and sink could be adjacent, which is forbidden in $G$-orientation. We will see that this requirement plays a crucial role in our construction of even triangulations later on.

Note that for a $G$-orientation pair $\mathcal{G}_1, \mathcal{G}_2$ and any face $q$ of $G$, the primary diagonal of $q$ with respect to $\mathcal{G}_1$ is the same as its primary diagonal with respect to $\mathcal{G}_2$. If $\mathcal{G}_1, \mathcal{G}_2$ do not form a $G$-orientation pair, then for some faces $q$ of $G$, the primary diagonal of $q$ with respect to $\mathcal{G}_1$ is different from that with respect to $\mathcal{G}_2$.

DEFINITION 2. *Let $G$ be a 2MBP graph and let $G^*$ be its dual graph with $\mathcal{S}(G^*) = \{S_1, \ldots, S_k\}$.*

1. *An* $S$-orientation *of $G^*$ is an orientation of $G^*$ such that every $S$-walk $S_i$ $(1 \leq i \leq k)$ is a directed closed walk.*
2. *Let $\mathcal{O}_1, \mathcal{O}_2$ be two $S$-orientations of $G^*$. If every $S_i$ $(1 \leq i \leq k)$ has reverse direction in $\mathcal{O}_1$ and $\mathcal{O}_2$, we say $\mathcal{O}_2$ is the* reverse *of $\mathcal{O}_1$. In this case, $\mathcal{O}_1$ and $\mathcal{O}_2$ are called an* $S$-orientation pair *of $G^*$.*
3. *Fix an $S$-orientation $\mathcal{O}$ of $G^*$. For each face $q$ of $G$, if an $S$-walk $S_i$ of $G^*$*

*steps out of (into, respectively) $q$ through an edge $e$ on the boundary of $q$, then $e$ is called an* out-edge *(*in-edge*, respectively) of $q$ (with respect to $\mathcal{O}$).*

We can assign two different directions to each $S$-walk. So, if $G^*$ has $k$ $S$-walks, it has $2^k$ distinct $S$-orientations and $2^{k-1}$ distinct $S$-orientation pairs.

Consider an arbitrary $S$-orientation $\mathcal{O}$ of $G^*$. It is easy to check that every face $q$ of $G$ has two out-edges and two in-edges with respect to $\mathcal{O}$, and the two in-edges of $q$ are always incident to a common vertex on the boundary of $q$. Thus there are always two nonadjacent vertices on the boundary of $q$ that are incident to both in-edges and out-edges of $q$. For example, consider the face $q_3$ in Figure 1. An $S$-orientation $\mathcal{O}$ of $G^*$ is shown in the figure. With respect to $\mathcal{O}$, the edge $(u, v)$ is an out-edge of $q_3$ and the edge $(w, z)$ is an in-edge of $q_3$. The vertices $u$ and $w$ are incident to both in-edges and out-edges of $q_3$.

Next we show that there exists a natural one-to-one mapping between the set of $S$-orientations of $G^*$ and the set of $G$-orientations of $G$ which preserves the pair relation.

Definition 3. *Let $G$ be a 2MBP graph and let $\mathcal{O}$ be an $S$-orientation of $G^*$. We define an orientation of $G$ from $\mathcal{O}$ as follows. Let $e$ be any edge of $G$ and let $e^*$ be its dual edge in $G^*$. Let $q_1$ and $q_2$ be the two faces of $G$ with $e$ on their boundaries. Suppose that $e^*$ is directed from $q_2$ to $q_1$ in $\mathcal{O}$. When traveling $e^*$ from $q_2$ to $q_1$, we direct $e$ from right to left. (In other words, $e$ is directed counterclockwise on the boundary of $q_2$ and clockwise on the boundary of $q_1$.) This orientation of $G$ will be called the* orientation induced *from $\mathcal{O}$ and denoted by $\pi(\mathcal{O})$.*

An example of the induced orientation is shown in Figure 2(a). The $S$-walks $S_i, S_j, S_m$ pass through the faces $q_1, q_2$ in the shown directions. The induced directions of the edges on the boundaries of $q_1$ and $q_2$ are also shown.

Lemma 1. *Let $G$ be a 2MBP graph. If $\mathcal{O}$ is an $S$-orientation of $G^*$, then $\pi(\mathcal{O})$ is a $G$-orientation of $G$. If $\mathcal{O}$ and $\mathcal{O}'$ form an $S$-orientation pair, then $\pi(\mathcal{O})$ and $\pi(\mathcal{O}')$ form a $G$-orientation pair of $G$.*

*Proof.* Let $\mathcal{O}$ be an $S$-orientation of $G^*$. For any face $q$ of $G$, its two in-edges with respect to $\mathcal{O}$ are incident and hence form a directed path of length 2, in a clockwise direction, in $\pi(\mathcal{O})$. Its two out-edges with respect to $\mathcal{O}$ are also incident and hence form a directed path of length 2, in a counterclockwise direction, in $\pi(\mathcal{O})$. Thus $\pi(\mathcal{O})$ is a $G$-orientation of $G$.

Let $\mathcal{O}$ and $\mathcal{O}'$ be an $S$-orientation pair of $G^*$. Let $\mathcal{G} = \pi(\mathcal{O})$ and $\mathcal{G}' = \pi(\mathcal{O}')$. The direction of each $S$-walk in $\mathcal{O}'$ is the reverse of that in $\mathcal{O}$. So for any face $q$ of $G$, its two *in-edges* with respect to $\mathcal{O}$ are the two *out-edges* with respect to $\mathcal{O}'$. Therefore, the direction of each edge $e$ in $\mathcal{G}'$ is the reverse of that in $\mathcal{G}$. Hence $\mathcal{G}$ and $\mathcal{G}'$ form a $G$-orientation pair. ∎

Let $\mathcal{O}$ be an $S$-orientation of $G^*$ and $\mathcal{G} = \pi(\mathcal{O})$. For any face $q$ of $G$, the primary diagonal $d$ of $q$ with respect to $\mathcal{G}$ is the diagonal connecting the two vertices on the boundary of $q$ that are incident to both the in-edges and the out-edges of $q$ with respect to $\mathcal{O}$. We also call $d$ the primary diagonal of $q$ with respect to $\mathcal{O}$. For example, consider the face $q_1$ in Figure 2(a). The vertices $v_1$ and $v_3$ are incident to both in-edges and out-edges of $q_1$. Thus the primary diagonal of $q_1$ with respect to $\mathcal{O}$ is $(v_1, v_3)$.

Note that if $q$ is a 1-walk face that occurs on an $S$-walk $S_i$ twice and if the direction of $S_i$ is reversed, the primary diagonal of $q$ remains unchanged. On the other hand, consider a 2-walk face $q$ that occurs on two $S$-walks $S_i$ and $S_j$. If both $S_i$ and $S_j$ reverse directions, the primary diagonal of $q$ remains unchanged. If only one

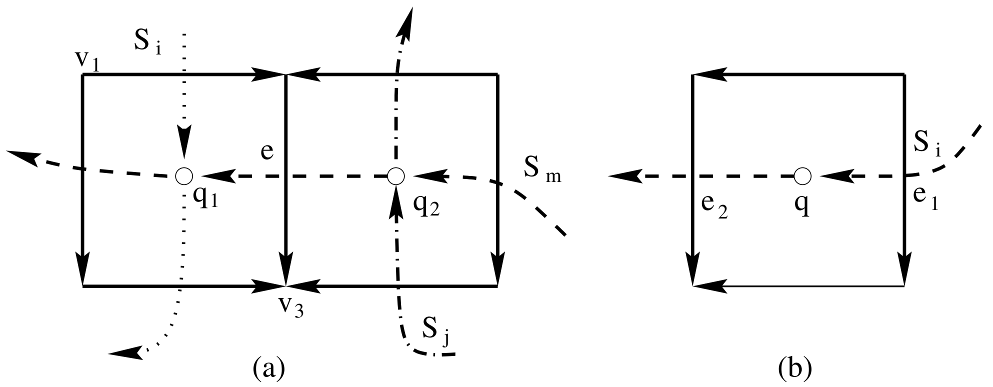

FIG. 2. (a) *An $S$-orientation $\mathcal{O}$ induces a $G$-orientation $\mathcal{G}$.* (b) *A $G$-orientation $\mathcal{G}$ derives an $S$-orientation $\mathcal{O}$.*

of the two $S$-walks reverses direction, then the primary and the secondary diagonals of $q$ swap.

DEFINITION 4. *Let $G$ be a 2MBP graph and let $\mathcal{G}$ be a $G$-orientation of $G$. We define an orientation of $G^*$ as follows. Consider any edge $e^*$ in $G^*$. Let $e$ be the edge in $G$ corresponding to $e^*$. When traveling $e$ along its direction in $\mathcal{G}$, we direct $e^*$ from the face $q_2$ on the left to the face $q_1$ on the right. This orientation of $G^*$ will be called the orientation* derived from $\mathcal{G}$ *and will be denoted by $\delta(\mathcal{G})$.*

LEMMA 2. *Let $G$ be a 2MBP graph. If $\mathcal{G}$ is a $G$-orientation $G$, then $\delta(\mathcal{G})$ is an $S$-orientation of $G^*$. If $\mathcal{G}, \mathcal{G}'$ form a $G$-orientation pair, then $\delta(\mathcal{G})$ and $\delta(\mathcal{G}')$ form an $S$-orientation pair.*

*Proof.* Let $\mathcal{S}(G^*) = \{S_1, S_2, \ldots, S_k\}$ be $S$-walks of $G^*$. Let $\mathcal{G}$ be a $G$-orientation of $G$. We want to show that every $S$-walk $S_i$ is a directed closed walk in the orientation $\mathcal{O} = \delta(\mathcal{G})$ of $G^*$. It is enough to show that any two consecutive edges on $S_i$ are assigned consistent directions in $\mathcal{O}$.

Consider any face $q$ on $S_i$. Let $e_1$ and $e_2$ be the two edges on the boundary of $q$ that are walked through by $S_i$. Note that $e_1$ and $e_2$ are opposite on the boundary of $q$. Let $e_1^*$ and $e_2^*$ be the dual edges corresponding to $e_1$ and $e_2$, respectively. Without lose of generality, assume $e_1^*$ is directed into $q$. We need to show $e_2^*$ is directed out of $q$ (see Figure 2(b)).

By the definition of $\delta(\mathcal{G})$, $e_1$ is clockwise on the boundary of $q$. Because $\mathcal{G}$ is a $G$-orientation, $e_1$ and $e_2$ must have different direction, and hence $e_2$ is directed counterclockwise on the boundary of $q$. By the definition of $\delta(\mathcal{G})$, $e_2^*$ is directed out of $q$ in $\mathcal{O}$, as will be shown. Since this is true for any face $q$ on $S_i$, $S_i$ is indeed a directed closed walk in $\mathcal{O}$. Hence $\mathcal{O}$ is an $S$-orientation of $G^*$.

Let $\mathcal{G}$ and $\mathcal{G}'$ be a $G$-orientation pair. For each edge $e$ of $G$, the direction of $e$ in $\mathcal{G}'$ is the reverse of that in $\mathcal{G}$. Hence, the direction of its dual edge $e^*$ in $\mathcal{O}' = \delta(\mathcal{G}')$ is the reverse of that in $\mathcal{O} = \delta(\mathcal{G})$. Therefore $\mathcal{O}$ and $\mathcal{O}'$ form an $S$-orientation pair of $G^*$. ☐

By Definitions 3 and 4, it's straightforward to verify that $\pi$ and $\delta$ are inverse mappings of each other. Hence we have the following.

THEOREM 4. *For a 2MBP $G$, the mapping $\pi$ (and $\delta$) is a one-to-one correspondence between the set of $G$-orientations of $G$ and the set of $S$-orientations of $G^*$, which preserves the pair relation.*

The following theorem describes how to obtain an even triangulation from a $G$-orientation of $G$.

THEOREM 5. *Let $G$ be a $2MBP$ graph.*

1. *Let $\mathcal{G}$ be a $G$-orientation of $G$. Then adding the primary diagonals into each face of $G$ results in an even triangulation of $G$, which is called the even triangulation* determined by $\mathcal{G}$, *denoted by $\mathcal{T}(\mathcal{G})$.*
2. *Let $\mathcal{G}$ and $\mathcal{G}'$ be two $G$-orientations of $G$. If $\mathcal{G}, \mathcal{G}'$ form a $G$-orientation pair of $G$, they determine the same even triangulation of $G$, i.e., $\mathcal{T}(\mathcal{G}) = \mathcal{T}(\mathcal{G}')$. If $\mathcal{G}, \mathcal{G}'$ do not form a $G$-orientation pair of $G$, they determine different even triangulations of $G$, i.e., $\mathcal{T}(\mathcal{G}) \neq \mathcal{T}(\mathcal{G}')$.*

*Proof.*

*Statement* 1. Let $G'$ be the graph resulting from adding the primary diagonals (with respect to $\mathcal{G}$) into the faces of $G$. Consider any vertex $v$ of $G$. Let $e_1, e_2, \dots, e_t$ be the edges in $G$ incident to $v$ in a clockwise direction. Thus $deg_G(v) = t$. Let $q_i$ $(1 \leq i \leq t)$ be the face incident to $v$ and with $e_i$ and $e_{i+1}$ on its boundary (where $e_{t+1} = e_1$).

We call $e_j$ a *go-in* (*go-out*, respectively) edge of $v$ if $e_j$ is directed into (out of, respectively) $v$ in $\mathcal{G}$. A face $q_i$ is called a *gap face* of $v$ if one of the two edges $e_i$ and $e_{i+1}$ is a go-in edge of $v$ and another is a go-out edge of $v$. $q_i$ is called a *good face* of $v$ if $e_i, e_{i+1}$ are both go-in edges of $v$ or both go-out edges of $v$. Denote the number of gap faces of $v$ by $gap(v)$. Since a gap face is always between a block of consecutive go-out edges and a block of consecutive go-in edges around $v$, it is easy to see that $gap(v)$ is always an even number.

The primary diagonal (with respect to $\mathcal{G}$) of each face $q$ is the diagonal connecting the starting and the ending vertices of the two directed paths on the boundary of $q$. Thus $v$ is incident to the primary diagonal of the face $q_i$ iff $q_i$ is a good face of $v$. Hence $deg_{G'}(v) = deg_G(v) + t - gap(v) = 2t - gap(v)$ is always even. Therefore $G' = \mathcal{T}(\mathcal{G})$ is an even triangulation of $G$.

Figure 3(a) shows an example of this construction. The solid lines are edges in $G$. The dotted lines are primary diagonals which are added into $G'$. The black dots indicate the gap faces. We have $deg_{G'}(v) = 2 \times 6 - 4 = 8$.

*Statement* 2. Suppose $\mathcal{G}$ and $\mathcal{G}'$ form a $G$-orientation pair of $G$. For any face $q$ of $G$, the primary diagonal of $q$ with respect to $\mathcal{G}$ is the same as that with respect to $\mathcal{G}'$. So $\mathcal{T}(\mathcal{G})$ is the same as $\mathcal{T}(\mathcal{G}')$.

Suppose $\mathcal{G}, \mathcal{G}'$ do not form a $G$-orientation pair. Then they have different sets of primary diagonals. So $\mathcal{T}(\mathcal{G})$ is different from $\mathcal{T}(\mathcal{G}')$. □

Note that the fact that the source and the sink of each face in a $G$-orientation are not adjacent plays a crucial role here. Only because of this, adding the primary diagonal (which connects the source and sink for each face) splits the quadrangle into two triangles. If the source and sink were adjacent, as possibly in the case of $st$-orientation, this would be impossible.

If $\mathcal{G}$ is induced from an $S$-orientation $\mathcal{O}$ of $G^*$, we also call $\mathcal{T}(\mathcal{G})$ the even triangulation *determined by* $\mathcal{O}$, and denote it by $\mathcal{T}(\mathcal{O})$.

Based on the discussion above, we have the following.

*New proof of Theorem* 1. Let $\mathcal{S}(G^*) = \{S_1, S_2, \dots, S_k\}$ be the $S$-walks of $G^*$. Arbitrarily assign a direction to each $S_i$. This gives an $S$-orientation $\mathcal{O}$ of $G^*$. By Lemma 1, we get a $G$-orientation $\mathcal{G} = \pi(\mathcal{O})$. By Theorem 5, we get an even triangulation $\mathcal{T}(\mathcal{G})$ of $G$. □

Theorem 5 states that every $G$-orientation pair determines an even triangula-

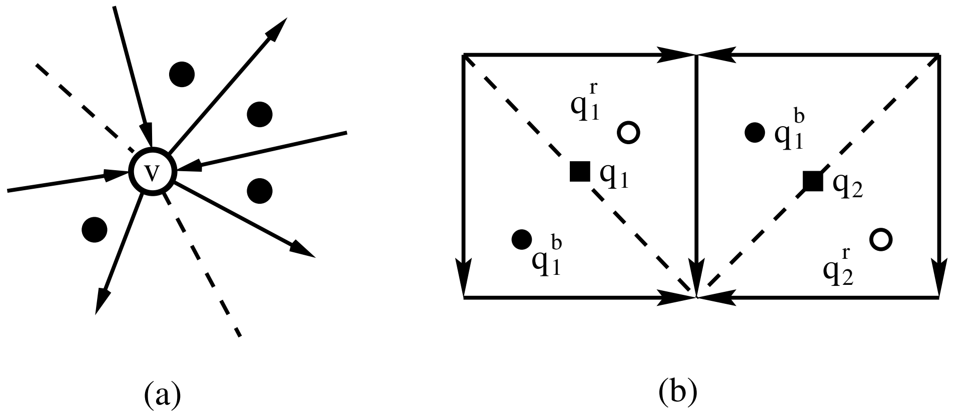

FIG. 3. (a) *Adding primary diagonals with respect to a G-orientation $\mathcal{G}$ results in even degree at vertex v.* (b) *An even triangulation of G induces a G-orientation $\mathcal{G}$ on faces $q_1$ and $q_2$.*

tion of $G$. Next we show that every even triangulation of $G$ is determined by a $G$-orientation pair of $G$.

THEOREM 6. *Let $G$ be a 2MBP graph and let $\mathcal{S}(G^*) = \{S_1, S_2, \ldots, S_k\}$ be the S-walks of $G^*$.*

1. *Every even triangulation $G'$ of $G$ is determined by a $G$-orientation pair of $G$.*
2. *$G$ has exactly $2^{k-1}$ distinct even triangulations.*

*Proof.*

*Statement* 1. Let $G'$ be any even triangulation of $G$. We want to show that there exists a $G$-orientation $\mathcal{G}$ of $G$ such that $G' = \mathcal{T}(\mathcal{G})$.

Let $G'^*$ be the dual graph of $G'$. For each face $q$ of $G$, the diagonal of $q$ from $G'$ splits $q$ into two faces, which will be called the *subfaces* of $G$. So $q$ contains two subfaces.

Since each vertex has even degree in $G'$, each facial cycle of $G'^*$ is of even length. Thus $G'^*$ is a bipartite plane graph. So we can color its vertices by two colors. In other words, we can color the subfaces of $G$ red and black so that no two red (black, respectively) subfaces are adjacent. Note that each face $q$ of $G$ contains one red and one black subface.

Consider any edge $e$ of $G$. Let $q_1$ and $q_2$ be the two faces of $G$ with $e$ on their common boundary. Let $q_1^r$ and $q_1^b$ be the red and the black subfaces contained in $q_1$, respectively. Let $q_2^r$ and $q_2^b$ be the red and the black subfaces contained in $q_2$, respectively. Note that exactly one red subface and one black subface from the four subfaces $q_1^r, q_1^b, q_2^r, q_2^b$ have $e$ on their boundaries. We direct $e$ clockwise on its neighboring red subface. (Hence, $e$ is directed counterclockwise on its black neighboring subface.) This way, each edge $e$ of $G$ is consistently assigned a direction. Let $\mathcal{G}$ denote this orientation of $G$.

Consider any face $q$ of $G$. Let $q^r$ and $q^b$ be the red and black subfaces contained in $q$, respectively. Two boundary edges of $q$ are the boundary edges of $q^r$. Hence they are directed clockwise and form a directed path of length 2 in $\mathcal{G}$. The other two boundary edges of $q$ are the boundary edges of $q^b$. Hence they are directed counterclockwise and form another directed path of length 2 in $\mathcal{G}$. Thus $\mathcal{G}$ is indeed a $G$-orientation of $G$.

Figure 3(b) shows an example of this construction. Two faces $q_1$ and $q_2$ are shown in the figure as black squares. Each of them contains two subfaces. The red subfaces are indicated by empty circles. The black subfaces are indicated by solid circles. The edges of $G$ are directed as described above.

For each face $q$ of $G$, the diagonal $d$ of $q$ from the even triangulation $G'$ is the diagonal which separates the red and the black subfaces of $q$. So it is the diagonal of $q$ connecting the starting and the ending vertices of the two directed paths on the boundary of $q$. Hence $d$ is the primary diagonal of $q$ with respect to $\mathcal{G}$. Therefore, the even triangulation $\mathcal{T}(\mathcal{G})$ determined by $\mathcal{G}$ is exactly $G'$.

*Statement* 2. It follows directly from the following facts:

- We can assign two directions to each $S$-walk $S_i$ $(1 \leq i \leq k)$. So $G^*$ has $2^k$ different $S$-orientations and $2^{k-1}$ different $S$-orientation pairs. By Theorem 4, there are exactly $2^{k-1}$ different $G$-orientation pairs of $G$.
- Each $G$-orientation pair determines a distinct even triangulation of $G$.
- Every even triangulation of $G$ is determined by a $G$-orientation pair. □

In order to provide a new proof of Theorem 3, we need the following.

LEMMA 3. *Let $G$ be a 2MBP and let $\mathcal{S}(G^*) = \{S_1, \dots, S_k\}$ be the $S$-walks of $G^*$. Let $\mathcal{O}_1$ be an $S$-orientation of $G^*$. Let $\mathcal{O}_2$ be the $S$-orientation of $G^*$ obtained from $\mathcal{O}_1$ by reversing the direction of an $S$-walk $S_i$.*

*Then $\mathcal{T}(\mathcal{O}_2)$ can be obtained from $\mathcal{T}(\mathcal{O}_1)$ by flipping the diagonals of all faces on $S_i$. (If $q$ occurs on $S_i$ twice, its diagonal is flipped twice and hence remains unchanged.)*

*Proof.* The proof directly follows from the following facts:

- If a face $q$ does not occur on $S_i$, its primary diagonal with respect to $\mathcal{O}_1$ is the same as that with respect to $\mathcal{O}_2$.
- If a face $q$ occurs on $S_i$ once, its primary diagonal with respect to $\mathcal{O}_1$ is its secondary diagonal with respect to $\mathcal{O}_2$.
- If a face $q$ occurs on $S_i$ twice, its primary diagonal with respect to $\mathcal{O}_1$ is the same as that with respect to $\mathcal{O}_2$. □

We are now ready to give the following.

*New proof of Theorem* 3.

*Statement* 1. Let $T$ be an even triangulation of a 2MBP $G$. Then $T$ is determined by an $S$-orientation $\mathcal{O}$ of $G^*$ by Theorem 6, i.e., $T = \mathcal{T}(\mathcal{O})$. Let $\mathcal{O}'$ be the $S$-orientation obtained from $\mathcal{O}$ by reversing the direction of an $S$-walk $S_i$. Let $T'$ be the even triangulation $\mathcal{T}(\mathcal{O}')$ of $G$ determined by $\mathcal{O}'$. By Lemma 3, $T'$ is obtained from $T$ by flipping the diagonals of the faces on $S_i$.

*Statement* 2. Let $T_1$ and $T_2$ be any two even triangulations of $G$. By Theorem 6, $T_1 = \mathcal{T}(\mathcal{O}_1)$ is determined by an $S$-orientation $\mathcal{O}_1$ and $T_2 = \mathcal{T}(\mathcal{O}_2)$ is determined by another $S$-orientation $\mathcal{O}_2$. Let $S_{i_1}, S_{i_2}, \dots, S_{i_t}$ $(t \leq k)$ be those $S$-walks whose directions in $\mathcal{O}_1$ and $\mathcal{O}_2$ are reversed. By repeated applications of Lemma 3, if we start with $T_1$ and flip the diagonals of the faces on the $S$-walks $S_{i_j}$ $(1 \leq j \leq t)$ one by one we get $T_2$. □

## 4. Algorithm.

Based on the discussion in section 3, we obtain the following:

ALGORITHM 1: EVEN TRIANGULATION.
INPUT: A 2-connected bipartite plane graph $G$.
OUTPUT: An even triangulation of $G$.

```
1. Add diagonals into $G$, if necessary, to make all facial cycles length 4. For
   simplicity, we still use $G$ to denote the resulting graph.
2. Construct the dual graph $G^*$.
```

3. Travel the edges of $G^*$ to trace the $S$-walks of $G^*$. Each $S$-walk is assigned a direction when being traveled.
4. For each face $q_i$ of $G$, identify its in-edges, out-edges, and the primary diagonal. Add the primary diagonal into $q_i$.

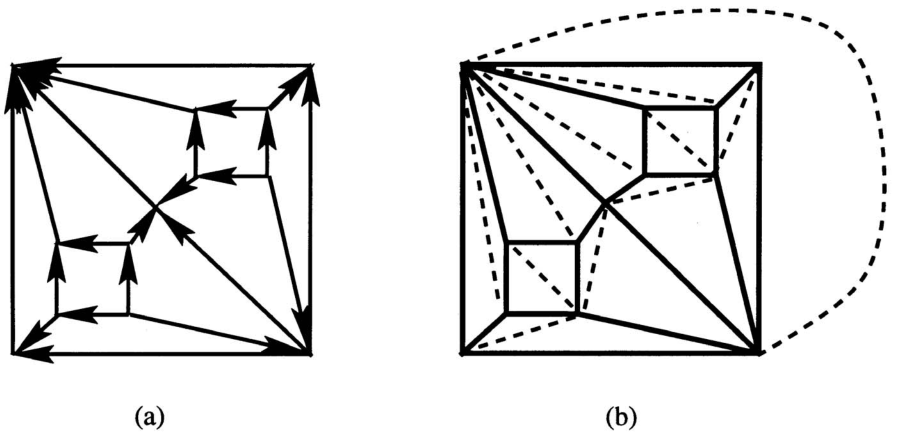

FIG. 4. (a) *A G-orientation $\mathcal{G}$ of $G$ corresponding to the S-orientation $\mathcal{O}$ in Figure* 1. (b) *An even triangulation of $G$ determined by $\mathcal{G}$.*

Figure 4 shows the even triangulation constructed by Algorithm 1 for the graph $G$ in Figure 1.

THEOREM 7. *Given a* 2*-connected bipartite plane graph $G$, Algorithm* 1 *finds an even triangulation of $G$ in $O(n)$ time.*

*Proof.* The correctness of Algorithm 1 directly follows from Theorem 5. All of the steps of Algorithm 1 can be easily implemented using elementary graph algorithm techniques (for example, see [2]), each in $O(n)$ time. □

Algorithm 1 may yield multiple edges as in the case of a quadrangle. It is impossible to obtain an even triangulation from a single quadrangle without allowing multiple edges.

## 5. Even triangulations of 2-connected graphs on high genus surfaces.

In this section, the term *surface* describes a closed, connected, orientable surface without boundary. Informally, it describes a sphere with $g$ ($g \geq 0$) handles where $g$ is the *genus* of the surface. We denote it by $\mathcal{F}_g$. A graph $G$ is said to be *embedded* on $\mathcal{F}_g$ if $G$ is drawn on $\mathcal{F}_g$ such that no two edges cross. The drawing of $G$ divides $\mathcal{F}_g$ into a number of connected regions. Each region is called a *face* of $G$. In this section, $G$ always denotes a graph that can be embedded on $\mathcal{F}_g$ and each of its faces is an open disc on $\mathcal{F}_g$. (Such a graph $G$ cannot be embedded on $\mathcal{F}_{g-1}$ without edge crossings. Although $G$ can be embedded on $\mathcal{F}_{g+1}$, some of its faces are not open discs on $\mathcal{F}_{g+1}$. See [6, 7].) Note that a plane graph is just a graph embedded on $\mathcal{F}_0$.

As for embedded planar graphs, an *even triangulation* $G'$ of $G$ is obtained from $G$ by adding diagonals into the faces of $G$ such that every face of $G'$ is a triangle and every vertex of $G'$ has even degree. In this section, we investigate the problem of determining the existence and the number of even triangulations of $G$. Note that, we also require the graph $G$ to be a multigraph without 2-cycle faces, which we will simply call graph $G$.

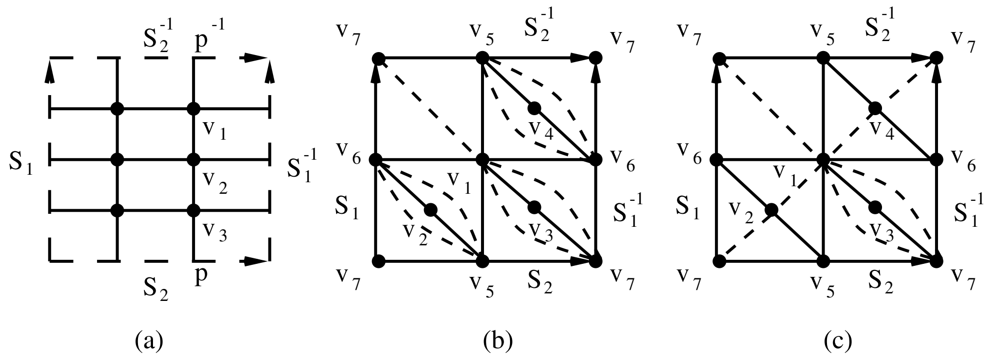

FIG. 5. (a) *A* 2*MEF graph* $G_1$ *on* $\mathcal{F}_1$ *with odd cycles.* (b) *An even triangulation of a* 2*MEF graph* $G$ *on* $\mathcal{F}_1$ *determined by its unique S-orientation pair.* (c) *An even triangulation of* $G$ *not determined by any S-orientation.*

If all of the facial cycles of $G$ are of even length, we call $G$ a 2-*connected even face graph on* $\mathcal{F}_g$ (or 2EF graph, for short). Obviously, if $G$ is a 2EF graph, we can add diagonals into its faces (if necessary) to make all of its facial cycles length 4. We call such a graph a 2-*connected maximal even face graph on* $\mathcal{F}_g$ (or 2MEF graph, for short). Note that 2MEF graphs are the counterpart of 2MBP graphs on high genus surfaces.

Our question is, given a 2MEF graph $G$, does $G$ always have an even triangulation? If so, how many?

According to Euler's formula, if $G$ is a 2MEF graph with $n$ vertices, $m$ edges, and $f$ faces, we have $n+f-m=2-2g$. Since each face of $G$ is a 4-cycle, we have $4f=2m$ and $f=n+2g-2$. The faces of $G$ will be denoted by $Q(G)=\{q_1,q_2,\ldots,q_{n+2g-2}\}$.

We can construct $\mathcal{F}_g$ from a $4g$ regular polygon on the plane (see [6, 7]). For example, to construct a torus $\mathcal{F}_1$ from a square (see Figure 5(a)), we glue the side $S_i$ with the side $S_i^{-1}$ ($i=1,2$) along their directions without twisting. The resulting surface is $\mathcal{F}_1$. Thus points $p$ and $p^{-1}$ in the figure become the same point on $\mathcal{F}_1$. The four corner points of the square become the same point on $\mathcal{F}_1$. In the figure, the line segment between point $v_1$ and point $p^{-1}$ and the line segment between point $p$ and point $v_3$ form a continuous line segment on $\mathcal{F}_1$ between $v_1$ and $v_3$. Figure 5(a) shows a 2MEF graph $G$ on $\mathcal{F}_1$ with 6 vertices (indicated by black dots), 12 edges (indicated by solid lines), and 6 faces. All the faces are 4-cycles. However, the three edges $(v_1,v_2),(v_2,v_3),(v_3,v_1)$ form a (nonfacial) cycle of length 3. So $G$ is *not* bipartite.

This example demonstrates a crucial difference between graphs on the plane and graphs on $\mathcal{F}_g$:

- If every face of a plane graph $G$ is an even cycle, then $G$ is bipartite.
- In contrast, even if every face of a graph $G$ embedded on $\mathcal{F}_g$ ($g>0$) is an even cycle, then $G$ is not necessarily bipartite.

As we will see, this difference makes it much harder to determine the number of distinct even triangulations of $G$.

Let $G$ be a 2MEF graph. Since $G$ is not necessarily bipartite, we cannot color the vertices of $G$ by two colors 0 and 1. So (1) does not make sense anymore. Hence we cannot rely on the existence of the solutions of (1) to show the existence of even triangulations of $G$. So the methods developed in [3, 4] cannot be used here at all.

On the other hand, most concepts and some theorems in sections 3 and 4 can be easily adapted to handle graphs $G$ on $\mathcal{F}_g$. Specifically, we can still construct the dual graph $G^*$ of $G$, where each vertex of $G^*$ is a face of $G$, and each edge of $G^*$ corresponds to an edge in $G$. Obviously $G^*$ can be embedded on $\mathcal{F}_g$. Moreover, since $\mathcal{F}_g$ is an orientable surface, it has two continuous normal vectors, and each remains consistent while traveling on $\mathcal{F}_g$. If we fix one normal vector of $\mathcal{F}_g$, we can still define the notions of clockwise, counterclockwise, right, and left directions on $\mathcal{F}_g$.

Thus the edge set of $G^*$ can still be partitioned into a set of $S$-walks. The concepts of 1-walk face, 2-walk face, $S$-orientation, $S$-orientation pair, $G$-orientation, $G$-orientation pair, the mappings $\pi$ and $\delta$, in-edge and out-edge, and primary diagonal can all be defined as in section 3 without any change. Moreover, the 2MEF graph versions of Lemmas 1 and 2 and Theorems 4 and 5 are still valid (whose proofs require no change). In particular, we state the following 2MEF graph version of Theorem 5.

THEOREM 8. *Let $G$ be a 2MEF graph on $\mathcal{F}_g$.*

1. *Let $\mathcal{G}$ be a $G$-orientation of $G$. Then adding the primary diagonals to each face of $G$ results in an even triangulation of $G$, which is called the even triangulation determined by $\mathcal{G}$, denoted by $\mathcal{T}(\mathcal{G})$.*
2. *Let $\mathcal{G}$ and $\mathcal{G}'$ be two $G$-orientations of $G$. If $\mathcal{G}, \mathcal{G}'$ form a $G$-orientation pair of $G$, they determine the same even triangulation of $G$, i.e., $\mathcal{T}(\mathcal{G}) = \mathcal{T}(\mathcal{G}')$. If $\mathcal{G}, \mathcal{G}'$ do not form a $G$-orientation pair of $G$, they determine different even triangulations of $G$, i.e., $\mathcal{T}(\mathcal{G}) \neq \mathcal{T}(\mathcal{G}')$.*

Because of Theorem 8, Algorithm 1 still correctly constructs an even triangulation of a 2EF graph $G$ in linear time. So the 2EF graph version of Theorem 7 is also valid.

Given any even triangulation $T$ of a 2MEF graph $G$, if we flip the diagonals of every face on an $S$-walk $S$ of $G^*$, we get another even triangulation. (If a face $q$ occurs twice on $S$, its diagonal is flipped twice and hence remains unchanged.) Thus statement 1 of Theorem 3 is still true.

The proof of statement 1 of Theorem 6 relies on the assumption that if all facial cycles of $G$ are even cycles, then $G$ is bipartite. Since this assumption is not true for 2MEF graphs, this proof is no longer valid. In fact, as we will show later, the two statements of Theorem 6 and statement 2 of Theorem 3 are *false* for 2MEF graphs.

We have the following weaker version of statement 2 of Theorem 6.

THEOREM 9. *Let $G$ be a 2MEF graph on $\mathcal{F}_g$ and let $\mathcal{S}(G^*) = \{S_1, \ldots, S_k\}$ be all $S$-walks of $G^*$. Then $G$ has at least $\max(2^{k-1}, 2^{2g-2})$ distinct even triangulations.*

*Proof.* Since we can assign two directions to each $S$-walk $S_i$ $(1 \le i \le k)$, $G^*$ has $2^{k-1}$ $S$-orientation pairs. Hence $G$ has $2^{k-1}$ distinct $G$-orientation pairs. By Theorem 8, $G$ has at least $2^{k-1}$ distinct even triangulations.

Now fix an even triangulation $T$ of $G$. We associate each face $q_i$ of $G$ with a $\{0,1\}$-valued variable $x_i$, and each triangulation $T'$ of $G$ with a vector $\vec{x} = (x_1, x_2, \ldots, x_{n+2g-2})$ in $GF(2)^{n+2g-2}$, where

$$T \text{ and } T' \text{ contain different diagonals of the face } q_i \Longleftrightarrow x_i = 1.$$

It is easy to see that (a) $T'$ is an even triangulation of $G$ iff its corresponding vector $\vec{x}$ is a solution of the following linear equation (2) over $GF(2)$; and (b) distinct even triangulations correspond to distinct solutions of (2) and vice versa:

$$\sum_{q_i \in Q_v} x_i = 0 \quad (\text{mod } 2) \quad (\forall v \in V). \tag{2}$$

Since (2) has $n$ equations and $n + 2g - 2$ variables, it has at least $2g - 2$ free variables. Thus, (2) has at least $2^{2g-2}$ distinct solutions (see [5]) and $G$ has at least $2^{2g-2}$ distinct even triangulations. ∎

Figures 5(b) and (c) show an example that the number of even triangulations of $G$ can be strictly bigger than $\max(2^{k-1}, 2^{2g-2})$. These figures show a 2MEF graph $G$ on $\mathcal{F}_1$ (after gluing the side $S_i$ with ${S_i}^{-1}$ for $i = 1, 2$). $G$ has 7 vertices (indicated by black dots and labeled $v_1, \ldots, v_7$) and 14 edges (indicated by solid lines). It can be verified that $G^*$ has a single $S$-walk on $\mathcal{F}_1$ and hence an unique $S$-orientation pair. Figures 5(b) and (c) show two distinct even triangulations of $G$ (where the added diagonals are indicated by dotted lines). The even triangulation shown in Figure 5(b) is determined by the unique $S$-orientation pair of $G^*$. So the even triangulation shown in Figure 5(c) is *not* determined by any $S$-orientation of $G^*$. Therefore statement 2 of Theorem 3 and all of Theorem 6 are not valid for a 2MEF graph $G$.

We raise the following open problem to conclude this paper: What properties of a 2MEF graph $G$ determine all its even triangulations and how many are they?

**Acknowledgment.** The authors would like to thank the anonymous referees for their helpful comments.

# FAULT-TOLERANT SCHEDULING*

BALA KALYANASUNDARAM† AND KIRK R. PRUHS‡

**Abstract.** We study fault-tolerant multiprocessor scheduling under the realistic assumption that the occurrence of faults cannot be predicted. The goal in these problems is to minimize the delay incurred by the jobs. Since this is an online problem we use competitive analysis to evaluate possible algorithms. For the problems of minimizing the makespan and minimizing the average completion time (for static release times), we give nonclairvoyant algorithms (both deterministic and randomized) that have provably asymptotically optimal competitive ratios. The main tool used by these algorithms to combat faults is redundancy. We also show that randomization has the same effect as redundancy.

**Key words.** makespan, fault-tolerant, multiprocessor scheduling, competitive analysis, transient faults, permanent faults

## 1. Introduction.

**1.1. Problem statement.** The scheduling of tasks in a multiprocessor system has been recognized as an important problem and has been extensively studied (see [6] for a survey). In a large multiprocessor system, processor faults are inevitable and fault-tolerance is a significant issue [11]. The vast majority of previous work on scheduling either assumes that there are no faults, or gives minimal analysis. In this paper we begin a theoretical investigation of the effect of processor faults on scheduling by considering several standard scheduling problems modified to allow faults. We assume that the pattern of faults cannot be predicted by the online scheduling algorithm. We then compare the schedules produced by the online algorithm to the schedules produced by an omniscient algorithm.

The setting for the generic multiprocessor scheduling problem is a collection $P_1, \ldots, P_m$ of processors. Each processor $P_j$ has a speed $s_j$. The processors are given a collection $J_1, \ldots, J_n$ of jobs. Each job $J_i$ has a *release time* $r_i$ that is the time that the online scheduling algorithm is first aware of $J_i$'s existence, and that is the earliest time that $J_i$ can begin execution. Furthermore, each $J_i$ has a length $x_i$, and running $J_i$ on $P_j$ takes $x_i/s_j$ units of time.

There are many variants of the multiprocessor scheduling problem depending on what assumptions one makes about the jobs and processors and on how one measures the desirability of a schedule. If all release times are 0, we say the release times are *static*. Otherwise, the release times are said to be *dynamic*. In the *identical processors case* all the processor speeds are equal. Otherwise, it is called the *related processors case*. A scheduling algorithm is *clairvoyant* if it learns each $x_i$ at time $r_i$,

and is *nonclairvoyant* if $x_i$ cannot be deduced until $J_i$ has been fully executed. A *preemptive* algorithm is allowed to suspend an executing job and later restart the job from the point of suspension. A *preemptive-with-restart* algorithm must begin the job afresh after suspending it. The *completion time* $c_i$ of a job $J_i$ is the time at which $J_i$ has been allocated enough time to finish execution. The *completion time* of $J_i$ is $w_i = c_i - r_i$. In this paper we primarily consider two scheduling measures, the *makespan* of a schedule, which is the maximum completion time, and the *average completion time*, which is $\frac{1}{n}\sum_{i=1}^{n} w_i$.

We assume that when a processor $P_j$ faults it is immediately detectable, and that the job currently being run on $P_j$ must be restarted from the beginning at some later point in time. A fault at $P_j$ can be classified as either *permanent*, in which case no more jobs may be run on $P_j$, or *transient*, in which case $P_j$ is inoperative for some finite period of time [11]. Note that a *nonclairvoyant* algorithm (also known as *online* algorithm) detects faults only at the time of their occurrence.

The *competitiveness* (or *competitive ratio*) of a deterministic algorithm for a particular problem and measure $\mathcal{M}$ is the supremum over all instances $\mathcal{I}$, of the ratio of the value of $\mathcal{M}$ for the schedule produced by the online algorithm given $\mathcal{I}$ as input to the optimal value of $\mathcal{M}$ for a schedule of $\mathcal{I}$ [9]. We can assume that the optimal value of $\mathcal{M}$ was computed by an offline algorithm with full advance knowledge of all the information about the jobs and the pattern of faults. For randomized algorithms we assume an oblivious adversary [2]; that is, the input (length of jobs and where, when, and how long the fault happens) must be specified in advance and may not be modified as a result of random events internal to the randomized algorithm. Thus the competitive ratio of a randomized algorithm on a particular problem and measure $\mathcal{M}$ is the supremum over all instances $\mathcal{I}$, of the ratio of the expected value of $\mathcal{M}$ for the schedule produced by the online algorithm given $\mathcal{I}$ as input to the optimal value of $\mathcal{M}$ for a schedule of $\mathcal{I}$.

The online algorithms that we give are nonclairvoyant; however, because our lower bound constructions all use equal length jobs, we can conclude that clairvoyance would not asymptotically help the online scheduling algorithm in the worst case. We always assume preemption-with-restart. As in most settings where fault-tolerance is an issue, the main tool available to combat faults is redundancy [11]. In this setting this generally means running multiple copies of the same job on different processors.

**1.2. Results.** The main results for the case of identical processors and preemption-with-restart are summarized in the table below. We use $\lambda$ to denote the total number of faults the scheduler will see over the entire length of its schedule. In the case of permanent faults we use $\eta = m - \lambda$ to denote the number of nonfaulty processors. The constant $\epsilon$ satisfies $0 < \epsilon < 1$. To determine the effect of the duration of faults on competitiveness, we assume that the duration of each transient fault is 0. That is, after a processor $P_j$ experiences a transient fault, a job may immediately be restarted on $P_j$. The results in this table suggest that for a moderate number (say, less than $\epsilon m$) of faults, the duration of the faults does not asymptotically affect the achievable competitive ratios. The function $\log^* x$ is defined to be the minimum $i$ such that $\log_2^{(i)} x \leq 1$, where $\log_2^{(i)}$ is the log function iterated $i$ times. The results for no faults come from [10, 8]. If one expects that permanent faults are largely independent, then the number of faults is likely to be approximately $\epsilon m$, where the constant $\epsilon$ is the probability that a particular processor faults. So in practice the most relevant line of the table is probably where $\lambda = \epsilon m$; note that the multiplicative constants here depend on $\epsilon$. These results show that the competitive ratios are effectively bounded in practice. The competitive ratio for average completion time is a constant, and the randomized competitive ratio for makespan is effectively bounded since $\log^* m$ is such a slowly growing function.

In the general related processors case, almost all the optimal competitive ratios listed in the table for permanent faults increase by a multiplicative factor of $R$, where $R$ is the ratio of the speed of the fastest processor to the speed of the slowest processor. For no faults, [10] showed a $\Theta(\min(\log R, \log m))$ bound on the optimal deterministic competitive ratio with respect to makespan, in the related processors case. In [8] it is implicitly shown that there exists a constant competitive algorithm for minimizing the average completion time in the general related processors case. The result is explicitly stated only for the identical processors case. This shows that as the system becomes more heterogeneous, the degradation of the optimal competitive ratio is much more rapid in the case of permanent faults.

Optimal Competitive Ratios for Identical Processors

| | Makespan | | Average completion time (static case) |
|---|---|---|---|
| Faults | Deterministic | Randomized | Deterministic and randomized |
| $\lambda = 0$ | $\Theta(1)$ [10] | $\Theta(1)$ [10] | $\Theta(1)$ [8] |
| $\lambda > 0$ Permanent | $\Theta(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{m}{\eta}))$ | $\Theta(\max(\log^* m - \log^* \frac{m}{\lambda}, \frac{m}{\eta}))$ | $\Theta(\frac{m}{\eta})$ |
| $\lambda = \epsilon m$ Permanent | $\Theta(\frac{\log m}{\log \log m})$ | $\Theta(\log^* m)$ | $\Theta(1)$ |
| $\lambda > 0$ Transient | $\Theta(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{\lambda}{m}))$ | $\Theta(\max(\log^* m - \log^* \frac{m}{\lambda}, \frac{\lambda}{m}))$ | $\Theta(\max(\frac{\lambda}{m}, 1))$ |

The results for makespan with permanent faults are given in section 2, and the results for average completion time with permanent faults are given in section 3. In section 4, we consider transient faults for the identical processors case. In section 5, we consider the effect of not allowing the online algorithm to run multiple copies of the same job at the same time. It is at least possible that this may be required in some situations where the programs have side effects or use external resources. We show that this restriction really cripples deterministic algorithms in that the optimal competitive ratio for both makespan and average completion time is $\Theta(\lambda)$ for permanent faults. We also show that the bounds on the competitive ratio, with respect to both makespan and average completion time, for randomized algorithms in the case of no redundancy are exactly the same as for deterministic algorithms that use redundancy.

We know of no previous theoretical investigations of this kind into fault-tolerant scheduling. Nonclairvoyant scheduling without faults is discussed in [5, 7, 8, 10]. In [8] it is shown that with dynamic release times and without faults, a nonclairvoyant deterministic (randomized) algorithm cannot be better than $\Omega(n^{1/3})$-competitive ($\Omega(\log n)$-competitive), with respect to average completion time, even allowing preemptions.

This shows that online scheduling algorithms face a much more daunting task when trying to minimize the average completion time of jobs with dynamic release times. For a general survey of fault-tolerant scheduling see [11].

## 2. Makespan.

**2.1. Lower bounds.** We use the following adversary to prove a lower bound on the competitive ratio, with respect to makespan, of any deterministic online algorithm. We define the *multiplicity* $\phi(J)$ of a job $J$ at some point in time to be the number of processors on which a copy of $J$ is being run at that time.

**2.1.1. Deterministic adversary.** *Adversary* DETERMINISTIC-DETER$(m, n, \lambda, \ell, \mathcal{A})$. Here $m$ is the number of unit speed processors, $\lambda$ is the number of faults, $n$ is the number of jobs, $\ell$ is the length of the jobs, and $\mathcal{A}$ is a deterministic online algorithm. We assume that $\ell$ is much larger than the length of a clock cycle. At time zero, the adversary presents $n$ jobs of length $\ell$ to $\mathcal{A}$. In the rest of the description, time is divided into stages, where the duration of each stage is $\ell$. Let $U(i)$, $1 \leq i \leq k$, be the collection of jobs that are not completed by $\mathcal{A}$ before the end of the $i$th stage. So $U(1)$ is the set of all $n$ jobs. We denote the cardinality of $U(i)$ by $u(i)$. We use $f(i)$ to denote the number of faults during the $i$th stage; we set the value of each $f(i)$ later. Intuitively, the goal of the adversary is to fault $f(i)$ working processors running jobs with lowest multiplicity just before the end of every stage $i$ (except possibly the last stage), so that the number of unfinished jobs at the end of the stage is maximized for $\mathcal{A}$. Observe that in order to force $\mathcal{A}$ not to finish a job $J$, the adversary must fault all of the machines running $J$.

We now show more formally how the adversary faults processors in each stage. Consider the multiplicity of jobs in $U(i)$ just before the end of the $i$th stage. Assume that the jobs in $U(i)$ are numbered and ordered such that $\phi(J_1) \leq \phi(J_2) \leq \cdots \leq \phi(J_{u(i)})$. Find the largest number $s$ such that $\sum_{j=1}^{s} \phi(J_j) \leq f(i)$. Let $U(i+1) = \{J_x : 1 \leq x \leq s\}$. Note that $s = u(i+1)$. Just before the end of the $i$th stage, the adversary faults every processor running a job in $U(i+1)$. Notice that since all the copies of jobs in $U(i+1)$ are terminated just before the end of the $i$th stage, by induction, no job in $U(i+1)$ can be completed before the end of the $(i+1)$st stage. Finally, let

$$D(i) = \begin{cases} U(i) - U(i+1) & \text{if } \sum_{j=1}^{s} \phi(J_j) = f(i), \\ U(i) - U(i+1) - \{J_{s+1}\} & \text{otherwise.} \end{cases}$$

We now explain how to set the value of the $f(i)$'s.

*Case* 1. If $m - \lambda \geq \frac{m \log \log m}{\log m}$, then each $f(i) = \lfloor \lambda / \log m \rfloor$ for $i \leq \log m$, and $f(i) = 0$ for $i > \log m$.

*Case* 2. If $m - \lambda < \frac{m \log \log m}{\log m}$, then $f(1) = f(2) = m/4$. In the permanent fault case, $f(3) = \lambda - m/2$, and $f(i) = 0$ for $i \geq 4$. In the transient fault case, $f(i) = m$ for $3 \leq i \leq 2 + \lfloor (\lambda - m)/m \rfloor$, and $f(i) = 0$ for $i > 2 + \lfloor (\lambda - m)/m \rfloor$.

**2.1.2. Analysis.** We first prove two simple lemmas that we will use often.

LEMMA 2.1. *Let $\alpha_1, \ldots, \alpha_k$ be a collection of nonnegative reals such that $\sum_1^k \alpha_i = \alpha$. Then there are at least $k/2$ integers $j$ such that $1 \leq j \leq k$ and $\alpha_j \leq 2\alpha/k$.*

*Proof.* To reach a contradiction, assume that for at most $k/2$ of the $j$'s we have $\alpha_j \leq 2\alpha/k$. Hence, there are at least $k/2$ $j$'s such that $\alpha_j > 2\alpha/k$. Therefore, the sum of those $\alpha_j$'s must be strictly larger than $(\frac{k}{2})(\frac{2\alpha}{k}) = \alpha$, a contradiction. ∎

LEMMA 2.2. *Let $g(i)$ be the number of working processors at the start of the $i$th stage. The adversary* DETERMINISTIC-DETER *guarantees that if $u(i) \geq \frac{g(i)}{c} + \frac{f(i)}{c-1}$, for some integer $c \geq 1$, then $u(i+1) \geq \lfloor \frac{f(i)}{c-1} \rfloor$.*

*Proof.* Consider some time just before the end of the $i$th stage. At this time there can be at most $g(i)/c$ jobs with multiplicity $c$ or greater. Hence, since $u(i) \geq \frac{g(i)}{c} + \frac{f(i)}{c-1}$, there must be at least $\lfloor \frac{f(i)}{c-1} \rfloor$ jobs with multiplicity $c-1$ or less. The result then follows by the definition of DETERMINISTIC-DETER. ◻

LEMMA 2.3. *Assume $\lambda \leq m - \frac{m \log \log m}{\log m}$ and $m \geq n \geq \lambda \geq 1$. Then for any online deterministic algorithm $\mathcal{A}$, the number of stages forced by the adversary* DETERMINISTIC-DETER$(m, n, \lambda, 1, \mathcal{A})$ *is $\Omega(\frac{\log m}{\log(\frac{m \log m}{\lambda})})$.*

*Proof.* Notice that the faults occur just before the end of every stage. We will assume that all $m$ processors are available to $\mathcal{A}$ at the beginning of every stage even if the faults are permanent. Therefore, the lower bound we will establish under this strong assumption holds for both permanent and transient fault cases. Notice that the required bound is constant if $\lambda \leq \sqrt{m}$. So it suffices to consider the case where $n \geq \lambda \geq \sqrt{m}$.

Consider the time just before the end of the $i$th stage. By the definition of $D(i)$, $m - \frac{\lambda}{\log m} \geq \sum_{J \in D(i)} \phi(J)$ and $|D(i)| \geq [u(i) - (1 + u(i+1))]$. The minimum multiplicity of a job in $D(i)$ is at least the maximum multiplicity of a job in $U(i+1)$, which in turn is at least $\frac{\lambda}{\log m} \cdot \frac{1}{1+u(i+1)}$. Therefore,

$$m - \frac{\lambda}{\log m} \;\geq\; \sum_{J \in D(i)} \phi(J) \;\geq\; [u(i) - (1 + u(i+1))] \, \frac{\lambda}{\log m} \, \frac{1}{1 + u(i+1)}.$$

Simplifying, we get $1+u(i+1) \geq u(i)(\frac{\lambda}{m \log m})$. By observing that $2u(i+1) \geq 1+u(i+1)$ for $u(i+1) \geq 1$, we get $u(i+1) \geq u(i)(\frac{\lambda}{2m \log m})$. Since $u(1) = n$, by induction we get $u(i+1) \geq n(\frac{\lambda}{2m \log m})^i$.

At the end of the last stage, say, $k$, we have $u(k+1) < 1$ and $u(k) \geq 1$. So

$$2 \geq 1 + u(k+1) \geq u(k) \left( \frac{\lambda}{m \log m} \right) \geq 2n \left( \frac{\lambda}{2m \log m} \right)^k.$$

Equivalently, we get $k \log(\frac{2m \log m}{\lambda}) \geq \log n$. Therefore, $k = \Omega(\frac{\log n}{\log(\frac{m \log m}{\lambda})})$. The result follows since $\log n \geq \frac{\log m}{2}$. ◻

LEMMA 2.4. *Assume that $\lambda$ satisfies $\lambda \geq m - \frac{m \log \log m}{\log m}$. Then for all deterministic online algorithms $\mathcal{A}$, the number of stages forced by the adversary* DETERMINISTIC-DETER$(m, m, \lambda, 1, \mathcal{A})$ *is $\Omega(\frac{m}{\eta})$ for the permanent fault case and $\Omega(\frac{\lambda}{m})$ for the transient fault case.*

*Proof.* Note that $f(1) = m/4$ and that there are $m$ working processors at the start of the first stage. Applying Lemma 2.2 with $c = 2$, $\mathcal{A}$ has at least $m/4$ jobs not completed by the start of the second stage. Note that $f(2) = m/4$ and that there are at most $m$ working processors at the start of the second stage. Applying Lemma 2.2 with $c = 6$, $\mathcal{A}$ has at least $m/20$ jobs not completed by the start of the third stage. Now consider the permanent fault case. Since there are exactly $\eta$ working processors at the end of the third stage and at least $m/20$ unfinished jobs before the end of the third stage, the number of stages is $\Omega(m/\eta)$. In the transient fault case, all processors are faulting for the next $\Omega(\lambda/m)$ stages. ◻

THEOREM 2.5. *In the case of identical processors and static release times, the competitive ratio, with respect to makespan, of any deterministic clairvoyant algorithm $\mathcal{A}$ is $\Omega(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{m}{\eta}))$ for $\lambda \geq 1$ permanent faults.*

*Proof.* Apply DETERMINISTIC-DETER$(m, m, \lambda, 1, \mathcal{A})$. Observe that the adversary faults a total of at most $m/2$ processors during the first two stages. As a consequence, at least $m/2$ processors do not experience a fault during the first two stages. These $m/2$ processors can complete $m$ jobs at the end of the second stage. Therefore, $OPT$, the makespan of the offline optimal algorithm, is at most 2. The result follows from Lemmas 2.3 and 2.4. ☐

THEOREM 2.6. *In the case of identical processors and static release times, the competitive ratio, with respect to makespan, of any deterministic clairvoyant algorithm $\mathcal{A}$ is $\Omega(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{\lambda}{m}))$ for $\lambda \geq 1$ transient faults.*

THEOREM 2.7. *In the case of related processors, the optimal deterministic competitive ratio, with respect to makespan, is then $\Omega(R \cdot \max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{m}{\eta}))$ for $\lambda \geq 1$ permanent faults.*

*Proof.* Let $\mathcal{A}$ be the given online algorithm. First we assume that $\lambda \leq \sqrt{m}$, where the lower bound we wish to establish is $\Omega(R)$. There are three processors with speed $R$ and $m - 3$ processors with speed 1. Initially, two jobs of length $R$ arrive. Just before the end of the first (unit time) stage, one speed $R$ processor faults so that there is an unfinished job at the end of the stage. At the end of the first stage, the two remaining speed $R$ processors fault. It is not hard to see that $OPT = 1$ and the online makespan is $\Omega(R)$.

We now assume that $\lambda > \sqrt{m}$. There are $\lambda/2$ processors with speed $R$ and $m - \lambda/2$ processors with speed 1. There are exactly $\lambda/4$ jobs of length $R$. Using Lemma 2.1, one can see that the adversary can fault $\lambda/4$ speed $R$ processors just before the end of the first stage such that at least $\lambda/16$ jobs are unfinished by the given online algorithm $\mathcal{A}$. The remaining speed $R$ processors fault right after time 1. Since $\lambda/4$ speed $R$ processors work for one full stage, $OPT = 1$. Now apply DETERMINISTIC-DETER$(m - \lambda/2, \lambda/16, \lambda/16, R, \mathcal{A})$. ☐

Note that in these lower bounds, the online algorithm is faced with a plethora of faults after the optimal schedule has finished, a phenomenon that may not be quite acceptable. It is not clear how to formulate an alternative reasonable model that avoids this phenomenon.

**2.1.3. Randomized case.** Using Yao's technique [3, 12], it suffices to prove the lower bound on the expected competitive ratio of any deterministic algorithm when faults occur according to a fixed probabilistic distribution. We first describe the instance of the input and the probability distribution on the faults. It is important to notice that the description of the following adversary is independent of the online algorithm.

*Adversary* OBLIVIOUS-DETER$(m, n, \lambda, \ell)$. Here $m$ is the number of unit speed processors, $\lambda$ is the number of faults, $n$ is the number of jobs, and $\ell$ is the length of the jobs. At time zero, the adversary releases $n$ jobs of length $\ell$. In the rest of the description, time is divided into stages, where the duration of each stage is $\ell$.

*Case* 1. Suppose $m - \lambda \geq \frac{m}{\log^* m}$. Just before the end of every stage (except possibly the last stage), each working processor will fault independently with probability $\frac{\lambda}{2m \log^* m}$.

*Case* 2. Suppose $m - \lambda < \frac{m}{\log^* m}$. Right before the end of the first two stages, each working processor faults independently with probability 1/5. In the permanent fault case, just before the end of the third stage, all but an arbitrary $m-\lambda$ processors fault. In the transient fault case, all processors fault just before the end of stages 3 through $2+\lfloor(\lambda-m)/m\rfloor$.

**2.1.4. Analysis.** Before analyzing this adversary we need the following definitions and facts.

DEFINITION 2.8. *For a nonnegative integer $k$, a real $\alpha \geq 2$, and a real $z \geq 1$, we inductively define*

$$\operatorname{tower}(\alpha,k,z) = \begin{cases} z & \text{if } k=0, \\ \alpha^{tower(\alpha,k-1,z)} & \text{otherwise.} \end{cases}$$

LEMMA 2.9. $(k-1)+\log^* \alpha^z \leq \log^*(\operatorname{tower}(\alpha,k,z)) \leq 2(k-1)+\log^* \alpha^z + O(1)$.

*Proof.* Notice that $2^{2^x} \geq \alpha^x$ if $x \geq \alpha \geq 2$. Therefore, for $k \geq 2$, we have

$$\operatorname{tower}(2,(k-1),\alpha^z) \leq \operatorname{tower}(\alpha,k,z) = \operatorname{tower}(\alpha,k-1,\alpha^z) \leq \operatorname{tower}(2,2(k-1),\alpha^z).$$

The result then follows since $\log^*(\operatorname{tower}(2,k,z)) = k+\log^* z + O(1)$. □

FACT 2.10. *If $p(x)$ is some fixed polynomially bounded function, then* $\log^* p(x) = \log^* x + O(1)$.

FACT 2.11. *Let $y$ be a random variable with expectation $\mu$ and variance $\sigma^2$. Then Chebyshev's inequality states that* $\operatorname{Prob}[|y-\mu| \geq \alpha\mu] \leq \frac{\sigma^2}{\alpha^2\mu^2}$. *If $\sigma^2 \leq \mu$, then* $\operatorname{Prob}[|y-\mu| \geq \alpha\mu] \leq \frac{1}{\alpha^2\mu}$.

LEMMA 2.12. *Assume $\lambda \leq m - \frac{m}{\log^* m}$ and $n = \Theta(m)$. Then for any deterministic online algorithm $\mathcal{A}$, the expected number of stages forced by the adversary* OBLIVIOUS-DETER$(m,n,\lambda,\ 1)$ *on $\mathcal{A}$ is $\Omega(\log^* m - \log^* \frac{m}{\lambda})$.*

*Proof.* In this proof we will assume that all $m$ processors are available to $\mathcal{A}$ at the beginning of every stage. Therefore, the desired bound holds for both permanent and transient fault cases. Notice that the required lower bound is $\Omega(1)$ if $\lambda \leq m/\log m$. So it suffices to consider the case where $\lambda > m/\log m$.

Consider a time just before the end of the $i$th stage. At this time let $u(i)$ be a random variable representing the number of jobs that are not completed by $\mathcal{A}$ before the end of the $i$th stage. We say that an unfinished job $J$ is *weak* if $\phi(J) \leq \frac{2m}{u(i)}$ at this time. Using Lemma 2.1, one can see that there are at least $u(i)/2$ *weak* jobs among these $u(i)$ jobs. We now show that with very high probability $u(i+1) \geq (\frac{u(i)}{4})(\frac{\lambda}{m\log^* m})^{\frac{2m}{u(i)}}$. Since processors fault independently with probability $\frac{\lambda}{2m\log^* m}$, the probability that no copy of a *weak* job $J$ is completed at the end of the $i$th stage is at least $(\frac{\lambda}{2m\log^* m})^{\phi(J)} \geq (\frac{\lambda}{2m\log^* m})^{\frac{2m}{u(i)}}$. Hence by linearity of expectation,

$$E[u(i+1)] \geq \left(\frac{u(i)}{2}\right)\cdot\left(\frac{\lambda}{2m\log^* m}\right)^{\frac{2m}{u(i)}}.$$

Since $u(i+1)$ is the sum of independent 0/1 valued random variables, the variance of $u(i+1)$ is at most the expected value of $u(i+1)$ (see [1]). So applying Chebyshev's inequality,

$$Pr[|u(i+1)-E[u(i+1)]| \geq E[u(i+1)]/2] \leq \frac{4}{E[u(i+1)]}.$$

We define a stage $i$ to be *good* if $|u(i+1)-E[u(i+1)]| \leq E[u(i+1)]/2$, and we define a stage $i$ to be *correct* if the number of faults during that stage does not exceed

$\lambda/\log^* m$. Assuming that all the stages are good and correct, we first show that there are $\Omega(\log^* m - \log^* \frac{m}{\lambda})$ stages. We then show that with probability $1-o(1)$ the first $\Theta(\log^* m - \log^* \frac{m}{\lambda})$ stages are good and correct.

If all stages are good as well as correct, then

$$u(i+1) \geq \frac{E[u(i+1)]}{2} \geq \left(\frac{u(i)}{4}\right) \cdot \left(\frac{\lambda}{2m\log^* m}\right)^{\frac{2m}{u(i)}}.$$

Let $r(i) = 2m/u(i)$; thus $r(1) = 2m/u(1) = 2m/n \geq 2$. Furthermore,

$$r(i+1) \leq 4r(i) \cdot \left(\frac{2m\log^* m}{\lambda}\right)^{r(i)}.$$

Since $r(i) \geq 2$, $\lambda \leq m$ and we have

$$r(i+1) \leq 2^{2+r(i)} \left(\frac{2m\log^* m}{\lambda}\right)^{r(i)} \leq \left(\frac{2m\log^* m}{\lambda}\right)^{3r(i)}.$$

Let $\alpha = (\frac{2m\log^* m}{\lambda})^3 \geq 8$. Therefore, we get $r(i+1) \leq \alpha^{r(i)}$, and so by induction we also get $r(i+1) \leq \text{tower}(\alpha, i, r(1))$.

Let $k$ be an integer such that $E[u(k)] > \sqrt{m}$ and $E[u(k+1)] \leq \sqrt{m}$. Our goal is to show that $k = \Omega(\log^* m - \log^* \frac{m}{\lambda})$. Since $|u(k+1) - E[u(k+1)]| \leq E[u(k+1)]/2$, we get $u(k+1) \leq 3\sqrt{m}/2$. As a consequence, $r(k+1) \geq 4\sqrt{m}/3$. Therefore, it must be the case that $\text{tower}(\alpha, k, r(1)) \geq 4\sqrt{m}/3$. Applying Lemma 2.9 we get that

$$\log^*(\text{tower}(\alpha, k, r(1))) \leq 2(k-1) + \log^* \alpha^{r(1)} + O(1) \quad \text{and}$$
$$\log^*(\text{tower}(\alpha, k, r(1))) \geq \log^*(4\sqrt{m}/3) \geq \log^* m.$$

Then by Fact 2.10

$$k \geq \frac{1}{2}(\log^* m - \log^* \alpha^{r(1)}) + O(1) = \frac{1}{2}\left(\log^* m - \log^* \frac{m\log^* m}{\lambda}\right) + O(1).$$

We now consider two cases. If $\lambda \leq m/\log^* m$, then $m/\lambda \geq \log^* m$. Thus

$$\log^* \frac{m\log^* m}{\lambda} \leq \log^* \left(\frac{m}{\lambda}\right)^2 = \log^* \frac{m}{\lambda} + O(1).$$

If $\lambda > m/\log^* m$, then $\log^* m - \log^* \frac{m\log^* m}{\lambda} = \Theta(\log^* m)$ and $\log^* m - \log^* \frac{m}{\lambda} = \Theta(\log^* m)$.

Let us now fix an $x$ such that $x \leq k$ and $x = \Theta(\log^* m - \log^* \frac{m}{\lambda})$. We now complete our proof by showing that the probability that the first $x$ stages are good and correct is $1-o(1)$. The probability that there exists a stage between 1 and $x$ that is not good is at most

$$\sum_{i=1}^{x} \frac{4}{E[u(i+1)]} \leq 4x/\sqrt{m}.$$

Hence, the probability that all the first $x$ stages are good is at least $1-o(1)$.

Since processors fault independently with probability $\lambda/2m\log^* m$, the expected number of faults per stage is at most $\lambda/2\log^* m$, and the variance does not exceed the expected number of faults. Applying Chebyshev's inequality, we get that the number of faults per stage is at most $\lambda/\log^* m$ with probability at least $1 - 2(\log^* m)/\lambda$. The probability that there is a stage between 1 and $x$ that is not correct is thus at most $2x(\log^* m)/\lambda$, which is $o(1)$ since $\lambda > m/\log m$. $\square$

We will use the following lemma repeatedly.

LEMMA 2.13. *Suppose that there are $n = \epsilon m$ unfinished unit length jobs and $m$ idle working processors at some time $t$. Let $\mathcal{A}$ be an assignment of these jobs to these processors. Further suppose that each processor faults independently with probability $p$ just before time $t+1$, where $p < 1$ is a constant. Then with probability $1 - O(1/m)$, the number of processors faulting just before time $t+1$ is at most $(1+\frac{1}{4})pm$. Also, with probability $1-O(1/m)$, the number of jobs unfinished before time $t+2$, using $\mathcal{A}$, is at least $\frac{\epsilon}{4}mp^{2/\epsilon} = \Theta(m)$.*

*Proof.* Since $p$ is a constant, $q = 1-p$ is also a constant. Let $x$ be the random variable representing the number of successes in $m$ Bernoulli trials, where the success probability is $p$. The expected number of successes $E(x)$ is $mp$ and the standard deviation $\sigma(x) = \sqrt{mpq} \le \sqrt{E(x)}$. Applying this to our case, the expected number of faults $E(x)$ is $mp$. Therefore, applying Chebyshev's inequality, the number of faults does not exceed $(1+\frac{1}{4})pm$ with probability $1 - 16/(p^2E(x)) = 1 - O(1/m)$.

Let $K$ be the set of jobs with multiplicity at most $2/\epsilon$ just before time $t+1$ in $\mathcal{A}$. Applying Lemma 2.1, we know that $|K| \ge n/2 = \epsilon m/2$. Since processors fault independently with probability $p$ just before time $t+1$, the probability that a job $J \in K$ is unfinished at time $t+1$ is $p^{2/\epsilon}$. Moreover, the probability that a job $J \in K$ is unfinished is independent of the probability that some other job is finished. Therefore, the expected number of jobs in $K$ that are not finished at time $t+1$ is at least $F = \frac{\epsilon}{2}mp^{2/\epsilon} = \Theta(m)$. Since the variance is smaller than the expected value, applying Chebyshev's inequality (see Fact 2.11), we get that with probability $1-4/F = 1-O(1/m)$, the number of unfinished jobs just before time $t+2$ is at least $F/2 \ge \frac{\epsilon}{4}mp^{2/\epsilon} = \Theta(m)$. ∎

LEMMA 2.14. *Assume $\lambda \ge m - \frac{m}{\log^* m}$ and $n = \Theta(m)$. Then for every deterministic online algorithm $\mathcal{A}$, the expected number of stages forced by the adversary* OBLIVIOUS-DETER$(m, n, \lambda, 1)$ *on $\mathcal{A}$ is $\Omega(\frac{m}{\eta})$ for the permanent fault case and $\Omega(\frac{\lambda}{m})$ for the transient fault case.*

*Proof.* Notice that the adversary (applying Case 2) faults each working processor independently with probability $1/5$ during the first two stages. So applying Lemma 2.13 twice, we get the following:

- With probability $1-O(1/m)$, the number of faults does not exceed $m/4$ during each of the first two stages.
- With probability $1-O(1/m)$, the number of jobs that cannot be finished before the end of the second stage is $\Omega(m)$.
- With probability $1-O(1/m)$, the number of jobs that cannot be completed before the end of the third stage is $\Omega(m)$.

The desired bound for the permanent fault case follows, since with probability $1-o(1)$, there are exactly $\eta$ working processors and $\Theta(m)$ unfinished jobs just before the end of the third stage. In the transient fault case, just before the end of each of the next $\lfloor(\lambda-m)/m\rfloor$ stages all $m$ processors fault. ∎

THEOREM 2.15. *In the case of identical processors and static release times, the competitive ratio, with respect to makespan, of any randomized clairvoyant algorithm $\mathcal{A}$ is $\Omega(\max(\log^* m - \log^* \frac{m}{\lambda}, \frac{m}{\eta}))$ for $\lambda \ge 1$ permanent faults.*

*Proof.* In the arguments of Lemmas 2.12 and 2.14, we also showed that at least $m/2$ processors are working during the first two stages with probability $1-o(1)$, and hence $OPT = 2$ for these cases. For other cases, $OPT$ is at most the makespan of $\mathcal{A}$. Therefore, $E[\frac{\text{makespan of } \mathcal{A}}{\text{makespan of } OPT}] = \Omega(\max(\log^* m - \log^* \frac{m}{\lambda}, \frac{m}{\eta}))$. Applying Yao's principle (see [3]), it is the case that the competitive ratio (against the oblivious adversary) of an online algorithm is not smaller than $E[\frac{\text{makespan of } \mathcal{A}}{\text{makespan of } OPT}]$. ∎

THEOREM 2.16. *In the case of identical processors and static release times, the competitive ratio, with respect to makespan, of any randomized clairvoyant algorithm $\mathcal{A}$ is $\Omega(\max(\log^* m - \log^* \frac{m}{\lambda}, \frac{\lambda}{m}))$ for $\lambda \geq 1$ transient faults.*

THEOREM 2.17. *In the case of related processors, the optimal randomized competitive ratio, with respect to makespan, is $\Omega(R)$ for $\lambda \geq 1$ permanent faults.*

*Proof.* Once again we use Yao's technique. There are three processors with speed $R$ and $m-3$ processors with speed 1. Initially, two jobs of length $R$ arrive. Just before the end of the first unit length stage, the adversary faults one of the three speed $R$ processors uniformly at random. As a consequence, with probability 1/3 there is an unfinished job at the end of the first stage. Now, at the end of the first stage, the remaining two speed $R$ processors fault. It is not hard to see that $OPT = 1$ and the expected makespan of any online algorithm is $\Omega(R)$. ∎

THEOREM 2.18. *In the case of related processors, the optimal randomized competitive ratio, with respect to makespan, is $\Omega(R \max(\log^* m, \frac{m}{\eta}))$ for $\lambda = \Theta(m)$ permanent faults.*

*Proof.* There are $\lambda/2$ processors with speed $R$ and $m - \lambda/2$ with speed 1. There are exactly $\lambda/4$ jobs of length $R$. Just before the end of the first stage, the adversary faults each of the speed $R$ processors independently with probability 1/3. Applying Lemma 2.13 we get the following:

- With probability $1-O(1/\lambda)$, the number of faults does not exceed $\lambda/4$ during the first stage.
- With probability $1 - O(1/\lambda)$, the number of jobs that cannot be finished before the end of the second stage is $\Omega(\lambda)$.

Since $\lambda = \Theta(m)$, with probability $1 - o(1)$ the number of unfinished jobs at the beginning of the second stage is $n = \Theta(\lambda)$ and at least $\lambda/4$ speed $R$ processors run without fault for one full stage; hence $OPT = 1$. At the end of the first stage, the adversary faults the remaining speed $R$ processors. Notice that $n \leq m$. Now the adversary applies the strategy OBLIVIOUS-DETER$(m-\lambda, \min(n, \lambda/2), \min(n, \lambda/2), R)$. Applying Lemmas 2.12 and 2.14, we get that with probability $1-o(1)$, the competitive ratio is $\Omega(R \cdot \max(\log^* m, \frac{m}{\eta}))$. Otherwise, the competitive ratio is at least 1. We get the desired result since the competitive ratio (against an oblivious adversary) is at least $E[\frac{\text{makespan of } \mathcal{A}}{\text{makespan of } OPT}]$. ∎

## 2.2. Upper bounds for makespan.

We define a randomized algorithm, which we call ROTARY, and analyze its deterministic worst-case performance and expected performance against permanent faults. We assume identical processors throughout this section.

DEFINITION 2.19. *The algorithm* ROTARY *breaks time into stages.*

1. *Let $S_i$ denote the ith stage.*
2. *Let $u(i)$ denote the number of unfinished jobs at the beginning of $S_i$.*
3. *Let $g(i)$ denote the number of working processors at the beginning of $S_i$.*
4. *Let $c(i)$ denote the number of distinct jobs completed during $S_i$.*
5. *Let $f(i)$ denote the number of faults experienced during $S_i$.*
6. *Let $OPT$ be the optimal makespan.*

### 2.2.1. Online algorithm.

ALGORITHM ROTARY. The algorithm divides time into stages. The first stage starts when the first job is released. We maintain the invariant that all working processors are idle at the start of a stage. At the beginning of a stage $S_i$, the algorithm initializes a queue $Q_i$ to contain the collection of jobs that have been released but not finished by the start of $S_i$. The ordering of the jobs in $Q_i$ is arbitrary. The rest of the execution of ROTARY depends on the relationship between $u(i)$ and $g(i)$.

Suppose $u(i) > g(i)$. Whenever a processor $P$ is idle, $P$ removes a job at the front of the queue $Q_i$ and runs it. If $Q_i$ is empty, $P$ remains idle for the rest of this stage. Stage $S_i$ ends at the earliest time such that every job in $Q_i$ has run to completion or has experienced a fault.

Now, suppose $u(i) \leq g(i)$. The algorithm selects uniformly at random an ordering of the $g(i)$ working processors and then assigns jobs to processors in this order. When considering a processor $P$, Rotary assigns $P$ the job $J$ currently at the front of $Q_i$, and then moves $J$ to the back of $Q_i$. No processor is assigned a second job. Stage $S_i$ ends at the earliest time such that every processor has either finished a job or has faulted.

**2.2.2. Basic properties of Rotary.** Note that Rotary often forces a processor to remain idle for the remainder of a stage after having completed a job. This enables us to simplify many of our definitions and proofs. The asymptotic bounds do not change if we allow some arbitrary collection of idle processors to run any unfinished job. Observe that when a new job arrives in the middle of a stage, it will not be added to the queue. It will be considered only during the following stages.

Our first goal is to show that by some reasonable time Rotary has reduced the number of unfinished jobs to $m$.

Fact 2.20. *For all jobs $J_i$, $x_i \leq OPT$.*

Lemma 2.21. Rotary *guarantees that the length of any stage $i$ is at most $(\frac{m}{\eta} + 1)OPT$.*

*Proof.* If $u(i) \leq g(i)$, then, applying Fact 2.20, the length of the stage is at most $OPT$. Suppose $u(i) > g(i)$. Since there are always at least $\eta$ fault-free processors, a simple counting argument shows that for every job $J$ in the queue, some processor must start executing a copy of $J$ by at least time $m \cdot OPT/\eta$ after the start of the stage. Using Fact 2.20, our claim follows. ▯

Lemma 2.22. Rotary *guarantees that there will be at most $m$ jobs left unfinished $(2\frac{m}{\eta} + 2)OPT$ time units after the release of the last job.*

*Proof.* By Lemma 2.21, a new stage $S$ starts no later than $(\frac{m}{\eta} + 1)OPT$ time units after the release of the last job. Since there are at most $m$ faults in stage $S$, at most $m$ jobs are left unfinished after stage $S$, which lasts at most $(\frac{m}{\eta} + 1)OPT$ units of time. ▯

Now we focus our attention on the case where the number of unfinished jobs is at most $m$. Intuitively, we will argue that for a stage in which the multiplicity of a job is not too small and not too many processors fault, the online algorithm makes good progress. On the other hand, we will also argue that there cannot be too many stages with either small multiplicity or too many faults.

Definition 2.23.

1. *Let $\phi(i)$ denote the minimum, over all unfinished jobs $J$ at the start of stage $S_i$, of the number of processors that ran a copy of $J$ in stage $i$.*
2. *Let stage $S_\beta$ be the first stage, after the release of the last job, for which the number of jobs left unfinished at the start of this stage is at most $m$.*
3. *Let $C = \{S_i : i \geq \beta\}$.*
4. *Let $F = \{S_i \in C : \phi(i) \leq 2\}$. $F$ is the set of all stages in $C$ such that the algorithm ran at most two copies of some unfinished job during that stage.*
5. *Let $H = \{S_i \in C - F : f(i) \leq g(i)/4\}$. $H$ is the set of all stages in $C - F$ such that the ratio of the number of working processors to the number of processors experiencing a fault is at least 4.*

LEMMA 2.24. ROTARY *guarantees that the number of copies of any unfinished jobs that are started during $S_i$ is either $\phi(i)$ or $\phi(i)+1$.*

Since $\eta$ processors never experience a fault, for any stage in $F$, at least $\lceil \eta/3 \rceil$ jobs will be completed. Therefore $|F| \le 3\lceil \frac{m}{\eta} \rceil$. On the other hand, we will derive a bound on $|C-F-H|$, since the number of faults in each stage in $C-F-H$ is large.

LEMMA 2.25. ROTARY *guarantees that if the length of a stage $S_i \in F$ is $\alpha \cdot OPT$, then $\lfloor \alpha - 1 \rfloor \le 3c(i)/\eta$.*

*Proof.* Assume that stage $S_i$ finished at time $t$. The last job assignment in this stage cannot be made earlier than time $t - OPT$ by Fact 2.20. Observe that any processor that does not experience a fault during a stage cannot be idle for more than $OPT$ time units. Thus the $\eta$ nonfaulty processors were all running jobs at all times before $t - OPT$, and thus by Fact 2.20 each of these processors must complete at least $\lfloor \alpha - 1 \rfloor$ jobs. Since $S_i \in F$, $\phi(i) \le 2$ and so by applying Lemma 2.24 we conclude that $c(i) \ge \eta \lfloor \alpha - 1 \rfloor / 3$. □

LEMMA 2.26. ROTARY *guarantees that the total length of the stages in $F$ is at most $9\lceil \frac{m}{\eta} \rceil$.*

*Proof.* First observe that $\eta$ nonfaulty processors complete a job in each stage. For a stage in $F$, at most three processors finish the same job. Since the number of jobs in any of the stages in $C$ is at most $m$, $|F| \le 3\lceil \frac{m}{\eta} \rceil$. Let $\alpha_i OPT$ be the length of stage $S_i \in F$. Consider the sum

$$\sum_{S_i \in F} \alpha_i OPT \le OPT \cdot \sum_{S_i \in F} (\lfloor \alpha_i - 1 \rfloor + 2).$$

Applying Lemma 2.25, this sum is at most $OPT \cdot (2|F| + 3\sum_{S_i \in F} c(i)/\eta)$. Applying the bound on $|F|$, the result follows since $\sum_{S_i \in F} c(i) \le m$. □

LEMMA 2.27. ROTARY *guarantees that the length of a stage in $C-F$ is at most $OPT$.*

*Proof.* Suppose $S_i \in C-F$. By the definition of $F$, $\phi(i) > 3$. This can happen only when $u(i) \le g(i)$. Under this situation, according to the description of ROTARY, no processor is assigned a second job during this stage. Applying Fact 2.20, the result follows. □

LEMMA 2.28. ROTARY *guarantees that $|C-F-H|$ is at most $\log_{4/3} \frac{m}{\eta}$.*

*Proof.* Observe that faults are permanent, and that initially there are $m$ working processors. Also, for any stage $S_i \in C-F-H$, $f(i) \ge \frac{1}{4} g(i)$. As a consequence, after $y$ stages in $C-F-H$, the number of remaining working processors is at most $m/(3/4)^y$. The result then follows, since $\eta$ processors never fault. □

LEMMA 2.29. *The cumulative length of the stages not in $H$ is $O(\frac{m}{\eta} OPT)$.*

*Proof.* The result follows from Lemmas 2.22, 2.26, 2.27, and 2.28. □

In order to prove the desired upper bound for ROTARY, it now suffices to prove that the cumulative length of the stages in $H$ is not large. Since $H \subseteq C-F$, by Lemma 2.27 it suffices to show an upper bound on the number of stages in $H$.

**2.2.3. Deterministic bound.** In this subsection, we will analyze the worst-case deterministic performance of ROTARY. We assume that the ordering of the processors in ROTARY is determined by some arbitrary deterministic procedure. We call the resulting algorithm DETERMINISTIC ROTARY.

DEFINITION 2.30. *For $1 \le j \le \lfloor 1 + \log \frac{m}{\eta} \rfloor$,*

1. *let $N_j = \{S_i \in H : m/2^j < g(i) \le m/2^{j-1}\}$;*
2. *let $\lambda_j$ be the total number of faults experienced during stages in $N_j$, i.e., $\lambda_j = \sum_{S_i \in N_j} f(i)$;*

3. *let* $n_j = |N_j|$.

LEMMA 2.31. ROTARY *guarantees that* $\lambda_j \le m/2^{j-1}$.

*Proof.* This follows since faults are permanent and $g(i) \le m/2^{j-1}$ for any stage $S_i \in N_j$. ∎

LEMMA 2.32. DETERMINISTIC ROTARY *guarantees that the cardinality of* $H$ *is* $O(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{m}{\eta}))$.

*Proof.* We say that a stage $S_i \in N_j$ is *good* if $f(i) \le 2\lambda_j/n_j$. By Lemma 2.1 there can be at most $n_j/2$ stages in $N_j$ that are not good. Hence, at least $\frac{1}{2}|H|$ stages in $H$ are good. From now on, we consider only good stages in $H$. Let $k$ be the total number of good stages in $H$.

Consider a good stage $S_i \in N_j$. The algorithm guarantees that $\phi(i) \ge \lfloor g(i)/u(i) \rfloor$. Notice that $H \cap F = \emptyset$. So $S_i \notin F$, and as a consequence $2\phi(i) \ge \phi(i)+1 \ge g(i)/u(i)$. Since $m/2^j < g(i) \le m/2^{j-1}$, we get $\phi(i) \ge m/(2^{j+1}u(i))$.

Since the multiplicity of a job is at least $\phi(i)$, it must be the case that $\phi(i)u(i+1) \le f(i)$. Since $S_i$ is good, $f(i) \le 2\lambda_j/n_j$ and so $u(i+1) \le (\frac{2\lambda_j}{n_j})/\phi(i)$. Now substituting $\phi(i) \ge m/(2^{j+1}u(i))$ into this inequality we get

$$u(i+1) \le u(i)\left(\frac{2\lambda_j}{n_j}\right)\left(\frac{2^{j+1}}{m}\right) = u(i)8\left(\frac{\lambda_j}{n_j}\right)\left(\frac{2^{j-1}}{m}\right). \tag{1}$$

Let $\ell = \lfloor 1 + \log_2 \frac{m}{\eta} \rfloor$. We now measure the progress made by good stages in $H$. We set $u'(i)$ to be equal to $u(x)$, where $S_x$ is the chronologically $i$th good stage. Applying Definition 2.23, the number of unfinished jobs in any stage in $H \subset C$ is at most $m$. Therefore, we have $u'(1) \le m$. Since at least $n_j/2$ stages in $N_j$ are good, applying induction we get

$$u'(k) \le m8^k \prod_{j=1}^{\ell} \left(\frac{\lambda_j}{n_j}\frac{2^{j-1}}{m}\right)^{n_j/2}. \tag{2}$$

Recall that $k$ is the number of good stages in $H$. First assume that $\eta > m/2$. Notice that then $\ell = 1$, $\lambda_1 \le \lambda$, and $k \le n_1 \le 2k$. Observe that $u'(k) \ge 1$; otherwise there will be at most $k-1$ stages. Then (2) implies

$$m8^k\left(\frac{\lambda}{n_1 m}\right)^{k/2} \ge 1 \quad \text{or} \quad \log m \ge \frac{k}{2}\log\left(\frac{n_1 m}{2\lambda}\right) - 3k \ge \frac{k}{2}\log\left(\frac{km}{2\lambda}\right) - 3k.$$

Therefore, $k = O(\frac{\log m}{\log(\frac{k \log k}{\lambda})})$.

We now consider the case that $m/2 \ge \eta \ge m/\log m$. Call an $n_j$ *big* if $n_j \ge k/(2\ell)$. Observe that by Lemma 2.31, $\lambda_j \le \frac{m}{2^{j-1}}$. Notice that the $u'(i)$'s do not increase as we move from one stage to another. As before, applying the fact that $u'(k) \ge 1$, we will show that $k$ is not large. In order to estimate $k$, we consider the rate at which the $u'(i)$'s decrease during a good stage where $n_i$ is *big*. So, applying $u'(k) \ge 1$, we can conclude that

$$m8^k \prod_{\text{big } n_j}\left(\frac{2\ell}{k}\right)^{n_j/2} \ge m8^k \prod_{\text{big } n_j}\left(\frac{\lambda_j}{n_j}\frac{2^{j-1}}{m}\right)^{n_j/2} \ge m8^k \prod_{j=1}^{\ell}\left(\frac{\lambda_j}{n_j}\frac{2^{j-1}}{m}\right)^{n_j/2} \ge 1. \tag{3}$$

In the above expression, the first and the second inequalities follow since $n_j \geq k/(2\ell)$ and for any $j$ in $[1, \ell]$, $\frac{\lambda_j}{n_j}\frac{2^{j-1}}{m} \leq 1$. Notice we can use Lemma 2.1 to show that $\sum_{\text{big } n_j} n_j \geq k/2$. Therefore, (3) implies

$$m8^k \prod_{\text{big } n_j} \left(\frac{2\ell}{k}\right)^{n_j/2} = m8^k \left(\frac{2\ell}{k}\right)^{\sum_{\text{big } n_j} n_j/2} \leq m8^k \left(\frac{2\ell}{k}\right)^{k/4}. \tag{4}$$

As a consequence, we get

$$m8^k \left(\frac{2\ell}{k}\right)^{k/4} \geq 1 \quad \text{or} \quad \frac{k}{4}\log\frac{k}{4\cdot 8^4\ell} \leq \log m. \tag{5}$$

Then by the definition of $\ell$, $\ell = O(\log\log m)$. Then (5) implies $k = O(\log m/\log\log m)$. Note that $\log m/\log\log m = O(\frac{\log m}{\log(\frac{m\log m}{\lambda})})$ if $m/2 \geq \eta \geq m/\log m$.

Now assume $\eta < m/\log m$. Since $\ell = O(k)$, statement (5) implies $k = O(\log m)$. Note that $\log m = O(\frac{m}{\eta})$ for $\eta < m/\log m$. The result follows since $k \geq \frac{1}{2}|H|$. ∎

THEOREM 2.33. *In the case of permanent faults and identical processors, the competitive ratio of* DETERMINISTIC ROTARY *is* $O(\max(\frac{\log m}{\log(\frac{m\log m}{\lambda})}, \frac{m}{\eta}))$ *for makespan.*

*Proof.* The result follows from Lemmas 2.29, 2.32, and 2.27. ∎

**2.2.4. Randomized bound.** We now examine the expected performance of the randomized algorithm ROTARY.

LEMMA 2.34. *The expected number of stages in $H$ for* ROTARY *is* $O(\log^* m - \log^* \frac{m}{\lambda})$.

*Proof.* In the following proof, we will not use the fact that $\lambda \leq m$. As a consequence, this lemma is also true for the transient faults case where $\lambda$ could be significantly larger than $m$. We will appeal to this fact when we discuss transient faults.

Let $S_i$ be a stage in $H$. For $1 \leq j \leq \phi(i)$, let $P_j(i)$ be the set of processors that were assigned a job from the $j$th time through the queue in $S_i$; e.g., the first $u(i)$ processors assigned jobs are in $P_1(i)$. Let $f_j(i)$ be a random variable representing the number of faults experienced by processors in $P_j(i)$ during stage $S_i$. Recall that $f(i)$ is the total number of faults during stage $S_i$.

For $1 \leq a \leq u(i)$, let $x_a$ be a random variable equal to 1 if all copies of the $a$th job starting $S_i$ experience a fault during stage $S_i$, and 0 otherwise. Observe that processors are randomly ordered before they start selecting a job from the queue. As a consequence, the probability that a job $J_a$ is not completed by a processor that selected $J_a$ during the $j$th time through the queue is $\frac{f_j(i)}{u(i)}$. Then

$$E[x_a] = Pr[J_a \text{ not finished during } S_i] \leq \prod_{i=1}^{\phi(i)} \frac{f_j(i)}{u(i)}. \tag{6}$$

For a fixed number $\delta$ of faults during the stage $S_i$ and $a \neq b$, notice that

$$Pr[x_a = 1 \mid x_b = 1,\, f(i) = \delta] \leq Pr[x_a = 1 \mid f(i) = \delta].$$

Therefore, we can conclude that

$$Pr[x_a = 1,\, x_b = 1 \mid f(i) = \delta] \leq Pr[x_a = 1 \mid f(i) = \delta] \cdot Pr[x_b = 1 \mid f(i) = \delta].$$

Since the $x_i$'s are 0/1-random variables, $\text{Cov}[x_a, x_b] = Pr[x_a = 1, x_b = 1] - Pr[x_a = 1] \cdot Pr[x_b = 1]$. As a consequence, for $a \neq b$, the covariance $\text{Cov}[x_a, x_b] \leq 0$. For 0/1-random variables $x_a$ (see [1]),

$$\text{(7)} \qquad \text{Var}\left[\sum_{j=1}^{u(i)} x_j\right] \leq E\left[\sum_{j=1}^{u(i)} x_j\right] + \sum_{a \neq b} \text{Cov}[x_a, x_b].$$

As a consequence, we get

$$\text{(8)} \qquad \text{Var}\left[\sum_{j=1}^{j=u(i)} x_j\right] \leq E\left[\sum_{j=1}^{j=u(i)} x_j\right].$$

The product in (6) is maximum subject to $\sum_{j=1}^{\phi(i)} f_j(i) \leq f(i)$ if each $f_j(i) = f(i)/\phi(i)$. Hence for $1 \leq a \leq u(i)$,

$$\text{(9)} \qquad E[x_a] \leq \prod_{i=1}^{\phi(i)} \frac{f(i)}{u(i)\phi(i)}.$$

Note $u(i)\phi(i) \geq u(i)(\frac{g(i)}{u(i)} - 1)$. Since $S_i \notin F$, it is the case that $u(i) \leq g(i)/2$ and $u(i)(\frac{g(i)}{u(i)} - 1) \geq g(i)/2$. Hence,

$$\text{(10)} \qquad E[x_a] \leq \prod_{i=1}^{\phi(i)} \frac{2f(i)}{g(i)}.$$

Let $k$ be the number of stages in $H$, and let $\alpha$ be the number of faults experienced during stages in $H$. Since $f(i) \leq g(i)/4$ for any $S_i$ in $H$, we have $2f(i)/g(i) \leq 1/2$. Call a stage $S_i \in H$ *good* if $f(i) \leq \frac{2\alpha}{k}$. Using Lemma 2.1 we can show that at least $\frac{1}{2}|H|$ stages in $H$ are good. So, it suffices to find an upper bound on the expected number of good stages in $H$. Let $S_i$ be a good stage under consideration. Hence,

$$\text{(11)} \qquad E[x_a] \leq \left(\min\left(\frac{1}{2}, \frac{4\alpha}{g(i)k}\right)\right)^{\phi(i)} \leq \left(\min\left(\frac{1}{2}, \frac{4\lambda}{g(i)k}\right)\right)^{\phi(i)}$$

and, applying linearity of expectation, we get

$$\text{(12)} \qquad E\left[\sum_{j=1}^{u(i)} x_j\right] = E[u(i+1)] = \sum_{j=1}^{u(i)} E[x_j] \leq u(i)\left(\min\left(\frac{1}{2}, \frac{8\lambda}{g(i)k}\right)\right)^{\phi(i)}.$$

Now, applying (8), we get

$$\text{(13)} \qquad \text{Var}[u(i+1)] \leq u(i)\left(\min\left(\frac{1}{2}, \frac{8\lambda}{g(i)k}\right)\right)^{\phi(i)}.$$

Call a stage $S_i$ in $H$ *unlucky* if $u(i+1) > 3E[u(i+1)]$. Since

$$3u(i)\left(\min\left(\frac{1}{2}, \frac{8\lambda}{g(i)k}\right)\right)^{\phi(i)} \geq 3E[u(i+1)],$$

we have

$$u(i+1) \leq 3u(i)\left(\min\left(\frac{1}{2}, \frac{8\lambda}{g(i)k}\right)\right)^{\phi(i)}$$

for any *lucky* stage. By Chebyshev's inequality, the probability that a stage is *unlucky* is at most $\mathrm{VAR}[u(i+1)]/(2E[u(i+1)])^2 \leq 1/4$. Since at least $k/2$ stages in $H$ are good, with probability $1 - O(1/k)$, at least $k/4$ good stages in $H$ are *lucky*.

Let $k' = \Theta(k)$ be the number of *lucky* stages in $H$. We ignore the progress made by ROTARY during stages in $H$ that are *unlucky*. Suppose stage $x$ is *lucky*. Then

$$u(x+1) \leq 3u(x)\left(\min\left(\frac{1}{2}, \frac{8\lambda}{g(x)k}\right)\right)^{\phi(x)} \leq 3u(x)\left(\min\left(\frac{1}{2}, \frac{8\lambda}{g(x)k}\right)\right)^{\frac{g(x)}{u(x)}}. \tag{14}$$

Since $\phi(x) \leq g(x)/u(x)$, by setting $r(x) = \frac{g(x)}{u(x)}$ and observing that $g(x) \geq g(x+1) = g(x) - f(x) \geq \frac{3}{4}g(x)$ for any stage $S_x \in H$, we get

$$r(x+1) \geq \frac{r(x)}{4}\left(\max\left(2, \frac{g(x)k}{8\lambda}\right)\right)^{r(x)}. \tag{15}$$

Since $r(1) \geq 3$, we have $r(2) \geq 4$. Therefore, for $x \geq 2$

$$r(x+1) \geq \left(\max\left(2, \frac{g(x)k}{8\lambda}\right)\right)^{r(x)}. \tag{16}$$

Observe that for all $i$, $g(i) \geq g(i+1)$ (equality holds in the case of transient faults). If $k'$ is the number of *lucky* stages, then by induction we get

$$r(k) \geq \text{tower}\left(\max\left(2, \frac{g(k)k}{32\lambda}\right), k'-2, r(2)\right).$$

Notice that $r(2) \geq 1$, $r(k) \leq m$, and $k \geq k'$. Notice that the required bound follows if $k \leq 16$. Now consider the case where $k > 16$. Therefore, we get

$$m \geq \text{tower}\left(\max\left(2, \frac{g(k)k}{8\lambda}\right), k'-1, 1\right) \geq \text{tower}\left(2, k'-2, \max\left(2, \frac{g(k)}{\lambda}\right)\right).$$

Taking the $\log^*$ of both sides and applying Lemma 2.9, we get

$$\log^* m \geq k' + \log^*\left(\max\left(2, \frac{g(k)}{\lambda}\right)\right) + O(1).$$

Suppose $\lambda \leq m/3$; then $g(k) \geq 2m/3$ and so $\frac{g(k)}{\lambda} \geq 2$. On the other hand, if $\lambda > m/3$, we have that $\max(2, \frac{g(k)}{\lambda})$ is in the range $[2, 3]$. Hence, the expected number of stages in $H$ is $O(\log^* m - \log^*(\frac{m}{\lambda}))$. □

THEOREM 2.35. *The competitive ratio of* ROTARY *is* $O(\max(\log^* m - \log^* \frac{m}{\lambda}, \frac{m}{\eta}))$.

*Proof.* The result follows from Lemmas 2.29 and 2.34. □

## 3. Average completion time.

We present a nonclairvoyant deterministic algorithm that is $O(\frac{m}{\eta})$-competitive with respect to average completion time. We then show that every randomized algorithm for this problem has a competitive ratio, with respect to average completion time, that is, $\Omega(R\frac{m}{\eta})$. We assume static release times and $m$ identical processors and consider only permanent faults. We also assume that we have a lower bound of 1 on the length of any task. This is not an unreasonable restriction since we could take our unit of length to be the time to execute one instruction on the fastest processor.

**3.1. Online algorithm.** Geometric Rotary. The algorithm consists of stages. Stage $S_0$ starts when all the jobs are released. Let $u(i)$ denote the number of jobs that have not yet been run to completion at the start of stage $S_i$. We call $S_i$ *full* if $u(i) \geq 2m$.

We now define the stage $S_i$. We first form a queue $Q$ of unfinished jobs. For a full stage, we add exactly one copy of each of the $u(i)$ jobs to the queue. In the case of a stage that is not full, we add $\lceil 2m/u(i) \rceil$ copies of each of these $u(i)$ jobs to $Q$.

During the stage when a processor $P$ becomes idle, the next job $J$ on $Q$ is removed from $Q$ and run from its beginning on $P$ until one of the following three conditions holds:

(a) job $J$ is completed, or
(b) $P$ ran $J$ for $2^i$ time units without completion, or
(c) a fault occurs while $P$ is processing $J$.

If case (a) occurs, $P$ immediately attempts to get another job from $Q$. If case (b) occurs, $P$ suspends $J$ and then immediately attempts to get another job from $Q$. If $Q$ is empty, $P$ idles until the end of the stage. Stage $S_i$ ends when all processors are idle and $Q$ is empty.

**3.2. Analysis.**

Fact 3.1. *Suppose that* $n$ *jobs of length* $\ell_1, \ell_2, \ldots, \ell_n$ *arrive at time* 0. *Let* $\ell_i \leq \ell_j$ *for* $1 \leq i \leq j \leq n$. *The optimal offline average completion time on a single unit speed processor is* $\frac{1}{n}\sum_{i=1}^{n}(n-i+1)\ell_i$.

First notice that doubling the size of jobs only doubles the average offline optimal completion time. This also holds for the multiprocessor case since the shortest processing time algorithm is optimal. So, for the purpose of our analysis, let us assume that we round the execution time of each job up to the next highest integer power of 2. Then for every job, if the length of the job is $\ell = 2^i$, we assume that its length is $2\ell$ (which may be up to 4 times its original length) when we calculate the optimal total completion time. We do so for the ease of analysis, and it is important to observe that the competitive ratio will be off by a factor of at most 2. This doubling idea has been used before; see, for example, [10].

Observe that Geometric Rotary "estimates" the length of a job by running it for a duration of at most $2^i$ during the $i$th stage. Based on this estimated length, we calculate a lower bound on the completion time for the offline optimal algorithm. As we move from one stage to another, the estimated lower bound increases due to an increase in the estimated length of some jobs from $2^i$ to $2^{i+1}$.

We use the terminology "increase in completion time experienced by Geometric Rotary during $S_i$" to mean the sum over all jobs $J$ of the portion of the competition time for $J$ that occurs during stage $S_i$.

At the beginning of a stage $S_i$, the estimated length of an unfinished job is $2^i$. Assuming that this estimated length is correct, one can compute the optimal total completion time. At the end of the stage $S_i$, Geometric Rotary will increase the estimated length of some unfinished jobs to $2^{i+1}$. As a consequence of this increase in estimated lengths of some jobs, there will be an increase in our lower bound of the optimal total competition time. This is what we call the "increase in the estimated lower bound on the completion time of the offline algorithm during a stage."

We will now compare the increase in completion time experienced by Geometric Rotary during $S_i$ to the corresponding increase in the estimated lower bound on the completion time of the offline optimal algorithm during this stage.

LEMMA 3.2. *If we have $k$ jobs of length $x$ to be run on $p$ processors, then every schedule (that doesn't unnecessarily idle the processors) is optimal and has total completion time*

$$\sum_{i=1}^{\lfloor k/p \rfloor} ipx + (k \bmod p)\lceil k/p \rceil x = \lfloor k/p \rfloor(\lfloor k/p \rfloor + 1)px/2 + (k \bmod p)\lceil k/p \rceil x.$$

*Proof.* The $i$th term in the sum represents the sum of completion times of the $i$th jobs executed on each of the $p$ processors. ∎

LEMMA 3.3. *If $S_i$ is full, then* GEOMETRIC ROTARY *guarantees that the increase in the total completion time experienced during $S_i$ is at most $2^{i+1}u(i)^2/\eta$.*

*Proof.* Since processors work in parallel, more processors imply less increase in completion time. At least $\eta$ processors work without fault during this stage. The increase in the completion time is maximized if we have only $\eta$ working processors. Thus the length of $S_i$ is at most $2^i\lceil u(i)/\eta \rceil \leq 2^{i+1}u(i)/\eta$. If all jobs are delayed this amount, then the increase in total completion time is $2^{i+1}u(i)^2/\eta$. ∎

LEMMA 3.4. *If $S_i$ is not full, then* GEOMETRIC ROTARY *guarantees that the increase in total completion time experienced during $S_i$ is at most $5u(i)m2^i/\eta$.*

*Proof.* The length of $S_i$ is at most $2^i\lceil u(i)\lceil 2m/u(i) \rceil/\eta \rceil \leq 2^i\lceil 4m/\eta \rceil \leq 5m2^i/\eta$. Since at most $u(i)$ jobs are delayed by this amount, we get the desired bound. ∎

LEMMA 3.5. *Assume we double the length of $k$ jobs from $x$ to $2x$.*

(a) *If $k \geq m$, then the increase in the offline optimal total completion time is at least $k^2x/8m$.*

(b) *If $k < m$, then the increase in the offline optimal total completion time is at least $kx$.*

*Proof.* Consider only the time required to run the additional $x$ units of each job. By Lemma 3.2 this is $\lfloor k/m \rfloor(\lfloor k/m \rfloor + 1)mx/2 + (k \bmod m)\lceil k/m \rceil x$. Suppose $k \geq m$; substituting $\lfloor k/m \rfloor \geq k/2m$ we get the desired result. If $k < m$, we get the desired bound since $(k \bmod m)\lceil k/m \rceil x = kx$. ∎

LEMMA 3.6. *In every stage $S_i$,* GEOMETRIC ROTARY *guarantees that at least half of the $u(i)$ jobs have at least one copy run the full $2^i$ time units on some processor.*

*Proof.* Recall our assumption that the length of a job is a power of 2. If $S_i$ is full, then this follows because there are at most $m$ faults. If $S_i$ is not full, then the number of jobs that can have all copies experience faults is at most $m/\lceil 2m/u(i) \rceil \leq u(i)/2$. ∎

THEOREM 3.7. *Given static release times,* GEOMETRIC ROTARY *is $O(\frac{m}{\eta})$-competitive, with respect to average completion time, for $\lambda = m - \eta$ permanent faults.*

*Proof.* For stage $S_i$, Lemma 3.6 shows that GEOMETRIC ROTARY runs at least half the jobs for their full $2^i$ time slice. Also, recall our assumption that whenever GEOMETRIC ROTARY runs and completes a job $J$ of length $2^i$, the length of $J$ for the adversary is $2^{i+1}$, and so $J$ can be considered as a job whose length increases from $2^i$ to $2^{i+1}$ when we apply Lemma 3.5. As a consequence, when we apply Lemma 3.5, we can set $k \geq u(i)/2$.

Suppose $u(i) \geq 2m$. Lemmas 3.3 and 3.5 show that the ratio of the increase in the completion time experienced by GEOMETRIC ROTARY and the optimal offline algorithm is at most $\frac{2^{i+1}u(i)^2/\eta}{k^2 2^i/8m}$, where $k \geq u(i)/2 \geq m$. Therefore, the ratio is at most $64m/\eta$.

Suppose $m \leq u(i) < 2m$. Lemmas 3.4 and 3.5 show that the ratio of the increase in the completion time experienced by GEOMETRIC ROTARY and the optimal offline algorithm is at most $\frac{5u(i)m2^i/\eta}{k^2 2^i/8m} \leq \frac{160m^2}{u(i)\eta} \leq 160m/\eta$.

Finally, suppose $u(i) < m$. Lemmas 3.4 and 3.5 show that the ratio of the increase in the completion time experienced by Geometric Rotary and the optimal offline algorithm is at most $10m/\eta$. ∎

Theorem 3.8. *With static release times and related processors, every randomized algorithm is $\Omega(R\frac{m}{\eta})$-competitive with respect to average completion time.*

*Proof.* Using Yao's technique [12], it suffices to bound the expected competitive ratio of any deterministic algorithm where the occurrence of fault is selected from some fixed probability distribution.

First we assume that $\lambda \leq m/2$. The desired lower bound is $\Omega(R)$. There are three processors with speed $R$ and $m - 3$ processors with speed 1. Initially, two jobs of length $R$ arrive. Just before the end of the first unit length stage, the adversary faults one of the three speed $R$ processors uniformly at random. As a consequence, with probability 1/3 there is an unfinished job at the end of the first stage. Now, at the end of the first stage, the remaining two speed $R$ processors fault. One can see that $OPT = 1$, and that the expected completion time of any online algorithm is $\Omega(R)$.

We now assume that $\lambda > m/2$. There are $\lambda$ processors with speed $R$ and $m - \lambda$ with speed 1. There are exactly $\lambda/2$ jobs of length $R$. Just before the end of the first stage, the adversary faults each of the speed $R$ processor independently with probability 1/3. Applying Lemma 2.13 we get the following:

- With probability $1 - O(1/\lambda)$, the number of faults does not exceed $\lambda/2$ before the end of the first stage.
- With probability $1 - O(1/\lambda)$, the number of jobs that cannot be finished before the end of the second stage is $\Omega(\lambda)$.

Since $\lambda > m/2$, with probability $1 - o(1)$, the number of unfinished jobs at the beginning of the second stage is $\Theta(\lambda)$ and at least $\lambda/2$ speed $R$ processors ran without fault for one full stage (and so $OPT = 1$).

At the end of the first stage, the adversary faults the remaining speed $R$ processors. Now there are $\eta = m - \lambda$ unit speed processors, $x = \Theta(\lambda)$ unfinished jobs of length $R$. Therefore, the total completion time for any deterministic online algorithm is at least

$$\sum_{i=1}^{\lfloor x/\eta \rfloor} Ri\eta = \Theta\left(\frac{R\lambda^2}{\eta}\right)$$

with probability $1 - o(1)$. Note that for the case under consideration, the number of jobs is $\Theta(\lambda)$ and $\lambda = \Theta(m)$. Therefore average completion time is $\Omega(R\frac{m}{\eta})$. The result follows since the competitive ratio (against oblivious adversary) is at least $E[\frac{\text{makespan of } \mathcal{A}}{\text{makespan of } OPT}]$. ∎

**4. Transient faults.** In this section we analyze the effect of transient faults, which by definition have duration 0. Here $\lambda$ denotes the total number of faults. Note that it is possible for the number of faults $\lambda$ to exceed $m$. We assume identical processors. The lower bound for makespan with transient faults was handled in section 2.1, so we begin with the upper bound for makespan.

We modify Rotary to immediately end a stage $S$; i.e., every processor suspends its current job if more than $m/2$ faults occur during this stage. We call the new algorithm Transient Rotary. Analogously, we also modify Deterministic Rotary and call this new algorithm Deterministic Transient Rotary. Because of the great similarity with the case of permanent faults, we will be brief in our discussion. Recall Definitions 2.19 and 2.23. Note that $g(i) = m$ for all $i$.

LEMMA 4.1. TRANSIENT ROTARY *guarantees that the length of any stage is at most* $O(OPT)$.

*Proof.* The proof is analogous to that of Lemma 2.21. It is important to observe that all $m$ (instead of at least $\eta$) processors are available at the start of the stage. Also at least $m/2$ (instead of $\eta$) processors are working throughout a stage. ☐

LEMMA 4.2. TRANSIENT ROTARY *guarantees that the total number of stages* $S_i$ *where* $f(i) \geq \frac{m}{4}$ *is at most* $\frac{4\lambda}{m} = O(\frac{\lambda}{m})$.

*Proof.* If more than $\frac{4\lambda}{m}$ stages have $\frac{m}{4}$ or more faults each, then the total number of faults will exceed $\lambda$. ☐

LEMMA 4.3. TRANSIENT ROTARY *guarantees that there will be at most* $m/4$ *jobs left unfinished after* $O(\frac{\lambda}{m})$ *stages starting from the arrival of the last job.*

*Proof.* After the arrival of the last job, consider a stage with total number of faults less than $m/4$. Clearly, there are at most $m/4$ unfinished jobs after this stage. Applying Lemmas 4.1 and 4.2, we get the desired result. ☐

THEOREM 4.4. *The competitive ratio, with respect to makespan, of* DETERMINISTIC TRANSIENT ROTARY *is* $O(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{\lambda}{m}))$ *for* $\lambda$ *transient faults.*

*Proof.* Given the previous three lemmas, it suffices to bound $|H|$. We ignore the progress made by the online algorithm on stages that are not in $H$. Let $H = \{S_1, S_2, \ldots, S_k\}$. For $1 \leq i \leq k$, the algorithm guarantees that $\phi(i) \geq \lfloor \frac{m}{u(i)} \rfloor$ and $u(i+1) \leq f(i)/\phi(i)$. Therefore, $u(i+1) \leq 2u(i)f(i)/m$. We say that a stage in $H$ is *good* if $f(i) \leq 2\lambda/k$. By Lemma 2.1 at least $|H|/2$ stages are good. Suppose $8\lambda/k \geq m$; then $k \leq 8\lambda/m$ and so the result follows. From now on consider the case $2\lambda/k < m/4$. So for a good stage $S_i$ we have $u(i+1) \leq \frac{4\lambda}{km} u(i)$. Proceeding as in the proof of Lemma 2.32, we are left solving the inequality $m \geq k \log \frac{km}{4\lambda}$ for $k$, which yields the fact that $k = O(\frac{\log m}{\log(\frac{m \log m}{\lambda})})$. ☐

THEOREM 4.5. *The competitive ratio, with respect to makespan, of* TRANSIENT ROTARY *is* $O(\max(\log^* m - \log^* \frac{m}{\lambda}, \frac{\lambda}{m}))$ *for* $\lambda$ *transient faults.*

*Proof.* Given the three previous lemmas, it suffices to show that $|H| = O(\max(\log^* m - \log^* \frac{m}{\lambda}, \frac{\lambda}{m}))$. Observe the fact that all $m$ processors are available at the start of each stage. That is, for all $i$, $g(i) = m$ in the proof of Lemma 2.34. The result follows from Lemma 2.34. ☐

As in the case of ROTARY, we modify GEOMETRIC ROTARY to repeat a stage if it experiences more than $m/2$ faults during that stage. Call the new algorithm TRANSIENT GEOMETRIC ROTARY.

THEOREM 4.6. *For static release times, the competitive ratio, with respect to average completion time, of* GEOMETRIC TRANSIENT ROTARY *is* $O(\max(1, \lambda/m))$ *for* $\lambda$ *transient faults.*

*Proof.* Notice that the increase in the completion time experienced by GEOMETRIC TRANSIENT ROTARY during a stage is at most the total completion time of the optimal offline algorithm. There can be at most $2\lambda/m$ stages that experience more than $m/2$ faults. For a stage that experiences fewer than $m/2$ faults, we can apply the analysis found in the permanent fault case where $\eta \geq m/2$. The result then follows. ☐

**5. No redundancy.** In this section we look at the effect of not allowing more than one copy of a job to be run at any one time. We consider only the case of identical processors. We first show that deterministic algorithms can have very high competitive ratios.

THEOREM 5.1. *If no redundancy is allowed, then the competitive ratio with respect to makespan and with respect to average completion time is $\Omega(\lambda)$ for $\lambda$ permanent faults or $\lambda$ transient faults in a system of identical processors.*

*Proof.* Assume that we have one job $J$. Allow a processor to run $J$ and fault it just before it is ready to complete the job. This process can be repeated $\lambda$ times. ∎

We say that an online algorithm $\mathcal{A}$ is *stage-based* if

1. the time spent by $\mathcal{A}$ is partitioned into stages;
2. at the start of each stage, all of the working processors are idle;
3. jobs considered for execution during a stage are exactly those that are released before the start of the stage;
4. it is possible to determine, at the start of the stage, the number of copies of each job that will be run during the stage;
5. the multiplicities of any two jobs during a stage differ by at most 1.

LEMMA 5.2. ROTARY, TRANSIENT ROTARY, GEOMETRIC ROTARY, *and* GEOMETRIC TRANSIENT ROTARY *are stage-based algorithms.*

For any *stage-based* deterministic algorithm $\mathcal{A}$, we define a randomized algorithm ONE-COPY-$\mathcal{A}$ that does not run multiple copies of a job simultaneously. At the start of a stage $S$, assume that $\mathcal{A}$ plans to run $k$ copies of a job $J_i$ during $S$. ONE-COPY-$\mathcal{A}$ selects an integer uniformly at random from the range 1 to $k$ inclusive, and assigns it to a variable $\alpha_i$. ONE-COPY-$\mathcal{A}$ then simulates $\mathcal{A}$ and when $\mathcal{A}$ makes the $\alpha_i$th assignment of $J_i$, ONE-COPY-$\mathcal{A}$ makes its only assignment of $J_i$ during this stage. The following lemma is the key to analyzing ONE-COPY-$\mathcal{A}$.

LEMMA 5.3. *Let $\mathcal{A}$ be a deterministic* stage-based *online algorithm that starts a stage $S_i$ with $u(i)$ jobs. Assume that for any pattern of $f(i)$ faults during this stage, $\mathcal{A}$ guarantees that at most $u'(i)$ jobs are unfinished at the end of the stage. Then the expected number of unfinished jobs by* ONE-COPY-$\mathcal{A}$ *is $O(u'(i))$ and the variance of the number of unfinished jobs is not greater than the expected value.*

*Proof.* Let $\mathcal{J} = \{J_1, J_2, \ldots, J_{u(i)}\}$ be the set of unfinished jobs at the start of the stage $S_i$. Let $\phi(J_j)$ be the number of copies of a job $J_j \in \mathcal{J}$ run by $\mathcal{A}$ in this stage. Without loss of generality, let $0 < \phi(J_a) \leq \phi(J_b)$ for $1 \leq a \leq b \leq u$. Let $x_a = 1$ if $J_a$ is not finished by ONE-COPY-$\mathcal{A}$ during the stage, and let $x_a = 0$ otherwise. Let $x = \sum_{i=1}^{u} x_a$ denote the number of jobs that are not completed during the stage by ONE-COPY-$\mathcal{A}$. Let $f_j(i)$ be the number of processors experiencing a fault while running a copy of $J_j$ using algorithm $\mathcal{A}$. First,

$$E[x] = \sum_{j=1}^{u(i)} E[x_j] = \sum_{j=1}^{u(i)} \frac{f_j(i)}{\phi(J_j)} \leq \sum_{j=1}^{u(i)} \frac{f_j(i)}{\phi(J_1)}.$$

Note that since in the worst case the adversary for $\mathcal{A}$ will fault all the low multiplicity jobs,

$$\sum_{j=1}^{u'(i)+1} \phi(J_j) > f(i) = \sum_{j=1}^{u(i)} f_j(i).$$

Since the multiplicity of each job is at most $\phi(J_1) + 1$, we get that

$$E[x] \leq \frac{1}{\phi(J_1)} \sum_{j=1}^{u(i)} f_j(i) \leq \frac{1}{\phi(J_1)} \sum_{j=1}^{u'(i)+1} \phi(J_j) \leq \frac{1+\phi(J_1)}{\phi(J_1)}(u'(i)+1) \leq 4u'(i).$$

For fixed $f_j(i)$'s, the $x_j$'s are independent. As a consequence, the variance of $x$ (the sum of 0/1-random variables) does not exceed the expected value of $x$. $\square$

THEOREM 5.4. *The randomized competitive ratio, with respect to makespan, of the algorithm* ONE-COPY-DETERMINISTIC ROTARY *is* $O(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{m}{\eta}))$ *for permanent faults and* $O(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{\lambda}{m}))$ *for transient faults in a system of identical processors.*

*Proof.* The analysis is analogous to the analysis of ROTARY. The major difference is in applying the proof of Lemma 2.34, which establishes a bound on $H$.

Of course, the bound we wish to establish is different from the one proved in Lemma 2.34. The recurrence relation established in (14) will be different in the current proof. We continue to follow the notation established in the proofs of Lemmas 5.3 and 2.34. Notice that $E(x) \leq \frac{1}{\phi(J_1)} f(i)$. Let $g(i)$ be the number of processors that did not experience a fault during the $i$th stage (i.e., $S_i$). Notice that $g(i)/u(i) \geq \phi(J_1) \geq \lfloor g(i)/u(i) \rfloor \geq 3$. As a consequence, $E(x) \leq \epsilon u(i) \frac{f(i)}{g(i)}$, where $\epsilon < 3/2$.

Recall that a stage $S_i \in H$ is defined to be *good* (in the proof of Lemma 2.34) if $f(i) \leq 2\alpha/k \leq 2\lambda/k$. We define a stage to be *unlucky* if $u(i+1) > 2E[u(i+1)]$. Therefore, at the end of a *lucky* stage $u(i+1) \leq 2\epsilon u(i) \frac{f(i)}{g(i)}$. Therefore, $u(i+1) \leq 2\epsilon u(i) \left(\min(\frac{1}{4}, \frac{4\lambda}{kg(i)})\right)$.

As before, at least $k/2$ stages in $H$ are *lucky*. Consider the rate at which the $u(i)$'s decrease on *lucky* stages. Applying the fact that $u(1) \leq m$ and $u(k) \geq 1$, we get $1 \leq u(k) \leq u(1)[2\epsilon \min(\frac{1}{4}, \frac{4\lambda}{kg(k)})]^{k/2}$. Solving for $k$ we get $k = \frac{\log m}{\log(\frac{m \log m}{\lambda})}$. $\square$

THEOREM 5.5. *If no redundancy is allowed, then the optimal randomized competitive ratio, with respect to makespan, is* $\Omega(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{m}{\eta}))$ *for permanent faults and* $\Omega(\max(\frac{\log m}{\log(\frac{m \log m}{\lambda})}, \frac{\lambda}{m}))$ *for transient faults in a system of identical processors.*

*Proof.* We convert DETERMINISTIC-DETER$(m, m, \lambda, 1, \mathcal{A})$ into a randomized adversary by selecting the faults in each stage uniformly at random among all working processors.

Suppose $\lambda \leq m - \frac{m \log \log m}{\log m}$. Therefore, case 1 of the adversary applies. Let $u(i)$ be a random variable that represents the number of unfinished jobs at the start of the $i$th stage. Since $\lambda/\log m$ processors are chosen uniformly at random, the probability that a given processor experiences a fault during this stage is at least $\frac{\lambda}{m \log m}$. Therefore $E[u(i+1)] \geq u(i) \frac{\lambda}{m \log m}$ and $\text{VAR}[u(i+1)] \leq E[u(i+1)]$.

Let $k$ be an integer such that $E[u(k)] > \sqrt{m}$ and $E[u(k+1)] \leq \sqrt{m}$. We now argue that with probability $1 - o(1)$, $k = \Omega(\frac{\log m}{\log(\frac{m \log m}{\lambda})})$. As in the proof of Lemma 2.14, we define a stage $i$ to be *good* if $|u(i+1) - E[u(i+1)]| \leq E[u(i+1)]/2$. Applying Chebyshev's inequality, with probability $\sum_{i=1}^{x} \frac{4}{E[(u(i+1)]} \leq \frac{4x}{\sqrt{m}}$, we have $|u(i+1) - E[u(i+1)]| \leq \frac{1}{2} E[u(i+1)]$ for all $i$ in the range 1 through $x$ $(\leq k)$. Substituting $u(1) = m$, we get $u(i+1) \geq \frac{u(i)}{2} \frac{\lambda}{m \log m} \geq m(\frac{\lambda}{2m \log m})^i$. Since $u(k+1) \leq \sqrt{m}/2$, we get $k = \Omega(\frac{\log m}{\log(\frac{m \log m}{\lambda})})$. The result follows since $OPT$ is $O(1)$.

Now, suppose $\lambda > m - \frac{m \log \log m}{\log m}$. Notice that during the first two stages, the probability that a working processor faults is $\Theta(1)$. Therefore with probability $1 - o(1)$, $\Theta(m)$ jobs will not be completed at the end of the second stage. The desired bound for the permanent fault case follows, since there are exactly $\eta$ working processors and $\Theta(m)$ unfinished jobs. On the other hand, in the case of transient faults, no progress is made for the next $\lfloor (\lambda - m)/m \rfloor$ stages since all $m$ processors fault just before the end of each of those stages. The result then follows. Note that the analysis is analogous to that in the proof of Lemma 2.4. □

THEOREM 5.6. *If no redundancy is allowed, then the optimal randomized competitive ratio, with respect to average completion time, is* $\Theta(\max(\frac{m}{\eta}, 1))$ *for permanent faults.*

*Proof.* The lower bound follows from Theorem 3.8. Applying Lemma 5.3, one can use the analysis of GEOMETRIC ROTARY to get the desired bound. □

**Acknowledgments.** We thank Taieb Znati for pointing out to us the need for a theoretical analysis of fault tolerant scheduling. We also thank Joel Wein, Sundar Vishwanathan, Sunondo Ghosh, and Daniel Mossé for helpful discussions. Finally, we would like to thank the referees for many useful comments and suggestions.

# CLASSIFYING THE COMPLEXITY OF CONSTRAINTS USING FINITE ALGEBRAS[*]

ANDREI BULATOV[†], PETER JEAVONS[‡], AND ANDREI KROKHIN[§]

**Abstract.** Many natural combinatorial problems can be expressed as constraint satisfaction problems. This class of problems is known to be **NP**-complete in general, but certain restrictions on the form of the constraints can ensure tractability. Here we show that any set of relations used to specify the allowed forms of constraints can be associated with a finite universal algebra and we explore how the computational complexity of the corresponding constraint satisfaction problem is connected to the properties of this algebra. Hence, we completely translate the problem of classifying the complexity of restricted constraint satisfaction problems into the language of universal algebra.

We introduce a notion of "tractable algebra," and investigate how the tractability of an algebra relates to the tractability of the smaller algebras which may be derived from it, including its subalgebras and homomorphic images. This allows us to reduce significantly the types of algebras which need to be classified. Using our results we also show that if the decision problem associated with a given collection of constraint types can be solved efficiently, then so can the corresponding search problem. We then classify all finite strictly simple surjective algebras with respect to tractability, obtaining a dichotomy theorem which generalizes Schaefer's dichotomy for the generalized satisfiability problem. Finally, we suggest a possible general algebraic criterion for distinguishing the tractable and intractable cases of the constraint satisfaction problem.

## 1. Introduction.

In a *constraint satisfaction problem* the aim is to find an assignment of values to a given set of variables, subject to *constraints* on the values which can be assigned simultaneously to certain specified subsets of the variables [39, 43]. One common example of such a problem is the standard propositional satisfiability problem [21], where the variables must be assigned Boolean values and the constraints are specified by clauses.

The mathematical framework used to describe constraint satisfaction problems has strong links with many other areas of computer science and mathematics. For example, links with relational database theory [22, 23, 34], with some notions of logic and group theory [1, 18, 20], and with universal algebra [31] have been investigated. There is an early survey of these results in [46].

Throughout the paper we assume that $\mathbf{P} \neq \mathbf{NP}$, and we call a problem *tractable* only if it belongs to $\mathbf{P}$. The constraint satisfaction problem is known to be **NP**-hard in general [39, 43]. However, certain restrictions on the form of the constraints have been shown to ensure tractability [8, 10, 30, 32, 33, 56].

One fundamental open research problem in this area is to characterize exactly the forms of constraint relations that give rise to tractable problem classes. This problem is important from a theoretical perspective, as it helps to clarify the boundary

between tractability and intractability in a wide range of combinatorial search problems. It is also important from a practical perspective, as it allows the development of constraint programming languages that exploit the existence of diverse families of tractable constraints to provide more efficient solution techniques [38, 50].

The problem of characterizing the tractable cases was completely solved for the important special case of Boolean constraint satisfaction problems by Schaefer in 1978 [52]. Schaefer established that for Boolean constraint satisfaction problems (which he called "generalized satisfiability problems"), there are exactly six different families of tractable constraints, and any problem involving constraints not contained in one of these six families is **NP**-complete. This important result is known as Schaefer's dichotomy theorem. Similar dichotomy results have also been obtained for other combinatorial problems over a Boolean domain that are related to the Boolean constraint satisfaction problem [11].

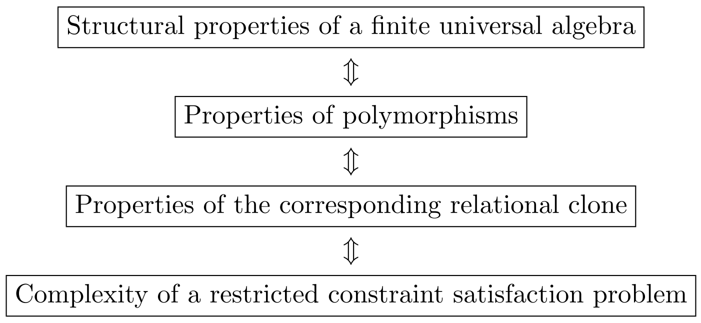
Schaefer [52] raised the question of how the analysis of complexity could be extended to larger sets of possible values (that is, sets with more than two elements). Some progress has been made with this question recently, and a number of tractable families of constraints have been identified, over both finite and infinite sets. In particular, Feder and Vardi [20] used techniques from logic programming and group theory to identify three broad families of tractable constraints, which include all of Schaefer's six classes. A series of papers by Jeavons and coauthors has shown that any individual tractable constraint class over a finite domain can be characterized using algebraic properties of relations [28, 29, 30, 32]. This approach was used by Bulatov to obtain a complete classification for the complexity of constraints on a three-element set [3]. Finally, we note that for temporal and spatial reasoning problems involving constraints over infinite sets of values, several tractable constraint classes have been identified [17, 44, 51], and a dichotomy theorem has been obtained for qualitative temporal reasoning problems over intervals expressed using Allen's interval algebra [35]. It has also been shown recently that the complexity of certain forms of constraint over infinite sets of values can be analyzed using algebraic properties [2].

However, there is still no complete classification for the complexity of constraints over finite sets with more than three elements, and no dichotomy has so far been established for arbitrary finite sets.

In our opinion, the main difficulty in addressing this question is the lack of a powerful and convenient language in which the properties of constraint satisfaction problems responsible for complexity can be expressed. Schaefer's dichotomy theorem is stated in terms of the syntactic properties of propositional forms, which is certainly not an appropriate language for non-Boolean constraints. A number of different attempts have been made to find such an appropriate language [13, 14, 20, 28, 30]; we believe that the most fruitful of these is the one that uses the algebraic properties of constraints [28, 30].

The first step in the algebraic approach exploits the well-known idea that, given an initial set of constraint relations, there will often be further relations that can be added to the set without changing the complexity of the associated problem class. In fact, it has been shown that it is possible to add all the relations that can be derived from the initial relations using certain simple rules. The larger sets of relations obtained using these rules are known as *relational clones* [16, 48]. Hence the first step in the analysis is to note that it is sufficient to analyze the complexity only for those sets of relations which are relational clones.

The next step in the algebraic approach is to note that relational clones can be characterized by their *polymorphisms*, which are algebraic *operations* on the same



Structural properties of a finite universal algebra
Properties of polymorphisms
Properties of the corresponding relational clone
Complexity of a restricted constraint satisfaction problem

FIG. 1.1. *Translating questions about the complexity of different forms of constraints into questions about the properties of algebras.*

underlying set [27, 30]. As well as providing a convenient and concise method for describing large families of relations, the polymorphisms also reflect certain aspects of the structure of the relations that can be used for designing efficient algorithms. This link between relational clones and polymorphisms has already played a key role in identifying many tractable constraint classes and developing appropriate efficient solution algorithms for them [3, 4, 6, 7, 12, 28].

However, as we shall see later on in this paper, working directly with the polymorphisms of a set of relations is sometimes not the most convenient and powerful way to investigate the complexity of the corresponding constraint satisfaction problems. In this paper we take the algebraic approach one step further by linking constraint satisfaction problems with finite universal algebras (see Figure 1.1). We show that the language of finite algebras provides a number of very powerful new tools for analyzing the complexity of constraint problems. In particular, using this language allows us to suggest a simple criterion for distinguishing tractable and intractable cases. This criterion makes extensive use of notions related to universal algebras, and is difficult to formulate concisely without using this language. Another advantage of this new translation is that it allows us to make use of the deep structural results developed for classifying the structure of finite algebras [25, 42, 53].

As the first fruit of using this machinery we exhibit a new dichotomy theorem for a class of algebras which properly includes all the two-element algebras, and hence provide a true generalization of Schaefer's dichotomy theorem.

The paper is organized as follows. In section 2 we define the class of constraint satisfaction problems we are considering, where the constraints are chosen from a specified set of relations. Then we define the way in which these sets of relations can be classified according to the complexity of the corresponding constraint satisfaction problems. We show how this question can be translated into an equivalent question about relational clones, and hence further translated into a question about classifying sets of operations. In section 3 we make the new step from sets of operations to finite algebras, which is the real focus of this paper. Using this final translation we introduce the notion of a tractable algebra. We are then able to restate Schaefer's dichotomy theorem in a much shorter and possibly clearer form, as a classification of two-element algebras with respect to tractability. In section 4 we prove that, in this context, it suffices to consider certain restricted classes of algebras. As a by-product we show that, if the decision problem for a set of constraint types can be solved efficiently, then so can the corresponding search problem. In section 5 we study how the tractability of a finite algebra relates to the tractability of its smaller derived algebras. In section 6 we use the results obtained to classify all strictly simple surjective algebras. Finally, in section 7, we use the new algebraic terminology to state a conjecture about the general structure of tractable algebras, and provide examples to illustrate and support this conjecture.

## 2. Definitions and earlier results.

### 2.1. Constraint satisfaction problems.

The central notion in the study of constraints and constraint satisfaction problems is the notion of a *relation*.

DEFINITION 2.1. *For any set $A$, and any natural number $n$, the set of all $n$-tuples of elements of $A$ is denoted by $A^n$. Any subset of $A^n$ is called an $n$-ary* relation *over $A$. The set of all finitary relations over $A$ is denoted by $R_A$. A* constraint language *over $A$ is a subset of $R_A$.*

The "constraint satisfaction problem" was introduced by Montanari [43] in 1974 and has been widely studied [15, 20, 36, 39, 40, 41]. In this paper we study a parameterized version of the standard constraint satisfaction problem, in which the parameter is a constraint language specifying the possible forms of the constraints.

DEFINITION 2.2. *For any set $A$ and any constraint language $\Gamma$ over $A$, the* constraint satisfaction problem $\mathbf{CSP}(\Gamma)$ *is the combinatorial decision problem with*

**Instance:** *A triple $(V, A, \mathcal{C})$, where*

- *$V$ is a set of* variables*;*
- *$\mathcal{C}$ is a set of* constraints*, $\{C_1, \dots, C_q\}$.*
  *Each constraint $C_i \in \mathcal{C}$ is a pair $\langle s_i, \rho_i \rangle$, where*
  - *$s_i$ is a tuple of variables of length $m_i$, called the* constraint scope*;*
  - *$\rho_i \in \Gamma$ is an $m_i$-ary relation over $A$, called the* constraint relation.

**Question:** *Does there exist a* solution*, that is, a function $\varphi$, from $V$ to $A$, such that, for each constraint $\langle s_i, \rho_i \rangle \in \mathcal{C}$, with $s_i = (x_{i_1}, \dots, x_{i_m})$, the tuple $(\varphi(x_{i_1}), \dots, \varphi(x_{i_m}))$ belongs to $\rho_i$?*

In this paper we shall consider only cases where the set $A$, specifying the possible values for the variables, is finite. In such cases the size of a problem instance can be taken to be the length of a string containing all constraint scopes and all tuples of all constraint relations from the instance.

*Example* 2.3. An instance of the standard propositional 3-SATISFIABILITY problem [21, 45] is specified by giving a formula in propositional logic consisting of a conjunction of clauses, each of which contains at most three literals, and asking whether there are values for the variables that make the formula true.

Suppose that $\Phi = F_1 \wedge \cdots \wedge F_n$ is such a formula, where the $F_i$ are clauses. The satisfiability question for $\Phi$ can be expressed as the constraint satisfaction problem instance $(V, \{0,1\}, \mathcal{C})$, where $V$ is the set of all variables appearing in the clauses $F_i$, the values 0 and 1 represent the logical values FALSE and TRUE, and $\mathcal{C}$ is the set of constraints $\{\langle s_1, \rho_1 \rangle, \dots, \langle s_n, \rho_n \rangle\}$, where each constraint $\langle s_k, \rho_k \rangle$ is constructed as follows:

- $s_k = (x_1^k, x_2^k, x_3^k)$, where $x_1^k, x_2^k, x_3^k$ are the variables appearing in clause $F_k$;
- $\rho_k = \{0,1\}^3 \setminus \{(a_1, a_2, a_3)\}$, where $a_i = 1$ if $x_i^k$ is negated in $F_k$ and $a_i = 0$ otherwise (i.e., $\rho_k$ contains exactly those 3-tuples that make $F_k$ true).

The solutions of this instance are exactly the assignments which make the formula $\Phi$ true.

If we define $\Gamma_{\text{3-SAT}}$ to be the constraint language over $\{0,1\}$ consisting of all relations expressible by 3-clauses, then any instance of 3-SATISFIABILITY can be expressed as an instance of $\mathbf{CSP}(\Gamma_{\text{3-SAT}})$ in this way, and vice versa. □

*Example* 2.4. An instance of GRAPH UNREACHABILITY consists of a graph $G = (V, E)$ and a pair of vertices, $v, w \in V$. The question is whether there is no path in $G$ from $v$ to $w$.

This can be expressed as the constraint satisfaction problem instance defined by $(V, \{0, 1\}, \mathcal{C})$, where

$$\mathcal{C} = \{\langle e, \{=_{\{0,1\}}\}\rangle \mid e \in E\} \cup \{\langle (v), \{(0)\}\rangle, \langle (w), \{(1)\}\rangle\},$$

where $=_{\{0,1\}}$ denotes the equality relation over the set $\{0, 1\}$.

If we define $\Gamma_{\text{GU}}$ to be the constraint language over $\{0, 1\}$ containing just the relations $=_{\{0,1\}}$, $\{(0)\}$ and $\{(1)\}$, then any instance of GRAPH UNREACHABILITY can be expressed as an instance of $\mathbf{CSP}(\Gamma_{\text{GU}})$ in this way. $\square$

*Example* 2.5. An instance of GRAPH $q$-COLORABILITY consists of a graph $G$. The question is whether the vertices of $G$ can be labelled with $q$ colors so that adjacent vertices are assigned different colors [21, 45].

This problem corresponds to the problem $\mathbf{CSP}(\{\neq_A\})$, where $A$ is a $q$-element set (of colors) and $\neq_A$ is the disequality relation over $A$, defined by

$$\neq_A \; = \{(a, b) \in A^2 \mid a \neq b\}. \qquad \square$$

*Example* 2.6. Given a fixed graph $H$, an instance of $H$-COLORABILITY consists of a graph $G$. The question is whether there is a mapping from the vertices of $G$ to the vertices of $H$, such that adjacent vertices in $G$ are mapped to adjacent vertices in $H$ [24]. (In the special case when $H$ is the complete graph on $q$ vertices, $K_q$, the $H$-COLORABILITY problem reduces to the GRAPH $q$-COLORABILITY problem described in Example 2.5.)

This problem corresponds to the problem $\mathbf{CSP}(\{E_H\})$, where $E_H$ is the edge relation of $H$, that is, the binary relation consisting of all adjacent pairs of vertices from $H$. $\square$

Many other examples of standard combinatorial problems expressed as constraint satisfaction problems can be found in [31]. For alternative formulations of the constraint satisfaction problem, such as the problem of deciding whether there is a homomorphism from one relational structure to another, see [20, 31, 34].

**2.2. Tractable constraint languages.** Throughout this paper we shall say that a problem is *tractable* if there exists a deterministic polynomial-time algorithm solving all instances of that problem. We can use Definition 2.2 to classify constraint languages according to the complexity of the corresponding constraint satisfaction problem.

In order to be able to classify infinite, as well as finite, constraint languages, we define the notion of a tractable constraint language in a way that depends on finite subsets only.

DEFINITION 2.7. *For any set $A$, a finite constraint language $\Gamma \subseteq R_A$ is said to be* tractable *if* $\mathbf{CSP}(\Gamma)$ *is tractable.*

*An infinite constraint language $\Gamma \subseteq R_A$ is said to be* tractable *if every finite subset of $\Gamma$ is tractable.*

*A constraint language $\Gamma \subseteq R_A$ is said to be* **NP**-complete *if* $\mathbf{CSP}(\Delta)$ *is* **NP**-*complete for some finite $\Delta \subseteq \Gamma$.*

*Example* 2.8. It is well known (see [21, 45]) that the GRAPH $q$-COLORABILITY problem described in Example 2.5 is tractable when $q \leq 2$ and is **NP**-complete otherwise. Hence, it follows from Example 2.5 that the finite constraint language containing just the single relation $\neq_A$ is tractable when $|A| \leq 2$ and is **NP**-complete otherwise. $\square$

*Example* 2.9. The complexity of the $H$-COLORABILITY problem for *undirected* graphs $H$ was completely characterized in [24], where it was shown that if an undirected graph $H$ is bipartite or has a loop, then the corresponding $H$-COLORABILITY problem is tractable; otherwise it is **NP**-complete.

Using this result, it follows from Example 2.6 that a constraint language $\Gamma = \{E\}$, consisting of a single symmetric binary relation $E$, is tractable if $E$ is the edge relation of a bipartite graph, or a graph with a loop. Otherwise $\Gamma$ is **NP**-complete. $\square$

A finite or infinite constraint language $\Gamma$ with the property that $\mathbf{CSP}(\Gamma)$ is tractable will be called *globally tractable*. Clearly any constraint language that is globally tractable is tractable in the sense of Definition 2.7, but it is not immediately clear whether or not the converse holds for all infinite languages. This is because for a certain infinite constraint language $\Gamma$, it may be the case that for each finite subset $\Delta \subseteq \Gamma$ there exists a polynomial-time algorithm $Alg(\Delta)$ solving $\mathbf{CSP}(\Delta)$, and yet there is no *uniform* polynomial-time algorithm solving $\mathbf{CSP}(\Gamma)$. However, we know of no examples where this is the case and we conjecture that any tractable constraint language is also globally tractable.

*Example* 2.10. Let $A$ be a finite field, and let $\Gamma_{\mathrm{LIN}}$ be the constraint language consisting of all relations over $A$ which consist of all solutions to some system of linear equations over $A$. Any relation from $\Gamma_{\mathrm{LIN}}$, and therefore any instance of $\mathbf{CSP}(\Gamma_{\mathrm{LIN}})$, can be represented by a system of linear equations over $A$. Indeed, if $\rho \in \Gamma_{\mathrm{LIN}}$, then it is the solution space of the system of linear equations obtained by the following procedure:

*Step* 1 Pick an arbitrary element $\overline{a}_0 = (a_{01}, \dots, a_{0n}) \in \rho$, and set $\rho_0 = \{\overline{b} - \overline{a}_0 \mid \overline{b} \in \rho\}$.

*Step* 2 For every member $(a_1, \dots, a_n)$ of $\rho_0$, form the equation $a_1x_1 + \cdots + a_nx_n = 0$, and find a basis, $\rho^{\perp}$, of the solution space of the resulting system of equations.

*Step* 3 For each $(b_1, \dots, b_n) \in \rho^{\perp}$, output the equation $b_1x_1 + \cdots + b_nx_n = b_0$, where $b_0 = b_1a_{01} + \cdots + b_na_{0n}$.

Since any instance of $\mathbf{CSP}(\Gamma_{\mathrm{LIN}})$ may be solved in polynomial time (e.g., by Gaussian elimination), it follows that $\Gamma_{\mathrm{LIN}}$ is a (globally) tractable constraint language. $\square$

A constraint language over the set $A = \{0, 1\}$ is known as a *Boolean* constraint language. The complexity of $\mathbf{CSP}(\Gamma)$ has been investigated [52] for all Boolean constraint languages $\Gamma$, and the following complete classification has been obtained.

THEOREM 2.11 (see Schaefer [52]). *A Boolean constraint language, $\Gamma$, is (globally) tractable if (at least) one of the following six conditions holds:*

1. *Every relation in $\Gamma$ contains a tuple in which all entries are $0$;*
2. *Every relation in $\Gamma$ contains a tuple in which all entries are $1$;*
3. *Every relation in $\Gamma$ is definable by a formula in conjunctive normal form in which each conjunct has at most one negated variable;*
4. *Every relation in $\Gamma$ is definable by a formula in conjunctive normal form in which each conjunct has at most one unnegated variable;*
5. *Every relation in $\Gamma$ is definable by a formula in conjunctive normal form in which each conjunct contains at most two literals;*
6. *Every relation in $\Gamma$ is the set of solutions of a system of linear equations over the finite field* GF(2).

*Otherwise it is* **NP**-*complete.*

In particular, Theorem 2.11 establishes that any Boolean constraint language can be classified as either tractable or **NP**-complete, and hence this result is known as Schaefer's dichotomy theorem.

A similar dichotomy theorem has been obtained for constraint languages over any set with three elements [3], using some of the algebraic methods described below. The classification problem for languages over larger finite sets is still open [20], and is the central topic of this paper.

PROBLEM 2.12 ("tractable relations problem"). *Characterize all tractable constraint languages over finite sets.*

*Example* 2.13. One of the first non-Boolean tractable constraint languages to be characterized was the set $\Gamma_{\text{ZOA}}$ of "0/1/all" relations described in [10]. The set $\Gamma_{\text{ZOA}}$ contains all relations over some fixed set $A$ of the following forms:

(i) all unary relations;
(ii) all binary relations of the form $A_1 \times A_2$ for subsets $A_1, A_2$ of $A$;
(iii) all binary relations of the form $\{(a, \pi(a)) \mid a \in A_1\}$ for some subset $A_1$ of $A$ and some permutation $\pi$ of $A$;
(iv) All binary relations of the form $\{(a,b) \in A_1 \times A_2 \mid a = a_1 \vee b = a_2\}$ for some subsets $A_1, A_2$ of $A$ and some elements $a_1 \in A_1, a_2 \in A_2$.

It was shown in [10] that $\mathbf{CSP}(\Gamma_{\text{ZOA}})$ is tractable, and that for any binary relation $\rho$ over $A$ which is *not* in $\Gamma_{\text{ZOA}}$, $\mathbf{CSP}(\Gamma_{\text{ZOA}} \cup \{\rho\})$ is **NP**-complete. □

**2.3. From arbitrary constraint languages to relational clones.** To describe the tractable Boolean constraint languages, Schaefer used syntactic properties of propositional formulas representing Boolean relations. In the non-Boolean case this method can no longer be used. We therefore need an adequate language in which it is possible to express the properties of constraint languages which are responsible for the complexity of the corresponding constraint satisfaction problems.

A useful first step in tackling this problem is to consider what additional relations can be added to a constraint language without changing the complexity of the corresponding problem class. This technique has been widely used in the analysis of Boolean constraint satisfaction problems [11, 52], and in the analysis of temporal and spatial constraints [17, 44, 51]; it was introduced for the study of constraints over arbitrary finite sets in [27].

To use this technique we first define a method for deriving new relations from given ones. The method we use involves defining the new relations using certain kinds of logical formulas involving the given relations. To define such formulas we use the standard correspondence between relations and predicates: a relation consists of all tuples of values for which the corresponding predicate holds. (We will use the same symbol for a predicate and its corresponding relation, since the meaning will always be clear from the context.)

DEFINITION 2.14 (see [48]). *A constraint language $\Gamma \subseteq R_A$ is called a* relational clone *if it contains every relation (predicate) expressible by a first-order formula involving*

(i) *relations (predicates) from $\Gamma \cup \{=_A\}$ (where $=_A$ is the equality relation on the set $A$);*
(ii) *conjunction; and*
(iii) *existential quantification.*

First-order formulas involving only conjunction and existential quantification are often called *primitive positive* (pp) formulas.

For any constraint language $\Gamma$, there is a unique smallest relational clone containing $\Gamma$, which is denoted $\langle\Gamma\rangle$ and is called the relational clone *generated by* $\Gamma$. The set $\langle\Gamma\rangle$ consists of all relations definable by pp-formulas over the relations in $\Gamma$ together with the equality relation.

*Example* 2.15. Consider the Boolean constraint language $\Gamma = \{R_1, R_2\}$, where $R_1 = \{(0,1),(1,0),(1,1)\}$ and $R_2 = \{(0,0),(0,1),(1,0)\}$.

It is straightforward to check that every binary Boolean relation can be expressed by a pp-formula involving $R_1$ and $R_2$. For example, the relation $R_3 = \{(0,0),(1,0),(1,1)\}$ can be expressed by the formula $R_3 = \exists y R_1(x,y) \wedge R_2(y,z)$. Hence the relational clone generated by $\Gamma$, $\langle\Gamma\rangle$, includes all 16 binary Boolean relations.

In fact it can be shown that $\langle\Gamma\rangle$ consists of precisely those Boolean relations (of any arity) that can be expressed as a conjunction of unary or binary Boolean relations [49, 53]. $\square$

There are a number of different but equivalent definitions of relational clones [16, 48], and a different definition was used in [27] to establish the following theorem. We give a proof here that uses Definition 2.14.

THEOREM 2.16 (see [27]). *For any set of relations* $\Gamma$ *and any finite set* $\Delta \subseteq \langle\Gamma\rangle$, *there is a polynomial time reduction from* $\mathbf{CSP}(\Delta)$ *to* $\mathbf{CSP}(\Gamma)$.

*Proof.* Let $\Delta = \{\varrho_1, \ldots, \varrho_k\}$ be a finite set of relations over the finite set $A$, where each $\varrho_i$ is expressible by a pp-formula involving relations from $\Gamma$ and the equality relation, $=_A$. Note that we may fix these representations.

Any instance $(V; A; \mathcal{C}) \in \mathbf{CSP}(\Delta)$ can be transformed as follows. For every constraint $\langle s, \rho\rangle \in \mathcal{C}$, where $s = (v_1, \ldots, v_l)$ and $\rho$ is representable by the pp-formula

$$\rho(v_1, \ldots, v_l) = \exists u_1, \ldots, u_m \; (\rho_1(w_1^1, \ldots, w_{l_1}^1) \wedge \cdots \wedge \rho_n(w_1^n, \ldots, w_{l_n}^n)),$$

where $w_1^1, \ldots, w_{l_1}^1, \ldots, w_1^n, \ldots, w_{l_n}^n \in \{v_1, \ldots, v_l, u_1, \ldots, u_m\}$,

(i) add the auxiliary variables $u_1, \ldots, u_m$ to $V$ (renaming if necessary so that none of them occurs before);

(ii) add the constraints $\langle (w_1^1, \ldots, w_{l_1}^1), \rho_1\rangle, \ldots, \langle (w_1^n, \ldots, w_{l_n}^n), \rho_n\rangle$ to $\mathcal{C}$;

(iii) remove $\langle s, \rho\rangle$ from $\mathcal{C}$.

It can easily be checked that the problem instance obtained by this procedure is equivalent to $(V; A; \mathcal{C})$ and belongs to $\mathbf{CSP}(\Gamma \cup \{=_A\})$. Moreover, since all the representations of relations from $\Delta$ are fixed, this transformation can be carried out in linear time in the size of the instance. Finally, all constraints of the form $\langle (v_1, v_2), =_A\rangle$ can be eliminated by replacing all occurrences of the variable $v_1$ with $v_2$. This transformation can also be carried out in polynomial time. $\square$

COROLLARY 2.17. *A set of relations* $\Gamma$ *is tractable if and only if the relational clone* $\langle\Gamma\rangle$ *is tractable.*

*Similarly,* $\Gamma$ *is* $\mathbf{NP}$*-complete if and only if* $\langle\Gamma\rangle$ *is* $\mathbf{NP}$*-complete.*

This result reduces the problem of characterizing tractable constraint languages to the problem of characterizing tractable relational clones.

*Example* 2.18. Reconsider the tractable constraint language of 0/1/all relations, $\Gamma_{\mathrm{ZOA}}$, defined in Example 2.13.

Note that for any fixed finite set $A$, the set of 0/1/all relations over $A$ contains only unary and binary relations and is therefore finite. However, it follows from Corollary 2.17 that the relational clone $\langle\Gamma_{\mathrm{ZOA}}\rangle$ is also tractable. This is an infinite set of relations containing relations of every possible arity.

In fact, the set $\langle \Gamma_{\mathrm{ZOA}} \rangle$ corresponds precisely to the *implicational* relations defined in [33]. Moreover, the set of 0/1/all relations, $\Gamma_{\mathrm{ZOA}}$, is precisely the set of unary and binary relations in the relational clone $\langle \Gamma_{\mathrm{ZOA}} \rangle$. $\square$

**2.4. From relational clones to sets of operations.** We have shown in the previous section that to analyze the complexity of arbitrary constraint languages it is sufficient to consider only relational clones. This considerably reduces the variety of languages to be studied. However, it immediately raises the question of how to represent and describe relational clones. For many relational clones the only known generating sets are rather sophisticated, and in some cases no generating sets are known [48].

Very conveniently, it turns out that there is a well-known alternative way to represent and describe any relational clone, using *operations*. In our definitions we follow [42] and [53].

Definition 2.19. *For any set $A$, and any natural number $n$, a mapping $f : A^n \to A$ is called an $n$-*ary operation *on $A$. The set of all finitary operations on $A$ is denoted by $O_A$.*

We first describe a fundamental algebraic relationship between operations and relations. Note that any operation on a set $A$ can be extended in a standard way to an operation on tuples of elements from $A$, as follows. For any ($m$-ary) operation $f$ and any collection of tuples $\overline{a}_1, \ldots, \overline{a}_m \in A^n$, where $\overline{a}_i = (a_{1i}, \ldots, a_{ni})$, define $f(\overline{a}_1, \ldots, \overline{a}_m)$ to be $(f(a_{11}, \ldots, a_{1m}), \ldots, f(a_{n1}, \ldots, a_{nm}))$.

Definition 2.20 (see [16, 48, 53]). *An $m$-ary operation $f \in O_A$* preserves *an $n$-ary relation $\rho \in R_A$ (or $f$ is a* polymorphism *of $\rho$, or $\rho$ is* invariant *under $f$) if $f(\overline{a}_1, \ldots, \overline{a}_m) \in \rho$ for all choices of $\overline{a}_1, \ldots, \overline{a}_m \in \rho$.*

For any given sets $\Gamma \subseteq R_A$ and $F \subseteq O_A$, let

$$\begin{aligned} \mathsf{Pol}(\Gamma) &= \{f \in O_A \mid f \text{ preserves each relation from } \Gamma\}, \\ \mathsf{Inv}(F) &= \{\rho \in R_A \mid \rho \text{ is invariant under each operation from } F\}. \end{aligned}$$

We remark that the operators $\mathsf{Pol}$ and $\mathsf{Inv}$ form a Galois correspondence between $R_A$ and $O_A$ (see Proposition 1.1.14 of [48]). Introductions to this correspondence can be found in [16, 47], and a comprehensive study in [48]. We note, in particular, that $\mathsf{Inv}(F) = \mathsf{Inv}(\mathsf{Pol}(\mathsf{Inv}(F)))$, for any set of operations $F$. Sets of the form $\mathsf{Inv}(F)$ are precisely the relational clones, as the next result indicates.

Proposition 2.21 (see [48]). *For any set $A$, and any $F \subseteq O_A$, the set $\mathsf{Inv}(F)$ is a relational clone. Conversely, any relational clone can be represented in the form $\mathsf{Inv}(F)$ for some set $F \subseteq O_A$. In particular, for any $\Gamma \subseteq R_A$, $\langle \Gamma \rangle = \mathsf{Inv}(\mathsf{Pol}(\Gamma))$.*

Using Proposition 2.21 together with Corollary 2.17, we can now translate our original problem of characterizing tractable sets of relations (Problem 2.12) into an equivalent problem for sets of operations. First, we define what it means for a set of operations to be tractable or **NP**-complete.

Definition 2.22. *A set $F \subseteq O_A$ is said to be* tractable *if $\mathsf{Inv}(F)$ is tractable. A set $F \subseteq O_A$ is said to be* **NP**-complete *if $\mathsf{Inv}(F)$ is* **NP***-complete.*

Using this definition, we obtain the following translation of Problem 2.12.

Problem 2.23 ("tractable operations problem"). *Characterize all tractable sets of operations on finite sets.*

In many cases the description of a set of operations provides a compact, concise way to describe the associated relational clone, as the next example indicates.

*Example* 2.24. Recall the constraint language $\Gamma_{\mathrm{ZOA}}$ of 0/1/all relations which was defined in Example 2.13 and extended to $\langle \Gamma_{\mathrm{ZOA}} \rangle$ in Example 2.18.

It was shown in [30] that $\langle \Gamma_{\text{ZOA}} \rangle$ is precisely the constraint language consisting of all relations which are invariant under the ternary "dual discriminator" operation $d$, defined as follows:

$$d(x, y, z) = \begin{cases} y & \text{if } y = z, \\ x & \text{otherwise.} \end{cases}$$

Hence this infinite tractable constraint language, which is rather complicated to describe in detail, may be represented very simply as the set of relations invariant under the tractable set of operations $\{d\}$. □

In many cases, it has been shown that the presence of a single operation satisfying certain simple conditions is sufficient to ensure the tractability of a set of operations.

*Example* 2.25. A binary operation $f(x, y)$ satisfying the following three conditions is said to be a semilattice operation:[1]

(i) $f(x, f(y, z)) = f(f(x, y), z)$ (associativity),
(ii) $f(x, y) = f(y, x)$ (commutativity),
(iii) $f(x, x) = x$ (idempotency).

Theorem 16 of [29] says that for any finite set $A$, any set of operations $F \subseteq O_A$ containing a semilattice operation is tractable. □

In contrast, we will now consider the properties of operations that are associated with **NP**-complete constraint languages.

DEFINITION 2.26. *An operation $f : A^n \to A$ is called* essentially unary *if there exists a (nonconstant) unary operation $g : A \to A$ and an index $i \in \{1, 2, \ldots, n\}$ such that $f(a_1, a_2, \ldots, a_n) = g(a_i)$ for all choices of $a_1, a_2, \ldots, a_n$. If $g$ is the identity operation, then $f$ is called a* projection.

*Any operation which is not essentially unary (including all constant operations) will be called* essentially nonunary.

PROPOSITION 2.27 (see Jeavons [27]). *For any finite set $A$ and any $\Gamma \subseteq R_A$, if $\mathsf{Pol}(\Gamma)$ contains essentially unary operations only, then* $\mathbf{CSP}(\Gamma)$ *is* **NP***-complete.*

*Example* 2.28. Consider the relation $N$ over the set $\{0, 1\}$, defined by

$$N = \{0, 1\}^3 \setminus \{(0, 0, 0), (1, 1, 1)\}.$$

It can be shown that $\mathsf{Pol}(\{N\})$ contains essentially unary operations only [49], and hence $\mathbf{CSP}(\{N\})$ is **NP**-complete, by Proposition 2.27.

We remark that the problem $\mathbf{CSP}(\{N\})$ was first shown to be **NP**-complete by Schaefer [52]; it corresponds to a restricted form of the NOT-ALL-EQUAL SATISFIABILITY problem [21, 45]. □

Boolean operations, that is, operations on $A = \{0, 1\}$, have been very well studied [49, 53]. In particular, it is known that if a Boolean constraint language is not contained in one of Schaefer's six tractable classes, then all of its polymorphisms are essentially unary operations [53]. Hence we may reformulate Schaefer's dichotomy theorem to obtain the following complete classification for Boolean operations.

COROLLARY 2.29 (Schaefer's dichotomy for operations). *A set of Boolean operations is tractable if it contains an essentially nonunary operation. Otherwise it is* **NP***-complete.*

[1]Note that in some earlier papers [27, 30, 46] the term *ACI operation* is used.

**3. Algebras.** We have shown in section 2 that the problem of analyzing the complexity of a constraint language can be translated into the problem of analyzing the complexity of the set of operations which preserve all of the relations in that language. In the Boolean case, this is sufficient to obtain a complete classification of complexity, but over larger sets we need to develop more powerful analytical tools, as the next example indicates.

*Example* 3.1. Consider the binary operation $\circ$ on the set $\{0, 1, 2\}$ defined by the following Cayley table:

| $\circ$ | 0 | 1 | 2 |
|---|---|---|---|
| 0 | 0 | 1 | 1 |
| 1 | 1 | 1 | 0 |
| 2 | 2 | 2 | 2 |

This operation does not fall into any known tractable class, nor is it essentially unary. Hence we cannot determine the complexity of this operation using the tools of the previous section (but see Example 5.5 below). □

In this section we shall open the way to the use of a further set of powerful analytical tools by making the final translation step, from sets of operations to *algebras.*

DEFINITION 3.2. *An* algebra *is an ordered pair* $\mathcal{A} = (A, F)$ *such that* $A$ *is a nonempty set and* $F$ *is a family of finitary operations on* $A$*. The set* $A$ *is called the* universe *of* $\mathcal{A}$*, and the operations from* $F$ *are called* basic*. An algebra with a finite universe is referred to as a* finite algebra.

To make the translation from sets of operations to algebras we simply note that any set of operations $F$ on a fixed set $A$ can be associated with the algebra $(A, F)$. Hence, we will define what it means for an algebra to be tractable by considering the tractability of the basic operations.

DEFINITION 3.3. *An algebra* $\mathcal{A} = (A, F)$ *is said to be* tractable *if* $F$ *is tractable.*
*An algebra* $\mathcal{A} = (A, F)$ *is said to be* **NP**-complete *if* $F$ *is* **NP**-*complete.*

Using Definition 3.3 we can now translate our original tractable relations problem (Problem 2.12) into the following equivalent problem for algebras.

PROBLEM 3.4 ("tractable algebras problem"). *Characterize all tractable algebras.*

Using Definition 3.3, we can reformulate Schaefer's dichotomy theorem [52] in yet another way, this time as a classification of the complexity of *algebras* defined on a two-element set.

COROLLARY 3.5 (Schaefer's dichotomy for algebras). *An algebra with a two-element universe is* **NP**-*complete if all of its basic operations are essentially unary. Otherwise it is tractable.*

The first advantage of using algebras instead of sets of operations is that we can make use of some standard constructions on algebras to obtain new results about the complexity of constraint languages. Another advantage is that finite algebras have been extensively studied, and a considerable body of structural theory has been developed [25, 42, 53]. We explore these ideas further in the remainder of the paper.

In our study it will be useful to describe an equivalence relation linking algebras that correspond to the same constraint language. As we noted earlier, the mappings $\mathsf{Pol}$ and $\mathsf{Inv}$ have the property that $\mathsf{Inv}(\mathsf{Pol}(\mathsf{Inv}(F))) = \mathsf{Inv}(F)$, and so we can extend a set of operations $F$ to the set $\mathsf{Pol}(\mathsf{Inv}(F))$ without changing the associated invariant relations. The set $\mathsf{Pol}(\mathsf{Inv}(F))$ consists of all operations that can be obtained from the operations in $F$, together with the set of all projection operations, by forming arbitrary compositions of operations [16, 48]. (If $f$ is an $n$-ary operation on $A$, and $g_1, g_2, \ldots, g_n$ are $k$-ary operations on $A$, then the *composition* of $f$ and $g_1, g_2, \ldots, g_n$ is the $k$-ary operation $h$ on $A$ defined by $h(a_1, a_2, \ldots, a_k) = f(g_1(a_1, \ldots, a_k), \ldots, g_n(a_1, \ldots, a_k))$.) The set of operations obtained in this way is usually referred to in universal algebra as the set of *term operations* over $F$ [16], so we will make the following definition.

DEFINITION 3.6. *For any algebra $\mathcal{A} = (A, F)$, an operation $f$ on $A$ will be called a* term operation *of $\mathcal{A}$ if $f \in \mathsf{Pol}(\mathsf{Inv}(F))$.*

*The set of all term operations of $\mathcal{A}$ will be denoted $\mathsf{Term}(\mathcal{A})$.*

Two algebras with the same universe are called *term equivalent* if they have the same set of term operations. Note that, for any algebra $\mathcal{A} = (A, F)$, we have $\mathsf{Inv}(F) = \mathsf{Inv}(\mathsf{Term}(\mathcal{A}))$, so two algebras are term equivalent if and only if they have the same set of associated invariant relations. It follows that we need to characterize tractable algebras only up to term equivalence.

*Example* 3.7. A *group* is an algebra with three basic operations: a binary multiplication operation, a unary converse operation, and a constant unit operation (see [37]). A *coset* of a group is a relation which is invariant under the ternary term operation $t(x, y, z) = xy^{-1}z$. It is stated in Theorem 33 of [20] that any constraint language consisting of cosets of a finite group is tractable. Hence any finite group is tractable, and moreover, any finite algebra with the ternary term operation $t$ is also tractable. $\square$

## 4. Special classes of algebras.

In this section we will show that, when studying the tractability of *finite* algebras, we can restrict our attention to certain special classes of algebras.

DEFINITION 4.1. *We call an algebra* surjective *if all of its term operations are surjective.*[2]

It is easy to verify that a finite algebra is surjective if and only if its unary term operations are all surjective and hence form a group of permutations.

It was shown in [27] that any unary polymorphism can be applied to a set of relations without changing the complexity of that set.

PROPOSITION 4.2 (see [27]). *For any set of relations $\Gamma$, and any unary operation $f \in \mathsf{Pol}(\Gamma)$, let $f(\Gamma)$ be the set of relations $\{f(\rho) \mid \rho \in \Gamma\}$, where $f(\rho) = \{f(\overline{a}) \mid \overline{a} \in \rho\}$. The set $\Gamma$ is tractable if and only if $f(\Gamma)$ is tractable, and $\Gamma$ is* **NP***-complete if and only if $f(\Gamma)$ is* **NP***-complete.*

Any algebra $\mathcal{A} = (A, F)$ which is not surjective will have a unary term operation $f$ which is not surjective, and hence has range $U$, where $U$ is a proper subset of $A$. By applying this operation to all of the relations in $\mathsf{Inv}(F)$, as described in Proposition 4.2, we can obtain a set of relations over $U$ without changing the tractability. The algebra corresponding to this new set of relations can be shown to be a *term induced* algebra of $\mathcal{A}$, which is defined as follows.

DEFINITION 4.3 (see [55]). *Let $\mathcal{A} = (A, F)$ be an algebra, and let $U$ be a nonempty subset of $A$. The* term induced algebra *$\mathcal{A}|_U$ is defined as $(U, \mathsf{Term}(\mathcal{A})|_U)$, where $\mathsf{Term}(\mathcal{A})|_U = \{g|_U : g \in \mathsf{Term}(\mathcal{A})$ and $g$ preserves $U\}$.*

By choosing a unary term operation $f$ with a range $U$ of *minimal* cardinality, we can ensure that the term induced algebra $\mathcal{A}|_U$ is surjective. Hence we have the following theorem.

THEOREM 4.4. *For any finite algebra $\mathcal{A}$, there exists a set $U$ such that*

(i) *the algebra $\mathcal{A}|_U$ is surjective, and*

[2]Note that in [54] an algebra is said to be surjective if all of its basic operations are surjective. However, such algebras can have nonsurjective term operations, so our definition is more restrictive.

(ii) *the algebra $\mathcal{A}$ is tractable if and only if $\mathcal{A}|_U$ is tractable, and is* **NP***-complete if and only if $\mathcal{A}|_U$ is* **NP***-complete.*

Theorem 4.4 shows that we can restrict our attention to surjective algebras. The next theorem shows that for many purposes we need consider only those surjective algebras with the additional property of being *idempotent*.

DEFINITION 4.5. *An operation $f$ on $A$ is called* idempotent *if it satisfies $f(x, \ldots, x) = x$ for all $x \in A$.*

*The* full idempotent reduct *of an algebra $\mathcal{A} = (A, F)$ is the algebra $(A, \mathsf{Term}_{id}(\mathcal{A}))$, where $\mathsf{Term}_{id}(\mathcal{A})$ consists of all idempotent operations from $\mathsf{Term}(\mathcal{A})$.*

Note that an operation $f$ on a set $A$ is idempotent if and only if it preserves all the relations in the set $\Gamma_{\text{CON}} = \{\{(a)\} \mid a \in A\}$, consisting of all unary one-element relations on $A$. Hence, $\mathsf{Inv}(\mathsf{Term}_{id}(\mathcal{A}))$ is the relational clone generated by $\mathsf{Inv}(F) \cup \Gamma_{\text{CON}}$.

To establish the next theorem we need an auxiliary lemma from [53].

LEMMA 4.6. *Let $\mathcal{A} = (\{a_1, a_2, \ldots, a_k\}, F)$ be a finite algebra whose unary term operations form a permutation group $G$. Then the relation $\rho_G$, defined by*

$$\rho_G = \{(g(a_1), \ldots, g(a_k)) \mid g \in G\},$$

*belongs to $\mathsf{Inv}(F)$.*

*Proof.* Proposition 1.3 of [53] states that relations of the form $\rho_G$ are preserved by all operations of the algebra $\mathcal{A}$ and hence belong to $\mathsf{Inv}(F)$. ◻

THEOREM 4.7. *A finite surjective algebra $\mathcal{A}$ is tractable if and only if its full idempotent reduct $\mathcal{A}_0$ is tractable. Moreover, $\mathcal{A}$ is* **NP***-complete if and only if $\mathcal{A}_0$ is* **NP***-complete.*

*Proof.* Let $\mathcal{A} = (A, F)$ be a finite surjective algebra, and let $\mathcal{A}_0$ be the full idempotent reduct of $\mathcal{A}$.

As observed above, $\mathsf{Inv}(\mathsf{Term}(\mathcal{A}_0))$ is the relational clone generated by the set $\mathsf{Inv}(F) \cup \Gamma_{\text{CON}}$, where $\Gamma_{\text{CON}} = \{\{(a)\} \mid a \in A\}$. By Corollary 2.17, it follows that $\mathcal{A}_0$ is tractable if and only if $\mathsf{Inv}(F) \cup \Gamma_{\text{CON}}$ is tractable, and $\mathcal{A}_0$ is **NP**-complete if and only if $\mathsf{Inv}(F) \cup \Gamma_{\text{CON}}$ is **NP**-complete. In the remainder of the proof we will show that $\mathbf{CSP}(\mathsf{Inv}(F) \cup \Gamma_{\text{CON}})$ is polynomial-time equivalent to $\mathbf{CSP}(\mathsf{Inv}(F))$.

Clearly, every instance of $\mathbf{CSP}(\mathsf{Inv}(F))$ may be considered as an instance of $\mathbf{CSP}(\mathsf{Inv}(F) \cup \Gamma_{\text{CON}})$, so there is a constant-time reduction from $\mathbf{CSP}(\mathsf{Inv}(F))$ to $\mathbf{CSP}(\mathsf{Inv}(F) \cup \Gamma_{\text{CON}})$.

For the converse result, let $\mathcal{P} = (V, A, \mathcal{C})$ be an instance of $\mathbf{CSP}(\mathsf{Inv}(F) \cup \Gamma_{\text{CON}})$ and let $\mathcal{P}'$ be the problem instance $(V', A, \mathcal{C}')$, where $V' = V \cup \{v_a \mid a \in A\}$ (each of the variables $v_a$ is a new variable not in $V$). To obtain the constraints $\mathcal{C}'$, take the original constraints $\mathcal{C}$ of $\mathcal{P}$, and replace each unary constraint of the form $\langle v, \{(a)\}\rangle$ in $\mathcal{C}$ with the constraint $\langle (v, v_a), =_A\rangle$, where $=_A$ is the binary equality relation on $A$. Finally, add the constraint $\langle (v_{a_1}, \ldots, v_{a_k}), \varrho_G\rangle$, where $a_1, a_2, \ldots, a_k$ are the elements of $A$ (in some order) and $\varrho_G$ is the relation defined in Lemma 4.6. Note that $\mathcal{P}'$ is an instance of $\mathbf{CSP}(\mathsf{Inv}(F))$ and that this construction can be carried out in polynomial time.

We claim that if the problem $\mathcal{P}'$ has a solution $\psi$, then it has a solution $\phi$ such that $\phi(v_a) = a$ for all $a \in A$. To establish this claim, note that, by the definition of $\rho_G$, there is $g \in G$ such that $\psi(v_a) = g(a)$ for all $a \in A$. Since $G$ is a group, the inverse operation $g^{-1} \in G$, which means that it is a term operation of $\mathcal{A}$. This implies that every relation in $\mathsf{Inv}(F)$ is invariant under $g^{-1}$, so $\phi = g^{-1}\psi$ is also a solution to $\mathcal{P}'$, and has the property that $g^{-1}\psi(v_a) = a$ for all $a \in A$.

Any solution $\phi$ satisfying this condition clearly satisfies all the constraints in $\mathcal{C}$, so the restriction of $\phi$ to $V$ is a solution to $\mathcal{P}$. Conversely, if $\psi$ is any solution to $\mathcal{P}$, then its extension $\psi'$ to $V'$ such that $\psi'(v_a) = a$, for all $a \in A$, is a solution to $\mathcal{P}'$. Hence this construction establishes a polynomial-time reduction from $\mathbf{CSP}(\mathsf{Inv}(F) \cup \Gamma_{\mathrm{CON}})$ to $\mathbf{CSP}(\mathsf{Inv}(F))$. $\square$

Theorem 4.7 can be restated in terms of constraint languages, as follows.

COROLLARY 4.8. *Let $\Gamma$ be a constraint language over a finite set $A$, and let $\Gamma_{\mathrm{CON}} = \{\{(a)\} \mid a \in A\}$ be the set of all unary one-element relations on $A$.*

*If all unary polymorphisms of $\Gamma$ are permutations, then $\Gamma$ is tractable if and only if $\Gamma \cup \Gamma_{\mathrm{CON}}$ is tractable, and $\Gamma$ is* **NP***-complete if and only if $\Gamma \cup \Gamma_{\mathrm{CON}}$ is* **NP***-complete.*

Corollary 4.8 has an interesting consequence connecting decision problems and search problems. In this paper we have formulated the constraint satisfaction problem as a *decision* problem (Definition 2.2), in which the question is to decide whether or not a solution exists. However, the corresponding *search* problem, in which the question is to *find* a solution, often arises in practice. We will now show that the tractable cases of these two forms of the problem coincide. (Note that the tractable cases of the search problem are those which belong to the complexity class **FP**.)

COROLLARY 4.9. *A decision problem $\mathbf{CSP}(\Gamma)$ is tractable if and only if the corresponding search problem can be solved in polynomial time.*

*Proof.* Obviously, tractability of the search problem implies tractability of the corresponding decision problem.

For the converse, let $\Gamma$ be a tractable set of relations over a finite set $A$. By choosing a unary polymorphism $f$ of $\Gamma$, whose image set $U$ is minimal, we can obtain a corresponding set of relations $\Gamma' = f(\Gamma)$ over $U$, such that every unary polymorphism of $\Gamma'$ is a permutation. By Proposition 4.2, $\Gamma'$ is also tractable.

Now consider any instance $\mathcal{P} = (V, A, \mathcal{C})$ of $\mathbf{CSP}(\Gamma)$. By the choice of $\Gamma$, we can decide in polynomial time in the size of $\mathcal{P}$ whether this instance has a solution. Assume that it has. Then the instance $\mathcal{P}' = (V, U, \mathcal{C}')$, obtained by replacing each constraint relation $\rho$ with the corresponding relation $f(\rho)$, also has a solution. Furthermore, every solution of $\mathcal{P}'$ is also a solution to $\mathcal{P}$.

Since $\mathcal{P}'$ has a solution, it follows that for each $v \in V$ there must be some $a \in A$ for which we can add the constraint $\langle (v), \{(a)\} \rangle$ and still have a solvable instance. Hence, by considering each variable in turn, and each possible value $a \in A$ for that variable, we can add such a constraint to each variable in turn, and hence obtain a solution to $\mathcal{P}'$. Checking for solvability for each possible value at each variable requires us to solve an instance of the decision problem $\mathbf{CSP}(\Gamma' \cup \Gamma_{\mathrm{CON}})$ at most $|V| \cdot |U|$ times, and hence can be completed in polynomial time in the size of $\mathcal{P}'$, by Corollary 4.8. $\square$

## 5. Constructions on algebras.

The results in this section link the complexity of a finite algebra with the complexity of its *subalgebras* and *homomorphic images* [9, 16, 42]. In many cases, we can use these results to reduce the problem of analyzing the complexity of an algebra to a similar problem involving an algebra with a smaller universe.

DEFINITION 5.1. *Let $\mathcal{A} = (A, F)$ be an algebra and $B$ a subset of $A$ such that, for any $f \in F$ and for any $b_1, \ldots, b_n \in B$, where $n$ is the arity of $f$, we have $f(b_1, \ldots, b_n) \in B$. Then the algebra $\mathcal{B} = (B, F|_B)$ is called a* subalgebra *of $\mathcal{A}$, where $F|_B$ consists of the restrictions of all operations in $F$ to $B$. If $B \neq A$, then $\mathcal{B}$ is said to be a* proper *subalgebra.*

THEOREM 5.2. *Let $\mathcal{A}$ be a finite algebra.*

(i) *If $\mathcal{A}$ is tractable, then so is every subalgebra of $\mathcal{A}$.*

(ii) *If $\mathcal{A}$ has an* **NP**-*complete subalgebra, then $\mathcal{A}$ is* **NP**-*complete.*

*Proof.* Let $\mathcal{B} = (B, F|_B)$ be a subalgebra of $\mathcal{A} = (A, F)$. It is easy to check that $\mathsf{Inv}(F|_B) \subseteq \mathsf{Inv}(F)$. Hence, $\mathbf{CSP}(\mathsf{Inv}(F|_B))$ can be reduced to $\mathbf{CSP}(\mathsf{Inv}(F))$ in constant time.

Now (i) and (ii) follow immediately from the existence of this reduction. ☐

DEFINITION 5.3. *Let $\mathcal{A}_1 = (A_1, F_1)$ and $\mathcal{A}_2 = (A_2, F_2)$ be such that $F_1 = \{f_i^1 \mid i \in I\}$ and $F_2 = \{f_i^2 \mid i \in I\}$, where both $f_i^1$ and $f_i^2$ are $n_i$-ary, for all $i \in I$.*

*A map $\varphi : A_1 \to A_2$ is called a* homomorphism *from $\mathcal{A}_1$ to $\mathcal{A}_2$ if*

$$\varphi f_i^1(a_1, \dots, a_{n_i}) = f_i^2(\varphi(a_1), \dots, \varphi(a_{n_i}))$$

*holds for all $i \in I$ and all $a_1, \dots, a_{n_i} \in A_1$.*

*If the map $\varphi$ is surjective, then $\mathcal{A}_2$ is said to be a* homomorphic image *of $\mathcal{A}_1$.*

THEOREM 5.4. *Let $\mathcal{A}$ be a finite algebra.*

(i) *If $\mathcal{A}$ is tractable, then so is every homomorphic image of $\mathcal{A}$.*

(ii) *If $\mathcal{A}$ has an* **NP**-*complete homomorphic image, then $\mathcal{A}$ is* **NP**-*complete.*

*Proof.* Let $\mathcal{B} = (B, F_B)$ be a homomorphic image of $\mathcal{A} = (A, F_A)$ and let $\varphi$ be the corresponding homomorphism. We will show that, for any finite $\Gamma \subseteq \mathsf{Inv}(F_B)$, $\mathbf{CSP}(\Gamma)$ is linear-time reducible to $\mathbf{CSP}(\Gamma')$ for some finite $\Gamma' \subseteq \mathsf{Inv}(F_A)$.

For $\rho \in \mathsf{Inv}(F_B)$, set $\varphi^{-1}(\rho) = \{\overline{a} \mid \varphi(\overline{a}) \in \rho\}$ where $\varphi$ acts componentwise. It is clear that $\varphi^{-1}(\rho)$ is a relation of the same arity as $\rho$. It can straightforwardly be checked that $\varphi^{-1}(\rho) \in \mathsf{Inv}(F_A)$. Let $\Gamma' = \{\varphi^{-1}(\rho) \mid \rho \in \Gamma\}$. Then $\Gamma'$ is a finite subset of $\mathsf{Inv}(F_A)$.

Take an instance $\mathcal{P} = (V, B, \mathcal{C})$ of $\mathbf{CSP}(\Gamma)$ and construct an instance $\mathcal{P}' = (V, A, \mathcal{C}')$ of $\mathbf{CSP}(\Gamma')$ where $\mathcal{C}' = \{\langle s, \varphi^{-1}(\rho)\rangle \mid \langle s, \rho\rangle \in \mathcal{C}\}$.

If $\psi$ is a solution of $\mathcal{P}'$, then $\varphi\psi$ is a solution of $\mathcal{P}$. Conversely, if $\xi$ is a solution of $\mathcal{P}$, then any function $\psi : V \to A$ such that $\varphi\psi(v) = \xi(v)$ for any $v \in V$ is a solution of $\mathcal{P}'$. ☐

We now give two examples to illustrate the use of Theorems 5.2 and 5.4. The examples show that *both* of these results can be useful (independently) to establish the complexity of certain algebras by reducing the question to an algebra over a smaller set.

*Example* 5.5. Reconsider Example 3.1. Let $\mathcal{A}$ be the idempotent algebra $(\{0, 1, 2\}, \circ)$, where $\circ$ is the binary operation defined by the following Cayley table:[3]

| $\circ$ | 0 | 1 | 2 |
|---|---|---|---|
| 0 | 0 | 1 | 1 |
| 1 | 1 | 1 | 0 |
| 2 | 2 | 2 | 2 |

By using Theorem 5.4, we will show that $\mathcal{A}$ is **NP**-complete even though all of its proper subalgebras are tractable.

Notice that, as the equalities $0 \circ 2 = 1$, $1 \circ 2 = 0$, $0 \circ 1 = 1 \circ 0 = 1$ show, $\mathcal{A}$ has only one proper subalgebra having more than one element, the algebra $\mathcal{B} = (\{0, 1\}, \circ|_{\{0,1\}})$. It is easy to check that $\circ|_{\{0,1\}}$ is a semilattice operation on $\{0, 1\}$. Hence, by Definition 3.3 and Theorem 16 of [29] (see Example 2.25), the algebra $\mathcal{B}$ is tractable.

[3]Note that we write $x \circ y$ instead of $\circ(x, y)$.

On the other hand, consider the algebra $\mathcal{C} = (C, *)$, where $C = \{a, b\}$ and for all $x, y \in \{a, b\}$, $x * y = x$. It is easy to check that the mapping $\varphi : \{0, 1, 2\} \to C$ such that $\varphi(0) = \varphi(1) = a$, $\varphi(2) = b$, is a homomorphism from $\mathcal{A}$ onto $\mathcal{C}$. By Corollary 3.5, $\mathcal{C}$ is **NP**-complete. Hence, by Theorem 5.4, $\mathcal{A}$ is **NP**-complete. ◻

*Example* 5.6. Consider the idempotent algebra $\mathcal{A} = (\{0, 1, 2\}, \circ)$, where $\circ$ is the binary operation defined by the following Cayley table:

| $\circ$ | 0 | 1 | 2 |
|---|---|---|---|
| 0 | 0 | 1 | 1 |
| 1 | 0 | 1 | 1 |
| 2 | 1 | 1 | 2 |

By using Theorem 5.2, we will show that $\mathcal{A}$ is **NP**-complete even though all of its smaller homomorphic images are tractable.

Since one-element algebras are certainly tractable, we need to consider only two-element homomorphic images $\mathcal{B}$ of $\mathcal{A}$. Let $\mathcal{B} = (\{a, b\}, *)$, where $*$ is a binary operation on $\{a, b\}$, and assume that $\varphi$ is a homomorphism from $\mathcal{A}$ onto $\mathcal{B}$. Then we have $\varphi(x \circ y) = \varphi(x) * \varphi(y)$ for all $x, y \in \{0, 1, 2\}$.

*Case* 1. $\varphi(0) = \varphi(1) = a$, $\varphi(2) = b$. In this case we have

$$\begin{aligned} a * a &= \varphi(0) * \varphi(0) = \varphi(0 \circ 0) = \varphi(0) = a, \\ a * b &= \varphi(0) * \varphi(2) = \varphi(0 \circ 2) = \varphi(1) = a, \\ b * a &= \varphi(2) * \varphi(0) = \varphi(2 \circ 0) = \varphi(1) = a, \\ b * b &= \varphi(2) * \varphi(2) = \varphi(2 \circ 2) = \varphi(2) = b. \end{aligned}$$

It is easy to check that $*$ is a semilattice operation on $\{a, b\}$. Hence, by Definition 3.3 and Theorem 16 of [29] (see Example 2.25), the algebra $\mathcal{B}$ is tractable.

*Case* 2. $\varphi(0) \neq \varphi(1)$.

It follows that $\varphi(2) \in \{\varphi(0), \varphi(1)\}$. If $\varphi(2) = \varphi(0)$, then

$$\varphi(0) = \varphi(0 \circ 0) = \varphi(0) * \varphi(0) = \varphi(0) * \varphi(2) = \varphi(0 \circ 2) = \varphi(1).$$

Alternatively, if $\varphi(2) = \varphi(1)$, then

$$\varphi(0) = \varphi(1 \circ 0) = \varphi(1) * \varphi(0) = \varphi(2) * \varphi(0) = \varphi(2 \circ 0) = \varphi(1).$$

Hence this second case is impossible, and we have shown that all smaller homomorphic images of $\mathcal{A}$ are tractable.

On the other hand, the algebra $\mathcal{A}$ has a subalgebra $\mathcal{A}' = (\{0, 1\}, \circ)$ such that $x \circ y = y$ for all $x, y \in \{0, 1\}$. By Corollary 3.5, $\mathcal{A}'$ is **NP**-complete. Hence, by Theorem 5.2, $\mathcal{A}$ is **NP**-complete. ◻

**6. Strictly simple surjective algebras.** The results of the previous section have established that a tractable algebra must have the property that all of its subalgebras and homomorphic images are tractable. Hence, a natural first question is whether we can classify the complexity of all algebras which do not have any smaller (nontrivial) subalgebras or homomorphic images. Classifying all such algebras can be viewed as a possible "base case for induction" in the pursuit of a general classification.

DEFINITION 6.1. *A finite algebra is called* simple *if all of its smaller homomorphic images are one-element; and* strictly simple[4] *if it is simple and all of its proper subalgebras are one-element.*

[4]In some papers appearing before 1990 such algebras are called *plain*.

By Theorem 4.4, it is sufficient to consider only surjective algebras. In this section we obtain a complete classification for all strictly simple surjective algebras.[5] We show that any algebra of this type is either tractable or **NP**-complete, and we give a complete characterization of the tractable cases. Such algebras include all surjective two-element algebras, as well as many algebras over larger universes, so this dichotomy result includes and generalizes Schaefer's dichotomy for algebras with a two-element universe (see Corollary 3.5 above).

To obtain the result, we make use of the complete description of finite strictly simple surjective algebras obtained by Szendrei [54]. To formulate Szendrei's result, we first need to introduce some further standard algebraic concepts and notation (for a general introduction to these algebraic concepts, see, for example, [37]).

Let $G$ be a permutation group acting on a set $A$. By $\mathcal{R}(G)$ we denote the set of operations on $A$ preserving each relation of the form $\{(a, g(a)) \mid a \in A\}$, for some $g \in G$. By $\mathcal{R}_{id}(G)$ we denote the set of idempotent operations in $\mathcal{R}(G)$.

A permutation group $G$ acting on a set $A$ is called *regular* if, for any $a, b \in A$, there exists $g \in G$ such that $g(a) = b$, and if each nonidentity member of $G$ has no fixed point. $G$ is called *primitive* if the algebra $(A, G)$ is simple.

Let $\overline{A} = (A, +)$ be a finite Abelian group, and let $K$ be a finite field. The finite dimensional vector space on $\overline{A}$ over $K$ will be denoted ${}_K\overline{A} = (A; +, K)$, the group of translations $\{x + a \mid a \in A\}$ will be denoted $T(\overline{A})$, and the endomorphism ring of ${}_K\overline{A}$ will be denoted $\mathsf{End}\ {}_K\overline{A}$. Note that one can consider $\overline{A}$ as a module over $\mathsf{End}\ {}_K\overline{A}$. This module will be denoted by ${}_{(\mathsf{End}\ {}_K\overline{A})}\overline{A}$.

Finally, let $\mathcal{F}_k^0$ denote the set of all operations preserving the relation

$$X_k^0 = \{(a_1, \dots, a_k) \in A^k \mid a_i = 0 \text{ for at least one } i,\ 1 \le i \le k\},$$

where 0 is some fixed element of $A$, and let $\mathcal{F}_\omega^0 = \bigcap_{k=2}^\infty \mathcal{F}_k^0$.

THEOREM 6.2 (see [54]). *Let $\mathcal{A}$ be a finite strictly simple surjective algebra.*

- *If $\mathcal{A}$ has no one-element subalgebras, then $\mathcal{A}$ is term equivalent to one of the following algebras:*
  - (a) *$(A, \mathcal{R}(G))$ for a regular permutation group $G$ acting on $A$;*
  - (b) *$(A, \mathsf{Term}_{\mathrm{id}}({}_{(\mathsf{End}\ {}_K\overline{A})}\overline{A}) \cup T(\overline{A}))$ for some vector space ${}_K\overline{A} = (A; +, K)$ over a finite field $K$;*
  - (c) *$(A, G)$ for a primitive permutation group $G$ on $A$.*
- *If $\mathcal{A}$ has one-element subalgebras, then $\mathcal{A}$ is idempotent and term equivalent to one of the following algebras:*
  - (a°) *$(A, \mathcal{R}_{id}(G))$ for a permutation group $G$ on $A$ such that every nonidentity member of $G$ has at most one fixed point;*
  - (b°) *$(A, \mathsf{Term}_{\mathrm{id}}({}_{(\mathsf{End}\ {}_K\overline{A})}\overline{A}))$ for some vector space ${}_K\overline{A}$ over a finite field $K$;*
  - (d) *$(A, \mathcal{R}_{id}(G) \cap \mathcal{F}_k^0)$ for some $k$ $(2 \le k \le \omega)$, some element $0 \in A$ and some permutation group $G$ acting on $A$ such that $0$ is the unique fixed point of every nonidentity member of $G$;*
  - (e) *$(A, F)$ where $|A| = 2$ and $F$ contains a semilattice operation;*
  - (f) *a two-element algebra with an empty set of basic operations.*

In the following theorem we determine all tractable finite strictly simple surjective algebras by analyzing each of the cases listed in Theorem 6.2.

[5]Note that the full idempotent reduct of a strictly simple surjective algebra is not always strictly simple. Hence we obtain a slightly stronger result by classifying all strictly simple surjective algebras, rather than just the strictly simple idempotent algebras.

THEOREM 6.3. *A finite strictly simple surjective algebra is* **NP***-complete if all of its term operations are essentially unary. Otherwise it is tractable.*

*Proof.* If $\mathcal{A}$ is an algebra of type (c) or (f), then all of its term operations are essentially unary. Hence $\mathsf{Pol}(\mathsf{Inv}(\mathsf{Term}(\mathcal{A})))$ contains essentially unary operations only, so $\mathcal{A}$ is **NP**-complete, by Proposition 2.27.

If $\mathcal{A} = (A, F)$ is an algebra of type (a) or (a°), then we claim that the dual discriminator operation $d(x, y, z)$ defined in Example 2.24 is a term operation of $\mathcal{A}$. To establish this claim, it is easy to verify that $d$ preserves every relation of the form $\{(a, g(a)) \mid a \in A\}$ where $g$ is a permutation on $A$. Since $d$ is an idempotent operation, it belongs to both $\mathcal{R}(G)$ and $\mathcal{R}_{id}(G)$. Hence, in cases (a) and (a°), every relation in $\mathsf{Inv}(F)$ is invariant under $d$. It follows from Theorem 5.7 of [30] that $\mathbf{CSP}(\mathsf{Inv}(F))$ is tractable (see Example 2.24). Hence, in this case $\mathcal{A}$ is tractable.

If $\mathcal{A}$ is an algebra of type (b) or (b°), then the affine operation $f(x, y, z) = x - y + z$ is a term operation of $\mathcal{A}$. Tractability of $\mathcal{A}$ then follows from Theorem 33 of [20] (see Example 3.7).

Now let $\mathcal{A} = (A, F)$ be an algebra of type (d) corresponding to some $k$ with $2 \leq k \leq \omega$. Consider the operation $f(x, y)$ defined as follows:

$$f(x,y) = \begin{cases} x & \text{if } x = y, \\ 0 & \text{otherwise.} \end{cases}$$

First, we show that $f$ preserves any relation of the form $g^\circ = \{(a, g(a)) \mid a \in A\}$ where $g \in G$. Let $\overline{a} = (a_1, a_2), \overline{b} = (b_1, b_2) \in g^\circ$. If $a_1 = b_1$, then $a_2 = g(a_1) = g(b_1) = b_2$, and, by definition of $f$, we have that the pair $f(\overline{a}, \overline{b})$ is equal to $(a_1, g(a_1))$ and hence belongs to $g^\circ$. If $a_1 \neq b_1$, then, since $g$ is a permutation, $a_2 \neq b_2$ and the pair $f(\overline{a}, \overline{b})$ equals $(0, 0)$, which also belongs to $g^\circ$ because 0 is a fixed point of $g$. Hence $f \in \mathcal{R}_{id}(G)$.

Next, we show that $f \in \mathcal{F}_k^0$. Let $\overline{a} = (a_1, \ldots, a_k), \overline{b} = (b_1, \ldots, b_k) \in X_k^0$; that is, each of $\overline{a}, \overline{b}$ contains 0. If, say, $a_i = 0$, then $f(a_i, b_i) = 0$, so the tuple $f(\overline{a}, \overline{b})$ contains 0 and hence belongs to $X_k^0$.

We have shown that $f \in \mathcal{R}_{id}(G) \cap \mathcal{F}_k^0$, and hence $f$ is a term operation of $\mathcal{A}$. It is easy to check that $f$ is a semilattice operation. By Theorem 16 of [29], this implies that $\mathbf{CSP}(\mathsf{Inv}(F))$ is tractable (see Example 2.25). Hence, in this case $\mathcal{A}$ is tractable.

Finally, if $\mathcal{A}$ is an algebra of type (e), then tractability again follows from Theorem 16 of [29]. ∎

## 7. Toward a general classification.

Theorem 6.3 gives a straightforward criterion to determine whether a finite strictly simple surjective algebra is tractable or **NP**-complete. In this section we examine what can be said about more general finite algebras.

Theorems 5.2 and 5.4 establish two separate necessary conditions for any finite algebra to be tractable. We can combine these conditions by using the standard algebraic notion of a *factor* [9].

DEFINITION 7.1. *A homomorphic image of a subalgebra of an algebra $\mathcal{A}$ is called a* factor *of $\mathcal{A}$. A factor whose universe contains only a single element is called a* trivial *factor.*

COROLLARY 7.2. *If $\mathcal{A}$ is a tractable finite algebra, then so is every factor of $\mathcal{A}$.*

Theorems 5.2 and 5.4 also establish two separate sufficient conditions for any finite algebra to be **NP**-complete. Using the notion of a factor, we can combine these results, together with Proposition 2.27, to obtain a single sufficient condition for **NP**-completeness.

Corollary 7.3. *A finite algebra $\mathcal{A}$ is* **NP**-*complete if it has a factor $\mathcal{B}$ all of whose term operations are essentially unary.*

However, the condition described in Corollary 7.3 is not a necessary condition for an arbitrary algebra $\mathcal{A}$ to be **NP**-complete, as the next example shows.

*Example* 7.4. Consider the algebra $\mathcal{A} = (\{0,1,2,3\}, \{d,f,p\})$, where $d$ is a binary operation and $f, p$ are unary operations, defined by the following tables:[6]

| $d$ | 0 | 1 | 2 | 3 |
|---|---|---|---|---|
| 0 | 0 | 3 | 0 | 3 |
| 1 | 2 | 1 | 2 | 1 |
| 2 | 2 | 1 | 2 | 1 |
| 3 | 0 | 3 | 0 | 3 |

| $x$ | $f(x)$ | $p(x)$ |
|---|---|---|
| 0 | 1 | 1 |
| 1 | 0 | 0 |
| 2 | 3 | 2 |
| 3 | 2 | 3 |

Since $f(0) = 1$, any subalgebra of $\mathcal{A}$ containing 0 also contains 1. Furthermore, since $f(1) = 0$, any subalgebra containing 1 also contains 0. Similarly, any subalgebra containing one of $2, 3$ also contains the other. Finally, since $d(0,1) = 3$ and $d(2,3) = 1$, it follows that the only subalgebra of $\mathcal{A}$ is $\mathcal{A}$ itself.

Now let $\phi$ be a homomorphism of $\mathcal{A}$. If $\phi(0) = \phi(1)$, then

$$\begin{aligned}\phi(2) &= \phi(d(1,0)) = d(\phi(1),\phi(0)) = d(\phi(0),\phi(0)) = \phi(0), \text{ and}\\ \phi(3) &= \phi(d(0,1)) = d(\phi(0),\phi(1)) = d(\phi(0),\phi(0)) = \phi(0),\end{aligned}$$

so $\phi$ maps all the elements of $\mathcal{A}$ to a single element. Furthermore, if $\phi(0) = \phi(2)$, then

$$\phi(0) = \phi(2) = \phi(p(2)) = p(\phi(2)) = p(\phi(0)) = \phi(p(0)) = \phi(1),$$

and we get the previous case. In all other cases a similar proof shows that if $\phi$ is not injective, then it maps all the elements of $\mathcal{A}$ to a single element.

Hence we have shown that the only nontrivial factor of $\mathcal{A}$ is $\mathcal{A}$ itself, and clearly not all the operations of $\mathcal{A}$ are essentially unary.

However, we will now show that $\mathcal{A}$ is **NP**-complete. (Note that this does not contradict Theorem 6.3 because $\mathcal{A}$ is not surjective.) To establish this, consider the ternary relation $\rho$, consisting of 36 tuples, defined as follows (where tuples are written as columns):

$$\rho = \begin{pmatrix} 0\,0\,0\,3\,3\,3\,0\,0\,0\,3\,3\,3\,1\,1\,1\,2\,2\,2\,1\,1\,1\,2\,2\,2\,1\,1\,1\,2\,2\,2\,0\,0\,0\,3\,3\,3 \\ 0\,3\,3\,0\,0\,3\,1\,1\,2\,1\,2\,2\,0\,0\,3\,0\,3\,3\,1\,2\,2\,1\,1\,2\,0\,0\,3\,0\,3\,3\,1\,1\,2\,1\,2\,2 \\ 1\,1\,2\,1\,2\,2\,0\,3\,3\,0\,0\,3\,0\,3\,0\,3\,0\,3\,0\,0\,3\,0\,3\,3\,1\,2\,2\,1\,1\,2\,1\,2\,1\,2\,1\,2 \end{pmatrix}.$$

It is straightforward to verify that this relation is invariant under the operations $d$, $f$, and $p$. However, if we set $h(x) = d(f(x), p(x))$, then $h(\rho) = N$, where $N$ is the relation defined in Example 2.28, and hence $\{h(\rho)\}$ is **NP**-complete. By Proposition 4.2, it follows that $\{\rho\}$ is **NP**-complete, and hence $\mathcal{A}$ is **NP**-complete. ☐

On the other hand, it was shown in Theorem 6.3 that the condition described in Corollary 7.3 is both necessary and sufficient for a finite strictly simple surjective algebra to be **NP**-complete (assuming that $\mathbf{P} \neq \mathbf{NP}$). Furthermore, all previously known forms of **NP**-complete constraint satisfaction problems (see [46, 52]) can be shown to be **NP**-complete using Corollary 7.3. Hence, we conjecture that the condition described in Corollary 7.3 is both necessary and sufficient for **NP**-completeness for any

[6]This algebra is, in fact, the *matrix square* [42] of $(\{0,1\}; ^{-})$, where $^{-}$ denotes the negation.

finite *surjective* algebra. We state this conjecture for the special case of idempotent algebras, where the only essentially unary operations are projections.

CONJECTURE 7.5 ("tractable algebras conjecture"). *A finite idempotent algebra $\mathcal{A}$ is* **NP***-complete if it has a nontrivial factor $\mathcal{B}$ all of whose operations are projections. Otherwise it is tractable.*

As shown in sections 2–4, the problem of determining the complexity of an arbitrary constraint language can be reduced to an equivalent problem for a certain idempotent algebra associated with the language. Therefore, this conjecture, if true, would solve all the various forms of the "tractability problem" mentioned above, including the original problem for arbitrary constraint languages, Problem 2.12.

The next examples show that Conjecture 7.5 is confirmed in a number of special cases, by existing dichotomy results. Moreover, we will show that in each case the existing dichotomy result can be obtained as a simple consequence of Conjecture 7.5.

*Example* 7.6. A dichotomy theorem for two-element algebras was given in Corollary 3.5. In this example we will show that this result is equivalent to Conjecture 7.5 restricted to two-element algebras.

Let $\mathcal{A}$ be a two-element algebra.

If $\mathcal{A}$ is idempotent, then Corollary 3.5 implies that either $\mathcal{A}$ is tractable, or else it is **NP**-complete and all of its operations are projections. Hence Corollary 3.5 implies that Conjecture 7.5 holds for any two-element algebra.

Conversely, we will now establish that Conjecture 7.5 implies Corollary 3.5. If $\mathcal{A}$ is not surjective, then it has a nonsurjective unary term operation, which must be constant, and hence $\mathcal{A}$ is tractable, by Theorem 4.4. On the other hand, if $\mathcal{A}$ is surjective, then by Theorem 4.7 we can consider its full idempotent reduct, $\mathcal{A}_0$. Assuming Conjecture 7.5 holds for any two-element algebra, we have that either $\mathcal{A}_0$ is tractable or else it is **NP**-complete and every operation of $\mathcal{A}_0$ is a projection. If every operation of $\mathcal{A}_0$ is a projection, then we claim that every operation of $\mathcal{A}$ must be essentially unary. To establish this claim, let $f$ be any term operation of $\mathcal{A}$. Since $\mathcal{A}$ is surjective, the unary term operation $g(x) = f(x, x, \ldots, x)$ must be a permutation. Now let $h$ be the composition of the inverse permutation $g^{-1}$ and $f$. It is easy to check that $h$ is an idempotent term operation of $\mathcal{A}$ and hence is an operation of $\mathcal{A}_0$. If $h$ is a projection, then $f$ must depend on only one of its arguments, which establishes the claim. Hence, we have shown that either $\mathcal{A}$ is tractable, or else every operation of $\mathcal{A}$ is essentially unary, which establishes that Conjecture 7.5 implies Corollary 3.5. □

*Example* 7.7. A dichotomy theorem for constraint languages on a three-element set was given as Theorem 4 of [3]. This result is stated in a very similar form to Conjecture 7.5, and is easily shown to be equivalent to this conjecture restricted to three-element algebras. □

*Example* 7.8. A constraint language containing all unary relations is called a *conservative* constraint language [5]. (One example of a problem with a conservative constraint language is the LIST $H$-COLORABILITY problem, defined in [19].)

It was shown in Theorem 4 of [5] that, for any conservative constraint language $\Gamma$ on a finite set $A$, either $\Gamma$ is tractable, or else there exists some two-element subset $B \subseteq A$, such that for every polymorphism $f$ of $\Gamma$, $f|_B$ is a projection. In this example we will show that this result is equivalent to Conjecture 7.5 restricted to algebras whose operations preserve all unary relations.

Let $\mathcal{A} = (A, F)$ be any finite algebra such that the set of relations $\Gamma = \mathsf{Inv}(F)$ contains all unary relations. Since $\Gamma$ contains every relation $\{(a)\}$, for each $a \in A$, the algebra $\mathcal{A}$ is idempotent. Furthermore, since $\Gamma$ contains every relation $\{(a_1), (a_2)\}$, for each two-element subset $B = \{a_1, a_2\} \subseteq A$, it follows that each of the corresponding algebras $\mathcal{B} = (B, F|_B)$ is a subalgebra of $\mathcal{A}$.

Hence, by Theorem 4 of [5], either $\Gamma$ is tractable, or else there exists some two-element subalgebra $\mathcal{B}$ of $\mathcal{A}$, all of whose operations are projections. Hence this result implies that Conjecture 7.5 holds for any algebra whose operations preserve all unary relations.

Conversely, to show that Conjecture 7.5 implies Theorem 4 of [5], assume that Conjecture 7.5 holds for the algebra $\mathcal{A}$. This implies that either $\Gamma$ is tractable, or else there exists some nontrivial factor $\mathcal{C}$ of $\mathcal{A}$ all of whose operations are projections. In the latter case, by the definition of a factor, $\mathcal{C}$ must be the image of some subalgebra $\mathcal{B}$ of $\mathcal{A}$ under some homomorphism $\varphi$. Choose elements $a_1, a_2 \in \mathcal{B}$ such that their images $\varphi(a_1), \varphi(a_2)$ in $\mathcal{C}$ are distinct. Since every two-element subset of $\mathcal{A}$ is a subalgebra, for any $f \in F$ we have that $f|_{\{a_1,a_2\}}$ has range $\{a_1, a_2\}$. Furthermore, the corresponding operation $f'$ of $\mathcal{C}$ is a projection, so we have that for any tuple $\overline{a}$ over $\{a_1, a_2\}$, the tuple $\varphi(f(\overline{a})) = f'(\varphi(\overline{a})) =$ the $i$th component of $\varphi(\overline{a})$ for some $i$. Hence $f|_{\{a_1,a_2\}}$ is also a projection, and we have shown that Conjecture 7.5 implies Theorem 4 of [5]. $\square$

Finally, we note that if Conjecture 7.5 is true, then it yields an effective procedure to determine whether any finite constraint language is tractable or **NP**-complete, as the following result indicates.

PROPOSITION 7.9. *Let $A$ be a finite set. If Conjecture 7.5 is true, then for any finite constraint language $\Gamma$ over $A$, it is possible to determine in polynomial time in the size of $\Gamma$ whether $\Gamma$ is* **NP***-complete or tractable.*

*Proof.* First set $\Gamma' = f(\Gamma) \cup \Gamma_{\text{CON}}$, where $f$ is a unary polymorphism of $\Gamma$ whose range $f(A) = U$ is minimal and $\Gamma_{\text{CON}} = \{\{(a)\} \mid a \in U\}$. (Note that the number of possible unary operations depends only on $|A|$, so $\Gamma'$ can be obtained in polynomial time in the size of $\Gamma$.) By Proposition 4.2 and Corollary 4.8, $\Gamma$ is **NP**-complete if and only if $\Gamma'$ is **NP**-complete, and $\Gamma$ is tractable if and only if $\Gamma'$ is tractable.

By Corollary 2.17 and Proposition 2.21, $\Gamma$ is **NP**-complete if and only if the idempotent algebra $\mathcal{A} = (U, Pol(\Gamma'))$ is **NP**-complete, and $\Gamma$ is tractable if and only if $\mathcal{A}$ is tractable. By Conjecture 7.5, $\mathcal{A}$ is **NP**-complete if it has a nontrivial factor $\mathcal{B}$ whose operations are all projections; otherwise it is tractable.

Assume first that $\mathcal{A}$ does have a nontrivial factor $\mathcal{B}$ whose operations are all projections, and let $\mathcal{B}$ be the homomorphic image of the subalgebra $\mathcal{A}'$ of $\mathcal{A}$ under the homomorphism $\varphi$. We may assume, without loss of generality, that the universe of $\mathcal{B}$ contains the set $\{0, 1\}$. The ternary **NP**-complete relation $N$, defined in Example 2.28, is preserved by all operations of $\mathcal{B}$, so the ternary relation $R = \varphi^{-1}(N)$ is preserved by all operations of $\mathcal{A}'$ and hence by all operations of $\mathcal{A}$. By Proposition 2.21, this implies that $R \in \langle \Gamma' \rangle$.

Conversely, assume that $R = \varphi^{-1}(N) \in \langle \Gamma' \rangle$, where $\varphi$ is an arbitrary unary function from some subset $A'$ of $U$ onto $\{0, 1\}$. By Proposition 2.21, $R$ is preserved by all operations of $\mathcal{A}$, and hence $A'$ is the universe of a subalgebra $\mathcal{A}'$ of $\mathcal{A}$. Furthermore, the relation $\varphi^{-1}(=_{\{0,1\}}) = \exists z R(x, z, z) \wedge R(y, z, z) \in \langle \Gamma' \rangle$. Using standard algebraic results (see Theorem 1.16 of [42]), this implies that $\varphi$ is a homomorphism from $\mathcal{A}'$ to a two-element factor $\mathcal{B}$ of $\mathcal{A}$ whose operations preserve $N$. Moreover, $\mathcal{B}$ is idempotent, so all its operations are projections.

It follows that $\Gamma$ is **NP**-complete if there is a relation $R \in \langle \Gamma' \rangle$ where $R$ is of the form $\varphi^{-1}(N)$ for some unary function $\varphi$ from some subset of $A$ onto $\{0, 1\}$, and in all other cases $\Gamma$ is tractable. By Proposition 1.1.19 of [48], the presence of any relation $R$ in $\langle \Gamma' \rangle$ can be determined by checking whether $R$ is preserved by all polymorphisms of $\Gamma'$ of arity bounded by $|R|$ (see [26] for an explicit construction). Since the number of possible unary functions $\varphi$ is less than $3^{|A|}$, and each $|R| \leq |A|^3$, this condition can be checked in polynomial time in the size of $\Gamma$, for any fixed finite set $A$. $\square$

**Acknowledgments.** The authors thank Victor Dalmau for reporting the result concerning idempotent reducts and for some comments simplifying the proof of Theorem 6.3, and David Cohen for drawing our attention to Corollary 4.9.

# ONLINE SCHEDULING OF PRECEDENCE CONSTRAINED TASKS[*]

YUMEI HUO[†] AND JOSEPH Y.-T. LEUNG[†]

**Abstract.** A fundamental problem in scheduling theory is that of scheduling a set of $n$ tasks, with precedence constraints, on $m \geq 1$ identical and parallel processors so as to minimize the makespan (schedule length). In the past, research has focused on the setting whereby all tasks are available for processing at the beginning (i.e., at time $t = 0$). In this article we consider the situation where tasks, along with their precedence constraints, are released at different times, and the scheduler has to make scheduling decisions without knowledge of future releases. In other words, the scheduler has to schedule tasks in an online fashion. We consider both preemptive and nonpreemptive schedules. We show that *optimal* online algorithms exist for some cases, while for others it is impossible to have one. Our results give a sharp boundary delineating the possible and the impossible cases.

**Key words.** schedule length, preemptive and nonpreemptive scheduling, online and offline scheduling, parallel and identical processors, precedence constraints, intrees, outtrees

## 1. Introduction.

A fundamental problem in scheduling theory is that of scheduling a set of $n$ tasks, with precedence constraints, on $m \geq 1$ identical and parallel processors so as to minimize the makespan (schedule length). In this setting we are given $n$ tasks, $1, 2, \ldots, n$, where each task $j$ has a processing time $p_j$. The tasks have precedence constraints, $\prec$, in that $i \prec j$ signifies that task $j$ cannot start until task $i$ is finished. The tasks, together with their precedence constraints, are described by a directed acyclic graph $G = (V, A)$, where $V$ is a set of vertices representing the tasks and $A$ is a set of directed arcs representing the precedence constraints; there is a directed arc from task $i$ to task $j$ if $i \prec j$. We assume the graph has no transitive edges. The tasks can be scheduled preemptively or nonpreemptively. In preemptive scheduling, a task can be interrupted before it completes and later resumed on a possibly different processor. We assume that there is no time loss in preemption. By contrast, in nonpreemptive scheduling, a task, once begun, cannot be interrupted until it completes. With respect to a schedule $S$, the completion time of task $i$ is denoted by $C_i$, and the makespan is denoted by $C_{\max} = \max\{C_i\}$. The goal is to schedule the set of tasks on $m \geq 1$ identical and parallel processors so as to minimize $C_{\max}$. In the three-field classification scheme introduced by Graham et al. [4], the problems considered in this article are $P \mid prec \mid C_{\max}$ and $P \mid pmtn, prec \mid C_{\max}$.

A task $i$ is said to be an *immediate predecessor* of another task $j$ if there is a directed arc $(i, j)$ in $G$; $j$ is said to be an *immediate successor* of $i$. Task $i$ is said to be a *predecessor* of task $j$ if there is a directed *path* from $i$ to $j$ in $G$; $j$ is said to be a *successor* of $i$. We say that $G$ is an *intree* if each vertex, except the root, has exactly one immediate successor. $G$ is an *outtree* if each vertex, except the root, has exactly one immediate predecessor. A *chain* is an outtree in which each vertex has at most

one immediate successor. We use *prec* to denote an arbitrary directed acyclic graph.

In the past, research in scheduling theory has concentrated on these four classes of precedence constraints: prec, intree, outtree, and chains. A number of polynomial-time algorithms have been developed. In nonpreemptive scheduling, the famous Coffman–Graham algorithm [1] is optimal for $P2 \mid p_j = 1, prec \mid C_{\max}$, while the well-known Hu algorithm [6] is optimal for $P \mid p_j = 1, intree \mid C_{\max}$ and $P \mid p_j = 1, outtree \mid C_{\max}$; we will describe these two algorithms in detail in the next section. It is known that $P \mid p_j = 1, prec \mid C_{\max}$ is strongly NP-hard [3], although the complexity is still open for each fixed $m \geq 3$. If the tasks have arbitrary processing times, then the problem becomes NP-hard in the ordinary sense even if we have two processors and the tasks are independent; i.e., $P2 \mid\mid C_{\max}$ is NP-hard in the ordinary sense [3].

For preemptive scheduling, the Muntz–Coffman algorithm [8, 9] is optimal for $P2 \mid pmtn, prec \mid C_{\max}$, $P \mid pmtn, intree \mid C_{\max}$, and $P \mid pmtn, outtree \mid C_{\max}$; we will describe this algorithm in detail in section 3. Again, $P \mid pmtn, prec \mid C_{\max}$ is strongly NP-hard [3], while the complexity is still open for each fixed $m \geq 3$.

All of the algorithms mentioned above assume that all tasks are available for processing at the beginning (i.e., at time $t = 0$). In this article, we consider the situation where tasks, along with their precedence constraints, are released at different times, and the scheduler has to make scheduling decisions without knowledge of future releases. In other words, the scheduler has to schedule tasks in an online fashion. We say that an online scheduling algorithm is *optimal* if it always produces a schedule with the minimum $C_{\max}$, i.e., a schedule as good as any schedule produced by any scheduling algorithm with full knowledge of future releases of tasks. Since an online scheduling algorithm has to schedule tasks in an online fashion, it is not clear that an optimal online scheduling algorithm necessarily exists. In this article, we show that online scheduling algorithms exist for some cases, while for others it is impossible to have one. Our results give a sharp boundary delineating the possible and the impossible cases.

We extend the notation of Graham et al. [4] to online scheduling problems in a natural way. For example, $P2 \mid p_j = 1, prec_i \textit{ released at } r_i \mid C_{\max}$ refers to the case where tasks with arbitrary precedence constraint, $prec_i$, are released at time $r_i$. In this case, there are two processors, each task has unit processing time, and preemption is not allowed. As another example, $P \mid pmtn, outtree_i \textit{ released at } r_i \mid C_{\max}$ refers to the case where tasks with outtree precedence constraint, $outtree_i$, are released at time $r_i$. In this case, there is an arbitrary number of processors, tasks have arbitrary processing times, and preemption is allowed.

Hong and Leung [5] have given an optimal online scheduling algorithm for a set of independent tasks on an arbitrary number of processors where preemption is allowed. The idea of their algorithm is to schedule tasks using a modified McNaughton wrap-around rule. (It is known that McNaughton's wrap-around rule is optimal for $P \mid pmtn \mid C_{\max}$ [7].) Tasks will be executed according to the schedule until new tasks arrive, at which time the algorithm will reschedule, by the same rule, the remaining portions of the unfinished tasks along with the newly arrived tasks. This process is repeated until all tasks are finished and no new tasks arrive.

Note that for nonpreemptive scheduling, it can be shown that it is impossible to have an optimal online algorithm for a set of independent tasks with arbitrary processing times, even if there are only two processors.

In this article, we show that optimal online scheduling algorithms exist for

(1) $P2 \mid p_j = 1, prec_i \textit{ released at } r_i \mid C_{\max}$;

(2) $P \mid p_j = 1, outtree_i \textit{ released at } r_i \mid C_{\max}$;

(3) $P2 \mid pmtn, prec_i\ released\ at\ r_i \mid C_{\max}$;
(4) $P \mid pmtn, outtree_i\ released\ at\ r_i \mid C_{\max}$.

Using an adversary argument, we show that it is impossible to have optimal online scheduling algorithms for

(1) $P3 \mid p_j = 1, intree_i\ released\ at\ r_i \mid C_{\max}$;
(2) $P2 \mid p_j = p, chains_i\ released\ at\ r_i \mid C_{\max}$;
(3) $P3 \mid pmtn, p_j = 1, intree_i\ released\ at\ r_i \mid C_{\max}$.

All of our optimal online scheduling algorithms follow the same format as the algorithm given in Hong and Leung [5]. For $P2 \mid p_j = 1, prec_i\ released\ at\ r_i \mid C_{\max}$, we use the Coffman–Graham algorithm to schedule tasks and follow the schedule to execute tasks until new tasks arrive, at which time we reschedule the remaining portions of the unfinished tasks along with the newly arrived tasks. We use Hu's algorithm for $P \mid p_j = 1, outtree_i\ released\ at\ r_i \mid C_{\max}$, and the Muntz–Coffman algorithm for $P2 \mid pmtn, prec_i\ released\ at\ r_i \mid C_{\max}$ and $P \mid pmtn, outtree_i\ released\ at\ r_i \mid C_{\max}$.

The organization of this article is as follows. In the next section we consider nonpreemptive scheduling, while preemptive scheduling will be considered in section 3. We draw some conclusions in the last section.

## 2. Nonpreemtive schedules.

In this section we consider nonpreemptive scheduling only. We first show that it is impossible to have optimal online algorithms for $P3 \mid p_j = 1, intree_i\ released\ at\ r_i \mid C_{\max}$ and $P2 \mid p_j = p, chains_i\ released\ at\ r_i \mid C_{\max}$. We then give an optimal online algorithm for $P2 \mid p_j = 1, prec_i\ released\ at\ r_i \mid C_{\max}$ in section 2.1 and an optimal online algorithm for $P \mid p_j = 1, outtree_i\ released\ at\ r_i \mid C_{\max}$ in section 2.2.

THEOREM 2.1. *It is impossible to have an optimal online algorithm for* $P3 \mid p_j = 1, intree_i\ released\ at\ r_i \mid C_{\max}$.

*Proof.* We will use an adversary argument to prove the theorem. Consider the intrees shown in Figure 2.1: the number of processors is three, $intree_1$ is released at $r_1 = 0$, and $intree_2$ is released at $r_2 = 4$.

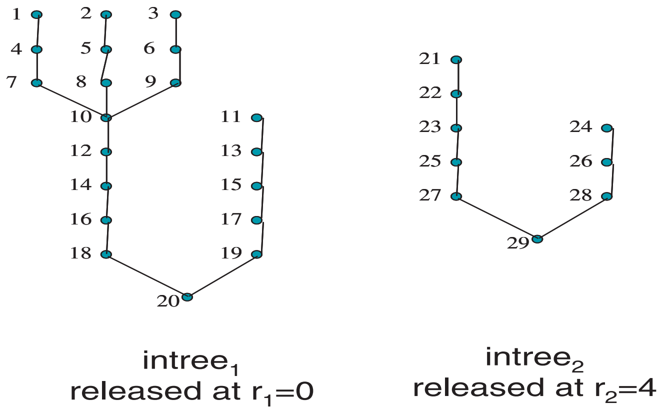

FIG. 2.1. *Example showing impossibility for* $P3|p_j = 1, intree_i\ released\ at\ r_i|C_{\max}$.

For $intree_1$, the length of the longest path is nine, so the makespan cannot be smaller than nine. To obtain the minimum makespan, task 10 must finish by time $t = 4$, which means that all its predecessors must be finished by time $t = 3$. Since task 10 has nine predecessors and since there are only three processors, all of the predecessors of task 10 must be executed in the first three time units. This means that there must be an idle processor in the time interval $[3, 4]$. Now, if $intree_2$ is released at time $t = 4$, then the makespan must be larger than 10. As shown in Figure 2.2, the optimal makespan is 10. On the other hand, if task 10 is not completed by time $t = 4$, then the schedule is already not optimal for $intree_1$.

FIG. 2.2. *Schedule for the example in Figure* 2.1.

Thus, the adversary first releases $intree_1$ at time $t = 0$. If the online algorithm did not finish task 10 by time $t = 4$, then the schedule produced by the online algorithm is already not optimal for $intree_1$. On the other hand, if the online algorithm completes task 10 by time $t = 4$, then the adversary releases $intree_2$ at time $t = 4$. The online algorithm cannot finish both intrees by time $t = 10$, but the optimal makespan is 10. Again, the online algorithm did not produce an optimal schedule. $\square$

THEOREM 2.2. *It is impossible to have an optimal online algorithm for* $P2 \mid p_j = p, chains_i \text{ released at } r_i \mid C_{\max}$.

*Proof.* Consider the chains shown in Figure 2.3: two chains released at $r_1 = 0$, one chain released at $r_2 = 5$; each task in the chains has two units of processing time; and the number of processors is two. The minimum makespan for the first two chains (released at time $t = 0$) is 6, which can be attained only if both chains execute continuously from time $t = 0$ until time $t = 6$. Now, if the second chain is released at time $t = 5$, then the makespan will be 16. However, as shown in Figure 2.3, the optimal makespan is 15.

Thus, the adversary first releases the two chains at time $t = 0$. If the online algorithm leaves a processor idle in the time interval $[0, 5]$, then the schedule is already not optimal for the two chains. On the other hand, if the online algorithm keeps both processors busy during the interval $[0, 5]$, then the adversary releases the second chain at time $t = 5$. The online algorithm cannot finish all the chains by time 15, but the optimal makespan is 15. Again, the online algorithm did not produce an optimal schedule. $\square$

## 2.1. UET tasks, arbitrary precedence constraint, and two processors.

The Coffman–Graham algorithm is optimal for $P2 \mid p_j = 1, prec \mid C_{\max}$. It works by first assigning a label to each task which corresponds to the priority of the task; tasks with higher labels have higher priority. Once the labels are assigned, tasks are scheduled as follows: whenever a processor becomes free, assign it a task, all of whose predecessors have already been executed and which has the largest label among those tasks not yet assigned.

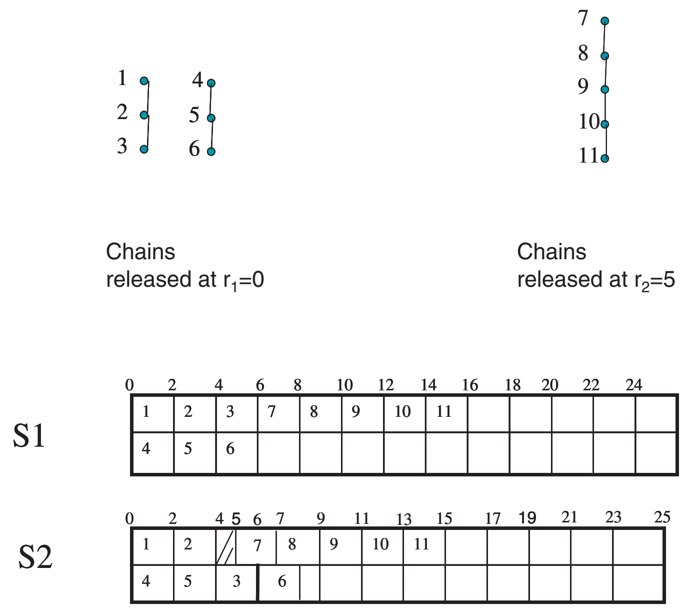

Fig. 2.3. *Example showing impossibility for* $P2 \mid p_j = p, chains_i$ *released at* $r_i \mid C_{\max}$.

Before we describe the labeling algorithm, we need to define a linear order on decreasing sequences of positive integers, as follows.

Definition 2.3. *Let* $N = (n_1, n_2, \ldots, n_t)$ *and* $N' = (n'_1, n'_2, \ldots, n'_{t'})$ *be two decreasing sequences of positive integers. We say that* $N < N'$ *if either of the following hold:*

1. *For some* $i$, $1 \le i \le t$, *we have* $n_j = n'_j$ *for all* $j$ *satisfying* $1 \le j \le i-1$ *and* $n_i < n'_i$.
2. $t < t'$ *and* $n_j = n'_j$ *for all* $j$ *satisfying* $1 \le j \le t$.

*Example.* $(8, 6, 4, 3) < (8, 6, 5)$ and $(9, 8, 6) < (9, 8, 6, 4, 3)$.

Let $n$ denote the number of tasks in *prec*. The labeling algorithm assigns to each task $i$ an integer label $\alpha(i) \in \{1, 2, \ldots, n\}$. The mapping $\alpha$ is defined as follows. Let $IS(i)$ denote the set of immediate successors of task $i$ and let $N(i)$ denote the decreasing sequence of integers formed by ordering the set $\{\alpha(j) \mid j \in IS(i)\}$.

1. An arbitrary task $i$ with $IS(i) = \emptyset$ is chosen and $\alpha(i)$ is defined to be 1.
2. Suppose for some $k \le n$ that the integers $1, 2, \ldots, k-1$ have been assigned. From the set of tasks for which $\alpha$ has been defined on all elements of their immediate successors, choose the task $j$ such that $N(j) \le N(i)$ for all such tasks $i$. Define $\alpha(j)$ to be $k$.
3. Repeat the assignment in step 2 until all tasks of *prec* have been assigned some integer.

*Example.* Figure 2.4 shows a set of tasks with their precedence constraints. The number inside each circle represents the task's index and the number next to each circle represents the label assigned to the task by the Coffman–Graham labeling algorithm. The schedule on two processors is also shown in Figure 2.4.

Our online algorithm utilizes the Coffman–Graham algorithm to schedule tasks. When new tasks arrive, the new tasks along with the unexecuted portion of the unfinished tasks will be rescheduled by the Coffman–Graham algorithm again.

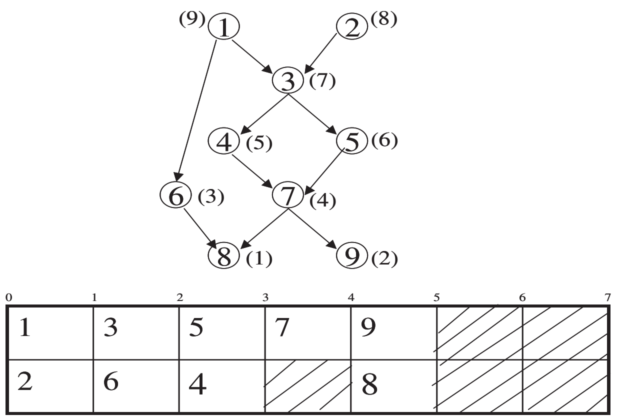

FIG. 2.4. *Example illustrating the Coffman–Graham algorithm.*

ALGORITHM A.

```
Whenever new tasks arrive, do {
    $t \leftarrow$ the current time;
    $U \leftarrow$ the set of tasks active (i.e., not finished) at time $t$;
    Call the Coffman–Graham algorithm to reschedule the tasks in $U$;
}
```

*Example.* Figure 2.5 shows another set of tasks released at time $r_2 = 2$ after the tasks in Figure 2.4 were released at time $r_1 = 0$. Note that tasks 4, 5, 7, 8, and 9 from the first release are unfinished at time $t = 2$. They are rescheduled, along with the new tasks from the second release, by the Coffman–Graham algorithm. The final schedule obtained by Algorithm A is also shown.

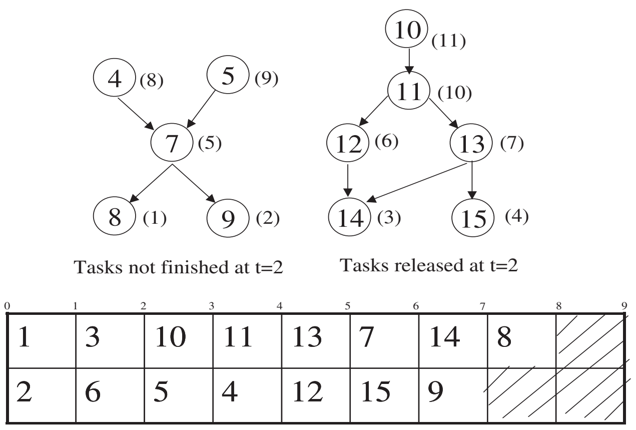

FIG. 2.5. *Example illustrating Algorithm* A.

The next lemma, whose proof will be omitted, is instrumental in proving that Algorithm A is optimal.

LEMMA 2.4. *Let S be a schedule for a set of tasks with arbitrary precedence constraints, where each task has unit processing time.*

1. *If S has the largest number of tasks completed at any time instant t, then S*

*must be optimal for $C_{\max}$.*

2. *If $S$ has the minimum idle processor time at any time instant $t$, then $S$ must be optimal for $C_{\max}$.*
3. *For two processors, the schedule $S'$ produced by the Coffman–Graham algorithm has the largest number of tasks completed at any time instant $t$.*

THEOREM 2.5. *Algorithm* A *is optimal for $P2 \mid p_j = 1, prec_i$ released at $r_i \mid C_{\max}$. Moreover, the schedule produced by Algorithm* A *has the largest number of tasks completed at any time instant $t$.*

*Proof.* We will prove the theorem by induction on the number, $i$, of release times. The basis case of $i = 1$ follows from Lemma 2.4. Assume the theorem is true for $i = k - 1$ release times; we will show that the theorem is true for $i = k$ release times.

Let $S_{k-1}$ denote the schedule obtained by Algorithm A after the first $k-1$ releases. By the induction hypothesis, $S_{k-1}$ is optimal for the tasks in the first $k - 1$ releases and has the largest number of tasks completed at any time instant $t$. The release time $r_k$ divides the tasks into two groups: (1) $\tau_1$, tasks completed by $r_k$ in $S_{k-1}$; and (2) $\tau_2$, tasks completed after $r_k$ in $S_{k-1}$. Let $S_k$ denote the schedule obtained by Algorithm A after the $k$th release. By the nature of Algorithm A, $S_k$ is identical to $S_{k-1}$ from time 0 until $r_k$. Thus, every task in $\tau_1$ is completed by $r_k$ in $S_k$ as well.

Let $\hat{S}_k$ be any schedule (including optimal schedules) for $k$ releases. The release time $r_k$ divides the tasks into two groups: (1) $\hat{\tau}_1$, tasks completed by $r_k$ in $\hat{S}_k$; and (2) $\hat{\tau}_2$, tasks completed after $r_k$ in $\hat{S}_k$. Let $prec_k$ denote all the tasks in the $k$th release. It is clear that the tasks in $\tau_1 \cup \tau_2$ are the same as the tasks in $\hat{\tau}_1 \cup \hat{\tau}_2 \setminus prec_k$.

We now construct another schedule $\bar{S}_k$ from $\hat{S}_k$ as follows: (1) Delete all the tasks in $\tau_1 \cup \tau_2$ from $\hat{S}_k$. (2) Schedule all the tasks in $\tau_1$ exactly as in $S_{k-1}$. The schedule $\bar{S}_k$ is identical to $S_{k-1}$ from time 0 until $r_k$. After $r_k$, it has tasks in $prec_k$ scheduled exactly as in $\hat{S}_k$ and idle processor times due to the deletion of the tasks in $\tau_1 \cup \tau_2$.

We want to show that we can schedule the tasks in $\tau_2$ into the idle processor times in $\bar{S}_k$ in such a way that the number of tasks completed at each time instant $t$ is not smaller than that in $\hat{S}_k$. By Lemma 2.4, $\bar{S}_k$ has the same makespan as $\hat{S}_k$.

Let $L$ be the list of tasks in $\tau_2$ in ascending order of their completion times in $S_{k-1}$. We schedule the tasks in $\tau_2$ as follows. Whenever there is an idle processor time, scan the list $L$ and assign the first ready task encountered in the scan to the idle time.

We keep assigning tasks by the above method until we first encounter a time $t^*$ such that both processors are idle in the time interval $[t^*, t^* + 1]$, $j$ is the only task from $\tau_2$ that can be assigned in the interval, and the number of tasks completed by $t^* + 1$ in $\bar{S}_k$ is smaller than that completed at the same time in $\hat{S}_k$. Since we cannot assign another task in the interval, the remaining unassigned tasks in $\tau_2$ must all be successors of task $j$. There are two cases to consider.

*Case* I. There is a time $t'$, $r_k \le t' < t^*$, such that both processors are executing some tasks in $prec_k$ in the time interval $[t', t' + 1]$. If there are several such times, let $t'$ be the largest.

Shown in Figure 2.6(a) is an example of Case I. In this figure, $x_j$ denotes a task in $prec_k$ and $y_j$ denotes a task in $\tau_2$. We transform the schedule to the one shown in Figure 2.6(b). After the transformation, task $j$ is completed by $t^*$ and an immediate successor of $j$ (task $k$ shown in the figure) can now be scheduled in the time interval $[t^*, t^* + 1]$. It is clear that there is no precedence constraint violation in the transformed schedule.

*Case* II. In every time interval $[t, t + 1]$, $r_k \le t < t^*$, at most one processor is

(Note: Task k is an immediate successor of task j)

Fig(b) The transformed schedule

FIG. 2.6. *Example illustrating the proof of Case* I.

executing some task in $prec_k$.

In this case we pull out all the tasks in $prec_k$ that were scheduled in the time interval $[r_k, t^* + 1]$ and reschedule all the tasks in $\tau_2$ as in $S_{k-1}$. By the induction hypothesis, $S_{k-1}$ has the largest number of tasks completed at any time instant, and hence it can complete all the tasks by $t^*$. The schedule will be rearranged so that in every time interval $[t, t+1]$, $r_k \leq t < t^*$, at least one processor is executing a task in $\tau_2$; i.e., there is no time interval $[t, t+1]$ such that both processors are idle. We now schedule the tasks in $prec_k$ into the idle processor times and an immediate successor of $j$ in the time interval $[t^*, t^*+1]$. It is clear that the schedule has no precedence constraint violation.

After we perform the above operations, the number of tasks completed by time $t^* + 1$ in $\bar{S}_k$ is identical to that in $\hat{S}_k$. We can continue this operation until all tasks in $\tau_2$ have been scheduled. Thus, the number of tasks completed at each time instant $t$ is not smaller than that in $\hat{S}_k$.

Observe that $S_k$ is identical to $S_{k-1}$ from time 0 until $r_k$. Thus, it has the largest number of tasks completed at each time instant $t$ from time 0 up until $r_k$. After $r_k$, the tasks are scheduled by the Coffman–Graham algorithm, and hence $S_k$ has the largest number of tasks completed at each time instant $t$. ◻

**2.2. UET tasks, outtrees, and arbitrary number of processors.** Hu's algorithm is optimal for $P \mid p_j = 1, outtree \mid C_{\max}$. Like the Coffman–Graham algorithm, it first assigns a label to each task which corresponds to the priority of the task; tasks with higher labels have higher priority. Once the labels are assigned, tasks are scheduled as follows: whenever a processor becomes free, assign it a task, all of whose predecessors have already been executed and which has the largest label among those tasks not yet assigned. In Hu's algorithm, the label of a task is a function of the *level* of the task.

DEFINITION 2.6. *The level of a task i with no immediate successor is its processing time $p_i$. The level of a task with immediate successor(s) is its processing time plus the maximum level of its immediate successor(s).*

Hu's labeling algorithm assigns higher labels to tasks at higher levels; ties are broken in an arbitrary manner.

*Example.* Figure 2.7 shows a set of tasks with outtree precedence constraint. The number inside each circle is the task's index and the number next to each circle is the label given by Hu's algorithm. A schedule on four processors produced by Hu's algorithm is also shown.

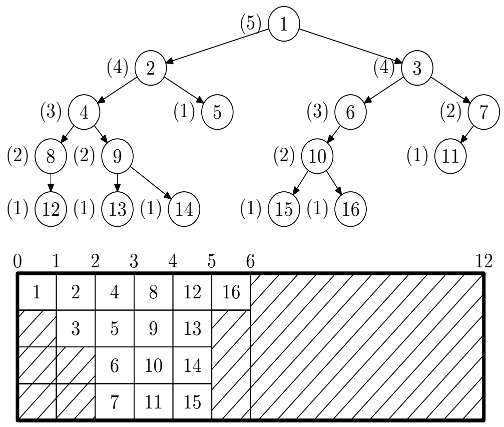

FIG. 2.7. *Example illustrating Hu's algorithm.*

Our online algorithm utilizes Hu's algorithm to schedule tasks. Whenever new tasks arrive, the new tasks along with the unexecuted portion of the unfinished tasks will be rescheduled by Hu's algorithm again.

ALGORITHM B.

```
Whenever new tasks arrive, do {
    $t \leftarrow$ the current time;
    $U \leftarrow$ the set of tasks active (i.e., not finished) at time $t$;
    Call Hu's algorithm to reschedule the tasks in $U$;
}
```

*Example.* Figure 2.8 shows another outtree released at time $r_2 = 3$ after the outtree shown in Figure 2.7 was released at time $r_1 = 0$. The schedule produced by Algorithm B is also shown.

THEOREM 2.7. *Algorithm* B *is optimal for* $P \mid p_j = 1, outtree_i$ *released at* $r_i \mid C_{\max}$. *Moreover, the schedule produced by Algorithm* B *has the largest number of tasks completed at any time instant* $t$.

*Proof.* Let $S$ be the schedule produced by Algorithm B for an instance of the $P \mid p_j = 1, outtree_i$ *released at* $r_i \mid C_{\max}$ problem and let $\hat{S}$ be any schedule (including optimal schedules). We will show, by contradiction, that the number of tasks completed in $S$ at each time instant $t$ is not smaller than that in $\hat{S}$. By Lemma 2.4, $S$ is an optimal schedule. Suppose this is not the case. Let $t'$ be the first time instant such that the number of tasks completed in $S$ is less than that in $\hat{S}$. Then there must be an idle processor in the time interval $[t' - 1, t']$ in $S$.

Consider the schedule $\hat{S}$. Let $k$ be the earliest completed task executed in $\hat{S}$ in the time interval $[0, t']$ that is not executed in $S$, and let $k$ be completed at time $t^*$ in $\hat{S}$. Assume that $k$ is in $outtree_i$. We claim that we can schedule $k$ in the time interval $[t' - 1, t']$ in $S$ as well. Suppose this is not the case. Then there must be a predecessor of $k$, say $j$, executing in the time interval $[t' - 1, t']$ in $S$. Let $t$ be the first time instant such that predecessors of $k$ are continuously executing from time $t$

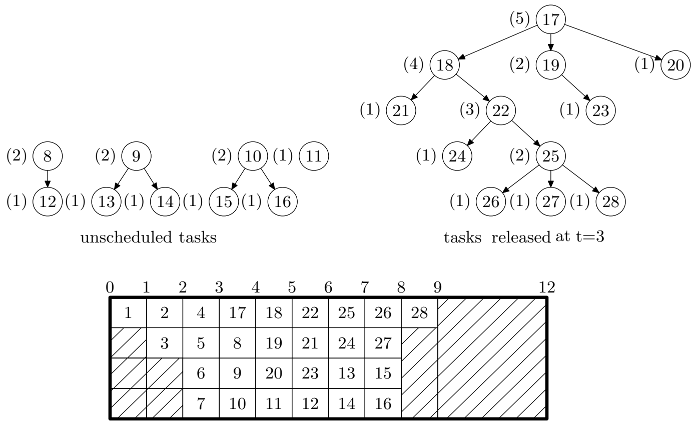

FIG. 2.8. *Example illustrating Algorithm* B.

until $t'$ in $S$, but that no predecessor of $k$ is executing in the time interval $[t-1, t]$. We have two cases to consider.

*Case* I. $t = r_i$.

In this case, it is clear that $k$ must be completed after $t'$ in any schedule whatsoever, contradicting our assumption that $k$ is completed by $t'$ in $\hat{S}$.

*Case* II. $t > r_i$.

Let $l$ be the predecessor of $k$ executed in the time interval $[t, t+1]$ in $S$. According to Hu's algorithm, $l$ was not executed in the time interval $[t-1, t]$ because the tasks executed in that time interval in $S$ all have levels greater than or equal to that of $l$, and because all processors are busy in the time interval. Since we are considering outtrees, every processor must be busy from time $t-1$ until $t'$, contradicting the fact that there is an idle processor in the time interval $[t'-1, t']$.

Repeating the above argument, we can show that the number of tasks completed by $t'$ in $S$ is not smaller than that in $\hat{S}$. $\square$

**3. Preemptive schedules.** In this section we consider preemptive scheduling only. We first show that it is impossible to have an optimal online algorithm for $P3 \mid pmtn, p_j = 1, intree_i \text{ released at } r_i \mid C_{\max}$. We then give an optimal online algorithm for $P2 \mid pmtn, prec_i \text{ released at } r_i \mid C_{\max}$ and $P \mid pmtn, outtree_i \text{ released at } r_i \mid C_{\max}$.

THEOREM 3.1. *It is impossible to have an optimal online algorithm for* $P3 \mid pmtn, p_j = 1, intree_i \text{ released at } r_i \mid C_{\max}$.

*Proof.* The proof given in Theorem 2.1 also proves this theorem since preemption won't help. $\square$

The Muntz–Coffman algorithm is optimal for the problems $P2 \mid pmtn, prec \mid C_{\max}$, $P \mid pmtn, intree \mid C_{\max}$, and $P \mid pmtn, outtree \mid C_{\max}$. It is essentially a highest-level-first strategy; see section 2.2 for the definition of level.

MUNTZ–COFFMAN ALGORITHM. Assign one processor each to the tasks at the highest level. If there is a tie among $y$ tasks (because they are at the same level) for the last $x$ $(x < y)$ processors, then assign $\frac{x}{y}$ processor to each of these $y$ tasks. Whenever either of the two events below occurs, reassign the processors to the unexecuted portion of the unfinished tasks according to the above rule. These are the following:

1. A task is completed.

2. We reach a point where, if we were to continue the present assignment, we would be executing some lower level tasks at a faster rate than other higher level tasks.

The schedule produced by the Muntz–Coffman algorithm is a processor-sharing schedule. We can convert it to a preemptive schedule by marking the time instants where processor assignment changes, and rescheduling the tasks executed between two adjacent time instants by McNaughton's wrap-around rule.

*Example.* Figure 3.1 shows a set of tasks with their precedence constraints. Inside each circle is the name of the task and its processing time. The number next to each circle is the level of the task. The processor-sharing schedule on two processors produced by the Muntz–Coffman algorithm is shown. Finally, the preemptive schedule constructed from the processor-sharing schedule is also shown.

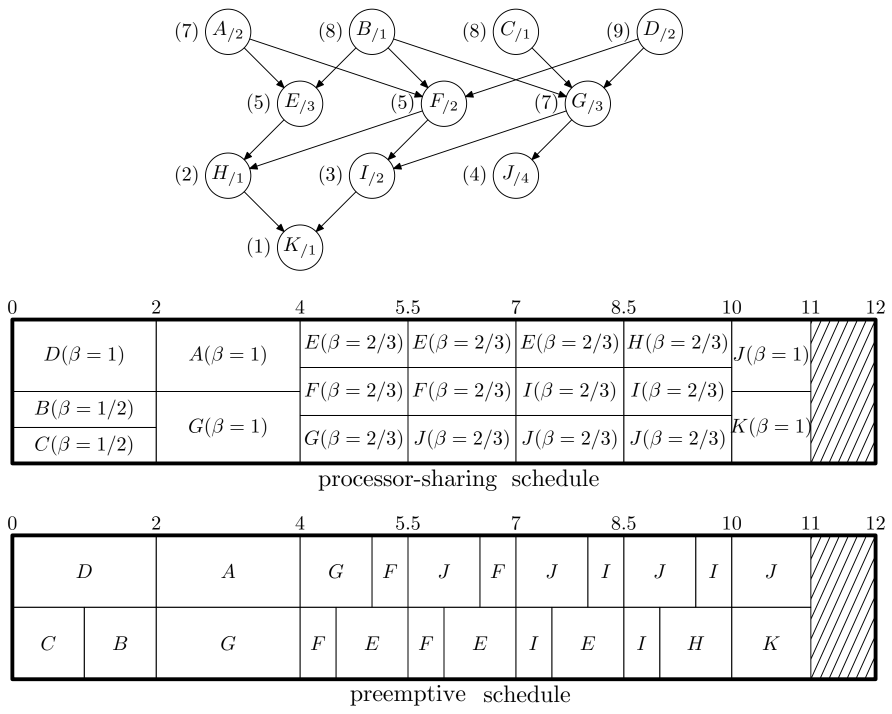

FIG. 3.1. *Example illustrating the Muntz–Coffman algorithm.*

Our online algorithm utilizes the Muntz–Coffman algorithm to schedule tasks. When new tasks arrive, the new tasks along with the unexecuted portion of the unfinished tasks will be rescheduled by the Muntz–Coffman algorithm again.

ALGORITHM C.

```
Whenever new tasks arrive, do {
    $t \leftarrow$ the current time;
    $U \leftarrow$ the set of tasks active (i.e., not finished) at time $t$;
    Call the Muntz–Coffman algorithm to reschedule the tasks in $U$;
}
```

Figure 3.2 shows another set of tasks released at time $r_2 = 6$ after the tasks in Figure 3.1 were released at time $r_1 = 0$. Algorithm C reschedules the unfinished portion of the unfinished tasks along with the new tasks. The processor-sharing

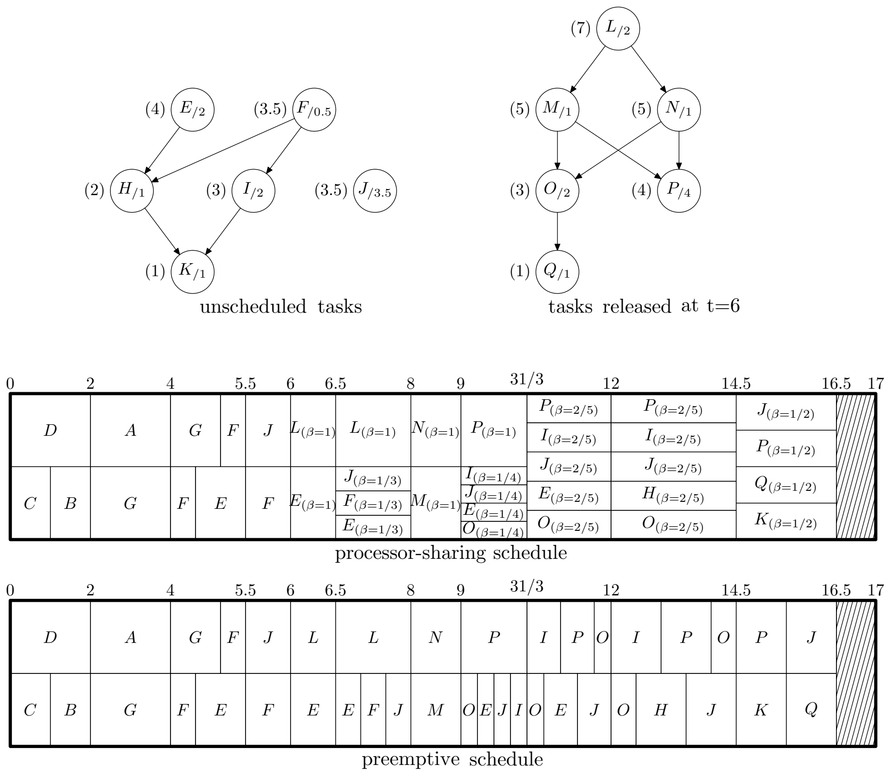

FIG. 3.2. *Example illustrating Algorithm* C.

schedule and the preemptive schedule are also shown.

Before we give the proofs that Algorithm C is optimal for $P2 \mid pmtn, prec_i$ *released at* $r_i \mid C_{\max}$ and $P \mid pmtn, outtree_i$ *released at* $r_i \mid C_{\max}$, we will give an optimal offline algorithm for these two cases.

ALGORITHM D. Assign one processor each to the tasks at the highest level. If there is a tie among $y$ tasks (because they are at the same level) for the last $x$ ($x < y$) processors, then assign $\frac{x}{y}$ processor to each of these $y$ tasks. Whenever one of the three events below occurs, reassign the processors to the unexecuted portion of the unfinished tasks according to the above rule. These are the following:

1. A task is completed.
2. We reach a point where, if we were to continue the present assignment, we would be executing some lower level tasks at a faster rate than other higher level tasks.
3. New tasks arrive.

Algorithm D is essentially the Muntz–Coffman algorithm, except that another new event—the arrival of new tasks—is added. In sections 3.1 and 3.2, we will prove that Algorithm D is an optimal offline algorithm for $P2 \mid pmtn, prec_i$ *released at* $r_i \mid C_{\max}$ and $P \mid pmtn, outtree_i$ *released at* $r_i \mid C_{\max}$, respectively. Shown in Figure 3.3 are the processor-sharing schedule and the preemptive schedule constructed by Algorithm D for the instance given in Figure 3.2.

Our proofs that Algorithm C is optimal for $P2 \mid pmtn, prec_i$ *released at* $r_i \mid C_{\max}$ and $P \mid pmtn, outtree_i$ *released at* $r_i \mid C_{\max}$ are based on the fact that Algorithm D

FIG. 3.3. *Example illustrating Algorithm* D.

is an optimal offline algorithm for these two cases.

**3.1. Arbitrary precedence constraint and two processors.** We first show that Algorithm D is an optimal offline algorithm for $P2 \mid pmtn, prec_i\ released\ at\ r_i \mid C_{\max}$, and then we show that Algorithm C is an optimal online algorithm for the same case.

LEMMA 3.2. *Let $S$ be the processor-sharing schedule produced by the Muntz–Coffman algorithm for an instance of $P2 \mid pmtn, prec \mid C_{max}$. Then $S$ has the minimum idle processor time at any time instant $t$.*

*Proof.* We will prove the lemma by contradiction. Let $S$ be the processor-sharing schedule produced by the Muntz–Coffman algorithm for an instance of $P2 \mid pmtn, prec \mid C_{max}$, and let $\hat{S}$ be any schedule (including optimal schedules) for the same instance. Let $t'$ be the first time instant such that the idle processor time in $S$ is larger than that in $\hat{S}$. Then there must be an idle processor in the time interval $[t', t' + \epsilon]$ in $S$ for some small positive number $\epsilon$. According to the Muntz–Coffman algorithm, the reason that a processor is idle in $[t', t' + \epsilon]$ is that no task is ready in the interval other than those that are already executing in the interval. Let $k$ be the earliest task executed in $\hat{S}$ in the time interval $[0, t' + \epsilon]$ but not in $S$, and let $k$ start its execution at time $t^*$ in $\hat{S}$. We assert that $k$ can be scheduled in the time interval $[t', t' + \epsilon]$ in $S$ as well. Suppose this is not the case. Then there must be a predecessor of $k$, say $j$, executing in the time interval $[t', t' + \epsilon]$ in $S$. Let $t$ be the first time instant such that predecessors of $k$ are continuously executing from time $t$ until $t' + \epsilon$ in $S$ but that no predecessor of $k$ is executing in the time interval $[t - \delta, t]$ for some small positive number $\delta$. We have two cases to consider.

*Case* I. $t = 0$.

If the predecessors of $k$ are continuously executed either by one full processor or without sharing any processors with jobs that are not predecessors of $k$ from time $t$ until $t' + \epsilon$, then it is clear that $k$ cannot be scheduled before $t' + \epsilon$ in any schedule whatsoever, contradicting the assumption that $k$ is scheduled by $t' + \epsilon$ in $\hat{S}$. On the other hand, if some predecessors of $k$ are sharing processors with a set of other tasks, say $U$, then there must be at least one ready task at time $t'$ that is either a task in $U$ or a successor of task(s) in $U$, and hence there will be no idle processor in $[t', t' + \epsilon]$, contradicting the assumption that there is at least one idle processor.

*Case* II. $t > 0$.

Let $l$ be the predecessor of $k$ executed at time $t$ in $S$. According to the Muntz–Coffman algorithm, $l$ was not executed in the time interval $[t-\delta, t]$ because the tasks executed in that interval all have levels greater than that of $l$ and all processors are busy in the time interval. Since the tasks in the time interval $[t-\delta, t]$ are not predecessors of $k$, there must be at least one job other than $l$ that is ready at time $t$. But this means that both processors are busy from time $t$ until $t' + \epsilon$, contradicting the fact that there is an idle processor in the time interval $[t', t' + \epsilon]$.

Repeating the above argument, we can show that the idle processor time in $S$ at each time instant $t$ is less than or equal to that in $\hat{S}$. □

Using the same technique as in Theorem 2.5 and the property given in Lemma 3.2, we can show that Algorithm D is an optimal offline algorithm for $P2 \mid pmtn, prec_i$ *released at* $r_i \mid C_{\max}$. This is stated in the next theorem, whose proof we will omit.

THEOREM 3.3. *Algorithm* D *is an optimal offline algorithm for* $P2 \mid pmtn, prec_i$ *released at* $r_i \mid C_{\max}$.

THEOREM 3.4. *Algorithm* C *is an optimal online algorithm for* $P2 \mid pmtn, prec_i$ *released at* $r_i \mid C_{\max}$.

*Proof.* Let $S$ be the schedule produced by Algorithm C for an instance of $P2 \mid pmtn, prec_i$ *released at* $r_i \mid C_{\max}$, and let $\hat{S}$ be the schedule produced by Algorithm D for the same instance. We will show, by induction on the number of release times, $i$, that $\hat{S}$ can be converted into $S$ without increasing the makespan and without violating any precedence constraints. Thus, $S$ is an optimal schedule as well.

The basis case, $i = 1$, is obvious, since $S$ and $\hat{S}$ are identical schedules. Assuming that the hypothesis is true for all $i \leq k-1$, we wish to show that the hypothesis is true for $i = k$. Let $t_1 < t_2 < \cdots < t_l$ be the time instants where event 1 or event 2 occurs in $\hat{S}$. Let $r_1$ and $r_2$ denote the first and second release times, respectively. There are two cases to consider.

*Case* I. $r_2 = t_j$ for some $1 \leq j \leq l$.

From time $r_1$ until $r_2$, $S$ is identical to $\hat{S}$. At time $r_2$, the remaining portions of the unfinished tasks in both schedules are identical. There are only $k-1$ releases from $r_2$ onward. By the induction hypothesis, $\hat{S}$ can be converted into $S$ without violating any precedence constraints.

*Case* II. $r_2$ is in the time interval $[t_j, t_{j+1}]$ for some $1 \leq j < l$.

There are two cases to consider.

*Case* II(a). Every task executing in the time interval $[t_j, t_{j+1}]$ is executing on a full processor.

The proof of this case is identical to that of Case I.

*Case* II(b). Some tasks are sharing processor(s) in the time interval $[t_j, t_{j+1}]$.

Let $x$ tasks be sharing $y$ processor(s) $(x > y)$ in the time interval $[t_j, t_{j+1}]$. Let $i_1, i_2, \ldots, i_x$ be the tasks sharing the $y$ processor(s). Since there are only two processors, there must be at most one task, say $j_1$, executing on a full processor. It is easy to see that from time $r_1$ until $t_j$, $S$ and $\hat{S}$ are identical schedules, but from $t_j$ until $r_2$, $S$ and $\hat{S}$ may not be the same.

The second release time, $r_2$, divides each task $i_1, i_2, \ldots, i_x$ in $S$ into two parts: those that were executed before $r_2$ and those that were executed after $r_2$. Let the level of a task, say $j$, at time $r_2$ be denoted by $level(j)$. We have $level(j_1) \geq level(i_l)$ for each $1 \leq l \leq x$, but the tasks $i_1, i_2, \ldots, i_x$ may have different levels. Consider now the schedule $\hat{S}$. We have $level(j_1) > level(i_1) = level(i_2) = \cdots = level(i_x)$. Note that $j_1$ may not exist if the tasks $i_1, i_2, \ldots, i_x$ share two processors.

We now convert the schedule $\hat{S}$ into one such that it is identical to $S$ in the interval

$[r_1, r_2]$ and such that the makespan is not increased and no precedence constraints are violated. From time $r_2$ and onward, there are $k-1$ releases. Thus, by the induction hypothesis, $\hat{S}$ can be converted into $S$ from time $r_2$ onward. Hence, $S$ is an optimal schedule as well.

From time $r_1$ until $t_j$, $\hat{S}$ and $S$ are identical schedules, but they may not be the same in the time interval $[t_j, r_2]$. We now show that we can convert $\hat{S}$ in the interval $[t_j, r_2]$ to be identical to $S$ in the same interval without increasing the makespan and without violating any precedence constraints. There are two cases to consider.

*Case* (i). Several tasks are sharing two processors in the time interval $[t_j, t_{j+1}]$.

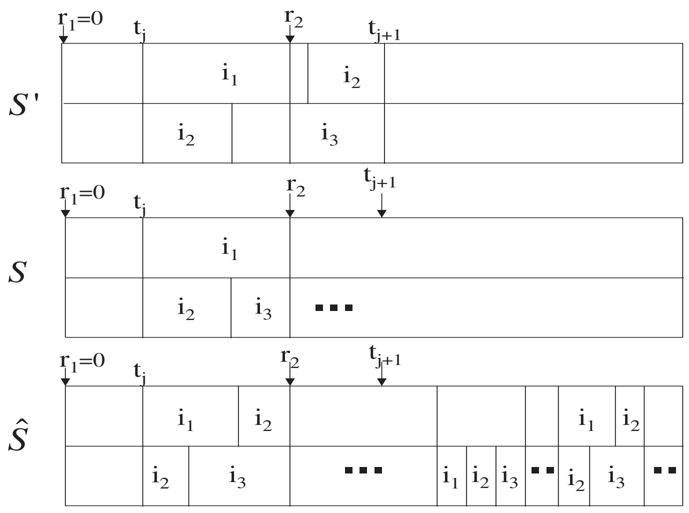

FIG. 3.4. *Example illustrating Case* (i).

An example of this case is shown in Figure 3.4: $S'$ is the schedule produced by Algorithm C before tasks were released at $r_2$, $S$ is the schedule obtained by Algorithm C after tasks were released at $r_2$, and $\hat{S}$ is the schedule produced by Algorithm D. We wish to show that the portions of the tasks scheduled in $S'$ in the interval $[r_2, t_{j+1}]$ can be rescheduled after time $r_2$ in $\hat{S}$ without increasing the makespan of $\hat{S}$ and without violating any precedence constraints.

Let $\hat{t}_1 < \hat{t}_2 < \cdots < \hat{t}_k$ be the time instants where event 1, 2, or 3 occurs in $\hat{S}$. We define $I_i$ to be the time interval $[\hat{t}_i, \hat{t}_{i+1}]$ in $\hat{S}$ for each $1 \le i < k$. Consider how the tasks $i_1$, $i_2$, and $i_3$ are scheduled after $r_2$ in $\hat{S}$. There are three cases to consider: (a) $i_1$, $i_2$, and $i_3$ share one processor in the intervals $I_{i_1}, I_{i_2}, \ldots, I_{i_p}$, but they are not scheduled in any other intervals; (b) $i_1$, $i_2$, and $i_3$ share two processors in the intervals $I_{j_1}, I_{j_2}, \ldots, I_{j_q}$, but they are not scheduled in any other intervals; and (c) $i_1$, $i_2$, and $i_3$ share one processor in the intervals $I_{i_1}, I_{i_2}, \ldots, I_{i_p}$ and two processors with other tasks in the intervals $I_{j_1}, I_{j_2}, \ldots, I_{j_q}$, and they are not scheduled in any other intervals.

In case (a), it is clear that we can schedule the tasks in the interval $[r_2, t_{j+1}]$ in $S'$ into the intervals $I_{i_1}, I_{i_2}, \ldots, I_{i_p}$ in $\hat{S}$ without increasing the makespan and without violating any precedence constraints. In case (b), we can divide the schedule in the interval $[r_2, t_{j+1}]$ in $S'$ into $q$ subintervals so that each subinterval will be scheduled into one of the intervals $I_{j_x}$, $1 \le x \le q$, in $\hat{S}$. Again, this will not increase the makespan or violate any precedence constraints. In case (c), let $l_0$ be the total length of all the intervals $I_{i_1}, I_{i_2}, \ldots, I_{i_p}$, and let $l_x$, $1 \leq x \leq q$, be the total execution time of the tasks $i_1$, $i_2$, and $i_3$ scheduled in $I_{j_x}$. We can schedule the tasks in the interval $[r_2, r_2 + \frac{l_0}{2}]$ in $S'$ into the intervals $I_{i_1}, I_{i_2}, \ldots, I_{i_p}$ in $\hat{S}$. We then divide the interval $[r_2 + \frac{l_0}{2}, t_{j+1}]$ in $S'$ into $q$ subintervals: the $x$th subinterval, $1 \leq x \leq q$, has length $\frac{l_x}{2}$. We take the tasks executed in $S'$ in the $x$th subinterval and schedule them in $I_{j_x}$ in $\hat{S}$, along with the other tasks executed in the same interval. It is easy to see that we can reschedule without increasing the makespan or violating any precedence constraints.

Using this approach, we can always convert $\hat{S}$ in $[t_j, r_2]$ to be identical to $S$ in the same interval without increasing the makespan of $\hat{S}$ and without violating any precedence constraints, no matter how many jobs are sharing the two processors in the time interval $[t_j, t_{j+1}]$.

*Case* (ii). One task is executing on a full processor while other tasks are sharing one processor in the time interval $[t_j, t_{j+1}]$.

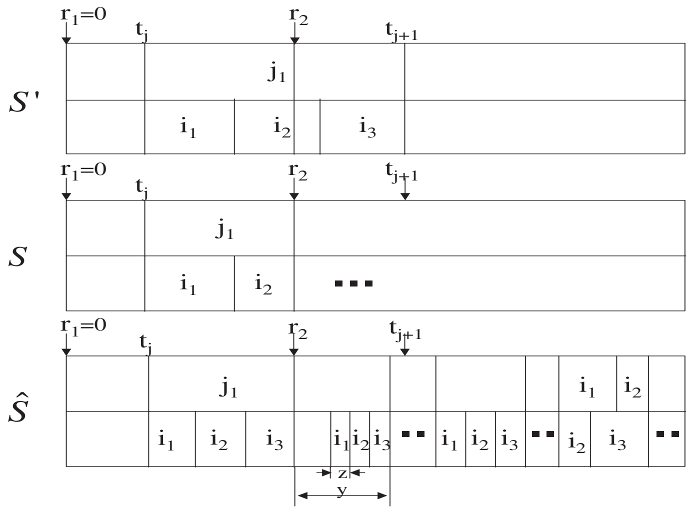

FIG. 3.5. *Example illustrating Case* (ii).

An example of this case is shown in Figure 3.5: $S'$ is the schedule constructed by Algorithm C before new tasks were released at $r_2$, $S$ is the schedule constructed by Algorithm C after new tasks were released at $r_2$, and $\hat{S}$ is the schedule produced by Algorithm D. Again, we want to show that the portions of the tasks scheduled in $S'$ in the interval $[r_2, t_{j+1}]$ can be rescheduled after time $r_2$ in $\hat{S}$ without increasing the makespan of $\hat{S}$ and without violating any precedence constraints.

As before, let $\hat{t}_1 < \hat{t}_2 < \cdots < \hat{t}_k$ be the time instants where event 1, 2, or 3 occurs in $\hat{S}$. We define $I_i$ to be the time interval $[\hat{t}_i, \hat{t}_{i+1}]$ in $\hat{S}$ for each $1 \leq i < k$. Consider how the tasks $i_1$, $i_2$, and $i_3$ are scheduled after $r_2$ in $\hat{S}$. There are two cases to consider: (a) $i_1$, $i_2$, and $i_3$ share one processor in the intervals $I_{i_1}, I_{i_2}, \ldots, I_{i_p}$, but they are not scheduled in any other intervals; (b) $i_1$, $i_2$, and $i_3$ share one processor in the intervals $I_{i_1}, I_{i_2}, \ldots, I_{i_p}$ and two processors with other tasks in the intervals $I_{j_1}, I_{j_2}, \ldots, I_{j_q}$, and they are not scheduled in any other intervals.

In case (a), it is clear that we can schedule the tasks on the second processor in $S'$ in the interval $[r_2, t_{j+1}]$ into the intervals $I_{i_1}, I_{i_2}, \ldots, I_{i_p}$ in $\hat{S}$ without increasing the makespan of $\hat{S}$ and without violating any precedence constraints. In case (b), let $y = t_{j+1} - r_2$. Assume that in the time interval $[r_2, t_{j+1}]$, $i_1, i_2, i_3$ have each executed $z$ units in $\hat{S}$, $0 \leq z \leq \frac{y}{3}$. This means that $y - 3z$ units of processor time are used by the newly released tasks in the same interval. It is easy to see that in $\hat{S}$, the remaining portions of $i_1, i_2, i_3$ at time $t_{j+1}$ are all $\frac{y}{3} - z$. On the other hand, the lengths of the remaining portions of $i_1, i_2, i_3$ in $S'$ in the interval $[r_2, t_{j+1}]$ are all different. Thus, after $r_2$, when we reschedule the tasks $i_1, i_2, i_3$ into the intervals $I_{j_1}, I_{j_2}, \ldots, I_{j_q}$, it is quite possible that we create overlaps. It is clear that the total length of all the overlaps is no more than $\frac{y-3z}{2}$.

Assume that both processors are used by a task, say $i_3$, in the time interval $[\lambda_1, \lambda_2]$. From $\lambda_1$ back to $r_2$, we use the following method to eliminate the overlap: Find the first time interval $[t^*, t^*+\epsilon]$ such that (1) one processor is used by $i_1, i_2, i_3, j_1$, or the successors of $j_1$, and the other processor, say the second processor, is used by other jobs; or (2) both processors are not used by $i_1, i_2, i_3, j_1$ or the successors of $j_1$. If (1) holds, then we can interchange the schedule on the second processor in $[t^*, t^* + \epsilon]$ with the schedule on the second processor in $[\lambda_2 - \epsilon, \lambda_2]$, so the overlap is reduced by $\epsilon$. (Note that if $i_3$ is executing in the interval $[t^*, t^* + \epsilon]$, the interchange does not reduce the overlap, but it has the effect of pushing backwards the time where the overlap occurs.) If (2) holds, then we interchange the schedule on the second processor in $[t^*, t^* + \epsilon]$ with the schedule on the second processor in $[\lambda_2 - \epsilon, \lambda_2]$, and we interchange the schedule on the first processor in $[t^*, t^* + \epsilon]$ with the schedule on the second processor in $[\lambda_2 - 2 * \epsilon, \lambda_2 - \epsilon]$. Again, the overlap is reduced by $\epsilon$ and no precedence constraints are violated.

We repeat the above operation until all of the overlaps are eliminated. Since in the time interval $[r_2, t_{j+1}]$, one processor has $y - 3z$ processor time used by the newly released tasks, we can always eliminate the overlap. Thus, we can convert the schedule in $[t_j, r_2]$ in $\hat{S}$ to be identical to $S$ in the same interval without increasing the makespan of $\hat{S}$ and without violating any precedence constraints.

Using this approach, we can always convert the schedule in $[t_j, r_2]$ in $\hat{S}$ to be identical to $S$ in the same interval without increasing the makespan and without violating any precedence constraints, no matter how many jobs are sharing one processor in the time interval $[t_j, t_{j+1}]$. $\square$

**3.2. Outtrees and arbitrary number of processors.** We first state, without proof, that Algorithm D is an optimal offline algorithm for $P \mid pmtn, outtree_i$ *released at* $r_i \mid C_{\max}$. The proof is similar to Lemma 3.2. We then prove that Algorithm C is an optimal online algorithm for the same case.

THEOREM 3.5. *Algorithm* D *is an optimal offline algorithm for* $P \mid pmtn, outtree_i$ *released at* $r_i \mid C_{\max}$.

THEOREM 3.6. *Algorithm* C *is an optimal online algorithm for* $P \mid pmtn, outtree_i$ *released at* $r_i \mid C_{\max}$.

*Proof.* Let $S$ be the schedule produced by Algorithm C for an instance of $P \mid pmtn, outtree_i$ *released at* $r_i \mid C_{\max}$ and let $\hat{S}$ be the schedule produced by Algorithm D for the same instance. We will show by induction on the number of release times, $i$, that the idle processor time in $S$ is less than or equal to that of $\hat{S}$ at each time instant $t$. Thus, $S$ is an optimal schedule as well.

The basis case, $i = 1$, is obvious, since $S$ and $\hat{S}$ are identical schedules. Assuming that the hypothesis is true for all $i \leq k - 1$, we wish to show that the hypothesis is true for $i = k$. Let $t_1 < t_2 < \cdots < t_l$ be the time instants where event 1 or event 2 occurs in $\hat{S}$. Let $r_1$ and $r_2$ denote the first and second release times, respectively.

There are two cases to consider.

*Case* I. $r_2 = t_j$ for some $1 \leq j \leq l$.

From time $r_1$ until $r_2$, $S$ is identical to $\hat{S}$. At time $r_2$, the remaining portions of the unfinished tasks in both schedules are identical. There are only $k-1$ releases from $r_2$ onward. By the induction hypothesis, the idle processor time in $S$ is less than or equal to that of $\hat{S}$ at each time instant $t$ after $r_2$.

*Case* II. $r_2$ is in the time interval $[t_j, t_{j+1}]$ for some $1 \leq j < l$.

There are two cases to consider.

*Case* II(a). Every task executing in the time interval $[t_j, t_{j+1}]$ is executing on a full processor.

The proof of this case is identical to that of Case I.

*Case* II(b). Some tasks are sharing processor(s) in the time interval $[t_j, t_{j+1}]$.

Let $x$ tasks be sharing $y$ processor(s) $(x > y)$ in the interval $[t_j, t_{j+1}]$. Since tasks are sharing processors, the number of available tasks at time $t_j$ must be greater than the number of processors. Let $i_1, i_2, \ldots, i_x$ be the tasks sharing the $y$ processor(s) and let $j_1, j_2, \ldots, j_z$ be the tasks executing on a full processor. We have $m = y + z$. It is easy to see that from time $r_1$ until $t_j$, $S$ and $\hat{S}$ are identical schedules, but from $t_j$ until $r_2$, $S$ and $\hat{S}$ may not be the same.

The second release time, $r_2$, divides each task $i_1, i_2, \ldots, i_x$ in $S$ into two parts: those that were executed before $r_2$ and those that were executed after $r_2$. Let the level of a task $j$ at time $r_2$ be denoted by $level(j)$. Without loss of generality, assume that $level(j_1) \geq level(j_2) \geq \cdots \geq level(j_z)$. Then we have $level(j_z) \geq level(i_l)$ for each $1 \leq l \leq x$, but the tasks $i_1, i_2, \ldots, i_x$ may have different levels. Without loss of generality, assume that $level(i_1) \geq level(i_2) \geq \cdots \geq level(i_x)$. Then we have $level(j_1) \geq level(j_2) \geq \cdots \geq level(j_z) > level(i_1) \geq level(i_2) \geq \cdots \geq level(i_x)$. Consider now the schedule $\hat{S}$. We have $level(j_1) \geq level(j_2) \geq \cdots \geq level(j_z) > level(i_1) = level(i_2) = \cdots = level(i_x)$.

Consider the schedule $S'$ obtained from $S$ by scheduling the remaining portions of the unfinished tasks at $r_2$ by Algorithm D. Since there are only $k-1$ release times (including $r_2$), by the induction hypothesis, the idle processor time in $S$ is less than or equal to that of $S'$ at each time instant $t$ after $r_2$. Thus, if we can show that the idle processor time in $S'$ is less than or equal to that of $\hat{S}$ at each time instant $t$ after $r_2$, then the theorem is proved. We will prove this assertion by contradiction.

Let $t^*$ be the first time instant where $S'$ has more idle processor time than $\hat{S}$. Clearly, $t^* \geq r_2$. Let $[t^*, t^* + \epsilon]$ be the time interval where $S'$ has more idle processor time than $\hat{S}$ for some small positive number $\epsilon$. Clearly, $S'$ must have some idle processors in the interval $[t^*, t^* + \epsilon]$. Let $i^*$ be the earliest executed task that is executed in the time interval $[r_1, t^* + \epsilon]$ in $\hat{S}$ but not in $S'$. We claim that $i^*$ can also be executed in the interval $[t^*, t^* + \epsilon]$ in $S'$, contradicting the definition of $i^*$.

If $i^*$ cannot be executed in the interval $[t^*, t^* + \epsilon]$ in $S'$, then it must have a predecessor executed in the interval. Let $i^*$ be a task in $outtree_l$, released at time $r_l$. We consider two cases.

*Case* (i). Task $i^*$ is not the successor of any of the task $i_h$, $1 \leq h \leq x$.

Since $i^*$ is not the successor of any of the task $i_h$, $1 \leq h \leq x$, the remaining portions of the predecessors of $i^*$ after $r_2$ in $S'$ must be identical to those in $\hat{S}$. Since $\hat{S}$ schedules $i^*$ by $t^* + \epsilon$ while $S'$ did not, there must be a time interval $[t', t' + \delta]$ such that either (1) in $S'$ the processors are all busy in the interval but none of the predecessors of $i^*$ are executing in the interval; or (2) a predecessor of $i^*$ is assigned fewer processors in the interval in $S'$ than in $\hat{S}$. In both cases there must be more than $m$ tasks ready for execution in the interval $[t', t' + \delta]$ in $S'$. This means that the processors are all busy from $t'$ until $t^* + \epsilon$, contradicting our assumption that $S'$ has some idle processors in the interval $[t^*, t^* + \epsilon]$.

*Case* (ii). Task $i^*$ is the successor of the task $i_h$ for some $1 \leq h \leq x$.

In this case, the remaining portions of the predecessors of $i^*$ after $r_2$ in $S'$ may not be the same as those in $\hat{S}$. If there is a time interval $[t', t' + \delta]$ such that either (1) in $S'$ the processors are all busy in the interval but none of the predecessors of $i^*$ are executing in the interval, or (2) a predecessor of $i^*$ is assigned less processor in the interval in $S'$ than in $\hat{S}$, then we can resort to the same argument as in Case (i). Thus, we may assume that at each time instant after $r_l$, the predecessors of $i^*$ are assigned an equal or greater number of processors in $S'$ than in $\hat{S}$. In this case the only reason that $i^*$ is executed in $\hat{S}$ but not in $S'$ is that the remaining portion of task $i_h$ after $r_2$ is larger in $S'$ than in $\hat{S}$. Let $i_h$ be finished at time $\bar{t}$ in $S'$. It is clear that every one of the tasks $i_1, i_2, \ldots, i_x$ must also be finished at $\bar{t}$. Furthermore, the tasks $j_1, j_2, \ldots, j_z$ are either finished at $\bar{t}$ or still active at $\bar{t}$, since they have higher levels than $i_h$. Thus, there are more active tasks than the number of processors. But this means that the processors are all busy from $\bar{t}$ until $t^* + \epsilon$, contradicting our assumption that $S'$ has some idle processors in the interval $[t^*, t^* + \epsilon]$. $\square$

## 4. Conclusion.

In this article we have given optimal online algorithms for the following problems:

(1) $P2 \mid p_j = 1, prec_i \textit{ released at } r_i \mid C_{\max}$.
(2) $P \mid p_j = 1, outtree_i \textit{ released at } r_i \mid C_{\max}$.
(3) $P2 \mid pmtn, prec_i \textit{ released at } r_i \mid C_{\max}$.
(4) $P \mid pmtn, outtree_i \textit{ released at } r_i \mid C_{\max}$.

We also show that it is impossible to have optimal online algorithms for the following problems:

(1) $P3 \mid p_j = 1, intree_i \textit{ released at } r_i \mid C_{\max}$.
(2) $P2 \mid p_j = p, chains_i \textit{ released at } r_i \mid C_{\max}$.
(3) $P3 \mid pmtn, p_j = 1, intree_i \textit{ released at } r_i \mid C_{\max}$.

Instead of the makespan objective, one wonders whether there are optimal online algorithms for the mean flow time objective. In this regard, it can be shown that Algorithm A is an optimal online algorithm for $P2 \mid p_j = 1, prec_i \textit{ released at } r_i \mid \sum C_j$, while Algorithm B is an optimal online algorithm for $P \mid p_j = 1, outtree_i \textit{ released at } r_i \mid \sum C_j$. The proof in Theorem 2.1 also shows that it is impossible to have optimal online algorithms for $P3 \mid p_j = 1, intree_i \textit{ released at } r_i \mid \sum C_j$ and $P3 \mid pmtn, p_j = 1, intree_i \textit{ released at } r_i \mid \sum C_j$. Relatively little is known about preemptive scheduling. For example, is it possible to have an optimal online algorithm for $P2 \mid pmtn, p_j = 1, prec_i \textit{ released at } r_i \mid \sum C_j$? Recently, Coffman, Sethuraman, and Timkovsky [2] gave an algorithm that simultaneously minimizes the makespan and the mean flow time for $P2 \mid pmtn, p_j = 1, prec_i \textit{ released at } r_i \mid \sum C_j$. Is it possible to adapt their algorithm to yield an optimal online algorithm for this case?

# PRIMAL-DUAL MEETS LOCAL SEARCH: APPROXIMATING MSTs WITH NONUNIFORM DEGREE BOUNDS[*]

J. KÖNEMANN[†] AND R. RAVI[‡]

**Abstract.** We present a new bicriteria approximation algorithm for the degree-bounded minimum-cost spanning tree (MST) problem: Given an undirected graph with nonnegative edge weights and a degree bound $B$, find a spanning tree of maximum node-degree $B$ and minimum total edge-cost. Our algorithm outputs a tree of maximum degree at most a constant times $B$ and total edge-cost at most a constant times that of a minimum-cost degree-$B$-bounded spanning tree.

While our new algorithm is based on ideas from Lagrangian relaxation, as is our previous work [*SIAM J. Comput.*, 31 (2002), pp. 1783–1793], it does not rely on computing a solution to a linear program. Instead, it uses a repeated application of Kruskal's MST algorithm interleaved with a combinatorial update of approximate Lagrangian node-multipliers maintained by the algorithm. These updates cause subsequent repetitions of the spanning tree algorithm to run for longer and longer times, leading to overall progress and a proof of the performance guarantee. A second useful feature of our algorithm is that it can handle nonuniform degree bounds on the nodes: Given distinct bounds $B_v$ for every node $v \in V$, the output tree has degree at most $O(B_v + \log |V|)$ for every $v \in V$. As before, the cost of the tree is at most a constant times that of a minimum-cost tree obeying all degree bounds.

## 1. Introduction.

### 1.1. Formulation.

In this paper, we address a natural nonuniform budget version of the *degree-bounded minimum-cost spanning tree problem* (nBMST). Given an undirected graph $G = (V, E)$, a cost function $c : E \to \mathbb{R}^+$, and positive integers $\{B_v\}_{v \in V}$ all greater than 1, our goal is to find a spanning tree $T$ of minimum total cost such that for all vertices $v \in V$ the degree of $v$ in $T$ is at most $B_v$.

### 1.2. Previous work and our result.

In an $n$-node graph, Ravi et al. [11, 12] showed how to compute a spanning tree $T$ of degree $O(B_v \log n)$ for all $v \in V$ and total cost at most $O(\log n)\,\texttt{opt}$, where $\texttt{opt}$ is the minimum cost of any tree in which the degree of node $v$ is bounded by $B_v$ for all $v \in V$. The authors generalized their ideas to Steiner trees, generalized Steiner forests, and the node-weighted case. Subsequently, Könemann and Ravi [8, 9] improved the results on the (edge-weighted) spanning tree version of the problem with uniform degree bounds (i.e., $B_v = B$ for all $v$). The main theorem from [9] is as follows.

Theorem 1.1 (see [9]). *There is an approximation algorithm that, given a graph $G = (V, E)$, a nonnegative cost function $c : E \to \mathbb{R}^+$, a constant $B \geq 2$, and a parameter $\omega > 1$, computes a spanning tree $T$ such that*

1. $\Delta(T) \leq \frac{\omega}{\omega-1} \cdot bB + \log_b n$, *and*

2. $c(T) < \omega \cdot \texttt{opt}$,

*where $b > 1$ is an arbitrary constant.*

The contributions of this paper are twofold: First, we present improved approximation algorithms for the nBMST problem in the presence of nonuniform degree bounds. Second, our algorithm is *direct* in the sense that we do not solve linear programs. The algorithm in [9] uses Lagrangian relaxation and thus needs to solve a linear program. The analysis in [9] relies crucially on the fact that we compute an exact solution to this linear program.

On the other hand, our new algorithm integrates elements from the primal-dual method for approximation algorithms for network design problems with local search methods for minimum-degree network problems [5, 13]. The algorithm goes through a series of spanning trees and improves the maximum deviation of any vertex degree from its respective degree bound progressively. A practical consequence of this is that we can terminate the algorithm at any point in time and still obtain a spanning tree of the input graph (whose node-degrees, of course, may not meet the worst-case guarantees we prove).

THEOREM 1.2. *There is a primal-dual approximation algorithm that, given a graph $G = (V, E)$, a nonnegative cost function $c : E \to \mathbb{R}^+$, integers $B_v > 1$ for all $v \in V$, and a parameter $\omega > 1$, computes a tree $T$ such that*

1. $\deg_T(v) \le \frac{\omega}{\omega-1} \cdot b \cdot B_v + 2 \cdot \log_b n$ *for all $v \in V$, and*
2. $c(T) < \omega \cdot \texttt{opt}$,

*where $b > 1$ is an arbitrary constant. The running time is $O(|E||V|^5 \log |V|)$.*

When $B = B_v$ for all $v \in V$, we can replace the additive term $2 \log_b n$ in the degree guarantee of Theorem 1.2 by $\log_b n$, matching Theorem 1.1 constructively.

The paper is organized as follows. First, we review the primal-dual interpretation of the well-known algorithm for MST by Kruskal [10]. Subsequently, we show how to use this algorithm for the nBMST problem and present an analysis of the performance guarantee and the running time of our method.

## 2. A primal-dual algorithm to compute MSTs.

In this section we review Kruskal's MST algorithm. More specifically, we discuss a primal-dual interpretation of this method that follows from [2]. We start by giving a linear programming formulation of the convex hull of incidence vectors of spanning trees.

### 2.1. The spanning tree polyhedron.

In the following, we formulate the MST problem as an integer program where we associate a $(0, 1)$-variable $x_e$ with every edge $e \in E$. In a solution $x$, the value of $x_e$ is 1 if $e$ is included in the spanning tree corresponding to $x$ and 0 otherwise. Our formulation relies on a complete formulation of the convex hull of incidence vectors of spanning trees (denoted by $\texttt{SP}_G$) given by Chopra [2].

Chopra's formulation uses the notion of a *feasible partition* of vertex set $V$. A feasible partition of $V$ is a set $\pi = \{V_1, \dots, V_k\}$ such that the $V_i$ are pairwise disjoint subsets of $V$. Moreover, $V = V_1 \cup \dots \cup V_k$ and the induced subgraphs $G[V_i]$ are connected. Let $G_\pi$ denote the (multi-) graph that has one vertex for each $V_i$ and in which edge $(V_i, V_j)$ occurs with multiplicity $|\{(v_i, v_j) : v_i \in V_i, v_j \in V_j\}|$. In other words, $G_\pi$ results from $G$ by contracting each $V_i$ to a single node. Define the *rank* $r(\pi)$ of $\pi$ as the number of nodes of $G_\pi$ and let $\Pi$ be the set of all feasible partitions of $V$. Chopra then shows that

$$\texttt{SP}_G = \left\{ x \in \mathbb{R}^m : \sum_{e \in E(G_\pi)} x_e \ge r(\pi) - 1 \quad \forall \pi \in \Pi \right\}.$$

We now let $\delta(v)$ denote the set of edges $e \in E$ that are incident to node $v$ and obtain an integer programming (IP) formulation for our problem:

$$
\begin{aligned}
\text{(IP)} \qquad & \min \quad \sum_{e\in E} c_e x_e \\
& \text{s.t.} \quad \sum_{e \in E[G_\pi]} x_e \geq r(\pi) - 1 \quad \forall \pi \in \Pi, \\
\text{(2.1)} \qquad & \qquad x(\delta(v)) \leq B_v \quad \forall v \in V, \\
& \qquad x \text{ integer.}
\end{aligned}
$$

The dual of the linear programming relaxation of (IP) is given by

$$
\begin{aligned}
\text{(D)} \qquad & \max \quad \sum_{\pi\in\Pi} (r(\pi) - 1) \cdot y_\pi - \sum_{v \in V} \lambda_v B_v \\
\text{(2.2)} \qquad & \text{s.t.} \quad \sum_{\pi : e \in E[G_\pi]} y_\pi \leq c_e + \lambda_u + \lambda_v \quad \forall e = uv \in E, \\
& \qquad y, \lambda \geq 0.
\end{aligned}
$$

We also let (IP-SP) denote (IP) without constraints of type (2.1). Let the linear programming relaxation be denoted by (LP-SP) and let its dual be (D-SP).

**2.2. A primal-dual interpretation of Kruskal's MST algorithm.** Kruskal's algorithm can be viewed as a continuous process over *time*: We start with an empty tree at time 0 and add edges as we go along. The algorithm terminates at time $t^*$ with a spanning tree of the input graph $G$. In this section we show that Kruskal's method can be interpreted as a primal-dual algorithm (see also [7]). For that reason, at any time $0 \leq t \leq t^*$ we keep a pair $(x_t, y_t)$, where $x_t$ is a partial (possibly infeasible) primal solution for (LP-SP) and $y_t$ is a feasible dual solution for (D-SP). Initially, we let $x_{e,0} = 0$ for all $e \in E$ and $y_{\pi,0} = 0$ for all $\pi \in \Pi$.

Let $E_t$ be the forest corresponding to partial solution $x_t$, i.e., $E_t = \{e \in E : x_{e,t} = 1\}$. We then denote by $\pi_t$ the partition induced by the connected components of $G[E_t]$. At time $t$, the algorithm then increases $y_{\pi_t}$ until a constraint of type (2.2) for edge $e \in E \setminus E_t$ becomes tight. Assume that this happens at time $t' > t$. The dual update is

$$y_{\pi_t, t'} = t' - t.$$

We then include $e$ in our solution, i.e., we set $x_{e,t'} = 1$. If more than one edge becomes tight at time $t'$, we can process these events in any arbitrary order. Thus, note that we can pick any such tight edge first in our solution.

Observe that the above primal-dual algorithm is indeed Kruskal's algorithm: If the algorithm adds an edge $e$ at time $t$, then $e$ is the minimum-cost edge connecting two connected components of $G[E_t]$. In the rest of this paper we use `MST` to refer to Kruskal's minimum-cost spanning tree algorithm.

The proof of the following lemma is folklore. We supply it for the sake of completeness.

LEMMA 2.1. *At time $t^*$, algorithm* `MST` *finishes with a pair $(x_{t^*}, y_{t^*})$ of primal and dual feasible solutions to* (IP-SP) *and* (D-SP)*, respectively, such that*

$$\sum_{e \in E} c_e x_{e,t^*} = \sum_{\pi \in \Pi} (r(\pi) - 1) \cdot y_{\pi, t^*}.$$

*Proof.* Notice that for all edges $e \in E_{t^*}$ we must have $c_e = \sum_{\pi : e \in E[G_\pi]} y_{\pi,t^*}$ and hence, we can express the cost of the final tree as follows:

$$c(E_{t^*}) = \sum_{e \in E_{t^*}} \sum_{\pi : e \in E[G_\pi]} y_{\pi,t^*} = \sum_{\pi \in \Pi} |E_{t^*} \cap E[G_\pi]| \cdot y_{\pi,t^*}.$$

By construction $E_{t^*}$ is a tree and we must have that the set $E_{t^*} \cap E[G_\pi]$ has cardinality exactly $r(\pi) - 1$ for all $\pi \in \Pi$ with $y_{\pi,t^*} > 0$. We obtain that $\sum_{e \in E} c_e x_{e,t^*} = \sum_{\pi \in \Pi} (r(\pi) - 1) \cdot y_{\pi,t^*}$ and this finishes the proof of the lemma. □

**3. Minimum-cost degree-bounded spanning trees.** In this section, we propose a modification of the above algorithm for approximating degree-bounded spanning trees of low total cost (for suitably weakened degree bounds). Our algorithm goes through a sequence of spanning trees $E^0, \dots, E^t$ and associated pairs of primal (infeasible) and dual feasible solutions $x^i$, $(y^i, \lambda^i)$ for $0 \leq i \leq t$. The idea is to reduce the degree of nodes $v \in V$ whose degree is substantially higher than their associated bound $B_v$, as we proceed through this sequence, while keeping the cost of the associated primal solution (tree) bounded with respect to the corresponding dual solution.

To begin, our algorithm first computes a minimum-cost spanning tree using the algorithm MST. This yields a feasible primal solution $x^0$ for (LP-SP) and a feasible dual solution $y^0$ for (D-SP). Notice that $y^0$ also induces a feasible solution for (D) by letting $\lambda^0_v = 0$ for all $v \in V$, while $x^0$ potentially violates constraints of type (2.1).

We introduce the notion of *normalized degree* of a node $v$ in a tree $T$ and denote it by

$$\texttt{ndeg}_T(v) = \max\{0, \deg_T(v) - \beta \cdot B_v\}, \tag{3.1}$$

where $\beta \geq 1$ is a constant to be specified later. Our algorithm successively computes pairs of spanning trees and associated dual solutions to (D), i.e.,

$$(x^1, \{y^1, \lambda^1\}), (x^2, \{y^2, \lambda^2\}), \dots, (x^t, \{y^t, \lambda^t\}).$$

From one such pair to the next, we try to reduce the degree of nodes of high normalized degree. Specifically, our algorithm runs as long as there is a node in the current tree with $\texttt{ndeg}(v) \geq 2 \log_b(n)$ for some constant $b > 1$.

Our algorithm keeps a cost $\widetilde{c}^i_e$ with each edge $e \in E$ and for each iteration $1 \leq i \leq t$. $x^i$ corresponds to an MST $E^i$ for cost function $\widetilde{c}^i$, and $y^i$ is the associated dual packing. Throughout the algorithm we maintain that

$$c_{uv} \leq \widetilde{c}^i_{uv} \leq c_{uv} + \lambda^i_u + \lambda^i_v \tag{3.2}$$

for all $uv \in E$. Hence, $(y^i, \lambda^i)$ is a feasible solution for (D).

Let $\Delta^i$ be the maximum normalized degree of any node in the tree $E^i$. The central piece of our algorithm is a *recompute step*, where we raise the $\lambda$ values of a carefully chosen set $S_d$ of nodes with high normalized degree. This introduces slack in many of the constraints of type (2.2).

We now increase the $\widetilde{c}$-cost of edges that are incident to nodes in $S_d$ (while maintaining (3.2)) and rerun MST on $G$ using the new edge-costs. Our hope is that the increased $\widetilde{c}$-cost of edges incident to nodes of high normalized degree leads MST to use edges that are incident to nodes of lower normalized degree in their place. We are able to show that the number of recompute steps is polynomial by arguing that we make substantial progress in the normalized degree sequence of all nodes.

As mentioned, each recompute step takes a pair of primal infeasible and dual feasible solutions $(x^i, (y^i, \lambda^i))$ and computes a new pair of primal (infeasible) and dual feasible solutions $(x^{i+1}, (y^{i+1}, \lambda^{i+1}))$. In the following we use $\texttt{ndeg}^i(v)$ as shorthand for $\texttt{ndeg}_{E^i}(v)$. We then adapt the notation from [4, 5] and let

$$S^i_d = \{v \in V : \texttt{ndeg}^i(v) \geq d\}$$

be the set of all nodes whose normalized degree is at least $d$ in the $i$th solution.

**Algorithm 1** The algorithm for the nBMST problem attempts to reduce the maximum normalized degree of any node in a given spanning tree.

```
1: Given: primal feasible solution $x^0$ to (LP-SP) and dual feasible solution $y^0$ to (D-SP)
2: $\lambda^0_v \leftarrow 0 \forall v \in V; \widetilde{c}^0_e \leftarrow c_e, \forall e \in E$
3: $i \leftarrow 0$
4: while $\Delta^i > 2\log_b(n)$ do
5:    Choose $d^i$ in $\{\Delta^i - 2\log_b(n)+1, \ldots, \Delta^i\}$ s.t. $\sum_{v \in S^i_{d^i-1}} B_v \leq b \cdot \sum_{v \in S^i_{d^i}} B_v$
6:    Choose $\epsilon^i > 0$
7:    $\lambda^{i+1}_v \leftarrow \lambda^i_v + \epsilon^i \forall v \in S^i_{d^i-1}$ and $\lambda^{i+1}_v \leftarrow \lambda^i_v$ otherwise
8:    $\widetilde{c}^{i+1}(e) \leftarrow \widetilde{c}^i(e) + \epsilon^i$ if either $e \in E^i$ and $e \cap S^i_{d^i} \neq \emptyset$ or $e \notin E^i$ and $e \cap S^i_{d^i-1} \neq \emptyset$
9:    $(x^{i+1}, y^{i+1}) \leftarrow \texttt{MST}(G, \widetilde{c}^{i+1})$
10:   $i \leftarrow i+1$
11: end while
```

A detailed description of the procedure is given in Algorithm 1. In step 5 of this algorithm, we choose a suitable set of nodes whose $\lambda$-values we increase. A simple argument in [4] can be extended to guarantee the feasibility of the choice in step 5 of the algorithm.

LEMMA 3.1. *There is a $d^i \in \{\Delta^i - 2\log_b(n)+1, \ldots, \Delta^i\}$ such that*

$$\sum_{v \in S^i_{d^i-1}} B_v \leq b \cdot \sum_{v \in S^i_{d^i}} B_v$$

*for a given constant $b > 1$.*

*Proof.* Suppose for a contradiction that for all $d^i \in \{\Delta^i - 2\log_b(n)+1, \ldots, \Delta^i\}$, we have

$$\sum_{v \in S^i_{d^i-1}} B_v > b \cdot \sum_{v \in S^i_{d^i}} B_v.$$

Note that since we may assume $B_v \leq (n-1)$ for all vertices, we must have $\sum_{v \in V} B_v \leq n(n-1)$. However, since $\sum_{v \in S^i_{\Delta^i}} B_v \geq 1$, we have in this case that

$$\sum_{v \in S^i_{\Delta^i - 2\log_b(n)}} B_v \geq b^{2\log_b(n)} = n^2,$$

a contradiction. □

When $B_v = B$ for all $v \in V$, the $2\log_b n$ term in the above lemma can be improved to $\log n$ using the previous arguments in [4]. This in turn leads to the slight improvement of our results claimed right after the statement of Theorem 1.2.

Step 6 of Algorithm 1 hides the details of choosing an appropriate $\epsilon^i$ by which edges in the current tree that are incident to nodes of normalized degree at least $d^i$ are lengthened. Our choice of $\epsilon^i$ and the following update of the $\widetilde{c}$ costs of the edges in $G$ will ensure that Kruskal's algorithm computes a new tree in which at least one edge $e^i \in E^i$ that is incident to a node of $S^i_{d^i}$ is replaced by an edge $\overline{e}^i \notin E^i$ that is incident to nodes of low normalized degree.

In fact, we show that a careful choice of $\epsilon^i$ ensures that $\overline{e}^i$ is incident to nodes of normalized degree at most $d^i-2$, while $e^i$ is incident to at least one node of normalized degree $d^i$ or higher. The main idea here is to increase $\lambda_v$ for nodes $v \in S^i_{d^i-1}$ by $\epsilon^i$ and increase the $\widetilde{c}$-cost of nontree edges that are incident to nodes of normalized degree at least $d^i - 1$ by $\epsilon^i$ as well. In other words, the cost of nontree edges incident to nodes of normalized degree at least $d^i - 1$ increases by the same amount as the cost of tree edges incident to nodes of normalized degree at least $d^i$. This way, we enforce that the edge we swap in touches nodes of normalized degree at most $d^i - 2$. Once we accomplish this, by adapting a potential function argument from [4] we can put a polynomial upper bound on the number of such iterations (see section 3.3).

Lemma 3.1 plays a key role in the later analysis of the performance guarantee achieved by Algorithm 1. Notice that step 7 of the algorithm increases the node multipliers of all nodes in $S^i_{d^i-1}$. On the other hand, in step 8, we increase only the $\widetilde{c}$-cost of those tree edges that are incident to nodes in $S^i_{d^i}$. Roughly, Lemma 3.1 provides us with a bound on the number of tree edges that are incident to nodes of normalized degree exactly $d^i - 1$.

We now describe how to choose $\epsilon^i$ so that the above conditions are satisfied.

## 3.1. Choosing $\epsilon^i$.

In this section we elaborate on the choice of $\epsilon^i$ in step 6 of Algorithm 1. In step 8, we increase $\widetilde{c}_{uv}$ by $\epsilon^i$ for all tree edges $uv$ that are incident to nodes of degree at least $d^i$ and for all nontree edges that are incident to nodes of degree at least $d^i-1$. We want to choose $\epsilon^i$ such that the subsequent update of $\widetilde{c}^i$ and the following run of `MST` yield a new tree $E^{i+1}$ that differs from $E^i$ by a single edge swap: $E^{i+1} = E^i \setminus \{e^i\} \cup \overline{e}^i$. Here, the edge $e^i \in E^i$ is a tree edge that is incident to a node from $S^i_{d^i}$. On the other hand we want $\overline{e}^i \in E \setminus E^i$ to be a nontree edge that is not incident to any node from $S^i_{d^i-1}$.

As indicated in the previous section, we want $E^{i+1}$ to be an MST of $G$ for cost function $\widetilde{c}^{i+1}$. In order to achieve this, $e^i$ must be on the unique cycle in $E^i \cup \{\overline{e}^i\}$ and we also must have

$$\widetilde{c}^{i+1}(e^i) = \widetilde{c}^i(e^i) + \epsilon^i = \widetilde{c}^{i+1}(\overline{e}^i).$$

In other words, the update of $\lambda_v$ for $v \in S^i_{d^i-1}$ creates one more beneficial swap.

We let $\mathcal{K}^i$ be the set of connected components of the forest $E^i \setminus S^i_{d^i}$, i.e., the forest that results from removing nodes of normalized degree at least $d^i$ from $E^i$. We say that an edge $e = uv \in E$ is a *cross-edge* if

1. $e$ is a nontree edge, i.e., $e \in E \setminus E^i$,
2. $u \in K_1, v \in K_2$ for $K_1, K_2 \in \mathcal{K}^i$, and $K_1 \neq K_2$, and
3. $\{u, v\} \cap S^i_{d^i-1} = \emptyset$.

We denote the set of cross-edges in iteration $i$ by $\mathcal{C}^i$. Observe that if $C^i = \emptyset$, then the set $S_{d^i-1}$ provides a witness to the infeasibility of the degree bounds imposed on the nodes in this set.

It is now clear that $E^i + e$ contains a unique cycle $C_e^i$ for each cross-edge $e \in \mathcal{C}^i$. Furthermore, there must be at least one vertex $v$ on $C_e^i$ that has normalized degree at least $d^i$.

For each cross-edge $e \in \mathcal{C}^i$, we now let

$$\epsilon_e^i = \min_{e' \in C_e^i, e' \cap S_{d^i}^i \neq \emptyset} \left(\widetilde{c}^i(e) - \widetilde{c}^i(e')\right).$$

Note that it follows from the fact that $E^i$ is an MST for cost function $\widetilde{c}^i$ that $\epsilon_e^i \geq 0$ for all $e \in \mathcal{C}^i$. Finally, we let $\epsilon^i = \min_{e \in \mathcal{C}^i} \epsilon_e^i$.

In the following, we let $\langle e^i, \overline{e}^i \rangle$ be the *witness pair* for $\epsilon^i$. In other words, let $\langle f, \overline{f} \rangle$ be a pair of edges where $\overline{f} \in E \setminus E^i$ is a nontree edge and $f \in C_{\overline{f}}^i$ is a tree edge that is incident to a node from $S_{d^i}^i$ and that lies on the unique cycle in $E^i + \overline{f}$. Then, we must have that

$$\widetilde{c}^i(f) + \epsilon^i \leq \widetilde{c}^i(\overline{f}),$$

and equality holds for $f = e^i$ and $\overline{f} = \overline{e}^i$. Notice that $\overline{e}^i$ is incident to nodes of normalized degree at most $d^i - 2$ by the definition of cross-edges.

An important observation is that $\epsilon^i$ can be 0. Such a step can be viewed as a *local-improvement* step along the lines of [5]. We do not modify the dual solution but decrease the normalized degree of a node of high normalized degree.

**3.2. Analysis: Performance guarantee.** Assume that Algorithm 1 terminates after iteration $t^*$. Recall that Theorem 1.2 requires us to show

$$c(E^{t^*}) \leq \omega \cdot \mathtt{opt}\,. \tag{3.3}$$

In this section we prove

$$c(E^i) = \sum_{e \in E^i} c_e \leq \omega \sum_{\pi \in \Pi} (r(\pi) - 1) \cdot y_\pi^i - \omega \cdot \sum_{v \in V} B_v \cdot \lambda_v^i \tag{3.4}$$

for all $1 \leq i \leq t^*$. Observe that $(y^i, \lambda^i)$ is a feasible solution for (D) and that the right-hand side of (3.4) is $\omega$ times the dual objective function induced by $(y^i, \lambda^i)$. Inequality (3.4) for $i = t^*$ together with weak duality implies (3.3). This line of proof extends that used in the analysis of primal-dual algorithms for minimum-cost networks developed in [1, 6].

In order to facilitate the proof of (3.4) for all $1 \leq i \leq t^*$, we maintain the following invariant inductively for all $0 \leq i \leq t^*$:

$$\omega \cdot \sum_{v \in V} B_v \lambda_v^i \leq (\omega - 1) \cdot \sum_{\pi \in \Pi} (r(\pi) - 1) \cdot y_\pi^i. \tag{Inv}$$

Recall that we assumed $\omega > 1$ in Theorem 1.2.

We now use the above invariant to provide a short proof of (3.4). Later in section 3.2.2, we prove (Inv) itself.

**3.2.1. Bounding the cost of $\boldsymbol{E^i}$.** Recall that we have $c_e \leq \widetilde{c}_e^i$ for all $e \in E$ and for all $1 \leq i \leq t$. As MST finishes we obtain from Lemma 2.1 that

$$c(E^{i+1}) \leq \widetilde{c}^{i+1}(E^{i+1}) = \sum_{e \in E^{i+1}} \widetilde{c}_e^{i+1} = \sum_{\pi \in \Pi} (r(\pi) - 1) \cdot y_\pi^{i+1}.$$

Adding (Inv) for iteration $(i+1)$ to the last inequality, we get

$$c(E^{i+1}) \leq \omega \cdot \left( \sum_{\pi \in \Pi} (r(\pi) - 1) \cdot y_\pi^{i+1} - \sum_{v \in V} B_v \lambda_v^{i+1} \right).$$

This finishes the proof of the performance guarantee claimed in Theorem 1.2. It remains to prove the invariant (Inv) for all $0 \leq i \leq t^*$.

**3.2.2. Proof of invariant (Inv).** We prove the validity of (Inv) for all $1 \leq i \leq t^*$ by induction over $i$. First, notice that (Inv) holds for $i = 0$ since $\lambda_v^0 = 0$ for all $v \in V$. To see the induction step of (Inv) we use the following lemma that ultimately yields (3.4). Recall the definition of normalized degree in (3.1) and the role of the parameter $\beta > 0$ in it.

LEMMA 3.2. *Let $b > 1$ be the constant chosen in Theorem 1.2. We must have*

$$\sum_{\pi \in \Pi} (r(\pi) - 1) \cdot y_\pi^{i+1} \geq \sum_{\pi \in \Pi} (r(\pi) - 1) \cdot y_\pi^i + \frac{\epsilon^i \beta}{b} \cdot \sum_{v \in S^i_{d^i - 1}} B_v$$

*for all $0 \leq i \leq t^*$.*

The lemma quantifies the increase in the dual objective function value as our algorithm moves from $y^i$ to $y^{i+1}$. Intuitively, the lemma shows that the increase in the dual objective function value is proportional to the total slack created by lengthening tree edges of $E^i$ that are incident to nodes of normalized degree at least $d^i - 1$.

Before presenting the proof of Lemma 3.2 we will use it to prove (Inv). Observe that the left-hand side of (Inv) increases by $\omega \epsilon^i \sum_{v \in S^i_{d^i-1}} B_v$ as a consequence of increasing the $\lambda$-values of nodes in $S^i_{d^i-1}$. Lemma 3.2 implies that the right-hand side of (Inv) increases by at least

$$(\omega - 1) \cdot \frac{\beta \epsilon^i}{b} \cdot \sum_{v \in S^i_{d^i-1}} B_v.$$

Choosing

$$\beta \geq b \cdot \frac{\omega}{\omega - 1} \tag{3.5}$$

completes the proof of invariant (Inv). Notice that this choice of $\beta$ together with the definition of normalized degree in (3.1) implies the degree-bound stated in Theorem 1.2.

We now prove Lemma 3.2.

*Proof of Lemma* 3.2. Let $E^i = \{e_1^i, \ldots, e_{n-1}^i\}$ and let $t_j^i$ be the time at which MST included edge $e_j^i$. W.l.o.g., assume that $t_1^i \leq \cdots \leq t_{n-1}^i$. From the description of MST we can rewrite

(3.6)
$$\sum_{\pi \in \Pi} (r(\pi) - 1) \cdot y_\pi^i = \sum_{j=1}^{n-1} (t_j^i - t_{j-1}^i) \cdot (n - j) = \sum_{j=1}^{n-1} t_j^i \left((n - j + 1) - (n - j)\right) = \sum_{j=1}^{n-1} t_j^i,$$

where we define $t_0^i = 0$.

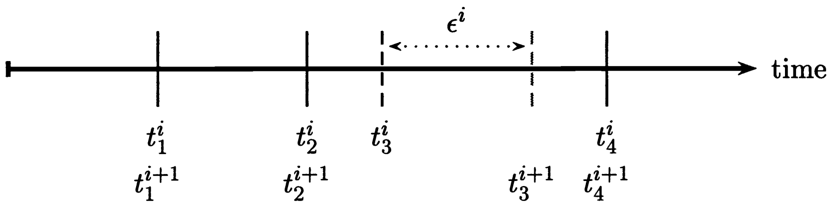

FIG. 3.1. *The figure shows two runs of* MST *in two consecutive iterations, $i$ and $i+1$. The horizontal line is the time axes while the vertical lines denote the times at which different edges become tight and are included. In the $i$th run edge $e_l$ becomes tight at time $t_l^i$. In this example, edge $e_3$ is the only edge incident to a vertex of normalized degree at least $d^i$. Its length increases and the time at which it becomes tight during* MST*'s execution is postponed by $\epsilon^i$ time units.*

Figure 3.1 illustrates the effect of iteration $i$. Observe that, by our choice of $\epsilon^i$, $E^i$ is an MST even for cost function $\widetilde{c}^{i+1}$. However, recall that there is a way to break ties such that step 9 in iteration $i$ correctly outputs $E^{i+1} = E^i \setminus \{e^i\} \cup \{\overline{e}^i\}$. This observation together with (3.6) enables us to quantify the change in dual in iteration $i$:

$$\sum_{\pi\in\Pi}(r(\pi)-1)\cdot\left(y_\pi^{i+1}-y_\pi^i\right) = \sum_{j=1}^{n-1}\left(t_j^{i+1}-t_j^i\right). \tag{3.7}$$

In iteration $i$, we increase the $\widetilde{c}$-cost of all edges $e \in E^i$ that are incident to nodes of normalized degree at least $d^i$ by $\epsilon^i$ while the $\widetilde{c}$-costs of all other tree edges remain unchanged. It is not hard to see that the time an edge becomes tight equals its $\widetilde{c}$-cost. In other words, all edges in $E^i$ that are incident to nodes of normalized degree at least $d^i$ become tight $\epsilon^i$ time units later. Together with (3.7) we obtain

$$\sum_{\pi\in\Pi}(r(\pi)-1)\cdot\left(y_\pi^{i+1}-y_\pi^i\right) = \epsilon^i\cdot\left|E\left(S_{d^i}^i\right)\cap E^i\right|, \tag{3.8}$$

where $E\left(S_{d^i}^i\right)$ denotes the set of edges in $E$ that are incident to nodes from $S_{d^i}^i$. (Note that we include in $E(S)$ edges with both endpoints in $S$.)

Recall the definition of normalized degree in (3.1). Notice that it follows from the termination condition in step 4 of Algorithm 1 that $\Delta^i > 2\log_b(n)$ and hence $d^i > 0$. Therefore, the real degree of any node $v \in S_{d^i}^i$ must be at least

$$\beta\cdot B_v + d_i \geq \beta\cdot B_v + 1.$$

Finally, notice that it follows from the fact that $E^i$ is a tree that there are at most $|S_{d^i}^i|-1$ edges in $E\left(S_{d^i}^i\right)$ that are incident to two nodes from $S_{d^i}^i$. We can use these observations to lower-bound the right-hand side of (3.8):

$$\sum_{\pi\in\Pi}(r(\pi)-1)\cdot\left(y_\pi^{i+1}-y_\pi^i\right) \geq \epsilon^i\cdot\left(\left(\sum_{v\in S_{d^i}^i}\beta\cdot B_v+1\right)-\left(|S_{d^i}^i|-1\right)\right) \geq \epsilon^i\beta\cdot\sum_{v\in S_{d^i}^i}B_v.$$

An application of Lemma 3.1 yields the lemma. ☐

**3.3. Analysis: Running time.** In this section, we show that Algorithm 1 terminates in polynomial time. We accomplish this by showing that there will be only a polynomial number of iterations of the main loop in Algorithm 1.

LEMMA 3.3. *Algorithm* 1 *terminates after* $O(n^4)$ *iterations.*

*Proof.* Following [4], we define the potential of spanning tree $E^i$ as

$$\Phi_i = \sum_{v \in V} 3^{\mathtt{ndeg}_i(v)},$$

where $\mathtt{ndeg}_i(v)$ denotes again the normalized degree of node $v$ in the tree $E^i$.

Notice that an iteration of Algorithm 1 swaps out a single edge $e^i$ that is incident to at least one node of normalized degree at least $d^i$. On the other hand, we swap in one edge $\overline{e}^i$ that is incident to two nodes of normalized degree at most $d^i - 2$. Hence, the reduction in the potential is at least

$$(3^{d^i} + 2 \cdot 3^{d^i-2}) - 3 \cdot 3^{d^i-1} \geq 2 \cdot 3^{d^i-2}.$$

Using the range of $d^i$, we can lower-bound the right-hand side of the last inequality by

$$2 \cdot 3^{\Delta^i - 2\log_b(n) - 2} = \Omega\left(\frac{3^{\Delta^i}}{n^2}\right).$$

The initial potential $\Phi_i$ is at most $n \cdot 3^{\Delta^i}$ and the decrease in the potential $\Phi_i$ in iteration $i$ is at least $\Omega\left(\frac{\Phi_i}{n^3}\right)$.

In other words, in $O(n^3)$ iterations, we reduce $\Phi$ by a constant factor. Since the initial potential is at most $n \cdot 3^n$ and the final potential is at least $n \cdot 3^2$, we obtain that Algorithm 1 terminates in $O(\log(n \cdot 3^n/(n \cdot 3^2))) = O(n)$ phases of $O(n^3)$ iterations each. Hence, the algorithm runs for $O(n^4)$ iterations total. Observing that each iteration can be implemented in time $O(m \log n)$ using standard priority-queue techniques (e.g., see [3]), we see that the whole algorithm runs in time $O(mn^5 \log n)$. ☐

# THE COMPLEXITY OF THE UNION OF $(\alpha, \beta)$-COVERED OBJECTS*

ALON EFRAT†

**Abstract.** An $(\alpha, \beta)$-covered object is a simply connected planar region $c$ with the property that for each point $p \in \partial c$ there exists a triangle contained in $c$ and having $p$ as a vertex, such that all its angles are at least $\alpha > 0$ and all its edges are at least $\beta \cdot \mathrm{diam}(c)$-long. This notion extends that of fat convex objects. We show that the combinatorial complexity of the union of $n$ $(\alpha, \beta)$-covered objects of "constant description complexity" is $O(\lambda_{s+2}(n) \log^2 n \log\log n)$, where $s$ is the maximum number of intersections between the boundaries of any pair of given objects, and $\lambda_s(n)$ denotes the maximum length of an $(n, s)$-Davenport–Schinzel sequence. Our result extends and improves previous results concerning convex $\alpha$-fat objects.

**Key words.** fat objects, realistic input models, motion planning

## 1. Introduction.

A planar object $c$ is $(\alpha, \beta)$-*covered* if the following conditions are satisfied:

1. $c$ is a compact simply connected set.
2. For each point $p \in \partial c$ we can place a triangle $\Delta$ fully inside $c$, such that $p$ is a vertex of $\Delta$, each angle of $\Delta$ is at least $\alpha$, and the length of each edge of $\Delta$ is at least $\beta \cdot \mathrm{diam}(c)$. We call such a triangle $\Delta$ a *good triangle* for $c$ at $p$.

The notion of an $(\alpha, \beta)$-covered object generalizes that of a convex fat object. A planar convex object $c$ is $\alpha$-*fat* if the ratio between the radii of the disks $s^+$ and $s^-$ is at most $\alpha$, where $s^-$ is the smallest disk containing $c$ and $s^+$ is a largest disk a contained in $c$; see [7]. It is easy to show that if $c$ is an $\alpha$-fat convex object, then it is also an $(\alpha', \beta')$-covered object for appropriate constants $\alpha', \beta'$ that depend only on $\alpha$. Indeed, let $p$ be a point on $\partial c$ and let $q_1, q_2$ be the two antipodal points on $\partial s^+$ such that $|\overline{pq_1}| = |\overline{pq_2}|$. Clearly the isosceles triangle $\Delta q_1 q_2 p$ is at least $\arctan(1/2\alpha)$-fat, and that the length of its edges is at least $\mathrm{diam}(c)/2\alpha$.

In this paper we also make the additional assumption that all the objects under consideration have *constant description complexity*, meaning that each object is a semialgebraic set defined by a constant number of polynomial equalities and inequalities of constant maximum degree. This assumption is critical, since even two convex $m$-gons (for any $m$) can create $2m$ vertices on their union.

The goal of this paper is to obtain sharp bounds for the maximum combinatorial complexity of the union of a collection $\mathcal{C}$ of $n$ $(\alpha, \beta)$-covered objects of constant description complexity for constant parameters $\alpha, \beta > 0$.

There are not too many previous results of this kind. If $\mathcal{C}$ is a collection of $\alpha$-fat triangles,[1] then the complexity of $\bigcup \mathcal{C}$ is $O(n \log\log n)$ (with the constant of proportionality depending on $\alpha$) [15, 16], and this bound improves to $O(n)$ if the triangles are nearly of the same size [2] or are infinite wedges. See also [14] and more

[1]For triangles, there is an equivalent definition of fatness that requires all angles to be at least some fixed constant $\alpha_0$; in [15, 16], this is called $\alpha_0$-fatness.

recently [16] for additional results concerning fat polygons. If $\mathcal{C}$ is a collection of $n$ *pseudodisks* (arbitrary simply connected regions bounded by closed Jordan curves, each pair of whose boundaries intersect at most twice), then the complexity of $\bigcup\mathcal{C}$ is $O(n)$ [13]. Of course, if we drop the fatness condition, the complexity of $\bigcup\mathcal{C}$ can be $\Theta(n^2)$, even for the case of (nonfat) triangles. Even for fat convex objects, some bound on the description complexity of each object must be assumed, or else the complexity of the union might be arbitrarily large.

In three dimensions, there are several relevant results about the union of objects. Agarwal and Sharir [1] showed that if $\mathcal{C}$ is the Minkowski sum of a ball and a set of $n$ disjoint triangles or lines in three dimensions, then the complexity of the boundary of $\bigcup\mathcal{C}$ is $O(n^{2+\varepsilon})$.[2] Among fat objects in three dimensions, one might consider balls and cubes as "basic cases" of fat objects in three dimensions. Pach, Safruti, and Sharir [17] showed that if $\mathcal{C}$ is the union of $n$ wedges, each determined by the intersection of two halfspaces with a dihedral angle at least $\alpha$, then the complexity of their union is $O(n^{2+\varepsilon})$. They also show that if each wedge of $S$ is the intersection of three halfspaces, each pair creating a solid angle at least $\alpha$ and the sum of the three face angles is at least $4\pi/3$, then the complexity of the union of these wedges is $O(n^{2+\varepsilon})$. The constant of proportionality depends on $\varepsilon, \alpha$, and in the latter case, $\gamma$. They also proved that the union of $n$ cubes in three dimensions, whose edge lengths are the same, up to a constant, is also $O(n^{2+\varepsilon})$.

Concerning fat nonpolygonal shapes in the plane, it was shown in [7] that if $\mathcal{C}$ is a collection of $n$ convex $\alpha$-fat objects of constant description complexity, then the complexity of $\bigcup\mathcal{C}$ is $O(n^{1+\varepsilon})$, for any $\varepsilon > 0$, where the constant of proportionality depends on $\varepsilon$, on the fatness parameter, and on the maximum description complexity of the given objects. In an attempt to remove the convexity restriction, the notion of $\kappa$-curviness was introduced in [8]. An object $c$ is *$\kappa$-curved* (for a parameter $\kappa > 0$) if for each point $p$ on its boundary there is a ball $B \subseteq c$ whose radius is at least $\kappa \cdot \mathrm{diam}(c)$, and which contains $p$ on its boundary. It was shown in [8] that if $\mathcal{C}$ is a collection of $n$ *$\kappa$-curved* objects in the plane of constant description complexity, then the complexity of $\bigcup\mathcal{C}$ is $O(\lambda_{s'}(n)\log^2 n)$, where $s'$ is a constant that depends on $\kappa$ and on the description complexity of the objects, and $\lambda_s(n)$ denotes the maximum length of an $(n, s)$-Davenport–Schinzel sequence [18]. This result was recently extended [3], where it was shown that if $\mathcal{C}$ is a collection of $n$ *$\kappa$-curved* objects in $\mathbb{R}^d$, for $d = 3$ and $d = 4$, then the complexity of the boundary of their union is $O(n^{2+\varepsilon})$ in $\mathbb{R}^3$ and $O(n^{3+\varepsilon})$ in $\mathbb{R}^4$. However, the class of $\kappa$-curved objects is rather restricted. For example, an $\alpha$-fat triangle is not a $\kappa$-curved object for any $\kappa$. On the other hand, the notion of $(\alpha, \beta)$-covered objects clearly generalizes the notion of $\kappa$-curved objects, as well as that of fat convex objects.

Let $\mathcal{C}$ be a collection of $n$ $(\alpha, \beta)$-covered objects of constant description complexity in general position; that is, no points lie on the boundaries of three objects, and the boundaries of each pair of objects of $\mathcal{C}$ have at most some constant number, $s$, of intersection points. In addition we assume that $s$ also bounds the number of points at which the boundary of an object in $\mathcal{C}$ is not $C^1$ or $C^2$, as well as the number of inflection points and locally $x$- and $y$-extremal points of any such boundary.

The following is the main result of this paper.

THEOREM 1.1. *Under the above assumptions, the combinatorial complexity of the union of $\mathcal{C}$ is $O(\lambda_{s+2}(n)\log^2 n \log\log n)$.*

[2]In this paper $\varepsilon$ stands for an arbitrary small positive constant.

The proof of Theorem 1.1 is given in the following sections. It is worth mentioning that if all objects of $\mathcal{C}$ are roughly of the same size, then the bound of Theorem 1.1 can be improved to $O(\lambda_{s+2}(n))$; see section 4 for further discussion.

Theorem 1.1, together with the previous works cited above, contribute to the study of the union of planar objects, an area that has many algorithmic applications, such as finding the maximal depth in an arrangement of fat objects (see [10]), hidden surface removal in a collection of fat objects in 3-space [12], point-enclosure queries in a collection of fat objects in the plane [11], and more; see [20] for more applications and other definitions of fat nonconvex objects. Theorem 1.1 both extends these results to the more general class of $(\alpha, \beta)$-covered objects and slightly improves the corresponding complexity bounds.

The contributions of this paper are as follows: (a) the introduction of a new class of "fat" nonconvex objects (namely, $(\alpha, \beta)$-covered objects), which, we believe, captures the characteristics of the input data in most realistic scenes; (b) a sharper bound on the union complexity than the bounds obtained in [7] (bringing them to within a polylogarithmic factor of the best-known lower bounds); and (c) the proof technique, which is much simpler than the analysis given in [7].

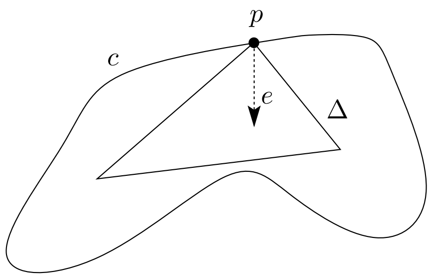

FIG. 1. *The point $p$ is $3\pi/2$-oriented.*

## 2. Preliminaries.

**2. Preliminaries.** Let $\mathcal{C}$ be a collection of $n$ $(\alpha, \beta)$-covered objects, as in the introduction. Let $c \in \mathcal{C}$, and let $p$ be a point on $\partial c$. We say that $p$ is *$\theta$-oriented* if there is a good triangle $\Delta$ for $c$ with $p$ as a vertex, such that the ray $e$ emerging from $p$ at orientation $\theta$ intersects the interior of $\Delta$. In this case we call $\Delta$ a *$\theta$-oriented* triangle at $p$. See Figure 1. Note that $p$ might be $\theta$-oriented for more than one value of $\theta$.

The idea behind our proof is as follows. We define, for each object $c$, a collection of *subobjects* so that every vertex of $\partial \bigcup \mathcal{C}$ is a vertex of the union of the subobjects of all objects $c \in \mathcal{C}$. Moreover, we classify such vertices into $O(\log^2 n)$ disjoint families and argue that the size of each family is only $O(\lambda_{s+2}(n) \log \log n)$.

Let $\Psi$ be the set of orientations $\{\frac{\alpha}{4}, \frac{2\alpha}{4}, \ldots, \frac{\alpha\lceil 8\pi/\alpha \rceil}{4}\}$. We call a triangle $\Delta$ a *$\theta$-critical* triangle at $p$ for $c$ if $\Delta$ is a good triangle at $p$ for $c$, and $\Delta$ is $(\theta - \frac{\alpha}{4})$-oriented at $p$, $\theta$-oriented at $p$, and $(\theta + \frac{\alpha}{4})$-oriented at $p$. We say that a point $p \in \partial c$ is *$\theta$-critical* for $c$ if there exists a $\theta$-critical triangle $\Delta$ at $p$ for $c$. For each $c \in \mathcal{C}$ and each $\theta \in \Psi$ let $\gamma_\theta(c)$ denote the portion of $\partial c$ consisting of $\theta$-critical points. By the constant description complexity assumption made in the introduction, $\gamma_\theta(c)$ consists of at most a constant (depending on $s$ and $\alpha$) connected portions of $\partial c$. We further divide these portions of $\gamma_\theta(c)$ into a constant number of not-too-long subarcs (that might overlap), called *primitive arcs*, or *p-arcs* for short. Each p-arc $\delta$ is required

(i) to be differentiable (that is, there exists a well-defined tangent at each point of the relative interior of $\delta$);

(ii) not to contain in its relative interior any inflection point of $\partial c$;

(iii) to satisfy the property that the difference in the orientations of the tangents at any pair of points of $\delta$ is at most $\pi/t$, where $t > 10$ is a constant to be specified in Claim 2.1 below that depends only on $\alpha$ and $\beta$, and such that $\pi/t < \alpha$;

(iv) to have length no more than $\operatorname{diam}(c)/t'$, where $t'$ is a constant to be specified in Claim 2.1 below and depends only on $\alpha$ and $\beta$.

A p-arc along the boundary of an object $c$ is *convex* if the segment connecting the endpoints of the arc is contained in $c$. Otherwise, we say that the p-arc is *concave.* See Figure 2.

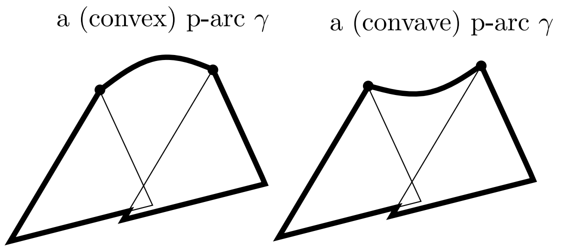

FIG. 2. *Example of convex and concave p-arcs.*

For each $c \in \mathcal{C}$ and for every $\theta \in \Psi$, we place a $\theta$-oriented triangle at each endpoint of every p-arc of $\gamma_\theta(c)$, and we let $P_c$ denote the collection of these triangles.

CLAIM 2.1. *We can choose $t', t$ so that the boundary of each connected component of $c \setminus \bigcup P_c$ contains at most a single p-arc. In other words, there is no path in $c$ that connects two p-arcs of $c$ and does not intersect $\bigcup P_c$.*

*Proof.* Assume $\operatorname{diam}(c) = 1$ (otherwise, we rescale $c$). We say that a point $p$ is *higher than* (resp., *lower than, to the left of, to the right of*) a point $q$, if $p.y \geq q.y$ (resp., $p.y \leq q.y$, $p.x \leq q.x$, $p.x \geq q.x$). Let $\gamma$ be a portion of $\partial c$ satisfying (i), (ii), (iii), and (iv). Assume without loss of generality that the tangent to the rightmost point of $\gamma$ is horizontal. We locate two $3\pi/2$-critical triangles $\Delta'_1, \Delta'_2$, where $p_i$ is a vertex of $\Delta'_i$ (for $i = 1, 2$). Clearly $\Delta'_i$ contains a triangle $\Delta_i \subseteq \Delta'_i$ such that the angle at $p_i$ equals exactly $\alpha/2$, the edge opposite $p_i$ is horizontal (see Figure 3), and the edges adjacent to $p_i$ have length exactly $\beta$ (for $i = 1, 2$). Assume that $p_1$ is to the left of and lower than $p_2$.

We show that if $t' \geq \frac{2}{3\beta \sin(\frac{\alpha}{4})}$ and $t \geq \pi / \arcsin(\beta \cos(\frac{\alpha}{4})/2)$, then $\Delta_1$ and $\Delta_2$ must intersect. Let $u$ and $z$ be the other two vertices of $\Delta_1$ ($u$ to the left of $z$). Let $u'$ be the middle point of $\overline{uz}$ and let $w$ be the middle point of $\overline{u'z}$. Let $w'$ be the point on $\partial \Delta_1$ vertically above $w$, and let $R$ be the axis-parallel rectangle whose two diagonal vertices are $u'$ and $w'$. Let $\mu$ be the left vertex of the lower edge of $\Delta_2$.

Note that if $\mu$ is to the left of $u'$, then clearly $\Delta_1$ and $\Delta_2$ intersect, since they are congruent triangles, $p_2$ is to the right of $p_1$, and $\gamma$ is $x$-monotone. So assume that $\mu$ is to the right of $u'$. To conclude that $\mu \in R$ and thus $\Delta_1$ and $\Delta_2$ intersect, we need to show only that $\mu$ is below and to the left of $w'$. Indeed

$$|\overline{ww'}| = |\overline{p_1 u'}|/2 = |\overline{p_1 z}| \cos\left(\frac{\alpha}{4}\right)/2 = \beta \cos\left(\frac{\alpha}{4}\right)/2 \quad \text{and} \quad |\overline{u'w}| = \beta \sin\left(\frac{\alpha}{4}\right)/2 \; .$$

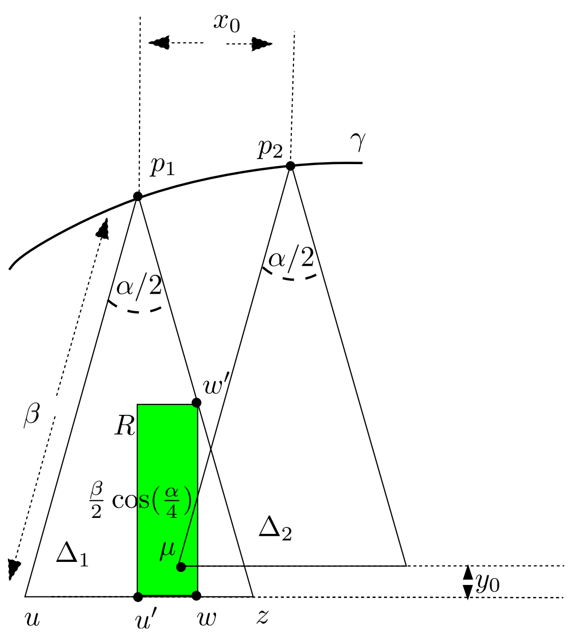

FIG. 3. *Illustration of Claim* 2.1.

Let $x_0 = p_2.x - p_1.x$. Since we set $t' \geq \frac{2}{3\beta\sin(\alpha/4)}$, it follows that

$$x_0 \leq |\gamma| \leq \frac{\text{diam(c)}}{t'} \leq \frac{3}{2}\beta\text{diam(c)}\sin\left(\frac{\alpha}{4}\right) = \frac{3}{2}\beta\sin\left(\frac{\alpha}{4}\right) ,$$

where we make use of the assumption that $\text{diam}(c) = 1$. Hence

$$\mu.x - u'.x \ = \ x_0 - \beta\sin\left(\frac{\alpha}{4}\right) \leq \frac{1}{2}\beta\sin\left(\frac{\alpha}{4}\right) \leq w.x - u'.x,$$

implying that $\mu$ is to the left of $w$. Finally, $\pi/t \leq \arcsin\left(\beta\cos\left(\frac{\alpha}{4}\right)/2\right)$. Hence

$$\mu.y - u'.y \leq |\overline{p_1p_2}|\sin\left(\frac{\pi}{t}\right) \leq \sin\left(\frac{\pi}{t}\right) \leq \beta\cos\left(\frac{\alpha}{4}\right)/2 \leq |\overline{w'w}| ,$$

where we have used the assumption that $|p_1p_2| \leq \text{diam}(c) = 1$. Thus $\mu$ is below $w'$, implying that $\mu \in R$, as claimed. $\square$

We call a maximally connected component of $c \setminus \bigcup P_c$ a *cap*, and the segment connecting the endpoints of its p-arc a *chord*. The union of a cap and the two triangles of $P_c$ adjacent to the endpoints of its p-arc is called a *subobject*. Figure 2 shows two subobjects. If a subobject is not simply connected, we "fill in" its holes and add them to the subobject. The boundary of a subobject consists of a single p-arc and of portions of edges of the good triangles of $P_c$ adjacent to the p-arc's endpoints. Note that the chord of the subobject is not always a part of the subobject. The collection of all subobjects of $c$ that are adjacent to p-arcs that are $\theta$-oriented is denoted by $c^\theta$. See Figure 4. Clearly $c^\theta$ consists of a constant number of subobjects. Let $\mathcal{C}^\theta = \bigcup_{c\in C} c^\theta$.

Fix $\theta \in \Psi$, which we assume for simplicity to be the negative vertical direction; otherwise, rotate the plane. Define a segment tree $\mathcal{T}_\theta$ (see [5] for a discussion of segment trees) over the set of intervals on the $y$-axis obtained by projecting each

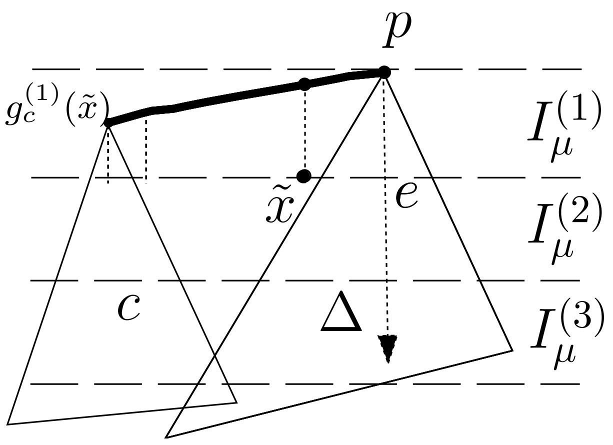

FIG. 4. *A subobject c, a slab and the strips it contains, and the graph of the function* $g_c^{(i)}(x)$.

subobject of $\mathcal{C}^\theta$ on the $y$-axis. Each node $\mu \in \mathcal{T}_\theta$ is associated with a subset $S_\mu \subseteq \mathcal{C}^\theta$ and with a horizontal slab $I_\mu$. See Figure 4. That is, a subobject $c \in C^\theta$ is in $S_\mu$ if and only if its $y$-projection contains the $y$-projection of $I_\mu$ but does not contain the $y$-projection of $I_{\text{parent}(\mu)}$.

Let $\mathcal{L}(\mathcal{T}_\theta, i)$, the $i$th level of $\mathcal{T}_\theta$, denote the collection of nodes of $\mathcal{T}_\theta$ whose distance from the root of $\mathcal{T}_\theta$ is $i$. Fix $\theta_A, \theta_B \in \Psi$ (not necessarily distinct) and levels $i_A$ of $\mathcal{T}_{\theta_A}$ and $i_B$ of $\mathcal{T}_{\theta_B}$. Note that there are $O(\log^2 n)$ quadruples $(\theta_A, \theta_B, i_A, i_B)$ of this form. Define $A = \bigcup_{\mu \in \mathcal{L}(T_{\theta_A}, i_A)} S_\mu$ and $B = \bigcup_{\mu \in \mathcal{L}(T_{\theta_B}, i_B)} S_\mu$. That is, $A$ (resp., $B$) is the collection of subobjects in $S_\mu$ for $\mu$ on the $i_A$th level of $\mathcal{T}_{\theta_A}$ (resp., the $i_B$th level of $\mathcal{T}_{\theta_B}$). Let $U(\theta_A, \theta_B, i_A, i_B)$ denote the set of "mixed" vertices of $\partial \bigcup (A \cup B)$ that lie on $\gamma_{\theta_A}(a)$ for some $a \in A$, and on $\gamma_{\theta_B}(b)$ for some $b \in B$. The next section is dedicated to the proof of the following lemma.

LEMMA 2.1. *The size of* $U(\theta_A, \theta_B, i_A, i_B)$ *is* $O(\lambda_{s+2}(n) \log\log n)$.

The proof of Theorem 1.1 follows immediately from Lemma 2.1. Indeed, for each vertex $v \in \partial \bigcup \mathcal{C}$ which lies on the boundaries of objects $a, b \in \mathcal{C}$ there is a direction $\theta_A \in \Psi$ (resp., $\theta_B \in \Psi$) such that $v$ is $\theta_A$-critical for $a$ at $v$ (resp., $\theta_B$-critical for $b$ at $v$). Hence there is a subobject $a' \subset a$ containing $v$ on its boundary, and a node $\mu_a \in \mathcal{T}_{\theta_A}$ with $a' \in S_{\mu_{a'}}$. Hence $v \in \partial \bigcup A$, where $A = \bigcup_{\mu \in \mathcal{L}(T_{\theta_A}, i_A)} S_\mu$, and $\mathcal{L}(T_{\theta_A}, i_A)$ is the level of $\mathcal{T}_{\theta_A}$ containing $a'$. Similarly there exist $\theta_B$ and $i_B$ such that $v \in \partial \bigcup B$, where $B = \bigcup S_{\mu \in \mathcal{L}(T_{\theta_B}, i_B)} S_\mu$. Thus $v \in U(\theta_A, \theta_B, i_A, i_B)$. Since there are only $O(\log^2 n)$ quadruples $(\theta_A, \theta_B, i_A, i_B)$, Theorem 1.1 follows immediately from Lemma 2.1.

**3. Proof of Lemma 2.1.** We fix a quadruple $(\theta_A, \theta_B, i_A, i_B)$, as above. We assume that $\theta_A = 3\pi/2$ (the negative $y$-direction) by rotating the plane if necessary. Let $\mu$ be a node in the $i_A$th level of $\mathcal{T}_{3\pi/2}$, and let $I_\mu$ be the horizontal slab associated with $\mu$. Let $c$ be a subobject of $S_\mu$, let $p \in \gamma_{3\pi/2}(c) \cap I_\mu$, and let $\Delta$ be a $(3\pi/2)$-oriented triangle of $c$ at $p$. Note that $\Delta$ is an $\alpha$-fat triangle, and the length of the $y$-span of $c$ is at least the width of $I_\mu$. Hence there is a constant integer $h$ (that depends only on $\alpha$ and $\beta$), such that the length of the $y$-span of each edge of $\Delta$ is at least $1/h$ times the width of $I_\mu$. We divide $I_\mu$ into $h$ interior-disjoint *strips*, $I_\mu^{(1)}, \ldots, I_\mu^{(h)}$, of equal width. Thus, $p$ lies in a different strip from the other two vertices of $\Delta$; see Figure 4. Therefore, for each strip $I_\mu^{(i)}$, we can express all points of $I_\mu^{(i)} \cap \gamma_{3\pi/2}(c)$ as a graph

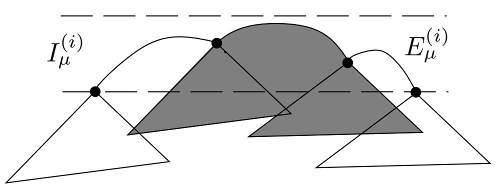

FIG. 5. *The upper envelope $E_\mu^{(i)}$ and some new subobjects defined by its vertices. One of the subobjects is shaded.*

$g_c^{(i)}(\tilde{x})$ of a (partial) function defined on the lower boundary of the strip $I_\mu^{(i)}$, with the property that the segment connecting the points $\tilde{x}$ to $g_c^{(i)}(\tilde{x})$ is fully contained inside $c$.

For each strip $I_\mu^{(i)}$, consider the upper envelope $E_\mu^{(i)}$ (see Figure 5) of the functions $g_c^{(i)}(\tilde{x})$ for $c \in \mathcal{S}_\mu$. Let $E_\mu$ denote the union of these upper envelopes for all strips of $I_\mu$, and let $E_A$ denote the union of all these envelopes taken over all nodes $\mu$ in the $i_A$th level of $\mathcal{T}_{\theta_A}$. Repeat the same analysis for $\theta_B$, and obtain a corresponding union $E_B$ of upper envelopes (relative to the $\theta_B$-direction).

Let $v$ be a vertex of $E_A$ incident to the boundaries of subobjects $c_1, c_2 \in A$. We add to $P_{c_1}$ a $\theta_A$-critical triangle for $c_1$ at $v$, and to $P_{c_2}$ a $\theta_A$-critical triangle for $c_2$ at $v$ (it is possible that these are similar triangles with a common vertex and overlapping edges). For each $c \in \mathcal{S}_\mu$ and each p-arc $\gamma$ of $c$ we also add $\theta_A$-critical triangles at each point where $\gamma$ crosses a boundary of a strip of $I_\mu$. We further refine the splitting of arcs into p-arcs, so that no p-arc $\gamma$ contains a vertex of a new triangle in the p-arc's interior. Subobjects are split as well, so that each subobject contains exactly one new p-arc on its boundary. Observe that now each p-arc is contained in at most one strip of $I_\mu$.

We next remove from $A$ all subobjects that do not participate in $E_A$. Thus each p-arc of a remaining subobject of $A$ is fully contained in $E_A$, and also fully contained in a single strip of some $I_\mu$. Analogously, we restructure the subobjects and p-arcs for $B$, the collections $\{P_b\}_{b \in B}$ and the union of envelopes $E_B$. We list several important properties of this construction:

(A1) Two p-arcs of $A$ either are disjoint or intersect only at their endpoints. Moreover, a p-arc $\gamma$ of a subobject $a_1 \in A$ may intersect the boundary of a different subobject $a_2 \in A$ only at an endpoint of $\gamma$ or at a point of $\partial \bigcup P_{a_2}$. Similar properties hold for $B$.

(A2) A necessary condition for a vertex $v$ to belong to $U(\theta_A, \theta_B, i_A, i_B)$ is that $v$ lies on $E_A$ and on $E_B$.

(A3) The complexities of $E_A$ and of $E_B$ are each $O(\lambda_{s+2}(n))$; see [18] for a discussion on the complexity of an upper envelope.

Recall that the parameter $t$ used in property (iii) satisfies $\pi/t \le \alpha$. We next state a slightly modified version of a lemma that appeared in [7].

LEMMA 3.1 (Efrat and Sharir [7]). *Let $K_a$ be the portion of a cap of some subobject $a \in \mathcal{C}^\theta$, enclosed between its convex p-arc $\gamma_a$ and its chord $e_a$. Let $\Delta_b \in P_b$ be a good triangle for some object $b \in \mathcal{C}$, such that an edge $e_b$ of $\Delta_b$ crosses $\gamma_a$. Then one of the following cases must occur:*

(i) *$e_a$ crosses $\partial \Delta_b$ (as in Figure* 6(i)*).*

(ii) *$K_a$ contains a vertex of $\Delta_b$ that is an endpoint of $e_b$ (as in Figure* 6(ii)*).*

(iii) *$\Delta_b$ contains a vertex of $K_a$ (as in Figure* 6(iii)*).*

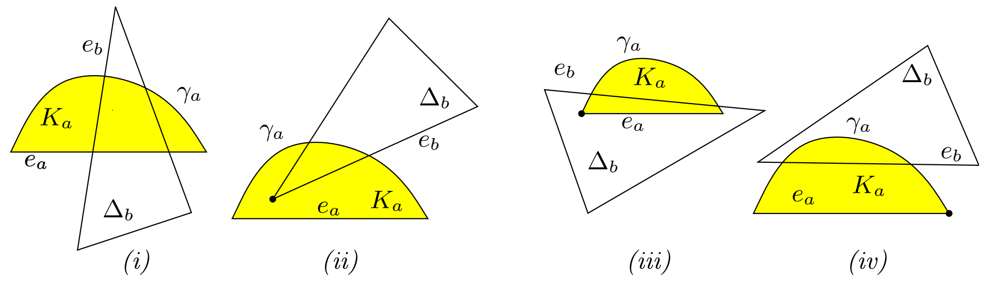

FIG. 6. *Illustrating the various cases in Lemma* 3.1.

(iv) *$\partial K_a$ and $\partial \Delta_b$ cross exactly twice, at two points that lie on $\partial a$ and on $e_b$, and $e_a$ is disjoint from $\Delta_b$ (as in Figure* 6(iv)*).*

So, for example, it cannot happen that $\gamma_a$ intersects two edges of $\Delta_b$, each edge in two points, and all vertices of $\Delta_b$ lie in the same side of the line containing $e_a$.

*Proof.* The proof is essentially identical to the one given in [7], with obvious modifications that are left to the reader. □

Consider the collections $P_A = \bigcup_{a \in A} P_a$, $P_B = \bigcup_{b \in B} P_b$. The result of [15, 16] implies that the complexity of $\bigcup P_A$, of $\bigcup P_B$, and of $\bigcup(P_A \cup P_B)$ are each $O(\lambda_{s+2}(n) \log\log n)$, as each triangle in these collections is an $\alpha$-fat triangle. The constants of proportionality depend on $\alpha$.

Our strategy in proving Lemma 2.1 is to proceed in several steps. First, we define below sets of new types of vertices, namely, $UP(A)$ and $UP(B)$. We obtain bounds on the cardinality of these sets, by charging (roughly speaking) each vertex $v$ of these sets to a vertex $u$ of $\bigcup(P_A \cup P_B)$, in a way that $u$ is not charged more than a constant number of times. Later on, we charge each vertex $w$ of $U(\theta_A, \theta_B, i_A, i_B)$ to a vertex of $\bigcup(P_A \cup P_B)$, or a vertex of $UP(A)$ or $UP(B)$.

We define $UP(A)$ as the set of all vertices of $E_A \cap \partial \bigcup(A \cup P_B)$. We define $UP(B)$ symmetrically, interchanging $A$ and $B$.

LEMMA 3.2. *The number of vertices of $UP(A)$ and of $UP(B)$ is $O(\lambda_{s+2}(n) \log\log n)$.*

*Proof.* It suffices to prove the lemma for $UP(B)$. Consider a p-arc $\gamma_b = \gamma_{\theta_B}(b)$ containing a vertex $v$ of $UP(B)$, defined by the intersection of $\gamma_b$ and an edge $e$ of $\partial \bigcup(P_A \cup P_B)$. Let $\Delta$ be the triangle adjacent to $e$ (note that $e$ might be a portion of an edge of $\Delta$) and let $\hat{e}$ be the edge of $\Delta$ containing $e$.

Let $u_1$, $u_2$ be the endpoints of $\gamma_b$; see Figure 7. Assume again that $\theta_B = 3\pi/2$, so the slabs of $\mathcal{T}_{\theta_B}$ are horizontal, and suppose $u_1$ is to the left of $u_2$. Let $\mu$ be the node of $\mathcal{T}_{\theta_B}$, on the $i_B$th level, associated with the subobject $b$ containing $v$ on its boundary. Let $t_1$ and $t_2$ be the triangles of $P_b$, which are $\theta_B$-critical for $b$ at $u_1$ and at $u_2$. Let $F = F(\gamma_b)$ be the axis-parallel rectangle formed by intersecting $I_\mu^{(i)}$ with the vertical strip spanned by $\gamma_b$ (the shaded area in Figure 7). Clearly $v$ lies in $F$. Note that if $\gamma_b, \gamma_{b'}$ are two distinct p-arcs of $A$, then the rectangles $F(\gamma_b)$ and $F(\gamma_{b'})$ are interior disjoint.

If $\Delta \cap \gamma_b$ fully contains one of the two portions of $\gamma_b$ connecting $v$ to one of the endpoints of $\gamma_b$, we charge $v$ to this endpoint. Since the number of endpoints is $O(\lambda_{s+2}(n))$ and each can be charged at most twice, from each direction, the number of vertices $v$ of this type is within the asserted bound. So assume this is not the case.

Recall that $\gamma_b$ is either concave or convex; so $e$ intersects $\gamma_b$ either once or twice. We call $e$ a *long* edge if both its endpoints are outside $F$; otherwise, $e$ is a *short* edge.

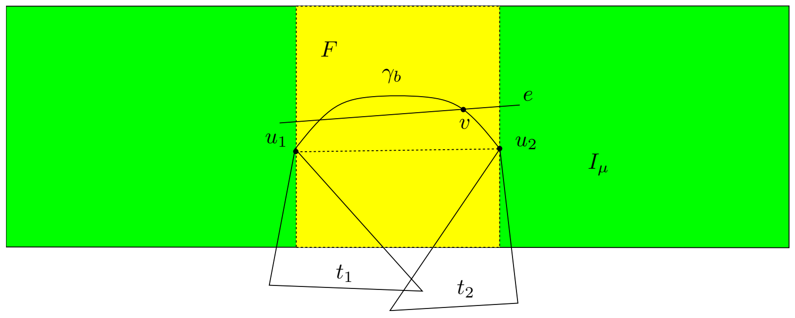

FIG. 7. *Illustrating the proof of Lemma* 3.2*; e is long.*

If $e$ is short, we charge $v$ to an endpoint of $e$ inside $F$ (which in turn can be charged at most twice); again, the number of such endpoints is within the asserted bound. So let us assume that $e$ is long.

If $e$ intersects $\gamma_b$ once, then $e$ must intersect $t_1$, $t_2$, or some other triangle of $P_A \cup P_B$, at a point inside $F$ and on $\partial \bigcup(P_A \cup P_B)$. Hence by following $e$ inward into $b$, we must reach a vertex $x$ of $\bigcup(P_A \cup P_B)$ that we can charge to $v$. So assume that $e$ intersects $\gamma_b$ twice. If $\gamma_b$ is concave, then if we trace $e$ from $v$ into $b$, we reach a vertex of $\partial \bigcup(P_A \cup P_B)$, to which we can charge $v$. So we may assume that $\gamma_b$ is convex, as depicted in Figure 7.

Let $z$ be the vertex of $\Delta$ that lies opposite $e$. We say that $e$ is *special* if $z$ lies inside $F$. We charge $v$ in this case to $z$, and $z$ could be charged at most twice (by the two vertices which lie on the edge of $\Delta$, and contained in $F$). Hence it suffices to consider the case where $e$ is nonspecial and long.

Applying Lemma 3.1 to the edge $\hat{e}$ of $\Delta$, and the appropriate cap portion, we see that if any of the cases (i)–(iii) arises, we can charge $v$ to a vertex of $\bigcup(P_A \cup P_B)$ inside the cap, as done above. So we may assume that case (iv) arises.

We now claim that the number of long nonspecial edges $e_1, \ldots, e_l$ of $\bigcup(P_A \cup P_B)$ incident to vertices of $U(\theta_A, \theta_B, i_A, i_B)$ on $\gamma_b$, satisfying property (iv) of Lemma 3.2, is at most two. Indeed, let $\Gamma(e_i)$ be the portion of $\gamma_b$ spanned between its two intersection points with $e_i$.

It is impossible that $\Gamma(e_i)$ and $\Gamma(e_j)$ intersect. Indeed if $\Gamma(e_i) \cap \Gamma(e_j) \neq \emptyset$, but neither $\Gamma(e_i) \subseteq \Gamma(e_j)$ nor $\Gamma(e_j) \subseteq \Gamma(e_j)$, then $e_i$ and $e_j$ must intersect inside $F$ (by the convexity of $\gamma$), and thus they are not long. On the other hand, it is impossible that one of them, say $\Gamma(e_i)$, is fully contained in $\Gamma(e_j)$, since they both satisfy property (iv), implying that then $\Gamma(e_i)$ is fully contained inside the triangle adjacent to $e_j$, and preventing $e_i$ from determining vertices of $U(\theta_A, \theta_B, i_A, i_B)$ on $\gamma_b$. Moreover, if $\Gamma(e_i)$ and $\Gamma(e_j)$ are disjoint (see Figure 8), then it is easily verified that $e_i$ and $e_j$ intersect different pairs of edges of $F$; thus there are only two such pairs that intersect $\gamma$. This concludes the proof of the Lemma 3.2. $\square$

We can now return to the proof of Lemma 2.1.

*Proof of Lemma* 2.1. Let $v$ be a vertex of $U = U(\theta_A, \theta_B, i_A, i_B)$, incident to a p-arc $\gamma_a$ and to another p-arc $\gamma_b$, for some $a \in A$, $b \in B$. Let $I_\mu$ (for $\mu \in \mathcal{T}_{\theta_B}$) be the strip containing $b$ and assume again that $\theta_B = 3\pi/2$; otherwise, rotate the plane. As in Lemma 3.2, let $F$ be the rectangle formed by the intersection of $I_\mu$ with the vertical strip spanned by $\gamma_b$. We call $\gamma_a$ *favorable* if $\gamma_a \cap F$ contains either an endpoint of $\gamma_a$, or a locally highest point, lowest point, rightmost point, or leftmost point of $\gamma_a$. Note

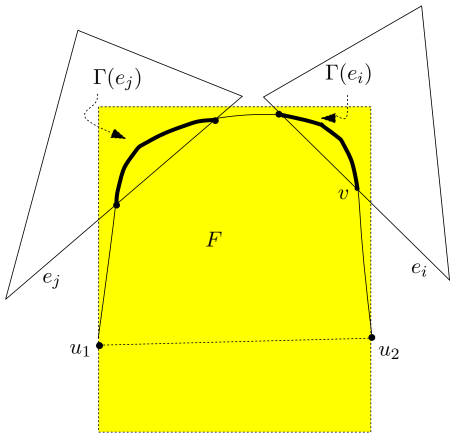

FIG. 8. *If* $\Gamma(e_i)$ *and* $\Gamma(e_j)$ *are disjoint, then* $e_i$ *and* $e_j$ *cross different pairs of edges of* $F$*.*

that if $\gamma_a$ is favorable, we can charge $v$, and the rest of the (at most $s-1$) vertices of $U \cap \gamma_a \cap \gamma_b$ to one of the extreme points listed above, since there is only a constant number of them on each object of $\mathcal{C}$.

Let $\mu_a$ and $\mu_b$ be the normals at $v$ to $\gamma_a$ and $\gamma_b$, pointing into $a$ and $b$, respectively. Let $\phi$ be the smaller angle between $\mu_a$ and $\mu_b$. Let $\phi_0 < \pi/10$ denote the maximal turning angle of any p-arc. See property (iii).

We distinguish among three cases:

*Case* (i). $\phi_0 \le \phi < \pi - 2\phi_0$ (see Figure 9(i)). Clearly, in this case $\gamma_a$ and $\gamma_b$ have at most one intersection point, which must be $v$ itself. Indeed, construct a line $\ell$ that passes through $v$ and forms angles $\phi$ and $-\phi/2$ with $\gamma_a$ and $\gamma_b$, respectively. Since neither $\gamma_a$ nor $\gamma_b$ can turn by more than $\phi$, it follows that, except at $v$, $\ell$ is disjoint from both $\gamma_a$ and $\gamma_b$. Hence, except at $v$, $\ell$ separates $\gamma_a$ from $\gamma_b$.

We follow $\gamma_a$ from $v$ in the direction in which it enters $b$. Since $\gamma_a$ has entered the cap of $b$ bounded by $\gamma_b$ and it does not intersect $\gamma_b$ again, it either ends within the cap or meets a triangle in $P_A \cup P_B$. In either case we can charge $v$ to this endpoint or intersection point. (Note that in the latter case, this intersection must be a vertex of $UP(A)$, whose number was bounded in Lemma 3.2.)

*Case* (ii). $\phi \ge \pi - 2\phi_0$ (see Figure 9(ii)). Without loss of generality, assume that the situation is as shown in Figure 9(ii). That is, $a$ lies above $\gamma_a$ near $v$ and $b$ lies below $\gamma_b$ near $v$, and as we trace $\gamma_a$ and $\gamma_b$ to the left, each of them enters into the other object. If we reach in any of these tracings a point on $\bigcup(P_A \cup P_B)$, then this is a vertex of either $UP(A)$ or $UP(B)$, to which we can charge $v$. So assume this is not the case. Hence, $\gamma_a$ and $\gamma_b$ must intersect again.

If one of the connected components of $\gamma_a \cap F$ intersects the same edge of $F$ twice, then it must contain an extreme point (lowermost, uppermost, rightmost, or leftmost) which is inside $F$, and hence $\gamma_a$ is favorable. We charge the $s$ or fewer intersection points of $\gamma_a$ and $\gamma_b$ inside $F$ to this extreme point. So again assume this is not the case. Assume that $\gamma_1, \dots, \gamma_l$ are all the nonfavorable p-arcs belonging to (not necessarily distinct) respective subobjects $a_1, \dots, a_l$ of $A$, that each defines a vertex $v_i$ of $U(\theta_A, \theta_B, i_A, i_B)$ that lies on $\gamma_b$, and that each $v_i$ is of the type discussed in case (ii) of Lemma 2.1. For each $i$, define $\Gamma(\gamma_i)$ as the portion of $\gamma_b \cap a_i$ incident to $v_i$.

Note that $\gamma_i$ cannot intersect $\gamma_j$ inside $F$ (for any $1 \le i < j \le l$) because each $\gamma_i$ is

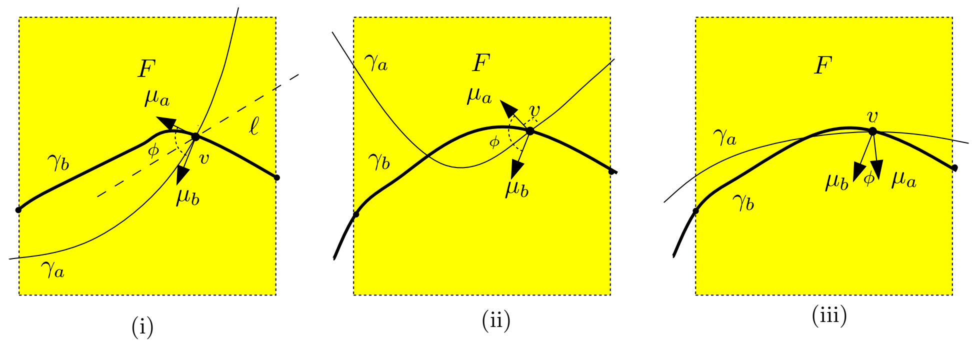

FIG. 9. *Illustration of the proof of Lemma* 2.1.

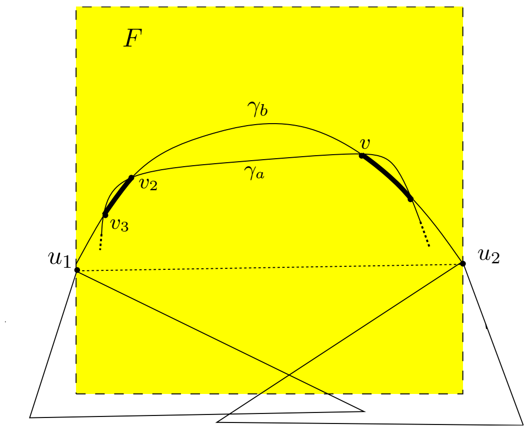

FIG. 10. *The third case of the proof of Lemma* 2.1.

a nonfavorable p-arc, and the p-arcs of $A$ (resp., $B$) intersect only at their endpoints. It is not hard to show that there can be at most 2 nonfavorable p-arcs $\gamma_i$, $\gamma_j$ of this type, such that $\Gamma(\gamma_i) \cap \Gamma(\gamma_j) = \emptyset$. Similarly there is no pair $\gamma_i, \gamma_i$ such that $\Gamma(\gamma_i) \cap \Gamma(\gamma_j)$ partially overlap (that is, $\Gamma(\gamma_i) \cap \Gamma(\gamma_j) \neq \emptyset$ but neither $\Gamma(\gamma_i) \subseteq \Gamma(\gamma_j)$ nor $\Gamma(\gamma_j) \subseteq \Gamma(\gamma_i)$). On the other hand, it is impossible that $\Gamma(\gamma_i) \subseteq \Gamma(\gamma_j)$, since in this case $\Gamma(\gamma_i) \subseteq a_j$ cannot be adjacent to a vertex of $U(\theta_A, \theta_B, i_A, i_B)$.

*Case* (iii). $\phi < \phi_0$ (see Figure 9(iii)). Observe that both $\gamma_a$ and $\gamma_b$ are $y$-monotone inside $F$. We follow $\gamma_a$ from $v$ in the direction inward $b$—say to the left (see Figure 10). If we reach a triangle of $P_A \cup P_B$, then this is a vertex $w$ of $UP(A)$ that we charge. Thus we assume that we reach another vertex $v_2$ on $\gamma_b \cap \gamma_a$, to the left of $v$. By property A1 we are guaranteed that we have not entered a subobject $a' \in A$ so far in the portion of $\gamma_a$ between $v$ and $v_2$. Hence we deduce that $v_2$ is also a vertex of $U(\theta_A, \theta_B, i_A, i_B)$. We continue following the portion of $\gamma_b$ to the left of $v_2$. As before if we do not reach a vertex of $UP(A)$, we reach a vertex $v_3$ which is also a vertex of $U(\theta_A, \theta_B, i_A, i_B)$. We can repeat this process at most $s$ times, discovering the vertices $v, v_2, v_3, \ldots$. This process must terminate when we reach a vertex $w$ of $UP(A)$ or of $UP(B)$ (which may be the left endpoint of $\gamma_b$). Note that by the manner in which we reach $w$, it is obvious that it is charged only to the at most $s$ vertices $v, v_2, v_3, \ldots$, which concludes the proof of Lemma 2.1. ∎

## 4. Concluding remarks.

1. The bound of Theorem 1.1 improves if the objects of $\mathcal{C}$ have roughly the same size. Assume that there are constants $d, \kappa$, such that $d \leq \mathrm{diam}(c) \leq \kappa d$ for each object of $c \in \mathcal{C}$. Then the bounds of Theorem 1.1 improve to $O(\lambda_{s+2}(n))$, with constant of proportionality depending on $\kappa$. This follows by modifying the preceding proof, and we will comment on only a few of the less trivial modifications that are required. In particular we do not need to use segment trees to determine the strips $I_\mu^{(j)}$, since these strips have the same width.
   For each orientation $\theta_A \in \Psi$, we divide the plane into infinite parallel strips of width $\mu d$ (for a sufficiently small constant $\mu$ that depends on $s, \alpha, \kappa$, and $\beta$), orthogonal to the $\theta_A$ direction, such that (as above) if $\Delta$ is a $\theta_A$-critical triangle for an object $c$ at a point $p \in \partial c$, then the other two vertices of $\Delta$ do not lie in the strip containing $p$. We define $A$ as the collection of subobjects incident to p-arcs of $\gamma_{\theta_A}(c)$ over all $c \in \mathcal{C}$. The definitions of $B$ and of all the other notation used in the proof are analogous. We also use the fact that all the oriented triangles in $P_A$ and $P_B$ are roughly of the same size, and thus the complexity of their union is only $O(n)$, as shown in [2].
2. The definition of an $(\alpha, \beta)$-covered object is not the first attempt to define fatness for nonconvex objects. In [20], van der Stappen gives the following definition to fatness. An object $c \subseteq \mathbb{R}^d$ with bounded-description complexity is $\delta$-fat (for $0 < \delta < 1$) if for each $d$-dimensional ball $B$, the center of which is inside $c$ but which does not contain $c$ completely, the volume of $B \cap c$ is at least $\delta$ times the volume of $B$. Two questions naturally arise: (i) What is the relation between the class of $(\alpha, \beta)$-covered objects and $\delta$-fat objects? (ii) Can one show a bound on the complexity of the union of $\delta$-fat objects? Recently van der Stappen [19] answered both questions: He showed that the definition of a $\delta$-fat object is more general than the definition of an $(\alpha, \beta)$-objects by showing that each $(\alpha, \beta)$-covered object is also a $\delta$-fat object for an appropriate parameter $\delta$ (that depends on $\alpha$ and $\beta$). He also answered the second question by presenting a construction showing that the boundary of the union of $n$ $\delta$-fat objects can have $\Omega(n^2)$ vertices, implying that $\delta$-fatness does not suffice to provide subquadratic union complexity in the plane.

**Acknowledgments.** We wish to thank Micha Sharir for helpful discussions and many useful ideas regarding the results of this paper. Thanks also to anonymous referees for numerous important remarks.

# STOCHASTIC MACHINE SCHEDULING WITH PRECEDENCE CONSTRAINTS[*]

MARTIN SKUTELLA[†] AND MARC UETZ[‡]

**Abstract.** We consider parallel, identical machine scheduling problems, where the jobs are subject to precedence constraints and release dates, and where the processing times of jobs are governed by independent probability distributions. Our objective is to minimize the expected value of the total weighted completion time. Building upon a linear programming relaxation by Möhring, Schulz, and Uetz [*J. ACM*, 46 (1999), pp. 924–942] and a delayed list scheduling algorithm by Chekuri et al. [*SIAM J. Comput.*, 31 (2001), pp. 146–166], we derive the first constant-factor approximation algorithms for this model.

**Key words.** approximation algorithms, stochastic scheduling, parallel machines, precedence constraints, release dates, list scheduling algorithms, LP-relaxation

## 1. Introduction.

This paper addresses stochastic parallel machine scheduling problems with the objective of minimizing the expected value of the total weighted completion time. Machine scheduling problems have attracted researchers for decades since such problems play an important role in various applications from the areas of operations research, management science, and computer science. The total weighted completion time objective is of particular importance in parallel processing, where many jobs are to be scheduled on a limited number of machines and a good average performance is desired. Prominent examples for such a scheduling situation are problems that arise, e.g., in compiler optimization [4] and in parallel computing [2]. The main characteristic of *stochastic* scheduling problems is the fact that the processing times of the jobs may be subject to random fluctuations. Hence, the effective processing times are not known with certainty in advance. This characteristic is of particular practical relevance in many applications.

**Problem definition.** Denote by $V = \{1, \dots, n\}$ a set of jobs which must be scheduled on $m$ parallel, identical machines. Each machine can handle only one job at a time, and the jobs can be scheduled on any of the machines. Once the processing of a job is started on one machine, it must be processed without preemption on this machine. Precedence constraints are given by an acyclic digraph $G = (V, A)$, where

any arc $(i, j) \in A$ restricts the start time of job $j$ to be not earlier than the completion time of job $i$. We consider problems with and without release dates $r_j$ for the jobs, with the intended meaning that job $j$ must not start earlier than $r_j$. In the classical (deterministic) setting, the objective is to minimize the total weighted completion time $\sum_{j\in V} w_j\, C_j$, where $w_j$ is a nonnegative weight and $C_j$ denotes the completion time of job $j$. In the stochastic model, it is assumed that the processing time $p_j$ of a job $j$ is not known in advance. It becomes known only upon completion of the job. However, the distribution of the corresponding random variable $P_j$ is given beforehand. Let $P = (P_1, \dots, P_n)$ denote the vector of random variables for the processing times, and denote by $p = (p_1, \dots, p_n)$ a particular realization of the processing times. By $\mathrm{E}[P_j]$ we denote the expected processing time of a job $j$. We assume throughout that the processing times of the jobs are stochastically independent. In the classical $\alpha\,|\,\beta\,|\,\gamma$ notation of Graham et al. [9], the problem of minimizing the expected total weighted completion time can be denoted by $\mathrm{P}|\,\mathit{prec}, r_j|\mathrm{E}\,[\sum w_j\, C_j]$. Here, P stands for the parallel machine environment, *prec* and $r_j$ the existence of precedence constraints and release dates, respectively, and $\mathrm{E}\,[\sum w_j\, C_j]$ the objective of minimizing the expected total weighted completion time.

**Dynamic view on stochastic scheduling.** The twist from deterministic to stochastic processing times changes the nature of the scheduling problem considerably. The solution of a stochastic scheduling problem is no longer a simple schedule, but a so-called *scheduling policy.* We adopt the notion of scheduling policies as defined by Möhring, Radermacher, and Weiss [14]. In the following, we briefly summarize what that means.

Apart from the data that specifies the input of the problem, the *state* of the system at any time $t \geqslant 0$ is determined by the time $t$ itself, as well as the (conditional) probability distributions of the jobs' processing times. At any time $t > 0$, the state thus depends on the observed *past* up to time $t$. This includes the start and completion times of the jobs already completed by $t$, together with the start times of the jobs in process at time $t$. The *action* of a scheduling policy at time $t$ is given by a set of jobs $B(t) \subseteq V$ that is started at $t$, together with a tentative next decision time $t_{\mathrm{tent}} > t$. The tentative decision time $t_{\mathrm{tent}}$ is the latest point in time when the next action of the policy takes place, subject to the condition that no other job is released or ends before $t_{\mathrm{tent}}$. Notice that $B(t)$ may be empty, and $t_{\mathrm{tent}} = \infty$ implies that the next action of the policy takes place when the next job is released or some job ends, whatever occurs first. Of course, the definition of $B(t)$ must respect potential release dates, precedence constraints, and the number of available machines. A policy is required to be *nonanticipatory*, meaning that the action of a policy at any time $t$ must depend only on the state of the system at time $t$ (together with the given input data, of course). The time instances at which a policy takes its actions are called *decision times.* Given an action of a policy at a decision time $t$, the next decision time is $t_{\mathrm{tent}}$, or the time of the next job completion, or the time when the next job is released, whatever occurs first. Depending on the action of the policy, the state at the next decision time is realized according to the (conditional) probability distributions of the jobs' processing times.

A given policy eventually yields a feasible $m$-machine schedule for each realization $p$ of the processing times. For a given policy, denoted by $\Pi$, let $S_j^{\Pi}(p)$ and $C_j^{\Pi}(p)$ denote the start and completion times, respectively, of job $j$ for a given realization $p$, and let $S_j^{\Pi}(P)$ and $C_j^{\Pi}(P)$ denote the associated random variables.

**Approximation.** It follows from simple examples that, in general, a scheduling policy cannot yield the optimal schedule for each possible realization of the processing times; see, e.g., [21]. Hence, our goal is to find a policy $\Pi$ which minimizes the objective, say $Z^{\Pi}(P)$, in expectation. But even under this mild notion of optimality, few special cases exist for which optimal scheduling policies are known to be efficiently computable. One example is the optimality of list scheduling according to SEPT (shortest expected processing time first) for the problem without precedence constraints or release dates, with unit weights, and with exponentially distributed processing times, $\mathrm{P}|\,p_j \sim \exp(\lambda_j)|\mathrm{E}\,[\sum C_j]$ [1, 24]. This result was extended by Kämpke [12] to the case where the weights $w_j$ are compliant with the expected processing times. In general, however, there exist examples which show that optimal policies can be rather complicated in the sense that they must indeed utilize the full information on the conditional distributions of the jobs' processing times; see, e.g., [22]. In this paper, we therefore concentrate on approximation algorithms. In stochastic scheduling, a scheduling policy $\Pi$ is said to be an *$\alpha$-approximation* if its expected performance $\mathrm{E}[Z^{\Pi}(P)]$ is within a factor of $\alpha$ of the expected performance $\mathrm{E}[Z^{\Pi^*}(P)]$ of an optimal (nonanticipatory) scheduling policy $\Pi^*$. The value $\alpha$ is called the *performance guarantee.*

**List scheduling policies.** There exist essentially three different classes of list scheduling policies, all of which have in common that there is a fixed priority list $L$ of jobs which determines the order in which the jobs are considered. We call a job $j$ *available* with respect to a partial schedule at time $t$ if all predecessors of $j$ are completed by $t$ and if $r_j \leqslant t$.

*Graham's list scheduling.* This is perhaps the most natural class of policies, often referred to as *the* list scheduling algorithm of Graham [7, 8]. Iterating over decision times, it greedily starts as many available jobs as possible, always in the order of the list $L$. It always holds that $t_{\text{tent}} = \infty$, and jobs are thus started only at release dates or upon completion of other jobs. If precedence constraints or release dates exist, it may happen that the order of start times of jobs differs from the order of the jobs in the priority list $L$; the jobs are scheduled "out of order" with respect to the priority list $L$. For the deterministic problem with *makespan* objective, $\mathrm{P}|prec|C_{\max}$, it is well known that Graham's list scheduling achieves a performance guarantee of $2 - 1/m$ for any priority list of the jobs [7]. This result straightforwardly extends to stochastic processing times and the expected makespan objective, $\mathrm{P}|\,prec|\mathrm{E}\,[C_{\max}]$ [3]. For the expected total weighted completion time, Graham's list scheduling in the WSEPT order[1] yields a constant-factor approximation for the problem without precedence constraints or release dates, $\mathrm{P}||\mathrm{E}\,[\sum w_j C_j]$ [15]. In the presence of release dates or precedence constraints, even in the deterministic setting, there are examples which show that the performance of Graham's algorithm can be arbitrarily bad. For an example with precedence constraints, see [18].

*Job-based list scheduling.* This is, in fact, the same list scheduling policy as before, only with the additional constraint that no job is started earlier than any of its predecessors in the priority list $L$. Hence, this policy preserves the order of the jobs in the priority list $L$ at the cost of deliberate idle times on the machines. For the deterministic problem $\mathrm{P}|r_j, prec|\sum w_j C_j$, the currently best known performance guarantee of 4 relies on (a slight variation of) job-based list scheduling, and the priority list is defined on the basis of an optimal solution to a linear programming relaxation [16].

[1]In the WSEPT order, jobs appear in nonincreasing order of the ratios $w_j/\mathrm{E}[P_j]$.

For the stochastic problem without precedence constraints, $\mathrm{P}|r_j|\mathrm{E}[\sum w_j C_j]$, job-based list scheduling yields a constant performance guarantee, too. This result is also based on a priority list that is defined on the basis of an optimal solution to an LP-relaxation [15].

*Delayed list scheduling.* As a matter of fact, approximation results for stochastic parallel machine scheduling were previously known only for problems without precedence constraints [23, 15]. In this paper, we close this gap, relying on yet another class of list scheduling policies which generalizes both Graham's and job-based list scheduling algorithms. It has been suggested in a paper by Chekuri et al. [5] to obtain a 5.828-approximation for the deterministic problem $\mathrm{P}|r_j, prec|\sum w_j C_j$. We consider the analogous stochastic variant of this algorithm. The basic idea is to extend Graham's list scheduling in such a way that a job may be scheduled out of order only if a certain amount of deliberate idle time has accumulated before. Thus, in this algorithm we use values $t_{\mathrm{tent}} < \infty$, and jobs may be started at times different from release dates or completion times of other jobs. The algorithm is parametric on a parameter $\beta \geqslant 0$ that controls the tradeoff between the amount of out-of-order processing of jobs and the desire to adhere to the order of the given priority list $L$. For $\beta = 0$ and $\beta = \infty$ we get Graham's and job-based list scheduling algorithms, respectively. The algorithm will be described in more detail in section 2.

**Contribution of this paper.** We derive the first constant performance guarantees for stochastic parallel machine scheduling with precedence constraints. The results are derived by borrowing heavily from two previous approaches. On the one hand, we use (an appropriate adaptation of) the delayed list scheduling algorithm of Chekuri et al. [5]. On the other hand, the priority list is derived from an optimal solution for (a generalized version of) the LP-relaxation by Möhring, Schulz, and Uetz [15]. It seems, however, that only this combination of the previous techniques is capable of yielding the desired approximation results.

Table 1 gives an overview of performance guarantees for stochastic parallel machine scheduling problems with the total weighted completion time objective. The last column indicates which of the results are proved in [15]; the asterisk [$*$] indicates that the results are derived in this paper. The term $\Delta$ denotes some common upper bound on the values $\mathrm{Var}[P_j]/(\mathrm{E}[P_j])^2$ for all jobs $j \in V$. In other words, $\sqrt{\Delta}$ is a common upper bound on the coefficient of variation $\mathrm{CV}[P_j] = \sqrt{\mathrm{Var}[P_j]}/\mathrm{E}[P_j]$ for all processing time distributions $P_j$, $j \in V$. Moreover, the number of machines is denoted by $m$, and $\beta$ is the nonnegative parameter used to control the delayed list scheduling algorithm. The third column shows the respective performance bounds for processing time distributions where the coefficient of variation is bounded by 1, which is the case for exponential, uniform, or Erlang distributions, to name a few.

**Relations to online optimization and other models.** Compared to the model described above, *online optimization* is another way of coping with the fact that the future is uncertain. We refer to Fiat and Woeginger [6] for details about online optimization. There is, however, a significant difference between the underlying paradigms of the above described analysis and the usual competitive analysis that prevails in online optimization. First, competitive analysis is based upon the a posteriori comparison, *"What was achieved under uncertainty about the future, and what could have been achieved if the future would not have been uncertain?"* This is expressed by the fact that the *adversary* is generally an oracle that knows the optimal solution. In contrast, stochastic scheduling addresses the a priori question, *"What is*

TABLE 1

| $\mathrm{P}\|in\text{-}forest\|\mathrm{E}\left[\sum w_j C_j\right]$ | $2 - \frac{1}{m} + \max\{1, \frac{m-1}{m}\Delta\}$ | $3 - \frac{1}{m}$ | [$*$] |
| $\mathrm{P}\|prec\|\mathrm{E}\left[\sum w_j C_j\right]$ | $(1+\beta)\big(1 + \frac{m-1}{m\,\beta} + \max\{1, \frac{m-1}{m}\Delta\}\big)$ | $3 + 2\sqrt{2} - \frac{1+\sqrt{2}}{m}$ | [$*$] |
| $\mathrm{P}\|r_j, prec\|\mathrm{E}\left[\sum w_j C_j\right]$ | $(1+\beta)\big(1 + \frac{1}{\beta} + \max\{1, \frac{m-1}{m}\Delta\}\big)$ | $3 + 2\sqrt{2}$ | [$*$] |

*the best that can be achieved under the given uncertainty about the future?"* Here, the underlying adversary is much weaker: the adversary must not anticipate future information, just like the policy itself. Second, in competitive analysis the adversary is allowed to determine, to a certain extent, the input distribution. This is not the case in the stochastic model considered here, since the input distributions are considered exogenous. It is interesting to note that two generalized online frameworks were suggested by Koutsoupias and Papadimitriou [13]. They restrict the adversary's power in two ways: its ability to choose an input distribution, and its ability to find an optimal solution. To some extent, the stochastic scheduling model incorporates both ideas, too. We refer to [13] for details and to [21] for a brief discussion. Another type of analysis for stochastic models has been proposed recently by Scharbrodt, Schickinger, and Steger [17]. They analyze the *expected competitive ratio* $\mathrm{E}[Z^{\Pi}(P)/Z^{\mathrm{OPT}}(P)]$, where $Z^{\mathrm{OPT}}(p)$ is the optimal solution value for a realization $p$. In this type of analysis the adversary is again an oracle that knows the optimal solution. We refer to [17] for a more detailed discussion of the benefits of their approach in comparison to the approach of this paper.

## 2. List scheduling with deliberate idle times.

We start with a few preliminaries that will be used later in the analysis. First, recall that we refer to a job $j$ *available* with respect to a partial schedule at time $t$ if all predecessors of $j$ are completed by $t$ and if $r_j \leqslant t$.

ASSUMPTION 2.1. *For any instance of* $\mathrm{P}|r_j, prec|\,\gamma$, *assume that* $r_j \geqslant r_i$ *whenever job* $i$ *is a predecessor of job* $j$ *in the precedence constraints.*

(Here, $\gamma$ is used to denote an arbitrary objective function.) Obviously, Assumption 2.1 can be made without loss of generality. Additionally, we use the following definitions.

DEFINITION 2.2 (critical predecessor). *Let some realization* $p$ *of the processing times and a feasible schedule be given. For any job* $j$, *a critical predecessor of* $j$ *is a predecessor* $i$ *of* $j$ (*with respect to the precedence constraints*) *with* $C_i > r_j$ *and* $C_i$ *maximal among all predecessors.*

DEFINITION 2.3 (critical chain). *Let some realization* $p$ *of the processing times and a feasible schedule be given. For a given job* $j$, *a critical chain for job* $j$ *and its length* $\ell_j(p)$ *is defined backwards recursively: If* $j$ *has no critical predecessor,* $j$ *is the only job in the critical chain, and* $\ell_j(p) = r_j + p_j$. *Otherwise,* $\ell_j(p) = p_j + \ell_k(p)$, *where job* $k$ *is a critical predecessor of job* $j$.

Definition 2.3 is illustrated in Figure 1. Notice that the critical chain as well

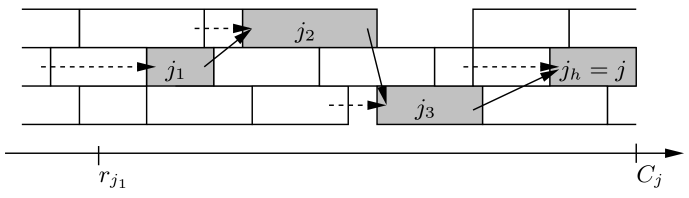

FIG. 1. *Example of a critical chain for job $j$. Its length is $\ell_j(p) = r_{j_1} + \sum_{i=1}^{h} p_{j_i}$ .*

as its length $\ell_j(p)$ depend on both the realization of the processing times $p$ and the underlying schedule. Moreover, since a critical predecessor is not necessarily unique, the critical chain and its length also depend on a tie-breaking rule for choosing critical predecessors. This is not relevant for our analysis, but in order to make the above definition unique, let us suppose that some arbitrary but fixed tie-breaking rule is used. Notice further that the first job $j_1$ of a critical chain is available at its release date $r_{j_1}$. This follows directly from the definition.

Like Graham's list scheduling, the algorithm we use iterates over decision times until all jobs have been scheduled. Assume a priority list $L$ is given. As with job-based list scheduling, the algorithm strives to schedule the jobs in the order of the list $L$ by leaving deliberate idle times. But if the accumulating deliberate idle time exceeds a certain threshold, the algorithm "panics" and schedules the first available job from the list. The algorithm is parametric on a parameter $\beta \geqslant 0$ that controls the tradeoff between the amount of out-of-order processing of jobs and the desire to adhere to the order of the given priority list $L$. At each stage of the algorithm, the sublist of $L$ containing all jobs that are not yet scheduled is referred to as the *residual list.* The following is a direct adaptation of the algorithm introduced by Chekuri et al. [5].

ALGORITHM CMNS (CHEKURI–MOTWANI–NATARAJAN–STEIN).[2] Whenever a machine is idle and the first job in the residual list is available, the job is scheduled. Otherwise, if the first job is not available, the first available job $j$ in the residual list (if any) is *deliberately delayed.* If $j$ was deliberately delayed for an accumulated time of $\beta\mathrm{E}[P_j]$, it is scheduled *out of order.*

We emphasize that *deliberate idle time* accumulates $m'$ times faster when a job is deliberately delayed while $m'$ machines are idle. For the purpose of analyzing the performance of Algorithm CMNS, any job $j$ gets *charged* the amount of deliberate idle time that accumulates during time intervals when $j$ is deliberately delayed. An alternative interpretation is the following: whenever a job $j$ is deliberately delayed, the tentative next decision time $t_{\text{tent}}$ is that point in time where the accumulated deliberate idle time charged to job $j$ would equal $\beta\mathrm{E}[P_j]$.

Analogous to [5], we introduce some additional notation. For a given job $j$, denote by $B_j$ and $A_j$ the sets of jobs that come before and after job $j$ in the priority list $L$, respectively; by convention, $B_j$ also includes job $j$. For the remaining definitions, we consider a fixed realization $p$ of the processing times and the resulting schedule constructed by Algorithm CMNS. Then, $r_j(p) \geqslant r_j$ denotes the earliest point in time when job $j$ becomes available; let $j_1, j_2, \ldots, j_h = j$ be the critical chain for job $j$ and

[2]The only difference between CMNS and the algorithm presented in [5] is the use of the threshold $\beta\mathrm{E}[P_j]$ instead of $\beta p_j$. CMNS coincides with the classical list scheduling algorithm of Graham [7] if we choose $\beta = 0$ and coincides with the job-based list scheduling algorithm if we choose $\beta = \infty$.

define $B_j(p) := B_j \setminus \{j_1, \dots, j_h\}$. That is, the set $B_j(p)$ contains all jobs that come before job $j$ in the priority list $L$, except for those which belong to the critical chain. Moreover, let $O_j(p) \subseteq A_j$ be the jobs in $A_j$ that are started out of order, that is, before $j$.

The following observation is the analogue to the results for the deterministic setting by Chekuri et al. [5, Fact 4.6, Lemma 4.7].

*Observation* 2.4. For any realization $p$ of the processing times and any job $j$,

(i) job $j$ is charged no more than $\beta\,\mathrm{E}[P_j]$ deliberate idle time;

(ii) the deliberate idle time in $[r_j(p), S_j(p)[$ is charged only to jobs in $B_j$;

(iii) there is no uncharged deliberate idle time.

*Proof.* Part (i) follows by construction of the algorithm and part (iii) by definition of deliberate idle time. Finally, for (ii), observe that no job from $A_j$ is the first available job from the residual list in the time interval $[r_j(p), S_j(p)[$, since job $j$ is available from $r_j(p)$ on, and $j$ has higher priority than any job in $A_j$. ∎

The following analysis of Algorithm CMNS closely resembles the analysis performed in [5] for the deterministic case. We first derive an upper bound on the completion time of any job for a fixed realization $p$.

LEMMA 2.5. *Consider the schedule constructed by Algorithm CMNS for any $\beta \geqslant 0$, any realization $p$ of the processing times, and any priority list $L$ which is a linear extension of the precedence constraints. Let $C_j(p)$ denote the resulting completion time of any job $j$, and let $\ell_j(p)$ denote the length of the critical chain for job $j$. Then*

$$C_j(p) \;\leqslant\; \frac{m-1}{m}\,\ell_j(p) + \frac{1}{m}\,r_j + \frac{1}{m}\left(\sum_{i\in B_j}\bigl(p_i + \beta\,\mathrm{E}[P_i]\bigr) \;+\; \sum_{i\in O_j(p)} p_i\right). \tag{2.1}$$

*Proof.* The basic idea resembles Graham's analysis for the makespan objective [7]. Consider the critical chain for job $j$ with total length $\ell_j(p)$, consisting of jobs $j_1, j_2, \dots, j_h = j$. Now partition the interval $[r_{j_1}, C_j(p)[$ into time intervals, where some job from the critical chain is in process, and the remaining time intervals. The latter are exactly $[r_i(p), S_i(p)[$, $i = j_1, \dots, j_h$. (Recall that $r_{j_1} = r_{j_1}(p)$ due to the definition of the critical chain.) By definition,

$$C_j(p) \;=\; \ell_j(p) + \sum_{i=j_1}^{j_h}\bigl(S_i(p) - r_i(p)\bigr). \tag{2.2}$$

To bound the total length of the intervals $[r_i(p), S_i(p)[$, $i = j_1, \dots, j_h$, observe that in each of these intervals there is no idle time except (possibly) deliberate idle time, since job $i$ is available in $[r_i(p), S_i(p)[$. Hence, the total processing in these intervals can be partitioned into three categories as follows:

– processing of jobs from $B_j$ which do not belong to the critical chain, i.e., jobs in $B_j(p)$;

– deliberate idle time;

– processing of jobs from $A_j$ which are scheduled out of order, i.e., jobs in $O_j(p)$.

Due to Observation 2.4(ii), all deliberate idle time in the interval $[r_i(p), S_i(p)[$ is charged only to jobs in $B_i$, $i = j_1, \dots, j_h$. Since the priority list $L$ is a linear extension of the precedence constraints, we have $B_{j_1} \subset B_{j_2} \subset \cdots \subset B_{j_h} = B_j$. Hence, all deliberate idle time in the intervals $[r_i(p), S_i(p)[$, $i = j_1, \dots, j_h$, is charged only to jobs in $B_j$. Since there is no uncharged deliberate idle time (Observation 2.4(iii)), and since each job $i \in B_j$ gets charged no more than $\beta\,\mathrm{E}[P_i]$ idle time (Observation 2.4(i)), the total amount of deliberate idle time in the intervals $[r_i(p), S_i(p)[$, $i = j_1, \dots, j_h$, is bounded from above by $\beta \sum_{i\in B_j} \mathrm{E}[P_i]$. This yields

$$\sum_{i=j_1}^{j_h} \big(S_i(p) - r_i(p)\big) \leqslant \frac{1}{m}\left(\sum_{i\in B_j(p)} p_i + \sum_{i\in B_j} \beta\,\mathrm{E}[P_i] + \sum_{i\in O_j(p)} p_i\right). \tag{2.3}$$

Finally, due to Assumption 2.1 we have $r_{j_1} \leqslant r_j$; thus

$$\sum_{i\in B_j(p)} p_i \leqslant \sum_{i\in B_j} p_i - \big(\ell_j(p) - r_j\big). \tag{2.4}$$

Now put (2.4) into (2.3), and then (2.3) into (2.2), and the claim follows. □

Before we take expectations in (2.1), we concentrate on the term $\sum_{i\in O_j(p)} p_i$. The following lemma shows that the expected total processing time of the jobs in $O_j(p)$—the jobs that are scheduled out of order with respect to $j$ (and $p$)—is independent of their actual processing times.

LEMMA 2.6. *We have*

$$\mathrm{E}\left[\sum_{i\in O_j(P)} P_i\right] = \mathrm{E}\left[\sum_{i\in O_j(P)} \mathrm{E}[P_i]\right].$$

*Proof.* We can write $\sum_{i\in O_j(P)} P_i$ equivalently as $\sum_{i\in A_j} \delta_i(P)\,P_i$, where $\delta_i(P)$ is a binary random variable which is 1 if and only if $i \in O_j(p)$. Linearity of expectation yields

$$\mathrm{E}\left[\sum_{i\in O_j(P)} P_i\right] = \mathrm{E}\left[\sum_{i\in A_j} \delta_i(P)\,P_i\right] = \sum_{i\in A_j} \mathrm{E}[\delta_i(P)\,P_i].$$

Notice that $\delta_i(P)$ is dependent on $\beta\mathrm{E}[P_i]$ but stochastically independent of $P_i$, as the decision to process job $i$ out of order is made before it is actually processed. (Here we require that the processing times be stochastically independent and that policies be nonanticipatory.) Hence,

$$\sum_{i\in A_j} \mathrm{E}[\delta_i(P)P_i] = \sum_{i\in A_j} \mathrm{E}[\delta_i(P)]\mathrm{E}[P_i] = \sum_{i\in A_j} \mathrm{E}\big[\delta_i(P)\mathrm{E}[P_i]\big] = \mathrm{E}\left[\sum_{i\in O_j(P)} \mathrm{E}[P_i]\right].$$

This concludes the proof. □

The following lemma bounds the expected amount of processing time of jobs from $A_j$ which are scheduled out of order in terms of the expected length of the critical chain for job $j$; compare to [5, Lemma 4.8].

LEMMA 2.7. *We have*

$$\frac{1}{m}\,\mathrm{E}\left[\sum_{i\in O_j(P)} \mathrm{E}[P_i]\right] \leqslant \frac{1}{\beta}\,\mathrm{E}[\ell_j(P)].$$

*Proof.* Consider a fixed realization $p$ of the processing times. If some job $i \in A_j$ is scheduled out of order, $i$ gets charged exactly $\beta\,\mathrm{E}[P_i]$ deliberate idle time. Hence, the total amount of deliberate idle time in $[0, S_j(p)[$ that is charged to jobs in $O_j(p)$ is $\beta \sum_{i \in O_j(p)} \mathrm{E}[P_i]$. Now consider the critical chain $j_1, \ldots, j_h = j$ for job $j$ with total length $\ell_j(p)$. From the proof of Lemma 2.5, we know that all deliberate idle time in the intervals $[r_i(p), S_i(p)[$, $i = j_1, \ldots, j_h$, is charged only to jobs in $B_j$. In other words, all deliberate idle time in $[0, S_j(p)[$ that is charged to jobs in $A_j$ lies in the complementary intervals $[0, r_{j_1}[$ and $[S_i(p), C_i(p)[$, $i = j_1, \ldots, j_{h-1}$. (Recall that $r_{j_1} = r_{j_1}(p)$ due to the definition of a critical chain.) The total length of these intervals is exactly $\ell_j(p) - p_j$. Hence, the total amount of deliberate idle time in $[0, S_j(p)[$ that is charged to jobs in $A_j$ is at most $m\,(\ell_j(p) - p_j) \leqslant m\,\ell_j(p)$. Hence, we obtain $\beta \sum_{i \in O_j(p)} \mathrm{E}[P_i] \leqslant m\,\ell_j(p)$ for any realization $p$ of the processing times. Taking expectations yields the claimed result. ☐

Finally, we obtain an upper bound on the expected completion time of any job under Algorithm CMNS; compare to [5, Theorem 4.9].

THEOREM 2.8. *For any instance of a stochastic scheduling problem* $\mathrm{P}|r_j, prec|\,\gamma$ *and any priority list L, which is a linear extension of the precedence constraints, the expected completion time of any job j under Algorithm CMNS* (*with parameter* $\beta \geqslant 0$) *fulfills*

$$\mathrm{E}[C_j(P)] \;\leqslant\; \left(\frac{m-1}{m} + \frac{1}{\beta}\right) \mathrm{E}[\ell_j(P)] \;+\; \frac{1+\beta}{m} \sum_{i \in B_j} \mathrm{E}[P_i] \;+\; \frac{1}{m}\, r_j\,. \tag{2.5}$$

(Again, $\gamma$ is used to denote an arbitrary objective function.)

*Proof.* Taking expectations in (2.1) together with Lemma 2.6 yields

$$\mathrm{E}[C_j(P)] \leqslant \frac{m-1}{m}\mathrm{E}[\ell_j(P)] + \frac{1}{m}\left( r_j \;+\; (1+\beta) \sum_{i \in B_j} \mathrm{E}[P_i] \;+\; \mathrm{E}\left[ \sum_{i \in O_j(P)} \mathrm{E}[P_i] \right] \right).$$

Plugging in the inequality from Lemma 2.7 gives the desired result. ☐

## 3. LP-relaxation.

To obtain a priority list $L$ as input for Algorithm CMNS, and to obtain a lower bound on the optimum, Chekuri et al. [5] use a single machine relaxation. This approach does not help in the stochastic setting, since the single machine problem does not necessarily provide a lower bound for the parallel machine problem; see [15, Ex. 4.1] for an example. Instead, we use LP-relaxations, which extend those used by Möhring, Schulz, and Uetz [15], adding inequalities which represent the precedence constraints. First, define $f : 2^V \to \mathbb{R}$ by

$$f(W) \;:=\; \frac{1}{2m}\left( \left( \sum_{j \in W} \mathrm{E}[P_j] \right)^2 + \sum_{j \in W} \mathrm{E}[P_j]^2 \right) - \frac{(m-1)(\Delta - 1)}{2m} \left( \sum_{j \in W} \mathrm{E}[P_j]^2 \right) \tag{3.1}$$

for $W \subseteq V$. Here, $\Delta \geqslant 0$ is a common upper bound on $\mathrm{Var}[P_j]/\mathrm{E}[P_j]^2$ for all jobs $j \in V$, where $\mathrm{Var}[P_j] = \mathrm{E}[P_j^2] - \mathrm{E}[P_j]^2$ is the variance of $P_j$. In other words, the *coefficient of variation*

$$\mathrm{CV}[P_j] \;:=\; \frac{\sqrt{\mathrm{Var}[P_j]}}{\mathrm{E}[P_j]}$$

of the distributions $P_j$ is bounded by $\sqrt{\Delta}$ for all $j \in V$. The following *load inequalities* are crucial for the derivation of our results.

THEOREM 3.1 (see [15, Cor. 3.1]). *If* $\mathrm{CV}[P_j] \leqslant \sqrt{\Delta}$ *for all* $P_j$ *and some* $\Delta \geqslant 0$, *the load inequalities*

$$\sum_{j\in W} \mathrm{E}[P_j]\, \mathrm{E}[C_j^{\Pi}(P)] \;\geqslant\; f(W) \tag{3.2}$$

*are valid for all* $W \subseteq V$ *and any nonanticipatory scheduling policy* $\Pi$.

In fact, as mentioned in [15], assuming that an upper bound exists on the coefficients of variation of the processing time distributions $P_j$ can be a reasonable assumption for many scheduling problems. For instance, assume that job processing times follow so-called *NBUE distributions*.

DEFINITION 3.2 (NBUE). *A nonnegative random variable* $X$ *is "new better than used in expectation" (NBUE) if* $\mathrm{E}\,[X - t | X > t] \leqslant \mathrm{E}\,[X]$ *for all* $t \geqslant 0$.

Here, $\mathrm{E}\,[X - t | X > t]$ is the conditional expectation of $X - t$ under the assumption that $X > t$. Roughly speaking, when processing times are NBUE, on average it is not disadvantageous to process a job. Examples for NBUE distributions are, among others, exponential, uniform, and Erlang distributions. A result of Hall and Wellner [11] states that the coefficient of variation $\mathrm{CV}[X]$ of any NBUE distribution $X$ is bounded by 1. Hence, by choosing $\Delta = 1$ the second term of the right-hand side of (3.2) can be neglected for NBUE distributions, which leads to simplified performance guarantees in section 4.

Observe that under any scheduling policy $\Pi$ the trivial inequalities

$$\mathrm{E}[C_j^{\Pi}(P)] \;\geqslant\; \mathrm{E}[C_i^{\Pi}(P)] + \mathrm{E}[P_j], \qquad (i,j) \in A,$$

and

$$\mathrm{E}[C_j^{\Pi}(P)] \;\geqslant\; \mathrm{E}[P_j], \qquad j \in V,$$

are valid, since they even hold pointwise for any realization of the processing times. Due to Theorem 3.1, the following is thus an LP-relaxation for the problem $\mathrm{P}|r_j, prec|\mathrm{E}\,[\sum w_j\, C_j]$:

$$\begin{aligned}
\text{Minimize} \quad & \sum_{j\in V} w_j\, C_j^{\mathrm{LP}} & \\
\text{subject to} \quad & \sum_{j\in W} \mathrm{E}[P_j]\, C_j^{\mathrm{LP}} \geqslant f(W), & W \subseteq V,\\
& C_j^{\mathrm{LP}} \geqslant C_i^{\mathrm{LP}} + \mathrm{E}[P_j], & (i,j) \in A,\\
& C_j^{\mathrm{LP}} \geqslant \mathrm{E}[P_j], & j \in V,
\end{aligned}$$

where $f : 2^V \to \mathbb{R}$ is the set function defined in (3.1). It is known that the load inequalities $\sum_{j\in W} \mathrm{E}[P_j]\, C_j^{\mathrm{LP}} \geqslant f(W)$, $W \subseteq V$, can be separated in time $O(n \log n)$ [15, 21]. Hence, due to the fact that the remaining number of inequalities is polynomial in terms of $n$, this LP-relaxation can be solved in time polynomial in $n$ by the equivalence of separation and optimization [10]. The following technical lemma of Möhring, Schulz, and Uetz [15] is required later in the analysis.

LEMMA 3.3 (see [15, Lemma 4.2]). *Let* $C^{LP} \in \mathbb{R}^n$ *be any point that satisfies the first and the last set of inequalities from the LP-relaxation. Assuming* $C_1^{LP} \leqslant C_2^{LP} \leqslant \cdots \leqslant C_n^{LP}$, *we then have for all* $j \in V$

$$\frac{1}{m}\sum_{k=1}^{j} \mathrm{E}[P_k] \;\leqslant\; \left(1 + \max\left\{1, \frac{m-1}{m}\Delta\right\}\right) C_j^{LP}.$$

## 4. Results.

We are now ready to prove approximation results for stochastic machine scheduling problems with precedence constraints.

**General precedence constraints.** We consider the general problem with precedence constraints and release dates, $\mathrm{P}|r_j, prec|\mathrm{E}\left[\sum w_j\, C_j\right]$. From an optimal solution for the LP-relaxation, we define a priority list $L$ according to nondecreasing "LP completion times" $C_j^{\mathrm{LP}}$. It is perhaps interesting to note that inequalities $C_j^{\mathrm{LP}} \geqslant C_i^{\mathrm{LP}} + \mathrm{E}[P_j]$, $(i,j) \in A$, are required only to ensure that the order according to nondecreasing LP completion times $C_j^{\mathrm{LP}}$ is a linear extension of the precedence constraints. They are not required elsewhere in the analysis. Moreover, instead of the weaker inequalities $C_j^{\mathrm{LP}} \geqslant \mathrm{E}[P_j]$ we could use $C_j^{\mathrm{LP}} \geqslant r_j + E[P_j]$ as well, but this does not yield an improvement of our results.

Theorem 4.1. *Consider an instance of the stochastic machine scheduling problem* $\mathrm{P}|r_j, prec|\mathrm{E}\left[\sum w_j\, C_j\right]$ *with* $\mathrm{CV}[P_j] \leqslant \sqrt{\Delta}$ *for all processing times* $P_j$ *and some* $\Delta \geqslant 0$. *Let* $L$ *be a priority list according to an optimal solution* $C^{LP}$ *of the LP-relaxation. Then Algorithm CMNS* (*with parameter* $\beta > 0$) *is an* $\alpha$*-approximation with*

$$\alpha \;=\; (1+\beta)\left(1 + \frac{1}{\beta} + \max\left\{1, \frac{m-1}{m}\Delta\right\}\right).$$

*Proof.* Since $L$ is a linear extension of the precedence constraints, Theorem 2.8 yields

$$\mathrm{E}[C_j(P)] \;\leqslant\; \left(\frac{m-1}{m} + \frac{1}{\beta}\right)\mathrm{E}[\ell_j(P)] \;+\; \frac{1+\beta}{m}\sum_{i\in B_j}\mathrm{E}[P_i] \;+\; \frac{1}{m}\, r_j$$

for any job $j \in V$. (Recall that $B_j$ denotes the jobs that come before job $j$ in the priority list $L$.) Lemma 3.3 yields

$$\frac{1}{m}\sum_{i\in B_j}\mathrm{E}[P_i] \;\leqslant\; \left(1 \;+\; \max\left\{1, \frac{m-1}{m}\Delta\right\}\right) C_j^{\mathrm{LP}}$$

for all $j \in V$. Hence,

$$\sum_{j\in V} w_j\, \mathrm{E}[C_j(P)] \leqslant \left(\frac{m-1}{m} + \frac{1}{\beta}\right)\sum_{j\in V} w_j\, \mathrm{E}[\ell_j(P)] + (1+\beta)\left(1 \;+\; \max\left\{1, \frac{m-1}{m}\Delta\right\}\right)\sum_{j\in V} w_j\, C_j^{\mathrm{LP}} + \frac{1}{m}\sum_{j\in V} w_j\, r_j\,.$$

Now, for any job $j$ and any realization $p$ of the processing times, the length $\ell_j(p)$ of a critical chain for job $j$ is a lower bound for job $j$'s completion time, $\ell_j(p) \leqslant C_j(p)$. This is true by definition of a critical chain. Hence, the value $\mathrm{E}[\ell_j(P)]$ is a lower bound on the expected completion time $\mathrm{E}[C_j(P)]$ of any job $j$ for any scheduling policy. (Notice that the critical chain may be different for different realizations of the processing times, and thus the fact that $\mathrm{E}[\ell_j(P)] \leqslant \mathrm{E}[C_j(P)]$ cannot be derived from the precedence constraints in the LP-relaxation.) Thus, $\sum_{j\in V} w_j\, \mathrm{E}[\ell_j(P)]$ is a lower bound on the expected performance of an optimal scheduling policy. Moreover, both terms $\sum_{j\in V} w_j\, C_j^{\mathrm{LP}}$ and $\sum_{j\in V} w_j\, r_j$ are lower bounds on the expected performance of an optimal scheduling policy as well. This gives a performance bound of

$$\left(\frac{m-1}{m} + \frac{1}{\beta}\right) + (1+\beta)\left(1 \;+\; \max\left\{1, \frac{m-1}{m}\Delta\right\}\right) + \frac{1}{m}.$$

Rearranging the terms yields the desired result. ∎

Notice that Theorem 4.1 implies a performance bound of $3 + 2\sqrt{2} \approx 5.828$ if $\beta = 1/\sqrt{2}$ and if the jobs' processing times are distributed according to NBUE distributions (see Definition 3.2). This matches the performance guarantee achieved in [5] for the corresponding deterministic scheduling problem $\mathrm{P}|r_j, prec|\sum w_j\, C_j$. The performance bound in Theorem 4.1 can be slightly improved if release dates are absent.

THEOREM 4.2. *Consider an instance of the stochastic machine scheduling problem* $\mathrm{P}|prec|\mathrm{E}\left[\sum w_j\, C_j\right]$ *with* $\mathrm{CV}[P_j] \leqslant \sqrt{\Delta}$ *for all processing times* $P_j$ *and some* $\Delta \geqslant 0$. *Let* $L$ *be a priority list according to an optimal solution* $C^{LP}$ *of the LP-relaxation. Then Algorithm CMNS* (*with parameter* $\beta > 0$) *is an* $\alpha$*-approximation with*

$$\alpha \;=\; (1+\beta)\left(1 + \frac{m-1}{m\,\beta} + \max\left\{1, \frac{m-1}{m}\Delta\right\}\right).$$

The tighter bound follows from two modifications in the proof of Theorem 4.1. On the one hand, in the proof of Lemma 2.7, one can show that

$$\frac{1}{m}\,\mathrm{E}\left[\sum_{i \in O_j(P)} \mathrm{E}[P_i]\right] \;\leqslant\; \frac{m-1}{m\,\beta}\,\mathrm{E}[\ell_j(P)].$$

The reason is that there are only $m - 1$ machines available for the deliberate idle time that is charged to jobs which are scheduled out of order: Simultaneous to the deliberate idle time, at least one job from the critical chain $j_1, j_2, \ldots, j_h$ is in process. (This argument does not hold if release dates are present, since deliberate idle time could possibly accumulate before $r_{j_1}$.) On the other hand, it is immediate that the last term $(1/m)\,r_j$ on the right-hand side of (2.5) disappears. With these modifications, the claim follows exactly as in Theorem 4.1.

**In-forest precedence constraints.** Let us now turn to the special case of the problem denoted by $\mathrm{P}|in\text{-}forest|\mathrm{E}\left[\sum w_j\, C_j\right]$. In-forest precedence constraints are characterized by the fact that each job has at most one successor. Moreover, we assume that there are no release dates. For this problem, the results of the preceding section can be further improved.

We start with the following observation which is also contained in [5, Lemma 4.16]; we nevertheless give a short proof for the sake of completeness.

LEMMA 4.3. *Consider the schedule constructed by Graham's list scheduling for an arbitrary priority list L, which is a linear extension of the* (*in-forest*) *precedence constraints, and any realization p of the processing times. Then, in the interval* $[r_j(p), S_j(p)[$ *there is no processing of jobs in* $A_j$.

*Proof.* Suppose the claim is false and, among all jobs which violate it, let job $j$ be one that is scheduled earliest. Obviously, $S_j(p) > r_j(p)$; otherwise the claim is trivially true. In the interval $[r_j(p), S_j(p)[$ no job from $A_j$ is started, since $j$ is available from time $r_j(p)$ on. Hence, there must be some job $k \in A_j$ that has been started before $r_j(p)$ and that is still in process at $r_j(p)$. Thus $r_j(p) > 0$. Denote by $h$ the number of jobs that are started at time $r_j(p)$. All of these jobs $i$ have higher priority than $j$, and the fact that $j$ is the first job that violates the claim yields $r_i(p) = r_j(p)$. (At this point it is crucial that the priority list extends the precedence constraints.) In other words, for each of these jobs a critical predecessor ends at time $r_j(p)$ and, due to the fact that the precedence constraints form an in-forest, all of these predecessors are different. Hence, including $j$'s critical predecessor, $h+1$ different jobs end at time

$r_j(p)$, but only $h$ are started. This is a contradiction since job $j$ is available at time $r_j(p)$. □

LEMMA 4.4. *For any instance of the stochastic scheduling problem* $\mathrm{P}|$*in-forest*$|\,\gamma$ *and any priority list $L$, which is a linear extension of the precedence constraints, the expected completion time of any job $j$ under Graham's list scheduling fulfills*

$$\mathrm{E}[C_j(P)] \leqslant \frac{m-1}{m}\mathrm{E}[\ell_j(P)] + \frac{1}{m}\sum_{i\in B_j}\mathrm{E}[P_i]. \tag{4.1}$$

(Again, $\gamma$ is used to denote an arbitrary objective function.)

*Proof.* Consider any realization $p$ of the processing times. Given any job $j$, consider a critical chain for $j$, consisting of jobs $j_1, j_2, \dots, j_h = j$ and with total length $\ell_j(p)$. The time interval $[0, C_j(p)]$ can be partitioned into time intervals, where a job from a critical chain for $j$ is in process, and the remaining time intervals. Due to Lemma 4.3, in each time interval $[r_i(p), S_i(p)[$ there is no job from $A_i$ in process for all $i = j_1, \dots, j_h$. Moreover, there is no idle time on any of the machines in these time intervals (we consider Graham's list scheduling, and there are no release dates). Since $A_{j_1} \supset A_{j_2} \supset \cdots \supset A_{j_h} = A_j$, it follows that the only jobs processing in these time intervals are the jobs in $B_j$, or more precisely, in $B_j(p)$. In other words, the total processing time of jobs in these time intervals is at most $\sum_{i\in B_j} p_i - \ell_j(p)$. Hence,

$$C_j(p) \leqslant \frac{m-1}{m}\ell_j(p) + \frac{1}{m}\sum_{i\in B_j} p_i$$

for any realization $p$. Taking expectations, we see that the claim follows. □

THEOREM 4.5. *Consider an instance of* $\mathrm{P}|$*in-forest*$|\mathrm{E}[\sum w_j C_j]$ *with* $\mathrm{CV}[P_j] \leqslant \sqrt{\Delta}$ *for all processing times $P_j$ and some $\Delta \geqslant 0$. Let $L$ be a priority list according to an optimal solution $C^{LP}$ of the LP-relaxation. Then Graham's list scheduling is an $\alpha$-approximation with*

$$\alpha = 2 - \frac{1}{m} + \max\left\{1, \frac{m-1}{m}\Delta\right\}.$$

*Proof.* Graham's list scheduling coincides with Algorithm CMNS for $\beta = 0$. The proof is therefore exactly the same as that of Theorem 4.1, except that Lemma 4.4 is used instead of Theorem 2.8. □

For NBUE distributions (see Definition 3.2), Theorem 4.5 yields a performance guarantee of $3 - 1/m$.

**Single machine problems.** Theorem 4.2 implies a 2-approximation for the special case of a single machine: In this case the term $(m-1)/(m\,\beta)$ disappears, and we can choose $\beta = 0$ to obtain performance guarantee 2. (For $\beta = 0$, the algorithm corresponds to Graham's list scheduling.) This holds for arbitrarily distributed, independent processing times. In fact, this matches the best bound currently known in the deterministic setting; see Open Problem 9 in the collection of Schuurman and Woeginger [19].

## 5. Further remarks.

A scheduling policy defines a mapping of processing times to start times of jobs. This mapping has to be universally measurable in order to grant existence of the expected objective function value [14]. Without going into further detail we just mention that the scheduling policies discussed in this paper fulfill this requirement; refer to [21, Cor. 3.6.15] for further details.

We point out that, apart from the expected processing times of the jobs, a uniform upper bound on their coefficients of variation is the sole stochastic information required as input for the presented scheduling policy. Nevertheless, in our analysis we compare its performance to a lower bound on the performance of *any* nonanticipatory scheduling policy. This refers to the broadest possible sense of scheduling policies as defined by Möhring, Radermacher, and Weiss [14]. In particular, an optimal scheduling policy is therefore allowed to take advantage of the *complete* knowledge of the conditional distributions of the processing times, at any time.

Finally, we mention that our analysis indeed requires policies to be nonanticipatory, because the LP lower bound does not hold otherwise. This can be seen from the observation that an anticipatory "scheduling policy" could, for instance, compute an optimal schedule for any realization of the processing times. Theorem 3.1, however, is no longer valid in this case; see [21]. In other words, our analysis is based upon an adversary that is just as powerful as the scheduling policy itself. This constitutes a major difference compared to the rather "unfair" competitive analysis known from online optimization.

**Acknowledgment.** We thank the anonymous referee for many valuable comments and suggestions for improvements. In particular, the compact formulation of the algorithm in section 2 was kindly proposed by the referee.

# IMPROVED COMBINATORIAL ALGORITHMS FOR FACILITY LOCATION PROBLEMS[*]

MOSES CHARIKAR[†] AND SUDIPTO GUHA[‡]

**Abstract.** We present improved combinatorial approximation algorithms for the uncapacitated facility location problem. Two central ideas in most of our results are *cost scaling* and *greedy improvement*. We present a simple greedy local search algorithm which achieves an approximation ratio of $2.414+\epsilon$ in $\tilde{O}(n^2/\epsilon)$ time. This also yields a bicriteria approximation tradeoff of $(1+\gamma, 1+2/\gamma)$ for facility cost versus service cost which is better than previously known tradeoffs and close to the best possible. Combining greedy improvement and cost scaling with a recent primal-dual algorithm for facility location due to Jain and Vazirani, we get an approximation ratio of 1.853 in $\tilde{O}(n^3)$ time. This is very close to the approximation guarantee of the best known algorithm which is linear programming (LP)-based. Further, combined with the best known LP-based algorithm for facility location, we get a very slight improvement in the approximation factor for facility location, achieving 1.728. We also consider a variant of the capacitated facility location problem and present improved approximation algorithms for this.

## 1. Introduction.

In this paper, we present improved combinatorial algorithms for some facility location problems. Informally, in the (uncapacitated) facility location problem we are asked to select a set of facilities in a network to service a given set of customers, minimizing the sum of facility costs as well as the distance of the customers to the selected facilities. (The precise problem definition appears in section 1.2). This classical problem, first formulated in the early 1960s, has been studied extensively in the operations research and computer science communities and has recently received a lot of attention (see [13, 33, 16, 9, 10, 11, 23]).

The facility location problem is NP-hard, and recent work has focused on obtaining approximation algorithms for the problem. The version where the assignment costs do not form a metric can be shown to be as hard to approximate as the set-cover problem. Shmoys, Tardos, and Aardal [33] gave the first constant factor approximation algorithm for metric facility location, where the assignment costs are based on a metric distance function.[1] This was subsequently improved by Guha and Khuller [16], Chudak [9], and Chudak and Shmoys [10], who achieved the currently best known approximation ratio of $1 + 2/e \approx 1.736$. All of these algorithms are based on solving

[1]Henceforth in this paper we will drop the term “metric” for brevity; all results referred to here assume a metric distance function.

linear programming (LP) relaxations of the facility location problem and rounding the solution obtained. Korupolu, Plaxton, and Rajaraman [23] analyzed a well-known local search heuristic and showed that it achieves an approximation guarantee of $(5+\epsilon)$. However, the algorithm has a fairly high running time of $O(n^4 \log n/\epsilon)$.

The facility location problem has also received a lot of attention due to its connection with the $k$-median problem. Lin and Vitter [25] showed that their filtering technique [26] can be used to round a fractional solution to the LP relaxation of the (metric) $k$-median problem, obtaining an integral solution of cost $2(1+\frac{1}{\epsilon})$ times the fractional solution while using $(1+\epsilon)k$ medians (facilities). Their algorithm is based on a technique called *filtering*, which was also used in [33], and has since found numerous other applications.

Jain and Vazirani [19] gave primal-dual algorithms for the facility location and $k$-median problems, achieving approximation ratios of 3 and 6 for the two problems. The running time of their algorithm for facility location is $O(n^2 \log n)$. The running time of the result can be made linear with a loss in the approximation factor using results in [18] if the distance function is given as an oracle. For results regarding the $k$-median problem, see [21, 25, 35, 38, 37, 4, 5, 6, 1, 8, 7, 30, 2]. See section 7 for work subsequent to this paper.

**1.1. Our results.** We present improved combinatorial algorithms for the facility location problem. The algorithms combine numerous techniques based on two central ideas. The first idea is that of *cost scaling*, i.e., to scale the costs of facilities relative to the assignment costs. The scaling technique exploits asymmetric approximation guarantees for the facility cost and the service cost. The idea is to apply the algorithm to the *scaled* instance and then scale back to get a solution for the original instance. On several occasions, this technique alone improves the approximation ratio significantly. The second idea used is *greedy local improvement.* If either the service cost or the facility cost is very high, greedy local improvement decreases the total cost by balancing the two. We show that greedy local improvement by itself yields a very good approximation for facility location in $\tilde{O}(n^2)$ time.

We first present a simple local search algorithm for facility location. This differs from (and is more general than) the heuristic proposed by Kuehn and Hamburger [24] and analyzed by Korupolu, Plaxton, and Rajaraman [23]. Despite the seemingly more complex local search step, each step can still be performed in $O(n)$ time. We are not aware of any prior work involving the proposed local search algorithm. We show that the (randomized) local search algorithm together with scaling yields an approximation ratio of $2.414+\epsilon$ in expected time $O(n^2(\log n + \frac{1}{\epsilon}))$ (with a multiplicative $\log n$ factor in the running time for a high probability result). This improves significantly on the local search algorithms considered by Korupolu, Plaxton, and Rajaraman, both in terms of running time and approximation guarantee. It also improves on the approximation guarantee of Jain and Vazirani, while still running in $\tilde{O}(n^2)$ time. We can also use the local search algorithm with scaling to obtain a bicriteria approximation for the facility cost and the service cost. We get a $(1+\gamma, 1+2/\gamma)$ tradeoff for facility cost versus service cost (within factors of $(1+\epsilon)$ for arbitrarily small $\epsilon$). Moreover, this holds even when we compare it with the cost of an arbitrary feasible solution to the facility location LP. Thus this yields a better tradeoff than that obtained by the *filtering* technique of Lin and Vitter [25] and the tradeoffs in [33, 23]. This gives bicriteria approximations for budgeted versions of facility location where the objective is to minimize either the facility cost or service cost subject to a budget constraint on the other. Further, our tradeoff is close to the best possible. We show that it is not possible to obtain a tradeoff better than $(1+\gamma, 1+1/\gamma)$.

Using both the local search algorithm and the primal-dual algorithm of [19] results in a $2\frac{1}{3}$ approximation for facility location in $\tilde{O}(n^2)$ time. We prove that a modified greedy improvement heuristic as in [16], along with the primal-dual algorithm in [19], together with scaling, yields an approximation ratio of 1.853 in $\tilde{O}(n^3)$ time. Interestingly, applying both this combinatorial algorithm (with appropriate scaling) and the LP-based algorithm of [9, 10] and taking the better of the two gives an approximation ratio of 1.728, marginally improving the best known approximation result for facility location. We construct an example to show that the dual constructed by the primal-dual facility location algorithm can be a factor $3-\epsilon$ away from the optimal solution. This shows that an analysis that uses only this dual as a lower bound cannot achieve an approximation ratio better than $3-\epsilon$.

Jain and Vazirani [19] show how a version of facility location with capacities (where multiple facilities are allowed at the same location) can be solved by reducing it to uncapacitated facility location. They obtain a 4 approximation for the capacitated problem in $\tilde{O}(n^2)$ time. Using their idea, from a $\rho$ approximation algorithm for the uncapacitated case, one can obtain an approximation ratio of $2\rho$ for the capacitated case. This was also observed by Shmoys [31]. This fact therefore implies approximation ratios of 3.7 in $\tilde{O}(n^3)$ time and 3.46 using LP-based techniques for the capacitated problem.

**1.2. Problem definition.** The *uncapacitated facility location problem* is defined as follows: Given a graph with an edge metric $c$ and cost $f_i$ of opening a center (or facility) at node $i$, select a subset of facilities to open so as to minimize the cost of opening the selected facilities plus the cost of assigning each node to its closest open facility. The cost of assigning node $j$ to facility $i$ is $d_j c_{ij}$, where $c_{ij}$ denotes the distance between $i$ and $j$. The constant $d_j$ is referred to as the demand of the node $j$.

Due to the metric property, this problem is also referred to as the metric uncapacitated facility location problem. In this paper we will refer to this problem as the facility location problem. We will denote the total cost of the facilities in a solution as the facility cost and the rest as the service cost. These costs will be denoted by $F$ and $C$, subscripted appropriately to define the context. For the LP relaxations of the problem and its dual, see section 4.

The *k-median problem* is defined as follows: given $n$ points in a metric space, we must select $k$ of these to be centers (facilities) and then assign each input point $j$ to the selected center that is closest to it. If location $j$ is assigned to a center $i$, we incur a cost $d_j c_{ij}$. The goal is to select the $k$ centers so as to minimize the sum of the assignment costs.

We will mostly present proofs assuming unit demands; however, since the arguments will be on a node by node basis, the results will extend to arbitrary demands as well.

## 2. Facility location and local search.

In this section we describe and analyze a simple greedy local search algorithm for facility location.

Suppose $F$ is the facility cost and $C$ is the service cost of a solution. The objective of the algorithm is to minimize the cost of the solution $F+C$. The algorithm starts from an initial solution and repeatedly attempts to improve its current solution by performing local search operations.

The initial solution is chosen as follows. The facilities are sorted in increasing order of facility cost. Let $F_i$ be the total facility cost and let $C_i$ be the total service cost for the solution consisting of the first $i$ facilities in this order. We compute the

$F_i$ and $C_i$ values for all $i$ and choose the solution that minimizes $F_i + C_i$. Lemma 2.1 bounds the cost of the initial solution in terms of the cost of an arbitrary solution $SOL$, and Lemma 2.2 shows that the initial solution can be computed in $O(n^2)$ time.

Let $\mathcal{F}$ be the set of facilities in the current solution. Consider a facility $i$. We will try to improve the current solution by incorporating $i$ and possibly removing some centers from $\mathcal{F}$. (Note that it is possible that $i \in \mathcal{F}$. In fact, this is required for reasons that will be made clear later.) Some nodes $j$ may be closer to $i$ than their currently assigned facility in $\mathcal{F}$. All such nodes are reassigned to $i$. Additionally, some centers in $\mathcal{F}$ are removed from the solution. If we remove a center $i' \in \mathcal{F}$, then all nodes $j$ that were connected to $i'$ are now connected to $i$. Note that the total change in cost depends on which nodes we choose to connect to $i$ and which facilities we choose to remove from the existing solution. The *gain* associated with $i$ (referred to as gain($i$)) is the largest possible decrease in $F + C$ as a result of this operation. If $F + C$ only increases as a result of adding facility $i$, gain($i$) is said to be 0. Lemma 2.3 guarantees that gain($i$) can be computed in $O(n)$ time.

The algorithm chooses a random node $i$ and computes gain($i$). If gain($i$) $> 0$, $i$ is incorporated in the current solution and nodes are reassigned as well as facilities removed, if required, so that $F + C$ decreases by gain($i$). This step is performed repeatedly. Note that at any point, demand nodes need not be assigned to the closest facility in the current solution. This may happen because the only reassignments we allow are to the newly added facility. When a new facility is added and existing facilities removed, reassigning to the new facility need not be the optimal thing to do. However, we do not reoptimize at this stage as this could take $O(n^2)$ time. Our analysis goes through for our seemingly suboptimal procedure. The reoptimization, if required, will be performed later if a facility $i$ already in $\mathcal{F}$ is *added* to the solution by the local search procedure. In fact, this is the reason that node $i$ is chosen from amongst all the nodes, instead of nodes not in $\mathcal{F}$.

We will compare the cost of the solution produced by the algorithm with the cost of an arbitrary feasible solution to the facility location LP (see [33, 9, 19]). The set of all feasible solutions to the LP includes all integral solutions to the facility location problem.

LEMMA 2.1. *The cost $F + C$ for the initial solution is at most $n^2 F_{SOL} + nC_{SOL}$, where $F_{SOL}$ and $C_{SOL}$ are the facility cost and service cost of an arbitrary solution $SOL$ to the facility location LP.*

*Proof.* Consider the solution $SOL$. Let $\mathcal{F}$ be the set of facilities $i$ such that $y_i \geq 1/n$. Note that $\mathcal{F}$ must be nonempty. Suppose the most expensive facility in $\mathcal{F}$ has cost $f$. Then $F_{SOL} \geq f/n$. We claim that every demand node $j$ must draw at least $1/n$ fraction of its service from the facilities in $\mathcal{F}$. Let $C_{\mathcal{F}}(j)$ be the minimum distance of demand node $j$ from a facility in $\mathcal{F}$ and let $C_{SOL}(j)$ be the service cost of $j$ in the solution $SOL$. Then $C_{SOL}(j) \geq \frac{1}{n} C_{\mathcal{F}}(j)$. Examine the facilities in increasing order of their facility cost and let $x$ be the last location in this order where a facility of cost $\leq f$ occurs. Then the solution that consists of the first $x$ facilities in this order contains all the facilities in $\mathcal{F}$. Thus, the service cost of this solution is at most $\sum_j C_{\mathcal{F}}(j) \leq n \sum_j C_{SOL}(j) = nC_{SOL}$. Also, the facility cost of this solution is at most $x \cdot f \leq n \cdot f \leq n^2 F_{SOL}$. Hence the cost $C + S$ for this solution is at most $n^2 F_{SOL} + nC_{SOL}$. Since this is one of the solutions considered in choosing an initial solution, the lemma follows. □

LEMMA 2.2. *The initial solution can be chosen in $O(n^2)$ time.*

*Proof.* First, we sort the facilities in increasing order of their facility cost. This takes $O(n \log n)$ time. We compute the costs of candidate solutions in an incremental fashion as follows. We maintain the cost of the solution consisting of the first $i$ facilities in this order (together with assignments of nodes to facilities). From this, we compute the cost of the solution consisting of the first $i+1$ facilities (together with assignments of nodes to facilities). The idea is that the solutions for $i$ and $i+1$ differ very slightly and the change can be computed in $O(n)$ time. Consider the effect of including the $(i+1)$st facility in the solution for $i$. Some nodes may now have to be connected to the new facility instead of their existing assignment. This is the only type of assignment change which will occur. In order to compute the cost of the solution for $i+1$ (and the new assignments), we examine each demand node $j$ and compare its current service cost with the distance of $j$ to the new facility. If it is cheaper to connect $j$ to the new facility, we do so. Clearly, this takes $O(n)$ time.

The initial solution consists of just the cheapest facility. Its cost can be computed in $O(n)$ time. Thus, the cost of the $n$ candidate solutions can be computed in $O(n^2)$ time. The lemma follows. $\square$

LEMMA 2.3. *The function* gain$(i)$ *can be computed in* $O(n)$ *time.*

*Proof.* Let $\mathcal{F}$ be the current set of facilities. For a demand node $j$, let $\sigma(j)$ be the facility in $F$ assigned to $j$. The maximum decrease in $F + C$ resulting from the inclusion of facility $i$ can be computed as follows. Consider each demand node $j$. If the distance of $j$ to $i$ is less than the current service cost of $j$, i.e., $c_{ij} < c_{\sigma(j)j}$, mark $j$ for reassignment to $i$. Let $D$ be the set of demand nodes $j$ such that $c_{ij} < c_{\sigma(j)j}$. The above step marks all the nodes in $D$ for reassignment to the new facility $i$. (Note that none of the marked nodes are actually reassigned; i.e., the function $\sigma$ is not changed in this step. The actual reassignment will occur only if gain$(i)$ is positive.) Having considered all the demand nodes, we consider all the facilities in $F$. Let $i'$ be the currently considered facility. Let $D(i')$ be the set of demand nodes $j$ that are currently assigned to $i'$, i.e., $D(i') = \{j : \sigma(j) = i'\}$. Note that some of the nodes that are currently assigned to $i'$ may have already been marked for reassignment to $i$. Look at the remaining unmarked nodes (possibly none) assigned to $i'$. Consider the change in cost if all these nodes are reassigned to $i$ and facility $i'$ removed from the current solution. The change in the solution cost as a result of this is $-f_{i'} + \sum_{j \in D(i') \setminus D}(c_{ij} - c_{i'j})$. If this results in a decrease in the cost, mark all such nodes for reassignment to $i$ and mark facility $i'$ for removal from the solution. After all the facilities in $F$ have been considered as above, we actually perform all the reassignments and facility deletions, i.e., reassign all marked nodes to $i$ and delete all marked facilities. Then gain$(i)$ is simply $(C_1 + S_1) - (C_2 + S_2)$, where $C_1, S_1$ are the facility and service costs of the initial solution and $C_2, S_2$ are the facility and service costs of the final solution. If this difference is $< 0$, gain$(i)$ is 0.

Now we prove that the above procedure is correct. Suppose that there is some choice of reassignments of demand nodes and facilities in $\mathcal{F}$ to remove such that the gain is more than gain$(i)$ computed above. It is easy to show that this cannot be the case. $\square$

Lemmas 2.6 and 2.7 relate the sum of the gains to the difference between the cost of the current solution and that of an arbitrary fractional solution. For ease of understanding, before proving the results in their full generality, we first prove simpler versions of the lemmas where the comparison is with an arbitrary integral solution.

LEMMA 2.4. $\sum$ gain$(i) \geq C - (F_{SOL} + C_{SOL})$, *where* $F_{SOL}$ *and* $C_{SOL}$ *are the facility and service costs for an arbitrary integral solution.*

*Proof.* Let $\mathcal{F}_{SOL}$ be the set of facilities in solution $SOL$. For a demand node $j$, let $\sigma(j)$ be the facility assigned to $j$ in the current solution and let $\sigma_{SOL}(j)$ be the facility assigned to $j$ in $SOL$. We now proceed with the proof.

With every facility $i \in \mathcal{F}_{SOL}$, we will associate a modified solution as follows. Let $D_{SOL}(i)$ be the set of all demand nodes $j$ which are assigned to $i$ in $SOL$. Consider the solution obtained by including facility $i$ in the current solution and reassigning all nodes in $D_{SOL}(i)$ to $i$. Let $\text{gain}'(i)$ be the decrease in cost of the solution as a result of this modification, i.e., $\text{gain}'(i) = -f_i + \sum_{j \in D_{SOL}(i)} (c_{\sigma(j)j} - c_{ij})$. Note that $\text{gain}'(i)$ could be $< 0$. Clearly, $\text{gain}(i) \geq \text{gain}'(i)$. We will prove that $\sum_{i \in \mathcal{F}_{SOL}} \text{gain}'(i) = C - (F_{SOL} + C_{SOL})$. Notice that for $j \in D_{SOL}(i)$, we have $i = \sigma_{SOL}(j)$. Therefore

$$\sum_{i \in \mathcal{F}_{SOL}} \text{gain}'(i) = \sum_{i \in \mathcal{F}_{SOL}} -f_i + \sum_{i \in \mathcal{F}_{SOL}} \sum_{j \in D_{SOL}(i)} (c_{\sigma(j)j} - c_{\sigma_{SOL}j}).$$

The first term evaluates to $-F_{SOL}$. The summation over the indices $i, j \in D_{SOL}(i)$ can be replaced simply by a sum over the demand points $j$. The summand therefore simplifies to two terms, $\sum_j c_{\sigma(j)j}$, which evaluates to $C$, and $-\sum_j c_{\sigma_{SOL}j}$, which evaluates to $-C_{SOL}$. Putting it all together, we get $\sum_i \text{gain}'(i) = -F_{SOL} + C - C_{SOL}$, which proves the lemma. ∎

LEMMA 2.5. $\sum \text{gain}(i) \geq F - (F_{SOL} + 2C_{SOL})$, *where* $F_{SOL}$ *and* $C_{SOL}$ *are the facility and service costs for an arbitrary integral solution.*

*Proof.* The proof will proceed along lines similar to the proof of Lemma 2.4. As before let $\mathcal{F}$ be the set of open facilities in the current solution. Let $\mathcal{F}_{SOL}$ be the set of facilities in solution $SOL$. For a demand node $j$, let $\sigma(j)$ be the facility assigned to $j$ in the current solution and let $\sigma_{SOL}(j)$ be the facility assigned to $j$ in $SOL$. For a facility $i \in \mathcal{F}$, let $D(i)$ be the set of demand nodes assigned to $i$ in the current solution. For a facility $i \in \mathcal{F}_{SOL}$, let $D_{SOL}(i)$ be the set of all demand nodes $j$ which are assigned to $i$ in $SOL$.

First, we associate every node $i' \in \mathcal{F}$ with its closest node $m(i') \in \mathcal{F}_{SOL}$. For $i \in \mathcal{F}_{SOL}$, let $R(i) = \{i' \in \mathcal{F} | m(i') = i\}$. With every facility $i \in \mathcal{F}_{SOL}$, we will associate a modified solution as follows. Consider the solution obtained by including facility $i$ in the current solution and reassigning all nodes in $D_{SOL}(i)$ to $i$. Further, for all facilities $i' \in R(i)$, the facility $i'$ is removed from the solution and all nodes in $D(i') \setminus D_{SOL}(i)$ are reassigned to $i$. Let $\text{gain}'(i)$ be the decrease in cost of the solution as a result of this modification, i.e.,

$$\text{gain}'(i) = -f_i + \sum_{j \in D_{SOL}(i)} (c_{\sigma(j)j} - c_{ij}) + \sum_{i' \in R(i)} \left( f_{i'} + \sum_{j \in D(i') \setminus D_{SOL}(i)} (c_{\sigma(j)j} - c_{ij}) \right). \tag{2.1}$$

Note that $\text{gain}'(i)$ could be $< 0$. Clearly, $\text{gain}(i) \geq \text{gain}'(i)$. We will prove that $\sum_{i \in \mathcal{F}_{SOL}} \text{gain}'(i) \geq F - (F_{SOL} + 2C_{SOL})$. In order to obtain a bound, we need an upper bound on the distance $c_{ij}$. From the triangle inequality, $c_{ij} \leq c_{i'j} + c_{i'i}$. Since $i' \in R(i)$, $m(i') = i$; i.e., $i$ is the closest node to $i'$ in $\mathcal{F}_{SOL}$. Hence, $c_{i'i} \leq c_{i'\sigma_{SOL}(j)} \leq c_{i'j} + c_{\sigma_{SOL}(j)j}$, where the last inequality follows from triangle inequality. Substituting this bound for $c_{i'i}$ in the inequality for $c_{ij}$, we get $c_{ij} \leq 2c_{i'j} + c_{\sigma_{SOL}(j)j} = 2c_{\sigma(j)j} + c_{\sigma_{SOL}(j)j}$, where the equality comes from the fact that $i' = \sigma(j)$. Substituting this bound for $c_{ij}$ in the last term of (2.1), we get

$$\begin{aligned}\text{gain}'(i) \geq -f_i + &\sum_{j \in D_{SOL}(i)} (c_{\sigma(j)j} - c_{ij}) \\ &+ \sum_{i' \in R(i)} \left( f_{i'} + \sum_{j \in D(i') \setminus D_{SOL}(i)} -(c_{\sigma(j)j} + c_{\sigma_{SOL}(j)j}) \right).\end{aligned}$$

The last term in the sum is a sum over negative terms, so if we sum over a larger set $j \in D(i')$ instead of $j \in D(i') \setminus D_{SOL}(i)$, we will still have a lower bound on $\text{gain}'(i)$:

$$\text{gain}'(i) \geq -f_i + \sum_{j \in D_{SOL}(i)} (c_{\sigma(j)j} - c_{ij}) + \sum_{i' \in R(i)} f_{i'} - \sum_{i' \in R(i)} \sum_{j \in D(i')} (c_{\sigma(j)j} + c_{\sigma_{SOL}(j)j}).$$

The first term in the expression $\sum_i \text{gain}'(i)$ is equal to $-F_{SOL}$, the second is $C - C_{SOL}$ since the double summation over indices $i$ and $j \in D_{SOL}(i)$ is a summation over all the demand nodes $j$, and $\sum_j c_{\sigma(j)j}$ is $C$ and $\sum_j c_{\sigma_{SOL}(j)j}$ is $C_{SOL}$. The third term is the sum of the facility costs of all the nodes in the current solution, which is $F$. The fourth term (which is negative) is equal to $-(C + C_{SOL})$ since the summation over the indices $i, i' \in R(i)$ and $j \in D(i')$ amounts to a summation over all the demand nodes $j$. Therefore we have

$$\sum_{i \in \mathcal{F}_{SOL}} \text{gain}'(i) \geq -F_{SOL} + (C - C_{SOL}) + F - (C + C_{SOL}),$$

which proves the lemma. $\square$

We now claim Lemmas 2.6 and 2.7 to compare with the cost of an arbitrary fractional solution to the facility location LP instead of an integral solution. We present the proofs in section 6 for a smoother presentation.

LEMMA 2.6. *$\sum \text{gain}(i) \geq C - (F_{SOL} + C_{SOL})$, where $F_{SOL}$ and $C_{SOL}$ are the facility and service costs for an arbitrary fractional solution SOL to the facility location LP.*

Similar to the above lemma, we generalize Lemma 2.5 to apply to any fractional solution of the facility location LP. See section 6 for the proof of the lemma.

LEMMA 2.7. *$\sum \text{gain}(i) \geq F - (F_{SOL} + 2C_{SOL})$, where $F_{SOL}$ and $C_{SOL}$ are the facility and service costs for an arbitrary fractional solution SOL to the facility location LP.*

Therefore if we are at a local optimum, where $\text{gain}(i) = 0$ for all $i$, the previous two lemmas guarantee that the facility cost $F$ and service cost $C$ satisfy

$$F \leq F_{SOL} + 2C_{SOL} \qquad \text{and} \qquad C \leq F_{SOL} + C_{SOL}.$$

Recall that a single improvement step of the local search algorithm consists of choosing a random vertex and attempting to improve the current solution; this takes $O(n)$ time. The algorithm will be: *at every step choose a random vertex, compute the possible improvement on adding this vertex (if the vertex is already in the solution, it has cost* 0*), and update the solution if there is a positive improvement.* We can easily argue that the process of computing the $\text{gain}(i)$ for a vertex can be performed in linear time. We now bound the number of improvement steps the algorithm needs to perform until it produces a low cost solution, which will fix the number of iterations we perform in the above steps. We will start by proving the following lemma.

LEMMA 2.8. *After $O(n\log(n/\epsilon))$ iterations we have $C+F \le 2F_{SOL}+3C_{SOL}+\epsilon(F_{SOL}+C_{SOL})$ with probability at least $\frac{1}{2}$.*

*Proof.* Suppose that after $s$ steps $C+F \ge 2F_{SOL}+3C_{SOL}+\epsilon(F_{SOL}+C_{SOL})/e$. Since the local search process decreases the cost monotonically, this implies that in all the intermediate iterations, the above condition on $C+F$ holds.

From Lemmas 2.4 and 2.5, we have

$$\sum_i \text{gain}(i) \ge \frac{1}{2}(C+F-(2F_{SOL}+3C_{SOL})).$$

Let $g(i)=\text{gain}(i)/(C+F-(2F_{SOL}+3C_{SOL}))$. Then in all intermediate iterations $\sum_i g(i) \ge \frac{1}{2}$. Let $P_t$ be the value of $C+F-(2F_{SOL}+3C_{SOL})$ after $t$ steps. Let $\text{gain}_t(i)$ and $g_t(i)$ be the values of $\text{gain}(i)$ and $g(i)$ at the $t$th step. Observe that $E[g_t(i)] \ge \frac{1}{2n}$.

Suppose $i$ is the node chosen for step $t+1$. Then, *assuming* $P_t > 0$,

$$\begin{aligned} P_{t+1} &= P_t - \text{gain}_t(i) = P_t(1-g_t(i)), \\ \frac{eP_{t+1}}{\epsilon(F_{SOL}+C_{SOL})} &= \frac{eP_t}{\epsilon(F_{SOL}+C_{SOL})}(1-g_t(i)), \\ \ln\left(\frac{eP_{t+1}}{\epsilon(F_{SOL}+C_{SOL})}\right) &= \ln\left(\frac{eP_t}{\epsilon(F_{SOL}+C_{SOL})}\right) + \ln(1-g_t(i)) \\ &\le \ln\left(\frac{eP_t}{\epsilon(F_{SOL}+C_{SOL})}\right) - g_t(i). \end{aligned}$$

Let $Q_t = \ln((eP_t)/(\epsilon(F_{SOL}+C_{SOL})))$. Then $Q_{t+1} \le Q_t - g_t(i)$. Note that the node $i$ is chosen uniformly and at random from amongst $n$ nodes. Our initial assumption implies that $P_t > \epsilon(F_{SOL}+C_{SOL})/e$ for all $t \le s$; hence, $Q_t > 0$ for all $t \le s$. Applying linearity of expectation,

$$E[Q_{s+1}] \le E[Q_s] - \frac{1}{2n} \le \cdots \le Q_1 - \frac{s}{2n}.$$

Note that the initial value $Q_1 \le \ln(en/\epsilon)$. So if $s = 2n\ln\frac{n}{\epsilon} - n$, then $E[Q_{s+1}] \le \frac{1}{2}$. By the Markov inequality, $\text{Prob}[Q_{s+1} \ge 1] \le \frac{1}{2}$. If $Q_{s+1} \le 1$, then $P_{s+1} \le \epsilon(F_{SOL}+C_{SOL})$, which proves the lemma. ▯

THEOREM 2.9. *The algorithm produces a solution such that $F \le (1+\epsilon)(F_{SOL}+2C_{SOL})$ and $C \le (1+\epsilon)(F_{SOL}+C_{SOL})$ in $O(n(\log n+\frac{1}{\epsilon}))$ steps (running time $O(n^2(\log n+\frac{1}{\epsilon}))$) with constant probability.*

*Proof.* We are guaranteed by Lemma 2.8 that after $O(n\log(n/\epsilon))$ steps we have the following:

$$C+F \le 2F_{SOL}+3C_{SOL}+\epsilon(F_{SOL}+C_{SOL}).$$

Once the above condition is satisfied, we say that we begin the second phase. We have already shown that with probability at least 1/2, we require $O(n\log(n/\epsilon))$ steps for the first phase.

We stop the analysis as soon as both $C \le F_{SOL}+C_{SOL}+\epsilon(F_{SOL}+C_{SOL})$ and $F \le F_{SOL}+2C_{SOL}+\epsilon(F_{SOL}+C_{SOL})$. At this point we declare that the second phase has ended.

Suppose one of these is violated. Then applying either Lemma 2.4 or Lemma 2.5, we get $\sum_i \text{gain}(i) \ge \epsilon(F_{SOL}+C_{SOL})$.

Define $\text{gain}_t(i)$ to be value of $\text{gain}(i)$ for a particular step $t$. Assuming the conditions of the theorem are not true for a particular step $t$ in the second phase, we have $E[\text{gain}_t(i)] \geq \frac{\epsilon}{n}(F_{SOL} + C_{SOL})$. Let the assignment and facility costs be $C_t$ and $F_t$ after $t$ steps into the second phase. Assuming we did not satisfy the conditions of the theorem in the $t$th step,

$$C_{t+1} + F_{t+1} \leq C_t + F_t - \text{gain}_t(i).$$

At the beginning of the second phase, we have

$$\begin{aligned} F_1 + C_1 &\leq 2F_{SOL} + 3C_{SOL} + \epsilon(F_{SOL} + C_{SOL}) \\ &\leq 3(F_{SOL} + C_{SOL}) + \epsilon(F_{SOL} + C_{SOL}). \end{aligned}$$

Conditioned on the fact that the second phase lasts for $s$ steps,

$$E[C_{s+1} + F_{s+1}] \leq 3(F_{SOL} + C_{SOL}) - \frac{s\epsilon}{n}(F_{SOL} + C_{SOL}).$$

Setting $s = n + 5n/(2\epsilon)$, we get $E[C_{s+1} + F_{s+1}] \leq (F_{SOL} + C_{SOL})/2$.

Observe that if $F_{SOL}, C_{SOL}$ are the facility and service costs for the optimum solution, we have obtained a contradiction to the fact that we can make $s$ steps without satisfying the two conditions. However, since we are claiming the theorem for any feasible solution $SOL$, we have to use a different argument.

If $E[C_{s+1} + F_{s+1}] \leq (F_{SOL} + C_{SOL})/2$, and since $C + F$ is always positive, with probability at least $\frac{1}{2}$ we have $C_{s+1} + F_{s+1} \leq (F_{SOL} + C_{SOL})$. In this case both conditions of the theorem are trivially true.

Thus with probability at least 1/4 we take $O(n \log(n/\epsilon) + n/\epsilon)$ steps. Assuming $1/\epsilon > \ln(1/\epsilon)$, we can drop the $\ln \epsilon$ term and claim the theorem. ∎

Following standard techniques, the above theorem yields a high probability result, losing another factor of $\log n$ in running time. The algorithm can be derandomized very easily, at the cost of a factor $n$ increase in the running time. Instead of picking a random node, we try all the $n$ nodes and choose the node that gives the maximum gain. Each step now takes $O(n^2)$ time. The number of steps required by the deterministic algorithm is the same as the expected number of steps required by the randomized algorithm.

THEOREM 2.10. *The deterministic algorithm produces a solution such that* $F \leq (1+\epsilon)(F_{SOL} + 2C_{SOL})$ *and* $C \leq (1+\epsilon)(F_{SOL} + C_{SOL})$ *in* $O(n(\log n + \frac{1}{\epsilon}))$ *steps with running time* $O(n^3(\log n + \frac{1}{\epsilon}))$.

## 3. Scaling costs.

In this section we will show how cost scaling can be used to show a better approximation guarantee. The idea of scaling exploits the asymmetry in the guarantees of the service cost and facility cost.

We will scale the facility costs uniformly by some factor (say $\delta$). We will then solve the modified instance using local search (or in later sections by a suitable algorithm). The solution of the modified instance will then be scaled back to determine the cost in the original instance.

*Remark.* Notice that the way the proof of Theorem 2.9 is presented, the termination condition of the algorithm that runs on the scaled instance is not obvious. We will actually run the algorithm for $O(n(\log n + 1/\epsilon))$ steps and construct that many different solutions. The analysis shows that with constant probability we find a solution such that both of the conditions are satisfied for at least one of these $O(n(\log n + 1/\epsilon))$ solutions. We will scale back all of these solutions and use the best solution. The same results will carry over with a high probability guarantee at the cost of another $O(\log n)$ in the running time. We first claim the following simple theorem.

THEOREM 3.1. *The uncapacitated facility location problem can be approximated to factor $1+\sqrt{2}+\epsilon$ in randomized $O(n^2/\epsilon+n^2\log n)$ time.*

*Proof.* Assume that the facility cost and the service costs of the optimal solution are denoted by $F_{OPT}$ and $C_{OPT}$. Then after scaling, there exists a solution to the modified instance of modified facility cost $\delta F_{OPT}$ and service cost $C_{OPT}$. For some small $\epsilon'$ we have a solution to the scaled instance, with service cost $C$ and facility cost $F$ such that

$$F \le (1+\epsilon')(\delta F_{OPT}+2C_{OPT}), \qquad C \le (1+\epsilon')(\delta F_{OPT}+C_{OPT}).$$

Scaling back, we will have a solution of the same service cost and facility cost $F/\delta$. Thus the total cost of this solution will be

$$C+F/\delta \le (1+\epsilon')\left[(1+\delta)F_{OPT}+\left(1+\frac{2}{\delta}\right)C_{OPT}\right].$$

Clearly setting $\delta=\sqrt{2}$ gives a $1+\sqrt{2}+\epsilon$ approximation, where $\epsilon=(1+\sqrt{2})\epsilon'$. ☐

Actually the above algorithm used only the fact that there existed a solution of a certain cost. In fact, the above proof will go through for any solution, even fractional. Let the facility cost of such a solution be $F_{SOL}$ and its service cost $C_{SOL}$. The guarantee provided by the local search procedure after scaling back yields facility cost $\hat{F}$ and service cost $\hat{C}$ such that

$$\hat{F} \le (1+\epsilon)(F_{SOL}+2C_{SOL}/\delta), \qquad \hat{C} \le (1+\epsilon)(\delta F_{SOL}+C_{SOL}).$$

Setting $\delta=2C_{SOL}/(\gamma F_{SOL})$, we get that the facility cost is at most $(1+\gamma)F_{SOL}$ and the service cost is $(1+2/\gamma)C_{SOL}$ up to factors of $(1+\epsilon)$ for arbitrarily small $\epsilon$.

In fact, the costs $F_{SOL}, C_{SOL}$ can be guessed up to factors of $1+\epsilon'$, and we will run the algorithm for all the resulting values of $\delta$. We are guaranteed to run the algorithm for some value of $\delta$ which is within a $1+\epsilon'$ factor of $2C_{SOL}/(\gamma F_{SOL})$. For this setting of $\delta$ we will get the result claimed in the theorem. This factor of $(1+\epsilon')$ can be absorbed by the $1+\epsilon$ term associated with the tradeoff.

Notice that we can guess $\delta$ directly and run the algorithm for all guesses. Each guess would return $O(n(\log n+\frac{1}{\epsilon}))$ solutions, such that one of them satisfies both the bounds (for that $\delta$). Thus if we consider the set of all solutions over all guesses of $\delta$, one of the solutions satisfies the theorem—in some sense we can achieve the tradeoff in an oblivious fashion. Of course this increases the running time of the algorithm appropriately. We need to ensure that, for every guess $\delta$, one of the $O(n(\log n+\frac{1}{\epsilon}))$ solutions satisfies the bounds on the facility cost and service cost.

THEOREM 3.2. *Let SOL be any solution to the facility location problem (possibly fractional) with facility cost $F_{SOL}$ and service cost $C_{SOL}$. For any $\gamma>0$, the local search heuristic proposed (together with scaling) gives a solution with facility cost at most $(1+\gamma)F_{SOL}$ and service cost at most $(1+2/\gamma)C_{SOL}$. The approximation is up to multiplicative factors of $(1+\epsilon)$ for arbitrarily small $\epsilon>0$.*

The known results on the tradeoff problem use a $(p,q)$ notation where the first parameter $p$ denotes the approximation factor of the facility cost and $q$ denotes the approximation factor for the service cost. This yields a better tradeoff for the $k$-median problem than the tradeoff $(1+\gamma, 2+2/\gamma)$ given by Lin and Vitter [25] as well as the tradeoff $(1+\gamma, 3+5/\gamma)$ given by Korupolu, Plaxton, and Rajaraman [23]. For facility location, our tradeoff is better than the tradeoff of $(1+\gamma, 3+3/\gamma)$ obtained by Shmoys, Tardos, and Aardal [33]. We note that the techniques of Marathe et al. [29] for bicriteria approximations also yield tradeoffs for facility cost versus service cost. Their results are stated in terms of tradeoffs for similar objectives, e.g., (cost, cost) or (diameter, diameter) under two different cost functions. However, their parametric search algorithm will also yield tradeoffs for different objective functions provided there exists a $\rho$ approximation algorithm to minimize the sum of the two objectives. By scaling the cost functions, their algorithm produces a tradeoff of $(\rho(1+\gamma), \rho(1+1/\gamma))$. For tradeoffs of facility cost versus service cost, $\rho$ is just the approximation ratio for facility location.

The above tradeoff is also interesting since the tradeoff of $(1+\gamma, 1+1/\gamma)$ is the best tradeoff possible; i.e., we cannot obtain a $(1+\gamma-\epsilon, 1+1/\gamma-\delta)$ tradeoff for any $\epsilon, \delta > 0$. This is illustrated by a very simple example.

**3.1. Lower bound for tradeoff.** We present an example to prove that the $(1+\gamma, 1+2/\gamma)$ tradeoff between facility and service costs is almost the best possible when comparing with a fractional solution of the facility location LP. Consider the following instance. The instance $\mathcal{I}$ consists of two nodes $u$ and $v$, $c_{uv} = 1$. The facility costs are given by $f_u = 1$, $f_v = 0$. The demands of the nodes are $d_u = 1$, $d_v = 0$.

THEOREM 3.3. *For any $\gamma > 0$, there exists a fractional solution to $\mathcal{I}$ with facility cost $F_{SOL}$ and service cost $C_{SOL}$ such that there is no integral solution with facility cost strictly less than $(1+\gamma)F_{SOL}$ and service cost strictly less than $(1+1/\gamma)C_{SOL}$.*

*Proof.* Observe that there are essentially two integral solutions to $\mathcal{I}$. The first, $SOL_1$, chooses $u$ as a facility, $F_{SOL_1} = 1$, $C_{SOL_1} = 0$. The second, $SOL_2$, chooses $v$ as a facility, $F_{SOL_2} = 0$, $C_{SOL_2} = 1$. For $\gamma > 0$, we will construct a fractional solution for $\mathcal{I}$ such that $F_{SOL} = 1/(1+\gamma)$, $C_{SOL} = \gamma/(1+\gamma)$. The fractional solution is obtained by simply taking the linear combination $(1/(1+\gamma))SOL_1 + (\gamma/(1+\gamma))SOL_2$. It is easy to verify that this satisfies the conditions of the lemma. ∎

Theorem 3.3 proves that a tradeoff of $(1+\gamma, 1+1/\gamma)$ for facility cost versus service cost is the best possible.

**3.2. Scaling and capacitated facility location.** The scaling idea can also be used to improve the approximation ratio for the capacitated facility location problem. Chudak and Williamson [12] prove that a local search algorithm produces a solution with the following properties (modified slightly from their exposition):

$$\begin{aligned} C &\leq (1+\epsilon')(F_{OPT} + C_{OPT}), \\ F &\leq (1+\epsilon')(5F_{OPT} + 4C_{OPT}). \end{aligned}$$

This gives a $6+\epsilon$ approximation for the problem. However, we can exploit the asymmetric guarantee by scaling. Scaling the facility costs by a factor $\delta$, we get a solution for the scaled instance such that

$$\begin{aligned} C &\leq (1+\epsilon')(\delta F_{OPT} + C_{OPT}), \\ F &\leq (1+\epsilon')(5\delta F_{OPT} + 4C_{OPT}). \end{aligned}$$

Scaling back, we get a solution of cost $C + F/\delta$. But

$$C + F/\delta \leq (1+\epsilon')\left[(5+\delta)F_{OPT} + \left(1+\frac{4}{\delta}\right)C_{OPT}\right].$$

Setting $\delta = 2\sqrt{2}-2$, we get a $3+2\sqrt{2}+\epsilon$ approximation.

**4. Primal-dual algorithm and improvements.** In this section we will show that the ideas of a primal-dual algorithm can be combined with augmentation and scaling to give a result better than those obtained by the pure greedy strategy and the primal-dual algorithm itself.

We will not be presenting the details of the primal-dual algorithm here, since we would be using the algorithm as a "black box." See [19, 7] for the primal-dual algorithm and its improvements. The following lemma is proved in [19].

LEMMA 4.1 (see [19]). *The primal-dual algorithm returns a solution with facility cost $F$ and a service cost $S$ such that $3F + S \leq 3OPT$, where $OPT$ denotes the cost of the optimal dual solution. The algorithm runs in time $O(n^2 \log n)$.*

In itself the primal-dual algorithm does not yield a better result than factor 3. In fact, a simple example shows that the dual constructed, which is used as a lower bound to the optimum, can be factor 3 away from the optimum. We will further introduce the notation that the facility cost of the optimal solution be $F_{OPT}$ and the service cost be $C_{OPT}$. *We would like to observe that these quantities are only used in the analysis.*

Let us first consider a simpler algorithm before presenting the best known combinatorial algorithm. If in the primal-dual algorithm we were to scale facility costs by a factor of $\delta = 1/3$ and use the primal-dual algorithm on this modified instance, we would have a feasible primal solution of cost $F_{OPT}/3 + C_{OPT}$. The primal-dual algorithm giving a solution with modified facility cost $F$ and service cost $C$ will guarantee that $3F + S$ is at most 3 times the feasible dual constructed which is less than the feasible primal solution of $F_{OPT}/3 + C_{OPT}$. After scaling back the solution, the cost of the final solution will be $3F + S$ due to the choice of $\delta$, which is at most $F_{OPT} + 3C_{OPT}$.

Now along with this compare the local search algorithm with $\delta = 2$ for which the cost of the final solution is $3F_{OPT} + 2C_{OPT}$ from the proof of Theorem 3.1. The smaller of the two solutions can be at most $2\frac{1}{3}$ times the optimum cost, which is $F_{OPT} + C_{OPT}$.

COROLLARY 4.2. *Using augmentation and scaling along with the primal-dual algorithm, the facility location problem can be approximated within a factor of $2\frac{1}{3} + \epsilon$ in time $O(n^2/\epsilon + n^2 \log n)$.*

**4.1. Gap examples for dual solutions of the primal-dual algorithm.** We present an example to show that the primal-dual algorithm for facility location can construct a dual whose value is $3 - \epsilon$ away from the optimal for arbitrarily small $\epsilon$. This means that it is not possible to prove an approximation ratio better than $3 - \epsilon$ using the dual constructed as a lower bound. This lower bound for the primal-dual algorithm is the analog of an integrality gap for LPs.

The example is shown in Figure 4.1. Here $r$ is a parameter. The instance is defined on a tree rooted at $w'$. $w'$ has a single child $w$ at unit distance from it. $w$ has $r^2$ children $v_1, \ldots, v_{r^2}$, each at unit distance from $w$. Further, each $v_i$ has a single child $v_i'$ at unit distance from it. All other distances are shortest path distances along the tree. Node $w'$ has a facility cost of 2, and the nodes $v_i$ have facility costs of $2 + 2/r$; all other nodes have facility cost of $\infty$. The node $w$ has demand $2r$. Each $v_i'$ has unit demand, and the rest of the nodes have zero demand. In the dual solution constructed by the algorithm, the $\alpha$ value of $w$ is $2r(1 + 1/r)$ and the $\alpha$ value for each $v_i'$ is $1 + 2/r$. The value of the dual solution is $r^2 + 4r + 2$. However, the value of the optimal solution is $3r^2 + 2r + 2/r$ (corresponding to choosing one of the facilities $v_i$). The ratio of the optimal solution value to dual solution value exceeds $3 - \epsilon$ for $r$ suitably large.

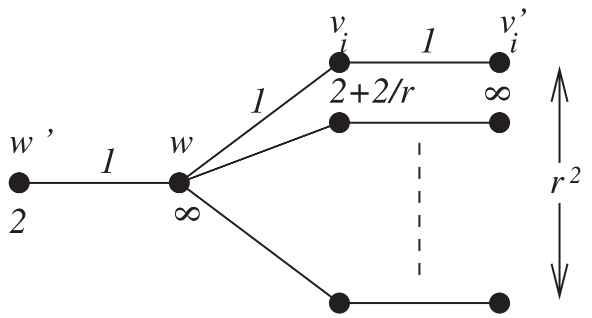

FIG. 4.1. *Lower bound example for the primal-dual facility location algorithm.*

**4.2. Greedy strategy.** We will use a slightly different augmentation technique as described in [16] and improve the approximation ratio. We will use a lemma proved in [16] about greedy augmentation; however the lemma proved therein was not cast in a form which we can use. The lemma as stated was required to know the value of the optimal facility cost. However, the lemma can be proved for any feasible solution by only assuming its existence. This also shows that the modification to the LP in [16] is not needed. We provide a slightly simpler proof.

The greedy augmentation process proceeds iteratively. At iteration $i$ we pick a node $u$ of cost $f_u$ such that if the service cost decreases from $C_i$ to $C'$ after opening $u$, the ratio $\frac{C_i - C' - f_u}{f_u}$ is maximized. Notice that this is gain$(u)/f_u$, where gain$(u)$ is defined as in section 2. That section used the node with the largest gain to get a fast algorithm; here we will use the best ratio gain to get a better approximation factor.

Assume we start with a solution of facility cost $F$ and service cost $C$. Initially $F_0 = F$ and $C_0 = C$. The node which has the maximum ratio can be found in time $O(n^2)$, and since no node will be added twice, the process will take time at most $O(n^3)$. We assume that the cost of all facilities is nonzero, since facilities with zero cost can always be included in any solution as a preprocessing step.

LEMMA 4.3 (see [16]). *If SOL is a feasible (fractional) solution and the initial solution has facility cost $F$ and service cost $C$, then after greedy augmentation the solution cost is at most*

$$F + F_{SOL} \max\left[0, \ln\left(\frac{C - C_{SOL}}{F_{SOL}}\right)\right] + F_{SOL} + C_{SOL}.$$

*Proof.* If the initial service cost is less than or equal to $F_{SOL} + C_{SOL}$, the lemma is true by observation.

Assume that at a point the current service cost $C_i$ is more than $F_{SOL} + C_{SOL}$. The proof of Lemma 2.6 shows that if $\sum_i y_i \text{gain}(i) \geq C_i - C_{SOL} - F_{SOL}$ and $\sum_i y_i f_i = F_{SOL}$, we are guaranteed to have a node with ratio at least $\frac{C_i - C_{SOL} - F_{SOL}}{F_{SOL}}$. Let the facility cost be denoted by $F_i$ at iteration $i$. We are guaranteed

$$\frac{C_i - C_{i+1} - (F_{i+1} - F_i)}{F_{i+1} - F_i} \geq \frac{C_i - C_{SOL} - F_{SOL}}{F_{SOL}}.$$

This equation rearranges to (assuming $C_i > C_{SOL} + F_{SOL}$)

$$F_{i+1} - F_i \leq F_{SOL}\left(\frac{C_i - C_{i+1}}{C_i - C_{SOL}}\right).$$

Suppose that at the $m$th iteration $C_m$ was less than or equal to $F_{SOL}+C_{SOL}$ for the first time. After this point the total cost only decreased. We will upper bound the cost at this step, and the result will hold for the final solution. The cost at this point is

$$F_m + C_m \le F + \sum_{i=1}^{m}(F_i - F_{i-1}) + C_m \le F + F_{SOL}\left(\sum_{i=1}^{m}\frac{C_{i-1}-C_i}{C_{i-1}-C_{SOL}}\right) + C_m.$$

The above expression is maximized when $C_m = F_{SOL}+C_{SOL}$. The derivative with respect to $C_m$ (which is $1-\frac{F_{SOL}}{C_{m-1}-C_{SOL}}$) is positive since $C_{m-1} > C_{SOL}+F_{SOL}$. Thus since $C_m \le F_{SOL}+C_{SOL}$, the boundary point of $C_m = F_{SOL}+C_{SOL}$ gives the maxima. In the following discussion we will assume that $C_m = C_{SOL}+F_{SOL}$.

We use the fact that for all $0 < x \le 1$, we have $\ln(1/x) \ge 1-x$. The cost is therefore

$$\begin{aligned} F + F_{SOL}\sum_{i=1}^{m}\frac{C_{i-1}-C_i}{C_{i-1}-C_{SOL}} + C_m &= F + F_{SOL}\sum_{i=1}^{m}\left(1-\frac{C_i-C_{SOL}}{C_{i-1}-C_{SOL}}\right) + C_m \\ &\le F + F_{SOL}\sum_{i=1}^{m}\ln\left(\frac{C_{i-1}-C_{SOL}}{C_i-C_{SOL}}\right) + C_m. \end{aligned}$$

The above expression for $C_0 = C$ and $C_m = F_{SOL}+C_{SOL}$ proves the lemma. □

**4.3. Better approximations for the facility location problem.** We now describe the full algorithm. Given a facility location problem instance we first scale the facility costs by a factor $\delta$ such that $\ln(3\delta) = 2/(3\delta)$ as in section 3. We run the primal-dual algorithm on the scaled instance. Subsequently, we scale back the solution and apply the greedy augmentation procedure given in [16] and described above. We claim the following.

THEOREM 4.4. *The facility location problem can be approximated within factor* $\approx 1.8526$ *in time* $O(n^3)$.

*Proof.* There exists a solution of cost $\delta F_{OPT}+C_{OPT}$ to the modified problem. Applying the primal-dual algorithm to this gives us a solution of (modified) facility cost $F'$ and service cost $C'$. If we consider this as a solution to the original problem, then the facility cost is $F = F'/\delta$ and the service cost $C = C'$. Now from the analysis of the primal-dual method we are guaranteed

$$3\delta F + C = 3F' + C' \le 3(\delta F_{OPT} + C_{OPT}).$$

If at this point we have $C \le F_{OPT}+C_{OPT}$, then

$$F + C \le \frac{3\delta F + C}{3\delta} + \left(1-\frac{1}{3\delta}\right)C \le \left(2-\frac{1}{3\delta}\right)F_{OPT} + \left(1+\frac{2}{3\delta}\right)C_{OPT}.$$

In the case when $C > F_{OPT}+C_{OPT}$, we also have $C \le 3\delta F_{OPT} - 3\delta F + 3C_{OPT}$. Since there is a solution of service cost $C_{OPT}$ and facility cost $F_{OPT}$, by Lemma 4.3, the cost after greedy augmentation is at most

$$F + F_{OPT}\ \ln\left(\frac{3\delta F_{OPT} - 3\delta F + 2C_{OPT}}{F_{OPT}}\right) + F_{OPT} + C_{OPT}.$$

Over the allowed interval of $F$ the above expression is maximized at $F = (2C_{OPT})/(3\delta)$, with cost

$$(1 + \ln(3\delta))F_{OPT} + \left(1 + \frac{2}{3\delta}\right) C_{OPT}.$$

Now for $\delta > 1/3$ the term $1 + \ln(3\delta)$ is larger than $2 - 1/(3\delta)$. Thus the case $C > F_{OPT} + C_{OPT}$ dominates. Consider the value of $\delta$ such that $\ln(3\delta) = 2/(3\delta)$, which is $\delta \approx 0.7192$, and the approximation factor is $\approx 1.8526$. The greedy augmentation takes maximum $O(n^3)$ time and the primal-dual algorithm takes $O(n^2)$ time. Thus, the theorem follows. ◻

It is interesting, however, that this result which is obtained from the above greedy algorithm can be combined with the algorithm of [9, 10] to obtain a very marginal improvement in the approximation ratio for the facility location problem. The results of [9, 10] actually provide a guarantee that if $\rho$ denotes the fraction of the facility cost in optimal solution returned by the LP formulation of the facility location problem, then the fractional solution can be rounded within a factor of $1+\rho \ln \frac{2}{\rho}$ when $\rho \leq 2/e$. The above primal-dual plus greedy algorithm when run with $\delta = 2/(3(e-1))$ gives an algorithm with approximation ratio $e - \rho(e - 1 - \log \frac{2}{e-1})$. It is easy to verify that the smaller of the two solutions has an approximation of 1.728. This is a very marginal ($\approx 0.008$) improvement over the LP-rounding algorithm. However, it demonstrates that the facility location problem can be approximated better.

THEOREM 4.5. *Combining the LP approach and the scaled, primal-dual plus greedy algorithms, the facility location problem can be approximated to a factor of* 1.728.

## 5. Capacitated facility location.

We consider the following capacitated variant of facility location: A facility at location $i$ is associated with a capacity $u_i$. Multiple facilities can be built at location $i$; each can serve a demand of at most $u_i$. This was considered by Chudak and Shmoys [11] who gave a 3 approximation for the case when all capacities are the same. Jain and Vazirani [19] extended their primal-dual algorithm for facility location to obtain a 4 approximation for the capacitated problem for general capacities. We use the ideas in [19] to improve the approximation ratio for this capacitated variant.

Given an instance $I$ of capacitated facility location, we construct an instance $I'$ of uncapacitated facility location with a modified distance function

$$c'_{ij} = c_{ij} + \frac{f_i}{u_i}.$$

The facility costs in the new instance are the same as the facility costs $f_i$ in the capacitated instance.[2] This construction is similar to the construction in [19].

The folowing lemma relates the assignment and facility costs for the original capacitated instance $I$ to those for the modified uncapacitated instance $I'$.

LEMMA 5.1. *Given a solution $SOL$ to $I$ of assignment cost $C_{SOL}$ and facility cost $F_{SOL}$, there exists a solution of $I'$ of assignment cost at most $C_{SOL} + F_{SOL}$ and facility cost at most $F_{SOL}$.*

*Proof.* Let $y_i$ be the number of facilities built at $i$ in $SOL$. Let $x_{ij}$ be an indicator variable that is 1 if and only if $j$ is assigned to $i$ in $SOL$. $C_{SOL} = \sum_{ij} x_{ij} c_{ij}$ and $F_{SOL} = \sum_i y_i f_i$. The capacity constraint implies that $\sum_j x_{ij} \leq u_i \cdot y_i$. Using $SOL$,

[2]As pointed out by a reviewer, setting $c'_{ji} = c'_{ij}$ preserves metric properties.

we construct a feasible solution $SOL'$ of $I'$ as follows: The assignments of nodes to facilities is the same as in $SOL$. A facility is built at $i$ if and only if at least one facility is built at $i$ in $SOL$.

Clearly the facility cost of $SOL'$ is at most $F_{SOL}$. The assignment cost of $SOL'$ is

$$\begin{aligned}\sum_{ij} x_{ij}c'_{ij} &= \sum_{ij} x_{ij}\left(c_{ij}+\frac{f_i}{u_i}\right)\\ &= \sum_{ij} x_{ij}c_{ij} + \sum_i f_i \frac{\sum_j x_{ij}}{u_i}\\ &\le \sum_{ij} x_{ij}c_{ij} + \sum_i f_i y_i\\ &= C_{SOL} + F_{SOL}. \qquad \square\end{aligned}$$

The following lemma states that given a feasible solution to $I'$, we can obtain a solution to $I$ of no greater cost.

LEMMA 5.2. *Given a feasible solution $SOL'$ to $I'$, there exists a feasible solution $SOL$ to $I$ such that the cost of $SOL$ is at most the cost of $SOL'$.*

*Proof.* Let $Y_i$ be an indicator variable that is 1 if and only if a facility is built at $i$ in $SOL'$. Let $x_{ij}$ be an indicator variable that is 1 if and only if $j$ is assigned to $i$ in $SOL'$. The solution $SOL$ for instance $I$ is obtained as follows: The assignment of nodes to facilities is exactly the same as in $SOL'$. The number of facilities built at $i$ is

$$y_i = \left\lceil \frac{\sum_j x_{ij}}{u_i} \right\rceil .$$

Thus $y_i \le \frac{\sum_j x_{ij}}{u_i} + Y_i$. The cost of $SOL'$ is

$$\begin{aligned}\sum_{ij} x_{ij}c'_{ij} + \sum Y_i f_i &= \sum_{ij} x_{ij}\left(c_{ij}+\frac{f_i}{u_i}\right) + \sum_i Y_i f_i\\ &= \sum_{ij} x_{ij}c_{ij} + \sum_i f_i\left(\frac{\sum_j x_{ij}}{u_i} + Y_i\right)\\ &\ge \sum_{ij} x_{ij}c_{ij} + \sum_i f_i y_i.\end{aligned}$$

Note that the last expression denotes the cost of $SOL$. Thus the cost of $SOL$ is at most the cost of $SOL'$. $\square$

Suppose we have instance $I$ of capacitated facility location. We first construct the modified instance $I'$ of uncapacitated facility location as described above. We will use an algorithm for uncapacitated facility location to obtain a solution to $I'$ and then translate it to a solution to $I$. Let $OPT(I)$ (resp., $OPT(I')$) denote the cost of the optimal solution for instance $I$ (resp., $I'$). First, we show that a $\rho$ approximation for uncapacitated facility location gives a $2\rho$ approximation for the capacitated version.

LEMMA 5.3. *Given a $\rho$ approximation for uncapacitated facility location, we can get a $2\rho$ approximation for the capacitated version.*

*Proof.* Lemma 5.1 implies that $OPT(I') \le 2OPT(I)$. Since we have a $\rho$ approximation algorithm for uncapacitated facility location, we can obtain a solution to $I'$

of cost at most $\rho OPT(I') \leq 2\rho OPT(I)$. Now, Lemma 5.2 guarantees that we can obtain a solution to $I$ of cost at most $2\rho OPT(I)$, yielding a $2\rho$ approximation for the capacitated version. $\square$

The above lemma implies an approximation ratio of $\approx 3.705$ in $O(n^3)$ time using the combinatorial algorithm of section 4.3 and an approximation ratio of $\approx 3.456$ in polynomial time using the guarantee of Theorem 4.5, combining the LP rounding and combinatorial algorithms.

By performing a more careful analysis, we can obtain a slightly better approximation guarantee for the combinatorial algorithm. Let $F_{OPT}$ and $C_{OPT}$ denote the facility and assignment costs for the optimal solution to $I$. Let $F'$ and $C'$ be the facility and assignment costs of the solution to $I'$ guaranteed by Lemma 5.1. Then $F' \leq F_{OPT}$ and $C' \leq F_{OPT} + C_{OPT}$.

LEMMA 5.4. *The capacitated facility location problem can be approximated within factor* $3 + \ln 2 \approx 3.693$ *in time* $O(n^3)$.

*Proof.* We use the approximation algorithm described in section 4.3 and analyzed in Theorem 4.4. We have a feasible solution to $I'$ of facility cost $F'$ and assignment cost $C'$. The proof of Theorem 4.4 bounds the cost of the solution obtained to $I'$ by

$$(1 + \ln(3\delta))F' + \left(1 + \frac{2}{3\delta}\right) C'.$$

Here $\delta$ is a parameter for the algorithm. Substituting the bounds for $F'$ and $C'$ and rearranging, we get the bound

$$\left(2 + \ln(3\delta) + \frac{2}{3\delta}\right) F_{OPT} + \left(1 + \frac{2}{3\delta}\right) C_{OPT}.$$

Setting $\delta = \frac{2}{3}$, so as to minimize the coefficient of $F_{OPT}$, we obtain the bound $(3 + \ln 2)F_{OPT} + 2C_{OPT}$. This yields the claimed approximation ratio. Also, the algorithm runs in $O(n^3)$ time. $\square$

## 6. Proofs of lemmas in section 2.

We present the proofs of the lemmas we omitted to avoid discontinuity in the presentation. Recall that the facility location LP is as follows:

$$\begin{aligned} \min \sum_i y_i f_i + \sum_{ij} x_{ij} c_{ij} & \\ \forall ij \quad x_{ij} &\leq y_i, \\ \forall j \quad \sum_i x_{ij} &\geq 1, \\ x_{ij}, y_i &\geq 0. \end{aligned}$$

Here $y_i$ indicates whether facility $i$ is chosen in the solution, and $x_{ij}$ indicates whether node $j$ is serviced by facility $i$.

LEMMA 2.6. $\sum \text{gain}(i) \geq C - (F_{SOL} + C_{SOL})$, *where* $F_{SOL}$ *and* $C_{SOL}$ *are the facility and service costs for an arbitrary fractional solution SOL to the facility location LP.*

*Proof.* Consider the fractional solution $SOL$ to the facility location LP. $F_{SOL} = \sum_i y_i f_i$ and $C_{SOL} = \sum_{ij} x_{ij} c_{ij}$. We will prove that $\sum_i y_i \cdot \text{gain}(i) \geq C - (F_{SOL} + C_{SOL})$. Assume without loss of generality that $y_i \leq 1$ for all $i$ and $\sum_i x_{ij} = 1$ for all $j$.

We first modify the solution (and make multiple copies of facilities) so as to guarantee that for all $ij$, either $x_{ij} = 0$ or $x_{ij} = y_i$. The pair $ij$ for which this condition is violated is said to be a violating $ij$. The modification is done as follows: Suppose there is a violating $ij$, i.e., there are a facility $i$ and demand node $j$ in our current solution such that $0 < x_{ij} < y_j$. Let $x = \min_j\{x_{ij} | x_{ij} > 0\}$. We create a copy $i'$ of node $i$ (i.e., $c_{i'i} = 0$, $c_{i'j} = c_{ij}$ for all $j$ and $f_{i'} = f_i$.) We set $y_{i'} = x$ and decrease $y_{i'}$ by $x$. Further, for all $j$ such that $x_{ij} > 0$, we decrease $x_{ij}$ by $x$ and set $x_{i'j} = x$. For all the remaining $j$, we set $x_{i'j} = 0$. Note that the new solution we obtain is a fractional solution with the same cost as the original solution. Also, all $i'j$ satisfy the desired conditions. Further, the number of violating $ij$ decreases. In at most $n^2$ such operations, we obtain a solution that satisfies the desired conditions. Suppose $i_1, \ldots, i_r$ are the copies of node $i$ created in this process; then the final value of $\sum_{l=1}^{r} y_{i_l}$ is the same as the initial value of $y_i$.

We now proceed with the proof. For a demand node $j$, let $\sigma(j)$ be the facility assigned to $j$ in the current solution. With every facility $i$, we will associate a modified solution as follows. Let $D_{SOL}(i)$ be the set of all demand nodes $j$ such that $x_{ij} > 0$. Note that $x_{ij} = y_i$ for all $i \in D_{SOL}(i)$. Consider the solution obtained by including facility $i$ in the current solution and reassigning all nodes in $D_{SOL}(i)$ to $i$. Let gain$'(i)$ be the decrease in cost of the solution as a result of this modification, i.e.,

$$\text{gain}'(i) = -f_i + \sum_{j \in D_{SOL}(i)} (c_{\sigma(j)j} - c_{ij}).$$

Note that gain$'(i)$ could be $< 0$. Clearly, $\text{gain}(i) \geq \text{gain}'(i)$. We will prove that $\sum_i y_i \cdot \text{gain}'(i) = C - (F_{SOL} + C_{SOL})$. Since $y_i = x_{ij}$ if $j \in D_{SOL}(i)$ (also using the fact that $x_{ij} = 0$ if $j \notin D_{SOL}(i)$ to simplify the index of the summation to $j$), we get

$$y_i \cdot \text{gain}'(i) = -y_i f_i + \sum_j x_{ij} c_{\sigma(j)j} - \sum_j x_{ij} c_{ij}.$$

Summing over all $i \in \mathcal{F}$, the first term evaluates to $-F_{SOL}$ and the third term to $-C_{SOL}$. The second term, if we reverse the order of the summation indices, using $\sum_i x_{ij} = 1$, simplifies to $\sum_j c_{\sigma(j)j}$, which evaluates to $C$, which proves $\sum \text{gain}(i) \geq -F_{SOL} + C - C_{SOL}$. □

LEMMA 2.7. *$\sum \text{gain}(i) \geq F - (F_{SOL} + 2C_{SOL})$, where $F_{SOL}$ and $C_{SOL}$ are the facility and service costs for an arbitrary fractional solution SOL to the facility location LP.*

*Proof.* Consider the fractional solution $SOL$ to the facility location LP. Let $y_i$ denote the variable that indicates whether facility $i$ is chosen in the solution and let $x_{ij}$ be the variable that indicates whether node $j$ is serviced by facility $i$. $F_{SOL} = \sum_i y_i f_i$ and $C_{SOL} = \sum_{ij} x_{ij} c_{ij}$. We will prove that $\sum_i y_i \cdot \text{gain}(i) \geq F - (F_{SOL} + 2C_{SOL})$. As before, assume without loss of generality that $y_i \leq 1$ for all $i$ and $\sum_i x_{ij} = 1$ for all $ij$.

Let $\mathcal{F}$ be the set of facilities in the current solution. Mimicking the proof of Lemma 2.5, we will match each node $i' \in \mathcal{F}$ to its "nearest" node in the fractional solution. However, since we have a fractional solution, this matching is a *fractional matching*, given by variables $m_{ii'} \geq 0$, where the value of $m_{ii'}$ indicates the extent to which $i'$ is matched to $i$. The variables satisfy the constraints $m_{ii'} \leq y_i$, $\sum_i m_{ii'} = 1$, and the values are chosen so as to minimize $\sum_i m_{ii'} c_{ii'}$. So for any $j$,

$$\sum_i m_{ii'} c_{ii'} \leq \sum_i x_{ij} c_{ii'} \leq \sum_i x_{ij}(c_{i'j} + c_{ij})$$
$$\leq c_{i'j} + \sum_i x_{ij} c_{ij}.$$

In particular, for $i' = \sigma(j)$, we get

$$\sum_i m_{i\sigma(j)} c_{i\sigma(j)} \leq c_{\sigma(j)j} + \sum_i x_{ij} c_{ij}. \tag{6.1}$$

As in the proof of Lemma 2.5, we modify the fractional solution by making multiple copies of facilities such that for every $ij$, either $x_{ij} = 0$ or $x_{ij} = y_i$ and additionally, for every $i, i'$, either $m_{ii'} = 0$ or $m_{ii'} = y_i$. (The second condition is enforced in exactly the same way as the first, by treating the variables $m_{ii'}$ just as the variables $x_{ij}$.)

For a demand node $j$, let $\sigma(j)$ be the facility assigned to $j$ in the current solution. Let $D(i')$ be the set of demand nodes $j$ assigned to facility $i'$ in the current solution. With every facility $i$, we will associate a modified solution as follows. Let $D_{SOL}(i)$ be the set of all demand nodes $j$ such that $x_{ij} > 0$. Let $R(i)$ be the set of facilities $i' \in \mathcal{F}$ such that $m_{ii'} > 0$. Note that $x_{ij} = y_i$ for all $j \in D_{SOL}(i)$ and $m_{ii'} = y_i$ for all $i' \in R(i)$. Consider the solution obtained by including facility $i$ in the current solution and reassigning all nodes in $D_{SOL}(i)$ to $i$. Further, for all facilities $i' \in R(i)$, the facility $i'$ is removed from the solution and all nodes in $D(i') \setminus D_{SOL}(i)$ are reassigned to $i$. Let gain$'(i)$ be the decrease in cost of the solution as a result of this modification, i.e.,

$$\text{gain}'(i) = -f_i + \sum_{j \in D_{SOL}(i)} (c_{\sigma(j)j} - c_{ij}) + \sum_{i' \in R(i)} \left( f_{i'} + \sum_{j \in D(i') \setminus D_{SOL}(i)} (c_{\sigma(j)j} - c_{ij}) \right).$$

Clearly, gain$(i) \geq$ gain$'(i)$. We will prove that $\sum_i y_i \cdot \text{gain}'(i) \geq F - (F_{SOL} + 2C_{SOL})$. We also know that if $i' \in R(i)$, then $m_{ii'} = y_i$. Since $m_{ii'} = 0$ if $i'$ is not in $R(i)$, we will drop the restriction on $i'$ in the summation:

$$y_i \cdot \text{gain}'(i) = -y_i f_i + \sum_{j \in D_{SOL}(i)} x_{ij}(c_{\sigma(j)j} - c_{ij})$$
$$+ \sum_{i'} m_{ii'} \left( f_{i'} + \sum_{j \in D(i') \setminus D_{SOL}(i)} (c_{\sigma(j)j} - c_{ij}) \right).$$

From triangle inequality we have $-c_{i'i} \leq c_{i'j} - c_{ij}$. We also replace $i'$ by $\sigma(j)$ wherever convenient. Therefore we conclude that

$$y_i \cdot \text{gain}'(i) \geq -y_i f_i + \sum_{j \in D_{SOL}(i)} x_{ij}(c_{\sigma(j)j} - c_{ij})$$
$$+ \sum_{i'} \left( m_{ii'} f_{i'} + \sum_{j \in D(i') \setminus D_{SOL}(i)} -m_{i\sigma(j)} c_{i\sigma(j)} \right).$$

Once again evaluating the negative terms in the last summand over a larger set (namely, all $i', j \in D(i')$ instead of $i', j \in D(i') \setminus D_{SOL}(i)$; but since the $D(i')$'s are disjoint this simplifies to a sum over all $j$) and summing the result over all $i$, we have

$$\sum_i y_i \cdot \text{gain}'(i) \geq -\sum_i y_i \cdot f_i + \sum_i \sum_{j \in D_{SOL}(i)} x_{ij}(c_{\sigma(j)j} - c_{ij}) + \sum_i \sum_{i'} m_{ii'} f_{i'} - \sum_i \sum_j m_{i\sigma(j)} c_{\sigma(j)i}.$$

The first term in the above expression is equal to $-F_{SOL}$. The second term has two parts, the latter of which is $\sum_{i,j} x_{ij}c_{ij}$, which evaluates to the fractional service cost, $C_{SOL}$. The first part of the second term evaluates to $\sum_j c_{\sigma(j)j}$ since, if we reverse the order of the summation, $\sum_{i,j \in D_{SOL}(i)} x_{ij} = 1$, since node $j$ is assigned fractionally. This part evaluates to $C$.

The third term is equal to $\sum_{i'} f_{i'}$, again reversing the order of the summation and using the fact that $\sum_i m_{ii'} = 1$ from the fractional matching of the nodes $i'$ in the current solution.

We now bound the last term in the expression. Notice the sets $R(i)$ may not be disjoint and we require a slightly different approach than that in the proof of Lemma 2.5. We use the inequality (6.1), and the term (which is now $-\sum_i \sum_j m_{i\sigma(j)}c_{\sigma(j)i}$) is at least $-\sum_j c_{\sigma(j)j} - \sum_{i,j} x_{ij}c_{ij}$. The first part evaluates to $-C$ and the second part to $-C_{SOL}$. Substituting these expressions, we get

$$\sum_i y_i \cdot \text{gain}'(i) \geq -F_{SOL} + F + C - C_{SOL} + F - C - C_{SOL},$$

which proves the lemma. □

**Implementing local search.** We ran some preliminary experiments with an implementation of the basic local search algorithm as described in section 2. We tested the program on the data sets at the OR-Library (http://people.brunel.ac.uk/~mastjjb/jeb/info.html). The results were very encouraging, and the program found the optimal solution for 10 of the 15 data sets. One set had 3.5% error, and the others had less than 1% error. The program took less than 10 seconds (on a PC) to run in all cases. This study is by no means complete, since we did not implement scaling, primal-dual algorithms, and the other well-known heuristics in the literature.

The heuristic deleted three nodes a few times and two nodes several times upon insertion of a new facility. Thus it seems that the generalization of deleting more than one facility (cf. add and drop heuristics; see Kuehn and Hamburger [24] and Korupolu, Plaxton, and Rajaraman [23]) was useful in the context of these data sets.

## 7. Concurrent and subsequent results.

Subsequent to the publication of the extended abstract of this paper [7], several results have been published regarding the facility location problem. The result in [27] provides a 1.86 approximation while running in time $O(m \log m)$ in a graph with $m$ edges using dual fitting. [36] also proves results in a similar vein. [20] gives a 1.61 approximation for the uncapacitated facility location problem, which is improved to 1.52 in [28]. [28] also gives a 2.88 approximation for the soft capacitated problem discussed in this paper.

Although this paper concentrates on the facility location problem, two results on the related $k$-median problem are of interest to the techniques considered here. The first is the result of Mettu and Plaxton [30], which gives an $O(1)$ approximation to the $k$-median problem, using combinatorial techniques. They output a list of points such that for any $k$, the first $k$ points in the output list give an $O(1)$ approximation to the $k$-median problem.

The second result is of Arya et al. in [2] where the authors present a $3 + \epsilon$ approximation algorithm for the $k$-median problem based on local search. They show how to use exchanges as opposed to the general delete procedure considered here to prove an approximation bound.

**Acknowledgments.** We would like to thank Chandra Chekuri, Ashish Goel, Kamal Jain, Samir Khuller, Rajeev Motwani, David Shmoys, Éva Tardos, and Vijay Vazirani for numerous discussions on these problems. We would also like to thank the referees for helping us improve the presentation of this manuscript significantly.

# ON THE RELATIONSHIP BETWEEN CLIQUE-WIDTH AND TREEWIDTH*

DEREK G. CORNEIL[†] AND UDI ROTICS[‡]

**Abstract.** Treewidth is generally regarded as one of the most useful parameterizations of a graph's construction. Clique-width is a similar parameterization that shares one of the powerful properties of treewidth, namely: if a graph is of bounded treewidth (or clique-width), then there is a polynomial time algorithm for any graph problem expressible in monadic second order logic, using quantifiers on vertices (in the case of clique-width you must assume a clique-width parse expression is given). In studying the relationship between treewidth and clique-width, Courcelle and Olariu [*Discrete Appl. Math.*, 101 (2000), pp. 77–114] showed that any graph of bounded treewidth is also of bounded clique-width; in particular, for any graph $G$ with treewidth $k$, the clique-width of $G$ is at most $4 * 2^{k-1} + 1$.

In this paper, we improve this result by showing that the clique-width of $G$ is at most $3 * 2^{k-1}$ and, more importantly, that there is an exponential lower bound on this relationship. In particular, for any $k$, there is a graph $G$ with treewidth equal to $k$, where the clique-width of $G$ is at least $2^{\lfloor k/2 \rfloor - 1}$.

**Key words.** clique-width, treewidth

## 1. Introduction.

One of the most fruitful graph theoretical developments of the last few decades has been the concept of treewidth, pioneered by Robertson and Seymour. Loosely speaking, the treewidth of a graph captures a way of constructing the graph in a "tree-like" fashion. The lower the treewidth of a graph, the closer it is to being a tree (connected treewidth one graphs are precisely trees). One of the major results in this area is that any problem expressible in monadic second order logic (which includes many NP-complete graph problems), when restricted to graphs of bounded treewidth $k$, has a linear time algorithm (albeit with a constant that grows exponentially with $k$). Although this result is very far reaching, it is still somewhat dissatisfying since many classes of "tame" graphs, for example, cliques, have arbitrarily high treewidth, yet have simple linear time algorithms for most of the problems mentioned above.

The clique-width of a graph is another attempt to parameterize the construction of a graph so that sweeping claims can be made about the graph's tractability for polynomial time solutions to difficult problems. The clique-width of a graph $G$, denoted by $cwd(G)$, is defined as the minimum number of labels needed to construct $G$, using the following four graph operations: creation of a new vertex $v$ with label $i$ (denoted $i(v)$), disjoint union ($\oplus$), connecting vertices with specified labels ($\eta$), and renaming labels ($\rho$). The construction of a graph $G$ using the above four operations

is represented by an algebraic expression called a *$k$-expression*, where $k$ is the number of labels used in the expression. More details are given in section 2. This notion was first introduced by Courcelle, Engelfriet, and Rozenberg in [5] and has been studied extensively in recent years.

For example, cographs (graphs with no induced $P_4$'s) are exactly the graphs of clique-width at most two, and trees have clique-width at most three [8]. $P_4$-sparse (every five vertices have at most one $P_4$) and $P_4$-tidy graphs (no induced $P_4$ has more than one partner, where a partner is a vertex whose inclusion in the $P_4$ results in at least two distinct $P_4$'s) have clique-width at most four [6]. The $(q, q-4)$ graphs for $q$ at least four and $(q, q-3)$ graphs for $q$ at least seven have clique-width at most $q$ [6, 12]. A $(q, t)$ graph is a graph in which every subgraph induced by $q$ vertices contains at most $t$ induced $P_4$'s.

As mentioned above, the motivation for studying clique-width is analogous to that of treewidth. In particular, problems defined by monadic second order logic formulas, using quantifiers on vertices but not on edges, can be solved in polynomial time on any class of graphs $\mathcal{C}$ of clique-width at most $k$, for some fixed $k$, assuming that the $k$-expression defining the input graph is given. For details, see [6, 7]. In addition, polynomial time algorithms can be obtained for other problems such as chromatic number, edge dominating set [11], and $ID_q$-partition problems [10], on any class of graphs $\mathcal{C}$ of clique-width at most $k$, for some fixed $k$, assuming that the $k$-expression defining the input graph is given.

This raises the obvious question about the relationship between treewidth and clique-width. Courcelle and Olariu [8] proved the following theorem.

THEOREM 1.1 (see [8]). *If the treewidth of $G$ is $k$, then $cwd(G) \leq 2^{k+1} + 1$ $(= 4 * 2^{k-1} + 1)$.*

This theorem guarantees that any class of graphs of bounded treewidth is also of bounded clique-width and thus, from the perspective of algorithmic tractability, clique-width is a more powerful concept. Note that since the clique-width of a clique on $n$ vertices is at most two and its treewidth is $n-1$, the gap between a graph's treewidth and clique-width can be arbitrarily high. The above theorem also raises the questions of whether the bound can be improved (note that for trees, $k$ equals one, and the theorem guarantees that the clique-width of a tree is at most five, whereas it is known that the clique-width of a tree is at most three) and more importantly, whether the exponential bound represented in the theorem can be replaced by a polynomial bound. To make this more precise, we let $\mathcal{G}_k = \{G : twd(G) = k\}$, where $twd(G)$ denotes the treewidth of $G$, and want to determine whether $f(\mathcal{G}_k) = max\{cwd(G) : G \in \mathcal{G}_k\}$ can grow polynomially with $k$.

In answer to these two questions, our paper proves the following two theorems.

THEOREM 1.2. *If the treewidth of $G$ is $k$, then $cwd(G) \leq 2^k + 2^{k-1}$ $(= 3 * 2^{k-1})$.*

THEOREM 1.3. *For any $k$, there is a graph $G$ where $twd(G) = k$ and $cwd(G) \geq 2^{\lfloor k/2 \rfloor - 1}$ (i.e., $f(\mathcal{G}_k) \geq 2^{\lfloor k/2 \rfloor - 1}$).*

*Overview of the paper.* The second section of the paper introduces the notation and definitions used throughout the paper. In particular, we present the concept of $k$-trees and partial $k$-trees. (Note that partial $k$-trees encompass an alternative definition of graphs having treewidth at most $k$.) We also describe how to construct the $k$-trees that will be used in the proofs of the two theorems. Sections 3 and 4 are devoted to the proofs of Theorems 1.2 and 1.3, respectively. The paper ends with concluding remarks and directions for further research.

## 2. Notation and definitions.

The graphs we consider in this paper are undirected and loop-free. For a graph $G$ and a vertex $u$ of $G$, we denote by $N_G(u)$ the

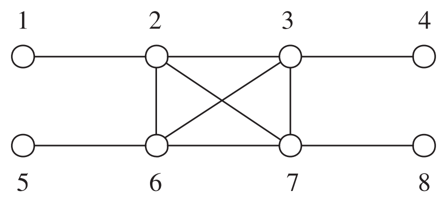

FIG. 1. *A graph $G$ of clique-width three.*

$$\begin{aligned}\mathbf{t_1} &= \boldsymbol{\rho}_{\mathbf{c}\to\mathbf{b}}(\boldsymbol{\eta}_{\mathbf{b,c}}(\boldsymbol{\eta}_{\mathbf{a,b}}(\mathbf{a(1)} \oplus \mathbf{b(2)}) \oplus \boldsymbol{\eta}_{\mathbf{a,c}}(\mathbf{a(5)} \oplus \mathbf{c(6)})))\\ \mathbf{t_2} &= \boldsymbol{\rho}_{\mathbf{b}\to\mathbf{c}}(\boldsymbol{\eta}_{\mathbf{b,c}}\,(\boldsymbol{\eta}_{\mathbf{a,b}}(\mathbf{a(4)} \oplus \mathbf{b(3)}) \oplus \boldsymbol{\eta}_{\mathbf{a,c}}(\mathbf{a(8)} \oplus \mathbf{c(7)})))\\ \mathbf{t} &= \boldsymbol{\eta}_{\mathbf{b}\to\mathbf{c}}(\mathbf{t_1} \oplus \mathbf{t_2})\end{aligned}$$

FIG. 2. *A 3-expression defining the graph of Figure 1.*

*neighborhood* of $u$ in $G$, which is the set of all vertices in $G$ that are adjacent to $u$. We denote by $N_G[u]$ the *closed neighborhood* of $u$ in $G$ which is equal to $N_G(u) \cup \{u\}$.

We first give more details on the definition of clique-width presented above. The *clique-width* of a graph $G$, denoted by $cwd(G)$, is defined as the minimum number of labels needed to construct $G$, using the following four graph operations: creation of a new vertex $v$ with label $i$ (denoted $i(v)$), disjoint union ($\oplus$), connecting vertices with specified labels ($\eta$), and renaming labels ($\rho$). The operation $\eta_{i,j}$ ($i \neq j$) adds all edges (that are not already present) between every vertex of label $i$ and every vertex of label $j$. The operation $\rho_{i\to j}$ renames all vertices of label $i$ with label $j$. An expression built from the above four operations is called a *clique-width expression.* A clique-width expression using $k$ labels is called a *$k$-expression.* Each $k$-expression $t$ uniquely defines a labeled graph $val(t)$, where the labels are integers $1, \dots, k$ associated with the vertices and each vertex has exactly one label. We say that a $k$-expression $t$ defines a graph $G$ if $G$ is equal to the graph obtained from the labeled graph $val(t)$ after removing its labels. The clique-width of a graph $G$ is equal to the minimum $k$ such that there exists a $k$-expression defining $G$.

For a $k$-expression $t$ defining a graph $G$, we denote by $tree(t)$ the parse tree constructed from $t$ in the usual way. The leaves of this tree are the vertices of $G$ with their initial labels, and the internal nodes correspond to the operations of $t$ and can be either binary corresponding to $\oplus$, or unary corresponding to $\eta$ or $\rho$. If $k$ equals $cwd(G)$, we say that $k$-expression $t$ is an *optimum clique-width expression* of $G$ and we say that $tree(t)$ is an *optimum clique-width parse tree* for $G$. For a vertex $u$ of $G$ and an internal node $a$ of $tree(t)$, such that $u$ occurs (as a leaf) in the subtree of $tree(t)$ rooted at $a$, the *label of $u$ at $a$* is defined as the label that $u$ has immediately before the operation $a$ is applied on the subtree of $tree(t)$ rooted at $a$.

*Example* 2.1. Figure 1 illustrates a graph $G$ of clique-width three. The 3-expression $t$ presented in Figure 2 defines the graph $G$ of Figure 1. Note that the labeled graph $val(t)$ can be obtained from the graph $G$ by adding label $a$ to vertices 1, 4, 5, and 8, label $b$ to vertices 2 and 3, and label $c$ to vertices 6 and 7. The 3-expression $t$ shows that $G$ is of clique-width at most three. Since $G$ has an induced $P_4$ and cographs (the graphs with no induced $P_4$'s) are exactly the graphs of clique-width at most two [8], it follows that the clique-width of $G$ is exactly three. Figure 3 presents the optimum clique-width parse tree, denoted $tree(t)$, that corresponds

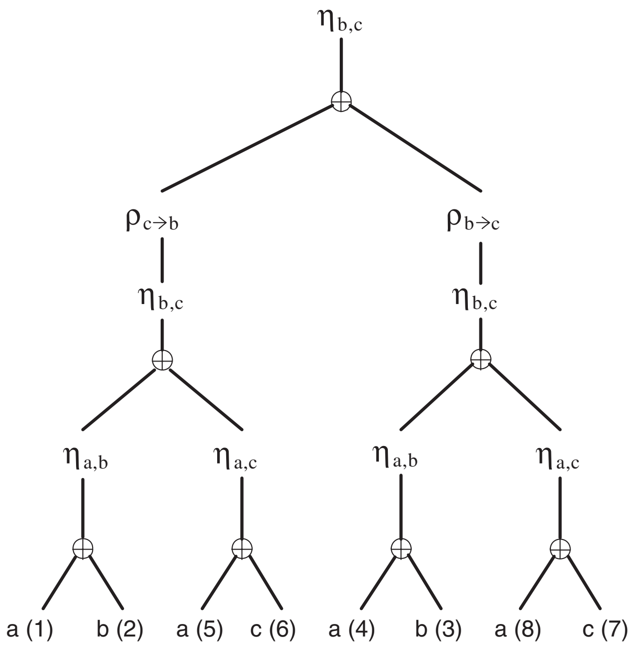

FIG. 3. *The optimum clique-width parse tree for the graph of Figure* 1 *corresponding to the* 3-*expression of Figure* 2.

to the 3-expression $t$ presented in Figure 2.

As mentioned above, $G$ being a partial $k$-tree is equivalent to $G$ having treewidth at most $k$. We now define $k$-trees and present notation for the $k$-tree that will be used to establish the upper and lower bounds presented in sections 3 and 4.

We denote by $K_k$ the clique with $k$ vertices. For a vertex $v$ and a set of vertices $S$ we say that $v$ is *universal* to $S$ if $v$ is adjacent to all the vertices in $S$. A graph $G$ is a *$k$-tree* if $G$ is either a $K_k$ or is formed from a $k$-tree $G'$, by adding a new vertex that is universal to a $K_k$ in $G'$. Thus, a $k$-tree $G$ can be constructed by taking an initial $K_k$ of $G$ and adding the other vertices of $G$ one after the other. At each step a new vertex $x$ is added to $G$ that is universal to a $k$-clique (denoted by $Q_x$) in $G$, consisting of $k$ vertices that were added to $G$ before $x$.

Note that 1-trees are precisely trees. $G$ is a *partial $k$-tree* (i.e., $twd(G) \leq k$) if $G$ is a partial subgraph of a $k$-tree. This recursive definition of $k$-trees immediately suggests that the construction of a given $k$-tree $G$ can be represented by a tree $T_G$ as defined below.

We let the initial $K_k$ be on the vertices $\{1, 2, \ldots, k\}$ and assume that the rest of the vertices of $G$ are numbered $k+1, k+2, \ldots, n$ in the order in which they were added to $G$. The nodes of the tree $T_G$ correspond to vertices $k, k+1, \ldots, n$ of $G$, where each node $i$ of $T_G$ corresponds to vertex $i$ of $G$. The root of $T_G$, denoted by $R$, corresponds to vertex $k$ of $G$. As mentioned above, when a vertex $i$ is added to the graph $G$, it is made universal to $Q_i$, a $k$-clique that consists of $k$ vertices that were added to $G$ before $i$. We denote by $p(i)$ the largest (according to the numbering of the vertices) vertex in $Q_i$. The tree $T_G$ is constructed by making each node $i$, $i > k$, of $T_G$, a child of $p(i)$.

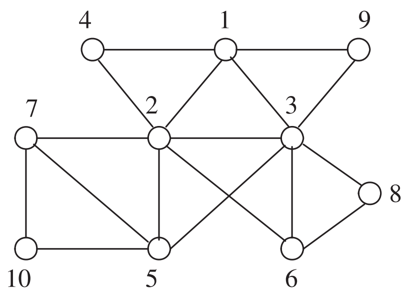

FIG. 4. *A 2-tree.*

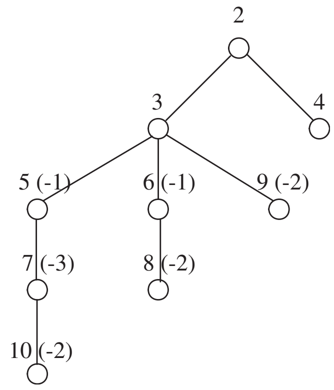

FIG. 5. *The construction tree for the graph of Figure 4.*

If $i$ is not a child of the root $R$, then $Q_i$ can be obtained from $Q_{p(i)}$ by removing vertex $j$ for some $j$ in $Q_{p(i)}$, $1 \leq j < p(i)$, and replacing it with vertex $p(i)$. In this case we will say that node $i$ is a $-j$ child of node $p(i)$ in the tree $T_G$. (Figure 4 contains an example of a 2-tree, and Figure 5 contains its construction tree.) If $i$ is a child of $R$, then $Q_i$ must be equal to $\{1, 2, \ldots, k\}$. Note that for the root $R$, $Q_R$ is not defined.

For a node $i$ of $T_G$ other than the root $R$, we call the $k-1$ vertices of $Q_i - \{p(i)\}$ the *sources* of $i$. Clearly, the sources of $i$ that are not in $\{1, 2, \ldots, k\}$ are ancestors of $i$ in the tree $T_G$.

## 3. Upper bound.

We now turn our attention to establishing the upper bound stated in Theorem 1.2.

THEOREM 1.2. *If the treewidth of $G$ is $k$, then $cwd(G) \leq 2^k + 2^{k-1}$* $(= 3 * 2^{k-1})$.

The bound is achieved for a $k$-tree, and in our proof, we will first prove it for $G$ a $k$-tree and then indicate the modifications for partial $k$-trees. We present an algorithm that is guaranteed to generate a clique-width expression that uses at most $3 * 2^{k-1}$ labels. It should be clear to the reader that this algorithm is an extension of the standard algorithm that shows that the clique-width of a tree (i.e., a 1-tree) is at most three.

Given $G$, let $T_G$ be a construction tree for it. For $x$, a node in $T_G$, we let $T_x$ denote the subtree of $T_G$ rooted at $x$. In the algorithm we will use the following two "metaoperations":

- Let $L = \{l_1, l_2, \ldots, l_h\}$ be a set of labels and let $l^*$ be another label. Then $\eta_{l^*,L}$

denotes the following sequence of $\eta$ operations: $\eta_{l^*,l_1}\,\eta_{l^*,l_2}\cdots\eta_{l^*,l_h}$. (Note that since there are no $\rho$ or $\oplus$ operations in the sequence, the order of these $\eta$ operations is not important.)

- Let $P = \{(l_1,l'_1),(l_2,l'_2),\dots,(l_h,l'_h)\}$ be a set of pairs of labels such that no label in $\{l_1,l_2,\dots,l_h\}$ is equal to a label in $\{l'_1,l'_2,\dots,l'_h\}$ and $l_i \neq l_j$ for $i \neq j$. Then $\rho_P$ denotes the following sequence of $\rho$ operations: $\rho_{l_1\to l'_1}\,\rho_{l_2\to l'_2}\cdots\rho_{l_h\to l'_h}$. (Note the requirements that no label in $\{l_1,l_2,\dots,l_h\}$ is equal to a label in $\{l'_1,l'_2,\dots,l'_h\}$ and $l_i \neq l_j$ imply that the order of these $\rho$ operations is not important.)

ALGORITHM 1.

**Overview.** The algorithm will proceed by bottom-up dynamic programming on $T_G$. Let $x$ be an arbitrary nonroot vertex in $T_G$ where the sources of $x$ are $\{s_1,s_2,\dots,s_{k-1}\}$ and $p(x)$ is $s_k$. Each child of $x$ will be a $-s_i$ node for some $i$ in $\{1,2,\dots,k\}$ (i.e., such a node will be universal to the $k$-clique consisting of $\{s_1,s_2,\dots,s_k\}-\{s_i\}\cup\{x\}$). Note that the subtree rooted at a $-s_i$ child of $x$ could contain vertices universal to any subset of $\{s_1,s_2,\dots,s_k\}-\{s_i\}\cup\{x\}$. When processing $x$ it will be assumed that the subtrees rooted at children of $x$ have a corresponding clique-width expression whose generation required at most $3*2^{k-1}$ labels and that each vertex in the subtree rooted at a $-s_i$ child of $x$ is labeled with one of $2^k$ labels indicating the subset of $\{s_1,s_2,\dots,s_k\}-\{s_i\}\cup\{x\}$ to which it is universal (clearly this assumption holds for the leaves of $T_G$).

The algorithm, using at most $3*2^{k-1}$ labels, will construct the clique-width expression $t_x$ for $T_x$ so that each vertex in $T_x$ is assigned one of $2^k$ labels indicating the subset of $\{s_1,s_2,\dots,s_k\}$ to which it is adjacent. For $1\le i\le k$, let $y_i$ denote a $-s_i$ child of $x$. Let set $\mathcal{T}_i$ be $\{T_{y_i} : y_i \text{ is a } -s_i \text{ child of } x\}$. All vertices in $\mathcal{T}_i$ adjacent to the same subset of $\{s_1,s_2,\dots,s_k\}-\{s_i\}\cup\{x\}$ will be assumed to have the same label. In particular, we let $t_i$ denote the clique-width expression for $\mathcal{T}_i$, constructed by the algorithm. We assume that the graph $val(t_i)$ has $2^k$ labels, each label corresponding to a subset of $\{s_1,\dots,s_k\}-\{s_i\}\cup\{x\}$. For each vertex $w$ in $val(t_i)$, its label indicates the set of vertices in $\{s_1,\dots,s_k\}-\{s_i\}\cup\{x\}$ to which it is adjacent. The labeling of the vertices in $val(t_1), val(t_2),\dots,val(t_k)$ is unique in the sense that the same label will be used in the various $val(t_i)$ to indicate a particular subset of $\{s_1,\dots,s_k\}\cup\{x\}$.

We now describe the steps of the algorithm. Steps 1 and 2 create $t_x$, the clique-width expression of $T_x$, for $x$ a nonroot vertex. Step 3 processes the root.

**Step 1.** Let $X$ be an arbitrary subset of $\{s_2,\dots,s_k\}$ and let $l_X$ (respectively, $l_{X\cup\{x\}}$) denote the label corresponding to $X$ (respectively, $X\cup\{x\}$). The set $\{l_{X\cup\{x\}} : X\subseteq\{s_2,\dots,s_k\}\}$ will be represented by $L_1$, and the set of pairs $\{(l_{X\cup\{x\}}, l_X) : X\subseteq\{s_2,\dots,s_k\}\}$ will be represented by $P_1$. The following operation will form the new clique-width expression $t'_1$ that introduces vertex $x$ where vertex $x$ is assigned a label (denoted $l^*$) that corresponds to the set $\{s_1,\dots,s_k\}$; note that since $x$ is the only vertex in $T_x$ adjacent to $\{s_1,s_2,\dots,s_k\}$, its label will not appear in any $t_i$, $1\le i\le k$. Recall that $t_1$ is the clique-width expression for $\mathcal{T}_1$:

$$t'_1 = \rho_{P_1}\,(\eta_{l^*,L_1}\,(l^*(x)\oplus t_1)).$$

This operation constructs a new union node with the two children being $x$ and the clique-width expression for $\mathcal{T}_1$. The $\eta_{l^*,L_1}$ operation adds all appropriate edges to $x$, and the $\rho_{P_1}$ operation "collapses" label class $X\cup\{x\}$ into $X$ for each $X\subseteq\{s_2,s_3,\dots,s_k\}$.

**Step 2.** For $i$ from 2 to $k$ consider the subtrees $\mathcal{T}_i$ rooted at the $-s_i$ children of $x$. We let $t'_{i-1}$ denote the clique-width expression formed after considering $\mathcal{T}_1 \cup \cdots \cup \mathcal{T}_{i-1}$. For each $i$, let $L_i$ be the set of labels $\{l_{X\cup\{x\}} : X \subseteq \{s_1, s_2, \ldots, s_{i-1}, s_{i+1}, \ldots, s_k\}\}$ and let $P_i$ be the set of pairs of labels $\{(l_{X\cup\{x\}}, l_X) : X \subseteq \{s_1, s_2, \ldots, s_{i-1}, s_{i+1}, \ldots, s_k\}\}$. The following operation will form $t'_i$ from the clique-width expression $t'_{i-1}$ by incorporating $t_i$, the clique-width expression for $\mathcal{T}_i$ (recall that $l^*$ is the label of $x$):

$$t'_i = \rho_{P_i}\ (\eta_{l^*,L_i}\ (t'_{i-1} \oplus t_i)).$$

This operation constructs a new union node with the two children being $t'_{i-1}$ and the clique-width expression for $\mathcal{T}_i$. As in Step 1, via a series of $\eta$ operations we add all the edges from appropriate vertices in $\mathcal{T}_i$ to vertex $x$ and then "collapse" label class $X \cup \{x\}$ into $X$ for each $X \subseteq \{s_1, s_2, \ldots, s_{i-1}, s_{i+1}, \ldots, s_k\}$.

After the loop ends, we set $t_x = t'_k$.

**Step 3.** Suppose that the children of the root $R$ are $\{x_1, x_2, \ldots, x_j\}$ and that each of $T_{x_1}, T_{x_2}, \ldots, T_{x_j}$ has been processed as above, resulting in clique-width expressions $t_{x_1}, t_{x_2}, \ldots, t_{x_j}$, respectively. Each vertex in $T_{x_1} \cup T_{x_2} \cup \cdots \cup T_{x_j}$ is adjacent to some subset of $\{1, 2, \ldots, k\}$, where all vertices adjacent to a particular subset have the same label. Let $l^*_1, l^*_2, \ldots, l^*_k$ denote new labels (they will be used in the creation of the vertices $1, 2, \ldots, k$) and define set $L_i$, $1 \le i \le k$, to be the union of $\{l^*_h : i < h \le k\}$ and the labels corresponding to subsets of $\{1, \ldots, k\}$ that contain vertex $i$. (Note that $L_i$ represents the vertices that are adjacent to $i$.)

The clique-width expression for the entire graph is

$$t_R = \eta_{l^*_k,L_k}\ (\cdots \eta_{l^*_2,L_2}\ (\eta_{l^*_1,L_1}\ (l^*_1(1) \oplus \cdots \oplus l^*_k(k) \oplus t_{x_1} \oplus \cdots \oplus t_{x_j}))\cdots).$$

Note that this operation forms the vertices in the clique $K$ with the $l^*_i(i)$ operations and forms the union of all these vertices and the $\{t_{x_i}\}$ expressions. Finally, the $\eta_{l^*_i,L_i}$ metaoperations add the edges in $K$ as well as the edges between $K$ and the rest of the graph.

*Example* 3.1. Consider the graph in Figure 4 and its construction tree presented in Figure 5. The $3*2^{2-1} = 6$ labels used by the algorithm will be denoted $a, b, c, d, e, f$. We construct the clique-width expression for the graph as indicated by the algorithm from bottom to top. At each step we indicate the set of vertices corresponding to the labels $a, b, \ldots, f$. Note that the same label (e.g., $a$) can correspond to different subsets of vertices at different stages of the algorithm.

When the algorithm processes $T_{10}$ (i.e., the leaf 10) it creates vertex number 10 and gives it label $a$. That is, the clique-width expression corresponding to $T_{10}$ is $a(10)$, where label $a$ corresponds to the set $\{5, 7\}$ consisting of 5 (the source of 10) and 7 (the parent of 10). When the algorithm processes $T_7$ (in Step 1) the clique-width expression for $T_7$ will be $t'_1 = \rho_{P_1}\ (\eta_{l^*,L_1}\ (l^*(7) \oplus t_1))$. In the last formula $t_1$ is the clique-width expression for $T_{10}$, which is $a(10)$, and the label $l^*$ is a new label corresponding to the set $\{2, 5\}$ that we denote by $b$. The sequence $\eta_{l^*,L_1}$ will reduce to $\eta_{b,a}$, and the sequence $\rho_{P_1}$ will reduce to renaming the label corresponding to the set $\{5, 7\}$ to the label corresponding to the set $\{5\}$. Since we do not have (in the current expression) a label corresponding to the set $\{5\}$ we can omit the $\rho_{P_1}$ from the formula and remember that label $a$ now corresponds to the set $\{5\}$. Thus the clique-width expression for $T_7$ is $\eta_{a,b}\ (b(7) \oplus a(10))$, where label $a$ corresponds to the set $\{5\}$ and label $b$ corresponds to the set $\{2, 5\}$.

Similarly, the clique-width expression obtained by the algorithm for $T_5$ is $\eta_{a,c}\ (\eta_{b,c}\ (c(5) \oplus \eta_{a,b}\ (b(7) \oplus a(10))))$, where label $c$ corresponds to $\{2, 3\}$, label $a$ corresponds to $\{\}$, and label $b$ corresponds to $\{2\}$. We denote the last expression by $z_5$.

When the algorithm processes $T_6$, the clique-width expression obtained is $\eta_{a,b}\ (b(6) \oplus a(8))$, where $a$ corresponds to $\{3\}$ and $b$ corresponds to $\{2, 3\}$. We denote the last expression by $z_6$. Since $T_6$ and $T_5$ have the same parent, the vertices in $val(z_6)$ are renamed in order to follow the assumption of the algorithm that labels corresponding to the same subset of vertices in $val(z_5)$ and in $val(z_6)$ are unique. Since label $b$ of $val(z_6)$ is the same as label $c$ of $val(z_5)$, label $b$ of $val(z_6)$ is renamed to $c$. Since label $a$ of $val(z_6)$ is different from label $a$ of $val(z_5)$, label $a$ of $val(z_6)$ is renamed to $d$. Thus the algorithm sets $z_6 = \rho_{b \to c}\ (\rho_{a \to d}\ (z_6))$, where labels $c$ and $d$ of $val(z_6)$ correspond to the sets $\{2, 3\}$ and $\{3\}$, respectively.

We now consider the actions of Steps 1 and 2 on $T_3$. The source of 3 is 1 and $p(3) = 2$. By definition, $\mathcal{T}_1 = T_5 \cup T_6$ and $\mathcal{T}_2 = T_9$, and $t_1$ and $t_2$ are the clique-width expressions of $\mathcal{T}_1$ and $\mathcal{T}_2$, respectively. The clique-width expression $t_1$ is the union of the clique-width expressions corresponding to $T_5$ and $T_6$. Thus $t_1 = z_5 \oplus z_6$, where labels $a$, $b$, $c$, and $d$ of $val(t_1)$ correspond to the sets $\{\}$, $\{2\}$, $\{2, 3\}$, and $\{3\}$, respectively. Similarly, $t_2 = e(9)$, where label $e$ corresponds to the set $\{1, 3\}$.

Now in Step 1, vertex 3 is processed together with $t_1$, yielding $t'_1 = \rho_{c \to b}\ (\rho_{d \to a}\ (\eta_{f,d}\ (\eta_{f,c}\ (f(3) \oplus t_1))))$, where labels $a$, $b$, and $f$ correspond to sets $\{\}$, $\{2\}$, and $\{1, 2\}$, respectively.

Step 2 yields $t_3 = t'_2 = \eta_{f,e}\ (t'_1 \oplus e(9))$, where labels $a$, $b$, $e$, and $f$ correspond to the sets $\{\}$, $\{2\}$, $\{1\}$, and $\{1, 2\}$, respectively.

Finally, we examine the outcome of Step 3, which calculates the clique-width expression of the graph. Note that $t_4 = f(4)$, where the label $f$ corresponds to the set $\{1, 2\}$:

$$t_R = \eta_{b,c}\ (\eta_{e,d}\ (\eta_{f,c}\ (\eta_{f,d}\ (\eta_{c,d}\ (c(2) \oplus d(1) \oplus t_3 \oplus t_4))))).$$

*Proof of correctness.* We now show that the above algorithm will construct an expression tree for $G$ and will use no more than $3 * 2^{k-1}$ labels. The fact that $G$ is the value of the clique-width expression constructed by the algorithm follows by a straightforward induction argument.

LEMMA 3.2. *The algorithm requires at most* $3 * 2^{k-1}$ *labels.*

*Proof.* First we note that a clique-width expression $t$ uses at most $h$ labels if and only if every subexpression $t'$ of $t$ uses at most $h$ labels. So, we assume by induction that for a nonroot vertex $x \in T_G$, all subexpressions $t_1, t_2, \ldots, t_k$ use at most $3 * 2^{k-1}$ labels and show that this is also true for the clique-width expression built for $t_x$ by the above algorithm. We also assume by induction that for $1 \le i \le k$, $val(t_i)$ has at most $2^k$ labels, and that these labels correspond to subsets of $\{s_1, \ldots, s_{i-1}, s_i, \ldots, s_k, x\}$. Clearly these assumptions hold for the leaves of $T_G$.

We will show that $val(t_x)$ has at most $2^k$ labels and that these labels correspond to subsets of $\{s_1, \ldots, s_k\}$. We will also show that $t_x$ does not use more than $2^k + 2^{k-1}$ $(= 3 * 2^{k-1})$ labels.

First by induction we assume that $t_1$ does not use more than $3 * 2^{k-1}$ labels and that the $val(t_1)$ labels correspond to the subsets of $\{s_2, \ldots, s_k, x\}$. Thus $val(l^*(x) \oplus t_1)$ has at most $2^k + 1$ labels. Due to the $\rho_{P_1}$ operation in Step 1 of the algorithm, all the labels of $val(t'_1)$ correspond to some (but not all) subsets of $\{s_1, \dots, s_k\}$. Now examine the clique-width expression $t_i$, $i > 1$ (Step 2). By induction, all $val(t_i)$ labels correspond to subsets of $\{s_1, \dots, s_{i-1}, s_{i+1}, \dots, s_k, x\}$. All $val(t'_{i-1})$ labels correspond to subsets of $\{s_1, \dots, s_k\}$. Thus the only new labels that $val(t'_{i-1})$ can add (to the labels of $val(t_i)$) are those labels that contain $s_i$ and there are at most $2^{k-1}$ such labels. Thus the graph $val(t'_{i-1} \oplus t_i)$ has at most $2^k + 2^{k-1}$ labels. Again, due to the $\rho_{P_i}$ operation, all the labels of $val(t'_i)$ are subsets of $\{s_1, \dots, s_k\}$. Thus the subexpression $t'_k$ $(= t_x)$ uses at most $3 * 2^{k-1}$ labels and $val(t_x)$ has at most $2^k$ labels, corresponding to the subsets of $\{s_1, \dots, s_k\}$, as required.

We now turn our attention to the root (Step 3 of the algorithm). In particular we show that the algorithm uses no more than $3 * 2^{k-1}$ labels. The fact that the algorithm requires no more than $3 * 2^{k-1}$ labels to process the children of the root follows immediately from the argument above. Note that equality may be achieved when $i = k$. To process the root, we note that $2^k$ labels (i.e., corresponding to all subsets of $\{1, 2, \dots, k\}$) are needed in $t_{x_1} \cup t_{x_2} \cup \cdots \cup t_{x_j}$. Similarly, $k$ different labels (i.e., $l^*_1, l^*_2, \dots, l^*_k$) are needed to label $1, 2, \dots, k$. Since $2^k + k \leq 3 * 2^{k-1}$ for $k \geq 1$, the result follows. $\square$

To finish the proof of Theorem 1.2 we just have to show that the algorithm will also work for partial $k$-trees. To see this, we first note that a partial $k$-tree may be constructed in a similar way as a $k$-tree. In particular, given a partial $k$-tree $G$, consider the construction tree $T_{G'}$ for $G'$, a $k$-tree that contains $G$. Since any initial graph on $k$ vertices, or fewer, can be formed using at most $k$ labels and the algorithm does not depend on the subset of existing vertices to which a vertex is adjacent being a clique, we see that a slight modification to the algorithm (namely, allowing each vertex to be adjacent to at most $k$, rather than exactly $k$, ancestors) solves the problem for partial $k$-trees as well.

## 4. Lower bound.

The purpose of this section is to establish the lower bound stated in Theorem 1.3.

THEOREM 1.3. *For any $k$, there is a graph $G$ where $twd(G) = k$ and $cwd(G) \geq 2^{\lfloor k/2 \rfloor - 1}$.*

Since the clique-width of any graph is at least one, the theorem is clearly true for $k$ at most three. Our proof assumes $k$ is at least four, and in particular, we define a $k$-tree $F$ and prove that $cwd(F) \geq 2^{\lfloor k/2 \rfloor - 1}$.

Using the notation of section 2, we define the $k$-tree $F$ by its construction tree $T_F$. Let the vertices of $F$ be numbered $\{1, \dots, n\}$. Like any $k$-tree, $F$ can be constructed by starting with the initial $k$-clique $\{1, \dots, k\}$ and at each step adding a new vertex $i$ that is universal to a $k$-clique in the intermediate graph, which we denote by $Q_i$.

The tree $T_F$ corresponds to the construction mentioned above. In the following we denote $T_F$ by $T$. Each node $i$ of the tree $T$ corresponds to vertex $i$ of $F$. The root of $T$ is denoted by $R$ and corresponds to vertex $k$ of $F$. The root $R$ has one child denoted by $B$ that corresponds to vertex $k+1$ of $F$. Clearly, $Q_B = \{1, 2, \dots, k\}$.

Let $L^j$ denote the set of all nodes of the tree $T$ that are at distance $j$ from the root $R$. We call $L^j$ the $j$th level of the tree $T$. Clearly $L^0 = \{R\}$ and $L^1 = \{B\}$. The tree $T$ has $\alpha$ levels, where $\alpha = (2k+1)2^{\lfloor k/2 \rfloor + 1}$. For $2 \leq l \leq \alpha$, the $l$th level of the tree $T$, $L^l$ is defined as follows:

- For every node $x$ of the $(l-1)$st level $L^{l-1}$, add $k$ new nodes $\{x_1, x_2, \dots, x_k\}$ to the $l$th level $L^l$, all of which are children of $x$ such that the following holds:
  - Let $Q_x = \{y_1, \dots, y_k\}$ be the $k$-clique to which $x$ is universal. Then for $1 \leq i \leq k$, $x_i$ is the $-y_i$ child of $x$. In other words, $x_i$ is universal to the $k$-clique $Q_{x_i} = Q_x \cup \{x\} - \{y_i\}$.

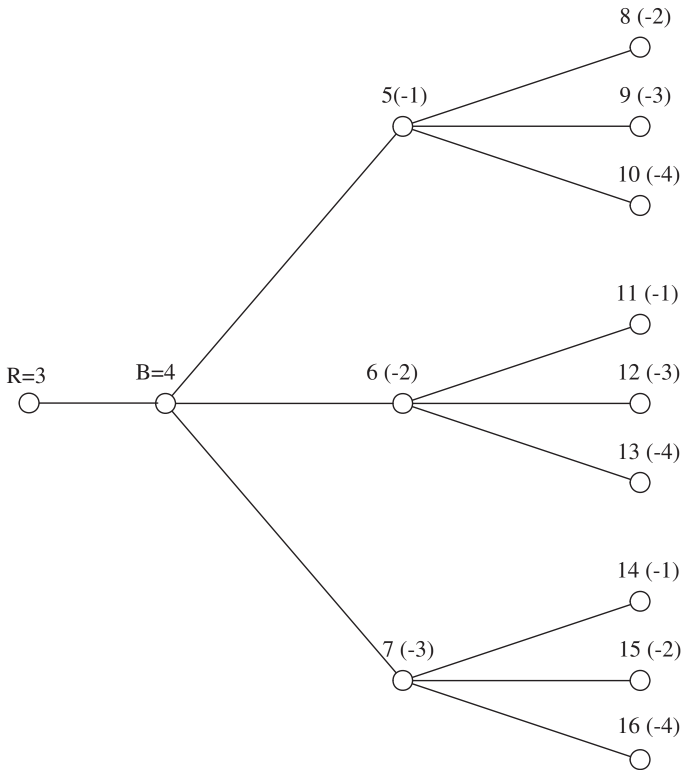

FIG. 6. *The beginning of the construction tree $T$ for the graph $F$ when $k$ is three.*

Note that all the leaves of $T$ are in level $L^\alpha$ and all internal nodes of $T$, except the root $R$, have exactly $k$ children.

*Example* 4.1. Figure 6 illustrates the beginning of the construction tree $T$ for the graph $F$ when $k$ is three. The root of this tree is $R$ which corresponds to vertex 3 of $F$. The root $R$ has one child $B$ which corresponds to vertex 4 of $F$. Level $L^0 = \{R\}$, level $L^1 = \{B\}$, level $L^2 = \{5, 6, 7\}$, and level $L^3 = \{8, 9, \dots, 16\}$. We omit from the figure the $k$-clique to which each node of the tree is universal. Instead, we employ a $(-i)$ label for a node $u$ indicating that $u$ is the $-i$ child of its parent. For example, node 12 is the $-3$ child of node 6, which is the $-2$ child of node 4. The $k$-clique to which node 12 is universal is $Q_{12} = \{1, 4, 6\}$. The parent of vertex 12 is $p(12) = 6$. Figure 7 illustrates the graph corresponding to the construction tree $T$ of Figure 6. Note that the graph of Figure 7 is the subgraph of the graph $F$ for $k$ equals three, induced by the vertices $\{1, 2, \dots, 16\}$.

The following four facts follow from the above definitions.

FACT 4.2. *Let $u, v$ be any two vertices of $F$ not in $Q_B = \{1, \dots, k\}$, such that $u$ is adjacent to $v$ in $F$. Then $u$ is either an ancestor or a descendant of $v$ in $T$.*

*Proof.* In the construction of $F$, whenever a new vertex (say $x$) is added it is made universal to a $k$-clique of vertices (denoted $Q_x$) that were already added to $F$. If a vertex $y$ was added to $F$ before $x$, then $x$ is adjacent to $y$ if and only if $y$ is in $Q_x$. An easy induction on the construction of the tree $T$ shows that for every node $x$ of $T$ that is not in $Q_B$, all the vertices of $Q_x$ that are not in $Q_B$ are ancestors of $x$ in $T$. Let $u$ and $v$ be two nodes of $T$ that are not in $Q_B$, such that vertices $u$ and $v$ are

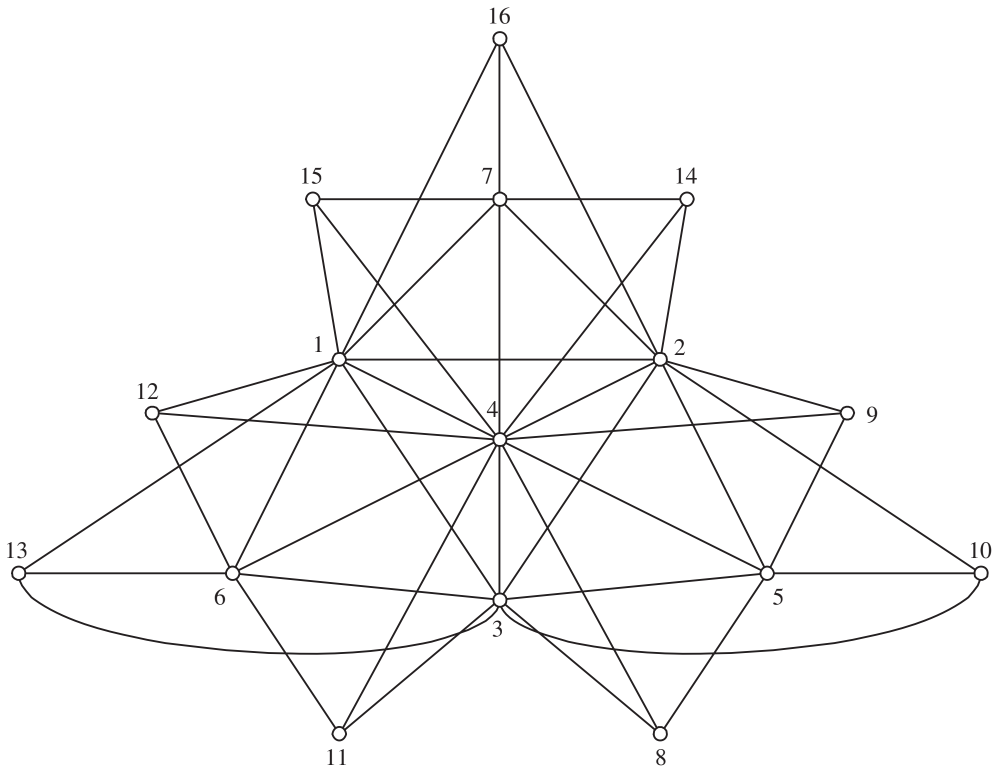

FIG. 7. *The graph corresponding to the construction tree of Figure* 6.

adjacent in $F$. Assume without loss of generality that $u$ was added to $F$ before $v$. Since $u$ is adjacent to $v$, $u$ must be in $Q_v$. By the above argument, all vertices of $Q_v$ are ancestors of $v$. Thus, $u$ must be an ancestor of $v$. □

FACT 4.3. *Let $u, w$ be any two adjacent vertices of $F$ not in $Q_B = \{1, \ldots, k\}$, such that $w$ is a descendant of $u$ in $T$. Then $u$ is in $Q_w$.*

*Proof.* From the construction of $F$, vertex $u$ is added to $F$ before $w$. When $w$ is added to $F$, it is made adjacent to all vertices of the $k$-clique $Q_w$. All the vertices of $F$ that are not in $Q_w$ and were added to $F$ before $w$ cannot be adjacent to $w$. Since $u$ is adjacent to $w$ we conclude that $u$ must be in $Q_w$. □

FACT 4.4. *Let $u, v, w$ be any three different vertices of $F$ not in $Q_B = \{1, \ldots, k\}$, such that $v$ is a descendant of $u$ in $T$, $w$ is a descendant of $v$ in $T$, $v$ is not adjacent to $u$ in $F$, and $w$ is adjacent to $v$ in $F$. Then $w$ is not adjacent to $u$ in $F$.*

*Proof.* Suppose $w$ is adjacent to $u$ in $F$. By Fact 4.3, both $v$ and $u$ belong to $Q_w$. Thus since $Q_w$ is a clique, $u$ must be adjacent to $v$ in $F$, a contradiction. □

FACT 4.5. *Let $u, w$ be any two vertices of $F$ not in $Q_B = \{1, \ldots, k\}$, such that $w$ is a child of $u$ in $T$. Then $Q_u - \{p(u)\} = Q_w - \{p(w)\}$ if and only if $w$ is the $-p(u)$ child of $u$.*

*Proof.* Suppose $w$ is the $-p(u)$ child of $u$. By definition, $Q_w = Q_u \cup \{u\} - \{p(u)\}$. Since $u = p(w)$ we conclude that $Q_w - \{p(w)\} = Q_u - \{p(u)\}$.

Suppose $Q_u - \{p(u)\} = Q_w - \{p(w)\}$. If $w$ is not the $-p(u)$ child of $u$, then $Q_w = Q_u \cup \{u\} - \{t\}$ for some vertex $t \in Q_u$ different from $p(u)$. Substituting $u = p(w)$, we see that $Q_w - \{p(w)\} = Q_u - \{t\}$, which contradicts $Q_u - \{p(u)\} = Q_w - \{p(w)\}$.

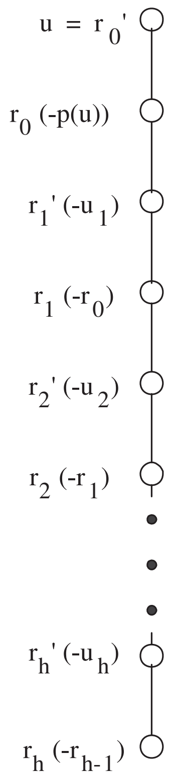

FIG. 8. *The nodes of the tree $T_u$ defined in the proof of Claim* 4.6.

Thus, $w$ must be the $-p(u)$ child of $u$. ◻

For a node $x$ of $T$, we denote by $T_x$ the subtree of $T$ rooted at $x$. We denote by $L_x^j$ the $j$th level of the tree $T_x$. We say that $T_x$ is a *complete tree* if $L_x^{2k+1}$ is not empty (i.e., the distance in $T$ between $x$ and the root $R$ is at most $\alpha - (2k+1)$). We now establish some properties of complete trees that will be used in subsequent arguments.

CLAIM 4.6. *Let $u$ be a node of $T$ other than the root $R$, such that $T_u$ is a complete tree in $T$. Then for every $S \subseteq Q_u - \{p(u)\}$, there exists vertex $r_S \in N_F[u] \cap T_u$ such that $(Q_{r_S} - \{p(r_S)\}) \cap (Q_u - \{p(u)\}) = S$. Furthermore, these $r_S$ vertices can be chosen such that the set $\mathcal{S} = \{r_S : S \subseteq Q_u - \{p(u)\}\} - \{u\}$ is an independent set.*

*Proof.* If $S = Q_u - \{p(u)\}$, then we take $r_S = u$. Now let $\{u_1, u_2, \ldots, u_h\} = Q_u - (\{p(u)\} \cup S)$. We define nodes in the subtree $T_u$ as presented in Figure 8. Let $r_0$ be the $-p(u)$ child of $u$. By Fact 4.5, $Q_{r_0} - \{u\} = Q_u - \{p(u)\}$. For $i$ from 1 to $h$, we let $r_i'$ be the $-u_i$ child of $r_{i-1}$ and we let $r_i$ be the $-r_{i-1}$ child of $r_i'$. Since $r_{i-1} = p(r_i')$, by Fact 4.5, $Q_{r_i} - \{p(r_i)\} = Q_{r_i'} - \{p(r_i')\}$. We set $r_S = r_h$ and we show that $r_S$ satisfies the required properties. Let $r_0' = u$. Now, by an easy induction on $i$, where $1 \le i \le h$,

$$Q_{r_i} - \{p(r_i)\} = Q_u \cup \{r_j' : 0 \le j < i\} - (\{p(u)\} \cup \{u_1, \ldots, u_i\}).$$

Thus, setting $r_S = r_h$ we see that $r_S$ satisfies the required properties.

We now show that $\mathcal{S}$ is an independent set. Suppose there exist two adjacent vertices $r_{S_1}$ and $r_{S_2}$ in $\mathcal{S}$. By Fact 4.2, $r_{S_1}$ is either an ancestor or a descendant

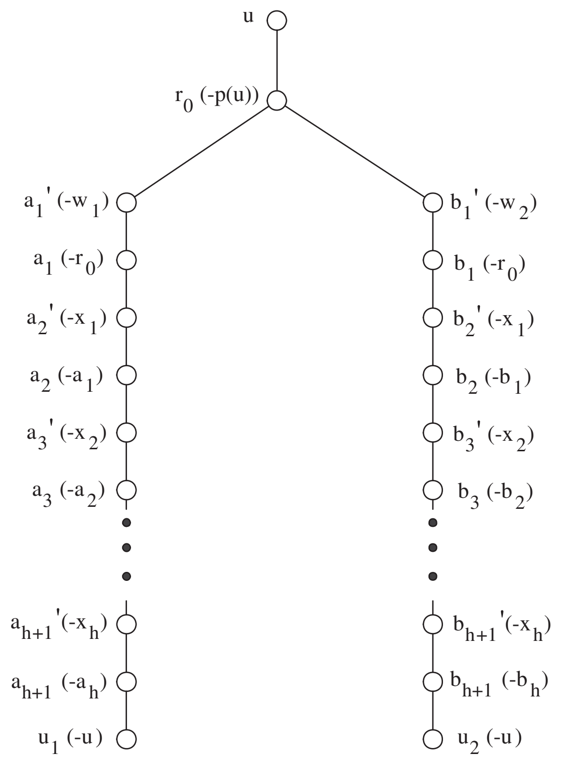

FIG. 9. *The nodes of the tree $T_u$ defined in the proof of Claim* 4.7.

of $r_{S_2}$ in $T$. Assume without loss of generality that $r_{S_1}$ is an ancestor of $r_{S_2}$ (i.e., $S_2 \subset S_1$). By Fact 4.3, $r_{S_1} \in Q_{r_{S_2}}$. By the above construction, there exist integers $x$ and $y$ such that $1 \leq y < x$, $Q_u - (\{p(u)\} \cup S_2) = \{u_1, u_2, \ldots, u_y, \ldots, u_x\}$, $r_{S_2} = r_x$, $Q_u - (\{p(u)\} \cup S_1) = \{u_1, u_2, \ldots, u_y\}$, and $r_{S_1} = r_y$. From the above formula

$$Q_{r_{S_2}} - \{p(r_{S_2})\} = Q_u \cup \{u, r'_1, \ldots, r'_{x-1}\} - (\{p(u)\} \cup \{u_1, \ldots, u_x\}),$$

which implies that $r_{S_1} \notin Q_{r_{S_2}}$, a contradiction. ▯

CLAIM 4.7. *Let $u$ be a node of $T$ other than the root $R$, such that $T_u$ is a complete tree. Then for any $W \subset Q_u - \{p(u)\}$ with $w_1, w_2 \in W$, there exist vertices $u_1, u_2 \in T_u$, at level at most $2k+1$ of $T_u$, such that $u_1$ is neither an ancestor nor a descendant of $u_2$, $Q_{u_i} - \{p(u_i)\} = (W - \{w_i\}) \cup Y_{u_i}$, where $i = 1, 2$, $Y_{u_i} \cap W = \emptyset$, all vertices of $Y_{u_i}$ are in $T_u$, $Y_{u_1} \cap Y_{u_2} = \emptyset$, and no vertex of $Y_{u_1}$ is an ancestor or a descendant of a vertex in $Y_{u_2}$.*

*Proof.* Let $Q_u - \{p(u)\} - W = \{x_1, \ldots, x_h\}$. Thus,

(1) $$W - \{w_1\} = Q_u - \{p(u), w_1, x_1, \ldots, x_h\},$$

(2) $$W - \{w_2\} = Q_u - \{p(u), w_2, x_1, \ldots, x_h\}.$$

We now define nodes in the subtree $T_u$ as presented in Figure 9. Let $r_0$ be the $-p(u)$ child of $u$. Let $a'_1$ be the $-w_1$ child of $r_0$ and let $a_1$ be the $-r_0$ child of $a'_1$. Let $b'_1$ be the $-w_2$ child of $r_0$ and let $b_1$ be the $-r_0$ child of $b'_1$. For $i$ from 2 to $h+1$, let $a'_i$ be the $-x_{i-1}$ child of $a_{i-1}$, let $b'_i$ be the $-x_{i-1}$ child of $b_{i-1}$, let $a_i$ be the $-a_{i-1}$ child of $a'_i$, and let $b_i$ be the $-b_{i-1}$ child of $b'_i$. We set $u_1$ as the $-u$ child of $a_{h+1}$ and $u_2$ as the $-u$ child of $b_{h+1}$. As in the proof of Claim 4.6 we get the following formulas:

$$Q_{a_{h+1}} - \{p(a_{h+1})\} = Q_u \cup \{u, a'_1, \dots, a'_h\} - (\{p(u)\} \cup \{w_1, x_1, \dots, x_h\}), \tag{3}$$

$$Q_{b_{h+1}} - \{p(b_{h+1})\} = Q_u \cup \{u, b'_1, \dots, b'_h\} - (\{p(u)\} \cup \{w_2, x_1, \dots, x_h\}). \tag{4}$$

Since $Q_{u_1} = Q_{a_{h+1}} \cup \{a_{h+1}\} - \{u\}$ we obtain from formula (3) that

$$Q_{u_1} - \{p(u_1)\} = Q_u \cup \{a'_1, \dots, a'_{h+1}\} - (\{p(u)\} \cup \{w_1, x_1, \dots, x_h\}). \tag{5}$$

From formulas (1) and (5) we get

$$Q_{u_1} - \{p(u_1)\} = (W - \{w_1\}) \cup \{a'_1, \dots, a'_{h+1}\}. \tag{6}$$

Similarly, from formulas (2) and (4),

$$Q_{u_2} - \{p(u_2)\} = (W - \{w_2\}) \cup \{b'_1, \dots, b'_{h+1}\}. \tag{7}$$

Thus, setting $Y_{u_1} = \{a'_1, \dots, a'_{h+1}\}$ and $Y_{u_2} = \{b'_1, \dots, b'_{h+1}\}$ we get from formulas (6) and (7) that $Q_{u_i} - \{p(u_i)\} = (W - \{w_i\}) \cup Y_{u_i}$, $i = 1, 2$. Since all the vertices of $Y_{u_i}$, $i = 1, 2$, are below $u$ and all vertices of $W$ are above $u$ in the tree $T$, $W \cap Y_{u_i} = \emptyset$, $i = 1, 2$. Clearly, $Y_{u_1} \cap Y_{u_2} = \emptyset$ and no vertex of $Y_{u_1}$ is an ancestor or a descendant of a vertex in $Y_{u_2}$. $\square$

For a node $x$ of $T$ other than the root $R$, we let $P_x$ denote a path $(x = x_0, x_1, \dots, x_\beta)$ of $T_x$, where $x_\beta$ is a leaf and

($\star$)
- $Q_{x_i} - \{p(x_i)\} = Q_{x_{i-1}} - \{p(x_{i-1})\}$, $i > 0$,
- $p(x_i) = x_{i-1}$, $i > 0$.

FACT 4.8. *Let $x$ be a node of $T$ other than the root $R$ and let $u$ and $v$ be two nonadjacent nodes on the path $P_x$ (that satisfies ($\star$)). Then $u$ and $v$ are not adjacent in $F$.*

*Proof.* We prove the claim by induction on the distance between $u$ and $v$ on the path $P_x$. Since $u$ and $v$ are not adjacent on the path, their distance on the path must be at least two. Assume without loss of generality that $v$ is a descendant of $u$.

Suppose the distance between $u$ and $v$ on the path $P_x$ is two. Since $P_x$ satisfies ($\star$), $v$ is the $-u$ child of $p(v)$, which implies that $u$ is not in $Q_v$. By Fact 4.3, $v$ cannot be adjacent to $u$ in $F$.

Suppose the distance between $u$ and $v$ on the path $P_x$ is greater than two. We can assume, by the induction hypothesis, that $p(v)$ is not adjacent to $u$ in $F$. Now since $v$ is adjacent to $p(v)$ in $F$ and $p(v)$ is not adjacent to $u$ in $F$ we get by Fact 4.4 that $v$ is not adjacent to $u$ in $F$. $\square$

For any node $x$ of $T$ other than the root $R$, where $T_x$ is a complete tree and $Q \subseteq Q_x - \{p(x)\}$, we let $X_x^Q = \{y : y \in L_x^{2k+1} \wedge (Q_y - \{p(y)\}) \cap (Q_x - \{p(x)\}) = Q\}$ (i.e., $X_x^Q$ denotes the set of vertices at level $2k + 1$ whose sources contain $Q$ and no vertices in $Q_x - \{p(x)\} - Q$). Furthermore, we let $P_x^Q = \{P_y : y \in X_x^Q\}$ (i.e., $P_x^Q$ denotes the paths rooted at $y \in X_x^Q$ that satisfy ($\star$) above).

CLAIM 4.9. *Let $x$ be a node in $T$ other than the root $R$, such that $T_x$ is a complete tree, and let $Q \subseteq Q_x - \{p(x)\}$. Then $|X_x^Q| \geq (k - |Q|)^{k+1}$.*

*Proof.* Let $Y^j$, $1 \leq j \leq k + 1$, denote the set of all vertices at level $j$ (of $T_x$) that include all the vertices of $Q$ in their sources. In other words, $Y^j = \{y : y \in L_x^j \wedge Q \subseteq Q_y - \{p(y)\}\}$. Note that any vertex $z$ at level $j$, where $1 \leq j < k + 1$, is created by making it adjacent to $k$ vertices, $|Q|$ of which are forced. Thus $z$ has $k-|Q|$ children that are in $Y^{j+1}$. It follows by a straightforward induction on $j$ that $|Y^j| = (k-|Q|)^j$, $1 \le j \le k+1$.

Let $y$ be a vertex of $Y^{k+1}$. It is easy to see that we can construct a path of length $k$ from $y$ to a vertex $y'$ of level $2k+1$ of $T_x$ such that $Q_{y'} - \{p(y')\} \cap Q_x - \{p(x)\} = Q$. Thus, each vertex $y$ of $Y^{k+1}$ corresponds to a unique vertex $y'$ of $X_x^Q$, implying that $|X_x^Q| \ge |Y^{k+1}| = (k-|Q|)^{k+1}$. $\square$

In order to argue about the clique-width of $F$, we let $\mathcal{T}$ denote an optimum clique-width parse tree for $F$. For $a$ an internal node of $\mathcal{T}$, we let $\mathcal{T}_a$ denote the subtree of $\mathcal{T}$ rooted at $a$ and let $V_a$ represent the leaves (i.e., vertices of $F$) of $\mathcal{T}_a$. As the following claim shows, having a set of vertices outside $V_a$ together with certain neighbors inside $V_a$ establishes a lower bound on the number of distinct labels required at $a$ (i.e., to label the vertices of $V_a$ at node $a$ of $\mathcal{T}$).

CLAIM 4.10. *Let $X$ be a set of $l$ vertices in $V - V_a$, where for each subset $Y$ of these vertices, there is a vertex inside $V_a$ adjacent to all vertices of $Y$ and to no other vertices in $X$. Then at least $2^l$ labels are required to label the vertices of $V_a$.*

*Proof.* For any two vertices $x, y$ inside $V_a$ adjacent to different subsets of $X$, there is at least one vertex outside $V_a$ that is adjacent to $x$ and not to $y$. Thus $x$ and $y$ must have different labels at position $a$ of the parse tree. Since there are $2^l$ such vertices, the result follows. $\square$

For $\mathcal{T}_1$ a subtree of $\mathcal{T}$ and $P_y$ a path of $T$ satisfying ($\star$), we say that $P_y$ is *full with respect to* $\mathcal{T}_1$ if all vertices of $P_y$ are in $\mathcal{T}_1$. Given a set $P_x^Q$, we will often choose a lowest possible internal node of $\mathcal{T}$, say $a$, such that some path in $P_x^Q$ is full with respect to $\mathcal{T}_a$ (i.e., for some path $P \in P_x^Q$ all of its vertices are in $V_a$; $P$ is said to be *full with respect to* $a$). If $T_u \cap V_a = \emptyset$ for some $u$, we say that $T_u$ is *empty with respect to* $a$.

CLAIM 4.11. *Assume $cwd(F) < 2^{\lfloor k/2 \rfloor -1}$. Let $x$ be a node in $T$ other than the root $R$, where $T_x$ is a complete tree, let $Q$ be a strict subset of $Q_x - \{p(x)\}$, and let $a$ be a lowest node in $\mathcal{T}$ such that some path in $P_x^Q$ is full with respect to $a$. Then there is a vertex $y \in X_x^Q$ such that $T_y$ is empty with respect to $a$.*

*Proof.* From the definition of $a$ it follows that $a$ must be an $\oplus$ node. Let $l$ and $r$ be the left and the right child of $a$ in the tree $\mathcal{T}$, respectively. From the definition of $a$ it follows that for each path $P$ in $P_x^Q$ that is full with respect to $a$, the vertices of $P$ are split between the two subtrees $\mathcal{T}_l$ and $\mathcal{T}_r$. Thus, for each path in $P_x^Q$ that is a full path with respect to $a$ in $\mathcal{T}$, at least one edge of the path (in $F$) must be created by an operation above $a$. Thus each such full path requires at least two new labels and these labels cannot be shared by other full paths with respect to $a$ in $P_x^Q$. Since $cwd(F) < 2^{\lfloor k/2 \rfloor -1}$, there are fewer than $2^{\lfloor k/2 \rfloor -2}$ full paths with respect to $a$ in $P_x^Q$. If a tree rooted at $z \in X_x^Q$ is neither empty nor has a full path with respect to $a$, then there is some vertex $w \in T_z$ that is in $V_a$, but $w'$, a neighbor of $w$ (in $T_z$), is not in $V_a$. Thus $w$ must have a new label and its label must be different from all of the pairs of labels required for the full paths and all of the labels required for other "partially present" trees. Now, the number of such partially present trees is less than $2^{\lfloor k/2 \rfloor}$.

Thus in $X_x^Q$ fewer than $2^{\lfloor k/2 \rfloor -2}$ vertices are the roots of full paths and fewer than $2^{\lfloor k/2 \rfloor}$ are the roots of partially present trees. By Claim 4.9, $|X_x^Q| \ge 2^{k+1}$ and thus there is at least one vertex that is the root of an empty tree with respect to $a$. $\square$

In order to prove Theorem 1.3 we will examine the $k$-tree $F$ and proceed by assuming $cwd(F) < 2^{\lfloor k/2 \rfloor -1}$ until we finally reach a contradiction.

Initially we will examine the vertices in $X_B^{2,\dots,k-1}$ and let $a$ be a lowest node in $\mathcal{T}$

such that some path in $P_B^{2,\ldots,k-1}$ is full with respect to $a$. We will then show that at least $\lfloor k/2 \rfloor$ vertices of $\{2,\ldots,k-1\}$ are in $V_a$ and have unique labels (unique in the sense that no two such vertices can have the same label) at $a$. We then proceed by induction by identifying other vertices in $T$ and looking at $b$, a lowest node in $\mathcal{T}$ such that some path rooted at one of these vertices is full with respect to $b$. We show that $V_a \subseteq V_b$ and that the set of vertices requiring unique labels at $a$ also requires unique labels at $b$ and that this set must be augmented by a new vertex that requires a new label. This augmentation continues until eventually this set has cardinality equal to $2^{\lfloor k/2 \rfloor -1}$, contradicting the assumption that $cwd(F) < 2^{\lfloor k/2 \rfloor -1}$, and thereby proving the theorem. The depth of $T$, $\alpha$ is chosen so that all subtrees used to generate full paths are complete and have depth of at least $2^{\lfloor k/2 \rfloor} + 2k + 1$. The length of the full paths generated by these subtrees will be at least $2^{\lfloor k/2 \rfloor}$, since the root of each such path is at level $2k+1$ of its corresponding subtree.

Following the above outline, we start by establishing some claims about $\mathcal{T}_a$.

CLAIM 4.12. *At least $\lfloor k/2 \rfloor$ vertices of $Q_B - \{1,k\}$ (i.e., $\{2,\ldots,k-1\}$) are in $V_a$ and each must have a unique label at $a$.*

*Proof.* Suppose there is a full path $P$ with respect to $a$ rooted at $z \in X_B^{Q_B-\{1,k\}}$. Since such a path has more than $2^{\lfloor k/2 \rfloor}$ vertices, at least two vertices $x$ and $y$ on this path must have the same label at $a$. Suppose $x$ is closer to $z$ than is $y$. Since $z \in X_B^{Q_B-\{1,k\}}$, by definition $(Q_z - \{p(z)\}) \cap (Q_B - \{p(B)\}) = Q_B - \{1,k\}$. Note that $p(B) = k$ (i.e., $R$). Since $P$ is a full path, $Q_z - \{p(z)\} = Q_x - \{p(x)\}$ and thus $(Q_x - \{p(x)\}) \cap (Q_B - \{k\}) = Q_B - \{1,k\}$. By Claim 4.6, for every subset $S$ of $Q_x - \{p(x)\}$, there exists vertex $r_S \in N_F[x] \cap T_x$ such that $(Q_{r_S} - \{p(r_S)\}) \cap (Q_x - \{p(x)\}) = S$. Let $\mathcal{S} = \{r_S : S \subseteq (Q_x - \{p(x)\}) \cap (Q_B - \{k\})\}$.

From the construction of the $r_S$ vertices given in the proof of Claim 4.6 it is clear that all the vertices in $\mathcal{S} - \{x\}$ are not on the path $P$ and therefore are neither ancestors nor descendants of $y$. By Fact 4.2 all these vertices are not adjacent to $y$ and thus must be in $V_a$ since they are adjacent to $x$ but not to $y$, and $x$ and $y$ have the same label at $a$. We have shown that all vertices of $\mathcal{S}$ must be in $V_a$.

Now suppose that fewer than $\lfloor k/2 \rfloor$ vertices of $Q_B - \{1,k\} = (Q_x - \{p(x)\}) \cap (Q_B - \{k\})$ are in $V_a$. Thus there are at least $\lfloor (k-1)/2 \rfloor$ vertices of $(Q_x - \{p(x)\}) \cap (Q_B - \{k\})$ that are outside $V_a$. Let $W'$ denote the set of these vertices and let $\mathcal{W} = \{r_S : S \subseteq W'\}$. Since $\mathcal{W} \subseteq \mathcal{S}$ we have shown above that all the vertices of $\mathcal{W}$ are in $V_a$. For every $S \subseteq W'$ the vertex $r_S$ is in $V_a$ and is adjacent to all the vertices of $S$ and to no other vertices in $W'$. Thus by Claim 4.10, all the vertices of $\mathcal{W}$ must have different labels at $a$. Now at least $|\mathcal{W}| \geq 2^{\lfloor (k-1)/2 \rfloor}$ different labels are needed at $a$. Since $2^{\lfloor (k-1)/2 \rfloor} \geq 2^{\lfloor k/2 \rfloor -1}$ we have contradicted $cwd(F) < 2^{\lfloor k/2 \rfloor -1}$.

Let $W$ denote the subset of $Q_B - \{1,k\}$ that is in $V_a$, where $|W| \geq \lfloor k/2 \rfloor$. We now show that all vertices in $W$ have unique labels at $a$. By Claim 4.11, there exists vertex $u \in X_B^{Q_B-\{1,k\}}$ such that $T_u$ is empty with respect to $a$. By Claim 4.6, for each vertex $w \in W$ there is a vertex $r_S$ in $T_u$ corresponding to the set $S = \{w\}$, such that $r_S$ is adjacent to $w$ and to no other vertex in $W$. Since $r_S$ is outside $V_a$, the label of the vertex $w$ at $a$ must be different from the labels at $a$ of all the other vertices of $W$. $\square$

We now prepare for the general induction step, each execution of which will add one more vertex requiring a new unique label. Thus executing the induction step $2^{\lfloor k/2 \rfloor -1} - \lfloor k/2 \rfloor$ times will complete the proof of the theorem. First we let $W$ denote a subset of $Q_B - \{1,k\}$ such that all elements of $W$ are in $V_a$ and $|W| = \lfloor k/2 \rfloor$. (Note that there may be more elements of $Q_B - \{1,k\}$ that are in $V_a$, but we only consider $\lfloor k/2 \rfloor$ of them.) By Claim 4.12 the set $W$ exists and all the vertices of $W$ have different labels at $a$.

Let $u$ be a vertex in $X_B^{Q_B - \{1,k\}}$ where $T_u$ is empty with respect to $a$. (Vertex $u$ is guaranteed by Claim 4.11.) Let $w_1$ and $w_2$ be arbitrary vertices in $W$. (Note that we require $k$ to be at least four in order to guarantee the existence of $w_1$ and $w_2$.) By Claim 4.7, $T_u$ contains vertices $u_1$ and $u_2$, at level at most $2k+1$ of $T_u$, such that $u_1$ is neither an ancestor nor a descendant of $u_2$ and

- $Q_{u_i} - \{p(u_i)\} = W_{u_i} \cup Y_{u_i}$, $i = 1, 2$, where $W_{u_i} = W - \{w_i\}$, $Y_{u_i} \cap W = \emptyset$, and $Y_{u_1} \cap Y_{u_2} = \emptyset$.

Note that $|W_{u_i}| = \lfloor k/2 \rfloor - 1$. Let $u'_i$ be an arbitrary element in $Y_{u_i}$ for $i = 1, 2$ and set $U = \{u_1, u_2\}$. Clearly, $W = \bigcup\{W_{u_i} : u_i \in U\}$. Let $P_U = \bigcup\{P_{u_i}^{Q_{u_i} - \{u'_i, p(u_i)\}} : u_i \in U\}$ and define $b$ to be a lowest vertex in $\mathcal{T}$ such that some path in $P_U$ is full with respect to $b$.

Note that since at least one path of $P_U$ must be in $V_b$ and all these paths are in $T_u$ and thus are not in $V_a$, we conclude that $b$ is not a descendant of $a$.

Claim 4.13. *$b$ is an ancestor of $a$.*

*Proof.* Suppose not and suppose $z \in X_{u_1}^{Q_{u_1} - \{u'_1, p(u_1)\}}$ is the root of a full path $P$ with respect to $b$, where $b$ is not an ancestor of $a$. Since such a path has more than $2^{\lfloor k/2 \rfloor}$ vertices, at least two vertices $x$ and $y$ on this path must have the same label at $b$. Suppose $x$ is closer to $z$ than is $y$. Since $P$ is a full path, $Q_z - \{p(z)\} = Q_y - \{p(y)\}$ and thus $W_{u_1} \subset Q_y - \{p(y)\}$. By Claim 4.6, for every subset $S$ of $W_{u_1}$, there exists a vertex $r_S \in N_F[y] \cap T_y$ such that $(Q_{r_S} - \{p(r_S)\}) \cap (Q_y - \{p(y)\}) = S$. Let $\mathcal{S} = \{r_S : S \subseteq W_{u_1}\}$ denote the set of all these vertices. From the construction of the $r_S$ vertices given in the proof of Claim 4.6 it is clear that all the vertices in $\mathcal{S} - \{y\}$ are adjacent to $y$ and are not adjacent to $p(y)$. We claim that all these vertices are not adjacent to $x$. If $x$ is the parent of $y$, then all these vertices are not adjacent to $x$, since $x = p(y)$ in this case. If $x$ is not the parent of $y$, then by Fact 4.8, $x$ and $y$ are not adjacent. Since all vertices of $\mathcal{S} - \{y\}$ are adjacent to $y$ and $y$ is not adjacent to $x$, it follows by Fact 4.4 that all these vertices are not adjacent to $x$. Thus, all vertices of $\mathcal{S} - \{y\}$ must be in $V_b$, since they are adjacent to $y$ but not to $x$. By definition, $y$ is in $V_b$ too. We have shown that all vertices of $\mathcal{S}$ must be in $V_b$.

By definition, all the vertices of $W_{u_1}$ are in $V_a$. Since we assume that $b$ is not an ancestor of $a$ and since $b$ cannot be a descendant of $a$ (as noted above) we see that all these vertices are not in $V_b$. For every $S \subseteq W_{u_1}$ there is a vertex $r_S$ in $V_b$ that is adjacent to all the vertices of $S$ and to no other vertices in $W_{u_1}$, and thus by Claim 4.10 all the vertices of $\mathcal{S}$ must have different labels at $b$. Since $|W_{u_1}| = \lfloor k/2 \rfloor - 1$, $|\mathcal{S}| = 2^{\lfloor k/2 \rfloor - 1}$, contradicting $cwd(F) < 2^{\lfloor k/2 \rfloor - 1}$. ∎

Claim 4.14. *For all $u_i \in U$, there is a vertex $y \in X_{u_i}^{Q_{u_i} - \{u'_i, p(u_i)\}}$ such that $T_y$ is empty with respect to $b$.*

*Proof.* If there is a path in $P_{u_i}^{Q_{u_i} - \{u'_i, p(u_i)\}}$ that is full with respect to $b$, this follows immediately from Claim 4.11. Otherwise, all trees rooted at vertices in $X_{u_i}^{Q_{u_i} - \{u'_i, p(u_i)\}}$ are mixed in the sense that some vertices are in $V_b$ and some are not. As in the proof of Claim 4.11, each such tree requires at least one label and these labels must all be different. Now, by Claim 4.9, the number of such trees is at least $2^{k+1}$, contradicting $cwd(F) < 2^{\lfloor k/2 \rfloor - 1}$. ∎

Claim 4.15. *All $W$ vertices have different labels at $b$.*

*Proof.* By the definitions, for all $w \in W$, there exists $u_i \in U$ such that $w \in W_{u_i}$. Now consider two arbitrary vertices $w', w''$ in $W$, and suppose $w' \in W_{u_1}$. (We will show that $w'$ and $w''$ must have different labels at $b$.) Let $y$ be a vertex in $X_{u_1}^{Q_{u_1}-\{u_1',p(u_1)\}}$ such that $T_y$ is empty with respect to $b$ (guaranteed by Claim 4.14). By definition, $(Q_y - \{p(y)\}) \cap (Q_{u_1} - \{p(u_1)\}) = Q_{u_1} - \{u_1', p(u_1)\}$. Since $w' \in Q_{u_1} - \{p(u_1)\}$ and $w'$ is not equal to $u_1'$, we get from the last formula that $w' \in Q_y - \{p(y)\}$.

Suppose $w'' \in Q_y - \{p(y)\}$. By Claim 4.6, there is a vertex $r_S$ in $T_y$ corresponding to the set $S = \{w'\}$, such that $r_S$ is adjacent to $w'$ and to no other vertex in $Q_y - \{p(y)\}$. Since $r_S$ is outside $V_b$ and is adjacent to $w'$ but not to $w''$, $w'$ and $w''$ must have different labels at $b$.

Suppose $w'' \notin Q_y - \{p(y)\}$. Again, let $r_S$ be a vertex (guaranteed by Claim 4.6) in $T_y$ corresponding to the set $S = \{w'\}$, such that $r_S$ is adjacent to $w'$ and to no other vertex in $Q_y - \{p(y)\}$. From the definition of $r_S$ in the proof of Claim 4.6 it is clear that except for $w'$, $r_S$ is adjacent just to vertices in $T_y$ and thus $r_S$ is not adjacent to $w''$. Since $r_S$ is outside $V_b$ and is adjacent to $w'$ but not to $w''$, $w'$ and $w''$ must have different labels at $b$. □

Let $u_1 \in U$ satisfy the existence of a vertex $z \in X_{u_1}^{Q_{u_1}-\{u_1',p(u_1)\}}$ such that $z$ is the root of a full path with respect to $b$.

CLAIM 4.16. *There are at least $\lfloor k/2 \rfloor$ vertices of $Q_{u_1} - \{u_1', p(u_1)\}$ that are in $V_b$.*

*Proof.* This proof is similar to that of Claim 4.12. As mentioned above, we assume that there is a full path $P$ with respect to $b$ rooted at $z \in X_{u_1}^{Q_{u_1}-\{u_1',p(u_1)\}}$. Since the path $P$ has more than $2^{\lfloor k/2 \rfloor}$ vertices, at least two vertices $x$ and $y$ on the path $P$ must have the same label at $b$. Suppose $x$ is closer to $z$ than is $y$. Since $z \in X_{u_1}^{Q_{u_1}-\{u_1',p(u_1)\}}$, by definition $(Q_z - p(z)) \cap (Q_{u_1} - p(u_1)) = Q_{u_1} - \{u_1', p(u_1)\}$. Since $P$ is a full path, $Q_z - \{p(z)\} = Q_x - \{p(x)\}$ and thus $(Q_x - p(x)) \cap (Q_{u_1} - p(u_1)) = Q_{u_1} - \{u_1', p(u_1)\}$. By Claim 4.6, for every subset $S$ of $Q_x - \{p(x)\}$, there exists vertex $r_S \in N_F[x] \cap T_x$ such that $(Q_{r_S} - \{p(r_S)\}) \cap (Q_x - \{p(x)\}) = S$. Let $\mathcal{S} = \{r_S : S \subseteq Q_{u_1} - \{u_1', p(u_1)\}$.

From the construction of the $r_S$ vertices given in the proof of Claim 4.6 it is clear that all the vertices in $\mathcal{S} - \{x\}$ are not on the path $P$ and therefore are neither ancestors nor descendants of $y$. By Fact 4.2 all these vertices are not adjacent to $y$ and thus must be in $V_b$ since they are adjacent to $x$ but not to $y$, and $x$ and $y$ have the same label at $b$. We have shown that all vertices of $\mathcal{S}$ must be in $V_b$.

Now suppose that fewer than $\lfloor k/2 \rfloor$ vertices of $Q_{u_1} - \{u_1', p(u_1)\}$ are in $V_b$. Thus there are at least $\lfloor (k-1)/2 \rfloor$ vertices of $Q_{u_1} - \{u_1', p(u_1)\}$ that are outside $V_b$. Let $M'$ denote the set of these vertices and let $\mathcal{M} = \{r_S : S \subseteq M'\}$. Since $\mathcal{M} \subseteq \mathcal{S}$, we have shown above that all the vertices of $\mathcal{M}$ are in $V_b$. For every set of vertices $S \subseteq M'$ the vertex $r_S$ is in $V_b$ and is adjacent to all the vertices of $S$ and to no other vertices in $M'$. Thus by Claim 4.10 all the vertices of $\mathcal{M}$ must have different labels at $b$. Thus at least $|\mathcal{M}| \geq 2^{\lfloor (k-1)/2 \rfloor}$ different labels are needed at $b$. Since $2^{\lfloor (k-1)/2 \rfloor} \geq 2^{\lfloor k/2 \rfloor - 1}$, we have contradicted $cwd(F) < 2^{\lfloor k/2 \rfloor - 1}$.

Let $M$ denote the subset of $Q_{u_1} - \{u_1', p(u_1)\}$ that is in $V_b$ where $|M| \geq \lfloor k/2 \rfloor$. We now show that all vertices in $M$ have unique labels at $b$. By Claim 4.11, there exists vertex $s \in X_{u_1}^{Q_{u_1}-\{u_1',p(u_1)\}}$ such that $T_s$ is empty with respect to $b$. By Claim 4.6, for each vertex $m \in M$ there is a vertex $r_S$ in $T_s$ corresponding to the set $S = \{m\}$, such that $r_S$ is adjacent to $m$ and to no other vertex in $M$. Since $r_S$ is outside $V_b$, the label of the vertex $m$ at $b$ must be different from the labels at $b$ of all the other vertices of $M$. □

Since $|W_{u_1}| = \lfloor k/2 \rfloor - 1$, there is a vertex $\widetilde{u_1} \in Y_{u_1} - \{u_1'\}$ that is in $V_b$. We now show that at $b$, $\widetilde{u_1}$ has a different label from all the vertices in $W$.

CLAIM 4.17. *At $b$, the label of $\widetilde{u_1}$ is different from the labels needed for the $W$ vertices.*

*Proof.* Suppose $\widetilde{u_1}$ and $w \in W$ have the same label at $b$. By Claim 4.14, there is a $y \in X_{u_1}^{Q_{u_1}-\{u'_1,p(u_1)\}}$ such that $T_y$ is empty with respect to $b$. By the definition of $y$, $Q_{u_1} - \{u'_1, p(u_1)\} \subset Q_y - \{p(y)\}$ and thus $\widetilde{u_1} \in Q_y - \{p(y)\}$. By Claim 4.6, there is a vertex $r_S$ in $T_y$ corresponding to the set $S = \{\widetilde{u_1}\}$, such that $r_S$ is adjacent to $\widetilde{u_1}$ and to no other vertex in $Q_y - \{p(y)\}$. Now, as in the proof of Claim 4.15, regardless of whether $w \in Q_y - \{p(y)\}$, it follows that $r_S$ is adjacent to $\widetilde{u_1}$ but not to $w$. Since $r_S$ is outside $V_b$, it follows that $\widetilde{u_1}$ and $w$ must have different labels at $b$. ∎

Thus this step has shown that at least $\lfloor k/2 \rfloor + 1$ distinct labels are required at $b$. To continue the process, we will augment $W$ with $\widetilde{u_1}$ and we will augment the set $U$ (as shown below) and define $c$ to be a lowest vertex in $\mathcal{T}$ such that some path in $P_U$ is full with respect to $c$. It will then be shown that $c$ is an ancestor of $b$ and that all vertices in $W$ must have different labels at $c$. A new vertex will be identified that must have a different label at $c$ from all vertices in $W$, and it will be added to $W$. This process continues by renaming $c$ to be $b$ and augmenting $U$.

From now on we assume that $W$ is augmented with $\widetilde{u_1}$. (Note that $W_{u_1}$ and $W_{u_2}$ are not changed.) Thus, the size of $W$ is now $\lfloor k/2 \rfloor + 1$. For augmenting $U$ we shall use the two vertices $u_{1,1}$ and $u_{1,2}$ guaranteed by the following claim.

CLAIM 4.18. *Let $\widetilde{w}$ be an arbitrary vertex in $W_{u_1}$. Then there exist vertices $u_{1,1}$ and $u_{1,2}$ in $T_{u_1}$ such that $u_{1,1}$ is neither an ancestor nor a descendant of $u_{1,2}$ and*

- *$Q_{u_{1,1}} - \{p(u_{1,1})\} = W_{u_{1,1}} \cup Y_{u_{1,1}}$, where $W_{u_{1,1}} = W_{u_1}$, and $Y_{u_{1,1}} \cap W = \emptyset$;*
- *$Q_{u_{1,2}} - \{p(u_{1,2})\} = W_{u_{1,2}} \cup Y_{u_{1,2}}$, where $W_{u_{1,2}} = W_{u_1} \cup \{\widetilde{u_1}\} - \{\widetilde{w}\}$, $Y_{u_{1,2}} \cap W = \emptyset$, $Y_{u_{1,1}} \cap Y_{u_{1,2}} = \emptyset$, and no vertex of $Y_{u_{1,1}}$ is an ancestor or a descendant of a vertex in $Y_{u_{1,2}}$.*

*Proof.* Using Claim 4.7 for $u = u_1$, $W = W_{u_1} \cup \{\widetilde{u_1}\}$, $w_1 = \widetilde{u_1}$, and $w_2 = \widetilde{w}$, there exist $u_{1,1}$ and $u_{1,2}$ in $T_{u_1}$ such that $u_{1,1}$ is neither an ancestor nor a descendant of $u_{1,2}$ and

- $Q_{u_{1,1}} - \{p(u_{1,1})\} = W_{u_{1,1}} \cup Y_{u_{1,1}}$, where $W_{u_{1,1}} = W_{u_1}$, $Y_{u_{1,1}} \cap (W_{u_1} \cup \{\widetilde{u_1}\}) = \emptyset$, and $Y_{u_{1,1}}$ is in $T_{u_1}$;
- $Q_{u_{1,2}} - \{p(u_{1,2})\} = W_{u_{1,2}} \cup Y_{u_{1,2}}$, where $W_{u_{1,2}} = W_{u_1} \cup \{\widetilde{u_1}\} - \{\widetilde{w}\}$, $Y_{u_{1,2}} \cap (W_{u_1} \cup \{\widetilde{u_1}\}) = \emptyset$, $Y_{u_{1,2}}$ is in $T_{u_1}$, $Y_{u_{1,1}} \cap Y_{u_{1,2}} = \emptyset$, and no vertex of $Y_{u_{1,1}}$ is an ancestor or a descendant of a vertex in $Y_{u_{1,2}}$.

To complete the proof of the claim we need to show that $Y_{u_{1,i}} \cap W = \emptyset$, $i = 1, 2$. We shall prove it for $i = 1$ (the case for $i = 2$ is the same). Suppose not, and let $t$ be a vertex in $Y_{u_{1,1}} \cap W$. Since $Y_{u_{1,1}} \cap (W_{u_1} \cup \{\widetilde{u_1}\}) = \emptyset$, it follows that $t$ is in $W - (W_{u_1} \cup \{\widetilde{u_1}\})$. By definition of $W$, $t \in W_{u_a}$ for some vertex $u_a$ in $U$ other than $u_1$. (Note that at the beginning there are just $u_1$ and $u_2$ in $U$ and thus in this case $u_a = u_2$. However, we use $u_a$ rather than $u_2$ so that the proof can be also applied for the more general case when the size of $U$ is greater than two.) Thus, $t$ is an ancestor of $u_a$. Now since $t \in Y_{u_{1,1}}$ and all vertices of $Y_{u_{1,1}}$ are in $T_{u_1}$, it follows that $t$ is a descendant of $u_1$. We conclude that $u_a$ is a descendant of $u_1$, a contradiction since no two vertices of $U$ are descendants of each other. ∎

*Augmenting $U$.* Vertex $u_1$ (a vertex in $U$ such that there is vertex $z \in X_{u_1}^{Q_{u_1}-\{u'_1,p(u_1)\}}$, where $z$ is the root of a full path with respect to $b$) will be replaced by the vertices $u_{1,1}$ and $u_{1,2}$ satisfying the conditions of Claim 4.18. As before, we let $u'_{1,1}$ and $u'_{1,2}$ be arbitrary elements in $Y_{u_{1,1}}$ and $Y_{u_{1,2}}$, respectively. After reindexing the elements of $U$ to be $u_1, u_2, \dots$, we define

- $P_U = \bigcup\{P_{u_i}^{Q_{u_i}-\{u'_i,p(u_i)\}} : u_i \in U\}$.

We now establish various claims about $U$.

CLAIM 4.19. *The following hold for $U$:*

1. *No vertex in $U$ is an ancestor (in $T$) of any other vertex in $U$.*
2. *For every vertex $u$ in $U$, we have $Q_u - \{p(u)\} = W_u \cup Y_u$, where $|W_u| = \lfloor k/2 \rfloor - 1$, $W_u \subset W$, and $Y_u \cap W = \emptyset$.*
3. *Set $W$ equals $\bigcup\{W_u : u \in U\}$.*
4. *For every pair $u, s$ of distinct vertices in $U$, $Y_u \cap Y_s = \emptyset$, and there is no vertex of $Y_u$ that is an ancestor or a descendant of a vertex of $Y_s$.*
5. *For every vertex $u$ in $U$, there is a vertex $y \in P_u^{Q_u - \{u', p(u)\}}$ such that $T_y$ is empty with respect to $b$.*
6. *All vertices in $W$ have different labels at $b$.*

*Proof.*

1. This follows by an easy induction argument and the fact that the new vertices $u_{1,1}$ and $u_{1,2}$ are descendants of $u_1$ and are not ancestors of each other.
2. Again we use an easy induction argument and the fact that the new vertices $u_{1,1}$ and $u_{1,2}$ satisfy the conditions of Claim 4.18.
3. This follows by an induction argument where it is assumed to be true for the unaugmented $U$ and $W$ (i.e., before $u_1$ was replaced by $u_{1,1}$ and $u_{1,2}$ and before $W$ was augmented with $\widetilde{u_1}$). Let $u_{1,1}$ and $u_{1,2}$ be the two new vertices replacing $u_1$. From the formula of Claim 4.18, it is clear that $W_{u_{1,1}} \cup W_{u_{1,2}} = W_{u_1} \cup \widetilde{u_1}$. Thus, replacing $W_{u_1}$ with $W_{u_{1,1}} \cup W_{u_{1,2}}$ in the formula $\bigcup\{W_u : u \in U\}$, we see that this formula is now equal to the augmented $W$.
4. Here the induction argument assumes it to be true for the unaugmented $U$. Let $u_{1,1}$ and $u_{1,2}$ be the two new vertices replacing $u_1$. If neither $u$ nor $s$ is in $\{u_{1,1}, u_{1,2}\}$, then the claim follows by the induction hypothesis. If both $u$ and $s$ are in $\{u_{1,1}, u_{1,2}\}$, then the claim follows from the formula of Claim 4.18. Suppose $u$ is in $\{u_{1,1}, u_{1,2}\}$ (say $u$ is equal to $u_{1,1}$) and $s$ is not in this set. By the formula of Claim 4.18, all vertices of $Y_{u_{1,1}}$ are in $T_{u_1}$, which implies that they are all descendants of $Y_{u_1}$. By the induction hypothesis, no vertex of $Y_{u_1}$ is an ancestor or a descendant of a vertex in $Y_s$. Thus, no vertex of $Y_{u_{1,1}} = Y_u$ is an ancestor or a descendant of a vertex in $Y_s$. This also implies that $Y_u \cap Y_s = \emptyset$.
5. For $u$ being neither $u_{1,1}$ nor $u_{1,2}$, this follows from Claim 4.14. For vertices $u_{1,1}$ or $u_{1,2}$, an argument almost identical to that used in the proof of Claim 4.11 suffices.
6. Immediate from Claims 4.15 and 4.17. $\square$

We now define $c$ to be a lowest vertex in $\mathcal{T}$ such that some path in $P_U$ is full with respect to $c$. Note that $c$ could be $b$, but from the definition of $c$ it is clear that $c$ cannot be a proper descendant of $b$. In order for the process to continue, the following analogues to Claims 4.13, 4.14, 4.15, 4.16, and 4.17 must hold. In all cases the proofs are the same as the proofs of the analogous claim and where appropriate use the facts established in Claim 4.19.

CLAIM 4.20 (analogue of Claim 4.13). *Vertex $c$ is an ancestor of $b$ (possibly a trivial ancestor of $b$).*

*Proof.* Suppose not and suppose $z \in X_{u_1}^{Q_{u_1} - \{u_1', p(u_1)\}}$ is the root of a full path $P$ with respect to $c$, where $c$ is not an ancestor of $b$. Since such a path has more than $2^{\lfloor k/2 \rfloor}$ vertices, at least two vertices $x$ and $y$ on this path must have the same label at $c$. Suppose $x$ is closer to $z$ than is $y$. Since $P$ is a full path, $Q_z - \{p(z)\} = Q_y - \{p(y)\}$ and thus $W_{u_1} \subset Q_y - \{p(y)\}$. By Claim 4.6, for every subset $S$ of $W_{u_1}$, there exists vertex

$r_S \in N_F[y] \cap T_y$ such that $(Q_{r_S} - \{p(r_S)\}) \cap (Q_y - \{p(y)\}) = S$. Let $\mathcal{S} = \{r_S : S \subseteq W_{u_1}\}$ denote the set of all these vertices. Using the same argument as in the proof of Claim 4.13, we conclude that all vertices of $\mathcal{S} - \{y\}$ must be in $V_c$, since they are adjacent to $y$ but not to $x$. Thus all vertices of $\mathcal{S}$ must be in $V_c$.

By definition, all the vertices of $W_{u_1}$ are in $V_b$. Since we assume that $c$ is not an ancestor of $b$ and since $c$ cannot be a proper descendant of $b$ (as noted above) we see that all these vertices are not in $V_c$. For every $S \subseteq W_{u_1}$ there is a vertex $r_S$ in $V_c$ that is adjacent to all the vertices of $S$ and to no other vertices in $W_{u_1}$, and thus by Claim 4.10, all the vertices of $\mathcal{S}$ must have different labels at $c$. By Claim 4.19 $|W_{u_1}| = \lfloor k/2 \rfloor - 1$. Thus, $|\mathcal{S}| = 2^{\lfloor k/2 \rfloor - 1}$, contradicting $cwd(F) < 2^{\lfloor k/2 \rfloor - 1}$. ∎

CLAIM 4.21 (analogue of Claim 4.14). *For all $u_i \in U$, there is a vertex $y \in X_{u_i}^{Q_{u_i} - \{u_i', p(u_i)\}}$ such that $T_y$ is empty with respect to $c$.*

*Proof.* The proof of this claim is obtained by rewriting the proof of Claim 4.14 replacing $b$ with $c$ everywhere. ∎

CLAIM 4.22 (analogue of Claim 4.15). *All $W$ vertices have different labels at $c$.*

*Proof.* By Claim 4.19, for all $w \in W$, there exists $u_i \in U$ such that $w \in W_{u_i}$. Now consider $w', w''$ two arbitrary vertices in $W$, and suppose $w' \in W_{u_1}$. Let $y$ be a vertex in $X_{u_1}^{Q_{u_1} - \{u_1', p(u_1)\}}$ such that $T_y$ is empty with respect to $c$ (guaranteed by Claim 4.21). The proof now continues as in the proof of Claim 4.15, replacing $b$ with $c$ everywhere to conclude that $w'$ and $w''$ must have different labels at $c$. ∎

As before, we let vertex $u_1 \in U$ satisfy the existence of a vertex $z \in X_{u_1}^{Q_{u_1} - \{u_1', p(u_1)\}}$, such that $z$ is the root of a full path with respect to $c$.

CLAIM 4.23 (analogue of Claim 4.16). *At least $\lfloor k/2 \rfloor$ vertices of $Q_{u_1} - \{u_1', p(u_1)\}$ are in $V_c$.*

*Proof.* The proof of this claim is obtained by rewriting the proof of Claim 4.16, replacing $b$ with $c$ everywhere. ∎

By Claim 4.19, $|W_{u_1}| = \lfloor k/2 \rfloor - 1$ and $Q_{u_1} - \{p(u_1)\} = W_{u_1} \cup Y_{u_1}$. Thus, by Claim 4.23, there is a vertex $\widetilde{u_1} \in Y_{u_1} - \{u_1'\}$ that is in $V_c$.

CLAIM 4.24 (analogue of Claim 4.17). *At $c$, the label of $\widetilde{u_1}$ is different from the labels needed for the $W$ vertices.*

*Proof.* Suppose $\widetilde{u_1}$ and $w \in W$ have the same label at $c$. By Claim 4.21, there is a $y \in X_{u_1}^{Q_{u_1} - \{u_1', p(u_1)\}}$ such that $T_y$ is empty with respect to $c$. By the definition of $y$, $Q_{u_1} - \{u_1', p(u_1)\} \subset Q_y - \{p(y)\}$ and thus $\widetilde{u_1} \in Q_y - \{p(y)\}$. By Claim 4.6, there is a vertex $r_S$ in $T_y$ corresponding to the set $S = \{\widetilde{u_1}\}$, such that $r_S$ is adjacent to $\widetilde{u_1}$ and to no other vertex in $Q_y - \{p(y)\}$. Now, as in the proof of Claim 4.22, regardless of whether $w \in Q_y - \{p(y)\}$, it follows that $r_S$ is adjacent to $\widetilde{u_1}$ but not to $w$. Since $r_S$ is outside $V_c$, it follows that $\widetilde{u_1}$ and $w$ must have different labels at $c$. ∎

Finally, we rename $c$ to be $b$ and again augment $W$ by adding $\widetilde{u_1}$ to $W$ and augment $U$ by replacing $u_1$ with the vertices $u_{1,1}$ and $u_{1,2}$ guaranteed by Claim 4.18. This augmentation continues until $|W| > 2^{\lfloor k/2 \rfloor - 1}$, thereby completing the proof of Theorem 1.3.

Note that these augmentation steps are based on the above claims where it is assumed that for every vertex $u$ in $U$, the depth of the tree $T_u$ is at least $2k+1+2^{\lfloor k/2 \rfloor}$. We now prove the correctness of this assumption. The vertex $u$ selected at the initial step is in $X_B^{Q_B - \{1,k\}}$ and thus is at level $2k+1$ of $T_B$. The set of vertices $U$ at the initial step is $\{u_1, u_2\}$, where, as indicated above, $u_1$ and $u_2$ are at level at most $2k+1$ of $T_u$. Thus, the vertices in the initial set $U$ are at level at most $2(2k+1)$ of $T_B$. By Claim 4.7, at each augmentation step the vertices $u_{1,1}$ and $u_{1,2}$ selected to replace $u_1$ in $U$ are at level at most $2k+1$ of $T_{u_1}$. Thus, after $2^{\lfloor k/2 \rfloor - 1}$ augmentation steps, all the vertices in $U$ are at level at most $(2k+1)2^{\lfloor k/2 \rfloor}$ of $T_B$. Now the claim follows since $\alpha$, the depth of $T$, is equal to $(2k+1)2^{\lfloor k/2 \rfloor + 1}$.

## 5. Concluding remarks.

The most important result in this paper is the fact that the clique-width of a graph can be exponentially higher than its treewidth. We fully expect that the bound expressed in Theorem 1.3 can be improved; the most interesting question, however, is to find a lower bound that confirms the bound achieved through some algorithm. In particular, we expect that the upper bound expressed in Theorem 1.2 is the best possible. Note that it is correct for $k$ equals one (trees) and for $k$ equals two (shown by a tedious exhaustive argument). Recently, Espelage, Gurski, and Wanke [9] have shown the existence of a linear time algorithm to determine whether a graph of bounded treewidth has clique-width at most $k$. Thus by using the result of Theorem 1.2 and running their algorithm for all values of $k$ from 1 to $3 * 2^{twd(G)-1}$, they have shown the existence of a linear time algorithm to determine the clique-width of a graph of bounded treewidth.

It is well appreciated that the most important open problems in the study of clique-width are the resolution of the general recognition problem (given graph $G$ and integer $k$, is $cwd(G) \leq k$?—strongly believed to be NP-complete) and the fixed $k$ recognition problem for $k \geq 4$. (The fixed $k$ recognition problem can be solved in polynomial time for $k \leq 3$; in particular the case when $k = 1$ is trivial, for $k = 2$ these are the cographs [8] which can be recognized in linear time [4], and for $k = 3$ an $O(n^2 m)$ algorithm is presented in [3].) It is interesting to note that the corresponding problems for treewidth are resolved. In particular, Arnborg, Corneil, and Proskurowski [1] showed that the general treewidth recognition problem (given graph $G$ and integer $k$, is $twd(G) \leq k$?) is NP-complete whereas the fixed recognition problem is in P. Bodlaender [2] later presented a linear time algorithm for the fixed $k$ treewidth recognition problem.

It seems as though the stumbling block for both problems is the difficulty in developing good arguments to provide strong lower bounds on the clique-width of a graph. Hopefully the techniques presented in section 4 can assist.

Another avenue of promising research is the development of polynomial time algorithms to determine the clique-width of restricted families of graphs, especially those where the clique-width can be arbitrarily large. Such families include permutation graphs, planar graphs, interval graphs, and even unit interval graphs. Again progress in this area depends on lower bound arguments that show that the clique-width achieved by a particular algorithm is the best possible.

# WORK-COMPETITIVE SCHEDULING FOR COOPERATIVE COMPUTING WITH DYNAMIC GROUPS[*]

CHRYSSIS GEORGIOU[†], ALEXANDER RUSSELL[‡], AND ALEXANDER A. SHVARTSMAN[§]

**Abstract.** The problem of cooperatively performing a set of $t$ tasks in a decentralized computing environment subject to failures is one of the fundamental problems in distributed computing. The setting with partitionable networks is especially challenging, as algorithmic solutions must accommodate the possibility that groups of processors become disconnected (and, perhaps, reconnected) during the computation. The efficiency of task-performing algorithms is often assessed in terms of *work*: the total number of tasks, counting multiplicities, performed by all of the processors during the computation. In general, the scenario where the processors are partitioned into $g$ disconnected components causes any task-performing algorithm to have work $\Omega(t \cdot g)$ even if each group of processors performs no more than the optimal number of $\Theta(t)$ tasks.

Given that such pessimistic lower bounds apply to *any* scheduling algorithm, we pursue a *competitive* analysis. Specifically, this paper studies a simple randomized scheduling algorithm for $p$ asynchronous processors, connected by a dynamically changing communication medium, to complete $t$ known tasks. The performance of this algorithm is compared against that of an omniscient off-line algorithm with full knowledge of the future changes in the communication medium. The paper describes a notion of *computation width*, which associates a natural number with a history of changes in the communication medium, and shows both upper and lower bounds on work-competitiveness in terms of this quantity. Specifically, it is shown that the simple randomized algorithm obtains the competitive ratio $(1 + \mathbf{cw}/e)$, where $\mathbf{cw}$ is the computation width and $e$ is the base of the natural logarithm ($e = 2.7182\dots$); this competitive ratio is then shown to be tight.

## 1. Introduction.

The problem of cooperatively performing a known set of tasks in a decentralized computing environment subject to failures is one of the fundamental problems in distributed computing. Variations on this problem have been studied in a variety of different settings, including, for example, message-passing models [7, 8, 11], shared-memory models [18, 17, 2, 21, 19], and partitionable network models [10, 20]. In the settings where network partitions may interfere with the progress of computation, the challenge is to maintain efficiency despite dynamically changing processor connectivity.

This problem is normally abstracted in terms of a set of $t$ tasks that must be performed in a distributed environment consisting of $p$ processors, subject to processor failures and communication disruptions. Algorithmic solutions for this problem are

typically evaluated by bounding their worst-case *work*: the total number of computation steps performed by all processors during the computation. We consider the situation where the tasks are *similar*, that is, completion of each task requires the same number of computation steps, and where task-oriented work dominates local bookkeeping. In this case the work incurred by an algorithm is simply the total number of tasks, counting multiplicities, completed by the processors.

The details of the computation model naturally have a dramatic impact on the existence of efficient (or even interesting) algorithms for the problem. In this paper, we consider the *partitionable network* scenario consisting of $p$ asynchronous processors with a communication medium that is subject to arbitrary *partitions* during the life of the computation. This model is motivated by the abstraction provided by a typical *group communication scheme*; see, for example, the surveys in [23]. Specifically, at each point of the computation, the communication medium effectively partitions the processors into nonoverlapping *groups*: communication within a group is instantaneous and reliable, communication across groups is impossible. Naturally, processors in the same group can share their knowledge of completed tasks and, while they remain connected, avoid doing redundant work. For the remainder of the paper we refer to a transition from one network partition to another as a *reconfiguration*.

We do not charge for coordination within a group, simply treating grouped processors as a single (virtual) asynchronous processor. In particular, if a group of processors performs a set of $t$ tasks during the lifetime of that group, we charge this group $t$ units of work, ignoring, for example, partially completed tasks which may remain at the group's demise or the cost of synchronizing processors' knowledge during the group's inception. Each processor may cease executing tasks *only* when it knows the results of all tasks. While processors are asynchronous, they do not crash.

An algorithm in this model is a rule which, given a group of processors and a set of tasks known by this group to be completed, determines a task for the group to complete next. In the case where all processors are disconnected during the entire computation, any algorithm must incur $\Omega(t \cdot p)$ work. On the other hand, any reasonable algorithm should attain $O(t)$ work in the case where all processors remain connected during the computation. Considering that *every* algorithm performs poorly in the totally disconnected case, it seems reasonable to treat the problem as an on-line problem and pursue competitive analysis.

Fix, for the moment, an algorithm $A$. For expository purposes, let us treat both the processors' asynchrony and the dynamics of the network as if they were determined by an adversary $\mathcal{A}$. The adversary determines an initial partition $\mathcal{P}_1$ of the processors into groups and determines how many tasks each group of this partition $\mathcal{P}_1$ completes before the next reconfiguration; while the *number* of tasks completed by each group is determined by the adversary, the actual subset of tasks (that is, the *identity* of the tasks) completed by each group is determined by the algorithm $A$. The adversary then determines a reconfiguration of the processors, giving rise to a new partition $\mathcal{P}_2$, and, as before, determines how many tasks each of the newly created groups of $\mathcal{P}_2$ completes before the next reconfiguration. Any group created during such a reconfiguration is assumed to have the combined knowledge of all its members: any task known to be completed by a processor of the group $G$ is known to be completed by all processors of $G$. This process of reconfiguration and computation continues until every processor is aware of the outcome of every task. Groups with knowledge of the outcome of all tasks cause no work: in effect, they may "idle" until the next reconfiguration. Note that for this algorithm $A$, the work caused by the adversary $\mathcal{A}$ is completely determined by (i) the collection of groups that existed during the computation, (ii) the number of tasks $\mathcal{A}$ permits each group to perform, and (iii) for each group $G$, the identities of all those groups in which processors of $G$ have previously been members. (Note that the initial knowledge of the group $G$ is determined in part by (iii).) These characteristics can be captured by a certain directed acyclic graph, to which we refer as a *computation pattern.* This is formally defined in the next section. Note that different sequences of reconfigurations can in fact give rise to the same computation pattern.

As an example, consider the scenario with 3 processors which, starting from isolation, are permitted to proceed synchronously until each has completed $t/2$ tasks; at this point an adversary chooses a pair of processors to merge into a group. It is easy to show that if $T_1$, $T_2$, and $T_3$ are subsets of $[t]$ of size $t/2$, then there is a pair $(T_i, T_j)$ (where $i \neq j$) so that $|T_i \cap T_j| \geq t/6$: in particular, for *any* scheduling algorithm, there is a pair of processors which, if merged at this point, will have $t/6$ duplicated tasks; this pair alone must then expend $t + t/6$ work to complete all $t$ tasks. The optimal off-line algorithm that schedules tasks with full knowledge of future merges, of course, accrues only $t$ work for the merged pair, as it can arrange for zero overlap. Furthermore, if the adversary partitions the two merged processors immediately after the merge (after allowing the processors to exchanged information about task executions), then the work performed by the merged and then partitioned pair is $t + t/3$; the work performed by the optimal algorithm remains unchanged, since it terminates at the merge.

**Contributions.** We study upper and lower bounds on the competitiveness of scheduling algorithms for the task-performing problem in partitionable networks. We analyze the natural randomized algorithm for $p$ processors and $t$ tasks, called RANDOM SELECT (RS), in which each processor (or group) determines the next task to complete by randomly selecting the task from the subset of tasks this group does not know to be completed. We compare the expected work of this algorithm to the work of an optimal off-line algorithm, which may schedule tasks with full knowledge of future partitions.

In order to precisely state the results of the paper, we pause to introduce some notation. In the literature, groups of processors are given structured names, such that a group $G$ is a pair $\langle G.id, G.set\rangle$, where $G.id$ is the unique identifier of $G$ and $G.set$ is the set of processor identifiers in $[p]$ that determine the members of the group. To reduce notational clutter, given a group named $G$, we use $G$ to stand for $G.set$ in this paper (e.g., if two, possibly distinct, groups $G$ and $G'$ have identical membership, we express this by $G = G'$).

As discussed previously, an adversary determines a *computation pattern* $C$ in a natural way; this is a directed acyclic graph (DAG), each vertex corresponding to a group of processors that exists during some point of the computation; a directed edge is placed from group $G$ to group $G'$ if $G \cap G' \neq \emptyset$ and $G'$ was formed by a reconfiguration involving processors in $G$ (this is discussed and formally defined in section 2). We say that two groups $G$ and $G'$ are *independent* if there is no directed path connecting one to the other. For such a pattern $C$, the *computation width* of $C$, denoted $\mathbf{cw}(C)$, is the maximum number of independent groups reachable (along directed paths) in this DAG from any vertex. We show the following:

- (Upper bound.) For any computation pattern $C$, the randomized algorithm RS discussed above is $(1 + \mathbf{cw}(C)/e)$-work competitive.
- (Lower bound.) For any scheduling algorithm $A(p, t)$, any $\epsilon > 0$, and any

nonzero $k \in \mathbb{N}$, there exist $p$, $t$, and a computation pattern $C$ so that $\mathbf{cw}(C) = k$ and the work performed by algorithm $A(p,t)$ is at least $(1 + k/e - \epsilon)$ times that of the off-line algorithm.

In particular, RS achieves the *optimal* competitive ratio over the set of all computation patterns with a given computation width.

**Prior and related work; motivation.** The problem of distributed cooperation for message-passing models was introduced and studied by Dwork, Halpern, and Waarts [11], who defined the notion of (task-oriented) work. The current problem of cooperation in *partitionable* networks has been the subject of active research. However, known solutions address narrow special cases, or provide substantially weaker bounds. Dolev, Segala, and Shvartsman [10] performed the first study of the problem in the partitionable setting. They model reconfiguration patterns for which the termination time of any on-line task-performing algorithm is greater than the termination time of an off-line task-performing algorithm by a factor linear in $p$. Malewicz, Russell, and Shvartsman [20] introduced the notion of *h-waste* that measures the worst-case redundant work performed by $h$ groups (or processors) when started in isolation and merged into a single group at some later time. While these results are deterministic, they only adequately describe such computation to the point of the *first* reconfiguration, where the reconfiguration is further assumed to simply *merge* groups together. Georgiou and Shvartsman [16] give upper bounds on work for an algorithm that performs work in the presence of network fragmentations and merges (i.e., limited patterns of reconfigurations) using a group communication service where processors initially start in a single group. They establish an upper bound of $O(\min(t{\cdot}p,\ t{+}t{\cdot}g(C)))$, where $g(C)$ is the total number of new groups formed during the computation pattern $C$. Note that $\mathbf{cw}(C) \leq g(C)$, and there can be an arbitrary gap between $\mathbf{cw}(C)$ and $g(C)$.

Thus prior work established reasonably tight (in the length of the processor schedule) results for a *single first* merge [20], illustrated the fact that on-line algorithms subject to diverging reconfiguration patterns incur linear (in $p$) overhead relative to an off-line algorithm [10], and showed an upper bound for an algorithm using group communication services for a limited pattern of reconfigurations starting with a *single* group [16].

The problem of cooperation on a common set of tasks in distributed settings has been studied in message-passing models [7, 8, 11]. These studies present various load-balancing techniques for structuring the work for computing devices that are able to communicate by means of point-to-point messages. The studies of Georgiades, Mavronicolas, and Spirakis [13] and Papadimitriou and Yannakakis [22] investigated the impact of communication topology on the effectiveness of load-balancing.

The notion of competitiveness was introduced by Sleator and Tarjan [26] (see also Bartal, Fiat, and Rabani [5], Awerbuch, Kutten, and Peleg [3], and Ajtai et al. [1]).

Group communication services have become important as building blocks for fault-tolerant distributed systems. Such services enable processors located in a failure-prone network to operate collectively as a group, using the services to multicast messages to group members (see the special issue [23]). To evaluate the effectiveness of partitionable group communication services, Sussman and Marzullo [27] proposed a measure (*cushion*) precipitated by a simple partition-aware application. Babaoglu et al. [4] studied systematic support for partition awareness based on group communication services in a wide range of application areas. As we mentioned earlier, cooperation on a common set of tasks has also been studied for algorithms using group communications [10, 16].

A related problem, referred to as Write-All, has been studied in the shared-memory model. Early work in this area was reported by Kanellakis and Shvartsman [18], Martel and Subramonian [21], Kedem, Palem, and Spirakis [19], and Anderson and Woll [2]. In this setting the processors cooperate on updating locations in shared memory. The algorithmic techniques and analysis found there are quite different from the ones we present in this paper. Another related shared-memory problem, called *Collect*, requires that each processor learn the private values of all other processors. This problem was introduced by Shavit [25] and studied by Saks, Shavit, and Woll [24].

The structure of this paper is as follows. In section 2 we define the problem and model of computation. In section 3 we present and analyze the randomized algorithm RS. In section 4 we prove a lower bound for the problem. We conclude in section 5.

Abstracts describing preliminary versions of the results in this paper appear in [14, 15].

## 2. Model and definitions.

We consider a distributed system consisting of $p$ asynchronous processors connected by communication links; each processor has a unique identifier from the set $[p] = \{1, 2, \ldots, p\}$; the value $p$ is known to all processors. The problem is then defined in terms of $t$ tasks with unique identifiers, initially known to all processors. The tasks are independent and idempotent—multiple executions of the same task have the same effect as a single execution. Processors may cease executing tasks only when they know the results of all tasks. This general problem is often referred to as *Do-All*.

The model is complicated by subjecting the processors to dynamic changes in the communication medium. In particular, at each instant of time, the network is partitioned into a collection of *groups*. Communication between processors in the same group is instantaneous and reliable, so that grouped processors may perfectly cooperate to complete tasks; communication across groups, however, is not possible. We consider the dynamic case where communication can be arbitrarily lost and reestablished. In particular, the computation of the processors is punctuated by a sequence of *reconfigurations*; each reconfiguration may induce an arbitrary change in the partition of the processors into groups. We shall assume that task executions are atomic with respect to reconfigurations. That is, a reconfiguration does not occur when some tasks are "halfway" through execution.

In order to focus on scheduling issues, we assume that processors in a single group work as a single virtual unit; indeed, we will treat them as a single asynchronous processor. In particular, upon the establishment of a new group by a reconfiguration, the processors in the group share their knowledge (of completed tasks) before they continue processing. A deterministic algorithm $D$ in this model is a rule which, given a processor (or group of processors) and a collection of tasks known to be completed, determines the next task for this processor (or group) to complete. Specifically, an algorithm is a function $D : 2^{[p]} \times 2^{[t]} \to [t]$; we note that the lower bounds proved in this paper actually apply to a wider class of algorithms that may in fact take into account the entire history of the computation of the group in question. For simplicity, we assume that $\forall P \subset [p], \forall T \subsetneq [t], D(P, T) \notin T$, which is to say that the algorithm never chooses to complete a task it already knows to be completed. Our goal will be to design algorithms that schedule the execution of the tasks to minimize the total *work*, where work is defined to be *the number of tasks executed by all the processors during the entire computation (counting multiplicities).* Ideally, the sets of tasks completed by two groups of processors when these groups are merged should be disjoint to avoid wasted effort. This is impossible in general, as processors must schedule their work in ignorance of future reconfigurations and, moreover, circumstances where two groups of processors merge that have collectively completed more than $t$ tasks will necessitate wasted work. A processor may cease executing tasks only when it knows the results of all tasks. We refer to this version of the Do-All problem as *Omni-Do*.

We will consider the behavior of an algorithm in the face of an adversary (which is *oblivious* in the sense of [6]) that determines both the *sequence of reconfigurations* and the *number of tasks completed* by each group before it is involved in another reconfiguration. Taken together, this information determines a *computation pattern*: this is a DAG, each vertex of which corresponds to a group $G$ of processors that existed during the computation; a directed edge is placed from $G_1$ to $G_2$ if $G_2$ was created by a reconfiguration involving $G_1$. We label each vertex of the DAG with the group of processors associated with that vertex and the total number of tasks that the adversary allows the group of processors to perform before the next reconfiguration occurs. As mentioned before, different adversaries (causing different sequences of reconfigurations) may give rise to the same computation pattern; the *work* caused by an adversary, however, depends only on the computation pattern determined by that adversary.

Specifically, if $t$ is the number of tasks and $p$ the number of processors, then such a computation pattern is a labeled and weighted DAG, which we call a $(p,t)$-DAG.

DEFINITION 2.1. *A $(p,t)$-DAG is a DAG $C = (V,E)$ augmented with a weight function $h : V \to [t] \cup \{0\}$ and a labeling $g : V \to 2^{[p]} \setminus \{\emptyset\}$ so that the following hold.*

- *For any maximal path $P = (v_1, \ldots, v_k)$ in $C$, $\sum h(v_i) \geq t$. (This guarantees that any algorithm terminates during the computation described by the DAG.)*
- *$g$ possesses the following "initial conditions":*

$$[p] = \dot{\bigcup}_{v:\ in(v)=0} g(v).$$

- *$g$ respects the following "conservation law":*
  *there is a function $\phi : E \to 2^{[p]} \setminus \{\emptyset\}$ so that for each $v \in V$ with $\mathrm{in}(v) > 0$,*

$$g(v) = \dot{\bigcup}_{(u,v)\in E} \phi\big((u,v)\big),$$

  *and for each $v \in V$ with $\mathrm{out}(v) > 0$,*

$$g(v) = \dot{\bigcup}_{(v,u)\in E} \phi\big((v,u)\big).$$

In the above definition, $\dot{\cup}$ denotes disjoint union, and $\mathrm{in}(v)$ and $\mathrm{out}(v)$ denote the in-degree and out-degree of $v$, respectively. Finally, for two vertices $u, v \in V$, we write $u \leq v$ if there is a directed path from $u$ to $v$; we then write $u < v$ if $u \leq v$ and $u$ and $v$ are distinct.

*Example.* As an example, consider the $(12,t)$-DAG shown on Figure 2.1. Here we have $g_1 = \{p_1\}$, $g_2 = \{p_2, p_3, p_4\}$, $g_3 = \{p_5, p_6\}$, $g_4 = \{p_7\}$, $g_5 = \{p_8, p_9, p_{10}, p_{11}, p_{12}\}$, $g_6 = \{p_1, p_2, p_3, p_4, p_6\}$, $g_7 = \{p_8, p_{10}\}$, $g_8 = \{p_9, p_{11}, p_{12}\}$, $g_9 = \{p_1, p_2, p_3, p_4, p_6, p_8, p_{10}\}$, $g_{10} = \{p_5, p_{11}\}$, and $g_{11} = \{p_9, p_{12}\}$.

This computation pattern models all asynchronous computations (adversaries) with the following behavior: (i) The processors in groups $g_1$ and $g_2$ and processor $p_6$ of group $g_3$ are regrouped during some reconfiguration to form group $g_6$. Processor $p_5$ of

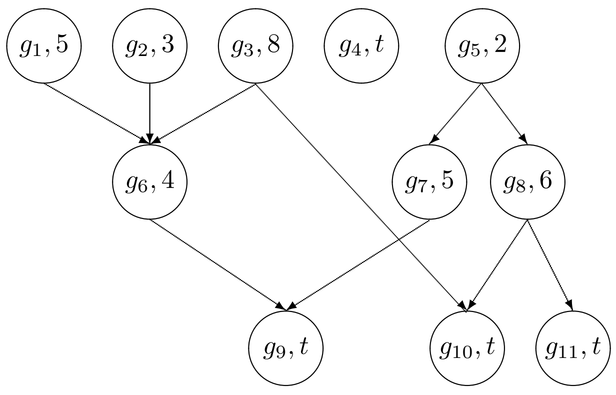

FIG. 2.1. *An example of a* $(12, t)$*-DAG.*

group $g_3$ becomes a member of group $g_{10}$ during the same reconfiguration (see below). Prior to this reconfiguration, processor $p_1$ (the singleton group $g_1$) has performed exactly 5 tasks, the processors in $g_2$ have cooperatively performed exactly 3 tasks, and the processors in $g_3$ have cooperatively performed exactly 8 tasks (assuming that $t > 8$). (ii) Group $g_5$ is partitioned during some reconfiguration into two new groups, $g_7$ and $g_8$. Prior to this reconfiguration, the processors in $g_5$ have performed exactly 2 tasks. (iii) Groups $g_6$ and $g_7$ merge during some reconfiguration and form group $g_9$. Prior to this merge, the processors in $g_6$ have performed exactly 4 tasks (counting only the ones performed after the formation of $g_6$ and assuming that there are at least 4 tasks remaining to be done) and the processors in $g_7$ have performed exactly 5 tasks. (iv) The processors in group $g_8$ and processor $p_5$ of group $g_3$ are regrouped during some reconfiguration into groups $g_{10}$ and $g_{11}$. Prior to this reconfiguration, the processors in group $g_8$ have performed exactly 6 tasks (assuming that there are at least 6 tasks remaining, otherwise they would have performed the remaining tasks). (v) The processors in $g_9$, $g_{10}$, and $g_{11}$ run until completion with no further reconfigurations. (vi) Processor $p_7$ (the singleton group $g_4$) runs in isolation for the entire computation.

Let $D$ be a deterministic algorithm for Omni-Do and $C$ a computation pattern. We then let $W_D(C)$ denote the total work expended by algorithm $D$, where reconfigurations are determined according to the computation pattern $C$. $W_D$ is formally defined as follows.

DEFINITION 2.2. *Let $C$ be a $(p, t)$-DAG and $D$ a deterministic algorithm for Omni-Do.* $\boldsymbol{W_D(C)}$ *is defined inductively as follows.*

- *For a vertex $v$ of $C$ with* $\text{in}(v) = 0$, *define $L_v$ to be the set containing the first $h(v)$ tasks completed by group $g(v)$ according to $D$.*
- *Otherwise,* $\text{in}(v) > 0$*; in this case, let $\check{L}_v = \bigcup_{u<v} L_u$ denote the collection of all tasks known to be complete at the inception of group $g(v)$. Then let $L_v$ be the first $h(v)$ tasks completed by group $g(v)$ according to $D$ starting with knowledge $\check{L}_v$. If $h(v) > t - |\check{L}_v|$, define $L_v = [t] \setminus \check{L}_v$.*

*Then* $W_D(C) = \sum_{v \in C} |L_v|$.

We treat randomized algorithms as distributions over deterministic algorithms; for a set $\Omega$ and a family of deterministic algorithms $\{D_r \mid r \in \Omega\}$ we let $R = \mathcal{R}(\{D_r \mid r \in \Omega\})$ denote the randomized algorithm where $r$ is selected uniformly at random from $\Omega$ and scheduling is done according to $D_r$. For a real-valued random variable $X$, we let $\mathbb{E}[X]$ denote its expected value. We let OPT denote the optimal (off-line) algorithm. Specifically, for each $C$ we define $W_{\mathrm{OPT}}(C) = \min_D W_D(C)$.

DEFINITION 2.3 (see [26, 12, 6]). *Let $\alpha$ be a real-valued function defined on the set of all $(p, t)$-DAGs ($\forall\, p$ and $t$). A randomized algorithm $R$ is $\alpha$-competitive if for all computation patterns $C$,*

$$\mathbb{E}[W_{D_r}(C)] \leq \alpha(C) W_{OPT}(C),$$

*this expectation being taken over uniform choice of $r \in \Omega$.*

Presently, we will introduce a function $\alpha$ that depends on a certain parameter (see Definition 2.7) of the graph structure of $C$. We note that, by definition, $\alpha \geq 1$.

We pause to develop some terminology that we will use in the rest of the paper.

DEFINITION 2.4. *A* partially ordered set, *or* poset, *is a pair $(P, \leq)$, where $P$ is a set and $\leq$ is a binary relation on $P$ for which* (i) *$\forall\, x \in P$, $x \leq x$;* (ii) *if $x \leq y$ and $y \leq x$, then $x = y$; and* (iii) *if $x \leq y$ and $y \leq z$, then $x \leq z$. For a poset $(P, \leq)$ we overload the symbol $P$, letting it denote both the set and the poset.*

DEFINITION 2.5. *Let $P$ be a poset. We say that two elements $x$ and $y$ of $P$ are* comparable *if $x \leq y$ or $y \leq x$; otherwise $x$ and $y$ are* incomparable. *A* chain *is a subset $H$ of $P$ such that any two elements of $H$ are comparable. An* antichain *is a subset $A$ of $P$ such that any two distinct elements of $A$ are incomparable. The* width *of $P$, denoted $\mathbf{w}(P)$, is the size of the largest antichain of $P$.*

Associated with any DAG $C = (V, E)$ is the natural *vertex poset* $(V, \leq)$, where $u \leq v$ if and only if there is a directed path from $u$ to $v$. Then the *width* of $C$, denoted $\mathbf{w}(C)$, is the width of the poset $(V, \leq)$.

DEFINITION 2.6. *Given a DAG $C = (V, E)$ and a vertex $v \in V$, we define the* predecessor graph at *$v$, denoted $P_C(v)$ (or $P(v)$ when $C$ is implied), to be the subgraph of $C$ that is formed by the union of all paths in $C$ terminating at $v$. Likewise, the* successor graph at *$v$, denoted $S_C(v)$ (or $S(v)$ when $C$ is implied), is the subgraph of $C$ that is formed by the union of all the paths in $C$ originating at $v$.*

DEFINITION 2.7. *The* computation width *of a DAG $C = (V, E)$, denoted $\mathbf{cw}(C)$, is defined as*

$$\mathbf{cw}(C) = \max_{v \in V} \mathbf{w}(S(v)).$$

Note that the processors that comprise a group formed during a computation pattern $C$ may be involved in many different groups at later stages of the computation, but no more than $\mathbf{cw}(C)$ of these groups will be forced to compute in ignorance of each other's progress.

In the $(12, t)$-DAG of Figure 2.1, the maximum width among all successor graphs is 3: $\mathbf{w}(S((g_5, 2))) = 3$. Hence, the computational width of this DAG is 3. Note that the width of the DAG is 6 (nodes $(g_1, 5)$, $(g_2, 3)$, $(g_3, 8)$, $(g_4, t)$, $(g_7, 5)$, and $(g_8, 6)$ form an antichain of maximum size).

## 3. Algorithm RS and its analysis.

In this section we present the RANDOM SELECT (RS) algorithm and its analysis.

### 3.1. Description of algorithm RS.

We consider the natural randomized algorithm RS, where a processor (or group), with knowledge that the tasks in a set $K \subset [t]$ have been completed, selects to next complete a task at random from the set $[t] \setminus K$. More formally, let $\Pi = (\pi_1, \ldots, \pi_p)$ be a $p$-tuple of permutations, where each $\pi_i$ is a permutation of $[t]$. We describe a deterministic algorithm $D_\Pi$ so that

$$\mathrm{RS} = \mathcal{R}\big(\{D_\Pi \mid \Pi \in (S_t)^p\}\big);$$

here $S_t$ is the collection of permutations on $[t]$. Let $G$ be a group of processors and $\gamma \in G$ the processor in $G$ with the lowest processor identifier. Then the deterministic algorithm $D_\Pi$ specifies that the group $G$, should it know that the tasks in $K \subset [t]$ have been completed, next completes the first task in the sequence $\pi_\gamma(1), \dots, \pi_\gamma(t)$ which is not in $K$.

**3.2. Analysis of algorithm RS.** We now analyze the competitive ratio (in terms of work) of algorithm RS. We write $W_{\text{RS}}(C) = \mathbb{E}\,[W_{\text{RS}}(C)]$, this expectation taken over the random choices of the algorithm. Where $C$ can be inferred from context, we simply write $W_{\text{RS}}$ and $W_{\text{OPT}}$.

We first recall Dilworth's lemma [9], a duality theorem for posets.

LEMMA 3.1 (see [9]). *The width of a poset $P$ is equal to the minimum number of chains needed to cover $P$. (A family of nonempty subsets of a given set $S$ is said to* cover *$S$ if their union is $S$.)*

We will also use a generalized degree-counting argument.

LEMMA 3.2. *Let $G = (U, V, E)$ be an undirected bipartite graph with no isolated vertices and $h : V \to \mathbb{R}$ a nonnegative weight function on $G$. For a vertex $v$, let $\Gamma(v)$ denote the vertices adjacent to $v$. Suppose that for some $A > 0$ and for every vertex $u \in U$ we have $\sum_{v\in\Gamma(u)} h(v) \le A$ and that for some $B > 0$ and for every vertex $v \in V$ we have $\sum_{u\in\Gamma(v)} h(u) \ge B$. Then*

$$\frac{\sum_{u\in U} h(u)}{\sum_{v\in V} h(v)} \ge \frac{B}{A}.$$

*Proof.* We compute the quantity $\sum_{(u,v)\in E} h(u)h(v)$ by expanding according to each side of the bipartition:

$$\begin{aligned} A\sum_{u\in U} h(u) &\ge \sum_{u\in U}\Big(h(u)\cdot\sum_{v\in\Gamma(u)} h(v)\Big) = \sum_{(u,v)\in E} h(u)h(v) \\ &= \sum_{v\in V}\Big(h(v)\cdot\sum_{u\in\Gamma(v)} h(u)\Big) \ge B\sum_{v\in V} h(v). \end{aligned}$$

As $A > 0$ and $\sum_v h(v) \ge B > 0$, we conclude that

$$\frac{\sum_{u\in U} h(u)}{\sum_{v\in V} h(v)} \ge \frac{B}{A},$$

as desired. ☐

We now establish an upper bound on the competitive ratio of algorithm RS.

THEOREM 3.3. *Algorithm RS is $(1 + \mathbf{cw}(C)/e)$-competitive for any $(p,t)$-DAG $C = (V, E)$.*

*Proof.* Let $C$ be a $(p,t)$-DAG; recall that associated with $C$ are the two functions $h : V \to [t] \cup \{0\}$ and $g : V \to 2^{[p]} \setminus \{\emptyset\}$. For a subgraph $C' = (V', E')$ of $C$, we let $H(C') = \sum_{v\in V'} h(v)$. Recall that $P_C(v)$ and $S_C(v)$ denote the predecessor and successor graphs of $C$ at $v$. Then we say that a vertex $v \in V$ is *saturated* if $H(P_C(v)) \le t$; otherwise, $v$ is *unsaturated.* Note that if $v$ is saturated, then the group $g(v)$ must complete $h(v)$ tasks *regardless of the scheduling algorithm used.* Along these same lines, if $v$ is an unsaturated vertex for which $t > \sum_{u<v} h(u)$, the group $g(v)$ must complete at least $\max(h(v), t - \sum_{u<v} h(u))$ tasks under any scheduling algorithm. As these portions of $C$ which correspond to computation that must be performed by

any algorithm will play a special role in the analysis, it will be convenient for us to rearrange the DAG so that all such work appears on saturated vertices. To achieve this, note that if $v$ is an unsaturated vertex for which $\sum_{u<v} h(u) < t$, we may replace $v$ with a pair of vertices, $v_s$ and $v_u$, where all edges directed into $v$ are redirected to $v_s$, all edges directed out of $v$ are changed to originate at $v_u$, the edge $(v_s, v_u)$ is added to $E$, and $h$ is redefined so that

$$h(v_s) = t - \sum_{u<v} h(u) \qquad \text{and} \qquad h(v_u) = h(v) - h(v_s).$$

Note that the graph $C'$ obtained by altering $C$ in this way corresponds to the same computation, in the sense that $W_D(C) = W_D(C')$ for any algorithm $D$. For the remainder of the proof we will assume that this alteration has been made at every relevant vertex, so that the graph $C$ satisfies the condition

$$v \text{ unsaturated } \Rightarrow \sum_{u<v} h(u) \geq t. \tag{3.1}$$

Finally, for a vertex $v$, we let $T_v$ be the random variable equal to the number of tasks that RS completes at vertex $v$. Note that if $v$ is saturated, then $T_v = h(v)$. Let $\mathcal{S}$ and $\mathcal{U}$ denote the sets of saturated and unsaturated vertices, respectively. Given the above definitions, we immediately have

$$W_{\mathrm{OPT}} \geq \sum_{s\in\mathcal{S}} h(s)$$

and, by linearity of expectation,

$$W_{\mathrm{RS}} = \mathbb{E}\Big[\sum_v T_v\Big] = \sum_{s\in\mathcal{S}} h(s) + \sum_{u\in\mathcal{U}} \mathbb{E}[T_u] \leq W_{\mathrm{OPT}} + \sum_{u\in\mathcal{U}} \mathbb{E}[T_u]. \tag{3.2}$$

Our goal is to conclude that for some appropriate $\beta$,

$$\mathbb{E}\left[\sum_{u\in\mathcal{U}} T_u\right] \leq \beta \cdot \sum_{s\in\mathcal{S}} h(s) \leq \beta \cdot W_{\mathrm{OPT}}$$

and hence that RS is $1 + \beta$ competitive. We will obtain such a bound by applying Lemma 3.2 to an appropriate bipartite graph, constructed next.

Given $C = (V, E)$, construct the (undirected) bipartite graph $G = (\mathcal{S}, \mathcal{U}, E_G)$, where $E_G = \{(s, u) \mid s < u\}$. As in Lemma 3.2, for a vertex $v$, we let $\Gamma(v)$ denote the set of vertices adjacent to $v$. Now assign weights to the vertices of $G$ according to the rule $h^*(v) = \mathbb{E}[T_v]$. Note that for $s \in \mathcal{S}, h^*(s) = h(s)$ and hence by condition (3.1) above, we immediately have the bound

$$\forall u \in \mathcal{U}, \quad \sum_{s\in\Gamma(u)} h^*(s) \geq t. \tag{3.3}$$

We now show that $\forall s \in \mathcal{S}$,

$$\sum_{u\in\Gamma(s)} h^*(u) \leq \mathbf{cw}(C) \cdot \frac{t}{e}. \tag{3.4}$$

Before proceeding to establish this bound, note that (3.3) and (3.4), together with Lemma 3.2, imply that

$$\begin{aligned} W_{\mathrm{RS}}(C) &\leq \sum_{s\in\mathcal{S}} h(s) + \sum_{u\in\mathcal{U}} h^*(u) \leq \Big(1+\frac{\mathbf{cw}(C)}{e}\Big)\sum_{s\in\mathcal{S}} h(s) \\ &\leq \Big(1+\frac{\mathbf{cw}(C)}{e}\Big) W_{\mathrm{OPT}}(C), \end{aligned}$$

as desired.

Returning now to (3.4), let $s \in \mathcal{S}$ be a saturated vertex and consider the successor graph (of $C$) at $s$, $S_C(s)$. By Lemma 3.1 (Dilworth's lemma), there exist $w \triangleq \mathbf{w}(S_C(s)) \leq \mathbf{cw}(C)$ paths in $S_C(s)$, $P_1, P_2, \ldots, P_w$, so that their union covers $S_C(s)$. Let $X_i$ be the random variable whose value is the number of tasks performed by RS on the portion of the path $P_i$ consisting of unsaturated vertices. Note that if $u \in V$ is unsaturated and $u \leq v$, then $v$ is unsaturated and hence, for each path $P_i$, there is a first unsaturated vertex $u_i^0$ after which every vertex of $P_i$ is unsaturated. Note now that for a fixed individual task $\tau$, conditioned upon the event that $\tau$ is not yet complete, the probability that $\tau$ is *not* chosen by RS for completion at a given selection point in $P_C(u_i^0)$ is no more than $(1-1/t)$. Let $L_i$ be the random variable whose value is the set of tasks left incomplete by RS at the formation of the group $g(u_i^0)$. As $u_i^0$ is unsaturated, $\sum_{v<u_i^0} h(v) \geq t$ by condition (3.1) and hence, for each $i$,

$$\Pr[\tau \in L_i] \leq (1-1/t)^t \leq 1/e.$$

As there are a total of $t$ tasks,

$$\mathbb{E}[|L_i|] \leq t/e.$$

Of course, since RS completes a new task at each step, $X_i \leq |L_i|$ so that $\mathbb{E}[X_i] \leq t/e$, and by linearity of expectation

$$\mathbb{E}\Big[\sum_i X_i\Big] \leq w \cdot t/e.$$

Now every unsaturated vertex in $S_C(s)$ appears in some $P_i$ and hence

$$\sum_{u\in\Gamma(s)} h^*(u) \leq \mathbb{E}\Big[\sum_i X_i\Big] \leq wt/e \leq \mathbf{cw}(C)\cdot t/e,$$

as desired. ◻

Theorem 3.3 implies a constant upper bound for patterns that consist entirely of merges (that is, where all reconfigurations are given by taking unions of existing groups). This subsumes the results reported in [14].

COROLLARY 3.4. *Algorithm RS is $\big(1+\frac{1}{e}\big)$-competitive for any $(p,t)$-DAG $C$ with* $\mathbf{cw}(C) = 1$.

*Remark.* The proof of Theorem 3.3 can be slightly modified to yield an interesting result for *deterministic* scheduling algorithms. Let $D$ be a deterministic scheduling algorithm for *Omni-Do*. In the proof of Theorem 3.3, $h^*(v)$ was defined as the expected number of tasks performed by algorithm RS at node $v$. For algorithm $D$, if we define $h^*(v)$ to be the actual number of tasks performed by the algorithm at node $v$, then it is not difficult to see that (3.4) becomes $\sum_{u\in\Gamma(s)} h^*(u) \leq \mathbf{cw}(C)\cdot t$ (provided that no processor in $D$ performs a task that already knows its result). This leads to the conclusion that *any (nontrivial) deterministic algorithm for Omni-Do is* $(1+\mathbf{cw}(C))$*-competitive for any computation pattern $C$.*

**4. A lower bound.** We begin with a lower bound for *deterministic* algorithms. This is then applied to give a lower bound for randomized algorithms in Corollary 4.2.

THEOREM 4.1. *Let $a : \mathbb{N} \to \mathbb{R}$ and $D$ be a deterministic scheduling algorithm for Omni-Do so that $D$ is $a(\mathbf{cw}(\cdot))$-competitive (that is, $D$ is $\alpha$-competitive, for a function $\alpha = a \circ \mathbf{cw}$)). Then $a(c) \geq 1 + c/e$.*

*Proof.* Fix $k \in \mathbb{N}$. Consider the case when $t = p = g \gg k$ and $t \bmod k = 0$, $g$ being the number of initial groups. We consider a computation pattern $C_{\mathbf{G}}$ determined by a tuple $\mathbf{G} = (G_1, \dots, G_{t/k})$, where each $G_i \subset [t]$ is a set of size $k$ and $\bigcup_i G_i = [t]$. Initially, the computation pattern $C_{\mathbf{G}}$ has the processors synchronously proceed until each has completed $t/k$ tasks; at this point, the processors in $G_i$ are merged and allowed to exchange information about task executions. Each $G_i$ is then immediately partitioned into $c$ groups (this establishes that the computation width is $c$). Note that the off-line optimal algorithm accrues exactly $t^2/k$ work for this computation history (it terminates prior to the partitions of the $G_i$).

We will show that for *any* scheduling deterministic Omni-Do algorithm $D$, there is a selection of the $G_i$ so that

$$W_D(C_{\mathbf{G}}) \geq t^2/k \left[1 + c\left(1 - \frac{1}{k}\right)^k - o(1)\right],$$

and hence that $a(c) \geq 1 + c/e$. Consider the behavior of $D$ when $\mathbf{G}$ is selected at random, uniformly among all such tuples. Let $P_i \subset [t]$ be the subset of $t/k$ tasks completed by processor $i$ before the merges take place; these sets are determined by the algorithm $D$. We begin by bounding

$$\mathbb{E}_{\mathbf{G}}\left[\left|\bigcup_{i \in G_1} P_i\right|\right].$$

To this end, consider an experiment where we select $k$ sets $Q_1, \dots, Q_k$, each $Q_i$ selected independently and uniformly from the set $\{P_i\}$. Now, for a specific task $\tau$, let $p_\tau = \Pr_{Q_1}[\tau \notin Q_1]$, so that $\Pr_{Q_i}[\tau \notin \bigcup_i Q_i] = p_\tau^k$. As the $Q_i$ are selected independently,

$$\mathbb{E}_{Q_i}\left[\left|[t] - \bigcup_i Q_i\right|\right] = \sum_\tau p_\tau^k.$$

Observe now that

$$\sum_\tau (1 - p_\tau) = \sum_\tau \Pr_{Q_1}[\tau \in Q_1] = \mathbb{E}_{Q_1}[|Q_1|] = t/k$$

and hence $\sum_\tau p_\tau = t(1 - 1/k)$. As the function $x \mapsto x^k$ is convex on $[0, \infty)$, $\sum_\tau p_\tau^k$ is minimized when the $p_\tau$ are equal, and we must have

$$\mathbb{E}_{Q_i}\left[\left|[t] - \bigcup_i Q_i\right|\right] \geq t \cdot \left(1 - \frac{1}{k}\right)^k.$$

Now observe that, conditioned on the $Q_i$ being distinct, the distribution of $(Q_1, \dots, Q_k)$ is identical to that of $(P_{g_1^1}, \dots, P_{g_k^1})$, where the random variable $G_1 = \{g_1^1, \dots, g_k^1\}$. Considering that $\Pr[\exists i \neq j, Q_i = Q_j] \leq k^2/t$, we have

$$\mathbb{E}_{Q_i}\left[\left|[t] - \bigcup_i Q_i\right|\right] \leq \left(1 - \frac{k^2}{t}\right) \mathbb{E}_{\mathbf{G}}\left[t - \left|\bigcup_{i \in G_1} P_i\right|\right] + 1 \cdot \frac{k^2}{t},$$

and hence as $t \to \infty$, we see that the expected number of tasks remaining for those processors in group $G_1$ is

$$\mathbb{E}_{\mathbf{G}}\left[t - \Big|\bigcup_{i\in G_1} P_i\Big|\right] \geq t(1-1/k)^k - o(1).$$

Of course, the distribution of each $G_i$ is the same, so that

$$\mathbb{E}_{\mathbf{G}}\left[\sum_{i=1}^{t/k}\left(t - \Big|\bigcup_{j\in G_i} P_j\Big|\right)\right] = [1-o(1)]\left(\frac{t}{k}\right)\cdot t\left(1-\frac{1}{k}\right)^k.$$

In particular, there must exist a specific selection of $\mathbf{G} = (G_1, \dots, G_{t/k})$ which achieves this bound. Recall that every $G_i$ is partitioned into $c$ groups. Therefore, for such $\mathbf{G}$, the total work is at least

$$\frac{t^2}{k}\cdot\left(1 + [1-o(1)]\cdot c\cdot\left(1-\frac{1}{k}\right)^k\right).$$

As $\lim_{k\to\infty}(1-\frac{1}{k})^k = \frac{1}{e}$, this completes the proof. ∎

As the above stochastic computation pattern $C_{\mathbf{G}}$ is independent of the deterministic algorithm $D$, this immediately gives rise to a lower bound for randomized algorithms.

COROLLARY 4.2. *Let $\mathcal{R}\big(\{D_r \mid r\in\Omega\}\big)$ be a randomized scheduling algorithm for Omni-Do that is $(a\circ\mathbf{cw})$-competitive. Then $a(c) \geq 1 + c/e$.*

*Proof.* Assume for contradiction that for some $c$, $a(c) < 1 + c/e$, and let $k$ be large enough so that $(1-\frac{1}{k})^k > a(c) - 1$. For this $k$ we proceed as in the proof above, considering a random $\mathbf{G}$ and the computation pattern $C_{\mathbf{G}}$ with $t = g = p$ congruent to 0 mod $k$, $g$ being the number of initial groups. Then, as above,

$$\begin{aligned}\mathbb{E}_{\mathbf{G}}\left[\mathbb{E}_r\left[W_{D_r}(C_{\mathbf{G}})\right]\right] &= \mathbb{E}_r\left[\mathbb{E}_{\mathbf{G}}\left[W_{D_r}(C_{\mathbf{G}})\right]\right]\\ &\geq \min_r\left[\mathbb{E}_{\mathbf{G}}\left[W_{D_r}(C_{\mathbf{G}})\right]\right]\\ &\geq \frac{t^2}{k}\cdot\left(1 + [1-o(1)]\cdot c\cdot\left(1-\frac{1}{k}\right)^k\right).\end{aligned}$$

Hence there exists a $\mathbf{G}$ so that $\mathbb{E}_r\left[W_{D_r}(C_{\mathbf{G}})\right] \geq \frac{t^2}{k}\cdot\left(1 + [1-o(1)]\frac{c}{e}\right)$, which completes the proof. ∎

**5. Conclusions and open problems.** We established bounds on the competitive ratio of a natural randomized algorithm for scheduling in partitionable networks and show, furthermore, that for the relevant gradation of computation patterns these bounds are tight. We showed how to characterize algorithm competitiveness in terms of computation width, a precise property of a DAG that describes the computation history. These results lead to a better understanding of the effectiveness of computation in *group communication schemes*, a widely used paradigm for computing in distributed environments.

One outstanding open question is how to derandomize the schedules used by task-performing algorithms in this work. Specifically, we would like to construct deterministic scheduling algorithms that are $(1 + \mathbf{cw}(C)/e)$-competitive for any computation pattern $C$. Another promising direction is to study the task-performing paradigm in the models of computation that combine network reconfigurations with processor failures. The goal is to establish complexity results that show how performance of task-performing algorithms depends both on the extent of the network reconfiguration and on the number of processor failures.

# CURVE-SENSITIVE CUTTINGS*

VLADLEN KOLTUN† AND MICHA SHARIR‡

**Abstract.** We introduce $(1/r)$-cuttings for collections of surfaces in 3-space, such that the cuttings are sensitive to an additional collection of curves. Specifically, let $S$ be a set of $n$ surfaces and let $C$ be a set of $m$ curves in $\mathbb{R}^3$, all of constant description complexity. Let $1 \le r \le \min\{m, n\}$ be a given parameter. We show the existence of a $(1/r)$-cutting $\Xi$ of $S$ of size $O(r^{3+\varepsilon})$, for any $\varepsilon > 0$, such that the number of crossings between the curves of $C$ and the cells of $\Xi$ is $O(mr^{1+\varepsilon})$. The latter bound improves, by roughly a factor of $r$, the bound that can be obtained for cuttings based on vertical decompositions. We view curve-sensitive cuttings as a powerful tool for various scenarios that involve curves and surfaces in three dimensions. As a preliminary application, we use the construction to obtain a bound of $O(m^{1/2}n^{2+\varepsilon})$, for any $\varepsilon > 0$, on the complexity of the multiple zone of $m$ curves in the arrangement of $n$ surfaces in 3-space. After the conference publication of this paper [V. Koltun and M. Sharir, *Proceedings of the* 19*th ACM Symposium on Computational Geometry*, 2003, pp. 136–143], curve-sensitive cuttings were applied to derive an algorithm for efficiently counting triple intersections among planar convex objects in three dimensions [E. Ezra and M. Sharir, *Proceedings of the* 20*th ACM Symposium on Computational Geometry*, 2004, pp. 210–219], and we expect additional applications to arise in the future.

## 1. Introduction.

**Motivation.** $(1/r)$-cuttings (see below for definitions) have attracted considerable attention in the computational geometry community, as they turned out to be crucial to the solution of many central problems in the field [5, 6, 7, 8, 9, 10, 14, 16, 17]. For some applications, special properties possessed by the cutting can lead to improved results. For instance, the tree structure of *hierarchical cuttings* [6] is of great help in numerous settings [4, 17].

We construct a $(1/r)$-cutting for a collection of surfaces in 3-space, such that the cutting is sensitive, in the sense defined below, to a collection of curves given as additional input to the construction. We apply this cutting to obtain a bound of $O(m^{1/2}n^{2+\varepsilon})$, for any $\varepsilon > 0$, on the complexity of the multiple zone of $m$ curves in the arrangement of $n$ surfaces in 3-space, all of constant description complexity. The multiple zone is defined as the collection of all cells of the arrangement of the given surfaces that are crossed by at least one of the curves. It is a generalization of both the concept of the zone of a curve in an arrangement [3, 13] and the widely studied notion of many faces/cells in arrangements [2].

We expect curve-sensitive cuttings to find additional uses in contexts that involve the interaction of curves and surfaces. It has already been applied, after the conference publication of this paper [15], to derive an algorithm for efficiently counting triple intersections among planar convex objects in three dimensions [12].

**Overview.** Let $S$ be a set of $n$ surfaces in $\mathbb{R}^3$ of constant description complexity, and let $C$ be a set of $m$ curves in $\mathbb{R}^3$ of constant description complexity; that is, each surface and curve is defined as a Boolean combination of a constant number of polynomial equations and inequalities of constant maximum degree. Let $1 \leq r \leq \min\{m, n\}$ be a given parameter. A $(1/r)$-*cutting* of $S$ is a subdivision of 3-space into connected cells, each of constant description complexity, so that each cell is crossed by at most $n/r$ surfaces of $S$. We wish to construct a $(1/r)$-cutting $\Xi$ of $S$ of size near $O(r^3)$, so that the number of pairs $(c, \tau)$, where $c \in C$, $\tau$ is a cell of $\Xi$, and $c \cap \tau \neq \emptyset$, is near $O(mr)$; that is, the average number of cells of $\Xi$ crossed by a curve of $C$ is near $O(r)$.

A standard method (in fact, the only general-purpose method known to date) for constructing a $(1/r)$-cutting for arrangements of nonlinear surfaces is to take an appropriate random sample $R$ of the surfaces of $S$ and construct the *vertical decomposition* of the arrangement $\mathcal{A}(R)$ of $R$ [18]. The construction of this decomposition proceeds in two stages. First, for every edge of $\mathcal{A}(R)$ and every vertical tangency curve (also known as the *silhouette*) on every surface of $R$, we erect a two-dimensional vertical *visibility wall*, defined as the union of all $z$-vertical segments that have an endpoint on this edge (or curve) and are interior-disjoint from all surfaces of $R$. This first stage results in a decomposition of $\mathcal{A}(R)$ into vertical pseudoprisms, such that the floor of each prism, if it exists, is contained in a single surface of $R$, and similarly for the ceiling of each prism. However, the combinatorial complexity of a single prism can still be fairly high.

In the second stage of the construction we refine the decomposition as follows. For every prism as above, consider its projection onto the $xy$-plane. It is a two-dimensional semialgebraic set, which we decompose in the plane by erecting zero, one, or two $y$-vertical (possibly infinite) visibility segments on each of its vertices and $y$-vertical tangency points on its edges, where a visibility segment is defined as a maximal $y$-vertical segment that has an endpoint on this vertex (or tangency point), is contained in the considered prism projection, and is interior-disjoint from its boundary. We then erect $z$-vertical two-dimensional walls inside the original prism, defined as its intersection with the $z$-vertical walls spanned by all the $y$-vertical segments erected by the planar decomposition. Repeating this process for each of the above prisms decomposes $\mathcal{A}(R)$ into cells of constant description complexity.

We can choose $R$ as a single sample from $S$ of size $ar \log r$, for an appropriate absolute constant $a$. It can then be argued that, with high probability, the resulting vertical decomposition of $\mathcal{A}(R)$ is indeed a $(1/r)$-cutting. This is a consequence of the probabilistic analyses of Haussler and Welzl [14] and of Clarkson [9]. Using a variant of the method of Chazelle and Friedman [7] or of Chazelle [6] slightly reduces the size of the resulting cutting from $O(r^3 \log^3 r)$ to $O(r^3)$.

Unfortunately, vertical decompositions may fail to satisfy our requirement concerning the number of crossings between the curves of $C$ and the cells of the cutting. In fact, a curve may cross nearly $\Omega(r^2)$ such cells. An example is shown in Figure 1, where $R$ is a collection of $r$ planes. Half of them are parallel to the $x$-axis and pass above it, all appearing on the lower envelope of this group, which looks like a tunnel in the $x$-direction with a convex roof that is symmetric about the $xz$-plane. The remain-

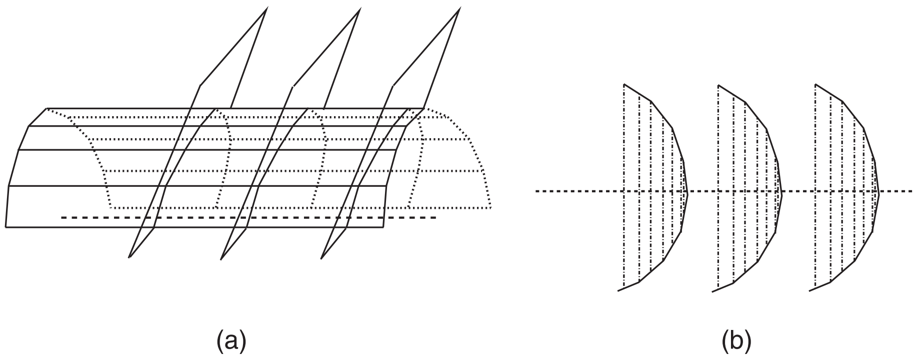

FIG. 1. *A curve (the x-axis, shown dashed) crossing a quadratic number of cells of the vertical decomposition.* (a) *A side view of the input set.* (b) *A view from above of the second-step subdivision of the cells mentioned in the text.*

ing $r/2$ planes are all parallel to the $y$-axis and form a fixed angle, say $45°$, with the $xy$-plane. These latter planes are sufficiently separated from each other so that their portions that lie above the $xy$-plane and below the lower envelope of the first group have pairwise disjoint $xy$-projections. The $x$-axis crosses $\Theta(r^2)$ cells of the vertical decomposition of these planes: Indeed, the first decomposition step creates (among others) $r/2$ cells whose top facet is the portion of some slanted plane of the second group that lies below the lower envelope of the first group. The second decomposition step subdivides each of these cells into $\Theta(r)$ subcells, and the $x$-axis crosses them all.

In contrast, the *undecomposed* arrangement of $\Theta(r \log r)$ surfaces is sensitive to the curves of $C$, because each curve crosses each surface at $O(1)$ points, so it crosses $O(r \log r)$ cells of the arrangement. However, the undecomposed arrangement is generally not a $(1/r)$-cutting. On the other hand, the decomposed arrangement is (with high probability) a $(1/r)$-cutting, but, as we have just seen, it may fail to be sensitive to $C$. (Actually, as we will show in section 2.1, the first stage of the vertical decomposition is also sensitive to $C$, but in general it is still not a $(1/r)$-cutting.)

In this paper we describe a technique that achieves the better of both worlds and constructs cuttings that satisfy the desired properties. The construction proceeds by taking a sample $R$ of the surfaces, as described above, and decomposing $\mathcal{A}(R)$ into vertical prisms using the *first stage* of the vertical decomposition construction. Inside each prism we construct a decomposition that takes into account the parts of the curves of $C$ that lie inside the prism. Specifically, we construct a hierarchical sequence of cuttings, somewhat reminiscent of the construction in Chazelle [6], that reduces the number of crossings between the curves of $C$ and the boundaries of the cells of the cuttings. We are able to guarantee that the curves of $C$ are not cut more than $O(mr^{1+\varepsilon})$ times, for any $\varepsilon > 0$, overall.

Before describing our results in detail, we remark that we can construct an alternative (and simpler) curve-sensitive decomposition scheme for the special case where the surfaces are planes and the curves are lines (as in the example of Figure 1) by using the Dobkin–Kirkpatrick hierarchical decomposition [11] in each cell of $\mathcal{A}(R)$. This approach, however, does not extend to general curves and surfaces. (An expanded discussion of this remark is given in the application paper [12].)

**2. A curve-sensitive decomposition.** In this section we present a new decomposition scheme that is a $(1/r)$-cutting for $S$ and satisfies the desired bounds on the number of cells and on the number of curve-cell crossings. For simplicity of exposition, we will base our analysis on a single random sample of surfaces from $S$ (rather than the more elaborate repeated-sampling scheme of [7]). Moreover, we consider samples of size $r$ (rather than $\Theta(r \log r)$). This simplifies the calculations, but will only produce an $O(\log r/r)$-cutting. We get the desired cutting by simply replacing $r$, at the end of the analysis, by the above larger sample size.

**2.1. First stage of the decomposition.** We begin with taking a random sample $R$ of $r$ surfaces of $S$, and a random sample $R'$ of $r$ curves of $C$. We form the arrangement $\mathcal{A}(R)$ of $R$ and apply to it the first step of the vertical decomposition. That is, we erect vertical walls up and down from each curve of an intersection of pairs of surfaces in $R$, as well as from the silhouette of each surface in $R$; the walls are extended until they hit another surface of $R$ or, failing that, all the way to $\pm\infty$. In addition, we erect similar vertical walls from each curve $c \in R'$, which are also extended to the first surface above and below.

Let $\mathcal{A}_1 = \mathcal{A}_1(R, R')$ denote the resulting decomposition. Note that each cell $\tau$ of $\mathcal{A}_1$ is a vertical prism-like cell: the intersection of each vertical line with $\tau$ is connected. However, the $xy$-projection $\tau^*$ of $\tau$ can have arbitrary shape and complexity.

For each cell $\tau$ of $\mathcal{A}_1$, let $\xi_\tau$ denote its combinatorial complexity (i.e., the number of vertices, edges, and faces on its boundary), and let $C_\tau$ denote the set of all connected components of the nonempty intersections between $\tau$ and the curves of $C$. Let $\lambda_q(r)$ denote, as usual, the maximum length of a Davenport–Schinzel sequence of order $q$ on $r$ symbols [18], and put $\beta_q(r) = \lambda_q(r)/r$, which is thus an extremely slow-growing function of $r$. We have the following lemma.

LEMMA 2.1. (a) *The number of cells of $\mathcal{A}_1$ and their overall combinatorial complexity are both $O(r^3\beta_q(r))$ for an appropriate parameter $q$ that depends on the algebraic complexity of the curves of $C$ and the surfaces of $S$.*

(b) $\sum_{\tau\in\mathcal{A}_1} |C_\tau| = O(mr\beta_q(r))$.

*Proof.* Let $\gamma$ be a fixed curve, which is either a curve in $C$, an intersection curve of two surfaces in $R$, or the silhouette of a surface in $R$. Let $V_\gamma$ denote the vertical 2-manifold (wall) spanned by $\gamma$. Let $V_\gamma^+$ (resp., $V_\gamma^-$) denote the portion of $V_\gamma$ that lies above (resp., below) $\gamma$. Let $\mathcal{A}^+$ (resp., $\mathcal{A}^-$) denote the cross section of $\mathcal{A}(R)$ with $V_\gamma^+$ (resp., $V_\gamma^-$). By construction, any point at which $\gamma$ crosses the boundary of some cell of $\mathcal{A}_1$ must be either the vertical projection on $\gamma$ of a vertex of the lower envelope of $\mathcal{A}^+$, a vertex of the upper envelope of $\mathcal{A}^-$ (or of both, if the vertex lies on $\gamma$ itself), or a point that lies vertically above or below a point on another curve of $R'$ (so that the two points are *vertically visible* in $\mathcal{A}(R)$). The complexity of each envelope is $O(\lambda_q(r)) = O(r\beta_q(r))$ for an appropriate constant $q$ [18], and the number of times $\gamma$ passes above or below any curve of $R'$ is $O(r)$ (over all curves of $R'$). This readily implies the lemma: Part (b) is an immediate consequence, while part (a) follows by applying this bound to each of the $O(r^2)$ intersection and $O(r)$ silhouette curves arising in the sample. □

**2.2. Second stage of the decomposition.** After constructing the decomposition $\mathcal{A}_1$, we perform a second decomposition step, which decomposes each cell $\tau$ of $\mathcal{A}_1$ as follows. Let $\partial\tau^*$ denote the boundary of $\tau^*$ and let $h_\tau$ denote the number of internal boundary components ("holes") of $\tau^*$. Note that $h_\tau \le \xi_\tau$. Since $\tau^*$ need not be simply connected, $\partial\tau^*$ may consist of more than one connected component (i.e., $h_\tau$ may be strictly positive). The potential existence of many components of $\partial\tau^*$ is the main source of technical difficulty in the analysis of our decomposition.

Put $m_\tau = |C_\tau|$. Let $C^*_\tau$ denote the set of the $xy$-projections of the arcs of $C_\tau$. Let $X_\tau$ denote the number of intersections between the curves of $C^*_\tau$. This is also equal to the number of *vertical visibility segments* between pairs of curves of $C_\tau$, where such a segment is parallel to the $z$-axis and connects a point on one curve to a point on the other (and is thus fully contained in $\tau$). We clearly have

$$\sum_{\tau \in \mathcal{A}_1} X_\tau = O(m^2). \tag{1}$$

In what follows, through the bulk of this section, we assume that $X_\tau \geq m_\tau$. The alternative case $X_\tau < m_\tau$ is considerably simpler to handle and will be described later in the analysis.

If $X_\tau = o(m_\tau^2)$, we carry out a preliminary decomposition stage that covers $\tau^*$ by the union of simpler-shaped subcells, so that, within each such subcell $\tau_0$, the number of intersections between the curves of $C^*_\tau$ that cross $\tau_0$ is roughly the square of the number of such curves. We employ a standard approach that proceeds as follows. (See, e.g., [5].) Put $s = s_\tau = \lceil m_\tau^2 / X_\tau \rceil$. We distinguish between the following two cases.

(a) Suppose first that $s \leq \xi_\tau$. We sample each curve of $C^*_\tau$ with probability $s/m_\tau$. This produces a random sample $R''$ of expected size $s$. The expected complexity of $\mathcal{A}(R'')$ is $O(s + (s/m_\tau)^2 X_\tau) = O(s)$, since each intersection counted in $X_\tau$ becomes a vertex of $\mathcal{A}(R'')$ with probability $(s/m_\tau)^2$. We construct the vertical decomposition of $\mathcal{A}(R'')$ and argue that, with high probability, it consists of $O(s)$ trapezoids, each of which is crossed by at most $O((m_\tau/s)\log s)$ curves of $C^*_\tau$. We next apply a modified version of the analysis of Chazelle and Friedman [7] to refine the decomposition, so that each of its cells is crossed by at most $m_\tau/s$ curves of $C^*_\tau$, while the number of cells remains $O(s)$.

Since the setup here is somewhat different from that in [7], we present details of the construction and of its analysis. This is done as follows. We take each cell $\Delta$ of the vertical decomposition that is crossed by $tm_\tau/s$ curves of $C^*_\tau$, for any $t > 1$, draw a random sample $R''_\Delta$ of $ct\log t$ of these curves, for an appropriate sufficiently large constant $c$, construct the vertical decomposition of the arrangement $\mathcal{A}(R''_\Delta)$, and clip each resulting cell to $\Delta$. With high probability, each cell in the resulting decomposition is crossed by at most $m_\tau/s$ curves of $C^*_\tau$, provided $c$ is chosen sufficiently large. To estimate the overall number of cells, we apply Lemma 2.2 of Agarwal, Matoušek, and Schwarzkopf [1], which, in our context, asserts that the expected number of cells that are crossed by at least $jm_\tau/s$ curves is $O(2^{-j})$ times the expected number of cells in a random sample of $s/j$ curves of $C^*_\tau$. The latter expected number of cells is easily seen to be $O(s/j)$, and thus the overall expected number of new cells is

$$O(s) + \sum_{j\geq 1} O(2^{-j}s/j) = O(s),$$

as claimed.

As we do throughout the analysis, we assume that all those subsamples meet their expected values, so that this property holds with certainty. This assumption can be made effective, e.g., by resampling at each stage of the construction until a good sample is obtained. See a remark to that effect following Theorem 2.3.

These trapezoids are the cells $\tau_0$ of the cutting decomposition (or, rather, covering) of $\tau^*$. Each cell $\tau_0$ contains on average $X_\tau/s = O(X_\tau^2/m_\tau^2)$ crossings between curves of $C^*_\tau$, which is roughly the square of the number $O(m_\tau/s) = O(X_\tau/m_\tau)$ of

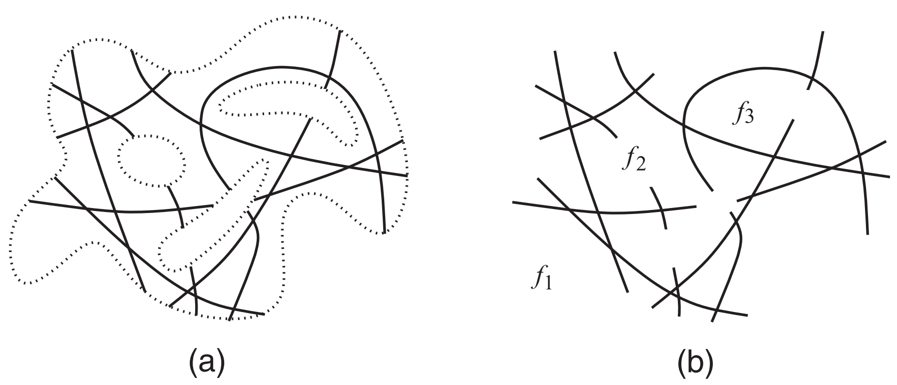

FIG. 2. *Stage* 2 *of the decomposition.* (a) *The curves of $Q \subseteq C^*_{\tau_0}$ (solid) and $\partial\tau^*$ (dotted).* (b) *The external faces of $\mathcal{A}(Q)$; note that $f_2$ contains two components of $\partial\tau^*$.*

these curves that cross $\tau_0$. It is important to note that this decomposition is defined only in terms of the curves in $C^*_\tau$, and is thus not necessarily confined within $\tau^*$. Thus our trapezoids constitute a *covering* of $\tau^*$. (Nevertheless, since all the curves of $C^*_\tau$ are fully contained in $\tau^*$, the portion of the covering outside $\tau^*$ is uninteresting; it is constructed simply because we do not want at this stage to let $\partial\tau^*$ affect the construction.) We shall later, towards the end of this section, take care to clip the new cells to within $\tau^*$.

(b) Suppose next that $s > \xi_\tau$. We then sample each curve of $C^*_\tau$ with probability $\xi_\tau/m_\tau$. Note that this quantity is indeed at most 1, because $s \le m_\tau$ (which follows from the assumption $X_\tau \ge m_\tau$) and $\xi_\tau < s$. This produces a random sample $R''$ of expected size $\xi_\tau$. The expected complexity of $\mathcal{A}(R'')$ is $O(\xi_\tau + (\xi_\tau/m_\tau)^2 X_\tau) = O(\xi_\tau)$, since $\xi_\tau < s$. We apply the same decomposition construction as in the preceding case, obtaining a new collection of $O(\xi_\tau)$ trapezoids, each of which is crossed by at most $m_\tau/\xi_\tau$ curves of $C^*_\tau$. These trapezoids are the cells $\tau_0$ of the cutting-cover of $\tau^*$.

This concludes the description of the preliminary covering of $\tau^*$ that is constructed only if $X_\tau = o(m_\tau^2)$. If $X_\tau = \Theta(m_\tau^2)$, we have $s = O(1)$ and the first case applies; we cover $\tau$ by a single $\tau_0$, which we take to be the entire $xy$-plane.

We now apply an additional decomposition step to each cell $\tau_0$ of this preliminary cutting. This decomposition consists of a recursively constructed hierarchical sequence of cuttings of the subset $C^*_{\tau_0}$ of those curves of $C^*_\tau$ that cross $\tau_0$, clipped to within $\tau_0$. This decomposition is somewhat reminiscent of the hierarchical cutting construction of Chazelle [6]. We begin by choosing a sufficiently large constant $\rho$, to be used throughout the construction. Put $m_{\tau_0} = |C^*_{\tau_0}|$.

**First level in the hierarchy.** We draw a random sample $Q$ of $\rho$ arcs of $C^*_{\tau_0}$ and consider all the faces of the planar arrangement $\mathcal{A}(Q)$ that contain components of $\partial\tau^*$. By the definition of $C_\tau$, the arcs of $C^*_{\tau_0}$ are contained within $\tau^*$, and thus each component of $\partial\tau^*$ lives in a single (not necessarily distinct) face of $\mathcal{A}(Q)$. We refer to such faces as the *external* faces of $\mathcal{A}(Q)$. Note also that, as defined, those faces are not confined within $\tau_0$ or within $\tau^*$. That is, $\partial\tau^*$ is not part of $\mathcal{A}(Q)$ and does not delimit any face of it. However, each component $\gamma$ of $\partial\tau^*$ bounds a connected component of the complement of $\tau^*$ which is fully disjoint from all the arcs of $Q$ (or of $C^*_{\tau_0}$ for that matter). See Figure 2.

For each external face $f$ of $\mathcal{A}(Q)$, we compute the two-dimensional vertical decomposition of $f$ into vertical pseudotrapezoids (see, e.g., [18]), which we refer to as *trapezoids* or *subcells*. With high probability (greater than, say, $1 - 1/\rho$), each resulting subcell $\sigma$ is crossed by at most $\frac{am_{\tau_0}}{\rho} \log \rho$ curves of $C^*_{\tau_0}$ for an appropriate absolute constant $a$ [9, 14]. As above, we assume that $Q$ is a sample that satisfies this property. For each connected component $\gamma$ of $\partial\tau^*$, the face $f_\gamma$ of $\mathcal{A}(Q)$ that contains $\gamma$ consists of $O(\rho\beta_q(\rho))$ subcells [18], so the total number of crossings between the arcs of $C^*_{\tau_0}$ and these subcells is $O(m_{\tau_0}\beta_q(\rho)\log\rho)$. Let $\kappa_{\tau_0}$ denote the number of distinct external faces of $\mathcal{A}(Q)$. Then we get a total of $O(\kappa_{\tau_0}\rho\beta_q(\rho))$ external trapezoids,[1] and the total number of crossings between the arcs of $C^*_{\tau_0}$ and these subcells is $O(\kappa_{\tau_0}m_{\tau_0}\beta_q(\rho)\log\rho)$.

An obvious upper bound on $\kappa_{\tau_0}$ is $1+h_{\tau_0}$, where $h_{\tau_0}$ denotes the number of internal connected components of $\partial\tau^*$ that are fully contained in $\tau_0$ (boundary components that cross $\partial\tau_0$ all lie in the single unbounded face of $\mathcal{A}(Q)$), but we will use in the following analysis a more refined bound. The need for a refined analysis comes from the observation that, at this initial stage of the hierarchy, the total number of faces of $\mathcal{A}(Q)$ is only a constant (at most $O(\rho^2)$), whereas $h_{\tau_0}$ can be much larger. Note that, trivially,

$$\sum_{\tau_0} h_{\tau_0} \le h_\tau \le \xi_\tau. \tag{2}$$

We also have $h_\tau = O(r)$, because we can charge each internal component of $\partial\tau^*$ either to a complete connected component of an intersection curve between the surface of $R$ forming the floor of $\tau$ with another surface in $R$, to a similar intersection component involving the surface forming the ceiling of $\tau$, or to a complete connected component of the silhouette of some surface of $R$ (which is completely contained in the interior of $\tau$), and the overall number of such components is clearly $O(r)$. In fact, applying this analysis to all the cells $\tau$ of $\mathcal{A}_1$ together, we obtain the following bound, which is crucial for our analysis:

$$\sum_{\tau\in\mathcal{A}_1} h_\tau = O(r^2). \tag{3}$$

In addition to decomposing the external faces as described above, we also partition the remainder of $\mathcal{A}(Q)$ (its *internal portion*) into vertical trapezoids. In doing so, we erase all the edges of $\mathcal{A}(Q)$ that are contained in the interior of the internal portion, and retain only the edges that also bound the external faces. Thus the number of trapezoids into which the internal portion is partitioned is also $O(\kappa_{\tau_0}\rho\beta_q(\rho))$. The total number of crossings between the arcs of $C^*_{\tau_0}$ and these internal subcells is $O(\kappa_{\tau_0}m_{\tau_0}\rho\beta_q(\rho))$. (Here we can no longer claim that each internal trapezoid is crossed by only a small number of curves, because it is not necessarily disjoint from the sampled curves in $Q$, so this bound is larger than the bound claimed for external trapezoids by nearly a factor of $\rho$.)

**Second level in the hierarchy.** We now apply a second partitioning step[2] within each external trapezoid $\sigma$ that has a nonempty intersection with $\partial\tau^*$. (All

[1]The number of external trapezoids is proportional to the combined complexity of the external faces. In general, better bounds are known for the complexity of $\kappa_{\tau_0}$ faces in an arrangement of $\rho$ curves (see, e.g., [8]), but the cruder bound that we use suffices for our purposes.

[2]To help the reader follow the construction, we present the second stage explicitly and separately, even though it is a special case of the general recursive step, described later. As a matter of fact, it is also similar to the first-level partitioning.

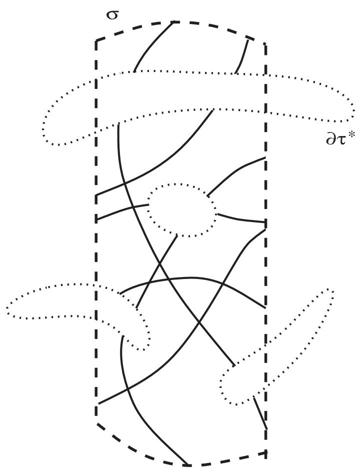

FIG. 3. *An external trapezoid $\sigma$ (dashed), the portions of $\partial\tau^*$ that meet $\sigma$ (dotted), and the arcs in $C^*_\sigma$ (solid).*

other external and internal trapezoids are not decomposed any further.) Let $C^*_\sigma$ denote the set of connected components of the intersections of the curves in $C^*_{\tau_0}$ with $\sigma$. As in the preceding step, $\sigma$ is not necessarily contained in $\tau^*$; however, each arc in $C^*_\sigma$ lies fully in $\sigma \cap \tau^*$. See Figure 3.

We draw a random sample $Q_\sigma$ of $\rho$ curves of $C^*_\sigma$ and compute all the faces of the planar arrangement $\mathcal{A}(Q_\sigma)$ that contain components of $\partial\tau^*$. As above, each component of $\partial\tau^*$ lives in a single ("external") face of $\mathcal{A}(Q_\sigma)$. Again, those faces are not necessarily distinct. This time, however, all external faces, with the exception of the unbounded one, are confined to within $\sigma$. Boundary components $\gamma$ of $\partial\tau^*$ that intersect $\sigma$ are of two types: those that are fully contained in the interior of $\sigma$, and those that cross $\partial\sigma$. All components $\gamma$ of the second type lie in the same (unbounded) face of $\mathcal{A}(Q_\sigma)$. Let $h_\sigma$, $\kappa_\sigma$ denote, respectively, the number of components $\gamma$ of the first type, and the number of distinct external faces of $\mathcal{A}(Q_\sigma)$. Clearly, $\kappa_\sigma \le 1 + h_\sigma$, and $\sum_\sigma h_\sigma \le h_\tau$ (where the sum extends over all $\sigma$ and all $\tau_0$). Again, however, we will have to use a more refined bound for $\kappa_\sigma$ in what follows.

For each external face $f$ of $\mathcal{A}(Q_\sigma)$, we compute the two-dimensional vertical decomposition of $f$. With high probability (larger than $1 - 1/\rho$), each resulting subcell $\sigma'$ is crossed by at most

$$\left(\frac{a \log \rho}{\rho}\right)^2 m_{\tau_0}$$

curves of $C^*_\sigma$, and, as above, we assume that $Q_\sigma$ is a sample that does satisfy this property. For each connected component $\gamma$ of $\partial\tau^*$ that meets $\sigma$, the face $f_\gamma$ of $\mathcal{A}(Q_\sigma)$ that contains $\gamma$ consists of $O(\rho\beta_q(\rho))$ subcells. Summing over all boundary components of $\partial\tau^*$ that meet $\sigma$, we get a total of $O(\kappa_\sigma \rho\beta_q(\rho))$ external trapezoids, and the total number of crossings between the arcs of $C^*_\sigma$ and these subcells is

$$O(\kappa_\sigma m_{\tau_0} \beta_q(\rho) \log^2 \rho/\rho).$$

Summing these bounds over all external trapezoids $\sigma$, we obtain bounds for the overall number of external trapezoids in the second hierarchical partitioning step and the total number of crossings between arcs in $C^*_{\tau_0}$ and these trapezoids. These bounds are, respectively,

$$\sum_{\sigma} O(\kappa_\sigma \rho \beta_q(\rho)) \tag{4}$$

and

$$\sum_{\sigma} O(\kappa_\sigma m_{\tau_0} \beta_q(\rho) \log^2 \rho/\rho),$$

where these sums are over all external trapezoids $\sigma$ in $\mathcal{A}(Q)$.

As above, we also partition the remaining internal portions of the arrangements $\mathcal{A}(Q_\sigma)$, over all trapezoids $\sigma$, into vertical trapezoids, using, as above, only the edges and vertices of these internal portions that bound also the external portions. Thus, the overall number of internal trapezoids is also bounded by (4), and the total number of crossings between arcs in $C^*_{\tau_0}$ and these internal trapezoids is at most

$$\sum_{\sigma \text{ an external trapezoid in } \mathcal{A}(Q)} O(\kappa_\sigma m_{\tau_0} \beta_q(\rho) \log \rho).$$

**Recursive construction of the hierarchy.** The above process is repeated recursively, each recursion stage refining the decomposition inside those "external" trapezoids constructed in the previous stage that are still crossed by (or contain) boundary components of $\partial\tau^*$. Let $j = j_{\tau_0}$ be the smallest integer such that

$$\rho^j \geq \xi_\tau / s.$$

We stop the recursive decomposition process after $j$ steps. In particular, if $\xi_\tau < s$, there is no recursion, and $\tau_0$ remains intact. Otherwise, we have $\rho^j = \Theta(\xi_\tau/s)$. Let us for now consider only the (much more involved) case $\xi_\tau \geq s$.

By an appropriate extension of the preceding arguments, the overall number of external and internal trapezoids produced in the $i$th step, for any $i = 1, \ldots, j$, is at most

$$\sum_{\sigma \text{ an external trapezoid in some } \mathcal{A}(Q_{\sigma'})} O(\kappa_\sigma \rho \beta_q(\rho)), \tag{5}$$

where $\sigma'$ is an external trapezoid constructed in the preceding $(i-1)$st step which intersects $\partial\tau^*$. With high probability (which we turn into certainty by choosing "good" samples $Q_{\sigma'}$), each external trapezoid constructed at the $i$th step is crossed by at most

$$O\left(\left(\frac{a \log \rho}{\rho}\right)^i m_{\tau_0}\right)$$

curves of $C^*_\tau$, and each such internal trapezoid is crossed by at most

$$O\left(\left(\frac{a \log \rho}{\rho}\right)^{i-1} m_{\tau_0}\right)$$

curves. Hence, the number of crossings between the arcs of $C^*_{\tau_0}$ and the external trapezoids is at most

$$\sum_\sigma O\left(\kappa_\sigma m_{\tau_0}\beta_q(\rho)\frac{a^i\log^i\rho}{\rho^{i-1}}\right),$$

and the number of crossings between the arcs of $C^*_{\tau_0}$ and the internal trapezoids is at most

$$\sum_\sigma O\left(\kappa_\sigma m_{\tau_0}\beta_q(\rho)\frac{a^{i-1}\log^{i-1}\rho}{\rho^{i-2}}\right), \tag{6}$$

where these sums are over all external trapezoids $\sigma$ in some $\mathcal{A}(Q_{\sigma'})$.

**Bounding the number of trapezoids.** We continue to assume in what follows that $\xi_\tau \geq s$; otherwise $\tau_0$ remains a single trapezoid. Let us analyze the number of trapezoids in more detail. Let $\gamma$ be a boundary component of $\partial\tau^*$. If at some step $i$, $\gamma$ crosses the boundary of some external trapezoid(s), it has no effect on the quantities $\kappa_\sigma$ from this step onward (inclusive). If on the other hand $\gamma$ remains confined to the interior of a single external trapezoid $\sigma$, then it may add 1 to $\kappa_\sigma$, but it will not affect $\kappa_{\sigma'}$, for any other external trapezoid $\sigma'$ produced at this step.

Elaborating this observation, we consider the tree $\mathcal{T}$ of all external trapezoids as they are generated during the recursive process. The root of the tree is $\tau_0$, and the children of each external trapezoid $\sigma$ are the external trapezoids that are constructed in the decomposition of $\sigma$. We say that a trapezoid is *pregnant* if it completely contains a component of $\partial\tau^*$ in its interior. Otherwise it is *empty*. An empty trapezoid can spawn at most $c\rho\beta_q(\rho)$ subtrapezoids (in a single decomposition step), for some constant $c$, whereas a pregnant trapezoid containing $t$ components of $\partial\tau^*$ in its interior can spawn as many as $(t+1)c\rho\beta_q(\rho)$ subtrapezoids, but no more than $c\rho^2$, which is the maximum number of trapezoids that can be generated in a single decomposition step (for simplicity, we use the same constant $c$ in both bounds). Moreover, the total number of pregnant trapezoids, over the entire tree, is only $O(h_{\tau_0})$.

The empty trapezoids are organized into subtrees, each rooted at some pregnant trapezoid. (If there are no pregnant trapezoids, the empty trapezoids comprise the entire tree $\mathcal{T}$, and the analysis becomes considerably simpler.) Consider such a subtree rooted at a pregnant trapezoid at depth $i$ (where the root of $\mathcal{T}$ is at depth 0). The degree of each node in the subtree is at most $c\rho\beta_q(\rho)$, so the size (or, more precisely, the number of leaves) of the subtree is at most $(c\rho\beta_q(\rho))^{j-i}$ (recall that $j$ is the depth of the entire recursion). We choose a threshold depth $k$, and distinguish between the cases $i \leq k$ and $i > k$. In the former case, the total number of trees whose roots are at depth $i$ is at most $c^i\rho^{2i}$, and their total size (i.e., number of leaves) is thus at most

$$c^i\rho^{2i}\cdot(c\rho\beta_q(\rho))^{j-i} = c^j\rho^{i+j}(\beta_q(\rho))^{j-i}.$$

Summing these bounds over all depths $i = 0,\ldots,k$, we obtain a total size of

$$O(c^j\rho^{k+j}(\beta_q(\rho))^{j-k})$$

trapezoids.

In the latter case ($i > k$), we bound the total number of trees whose roots are at depth greater than $k$ simply by $O(h_{\tau_0})$, and bound the size of any such subtree by $(c\rho\beta_q(\rho))^{j-k}$. Hence, the total size of these subtrees is at most

$$O(h_{\tau_0})\cdot(c\rho\beta_q(\rho))^{j-k}.$$

To fix the value of $k$, we first assume that $(c\rho^2)^j \le h_{\tau_0}$, set $k = j$, and note that only the case $i \le k$ remains relevant. The overall number of external trapezoids produced within $\tau_0$ under this assumption is

$$O(c^j \rho^{2j}) = O(h_{\tau_0}).$$

Assuming now that $(c\rho^2)^j > h_{\tau_0}$, we choose $k$ so that $(c\rho^2)^k = \Theta(h_{\tau_0})$, and assume that $\rho$ is a sufficiently large constant, as a function of a prescribed $\varepsilon > 0$, to conclude that the overall number of external trapezoids in this setting is

$$O(h_{\tau_0}^{1/2} \rho^{j(1+\varepsilon)}) = O\left( h_{\tau_0}^{1/2} \left( \frac{\xi_\tau}{s} \right)^{1+\varepsilon} \right).$$

By construction, the number of internal trapezoids has the same asymptotic upper bound.

Note that when $h_{\tau_0} = 0$, there is only one subtree, with $(c\rho\beta_q(\rho))^j = O((\xi_\tau/s)^{1+\varepsilon})$ trapezoids.

We sum the above two bounds over all cells $\tau_0$ (for the fixed first-stage cell $\tau$), use the Cauchy–Schwarz inequality and the facts that $\sum_{\tau_0} h_{\tau_0} \le h_\tau$ and that the number of trapezoids $\tau_0$ is $O(s)$, and cater to both cases $h_{\tau_0} > 0$ and $h_{\tau_0} = 0$ to conclude that the total number of trapezoids into which $\tau$ is partitioned is

$$\begin{aligned} (7) \qquad & O\left( \sum_{\tau_0} h_{\tau_0} \right) + O\left( \left( \frac{\xi_\tau}{s} \right)^{1+\varepsilon} \right) \cdot \sum_{\tau_0} \max\{1, h_{\tau_0}\}^{1/2} \\ &= O\left( \sum_{\tau_0} h_{\tau_0} \right) + O\left( \left( \frac{\xi_\tau}{s} \right)^{1+\varepsilon} (h_\tau + s)^{1/2} s^{1/2} \right) \\ &= O\left( h_\tau + (1 + h_\tau^{1/2}) \xi_\tau^{1+\varepsilon} \right). \end{aligned}$$

We now cater to the case $\xi_\tau < s$. In this case, $\tau$ is covered by $O(\xi_\tau)$ trapezoids $\tau_0$, and each of them remains intact, so the total number of trapezoids is $O(\xi_\tau)$, which is subsumed in the bound (7).

**Bounding the number of curve-cell crossings.** Next consider the bounds (6) on the number of curve-cell crossings, and we analyze them in more detail, using our tree representation of the external trapezoids. We continue to assume that $X_\tau \ge m_\tau$, and that $\xi_\tau \ge s$. For simplicity of exposition, we consider only crossings with external trapezoids, observing that at each step of the construction, the number of internal trapezoids has the same upper bound as the number of external trapezoids, and that, with high probability (which, as usual, we take to hold with certainty), the bound on the number of curves of $C_\sigma^*$ that cross an internal trapezoid is at most $\rho/(a \log \rho)$ times larger than the same bound for external trapezoids. Hence, up to this constant, the number of crossings with internal trapezoids has the same upper bound as the number of crossings with external trapezoids, so we concentrate only on bounding the latter quantity.

Consider our tree $\mathcal{T}$ of external trapezoids. As in the preceding analysis, we distinguish between the cases $h_{\tau_0} > 0$ and $h_{\tau_0} = 0$. We treat only the case $h_{\tau_0} > 0$; the other case is handled similarly, by replacing $h_{\tau_0}$ by 1. With high probability (which, as usual, we take to hold with certainty), an external trapezoid at depth $i$ is crossed by at most $(\frac{a \log \rho}{\rho})^i m_{\tau_0}$ curves of $C_{\tau_0}^*$. We fix a threshold value $k$ as above, taking also into consideration the case where $(c\rho^2)^j \le h_{\tau_0}$. Suppose first that $i \le k$. The number of external trapezoids at depth $i$ is at most $c^i\rho^{2i}$, so the overall number of curve-cell crossings with these trapezoids is at most $(ac\rho\log\rho)^i m_{\tau_0}$. Summing this over all depths $i = 0,\dots,k$, we get a total of $O((ac\rho\log\rho)^k m_{\tau_0})$ crossings. For both possible values of $k$, by the choices of $j$ and $\rho$, the above bound can be written as

$$O\left((ac^{1/2}\log\rho)^k(c^{1/2}\rho)^k m_{\tau_0}\right) = O\left(h_{\tau_0}^{1/2}(\xi_\tau/s)^\varepsilon m_{\tau_0}\right).$$

Consider next the case $i > k$ (which applies only when $(c\rho^2)^j > h_{\tau_0}$). The number of external trapezoids at depth $i$ can be estimated as follows. All these trapezoids belong to $O(h_{\tau_0})$ subtrees rooted at the pregnant trapezoids, or, if $h_{\tau_0} = 0$, to the entire tree $\mathcal{T}$. To maximize the number of our trapezoids, the subtrees should be rooted as close to the root of $\mathcal{T}$ as possible. By the choice of $k$, it is easily seen that this happens when all the pregnant nodes lie roughly at level $k$ of $\mathcal{T}$. Assuming this "worst-case" scenario, the number of external trapezoids at depth $i$ is at most

$$O\left((c\rho^2)^k \cdot (c\rho\beta_q(\rho))^{i-k}\right) = O\left(c^i\rho^{i+k}\beta_q^{i-k}(\rho)\right).$$

Since, with high probability (which we take to hold with certainty), each of these trapezoids is crossed by at most $(\frac{a\log\rho}{\rho})^i m_{\tau_0}$ curves of $C^*_{\tau_0}$, the total number of curve-cell crossings with these trapezoids is at most

$$(ac\beta_q(\rho)\log\rho)^i\,(\rho/\beta_q(\rho))^k\,m_{\tau_0}.$$

As in the preceding subcase, for both possible values of $k$, summing over all depths $i = k+1,\dots,j$, and using the choices of $j$ and $\rho$, this can be bounded by

$$O\left((ac\beta_q(\rho)\log\rho)^j\rho^k m_{\tau_0}\right) = O\left(h_{\tau_0}^{1/2}(\xi_\tau/s)^\varepsilon m_{\tau_0}\right).$$

Hence the total number of curve-cell crossings within $\tau_0$, taking also into account the case $h_{\tau_0} = 0$, is $O\left(\max\{1,h_{\tau_0}\}^{1/2}(\xi_\tau/s)^\varepsilon m_{\tau_0}\right)$.

We sum the bound just derived over all cells $\tau_0$ of $\mathcal{A}(R'')$, calibrate the value of $\varepsilon$ appropriately, and use the facts that the number of cells $\tau_0$ is $O(s)$, that $m_{\tau_0} \le m_\tau/s$, and that $s = \lceil m_\tau^2/X_\tau\rceil$. This yields the following overall bound:

$$\begin{aligned}
&O\left(\left(\frac{\xi_\tau}{s}\right)^\varepsilon\right)\cdot\sum_{\tau_0} O(m_{\tau_0}\max\{1,h_{\tau_0}\}^{1/2})\\
&= O\left(\frac{m_\tau\xi_\tau^\varepsilon}{s^{1+\varepsilon}}\cdot\left(\sum_{\tau_0}(1+h_{\tau_0})\right)^{1/2}\cdot s^{1/2}\right)\\
&= O\left(m_\tau\xi_\tau^\varepsilon\frac{(h_\tau+s)^{1/2}}{s^{1/2+\varepsilon}}\right)\\
&= O\left(\frac{\xi_\tau^\varepsilon}{s^\varepsilon}\left(m_\tau+\frac{m_\tau h_\tau^{1/2}}{s^{1/2}}\right)\right)\\
&= O\left((X_\tau^{1/2}h_\tau^{1/2}+m_\tau)\xi_\tau^\varepsilon\right) \qquad (8)
\end{aligned}$$

for any $\varepsilon > 0$.

If $\xi_\tau < s$, then $\tau_0$ remains intact and the number of crossings between curves and trapezoids within $\tau_0$ is thus $m_{\tau_0}$. We sum this over all $O(\xi_\tau)$ cells $\tau_0$ and use the fact that $m_{\tau_0} \le m_\tau/\xi_\tau$ for each $\tau_0$ to obtain the bound $O(m_\tau)$, which is subsumed in (8).

**The case $X_\tau < m_\tau$.** So far in the description of the second stage of the decomposition we have assumed that $X_\tau \geq m_\tau$. We now address the case $X_\tau < m_\tau$. By breaking each curve of $C^*_\tau$ at the points where it crosses other curves, we obtain a collection of pairwise openly disjoint curves, whose number is only $O(m_\tau)$. Assuming first that $\xi_\tau \leq m_\tau$, we now sample each (new) curve in $C^*_\tau$ with probability $\xi_\tau/m_\tau$, obtaining a random sample $R^*$ of expected size $\xi_\tau$. The expected complexity of the vertical decomposition of $\mathcal{A}(R^*)$ is thus also $O(\xi_\tau)$. By further refining the decomposition, we obtain a collection of $O(\xi_\tau)$ trapezoids, each crossed by at most $O(m_\tau/\xi_\tau)$ curves, for a total of $O(m_\tau)$ crossings between curves and cells. If $m_\tau < \xi_\tau$, we "sample" all curves in $C^*_\tau$ and construct the vertical decomposition of their arrangement. This yields $O(m_\tau) = O(\xi_\tau)$ trapezoids, each of which crosses no curve of $C^*_\tau$.

**Completion.** We now form the final two-dimensional decomposition by taking $\partial\tau^*$ into account. In the description below we address the more involved construction of the case $X_\tau \geq m_\tau$. The derived bounds can be shown to hold also when $X_\tau < m_\tau$ (with a significantly simpler analysis).

The final decomposition in the case $X_\tau \geq m_\tau$ is formed as follows. The hierarchy of trapezoids constructed so far is induced by various samples of (pieces of) curves from $C^*_\tau$. Let $\Gamma_\tau$ denote the collection of all curve portions that constitute the floors and ceilings of all these trapezoids. By construction, no two curve portions in $\Gamma_\tau$ intersect transversally. (Some pairs, constituting, e.g., floors of trapezoids that are nested in the hierarchy, may partially overlap; this has no effect on the analysis about to be presented.) Clearly, the number of trapezoids is $\Theta(|\Gamma_\tau|)$.

Consider now the union $\Gamma'_\tau$ of $\Gamma_\tau$ with the set of arcs forming $\partial\tau^*$. The arcs of $\Gamma'_\tau$ are also pairwise openly disjoint (recalling that the arcs of $\Gamma_\tau$ have been clipped at their points of intersection with $\partial\tau^*$). Form the vertical trapezoidal decomposition of $\Gamma'_\tau$. Using (7), the number of trapezoids in this decomposition is

$$O(|\Gamma'_\tau|) = O((1 + h_\tau^{1/2})\xi_\tau^{1+\varepsilon} + \xi_\tau + h_\tau) = O((1 + h_\tau^{1/2})\xi_\tau^{1+\varepsilon} + h_\tau).$$

We retain only those trapezoids that are fully contained in $\tau^*$ (the others are disjoint from $\tau^*$).

We next consider the number of crossings between the curves of $C^*_\tau$ and the new trapezoids. Each such crossing can be charged to a crossing of a curve $\gamma \in C^*_\tau$ with the boundary of a new trapezoid $\sigma$ (unless $\gamma$ is fully contained in $\sigma$; the number of such latter pairs is clearly at most $m_\tau$). If such a crossing occurs on the floor or ceiling of $\sigma$, then either it is also a crossing with the boundary of an old trapezoid, and is thus counted in (8), or it is an endpoint of a curve in $C^*_\tau$ (lying on a boundary component of $\partial\tau^*$), and the number of such endpoints is at most $2m_\tau$. If it occurs at a vertical wall erected from an endpoint (or a locally $x$-extreme point) $p$ of some arc in $\Gamma_\tau$, then the new wall is equal to or shorter than the old wall erected from $p$. Hence the number of such crossings is also upper bounded by (8). The only remaining case is a vertical wall erected from some vertex of $\partial\tau^*$ or from a locally $x$-extreme point on some arc of $\partial\tau^*$. The number of such walls is $O(\xi_\tau)$, and any such wall is fully contained in an old external trapezoid, and is thus crossed by at most

$$O((a \log\rho/\rho)^j m_{\tau_0}) = O((a \log\rho/\rho)^j (m_\tau/s))$$

curves of $C^*_\tau$. Hence the total number of crossings of this kind is (recall that $\rho^j = \Theta(\xi_\tau/s)$)

$$O(\xi_\tau (a \log\rho/\rho)^j (m_\tau/s)) = O(m_\tau \xi_\tau^\varepsilon)$$

for any $\varepsilon > 0$. This bound also takes care of the case $\xi_\tau < s$, and, as mentioned above, it also trivially holds when $X_\tau < m_\tau$.

The new decomposition is clearly a partition of $\tau^*$ into subcells (trapezoids) of constant description complexity. Each of these subcells is lifted vertically in the $z$-direction to within $\tau$, thereby obtaining a partition of $\tau$ itself. The collection of all these partitionings, over all cells $\tau$ of $\mathcal{A}_1$, constitutes our final decomposition.

Since each resulting (three-dimensional) cell has constant description complexity, it follows by the $\varepsilon$-net theory of Haussler and Welzl [14] that, with high probability, each of them is crossed by at most $\frac{a'n}{r}\log r$ surfaces of $S$, for an appropriate absolute constant $a' > 0$, so it is an $O((\log r)/r)$-cutting of $S$.

Lemma 2.2. (a) *The total number of cells of the above decomposition is* $O(r^{3+\varepsilon})$ *for any* $\varepsilon > 0$.

(b) *The total number of crossings between the curves of* $C$ *and these cells is* $O(mr^{1+\varepsilon})$ *for any* $\varepsilon > 0$.

*Proof.* (a) By (7), the number of cells is

$$O\left(\sum_{\tau\in\mathcal{A}_1}\left((1+h_\tau^{1/2})\xi_\tau^{1+\varepsilon}+h_\tau\right)\right) = O\left(r^2+\sum_{\tau\in\mathcal{A}_1}(1+h_\tau^{1/2})\xi_\tau^{1+\varepsilon}\right).$$

We analyze the quantity $O(\sum_{\tau\in\mathcal{A}_1}(1+h_\tau^{1/2})\xi_\tau^{1+\varepsilon})$. By Lemma 2.1(a), $\sum_\tau \xi_\tau^{1+\varepsilon} = O(r^{3+\varepsilon})$ for any $\varepsilon > 0$. This bound takes care of all cells for which $h_\tau = 0$. The number of cells with $h_\tau > 0$ is only $O(r^2)$. Moreover, the complexity of a single cell $\tau$ of $\mathcal{A}_1$ is only $O(r\beta_q(r))$. Indeed, such a cell has a fixed floor and a fixed ceiling, contained in two respective surfaces $\sigma^-, \sigma^+$ of $R$. We form a collection of curves consisting of the $xy$-projections of (i) the intersections of $\sigma^-$ and $\sigma^+$ with all the remaining surfaces of $R$, (ii) the silhouettes of the surfaces in $R$, and (iii) the curves in $R'$. We obtain a collection of $O(r)$ curves in the plane, and it is easily seen that $\tau^*$ is a cell of their arrangement. Hence the complexity of $\tau^*$, and thus of $\tau$, is $O(r\beta_q(r))$, as claimed (see [18] for details). Hence

$$\sum_{\tau\in\mathcal{A}_1} h_\tau^{1/2}\xi_\tau^{1+\varepsilon} = O\left(\left(\sum_{\tau\in\mathcal{A}_1} h_\tau\right)^{1/2}\cdot (r^2)^{1/2}\cdot r^{1+\varepsilon}\right) = O(r^{3+\varepsilon})$$

for any $\varepsilon > 0$, and this establishes (a).

(b) By (8) and the preceding discussion, the number of crossings is

$$\sum_\tau O\left((X_\tau^{1/2}h_\tau^{1/2}+m_\tau)\xi_\tau^{\varepsilon}\right)$$

for any $\varepsilon > 0$. Using (1) and (3), the Cauchy–Schwarz inequality, and Lemma 2.1(a,b), and recalibrating $\varepsilon$, this can be upper bounded by

$$O(r^\varepsilon)\cdot\left[\sum_\tau O(X_\tau^{1/2}h_\tau^{1/2})+\sum_\tau O(m_\tau)\right]$$

$$= O(r^\varepsilon)\cdot\left(\sum_\tau X_\tau\right)^{1/2}\cdot\left(\sum_\tau h_\tau\right)^{1/2} + O(mr^{1+\varepsilon}) = O(mr^{1+\varepsilon})$$

for any $\varepsilon > 0$. □

By replacing $r$ by $ar \log r$, for an appropriate absolute constant $a$, as discussed above, we obtain the following main result.

THEOREM 2.3. *Let $S$ be a set of $n$ surfaces in $\mathbb{R}^3$ of constant description complexity, and let $C$ be a set of $m$ curves in $\mathbb{R}^3$ of constant description complexity. Let $1 \le r \le \min\{m, n\}$ be a given parameter. Then there exists a $(1/r)$-cutting $\Xi$ of $S$ of size $O(r^{3+\varepsilon})$, for any $\varepsilon > 0$, such that the number of crossings between the curves of $C$ and the cells of $\Xi$ is $O(mr^{1+\varepsilon})$.*

*Remark* 1. We have ignored so far the algorithmic issue of constructing the cutting. However, the proof is constructive. Moreover, since at each step of the second decomposition stage we deal with samples of only $O(1)$ curves, the overall cost of the construction can be shown to be $O(nr^{2+\varepsilon} + mr^{1+\varepsilon})$ for any $\varepsilon > 0$. Recall that in the proof we assume that each random sample is a good sample. This can be algorithmically enforced by the standard approach of repeatedly sampling until a good sample is found. Since we use only constant-size samplings in the second decomposition stage, verifying that a sample is good is inexpensive. This approach increases the running time of the algorithm by a constant factor on expectation.

*Remark* 2. Theorem 2.3 bounds only the overall number of crossings between the curves and cells. A stronger result would be to show that, in addition, each cell of the cutting is crossed by $O(m/r)$ curves of $C$. We have not carried out this extension, but we believe that this stronger property can be achieved via a modified version of the preceding analysis.

**3. The complexity of a multiple zone.** Let $S$ and $C$ be as above. Define the zone $Z(C)$ of $C$ in $\mathcal{A}(S)$ to be the collection of all cells of $\mathcal{A}(S)$ that are crossed by at least one curve of $C$.

THEOREM 3.1. *The complexity of $Z(C)$ is $O(m^{1/2}n^{2+\varepsilon})$ for any $\varepsilon > 0$.*

*Proof.* Since the complexity of the entire arrangement is $O(n^3)$, the bound in the theorem is nontrivial only when $m = O(n^2)$, which is what we assume in the proof. Fix a parameter $r$, and construct a $C$-sensitive $(1/r)$-cutting of $\mathcal{A}(S)$, consisting of $O(r^{3+\varepsilon})$ cells, each crossed by at most $n/r$ surfaces of $S$, so that the total number of crossings between these cells and the curves of $C$ is at most $O(m^{1+\varepsilon}r)$.

Fix a cell $\tau$ of the cutting. Let $S_\tau$ (resp., $C_\tau$) denote the set of surfaces of $S$ (resp., curves of $C$) that cross $\tau$, clipped to within $\tau$. The complexity of $Z(C) \cap \tau$ can be upper bounded as follows: First, the zone of a single curve in an arrangement of $N$ surfaces of constant description complexity is $O(N^{2+\varepsilon})$ for any $\varepsilon > 0$ [13]. Hence, the overall complexity of the $|C_\tau|$ separate zones of each of the curves in $C_\tau$ in $\mathcal{A}(S_\tau)$ is at most $O(|C_\tau||S_\tau|^{2+\varepsilon})$. In addition, portions of the boundary of the external cell of $\mathcal{A}(S_\tau)$ may also belong to $Z(C)$, because they may bound cells of $\mathcal{A}(S)$ that are crossed by curves of $C$ that do not cross $\tau$. The complexity of this external cell is $O(|S_\tau|^{2+\varepsilon})$. Hence, putting $m_\tau = |C_\tau|$, the overall complexity of $Z(C)$ is (we use the same $\varepsilon$ both in the bounds in Theorem 2.3 and for the bound on the complexity of the zone of a curve)

$$O\left(\sum_\tau (m_\tau + 1)\left(\frac{n}{r}\right)^{2+\varepsilon}\right) = O\left(\frac{mn^{2+\varepsilon}}{r} + n^{2+\varepsilon}r\right),$$

where we use Theorem 2.3 to infer that $\sum_\tau m_\tau = O(mr^{1+\varepsilon})$. Choosing $r = m^{1/2}$ completes the proof of the theorem. □

*Remark* 3. A lower bound for $Z(C)$ is $\Omega(m^{2/3}n^{5/3})$. To establish it, take a planar arrangement of $n/2$ lines that has $m$ distinct faces of overall complexity $\Theta(m^{2/3}n^{2/3})$. Lift each of these lines to a vertical plane in three dimensions, and add to the resulting arrangement $n/2$ additional horizontal planes. The resulting collection of $n$ planes is our set $S$. For the set $C$ of curves, take $m$ vertical lines, each intersecting the $xy$-plane at a point inside one of the $m$ marked faces. The complexity of the multiple zone $Z(C)$ is easily seen to be $\Theta(m^{2/3}n^{5/3})$.

**Acknowledgments.** We would like to thank Gábor Tardos for suggesting the problem, and thank him and János Pach for valuable discussions. We also deeply thank two anonymous referees for very helpful comments on the paper, which have led to considerable improvements. In addition, we are greatly indebted to one of the referees, who has pointed out a serious technical problem in an earlier version of the paper.

# LOW-DIMENSIONAL LINEAR PROGRAMMING WITH VIOLATIONS*

TIMOTHY M. CHAN†

**Abstract.** Two decades ago, Megiddo and Dyer showed that linear programming (LP) in two and three dimensions (and subsequently any constant number of dimensions) can be solved in linear time. In this paper, we consider the LP problem with at most $k$ *violations*, i.e., finding a point inside all but at most $k$ halfspaces, given a set of $n$ halfspaces. We present a simple algorithm in two dimensions that runs in $O((n+k^2)\log n)$ expected time; this is faster than earlier algorithms by Everett, Robert, and van Kreveld (1993) and Matoušek (1994) for many values of $k$ and is probably near-optimal. An extension of our algorithm in three dimensions runs in near $O(n + k^{11/4}n^{1/4})$ expected time. Interestingly, the idea is based on concave-chain decompositions (or covers) of the ($\leq k$)-level, previously used in proving combinatorial $k$-level bounds.

Applications in the plane include improved algorithms for finding a line that misclassifies the fewest among a set of bichromatic points, and finding the smallest circle enclosing all but $k$ points. We also discuss related problems of finding local minima in levels.

## 1. Introduction.

**1.1. Motivation: Outliers in geometric optimization.** Consider the following formulation of a line-fitting problem, well known in computational geometry: given a set of data points $(x_1, y_1), \ldots, (x_n, y_n)$ in the plane, find a line that minimizes its largest vertical distance to the points. The problem is equivalent to a linear program (LP) in three variables (the slope $m$, the intercept $b$, and the tolerance $\delta$), where the goal is to minimize $\delta$ subject to the constraints $-\delta \leq mx_i + b - y_i \leq \delta$ for $i = 1, \ldots, n$. By known methods [22, 30, 49, 50, 57, 60], the problem can thus be solved in $O(n)$ time.

Though efficient methods exist, whether this formulation is the "right" one for real applications is debatable, as the presence of an occasional faulty data point (a so-called outlier) can drastically change the optimum. Statisticians have looked at more robust formulations of the line-fitting problem, but here we try to address the issue of outliers from a different direction by asking the following natural computational questions, keeping the largest vertical distance as the fitness measure: Given a small integer $k \leq n$, how can we find the line that best fits all but $k$ of the given points? Or, given a prescribed tolerance $\delta$, how can we find the smallest integer $k$ such that a line fitting all but $k$ points exists?

Low-dimensional LP-type techniques can solve other common optimization problems. For example, finding the smallest enclosing circle of a planar point set (the standard 1-center problem) is an instance of three-dimensional (3-d) convex programming,

*Received by the editors December 31, 2003; accepted for publication (in revised form) October 25, 2004; published electronically May 12, 2005. and finding the smallest-area enclosing annulus of a planar point set (a circle-fitting problem) is an instance of four-dimensional (4-d) LP. Due to applications in statistical analysis and computational metrology, it is again natural to consider generalizations of these optimization problems that allow a small number $k$ of violations.

**1.2. LP with violations: The problem and background.** We can define the problem of *linear programming with at most k violations* in $d$ dimensions as follows:

> Given a set $H$ of $n$ closed halfspaces in $\mathbb{R}^d$, a linear objective function $f$, and a number $0 \leq k < n/2$, we want to minimize $f$ over the region
>
> $$I_k(H) = \{q \in \mathbb{R}^d \mid q \text{ lies outside at most } k \text{ halfspaces of } H\},$$
>
> or report that $I_k(H) = \emptyset$.

Since our interest is in geometric applications, we confine our discussion to small constant values of $d$. The problem for arbitrary dimensions is NP-complete (for example, see [7, 8]).

Note that $I_0(H)$, the intersection of all halfspaces, is the feasible region of the original LP problem. Following Matoušek [47], we call the special case of the problem in which $I_0(H) \neq \emptyset$ the *feasible* case. In the feasible case (where, by an affine transformation, we may assume that the halfspaces are all lower halfspaces or all upper halfspaces), the boundary of $I_k(H)$ is commonly called the *k-level*, and the 0-level, 1-level, ..., $k$-level collectively form the *$(\leq k)$-level*.

The simplest case, the two-dimensional (2-d) feasible problem, can be solved in near-linear time by a parametric or binary search [47, 56]; the current best time bound was obtained by this author [14] using randomization and almost matched the one-dimensional (1-d) $O(n + k \log k)$ bound.

The next simplest case, the general 2-d problem, has already baffled researchers. Everett, Robert, and van Kreveld [37] first investigated the problem in 1993; they proposed a simple approach that effectively explores the entire solution space by constructing the $(\leq k)$-level of the upper halfplanes and the $(\leq k)$-level of the lower halfplanes and "intersecting" the two structures, so to speak. As the $(\leq k)$-level has $O(nk)$ complexity [6, 40] in the plane, they solved the 2-d problem in $O(n \log n + nk)$ time. The approach can probably (though nontrivially) be extended to any fixed dimension, but the running time would be higher, since the $(\leq k)$-level has worst-case complexity $\Theta(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil})$ in $\mathbb{R}^d$ [24] (in three dimensions, a near-$O(nk^2)$ algorithm was indeed obtained by Efrat, Lindenbaum, and Sharir [34]).

Shortly after, in 1994, Matoušek [47] proposed another simple approach; it works quite differently and is best described in the feasible case. The algorithm enumerates all local minima of $I_0(H), \ldots, I_k(H)$ by computing the minimum of $I_0(H)$ by LP and repeatedly removing a solution's defining halfspace and reoptimizing, to generate $I_1(H)$ minima from the $I_0(H)$ minimum, $I_2(H)$ minima from the $I_1(H)$ minima, and so on. As the $(\leq k)$-level has $O(k^d)$ local minima [51], the cost of the algorithm is dominated by the cost of $O(k^d)$ dynamic LP operations. The general 2-d problem can be "lifted" to a feasible 3-d problem, and with the appropriate data structures [53], these $O(k^3)$ operations can be carried out in $O(n \log n + k^3 \log^2 n)$ time. The first term has been lowered to $O(n \log k)$ by the author [11, 12]; the second term can probably be lowered slightly as well by adopting recent data structures for dynamic convex hulls [16] (though the particular LP queries needed were not explicitly considered in [16]).

Table 1

*Time bounds for LP with at most $k$ violations. (In this paper, $\varepsilon > 0$ denotes an arbitrarily small constant, and $c$ denotes a specific constant.)*

| Problem | Best previous result(s) | (Refs.) | New result |
|---|---|---|---|
| 2-d feasible | $O(n + k^{1-\varepsilon} n^{\varepsilon} \log n)$ | [56, 14] | |
| 2-d general | $O(n \log n + nk)$ | [37] | |
| | $O(n \log k + k^3 \log^2 n)$ | [47, 11] | $O((n + k^2) \log n)$ |
| 3-d feasible | $O(n \log k + k^3 n^{\varepsilon})$ | [47, 11] | $O(n \log n + k^2 \log^2 n)$ |
| 3-d general | $O(nk^2(\log n + \log^2(n/k)))$ | [34] | |
| | $O(n \log k + k^4 n^{\varepsilon})$ | [47, 11] | $O(n \log n + k^{11/4} n^{1/4} \log^c n)$ |
| 4-d feasible | $O(n \log k + k^{8/3} n^{2/3+\varepsilon} + k^4 n^{1/3+\varepsilon})$ | [47, 11] | $O(n \log n + k^{11/4} n^{1/4} \log^c n)$ |

Modulo these small improvements, the rough bounds of $O(nk)$ by Everett, Robert, and van Kreveld (for large $k \geq \sqrt{n}$) and $O(n + k^3)$ by Matoušek (for small $k \leq \sqrt{n}$) have surprisingly remained the record for the general 2-d problem for about eight years. There seems no natural way to combine the two approaches to get a uniform time bound for all $k$. Concerning his algorithm, Matoušek [47] wondered whether it is possible to generate the local minima of $I_k(H)$ directly, without going through $I_0(H), I_1(H), \ldots$, since the number of local minima in the $k$-level is only $O(k^{d-1})$ [23, 52]. In particular, for the general 2-d problem, is it possible to bypass intermediate "infeasible" minima (defined by triples after the lifting) and generate only solutions (vertices) defined by pairs of halfplanes, as in Everett, Robert, and van Kreveld's algorithm? To put it bluntly, can Matoušek's 2-d algorithm be made more "planar"?

With the status of the 2-d problem unresolved, our understanding of LP with violations in higher dimensions is even more tentative. A suspected lower bound for the general $d$-dimensional problem (for $k \ll n/2$) is $\Omega(n + k^d)$ because of the following argument: Given a collection of $N$ hyperplanes, the problem of detecting affine degeneracy, i.e., a subset of $d+1$ hyperplanes intersecting at a common point, is conjectured to require $\Omega(N^d)$ time. (See [36] for a proof in a restricted model; for $d = 2$, the problem is so-called 3SUM-*hard* [38].) This problem can be reduced to LP with violations for any $n \geq 2N$ and $k = N - d - 1$; just take the $2N$ lower and upper (closed) halfspaces defined by the $N$ hyperplanes together with $n - 2N$ copies of the halfspace $x \leq M$ for a sufficiently large $M$.

**1.3. Main results.** Table 1 summarizes the previous results and our new results. We focus on the general case since, as we will demonstrate in section 4, the feasible problem in $d$ dimensions reduces to the general problem in $d-1$ dimensions by parametric or randomized search.

Our main result, presented in section 2, is an algorithm for the general 2-d problem that runs in $O((n+k^2) \log n)$ expected time (randomization is used in just one step of the algorithm). This algorithm not only simultaneously improves Everett, Robert, and van Kreveld's and Matoušek's algorithms for most values of $k$ (between $n^{\varepsilon}$ and $n/\log n$) but also essentially settles the complexity of the 2-d problem up to a logarithmic factor, assuming that the conjectured lower bound holds. The algorithm, like Matoušek's, actually generates all $O(k^2)$ local minima of $I_0(H), \ldots, I_k(H)$. The basic algorithm uses simpler data structures than Matoušek's and is arguably simpler than Everett, Robert, and van Kreveld's as well. The approach is noteworthy: although like Everett, Robert, and van Kreveld we will use the $(\leq k)$-level of the lower/upper halfplanes, we will not build the entire $(\leq k)$-level (which has size $O(nk)$) but instead will work with its "concave/convex-chain decomposition" (which involves only

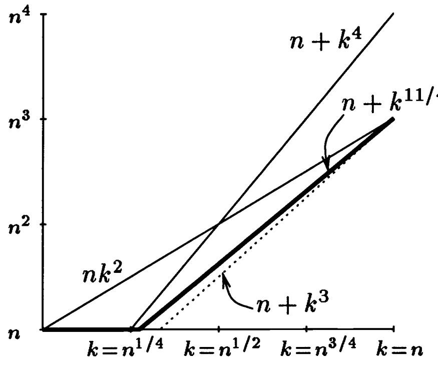

FIG. 1. *Comparison of time bounds for the general* 3*-d problem.*

a small $O(k)$ number of chains of total size $O(n)$). The concave-chain decomposition idea was instrumental in the recent breakthroughs on $k$-level complexity and related combinatorial problems [1, 27, 59]; because concave chains and convex polygons enjoy nice computational properties, we demonstrate that this very idea has algorithmic applications as well.

In section 3, we use similar ideas to obtain an $O(n \log n + k^3 \log^2 n)$ expected time bound for generating an $O(k^3)$-size superset of the local minima of $I_0(H), \dots, I_k(H)$ in three dimensions. The generalization is not trivial, as an analogous concave-surface decomposition of the ($\leq k$)-level in three dimensions is not known (but see [43] for a variant); nevertheless, we prove here that a small concave-surface *cover* always exists and can be computed efficiently. Unfortunately, unlike the 2-d algorithm, the 3-d algorithm does not automatically filter out the local minima of $I_0(H), \dots, I_k(H)$ from the superset. This filtering step turns out to be the computational bottleneck. Sophisticated static data structures for range searching are required to yield our final expected time bound of $O(n \log n + k^{11/4} n^{1/4} \log^c n)$. Although this does not quite approach the suspected lower bound $\Omega(n + k^3)$, it is not far off (see Figure 1) and in particular improves both Efrat, Lindenbaum, and Sharir's near-$O(nk^2)$ bound and Matoušek's near-$O(n + k^4)$ bound (the latter requires sophisticated dynamic data structures).

For very small $k = O(n^\varepsilon)$, Matoušek's algorithm can be made to run in $O(n \log k)$ time, as shown by the author [11, 12]. So, by combining two algorithms, we can automatically replace all $\log n$ factors with $\log k$ in the time bounds.

**1.4. Applications.** We can use our algorithms to find the smallest $k$ such that $I_k(H) \neq \emptyset$ within the same time bounds: Given an upper bound $K \geq k$, we can generate all local minima of $I_0(H), \dots, I_K(H)$ and thus identify the value of $k$. We can "guess" an upper bound by a standard trick (as in [12]); for example, in two dimensions, by trying $K = \sqrt{n}, 2\sqrt{n}, 4\sqrt{n}, \dots$, the total running time can be bounded by a geometric series and remains $O((n + k^2) \log n)$.

The 2-d algorithm can also be modified for convex programming with nearly the same running time, provided that a linear objective function is used, as explained in the remarks in section 2. The sample applications below thus follow immediately from these observations (all the bounds except the last are probably near-optimal for all $k \ll n/2$).

- Given $n$ red/blue points in the plane, we can find a line $\ell$ that minimizes $k$, the total number of red points above $\ell$ and blue points below $\ell$, in $O((n+k^2)\log n)$ expected time. (This was the original dual problem considered by Everett, Robert, and van Kreveld [37].)

- Given $n$ points in the plane and a fixed value $\delta$, we can find a line $\ell$ that minimizes $k$, the number of points at a vertical distance exceeding $\delta$ from $\ell$, in $O((n+k^2)\log n)$ expected time.
- Given $n$ points in the plane and a fixed convex set $C$ of constant complexity, we can translate $C$ to minimize $k$, the number of points outside $C$, in $O((n\beta(n)+k^2)\log n)$ expected time, where $\beta(\cdot)$ is a slow-growing, inverse-Ackermann-like function.
- Given $n$ points in the plane and a fixed value $\delta$, we can find an annulus $A$ of area $\delta$ that minimizes $k$, the number of points outside $A$, in $O(n\log n + k^{11/4}n^{1/4}\log^c n)$ expected time.

We can also use our algorithms to solve feasible LPs with violations in one dimension higher, as explained in section 4. The applications below follow:

- Given $n$ points in the plane and a number $k$, we can find the line that minimizes its largest vertical distance to all but $k$ points in $O(n\log n + k^2\log^2 n)$ expected time.
- Given $n$ points in the plane and a number $k$, we can find the smallest circle enclosing all but $k$ points in $O(n\beta(n)\log n + k^2 n^{\varepsilon})$ expected time. (This was the motivating problem considered by Matoušek [47]. Note that, in contrast, the related problem of finding the smallest circle enclosing $k$ points is believed to have complexity near $\Theta(nk)$ [26, 35, 42, 46].)
- Given $n$ points in the plane and a number $k$, we can find the minimum-area annulus enclosing all but $k$ points in $O(n\log n + k^{11/4}n^{1/4}\log^c n)$ expected time.

In the feasible case, several researchers have explored the problem of finding all local minima of the $k$-level and the $(\leq k)$-level.

- By specializing our 2-d algorithm in section 2 to the feasible case, we can immediately find all $O(k^2)$ local minima of the 2-d $(\leq k)$-level in $O((n+k^2)\log n)$ expected time, thus improving the previous $O(n\log n + k^2\log^{3/2} n)$ bound [16, 47].
- As shown in the appendix, we can also find all $O(k)$ local minima of the 2-d $k$-level in $O((n+(nk)^{3/5})\log^{O(1)} n)$ expected time, improving Katoh and Tokuyama's recent $O((n+(nk)^{2/3})\log^{O(1)} n)$ bound [44].

Again, all $\log n$ factors above can be replaced by $\log k$ by switching to Matoušek's algorithm when $k = O(n^{\varepsilon})$.

## 2. A 2-d algorithm to find all local minima of $I_0(H), \ldots, I_k(H)$.

Let $L^-$ and $L^+$ be the sets of lines bounding the given lower and upper halfplanes, respectively. Without loss of generality, assume that the objective is to minimize the $x$-coordinate. For simplicity, assume also that the input is in general position. The outline of our 2-d algorithm is remarkably simple:

1. Form $O(k)$ concave chains whose union covers (i.e., contains) the $(\leq k)$-level of the lower halfplanes; the polygonal chains are made from lines in $L^-$, are nonoverlapping (i.e., they intersect only at vertices), and have $O(n)$ total size (see Figure 2(a)). Similarly, form $O(k)$ convex chains for the lines in $L^+$.
2. For each pair of concave and convex chains, compute their left and right intersection points (if they exist). Let $S$ be the $O(k^2)$ left intersection points.

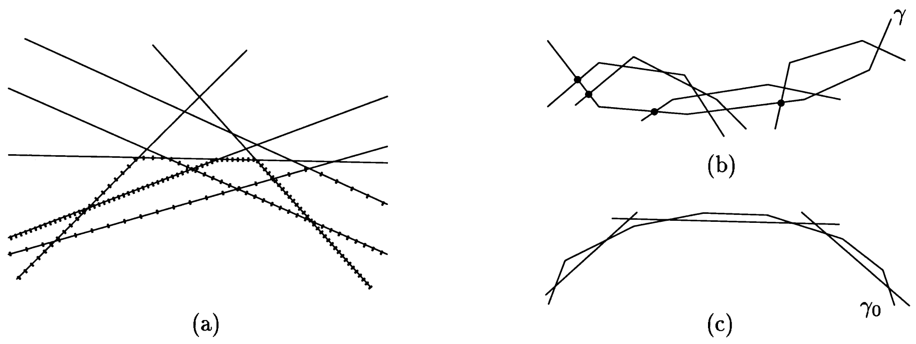

FIG. 2. (a) *The* $(\leq 2)$*-level of a set of lower halfplanes is covered by three concave chains (in dotted lines); in this example, the cover happens to be a decomposition.* (b) *Step* 3*: Counting concave chains below each point* $p \in S$ *(in black) on a convex chain* $\gamma$ *becomes an interval counting problem.* (c) *Step* 1*, second option: Forming concave chains becomes an interval coloring problem.*

3. For each $p \in S$, determine

$$k^-(p) = \min\{k+1, \text{number of lines of } L^- \text{ strictly below } p\}, \text{ and}$$
$$k^+(p) = \min\{k+1, \text{number of lines of } L^+ \text{ strictly above } p\}.$$

If $k^-(p) + k^+(p) \leq k$, then report $p$ as a local minimum of $I_{k^-(p)+k^+(p)}(H)$.

To check the correctness of the algorithm, we just have to observe that all local minima of $I_0(H), \ldots, I_k(H)$ are contained in $S$; each such local minimum lies on both the $(\leq k)$-level of the upper halfplanes and the $(\leq k)$-level of the lower halfplanes and thus is at the intersection of a concave and a convex chain.

We now explain how to implement the three steps, in order of difficulty, so that the total expected running time is $O((n + k^2)\log n)$.

**Step 2: Computing $S$.** The intersection of a concave and a convex chain can be found in logarithmic time by known binary-search algorithms (for example, see [20, 28]). So step 2 can be carried out in $O(k^2 \log n)$ time.

**Step 3: Computing $k^-(p)$ and $k^+(p)$.** By symmetry, it suffices to consider the computation of the $k^-(p)$ values. Observe that $k^-(p) = \min\{k + 1, \text{number of concave chains strictly below } p\}$: if $p$ is on the $(\leq k)$-level of the lower halfplanes, the number of lines of $L^-$ strictly below $p$ is the equal to the number of concave chains strictly below $p$, since the concave chains cover the $(\leq k)$-level and are nonoverlapping; if $p$ is strictly above the $(\leq k)$-level, both numbers exceed $k + 1$.

Fix a convex chain $\gamma$. Each concave chain defines an open interval on $\gamma$ delimited by the chain's left and right intersection points with $\gamma$. (The interval can be half-infinite or empty.) Given a point $p$ lying on $\gamma$, a concave chain is strictly below $p$ iff the corresponding interval does not contain $p$. (See Figure 2(b).) Thus, computing $k^-(p)$ for all points $p \in S$ lying on $\gamma$ can be reduced to a 1-d counting problem: given $O(k)$ points and $O(k)$ intervals, count how many intervals contain each point. This 1-d problem can be solved in $O(k \log k)$ time by sorting and a linear scan. Repeating the process for each convex chain $\gamma$ gives $k^-(p)$ for all points $p \in S$ in $O(k^2 \log k)$ time.

**Step 1: Constructing the concave/convex chains—first option.** By symmetry, it suffices to consider the computation of the concave chains. Pick a random integer $k' \in [k, 2k]$. Since the $k$-level, ..., $2k$-level have combined size $O(nk)$, the $k'$-level has expected size $O(n)$.

We use a standard idea to decompose the $(\leq k')$-level of the lower halfplanes into concave chains (for example, see [1]): Track the $k' + 1$ lowest lines of $L^-$ at a vertical sweep line as the sweep line moves from left to right. At $x = -\infty$, our $k' + 1$ chains start at the initial $k' + 1$ lowest lines. When the $(k' + 1)$st lowest line $\ell_1$ and the $(k' + 2)$nd lowest line $\ell_2$ are about to switch, the chain currently at $\ell_1$ will correspondingly turn right to follow $\ell_2$. Switches occur only at concave $k'$-level vertices, so the $k' + 1$ chains thus defined have total expected size $O(n)$ and can be formed in linear time once the $k'$-level has been constructed. (The example in Figure 2(a) is obtained this way.)

The $k'$-level can be computed by several output-sensitive algorithms, as surveyed in [15]. The simplest to implement is probably Basch, Guibas, and Hershberger's method using kinetic tournament trees [9]; for an expected $O(n)$-size output, the expected running time is $O(n\alpha(n) \log^2 n)$, where $\alpha(n)$ is the slow-growing inverse Ackermann function. The more complicated, randomized algorithms by Agarwal et al. [2, 15] and Har-Peled [41] are faster, with time bounds of $O(n\alpha(n)^2 \log n)$ and $O(n\alpha(n) \log n)$, respectively. Brodal and Jacob's recent announcement on dynamic convex hulls and kinetic heaps [10] implies the ultimate expected running time of $O(n \log n)$.

**Step 1: Constructing the concave chains—second option.** We now offer a different method for step 1 that also achieves $O(n \log n)$ expected time but has the advantage of being generalizable to three dimensions (as we will see in section 3).

This second option is based on Matoušek's shallow cutting lemma [45]. Ramos [54] (building on [2, 17]) has given an $O(n \log n)$ randomized algorithm to construct such a cutting in two and three dimensions. We restate the 2-d result in the following convenient form.

LEMMA 2.1. *Given $n$ lower halfplanes in $\mathbb{R}^2$, the $(\leq k)$-level can be covered by $O(n/k)$ cells, each intersecting $O(k)$ bounding lines. More specifically, the cells are taken from the vertical decomposition of the region underneath a concave chain $\gamma_0$ of size $O(n/k)$. The cells, the list of lines intersecting each cell, and $\gamma_0$ can all be constructed in $O(n \log n)$ expected time.*

*Proof.* Matoušek's shallow cutting lemma [45] and Ramos's algorithm [54] give a set $\Xi$ of cells (triangles) satisfying the first statement in $O(n \log n)$ expected time. To achieve the second statement, we modify the construction. Suppose that the maximum number of lines intersecting a cell is less than $bk$ for some constant $b$. Remove a cell from $\Xi$ if one of its vertices is above more than $(b + 1)k$ lines (because if this is true, the cell does not intersect the $(\leq k)$-level anyway); this condition can be tested in $O(\log n + k)$ time per cell, after preprocessing in $O(n \log n)$ time, by a known data structure for halfplane range reporting queries [21].

Now, let $\gamma_0$ be the boundary of the upper hull of the vertices of $\Xi$, and take the $O(n/k)$ cells (unbounded trapezoids) of its vertical decomposition, which is computable in $O((n/k) \log(n/k))$ time. Clearly, the new cells cover the $(\leq k)$-level. Since a line intersecting a cell must lie below one of its (two) vertices, the list of lines intersecting each new cell has at most $2(b + 1)k$ elements and can be generated in $O(\log n + k)$ time per cell, again by halfplane range reporting. ☐

Say that two lines are *compatible* in a region $R$ if no point in $R$ is above both lines. The problem of constructing the concave chains can be reduced to coloring the lines of $L^-$ so that lines of the same color are compatible in the $(\leq k)$-level of the lower halfplanes (or in any region covering the ($\leq k$)-level): Indeed, nonoverlapping concave chains can be formed by simply taking the lower envelope of lines of each color; the chains cover the ($\leq k$)-level, because given a point $p$ on the ($\leq k$)-level incident to some line $\ell$, $p$ cannot be above another line of the same color as $\ell$ and so must appear in the lower envelope of that color.

To solve this coloring problem, we invoke Lemma 2.1 to get a concave chain $\gamma_0$ above the ($\leq k$)-level. Each line of $L^-$ defines an interval (possibly half-infinite or empty) on $\gamma_0$ delimited by the line's left and right intersection points with $\gamma_0$; each interval can again be computed in logarithmic time by binary search. Two lines are compatible in the region underneath $\gamma_0$ iff their corresponding intervals are disjoint. (See Figure 2(c).) Thus, our problem is reduced to coloring of an interval graph.

Observe that the intervals have *depth* $O(k)$, i.e., each point $p$ on $\gamma_0$ is contained in at most $O(k)$ intervals: $p$ is contained in an interval iff $p$ lies above the corresponding line, but $p$ is above only $O(k)$ lines since each cell intersects $O(k)$ lines by construction. As is well known (see, e.g., [39]), the chromatic number of an interval graph is equal to the depth (also equal to the clique number), and an optimal coloring can be found in $O(n \log n)$ time by a standard greedy strategy (sequentially coloring the intervals in sorted order of left endpoints). This gives an $O(k)$-coloring, and thus a cover by $O(k)$ concave chains, in $O(n \log n)$ expected time.

We have thus proved the following theorem.

Theorem 2.2. *For $n$ halfplanes in $\mathbb{R}^2$, LP with at most $k$ violations can be solved in $O((n + k) \log n)$ expected time.*

*Remarks.* The construction [54] used in Lemma 3.1 is fairly involved. A much simpler alternative is to choose a random sample of $\frac{n}{2k}$ bounding planes and take the vertical decomposition of their lower envelope. This construction behaves the same "on average" but is only guaranteed to cover each vertex of the ($\leq k$)-level with constant probability (for example, as observed in [1]). The resulting algorithm would be Monte Carlo.

Degenerate cases can be handled by direct modifications of the algorithm or by general symbolic perturbation techniques [31, 32]. With the latter choice, we need to perturb the lines in $L^-$ upward and the lines in $L^+$ downward (as also suggested by Matoušek [47]), so that a vertex $v$ (lying on possibly more than two lines) violates at most $k$ constraints iff some point in the neighborhood of $v$ violates at most $k$ constraints after the perturbation.

The algorithm can be modified to work if the constraints $H$ are not halfplanes but convex sets of constant description complexity: For each convex set, we form a concave/convex $x$-monotone curve by taking its upper/lower boundary and attaching near-vertical downward/upward rays at the two endpoints. We let $L^-$ and $L^+$ instead be the sets of these concave and convex curves, respectively. Step 1 still works using the first option, since many of the $k$-level algorithms [2, 9, 15, 41] generalize to curves, with $\alpha(n)$ replaced by a similar slow-growing function $\beta(n)$ in the time bound. Step 2 generalizes, since concave/convex chains formed by concave/convex curves are still concave/convex. Step 3 requires a change, though. Given that $k^-(p), k^+(p) \leq k$, the number of constraints violated by $p$ is not necessarily $k^-(p) + k^+(p)$ but is rather $k^-(p) + k^+(p) - k_0(p)$, where $k_0(p)$ = number of convex sets whose $x$-projection does not contain $p$. Fortunately, computing the $k_0(p)$'s is also a 1-d interval counting problem and can be solved by sorting. The total expected running time is $O((n\beta(n) + k^2) \log n)$.

## 3. A 3-d algorithm to find all local minima of $I_0(H), \ldots, I_k(H)$.

Let $\Pi^-$ and $\Pi^+$ be the sets of planes bounding the given lower and upper halfspaces, respectively. Our 3-d algorithm proceeds similarly:

1. Form $O(k)$ concave surfaces whose union covers the $(\leq k)$-level of the lower halfspaces; the polyhedral surfaces are made from planes of $\Pi^-$, are nonoverlapping (i.e., they intersect only at zero-dimensional (0-d) or 1-d features), and have $O(n)$ total size. Similarly, form $O(k)$ convex surfaces for the planes of $\Pi^+$.
2. For each subset of at most three surfaces, find the minimum point in the intersection of the at most three convex polytopes bounded by these surfaces. Let $S$ be the $O(k^3)$ minima obtained.
3. For each $p \in S$, determine

$$k^-(p) = \min\{k+1, \text{number of planes of } \Pi^- \text{ strictly below } p\}, \text{ and}$$
$$k^+(p) = \min\{k+1, \text{number of planes of } \Pi^+ \text{ strictly above } p\}.$$

   If $k^-(p) + k^+(p) \leq k$, then report $p$ as a local minimum of $I_{k^-(p)+k^+(p)}(H)$.

Correctness follows since $S$ contains all local minima of $I_0(H), \ldots, I_k(H)$: each such local minimum $p$ lies on the $(\leq k)$-level of the lower halfspaces and of the upper halfspaces; in the neighborhood of $p$, its three defining halfspaces are part of up to three concave/convex surfaces; $p$ is the minimum point in the intersection of the corresponding polytopes.

We now explain how to implement each step.

**Step 2: Computing $S$.** If the polytopes are stored in hierarchical representations [29], which require $O(n)$ preprocessing time, then the minimum in the intersection of three (or fewer) convex polytopes can be found by an $O(\log^3 n)$ algorithm [33]. If the polytopes are instead stored in drum representations [55], which require $O(n \log n)$ preprocessing time [13], then the minimum can be found by an $O(\log^2 n)$ algorithm [13]. With the latter option, this step takes $O(k^3 \log^2 n)$ time.

**Step 1: Constructing the concave/convex surfaces—existence proof.** By symmetry, it suffices to consider the computation of the concave surfaces. Following the second option in section 2, we reduce the problem to coloring the planes of $\Pi^-$ so that two planes of the same color are compatible in the $(\leq k)$-level of the lower halfspaces (i.e., no point in the region is above both planes). We use the following 3-d version of Lemma 2.1.

LEMMA 3.1. *Given $n$ lower halfspaces in $\mathbb{R}^3$, the $(\leq k)$-level can be covered by $O(n/k)$ cells, each intersecting $O(k)$ bounding planes. More specifically, the cells are taken from the vertical decomposition of the region underneath a polyhedral concave surface $\gamma_0$ of size $O(n/k)$. The cells, the list of planes intersecting each cell, and $\gamma_0$ can all be constructed in $O(n \log n)$ expected time.*

*Proof.* As in the proof of Lemma 2.1, we apply Matoušek's shallow cutting lemma and Ramos's algorithm, which work in three dimensions. We modify the construction in the same way, this time using a randomized data structure for 3-d halfspace range reporting [17]. ☐

To solve the coloring problem, we invoke Lemma 3.1 to get a concave surface $\gamma_0$ lying above the $(\leq k)$-level. Each plane of $\Pi^-$ defines a set on $\gamma_0$ formed by intersecting its upper halfspace with $\gamma_0$. Two planes are compatible in the region underneath $\gamma_0$ iff the corresponding sets are disjoint.

As before, the sets have depth $O(k)$: a point $p$ on $\gamma$ lies above at most $O(k)$ planes since each cell intersects $O(k)$ planes by construction. We would like to infer that the intersection graph of planar convex sets of depth $O(k)$ is $O(k)$-colorable; however, this is not necessarily true in general. Fortunately, our sets are *pseudodisks*, i.e., the boundaries of each pair intersect at most twice: the intersection of two planes is a line, and a line intersects $\gamma_0$ at most twice. By a lemma of Sharir [58] (which extends a lemma of Pach), a 2-d arrangement of $n$ pseudodisks has $O(nk)$ intersections if their depth is $O(k)$. It follows that there exists a pseudodisk that intersects at most $O(k)$ other pseudodisks. Remove this pseudodisk and repeat. As a result, we obtain an acyclic orientation of the intersection graph so that the maximum in-degree $\delta$ is bounded by $O(k)$ (i.e., the *degeneracy* or *inductiveness* of the graph is $O(k)$). As is well known (see, e.g., [39]), the chromatic number is bounded by $\delta + 1$, and a corresponding coloring can be found by a standard greedy strategy. We conclude that an $O(k)$-coloring of the pseudodisks, and hence a cover by $O(k)$ concave surfaces, exists.

**Step 1: Constructing the concave surfaces—algorithmic proof.** Further ideas are needed to turn the above proof into an efficient algorithm, as we cannot afford to build the intersection graph of the pseudodisks and color sequentially. Here, we return to Matoušek's shallow cutting lemma (Lemma 3.1) and avoid Sharir's lemma (both were incidentally proven by random sampling arguments). Recall that we have $a|\Pi^-|/k$ cells, each intersected by at most $bk$ planes, for some constants $a$ and $b$. Call a plane *heavy* if it intersects more than $2ab$ cells and *light* otherwise (this is inspired by a similar definition of "bad" and "good" in [4]). At most half of the planes of $\Pi^-$ are heavy.

First, recursively color the heavy planes from the palette $\{1, \ldots, 4ab^2k\}$ so that planes of the same color are compatible in the $(\leq k)$-level of the corresponding heavy halfspaces (and thus in the $(\leq k)$-level of all lower halfspaces). Stop if the number of planes drops below $4ab^2k$. For each cell, maintain a dictionary of the colors used so far among the planes intersecting the cell.

Now, take each light plane $\pi$ (in any order). Randomly select a color from $\{1, \ldots, 4ab^2k\}$. Check that the color is not in the dictionary of any of the at most $2ab$ cells $\pi$ intersects. If so, give $\pi$ that color and update the dictionaries; otherwise, retry with another random selection. Since each of the at most $2ab$ dictionaries contains at most $bk$ colors, the probability of success in each trial is at least $1/2$, so this process takes expected $O(1)$ dictionary operations for each $\pi$. If the plane $\pi$ and a previous plane are incompatible in the region underneath $\gamma_0$, then some cell is intersected by both planes, and their colors are different by construction. So, after all light planes are processed, we have a correct $(4ab^2k)$-coloring.

The expected running time satisfies the recurrence $T(n) = T(n/2) + O(n \log n)$, which solves to $O(n \log n)$.

**Step 3: Computing $k^-(p)$ and $k^+(p)$.** By symmetry, it suffices to consider the computation of the $k^-(p)$ values. The geometry of concave/convex surfaces does not seem to help here, unlike in the 2-d algorithm, and we need to resort to more complicated techniques.

We wish to determine the number of planes strictly below each of $O(k^3)$ points. In dual space, this is the halfspace range counting problem. Since an upper limit $k+1$ is placed on the counts, one solution is to use known output-sensitive results, as given in [18, Theorem 6], to answer each halfspace range counting query in $O((1 + (nk^2/m)^{1/3})n^{\varepsilon})$ time after preprocessing in $O(mn^{\varepsilon})$ time. By setting the tradeoff parameter $m = \max\{k^{11/4}n^{1/4}, n\}$, the total cost of $O(k^3)$ queries becomes $O(n^{1+\varepsilon} + k^{11/4}n^{1/4+\varepsilon})$.

Alternatively, a more direct solution is to use Lemma 3.1. To compute $k^-(p)$, locate the cell $\Delta$ that contains $p$ (by 2-d point location), extract the list of the $O(k)$

planes intersecting $\Delta$, and count the number of planes in this list strictly below $p$. Recalling that $q$ halfspace range counting queries on a set of size $O(k)$ in three dimensions take $O(k \log k + (kq)^{3/4} \log^c k)$ time [3], we obtain the following bound on the total cost, where the $q_i$'s sum to $O(k^3)$:

$$O\left(n \log n + \sum_{i=1}^{O(n/k)} (kq_i)^{3/4} \log^c k\right) = O(n \log n + (n/k)^{1/4}(k \cdot k^3)^{3/4} \log^c k)$$
$$= O(n \log n + k^{11/4} n^{1/4} \log^c k).$$

Since range searching structures are used as a subroutine, the result is admittedly theoretical, but because the queries are off-line, (hierarchical) cuttings instead of partition trees are sufficient [3, 19] and the constant $c$ is small. (Without sophisticated data structures, one can still get a near-$O(n + k^4)$ time bound.)

We have thus proved the following theorem.

THEOREM 3.2. *For $n$ halfspaces in $\mathbb{R}^3$, LP with at most $k$ violations can be solved in $O(n \log n + k^{11/4} n^{1/4} \log^{O(1)} n)$ expected time.*

**4. On the feasible case.** We now solve the feasible LP problem with violations in $\mathbb{R}^d$ by reducing it to general LP with violations in $\mathbb{R}^{d-1}$.

Assume the objective is to minimize the first coordinate $x$. Let $\xi^*$ be the minimum $x$-coordinate in $I_k(H)$. First, find some $v_0 \in I_0(H)$ by LP. Since $I_k(H)$ is connected in the feasible case, given $\xi$ smaller than the $x$-coordinate of $v_0$, we can decide whether $\xi^* \leq \xi$ by testing whether $I_k(H)$ intersects the vertical hyperplane $x = \xi$ or, equivalently, whether $I_k(H_\xi) \neq \emptyset$, where $H_\xi$ is the set of $(d-1)$-d halfspaces formed by intersecting the halfspaces of $H$ with $x = \xi$.

**4.1. 3-d feasible LP with violations.** In the $d = 3$ case, the decision problem can therefore be solved by the 2-d algorithm of section 2 in $O((n + k^2) \log n)$ time. To solve the optimization problem, we can apply parametric search [48]. (We assume that the reader is familiar with this technique; if not, see [5] for more information.) Unfortunately, step 1 of our algorithm, the construction of the concave/convex chains, appears difficult to parallelize efficiently.

To circumvent this difficulty, we preprocess before parametric searching by constructing the 3-d concave/convex surface cover using step 1 of the algorithm of section 3, in $O(n \log n)$ expected time. If the bounding polytopes are stored in drum representations [55] via persistent search trees, as suggested in [13], we can retrieve a binary-searchable copy of the intersection of each surface with any vertical plane $x = \xi$ in logarithmic time. These 2-d slices form concave/convex chains covering the $(\leq k)$-level of the lower/upper halfplanes of $H_\xi$. Thus, for any given $\xi$, we can decide whether $I_k(H_\xi) = \emptyset$ in $O(k^2 \log n)$ time using steps 2 and 3 of the 2-d algorithm. These two steps are parallelizable in $O(\log n)$ time with $O(k^2)$ processors, by using the AKS sorting network for the interval counting problem in step 3 (the linear scan does not need to be parallelized because no more comparisons with $\xi$ are involved after sorting). Thus, $\xi^*$ can be found by Megiddo's parametric search [48], with Cole's improvement [25], in $O(k^2 \log^2 n)$ time. Including the preprocessing, the entire algorithm takes $O(n \log n + k^2 \log^2 n)$ expected time.

**4.2. 4-d feasible LP with violations.** Parametric search is more problematic in the $d = 4$ case. Not only is the decision algorithm (the 3-d algorithm of section 3) difficult to parallelize (because of step 1), but an efficient global preprocessing in four dimensions is not available to remedy the situation. Fortunately, the author's randomized optimization technique [14] is applicable (which uses the decision algorithm only as a black box) and yields the best result in this case.

LEMMA 4.1. *If LP with at most $k$ violations in $\mathbb{R}^{d-1}$ can be solved in $O(T(n,k))$ expected time, then feasible LP with at most $k$ violations in $\mathbb{R}^d$ can be solved in $O(T(n,k))$ expected time, provided that $T(n,k)/n^\varepsilon$ is monotone increasing in $n$.*

The $d = 2$ case of the above lemma is shown in [14, Theorem 5.2]. Since the proof in higher dimensions is essentially identical (using known constant-size cuttings in higher dimensions), we will not repeat the proof here.

By Lemma 4.1 and the algorithm of section 3, we can thus solve the 4-d feasible case in $O(n \log n + k^{11/4} n^{1/4} \log^c n)$ expected time.

THEOREM 4.2. *For $n$ halfspaces in $\mathbb{R}^3$ with a nonempty common intersection, LP with at most $k$ violations can be solved in $O(n \log n + k^2 \log^2 n)$ expected time.*

*For $n$ halfspaces in $\mathbb{R}^4$ with a nonempty common intersection, LP with at most $k$ violations can be solved in $O(n \log n + k^{11/4} n^{1/4} \log^{O(1)} n)$ expected time.*

*Remark.* A similar approach can be used to find the smallest circle enclosing all but $k$ points, given $n$ points $\{(a_i, b_i)\}_i$ in the plane. This problem is a variant of 3-d feasible LP with violations: the objective is now to minimize a convex function $x^2 + y^2 + z$, but the constraints $z \geq -2a_i x - 2b_i y + a_i^2 + b_i^2$ are still linear. The same technique for Lemma 4.1 reduces the problem to 2-d convex programming with violations (deciding whether there exists a point lying in all but $k$ planar convex sets), which can be solved in $O((n\beta(n) + k) \log n)$ expected time by the remark in section 2. The upper bound $T(n) = O(n\beta(n) \log n + kn^\varepsilon)$ can then be used.

(Alternatively, it might be possible to solve this problem by parametric search, but certain details are unclear, so we will not comment further.)

**5. Conclusions.** We have presented a new, simple approach to solving LPs with violations in two and three dimensions. The running time of our 2-d algorithm ($O((n + k^2) \log n)$) is almost optimal for all values of $k \ll n/2$ under a well-known conjecture; an open question is whether the time bound can be further improved to $O(n \log k + k^2)$. Our algorithm uses $O(n + k^2)$ space; another question is whether the storage requirement can be reduced to $O(n)$.

For the general 3-d problem, there is still a small gap between our time bound and the conjectured $\Omega(n + k^3)$ lower bound. For the general 4-d problem, our approach does not seem to work as well due to various reasons (for instance, we can no longer afford to construct concave/convex surfaces explicitly, since convex polytopes defined by $n$ hyperplanes in $\mathbb{R}^d$ may have $\Omega(n^{\lfloor d/2 \rfloor})$ size). Determining the complexity of LP with violations in dimension four and beyond thus remains a challenging problem.

**Appendix: Finding all local minima of $I_k(H)$ in the 2-d feasible case.** In the 2-d feasible case, Katoh and Tokuyama [44] recently showed that all $O(k)$ local $y$-maxima of the $k$-level of $n$ lower halfplanes can be enumerated in $O(n \log n + (nk)^{2/3} \log^{O(1)} n)$ time. In this appendix, we note that the time bound can be reduced to $O((n + (nk)^{3/5}) \log^{O(1)} n)$ using randomization. This result is independent of the rest of the paper and is of mainly theoretical interest, because in practice the $k$-level in two dimensions tends to have near-linear size, in which case the problem can be solved directly in near-linear time.

First, it is no loss of generality in the feasible case to assume that the objective is to maximize the $y$-coordinate and the halfplanes are all lower halfplanes: the first condition can be met by rotation; for the second condition, we can find a point $v_0 \in$

$I_0(H)$ by LP, make $v_0$ the origin by translation, and then transform each halfplane $ax + by \leq 1$ to the lower halfplane $y' \leq ax' - b$ by an affine map ($x' = -x/y$, $y' = -1/y$).

Our result is obtained by the following observation (which was also used in an algorithm in [15]): although the current best bound on size of the $k$-level is $O(nk^{1/3})$ by Dey [27], a random level nearby has lower complexity. Let $j$ be a parameter to be set later. Pick a random integer $j' \in [0, j]$ and construct the $(k - j')$-level $\mathcal{L}^-$ and the $(k + j')$-level $\mathcal{L}^+$. Since the $(k - j)$-level, …, $(k + j)$-level have combined size $O(nk^{1/3}j^{2/3})$ [27], $\mathcal{L}^-$ and $\mathcal{L}^+$ have expected size $O(n(k/j)^{1/3})$ and can therefore be constructed in $O(n(k/j)^{1/3} \log^{O(1)} n)$ expected time by known output-sensitive algorithms [15].

Among the $n$ bounding lines, track the subset formed by the $(k - j' + 1)$st, …, $(k + j' + 1)$st lowest lines at a vertical sweep line as the sweep line moves from left to right. Changes to the subset occur only at vertices of $\mathcal{L}^-$ and $\mathcal{L}^+$, and thus this process takes $O(n(k/j)^{1/3})$ time.

Now, divide the plane into $m = O(nk^{1/3}/j^{4/3})$ vertical slabs, each containing at most $j$ vertices of $\mathcal{L}^-$ and $\mathcal{L}^+$. Take each slab $\sigma$. A line intersecting the $k$-level within $\sigma$ must intersect $\mathcal{L}^-$ or $\mathcal{L}^+$, or be among the $(k - j' + 1)$st, …, $(k + j' + 1)$st lowest lines at the left/right wall of $\sigma$. Therefore, we can form a list $L_\sigma$ of $O(j)$ size that contains all lines involved in the $k$-level within $\sigma$. Within $\sigma$, the $k$-level of all lower halfplanes coincides with a level of the $O(j)$ lower halfplanes defined by $L_\sigma$. We can apply Katoh and Tokuyama's algorithm to find all $k_\sigma$ local $y$-maxima within $\sigma$ in $O(j \log j + (jk_\sigma)^{2/3} \log^{O(1)} j)$ time, because their algorithm is output-sensitive [44]. The total time over all slabs is given below, up to polylogarithmic factors, where the $k_\sigma$'s sum to $O(k)$:

$$\begin{aligned} O\left(mj + \sum_\sigma (jk_\sigma)^{2/3}\right) &= O(mj + m^{1/3}j^{2/3}k^{2/3}) \\ &= O(n(k/j)^{1/3} + n^{1/3}k^{7/9}j^{2/9}). \end{aligned}$$

Setting $j = \min\{n^{6/5}/k^{4/5}, k\}$ yields an expected time bound of $O((n + (nk)^{3/5}) \log^{O(1)} n)$.

*Remark.* If Dey's bound on the combined size of the $(k-j)$-level, …, $(k+j)$-level can be improved to $O(nk^\alpha j^{1-\alpha})$ for some constant $\alpha > 0$, then the time bound would work out to be $O((n + (nk^{3\alpha})^{1/(1+2\alpha)}) \log^{O(1)} n)$.

# DYNAMIC LCA QUERIES ON TREES*

RICHARD COLE† AND RAMESH HARIHARAN‡

**Abstract.** We show how to maintain a data structure on trees which allows for the following operations, all in worst-case constant time:

1. insertion of leaves and internal nodes,
2. deletion of leaves,
3. deletion of internal nodes with only one child,
4. determining the least common ancestor of any two nodes.

We also generalize the Dietz–Sleator "cup-filling" scheduling methodology, which may be of independent interest.

**Key words.** LCA, dynamic LCA, "cup-filling" scheduling

**AMS subject classifications.** 68W05, 68W40, 68Q25, 68P05

**DOI.** 10.1137/S0097539700370539

## 1. Introduction.

Finding *least common ancestors (LCAs)* in trees is a fundamental problem that arises in a number of applications. For example, it arises in computing maximum weight matchings in graphs [Ga90], in computing longest common extensions of strings, finding maximal palindromes in strings, matching patterns with $k$ mismatches, and finding $k$-mismatch tandem repeats [Gus97]. The tree involved in all but the first of these applications is a *suffix tree*.

The primary use of LCA computations in a suffix tree is to determine the longest common prefix of two substrings in constant time. This operation is used heavily in the above applications. The suffix tree for a given string can be constructed in linear time [M76]. Each node in this tree corresponds to a substring of the given string. The longest common prefix of any two substrings is the string corresponding to the LCA of the corresponding nodes.

The first constant time LCA computation algorithm was developed by Harel and Tarjan [HT84]. This algorithm preprocesses a tree in linear time and subsequently answers LCA queries in constant time. Subsequently, Schieber and Vishkin [SV88], Berkman and Vishkin [BV94], and Bender and Farach-Colton [BF00], gave simpler algorithms with the same performance.

In this paper, we consider the dynamic version of the problem, i.e., maintaining a data structure which supports the following tree operations: insertion of leaves and internal nodes, deletion of internal nodes with only one child, and LCA queries. We assume that when a new node is inserted, a pointer to the insertion site in the tree is also given. The motivation is to maintain a suffix tree under insertion of new strings, deletion of strings, and longest common prefix queries. One application of this problem arises in maintaining a databaseof strings in order to answer queries of the following kind: given a pattern string, find all its occurrences with up to $k$ mismatches in the

strings in the database. Efficient algorithms for finding all occurrences of a pattern in a text with up to $k$ mismatches [LV86, CH97] require maintaining the suffix tree of the text and processing it for LCA queries. Extending these algorithms to maintain a database of strings supporting $k$-mismatch queries would require maintaining LCAs dynamically.[1] Additions and deletions of new strings to the database will change the suffix tree as well as the LCA data structure. A new string can be inserted into a suffix tree in time proportional to its length. The number of nodes inserted in the process is proportional to the length of the string inserted. These nodes could be leaves or internal nodes. Similarly, deletion of a string will cause the removal of some nodes. Our goal is to minimize the work needed to maintain the data structure for each node inserted or deleted.

Harel and Tarjan [HT84] gave an algorithm to maintain a forest under *linking* and finding LCAs. This is useful in computing maximum weight matchings in graphs. The link operation generalizes insertions of new leaves. Harel and Tarjan's link operation allowed only linking of whole trees, not linking of a tree to a *subtree* of another tree. The amortized time taken by their link operation was $\alpha(m,n)$, where $n$ is the size of the tree and $m$ is the number of operations. LCA queries were answered in constant time. Gabow [Ga90] gave an algorithm which performs additions and deletions of leaves in constant amortized time and also supports linking of trees to subtrees in $\alpha(m,n)$ amortized time. The worst-case time for update operations in both these algorithms was $\Omega(n)$. The worst-case time for an LCA query was $O(1)$. Both the above algorithms were motivated by the maximum weighted matching problem in graphs.

Since our focus is different, namely suffix trees, we consider insertions and deletions of leaves and internal nodes, but not the link operation. Note that neither of the above algorithms considered insertions of internal nodes. Westbrook [We92] built upon Gabow's approach above to give an $O(1)$ amortized time algorithm which could perform insertions and deletions of leaves as well as internal nodes. Our focus, however, is on worst-case insertion time rather than amortized time.

We give an algorithm which performs insertions and deletions of leaves and internal nodes while supporting LCA queries, all in *constant worst-case* time. This algorithm is obtained in two stages. First, we give an algorithm which takes $O(\log^3 n)$ worst-case time for insertions and deletions and $O(1)$ worst-case time for queries. This is the core of our algorithm. Subsequently, we show how to improve the worst-case time for insertions and deletions to $O(1)$ by using a standard multilevel scheme. The space taken by our algorithm is $O(n)$.

Our basic $O(\log^3 n)$ worst-case time algorithm broadly follows Gabow's and Schieber and Vishkin's algorithm. The overall approach is to decompose the tree into centroid paths and assign a code to each node. From the codes for two given nodes, the centroid path at which their paths from the root separate can be easily determined in constant time. And given two vertices on the same centroid path, the one closer to the root can be determined by a simple numbering. Together, the codes and numberings yield the LCA. The basic problem we have to solve is to maintain the centroid paths and codes over insertions and deletions. Gabow's algorithm does this in bursts, reorganizing whole subtrees when they grow too large. This makes the worst-case time large. However, the amortized time is $O(\log n)$ because each reorganization is coupled

[1]However, just maintaining LCAs alone is not sufficient to solve the dynamic $k$ mismatches problem with query time smaller than the obvious static algorithm. Therefore, we do not obtain any results on the dynamic $k$ mismatches problem here.

with a doubling in size; this time is reduced to $O(1)$ using a multilevel scheme. Note, also, that Gabow does not consider insertions of internal nodes. Thus, two main issues need to be tackled to get constant worst-case time.

The first issue is that of maintaining numbers on centroid paths so that the LCA of two given nodes on the same centroid path can be found in constant time. For this purpose, we use the Dietz–Sleator [DS87] data structure (or the Tsakalidis [Ts84] data structure) which maintains order in a list under insertions and deletions.[2]

The second and the more serious issue by far is that of reorganizing trees to maintain centroid paths and codes in constant worst-case time. Since we seek constant worst-case time, there is little option but to delay this reorganization. We amortize this reorganization over future insertions and deletions, i.e., spread the $O(1)$ amortized work of Gabow's algorithm over future insertions/deletions so each insertion and deletion does only a constant amount of work. This approach is not new and has been used by Dietz and Sleator [DS87] and Willard [W82] among others. However, the problems caused by this approach are nontrivial and specific to this setting.

The problem with this approach is that any change at a node $v$ causes the codes at all the nodes in the subtree rooted at $v$ to change. Since updates of these codes are spread over future insertions and deletions, queries at any given instant will find a mixture of updated and not yet updated codes. This could potentially give wrong answers. We avoid this with a two-phase update of a two-copy code.

What further complicates the situation is that reorganizations could be taking place at many subtrees simultaneously, one nested inside the other. This implies that the variation amongst nodes in the degree to which their codes have been updated at any given instant could be arbitrarily large. Nonetheless, the two-phase update ensures correct answers to the queries.

An additional complication is that the various nested reorganizations could proceed at very different speeds, depending upon the distribution of the inserted nodes. In this respect, the situation is analogous to that encountered in asynchronous distributed computing, where interacting processes proceeding at arbitrarily different speeds need to ensure they collectively make progress on their shared computation.

Our main contribution is to organize the various nested processes so that they complete in time and also maintain codes which give correct answers to queries. This is obtained by a nontrivial scheduling procedure coupled with an analysis which bounds the total sizes of nested processes.

To understand our scheduling procedure it is helpful to recall the Dietz–Sleator cup-filling methodology. It concerns a collection of tasks in which priorities increase in an unknown but bounded way (i.e., adversarially set), each time unit; the scheduling is very simple: simply select the current highest priority task and run it to completion. They show this algorithm has a good performance which they tightly bound. We are concerned with a similar scenario, but in which priorities are only approximately known; naturally, we schedule the apparently highest priority task. We also allow the tasks to be somewhat divisible so that they need not be run to completion once started. Details appear in section 6.8.

## 2. Overview.

We assume that the tree is a binary tree, without loss of generality.

[2] We can also use the data structure given here but supporting only leaf insertion and deletion. This results in the centroid paths being modified only at their endpoints, and a trivial numbering scheme suffices to maintain order. This approach was suggested by Farach-Colton [F99].

First, we consider only insertions. Deletions are handled easily by just ignoring them until they form a significant fraction of the number of nodes, at which point the entire data structure is rebuilt. The original data structure is also maintained until this rebuilding is complete in order to answer queries. Details on handling deletions are deferred to section 8.

We also assume that the insertions at most double the tree size. This assumption is also handled easily by rebuilding when the size of the tree increases by some suitable constant factor, and again is addressed in section 8.

The paper is organized as follows. We give some definitions in section 3. Then we describe the algorithm for the static case in section 4 and Gabow's dynamic algorithm in section 5. In section 6, we describe our $O(\log^3 n)$ worst-case time algorithm. Sections 7 and 8 describe the improvement to $O(1)$ time and the handling of deletions, respectively.

**3. Definitions.** We partition the tree $T$ into paths, called *centroid paths*, as follows. Let $T_y$ denote the subtree of $T$ rooted at node $y$. Suppose $2^i \leq |T_y| < 2^{i+1}$. Then, $y$ is called a *tail* node if $|T_z| < 2^i$ for all children $z$ of $y$, if any. Such vertices $y$ will lie in distinct centroid paths and will be the *tails*, i.e., bottommost vertices, in their respective centroid paths. The centroid path containing $y$ connects $y$ to its farthest ancestor $x$ such that $2^i \leq |T_x| < 2^{i+1}$. $x$ is called the *head* of this path. It is easy to see that centroid paths defined as above are disjoint.

A centroid path $\pi$ is said to be an ancestor of a node $x$ if $\pi$ contains an ancestor[3] of $x$. A centroid path $\pi$ is said to be an ancestor of another path $\pi'$ if $\pi$ is an ancestor of the head of $\pi'$. A centroid path $\pi$ is a child of another path $\pi'$ if the head of $\pi$ is a child of a node on $\pi'$.

The *least common centroid path (LCCP)* of two nodes is the centroid path containing their LCA. An *off-path node* with respect to a particular centroid path $\pi$ is a node not on $\pi$ whose parent is on $\pi$. The *branching pair (BP)* of two nodes $x, y$ is the pair of nodes $x', y'$ on the LCCP which are the least common ancestors of $x, y$, respectively.

**4. Outline of the static algorithm.** The nodes of the tree are partitioned into centroid paths. The nodes are then numbered so that parents have smaller numbers than their children. In fact, the numbering need satisfy only the following property: if $x$ and $y$ are distinct vertices on the same centroid path and $x$ is a strict ancestor of $y$ then $number(x) < number(y)$.

Each vertex is given a code of length $O(\log n)$ with the following property: the LCCP and BP of $x$ and $y$ can be determined easily from the first bit in which the codes for $x$ and $y$ differ. Let $code(x)$ denote the code for node $x$.

The LCA of two nodes $x, y$ is now easy to determine. The LCCP and BP of $x, y$ are found in constant time using a RAM operation for finding the leftmost bit which differs in $code(x)$ and $code(y)$.[4] Note that the nodes in the BP need not be distinct (see Figure 1). The node in the BP with the smaller number is the desired LCA.

**4.1. The codes.** We still need to describe the assignment of codes to nodes. Note that if the tree was a complete binary tree, all centroid paths would be just single nodes. Furthermore, $code(x)$ could be the canonical code obtained by labelling the left-going edges 0 and right-going edges 1, and reading off the path labels from the root to $x$.

[3] All references to ancestors in this paper will be in the nonstrict sense, unless otherwise stated.
[4] Or perhaps, using table look-up on a precomputed set of answers.

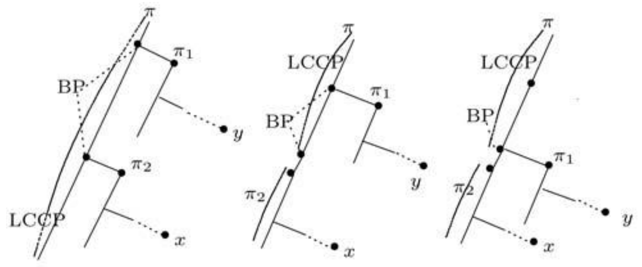

FIG. 1. *LCCP and BP.*

For a general tree, *code*$(x)$ is a concatenation of smaller bit strings, one for each centroid path containing an ancestor of $x$.

First, we assign to each centroid path $\pi$ a bit string called *separator*$(\pi)$. These strings have the following property. For each centroid path $\pi$, the separator strings assigned to children centroid paths of $\pi$ form a prefix-free set (i.e., no string is a prefix of another string). The length of *separator*$(\pi)$ is $O(\log \frac{|T_x|}{|T_y|})$, where $y$ is the head of $\pi$ and $x$ is the head of the centroid path containing the parent of $y$.

*code*$(x)$ is a concatenation of the separator strings assigned to ancestor centroid paths of $x$ (including the path containing $x$) in order of increasing distance from the root. It is easy to show that the length of the code is $O(\log n)$ (take any sequence of centroid paths encountered on a path from the root to a leaf and let $x_1 \ldots x_k$ be the heads of these centroid paths; then the sum $\sum_{i=2}^{k} \log \frac{|T_{x_{i-1}}|}{|T_{x_i}|}$ equals $O(\log |T_{x_1}|) = O(\log n)$).

It will be convenient to have *separator*$(\pi)$ be of length $a(\lceil \log |T_x| \rceil - \lceil \log |T_y| \rceil)$ for a suitable constant integer $a \geq 1$, if need be by padding *separator*$(\pi)$ with zeros at the right end. This ensures that the length and position of *separator*$(\pi)$ in a code is fully determined by $|T_x|$ and $|T_y|$.

Each separator string in *code*$(x)$ is *tagged* with the name of the corresponding centroid path, i.e., given the index of a bit in *code*$(x)$, we can recover the name of the path within whose separator this bit lies, in $O(1)$ time. The functions *number*$(x)$, *separator*$(\pi)$, *code*$(x)$, and the above tagging can all be computed in $O(n)$ time (we comment briefly on this below).

The LCCP of nodes $x$ and $y$ is determined from *code*$(x)$ and *code*$(y)$ in $O(1)$ time as follows. We find the leftmost bit in which *code*$(x)$ and *code*$(y)$ differ; subsequently, using the above tagging, we find the name of the two paths whose separators contain this mismatch bit in *code*$(x)$ and *code*$(y)$, respectively. The parents of the heads of these two paths will give the BP (see Figure 1) and the path containing this BP is the LCCP. To see this, note that the separator strings in both codes corresponding to the LCCP and centroid paths above the LCCP are identical. In addition, due to the above prefix-free property, the separator strings corresponding to the two children paths of the LCCP which are ancestors of $x$ and $y$, respectively, necessarily differ in some bit.

A special case arises when one or both of $x, y$ are part of the LCCP. If both are part of the LCCP, then the one with smaller *number*() is the LCA. Otherwise, if $x$ is part of the LCCP but $y$ is not, then *code*$(x)$ is a prefix of *code*$(y)$. The path containing $x$ is the LCCP; BP is easy to determine as well.

*Computation.* We briefly touch upon how *number*$(x)$, *separator*$(\pi)$, and *code*$(x)$

can be computed in $O(n)$ time and, further, how each separator string in *code*$(x)$ can be tagged with the name of the corresponding path.

Computing *number*$(x)$ is clearly easy: in any centroid path the numbers only need to be in increasing order of distance from the root.

Computing *separator*$(\pi)$ involves assigning prefix-free codes. We outline how this is done for child paths of a centroid path $\pi$ with head $x$, given that the separator for $\pi$ has already been determined. Let $\pi_1 \dots \pi_k$ denote the child paths of $\pi$ and $x_1 \dots x_k$ their respective heads. We construct a weight-balanced binary search tree on the weights $|T_{x_1}| \dots |T_{x_k}|$. This tree can be constructed in $O(k)$ time [Meh77] and has the property that the height of the leaf corresponding to $x_i$ is $O(\log \frac{\sum_{j=1}^{k} |T_{x_j}|}{|T_{x_i}|}) = O(\log \frac{|T_x|}{|T_{x_i}|})$. Separator codes for $\pi_1 \dots \pi_k$ are obtained by encoding left edges in the weight-balanced tree by 0, encoding right edges by 1, and reading off the labels on the path from the root to the appropriate leaves in this tree. Clearly, codes thus obtained are prefix-free. The whole procedure takes $O(k)$ time, which translates to $O(n)$ time over all of $T$.

*code*$(x)$ is computed in $O(1)$ time from *code*$(y)$, where $y$ is the parent of $x$, as follows. If $x$ and $y$ are in the same centroid path, then the codes are the same. Otherwise, $x$ is in a child path $\pi$ of the path containing $y$, and *code*$(x)$ is obtained by concatenating *code*$(y)$ and *separator*$(\pi)$. This is done in $O(1)$ time using a RAM operation.

There is one issue which needs clarification. Recall the tagging mentioned above. One method to find the name of the centroid path whose separator string contains a particular mismatch bit is to keep an array of size $O(\log n)$ for each vertex $x$; the array for vertex $x$ stores the relevant path name for each potential mismatch bit. Clearly, given the leftmost bit in which *code*$(x)$ differs from *code*$(y)$, indexing into the above arrays (one each for $x$ and $y$) using the location of the mismatch bit will give us the names of the required separator paths in $O(1)$ time. However, setting this up would require $O(n \log n)$ space and, therefore, $O(n \log n)$ time, over all nodes $x$. Both terms can be reduced to $O(n)$ in one of two ways.

The first involves using a multilevel data structure, similar to the one used by Gabow [Ga90] and the one we use to get $O(1)$ query time for the dynamic case; this is elaborated upon further in section 7. In this paper, we will assume the framework of this solution.

In the second solution, this tagging is avoided altogether. Instead, centroid paths are named by the code given to their respective heads and the name of the LCCP of two given nodes $x$ and $y$ is easily recovered in $O(1)$ time, given their codes. Indeed, only the following operation needs to be performed to determine the name of the LCCP: given the mismatch bit in *code*$(x)$, return the prefix of *code*$(x)$ comprising separators of all those centroid paths which are ancestors of that centroid path whose separator contains the mismatch bit (and likewise for *code*$(y)$). This is easily done using look-up tables of $O(n)$ size.

## 5. The dynamic case: Gabow's amortized bound.

The main problem in the dynamic case is to maintain the centroid paths along with the quantities *number*$(x)$, *separator*$(\pi)$, and *code*$(x)$.

Gabow [Ga90] gave an algorithm for the case when only leaf insertions were allowed. Maintenance of *number*$(x)$ is trivial in this case: new leaves are assigned successively larger numbers. However, if insertions of internal nodes is allowed, then it is not clear how to maintain *number*$(x)$.

Gabow's approach to maintaining centroid paths is as follows. As insertions are made, the centroid paths in the tree will change, in a manner yet to be described. Gabow updates the centroid paths not incrementally but in bursts. Whenever the subtree rooted at the head of a centroid path doubles[5] in size, the entire subtree is reorganized, i.e., reprocessed to construct new centroid paths, separators, and codes.

Gabow maintains separators and codes as follows. Instead of prefix-free separators, Gabow maintains a family of nested intervals. The interval for a centroid path is a subinterval of the interval for any ancestor centroid path. In addition, the intervals for the centroid paths which are children of a path $\pi$ are all disjoint. A constrained version of this approach is equivalent to maintaining separators, as we shall describe shortly in section 6.2.

When a new off-path node $y$ with respect to a particular centroid path $\pi$ is inserted, a new interval within the interval for $\pi$ and to the right of all other intervals for children of $\pi$ is assigned to $y$. Gabow shows that there is always sufficient space for this new interval, given that a subtree is reprocessed whenever its size doubles, at which point intervals nested within another are packed together. We follow a similar approach.

The time taken by Gabow's algorithm on any single insertion is proportional to the size of the subtree which is reorganized. Thus the worst-case time for an insertion could be $\Omega(n)$. However, since the reorganization of a subtree is coupled with the doubling in its size, the amortized time for an insertion is $O(\log n)$. Gabow converts this to $O(1)$ amortized time by using a multilevel approach.

## 6. Our $O(\log^3 n)$ time worst-case algorithm.

As described above, there are two main hurdles to improving Gabow's scheme to run in constant worst-case time, or even poly-logarithmic worst-case time. The first is the maintenance of *number*$(x)$ when internal nodes are inserted. The second is the reorganization of subtrees.

The first problem is easy to overcome using an algorithm for maintaining order in a list under insertions and deletions in $O(1)$ worst-case time, due to Dietz and Sleator [DS87]. We maintain each centroid path as an ordered list using this algorithm, allowing us to answer queries about which node in a particular BP is closer to the root in $O(1)$ worst-case time.

The second problem is more serious. Our basic approach is to distribute the reorganization of a subtree caused by a particular insertion over subsequent insertions. In other words, the various operations involved in reorganizing a subtree are performed, a poly-logarithmic number at a time, over future insertions.[6] This means that queries which come while a subtree is being reorganized will see a partially reorganized subtree and therefore risk returning wrong answers. We describe our algorithm for the reorganization in further detail next.

### 6.1. Weighted nodes.

Our $O(1)$ time algorithm for the LCA problem uses as a subroutine an $O(\log^3 n)$ algorithm for a slightly generalized problem. We indicate the reasons behind the need for a generalization next.

Let $T$ be the tree on which the LCA queries are being performed. Our approach is to select $\Theta(n/\log^3 n)$ nodes of $T$, which partition $T$ into subtrees of size $O(\log^3 n)$, called *small* subtrees. The selected nodes are formed into an induced tree $T_1$, to which we apply the $O(\log^3 n)$ time algorithm. It will be the case that for each $\Theta(\log^3 n)$

[5] When it crosses a power of two boundary, actually.

[6] This general approach has also been followed by Dietz and Sleator [DS87] and by Willard [W82] to convert algorithms with good amortized performance to worst-case performance.

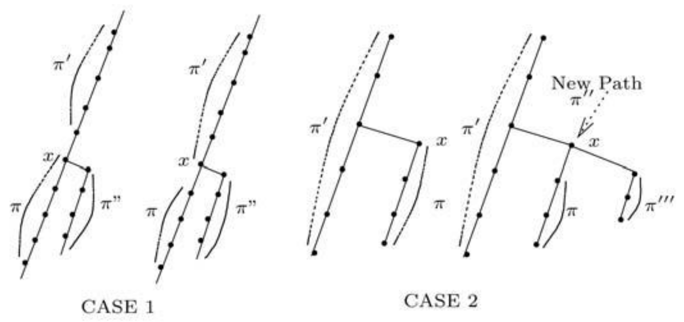

FIG. 2. *Changing centroid paths.*

insertions into one of these small subtrees just $O(1)$ nodes are added to $T_1$. To achieve the $O(1)$ worst-case time bound, we need to perform the $O(\log^3 n)$ operations stemming from an insertion to $T_1$ over the corresponding $O(\log^3 n)$ insertions to the relevant small subtree of $T$, at a rate of $O(1)$ operations per insertion. To control this appropriately, we weight the nodes of $T_1$ as follows.

Weight constraints:

(i) All weights are integer multiples of $1/\log^3 n$.[7]

(ii) Node weights are in the range $[0, 1]$.

(iii) If a node has weight less than 1, its parent has weight 1.

(iv) A weight 1 node has at most one child of weight less than 1.

Weight increases occur in integer multiples of $1/\log^3 n$; the largest possible increase is by $1/\log^2 n$, as we will see in Remark 6.23. We will show that we can maintain $T_1$ with $O(\log^3 n)$ operations per unit increase in weight. Later we will see that each insertion to $T$ results in at most a $4/\log^3 n$ increase in weight, and we will show that $T_1$ can be maintained with $O(1)$ work per insertion to $T$. For intuition, the reader may find it helpful to think of nodes being inserted with weight 1 with the caveat that this is not exactly the scenario we are describing.

When a node is inserted in $T_1$ it will have weight zero initially. As the relevant inservations to $T$ occur, its weight is increased. Until its weight reaches 1, no further nodes can be inserted in its neighborhood in $T_1$, so as to meet constraints (iii) and (iv) above.

**6.2. Updating centroid paths.** When a node's weight is increased (by up to $1/\log^2 n$), each of its $O(\log n)$ ancestor centroid paths could shift down by one or two nodes as shown in Figure 2, Case 1. New centroid paths of one or two nodes could begin as well, as shown in Figure 2, Case 2. (If all node weights are equal to 1, the shifts are only by one node and the new paths each have only one node.)

We would like to maintain the invariant that for each centroid path there is an integer $i$ such that for each node $w$ on the path, $2^i \le |T_w| < 2^{i+1}$, where $|T_w|$ denotes the weight of the subtree $T_w$ rooted at $w$. We call such paths *$i$-paths.* Unfortunately, as it is expensive to update the codes associated with the subtrees of a centroid path, the changes to a centroid path may lag the increases in the sizes of the trees $T_w$. Consequently, we will allow centroid paths to overlap.

More specifically, an $i$-path $\pi$, as in the static structure, comprises a maximal

[7]$n$ is restricted to a range $[2^i, 2^{i+a}]$ for some constant $a$, and we take $\log^3 n$ to be the fixed value $(i+a)^3$.

sequence of nodes $w$ with $2^i \leq |T_w| < 2^{i+1}$, but in addition may include further nodes $z$ with $2^{i+1} \leq |T_z| < 2^{i+1} + 2^{i-1} + 2^{i-2}$, for $i \geq 1$. Any such node $z$ is also part of an $(i+1)$-path $\pi'$. Naturally, the nodes of $\pi$ are required to form a path.

Further, to accommodate leaves, which may have weight 0, we define a 0-path to comprise a maximal sequence of nodes $w$ such that $0 \leq |T_w| < 2$, and in addition it may include further nodes $z$ with $2 \leq |T_z| < 2\,\frac{3}{4}$.

If node $v$ lies on both an $i$-path $\pi$ and an $(i+1)$-path $\pi'$, $\pi$ is said to be its *primary* path and $\pi'$ its *secondary* path. If $v$ lies on a single path $\pi$, $\pi$ is its primary path.

We need to redefine the notion of parenthood for these paths.

DEFINITION 6.1. *Let $\pi$ be a centroid path with topmost node $x$, called head($\pi$). If $x$ is secondary on path $\pi'$, then $\pi'$ is the parent of $\pi$. Otherwise, if $x$ is not secondary on any path, the parent of $\pi$ is given by the primary path of parent($x$).*

LEMMA 6.2. *Suppose that $u$ and $v$ are adjacent secondary nodes on $(i+1)$-path $\pi'$. Then $u$ and $v$ are primary nodes on the same $i$-path $\pi$, where $\pi'$ is the parent of $\pi$.*

*Proof.* W.L.O.G., let $u$ be the parent of $v$. $|T_v| \geq 2^{i+1}$ as $v$ lies on $\pi'$. Let $w$ be $u$'s other child, if any. Suppose, for a contradiction, that $u$ and $v$ were on different $i$-paths. Also suppose that $u$ is on $i$-path $\pi$. Then $w$ must have been part of $\pi$ before $|T_v|$ reached $2^i$, as otherwise at that point $v$ would have joined $\pi$. For $i \geq 1$, it follows that $|T_w| \geq 2^i$. For $i = 0$, by weight constraint (iv), $weight(w)$ must reach 1 before $v$ is inserted (with initial weight 0) in $T_1$; thus here too, $|T_w| \geq 2^i$. Thus $|T_u| = weight(u) + |T_w| + |T_v| \geq 2^{i+1} + 2^i$, and thus $u$ cannot be on an $i$-path, contrary to assumption. ∎

The increment in weight of a node $z$ may cause changes to the tails of some or all of its ancestral centroid paths. Changes to the heads of the paths may be deferred; their handling is described in subsequent sections. The reason for delaying changes to the head is that such a change entails updating the codes of all the nodes in the off-path subtree of the head node. The following changes may occur to an $i$-path with tail $y$ and head $x$.

1. If node $z$ is not a descendant of $y$, then the tail of $\pi$ is unchanged.
2. If $z$ is a descendant of $x$ and $|T_x|$ increases from less than $2^{i+1}$ to at least $2^{i+1}$ due to the weight change, then $x$ is added to an $(i+1)$-path. If the path $\pi''$, the parent of $\pi$, is an $(i+1)$-path, then $x$ becomes the tail of $\pi''$. If not, a new $(i+1)$-path is created, comprising the single node $x$. In any event, $x$ remains on $\pi$ for now. Note that there may be two nodes $x_1$ and $x_2$ for which $|T_{x_h}|$, $h = 1, 2$, increases from less than $2^{i+1}$ to at least $2^{i+1}$.

REMARK 6.3. *Clearly, as weights increase in the subtree rooted at the head $x$ of path $\pi$, eventually $x$ must be removed from the head of $\pi$ in order to maintain the invariant that $|T_{head(\pi)}| < 2^{i+1} + 2^{i-1} + 2^{i-2}$. Thus, over time, the path $\pi$ will migrate down the (growing) tree, but will never disappear.*

REMARK 6.4. *Actually, the tail node $u$ of an $i$-path might have children $v$ and $w$ with $|T_v|, |T_w| < 2^{i-1}$, but at least one of $|T_v|, |T_w|$ will be of size $2^{i-2}$ or larger (for to contradict this we would need $2^i \leq |T_u| = wt(u) + |T_v| + |T_w| < 1 + 2 \cdot 2^{i-2}$, i.e., $2^{i-1} < 1$ or $i < 1$, and then $u$ is a leaf). Thus as $(i-1)$-path $\pi'$ migrates down the tree from such a node $u$ it might disappear; to avoid this we preserve it as a zero length path at the "bottom" of node $u$ and ancestral to both $v$ and $w$. Later if either $|T_v|$ or $|T_w|$ reaches size $2^{i-1}$, then the corresponding node ($v$ or $w$) joins $\pi'$. When a node $z$ is inserted it joins a centroid path according to the following rules.*

1. If $z$ is inserted between two nodes in $\pi$, then $z$ is added to $\pi$ at the appropriate place (possibly, $z$ is added to two paths in this way, once as a primary node and once as a secondary node).

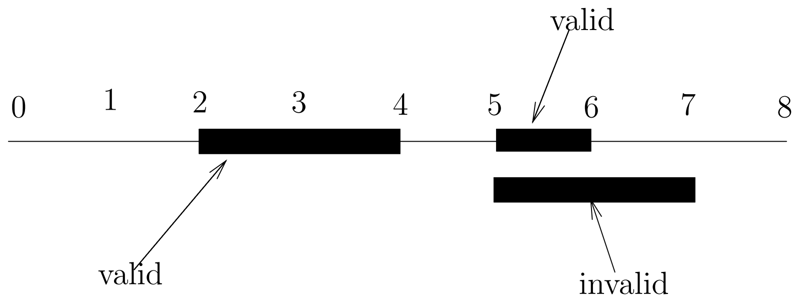

FIG. 3. *Constrained intervals.*

2. If node $z$ is inserted between $x$, the head of path $\pi$, and $x$'s parent $z'$, then $z$ is added to the centroid path or paths to which $x$ belongs. If as a result $z$ is on both an $i$- and an $(i+1)$-path, it will be the case that $|T_z| < 2^{i+1}+2^{i-1}+2^{i-2}$, since $|T_z| = |T_x|$ at this point.

**6.3. Updating separators.** Separators and codes have to be updated to reflect the above changes in the centroid paths; the update begins when a node previously on an $i$-path joins an $(i+1)$-path. When the update completes, the node leaves the $i$-path. In between times it lies on both paths.

The following interpretation of separators in terms of intervals is helpful.

*Separators as constrained intervals.* Consider an interval of length $m = 2^k$. All subintervals we consider will have lengths which are powers of 2. Each integer point on this interval has an associated $k$ bit code (the leftmost point is coded with the all 0s string, subsequent points are coded by the binary encoding of their distance from the leftmost point; this encoding has length $k$). We allow a subinterval of length $2^i$ to begin only at those integer points which have $i$ trailing 0s in their bits (see Figure 3); with such a subinterval, we associate a bit string of length $k-i$ given by the leading $k-i$ bits of the code for the starting point. It can easily be seen that given a set of disjoint subintervals with this property, the bit strings assigned to the subintervals form a prefix-free set. Thus assigning prefix-free separators is identical to assigning subintervals with the above constraints. Henceforth, all our references to intervals will be to intervals with the above constraints.

*Mapping paths to intervals.* With each $i$-path $\pi$ we maintain an interval $int_\pi$ of length either $2^{ic}$ or $2^{ic+c'}$, $c' < c$, where $c$ and $c'$ are constants to be determined. When $\pi$ is created, $int_\pi$ has length $2^{ic}$. At some point between the time $T_{head(\pi)}$ reaches size $2^{i+1} - 2^{i-3}$ and the time it reaches size $2^{i+1}$, $int_\pi$ will gain length $2^{ic+c'}$. There are two goals. The first is to ensure that if the parent of $head(\pi)$ lies on an $i$-path (not $\pi$) as well as an $(i+1)$-path, then $int_\pi$ has length $2^{ic}$. The second is to ensure that if a node originally on $\pi$ is also secondary on path $\pi'$ then $int_\pi$ has length $2^{ic+c'}$. By definition, once $T_{head(\pi)}$ first reaches size $2^i+2^{i-1}+2^{i-2}$ the first situation no longer applies. The second situation applies once $T_{head(\pi)}$ reaches size $2^{i+1}$ (as $head(\pi)$ changes the size of $T_{head(\pi)}$ may subsequently drop). Note that constraints on $c$ and $c'$ will be imposed by Lemma 6.10 below; setting $c' = 5$ and $c = 10$ suffices.

A crucial property of an interval for an $i$-path $\pi$ is that the rightmost bit for its separator ends at a fixed location, so that in each code in which it occurs there are a specified number of bits to its right whose values depend only on the separators for $h$-paths, $h < i$, to which the relevant node belongs. The number of these bits is either $ic$ or $ic + c'$, corresponding to the size of $int_\pi$. This allows the code for $int_\pi$

to be changed without requiring any change to the separators for $h$-paths, $h < i$, contained in the codes in which $int_\pi$ occurs. The one exception arises when the size of the interval for $\pi$ increases. But this can be viewed as simply prefixing $c'$ zeros to the separator following $\pi$ in the code for each node in $T_{head(\pi)}$.

*Updating intervals.* The following updates need to be performed. See Figure 2.

1. Node $x$ lies on paths $\pi$ and $\pi'$; $x$ is the head of $\pi$ and is being removed from $\pi$; in addition, there is a proper ancestor of $x$ that is or had been on $\pi'$. Then the centroid path $\pi''$ whose head was the off-path child of $x$ (with respect to $\pi$) must be assigned a new interval. The interval for $\pi''$ was earlier nested within $int_\pi$ and $int_{\pi'}$. Now this interval must be reassigned so as to be disjoint from $int_\pi$ but still nested within $int_{\pi'}$. The process which does this is called *Reassign*$(x)$.
2. Node $x$ is on paths $\pi$ and $\pi'$, and $x$ is the head node of $\pi$ and $\pi'$. Then $\pi'$ is a new centroid path, and a new interval has to be assigned to $\pi'$. This interval $int_{\pi'}$ must be nested within the interval $int_{\pi''}$ for the path $\pi''$, the previous parent of $\pi$, and now the parent of $\pi'$. Further, $int_\pi$ must be reassigned so it is nested within $int_{\pi'}$. This is done by a procedure called *Assign*$(\pi')$. In addition, the interval associated with the path $\pi''$ containing the off-path child of $x$ (with respect to $\pi$) must be reassigned so that it is also nested within $int_{\pi'}$. This is done by a procedure called *Reassign*$(x)$. There are a few details associated with this case which will be explained later in section 6.4.
3. Node $x$ is the head of $i$-path $\pi$, and its parent $y$ lies on class $i$ path $\pi' \neq \pi$ and also necessarily on class $i+1$ path $\pi''$ (for by the maximality of $\pi$, $|T_y| \geq 2^{i+1}$). Note that by the time $|T_{head(\pi)}| = 2^{i+1}$, $y$ will no longer be on $\pi'$. Between this time and before the time $|T_{head(\pi)}|$ reaches $2^{i+1} + 2^{i-1} + 2^{i-2}$, a new larger interval will have been assigned to path $\pi$; this new interval will be contained within $int_{\pi''}$. This is done by a process called *Rescale*$(\pi)$.

Thus as time proceeds, subintervals move from one interval to another and new intervals are created. This movement and creation is done as follows. When a subinterval has to be removed from an interval, the subinterval is just marked as deleted but not removed. When a new subinterval has to be assigned to $\pi$ within $int_{\pi'}$, where $\pi'$ is the parent path of $\pi$, it is assigned in either the first half of $int_{\pi'}$ or the second half of $int_{\pi'}$, based on a logic to be described. In either case, it is assigned to the leftmost available slot to the right of all assigned subintervals in constant time. Note that a particular weight increase creates at most constant number of *Rescale*, *Reassign*, or *Assign* processes at each ancestor centroid path of the reweighted node.

We need to ensure that *Assign*$(\pi)$, *Rescale*$(\pi)$, and *Reassign*$(x)$ will always find an empty slot as above to assign to the new interval for $\pi$. This is not hard to ensure if nondeleted subintervals are separated by small gaps only. However, large gaps could build up as subintervals enter and leave intervals. Consequently, we need a background process which will start removing deleted subintervals and compacting nondeleted subintervals within an interval, once the interval reaches a certain fraction of its capacity. This process is described next.

*The compacting process for an $i$-path $\pi$.* The compacting process maintains the interval $int_\pi$ as two halves. At any given time, one half, the insertion half, will be receiving newly inserted subintervals. At the same time the deleted subintervals in the other half are being removed and the nondeleted subintervals are being moved to the insertion half. By the time the insertion half is filled, the noninsertion half will be empty, and then their roles are toggled. Actually, the toggling occurs at a predetermined time when it is guaranteed that the noninsertion half is empty and the insertion half has not overflowed. W.L.O.G., consider the instant at which the right half becomes the insertion half. The compaction process moves through the subintervals in the left half from left to right removing deleted subintervals and reassigning undeleted subintervals at the leftmost possible slot in the right half (to the right of already assigned subintervals in this half). Insertions subsequent to the beginning of the compaction process will also be made in the right half until the stopping time, which is no later than when the right half becomes full. We will show that the compaction process in the left half will have finished by the time this happens. At this point, the compaction process will become active in the right half and insertions will be performed in the left half. We call the above process *Compact*$(\pi)$. Note that a single insertion can initiate a compaction process at each of its ancestor centroid paths.

Thus there are four kinds of processes which could be created when a node is inserted: *Assign*( ), *Rescale*( ), *Reassign*( ), and *Compact*( ). Each process is expensive and takes time at least proportioned to the size of the subtree in which it modifies codes (this updating of codes will be elaborated upon shortly in section 6.4). Thus these processes have to be performed, a poly-algorithmic number of operations at a time, over future insertions. Therefore, at any instant a number of such processes could be underway.

**6.4. Updating codes.** We consider the updates that need to be made to the various codes as a result of changes made to the intervals by *Assign*( ), *Reassign*( ), *Rescale*( ), and *Compact*( ) processes (as described in section 6.3).

First, consider an *Assign*$(\pi')$ process initiated by some node $x$, which is the head node on $i$-path $\pi$ and becomes the first node on $(i+1)$-path $\pi'$. *Assign*$(\pi')$ must assign a new interval to $\pi'$ and a new interval to $\pi$ nested within the interval for $\pi'$. It must then change the codes at all nodes in $T_x$ to reflect the change to the above two intervals. This is done as follows. The old separator string for $\pi$ in the codes at nodes in $T_x$ (including $x$ itself) will be updated to the new separator string for $\pi$. In addition, the separator string for $\pi'$ will be incorporated into the codes at all nodes in $T_x$. Thus the effect of *Assign*$(\pi')$ on the codes in $T_x$ is to make $\pi'$ appear as a path in their codes, but as a path with no primary nodes. *Reassign*$(x)$ will perform the changes needed to make $x$ a primary node on $\pi'$.

Next, consider a *Reassign*$(x)$ process. It is initiated when $x$ is in the process of leaving $i$-path $\pi$ on which it is currently primary (recall $x$ is also secondary on $(i+1)$-path $\pi'$ in this scenario). The process must remove the separator string for $\pi$ from the code at $x$ and from the codes at all the nodes in the subtree rooted at that child $y$ of $x$ which is not on $\pi$. In addition, this process must assign a new separator string for the path containing $y$ and modify the codes at all nodes in the subtree rooted at $y$ to reflect this.

We need to specify the scheduling of *Reassign*$(x)$ in more detail. When *size*$(x)$ reaches $2^{i+1}$, *Reassign*$(x)$ is made pending. At some future point, *Reassign*$(x_i)$ processes, $1 \le i \le k$, are all initiated, where nodes $x_1, x_2, \ldots, x_k$ are all the nodes currently primary on $\pi$ and secondary on $\pi'$. These *Reassign*( ) processes are performed in top-to-bottom order (i.e., if the nodes $x_1, x_2, \ldots, x_k$ are in top-to-bottom order, then *Reassign*$(x_1)$, *Reassign*$(x_2), \ldots,$ *Reassign*$(x_k)$ are performed in turn). This collection of *Reassign* processes is called a *Reassign* superprocess.

A *Compact*$(\pi)$ process for an $i$-path $\pi$ must assign a new separator code to all child paths of primary nodes on $\pi$ (secondary nodes are themselves contained in a child path of a primary node on $\pi$ by Lemma 6.2). *Compact*$(\pi)$ must also update codes at all nodes in the subtree rooted at the head of $\pi$ (other than codes for primary nodes on $\pi$). If $\pi$ happens to be a zero length path, the above description applies to its one or two child paths.

Finally, a *Rescale*$(\pi)$ process must assign a new interval $int_\pi$ to $\pi$ contained within $int_{\pi'}$, where $\pi'$ is the parent of $\pi$. In addition, the process must update the codes of all nodes in $T_{head(\pi)}$, replacing the old separator for $\pi$ with the new separator (corresponding to the change to interval $int_\pi$).

In addition to updating the codes, it is also necessary to update the annotations on the codes; recall the annotations label each bit in the code with the name of the centroid path whose separator contains this bit (also note the tagging mentioned in section 4.1). This can be done in $O(\log n)$ time per node.

We have now described the overall structure of the algorithm. For each unit weight increase in a node (from 0 to 1), which occurs as a node is inserted, $O(\log n)$ work is done in updating the ancestor centroid paths of the inserted node and initiating a constant number of *Assign*, *Rescale*, *Reassign*, and *Compact* processes for each such centroid path. A further $O(\log n)$ work is done to construct the code for the inserted node along with the annotations, using the code for its parent or child (this is explained in section 6.5). The work needed to be done on this insertion in order to further the progress of unfinished processes will be described in section 6.6. This part of the algorithm is what leads to the $O(\log^3 n)$ bound. Before describing this work, we introduce one more crucial aspect of the algorithm and also some crucial invariants which we will maintain.

*Two codes instead of one.* Even though all of the above description has been in terms of one code per node, we will actually maintain not one but two codes at each node. We will refer to these two codes as the *first code* and the *second code*. The reason for two codes is the following.

Consider two nodes $x, y$ and any process which needs to modify codes at both these nodes. At some intermediate time instant, this process could have modified the code at $x$ but not at $y$; as a consequence, the first bit of difference will no longer be related to the LCCP of $x$ and $y$. To make matters worse, there could be several such processes which have modified codes at one but not both of $x$ and $y$ (actually, our algorithm will ensure that there is only one such process).

To ensure that LCAs are indeed related to the very first bit of difference, we will maintain two codes instead of one at each vertex. Each process will be required to update both codes for all vertices of interest. However, all first codes will be updated first, and all second codes will be updated only after all first codes have been updated. The critical property is that at any instant of time, either both the first codes at $x, y$ would have been modified, or neither second code at $x, y$ has been modified. Thus either the first codes or the second codes will retain the relationship of the leftmost difference bit to the LCCP at each instant of time.

In what follows, unless explicitly stated, we will refer to both the codes for node $x$ collectively as the code at node $x$, or as *code*$(x)$.

**6.5. Invariants maintained.** To ensure that queries are answered correctly at every instant, we schedule the various processes so that the two invariants described below are maintained.

Invariant 1 states that each process finishes before the situation which caused the initiation of the process changes too dramatically. Some additional terminology will be helpful.

Definition 6.5. *A process associated with an i-path is called an i-process (i-Assign, etc.).*

Definition 6.6. *The size of path $\pi$, $size(\pi)$, is defined to be $|T_{head(\pi)}|$.*

Definition 6.7. *A weight increase is in the domain of path $\pi$, or into $\pi$ for short, if it is applied to a node in the subtree rooted at the current head of $\pi$.*

*Invariant* 1. Each process associated with $i$-path $\pi$ completes within a weight increase of $2^{i-3}$ into $\pi$ from the time the process was initiated. In addition to this, the following rules apply:

(a) *Assign*$(\pi)$ is initiated when $size(\pi)$ reaches $2^i$. (As $size(\pi)$ may never be exactly $2^i$, it is helpful to pretend that time is continous and that the weight increases occur continuously, and then we can define the initiation of *Assign*$(\pi)$ to occur exactly when $size(\pi) = 2^i$.)

(b) *Compact*$(\pi)$ is initiated following each weight increase of $2^{i+1}$ into $\pi$ from the time of $\pi$'s creation (i.e., *Assign*$(\pi)$'s initiation).

(c) Pending *Reassign*$(x)$ processes associated with $\pi$ are initiated following weight increase $h\,2^{i-2} + 2^{i-3}$ into $\pi$, from the time of $\pi$'s creation, for each integer $h \geq 4$.

(d) *Rescale*( ) is initiated when $size(\pi)$ reaches $2^{i+1} - 2^{i-3}$.

Corollary 6.8. *A Reassign$(x)$ process associated with $(i+1)$-path $\pi'$, which removes $x$ from i-path $\pi$, becomes pending when $size(\pi) = 2^{i+1}$ and $head(\pi) = x$, and completes before a further weight increase of $2^{i-1} + 2^{i-2}$ into $\pi$. In addition, if a Reassign$(z)$ process is created when node $z$ is inserted as the parent of node $x$ with an already pending Reassign$(x)$ process, the Reassign$(z)$ completes before the Reassign$(x)$ process completes.*

*Finally, $size(\pi) < 2^{i+1} + 2^{i-1} + 2^{i-2}$.*

*Proof.* *Reassign*$(x)$ becomes pending when $x$ becomes secondary on $\pi'$, i.e., when $size(\pi) = 2^{i+1}$ with $head(\pi) = x$. By Invariant 1(c) applied to $\pi'$, *Reassign*$(x)$ is initiated before a further weight increase of $2^{i-1}$ into $\pi'$ and completes within another weight increase of $2^{i-2}$ into $\pi'$. Any weight increase into $\pi$ during this time is also into $\pi'$. The first claim follows. The claim about *Reassign*$(z)$ follows due to the scheduling of *Reassign*( ) processes in top-to-bottom order.

To obtain the bound on $size(\pi)$ we show that $size(\pi)$ is less than $2^{i+1} + 2^{i-1}$ at the moment when a bunch of *Reassign*( ) processes removing nodes from $\pi$ are initiated. Let $x$ be the highest node on $\pi$ not being reassigned. Then, at that moment, $|T_x| < 2^{i+1}$. Following a weight increase of $2^{i-1}$ into $\pi'$, all the nodes being reassigned have been removed, and the next bunch of *Reassign*( ) processes is being initiated; at that moment again $size(\pi) < 2^{i+1} + 2^{i-1}$. The maximum size for $\pi$ therefore occurs just before the *Reassign*( ) processes are completed, i.e., just before a weight increase of $2^{i-2}$ into $\pi'$ (and hence into $\pi$) from the moment the *Reassign*( ) processes are initiated. This yields the claimed bound on $size(\pi)$. ☐

Corollary 6.9. *For each path $\pi$, there is at most one Assign$(\pi)$, Rescale( ), Reassign$(x)$ for $x$ secondary on $\pi$, or Compact$(\pi)$ under way at any given time.*

*Invariant* 2. For any pair of nodes $x, y$ there is at most one *Assign*( ), *Reassign*( ), *Rescale*( ), or *Compact*( ) process which must modify the codes at both $x$ and $y$ and which has modified one but not both the first codes at these nodes. Similarly, there is at most one process which must modify the codes at both $x$ and $y$ and which has modified one but not both the second codes at these nodes. Finally, if a process with the former description exists, then a process with the latter description cannot exist.

We remark that Invariant 1 is not hard to maintain. Similarly, Invariant 2 is easy to maintain using a simple blocking mechanism for processes. However, maintaining both invariants simultaneously is nontrivial. This is because weight increases in different parts of the tree may occur at different rates and unfinished processes will therefore be driven at different speeds by these weight increases. In particular, a process could be blocked indefinitely. One solution to this problem is to make a blocked process help the blocking process. This will be described in detail in section 6.6.

We are now ready to show that the intervals are sufficiently large.

LEMMA 6.10. *Suppose Invariant* 1 *holds and that* $c' \geq 5$ *and* $c = 2c'$. *Let* $\pi$ *be an* $i$*-path.*

(a) *The insertion side of* $int_\pi$ *cannot be filled up prior to the completion of* $Rescale(\pi)$ *(recall that* $int_\pi$ *has size* $2^{ic}$ *before* $Rescale(\pi)$ *completes).*
(b) *The insertion side of* $int_\pi$ *following the completion of* $Rescale(\pi)$ *will not fill up before the first initiation of* $Compact(\pi)$ *(*$int_\pi$ *now has size* $2^{ic+c'}$*).*
(c) *Consider an initiation of* $Compact(\pi)$. *Over a subsequent weight increase of* $2^{i+1}$ *into* $\pi$, *the side of* $int_\pi$ *being filled by* $Compact(\pi)$ *will have room for the subintervals being added to* $int_\pi$.

*Proof.* The proof uses an induction on $i$. The result is trivially true for $i = 0$. Thus the inductive step remains to be proven. We start with part (a). Up to the completion of $Rescale(\pi)$, $size(\pi)$ remains less than $2^{i+1}$. We show that all the subintervals that could be generated until $Rescale(\pi)$ completes will fit into $int_\pi$.

We sum the length of all the subintervals inserted into $int_\pi$ since the initiation of $Assign(\pi)$. Some of these intervals may have been deleted by the time $Rescale(\pi)$ completes. The length of each interval that is inserted is at most $2^{(i-1)c+c'}$. A particular subtree rooted at an off-path node could repeatedly delete and insert subintervals increasing in size by successive factors of $2^{2c'}$. Thus such a subtree, whose root is a primary node in an $h$-path, could be responsible for a total subinterval of length $\sum_{j=0}^{2h+1} 2^{jc'} < \frac{2^{(2h+2)c'}}{2^{c'}-1}$. The total length of gaps between subintervals is at most the total length of the subintervals. Since $Rescale(\pi)$ completes following a weight increase of $2^i$ into $\pi$ from the time $\pi$ was created, the total length of $int_\pi$ occupied by deleted and undeleted subintervals and the gaps between them is at most $2\sum_r \frac{2^{c'(2h_r+2)}}{2^{c'}-1}$, where $\sum_r 2^{h_r} \leq 2^{i+1} = 4 \cdot 2^{i-1}$ and $h_r \leq i-1$. This is at most $\frac{8 \cdot 2^{ic'}}{2^{c'}-1} \leq \frac{2^{2ic'}}{2}$ for $c' \geq 5$.

The proof of part (c) is broadly similar. W.L.O.G., we assume that $Compact(\pi)$ inserts into the right half of $int_\pi$ (now $int_\pi$ has size $2^{ic+c'}$). We show that from the time of the initiation of $Compact(\pi)$, the subintervals in $int_\pi$ when $Compact(\pi)$ was initiated together with any new subintervals inserted up until the next initiation of $Compact(\pi)$ will all fit in the right half of $int_\pi$. When $Compact(\pi)$ is initiated, $size(\pi) < 2^{i+1} + 2^{i-1} + 2^{i-2}$; the next initiation of $Compact(\pi)$ occurs following a weight increase of $2^{i+1}$ into $\pi$. The length of each subinterval inserted into $int_\pi$ is at most $2^{2ic'}$; such a subinterval would be due to a subtree of size at least $2^i$. Similarly to before, the total length of subintervals for which such a subtree could be responsible is less than $2^{2ic'} + \sum_{j=0}^{2i-1} 2^{jc'} < \frac{2^{(2i+1)\,c'}}{2^{c'}-1}$. A smaller subtree, whose root is a primary node on an $h$-path could contribute subintervals of total length no more than $\frac{2^{(2h+2)\,c'}}{2^{c'}-1}$. As before, the total length of the right half of $int_\pi$ occupied by deleted and undeleted subintervals and the gaps between them is less than $\frac{2a \cdot 2^{(2i+1)\,c'}}{2^{c'}-1} + 2\sum_r \frac{2^{(2h_r+2)\,c'}}{2^{c'}-1}$, where $a \cdot 2^i + \sum_r 2^{h_r} < 2^{i+1} + 2^{i-1} + 2^{i-2} + 2^{i+1}$ and $h_r \leq i-1$. This is at most $(8 \cdot 2^{(2i+1)\,c'} + 4 \cdot 2^{2ic'})/(2^{c'}-1) \leq 12 \cdot 2^{(2i+1)\,c'}/(2^{c'}-1) \leq 2^{(2i+1)\,c'}/2$, if $c' \geq 5$.

The proof of part (b) is identical to that of part (c) except that we need only consider the intervals due to an initial weight of $2^i$ (when $\pi$ was created) and a weight increase of $2^{i+1}$ (namely, up to the time when *Compact*($\pi$) is first initiated). ◻

**6.6. Some details of processes.** Before proceeding, some details of *Assign*( ), *Reassign*( ), *Rescale*( ), and *Compact*( ) processes need to be carefully examined. These details arise because a process is performed over a sequence of future insertions. A fundamental issue here is that nodes can lie on two paths: on one as a primary node and on the other as a secondary node.

Our goal, which enables the $O(1)$ query procedure, is to establish the following claim.

CLAIM 6.11. *The changes due to $x$ becoming primary on path $\pi'$ and ceasing to be primary on path $\pi$ are reflected in the code at a descendant node $y$ of $x$ only due to the modifications performed by the process carrying out $x$'s change of primary paths.*

*Process blocking.* To maintain Invariant 2, the following strategy is used. A process first updates all the first codes for the nodes it needs to process in preorder and then updates all the second codes, again in preorder. When the process begins work on the first codes of a subtree rooted at a node $z$ it will mark $z$ as blocked and will only remove the mark when it has finished updating the first codes in $z$'s subtree. It will follow the same blocking procedure when updating second codes. If a process $P$ comes to a blocked node it will not proceed with its work until the node is unblocked (later, we explain the helping of the blocking process undertaken by $P$ while it is waiting).

In addition, a process keeps the topmost node it is updating blocked until it is completed. Finally, a *Reassign*($x$) process, in addition to keeping $x$ blocked throughout its processing, will as its last step make $x$ primary on the path on which $x$ had been secondary.

We specify later just how a newly inserted node is marked.

*Constructing codes for newly inserted nodes.* Recall that each node has two associated codes, a first code and a second code. For a newly inserted node $x$, each code is obtained from the corresponding code for its parent or child as follows.

1. If $x$ is inserted as a child of a leaf node, then it is given the same code as its parent. This reflects the fact that $x$ lies on the same 0-path as its parent. Of course, if and when $x$'s weight increases sufficiently, its parent will leave this 0-path.
2. If $x$ is inserted as a leaf child of an internal node $v$, then it forms a new singleton path. A new interval is assigned for this path. The code for $x$ is just the code for its parent appended with the separator string for this new singleton path. There is one more complicated scenario, which arises when a *Reassign*($v$) process is underway, and the first code for $v$ has been updated, but the second has not. Let $\pi$ be $v$'s primary path and $\pi'$ its secondary path. In this case, $x$ is assigned two subintervals, one in $int_{\pi'}$ for its first code and one in $int_{\pi}$ for its second code. When the *Reassign*($v$) process updates second codes it will replace the subinterval in $x$'s second code with the subinterval in $int_{\pi'}$ used in its first code.
3. If $x$ is inserted as an internal node, then the code for $x$ is made identical to that for its child. This makes $x$ primary on the same path $\pi$ as its child. In addition, if $x$'s child is marked, then so is $x$. Of course, it may be that $x$ is also added to the parent path of $\pi$, in which case a *Reassign*($x$) process is created. There is one exception. Let $y$ be $x$'s child. If a *Reassign*($y$) is already underway, the code for $x$ is set to the updated code for $y$, i.e., the

code with separator($\pi$) removed, and in this case $x$ is not marked.

We mention here that Invariant 2 also applies to newly inserted nodes $x$ and $y$ which inherit their codes from partially processed nodes (i.e., nodes for which one but not both codes have been updated by some process).

*Process roots.* Each process must modify codes at certain nodes in the tree. The node closest to the root of $T_1$ whose code a process must modify is called the *root* of the process. Since nodes are inserted dynamically, the root of a process needs to be defined more precisely. For an $Assign(\pi)$, $Compact(\pi)$, or $Rescale(\pi)$ process, $head(\pi)$ is the root of the process; if a new node $z$ is inserted and becomes the head of $\pi$ as one of these processes is underway, $z$ becomes the new root of the process. While one of these processes is underway no node $x$ leaves $\pi$ due to a $Reassign(x)$ process until the $Assign(\pi)$, $Rescale(\pi)$, or $Compact(\pi)$ has completed; this is a consequence of the blocking strategy. For a $Reassign(x)$ process, the root is always $x$.

*Helping a blocking process.* If a process $P$ reaches a marked node $x$, it will seek to help an unblocked process in $T_x$ so as to advance the processing that will lead to the removal of the mark on $x$. To this end it traverses a path of marked nodes from $x$; at the last marked node $y$, it discovers the process $Q$ that marked $y$ and performs the next code update for $Q$. This may entail unmarking $O(\log n)$ nodes and marking up to one node (since $Q$ marks a nonleaf node prior to updating it). To facilitate this process, each mark includes the name of the process making the mark. As it suffices to have $P$ help some unblocked process on which it is waiting either directly or indirectly, it suffices that $P$ traverse a maximal path of marked nodes in $T_x$; thus this process takes $O(\log n)$ time. It is called a *basic step.*

$i$-process $P$ could be blocked by an ancestral process or by a descendant process. We will need to ensure that $P$ is blocked by at most one ancestral process. Further, this only happens at $P$'s initiation. If $P$ is so blocked, it puts a subsidiary mark on its root. The meaning of this mark is that as soon as $Q$'s mark is removed, where $Q$ is the blocking process, $P$'s mark is then instantiated. As there is only one active process per path, there are at most two such subsidiary marks per node (two paths can share a root, either because a new path has only secondary nodes and hence shares its root with a child path, or because a path temporarily has no nodes; the nodeless path will use its parent node as its root for any associated processes). In the case that two marks are present, the mark for the deeper path will be instantiated. It remains the case that each process $P$ is blocked by at most one ancestral process.

*Process interleaving and its effect on code updates.* We need to examine the interleaving of processes for paths $\pi$ and $\pi'$, $\pi'$ a child of $\pi$, and how this may affect the update of code portions corresponding to $sep(\pi)$ and $sep(\pi')$.

Because of their relative timing, $Compact(\pi)$, $Rescale(\pi)$, $Assign(\pi)$, and $Reassign(x)$ for $x$ secondary on $\pi$ do not overlap.

$Compact(\pi)$ and $Reassign(x)$ for $x$ secondary on $\pi$, update only the portion of the code corresponding to $sep(\pi')$ for $\pi'$ a child of $\pi$; $Rescale(\pi)$ updates only the portion of the code corresponding to $sep(\pi)$; $Assign(\pi)$, on the other hand, updates the portions of the code corresponding to both $sep(\pi)$ and $sep(\pi')$, where $\pi'$ is the primary path for nodes secondary on $\pi$. Thus we will need to consider the possible interaction of $Compact(\pi)$ and $Assign(\pi')$ or $Rescale(\pi')$, and of $Reassign(x)$ and $Assign(\pi''')$ or $Rescale(\pi''')$ where $x$ is secondary on $\pi$, primary on $\pi'$, and $\pi'''$ is the off-path child of $x$ (w.r.t. $\pi'$).

Consider such a $Compact(\pi)$ process. Let $y$ be an off-path child of $\pi$, secondary on $\pi'$ and primary on $\pi''$. So there is an $Assign(\pi')$ process at hand. If the $Compact(\pi)$ process updates $code(y)$ first, then $\pi''$ receives a new subinterval in the insertion half of $int_\pi$, the right half say; subsequently, the $Assign(\pi')$ gives $\pi'$ a new subinterval in the right half of $int_\pi$. On the other hand, if the $Assign(\pi')$ process updates $code(y)$ first, but after the $Compact(\pi)$ process has been initiated, then the $Assign(\pi')$ process gives $\pi'$ a new subinterval in the right half of $int_\pi$, and subsequently the $Compact(\pi)$ process does nothing further to $int_{\pi'}$ and the codes for nodes in $T_y$. The possible interactions of $Compact(\pi)$ and $Rescale(\pi')$ are identical.

Next, we consider a $Reassign(x)$ process for a node $x$, primary on $\pi'$ and secondary on $\pi$. Let $y$ be the child of $x$ which is not on $\pi'$. Let $\pi''$ be the path containing $y$. After the creation of the $Reassign(x)$ process suppose that $y$ becomes secondary on a new centroid path $\pi'''$. $\pi'''$ now becomes the parent of $\pi''$ and an $Assign(\pi''')$ process is initiated. We consider two cases in turn.

First, suppose that $Assign(\pi''')$ modifies the code for $y$ before $Reassign(x)$ does so. Then the separator for $\pi'$ will be in $code(y)$ when it is processed by $Assign(\pi''')$. Thus $int_{\pi'''}$ will be assigned so that it is nested within $int_{\pi'}$. At some subsequent point, $Reassign(x)$ will remove the separator string for $\pi'$ from $code(y)$ and reassign $int_{\pi'''}$ so that it is nested within $int_\pi$.

Second, suppose that $Reassign(x)$ has updated $code(y)$ before $Assign(\pi''')$. Then, when $Assign(\pi''')$ processes $code(y)$ it no longer contains the separator for $\pi'$. The behavior of $Assign(\pi''')$ is now as expected with $int_{\pi'''}$ being assigned so as to be nested within $int_\pi$. But note that when $Reassign(x)$ processed $code(y)$, $code(y)$ indicated that $y$ was primary on $\pi''$. So $\pi''$ was reassigned a new subinterval within $int_\pi$ and the resulting separator string was included within $code(y)$. At some later instant, $Assign(\pi''')$ included the separator string for $\pi'''$ in $code(y)$ and replaced the current separator string for $\pi''$ with a new separator string corresponding to a subinterval nested within $int_{\pi'''}$. Ultimately, the $Reassign(y)$ process created by $y$ becoming secondary on $\pi'''$ removed the latter separator string from $code(y)$. Again, the possible interactions of $Reassign(x)$ and $Rescale(\pi''')$ are identical.

Consider Claim 6.11. Note that it would not hold if, in the first case above, $Assign(\pi''')$ assigned an interval to $\pi'''$ nested within the interval for $\pi$ and incorporated the associated separator into $code(y)$. For if $Assign(\pi''')$ did so then the change resulting from $x$ becoming primary on $\pi$ would be reflected in $code(y)$ by a modification made by $Assign(\pi''')$ and not by $Reassign(x)$.

It is possible for the updates described above involving two processes ($Compact(\pi)$ and $Assign(\pi')$ or $Rescale(\pi')$, $Reassign(x)$ and $Assign(\pi''')$ or $Rescale(\pi''')$) to occur in a different order on the two codes. The only possible interleaving for the $Compact(\pi)$ process is that first $Compact(\pi)$ updates the first codes of nodes in $T_y$, then $Assign(\pi')$ (or $Rescale(\pi')$) updates both codes of nodes in $T_y$, and then $Compact(\pi)$ examines $T_y$ but makes no further updates to the codes. For the $Reassign(x)$ process, the only possible interleaving is that first $Reassign(x)$ updates the first codes of nodes in $T_y$, then $Assign(\pi''')$ (or $Rescale(\pi''')$) updates both codes of nodes in $T_y$, the $Reassign(x)$ updates the second codes of nodes in $T_y$. Each update follows the appropriate rules for the codes it encounters which will differ for the first and second codes. All we have to ensure is that the subintervals chosen for the second codes within a particular interval are the same as those selected for the first codes within the same interval. Thus, for example, in the $Reassign(x)/Assign(\pi''')$ scenario above, $Assign(\pi''')$ assigns a separator for $\pi'''$ to $code(y)$, $(sep(\pi'''))^1$ say, contained in $int_\pi$, while for the second code it assigns a separator $(sep(\pi'''))^2$ for $\pi'''$ contained within $int_{\pi'}$, and then $Reassign(x)$ replaces this separator with $(sep(\pi'''))^1$.

**6.7. Processing queries.** The algorithm ensures that the first bit of difference between either the first codes at $x$ and $y$ or the second codes at $x$ and $y$ is related to the LCCP, which itself can be obtained using the algorithm detailed below. The first step is to find the leftmost bit of difference $d_{first}$, between the first codes at $x$ and $y$, and thereby to find the rightmost path $\pi_{first}$ such that the first codes at $x$ and $y$ agree on all separators up to and including that for $\pi_{first}$. Similarly, $d_{second}$ and $\pi_{second}$ are identified with respect to the second codes at $x$ and $y$.

Consider $z_{first} = head(\pi_{first})$ and $z_{second} = head(\pi_{second})$. As we will see, if the first code of $z_{first}$ agrees with the first code of $x$ (and of $y$) on all separators up to $\pi_{first}$ and the same is true for $z_{second}$, then one of $\pi_{first}$ and $\pi_{second}$ is the LCCP of $x$ and $y$; if it holds only for $z_{first}$, then $\pi_{first}$ is the LCCP, and similarly for $z_{second}$.

LEMMA 6.12. *If a process $P$ updates the separator $sep(\pi)$ for a path $\pi$, then $sep(\pi)$ is identical either for all first codes for nodes in $T_{head(\pi)}$ or for all second codes for nodes in $T_{head(\pi)}$, and when $P$ unmarks $T_{head(\pi)}$ it is identical both for all first codes for nodes in $T_{head(\pi)}$ and for all second codes, although its encoding in the first and second codes may differ.*

*Proof.* The proof uses an induction on time. So assume that the result is true at the moment $P$ marks $T_{head(\pi)}$. Any process that updates $sep(\pi)$ must mark $T_{head(\pi)}$, thus until $P$ unmarks $T_{head(\pi)}$, only $P$ can update $sep(\pi)$ in the codes for nodes in $T_{head(\pi)}$. The lemma follows. □

*Comment.* The interleaving described in the previous section shows that the two codes may differ following completion of a process, though when the second process touching these codes also completes, the equality will be restored.

LEMMA 6.13. *If $sep(\pi)$ appears in $code(x)$, then $head(\pi)$ is an ancestor of $x$.*

*Proof.* The proof is by induction on time. When a node is inserted, if a leaf it inherits its code from its parent and thus the claim is true at this point; if an internal node, it inherits its code from its child and the claim is true at this point too.

An update which changes $head(\pi)$ will occur only after $sep(\pi)$ is appropriately updated in the codes for all descendants of $head(\pi)$ and thus the claim continues to hold. □

Let $z$ be the LCA of $x$ and $y$, and suppose that $z$ is primary on $\pi$ and let $w = head(\pi)$. Then we have the following.

LEMMA 6.14. *Suppose either that $w$ is not marked, or if $w$ is marked, then W.L.O.G. it is the second codes in $T_w$ that are begin updated. Then $z$ and $z_{first}$ lie on the same path. Also, the first code of $z_{first}$ agrees with the first code of $x$ on all the separators up to $\pi_{first}$. Finally, $\pi_{first}$ is the LCCP of $x$ and $y$.*

*Proof.* By Lemma 6.12, any encoding $sep(\widetilde{\pi})$ for path $\widetilde{\pi}$ appearing in the first code of $z$ must also appear in the first codes of $x$ and $y$. Thus $z_{first}$ lies on the same path as $z$ or is a descendant of $z$. But clearly if $sep(\widetilde{\pi})$ appears in $code(x)$, then there is a node $v$ on $\widetilde{\pi}$ with $v$ an ancestor of $x$ ($v$ may be primary or secondary on $\widetilde{\pi}$). Thus there are nodes on $\pi_{first}$ ancestral to each of $x$ and $y$, which must include $z_{first} = head(\pi_{first})$. Thus $z_{first}$ and $z$ lie on the same path. □

COROLLARY 6.15. *One of $\pi_{first}$ and $\pi_{second}$ is the LCCP of $x$ and $y$.*

By Lemma 6.13 $\pi_{first}$ and $\pi_{second}$ are both ancestral to each of $x$ and $y$. Thus if $\pi_{first} = \pi_{second}$ they are both the LCCP. Otherwise, let $\pi_{first}$ be a $j$-path and $\pi_{second}$ a $k$-path. The one with the larger index (among $j$ and $k$) provides the LCCP.

This yields the $O(1)$ algorithm for finding the LCCP and hence the LCA.

**6.8. Running time.** In order to maintain Invariant 2 while meeting Invariant 1, a process may need to help (perform the work of) other processes that are blocking it.

Thus the main issue is to determine how much work a process may do. We measure this work in *basic steps*.

DEFINITION 6.16. *A basic step of a process is the traversal of $O(\log n)$ edges of the subtree it is processing followed by the updating of one of the codes at a single node in this subtree. (The final basic step entails only edge traversals.)*

CLAIM 6.17.

(i) *A basic step takes $O(\log n)$ time to perform.*

(ii) *A process rooted at node $x$ performs at most $2|T_x| + 1$ basic steps on its task, where $|T_x|$ is the size of tree $T_x$ in vertices immediately before the completion of the process.*

LEMMA 6.18. *An Assign$(\pi)$, Compact$(\pi)$, Rescale$(\pi)$, or Reassign superprocess associated with class $i$ path $\pi$ performs at most $e \cdot 2^i \cdot i$ basic steps on itself and all the tasks it helps, for a suitable constant $e > 0$.*

Lemma 6.18 depends on a scheduling algorithm which ensures that for each weight increase of $2^{i-3}$ into path $\pi$, at least $e \cdot i \cdot 2^i$ basic steps are performed on process $P$ and the tasks it helps, where $P$ is associated with path $\pi$. We describe the scheduler later. Clearly, if the scheduler exists, then the truth of Lemma 6.18 up to a given time immediately implies Invariant 1 also holds up to that time.

*Proof of Lemma* 6.18. The proof uses a double induction, the outer induction being on $t$, the weight increase since the data structure was initiated (time for short), and the inner induction being on the class $i$ of the $i$-path $\pi$. Note that time proceeds in increments of $1/\log^3 n$. Our proof depends on the following claim, whose proof uses the inductive hypothesis. □

CLAIM 6.19. *Suppose Lemma* 6.18 *holds through time $t$ and for processes associated with $h$-paths, $h < i$, at time $t + 1/\log^3 n$. Then consider an $i$-path $\pi$ at time $t + 1/\log^3 n$ with head $x$. Consider the collection of all $h$-processes, $h < i$, having roots in $T_x$ which have been activated by time $t + 1/\log^3 n$. The total number of basic steps that have been performed on all these processes through time $t + 1/\log^3 n$ since their first activation is $O(i \cdot 2^i)$.*

*Proof of Claim* 6.19. We first note that if Lemma 6.18 holds for a given process $P$ associated with an $i$-path at its termination, then the size of the subtree rooted at $P$'s root at its termination is less than $2^{i+1} + 2^{i-1} + 2^{i-2}$, by Corollary 6.8. Consequently, if a process associated with an $i$-path is not complete at a time $t'$ for which Lemma 6.18 holds, then the subtree rooted at the process root has size less than $2^{i+1} + 2^{i-1} + 2^{i-2}$. In particular, the subtree rooted at $P$'s root has size less than $2^{i+1} + 2^{i-1} + 2^{i-2}$ at time $t$, and hence size less than $2^{i+1} + 2^{i-1} + 2^{i-2} + 1/\log^2 n$ at time $t + 1/\log^3 n$.

Now, we bound the number of basic steps performed by each type of process having its root in $T_x$, where $x$ is $P$'s root.

*Assign( ) processes.* There is one *Assign*( ) process for each path inside $T_x$. By the inductive hypothesis, for an *Assign*$(\pi')$ process associated with $h$-path $\pi'$, $h < i$, the associated subtree has size less than $2^{h+1} + 2^{h-1} + 2^{h-2}$ at time $t + 1/\log^3 n$ and hence the *Assign*$(\pi')$ process has had at most $O(2^h)$ basic steps performed on it. For each $h < i$, each $h$-path has a distinct set of nodes of combined size at least $2^h$ associated with it, namely either the subtree rooted at the head of the path, or if the $h$-path $\pi'$ has $h$-path $\pi''$ as a child, the associated nodes are given by $T_{head(\pi')} - T_{head(\pi'')}$. Thus there are at most $(2^{i+1} + 2^{i-1} + 2^{i-2} + 1/\log^2 n)/2^h$ $h$-paths in $T_x$, and the total number of basic steps performed through time $t + 1/\log^3 n$ on their *Assign*( ) processes is $O(2^i)$. Summing over all $h < i$ gives a bound of $O(i \cdot 2^i)$ on the number of basic steps performed on *Assign*( ) processes for $h$-paths, $h < i$, inside $T_x$.

*Rescale*( ) *processes.* The analysis is identical to that for the *Assign*( ) processes.

*Compact*( ) *processes.* Recall that successive *Compact*($\pi'$) processes for $h$-path $\pi'$ are separated by weight increases of $2^{h+1}$ into $\pi'$. Likewise the first *Compact*($\pi'$) process occurs following a weight increase $2^{h+1}$ from the initiation of *Assign*($\pi'$). Further, each weight increase at a node contributes only to the weight increase for paths that are the node's ancestors, hence for at most two $h$-paths for each value of $h$. Thus at most $2(2^{i+1}+2^{i-1}+2^{i-2}+1/\log^2 n)\,/2^{h+1}$ *Compact*($\pi'$) processes have been activated for $h$-paths $\pi'$ contained in $T_x$. By the inductive hypothesis, these processes have each had at most $O(2^h)$ basic steps performed on them by time $t+1/\log^3 n$, and hence summing over all $h < i$, and all paths in $T_x$, yields a bound of $O(i \cdot 2^i)$ basic steps performed on the *Compact*( ) processes for $h$-paths, $h < i$, inside $T_x$.

*Reassign*( ) *processes.* The argument is very similar to that for the *Compact*( ) processes, with each bunched *Reassign*( ) superprocess resembling a *Compact*( ) process in its cost. We account for a bunched $h$-superprocess by associating it with the at least $2^{h-2}$ insertions to its associated $h$-path $\pi'$ from either the time of the creation of $\pi'$ or the start of the previous *Reassign*( ) superprocess associated with $\pi'$, whichever is more recent, to the moment the current superprocess begins to be processed.

Consider a weight increase; it is charged for the *Reassign*( ) superprocesses at its ancestors, i.e., for at most two *Reassign*( ) $h$-superprocesses, for each $h$. It follows that there have been at most $2(2^{i+1}+2^{i-1}+2^{i-2}+1/\log^2 n)\,/2^{h-2}$ such superprocesses activated in $T_x$. Summing over all paths and $h < i$, we conclude that a total of $O(i\cdot 2^i)$ basic operations have been performed on the *Reassign*( ) superprocesses with roots in $T_x$.

This concludes the proof of Claim 6.19.

We now complete the proof of Lemma 6.18.

Consider the currently active process $P$ associated with $i$-path $\pi$, if any. By Claim 6.19, $P$ has performed at most $O(i \cdot 2^i)$ basic operations helping processes associated with $h$-paths, $h < i$. Since $P$ has not completed at time $t$, as already noted, $|T_x| < 2^{i+1} + 2^{i-1} + 2^{i-2} + 1/\log^2 n$ at time $t + 1/\log^3 n$. Thus the number of basic steps performed on $P$'s task and the up to one other task it may help associated with some ancestral $j$-path, $j > i$, is $O(2^i)$. This gives a total bound of $O(i \cdot 2^i)$ on the basic steps performed by $P$. □

We must still describe the processing performed following a weight increase. Following a $\Theta(1/\log n)$ weight increase at a node, the size of each of its $O(\log n)$ ancestral central paths are incremented, up to $O(\log n)$ new secondary nodes are added to the paths to which they newly belong, and up to $O(\log n)$ new processes are initiated. Then $e$ basic steps are performed on the active process at each ancestral centroid path, if any, for a total of $O(\log n)$ basic steps, which takes $O(\log^2 n)$ time. Node insertion costs $O(\log n)$ per node, but there are $O(1)$ node insertions per unit weight increase, so this is relatively insignificant.

The $O(1)$ time algorithm requires a more elaborate scheduling procedure for two reasons. First, we cannot keep the recorded sizes of the centroid paths completely up to date and so processes may be late in getting underway, and second, we do not want to have multiple basic steps partially completed. This leads us to perform basic steps over a $\Theta(1/\log^2 n)$ weight increase once started, even if the weight increase is not all occuring in the relevant subtree. Our scheduling procedure is based on a variant of the Dietz–Sleator "cup-filling" methodology [DS87], which we develop in the next section.

**6.9. Dietz–Sleator "cup-filling" with dated priorities.** We seek to handle a task scheduling scenario of the following flavor. There are at most $k$ tasks at any one time. Tasks have associated priorities which increase, possibly at different rates, as they are delayed. Furthermore, the known priorities may be somewhat dated and hence potentially inaccurate. Our goal is to determine conditions under which the following strategy is effective: schedule for *atom* steps the task with current highest known priority and iterate.

So let $\Gamma = \{P_1, P_2, \ldots\}$ be a collection of no more than $k$ tasks. Suppose each task is performed in atomic chunks of length *atom* and suppose each task has length at most $\ell$, an integer multiple of atom. Task $P_i$ has an associated priority $p_i \geq 0$. Priorities only increase. At any time a new task of priority 0 may be created so long as there are at most $k$ tasks altogether. It will be convenient to keep placeholder tasks of priority 0 to ensure that there are always exactly $k$ tasks at hand.

After every atom steps a task $P_i$ is chosen to be executed for the next *atom* steps (possibly, but not necessarily, the same task as on the previous *atom* steps) which satisfies the following rule:

$$\lambda p_i - \text{work performed on } P_i + \lambda \cdot \mathit{error} \geq \lambda p_j - \text{work performed on } P_j \text{ for all } j \neq i,$$

where *error* represents the maximum error in the recorded priorities (as opposed to the actual priorities $p_i$, $p_j$) and $\lambda > 0$ is a scale parameter relating priorities to steps executed. After executing these *atom* steps, the priorities of an arbitrary subset of tasks are increased by a combined total of at most *p-inc*.

LEMMA 6.20. *The above scheduling algorithm, if atom* $\geq 4\lambda \max\{\mathit{error}, \textit{p-inc}\}$, *satisfies*

$$\lambda p_i + \ell - \textit{work performed on } P_i \leq \lambda\,(\mathit{error} + \textit{p-inc}) + (\mathit{atom} + \ell) \\ + 4\lambda(\mathit{error} + \textit{p-inc}) \log k.$$

COROLLARY 6.21. $p_i \leq (\mathit{error} + \textit{p-inc}) + 1/\lambda(\mathit{atom} + \ell) + 4(\mathit{error} + \textit{p-inc}) \log k.$

*Proof of Lemma* 6.20. We use a potential argument. We show that if there is a task $P_j$ with priority plus $1/\lambda$ times remaining work (strictly, $1/\lambda(\ell -$ work performed on $P_j))$ at least $\ell/\lambda + \mathit{error} + \mathit{atom}/\lambda$, when a task is chosen to have *atom* steps executed, then the potential will not increase following these *atom* steps being performed and the applying of the combined *p-inc* increment to the priorities.

We associate potential $c^{r_i}$ with task $P_i$, $1 \leq i \leq k$, where $c > 1$ is a suitable constant and $r_i$ is defined as follows: $r_i = \lambda p_i + \ell -$ work performed on $P_i$.

Clearly, following *atom* steps being executed on $P_i$ and potentials being incremented by *p-inc*, the maximum increase in potential occurs if all the incremental priority is concentrated on the task $P_j$ with largest $r_j$. We note that $r_i + \lambda \cdot \mathit{error} \geq r_j$ prior to the execution of *atom* steps on $P_i$. Thus if $r_j \geq \ell + \lambda \cdot \mathit{error} + \mathit{atom}$, then $r_i \geq \ell + \mathit{atom}$, so after *atom* steps of work are performed on $P_i$, $P_i$'s potential decreases by a multiplicative factor of $c^{\mathit{atom}}$. We want to ensure that the potential does not increase. For this, it suffices that

$$c^{r_j + \lambda\, \textit{p-inc}} + c^{r_i - \mathit{atom}} \leq c^{r_j} + c^{r_i}.$$

Clearly, this is hardest to satisfy with $r_i + \lambda \cdot \mathit{error} = r_j$; so it suffices that

$$c^{\lambda(\mathit{error}\ +\ \textit{p-inc})} + c^{-\mathit{atom}} \leq c^{\lambda\ \cdot\ \mathit{error}} + 1.$$

Let $\Delta = \lambda \max\{error, \textit{p-inc}\}$. Choosing $c$ so that $c^{2\Delta} = \sqrt{2}$ and choosing $atom \geq 4\Delta$ yields a sufficient condition of

$$\sqrt{2} + (1/\sqrt{2})^2 \leq 1 + 1,$$

which is true.

Thus the largest potential possible is less than

$$(k-1)\, c^{\lambda error + (atom+\ell)} + c^{\lambda(error + \textit{p-inc}) + (atom+\ell)} \leq k\, c^{\lambda(error+\textit{p-inc})+(atom+\ell)}.$$

Hence $c^{r_i} \leq k\, c^{\lambda(error+\textit{p-inc})+(atom+\ell)}$ for all $i$, from which the claimed bound on $r_i$ follows. □

A special case arises when $error = 0$ and $atom = \ell$.

COROLLARY 6.22. *If $error = 0$ and $atom = \ell$, then $p_i \leq (9 + 4\log k)\,\textit{p-inc}$.*

*Proof.* Set $\lambda = atom/(4\textit{p-inc})$. □

Dietz and Sleator proved this bound with somewhat tighter constants, namely $p_i \leq \textit{p-inc} \cdot (\log k + O(1))$. This is often called the Dietz–Sleator cup-filling lemma.

**6.10. Scheduling in the $O(1)$ time algorithm.** In the $O(1)$ time algorithm a layered structure will be used. The tree is binarized and partitioned into subtrees of size $O(\log^3 n)$. The roots of these subtrees and their LCAs form an implicit tree on which the previous $O(\log^3 n)$ time update algorithm is run. Intuitively, the subtree roots change only every $\Theta(\log^3 n)$ insertions, which provides enough time to perform the $O(\log^3 n)$ operations needed for an update.

Let $T$ denote the tree of $n$ nodes on which LCA queries are being performed and let $T_1$ denote the implicit tree. As we will see, $T_1$ has at most $4n/\log^3 n$ nodes, and this relationship applies to each subtree of $T$ and the corresponding subtrees of $T_1$. An insertion of a node $v$ in $T$ will result in a weight increase of either 0 or $4/\log^3 n$ to the following node in $T_1$: the node that is the root of the size $O(\log^3 n)$ subtree containing $v$ in the binarized version of $T$. The rule for the weight increase is discussed later in section 7 when we discuss how to maintain the size $O(\log^3 n)$ subtrees.

Also, a new node of weight zero may be inserted in $T_1$ as a result of an insertion into $T$. As already noted, weight 0 nodes are adjacent only to weight 1 nodes. Again, details on when this happens are given in section 7.

At this point, we describe a schedule that updates path weights and performs *Assign*( ), *Rescale*( ), *Reassign*( ), and *Compact*( ) processes as needed but with only $O(1)$ work per insertion to $T$.

The major difficulty we face is that on updating the weight of a node (as a result of an insertion in $T$), we cannot immediately update the weights of all the ancestral centroid paths (note that we only track the weight of the subtrees rooted at the heads of centroid paths—together with the individual node weights, this suffices to track the weight changes when a head node leaves a centroid path). Instead we create a weight update task for each node in $T_1$. The weight update task for node $v$ is responsible for updating the weights of head nodes ancestral to $v$ to reflect an increase in $v$'s weight. It may be run multiple times. The execution of weight update tasks is alternated with the execution of *Assign*( ), *Rescale*( ), *Reassign*( ), and *Compact*( ) processes in stages of length $\Theta(\log n)$, with each update weight task being run to completion once initiated. An update weight task will take $O(\log n)$ time to run to completion, as we will see. This ensures that the *Assign*( ), *Rescale*( ), *Reassign*( ), and *Compact*( ) processes, when underway, always see a tree $T_1$ with consistent weights at the different head nodes.

Recall that we also need to track the weight of insertions made to each $i$-path so as to know when to initiate an $i$-process (it suffices to keep track of this value mod $2^{i+1}$). To this end, each update weight task also increments these weights. The update weight task for node $v$ needs to store two values: the first value is the increment being made to each of its ancestral centroid paths if it is underway, which equals the weight increment to $v$ between the start of the previous and current runs of the task; the second value is the weight increment to $v$ since the task last began running.

The weight update tasks are scheduled using the standard Dietz–Sleator cup-filling scheduler. A task's priority is given by the sum of the two increment values it holds. Here $atom = \Theta(p\text{-}inc) = \Theta(1/\log^2 n)$ and $k = \Theta(n/\log^3 n)$, for $p\text{-}inc$, the increase in priority during the execution of one task is defined to be a tight upper bound on the total weight increase to $T_1$ when performing one run of one task. We choose the constant of proportionality so that the start of successive runs of the task for a node $v$ are separated by at most a weight increase of $\alpha/\log n$ on $v$'s part, for a suitable constant $\alpha > 0$.

REMARK 6.23. *This implies that when a weight is updated, it is updated by at most* $p\text{-}inc \le \alpha/(4\log^2 n) \le 1/\log^2 n$, *as we will choose* $\alpha \le 1$.

By Corollary 6.22 this entails that $(9 + 4\log n)\, p\text{-}inc \le \alpha/\log n$, i.e., that an update task runs to completion during a period bounded by a weight increase of $\alpha/[(9 + 4\log n)\log n]$ to $T_1$. But such a weight increase requires $\Omega(\log n)$ insertions, and as one run of the task takes $O(\log n)$ time, this takes $O(1)$ time per insertion to $T$.

Now we can show the following lemma.

LEMMA 6.24. *The recorded size of an $i$-path is at most* $\alpha(2^{i+1}+2^{i-1}+2^{i-2})/\log n$ *smaller than the actual size and no larger than the actual size, assuming the actual size is less than* $2^{i+1} + 2^{i-1} + 2^{i-2}$.

*Proof.* Consider the subtree rooted at the head node of the $i$-path. If it has $r$ nodes of weight 1 it has at most $2r + 1$ nodes of weight less than 1 (since all but possibly one node of weight less than 1 has a parent, necessarily of weight 1, and since each weight 1 node has at most one child of weight less than 1). Since the subtree has size less than $2^{i+1} + 2^{i-1} + 2^{i-2}$, it has at most $2^{i+1} + 2^{i-1} + 2^{i-2}$ nodes of weight less than 1. But the recorded weight of each such node is in deficit by at most $\alpha/\log n$, and the result follows. ∎

We are ready to describe the scheduling of the *Assign*( ), *Rescale*( ), *Reassign*( ), and *Compact*( ) processes. For each $i$, we run a separate modified cup-filling procedure for the $i$-processes. The priority of a process is simply the weight of insertions in the associated subtree since the moment when the process would have been initiated in our original algorithm. For an *Assign*($\pi$) process this is approximated using the current size of $i$-path $\pi$ minus $2^i$; the size of $\pi$ when *Assign*($\pi$) should have been initiated. For *Compact*($\pi$) and *Reassign*( ) superprocesses, we need to record the weight of insertions mod $2^{i+1}$ that have occurred in the subtree rooted at the head of $i$-path $\pi$ since $\pi$ was created. This term minus the starting time of the process mod $2^{i+1}$, as specified in Invariant 1, yields the priority (for *Reassign*( ), the priority is calculated with a shift of $2^{i-3}$ mod $2^{i+1}$). It follows the recorded priority maybe too small, but by at most $\alpha(2^{i+1} + 2^{i-1} + 2^{i-2})/\log n$.

We perform each scheduled process for one basic step, cycling among the classes of processes for each class of $i$-path ($i = 0, 1, 2, \ldots$) in round robin order. We alternate between performing one basic step and one complete task updating path sizes. This ensures the recorded sizes of the centroid paths are always consistent when basic steps are being performed. Thus every $\Theta(\log^2 n)$ insertions, one basic step is performed on one process associated with a class $i$-path for each $i = 1, 2, \ldots$.

LEMMA 6.25. *With the following parameter choices, each $i$-process finishes within the time for $2^i/8$ weighted insertions into the corresponding $i$-path, assuming $n \geq 2$. The parameter choices are: error $= 11\,\alpha 2^{i-1}/\log n$, $\ell = e' \cdot i \cdot 2^i$ (measured in basic steps), $\lambda = d \log n$, p-inc $=$ atom$/(4d\log n)$, atom $= 44\alpha\ d\ 2^{i-1}$, $d = 2/\alpha$, $e' = \lceil \frac{e}{44} \rceil \cdot 44$, and $\alpha = 1/[4(154 + e')]$.*

*Proof.* We note that for these parameter values, $\ell$ is an integer multiple of *atom*, *atom* $\geq 4\lambda \max\{$*error*, *p-inc*$\}$, so Lemma 6.20 applies. Thus the process priorities are always bounded by $11\alpha\ 2^{i-1}/\log n + 11\alpha\ 2^{i-1}/\log n + 1/(d\log n)(44\alpha\ d\ 2^{i-1} + e' \cdot i \cdot 2^i) + 4(11\alpha\ 2^{i-1}/\log n + 11\alpha\ 2^{i-1}/\log n)\log n \leq \alpha\ 2^{i-1}(66/\log n + e' \cdot i/\log n + 88) \leq 2^i/[8 \cdot 4\,(154 + e')\,\alpha] = 2^i/8$, assuming $n \geq 2$. □

It remains to show that $O(1)$ work per weight increase of $4/\log^3 n$ suffices.

LEMMA 6.26. *It suffices to perform $O(1)$ work per weight increase of $4/\log^3 n$ to ensure that in the period in which an $i$-process performs atom basic steps the overall weight and hence priority increase by at most p-inc.*

*Proof.* These atom basic steps are performed over a period of $\Theta($*atom* $\log^2 n)$ insertions assuming $O(1)$ work per insertion. (Recall that we cycle among the $i$-processes for $i = 0, 1, \ldots, \log n$ in round robin order, performing one basic step on an $i$-process for each $i$, and each basic step takes $O(\log n)$ work.) Since each insertion causes a weight increase of at most $4/\log^3 n$, the resulting weight gain is $O($*atom*$/\log n)$. Notice that the more work per insertion, the fewer insertions needed to complete the *atom* basic steps and the smaller the weight increase. Thus with a large enough $O(1)$ work per insertion, the result holds. □

We have shown the following theorem.

THEOREM 6.27. *The implicit tree $T_1$ described above can be maintained in $O(1)$ work per insertion, assuming that each insertion results in a weight increase of $0$ or $4/\log^3 n$, that each insertion adds at most one weight $0$ node $v$ to $T_1$, and further that such a node $v$ is adjacent only to weight $1$ nodes. Further, LCA queries on $T_1$ can be answered in $O(1)$ time.*

## 7. The $O(1)$ worst-case algorithm.

The tree $T$ on which LCA queries are being performed is made binary, using a standard binarization. More specifically, a node $v$ with $d$ children is represented by $d$ copies of $v$ forming a chain of right children. The actual children of $v$ will be stored as the left children of this chain of nodes. Note that if $n$ items are inserted in an initially empty tree the binarized tree will contain at least $n$ nodes and at most $2n - 1$. As a result, an insertion may entail the addition of two nodes to the binarized tree, called $T$ henceforth. To simplify the discussion, from now on we term a node addition to $T$ an insertion, understanding that a real insertion may induce two insertions into $T$.

As already noted, $T$ is kept partitioned in at most $4n/\log^3 n$ subtrees, called partitioning subtrees, each of size at most $\log^3 n/4$ (strictly, $\lfloor (\log n)/4 \rfloor^3$). We assume that $n$ lies in the range $[n, 2n)$; section 8 explains how to handle $n$ increasing to $2n$ or beyond. We create a tree $T_1$ which contains the root of each subtree in the partition of $T$. These subtrees are chosen so that the LCA of the roots of any two partitioning subtrees is itself the root of a partitioning subtree. A node $v$ in $T_1$ is the parent of node $w$ in $T_1$ if $v$ is the nearest ancestor of $w$ in $T$ such that $v$ is in $T_1$. Clearly, as $T$ is binary, so is $T_1$.

When a partitioning subtree grows too large it is split, causing the addition of one or two nodes to $T_1$ (two nodes may be needed to maintain the LCA property on subtree roots). But, as we will see, a newly created partitioning subtree once initiated is itself partitioned only following $\Theta(\log^3 n)$ insertions into itself.

A partition of partitioning subtree $S$, rooted at node $v$, proceeds as follows. Once initiated, within $\frac{1}{4}\log^3 n$ further insertions into $S$ it determines the root(s) of the new subtrees. It then inserts one of the news roots in $T_1$ as a child of $v$, giving it weight 0. Over the next $\frac{1}{4}\log^3 n$ insertions into $S$ the weight of the new root is increased in increments of $4/\log^3 n$ until its actual weight is 1. Within the next $\frac{1}{8}\log^3 n$ insertions into $S$, we ensure $v$'s recorded weight becomes 1, as follows. Instead of following the previously stated rule for giving priorities to weight update tasks, once the actual weight of a node reaches 1, on each insertion to subtree $S$, we continue incrementing its priority by $4/\log^3 n$. To bring the new root's recorded weight to 1 may need the completion of one run of its weight increase task and a full second run of the task. We have ensured this occurs within a weight increase of $2\alpha/\log n$, so it suffices that $2\alpha/\log n \leq \frac{1}{8}\log^3 n \cdot 4/\log^3 n$, and $\alpha \leq 1/4$ suffices for $n \geq 2$. The second new root, if any, is then inserted in the same way. Note that this ensures that any node in $T_1$ of weight less than 1 is adjacent only to nodes of weight 1, and nodes of weight 1 have at most one child of weight less than 1.

To answer a query LCA$(u, v)$, we first determined if $u$ and $v$ are in different partitioning subtrees by finding, in $O(1)$ time, the roots $r_u$ and $r_v$ of their respective partitioning subtrees. If $r_u \neq r_v$, we compute LCA$(r_u, r_v)$ on $T_1$ in $O(1)$ time as previously described (see Theorem 6.27). Otherwise, the query is handled recursively.

To support queries on the partitioning subtrees, they are partitioned in turn into subtrees of size at most $4\log\log^3 n$.[8] For each partitioning subtree $S$ of $T$ we maintain a tree $S_1$ comprising the roots of $S$'s partitioning subtrees. Updates are performed using our previous algorithm, i.e., with $O(\log\log^3 n)$ work over $\Theta(\log\log^3 n)$ insertions. Queries are performed as in the previous paragraph. It is helpful to let $T_2$ denote the union of all the $S_1$ trees.

The recursion bottoms out at the partitioning subtrees of size $O(\log\log^3 n)$ for, as we will see, there are $o(n)$ distinct partitioning trees of this size, and their updating can be done via table lookup in $O(1)$ time per insertion, as can LCA queries. The requisite tables use $o(n)$ space.

## 7.1. Details of the data structures.

Each node in $T$ keeps a pointer to its newest ancestor in $T_2$, the root of the size $O(\log\log^3 n)$ partitioning subtree to which it belongs. Similarly, each node in $T_2$ keeps a pointer to its nearest ancestor in $T_1$, the root of the size $O(\log^3 n)$ partitioning subtrees to which it belongs. On an insertion, the weight of the appropriate nodes in $T_2$ and $T_1$ are incremented in $O(1)$ time, using the above pointers.

Definition 7.1. *The size of a partitioning subtree is the sum of the weights of the nodes it contains.*

The size of partitioning subtrees are recorded with their roots. On an insertion, the up to two subtree sizes that change are incremented (by $4/\log\log^3 n$ and $4/\log^3 n$, respectively); these sizes are stored at the subtrees' roots.

Additional data is needed to support the splitting of the partitioning subtrees. We begin by describing what is needed for splitting the size $O(\log\log^3 n)$ partitioning subtrees. In addition to storing the subtrees themselves, we keep a table of all possible trees, represented canonically. Using the canonical representation, in $O(1)$ time we will be able to answer LCA queries and to determine the new canonical tree resulting

[8] $\log\log^3 n$ is our notation for $(\log\log n)^3$.

from an insertion. Finally, by linking the nodes of the actual tree to those of the corresponding canonical tree, we will be able to translate query answers on canonical tree to answers on the actual tree in $O(1)$ time.

The following information is maintained for each actual tree $S$.

1. For each node $v$ in $S$, a distinct label, denoted $label(v)$ in the range $[1, \log\log^3 n]$. In addition, the up to two edges going to children outside $S$ are also recorded. (The structure of $S$ along with the associated labels provides the appropriate canonical labelled tree used to answer LCA queries on $S$.)
2. An array $\ell\_to\_n(S)$ storing, for each label in the range $[1, \log\log^3 n]$, the node in $S$ corresponding to this label, if any. This inverse map is used to convert the LCA obtained using lookup tables on the canonical tree from a label to an actual node (for the canonical tree nodes are named by their labels).
3. The name $name(S)$ of the labelled canonical tree associated with $S$, the root $root(S)$, of $S$, along with a pointer $pointer(v)$ from each node $v$ in $S$ to the location storing $\ell\_to\_n(S)$, $name(S)$, $root(S)$, $size(S)$, and $flag(S)$. The role of $flag(S)$ is explained next.
4. Actually, two copies of $label(v)$ and $pointer(v)$ are maintained for each node $v$ in $S$. One of these copies will be "old" and the other "current." This will be indicated by the $flag(S)$ field above. The $flag(S)$ field pointed to by the "old" $pointer(v)$ will be set to 0 while that pointed to by the "current" $pointer(v)$ will be set to 1.
5. In addition to the above, there is a static table for each labelled tree of size at most $4\log\log^3 n$ supporting the following queries: given two labels in the tree, return the label of the LCA, and given a new label (corresponding to a newly inserted node) and the label(s) corresponding to the node(s) at the insertion site, return the name of the resulting labelled tree. Note that labels for nodes in $S$ are allocated in sequential order of insertion.

   Since there are $O(2^{8\log\log^3 n}(4\log\log^3 n)^{4\log\log^3 n})$ labelled binary trees of size at most $4\log\log^3 n$ with labels in the range $[1, \log\log^3 n]$, the total space occupied by the above tables is $O(n)$. These tables can also be built in $O(n)$ time.

*Processing insertions.* Each insertion will do $O(1)$ work at each of the 3 levels. This will result in $\Theta(\log^3 n)$ work being available for each insertion into $T_1$ and $\Theta(\log\log^3 n)$ work for each insertion into $T_2$.

Insertions into $T$ will require the following actions. First, the insertion into the appropriate size $O(\log\log^3 n)$ partitioning subtree $S$ of $T$ rooted at a node in $T_2$ is made. This is done using a constant time table lookup to calculate the name of the new subtree after insertion. Second, if $S$ reaches size $3(\log\log^3 n)$ then it is partitioned into two or three subtrees, each of size at most $3\log\log^3 n$, over the next $\log\log^3 n$ insertions to $S$.

An insertion of node $u$ into $T$ is processed as follows.

Let $v$ be the parent of $u$ in $T$. $u$ is viewed as being inserted into the partitioning subtrees $S_b$ and $S_a$ containing $v$, of sizes $O(\log\log^3 n)$ and $O(\log^3 n)$ and rooted in $T_2$ and $T_1$, respectively. On following $pointer(v)$, $\ell\_to\_n(S_b)$, $name(S_b)$, and $size(S_b)$ are readily updated in $O(1)$ time (using table lookup for $name(S_b)$). If $size(S_b)$ reaches $3\log\log^3 n$, a split of $S_b$ is initiated. It is carried out as described below. $O(1)$ work is then performed on the tasks associated with the trees $T_1$ and $T_2$.

*Splitting $S = S_b$.* The first step is to find a splitting location that divides the tree into two pieces each of size at least $\log\log^3 n$. This can be done by depth first search in $O(\log\log^3 n)$ time, or by table lookup in $O(1)$ time. To ensure that the new trees have at most two external children each, we find the LCAs of the new roots and the up to two external children; if one of these LCAs is not a new root, it is also introduced as a third root. The one or two new roots are added to tree $T_2$ with the already explained timing (it suffices to carry out the depth first search within $\frac{1}{4}\log\log^3 n$ insertions). To simplify the notation, we continue to suppose that only two new trees are created; the changes if there are three new trees are evident.

The new roots define $S_1$ and $S_2$, the trees that $S_b$ is split into. Next, $\mathit{root}(S_1)$, $\ell\_to\_n(S_1)$, $\mathit{name}(S_1)$, $\mathit{size}(S_1)$, $\mathit{root}(S_2)$, $\ell\_to\_n(S_2)$, $\mathit{size}(S_2)$, and $\mathit{name}(S_2)$ are computed in the obvious way in $O(\log\log^3 n)$ time (e.g., by traversing each of $S_1$ and $S_2$ in turn and "inserting" their nodes one by one). Then for each node $w$ the "old" $\mathit{label}(w)$ and $\mathit{pointer}(w)$ are updated to be in accordance with $S_1$ or $S_2$, whichever contains $v$, also in $O(\log\log^3 n)$ time.

Note that all this while the "current" $\mathit{label}(v)$, $\mathit{pointer}(v)$, $\mathit{name}(S)$, $\mathit{root}(S)$, and $\ell\_to\_n(S)$ are used to answer LCA queries; furthermore these structures are updated with each insertion that occurs even after the splitting process starts. Also note that after the splitting process starts, new insertions are neglected in constructing $S_1$ and $S_2$ and the associated fields $\mathit{name}(S_1)$, $\mathit{root}(S_1)$, $\ell\_to\_n(S_1)$, $\mathit{name}(S_2)$, $\mathit{root}(S_2)$, $\ell\_to\_n(S_2)$. This is easily implemented by putting a time-stamp on each inserted node and ignoring nodes which are time-stamped later than the start of the splitting process. These insertions are just queued up and performed on $S_1$ or $S_2$ as appropriate after they have been constructed. When all $\log\log^3 n$ insertions have been performed, $\mathit{flag}(S_1)$ and $\mathit{flag}(S_2)$ are set and $\mathit{flag}(S)$ is reset so that for each $v$ in $S_1$ and $S_2$ the "old" $\mathit{label}(v)$ and $\mathit{pointer}(v)$ become "current" and vice versa; this takes $O(1)$ time. Note that $S_1$ and $S_2$ each have size at most $3\log\log^3 n$ at this point.

*Splitting algorithm for a size $O(\log^3 n)$ partitioning subtree $S_a$.* The splitting algorithm on $S_a$ begins when its size reaches $3\log^3 n$ and is similar to the previous splitting algorithm but is done without table lookup. For each partitioning $S_a$ the following information is maintained, in addition to the data structure storing the tree itself.

1. For each node $v$, $\mathit{code}(v)$, along with the annotations, and $\mathit{number}(v)$.
2. The structure $\mathit{cpath}(S_a)$ storing centroid paths and associated information for paths in $S_a$.
3. For each node $v$, a pointer $\mathit{pointer}(v)$ to the location storing $\mathit{cpath}(S_a)$, $\mathit{root}(S_a)$, and $\mathit{flag}(S_a)$.
4. Two copies of $\mathit{code}(v)$, $\mathit{number}(v)$, $\mathit{pointer}(v)$, maintained as before. One of these copies will be "old" and the other "current." The appropriate $\mathit{flag}(S_a)$ indicates which of these copies is current.

The algorithm proceeds as before. First, the location of the split is determined in $O(\log^3 n)$ time using depth-first search. This splits $S_a$ into two pieces each of size at least $\log^3 n$, thereby defining $S_1$ and $S_2$. Then the data structures for $S_1$ and $S_2$ are computed, the backlog of insertions is applied, and finally the appropriate flats are set. This all takes $O(\log^3 n)$ time.

We have shown the following lemma.

LEMMA 7.2. *There is a data structure for trees of size in the range $[n, 2n)$ which answers LCA queries in $O(1)$ time and performs insertions to the tree in $O(1)$ time.*

REMARK 7.3. *Although space is not freed when subtrees are split, the space used is still linear. For each split of a size $s$ tree, using space $\Theta(s)$, only happens after $\Theta(s)$ insertions.*

## 8. Handling deletions and changing values of $n$.

We note that the need for the limited range in Lemma 7.2 arises for two reasons: first, the construction in section 7 requires a fixed value of $\log^3 n$ (and of $\log\log^3 n$), and second, the basic algorithm takes $O(\log^3 n)$ time per update; here the $\log^3 n$ is not fixed. But we could readily change the range to $[n, 2^d n)$ for any fixed $n$ by replacing $\log^3 n$ by $(\log n + d)^3$ in section 7. As we will see, $d = 3$ suffices.

We do not perform deletions explicitly. Instead, deleted items will just be marked as such, or rather the topmost copy of the corresponding node will be so marked. Thus the size of the current tree would include the count of both deleted and nondeleted nodes. We will periodically rebuild the data structure from scratch, in the background, so as to maintain the following invariant.

*Invariant* 3. The insertion count, the number of items in the data structure plus the number of items marked deleted, lies in the range $[4\cdot 2^i, 32\cdot 2^i]$; the actual number of items in the data structure lies in the range $[6\cdot 2^i, 32\cdot 2^i]$. In addition, the number of deleted items is at most $3\cdot 2^i$. Furthermore, immediately after being rebuilt the insertion count is in the range $[8\cdot 2^i, 31\cdot 2^i]$, the actual count in the range $[7\cdot 2^i, 31\cdot 2^i]$, and the deletion count is at most $2^{i+1}$.

Invariant 3 implies that the number of nodes in the tree lies in the range $[4\cdot 2^i, 64\cdot 2^i)$, and thus $d = \log 64/4 = 4$ suffices.

Let the actual size of the data structure denote the number of undeleted items. If the insertion count reaches $31\cdot 2^i$, the data structure is rebuilt in the range $[8\cdot 2^i, 64\cdot 2^i]$; if the actual size decreases to $7n$, then it is rebuilt in the range $[2\cdot 2^i, 16\cdot 2^i]$; if neither of these apply but the number of items marked deleted reaches $2^{i+1}$, then it is rebuilt either in the range $[4\cdot 2^i, 32\cdot 2^i]$ if the actual size is at least $8n$, and in the range $[2\cdot 2^i, 16\cdot 2^i]$ otherwise. The rebuilding is completed within $2^i$ insertions; this takes $O(1)$ time per insertion. It is readily checked that Invariant 3 continues to hold following the rebuilding.

An easy way to perform the rebuilding is to traverse the current tree, determining the undeleted items and then inserting them in the new tree, one by one, using the appropriate value for $\log^3 n$. Of course, new insertions and deletions are performed on the current tree and queued so they can be performed on the new tree.

We have shown the following theorem.

THEOREM 8.1. *There is a linear time data structure that supports LCA queries on a tree undergoing insertions and deletions such that each update and query can be performed in worst case $O(1)$ time.*

**Acknowledgments.** We thank the referees for urging us to seek a less complex solution which led us to the present version of the data structure.

# ORDERLY SPANNING TREES WITH APPLICATIONS*

YI-TING CHIANG†, CHING-CHI LIN†, AND HSUEH-I LU‡

**Abstract.** We introduce and study *orderly spanning trees* of plane graphs. This algorithmic tool generalizes *canonical orderings*, which exist only for triconnected plane graphs. Although not every plane graph admits an orderly spanning tree, we provide an algorithm to compute an *orderly pair* for any connected planar graph $G$, consisting of an embedded planar graph $H$ isomorphic to $G$, and an orderly spanning tree of $H$. We also present several applications of orderly spanning trees: (1) a new constructive proof for Schnyder's realizer theorem, (2) the first algorithm for computing an area-optimal 2-visibility drawing of a planar graph, and (3) the most compact known encoding of a planar graph with $O(1)$-time query support. All algorithms in this paper run in linear time.

**Key words.** planar graph algorithm, graph drawing, realizer, visibility representation, canonical ordering, orderly spanning tree, graph encoding, triangulation, unit-cost RAM model, succinct data structure, data compression

## 1. Introduction.

A plane graph is a planar graph equipped with a plane embedding. *Canonical orderings* of triconnected plane graphs [11, 19, 27, 28] are crucial in several graph-drawing and graph-encoding algorithms [7, 8, 9, 16, 20, 22]. This paper introduces the *orderly spanning tree* as an algorithmic tool that generalizes the concept of canonical orderings for plane graphs that are not required to be triconnected. The concept of orderly spanning trees of plane graphs originates from that of canonical spanning trees of triconnected plane graphs [9], but the former is more general even for triconnected plane graphs (see section 2.1 and Figure 2.1(b)).

We say that $(H, T)$ is an *orderly pair* of $G$ if (1) $T$ is an orderly spanning tree of plane graph $H$, and (2) $G$ and $H$, ignoring their embeddings, are isomorphic planar graphs. Although not every connected plane graph admits an orderly spanning tree (see section 2.1 and Figure 2.2(a)), we provide a linear-time algorithm (see section 2.2) to compute an orderly pair for any connected planar or plane graph. We also present three applications of orderly spanning trees in the paper.

*Application* 1: *Realizers of planar graphs.* A graph is *simple* if it contains no multiple edges. For the first application of orderly spanning trees, we present a new linear-time algorithm to compute a *realizer* for any plane triangulation (i.e., simple triangulated plane graph with at least three nodes). Schnyder [38] gave the first known linear-time algorithm that computes a realizer for any plane triangulation, thereby settling the open question on the dimension [42, 14] of planar graphs. This celebrated result also yields the best known straight-line drawing of planar graphs on

the grid [39]. Our proof, based upon the existence of an orderly spanning tree for any simple plane triangulation, is quite simple.

*Application* 2: *Optimal* 2*-visibility drawings of planar graphs.* For the second application of orderly spanning trees, we give an $O(n)$-time algorithm that produces a 2-visibility drawing of area at most $(n-1) \times \lfloor \frac{2n+1}{3} \rfloor$ for any $n$-node simple plane graph $H$ with $n \geq 3$. Let $v_1, v_2, \ldots, v_n$ be the nodes of $H$. A 2*-visibility drawing* [16] of $H$ consists of $n$ nonoverlapping rectangles $b_1, b_2, \ldots, b_n$ such that if $v_i$ and $v_j$ are adjacent in $H$, then $b_i$ and $b_j$ are visible to each other either horizontally or vertically.[1] For example, the picture in Figure 1.1(b) is a 2-visibility drawing of the plane graph in Figure 1.1(a). Fößmeier, Kant, and Kaufmann [16] gave an $O(n)$-time algorithm to compute an $x \times y$ 2-visibility drawing for $H$ with $x + y \leq 2n$ and conjectured that it is "not trivial" to improve their upper bound. Moreover, they showed an $n$-node plane triangulation whose $x \times y$ 2-visibility drawing requires $x + y \geq n - 1 + \lfloor \frac{2n+1}{3} \rfloor$ and $\min\{x, y\} \geq \lfloor \frac{2n+1}{3} \rfloor$.[2] According to their lower bounds, the 2-visibility drawing produced by our algorithm is worst-case optimal.

In order to take advantage of the wonderful properties of canonical orderings, many drawing algorithms work on triangulated versions of input plane graphs. As pointed out in [19], the initial triangulation tends to ruin the original plane graph's structure. Our orderly pair algorithm appears as a promising tool for drawing graphs neatly and compactly, without first triangulating the given plane graphs. The concept of an orderly pair is more general than that of a canonical ordering, since all known canonical orderings are only defined for triconnected plane graphs. The technique of orderly pairs is potentially more powerful, since it exploits the flexibility of planar graphs whose planar embeddings are not predetermined.

*Application* 3: *Convenient encodings of planar graphs.* For the third application of orderly spanning trees, we investigate the problem of encoding a graph $G$ into a binary string $S$ with the requirement that $S$ can be decoded to reconstruct $G$. This problem has been extensively studied with three objectives: (1) minimizing the length of $S$, (2) minimizing the time required to compute and decode $S$, and (3) supporting queries efficiently. As these objectives are often conflicting, a number of coding schemes with different trade-offs have been proposed in the literature. The widely useful adjacency-list encoding of an $n$-node $m$-edge graph $G$ requires $2m\lceil \log_2 n \rceil$ bits. See [9, 22, 23, 29, 34, 37, 43] for $O(n)$-bit encodings of $n$-node planar graphs without efficient query supports.

Under the model of unit-cost RAM [5, 10, 17, 40, 41, 45], where operations such as read, write, and add on $O(\log n)$ consecutive bits take $O(1)$ time, an encoding $S$ of $G$ is *weakly convenient* [9] if it takes (i) $O(m+n)$ time to encode $G$ and decode $S$, (ii) $O(1)$ time to determine from $S$ the adjacency of any two nodes in $G$, and (iii) $O(d)$ time to determine from $S$ the neighbors of a degree-$d$ node in $G$. If the degree of a node can be determined from a weakly convenient encoding $S$ in $O(1)$ time, then $S$ is *convenient* [9]. For a planar graph $G$ having multiple edges but no self-loops, Munro and Raman [35] gave the first nontrivial convenient encoding of $G$ with $2m + 8n + o(m+n)$ bits. Their result is based on the four-page decomposition of planar graphs [46] and auxiliary strings, encoding an involved three-level data

[1]A closely related *rectangle-visibility drawing* [13, 12, 25, 3] of $H$ requires that $v_i$ and $v_j$ are adjacent in $H$ *if and only if* $b_i$ and $b_j$ are visible to each other.

[2]The lower bounds stated in [16] are $x + y \geq \frac{5n}{3}$ and $\min\{x, y\} \geq \frac{2n}{3}$. Based on the given sketch of proof, however, it is not hard to see that their lower bound should be corrected as $x + y \geq n - 1 + \lfloor \frac{2n+1}{3} \rfloor$ and $\min\{x, y\} \geq \lfloor \frac{2n+1}{3} \rfloor$.

structure for any string of parentheses. For a planar graph $G$ that has (respectively, has no) multiple edges, Chuang, Garg, He, Kao, and Lu [9] improved the bit count to $2m + \left(5 + \frac{1}{k}\right)n + o(m+n)$ (respectively, $\frac{5}{3}m + \left(5 + \frac{1}{k}\right)n + o(n)$) for any positive constant $k$. They also provided a weakly convenient encoding of $2m + \frac{14}{3}n + o(m+n)$ (respectively, $\frac{4}{3}m + 5n + o(n)$) bits for a planar graph $G$ that has (respectively, has no) multiple edges. Based on our orderly pair algorithm, in this paper we present the best known convenient encodings for a planar graph $G$: If $G$ may (respectively, does not) contain multiple edges, then the bit count of our encoding is $2m + 3n + o(m+n)$ (respectively, $2m + 2n + o(n)$), which is even less than that of the weakly convenient encodings of Chuang et al. [9]. The bit counts are very close to Tutte's information-theoretical lower bound of roughly $3.58m$ bits for encoding connected plane graphs without any query support [44]. The bit count of our encoding for a planar graph $G$ without multiple edges matches that of the best known convenient encoding for an outerplanar graph [35]. Besides relying on the orderly pair algorithm, our results are also based on an improved auxiliary string for a folklore encoding [9, 21, 35] of a rooted tree $T$. With the auxiliary strings of Munro and Raman [35], computing the degree of a degree-$d$ node in $T$ requires $\Theta(d)$ time. In this paper, we present a nontrivial auxiliary string, in Lemma 5.3, to support the degree query in $O(1)$ time.

*Recent applications.* Besides the applications presented in the present paper, our orderly pair algorithm also yields the following recent results:

- Improved compact distributed routing tables for any $n$-node distributed planar network [33], improving the best previously known design of Gavoille and Hanusse [18] by reducing the worst-case table size count from $8n + o(n)$ bits to $7.181n + o(n)$ bits, without increasing the time complexity of preprocessing and query.
- A linear-time algorithm for compact floor-plans of plane triangulations [30, 31], which is not only much simpler than the previous methods in the literature [20, 47] but also provides the first known nontrivial upper bound on the floor-plan's area.
- Compact Podevs drawings for plane graphs and an alternative proof for the sufficient and necessary condition for a planar graph to admit a rectangular dual [6].
- Improved upper bounds on the number of planar graphs via so-called *well orderly spanning trees*, which are orderly spanning trees with additional prop-

erties [2].

*Organization of the paper.* The rest of the paper is organized as follows. Section 2 gives the linear-time algorithm for computing an orderly pair of any given planar graph. Applications are given in sections 3–5. Section 3 gives the linear-time algorithm for computing a realizer of any given plane triangulation. Section 4 shows the linear-time algorithm for obtaining an area-optimal 2-visibility drawing of any given plane graph. Section 5 presents the best known convenient encodings for planar graphs.

## 2. Orderly spanning trees for plane graphs.

### 2.1. Basics.

Unless stated otherwise, all graphs in sections 2–4 are simple. Let $H$ be a plane graph. The *outer boundary* of $H$ is the boundary of the external face of $H$. The nodes and edges on the outer boundary of $H$ are *external* in $H$; and the other nodes and edges are *internal* in $H$.

Let $T$ be a rooted spanning tree of a connected plane graph $H$. Two distinct nodes of $H$ are *unrelated* with respect to $T$ if neither of them is an ancestor of the other in $T$. An edge $e$ of $H$ is *unrelated* with respect to $T$ if the endpoints of $e$ are unrelated with respect to $T$. Let $v_1, v_2, \ldots, v_n$ be the counterclockwise preordering of the nodes in $T$. A node $v_i$ is *orderly* in $H$ with respect to $T$ if the neighbors of $v_i$ in $H$ form the following four blocks of $H$ with respect to $T$ in counterclockwise order around $v_i$, where each block could be empty.

- $P(v_i)$: the parent of $v_i$ in $T$;
- $U_<(v_i)$: the nodes $v_j$ with $j < i$ that are unrelated to $v_i$ with respect to $T$;
- $D(v_i)$: the children of $v_i$ in $T$; and
- $U_>(v_i)$: the nodes $v_j$ with $j > i$ that are unrelated to $v_i$ with respect to $T$.

(See Figure 2.1(c).) $T$ is an *orderly spanning tree* of $H$ if (i) $v_1$ is on the outer boundary of $H$ and (ii) each node $v_i$ is orderly in $H$ with respect to $T$. If $T$ is an orderly spanning tree of $H$, then each incident edge of $v_1$ in $H$ belongs to $T$. An example of an orderly spanning tree is given in Figure 1.1(a). Figure 2.1(a) provides a negative example of an orderly spanning tree, where nodes 1, 3, 8, and 10 are not orderly in $H$ with respect to $T$.

Not every connected plane graph admits an orderly spanning tree. However, as to be shown in this section, there always exists a planar embedding for any given planar graph that admits an orderly spanning tree. For example, consider the plane graph

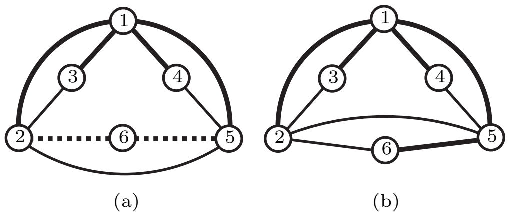

FIG. 2.2. (a) *A plane graph $H$ that has no orderly spanning trees.* (b) *A different planar embedding of $H$ that admits an orderly spanning tree rooted at node* 1*, consisting of the thick edges.*

$H$ in Figure 2.2(a). Assume for a contradiction that $H$ admits an orderly spanning tree $T$ rooted at node 1. Observe that the thick edges must be in $T$, and thus the thin edges cannot be in $T$. Now, $T$ contains exactly one of the dashed edges. In either case, however, the parent of node 6 in $T$ is not orderly in $H$ with respect to $T$, thereby contradicting the assumption that $T$ is an orderly spanning tree rooted at node 1. Since $H$ is rotationally symmetric, $H$ admits no orderly spanning trees. If we change the planar embedding of $H$ by moving edge $(2, 5)$ to the interior of $H$, as shown in Figure 2.2(b), then the new plane graph has an orderly spanning tree rooted at node 1 consisting of the thick edges.

The concept of orderly spanning trees of plane graphs originates from those of canonical orderings and canonical spanning trees of triconnected plane graphs. Let $H$ be a triconnected plane graph. A canonical ordering of $H$ is a certain ordering of the vertices in $H$, first introduced by de Fraysseix, Pach, and Pollack [11] for plane triangulations, and extended to triconnected plane graphs by Kant [27]. Specifically, let $v_1, v_2, \ldots, v_n$ be an ordering of the nodes of $H$. Let $H_i$ be the subgraph of $H$ induced by $v_1, v_2, \ldots, v_i$. Let $B_i$ be the outer boundary of $H_i$. This ordering is *canonical* if the interval $[3, n]$ can be partitioned into $I_1, \ldots, I_K$ with the following properties for each $I_j$. Suppose $I_j = [k, k + q]$. Let $C_j$ be the path $v_k, v_{k+1}, \ldots, v_{k+q}$.

- $H_{k+q}$ is biconnected. $B_{k+q}$ contains the edge $(v_1, v_2)$ and $C_j$. $C_j$ has no chord in $H$.
- If $q = 0$, $v_k$ has at least two neighbors in $H_{k-1}$, all on $B_{k-1}$. If $q > 0$, $C_j$ has exactly two neighbors in $H_{k-1}$, both on $B_{k-1}$, where the left neighbor is incident to $C_j$ only at $v_k$ and the right neighbor only at $v_{k+q}$.
- For each $v_i$ with $k \le i \le k + q$, if $i < n$, $v_i$ has at least one neighbor in $H - H_{k+q}$.

Chuang et al. [9] defined a canonical spanning tree $T$ of $H$ as a way to find parents in $T$ for all except one node of $H$ according to any given canonical ordering of $H$. Specifically, for the given canonical ordering of $H$, the *canonical spanning tree* $T$ of $H$ rooted at $v_1$ is the one formed by the edge $(v_1, v_2)$ together with the paths $C_j$ and the edges $(v_\ell, v_k)$ over all $I_j$, where $v_\ell$ is the leftmost neighbor of $C_j$ on $B_{k-1}$. By the triconnectivity of $H$, it is implicit in [9] that (a) any canonical spanning tree $T$ of $H$ has to be an orderly spanning tree of $H$, and (b) the counterclockwise preordering of $T$ is the given canonical ordering of $H$. As shown in Figure 2.1(b), however, the counterclockwise preordering of an orderly spanning tree for a triconnected plane graph $H$ may not be a canonical ordering of $H$. Therefore, the concept of orderly spanning trees is more general than that of canonical spanning trees even for triconnected plane graphs. The counterclockwise preordering of any orderly spanning tree of a plane triangulation $\Delta$ has to be a canonical ordering of $\Delta$, though.

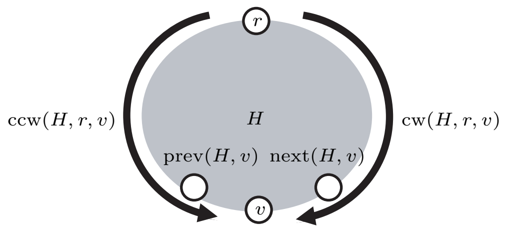

FIG. 2.3. *Illustration of the definitions of prev*$(H,v)$*, next*$(H,v)$*, cw*$(H,r,v)$*, and ccw*$(H,r,v)$*.*

**2.2. The orderly pair algorithm.** For plane graphs $H$ and $G$, $H \sim G$ denotes that $H$ and $G$ (ignoring their plane embeddings) are isomorphic planar graphs. We say that $(H,T)$ is an *orderly pair* of a connected planar graph $G$ with respect to $r$ if (i) $H \sim G$ and (ii) $T$ rooted at $r$ is an orderly spanning tree of $H$. This subsection shows how to compute an orderly pair for any planar graph in linear time. Without loss of generality, we may assume that the input planar graph is already equipped with a planar embedding represented by an adjacency list, where each node $v$ keeps a doubly linked list, storing its neighbors in counterclockwise order around $v$. Moreover, the two copies of each edge are cross-linked to each other. Such a representation can be obtained as a by-product by running the linear-time planarity-testing algorithm of Hopcroft and Tarjan [24] or that of Boyer and Myrvold [4]. Based upon this representation, deleting an edge takes $O(1)$ time. Moreover, moving an edge $e$ to the interior of a face $F$ can be conducted in $O(1)$ time, as long as an edge on the boundary of $F$ incident to each endpoint of $e$ is provided. (Our algorithm moves an edge $e$ to the interior of $F$ only when it traverses the boundary of $F$.)

To describe the algorithm, we need some definitions for a 2-connected plane graph $H$. If $v$ is an external node in $H$, then let $\mathrm{next}H, v$ (respectively, $\mathrm{prev}H, v)$ denote the external node of $H$ that immediately succeeds (respectively, precedes) $v$ in counterclockwise order around the outer boundary of $H$. For any two distinct external nodes $r$ and $v$ of $H$, let $\mathrm{ccw}(H,r,v)$ (respectively, $\mathrm{cw}(H,r,v)$) denote the sequence of the external nodes of $H$ from $r$ to $v$ in counterclockwise (respectively, clockwise) order around the outer boundary of $H$. Observe that $\mathrm{prev}(H,v) \in \mathrm{ccw}(H,r,v)$ and $\mathrm{next}(H,v) \in \mathrm{cw}(H,r,v)$. Define $\mathrm{boundary}(H,r) = \mathrm{ccw}(H,r,\mathrm{prev}(H,r))$, i.e., the sequence of the external nodes of $H$ from $r$ to $\mathrm{prev}(H,r)$ in counterclockwise order around the outer boundary of $H$. See Figure 2.3 for an illustration. For example, if $H$ is the plane graph shown in Figure 2.2(b), then we have that $\mathrm{next}(H,2) = 6$, $\mathrm{prev}(H,2) = 1$, $\mathrm{ccw}(H,1,6) = (1,2,6)$, $\mathrm{cw}(H,1,6) = (1,5,6)$, and $\mathrm{boundary}(H,1) = (1,2,6,5)$.

The key component of our orderly pair algorithm is the recursive subroutine $\mathsf{block}(G,r,v)$ shown below. Given any 2-connected plane graph $G$ and two distinct external nodes $r$ and $v$ of $G$, the subroutine $\mathsf{block}(G,r,v)$ computes an orderly pair $(H,T)$ of $G$ with respect to $r$. Let us emphasize that $v$ can be any external node of $G$ other than $r$. The high-level strategy of $\mathsf{block}(G,r,v)$ is to identify a neighbor $p$ of $v$ in $G$ that can be the parent of $v$ in $T$. The subroutine then deletes $v$ and its incident edges and recursively works on each 2-connected component of the remaining graph. The difficulty lies in efficiently choosing an appropriate parent of $v$ with possible modification to the plane embedding of $G$. More precisely, we want the subroutine to alter the embedding of $G$ into $H$ and find a neighbor $p$ of $v$ such that (1) the required time is linear in the total size of the internal faces of $G$ that contains $v$ and (2) the following *property* $\Pi$ holds for $H$ and $p$:

> For each neighbor $x$ of $v$ in $H$ other than $p$, if $x$ and $\mathrm{prev}(H, v)$ (respectively, $\mathrm{next}(H, v)$) are on the same side of $(v, p)$ in $H$, then $(v, x)$ is on the first (respectively, last) internal face of $H$ containing $v$ and $x$ in counterclockwise order around $v$ starting from the one containing $(v, \mathrm{next}(H, v))$.

(See Figure 2.5(b) for an illustration of property $\Pi$.) It turns out that a two-phase process serves the purpose: We say that an edge of $G$ is *movable* if the embedding of $G$ can be changed by moving the edge into a face of $G$. For example, edges $(1, 2)$, $(2, 5)$, and $(5, 1)$ are the movable edges in the plane graph shown in Figure 2.2(a). Imagine that node $v$ is at the "bottom" of $G$. The first phase flips each movable incident edge of $v$ to the leftmost possible face. At the end of the first phase, the node $p$ is exactly the neighbor of $v$ on $\mathrm{cw}(G, r, v)$ that is closest to $r$. After determining $p$, the second phase flips each movable incident edge of $v$ that is to the left of edge $(p, v)$ to the rightmost possible face.

When recursively taking care of each 2-connected component $G_i$ of $G'$, the subroutine has to choose two distinct nodes $r_i$ and $v_i$ on the outer boundary of $G_i$ for the recursive subroutine call $\mathsf{block}(G_i, r_i, v_i)$. For any choice of $r_i$ and $v_i$, the subroutine call will return an orderly pair $(H_i, T_i)$ of $G_i$ with respect to $r_i$. However, to ensure that gluing all returned orderly pairs together yields an orderly pair of $G$, we have to be careful about the choice of each $v_i$.

The detailed description of $\mathsf{block}(G, r, v)$ is as follows.

**Subroutine block($G, r, v$).**

*Step* 1. If $G$ consists of a single edge $(r, v)$, then return $(G, G)$; otherwise, perform steps 2–7.

*Step* 2. Perform step 2.1 for each internal face $F$ incident to node $v$ in $G$ in clockwise order around $v$ starting from the one containing $(v, \mathrm{prev}(G, v))$.

- *Step* 2.1. For any node $x$ in $F$ such that $(v, x)$ is an edge of $G$ succeeding $F$ in clockwise order around $v$ starting from $(v, \mathrm{next}(G, v))$, update the planar embedding of $G$ by flipping $(v, x)$ into the interior of $F$.

  *Remark.* For instance, if $v$ and $F$ are as shown in Figure 2.4, then $(v, x_1)$ and $(v, x_2)$ will be flipped into the interior of $F$ by step 2.1.

*Step* 3. Let $p$ be the neighbor of $v$ in $G$ closest to $r$ in $\mathrm{cw}(G, r, v)$.

*Step* 4. Perform step 4.1 for each internal face $F$ of $G$ that succeeds $(v, p)$ in counterclockwise order around $v$ starting from the face containing $(v, p)$:

- *Step* 4.1. For any node $x$ in $F$ such that $(v, x)$ is an edge of $G$ succeeding $F$ in counterclockwise order around $v$ starting from $(v, \mathrm{next}(G, v))$, update the planar embedding of $G$ by flipping $(v, x)$ into the interior of $F$.

  *Remark.* For instance, if $v$ and $F$ are as shown in Figure 2.4, then $(v, x_3)$ and $(v, x_4)$ will be flipped into the interior of $F$ by step 4.1.

*Step* 5. Let $G'$ be the graph obtained by deleting all the incident edges of $v$ in $G$, except for $(v, p)$. Compute the 2-connected components of $G'$ by traversing the segment of the outer boundary of $G'$ from $\mathrm{prev}(G, v)$ to $\mathrm{next}(G, v)$ in counterclockwise order around the outer boundary of $G'$.

*Remark.* Since $G$ is 2-connected, we know that all 2-connected components of $G'$ are external to one another. Therefore, the above traversal of part of the outer boundary will suffice. Also, by the definitions of $G'$ and $p$, one of the 2-connected components of $G'$ consists of the single edge $(v, p)$.

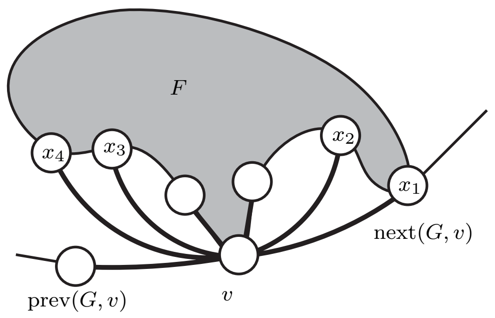

FIG. 2.4. *$F$ is an internal face of $G$ containing nodes $v$ and $x_i$, but not edge $(v, x_i)$ for each $i \in \{1, 2, 3, 4\}$.*

*Step* 6. Compute $(H_i, T_i) = \mathsf{block}(G_i, r_i, v_i)$ for each 2-connected component $G_i$ of $G'$, where $r_i$ is the node of $G_i$ closest to $r$ in $G'$, and $v_i$ is defined as follows:
*Case* 1. $G_i = (v, p)$. Let $v_i = v$.
*Case* 2. $G_i$ and $\text{prev}(G, v)$ are on the same side of $(v, p)$ in $G$. Let $S$ consist of the nodes in both $\text{ccw}(G_i, \text{next}(G_i, r_i), \text{prev}(G_i, r_i))$ and $\text{ccw}(G, r, v)$. If $S$ is empty, then let $v_i = \text{next}(G_i, r_i)$. Otherwise, let $v_i$ be the last node of $S$ in counterclockwise order around the outer boundary of $G_i$.
*Case* 3. $G_i$ and $\text{next}(G, v)$ are on the same side of $(v, p)$ in $G$. Let $S$ consist of the nodes in both $\text{ccw}(G_i, \text{next}(G_i, r_i), \text{prev}(G_i, r_i))$ and $\text{cw}(G, r, v)$. If $S$ is empty, then let $v_i = \text{prev}(G_i, r_i)$. Otherwise, let $v_i$ be the first node of $S$ in counterclockwise order around the outer boundary of $G_i$.

*Step* 7. Return $(H, T)$, where $H$ is obtained from $G$ by replacing each $G_i$ with $H_i$, and $T$ is the union of all $T_i$.

An illustration of $\mathsf{block}(G, r, v)$ is given in Figure 2.5. Let $G$ be the 2-connected plane graph shown in Figure 2.5(a). At the completion of step 4, the resulting embedding of $G$ and $p$ are as shown in Figure 2.5(b), where the gray ellipse with label $i$ is the $i$th 2-connected component $G_i$ of $G'$. Note that $(v, p)$ is also a 2-connected component of $G'$. One can verify that after step 6 we have that $r_1 = r$, $r_2 = r_6$, $r_8 = r_9$, $r_{11} = r_{12} = p$, and $v_{11} = v$. For the 2-connected components lying on the same side of $(v, p)$ with $\text{prev}(G, v)$, we have $v_1 = r_2$, $v_2 = r_3$, $v_3 = r_4$, $v_4 = \text{prev}(G, v)$, and that $v_i = \text{next}(G_i, r_i)$ holds for each $i \in \{5, 6, \ldots, 10\}$. For the 2-connected components lying on the same side of $(v, p)$ with $\text{next}(G, v)$, we have $v_{12} = r_{13}$, $v_{13} = r_{15}$, $v_{14} = \text{prev}(G_{14}, r_{14})$, and $v_{15} = \text{next}(G, v)$.

LEMMA 2.1. *If $r$ and $v$ are two distinct external nodes of a 2-connected plane graph $G$, then $\mathsf{block}(G, r, v)$ outputs an orderly pair of $G$ with respect to $r$.*

*Proof.* Let $(H, T)$ be the output of $\mathsf{block}(G, r, v)$. We prove the following properties of $(G, H, T, r, v)$ by induction on the number of edges in $G$:

1. Each external node of $G$ remains external in $H$. Moreover, $\text{boundary}(G, r)$ is a subsequence of $\text{boundary}(H, r)$.
2. (Property $\Pi$.) For each neighbor $x$ of $v$ in $H$ other than $p$, if $x$ and $\text{prev}(H, v)$ (respectively, $\text{next}(H, v)$) are on the same side of $(v, p)$ in $H$, then $(v, x)$ is on the first (respectively, last) internal face of $H$ containing $v$ and $x$ in counterclockwise order around $v$ starting from the one containing $(v, \text{next}(H, v))$.
3. $T$ rooted at $r$ is a spanning tree of $H$ such that exactly one of the following

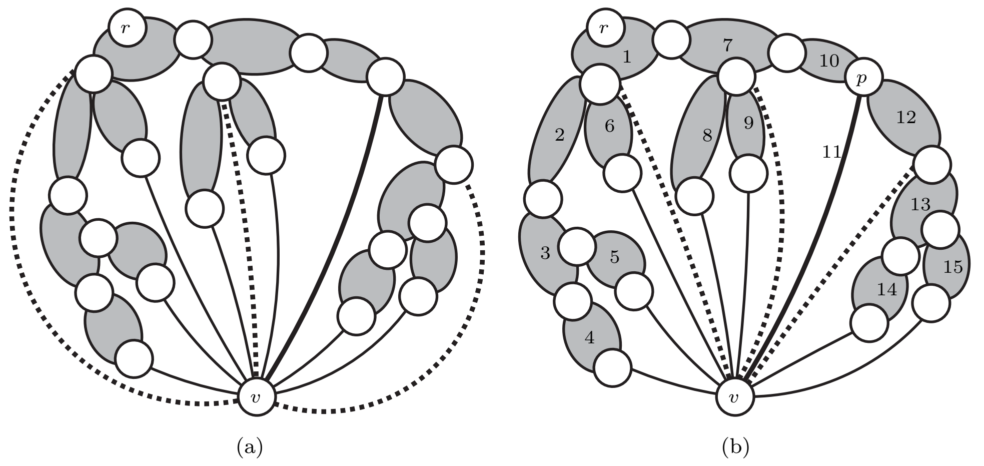

FIG. 2.5. (a) *A* 2*-connected plane graph $G$, where each gray ellipse is a* 2*-connected component of $G - \{v\}$.* (b) *The plane graph $G$ at the completion of performing steps* 1–4 *of* $\mathsf{block}(G, r, v)$*. Observe that all edges incident to $v$, especially those dashed* (*i.e., movable*) *edges, satisfy property* Π.

conditions holds for each node $u$ in $\text{ccw}(H, r, v)$ (respectively, $\text{cw}(H, r, v)$): (i) $u$ is a leaf of $T$; or (ii) $\text{next}(H, u)$ (respectively, $\text{prev}(H, u)$) is the lowest-indexed (respectively, highest-indexed) child of $u$ in $T$.

4. $H \sim G$.
5. $T$ rooted at $r$ is an orderly spanning tree of $H$.

Properties 4 and 5 suffice, but we need the other properties to enable the induction step. When $G$ consists of a single edge $(r, v)$, by step 1 we have $H = T = G$. It is not difficult to see the inductive basis of each property holds. Suppose that $G'$ consists of $k$ 2-connected components. By step 6, we have $r_i \neq v_i$ for each $i$. It follows from the inductive hypothesis that properties 1–5 of $(G_i, H_i, T_i, r_i, v_i)$ hold for each $i \in \{1, 2, \ldots, k\}$. The rest of the proof shows the induction step. For brevity, for each $j = 1, 2, \ldots, 5$, we abbreviate "property $j$ of $(G_i, H_i, T_i, r_i, v_i)$" to "property $j$ of $G_i$" and use "property $j$ (of $G$)" to stand for "property $j$ of $(G, H, T, r, v)$."

*Property* 1. Observe that throughout the execution of $\mathsf{block}(G, r, v)$, without accounting for its subsequent subroutine calls to $\mathsf{block}$, the embedding of $G$ changes only by flipping edges into the interior of internal faces of $G$ in steps 2 and 4. Thus, based on how $H$ is obtained from $G$ in step 7, it follows from property 1 of $G_i$ for each $i \in \{1, 2, \ldots, k\}$ that the property holds.

*Property* 2. Let property $2'$ stand for the property obtained from property 2 by replacing each $H$ with a $G$. From steps 2 and 4, one can verify that the plane graph $G$ at the completion of performing step 4 satisfies property $2'$. From property 2 and how $H$ is obtained from $G$ in step 7, we know that the relative order among the incident edges of $v$ and the faces containing $v$ remains the same in $G$ and $H$. Therefore the property follows from property $2'$.

*Property* 3. For each $i \in \{1, 2, \ldots, k\}$, property 3 of $G_i$ implies that $T_i$ is a spanning tree of $H_i$. Since $H_1, H_2, \ldots, H_k$ are edge disjoint, and each node of $H$ belongs to some $H_i$, we know that $T$, the union of all $T_i$, is a spanning tree of $H$. Since $v$ is a leaf of $T$, the required property holds for $v$. Let $x$ be an external node of $H$ other than $v$. If $(x, v)$ is not an external edge of $H$ belonging to $H - T$, then the required property for $x$ follows from the property of $x$ guaranteed by property 3 of

$G_i$ for each index $i$ with $x \in H_i$. Otherwise, by property 2, $x$ is either $\text{prev}(H, v)$ or $\text{next}(H, v)$. Let $H_j$ be the 2-connected component of $H'$ containing $x$. We have that $v_j = x$. By property 3 of $G_j$, $x$ is a leaf of $T_j$. Since $(x, v) \notin T$, $x$ is also a leaf of $T$ and property 3 holds for $x$.

*Property* 4. Observe that steps 2 and 4 flip an edge $(v, x)$ into the interior of $F$ only if $F$ contains both $v$ and $x$. Therefore, the resulting embedding of $G$ at the completion of step 4 is still planar. According to how $H$ is obtained from $G$ in step 7, the property follows from property 1 of $G$ and properties 4 of $G_i$ for all indices $i \in \{1, 2, \ldots, k\}$.

*Property* 5. Each neighbor of $r$ in $H$ is a child of $r$ in $T$; hence $r$ is orderly in $H$ with respect to $T$. The rest of the proof shows that each node $x$ other than $r$ is orderly in $H$ with respect to $T$. Let $H'$ be the graph obtained from $H$ by deleting each incident edge of $v$ in $H - T$. Observe that $H' \sim G'$ and that each $H_i$ is a 2-connected component of $H'$. Let $I_x$ consist of the indices $i$ with $x \in H_i$. As $x \neq r$, one can verify that there is an index $j$ in $I_x$ such that $x \neq r_j$ and $x = r_i$ for each index $i \in I_x - \{j\}$.

We first show that if $(v, x)$ is an edge of $H - H'$, then $(v, x)$ is unrelated with respect to $T$. If the index of $x$ is higher than that of $v$, then by the fact that $v$ is a leaf in $T$, we know that $(v, x)$ is unrelated. As for the case with the index of $x$ lower than that of $v$, let us assume for a contradiction that $x$ is an ancestor of $v$ in $T$. Since $(v, x) \in H - T$ and $p$ is the parent of $v$ in $T$, we know that $x$ is also an ancestor of $p$ in $T$. Let $P$ be the path of $T$ between $r$ and $p$. Thus, $x \in P$. Let $y$ be the node of $H_j$ closest to $p$ in $P$. It is not difficult to see that $y \in \text{cw}(H, r, p)$ and $y \in \text{cw}(H_j, r_j, x)$. Since $(v, p) \in T$, $(v, x) \in H - T$, and $y \in \text{cw}(H, r, p)$, we know $y \neq x$. Otherwise, $x$ would have been a neighbor of $v$ in $H$ closer to $r$ than $p$ in $\text{cw}(H, r, v)$, thereby contradicting the choice of $p$ in step 3. As $y \neq x$, $x$ is not a leaf of $T_j$. By step 6(2), $x \in \text{cw}(H_j, r_j, v_j)$. Let $z = \text{prev}(H_j, x)$. By property 3 of $G_j$, node $z$ has to be the largest-indexed child of $x$ in $T_j$. Since $x \neq r_j$ and $y \in \text{cw}(H_j, r_j, x)$, we know that $y$ and $z$ are on different sides of the path of $T_j$ between $r_j$ and $x$ in $H_j$, thereby contradicting the fact that $z$ is the highest-indexed child of $x$ in $T_j$.

We then show that $x$ is orderly in $H'$ with respect to $T$. If $|I_x| = 1$, then the orderly pattern of $x$ in $H'$ with respect to $T$ follows immediately from that in $H_j$ with respect to $T_j$, which is ensured by property 5 of $G_j$. When $|I_x| \geq 2$, by properties 5 of $G_i$ for all $i \in I_x - \{j\}$, each neighbor of $x$ in $\bigcup_{i \in I_x - \{j\}} H_i$ is a child of $x$ in $T$. It follows from property 3 of $G_j$ that all children of $x$ in $T$ are consecutive in $H'$ around $x$. Since $x$ is orderly in $H_j$ with respect to $T_j$, one can see that $x$ is orderly in $H'$ with respect to $T$.

Since $v$ is a leaf of $T$, we know that $v$ is orderly in $H$ with respect to $T$. It remains to show that each neighbor $x$ of $v$ in $H - H'$ is orderly in $H$ with respect to $T$. Let $z_1$ (respectively, $z_2$) be the neighbor of $x$ that precedes (respectively, succeeds) $v$ in counterclockwise order around $x$. It suffices to show that if the index of $x$ is lower (respectively, higher) than that of $v$, then $z_2$ (respectively, $z_1$) belongs to $P(x)$ or $D(x)$ (respectively, $P(x)$ or $U_<(x)$) of $H'$ with respect to $T$ as follows: If the index of $x$ is lower than that of $v$, then $z_2 = \text{next}(H_j, x)$ by property 2. By step 6, one can verify that $x$ belongs to $\text{cw}(H_j, r_j, v_j)$. By property 3, we have that $z_2$ belongs to either $P(x)$ or $D(x)$ of $H'$ with respect to $T$. If the index of $x$ is higher than that of $v$, then we know $z_1 = \text{prev}(H_j, x)$ from property 2. By step 6, one can verify that $x$ belongs to $\text{ccw}(H_j, r_j, v_j)$. From property 3, we have that $z_1$ belongs to either $P(x)$ or $U_<(x)$ of $H'$ with respect to $T$. ◻

LEMMA 2.2. *If $r$ and $v$ are two distinct external nodes of an $n$-node 2-connected* *plane graph $G$, then* $\mathsf{block}(G, r, v)$ *runs in $O(n)$ time.*

*Proof.* The execution of $\mathsf{block}(G, r, v)$ consists of a sequence of subroutine calls to $\mathsf{block}$. One can see that each node of $G$ can be the parameter $v$ for no more than two subroutine calls to $\mathsf{block}$—one with $G \neq (r, v)$ and the other with $G = (r, v)$. If $G = (r, v)$, then the subroutine call $\mathsf{block}(G, r, v)$ runs in $O(1)$ time. Let $\ell$ be the number of subroutine calls to $\mathsf{block}(G, r, v)$ with $G \neq (r, v)$. For each $j \in \{1, 2, \ldots, \ell\}$, let $\mathsf{block}(G^j, r^j, v^j)$ be the $j$th subroutine call to $\mathsf{block}$ with $G^j \neq (r^j, v^j)$ throughout the execution of $\mathsf{block}(G, r, v)$, where $G^1 = G$, $r^1 = r$ and $v^1 = v$. Clearly, $v^j \neq v^{j'}$ holds for any two distinct indices $j$ and $j'$, thereby implying that $\ell \leq n$. Let $E_j$ consist of the edges of $G$ belonging to the boundaries of the internal faces of $G^j$ that contain $v^j$. Let $t_j$ be the time required by $\mathsf{block}(G^j, r^j, v^j)$, without accounting for that required by its subsequent subroutine calls to $\mathsf{block}$. Observe that $t_j = O(|E_j|)$ holds for each $j$. It is not difficult to implement the algorithm $\mathsf{block}$ such that the running time of $\mathsf{block}(G, r, v)$ is dominated by $\sum_{j=1}^{\ell} t_j = \sum_{j=1}^{\ell} O(|E_j|)$. Since $G$ has $O(n)$ edges, it suffices to show as follows that any edge $(x, y)$ of $G$ belongs to no more than two of the sets $E_1, E_2, \ldots, E_\ell$: Let $j_1$ be the smallest index $j$ with $(x, y) \in E_j$. If $v^{j_1} \in \{x, y\}$, then $j_1$ is also the largest index $j$ with $(x, y) \in E_j$. It remains to consider the case $v^{j_1} \notin \{x, y\}$. Let $j_2$ be the smallest index $j$ with $j > j_1$ and $(x, y) \in E_j$. From the definition of $\mathsf{block}$, edge $(x, y)$ has to be on the outer boundary of $G^{j_2}$, implying $v^{j_2} \in \{x, y\}$. Therefore, $j_2$ is the largest index $j$ with $(x, y) \in E_j$. □

Finally, we have the next theorem.

THEOREM 2.3. *It takes $O(n)$ time to compute an orderly pair for an $n$-node connected planar graph.*

## 3. Realizers for plane triangulations.

This section provides a new linear-time algorithm for computing a realizer for any $n$-node plane triangulation $\Delta$. As defined by Schnyder [39, 38], $(T_1, T_2, T_n)$ is a *realizer* of $\Delta$ if

- the internal edges of $\Delta$ are partitioned into three edge-disjoint trees $T_1$, $T_2$, and $T_n$, each rooted at a distinct external node of $\Delta$; and
- the neighbors of each internal node $v$ of $\Delta$ form six blocks $U_1$, $D_n$, $U_2$, $D_1$, $U_n$, and $D_2$ in counterclockwise order around $v$, where for each $j \in \{1, 2, n\}$, $U_j$ (respectively, $D_j$) consists of the parent (respectively, children) of $v$ in $T_j$.

A realizer of the plane triangulation in Figure 1.1(a) is shown in Figure 1.1(c).

LEMMA 3.1. *Given an orderly spanning tree of $\Delta$, a realizer of $\Delta$ is computable in $O(n)$ time.*

*Proof.* Let $T$ be the given orderly spanning tree of $\Delta$ rooted at $v_1$. Let $v_1, \ldots, v_n$ be the counterclockwise preordering of $T$, where $v_1$, $v_2$, and $v_n$ are the external nodes of $\Delta$ in counterclockwise order. Note that $(v_1, v_2)$ and $(v_1, v_n)$ must be in $T$. Since $\Delta$ is a plane triangulation and the edges of $\Delta - T$ are unrelated with respect to $T$, both $U_<(v_i)$ and $U_>(v_i)$ are nonempty for each $3 \leq i \leq n-1$. (To see this, one can verify that if $U_<(v_i)$ or $U_>(v_i)$ were empty, then the edge between $v_i$ and the parent of $v_i$ in $T$ would belong to a face of $\Delta$ consisting of at least four edges, contradicting the assumption that $\Delta$ is a plane triangulation.) Let $p_i$ (respectively, $q_i$) be the index of the last (respectively, first) node in $U_<(v_i)$ (respectively, $U_>(v_i)$) in counterclockwise order around $v_i$. Let $T_1$ be obtained from $T$ by deleting $(v_1, v_2)$ and $(v_1, v_n)$. Let $T_2 = \{(v_i, v_{p_i}) \mid 3 \leq i \leq n-1\}$ and $T_n = \{(v_i, v_{q_i}) \mid 3 \leq i \leq n-1\}$. An example is shown in Figure 1.1(c). Observe that $p_i < i < q_i$ holds for each $3 \leq i \leq n-1$, implying that both $T_2$ and $T_n$ are acyclic. It can be proved as follows that exactly one of the equalities $i = p_j$ and $j = q_i$ holds for each edge $(v_i, v_j) \in \Delta - T$ with $i < j$.

> Since each face of $\Delta$ has size three, there is a node $v_k$ that is (i) the neighbor of $v_i$ immediately succeeding $v_j$ in clockwise order around $v_i$ and (ii) the neighbor of $v_j$ immediately preceding $v_i$ in clockwise order around $v_j$. Clearly, $i < j < k$ implies $i = p_j$ and $j \neq q_i$; and $k < i < j$ implies $j = q_i$ and $i \neq p_i$. As for the remaining case that $i < j < k$, one can verify that $v_i$ has to be the parent of $v_k$ in $T$, thereby implying $j = q_i$ and $i \neq p_j$.

It follows that each internal edge of $\Delta$ belongs to exactly one of $T_1$, $T_2$, and $T_n$. By the definitions of $p_i$ and $q_i$, one can verify that the neighbors of each internal node $v_i$ of $\Delta$ indeed form the required pattern for $(T_1, T_2, T_n)$ as a realizer of $\Delta$. Since it takes $O(n)$ time to determine all $p_i$ and $q_i$, the lemma is proved. □

THEOREM 3.2 (see also [39, 38]). *A realizer of any plane triangulation is derivable in linear time.*

*Proof.* The proof is straightforward by Theorem 2.3 and Lemma 3.1. □

**4. 2-visibility drawings for plane graphs.** This section shows how to obtain in $O(n)$ time an $(n-1) \times \lfloor \frac{2n+1}{3} \rfloor$ 2-visibility drawing for any $n$-node plane graph $G$. For calculating the area of a 2-visibility drawing, we follow the convention of [16], stating that the corner coordinates of each rectangle are integers, and that each rectangle is no smaller than $1 \times 1$. For example, the area of the 2-visibility drawing shown in Figure 1.1(b) is $9 \times 8$. Let $\Delta$ be a plane triangulation obtained by triangulating $G$. Since any 2-visibility drawing of $\Delta$ is also a 2-visibility drawing of $G$, the rest of the section assumes that the input is the plane triangulation $\Delta$.

Let $T$ be an orderly spanning tree of $\Delta$. Let $v_1, v_2, \ldots, v_n$ be the counterclockwise preordering of the nodes in $T$. Our algorithm $\mathsf{draw}(\Delta, T)$ consists of $n$ iterations, where the $i$th iteration performs the following steps:

*Step* 1. If $i \neq 1$ and $v_i$ is not the first child of its parent in $T$, then lengthen each ancestor of $v_i$ in $T$ to the right by one unit.

*Step* 2. Draw $v_i$ as a unit square beneath the parent of $v_i$ in $T$ such that $v_i$ and all ancestors of $v_i$ in $T$ align along the right boundary. Now, $v_i$ is vertically visible to its parent in $T$.

*Step* 3. Lengthen downward $v_i$ and each neighbor $v_j$ of $v_i$ in $\Delta$ with $j < i$, if necessary, so that $v_i$ and $v_j$ are horizontally visible to each other.

If $\Delta$ and $T$ are as shown in Figure 4.1(a), then the intermediate (respectively, resulting) drawing obtained by $\mathsf{draw}(\Delta, T)$ is shown in Figure 4.1 (respectively, Figure 4.1(b)).

LEMMA 4.1. *The algorithm* $\mathsf{draw}(\Delta, T)$ *obtains an* $h \times w$ *2-visibility drawing of* $\Delta$ *with* $h \leq n - 1$ *and such that* $w$ *equals the number of leaves in* $T$.

*Proof.* Since $T$ is a spanning tree of $\Delta$, $\mathsf{draw}(\Delta, T)$ is well defined. Also, the output of $\mathsf{draw}(\Delta, T)$ is indeed a 2-visibility drawing of $\Delta$ with width equal to the number of leaves in $T$. The rest of the proof shows that the height of the output of $\mathsf{draw}(\Delta, T)$ is at most $n - 1$. For any two distinct edges $e$ and $e'$ in $\Delta - T$, we say that $e$ *encloses* $e'$ if $e'$ is in the interior of the cycle consisting of $e$ and the path of $T$ between the endpoints of $e$. By the planarity of $\Delta$, the above "enclosing" relation defines a nesting structure among the edges of $\Delta - T$. Let $\ell(e)$ denote the "level" of edge $e$ in the nesting structure:

> If $e$ does not enclose any other edge in $\Delta - T$, then let $\ell(e) = 1$; otherwise, let $\ell(e)$ be one plus the maximum of $\ell(e')$ over all the edges $e'$ in $\Delta - T$ that are enclosed by $e$.

If we are to draw edge $e = (u, v)$ as a horizontal line segment connecting the rectangles

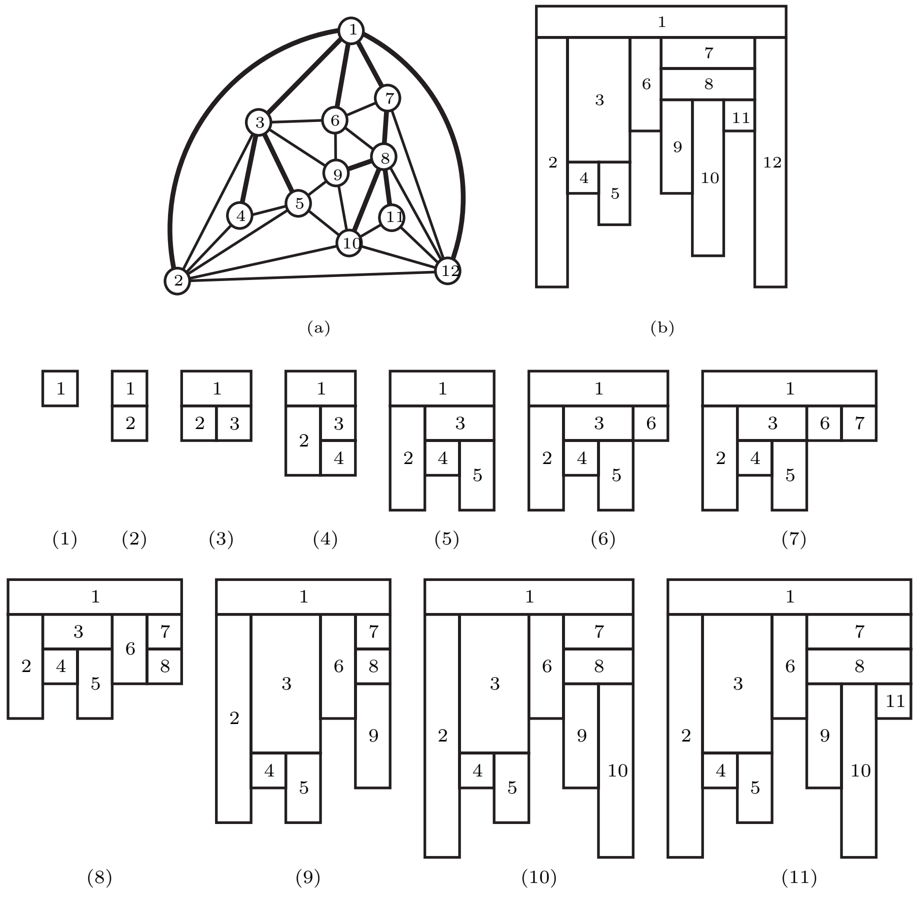

FIG. 4.1. *An illustration of the intermediate steps of* draw$(\Delta, T)$, *where* $\Delta$ *and* $T$ *are as shown in* (a) *and the final drawing is as shown in* (b).

representing nodes $u$ and $v$ without intersecting other rectangles or line segments, then $1 + \ell(e)$ is the minimum possible (vertical) distance between the line segment representing $e$ and the rectangle representing the lowest common ancestor of $u$ and $v$ in $T$. Let edge $\hat{e}$ be $(v_2, v_n)$, which encloses all the other edges in $\Delta - T$. The height of the output of draw$(\Delta, T)$ is exactly $1 + \ell(\hat{e})$. It remains to show $\ell(\hat{e}) \leq n - 2$ as follows: Assume for the sake of contradiction that $e_1, e_2, \ldots, e_{n-1}$ is a sequence of edges in $\Delta - T$ such that $e_i$ encloses $e_1, e_2, \ldots, e_{i-1}$ for each $i \in \{2, 3, \ldots, n-1\}$. For each $i \in \{1, 2, \ldots, n-1\}$, let $X_i$ consist of the endpoints of $e_i, e_{i+1}, \ldots, e_{n-1}$. For each $i \in \{1, 2, \ldots, n-2\}$, there must be an endpoint of $e_i$ that is not in $X_{i+1}$. (To see this, assume for the sake of contradiction that $j$ and $k$ with $i < j < k \leq n-1$ are two indices such that $e_j$ and $e_k$ are incident to the endpoints $u$ and $v$ of $e_i$, respectively. Let $C$ be the cycle consisting of $e_j$ and the path of $T$ that connects the endpoints of $e_j$. Since $e_i$ is in the interior of $C$ and $e_k$ is outside of $C$, the assumption that $e_k$ is incident to $v$ violates the orderly property of $v$.) Therefore, $X_1$ contains at least $n$ distinct nodes. Since $T$ is an orderly spanning tree of $\Delta$, $v_1$ is not incident to any edges of $\Delta - T$. Therefore, $v_1 \notin X_1$, which contradicts that $\Delta$ has $n$ nodes. ◻

LEMMA 4.2. *It takes $O(n)$ time to compute an orderly spanning tree of $\Delta$ with*

$\lfloor \frac{2n+1}{3} \rfloor$ *or fewer leaves.*

*Proof.* Let $v_1$, $v_2$, and $v_n$ be the external nodes of $\Delta$ in counterclockwise order around the outer boundary of $\Delta$. By Theorem 3.2, a realizer $(T'_1, T'_2, T'_n)$ of $\Delta$, where each $T'_i$ is rooted at $v_i$, can be obtained in $O(n)$ time. Let $I = \{1, 2, n\}$. For each $i \in I$, let $T_i = T'_i \cup \{(v_i, v_{i_1}), (v_i, v_{i_2})\}$, where $\{i_1, i_2\} = I - \{i\}$. Observe that $T_1$, $T_2$, and $T_n$ are three spanning trees of $\Delta$ with $T_1 \cup T_2 \cup T_n = \Delta$. We first show that each $T_i$ is an orderly spanning tree of $\Delta$. Since the relation between $T_1$, $T_2$, and $T_n$ is rotationally symmetric, it suffices to verify that each node is orderly with respect to $T_1$. Let $v_1, v_2, \ldots, v_n$ be the counterclockwise preordering of $T_1$. For each $i \in I$ and $j \in \{1, 2, \ldots, n\}$, let $Q_{i,j}$ be the path of $T_i$ between $v_i$ and $v_j$. Note that $Q_{1,j}$, $Q_{2,j}$, and $Q_{n,j}$ are three edge-disjoint paths of $\Delta$ that intersect only at $v_j$. If $v_j$ is not a leaf of $T_1$, then the children of $v_j$ in $T_1$ are consecutive in $\Delta$ in counterclockwise order around $v_j$. Therefore, to ensure that each node is orderly with respect to $T_1$, it suffices to prove that each edge of $\Delta - T_1$ is unrelated with respect to $T_1$: If $v_{j'}$ were an ancestor of $v_j$, that is, also a neighbor of $v_j$ in $\Delta - T_1$, then $v_j$ and $v_{j'}$ would be on different sides of $Q_{2,j''} \cup Q_{n,j''}$ in $\Delta$, where $v_{j''}$ is the parent of $v_j$ in $T_1$, thereby contradicting the planarity of $\Delta$.

It remains to show that $T_1$, $T_2$, or $T_n$ has at most $\frac{2n+1}{3}$ leaves. For each $i \in I$, let leaf$(T'_i)$ consist of the leaves of $T'_i$. Since the number of leaves in $T_i$ is precisely $2 + |\text{leaf}(T'_i)|$, it suffices to show that $\sum_{i \in I} |\text{leaf}(T'_i)| \leq 2n - 5$. Let $v$ be a node in leaf$(T'_i)$. Observe that $v$ is internal in $\Delta$. For each $i \in I$, let $p_i(v)$ denote the parent of $v$ in $T_i$. Let $i_1$ and $i_2$ be the indices in $I - \{i\}$. Since $(T'_1, T'_2, T'_n)$ is a realizer of $\Delta$, there is a unique internal face $F_i(v)$ of $\Delta$ containing $v$, $p_{i_1}(v)$, and $p_{i_2}(v)$. We have that $p_{i_1}(v) \notin \text{leaf}(T'_{i_1})$ and $p_{i_2}(v) \notin \text{leaf}(T'_{i_2})$. It follows that $F_i(v) \neq F_{i_1}(u_1)$ for any node $u_1$ in leaf$(T'_{i_1})$ and that $F_i(v) \neq F_{i_2}(u_2)$ for any node $u_2$ in leaf$(T'_{i_2})$. Therefore, $\sum_{i \in I} |\text{leaf}(T'_i)|$ is no more than the number of internal faces of $\Delta$, which is precisely $2n - 5$ by Euler's formula. □

THEOREM 4.3. *An* $(n-1) \times \lfloor \frac{2n+1}{3} \rfloor$ *2-visibility drawing of any n-node planar graph is computable in* $O(n)$ *time.*

*Proof.* A naive implementation of algorithm draw runs in $O(n^2)$ time, since one stretching of a node's rectangle affects the horizontal spans of all its descendants. However, it is not difficult to implement the algorithm to run in $O(n)$ time. The width of the rectangle representing a node $v$ is exactly the number of leaves in the subtree of $T$ rooted at $v$. Therefore, one can easily calculate the $x$-coordinates of all rectangles in linear time. Also, the $y$-coordinates of all rectangles can be computed in linear time via the values $\ell(e)$ for all edges $e$ in $G - T$. (See, e.g., Figure 3.2 of [32] for related implementation techniques.) Therefore, the theorem follows from Lemmas 4.1 and 4.2. □

## 5. Convenient encodings for planar graphs.

This section gives the best known convenient encoding for an $n$-node $m$-edge planar graph as an application of our orderly pair algorithm. We need some notation to describe the data structures required by our convenient encodings. Let $|S|$ denote the length of a string $S$, i.e., the number of symbols in $S$. Unless clearly stated otherwise, all strings in this section have length $O(m + n)$. A string $S$ consisting of $t$ distinct symbols can be encoded in $|S| \lceil \log_2 t \rceil$ bits. For example, if $S$ consists of parentheses and brackets, including open and closed ones, then $S$ can be encoded in $2|S|$ bits. $S$ is *binary* if it consists of two distinct symbols. For each $1 \leq i \leq j \leq |S|$, let $S[i, j]$ be the length-$(j - i + 1)$ substring of $S$ from the $i$th position to the $j$th position. If $i > j$, then let $S[i, j]$ be the empty string. Define $S[i] = S[i, i]$. $S[k]$ is *enclosed* by $S[i]$ and $S[j]$ in $S$ if $i < k < j$.

Let select$(S, i, \Box)$ be the position of the $i$th $\Box$ in $S$. Let rank$(S, k, \Box)$ be the number of $\Box$'s before or at the $k$th position of $S$. If $k = \text{select}(S, i, \Box)$, then $i = \text{rank}(S, k, \Box)$.

An *auxiliary string* $\chi$ of $S$ is a binary string with $|\chi| = o(|S|)$ which is obtainable from $S$ in $O(|S|)$ time.

FACT 5.1 (see [1, 15]). *For any strings $S_1, S_2, \ldots, S_k$ with $k = O(1)$, there is an auxiliary string $\chi_0$ such that, given the concatenation of $\chi_0, S_1, S_2, \ldots, S_k$ as input, the index of the first symbol of any given $S_i$ in the concatenation is computable in $O(1)$ time.*

Let $S_1 \circ S_2 \circ \cdots \circ S_k$ denote the concatenation of $\chi_0, S_1, S_2, \ldots, S_k$ as in Fact 5.1.

Suppose that $S$ is a string of multiple types of parentheses. Let reverse$(S)$ be the string $R$ such that $R[i]$ is the opposite parenthesis of the same type as $S[|S|+1-i]$. For example, reverse("`)()]])[`") = "`](([()(`." For an open parenthesis $S[i]$ and a closed one $S[j]$ of the same type with $i < j$, the two *match* in $S$ if every parenthesis of the same type that is enclosed by them matches one enclosed by them. $S$ is *balanced in type $k$* if every parenthesis of type $k$ in $S$ belongs to a matching parenthesis pair. $S$ is *balanced* if $S$ is empty or is balanced in all types of parentheses. Here are some queries defined for a balanced string $S$. Let match$(S, i)$ be the position of the parenthesis in $S$ that matches $S[i]$. Let enclose$_k(S, i_1, i_2)$ be the position pair $(j_1, j_2)$ of the closest matching parenthesis pair of the $k$th type that encloses $S[i_1]$ and $S[i_2]$.

FACT 5.2 (see [35, 9]). *For any balanced string $S$ of $O(1)$ types of parentheses, there is an auxiliary string $\chi_1(S)$ such that each of* rank$S, i, \Box$, *select$(S, i, \Box)$, match$(S, i)$, and enclose$_k(S, i, j)$ can be determined from $S \circ \chi_1(S)$ in $O(1)$ time.*

For a string $S$ of parentheses that may be unbalanced, we define wrapped$(S, i)$ as follows. For the case that $S[i]$ is an open parenthesis of type $k$, let $S'$ be a string obtained from $S$ by appending some closed parentheses of type $k$, if necessary, such that $S'[i]$ is matched in $S'$. Define wrapped$(S, i)$ to be the number of indices $j$ satisfying $i < j \le |S|$, $\text{enclose}_k(S', j, \text{match}(S', j)) = (i, \text{match}(S', i))$, and $S[j]$ is of type $k$. For the case that $S[i]$ is closed, let $\text{wrapped}(S, i) = \text{wrapped}(\text{reverse}(S), |S| + 1 - i)$. Therefore, if

(5.1) $S = \texttt{(()[[[[[(](])[(]])[[)[[(])[[[(](](]]])[(]]])[[(])[)[)[(]]]]]))},$

```
122.....3.4.4.5..5..3..6.6...7.8.9...9.A...A..B.B.8.7.C.....C1
```

then we have wrapped$(S, 1) = 10$ and wrapped$(S, 6) = 4$. If $S$ is balanced, then wrapped$(S, i)$ is an even number for each $i$, i.e., twice the number of parenthesis pairs that are enclosed by the parenthesis pair in question. The next lemma extends the set of queries supported in Fact 5.2.

LEMMA 5.3. *For any balanced string $S$ of $O(1)$ types of parentheses, there is an auxiliary string $\chi_2(S)$ such that wrapped$(S, i)$ can be computed from $S \circ \chi_2(S)$ in $O(1)$ time.*

*Proof.* Define $\text{width}(i, j) = |i - j| + 1$. We say that parentheses of the same type with property $\pi$ are *$d$-disjoint* if

- $\text{width}(i, \text{match}(S, i)) > d$ holds for any parenthesis $S[i]$ with property $\pi$; and
- any two property-$\pi$ parentheses $S[i]$ and $S[j]$ with $S[i] = S[j]$ satisfy at least one of $\text{width}(i, j) > d$ and $\text{width}(\text{match}(S, i), \text{match}(S, j)) > d$.

Intuitively, $d$-disjoint parentheses have to be sparse: Suppose that parentheses with property $\pi$ are $d$-disjoint. Then, for any property-$\pi$ open parenthesis $S[i]$, either $S[i]$ is the only property-$\pi$ open parenthesis in $S[i - d + 1, i]$ or $S[\text{match}(S, i)]$ is the only property-$\pi$ closed parenthesis in $S[\text{match}(S, i), \text{match}(S, i) + d - 1]$. As a result, suppose that we partition $S$ into segments of length $d$. For each segment, let us mark (a) the property-$\pi$ open parenthesis with the smallest index in the segment and

(b) the property-$\pi$ closed parenthesis with the largest index in the segment. Then, for each parenthesis $S[i]$ with property $\pi$, at least one of $S[i]$ and $S[\text{match}(S,i)]$ is marked. Therefore, there are only $O(s/d)$ parentheses with property $\pi$.

Let $s = |S|$. For a carefully chosen number $\ell = \Theta(\log s)$, we say that

- parenthesis $S[i]$ is *narrow* if $\text{width}(i, \text{match}(S,i)) \leq \ell$;
- parenthesis $S[i]$ is *wide* if $\text{wrapped}(S,i) > 2\ell^2$; and
- parenthesis $S[i]$ is *medium* if it is neither narrow nor wide.

We apply the commonly used preprocessing technique (see, e.g., [10, 35]) in the unit-cost RAM model which allows the query $\text{wrapped}(S,i)$ for any narrow $S[i]$ to be answered in $O(1)$ time from the linear-time precomputable $o(s)$-bit table (i.e., the table $M_1 \circ M_2$ to be described later). It is not difficult to see that wide parentheses are $\ell^2$-disjoint. Therefore, we can afford to encode $(i, \text{wrapped}(S,i))$ for all wide parentheses $S[i]$ using $o(s)$ bits. Although medium parentheses are not necessarily $\ell$-disjoint, we identify *special* parentheses, which are medium parentheses that have to be $\ell$-disjoint, and encode $(i, \text{wrapped}(S,i))$ for all special medium parentheses $S[i]$ using $o(s)$ bits. As for medium parentheses that are not special, we will show that two queries to the $o(s)$-bit precomputed table suffice. The details are as follows.

Let $t$ be the number of distinct types of parentheses in $S$. Let $b$ be the smallest integer with $2t \leq 2^b$. Each symbol of $S$ can be encoded in $b$ bits. As $t = O(1)$, we have $b = O(1)$. Let $\ell = \left\lfloor \frac{1}{2} \log_{2^b} s \right\rfloor$. Any substring $S[i,j]$ with $j \leq i+\ell-1$ has $O(\sqrt{s})$ possible distinct values. Define tables $M_1$ and $M_2$ for $S$ by letting $M_1[S[i,i+\ell-1]] = \text{wrapped}(S[i,i+\ell-1],1)$ and $M_2[S[i,j]] = \text{wrapped}(\text{reverse}(S[i,j]),1)$ for any $i,j$ with $1 \leq i \leq j \leq i+\ell-1$. One can easily come up with an $o(s)$-bit string $\chi_2'$ from which each entry of $M_1$ and $M_2$ can be obtained in $O(1)$ time.

For each $k \in \{1,2,\ldots,t\}$, define tables $M_3^k$ and $M_4^k$ as follows. For each $i = 1,2,\ldots,\left\lceil \frac{s}{\ell^2} \right\rceil$,

- let $M_3^k[i] = (j, \text{wrapped}(S,j))$, where index $j$ is the smallest index, if any, with $(i-1)\ell^2 < j \leq i\ell^2$ such that $S[j]$ is a wide open parenthesis of type $k$; and
- let $M_4^k[i] = (j, \text{wrapped}(S,j))$, where index $j$ is the largest index, if any, with $(i-1)\ell^2 < j \leq i\ell^2$ such that $S[j]$ is a wide close parenthesis of type $k$.

Since each entry of $M_3^k$ and $M_4^k$ can be encoded in $O(\log s)$ bits, one can easily obtain an $o(s)$-bit string $\chi_2''$ from which each entry of $M_3^k$ and $M_4^k$ can be determined in $O(1)$ time.

A medium open parenthesis $S[i]$ is *special* if at least one of the inequalities $\text{width}(i,j) > \ell$ and $\text{width}(\text{match}(S,i), \text{match}(S,j)) > \ell$ holds for each index $j$ with $i < j < \text{match}(S,i)$ and $S[j] = S[i]$. A closed parenthesis $S[i]$ is *special* if $S[\text{match}(S,i)]$ is special. One can verify that special parentheses are $\ell$-disjoint. For each $k \in \{1,2,\ldots,t\}$, define tables $M_5^k$ and $M_6^k$ as follows. For each $i \in \{1,2,\ldots,\left\lceil \frac{s}{\ell} \right\rceil\}$,

- let $M_5^k[i] = (j, \text{wrapped}(S,j))$, where $j$ is the smallest index, if any, with $(i-1)\ell < j \leq i\ell$ such that $S[j]$ is a special open parenthesis of type $k$; and
- let $M_6^k[i] = (j, \text{wrapped}(S,j))$, where $j$ is the largest index, if any, with $(i-1)\ell < j \leq i\ell$ such that $S[j]$ is a special close parenthesis of type $k$.

Observe that $M_5^k[i] = (j,c)$ or $M_6^k[i] = (j,c)$ implies $0 \leq i\ell - j \leq \ell$ and $0 \leq c \leq 2\ell^2$. Therefore, each entry of $M_5^k$ and $M_6^k$ can be encoded in $O(\log \ell) = O(\log\log s)$ bits. As a result, one can easily come up with an $o(s)$-bit string $\chi_2'''$ from which each entry of $M_5^k$ and $M_6^k$ can be determined in $O(1)$ time. Let $\chi_2(S) = \chi_2' \circ \chi_2'' \circ \chi_2'''$. The $o(s)$-bit string $\chi_2(S)$ can be derived from $S$ in $O(s)$ time.

It remains to show that $\text{wrapped}(S,i)$ can be determined from $S$ and $\chi_2(S)$ by

```
function wrapped$(S, i)$ {
    Step 1. let $k$, with $1 \leq k \leq t$, be the type of $S[i]$;
    Step 2. let $i_1 = \min\{i, \text{match}(S, i)\}$;
    Step 3. let $i_2 = \text{match}(S, i_1)$;
    Step 4. let $(j, c) = M_3^k\left[\lceil i_1/\ell^2 \rceil\right]$; if $j = i_1$, then return $c$;
    Step 5. let $(j, c) = M_4^k\left[\lceil i_2/\ell^2 \rceil\right]$; if $j = i_2$, then return $c$;
    Step 6. let $(j, c) = M_5^k[\lceil i_1/\ell \rceil]$; if $j = i_1$, then return $c$;
    Step 7. let $(j, c) = M_6^k[\lceil i_2/\ell \rceil]$; if $j = i_2$, then return $c$;
    Step 8. if width$(i_1, i_2) \leq \ell$, then return $M_1[S[i_1, i_2]]$;
    Step 9. if width$(i_1, i_2) \leq 2\ell$, then return $M_1[S[i_1, i_1 + \ell - 1]] + M_2[S[i_1 + \ell, i_2]]$;
    Step 10. return $M_1[S[i_1, i_1 + \ell - 1]] + M_2[S[i_2 - \ell + 1, i_2]]$;
}
```

FIG. 5.1. *An $O(1)$-time algorithm that computes* wrapped(S,i).

the algorithm shown in Figure 5.1, which clearly runs in $O(1)$ time. If a value $c$ is returned from steps 4–9, we have $c = \text{wrapped}(S, i)$. The rest of the proof assumes that step 10 is executed. Since wide parentheses are $\ell^2$-disjoint and special parentheses are $\ell$-disjoint, parentheses $S[i_1]$ and $S[i_2]$ at step 10 satisfy $\text{width}(i_1, i_2) > 2\ell$ and form a matching pair of medium parentheses that are not special. By definition of special parentheses, there are indices $j_1$ and $j_2$ with $i_1 < j_1 < j_2 = \text{match}(S, j_1) < i_2$ and $S[i_1] = S[j_1]$ (thus $S[j_2] = S[i_2]$) such that $\text{width}(i_1, j_1) \leq \ell$ and $\text{width}(j_2, i_2) \leq \ell$. Since $\text{width}(i_1, i_2) > 2\ell$, we have $\text{wrapped}(S, i_1) = M_1[S[i_1, i_1 + \ell - 1]] + M_2[S[i_2 - \ell + 1, i_2]]$. Therefore, step 10 correctly returns $\text{wrapped}(S, i)$. □

A folklore encoding [22, 35, 9] $S$ of an $n$-node simple rooted tree $T$ is a balanced string of $2n$ parentheses representing a counterclockwise depth-first traversal of $T$. Initially, an open (respectively, closed) parenthesis denotes a descending (respectively, ascending) edge traversal. Then, this string is enclosed by an additional matching parenthesis pair. For example, the string in (5.2) is the folklore encoding for the tree $T$ in Figure 1.1(a). Let $v_i$ be the $i$th node in the counterclockwise depth-first traversal. Let $(_i$ be the $i$th open parenthesis in $S$. Let $)_i$ be the closed parenthesis of $S$ that matches $(_i$ in $S$. Node $v_i$ corresponds to $(_i$ and $)_i$ in that $v_i$ is the parent of $v_j$ in $T$ if and only if $(_i$ and $)_i$ form the closest pair of matching parentheses that encloses $(_j$ and $)_j$. Also, the number of children of $v_i$ in $T$ is precisely $\text{wrapped}(S, \text{select}(S, i, ())/2$, which is also equal to $\text{wrapped}(S, \text{match}(S, \text{select}(S, i, ()))/2$.

Let $H$ be an $n$-node connected plane graph that may have multiple edges but no self-loops. Let $T$ be a spanning tree of $H$ rooted at $v_1$. Let $v_1 v_2 \cdots v_n$ be the counterclockwise preordering of $T$. Let degree($i$) be the number of edges incident to $v_i$ in $H$. Let children($i$) be the number of children of $v_i$ in $T$. Let above($i$) (respectively, below($i$)) be the number of edges $(v_i, v_j)$ of $H$ such that $v_j$ is the parent (respectively, a child) of $v_i$ in $T$. Let low($i$) (respectively, high($i$)) be the number of edges $(v_i, v_j)$ of $H$ such that $j < i$ (respectively, $j > i$) and $v_j$ is neither the parent nor a child of $v_i$ in $T$. Now, $\text{degree}(i) = \text{above}(i) + \text{below}(i) + \text{low}(i) + \text{high}(i)$. If $H$ has no multiple edges, then $\text{below}(i) = \text{children}(i)$. If $H$ and $T$ are as shown in Figure 1.1(a), for instance, then $\text{above}(3) = 1$, $\text{below}(3) = \text{children}(3) = 2$, $\text{low}(3) = 1$, $\text{high}(3) = 2$, and $\text{degree}(3) = 6$.

The *$T$-code* of $H$ is a triple $(S_1, S_2, S_3)$ of the binary strings $S_1, S_2, S_3$, where $\delta_{i \geq 2}$ equals 1 if $i \geq 2$ and 0 otherwise.

- $S_1$ is the folklore encoding of $T$.

- Let $p_i = \text{select}(S_1, i, \texttt{(})$ and $q_i = \text{match}(S_1, p_i)$. $S_2$ has exactly $2n$ copies of 1, in which low$(i)$ copies of 0 immediately succeed the $p_i$th 1, and high$(i)$ copies of 0 immediately succeed the $q_i$th 1.
- $S_3$ has exactly $n$ copies of 1, where above$(i)$ + below$(i)$ − children$(i)$ − $\delta_{i\geq 2}$ copies of 0 immediately succeed the $i$th 1.

For example, if $H$ and $T$ are as shown in Figure 1.1(a), then

$$S_1 = \texttt{(()(()())()((()()()))());} \tag{5.2}$$
$$S_2 = \texttt{11100000101010100100100101000101010001010001001010101010000011;}$$
$$S_3 = \texttt{111111111111.}$$

We have that

$$|S_1| = 2n;$$
$$|S_2| = 2n + \sum_{i=1}^{n} (\text{low}(i) + \text{high}(i));$$
$$|S_3| = 1 + \sum_{i=1}^{n} (\text{above}(i) + \text{below}(i) - \text{children}(i)).$$

Therefore, $|S_1| + |S_2| + |S_3| = 2m + 3n + 2$. Moreover, if $H$ has no multiple edges, then $|S_3| = n$, and thus $|S_1| + |S_2| = 2m + 2n + 2$.

The next theorem describes our convenient encoding. The techniques in the proof are mostly adapted from [9]. (Their encoding needs initial augmentation to the input graph to ensure that the resulting graph admits a canonical spanning tree. As a result, their encoding requires an additional number of bits to tell which edges are original.)

THEOREM 5.4. *Let $G$ be an input $n$-node $m$-edge planar graph having no self-loops. If $G$ has* (*respectively, has no*) *multiple edges, then $G$ has a convenient encoding, obtainable in $O(m+n)$ time, with $2m + 3n + o(m+n)$* (*respectively, $2m + 2n + o(n)$*) *bits.*

*Proof.* We focus on the case that $G$ is connected. As sketched at the end of the proof, it is not difficult to remove this restriction. By Theorem 2.3, an orderly pair $(H, T)$ of $G$ can be derived in $O(m + n)$ time. Let $(S_1, S_2, S_3)$ be the $T$-code of $H$. We prove that there exists an $o(m + n)$-bit string $\chi$, obtainable in $O(m + n)$ time, such that $S_1 \circ S_2 \circ S_3 \circ \chi$ is a convenient encoding of $G$. If $G$ has no multiple edges, then $S_3$ consists of $n$ copies of 1, and thus $S_1 \circ S_2 \circ \chi$ will suffice.

To support degree queries, let $p_i = \text{select}(S_1, i, \texttt{(})$ and $q_i = \text{match}(S_1, p_i)$. Since $S[p_i]$ and $S[q_i]$ are a matching parenthesis pair, we have that

$$\text{low}(i) = \text{select}(S_2, p_i + 1, 1) - \text{select}(S_2, p_i, 1) - 1,$$
$$\text{high}(i) = \text{select}(S_2, q_i + 1, 1) - \text{select}(S_2, q_i, 1) - 1.$$

Observe that children$(i)$ = wrapped$(S_1, p_i)/2$. From the definition of $S_3$, we know above$(i)$ + below$(i)$ − children$(i)$ = select$(S_3, i + 1, 1)$ − select$(S_3, i, 1) - 1 + \delta_{i\geq 2}$. Let $\chi' = \chi_1(S_1) \circ \chi_1(S_2) \circ \chi_1(S_3) \circ \chi_2(S_1)$. From degree$(i)$ = above$(i)$ + below$(i)$ + low$(i)$ + high$(i)$, Fact 5.2, and Lemma 5.3, we determine that degree$(i)$ is computable from $S_1 \circ S_2 \circ S_3 \circ \chi'$ in $O(1)$ time.

To support adjacency queries and listing of all neighbors, we introduce a string $S$ of two types of parentheses derived from $S_1$ and $S_2$ as follows. Although $S$ is only implicitly represented in our convenient encoding, any $O(\log n)$ consecutive parentheses of $S$ can be obtained from $S_1$, $S_2$, and some auxiliary string in $O(1)$ time. Let $\texttt{(}$

and `)` be of type 1, and let `[` and `]` be of type 2. Initially, for each $i = 1, 2, \ldots, 2n$, replace the $i$th 1 of $S_2$ with $S_1[i]$. Then, replace each 0 of $S_2$ with a bracket such that the bracket is open if and only if the last parenthesis in $S$ preceding this 0 is closed. More precisely, for each $i = 1, 2, \ldots, |S_2|$, let

$$S[i] = \begin{cases} S_1[j_1] & \text{if } S_2[i] = 1, \\ \texttt{]} & \text{if } S_2[i] = 0 \text{ and } S_1[j_i] = \texttt{(}, \\ \texttt{[} & \text{if } S_2[i] = 0 \text{ and } S_1[j_i] = \texttt{)}, \end{cases}$$

where $j_i = \operatorname{rank}(S_2, i, 1)$. For example, if $H$ and $T$ are as given in Figure 1.1(a), then $S$ is as in (5.1). There exists an auxiliary string $\chi_3$ such that any $O(\log n)$ consecutive symbols of $S$ are obtainable from $S_1 \circ S_2 \circ \chi_3$ in $O(1)$ time: Let $\ell = \lfloor \frac{1}{8} \log_2 n \rfloor$. Observe that the content of $S[i, i + \ell - 1]$ can be uniquely determined from the concatenation $S'$ of $S_2[i, i + \ell - 1]$ and $S_1[j, j + \ell - 1]$ with $j = \operatorname{rank}(S_2, i, 1)$. Also, $S'$ is obtainable from $S_1 \circ S_2 \circ \chi_1(S_2)$ in $O(1)$ time. Since $S'$ has $4^\ell$ distinct values, we can precompute in $O(n)$ time an $o(n)$-bit table $M$ such that the content of $S[i, i + \ell - 1]$ is obtainable from $S'$ and $M$ in $O(1)$ time. Hence, it suffices to let $\chi_3 = M \circ \chi_1(S_2)$.

With the help of $S$ and its auxiliary strings, adjacency queries can be supported as follows. For any two integers $a$ and $b$, let $[a, b]$ consist of the integers $a, a+1, \ldots, b$. For each $i \in \{1, 2, \ldots, n\}$, let

$$\begin{aligned} L_i &= [\ell_i + 1, \operatorname{select}(S_2, \operatorname{rank}(S_2, \ell_i, 1) + 1, 1) - 1], \\ R_i &= [h_i + 1, \operatorname{select}(S_2, \operatorname{rank}(S_2, h_i, 1) + 1, 1) - 1], \end{aligned}$$

where $\ell_i = \operatorname{select}(S, i, \texttt{(})$ and $h_i = \operatorname{match}(S, \ell_i)$. Let $(v_i, v_j)$ and $(v_{i'}, v_{j'})$, with $i < j$ and $i' < j'$, be two unrelated edges of $H$ with respect to $T$. Since $T$ is an orderly spanning tree of $H$, one can see that if $(v_{i'}, v_{j'})$ is enclosed by the cycle of $H$ determined by $T$ and $(v_i, v_j)$, then $h_i < h_{i'} < \ell_{j'} < \ell_j$. One can prove that

> $v_i$ and $v_j$, with $i < j$, are adjacent in $H - T$ if and only if there exists an index $\ell \in R_i$ with $\operatorname{match}(S, \ell) \in L_j$

by the following induction on the number $b$ of matching bracket pairs in $S$:

> The above statement clearly holds when $b = 0$. To show the induction step for any $b \geq 1$, let $e = (v_x, v_y)$ be an edge in $H - T$. We know that $T$ is also an orderly spanning tree of $H - \{e\}$. Let $\hat{S}$, $\hat{R}_i$, and $\hat{L}_i$ be the corresponding notation for $H - \{e\}$ with respect to $T$. Observe that $\hat{S}$ can be obtained from $S$ by deleting an open bracket in a position in $R_x$ and deleting a closed bracket in a position in $L_y$. Since $v_x$ and $v_y$ are not adjacent in $H - \{e\}$, it follows from the inductive hypothesis that $\operatorname{match}(\hat{S}, \ell) \notin \hat{L}_y$ holds for any index $\ell$ in $\hat{R}_x$; and $\operatorname{match}(\hat{S}, \ell) \notin \hat{R}_x$ holds for any index $\ell$ in $\hat{L}_y$. Therefore, there is a position in $\hat{R}_x$ and a position in $\hat{L}_y$ such that if we insert an open bracket in the first position and a closed bracket in the second position, then the brackets will match each other in the resulting string, which is exactly $S$. Thus, the above statement is proved.

Thus, one can determine whether $(v_i, v_j)$ is an unrelated edge of $H$ with respect to $T$, by checking whether $i'' \in R_i$ and $j'' \in L_j$ hold, where

$$(i'', j'') = \operatorname{enclose}_2(S, \operatorname{select}(S, \operatorname{rank}(S_2, h_i, 1) + 1, \texttt{(}), \ell_j).$$

Therefore, the answer to each adjacency query is derivable from $S_2 \circ S \circ \chi_1(S_2) \circ \chi_1(S)$ in $O(1)$ time.

The neighbors of a degree-$d$ node $v_i$ can be listed from $S \circ \chi_1(S)$ in $O(d)$ time: If $v_i$ is not the root of $T$, then the parent of $v_i$ is $v_j$, where $j$ is computable by letting

$$\begin{aligned}(j_1, j_2) &= \mathrm{enclose}(S, \mathrm{select}(S, i, (), \mathrm{match}(S, \mathrm{select}(S, i, ()));\\ j &= \mathrm{rank}(S, j_1, ().\end{aligned}$$

If $v_i$ is not a leaf of $T$, then $v_{i+1}$ is the first child of $v_i$ in $T$. If $v_j$ is the $t$th child of $v_i$ in $T$, then the $(t+1)$st child of $v_i$ in $T$ is $v_k$, where

$$k = \mathrm{rank}(S, 1 + \mathrm{match}(S, \mathrm{select}(S, j, ()), ().$$

If $t \le |U_<(v_i)|$, the $t$th neighbor of $v_i$ in $U_<(v)$ with respect to $T$ is $v_j$, where $j$ is computable by

$$\begin{aligned}j_1 &= \mathrm{match}(S, t + \mathrm{select}(S, i, ());\\ j_2 &= \mathrm{select}(S, \mathrm{rank}(S, j_1, )), ));\\ j &= \mathrm{rank}(S, \mathrm{match}(S, j_2), ().\end{aligned}$$

If $t \le |D(v_i)|$, then the $t$th neighbor of $v_i$ in $D(v)$ with respect to $T$ is $v_j$, where $j$ is computable by $j_1 = \mathrm{match}(S, \mathrm{select}(S, i, ())$ and $j = \mathrm{rank}(S, \mathrm{match}(S, j_1 + t), ()$.

It is not difficult to verify that $G$ can be reconstructed from $S$ and $S_3$ in $O(m + n)$ time. Therefore, the theorem for connected planar graphs is proved by letting $\chi = \chi' \circ \chi_3 \circ \chi_1(S)$. As for the case that $G$ has $k \ge 2$ connected components, by Theorem 2.3, an orderly pair $(H^i, T^i)$ of the $i$th connected component $G^i$ of $G$ can be derived in overall $O(m + n)$ time. Let $(S_1^i, S_2^i, S_3^i)$ be the $T^i$-code of $H^i$. For each $j = 1, 2, 3$, let $S_j$ be the concatenation of $S_j^1, S_j^2, \ldots, S_j^k$. The theorem can then be proved similarly using $S_1$, $S_2$, and $S_3$. ☐

# $\Omega(\log n)$ LOWER BOUNDS ON THE AMOUNT OF RANDOMNESS IN 2-PRIVATE COMPUTATION*

ANNA GÁL[†] AND ADI ROSÉN[‡]

**Abstract.** We consider the amount of randomness necessary in information-theoretic private protocols. We prove that at least $\Omega(\log n)$ random bits are necessary for the $t$-private computation of the function xor by $n$ players for any $t \geq 2$. In view of the upper bound of $O(t^2 \log(n/t))$ [E. Kushilevitz and Y. Mansour, *SIAM J. Discrete Math.*, 10 (1997), pp. 647–661], this bound is tight, up to constant factors, for any fixed $t$. For a class of protocols obeying certain restrictions, we give a stronger lower bound of $\Omega(t \log(n/t))$. We note that all known randomness efficient private protocols designed specifically for xor belong to this class. In fact we prove slightly stronger statements: we prove that on *every* input there is a run where the number of random bits used is large, rather than proving only that on some input there is a run where the number of random bits used is large. All our lower bounds hold for the "trusted dealer" model as well, and the $\Omega(t \log(n/t))$ lower bound for restricted protocols is tight, up to constant factors, for any $t \geq 2$ in this model.

In comparison, the previous lower bounds on the amount of randomness required by $t$-private computation of explicit functions did not grow with $n$ for constant values of $t$, and our results improve the previous lower bounds for xor for any $2 \leq t = o(\log n)$. Our results also show that already for $t = 2$, $\Omega(\log n)$ random bits are necessary, while it is known that for the case of $t = 1$ a single random bit is sufficient for privately computing xor for any number of players.

Our proofs use novel techniques by which we extract random variables from a $t$-private protocol, and then use the $t$-privacy property of the protocol to prove properties of these random variables. These properties in turn imply that the number of random bits used by the players is large.

**Key words.** private computation, randomness, lower bounds

## 1. Introduction.

A *t-private* protocol for computing a function $f$ is a distributed protocol that allows $n$ players $P_i$, $1 \leq i \leq n$, each possessing an individual secret input $x_i$, to compute the value of $f(\vec{x})$ in a way that does not reveal any "unnecessary" information to any coalition of at most $t$ players. The players proceed in rounds, where in each round each player can send a private message to any other player (i.e., each player sends to each other player a message that cannot be seen by any of the remaining players). The $t$-privacy property means that any coalition of at most $t$ players cannot learn anything from the execution of the protocol, except what is implied by the value of $f(\vec{x})$ and the inputs of the members of the coalition. In particular, the members of the coalition do not learn anything about the inputs of the other players. Private computation in this setting was the subject of considerable research; see, e.g., [2, 3, 4, 6, 7, 11, 13, 14, 15, 16, 17, 19, 21, 23, 24, 29]. Randomness is necessary to perform private computations involving more than two players (except for the computation of very degenerate functions). That is, the players must have access to a random source. As randomness is regarded as a scarce

resource, methods for saving random bits in various contexts have been suggested in the literature; see, e.g., [28, 18] for a survey. Thus, an important research topic is the design of randomness-efficient private protocols, and the quantification of the amount of randomness needed to perform private computations of various functions and under various constraints. This line of research has received considerable attention in recent years; see, e.g., [27, 23, 25, 17, 7, 8, 10, 26, 5, 20]. This study also showed that the randomness complexity of the private computation of a function is related to other complexity measures, such as sensitivity and circuit size [27, 25, 17, 7, 26]. The specific function `xor` (addition modulo 2) was the subject of considerable research in this context due to its being a basic operation and its relative simplicity [27, 26, 8, 23].

Previous work on the randomness complexity of private computations revealed that there is a tradeoff between randomness and time (i.e., number of communication rounds) for the 1-private computation of the function `xor` [27, 17]. These works also gave lower bounds on the number of rounds necessary to 1-privately compute any function in terms of the sensitivity of the function and the amount of randomness used. If one is allowed an arbitrary number of rounds for the computation, there are no known lower bounds on the number of random bits for 1-private protocols computing explicit functions (except that randomness is necessary, i.e., no deterministic private protocol exists). In fact, Kushilevitz, Ostrovsky, and Rosén [25] gave a relation between the number of random bits necessary to 1-privately compute a function and the Boolean circuit size necessary to compute it; it is proved that the class of functions that have $O(1)$-random, 1-private protocols is equal to the class of functions that have linear-size circuits. This surprising connection explains the lack of $\omega(1)$ lower bounds on the number of random bits for explicit functions in the case of 1-privacy, as such results would imply superlinear lower bounds on circuit size.

Before our work, $\omega(1)$ lower bounds on the number of random bits of $t$-private protocols (without limiting the number of rounds) have been proved for explicit functions only for values of $t$ that grow with $n$, and no such bounds have been known if $t$ itself is constant. More precisely, Kushilevitz and Mansour [23] proved that any $t$-private protocol for `xor` requires at least $t$ random bits. Blundo et al. [7] gave lower bounds for two special cases. Namely, they proved that if $t = n - c$ for some constant $c$, then $\Omega(n^2)$ random bits are necessary, and if $t \geq (2 - \sqrt{2})n$, then $\Omega(n)$ random bits are necessary. As for upper bounds, Canetti et al. [10] gave randomness-efficient generic protocols to $t$-privately compute (for $t < n/2$) any Boolean function $f$. They showed that any function $f$ with circuit size of $m$ gates can be computed by a $t$-private protocol ($t < n/2$) using $O(t^2 \log n + (m/n)t^5 \log t)$ random bits. Kushilevitz and Mansour [23] gave protocols that compute the function `xor` $t$-privately, for any $t$, using $O(t^2 \log(n/t))$ random bits.

In the present paper we develop new techniques for proving lower bounds on the number of random bits necessary in $t$-private computations (for $t \geq 2$) and obtain $\Omega(\log n)$ lower bounds on the number of random bits necessary to $t$-privately compute the function `xor` for any $t \geq 2$.[1] More precisely, we prove the following theorem. (See section 2 for a formal definition of a $d$-random protocol.)

THEOREM 1.1. *Let $t \geq 2$, and let $\mathcal{A}$ be a $d$-random, $t$-private protocol for computing $f(\vec{x}) = x_1 + \cdots + x_n \pmod 2$. Then $d = \Omega(\log n)$.*

In fact, we prove a slightly stronger statement: we prove that $\Omega(\log n)$ random bits are necessary on *every* input.

[1]Blundo, Galdi, and Persiano [9] recently reported obtaining similar results independently, using a different approach.

In view of the upper bound of $O(t^2 \log(n/t))$ of [23], our lower bound is tight, up to constant factors, for any fixed $t$. This is the first result showing that the number of random bits necessary for $t$-private computation grows with $n$ for constant values of $t$, and it improves the lower bound of [23] for any $t = o(\log n)$. It is interesting to note that our $\Omega(\log n)$ lower bound holds already for $t = 2$, while for the case of $t = 1$, it is known that the function `xor` can be computed 1-privately, for any number of players $n$, with only 1 random bit.

All known randomness-efficient private protocols designed specifically for the function `xor` [27, 23, 26, 8] are built in the following special way. They are based on a deterministic, nonprivate protocol for `xor`. Then this protocol is modified by changing any message so it is the sum (modulo 2) of the original message, and a value which is a function of the random bits only. Thus, the private protocol is built by masking the original messages of the nonprivate protocol. We give stronger lower bounds for protocols of this class (see section 4 for a formal definition of this class). Namely, we give a lower bound of $\Omega(t \log(n/t))$ on the number of random bits required by any protocol of this class to compute `xor` for $n$ players.

All our lower bounds hold also in the "trusted dealer" model, considered in [23, 10]. In this model, the $n$ players are deterministic, and there is an additional player, the "trusted dealer," who does not get any input, and whose role is limited to "deal" random bits to the other players (hence a "dealer"). This player never participates in any coalition (hence it is "trusted"). For this model, our lower bound of $\Omega(t \log(n/t))$ for protocols of the above restricted class is tight up to constant factors for every $t \geq 2$, as [23] gave a protocol (of this class) in the trusted dealer model using $O(t \log(n/t))$ random bits.

Our proofs use novel techniques by which we extract from a private protocol random variables that depend on the randomness that the players use. We then use the $t$-privacy property of the protocol to prove that these random variables must have certain properties (for example, linear independence or $t$-wise independence). Based on these properties we show that the amount of randomness used by the players must be large. We believe that these new techniques may prove useful for proving other properties of private protocols.

## 2. Preliminaries.

In this paper we consider information-theoretic privacy (as in [4, 11]), where the players have unlimited computational power, no intractability assumptions are made, and messages are sent over private channels.

Let $f : \{0,1\}^n \to \{0,1\}$ be an arbitrary Boolean function. A set of $n$ players $P_i$ ($1 \leq i \leq n$), each possessing a single private input bit $x_i$ (i.e., $x_i$ is known *only* to $P_i$), collaborate in a protocol to compute the value of $f(\vec{x})$. The protocol is probabilistic. During the course of the protocol each player can toss random coins, where the coin tosses are unbiased and independent. The protocol operates in rounds. In each round, each player may toss some coins, and then sends messages to the other players (messages are sent over private channels so that, other than the intended receiver, no other player can access them). The player then receives the messages sent to it by the other players. Each player chooses to output the value of the function at a certain round. In a correct protocol, each player must output the correct value $f(\vec{x})$, and stop its operation in a finite number of steps (it may output $f(\vec{x})$ before stopping). That is, for every input assignment $\vec{x}$ and for every outcome of the coin tosses of all players, each player outputs $f(\vec{x})$ and stops in a finite number of steps.

In Claim 1 below we formally argue that for a given correct protocol involving $n$ players, there is a finite upper bound $\ell$ on the number of coin tosses any single player performs during the course of the protocol. We in fact show that there is a finite upper bound $\ell$ on the total number of coin tosses performed by all players. Claim 1 gives a formal argument for the intuition that a protocol for which such an upper bound does not exist is not a correct protocol. For example, consider a protocol where some player keeps tossing coins until it gets a 1 before sending any message. For such a protocol, the property claimed does not hold. But such a protocol does not satisfy the definition of correctness either, as there are possible outcomes of the coin tosses for which some player does not stop in a finite number of steps. We note that since we prove lower bounds on the number of random bits used, we could avoid using Claim 1 by the following argument: we could argue that if on some input, some player may toss more than $\ell$ coins, then a lower bound of $\ell$ is obtained; otherwise one can assume that no player ever tosses more than $\ell$ coins. This would be sufficient to prove lower bounds on the randomness complexity of the protocol (see Definition 2.1). However, we prove stronger statements. Claim 1 is useful in proving that on *every* input there is a run where the number of coin tosses performed is large, rather than only proving that on some input there is a run where the number of coin tosses performed is large.

CLAIM 1. *Given a correct protocol involving $n$ players, there is a finite upper bound $\ell$ on the total number of coin tosses performed by all players in any run of the protocol.*

*Proof.* We show below that for any input assignment $\vec{x}$ there is a finite upper bound $\ell(\vec{x})$ on the total number of coin tosses performed by all players in any run of the protocol in which the input assignment is $\vec{x}$. Since there is a finite number of input assignments $\vec{x} \in \{0,1\}^n$, the claim follows by letting $\ell = \max_{\vec{x}\in\{0,1\}^n}\{\ell(\vec{x})\}$.

Fix an input assignment $\vec{x} \in \{0,1\}^n$. As in the proof of Lemma 4.10 in [27], we build a binary tree $T_{\vec{x}}$ representing the coin tosses of the players on a given input $\vec{x}$. Each node of the tree is labeled by the name of a player $P_i$, which tosses a coin. The two outgoing edges from a node are labeled 0 and 1 according to the outcome of the coin toss. Coin tosses in the run of the protocol are ordered by round number, then by player number, and then by a serial number (for that player in that round). Note that the identity of the player to toss the first coin on $\vec{x}$, that is, the label of the root, is determined by $\vec{x}$, and the identity of any subsequent player to toss a coin is determined by $\vec{x}$ and the outcomes of the previous coin tosses, that is, by the path leading to a given node of the tree.

Observe that a path of length $k$ from the root to another node represents a run (or a prefix of a run) of the protocol in which $k$ coin tosses occur. Assume towards a contradiction that there is no finite upper bound $\ell(\vec{x})$ on the number of coin tosses performed by the players on input $\vec{x}$. Then for every finite $k$ there is a path of length $k$ in the tree. Since the outdegree of each node of the tree is at most 2, this means that the tree $T_{\vec{x}}$ must contain an infinite path starting from the root (cf. König's lemma in [22]). This path corresponds to a possible run of the protocol (defined by $\vec{x}$ and the results of the coin tosses as defined by the edges along the path). In this run at least one player tosses an infinite number of coins, i.e., this player does not stop in a finite number of steps, contradicting the correctness of the protocol. ∎

We thus model the players in a correct protocol as being provided with finite binary random tapes. That is, in a correct protocol involving $n$ players to compute a function $f$, each player $P_i$ is provided with a local binary random tape $R_i$ of length $\ell$. Note that the value of $\ell$ may be different for different protocols and different numbers of players $n$. The bits in the random tapes are unbiased and independent. We denote by $\vec{R} = (R_1, \ldots, R_n)$ a given vector of random tapes of all players, and we think of $\vec{R}$ as a binary vector of length $n\ell$.

The following definition is used to measure the amount of randomness used in a protocol.

Definition 2.1 (randomness complexity of a protocol). *A $d$-random protocol is a protocol such that for any input assignment and any vector of local random tapes, the total number of random bits read from the local random tapes by all players is at most $d$.*

We emphasize that the definitions allow, for example, that in different executions of a protocol (i.e., different input assignments and different local random tapes), a given player reads a different number of random bits from its local random tape. The number of random bits read by the player may depend on both the inputs of the players and the random bits read by all players.

We now proceed to consider the messages exchanged by the players. Each player $P_i$ receives during the execution of the protocol a sequence of messages. In different runs of a protocol the various players may receive different messages. These depend on the input to the players and on the random tapes. We denote the communication seen by a player as follows.

Definition 2.2. *The* communication $c_i(\vec{x}, \vec{R})$, *of player $P_i$, on input $\vec{x}$ and vector of random tapes $\vec{R} = \{R_i\}_{1 \le i \le n}$, is the sequence of messages that player $P_i$ receives during the execution of the protocol when the input is $\vec{x}$ and the vector of random tapes of all players is $\vec{R}$.*

Thus, $c_i$ is the (random) variable of the sequence of messages received by $P_i$. For a subset of the players $S$, we denote by $c_S$ the (random) variable of the sequences of messages received by all the players in $S$. Informally, *$t$-privacy* means that any coalition of up to $t$ players cannot learn anything (in particular, the inputs of the other players) from the communication that the members of the coalition receive, except what is implied by the input bits of the members of that coalition, and the value of the function computed. Formally, we give the following definition.

Definition 2.3 (privacy). *A protocol for computing a function $f$ is private with respect to a subset of the players $S \subseteq [n]$ if the following holds. For any two input vectors $\vec{x}$ and $\vec{y}$ such that $f(\vec{x}) = f(\vec{y})$, and $x_i = y_i$ for any $i \in S$, and for any sequence of messages $C_S$, and for any vector of random tapes for the subset $S$, $\{R_i\}_{i \in S}$,*

$$\Pr[c_S = C_S | \{R_i\}_{i \in S}, \vec{x}\,] = \Pr[c_S = C_S | \{R_i\}_{i \in S}, \vec{y}\,] \ ,$$

*where the probability is over the random tapes of the players.*

A protocol is said to be $t$-private if it is private with respect to any subset of players $S$ such that $|S| \le t$.

It will be convenient in our proofs to use a weaker privacy requirement, directly implied by the $t$-privacy property, as stated in the following lemma. (Note that since we prove lower bounds, this only makes our results stronger.)

Lemma 2.4. *Consider any $t$-private protocol. For any subset $S$ of the players $S \subseteq [n]$ such that $|S| \le t$, and for any two input vectors $\vec{x}$ and $\vec{y}$ such that $f(\vec{x}) = f(\vec{y})$ and $x_i = y_i$ for any $i \in S$, the following holds:*

1. *For any sequence of messages $C_S$,*

$$\Pr[c_S = C_S | \vec{x}\,] = \Pr[c_S = C_S | \vec{y}\,] \ ,$$

*where the probability is over the vectors $\vec{R}$ chosen uniformly from $\{0,1\}^{n\ell}$.*

2. *For any function $\phi^S$ of $c_S$, and for any value $\Phi$ in the range of $\phi^S$,*

$$\Pr[\phi^S = \Phi | \vec{x}\,] = \Pr[\phi^S = \Phi | \vec{y}\,] \ ,$$

*where the probability is over the vectors $\vec{R}$ chosen uniformly from $\{0,1\}^{n\ell}$.*

*Proof.* Let $s$ be the size of $S$, i.e., $s = |S|$. Fixing a vector of random tapes for the subset $S$, $\{R_i\}_{i \in S}$, is equivalent to fixing a binary vector of length $s\ell$. The probability of each of these $2^{s\ell}$ vectors is $2^{-s\ell}$, and the events corresponding to the various vectors are disjoint. Therefore we have

$$\Pr[c_S = C_S | \vec{x}\,] = 2^{-s\ell} \sum_{\{R_i\}_{i \in S} \in \{0,1\}^{s\ell}} \Pr[c_S = C_S | \{R_i\}_{i \in S}, \vec{x}\,] \ .$$

Using the same arguments, applied to $\vec{y}$ instead of $\vec{x}$, we have that

$$\Pr[c_S = C_S | \vec{y}\,] = 2^{-s\ell} \sum_{\{R_i\}_{i \in S} \in \{0,1\}^{s\ell}} \Pr[c_S = C_S | \{R_i\}_{i \in S}, \vec{y}\,] \ .$$

But, by the privacy property of the protocol we have that for any vector of random tapes for the subset $S$, $\{R_i\}_{i \in S}$,

$$\Pr[c_S = C_S | \{R_i\}_{i \in S}, \vec{x}\,] = \Pr[c_S = C_S | \{R_i\}_{i \in S}, \vec{y}\,] \ .$$

We therefore obtain that

$$\Pr[c_S = C_S | \vec{x}\,] = \Pr[c_S = C_S | \vec{y}\,] \ .$$

The second statement of the lemma follows by observing that the value of $\phi^S$ is fixed given any communication $C_S$. □

From the point of view of an observer of the protocol, one can define the *transcript* of a given run of the protocol, which is the sequence of all messages sent between all players during the execution of the protocol on input $\vec{x}$ and vector of random tapes $\vec{R}$. The transcript is in fact the ordered vector of the communication of all players.

Definition 2.5. *The* transcript $Trans(\vec{x}, \vec{R})$ *of a protocol on input $\vec{x}$ and vector of random tapes $\vec{R} = \{R_i\}_{1 \leq i \leq n}$ is $(c_1(\vec{x}, \vec{R}), c_2(\vec{x}, \vec{R}), \ldots, c_n(\vec{x}, \vec{R}))$.*

The following lemma follows immediately from the arguments of the proof of Lemma 4.10 in [27]. We will use this lemma in our proofs.

Lemma 2.6 (see [27]). *For a given input $\vec{x}$, let $d$ be the maximum, over all runs on input $\vec{x}$, of the total number of random bits read from the random tapes by all players during a given run. Then the number of different transcripts of runs on input $\vec{x}$ is at most $2^d$.*

It is convenient in our proofs to consider the messages sent by the players as being messages of single bits. This is done by "breaking" each message into the bits of its binary representation. Formally, for a given protocol involving $n$ players, let $M$ be the set of all different messages that can be sent in the protocol in all different runs (over all possible inputs $\vec{x} \in \{0,1\}^n$ and all possible vectors of random tapes $\vec{R} \in \{0,1\}^{n\ell}$). Fix an arbitrary one-to-one binary encoding of fixed length for the messages in $M$. We note that the empty message is one of the elements of $M$. We consider a protocol where each player sends, instead of a given message from $M$, a sequence of single-bit messages that represents the binary encoding of the original message from $M$. Henceforth, when we refer to *messages* we refer to these single-bit messages. It is important for our argument that the number of transcripts of the protocol, on any given input $\vec{x}$, remains the same. This follows since we use a one-to-one encoding.

Since we consider each message as being a single bit, we can think of a given message $m$ as a Boolean function of the input $\vec{x}$, which is a binary vector of length $n$, and the random tapes of all players, which is a binary vector of length $n\ell$. We therefore can write $m$ as $m = m(\vec{x}, \vec{R})$.

Our lower bound exploits the fact that the function xor has large sensitivity on every input. Sensitivity is defined as follows.

DEFINITION 2.7 (sensitivity).

- *Given $\vec{x} \in \{0,1\}^n$, we denote by $\vec{x}^{(i)}$ the vector $\vec{x}$ with its ith bit flipped. (Similarly, $\vec{x}^{(i,j)}$ is $\vec{x}$ with its ith and jth bits flipped.)*
- *A function $f$ is* sensitive *to its ith variable on input $\vec{x}$ if $f(\vec{x}) \neq f(\vec{x}^{(i)})$.*
- *$s(f, \vec{x})$ is the number of variables to which the function $f$ is sensitive on input $\vec{x}$.*
- *The* sensitivity *of a function $f$ is $s(f) = \max_{\vec{x}} s(f, \vec{x})$.*

Note that the function xor (addition modulo 2) of $n$ binary variables is sensitive to all its $n$ variables on any input. This immediately follows since for any $\vec{x} \in \{0,1\}^n$, and for any $i \in [n]$, $\texttt{xor}(\vec{x}) \neq \texttt{xor}(\vec{x}^{(i)})$.

We will further need the following definitions.

DEFINITION 2.8.

- *A message $m$ depends on the variable $x_i$ if there exist $\vec{x}$ and $\vec{R}$, such that $m(\vec{x}, \vec{R}) \neq m(\vec{x}^{(i)}, \vec{R})$. In other words, $m$ depends on the variable $x_i$ if $m$ is sensitive to $x_i$ on some $\vec{x}$ and $\vec{R}$.*
- *For $i \leq j$, a message $m$ depends on a variable $x_j$ under the partial assignment $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$ if there exists an assignment to the remaining variables $x_i, \ldots, x_n$ and there exists $\vec{R}$, such that $m(\alpha_1, \ldots, \alpha_{i-1}, x_i, \ldots, x_j, \ldots, x_n, \vec{R}) \neq m(\alpha_1, \ldots, \alpha_{i-1}, x_i, \ldots, \bar{x_j}, \ldots, x_n, \vec{R})$.*

We will use the following simple observation.

OBSERVATION 1. *Let $m = m(\vec{x}, \vec{R}) = \phi(f_1(\vec{x}, \vec{R}), \ldots, f_u(\vec{x}, \vec{R}))$. If $m$ depends on a variable $x_j$ under the partial assignment $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$, then at least one of the functions $f_1, \ldots, f_u$ depends on the variable $x_j$ under the partial assignment $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$.*

## 3. Lower bound for general protocols.

In this section we give a lower bound that applies to any $t$-private protocol for xor for $t \geq 2$. We first outline our approach, which is common to the general lower bound and to the stronger lower bound for the restricted class of protocols (given in section 4) and then proceed to give the proof of Theorem 1.1.

### 3.1. Our approach.

We state informally the approach we use in our proofs. Our proofs proceed in two stages. First, we prove that in any $t$-private protocol for xor we can identify $q = \Omega(n)$ distinct messages $m_1, \ldots, m_q$ with certain properties. Informally these properties are as follows:

(1) We can permute the input vector (and accordingly the set of players), such that for any $i$, message $m_i$ depends on input $x_i$ but does not depend on any input $x_j$, $j > i$.

(2) The set of receivers of these messages is disjoint from the set of players that have access to the inputs $x_i$, $1 \leq i \leq q$.

In the second stage of our proofs we consider the values of these selected messages on a given input assignment. That is, we consider the vectors representing the values of these messages over the possible random tapes to all players, when the input assignment is fixed. Using the properties of the private protocol and the properties of the special set of selected messages, we then prove, in the case of a general $t$-private protocol, that these vectors are linearly independent. In the case of a protocol of the restricted class, we prove that all the vectors obtained from sums of at most $t/2$ original vectors are linearly independent. In each case, this allows us to conclude that the number of different columns in the matrix obtained from the vectors as rows is "large" (where the extent to which this number is large is different in each case). It follows that the number of transcripts of the protocol on the given input is "large," and hence, using Lemma 2.6, the randomness complexity of the protocol is "high."

**3.2. Proof of Theorem 1.1.** In this section, as well as in section 4, we always assume that the computed function is `xor`. We now proceed to prove Theorem 1.1. In fact we prove here a stronger claim than the claim of Theorem 1.1. We prove that for any input assignment $\vec{\alpha} = \alpha_1, \ldots, \alpha_n$, there is a run in which the number of random bits read by the players from their random tapes is $\Omega(\log n)$.

**3.2.1. Selecting the messages.** Let $\vec{\alpha} = \alpha_1, \ldots, \alpha_n$ be an arbitrary input assignment. Given a fixed $\vec{\alpha}$, we will define a sequence of messages. (We will not indicate in our notation that the choice of this sequence depends on $\vec{\alpha}$, but this should be clear from the context.)

We define an ordering of all the messages sent during the protocol in order to be able to refer to *the first* message with a given property. Then, based on this ordering, we select a sequence of messages with certain properties. The choice of these messages will induce a particular permutation of the input bits; and since each input bit belongs to a given player, this induces a permutation of the players as well.

DEFINITION 3.1. *We define an ordering of all messages, such that in this ordering, any message sent in round $i$ precedes any message sent in round $j$ for $i < j$. For the messages sent within the same round we choose an arbitrary ordering.*

When we refer to the first message with a given property, we mean the first message according to the above ordering that satisfies that property.

During the process of selecting the sequence of messages, we also assign a particular numbering to the input bits and to the players. To this end, when selecting a given message, a variable and a player are also selected, and both are given the same number as the message. That is, when the first $i$ messages $m_1, \ldots, m_i$ have been selected, the variables $x_1, \ldots, x_i$ and the players $P_1, \ldots, P_i$ are also already selected. (We assume an arbitrary permutation of the remaining indices $i + 1, \ldots, n$ for the remaining variables and players.) When the process ends (after selecting $n$ messages) a permutation of the variables and a permutation of the players is fixed.

We now proceed to the selection process. Let $m_1$ be the first message in the protocol that depends on at least one input variable. We will argue below that since this is the first such message, it can depend on only one input variable, and without loss of generality, we denote this input variable by $x_1$, and the player that has access to it by $P_1$.

Let $m_2$ be the first message in the protocol that depends on at least one input variable under $x_1 = \alpha_1$. We will argue below that since this is the first such message, there is only one such input variable, and without loss of generality we denote it by $x_2$, and the player that has access to it by $P_2$.

Inductively, let $m_i$ be the first message sent in the protocol that depends on some input variable under $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$. We prove the following claim.

CLAIM 2. *Let $x_k$ be any input variable on which $m_i$ depends under $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$. Then the sender of the message $m_i$ must be the player that has access to the variable $x_k$, that is, player $P_k$.*

*Proof.* Suppose that the sender of the message $m_i$ is a player $P_j$ such that $j \neq k$ (i.e., $P_j$ is not the owner of $x_k$). Note that a message $m$ sent in a given round by player $P_j$ is a function of only the communication to player $P_j$ in previous rounds, its input $x_j$, and its random tape $R_j$. Thus, by Observation 1, if $P_j$ is not the owner of the variable $x_k$, it can send a message that depends on $x_k$ under $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$ only if it received in an earlier round a message that depends on $x_k$ under $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$. But this contradicts the assumption that $m_i$ is the first such message. □

The above claim implies that there is only one input variable on which $m_i$ depends under $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$. Without loss of generality we denote it by $x_i$, and the player that has access to it by $P_i$. Thus we derive the following.

CLAIM 3.

1. *The message $m_i$ is sensitive to $x_i$ on the input $\vec{\alpha}$ and some vector of random tapes $\vec{R}$.*
2. *Let $\vec{\beta}$ be any input that agrees with $\vec{\alpha}$ in the first $i-1$ coordinates, and let $j > i$. Then the message $m_i$ is not sensitive to the variable $x_j$ on $\vec{\beta}$ and $\vec{R}$ for any $\vec{R}$.*

*Proof.* We selected $m_i$ such that $m_i$ depends on $x_i$ under $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$. This means that there is some assignment to the remaining variables and some $\vec{R}$ such that $m_i$ is sensitive to $x_i$ on the input obtained by the additional assignment and $\vec{R}$. But since $x_i$ is the only input variable on which $m_i$ depends under $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$ this also means that $m_i$ is sensitive to $x_i$ on $\vec{\alpha}$ and $\vec{R}$.

We obtain the second statement using the observation that $x_i$ is the only input variable on which $m_i$ depends under $x_1 = \alpha_1, \ldots, x_{i-1} = \alpha_{i-1}$. □

CLAIM 4. *We can continue the above procedure of selecting messages for $n$ steps and define the sequence of messages $m_1, \ldots, m_n$.*

*Proof.* In a correct protocol to compute the function $f$, the output of each player has to be equal to $f(\vec{\alpha})$ on any input $\vec{\alpha}$. Note that the output of a given player depends only on the communication it received, its input bit, and its random tape. Since the sensitivity $s(f, \vec{\alpha})$ of the function $f(\vec{x}) = x_1 + \cdots + x_n \pmod 2$ is $n$ on every input $\vec{\alpha}$, we have by Observation 1, for each player $P_i$ and each variable $x_j$ such that $j \neq i$, that the communication received by $P_i$ must contain at least one message that is sensitive to $x_j$ on the input $\vec{\alpha}$ and some $\vec{R}$. Thus, on any input $\vec{\alpha}$, there exists at least one message for each variable $x_j$ that is sensitive to $x_j$ on $\vec{\alpha}$ and some $\vec{R}$. If our procedure cannot be continued after $k < n$ steps on some input $\vec{\alpha}$, that would mean by Claim 3 that no message is sensitive to any of the remaining variables on $\vec{\alpha}$ and $\vec{R}$ for any $\vec{R}$, which would be a contradiction. □

As argued above, the senders of the messages $m_1, \ldots, m_n$ are $P_1, \ldots, P_n$, respectively. Denote by $Q_1, \ldots, Q_n$ the receivers of these messages. Note that the $n$ receivers are not necessarily $n$ distinct players. We now select a subset of the above $n$ messages, $m_{i_1}, \ldots, m_{i_q}$, with the property that $\{P_{i_j} : j \in [q]\} \cap \{Q_{i_j} : j \in [q]\} = \emptyset$. That is, none of the receivers of the selected messages is a sender of a selected message.

LEMMA 3.2. *There is a subset of size $q \geq \frac{n}{4}$ of the above $n$ messages, denoted $m_{i_1}, \ldots, m_{i_q}$, such that the receivers of these messages, $Q_{i_1}, \ldots, Q_{i_q}$ are disjoint from the senders of these messages, $P_{i_1}, \ldots, P_{i_q}$.*

*Proof.* For the purpose of the proof we define an undirected graph. The set of nodes consists of $n$ nodes, each node $v_i$ representing a message $m_i$ of the original set of $n$ messages. Recall that each distinct message $m_i$ is sent by a distinct player $P_i$. Therefore we can also think of the nodes as representing $n$ distinct players. For each message $m_i$, we put an edge between node $v_i$ and node $v_j$ if player $P_j$ is the receiver of message $m_i$.

We now have a graph of $n$ nodes and at most $n$ edges. The graph therefore contains an independent set of size at least $\frac{n}{4}$ (cf. [1, Theorem 3.2.1]). We select the messages that correspond to the nodes of this independent set. $\square$

To simplify notation, in what follows we denote by $m_1, \ldots, m_q$, $P_1, \ldots, P_q$, $x_1, \ldots, x_q$, and $Q_1, \ldots, Q_q$ the selected messages, their senders, the input variables these senders have access to, and the receivers of the messages, respectively.

**3.2.2. Properties of the vectors defined by the selected messages.** We will now consider the $2^{n\ell}$-bit binary vectors that represent these messages on input $\vec{\alpha}$. We denote by $\vec{m}(\vec{\alpha})$ the binary vector of length $2^{n\ell}$ that consists of the bits $m(\vec{\alpha}, \vec{R})$. Thus, for any $i$, the vector $\vec{m}_i(\vec{\alpha})$ consists of the bits $m_i(\vec{\alpha}, \vec{R})$. For $\emptyset \neq S \subseteq [q]$ we denote by $\vec{m}_S(\vec{\alpha})$ the bitwise mod 2 sum of the vectors $\vec{m}_i(\vec{\alpha})$ for $i \in S$. That is, $m_S(\vec{\alpha}, \vec{R}) = \oplus_{i \in S} m_i(\vec{\alpha}, \vec{R})$.

LEMMA 3.3. *Let $m_1, \ldots, m_q$ be selected as above in a $t$-private protocol. For any $\emptyset \neq S \subseteq [q]$ of size at most $t$, and any $i, j \in [q]$ (where $i \neq j$),*

$$\Pr_{\vec{R}}[m_S(\vec{\alpha}, \vec{R}) = 1] = \Pr_{\vec{R}}[m_S(\vec{\alpha}^{(i,j)}, \vec{R}) = 1] .$$

*Proof.* Consider the set of players $S' = \{Q_i | i \in S\}$, that is, the coalition formed by the receivers of the messages $m_i$ for $i \in S$. Then $\phi^{S'}(c_{S'}) = \oplus_{i \in S} m_i(\vec{\alpha}, \vec{R}) = m_S(\vec{\alpha}, \vec{R})$ is a function of the sequence of messages received by the players in $S'$. Recall that the set of senders of the messages $m_i$ is disjoint from the set of the receivers, that is, $\{P_i : i \in [q]\} \cap \{Q_i : i \in [q]\} = \emptyset$, which implies that $\{P_i : i \in [q]\} \cap S' = \emptyset$, and therefore for any $i, j \in [q]$, $P_i$ and $P_j$ are not in $S'$. This means that for any $i, j \in [q]$ and for any $l \in S'$, $\alpha_l = \alpha_l^{(i,j)}$, that is, the input bits held by the members of the coalition $S'$ are not changed when one flips the $i$th and $j$th bits of $\vec{\alpha}$. Note also that flipping two bits does not change the value of the `xor` function, that is, $f(\vec{\alpha}) = f(\vec{\alpha}^{(i,j)})$ for any $i, j \in [q]$, when $f$ is the `xor` function. Thus, we can apply Lemma 2.4 to $S'$ and $\phi^{S'} = m_S$, and the second statement of Lemma 2.4 directly implies the statement of the present lemma. $\square$

For $i = 1, \ldots, q$, we denote by $\vec{h}_i(\vec{\alpha})$ the bitwise mod2 sum of the vectors $\vec{m}_i(\vec{\alpha})$ and $\vec{m}_i(\vec{\alpha}^{(i)})$. Thus, the vector $\vec{h}_i(\vec{\alpha})$ is 1 in the coordinates corresponding to $\vec{R}$ such that $m_i(\vec{\alpha}, \vec{R})$ and $m_i(\vec{\alpha}^{(i)}, \vec{R})$ differ, and 0 where they agree. We denote by $h_i(\vec{\alpha}, \vec{R})$ the entry of $\vec{h}_i(\vec{\alpha})$ in the coordinate corresponding to $\vec{R}$.

CLAIM 5. *The vectors $\vec{h}_i(\vec{\alpha})$, $i = 1, \ldots, q$, are not identically* 0.

*Proof.* The proof follows by the definition of the messages $m_i$ and the first statement of Claim 3. $\square$

LEMMA 3.4. *Let $m_1, \ldots, m_q$ be selected as above in a $t$-private protocol. Let $\emptyset \neq S \subseteq [q-1]$ be a subset of size at most $t$, and let $k$ be the largest element of $S$. Then*

$$\Pr_{\vec{R}}[m_S(\vec{\alpha}, \vec{R}) = 1 | h_k(\vec{\alpha}, \vec{R}) = 1] = 1/2 .$$

*Proof.* Since $k$ is the largest element of $S$ and $q$ is larger than any element in $S$, we get by Claim 3 that $\vec{m}_S(\vec{\alpha}^{(k,q)})$ is the bitwise mod 2 sum of the vectors $\vec{m}_S(\vec{\alpha})$ and $\vec{h}_k(\vec{\alpha})$. To see this observe that for any $1 \leq i < k$, $m_i(\vec{\alpha}^{(k)}, \vec{R}) = m_i(\vec{\alpha}, \vec{R})$ by the second statement of Claim 3, and $m_i(\vec{\alpha}^{(k,q)}, \vec{R}) = m_i(\vec{\alpha}^{(k)}, \vec{R})$ again by the second statement of Claim 3. At the same time, $m_k(\vec{\alpha}^{(k,q)}, \vec{R}) = m_k(\vec{\alpha}^{(k)}, \vec{R})$ by the second statement of Claim 3, and $m_k(\vec{\alpha}^{(k)}, \vec{R}) = m_k(\vec{\alpha}, \vec{R}) + h_k(\vec{\alpha}, \vec{R})$ by the definition of $h_k$. Thus, $m_S(\vec{\alpha}^{(k,q)}, \vec{R})$ and $m_S(\vec{\alpha}, \vec{R})$ are complements of each other in the coordinates where $h_k(\vec{\alpha}, \vec{R})$ is 1, and agree where $h_k(\vec{\alpha}, \vec{R})$ is 0. We therefore have

$$\begin{aligned}\Pr_{\vec{R}}[m_S(\vec{\alpha}, \vec{R}) = 1] = \Pr_{\vec{R}}&[m_S(\vec{\alpha}, \vec{R}) = 1 \wedge h_k(\vec{\alpha}, \vec{R}) = 1] \\ &+ \Pr_{\vec{R}}[m_S(\vec{\alpha}, \vec{R}) = 1 \wedge h_k(\vec{\alpha}, \vec{R}) = 0]\end{aligned}$$

and

$$\begin{aligned}\Pr_{\vec{R}}[m_S(\vec{\alpha}^{(k,q)}, \vec{R}) = 1] = \Pr_{\vec{R}}&[m_S(\vec{\alpha}, \vec{R}) = 0 \wedge h_k(\vec{\alpha}, \vec{R}) = 1] \\ &+ \Pr_{\vec{R}}[m_S(\vec{\alpha}, \vec{R}) = 1 \wedge h_k(\vec{\alpha}, \vec{R}) = 0] \ .\end{aligned}$$

Since by Lemma 3.3

$$\Pr_{\vec{R}}[m_S(\vec{\alpha}, \vec{R}) = 1] = \Pr_{\vec{R}}[m_S(\vec{\alpha}^{(k,q)}, \vec{R}) = 1] \ ,$$

we have that

$$\Pr_{\vec{R}}[m_S(\vec{\alpha}, \vec{R}) = 1 \ \wedge \ h_k(\vec{\alpha}, \vec{R}) = 1] = \Pr_{\vec{R}}[m_S(\vec{\alpha}, \vec{R}) = 0 \ \wedge \ h_k(\vec{\alpha}, \vec{R}) = 1] \ .$$

Since $\Pr_{\vec{R}}[h_k(\vec{\alpha}, \vec{R}) = 1] \neq 0$ by Claim 5, this implies the statement of the lemma. ◻

For $i = 1, \dots, q$ we denote by $\vec{\omega}_i(\vec{\alpha})$ the binary vector of length $2^{n\ell}$ that we get by replacing each 0 in $\vec{m}_i(\vec{\alpha})$ by 1, and replacing each 1 in $\vec{m}_i(\vec{\alpha})$ by $-1$. Similarly, for $\emptyset \neq S \subseteq [q]$ we denote by $\vec{\omega}_S(\vec{\alpha})$ the binary vector of length $2^{n\ell}$ that we get by replacing each 0 in $\vec{m}_S(\vec{\alpha})$ by 1, and replacing each 1 in $\vec{m}_S(\vec{\alpha})$ by $-1$. That is, we move from the domain $\{0, 1\}$ to the domain $\{1, -1\}$, and we obtain the vectors $\vec{\omega}_i(\vec{\alpha})$, for $i = 1, \dots, q$, from the vectors $\vec{m}_i(\vec{\alpha})$ using the standard transformation that replaces each value $b$ by $(-1)^b$. The vectors $\vec{\omega}_S(\vec{\alpha})$, for $\emptyset \neq S \subseteq [q]$, are obtained from the vectors $\vec{m}_S(\vec{\alpha})$ in the same way.

LEMMA 3.5. *Let $\vec{\omega}_1, \dots, \vec{\omega}_q$ be selected as above in a $t$-private protocol for $t \geq 2$. Then the vectors $\vec{\omega}_i(\vec{\alpha})$, $i = 1, \dots, q-1$, are linearly independent over the reals.*

*Proof.* As we will see in the next section, our job would be much easier (and we could obtain stronger bounds) if the vectors $\vec{h}_k(\vec{\alpha})$ were the same for each $k$. In that case we could show that the vectors $\vec{\omega}_i(\vec{\alpha})$, $i = 1, \dots, q-1$ (or some projections of them), are pairwise orthogonal. However, in general the vectors $\vec{h}_k(\vec{\alpha})$ may not be the same. Nevertheless, we can show that a given projection of each vector $\vec{\omega}_k(\vec{\alpha})$ is orthogonal to the same projection of each preceding vector $\vec{\omega}_i(\vec{\alpha})$ for $i < k$. This will let us show that for any $k$ such that $2 \leq k \leq q-1$, the vector $\vec{\omega}_k(\vec{\alpha})$ cannot be obtained as a linear combination of the vectors $\vec{\omega}_1(\vec{\alpha}), \dots, \vec{\omega}_{k-1}(\vec{\alpha})$.

Consider an arbitrary $k \in \{2, \dots, q-1\}$, and consider the following projection of the vectors $\vec{\omega}_1(\vec{\alpha}), \dots, \vec{\omega}_k(\vec{\alpha})$. Note that our choice of the projection depends on $k$ (via $\vec{h}_k(\vec{\alpha})$) and this is indicated in the notation by the superscript $k$. For $i = 1, \dots, k$, denote by $\vec{v}_i^k$ the projection of the vector $\vec{\omega}_i(\vec{\alpha})$ to only those coordinates where $h_k(\vec{\alpha}, \vec{R}) = 1$. Note that $\vec{h}_k(\vec{\alpha})$ is not identically 0, as stated in Claim 5, so there is always at least one such coordinate.

Since $t \geq 2$, by applying Lemma 3.4 to the sets $\{i, k\}$ for $i < k$ we get that the inner product of $\vec{v}_k^k$ with any of the vectors $\vec{v}_i^k$ for $i < k$ is 0. To see this, consider $\vec{\omega}_S(\vec{\alpha})$ for $S = \{i, k\}$. Considering $\{1, -1\}$ vectors instead of $\{0, 1\}$ vectors, Lemma 3.4 states that

$$\Pr_{\vec{R}}[\omega_S(\vec{\alpha}, \vec{R}) = 1 | h_k(\vec{\alpha}, \vec{R}) = 1] = \Pr_{\vec{R}}[\omega_S(\vec{\alpha}, \vec{R}) = -1 | h_k(\vec{\alpha}, \vec{R}) = 1] = 1/2 \ .$$

Thus, $\sum_{\{\vec{R}:h_k(\vec{\alpha},\vec{R})=1\}} \omega_S(\vec{\alpha},\vec{R}) = 0$. Notice that for $S = \{i,k\}$, the above sum is exactly the inner product of the vectors $\vec{v}_i^k$ and $\vec{v}_k^k$, since $\omega_S(\vec{\alpha},\vec{R}) = \omega_i(\vec{\alpha},\vec{R}) \cdot \omega_k(\vec{\alpha},\vec{R})$. Therefore, we get that the inner product of $\vec{v}_k^k$ with any of the vectors $\vec{v}_i^k$ for $i < k$ is 0, as claimed.

Suppose that $\vec{\omega}_k(\vec{\alpha})$ can be obtained as a linear combination of the vectors $\vec{\omega}_1(\vec{\alpha}),\ldots,\vec{\omega}_{k-1}(\vec{\alpha})$. Then $\vec{v}_k^k$ can be obtained as a linear combination of the vectors $\vec{v}_1^k,\ldots,\vec{v}_{k-1}^k$. But since the inner product of $\vec{v}_k^k$ with each $\vec{v}_i^k$ for $i < k$ is 0, this would imply that the inner product of $\vec{v}_k^k$ with itself is 0. Since $\vec{v}_k^k$ has only 1 or $-1$ entries, this is not possible. ▯

Let us now consider the $(q-1) \times 2^{n\ell}$ matrix, formed by the vectors $\vec{\omega}_i(\vec{\alpha})$, $i = 1,\ldots,q-1$, as row vectors. Since the vectors $\vec{\omega}_i(\vec{\alpha})$, $i = 1,\ldots,q-1$, are linearly independent, this matrix has at least $q-1$ different columns. This implies that the protocol has at least $q-1$ different transcripts on input $\vec{\alpha}$. Since $q = \Omega(n)$, Theorem 1.1 follows by Lemma 2.6.

## 4. Restricted protocols.

In this section we consider a class of restricted protocols that we define below. Our motivation to consider this class is that all known randomness-efficient protocols designed specifically for `xor` obey this restriction, or can be easily brought to this form without changing the number of coin tosses performed [27, 23, 26, 8]. Informally one can describe the protocols of this class in the following way. First, a deterministic, nonprivate protocol to compute $f$ is defined. Then this protocol is modified by masking each message with randomness by adding to it (modulo 2) a value that depends on the randomness only. This restriction was previously considered in [27]. Formally the restriction we consider here is defined as follows.

DEFINITION 4.1. *We say that a given protocol involving* $n$ *players has a restricted form if each message of the protocol can be obtained as a mod 2 sum of a Boolean function* $u : \{0,1\}^n \to \{0,1\}$ *that depends on the input variables only, and a Boolean function* $v : \{0,1\}^{n\ell} \to \{0,1\}$ *that depends on the random tapes only. That is, each message* $m$ *can be written as* $m(\vec{x},\vec{R}) = u(\vec{x}) + v(\vec{R})$ *mod* 2.

THEOREM 4.2. *Let* $t \geq 2$*, and let* $\mathcal{A}$ *be a* $d$*-random,* $t$*-private protocol, obeying the above restriction, for computing* $f(\vec{x}) = x_1 + \cdots + x_n$ *(mod 2). Then* $d = \Omega(t\log(n/t))$.

As in our proof for general protocols, here too we prove in fact a stronger claim. We prove that for any input assignment $\vec{\alpha} = \alpha_1,\ldots,\alpha_n$, there is a run of the protocol in which the number of random bits read by the players from their random tapes is $\Omega(t\log(n/t))$.

*Proof.* Let $\vec{\alpha} = \alpha_1,\ldots,\alpha_n$ be an arbitrary input assignment. We select a sequence of messages $m_1,\ldots,m_q$ and define the corresponding vectors as in the previous section. Recall that $\vec{h}_i(\vec{\alpha})$ denotes the bitwise mod 2 sum of the vectors $\vec{m}_i(\vec{\alpha})$ and $\vec{m}_i(\vec{\alpha}^{(i)})$. The restriction on the protocols we consider allows us to have the following claim.

CLAIM 6. *The vectors* $\vec{h}_i(\vec{\alpha})$*,* $i = 1,\ldots,q$*, are identically* 1.

*Proof.* We know by Claim 5 that the vectors $\vec{h}_i(\vec{\alpha})$ are not identically 0. That is, they have at least one entry with value 1. This means that $m_i(\vec{\alpha},\vec{R}) \neq m_i(\vec{\alpha}^{(i)},\vec{R})$ for at least one $\vec{R}$. But $m_i(\vec{x},\vec{R})$ can be written as $m_i(\vec{x},\vec{R}) = u_i(\vec{x}) + v_i(\vec{R})$ mod 2. It follows that $u_i(\vec{\alpha}) \neq u_i(\vec{\alpha}^{(i)})$, and therefore for any $\vec{R}$, $m_i(\vec{\alpha},\vec{R}) \neq m_i(\vec{\alpha}^{(i)},\vec{R})$. ▯

The above claim allows us to obtain a stronger bound using the machinery of the previous section. We now prove the following lemma.

LEMMA 4.3. *Let* $\vec{\omega}_S$ *be defined as above in a* $t$*-private protocol obeying the above* *restriction for $t \geq 2$. Then the vectors $\vec{\omega}_S(\vec{\alpha})$, such that $\emptyset \neq S \subseteq [q-1]$ and $|S| \leq \lfloor t/2 \rfloor$, are linearly independent over the reals.*

*Proof.* First note that since $t \geq 2$, there exist sets $S$, such that $\emptyset \neq S \subseteq [q-1]$ and $|S| \leq \lfloor t/2 \rfloor$; thus the statement of the lemma is meaningful (assuming $n \geq 5$; otherwise $q-1$ could be less than 1, since the guarantee of Lemma 3.2 is that $q \geq \frac{n}{4}$). Since by Claim 6 for each $i \in [q]$ the vector $\vec{h}_i(\vec{\alpha})$ is identically 1, Lemma 3.4 gives that $\Pr_{\vec{R}}[m_T(\vec{\alpha}, \vec{R}) = 1] = 1/2$ for any $\emptyset \neq T \subseteq [q-1]$ of size at most $t$. This implies that the sum of entries of the vector $\vec{\omega}_T(\vec{\alpha})$ is 0 for any $\emptyset \neq T \subseteq [q-1]$ of size at most $t$. Notice that for any two sets $S_1$ and $S_2$, we have $\omega_{S_1}(\vec{\alpha}, \vec{R}) \cdot \omega_{S_2}(\vec{\alpha}, \vec{R}) = \omega_{S_1 \triangle S_2}(\vec{\alpha}, \vec{R})$. Thus, for sets $\emptyset \neq S_1 \subseteq [q-1]$ and $\emptyset \neq S_2 \subseteq [q-1]$, each of size at most $\lfloor t/2 \rfloor$, the inner product of $\vec{\omega}_{S_1}(\vec{\alpha})$ and $\vec{\omega}_{S_2}(\vec{\alpha})$ must be 0. We get that the vectors $\vec{\omega}_S(\vec{\alpha})$ for $\emptyset \neq S \subseteq [q-1]$ and $|S| \leq \lfloor t/2 \rfloor$ are pairwise orthogonal, and therefore they must be linearly independent over the reals. ∎

We denote by $\binom{a}{\leq b}$ the sum $\sum_{i=1}^{\min(a,b)} \binom{a}{i}$ for integers $a, b \geq 1$. Let us now consider the $\binom{q-1}{\leq \lfloor t/2 \rfloor} \times 2^{n\ell}$ matrix, formed by the vectors $\vec{\omega}_S(\vec{\alpha})$, such that $\emptyset \neq S \subseteq [q-1]$ and $|S| \leq \lfloor t/2 \rfloor$, as row vectors. Since the vectors $\vec{\omega}_S(\vec{\alpha})$ are linearly independent, this matrix has at least $\binom{q-1}{\leq \lfloor t/2 \rfloor}$ different columns. Note that each column of the matrix is associated with a fixed vector of random tapes $\vec{R}$, and each column is completely determined by the transcript of the protocol on the given $\vec{R}$ and $\vec{\alpha}$. This implies that the protocol has at least $\binom{q-1}{\leq \lfloor t/2 \rfloor}$ different transcripts on input $\vec{\alpha}$. Since $q = \Omega(n)$, the theorem follows by Lemma 2.6. ∎

We find it worthwhile to note that our proof also implies that the random variables associated with the messages $m_1, \ldots, m_q$ on input $\vec{\alpha}$ are $t$-wise independent in any $t$-private protocol that obeys the above restriction. Thus, we could conclude the proof of Theorem 4.2 by referring to the known lower bounds on the size of sample spaces with $t$-wise independent random variables [12, 1]. In fact, part of the proof of Lemma 4.3 is analogous to the corresponding part of the argument used in [12]. The $t$-wise independence property of the random variables associated with the messages $m_1, \ldots, m_q$ on input $\vec{\alpha}$ follows by Lemma 3.4, which, as we have shown above, gives in the case of the restricted protocols that $\Pr_{\vec{R}}[m_S(\vec{\alpha}, \vec{R}) = 1] = 1/2$ for any $\emptyset \neq S \subseteq [q-1]$ of size at most $t$. This implies $t$-wise independence of the corresponding random variables by the results of [12].

# A LOWER BOUND ON THE COMPLEXITY OF POLYNOMIAL MULTIPLICATION OVER FINITE FIELDS*

MICHAEL KAMINSKI†

**Abstract.** It is shown that computing the coefficients of the product of two degree-$n$ polynomials over a $q$-element field by means of a quadratic algorithm requires at least $(3 + \frac{(q-1)^2}{q^5+(q-1)^3})n - o(n)$ multiplications.

**Key words.** polynomial multiplication, quadratic algorithms, linear recurring sequences, Hankel matrices, error-correcting codes

**DOI.** 10.1137/S0097539704442118

## 1. Introduction.

In infinite fields it is possible to compute the coefficients of the product of two polynomials of degree $n$ in $2n + 1$ nonscalar multiplications. It is known from [23] that each algorithm for computing the product in $2n + 1$ nonscalar multiplications must evaluate the multiplicands at $2n + 1$ distinct points (possibly including $\infty$), multiply the samples, and interpolate the result. However, in finite fields this method fails if $2n$ exceeds the number of the field elements. Thus, in general, the $2n + 1$ tight bound cannot be achieved in finite fields.

Let $\mu_F(n)$ denote the number of multiplications required to compute the coefficients of the product of a polynomial of degree $n$ and a polynomial of degree $n - 1$ over field $F$ by means of quadratic algorithms¹ and let $F_q$ denote the $q$-element field. For $q \geq 3$, the best lower bound on $\mu_{F_q}(n)$ known from the literature is $3n - o(n)$ (see [15] and [6, Theorem 18.10]) and, for sufficiently large $n$, $\mu_{F_2}(n) > 3.52n$ (see [3]). On the other hand, if $q \geq 3$, computing the coefficients of the minimal degree residue of the product of two polynomials of degree $n$ modulo a fixed irreducible polynomial of degree $n + 1$ over $F_{q^2}$ can be done in $2(1 + \frac{1}{q-2})n + o(n)$ multiplications; see [7] and [20]. Thus, for $q \geq 3$, $\mu_{F_{q^2}}(n) \leq 4(1+\frac{1}{q-2})n+o(n)$. This small difference between the upper and the lower bounds motivates a further search for better (both upper and lower) bounds on the complexity of polynomial multiplications. Also, apart from being of interest in their own right, algorithms for polynomial multiplication over finite fields are tightly connected to error-correcting codes; see [2, 3, 7, 14, 16, 17].

In our paper we prove the following lower bound on $\mu_{F_q}(n)$.

THEOREM 1. *We have*

$$\mu_{F_q}(n) \geq \left(3 + \frac{(q-1)^2}{q^5 + (q-1)^3}\right) n - o(n).$$

¹A straightforward substitution argument shows that the number of multiplications required to compute the coefficient of the product of two polynomials of degree $n$ over $F$ exceeds $\mu_F(n)$ by at least 1.

The proof of Theorem 1 is based on a novel combination of two known techniques. One technique is the analysis of *Hankel* matrices representing bilinear forms defined by linear combinations of the coefficients of the polynomial product; see [15]. The other technique is a counting argument from the coding theory; see [16].

The reason for combining these two techniques is that the Hankel matrix approach uses very few properties of finite fields and the coding approach does not use at all a very special structure of bilinear forms defined by linear combinations of the coefficients of the polynomial product. In fact, our paper indicates that the Hankel matrix approach is, in some sense, richer than Baur's technique; see [6, proof of Theorem 18.10]. In particular, as a byproduct, using the tools developed for the proof of Theorem 1, we obtain a more intuitive alternative proof of the lower bound on the complexity of multiplication of polynomials modulo a polynomial established in [4] and [7].

We end this section with the note that if a set of quadratic forms over an infinite field can be computed by a (general) *straight-line algorithm* in $t$ multiplications/divisions, then it can be computed in $t$ multiplications by a quadratic algorithm whose total number of operations differs from that of the original one by a factor of a small constant; see [21]. It is unknown whether a similar result holds for finite fields; cf. [5]. However, the proof in [21] easily extends to finite fields if, for some input that belongs to the underlying finite field, the original straight-line algorithm does not divide by zero. Therefore, in the case of multiplication of polynomials over $F_q$, our lower bound applies to all straight-line algorithms which compute the coefficients of the product of at least one pair of polynomials whose coefficients all belong to $F_q$. Finally, one can easily prove that quadratic algorithms for computing a set of bilinear forms are optimal within the class of algorithms without divisions, and all algorithms for polynomial multiplication over finite fields known from the literature are quadratic (and even *bilinear*).

The paper is organized as follows. In the next section we gather the definitions and some basic facts used in this paper. In section 3 we indicate some limitations of the known tools and present an example through which we develop a technique used for the proof of Theorem 1. Then, in section 4, we outline the proof of the theorem. The proof itself is based on an improvement of a known lower bound presented in section 5 and a number of technical constructions presented in sections 6, 7, and 8. In particular, the improved lower bound in section 5 is based on a counting argument from the coding theory and can be used for an alternative proof of the complexity of multiplication of polynomials modulo a polynomial.

## 2. Notation, definitions, and auxiliary results.

This section contains the definitions and some basic results known from the literature which we use in this paper. First we define the notion of a quadratic algorithm. Then we introduce notation and definitions from linear recurring sequence theory and state the major auxiliary technical lemmas. We conclude this section with some basic calculations from the coding theory and an example that will be used for the proof of Theorem 1.

### 2.1. Quadratic algorithms for polynomial multiplication.

In this paper we deal only with quadratic algorithms defined below.

Let $\boldsymbol{s}$ be a set of indeterminates. We remind the reader that a *quadratic* algorithm over field $F$ for computing a set $\boldsymbol{Q}$ of quadratic forms of the elements of $\boldsymbol{s}$ is a straight-line algorithm whose nonscalar multiplications are of the form $L' {*} L''$, where $L'$ and $L''$ are linear forms of the elements of $\boldsymbol{s}$ over $F$ and each form in $\boldsymbol{Q}$ is a linear combination of these products. The minimal number of such multiplications is called the *quadratic complexity of $\boldsymbol{Q}$ over $F$* and is denoted by $\mu_F(\boldsymbol{Q})$.

Let $\boldsymbol{Q} = \{\boldsymbol{x}^T M \boldsymbol{y} : M \in \boldsymbol{M}\}$, where $\boldsymbol{M}$ is a set of matrices. That is, the quadratic (in fact, *bilinear*) forms in $\boldsymbol{Q}$ are defined by the elements of $\boldsymbol{M}$.

*In what follows we shall identify $\boldsymbol{Q}$ with $\boldsymbol{M}$ and often write $\mu_F(\boldsymbol{M})$ instead of $\mu_F(\boldsymbol{Q})$. Also, we shall identify a quadratic algorithm with the corresponding set of pairs of linear forms.*

Let $\boldsymbol{x} = (x_0, x_1, \ldots, x_n)^T$ and $\boldsymbol{y} = (y_0, y_1, \ldots, y_{n-1})^T$ be column vectors of the multiplicands' coefficients. We have to compute

$$z_k = z_k(\boldsymbol{x}, \boldsymbol{y}) = \sum_{i+j=k} x_i y_j, \quad k = 0, \ldots, 2n-1. \tag{1}$$

Assume that $\mu_F(n) = t$, i.e., there exist $t$ linear forms $L_1'(\boldsymbol{x}, \boldsymbol{y}), \ldots, L_t'(\boldsymbol{x}, \boldsymbol{y})$ and $t$ linear forms $L_1''(\boldsymbol{x}, \boldsymbol{y}), \ldots, L_t''(\boldsymbol{x}, \boldsymbol{y})$ of $\boldsymbol{x}$ and $\boldsymbol{y}$ such that each $z_k$ is a linear combination of products $L_i'(\boldsymbol{x}, \boldsymbol{y}) L_i''(\boldsymbol{x}, \boldsymbol{y})$, $i = 1, 2, \ldots, t$.

Let $\boldsymbol{z} = (z_0, z_1, \ldots, z_{2n-1})^T$ and let $\boldsymbol{p}$ be a column vector of the above products. That is,

$$\boldsymbol{p} = \begin{pmatrix} L_1'(\boldsymbol{x}, \boldsymbol{y}) L_1''(\boldsymbol{x}, \boldsymbol{y}) \\ L_2'(\boldsymbol{x}, \boldsymbol{y}) L_2''(\boldsymbol{x}, \boldsymbol{y}) \\ \vdots \\ L_t'(\boldsymbol{x}, \boldsymbol{y}) L_t''(\boldsymbol{x}, \boldsymbol{y}) \end{pmatrix},$$

say. Then there exists a $2n \times t$ matrix $U$ such that $\boldsymbol{z} = U\boldsymbol{p}$.

By definition, $z_k = \boldsymbol{x}^T A_k \boldsymbol{y}$, where $A_k = (a_{i,j,k})$ is an $(n+1) \times n$ Hankel matrix defined by

$$a_{i,j,k} = \begin{cases} 1 & \text{if } i + j = k + 2, \\ 0 & \text{otherwise.} \end{cases}$$

In particular, $z_0 = \boldsymbol{x}^T A_0 \boldsymbol{y} = x_0 y_0$ is the value of polynomial $\sum_{k=0}^{2n-1} z_k \alpha^k$ at zero, and $z_{2n-1} = \boldsymbol{x}^T A_{2n-1} \boldsymbol{y} = x_n y_{n-1}$ is its value at infinity.

Since matrices $A_0, A_1, \ldots, A_{2n-1}$ are linearly independent, $\operatorname{rank} U = 2n$. Permuting the components of $\boldsymbol{p}$ if necessary, we may assume that the first $2n$ columns of $U$ are linearly independent. Hence there exist a nonsingular $2n \times 2n$ matrix $W$ and a $2n \times (t - 2n)$ matrix $V$ such that

$$W\boldsymbol{z} = (\boldsymbol{I}_{2n}, V)\boldsymbol{p}, \tag{2}$$

where $\boldsymbol{I}_{2n}$ denotes the $2n \times 2n$ identity matrix. That is, the first $2n$ columns of $WU$ are those of $\boldsymbol{I}_{2n}$.

Let $W\boldsymbol{z} = (\boldsymbol{x}^T D_1 \boldsymbol{y}, \boldsymbol{x}^T D_2 \boldsymbol{y}, \ldots, \boldsymbol{x}^T D_{2n} \boldsymbol{y})^T$ and $\boldsymbol{D} = \{D_1, D_2, \ldots, D_{2n}\}$. Then $\mu_F(n) = \mu_F(\boldsymbol{D})$, which together with (2) easily implies Proposition 2 below.

PROPOSITION 2 (cf. [1, Proposition 1]). *Let $\boldsymbol{D}$ be as above and let $\boldsymbol{D}' \subseteq \boldsymbol{D}$. Then*

$$\mu_F(n) \geq 2n + 1 + \mu_F(\boldsymbol{D}') - |\boldsymbol{D}'|.[2]$$

We apply Proposition 2 for the proof of Theorem 1 in a standard manner; see [1], [5], [6, proof of Theorem 18.10], and [15]. Namely, we prove that there exists a subset $\boldsymbol{D}'$ of $\boldsymbol{D}$ of cardinality $o(n)$ such that

$$\mu_{F_q}(\boldsymbol{D}') \geq \left(1 + \frac{(q-1)^2}{q^5 + (q-1)^3}\right) n;$$

[2]As usual, for a set $X$, $|X|$ denotes the number of elements of $X$.

cf. [6, proof of Theorem 18.10] and [15]. For this purpose we refine the technique developed in [15].

**2.2. Hankel matrices and linear recurring sequences.** In this section we recall the notation and state major auxiliary lemmas from [5] and [15].

Let $F$ be a field, let $k$ be a positive integer, and let $a_0, \ldots, a_{k-1} \in F$. A sequence $\sigma = s_0, s_1, \ldots, s_\ell$ of elements of $F$ satisfying the relation

$$s_{m+k} = a_{k-1}s_{m+k-1} + a_{k-2}s_{m+k-2} + \cdots + a_0 s_m, \quad m = 0, 1, \ldots, \ell - k,$$

is called a (finite $k$th-order homogeneous) *linear recurring sequence* in $F$. The terms $s_0, s_1, \ldots, s_{k-1}$ are called *initial values*, and the polynomial

$$f(\alpha) = \alpha^k - a_{k-1}\alpha^{k-1} - a_{k-2}\alpha^{k-2} - \cdots - a_0 \in F[\alpha]$$

is called a *characteristic polynomial* of $\sigma$. The characteristic polynomial of $\sigma$ of the minimal degree is called the *minimal polynomial* of $\sigma$ and is denoted by $f_\sigma(\alpha)$.

Proposition 3 below shows that if a finite linear recurring sequence is "sufficiently long," then it possesses an important property of infinite linear recurring sequences.

PROPOSITION 3 (see [15, Proposition 1]). *Let $\sigma$, $f(\alpha)$, and $f_\sigma(\alpha)$ be as above. If* $\deg f_\sigma(\alpha) + \deg f(\alpha) \le \ell + 1$, *then $f_\sigma(\alpha)$ divides $f(\alpha)$.*

For a sequence $\sigma = s_0, s_1, \ldots, s_{2n-1}$ we define the $(n+1)\times n$ *Hankel* matrix $H(\sigma)$ by

$$H(\sigma) = \begin{pmatrix} s_0 & s_1 & \cdots & s_{n-1} \\ s_1 & s_2 & \cdots & s_n \\ \vdots & \vdots & & \vdots \\ s_n & s_{n+1} & \cdots & s_{2n-1} \end{pmatrix}.$$

The proof of Theorem 1 is based on the fact that linear combinations of the coefficients of the product of two polynomials are defined by Hankel matrices and vice versa.

We proceed with Definition 4 below, for which we need the following notation.

We denote by $\vec{H}^i$, $i = 0, 1, \ldots, n$, the $(i+1)$th row of a $(n+1)\times n$ Hankel matrix $H$.

DEFINITION 4. *Let $\sigma = s_0, s_1, \ldots, s_{2n-1}$, $H = H(\sigma)$, and let $k$ be the minimal integer for which there exist $a_0, a_1, \ldots, a_{k-1} \in F$ such that*

$$\sum_{i=0}^{k-1} a_i \vec{H}^i = \vec{H}^k.$$

*The sequence $\tilde{\sigma} = \tilde{s}_0, \tilde{s}_1, \ldots, \tilde{s}_{2n-1}$ is defined by linear recurrence*

$$\tilde{s}_{i+k} = a_{k-1}\tilde{s}_{i+k-1} + a_{k-2}\tilde{s}_{i+k-2} + \cdots + a_0\tilde{s}_i, \tag{3}$$

*with initial values $\tilde{s}_i = s_i$, $i = 0, 1, \ldots, k-1$.*

*The sequence $\sigma - \tilde{\sigma}$ is denoted by $\bar{\sigma}$, and $(n+1)\times n$ Hankel matrices $H(\tilde{\sigma})$ and $H(\bar{\sigma})$ are denoted by $\tilde{H}$ and $\bar{H}$, respectively.*

*We denote characteristic polynomial $\alpha^k - \sum_{i=0}^{k-1} a_i\alpha^i$ of the sequence defined by recurrence* (3) *by $f_{\tilde{H}}(\alpha)$*[3] *and we define the (integral)* divisor $\boldsymbol{f}_H(\alpha)$ *by*

$$\boldsymbol{f}_H(\alpha) = f_{\tilde{H}}(\alpha)(\alpha - \infty)^{rank(\bar{H})}.$$

[3]In fact, $f_{\tilde{H}}(\alpha)$ is the *minimal* polynomial of this sequence and, in particular, of $\tilde{\sigma}$; see [15, section 3].

*Example* 5. Let $d \leq n-1$ and let $\sigma = s_0, s_1, \ldots, s_{2n}$ be such that $s_d \neq 0$ and $s_j = 0$ for all $j = d+1, d+2, \ldots, 2n$. Then $\boldsymbol{f}_{H(\sigma)}(\alpha) = \alpha^d$. Similarly, for $\sigma' = s'_0, s'_1, \ldots, s'_{2n}$, where $s'_{2n-d} \neq 0$ and $s'_j = 0$ for all $j = 0, 1, \ldots, 2n-d-1$, $\boldsymbol{f}_{H(\sigma')}(\alpha) = (\alpha - \infty)^d$. Thus, in particular, for the zero $(n+1) \times n$ matrix $\mathbf{0}_{(n+1)\times n}$, $\boldsymbol{f}_{\mathbf{0}_{(n+1)\times n}}(\alpha) = 1$.

PROPOSITION 6 (see [15, Proposition 2]). *Let $H$ be an $(n+1)\times n$ Hankel matrix. Then* $\operatorname{rank}(H) = deg \boldsymbol{f}_H(\alpha)$.

A part of the proof of Theorem 1 is based on Lemmas 7–11 below. To state these lemmas we need the following notation.

Let $\boldsymbol{S}$ be a set of $(n+1) \times n$ Hankel matrices. We denote by $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$ the least common multiple of $\{\boldsymbol{f}_H(\alpha) : H \in \boldsymbol{S}\}$:

$$\boldsymbol{f}_{\boldsymbol{S}}(\alpha) = \operatorname{lcm}\{\boldsymbol{f}_H(\alpha) : H \in \boldsymbol{S}\}.$$

Let $V$ be a vector space over $F$ and let $V' \subseteq V$. We denote by $[V']$ the linear subspace of $V$ spanned by the elements of $V'$.

Finally, we denote the maximal possible number of distinct factors of a polynomial of degree $n$ over $F_q$ by $i_q(n)$. It is well known that for $q \geq 3$, $i_q(n) < \frac{n}{\lg_q n - 3}$; e.g., see [15, Appendix 1].

LEMMA 7 (see [15, Lemma 1]). *Let $\boldsymbol{S}$ be a set of $(n+1)\times n$ Hankel matrices. Then* $\dim([\boldsymbol{S}]) \leq \deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha)$.

LEMMA 8 (see [15, Lemma 2] and [5, Lemma 1]). *Let $\boldsymbol{S}$ be a set of $(n+1)\times n$ Hankel matrices over a field $F$ such that* $\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \geq n+1$. *Then* $\mu_F(\boldsymbol{S}) \geq n+1$.

LEMMA 9 (see [15, Lemma 3] and [5, Lemma 1]). *Let $\boldsymbol{S}$ be a set of $(n+1)\times n$ Hankel matrices over a field $F$ such that* $\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) < n+1$. *Then* $\mu_F(\boldsymbol{S}) \geq \deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha)$.

LEMMA 10 (see [5, Lemma 2]). *Let $\boldsymbol{S}$ and $\boldsymbol{S}'$ be sets of $(n+1)\times n$ Hankel matrices such that $[\boldsymbol{S}] = [\boldsymbol{S}']$. If* $\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \leq n$, *then* $\boldsymbol{f}_{\boldsymbol{S}'}(\alpha) = \boldsymbol{f}_{\boldsymbol{S}}(\alpha)$.

LEMMA 11 (see [15, Lemma 4]). *Let $\boldsymbol{M}$ be a set of $(n+1)\times n$ Hankel matrices over $F_q$. Then for each $m \leq \dim(\boldsymbol{M})$ there exists a subset $\boldsymbol{M}'$ of $\boldsymbol{M}$ containing $i_q(m)$ or fewer elements such that* $\deg \boldsymbol{f}_{\boldsymbol{M}'}(\alpha) \geq m$.

The following example illustrates the power of the tools listed so far.

*Example* 12 (see [15, proof of Theorem 1]). Let $\boldsymbol{D}$ be the set of Hankel matrices defining the components of $W\boldsymbol{z}$ in (2). Then $\dim(\boldsymbol{D}) = 2n$ and, by Lemma 11, there is a subset $\boldsymbol{D}'$ of $\boldsymbol{D}$ of cardinality not exceeding $i_q(n+1)$ such that $\deg \boldsymbol{f}_{\boldsymbol{D}'}(\alpha) \geq n+1$. By Lemma 8, $\mu_{F_q}(\boldsymbol{D}') \geq n+1$ which, together with Proposition 2, implies $\mu_{F_q}(n) = 3n - o(n)$.

**2.3. Bounds from the coding theory.** This section contains some elementary calculations from the coding theory needed for the proof of Theorem 1.

The most basic notion of the coding theory is the *weight* of a vector $\boldsymbol{v}$, denoted $\boldsymbol{wt}(\boldsymbol{v})$, that is the number of nonzero components of $\boldsymbol{v}$.

PROPOSITION 13 (see [19, problem 3.6, p. 73]). *Let $U$ be a $k \times t$ matrix over $F_q$ without zero columns. Then*

$$\sum_{\boldsymbol{v} \in F_q^k} \boldsymbol{wt}(\boldsymbol{v}U) = t(q^k - q^{k-1}).$$

COROLLARY 14. *Let $U$ be a $2 \times t$ matrix over $F_q$ without zero columns. Then*

$$t = \frac{\boldsymbol{wt}((0,1)U) + \sum_{v \in F_q} \boldsymbol{wt}((1,v)U)}{q}.$$

The proof of this corollary is immediate and is left to the reader.

COROLLARY 15 (cf. [16, proof of Theorem 1]). *Let $\boldsymbol{S} = \{H_1, H_2, \ldots, H_k\}$ be a set of $(n+1) \times n$ Hankel matrices over $F_q$. Then*

$$\mu_{F_q}(\boldsymbol{S}) \geq \frac{\sum_{H \in [\boldsymbol{S}]} \deg \boldsymbol{f}_H(\alpha)}{q^k - q^{k-1}}.$$

*Proof.* Let $\mu_{F_q}(\boldsymbol{S}) = t$ and let $\{(L_i'(\boldsymbol{x},\boldsymbol{y}), L_i''(\boldsymbol{x},\boldsymbol{y}))\}_{i=1,2,\ldots,t}$ be a quadratic algorithm over $F_q$ that computes the bilinear forms defined by the elements of $\boldsymbol{S}$. Let $\boldsymbol{p}$ be a column vector of products $L_i'(\boldsymbol{x},\boldsymbol{y})L_i''(\boldsymbol{x},\boldsymbol{y})$, $i = 1, 2, \ldots, t$, and let $U$ be a $k \times t$ matrix over $F_q$ such that

$$(\boldsymbol{x}^T H_1 \boldsymbol{y}, \boldsymbol{x}^T H_2 \boldsymbol{y}, \ldots, \boldsymbol{x}^T H_k \boldsymbol{y})^T = U\boldsymbol{p}.$$

Let $\vec{\boldsymbol{S}} = (H_1, H_2, \ldots, H_k)^T$. Then, for each $\boldsymbol{v} \in F_q^k$,

$$\boldsymbol{x}^T(\boldsymbol{v}\vec{\boldsymbol{S}})\boldsymbol{y} = \boldsymbol{v}U\boldsymbol{p},$$

implying $\mu_{F_q}(\boldsymbol{v}\vec{\boldsymbol{S}}) \leq \boldsymbol{wt}(\boldsymbol{v}U)$. Since $\mu_{F_q}(\boldsymbol{v}\vec{\boldsymbol{S}}) = \operatorname{rank}(\boldsymbol{v}\vec{\boldsymbol{S}})$ and, by Proposition 6, $\operatorname{rank}(\boldsymbol{v}\vec{\boldsymbol{S}}) = \deg \boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}}(\alpha)$, we have

$$\begin{aligned} t(q^k - q^{k-1}) &= \sum_{\boldsymbol{v} \in F^k} \boldsymbol{wt}(\boldsymbol{v}U) \\ &\geq \sum_{\boldsymbol{v} \in F^k} \mu_{F_q}(\boldsymbol{v}\vec{\boldsymbol{S}}) = \sum_{\boldsymbol{v} \in F^k} \deg \boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}}(\alpha) = \sum_{H \in [\boldsymbol{S}]} \deg \boldsymbol{f}_H(\alpha), \end{aligned}$$

which implies the desired inequality. ◻

We conclude this section with an example that will be used for the proof of Theorem 1.

*Example* 16. Let

$$\epsilon_q = \frac{q^4}{q^5 + (q-1)^3} \tag{4}$$

and let $\boldsymbol{D}$ be the set of Hankel matrices defining the components of $W\boldsymbol{z}$ in (2). *If there exists a subset $\boldsymbol{D}'$ of $\boldsymbol{D}$ of cardinality $\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil$ such that for each $H \in [\boldsymbol{D}']$, $\deg \boldsymbol{f}_H(\alpha) \geq (1 - \epsilon_q)n$, then*

$$\mu_{F_q}(n) \geq \left(3 + \frac{(q-1)^2}{q^5 + (q-1)^3}\right) n - o(n).$$

That is, Theorem 1 is true in this degenerate case.

Indeed, by Corollary 15,

$$\begin{aligned}\mu_{F_q}(\boldsymbol{D}') &\ge \frac{\sum\limits_{H\in[\boldsymbol{D}']}\deg \boldsymbol{f}_H(\alpha)}{q^{\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n\rceil} - q^{\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n\rceil - 1}}\\ &\ge \frac{(q^{\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n\rceil} - 1)(1-\epsilon_q)n}{q^{\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n\rceil} - q^{\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n\rceil - 1}}\\ &\ge \left(1+\frac{1}{q-1}\right)(1-\epsilon_q)n - \frac{(1-\epsilon_q)n \lg_q \lg_q n}{\lg_q n}\end{aligned}$$

and the desired inequality follows from (4) and Proposition 2.

## 3. Limitations of Lemma 8 and its extension.

First we observe that Example 12 does not use much of the finiteness of the underlying field, because Lemma 8 holds for any field. In addition, Lemma 11 uses only "a half" of the dimension of $[\boldsymbol{D}]$ that equals $2n$. It seems that a better bound could be achieved by extending Lemma 8 "beyond $n+1$" (just in the case of a finite field), which would allow us to use a "bigger portion of $\dim([\boldsymbol{D}])$." As shown in Theorem 21 in section 3.2, Lemma 8 can indeed be extended, and we apply its extension for the proof of Theorem 1.

This section is organized as follows. First we present an example that indicates some limitations of Lemma 8. Then we state and prove Theorem 21 that extends Lemma 8.

### 3.1. Limitations of Lemma 8.

Our example illustrating some of the limitations of Lemma 8 is based on the following lemma.

LEMMA 17. *Let $H'$ and $H''$ be $(n+1)\times n$ Hankel matrices over $F_q$ and let $\alpha \in F_{q^2}\setminus F_q$.*[4] *Then each quadratic algorithm over $F_q$ that computes $\boldsymbol{x}^T(H'+\alpha H'')\boldsymbol{y}$ also computes $\boldsymbol{x}^T H'\boldsymbol{y}$ and $\boldsymbol{x}^T H''\boldsymbol{y}$.*

*Proof.* Let $\{(L_i'(\boldsymbol{x},\boldsymbol{y}), L_i''(\boldsymbol{x},\boldsymbol{y}))\}_{i=1,2,\ldots,t}$ be a quadratic algorithm over $F_q$ that computes $\boldsymbol{x}^T(H'+\alpha H'')\boldsymbol{y}$. That is, there exist $a_i, b_i \in F_q$, $i=1,2,\ldots,t$, such that

$$\begin{aligned}\boldsymbol{x}^T(H'+\alpha H'')\boldsymbol{y} &= \boldsymbol{x}^T H'\boldsymbol{y} + \alpha \boldsymbol{x}^T H''\boldsymbol{y}\\ &= \sum_{i=1}^t (a_i+\alpha b_i) L_i'(\boldsymbol{x},\boldsymbol{y}) L_i''(\boldsymbol{x},\boldsymbol{y})\\ &= \sum_{i=1}^t a_i L_i'(\boldsymbol{x},\boldsymbol{y}) L_i''(\boldsymbol{x},\boldsymbol{y}) + \alpha \sum_{i=1}^t b_i L_i'(\boldsymbol{x},\boldsymbol{y}) L_i''(\boldsymbol{x},\boldsymbol{y}).\end{aligned}$$

Since the coefficients of all $L_i'(\boldsymbol{x},\boldsymbol{y})$ and $L_i''(\boldsymbol{x},\boldsymbol{y})$, $i=1,2,\ldots,t$, belong to $F_q$, $\boldsymbol{x}^T H'\boldsymbol{y} = \sum_{i=1}^t a_i L_i'(\boldsymbol{x},\boldsymbol{y}) L_i''(\boldsymbol{x},\boldsymbol{y})$ and $\boldsymbol{x}^T H''\boldsymbol{y} = \sum_{i=1}^t b_i L_i'(\boldsymbol{x},\boldsymbol{y}) L_i''(\boldsymbol{x},\boldsymbol{y})$. ☐

*Remark* 18. A bit more involved argument shows that Lemma 17 holds for any two fields $F \subset F'$ and any $\alpha \in F'\setminus F$.

Now we are ready to present our example on which we base the proof of Theorem 1.

*Example* 19. Let $n$ be even and let $M, M'$, and $M''$ be $(n+1)\times n$ Hankel matrices over $F_q$ such that $\boldsymbol{f}_M(\alpha)$, $\boldsymbol{f}_{M'}(\alpha)$, and $\boldsymbol{f}_{M''}(\alpha)$ are pairwise coprime divisors of degree $\frac{n+1}{2}$. Below we prove that $\mu_{F_q}(\{M,M',M''\}) \ge (1+\frac{1}{2q^2})(n+1)$, whereas Lemma 8 gives us only $\mu_{F_q}(\{M,M',M''\}) \ge n+1$.

[4]Of course, we may assume that $F_q \subset F_{q^2}$.

Let $\{(L'_i(\boldsymbol{x},\boldsymbol{y}), L''_i(\boldsymbol{x},\boldsymbol{y}))\}_{i=1,2,\ldots,t}$ be a quadratic algorithm over $F_q$ that computes the bilinear forms defined by those three matrices. Then this algorithm also computes the bilinear forms over $F_{q^2}$ defined by $M+\alpha M'$ and $M''$, where $\alpha \in F_{q^2} \setminus F_q$ is as in Lemma 17. Let $\boldsymbol{p}$ be a column vector of products $L'_i(\boldsymbol{x},\boldsymbol{y})L''_i(\boldsymbol{x},\boldsymbol{y})$, $i=1,2,\ldots,t$. Then there exists a $2\times t$ matrix $U$ over $F_{q^2}$ such that

$$\left(\begin{array}{c} \boldsymbol{x}^T(M+\alpha M')\boldsymbol{y} \\ \boldsymbol{x}^T M''\boldsymbol{y} \end{array}\right) = U\boldsymbol{p}.$$

Therefore,

$$\boldsymbol{x}^T M''\boldsymbol{y} = (0,1)U\boldsymbol{p},$$

implying

$$\boldsymbol{wt}((0,1)U) \geq \mu_{F_q}(\{M''\}). \tag{5}$$

In addition, for $u,v \in F_q$,

$$\begin{aligned}\boldsymbol{x}^T((M+uM'')+\alpha(M'+vM''))\boldsymbol{y} &= \boldsymbol{x}^T((M+\alpha M')+(u+v\alpha)M'')\boldsymbol{y} \\ &= (1,u+v\alpha)U\boldsymbol{p},\end{aligned}$$

implying, by Lemma 17,

$$\boldsymbol{wt}((1,u+v\alpha)U) \geq \mu_{F_q}(\{M+uM'', M'+vM''\}). \tag{6}$$

Now, combining (5) and (6) with Corollary 14, we obtain

$$t \geq \frac{\mu_{F_q}(\{M''\}) + \displaystyle\sum_{u,v\in F_q} \mu_{F_q}(\{M+uM'', M'+vM''\})}{q^2}. \tag{7}$$

Since

$$\mu_{F_q}(\{M''\}) = \mathrm{rank}(M'') = \deg \boldsymbol{f}_{M''}(\alpha) = \frac{n+1}{2}$$

and, by Lemma 8, $\mu_{F_q}(\{M+rM'', M'+sM''\}) \geq n+1$, the desired inequality $t \geq (1+\frac{1}{2q^2})(n+1)$ follows from (7).

*Remark* 20. Replacing $\{M+\alpha M', M''\}$ in the above example with $\{M+\alpha M', M+\alpha M''\}$, one can show that $\mu_{F_q}(\{M,M',M''\}) \geq (1+\frac{1}{q^2})(n+1)$. However, we do not know how to generalize this approach.

**3.2. A generalization of Example 19.** Theorem 21 below (whose proof is presented in the next section) generalizes Example 19 by extending Lemma 8 "beyond $n+1$." We precede the statement of the theorem with the following notation.

For a set $\boldsymbol{H}$ of $(n+1)\times n$ Hankel matrices we denote by $\|\boldsymbol{H}\|$ the minimum of $\{\deg \boldsymbol{f}_H(\alpha) : H \in [\boldsymbol{H}] \setminus \{\boldsymbol{0}_{(n+1)\times n}\}$ and we denote by $\deg \boldsymbol{H}$ the minimum of $\{\deg \boldsymbol{f}_{\boldsymbol{H}'}(\alpha) : [\boldsymbol{H}'] = [\boldsymbol{H}]\}$.[5]

THEOREM 21. *Let $\boldsymbol{M}$ be a set of three linearly independent $(n+1)\times n$ Hankel matrices over $F_q$ such that $\deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) \geq n+1$.*

[5] Note the difference between $\deg \boldsymbol{H}$ and $\deg \boldsymbol{f}_{\boldsymbol{H}}(\alpha)$. Whereas the latter refers to a particular set of Hankel matrices $\boldsymbol{H}$, the former is the minimum over all sets $\boldsymbol{H}'$ which span $[\boldsymbol{H}]$. Nevertheless, by Lemma 10, they are equal, if either of them is less than $n+1$.

1. *If there is a basis* $\{M, M', M''\}$ *of* $[\boldsymbol{M}]$ *such that*

$$\deg \boldsymbol{f}_{\{M,M''\}}(\alpha), \deg \boldsymbol{f}_{\{M,M'\}}(\alpha), \deg \boldsymbol{f}_{\{M',M''\}}(\alpha) \le n, \tag{8}$$

*then*

$$\mu_{F_q}(\boldsymbol{M}) \ge n + 1 + \frac{\deg \boldsymbol{f}_{\{M,M',M''\}}(\alpha) - n - 1}{q^2}.$$

2. *If for each basis* $\{M, M', M''\}$ *of* $[\boldsymbol{M}]$ (8) *does not hold, then*

$$\mu_{F_q}(\boldsymbol{M}) \ge n + 1 + \frac{\|\boldsymbol{M}\|}{q^2}.$$

COROLLARY 22. *Let* $\boldsymbol{M}$ *be a set of three linearly independent* $(n+1) \times n$ *Hankel matrices over* $F_q$*. If* $\deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) \ge n+1$*, then*

$$\mu_{F_q}(\boldsymbol{M}) \ge n + 1 + \frac{\min(\deg \boldsymbol{M} - n - 1, \|\boldsymbol{M}\|)}{q^2}.$$

In view of Corollary 22, we shall search for a subset $\boldsymbol{D}'$ of $\boldsymbol{D}$, where $\boldsymbol{D}$ is the set of Hankel matrices defining the components of $W\boldsymbol{z}$ in (2), such that

- $|\boldsymbol{D}'| = o(n)$ and
- $[\boldsymbol{D}']$ includes a set $\boldsymbol{M}$ of three linearly independent $(n+1)\times n$ Hankel matrices satisfying

$$\min(\deg \boldsymbol{M} - n - 1, \|\boldsymbol{M}\|) \ge \frac{(q-1)^2}{q^2}\epsilon_q n,$$

where $\epsilon_q$ is defined by (4).

**3.3. Proof of Theorem 21.** We start with the proof of the first claim of the theorem. In this case we may assume that $\boldsymbol{M} = \{M, M', M''\}$, where $M$, $M'$, and $M''$ satisfy (8). Since $\mu_{F_q}(\{M''\}) = \deg \boldsymbol{f}_{M''}(\alpha)$, by (7), $\mu_{F_q}(\boldsymbol{M})$ is bound from below by

$$\frac{\deg \boldsymbol{f}_{M''}(\alpha) + \sum\limits_{u,v \in F} \mu_{F_q}(\{M + uM'', M' + vM''\})}{q^2}, \tag{9}$$

which we are going to estimate.

Let $\boldsymbol{f}_{\boldsymbol{M}}(\alpha) = \prod_{i=1}^{\ell} p_i^{d_i}(\alpha)$ be the decomposition of $\boldsymbol{f}_{\boldsymbol{M}}(\alpha)$ into irreducible factors. Then $M = \sum_{i=1}^{\ell} M_i$, $M' = \sum_{i=1}^{\ell} M_i'$, and $M'' = \sum_{i=1}^{\ell} M_i''$, where each of $\boldsymbol{f}_{M_i}(\alpha)$, $\boldsymbol{f}_{M_i'}(\alpha)$, and $\boldsymbol{f}_{M_i''}(\alpha)$ divides $p_i^{d_i}(\alpha)$, $i = 1, 2, \ldots, \ell$.[6] Thus,

$$M + uM'' = \sum_{i=1}^{\ell} (M_i + uM_i'')$$

and

$$M' + vM'' = \sum_{i=1}^{\ell} (M_i' + vM_i'').$$

We shall need the following property of matrices $M_i$, $M_i'$, and $M_i''$, $i = 1, 2, \ldots, \ell$.

PROPOSITION 23. *For each* $i = 1, 2, \ldots, \ell$

[6]Of course, some of $M_i$, $M_i'$, and $M_i''$, $i = 1, 2, \ldots, \ell$, may be $\mathbf{0}_{(n+1)\times n}$.

1. *inequality*

$$\boldsymbol{f}_{\{M_i+uM_i'',M_i'+vM_i''\}}(\alpha) \neq p_i^{d_i}(\alpha) \tag{10}$$

*implies* $\boldsymbol{f}_{M_i''}(\alpha) = p_i^{d_i}(\alpha)$, *and*

2. (10) *holds for at most one pair* $(u,v) \in F_q^2$.

*Proof.* Assume that $\boldsymbol{f}_{M_i''}(\alpha) \neq p_i^{d_i}(\alpha)$. Then, by the definition of $M_i$, $M_i'$, and $M_i''$, $\boldsymbol{f}_{\{M_i,M_i'\}}(\alpha) = p_i^{d_i}(\alpha)$, because $\boldsymbol{f}_{M_i''}(\alpha)$ properly divides $p_i^{d_i}(\alpha)$. However, $\boldsymbol{f}_{\{M_i,M_i'\}}(\alpha) = p_i^{d_i}(\alpha)$ together with $\boldsymbol{f}_{M_i''}(\alpha) \neq p_i^{d_i}(\alpha)$ (and Lemma 10) contradicts (10).

For the proof of the second claim, assume to the contrary that for two distinct pairs $(u_1,v_1)$ and $(u_2,v_2)$ neither of polynomials $\boldsymbol{f}_{\{M_i+u_1M_i'',M_i'+v_1M_i''\}}(\alpha)$ and $\boldsymbol{f}_{\{M_i+u_2M_i'',M_i'+v_2M_i''\}}(\alpha)$ equals $p_i^{d_i}(\alpha)$. We assume that $u_1 \neq u_2$ (the case of $v_1 \neq v_2$ is treated in a similar manner).

By the definition of $M_i$, $M_i'$, and $M_i''$, both $\boldsymbol{f}_{M_i+u_1M_i''}(\alpha)$ and $\boldsymbol{f}_{M_i+u_2M_i''}(\alpha)$ divide $p_i^{d_i-1}(\alpha)$. Therefore, by Lemma 10, $\boldsymbol{f}_{M''}(\alpha)$ also divides $p_i^{d_i-1}(\alpha)$, which contradicts the first claim of the proposition. □

Now, for a pair $(u,v) \in F_q^2$, let the set $\boldsymbol{I}_{(u,v)}$ consist of all integers $i = 1,2,\ldots,\ell$ which satisfy (10). Then

$$\begin{aligned}\deg \boldsymbol{f}_{\{M+uM'',M'+vM''\}}(\alpha) &= \sum_{i=1}^{\ell} \deg \boldsymbol{f}_{\{M_i+uM_i'',M_i'+vM_i''\}}(\alpha) \\ &\geq \deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) - \deg \prod_{i\in \boldsymbol{I}_{(u,v)}} p_i^{d_i}(\alpha),\end{aligned}$$

implying, by Lemmas 8 and 9,

$$\mu_{F_q}(\{M_i+uM_i'',M_i'+vM_i''\}) \geq \min\left(n+1, \deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) - \deg \prod_{i\in \boldsymbol{I}_{(u,v)}} p_i^{d_i}(\alpha)\right). \tag{11}$$

Therefore, summing over all pairs $(u,v) \in F_q^2$ and adding $\deg \boldsymbol{f}_{M''}(\alpha)$, we obtain

$$\begin{aligned}&\deg \boldsymbol{f}_{M''}(\alpha) + \sum_{(u,v)\in F_q^2} \mu_{F_q}(\{M+uM'',M'+vM''\}) \\ &\geq \deg \boldsymbol{f}_{M''}(\alpha) + \sum_{(u,v)\in F_q^2} \min\left(n+1, \deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) - \deg \prod_{i\in \boldsymbol{I}_{(u,v)}} p_i^{d_i}(\alpha)\right) \\ &\geq \deg \boldsymbol{f}_{M''}(\alpha) + (q^2-1)(n+1) \\ &\qquad + \min\left(n+1, \deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) - \sum_{(u,v)\in F_q^2} \deg \prod_{i\in \boldsymbol{I}_{(u,v)}} p_i^{d_i}(\alpha)\right) \\ &\geq \deg \boldsymbol{f}_{M''}(\alpha) + (q^2-1)(n+1) + \min(n+1, \deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) - \deg \boldsymbol{f}_{M''}(\alpha)) \\ &= \deg \boldsymbol{f}_{M''}(\alpha) + (q^2-1)(n+1) + (\deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) - \deg \boldsymbol{f}_{M''}(\alpha)) \\ &= q^2(n+1) + (\deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) - n - 1),\end{aligned}$$

where the first inequality follows from (11) and the second inequality follows from a trivial observation that for positive real numbers $a$, $b$, and $c$ such that $c \geq n+1$,

$$\min(n+1, c-a) + \min(n+1, c-b) \geq n+1+\min(n+1, c-(a+b)).$$

To prove the last inequality we observe that, by the second claim of Proposition 23, sets $\boldsymbol{I}_{(u,v)}$ are mutually disjoint. Thus, by the first claim of that proposition, $\prod_{(u,v)\in F_q^2}\prod_{i\in \boldsymbol{I}_{(u,v)}} p_i^{d_i}(\alpha)$ divides $\boldsymbol{f}_{M''}(\alpha)$.

Finally, the first equality follows from $\deg \boldsymbol{f}_{\boldsymbol{M}}(\alpha) - \deg \boldsymbol{f}_{M''}(\alpha) \leq n$. This is because $\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) \leq n$ and $\boldsymbol{M} = \{M, M', M''\}$.

Now, the first claim of the theorem follows from (7).

For the proof of the second claim it suffices to find a basis $\{M, M', M''\}$ of $\boldsymbol{M}$ such that for all $u, v \in F_q$,

$$\mu_{F_q}(\{M+uM'', M'+vM''\}) \geq n+1. \tag{12}$$

This, together with (9), would imply

$$\mu_{F_q}(\boldsymbol{M}) \geq n+1+\frac{\deg \boldsymbol{f}_{M''}(\alpha)}{q^2},$$

which, in turn, would imply the second claim of the theorem.

So, let $\{M, M', M''\}$ be a basis of $[\boldsymbol{M}]$. If for all $u, v \in F_q$ it satisfies (12), we are done. Otherwise, it follows from Lemma 8 that for some elements $u$ and $v$ of $F_q$, $\deg \boldsymbol{f}_{\{M+uM'', M'+vM''\}}(\alpha) \leq n$, and we replace $M$, $M'$, and $M''$ with $M+uM''$, $M''$, and $M'+vM''$, respectively, which we shall also denote by $M$, $M'$, and $M''$, respectively. That is, we may assume that

$$\deg \boldsymbol{f}_{\{M,M''\}}(\alpha) \leq n. \tag{13}$$

Again, if for all $u, v \in F_q$, (12) holds (in the new basis), we are done.

Otherwise, for some $u, v \in F_q$, $\deg \boldsymbol{f}_{\{M+uM'', M'+vM''\}}(\alpha) \leq n$, and we replace $M$, $M'$, and $M''$ with $M'+vM''$, $M''$, and $M+uM''$, respectively, which we shall also denote by $M$, $M'$, and $M''$, respectively. Then, in view of (13), we may assume that

$$\deg \boldsymbol{f}_{\{M,M''\}}(\alpha), \deg \boldsymbol{f}_{\{M',M''\}}(\alpha) \leq n. \tag{14}$$

Now we contend that for all $u, v \in F_q$, (12) holds (in the new basis).

To prove our contention, assume to the contrary that for some $u, v \in F_q$, (12) does not hold. Then, by Lemma 8, $\deg \boldsymbol{f}_{\{M+uM'', M'+vM''\}}(\alpha) \leq n$, and we replace $M$ and $M'$ with $M+uM''$ and $M'+vM''$, respectively, which we shall also denote by $M$ and $M'$, respectively. Then, in view of (14),

$$\deg \boldsymbol{f}_{\{M,M''\}}(\alpha), \deg \boldsymbol{f}_{\{M,M'\}}(\alpha), \deg \boldsymbol{f}_{\{M',M''\}}(\alpha) \leq n,$$

in contradiction with the assumption of the second claim of the theorem.

**4. Outline of the proof of Theorem 1.** In this very short section we outline the proof of Theorem 1.

Let $\epsilon_q$ be as in (4) and let $\boldsymbol{D} = \{D_1, D_2, \ldots, D_{2n}\}$ be the set of Hankel matrices defining the components of $W\boldsymbol{z}$ in (2). In view of Example 16, we may assume that the linear closure of each subset of $\boldsymbol{D}$ of cardinality $\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil$ contains an element $H$ such that $\deg \boldsymbol{f}_H(\alpha) < (1-\epsilon_q)n$. Under this assumption we shall construct a subset of $\boldsymbol{D}$ of cardinality $o(n)$ whose linear closure contains three Hankel matrices $M, M'$, and $M''$ such that

$$\min(\deg\{M, M', M''\} - n - 1, \|\{M, M', M''\}\|) \geq \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{15}$$

This together with Corollary 22, Proposition 2, and (4) will prove Theorem 1.

The rest of the paper is organized as follows. In the next section we improve the known lower bound given by Lemma 9 and in section 6 we choose a small cardinality subset $\boldsymbol{D}'$ of $\boldsymbol{D}$ whose linear closure includes a set $\boldsymbol{S}$ of Hankel matrices possessing some special properties. The set $\{M, M', M''\}$ that satisfies (15) is chosen from $[\boldsymbol{S}]$. Matrices $M$ and $M'$ are constructed in section 7, and matrix $M''$ is constructed in section 8.

## 5. A coding-like lower bound, an extension of Lemma 9, and multiplication of polynomials modulo a polynomial.

In section 5.1 we prove a major technical lemma according to which linear spaces of Hankel matrices contain a matrix with an associated divisor of a (relatively) high degree and in section 5.2 we extend Lemma 9 and apply the extension to multiplication of polynomials modulo a polynomial.

### 5.1. A coding-like lower bound.

In this section we estimate the sum of the degrees of the divisors associated with all linear combinations of a set of Hankel matrices. We start with notation that will be used throughout the rest of this paper.

Let $\boldsymbol{S} = \{H_1, H_2, \ldots, H_k\}$ be a set of $(n+1)\times n$ Hankel matrices and let $\boldsymbol{f}_{\boldsymbol{S}}(\alpha) = \prod_{i=1}^{\ell} p_i^{d_i}(\alpha)$ be the decomposition of $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$ into irreducible factors. Then for each $H \in \boldsymbol{S}$ and each $i = 1, 2, \ldots, \ell$ there is the unique Hankel matrix $H|_i$—the $p_i(\alpha)$-component of $H$—such that $\boldsymbol{f}_{H|_i}(\alpha)$ divides $p_i^{d_i}(\alpha)$ and $H = \sum_{i=1}^{\ell} H|_i$; cf. the proof of Theorem 21. The set of all $p_i(\alpha)$-components of the elements of $\boldsymbol{S}$, $i = 1, 2, \ldots, \ell$, will be denoted by $\boldsymbol{S}|_i$. That is,

$$\boldsymbol{S}|_i = \{H|_i : H \in \boldsymbol{S}\}.$$

We shall denote by $\vec{\boldsymbol{S}}$ and $\vec{\boldsymbol{S}}|_i$, $i = 1, 2, \ldots, \ell$, the column vectors of the elements of $\boldsymbol{S}$ and $\boldsymbol{S}|_i$, respectively. That is, $\vec{\boldsymbol{S}} = (H_1, H_2, \ldots, H_k)^T$ and $\vec{\boldsymbol{S}}|_i = (H_1|_i, H_2|_i, \ldots, H_k|_i)^T$, say. Vector $\vec{\boldsymbol{S}}|_i$, $i = 1, 2, \ldots, \ell$, will be referred to as the $p_i(\alpha)$-*component* of $\vec{\boldsymbol{S}}$, and the set of all $p_i(\alpha)$-components of $\vec{\boldsymbol{S}}$, $i = 1, 2, \ldots, \ell$, will be denoted $\mathcal{C}(\vec{\boldsymbol{S}})$.

Next, for a vector $\boldsymbol{v} \in F_q^k$, the set of Hankel matrices $\{\boldsymbol{v}\vec{\boldsymbol{S}}|_i : i = 1, 2, \ldots, \ell\}$ will be denoted by $\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})$. In this notation, $\boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)$ is the product $\prod_{i=1}^{\ell} \boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}|_i}(\alpha)$ of the divisors $\boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}|_i}(\alpha)$ associated with the summands $\boldsymbol{v}\vec{\boldsymbol{S}}|_i$ of $\boldsymbol{v}\vec{\boldsymbol{S}}$, $i = 1, 2, \ldots, \ell$.

In particular, if each $\boldsymbol{f}_{H_i}(\alpha)$ is the minimal polynomial of an infinite linear recurring sequence $\sigma_i$ and $\boldsymbol{v} = (v_1, v_2, \ldots, v_k)$, then $\boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)$ is the minimal polynomial of $\sum_{i=1}^{k} v_i\sigma_i$.

*Remark* 24. Note the difference between $\boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}}(\alpha)$ and $\boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)$. The degree of the former is at most $n$, whereas the degree of the latter can exceed it. The divisors are equal if and only if $\deg \boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \leq n$.

Proposition 25. *For each $\boldsymbol{v}', \boldsymbol{v}'' \in F_q^k$,*

$$\begin{aligned}\deg \boldsymbol{f}_{\boldsymbol{v}'\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) + \deg \boldsymbol{f}_{\boldsymbol{v}''\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) &\geq \deg \operatorname{lcm}\{\boldsymbol{f}_{\boldsymbol{v}'\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha), \boldsymbol{f}_{\boldsymbol{v}''\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)\}\\ &\geq \deg \boldsymbol{f}_{(\boldsymbol{v}'+\boldsymbol{v}'')\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha).\end{aligned}$$

*Proof.* Since, by definition, $\boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) = \prod_{i=1}^{\ell} \boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}|_i}(\alpha)$, $i = 1, 2, \ldots, \ell$, it suffices to show that

$$\begin{aligned}\deg \boldsymbol{f}_{\boldsymbol{v}'\vec{\boldsymbol{S}}|_i}(\alpha) + \deg \boldsymbol{f}_{\boldsymbol{v}''\vec{\boldsymbol{S}}|_i}(\alpha) &\geq \deg \operatorname{lcm}\{\boldsymbol{f}_{\boldsymbol{v}'\vec{\boldsymbol{S}}|_i}(\alpha), \boldsymbol{f}_{\boldsymbol{v}''\vec{\boldsymbol{S}}|_i}(\alpha)\}\\ &\geq \deg \boldsymbol{f}_{(\boldsymbol{v}'+\boldsymbol{v}'')\vec{\boldsymbol{S}}|_i}(\alpha).\end{aligned}$$

The first inequality is trivial and the second inequality holds because, by the definition of $\boldsymbol{S}|_i$, one of the divisors $\boldsymbol{f}_{\boldsymbol{v}'\vec{\boldsymbol{S}}|_i}(\alpha)$ and $\boldsymbol{f}_{\boldsymbol{v}''\vec{\boldsymbol{S}}|_i}(\alpha)$ divides the other. □

Finally, for divisors $\boldsymbol{f}(\alpha)$ and $\boldsymbol{g}(\alpha)$ we denote by $\deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}(\alpha)$ the degree of $\frac{\operatorname{lcm}\{\boldsymbol{g}(\alpha), \boldsymbol{f}(\alpha)\}}{\boldsymbol{g}(\alpha)}$. That is,

$$\deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}(\alpha) = \deg \operatorname{lcm}\{\boldsymbol{g}(\alpha), \boldsymbol{f}(\alpha)\} - \deg \boldsymbol{g}(\alpha). \tag{16}$$

Proposition 26 (cf. Proposition 13). *Let $\boldsymbol{S}$ be a k-element set of $(n+1) \times n$ Hankel matrices. Then*

$$\sum_{\boldsymbol{v} \in F_q^k} \deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \geq (q^k - q^{k-1}) \deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{S}}(\alpha). \tag{17}$$

*Proof.* Let $\boldsymbol{f}_{\boldsymbol{S}}(\alpha) = \prod_{i=1}^{\ell} p_i^{d_i}(\alpha)$. It follows from the definition of $\boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)$ and (16) that

$$\deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) = \sum_{i=1}^{\ell} \deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}|_i}(\alpha).$$

Therefore,

$$\sum_{\boldsymbol{v} \in F_q^k} \deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) = \sum_{i=1}^{\ell} \sum_{\boldsymbol{v} \in F_q^k} \deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}|_i}(\alpha), \tag{18}$$

and we start with the calculation of $\sum_{\boldsymbol{v} \in F_q^k} \deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}|_i}(\alpha)$.

Let

$$\boldsymbol{S}_{i,j} = \{H \in [\boldsymbol{S}|_i] : \boldsymbol{f}_H(\alpha) | p_i^j(\alpha)\}, \tag{19}$$

where $i = 1, 2, \ldots, \ell$ and $j = 0, 1, \ldots, d_i$. Then $\boldsymbol{v}\vec{\boldsymbol{S}}|_i \in \boldsymbol{S}_{i,j} \setminus \boldsymbol{S}_{i,j-1}$ implies

$$\deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}|_i}(\alpha) = \deg_{\boldsymbol{g}(\alpha)} p_i^j(\alpha). \tag{20}$$

First, for each $j = 0, 1, \ldots, d_i$ we shall calculate the number of vectors $\boldsymbol{v} \in F_q^k$ such that $\boldsymbol{v}\vec{\boldsymbol{S}}|_i \in \boldsymbol{S}_{i,j}$ or, equivalently,

$$\boldsymbol{v}\vec{\boldsymbol{S}}|_i \equiv \boldsymbol{0}_{(n+1)\times n} \bmod \boldsymbol{S}_{i,j}. \tag{21}$$

Since the dimension of the vector space of solutions of (21) is

$$k - \dim(\boldsymbol{S}_{i,d_i}/\boldsymbol{S}_{i,j}) = k - (\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j}),$$

where, as usual, $\boldsymbol{S}_{i,d_i}/\boldsymbol{S}_{i,j}$ denotes the quotient vector space of $\boldsymbol{S}_{i,d_i}$ modulo $\boldsymbol{S}_{i,j}$, the number of vectors $\boldsymbol{v}$ satisfying (21) is $q^{k-(\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j})}$. Therefore, the number of vectors $\boldsymbol{v}$ such that $\boldsymbol{v}\vec{\boldsymbol{S}}|_i \in \boldsymbol{S}_{i,j} \setminus \boldsymbol{S}_{i,j-1}$ is

$$q^{k-(\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j})} - q^{k-(\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j-1})},$$

and it follows from (18) and (20) that

$$\begin{aligned} &\sum_{\boldsymbol{v}\in F_q^k} \deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \\ &= \sum_{i=1}^{\ell}\sum_{j=1}^{d_i} \deg_{\boldsymbol{g}(\alpha)} p_i^j(\alpha)\left(q^{k-(\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j})} - q^{k-(\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j-1})}\right). \end{aligned} \tag{22}$$

With no loss of generality, replacing $\boldsymbol{g}(\alpha)$ with $\gcd(\boldsymbol{f}_{\boldsymbol{S}}(\alpha), \boldsymbol{g}(\alpha))$ if necessary, we may assume that $\boldsymbol{g}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$. That is, $\boldsymbol{g}(\alpha) = \prod_{i=1}^{\ell} p_i^{e_i}(\alpha)$, where $e_i \le d_i$, $i = 1, 2, \ldots, \ell$. Then for $i = 1, 2, \ldots, \ell$ and a nonnegative integer $j$,

$$\deg_{\boldsymbol{g}(\alpha)} p_i^j(\alpha) = \begin{cases} \deg p_i^{j-e_i}(\alpha) & \text{if } j \ge e_i, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, by (22), the left-hand side of (17) equals

$$\begin{aligned} &\sum_{i=1}^{\ell} \deg p_i(\alpha) \sum_{j=e_i+1}^{d_i} (j-e_i)\left(q^{k-(\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j})} - q^{k-(\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j-1})}\right) \\ &= \sum_{i=1}^{\ell} q^{k-\dim \boldsymbol{S}_{i,d_i}} \deg p_i(\alpha) \sum_{j=e_i+1}^{d_i} (j-e_i)\left(q^{\dim \boldsymbol{S}_{i,j}} - q^{\dim \boldsymbol{S}_{i,j-1}}\right). \end{aligned} \tag{23}$$

Since

$$\begin{aligned} &\sum_{j=e_i+1}^{d_i} (j-e_i)\left(q^{\dim \boldsymbol{S}_{i,j}} - q^{\dim \boldsymbol{S}_{i,j-1}}\right) \\ &= \sum_{j=e_i+1}^{d_i} (j-e_i) q^{\dim \boldsymbol{S}_{i,j}} - \sum_{j=e_i+1}^{d_i} (j-e_i) q^{\dim \boldsymbol{S}_{i,j-1}} \\ &= \sum_{j=e_i+1}^{d_i} (j-e_i) q^{\dim \boldsymbol{S}_{i,j}} - \sum_{j=e_i}^{d_i-1} (j-e_i+1) q^{\dim \boldsymbol{S}_{i,j}} \\ &= (d_i - e_i) q^{\dim \boldsymbol{S}_{i,d_i}} - \sum_{j=e_i}^{d_i-1} q^{\dim \boldsymbol{S}_{i,j}}, \end{aligned}$$

(23) equals

$$\begin{aligned} &\sum_{i=1}^{\ell} q^{k-\dim \boldsymbol{S}_{i,d_i}} \deg p_i(\alpha) \left( (d_i-e_i) q^{\dim \boldsymbol{S}_{i,d_i}} - \sum_{j=e_i}^{d_i-1} q^{\dim \boldsymbol{S}_{i,j}} \right) \\ &= q^k \deg_{\boldsymbol{g}(\alpha)} \boldsymbol{f}_{\boldsymbol{S}}(\alpha) - q^{k-1} \sum_{i=1}^{\ell} \deg p_i(\alpha) \sum_{j=e_i}^{d_i-1} \frac{q}{q^{\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j}}}. \end{aligned} \tag{24}$$

Now, adding to (24) the zero sum

$$-q^{k-1}\deg_{\boldsymbol{g}(\alpha)}\boldsymbol{f}_{\boldsymbol{S}}(\alpha)+q^{k-1}\sum_{i=1}^{\ell}(d_i-e_i)\deg p_i(\alpha),$$

we obtain

$$\begin{aligned}&\sum_{\boldsymbol{v}\in F_q^k}\deg_{\boldsymbol{g}(\alpha)}\boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)\\ &=(q^k-q^{k-1})\deg_{\boldsymbol{g}(\alpha)}\boldsymbol{f}_{\boldsymbol{S}}(\alpha)\\ &\quad+q^{k-1}\sum_{i=1}^{\ell}\left((d_i-e_i)-\sum_{j=e_i}^{d_i-1}\frac{q}{q^{\dim\boldsymbol{S}_{i,d_i}-\dim\boldsymbol{S}_{i,j}}}\right)\deg p_i(\alpha).\end{aligned}\tag{25}$$

Since for $j<d_i$, $\dim\boldsymbol{S}_{i,d_i}>\dim\boldsymbol{S}_{i,j}$, we have

$$(d_i-e_i)-\sum_{j=e_i}^{d_i-1}\frac{q}{q^{\dim\boldsymbol{S}_{i,d_i}-\dim\boldsymbol{S}_{i,j}}}\geq 0,$$

which together with (25) completes the proof. ☐

We conclude this section with an example that will be used in the proof of Theorem 1.

*Example* 27. Let $\boldsymbol{S}=\{H_1,H_2,\ldots,H_k\}$. *If for all* $\boldsymbol{v}\in F_q^k$,

$$\deg\boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)\leq n,\tag{26}$$

*then* $\mu_{F_q}(\boldsymbol{S})\geq\deg\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$.

Indeed,

$$\mu_{F_q}(\boldsymbol{S})\geq\frac{\sum_{\boldsymbol{v}\in F_q^k}\deg\boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}}(\alpha)}{q^k-q^{k-1}}=\frac{\sum_{\boldsymbol{v}\in F_q^k}\deg\boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)}{q^k-q^{k-1}}\geq\deg\boldsymbol{f}_{\boldsymbol{S}}(\alpha),$$

where the first inequality is by Corollary 15 (because $[\boldsymbol{S}]=\{\boldsymbol{v}\vec{\boldsymbol{S}}:\boldsymbol{v}\in F_q^k\}$), the equality is by (26) and Remark 24, and the last inequality follows from Proposition 26 with $\boldsymbol{g}(\alpha)=1$.

## 5.2. An extension of Lemma 9 and multiplication of polynomials modulo a polynomial.

We start with the following extension of Lemma 9.

LEMMA 28. *Let* $\boldsymbol{S}$ *be a set of* $(n+1)\times n$ *Hankel matrices. Let* $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)=\prod_{i=1}^{\ell}p_i^{d_i}(\alpha)$ *be the decomposition of* $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$ *into irreducible factors and let* $\boldsymbol{S}_{i,j}$, $i=1,2,\ldots,\ell$, $j=0,1,\ldots,d_i$, *be as in the proof of Proposition* 26. *If* $\deg\boldsymbol{f}_{\boldsymbol{S}}(\alpha)\leq n$, *then*

$$\mu_{F_q}(\boldsymbol{S})\geq\left(1+\frac{1}{q-1}\right)\deg\boldsymbol{f}_{\boldsymbol{S}}(\alpha)-\frac{1}{q-1}\sum_{i=1}^{\ell}\left(\sum_{j=0}^{d_i-1}\frac{q}{q^{\dim\boldsymbol{S}_{i,d_i}-\dim\boldsymbol{S}_{i,j}}}\right)\deg p_i(\alpha).$$

*Proof.* Since $\deg\boldsymbol{f}_{\boldsymbol{S}}(\alpha)\leq n$, by Lemma 10 and Remark 24, $\boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)=\boldsymbol{f}_{\boldsymbol{v}\vec{\boldsymbol{S}}}(\alpha)$ for each $\boldsymbol{v}\in F_q^k$. Therefore, the lemma follows from Corollary 15, (25) with $\boldsymbol{g}(\alpha)=1$,[7] and equality $\deg\boldsymbol{f}_{\boldsymbol{S}}(\alpha)=\sum_{i=1}^{\ell}d_i\deg p_i(\alpha)$. ☐

[7]Of course, in both Corollary 15 and (25), $k=|\boldsymbol{S}|$.

In particular, as an easy corollary to Lemma 28, we obtain a more intuitive and direct proof of the lower bound on the complexity of multiplication of polynomials modulo a polynomial ([4] and [7]) with a better lower order term.

We shall need the following notation. Let $P(\alpha)$ be a polynomial of degree $n$ over $F_q$, and let $\boldsymbol{C}_{P(\alpha)}$ be the set of the coefficients of the minimal degree residue of $\sum_{k=0}^{2n-1} z_k \alpha^k$ modulo $P(\alpha)$, where $z_k$s are defined by (1).

Corollary 29 (cf. [4] and [7, Corollary 4.5]). *We have*

$$\mu_{F_q}(\boldsymbol{C}_{P(\alpha)}) \geq \left(2 + \frac{1}{q-1}\right) n - o(n).$$

*Proof.* Assume that $\mu_{F_q}(\boldsymbol{C}_{P(\alpha)}) = t$. That is, there exist $t$ pairs of linear forms $(L_1'(\boldsymbol{x},\boldsymbol{y}), L_1''(\boldsymbol{x},\boldsymbol{y})), \ldots, (L_t'(\boldsymbol{x},\boldsymbol{y}), L_t''(\boldsymbol{x},\boldsymbol{y}))$ such that the elements of $\boldsymbol{C}_{P(\alpha)}$ are linear combinations of products $L_i'(\boldsymbol{x},\boldsymbol{y})L_i''(\boldsymbol{x},\boldsymbol{y})$, $i = 1,2,\ldots,t$. Let $\boldsymbol{p}$ be a column vector of the above products. Since $\dim[\boldsymbol{C}_{P(\alpha)}] = n$, there exists an $n \times t$ matrix $U$ such that $\vec{\boldsymbol{C}}_{P(\alpha)} = U\boldsymbol{p}$, where $\vec{\boldsymbol{C}}_{P(\alpha)}$ is a column vector of the elements of $\boldsymbol{C}_{P(\alpha)}$.

Permuting the components of $\boldsymbol{p}$ if necessary, we may assume that the first $n$ columns of $U$ are linearly independent. Hence there exist a nonsingular $n \times n$ matrix $W$ and an $n \times (t-n)$ matrix $V$ such that

$$W\vec{\boldsymbol{C}}_{P(\alpha)} = (\boldsymbol{I}_n, V)\boldsymbol{p}.$$

Let $\boldsymbol{C}^W$ denote the set of the components of $W\vec{\boldsymbol{C}}_{P(\alpha)}$. By [15, Lemma 6], $\boldsymbol{f}_{\boldsymbol{C}_{P(\alpha)}}(\alpha) = P(\alpha)$. Therefore, by Lemma 10, $\boldsymbol{f}_{\boldsymbol{C}^W}(\alpha) = P(\alpha)$ as well, implying that $\boldsymbol{C}^W$ is a basis of $\{H : \boldsymbol{f}_H(\alpha) | P(\alpha)\}$, because the elements of $\boldsymbol{C}^W$ are linearly independent.

Let $P(\alpha) = \prod_{i=1}^{\ell} p_i^{d_i}(\alpha)$ be the decomposition of $P(\alpha)$ into irreducible factors and let $k_i = \lceil \lg_q \deg p_i^{d_i}(\alpha) \rceil$, $i = 1,2,\ldots,\ell$.

For each $i = 1,2,\ldots,\ell$, let $\boldsymbol{C}_i$ be a $k_i$-element subset of $\boldsymbol{C}^W$ such that the elements of $\boldsymbol{C}_i|_i$ are linearly independent modulo $[\boldsymbol{C}_{p_i^{d_i - \lfloor k_i / \deg p_i(\alpha) \rfloor - 1}}(\alpha)]$ and $\boldsymbol{C}_i|_i$ contains a basis of $[\boldsymbol{C}^W|_i]$ modulo $[\boldsymbol{C}_{p_i^{d_i - \lfloor k_i / \deg p_i(\alpha) \rfloor}}(\alpha)]$.

Let $\boldsymbol{S} = \bigcup_{i=1}^{\ell} \boldsymbol{C}_i$. Similarly to [1, Proposition 1], one can show that

$$\mu_{F_q}(\boldsymbol{C}^W) \geq n + \mu_{F_q}(\boldsymbol{S}) - |\boldsymbol{S}|. \tag{27}$$

Since $[\boldsymbol{C}_{P(\alpha)}] = [\boldsymbol{C}^W]$, $\mu_{F_q}(\boldsymbol{C}_{P(\alpha)}) = \mu_{F_q}(\boldsymbol{C}^W)$, and it follows from the definition of $\boldsymbol{S}$ that $|\boldsymbol{S}| \leq \sum_{i=1}^{\ell} k_i$. This together with (27) implies

$$\mu_{F_q}(\boldsymbol{C}_{P(\alpha)}) \geq n + \mu_{F_q}(\boldsymbol{S}) - \sum_{i=1}^{\ell} k_i.$$

By the definition of $\boldsymbol{C}_i$, $\boldsymbol{f}_{\boldsymbol{C}_i}(\alpha) = p_i^{d_i}(\alpha)$, $i = 1,2,\ldots,\ell$. Therefore,

$$\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) = \sum_{i=1}^{\ell} d_i \deg p_i(\alpha) = \deg P(\alpha) = n,$$

which together with Lemma 28 implies

$$\mu_{F_q}(\boldsymbol{S}) \geq \left(1 + \frac{1}{q-1}\right) n - \frac{q}{q-1} \sum_{i=1}^{\ell} \left( \sum_{j=0}^{d_i - 1} \frac{1}{q^{\dim \boldsymbol{S}_{i,d_i} - \dim \boldsymbol{S}_{i,j}}} \right) \deg p_i(\alpha).$$

Hence it suffices to show that

$$\sum_{i=1}^{\ell}\left(\frac{q}{q-1}\left(\sum_{j=0}^{d_i-1}\frac{1}{q^{\dim \boldsymbol{S}_{i,d_i}-\dim \boldsymbol{S}_{i,j}}}\right)\deg p_i(\alpha)+k_i\right) \tag{28}$$

is $o(n)$.

It follows from the definition of $\boldsymbol{S}$ that

- $\dim \boldsymbol{S}_{i,d_i}-\dim \boldsymbol{S}_{i,j}=(d_i-j)\deg p_i(\alpha)$ if $j\ge d_i-\lfloor k_i/\deg p_i(\alpha)\rfloor$ and
- $\dim \boldsymbol{S}_{i,d_i}-\dim \boldsymbol{S}_{i,j}\ge k_i$ otherwise.

Therefore,

$$\begin{aligned}\sum_{j=0}^{d_i-1}\frac{1}{q^{\dim \boldsymbol{S}_{i,d_i}-\dim \boldsymbol{S}_{i,j}}} &\le \sum_{j=1}^{\lfloor k_i/\deg p_i(\alpha)\rfloor}\frac{1}{q^{j\deg p_i(\alpha)}}+\frac{d_i-\lfloor k_i/\deg p_i(\alpha)\rfloor}{q^{k_i}}\\ &= \frac{1}{q^{\deg p_i(\alpha)}}\frac{1-q^{-\lfloor k_i/\deg p_i(\alpha)\rfloor\deg p_i(\alpha)}}{1-q^{-\deg p_i(\alpha)}}+\frac{d_i-\lfloor k_i/\deg p_i(\alpha)\rfloor}{q^{k_i}}\\ &\le \frac{1}{q^{\deg p_i(\alpha)}-1}+\frac{d_i}{q^{k_i}}.\end{aligned}$$

Consequently,

$$\left(\sum_{j=0}^{d_i-1}\frac{1}{q^{\dim \boldsymbol{S}_{i,d_i}-\dim \boldsymbol{S}_{i,j}}}\right)\deg p_i(\alpha)\le \frac{\deg p_i(\alpha)}{q^{\deg p_i(\alpha)}-1}+\frac{d_i\deg p_i(\alpha)}{q^{k_i}}\le\frac{q+1}{q-1},$$

because

$$\frac{\deg p_i(\alpha)}{q^{\deg p_i(\alpha)}-1}\le\frac{1}{q}$$

and, by the definition of $k_i$,

$$q^{k_i}\ge d_i\deg p_i(\alpha).$$

Therefore,

$$\frac{q}{q-1}\left(\sum_{j=0}^{d_i-1}\frac{1}{q^{\dim \boldsymbol{S}_{i,d_i}-\dim \boldsymbol{S}_{i,j}}}\right)\deg p_i(\alpha)+k_i\le\frac{q(q+1)}{(q-1)^2}+k_i,$$

which, in turn, implies that (28) is bound by

$$\begin{aligned}\frac{q(q+1)}{(q-1)^2}\ell+\sum_{i=1}^{\ell}k_i &\le \frac{q(q+1)}{(q-1)^2}\ell+\sum_{i=1}^{\ell}\lg_q\deg p_i^{d_i}(\alpha)+\ell\\ &\le \frac{q(q+1)}{(q-1)^2}i_q(n)+\lg_q\deg\prod_{i=1}^{\ell}p_i^{d_i}(\alpha)+i_q(n)\\ &= \frac{2q^2-q+1}{(q-1)^2}i_q(n)+\lg_q n,\end{aligned}$$

which completes the proof. □

*Remark* 30. A straightforward inspection shows that [15, Lemma 6] extends to divisors. That is, for a divisor $P(\alpha)$, $\boldsymbol{f}_{\boldsymbol{C}_{P(\alpha)}}(\alpha)=P(\alpha)$.[8] Therefore, Corollary 29 holds for computation of the polynomial product modulo a divisor as well.

[8]See [1, section 2] for the definition of the minimal degree residue modulo a divisor.

## 6. Proof of Theorem 1. Part 1: Construction of a subset of $\boldsymbol{D}$ of a small cardinality.

First, in section 6.1 we prove a number of auxiliary results needed for our constructions. Then, in section 6.2 we choose a small cardinality subset $\boldsymbol{D}'$ of $\boldsymbol{D}$ whose linear closure includes a set of Hankel matrices $\boldsymbol{S}$ needed for the construction of $M$, $M'$, and $M''$.

### 6.1. An extension of Lemma 10.

In this section we describe divisors of some elements of the vector space spanned by a set of Hankel matrices.

PROPOSITION 31 (cf. Lemma 10). *Let $\boldsymbol{S}$ be a set of $(n+1)\times n$ Hankel matrices and let $H \in [\boldsymbol{S}]$. If $\deg \boldsymbol{f}_{\boldsymbol{S}\cup\{H\}}(\alpha) \le 2n$, then $\boldsymbol{f}_H(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$.*

The proof of Proposition 31 is based on its particular cases treated by Lemmas 32 and 33 below.

LEMMA 32. *Let $H'$ and $H''$ be $(n+1)\times n$ Hankel matrices such that $\boldsymbol{f}_{H'}(\alpha)$ and $\boldsymbol{f}_{H''}(\alpha)$ are coprime and*

$$\deg \boldsymbol{f}_{H'}(\alpha) + \deg \boldsymbol{f}_{H''}(\alpha) + \deg \boldsymbol{f}_{H'+H''}(\alpha) \le 2n. \tag{29}$$

*Then $\boldsymbol{f}_{H'+H''}(\alpha)$ divides $\boldsymbol{f}_{H'}(\alpha)\boldsymbol{f}_{H''}(\alpha)$.*

*Proof.* We shall denote $H' + H''$ by $H$.

Let $H$, $H'$, and $H''$ be defined by sequences $\sigma = s_0, s_1, \ldots, s_{2n-1}$, $\sigma' = s'_0, s'_1, \ldots, s'_{2n-1}$, and $\sigma'' = s''_0, s''_1, \ldots, s''_{2n-1}$, respectively.

Since $\boldsymbol{f}_{H'}(\alpha)$ and $\boldsymbol{f}_{H''}(\alpha)$ are coprime, we may assume that $\bar{H}''$ is the zero $(n+1)\times n$ matrix $\mathbf{0}_{(n+1)\times n}$.[9]

We contend that $\bar{H} = \bar{H}'$. By [18, Theorem 8.55, p. 425], $\boldsymbol{f}_{\tilde{H}'}(\alpha)\boldsymbol{f}_{\tilde{H}''}(\alpha)\boldsymbol{f}_{\tilde{H}}(\alpha)$ is a characteristic polynomial of $\tilde{\sigma}' + \tilde{\sigma}'' - \tilde{\sigma}$, and it follows from (29) that

$$\deg \boldsymbol{f}_{\tilde{H}'}(\alpha)\boldsymbol{f}_{\tilde{H}''}(\alpha)\boldsymbol{f}_{\tilde{H}}(\alpha) \le 2n - \max\{\mathrm{rank}(\bar{H}), \mathrm{rank}(\bar{H}')\}. \tag{30}$$

In addition, since

$$\tilde{H}' + \tilde{H}'' - \tilde{H} = (H' - \bar{H}') + (H'' - \bar{H}'') - (H - \bar{H}) = \bar{H} - \bar{H}', \tag{31}$$

the first $2n - \max\{\mathrm{rank}(\bar{H}), \mathrm{rank}(\bar{H}')\}$ elements of $\tilde{\sigma}' + \tilde{\sigma}'' - \tilde{\sigma}$ are 0. Thus, by (30), all elements of $\tilde{\sigma}' + \tilde{\sigma}'' - \tilde{\sigma}$ are 0 as well. This together with (31) implies

$$\tilde{H}' + \tilde{H}'' - \tilde{H} = \bar{H} - \bar{H}' = \mathbf{0}_{(n+1)\times n},$$

which, in turn, implies the desired equality $\bar{H} = \bar{H}'$.

It remains to show that $\boldsymbol{f}_{\tilde{H}}(\alpha)$ divides $\boldsymbol{f}_{\tilde{H}'}(\alpha)\boldsymbol{f}_{\tilde{H}''}(\alpha)$. Let

$$\mathrm{rank}(\bar{H}') = d \quad (= \mathrm{rank}(\bar{H}))$$

and let $\sigma|_{2n-d-1}$, $\sigma'|_{2n-d-1}$, and $\sigma''|_{2n-d-1}$ consist of the first $2n-d$ elements of $\sigma$, $\sigma'$, and $\sigma''$, respectively. Then $\boldsymbol{f}_{\tilde{H}'}(\alpha)$ and $\boldsymbol{f}_{\tilde{H}''}(\alpha)$ are characteristic polynomials of $\sigma'|_{2n-d-1}$ and $\sigma''|_{2n-d-1}$, respectively, and, by [18, Theorem 8.55, p. 425], $\boldsymbol{f}_{\tilde{H}'}(\alpha)\boldsymbol{f}_{\tilde{H}''}(\alpha)$ is a characteristic polynomial of $\sigma'|_{2n-d-1} + \sigma''|_{2n-d-1}$.

Since $\sigma'|_{2n-d-1} + \sigma''|_{2n-d-1} = \sigma|_{2n-d-1}$ and $\boldsymbol{f}_{\tilde{H}}(\alpha)$ is the minimal polynomial of $\sigma|_{2n-d-1}$, the result follows from Proposition 3 (that applies in view of (29)). ∎

LEMMA 33. *Let $\boldsymbol{S}$ be a set of $(n+1)\times n$ Hankel matrices and let $H \in [\boldsymbol{S}]$. If $\deg \boldsymbol{f}_H(\alpha) + \deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \le 2n$, then $\boldsymbol{f}_H(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$.*

[9]See Definition 4 and Example 5.

*Proof.* Let $\boldsymbol{f}_{\boldsymbol{S}}(\alpha) = \prod_{i=1}^{\ell} p_i^{d_i}(\alpha)$ be the decomposition of $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$ into irreducible factors. Then $H = \sum_{i=1}^{\ell} H_i$, where $\boldsymbol{f}_{H_i}(\alpha)$ divides $p_i^{d_i}(\alpha)$, $i = 1, 2, \ldots, \ell$.

Since $\prod_{i=1}^{\ell} \boldsymbol{f}_{H_i}(\alpha)$ divides $\prod_{i=1}^{\ell} p_i^{d_i}(\alpha) = \boldsymbol{f}_{\boldsymbol{S}}(\alpha)$, it suffices to show that $\boldsymbol{f}_H(\alpha)$ divides $\prod_{i=1}^{\ell} \boldsymbol{f}_{H_i}(\alpha)$.

A straightforward induction based on Lemma 32 shows that $\boldsymbol{f}_{\sum_{i=1}^{k} H_i}(\alpha)$ divides $\prod_{i=1}^{k} \boldsymbol{f}_{H_i}(\alpha)$, $k = 2, 3, \ldots, \ell$, and the result follows with $k = \ell$. ◻

*Proof of Proposition* 31. Let $H = H' + H''$, where $\boldsymbol{f}_{H'}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$ and $\boldsymbol{f}_{H''}(\alpha)$ is coprime with $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$.

Since $H \in [\boldsymbol{S}]$, $H'' \in [\boldsymbol{S} \cup \{H'\}]$. Therefore,

$$\deg \boldsymbol{f}_{\boldsymbol{S} \cup \{H'\}}(\alpha) + \deg \boldsymbol{f}_{H''}(\alpha) = \deg \boldsymbol{f}_{\boldsymbol{S} \cup \{H\}}(\alpha) \leq 2n.$$

Thus, by Lemma 33, $\boldsymbol{f}_{H''}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{S} \cup \{H'\}}(\alpha)$, which together with the definition of $H''$ implies $H'' = \mathbf{0}_{(n+1)\times n}$. That is, $H = H'$, which completes the proof. ◻

**6.2. Construction of $\boldsymbol{S}$.** Let $\boldsymbol{D} = \{D_1, D_2, \ldots, D_{2n}\}$ be the set of Hankel matrices defining the components of $W\boldsymbol{z}$ in (2). Lemma 34 below provides us with a small cardinality subset $\boldsymbol{D}'$ of $\boldsymbol{D}$ and a subset $\boldsymbol{S}$ of $[\boldsymbol{D}']$ needed for the construction of three matrices $M$, $M'$, and $M''$ satisfying (15).

LEMMA 34. *Assume that the linear closure of each subset of $\boldsymbol{D}$ of cardinality $\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil$ contains a matrix $H$ such that $\deg \boldsymbol{f}_H(\alpha) < (1 - \epsilon_q)n$. Then there exists a subset $\boldsymbol{D}'$ of $\boldsymbol{D}$ of cardinality at most $\frac{(1+\epsilon_q)n \lg_q \lg_q n}{\lg_q((1+\epsilon_q)n)}$ and there exists a subset $\boldsymbol{S}$ of $[\boldsymbol{D}']$ such that*

1. *for each $H \in \boldsymbol{S}$, $\deg \boldsymbol{f}_H(\alpha) < (1 - \epsilon_q)n$ and*
2. *$\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \geq (1 + \epsilon_q)n$.*

*Proof.* For a $\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil$-element subset $\boldsymbol{C}$ of $\boldsymbol{D}$, let $H_{\boldsymbol{C}} \in [\boldsymbol{C}]$ be such that $\deg \boldsymbol{f}_{H_{\boldsymbol{C}}}(\alpha) < (1 - \epsilon_q)n$ and let

$$\boldsymbol{H} = \{H_{\boldsymbol{C}} : |\boldsymbol{C}| = \lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil\}. \tag{32}$$

We contend that $\dim[\boldsymbol{H}] \geq 2n - \lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil$. For the proof, assume to the contrary that $\dim[\boldsymbol{H}] < 2n - \lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil$. Let $\vec{\boldsymbol{D}}$ be a column vector of the elements of $\boldsymbol{D}$ and let $U$ be a $\dim[\boldsymbol{H}] \times 2n$ matrix such that the components of $U\vec{\boldsymbol{D}}$ form a basis of $[\boldsymbol{H}]$. Permuting the components of $\vec{\boldsymbol{D}}$ and applying linear transformations if necessary, we may assume that $U$ is of the form $(\boldsymbol{I}_{\dim[\boldsymbol{H}]}, V)$. Then

$$[\boldsymbol{H}] \cap [\{D_{2n-i} : i = 0, 1, \ldots, \lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil - 1\}] = \emptyset.$$

Therefore,

$$H_{\{D_{2n-i} : i=0,1,\ldots,\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil - 1\}} \notin \boldsymbol{H},$$

in contradiction with the definition of $\boldsymbol{H}$. This proves our contention.

Since

$$2n - \lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil > (1 + \epsilon_q)n,$$

by Lemma 11, there exists a subset $\boldsymbol{S}$ of $\boldsymbol{H}$ of cardinality at most $i_q((1 + \epsilon_q)n)$ such that $\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \geq (1 + \epsilon_q)n$.

It remains to construct a small cardinality subset $\boldsymbol{D}'$ of $\boldsymbol{D}$ such that $\boldsymbol{S} \subseteq [\boldsymbol{D}']$.

For each element $H$ of $\boldsymbol{S}$, let $\boldsymbol{C}_H$ be a $\lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil$-element subset of $\boldsymbol{D}$ such that $H = H_{\boldsymbol{C}_H}$ and let

$$\boldsymbol{D}' = \bigcup_{H \in \boldsymbol{S}} \boldsymbol{C}_H.$$

Then $\boldsymbol{S} \subset [\boldsymbol{D}']$ and

$$|\boldsymbol{D}'| \leq \lceil \lg_q \lg_q n - \lg_q \lg_q \lg_q n \rceil i_q((1+\epsilon_q)n) \leq \frac{(1+\epsilon_q)n \lg_q \lg_q n}{\lg_q((1+\epsilon_q)n)},$$

which completes the proof. □

COROLLARY 35. *Let $\boldsymbol{S}$ be as in Lemma* 34. *Then* $\deg \boldsymbol{S} \geq (1+\epsilon_q)n$.

*Proof.* Assume to the contrary that for some basis $\boldsymbol{S}'$ of $[\boldsymbol{S}]$, $\deg \boldsymbol{f}_{\boldsymbol{S}'}(\alpha) < (1+\epsilon_q)n$. Let $H \in \boldsymbol{S}$. Then $H \in [\boldsymbol{S}']$, because $\boldsymbol{S}'$ is a basis of $[\boldsymbol{S}]$. Also, by Lemma 34, $\deg \boldsymbol{f}_H(\alpha) < (1-\epsilon_q)n$, implying

$$\deg \boldsymbol{f}_{\boldsymbol{S}'}(\alpha) + \deg \boldsymbol{f}_H(\alpha) < (1+\epsilon_q)n + (1-\epsilon_q)n = 2n.$$

Therefore, by Lemma 33, $\boldsymbol{f}_H(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{S}'}(\alpha)$, and, consequently, $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{S}'}(\alpha)$. However, this contradicts our assumption $\deg \boldsymbol{f}_{\boldsymbol{S}'}(\alpha) < (1+\epsilon_q)n$, because $\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \geq (1+\epsilon_q)n$. □

Let $\boldsymbol{S}$ be as in Lemma 34. Deleting some elements from $\boldsymbol{S}$ if necessary, we may assume that for no proper subset $\boldsymbol{S}'$ of $\boldsymbol{S}$, $\deg \boldsymbol{f}_{\boldsymbol{S}'}(\alpha) \geq (1+\epsilon_q)n$. Also, replacing $\boldsymbol{H}$ defined in the proof of Lemma 34 with its maximal linearly independent subset, we may assume that the elements of $\boldsymbol{S}$ are linearly independent.

## 7. Proof of Theorem 1. Part 2: Construction of $M$ and $M'$.

Let $\boldsymbol{S}$ be the set of matrices constructed in section 6.2. In this section we construct Hankel matrices $M$ and $M'$, $M, M' \in [\boldsymbol{S}]$, such that

$$\deg \boldsymbol{f}_M(\alpha) < \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right)n, \tag{33}$$

$$\deg \boldsymbol{f}_{M'}(\alpha) < \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right)n, \tag{34}$$

$$\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) \geq \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right)n, \tag{35}$$

and

$$\|\{M, M'\}\| \geq \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{36}$$

The construction is as follows. Let $\boldsymbol{S} = \{H_1, H_2, \ldots, H_k\}$. In view of Example 27 and Proposition 2, we may assume that for some $\boldsymbol{v} \in F_q^k$,

$$\deg \boldsymbol{f}_{\boldsymbol{v}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) > n, \tag{37}$$

and we fix such a vector $\boldsymbol{v} = (v_1, v_2, \ldots, v_k)$ through the end of this section.

The first two matrices $M$ and $M'$ are appropriate subsums of $\boldsymbol{v}\vec{\boldsymbol{S}}$, and the third matrix $M''$ is constructed from the quotient vector space $[\boldsymbol{S}]/[M, M']$.

To construct $M$ and $M'$, which satisfy (33)–(36), we shall distinguish between the cases of

$$\max\{\deg \boldsymbol{f}_{H_i}(\alpha) : v_i \neq 0\} < \frac{(q-1)^2}{q^2}\epsilon_q n \tag{38}$$

and

$$\max\{\deg \boldsymbol{f}_{H_i}(\alpha) : v_i \neq 0\} \geq \frac{(q-1)^2}{q^2}\epsilon_q n \tag{39}$$

and use the following notation.

For $I \subseteq \{1, 2, \ldots, k\}$ we define a $k$-dimensional vector $\boldsymbol{v}^I = (v_1^I, v_2^I, \ldots, v_k^I)$ by

$$v_i^I = \begin{cases} v_i & \text{if } i \in I, \\ 0 & \text{otherwise,} \end{cases} \qquad i = 1, 2, \ldots, k.$$

**7.1. The case of $\max\{\deg \boldsymbol{f}_{H_i}(\alpha) : v_i \neq 0\} < \frac{(q-1)^2}{q^2}\epsilon_q n$.** Let $J$ be a minimal (with respect to inclusion) subset of $\{1, 2, \ldots, k\}$ such that

$$\deg \boldsymbol{f}_{\boldsymbol{v}^J \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) > \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right) n \tag{40}$$

and let $I$ be a minimal (with respect to inclusion) subset of $J$ such that

$$\deg \boldsymbol{f}_{\boldsymbol{v}^I \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \geq \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{41}$$

Proposition 36. *We have*

$$\deg \boldsymbol{f}_{\boldsymbol{v}^I \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) < 2\left(\frac{(q-1)^2}{q^2}\epsilon_q n\right).$$

*Proof.* Assume to the contrary that

$$\deg \boldsymbol{f}_{\boldsymbol{v}^I \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \geq 2\left(\frac{(q-1)^2}{q^2}\epsilon_q n\right). \tag{42}$$

Then, for each $i \in I$,

$$\begin{aligned}\deg \boldsymbol{f}_{\boldsymbol{v}^{I\setminus\{i\}} \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) &\geq \deg \boldsymbol{f}_{\boldsymbol{v}^I \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) - \deg \boldsymbol{f}_{\boldsymbol{v}^{\{i\}} \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \\ &\geq 2\left(\frac{(q-1)^2}{q^2}\epsilon_q n\right) - \frac{(q-1)^2}{q^2}\epsilon_q n = \frac{(q-1)^2}{q^2}\epsilon_q n,\end{aligned}$$

where the first inequality is by Proposition 25 and the last inequality follows from (42) and (38). However,

$$\deg \boldsymbol{f}_{\boldsymbol{v}^{I\setminus\{i\}} \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \geq \frac{(q-1)^2}{q^2}\epsilon_q n$$

contradicts the definition of $I$ as a minimal subset of $J$ satisfying (41). $\square$

By Proposition 36 and Remark 24, $\deg \boldsymbol{f}_{\boldsymbol{v}^I \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) = \deg \boldsymbol{f}_{\boldsymbol{v}^I \vec{\boldsymbol{S}}}(\alpha)$, and we let $M$ be $\boldsymbol{v}^I \vec{\boldsymbol{S}}$. Then (33) follows from Proposition 36 and (4).

Let $I'$ be a minimal (with respect to inclusion) subset of $J \setminus I$ such that

$$\deg \operatorname{lcm}\{\boldsymbol{f}_{\boldsymbol{v}^I \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha), \boldsymbol{f}_{\boldsymbol{v}^{I'} \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)\} \geq \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right) n. \tag{43}$$

The existence of $I'$ follows from (40) and Proposition 25.

It follows from the minimality assumption on $J$ that

$$\deg \boldsymbol{f}_{\boldsymbol{v}^{I'} \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) < \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right) n. \tag{44}$$

Therefore, by Remark 24,

$$\deg \boldsymbol{f}_{\boldsymbol{v}^{I'} \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) = \deg \boldsymbol{f}_{\boldsymbol{v}^{I'} \vec{\boldsymbol{S}}}(\alpha)$$

and we let $M'$ be $\boldsymbol{v}^{I'} \vec{\boldsymbol{S}}$. Then (34) follows from (44), and (35) follows from (43).

For the proof of (36) we need Proposition 37 below.

Proposition 37. *We have*

$$\deg \boldsymbol{f}_{M'}(\alpha) \geq \left(1 - 3\left(\frac{(q-1)^2}{q^2}\epsilon_q\right)\right) n.$$

*Proof.* Were

$$\deg \boldsymbol{f}_{M'}(\alpha) = \deg \boldsymbol{f}_{\boldsymbol{v}^{I'} \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) < \left(1 - 3\left(\frac{(q-1)^2}{q^2}\epsilon_q\right)\right) n, \tag{45}$$

by Propositions 36 and 25, we would have

$$\begin{aligned}\left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right) n &= 2\left(\frac{(q-1)^2}{q^2}\epsilon_q n\right) + \left(1 - 3\left(\frac{(q-1)^2}{q^2}\epsilon_q\right)\right) n \\ &> \deg \boldsymbol{f}_{\boldsymbol{v}^I \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) + \deg \boldsymbol{f}_{\boldsymbol{v}^{I'} \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \\ &\geq \deg \operatorname{lcm}\{\boldsymbol{f}_{\boldsymbol{v}^I \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha), \boldsymbol{f}_{\boldsymbol{v}^{I'} \mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)\},\end{aligned}$$

which contradicts (43). $\square$

In view of (41), for the proof of (36), it suffices to show that for all $v \in F_q$, $\deg \boldsymbol{f}_{vM+M'}(\alpha) \geq \frac{(q-1)^2}{q^2}\epsilon_q n$.

This is indeed so, because

$$\begin{aligned}\deg \boldsymbol{f}_{vM+M'}(\alpha) &\geq \deg \boldsymbol{f}_{M'}(\alpha) - \deg \boldsymbol{f}_M(\alpha) \\ &\geq \left(1 - 3\left(\frac{(q-1)^2}{q^2}\epsilon_q\right)\right) n - 2\left(\frac{(q-1)^2}{q^2}\epsilon_q\right) n \\ &\geq \frac{(q-1)^2}{q^2}\epsilon_q n,\end{aligned}$$

where the first inequality follows from Proposition 25, the second inequality follows from Propositions 37 and 36, and the last inequality follows from (4).

This completes the construction of $M$ and $M'$ in the case of (38).

We conclude this section with the observation that

$$\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) < n. \tag{46}$$

This observation will be used in the construction of matrix $M''$ in section 8.1.2.

For the proof of (46), assume to the contrary that

$$\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) = \deg \operatorname{lcm}\{\boldsymbol{f}_{\boldsymbol{v}^I\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha), \boldsymbol{f}_{\boldsymbol{v}^{I'}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)\} \geq n.$$

This together with (38) and (4) implies that for each $i \in I'$,

$$\begin{aligned}&\deg \operatorname{lcm}\{\boldsymbol{f}_{\boldsymbol{v}^I\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha), \boldsymbol{f}_{\boldsymbol{v}^{I'\setminus\{i\}}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)\}\\ &\geq \deg \operatorname{lcm}\{\boldsymbol{f}_{\boldsymbol{v}^I\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha), \boldsymbol{f}_{\boldsymbol{v}^{I'}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)\} - \deg \boldsymbol{f}_{H_i}(\alpha)\\ &\geq n - \frac{(q-1)^2}{q^2}\epsilon_q n = \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right) n,\end{aligned}$$

which contradicts the definition of $I'$ as a minimal subset of $J \setminus I$ satisfying (43).

**7.2. The case of $\max\{\deg \boldsymbol{f}_{H_i}(\alpha) : v_i \neq 0\} \geq \frac{(q-1)^2}{q^2}\epsilon_q n$.** Let $i = 1, 2, \ldots, k$ be such that $\deg \boldsymbol{f}_{H_i}(\alpha) \geq \frac{(q-1)^2}{q^2}\epsilon_q n$ and let $I$ be a maximal (with respect to inclusion) subset of $\{1, 2, \ldots, k\}$ containing $i$ such that

$$\deg \boldsymbol{f}_{\boldsymbol{v}^I\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) < \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right) n. \tag{47}$$

By Remark 24, $\deg \boldsymbol{f}_{\boldsymbol{v}^I\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) = \deg \boldsymbol{f}_{\boldsymbol{v}^I\vec{\boldsymbol{S}}}(\alpha)$, and we let $M$ be $\boldsymbol{v}^I\vec{\boldsymbol{S}}$. Then (33) immediately follows from the definition.

To construct $M'$ we shall distinguish between the cases of

$$\max\{\deg \boldsymbol{f}_{H_i}(\alpha) : i \in \{1, 2, \ldots, k\} \setminus I\} \geq \frac{(q-1)^2}{q^2}\epsilon_q n \tag{48}$$

and

$$\max\{\deg \boldsymbol{f}_{H_i}(\alpha) : i \in \{1, 2, \ldots, k\} \setminus I\} < \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{49}$$

If (48), let $M'$ be an element of $\{H_i : i \in \{1, 2, \ldots, k\} \setminus I\}$ such that

$$\deg \boldsymbol{f}_{M'}(\alpha) \geq \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{50}$$

Then (34) immediately follows from the first claim of Lemma 34.

Otherwise, i.e., if (49), let $I'$ be a minimal (with respect to inclusion) subset of $\{1, 2, \ldots, k\} \setminus I$ such that

$$\deg \boldsymbol{f}_{\boldsymbol{v}^{I'}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \geq \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{51}$$

The existence of $I'$ follows from (37), (47), and Proposition 25. Similarly to the proof of Proposition 36 one can show that

$$\deg \boldsymbol{f}_{\boldsymbol{v}^{I'}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) < 2\left(\frac{(q-1)^2}{q^2}\epsilon_q n\right). \tag{52}$$

Therefore, by Remark 24, $\deg \boldsymbol{f}_{\boldsymbol{v}^{I'}\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) = \deg \boldsymbol{f}_{\boldsymbol{v}^{I'}\vec{\boldsymbol{S}}}(\alpha)$ and we let $M'$ be $\boldsymbol{v}^{I'}\vec{\boldsymbol{S}}$. Then (34) follows from (52) and (4), and (35) follows from the definition of $I$ in the beginning of this section.

It remains to prove (36). In view of (50) and (51), for the proof it suffices to show that for all $v \in F_q$, $\deg \boldsymbol{f}_{M+vM'}(\alpha) \geq \frac{(q-1)^2}{q^2}\epsilon_q n$.

So, assume to the contrary that for some $v \in F_q$, $\deg \boldsymbol{f}_{M+vM'}(\alpha) < \frac{(q-1)^2}{q^2}\epsilon_q n$. By Corollary 35, with no loss of generality, we may assume that $\boldsymbol{S}$ is a basis of $[\boldsymbol{S}]$ with the maximal number of elements $H$ such that

$$\deg \boldsymbol{f}_H(\alpha) < \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{53}$$

However, $(\boldsymbol{S} \setminus \{H_i\}) \cup \{M + vM'\}$, where $i$ is as in the definition of $I$ in the beginning of this section, is a basis of $[\boldsymbol{S}]$ with more matrices $H$ satisfying (53), which contradicts our assumption.

**8. Proof of Theorem 1. Part 3: Construction of $M''$.** As we have already mentioned in the beginning of section 7, $M''$ is constructed from the quotient vector space $[\boldsymbol{S}]/[M, M']$. We remind the reader that $\boldsymbol{S} = \{H_1, H_2, \ldots, H_k\}$ is the set of Hankel matrices constructed in section 6.2. In view of Corollary 35, we may assume that

$$\{H_1, H_2\} = \{M, M'\}, \tag{54}$$

where $M$ and $M'$ are the matrices constructed in section 7.

Also, changing the indices of the elements of $\boldsymbol{S}$ if necessary, we may assume that

$$\begin{aligned}&\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) - \deg \boldsymbol{f}_{\{H_1,H_2,\ldots,H_{k-1}\}}(\alpha)\\ &= \min\{\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) - \deg \boldsymbol{f}_{\boldsymbol{S}\setminus\{H\}}(\alpha) : H \in \boldsymbol{S} \setminus \{H_1, H_2\}\}.\end{aligned}$$

Then, for each $i = 2, 3, \ldots, k-1$,

$$\begin{aligned}&\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) - \deg \boldsymbol{f}_{\boldsymbol{S}\setminus\{H_k\}}(\alpha)\\ &\leq \deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) - \deg \boldsymbol{f}_{\boldsymbol{S}\setminus\{H_{i+1}\}}(\alpha)\\ &\leq \deg \boldsymbol{f}_{\{H_1,H_2,\ldots,H_i,H_{i+1}\}}(\alpha) - \deg \boldsymbol{f}_{\{H_1,H_2,\ldots,H_i\}}(\alpha),\end{aligned}$$

because each factor of $\boldsymbol{f}_{H_{i+1}}(\alpha)$ that does not divide $\boldsymbol{f}_{\boldsymbol{S}\setminus\{H_{i+1}\}}(\alpha)$ does not divide $\boldsymbol{f}_{\{H_1,H_2,\ldots,H_i\}}(\alpha)$ either. Therefore,

$$\begin{aligned}&(k-3)(\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) - \deg \boldsymbol{f}_{\{H_1,H_2,\ldots,H_{k-1}\}}(\alpha))\\ &\leq \sum_{i=2}^{k-2}(\deg \boldsymbol{f}_{\{H_1,H_2,\ldots,H_i,H_{i+1}\}}(\alpha) - \deg \boldsymbol{f}_{\{H_1,H_2,\ldots,H_i\}}(\alpha))\\ &= \deg \boldsymbol{f}_{\boldsymbol{S}\setminus\{H_k\}}(\alpha) - \deg \boldsymbol{f}_{\{H_1,H_2\}}(\alpha),\end{aligned}$$

implying

$$\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \leq \deg \boldsymbol{f}_{\boldsymbol{S}\setminus\{H_k\}}(\alpha) + \frac{\deg \boldsymbol{f}_{\boldsymbol{S}\setminus\{H_k\}}(\alpha) - \deg \boldsymbol{f}_{\{H_1,H_2\}}(\alpha)}{k-3}. \tag{55}$$

For the construction of the third matrix $M''$ we shall distinguish between the cases of $k \geq 5$ and $k \leq 4$.

**8.1. The case of $\boldsymbol{k \geq 5}$.** By the minimality assumption on $\boldsymbol{S}$ in the end of section 6.2,

$$\deg \boldsymbol{f}_{\boldsymbol{S}\setminus\{H_k\}}(\alpha) \leq (1+\epsilon_q)n$$

and, by (54) and (35),

$$\deg \boldsymbol{f}_{\{H_1,H_2\}}(\alpha) \geq \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right) n.$$

Therefore, it follows from (55) that

$$\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \leq (1+\epsilon_q)n + \frac{\epsilon_q + \dfrac{(q-1)^2}{q^2}\epsilon_q}{k-3} n,$$

which together with (4) and $k \geq 5$ implies

$$\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \leq \left(2 - 2\left(\frac{(q-1)^2}{q^2}\epsilon_q\right)\right) n. \tag{56}$$

*Remark* 38. Actually, (56) is the only reason we need the condition $k \geq 5$; see also section 8.2.3.

The construction of the third matrix $M''$ is based on Lemma 39 below.

LEMMA 39. *Let $\boldsymbol{S}$ be the set of matrices constructed in section* 6.2*, let $M$ and $M'$ be the matrices constructed in section* 7*, and let $\boldsymbol{v}'' \in F_q^k$ be such that*

$$\deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}''\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \geq \left(1 - \frac{1}{q}\right) \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\boldsymbol{S}}(\alpha). \tag{57}$$

*Then*

$$\deg\{M, M', \boldsymbol{v}''\vec{\boldsymbol{S}}\} \geq \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n. \tag{58}$$

*Moreover, if* $\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) \geq n$*, then*

$$\deg\{M, M', \boldsymbol{v}''\vec{\boldsymbol{S}}\} \geq \left(1 + \frac{q-1}{q}\epsilon_q\right) n. \tag{59}$$

*Proof.* For the proof of the first part of the lemma, assume to the contrary that for some basis $\boldsymbol{B}$ of $[\{M, M', \boldsymbol{v}''\vec{\boldsymbol{S}}\}]$,

$$\deg \boldsymbol{f}_{\boldsymbol{B}}(\alpha) < \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n. \tag{60}$$

Then it follows from (33), (34), and Lemma 33 that $\boldsymbol{f}_{\{M,M'\}}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{B}}(\alpha)$. Thus, we may assume that $\boldsymbol{B} = \{M, M', H\}$ for some $H \in [\{M, M', \boldsymbol{v}''\vec{\boldsymbol{S}}\}]$, in which case it follows from (60) and (35) that

$$\begin{aligned}\deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_H(\alpha) &= \deg \boldsymbol{f}_{\boldsymbol{B}}(\alpha) - \deg \boldsymbol{f}_{\{M,M'\}}(\alpha)\\ &< \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n - \left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right) n = 2\left(\frac{(q-1)^2}{q^2}\epsilon_q n\right).\end{aligned} \tag{61}$$

We contend that $\boldsymbol{f}_{\boldsymbol{v}''\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{B}}(\alpha)$.

Let $\boldsymbol{f}_{\boldsymbol{S}}(\alpha) = \prod_{i=1}^{\ell} p_i^{d_i}(\alpha)$ be the decomposition of $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$ into irreducible factors. By the definition of $\boldsymbol{f}_{\boldsymbol{v}''\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)$, it suffices to show that for each $i = 1, 2, \ldots, \ell$, $\boldsymbol{f}_{\boldsymbol{v}''\vec{\boldsymbol{S}}|_i}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{B}}(\alpha)$.

Since $\sum_{i=1}^{\ell} \boldsymbol{v}''\vec{\boldsymbol{S}}|_i = \boldsymbol{v}''\vec{\boldsymbol{S}}$ and $H \in [\{M, M', \boldsymbol{v}''\vec{\boldsymbol{S}}\}]$, for each $i = 1, 2, \ldots, \ell$,

$$\boldsymbol{v}''\vec{\boldsymbol{S}}|_i \in [\{M, M', H\} \cup \{\boldsymbol{v}''\vec{\boldsymbol{S}}|_j : j \neq i\}].$$

We observe next that

$$\begin{aligned}\deg \boldsymbol{f}_{\boldsymbol{S}\cup\{H\}}(\alpha) &= \deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) + (\deg \boldsymbol{f}_{\boldsymbol{S}\cup\{H\}}(\alpha) - \deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha)) \\ &\leq \deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) + (\deg \boldsymbol{f}_{\boldsymbol{B}}(\alpha) - \deg \boldsymbol{f}_{\{M,M'\}}(\alpha)) \leq 2n,\end{aligned}$$

where the first inequality holds because each factor of $\boldsymbol{f}_H(\alpha)$ that does not divide $\boldsymbol{f}_{\boldsymbol{S}}(\alpha)$ does not divide $\boldsymbol{f}_{\{M,M'\}}(\alpha)$ either, and the second inequality follows from (56) and (61). Therefore,

$$\deg \boldsymbol{f}_{\{M,M',H\}\cup\{\boldsymbol{v}''\vec{\boldsymbol{S}}|_i : i=1,2,\ldots,\ell\}}(\alpha) \leq 2n$$

as well, because $\boldsymbol{f}_{\{M,M',H\}\cup\{\boldsymbol{v}''\vec{\boldsymbol{S}}|_i : i=1,2,\ldots,\ell\}}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{S}\cup\{H\}}(\alpha)$. Hence, by Proposition 31, $\boldsymbol{f}_{\boldsymbol{v}''\vec{\boldsymbol{S}}|_i}(\alpha)$ divides $\boldsymbol{f}_{\{M,M',H\}\cup\{\boldsymbol{v}''\vec{\boldsymbol{S}}|_j : j\neq i\}}(\alpha)$.

Consequently, since for all $j = 1, 2, \ldots, i-1, i+1, \ldots, \ell-1, \ell$, $\boldsymbol{f}_{\boldsymbol{v}''\vec{\boldsymbol{S}}|_i}(\alpha)$ and $\boldsymbol{f}_{\boldsymbol{v}''\vec{\boldsymbol{S}}|_j}(\alpha)$ are coprime, $\boldsymbol{f}_{\boldsymbol{v}''\vec{\boldsymbol{S}}|_i}(\alpha)$ divides $\boldsymbol{f}_{\{M,M',H\}}(\alpha)$, and the contention follows.

Therefore,

$$\begin{aligned}\deg \boldsymbol{f}_{\boldsymbol{B}}(\alpha) &= \deg \boldsymbol{f}_{\{M,M',H\}}(\alpha) \\ &\geq \deg \operatorname{lcm}(\{\boldsymbol{f}_{\{M,M'\}}(\alpha), \boldsymbol{f}_{\boldsymbol{v}''\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha)\}) \\ &= \deg \boldsymbol{f}_{\{M,M'\}}(\alpha) + \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}''\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \\ &\geq \deg \boldsymbol{f}_{\{M,M'\}}(\alpha) + \left(1 - \frac{1}{q}\right)(\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) - \deg \boldsymbol{f}_{\{M,M'\}}(\alpha)) \\ &\geq \left(1 - \frac{1}{q}\right)(1+\epsilon_q)n + \frac{1}{q}\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) \\ &\geq \left(1 - \frac{1}{q}\right)(1+\epsilon_q)n + \frac{1}{q}\left(1 - \frac{(q-1)^2}{q^2}\epsilon_q\right)n \qquad (62) \\ &\geq \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right)n, \qquad (63)\end{aligned}$$

where the first inequality follows from the above contention, the second inequality follows from (57), the third inequality follows from the second clause of Lemma 34, and the fourth inequality follows from (35). That is, we arrived at a contradiction with (60), which completes the proof of the first part of the lemma.

The proof of the second part is similar to the above. The only difference is that, under its assumption, (60) becomes

$$\deg \boldsymbol{f}_{\boldsymbol{B}}(\alpha) < \left(1 + \epsilon_q - \frac{\epsilon_q}{q}\right)n,$$

the second line of (61) becomes

$$\left(1 + \epsilon_q - \frac{\epsilon_q}{q}\right)n - n = \left(\epsilon_q - \frac{\epsilon_q}{q}\right)n,$$

(62) becomes

$$\left(1-\frac{1}{q}\right)(1+\epsilon_q)\,n-\frac{n}{q},$$

and (63) becomes

$$\left(1+\epsilon_q-\frac{\epsilon_q}{q}\right)n.$$

We leave the details to the reader. $\square$

It follows from Proposition 26, by the standard average-counting argument, that we can find a vector $\boldsymbol{v}'' \in F_q^k$ such that

$$\deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\boldsymbol{v}''\mathcal{C}(\vec{\boldsymbol{S}})}(\alpha) \geq \left(1-\frac{1}{q}\right)\deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\boldsymbol{S}}(\alpha). \tag{64}$$

That is, $\boldsymbol{v}''$ satisfies prerequisite (57) of Lemma 39. Therefore, by the first part of the lemma, if

$$\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) < \left(1+\frac{(q-1)^2}{q^2}\epsilon_q\right)n,$$

then

$$\boldsymbol{v}''\vec{\boldsymbol{S}} \notin [\{M,M'\}]. \tag{65}$$

At this point we shall distinguish between the cases of

$$\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) \leq n,$$

i.e., the case of (46),

$$n < \deg \boldsymbol{f}_{\{M,M'\}}(\alpha) < \left(1+\frac{(q-1)^2}{q^2}\epsilon_q\right)n, \tag{66}$$

and

$$\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) \geq \left(1+\frac{(q-1)^2}{q^2}\epsilon_q\right)n.$$

**8.1.1. The case of $\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) \leq n$.** We let $M''$ be $\boldsymbol{v}''\vec{\boldsymbol{S}}$, where $\boldsymbol{v}''$ is as in (64). Then, by the first part of Lemma 39,

$$\deg\{M,M',M''\} \geq \left(1+\frac{(q-1)^2}{q^2}\epsilon_q\right)n$$

and, in view of (65), we just have to show that

$$\|\{M,M',M''\}\| \geq \frac{(q-1)^2}{q^2}\epsilon_q n.$$

For the proof, assume to the contrary that

$$\deg \boldsymbol{f}_H(\alpha) < \frac{(q-1)^2}{q^2}\epsilon_q n$$

for some matrix $H \in [\{M, M', M''\}]$. Then, by (36), $H \notin [\{M, M'\}]$, implying $[\{M, M', H\}] = [\{M, M', M''\}]$. However,

$$\deg \boldsymbol{f}_{\{M,M',H\}}(\alpha) \le \deg \boldsymbol{f}_{\{M,M'\}}(\alpha) + \deg \boldsymbol{f}_H(\alpha) < \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n$$

contradicts (58).

*Remark* 40. As we have seen in the end of section 7.1, (38) implies (46). In addition, it follows from (4) and (38) that $k \ge 5$. Therefore, the construction of $M, M'$, and $M''$ is completed in the case of (38) as well.

**8.1.2. The case of $n < \deg \boldsymbol{f}_{\{M,M'\}}(\alpha) < (1 + \frac{(q-1)^2}{q^2}\epsilon_q)n$.** Let $\boldsymbol{v}''$ be as in (64). If

$$\|\{M, M', \boldsymbol{v}''\vec{\boldsymbol{S}}\}\| \ge \frac{(q-1)^2}{q^2}\epsilon_q n,$$

then, by Lemma 39 and (65), we let $M''$ be $\boldsymbol{v}''\vec{\boldsymbol{S}}$.

Otherwise, i.e., if

$$\|\{M, M', \boldsymbol{v}''\vec{\boldsymbol{S}}\}\| < \frac{(q-1)^2}{q^2}\epsilon_q n, \tag{67}$$

let $H_{\min} \in [\{M, M', \boldsymbol{v}\vec{\boldsymbol{S}}\}]$ be such that $\deg \boldsymbol{f}_{H_{\min}}(\alpha) = \|\{M, M', \boldsymbol{v}\vec{\boldsymbol{S}}\}\|$. Then, by (67),

$$\deg \boldsymbol{f}_{H_{\min}}(\alpha) < \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{68}$$

Now we need Lemma 41 below.

LEMMA 41. *Let $H$ be a Hankel matrix such that*

$$\deg \boldsymbol{f}_H(\alpha) \le (1 - \epsilon_q)n. \tag{69}$$

*Then, for some $v_H \in F_q$,*

$$\deg\{M, M', H + v_H H_{\min}\} \ge \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n. \tag{70}$$

We postpone the proof of Lemma 41 until the end of this section and proceed with the construction of $M''$. Let $\boldsymbol{H}$ be as in the beginning of the proof of Lemma 34; see (32).

If for some $H \in \boldsymbol{H} \setminus [\{M, M', H_{\min}\}]$,

$$\|\{M, M', H + v_H H_{\min}\}\| \ge \frac{(q-1)^2}{q^2}\epsilon_q n,[10]$$

we just let $M''$ be $H + v_H H_{\min}$.

Otherwise, i.e., if for each $H \in \boldsymbol{H} \setminus [\{M, M', H_{\min}\}]$,

$$\|\{M, M', H + v_H H_{\min}\}\| < \frac{(q-1)^2}{q^2}\epsilon_q n,$$

[10]Here, of course, $v_H \in F_q$ is from Lemma 41. That is, $v_H$ satisfies (70).

we reduce the case of (66) to Remark 40. The reduction is as follows.

For each $H \in \boldsymbol{H} \setminus [\{M, M', H_{\min}\}]$, let $D_H \in [\{M, M', H + v_H H_{\min}\}]$ be such that

$$\deg \boldsymbol{f}_{D_H}(\alpha) < \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{71}$$

It follows from the definition of $\boldsymbol{H}$ that

$$\dim([\{D_H : H \in \boldsymbol{H} \setminus [\{M, M', H_{\min}\}]\}]) = 2n - o(n).$$

Thus, by Lemma 11, there exists a subset $\boldsymbol{S}'$ of $\{D_H : H \in \boldsymbol{H}\}$ containing $i_q((1+\epsilon_q)n)$ or fewer elements such that $\deg \boldsymbol{f}_{\boldsymbol{S}'}(\alpha) \geq (1+\epsilon_q)n$.

Let

$$\boldsymbol{D}'' = \boldsymbol{D}' \cup \bigcup_{D_H \in \boldsymbol{S}'} \boldsymbol{C}_H,$$

where $\boldsymbol{C}_H$ is as in the proof of Lemma 34. By definition, $\boldsymbol{S}' \subseteq [\boldsymbol{D}'']$. Also

$$\left| \bigcup_{D_H \in \boldsymbol{S}'} \boldsymbol{C}_H \right| \leq \frac{2(1+\epsilon_q)n \lg_q \lg_q n}{\lg_q((1+\epsilon_q)n)}$$

implies

$$|\boldsymbol{D}''| \leq \frac{2(1+\epsilon_q)n \lg_q \lg_q n}{\lg_q((1+\epsilon_q)n)} = o(n).$$

Therefore, we may replace $\boldsymbol{S}$ and $\boldsymbol{D}'$ constructed in Lemma 34 with, respectively, $\boldsymbol{S}'$ and $\boldsymbol{D}''$ that we have just described. Since, by (71),

$$\max\{\deg \boldsymbol{f}_H(\alpha) : H \in \boldsymbol{S}'\} < \frac{(q-1)^2}{q^2}\epsilon_q n,$$

we have the prerequisite of Remark 40.

Thus, to complete the construction, it remains to prove Lemma 41.

*Proof of Lemma* 41. If

$$\deg\{M, M', H\} \geq \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n,$$

we just let $v_H$ be 0.

Otherwise, i.e., if

$$\deg\{M, M', H\} < \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n,$$

we proceed as follows.

We observe first that

$$\deg_{\{M,M'\}} \boldsymbol{f}_H(\alpha) < \frac{(q-1)^2}{q^2}\epsilon_q n. \tag{72}$$

Indeed, let $\boldsymbol{B}$ be a basis of $[\{M, M', H\}]$ such that

$$\deg \boldsymbol{f}_{\boldsymbol{B}}(\alpha) < \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n.$$

Then, by Lemma 33, all $\boldsymbol{f}_M(\alpha), \boldsymbol{f}_{M'}(\alpha)$, and $\boldsymbol{f}_H(\alpha)$ divide $\boldsymbol{f}_{\boldsymbol{B}}(\alpha)$, and (72) follows from the left inequality of (66).

Next, since

$$\deg \boldsymbol{f}_H(\alpha) + \deg \boldsymbol{f}_{H_{\min}}(\alpha) < (1-\epsilon_q)n + \frac{(q-1)^2}{q^2}\epsilon_q n < n,$$

by Remark 24, for all $u, v \in F_q$,

$$\boldsymbol{f}_{(u,v)\mathcal{C}((H,H_{\min})^T)}(\alpha) = \boldsymbol{f}_{uH+vH_{\min}}(\alpha).$$

Therefore, by Proposition 26 with $\boldsymbol{g}(\alpha) = \boldsymbol{f}_{\{M,M'\}}(\alpha)$ and $\boldsymbol{S} = \{H_{\min}, H\}$,

$$\sum_{(u,v)\in F_q^2} \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{uH+vH_{\min}}(\alpha) \geq (q^2-q) \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\{H_{\min},H\}}(\alpha).$$

Consequently, since

$$\deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{H_{\min}}(\alpha) \leq \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\{H_{\min},H\}}(\alpha),$$

we have

$$\begin{aligned}\sum_{(u,v)\in F_q^2\setminus(\{0\}\times F_q)} & \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{uH+vH_{\min}}(\alpha) \\ & \geq (q^2-2q+1) \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\{H_{\min},H\}}(\alpha),\end{aligned}$$

and, by the standard average-counting argument, for some $v_H \in F_q$,

$$\begin{aligned}\deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{H+v_H H_{\min}}(\alpha) &\geq \left(1-\frac{1}{q}\right) \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\{H_{\min},H\}}(\alpha) \\ &\geq \left(1-\frac{1}{q}\right) \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\{H_{\min}\}}(\alpha).\end{aligned}$$

By the definition of $\deg_{\boldsymbol{f}_{\{M,M'\}}}$ (see (16)),

$$\deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{H+v_H H_{\min}}(\alpha) = \deg \boldsymbol{f}_{\{M,M',H+v_H H_{\min}\}}(\alpha) - \deg \boldsymbol{f}_{\{M,M'\}}(\alpha)$$

and

$$\deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\{H_{\min}\}}(\alpha) = \deg \boldsymbol{f}_{\{M,M',H_{\min}\}}(\alpha) - \deg \boldsymbol{f}_{\{M,M'\}}(\alpha).$$

Therefore, it follows from the inequality above that

$$\begin{aligned}&\deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{\{M,M',H+v_H H_{\min}\}}(\alpha) \\ &\geq \left(1-\frac{1}{q}\right)(\deg \boldsymbol{f}_{\{M,M',H_{\min}\}}(\alpha) - \deg \boldsymbol{f}_{\{M,M'\}}(\alpha)) + \deg \boldsymbol{f}_{\{M,M'\}}(\alpha)\end{aligned}$$

$$
\begin{aligned}
&= \left(1-\frac{1}{q}\right)\deg \boldsymbol{f}_{\{M,M',H_{\min}\}}(\alpha) + \frac{\deg \boldsymbol{f}_{\{M,M'\}}(\alpha)}{q}\\
&\geq \left(1-\frac{1}{q}\right)\left(1+\frac{q-1}{q}\epsilon_q\right)n + \frac{\deg \boldsymbol{f}_{\{M,M'\}}(\alpha)}{q}\\
&= \left(1+\frac{(q-1)^2}{q^2}\epsilon_q\right)n - \frac{n}{q} + \frac{\deg \boldsymbol{f}_{\{M,M'\}}(\alpha)}{q}\\
&\geq \left(1+\frac{(q-1)^2}{q^2}\epsilon_q\right)n,
\end{aligned}
$$

where the second inequality is by the second part of Lemma 39 and the last inequality is by the left inequality of (66).

Now, the proof of (70) is similar to that of Lemma 39. Assume to the contrary that for some basis $\boldsymbol{B}$ of $[\{M, M', H + v_H H_{\min}\}]$,

$$
\deg \boldsymbol{f}_{\boldsymbol{B}}(\alpha) < \left(1+\frac{(q-1)^2}{q^2}\epsilon_q\right)n. \tag{73}
$$

Then it follows from (33), (34), and Lemma 33 that $\boldsymbol{f}_{\{M,M'\}}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{B}}(\alpha)$, which allows us to assume that $\boldsymbol{B} = \{M, M', H'\}$ for some $H' \in [\{M, M', H + v_H H_{\min}\}]$.

We have

$$
\begin{aligned}
&\deg \boldsymbol{f}_{\{M,M',H'\}\cup\{H+v_H H_{\min}\}}(\alpha)\\
&= \deg \boldsymbol{f}_{\{M,M',H'\}}(\alpha) + \deg_{\boldsymbol{f}_{\{M,M',H'\}}(\alpha)} \boldsymbol{f}_{H+v_H H_{\min}}(\alpha)\\
&\leq \deg \boldsymbol{f}_{\{M,M',H'\}}(\alpha) + \deg_{\boldsymbol{f}_{\{M,M',H'\}}(\alpha)} \boldsymbol{f}_{H}(\alpha) + \deg_{\boldsymbol{f}_{\{M,M',H'\}}(\alpha)} \boldsymbol{f}_{H_{\min}}(\alpha)\\
&\leq \deg \boldsymbol{f}_{\{M,M',H'\}}(\alpha) + \deg_{\boldsymbol{f}_{\{M,M'\}}(\alpha)} \boldsymbol{f}_{H}(\alpha) + \deg \boldsymbol{f}_{H_{\min}}(\alpha)\\
&\leq \left(1+\frac{(q-1)^2}{q^2}\epsilon_q\right)n + \frac{(q-1)^2}{q^2}\epsilon_q n + \frac{(q-1)^2}{q^2}\epsilon_q n < 2n,
\end{aligned}
$$

where the last inequality follows from (73), (72), and (68).

Thus, by Proposition 31, $\boldsymbol{f}_{\{M,M',H+v_H H_{\min}\}}(\alpha)$ divides $\boldsymbol{f}_{\boldsymbol{B}}(\alpha)$. Since

$$
\deg \boldsymbol{f}_{\{M,M',H+v_H H_{\min}\}}(\alpha) \geq \left(1+\frac{(q-1)^2}{q^2}\epsilon_q\right)n,
$$

this contradicts our assumption (73). □

**8.1.3. The case of $\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) \geq (1+\frac{(q-1)^2}{q^2}\epsilon_q)n$.** This is a particular case of the previous section. The only modification is to ignore Lemma 41 and to replace $H_{\min}$ with $\mathbf{0}_{(n+1)\times n}$. We leave this easy exercise to the reader.

**8.2. The case of $k \leq 4$.** To construct $M''$, we shall treat each of the cases of $k = 2$, $k = 3$, and $k = 4$ separately.

**8.2.1. The case of $k = 2$.** It follows from (54) that $\deg \boldsymbol{f}_{\{M,M'\}}(\alpha) \geq (1+\epsilon_q)n$, which is the case in section 8.1.3.

**8.2.2. The case of $k = 3$.** It follows from (54) that, in particular,

$$\deg \boldsymbol{f}_{\{M,M',H_3\}}(\alpha) \geq \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n,$$

which is the case in section 8.1.2. The only modification required is to replace $\boldsymbol{v}''\vec{\boldsymbol{S}}$ with $H_3$.

**8.2.3. The case of $k = 4$.** If

$$\deg \boldsymbol{f}_{\{H_1,H_2,H_3\}}(\alpha) \geq \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n,$$

we are in the case of section 8.2.2.

Otherwise, it follows from (55) and (35) that

$$\deg \boldsymbol{f}_{\boldsymbol{S}}(\alpha) \leq \left(1 + \frac{(q-1)^2}{q^2}\epsilon_q\right) n + 2\left(\frac{(q-1)^2}{q^2}\epsilon_q n\right),$$

which together with (4) implies (56). Therefore, all arguments of section 8.1 apply to the latter case; see Remark 38.

This completes the construction of matrices $M, M'$, and $M''$ and the proof of Theorem 1.

# A WORK-OPTIMAL DETERMINISTIC ALGORITHM FOR THE CERTIFIED WRITE-ALL PROBLEM WITH A NONTRIVIAL NUMBER OF ASYNCHRONOUS PROCESSORS[*]

GRZEGORZ MALEWICZ[†]

**Abstract.** Martel [C. Martel, A. Park, and R. Subramonian, *SIAM J. Comput.*, 21 (1992), pp. 1070–1099] posed a question for developing a work-optimal deterministic asynchronous algorithm for the fundamental load-balancing and synchronization problem called Certified Write-All (CWA). In this problem, introduced in a slightly different form by Kanellakis and Shvartsman in a PODC'89 paper [P. C. Kanellakis and A. A. Shvartsman, *Distributed Computing*, 5 (1992), pp. 201–247], $p$ processors must update $n$ memory cells and only then signal the completion of the updates. It is known that solutions to this problem can be used to simulate synchronous parallel programs on asynchronous systems with worst-case guarantees for the overhead of a simulation. Such simulations are interesting because they may increase productivity in parallel computing since synchronous parallel programs are easier to reason about than are asynchronous ones.

This paper presents the first solution to the question of Martel, Park, and Subramonian. Specifically, we show a deterministic asynchronous algorithm for the CWA problem. Our algorithm has the work complexity of $O(n + p^4 \log n)$. This work complexity is asymptotically optimal for a nontrivial number of processors $p \le (n/\log n)^{1/4}$. In contrast, all known deterministic algorithms require superlinear in $n$ work when $p = n^{1/r}$ for any fixed $r \ge 1$.

Our algorithm generalizes the collision principle introduced by Buss et al. [J. Buss, P. C. Kanellakis, P. L. Ragde, and A. A. Shvartsman, *J. Algorithms*, 20 (1996), pp. 45–86] in 1996, which has not been previously generalized despite various attempts. Each processor maintains a collection of intervals of $\{1, 2, \ldots, n\}$. Any processor iteratively selects an interval and works from its tip toward the other tip until it finishes the work or collides with another processor. Collisions are detected effectively using a special Read-Modify-Write operation. In any case, the processor transforms its collection appropriately. Our analysis shows that the transformations preserve some structural properties of collections of intervals. This guarantees that work is assigned to processors in an efficient manner.

## 1. Introduction.

This paper shows a deterministic algorithm where $p$ asynchronous processors update $n$ cells of shared memory and only then signal the completion of the updates. The algorithm has asymptotically optimal work complexity of $O(n)$ for a nontrivial number of processors $p \le (n/\log n)^{1/4}$. This result is the first solution to the question posed by Martel, Park, and Subramonian [33] in 1992.

[*]Received by the editors May 19, 2003; accepted for publication (in revised form) October 4, 2004; published electronically May 27, 2005. An extended abstract of this research appeared in the Proceedings of the 22nd ACM Symposium on Principles of Distributed Computing (PODC'03). The work of Grzegorz Malewicz was done during a visit to the Supercomputing Technologies Group ("the Cilk Group"), Massachusetts Institute of Technology, headed by Prof. Charles E. Leiserson. Grzegorz Malewicz was visiting this group during the 2002/2003 academic year while in his final year of the Ph.D. program at the University of Connecticut where his advisor was Prof. Alex Shvartsman. Part of this research was supported by the Singapore/MIT Alliance.

Many existing parallel systems are asynchronous. However, writing correct parallel programs on an asynchronous shared memory system is often difficult, for example, because of data races, which are difficult to detect in general [7, 38]. When the instructions of a parallel program are written with the intention of being executed on a system that is synchronous, then it is easier for a programmer to write correct programs because it is easier to reason about synchronous parallel programs than asynchronous ones. Therefore, in order to improve productivity in parallel computing, one could offer programmers the illusion that their programs run on a parallel system that is synchronous, while in fact the programs would be simulated on an asynchronous system.

Simulations of a parallel system that is synchronous on a system that is asynchronous have been studied for over a decade [3, 4, 5, 6, 10, 14, 16, 20, 22, 23, 24, 25, 30, 31, 32, 33, 35, 40, 41]. Simplifying considerably, such simulations assume that there is a system with $p$ asynchronous processors, and that the system must simulate a program written for $n$ synchronous processors. The simulations use three main ideas: idempotence, load balancing, and synchronization. Specifically, the execution of the program is divided into a sequence of phases. A phase executes an instruction for each of the $n$ synchronous programs. A phase is divided into two stages. First, the $n$ instructions are executed and the results are saved to a scratch memory. Only then cells of the scratch memory are copied back to desired cells of the main memory. This ensures that the result of the phase is the same even if multiple processors execute the same instruction in a phase, which may happen due to asynchrony. The $p$ processors run a load-balancing algorithm to ensure that the $n$ instructions of the phase are executed quickly despite possibly varying speeds of the $p$ processors. In addition, the $p$ processors are synchronized at every stage (twice per phase), so as to ensure that the simulated program proceeds in lock-step. Such simulation implements the PRAM model [15] on an asynchronous system.

One challenge in realizing the simulations is the problem of "late writers," i.e., when a slow processor clobbers the memory of a simulation with a value from an old phase. This problem has been addressed in various ways: by replication of variables [23]; by a combination of hashing, replication, and error correction [4]; by approximate detection of who is late, and replication of variables [5]; by using instructions that execute relatively fast [33]; by versioning of variables using extra atomic primitives [34]; or by restricting a class of computations that can be simulated [33].

Another challenge is the development of efficient load-balancing and synchronization algorithms. This challenge is abstracted as the Certified Write-All (CWA) problem. In this problem, introduced in a slightly different form by Kanellakis and Shvartsman [20], there are $p$ processors and an array $w$ with $n$ cells and a flag $f$, all initially 0, and the processors must set the $n$ cells of $w$ to 1, and only then set $f$ to 1. One efficiency criterion for the simulation is to reduce the wasteful use of computing resources. This use can be abstracted as the *work* complexity (or work for short) that is equal to the worst-case total number of instructions executed by the simulation. A simulation uses an algorithm that solves the CWA problem. Therefore, it is desirable to develop low-work algorithms that solve the CWA problem.

When creating a simulation of a given parallel program for $n$ processors, one may have a choice of the number $p$ of simulating processors. On the one hand, when a CWA algorithm for $p \gg n$ is used in a simulation, the simulation may be faster as compared to the simulation that uses an algorithm for $p \ll n$ processors, simply because of higher parallelism, which means that more processors are available to perform the simulation. On the other hand, however, processors that access shared memory may create hotspots, which may cause delays, and as a result an algorithm for $p \gg n$ may in fact run slower than an algorithm for $p \ll n$ (memory contention is disregarded in the model studied in this paper). The actual speed of a simulation may depend on system parameters, and so it is interesting to study CWA algorithms for different relationships between $p$ and $n$.

The best known randomized algorithm that solves the CWA problem on an asynchronous system was given by Martel and Subramonian [36]. Their algorithm has expected work of $O(n)$ when $p \leq n/\log n$, and expected work of $O(n \log n)$ when $p = n$. They also showed a lower bound of $\Omega(n + p \log p)$ on expected work of Las Vegas CWA algorithms against an oblivious adversary.

Deterministic algorithms that solve the CWA problem on an asynchronous system can be used to create simulations that have bounded worst-case overhead. Thus several deterministic algorithms have been studied [1, 8, 9, 18, 21, 37]. Fixing $r \geq 1$ when $p = n^{1/r}$, all these deterministic algorithms have work $\omega(n)$. Specifically, when $r = 1$ the first asynchronous CWA algorithm, called X, was developed by Buss et al. [8]. This algorithm was later generalized by Anderson and Woll [1]. Using a lower bound on *contention* of permutations (a value related to the number of left-to-right maxima in the permutations; see [1] for a formal definition) due to Lovász [29] and Knuth [27], Malewicz [31] showed that the generalized algorithm, called AWT, has work $\Omega(n^{1+\sqrt{\ln\ln n/\ln n}/2})$. When $r \geq 2$, a trivial algorithm, where each processor writes to every cell of the array $w$, has work $\Omega(n^{1+1/r})$. The best known algorithm for $r \geq 2$ was given by Anderon and Woll [1]. This algorithm, called AW, has work $\Omega(n \log n)$, which can be shown using the same lower bound of Lovász and Knuth (this algorithm can be instantiated using results of Naor and Roth [37], Kanellakis and Shvartsman [21], and Chlebus et al. [9], with the same asymptotic lower bound on work). Algorithms X, AW, and AWT access shared memory through atomic read and write instructions. The elegant algorithm of Groote et al. [18] has work $\Omega(n^{1+1/(2r2^r \ln 2)})$, and it uses a Test-and-Set instruction [19]. All these deterministic algorithms have work $\omega(n)$ when $r \geq 1$ is fixed.

An interesting deterministic algorithm, called T, for 3 processors was shown by Buss et al. [8]. In this algorithm, two processors start from the two opposite tips of the array $w$, and each works toward the opposite tip. The third processor starts from the middle of the array and "expands" by setting to 1 further and further cells on each side of the starting cell. When a "collision" between two processors occurs, the two processors "jump" to repeat the pattern of work recursively in a different part of the array. The algorithm has work $O(n)$, and at most $n + O(\log n)$ cells of the array are set to 1. A generalization of this algorithm to more than 3 processors is an open problem posed by Buss et al. in 1996. In a recent paper by Groote et al. [18] it is stated that "Algorithm T does not appear to be generalizable to larger numbers of processes."

**Contributions.** This paper presents, for the first time, a deterministic algorithm for the CWA problem that has asymptotically optimal work for a nontrivial number of asynchronous processors. Specifically, we consider a shared memory setting with $p$ asynchronous processors. The processors must solve the CWA problem: given an array $w$ with $n$ cells and a flag $f$, all initially 0, set all elements of $w$ to 1, and only then set $f$ to 1. We present a deterministic algorithm that solves the problem in this shared memory setting. Our algorithm has the work complexity of $O(n + p^4 \log n)$ (appearing in Theorem 3.15). The algorithm has asymptotically optimal work $O(n)$ for a nontrivial number of processors $p \leq (n/\log n)^{1/4}$. In contrast, all known deterministic algorithms require as much as $\omega(n)$ work when $p = n^{1/r}$, for any fixed $r \geq 1$. The processors use $O(n + p^4 \log n)$ memory cells for coordinating their work (shown in Theorem 3.16). Our algorithm generalizes the collision principle used by the algorithm T. Namely, each processor has a collection of intervals of $w$ and iteratively selects an interval to work on. The processor proceeds from one tip of the interval toward the other tip. When processors collide, they exchange appropriate information and schedule their future work accordingly. Our algorithm uses a special atomic Read-Modify-Write (RMW) instruction to detect collisions. Such strong primitives were not used by previous algorithms, except for the algorithm of Groote et al. [18]. Our paper contributes to solving the problems posed by Martel, Park, and Subramonian [33] and by Buss et al. [8].

**Subsequent work.** Subsequent to the conference version of this paper [30], Kowalski and Shvartsman presented [26] a deterministic asynchronous algorithm for the CWA problem. Their algorithm has asymptotically optimal work when the number of processors is $p < n^{1/(2+\epsilon)}$. This range is significantly wider than the range of $p$ while the algorithm presented here is proven to have asymptotically optimal work. However, it is not clear that our upper bound on work is tight. It would be interesting to develop tight bounds on work for each algorithm and compare the bounds. The algorithm of Kowalski and Shvartsman uses atomic reads and writes, while our algorithm requires a much stronger primitive of RMW. Their algorithm uses a collection of $q$ permutations with contention $O(q \log q)$, while it is not known to date how to construct such permutations in polynomial time. Thus their result is, so far, existential, while ours is explicit.

**Paper organization.** The remainder of the paper is organized as follows. In section 2, we define the asynchronous shared memory model of computation used in the paper and the CWA problem. In section 3, we present our deterministic algorithm and its analysis. Finally, in section 4, we conclude with future work.

## 2. Model and definitions.

We consider a shared memory system where processors can work at arbitrarily varying paces. Our formal definition is based on the Atomic Asynchronous Parallel System as presented by [5] (cf. [2, 11, 12, 13, 17, 28, 33, 39, 42]).

The system consists of $p$ processors, each of which has a dedicated local memory, and every processor has access to shared memory. Any memory is composed of *cells*. The initial section of $n$ cells of shared memory stores an array $w[0, \ldots, n-1]$. The subsequent cell stores a flag $f$. Any cell of any memory can store any $O(\log n)$-bit number. Any processor has a distinct identifier from $\{1, \ldots, p\}$.

Each processor has a discrete local clock ranging over $\mathbb{N} = \{1, 2, 3, \ldots\}$. A processor executes exactly one *basic action* at any tick of the local clock unless the processor has halted. The basic actions that a processor can execute are a $Halt$ action that stops the operation of the processor, any operation on a constant number of cells from the local memory, and a transfer between the local memory and shared memory. The possible transfers are reading a single cell of shared memory into a cell of the local memory; writing from a cell of the local memory to a cell of shared memory; and performing a special RMW action that compares the value stored at a cell of shared memory with the value stored at a cell of the local memory, and if they are equal, the action transfers a constant number of cells from the local memory to a constant number of cells of shared memory, but in any case returns the result of the comparison

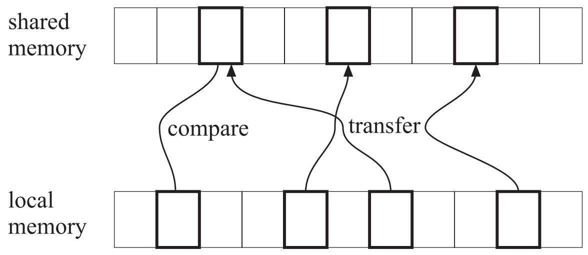

FIG. 1. *The special RMW operation used by the algorithm first compares two cells, and then possibly transfers a constant number of cells from local memory to shared memory. All this is done atomically.*

(see Figure 1 and also an example of syntax in Figure 2).

An execution of an algorithm progresses according to the following model of asynchrony. Local time of processor $i$ is mapped to global time through a strictly increasing function $T_i : \mathbb{N} \to \mathbb{R}$. We assume that no local clock ticks of two processors are mapped to the same instant of global time, i.e., if $T_i(x) = T_j(y)$, then $i = j$ and $x = y$. A tuple $\langle T_1, \ldots, T_p \rangle$ with mappings that satisfy these conditions is called *a valid tuple of mappings*. When a valid tuple $\langle T_1, \ldots, T_p \rangle$ has been fixed, each processor executes basic actions dictated by its algorithm. The processors take turns according to the total order prescribed by the mappings. Any processor $i$ does not execute basic actions after the tick when the processor executed the $Halt$ action, if the processor executed the action. The execution of any basic action is instantaneous, and so the resulting memory updates are atomic.

We adopt the following definition of the CWA problem: given the array $w[0, \ldots, n-1]$ with $n$ cells and the flag $f$, all initially 0, set the $n$ cells of $w$ to 1, and only then set $f$ to 1. An algorithm *solves* the CWA problem for $p$ processors and $n$ cells if, for any valid tuple $\langle T_1, \ldots, T_p \rangle$ of mappings, the following three conditions hold:

(i) (Termination) each processor halts after a finite number of local clock ticks,
(ii) (Certification) when any processor halts, the flag $f$ has been set to 1,
(iii) (Validity) when the flag $f$ is set to 1, all cells of $w$ have been set to 1.

The *work* complexity of a deterministic algorithm that solves the CWA problem for $p$ processors and $n$ cells measures the maximum total number of basic actions executed by the processors. Consider any valid tuple $\langle T_1, \ldots, T_p \rangle$ of mappings. Let $h_i$ be the first local clock tick when processor $i$ executes the $Halt$ action, or $\infty$ if it does not execute the action. Then the total number of basic actions executed by the processors is $\sum_{i=1}^{p} h_i$. The work of the algorithm is defined as the maximum value of the sum across valid tuples of mappings. (Work is a function of $n$ and $p$.)

DEFINITION 2.1. *The work of a deterministic algorithm $A$ for $p$ processors and $n$ cells that solves the CWA problem is defined as*

$$work(A, p, n) = \max_{\langle T_1, \ldots, T_p \rangle} \sum_{i=1}^{p} h_i(T_1, \ldots, T_p),$$

*where the maximum is taken over all valid tuples of mappings; and where $h_i(T_1, \ldots, T_p)$ is a number from $\mathbb{N}$ that is the first tick of the local clock of processor $i$ during which the processor executes the Halt basic action, when local time of processors have been mapped to global time using the maps $T_1, \ldots, T_p$.*

Note that in this model, there is a trivial Write-All algorithm for $n = p$ where the first basic action that a processor $i$, $0 \leq i \leq n-1$, executes is an assignment of 1 to cell $i$ of the array $w$ (because the model ensures that each processor will eventually perform a basic action). This takes $O(n)$ work in total. However, in general, no processor can certify and halt immediately after performing its first basic action without violating the validity condition. The processor simply cannot always ensure that each of the $n$ cells has been set to 1, due to the fact that other processors may be delayed.

## 3. Collision algorithm and its analysis.

This section presents a deterministic algorithm for the CWA problem with asynchronous processors (see Figure 2). The algorithm generalizes the collision principle of algorithm T. The main algorithmic approaches of our algorithm are: to ensure that any processor often works on a relatively large interval of unset cells of the array $w$, according to a sequence that enables rapid detection of two processors setting to 1 the same cell of the array; and, when redundancy occurs, to ensure an effective mechanism for reassigning work to processors. Briefly speaking, all processors share an array *tab* with $n$ cells used for coordination of their work. Each processor maintains a collection of intervals of the set $\{0, 1, \dots, n-1\}$ (an interval is a subset of consecutive elements of the set). A processor takes an interval from the collection and keeps setting cell $w[x]$ to 1 and storing some special information in cell $tab[x]$, while working through cells $x$ from a tip of this interval toward the opposite tip. Later, the processor removes some intervals or their parts from the collection, possibly based on information obtained from other processors. This process is repeated as long as there is an interval in the collection. When the collection becomes empty, then the processor sets the flag $f$ to 1 and halts.

There are several challenges that we solve to ensure that our algorithm avoids doing too much redundant work. It may happen that two processors "collide" at the same cell while working in opposite or the same directions. When they work in opposite directions, they could "cross" each other and duplicate the work that the other processor already did. When they work in the same direction, they may keep on working "side-by-side" and again duplicate the work that the other processor is doing. Another potential problem is that even if we are able to detect collisions, then a processor that collides must decide upon a cell of the array where the processor will resume its work. Ideally, the processor should choose to work from a tip of an interval so that this tip is "far away" from any cell that any other processor is currently working on. This is desirable because it would help to ensure that when the next collision of this processor occurs, a substantial number of distinct new cells of the array $w$ have been set to 1.

Intuitively, our algorithm solves these challenges as follows. The processors coordinate their work on intervals using atomic RMW instructions. This ensures that whenever a processor does a successful RMW to a cell, no other processor can succeed. As a result, a colliding processor sets at most one cell of $w$ to 1 before it detects a collision with another processor, and has an opportunity to reassign its own future work. The choice of a relatively long interval located in a rather unassigned part of the array is intuitively done by a processor always working on an interval that is at least as long as half of the length of a longest interval in the collection. In addition, we ensure that a colliding processor obtains knowledge from the other processor about which cells of $w$ remain to be set to 1, and this allows us to guarantee that when a processor often collides, it must substantially reduce the amount of work that it "thinks" remains to be done, even though it has *not* actually recently set to 1 any distinct cells of $w$.

The following sections present details of this intuitive explanation. We begin, in

```
shared variables: $f$, arrays $w[0,\dots,n-1]$, $tab[0,\dots,n-1]$
initially $f=0$, $w[x]=0$, $tab[x]=\langle 0,\emptyset,\emptyset\rangle$, for $x=0,\dots,n-1$

COLLIDE
local variables: $dir, U, D, dir', U', D', c, s, e, x, failed$
01 $U := \{[0,n-1]\}$, tips are unmarked unless explicitly marked
02 while true
--------------------------------------------------------------------------------
03     let $s$ be an unmarked tip of an interval from $U$ and $e$ the other tip  } select an interval
04     if $s \le e$, then $dir := R$ else $dir := L$                             }
--------------------------------------------------------------------------------
05     $D := \emptyset$                                                          } work from tip $s$ to tip
06     for $x := s$ to/downto $e$                                                } $e$ of the interval
07         $w[x] := 1$                                                           }
08         RMW($x$)            // see line 30                                    }
09         if $failed$, then goto 11                                             }
10         $D := D \cup \{x\}$                                                   }
--------------------------------------------------------------------------------
11     if not $failed$, then                                                     } no collision,
12         $U := U \setminus D$                                                  } record progress
--------------------------------------------------------------------------------
13     else                                                                      } collision,
14         $\langle dir', U', D'\rangle := tab[x]$                               } retrieve information
--------------------------------------------------------------------------------
15         if $maxlen(U) > maxlen(U')$, then $U := U' \cap U$                    } intersect collections
16         else                                                                  }
17             $U := U \cap U'$                                                  }
--------------------------------------------------------------------------------
18         if $dir \ne dir'$, then                                               } head-on-head collision,
19             $U := U \setminus (D \cup D')$                                    } record joint progress

section 3.1 with an overview of the collision algorithm to help the reader gain familiarity with the code of the algorithm and how the algorithm works. In the algorithm, processors maintain collections of intervals and sometimes incorporate knowledge from collections of other processors. Then in section 3.2, we detail the operations on collections of intervals that processors use. The operations incorporate knowledge so that the resulting collections of intervals are "well-behaved" in a precise sense. Finally, in section 3.3, this good behavior of operations helps us prove a bound on work for our algorithm.

**3.1. Overview of the collision algorithm.** We outline the collision algorithm. We begin with the shared and the local memory variables that processors access, and then describe how the algorithm works. Recall that $n$ denotes the number of cells in the Write-All array and $p$ denotes the number of processors. We assume that $n$ and $p$ are powers of two. Line numbers mentioned in this section refer to the code in Figure 2.

Each processor has access to three shared variables: the completion flag $f$, the Write-All array $w[0,\ldots,n-1]$, and an array $tab[0,\ldots,n-1]$ called the *trace table*. The trace table is of paramount significance to the collision algorithm because information about completed work is disseminated through the trace table. Each cell $tab[x]$ of the trace table is a record with three fields denoted by $tab[x].dir$, $tab[x].U$, and $tab[x].D$ (an example of content of a trace table is given in Figure 3(a)). The first field is a bit equal to either $L$ or $R$. The second field is a collection of intervals of $\{0,\ldots,n-1\}$. As we will see later, at most $p/2$ intervals are ever stored in this field. The third field is an interval of $\{0,\ldots,n-1\}$. Note that each interval can be represented as two numbers—the interval tips. Hence, any cell of $tab$ contains $O(p \log n)$ bits. We will later see how to use a pointer representation of collections so as to ensure that each cell of the trace table stores only $O(\log n)$ bits. For now, we use the "expanded" representation for simplicity of exposition. We assume that when processors begin execution, these shared variables are initialized as follows: $f$ and cells of $w$ to zero, and every cell of $tab$ to $\langle L,\emptyset,\emptyset\rangle$ (i.e., $tab[x].dir = L$, $tab[x].U = \emptyset$, and $tab[x].D = \emptyset$, for any $0 \le x \le n-1$).

Each processor has a few local variables. The variable $U$ contains a collection of intervals of $\{0,\ldots,n-1\}$. As we will see later, $U$ can contain at most $p/2$ intervals at any time during execution. These intervals cover all cells that remain to be written to, and so any cell that is not in one of the intervals must necessarily have already been written to. However, some cells covered by intervals from $U$ may already be written to, because of the concurrent work of other processors and possibly delayed dissemination of knowledge. Each tip of any interval in $U$ has a flag equal to *marked* or *unmarked*. The processor has other local variables: $U'$ is a collection of intervals of $\{0,\ldots,n-1\}$ (again, it will contain at most $p/2$ intervals); $D$ and $D'$ are intervals of $\{0,\ldots,n-1\}$; $c$, $s$, $e$, $x$ are integers from $\{0,\ldots,n-1\}$; $dir$, $dir'$, and $failed$ are bits.

Note that the algorithm is uniform (i.e., it is the same for each processor), so we describe it for a given processor $i$. The processor begins by setting its collection $U$ to a set that contains just one interval $[0,n-1]$ (line `01`). The tips of this interval are unmarked. Note that then $U$ contains an interval with an unmarked tip. Next the processor enters a big while loop (lines `02` to `29`). In general, every time the processor starts an iteration of the while loop (line `03`), the following loop invariant holds: the collection $U$ contains at least one interval with an unmarked tip; the other tip and some tips of other intervals, if any, may be marked. The body of the while loop has several sections of code, each carrying out a specific function.

The processor selects an interval from $U$ (lines `03` and `04`). The interval is chosen so that it has an unmarked tip $s$ and $e$ is the other tip of the interval. The processor will attempt to work on the interval from $s$ to $e$. The relationship between $s$ and $e$ determines the direction of work: either $L$, meaning left, or $R$, right.

Then the processor works on the interval by iterating through cells $x$ from tip $s$ to tip $e$ (lines `05` to `10`). At the end of each iteration, the interval $D$ contains the

cells through which the processor has iterated so far. At every iteration of the loop, the processor writes to the cell $w[x]$ of the Write-All array, and "leaves a trace" of its work inside a cell $tab[x]$ of the trace table (see animation in Figure 3(a)). Writing to cell $tab[x]$ is done using the RMW atomic operation so as to ensure that no two processors succeed in writing to a cell of $tab$ (lines 30 to 35). Specifically, the write tests the value of the third field of the cell, and only if it is equal to the empty set, the write proceeds by setting the field to a value of $D \cup \{x\}$ that is always different from the empty set. The interval $D \cup \{x\}$ contains all cells to which the processor has successfully RMWed during the work on the interval. In addition to modifying the third field, a successfully performed RMW stores in $tab[x]$ the direction $dir$ of work and the collection $U$. Two events can happen during the time when the processor iterates from $s$ to $e$: (1) either the processor reaches the tip $e$ of the interval because it has successfully RMWed to all cells of the interval or (2) the processor fails on a RMW operation because earlier some processor $j$ successfully RMWed to a cell of the interval; if this happens we say that processor $i$ *collides* with processor $j$. The actions of processor $i$ depend on whether $i$ collided or not.

When processor $i$ has not collided, it records recent progress (lines `11` and `12`). Specifically, then the interval $D$ is equal to the interval from $U$ with tips $s$ and $e$ on which the processor has just finished working. The processor removes this interval from $U$ (see Figure 3(b)).

Slightly more complicated operations are performed when processor $i$ has collided. In such a case, processor $i$ will incorporate the knowledge gained from the processor $j$ with whom the collision has occurred. The incorporation of knowledge proceeds in several stages.

First, processor $i$ retrieves information about processor $j$ from the trace table (lines `13` and `14`). Recall that a collision occurs when a processor fails on an RMW to a cell $tab[x]$ of the trace table. This means that a processor $j$ has already performed a successful RMW to the cell. This cell must contain the collection $U$ of intervals that processor $j$ had at the time when it performed a successful RMW to the cell $tab[x]$. The cell also contains the direction $dir$ in which processor $j$ was working at that time, and the part $D$ of the interval that processor $j$ had successfully worked on until the time it performed the RMW. So processor $i$ can retrieve these three pieces of information from the trace table by reading $tab[x]$ (see Figure 3(c)). We denote the pieces by $U'$, $dir'$, and $D'$. Note that the local variables $U$, $dir$, and $D$ of processor $j$ at the time when $i$ retrieves information from the cell $tab[x]$ may be different from $U'$, $dir'$, and $D'$ because $j$ might have executed many instructions since it performed RMW to $tab[x]$.

Second, processor $i$ intersects the two collections of intervals, its own $U$ with the collection $U'$ of processor $j$ (lines `15` and `17`). A collection with the longest interval is taken, and its intervals are trimmed by the union of the intervals from the other collection. A detailed specification of the intersection operation is given in Lemma 3.3. As a result of the intersection, $U$ contains some intervals.

Then the actions that processor $i$ takes depend on whether the colliding processors $i$ and $j$ worked in the same or opposite directions.

If they worked in opposite directions, then processor $i$ records progress $D$ and $D'$ (lines `18` and `19`). It removes from $U$ all intervals, or their parts, that are contained in either the interval $D$ that $i$ successfully worked on or the interval $D'$ that $j$ successfully worked on (see Figure 4(a)). A detailed specification of the removal operation is given in Lemma 3.5.

If, on the other hand, processors $i$ and $j$ worked in the same direction, then progress $D$ and $D'$ is recorded in a different way (lines `20` to `23`). Two kinds of a "head-on-back" collision are distinguished. The first kind is when processor $i$ failed on its first RMW in the work on the interval from $s$ to $e$, and the second kind is when processor $i$ succeeded on the first RMW and thus "bumped into the back" of the trace of processor $j$ later during the work on the interval. When processor $i$ succeeded on the first RMW, then $D \neq \emptyset$ (line `21`). Here processor $j$ cannot have arrived at $x$ "from behind" of processor $i$, and so $j$ must have just started working on its interval when it RMWed to cell $tab[x]$ (see Figure 4(b)). Then processor $i$ removes from $U$ the

interval $D$ that it has just successfully worked on (line 21). A detailed specification of the removal operation is given in Lemma 3.7. As a result of the removal, cell $x$ becomes a tip of an interval in $U$. When, on the other hand, processor $i$ failed on the first RMW, then $D = \emptyset$ (line 22). Here processor $j$ must have successfully worked on at least one cell, but possibly more (see Figure 4(c)). Processor $i$ removes from $U$ the interval $D'$ that $j$ worked on, except for the cell $x$ where collision took place (line 22). A detailed specification of the removal operation is given in Lemma 3.9. No matter which of the two kinds of "head-on-back" collisions occurred, as a result $x$ is a tip of an interval in $U$, and processor $i$ marks the tip (line 23). Marking allows us to keep track of the tips where head-on-back collisions took place. A marked cell is known to have been set to 1.

In any case, whether processor $i$ collided or not, the processor then checks if all cells have been written to (lines 24 and 25). As the algorithm iterates, intervals of length 1 with a marked tip may emerge in the collection $U$. Such intervals are removed from $U$, as we are certain that the corresponding cells must have been written to. If $U$ does not contain any more intervals, then the processor certifies and halts. As a result of the removal, any interval with a marked tip has length at least 2.

The final action performed by processor $i$ in the body of the while loop is a possible partition of an interval (lines 26 to 29). If all tips of all intervals in $U$ are marked, then the processor takes a longest interval in $U$ and partitions it into two halves. The two tips that are being exposed are unmarked. This ensures that there is at least one interval in $U$ with an unmarked tip. So the while loop invariant holds again.

**3.2. Collections of intervals, their transformations, and preserved properties.** During the time when a processor executes the collision algorithm, the processor interacts with other processors through the trace table. As a result, the processor transforms its collection $U$ in various ways. Lines 11 through 29 of the algorithm list the conditions under which the transformations are performed. The current section is devoted to defining these transformations and demonstrating their effect on $U$. We first introduce the notions of "regularity" and "monotonicity" of collections of intervals. We then show that the transformations maintain regularity and monotonicity of $U$, and that the number of elements contained in the intervals of $U$ gets reduced rapidly under certain conditions. These observations will be useful when reasoning about correctness and work of the algorithm.

We define regularity and monotonicity of collections of intervals (see Figure 5 for illustration). All intervals in this and subsequent sections are over the set of integers $\{0, 1, \ldots, n-1\}$.

DEFINITION 3.1. *Let $U_0, \ldots, U_g$ be collections of intervals over $\{0, \ldots, n-1\}$. We say that the collections are* regular *iff the following three properties are satisfied:*

(i) *Each collection is composed of mutually disjoint nonempty intervals, each interval has length that is a power of two (length can be 1), and the lengths of any two intervals from the same collection differ by at most a factor of 2.*

(ii) *For any two intervals $I$ and $J$, each from a different collection, either $I \subseteq J$, or $J \subseteq I$, or $I \cap J = \emptyset$.*

(iii) *If $I \subseteq J$ are two intervals from different collections, then $J$ can be partitioned into a number of intervals such that this number is a power of 2 (the number can be 1), the intervals have the same length, and $I$ is one of the intervals.*

*We say that the collections are* monotonic *iff the following property is satisfied:*

(iv) *For any $j$, $0 \leq j < g$, if interval $I$ belongs to $U_{j+1}$, then there is interval $J$ that belongs to $U_j$ such that $J \supseteq I$.*

We now show a simple fact that halving any interval in the last collection preserves monotonicity.

LEMMA 3.1. *Let $U_0, \ldots, U_g$ be monotonic collections of intervals, and let $U$ be equal to $U_g$ except that instead of an interval from $U_g$ of length 2 or more, $U$ contains the two halves of the interval. Then the collections $U_0, \ldots, U_g, U$ are monotonic.*

The following lemma states that halving a relatively long interval in any collection preserves regularity.

LEMMA 3.2. *Let $U_0, \ldots, U_g$ be regular collections of intervals, $0 \leq i \leq g$, and let $U$ be equal to $U_i$ except that instead of a longest interval from $U_i$ of length 2 or more, $U$ contains the two halves of the interval. Then the collections $U_0, \ldots, U_g, U$ are regular.*

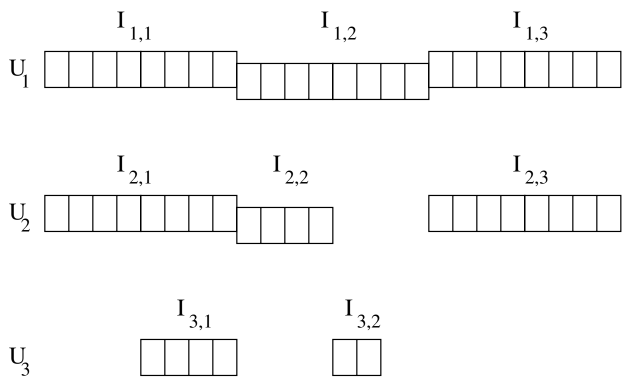

FIG. 5. *This figure illustrates the definition of regular and monotonic collections of intervals. In the example above we have three collections $U_1$, $U_2$, and $U_3$ of intervals of cells. These collections are regular for the following reasons. Any collection has disjoint intervals whose lengths are powers of 2, and the lengths of intervals in any collection differ by the factor of 2, at most (they do not differ for $U_1$, but differ for $U_2$ and for $U_3$). Any two intervals from any two distinct collections are either disjoint or one is contained in the other, i.e., there are no partial overlaps. If one is contained in the other, then the subset must be properly aligned inside the superset, i.e., the superset can be partitioned into intervals of the same length, the number of these intervals is a power of two, and the subset is one of the intervals (e.g., $I_{2,1}$ can be partitioned into two intervals, the right of which is $I_{3,1}$). Note that collections $U_1, U_2$ are monotonic, because for each interval of $U_2$ there is a superset interval in $U_1$. On the other hand, collections $U_2, U_3$ are not monotonic because there is no interval in $U_2$ that contains interval $I_{3,2}$.*

Taking a specific intersection of two collections preserves regularity and monotonicity, as shown below. In this intersection, a collection with the longest interval is taken, and its intervals are trimmed by the union of the intervals from the other collection.

LEMMA 3.3. *Let $k_1, \dots, k_p \ge 0$, let the collections $U_1^0, \dots, U_1^{k_1}, \dots\dots, U_p^0, \dots, U_p^{k_p}$ be regular, and let the collections $U_h^0, \dots, U_h^{k_h}$ be monotonic for any $h$, $1 \le h \le p$. Let $i \ne j$ be two numbers from $\{1, \dots, p\}$, $0 \le m \le k_j$, and $U = U_i^{k_i}$ and $U' = U_j^m$. Let $2^k$ be the maximum length of an interval in $U$ and $2^{k'}$ be the maximum length of an interval in $U'$. Let $V$ be the collection*

$$V = \begin{cases} U' \cap U := \left\{ \ H \mid H \ne \emptyset \ \wedge \ J \in U' \ \wedge \ H = J \cap \bigcup_{I \in U} I \ \right\} & \text{if } k > k', \\ U \cap U' := \left\{ \ H \mid H \ne \emptyset \ \wedge \ I \in U \ \wedge \ H = I \cap \bigcup_{J \in U'} J \ \right\} & \text{if } k \le k'. \end{cases}$$

*Then the number of intervals in $V$ is at most the maximum of the number of intervals in $U$ and in $U'$, i.e., $|V| \le \max\{|U|, |U'|\}$. If $k > k'$, then $V$ contains some complete intervals from $U'$, and when $k < k'$, some complete intervals from $U$. If $k = k'$, then $V$ contains some complete intervals from $U$ and a single half for each of some other intervals of length $2^k$ from $U$ ($V$ never contains two halves of any interval from $U$). The collections $V, U_1^0, \dots, U_1^{k_1}, \dots, \dots, \dots, U_p^0, \dots, U_p^{k_p}$ are regular, and the collections $U_i^0, \dots, U_i^{k_i}, V$ are monotonic.*

*Proof.* We shall study the content of $V$ based on the relationship between the length of a longest interval in $U$ and the length of a longest interval in $U'$. In preparation for the case analysis we record what the lengths of intervals in these collections may be. Since collections are regular, by property (i), we indeed know that the length of a longest interval in $U$ is $2^k$ and the length of a longest interval in $U'$ is $2^{k'}$, for some integers $k, k' \geq 0$. We also know that intervals in $U$ have length $2^k$ or $2^{k-1}$, and the intervals in $U'$ have length $2^{k'}$ or $2^{k'-1}$.

For the first case, suppose that $k > k'$, and let us investigate common parts between $U'$ and $U$. Let $I$ be an interval from $U$, and $J$ from $U'$. The interval $I$ cannot be shorter than $2^{k-1}$, and the interval $J$ cannot be longer than $2^{k-1}$. Therefore, $J$ is too short to be a strict superset of $I$. Hence, by property (ii), any interval $J$ from $U'$ is either a subset of some interval from $U$ or does not intersect with any interval from $U$. Consequently, the set $U' \cap U$ contains only some complete nonempty intervals from $U'$. The length of a longest interval in $U' \cap U$ is reduced by a factor of 2 or more compared to the length of a longest interval in $U$. Since removing an interval from a collection does not invalidate the properties, the collections $V, U_1^0, \dots, U_1^{k_1}, \dots\dots, U_p^0, \dots, U_p^{k_p}$ are regular and the collections $U_i^0, \dots, U_i^{k_i}, V$ are monotonic.

The second case is when $k < k'$. We can carry out an analysis similar to the one presented in the previous paragraph. The set $U \cap U'$ contains only some complete nonempty intervals from $U$, and regularity and monotonicity hold. However, we do not guarantee that the length of a longest interval in $U$ is reduced, because it could happen that any interval from $U$ is included in an interval from $U'$.

The final case is when $k = k'$. Let us again investigate the result of the operation $U \cap U'$. Take any interval $I$ from $U$, and let us see what part of this interval is contained in $U \cap U'$, if any. By property (ii), for any interval $J$ from $U'$ we have either $I \subseteq J$, or $I \supset J$, or $I \cap J = \emptyset$. If the first subcase occurs, then we are guaranteed that complete $I$ is contained in $U \cap U'$. Suppose that the first subcase does not happen, and so for all $J$, either $I \supset J$ or $I \cap J = \emptyset$ (but never $I \subseteq J$). The result now depends on how many distinct $J$ there are that satisfy $I \supset J$. Suppose that $I \supset J$. Our assumption about the length of intervals ensures that the length of such $J$ is $2^{k-1}$ and of $I$ is $2^k$. By property (i), we can have either zero, or one, or two intervals in $U'$ that are strict subsets of $I$. In the former situation all intervals $J$ have empty intersection with $I$, and so $I$ is not contained in $U \cap U'$. In the latter situation the two intervals combined must yield $I$, and so complete $I$ is contained in $U \cap U'$. The discussion presented in this paragraph so far implies that regularity and monotonicity trivially hold because the intervals contained in $U \cap U'$ are complete intervals from $U$. In the middle scenario, by property (iii), the interval $I$ is partitioned into two halves: $J$ and $I \setminus J$, and so only the half $J$ is contained in $U \cap U'$, but not the other half. An argument similar to that in Lemma 3.1 shows that monotonicity is preserved and another similar to that in Lemma 3.2 shows that regularity is preserved. ∎

The operation of intersection defined in the preceding lemma yields a certain reduction of size or length of the intervals in the resulting collection $V$, compared to the given collection $U$.

COROLLARY 3.4. *If $V \neq U$, then either*

(i) *the length of a longest interval in $V$ is at most half of the length of a longest interval in $U$, i.e.,* $\max_{I \in V} |I| \leq 1/2 \cdot \max_{I \in U} |I|$, *or*

(i) *the total number of elements in the intervals of $V$ is at most the total number of elements in the intervals of $U$ minus half of the length of a longest interval in $U$, i.e.,* $|\cup_{I \in V} I| \leq |\cup_{I \in U} I| - 1/2 \cdot \max_{I \in U} |I|$.

*Proof.* The analysis again proceeds by considering the relationship between the lengths of longest intervals in $U$ and $U'$. We consider three mutually exclusive cases. Suppose that $k > k'$. Then, by Lemma 3.3, the length of a longest interval in $V$ is at most half of the length of a longest interval in $U$. If $k < k'$, then $V$ contains some complete intervals from $U$, and since $U \neq V$, one of them must be missing in

$V$. This missing interval has length at least half of the length of a longest interval in $U$. If $k = k'$, then $V$ contains complete intervals from $U$ or their halves. Again, since $U \neq V$, either one interval or its half is missing. If a half is missing, then this half must contain at least $2^{k-1}$ elements. ∎

From now until the end of section 3.2, let us fix the values of the collections $U_1^0, \ldots, U_1^{k_1}, \ldots\ldots, U_p^0, \ldots, U_p^{k_p}$ as well as the values of variables $i$, $j$, and $m$. Let $V$ be the collection defined in Lemma 3.3 for the fixed values of the collections and the variables. We let $I$ be a fixed interval from the collection $U_i^{k_i}$, and $J$ a fixed interval from the collection $U_j^m$, such that these two intervals have nonempty intersection. This intersection contains a cell $x$ where processor $i$ collides with a different processor $j$. The lemmas and corollaries in the remainder of section 3.2 show transformations on collections that preserve regularity and monotonicity, and lead to certain reductions in the number of elements contained in the intervals of the resulting collections. The proofs are similar to the proofs of Lemma 3.3 and Corollary 3.4 (see Figure 6 for illustrations).

LEMMA 3.5. *Let $D$ be a possibly empty prefix of $I$ and $D'$ a possibly empty suffix of $J$, or conversely, let $D$ be a suffix and $D'$ a prefix, such that $D \cap D' = \emptyset$ and $D \cup D'$ is a nonempty interval. Let $W$ be the collection*

$$W = V \setminus (D \cup D') := \{\ H \mid H \neq \emptyset \ \wedge\ K \in V \ \wedge\ H = K \setminus (D \cup D')\ \}.$$

*Then the number of intervals in $W$ is at most the number of intervals in $V$. If $k \neq k'$, then the collection $W$ contains some complete intervals from $V$. If $k = k'$, then $W$ contains some complete intervals from $V$ and a single half for each of some other intervals from $V$. The collections $W, U_1^0, \ldots, U_1^{k_1}, \ldots\ldots, U_p^0, \ldots, U_p^{k_p}$ are regular, and the collections $U_i^0, \ldots, U_i^{k_i}, V, W$ are monotonic.*

*Proof.* To prove the lemma, we take any interval $K$ from $V$ and argue about what the result of subtracting $D \cup D'$ from $K$ is. We arrange the argument in three cases by the relationship between the length of a longest interval in $U$ and in $U'$.

For the first case suppose that $k > k'$. Then, by Lemma 3.3, the collection $V$ contains only some complete intervals from $U'$. Inspecting the possible lengths of intervals from $U$ and $U'$ reveals that it cannot happen that an interval from $U$ is a strict subset of some interval from $U'$, and so, by property (ii), $J \subseteq I$ (recall that we assume that $I \cap J \neq \emptyset$). Similarly, for any $K$ from $V$, $K \subseteq I$ or $K \cap I = \emptyset$. Note that the interval $D \cup D'$ starts at a tip of $I$, runs through entire $J$, and ends at the opposite tip of $J$. Thus the three sets $(D \cup D') \setminus J$, $J$, and $I \setminus (D \cup D')$ are disjoint possibly empty intervals whose union is $I$. If $K$ does not intersect with $I$, then $K \setminus (D \cup D') = K$. Assume now that $K$ is a subset of $I$. Since $J$ and $K$ are intervals from $U'$, we have, by property (i), that either $J = K$ or $J \cap K = \emptyset$. In the first subcase $K \setminus (D \cup D') = \emptyset$, while in the second subcase $K$ either belongs to $(D \cup D') \setminus J$ or to $I \setminus (D \cup D')$ and so $K \setminus (D \cup D')$ is equal to $\emptyset$ or $K$, respectively. Thus $W$ is equal to $V$ except for possibly some complete intervals removed, and so desired regularity and monotonicity hold.

A symmetric case is when $k < k'$. Now collection $V$ contains only some complete intervals from $U$, and it must be that $I \subseteq J$, and that for any $K$ from $V$, $K \subseteq J$ or $K \cap J = \emptyset$. As above, if $K$ does not intersect with $J$, then $K \setminus (D \cup D')$ is equal to $K$, while if $K \subseteq J$, then $K \setminus (D \cup D')$ is either empty or equal to $K$, and so desired regularity and monotonicity hold.

Finally, consider the case when $k = k'$. Since $I \cap J \neq \emptyset$, by property (ii), we have three subcases: $J \subset I$, $I \subset J$, $I = J$. We consider them in turn. For the first

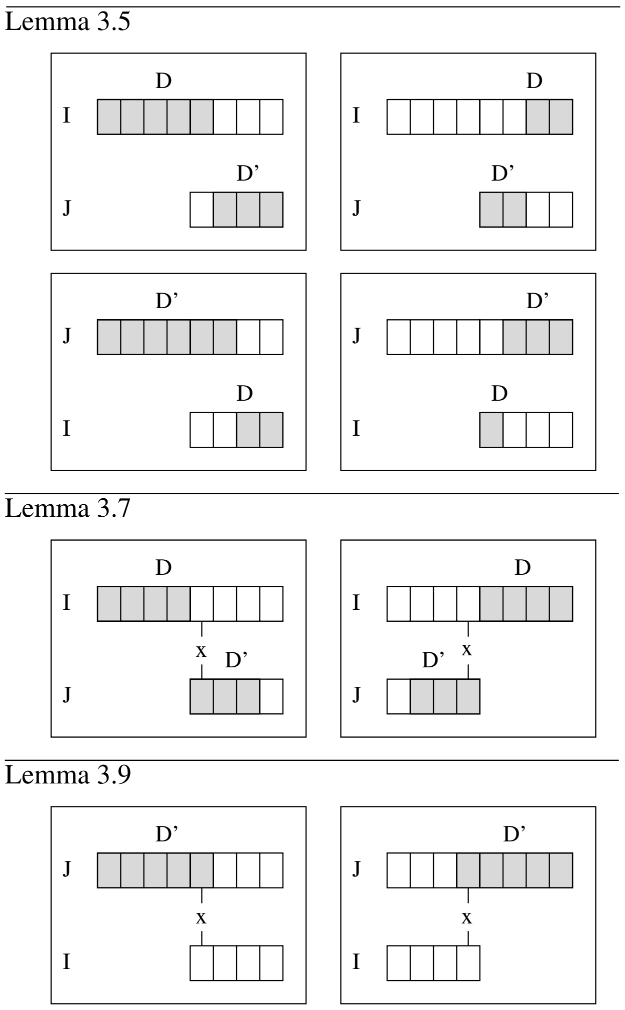

FIG. 6. *This figure illustrates the assumptions of Lemmas* 3.5, 3.7, *and* 3.9.

subcase suppose that $J \subset I$. Since, by property (i), the length of $I$ and $J$ can be either $2^k$ or $2^{k-1}$, the length of $I$ is $2^k$ and, by property (iii), $J$ is a half of $I$ and has length $2^{k-1}$. Thus $D \cup D'$ is either equal to $I$ or equal to a half of $I$. Take any $K$ from $V$. By Lemma 3.3, $V$ contains complete intervals from $U$ or halves of some other intervals form $U$ but never two halves of the same interval from $U$. If $K$ is an interval from $U$, then, by property (i), $K$ is either equal to $I$ or has empty intersection with $I$. If $K \cap I = \emptyset$, then $K \setminus (D \cup D') = K$. If $K = I$, then $K \setminus (D \cup D')$ is equal to either a half of $K$ or an empty set depending on whether $D \cup D'$ is the other half of $K$ or not. If $K$ is a half of an interval from $U$, then either $K \cap I = \emptyset$ or $K$ is a half of $I$. If $K$ is a half of $I$, then $K \setminus (D \cup D')$ is either $K$ or an empty set. Thus in the first subcase the set $K \setminus (D \cup D')$ has length either $2^k$ or $2^{k-1}$ or 0 and is equal to $K$, or a half of $K$, or the empty set. Hence desired regularity and monotonicity hold. For the second subcase suppose now that $I \subset J$. Then $J$ has length $2^k$, $I$ is its half of length $2^{k-1}$, and $D \cup D'$ is equal to $J$ or $I$. Take any $K$ from $V$. Since $K$ is an interval from $U$ or its half and has length $2^k$ or $2^{k-1}$, $K$ is too short to be a strict superset of $J$, and, by property (ii), $K \subseteq J$ or $K \cap J = \emptyset$. When the latter is true, $K \setminus (D \cup D') = K$. Let $K \subseteq J$. If the length of $K$ is $2^k$, then $K = J$ and $K \setminus (D \cup D')$ is equal to $\emptyset$ or a half of $K$. If the length of $K$ is $2^{k-1}$, then $K \setminus (D \cup D')$ is equal to $K$ or $\emptyset$. Thus in the second subcase the set $K \setminus (D \cup D')$ has length either $2^k$ or $2^{k-1}$ or 0. Hence desired regularity and monotonicity hold. Finally, consider the last subcase when $I = J$. Then the set $K \setminus (D \cup D')$ is either empty or equal to $K$, and so it has length either $2^k$, or $2^{k-1}$, or 0, and so desired regularity and monotonicity hold. □

COROLLARY 3.6. *If $U = V$, then the total number of elements in the intervals of $W$ is at most the total number of elements in the intervals of $U$ minus half of the length of a longest interval in $U$, i.e., $|\cup_{I \in W} I| \leq |\cup_{I \in U} I| - 1/2 \cdot \max_{I \in U} |I|$.*

*Proof.* If $U = V$, then the $I$ used in the statement of Lemma 3.5 belongs to $V$. Consequently, one of the sets $K$ from the statement of Lemma 3.5 is equal to $I$. We now follow the last three paragraphs of the proof of Lemma 3.5 to see what the difference is between $V$ and $W$. It cannot be that $k > k'$, because then $U \neq V$. If $k < k'$, then the set $D \cup D'$ used in the statement of Lemma 3.5 contains $I$, and so the collection $W$ does not contain the interval $I$, which has length at least half of the length of the longest interval is $U$. If $k = k'$, then we have the following: when $J \subset I$, then $I$ has the length of a longest interval in $U$ and the set $D \cup D'$ is at least a half of $I$, which is removed; when $I \subset J$, then $D \cup D'$ contains $I$, and so $I$ is removed; when $I = J$, then $I$ is removed. □

LEMMA 3.7. *Let $D \neq \emptyset$ be a prefix of $I$ and let $D' \neq \emptyset$ be a prefix of $J$ such that $x$ is the smallest element in $D'$ and $x - 1$ is the largest element in $D$, or conversely, let $D \neq \emptyset$ be a suffix of $I$ and let $D' \neq \emptyset$ be a suffix of $J$ such that $x$ is the largest element in $D'$ and $x + 1$ is the smallest element in $D$. Let $Q$ be the collection*

$$Q = V \setminus D := \{ \ H \ | \ H \neq \emptyset \ \wedge \ K \in V \ \wedge \ H = K \setminus D \ \}.$$

*Then the number of intervals in $Q$ is at most the number of intervals in $V$. If $k \neq k'$, then $Q$ contains some complete intervals from $V$. If $k = k'$, then $Q$ contains some complete intervals from $V$ and a single half for each of some other intervals from $V$. The collections $Q, U_1^0, \ldots, U_1^{k_1}, \ldots, U_p^0, \ldots, U_p^{k_p}$ are regular, and the collections $U_i^0, \ldots, U_i^{k_i}, V, Q$ are monotonic.*

*Proof.* We begin by showing that there are just two cases to consider. Since $I \cap J \neq \emptyset$, by property (ii), we know that either $I \subseteq J$ or $J \subset I$. Suppose that $I \subseteq J$. Then, when $D'$ is a prefix of $J$, $x$ must be the smallest element in $J$, and so $x - 1$ does not belong to $J$ and so cannot belong to $I$ either, while we know that $x$ belongs to $I$, or when $D'$ is a suffix of $J$, $x$ is the largest element in $J$ and so $x + 1$ does not belong to $J$ and so cannot belong to $I$ either. Hence the assumption that $I \subseteq J$ leads to a contradiction. Consequently it must be that $J \subset I$, and so either $k = k'$ or $k > k'$.

For the first case suppose that $k > k'$. Then $V$ contains only some complete intervals from $U'$. Take any $K$ from $V$. By property (ii), we have one of the three subcases: $K \subseteq I$, $K \supset I$, $K \cap I = \emptyset$. The interval $K$ is too short to be a strict superset of $I$, so the middle subcase cannot happen. If the last subcase happens, then $K \setminus D = K$. Let us now focus on the first subcase when $K \subseteq I$. Notice that the sets $D$, $J$, and $I \setminus (D \cup J)$ are disjoint intervals and their union is $I$. By property (i), either $K = J$ or $K \cap J = \emptyset$. If $K = J$, then $K \setminus D = K$, while when $K$ does not intersect with $J$, then $K \setminus D$ is either empty or equal to $K$. Consequently the collection $Q$ contains only some complete intervals from $V$, and so desired regularity and monotonicity hold.

Finally, consider the second case when $k = k'$. Take any $K$ from $V$. The collection $V$ contains some complete intervals from $U$ or halves of some other intervals from $U$, but never two halves of any interval from $U$. Hence, by property (i), either $K \cap I = \emptyset$, or $K = I$, or $K$ is a half of $I$, but then there is no other interval in $V$ that is equal to the other half of $I$. In the first subcase $K \setminus D = K$, and so let us focus on the two remaining subcases. Note that the length of $J$ can be either $2^k$ or $2^{k-1}$, but since $J \subset I$, the length of $J$ must be $2^{k-1}$, and $J$ must be a half of $I$. As a result, $D$ and $J$ are the two halves of $I$. So if $K = I$, then $K \setminus D$ is equal to $J$, a half of $K$. If $K$ is a half of $I$, then $K \setminus D$ is either $K$ or empty. Again regularity and monotonicity hold for $Q$. $\square$

COROLLARY 3.8. *If $U = V$, then the total number of elements in the intervals of $Q$ is at most the total number of elements in the intervals of $U$ minus half of the length of a longest interval in $U$, i.e., $|\cup_{I\in Q} I| \le |\cup_{I\in U} I| - 1/2 \cdot \max_{I\in U} |I|$.*

*Proof.* As explained in Corollary 3.6, we have that $k \le k'$ and $I$ is in $V$, and so $I = K$ for some $K$ from the statement of the Lemma 3.7. It cannot be that $k < k'$ because this is disallowed by the proof of Lemma 3.7. Thus the only possible relationship between $k$ and $k'$ is that $k = k'$. In this case $I$ has length $2^k$ and a half of $I$ is removed. $\square$

LEMMA 3.9. *Let $x$ be the smallest element in $I$ and $D' \ne \emptyset$ be a prefix of $J$ such that $x$ is the largest element in $D'$, or conversely, let $x$ be the largest element in $I$ and $D' \ne \emptyset$ be a suffix of $J$ such that $x$ is the smallest element in $D'$. Let $R$ be the collection*

$$R = V \setminus (D' \setminus \{x\}) := \{\ H \mid H \ne \emptyset \ \wedge\ K \in V \ \wedge\ H = K \setminus (D' \setminus \{x\})\ \}.$$

*Then the number of intervals in $R$ is at most the number of intervals in $V$. The collection $R$ contains some complete intervals from $V$. The collections $R, U_1^0, \ldots, U_1^{k_1}, \ldots, U_p^0, \ldots, U_p^{k_p}$ are regular, and the collections $U_i^0, \ldots, U_i^{k_i}, V, R$ are monotonic.*

*Proof.* The argument is similar to that of Lemma 3.5: we take an interval $K$ from $V$ and argue what part of the interval is in $R$. We start with an observation that when $D'$ contains just one element $x$ then the result is trivial because $R = V$. Assume therefore that $D'$ contains at least two elements. But then $J$ contains an element that is not in $I$ and so, by property (ii), $I \subset J$. Consequently, we have just two cases to consider: $k = k'$ and $k < k'$. We will study them in turn.

For the first case suppose that $k = k'$. Take any $K$ from $V$. The collection $V$ contains some complete intervals from $U$ or halves of some other intervals from $U$. Hence, by property (i), either $K \cap I = \emptyset$, or $K = I$, or $K$ is a half of $I$. Note that the length of $K$ can be either $2^k$ or $2^{k-1}$ and the length of $I$ is $2^{k-1}$, so $K$ cannot be a half of $I$. As a result, the last subcase does not happen and we have either $K \cap I = \emptyset$ or $K = I$. If $K = I$, then $K \setminus (D' \setminus \{x\}) = K$, while if $K \cap I = \emptyset$, then $K \setminus (D' \setminus \{x\})$ can be either $K$ or empty. Again, regularity and monotonicity hold for $R$.

Finally, consider the second case when $k < k'$. This case is very similar to the case when $k > k'$ in the proof of Lemma 3.7. We shall show it here for completeness. Then $V$ contains only some complete intervals from $U$. Take any $K$ from $V$. By property (ii), we have one of the three mutually exclusive subcases: $K \subseteq J$, $K \supset J$, or $K \cap J = \emptyset$. The interval $K$ is too short to be a strict superset of $J$ so the middle subcase cannot happen. If the last subcase happens, then $K \setminus (D' \setminus \{x\}) = K$. Let us now focus on the first subcase when $K \subseteq J$. Notice that the sets $D' \setminus \{x\}$, $I$, and

$J \setminus ((D' \setminus \{x\}) \cup I)$ are disjoint intervals and their union is $J$. By property (i), either $K = I$ or $K \cap I = \emptyset$. If $K = I$, then $K \setminus (D' \setminus \{x\}) = K$, while when $K$ does not intersect with $I$, then $K \setminus (D' \setminus \{x\})$ is either empty or equal to $K$. Consequently, the collection $R$ contains only some complete intervals from $V$, and so desired regularity and monotonicity hold. ∎

COROLLARY 3.10. *If $U = V$ and $R \neq V$, then the total number of elements in the intervals of $R$ is at most the total number of elements in the intervals of $U$ minus half of the length of a longest interval in $U$, i.e., $|\cup_{I\in R} I| \leq |\cup_{I\in U} I| - 1/2 \cdot \max_{I\in U} |I|$.*

*Proof.* Since $U = V$, then each interval $K$ from the statement of the Lemma 3.9 has length at least half of the length of a longest interval in $U$. But $R \neq V$ and so at least one interval or its part must have been removed. Lemma 3.9 shows that a complete interval is either removed or not a part of it at all. Thus at least one $K$ is missing in $R$ compared to $V$. ∎

## 3.3. Analysis of the algorithm.

This section presents an analysis of the collision algorithm given in Figure 2. Line numbers refer to the code in the figure. Recall that $n$ and $p$ are powers of 2. Without loss of generality, we assume that RMW can transfer $O(p)$ cells between local and shared memory (this assumption can be easily relaxed to comply with our model by first transferring the $O(p)$ cells to a dedicated region of shared memory and then making RMW store a pointer to this region in a cell of the trace table; see the proof of Theorem 3.16 for details).

The basic idea of the proof is to "convert" any asynchronous execution of the algorithm into collections of intervals and then reason about the collections. Any processor iterates through the big while loop (lines `03` to `29`) possibly many times. A brief inspection of the code of the algorithm reveals that at the beginning of each iteration, the collection $U$ that the processor maintains in its local memory contains intervals of cells of the Write-All array and that one of the intervals has an unmarked tip. Intuitively, the cells contained in the intervals are the only ones that may still need to be written to because all other cells have already been written to. An external observer can record (or "remember") the value of the collection $U$ of each processor as the processors iterate, and then reason about the properties of all recorded collections, to conclude that a certain bound on work must hold.

Formally, each time a processor $i$ executes line `03`, we record the value of the local variable $U$ of the processor (the collection $U$ does not change in line `03`, but we can still record $U$). This gives rise to a sequence $U_i^0, U_i^1, U_i^2, \ldots$ of collections of intervals, where $U_i^k$ is the value of collection $U$ of processor $i$ recorded in line `03` of the iteration number $k+1$ of the while loop, or $U_i^k = \emptyset$ when processor $i$ does not reach iteration $k+1$, in the given execution. A convenient way to think about the superscript $k$ is that $U_i^k$ is the collection $U$ of processor $i$ recorded immediately *after* iteration $k$ has been completed by the processor—this is why we start the sequence of superscripts from zero. For example, $U_i^0$ is the value of the collection $U$ recorded at the beginning of the first iteration (immediately after "iteration zero" has been completed). By inspecting the code, we see that $U_i^0$ is always equal to $\{[0, n-1]\}$ for any $i$, because when processor $i$ executes line `03` for the first time, the only instructions that it has executed earlier are these in lines `01` and `02`. Processor $i$ may or may not halt in a given execution. If it does not halt, then the value $U_i^k$ is well defined by the first segment of the definition (processor $i$ will execute line `03` for iteration number $k+1$, for all $k \geq 0$). However, if the processor halts in iteration number $k+1 < \infty$ for some $k \geq 0$, then $U_i^k$ is the last collection recorded for processor $i$, and line `03` will not be reached in iterations $k+2, k+3, \ldots$. Then the second segment of the definition

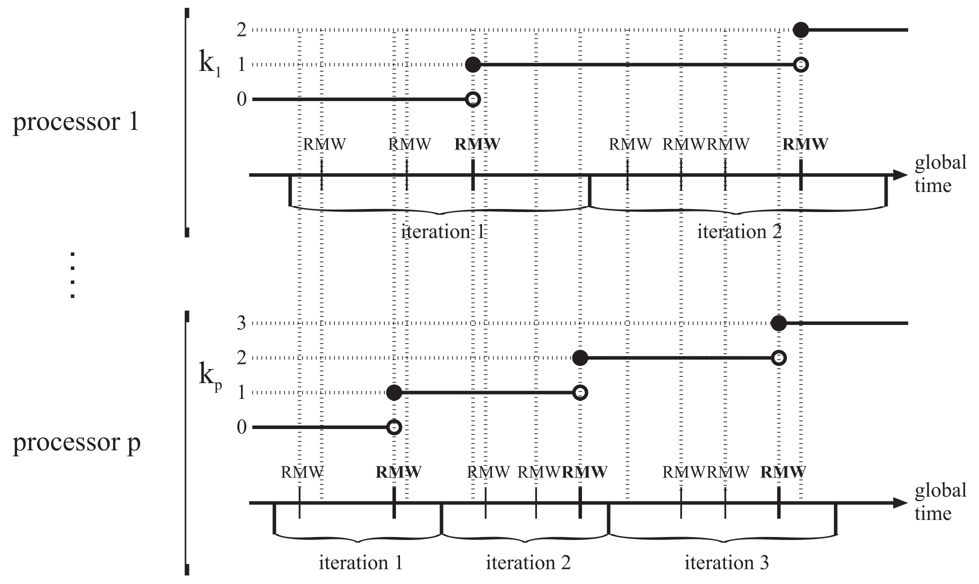

FIG. 7. *The value $k_i$ for processor $i$ increases at the moment when the last RMW instruction is executed in any iteration of the while loop that this processor executes. The induction of Lemma* 3.11 *focuses on these moments.*

puts $U_i^r = \emptyset$ for all $r \geq k+1$. So the sequences of collections are well defined for any execution and any processor.

We introduce additional terminology and notation used in the analysis of the algorithm. We say that a processor *is working on an interval* when it is executing its first RMW in the for loop (lines `06` to `10`) or any instruction during this loop until the processor has executed the last RMW in the for loop. At the moment when this last RMW has been executed, we say that the processor *has completed working on an interval.* Note that this last RWM can be executed either successfully or not. Also, during each iteration of the while loop, the processor may be working on a different interval than in other iterations. For a fixed execution, processor, and iteration of the while loop, we let $U^z$ denote the value of $U$ right before the processor executes line number $z$ of the iteration and $U_z$ denote the value of $U$ immediately after line number $z$. It will be clear from the context which execution, processor, and iteration $U^z$ or $U_z$ refer to.

The analysis starts with three lemmas and a corollary that reduce the analysis of the algorithm to the analysis of properties of collections of intervals. The first lemma shows that the collections of intervals, recorded over time as the algorithms unfolds, have specific structure.

LEMMA 3.11. *Consider any moment (of the global clock) during an execution of the algorithm, and let $k_i \geq 0$ for $1 \leq i \leq p$ be the number of times processor $i$ has completed working on an interval at that time. Then each processor $i$ either will begin work on an interval from $U_i^{k_i}$, or is working on an interval from $U_i^{k_i}$, or will halt without doing any more RMW, or has halted. The intervals $U_1^0, \ldots, U_1^{k_1}, \ldots, U_p^0, \ldots, U_p^{k_p}$ are regular, and the intervals $U_i^0, \ldots, U_i^{k_i}$ are monotonic for any $1 \leq i \leq p$.*

*Proof.* The proof is by induction on the moments in the execution when the values of $k_i$'s change (see Figure 7). We shall see that the lemma holds from the moment when processors begin execution until, but excluding, the first time any processor has completed working on an interval. Then we will consider two moments: a moment immediately before any moment when a processor $i$ has completed working on an interval, and the moment when the processor has completed working on the interval. Thus the value of $k_i$ increases by one from the first moment to the second, and no processor executes any action between these moments. We will argue that if the hypothesis holds at the first moment, it holds at the second moment as well, and also later, until immediately before the next time when a processor (possibly different than $i$) has completed working on an interval.

Let us consider the base case. The lemma is true immediately before, for the first time, a processor has completed working on an interval. Indeed, the first line of the collision algorithm for any processor $i$ sets $U$ to $\{[0, n-1]\}$, and the value of $U$ is not changed at least until the processor reaches line `11` of the first iteration of the while loop. Thus $U_i^0 = \{[0, n-1]\}$ for any $1 \leq i \leq p$. At the moment immediately before a last RMW is executed for the first time by any processor, each processor $i$ either is working or will work on an interval from $U_i^0$. Note that collections $U_1^0, \dots, U_p^0$ are regular, as each contains the same single interval of length that is a power of two. Trivially, the collection $U_i^0$ is monotonic for any $1 \leq i \leq p$ because any single collection is always monotonic.

For the inductive step, pick a moment immediately before any moment when a processor has completed working on an interval, and assume that the lemma is true then. Let this be processor $i$, and let $k_h \geq 0$ denote the number of times processor $h$ has competed working on an interval. Processor $i$ is executing iteration number $k_i + 1$ of the while loop and is about to complete working on an interval for the $(k_i + 1)$-th time. When processor $i$ has finally completed working on the interval, we have two cases: either the processor has succeeded on the last RMW or has failed.

*Case* 1. If processor $i$ succeeds on the last RMW, then it means that the processor has successfully RMWed to all cells in the interval $I$ that it has been working on. Notice that the processor never reads any memory cell that could be written to by a different processor between now and the moment when the processor reaches line `03` again in the next iteration number $k_i + 2$ of the while loop, if the processor ever reaches this line again. Therefore, the value of $U_i^{k_i+1}$ is already determined. Since the processor has been working on an interval $I$ from $U = U_i^{k_i}$, then, in line `12`, the processor removes the interval from the collection. Let $V$ denote the resulting collection of intervals. Clearly, the collections $U_i^0, \dots, U_i^{k_i}, V$ are monotonic and the collections $V, U_1^0, \dots, U_1^{k_1}, \dots, U_p^0, \dots, U_p^{k_p}$ are regular.

When processor $i$ reaches line `24`, the collections $U^{24}, U_1^0, \dots, U_1^{k_1}, \dots, U_p^0, \dots, U_p^{k_p}$ are regular, and the collections $U_i^0, \dots, U_i^{k_i}, U^{24}$ are monotonic. By property (i), if $U^{24}$ contains an interval of length 1, then $U^{24}$ contains intervals of length 1 or 2 only. Hence a possible removal of intervals of length 1 preserves regularity and monotonicity. If $U^{25}$ is empty, then processor $i$ halts and $U_i^{k_i+1} = \emptyset$. Suppose that $U^{25}$ is not empty. The processor will begin work on an interval from a collection, as explained next. When not all tips of intervals in $U^{25}$ are marked, then $U_i^{k_i+1} = U^{25}$ and the processor will begin work on an interval with an unmarked tip from the collection. Alternatively, all tips of intervals in $U^{25}$ are marked. Then $U^{25}$ cannot contain intervals of length 1, because these were just removed. Also $U^{25}$ is not empty. So it contains at least one interval that has length at least 2. Let $R$ be a collection equal to $U^{25}$ except for a longest interval replaced by its two halves (lines `27` to `29`). By Lemma 3.2, the collections $R, U_1^0, \dots, U_1^{k_1}, \dots, U_p^0, \dots, U_p^{k_p}$ are regular, and, by Lemma 3.1, the collections $U_i^0, \dots, U_i^{k_i}, R$ are monotonic. Then $U_i^{k_i+1} = R$. Note that at any moment until the next time a processor will have completed working on an interval, properties related to processors other than $i$ carry over from the inductive assumption. That is, any processor $j \neq i$ will begin work on an interval from $U_j^{k_j}$, or is working on an interval from $U_j^{k_j}$, or will halt without doing any more RMW, or has halted, while processor $i$ will begin work on an interval from $U_i^{k_i+1}$, or is working on an interval from $U_i^{k_i+1}$, or will halt without doing any more RMW, or has halted.

The argument presented so far ensures that the inductive step holds in the case when processor $i$ succeeds on the last RMW.

*Case* 2. Suppose that processor $i$ fails on RMW to a cell $x$ that belongs to the interval $I$ that the processor has been working on. Then the processor reaches line `14` and, if the processor was working on $I$ from left to right, the set $D$ contains a prefix of $I$ up to, but excluding, $x$, or, if the processor was working from right to left, a suffix of $I$ up to, but excluding, $x$. Suppose that it was a processor $j$ that has done a successful RMW to the cell $x$. This must have happened when processor $j$ was working on an interval $J$ either from its left tip toward its right tip or vice versa, and so the set $D'$ read by processor $i$ in line `14` of iteration $k_i + 1$ is a prefix of $J$ ending at $x$, or conversely it is a suffix of $J$ ending at $x$. Note that $i \neq j$ because if a processor does a successful RMW to a cell, then it never again even attempts to do RMW to this cell. Thus the collection $U'^{15}$ is equal to $U_j^m$ for some $0 \leq m \leq k_j$.

We now consider the changes to $U$ that can happen from line `15` to line `23` and see how these changes affect regularity and monotonicity.

After processor $i$ has executed lines `15` to `17` the desired properties hold. Indeed, by Lemma 3.3, the collections $U^{18}, U_1^0, \dots, U_1^{k_1}, \dots, U_p^0, \dots, U_p^{k_p}$ are regular, and the collections $U_i^0, \dots, U_i^{k_i}, U^{18}$ are monotonic.

The execution of processor $i$ now depends on whether $i$ collided with $j$ when working in opposite directions or the same direction.

First, suppose that processor $j$ was working on its interval $J$ in the opposite direction to the direction in which processor $i$ was working. Then $i$ will execute line `19`. As a result, by Lemma 3.5, the collections $U_{19}, U_1^0, \dots, U_1^{k_1}, \dots, U_p^0, \dots, U_p^{k_p}$ are regular, and the collections $U_i^0, \dots, U_i^{k_i}, U_{19}$ are monotonic, and so the collection $U^{24}$ is equal to $U_{19}$.

Second, assume that processor $j$ was working on $J$ in the same direction as processor $i$ has been on $I$. We now study two subcases depending on the success of $i$ in RMW to any cell in $I$.

Subcase number one is when processor $i$ has managed to successfully RMW to at least one cell in $I$. Then $D \neq \emptyset$ and so the processor will execute line `21`. We now argue that specific relationships must hold between $D$, $D'$, and $x$. If $i$ and $j$ worked to the right, then $x$ cannot be the second or later to the right element of $J$, because then the first element of $J$ would be successfully RMWed by $j$, and so $i$ would have failed on an RMW to an element different than $x$, as ensured by the fact that $i$ has been working on consecutive elements from the interval $I$ and that $D \neq \emptyset$. So $x$ must be the first element of $J$, and so $x$ is the smallest element of $D'$ and $x-1$ is the largest element of $D$. Similarly, if $i$ and $j$ were working to the left, then $x$ is the largest element of $D'$ and $x+1$ is the smallest element of $D$. These relationships ensure that when $i$ has executed line `21`, by Lemma 3.7, collections $U_{21}, U_1^0, \dots, U_1^{k_1}, \dots, U_p^0, \dots, U_p^{k_p}$ are regular, and the collections $U_i^0, \dots, U_i^{k_i}, U_{21}$ are monotonic. Then the collection $U^{24}$ is equal to $U_{21}$.

Subcase number two is when processor $i$ failed on its first RMW to a cell in $I$. Then $D = \emptyset$ and so processor $i$ will execute line 22. Since $i$ has failed on its first RMW, then, when $i$ works to the right, $x$ must be the smallest element in $I$ and $x$ the largest element in $D'$, or, when $i$ works to the left, then $x$ is the largest element in $I$ and $x$ the smallest element in $D'$. As a result, after $i$ has executed line 22, by Lemma 3.9, the collections $U_{22}, U_1^0, \dots, U_1^{k_1}, \dots, U_p^0, \dots, U_p^{k_p}$ are regular, and the collections $U_i^0, \dots, U_i^{k_i}, U_{22}$ are monotonic. Then the collection $U^{24}$ is equal to $U_{22}$.

Let us summarize how the changes to $U$ done by processor $i$ from line 14 to line 23 can affect regularity and monotonicity immediately before $i$ reaches line 24. By the above argument, when processor $i$ fails on the RMW, we know that collections $U^{24}, U_1^0, \dots, U_1^{k_1}, \dots, U_p^0, \dots, U_p^{k_p}$ are regular, and the collections $U_i^0, \dots, U_i^{k_i}, U^{24}$ are monotonic. We can carry out the same analysis as in the case of a successful last RMW described in Case 1 earlier to show that any processor either has halted, will halt, is working, or will begin work on an interval at any moment before the next time some $k_g$ is increased, and that the collections are regular and monotonic as desired.

This completes the inductive step and the proof. ∎

The technique used in the proof of Lemma 3.11 could be called the technique of eventual invariant. We formulate an invariant, take any execution that is a sequence of events, show that there is an event when the invariant holds and that, due to the properties of the asynchronous model, eventually there is another event when the invariant holds again, or the algorithm terminates.

Corollary 3.12. *Consider any moment during an execution of the algorithm and let $k_i \geq 0$ for $1 \leq i \leq p$ be the number of times processor $i$ has completed working on an interval at that time. Then the cells $\{0, \dots, n-1\} \setminus U_i^{k_i}$ of the array $w$ have been set to 1 for any $i$. When a processor sets the flag $f$ to 1 and halts, then each cell of $w$ has been set to 1.*

*Proof.* Using a straightforward inductive argument similar to that given in Lemma 3.11, we can demonstrate that any cell $x \in \{0, \dots, n-1\} \setminus U_i^{k_i}$ has been set to 1. In particular, given any processor and its collection $U$ at any moment of the execution, any cell in $\{0, \dots, n-1\} \setminus U$ is known to have been set to 1, along with tips marked by the processor. For the second part, observe that a processor halts only when its $U$ is empty. ∎

The next lemma shows that any processor has at most $p/2$ intervals in its collection $U$ at any time during execution. The key algorithmic tool that yields this bound is the technique of marking tips of intervals. Recall that a processor splits an interval only when all tips of all intervals in $U$ are marked. So in order to produce many intervals, there must be a moment when the processor has many marked tips. This, however, means that the processor must have collided with many other processors. We can infer that during these collisions, knowledge about progress must necessarily be transferred from one processor to the other processor, and so the processor must necessarily remove a tip, thus preventing the number of intervals from growing too much.

Lemma 3.13. *Consider any moment during an execution of the algorithm and let $k_i \geq 0$ for $1 \leq i \leq p$ be the number of times processor $i$ has completed working on an interval at that time. Then for each processor $i$, the collection $U_i^{k_i}$ has at most $p/2$ intervals. None of the collections can have $p$ marked tips.*

*Proof.* The proof is by induction on the moments in the execution when the values of $k_i$'s change, as in Lemma 3.11.

For the base case, we observe that the lemma is true immediately before, for the first time, a processor has completed working on an interval, because $U_1^0 = \cdots = U_p^0$ are collections, each containing just one interval $[0, n-1]$ with no marked tip.

For the inductive step, pick a moment immediately before any moment when a processor has completed working on an interval. Let this be processor $i$, and let $k_h \geq 0$ be the number of times processor $h$ has completed working on an interval then. Assume that collection $U_h^k$ has at most $p/2$ intervals for any $1 \leq h \leq p$ and $0 \leq k \leq k_h$. Processor $i$ is executing iteration number $k_i + 1$ of the while loop and is about to complete working on an interval for the $(k_i + 1)$-th time.

Let us bound the number of intervals in $U$ when processor $i$ reaches line 24 of this iteration. During the time when $i$ is working on the interval, collection $U$ of $i$ is equal to $U_i^{k_i}$. If the last RMW in this iteration is successful, then when the processor reaches line 24, the number of intervals in $U$ is one fewer than in $U_i^{k_i}$, and so it is at most $p/2 - 1$. If the RMW failed, then the processor must have collided with a different processor $j$, and so the value of the variable $U'_{14}$ of processor $i$ is equal to $U_j^m$ for some $0 \leq m \leq k_j$. By the inductive hypothesis the number of intervals in $U'_{14}$ is at most $p/2$. After the processor $i$ has executed lines 15 to 23, the number of intervals in $U$ can be at most the maximum of the number of intervals in $U_i^{k_i}$ and $U_j^m$, because of Lemmas 3.3, 3.5, 3.7, and 3.9. And so $U^{24}$ has at most $p/2$ intervals.

We now study the evolution of $U$ until processor $i$ reaches line 03 again, if ever. We begin the evaluation with three simple cases. First, if $U_{24}$ is empty, then the result is trivial because $U_i^{k_i+1}$ is empty. Second, if $U_{24}$ has an interval with an unmarked tip, then processor $i$ does not execute lines 27 to 29, and so $U_i^{k_i+1}$ is equal to $U_{24}$. Third, if $U_{24}$ is not empty, all tips of all intervals in $U_{24}$ are marked, and $U_{24}$ has strictly fewer than $p/2$ intervals, then the processor $i$ executes lines 27 to 29. But then splitting an interval increases the number of intervals by exactly one. Consequently, in the third case, $U_i^{k_i+1}$ has one interval more compared to $U_{24}$, and so the number of intervals is bounded by $p/2$. In all three cases the inductive step follows.

The final and most interesting case of the inductive step is when the collection $U_{24}$ has exactly $p/2$ intervals and all their tips are marked. We show that this cannot happen by way of contradiction.

Let the collection $U_{24}$ be composed of the intervals $I_1, \ldots, I_{p/2}$. Since all intervals of length 1 with marked tips were removed in line 24, each of the $p/2$ intervals has length at least 2. Thus the intervals have exactly $p$ distinct tips and the tips are marked.

How can the tips get marked? By inspecting the code we see that a tip $x$ can get marked only after $i$ collides with a processor that worked in the same direction when performing RMW to $x$. Then either $D = \emptyset$ or $D \neq \emptyset$. When $D = \emptyset$, $i$ fails on RMW to tip $s$ in an iteration, and then $s$ remains as a tip and gets marked in this very iteration. When $D \neq \emptyset$, $i$ fails on RMW to $x$ other than $s$ in an iteration, and then $x$ becomes a tip and gets marked in this very iteration. Consequently, in order for any tip $x$ to be marked, processor $i$ must fail on RMW to $x$. So processor $i$ must have failed on RMW to the $p$ distinct tips by the moment it reaches line 24 of iteration $k_i + 1$.

Could any of these tips be successfully RMWed by $i$? Note that if processor $i$ had done a successful RMW to a tip of its interval during the for loop in a $k$th iteration of the while loop, $k \leq k_i + 1$, then this tip (not necessarily entire interval) would have been removed from its collection before the processor $i$ reaches line 24 of the while loop in iteration number $k$, and, by the monotonicity property (iv), no subsequent collection $U$ of processor $i$ can contain the tip. Therefore, when processor $i$ reaches line 24 of the current iteration number $k_i + 1$, all $p$ distinct tips of the intervals $I_1, \ldots, I_{p/2}$ have been successfully RMWed by processors other than $i$.

By the pigeonhole principle, therefore, there is a processor $j$ other than $i$, such that the processor $j$ had successfully RMWed to two of the $p$ tips on which $i$ failed. Let $x$ and $y$ be these two tips, such that $x$ was RMW before $y$ was, according to the total order established by the RMW instructions. Let $j_x \leq j_y$ be the iteration numbers of the while loop of processor $j$ during which the processor did successful RMWs to the two tips $x$ and $y$, respectively. We consider two cases depending on whether $x$ and $y$ were RMW in the same iteration or different iterations of the while loop.

For the first case, suppose that $x$ was RMW in an earlier iteration, i.e., $j_x < j_y$. Then processor $j$ must have removed the cell $x$ from its set $U$ by the end of the iteration $j_x$, and so in all subsequent iterations the collection $U$ of processor $j$ does not contain any interval that contains $x$. So when $j$ performs a successful RMW to cell $y$, it stores a collection there, so that none of the intervals of the collection contains $x$. Subsequently, processor $i$ fails on RMW to cell $y$, and then the processor retrieves the collection stored in the cell. At that time, no interval of the collection $U'_{14}$ of processor $i$ contains element $x$. Hence, after intersection and by monotonicity, the interval $U_{24}$ of the iteration number $k_i + 1$ of processor $i$ does not contain any interval that contains $x$. This is a desired contradiction because we assumed that $x$ is a marked tip of an interval in the collection $U_{24}$.

For the second and final case, assume that $x$ and $y$ were RMW during the same iteration of processor $j$'s while loop, i.e., $j_x = j_y$. Hence when $j$ does RMW to cell $y$, its interval $D$ contains $x$. Subsequently, processor $i$ fails on RMW to cell $y$ and retrieves the interval from the cell. So in the iteration when the retrieval occurs, the $D'_{14}$ of processor $i$ contains two distinct elements $x$ and $y$. Suppose that during this iteration $i$ was working in the same direction as the direction in which $j$ was working when $j$ did a successful RMW to $y$. Assume for a moment that the direction was R (right). Moreover, assume that processor $i$ succeeded in one or more RMW in this iteration. Since $y$ is the only cell on which processor $i$ can fail in this iteration, $i$ must have succeeded on the RMW to cell $y-1$. But this cannot be the case, because $x$ is to the left of $y$ and all cells between $x$ and $y$ inclusive had been successfully RMWed by $j$. A similar contradiction is reached when the direction of work was L (left). Hence, in the iteration when retrieval occurred, it cannot be the case that processor $i$ worked in the same direction as processor $j$, $dir_{14} = dir'_{14}$, and processor $i$ succeeded in an RMW, $D_{14} \neq \emptyset$. As a result, $i$ cannot execute line 21 in this iteration and must execute either line 19 or line 22. Consequently, at least one $x$ or $y$ is removed from $U$. Again, this leads to a contradiction.

The inductive step is completed, which proves the lemma. ∎

During an execution, a processor performs some number of iterations of the while loop. The next lemma shows an upper bound on this number. The lemma is proven by noticing that the sequence $U_i^0, U_i^1, U_i^2, \ldots$ of collections of intervals cannot have too long subsequences of equal collections, because the number of marked tips would increase, and that when two consecutive collections are different, then processor $i$ makes substantial progress on its work. This means that the successive collections quickly become "slimmer and slimmer" and eventually become empty.

LEMMA 3.14. *In any execution of the algorithm any processor performs at most* $p^2 + p\,(2p+1)\log n$ *iterations of the while loop.*

*Proof.* Let us consider any execution, any processor $i$, and the sequence of all collections $U_i^0, U_i^1, U_i^2, \ldots$ that have been recorded for this processor in this execution. Since each collection was recorded, the collection is nonempty. This sequence may perhaps be infinite. We will argue that the sequence of recorded collections cannot have too long subsequences of consecutive equal collections, and that when two subsequent collections are different, then there is substantial difference in the total number of elements that belong to the intervals of the consecutive collections. Hence the sequence of collections "slims fast." As a result, we will be able to conclude that the sequence of recorded collections is finite, and in fact quite short. Thus the number of iterations will be small, too, because the number of iterations is exactly equal to the number of recorded collections.

We begin with an observation that if two consecutive recorded collections are equal, then there is one tip that is unmarked in the previous collection and the tip is marked in the subsequent collection, while all tips already marked in the previous collection remain marked in the subsequent collection. Indeed, suppose that $U_i^k = U_i^{k+1}$. Note that when a processor is working on an interval, then the tip $s$ from which the processor has started the work is unmarked. Recall that $U_i^k$ is recorded at the beginning of iteration $k+1$ and $U_i^{k+1}$ is recorded at the beginning of iteration $k+2$. Since the two collections are equal, and transformations applied to $U$ in the iteration are monotonic, the value of the collection $U$ must stay intact during iteration $k+1$. In particular, $U$ does not change from the moment immediately before line `11` until immediately after line `29`. In order for $U$ to remain the same, the processor must have failed on its first RMW to the tip $s$ of the interval on which $i$ was working, and the failure must have been because a different processor $j$ had successfully RMWed to $s$ while $j$ had been working on an interval in the same direction as $i$ was when $i$ attempted an RMW to $s$ (otherwise the value of $U$ would change). As a result, the tip $s$ that was previously unmarked becomes marked in line `23`. Note that no tip $x$ of any interval in any collection is ever unmarked by a processor, unless a part of the interval that contains $x$ is removed from the collection. Hence the number of marked tips in $U_i^{k+1}$ is one plus the number of marked tips in $U_i^k$.

This leads to an observation that the length of a sequence of consecutive equal collections must be bounded. Suppose that for some $k \geq 0$ and $c \geq 0$, collections $U_i^k, U_i^{k+1}, \ldots, U_i^{k+c}$ have been recorded, and they are equal to $U_i^k = U_i^{k+1} = \cdots = U_i^{k+c}$. By Lemma 3.13, the collection $U_i^k$ has at most $p/2$ intervals and so at most $p$ unmarked tips. Because each subsequent collection in the sequence has one fewer unmarked tip and, by Lemma 3.13, no collection can have $p$ marked tips, $c$ can be at most $p-1$. So in the sequence of recorded collections, there can be at most $p$ consecutive equal collections.

We inspect what must happen when two consecutive collections are different. Take any $k \geq 0$ such that $U_i^k, \ldots, U_i^{k+c}, U_i^{k+c+1}$ have been recorded, and $c$ is the largest number so that $U_i^k = U_i^{k+1} = \cdots = U_i^{k+c}$; thus $U_i^{k+c} \neq U_i^{k+c+1}$. Our plan is to show that the difference between collections $U_i^{k+c}$ and $U_i^{k+c+1}$ is "big." Recall that $U_i^{k+c}$ was recorded at the beginning of iteration $k+c+1$, and $U_i^{k+c+1}$ at the beginning of $k+c+2$. So the value of $U^{11}$ in iteration $k+c+1$ is equal to $U_i^{k+c}$, while the value of $U_{29}$ is equal to $U_i^{k+c+1}$. We consider all the ways in which the execution of the processor $i$ may proceed from line `11` until line `29` of iteration $k+c+1$, and study the changes to $U$.

The plan for the subsequent analysis is to consider the first moment when $U$ changes in lines `11` to `29`. We know that a change must occur somewhere inside these lines. Then, by the properties of the transformations of intervals, we can conclude that a "big" modification must occur, and that this modification must carry over to the end of the iteration, by monotonicity of transformations. Then we can count how many times these modifications can happen in the sequence $U_i^0, U_i^1, U_i^2, \ldots$ until $U_i^k$ becomes empty. In the paragraphs that follow we will be assuming that $U$ does not change throughout larger and larger initial sections of the code of lines `11` to `29`.

If processor $i$ succeeded on the last RMW, then it executes line `12`, where an interval is removed from $U$. By property (i), this interval has length that is equal to at least half of the length of a longest interval in $U_i^{k+c}$. Due to monotonicity of subsequent transformations in the iteration, the total number of elements in the intervals of $U_i^{k+c+1}$ is at most the total number of elements in the intervals of $U_i^{k+c}$ minus half of the length of a longest interval in $U_i^{k+c}$.

Suppose, on the other hand, that the processor failed on the RMW to a cell $x$, and so it executes line `14`. If the execution of lines `15` to `17` leads to a change in the value of $U$, then, by Corollary 3.4, either the length of a longest interval in $U^{18}$ is at most half of the length of a longest interval in $U_i^{k+c}$, or the total number of elements in the intervals of $U^{18}$ is at most the total number of elements in the intervals of $U_i^{k+c}$ minus half of the length of a longest interval in $U_i^{k+c}$. Again, due to monotonicity, this relative difference carries over to the difference between $U_i^{k+c}$ and $U_i^{k+c+1}$.

It is possible that processor $i$ has failed on the RMW to the cell $x$, and the execution of lines `15` to `17` does not change $U$. Then $U^{18} = U_i^{k+c}$. Let $j \neq i$ be the processor that successfully RMWed to the cell $x$ while working on an interval. Now we have two cases: either processor $i$ and $j$ worked in opposite directions or the same direction.

For the first case, assume that the colliding processors $i$ and $j$ worked in different directions. Then, by Corollary 3.6, the total number of elements in the intervals of $U_{19}$ is at most the total number of elements in the intervals of $U_i^{k+c}$ minus half of the length of a longest interval in $U_i^{k+c}$. Again, due to monotonicity, the intervals of $U_i^{k+c+1}$ can only have even fewer elements.

For the second case, assume that $i$ and $j$ worked in the same direction. Then processor $i$ executes either line `21` or `22`. In the former case, the value of $U$ always changes; in the latter it may change or not. Suppose that $U$ changes, i.e., $U^{23} \neq U^{21}$. Then, by Corollaries 3.8 and 3.10, the total number of elements in the intervals of $U^{24}$ is at most the total number of elements in the intervals of $U_i^{k+c}$ minus half of the length of a longest interval in $U_i^{k+c}$. It may, however, happen that $U^{23} = U^{21}$, and then we have that $U^{24} = U_i^{k+c}$. Consequently, if any interval of length 1 is removed in line `24`, then, by property (i), this interval is at least as long as half of the length of a longest interval in $U_i^{k+c}$. Finally, assume that no interval of length 1 is removed. Since $U_i^{k+c+1}$ is recorded, then $i$ does not halt in line `25`, and so $U^{26} = U_i^{k+c}$. Then it cannot be the case that there is an unmarked tip, because we assumed that $U_i^{k+c} \neq U_i^{k+c+1}$. Hence a longest interval in $U^{26}$ gets split, and so $U_i^{k+c+1}$ is equal to $U_i^{k+c}$ except for a longest interval split into two halves.

Let us sum up the above study of the modifications to $U$ that must occur from line `11` to line `29`, when the collection $U_i^{k+c+1}$ is different than the collection $U_i^{k+c}$. There are three possible modifications: either the length of a longest interval in $U_i^{k+c+1}$ is at most half of the length of a longest interval in $U_i^{k+c}$, or $U_i^{k+c+1}$ is equal to $U_i^{k+c}$ except for a longest interval being split into two halves, or the total number of elements in the intervals of $U_i^{k+c+1}$ is at most the total number of elements in the intervals of $U_i^{k+c}$ minus half of the length of a longest interval in $U_i^{k+c}$.

We now count how many times each of these three modifications can happen until

$U$ becomes empty (in which case processor $i$ must halt). Reduction of length by the factor of 2 or more can happen at most $\log n$ times, a longest interval can be split into two halves at most $p \log n$ times (because the number of intervals in a collection is bounded by $p/2$), and at least half of a longest interval can be removed at most $p\,(1 + \log n)$ times. As a result $U_i^{p(\log n + p \log n + p(1+\log n))} = \emptyset$, and the lemma has been proven. ◻

We are now ready to prove the main result of this paper.

THEOREM 3.15. *The algorithm solves the CWA problem and has work of $O(n + p^4 \log n)$; the processors combined set at most $n + 4p^3 \log n$ cells of $w$ to 1.*

*Proof.* Consider any execution of the algorithm. By Lemma 3.13 each processor performs a bounded number of iterations, and, by Corollary 3.12, when a processor stops all cells of $w$ have been set to 1. Hence the algorithm solves the CWA problem.

We now argue about the work complexity of the algorithm. Let us fix a processor and divide each of its iterations of the while loop into two parts. The first part contains the instructions starting from the first RMW of the for loop until but not including the last RMW of the for loop, while the second part contains all other instructions in the iteration (the second part has two discontinuous sections of instructions). Note that all RMW in the first part are successful and so the combined work of all processors on the first parts is $O(n)$ (using a pointer representation of the collections) and at most $n$ cells of the array $w$ are set to 1 by the $p$ processors during the first parts. For any processor, the number of second parts is equal to the number of iterations, which is bounded, by Lemma 3.14, by $p^2 + p\,(2p+1) \log n$. So the total number of iterations performed by all processors is bounded by $p\left(p^2 + p\,(2p+1)\log n\right)$. During each second part at most one cell of $w$ can be set to 1, and so the $p$ processors combined may set to 1 at most $p^3 + p^2\,(2p+1)\log n$ cells of $w$ in their second parts. Recall that, by Lemma 3.13, the number of intervals in any collection during the execution is at most $p/2$ and so any second part takes $O(p)$ instructions to execute. Thus the combined work that processors performed on the second parts is $O(p^4 \log n)$. This completes the proof. ◻

Recall that the code of the algorithm assumes that RMW can transfer $O(p)$ cells between local and shared memory. We now discuss how to relax this assumption to comply with our model which allows only $O(1)$ cells to be transferred. The relaxation can be accomplished using pointer representation of collection $U$.

THEOREM 3.16. *In a single execution of the collision algorithm, the $p$ processors combined use at most $O(n + p^4 \log n)$ cells of shared memory.*

*Proof.* Each processor $i$ maintains a shared memory array where collections $U_i^0, U_i^1, U_i^2, \ldots$ will be placed (see Figure 8). The array has $p/2$ rows and $p^2 + p\,(2p+1)\log n$ columns, and is stored in a dedicated section of shared memory. The location of the section inside shared memory can be selected using the unique identifier of the processor. Each entry of the array stores two numbers representing tips of an interval. Recall that in our model each memory cell can accommodate $O(\log n)$ bits. Hence the total number of shared memory cells sufficient for the $p$ arrays is $O(p^4 \log n)$.

When processor $i$ begins iteration $k$, it transfers the collection $U$ to column $k$ of the array. In the algorithm as stated in Figure 2, each RMW transfers the current collection $U$ to a cell of the trace table *tab*. This violates the model because we may need to transfer $O(p)$ cells while in our model we assume that RMW can access a constant number of cells only. In the actual version of the collision algorithm, the processor will transfer a pointer to column $k$ of the array during any RMW operation

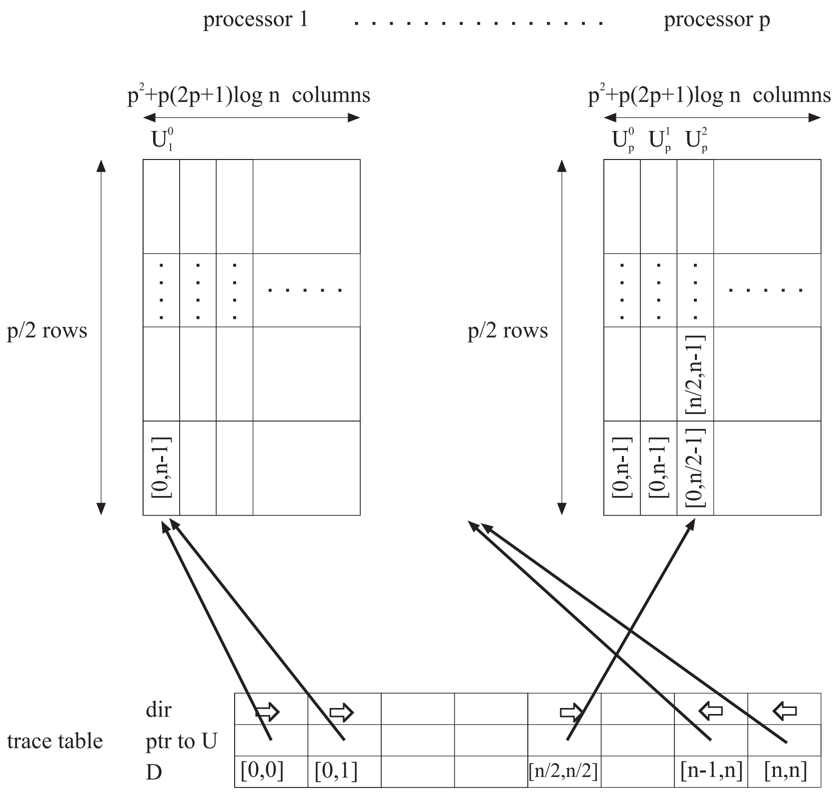

FIG. 8. *Pointer representation of collections of intervals. There are p shared memory arrays, each dedicated to a processor. Collections U generated by a processor are stored in columns of the array. The trace table, also in shared memory, contains pointers to columns.*

of iteration $k$. Thus, assuming that a pointer takes $O(\log n)$ bits, RMW needs only to transfer a constant number of cells. In the algorithm stated in Figure 2, processor reads $U$ directly from the trace table. In the actual algorithm, the processor will read a pointer to a column of an array, and retrieve a collection of intervals from the column.

The number of rows allocated for each processor is sufficient, by Lemma 3.13, to accommodate any $U$ produced during any execution of the algorithm. The number of columns is sufficient, by Lemma 3.14, to complete one execution of the collision algorithm. $\square$

**4. Future work.** It should be possible to tighten the analysis of work complexity of the algorithm by further exploring the information flow between processors. We believe that the actual work complexity of our algorithm is no more than $O(n + p^3 \log n)$ because the analysis given in the proof of Lemma 3.14 appears to have a fair amount of slack.

We believe that it should be possible to further reduce the work and space complexities of the algorithm by modifying data structures. Specifically, instead of creating a new $U$ during each iteration, we could try to reuse the parts of $U$ that have not changed since the prior iteration. This should decrease space complexity, but may increase work complexity as the new representation of $U$ may be more "dispersed." In the proof of Theorem 3.15, we bounded by $O(p)$ the time to perform the transformations of $U$. Is $\Theta(p)$ necessary? It would be interesting to find a representation of $U$ that would allow the performance of $r$ transformations in time $o(rp)$ and space $o(rp)$, possibly by exploiting regularity and monotonicity.

In our algorithm there may be more than one unmarked tip to select from at the beginning of an iteration of the while loop. Currently, the algorithm arbitrarily selects an unmarked tip of an interval. However, one can consider a more refined process of selection when there are choices. One could apply the techniques of "oblivious schedules" of Anderson and Woll [1], in conjunction with identifiers of processors, so as to select a tip to begin work from, so that overall not too many processors also select this tip. The combination of the collision technique and the oblivious technique seems a promising approach for constructing an algorithm that would have asymptotically optimal work for a wider range of the number of processors.

The algorithm uses a special RMW primitive to efficiently detect collisions. Is the use of such a primitive essential for obtaining an algorithm with asymptotically optimal work for a wide range of the number of processors? Would the use of a more standard single word RMW, compare and swap, or even atomic reads and writes be sufficient? A recent paper of Kowalski and Shvartsman [26] shows that atomic reads and writes are sufficient.

Work of any deterministic asynchronous algorithm for the CWA problem with $p \leq n^{1-\epsilon}$ processors must obviously be $\Omega(n)$. We have shown that there is an $O(n)$ algorithm when $1 \geq \epsilon \geq 4/5$. Is it true that there exists an $O(n)$ algorithm for $\epsilon$ arbitrary close to 0? For what values of $p$ compared to $n$ is there a nontrivial lower bound on work of a deterministic algorithm? In particular, is $\omega(n)$ work necessary when $p$ is $o(n/\log n)$?

**Acknowledgments.** The author thanks his host, Charles Leiserson, for an invitation to join the Supercomputing Technologies Group and for discussions, including those on how to write a better proof. This paper was inspired by earlier work with Alex Shvartsman. The author thanks Bogdan Chlebus, Piotr Indyk, Arnold Rosenberg, Alex Russell, Alex Shvartsman, and the anonymous PODC'03 reviewers for reading drafts of the paper and commenting on them. Their input improved the clarity of the presentation. The author particularly acknowledges the three *SIAM Journal on Computing* reviewers for their careful reading of the manuscript, many detailed comments, and suggestions to better explain how the algorithm works. Finally, the author thanks Mumtaz Lohawala for hosting him in her house for one year during the author's visit to MIT.

# THE BISIMULATION PROBLEM FOR EQUATIONAL GRAPHS OF FINITE OUT-DEGREE*

GÉRAUD SÉNIZERGUES†

**Abstract.** The *bisimulation* problem for equational graphs of finite out-degree is shown to be decidable. We reduce this problem to the $\eta$-bisimulation problem for deterministic rational (vectors of) boolean series on the alphabet of a deterministic pushdown automaton $\mathcal{M}$. We then exhibit a *complete formal system* for deducing equivalent pairs of such vectors.

**Key words.** bisimulation, equational graphs, deterministic pushdown automata, rational languages, finite dimensional vector spaces, matrix semigroups, complete formal systems

**AMS subject classifications.** Primary, 68Q70; Secondary, 03D05, 05C75, 20M35

**DOI.** 10.1137/S0097539700377256

## 1. Introduction.

### 1.1. Motivations.

**Processes.** In the context of concurrency theory, several notions of "behavior of a process" and "behavioral equivalence between processes" have been proposed. Among them, the notion of *bisimulation* equivalence seems to play a prominent role (see [26]). The question of whether this equivalence is *decidable* or not for various classes of infinite processes has been the subject of many works in the last fifteen years (see, for example, [1, 5, 18, 7, 14, 17, 8, 6, 45, 19, 37, 44, 22]).

The aim of this work is to show decidability of the bisimulation equivalence for the class of all processes defined by pushdown automata (pda) whose $\epsilon$-transitions are deterministic and decreasing (of course, we assume that $\epsilon$-transitions are *not* visible, which implies that the graphs of the processes considered here might have infinite in-degree). This problem was raised in [6] (see Problem 6.2 of this reference) and is a significant subcase of the problem raised in [45] (as the bisimulation problem for processes "of type $-1$").

**Infinite graphs.** A wide class of graphs enjoying interesting decidability properties has been defined in [11, 2, 3] (see [12] for a survey). In particular it is known that the problem

$$\textit{are } \Gamma, \Gamma' \textit{ isomorphic?}$$

is decidable for pairs $\Gamma, \Gamma'$ of equational graphs. It seems quite natural to investigate whether the problem

$$\textit{are } \Gamma, \Gamma' \textit{ bisimilar?}$$

is decidable for pairs $\Gamma, \Gamma'$ of equational graphs. We show here that this problem is decidable for equational graphs of finite out-degree.

†LaBRI, Université de Bordeaux I, 351, Cours de la Libération 33405 Talence, France (ges@labri.fr).

**Formal languages.** Another classical equivalence relation between processes is the notion of *language* equivalence. The decidability of language equivalence for *deterministic* pushdown automata (dpda) has been established in [34, 40] (see also [36, 35] for shorter expositions of this result). It was first noticed in [1] that, in the case of deterministic processes, language equivalence and bisimulation equivalence are identical. Moreover dpda can always be normalized (with preservation of the language) in such a way that $\epsilon$-transitions are all decreasing. Hence the main result of this work is a generalization of the decidability of the equivalence problem for dpda.

**Mathematical generality.** More precisely, the present work *extends the notions* developed in [34] so as to obtain a more general result. As a by-product of this extension, we obtain a deduction system which, in the deterministic case, seems *simpler* than the one presented in [34] (see system $\mathcal{B}_3$ in section 10).

The present work can also be seen as a common generalization of three different results: the results of [45, 19] establishing decidability of the bisimulation equivalence in two nondeterministic subclasses of the class considered here, and the result of [34] dealing only with deterministic pda (or processes).

**Logics.** Our solution consists in constructing a *complete* formal system, in the general sense taken by this word in mathematical logics; i.e., it consists of a set of well-formed assertions, a subset of basic assertions, the axioms, and a set of deduction rules allowing one to derive new assertions from assertions which are already generated. The well-formed assertions we are considering are pairs $(S, T)$ of rational boolean series over the nonterminal alphabet $V$ of some strict-deterministic grammar $G = \langle X, V, P \rangle$. Such an assertion is true when the two series $S, T$ are bisimilar.

Several simple formal systems generating all the identities between boolean rational expressions have been the subject of several works (see [32, 4, 21]); the case of bisimilar rational expressions has been addressed in [25, 20].

A tableau proof-system generating all the bisimilar pairs of words with respect to a given context-free grammar in Greibach normal form was also given in [18].

Our complete formal systems can be seen as participating in this general research stream ([39] provides an overview of this subject in the context of equivalence problems for pda).

### 1.2. Results.

The main decidability result of this work is the following.

THEOREM 10.7. *The bisimulation problem for rooted equational* 1*-graphs of finite out-degree is decidable.*

The main structural result obtained here is as follows.

THEOREM 10.14. *$\mathcal{B}_3$ is a complete deduction system.*

Here, $\mathcal{B}_3$ is a formal system whose elementary rules just express the basic algebraic properties of bisimulation: the fact that it is an equivalence relation, that it is compatible with right and left (matricial) product, that Arden's lemma remains true modulo bisimulation and, at last, its link with one-step derivation (rule (R34)). Completeness means here that *all* pairs of bisimilar rational "deterministic" boolean series are generated by this formal system.

### 1.3. Overview and roadmap.

**Overview: Large scale.** Let us describe the principal flow of ideas which underpins our proof.

*Step* 1: *Reduction.* We reduce the bisimulation problem for vertices $v, v'$ of an equational graph $\Gamma$ of finite out-degree to an analogous problem, but with more algebraic flavor: given two deterministic rational row-vectors $S, S'$, are they $\eta$-bisimilar?

The precise definition of what is a deterministic rational row-vector is given in section 3.1, the notion of $\eta$-bisimilarity for vectors is defined in section 3.2, and the reduction itself is stated in Lemma 3.25.

*Step* 2: *Logical system.* We define a formal system, named $\mathcal{B}_0$, whose assertions are the pairs of deterministic rational row-vectors $(S, S')$. Such an assertion is considered as true iff the vectors $S, S'$ are $\eta$-bisimilar. The system $\mathcal{B}_0$ is defined in section 4.3 and its soundness is immediately proved there.

*Step* 3: *Strategies for* $\mathcal{B}_0$. We define some suitable notions of *strategies* for a formal system: a strategy is a map sending every partial proof $P$ into a partial proof $P'$ containing $P$. What we have in mind is to build, step by step, a proof for a given true assertion by iteratively applying a strategy. Section 7 is devoted to the construction of such strategies for the system $\mathcal{B}_0$.

*Step* 4: *Completeness of* $\mathcal{B}_0$. We proceed to a close analysis of the "proof-trees" produced by the above strategies in order to show that, starting from a true assertion $(S, S')$, a finite proof-tree is always reached. This succeeds in proving that $\mathcal{B}_0$ is a *sound* and *complete* logical system. Unfortunately, $\mathcal{B}_0$ cannot be easily shown to be *recursively enumerable*, due to one of its rules, namely, rule (R5).

*Step* 5: *Elimination.* It turns out that this problematic rule (R5) can be *eliminated* from $\mathcal{B}_0$, resulting in a smaller system $\mathcal{B}_1$ which is still sound, complete, and recursively enumerable. This logical result allows us to prove decidability of the $\eta$-bisimulation problem for deterministic rational row-vectors, and hence of the bisimulation problem for vertices of an equational graph of finite out-degree (by Step 1).

*Step* 6: *Simplifications.* This last step is useless for decidability purposes but sheds light on the *structure* of bisimulation equivalence. Successive elimination arguments lead us to a fairly simple logical system, named $\mathcal{B}_3$, which is still sound and complete. The rules of $\mathcal{B}_3$ are just consisting of the principal algebraic properties of vectors-$\eta$-bisimulation and a single rule expressing the precise grammar (or process) we are examining (rule (R34)).

**Overview and roadmap: Medium scale.** Let us describe now, section by section, the main successive technical contributions to the general flow described in the previous overview.[1]

*Section* 2.

2.1. We recall the notion of graph-bisimulation as classically stated in the literature.

2.2. As well, we recall the notion of pda.

2.3. We characterize the class of graphs under scrutiny, the "equational 1-graphs of finite out-degree," as the computation-graphs of normalized pda (a precise proof is delayed to the appendix).

2.4. We recall the definition of a deterministic context-free grammar.

2.5. We state the basic definitions allowing us to translate the usual notions of left-derivation with respect to (w.r.t.) (resp., language generated by) a context-free grammar $G$ into a more algebraic framework: everything is formulated now within semirings of boolean series over finite sets of undeterminates,

[1]Sections 1 and 11 do not participate in the proof itself and therefore are left out of this overview. The appendix is also neglected here because of its marginality.

endowed with two right-actions $\odot, \bullet$: the first right-action expresses a one-step left-derivation, while the second right-action is just the well-known residual-action.

*Section* 3.

3.1. We recall the notion of *deterministic boolean series*, which plays a role analogous to that of "configuration" of a dpda. The advantage of this notion is that it allows extensions to vectors and matrices and supports several well-behaved operations.

3.2. We reduce the initial bisimulation problem over graphs to a bisimulation problem over deterministic rational row-vectors (we call this new kind of bisimulation the $\sigma$-$\eta$-bisimulation). For every pair $(S, S')$ of deterministic series, we introduce a notion of word-$\eta$-bisimulation which is a kind of equivalence relation over words that "witnesses" the fact that $(S, S')$ are indeed $\sigma$-$\eta$-bisimilar. Operations on such word-$\eta$-bisimulations are introduced in order to prove, later on, some algebraic properties of $\sigma$-$\eta$-bisimulation.

3.3. The usual notions of derivation and *stacking* derivation are translated in our framework. Some basic properties are demonstrated.

*Section* 4.

4.1. We define a very general notion of *deduction system.* Its only nonstandard aspect, as compared to the usual "Hilbert-style systems," is that the proofs can "loop": it may happen that a correct proof contains an assertion $A$, which is deduced, by means of finitely many steps, from a set of axioms and (though such a feature was not expected) $A$ itself.

4.2. We introduce a general notion of *strategy* w.r.t. a given deduction system: it is just a map sending every partial proof $P$ into a partial proof $P'$ containing $P$. The desirable properties of such strategies are defined there.

4.3. We define here *the* principal deduction system $\mathcal{B}_0$ that we expect to be able to generate exactly the set of $\sigma$-$\eta$-bisimilar pairs of vectors $(S, S')$. We immediately establish that $\mathcal{B}_0$ is sound (Lemma 4.9). Some interesting algebraic corollaries are deduced.

4.4. We isolate a subsystem of $\mathcal{B}_0$, which we name $\mathcal{C}$, that is independent of any graph or automaton: the rules of $\mathcal{C}$ capture the essential algebraic properties relating the $\sigma$-$\eta$-bisimulation relation with the matricial product. We then state four useful general deductions within the system $\mathcal{C}$.

*Section* 5.

5.1. A set of row-vectors which is closed under linear combination is named a *d-space.* Such a d-space, endowed with the right-operation $\odot$, is the key algebraic structure we shall use later. We define a natural notion of *linear independence* for families of vectors and show that it enjoys one of the usual properties of linear independence: if a family is dependent, then one of the vectors of the family is a linear combination of the others.

5.2. Applying repeatedly the above property of dependent families, we exhibit a "triangulation process" for systems of equations: given a system $\mathcal{S}$ of $n$ equations $\sum_{j=1}^{d} \alpha_{i,j} S_j \sim \sum_{j=1}^{d} \beta_{i,j} S_j$ (where $\sim$ denotes the $\sigma$-$\eta$-bisimulation) one can transform $\mathcal{S}$ in such a way that the last equation, which we call the *inverse equation*, combines the coefficients $\alpha_{i,\star}, \beta_{i,\star}$ but does not involve the $S_j$ anymore. The exact relationship between $\mathcal{S}$ and the inverse equation, INV($\mathcal{S}$), is studied there.

In fact, the above description is accurate only when $\eta$ is just the equality relation. In the general case we are lead to introduce the notion of an *oracle*: an oracle is a choice of word-$\eta$-bisimulation for every pair of $\eta$-bisimilar vectors. The "inverse" equation determined by $\mathcal{S}$ and by an oracle $\mathcal{O}$ is denoted by $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})$.

*Section* 6. Here are collected all the definitions of "constants" used throughout this article: these are all the integers, depending on a given initial automaton $\mathcal{M}$, an equivalence $\eta$, and an initial pair of vectors $(S_0^-, S_0^+)$ which one would like to test for $\sigma$-$\eta$-bisimilarity.

*Section* 7. We define here strategies for the particular deduction system $\mathcal{B}_0$.

7.1. We define several substrategies based on both the algebraic properties established in section 4.3 and the triangulation process studied in section 5.2.

7.2. All the substrategies from section 7.1 are synthesized into a global strategy $\hat{\mathcal{S}}_{ABC}$.

*Section* 8. The proofs built by $\hat{\mathcal{S}}_{ABC}$ are naturally structured as "proof-trees." We examine here a hypothetical infinite branch belonging to some infinite proof built by $\hat{\mathcal{S}}_{ABC}$. In section 8.2 we prove that such an infinite branch must possess an infinite suffix, which is a *B-stacking sequence*: roughly speaking, it begins with a $T_B$-application and later on, each time some $T_B^\alpha$ is applied, the vector which is used by $T_B^\alpha$ for constructing the new vector (on side $\alpha$) has a norm which is *large enough.*

We show carefully (Lemmas 8.4 to 8.10) that such a sequence of equations contains a subsequence of equations, on which the triangulation process (section 5) can be applied. Consequently the substrategy $T_C$ could apply to one node of this suffix.

*Section* 9. From the technical result proved in section 8, we quickly deduce that $\hat{\mathcal{S}}_{ABC}$ cannot build an *infinite* proof-tree from any true assertion. Unfortunately two problems remain to be solved:

- we must show that $\hat{\mathcal{S}}_{ABC}$ really builds a finite proof-tree from every true assertion, i.e., that $\hat{\mathcal{S}}_{ABC}$ is *closed*;
- at this point we do not know whether $\mathcal{B}_0$ is recursively enumerable or not, because of metarule (R5): this rule specifies that the conclusion is a pair of ... $\sigma$-$\eta$-bisimilar vectors, which is somewhat circular.

*Section* 10.

10.1. We overcome here the two difficulties quoted above:

- $\hat{\mathcal{S}}_{ABC}$ is shown to be *closed*;
- we show that every proof-tree constructed by $\hat{\mathcal{S}}_{ABC}$ is in fact also a proof for the smaller system $\mathcal{B}_1$ obtained from $\mathcal{B}_0$ by removing rule (R5) (proof of Theorem 10.6).

In other words we show that (R5) can be *eliminated* from $\mathcal{B}_0$, while preserving completeness. Hence $\mathcal{B}_1$ is a deduction system which is sound, complete, and recursively enumerable. The main decidability theorem (Theorem 10.7) follows: The bisimulation problem for rooted equational 1-graphs of finite out-degree is decidable.

10.2, 10.3. We perform successive simplifications of system $\mathcal{B}_1$. We finally obtain a system $\mathcal{B}_3$ whose elementary rules just express the basic algebraic properties of bisimulation: the fact that it is an equivalence relation, that it is compatible with right and left (matricial) products, that Arden's lemma remains true modulo bisimulation and, at last, its link with one-step derivation (rule (R34)).

We provide the reader with a roadmap which might help him in finding his way across the different sections (see Figure 1). The essential steps of the proof are placed in a column corresponding to the main theme to which they belong (Graphs, Algebra,

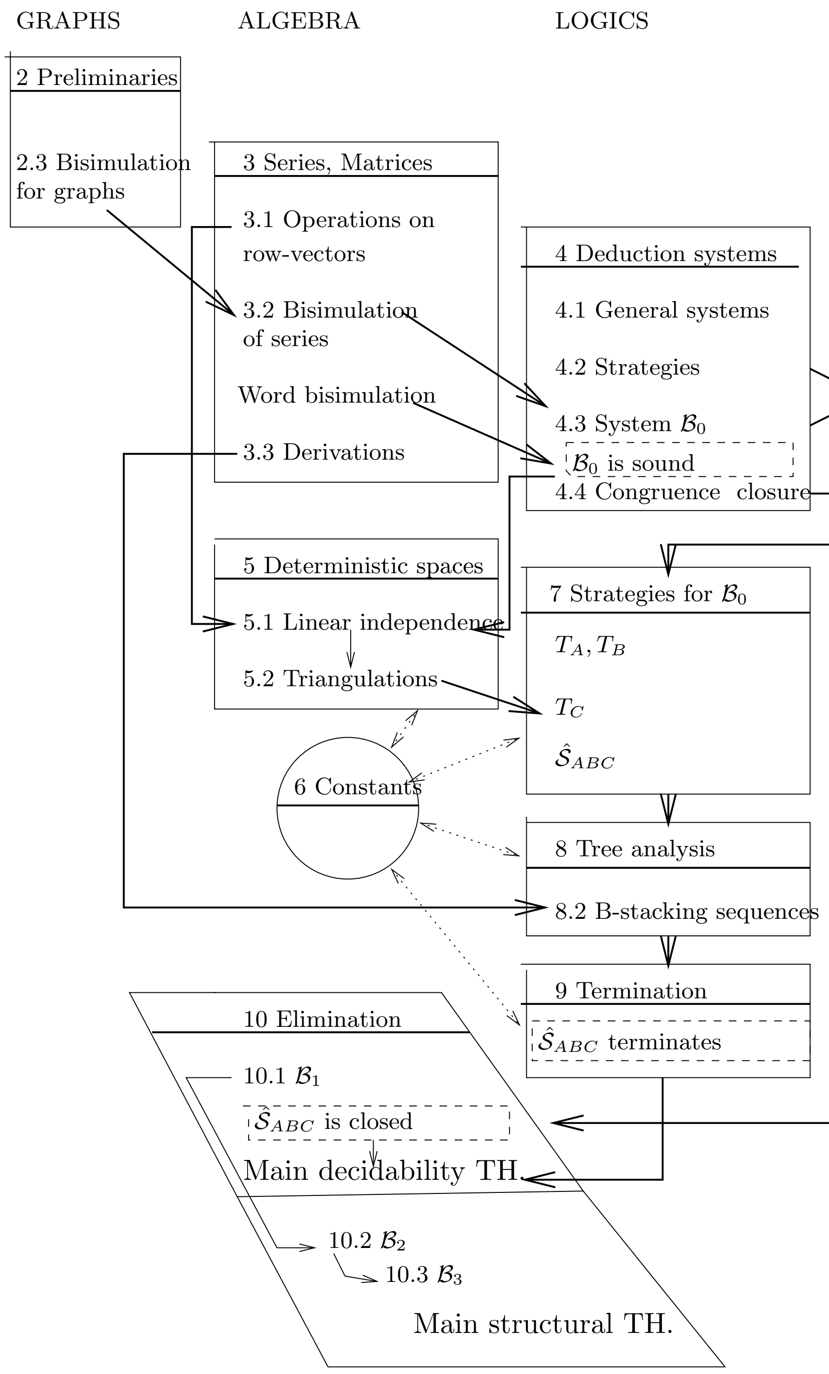

FIG. 1. *Roadmap.*

or Logics) and in a line corresponding to the physical linear ordering of the proof (from beginning to end). Arrows are added showing the main logical dependencies (they define a partial ordering over the steps that the written proof must extend into a total ordering).

**Overview: Small scale.** The proof exposed here is an updated version of the full proof given in [33] and presented concisely in [37]. This last reference can be used as a small-scale overview of our proof.

## 2. Preliminaries.

**2.1. Graphs.** Let $X$ be a finite alphabet. We call *graph over* $X$ any pair $\Gamma = (V_\Gamma, E_\Gamma)$ where $V_\Gamma$ is a set and $E_\Gamma$ is a subset of $V_\Gamma \times X \times V_\Gamma$. For every integer $n \in \mathbb{N}$, we call an $n$-graph every $n+2$-tuple $\Gamma = (V_\Gamma, E_\Gamma, v_1, \ldots, v_n)$ where $(V_\Gamma, E_\Gamma)$ is a graph and $(v_1, \ldots, v_n)$ is a sequence of distinguished vertices: they are called the *sources* of $\Gamma$.

A 1-graph $(V, E, v_1)$ is said to be *rooted* iff $v_1$ is a root of $(V, E)$ and $V \neq \{v_1\}$. A 2-graph $(V, E, v_1, v_2)$ is said *birooted* iff $v_1$ is a root, $v_2$ is a coroot of $(V, E)$, $v_1 \neq v_2$, and there is no edge going out of $v_2$ (this last technical condition will be useful for reducing the bisimilarity notion for graphs to an analogous notion on series; see sections 2.1, 2.3, and 3.2).

The *equational* graphs are the least solutions (in a suitable sense) of the systems of (hyperedge) graph-equations (see [12] for precise definitions). Let us mention that the equational graphs of *finite degree* are exactly the *context-free* graphs defined in [27].

**Bisimulations.**

DEFINITION 2.1. *Let $\Gamma = (V_\Gamma, E_\Gamma, v_1, \ldots, v_n)$, $\Gamma' = (V_{\Gamma'}, E_{\Gamma'}, v'_1, \ldots, v'_n)$ be two $n$-graphs over an alphabet $X$. Let $\mathcal{R}$ be some binary relation $\mathcal{R} \subseteq V_\Gamma \times V_{\Gamma'}$. $\mathcal{R}$ is a* simulation *from $\Gamma$ to $\Gamma'$ iff*

(1) $\mathrm{dom}(\mathcal{R}) = V_\Gamma$,

(2) $\forall i \in [1, n]$, $(v_i, v'_i) \in \mathcal{R}$,

(3) $\forall v \in V_\Gamma$, $w \in V_\Gamma$, $v' \in V_{\Gamma'}$, $x \in X$, *such that* $(v, x, w) \in E_\Gamma$ *and* $v\mathcal{R}v'$, *there exists* $w' \in V_{\Gamma'}$ *such that* $(v', x, w') \in E_{\Gamma'}$ *and* $w\mathcal{R}w'$.

*$\mathcal{R}$ is a* bisimulation *from $\Gamma$ to $\Gamma'$ iff $\mathcal{R}$ is a simulation from $\Gamma$ to $\Gamma'$ and $\mathcal{R}^{-1}$ is a simulation from $\Gamma'$ to $\Gamma$.*

This definition corresponds to the standard one [29, 26, 6] in the case where $n = 0$. The $n$-graphs $\Gamma, \Gamma'$ are said to be *bisimilar*, which we denote by $\Gamma \sim \Gamma'$, iff there exists a bisimulation $\mathcal{R}$ from $\Gamma$ to $\Gamma'$.

Let us now extend this definition by means of a relational morphism between free monoids.

DEFINITION 2.2. *Let $X, X'$ be two alphabets. A binary relation $\eta \subseteq X^* \times X'^*$ is called a strong relational morphism from $X^*$ to $X'^*$ iff*

(1) *$\eta$ is a submonoid of $X^* \times X'^*$,*

(2) $\mathrm{dom}(\eta) = X^*$, $\mathrm{im}(\eta) = X'^*$,

(3) *$\eta$ is generated (as a submonoid) by the subset $\eta \cap (X \times X')$.*

One can easily check that strong relational morphisms are preserved by inversion and composition and that any surjective map $\eta : X \to X'$ induces a strong relational morphism from $X^*$ to $X'^*$. Let $\Gamma = (V_\Gamma, E_\Gamma, v_1, \ldots, v_n)$ be an $n$-graph over the alphabet $X$, and let $\Gamma' = (V_{\Gamma'}, E_{\Gamma'}, v'_1, \ldots, v'_n)$ be an $n$-graph over the alphabet $X'$. Let $\eta \subseteq X^* \times X'^*$ be some strong relational morphism, and let $\mathcal{R}$ be some binary relation $\mathcal{R} \subseteq V_\Gamma \times V_{\Gamma'}$.

DEFINITION 2.3. *$\mathcal{R}$ is an $\eta$-*simulation *from $\Gamma$ to $\Gamma'$ iff*

(1) $\mathrm{dom}(\mathcal{R}) = V_\Gamma$,

(2) $\forall i \in [1, n]$, $(v_i, v'_i) \in \mathcal{R}$,

(3) $\forall v, w \in V_\Gamma$, $v' \in V_{\Gamma'}$, $x \in X$, *such that* $(v, x, w) \in E_\Gamma$ *and* $v\mathcal{R}v'$,

$$\exists w' \in V_{\Gamma'},\ x' \in \eta(x) \text{ such that } (v', x', w') \in E_{\Gamma'} \text{ and } w\mathcal{R}w'.$$

$\mathcal{R}$ *is an* $\eta$-bisimulation *iff* $\mathcal{R}$ *is an* $\eta$*-simulation and* $\mathcal{R}^{-1}$ *is an* $\eta^{-1}$*-simulation.*

For every $v \in V_\Gamma$, $v' \in V_{\Gamma'}$, we denote by $v \sim v'$ the fact that there exists some $\eta$-bisimulation $\mathcal{R}$ from $\Gamma$ to $\Gamma'$ such that $(v, v') \in \mathcal{R}$. Throughout this work, the composition of binary relations is denoted by $\circ$ and defined by the following: if $\mathcal{R}_1 \subseteq E \times F$ and $\mathcal{R}_2 \subseteq F \times G$, then

$$\mathcal{R}_1 \circ \mathcal{R}_2 = \{(x, z) \in E \times G \mid \exists y \in F, (x, y) \in \mathcal{R}_1, (y, z) \in \mathcal{R}_2\}. \tag{2.1}$$

FACT 2.4.
(1) *If* $\mathcal{R}$ *is an* $\eta$*-bisimulation, then* $\mathcal{R}^{-1}$ *is an* $\eta^{-1}$*-bisimulation.*
(2) *If* $\mathcal{R}_1$ *is an* $\eta_1$*-bisimulation and* $\mathcal{R}_2$ *is an* $\eta_2$*-bisimulation, then* $\mathcal{R}_1 \circ \mathcal{R}_2$ *is an* $\eta_1 \circ \eta_2$*-bisimulation.*
(3) *If for every* $i \in I$*,* $\mathcal{R}_i$ *is an* $\eta$*-bisimulation, then* $\bigcup_{i\in I} \mathcal{R}_i$ *is an* $\eta$*-bisimulation.*

**2.2. Pushdown automata.** A *pushdown automaton* (pda) on the alphabet $X$ is a 7-tuple $\mathcal{M} = \langle X, Z, Q, \delta, q_0, z_0, F\rangle$ where $Z$ is the finite stack-alphabet, $Q$ is the finite set of states, $q_0 \in Q$ is the initial state, $z_0$ is the initial stack-symbol, $F$ is a finite subset of $QZ^*$, the set of *final* configurations, and $\delta$, the transition function, is a mapping $\delta : QZ \times (X \cup \{\epsilon\}) \to \mathcal{P}_f(QZ^*)$.

Let $q, q' \in Q$, $\omega, \omega' \in Z^*$, $z \in Z$, $f \in X^*$, and $a \in X \cup \{\epsilon\}$; we note that $(qz\omega, af) \longmapsto_{\mathcal{M}} (q'\omega'\omega, f)$ if $q'\omega' \in \delta(qz, a)$. The binary relation $\overset{*}{\longmapsto}_{\mathcal{M}}$ is the reflexive and transitive closure of $\longmapsto_{\mathcal{M}}$.

For every $q\omega, q'\omega' \in QZ^*$ and $f \in X^*$, we note $q\omega \xrightarrow{f}_{\mathcal{M}} q'\omega'$ iff $(q\omega, f) \overset{*}{\longmapsto}_{\mathcal{M}} (q'\omega', \epsilon)$.

$\mathcal{M}$ is said to be *deterministic* iff, for every $z \in Z$, $q \in Q$, $x \in X$,

$$\mathrm{Card}(\delta(qz, \epsilon)) \in \{0, 1\}, \tag{2.2}$$

$$\mathrm{Card}(\delta(qz, \epsilon)) = 1 \Rightarrow \mathrm{Card}(\delta(qz, x)) = 0, \tag{2.3}$$

$$\mathrm{Card}(\delta(qz, \epsilon)) = 0 \Rightarrow \mathrm{Card}(\delta(qz, x)) \leq 1. \tag{2.4}$$

$\mathcal{M}$ is said to be *real-time* iff, for every $q \in Q$, $z \in Z$, $\mathrm{Card}(\delta(qz, \epsilon)) = 0$.

A configuration $q\omega$ of $\mathcal{M}$ is said to be $\epsilon$-bound iff there exists a configuration $q'\omega'$ such that $(q\omega, \epsilon) \longmapsto_{\mathcal{M}} (q'\omega', \epsilon)$; $q\omega$ is said to be $\epsilon$-free iff it is not $\epsilon$-bound.

A pda $\mathcal{M}$ is said to be *normalized* iff it fulfills conditions (2.2), (2.3) above and (2.5), (2.6), (2.7):

$$q_0 z_0 \text{ is } \epsilon\text{-free} \tag{2.5}$$

and for every $q \in Q$, $z \in Z$, $x \in X$,

$$q'\omega' \in \delta(qz, x) \Rightarrow \mid \omega' \mid \leq 2, \tag{2.6}$$

$$q'\omega' \in \delta(qz, \epsilon) \Rightarrow \mid \omega' \mid = 0. \tag{2.7}$$

All the pda considered here are assumed to fulfill condition (2.5). A pda $\mathcal{M}$ is called *birooted* iff it fulfills (2.8) and (2.9):

$$\exists \bar{q} \in Q, F = \{\bar{q}\}, \tag{2.8}$$

$$\forall q \in Q, \omega \in Z^*, f \in X^*, \quad q_0 z_0 \xrightarrow{f}_{\mathcal{M}} q\omega \Rightarrow \exists g \in X^*, q\omega \xrightarrow{g}_{\mathcal{M}} \bar{q}. \tag{2.9}$$

The *language recognized* by $\mathcal{M}$ is

$$\mathrm{L}(\mathcal{M}) = \{w \in X^* \mid \exists c \in F, q_0 z_0 \xrightarrow{w}_{\mathcal{M}} c\}.$$

It is a “folklore” result that, given a dpda $\mathcal{M}$, one can effectively compute another dpda $\mathcal{M}'$ which is normalized and fulfills

$$\mathrm{L}(\mathcal{M}') = \mathrm{L}(\mathcal{M}) - \{\varepsilon\}.$$

## 2.3. Graphs and pda.

**Equational graphs and pda.** We call a *transition-graph* of a pda $\mathcal{M}$, denoted $\mathcal{T}(\mathcal{M})$, the 0-graph $\mathcal{T}(\mathcal{M}) = (V_{\mathcal{T}(\mathcal{M})}, E_{\mathcal{T}(\mathcal{M})})$, where $V_{\mathcal{T}(\mathcal{M})} = \{q\omega \mid q \in Q,\ \omega \in Z^*,$ $q\omega$ is $\epsilon$-free$\}$ and

$$E_{\mathcal{T}(\mathcal{A})} = \{(c, x, c') \in V_{\mathcal{T}(\mathcal{M})} \times V_{\mathcal{T}(\mathcal{M})} \mid c \xrightarrow{x}_{\mathcal{M}} c'\}. \tag{2.10}$$

We call a *computation* 1-*graph* of the pda $\mathcal{M}$, denoted $(\mathcal{C}(\mathcal{M}), v_{\mathcal{M}})$, the subgraph of $\mathcal{T}(\mathcal{M})$ induced by the set of vertices which are accessible from the vertex $q_0 z_0$, together with the source $v_{\mathcal{M}} = q_0 z_0$. In the case where $\mathcal{M}$ is birooted, we call a *computation* 2-*graph* of the pda $\mathcal{M}$, denoted $(\mathcal{C}(\mathcal{M}), v_{\mathcal{M}}, \bar{v}_{\mathcal{M}})$, the graph $\mathcal{C}(\mathcal{M})$ defined just above, together with the sources $v_{\mathcal{M}} = q_0 z_0$, $\bar{v}_{\mathcal{M}} = \bar{q}$.

THEOREM 2.5. *Let $\Gamma = (\Gamma_0, v_0)$ be a rooted 1-graph over $X$. The following conditions are equivalent:*

(1) $\Gamma$ *is equational and has finite out-degree.*

(2) $\Gamma$ *is isomorphic to the computation 1-graph $(\mathcal{C}(\mathcal{M}), v_{\mathcal{M}})$ of some normalized pda $\mathcal{M}$.*

The formal proof of this theorem is quite technical and is omitted here. (See the appendix for a sketch of proof.)

COROLLARY 2.6. *Let $\Gamma = (\Gamma_0, v_0, \bar{v})$ be a birooted 2-graph over $X$. The following conditions are equivalent:*

(1) $\Gamma$ *is equational and has finite out-degree.*

(2) $\Gamma$ *is isomorphic to the computation 2-graph $(\mathcal{C}(\mathcal{M}), v_{\mathcal{M}}, \bar{v}_{\mathcal{M}})$ of some birooted normalized pda $\mathcal{M}$.*

**Bisimulation for nondeterministic (versus deterministic) graphs.** In this section, we reduce the classical notion of *bisimulation* for equational graphs to the notion of $\eta$-bisimulation for *deterministic* equational graphs, where $\eta$ has been suitably chosen (see Definition 2.3).

LEMMA 2.7. *Let $\Gamma_1$ be some rooted equational 1-graph over a finite alphabet $Y_1$ and let # be a new letter $\# \notin Y_1$. Then one can construct an equational birooted 2-graph $\Gamma$ over the alphabet $Y = Y_1 \cup \{\#\}$ such that*

(1) $V_{\Gamma_1} \subseteq V_\Gamma$,

(2) *for every $v, v' \in V_{\Gamma_1}$, ($v, v'$ are bisimilar in $\Gamma_1$) iff ($v, v'$ are bisimilar in $\Gamma$),*

(3) $\Gamma_1$ *has finite out-degree iff $\Gamma$ has finite out-degree.*

*Sketch of proof.* Let us define $\Gamma$ from $\Gamma_1$ by

$$V_\Gamma = V_{\Gamma_1} \cup \{\bar{v}\}, \quad E_\Gamma = E_{\Gamma_1} \cup \{(w, \#, \bar{v}) \mid w \in V_{\Gamma_1}\}, \quad \Gamma = (\Gamma_1, \bar{v}),$$

where $\bar{v}$ is a new vertex $\bar{v} \notin V_{\Gamma_1}$. One can easily check that $\Gamma$ is equational iff $\Gamma_1$ is equational and that, provided $\Gamma_1$ is rooted, $\Gamma$ is birooted. Points (1) and (3) of the lemma are clear. One can check that the mapping $\mathcal{R} \mapsto \mathcal{R} \cup \{(\bar{v}, \bar{v})\}$ is a bijection from the set of all the bisimulations over $\Gamma_1$ (i.e., from $\Gamma_1$ to $\Gamma_1$) to the set of all the bisimulations over $\Gamma$. Hence point (2) is true. $\square$

Let us consider finite alphabets $X, Y$, a length-preserving homomorphism $\psi : X^* \to Y^*$, and the strong relational morphism $\bar{\psi} = \psi \circ \psi^{-1} \subseteq X^* \times X^*$. An $n$-graph $\Gamma$ over $X$ will be called *$\bar{\psi}$-saturated* iff, for every $v \in V_\Gamma$, for every $(x, x') \in \bar{\psi}$,

$$(\exists v_1 \in V_\Gamma, (v, x, v_1) \in E_\Gamma) \Leftrightarrow (\exists v_1' \in V_\Gamma, (v, x', v_1') \in E_\Gamma).$$

LEMMA 2.8. *Let $\Gamma_1$ be an equational birooted 2-graph of finite out-degree over an alphabet $Y$. One can construct a finite alphabet $X$, a surjective length-preserving homomorphism $\psi : X^* \to Y^*$, and an equational, birooted 2-graph $\Gamma$ over the alphabet $X$, such that*

(1) $\Gamma$ *is deterministic,*
(2) $\Gamma$ *is $\bar{\psi}$-saturated,*
(3) $V_{\Gamma_1} = V_\Gamma$,
(4) $\mathrm{Id} : V_\Gamma \to V_{\Gamma_1}$ *is a $\psi$-bisimulation from $\Gamma$ to $\Gamma_1$.*

*Sketch of proof.* By Lemma 2.6, we can suppose that $\Gamma_1$ is the computation 2-graph $(\mathcal{C}(\mathcal{M}_1), v_{\mathcal{M}_1}, \bar{v}_{\mathcal{M}_1})$ of some birooted normalized pda $\mathcal{M}_1 = \langle Y, Z, Q, \delta_1, q_0, z_0, \{\bar{q}\}\rangle$. Let us consider the following integers: $\forall q \in Q$, $z \in Z$, $y \in Y$,

$$t_1(qz, y) = \mathrm{Card}(\delta_1(qz, y)), \quad \bar{t_1} = \max\{t_1(qz, y) \mid q \in Q, z \in Z, y \in Y\}.$$

Let $X = Y \times [1, \bar{t_1}]$ and let $\psi : X \to Y$ be the first projection. Let $\rho : QZ \times Y \times \mathbb{N} \to QZ^*$ such that $\mathrm{dom}(\rho) = \bigcup_{q \in Q, z \in Z, y \in Y} \{qz\} \times \{y\} \times [1, t_1(qz, y)]$ and

$$\rho(qz, y, \star) : \{qz\} \times \{y\} \times [1, t_1(qz, y)] \to \delta_1(qz, y)$$

is a bijection (for every triple $(q, z, y)$). We then define $\mathcal{M} = \langle X, Z, Q, \delta, q_0, z_0, \{\bar{q}\}\rangle$ by the following: for every $q \in Q$, $z \in Z$, $y \in Y$, $i \in [1, \bar{t_1}]$,

$$\delta(qz, \epsilon) = \delta_1(qz, \epsilon) \text{ if } qz \text{ is } \epsilon\text{-bound},$$

$$\delta(qz, (y, i)) = \{q'\omega'\} \text{ if}$$
$$\rho(qz, y, i) = q'\omega' \text{ or } [(1 \le t_1(qz, y) < i \le \bar{t_1} \text{ and } \rho(qz, y, 1) = q'\omega')].$$

The 2-graph $\Gamma = (\mathcal{C}(\mathcal{M}), v_\mathcal{M}, \bar{v}_\mathcal{M})$ fulfills the required properties. $\square$

Let us remark that, by point (4) and by composition of $\eta$-bisimulations, for every $v, v' \in V_\Gamma$, $v, v'$ are $\bar{\psi}$-bisimilar (w.r.t. $\Gamma$) iff $v, v'$ are bisimilar (w.r.t. $\Gamma_1$).

**2.4. Deterministic context-free grammars.** Let $\mathcal{M}$ be some dpda (we suppose here that $\mathcal{M}$ is normalized). The *variable* alphabet $V_\mathcal{M}$ associated to $\mathcal{M}$ is defined as

$$V_\mathcal{M} = \{[p, z, q] \mid p, q \in Q, z \in Z\}.$$

The *context-free* grammar $G_\mathcal{M}$ associated to $\mathcal{M}$ is then

$$G_\mathcal{M} = \langle X, V_\mathcal{M}, P_\mathcal{M}\rangle,$$

where $P_\mathcal{M}$ is the set of all the pairs of one of the following forms:

$$([p,z,q], x[p',z_1,p''][p'',z_2,q]), \tag{2.11}$$

where $p,q,p',p'' \in Q$, $x \in X$, $p'z_1z_2 \in \delta(pz,x)$,

$$([p,z,q], x[p',z',q]), \tag{2.12}$$

where $p,q,p' \in Q$, $x \in X$, $p'z' \in \delta(pz,x)$,

$$([p,z,q], a), \tag{2.13}$$

where $p,q, \in Q$, $a \in X \cup \{\epsilon\}$, $q \in \delta(pz,a)$. $G_{\mathcal{M}}$ is a *strict-deterministic* grammar (see Definition 3.7 below). A general theory of this class of grammars is presented in [15] and used in [16].

**2.5. Free monoids acting on semirings.**

**Semiring $\mathsf{B}\langle\langle\, W \,\rangle\rangle$.** Let $(\mathsf{B},+,\cdot,0,1)$, where $\mathsf{B}=\{0,1\}$ denotes the semiring of "booleans." Let $W$ be some alphabet. By $(\mathsf{B}\langle\langle\, W \,\rangle\rangle,+,\cdot,\emptyset,\epsilon)$ we denote the semiring of *boolean series* over $W$: the set $\mathsf{B}\langle\langle\, W \,\rangle\rangle$ is defined as $\mathsf{B}^{W^*}$; the sum and product are defined as usual; each word $w \in W^*$ can be identified with the element of $\mathsf{B}^{W^*}$ mapping the word $w$ on 1 and every other word $w' \neq w$ on 0; every boolean series $S \in \mathsf{B}\langle\langle\, W \,\rangle\rangle$ can then be written in a unique way as

$$S = \sum_{w \in W^*} S_w \cdot w,$$

where, for every $w \in W^*$, $S_w \in \mathsf{B}$.

The *support* of $S$ is the language

$$\mathrm{supp}(S) = \{w \in W^* \mid S_w \neq 0\}.$$

In the particular case where the semiring of coefficients is $\mathsf{B}$ (which is the only case considered in this article) we sometimes identify the series $S$ with its support. A series $S \in \mathsf{B}\langle\langle\, W \,\rangle\rangle$ is called a boolean *polynomial* over $W$ iff its support is *finite.* The set of all boolean polynomials over $W$ is denoted by $\mathsf{B}\langle W\rangle$.

The usual ordering $\leq$ on $\mathsf{B}$ extends to $\mathsf{B}\langle\langle\, W \,\rangle\rangle$ by

$$S \leq S' \text{ iff } \forall w \in W^*,\, S_w \leq S'_w.$$

We recall that for every $S \in \mathsf{B}\langle\langle\, W \,\rangle\rangle$, $S^*$ is the series defined by

$$S^* = \sum_{0 \leq n} S^n. \tag{2.14}$$

Given two alphabets $W, W'$, a map $\psi : \mathsf{B}\langle\langle\, W \,\rangle\rangle \to \mathsf{B}\langle\langle\, W' \,\rangle\rangle$ is said to be *$\sigma$-additive* iff it fulfills the following condition: for every denumerable family $(S_i)_{i\in\mathbb{N}}$ of elements of $\mathsf{B}\langle\langle\, W \,\rangle\rangle$,

$$\psi\left(\sum_{i\in\mathbb{N}} S_i\right) = \sum_{i\in\mathbb{N}} \psi(S_i). \tag{2.15}$$

A map $\psi : \mathsf{B}\langle\langle\, W \,\rangle\rangle \to \mathsf{B}\langle\langle\, W' \,\rangle\rangle$ which is both a semiring homomorphism and a $\sigma$-additive map is usually called a *substitution.*

**Actions of monoids.** Given a semiring $(\mathsf{S},+,\cdot,0,1)$ and a monoid $(\mathsf{M},\cdot,1_M)$, a map $\circ : \mathsf{S}\times\mathsf{M}\to\mathsf{S}$ is called a *right-action* of the monoid $\mathsf{M}$ over the semiring $\mathsf{S}$ iff, for every $S,T\in\mathsf{S}$, $m,m'\in\mathsf{M}$,

$$\begin{gathered} 0\circ m = 0, \quad S\circ 1_M = S, \\ (S+T)\circ m = (S\circ m)+(T\circ m), \quad S\circ(m\cdot m') = (S\circ m)\circ m'. \end{gathered} \tag{2.16}$$

In the particular case where $\mathsf{S}=\mathsf{B}\langle\langle\, W\,\rangle\rangle$, $\circ$ is said to be a $\sigma$-right-action if it fulfills the additional property that, for every denumerable family $(S_i)_{i\in\mathbb{N}}$ of elements of $\mathsf{S}$ and $m\in\mathsf{M}$,

$$\left(\sum_{i\in\mathbb{N}} S_i\right)\circ m = \sum_{i\in\mathbb{N}}(S_i\circ m). \tag{2.17}$$

**The action of $W^*$ on $\mathsf{B}\langle\langle\, W\,\rangle\rangle$.** We recall the following classical $\sigma$-right-action $\bullet$ of the monoid $W^*$ over the semiring $\mathsf{B}\langle\langle\, W\,\rangle\rangle$: $\forall S,S'\in\mathsf{B}\langle\langle\, W\,\rangle\rangle$, $u\in W^*$,

$$S\bullet u = S' \Leftrightarrow \forall w\in W^*, (S'_w = S_{u\cdot w})$$

(i.e., $S\bullet u$ is the *left-quotient* of $S$ by $u$, or the *residual* of $S$ by $u$).

For every $S\in\mathsf{B}\langle\langle\, W\,\rangle\rangle$ we denote by $\mathsf{Q}(S)$ the set of residuals of $S$:

$$\mathsf{Q}(S) = \{S\bullet u \mid u\in W^*\}.$$

We recall that $S$ is said to be *rational* iff the set $\mathsf{Q}(S)$ is *finite*. We define the *norm* of a series $S\in\mathsf{B}\langle\langle\, W\,\rangle\rangle$, denoted $\|S\|$, by

$$\|S\| = \mathrm{Card}(\mathsf{Q}(S))\in\mathbb{N}\cup\{\infty\}.$$

**The reduced grammar $G$.** The classical reduced and $\epsilon$-free grammar associated with $G_{\mathcal{M}}$ is $G_0=\langle X,V_0,P_0\rangle$, where

$$V_0 = \{v\in V_{\mathcal{M}} \mid \exists w\in X^+, v\overset{*}{\longrightarrow}_{P_{\mathcal{M}}} w\}, \tag{2.18}$$

$$\varphi_0 : \mathsf{B}\langle\langle\, V\,\rangle\rangle \to \mathsf{B}\langle\langle\, V_0\,\rangle\rangle$$

is the unique substitution such that, for every $v\in V$,

$$\varphi_0(v)=v \text{ (if } v\in V_0), \quad \varphi_0(v)=\epsilon \text{ (if } v\overset{*}{\longrightarrow}_{P_{\mathcal{M}}}\epsilon), \quad \varphi_0(v)=\emptyset \text{ (otherwise)},$$

$$\begin{aligned} P_0 = \{&(v,w')\in V_0\times(X\cup V_0)^+ \mid \\ &v\in V_0, \exists w\in(X\cup V_{\mathcal{M}})^*, (v,w)\in P_{\mathcal{M}}, w'=\varphi_0(w)\}. \end{aligned} \tag{2.19}$$

$G_0$ is the *reduced* and *$\epsilon$-free* form of $G_{\mathcal{M}}$. It is well known that, $\forall v\in V_0$,

$$\exists w\in X^+, v\overset{*}{\longrightarrow}_{P_0} w,$$

$$\{w\in X^*, v\overset{*}{\longrightarrow}_{P_{\mathcal{M}}} w\} = \{w\in X^*, v\overset{*}{\longrightarrow}_{P_0} w\}.$$

For technical reasons (which will be made clear in section 7), we introduce an alphabet of "marked variables" $\bar{V}_0$ together with a fixed bijection: $v\mapsto\bar{v}$ from $V_0$ to $\bar{V}_0$. Let

$V = V_0 \cup \bar{V}_0$. We denote by $\rho_e$ (the letter $e$ stands here for "erasing the marks") the literal morphism $V^* \to V_0^*$ defined by the following: for every $v \in V_0$,

$$\rho_e(v) = v, \quad \rho_e(\bar{v}) = v.$$

Similarly, $\bar{\rho}_e$ is the literal morphism $V^* \to \bar{V}_0^*$ defined by the following: for every $v \in V_0$,

$$\bar{\rho}_e(v) = \bar{v}, \quad \bar{\rho}_e(\bar{v}) = \bar{v}.$$

We denote also by $\rho_e, \bar{\rho}_e$ the unique substitutions extending these monoid homomorphisms.

At last, the grammar $G$ is defined by $G = \langle X, V, P \rangle$, where

$$P = P_0 \cup \{(\bar{\rho}_e(v), \bar{\rho}_e(w)) \mid (v, w) \in P_0\}.$$

In other words, the rules of $G$ consist of the rules of the usual proper and reduced grammar associated with $\mathcal{M}$ together with their marked copies.

**The action of $X^*$ on $\mathsf{B}\langle\langle\ V\ \rangle\rangle$.** Let us now fix a deterministic (normalized) pda $\mathcal{M}$ and consider the associated grammar $G$. We define a $\sigma$-right-action $\odot$ of the monoid $X^*$ over the semiring $\mathsf{B}\langle\langle\ V\ \rangle\rangle$ by the following: for every $v \in V$, $\beta \in V^*$, $x \in X$,

$$(v \cdot \beta) \odot x = \left( \sum_{(v,h) \in P} h \bullet x \right) \cdot \beta, \tag{2.20}$$

$$\epsilon \odot x = \emptyset. \tag{2.21}$$

Let us consider the unique substitution $\varphi : \mathsf{B}\langle\langle\ V\ \rangle\rangle \to \mathsf{B}\langle\langle\ X\ \rangle\rangle$ fulfilling the following: for every $v \in V$,

$$\varphi(v) = \{u \in X^* \mid v \overset{*}{\longrightarrow}_P u\}$$

(in other words, $\varphi$ maps every subset $L \subseteq V^*$ on the language generated by the grammar $G$ from the set of axioms $L$).

LEMMA 2.9. *For every $S \in \mathsf{B}\langle\langle\ V\ \rangle\rangle$, $u \in X^*$, $\varphi(S \odot u) = \varphi(S) \bullet u$ (i.e., $\varphi$ is a morphism of right-actions).*

*Proof.* Let $v \in V$, $\beta \in V^*$, $x \in X$. Recall that $G$ is in Greibach normal form (i.e., $P \subseteq V \times X \cdot V^*$). One can then check with formulas (2.20), (2.21) that

$$\varphi(\epsilon \odot x) = \varphi(\epsilon) \bullet x \quad \text{and} \quad \varphi((v \cdot \beta) \odot x) = \varphi(v \cdot \beta) \bullet x.$$

By induction on $|w|$, it follows that, $\forall w \in V^*$,

$$\varphi(w \odot x) = \varphi(w) \bullet x.$$

By $\sigma$-additivity of $\varphi$, it follows that, $\forall S \in \mathsf{B}\langle\langle\ V\ \rangle\rangle$,

$$\varphi(S \odot x) = \varphi(S) \bullet x.$$

By induction on $|u|$, it follows that, $\forall u \in X^*$,

$$\varphi(S \odot u) = \varphi(S) \bullet u. \qquad \square$$

We denote by $\equiv$ the kernel of $\varphi$, i.e., for every $S, T \in \mathsf{B}\langle\langle\ V\ \rangle\rangle$,

$$S \equiv T \Leftrightarrow \varphi(S) = \varphi(T).$$

## 3. Series and matrices.

**3.1. Deterministic series, vectors, and matrices.** We introduce here a notion of *deterministic* series which, in the case of the alphabet $V$ associated to a dpda $\mathcal{M}$, generalizes the classical notion of *configuration* of $\mathcal{M}$. The main advantage of this notion is that, unlike for configurations, we shall be able to define *nice algebraic operations* on these series (see, in particular, section 5.1). Let us consider a pair $(W, \smile)$ where $W$ is an alphabet and $\smile$ is an equivalence relation over $W$. We call $(W, \smile)$ a *structured* alphabet. We have the following two examples in mind:

- the case where $W = V_{\mathcal{M}}$, the variable alphabet associated to $\mathcal{M}$ and $[p, z, q] \smile [p', z', q']$ iff $p = p'$ and $z = z'$ (see [15]);
- the case where $W = X$, the terminal alphabet of $\mathcal{M}$ and $x \smile y$ holds for every $x, y \in X$ (see [15]).

**Definitions.**

DEFINITION 3.1. *Let $S \in \mathsf{B}\langle\langle\ W\ \rangle\rangle$. $S$ is said to be* left-deterministic *iff either*

(1) $S = \emptyset$ *or*
(2) $S = \epsilon$ *or*
(3) $\exists i_0 \in [1, m]$, $S_{i_0} \neq \emptyset$ *and* $\forall w, w' \in W^*$, $S_w = S_{w'} = 1 \Rightarrow [\exists A, A' \in W$, $w_1, w'_1 \in W^*$, $A \smile A'$, $w = A \cdot w_1$, *and* $w' = A' \cdot w'_1]$.

A left-deterministic series $S$ is said to have the type $\emptyset$ (resp., $\epsilon$, $[A]_\smile$) if case (1) (resp., (2), (3)) occurs.

DEFINITION 3.2. *Let $S \in \mathsf{B}\langle\langle\ W\ \rangle\rangle$. $S$ is said to be* deterministic *iff, for every $u \in W^*$, $S \bullet u$ is left-deterministic.*

This notion is the straightforward extension to the infinite case of the notion of a (finite) *set of associates* defined in [16, Definition 3.2, p. 188].

We denote by $\mathsf{DB}\langle\langle\ W\ \rangle\rangle$ the subset of deterministic boolean series over $W$. Let us denote by $\mathsf{B}_{n,m}\langle\langle\ W\ \rangle\rangle$ the set of $(n, m)$-matrices with entries in the semiring $\mathsf{B}\langle\langle\ W\ \rangle\rangle$.

DEFINITION 3.3. *Let $m \in \mathbb{N}$, $S \in \mathsf{B}_{1,m}\langle\langle\ W\ \rangle\rangle : S = (S_1, \ldots, S_m)$. $S$ is said to be* left-deterministic *iff either*

(1) $\forall i \in [1, m]$, $S_i = \emptyset$ *or*
(2) $\exists i_0 \in [1, m]$, $S_{i_0} = \epsilon$ *and* $\forall i \neq i_0$, $S_i = \emptyset$ *or*
(3) $\forall w, w' \in W^*$, $\forall i, j \in [1, m]$, $(S_i)_w = (S_j)_{w'} = 1 \Rightarrow [\exists A, A' \in W$, $w_1, w'_1 \in V^*$, $A \smile A'$, $w = A \cdot w_1$, *and* $w' = A' \cdot w'_1]$.

A left-deterministic row-vector $S$ is said to have the type $\emptyset$ (resp., $(\epsilon, i_0)$, $[A]_\smile$) if case (1) (resp., (2), (3)) occurs.

The right-action $\bullet$ on $\mathsf{B}\langle\langle\ W\ \rangle\rangle$ is extended componentwise to $\mathsf{B}_{n,m}\langle\langle\ W\ \rangle\rangle$: for every $S = (s_{i,j})$, $u \in W^*$, the matrix $T = S \bullet u$ is defined by

$$t_{i,j} = s_{i,j} \bullet u.$$

The ordering $\leq$ on $\mathsf{B}$ is also extended componentwise to $\mathsf{B}_{n,m}\langle\langle\ W\ \rangle\rangle$.

DEFINITION 3.4. *Let $S \in \mathsf{B}_{1,m}\langle\langle\ W\ \rangle\rangle$. $S$ is said to be* deterministic *iff, for every $u \in W^*$, $S \bullet u$ is left-deterministic.*

We denote by $\mathsf{DB}_{1,m}\langle\langle\ W\ \rangle\rangle$ the subset of deterministic row-vectors of dimension $m$ over $\mathsf{B}\langle\langle\ W\ \rangle\rangle$.

DEFINITION 3.5. *Let $S \in \mathsf{B}_{n,m}\langle\langle\ W\ \rangle\rangle$. $S$ is said to be* deterministic *iff, for every $i \in [1, n]$, $S_{i,\cdot}$ is a deterministic row-vector.*

Let us note first some easy facts about deterministic matrices.

FACT 3.6. *Let $S \in \mathsf{DB}\langle\langle\, W\,\rangle\rangle$. For every $T \in \mathsf{B}\langle\langle\, W\,\rangle\rangle$, $u \in W^*$*
(1) $T \leq S \Rightarrow T \in \mathsf{DB}\langle\langle\, W\,\rangle\rangle$.
(2) $T = S \bullet u \Rightarrow T \in \mathsf{DB}\langle\langle\, W\,\rangle\rangle$.

**Norm.** Let us generalize the classical definition of *rationality* of series in $\mathsf{B}\langle\langle\, W\,\rangle\rangle$ to matrices. Given $M \in \mathsf{B}_{n,m}\langle\langle\, W\,\rangle\rangle$ we denote by $\mathsf{Q}(M)$ the set of *residuals* of $M$:

$$\mathsf{Q}(M) = \{M \bullet u \mid u \in W^*\}.$$

Similarly, we denote by $\mathsf{Q}_r(M)$ the set of *row-residuals* of $M$:

$$\mathsf{Q}_r(M) = \bigcup_{1\leq i\leq n} \mathsf{Q}(M_{i,*}).$$

$M$ is said to be *rational* iff the set $\mathsf{Q}(M)$ is finite. One can check that it is equivalent to the property that every coefficient $M_{i,j}$ is rational, or to the property that $\mathsf{Q}_r(M)$ is finite. We denote by $\mathsf{RB}_{n,m}\langle\langle\, W\,\rangle\rangle$ (resp., $\mathsf{DRB}_{n,m}\langle\langle\, W\,\rangle\rangle$) the set of rational (resp., deterministic, rational) matrices over $\mathsf{B}\langle\langle\, W\,\rangle\rangle$. For every $M \in \mathsf{RB}_{n,m}\langle\langle\, W\,\rangle\rangle$, we define the norm of $M$ as

$$\|M\| = \mathrm{Card}(\mathsf{Q}_r(M)).$$

**Grammars.**
DEFINITION 3.7. *Let $G = \langle X, V, P\rangle$ be a context-free grammar in Greibach normal form. $G$ is said to be* strict-deterministic *iff there exists an equivalence relation $\smile$ over $V$ fulfilling the following condition: for every $E \in V$, $x \in X$, if $(E_k)_{1\leq k\leq m}$ is a bijection $[1,m] \to [E]_\smile$, and $H_k = \sum_{(E_k,h)\in P} h \bullet x$, then*

$$(H_1, H_2, \ldots, H_m) \text{ is a deterministic vector.}$$

*Any equivalence $\smile$ satisfying the above condition is said to be a* strict equivalence *for the grammar $G$.*

This definition is a reformulation of [15, Definition 11.4.1, p. 347] adapted to the case of a Greibach normal form.

THEOREM 3.8. *Let $G_1 = \langle X, V_1, P_1\rangle$ be a strict-deterministic grammar. Then its reduced form $G_0 = \langle X, V_0, P_0\rangle$, as defined in formulas* (2.18), (2.19), *is strict-deterministic too. Moreover, if $\smile$ is a strict equivalence for $G_1$, its restriction over $V_0$ is a strict equivalence for $G_0$.*

The proof would consist in slightly extending the proof of [15, Theorem 11.4.1, p. 350].

It is known that, given a dpda $\mathcal{M}$, its associated grammar $G_{\mathcal{M}}$ is strict-deterministic. By Theorem 3.8 $G_0$ is strict-deterministic too. Let us consider the minimal strict equivalence $\smile$ for $G_0$ and extend it to $V$ by, $\forall v, v' \in V_0$,

$$\bar{v} \smile \bar{v}' \Leftrightarrow v \smile v'; \quad \bar{v} \not\smile v'.$$

Then $\smile$ is a strict equivalence for $G$ (the grammar $G$ is defined in section 2.5). This ensures that $G$ is strict-deterministic.

**Residuals.**
LEMMA 3.9 (see [42, Lemma 37]). *Let $S \in \mathsf{DB}\langle\langle\, W\,\rangle\rangle$, $T \in \mathsf{B}\langle\langle\, W\,\rangle\rangle$, $u \in W^*$. If $S \bullet u \neq \emptyset$, then $(S \cdot T) \bullet u = (S \bullet u) \cdot T$.*

LEMMA 3.10 (see [42, Lemma 39]). *Let $S \in \mathsf{DB}_{1,m}\langle\langle\, W\,\rangle\rangle$, $T \in \mathsf{B}_{m,s}\langle\langle\, W\,\rangle\rangle$, $u \in W^*$, and $U = S \cdot T$. Exactly one of the following cases is true:*

(1) $\exists j$, $S_j \bullet u \notin \{\emptyset, \epsilon\}$. *In this case* $U \bullet u = (S \bullet u) \cdot T$.
(2) $\exists j_0$, $\exists u', u''$, $u = u' \cdot u''$, $S_{j_0} \bullet u' = \epsilon$. *In this case* $U \bullet u = T_{j_0} \bullet u''$.
(3) $\forall j$, $\forall u' \preceq u$, $S_j \bullet u = \emptyset$, $S_j \bullet u' \neq \epsilon$. *In this case* $U \bullet u = \emptyset = (S \bullet u) \cdot T$.

LEMMA 3.11. *For every* $S \in \mathsf{DB}_{n,m}\langle\langle\ W\ \rangle\rangle$, $T \in \mathsf{DB}_{m,s}\langle\langle\ W\ \rangle\rangle$, $S \cdot T \in \mathsf{DB}_{n,s}\langle\langle\ W\ \rangle\rangle$.

LEMMA 3.12. *Let* $A \in \mathsf{DB}_{n,m}\langle\langle\ W\ \rangle\rangle$, $B \in \mathsf{B}_{m,s}\langle\langle\ W\ \rangle\rangle$. *Then* $\|A \cdot B\| \leq \|A\| + \|B\|$.

The two above lemmas correspond to [42, Lemma 310].

***W* = *V*.** Let $(W, \smile)$ be the structured alphabet $(V, \smile)$ associated with $\mathcal{M}$ and let us consider a bijective numbering of the elements of $Q$: $(q_1, q_2, \dots, q_{n_Q})$. Let us define here a handful of notations for some particular vectors or matrices. Let us use the *Kronecker symbol* $\delta_{i,j}$ to mean $\epsilon$ if $i = j$ and $\emptyset$ if $i \neq j$. For every $1 \leq n$, $1 \leq i \leq n$, we define the row-vector $\epsilon_i^n$ as

$$\epsilon_i^n = (\epsilon_{i,j}^n)_{1 \leq j \leq n}, \quad \text{where } \forall j,\ \epsilon_{i,j}^n = \delta_{i,j}.$$

We call any vector of the form $\epsilon_i^n$ a *unit row-vector.*

For every $1 \leq n$, we denote by $\emptyset^n \in \mathsf{DB}_{1,n}\langle\langle\ V\ \rangle\rangle$ the row-vector

$$\emptyset^n = (\emptyset, \dots, \emptyset).$$

For every $\omega \in Z^*$, $p, q \in Q$, $[p\omega q]$ is the deterministic series defined inductively by

$$[p\epsilon q] = \emptyset \text{ if } p \neq q, \quad [p\epsilon q] = \epsilon \text{ if } p = q,$$

$$[p\omega q] = \sum_{r \in Q} [p, z, r] \cdot [r\omega' q] \text{ if } \omega = z \cdot \omega' \text{ for some } z \in Z,\ \omega' \in Z^*.$$

Let us define

$$K_0 = \max\{\|(E_1, E_2, \dots, E_n) \odot x\| \mid (E_i)_{1 \leq i \leq n} \text{ is a bijective numbering of some class in } V/\smile,\ x \in X\}. \tag{3.1}$$

LEMMA 3.13 (see [42, Lemma 318]). *For every* $S \in \mathsf{DB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $u \in X^*$,
(1) $S \odot u \in \mathsf{DB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$,
(2) $\|S \odot u\| \leq \|S\| + K_0 \cdot |u|$.

LEMMA 3.14 (see [42, Lemma 319]). *Let* $\lambda \in \mathbb{N} - \{0\}$, $S \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $u \in X^*$. *One of the three following cases must occur:*
(1) $S \odot u = \emptyset^\lambda$.
(2) $S \odot u = \epsilon_j^\lambda$ *for some* $j \in [1, \lambda]$.
(3) $\exists u_1, u_2 \in X^*$, $v_1 \in V^*$, $q \in \mathbb{N}$, $E_1, \dots, E_k, \dots, E_q \in V$, $\Phi \in \mathsf{DRB}_{q,\lambda}\langle\langle\ V\ \rangle\rangle$ *such that*

$$u = u_1 \cdot u_2,\ S \odot u_1 = S \bullet v_1 = \sum_{k=1}^{q} E_k \cdot \Phi_k,\ S \odot u = \sum_{k=1}^{q} (E_k \odot u_2) \cdot \Phi_k, \text{ and}$$

$$\forall k \in [1, q], E_k \smile E_1, E_k \odot u_2 \notin \{\epsilon, \emptyset\}.$$

We now give an adaptation of Lemma 3.10 to the action $\odot$ in place of $\bullet$.

LEMMA 3.15 (see [42, Lemma 321]). *Let* $S \in \mathsf{DB}_{1,m}\langle\langle\ V\ \rangle\rangle$, $T \in \mathsf{B}_{m,s}\langle\langle\ V\ \rangle\rangle$, $u \in X^*$, *and* $U = S \cdot T$. *Exactly one of the following cases is true:*
(1) $S \odot u \notin \{\emptyset^m\} \cup \{\epsilon_j^m \mid 1 \leq j \leq m\}$. *In this case* $U \odot u = (S \odot u) \cdot T$.
(2) $\exists j_0$, $\exists u', u''$, $u = u' \cdot u''$, $S \odot u' = \epsilon_{j_0}^s$. *In this case* $U \odot u = T_{j_0} \odot u''$.
(3) $\forall j$, $\forall u' \preceq u$, $S \odot u = \emptyset^m$ *and* $S \odot u' \neq \epsilon_j^m$. *In this case* $U \odot u = \emptyset^s = (S \odot u) \cdot T$.

**Marks.** A word $w \in V^*$ is said to be *marked* iff $w \in V^* \cdot \bar{V}_0 \cdot V^*$; it is said to be *fully marked* iff $w \in \bar{V}_0^*$.

A series $S \in \mathsf{B}\langle\langle\ V\ \rangle\rangle$ is said to be *marked* iff $\exists w \in \mathrm{supp}(S)$, $w$ is marked; it is said to be *fully marked* iff $\forall w \in \mathrm{supp}(S)$, $w$ is fully marked. It is said to be *unmarked* iff it is *not* marked. A matrix $S \in \mathsf{B}_{m,n}\langle\langle\ V\ \rangle\rangle$ is said to be marked (resp., fully marked, unmarked) iff, for every $i \in [1, m]$, the series $\sum_{j=1}^{n} S_{i,j}$ is marked (resp., fully marked, unmarked).

Definition 3.16. *Let $d \in \mathbb{N}$. A vector $S \in \mathsf{DB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$ is said to be d-marked iff there exists $q \in \mathbb{N}$, $\alpha \in \mathsf{DRB}_{1,q}\langle V\rangle$, $\Phi \in \mathsf{DRB}_{q,\lambda}\langle\langle\ V\ \rangle\rangle$ such that*

$$S = \sum_{k=1}^{q} \alpha_k \cdot \Phi_k \text{ and } \|\alpha\| \le d,$$

*and $\Phi$ is unmarked.*

Lemma 3.17. *For every $S \in \mathsf{DB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$,*

(1) *$\rho_e(S) \in \mathsf{DB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$,*

(2) *$\|\rho_e(S)\| \le \|S\|$.*

*Sketch of proof.*

(1) Let us notice that the homomorphism $\rho_e : V^* \to V^*$ preserves the equivalence $\smile$: for every $v, v' \in V$, if $v \smile v'$, then $\rho_e(v) \smile \rho_e(v')$. It follows that the corresponding substitution $\rho_e$ preserves determinism.

(2) Let $S \in \mathsf{DB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$. For every $v \in V_0$,

$$\rho_e(S) \bullet v = \rho_e(S \bullet v) \quad \text{or} \quad \rho_e(S) \bullet v = \rho_e(S \bullet \bar{v})$$

according to the fact that the leftmost letters of the monomials of $S$ are in $[v]_\smile$ or in $[\bar{v}]_\smile$; both formulas are true when $S$ is null or is a unit.

By induction on the length, it follows that, for every $w \in V_0^*$, there exists $w' \in V^*$ such that

$$\rho_e(w') = w \quad \text{and} \quad \rho_e(S) \bullet w = \rho_e(S \bullet w').$$

Moreover, for every $w \in V^* \bar{V}_0 V^*$,

$$\rho_e(S) \bullet w = \emptyset^\lambda,$$

but in this case, too, there exists some $w' \in V^*$ such that $\rho_e(S) \bullet w = \rho_e(S \bullet w')$.

The map $T \mapsto \rho_e(T)$ is then a surjective map from $\mathsf{Q}(S)$ onto $\mathsf{Q}(\rho_e(S))$, which proves that $\|\rho_e(S)\| \le \|S\|$. □

**Operations on row-vectors.** Let us introduce two new operations on row-vectors and prove some technical lemmas about them.

Given $A, B \in \mathsf{B}_{1,m}\langle\langle\ W\ \rangle\rangle$ and $1 \le j_0 \le m$ we define the vector $C = A \nabla_{j_0} B$ as follows: if $A = (a_1, \ldots, a_j, \ldots, a_m)$, $B = (b_1, \ldots, b_j, \ldots, b_m)$, then $C = (c_1, \ldots, c_j, \ldots, c_m)$, where

$$c_j = a_j + a_{j_0} \cdot b_j \text{ if } j \ne j_0, \quad c_j = \emptyset \text{ if } j = j_0.$$

Lemma 3.18 (see [42, Lemma 311]). *Let $A, B \in \mathsf{B}_{1,m}\langle\langle\ W\ \rangle\rangle$ and $1 \le j_0 \le m$.*

(1) *If $A, B$ are deterministic, then $A \nabla_{j_0} B$ is deterministic.*

(2) *If $A, B$ are deterministic, then $\|A \nabla_{j_0} B\| \le \|A\| + \|B\|$.*

Given $A \in \mathsf{DB}_{1,m}\langle\langle\ W\ \rangle\rangle$ and $1 \leq j_0 \leq m$ we define the vector $A' = \nabla^*_{j_0}(A)$ as follows: if $A = (a_1, \ldots, a_j, \ldots, a_m)$, then $A' = (a'_1, \ldots, a'_j, \ldots, a'_m)$, where

$$a'_j = a^*_{j_0} \cdot a_j \text{ if } j \neq j_0, \quad a'_j = \emptyset \text{ if } j = j_0.$$

Lemma 3.19 (see [42, Lemma 312]). *Let $A \in \mathsf{DB}_{1,m}\langle\langle\ W\ \rangle\rangle$ and $1 \leq j_0 \leq m$. Then $\nabla^*_{j_0}(A) \in \mathsf{DB}_{1,m}\langle\langle\ W\ \rangle\rangle$ and $\|\nabla^*_{j_0}(A)\| \leq \|A\|$.*

**3.2. Bisimulation of series.** Up to the end of this section, we consider the structured alphabet $V$ associated with a dpda $\mathcal{M}$ over $X$. We suppose a strong relational morphism $\eta \subseteq X^* \times X^*$ is given (see Definition 2.2).

**Series, words, and graphs.** Let us first give a slight adaptation of Definition 2.1 to the $n$-graph $(\mathsf{DRB}_{1,n}\langle\langle\ V\ \rangle\rangle, \odot, (\epsilon^n_i)_{1\leq i\leq n})$.

Definition 3.20. *Let $\mathcal{R}$ be some binary relation $\mathcal{R} \subseteq \mathsf{DRB}_{1,n}\langle\langle\ V\ \rangle\rangle \times \mathsf{DRB}_{1,n}\langle\langle\ V\ \rangle\rangle$. $\mathcal{R}$ is a $\sigma$-$\eta$-bisimulation iff*

(1) $\forall (S, S') \in \mathcal{R}$, $\forall x \in X$,

$$\exists x' \in \eta(x),\ (S \odot x, S' \odot x') \in \mathcal{R} \textit{ and } \exists x'' \in \eta^{-1}(x),\ (S \odot x'', S' \odot x) \in \mathcal{R},$$

(2) $\forall (S, S') \in \mathcal{R}$, $\forall i \in [1, n]$, $(S = \epsilon^n_i \Leftrightarrow S' = \epsilon^n_i)$.

We denote by $S \sim S'$ the fact that there exists some $\sigma$-$\eta$-bisimulation $\mathcal{R}$ such that $(S, S') \in \mathcal{R}$. One can notice that $\sim$ is the greatest $\sigma$-$\eta$-bisimulation (w.r.t. the inclusion ordering) over $\mathsf{DRB}_{1,n}\langle\langle\ V\ \rangle\rangle$. The $\sigma$-bisimulation relations can be conveniently expressed in terms of *word*-bisimulations.

Definition 3.21. *Let $S, S' \in \mathsf{DRB}_{1,n}\langle\langle\ V\ \rangle\rangle$ and $\mathcal{R} \subseteq X^* \times X^*$. $\mathcal{R}$ is a $w$-$\eta$-bisimulation with respect to $(S, S')$ iff $\mathcal{R} \subseteq \eta$ and*

(1) totality: $\mathrm{dom}(\mathcal{R}) = X^*$, $\mathrm{im}(\mathcal{R}) = X^*$*;*

(2) extension: $\forall (u, u') \in \mathcal{R}$, $\forall x \in X$,

$$\exists x' \in \eta(x),\ (u \cdot x, u' \cdot x') \in \mathcal{R} \textit{ and } \exists x'' \in \eta^{-1}(x),\ (u \cdot x'', u' \cdot x) \in \mathcal{R};$$

(3) coherence: $\forall (u, u') \in \mathcal{R}$, $\forall i \in [1, n]$, $(S \odot u = \epsilon^n_i) \Leftrightarrow (S' \odot u' = \epsilon^n_i)$*;*

(4) prefix: $\forall (u, u') \in X^* \times X^*$, $\forall (x, x') \in X \times X$, $(u \cdot x, u' \cdot x') \in \mathcal{R} \Rightarrow (u, u') \in \mathcal{R}$.

(Condition (1) can be equivalently replaced by "$(\epsilon, \epsilon) \in \mathcal{R}$.") $\mathcal{R}$ is said to be a $w$-$\eta$-bisimulation of *order* $m$ w.r.t. $(S, S')$ iff it fulfills conditions (3)–(4) above and the modified conditions

(1′) $\mathrm{dom}(\mathcal{R}) = X^{\leq m}$, $\mathrm{im}(\mathcal{R}) = X^{\leq m}$,

(2′) $\forall (u, u') \in \mathcal{R} \cap (X^{\leq m-1} \times X^{\leq m-1})$, $\forall x \in X$,

$$\exists x' \in \eta(x), (u \cdot x, u' \cdot x') \in \mathcal{R} \quad \text{and} \quad \exists x'' \in \eta^{-1}(x), (u \cdot x'', u' \cdot x) \in \mathcal{R}.$$

The $w$-$\eta$-bisimulations are also called $w$-$\eta$-bisimulations of *order* $\infty$. Lemmas 3.22 and 3.25 below relate the notions of $w$-$\eta$-bisimulation (on words), $\sigma$-$\eta$-bisimulation (on series), and $\eta$-bisimulation (on the vertices of the computation 2-graph of $\mathcal{M}$).

Lemma 3.22. *Let $S, S' \in \mathsf{DRB}_{1,n}\langle\langle\ V\ \rangle\rangle$. The following properties are equivalent:*

(i) *$S \sim S'$.*

(ii) *There exists $\mathcal{R} \subseteq X^* \times X^*$ which is a $w$-$\eta$-bisimulation w.r.t. $(S, S')$.*

(iii) *$\forall m \in \mathbb{N}$, there exists $\mathcal{R}_m \subseteq X^{\leq m} \times X^{\leq m}$ which is a $w$-$\eta$-bisimulation of order $m$ w.r.t. $(S, S')$.*

*Proof.* **(i) $\Rightarrow$ (iii):** Suppose that $\mathcal{S}$ is a $\sigma$-$\eta$-bisimulation w.r.t. $(S, S')$. Let us prove by induction on the integer $m$ the following property $\mathcal{P}(m)$: $\exists \mathcal{R}_m$, $w$-$\eta$-bisimulation of order $m$ w.r.t. $(S, S')$ such that

$$\forall (u, u') \in \mathcal{R}_m, \quad (S \odot u, S' \odot u') \in \mathcal{S}. \tag{3.2}$$

***m* = 0:** Let $\mathcal{R}_0 = \{(\epsilon, \epsilon)\}$. $\mathcal{R}_0$ clearly fulfills points (1′), (2′), (4) of the above definition. Moreover, as $(S, S') \in \mathcal{S}$, where $\mathcal{S}$ fulfills condition (2) of Definition 3.20, $\mathcal{R}_0$ fulfills point (3) of Definition 3.21.

**$m = m' + 1$:** Let $\mathcal{R}_{m'}$ be some $w$-$\eta$-bisimulation of order $m'$ w.r.t. $(S, S')$. Let us define $\mathcal{R}_m = \mathcal{R}_{m'} \cup \{(u \cdot x, u' \cdot x') \mid (u, u') \in \mathcal{R}_{m'}, (S \odot ux, S' \odot u'x') \in \mathcal{S}$, and $(x, x') \in \eta\}$. Property (1) of $\mathcal{S}$ and property (1′) of $\mathcal{R}_{m'}$ imply that

$$\mathrm{dom}(\mathcal{R}_m) = X^{\leq m}, \quad \mathrm{im}(\mathcal{R}_m) = X^{\leq m}. \tag{3.3}$$

Property (1) of $\mathcal{S}$ and property (2′) of $\mathcal{R}_{m'}$ imply that $\forall (u, u') \in \mathcal{R}_m \cap (X^{\leq m-1} \times X^{\leq m-1})$, $\forall x \in X$,

$$\exists x' \in \eta(x), (u \cdot x, u' \cdot x') \in \mathcal{R}_m \quad \text{and} \quad \exists x'' \in \eta^{-1}(x), (u \cdot x'', u' \cdot x) \in \mathcal{R}_m. \tag{3.4}$$

Property (2) of $\mathcal{S}$ and property (3) of $\mathcal{R}_{m'}$ imply that

$$\forall (u, u') \in \mathcal{R}_m, \forall i \in [1, n], \quad (S \odot u = \epsilon_i^n) \Leftrightarrow (S' \odot u' = \epsilon_i^n). \tag{3.5}$$

Property (4) of $\mathcal{R}_{m'}$ and the definition of $\mathcal{R}_m$ imply that

$$\forall (u, u') \in X^* \times X^*, \forall (x, x') \in X \times X, \quad (u \cdot x, u' \cdot x') \in \mathcal{R}_m \Rightarrow (u, u') \in \mathcal{R}_m. \tag{3.6}$$

Property (3.2) for $\mathcal{R}_{m'}$ and the definition of $\mathcal{R}_m$ imply that (3.2) is fulfilled by $\mathcal{R}_m$ too. Equations (3.3), (3.4), (3.5), (3.6) prove that $\mathcal{R}_m$ is a $w$-$\eta$-bisimulation of order $m$ w.r.t. $(S, S')$, and hence $\mathcal{P}(m)$ is proved.

**(iii) $\Rightarrow$ (ii):** Let us notice that, as the alphabet $X$ is finite, for every $w$-$\eta$-bisimulation $\mathcal{R}$ of order $m$ w.r.t. $(S, S')$,

$$\mathrm{Card}\{\mathcal{R}' \subseteq X^* \times X^* \mid \mathcal{R} \subseteq \mathcal{R}', \mathcal{R}' \text{ is a } w\text{-}\eta\text{-bisim. of ord. } m+1 \text{ w.r.t. } (S, S')\} < \infty.$$

Hence, by Koenig's lemma, if (iii) is true, then there exists an infinite sequence $(\mathcal{R}_m)_{m \in \mathbb{N}}$ such that for every $m \in \mathbb{N}$, $\mathcal{R}_m$ is a $w$-$\eta$-bisimulation of order $m$ w.r.t. $(S, S')$ and $\mathcal{R}_m \subseteq \mathcal{R}_{m+1}$. Let us then define

$$\mathcal{R} = \bigcup_{m \geq 0} \mathcal{R}_m.$$

$\mathcal{R}$ is a $w$-$\eta$-bisimulation of order $\infty$ w.r.t. $(S, S')$.

**(ii) $\Rightarrow$ (i):** Let $\mathcal{R}$ be a $w$-$\eta$-bisimulation of order $\infty$ w.r.t. $(S, S')$. Let us define a relation $\mathcal{S}$ by

$$\mathcal{S} = \{(S \odot u, S' \odot u') \mid (u, u') \in \mathcal{R}\}.$$

The totality property of $\mathcal{R}$ implies that $(S, S') \in \mathcal{S}$. The extension property of $\mathcal{R}$ implies that $\mathcal{S}$ fulfills condition (1) of Definition 3.20 and the coherence property of $\mathcal{R}$ implies that $\mathcal{S}$ fulfills condition (2). $\square$

Lemma 3.22 leads naturally to the following definition. We denote by $\mathcal{B}_n(T, T')$ the set of all $w$-$\eta$-bisimulations of order $n$ w.r.t. $(T, T')$.

DEFINITION 3.23. *Let $\lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$. We define the* divergence *between $S$ and $S'$ as*

$$\mathrm{Div}(S, S') = \inf\{n \in \mathbb{N} \mid \mathcal{B}_n(S, S') = \emptyset\}.$$

*(It is understood that* $\inf(\emptyset) = \infty$.*)*

Let us suppose that the dpda $\mathcal{M} = \langle X, Z, Q, \delta, q_0, z_0, \{\bar{q}\}\rangle$ is normalized and birooted. Let $\psi : X^* \to Y^*$ be a monoid homomorphism such that $\psi(X) \subseteq Y$ and let $\bar{\psi} = \psi \circ \psi^{-1}$ ($\bar{\psi}$, the kernel of $\psi$, is a strong relational morphism which is also an equivalence relation; this additional property will be used in what follows). Let $\Gamma$ be the computation 2-graph of $\mathcal{M}$ and let us suppose $\Gamma$ is $\bar{\psi}$-saturated.

Let $\theta : V_\Gamma \to \mathsf{DRB}\langle\langle\ V\ \rangle\rangle$ be the mapping defined by the following: $\forall q \in Q$, $\forall \omega \in Z^*$, such that $q\omega \in V_\Gamma$,

$$\theta(q\omega) = \varphi_0([q\omega\bar{q}]).$$

For every $q\omega \in V_\Gamma$, $S \in \mathsf{DRB}\langle\langle\ V\ \rangle\rangle$ we also define

$$\mathrm{L}(q\omega) = \{u \in X^*, q\omega \xrightarrow{u}_\Gamma \bar{q}, \}; \quad \mathrm{L}(S) = \{u \in X^*, S \odot u = \epsilon\}.$$

LEMMA 3.24. *For every $q\omega \in V_\Gamma$, $\mathrm{L}(q\omega) = \mathrm{L}(\varphi_0([q\omega\bar{q}]))$.*

This lemma follows from the classical result that the language recognized by $\mathcal{M}$ with starting configuration $q\omega$ and final configuration $\bar{q}$ is exactly the language generated by $G_\mathcal{M}$ from the polynomial $[q\omega\bar{q}]$, which, in turn, is equal to the language generated by $G_0$ from the polynomial $\varphi_0([q\omega\bar{q}])$. At last, $G$ and $G_0$ generate the same language from any given polynomial over $V_0$.

LEMMA 3.25. *Let $v, v'$ be vertices of $\Gamma$. Then $v \sim v'$, in the sense of Definition* 2.1 *iff $\theta(v) \sim \theta(v')$, in the sense of Definition* 3.20.

*Proof.* In this proof we denote by $\odot_\Gamma$ the right-action of $X^*$ over $V_\Gamma \cup \{\perp\}$ defined by the following: for every $v, v' \in V_\Gamma, u \in X^*$,

$$v \odot_\Gamma u = v' \text{ if } v \xrightarrow{u}_\Gamma v',$$
$$v \odot_\Gamma u = \perp \text{ if there is no } v'', \text{ such that } v \xrightarrow{u}_\Gamma v'',$$
$$\perp \odot_\Gamma u = \perp.$$

*Step* 1. Let us suppose that $(v, v') \in \mathcal{R}$, where $\mathcal{R}$ is some $\bar{\psi}$-bisimulation over $\Gamma$.

Let $\mathcal{S} = \{(\theta(v) \odot u, \theta(v') \odot u') \mid (u, u') \in \bar{\psi}, (v \odot_\Gamma u, v' \odot_\Gamma u') \in \mathcal{R}\} \cup \{(\emptyset, \emptyset)\}$. Let us show that $\mathcal{S}$ is a $\sigma$-$\bar{\psi}$-bisimulation.

Let us consider some pair of series in $\mathcal{S}$. If the given pair is $(\emptyset, \emptyset)$, points (1), (2) of Definition 3.20 are clearly fulfilled. Otherwise, it has the form $(\theta(v) \odot u, \theta(v') \odot u')$, where $(u, u') \in \bar{\psi}$ and $(v \odot_\Gamma u, v' \odot_\Gamma u') \in \mathcal{R}$.

*Step* 1.1. Let $x \in X$.

*Case* 1.1.1. $\theta(v) \odot ux \neq \emptyset$.

$$\mathrm{L}(\theta(v) \odot ux) \neq \emptyset$$

(because the grammar $G$ is reduced); hence, using Lemma 3.24,

$$\mathrm{L}(v \odot_\Gamma ux) = \mathrm{L}(v) \bullet ux = \mathrm{L}(\theta(v)) \bullet ux \neq \emptyset.$$

It follows that

$$v \odot_\Gamma ux \neq \perp.$$

As $\mathcal{R}$ is a $\bar{\psi}$-simulation, there must exist some $x' \in \bar{\psi}(x)$ such that

$$(v \odot_\Gamma ux, v' \odot_\Gamma u'x') \in \mathcal{R}.$$

Hence

$$(\theta(v) \odot ux, \theta(v') \odot u'x') \in \mathcal{S}.$$

*Case* 1.1.2. $\theta(v) \odot ux = \emptyset$. In this case, by Lemma 3.24 and the fact that $\Gamma$ is birooted, $v \odot_\Gamma ux$ must be equal to $\perp$. As $\Gamma$ is $\bar{\psi}$-saturated, it follows that

$$\forall x' \in \bar{\psi}(x), \quad v \odot_\Gamma ux' = \perp.$$

As $\mathcal{R}^{-1}$ is a $\bar{\psi}^{-1}$-simulation, it must also be true that

$$\forall x' \in \bar{\psi}(x), \quad v' \odot_\Gamma u'x' = \perp.$$

Choosing some particular $x' \in \bar{\psi}(x)$, and again using Lemma 3.24, we obtain

$$\theta(v') \odot u'x' = \emptyset.$$

In both cases, as $v, v'$ are playing symmetric roles, property (1) of Definition 3.20 has been verified. If the starting pair in $\mathcal{S}$ is $(\emptyset, \emptyset)$, property (1) is again verified.

*Step* 1.2. Let us suppose that $\theta(v) \odot u = \epsilon$. This means that

$$\mathrm{L}(\theta(v)) \bullet u = \epsilon,$$

and hence, using Lemma 3.24, that

$$\mathrm{L}(v \odot_\Gamma u) = \epsilon;$$

hence

$$v \odot_\Gamma u = \bar{q}.$$

As $\Gamma$ is birooted, $\bar{q}$ is the only vertex having no outgoing edge (see section 2.1). As $\mathcal{R}$ is a $\bar{\psi}$-bisimulation, $v' \odot_\Gamma u'$, we must also have no outgoing edge; hence

$$v' \odot_\Gamma u' = \bar{q},$$

and by the same arguments, used backwards now,

$$\mathrm{L}(\theta(v')) \bullet u' = \epsilon,$$

which, as the grammar $G$ is proper and reduced, implies

$$\theta(v') \odot u' = \epsilon.$$

As $(v, v')$ are playing symmetric roles, property (2) of Definition 3.20 has been verified.

*Step* 2. Let us suppose that $(\theta(v),\theta(v')) \in \mathcal{S}$, where $\mathcal{S}$ is some $\sigma$-$\bar{\psi}$-bisimulation.

Let $\mathcal{R} = \{(v \odot_\Gamma u, v' \odot_\Gamma u') \mid (u,u') \in \bar{\psi}, (\theta(v) \odot u, \theta(v') \odot u') \in \mathcal{S} - \{(\emptyset,\emptyset)\}\} \cup \{(c,c) \mid c \in V_\Gamma\}$. We show that $\mathcal{R}$ is a $\bar{\psi}$-bisimulation over $\Gamma$.

*Step* 2.1. Using Lemma 3.24, we obtain

$$\theta(v) \odot u \neq \emptyset \Rightarrow v \odot_\Gamma u \neq \perp.$$

Hence

$$\mathrm{dom}(\mathcal{R}) \subseteq V_\Gamma.$$

Conversely, due to the term $\{(c,c) \mid c \in V_\Gamma\}$,

$$\mathrm{dom}(\mathcal{R}) \supseteq V_\Gamma.$$

Finally, point (1) of Definition 2.1 is fulfilled.

*Step* 2.2. Due to the term $\{(c,c) \mid c \in V_\Gamma\}$, point (2) of Definition 2.1 is fulfilled.

*Step* 2.3. Let us consider some pair of configurations in $\mathcal{R}$. It must have the form $(v \odot_\Gamma u, v' \odot_\Gamma u')$, where $(u,u') \in \bar{\psi}$ and $(\theta(v) \odot u, \theta(v') \odot u') \in \mathcal{S} - \{(\emptyset,\emptyset)\}$.

By the same arguments as in Case 1.1.1 above, one can show that, for every $x \in X$, such that

$$v \odot_\Gamma ux \neq \perp,$$

there exists some $x' \in \bar{\psi}(x)$ such that

$$v' \odot_\Gamma u'x' \neq \perp.$$

Hence $\mathcal{R}$ fulfills the three points of Definition 2.1. By the same means, $\mathcal{R}^{-1}$ fulfills them too, so that $\mathcal{R}$ is a $\bar{\psi}$-bisimulation over the graph $\Gamma$. $\square$

**Extension to matrices.** Let $\delta, \lambda \in \mathbb{N} - \{0\}$. We extend the binary relation $\sim$ from vectors in $\mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$ to matrices in $\mathsf{DRB}_{\delta,\lambda}\langle\langle\ V\ \rangle\rangle$ as follows: for every $T, T' \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\ V\ \rangle\rangle$,

$$T \sim T' \Leftrightarrow \forall i \in [1,\delta], T_{i,*} \sim T'_{i,*}. \tag{3.7}$$

We call a *w-$\eta$-bisimulation* of order $n \in \mathbb{N} \cup \{\infty\}$ with respect to $(T,T')$ every

$$\mathcal{R} = (\mathcal{R}_i)_{i \in [1,\delta]} \text{ such that } \forall i \in [1,\delta],\ \mathcal{R}_i \in \mathcal{B}_n(T_{i,*}, T'_{i,*}).$$

We denote by $\mathcal{B}_n(T,T')$ the set of $w$-$\eta$-bisimulations of order $n$ w.r.t. $(T,T')$.

Some algebraic properties of this extended relation $\sim$ will be established in Corollary 4.10.

**Operations on $w$-bisimulations.** The following operations on word-$\bar{\psi}$-bisimulations turn out to be useful.

*Right-product.* Let $\delta, \lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\delta}\langle\langle\ V\ \rangle\rangle$, $T \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\ V\ \rangle\rangle$. For every $n \in \mathbb{N} \cup \{\infty\}$ and $\mathcal{R} \in \mathcal{B}_n(S,S')$ we define

$$\begin{aligned} \langle S|\mathcal{R}\rangle = [&\{(u,u') \in \mathcal{R} \mid \forall v \preceq u, \forall i \in [1,\delta], S \odot v \neq \epsilon_i^\delta\} \\ &\cup \{(u \cdot w, u' \cdot w) \mid (u,u') \in \mathcal{R}, w \in X^*, \exists i \in [1,\delta], S \odot u = \epsilon_i^\delta\}] \\ &\cap X^{\leq n} \times X^{\leq n}. \end{aligned} \tag{3.8}$$

One can check that $\langle S|\mathcal{R}\rangle \in \mathcal{B}_n(S \cdot T, S' \cdot T)$.

*Left-product.* Let $\delta, \lambda \in \mathbb{N} - \{0\}$, $S \in \mathsf{DRB}_{1,\delta}\langle\langle\ V\ \rangle\rangle$, $T, T' \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\ V\ \rangle\rangle$. For every $n \in \mathbb{N} \cup \{\infty\}$ and $\mathcal{R} \in \mathcal{B}_n(T, T')$ we define

$$\begin{aligned}\langle S, \mathcal{R}\rangle = [&\{(u,u) \mid u \in X^*, \forall v \preceq u, \forall i \in [1,\delta], S \odot v \neq \epsilon_i^\delta\}\\ &\cup \{(u\cdot w, u \cdot w') \mid u \in X^*, \exists i \in [1,\delta], S \odot u = \epsilon_i^\delta, (w,w') \in \mathcal{R}_i\}]\\ &\cap X^{\leq n} \times X^{\leq n}.\end{aligned} \tag{3.9}$$

One can check that $\langle S, \mathcal{R}\rangle \in \mathcal{B}_n(S \cdot T, S \cdot T')$.

*Star.* Let $\lambda \in \mathbb{N} - \{0\}$, $S_1 \in \mathsf{DRB}_{1,1}\langle\langle\ V\ \rangle\rangle$, $S_1 \neq \epsilon$, $(S_1, S) \in \mathsf{DRB}_{1,\lambda+1}\langle\langle\ V\ \rangle\rangle$, $T \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$. For every $n \in \mathbb{N} \cup \{\infty\}$ and $\mathcal{R} \in \mathcal{B}_n(S_1 \cdot T + S, T)$ we define

$$\mathcal{R}_0 = \mathcal{R}, \tag{3.10}$$

$$\mathcal{S}_0 = \begin{pmatrix} \mathcal{R}_0 \\ \vdots \\ \mathcal{R}_0 \end{pmatrix}, \tag{3.11}$$

$$\forall k \geq 0, \mathcal{R}_{k+1} = \langle (S_1, S), \mathcal{S}_k \rangle \circ \mathcal{R}_0, \tag{3.12}$$

$$\mathcal{S}_k = \begin{pmatrix} \mathcal{R}_k \\ \vdots \\ \mathcal{R}_k \end{pmatrix}, \tag{3.13}$$

and finally

$$\mathcal{R}^{\langle S_1, *\rangle} = \bigcup_{k \geq 0} \mathcal{R}_k \cap X^{\leq k} \times X^{\leq k}. \tag{3.14}$$

One can check that, for every $k \geq 0$,

$$\mathcal{R}_k \in \mathcal{B}_n\left(S_1^{k+1} + \sum_{i=0}^{k} S_1^i \cdot S, T\right), \tag{3.15}$$

$$\mathcal{S}_k \in \mathcal{B}_n\left(\begin{pmatrix} S_1^{k+1} + \sum_{i=0}^{k} S_1^i \cdot S \\ \mathrm{I}_\lambda \end{pmatrix}, \begin{pmatrix} T \\ \mathrm{I}_\lambda \end{pmatrix}\right), \tag{3.16}$$

and finally $\mathcal{R}^{\langle S_1, *\rangle} \in \mathcal{B}_n(S_1^* \cdot S, T)$.

REMARK 3.26. *In fact operations could be more adequately defined on "pointed" w-bisimulations, i.e., on binary relations with sets of "terminal pairs of words" of type $i \in [1, \delta]$ corresponding to the pairs $(u, u')$ such that $S \odot u = \epsilon_i^\delta$, $S' \odot u' = \epsilon_i^\delta$. The two different external operations $\langle S, \mathcal{R}\rangle, \langle S|\mathcal{R}\rangle$ could then be replaced by only one binary operation $\langle \mathcal{R}_1, \mathcal{R}_2\rangle$ over "pointed" w-bisimulations.*

**3.3. Derivations.** For every $u \in X^*$ we define the binary relation $\uparrow(u)$ over $\mathsf{DB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$ by the following: for every $S, S' \in \mathsf{DB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $S \uparrow (u) S' \Leftrightarrow \exists q \in \mathbb{N}$, $\exists E_1, \ldots, E_k, \ldots, E_q \in V$, $\Phi \in \mathsf{DB}_{q,\lambda}\langle\langle\ V\ \rangle\rangle$ such that

$$S = \sum_{k=1}^{q} E_k \cdot \Phi_k, \qquad S' = \sum_{k=1}^{q} (E_k \odot u) \cdot \Phi_k,$$

and $\forall k \in [1, q]$, $E_1 \smile E_k$, $E_k \odot u \notin \{\emptyset, \epsilon\}$.

It is clear that if $S \uparrow (u)S'$, then $S \odot u = S'$ and that the converse is not true in general. A sequence of deterministic row-vectors $S_0, S_1, \dots, S_n$ is a *derivation* iff there exist $x_1, \dots, x_n \in X$ such that $S_0 \odot x_1 = S_1, \dots, S_{n-1} \odot x_n = S_n$. The *length* of this derivation is $n$. If $u = x_1 \cdot x_2 \cdot \dots \cdot x_n$, we call $S_0, S_1, \dots, S_n$ the derivation *associated* with $(S, u)$. We denote this derivation by $S_0 \xrightarrow{u} S_n$.

A derivation $S_0, S_1, \dots, S_n$ is said to be *stacking* iff it is the derivation associated to a pair $(S, u)$ such that $S = S_0$ and $S_0 \uparrow (u)S_n$. A derivation $S_0, S_1, \dots, S_n$ is said to be a *subderivation* of a derivation $S'_0, S'_1, \dots, S'_m$ iff there exists some $i \in [0, m]$ such that, $\forall j \in [1, n]$, $S_j = S'_{i+j}$.

DEFINITION 3.27. *A vector $S \in \mathsf{DRB}_{1,\lambda}\langle\langle V \rangle\rangle$ is said to be* loop-free *iff for every $v \in V^+$, $S \bullet v \neq S$.*

Let us note that every polynomial is loop-free. The following two lemmas give other examples of loop-free vectors.

LEMMA 3.28. *Let $\alpha \in \mathsf{DB}_{1,n}\langle V \rangle$, $\Phi \in \mathsf{B}_{n,\lambda}\langle\langle V \rangle\rangle$, such that $\infty > \|\alpha \cdot \Phi\| > \|\Phi\|$. Then $\alpha \cdot \Phi$ is loop-free.*

*Proof.* Let $\alpha, \Phi$ fulfill the hypothesis of the lemma and suppose, for the sake of contradiction, that there exists some $v \in V^+$ such that

$$(\alpha \cdot \Phi) \bullet v = \alpha \cdot \Phi.$$

By induction, for every $n \geq 0$,

$$(\alpha \cdot \Phi) \bullet v^n = \alpha \cdot \Phi. \tag{3.17}$$

As $\alpha$ is a polynomial, there exists some $n_0 \geq 0$ such that $|v^{n_0}|$ is greater than the greatest length of a monomial of $\alpha$. Using Lemma 3.10, equality (3.17) for such an integer $n_0$ means that there exists some $k \in [1, n]$, $v''$ suffix of $v^{n_0}$ such that

$$\Phi_k \bullet v'' = \alpha \cdot \Phi. \tag{3.18}$$

Using the hypothesis of the lemma, we conclude that

$$\|\Phi\| \geq \|\Phi_k \bullet v''\| = \|\alpha \cdot \Phi\| > \|\Phi\|,$$

which is contradictory. □

LEMMA 3.29. *Let $S \in \mathsf{DRB}_{1,\lambda}\langle\langle V \rangle\rangle$, $u \in X^*$, such that $\|S \odot u\| > \|S\|$. Then $S \odot u$ is loop-free.*

*Proof.* Let us consider $S, u$ fulfilling the hypothesis of the lemma and let us consider the three possible forms of $S \odot u$ proposed by Lemma 3.14. The forms (1) or (2) are incompatible with the inequality $\|S \odot u\| > \|S\|$. Hence $S \odot u$ has the form (3):

$$u = u_1 \cdot u_2, \quad S \odot u_1 = S \bullet v_1 = \sum_{k=1}^{q} E_k \cdot \Phi_k, \quad S \odot u = \sum_{k=1}^{q} (E_k \odot u_2) \cdot \Phi_k, \quad \text{and}$$

$$\forall k \in [1, q], E_k \smile E_1, E_k \odot u_2 \notin \{\epsilon, \emptyset\}.$$

Hence $S \odot u = \alpha \cdot \Phi$ for some polynomial $\alpha \in \mathsf{DRB}_{1,q}\langle V \rangle$. As for every $k$, $\Phi_k = S \bullet (v_1 E_k)$, we obtain that $\|S\| \geq \|\Phi\|$. Finally

$$\infty > \|S \odot u\| = \|\alpha \cdot \Phi\| > \|S\| \geq \|\Phi\|,$$

and by Lemma 3.28, $S \odot u$ is loop-free. □

Lemma 3.30. *Let $S \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $w \in X^*$, such that*

(1) *$S$ is loop-free,*

(2) *$\forall u \preceq w$, $\|S \odot u\| \geq \|S\|$.*

*Then the derivation $S \xrightarrow{w} S \odot w$ is stacking.*

*Proof.* $S$ is left-deterministic. If it has type $\emptyset$ or $(\epsilon, j)$, the lemma is trivially true. Otherwise

$$S = \sum_{k=1}^{q} E_k \cdot \Phi_k$$

for some class of letter $[E_1]_\smile = \{E_1, \ldots, E_q\}$ and some matrix $\Phi \in \mathsf{DRB}_{q,\lambda}\langle\langle\ V\ \rangle\rangle$. Suppose that for some prefix $u \preceq w$ and $k \in [1, q]$,

$$E_k \odot u = \epsilon. \tag{3.19}$$

Then $S \odot u = \Phi_k$ so that $\|S \odot u\| \leq \|\Phi\| \leq \|S\|$, which shows that $S = S \odot u$ while $u \neq \epsilon$. This would contradict the hypothesis that $S$ is loop-free; hence (3.19) is impossible.

Let us apply now Lemma 3.15 to the expression $(E \cdot \Phi) \odot w$: case (2) is impossible, and hence

$$(E \cdot \Phi) \odot w = (E \odot w) \cdot \Phi,$$

which is equivalent to

$$S \uparrow (w) S \odot w. \qquad \square$$

Lemma 3.31. *Let $S \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $w \in X^*$, $k \in \mathbb{N}$, such that*

$$\|S \odot w\| \geq \|S\| + k \cdot K_0 + 1.$$

*Then the derivation $S \xrightarrow{w} S \odot w$ contains some stacking subderivation of length $k$.*

*Sketch of proof.* Let $S = S_0, \ldots, S_i, \ldots, S_n$ be the derivation associated to $(S, w)$. Let $i_0 = \max\{i \in [0, n] \mid \|S_i\| = \min\{\|S_j\| \mid 0 \leq j \leq n\}\}$ and $i_1 = \max\{i \in [i_0+1, n] \mid \|S_i\| = \min\{\|S_j\| \mid i_0 + 1 \leq j \leq n\}\}$. Let $w = w_0 w_1 w'$, where $|w_0| = i_0$, $|w_0 w_1| = i_1$.

As $\|S \odot w_0 w_1\| > \|S \odot w_0\|$, by Lemma 3.29 $S \odot w_0 w_1 = S_{i_1}$ is loop-free. Using Lemma 3.13,

$$\|S_n\| - \|S_{i_1}\| \geq \|S_n\| - \|S_{i_0}\| - (\|S_{i_1}\| - \|S_0\|) \geq (k-1) \cdot K_0 + 1.$$

Using Lemma 3.13 we must have $|w'| \geq k$. Let $w' = w_2 w_3$ with $|w_2| = k$. By definition of $i_1$, $\forall i \in [i_1 + 1, i_1 + k]$, $\|S_i\| \geq \|S_{i_1}\| + 1$.

By Lemma 3.30, the subderivation $S_{i_1}, \ldots, S_{i_1+k}$ (associated to $(S_{i_1}, w_2)$) is stacking. $\square$

Lemma 3.32. *Let $S, S' \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $w \in X^*$, $k, d, d' \in \mathbb{N}$, such that $S$ is d-marked and*

(1) *the derivation $S \xrightarrow{w} S'$ contains no stacking subderivation of length $k$,*

(2) *$|w| \geq d \cdot k$.*

*Then $S'$ is unmarked.*

*Proof.* By the hypothesis,

$$S = \sum_{k=1}^{q} \alpha_k \cdot \Phi_k$$

for some $\alpha \in \mathsf{DRB}_{1,q}\langle\ V\ \rangle$, $\Phi \in \mathsf{DRB}_{q,\lambda}\langle\langle\ V\ \rangle\rangle$, $\|\alpha\| \leq d$, $\Phi$ unmarked.

Let $S \xrightarrow{w} S' = (S_0, \ldots, S_n)$. By induction on $\ell$, using hypothesis (1) and Lemma 3.30 (on polynomials, which are particular cases of loop-free series) one can show that for every $\ell \in [0, d]$, there exists some prefix $w_\ell$ of $w$, with length $|w_\ell| \leq k \cdot \ell$, such that either

$$S \odot w_\ell = \sum_{k=1}^{q} (\alpha_k \odot w_\ell) \cdot \Phi_k \text{ with } \|\alpha_\odot w_\ell\| < \|\alpha\| - \ell \tag{3.20}$$

or there exists an integer $k \in [1, q]$ such that

$$S \odot w_\ell = \Phi_k. \tag{3.21}$$

Let us apply this property to $\ell = d$: inequality (3.20) is not possible for this value of $\ell$ because, by hypothesis (2) of the lemma, $\|\alpha\| - \ell \leq 0$. Hence (3.21) is true and, as $\Phi$ is unmarked, $\Phi_k$ is unmarked, so that $S \odot w$ is unmarked. $\square$

## 4. Deduction systems.

### 4.1. General formal systems.

We follow here the general philosophy of [16, 9]. Let us call a *formal system* any triple $\mathcal{D} = \langle \mathcal{A}, H, \models\!\!- \rangle$ where $\mathcal{A}$ is a denumerable set called the *set of assertions*, $H$, the *cost function*, is a mapping $\mathcal{A} \to \mathbb{N} \cup \{\infty\}$, and $\models\!\!-$, the *deduction relation*, is a subset of $\mathcal{P}_f(\mathcal{A}) \times \mathcal{A}$; $\mathcal{A}$ is given with a fixed bijection with $\mathbb{N}$ (an "encoding" or "Gödel numbering") so that the notions of recursive subset, recursively enumerable subset, recursive function, over $\mathcal{A}, \mathcal{P}_f(\mathcal{A})$, are defined, up to this fixed bijection; we assume that $\mathcal{D}$ satisfies the following axioms:

(A1) $\forall (P, A) \in \models\!\!-$, $(\min\{H(p), p \in P\} < H(A))$ or $(H(A) = \infty)$.

(We let $\min(\emptyset) = \infty$.) We call $\mathcal{D}$ a *deduction system* iff $\mathcal{D}$ is a formal system satisfying the additional axiom:

(A2) $\models\!\!-$ is recursively enumerable.

In what follows we use the notation $P \models\!\!- A$ for $(P, A) \in \models\!\!-$. We call a *proof* in the system $\mathcal{D}$, *relative to the set of hypotheses* $\mathcal{H} \subseteq \mathcal{A}$, any subset $P \subseteq \mathcal{A}$ fulfilling

$$\forall p \in P,\ (\exists Q \subseteq P, Q \models\!\!- p) \text{ or } (p \in \mathcal{H}).$$

We call $P$ a *proof* iff

$$\forall p \in P, (\exists Q \subseteq P, Q \models\!\!- p)$$

(i.e., iff $P$ is a proof relative to $\emptyset$).

Let us define the total map $\chi : \mathcal{A} \to \{0, 1\}$ and the partial map $\overline{\chi} : \mathcal{A} \to \{0, 1\}$ by

$$\chi(A) = 1 \text{ if } H(A) = \infty, \quad \chi(A) = 0 \text{ if } H(A) < \infty,$$

$$\overline{\chi}(A) = 1 \text{ if } H(A) = \infty, \quad \overline{\chi} \text{ is undefined if } H(A) < \infty.$$

($\chi$ is the "truth-value function"; $\overline{\chi}$ is the "1-value function.")

LEMMA 4.1. *Let $P$ be a proof relative to $\mathcal{H} \subseteq H^{-1}(\infty)$ and $A \in P$. Then $\chi(A) = 1$.*

In other words, if an assertion is provable from true hypotheses, then it is true.

*Proof.* Let $P$ be a proof. We prove by induction on $n$ that

$$\mathcal{P}(n) : \forall p \in P, H(p) \geq n.$$

It is clear that, $\forall p \in P$, $H(p) \geq 0$. Suppose that $\mathcal{P}(n)$ is true. Let $p \in P - \mathcal{H} : \exists Q \subseteq P$, $Q \vdash\!\!- p$. By the induction hypothesis, $\forall q \in Q$, $H(q) \geq n$ and by (A1), $H(p) \geq n+1$. It follows that, $\forall p \in P - \mathcal{H}$, $H(p) = \infty$. But by the hypothesis, $\forall p \in \mathcal{H}$, $H(p) = \infty$. ☐

A formal system $\mathcal{D}$ will be *complete* iff, conversely, $\forall A \in \mathcal{A}$, $\chi(A) = 1 \Longrightarrow$ there exists some *finite* proof $P$ such that $A \in P$. (In other words, $\mathcal{D}$ is complete iff every true assertion is "finitely" provable.)

LEMMA 4.2. *If $\mathcal{D}$ is a complete deduction system, $\overline{\chi}$ is a recursive partial map.*

*Proof.* Let $i \mapsto P_i$ be some recursive function whose domain is $\mathbb{N}$ and whose image is $\mathcal{P}_f(\mathcal{A})$. Let $h : (\mathcal{P}_f(\mathcal{A}) \times \mathcal{A} \times \mathbb{N}) \to \{0,1\}$ be a total recursive function such that

$$P \vdash\!\!- A \text{ iff } \exists n \in \mathbb{N},\ h(P, A, n) = 1$$

(such an $h$ exists, because the recursively enumerable sets are the projections of the recursive sets; see [30]).

The following (informal) semialgorithm computes $\overline{\chi}$ on the assertion A:

```
1. $i$ := 0 ; $n$ := 0 ; $s$ := $i+n$;
2. $P$ := $P_i$;
3. $b$ := $\min_{p \in P}\{\max_{Q \subseteq P}\{h(Q,p,n)\}\}$;
4. $c$ := $(A \in P)$;
5. if $(b \wedge c)$ then $(\overline{\chi}(A) = 1$ ; stop);
6. if $i = 0$ then $(i := s+1$ ; $n := 0$; $s := i+n)$
   else $(i := i-1$ ; $n := n+1)$;
7. goto 2;
```
☐

In order to define deduction relations from more elementary ones, we set the following definitions.

Let $\vdash\!\!- \subseteq \mathcal{P}_f(\mathcal{A}) \times \mathcal{A}$. For every $P, Q \in \mathcal{P}_f(\mathcal{A})$ we set

- $P \overset{[0]}{\vdash\!\!-} Q$ iff $P \supseteq Q$,
- $P \overset{[1]}{\vdash\!\!-} Q$ iff $\forall q \in Q$, $\exists R \subseteq P$, $R \vdash\!\!- q$,
- $P \overset{\langle 0 \rangle}{\vdash\!\!-} Q$ iff $P \overset{[0]}{\vdash\!\!-} Q$,
- $P \overset{\langle 1 \rangle}{\vdash\!\!-} Q$ iff $\forall q \in Q$, $(\exists R \subseteq P,\ R \vdash\!\!- q)$ or $(q \in P)$,
- $P \overset{\langle n+1 \rangle}{\vdash\!\!-} Q$ iff $\exists R \in \mathcal{P}_f(A)$, $P \overset{\langle 1 \rangle}{\vdash\!\!-} R$ and $R \overset{\langle n \rangle}{\vdash\!\!-} Q$ (for every $n \geq 0$),
- $\overset{\langle * \rangle}{\vdash\!\!-} = \bigcup_{n \geq 0} \overset{\langle n \rangle}{\vdash\!\!-}$.

Given $\vdash\!\!-_1, \vdash\!\!-_2 \subseteq \mathcal{P}_f(\mathcal{A}) \times \mathcal{P}_f(\mathcal{A})$, for every $P, Q \in \mathcal{P}_f(\mathcal{A})$ we set

$$P(\vdash\!\!-_1 \circ \vdash\!\!-_2)Q \text{ iff } \exists R \subseteq \mathcal{A},\ (P \vdash\!\!-_1 R) \wedge (R \vdash\!\!-_2 Q).$$

**4.2. Strategies.** We define here a notion of strategy which consists of a map allowing us to build proofs within a formal system $\mathcal{D}$. This notion will be an essential tool for proving that a formal system is *complete.* Let $\mathcal{D} = \langle \mathcal{A}, H, \vdash\!\!- \rangle$ be a formal system. We call a *strategy* for $\mathcal{D}$ any map $\mathcal{S} : \mathcal{A}^+ \to \mathcal{P}(\mathcal{A}^*)$ such that

(S1) if $B_1 \cdots B_m \in \mathcal{S}(A_1 A_2 \cdots A_n)$, then $\exists Q \subseteq \{A_i \mid 1 \leq i \leq n-1\}$ such that

$$\{B_j \mid 1 \leq j \leq m\} \cup Q \vdash\!\!- A_n;$$

(S2) if $B_1 \cdots B_m \in \mathcal{S}(A_1 A_2 \cdots A_n)$, then

$$\min\{H(A_i) \mid 1 \leq i \leq n\} = \infty \Longrightarrow \min\{H(B_j) \mid 1 \leq j \leq m\} = \infty.$$

REMARK 4.3. *It may happen that $\epsilon \in \mathcal{S}(A_1 A_2 \cdots A_n)$ (and, correspondingly, that $m = 0$ in the above conditions): it just means that $\{A_1, \ldots, A_{n-1}\} \mid\!\!-\!\!- A_n$. It may also happen that $\mathcal{S}(A_1 A_2 \cdots A_n) = \emptyset$: this means, intuitively, that $\mathcal{S}$ "does not know" how to extend a proof (with hypothesis), with the only information being that the given proof contains the assertions $A_1, A_2, \ldots, A_n$.*

REMARK 4.4. *Axiom* (A1) *on systems is similar to the "monotonicity" condition of* [16] *or axiom* (2.4.2′) *of* [9]. *Axiom* (S2) *on strategies is similar to the "validity" condition of* [16] *or property* (2.4.1′) *of* [9].

Given a strategy $\mathcal{S}$, we define $\mathcal{T}(\mathcal{S}, A)$, the set of proof-trees associated to the strategy $\mathcal{S}$ and the assertion $A$, as the set of all trees $t$ fulfilling the following properties:

$$\varepsilon \in \mathrm{dom}(t), \quad t(\varepsilon) = A, \tag{4.1}$$

and, for every path $x_0 x_1, \ldots, x_{n-1}$ in $t$, with labels $t(x_i) = A_{i+1}$ (for $0 \le i \le n-1$), if $x_{n-1}$ has $m$ sons $x_{n-1} \cdot 1, \ldots, x_{n-1} \cdot m \in \mathrm{dom}(t)$ with labels $t(x_{n-1} \cdot j) = B_j$ (for $1 \le j \le m$), then

$$(B_1 \cdots B_m) \in \mathcal{S}(A_1 \cdots A_n) \quad \text{or} \quad m = 0. \tag{4.2}$$

The proof-tree $t$ is said to be *closed* iff it fulfills the following additional condition: for every path $x_0 x_1, \ldots, x_{n-1}$ in $t$, with labels $t(x_i) = A_{i+1}$ (for $0 \le i \le n-1$), if $x_{n-1}$ has $m$ sons $x_{n-1} \cdot 1, \ldots, x_{n-1} \cdot m \in \mathrm{dom}(t)$ with labels $t(x_{n-1} \cdot j) = B_j$ (for $1 \le j \le m$), then

$$m = 0 \Rightarrow ((\exists i \in [1, n-1],\, A_i = A_n) \text{ or } (\varepsilon \in \mathcal{S}(A_1 \cdots A_n))). \tag{4.3}$$

A node $x \in \mathrm{dom}(t)$ is said to be *closed* iff it is an internal node or it is a leaf fulfilling property (4.3) above.

The proof-tree $t$ is said to be *repetition-free* iff, for every $x, x' \in \mathrm{dom}(t)$,

$$[x \preceq x' \text{ and } t(x) = t(x')] \quad \Rightarrow \quad x = x' \text{ or } x' \text{ is a leaf.}$$

For every tree $t$ let us define

$$\mathcal{L}(t) = \{t(x) \mid \forall y \in \mathrm{dom}(t), x \preceq y \Rightarrow x = y\}, \quad \mathcal{I}(t) = \{t(x) \mid \exists y \in \mathrm{dom}(t), x \prec y\}.$$

(Here $\mathcal{L}$ stands for "leaves" and $\mathcal{I}$ stands for "internal nodes.")

LEMMA 4.5. *If $\mathcal{S}$ is a strategy for the deduction-system $\mathcal{D}$, then, for every true assertion $A$ and every $t \in \mathcal{T}(\mathcal{S}, A)$,*

(1) *the set of labels of $t$ is a $\mathcal{D}$-proof, relative to the set $\mathcal{L}(t) - \mathcal{I}(t)$;*

(2) *every label of a leaf is true.*

*Proof.* Let us suppose that $H(A) = \infty$. Let $t \in \mathcal{T}(\mathcal{S}, A)$, $P = \mathrm{im}(t)$ (the set of labels of $t$), $\mathcal{H} = \mathcal{L}(t) - \mathcal{I}(t)$.

Using (S2), one can prove by induction on the depth of $x \in \mathrm{dom}(t)$ that $H(t(x)) = \infty$. Point (2) is then proved. Let $x$ be an internal node of $t$, with sons $x \cdot 1, x \cdot 2, \ldots, x \cdot m$ ($m \ge 1$), and with ancestors $y_1, y_2, \ldots, y_{n-1}, y_n = x$ ($n \ge 1$), such that

$$t(y_1) \cdots t(y_n) = A_1 \cdots A_n, \quad t(x_1) \cdots t(x_m) = B_1 \cdots B_m.$$

By definition of $\mathcal{T}(\mathcal{S}, A)$,

$$B_1 \cdots B_m \in \mathcal{S}(A_1 \cdots A_n),$$

and by condition (S1),

$$\exists Q \subseteq \{A_i \mid i \leq n-1\}, \text{ such that } \{B_j \mid 1 \leq j \leq m\} \cup Q \mathrel{|\!\!-\!\!-} A_n.$$

It follows that for every $p \notin \mathcal{H}$, $\exists R \subseteq P$, $R \mathrel{|\!\!-\!\!-} p$; hence

$$\forall p \in P, \quad (\exists R \subseteq P,\ R \mathrel{|\!\!-\!\!-} p) \text{ or } p \in \mathcal{H}.$$

Point (1) is proved. ∎

For every $\mathcal{D}$-strategy $\mathcal{S}$, we use the notation

$$\mathcal{T}(\mathcal{S}) = \bigcup_{A \in H^{-1}(\infty)} \mathcal{T}(\mathcal{S}, A).$$

We call a *global strategy* w.r.t. $\mathcal{S}$ any total map $\hat{\mathcal{S}} : \mathcal{T}(\mathcal{S}) \to \mathcal{T}(\mathcal{S})$ such that

$$\forall t \in \mathcal{T}(\mathcal{S}), \quad t \preceq \hat{\mathcal{S}}(t). \tag{4.4}$$

$\hat{\mathcal{S}}$ is a *terminating* global strategy iff

$$\forall A_0 \in H^{-1}(\infty),\ \exists n_0 \in \mathbb{N}, \quad \hat{\mathcal{S}}^{n_0}(A_0) = \hat{\mathcal{S}}^{n_0+1}(A_0), \tag{4.5}$$

and $\hat{\mathcal{S}}$ is a *closed* global strategy iff

$$\forall A_0 \in H^{-1}(\infty), \forall n \in \mathbb{N}, \quad \hat{\mathcal{S}}^{n}(A_0) \text{ is closed} \iff \hat{\mathcal{S}}^{n}(A_0) = \hat{\mathcal{S}}^{n+1}(A_0) \tag{4.6}$$

(where the assertion $A_0$ is identified with the tree reduced to one node whose label is $A_0$).

LEMMA 4.6. *Let $\mathcal{D}$ be a formal system, $\mathcal{S}$ a strategy for $\mathcal{D}$, and $\hat{\mathcal{S}}$ a global strategy w.r.t. $\mathcal{S}$. If $\hat{\mathcal{S}}$ is terminating and $\hat{\mathcal{S}}$ is closed, then $\mathcal{D}$ is complete.*

*Proof.* Let $A_0 \in \mathcal{A}$. Under the hypothesis of the lemma, $\exists n_0 \in \mathbb{N}$ such that (4.5) and (4.6) are both true. Hence $t_\infty = \hat{\mathcal{S}}^{n_0}(A_0)$ is a closed proof-tree for $\mathcal{S}$. By Lemma 4.5 $\mathrm{im}(t_\infty)$ is a $\mathcal{D}$-proof relative to the set $\mathcal{L}(t_\infty) - \mathcal{I}(t_\infty)$. Let $x$ be a leaf such that $t_\infty(x) \in \mathcal{L}(t_\infty) - \mathcal{I}(t_\infty)$. Let $A_0, A_1, \ldots, A_n = t_\infty(x)$ be the word labeling the path from the root to $x$. As $x$ is closed and $t_\infty(x) \in \mathcal{L}(t_\infty) - \mathcal{I}(t_\infty)$ by (4.3), $\varepsilon \in \mathcal{S}(A_1 \cdots A_n)$; hence $\{A_1, \ldots, A_{n-1}\} \mathrel{|\!\!-\!\!-} t_\infty(x)$. It follows that $\mathrm{im}(t_\infty)$ is a $\mathcal{D}$-proof. ∎

**4.3. System $\mathcal{B}_0$.** Let us define here a particular formal system $\mathcal{B}_0$ "tailored for the $\sigma$-$\bar{\psi}$-bisimulation problem for deterministic series."

Let us fix two finite alphabets $X, Y$, a surjection $\psi : X \to Y$ (which induces a surjection $X^* \to Y^*$ denoted by the same symbol $\psi$), and its kernel $\bar{\psi} = \mathrm{Ker}\,\psi \subseteq X^* \times X^*$ (see section 3.2). We also fix a dpda $\mathcal{M}$ over the terminal alphabet $X$ and consider the variable alphabet $V$ associated to $\mathcal{M}$ (see section 3.1) and the sets $\mathsf{DRB}_{\delta,\lambda}\langle\langle V \rangle\rangle$ (the sets of deterministic rational boolean matrices over $V^*$, with $\delta$ rows and $\lambda$ columns). The set of assertions is defined by

$$\mathcal{A} = \bigcup_{\lambda \geq 1} \mathbb{N} \times \mathsf{DRB}_{1,\lambda}\langle\langle V \rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle V \rangle\rangle;$$

i.e., an assertion is here a *weighted equation* over $\mathsf{DRB}_{1,\lambda}\langle\langle V \rangle\rangle$ for some integer $\lambda$.

For every $n \geq 0$ we define

$$\bar{\mathcal{B}}_n = \{\mathcal{R} \subseteq \bar{\psi} \mid \mathcal{R} \text{ fulfills conditions } (1'), (2'), \text{ and } (4) \text{ of Definition 3.21}\}. \tag{4.7}$$

We call the elements of $\bar{\mathcal{B}}_n$ the *admissible* relations of order $n$ over $X^* \times X^*$. For every pair $(S, S') \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$, and $n \in \mathbb{N} \cup \{\infty\}$, we define

$$\mathcal{B}_n(S, S') = \{\mathcal{R} \subseteq \bar{\psi} \mid \mathcal{R} \text{ is a } w\text{-}\bar{\psi}\text{-bisimulation of order } n \text{ w.r.t. } (S, S')\}. \tag{4.8}$$

The "cost-function" $H : \mathcal{A} \to \mathbb{N} \cup \{\infty\}$ is defined by

$$H(n, S, S') = n + 2 \cdot \mathrm{Div}(S, S'),$$

where $\mathrm{Div}(S, S')$ is the *divergence* between $S$ and $S'$ (Definition 3.23). We recall that it is defined by

$$\mathrm{Div}(S, S') = \inf\{n \in \mathbb{N} \mid \mathcal{B}_n(S, S') = \emptyset\}.$$

(We recall $\inf(\emptyset) = \infty$.)

Let us note that, by Lemma 3.22,

$$\chi(n, S, S') = 1 \Longleftrightarrow S \sim S'.$$

We define a binary relation $|\!\!\vdash\!\!-\; \subseteq \mathcal{P}_f(\mathcal{A}) \times \mathcal{A}$, the *elementary deduction relation*, as the set of all the pairs having one of the following forms:

(R0)

$$\{(p, S, T)\} \;|\!\!\vdash\!\!-\; (p + 1, S, T)$$

for $p \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$;

(R1)

$$\{(p, S, T)\} \;|\!\!\vdash\!\!-\; (p, T, S)$$

for $p \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$;

(R2)

$$\{(p, S, S'), (p, S', S'')\} \;|\!\!\vdash\!\!-\; (p, S, S'')$$

for $p \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$;

(R3)

$$\emptyset \;|\!\!\vdash\!\!-\; (0, S, S)$$

for $S \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$;

(R′3)

$$\emptyset \;|\!\!\vdash\!\!-\; (0, S, \rho_e(S))$$

for $S \in \mathsf{DRB}_{1,1}\langle\langle\, V\,\rangle\rangle$;

(R4)

$$\{(p + 1, S \odot x, T \odot x') \mid (x, x') \in \mathcal{R}_1\} \;|\!\!\vdash\!\!-\; (p, S, T)$$

for $p \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$, $(S \neq \epsilon \wedge T \neq \epsilon)$, and $\mathcal{R}_1 \in \bar{\mathcal{B}}_1$;

(R5)

$$\{(p, S, S')\} \;|\!\!\vdash\!\!-\; (p + 2, S \odot x, S' \odot x')$$

for $p \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$, $(x, x') \in \bar{\psi}$, $S \sim S' \wedge S \odot x \sim S' \odot x'$;

(R6)

$$\{(p, S_1 \cdot T + S, T)\} \,||\!\!-\!\!- (p, S_1^* \cdot S, T)$$

for $p \in \mathbb{N}$, $\lambda \in \mathbb{N}-\{0\}$, $S_1 \in \mathsf{DRB}_{1,1}\langle\langle\, V\,\rangle\rangle$, $S_1 \neq \epsilon$, $(S_1, S) \in \mathsf{DRB}_{1,\lambda+1}\langle\langle\, V\,\rangle\rangle$, $T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$;

(R7)

$$\{(p, S, S')\} \,||\!\!-\!\!- (p, S \cdot T, S' \cdot T)$$

for $p \in \mathbb{N}$, $\delta, \lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\delta}\langle\langle\, V\,\rangle\rangle$, $T \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\, V\,\rangle\rangle$;

(R8)

$$\{(p, T_{i,*}, T'_{i,*}) \mid 1 \leq i \leq \delta\} \,||\!\!-\!\!- (p, S \cdot T, S \cdot T')$$

for $p \in \mathbb{N}$, $\delta, \lambda \in \mathbb{N} - \{0\}$, $S \in \mathsf{DRB}_{1,\delta}\langle\langle\, V\,\rangle\rangle$, $T, T' \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\, V\,\rangle\rangle$.

REMARK 4.7. *We do not claim that this formal system is* recursively enumerable*: due to rule* (R5)*, establishing this property is as difficult as solving the general bisimulation problem for equational graphs of finite out-degree. This difficulty will be overcome in section* 10 *by an* elimination *lemma.*

LEMMA 4.8. *Let $P \in \mathcal{P}_f(\mathcal{A})$, $A \in \mathcal{A}$, such that $P \,||\!\!-\!\!- A$. Then* $\min\{H(p) \mid p \in P\} \leq H(A)$.

Let us introduce the following notation: for every $n \in \mathbb{N} \cup \{\infty\}$, $\lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$,

$$S \sim_n S' \Leftrightarrow \mathcal{B}_n(S, S') \neq \emptyset.$$

*Proof.* Let us check this property for every type of rule.

(R0) $p + 2 \cdot \mathrm{Div}(S, T) \leq p + 1 + 2 \cdot \mathrm{Div}(S, T)$.

(R1) $p + 2 \cdot \mathrm{Div}(S, T) = p + 2 \cdot \mathrm{Div}(T, S)$.

(R2) As the weight $p$ is the same in all the considered equations, we are reduced to proving that $\forall n \in \mathbb{N}$, $S \sim_n S' \wedge S' \sim_n S'' \Longrightarrow S \sim_n S''$. This is true because, if $\mathcal{R} \in \mathcal{B}_n(S, S')$ and $\mathcal{R}' \in \mathcal{B}_n(S', S'')$, then $\mathcal{R} \circ \mathcal{R}' \in \mathcal{B}_n(S, S'')$.

(R3) Let us note that $\mathrm{Id}_{X^*} \subseteq \bar{\psi}$. It follows that $\infty = \mathrm{Div}(S, S)$.

(R′3) The definition of $G$ from $G_0$ is such that $S \equiv \rho_e(S)$; hence $S \sim \rho_e(S)$ and $\infty = \mathrm{Div}(S, \rho_e(S))$.

(R4) Let $n \in \mathbb{N}$ such that

$$\forall (x, x') \in \mathcal{R}_1, \quad n \leq \mathrm{Div}(S \odot x, S' \odot x').$$

Let us choose, for every $(x, x') \in \mathcal{R}_1$, some $\mathcal{R}_{x,x'} \in \mathcal{B}_n(S \odot x, S' \odot x')$. Let us then define

$$\mathcal{R} = \bigcup_{(x,x') \in \mathcal{R}_1} (x, x') \cdot \mathcal{R}_{x,x'}.$$

$\mathcal{R}$ belongs to $\mathcal{B}_{n+1}(S, S')$. It follows that

$$\min\{\mathrm{Div}(S \odot x, S' \odot x') \mid (x, x') \in \mathcal{R}_1\} + 1 \leq \mathrm{Div}(S, S'),$$

and hence that

$$\min\{H(p + 1, S \odot x, S' \odot x') \mid (x, x') \in \mathcal{R}_1\} \leq H(p, S, S') - 1.$$

(R5) By the hypothesis, $H(p+2, S \odot x, S' \odot x') = \infty$.

(R6) Let $n \in \mathbb{N}$ such that

$$n \leq \mathrm{Div}(S_1 \cdot T + S, T).$$

Let $\mathcal{R} \in \mathcal{B}_n(S_1 \cdot T + S, T)$. Let $\mathcal{R}' = \mathcal{R}^{\langle S_1, * \rangle}$ (see definition (3.14) in section 3.2). Since we have

$$\mathcal{R}' \in \mathcal{B}_n(S_1^* \cdot S, T),$$

we get the inequality $\mathrm{Div}(S_1 \cdot T + S, T) \leq \mathrm{Div}(S_1^* \cdot S, T)$.

(R7) Let $n \leq \mathrm{Div}(S, S')$ and $\mathcal{R} \in \mathcal{B}_n(S, S')$. Let us consider $\mathcal{R}' = \langle S | \mathcal{R} \rangle$ (see definition (3.8) in section 3.2). Since we have $\mathcal{R}' \in \mathcal{B}_n(S \cdot T, S' \cdot T)$, the required inequality is proved.

(R8) Let $n \leq \min\{\mathrm{Div}(T_{i,*}, T'_{i,*}) \mid 1 \leq i \leq \delta\}$ and, for every $i \in [1, \delta]$, let $\mathcal{R}_i \in \mathcal{B}_n(T_{i,*}, T'_{i,*})$. Let us consider $\mathcal{R}' = \langle S, \mathcal{R} \rangle$ (see definition (3.9) in section 3.2). Since we know that

$$\mathcal{R}' \in \mathcal{B}_n(S \cdot T, S \cdot T'),$$

the required inequality is proved. □

Let us define $\vdash\!\!-$ as follows: for every $P \in \mathcal{P}_f(\mathcal{A})$, $A \in \mathcal{A}$,

$$P \vdash\!\!- A \iff P \overset{\langle * \rangle}{||\!\!\vdash\!\!-} \circ \overset{[1]}{||\!\!\vdash\!\!-}_{0,3,4} \circ \overset{\langle * \rangle}{||\!\!\vdash\!\!-} \{A\},$$

where $||\!\!\vdash\!\!-_{0,3,4}$ is the relation defined by $R_0, R_3, R'_3, R_4$ only. We let

$$\mathcal{B}_0 = \langle \mathcal{A}, H, \vdash\!\!- \rangle.$$

LEMMA 4.9. *$\mathcal{B}_0$ is a formal system.*

*Proof.* Using Lemma 4.8, one can show by induction on $n$ that

$$P \overset{\langle n \rangle}{||\!\!\vdash\!\!-} Q \Longrightarrow \forall q \in Q, \quad \min\{H(A) \mid A \in P\} \leq H(q).$$

The proof of Lemma 4.8 also reveals that

$$P \,||\!\!\vdash\!\!-_{\{0,3,4\}} q \Longrightarrow (\min\{H(p) \mid p \in P\} < H(q)) \quad \text{or} \quad H(q) = \infty.$$

It follows that, for every $m, n \geq 0$,

$$P \overset{\langle n \rangle}{||\!\!\vdash\!\!-} Q \overset{[1]}{||\!\!\vdash\!\!-}_{0,3,4} R \overset{\langle m \rangle}{||\!\!\vdash\!\!-} q \Longrightarrow (\min\{H(p) \mid p \in P\} < H(q)) \quad \text{or} \quad H(q) = \infty.$$

Hence axiom (A1) is fulfilled. □

Let us note the following algebraic corollaries of Lemma 4.8.

COROLLARY 4.10.

(C1) $\forall \lambda \in \mathbb{N} - \{0\}$, $S_1 \in \mathsf{DRB}_{1,1}\langle\langle\, V \,\rangle\rangle$, $S_1 \not\equiv \epsilon$, $(S_1, S) \in \mathsf{DRB}_{1,\lambda+1}\langle\langle\, V \,\rangle\rangle$, $T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V \,\rangle\rangle$,

$$S_1 \cdot T + S \sim T \Longrightarrow S_1^* \cdot S \sim T.$$

(C2) $\forall \delta, \lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\delta}\langle\langle\, V \,\rangle\rangle$, $T \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\, V \,\rangle\rangle$,

$$S \sim S' \Longrightarrow S \cdot T \sim S' \cdot T.$$

(C3) $\forall \lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,1}\langle\langle\ V\ \rangle\rangle$, $T \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$,

$$[S \cdot T \sim S' \cdot T \text{ and } T \neq \emptyset^{\lambda}] \Longrightarrow S \sim S'.$$

(C4) $\forall \delta, \lambda \in \mathbb{N} - \{0\}$, $S \in \mathsf{DRB}_{1,\delta}\langle\langle\ V\ \rangle\rangle$, $T, T' \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\ V\ \rangle\rangle$,

$$T \sim T' \Longrightarrow S \cdot T \sim S \cdot T'.$$

*Proof.* Statement (C$i$) (for $i \in \{1, 2, 4\}$) is a direct corollary of the fact that the value of $H$ on the left-hand side of some rule (R$j$) is smaller than or equal to the value of $H$ on the right-hand side of rule (R$j$): (C1) is justified by (R6), (C2) by (R7), (C4) by (R8).

Let us prove (C3): Suppose that $\lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,1}\langle\langle\ V\ \rangle\rangle$, $T \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, and

$$S \cdot T \sim S' \cdot T \quad \text{and} \quad S \not\sim S'. \tag{4.9}$$

Let $\mathcal{R} \in \mathcal{B}_{\infty}(S \cdot T, S' \cdot T)$ and let

$$(u, u') = \min\{(v, v') \in \mathcal{R} \mid (S \odot v = \epsilon) \Leftrightarrow (S' \odot v' \neq \epsilon)\}.$$

From the hypothesis that $\mathcal{R} \in \mathcal{B}_{\infty}(S \cdot T, S' \cdot T)$, we get that

$$\forall (v, v') \in \mathcal{R}, \quad (S \cdot T) \odot v \sim (S' \cdot T) \odot v',$$

and by the choice of $(u, u')$ we obtain that

$$T \sim (S' \odot u') \cdot T \quad \text{or} \quad (S \odot u) \cdot T \sim T,$$

which, by (C1), implies

$$T \sim (S' \odot u')^{*} \cdot \emptyset^{\lambda} \quad \text{or} \quad (S \odot u)^{*} \cdot \emptyset^{\lambda} \sim T,$$

i.e., $T \sim \emptyset^{\lambda}$, which implies (because $G$ is a reduced grammar) that

$$T = \emptyset^{\lambda}. \tag{4.10}$$

We have proved that (4.9) implies (4.10), and hence (C3). □

**4.4. Congruence closure.** Let us consider the subset $\mathcal{C}$ of the rules of $\mathcal{B}_0$, consisting of all the instances of the metarules (R0), (R1), (R2), (R3), (R′3), (R6), (R7), (R8). We also denote by $||\!\!-_{\mathcal{C}} \subseteq \mathcal{P}_f(\mathcal{A}) \times \mathcal{A}$ the set of all instances of these metarules. We are interested here (and later in section 10.1) in special subsets of $\mathcal{A}$ which express an ordinary weighted equation $(p, S, S')$ together with an admissible binary relation $\mathcal{R}$ of finite order (which is a *candidate* to be a $w$-$\bar{\psi}$-bisimulation w.r.t. $(S, S')$).

For every $p, n \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $\mathcal{R} \in \bar{\mathcal{B}}_n$, we use the notation

$$[p, S, S', \mathcal{R}] = \{(p + |u|, S \odot u, S' \odot u') \mid (u, u') \in \mathcal{R}\}. \tag{4.11}$$

One can check the following properties.

*Composition.* For every $p, n \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $\mathcal{R}_1, \mathcal{R}_2 \in \bar{\mathcal{B}}_n$,

$$[p, S, S', \mathcal{R}_1] \cup [p, S', S'', \mathcal{R}_2] \ \overset{\langle * \rangle}{||\!\!-}_{\mathcal{C}} \ [p, S, S'', \mathcal{R}_1 \circ \mathcal{R}_2].$$

*Star.* For every $p, n \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S_1 \in \mathsf{DRB}_{1,1}\langle\langle\ V\ \rangle\rangle$, $S_1 \not\equiv \epsilon$, $(S_1, S) \in \mathsf{DRB}_{1,\lambda+1}\langle\langle\ V\ \rangle\rangle$, $T \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $\mathcal{R} \in \bar{\mathcal{B}}_n$,

$$[p, S_1 \cdot T + S, T, \mathcal{R}] \ \overset{\langle * \rangle}{|\!\!\vdash\!\!-}_{\mathcal{C}} [p, S_1^* \cdot S, T, \mathcal{R}^{\langle S_1, * \rangle}].$$

*Right-product.* For every $p, n \in \mathbb{N}$, $\delta, \lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\delta}\langle\langle\ V\ \rangle\rangle$, $T \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\ V\ \rangle\rangle$, $\mathcal{R} \in \bar{\mathcal{B}}_n$,

$$[p, S, S', \mathcal{R}] \ \overset{\langle * \rangle}{|\!\!\vdash\!\!-}_{\mathcal{C}} [p, S \cdot T, S' \cdot T, \langle S | \mathcal{R} \rangle].$$

*Left-product.* For every $p, n \in \mathbb{N}$, $\delta, \lambda \in \mathbb{N} - \{0\}$, $S \in \mathsf{DRB}_{1,\delta}\langle\langle\ V\ \rangle\rangle$, $T, T' \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\ V\ \rangle\rangle$, $\mathcal{R}_1, \ldots, \mathcal{R}_\delta \in \bar{\mathcal{B}}_n$,

$$\bigcup_{1 \le i \le \delta} [p, T_{i,*}, T'_{i,*}, \mathcal{R}_i] \ \overset{\langle * \rangle}{|\!\!\vdash\!\!-}_{\mathcal{C}} [p, S \cdot T, S \cdot T', \langle S, \mathcal{R} \rangle].$$

Given a subset $P \in \mathcal{P}_f(\mathcal{A})$, we define the *congruence closure* of $P$, denoted by $\mathrm{Cong}(P)$, to be the set

$$\mathrm{Cong}(P) = \{A \in \mathcal{A} \mid P \ \overset{\langle * \rangle}{|\!\!\vdash\!\!-}_{\mathcal{C}} \{A\}\}. \tag{4.12}$$

Also, for every integer $q \ge 0$ we define

$$\mathrm{Cong}_q(P) = \{A \in \mathcal{A} \mid P \ \overset{\langle q \rangle}{|\!\!\vdash\!\!-}_{\mathcal{C}} \{A\}\}. \tag{4.13}$$

## 5. Deterministic spaces.

### 5.1. Linear independence.

We adapt here the key idea of [23, 24] to bisimulation of vectors.

*Definitions.* Let $(W, \sim)$ be some structured alphabet. A vector $U = \sum_{i=1}^n \gamma_i \cdot U_i$ where $\vec{\gamma} \in \mathsf{DRB}_{1,n}\langle\langle\ W\ \rangle\rangle$, $U_i \in \mathsf{DRB}_{1,\lambda}\langle\langle\ W\ \rangle\rangle$ is called a *linear combination* of the $U_i$'s. We define as a *deterministic space* of rational vectors (d-space for short) any subset $\mathsf{V}$ of $\mathsf{DRB}_{1,\lambda}\langle\langle\ W\ \rangle\rangle$ which is closed under finite linear combinations. Given any set $\mathcal{G} = \{U_i \mid i \in I\} \subseteq \mathsf{DRB}_{1,\lambda}\langle\langle\ W\ \rangle\rangle$, one can check that the set $\mathsf{V}$ of all (finite) linear combinations of elements of $\mathcal{G}$ is a d-space (by Lemma 3.11) and that it is the smallest d-space containing $\mathcal{G}$. Therefore we call $\mathsf{V}$ the d-space *generated* by $\mathcal{G}$ and we call $\mathcal{G}$ a *generating set* of $\mathsf{V}$ (we note $\mathsf{V} = \mathsf{V}(\{U_i \mid i \in I\})$). (Similar definitions can be given for *families* of vectors.)

*Linear independence.* We now let $W = V$. Following an analogy with classical linear algebra, we now develop a notion corresponding to a kind of *linear independence* of the classes (mod $\sim$) of the given vectors. Let us extend the equivalence relation $\sim$ to d-spaces, as follows: if $\mathsf{V}_1, \mathsf{V}_2$ are d-spaces,

$$\mathsf{V}_1 \sim \mathsf{V}_2 \Leftrightarrow \forall i, j \in \{1, 2\}, \forall S \in \mathsf{V}_i, \exists S' \in \mathsf{V}_j, S \sim S'.$$

LEMMA 5.1. *Let $S_1, \ldots, S_j, \ldots, S_m \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$. The following are equivalent:*

(1) $\exists \vec{\alpha}, \vec{\beta} \in \mathsf{DRB}_{1,m}\langle\langle\ V\ \rangle\rangle$, $\vec{\alpha} \not\sim \vec{\beta}$, *such that*

$$\sum_{j=1}^m \alpha_j \cdot S_j \sim \sum_{j=1}^m \beta_j \cdot S_j.$$

(2) $\exists j_0 \in [1,m]$, $\exists \vec{\gamma} \in \mathsf{DRB}_{1,m}\langle\langle\ V\ \rangle\rangle$, $\vec{\gamma} \not\sim \epsilon^m_{j_0}$, *such that*

$$S_{j_0} \sim \sum_{j=1}^{m} \gamma_j \cdot S_j.$$

(3) $\exists j_0 \in [1,m]$, $\exists \vec{\gamma}' \in \mathsf{DRB}_{1,m}\langle\langle\ V\ \rangle\rangle$, $\gamma'_{j_0} \sim \emptyset$, *such that*

$$S_{j_0} \sim \sum_{j=1}^{m} \gamma'_j \cdot S_j.$$

(4) $\exists j_0 \in [1,m]$, *such that*

$$\mathsf{V}((S_j)_{1\le j\le m}) \sim \mathsf{V}((S_j)_{1\le j\le m, j\ne j_0}).$$

The equivalence between (1), (2), and (3) was first proved in [23, 24] in the case where the $S_j$'s are configurations $q_j\omega$, with the same $\omega$ and $\bar{\psi} = \mathrm{Id}_{X^*}$, and hence $\sim$ is just the language equivalence relation $\equiv$. This is the key idea around which we have developed the notion of d-spaces.

*Proof.* **(1) ⇒ (2):** Let us consider $\mathcal{R} \in \mathcal{B}_\infty(\vec{\alpha}\cdot S, \vec{\beta}\cdot S)$, $\nu = \mathrm{Div}(\vec{\alpha}, \vec{\beta})$, and

$$\begin{aligned}(u,v) = \min\{(w,w') \in \mathcal{R} \cap X^{\le\nu} \times X^{\le\nu} \mid \exists j \in [1,m],\\ (\vec{\alpha}\odot w = \epsilon^m_j) \Leftrightarrow (\vec{\beta}\odot w' \ne \epsilon^m_j)\}.\end{aligned} \tag{5.1}$$

Let us suppose, for example, that $\vec{\alpha}\odot u = \epsilon^m_{j_0}$ while $\vec{\beta}\odot v \ne \epsilon^m_{j_0}$ and let $\vec{\gamma} = \vec{\beta}\odot u$. As $(u,v) \in \mathcal{R} \in \mathcal{B}_\infty(\vec{\alpha}\cdot S, \vec{\beta}\cdot S)$,

$$(\vec{\alpha}\cdot S)\odot u \sim (\vec{\beta}\cdot S)\odot v. \tag{5.2}$$

Using Lemma 3.15 we obtain

$$(\vec{\alpha}\cdot S)\odot u = S_{j_0}. \tag{5.3}$$

Let us examine now the right-hand side of equality (5.2). Let $(u',v') \prec (u,v)$ with $|u'| = |v'|$. By condition (4) in Definition 3.21 $(u',v') \in \mathcal{R}$ (here is the main place where this condition (4) is used) and by minimality of $v$, $\vec{\beta}\odot v'$ is a unit iff $\vec{\alpha}\odot u'$ is a unit. But if $\vec{\alpha}\odot u'$ is a unit, then $\vec{\alpha}\odot u = \emptyset$, which is false. Hence $\vec{\beta}\odot v'$ is not a unit. Hence, $\forall v' \prec v$, $\vec{\beta}\odot v'$ is not a unit. By Lemma 3.15

$$(\vec{\beta}\cdot S)\odot v = (\vec{\beta}\odot v)\cdot S. \tag{5.4}$$

Let us plug equalities (5.3) and (5.4) into equivalence (5.2) and let us define $\vec{\gamma} = \vec{\beta}\odot v$. We obtain

$$S_{j_0} \sim \vec{\gamma}\cdot S, \qquad \vec{\gamma} \ne \epsilon^m_{j_0}.$$

**(2) ⇒ (3):**

$$S_{j_0} \sim \gamma_{j_0}\cdot S_{j_0} + \left(\sum_{j\ne j_0} \gamma_j \cdot S_j\right), \quad \gamma_{j_0} \ne \epsilon.$$

By Corollary 4.10, point (C1), we can deduce that

$$S_{j_0} \sim \sum_{j \neq j_0} \gamma_{j_0}^* \gamma_j \cdot S_j = \nabla_{j_0}^*(\gamma) \cdot S.$$

Taking $\gamma' = \nabla_{j_0}^*(\gamma)$ we obtain

$$S_{j_0} \sim \gamma' \cdot S, \text{ where } \gamma'_{j_0} = \emptyset.$$

**(3) ⇒ (4):** Let us denote by $\hat{S}$ the vector $(S_1, \ldots, S_{j_0-1}, \emptyset, S_{j_0+1} \ldots, S_m) \in \mathsf{DB}_{m,1}\langle\langle\, V\,\rangle\rangle$. If $T = \vec{\alpha} \cdot S$, then $T \sim (\vec{\alpha}\nabla_{j_0}\vec{\gamma'}) \cdot \hat{S}$.

**(4) ⇒ (1):** Let us suppose (4) is true for some integer $j_0$. The element $S_{j_0}$ is clearly equivalent (mod $\sim$) to two linear combinations of the $S_j$'s with nonequivalent vectors of coefficients (mod $\sim$). Hence (1) is true. □

**5.2. Triangulations.** Let $S_1, S_2, \ldots, S_d$ be a family of deterministic row-vectors over the structured alphabet $V$ (i.e., $S_i \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$, where $\lambda \in \mathbb{N} - \{0\}$). We recall that $V$ is the alphabet associated with some dpda $\mathcal{M}$ as defined in section 2.4.

Let us consider a sequence $\mathcal{S}$ of $n$ "weighted" linear equations:

$$(\mathcal{E}_i) : p_i, \sum_{j=1}^{d} \alpha_{i,j} S_j, \sum_{j=1}^{d} \beta_{i,j} S_j, \tag{5.5}$$

where $p_i \in \mathbb{N} - \{0\}$, and $A = (\alpha_{i,j})$, $B = (\beta_{i,j})$ are deterministic rational matrices of dimension $(n, d)$, with indices $m \leq i \leq m + n - 1$, $1 \leq j \leq d$.

For any weighted equation, $\mathcal{E} = (p, S, S')$, we recall that the "cost" of this equation is $H(\mathcal{E}) = p + 2 \cdot \mathrm{Div}(S, S')$.

Let us define an *oracle* on deterministic vectors as a mapping $\mathcal{O} : \bigcup_{\lambda \geq 1} \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle \to \mathcal{P}(X^* \times X^*)$ such that

$$\forall (S, S') \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle, \quad S \sim S' \Rightarrow \mathcal{O}(S, S') \in \mathcal{B}_\infty(S, S').$$

In other words, an oracle is a *choice* of $w$-$\bar{\psi}$-bisimulation for every pair of equivalent vectors (modulo $\sim$). Let us denote by $\Omega$ the set of all oracles. Let us fix an oracle $\mathcal{O}$ throughout this section.

We associate to every system (5.5) another equation, $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})$, which "translates the equations of $\mathcal{S}$ into equations over the coefficients $(\alpha_{i,j}, \beta_{i,j})$ only."[2] The general idea of the construction of $\mathrm{INV}^{(\mathcal{O})}$ consists in iterating the transformation used in the proof of (1) ⇒ (2) ⇒ (3) in Lemma 5.1, i.e., the classical idea of *triangulating* a system of linear equations. Of course we must deal with the weights and relate the construction with the deduction system $\mathcal{B}_0$.

We assume here that

$$\forall j \in [1, d], \quad S_j \neq \emptyset^\lambda. \tag{5.6}$$

Let us define $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}), \mathrm{W}^{(\mathcal{O})}(\mathcal{S}) \in \mathbb{N} \cup \{\perp\}$, $\mathrm{D}^{(\mathcal{O})}(\mathcal{S}) \in \mathbb{N}$ by induction on $n$. $\mathrm{W}^{(\mathcal{O})}(\mathcal{S})$ is the *weight* of $\mathcal{S}$. $\mathrm{D}^{(\mathcal{O})}(\mathcal{S})$ is the *weak codimension* of $\mathcal{S}$.

[2]The function INV defined in [34] was an "elaborated version" of the *inverse* systems defined in [23, 24] in the case of a single equation. We consider here a *relativization* of this notion to some oracle $\mathcal{O}$.

*Case* 1. $\alpha_{m,*} \sim \beta_{m,*}$.

$$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) = (\mathrm{W}^{(\mathcal{O})}(\mathcal{S}), \alpha_{m,*}, \beta_{m,*}), \quad \mathrm{W}^{(\mathcal{O})}(\mathcal{S}) = p_m - 1, \quad \mathrm{D}^{(\mathcal{O})}(\mathcal{S}) = 0.$$

*Case* 2. $\alpha_{m,*} \not\sim \beta_{m,*}$, $n \geq 2$, $p_{m+1} - p_m \geq 2 \cdot \mathrm{Div}(\alpha_{m,*}, \beta_{m,*}) + 1$. Let us consider $\mathcal{R} = \mathcal{O}(\sum_{j=1}^{d} \alpha_{m,j} S_j, \sum_{j=1}^{d} \beta_{m,j} S_j)$, $\nu = \mathrm{Div}(\alpha_{m,*}, \beta_{m,*})$, and

$$(u, u') = \min\{(v, v') \in \mathcal{R} \cap X^{\leq \nu} \times X^{\leq \nu} \mid \exists j \in [1, d], \\ (\alpha_{m,*} \odot v = \epsilon_j^{\lambda}) \Leftrightarrow (\beta_{m,*} \odot v' \neq \epsilon_j^{\lambda})\}. \tag{5.7}$$

Let us consider the integer $j_0 \in [1, d]$ such that $(\alpha_{m,*} \odot u = \epsilon_{j_0}^{\lambda}) \Leftrightarrow (\beta_{m,*} \odot u' \neq \epsilon_{j_0}^{\lambda})$.

*Subcase* 1. $\alpha_{m,j_0} \odot u = \varepsilon$, $\beta_{m,j_0} \odot u' \neq \varepsilon$. Let us consider the equation

$$(\mathcal{E}'_m) : p_m + 2 \cdot |u|,\ S_{j_0},\ \sum_{\substack{j=1 \\ j \neq j_0}}^{d} (\beta_{m,j_0} \odot u')^* (\beta_{m,j} \odot u') S_j$$

and define a new system of weighted equations $\mathcal{S}' = (\mathcal{E}'_i)_{m+1 \leq i \leq m+n-1}$ by

$$(\mathcal{E}'_i) : p_i,\ \sum_{j \neq j_0} [(\alpha_{i,j} + \alpha_{i,j_0} (\beta_{m,j_0} \odot u')^* (\beta_{m,j} \odot u')] S_j, \\ \sum_{j \neq j_0} [(\beta_{i,j} + \beta_{i,j_0} (\beta_{m,j_0} \odot u')^* (\beta_{m,j} \odot u')] S_j, \tag{5.8}$$

where the above equation is seen as an equation between two linear combinations of the $S_i$'s, $1 \leq i \leq d$, where the $j_0$th coefficient is $\emptyset$ on both sides. We then define

$$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) = \mathrm{INV}^{(\mathcal{O})}(\mathcal{S}'), \quad \mathrm{W}^{(\mathcal{O})}(\mathcal{S}) = \mathrm{W}^{(\mathcal{O})}(\mathcal{S}'), \quad \mathrm{D}^{(\mathcal{O})}(\mathcal{S}) = \mathrm{D}^{(\mathcal{O})}(\mathcal{S}') + 1.$$

*Subcase* 2. $\alpha_{m,j_0} \odot u \neq \varepsilon$, $\beta_{m,j_0} \odot u' = \varepsilon$ (analogous to Subcase 1).

*Case* 3. $\alpha_{m,*} \not\sim \beta_{m,*}$, $n = 1$. We then define

$$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) = \perp, \quad \mathrm{W}^{(\mathcal{O})}(\mathcal{S}) = \perp, \quad \mathrm{D}^{(\mathcal{O})}(\mathcal{S}) = 0,$$

where $\perp$ is a special symbol which can be understood as meaning "undefined."

*Case* 4. $\alpha_{m,*} \not\sim \beta_{m,*}$, $n \geq 2$, $p_{m+1} - p_m \leq 2 \cdot \mathrm{Div}(\alpha_{m,*}, \beta_{m,*})$. We then define

$$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) = \perp, \quad \mathrm{W}^{(\mathcal{O})}(\mathcal{S}) = \perp, \quad \mathrm{D}^{(\mathcal{O})}(\mathcal{S}) = 0.$$

LEMMA 5.2. *Let $\mathcal{S}$ be a system of weighted linear equations with deterministic rational coefficients. If $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \neq \perp$, then $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})$ is a weighted linear equation with deterministic rational coefficients.*

*Proof.* The proof follows from Lemmas 3.18 and 3.19 and the formula defining $\mathcal{S}'$ from $\mathcal{S}$. □

From now on, and up to the end of this section, we simply write "linear equation" to mean "weighted linear equations with deterministic rational coefficients."

LEMMA 5.3. *Let $\mathcal{S}$ be a system of linear equations. If $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \neq \perp$, then*

(1) $\{\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})\} \cup \{\mathcal{E}_i \mid m \leq i \leq m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S}) - 1\} \mid\!\!\!-\!\!- \mathcal{E}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}$;

(2) $\min\{H(\mathcal{E}_i) \mid m \leq i \leq m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S})\} = \infty \Longrightarrow H(\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})) = \infty$.

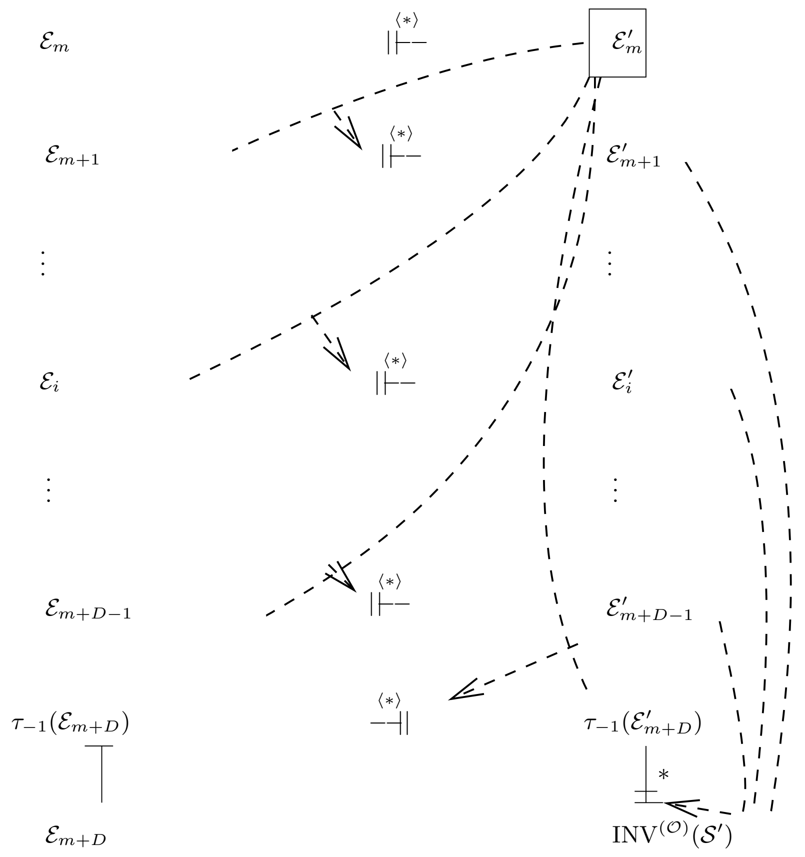

FIG. 2. *Proof of Lemma* 5.2.

*Proof.* See in Figure 2 the "graph of the deductions" we use for proving point (1). Let us prove by induction on $\mathrm{D}^{(\mathcal{O})}(\mathcal{S})$ the following strengthened version of point (1):

$$\{\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})\} \cup \{\mathcal{E}_i \mid m \leq i \leq m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S}) - 1\} \overset{\langle * \rangle}{||\!\!-\!\!-} \tau_{-1}(\mathcal{E}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}), \tag{5.9}$$

where, for every integer $k \in \mathbb{Z}$, $\tau_k : \{(p, S, S') \in \mathcal{A} \mid p \geq -k\} \to \mathcal{A}$ is the *translation* map on the weights $\tau_k(p, S, S') = (p + k, S, S')$.

**If $\mathbf{D}^{(\mathcal{O})}(\mathcal{S}) = 0$:** As $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \neq \perp$, $\mathcal{S}$ must fulfill the hypothesis of Case 1.

$$\mathcal{E}_m = \left(p_m, \sum_{j=1}^{d} \alpha_{m,j} S_j, \sum_{j=1}^{d} \beta_{m,j} S_j\right) = \mathcal{E}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})},$$

$$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) = (p_m - 1, \alpha_{m,*}, \beta_{m,*}).$$

Using rule (R7) we obtain

$$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \overset{\langle * \rangle}{||\!\!-\!\!-} \left(p_m - 1, \sum_{j=1}^{d} \alpha_{m,j} S_j, \sum_{j=1}^{d} \beta_{m,j} S_j\right) = \tau_{-1}(\mathcal{E}_m).$$

**If $\mathrm{D}^{(\mathcal{O})}(\mathcal{S}) = n+1$, $n \geq 0$:** $\mathcal{S}$ must fulfill Case 2.

• Suppose Case 2, Subcase 1 occurs.

As the relation $\mathcal{R}$ used in the construction of $\mathcal{E}'_m$ from $\mathcal{E}_m$ is a $w$-$\bar{\psi}$-bisimulation w.r.t. the pair of sides of equation $\mathcal{E}_m$, using (R5) and then (R6) (this is possible because $\beta_{m,j_0} \odot u' \neq \epsilon$), we obtain a deduction:

$$\mathcal{E}_m \overset{\langle 2\cdot|u|+1\rangle}{||\!\!-\!\!-} \mathcal{E}'_m. \tag{5.10}$$

Using (R2), (R8) we get that, for every $i \in [m+1, m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})]$,

$$\{\mathcal{E}_i, \mathcal{E}'_m\} \overset{\langle * \rangle}{||\!\!-\!\!-}$$

$$\left(\max\{p_i, p_m + 2\,|u|\}, \sum_{j\neq j_0}(\alpha_{i,j} + \alpha_{i,j_0}(\beta_{m,j}\odot u'))S_j, \sum_{j\neq j_0}(\beta_{i,j} + \beta_{i,j_0}(\beta_{m,j}\odot u'))S_j\right)$$

but the hypothesis of Case 2 implies that $\max\{p_{m+1}, p_m + 2 \mid u \mid\} = p_{m+1}$, and the fact that $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}')$ is defined implies that $\forall i \in [m+1, m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})]$, $p_i \geq p_{m+1}$; hence, $\max\{p_i, p_m + 2 \mid u \mid\} = p_i$ and the right-hand side of the above deduction is exactly $\mathcal{E}'_i$. Therefore,

$$\forall i \in [m+1, m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})], \quad \{\mathcal{E}_i, \mathcal{E}'_m\} \overset{\langle * \rangle}{||\!\!-\!\!-} \mathcal{E}'_i. \tag{5.11}$$

Using deductions (5.10) and (5.11), we obtain that

$$\{\mathcal{E}_i \mid m \leq i \leq m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})-1\} \overset{\langle * \rangle}{||\!\!-\!\!-} \{\mathcal{E}'_i \mid m \leq i \leq m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})-1\}. \tag{5.12}$$

By the induction hypothesis,

$$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}') \cup \{\mathcal{E}'_i \mid m+1 \leq i \leq m+1+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}')-1\} \overset{\langle * \rangle}{||\!\!-\!\!-} \tau_{-1}(\mathcal{E}'_{m+1+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}')}),$$

which is equivalent to

$$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \cup \{\mathcal{E}'_i \mid m+1 \leq i \leq m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})-1\} \overset{\langle * \rangle}{||\!\!-\!\!-} \tau_{-1}(\mathcal{E}'_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}). \tag{5.13}$$

As $p_m + 2\cdot|u| \leq p_{m+1} - 1 \leq p_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})} - 1$, we have also the following inverse deduction (which is similar to deduction (5.11)):

$$\{\mathcal{E}'_m, \tau_{-1}(\mathcal{E}'_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})})\} \overset{\langle * \rangle}{||\!\!-\!\!-} \tau_{-1}(\mathcal{E}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}). \tag{5.14}$$

Combining deductions (5.12), (5.13), and (5.14), we have proved (5.9). Using rule (R0), this last deduction leads to point (1) of the lemma.

• Suppose now that Case 2, Subcase 2 occurs.

This case can be treated in the same way as Subcase 1, by simply exchanging the roles of $\alpha, \beta$.

Let us prove statement (2) of the lemma.

We prove by induction on $\mathrm{D}^{(\mathcal{O})}(\mathcal{S})$ the statement

$$\min\{H(\mathcal{E}_i) \mid m \leq i \leq m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S})\} = \infty \Longrightarrow H(\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})) = \infty. \tag{5.15}$$

**If $\mathbf{D}^{(\mathcal{O})}(\mathcal{S}) = 0$:** As $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \neq \perp$, Case 1 must occur. $\alpha_{m,*} \sim \beta_{m,*}$ implies that $H(\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})) = \infty$, and hence the statement is true.

**If $\mathbf{D}^{(\mathcal{O})}(\mathcal{S}) = p + 1$, $p \geq 0$:** As $\mathrm{D}^{(\mathcal{O})}(\mathcal{S}) \geq 1$ and $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \neq \perp$, Case 2 must occur.

Using deductions (5.10) and (5.11) established above we obtain that

$$\{\mathcal{E}_i \mid m \leq i \leq m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S})\} \overset{\langle * \rangle}{||\!\!-\!\!-} \{\mathcal{E}'_i \mid m + 1 \leq i \leq m + 1 + \mathrm{D}^{(\mathcal{O})}(\mathcal{S}')\},$$

which proves that

$$\min\{H(\mathcal{E}_i) \mid m \leq i \leq m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S})\} \leq \min\{H(\mathcal{E}'_i) \mid m + 1 \leq i \leq m + 1 + \mathrm{D}^{(\mathcal{O})}(\mathcal{S}')\}. \tag{5.16}$$

Since $\mathrm{D}^{(\mathcal{O})}(\mathcal{S}') = \mathrm{D}^{(\mathcal{O})}(\mathcal{S}) - 1$, we can use the induction hypothesis

$$\min\{H(\mathcal{E}'_i) \mid m + 1 \leq i \leq m + 1 + D(\mathcal{S}')\} = \infty \Longrightarrow H(\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}')) = \infty. \tag{5.17}$$

Since $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) = \mathrm{INV}^{(\mathcal{O})}(\mathcal{S}')$, (5.16), (5.17) imply statement (5.15). $\square$

LEMMA 5.4. *Let $\mathcal{S}$ be a system of linear equations satisfying the hypothesis of Case 2. Then, $\forall i \in [m+1, m+n-1]$,*

$$\| \alpha'_{i,*} \| \leq \| \alpha_{i,*} \| + \| \beta_{m,*} \| + K_0 \mid u \mid,$$
$$\| \beta'_{i,*} \| \leq \| \beta_{i,*} \| + \| \beta_{m,*} \| + K_0 \mid u \mid .$$

*Proof.* The formula defining $\mathcal{S}'$ from $\mathcal{S}$ shows that

$$\alpha'_{i,*} = \alpha_{i,*} \nabla_{j_0}(\nabla^*_{j_0}(\beta_{m,*} \odot u')),$$
$$\beta'_{i,*} = \beta_{i,*} \nabla_{j_0}(\nabla^*_{j_0}(\beta_{m,*} \odot u')).$$

From these equalities and Lemmas 3.18, 3.19, and 3.13, the inequalities on the norm follow. $\square$

Let us consider the function $F$ defined by

$$F(d, n) = \max\{\mathrm{Div}(A, B) \mid A, B \in \mathsf{DRB}_{1,d}\langle\langle V \rangle\rangle, \| A \| \leq n, \| B \| \leq n, A \not\sim B\}.$$

For every integer parameter $K_0, K_1, K_2, K_3, K_4 \in \mathbb{N} - \{0\}$, we define integer sequences $(\delta_i, \ell_i, L_i, s_i, S_i, \Sigma_i)_{m \leq i \leq m+n-1}$ by

(5.18) $$\delta_m = 0,\ \ell_m = 0,\ L_m = K_2,\ s_m = K_3 \cdot K_2 + K_4,\ S_m = 0,\ \Sigma_m = 0,$$

(5.19) $$\begin{cases} \delta_{i+1} = 2 \cdot F(d, s_i + \Sigma_i) + 1, \\ \ell_{i+1} = 2 \cdot \delta_{i+1} + 3, \\ L_{i+1} = K_1 \cdot (L_i + \ell_{i+1}) + K_2, \\ s_{i+1} = K_3 \cdot L_{i+1} + K_4, \\ S_{i+1} = s_i + \Sigma_i + K_0 F(d, s_i + \Sigma_i), \\ \Sigma_{i+1} = \Sigma_i + S_{i+1} \end{cases}$$

for $m \leq i \leq m + n - 2$.

These sequences are intended to have the following meanings when $K_0, K_1, K_2, K_3, K_4$ are chosen to be the constants defined in section 6 and the equations $(\mathcal{E}_i)$ are labeling nodes of a B-stacking sequence (see section 8.2):

- $\delta_{i+1} \leq$ increase of weight between $\mathcal{E}_i, \mathcal{E}_{i+1}$.
- $\ell_{i+1} \geq$ increase of depth between $\mathcal{E}_i, \mathcal{E}_{i+1}$.
- $L_{i+1} \geq$ increase of depth between $\mathcal{E}_m, \mathcal{E}_{i+1}$.
- $s_{i+1} \geq$ size of the coefficients of $\mathcal{E}_{i+1}$.
- $S_{i+1} \geq$ size of the coefficients of $\mathcal{E}_{i+1}^{(i+1-m)}$ (these systems are introduced below in the proof of Lemma 5.5).
- $\Sigma_{i+1} \geq$ increase of the coefficients between $\mathcal{E}_k^{(i-m)}$, $\mathcal{E}_k^{(i+1-m)}$ (for $k \geq i + 1$).

For every linear equation $\mathcal{E} = (p, \sum_{j=1}^{d} \alpha_j S_j, \sum_{j=1}^{d} \beta_j S_j)$, we define

$$||| \mathcal{E} ||| = \max\{\| (\alpha_1, \ldots, \alpha_d) \|, \| (\beta_1, \ldots, \beta_d) \|\}.$$

LEMMA 5.5. *Let $\mathcal{S} = (\mathcal{E}_i)_{m \leq i \leq m+d-1}$ be a system of $d$ linear equations such that $H(\mathcal{E}_i) = \infty$ (for every $i$) and*

(1) *$\forall i \in [m, m + d - 1]$, $||| \mathcal{E}_i ||| \leq s_i$,*
(2) *$\forall i \in [m, m + d - 2]$, $\mathrm{W}(\mathcal{E}_{i+1}) - \mathrm{W}(\mathcal{E}_i) \geq \delta_{i+1}$.*

*Then*

(3) *$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \neq \perp$,*
(4) *$\mathrm{D}^{(\mathcal{O})}(\mathcal{S}) \leq d - 1$,*
(5) *$||| \mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) ||| \leq \Sigma_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})} + s_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}$.*

*Proof.* (Figure 3 might help the reader to follow the definitions below.) Let us define a sequence of systems $\mathcal{S}^{(i-m)} = (\mathcal{E}_k^{(i-m)})_{m \leq i \leq k \leq m+d-1}$, where $i \in [m, m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S})]$; by induction

- $\mathcal{E}_k^{(0)} = \mathcal{E}_k$ for $m \leq k \leq m + d - 1$;
- if Case 1 or Case 3 or Case 4 is realized, $\mathrm{D}^{(\mathcal{O})}(\mathcal{S}) = 0$; hence $\mathcal{S}^{(i-m)}$ is well-defined for $m \leq i \leq m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S})$;
- if Case 2 is realized, then we set, $\forall i \geq m + 1$, $\mathcal{E}_k^{(i-m)} = (\mathcal{E}'_k)^{(i-m-1)}$ for $m + 1 \leq k \leq m + d - 1$.

Let us prove by induction on $i \in [m, m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S})]$ that, $\forall k \in [i, m + d - 1]$,

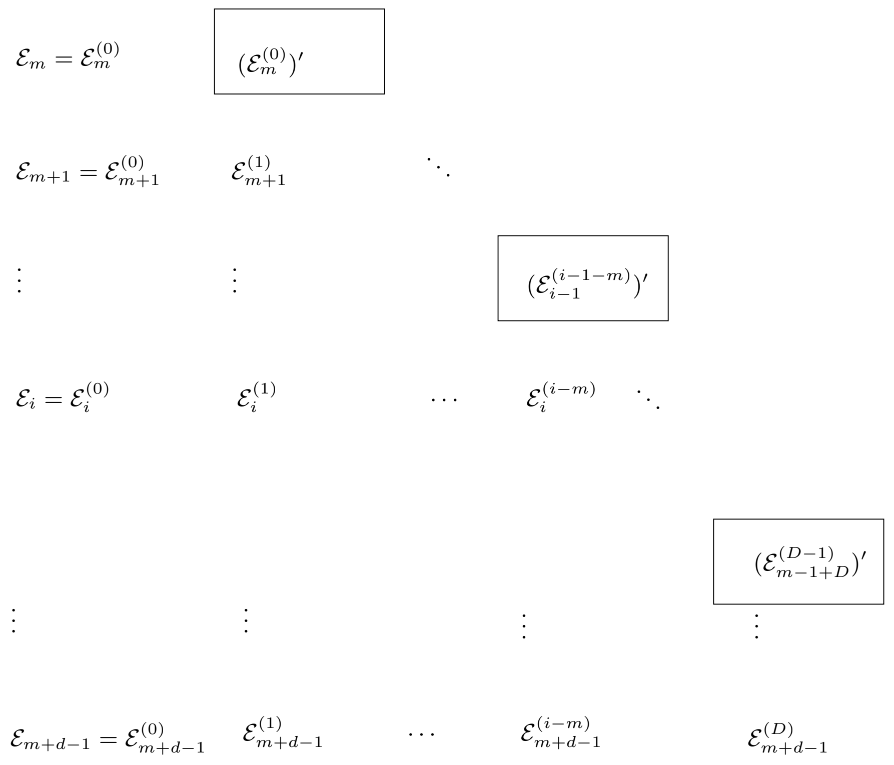
(5.20) $$||| \mathcal{E}_k^{(i-m)} ||| \leq s_k + \Sigma_i.$$

***i* = *m*:** In this case

$$||| \mathcal{E}_k^{(i-m)} ||| = ||| \mathcal{E}_k ||| \leq s_k = s_k + \Sigma_m.$$

**$i + 1 \leq m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S})$:** In this case, by Lemma 5.4,

$$||| \mathcal{E}_k^{(i+1-m)} ||| \leq ||| \mathcal{E}_k^{(i-m)} ||| + ||| \mathcal{E}_i^{(i-m)} ||| + K_0 \mid u \mid,$$



$\mathcal{E}_m = \mathcal{E}_m^{(0)}$
$(\mathcal{E}_m^{(0)})'$
$\mathcal{E}_{m+1} = \mathcal{E}_{m+1}^{(0)}$
$\mathcal{E}_{m+1}^{(1)}$
$(\mathcal{E}_{i-1}^{(i-1-m)})'$
$\mathcal{E}_i = \mathcal{E}_i^{(0)}$
$\mathcal{E}_i^{(1)}$
$\mathcal{E}_i^{(i-m)}$
$(\mathcal{E}_{m-1+D}^{(D-1)})'$
$\mathcal{E}_{m+d-1} = \mathcal{E}_{m+d-1}^{(0)}$
$\mathcal{E}_{m+d-1}^{(1)}$
$\mathcal{E}_{m+d-1}^{(i-m)}$
$\mathcal{E}_{m+d-1}^{(D)}$

FIG. 3. *Proof of Lemma* 5.4.

where $\mathcal{R} = \mathcal{O}(\sum_{j=1}^{d} \alpha_{i,j}^{(i-m)} S_j, \sum_{j=1}^{d} \beta_{i,j}^{(i-m)} S_j)$, $\nu = \mathrm{Div}(\alpha_{i,*}^{(i-m)}, \beta_{i,*}^{(i-m)})$, and

$$(u, u') = \min\{(v, v') \in \mathcal{R} \cap X^{\leq \nu} \times X^{\leq \nu} \mid \exists j \in [1, d],$$
$$(\alpha_{i,*}^{(i-m)} \odot v = \epsilon_j^{\lambda}) \Leftrightarrow (\beta_{i,*}^{(i-m)} \odot v' \neq \epsilon_j^{\lambda})\}.$$

By definition of $F$ and the induction hypothesis,

$$\mid u \mid \leq F(d, \||\, \mathcal{E}_i^{(i-m)} \,\||) \leq F(d, s_i + \Sigma_i).$$

Hence

$$\begin{aligned} \||\, \mathcal{E}_k^{(i+1-m)} \,\|| \leq (s_k + \Sigma_i) + (s_i + \Sigma_i) + K_0 F(d, s_i + \Sigma_i) &= (s_k + \Sigma_i) + S_{i+1} \\ &= s_k + \Sigma_{i+1}. \end{aligned}$$

Let us note that $\mathrm{D}^{(\mathcal{O})}(\mathcal{S})$ is always an integer and that this proof is valid for $m \leq i \leq m + \mathrm{D}^{(\mathcal{O})}(\mathcal{S})$, $i \leq k \leq m + d - 1$.

We now prove that $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \neq \perp$. Let us consider the system

$$(\mathcal{E}_k^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))})_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}) \leq k \leq m+d-1}.$$

**If $\mathbf{D^{(\mathcal{O})}(\mathcal{S}) = d-1}$:** $(\mathcal{E}^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))})$ fulfills either Case 1 or Case 3 of the definition of $\mathrm{INV}^{(\mathcal{O})}$ (just because this system consists of a single equation).

Using the successive deductions (5.10), (5.11) established in the proof of Lemma 5.3 we get that

$$\{\mathcal{E}_i \mid m \leq i \leq m+d-1\} \overset{\langle * \rangle}{||\!\!-\!\!-} \{\mathcal{E}^{(d-1)}_{m+d-1}\}.$$

Using now the hypothesis that $H(\mathcal{E}_i) = \infty$ (for $m \leq i \leq m+d-1$), we obtain

$$H(\mathcal{E}^{(d-1)}_{m+d-1}) = \infty. \tag{5.21}$$

For any system of equations $\mathcal{S}$, let us define the *support* of the system as

$$\operatorname{supp}(\mathcal{S}) = \left\{ j \in [1,d] \;\middle|\; \sum_{i=m}^{m+n-1} \alpha_{i,j} + \beta_{i,j} \neq \emptyset \right\}.$$

Let us consider $\delta = \operatorname{Card}(\operatorname{supp}(\mathcal{S}^{(d-1)})$. One can prove by induction on $i$ that

$$\operatorname{Card}(\operatorname{supp}(\mathcal{S}^{(i-m)}) \leq d - i + m,$$

and hence

$$\delta = \operatorname{Card}(\operatorname{supp}(\mathcal{S}^{(d-1)}) \leq d - (d-1) = 1.$$

- If $\delta = 1$, $\operatorname{supp}(\mathcal{S}^{(d-1)}) = \{j_0\}$ for some $j_0 \in [1,d]$.
  By Corollary 4.10, point (C3), and by hypothesis (5.6), the implication

  $$[(\alpha^{(d-1)}_{m+d-1,j_0} S_{j_0} \sim \beta^{(d-1)}_{m+d-1,j_0} S_{j_0}) \Longrightarrow \alpha^{(d-1)}_{m+d-1,j_0} \sim \beta^{(d-1)}_{m+d-1,j_0}]$$

  holds. Hence, by (5.21), $\alpha^{(d-1)}_{m+d-1,j_0} \sim \beta^{(d-1)}_{m+d-1,j_0}$; i.e., $\mathcal{S}^{(d-1)}$ fulfills Case 1, so that

  $$\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) = \mathrm{INV}^{(\mathcal{O})}(\mathcal{S}^{(d-1)}) \neq \perp.$$

- If $\delta = 0$, $\operatorname{supp}(\mathcal{S}) = \emptyset$.
  Then $\alpha^{(d-1)}_{m+d-1,*} = \beta^{(d-1)}_{m+d-1,*} = \emptyset^d$. Here also $\mathcal{S}^{(d-1)}$ fulfills Case 1.

**If $\mathbf{D}^{(\mathcal{O})}(\mathcal{S}) < d-1$:** By the hypothesis,

$$\begin{aligned}\mathrm{W}(\mathcal{E}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})+1}) - \mathrm{W}(\mathcal{E}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}) &\geq \delta_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})+1} \\ &= 2F(d, s_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})} + \Sigma_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}) + 1.\end{aligned}$$

If $\alpha^{\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}),*} \sim \beta^{\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}),*}$, then $\mathcal{E}^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}$ fulfills Case 1 of the definition of $\mathrm{INV}^{(\mathcal{O})}$; hence $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \neq \perp$.

Otherwise, let us consider

$$\mathcal{R} = \mathcal{O}\left( \sum_{j=1}^{d} \alpha^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}),j} S_j, \sum_{j=1}^{d} \beta^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}),j} S_j \right),$$

$$\nu = \operatorname{Div}\left( \alpha^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}),*}, \beta^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}),*} \right), \text{ and}$$

$$(u,u') = \min\left\{ (v,v') \in \mathcal{R} \cap X^{\leq \nu} \times X^{\leq \nu} \;\middle|\; \exists j \in [1,d], \left( \alpha^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}),*} \odot v = \epsilon^{\lambda}_{j} \right) \Leftrightarrow \left( \beta^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S}),*} \odot v' \neq \epsilon^{\lambda}_{j} \right) \right\}.$$

By the definition of $F$ and inequality (5.20),

$$| u | \leq F\left(d, \left\| \left\| \mathcal{E}^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})} \right\| \right\|\right) \leq F(d, s_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})} + \Sigma_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}).$$

Hence $p_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})+1} - p_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})} \geq 2|u| + 1$; i.e., the hypothesis of Case 2 is realized. This proves that $\mathrm{D}^{(\mathcal{O})}(\mathcal{S}^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}) \geq 1$, while in fact $\mathrm{D}^{(\mathcal{O})}(\mathcal{S}^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}) = 0$. This contradiction shows that this last case ($\mathrm{D}^{(\mathcal{O})}(\mathcal{S}) < d - 1$ and $\mathcal{E}^{(\mathrm{D}^{(\mathcal{O})}(\mathcal{S}))}_{m+\mathrm{D}^{(\mathcal{O})}(\mathcal{S})}$ not fulfilling Case 1 of definition of $\mathrm{INV}^{(\mathcal{O})}$) is impossible. We have proved point (3) of the lemma. ∎

## 6. Constants.

**6. Constants.** Let us *fix* a birooted dpda $\mathcal{M}$, a strong relational morphism $\bar{\psi}$, and an initial equation $A_0 = (\Pi_0, S_0^-, S_0^+) \in \mathbb{N} \times \mathsf{DRB}_{1,\lambda_0}\langle\langle\ V\ \rangle\rangle \times \mathsf{DRB}_{1,\lambda_0}\langle\langle\ V\ \rangle\rangle$ in the corresponding set of assertions. This short section is devoted to the definition of some integer *constants*: these integers are constant in the sense that they depend only on this triple: $(\mathcal{M}, \bar{\psi}, A_0)$. The *motivation* of each of these definitions will appear later on, in different places for the different constants. The equations below provide merely an overview of the dependencies between these constants and allow us to check that the definitions are sound (i.e., there is no hidden loop in the dependencies).

$$k_0 = \max\{\nu(v) \mid v \in V\}, \quad k_1 = \max\{2k_0 + 1, 3\}, \tag{6.1}$$

$$K_0 = \max\{\|(E_1, E_2, \ldots, E_n) \odot x\| \mid (E_i)_{1 \leq i \leq n} \text{ is a bijective numbering of some class in } V/\smile,\ x \in X\}. \tag{6.2}$$

$K_0$ serves as an upper-bound on the possible increase of norm under the right-action of a single letter $x \in X$; see Lemma 3.13.

$$D_1 = k_0 \cdot K_0 + |Q| + 2, \quad k_2 = D_1 \cdot k_1 \cdot K_0 + 2 \cdot k_1 \cdot K_0 + K_0. \tag{6.3}$$

$k_1$ is used in the definition of strategy $T_B$ (section 7), $D_1$ appears as an upper-bound on the marked part of series, and $k_2$ is used in Lemma 8.4.

$$k_3 = k_2 + k_1 \cdot K_0, \quad k_4 = (k_3 + 1) \cdot K_0 + k_1. \tag{6.4}$$

$k_3$ appears in in Lemma 8.5, and $k_4$ is used in the definition (8.15) of the d-space $V_0$.

$$\begin{aligned} &K_1 = k_1 \cdot K_0 + 1, \\ &K_2 = k_1^2 \cdot D_1 \cdot K_0 + k_1^2 \cdot K_0 + 2 \cdot k_1 \cdot K_0 + D_1 \cdot k_1 + 2 \cdot k_1 + 4. \end{aligned} \tag{6.5}$$

These constants $K_1, K_2$ appear in Lemma 8.7.

$$K_3 = k_0|Q|, \quad K_4 = D_1. \tag{6.6}$$

These constants $K_3, K_4$ appear in Lemma 8.8.

$$d_0 = \mathrm{Card}(X^{\leq k_4}). \tag{6.7}$$

$d_0$ appears as an upper-bound on the dimension of the d-space $V_0$ defined by equation (8.15) and used in Lemma 8.7. We consider now the integer sequences $(\delta_i, \ell_i, L_i, s_i, S_i, \Sigma_i)_{m \leq i \leq m+n-1}$ defined by the relations (5.19) of section 5.2 where the parameters

$K_0, K_1, \ldots, K_4$ are chosen to be the above constants and $m = 1$, $n = d = d_0$. Equivalently, they are defined by

$$\delta_1 = 0,\ \ell_1 = 0,\ L_1 = K_2,\ s_1 = K_3 \cdot K_2 + K_4,\ S_1 = 0,\ \Sigma_1 = 0, \tag{6.8}$$

$$\begin{cases} \delta_{i+1} = 2 \cdot F(d_0, s_i + \Sigma_i) + 1, \\ \ell_{i+1} = 2 \cdot \delta_{i+1} + 3, \\ L_{i+1} = K_1 \cdot (L_i + \ell_{i+1}) + K_2, \\ s_{i+1} = K_3 \cdot L_{i+1} + K_4, \\ S_{i+1} = s_i + \Sigma_i + K_0 \cdot F(d_0, s_i + \Sigma_i), \\ \Sigma_{i+1} = \Sigma_i + S_{i+1} \end{cases} \tag{6.9}$$

for $1 \leq i \leq d_0 - 1$. The function $F$ is defined in section 5.2 and depends on the pair $(\mathcal{M}, \bar{\psi})$ only.

$$D_2 = \max\{\Sigma_{d_0} + s_{d_0}, \|S_0^-\|, \|S_0^+\|\}. \tag{6.10}$$

$\Sigma_{d_0} + s_{d_0}$ appears in the conclusion of Lemma 5.5 when we take $d = d_0$ in the hypothesis and suppose that $\mathrm{D}^{(\mathcal{O})}(\mathcal{S})$ has its maximal possible value, i.e., $\mathrm{D}^{(\mathcal{O})}(\mathcal{S}) = d_0 - 1$. It is used as an upper-bound on the norm of vectors at the root of the trees $\tau$ analyzed in section 8 (inequality (8.1)).

$$\lambda_2 = \max\{\lambda_0, d_0\}. \tag{6.11}$$

The integer $\lambda_2$ is used as an upper-bound on the length of vectors at the root of the trees $\tau$ analyzed in section 8 (inequality (8.2)).

$$N_0 = 1 + k_3 + D_2. \tag{6.12}$$

$N_0$ appears as a lower-bound for the norm in the definition of a B-stacking sequence (section 8.2, condition (8.5)).

## 7. Strategies for $\mathcal{B}_0$.

Let us define strategies for the particular system $\mathcal{B}_0$.

**7.1. Strategies.** We shall first define auxiliary strategies $T_{cut}, T_\emptyset, T_\varepsilon$; and then for every oracle $\mathcal{O} \in \Omega$ auxiliary strategies $T_A^{(\mathcal{O})}, T_B^{(\mathcal{O})}, T_C^{(\mathcal{O})}$, we define the strategies $T_A, T_B, T_C$ and finally the "compound" strategies $\mathcal{S}_{AB}^{(\mathcal{O})}, \mathcal{S}_{ABC}^{(\mathcal{O})}, \mathcal{S}_{AB}, \mathcal{S}_{ABC}$. Let us fix here some total ordering on $X : x_1 < x_2 < \cdots < x_\alpha$.

- $T_{cut}$:
  $B_1 \cdots B_m \in T_{cut}(A_1 \cdots A_n)$ iff $\exists i \in [1, n-1]$, $\exists S, T$,
  $$A_i = (p_i, S, T),\ A_n = (p_n, S, T),\ p_i < p_n, \text{ and } m = 0.[3]$$
- $T_\emptyset$:
  $B_1 \cdots B_m \in T_\emptyset(A_1 A_2 \cdots A_n)$ iff $\exists S, T$,
  $$A_n = (p, S, T),\ p \geq 0,\ S = T = \emptyset^\lambda, \text{ and } m = 0.$$
- $T_\varepsilon$:
  $B_1 \cdots B_m \in T_\varepsilon(A_1 \cdots A_n)$ iff
  $$A_n = (p, S, T),\ p \geq 0,\ S = T = \varepsilon_i^\lambda \text{ (for some } i \in [1, \lambda]\text{), and } m = 0.$$

[3]That is, $B_1 \cdots B_m = \epsilon$.

Let us consider an oracle $\mathcal{O} \in \Omega$.

- $T_A^{(\mathcal{O})}$:
  $B_1 \cdots B_m \in T_A^{(\mathcal{O})}(A_1 \cdots A_n)$ iff

$$A_n = (p, S, T), \quad | X | \leq m \leq | X |^2,$$

$$B_1 = (p+1, S \odot x_1, T \odot x'_1), \ldots, B_m = (p+1, S \odot x_m, T \odot x'_m),$$

  where $S \not\equiv \varepsilon$, $T \not\equiv \varepsilon$, $\mathcal{O}(S,T) \cap X \times X = \{(x_1, x'_1), \ldots, (x_i, x'_i), \ldots, (x_m, x'_m)\}$.
- $T_B^{(\mathcal{O}),+}$:
  $B_1 \cdots B_m \in T_B^+(A_1 \cdots A_n)$ iff $n \geq k_1 + 1$, $A_{n-k_1} = (\pi, \overline{U}, U')$ (where $\overline{U}$ is unmarked)

$$U' = \sum_{k=1}^{q} E_k \cdot \Phi_k \quad \text{for some } q \in \mathbb{N},\ E_k \in V,$$

  $(E_k)_{1 \leq k \leq q}$ is the bijective numbering of a class in $V/\smile$, $\Phi_k \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$, $A_i = (\pi + k_1 + i - n, U_i, U'_i)$ for $n - k_1 \leq i \leq n$, $(U_i)_{n-k_1 \leq i \leq n}$ is a derivation, $(U'_i)_{n-k_1 \leq i \leq n}$ is a "stacking derivation" (see definitions in section 3.3),

$$U'_n = \sum_{k=1}^{q} (E_k \odot u) \cdot \Phi_k \quad \text{for some } u \in X^*,$$

  $m = 1$, $B_1 = (\pi + k_1 - 1, V, V')$, $V = U_n$,

$$V' = \sum_{k=1}^{q} \bar{\rho}_e(E_k \odot u) \cdot (\overline{U} \odot u_k),$$

  where $\forall k \in [1,q]$, $u'_k = \min(\varphi(E_k))$, and if $\mathcal{R} = \mathcal{O}(S,T)$, $\forall k \in [1,q]$, $u_k = \min\{\mathcal{R}^{-1}(u'_k)\}$.
- $T_B^{(\mathcal{O}),-}$:
  $T_B^{(\mathcal{O}),-}$ is defined in the same way as $T_B^{(\mathcal{O}),+}$ by exchanging the left series $(S^-)$ and right series $(S^+)$ in every assertion $(p, S^-, S^+)$.
- $T_C^{(\mathcal{O})}$:
  $B_1 \cdots B_m \in T_C^{(\mathcal{O})}(A_1 \cdots A_n)$ iff there exists $d \in [1, d_0]$, $D \in [0, d-1]$, $\lambda \in \mathbb{N} - \{0\}$, $S_1, S_2, \ldots, S_d \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle - \{\emptyset^\lambda\}$, $1 \leq \kappa_1 < \kappa_2 < \cdots < \kappa_{D+1} = n$, such that
  (C1) every equation $\mathcal{E}_i = A_{\kappa_i} = (p_{\kappa_i} S^-_{p_{\kappa_i}}, S^+_{p_{\kappa_i}})$ is a weighted equation over $S_1, S_2, \ldots, S_d$, with $p_{\kappa_i} \geq 1$;
  (C2) $\mathrm{D}^{(\mathcal{O})}(\mathcal{S}) = D$ (where $\mathcal{S} = (\mathcal{E}_i)_{1 \leq i \leq D+1}$);
  (C3) $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}) \neq \perp$, $|||\ \mathrm{INV}^{(\mathcal{O})}(\mathcal{S})\ ||| \leq \Sigma_{d_0} + s_{d_0}$;
  (C4) $m = 1$ and $B_1 = \rho_e(\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}))$ (where $\rho_e$ is the obvious extension of $\rho_e$ to weighted pairs of deterministic row-vectors; in other words the result of $T_C^{(\mathcal{O})}$ is $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})$, where the marks have been removed).

We then set, for every $W \in \mathcal{A}^+$,

$$T_A(W) = \bigcup_{\mathcal{O} \in \Omega} T_A^{(\mathcal{O})}(W),$$

$$T_B^+(W) = \bigcup_{\mathcal{O} \in \Omega} T_B^{(\mathcal{O}),+}(W), \quad T_B^-(W) = \bigcup_{\mathcal{O} \in \Omega} T_B^{(\mathcal{O}),-}(W),$$

$$T_C(W) = \bigcup_{\mathcal{O} \in \Omega} T_C^{(\mathcal{O})}(W).$$

LEMMA 7.1. *$T_{cut}, T_\emptyset, T_\varepsilon, T_A$ are $\mathcal{B}_0$-strategies.*

*Proof.*

$T_{cut}$: (S1) is true by rule (R0). (S2) is trivially true.

$T_\emptyset$: (S1) is true by rule (R$'$3). (S2) is trivially true.

$T_\varepsilon$: (S1) is true by rule (R$'$3). (S2) is trivially true.

$T_A$: By rule (R4), $\{B_j \mid 1 \leq j \leq m\} \mid\!\!\vdash\!\!-_4 A_n$, which proves (S1). Suppose $H(A_n) = \infty$, i.e., $S \sim T$. Then, $\forall j \in [1, m]$, $S \odot x_j \sim T \odot x'_j$, so that $\min\{H(B_j) \mid 1 \leq j \leq m\} = \infty$. (S2) is proved. □

LEMMA 7.2. *$T_B^+, T_B^-$ are $\mathcal{B}_0$-strategies.*

*Proof.* Let us show that $T_B^+$ is a $\mathcal{B}_0$-strategy.

We use the notation of the definition of $T_B^{(\mathcal{O}),+}$. Let $\mathcal{H} = \{(\pi, \overline{U}, U'), (\pi + k_1 - 1, V, V')\}$. Let us show that

$$\mathcal{H} \overset{\langle * \rangle}{\mid\!\!\vdash\!\!-}_{\mathcal{B}_0} (\pi + k_1 - 1, U_n, U'_n). \tag{7.1}$$

Using rule (R5) we obtain, $\forall k \in [1, q]$,

$$\begin{aligned}\{(\pi, \overline{U}, U')\} = \left\{\left(\pi, \overline{U}, \sum_{j=1}^{q} E_j \cdot \Phi_j\right)\right\} &\overset{\langle * \rangle}{\mid\!\!\vdash\!\!-}_{R5} (\pi + 2 \cdot \mid u_k \mid, \overline{U} \odot u_k, U' \odot u'_k) \\ &\overset{\langle * \rangle}{\mid\!\!\vdash\!\!-}_{R0} (\pi + 2 \cdot k_0, \overline{U} \odot u_k, U' \odot u'_k) \\ &= \quad (\pi + 2 \cdot k_0, \overline{U} \odot u_k, \Phi_k).\end{aligned} \tag{7.2}$$

Using rule (R$'$3),

$$\emptyset \mid\!\!\vdash\!\!-_{R'3} (0, (\rho_e(E_1 \odot u), \ldots, \rho_e(E_q \odot u)), (E_1, \ldots, E_q)). \tag{7.3}$$

Using (7.3), (7.2) and rules (R3), (R7), (R8), we obtain

$$\begin{aligned}\{(\pi, \overline{U}, U')\} &\overset{\langle * \rangle}{\mid\!\!\vdash\!\!-}_{\mathcal{B}_0} \left(\pi + 2k_0, \sum_{k=1}^{q} (E_k \odot u) \cdot \Phi_k, \sum_{k=1}^{q} \rho_e(E_k \odot u) \cdot (\bar{U} \odot u_k)\right) \\ = \quad \{(\pi, \overline{U}, U')\} &\overset{\langle * \rangle}{\mid\!\!\vdash\!\!-} (\pi + 2k_0, U'_n, V').\end{aligned} \tag{7.4}$$

Let us recall that $U_n = V$. Hence, by (R0), (R1), (R2)

$$\{(\pi + k_1 - 1, V, V'), (\pi + 2k_0, U'_n, V')\} \overset{\langle * \rangle}{\mid\!\!\vdash\!\!-}_{\mathcal{C}} (\pi + k_1 - 1, U_n, U'_n). \tag{7.5}$$

By (7.4) and (7.5), (7.1) is proved. Now, using (7.1) and rule (R0), we obtain

$$\mathcal{H} \overset{\langle * \rangle}{||\!\!-\!\!-}_{\mathcal{B}_0} (\pi + k_1 - 1, U_n, U'_n) \vdash\!\!-_{R0} (\pi + k_1, U_n, U'_n), \tag{7.6}$$

i.e., $T_B^+$ fulfills (S1).

Let us suppose now that $\forall i \in [n - k_1, n]$, $U_i \sim U'_i$. Then, by (7.4), $U'_n \sim V'$ and by the hypothesis, $V = U_n \sim U'_n$. Hence $V \sim V'$. This shows that $T_B^+$ fulfills (S2).

An analogous proof can obviously be written for $T_B^-$. ◻

LEMMA 7.3. *Let $(p, S, S')$ be a weighted equation, i.e., $p \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$. Then*

$$\{(p, S, S')\} \overset{\langle * \rangle}{||\!\!-\!\!-}_{\mathcal{C}} \{(p, \rho_e(S), \rho_e(S'))\},$$

$$\{(p, \rho_e(S), \rho_e(S'))\} \overset{\langle * \rangle}{||\!\!-\!\!-}_{\mathcal{C}} \{(p, S, S')\}.$$

*Proof.* The proof follows easily from (R1), (R2), (R′3). ◻

LEMMA 7.4. *For every $\mathcal{O} \in \Omega$, $T_C^{\mathcal{O}}$ is a $\mathcal{B}_0$-strategy.*

*Proof.* By Lemma 5.3, point (1), combined with Lemma 7.3, (S1) is proved. By Lemma 5.3, point (2), combined with Lemma 7.3, (S2) is proved. ◻

Let us define the strategy $\mathcal{S}_{ABC}$ by the following: for every $W = A_1 A_2 \cdots A_n$,

(0) if $T_{cut}(W) \neq \emptyset$, then $\mathcal{S}_{ABC}(W) = T_{cut}(W)$;
(1) else if $T_\emptyset(W) \neq \emptyset$, then $\mathcal{S}_{ABC}(W) = T_\emptyset(W)$;
(2) else if $T_\varepsilon(W) \neq \emptyset$, then $\mathcal{S}_{ABC}(W) = T_\varepsilon(W)$;
(3) else if $T_B^+(W) \cup T_B^-(W) \neq \emptyset$, then $\mathcal{S}_{ABC}(W) = T_B^+(W) \cup T_B^-(W) \cup T_C(W)$;
(4) else $\mathcal{S}_{ABC}(W) = T_A(W) \cup T_C(W)$.

The strategy $\mathcal{S}_{AB}$ is obtained from $\mathcal{S}_{ABC}$ by removing the occurrence of $T_C$ in cases (3) and (4).

**7.2. Global strategy.** Let us define a global strategy $\hat{\mathcal{S}}_{ABC}$ w.r.t. the strategy $\mathcal{S}_{ABC}$. Let us fix (until the end of this article) a total well-ordering $\sqsubseteq$ over the set of oracles $\Omega$. We need now three technical definitions.

DEFINITION 7.5. *Let $P \in \mathcal{P}_f(\mathcal{A})$, $\mathcal{O} \in \Omega$, and $\bar{\pi} \in \mathbb{N} \cup \{\infty\}$. $\mathcal{O}$ is* $\bar{\pi}$-consistent *with $P$ iff, for every $(\pi, S, S') \in \mathrm{Cong}(P)$ and every $n \in \mathbb{N}$, if*

$$\pi + n - 1 < \bar{\pi},$$

*then the binary relation $\mathcal{R}_n = \mathcal{O}(S, S') \cap X^{\leq n} \times X^{\leq n}$ fulfills*

$$[\pi, S, S', \mathcal{R}_n] \subseteq \mathrm{Cong}(P).$$

We use the notation

$$\Omega(\bar{\pi}, P) = \{\mathcal{O} \in \Omega \mid \mathcal{O} \text{ is } \bar{\pi}\text{-consistent with } P\}.$$

DEFINITION 7.6. *Let $P$ be a finite subset of $\mathcal{A}$, and let $\bar{\pi} \in \mathbb{N} \cup \{\infty\}$. $P$ is said to be* $\bar{\pi}$-consistent *iff there exists some oracle $\mathcal{O} \in \Omega$, which is $\bar{\pi}$-consistent with $P$.*

For every proof-tree $t \in \mathcal{T}(\mathcal{S}_{ABC})$, we denote by $\bar{\Pi}(t)$ the integer

(7.7)
$$\bar{\Pi}(t) = \min\{\pi \in \mathbb{N} \mid \exists x \in \mathrm{dom}(t),\ x \text{ is not closed for } \mathcal{S}_{ABC},\ \exists S, S',\ t(x) = (\pi, S, S')\}.$$

(We admit here that $\min(\emptyset) = \infty$.)

DEFINITION 7.7. *Let $t$ be a finite proof-tree for the strategy $\mathcal{S}_{ABC}$, $t \in \mathcal{T}(\mathcal{S}_{ABC})$. $t$ is* consistent *iff* $\mathrm{im}(t)$ *is* $\bar{\Pi}(t)$*-consistent.*

Let us consider some tree $t \in \mathcal{T}(\mathcal{S}_{ABC})$ which is consistent and not closed. Let $\bar{\pi} = \bar{\Pi}(t)$, and let $x$ be the smallest unclosed node of weight $\bar{\pi}$. Let

$$W = A_1 \cdots A_n \tag{7.8}$$

be the word labeling the path from the root to $x$ in $t$. (One can notice that, as $x$ is not closed, $T_{cut}(W) \cup T_{\emptyset}(W) \cup T_{\varepsilon}(W) = \emptyset$.) We define a tree of height one, $\hat{\Delta}(t)$, as follows:

(0) If $\exists \mathcal{O} \in \Omega(\bar{\pi}, \mathrm{im}(t))$, $T_C^{(\mathcal{O})}(W) \neq \emptyset$, then

$$\mathcal{O}_0 = \min\{\mathcal{O} \in \Omega(\bar{\pi}, \mathrm{im}(t)), T_C^{(\mathcal{O})}(W) \neq \emptyset\}, \quad \hat{\Delta}(t) = A_n(T_C^{(\mathcal{O}_0)}(W));$$

(1) else if $T_B^{+}(W) \neq \emptyset$, then

$$\mathcal{O}_0 = \min(\Omega(\bar{\pi}, \mathrm{im}(t))), \quad \hat{\Delta}(t) = A_n(T_B^{(\mathcal{O}_0),+}(W));$$

(2) else if $T_B^{-}(W) \neq \emptyset$, then

$$\mathcal{O}_0 = \min(\Omega(\bar{\pi}, \mathrm{im}(t))), \quad \hat{\Delta}(t) = A_n(T_B^{(\mathcal{O}_0),-}(W));$$

(3) else

$$\mathcal{O}_0 = \min(\Omega(\bar{\pi}, \mathrm{im}(t))), \quad \hat{\Delta}(t) = A_n(T_A^{(\mathcal{O}_0)}(W)).$$

(In the above definition, by $A(W')$, where $A \in \mathcal{A}$, $W' \in \mathcal{A}^+$, we mean the tree of height one with root labeled by $A$ and whose sequence of leaves is the word $W'$.)

$$\hat{\mathcal{S}}_{ABC}(t) = t[\hat{\Delta}(t)/x], \tag{7.9}$$

i.e., $\hat{\mathcal{S}}_{ABC}(t)$ is obtained from $t$ by substituting $\hat{\Delta}(t)$ at the leaf $x$.

LEMMA 7.8. *For every $t \in \mathcal{T}(\mathcal{S}_{ABC})$, if $t$ is consistent, then $\hat{\Delta}(t)$ is defined.*

*Proof.* By the definition of consistency the oracle $\mathcal{O}_0$ is always defined (that is, $\Omega(\bar{\pi}, \mathrm{im}(t)) \neq \emptyset$), and for the word $W$ defined above, $T_{\varepsilon}(W) = \emptyset \Rightarrow \forall \mathcal{O} \in \Omega$, $T_A^{(\mathcal{O})}(W) \neq \emptyset$; hence one of cases (0)–(3) must occur. $\square$

If $t$ is not consistent or is closed, then we define

$$\hat{\mathcal{S}}_{ABC}(t) = t. \tag{7.10}$$

LEMMA 7.9. *$\hat{\mathcal{S}}_{ABC}$ is a global strategy for $\mathcal{S}_{ABC}$.*

*Sketch of proof.* By Lemma 7.8 $\hat{\mathcal{S}}_{ABC}$ is defined on every $t \in \mathcal{T}(\mathcal{S}_{ABC})$. It suffices to check that, in every case, the word constituted by the leaves of $\hat{\Delta}(t)$ belongs to $\mathcal{S}_{ABC}(W)$ (where $W$ is the word considered in (7.8)). $\square$

## 8. Tree analysis.

**8. Tree analysis.** This section is devoted to the analysis of the proof-trees $\tau$ produced by the strategy $\mathcal{S}_{AB}$ defined in section 7. The main results are Lemmas 8.9 and 8.10, whose combination asserts that if some branch of $\tau$ is infinite, then there exists some finite prefix on which $T_C$ has a nonempty value. This key technical result will ensure termination of the global strategy $\hat{\mathcal{S}}_{ABC}$ (see section 9).

We fix throughout this section a tree $\tau \in \mathcal{T}(\mathcal{S}_{AB}, (\pi_0, U_0^-, U_0^+))$ (i.e., $\tau$ is a proof-tree associated to the assertion $(\pi_0, U_0^-, U_0^+))$ by the strategy $\mathcal{S}_{AB}$). We suppose that

$$\|U_0^-\| \leq D_2, \quad \|U_0^+\| \leq D_2, \quad U_0^-, U_0^+ \text{ are both unmarked,} \tag{8.1}$$

$$U_0^-, U_0^+ \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\, \rangle\rangle \text{ with } \lambda \leq \lambda_2, \tag{8.2}$$

$$U_0^- \equiv U_0^+. \tag{8.3}$$

We recall that, formally, $\tau$ is a map $\mathrm{dom}(\tau) \to \mathbb{N} \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V\, \rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V\, \rangle\rangle$ such that $\mathrm{dom}(\tau) \subseteq \{1, \ldots, |X|^2\}^*$ is closed under prefix and under "left-brother" (i.e., $w \cdot (i+1) \in \mathrm{dom}(\tau) \Rightarrow w \cdot i \in \mathrm{dom}(\tau)$). We denote by $pr_{2,3} : \mathbb{N} \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V\, \rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V\, \rangle\rangle \to \mathsf{DRB}_{1,\lambda}\langle\langle\, V\, \rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V\, \rangle\rangle$ the projection $(\pi, U, U') \mapsto (U, U')$. By $\tau_s$ we denote the tree obtained from $\tau$ by forgetting the weights $\tau_s = \tau \circ pr_{2,3}$.

**8.1. Depth and weight.** In this paragraph we check that the *weight* and the *depth* of a given node are closely related. Let us say that the strategy $T$ "occurs at" node $x$ iff

$$\tau(x) \in T(\tau(x[0]) \cdot \tau(x[1]) \cdots \tau(x[|x| - 1]));$$

i.e., the label of $x$ belongs to the image of the path from $\epsilon$ (included) to $x$ (excluded) by the strategy $T$.

LEMMA 8.1. *Let $\alpha \in \{-, +\}$, $A_1, \ldots, A_n \in \mathcal{A}$ such that $T_B^\alpha(A_1 \cdots A_n) \neq \emptyset$. Then, $\forall i \in [n - k_1 + 1, n]$, $A_i \notin T_B(A_1 \cdots A_{i-1})$.*

In other words, if $T_B$ occurs at node $x$ of $\tau$, it cannot occur at any of its $k_1$ above immediate ancestors.

*Proof.* Suppose that $\exists i \in [n - k_1 + 1, n]$, $A_i \in T_B(A_1 \cdots A_{i-1})$. Hence $\pi_i = \pi_{i-1} - 1 < \pi_{n-k_1} + i$, contradicting one of the hypotheses under which $T_B(A_1 \cdots A_n)$ is not empty. □

Lemma 8.1 ensures that, in every branch $(x_i)_{i \in I}$ and for every interval $[n + 1, n + 4] \subseteq I$, at most one integer $j$ is such that $T_B$ occurs at $j$.

LEMMA 8.2. *Let $\tau$ be a proof-tree associated to the strategy $\mathcal{S}_{AB}$. Let $x, x' \in \mathrm{dom}(\tau)$, $x \preceq x'$. Then $\mid W(x') - W(x) \mid \leq |x'| - |x| \leq 2 \cdot (W(x') - W(x)) + 3$.*

(We recall the *depth* of a node $x$ is just its length $|x|$.) We denote by $W(x)$ the weight of $x$ which we define as the first component of $\tau(x)$, i.e., the weight of the equation labeling $x$.

*Proof.* Let $x, x'$ be such that $|x'| = |x| + 1$. Then $W(x') - W(x) \in \{-1, +1\}$, and hence the inequality $\mid W(x') - W(x) \mid \leq |x'| - |x|$ is fulfilled by such nodes. The general case follows by induction on $(|x'| - |x|)$.

Let us prove now the other inequality. We distinguish two cases.

*Case* 1. $|x'| - |x| \leq 3$. Then $|x'| - |x| \leq 2 \cdot (W(x') - W(x)) + 3$ (because there is at most one $T_B$ step in a sequence of length $\leq 3$).

*Case* 2. $|x'| - |x| \geq 4$. Let $x = x_0, x_1, \ldots, x_q, x'$ be the sequence of nodes such that $|x'| - |x| = 4 \cdot q + r$, $0 \leq r < 4$, and $\forall i \in [0, q - 1]$, $|x_{i+1}| - |x_i| = 4$.

By Lemma 8.1, in every set $\{y \in \mathrm{dom}(\tau) \mid x_i \prec y \preceq x_{i+1}\}$ at most one node $z$ is such that $T_B$ occurs at $z$. Hence $W(x_{i+1}) - W(x_i) \geq 2$.

It follows that

$$\begin{aligned}
|x'| - |x| &= \sum_{i=0}^{q-1}[|x_{i+1}| - |x_i|] + |x'| - |x_q| \\
&\leq \sum_{i=0}^{q-1} 2(W(x_{i+1} - W(x_i)) + |x'| - |x_q| \\
&\leq 2(W(x_q) - W(x)) + 2(W(x') - W(x_q)) + 3 \ \text{(by the first case)} \\
&\leq 2(W(x') - W(x)) + 3. \qquad \square
\end{aligned}$$

Let us recall the values of some constants (defined in section 6):

$$k_0 = \max\{\nu(v) \mid v \in V\}, \quad k_1 = \max\{2k_0 + 1, 3\}, \quad D_1 = k_0 \cdot K_0 + |Q| + 2,$$

$$k_2 = D_1 \cdot k_1 \cdot K_0 + 2 \cdot k_1 \cdot K_0 + K_0, \quad k_3 = k_2 + k_1 \cdot K_0,$$

$$k_4 = (k_3 + 1) \cdot K_0 + k_1, \quad d_0 = \mathrm{Card}(X^{\leq k_4}), \quad N_0 = 1 + k_3 + D_2.$$

**8.2. B-stacking sequences.** We establish here that every infinite branch must contain an infinite suffix (a "B-stacking sequence") where at least $d_0$ labels $(U, U')$ belong to the same d-space $V_0$ of dimension $\leq d_0$ with coordinates not greater than $s_{d_0}$ (over some fixed generating family of cardinality $\leq d_0$).

Let $\sigma = (x_i)_{i \in I}$ be a path in $\tau$, where $I = [i_0, \infty[$ and let $(x_i)_{i \geq 0}$ be the unique branch of $\tau$ containing $\sigma$. Let us note $\tau(x_i) = (\pi_i, U_i^-, U_i^+)$.

We call $\sigma$ a *B-stacking sequence* iff there exists some $\alpha_0 \in \{-, +\}$ such that

$$T_B^{\alpha_0} \text{ occurs at } x_{i_0+k_1+1}, \tag{8.4}$$

and, for every $i \in I, \alpha \in \{-, +\}$, if $T_B^{\alpha}$ occurs at $x_{i+k_1+1}$, then

$$\|U_i^{-\alpha}\| \geq \|U_{i_0}^{-\alpha_0}\| \geq N_0. \tag{8.5}$$

From now on and until Lemma 8.10, we fix a B-stacking sequence $\sigma = (x_i)_{i \in I}$ and denote by $S_0$ the series $U_{i_0}^{-\alpha_0}$.

LEMMA 8.3. *There exists some word $u_0 \in X^*$ and some sign $\alpha_0' \in \{-, +\}$ such that $S_0 = U_0^{\alpha_0'} \odot u_0$.*

*Proof.* One can prove by induction on $i \in \mathbb{N}$ that, for every $\alpha \in \{-, +\}$, $U_i^{\alpha}$ has one of the two following forms:

(1) $U_i^{\alpha} = U_0^{\alpha'} \odot u$ for some $\alpha' \in \{-, +\}$, $|u| \leq i$;

(2) $U_i^{\alpha} = \sum_{k=1}^{q} \beta_k \cdot (U_0^{\alpha'} \odot uu_k)$

for some deterministic rational vector $\beta$, $\alpha' \in \{-, +\}$, $|u \cdot u_k| \leq i$, $|u_k| \leq k_0$. $\square$

LEMMA 8.4. *Suppose that $i_0 \leq j < i$, no $T_B$ occurs in $[j + 1, i]$, $U_j^{-\alpha}$ is $D_1$-marked, and $U_j^{\alpha}$ is unmarked. Then, for every $j' \in [j, i]$, $\|U_{j'}^{\alpha}\| \geq \|U_i^{\alpha}\| - k_2$.*

*Proof.* Let $i, j$ fulfill the hypothesis of the lemma.

(1) Let us first treat the case where $j' = j$. If $(i - j) \leq (D_1 + 1)k_1$, then, by Lemma 3.13,

$$\|U_i^{\alpha}\| \leq \|U_j^{\alpha}\| + (D_1 + 1) \cdot k_1 \cdot K_0 \leq k_2;$$

hence the lemma is true.

Let us suppose now that $(i - j) \geq (D_1 + 1)k_1 + 1$. We can then define the integers $j < i_1 < i_2 < i$ by

$$i_1 = j + D_1 \cdot k_1, \ i_2 = i - k_1 - 1.$$

By Lemma 3.13 we know that

$$\|U^{\alpha}_{i_1}\| \leq \|U^{\alpha}_{j}\| + D_1 \cdot k_1 \cdot K_0 \quad \text{and} \quad \|U^{\alpha}_{i}\| \leq \|U^{\alpha}_{i_2}\| + (k_1+1) \cdot K_0. \tag{8.6}$$

If there were some stacking subderivation of length $k_1$ in $U^{-\alpha}_{j} \to U^{-\alpha}_{i_1}$, as all the $U^{\alpha}_{k}$ (for $k \in [j,i]$) are unmarked, $T_B$ would occur at some integer in $[j+k_1+1, i_1+1]$, which is untrue. Hence there is no such stacking subderivation, and by Lemma 3.32 $U^{-\alpha}_{i_1}$ is unmarked.

If there were some stacking subderivation of length $k_1$ in $U^{\alpha}_{i_1} \to U^{\alpha}_{i_2}$, as all the $U^{-\alpha}_{k}$ (for $k \in [i_1,i]$) are unmarked, $T_B$ would occur at some integer in $[i_1+k_1+1, i]$, which is untrue. Hence there is no such stacking subderivation, and by Lemma 3.31

$$\|U^{\alpha}_{i_2}\| \leq \|U^{\alpha}_{i_1}\| + k_1 \cdot K_0. \tag{8.7}$$

Adding inequalities (8.6), (8.7) we obtain

$$\|U^{\alpha}_{i}\| \leq \|U^{\alpha}_{j}\| + (D_1 \cdot k_1 + 2 \cdot k_1 + 1) \cdot K_0 = \|U^{\alpha}_{j}\| + k_2,$$

which was to be proved.

(2) Let us suppose now that $j \leq j' \leq i$. If $(i-j) \leq (D_1+1)k_1$, the same inequality is true for $i-j'$ and the conclusion is true for $j'$.

Otherwise, if $j' \leq i_1$, then (8.6), (8.7) are still true for $j'$ instead of $j$, and hence the conclusion too.

Otherwise, by the arguments of part (1), $U^{-\alpha}_{j'}, U^{\alpha}_{j'}$ are both unmarked. Therefore the hypotheses of part (1) are met by $(j', i)$ instead of $(j,i)$, and hence the conclusion is met too. (We illustrate our argument in Figure 4.) □

LEMMA 8.5. *Let $i \in I$, $\alpha \in \{-,+\}$ such that $T^{\alpha}_{B}$ occurs at $i+k_1+1$. Then there exists $u \in X^*$, $|u| \leq (i-i_0)$, $U^{-\alpha}_{i} = S_0 \odot u$, and, for every prefix $w \preceq u$,*

$$\|S_0 \odot w\| \geq \|S_0\| - k_3.$$

*Proof.* We prove the lemma by induction on $i \in [i_0, \infty[$.

**Basis:** $i = i_0$.

Choosing $u = \epsilon$, the lemma is true.

**Induction step:** $i_0 \leq i' < i$, $T^{\alpha'}_{B}$ occurs at $i'+k_1+1$, $T^{\alpha}_{B}$ occurs at $i+k_1+1$, and $T_B$ does not occur in $[i'+k_1+2, i+k_1]$.

By the induction hypothesis, there exists some $u' \in X^*$, $|u'| \leq (i'-i_0)$, fulfilling

$$U^{-\alpha'}_{i'} = S_0 \odot u', \tag{8.8}$$

$$\forall w' \preceq u', \quad \|S_0 \odot w'\| \geq \|S_0\| - k_3. \tag{8.9}$$

Let us define $j = i'+k_1+1$.

Let $\bar{u} \in X^*$ be the word such that

$$U^{-\alpha}_{j} \xrightarrow{\bar{u}} U^{-\alpha}_{i} \tag{8.10}$$

is the derivation described by the $-\alpha$ component of the path from $x_j$ to $x_i$.

*Case* 1. $\alpha' = \alpha$.

$$U^{-\alpha}_{j} = U^{-\alpha'}_{i'} \odot u_1$$

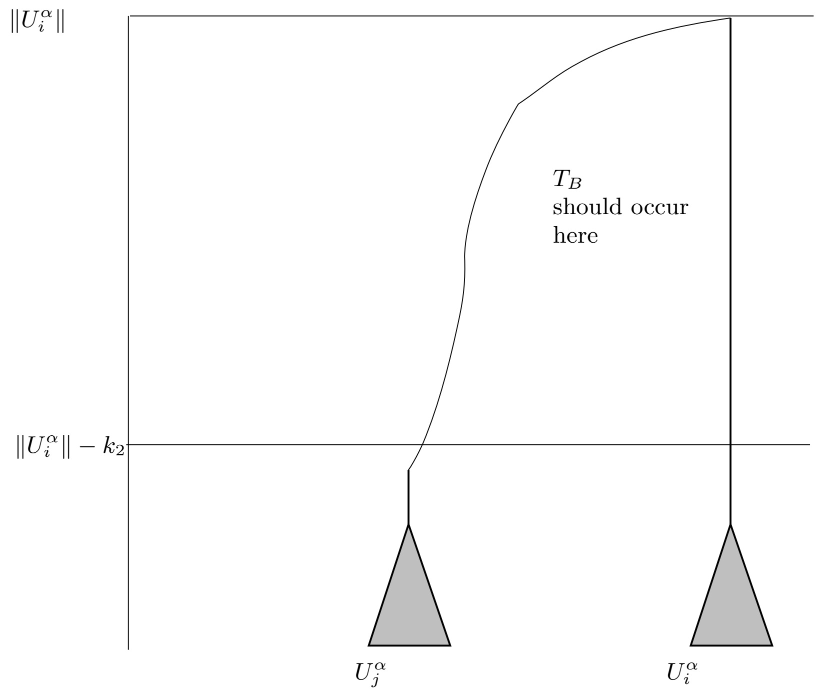


FIG. 4. $\|U_j^\alpha\|$ *too small is impossible.*

for some $u_1 \in X^*$, $|u_1| = k_1$, and $U_j^\alpha$ is $D_1$-marked. Let us choose $u = u' \cdot u_1 \cdot \bar{u}$. Hence

$$U_i^{-\alpha} = S_0 \odot u. \tag{8.11}$$

Let us consider some prefix $w$ of $u$.

*Subcase* 1. $w \preceq u'$. By (8.9) we know that $\|S_0 \odot w\| \geq \|S_0\| - k_3$.

*Subcase* 2. $w = u' \cdot u_1 \cdot u''$ for some $u'' \preceq \bar{u}$. By Lemma 8.4 we know that $\|S_0 \cdot w\| \geq \|U_i^\alpha\| - k_2$, and by the definition of a B-stacking sequence we also know that $\|U_i^\alpha\| \geq \|S_0\|$. Hence

$$\|S_0 \odot w\| \geq \|S_0\| - k_2.$$

*Subcase* 3. $w = u' \cdot u_1'$, where $u_1'$ is a prefix of $u_1$. Then, by Lemma 3.13 and the above inequality, we get

$$\|S_0 \odot w\| \geq \|S_0 \odot u'u_1\| - k_1 \cdot K_0 \geq \|S_0\| - k_3.$$

*Case* 2. $-\alpha' = \alpha$.

$$U_j^{-\alpha} = \sum_{k=1}^{q} \beta_k \cdot (U_{i'}^\alpha \odot u_k),$$

where $\beta$ is a polynomial which is fully marked and every $|u_k| \leq k_0$.

By Lemma 3.15 either $U_i^{-\alpha} = \sum_{k=1}^{q} (\beta_k \odot \bar{u}) \cdot (U_{i'}^\alpha \odot u_k)$ or there exists a decomposition

$$\bar{u} = \bar{u}_1 \cdot \bar{u}_2 \tag{8.12}$$

and an integer $k \in [1, q]$ such that

$$U_i^{-\alpha} = U_{i'}^{\alpha} \odot u_k \bar{u}_2. \tag{8.13}$$

But, as $U_i^{-\alpha}$ is unmarked (by definition of $T_B^{\alpha}$), the first formula is impossible unless $\beta \odot \bar{u}$ is unitary or null. Hence (8.12), (8.13) is the only possibility.

Let us choose $u = u' \cdot u_k \cdot \bar{u}_2$. It is clear from (8.13) that $U_i^{-\alpha} = S_0 \odot u$.

Let us consider some prefix $w$ of $u$.

*Subcase* 1. $w \preceq u'$. We use the same arguments as in Case 1, Subcase 1.

*Subcase* 2. $w = u' \cdot u_k \cdot u''$ for some $u'' \preceq \bar{u}_2$. By Lemma 8.4 applied to the interval $[j + |\bar{u}_1| + 1, i]$, we can conclude that

$$\|S_0 \odot w\| \geq \|S_0\| - k_3.$$

*Subcase* 3. $w = u' \cdot u'_k$, where $u'_k$ is a prefix of $u_k$. We use the same arguments as in Case 1, Subcase 3. $\square$

Let us now define the following set of vectors and d-spaces:

$$\mathcal{G}_0 = \{S_0 \odot u \mid u \in X^*, |u| \leq k_4\}, \tag{8.14}$$

$$V_0 = \mathsf{V}(\mathcal{G}_0). \tag{8.15}$$

LEMMA 8.6. *Let $i \geq i_0$ such that $T_B$ occurs at $i$. Then $U_i^-, U_i^+ \in V_0$.*

*Proof.* Let us suppose that $T_B^{\alpha}$ occurs at $i$. By Lemma 8.5, $U_{i-k_1-1}^{-\alpha} = S_0 \odot u$ and, for every prefix $w \preceq u$,

$$\|S_0 \odot w\| \geq \|S_0\| - k_3.$$

By Lemma 3.14, $\exists u_1, u_2 \in X^*$, $v_1 \in V^*$, $E_1, \ldots, E_k \in V$, $E_1 \smile E_2 \smile \cdots \smile E_k$, $\Phi \in \mathsf{DRB}_{q,\lambda}\langle\langle\ V\ \rangle\rangle$, such that $u = u_1 \cdot u_2$,

$$S_0 \odot u_1 = S_0 \bullet v_1 = \sum_{k=1}^{q} E_k \cdot \Phi_k, \tag{8.16}$$

$$S_0 \odot u = \sum_{k=1}^{q} (E_k \odot u_2) \cdot \Phi_k. \tag{8.17}$$

Without loss of generality, we can suppose that $v_1$ is a minimal word realizing the equality (8.16). Let us notice that, as $G$ is a reduced grammar, for every $v \preceq v_1$, there exists some $\bar{v} \in X^*$, such that $S_0 \bullet v = S_0 \odot \bar{v}$. Hence, for every $v \preceq v_1$,

$$S_0 \bullet v = U_0^{\alpha'_0} \odot u_0 \cdot \bar{v} \quad \text{and} \quad \|U_0^{\alpha'_0} \odot u_0 \cdot \bar{v}\| \geq \|S_0 \odot u_1\| > D_2 = \|U_0^{\alpha'_0}\|.$$

By Lemma 3.29, all the vectors $S_0 \bullet v$ for $v \preceq v_1$ are loop-free. It follows that, for every $v \preceq v' \preceq v_1$,

$$v \prec v' \Rightarrow \|S_0 \bullet v\| > \|S_0 \bullet v'\|,$$

and hence

$$|v_1| \leq \|S_0\| - \|S_0 \bullet v_1\| \leq k_3.$$

The formula (8.17) can be rewritten

$$U^{-\alpha}_{i-k_1-1} = \sum_{k=1}^{q}(E_k \odot u_2) \cdot (S_0 \bullet v_1 E_k) = \sum_{k=1}^{q}(E_k \odot u_2) \cdot (S_0 \odot \bar{u}_k),$$

where $\bar{u}_k \in X^*$, $|\bar{u}_k| \leq (k_3 + 1) \cdot K_0$.

Using Lemmas 3.15 and 3.11 we can deduce from the above form of $U^{-\alpha}_{i-k_1-1}$ that

$$U^{\alpha}_{i} \in \mathsf{V}(\{S_0 \odot w \mid w \in X^*, |w| \leq (k_3 + 1) \cdot K_0 + k_0\}),$$
$$U^{-\alpha}_{i} \in \mathsf{V}(\{S_0 \odot w \mid w \in X^*, |w| \leq (k_3 + 1) \cdot K_0 + k_1\}),$$

and hence that both $U^{-\alpha}_i, U^{\alpha}_i$ belong to $V_0$. □

We recall that

$$K_1 = k_1 \cdot K_0 + 1, \quad K_2 = k_1^2 \cdot D_1 \cdot K_0 + k_1^2 \cdot K_0 + 2 \cdot k_1 \cdot K_0 + D_1 \cdot k_1 + 2 \cdot k_1 + 4.$$

LEMMA 8.7. *For every $L \geq 0$ there exists $i \in [i_0 + L, i_0 + K_1 \cdot L + K_2]$ such that $U^-_i, U^+_i \in V_0$.*

*Proof.* Let us establish that

(8.18)
$$\exists i \in [i_0 + L, i_0 + K_1 \cdot L + K_2 - k_1 - 1], \exists \alpha \in \{-, +\}, \quad T^{\alpha}_{B} \text{ occurs at } i + k_1 + 1.$$

Let $L \geq 0$ and let $i' \geq i_0$ be the greatest integer in $[i_0, i_0 + L]$ such that $T_B$ occurs at $i' + k_1 + 1$. Let $j = i' + k_1 + 1$. We then have

$$U^{\alpha'}_{j} = \sum_{k=1}^{q} \beta_k \cdot (U^{-\alpha'}_{i'} \odot u_k),$$

where $\|\beta\| \leq D_1$ and $U^{-\alpha'}_{j}$ is unmarked.

*Case* 1. *There exists $i \in [j, j + k_1 \cdot D_1]$, such that $T_B$ occurs at $i + k_1 + 1$.* In this case the small constants $K_1 = 0$, $K_2 = k_1 \cdot D_1 + k_1 + 1$ would be sufficient to satisfy (8.18). A fortiori the given constants satisfy (8.18).

*Case* 2. *There exists no $i \in [j, j + k_1 \cdot D_1]$, such that $T_B$ occurs at $i + k_1 + 1$.* Then there is no stacking subderivation of length $k_1$ in $U^{\alpha'}_{j} \longrightarrow U^{\alpha'}_{j+k_1 \cdot D_1}$. By Lemma 3.32 it follows that both $U^{\alpha}_{j+D_1 \cdot k_1}$ are unmarked.

(1) Let $j_1 = j + D_1 \cdot k_1$ and let us show that there exists some $i \geq j_1$ such that $T_B$ occurs at $i + k_1 + 1$.

If such an $i$ does not exist, then for every $\alpha \in \{-, +\}$, the infinite derivation

$$U^{\alpha}_{j_1} \longrightarrow U^{\alpha}_{j_1+1} \longrightarrow \cdots$$

does not contain any stacking sequence of length $k_1$. By Lemma 3.31 we would have

$$\forall k \geq j_1, \quad \|U^{\alpha}_{k}\| \leq \|U^{\alpha}_{j_1}\| + k_1 \cdot K_0.$$

As the set $\{\|U^{\alpha}_{k}\|, k \geq j_1, \alpha \in \{-, +\}\}$ is finite, there would be a repetition

$$(U^-_k, U^+_k) = (U^-_{k'}, U^+_{k'}) \quad \text{with } j_1 \leq k < k' \text{ and } \pi_k < \pi_{k'},$$

so that $T_{cut}$ would have been defined on some finite prefix of the branch, contradicting the hypothesis that the branch is infinite.

(2) Let $i > i'$ be the smallest integer (in $[j_1, \infty[$ ) fulfilling point (1) above, and suppose that $T_B^\alpha$ occurs at $i + k_1 + 1$.

By Lemma 8.4,

$$\forall \ell \in [j_1, i], \quad \|U_\ell^{-\alpha}\| \geq N_0 - k_2 > D_2.$$

Using Lemma 8.3, Lemma 3.29, and inequality (8.1) we conclude that

$$\forall \ell \in [j_1, i], \quad U_\ell^{-\alpha} \text{ is loop-free.}$$

By an argument analogous to that used in Lemma 8.3 we see that $U_{j_1}^{-\alpha} = S_0 \odot u$ for some $|u| \leq (j_1 - i_0)$, and by Lemma 3.13 we get

$$\|U_{j_1}^{-\alpha}\| \leq (j_1 - i_0) \cdot K_0 + \|S_0\|. \tag{8.19}$$

We also know that

$$\|S_0\| \leq \|U_i^{-\alpha}\| \leq \|U_{i-1}^{-\alpha}\| + K_0. \tag{8.20}$$

As the derivation $U_{j_1}^{-\alpha} \longrightarrow U_{i-1}^{-\alpha}$ contains no stacking subderivation of length $k_1$ and consists of loop-free series only, by Lemma 3.30 we obtain

$$\|U_{i-1}^{-\alpha}\| \leq \|U_{j_1}^{-\alpha}\| - (i - j_1 - 2)/k_1. \tag{8.21}$$

Combining the three inequalities (8.19), (8.20), (8.21) we get successively

$$\|S_0\| \leq \|S_0\| + (j_1 - i_0 + 1) \cdot K_0 - (i - j_1 - 2)/k_1,$$

$$(i - j_1 - 2) \leq (j_1 - i_0 + 1) \cdot k_1 K_0,$$

(8.22)
$$\begin{aligned}(i - i') &= (i - j_1 - 2) + (j_1 - i' + 2) \leq (j_1 - i_0 + 1) \cdot k_1 \cdot K_0 + D_1 \cdot k_1 + k_1 + 3\\ &= (i' - i_0) \cdot k_1 \cdot K_0 + k_1^2 \cdot D_1 \cdot K_0 + k_1^2 \cdot K_0 + 2 \cdot k_1 \cdot K_0 + D_1 \cdot k_1 + k_1 + 3\\ &= (K_1 - 1)(i' - i_0) + K_2 - k_1 - 1.\end{aligned}$$

(3) By the choice of $i', i$, we know that $i' \leq i_0 + L \leq i$. Using (8.22) we obtain

$$i \leq i' + (K_1 - 1)(i' - i_0) + K_2 - k_1 - 1,$$

$$i \leq i_0 + K_1 \cdot L + K_2 - k_1 - 1.$$

Assertion (8.18) is now established for Case 2 as well as for Case 1.

From (8.18) and Lemma 8.6 the lemma follows.

(We illustrate our argument in Figure 5.) $\square$

Let us give now a stronger version of Lemma 8.7 in which we analyze the *size of the coefficients* of the linear combinations whose existence is proved in Lemma 8.7. We recall that

$$K_3 = K_0|Q|, \quad K_4 = D_1.$$

Let us fix a total ordering on $\mathcal{G}_0$:

$$\mathcal{G}_0 = \{\theta_1, \theta_2, \ldots, \theta_d\}, \text{ where } d = \mathrm{Card}(\mathcal{G}_0).$$

Let us remark that $d \leq \mathrm{Card}(X^{\leq k_4}) = d_0$.

LEMMA 8.8. *Let $L \geq 0$. There exists $i \in [i_0 + L, i_0 + K_1 \cdot L + K_2]$ and, for every $\alpha \in \{-, +\}$, there exists a deterministic rational family $(\beta_{i,j}^\alpha)_{1 \leq j \leq d}$ fulfilling*

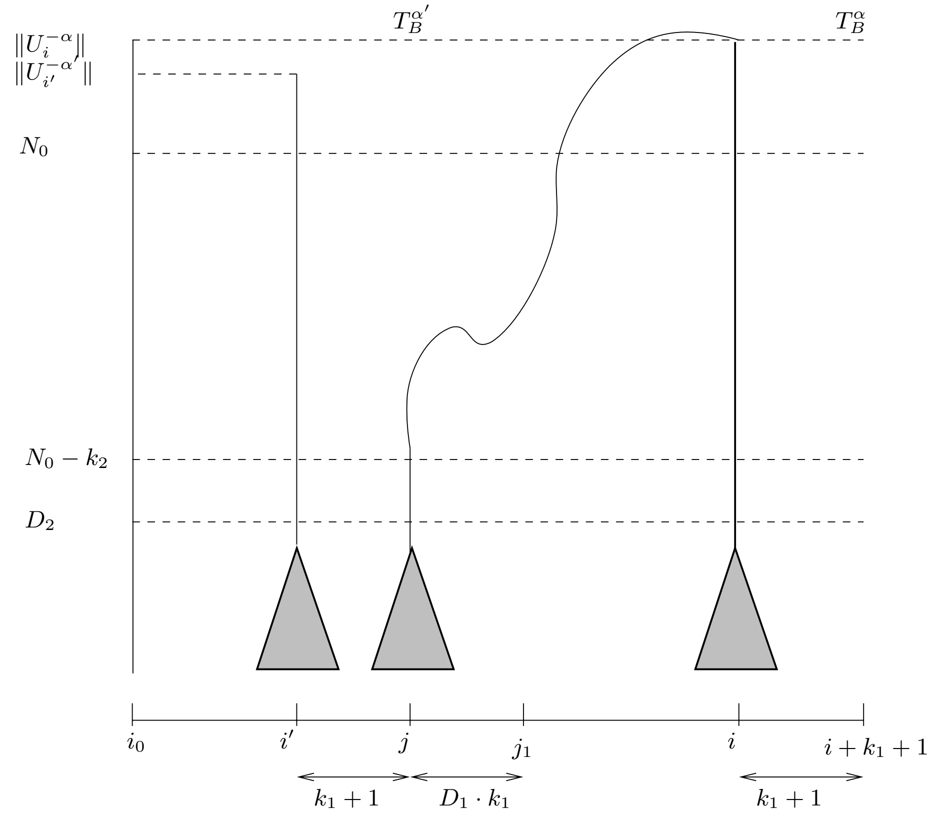

FIG. 5. *Two successive $T_B$.*

(1) $U_i^{\alpha} = \sum_{j=1}^{d} \beta_{i,j}^{\alpha} \cdot \theta_j$,
(2) $\|\beta_{i,*}^{\alpha}\| \le K_3 \cdot (i - i_0) + K_4$.

*Proof.* By Lemma 8.7 there exists $i \in [i_0 + L, i_0 + K_1 \cdot L + K_2]$ and $\alpha \in \{-, +\}$ such that $T_B^{\alpha}$ occurs at $i$. Let us use the notation of the proof of Lemma 8.6 and compute upper-bounds on the coefficients of $U_i^{-\alpha}, U_i^{\alpha}$ expressed as linear combinations of the vectors of $\mathcal{G}_0$.

*Coefficients of $U_i^{-\alpha}$.* $U_i^{-\alpha} = U_{i-k_1-1}^{-\alpha} \odot u'$ for some $u' \in X^*$, $|u'| = k_1$. By Lemma 3.15, $U_i^{-\alpha}$ can be expressed in one of the two following forms:

$$U_i^{-\alpha} = S_0 \odot (\bar{u}_k u''), \text{ where } u'' \text{ is a suffix of } u', \tag{8.23}$$

$$U_i^{-\alpha} = \sum_{k=1}^{q} (E_k \odot u_2 u') \cdot (S_0 \odot \bar{u}_k). \tag{8.24}$$

In case (8.23) we can choose as vector of coordinates: $\beta_{i,\star}^{-\alpha} = \epsilon_{j_0}^{d}$. We then have $\|\beta_{i,\star}\| = 2 \le K_4$.

In case (8.24), we can choose $\beta_{i,\star}^{-\alpha} = E \odot u_2 u'$ (completed with $\emptyset$ in all the columns $j$ not corresponding to some vector $S_0 \odot \bar{u}_k$ of $\mathcal{G}_0$). We then have

$$\|\beta_{i,\star}\| = \|E \odot u_2 u'\| \le K_0 \cdot (i - i_0) \le K_3 \cdot (i - i_0).$$

*Coefficients of $U_i^\alpha$.* By the definition of $T_B^\alpha$

$$U_i^\alpha = \sum_{\ell=1}^{r} \tau_\ell \cdot (U_{i-k_1-1}^{-\alpha} \odot \bar{w}_\ell), \tag{8.25}$$

where $\|\tau\| \leq D_1$, $|\bar{w}_\ell| \leq k_0$.

Replacing $u'$ by $\bar{w}_\ell$ in the above analysis, we get

$$\forall \ell \in [1, r], \quad U_{i-k_1-1}^{-\alpha} \odot \bar{w}_\ell = \sum_{j=1}^{d} \gamma_{\ell,j} \cdot \theta_j, \tag{8.26}$$

with $\|\gamma_{\ell,\star}\| \leq K_0 \cdot (i - i_0)$.

Equalities (8.25), (8.26) show that

$$U_i^\alpha = \tau \cdot \gamma \cdot \theta,$$

where $\tau$, $\gamma$, $\theta$ are deterministic rational matrices of dimensions $(1, r)$, $(r, d)$, $(d, 1)$, respectively. Let us choose $\beta_{i,\star} = (\tau \cdot \gamma)$.

$$\|\beta_{i,\star}\| \leq \|\tau\| + \|\gamma\| \leq D_1 + r \cdot K_0 \cdot (i - i_0)$$
$$\leq D_1 + |Q| \cdot K_0 \cdot (i - i_0) = K_3 \cdot (i - i_0) + K_4. \qquad \square$$

Lemma 8.9. *There exists $i_0 \leq \kappa_1 < \kappa_2 < \cdots < \kappa_d$ and deterministic rational vectors $(\beta_{i,j}^\alpha)_{1 \leq j \leq d}$ (for every $i \in [1, d]$) such that*

(0) $W(\kappa_1) \geq 1$,

(1) $\forall i, \forall \alpha, U_{\kappa_i}^\alpha = \sum_{j=1}^{d} \beta_{i,j}^\alpha \theta_j \in V_0$,

(2) $\forall i, \forall \alpha, \|\beta_{i,*}^\alpha\| \leq s_i$,

(3) $\forall i, W(\kappa_{i+1}) - W(\kappa_i) \geq \delta_{i+1}$,

*where the sequences $(\delta_i, \ell_i, L_i, s_i, S_i, \sigma_i)$ are those defined by relations* (6.8), (6.9) *in section* 6.

*Proof.* Let us consider the additional property

(4) $\kappa_i - i_0 \leq L_i$.

We prove by induction on $i$ the conjunction (1) $\wedge$ (2) $\wedge$ (3) $\wedge$ (4).

$\boldsymbol{i = 1}$**:** By Lemma 8.8, there exists $\kappa_1 \in [i_0, i_0 + K_2]$ such that $\forall \alpha \in \{-, +\}$, there exists a deterministic vector $(\beta_{1,j}^\alpha)_{1 \leq j \leq d}$, such that

$$U_{\kappa_1}^\alpha = \sum_{j=1}^{d} \beta_{1,j}^\alpha \theta_j,$$

and in addition $\|\beta_{1,*}^\alpha\| \leq K_3 K_2 + K_4 = s_1$.

$\boldsymbol{i \longrightarrow i + 1}$**:** Suppose that $\kappa_1 < \kappa_2 < \cdots < \kappa_i$ fulfill (1) $\wedge$ (2) $\wedge$ (3) $\wedge$ (4). By Lemma 8.8, there exists $\kappa_{i+1} \in [i_0 + L_i + \ell_{i+1}, i_0 + K_1(L_i + \ell_{i+1}) + K_2]$ such that $\forall \alpha \in \{-, +\}$, there exists a deterministic vector $(\beta_{i+1,j}^\alpha)_{1 \leq j \leq d}$, such that

$$U_{\kappa_{i+1}}^\alpha = \sum_{j=1}^{d} \beta_{i+1,j}^\alpha \theta_j, \tag{8.27}$$

and in addition

$$\begin{aligned} \|\beta_{i+1,*}^\alpha\| \leq K_3(K_1(L_i + \ell_{i+1}) + K_2) + K_4 &= K_3 L_{i+1} + K_4 \\ &= s_{i+1}. \end{aligned} \tag{8.28}$$

By Lemma 8.2

$$2(W(\kappa_{i+1}) - W(\kappa_i)) + 3 \geq \kappa_{i+1} - \kappa_i \geq \ell_{i+1} = 2\delta_{i+1} + 3,$$

and hence

$$W(\kappa_{i+1}) - W(\kappa_i) \geq \delta_{i+1}. \tag{8.29}$$

Finally,

$$\kappa_{i+1} - i_0 \leq K_1(L_i + l_{i+1}) + K_2 = L_{i+1}. \tag{8.30}$$

The above properties (8.27)–(8.30) prove the required conjunction.

It remains to prove point (0): the integer $\kappa_1$ introduced by Lemma 8.8 is such that $T_B$ occurs at $\kappa_1$, and hence

$$\begin{aligned} W(\kappa_1) &= W(\kappa_1 - k_1 - 1) + k_1 - 1 \\ &\geq W(\kappa_1 - k_1 - 1) + 2 \geq 1. \qquad \square \end{aligned}$$

LEMMA 8.10. *Let $(x_i)_{i\in\mathbb{N}}$ be an infinite branch of $\tau$. Then there exist some $i_0 \in \mathbb{N}$ such that $(x_i)_{i\geq i_0}$ is a B-stacking sequence.*

*Proof.* Let us distinguish, a priori, several cases, and see that only the case where $\tau$ admits a B-stacking sequence is possible.

*Case* 1. *$T_B$ occurs finitely often on $\tau$.* Let $j$ be the largest integer such that $T_B$ occurs at $j$. By the arguments used in the proof of Lemma 8.7, Case 2, we know that $U^-_{j+k_1\cdot D_1}, U^+_{j+k_1\cdot D_1}$ are both unmarked, and that

$$\forall k \geq j + k_1 \cdot D_1, \forall \alpha \in \{-,+\}, \quad \|U^\alpha_k\| \leq \|U^\alpha_{j+k_1\cdot D_1}\| + k_1 \cdot K_0.$$

This would imply that the branch contains a finite prefix on which $T_{cut}$ is defined, which is impossible on an infinite branch.

*Case* 2. *For some sign $\alpha$, there are infinitely many integers $i$ such that $[T^\alpha_B$ occurs at $i + k_1 + 1$ and $\|U^{-\alpha}_i\| < N_0]$.* In this case there would exist an infinite sequence of integers $i_1 < i_2 < \cdots < i_\ell <$ such that

$$\forall \ell \geq 0, \quad U^{-\alpha}_{i_1} = U^{-\alpha}_{i_\ell}.$$

For a given $U^{-\alpha}_i$, only a finite number of values are possible for the pair $(U^-_{i+k_1+1}, U^+_{i+k_1+1})$. Hence there exist integers $\ell < \ell'$ such that

$$\ell < \ell', \quad \pi_\ell < \pi_{\ell'}, \quad \text{and} \quad (U^-_{\ell+k_1+1}, U^+_{\ell+k_1+1}) = (U^-_{\ell'+k_1+1}, U^+_{\ell'+k_1+1}).$$

Here again $T_{cut}$ would have a nonempty value on some prefix of $\tau$, which is impossible.

*Case* 3. *$T_B$ occurs infinitely often on $\tau$ and, for every sign $\alpha$, there are only finitely many integers $i$ such that $[T^\alpha_B$ occurs at $i + k_1 + 1$ and $\|U^{-\alpha}_i\| < N_0]$.*

Let us consider the set $I_0$ of the integers $i$ such that there exists a sign $\alpha_i$ such that

$$[T^{\alpha_i}_B \text{ occurs at } i + k_1 + 1 \text{ and } \|U^{-\alpha_i}_i\| \geq N_0].$$

By the hypothesis of Case 3, $I_0 \neq \emptyset$. Let $i_0$ be such that

$$\|U^{-\alpha_{i_0}}_{i_0}\| = \min\{\|U^{-\alpha_i}_i\| \mid i \in I_0\}.$$

Then $(x_i)_{i\geq i_0}$ is a B-stacking sequence. $\square$

## 9. Termination.

LEMMA 9.1. *$\hat{\mathcal{S}}_{ABC}$ is terminating on every unmarked assertion $A_0$: if $A_0 \in \mathcal{A}$ is unmarked, then $\exists n_0 \in \mathbb{N}$, $\hat{\mathcal{S}}_{ABC}^{n_0+1}(A_0) = \hat{\mathcal{S}}_{ABC}^{n_0}(A_0)$.*

*Proof.* Suppose $A_0 \in \mathcal{A}$, $A_0$ is true, $A_0$ is unmarked, and

$$\forall n \in \mathbb{N}, \quad \hat{\mathcal{S}}_{ABC}^{n}(A_0) \prec \hat{\mathcal{S}}_{ABC}^{n+1}(A_0). \tag{9.1}$$

Let us consider all the constants associated to this precise $A_0$, the equivalence $\bar{\psi}$, and the dpda $\mathcal{M}$ in section 6. Let us note that $t_n = \hat{\mathcal{S}}_{ABC}^{n}(A_0)$ (for every $n \in \mathbb{N}$) and let

$$t_\infty = \text{least upper-bound}\{t_n \mid n \in \mathbb{N}\}.$$

Let us note that, by definition (7.10), the strict inequality (9.1) implies that

$$\forall n \in \mathbb{N}, \quad t_n \text{ is consistent.} \tag{9.2}$$

Let us denote by $x_n$ the node of $t_n$ such that $t_{n+1} = t_n[\hat{\Delta}(t_n)/x_n]$. Let us notice that as every $x_n$ is unclosed in $t_n$, one can prove by induction that every $t_n$ is repetition-free. Hence

$$t_\infty \text{ is repetition-free.} \tag{9.3}$$

By Koenig's lemma, $t_\infty$ contains an infinite branch $y_0 y_1 \cdots y_s \cdots$ whose (infinite) labeling word is $A_0 A_1 \cdots A_s \cdots$ (where $A_s = t_\infty(y_s)$).

Condition (C3) in the definition of $T_C^{(\mathcal{O})}$, combined with Lemma 3.17, shows that every equation $(\pi, T, U)$ produced by $T_C$ has size

$$\max\{\|T\|, \|U\|\} \leq D_2, \tag{9.4}$$

and hence that the number of possible unweighted equations produced by $T_C$ is *finite*. Hence $T_C$ occurs only a finite number of times on this branch (because $t_\infty$ is repetition-free (9.3) and $T_{cut}$ cannot occur on an infinite branch). Let $n_0$ be the last point where $T_C$ occurs (or $n_0 = 0$ if $T_C$ never occurs on this branch). $(y_{n_0+i})_{i \geq 0}$ is a branch of a tree $t' \in \mathcal{T}(\mathcal{S}_{AB}, A_{n_0})$. Let us notice also that

$$\text{every equation produced by } T_C \text{ is unmarked} \tag{9.5}$$

(by condition (C4) in the definition of $T_C^{(\mathcal{O})}$; see section 7), and

$$\text{every equation produced by } T_C \text{ has a length } \lambda \leq \lambda_2, \tag{9.6}$$

because it has a length $\leq d_0$ and $d_0 \leq \lambda_2$ by definition (6.11) in section 6. Moreover, the root $A_0$ of $t_\infty$ must have a size $\leq D_2$ (by definition (6.10) in section 6), must be unmarked (by the hypothesis of the lemma), and must have a length $\lambda_0 \leq \lambda_2$ (by definition (6.11) in section 6). Hence, in either case, $t'$ fulfills the hypotheses (8.1) and (8.2) stated in section 3.3 and assumed in section 8.

As $\mathcal{S}_{ABC}$ is a strategy for $\mathcal{B}_0$ and $A_0$ is true, $A_{n_0}$ is also true, and hence hypothesis (8.3) assumed in section 8 is fulfilled. We may now apply the results obtained in section 8.2.

By Lemma 8.10, the branch $(y_{n_0+i})_{i \geq 0}$ must contain an infinite B-stacking sequence. Let us remark that, as $T_\emptyset$ does not occur (otherwise the branch would be finite), every equation $(\pi, U^-, U^+)$ labeling this branch is such that $U^- \neq \emptyset$, $U^+ \neq \emptyset$.

By Lemma 8.9 such a B-stacking sequence contains a subsequence $(A_{\kappa_1}, A_{\kappa_2}, \dots, A_{\kappa_d})$ with $d \leq d_0$, fulfilling hypotheses (1), (2) of Lemma 5.5, and by the above remark it fulfills hypothesis (5.6) of section 5.2 too. Let $n_i \in \mathbb{N}$ such that $x_{n_i} = y_{\kappa_i}$ for $1 \leq i \leq d$. By (9.2), $\Omega(\bar{\Pi}(t_{n_d}), \mathrm{im}(t_{n_d})) \neq \emptyset$. Let us consider some

$$\mathcal{O} \in \Omega(\bar{\Pi}(t_{n_d}), \mathrm{im}(t_{n_d})).$$

Let $\mathcal{S}_d = (A_{\kappa_i})_{1 \leq i \leq d}$ and $D = \mathrm{D}^{(\mathcal{O})}(\mathcal{S}_d)$. By Lemma 5.5,

$$(9.7) \qquad \mathrm{INV}^{(\mathcal{O})}(\mathcal{S}_d) \neq \perp, \quad D \in [0, d-1], \quad \text{and} \quad \|| \mathrm{INV}^{(\mathcal{O})}(\mathcal{S}_d) \|| \leq \Sigma_{d_0} + s_{d_0}.$$

Let $\mathcal{S}_{D+1} = (A_{\kappa_i})_{1 \leq i \leq D+1}$. By hypothesis (2) of Lemma 5.5 (we established that this hypothesis is true),

$$\bar{\Pi}(t_{n_{D+1}}) \leq \bar{\Pi}(t_{n_d}),$$

and it is straightforward that

$$\mathrm{im}(t_{n_{D+1}}) \subseteq \mathrm{im}(t_{n_d});$$

hence,

$$(9.8) \qquad \mathcal{O} \in \Omega(\bar{\Pi}(t_{n_{D+1}}), \mathrm{im}(t_{n_{D+1}})).$$

Let $W_{D+1} = A_0 \cdot A_1 \cdots A_{\kappa_1} \cdots A_{\kappa_{D+1}}$ (the word from the root to $y_{\kappa_{D+1}}$). Let us notice that

$$(9.9) \qquad \mathrm{D}^{(\mathcal{O})}(\mathcal{S}_{D+1}) = \mathrm{D}^{(\mathcal{O})}(\mathcal{S}_d) = D, \quad \mathrm{INV}^{(\mathcal{O})}(\mathcal{S}_{D+1}) = \mathrm{INV}^{(\mathcal{O})}(\mathcal{S}_d).$$

By (9.7), (9.9),

$$(9.10) \qquad \rho_e(\mathrm{INV}^{(\mathcal{O})}(\mathcal{S}_{D+1})) \in T_C^{(\mathcal{O})}(W_{D+1}).$$

By (9.8), (9.10), the set $\{\mathcal{O} \in \Omega(\bar{\Pi}(t_{n_{D+1}}), \mathrm{im}(t_{n_{D+1}})), T_C^{(\mathcal{O})}(W_{D+1}) \neq \emptyset\}$ is not empty, so that case (0) of the definition of $\hat{\Delta}(t)$ (see section 7) is fulfilled and

$$\hat{\Delta}(t_{n_{D+1}}) = A_{n_{D+1}}(T_C^{(\mathcal{O}_0)}(W_{D+1})),$$

i.e., $T_C$ occurs at $y_{\kappa_{D+1}+1}$. This is a contradiction with the minimality of $n_0$. We have proved that hypothesis (9.1) is impossible. Hence the lemma is proved. $\square$

## 10. Elimination.

**10.1. System $\mathcal{B}_1$.** We prove here that the new formal system $\mathcal{B}_1$ obtained by *elimination* of metarule (R5) in $\mathcal{B}_0$ is recursively enumerable and complete. The decidability of the bisimulation problem follows.

Let $\mathcal{B}_1 = \langle \mathcal{A}, H, \mid\!\!\!-\!\!-_{\mathcal{B}_1} \rangle$, where $\mathcal{A}, H$ are the same as in $\mathcal{B}_0$, but the *elementary deduction relation* $|\!\mid\!\!\!-\!\!-_{\mathcal{B}_1}$ is the relation generated by the subset of metarules (R0), (R1), (R2), (R3), (R′3), (R4), (R6), (R7), (R8), i.e., all the metarules of $\mathcal{B}_0$ except (R5). The deduction relation $\mid\!\!\!-\!\!-_{\mathcal{B}_1}$ is now defined by

$$\mid\!\!\!-\!\!-_{\mathcal{B}_1} = \overset{\langle * \rangle}{|\!\mid\!\!\!-\!\!-}_{\mathcal{B}_1} \circ \overset{[1]}{|\!\mid\!\!\!-\!\!-}_{R0,R3,R'3,R4} \circ \overset{\langle * \rangle}{|\!\mid\!\!\!-\!\!-}_{\mathcal{B}_1}.$$

LEMMA 10.1. *$\mathcal{B}_1$ is a deduction system.*

*Sketch of proof.* As $\mid\!\!\!-\!\!-_{\mathcal{B}_1} \subseteq \mid\!\!\!-\!\!-_{\mathcal{B}_0}$, property (A1) is fulfilled by $\mid\!\!\!-\!\!-_{\mathcal{B}_1}$.

By the well-known decidability properties for finite-automata, rules (R0), (R1), (R2), (R3), (R′3), (R4), (R6), (R7), (R8) are recursively enumerable. Hence property (A2) is fulfilled by $\mathcal{B}_1$. $\square$

**Completeness.**

Definition 10.2. *Let $P$ be a finite subset of $\mathcal{A}$ and let $\bar{\pi} \in \mathbb{N}$. $P$ is said to be* locally $\bar{\pi}$-consistent *iff, for every $(\pi, S, S') \in P$, if*

$$\pi < \bar{\pi},$$

*then there exists $\mathcal{R}_1 \in \bar{\mathcal{B}}_1$ such that*

$$[\pi, S, S', \mathcal{R}_1] \subseteq \mathrm{Cong}(P).$$

Lemma 10.3. *Let $P$ be a finite subset of $\mathcal{A}$ and let $\bar{\pi} \in \mathbb{N}$. If $P$ is locally $\bar{\pi}$-consistent, then $P$ is $\bar{\pi}$-consistent.*

*Proof.* Let us consider, for every integer $n \geq 0$ $p \geq 0$, the following property $\mathcal{Q}(n,p)$: $\forall \pi \in \mathbb{N}$, $\lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V\,\rangle\rangle$,

$$(\pi, S, S') \in \mathrm{Cong}_p(P) \quad \text{and} \quad \pi + n - 1 < \bar{\pi} \Rightarrow$$
$$\exists \mathcal{R}_n \in \mathcal{B}_n(S, S'), \quad [\pi, S, S', \mathcal{R}_n] \subseteq \mathrm{Cong}(P). \tag{10.1}$$

Let us prove by lexicographic induction on $(n, p)$ that

$$\forall (n,p) \in \mathbb{N} \times \mathbb{N}, \quad \mathcal{Q}(n,p). \tag{10.2}$$

***n* = 0, *p* = 0:** The only possible value of $\mathcal{R}_0 \in \mathcal{B}_0(S, S')$ is $\mathcal{R}_0 = \{(\epsilon, \epsilon)\}$, and $[\pi, S, S', \mathcal{R}_0] = \{(\pi, S, S')\} \subseteq \mathrm{Cong}_0(P)$.

***p* > 0:** There exists a subset $Q \subseteq \mathcal{P}_f(\mathcal{A})$, such that

$$P \overset{\langle p-1\rangle}{||\!\!-\!\!-}_{\mathcal{C}}\, Q \quad \text{and} \quad Q \overset{\langle 1\rangle}{||\!\!-\!\!-}_{\mathcal{C}}\, \{(\pi, S, S')\}.$$

As every rule of $\mathcal{B}_0$ increases the weight, we can suppose that every assertion of $Q$ has a weight $\leq \pi$. Hence, by the induction hypothesis,

$$\forall (\pi', T, T') \in Q,\ \exists \mathcal{R}_n \in \mathcal{B}_n(T, T'), \quad [\pi', T, T', \mathcal{R}_n] \subseteq \mathrm{Cong}(P). \tag{10.3}$$

Let us consider the type of rule used in the last step, $Q \overset{\langle 1\rangle}{||\!\!-\!\!-}_{\mathcal{C}} \{(\pi, S, S')\}$, of the above deduction.

(R0): $(\pi - 1, S, S') \in Q$. By (10.3), $\exists \mathcal{R}_n \in \mathcal{B}_n(S, S')$,

$$[\pi - 1, S, S', \mathcal{R}_n] \subseteq \mathrm{Cong}(P).$$

As $[\pi - 1, S, S', \mathcal{R}_n] \overset{\langle 1\rangle}{||\!\!-\!\!-}_{\mathcal{C}} [\pi, S, S', \mathcal{R}_n]$,

$$[\pi, S, S', \mathcal{R}_n] \subseteq \mathrm{Cong}(P).$$

(R1): $(\pi, S', S) \in Q$ (analogous to the above case).

(R2): $(\pi, S, T), (\pi, T, S') \in Q$. By (10.3), $\exists \mathcal{R}_n \in \mathcal{B}_n(S, T)$, $\mathcal{R}'_n \in \mathcal{B}_n(T, S')$,

$$[\pi, S, T, \mathcal{R}_n] \subseteq \mathrm{Cong}(P), [\pi, T, S', \mathcal{R}'_n] \subseteq \mathrm{Cong}(P).$$

Using the properties mentioned in section 4.4, we get that

$$[\pi, S, S', \mathcal{R}_n \circ \mathcal{R}'_n] \subseteq \mathrm{Cong}(P).$$

(R3): In this case, $\mathcal{R}_n = \mathrm{Id} \cap X^{\leq n} \times X^{\leq n} \in \mathcal{B}_n(S, S')$, and

$$[\pi, S, S', \mathcal{R}_n] \subseteq \{(\pi, S, S')\} \cup \{(\pi + k, T, T), 1 \leq k \leq n, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle\} \\ \subseteq \mathrm{Cong}(P).$$

(R′3): In this case, $\mathcal{R}_n = \mathrm{Id} \cap X^{\leq n} \times X^{\leq n} \in \mathcal{B}_n(S, S')$, and

$$[\pi, S, S', \mathcal{R}_n] = \{(\pi + k, S \odot u, \rho_e(S) \odot u) \mid 0 \leq k \leq n, u \in X^k\} \subseteq \mathrm{Cong}(P)$$

(because $\rho_e(S) \odot u = \rho_e(S \odot u)$).

(R6): $(\pi, S_1 \cdot S' + U, S') \in Q$, $S = S_1^* \cdot U$. By (10.3), $\exists \mathcal{R}_n \in \mathcal{B}_n(S_1 \cdot S' + U, S')$,

$$[\pi, S_1 \cdot S' + U, S', \mathcal{R}_n] \subseteq \mathrm{Cong}(P).$$

Using the properties mentioned in section 4.4, we get that

$$\begin{aligned}[\pi, S, S', \mathcal{R}_n^{\langle S_1, *\rangle}] &= [\pi, S_1^* \cdot U, S', \mathcal{R}_n^{\langle S_1, *\rangle}] \\ &\subseteq \mathrm{Cong}[\pi, S_1 \cdot S' + U, S', \mathcal{R}_n] \\ &\subseteq \mathrm{Cong}(Q) \subseteq \mathrm{Cong}(P).\end{aligned}$$

(R7): $(\pi, S_1, S_1') \in Q$, $S = S_1 \cdot T$, $S' = S_1' \cdot T$. By (10.3), $\exists \mathcal{R}_n \in \mathcal{B}_n(S_1, S_1')$, $[\pi, S_1, S_1', \mathcal{R}_n] \subseteq \mathrm{Cong}(P)$. Using the properties mentioned in section 4.4, we get that

$$\begin{aligned}[\pi, S, S', \langle S_1 | \mathcal{R}_n\rangle] &= [\pi, S_1 \cdot T, S_1' \cdot T, \langle S_1 | \mathcal{R}_n\rangle] \\ &\subseteq \mathrm{Cong}([\pi, S_1, S_1', \mathcal{R}_n]) \\ &\subseteq \mathrm{Cong}(Q) \subseteq \mathrm{Cong}(P).\end{aligned}$$

(R8): $\forall i \in [1, \delta]$, $(\pi, T_{i,*}, T'_{i,*}) \in Q$, $S = S_1 \cdot T$, $S' = S_1 \cdot T'$. By (10.3), $\exists \mathcal{R}_{1,n}, \ldots, \mathcal{R}_{\delta,n} \in \mathcal{B}_n(T_{i,*}, T'_{i,*})$, such that

$$[\pi, T_{i,*}, T'_{i,*}, \mathcal{R}_{i,n}] \subseteq \mathrm{Cong}(P).$$

Using the properties mentioned in section 4.4, we get that

$$\begin{aligned}[\pi, S, S', \langle S, \mathcal{R}_{*,n}\rangle] &= [\pi, S_1 \cdot T, S_1 \cdot T', \langle S, \mathcal{R}_{*,n}\rangle] \\ &\subseteq \mathrm{Cong}\left(\bigcup_{1 \leq i \leq \delta} [\pi, T_{i,*}, T'_{i,*}, \mathcal{R}_{i,n}]\right) \\ &\subseteq \mathrm{Cong}(Q) \subseteq \mathrm{Cong}(P).\end{aligned}$$

In all cases $\mathcal{Q}(n, p)$ has been established.

***n* > 0, *p* = 0:** $(\pi, S, S') \in P$. As $P$ is locally $\bar{\pi}$-consistent and $\pi \leq \pi + n - 1 < \bar{\pi}$, there exist $\mathcal{R}_1 \in \mathcal{B}_1(S, S')$, $q \in \mathbb{N}$ such that

$$[\pi, S, S', \mathcal{R}_1] \subseteq \mathrm{Cong}_q(P). \tag{10.4}$$

As $(n-1, q) < (n, 0)$, by the induction hypothesis, $\forall (x, x') \in \mathcal{R}_1 \cap X \times X$, $\exists \mathcal{R}_{x,x',n-1} \in \mathcal{B}_{n-1}(S \odot x, S' \odot x')$ such that

$$[\pi + 1, S \odot x, S' \odot x', \mathcal{R}_{x,x',n-1}] \subseteq \mathrm{Cong}(P). \tag{10.5}$$

Let us consider $\mathcal{R}_n = \{(\epsilon,\epsilon)\} \bigcup_{(x,x') \in \mathcal{R}_1 \cap X \times X} \{(x,x')\} \cdot \mathcal{R}_{x,x',n-1}$. One can check that $\mathcal{R}_n \in \mathcal{B}_n(S,S')$ and, by (10.4), (10.5), we obtain

$$[\pi, S, S', \mathcal{R}_n] = \{(\pi,S,S')\} \bigcup_{(x,x') \in \mathcal{R}_1 \cap X \times X} [S \odot x, S' \odot x', \mathcal{R}_{x,x',n-1}] \subseteq \mathrm{Cong}(P).$$

Let us define now an oracle $\mathcal{O} \in \Omega$ which is $\bar{\pi}$-consistent with $P$. For every $(S,S') \in \bigcup_{\lambda \geq 1} \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\ V\ \rangle\rangle$ occurring in $\mathrm{Cong}(P)$ (i.e., as the last two components of an assertion in $\mathrm{Cong}(P)$), let us note the following:

$$\begin{aligned} W(S,S') &= \min\{\pi \in \mathbb{N} \mid (\pi,S,S') \in \mathrm{Cong}(P)\},\\ D(S,S') &= \max\{\bar{\pi} - W(S,S'), 0\},\\ C(S,S') &= \min\{\mathcal{R} \in \mathcal{B}_{D(S,S')}(S,S') \mid [W(S,S'),S,S',\mathcal{R}] \subseteq \mathrm{Cong}(P)\}. \end{aligned}$$

Notice that $C(S,S')$ is well-defined, owing to property (10.2). We then define $\mathcal{O}$ as follows: for every $(S,S')$ occurring in $\mathrm{Cong}(P)$,

$$\mathcal{O}(S,S') = \min\{\mathcal{R} \in \mathcal{B}_\infty(S,S') \mid C(S,S') = \mathcal{R} \cap (X^{\leq D(S,S')} \times X^{\leq D(S,S')})\}, \tag{10.6}$$

and for every $(S,S')$ not occurring in $\mathrm{Cong}(P)$,

$$\begin{aligned} &\mathcal{O}(S,S') = \min\{\mathcal{R} \in \mathcal{B}_\infty(S,S')\} \ \text{(if } S \sim S'),\\ &\mathcal{O}(S,S') = \mathrm{Id}_{X^*} \ \text{(if } S \not\sim S'). \end{aligned} \tag{10.7}$$

One can check that, by the choice of $C(S,S')$, $\mathcal{O}$ is $\bar{\pi}$-consistent with $P$. □

LEMMA 10.4. *Let $A_0 \in \mathcal{A}$ such that $H(A_0) = \infty$. Let us consider the sequence of trees $t_n = \hat{\mathcal{S}}^n_{ABC}(A_0)$. For every integer $n \geq 0$, $t_n$ is consistent.*

Let us say that the strategy $T$ "applies to" node $x$ iff $x$ has exactly $m$ sons $x \cdot 1, x \cdot 2, \dots, x \cdot m$ and

$$\tau(x1) \cdot \tau(x \cdot 2) \cdots \tau(x \cdot m) \in T(\tau(x[0]) \cdot \tau(x[1]) \cdots \tau(x[|x|]));$$

i.e., the word consisting of the labels of the sons of $x$ belongs to the image of the path from $\epsilon$ (included) to $x$ (included) by the strategy $T$.

*Proof.* For every $k \in \mathbb{N}$ we define

$$\bar{\pi}_k = \bar{\Pi}(t_k).$$

We prove by induction on $(n,\pi)$ the following property $\mathcal{R}(n,\pi)$:

$$\forall x \in \mathrm{dom}(t_n), \text{ if } t_n(x) = (\pi,S,S') \text{ with } \pi < \bar{\pi}_n, \text{ then} \tag{10.8}$$

$$\exists \mathcal{R}_1 \in \mathcal{B}_1(S,S'), [\pi,S,S',\mathcal{R}_1] \subseteq \mathrm{Cong}(\mathrm{im}(t_n)). \tag{10.9}$$

At every step of our proof by induction, we consider some node $x$ of $t_n$ fulfilling hypothesis (10.8) and show that it must fulfill (10.9). Let us notice that if $x$ is not closed, then hypothesis (10.8) cannot be true, by minimality of $\bar{\pi}_n$. Let us notice also that if $x$ is closed, but there is some $x' \prec x$ such that $t_n(x') = t_n(x)$, then (10.9) on $x$ is the same property as (10.9) for $x'$. Hence, in what follows, we can suppose that $x$ is closed and that it is minimal (w.r.t. $\preceq$):

$$x = \min_{\preceq}\{y \in \mathrm{dom}(t_n) \mid t_n(y) = t_n(x)\}. \tag{10.10}$$

***$n = 0$, $\pi = 0$:*** $\mathrm{dom}(t_0) = \{\epsilon\}$, $t_0(\epsilon) = A_0$. If $\epsilon$ is not closed, then $\bar{\pi}_0 = \pi = 0$, and hence there is no node $x$ fulfilling hypothesis (10.8). Otherwise, $\bar{\pi}_0 = \infty$ and $x = \epsilon$ is closed: either $T_\emptyset(A_0) = \{\epsilon\}$ or $T_\varepsilon(A_0) = \{\epsilon\}$. Let us choose

$$\mathcal{R}_1 = \mathrm{Id}_{X^*} \cap X^{\leq 1} \times X^{\leq 1}. \tag{10.11}$$

If we note $A_0 = (\pi, S_0^-, S_0^+)$, then

$$[\pi, S_0^-, S_0^+, \mathcal{R}_1] = \{(\pi, S_0^-, S_0^+)\} \cup \{(\pi + 1, S_0^- \odot x, S_0^+ \odot x) \mid x \in X\},$$

where, $\forall x \in X$, $S_0^- \odot x \equiv S_0^+ \odot x \equiv \emptyset$. Using rule (R$'$3), we see that

$$[\pi, S, S', \mathcal{R}_1] \subseteq \mathrm{Cong}(\emptyset) \subseteq \mathrm{Cong}(\mathrm{im}(t_n)). \tag{10.12}$$

***$n > 0$, $\pi = 0$:*** Let $x$ be some node of $t_n$ such that $\exists S, S'$, $t_n(x) = (\pi, S, S')$ and $\pi < \bar{\pi}_n$. Let us denote by $W_x$ the word labeling the path from the root of $t_n$ (included) to $x$ (included).

*Case* 1. *$\exists x' \in \mathrm{dom}(t_n)$, $x'$ internal node, such that $t_n(x') = t_n(x)$.* As $\pi = 0$, the sons $x' \cdot 1, x' \cdot 2, \ldots, x' \cdot m$ of $x'$ are such that $t_n(x' \cdot 1) \cdot t_n(x' \cdot 2) \cdots t_n(x' \cdot m) \in T_A^{(\mathcal{O})}(W_{x'})$ for some oracle $\mathcal{O}$. Let us choose

$$\mathcal{R}_1 = \mathcal{O}(S, S') \cap X^{\leq 1} \times X^{\leq 1}. \tag{10.13}$$

Then

$$[\pi, S, S', \mathcal{R}_1] \subseteq \mathrm{im}(t_n). \tag{10.14}$$

*Case* 2. *$T_\emptyset(W_x) = \{\epsilon\}$ or $T_\varepsilon(W_x) = \{\epsilon\}$.* In this case the choice $\mathcal{R}_1 = \mathrm{Id}_{X^*} \cap X^{\leq 1} \times X^{\leq 1}$ again satisfies (10.12).

***$\pi > 0$:*** Let $x$ fulfill hypothesis (10.8). As $t_n$ is a proof-tree for $\mathcal{S}_{ABC}$, and as we suppose $x$ is closed and minimal (10.10), one of the following cases must occur.

*Case* 1. *$T_{cut}$ applies to $x$.* There exists $x' \in \mathrm{dom}(t_n)$, $\exists \pi' \in \mathbb{N}$, such that

$$t_n(x') = (\pi', S, S') \quad \text{and} \quad \pi' < \pi.$$

By the induction hypothesis

$$\exists \mathcal{R}_1 \in \mathcal{B}_1(S, S'), \quad [\pi', S, S', \mathcal{R}_1] \subseteq \mathrm{Cong}(\mathrm{im}(t_n)),$$

and by means of rule (R0),

$$[\pi, S, S', \mathcal{R}_1] \subseteq \mathrm{Cong}([\pi', S, S', \mathcal{R}_1]).$$

Hence (10.9) is true.

*Case* 2. *$T_\emptyset$ or $T_\epsilon$ applies to $x$.* Here again, the choice (10.11) fulfills property (10.12).

In the remaining cases we use the following notation: for every $k \in \mathbb{N}$ such that $t_k$ is not closed,

$$x_k = \min\{x \in \mathrm{dom}(t_k),\ x \text{ is not closed for } \mathcal{S}_{ABC} \text{ and } \exists S, S',\ t(x) = (\bar{\pi}_k, S, S')\}.$$

If $\exists k < n \mid t_k$ is not consistent or is closed, then by (7.10), $t_k = t_{k+1} = \cdots = t_n$; hence $\mathcal{R}(n, \pi) \Leftrightarrow \mathcal{R}(k, \pi)$, and this last property is true by the induction hypothesis.

Let us suppose now that $\forall k < n$, $t_k$ is consistent and unclosed. According to formula (7.9),

$$t_{k+1} = t_k[e_{k+1}/x_k]$$

for some tree of depth one, $e_{k+1}$.

Let $k \in [0, n-1]$, $x = x_k$, $\pi = \bar{\pi}_k$ (such a $k$ must exist because $x$ is internal). Let $x \cdot 1, \ldots, x \cdot \mu$ be the sequence of sons of $x$.

*Case* 3. *$T_A$ applies to $x$.* Hence there exists some oracle $\mathcal{O}$ such that $T_A^{(\mathcal{O})}$ applies to $x$. The choice (10.13) fulfills property (10.14).

*Case* 4. *$T_B^{\alpha}$ applies to $x$ (for some $\alpha \in \{-,+\}$).* Let us suppose $\alpha = +$. Let $x' = x(|x| - k_1)$ (the prefix of $x$ having length $|x| - k_1$), $t_n(x') = (\pi', \bar{U}, U')$. By definition of $\hat{\mathcal{S}}_{ABC}$, there exists some oracle $\mathcal{O}$ which is $\bar{\pi}_k$-consistent with $\mathrm{im}(t_k)$ and such that

$$\mu = 1 \quad \text{and} \quad t_n(x \cdot 1) = T_B^{(\mathcal{O}),+}(W_x).$$

Let us look at the proof of Lemma 7.2 in the particular case of this oracle $\mathcal{O}$: as the pairs $(u_\ell, u'_\ell)$ belong to $\mathcal{O}(\bar{U}, U')$ (for every $\ell \in [1, q]$) and $\pi' + |u_\ell| - 1 < \pi' + k_0 \leq \pi' + 2 \cdot k_0 < \bar{\pi}_k$, deduction (7.2) can be obtained just by using rules in $\mathcal{C}$. As deduction (7.2) is the only one (in the proof of Lemma 7.2) using rules in $\mathcal{B}_0 - \mathcal{C}$ we conclude that deduction (7.1) can be replaced by

$$\{t_n(x'), t_n(x \cdot 1)\} \cup \mathrm{im}(t_k) \overset{\langle * \rangle}{||\!\!-\!\!-}_{\mathcal{C}} \tau_{-1}(t_n(x)). \tag{10.15}$$

(We recall that $\tau_{-1}$ consists in replacing the weight of a given weighted equation into its predecessor.) Deduction (10.15) implies that

$$\exists p \in \mathbb{N}, \quad (\pi - 1, S, S') \in \mathrm{Cong}_p(\mathrm{im}(t_n)). \tag{10.16}$$

By the induction hypothesis, as $\pi - 1 < \bar{\pi}_n$, $\mathrm{im}(t_n)$ is locally $\pi - 1$-consistent, and hence, by Lemma 10.3, $\mathrm{im}(t_n)$ is $\pi - 1$-consistent. Hypothesis (10.16) implies that

$$\exists \mathcal{R}_1 \in \mathcal{B}_1(S, S'), \quad [\pi - 1, S, S', \mathcal{R}_1] \subseteq \mathrm{Cong}(\mathrm{im}(t_n)),$$

and hence, using (R0), that

$$\exists \mathcal{R}_1 \in \mathcal{B}_1(S, S'), \quad [\pi, S, S', \mathcal{R}_1] \subseteq \mathrm{Cong}(\mathrm{im}(t_n)).$$

*Case* 5. *$T_C$ applies to $x$.* By definition of $\hat{\mathcal{S}}_{ABC}$, there exists some oracle $\mathcal{O}$ which is $\bar{\pi}_k$-consistent with $\mathrm{im}(t_k)$ and such that

$$\mu = 1 \quad \text{and} \quad t_n(x \cdot 1) = T_C^{(\mathcal{O})}(W_x).$$

Let $W_x = A_1 \cdots A_\ell \cdots A_{|x|+1}$, $\kappa_1 < \cdots < \kappa_i < \kappa_{i+1} < \cdots \kappa_{D+1} = |x| + 1$, $\mathcal{S} = (\mathcal{E}_i)_{1 \leq i \leq D+1}$, where, for every $1 \leq i \leq d$,

$$\mathcal{E}_i = A_{\kappa_i} = \left( \pi_i, \sum_{j=1}^{d} \alpha_{i,j} S_j, \sum_{j=1}^{d} \beta_{i,j} S_j \right)$$

and

$$T_C^{(\mathcal{O})}(W_x) = \rho_e(\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})), \quad \mathrm{W}^{(\mathcal{O})}(\mathcal{S}) \neq \perp, \quad \mathrm{D}^{(\mathcal{O})}(\mathcal{S}) = D \leq d - 1.$$

Let us look at the proof of Lemma 5.3 in the particular case of this oracle $\mathcal{O}$: the only place where a rule in $\mathcal{B}_0 - \mathcal{C}$ is used is in deduction (5.10), when Case 2, Subcase 1 (or Case 2, Subcase 2) of the recursive definition of $\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})$ occurs. Let us recall that the pair $(u, u')$ chosen by the oracle $\mathcal{O}$ is such that

$$\mathcal{R} = \mathcal{O}\left(\sum_{j=1}^{d} \alpha_{1,j} S_j, \sum_{j=1}^{d} \beta_{1,j} S_j\right),$$

$$\nu = \mathrm{Div}(\alpha_{1,*}, \beta_{1,*}), \quad \mathcal{R}_\nu = \mathcal{R} \cap X^{\le \nu} \times X^{\le \nu}, \quad (u, u') \in \mathcal{R}_\nu.$$

Note that $\pi_1 + \nu - 1 < \pi_1 + 2 \cdot \nu < \pi_2 \le \mathrm{W}^{(\mathcal{O})}(\mathcal{S}) + 1 = \pi = \bar{\pi}_k$. As $\mathcal{O}$ is $\bar{\pi}_k$-consistent with $\mathrm{im}(t_k)$, we conclude that

$$\left(\pi_1 + |u|, \left(\sum_{j=1}^{d} \alpha_{i,j} S_j\right) \odot u, \left(\sum_{j=1}^{d} \beta_{i,j} S_j\right) \odot u'\right) \in \left[\pi_1, \sum_{j=1}^{d} \alpha_{i,j} S_j, \sum_{j=1}^{d} \beta_{i,j} S_j, \mathcal{R}_\nu\right] \subseteq \mathrm{Cong}(\mathrm{im}(t_k)).$$

Hence deduction (5.10) can be replaced by

$$\mathcal{E'}_1 \in \mathrm{Cong}(\mathrm{im}(t_k)). \tag{10.17}$$

Similarly, for every $i \in [2, D]$, as $\pi_i + 2 \cdot \mathrm{Div}(\alpha_{i,*}^{(i-1)}, \beta_{i,*}^{(i-1)}) < \pi_{i+1} \le \mathrm{W}^{(\mathcal{O})}(\mathcal{S}) + 1 = \pi = \bar{\pi}_k$, and $\mathcal{E}_i^{(i-1)} \in \mathrm{Cong}(\mathrm{im}(t_k))$,

$$(\mathcal{E}_i^{(i-1)})' \in \mathrm{Cong}(\mathrm{im}(t_k)). \tag{10.18}$$

It follows that deduction (5.9) can be replaced by

$$\{\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})\} \cup \mathrm{im}(t_k) \overset{\langle * \rangle}{|\!\!\vdash\!\!-}_{\mathcal{C}} \tau_{-1}(t_n(x)). \tag{10.19}$$

Using the facts that $\rho_e(\mathrm{INV}^{(\mathcal{O})}(\mathcal{S})) \overset{\langle * \rangle}{|\!\!\vdash\!\!-}_{\mathcal{C}} \mathrm{INV}^{(\mathcal{O})}(\mathcal{S})$ and $\mathrm{im}(t_k) \subseteq \mathrm{im}(t_n)$ we may conclude that

$$\{t_n(x \cdot 1)\} \cup \mathrm{im}(t_n) \overset{\langle * \rangle}{|\!\!\vdash\!\!-}_{\mathcal{C}} \tau_{-1}(t_n(x)) = (\pi - 1, S, S'). \tag{10.20}$$

From (10.20) and the induction hypothesis, we can conclude, as in Case 4, that

$$\exists \mathcal{R}_1 \in \mathcal{B}_1(S, S'), \quad [\pi, S, S', \mathcal{R}_1] \subseteq \mathrm{Cong}(\mathrm{im}(t_n)).$$

(This ends the induction.)

By the above induction, for every $n \in \mathbb{N}$, $\mathrm{im}(t_n)$ is $\bar{\pi}_n$-consistent, i.e., $t_n$ is consistent. □

LEMMA 10.5. *$\hat{\mathcal{S}}_{ABC}$ is closed.*

*Proof.* Let $A_0 \in \mathcal{A}$. By Lemma 10.4, $\forall n \in \mathbb{N}$, $\hat{\mathcal{S}}_{ABC}^n(A_0)$ is consistent.

If $\hat{\mathcal{S}}_{ABC}^n(A_0)$ is consistent and is not closed, then, by definition (7.9),

$$\hat{\mathcal{S}}_{ABC}^n(A_0) \ne \hat{\mathcal{S}}_{ABC}^{n+1}(A_0);$$

if $\hat{\mathcal{S}}^n_{ABC}(A_0)$ is consistent and is closed, then, by definition (7.10),

$$\hat{\mathcal{S}}^n_{ABC}(A_0) = \hat{\mathcal{S}}^{n+1}_{ABC}(A_0).$$

Hence the equivalence (4.6), which defines the notion of closed global strategy, is fulfilled by $\hat{\mathcal{S}}_{ABC}$. □

THEOREM 10.6. *The formal systems $\mathcal{B}_0, \mathcal{B}_1$ are complete.*

*Proof.* By Lemma 9.1 $\hat{\mathcal{S}}_{ABC}$ is terminating on every unmarked assertion, and by Lemma 10.5 $\hat{\mathcal{S}}_{ABC}$ is closed. Let $A_0$ be some unmarked true assertion. According to the proof of Lemma 4.6, $\exists n_0 \in \mathbb{N}$ such that $t_\infty = \hat{\mathcal{S}}^{n_0}(A_0)$ is a proof-tree which is closed, and hence such that $\bar{\Pi}(t_\infty) = \infty$. By Lemma 10.5, $t_\infty$ is consistent, i.e., $\mathrm{im}(t_\infty)$ is $\infty$-consistent: $\forall(\pi, S, S') \in \mathrm{im}(t_\infty)$,

$$\exists \mathcal{R}_1 \in \mathcal{B}_1(S, S'), \quad [\pi, S, S', \mathcal{R}_1] \subseteq \mathrm{Cong}(\mathrm{im}(t_\infty));$$

hence,

$$\mathrm{im}(t_\infty) \overset{\langle * \rangle}{||\!\!-\!\!-}_{\mathcal{C}} [\pi, S, S', \mathcal{R}_1] \mid\!\!-\!\!-_{R4} (\pi, S, S'). \tag{10.21}$$

As the rules of $\mathcal{C}$ and (R4) are rules of $\mathcal{B}_1$, deduction (10.21) shows that

$$\mathrm{im}(t_\infty) \mid\!\!-\!\!-_{\mathcal{B}_1} (\pi, S, S'); \tag{10.22}$$

i.e., $\mathrm{im}(t_\infty)$ is a $\mathcal{B}_1$-proof.

In the general case where $A_0 = (\pi_0, U_0^-, U_0^+)$ might be marked, we observe that, owing to rules (R1), (R2), (R$'$3),

$$\{\rho_e(A_0)\} \overset{\langle * \rangle}{||\!\!-\!\!-}_{\mathcal{C}} \{A_0\}.$$

This deduction, combined with some $\mathcal{B}_1$-proof of $\rho_e(A_0)$, gives a $\mathcal{B}_1$-proof of $A_0$. □

THEOREM 10.7. *The bisimulation problem for rooted equational* 1*-graphs of finite out-degree is decidable.*

*Proof.* Let us consider the sequence of statements: Lemma 2.7, Lemma 2.8, Corollary 2.6 and Lemma 3.25. By means of the above statements, the bisimulation problem for rooted equational 1-graphs of finite out-degree reduces to the following decision problem (we call it the bisimulation problem for deterministic vectors):

*Instance:* a birooted, normalized dpda $\mathcal{M}$, its terminal alphabet $X$, a surjective literal morphism $\psi : X^* \to Y^*$ (we denote its kernel by $\bar{\psi}$), and $\lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\lambda}\langle\langle V \rangle\rangle$ (where $V$ is the structured alphabet associated with $\mathcal{M}$).

*Question:* $S \sim S'$? (where $\sim$ is the $\bar{\psi}$-bisimulation relation).

Let us consider $\mathcal{M}, X, V, \bar{\psi}$ given by some instance.

The equivalence relation $\sim$ on $\mathsf{DRB}_{1,\lambda}\langle\langle V \rangle\rangle$ has a recursively enumerable complement (this is well known). By Theorem 10.6 and Lemma 4.2, relation $\sim$ is recursively enumerable too. Hence $\sim$ is recursive.

But the function associating to every $\mathcal{M}, X, V, \bar{\psi}$ the corresponding deduction system $\mathcal{B}_1$ is recursive. Hence the bisimulation problem for deterministic vectors is decidable. □

## 10.2. System $\mathcal{B}_2$.

We exhibit here a deduction system $\mathcal{B}_2$ which is simpler than $\mathcal{B}_1$ and is still complete.

**Elementary rules.** Let us *eliminate* the weights in the rules of $\mathcal{B}_1$: we define a new set of assertions, $\mathcal{A}_2$, by

$$\mathcal{A}_2 = \bigcup_{\lambda \in \mathbb{N}-\{0\}} \mathsf{DRB}_{1,\lambda}\langle\langle\, V \,\rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V \,\rangle\rangle.$$

We define a binary relation $||\!\!\!-\!\!\!- \subseteq \mathcal{P}_f(\mathcal{A}_2) \times \mathcal{A}_2$, the *elementary deduction relation*, as the set of all the pairs having one of the following forms:

(R21)

$$\{(S,T)\} \,||\!\!\!-\!\!\!-\, (T,S)$$

for $\lambda \in \mathbb{N} - \{0\}$, $S,T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V \,\rangle\rangle$;

(R22)

$$\{(S,S'),(S',S'')\} \,||\!\!\!-\!\!\!-\, (S,S'')$$

for $\lambda \in \mathbb{N} - \{0\}$, $S,T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V \,\rangle\rangle$;

(R23)

$$\emptyset \,||\!\!\!-\!\!\!-\, (S,S)$$

for $S \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V \,\rangle\rangle$;

(R′23)

$$\emptyset \,||\!\!\!-\!\!\!-\, (S,\rho_e(S))$$

for $S \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V \,\rangle\rangle$;

(R24)

$$\{(S \odot x, T \odot x') \mid (x,x') \in \mathcal{R}_1\} \,||\!\!\!-\!\!\!-\, (S,T)$$

for $\lambda \in \mathbb{N} - \{0\}$, $S,T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V \,\rangle\rangle$, $(S \not\equiv \epsilon \wedge T \not\equiv \epsilon)$, and $\mathcal{R}_1 \in \bar{\mathcal{B}}_1$;

(R25)

$$\{(S_1 \cdot T + S, T)\} \,||\!\!\!-\!\!\!-\, (S_1^* \cdot S, T)$$

for $\lambda \in \mathbb{N} - \{0\}$, $S_1 \in \mathsf{DRB}_{1,1}\langle\langle\, V \,\rangle\rangle$, $S_1 \not\equiv \epsilon$, $(S_1,S) \in \mathsf{DRB}_{1,\lambda+1}\langle\langle\, V \,\rangle\rangle$, $T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V \,\rangle\rangle$;

(R26)

$$\{(S,S')\} \,||\!\!\!-\!\!\!-\, (S \cdot T, S' \cdot T)$$

for $\delta,\lambda \in \mathbb{N} - \{0\}$, $S,S' \in \mathsf{DRB}_{1,\delta}\langle\langle\, V \,\rangle\rangle$, $T \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\, V \,\rangle\rangle$;

(R27)

$$\{(T_{i,*},T'_{i,*}) \mid 1 \le i \le \delta\} \,||\!\!\!-\!\!\!-\, (S \cdot T, S \cdot T')$$

for $\delta,\lambda \in \mathbb{N} - \{0\}$, $S \in \mathsf{DRB}_{1,\delta}\langle\langle\, V \,\rangle\rangle$, $T,T' \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\, V \,\rangle\rangle$.

We define $|\!\!-\!\!-_{\mathcal{B}_2}$ as follows: for every $P \in \mathcal{P}_f(\mathcal{A}_2)$, $A \in \mathcal{A}_2$,

$$P \,|\!\!-\!\!-\, A \iff P \,\overset{\langle * \rangle}{||\!\!\!-\!\!\!-}\, \circ \,\overset{[1]}{||\!\!\!-\!\!\!-}_{23,24} \circ \,\overset{\langle * \rangle}{||\!\!\!-\!\!\!-}\, \{A\},$$

where $||\!\!\!-\!\!\!-_{23,24}$ is the relation defined by (R23), (R′23), (R24) only.

We define a simpler cost function $H_2 : \mathcal{A}_2 \to \mathbb{N} \cup \{\infty\}$ by

$$\forall (S, S') \in \mathcal{A}_2, \quad H_2(S, S') = \mathrm{Div}(S, S').$$

We let

$$\mathcal{B}_2 = \langle \mathcal{A}_2, H_2, \mid\!\!\!-\!\!-_{\mathcal{B}_2} \rangle.$$

LEMMA 10.8. *$\mathcal{B}_2$ is a deduction system.*

**Completeness.** Let us denote by $\mathcal{C}_2$ the subset of rules of $\mathcal{B}_2$ obtained by removing the weights in the rules of $\mathcal{C}$.

DEFINITION 10.9. *Let $P \in \mathcal{P}_f(\mathcal{A}_2)$. $P$ is said to be* self-generating *iff, for every $(S, S') \in P$,*

1. *either $S = S' = \epsilon$, or*
2. *$\exists \mathcal{R}_1 \in \bar{\mathcal{B}}_1(S, S')$, $\forall (x, x') \in \mathcal{R}_1$, $P \overset{\langle * \rangle}{|\!\!\mid\!\!\!-\!\!-}_{\mathcal{C}_2} (S \odot x, S' \odot x')$.*

(See Remark 10.12 below for the origins of this notion.)

LEMMA 10.10. *Let $A \in \mathcal{A}_2$ such that $A$ is unmarked. Then $H(A) = \infty$ iff there exists a finite self-generating set $P \subseteq \mathcal{A}_2$ such that $A \in P$.*

*Proof.* Owing to metarules (R23), (R24) it is clear that every self-generating set $P \in \mathcal{P}_f(\mathcal{A}_2)$ is a $\mathcal{B}_2$-proof. Hence, if $A$ belongs to some self-generating set, then $H(A) = \infty$.

Let us suppose now that $H_2(A) = \infty$. Let us consider the closed proof-tree $t_\infty$ obtained by applying the global strategy $\hat{S}_{ABC}$ on the assertion $(0, A)$. By Lemma 9.1 $t_\infty$ is finite, and by Lemma 10.5 $t_\infty$ is consistent, which means that $\mathrm{im}(t_\infty)$ is $\infty$-consistent. Let

$$P = pr_{2,3}(\mathrm{im}(t_\infty))$$

(where $pr_{2,3} : \mathcal{A} \to \mathcal{A}_2$ is the map erasing the weights).

As $\mathrm{im}(t_\infty)$ is $\infty$-consistent, $P$ is self-generating and $A \in P$. □

THEOREM 10.11. *$\mathcal{B}_2$ is a complete deduction system.*

*Proof.* We already noticed that every self-generating set is a $\mathcal{B}_2$-proof. Hence Lemma 10.10 proves that every true, unmarked assertion possesses some finite $\mathcal{B}_2$-proof.

Let $A$ be any true assertion. $\rho_e(A)$ has a finite proof $P$. Owing to rules (R1), (R2), (R′3), $Q = P \cup \{A\}$ is a $\mathcal{B}_2$-proof of $A$. □

**10.3. System $\mathcal{B}_3$.** We exhibit here a deduction system $\mathcal{B}_3$ which is even simpler than $\mathcal{B}_2$ and is still complete. Let us consider $\mathcal{B}_3 = \langle \mathcal{A}_3, H_3, \mid\!\!\!-\!\!-_{\mathcal{B}_3} \rangle$, where

$$\mathcal{A}_3 = \bigcup_{\lambda \in \mathbb{N} - \{0\}} \mathsf{DRB}_{1,\lambda}\langle\langle\, V_0 \,\rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\, V_0 \,\rangle\rangle.$$

$H_3 = H_{2|\mathcal{A}_3}$ and $\mid\!\!\!-\!\!-_{\mathcal{B}_3}$ is defined below: the metarules of $\mathcal{B}_3$ are essentially those of $\mathcal{B}_2$, but restricted to the unmarked vectors.

(R31)

$$\{(S, T)\} \,|\!\!\mid\!\!\!-\!\!-\, (T, S)$$

for $\lambda \in \mathbb{N} - \{0\}$, $S, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V_0 \,\rangle\rangle$;

(R32)

$$\{(S,S'),(S',S'')\} \mid\!\!\vdash\!- (S,S'')$$

for $\lambda \in \mathbb{N} - \{0\}$, $S,T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V_0 \,\rangle\rangle$;

(R33)

$$\emptyset \mid\!\!\vdash\!- (S,S)$$

for $S \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V_0 \,\rangle\rangle$;

(R34)

$$\{(S \odot x, T \odot x') \mid (x,x') \in \mathcal{R}_1\} \mid\!\!\vdash\!- (S,T)$$

for $\lambda \in \mathbb{N} - \{0\}$, $S,T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V_0 \,\rangle\rangle$, $(S \not\equiv \epsilon \wedge T \not\equiv \epsilon)$, and $\mathcal{R}_1 \in \bar{\mathcal{B}}_1$;

(R35)

$$\{(S_1 \cdot T + S, T)\} \mid\!\!\vdash\!- (S_1^* \cdot S, T)$$

for $\lambda \in \mathbb{N} - \{0\}$, $S_1 \in \mathsf{DRB}_{1,1}\langle\langle\, V_0 \,\rangle\rangle$, $S_1 \not\equiv \epsilon$, $(S_1, S) \in \mathsf{DRB}_{1,\lambda+1}\langle\langle\, V_0 \,\rangle\rangle$, $T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V_0 \,\rangle\rangle$;

(R36)

$$\{(S,S')\} \mid\!\!\vdash\!- (S \cdot T, S' \cdot T)$$

for $\delta, \lambda \in \mathbb{N} - \{0\}$, $S,S' \in \mathsf{DRB}_{1,\delta}\langle\langle\, V_0 \,\rangle\rangle$, $T \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\, V_0 \,\rangle\rangle$;

(R37)

$$\{(T_{i,*}, T'_{i,*}) \mid 1 \le i \le \delta\} \mid\!\!\vdash\!- (S \cdot T, S \cdot T')$$

for $\delta, \lambda \in \mathbb{N} - \{0\}$, $S \in \mathsf{DRB}_{1,\delta}\langle\langle\, V_0 \,\rangle\rangle$, $T, T' \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\, V_0 \,\rangle\rangle$.

We then define $\vdash\!-_{\mathcal{B}_3}$ as follows: for every $P \in \mathcal{P}_f(\mathcal{A}_3)$, $A \in \mathcal{A}_3$,

$$P \vdash\!-_{\mathcal{B}_3} A \iff P \overset{\langle * \rangle}{\mid\!\!\vdash\!-}_{\mathcal{B}_3} \circ \overset{[1]}{\mid\!\!\vdash\!-}_{33,34} \circ \overset{\langle * \rangle}{\mid\!\!\vdash\!-}_{\mathcal{B}_3} \{A\},$$

where $\mid\!\!\vdash\!-_{33,34}$ is now the relation defined by (R33), (R34) only.

As $\vdash\!-_{\mathcal{B}_3} \subseteq \vdash\!-_{\mathcal{B}_2}$, $H_3 = H_2$, it is clear that $\mathcal{B}_3$ is a deduction system.

**Completeness.** Let us call $\mathcal{C}_3$ the intersection of the set of the rules of $\mathcal{C}$ with the set of the rules of $\mathcal{B}_3$ (it is also equal to the set of instances of (R31), (R32), (R33), (R35), (R36), (R37)). Let us now call $P \in \mathcal{P}_f(\mathcal{A}_3)$ a $\mathcal{C}_2$-*self-generating* set iff it fulfills Definition 10.9 and a *self-generating* set iff it fulfills Definition 10.9 but where $\mathcal{C}_2$ is replaced by $\mathcal{C}_3$.

REMARK 10.12.

1. *This notion of a "self-generating set (of pairs)" is a straightforward adaptation to our d-space of vectors of the notion of the "self-proving set of pairs" defined in* [10, p. 162] *for the magma $M(F \cup \Phi, V)$.*

2. *The notion of "self-bisimulation" (introduced in* [5] *and also used in* [18, 17]*) was also such an adaptation, but in the context of a monoid-structure. The notion we use in this work can be seen, as well, as a generalization of this notion of self-bisimulation: when every class in $V_0/\smile$ has just one element, the only "rational deterministic boolean series" over $V_0$ are the words; in this case the self-bisimulations are exactly the self-generating sets.*

LEMMA 10.13. *Let $A \in \mathcal{A}_3$. Then $H_3(A) = \infty$ iff there exists a finite self-generating set $P \subseteq \mathcal{A}_3$ such that $A \in P$.*

*Proof.* Owing to metarules (R33) and (R34), every self-generating set is a $\mathcal{B}_3$-proof.

Let $A \in \mathcal{A}_3$ such that $H_3(A) = \infty$. By Lemma 10.10, there exists some $\mathcal{C}_2$-self-generating set $P$ such that $A \in P$.

Let us consider $Q = \{\rho_e(B) \mid B \in P\}$.

One can check that $\rho_e$ maps the set of rules of $\mathcal{C}_2$ into the set of rules of $\mathcal{C}_3$. One can also check that $\rho_e$ and $\odot$ are commuting (i.e., $\rho_e(S \odot u) = \rho_e(S) \odot u$). Hence $Q$ is such that, for every $(S, S') \in Q$,

1. either $S = S' = \epsilon$, or
2. $\exists \mathcal{R}_1 \in \bar{\mathcal{B}}_1(S, S')$, $\forall (x, x') \in \mathcal{R}_1$, $Q \overset{\langle * \rangle}{|\!\!\vdash\!\!-}_{\mathcal{C}_3} (S \odot x, S' \odot x')$.

That is, $Q$ is self-generating. □

THEOREM 10.14. *$\mathcal{B}_3$ is a complete deduction system.*

*Proof.* Lemma 10.13 implies the completeness property. □

**10.4. System $\mathcal{B}_4$.** We exhibit here a formal system $\mathcal{B}_4$ whose elementary rules can be considered as more natural than those of $\mathcal{B}_3$: they just consist in the rules expressing the basic algebraic properties of the bisimulation equivalence $\sim$ augmented with the grammatical rules (i.e., the rules of grammar $G_0$). This system $\mathcal{B}_4$ is still complete. Below, we just sketch the completeness proof, which is just a slight modification of the above completeness proofs.

Let us consider the alphabet $V_4 = V_0 \cup X$. The equivalence relation $\smile$ on $V_0$ is extended to $V_4$ as follows: for every $v, v' \in V_4$, $v \sim v'$ iff [$v \in V$, $v' \in V$, and there are equivalent in the sense used before] or [$v \in X$, $v' \in X$]. (This equivalence is the one considered in [15].) The right-action $\odot$ is extended to $\mathsf{B}\langle\langle\ V_4\ \rangle\rangle \times X^*$ as follows: for every $x \in X$, $\beta \in V_4^*$, $x' \in X$,

$$(x \cdot \beta) \odot x' = (x \cdot \beta) \bullet x', \tag{10.23}$$

$$\mathcal{A}_4 = \bigcup_{\lambda \in \mathbb{N} - \{0\}} \mathsf{DRB}_{1,\lambda}\langle\langle\ V_4\ \rangle\rangle \times \mathsf{DRB}_{1,\lambda}\langle\langle\ V_4\ \rangle\rangle.$$

This extension of $\odot$ leads naturally to extensions of the relation $\sim$ and of the notion of divergence. The cost $H_4$ is still defined by

$$\forall (S, S') \in \mathcal{A}_4, \quad H_4(S, S') = \mathrm{Div}(S, S').$$

**Elementary rules.**

(R41)

$$\{(S, T)\} \,|\!\!\vdash\!\!-\, (T, S)$$

for $\lambda \in \mathbb{N} - \{0\}$, $S, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V_4\ \rangle\rangle$;

(R42)

$$\{(S, S'), (S', S'')\} \,|\!\!\vdash\!\!-\, (S, S'')$$

for $\lambda \in \mathbb{N} - \{0\}$, $S, T \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V_4\ \rangle\rangle$;

(R43)

$$\emptyset \,|\!\!\vdash\!\!-\, (S, S)$$

for $S \in \mathsf{DRB}_{1,\lambda}\langle\langle\ V_4\ \rangle\rangle$;

(R$'$44)

$$\emptyset \mid\!\!\vdash\!\!- ((E_1, \ldots, E_i, \ldots, E_\lambda), (P_1, \ldots, P_i, \ldots, P_\lambda))$$

for $\lambda \in \mathbb{N} - \{0\}$, $(E_i)_{1 \leq i \leq \lambda}$, bijective numbering of some class in $V/\smile$ and $P_i$ equal to the right-hand side of $E_i$ in grammar $G_0$;

(R$''$44)

$$\{(S_x, T_{x'}) \mid (x, x') \in \mathcal{R}_1\} \mid\!\!\vdash\!\!- \left(\sum_{x \in X} x \cdot S_x, \sum_{x \in X} x \cdot T_x\right)$$

for $\lambda \in \mathbb{N} - \{0\}$, $S_x, T_x \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V_4 \,\rangle\rangle$, and $\mathcal{R}_1 \in \bar{\mathcal{B}}_1$;

(R45)

$$\{(S_1 \cdot T + S, T)\} \mid\!\!\vdash\!\!- (S_1^* \cdot S, T)$$

for $\lambda \in \mathbb{N} - \{0\}$, $S_1 \in \mathsf{DRB}_{1,1}\langle\langle\, V_4 \,\rangle\rangle$, $S_1 \not\equiv \epsilon$, $(S_1, S) \in \mathsf{DRB}_{1,\lambda+1}\langle\langle\, V_4 \,\rangle\rangle$, $T \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V_4 \,\rangle\rangle$;

(R46)

$$\{(S, S')\} \mid\!\!\vdash\!\!- (S \cdot T, S' \cdot T)$$

for $\delta, \lambda \in \mathbb{N} - \{0\}$, $S, S' \in \mathsf{DRB}_{1,\delta}\langle\langle\, V_4 \,\rangle\rangle$, $T \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\, V_4 \,\rangle\rangle$;

(R47)

$$\{(T_{i,*}, T'_{i,*}) \mid 1 \leq i \leq \delta\} \mid\!\!\vdash\!\!- (S \cdot T, S \cdot T')$$

for $\delta, \lambda \in \mathbb{N} - \{0\}$, $S \in \mathsf{DRB}_{1,\delta}\langle\langle\, V_4 \,\rangle\rangle$, $T, T' \in \mathsf{DRB}_{\delta,\lambda}\langle\langle\, V_4 \,\rangle\rangle$.

**Completeness.**

PROPOSITION 10.15. *$\mathcal{B}_4$ is a complete deduction system.*

*Sketch of proof.* Let $(S, S') \in \mathcal{A}_4$ such that $S \sim S'$. Lemma 10.13 could be proved for assertions in $\mathcal{A}_4$ in the same way that it has been proved for assertions in $\mathcal{A}_3$. Hence there exists some self-generating set $P$ containing $(S, S')$.

In order to prove that $P$ is a $\mathcal{B}_4$-proof, we just have to check that every instance of (R34) belongs to $\vdash\!\!-_{\mathcal{B}_4}$.

Let $T, T' \in \mathsf{DRB}_{1,\lambda}\langle\langle\, V_4 \,\rangle\rangle$ (for some $\lambda \geq 1$). Using metarule (R$''$44) we get

(10.24)
$$\{(T \odot x, T' \odot x') \mid (x, x') \in \mathcal{R}_1\} \vdash\!\!-_{\mathcal{B}_4} \left\{\left(\sum_{x \in X} x \cdot (T \odot x), \sum_{x \in X} x \cdot (T' \odot x)\right)\right\}.$$

Using metarule (R$'$44) (as well as other auxiliary rules) we get

$$\emptyset \vdash\!\!-_{\mathcal{B}_4} \left\{\left(T, \sum_{x \in X} x \cdot (T \odot x)\right)\right\}; \quad \emptyset \vdash\!\!-_{\mathcal{B}_4} \left\{\left(T', \sum_{x \in X} x \cdot (T' \odot x)\right)\right\}. \tag{10.25}$$

From deductions (10.24), (10.25) and metarules (R41), (R42) one derives

$$\{(T \odot x, T' \odot x') \mid (x, x') \in \mathcal{R}_1\} \vdash\!\!-_{\mathcal{B}_4} \{(T, T')\}. \qquad \square$$

## 11. Comparisons and perspectives.

**11.1. Old tools.** We have reused here the notions developed in [34]:

- the *deduction systems* (which were in turn inspired by [9]);
- the *deterministic boolean series* (which were in turn inspired by [16]);
- the *deterministic spaces* (which were elaborated around the Meitus notion of linear independence [23, 24]);
- the *analysis* of the proof-trees generated by a suitable strategy (which was somehow similar to the analysis of the parallel computations, interspersed with replacement moves, done in [49, 31, 28]).

Some simplifications of [34] found by Stirling [46] were taken into account in this proof too:

- the technical notion of the "N-stacking sequence" is replaced by the slightly simpler notion of the "B-stacking sequence" (see section 8.2);
- the analysis of section 8 uses a choice of "generating set" which is simpler than the choice given in [33, 37];
- a main simplification linked with this more clever choice is that we can restrict ourselves to the case of a *proper, reduced* strict-deterministic grammar (as is done in [46]), while in [33, 37] we could not assume this restriction.

**11.2. New tools.** We also have introduced new ideas:

1. the notion of *$\eta$-bisimulation* over deterministic row-vectors of boolean series (which, in some sense, translates the usual notion of bisimulation to the d-space of row-vectors of series);
2. the notion of *oracle*, which is a choice of bisimulation for every pair of bisimilar vectors; the notion of triangulation of systems of linear equations is now "parametrized" by such an oracle $\mathcal{O}$ (see section 5.2); the strategies are now parametrized by an oracle too (see section 7);
3. the *elimination* argument: roughly speaking, this argument shows that, in a proof-tree $t$, if we take into account not only the *branch* ending at a node $x$, but also the *whole* proof-tree, then the metarule (R5)

$$\{(p, S, S')\} \mid\!\vdash\!- (p+2, S \odot x, S' \odot x')$$

is not needed to show that $\mathrm{im}(t) \vdash\!- \{t(x)\}$ (see section 10.1); a nice (and unexpected) by-product of this elimination is that the *weights* can be removed from the equations (see sections 10.2, 10.3).

**11.3. Perspectives and related works.** In view of the above main result (and of other closely related results), many directions for future work naturally arise:

- Whether the bisimulation problem is decidable or not, for equational graphs of arbitrary out-degree, which was raised by [6], remains an open problem.
- The class of processes of type $-1$ was introduced in [45]: they correspond to the computation-graphs of pda with only decreasing $\varepsilon$-moves. Whether the bisimulation problem is decidable or not for such processes is a natural challenge: the present article gives hope that it is decidable, while the negative results from [44, 22] suggest it might be undecidable.
- Once we know that the bisimulation problem is decidable for equational 1-graphs, it is natural to ask what the intrinsic complexity of this problem is. It is proved in [48] that the equivalence problem for *deterministic pda* is primitive recursive. It is tempting to examine what techniques could be extracted from this work and adapted to the above complexity problem (we

discuss in section 11.4 below the difficulty of such adaptations). In [43] a general algebraic tool (which generalizes the "extension-theorem" from [48]), called the "subwords lemma," is introduced for deterministic dpda. It is also tempting to try to adapt this tool to nondeterministic pda (we discuss in section 11.4 below the difficulty of such an adaptation).

- The intrinsic complexity of the bisimulation problem for some subclasses of graphs would be interesting too: let us quote the *context-free graphs* and the computation-graphs of *finite-turn* pda.
- The equivalence problem for *deterministic pushdown transducers* from a free monoid into a free group (or a linear group) is shown decidable in [38]. We strongly believe that this result can be unified with the result proved here (Theorem 10.7) into a more general statement saying that "the bisimulation problem is decidable for nondeterministic pushdown transducers, with outputs in a linear group and with only deterministic, decreasing, $\varepsilon$-moves" (i.e., whose underlying pda fulfills the hypotheses of the present article). Of course the notion of bisimulation for transducers has to be defined carefully.
- Let us recall that, given two directed graphs $G, G'$, labeled over the same alphabet $X$, $G'$ is a *quotient* of $G$ iff there exists a functional bisimulation from $G$ to $G'$. It is proved in [41] that the quotient problem is decidable for deterministic equational 1-graphs. The same decision problem remains open for the equational 1-graphs of finite out-degree. It is open for the subclass of context-free graphs too.

**11.4. Language equivalence versus bisimulation.** Let us stress here some differences between the behavior of the equivalence $\equiv$ (on one hand) and the behavior of $\sim$ (on the other hand), w.r.t. important algebraic notions. These differences explain some otherwise "odd" aspects of the present article, as well as point to difficulties that must be overcome for reaching the above-mentioned perspectives. For illustrating these differences, we shall always refer to the following example.

EXAMPLE 11.1. *Let $G = \langle X, V, P \rangle$, where*

$$X = \{a_i \mid 1 \leq i \leq 6\} \cup \{b_i \mid 1 \leq i \leq 6\} \cup \{h, h', h''\},$$

$$V = \{A_i \mid 1 \leq i \leq 6\} \cup \{B_i \mid 1 \leq i \leq 6\} \cup \{H, H', H''\},$$

$$P = \{(A_i, a_i) \mid 1 \leq i \leq 6\} \cup \{(B_i, b_i) \mid 1 \leq i \leq 6\} \cup \{(H, h), (H', h'), (H'', h'')\}.$$

*We define the equivalence relation $\smile$ on $V$ as the coarsest one:*

$$\forall v \in V, \quad [v]_{\smile} = V.$$

*The grammar $G$ is strict-deterministic and admits the partition $\smile$. Let $Y = \{a, b, h, h, h''\}$ and let $\Psi : X^* \to Y^*$ be the strict-alphabetical homomorphism defined by*

$$\Psi(a_i) = a, \quad \Psi(b_i) = b, \quad \Psi(h) = h, \quad \Psi(h') = h', \quad \Psi(h'') = h''.$$

*We define $\eta$ as the kernel of $\Psi$:*

$$\eta = \{(w, w') \in X^* \mid \Psi(w) = \Psi(w')\}.$$

**Direct product.** We show here that, unlike for the equivalence $\equiv$, relation $\sim$ over vectors does not easily reduce to the same relation over series, because it is *not* *compatible with direct product.* This explains the need for some *row-vectors* in the assertions as well as for some *matricial* rules in the systems $\mathcal{B}_i$ for $1 \leq i \leq 3$.

More precisely, it can be shown that, for every $(S_1, S_2), (T_1, T_2) \in \mathsf{DB}_{1,2}\langle\langle\ V\ \rangle\rangle$,

$$[(S_1, S_2) \equiv (T_1, T_2)] \Leftrightarrow [S_1 \equiv T_1 \text{ and } S_2 \equiv T_2], \tag{11.1}$$

while for the chosen series (see below)

$$[(S_1, S_2) \not\sim (T_1, T_2)] \quad \text{and} \quad [S_1 \sim T_1 \text{ and } S_2 \sim T_2]. \tag{11.2}$$

Let us choose:

$$S_1 = A_1 A_2; \quad S_2 = A_1 A_3 A_3; \quad T_1 = A_4 A_6; \quad T_2 = A_5 A_6 A_6.$$

The following binary relation $\mathcal{R}_1$ (resp., $\mathcal{R}_2$) over $X^*$ is a word-$\eta$-bisimulation for $(S_1, T_1)$ (resp., $(S_2, T_2)$):

$$\begin{aligned}
\mathcal{R}_1 = {} & \{(\varepsilon, \varepsilon)\} \cup \{(a_1, a_4)\} \cup \{(a_4 u, a_1 u) \mid u \in X^*\} \cup \{(a_i u, a_i u) \mid i \in \{2,3,5,6\}, u \in X^*\} \\
& \cup \{(a_1 a_2 u, a_4 a_6 u) \mid u \in X^*\} \cup \{(a_1 a_6 u, a_4 a_2 u) \mid u \in X^*\} \\
& \cup \{(a_1 a_i u, a_4 a_i u) \mid i \in \{1,3,4,5\}, u \in X^*\}, \\
\mathcal{R}_2 = {} & \{(\varepsilon, \varepsilon)\} \cup \{(a_1, a_5\}) \cup \{(a_5 u, a_1 u) \mid u \in X^*\} \cup \{(a_i u, a_i u) \mid i \in \{2,3,4,6\}, u \in X^*\} \\
& \cup \{(a_1 a_3, a_5 a_6)\} \cup \{(a_1 a_6 u, a_5 a_3 u) \mid u \in X^*\} \cup \{a_1 a_i u, a_5 a_i u \mid i \in \{1,2,4,5\}, u \in X^*\} \\
& \cup \{(a_1 a_3 a_3 u, a_5 a_6 a_6 u) \mid u \in X^*\} \cup \{(a_1 a_3 a_6 u, a_5 a_6 a_3 u) \mid u \in X^*\} \\
& \cup \{(a_1 a_3 a_i u, a_5 a_6 a_i u) \mid i \in \{1,2,4,5\}, u \in X^*\}.
\end{aligned}$$

Let us now check that

$$S_1 + S_2 \not\sim T_1 + T_2. \tag{11.3}$$

Let us consider some binary relation $\mathcal{R} \subseteq X^* \times X^*$ and show that it cannot be a word-$\eta$-bisimulation for $(S_1 + S_2, T_1 + T_2)$.

If $\mathcal{R}$ does not possess a pair with first component $a_1$, then it does not fulfill the totality condition.

If $(a_1, a_i) \in \mathcal{R}$, with $i \notin \{4, 5\}$, as $(S_1 + S_2) \odot a_1 = A_2 + A_3 A_3$ while $(T_1 + T_2) \odot a_i = \emptyset$, then $\mathcal{R}$ cannot be a word-$\eta$-bisimulation.

If $(a_1, a_4) \in \mathcal{R}$, as $(T_1 + T_2) \odot a_4 = A_6$, and the set of lengths of the words generated from $A_2 + A_3 A_3$ is $\{1, 2\}$ while the set of lengths of the words generated from $A_6$ is $\{1\}$, again $\mathcal{R}$ cannot be a word-$\eta$-bisimulation.

If $(a_1, a_5) \in \mathcal{R}$, as $A_2 + A_3 A_3 \not\sim A_6 A_6$ (apply the same argument on the set of lengths), then $\mathcal{R}$ cannot be a word-$\eta$-bisimulation.

We have proved (11.3).

But the properties established in section 4.3, namely, the soundness of rule (R8), applied with $T = T'$ equal to the column vector with two lines with entry $\varepsilon$ show that we must then have

$$(S_1, S_2) \not\sim (T_1, T_2).$$

This ends the proof of (11.2). Let us notice that, of course, the implication from left to right, in (11.1), also holds for $\sim$. It is the implication from right to left which may fail for $\eta$-bisimulation.

**Extension theorem.** We show here that the "extension theorem," which is the main new tool introduced in [48], does not hold for $\eta$-bisimulation.

*The vectors.* Let us consider the deterministic vectors and matrices $S, T \in \mathsf{DB}_{2,1}\langle\langle V \rangle\rangle$, $A \in \mathsf{DB}_{2,2}\langle\langle V \rangle\rangle$, $\alpha, \beta \in \mathsf{DB}_{1,2}\langle\langle V \rangle\rangle$:

$$S = \begin{pmatrix} H \\ \varepsilon \end{pmatrix}, \quad T = \begin{pmatrix} H' \\ \varepsilon \end{pmatrix}, \quad A = \begin{pmatrix} H'' & 0 \\ 0 & H \end{pmatrix},$$

$$\alpha = (\alpha_1, \alpha_2), \quad \beta = (\beta_1, \beta_2) \quad \text{with}$$

$$\begin{aligned}
\alpha_1 &= A_1,\\
\alpha_2 &= A_2H + A_3H' + A_4H' + A_5H'' + A_6H''\\
&\quad + B_1H + B_2H + B_3H' + B_4H' + B_5H'' + B_6H'',\\
\beta_1 &= B_1,\\
\beta_2 &= B_2H + B_3H' + B_4H' + B_5H'' + B_6H''\\
&\quad + A_1H + A_2H + A_3H' + A_4H' + A_5H'' + A_6H''.
\end{aligned}$$

*The equations.* The following equations are true:

$$\alpha \cdot S \sim \beta \cdot S, \tag{11.4}$$

$$\alpha \cdot AS \sim \beta \cdot AS, \tag{11.5}$$

$$\alpha \cdot T \sim \beta \cdot T. \tag{11.6}$$

The reason for these three equivalences is that

$$\alpha_1 \cdot H + \alpha_2 \sim \beta_1 \cdot H + \beta_2$$

(this equation is even true for language equivalence),

$$\alpha_1 \cdot H' + \alpha_2 \sim \beta_1 \cdot H' + \beta_2 \quad \text{and} \quad \alpha_1 \cdot H'' + \alpha_2 \sim \beta_1 \cdot H'' + \beta_2;$$

these last two equivalences are due to the fact that the number of occurrences of some $A_iH$ (resp., $A_iH'$, $A_iH''$, $A_i0$, $B_iH$, $B_iH'$, $B_iH''$, $B_i0$) in a deterministic sum does not modify its class modulo $\sim$, provided that this number remains nonnull (or remains null). We assert now that

$$\alpha \cdot AT \not\sim \beta \cdot AT. \tag{11.7}$$

Let us prove inequality (11.7). It reduces to

$$\alpha_1 \cdot H''H' + \alpha_2 \cdot H \not\sim \beta_1 \cdot H''H' + \beta_2 \cdot H,$$

but there is no word-$\eta$-bisimulation of depth 3 for the pair above, since

$$(\alpha_1 \cdot H''H' + \alpha_2 \cdot H) \odot a_1h''h' = \varepsilon,$$

while there is no pair $(a_1h''h', w) \in \eta$ such that

$$(\beta_1 \cdot H''H' + \beta_2 \cdot H) \odot w = \varepsilon.$$

*The extension theorem.* The "extension theorem" stated in [48, Theorem 1, p. 828] asserts that when $\sim$ is taken as the language equivalence relation, in the case where $n = 1$, $k = 0$, $m = \infty$, the conjunction of (11.4), (11.5), (11.6) implies

$$\alpha \cdot AT \sim \beta \cdot AT. \tag{11.8}$$

The above example shows that this theorem no longer holds when the equivalence relation $\sim$ is the $\eta$-bisimulation relation. (The same example also holds for depth $m = 3$ by the proof above.)

**Subwords lemma.** We show here that the "subwords lemma," which is the main new tool introduced in [43], does not hold for $\eta$-bisimulation.

The "subwords lemma" stated in [43, pp. 478–489] asserts that when $\sim$ is taken as the language equivalence relation, in the case where $\lambda = 2$, $n = \infty$, the conjunction of

$$\begin{aligned} \alpha \cdot S &\sim \beta \cdot S, \\ \alpha \cdot AS &\sim \beta \cdot AS, \\ \alpha \cdot BS &\sim \beta \cdot BS \end{aligned} \tag{11.9}$$

implies

$$\alpha \cdot ABS \sim \beta \cdot ABS. \tag{11.10}$$

But if we take

$$B = \begin{pmatrix} H' & 0 \\ 0 & H \end{pmatrix}$$

in the above example, the three premises (11.9) are valid, while (11.10) is equivalent to

$$\alpha_1 \cdot H''H'H + \alpha_2 \cdot HH \sim \beta_1 \cdot H''H'H + \beta_2 \cdot HH.$$

As the equivalence $\sim$ is right-cancellative (by Corollary 4.10, point (C3)), this equation is equivalent to

$$\alpha_1 \cdot H''H' + \alpha_2 \cdot H \sim \beta_1 \cdot H''H' + \beta_2 \cdot H,$$

which has been shown nonvalid in section 11.4.

**Unifiers.** We show here that, unlike for the equivalence $\equiv$, there is no unique most general unifier (modulo $\sim$) for a given finite system of linear equations (modulo $\sim$). This explains the need for some *oracle* in the definition of the triangulation process and, consequently, in the definition of strategy $T_C$.

It can be deduced from the type of reasoning used in [34], or even in the earlier paper [24], that any equation of the form

$$\alpha S \equiv \beta S \tag{11.11}$$

(where $\alpha, \beta$ are deterministic row-vectors in $\mathsf{DB}_{1,\lambda}\langle\langle V \rangle\rangle$) has a single "most-general unifier" up to $\equiv$, i.e., there exists a single column vector $S \in \mathsf{DB}_{\lambda,1}\langle\langle V \cup \mathcal{U} \rangle\rangle$, fulfilling (11.11) and such that all the solutions of (11.11) are obtained from $S$ by substituting an arbitrary element of $\mathsf{DB}_{1,1}\langle\langle V \rangle\rangle$ to every variable in $\mathcal{U}$ (here $\mathcal{U}$ is a new alphabet of variables, disjoint from $V$ and with cardinality $\leq \lambda$).

We have exhibited such an equation above, and we have seen that it admits at least three minimal unifiers,

$$\begin{pmatrix} HU \\ U \end{pmatrix}, \quad \begin{pmatrix} H'U \\ U \end{pmatrix}, \quad \begin{pmatrix} H''U \\ U \end{pmatrix},$$

where $U \in \mathcal{U}$ is a free variable. We could modify the example in such a way that the number of minimal unifiers matches an arbitrary value $p$. We can conclude that, in general, a left-linear equation modulo $\sim$ admits a finite number of minimal unifiers, but not a single one. This fact makes more difficult the treatment of systems of equations modulo bisimulation as compared to systems of equations modulo language equivalence.

**Appendix.** Let us sketch here a proof of Theorem 2.5.

LEMMA A.1. *Let $\Gamma = (\Gamma_0, v_0)$ be the computation 1-graph $(\mathcal{C}(\mathcal{M}), v_{\mathcal{M}})$ of some normalized pda $\mathcal{M}$. Then $\Gamma$ is equational and has finite out-degree.*

*Proof.* Let $\mathcal{M} = \langle X, Z, Q, \delta, q_0, z_0, F\rangle$ be a normalized pda. Let us consider a new letter $e \notin X$ and build the real-time pda $\mathcal{M}_e = \langle X \cup \{e\}, Z, Q, \delta_e, q_0, z_0, F\rangle$ obtained by setting that, for every $x \in X$ and $q \in Q$, $z \in Z$,

$$\delta_e(qz, x) = \delta(qz, x); \quad \delta_e(qz, e) = \delta(qz, \epsilon).$$

By [27, Theorem 2.6, p. 62], the computation-graph $\mathcal{C}(\mathcal{M}_e)$ is context-free, and by [3, Theorem 6.3, p. 187] every context-free graph is equational. Hence $\mathcal{C}(\mathcal{M}_e)$ is equational. Let us remark that $\mathcal{C}(\mathcal{M})$ is obtained from this graph just by contracting all the edges labeled by $e$. Let us contract the edges labeled by $e$ in some system of equations $S_e$ defining $\mathcal{C}(\mathcal{M}_e)$: we obtain a system of equations $S$ defining $\mathcal{C}(\mathcal{M})$. ∎

We now use the notation of [13]. Given a system of graph equations $S = \langle u_i = H_i;\ i \in [1, n]\rangle$, by $\mathcal{G}(S, u_i)$ we denote the $i$th component of the canonical solution of $S$.

DEFINITION A.2. *Let $S = \langle u_i = H_i;\ i \in [1, n]\rangle$ be a system of graph equations. It is* standard *iff it fulfills the following conditions:*

(1) *for every $i \in [1, n]$ and every distinct integer $k, \ell \in [1, \tau(H_i)]$, the sources $src(H_i, k)$, $src(H_i, \ell)$ are distinct vertices of $H_i$;*
(2) *for every $i \in [1, n]$ and every hyperedge $h$ of $H_i$ which is labeled by some unknown, all the vertices of $h$ are distinct;*
(3) *for every $i \in [1, n]$, $k \in [1, \tau(u_i)]$, $\lambda \in \mathbb{N}$, if there exist $\lambda$ edges going out of $src(\mathcal{G}(S, u_i), k)$, inside the graph $\mathcal{G}(S, u_i)$, then there exist also $\lambda$ edges going out of $src(H_i, k)$, inside the graph $H_i$.*

LEMMA A.3. *Let $S = \langle u_i = H_i;\ i \in [1, n]\rangle$ be a system of graph equations where the unknown $u_1$ has type 1. One can compute from $S$ a* standard *system of graph equations $S' = \langle u'_i = H'_i;\ i \in [1, n']\rangle$ such that the canonical solution of $S'$ has a first component $\mathcal{G}(S', u'_1) = \mathcal{G}(S, u_1)$.*

*Proof.* From $S$ one can construct a first system $S_1$ which generates the same first component $\mathcal{G}(S_1, u_1) = \mathcal{G}(S, u_1)$ and such that restrictions (1) and (2) of the lemma are fulfilled: this follows from [13, Proposition 2.10, p. 209] (notice that the condition "separated" in this reference is exactly the conjunction (1) $\wedge$ (2)).

Let $S_1 = \langle v_i = K_i;\ i \in [1, m]\rangle$. Let us replace every right-hand side $K_i$ by a finite hypergraph $L_i$ obtained by unfolding the graph $K_i$, according to the rules $v_j \to K_j$, as many times as necessary in order that every source $src(K_i, k)$ gets as many outgoing edges in $L_i$ as in the "complete unfolded graph" $\mathcal{G}(S_1, v_i)$. The new system $S' = \langle v_i = L_i;\ i \in [1, m]\rangle$ still fulfills conditions (1) and (2), it also fulfills condition (3), and for every $i \in [1, m]$, $\mathcal{G}(S_1, v_i) = \mathcal{G}(S', v_i)$. Hence $S'$ satisfies the conclusion of the lemma. ∎

LEMMA A.4. *Let $\Gamma = (\Gamma_0, v_0)$ be a rooted 1-graph over $X$ which is the first component of the canonical solution of some standard system of graph equations. Then $\Gamma$ is isomorphic to the computation 1-graph $(\mathcal{C}(\mathcal{M}), v_{\mathcal{M}})$ of some normalized pda $\mathcal{M}$.*

*Sketch of proof.* Let $S = \langle u_i = H_i;\ i \in [1, n]\rangle$ be a standard system of graph equations such that $\Gamma = \mathcal{G}(S, u_1)$.

Let us define $\mathcal{M} = \langle X, Z, Q, \delta, q_0, z_0, F\rangle$ as follows. In every right-hand side $H_i$ we number bijectively all the unknown hyperedges, $\{h_{1,i}, \ldots, h_{j,i}, \ldots, h_{n_i,i}\}$, and all the vertices, $\{v_{1,i}, \ldots, v_{q,i}, \ldots, v_{N_i,i}\}$. Let us denote by $\beta(j,i)$ the label of $h_{j,i}$.

$$Z = \{[j,i] \mid 1 \le i \le n, 1 \le j \le n_i\} \cup \{[1,0]\}.$$

(We extend $\beta$ by defining $\beta(1,0) = 1$.)

Intuitively every symbol $[j,i]$ describes the situation of a vertex which belongs to a component which has been glued to the $j$th unknown hyperedge of $H_i$.

Let $Q = [1,N]$, where $N$ is the maximum number of vertices in the graphs $H_i$. Intuitively, the transitions of $\mathcal{M}$ starting from a mode $q[j,i]$ describe the edges starting from the $q$th vertex of $H_{\beta(j,i)}$. Let us define precisely the transitions starting from a mode $q[j,i]$:

*Case* 1. *$q$ is strictly larger than the number of vertices of $H_{\beta(j,i)}$*. Then there is no transition starting from $q[j,i]$.

*Case* 2. *The vertex number $q$ of $H_{\beta(j,i)}$ is a source of $H_{\beta(j,i)}$ and $i \neq 0$*. Then

$$q[j,i] \xrightarrow{\varepsilon} q',$$

where $q'$ is the number of the vertex of $H_i$ to which it is glued (it is some vertex of $h_{j,i}$).

*Case* 3. *The vertex number $q$ of $H_{\beta(j,i)}$ is not a source of $H_{\beta(j,i)}$ or $i = 0$*.

*Internal edges*. For every edge $(v_{q,\beta(j,i)}, x, v_{q',\beta(j,i)})$, we add the transition

$$q[j,i] \xrightarrow{x} q'[j,i].$$

*External edges*. Let $k = \beta(j,i)$. For every $\ell$ such that $v_{q,\beta(j,i)}$ is a vertex of $h_{\ell,k}$ and every edge $(v_{r,\beta(\ell,k)}, x, v_{q',\beta(\ell,k)})$ where the vertex $v_{r,\beta(\ell,k)}$ of $H_{\beta(\ell,k)}$ is glued to the vertex $v_{q,\beta(j,i)}$ by the rewriting rule $u_{\beta(\ell,k)} \to H_{\beta(\ell,k)}$, we add the transition

$$q[j,i] \xrightarrow{x} q'[\ell,k][j,i].$$

The starting configuration is $1[1,0]$ (i.e., $q_0 = 1$, $z_0 = [1,0]$).

This pda is normalized (this is easy to check) and has a computation graph whose isomorphism class is exactly $\mathcal{G}(S, u_1)$ (this would be much more tedious to prove formally). $\square$

Theorem 2.5 clearly follows from these three lemmas.

**Acknowledgments.** I thank O. Burkart, D. Caucal, P. Jancar, F. Moller, and C. Stirling for useful discussion and information about the subject treated in this work. This work has also benefited from the incisive questions, comments, and criticism of O. Burkart and C. Stirling about [34].

# LEARNING RANDOM LOG-DEPTH DECISION TREES UNDER UNIFORM DISTRIBUTION*

JEFFREY C. JACKSON† AND ROCCO A. SERVEDIO‡

**Abstract.** We consider three natural models of random logarithmic depth decision trees over Boolean variables. We give an efficient algorithm that for each of these models learns all but an inverse polynomial fraction of such trees using only uniformly distributed random examples from $\{0,1\}^n$. The learning algorithm constructs a decision tree as its hypothesis.

**Key words.** computational learning theory, decision trees, PAC learning

**AMS subject classifications.** 68Q32, 68T05

## 1. Introduction.

Decision trees are widely used to represent various forms of knowledge. The apparent ease with which humans can understand and work with decision trees has also made them a popular form of representation for knowledge obtained through heuristic machine learning algorithms (see, e.g., [4, 10]). While heuristic algorithms have proved reasonably successful for many applications, there is some reason to believe that arbitrary decision trees are not efficiently learnable from random examples alone, as the class of decision trees is provably not efficiently learnable in the statistical query model, even when the examples are uniformly distributed [3].

Given the apparent difficulty of learning decision trees in polynomial time, many researchers have considered alternative learning scenarios. One line of work which has been pursued is to consider algorithms that run in superpolynomial time. Ehrenfeucht and Haussler [6] have shown that the class of size-$s$ decision trees over $\{0,1\}^n$ can be PAC learned in $n^{\log s}$ time steps. This result was later simplified by Blum [1]. Another approach which has been pursued is to study decision tree learnability in alternate learning models in which the learner has more power and the classifier produced need not be a decision tree itself. Kushilevitz and Mansour [9] gave a polynomial time algorithm which uses membership queries and can learn decision trees under the uniform distribution. The hypothesis produced by this algorithm is a weighted threshold of parity functions. Using different techniques, Bshouty [5] gave a polynomial time algorithm which learns decision trees in the model of exact learning from membership and (nonproper) equivalence queries; this implies that decision trees can be PAC learned in polynomial time under any distribution if membership queries are allowed. The hypothesis in this case is a depth-three Boolean circuit.

**1.1. Our approach and results.** In this work we propose a third approach to coping with the difficulty of learning decision trees: looking at the average case. Since we have been unable to design algorithms which can learn all decision trees, we focus instead on algorithms which can efficiently learn most decision trees. Also, unlike some of the earlier approaches, our hypothesis is a decision tree.

We consider three natural models of random log-depth decision trees, i.e., decision trees over $n$ Boolean variables which are of depth $O(\log n)$. (Note that decision trees of logarithmic depth are a natural class to study in the context of uniform distribution learning, since under the uniform distribution any decision tree of poly($n$) size can be approximated to any inverse polynomial accuracy by a decision tree of $O(\log n)$ depth.) Our main result is a polynomial time algorithm that for each of these models learns, using decision tree hypotheses, all but a $1/p(n)$ fraction of such trees using only uniformly distributed random examples, where $p(n)$ is any polynomial function of $n$.

There are several motivations for this study. One natural motivation is that since decision tree learning is an interesting and important problem, yet worst-case theoretical analyses seem quite hard, it is natural to consider the average case. Another motivation comes from the work of Blum et al. [2], who proposed an approach to constructing cryptographic primitives such as pseudorandom generators and one-way functions based on the (presumed) intractability of certain learning problems. They defined a framework of learning from uniformly random examples in which the target function is also selected at random from the concept class according to some distribution. One of the main results of [2] is a proof that the existence of concept classes which are hard to learn in this average-case sense implies the existence of corresponding one-way functions whose circuit complexity is closely related to the circuit complexity of the concepts in the hard-to-learn class. Since decision trees are "simple" in terms of circuit complexity yet widely viewed as an intractable learning problem, one natural application of the Blum et al. paradigm would be to construct one-way functions based on the presumed intractability of decision tree learning. However, our results (which show that log-depth decision trees are *not* hard to learn in the average case) indicate that this approach does not yield secure one-way functions.

In section 2 we give the necessary background on uniform distribution learning and decision trees, and describe the three models of random decision trees which we consider. Section 3 gives useful Fourier properties of decision trees. In section 4 we present the learning algorithm, and sections 5 through 9 contain the proofs of correctness for the learning algorithm. We conclude in section 10.

## 2. Preliminaries.

A *Boolean decision tree* $T$ is a rooted binary tree in which each internal node has two children and is labeled with a variable, and each leaf is labeled with a bit $b \in \{-1, +1\}$. The children are ordered, i.e., each internal node has a definite left child and right child. We refer to an internal node whose two children are both leaves as a *preleaf node*. Because we will deal exclusively with Boolean decision trees in this paper, for convenience we will refer to them simply as decision trees.

A decision tree $T$ computes a Boolean function $f : \{-1,1\}^n \rightarrow \{-1,1\}$ in the obvious way: on input $x$, if variable $x_i$ is at the root of $T$, we go to either the left or right subtree depending on whether $x_i$ is $-1$ or 1. We continue in this fashion until reaching a bit leaf; the value of this bit is $f(x)$.

We define the *depth of a node* in a decision tree as follows. First, every decision tree must have at least one node; we do not admit the empty (0-node) decision tree. In a tree consisting of a single leaf node (labeled with some bit), the depth of this node is $-1$; we call such a tree *trivial.* The depth of the root in a nontrivial tree is 0, and the depth of any nonroot node is one greater than the depth of its parent. The *depth of a decision tree* $T$ is $-1$ if $T$ is trivial and the maximum depth over all preleaf nodes of $T$ otherwise.

A decision tree is *nonredundant* if no variable occurs more than once on any root-to-leaf path. We consider only nonredundant decision trees in this paper.

We let $\mathcal{U}$ be the uniform distribution on $\{-1,1\}^n$. We write $EX(f,\mathcal{U})$ to denote a uniform random example oracle for $f:\{-1,1\}^n \to \{-1,1\}$ which, when invoked, outputs a labeled example $\langle x, f(x)\rangle$ where $x$ is drawn from $\mathcal{U}$.

We say that a collection $\mathcal{C}$ of representations of Boolean functions (such as decision trees) is *PAC learnable under distribution* $\mathcal{D}$ *in* $t$ *time steps* if there is an algorithm $\mathcal{A}$ such that for every $f \in \mathcal{C}$ and for every positive $\epsilon$ and $\delta$, when $\mathcal{A}$ is run using $EX(f,\mathcal{D})$ as an oracle, then with probability at least $1-\delta$ (over the random draws from the oracle and any random choices made by $\mathcal{A}$) $\mathcal{A}$ runs for at most $t$ steps and produces a hypothesis function $h$ such that $\Pr_{a\sim\mathcal{D}}[f(a) \neq h(a)] \leq \epsilon$. We will focus on the specific question of PAC learnability of a subset of the class of all decision trees under the uniform distribution for $t$ bounded by a polynomial in $n$, $1/\epsilon$, and $1/\delta$. More generally, $\mathcal{C}$ is *PAC learnable in* $t$ *time steps* if for every distribution $\mathcal{D}$ it is PAC learnable under $\mathcal{D}$ in $t$ time steps.

We consider three models of random decision trees. Our primary model is the uniform distribution over the set of all nonredundant decision tree representations of depth at most $d$ on the variable set $\{x_1,\dots,x_n\}$. We call this the *uniform* model and will represent this distribution by $\mathcal{T}^U_{d,n}$. Note that not every Boolean function that can be represented by a depth-$d$ tree has the same probability mass under $\mathcal{T}^U_{d,n}$; some functions may have more $\mathcal{T}^U_{d,n}$-good trees which represent them than others. That is, $\mathcal{T}^U_{d,n}$ is a distribution over syntactic representations of decision tree functions, and not over the functions themselves.

In each of our other two models, the internal nodes form a complete tree of depth $d$ and are labeled uniformly at random using the variables $\{x_1,\dots,x_n\}$, with the restriction that the tree must be nonredundant. These models, denoted by $\mathcal{T}^C_{d,n}$ and $\mathcal{T}^B_{d,n}$, differ in that the leaves in $\mathcal{T}^C_{d,n}$ are selected independently and uniformly from $\{-1,1\}$, while in $\mathcal{T}^B_{d,n}$ each sibling pair must have opposite signs, although the sign of the left node is independently and uniformly chosen from $\{-1,1\}$. We call these the *complete* and *balanced* models, respectively.

We assume throughout that $d$ is $O(\log n)$ and that the learning algorithm knows the exact value of $d$. This latter assumption is without loss of generality (w.l.o.g.) since the algorithm can try all values $d=1,2,\dots$ until it succeeds.

**3. Fourier properties of decision trees.** We will be interested in carefully measuring the correlation between a decision tree $f$ and each of $f$'s variables. Define $e_i$ to be the $n$-bit vector that has a 1 in position $i$ and 0's elsewhere and define $\hat{f}(e_i)$ to be $E_{a\sim\mathcal{U}}[a_i f(a)]$. Since $f(a)$ and $a_i$ take values in $\{-1,1\}$ we have $\hat{f}(e_i) = \Pr_{a\sim\mathcal{U}}[f(a)=a_i] - \Pr_{a\sim\mathcal{U}}[f(a)\neq a_i]$. Each $\hat{f}(e_i)$ is a *first-order Fourier coefficient* of $f$.

Kushilevitz and Mansour [9] showed that decision trees have some particularly useful Fourier properties.[1] Define $L(i)$ to be the set of all leaves in a decision tree $f$

[1]In [9] Kushilevitz and Mansour considered decision trees in which internal nodes can contain arbitrary parity functions; however, as noted earlier we allow only single variables at internal nodes.

that are descendants of some node labeled by variable $x_i$, and let $d(\ell)$ represent the depth of a leaf $\ell$ in $f$. The analysis of [9] directly implies the following.

Corollary 3.1 (Kushilevitz–Mansour). *For every decision tree $f$ and every $1 \le i \le n$, there is a function $\sigma_i : L(i) \to \{-1, 1\}$ such that*

$$\hat{f}(e_i) = \sum_{\ell \in L(i)} 2^{-d(\ell)} \sigma_i(\ell).$$

Note that this corollary implies that in any tree of depth $d$, each $\hat{f}(e_i)$ is of the form $j/2^d$ for some integer $j$. This is because any leaf at depth $d+1$ must have a sibling leaf, so the total number of $\pm 1/2^{d+1}$ contributions to $\hat{f}(e_i)$ is even. We say that any first-order Fourier coefficient of the form $\frac{2k+1}{2^d}$ for some integer $k$ is an *odd coefficient*, and all other first-order coefficients are *even coefficients*.

From the above corollary we can obtain the following.

Lemma 3.2. *For every decision tree $f$ of depth $d$ and every $1 \le i \le n$, $\hat{f}(e_i)$ is an odd coefficient if and only if the total number of occurrences of the following conditions is odd for $x_i$:*

1. *A node at depth $d$ is labeled $x_i$ and the children of this node (both leaves) have opposite signs.*
2. *A leaf at depth $d$ has an ancestor labeled $x_i$.*
3. *A pair of sibling leaves at depth $d+1$ have the same sign, $x_i$ labels an ancestor of this pair of leaves, and $x_i$ is not the label of the parent of the pair.*

*Proof.* Fix an arbitrary $i$. By the corollary, only leaves in $L(i)$ that are at depth $d$ or $d+1$ can affect whether $\hat{f}(e_i)$ is an even or odd coefficient. Also, as noted earlier, each leaf at depth $d+1$ has a sibling leaf. Let "leaf set" denote either a leaf at depth $d$ or a sibling pair of leaves at depth $d+1$. Then notice that every leaf set in $L(i)$ is covered by at most one of the conditions of the lemma. We will show that each leaf set in $L(i)$ that is not covered by a condition contributes nothing to $\hat{f}(e_i)$, while every covered leaf set contributes $\pm 1/2^d$. From this, the lemma follows.

First, again by the corollary, each leaf in $L(i)$ at depth $d$ contributes $\pm 1/2^d$ to $\hat{f}(e_i)$. For sibling leaves at depth $d+1$ there are two cases: the siblings have either the same sign or different signs. If sibling leaves at depth $d+1$ have the same sign, then their immediate parent is irrelevant: the tree is equivalent to one with a leaf at depth $d$ in place of the parent node. Thus, in this case, the nonparent ancestor nodes each receive a $\pm 1/2^d$ contribution to their corresponding Fourier coefficients, while the parent node receives no contribution to its coefficient. For the case in which the siblings have different signs, it is not hard to see from the definition of $\hat{f}(e_i)$ that the net contribution to $\hat{f}(e_i)$ of the set of all bit-vectors $a$ that reach these two leaves will be $\pm 1/2^d$ if $x_i$ is the parent of the leaves and 0 if $x_i$ is a nonparent ancestor of the leaves. □

Conditions 2 and 3 of this lemma may seem redundant, since a tree with two sibling leaves having the same sign is equivalent to a tree that has a single leaf in place of the parent of the siblings. We include both conditions because these are syntactically different structures, both of which may arise in the various trees we consider.

A key observation which follows from this lemma is Lemma 3.3.

Lemma 3.3. *Fix any Boolean decision tree structure of depth $d$ and assign variables $x_1$ through $x_n$ arbitrarily to the internal nodes of the tree, with the constraint* *that the resulting tree is nonredundant. Assign each leaf bit by independently and uniformly selecting from* $\{-1,1\}$*. Then for every* $1 \le i \le n$ *such that* $x_i$ *is an ancestor of at least one leaf at depth* $d+1$*, we have* $\Pr[\hat{f}(e_i)$ *is an odd coefficient* $] = \frac{1}{2}$.

*Moreover, let* $S$ *be any subset of variables* $x_1, \ldots, x_n$ *with the following property: there is a collection* $C$ *of* $|S|$ *preleaves in* $T$*, each of which is at depth* $d$ *and is labeled with a different element of* $S$*, such that no variable in* $S$ *occurs on any of the paths from the root to any of these preleaves. Then we have that* $\Pr[$*for all* $i \in S$ $\hat{f}(e_i)$ *is an even coefficient* $] = \frac{1}{2^{|S|}}$.

*Proof.* We can view certain leaves of the tree as defining the "parity" of the internal nodes in a way that corresponds to the conditions of Lemma 3.2. More precisely, all internal nodes begin with even parity, and then their parities are computed by applying the following rules to each leaf and each pair of leaves (each leaf or leaf pair will meet the conditions of at most one rule):

1. If a pair of sibling leaves is at depth $d+1$ and the leaves have opposite signs, then the parity of their depth-$d$ parent node is toggled.
2. If a leaf is at depth $d$, then the parity of each ancestor node is toggled.
3. If a pair of sibling leaves is at depth $d+1$ and the leaves have identical signs, then the parity of each ancestor node except its parent node is toggled.

We can then define the parity of a variable $x_i$ as the parity of the parity of all nodes that are labeled $x_i$. It is clear that for each $i$, the first-order Fourier coefficient $\hat{f}(e_i)$ is odd if and only if $x_i$ has odd parity according to this definition.

Next, notice that since sibling leaves are labeled uniformly at random, any pair of sibling leaves at depth $d+1$ is equally likely to satisfy rule 1 or rule 3 above. So the probability that any given ancestor node of a pair of such sibling leaves has its parity toggled by a random assignment to these leaf bits is exactly 1/2. The same is true of the parity of the variable labeling the node. Since all leaves at depth $d+1$ have sibling leaves (because the tree depth is $d$), all possible assignments to leaves at depth $d+1$ are covered by the conditions of rules 1 and 3. Thus, any variable $x_i$ that is an ancestor of at least one leaf at depth $d+1$ will have odd parity with probability exactly 1/2, and the first equation is proved.

To see that the second equation also holds, observe that the $|S|$ preleaves in $C$ will each toggle the parity of the corresponding variable with probability 1/2. Since no variable in $S$ occurs on any path to a node in $C$, the final parities of these variables are all independent of each other, and the lemma follows. ∎

Kushilevitz and Mansour also observed that it follows from Corollary 3.1 and Chernoff bounds that for any decision tree $f$ and any $\delta > 0$, a uniformly distributed sample $S$ of $m$ labeled pairs $\langle x, f(x)\rangle$ is—with probability at least $1-\delta$ over the choice of $S$—sufficient to compute all of the first-order Fourier coefficients of $f$ exactly, for $m$ exponential in the depth $d$ of $f$ and polynomial in $\log(n/\delta)$. In particular, with probability at least $1-\delta$ over the random draw of $S$, $\hat{f}(e_i) = R\left((\sum_{a \in S} a_i f(a))/m\right)$, where $R(\cdot)$ represents "rounding" the argument to the nearest rational number having denominator $2^d$. Therefore, we also have the following corollary.

COROLLARY 3.4 (Kushilevitz–Mansour). *There is an algorithm FCExact such that, given* $\delta > 0$ *and access to* $EX(f,\mathcal{U})$ *for any decision tree* $f$ *of depth* $O(\log n)$*, with probability at least* $1-\delta$ *FCExact*$(n, \delta, EX(f,\mathcal{U}))$ *computes all of the first-order Fourier coefficients of* $f$ *exactly in time poly*$(n, \log(1/\delta))$.

For our algorithm we will need uniform random examples which are labeled not only according to the original tree $f$, but also according to certain subtrees obtained by restricting a subset of the variables of $f$. Each such subset will lie along a root-

FIG. 4.1. *The algorithm for learning random log-depth decision trees.*

to-leaf path in $f$ and—since we consider only trees of depth $O(\log n)$—will therefore have cardinality $O(\log n)$. We can simulate exactly an example oracle for such a restricted $f'$ given an oracle $EX(f,\mathcal{U})$ by simply drawing examples from $EX(f,\mathcal{U})$ until we obtain one that satisfies the restriction on the $O(\log n)$ variables. Since each example from $EX(f,\mathcal{U})$ will satisfy such a restriction with probability $1/\text{poly}(n)$, the probability of failing to obtain such an example after poly$(n)$ many draws from $EX(f,\mathcal{U})$ can be made exponentially small. Thus the simulation of these subtree oracles is both exact and efficient. We will use $EX(f',\mathcal{U})$ to represent the simulated oracle for a restriction $f'$.

## 4. The algorithm for learning random decision trees.

Our algorithm for learning random decision trees, which we call LearnTree (see Figure 4.1), operates in two phases. In the first phase (lines 4–11) the algorithm uses the Fourier properties outlined above to find a root-like variable for the original tree. (Informally, a root-like variable has the property that it can be taken as the root of the tree without increasing the depth of the tree; we give precise definitions later.) Once this is done, it recursively finds a good root for each of the two subtrees induced by this root, and so on. The process stops at depth $d - \frac{1}{2}\log n$, so when it stops there are at most $2^d/\sqrt{n}$ subtrees remaining, each of depth at most $\frac{1}{2}\log n$. (Recall that w.l.o.g. we may assume the algorithm knows the exact value of $d$.) In the second phase (lines 1–3) we employ an algorithm UnikDTLearn$(n, \epsilon, \delta, EX(T,\mathcal{U}))$ due to Hancock [7] to learn the remaining "shallow" decision trees. (If $d < \frac{1}{2}\log n$, then our algorithm performs only the second phase.)

The intuition underlying the algorithm is that at each step in the first phase, each of the two subtrees of the root $x_i$ of a decision tree $T$ will obviously have depth at least one less than that of the original tree. These subtrees will therefore contain no odd first-order Fourier coefficients by Lemma 3.2, and thus the root $x_i$ will pass the test at line 8. On the other hand, we will show that in our random decision tree models, if we consider a variable $x_j$ which is not the root (or, more accurately, is not root-like in a sense defined below), then projecting on $x_j$ will result in at least one projection containing odd first-order coefficients. (This will follow from our earlier Fourier analysis of decision trees plus some combinatorial arguments showing that if $x_j$ is not root-like, then with very high probability the trees resulting from restricting on $x_j$ will have an $\omega(\log n)$-size collection $C$ of preleaves as in Lemma 3.3.)

Hancock's UnikDTLearn is efficient, so LearnTree clearly runs in time poly$(n)$ for any value $d = O(\log n)$. The rest of this paper shows that the algorithm with high probability outputs an accurate decision tree for our various models of random decision trees.

## 5. Bottlenecks and recursing the algorithm.

The first phase of our algorithm attempts to select recursively the root of the original tree $T$ and its subtrees. One difficulty is that $T$ may have more than one variable that "acts like" a root, in the sense that putting any of these variables at the root does not increase the depth of the tree. For example, consider a decision tree representation of the function $x_1 \oplus x_2$. Although we might represent this with a tree $T$ having $x_1$ at the root, it can be represented equally well by a tree with $x_2$ at the root.

The following definition captures the notion of a "root-like" variable for us.

DEFINITION 5.1. *A variable $x_i$ is a* bottleneck *for a decision tree $T$ if $T$ is nontrivial and $x_i$ occurs on every root-to-leaf path in $T$.*

Clearly the variable labeling the root is always a bottleneck for any tree. We note that if $x_i$ is the root of a tree $T$, then a variable $x_j \neq x_i$ is a bottleneck in $T$ if and only if $x_j$ is a bottleneck in both the left and right subtrees of $T$. Notice also that any bottleneck variable will pass the test at line 8 of LearnTree, so some variable $x_i$ will pass the test at every stage of the recursion given that FCExact returns accurate values for all first-order Fourier coefficients.

For the rest of this section let $\mathcal{T}_{d,n}$ denote any fixed one of the three random tree models $\mathcal{T}^B_{d,n}, \mathcal{T}^C_{d,n}, \mathcal{T}^U_{d,n}$. In later sections we will show that for a random tree $T$ drawn from $\mathcal{T}_{d,n}$, any nonbottleneck variable will with very high probability not pass the test of line 8. Thus each recursive call of LearnTree is performed by restricting some bottleneck variable; however, the bottleneck may or may not be the root. If the root is the bottleneck chosen, then it is easy to see that each of the two subtrees will be drawn from $\mathcal{T}_{d-1,n-1}$ (over a suitable set of $n-1$ variables) as desired, and the inductive assumption of LearnTree (that the tree it is given is drawn from $\mathcal{T}_{d,n}$) will be valid. If a nonroot bottleneck is chosen, however, it is not a priori clear that the two resulting subfunctions for the recursive call correspond to draws from $\mathcal{T}_{d-1,n-1}$.

We will show shortly that as long as any bottleneck is chosen, the two resulting subfunctions do indeed correspond to draws from $\mathcal{T}_{d-1,n-1}$. (The correspondence is exact for the complete model; for the other models the subfunctions correspond to draws from a distribution which has negligible statistical difference from $\mathcal{T}_{d-1,n-1}$.) While the two draws are not independent of each other, this does not negatively impact the algorithm.

First, we define some terms. Figure 5.1 defines a tree restructuring operation we call a *root swap.* Notice that this operation can be performed on a tree only if the children of the root are both labeled with the same variable; we call a tree with this property *root swappable.* More generally, a *swap* operation takes a tree $T$ and a node $\eta$ in the tree such that the subtree $S$ rooted at $\eta$ is root swappable and returns a tree $T'$ which is identical to $T$ except that the subtree rooted at $\eta$ is replaced with the root swap of $S$.

We next define an equivalence relation on decision trees which we call *structural*

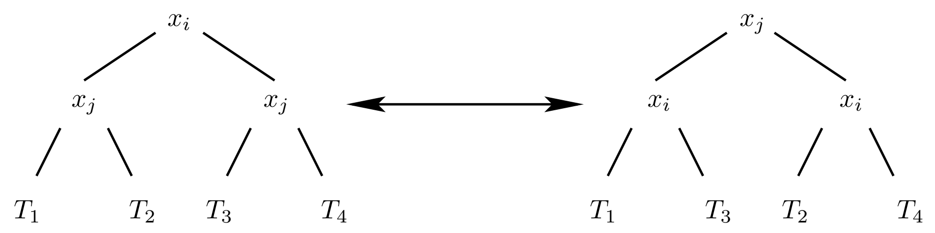

FIG. 5.1. *Applying a root swap operation to the tree on the left (right) produces the tree on the right (left). Note that the tree produced by a root swap computes the same function as the original tree.*

*equivalence*. Formally, this relation is defined inductively as follows.

DEFINITION 5.2. (i) *Two decision trees $T$ and $T'$, both of depth $d < 1$, are structurally equivalent if and only if they are identical.* (ii) *Two decision trees $T$ and $T'$, both of depth $d \geq 1$, are structurally equivalent if and only if there exists a sequence of swap operations that will transform $T'$ to a tree $T''$ such that $T$ and $T''$ have the same root variable and each of the child subtrees of the root of $T''$ is structurally equivalent to its corresponding subtree in $T$.* (iii) *Two decision trees $T$ and $T'$ of different depths are not structurally equivalent.*

Informally, two decision trees $T$ and $T'$ are structurally equivalent if $T'$ can be obtained from $T$ by performing a sequence of swaps. Note that if two trees are structurally equivalent, then they compute the same function. The following lemma, which we prove in Appendix A, shows that bottleneck variables can be swapped to the root of a tree in a way that preserves structural equivalence.

LEMMA 5.3. *Let $T$ be any decision tree. If variable $x_i$ is a bottleneck for $T$, then there is a tree $T'$ having $x_i$ at its root that is structurally equivalent to $T$.*

Let $\mathcal{T}^i_{d,n}$ be the induced distribution over trees obtained by restricting $\mathcal{T}^C_{d,n}$ to trees for which $x_i$ is a bottleneck, and let $\mathcal{T}^{\tilde{i}}_{d,n}$ be the distribution over trees obtained by first selecting a tree $T$ according to $\mathcal{T}^i_{d,n}$ and then performing a minimal sequence of swap operations (as implicitly described in the proof of Lemma 5.3) to produce a structurally equivalent $\tilde{T}$ having $x_i$ as its root. Finally, let $\mathcal{T}^{-1}_{d-1,n-1}$ (resp., $\mathcal{T}^{1}_{d-1,n-1}$) represent the distribution over trees corresponding to a random variable that selects a tree $\tilde{T}$ according to $\mathcal{T}^{\tilde{i}}_{d,n}$ and then returns the left (resp., right) subtree as the value of the random variable. Then for the complete model, it suffices to prove the following lemma.

LEMMA 5.4. *Let $\mathcal{T}^i_{d,n}$, $\mathcal{T}^{-1}_{d-1,n-1}$, and $\mathcal{T}^{1}_{d-1,n-1}$ be as defined above. Then for all $1 \leq i, d \leq n$, $\mathcal{T}^{-1}_{d-1,n-1}$ and $\mathcal{T}^{1}_{d-1,n-1}$ are both identical to $\mathcal{T}^{C}_{d-1,n-1}$.*

*Proof.* The proof is by induction on $d$. For the base case $d = 1$, any tree $T$ drawn from $\mathcal{T}^i_{1,n}$ has either $x_i$ at the root or some other variable $x_j$ at the root and $x_i$ as the root of both children of $x_j$. In either case, the corresponding tree $\tilde{T}$ of the process defining $\mathcal{T}^{\tilde{i}}_{1,n}$ will have $x_i$ at the root with two depth-0 children. It is easy to see that, over random draws from $\mathcal{T}^{\tilde{i}}_{1,n}$, the root variables of these children of $x_i$ are each uniformly distributed over the $n-1$ variables excluding $x_i$ (although the distributions of these root variables are not necessarily independent). The values of the leaves are also uniformly and independently distributed. Therefore, the base case has been shown.

For the inductive case, consider a tree $T$ drawn from $\mathcal{T}^i_{d,n}$ for fixed $d > 1$. Since $x_i$ must be a bottleneck in $T$, it either is the root of $T$ or is a bottleneck in both children of the root of $T$. If $x_i$ is the root of $T$, the lemma obviously holds. So we are left with the case in which some variable $x_j$—uniformly chosen from the $n-1$ variables excluding $x_i$—labels the root of $T$ and $x_i$ is a bottleneck in both children of $x_j$. Let $T_{-1}$ ($T_1$) represent the left (right) subtree of $T$, and let $\tilde{T}_{-1}$ ($\tilde{T}_1$) represent the tree obtained by swapping $x_i$ to the root of $T_{-1}$ ($T_1$). Since $x_i$ is a bottleneck in $T_{-1}$ ($T_1$), the children of $x_i$ in $\tilde{T}_{-1}$ ($\tilde{T}_1$) are drawn from $\mathcal{T}^C_{d-2,n-2}$, by the inductive hypothesis.[2] Notice also that, although the distribution over each child of $x_i$ in $\tilde{T}_{-1}$ may be dependent on its sibling's distribution, each is independent of both of the distributions over children of $x_i$ in $\tilde{T}_1$. Therefore, after performing a final swap of the $x_i$'s at the roots of $\tilde{T}_{-1}$ and $\tilde{T}_1$ with the root $x_j$ of $T$, we obtain a tree $\tilde{T}$ in which each child of the root $x_i$ is a tree rooted at uniformly (over $n-1$ variables) chosen $x_j$ and in which the children of $x_j$ are independently distributed according to $\mathcal{T}^C_{d-2,n-2}$. That is, each child of $x_i$ in $\tilde{T}$ is distributed according to $\mathcal{T}^C_{d-1,n-1}$. Since $\tilde{T}$ is by construction distributed according to $\mathcal{T}^{\tilde{i}}_{d,n}$, the lemma follows. $\square$

This proof does not immediately apply to either of the other two tree models. The problem for balanced trees is in the base case: a swap in a balanced tree of depth 1 can produce a tree that is no longer balanced. For uniform trees, there is a technical difficulty in that the distribution over children will only be exactly $\mathcal{T}^U_{d-1,n-1}$ in the case in which no swap is performed (the root is chosen as the bottleneck variable). If a nonroot bottleneck is chosen, a swap must be performed, and the children of the root then must not be leaves. But leaves have nonzero probability in $\mathcal{T}^U_{d-1,n-1}$, so the children are not distributed according to $\mathcal{T}^U_{d-1,n-1}$ in this case.

We can, however, still say that with very high probability over the choice of tree according to either $\mathcal{T}^B_{d,n}$ or $\mathcal{T}^U_{d,n}$, the choice of bottleneck variable on which to recurse will not affect the distribution over the recursive subtree problems. We use two lemmas to show this. First, we will later prove the following lemma in the context of some of our other combinatorial lemmas in Appendix E.

LEMMA 5.5. *Let $T$ be drawn from $\mathcal{T}_{d,n}$ where $d \geq \frac{1}{2}\log n$ and $d = O(\log n)$. The probability that $T$ has any bottleneck variable which occurs at some depth $k \geq \frac{1}{8}\log n$ is $1/n^{\omega(1)}$.*

For the balanced model, this means that the sequence of swaps performed to transform $T$ chosen according to $\mathcal{T}^B_{d,n}$ into $\tilde{T}$ having bottleneck $x_i$ at the root will almost certainly not perform a swap involving $x_i$ nodes whose children are leaf bits. And a simple modification to the proof of Lemma 5.4 shows the following.

LEMMA 5.6. *Let $\mathcal{T}^{\bar{i}}_{d,n}$ be the induced distribution over trees obtained by restricting $\mathcal{T}^B_{d,n}$ to trees for which $x_i$ is a bottleneck that does not appear at depth $d$. Let $\mathcal{T}^{-1}_{d-1,n-1}$ and $\mathcal{T}^1_{d-1,n-1}$ be induced distributions defined as before except relative to $\mathcal{T}^{\bar{i}}_{d,n}$ rather than $\mathcal{T}^i_{d,n}$. Then for all $1 \leq i, d \leq n$, $\mathcal{T}^{-1}_{d-1,n-1}$ and $\mathcal{T}^1_{d-1,n-1}$ are both identical to $\mathcal{T}^B_{d-1,n-1}$.*

So in the balanced model, there is a negligible chance that the choice of bottleneck variable will negatively affect the algorithm. For the uniform model, we will also use the following lemma, which is again proved in Appendix E.

LEMMA 5.7. *Let $T$ be drawn from $\mathcal{T}^U_{d,n}$, where $d \geq \frac{1}{4}\log n$. The probability that $T$ has a leaf at depth less than $d - \frac{1}{4}\log n$ is $1/2^{n^{\Omega(1)}}$.*

[2]Strictly speaking, the children of $x_i$ are fixed for any given $T$. What we are actually claiming here is that over draws of $T$ from $\mathcal{T}^i_{d,n}$, for fixed $d > 1$, the children of $x_i$ in $\tilde{T}_{-1}$ are distributed according to $\mathcal{T}^C_{d-2,n-2}$. But for ease of exposition, here and below we often blur the distinction between a single tree produced by one application of a random process defining a distribution over trees and the distribution itself.

Combining this with Lemma 5.5, for $d \geq \frac{1}{2}\log n$, with probability at least $1 - 1/n^{\omega(1)}$ (which we will refer to in this section as "very high probability"), a tree $T$ drawn from $\mathcal{T}^U_{d,n}$ has no leaves through depth $d - \frac{1}{4}\log n$, while all bottleneck variables are at shallower depths. Fix $t$ to be any depth ($\frac{3}{16}\log n$ will do) such that with very high probability all the bottleneck variables in $T$ drawn from $\mathcal{T}^U_{d,n}$ have depth less than $t$ and all leaves have depth greater than $t$.

Notice that (with very high probability) we have $2^t$ nodes at depth $t$ in $T$ and that the subtrees rooted at these nodes are independently and identically (up to variable renaming) distributed according to $\mathcal{T}^U_{d-t,n-t}$. Furthermore, notice that all of the nodes labeled by any bottleneck variable are with very high probability located in the portion of the tree above these new "leaves." So the proof of Lemma 5.4 shows that, with very high probability, swapping a bottleneck variable $x_i$ to the root of $T$ produces a tree $\tilde{T}$ in which the children of $x_i$ are each distributed according to the complete distribution down to depth $t-1$ and then according to $\mathcal{T}^U_{d-t,n-t}$. But this is just $\mathcal{T}^U_{d-1,n-1}$ restricted to contain no leaves until depth $t$, which by Lemma 5.7 is negligibly different from $\mathcal{T}^U_{d-1,n-1}$.

Therefore, in the uniform model, the recursive distributions obtained if a nonroot bottleneck is chosen are negligibly different from the distributions that would be obtained if the root variable were selected. Thus, in both the balanced and the uniform models, the probability that LearnTree fails as a result of distribution differences induced by selecting a nonroot bottleneck is negligibly small. This failure probability will be covered by a portion of the PAC confidence parameter $\delta$.

It remains to show that LearnTree will with high probability choose a bottleneck at each stage of the recursion in the first phase, and that Hancock's algorithm can be used to efficiently learn $\mathcal{T}_{d,n}$-random trees of depth $\frac{1}{2}\log n$ with high probability. We address the second point first in the next section.

## 6. Learning random ($\frac{1}{2}\log n$)-depth trees.

We stop the recursion in LearnTree at depth $\frac{1}{2}\log n$ because our analysis depends on trees being somewhat deep. So we use another method for learning random trees of depth less than $\frac{1}{2}\log n$, which is based on the following lemma plus the UnikDTLearn algorithm due to Hancock [7].

Recall that a decision tree $T$ is *read-$k$* if each variable labels at most $k$ nodes in $T$. We again write $\mathcal{T}_{d,n}$ to represent any of our three random tree models. We prove the following easy lemma in Appendix B.

LEMMA 6.1. *Let $r = ((1-\epsilon)\log n) - 2$ for some constant $\epsilon > 0$. Let $C$ be any constant. Then we have $\Pr_{T \in \mathcal{T}_{r,n}}[T \text{ is not read-}k] \leq 1/n^C$ for $k = (C+2)/\epsilon$.*

Thus, if $r = (\frac{1}{2}\log n)$, then for any constant $C$ we may take $k = 8C + 16$, and with probability at least $1 - \frac{4}{(n-2)^C}$ a tree $T$ drawn from $\mathcal{T}_{d,n}$ is read-$k$ (since each of the four subtrees of depth $r-2$ is not read-$(2C+4)$ with probability at most $1/(n-2)^C$).

Hancock [7] has given an algorithm UnikDTLearn and shown that it (or more precisely, a version which takes $k$ as an input along with the parameters given earlier) efficiently learns read-$k$ trees with respect to the uniform distribution, producing a decision tree (not necessarily read-$k$) as its hypothesis. Given any constant $k$, his algorithm terminates in time polynomial in $n$, $1/\epsilon$, and $1/\delta$, regardless of whether or not the target function $f$ is actually a read-$k$ decision tree. So our version of UnikDTLearn($n, \epsilon, \delta, EX(T, \mathcal{U})$) will begin by finding the smallest integer $C$ such that $1/n^C \leq \delta/2$. If the $\delta$ originally provided to LearnTree is inverse polynomial in $n$, then this value $C$ will be a constant independent of $n$. Taking $k = 8C + 16$, this means that the target function provided to UnikDTLearn is a read-$k$ decision tree with probability at least $1 - \delta/2$. Then running Hancock's original UnikDTLearn with this value of $k$ and with $\delta/2$ as the confidence parameter will succeed at learning an $\epsilon$-approximating tree with probability at least $1-\delta/2$, for an overall success probability at the bottom of the recursion of $1 - \delta$. In short, we have the following lemma.

LEMMA 6.2. *If the function $f$ in the oracle $EX(f,\mathcal{U})$ in the call to UnikDTLearn in LearnTree is distributed according to $\mathcal{T}_{d,n}$, then UnikDTLearn returns a decision tree that $\epsilon$-approximates $f$ with probability (over the random choice of $T$ and the randomness in $EX(f,\mathcal{U})$) at least $1-\delta$.*

It remains to show that the first stage of the algorithm successfully finds a bottleneck variable with high probability given a decision tree drawn at random according to one of our tree models and with depth at least $\frac{1}{2}\log n$. Throughout the rest of the paper we thus have $d = \Theta(\log n), d \geq \frac{1}{2}\log n$. We will consider each model separately, beginning with the complete model.

**7. Identifying bottlenecks in the complete model $\mathcal{T}^C_{d,n}$.** Since we have already shown that any bottleneck makes an equally good root in the hypothesis, and since it is easily seen that all bottlenecks (including the root of $T$) will pass the test at line 8 of LearnTree, it remains to show the following: for each $i = 1,\dots,n$, if $x_i$ is *not* a bottleneck in a random tree $T$, then the probability that $x_i$ passes the test in line 8 is negligibly small.

Our general plan of attack is as follows: we will prove that if $x_1$ is *not* a bottleneck, then with $1 - \frac{1}{n^{\omega(1)}}$ probability there are many root-to-leaf paths in $T$ that do not include $x_1$. We then argue that, conditioned on there being many such paths, among these preleaves there is a collection $C$ satisfying the condition of Lemma 3.3 which has $|C| = \omega(\log n)$. Combining this with the Fourier properties of random decision trees derived earlier gives us our result.

More precisely, the argument is as follows. Let $S$ be a random variable which denotes the number of $x_1$-free paths from the root to a preleaf in $T \in \mathcal{T}^C_{d,n}$. (Note that each such path ends at a depth-$d$ preleaf since we are in the complete model. Note also that since we are in the complete model, $S > 0$ if and only if $x_1$ is not a bottleneck.) We will prove the following lemmas in Appendix C.

LEMMA 7.1. *For $0 \leq d \leq n-1$ we have* $\Pr_{T\in\mathcal{T}^C_{d,n}}[S=0] \leq \frac{1}{n-d}$.

LEMMA 7.2. *For any value $1 \leq k \leq (\log n)^{3/2}$ we have* $\Pr[S=k] = 1/n^{\omega(1)}$.

LEMMA 7.3. *Let $T$ be drawn from $\mathcal{T}^C_{d,n}$ conditioned on its having some set of $(\log n)^{3/2}$ preleaves at depth $d$, each of which has no $x_1$-labeled node as an ancestor. Then with probability $1 - 1/n^{\omega(1)}$ there is a set $C$ of $(\log n)^{5/4}$ preleaves at depth $d$, each labeled with a distinct variable, each of which has no ancestor labeled with $x_1$ or with a variable that labels any element of $C$.*

From these lemmas it is easy to prove that each nonbottleneck will pass the test at line 8 with negligible probability.

THEOREM 7.4. *Let $T \in \mathcal{T}^C_{d,n}$, where $d = \Theta(\log n), d \geq \frac{1}{2}\log n$. If $x_1$ is not a bottleneck, then the probability that $x_1$ passes the test in line 8 is $1/n^{\omega(1)}$.*

*Proof.* Since $S = 0$ if and only if $x_1$ is a bottleneck, we have

$$\begin{aligned}\Pr_{T\in\mathcal{T}^C_{d,n}}[S < (\log n)^{3/2} \mid x_1 \text{ is not a bottleneck}] &= \frac{\Pr[S < (\log n)^{3/2} \ \&\ S > 0]}{\Pr[S>0]} \\ &= \frac{\Pr[1 \leq S < (\log n)^{3/2}]}{\Pr[S>0]} \\ &= 1/n^{\omega(1)},\end{aligned}$$

where the last equality follows from Lemmas 7.1 and 7.2. Thus we may assume that $S \geq (\log n)^{3/2}$. Lemma 7.3 now implies that there is a set $C$ of $(\log n)^{5/4}$ preleaves with the stated properties. Now we observe that if a preleaf belongs to $C$, then under any restriction $x_1 \leftarrow b$, the preleaf will still occur at depth $d$ with the desired property (that no variable labeling any node of $C$ occurs as an ancestor of any node of $C$) in the tree resulting from the restriction. Thus by Lemma 3.3, the probability that all variables labeling nodes in $C$ have even coefficients in the restricted tree is at most $1/2^{(\log n)^{5/4}} = 1/n^{\omega(1)}$. Hence $x_1$ passes the test at line 8 with negligible probability, and the theorem is proved. ∎

Combined with our earlier remarks, this establishes the following theorem.

THEOREM 7.5. *For any $n$, any polynomial $p(\cdot)$, any $\delta > 1/p(n)$, and any $\epsilon > 0$, algorithm LearnTree will with probability at least $1-\delta$ (over a random choice of tree $T$ from $\mathcal{T}^C_{d,n}$ and the randomness of the example oracle) produce a hypothesis decision tree $T'$ that $\epsilon$-approximates the target with respect to the uniform distribution. LearnTree runs in time polynomial in $n$ and $1/\epsilon$.*

*Proof.* By Lemma 6.2, the base case of the algorithm will succeed with probability at least $1-\delta$ as long as it is run on a tree drawn from $\mathcal{T}^C_{c,n}$ for some $c \leq \frac{1}{2}\log n$. In the recursive phase, all first-order Fourier coefficients will be computed exactly with probability at least $1-\delta/4$. Furthermore, assuming that the coefficients are correctly computed, every bottleneck variable will pass the test at line 8 of LearnTree, and by the preceding theorem the probability is negligible that any nonbottleneck variable will pass this test. Thus, in the recursive phase of the algorithm, with probability at least $1-\delta/4$ a bottleneck variable will be chosen by the test. By the arguments of section 5, the two functions obtained by restricting on either value of this bottleneck variable will both be distributed according to $\mathcal{T}^C_{d,n}$. Therefore, the two recursive calls to LearnTree will succeed with probability at least $1-\delta/2$, so that overall the recursive phase succeeds with probability at least $1-\delta$. Furthermore, it is easy to see that the tree returned by the recursive phase will be an $\epsilon$-approximator to the target if each of the subtrees returned by the recursive call is an $\epsilon$-approximator. Finally, for $d = O(\log n)$, the number of recursive calls is clearly polynomially bounded, and thus the algorithm runs in the time claimed given the previously mentioned bounds on UnikDTLearn and FCExact. ∎

**8. Identifying bottlenecks in the balanced model $\mathcal{T}^B_{d,n}$.** We first need an analogue of Lemma 3.3 for the balanced model. Let $T$ be a decision tree drawn from $\mathcal{T}^B_{d,n}$. Let $T'$ be the tree that results from applying the restriction $x_1 \leftarrow 1$ to $T$; i.e., $T'$ is obtained from $T$ by replacing each occurrence of $x_1$ in $T$ with its right subtree.

As in Lemma 3.3, each internal node of $T'$ has a "parity" which is defined exactly as in the proof of Lemma 3.3, and each variable $x_i$ has a parity which equals the parity of the parity of all nodes labeled $x_i$ in $T'$. It is easily seen that rule 1 contributes to the parity of $x_i$ in $T'$ precisely once for each occurrence of $x_i$ as a preleaf in $T$ which lies on an $x_1$-free path from the root in $T$; let $N_{i,1}$ denote the number of such occurrences. Rule 2 contributes to the parity of $x_i$ in $T'$ precisely once for each occurrence of $x_1$ as a preleaf in $T$ which lies on a path from the root in $T$ which contains $x_i$; let $N_{i,2}$ denote the number of such occurrences. (Rule 3 can never be satisfied since each pair of sibling leaf bits in $T'$ must have opposite signs.) Note that the values of $N_{i,1}$ and $N_{i,2}$ are independent of whether we defined $T'$ by the restriction $x_1 \leftarrow -1$ or $x_1 \leftarrow 1$ in the previous paragraph.

As in section 7, to prove that LearnTree succeeds for random $T$ drawn from $\mathcal{T}^B_{d,n}$, we must show that if $x_1$ is not a bottleneck in a random $T$ drawn from $\mathcal{T}^B_{d,n}$, then the probability that $x_1$ passes the test in line 8 is $1/n^{\omega(1)}$. From the discussion of the previous paragraph, this is equivalent to showing that

$$\Pr[N_{i,1} + N_{i,2} \text{ is even for all } i = 2, \dots, n] = 1/n^{\omega(1)}. \tag{8.1}$$

We prove this as follows. As in section 7 let $S$ be a random variable which denotes the number of $x_1$-free paths from the root to a preleaf in $T$. (The difference is that now $T$ is drawn from $\mathcal{T}^B_{d,n}$ instead of $\mathcal{T}^C_{d,n}$; however, these two distributions are identical as regards the internal nodes of a tree drawn from one of them.) By Lemmas 7.1 and 7.2 we know that conditioned on $x_1$ not being a bottleneck in $T$, we have $\Pr_{T\in\mathcal{T}^B_{d,n}}[S > (\log n)^{3/2}] = 1 - 1/n^{\omega(1)}$ (these lemmas are easily seen to hold for $\mathcal{T}^B_{d,n}$ as well as $\mathcal{T}^C_{d,n}$). We thus may safely assume that there are $S \geq (\log n)^{3/2}$ many root-to-preleaf $x_1$-free paths in $T$.

Now fix any set of $S$ preleaf nodes in a complete binary tree of depth $d$. Fix a labeling of variables for each node on each of these paths except for the preleaves themselves (where the labeling is nonredundant and never uses $x_1$); call this labeling $L$. Fix any bit string $v = v_2, \dots, v_n \in \{0,1\}^{n-1}$ corresponding to the parities of $N_{2,2}, \dots, N_{n,2}$. We will show that conditioned on $L$ being the labeling of the set of nonpreleaf nodes on the $x_1$-free paths in $T$, the probability (over the random labeling of the $S$ preleaf nodes) that each variable $x_2, \dots, x_n$ occurs with the "right" parity $v_2, \dots, v_n$ among the $S$ preleaf nodes is $1/n^{\omega(1)}$. (In other words, we will show that regardless of what parities $N_{2,2}, \dots, N_{n,2}$ have, the probability that each $N_{i,1}$ exactly matches the corresponding parity of $N_{i,2}$ is $1/n^{\omega(1)}$.) This suffices to establish (8.1). Thus, it suffices to prove the following lemma (the proof is given in Appendix D).

LEMMA 8.1. *Fix $S \geq 2(\log n)^{3/2}$. For $i = 1, \dots, S$ fix $P_i$ to be some set of exactly $n - d$ "permissible" elements of $\{1, \dots, n\}$. Fix $v = v_1, \dots, v_n \in \{0,1\}^n$. Let $P$ denote $P_1 \times P_2 \times \cdots \times P_S$, so $|P| = (n-d)^S$. Given $z = (z_1, \dots, z_S) \in P$, for $j = 1, \dots, n$ let $par_j(z)$ denote the number of occurrences modulo 2 of $j$ in $z$. Then we have $\Pr_{z\in P}[par_j(z) = v_j$ for all $j = 1, \dots, n] = \frac{1}{n^{\omega(1)}}$.*

We thus have the following balanced model analogues of Theorems 7.4 and 7.5.

THEOREM 8.2. *Let $T \in \mathcal{T}^B_{d,n}$, where $d = \Theta(\log n), d \geq \frac{1}{2}\log n$. If $x_1$ is not a bottleneck, then the probability that $x_1$ passes the test in line 8 is $1/n^{\omega(1)}$.*

THEOREM 8.3. *For any $n$, any polynomial $p(\cdot)$, any $\delta > 1/p(n)$, and any $\epsilon > 0$, algorithm LearnTree will with probability at least $1-\delta$ (over a random choice of tree $T$ from $\mathcal{T}^B_{d,n}$ and the randomness of the example oracle) produce a hypothesis decision tree $T'$ that $\epsilon$-approximates the target with respect to the uniform distribution. LearnTree runs in time polynomial in $n$ and $1/\epsilon$.*

## 9. Identifying bottlenecks in the uniform model $\mathcal{T}^U_{d,n}$.

As in section 7, it suffices to prove that if $x_1$ is not a bottleneck in a random tree $T$ drawn from $\mathcal{T}^U_{d,n}$, then $\Pr[x_1$ passes the test in line 8$] = 1/n^{\omega(1)}$. Our basic approach is similar to section 7, but there are some differences, as shown below.

We now let $S$ be a random variable which denotes the number of $x_1$-free paths from the root to a preleaf of depth $d$ in a random $T$ drawn from $\mathcal{T}^U_{d,n}$. Note that in $\mathcal{T}^U_{d,n}$ it *is* possible to have $S = 0$ even if $x_1$ is not a bottleneck; this can happen if there exist $x_1$-free root-to-preleaf paths in $T$ but all such pre-leaves have depth less than $d$. We will establish the following lemma in Appendix E.

LEMMA 9.1. *For any value $0 \leq k \leq (\log n)^{3/2}$ we have $\Pr_{T\in\mathcal{T}^U_{d,n}}[S = k \mid x_1$ is not a bottleneck $] = 1/n^{\omega(1)}$.*

With this lemma we can prove a uniform model analogue of Theorem 7.4.

THEOREM 9.2. *Let $T \in \mathcal{T}^U_{d,n}$, where $d = \Theta(\log n), d \geq \frac{1}{2}\log n$. If $x_1$ is not a bottleneck, then the probability that $x_1$ passes the test in line 8 is $1/n^{\omega(1)}$.*

*Proof.* Since $x_1$ is not a bottleneck, we have $S \geq (\log n)^{3/2}$ with probability $1 - \frac{1}{n^{\omega(1)}}$ by Lemma 9.1. We now observe that Lemma 7.3 holds identically (with the same proof) if in its statement $T$ is drawn from $\mathcal{T}^U_{d,n}$ and we further condition on $x_1$ not being a bottleneck in $T$. We thus have that with $1 - \frac{1}{n^{\omega(1)}}$ probability there is a set $C$ of $(\log n)^{5/4}$ variables with the properties stated in Lemma 7.3. The rest of the proof follows exactly the proof of Theorem 7.4. □

Now a nearly[3] identical proof to that of Theorem 7.5 gives us our main learning result for uniform random trees.

THEOREM 9.3. *For any $n$, any polynomial $p(\cdot)$, any $\delta > 1/p(n)$, and any $\epsilon > 0$, algorithm LearnTree will with probability at least $1-\delta$ (over a random choice of tree $T$ from $\mathcal{T}^U_{d,n}$ and the randomness of the example oracle) produce a hypothesis decision tree $T'$ that $\epsilon$-approximates the target with respect to the uniform distribution. LearnTree runs in time polynomial in $n$ and $1/\epsilon$.*

## 10. Conclusions and future work.

We have given positive results for learning several natural models of random log-depth decision trees under the uniform distribution. Many interesting questions remain about related models of average-case learning:

- Can similar results be established for natural models of random decision trees of polynomial size (as opposed to logarithmic depth)?
- Can similar results be established for random disjunctive normal form (DNF) formulas or random monotone DNF?
- Can our results be extended to learning under a broader class of distributions?
- Can similar ideas be used to learn with high probability when the target is drawn randomly from an interesting nonuniform distribution over log-depth trees?

It seems possible that progress in these directions could eventually lead to useful practical algorithms.

## Appendix A. Proof of Lemma 5.3.

The proof is by induction on the depth $d$ of $T$. If $d < 1$, then the only possible bottleneck in $T$ is the root and the lemma holds vacuously. For the inductive step, consider a tree $T$ of depth $d \geq 1$.

- If $x_i$ is the root of $T$, then $T'$ is just $T$.
- If $x_i$ is not the root of $T$, then $T$ has some variable $x_j$ at the root with left subtree denoted by $T_1$ and right subtree $T_2$. Since $x_i$ is a bottleneck in $T$ but is not the root of $T$, $x_i$ must be a bottleneck in $T_1$ and in $T_2$. By the induction hypothesis there are trees $T_1', T_2'$ each of which has $x_i$ at its root and such that each is structurally equivalent to $T_1, T_2$, respectively. By definition of structural equivalence, the tree $T''$ with $x_j$ at its root and $T_1'$, $T_2'$ as the left and right child subtrees of the root is structurally equivalent to $T$. Performing a root swap on $T''$ gives the required $T'$.

## Appendix B. Proof of Lemma 6.1.

We prove the lemma for the complete tree model $\mathcal{T}^C_{d,n}$; the proof holds unchanged for $\mathcal{T}^B_{d,n}$ and is easily adapted to $\mathcal{T}^U_{d,n}$. We

[3]We need to fold the distribution irregularity noted in section 5 into $\delta$ at the obvious point in the proof.

have

$$\Pr[T \text{ is not read-}k] \leq n \cdot \Pr[x_1 \text{ occurs } k' > k \text{ times in } T \text{ for some } k'].$$

Since $T$ is of depth $r$, there are $2^{r+1}-1$ occurrences of variables in $T$. The probability that $x_1$ occurs $k'$ times in $T$ is at most $\binom{2^{r+1}-1}{k'} \cdot \left(\frac{1}{n-r}\right)^{k'}$. This is because there are at most $\binom{2^{r+1}-1}{k'}$ possible sets of locations for the $k'$ occurrences of $x_1$ in $T$, and for each location the probability that $x_1$ actually occurs there is at most $1/(n-r)$ (even conditioned on any labeling of the other nodes of the tree), since each location has at most $r$ ancestors.

Since $\binom{a}{b} \leq a^b$ and $1/(n-r) < 2/n$, we can upper bound this probability by

$$2^{(r+1)k'} \cdot 2^{k'}/n^{k'} = 2^{(r+2)k'}/n^{k'} = n^{(1-\epsilon)k'}/n^{k'} = 1/n^{\epsilon k'} \leq 1/n^{\epsilon k}.$$

Since there are at most $n$ possible values of $k' \geq k$ (no variable can occur more than $n$ times since the size of the tree is less than $n$) all in all we have

$$\Pr_{T \in \mathcal{T}_{r,n}}[T \text{ is not read-}k] \leq 1/n^{\epsilon k - 2} = 1/n^C. \qquad \square$$

**Appendix C. Proofs of Lemmas 7.1, 7.2, and 7.3.** We first prove Lemma 7.1. Let us write $p_{d,n}$ to denote the probability that $S = 0$ for a random $T$ drawn from $\mathcal{T}^C_{d,n}$, i.e.,

$$p_{d,n} = \Pr_{T \in \mathcal{T}^C_{d,n}}[x_1 \text{ is a bottleneck in } T].$$

Lemma 7.1 follows directly from the following.

PROPOSITION C.1. *For* $0 \leq d \leq n-1$ *we have* $p_{d,n} \leq \frac{1}{n-d}$.

*Proof.* Clearly $p_{0,n} = \frac{1}{n}$. For $d \geq 1, n \geq 1$ we have $p_{d,n} = \frac{1}{n} + \frac{n-1}{n}(p_{d-1,n-1})^2$. This is because with probability $\frac{1}{n}$ the root is $x_1$. With probability $\frac{n-1}{n}$ the root is some $x_j \neq x_1$, in which case each of the subtrees of the root is drawn from $\mathcal{T}^C_{d-1,n-1}$, and $x_1$ is a bottleneck if and only if it is a bottleneck in each of these two subtrees.

Fix any $m > 0$. We prove that for all $d \geq 0$ we have $p_{d,d+m} \leq \frac{1}{m}$; the proof is by induction on $d$. The base case holds since $p_{0,m} = \frac{1}{m}$. For the induction step, we have

$$\begin{aligned} p_{d+1,d+m+1} = \frac{1}{d+m+1} + \frac{d+m}{d+m+1}(p_{d,d+m})^2 &\leq \frac{1}{d+m+1} + \frac{d+m}{d+m+1}\left(\frac{1}{m}\right)^2 \\ &= \frac{m^2+m+d}{m^2(m+d+1)}. \end{aligned}$$

This is at most $\frac{1}{m}$ if and only if $m^3 + dm + m^2 \leq m^3 + dm^2 + m^2$, which is true since $m \geq 1$, so the proposition is proved. $\square$

We will prove Lemma 7.2 in a moment using Lemma C.2 below. First, a definition and some introductory analysis.

Let $p_{k,d,n}$ denote $\Pr_{T \in \mathcal{T}^C_{d,n}}[S = k]$. For $k \geq 1$ and $d \geq 1$ we have

$$p_{k,d,n} = \frac{n-1}{n} \sum_{i=0}^{k} p_{i,d-1,n-1} p_{k-i,d-1,n-1}. \tag{C.1}$$

To see this, note that there are exactly $k$ $x_1$-free root-to-preleaf paths in $T$ if and only if (1) the root is some variable other than $x_1$, and (2) the left and right subtrees (each of which is drawn from $\mathcal{T}^C_{d-1,n-1}$) have $i$ and $k-i$ $x_1$-free root-to-preleaf paths, respectively, for some $1 \le i \le k$. For the base cases, we have $p_{c,0,n} = 0$ for $c \ge 2$ since it is impossible to have two paths to preleaves in a tree of depth 0. $p_{1,0,n} = \frac{n-1}{n}$ since there is exactly one $x_1$-free path as long as the root is not $x_1$. $p_{0,0,n} = \frac{1}{n}$ by the same reasoning. Finally, $p_{0,d,n} \le \frac{1}{n-d}$ by Lemma 7.1.

The following lemma is proved in section C.1.

LEMMA C.2. *Let $c = \Theta(\log n), c \ge \frac{3}{8}\log n$, and $\ell \le poly(n)$. Then*

$$p_{\ell,c,n} \le t(n) + \sum_{j=1}^{(\log n)^{1/3}} \sum_{i=(1/4)\log n+1}^{\ell-(1/4)\log n-1} p_{i,c-j,n-j}, \tag{C.2}$$

*where $t(n) = 1/n^{\omega(1)}$.*

*Proof of Lemma* 7.2. Recall that $k \le (\log n)^{3/2}$, $d = \Theta(\log n)$, and $d \ge \frac{1}{2}\log n$. By Lemma C.2 we have

$$p_{k,d,n} \le t(n) + \sum_{j=1}^{(\log n)^{1/3}} \sum_{i=(1/4)\log n+1}^{k-(1/4)\log n-1} p_{i,d-j,n-j}. \tag{C.3}$$

We now repeatedly apply Lemma C.2 to the right-hand side of inequality (C.3). The key observation is that each time we apply Lemma C.2 to bound some $p_{\ell,c,n'}$ by the right side of (C.2), the first subscript ($\ell$) decreases by at least $\frac{1}{4}\log n$ in every new occurrence of $p_{\cdot,\cdot,\cdot}$. Hence the "depth" of this repeated replacement will be at most $4(\log n)^{1/2}$ (since $k \le (\log n)^{3/2}$), at which point the summation over $i$ in the right-hand side of (C.2) will be empty.

We now observe that each application of Lemma C.2 replaces one $p_{\cdot,\cdot,\cdot}$ with at most $(\log n)^{1/3} \cdot (\log n)^{3/2} < (\log n)^2$ new $p_{\cdot,\cdot,\cdot}$'s. Since the replacement depth is at most $4(\log n)^{1/2}$ and $t(n) = 1/n^{\omega(1)}$, it follows that

$$p_{k,d,n} \le \frac{1}{n^{\omega(1)}} \cdot \left((\log n)^2\right)^{4(\log n)^{1/2}} = \frac{1}{n^{\omega(1)}} \cdot 2^{8(\log n)^{1/2}\log\log n} = \frac{1}{n^{\omega(1)}},$$

and Lemma 7.2 is proved. $\square$

Now we prove Lemma 7.3.

*Proof of Lemma* 7.3. Fix any set $R$ of $(\log n)^{3/2}$ preleaf nodes in a complete binary tree structure of depth $d$. Fix any nonredundant labeling of all of the ancestors of all of these preleaves which does not use $x_1$ anywhere. Now each labeling of the nodes in $R$ which does not use $x_1$ and maintains nonredundancy is equally as likely under the conditioning of the lemma. Note that for each node in $R$ there are $n-d-1$ legal labelings (since the label must not use $x_1$ or any of the $d$ ancestors of the node).

Consider a random legal labeling of the nodes in $R$. Partition the nodes of $R$ into $(\log n)^{5/4}$ disjoint subsets $R_1, \dots, R_{(\log n)^{5/4}}$ each of size $(\log n)^{1/4}$. Let $F$ denote a set of "forbidden" labels; initially $F$ is the set of all variables which label ancestors of nodes in $R$ (plus $x_1$). Let $F_0$ denote the size of this initial set, so initially we have $|F| = F_0 \le 1 + d(\log n)^{3/2} = O((\log n)^{5/2})$. We consider the subsets $R_1, \dots$ in turn. The probability that every node in $R_1$ is assigned a forbidden label is at most $\left(\frac{F_0}{n-d-1}\right)^{(\log n)^{1/4}} = 1/n^{\omega(1)}$. Thus we may suppose that there is some preleaf $v_1 \in R_1$ which receives a nonforbidden label; we add this label to $F$. Now the probability that every node in $R_2$ receives a forbidden label is at most $\left(\frac{F_0+1}{n-d-1}\right)^{(\log n)^{1/4}} = 1/n^{\omega(1)}$, so we may suppose that there is some preleaf $v_2 \in R_2$ which receives a nonforbidden label; we add this label to $F$. Continuing in this fashion for $(\log n)^{5/4}$ steps, and noting that $|F|$ never exceeds $O((\log n)^{5/2})$, we have that with probability $1 - 1/n^{\omega(1)}$ there is a set $v_1, \ldots, v_{(\log n)^{5/4}}$ of nodes each of which receives a nonforbidden label. This set is easily seen to satisfy the desired conditions for $C$. ∎

**C.1. Proof of Lemma C.2.** Our proof of Lemma C.2 will use the following intermediate lemma. Note that we allow a slightly weaker bound on $d$ than usual in this lemma; we will need this slightly weaker bound later.

LEMMA C.3. *For any value* $1 \le k \le \frac{1}{4}\log n$ *and any value* $d \ge \frac{1}{3}\log n$ *we have* $p_{k,d,n} = \Pr_{T \in \mathcal{T}^C_{d,n}}[S = k] = 1/n^{\omega(1)}$.

*Proof.* We first consider the case $k = 1$. There are exactly $2^d$ possible locations (preleaves) where an $x_1$-free path from the root to a preleaf could end. Consider any such location. In order for this to be the only $x_1$-free path to a preleaf in $T$, it must be the case that every node on this path (except the root) has the property that the subtree rooted at its sibling has $x_1$ as a bottleneck. These $d$ subtrees are clearly disjoint; the one at depth $\ell$ is drawn from $\mathcal{T}^C_{d-\ell,n-\ell}$ (over a suitable set of $n - \ell$ variables which includes $x_1$ since the path is $x_1$-free), and hence by Lemma 7.1 each subtree has $x_1$ as a bottleneck with probability at most $\frac{2}{n}$. Thus $\Pr[S = 1]$ is at most $2^d \cdot \left(\frac{2}{n}\right)^d = \left(\frac{4}{n}\right)^d$, which is $1/n^{\omega(1)}$ since $d \ge \frac{1}{3}\log n$.

The general case for any $1 \le k \le \frac{1}{4}\log n$ is similar. We use the following fact, which we prove later.

FACT 1. *Fix any set of $k$ root-to-preleaf paths in $T$. Let $N$ be the number of subtrees of $T$ which are rooted at an internal node and* (1) *are not rooted on any of these $k$ paths, but* (2) *have their parent on one of these $k$ paths. Then $N \ge d - \log k$.*

There are $\binom{2^d}{k}$ possible sets of $k$ preleaves where the $x_1$-free paths might end. As in the case $k = 1$, each subtree as in Fact 1 must have $x_1$ as a bottleneck, but as in the $k = 1$ case each such subtree has $x_1$ as a bottleneck with probability at most $2/n$. Thus the probability that $S = k$ is at most (by Fact 1)

$$\binom{2^d}{k} \cdot \left(\frac{2}{n}\right)^{d-\log k} \le 2^{dk}\left(\frac{2}{n}\right)^{d-\log k} \le n^{d/4} \cdot \left(\frac{2}{n}\right)^d \cdot n^{\log k} = n^{\log k}\left(\frac{2}{n^{3/4}}\right)^d,$$

where the second inequality uses $k \le \frac{1}{4}\log n$. This is $1/n^{\omega(1)}$ since $d \ge \frac{1}{3}\log n$ and $k \le \frac{1}{4}\log n$. ∎

*Proof of Fact* 1. It is clear that there are exactly $2^d - k$ preleaves contained in the desired subtrees of $T$. Each subtree contains $2^i$ of these preleaves for some $i$, and clearly different subtrees have disjoint sets of preleaves. Since the binary representation of $2^d - k$ starts with $d - \log k$ ones, there must be at least $d - \log k$ such subtrees (it is impossible to add up $t$ powers of 2 and get a binary number with more than $t$ ones). ∎

Now we prove Lemma C.2. From the recursive equation (C.1) we have

$$p_{\ell,c,n} \le 2p_{0,c-1,n-1}p_{\ell,c-1,n-1} + \sum_{i=1}^{\ell-1} p_{i,c-1,n-1}p_{\ell-i,c-1,n-1}$$

$$\le \frac{4}{n}p_{\ell,c-1,n-1} + \sum_{i=1}^{\ell-1} p_{i,c-1,n-1}p_{\ell-i,c-1,n-1}, \tag{C.4}$$

where the last inequality holds (with room to spare) by Lemma 7.1 since $c = \Theta(\log n) <$

$n/2$. Repeatedly applying (C.4), we have

$$\begin{aligned}p_{\ell,c,n} &\le \left(\frac{4}{n}\right)^2 p_{\ell,c-2,n-2} + \frac{4}{n}\sum_{i=1}^{\ell-1} p_{i,c-2,n-2}p_{\ell-i,c-2,n-2} + \sum_{i=1}^{\ell-1} p_{i,c-1,n-1}p_{\ell-i,c-1,n-1}\\ &\le \cdots\\ &\le \left(\frac{4}{n}\right)^c p_{\ell,0,n-c} + \sum_{j=1}^{c}\left(\frac{4}{n}\right)^{j-1}\sum_{i=1}^{\ell-1} p_{i,c-j,n-j}p_{\ell-i,c-j,n-j}.\end{aligned}$$

Since each value $p_{\cdot,\cdot,\cdot}$ is a probability, it is easy to see that for any value of $j$ the inner sum over $i$ is at most $\ell =$poly$(n)$. Recalling that $c \ge \frac{3}{8}\log n$, we may truncate the sum over $j$ at (say) $(\log n)^{1/3}$ and thus have

$$\begin{aligned}p_{\ell,c,n} &\le \frac{1}{n^{\omega(1)}} + \sum_{j=1}^{(\log n)^{1/3}}\sum_{i=1}^{\ell-1} p_{i,c-j,n-j}p_{\ell-i,c-j,n-j}\\ &\le \frac{1}{n^{\omega(1)}} + \sum_{j=1}^{(\log n)^{1/3}}\left[2\sum_{i=1}^{(1/4)\log n} p_{i,c-j,n-j} + \sum_{i=(1/4)\log n+1}^{\ell-(1/4)\log n-1} p_{i,c-j,n-j}\right].\end{aligned}$$

Since $c-(\log n)^{1/3}$ is at least $(1/3)\log n$, Lemma C.3 implies that the first sum over $i$ inside the brackets is $1/n^{\omega(1)}$ for all $j = 1,\ldots,(\log n)^{1/3}$. We thus have

$$p_{\ell,c,n} \le \frac{1}{n^{\omega(1)}} + \sum_{j=1}^{(\log n)^{1/3}}\sum_{i=(1/4)\log n+1}^{\ell-(1/4)\log n-1} p_{i,c-j,n-j}$$

as desired, and Lemma C.2 is proved.

**Appendix D. Proof of Lemma 8.1.** We say that $z \in P$ *yields* $v \in \{0,1\}^n$ if $par_j(z) = v_j$ for all $j$. Let $V \subseteq P$ denote the set of all $z$ which yield $v$; thus our goal is to show that $|V|/|P| = 1/n^{\omega(1)}$. We do this by defining a mapping $M$ with the following properties:

1. $M$ assigns to each $z \in V$ a set of $(n-d-2\log n)^{\log n}$ strings all of which are in $P - V$.
2. For each $z \in V$, for any $x \in M(z)$, the number of $z' \in V$ such that $x \in M(z')$ is at most $(1/n^{\omega(1)}) \cdot (n-d-2\log n)^{\log n}$.

These properties imply that $|V|/|P-V| = 1/n^{\omega(1)}$, which establishes the lemma.

The mapping $M$ is defined as follows: given $z \in V$, the elements of $M(z)$ are those $x \in P$ which satisfy the following conditions:

- $x_i = z_i$ for all $i = 1,\ldots,S-\log n$.
- For $i = S-\log n+1,\ldots,S$, coordinate $x_i$ is an element of $P_i$ which (a) does not occur in the last $\log n$ coordinates of $z$, and (b) does not equal $x_j$ for any other value $j \in S-\log n+1,\ldots,S$.

There are at least $(n-d-2\log n)^{\log n}$ elements of $M(z)$ since the second condition above rules out at most $2\log n$ of the $n-d$ elements of $P_i$ for each $i$.

Fix some $z \in V$ and some $x \in M(z)$. We now show that there are few $z' \in V$ such that $x \in M(z')$. Note first that in order for $z'$ to have $x \in M(z')$ it must be the case that $z'_i = z_i$ for all $i = 1,\ldots,S-\log n$. Let $z^*$ denote this $S-\log n$ character prefix $z_1\ldots z_{S-\log n}$. We now show that only a small number of the $(n-d)^{\log n}$ possible completions $\sigma \in P_{S-\log n+1}\times\cdots\times P_S$ will be such that $z' = z^*\sigma$ belongs to $V$.

We prove this by showing that in fact only a small number of the $n^{\log n}$ possible completions $\sigma \in \{1,\dots,n\}^{\log n}$ will be such that $z^*\sigma$ belongs to $V$. To see this, note that in order for $z^*\sigma$ to belong to $V$, each $j \in \{1,\dots,n\}$ must occur either an even or an odd number of times in $\sigma$ (depending on whether $par_j(z^*)$ does or does not match $v_j$). Now we observe that the probability that these $n$ parity conditions are all satisfied by a random $\sigma \in \{1,\dots,n\}^{\log n}$ is precisely the probability that a uniform random walk in the Boolean cube $\{0,1\}^n$ ends up, after precisely $\log n$ steps, at some particular vertex $w \in \{0,1\}^n$ (where the walk starts at $0^n$ and proceeds to a randomly chosen neighbor of the current node at each step). Since $d = \Theta(\log n)$ we have $(n-d-2\log n)^{\log n}/n^{\log n} = \Theta(1)$, and thus Lemma 8.1 follows from the following elementary fact, which for completeness we now prove.

PROPOSITION D.1. *For all $w \in \{0,1\}^n$, the probability that a uniform random walk of precisely $\log n$ steps starting at $0^n$ ends at $w$ is $1/n^{\omega(1)}$.*

*Proof.* Let $|w|$ denote the number of nonzero coordinates in $w$. Let $p_w$ denote the probability that the walk ends at $w$. We first observe that if $|w| = |w'|$, then by symmetry $p_w = p_{w'}$. Thus for any $w$ such that $|w| \geq \frac{1}{3}\log n$ we clearly have $p_w \leq 1/\binom{n}{(1/3)\log n} = 1/n^{\omega(1)}$. Thus we may suppose that $|w| \leq \frac{1}{3}\log n$. Any walk of $\log n$ steps which ends at such a $w$ must select at most $\frac{2}{3}\log n$ distinct indices from $\{1,\dots,n\}$ in total, since at most $\frac{1}{3}\log n$ of the indices selected are selected exactly once. The number of possible $\log n$ step walks which select at most $\frac{2}{3}\log n$ distinct indices is at most $\binom{n}{(2/3)\log n} \cdot (2/3\log n)^{\log n}$, since there are $\binom{n}{(2/3)\log n}$ ways to choose the selected indices and then $(2/3\log n)^{\log n}$ ways to choose the walk using these indices. This is less than $n^{2/3\log n} \cdot (n^{1/6})^{\log n} = n^{(5/6)\log n}$, and hence such walks occur with total probability at most $1/n^{(1/6)\log n}$ since there are $n^{\log n}$ possible walks in total. ∎

**Appendix E. Proofs of Lemmas 9.1, 5.5, and 5.7.** Before proving Lemma 9.1 we first establish some useful notation and observations.

Let $C_{d,n}$ denote the number of nonredundant decision trees over $\{x_1,\dots,x_n\}$ of depth at most $d$. (So $C_{-1,n} = 2$ since a single leaf can be either $-1$ or 1; $C_{0,n} = 2+4n$ since there are $4n$ possibilities for a depth-0 tree depending on the variable at the root and the two leaf bits; etc.) The following observation will be useful.

OBSERVATION 2. *Drawing a random $T$ from $\mathcal{T}^U_{d,n}$ is equivalent to generating $T$ via the following randomized process which we call $\texttt{MakeTree}_{d,n}$:*

- *With probability $1/C_{d,n}$ take $T$ to be the one-node tree $+1$ and halt. Likewise, with probability $1/C_{d,n}$ take $T$ to be the one-node tree $-1$ and halt.*
- *With probability $1 - 2/C_{d,n}$ pick a random variable from $x_1,\dots,x_n$ as the root of $T$. Construct its left and right subtrees by independently performing two calls to $\texttt{MakeTree}_{d-1,n-1}$, using for each call the set of $n-1$ variables which were not selected for the root.*

We write $q_{d,n}$ to denote $1 - \frac{2}{C_{d,n}}$; i.e., $q_{d,n}$ is the probability that a randomly drawn $T$ from $\mathcal{T}^U_{d,n}$ is nontrivial (recall that there are exactly two trivial trees).

We now write $p_{d,n}$ to denote the probability that a random $T$ drawn from $\mathcal{T}^U_{d,n}$ has $x_1$ as a bottleneck:

$$p_{d,n} \equiv \Pr_{T\in\mathcal{T}^U_{d,n}}[x_1 \text{ is a bottleneck}].$$

We have the following analogue of Lemma 7.1.

LEMMA E.1. *For all $0 \leq d \leq n-1$, $p_{d,n} \leq \frac{1}{n-d}$.*

*Proof.* The proof differs only slightly from that of Lemma 7.1. We now have $p_{0,n} = \frac{4}{4n+2} < \frac{1}{n}$ since exactly four of the $4n+2$ trees of depth at most 0 have $x_1$ as a bottleneck (i.e., as the root). For $d \geq 1, n \geq 1$ we now have

$$p_{d,n} = q_{d,n}\left(\frac{1}{n} + \frac{n-1}{n}(p_{d-1,n-1})^2\right). \tag{E.1}$$

To see this, note that $x_1$ is a bottleneck only if $T$ is nontrivial, which occurs with probability $q_{d,n}$. If $T$ is nontrivial, then with probability $\frac{1}{n}$ the root is $x_1$, in which case $x_1$ is a bottleneck. Otherwise, $x_1$ is a bottleneck if and only if $x_1$ is a bottleneck in the left and right subtrees of $T$, each of which is drawn from $\mathcal{T}^U_{d-1,n-1}$.

Comparing the initial conditions and recurrence relation for $p_{d,n}$ with those of Lemma 7.1 it is clear that the current $p_{d,n}$ is dominated by the earlier recurrence, and the lemma is proved. ◻

Now we can prove Lemma 9.1. We have that

$$\begin{aligned}\Pr_{T\in\mathcal{T}^U_{d,n}}[S = k \mid x_1 \text{ is not a bottleneck}] &= \frac{\Pr[S = k \;\&\; x_1 \text{ is not a bottleneck}]}{\Pr[x_1 \text{ is not a bottleneck}]}\\ &< 2\Pr[S = k \;\&\; x_1 \text{ is not a bottleneck}]\\ &\leq 2\Pr[S = k],\end{aligned}$$

where the first inequality is by Lemma E.1. Thus it suffices to prove the following two lemmas.
