For various optimization problems dealing with geometric regions, there is a notable difference in complexity between a region with holes and a *simple* region that does not have any holes. (In particular, it can be decided in polynomial time whether a given grid graph without holes has a Hamiltonian cycle [44], even though the complexity of the TSP on these graphs is still open.) Our NP-hardness proof makes strong use of holes; furthermore, the complexity of the PTAS described above is exponential in the number of holes. This raises the following natural question.

PROBLEM 6.2. *Is there a polynomial-time algorithm for exactly computing a minimum-turn covering tour for simple orthogonal polygons?*

It may be possible to improve the performance of some of our approximation algorithms. In particular, the following remains unclear.

PROBLEM 6.3. *Is the analysis of the 3.75-approximation algorithm tight?*

We believe that it may be possible to improve the factor. We also believe that there is room for improvement in approximating nonintegral orthogonal milling, in particular by improving the cost of finding a strip cover.

PROBLEM 6.4. *What is the complexity of computing a minimum strip cover in nonintegral orthogonal polygons?*

An important tool for our approximation algorithms is a strip cover of small cost; finding a strip cover remains a possible approach even if strips may be parallel to more than two directions. This is closely related to other decomposition problems; see [34] for a survey.

PROBLEM 6.5. *What is the complexity of computing minimum strip covers in nonorthogonal polygons?*

The answer may very well be “NP-hard, even for three directions”: Hassin and Megiddo [26] show that the problem of hitting a set of points with a minimum number of lines with three slopes is hard. However, their proof constructs a disconnected set of grid points and cannot be applied directly to milling problems. In any case, even an approximation would be of interest, in particular if it achieves the following property.

PROBLEM 6.6. *Is there a strip cover approximation algorithm for d directions whose performance ratio is independent of d ?*

This would imply a positive result for a special case of the following, even more general, problem.

PROBLEM 6.7. *Can one obtain approximation algorithms for unrestricted directions in an arbitrary polygonal domain, and an appropriately shaped cutter?*

Acknowledgments. We are obliged to Valentin Polishchuk for a very thorough list of suggestions, and thank three anonymous referees for various comments that helped to improve the presentation of the paper. We thank Regina Estkowski for helpful discussions.

ON THE COMPLEXITY OF NETWORK SYNCHRONIZATION*

DARIN GOLDSTEIN[†] AND KOJIRO KOBAYASHI[‡]

Abstract. We show that if a minimal-time solution to a fundamental distributed computation primitive, synchronizing a network path of finite-state processors, exists on the three-dimensional, undirected grid, then we can conclude the purely complexity-theoretic result $P = NP$.

Every previous result on network synchronization for various network topologies either demonstrates the existence of fast synchronization solutions or proves that a synchronization solution cannot exist at all. To date, it is unknown whether there is a network topology for which there exists a synchronization solution but for which no *minimal-time* synchronization solution exists. Under the assumption that $P \neq NP$, this paper solves this longstanding open problem in the affirmative.

Key words. firing squad synchronization problem, network synchronization, distributed computation

AMS subject classifications. 68Q25, 68W40

DOI. 10.1137/S0097539705447086

1. Introduction. The firing squad synchronization problem (FSSP) is a famous problem originally posed almost half a century ago. A prisoner is about to be executed by firing squad. The firing squad is made up of soldiers who have formed in a straight line with muskets aimed at the prisoner. Some of the soldiers are using blanks and some are using real bullets. There are good reasons for this: Nobody will ever know who the true executioner of the prisoner is, and no single member of the firing squad is able to save the condemned man's life by not firing, which reduces the moral compulsion not to fire when the order is given. But for these same reasons, it is absolutely imperative that all of the soldiers fire simultaneously.

The general stands on the left side of the line, ready to give the order, but he knows that he can only communicate with the soldier to his right. In fact, each soldier can only communicate with the soldier to his immediate left and/or right but nobody else. Soldiers have limited memory and can only pass along simple instructions. Is it possible to come up with a protocol, independent of the size of the line, for getting all of the soldiers to fire at the prisoner simultaneously if their only means of communication are small, whispered instructions only to adjacent soldiers? (The possibility of counting the number of soldiers in the line can be discounted because no soldier can remember such a potentially large amount of information; each soldier can only remember messages that are independent of the size of the line.)

The problem itself is interesting as a mathematical puzzle. More importantly, there are also applications to the synchronization of small, fast processors in large networks. In the literature on the subject (e.g., [29, 18]), the problem has been referred to as “macrosynchronization given microsynchronization” and “realizing global

synchronization using only local information exchange.” The synchronization of multiple small but fast processors in general networks is a fundamental problem of parallel processing and a computing primitive of distributed computation.

1.1. Early history. The FSSP has a rich history; solutions to various subproblems have been discovered over a period of decades. We summarize the history here. J. Myhill introduced the problem in 1957, though the first published reference is [26] from 1962. McCarthy and Minsky first solved the problem for the bidirectional line (as described above) in [25]. In an unpublished 1962 manuscript, Goto [11] also solved the problem on the bidirectional line. Goto’s solution fired the bidirectional line in time $2n - 2$, where n is the number of soldiers in the line; $2n - 2$ is equal to the time it would take a message to percolate from the general to the furthest soldier and back again and is therefore obviously minimal-time. Goto’s solution required a great number of states, but researchers have since reduced the number to six over a period of decades (culminating with Mazoyer’s solution in [22]). As the number of states required per automata to perform the computation has decreased from thousands to merely six, the allowable speed of the process has correspondingly increased; in general, smaller processors have higher clock speeds.¹ Given that processor synchronization is a fundamental primitive of distributed computation, it is an important problem to find solutions that are both theoretically minimal-time (i.e., requiring minimal-time steps) and as small as possible (i.e., allowing for higher clock speed/lower actual time per step).

1.2. The model. As mentioned previously, we wish to model the operation of a large network of processors whose computations are all governed synchronously by the same global clock. The model is intended to mathematically abstract a physical switching network or a very large-scale parallel processing machine. The processors are designed to be small, fast, and unable to access large memory caches. Each processor is identical and assumed to have a fixed constant number of ports which can both send and receive a constant amount of data per clock cycle. (“Constant” quantities must be independent of the size and topology of the network.) One processor is specified as the root. Its purpose is to begin the algorithm. (Intuitively, the root has the job of the “general.”)

More formally, the problem is to construct a deterministic finite-state automaton with a transition function that satisfies certain conditions. We assume that each processor in the network is identical. Initially, the root is in a special “general” state. All other nodes are initially in a special “quiescent” state, in which, at each time step, the processor sends a “blank” character through all of its ports. A processor remains in the quiescent state until a nonblank character is received by one of its inports. We consider connected networks of such identical synchronous finite-state automata with vertex degree uniformly bounded by a constant.² These automata are meant to model very small, fast processors. The network itself may have a specific topology (see below) but potentially unbounded size. The network is formed by connecting ports of a given automaton to those of other automata with wires. Not all ports of a given automaton need necessarily be connected to other automata. The network has a global clock, the pulses between which each processor performs its computations.

¹Note that the number of clock cycles required by the algorithm does not necessarily decrease. It is the time taken by *each* clock cycle that decreases.

²The vertex degree of each processor must be bounded uniformly by a constant; otherwise, a constant-sized automaton might not be able to distinguish its own ports.

Processors synchronously, within a single global clock pulse, perform the following actions in order: read in the inputs from each of their ports, process their individual state changes, and prepare and broadcast their outputs. As mentioned, our network structure is specifically designed to model the practical situation of many small and fast processors performing a synchronous distributed computation. The goal of the protocol is to cause every process in the network to enter the same special “firing” state for the first time *simultaneously*. In keeping with current technological trends that are likely to continue indefinitely, we assume that the time it takes for messages to travel along the various wires is vastly greater than the time for a simple processor state change. Our global clock pulses are therefore used to count the number of global “message interchanges” that occur.

A *solution* A for a given network topology (e.g., the bidirectional line, as above) is defined to be the instantiation of an automaton with a transition function that satisfies the firing conditions outlined above for any network size. (So, by this definition, a *solution* for the bidirectional line must function for a bidirectional line of *any* size.) Assuming a solution A is specified, the *firing time* of A on a given network will refer to the number of clock cycles it takes for this network of processors programmed with the solution A to complete the protocol and simultaneously fire. The *minimum firing time* of a given network (of a specified topology) will refer to the minimum over all solutions A of the firing time of the network of processors programmed with solution A . A *minimal-time solution* A_{min} for a given network topology will be a solution such that the firing time for a network of any given size (with the given topology) programmed with the algorithm A_{min} will equal the minimum firing time of the network. Note that even though the network can be of arbitrary size, the size of the algorithm A_{min} must be fixed.

1.3. Additional history. Numerous other variations of the problem have also been studied, and there is a large body of results that spans almost 50 years. Mazoyer provides an overview of the problem (up to 1986, at least) in addition to some of its history in [23]. We give a brief survey of results and open problems restricting ourselves only to variations that satisfy the following conditions.

- ◇ The structure of the configurations (placements of soldiers) that we consider will not change dynamically. Once the protocol is initiated, the network is considered static.
- ◇ Adjacent soldiers can exchange information with one unit time delay. (Automata-theoretically speaking, the state of a soldier at time t depends only on the states of the soldier and adjacent soldiers at time $t - 1$.)
- ◇ There are no restrictions on how much information is exchanged between adjacent soldiers. For example, there are variations of the problem that restrict the messages to be only a single bit long. Because the automata under consideration are finite-state, messages are restricted to be of constant size but not necessarily just a single bit.

1.3.1. Variations for which minimal-time solutions are known. The following lists some of the variations for which minimal-time solutions to the FSSP are known and their corresponding minimum firing times.

- The original FSSP on the bidirectional line of length n : The minimum firing time is $2n - 2$ (see Goto [11], Waksman [38], Balzer [1], and Mazoyer [22]).
- The one-dimensional line of length n such that the position of the root may be at any position: The minimum firing time is $2n - 2 - \min\{k - 1, n - k\}$, where k is the position of the root ($1 \leq k \leq n$) (see Moore and Langdon [27],

FIG. 1.1. An example of a 2PATH configuration.

Varshavsky, Marakhovsky, and Peschansky [37], Szwerinski [36], and Settle and Simon [34]).

- The square of size $n \times n$: The minimum firing time is $2n - 2$ (see Shinahr [35]).
- The rectangle of size $m \times n$: The minimum firing time is $m + n + \max\{m, n\} - 3$ (see Shinahr [35]).
- The cube of size $n \times n \times n$: The minimum firing time is $3n - 3$ (see Shinahr [35]).
- The bilateral ring of size n : The minimum firing time is n (see Culik [5] and Berthiaume et al. [3]).
- The ring of size n with one-way information flow: The minimum firing time is $2n - 1$ (see Kobayashi [20] and LaTorre, Napoli, and Parente [21]).

1.3.2. Variations for which minimal-time solutions are not known. The following lists five basic variations for which solutions have been shown to exist but for which no minimal-time solutions are known.

- FSSP for paths in the two-dimensional or the three-dimensional grid spaces: A configuration is a path in the two-dimensional or the three-dimensional grid spaces, and the position of the root is at one of the two endpoints. We abbreviate these problems 2PATH and 3PATH, respectively. In Figure 1.1 we show an example of such configurations for 2PATH. These are the natural generalizations of the original FSSP.
- FSSP for paths in the two-dimensional or the three-dimensional grid spaces such that the position of the root may be at any position in the path: We call these problems the generalized FSSP for paths in the two-dimensional or the three-dimensional grid spaces, respectively, and abbreviate them g-2PATH and g-3PATH. These problems are natural generalizations of the variation studied by Moore and Langdon [27].
- FSSP for regions in the two-dimensional or the three-dimensional grid spaces: A configuration is a connected finite subset of grid points in the two-dimensional or the three-dimensional grid spaces. We abbreviate these problems 2REG and 3REG, respectively. These problems are natural generalizations of squares, rectangles, and cubes. In Figure 1.2, we show an example of a 2REG configuration. We discuss the 2REG, a subproblem of FSSP for general undirected networks, in greater detail below. The first solution by Rosenstiehl [31] and Rosenstiehl, Fiksel, and Holliger [32] for the latter FSSP was also the first solution for 2REG. Romani [30] improved that solution, and this improvement also applied to 2REG. At present, the best solution by

FIG. 1.2. An example of a 2REG configuration.

Nishitani and Honda [28] for FSSP for general undirected networks mentioned below is also the best solution for 2REG. Some fast solutions that work only for some special types of two-dimensional regions are also known (see Grasselli [12] and Kobayashi [15]).

- FSSP for general undirected networks:
Each soldier is modeled by a finite automaton having a constant number of bidirectional terminals. The study of this version of the FSSP started with Rosenstiehl [31] and Rosenstiehl, Fiksel, and Holliger [32]. At present, the solution with the smallest firing time is by Nishitani and Honda [28]. The firing time of their solution is $3r - 1$, where r is the radius of the network. The coefficient 3 is optimal in the sense that there is no solution having firing time $cr + c'$ for any constants $c < 3$ and c' . The basic idea used for their solution is to create two basic data structures within the network: a “directed ring” (that is, a firing squad in the shape of a circle with the caveat that soldiers may only listen to the man on their left and speak to the man on their right) and a “ring-of-trees” (that is, networks which include a loop, containing the root, whose length is at least as great as the maximum distance from the root to any processor).
- FSSP for general directed networks:
Each soldier is modeled by a finite automaton that has a fixed number of input terminals and a fixed number of output terminals. Edges connect output terminals to input terminals. Each output terminal is connected to at most one input terminal (that is, fan-out is at most 1). The first solution of this variation is by Kobayashi [16]. The firing time of his solution is an exponential function of the number n of soldiers, and the solution essentially uses the same structures as Nishitani and Honda. Even, Litman, and Winkler [8] constructed a solution with firing time $O(n^2)$. This solution again uses the same data structures as Nishitani and Honda, but they are constructed in a faster way thanks to their invention of network-traversing “snakes.” Ostrovsky and Wilkerson [29] improved the firing time to $O(nd)$, where d refers to the diameter of the network, which remains the best to date.

1.3.3. Variations that have no minimal-time solutions. There are only a couple of “lower bound” results in the literature. The first is an impossibility result for the specific topology in which processors may have unbounded fan-out from any given output (proved in [17]); there cannot exist any solution at all for this particular

topology. Additionally, Jiang [14, 13] showed that the FSSP for the bilateral ring with an arbitrary number of roots has no solution. In this case, all the soldiers may potentially be roots, and all roots are activated simultaneously. (Note that there are many variations of FSSP with multiple roots that have solutions. For example, Culik [5] showed that FSSP for the one-dimensional line with roots at the leftmost and rightmost ends does have a minimal-time solution.)

1.4. Our contribution. It has been a longstanding open problem to determine whether there is a network topology for which a synchronization solution is known to exist, but a *minimal-time* synchronization solution provably does not exist. After many years, the contribution of this paper is to finally answer this question in the affirmative under the assumption that $P \neq NP$. In this paper, we show that 3PATH, g-3PATH, and 3REG have no minimal-time solutions if $P \neq NP$. Hence, of the eight variations of FSSP mentioned above, at least three are highly unlikely to have minimal-time solutions.

The main result of this paper is the following theorem.

THEOREM 1.1. *If $P \neq NP$, then there does not exist a minimal-time solution to FSSP for the network topology introduced below as variation 3PATH, the direct three-dimensional analogue of Kobayashi's variation 7 from [18].*

Note that, by this theorem, the straightforward complexity-theoretic statement $P \neq NP$ implies a result about the absence of minimal-time solutions (i.e., instantiations of automata) for synchronization, two seemingly unconnected subjects. Or, equivalently, the existence of a minimal-time solution for a distributed computation synchronization primitive implies the purely complexity-theoretic result $P = NP$.

In order to prove this theorem, we need to define the three-dimensional equivalent to a problem proposed in [18, 19], the three-dimensional path extension problem (or 3PEP), which we define rigorously in section 2. The proof proceeds in steps as follows.

1. We show that a minimal-time solution for FSSP on variation 3PATH implies that there exists a deterministic Turing machine that can solve the problem 3PEP in polynomial time.
2. We prove that if $3PEP \in P$, then two simpler versions of the 3PEP problem, 1CUBE and 2CUBE, are also solvable in polynomial time. The fact that the reduction below is polynomial-time depends heavily on these two problems also being polynomial-time.
3. Given the result in step 2, we show that $3PEP \in P \rightarrow HAM \in P$, where HAM represents a restricted NP-complete version of the Hamilton path problem.

Aside from being theoretically interesting, this result is important to the field of parallel processing, as fast network processor synchronization is a fundamental computing primitive. Indeed, decades of research have focused on extending the network topologies for which there exist solutions [8, 28, 16, 29], minimizing the time and space complexity [11, 22, 38, 39], and even proving the asymptotic time equivalence of a number of other common network problems to FSSP [10].

1.5. Additional remarks. Before concluding this section we should mention some results by Mazoyer and by Schmid and Worsch and make an additional comment on the formulation of FSSP we use in this paper.

1.5.1. Results by Mazoyer and by Schmid and Worsch. In section 1.3, we surveyed known results on variations of FSSP that are generalizations of the original FSSP to more general network topologies. However, if we do not restrict ourselves to these types of variations, we know at least two others that have solutions yet no

minimal-time solutions, and the nonexistence of minimal-time solutions can be shown without a complexity-theoretical assumption such as $P \neq NP$.

Mazoyer [24] considered the following variation of FSSP. There is only one general and one soldier. The information exchange between the two nodes takes τ units of time (where τ is a positive integer). The state of a given node at time t is determined by the state of the node at time $t - 1$ and the state of the other node at time $t - \tau$. Neither node knows the value τ . The minimum firing time is a function of τ , and the notion of the minimal-time solutions is naturally defined. Mazoyer proved that this variation of FSSP has a solution yet no minimal-time solution.

Schmid and Worsch [33] considered a variation of the original FSSP on the bidirectional line such that each node may be either a general or a soldier, and generals are activated independently. A problem instance of this variation is specified by the following values: (1) the number n of nodes, (2) the number k of generals ($1 \leq k \leq n$), and (3) for each i ($1 \leq i \leq k$) the position p_i of the i th general ($1 \leq p_i \leq n$) and the time t_i at which the i th general is activated ($0 \leq t_i$). All the nodes start with the quiescent state, and for each i the node at the position p_i is forced to enter the state of a general at time t_i . They proved that this variation has a solution but has no minimal-time solution.

1.5.2. The formulation of FSSP. In this section, we give a more formal description of the FSSP. First, we review the classical formulation and then introduce and justify our slight modification.

The usual/classical formulation of FSSP can be summarized as follows. Each node of a network is a copy of a finite automaton. The set of the states of the finite automaton includes at least three different states, the *general state* G , the *quiescent state* Q , and the *firing state* F . Each input terminal of a node receives the state of the node to which the terminal is connected or a special symbol $\#$ if the input terminal is open. The state of a node at time $t + 1$ is completely determined by its state and the states of its adjacent nodes at time t . A node in the state Q remains in that state until the value of at least one of its input terminals is neither G nor $\#$. At time 0, the state of a node is G or Q depending on whether or not it happens to be the root. The goal of FSSP for a network topology is to design the finite automaton so that, for each network of that network topology, all of the nodes enter the state F simultaneously for the first time.

As a model of current network synchronization algorithms, this formulation has two problems. The first is that there is only one general state G , and hence the root cannot know its boundary condition (the existence or nonexistence of adjacent nodes for each input terminal) at time 0. In reality, the time for a node to check its boundary condition is negligibly small compared with the time for an information exchange between adjacent nodes. Hence it is natural to assume that the root can know its boundary condition at time 0. The second problem is that the general state G and the firing state F must be different, and hence the root cannot fire at time 0 even if the network has only one node. By the same reasoning, it is natural to assume that the root can fire at time 0 when the network has only one node.

Based on these considerations we modify the formulation of FSSP in the following way. First, we allow the automaton to have more than one general state. The general state to be used is uniquely determined by the boundary condition of the root. This modification solves the first problem. Second, instead of using one firing state F , we specify multiple firing states. A general state may be also specified as one of the firing states. However, the quiescent state Q cannot be specified as a firing state. All the

nodes should enter some firing state simultaneously for the first time. Different nodes may enter different firing states. If we specify the general state that corresponds to the root having no adjacent nodes as one of the firing states, the root can fire at time 0. Hence this modification solves the second problem.

We show the proofs for our main results (Theorems 1.1 and 4.3) using this modified formulation of FSSP. However, all of these results are also true for the usual formulation of FSSP. At the end of section 4 we will briefly explain how to modify the proofs for the other formulation.

The rest of the paper is organized as follows. In section 2, we rigorously define our new variation 3PATH. In section 3, we outline steps 1, 2, and 3 of the proof of Theorem 1.1. In section 4, we present the generalizing theorems for variations g-3PATH and 3REG and the corresponding proofs. Finally, section 5 explores possible avenues of further research.

2. Variation 3PATH. In this section, we will introduce the new network topology 3PATH.

We can place a processor on any point $(x_1, x_2, x_3) \in \mathcal{Z}^3$ in the three-dimensional grid. We say that two processors in positions (x_1, x_2, x_3) and (y_1, y_2, y_3) are *adjacent* if and only if $|x_i - y_i| = 1$ for exactly one value of i and for all $j \neq i$, $x_j = y_j$. Note that processors have six available ports for adjacent processors: North, South, East, West, Up, and Down.

We can abstract this type of network by a three-dimensional orthogonal grid graph in which certain vertices are marked. Each marked vertex corresponds to the position of a processor, and each edge corresponds to a bidirectional link between processor ports.

DEFINITION 2.1 (variation 3PATH). *We define a path in the infinite three-dimensional orthogonal grid \mathcal{Z}^3 as follows. A path is a sequence of distinct vertices $p_1, p_2, \dots, p_n \in \mathcal{Z}^3$ that satisfy the following properties. For any $1 \leq i < n$, p_i is adjacent to p_{i+1} . With the exception of p_1 and p_n , all vertices in the path must have exactly two adjacent vertices. If $n \geq 2$, p_1 and p_n must have exactly one adjacent vertex each. (Diagonal vertices, though allowed, are not considered adjacent by the definition above.) The root processor must be placed at p_1 . If two processors are placed in adjacent positions, we assume that the adjacent port is connected by a bidirectional wire; only adjacent processors can be connected.*

Note that this definition implies that the configuration is connected in the sense that a signal released by any processor must be able to eventually reach any other processor in the network via data transfers passed back and forth through the processors' ports.

The length of a path $p_1 p_2 \dots p_n$ is defined to be n .

This definition corresponds to the intuitive definition of a self-avoiding network path in three dimensions. The path is “self-avoiding” in the following sense: not only must the path not intersect itself, but it cannot even become adjacent to itself. If it does, then there must exist some vertex with three or more neighbors (or the boundary conditions must be violated).

A solution to this variation of the FSSP trivially exists because solutions have been found for arbitrary undirected (and directed) networks. The same solutions will function on this subvariation, just not in minimal time.

3. The results. In this section, we will outline steps 1, 2, and 3 of the proof of Theorem 1.1.

3.1. A minimal-time solution to variation 3PATH implies 3PEP ∈ P.

This section will be devoted to step 1 of the proof of Theorem 1.1. First, we need to define the problem 3PEP.

DEFINITION 3.1 (3PEP). *A problem instance will be a path as in Definition 2.1. We assume that $p_1 = (0, 0, 0)$ and represent a path as a sequence of directions: North, South, East, West, Up, and Down. The decision problem 3PEP is as follows: Is it possible to extend the given path instance to double its length from its end (and still remain a path as in Definition 2.1)?*

This is precisely the three-dimensional analogue of the two-dimensional path problem presented in [18, 19].

The proof that a minimal-time FSSP solution to variation 3PATH implies 3PEP ∈ P is a direct three-dimensional adaptation of that given in [18, 19], and we will present only a short explanation here for the sake of completeness. For a much more thorough treatment, we recommend consulting the stated references. In the following, whenever we refer to a “path,” we mean a path in the sense of Definition 2.1.

Let $p_1p_2 \dots p_n$ be a path. For $1 \leq i \leq n$, let the value $e(p_1p_2 \dots p_n, i)$ be the value of the length of the longest possible consistent extension to the path $p_1p_2 \dots p_i$ if $i < n$ (i.e., the maximum value³ m such that there exists a path $p_1p_2 \dots p_i p_{i+1}q_2 \dots q_m$) and 0 if $i = n$.

LEMMA 3.2. *Let $p_1p_2 \dots p_n$ be a path, and let $i_0 = \min\{i : 1 \leq i \leq n, i \geq e(p_1p_2 \dots p_n, i)\}$. Intuitively, i_0 represents the label of the first vertex after which point we are guaranteed that any signal released from the root has traversed at least half the total “possible” path length.*

Then a minimal-time FSSP solution for variation 3PATH, if it exists, running on the network $p_1p_2 \dots p_n$, will fire the network in number of clock steps equal to either $2i_0 - 1$ if $i_0 = e(p_1p_2 \dots p_n, i_0)$ or $2i_0 - 2$ if $i_0 > e(p_1p_2 \dots p_n, i_0)$.

Proof. First, we show that the firing time of any solution A to FSSP for variation 3PATH is at least the value stated in the lemma.

Suppose that $i_0 = e(p_1p_2 \dots p_n, i_0)$. This implies that $i_0 < n$ and that there is a path of the form $p_1p_2 \dots p_{i_0}p_{i_0+1}q_2 \dots q_{i_0}$. Consider running the solution A on both of the paths $\alpha = p_1p_2 \dots p_n$ and $\beta = p_1p_2 \dots p_{i_0}p_{i_0+1}q_2 \dots q_{i_0}$. Then, at the time $2i_0 - 2$, the states of A at p_1 in α and p_1 in β are the same, and the state of A at q_{i_0} in β is the quiescent state Q . Hence the solution A cannot fire on $\alpha = p_1p_2 \dots p_n$ at the time $2i_0 - 2$. Therefore the firing time of A for $\alpha = p_1p_2 \dots p_n$ is at least $2i_0 - 1$.

Now suppose that $i_0 > e(p_1p_2 \dots p_n, i_0)$. If $i_0 = 1$, the firing time is at least $2i_0 - 2$ because $2i_0 - 2 = 0$. Suppose that $i_0 \geq 2$. Then we have $i_0 \leq e(p_1p_2 \dots p_n, i_0 - 1)$. Hence there exists a path of the form $\beta = p_1p_2 \dots p_{i_0-1}p_{i_0}q_2 \dots q_{i_0}$. As in the previous case, using this we can show that the firing time of A for $\alpha = p_1p_2 \dots p_n$ is at least $2i_0 - 2$.

Next we show that there exists a solution whose firing time for $p_1p_2 \dots p_n$ is at most the value stated in the lemma. We consider only the case where $i_0 < n$. The modification for the case where $i_0 = n$ is easy. Assume we are given some solution A to FSSP for variation 3PATH that is not necessarily minimal-time for all paths. For any path $p_1p_2 \dots p_n$, we can modify the solution to a new solution A' which is minimal-time for that particular path. Along with all other signals sent by A , send a searcher signal down the path until it reaches processor p_{i_0} .

³If a maximum value m does not exist (i.e., if the path could extend indefinitely), we define $e(p_1p_2 \dots p_n, i) = \infty$.

Suppose that the searcher signal⁴ finds that the current problem instance has the same initial sequence as the special path $p_1p_2 \dots p_{i_0}p_{i_0+1}$. The searcher signal finds this at time $i_0 - 1$ arriving at p_{i_0} .⁵ Then the distance between p_{i_0} and any vertex p_i behind it ($1 \leq i < i_0$) is at most $i_0 - 1$, and the distance between p_{i_0} and any possible vertex ahead of it is at most i_0 if $i_0 = e(p_1p_2 \dots p_n, i_0)$ and at most $i_0 - 1$ if $i_0 > e(p_1p_2 \dots p_n, i_0)$. Hence, as soon as the searcher signal arrives at p_{i_0} at time $i_0 - 1$, it sends a signal back to both ends of the line saying “fire after i_0 more steps” if $i_0 = e(p_1p_2 \dots p_n, i_0)$ and “fire after $i_0 - 1$ more steps” if $i_0 > e(p_1p_2 \dots p_n, i_0)$. After each time step, the signal decreases its countdown by one. When the countdown reaches 0, every processor simultaneously fires. The firing time is $(i_0 - 1) + i_0 = 2i_0 - 1$ if $i_0 = e(p_1p_2 \dots p_n, i_0)$ and $(i_0 - 1) + (i_0 - 1) = 2i_0 - 2$ if $i_0 > e(p_1p_2 \dots p_n, i_0)$.

If the searcher signal fails to find that the current problem instance has the same initial sequence, the algorithm simply uses the signals from the original protocol, A .

Thus, the minimum firing time of the network given by the path $p_1p_2 \dots p_n$ is at most $2i_0 - 1$ if $i_0 = e(p_1p_2 \dots p_n, i_0)$ and at most $2i_0 - 2$ if $i_0 > e(p_1p_2 \dots p_n, i_0)$. \square

THEOREM 3.3 (step 1 in the proof of Theorem 1.1). *If a minimal-time FSSP solution to variation 3PATH exists, then 3PEP \in P.*

Proof. Assume that a minimal-time FSSP solution MIN to variation 3PATH exists. Let $p_1p_2 \dots p_n$ be an instance of 3PEP, encoded appropriately.

Consider the path $p_1p_2 \dots p_n$. At the vertex p_n , there are five different directions for extending the path. If it is impossible to extend the path by one more vertex from p_n , then clearly the answer to 3PEP is NO.

We will assume that the path can be extended in some direction to $p_1p_2 \dots p_nr$. Arrange $n + 1$ copies of the solution MIN on the $n + 1$ vertices of $p_1p_2 \dots p_nr$. Simulate the algorithm and note the firing time. Let $i_0(r)$ be the value $\min\{i : 1 \leq i \leq n + 1, i \geq e(p_1p_2 \dots p_nr, i)\}$. Lemma 3.2 yields the following results:

- If the firing time is greater than or equal to $2n$, then either $2i_0(r) - 1 \geq 2n$ or $2i_0(r) - 2 \geq 2n$, and hence $i_0(r) - 1 \geq n$. This together with $i_0(r) \leq n + 1$ implies $i_0(r) = n + 1$. From $i_0(r) \leq e(p_1p_2 \dots p_nr, i_0(r) - 1)$, or equivalently $n + 1 \leq e(p_1p_2 \dots p_nr, n)$, we know that $p_1p_2 \dots p_nr$ has an extension of length at least $n + (n + 1) = 2n + 1$. Therefore the answer to 3PEP is YES.
- If the firing time is $2n - 1$, then $n = i_0(r) = e(p_1p_2 \dots p_nr, n)$. Hence $p_1p_2 \dots p_nr$ has an extension of length $n + n = 2n$. Therefore the answer to 3PEP is YES.
- If the firing time is $2n - 2$, then $n = i_0(r) > e(p_1p_2 \dots p_nr, n)$. Hence the length of any extension of $p_1p_2 \dots p_nr$ is at most $n + (n - 1) = 2n - 1$. Therefore the path $p_1p_2 \dots p_nr$ cannot be extended to an extension of length $2n$, and we need to check other possible directions for r .
- Finally, if the firing time is less than or equal to $2n - 3$, then either $2i_0(r) - 1 \leq 2n - 3$ or $2i_0(r) - 2 \leq 2n - 3$, and hence $i_0(r) \leq n - 1$. From $i_0(r) \geq e(p_1p_2 \dots p_nr, i_0(r))$ we know that the length of any extension of $p_1p_2 \dots p_{i_0(r)}p_{i_0(r)+1}$ is at most $i_0(r) + i_0(r) \leq 2n - 2$. Therefore the path

⁴The size of the searcher signal and the other signals sent by this algorithm depend critically on the number i_0 . If we attempt to create a minimal-time solution for *all paths* using this construction, we will run into a serious problem. As the paths grow in size, the size of this number i_0 may become unbounded. However, if we fix some particular i_0 and tailor a specific solution for that i_0 , even though the size of the automata will depend on i_0 , once we fix its value, it is a constant. Therefore, for any *fixed* path, there exists a solution that is minimal-time for that particular path.

⁵Note that the signal need not reach p_{i_0+1} in order to verify its existence. Once it reaches processor p_{i_0} , the processor can “inform” the signal if it is connected in the correct direction.

$p_1p_2 \dots p_n$ cannot be extended to twice its length, and hence the answer to 3PEP is NO.

So to determine the answer to 3PEP for the path $p_1p_2 \dots p_n$, we can have the deterministic Turing machine simulate the operation of a network on $p_1p_2 \dots p_nr$ for each r , using the minimal-time FSSP solution MIN . We check every possible direction for r (only five at most). If a single choice for r yields a definitive answer, then we return that answer as the answer to 3PEP. Otherwise, the answer is NO. This clearly takes polynomial time in the input size. \square

3.2. 3PEP \in P \rightarrow 1CUBE \in P and 3PEP \in P \rightarrow 2CUBE \in P. In this section, we complete step 2 of Theorem 1.1. The final step in the proof of Theorem 1.1 is a reduction that depends heavily on these two problems being polynomial-time solvable.

We will make use of four basic building blocks illustrated in Figures 3.1, 3.2, 3.3, and 3.4. They are closed walls, open walls, spigots, and connectors. We will show how they are used to make more complicated structures later in this section. We make the convention in all our constructions below that all walls are square as they are above. (This is not essential to the proof, but it makes explanations conveniently shorter.) A path will never pass through a closed wall and can only pass through an open wall through the 6×4 opening. Note that the basic building blocks are all composed of a single path.

We now describe the formation of the “2-holed cube.” A 2-holed cube will consist of 4 closed walls, 2 open walls, 2 spigots, and 7 paths connecting the various building blocks together. This structure is confusing to view in a single picture all at once. We will describe the steps used to create it using a sequence of pictures. Figures 3.2 and 3.3 illustrate how the spigot should be placed so that the multiple potential openings in the open wall will not “leak.” Figure 3.5 illustrates the appropriate placement of the cube walls.

We will now define the decision problems 1CUBE and 2CUBE.

DEFINITION 3.4 (1CUBE). *A problem instance will be a number n represented in unary⁶ and a positive integer K . The decision problem 1CUBE is as follows: Does an $n \times n \times n$ 2-holed cube in \mathcal{Z}^3 admit an avoiding⁷ path (as in Definition 2.1) of length at least K that begins in the middle of the spigots of one of the open walls, enters the cube, and remains inside the cube? The path may end at the center of the spigot of the other open wall but may not pass through.*

DEFINITION 3.5 (2CUBE). *A problem instance will be a number n represented in unary and a positive integer K . The decision problem 2CUBE is as follows: Does an $n \times n \times n$ 2-holed cube in \mathcal{Z}^3 admit an avoiding path (as in Definition 2.1) of length at least K that begins at the center of the spigot of one of the open walls, enters the cube, and ends at the center of the spigot of the other open wall?*

THEOREM 3.6. 3PEP \in P \rightarrow 1CUBE \in P.

Proof. Assume that 3PEP is solvable in polynomial time. Consider the problem 1CUBE with parameters n and K . In the three-dimensional grid, we form a 2-holed cube of size $n \times n \times n$. We form this cube from a single path beginning outside the cube and ending outside the cube in the position adjacent to the center of one of the

⁶The reason we represent the number n in unary here and in Definition 3.5 is that we wish to be able to construct the cube in \mathcal{Z}^3 as a polynomial-time part of the problem instance. Note that in Definition 3.1, the path is also explicitly constructed.

⁷The term *avoiding* refers to the fact that the path must never become adjacent to itself or the walls of the cube. We use this term in the same manner in Definition 3.5.

FIG. 3.1. This figure illustrates some of the simple building blocks we will use to create the more complicated structures below. The upper left picture is a “closed” wall formed by a single path. Just to the right, we provide a snapshot of the center of the closed wall. Note that even though there is not a solid mass of vertices, a continuation of the path could not possibly pass through the wall, as it would violate the definition of a path (Definition 2.1).

Below these two is an “open” wall and a “spigot.” Note that because the height of the hole in the center is 6 edges tall and 4 edges wide, it is possible for the path to pass through the center of this structure without violating any path properties. (We provide a close-up of the center of the open wall in Figure 3.2.) Unfortunately, there are several potential places for a path to pass through our open wall. We would prefer that there be only a single unique entrance/exit point for any open wall; we therefore place a “spigot” at the opening of every open wall. Of course, it must be placed 2 units from the wall opening so as not to violate the path definition. This concept will be further outlined in Figure 3.2.

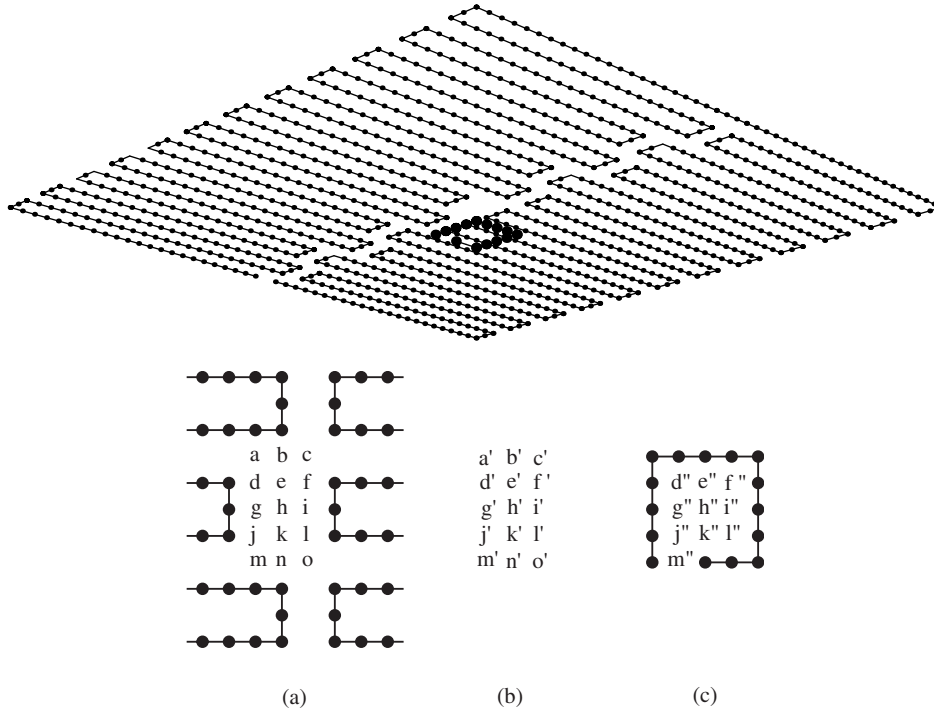

FIG. 3.2. This figure shows the shapes of holes and spigots and their relative placement. Above is a figure illustrating the general idea of where the spigot would be placed: 2 units away from the wall in the center of the hole. The lower figure makes this more precise:

Three figures (a), (b), (c) represent three adjacent planes. A snapshot of the center of an open wall is on the plane (a) and a spigot is on the plane (c). The plane (b) is between the two planes (a) and (c) and is empty. Three positions d, d', d'' are on one straight line, and similarly for the other letters. We may regard the hole in (a) as a rectangle with dimensions 6 edges tall and 4 edges wide containing 15 inner grid points a, b, c, \dots, o . For a path to enter into the wall through the hole, the path must pass through the center h'' of the spigot. After that position, there are numerous ways for the path to proceed, e.g., $h'' \rightarrow h' \rightarrow h \rightarrow \text{inside}$, $h'' \rightarrow h' \rightarrow h \rightarrow e \rightarrow \text{inside}$, $h'' \rightarrow h' \rightarrow h \rightarrow k \rightarrow \text{inside}$, $h'' \rightarrow h' \rightarrow e' \rightarrow e \rightarrow \text{inside}$, and $h'' \rightarrow h' \rightarrow k' \rightarrow k \rightarrow \text{inside}$. Note that if we do not place the spigot, a path can pass through the hole at least four times, for example, enter through c , exit through e , enter through k , and exit through o . The spigot forces the path to enter (or exit) only once through one fixed position h'' .

spigots. We create an extension from the beginning of the path in such a way that the path begins at a distance 2 away from the center of the other spigot. See Figure 3.6 for an illustration of the beginning of the path “plugging” one of the opening spigots. Note that the path, when extended from the end, must lead into the cube. Either the parameter K is less than the number of processors in the current path or it is not. If K happens to be less than the current number of processors in the path, then for large enough n , the answer to 1CUBE is YES because the volume inside the cube is $\Theta(n^3)$ and $K = O(n^2)$.

Now assume that K is greater than or equal to the number of processors in the current path. Extend the beginning of the path outwards until the total path length is precisely equal to K . We can now use the polynomial-time oracle for 3PEP to determine the answer for the 1CUBE problem. If we run the 3PEP algorithm on the constructed path, the answer will be the same as that for 1CUBE. \square

FIG. 3.3. This figure illustrates a potential pitfall of the spigot placement: If we place them in the way illustrated here rather than correctly (as in Figure 3.2), a path can enter into the wall through the positions o' and o without passing through the spigot. For one fixed orientation of the hole there are eight ways to place the spigot, and we must avoid two of them, those with the vacant position of the spigot at c'' and o'' .

FIG. 3.4. This figure illustrates a “connector” that connect two open walls together. Note that the ends of the connector are simply two spigots.

Note that because the 1CUBE decision problem is solvable in polynomial time, it is trivial to construct a polynomial-time algorithm to determine the length of the longest path that enters an $n \times n \times n$ cube once through the middle of a face and remains inside.

THEOREM 3.7. $3PEP \in P \rightarrow 2CUBE \in P$.

Proof. Assume that 3PEP is solvable in polynomial time. Consider the problem 2CUBE with parameters n and K . In the three-dimensional grid, we form a 2-holed cube of size $n \times n \times n$. This cube is again formed from a single path beginning outside the cube and ending outside the cube in the position adjacent to the center of one of the spigots; thus the path, when extended, again must lead into the cube. We also form another $n^2 \times n^2 \times n^2$ 2-holed cube at a distance n away such that the opening for the $n \times n \times n$ cube lines up exactly with the uncovered opening from the larger cube. We then connect the two with a connector as illustrated in Figure 3.7. Using the same construction as in the proof of Theorem 3.6, we close off the other opening

FIG. 3.5. This figure illustrates the placement of the walls for the formation of the cube structure. We choose four of the walls to be closed and the other two open. The two open walls must be adjacent. If (x_1, y_1, z_1) , (x_2, y_2, z_2) , (x_3, y_3, z_3) are the coordinates of the three vertices at the corner of the cube, then we specify that for each i, j ($1 \leq i < j \leq 3$), of the three values $|x_i - x_j|$, $|y_i - y_j|$, $|z_i - z_j|$, two have value 1 and the other has value 0. Hence, a path can pass through neither the corner nor the edge of a cube. Each opening in the open walls is a rectangle of size 4×6 . We require that the two open walls are always placed so that the four sides of length 6 of the rectangles are always parallel.

FIG. 3.6. This figure illustrates a spigot plug. Note that the path begins at a distance 2 from the center of the spigot. Because the only exit from the spigot is through the center, this effectively stops any path inside the cube from exiting through the hole.

of the larger cube. The entire structure is built from a single path.

Given the result from Theorem 3.6 and the subsequent remark, it is possible to determine the length of the longest path that can be contained within the one-holed cube of size $n^2 \times n^2 \times n^2$. Call this length L . We also know that the distance from the exit of the $n \times n \times n$ 2-holed cube to the entrance of the other is n .

Note that for large enough n , the current path length must be strictly less than the quantity $L + n + K$ because $L = \Theta(n^6)$. We can therefore extend the beginning of the current path until it has length exactly $L + n + K$. We can now use the polynomial-time oracle for 3PEP to determine the answer for the 2CUBE problem.

FIG. 3.7. This figure illustrates the connection of open cube faces via a connector, one of the basic building blocks. Note that the connector stops at a distance of 2 units away from the faces of the cube. The connector, by construction, conveniently has a spigot on both ends. Note that we must be very careful with the placement of the spigots on the holes in the cubes as illustrated by Figures 3.2 and 3.3. A misplacement may allow a path to enter a cube via a “bad” path. (We need the entrances and exits to be exactly the same for each cube so that the problems 1CUBE and 2CUBE are well defined.) Luckily our construction allows us to move cubes and connectors by a constant amount, so we can always assume that the spigots connect in exactly the right way.

If we run the 3PEP algorithm on the constructed path, the answer will be the same as that for 2CUBE. \square

Note that because the 2CUBE decision problem is solvable in polynomial time, we can also trivially construct an algorithm for determining the length of the longest path completely enclosed by the $n \times n \times n$ cube that is required to begin at the “entrance” and end at the “exit.”

3.3. 3PEP \in P \rightarrow HAM \in P. In this section, we will justify step 3 in the proof of Theorem 1.1.

In order to do so, we need to introduce an operation on graphs in \mathcal{Z}^3 , called a *blow-up*, by a factor of k . The idea behind this operation is simple. We apply the linear map $(x_1, x_2, x_3) \mapsto (kx_1, kx_2, kx_3)$ to every point in \mathcal{Z}^3 . Note that the blow-up operation preserves slopes of lines but increases distances by a factor of k .

THEOREM 3.8 (step 3 in the proof of Theorem 1.1). *Let HAM be the following special case of the Hamilton path problem. As stated in [9], the Hamilton path problem [GT39] remains NP-complete under the assumption that the graph G is planar, cubic, 3-connected, and has no face with fewer than five edges. (A cubic graph is one with every vertex of degree 3. We will not need the latter two properties.) Then we have the following result: 3PEP \in P \rightarrow HAM \in P.*

Proof. Assume that we are given a planar, cubic graph G and that 3PEP \in P. We first choose two vertices in G , v_{start} and v_{end} , and remove two edges from each vertex, leaving only one edge remaining per vertex. These vertices will correspond to the start and end of a potential Hamilton path in the graph G . Call the new graph G' .

Our first nontrivial goal will be to illustrate how it is possible to build a three-dimensional connected structure out of a single path that has the same connectivity properties as G' . The structure will contain an “inside” and an “outside” such that a path originating on the inside of the structure cannot possibly make it to the outside and vice versa. The beginning of the path (root) will be required to be outside the

structure, and the end of the path will be inside the structure. We will then show how it is possible to solve the Hamilton path problem on G' utilizing a solution to the 3PEP problem.

An integer-grid straight-line drawing of a planar graph G is an embedding of G in the two-dimensional integer grid such that the vertices of G are grid points and the edges of G are noncrossing straight lines. In [7, 6], it is shown how an n -vertex planar graph can be embedded as an integer grid straight-line drawing into the plane in $O(n^2)$ space, requiring a grid of size $O(n) \times O(n)$, and polynomial time. In fact, [4] does the same in linear time. Many other references on graph embedding can be found in [2]. Embed the graph G' in the xy -plane (i.e., $z = 0$) in \mathcal{Z}^3 in this way. (Note that it is possible to create the structure outlined below without making use of the planarity and the integer-grid straight-line drawing. Eliminating these restrictions will not change the ultimate result, though it will increase the length of the explanation significantly by forcing us to explicitly describe a separate method for the relevant constructions.)

In the following discussion, we will assume that n is large enough to dwarf all constants hidden by the asymptotic notation.

We now have a planar graph in \mathcal{Z}^3 with no crossing edges. Blow-up \mathcal{Z}^3 by a factor of n^5 . Note that, by elementary geometry, any vertex or line without an endpoint at v must have been at least distance $\Omega(\frac{1}{n})$ from v before the blow-up. Blow-ups increase distances by factors. Thus, for any vertex v , we can be guaranteed that all other vertices and lines without an endpoint at v are at least a distance $\Omega(n^4)$ from v . Around each vertex v , we can draw the following figure using our building blocks: (a) an “inner” $\Theta(n^3)$ -sized 2-holed cube with v at the center (following the same construction as in Theorems 3.6 and 3.7), (b) for all vertices other than v_{start} and v_{end} , a “surrounding” 3-holed cube with v at the center and with edge size $\Theta(1)$ larger than the 2-holed cube, and (c) for v_{start} and v_{end} , a “surrounding” 1-holed cube with the appropriate center vertex and size. We specify that any 3-holed cube must have each open face adjacent to the other two open faces. One of the open faces must be facing in the positive z -direction. The 1-holed cube must also have its single opening face in the positive z -direction. Both 1-holed and 3-holed cubes are required to have spigots on all open faces in the appropriate places to plug leaks. We are guaranteed that no surrounding cube comes within a distance of $\Omega(n^4)$ of any other surrounding cube. Once the cubes have been drawn, delete the vertex v . (In other words, we are replacing vertices with cubes.)

At this point, we have a three-dimensional situation in which the vertices are represented by two large cubes, one inside the other, and are connected by straight-line segments. We now concentrate on replacing the edges of the original straight-line drawing with three-dimensional structures. Our goal is to replace the straight lines that would otherwise enter the vertices with three-dimensional connectors. Of course, these straight line segments do not necessarily proceed along a rectilinear path, as the three-dimensional connectors do, and we are therefore required to use the third dimension: If a connector needs to make a rectilinear turn, we simply direct it into a small $\Theta(1)$ -sized box⁸ and open a second face of the box in the direction that we wish to turn, continuing a second connector out of this new opening. We replace every straight-line segment by an appropriate string of connectors that turn as necessary.

⁸*Terminology:* Note that a “box” is used for a turn and is always constant-sized. “Cubes” are the structures that replaced the vertices above, and all have edge size $\Theta(n^3)$. We use two different words to distinguish between these two, even though both shapes are the same; their size and utility are different.

In order to make the new three-dimensional structure have the same connectivity properties as G' , we need to guarantee that all connectors are able to enter and leave the appropriate cubes without crossing or interfering with the rest of the structure. Recall that the original graph G' was embedded in the xy -plane in \mathcal{Z}^3 . Number each of the $O(n^2)$ edges of G' . (In fact, because G' is cubic, an even better bound of $O(n)$ edges applies, but throughout this paper we will need only the $O(n^2)$ bound. The cubic nature of the graph G' is used in a different essential way in the construction: it is trivial to insert the constant-sized holes in the sides of the cubes if there only need to be three of them.) Note that if we proceed upwards in the z -direction, after $\Theta(n^3)$ distance (the maximum distance that any cube stretches outwards), the space is structure-free. Assign each edge a unique space in which to maneuver from cube to cube. Let the edge size of the “turn” box for the connectors be $c_{turn} = \Theta(1)$. Edge i will receive the grid space between $(c_{turn} + 4) * i + \Theta(n^3)$ and $(c_{turn} + 4) * (i + 1) + \Theta(n^3)$ in the z -direction.⁹ (In other words, edge i receives all grid points of the form (x, y, z) where $(c_{turn} + 4) * i + \Theta(n^3) \leq z < (c_{turn} + 4) * (i + 1) + \Theta(n^3)$.) We connect Cubes A and B with connectors as follows: upon leaving Cube A , we simply make a turn directly upwards (if necessary), move to the appropriate maneuver space, proceed to the spot above Cube B using only at most two more turns, turn downwards towards Cube B , and then turn towards Cube B (if necessary) to enter. In this way, the new three-dimensional graph has the same connectivity properties as the original graph G' .

At this point, we have a three-dimensional structure that is broken into many separate pieces. We connect these pieces into one long path G'_{3D} by connecting the beginning of one structure with the end of the next structure.¹⁰ Let the path G'_{3D} end between the inner and outer cubes of the vertex v_{start} ; thus, the path must extend into the unique connector of v_{start} with or without entering the inner cube. G'_{3D} will begin outside the enclosed structure. We now have a connected three-dimensional structure G'_{3D} that represents the graph G' in three dimensions, where the vertices are pairs of large concentric cubes, edges are three-dimensional connectors, and the entire structure is drawn with a single path originating outside the structure and terminating in such a way that any extension must continue inside the structure.

Before continuing with the analysis, we must guarantee that the number of vertices in the path represented by G'_{3D} is bounded above by a polynomial in n (the input size of G) and that the time it took to construct G'_{3D} is also polynomial in n . We omit a lengthy but fairly easy proof of both of these statements.

We now examine the structure G'_{3D} . Note that the size of each cube in the structure is $\Theta(n^3)$. Because $3PEP \in P$ by assumption, we know from Theorems 3.6 and 3.7 that $1CUBE \in P$ and $2CUBE \in P$. By the subsequent remarks, we can determine the maximum path length that a given cube of either type admits in polynomial time in n . Let this maximum path length be $L_1(n)$ for $1CUBE$ and $L_2(n)$ for $2CUBE$. Both quantities are clearly $\Theta(n^9)$. (Again, we omit the fairly trivial proof of the previous statements.)

The length of the path given by G'_{3D} is $O(n^8)$. Because the path originates outside the structure G'_{3D} we have formed, we can extend the beginning (the root) as far as we like. Extend the beginning of the path so that the length of the path

⁹The extra 4 in the expressions is a guarantee that we have a two unit buffer on either side of the connector, so the path remains true to Definition 2.1. We require the extra $\Theta(n^3)$ to make sure that we make it over the tops of all of the cubes we have already made and into the structure-free space.

¹⁰This is actually a nontrivial exercise in practice. Theoretically, however, it is trivial that it is possible to make these connections given the huge amount of space between each structure.

structure G'_{3D} ends up being $(n - 1)L_2(n) + L_1(n) - \lfloor \frac{L_2(n)}{2} \rfloor$. Call this new path $G'_{3D,ext}$. We then ask the following question (3PEP): Can we extend the path given by $G'_{3D,ext}$ to double its length? (In other words, can we extend $G'_{3D,ext}$ by length at least $(n - 1)L_2(n) + L_1(n) - \lfloor \frac{L_2(n)}{2} \rfloor$ and still have the resulting structure satisfy the properties for a path in Definition 2.1?)

We claim that a Hamilton path exists in the graph G' if and only if the answer to this question for the corresponding path $G'_{3D,ext}$ is YES.

There are two cases to consider.

1. Assume that there is a Hamilton path in the graph G that starts at v_{start} , uses the edge from v_{start} that was not removed, and terminates at v_{end} via the single edge not removed. Then we can guarantee that there exists a path extension of $G'_{3D,ext}$ that enters and exits exactly $n - 1$ inner cubes and enters and possibly remains inside one additional inner cube. The length of this path extension can be made to exceed $(n - 1)L_2(n) + L_1(n)$. Therefore the maximal path extension of $G'_{3D,ext}$ must have at least this length, clearly greater than $(n - 1)L_2(n) + L_1(n) - \lfloor \frac{L_2(n)}{2} \rfloor$.
2. Assume that there is *not* a Hamilton path in the graph G that starts at v_{start} , uses the edge from v_{start} that was not removed, and terminates at v_{end} via the single edge not removed.

We claim that any path extension of $G'_{3D,ext}$ can pass through at most $n - 1$ outer cubes. To see this, assume that $G'_{3D,ext}$ has a path extension that passes through all of the n outer cubes. If the extension ends in a connector, delete its tail in the connector so that the extension ends in an outer cube. Then this extension naturally determines a path in G' such that (i) it starts with v_{start} , (ii) it touches all nodes of G' , and (iii) it never passes through an edge more than once. This path starts at v_{start} and proceeds through the only edge from v_{start} and eventually through the only edge to v_{end} , finally terminating at v_{end} . Each vertex other than v_{start} and v_{end} has three edges; hence the path passes through each exactly once. However, this means that the path is a Hamilton path of G' , and this is a contradiction.

Thus, a maximal path extension of $G'_{3D,ext}$ can only enter at most $n - 1$ outer cubes and hence only at most $n - 1$ inner cubes. Consider an extension to $G'_{3D,ext}$ that does not enter every inner cube in the drawing. The total length of all of the “connector” edges is at most $O(n^8)$ because there are at most $O(n^2)$ edges, each of which has “length” at most $O(n^6)$. If we skip at least one cube, then the most the path can be is either $(n - 2)L_2(n) + L_1(n) + O(n^8)$ or $(n - 1)L_2(n) + O(n^8)$, and both of them are at most $(n - 2)L_2(n) + L_1(n) + O(n^8) < (n - 1)L_2(n) + L_1(n) - \lfloor \frac{L_2(n)}{2} \rfloor$ because $L_2(n) \leq L_1(n)$.

In this way, we can decide whether or not the graph G' has a Hamilton path in polynomial time. To decide whether or not the original graph G has a Hamilton path, we need to perform the above decision for each combination of v_{start} , v_{end} , and edge removal. The answer to HAM for G is YES if and only if the answer is YES for at least one combination. The number of combinations is a polynomial in n . Hence, we can decide HAM for G in polynomial time under the assumption that 3PEP \in P. \square

4. FSSP for generalized 3PATH and 3REG. In this section we prove results similar to Theorem 1.1 for two other variations g-3PATH and 3REG. First, we give the definitions of these variations.

DEFINITION 4.1 (variation g-3PATH). *The FSSP for generalized three-dimensional paths in the three-dimensional grid, or g-3PATH for short, is the FSSP such*

that a problem instance is a path $p_1p_2\dots p_n$ in \mathcal{Z}^3 and the position of the root may be any vertex p_i of the path ($1 \leq i \leq n$).

DEFINITION 4.2 (variation 3REG). *The FSSP for regions in the three-dimensional grid, or 3REG for short, is the FSSP such that a problem instance is a nonempty finite connected subset X of \mathcal{Z}^3 and the position of the root may be any vertex in X . (A subset X of \mathcal{Z}^3 is said to be connected if for any p, p' in X there exists a path $p_1p_2\dots p_n$ such that $p_1 = p$, $p_n = p'$, and $\{p_1, p_2, \dots, p_n\} \subseteq X$.)*

In this section we prove the following theorem for g-3PATH and 3REG that corresponds to Theorem 1.1 for 3PATH.

THEOREM 4.3. *If $P \neq NP$, then there do not exist minimal-time solutions of g-3PATH or 3REG.*

We prove this theorem by outlining a result for g-3PATH and 3REG that corresponds to Lemma 3.2. The rest follows trivially from this observation.

The following lemma corresponds to Lemma 3.2.

LEMMA 4.4. *Let $p_1p_2\dots p_n$ be a path. We regard this path as a problem instance of g-3PATH or 3REG such that p_1 is the position of the root. Let i_0 be $\min\{i : 1 \leq i \leq n, i \geq e(p_1p_2\dots p_n, i)\}$.*

Then a minimal-time FSSP solution of variation g-3PATH or 3REG, if it exists, running on $p_1p_2\dots p_n$ will fire at time either $2i_0 - 1$ if $i_0 = e(p_1p_2\dots p_n, i_0)$ or $2i_0 - 2$ if $i_0 > e(p_1p_2\dots p_n, i_0)$.

In other words, a minimal-time FSSP solution of variation g-3PATH or 3REG runs in exactly the same time as a minimal-time FSSP solution of variation 3PATH when running on a 3PATH problem instance.

Proof. By Lemma 3.2 we know that the minimum firing time of $p_1p_2\dots p_n$ for 3PATH is $2i_0 - 1$ if $i_0 = e(p_1p_2\dots p_n, i_0)$ and $2i_0 - 2$ if $i_0 > e(p_1p_2\dots p_n, i_0)$. Moreover, g-3PATH is a subproblem of 3REG, and 3PATH is a subproblem of g-3PATH. Consequently, the minimum firing time of 3REG is at least that of g-3PATH, and the minimum firing time of g-3PATH is at least that of 3PATH. Hence, to prove the lemma it suffices to show that there is a solution of 3REG whose firing time for $p_1p_2\dots p_n$ is at most this quantity.

We can use the same searcher signal idea as in Lemma 3.2. Suppose that the searcher signal finds that the current problem instance has the same initial sequence as the special path $p_1p_2\dots p_{i_0}p_{i_0+1}$. The searcher signal finds this at time $i_0 - 1$ arriving at p_{i_0} . Then the distance between p_{i_0} and any vertex p_i behind it ($1 \leq i < i_0$) is at most $i_0 - 1$; the distance between p_{i_0} and any possible vertex ahead of it is at most i_0 if $i_0 = e(p_1p_2\dots p_n, i_0)$ and at most $i_0 - 1$ if $i_0 > e(p_1p_2\dots p_n, i_0)$ independent of whether the remainder of the configuration is a path or a connected vertex set. Thus, the remainder of the proof concludes exactly as in Lemma 3.2. \square

By Lemma 4.4, all of the previous results that were applicable to the variation 3PATH continue to apply to the variations g-3PATH and 3REG because only 3PATH configurations are used in all of the proofs.

As was stated in section 1.5.2, our main results Theorems 1.1 and 4.3 were proved using a modified formulation of FSSP. We will briefly explain how to modify the proofs for the usual formulation of FSSP.

The proof of Theorem 1.1 (the result for 3PATH) needs no modifications. The proofs of Theorem 4.3 (the results for g-3PATH and 3REG) need the following modifications.

In the proof of Lemma 4.4 we use the searcher signal. For g-3PATH and 3REG, the signal must check that the root p_1 has only one neighbor p_2 . In the usual formulation of FSSP, this needs one unit time because the root cannot know its boundary condition

at time 0, and the signal starts at p_1 at time 1 instead of at time 0. Hence, all we know on the minimum firing time is that it is either j_0 or $j_0 + 1$, where j_0 is $2i_0 - 1$ or $2i_0 - 2$ depending on whether $i_0 = e(p_1 p_2 \dots p_n, i_0)$ or $i_0 > e(p_1 p_2 \dots p_n, i_0)$.

This uncertainty of 1 on the minimum firing time influences Theorems 3.3, 3.6, and 3.7. As for Theorem 3.3, we can construct a polynomial-time algorithm for 3PEP that may give an incorrect answer when the length m of the longest extension of the given input path $p_1 p_2 \dots p_n$ satisfies $|m - 2n| \leq c_1$ for some constant c_1 . As for Theorems 3.6 and 3.7, we can construct polynomial-time algorithms that calculate values $L'_1(n)$, $L'_2(n)$ such that $|L_1(n) - L'_1(n)| \leq c_2$, $|L_2(n) - L'_2(n)| \leq c_3$ for some constants c_2, c_3 for the functions $L_1(n)$, $L_2(n)$ defined in the proof of Theorem 3.8. As is easily seen, these results are sufficient for proving Theorem 3.8.

5. Conclusions and topics for further research. We have shown that there cannot exist minimal-time solutions to the FSSP for our variations 3PATH, g-3PATH, and 3REG if $P \neq NP$, as most researchers believe. The most obvious open problems we leave are the other five variations in section 1.3.2, that is, 2PATH, g-2PATH, 2REG, general undirected networks, and general directed networks. In [19], Kobayashi has shown that a solution to 2PATH is highly unlikely to exist if the two-dimensional path extension problem, 2PEP, is NP-complete. This result can be readily extended to g-2PATH and 2REG. Unfortunately, the computational complexity of 2PEP is unknown and seems difficult to pin down. If there happens to be a polynomial-time solution to 2PEP, it would be interesting from a strictly mathematical point of view, as it is very likely to be nontrivial.

We showed that if 3PEP is decidable in polynomial time, then HAM is decidable in polynomial time. However, this does not imply that 3PEP is NP-complete via a many-one reduction. Our result is only a Turing reduction because the determination of the two values $L_1(n)$ and $L_2(n)$ repeatedly use 3PEP as an oracle. However, it is highly probable that both of the problems 1CUBE and 2CUBE have polynomial-time algorithms, although to prove it will likely require a very tedious and deep analysis of the lengths of paths in cubes. If one can show this, the construction in Theorem 3.8 gives the stronger many-one reduction of HAM to 3PEP.

Another obviously interesting area of exploration would be the opposite direction of Theorem 1.1. What does the complexity-theoretic statement $P = NP$ imply about the existence of a minimal-time solution to the synchronization problem on these networks?

Finally, given that a minimal-time solution to the variation we studied in this paper will most likely not be found (as most researchers believe that $P \neq NP$), it is also an interesting question to ask for approximations. Can we get within a small constant factor of optimal? Given the importance of the synchronization primitive to parallel processing, determining the best approximating factor seems to be a promising and practical avenue of further exploration.

Acknowledgments. We would like to thank Prof. J. Mazoyer for giving us valuable information on minimal-time solutions of variations of FSSP and the reviewers for helpful suggestions for improvements.

STOCHASTIC RELATIONS: CONGRUENCES, BISIMULATIONS AND THE HENNESSY–MILNER THEOREM*

ERNST-ERICH DOBERKAT†

Dedicated to Professor Gerhard Goos

Abstract. The relationship between congruences and bisimulations is investigated for stochastic relations. It is shown that stochastic relations are bisimilar provided they have congruences that generate each other; from this is derived that relations that have isomorphic factor spaces are bisimilar. Stochastic Kripke models are introduced for a modal logic and illustrated for some popular logics. The criterion developed here permits proving for the general case that Kripke models are bisimilar iff they accept exactly the same formulas.

Key words. stochastic relations, stochastic Kripke models, congruences, bisimulations, modal logic, Hennessy–Milner theorem

1. Introduction and motivation. Larsen and Skou propose in [18] a systematic framework for testing a process against its specification, where a specification may be formulated in formalisms like modal logic, temporal logic, or using process algebra. Testable properties are formulated, and among the logics through which these properties may be formulated a new probabilistic logic is proposed and investigated. The associated process equivalence is called probabilistic bisimulation, and one of the central statements is that—under the technical assumption that the probabilities are not too close to each other—two processes are probabilistically bisimilar iff they satisfy the same formulas in the probabilistic modal logic [18, Theorem 6.4]. This equivalence is dubbed here the *Hennessy–Milner property* for the sake of discussion. The probability theory involved is discrete, so issues of measurability are not really important. Bisimulations are formulated in terms of binary relations on the involved sets.

A little later, Joyal, Nielsen, and Winskel [15] argued that bisimulation between processes can be formulated in terms of spans of open maps between them, hereby pointing to the presentation of models for concurrency through categories of models [15] with the desire for a uniform treatment of all these models. Coalgebras enter the field, and it is shown that the relational formulation of bisimulation for coalgebras for functors based on the category of sets and maps is equivalent with a formulation in terms of spans of projections [25, Example 2.1]. Panangaden’s work [23, 22] suggests that it may be worthwhile to look not only at discrete probability spaces when formulating labeled Markov transition systems, but that nondiscrete probabilities are necessary for modelling concurrency as well. This leads to the question of whether the equivalence of bisimilarity and the acceptance of the same formulas of a modal logic, the Hennessy–Milner property, holds also in a more general probabilistic set-

ting. In fact, Desharnais, Edalat, and Panangaden [6] show that this equivalence is valid when the underlying space is a Polish space (i.e., a completely metrizable and separable topological space) or even an analytic space (i.e., the image of a Polish space under a Borel map) [6]. The elegant solution had a small catch, however: it requires the existence of semipullbacks in the category of stochastic relations. This in turn could only be guaranteed if the transition probabilities are universally measurable, i.e., measurable with respect to an σ -algebra that arises from the Borel sets through an elaborate completion process which adds certain sets of measure zero.

But the natural notion of measurability is Borel measurability, so there remained the question whether the equivalence result can be established for the Borel measurable case, too. This question is not only of conceptual interest: when one wants to apply these results for testing, one definitively does not want to go through a somewhat complex completion process when the Borel sets are readily available. It could be shown in [9, 13] that the semipullback of stochastic relations exists in Polish and in analytic spaces, when the measurable structure is given through the Borel sets. As a consequence of this, the Hennessy–Milner property is established in this scenario, too, under a technical condition that is called *smallness* in [9].

This paper investigates the relationship between modal logics and stochastic relations: it is shown how a general modal logic can be interpreted through a stochastic Kripke model, and that the Hennessy–Milner property holds in general for these stochastic Kripke models. This is dealt with in a somewhat wider context: the argumentation in [6, 9] shows that the equivalence on the states on which the Hennessy–Milner property is based (viz., to be valid for exactly the same formulas) has the property that it is countably generated, leading to the notion of smooth equivalence relations, and to congruences for stochastic relations. Thus we discuss the triangle *congruences*, *bisimulations*, and the *Hennessy–Milner property* in this paper. The following questions are central to the investigations:

1. Can we find an intrinsic criterion for bisimilarity of stochastic relations? “Intrinsic” means that we do not have to appeal to an external instance like a logic for knowing whether or not two relations are bisimilar.

2. Can we formulate stochastic Kripke models for arbitrary modal logics, and does the Hennessy–Milner property still hold?

Both answers are in the positive; we give a sufficient condition for bisimilarity in terms of equivalent congruences. We show that stochastic relations that have isomorphic nontrivial subsystems are bisimilar, and, conversely, that under a topological condition bisimilar relations have nontrivial isomorphic subsystems. The topological condition refers to compactness and continuity, hence it is rather substantial. We conjecture, however, that bisimilarity and the existence of isomorphic factor spaces are equivalent for general analytic spaces. Addressing the second question, we show that bisimilarity and validity for exactly the same formulas are equivalent, so that a general Hennessy–Milner theorem can also be established for the stochastic interpretation of general modal logic. This includes the well-known versions from [6, 9] as special cases. These properties hold under small restrictions (similar to Larsen and Skou’s assumption of not having too-close probabilities) which prevent trivial conditions from creeping in and invalidating the results.

The main cornerstone for these constructions is the existence of semipullbacks for stochastic relations over analytic spaces [13]. We also have a look at smooth equivalence relations over analytic spaces which are of independent interest. We show that these relations have a confluence property that is also crucial in establishing the relationship between congruences and bisimulations for the compact case.

Organization. Section 2 introduces stochastic relations and collects some measure-theoretic results that will be useful. This section also contains the definition of stochastic relations with their morphisms, and of bisimulations. Smooth equivalence relations are introduced formally in section 4, some measure-theoretic machinery associated with them is also developed there, so that we are prepared to enter the world of congruences in section 4. The notion of equivalent congruences is proposed here (after some preparatory work in section 3), it is shown that relations that have equivalent congruences are bisimilar, and an application of this general result to relations with isomorphic factor spaces is formulated and proved. The next two sections give an application to modal logic: section 5 defines Kripke models for a modal similarity type, both nondeterministic and stochastic ones. It is demonstrated in section 5.1 that this can be applied to various well-known logics. Section 5.2 proposes the refinement of a nondeterministic Kripke model through a stochastic one and shows that these refinements exist under some mild topological assumptions. Section 6 is devoted to bisimulations for Kripke models. It is argued that the notion of morphism and, consequently, of bisimulation has to be strengthened for Kripke models, and that then a Hennessy–Milner theorem can be proved: two Kripke models are strongly bisimilar iff they accept exactly the same formulas. Section 7 discusses related work, and section 8 draws some conclusions and gives some indications for further work.

2. Stochastic relations. This section collects in section 2.1 some basic facts and constructions from measure theory for convenience and for later reference. Stochastic relations and the categories we are working with are defined, we provide also a definition of bisimulation.

2.1. Preliminaries.

Polish and analytic spaces. A Polish space (X, \mathcal{G}) is a topological space which is second countable, i.e., which has a countable dense subset, and which is metrizable through a complete metric. A measurable space (X, \mathcal{A}) is a set X with a σ -algebra \mathcal{A} . The Borel sets $\mathcal{B}(X, \mathcal{G})$ for the topology \mathcal{G} is the smallest σ -algebra on X which contains \mathcal{G} . Given two measurable spaces (X, \mathcal{A}) and (Y, \mathcal{B}) , a map $f : X \rightarrow Y$ is \mathcal{A} – \mathcal{B} -measurable whenever

$$f^{-1}[\mathcal{B}] \subseteq \mathcal{A}$$

holds, where

$$f^{-1}[\mathcal{B}] := \{f^{-1}[B] \mid B \in \mathcal{B}\}$$

is the set of inverse images

$$f^{-1}[B] := \{x \in X \mid f(x) \in B\}$$

of elements of \mathcal{B} . Note that $f^{-1}[\mathcal{B}]$ is a σ -algebra, provided \mathcal{B} is one. If the σ -algebras are the Borel sets of some topologies on X and Y , resp., then a measurable map is called *Borel measurable* or simply a *Borel map*. The real numbers \mathbb{R} carry always the Borel structure induced by the usual topology which will usually not be mentioned explicitly when talking about Borel maps.

An *analytic set* $X \subseteq Z$ for a Polish space Z is the image $f[Y]$ of a Polish space Y for some Borel measurable map $f : Y \rightarrow Z$. Endow X with the trace \mathcal{A} of $\mathcal{B}(Z)$ on X , i.e.,

$$\mathcal{A} = \mathcal{B}(Z) \cap X := \{B \cap X \mid B \in \mathcal{B}(Z)\},$$

the elements of which are still called Borel sets. A measurable space (X', \mathcal{A}') which is Borel isomorphic to (X, \mathcal{A}) is called an *analytic space* (a Borel isomorphism is a Borel measurable and bijective map the inverse of which is also Borel measurable).

Inverse systems. The product $(X_1 \times X_2, \mathcal{A}_1 \otimes \mathcal{A}_2)$ of two measurable spaces (X_1, \mathcal{A}_1) and (X_2, \mathcal{A}_2) is the Cartesian product $X_1 \times X_2$ endowed with the σ -algebra

$$\mathcal{A}_1 \otimes \mathcal{A}_2 := \sigma(\{A_1 \times A_2 \mid A_1 \in \mathcal{A}_1, A_2 \in \mathcal{A}_2\}).$$

This is the smallest σ -algebra which contains all the measurable rectangles $A_1 \times A_2$, and it is the smallest σ -algebra \mathcal{E} on $X_1 \times X_2$ which makes the projections $\pi_i : X_1 \times X_2 \rightarrow X_i$ \mathcal{E} - \mathcal{A}_i -measurable for $i = 1, 2$.

Given finite measures μ_i on \mathcal{A}_i , there exists a unique finite measure $\mu_1 \otimes \mu_2$ on $\mathcal{A}_1 \otimes \mathcal{A}_2$ such that

$$(\mu_1 \otimes \mu_2)(A_1 \times A_2) = \mu_1(A_1) \cdot \mu_2(A_2)$$

holds for each $A_1 \in \mathcal{A}_1, A_2 \in \mathcal{A}_2$.

Extending this, let $(\mu_n)_{n \in \mathbb{N}}$ be an inverse system of probabilities on $(X_i, \mathcal{B}(X_i))_{i \in \mathbb{N}}$ for some Polish spaces X_i ; see [24, section V.3]. Thus μ_n is a probability measure on $\mathcal{B}(X_1 \times \dots \times X_n)$ for each natural n such that $\mu_{n+1}(B \times X_{n+1}) = \mu_n(B)$, whenever $B \subseteq X_1 \times \dots \times X_n$ is a Borel set. Then there exists a unique probability measure μ^* on the Borel sets of $\prod_{n \in \mathbb{N}} X_n$ with the property that

$$\mu^* \left(B \times \prod_{m > n} X_m \right) = \mu_n(B)$$

for each Borel set $B \subseteq X_1 \times \dots \times X_n$; see [24, Theorem V.3.1]. μ^* is usually called the *inverse limit* of $(\mu_n)_{n \in \mathbb{N}}$. We will use this construction when illustrating a logic for model checking.

The *direct sum* $(X_1 + X_2, \mathcal{A}_1 + \mathcal{A}_2)$ of the measurable spaces (X_1, \mathcal{A}_1) and (X_2, \mathcal{A}_2) has the direct sum of the underlying base sets as a base set. Then $A \in \mathcal{A}_1 + \mathcal{A}_2$ iff both $A \cap X_1 \in \mathcal{A}_1$ and $A \cap X_2 \in \mathcal{A}_2$ hold. If both spaces are Polish, resp., analytic, their sum is $\mathcal{B}(X_1 + X_2) = \mathcal{B}(X_1) + \mathcal{B}(X_2)$.

We will occasionally talk about the trivial σ -algebra on a set X : the σ -algebra \mathcal{A} is called trivial iff $\mathcal{A} = \{\emptyset, X\}$, hence iff it consists only of the empty set and the entire set X .

When the context is clear, we will write down topological or measurable spaces without their topologies and σ -algebras, resp., and the Borel sets are always understood with respect to the topology under consideration.

Measurable relations. Measurable relations will provide a link between nondeterministic and stochastic systems, as we will see. Let us fix some notations first. Assume that Y and Z is a measurable, resp., Polish space. Consider a set-valued map $R : Y \rightarrow \mathcal{P}(Z)$, (equivalently, a relation $R \subseteq Y \times Z$. We will not distinguish too narrowly between relations and set-valued maps, so that even for a relation R the set $R(x)$ will be defined.) If $R(y)$ always takes closed and nonempty values, and if the (weak) inverse

$$(\exists R)(G) := \{y \in Y \mid R(y) \cap G \neq \emptyset\}$$

is a measurable set, whenever $G \subseteq Z$ is open, then R is called a *measurable relation* on $Y \times Z$. Since Z is Polish, R is a measurable relation iff the strong inverse

$$(\forall R)(F) := \{y \in Y \mid R(y) \subseteq F\}$$

is measurable, whenever $F \subseteq Z$ is closed [14, Theorem 3.5].

We note for later use the representation of weakly measurable relations through measurable selectors (some times called a *Castaing representation*). This representation implies in particular that a weakly measurable set-valued map has a measurable selector. It is established in [27, Theorem 4.2.e].

PROPOSITION 2.1. *Given the Polish spaces Y and Z and a set-valued map $R \subseteq Y \times Z$, then R is weakly measurable iff there exists a sequence $(f_n)_{n \in \mathbb{N}}$ of Borel measurable maps $f_n : Y \rightarrow Z$ such that $\{f_n(y) \mid n \in \mathbb{N}\}$ is dense in $R(y)$ for each $y \in Y$.*

Thus measurable relations have measurable selectors. This will be used when providing a link between nondeterministic and stochastic Kripke models in section 5.2, and it will also help establishing the smoothness of an equivalence relation in section 3.

It is interesting to note that this kind of construction did recently become of interest in modal logics: see, e.g., the discussion of Stone duality in the context of Vietoris topologies on hyperspaces in [17] or the discussion of descriptive general frame in [3, Chapter 5.5].

2.2. Categories of stochastic relations. The intuition behind stochastic relations over, say, a set of states is that each state is assigned not deterministically a new state or a set of possible new states but rather a distribution over the states, indicating with which probability a transition to another state may happen. This is generalized somewhat: first, we will not deal exclusively with probabilities but rather take subprobabilities into account; this is helpful when, e.g., nonterminating computations are modeled. Second, we will not only consider transitions on a space to itself but rather consider something as input-output behavior, so that we get a richer structure (which will pay off when discussing arbitrary modal logics with an operator of arbitrary arity). We will define these stochastic relations now and indicate the basic constructions.

Given two measurable spaces (X, \mathcal{A}) and (Y, \mathcal{B}) , a *stochastic relation* $K : (X, \mathcal{A}) \rightsquigarrow (Y, \mathcal{B})$ is a Borel map from X to the set $\mathfrak{S}(Y, \mathcal{B})$, the latter denoting the set of all subprobability measures on (Y, \mathcal{B}) which carries the *weak*- σ -algebra*. This is the smallest σ -algebra on $\mathfrak{S}(Y, \mathcal{B})$ which renders all maps $\mu \mapsto \mu(D)$ measurable, where $D \in \mathcal{B}$. Hence $K : (X, \mathcal{A}) \rightsquigarrow (Y, \mathcal{B})$ is a *stochastic relation* iff

1. $K(x)$ is a subprobability measure on (Y, \mathcal{B}) for all $x \in X$,
2. $x \mapsto K(x)(D)$ is a measurable map for each measurable set $D \in \mathcal{B}$.

This is a more common formulation of stochastic relations. Note that the *only if*-part follows directly from the definition of the weak*- σ -algebra, and from the fact that the composition of measurable maps is measurable. The *if*-part follows from the observation that a map into $\mathfrak{S}(Y, \mathcal{B})$ for which the setwise evaluations are measurable is weak*-measurable. We will deal usually with stochastic relations between Polish or between analytic spaces. Accordingly, we then call (X, Y, K) a *Polish*, resp., an *analytic object*.

An \mathcal{A} - \mathcal{B} -measurable map $f : X \rightarrow Y$ between the measurable spaces (X, \mathcal{A}) and (Y, \mathcal{B}) induces a map $\mathfrak{S}(f) : \mathfrak{S}(X, \mathcal{A}) \rightarrow \mathfrak{S}(Y, \mathcal{B})$ upon setting

$$\mathfrak{S}(f)(\mu)(D) := \mu(f^{-1}[D])$$

(for $\mu \in \mathfrak{S}(X, \mathcal{A})$, $D \in \mathcal{B}$). It is easy to see that $\mathfrak{S}(f)$ is measurable.

If the stochastic relation $K : (X, \mathcal{A}) \rightsquigarrow (Y, \mathcal{B})$ has the property that $K(x)(Y) = 1$ holds for all $x \in X$, then K is called a *probabilistic relation*. A stochastic relation (X, Y, K) such that Y consists of exactly one point only will be called *degenerate*.

Morphisms. The category **Stoch** has as objects stochastic relations $K = (X, Y, K)$ for measurable spaces X, Y and $K : X \rightsquigarrow Y$. A *morphism*

$$f : K \rightarrow K'$$

between the objects $K = (X, Y, K)$ and $K' = (X', Y', K')$ is a pair $f = (\phi, \psi)$ of surjective measurable maps $\phi : X \rightarrow X'$ and $\psi : Y \rightarrow Y'$ such that

$$K' \circ \phi = \mathfrak{S}(\psi) \circ K$$

holds, i.e., such that the diagram

$$\begin{array}{ccc} X & \xrightarrow{\phi} & X' \\ K \downarrow & & \downarrow K' \\ \mathfrak{S}(Y) & \xrightarrow{\mathfrak{S}(\psi)} & \mathfrak{S}(Y') \end{array}$$

is commutative. The maps underlying morphisms are assumed to be surjective in order to make sure that each target element is actually coming from some source element; technically, surjectivity is required for establishing the existence of semipullbacks; see Theorem 2.2.

The morphisms defined here correspond to *zig-zag-morphisms* in [6, Definition 5.1] when $X = Y$ and $X' = Y'$; because the approach proposed here does not need to work with what is called *simulation morphism* in [6] we need not distinguish the two kinds of morphisms.

We will usually investigate morphisms for stochastic relations based on Polish or analytic spaces. Accordingly, we denote by **P – Stoch** and **A – Stoch** the full subcategories having Polish, resp., analytic objects as their objects.

We note for later use [13, Theorem 2] the existence of semipullbacks in **P – Stoch** and **A – Stoch** (recall that a *semipullback* in a category for a pair of morphisms $f : a \rightarrow c$ and $g : b \rightarrow c$ with the same target is a pair of morphisms $t : p \rightarrow a$ and $s : p \rightarrow b$ with the same source such that $f \circ t = g \circ s$). Since we will refer to the specific shape of the underlying spaces, we indicate its components.

THEOREM 2.2. *Let*

$$K_1 \xrightarrow{f_1} L \xleftarrow{f_2} K_2$$

be morphisms in **A – Stoch** with $f_i = (\phi_i, \psi_i)$, $K_i = (X_i, Y_i, K_i)$, and $L = (A, B, L)$. There exist Polish topologies on

$$\begin{aligned} S &:= \{\langle x_1, x_2 \rangle \in X_1 \times X_2 \mid \phi_1(x_1) = \phi_2(x_2)\}, \\ T &:= \{\langle y_1, y_2 \rangle \in Y_1 \times Y_2 \mid \psi_1(y_1) = \psi_2(y_2)\} \end{aligned}$$

and a stochastic relation $M = (S, T, M)$ such that

1. $p_i : M \rightarrow K_i$ are morphisms in **A – Stoch**, where $p_i = (\pi_{i,S}, \pi_{i,T})$ is constituted by the respective projections, $i = 1, 2$,
2. $f_1 \circ p_1 = f_2 \circ p_2$.

Consequently, both **P – Stoch** and **A – Stoch** have semipullbacks, the underlying object of which is Polish.

Bisimilarity. Bisimilarity is introduced essentially as a span of morphisms [15, 25, 9]. For coalgebras based on the category of sets, this definition agrees with the one through relations originally given by Milner; see [25]. In [7] the authors call a bisimulation what we will introduce as congruence, albeit that paper restricts itself to labeled Markov transition systems, thus technically to families of stochastic relations $S \rightsquigarrow S$ for some state space S . It seems conceptually to be clearer to distinguish spans of morphisms from equivalence relations, thus we make this distinction here. Later we will see some very close connections. We introduce an additional condition which models the tight relationship between bisimilar relations.

DEFINITION 2.3. *The stochastic relations $K = (X, Y, K)$ and $L = (V, W, L)$ are called bisimilar iff there exist a stochastic relation $M = (A, B, M)$, morphisms $f = (\phi, \psi) : M \rightarrow K$, and $g = (\gamma, \delta) : M \rightarrow L$ such that*

1. *the diagram*

$$\begin{array}{ccccc}
 X & \xleftarrow{\phi} & A & \xrightarrow{\gamma} & V \\
 K \downarrow & & M \downarrow & & \downarrow L \\
 \mathfrak{S}(Y) & \xleftarrow{\mathfrak{S}(\psi)} & \mathfrak{S}(B) & \xrightarrow{\mathfrak{S}(\delta)} & \mathfrak{S}(W)
 \end{array}$$

is commutative,

2. *the σ -algebra $\psi^{-1}[\mathcal{B}(Y)] \cap \delta^{-1}[\mathcal{B}(W)]$ is nontrivial, i.e., contains not only \emptyset and B .*

The relation M is called mediating.

The first condition on bisimilarity states that f and g form a span of **Stoch**-morphisms

$$K \xleftarrow{f} M \xrightarrow{g} L;$$

thus we have for each $a \in A, D \in \mathcal{B}(Y), E \in \mathcal{B}(W)$ that the equalities

$$K(\phi(a))(D) = (\mathfrak{S}(\phi) \circ M)(a)(D) = M(a)(\phi^{-1}[D])$$

and

$$L(\psi(a))(E) = (\mathfrak{S}(\psi) \circ M)(a)(E) = M(a)(\psi^{-1}[E])$$

hold. The second condition states that we can find an event $C^* \in \mathcal{B}(B)$ which is common to both K and L in the sense that

$$\psi^{-1}[D] = C^* = \delta^{-1}[E]$$

for some $D \in \mathcal{B}(Y)$ and $E \in \mathcal{B}(W)$ such that both $C^* \neq \emptyset$ and $C^* \neq B$ hold (note that for $C^* = \emptyset$ or $C^* = W$ we can always take the empty or full set, resp.). Given such a C^* with D and E from above we get for each $a \in A$

$$\begin{aligned}
 K(\phi(a))(D) &= M(a)(\psi^{-1}[D]) \\
 &= M(a)(C^*) \\
 &= M(a)(\delta^{-1}[E]) \\
 &= L(\gamma(a))(E);
 \end{aligned}$$

thus the event C^* ties K and L together. Loosely speaking, $\psi^{-1}[\mathcal{B}(Y)] \cap \delta^{-1}[\mathcal{B}(W)]$ can be described as the σ -algebra of common events, which is required to be nontrivial.

Note that without the second condition the two relations K and L , which are strictly probabilistic (i.e., for which the entire space is always assigned probability one), would always be bisimilar: Put $A := X \times V, B := Y \times W$ and set for $\langle x, v \rangle \in A$ as the mediating relation $M(x, v) := K(x) \otimes L(v)$; then the projections will make the diagram commutative. It is also clear that this argument does not work for the sub-probabilistic case. This curious behavior of probabilistic relations is a bit surprising, but it occurs in other situations as well: e.g., it turns out that the full subcategory of probabilistic relations in $\mathbf{A} - \mathbf{Stoch}$ has a final object, while $\mathbf{A} - \mathbf{Stoch}$ itself does not have one; see [12]. The second condition serves to prevent this somewhat anomalous behavior; it is technically not too restrictive, as we will see below.

3. Smooth equivalence relations. Observing systems leads to identifying states, which in turn gives rise to an equivalence relation. Those relations that are suited for our purposes have a countable generator, so that by looking at a countable family of sets it can be decided whether or not two states are equivalent. We call these relations smooth. They may be characterized as the kernels of Borel measurable maps and have technically the remarkable property that factoring does not leave the realm of analytic spaces. We define these relations in this section and carry out some technical constructions which, albeit used for stochastic relations, are discussed best in isolation. The operations concern factoring and an operation we call *spawning*. The latter one permits the description of an equivalence relation and of the associated measurable structure through the machinery of another one. We will need this kind of operation for describing equivalent congruences later on, and we show that isomorphic factor spaces have the property that the relations spawn each other. These results will be taken to bear fruit for stochastic relations in a later section. We show also that in the case of compact base spaces two smooth relations are always related to each other through a kind of confluence property.

Although the results presented here are preparatory in nature, some of them appear to be interesting in their own right.

DEFINITION 3.1. *An equivalence relation ρ on a measurable space (X, \mathcal{A}) is said to be smooth iff there exists a sequence $(A_n)_{n \in \mathbb{N}} \subseteq \mathcal{A}$ such that*

$$x \rho x' \text{ iff } \forall n \in \mathbb{N} : [x \in A_n \Leftrightarrow x' \in A_n].$$

We say that the sequence $(A_n)_{n \in \mathbb{N}}$ determines relation ρ .

A smooth relation ρ on X can be represented as a subset of $X \times X$ as [26, Exercise 5.1.10] shows:

$$\rho = (X \times X) \setminus \bigcap (A_n \times (X \setminus A_n));$$

thus it follows that a smooth equivalence relation is a Borel subset of $X \times X$. The equivalence classes can be expressed in terms of the sequence $(A_n)_{n \in \mathbb{N}}$:

$$[x]_\alpha = \bigcap \{A_n | x \in A_n\} \cap \bigcap \{X \setminus A_n | x \notin A_n\};$$

hence each class is a Borel subset of X .

It is easy to see that ρ is smooth iff $\rho = \ker(f)$ for some $\mathcal{A} - \mathcal{B}(Y)$ -measurable map $f : X \rightarrow Y$ with an analytic space Y . Here

$$\ker(f) := \{\langle x, x' \rangle \mid f(x) = f(x')\}$$

is the kernel of f .

Denote by

$$\mathcal{I}NV(\mathcal{A}, \rho) := \{A \in \mathcal{A} \mid A \text{ is } \rho\text{-invariant}\}$$

the σ -algebra of ρ -invariant measurable sets. Here $A \subseteq X$ is called ρ -invariant iff $A = \bigcup\{[x]_\rho \mid x \in A\}$ holds, thus iff $x \in A$ and $x \rho x'$ together imply $x' \in A$. We will see that smooth equivalence relations with their invariant sets are just the natural kind of equivalence relations compatible with the structure of stochastic relations.

Denote for the equivalence relation ρ on the analytic space X by X/ρ the set of equivalence classes, and let $\eta_\rho : x \mapsto [x]_\rho$ assign to each x its class $[x]_\rho$; denote by $\mathcal{B}(X)/\rho$ the final σ -algebra on X/ρ with respect to the Borel sets $\mathcal{B}(X)$ on X and the natural projection η_ρ .

Smooth equivalence relations arise in a natural fashion from kernels of measurable maps, as we will see in a moment. These relations enjoy the technically interesting property that the factor space $(X/\rho, \mathcal{B}(X)/\rho)$ for an analytic space X and a smooth relation ρ is an analytic space again; cf. [26, Exercise 5.1.14]. In particular, $\mathcal{B}(X/\rho) = \mathcal{B}(X)/\rho$ holds. A little bit more can be said. We introduce a kind of multiplicative operation first. Assume that ρ is a smooth equivalence relation on the analytic space X , and that θ is a smooth equivalence on X/ρ . Define for $x, x' \in X$

$$x (\theta \bullet \rho) x' \Leftrightarrow [x]_\rho \theta [x']_\rho.$$

For later use some useful properties of this operation, and of smooth relations in general, are collected from [11].

LEMMA 3.2. *Let X be an analytic space and ρ a smooth equivalence relation on X .*

1. *Let S be an analytic space, and assume that $f : X \rightarrow S$ is a surjective and Borel measurable map. Then $\ker(f)$ is smooth, and $f^{-1}[\mathcal{B}(S)] = \mathcal{I}NV(\mathcal{B}(X), \ker(f))$.*

2. *The ρ -invariant Borel sets of X are exactly the inverse images of the canonic projection η_ρ , viz., $\mathcal{I}NV(\mathcal{B}(X), \rho) = \eta_\rho^{-1}[\mathcal{B}(X/\rho)]$ holds. If ρ is determined by the sequence $(A_n)_{n \in \mathbb{N}}$ of Borel sets $A_n \subseteq X$, then*

$$\mathcal{I}NV(\mathcal{B}(X), \rho) = \sigma(\{A_n \mid n \in \mathbb{N}\}).$$

3. *If θ is smooth on X/ρ , then $\theta \bullet \rho$ is smooth, and the analytic spaces $X/\theta \bullet \rho$ and $(X/\rho)/\theta$ are Borel isomorphic.*

4. *The following conditions are equivalent for a smooth equivalence relation σ on X :*

- (a) $\rho \subseteq \sigma$,
- (b) *there exists a smooth equivalence relation θ on X/ρ such that $\sigma = \theta \bullet \rho$.*

As a first application, we establish that smoothness is preserved through finite products, and we represent the corresponding invariant Borel sets.

LEMMA 3.3. *Let α and α' be smooth equivalence relations on the analytic spaces X , resp., X' . Define*

$$\langle x_1, x'_1 \rangle (\alpha \times \alpha') \langle x_2, x'_2 \rangle \Leftrightarrow x_1 \alpha x_2 \wedge x'_1 \alpha' x'_2.$$

Then

- 1. $\alpha \times \alpha'$ is a smooth equivalence relation on $X \times X'$,
- 2. $\mathcal{I}NV(\mathcal{B}(X \times X'), \alpha \times \alpha') = \mathcal{I}NV(\mathcal{B}(X), \alpha) \otimes \mathcal{I}NV(\mathcal{B}(X'), \alpha')$.

Proof. Let $\{A_n \mid n \in \mathbb{N}\}$ and $\{A'_n \mid n \in \mathbb{N}\}$ be the generators for $\mathcal{I}NV(\mathcal{B}(X), \alpha)$ and $\mathcal{I}NV(\mathcal{B}(X'), \alpha')$, resp. Then $\{A_n \times A'_n \mid n \in \mathbb{N}\}$ generates

$$\mathcal{I}NV(\mathcal{B}(X), \alpha) \otimes \mathcal{I}NV(\mathcal{B}(X'), \alpha'),$$

and

$$\langle x_1, x'_1 \rangle (\alpha \times \alpha') \langle x_2, x'_2 \rangle \Leftrightarrow \forall n \in \mathbb{N} : [\langle x_1, x'_1 \rangle \in A_n \times A'_n \Leftrightarrow \langle x_2, x'_2 \rangle \in A_n \times A'_n]. \quad \square$$

We will establish a confluence property for later use. This property will be helpful for the investigation of the relationship between congruences and bisimulations: we will use this confluence property in a crucial way when it comes to show that bisimilar relations have isomorphic factors.

PROPOSITION 3.4. *Let T be a compact metric space, and assume that $\rho = \ker(\phi), \sigma = \ker(\psi)$ for some continuous maps $\phi : T \rightarrow N, \psi : T \rightarrow N'$ with metric spaces N, N' . There exist smooth equivalence relations θ on T/σ and θ' on T/ρ such that*

1. $\theta' \bullet \rho = \theta \bullet \sigma$,
2. θ and θ' are minimal: if $\theta'_0 \bullet \rho = \theta_0 \bullet \sigma$, for smooth equivalence relations θ_0 on T/σ and θ'_0 on T/ρ , then $\theta \subseteq \theta_0$ and $\theta' \subseteq \theta'_0$.

The following diagram visualizes this claim and suggests the characterization as a confluence property.

Note that the universal relations on the respective factor spaces would satisfy the first condition. But since the universal relation is usually no congruence, it is of no use for our purposes.

The proof will be broken into several parts. Because of part 4 in Lemma 3.2 we will first find a smooth equivalence relation θ on T/σ such that $\rho \subseteq \theta \bullet \sigma$ holds. We will assume through the end of the proof of Proposition 3.4 that T is a compact metric space, and that $\rho = \ker(\phi), \sigma = \ker(\psi)$.

CLAIM 1. *T/σ is a compact metric space when endowed with the final topology for η_σ .*

Proof. Let d' be the metric on N' , and put for $t, t' \in T$

$$D([t]_\sigma, [t']_\sigma) := d'(\psi(t), \psi(t')),$$

then D is a metric on T/σ (since $\sigma = \ker(\psi)$ by assumption). Let \mathcal{T} be the topology on T/σ induced by η_σ , then a set $G \subseteq T/\sigma$ which is D -open is also \mathcal{T} -open. This follows easily from the continuity of ψ . Conversely, let F be \mathcal{T} -closed, and assume that $([t_n]_\sigma)_{n \in \mathbb{N}}$ be a sequence in F such that $D([t_n]_\sigma, [t]_\sigma) \rightarrow 0$, as $n \rightarrow \infty$. Select an arbitrary $x_n \in [t_n]_\sigma$; thus $x_n \in \eta_\sigma^{-1}[F]$. The latter is a closed, hence compact, set. Thus we can find a convergent subsequence (which we take w.l.o.g. the sequence

itself), so that there exists $x^* \in \eta_\sigma^{-1}[F]$ with $x_n \rightarrow x^*$. By the continuity of ψ we may conclude $\psi(x_n) \rightarrow \psi(x^*)$. This implies $x^* \in [t]_\sigma$; thus $[t]_\sigma \in F$. Hence F is also metrically closed, and the topologies coincide. \square

Claim 1 shows among other things that the Borel sets in T/σ come from a compact metric space. This observation will make some arguments easier. When talking about the topology on T/σ , we refer interchangeably to the metric topology and the topology induced by the canonic projection.

CLAIM 2. *Put*

$$\zeta := \{\langle s, s' \rangle \mid s, s' \in T/\sigma, s \times s' \cap \rho \neq \emptyset\}.$$

Then $\zeta \subseteq (T/\sigma)^2$ is reflexive, symmetric, and a closed subset of $(T/\sigma)^2$.

Proof. Since ρ is reflexive and symmetric, ζ is also. Now let $\langle s_n, s'_n \rangle \in \zeta$ be a convergent sequence, say, $s_n \rightarrow s, s'_n \rightarrow s'$. For s_n there exists by the construction of ζ a pair $\langle t_n, t'_n \rangle \in \rho$ with $t_n \in s_n, t'_n \in s'_n$. In particular, $\phi(t_n) = \phi(t'_n)$. Compactness implies the existence of a subsequence $(q(n))_{n \in \mathbb{N}}$ and of elements t, t' such that $t_{q(n)} \rightarrow t, t'_{q(n)} \rightarrow t'$, as $n \rightarrow \infty$. Continuity implies $\langle t, t' \rangle \in \ker(\phi) = \rho$, and $s = [t]_\sigma, s' = [t']_\sigma$. Thus ζ is closed. \square

Now define inductively the n -fold composition of ζ :

$$\begin{aligned} \zeta^{(1)} &:= \zeta, \\ \zeta^{(n+1)} &:= \zeta^{(n)} \circ \zeta, \end{aligned}$$

where \circ denotes the usual relational composition.

The following properties are easily established through a compactness argument using induction on n .

CLAIM 3. *For each $n \in \mathbb{N}$*

1. $\zeta^{(n)} \subseteq T/\sigma$ is closed,
2. if $C \subseteq T/\sigma$ is compact, then the set

$$\exists \zeta^{(n)}(C) = \{s \in T/\sigma \mid \exists s' \in C : \langle s, s' \rangle \in \zeta^{(n)}\}$$

is closed.

CLAIM 4. *The transitive closure θ of ζ is a smooth equivalence relation on T/σ .*

Proof. It is clear from the properties of ζ that θ is an equivalence relation. Smoothness needs to be shown, and we will exhibit a Borel measurable map into a Polish space with θ as its kernel. Write θ as

$$\theta = \bigcup_{n \in \mathbb{N}} \zeta^{(n)},$$

and let $C \subseteq T/\sigma$ be a compact set; then

$$\exists \theta(C) = \{s \in T/\sigma \mid \exists s' \in C : \langle s, s' \rangle \in \theta\}$$

is a measurable subset of T/σ by Claim 3. By Proposition 2.1 we can find a measurable selector w for the set-valued map $s \mapsto \eta_\theta(s)$, and hence a Borel measurable map $w : T/\sigma \rightarrow T/\sigma$ such that $w(s) \in [s]_\theta$ for each $s \in T/\sigma$. Now we know that T/σ is a Polish space, and from $\theta = \ker(w)$ we can infer that θ is smooth. \square

We are in a position now to establish Proposition 3.4.

Proof of Proposition 3.4. 1. It is sufficient for the first part to establish $\rho \subseteq \theta \bullet \sigma$. In fact, let $t \rho t'$; then $[t]_\sigma \times [t']_\sigma \cap \rho \neq \emptyset$. This implies $\langle [t]_\sigma, [t']_\sigma \rangle \in \zeta \subseteq \theta$, which in turn establishes the inclusion and hence the proposition.

2. Now assume that $\theta'_0 \bullet \rho = \theta_0 \bullet \sigma$, for smooth equivalence relations θ_0 on T/σ and θ'_0 on T/ρ . From part 4 of Lemma 3.2 we infer $\sigma \subseteq \theta'_0 \bullet \rho$ and $\rho \subseteq \theta_0 \bullet \sigma$. In order to establish $\theta \subseteq \theta_0$ it is enough to show that $\zeta \subseteq \theta_0$. But if $\langle s, s' \rangle \in \zeta$, we know that $s \times s' \cap \rho \neq \emptyset$. The remark above implies that $s \times s' \cap \theta_0 \bullet \sigma \neq \emptyset$; thus $\langle t, t' \rangle \in \theta_0 \bullet \sigma$ for some $t \in s = [t]_\sigma, t' \in s' = [t']_\sigma$. Consequently, $s \theta_0 s'$ holds. Interchanging the roles of ρ and σ establishes that $\theta' \subseteq \theta'_0$ also holds. \square

For later use we record a property of θ -invariant Borel sets that characterizes these sets in terms of the equivalence relations from which θ is constructed. It gives an easy criterion on invariance and shows that the relation θ is probably not as unpractical as it appears on first sight.

LEMMA 3.5. *Under the assumptions of Proposition 3.4, let $D \subseteq T/\sigma$ be a Borel set, where θ is defined as in Claim 4 as the equivalence relation generated through $\{\langle s, s' \rangle \mid s, s' \in T/\sigma, s \times s' \cap \rho \neq \emptyset\}$. Then these conditions are equivalent:*

1. D is θ -invariant,
2. $\eta_\sigma^{-1}[D] \in \text{INV}(\mathcal{B}(T), \sigma) \cap \text{INV}(\mathcal{B}(T), \rho)$.

Proof. 1. “ $1 \Rightarrow 2$ ”: We know from part 2 of Lemma 3.2 that $\eta_\sigma^{-1}[D] \in \text{INV}(\mathcal{B}(T), \sigma)$, because $D \subseteq T/\sigma$ is a Borel set. Now let $t \in \eta_\sigma^{-1}[D]$ with $t \rho t'$. Then $[t]_\sigma \in D$ and $[t]_\sigma \times [t']_\sigma \cap \rho \neq \emptyset$; thus $\langle [t]_\sigma, [t']_\sigma \rangle \in \theta$, and, since D is θ -invariant, $t' \in \eta_\sigma^{-1}[D]$. Hence $\eta_\sigma^{-1}[D]$ is also ρ -invariant.

2. The implication “ $2 \Rightarrow 1$ ” is established through a routine argument using induction accounting for the construction of θ . \square

As a preparation for the definition of how two smooth relations may be to each other we will have a quick look at how the atoms of a countably generated σ -algebra are characterized through the generators. This representation is established in the proof of [26, section 3.1.15].

LEMMA 3.6. *Let $\mathcal{E} = \sigma(\{E_n \mid n \in \mathbb{N}\})$ be a countably generated σ -algebra over a set E . Define $A^1 := A, A^0 := E \setminus A$ for $A \subseteq E$. Then there exists $\mathbf{F} \subseteq \{0, 1\}^\mathbb{N}$ such that*

$$\left\{ \bigcap_{n \in \mathbb{N}} E_n^{\alpha(n)} \mid \alpha \in \mathbf{F} \right\}$$

are exactly the atoms of \mathcal{E} .

We are ready for a technical definition that permits stating how a smooth equivalence relation is transported through a map between classes in such a way that important properties are maintained. We call this *spawning*. This definition of spawning is still done only for equivalence relations, but it will be later extended to incorporate congruences.

DEFINITION 3.7. *Let α and β be smooth equivalence relations on the analytic spaces X , resp., Y , and assume that $\Upsilon : X/\alpha \rightarrow Y/\beta$ is a map between the equivalence classes. We say that α spawns β via $(\Upsilon, \mathcal{A}_0)$ iff \mathcal{A}_0 is a countable generator of $\text{INV}(\mathcal{B}(X), \alpha)$ such that*

1. \mathcal{A}_0 is closed under finite intersections,
2. $\{\Upsilon_A \mid A \in \mathcal{A}_0\}$ is a generator of $\text{INV}(\mathcal{B}(Y), \beta)$, where $\Upsilon_A := \bigcup \{\Upsilon([x]_\alpha) \mid x \in A\}$,
3. $[x_1]_\alpha = [x_2]_\alpha$ implies the equality of

$$\bigcap \{\Upsilon_A \mid A \in \mathcal{A}_0, x_1 \in A\} \cap \bigcap \{X' \setminus \Upsilon_A \mid A \in \mathcal{A}_0, x_1 \notin A\}$$

and

$$\bigcap \{\Upsilon_A | A \in \mathcal{A}_0, x_2 \in A\} \cap \bigcap \{X' \setminus \Upsilon_A | A \in \mathcal{A}_0, x_2 \notin A\}.$$

Thus if α spawns β , then the measurable structure induced by α on X is all we need for constructing the measurable structure induced by β on Y : the map Υ can be made to carry over the generator \mathcal{A}_0 from $\mathcal{I}NV(\mathcal{B}(X), \alpha)$ to $\mathcal{I}NV(\mathcal{B}(Y), \beta)$ and—in light of Lemma 3.6—to transport the atoms from one σ -algebra to the other. This is of particular interest since the atoms constitute the equivalence classes. Hence α together with Υ and the generator \mathcal{A}_0 is all we may care to know or to learn about β .

The first condition reflects a measure-theoretic precaution: we will need to make sure, e.g., in the construction of the direct sum of stochastic relations that measures are uniquely determined by their values on a generator. This, however, can best be guaranteed if the generator is stable against taking finite intersections. Note that $\Upsilon_{A_1 \cap A_2} = \Upsilon_{A_1} \cap \Upsilon_{A_2}$ also holds, so that closedness under intersections is inherited through Υ .

Whenever we have two smooth equivalence relations such that one spawns the other we obtain on the sum of the underlying spaces a unique smooth relation, the traces of which on the summands are just the given relations. Since we will introduce later on the sum of two relations, this effect will now be studied in greater detail.

LEMMA 3.8. *Let α and β be smooth equivalence relations on the analytic spaces X , resp., Y .*

1. *If α spawns β via $(\Upsilon, \mathcal{A}_0)$, then there exists exactly one smooth equivalence relation γ on $X + Y$ such that $[x]_\gamma \cap X = [x]_\alpha$ and $[x]_\gamma \cap Y = \Upsilon([x]_\alpha)$ hold for all $x \in X$.*
2. *If in addition β spawns α via (Θ, \mathcal{B}_0) , then we have for all $x \in X, y \in Y$ the equivalence*

$$[y]_\beta = \Upsilon([x]_\alpha) \Leftrightarrow [x]_\alpha = \Theta([y]_\beta).$$

Proof. 1. In order to establish property 1, we consider the equivalence relation γ generated from $\{A_n + \Upsilon_{A_n} \mid n \in \mathbb{N}\}$ with $\mathcal{A}_0 = \{A_n \mid n \in \mathbb{N}\}$. Relation γ is evidently smooth and it is uniquely determined through α and β . Let $x \in X$; then we can find $y \in Y$ with $\Upsilon([x]_\alpha) = [y]_\beta$, since Υ maps X/α to Y/β . It is easy to see that

$$\Upsilon([x]_\alpha) = \bigcap \{\Upsilon_{A_n} \mid A_n \in \mathcal{A}_0, x \in A_n\} \cap \bigcap \{Y \setminus \Upsilon_{A_n} \mid A_n \in \mathcal{A}_0, x \notin A_n\}.$$

This establishes part 1.

2. The claim in part 2 follows from the observation that β is the relation on Y which is generated from $\{\Upsilon_{A_n} \mid n \in \mathbb{N}\}$, and that α is the relation on X which is generated from $\{\Theta_{B_n} \mid n \in \mathbb{N}\}$, where $\mathcal{B}_0 = \{B_n \mid n \in \mathbb{N}\}$. \square

We need this construction later on, so we fix it in the following definition.

DEFINITION 3.9. *Let α and β be smooth equivalence relations on the analytic spaces X , resp., Y , and assume that α spawns β via $(\Upsilon, \mathcal{A}_0)$ and β spawns α via (Θ, \mathcal{B}_0) ; the equivalence relation constructed in Lemma 3.8 on $X + Y$ is denoted by $\alpha + \beta$.*

The isomorphism of two factor systems is another illustration of the concept of spawning.

PROPOSITION 3.10. *Let T, T' be analytic spaces with smooth equivalence relations ρ , resp., ρ' . Assume that $\Upsilon : T/\rho \rightarrow T'/\rho'$ is a Borel isomorphism, and let \mathcal{A} be*

a countable generator of $\mathcal{I}NV(\mathcal{B}(X), \rho)$ which is closed under finite intersections. Then ρ spawns ρ' via (Υ, \mathcal{A}) .

Proof. The assumption that the generator \mathcal{A} is closed under finite intersections is easily met: take an arbitrary countable generator \mathcal{A}_0 ; then

$$\{\bigcap \mathcal{F} \mid \mathcal{F} \subseteq \mathcal{A}_0 \text{ is finite}\}$$

is a countable generator which is closed under finite intersections.

1. If $A \in \mathcal{I}NV(\mathcal{B}(T), \rho)$ is a ρ -invariant Borel set, then Υ_A is ρ' -invariant, and it is easily established that

$$\Upsilon_A = \eta_{\rho'}^{-1} [\Upsilon [\eta_{\rho} [A]]]$$

holds. From part 2 in Lemma 3.2 we infer that \mathcal{C}_1 is a generator for $\mathcal{B}(T/\rho)$ where $\mathcal{C}_1 := \eta_{\rho} [\mathcal{I}NV(\mathcal{B}(T), \rho)]$. Consequently, $\{\Upsilon_A \mid A \in \mathcal{A}\}$ is a generator for the ρ' -invariant Borel sets $\mathcal{I}NV(\mathcal{B}(T'), \rho')$, because we may conclude that

$$\begin{aligned} \mathcal{I}NV(\mathcal{B}(T'), \rho') &= \eta_{\rho'}^{-1} [\mathcal{B}(T'/\rho')] \text{ (by Lemma 3.2)} \\ &= \eta_{\rho'}^{-1} [\Upsilon [\mathcal{B}(T'/\rho')]] \text{ (since } \Upsilon \text{ is a Borel isomorphism)} \\ &= \sigma(\{\eta_{\rho'}^{-1} [\Upsilon [C]] \mid C \in \mathcal{C}_1\}) \text{ (by construction of } \mathcal{C}_1\text{)} \\ &= \sigma(\{\Upsilon_A \mid A \in \mathcal{I}NV(\mathcal{B}(T), \rho)\}) \\ &= \sigma(\{\Upsilon_A \mid A \in \mathcal{A}\}) \text{ (since } \mathcal{A} \text{ generates } \mathcal{I}NV(\mathcal{B}(T), \rho)\text{)}. \end{aligned}$$

2. As in the proof of [11, Corollary 1] one shows that

$$\Upsilon([t]_{\rho}) = \bigcap \{\eta_{\rho'} [\Upsilon_A] \mid A \in \mathcal{A}, t \in A\} \cap \bigcap \{\eta_{\rho'} [T' \setminus \Upsilon_A] \mid A \in \mathcal{A}, t \notin A\}.$$

This settles the condition of well-defined atoms and concludes the proof. \square

The proof is technically a bit laborious. The statement, however, will be most useful in permitting us to show that stochastic relations are bisimilar, provided they have isomorphic factors. Working with isomorphisms alone for characterizing bisimilarity may be too strong a condition. In the application to modal logic below we will see that the equivalence relation which is induced on states through having the same logic satisfies the condition on spawning, but it is far from clear in this case whether or not the corresponding factor spaces are Borel isomorphic. Consequently, it seems to be worthwhile to work with the weaker condition.

4. Equivalent congruences. Observing a stochastic system $K : X \rightsquigarrow Y$, pairs with equivalent behavior are identified. This leads to a pair (α, β) of equivalence relations on the inputs X , resp., the outputs Y , with the idea that equivalent inputs lead to equivalent outputs. While equivalent inputs can be described directly through α , the equivalence of outputs requires a description of the level of measurable sets. We argue that a set $B \subseteq Y$ does not distinguish between equivalent outputs iff it is invariant under β , i.e., if $y \in B$ and $y \beta y'$ together imply $y' \in B$. This leads naturally to the notion of a congruence.

DEFINITION 4.1. A congruence $\mathfrak{c} = (\alpha, \beta)$ for the stochastic relation $K = (X, Y, K)$ is a pair of smooth equivalence relations α on X and β on Y such that $K(x)(D) = K(x')(D)$ holds whenever $x \alpha x'$ and D is a β -invariant measurable subset of Y . The congruence \mathfrak{c} is called nontrivial iff the σ -algebra $\mathcal{I}NV(\mathcal{B}(Y), \beta)$ is nontrivial.

Note that each equivalence class of a smooth equivalence relation is an invariant Borel set; thus if we know that $\mathcal{INV}(\mathcal{B}(Y), \beta)$ is trivial for a smooth relation β , then this implies $\beta = Y \times Y$. The exclusion of the universal relation from our discussions is justified through the observation that this relation does not provide us with additional information. If α is a smooth equivalence relation, then $(\alpha, Y \times Y)$ is a congruence, provided $K(x)(Y) = K(x')(Y)$ holds for $x \alpha x'$. But this is not really enough information to work with, because $\mathcal{INV}(\mathcal{B}(Y), Y \times Y) = \{\emptyset, Y\}$, so the invariant sets are not rich enough.

For later use we extend the \bullet -notation to congruences, and order congruences by componentwise refinement. Formally, if $\mathbf{c} = (\alpha, \beta), \mathbf{c}' = (\alpha', \beta')$, then $\mathbf{c} \preceq \mathbf{c}'$ iff both $\alpha \subseteq \alpha'$ and $\beta \subseteq \beta'$ hold.

The next lemma shows that kernels of morphisms and congruences are basically the same thing.

LEMMA 4.2. *If $f : \mathbb{K} \rightarrow \mathbb{K}'$ is a morphism for the stochastic relations \mathbb{K} and \mathbb{K}' , then $\ker(f)$ is a congruence for \mathbb{K} .*

Proof. Let $\mathbb{K} = (X, Y, K)$ and $\mathbb{K}' = (X', Y', K')$ with $f = (\phi, \psi)$. Let $x_1 \in \ker(\phi) \cap x_2$ and $D \subseteq Y$ be a $\ker(\psi)$ -invariant Borel subset of Y . Lemma 3.2 shows that $D = \psi^{-1}[D']$ for some Borel set $D' \subseteq Y'$. Thus we obtain from $f = (\phi, \psi)$ being a morphism

$$\begin{aligned} K(x_1)(D) &= K(x_1)(\psi^{-1}[D']) \\ &= (\mathfrak{S}(\psi) \circ K)(x_1)(D') \\ &= (K' \circ \phi)(x_1)(D') \\ &= K'(\phi(x_1))(D') \\ &= K'(\phi(x_2))(D') \\ &= (K' \circ \phi)(x')(D') \\ &= K(x_2)(D), \end{aligned}$$

the last equality just reversing the argument for the first ones. This establishes the claim. \square

This construction permits introducing factor objects which will be heavily used throughout.

PROPOSITION 4.3. *Let $\mathbf{c} = (\alpha, \beta)$ be a congruence on the stochastic relation $\mathbb{K} = (X, Y, K)$, and define*

$$K_{\alpha, \beta}([x]_{\alpha})(D) := K(x)(\eta_{\beta}^{-1}[D])$$

for $x \in X, D \in \mathcal{B}(Y/\beta)$; then

1. $K_{\alpha, \beta} : X/\alpha \rightsquigarrow Y/\beta$ is a stochastic relation,
2. $\eta_{\mathbf{c}} := (\eta_{\alpha}, \eta_{\beta}) : \mathbb{K} \rightarrow \mathbb{K}/\mathbf{c}$ is a morphism.

We call $\mathbb{K}/\mathbf{c} := (X/\alpha, Y/\beta, K_{\alpha, \beta})$ the factor object (of \mathbb{K} with respect to \mathbf{c}).

Proof. 1. Given $D \in \mathcal{B}(Y/\beta)$, $\eta_{\beta}^{-1}[D]$ is an invariant Borel set; thus $K(x)(\eta_{\beta}^{-1}[D])$ does depend only on the α -class of $x \in X$. Consequently, $K_{\alpha, \beta}$ is well defined.

2. $K_{\alpha, \beta} : X/\alpha \rightsquigarrow Y/\beta$ is a stochastic relation. In fact, it is plain that $K_{\alpha, \beta}([x]_{\alpha})$ is a subprobability measure on $\mathcal{B}(Y/\beta)$, so it remains to be shown that $t \mapsto K_{\alpha, \beta}(t)(D)$ is a $\mathcal{B}(X/\alpha)$ -measurable map for each $D \in \mathcal{B}(Y/\beta)$. Fix such a D and a Borel set $F \subseteq \mathbb{R}$; then

$$F_D := \{x \in X \mid K(x)(\eta_{\beta}^{-1}[D]) \in F\}$$

is a Borel set in X , and since $\eta_\beta^{-1}[D]$ is β -invariant, F_D is α -invariant with

$$\{t \in X/\alpha \mid K_{\alpha,\beta}(t)(D) \in F\} = \eta_\alpha[F_D] \in \mathcal{B}(X/\alpha)$$

by Lemma 3.2. This establishes measurability.

3. The construction of $K_{\alpha,\beta}$ yields $K_{\alpha,\beta} \circ \eta_\alpha = \mathfrak{S}(\eta_\beta) \circ K$; hence η_c is a morphism. \square

An important instance of congruences and factor spaces is furnished through equivalent congruences.

DEFINITION 4.4. Let $K = (X, Y, K)$ and $K' = (X', Y', K')$ be Polish objects with congruences $\mathfrak{c} = (\alpha, \beta)$ and $\mathfrak{c}' = (\alpha', \beta')$, respectively.

1. Call \mathfrak{c} proportional to \mathfrak{c}' (symbolically $\mathfrak{c} \propto \mathfrak{c}'$) iff α spawns α' via $(\Upsilon, \mathcal{A}_0)$ and β spawns β' via (Θ, \mathcal{B}_0) such that

$$\forall x \in X \forall x' \in \Upsilon([x]_\alpha) \forall B \in \mathcal{B}_0 : K(x)(B) = K'(x')(\Theta_B).$$

2. Call these congruences equivalent iff both $\mathfrak{c} \propto \mathfrak{c}'$ and $\mathfrak{c}' \propto \mathfrak{c}$ hold.

Thus equivalent congruences behave in exactly the same way. The same behavior is exhibited on each atom, i.e., equivalence class, as far as the input is concerned, and the respective invariant output sets. It becomes visible now that a characterization of equivalent behavior through congruences requires the double face of congruences: it is certainly necessary to use the equivalence relation on the input spaces, but since the behavior on the output spaces is modeled through probabilities, we also need the invariant Borel sets for a characterization.

We will now show how equivalent congruences on stochastic relations give rise to a factor object built on their sum. This construction will be of use in Proposition 4.5 for investigating the bisimilarity of stochastic relations.

Assume that \mathfrak{c} and \mathfrak{c}' are equivalent congruences on the Polish objects $K = (X, Y, K)$ and $K' = (X', Y', K')$, respectively. Construct for K and K' the direct sum

$$K \oplus K' := (X + X', Y + Y', K \oplus K'),$$

where the only nonobvious construction is $K \oplus K'$: put for the Borel set $E \subseteq Y + Y'$

$$(K \oplus K')(z)(E) := \begin{cases} K(z)(E \cap Y) & \text{if } z \in X, \\ K'(z)(E \cap Y') & \text{if } z \in X'. \end{cases}$$

Then clearly $K \oplus K' : X + X' \rightsquigarrow Y + Y'$. Define on $X + X'$, resp., $Y + Y'$, the σ -algebras

$$\begin{aligned} \mathcal{G} &:= \{C + C' \mid C \in \text{INV}(\mathcal{B}(X), \alpha), C' \in \text{INV}(\mathcal{B}(X'), \alpha')\}, \\ \mathcal{H} &:= \{D + D' \mid D \in \text{INV}(\mathcal{B}(Y), \beta), D' \in \text{INV}(\mathcal{B}(Y'), \beta')\}. \end{aligned}$$

Then \mathcal{G} and \mathcal{H} are countable generated sub- σ -algebras of the respective Borel sets. Because the σ -algebras in question are countably generated, so is their sum, and because the congruences are equivalent, we claim that $z \sim (\alpha + \alpha') z'$ implies that $(K \oplus K')(z)(F) = (K \oplus K')(z')(F)$ holds for all $F \in \mathcal{H}$. To establish this, fix $z \in X, z' \in X'$, and consider

$$\mathcal{S} := \{F \in \mathcal{H} \mid (K \oplus K')(z)(F) = (K \oplus K')(z')(F)\}.$$

Since the congruences are equivalent, this is a σ -algebra containing the generator $\{D_n + \Theta_{D_n} \mid n \in \mathbb{N}\}$, where β spawns β' via $(\Theta, \{D_n \mid n \in \mathbb{N}\})$. Since the generator is closed under finite intersections, measures are uniquely determined. This implies $\mathcal{H} \subseteq \sigma(\mathcal{S})$, and thus $\mathcal{H} = \mathcal{S}$. Consequently,

$$\begin{aligned} \mathcal{G} &= \text{INV}(\mathcal{B}(X + X'), \alpha + \alpha'), \\ \mathcal{H} &= \text{INV}(\mathcal{B}(Y + Y'), \beta + \beta'), \end{aligned}$$

and $\mathbf{c} + \mathbf{c}' := (\alpha + \alpha', \beta + \beta')$ is a congruence on $\mathbf{K} \oplus \mathbf{K}'$.

The factor object

$$(\mathbf{K} \oplus \mathbf{K}') / (\mathbf{c} + \mathbf{c}')$$

constructed in this way will be investigated more closely in Proposition 4.5 below when we establish that \mathbf{K} and \mathbf{K}' are bisimilar, provided they have equivalent nontrivial congruences.

Equivalent congruences give rise to bisimilar stochastic relations. This is a rather far-reaching generalization of the by now well-known characterization of bisimilarity of labeled Markov transition systems through mutually equivalent states. Note that this is an intrinsic characterization of bisimilarity: we investigate the relations and their congruences on their own, but we do not need an external instance (like a logic) to determine bisimilarity.

PROPOSITION 4.5. *If \mathbf{c}_i are equivalent nontrivial congruences on the Polish objects \mathbf{K}_i for $i = 1, 2$, then \mathbf{K}_1 and \mathbf{K}_2 are bisimilar.*

Proof. 1. Let $\mathbf{K}_i = (X_i, Y_i, K_i)$ and $\mathbf{c}_i = (\alpha_i, \beta_i)$ for $i = 1, 2$. Construct the sum $\mathbf{K}_1 \oplus \mathbf{K}_2$ as above, and let (κ_i, λ_i) be the corresponding injections, which are, however, not morphisms. Let

$$(\eta_{\alpha_1 + \alpha_2}, \eta_{\beta_1 + \beta_2}) : \mathbf{K}_1 \oplus \mathbf{K}_2 \rightarrow (\mathbf{K}_1 \oplus \mathbf{K}_2) / (\mathbf{c}_1 + \mathbf{c}_2)$$

be the canonical injection; then

$$(\eta_{\alpha_1 + \alpha_2} \circ \kappa_i, \eta_{\beta_1 + \beta_2} \circ \lambda_i)$$

constitutes a morphism $\mathbf{K}_i \rightarrow (\mathbf{K}_1 \oplus \mathbf{K}_2) / (\mathbf{c}_1 + \mathbf{c}_2)$, as will be shown now. Surjectivity has to be established, and we have to show that the σ -algebra of common events is nontrivial.

2. Each equivalence class $a \in (X_1 + X_2) / (\alpha_1 + \alpha_2)$ can be represented as

$$a = [x_1]_{\alpha_1} + [x_2]_{\alpha_2}$$

for some suitably chosen $x_1 \in X_1, x_2 \in X_2$. Similarly, each equivalence class $b \in (Y_1 + Y_2) / (\beta_1 + \beta_2)$ can be written as

$$b = [y_1]_{\beta_1} + [y_2]_{\beta_2}$$

for some $y_1 \in Y_1, y_2 \in Y_2$. Conversely, the sum of classes is a class again. This follows from Lemma 3.8.

3. The semipullback of the pair of morphisms with a joint target constructed in the first step exists by Theorem 2.2. It is a Polish object (A, B, M) , where

$$B = \{\langle y_1, y_2 \rangle \in Y_1 \times Y_2 \mid [y_1]_{\beta_1 + \beta_2} = [y_2]_{\beta_1 + \beta_2}\}.$$

Since \mathbf{c} is nontrivial, we can find an invariant Borel set $D \in \mathcal{I}NV(\mathcal{B}(Y_1), \beta_1)$ with $\emptyset \neq D \neq Y_1$. Assume that β_1 spawns β_2 via $(\Theta, \{D_n \mid n \in \mathbb{N}\})$; then $\emptyset \neq \Theta_D \neq Y_2$ also holds. Because D is β_1 -invariant,

$$\begin{aligned} \pi_{1,Y_1}^{-1}[D] &= \{\langle y_1, y_2 \rangle \mid y_1 \in D\} \\ &= \{\langle y_1, y_2 \rangle \mid y_2 \in \Theta_D\} \\ &= \pi_{2,Y_2}^{-1}[\Theta_D]; \end{aligned}$$

thus

$$\pi_{1,Y_1}^{-1}[D] \in \pi_{1,Y_1}^{-1}[\mathcal{B}(Y_1)] \cap \pi_{2,Y_2}^{-1}[\mathcal{B}(Y_2)],$$

and we are done once it is shown that $\pi_{1,Y_1}^{-1}[D] \neq B$. Since $D \neq Y_1$ is invariant, there exists y_1 with

$$[y_1]_{\beta_1+\beta_2} \cap D = [y_1]_{\beta_1} \cap D = \emptyset.$$

Let $[y_2]_{\beta_2} := \Theta([\psi_1]_{\beta_1})$; then

$$[y_2]_{\beta_1+\beta_2} \cap \Theta_D = [y_2]_{\beta_2} \cap \Theta_D = \emptyset.$$

Consequently, $\langle y_1, y_2 \rangle \in B \setminus \pi_{1,Y_1}^{-1}[D]$. This shows that $\pi_{1,Y_1}^{-1}[\mathcal{B}(Y_1)] \cap \pi_{2,Y_2}^{-1}[\mathcal{B}(Y_2)]$ is nontrivial. \square

The proof's strategy is to make sure that the classes associated with the congruences are distributed evenly among the summands in the sense that each class in the sum is the sum of appropriate classes. This then implies that we can construct surjective maps, and from them morphisms through some general mechanisms. This idea works, in particular, with isomorphic factor spaces.

PROPOSITION 4.6. *Let K and K' be analytic objects such that K/\mathbf{c} is isomorphic to K'/\mathbf{c}' for some nontrivial congruences \mathbf{c} and \mathbf{c}' . Then K and K' are bisimilar.*

Proof. Let $K = (X, Y, K)$ with $\mathbf{c} = (\alpha, \beta)$, and similarly for K' and \mathbf{c}' . Assume that $\mathbf{f} = (\Phi, \Psi)$ is the isomorphism $K/\mathbf{c} \rightarrow K'/\mathbf{c}'$ which is composed of the Borel isomorphisms $\Phi : X/\alpha \rightarrow X'/\alpha'$ and $\Psi : Y/\beta \rightarrow Y'/\beta'$. Moreover, let \mathcal{A} and \mathcal{B} be countable generators of $\mathcal{I}NV(\mathcal{B}(X), \alpha)$ and $\mathcal{I}NV(\mathcal{B}(Y), \beta)$ which are closed under finite intersections. We know from Proposition 3.10 that α spawns α' via (Φ, \mathcal{A}) , and that β spawns β' via (Ψ, \mathcal{B}) . Hence we have to establish for each $x \in X, x' \in \Phi([x]_\alpha)$ and for each β -invariant Borel subset $B \subseteq Y$ that

$$K(x)(B) = K'(x')(\Psi_B)$$

holds. This will imply $\mathbf{c} \propto \mathbf{c}'$. Interchanging the roles of \mathbf{c} and \mathbf{c}' then will yield the result.

1. Given $B \in \mathcal{I}NV(\mathcal{B}(Y), \beta)$ we know from Lemma 3.2 that we can find a Borel set $B_1 \in \mathcal{B}(Y/\beta)$ such that $B = \eta_\beta^{-1}[B_1]$. Since Ψ is a Borel isomorphism, we find $B_2 \in \mathcal{B}(Y'/\beta')$ with $B_1 = \Psi^{-1}[B_2]$. A routine calculation shows that $\Psi_B = \eta_{\beta'}^{-1}[B_2]$. Now assume that $x \in X, x' \in \Phi([x]_\alpha)$; then the following chain of equations is obtained from the argumentation above, and from the assumption that \mathbf{f} is an isomorphism.

$$\begin{aligned} K(x)(B) &= K(x)(\eta_\beta^{-1}[\Psi^{-1}[B_2]]) \\ &= K_{\alpha,\beta}([x]_\alpha)(\Psi^{-1}[B_2]) \\ &= K'_{\alpha',\beta'}(\Phi([x]_\alpha))(B_2) \\ &= K'(x')(\eta_{\beta'}^{-1}[B_2]) \\ &= K'(x')(\Psi_B). \end{aligned}$$

This establishes the desired relation $c \propto c'$ and completes the proof. \square

Thus isomorphic factor spaces make sure that the relations are bisimilar. The natural question is whether or not the converse also holds: given bisimilar relations, do they have isomorphic factor spaces? A first step toward an answer is shown in the following proposition.

PROPOSITION 4.7. *If the Polish objects K and K' are bisimilar such that the mediating object is compact with continuous morphisms, then K and K' have isomorphic nondegenerate factor spaces.*

Proof. 1. Let

$$K \xleftarrow{f} M \xrightarrow{f'} K'$$

be the span of morphisms constituting bisimilarity. Because K is isomorphic to $M/\ker(f)$ by [11, Corollary 3], we may restrict our attention to factors of M . Thus we assume that $K = M/c, K' = M/c'$, where both c and c' are the kernels of continuous morphisms. Suppose that we can find congruences d and d' such that $d \bullet c = d' \bullet c'$. Then

$$\begin{aligned} K/d &= (M/c)/d \\ &\cong M/d \bullet c \text{ (by [11, Proposition 2])} \\ &= M/d' \bullet c' \\ &= (M/c')/d' \\ &\cong K'/d' \end{aligned}$$

(\cong indicating isomorphism), and we are done, provided K/d is shown to be nondegenerate, or, equivalently, d not to have the universal relation as its second component. When looking for suitable congruences d and d' it is in view of [11, Corollary 4] sufficient to find a congruence $d' = (\gamma, \delta)$ with $c \preceq d' \bullet c'$ for the given congruences c and c' , and δ is not universal.

2. Assume $M = (X, Y, M)$, and suppose $c = (\alpha, \beta), c' = (\alpha', \beta')$. We know that there exist smooth equivalence relations γ and δ with $\alpha \subseteq \gamma \bullet \alpha'$ and $\beta \subseteq \delta \bullet \beta'$; moreover, we know for a δ -invariant Borel subset $D \in \text{INV}(Y/\beta', \delta)$ that

$$\eta_{\beta'}^{-1}[D] \in \text{INV}(\mathcal{B}(Y), \beta) \cap \text{INV}(\mathcal{B}(Y), \beta').$$

This was shown in Proposition 3.4 and Lemma 3.5.

We show that $d = (\gamma, \delta)$ is a congruence; thus we have to show that $K_{\alpha', \beta'}(s)(D) = K_{\alpha', \beta'}(s')(D)$, whenever D is a δ -invariant Borel subset of Y/β' and $s \gamma s'$.

Assume first that

$$\langle s, s' \rangle \in \gamma_0 := \{ \langle t, t' \rangle \mid t, t' \in X/\alpha', t \times t' \cap \alpha \neq \emptyset \}.$$

Then we can find $\langle x, x' \rangle \in \alpha$ such that $s = [x]_{\alpha'}, s' = [x']_{\alpha'}$, and $[x]_{\alpha} = [x']_{\alpha}$. Thus we obtain from D 's invariance properties

$$\begin{aligned} K_{\alpha', \beta'}(s)(D) &= K(x)(\eta_{\beta'}^{-1}[D]) \\ &= K(x')(\eta_{\beta'}^{-1}[D]) \\ &= K_{\alpha', \beta'}(s')(D). \end{aligned}$$

This means that the assertion is true for all $\langle s, s' \rangle \in \gamma_0$.

Now consider

$$\hat{\gamma} := \{ \langle t, t' \rangle \mid t, t' \in X/\alpha', K_{\alpha', \beta'}(t)(D) = K_{\alpha', \beta'}(t')(D) \};$$

then $\hat{\gamma}$ is an equivalence relation which contains γ_0 , and, consequently, it contains γ , as the construction of γ as the transitive closure of γ_0 shows (see Claim 4).

3. Since M/c and M'/c' are bisimilar, we can find $F \in \text{INV}(\mathcal{B}(Y), \beta) \cap \text{INV}(\mathcal{B}(Y), \beta')$ with $\emptyset \neq F \neq Y$ (this is so since, e.g., $\text{INV}(\mathcal{B}(Y), \beta) = \eta_\beta^{-1}[\mathcal{B}(Y/\beta)]$ by Lemma 3.2, part 1). Now minimality of the construction leading to Proposition 3.4 enters the game: from Lemma 3.5 we infer that

$$\eta_{\beta'}^{-1}[\text{INV}(\mathcal{B}(Y/\beta'), \delta)] = \text{INV}(\mathcal{B}(Y), \beta) \cap \text{INV}(\mathcal{B}(Y), \beta')$$

holds; thus we can find $F_0 \in \text{INV}(\mathcal{B}(Y/\beta'), \delta)$ with $\emptyset \neq F_0 \neq Y/\beta'$. Consequently, δ is not universal and we are done. \square

Summarizing, we have established the following characterization of bisimilarity through congruences.

THEOREM 4.8. *Consider for analytic objects K and K' the following statements.*

1. *There exist nontrivial congruences c and c' on K , resp., K' , such that K/c and K'/c' are isomorphic.*
2. *K and K' are bisimilar.*

Then $1 \Rightarrow 2$ holds always, and $2 \Rightarrow 1$ holds in the case that the mediating object is compact and the associated morphisms are continuous.

This is an intrinsic characterization of bisimilarity through congruences, because we can look at the stochastic relations and say that they are bisimilar without having to look at an external instance (like the sentences of a modal logic). It would be most valuable to lift the rather strong condition on compactness. The proofs given above, in particular in section 3, are Claims 1 through 4 relying on compact spaces via the possibility to extract from each sequence a converging subsequence (hence on sequential compactness, to be specific). Otherwise smoothness cannot be guaranteed, but smoothness is crucial since it makes sure that the factor space is analytic.

Conjecture. The characterization of bisimilarity through isomorphic factor spaces is valid for all stochastic relations over analytic spaces.

5. Interpretations of modal logic. We have so far established a criterion for bisimilarity through equivalent congruences and discussed bisimilarity in terms of isomorphic factor spaces. The rest of the paper will apply this to modal logic. This section defines the logic we will be working with, and Kripke models are defined in their usual nondeterministic and stochastic versions, together with their satisfaction relation. In section 5.1 some examples are given in order to demonstrate how probabilistic models are defined for specific logics, and in section 5.2 we relate nondeterministic to stochastic interpretations by introducing probabilistic refinements.

Let P be a countable set of propositional letters which is fixed throughout; $O \neq \emptyset$ is a set of modal operators. Following [3], $\tau = (O, \rho)$ is called a *modal similarity type* iff $O \neq \emptyset$, and if $\rho : O \rightarrow \mathbb{N}$ is a map, assigning each modal operator Δ its arity $\rho(\Delta) \geq 1$. We will not deal with modal operators of arity zero, since as modal constants they do not have to be dealt with in an interpretation. The similarity type τ will be fixed.

We define three modal languages based on τ and P . The formulas of the *basic modal language* $\mathfrak{Mod}_b(\tau, P)$ are given by the syntax

$$\varphi ::= p \mid \top \mid \varphi_1 \wedge \varphi_2 \mid \neg\varphi \mid \Delta(\varphi_1, \dots, \varphi_{\rho(\Delta)}),$$

where $p \in P$. Omitting negation defines the formulas in the *negation free basic modal language* $\mathfrak{Mod}_1(\tau, P)$. Finally, the *extended modal language* $\mathfrak{Mod}_s(\tau, P)$ is defined through the syntax

$$\varphi ::= p \mid \top \mid \varphi_1 \wedge \varphi_2 \mid \neg\varphi \mid \Delta_q(\varphi_1, \dots, \varphi_{\rho(\Delta)}),$$

where $q \in \mathbb{Q} \cap [0, 1]$ is a rational number, and $p \in P$ is a propositional letter.

A *nondeterministic τ -Kripke model* $\mathcal{R} = (S, R_\tau, V)$ consists of a state space S , a family $R_\tau = ((R_\Delta)_{\Delta \in O})$ of set-valued maps $R_\Delta : S \rightarrow \mathcal{P}(S^{\rho(\Delta)})$, and a set-valued map $V : P \rightarrow \mathcal{P}(S)$.

The satisfaction relation for a nondeterministic τ -Kripke model \mathcal{R} is defined as usual for $\mathfrak{Mod}_b(\tau, P)$:

- (i) $\mathcal{R}, s \models p \Leftrightarrow s \in V(p)$,
- (ii) $\mathcal{R}, s \models \neg\varphi \Leftrightarrow \mathcal{R}, s \not\models \varphi$,
- (iii) $\mathcal{R}, s \models \varphi_1 \wedge \varphi_2 \Leftrightarrow \mathcal{R}, s \models \varphi_1$ and $\mathcal{R}, s \models \varphi_2$,
- (iv) $\mathcal{R}, s \models \Delta(\varphi_1, \dots, \varphi_{\rho(\Delta)}) \Leftrightarrow \exists \langle s_1, \dots, s_{\rho(\Delta)} \rangle \in R_\Delta(s) : \mathcal{R}, s_i \models \varphi_i$ for $1 \leq i \leq \rho(\Delta)$.

Denote by $\llbracket \varphi \rrbracket_{\mathcal{R}} := \{s \in S \mid \mathcal{R}, s \models \varphi\}$ the set of states for which formula φ is valid, and by

$$Th_{\mathcal{R}}(s) := \{\varphi \in \mathfrak{Mod}_b(\tau, P) \mid \mathcal{R}, s \models \varphi\}$$

the theory of state s in \mathcal{R} .

An easy calculation shows that

$$\mathcal{R}, s \models \Delta(\varphi_1, \dots, \varphi_{\rho(\Delta)}) \Leftrightarrow R_\Delta(s) \cap \llbracket \varphi_1 \rrbracket_{\mathcal{R}} \times \dots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{R}} \neq \emptyset.$$

In analogy, a *stochastic τ -Kripke model* $\mathcal{K} = (S, K_\tau, V)$ has a state space S which is endowed with a σ -algebra, a family $K_\tau = (K_\Delta)_{\Delta \in O}$ of stochastic relations $K_\Delta : S \rightsquigarrow S^{\rho(\Delta)}$, and a set-valued map $V : P \rightarrow \mathcal{P}(S)$ such that $V(p)$ is always a measurable set (we leave the σ -algebra on the state space anonymous to avoid cluttering the notation; note that $S^{\rho(\Delta)}$ carries the product σ -algebra).

The interpretation of formulas in $\mathfrak{Mod}_s(\tau, P)$ for a stochastic τ -Kripke model \mathcal{K} is fairly straightforward, the interesting case arising when a modal operator is involved:

$$\mathcal{K}, s \models \Delta_q(\varphi_1, \dots, \varphi_{\rho(\Delta)})$$

holds iff there exists measurable subsets $A_1, \dots, A_{\rho(\Delta)}$ of S such that $\mathcal{K}, s_i \models \varphi_i$ holds for all $s_i \in A_i$ for $1 \leq i \leq \rho(\Delta)$, and

$$K_\Delta(s)(A_1 \times \dots \times A_{\rho(\Delta)}) \geq q.$$

Arguing from the point of view of state transition systems, this interpretation of validity reflects that upon the move indicated by Δ_q , a state s satisfies $\Delta_q(\varphi_1, \dots, \varphi_{\rho(\Delta)})$ iff we can find states s_i satisfying φ_i with a K_Δ -probability exceeding q . Note that the usual operators Δ and ∇ are replaced by a whole spectrum of operators Δ_q which permit a finer and probabilistically more adequate notion of satisfaction (see [18]).

Again, let $\llbracket \varphi \rrbracket_{\mathcal{K}}$ be the set of all states for which $\varphi \in \mathfrak{Mod}_s(\tau, P)$ is satisfied under \mathcal{K} , and

$$Th_{\mathcal{K}}(s) := \{\varphi \in \mathfrak{Mod}_s(\tau, P) \mid \mathcal{K}, s \models \varphi\}$$

the state’s theory.

It turns out that the sets $\llbracket \varphi \rrbracket_{\mathcal{K}}$ are measurable, so that they may be used as arguments for the stochastic relations we are working with.

LEMMA 5.1. $\llbracket \varphi \rrbracket_{\mathcal{K}}$ is a measurable subset of S for each $\varphi \in \mathfrak{Mod}_s(\tau, P)$.

Proof. The proof proceeds by induction on φ . If $\varphi = p \in P$, then $\llbracket \varphi \rrbracket_{\mathcal{K}} = V(p)$ holds, which is measurable by assumption. Since the measurable sets are closed under complementation and intersection, the only interesting case is again the one in which a modal operator is involved. Since

$$\llbracket \Delta_q(\varphi_1, \dots, \varphi_{\rho(\Delta)}) \rrbracket_{\mathcal{K}} = \{s \in S \mid K_{\Delta}(s)(\llbracket \varphi_1 \rrbracket_{\mathcal{K}} \times \dots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{K}}) \geq q\},$$

the assertion follows from the induction hypothesis and the fact that K_{Δ} is a stochastic relation. \square

As in the case of stochastic relations, we need to exclude trivial cases.

DEFINITION 5.2. A τ -Kripke model \mathcal{K} with state space S is called degenerate iff $\llbracket \varphi \rrbracket_{\mathcal{K}} = S$ or $\llbracket \varphi \rrbracket_{\mathcal{K}} = \emptyset$ holds for each formula $\varphi \in \mathfrak{Mod}_s(\tau, P)$.

Hence a degenerate model does not carry useful information.

5.1. Examples. We show how some popular logics may be interpreted through Kripke models, indicating that specific logics require specific probabilistic arguments. But first we indicate that each stochastic relation may be “trained” to interpret a modal logic simply by interpreting the subformulas of a compound formula as stochastically independent. Then we introduce the well-known logic associated with labeled transition systems. This example is of historic significance, given the seminal work of Larsen and Skou [18]. It is shown also how the basic temporal language may be interpreted stochastically by reversing a relation, and arrow logic as a popular logic modelling simple programming constructs is interpreted through a simple transformation of a distribution. The last example leaves the realm of modal logics somewhat by tackling a logic that is used for model checking. It will be shown how a stochastic relation generates path probabilities (through an inverse limit construction), and how this can be made use of for a probabilistic interpretation of a simple kind of tree logic.

A stochastic relation on the state space induces a stochastic τ -Kripke model. This is illustrated through the following example.

Example 5.1. Let $K : S \rightsquigarrow S$ be a stochastic relation on the state space S , and define for $s \in S$ and for the modal operator Δ

$$K_{\Delta}(s) := \bigotimes_{i=1}^{\rho(\Delta)} K(s).$$

Then $K_{\Delta} : S \rightsquigarrow S^{\rho(\Delta)}$ is a stochastic relation. If $V(p) \subseteq S$ is a measurable subset of S , then

$$\mathcal{K}_{K,V} := (S, (K_{\Delta})_{\Delta \in O}, V)$$

is a stochastic τ -Kripke model such that

$$\mathcal{K}_{K,V}, s \models \Delta_q(\varphi_1, \dots, \varphi_{\rho(\Delta)}) \Leftrightarrow K(s)(\llbracket \varphi_1 \rrbracket_{\mathcal{K}_{K,V}}) \cdots K(s)(\llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{K}_{K,V}}) \geq q.$$

Thus the arguments to each modal operator are stochastically independent.

Example 5.2. Suppose that L is a countable alphabet of actions. Each action $a \in L$ is associated with a unary modal operator $\langle a \rangle$, so put $\tau := (O, \rho)$ with $O := \{\langle a \rangle \mid a \in L\}$ and $\rho(\langle a \rangle) := 1$.

A nondeterministic τ -Kripke model is based on a labeled transition system $(S, (\rightarrow_a)_{a \in \mathbb{L}})$ which associates with each action a a binary relation $\rightarrow_a \subseteq S \times S$. Thus

$$s \models \langle a \rangle \varphi \Leftrightarrow \exists s' : s \rightarrow_a s' \wedge s' \models \varphi.$$

A stochastic τ -model is based on a labeled Markov transition system [18, 6, 9] $(S, (k_a)_{a \in \mathbb{L}})$ which associates with each action a a stochastic relation $k_a : S \rightsquigarrow S$. Thus

$$s \models \langle a \rangle_q \varphi \Leftrightarrow k_a(s)(\llbracket \varphi \rrbracket) \geq q,$$

and hence making a transition is replaced by a probability with which a transition can happen.

Variants of the logic $\mathfrak{M}\mathfrak{o}\mathfrak{d}_s(\tau, P)$ with $P = \emptyset$ were investigated in [18, 6] with a reference to the logic investigated by Hennessy and Milner; we refer to them also as *Hennessy–Milner logic*.

Example 5.3. The basic temporal language has two unary modal operators **F** (forward) and **B** (backward), so that $O = \{\mathbf{F}, \mathbf{B}\}$. A nondeterministic τ -Kripke model interprets the forward operator **F** through a relation $R \subseteq S \times S$ and the backward operator **B** through the converse R^\smile , so that

$$s \models \mathbf{B}\varphi \Leftrightarrow \exists t \in S : \langle t, s \rangle \in R \wedge t \models \varphi$$

holds.

A probabilistic interpretation interprets **F** through a stochastic relation $K : S \rightsquigarrow S$, so that

$$s \models \mathbf{F}_q \varphi \Leftrightarrow K(s)(\llbracket \varphi \rrbracket) \geq q.$$

The backward operator **B** is interpreted through the converse $K_\mu^\smile : S \rightsquigarrow S$, provided the state space S is Polish and an initial probability μ is given (the converse K_μ^\smile of K given μ is the stochastic relation $L : S \rightsquigarrow S$ such that

$$\int_S K(s)(\{s' \mid \langle s, s' \rangle \in B\}) \mu(ds) = \int_S L(s')(\{s \mid \langle s, s' \rangle \in B\}) \mu(ds')$$

holds for each Borel set $B \subseteq S \times S$; see [1] for algebraic and [10] for relational and measure-theoretic properties of the converse). Thus

$$s \models \mathbf{B}_q \varphi \Leftrightarrow K_\mu^\smile(s)(\llbracket \varphi \rrbracket) \geq q.$$

An easy calculation shows that

$$\begin{aligned} s \models \mathbf{B}_1 \mathbf{F}_1 \varphi &\Leftrightarrow K_\mu^\smile(s)(\{s' \mid K(s')(\llbracket \varphi \rrbracket) = 1\}) = 1 \\ &\Leftrightarrow \int_S K(s')(\llbracket \varphi \rrbracket) K_\mu^\smile(s)(ds') = 1. \end{aligned}$$

Note that the definition of the converse requires an initial probability (this is intuitively clear: if the probability for a backward running process is described, one has to say where to start). It is also noteworthy that a topological assumption has been made; if the state space is not a Polish space, then the technical arguments permitting the definition of the converse are not available.

Example 5.4. Arrow logic has three modal operators modelling reversal, composition, and skip, resp.; thus $O = \{\mathbf{1}, \otimes, \circ\}$ with respective arities $\rho(\mathbf{1}) = 0, \rho(\otimes) = 1, \rho(\circ) = 2$. The usual interpretation of arrow logic is done over a world of pairs, so the base state space is $S \times S$ for some S , with associated relations

$$\begin{aligned} R_{\mathbf{1}} &= \{\langle s, s \rangle \mid s \in S\}, \\ R_{\otimes} &= \{\langle \langle s_0, s_1 \rangle, \langle s_1, s_0 \rangle \rangle \mid s_0, s_1 \in S\}, \\ R_{\circ} &= \{\langle \langle s_0, s_1 \rangle, \langle s_0, s \rangle, \langle s, s_1 \rangle \rangle \mid s, s_0, s_1 \in S\} \end{aligned}$$

(see [3, Example 1.27]). Thus, e.g.,

$$\langle s, s' \rangle \models \phi \circ \psi \Leftrightarrow \exists s_0 : \langle s, s_0 \rangle \models \phi \wedge \langle s_0, s' \rangle \models \psi$$

and

$$\langle s, s' \rangle \models \otimes \phi \Leftrightarrow \langle s', s \rangle \models \phi.$$

Now assume that S is a Polish space and let $\mu \in \mathfrak{S}(S)$ be a subprobability. Put for $A \in \mathcal{B}(S \times S)$

$$\hat{\mu}(A) := \mu(\{s \in S \mid \langle s, s \rangle \in A\}).$$

Thus $\hat{\mu}$ transports a Borel set in S to a Borel set in the diagonal of $S \times S$. Denote by δ_a the Dirac measure on a .

Interpret the composition operator \circ_q through the stochastic relation

$$K_{\circ}(s, s') := \delta_s \otimes \hat{\mu} \otimes \delta_{s'}.$$

Note that the operator \otimes is somewhat overloaded: it denotes the modal operator for reversal, and the product operator for measures; the context should make it clear which version is meant.

We then obtain

$$\begin{aligned} K_{\circ}(s, s')(\llbracket \phi \rrbracket \times \llbracket \psi \rrbracket) &= (\delta_s \otimes \hat{\mu} \otimes \delta_{s'}) (\llbracket \phi \rrbracket \times \llbracket \psi \rrbracket) \\ &= \hat{\mu}(\{\langle s_1, s_2 \rangle \mid \langle s, s_1 \rangle \in \llbracket \phi \rrbracket, \langle s_2, s' \rangle \in \llbracket \psi \rrbracket\}) \\ &= \mu(\{s_1 \mid \langle s, s_1 \rangle \in \llbracket \phi \rrbracket, \langle s_1, s' \rangle \in \llbracket \psi \rrbracket\}). \end{aligned}$$

Consequently,

$$\langle s, s' \rangle \models \phi \circ_1 \psi \Leftrightarrow \langle s, s_1 \rangle \models \phi \wedge \langle s_1, s' \rangle \models \psi \text{ for } \mu\text{-almost all } s_1.$$

(Here μ -almost all s_1 means as usual that the set of all s_1 for which the property does not hold has μ -measure 0.) More generally,

$$\langle s, s' \rangle \models \phi \circ_q \psi \Leftrightarrow \langle s, s_1 \rangle \models \phi \wedge \langle s_1, s' \rangle \models \psi \quad \forall s_1 \text{ from a Borel set } S_0 \text{ with } \mu(S_0) \geq q.$$

Finally, put

$$K_{\otimes}(s, s') := \delta_{\langle s, s' \rangle};$$

then

$$\langle s, s' \rangle \models \otimes_q \phi \Leftrightarrow \langle s', s \rangle \models \phi$$

for all rational q with $0 \leq q \leq 1$ (which is independent of q). Let

$$K_{\mathbf{1}}(s, s') := \begin{cases} 0, & s \neq s', \\ \delta_{\langle s, s \rangle}, & s = s' \end{cases}$$

(here 0 is the null measure). Then

$$\langle s, s' \rangle \models \mathbf{1} \Leftrightarrow s = s'.$$

Note that in general we did exclude modal constants, i.e., modal operators of arity 0, when defining modal similarity types, since they will not contribute to the discussion. The example shows that it is possible to include them nevertheless.

The next example will deal with a logic that is used for model checking. Since this logic (sometimes called **pCTL***) incorporates both temporal and probabilistic properties, we leave the strict realm of modal logic.

The example requires some preparations. Fix a Polish state space S and assume that a family $(K_n)_{n \in \mathbb{N}}$ of probabilistic relations $K_n : S \rightsquigarrow S$ is given with $K_n(s)(S) = 1$ for each $s \in S, n \in \mathbb{N}$. $K_n(s)$ governs the state transitions at time n when the system is in state $s \in S$. We will have to deal with path probabilities, so let $S^\infty := \prod_{n \in \mathbb{N}} S$ be the set of all S -sequences, which is a Polish space in the product topology (this is the smallest topology on S^∞ which contains all sets of the form $\prod_{n \in \mathbb{N}} G_n$ where $G_n = S$ for all but a finite number of n , and all G_n are open in S). Similarly, the Borel sets $\mathcal{B}(S^\infty)$ are the smallest σ -algebra on S^∞ which contains all sets of the form $\prod_{n \in \mathbb{N}} B_n$ where $B_n = S$ for all but a finite number of n , and all B_n are Borel sets in S ; S^n denotes the n -fold product of S .

Define inductively a sequence $K^n : S \rightsquigarrow S^n$ by setting $K^1 := K_1$, and for $s \in S, A \subseteq S^{n+1}$ measurable

$$K^{n+1}(s)(A) := \int_{S^n} K_{n+1}(s_n)(\{s_n | \langle s_1, \dots, s_n \rangle \in A\}) K^n(s)(d\langle s_1, \dots, s_n \rangle).$$

Since K_n specifies probabilistically the n th state transition, $K^n(s)(A)$ gives the probability that the sequence $\langle s_1, \dots, s_n \rangle$ is an element of A , provided the system was initially in state s .

It is not difficult to see that the sequence $(K^n(s))_{n \in \mathbb{N}}$ forms an inverse system for each state $s \in S$, since for the measurable subset $A \subseteq S^n$ and for $s \in S$ the equality

$$K^{n+1}(s)(A \times X) = K^n(s)(A)$$

holds for each $n \in \mathbb{N}$. Denote for $s \in S$ by $K^\infty(s)$ the inverse limit of the inverse system $(K^n(s))_{n \in \mathbb{N}}$ of probabilities; see section 2.1. Then we claim that $K^\infty : S \rightsquigarrow S^\infty$ defines a stochastic relation.

For establishing this, we have to demonstrate that for each Borel subset $B \subseteq S^\infty$ the map $s \mapsto K^\infty(s)(B)$ is measurable. In fact, consider the set

$$\mathcal{S} := \{B \in \mathcal{B}(S^\infty) \mid s \mapsto K^\infty(s)(B) \text{ is measurable}\}.$$

Then \mathcal{S} is a σ -algebra which contains all sets of the form $\prod_{n \in \mathbb{N}} B_n$ where $B_n = S$ for all but a finite number of n , and all B_n are Borel sets in S . This is so since by construction

$$K^\infty(s) \left(\prod_{n \in \mathbb{N}} B_n \right) = K^m(s)(B_1 \times \dots \times B_m),$$

where m is an index such that $B_k = S$ for all $k > m$. Thus \mathcal{S} contains the generator for $\mathcal{B}(S^\infty)$, and since \mathcal{S} is comprised of Borel sets, \mathcal{S} must equal the Borel σ -algebra of S^∞ .

It may be noted that this representation is a bit simplistic in that a transition is assumed to be possible between two arbitrary states. Actually, one constructs an infinite tree from a relation modelling a more restricted transition graph. But this would have only increased the technical complexity without adding to the example.

Example 5.5. Model checking is a popular technique for verifying system properties. It is used in connection with stochastic techniques for the verification of non-functional properties in distributed systems; see, e.g., [4] where we show how the stochastic framework in the latter paper can be encoded in the approach proposed here. For a similar logic, see [2, 8]. An approach based on the mu-calculus is presented in [21] and could be dealt with in a similar way (this requires dealing appropriately with the \mathbb{E} -operator discussed in that paper).

A state formula ψ is given through the syntax

$$\psi ::= p \mid \top \mid \psi_1 \wedge \psi_2 \mid \neg\psi \mid [\varphi_1 \mathcal{U}_{\sim c} \varphi_2] \bowtie q,$$

where φ is given through

$$\varphi ::= p \mid \top \mid \varphi_1 \wedge \varphi_2$$

(here $p \in P, c \in \mathbb{N} \cup \{0\}, q \in \mathbb{Q} \cap [0, 1]$, and \sim, \bowtie are relational symbols from $\{<, >, \leq, \geq\}$).

A state formula $[\varphi_1 \mathcal{U}_{\sim c} \varphi_2] \bowtie q$ can only be used on the top level and cannot be nested. Various modal operators may be obtained as special cases, e.g., $\diamond_q \psi$ as $[\top \mathcal{U} \geq 0 \psi] \leq q$.

Validity for a state formula which does not contain the until operator is given in the usual way, and if σ is a path, then

$$\sigma \models [\varphi_1 \mathcal{U}_{\sim c} \varphi_2] \geq 1 \Leftrightarrow \exists x \sim c : (\sigma_x \models \varphi_2 \wedge \forall y \in [0, x[: \sigma_y \models \varphi_1)$$

(here σ_k is the k th component of σ).

For modelling validity of the \mathcal{U} -operator on paths, we assume that we are given a stochastic relation $K : S \rightsquigarrow S$. Construct from K the inverse system $K^n : S \rightsquigarrow S^n$, and let $K^\infty : S \rightsquigarrow S^\infty$ be the stochastic relation corresponding to the inverse limit of this system. Then we set

$$s \models [\varphi_1 \mathcal{U}_{\sim c} \varphi_2] \bowtie q \Leftrightarrow K^\infty(s) (\{\sigma \in S^\infty \mid \sigma^1 = s \wedge \sigma \models [\varphi_1 \mathcal{U}_{\sim c} \varphi_2] \geq 1\}) \bowtie q.$$

In this way satisfaction of state formulas through the stochastic system generated from the relation K can be modeled.

This example requires the construction of the inverse limit as a stochastic relation that relates states to infinite sequences of states which is in addition compatible with the transitions being done in each step.

5.2. Refinements. Given a nondeterministic and a stochastic interpretation, we want to compare both. Intuitively, the stochastic interpretation is more precise than its nondeterministic cousin, whereas nondeterministically we can only talk about possibilities (we can assign weights to these possibilities using probabilities). To say that after a certain input the output put will be a , b , or c conveys certainly less

information than saying that the probabilities for these outputs will be, resp., $p(a) = 1/100$, $p(b) = 1/50$, and $p(c) = 97/100$.

Since negation has its own problems, we will restrict ourselves to the negation free logic $\mathfrak{Mod}_1(\tau, P)$ and will deal with probabilistic relations (see section 2.2: the whole space is always assigned probability one).

DEFINITION 5.3. *Let \mathcal{R} and \mathcal{K} be a nondeterministic and a stochastic τ -Kripke model, resp., and assume that $K_\Delta(s)(S \times \cdots \times S^{\rho(\Delta)}) = 1$ holds for each $s \in S$ (we will call these models probabilistic). \mathcal{K} is said to refine \mathcal{R} ($\mathcal{K} \vdash \mathcal{R}$) iff*

$$\forall \varphi \in \mathfrak{Mod}_1(\tau, P) : \llbracket \varphi \rrbracket_{\mathcal{K}} \subseteq \llbracket \varphi \rrbracket_{\mathcal{R}}.$$

Consequently, given the interpretations \mathcal{K} and \mathcal{R} , we have $\mathcal{K} \vdash \mathcal{R}$ if $\mathcal{R}, s \models \varphi$ holds only if $\mathcal{K}, s \models \varphi$ is true for each formula φ in the negation free part of the logic.

We will investigate here the relationship between nondeterministic and stochastic satisfaction by showing that for each stochastic interpretation \mathcal{K} we can find a nondeterministic one \mathcal{R} with $\mathcal{K} \vdash \mathcal{R}$ by simply taking all possible state changes and making it into a Kripke model. Conversely, we will look into the possibility of refining a given nondeterministic Kripke model into a stochastic model. This requires some topological assumptions (for otherwise the notion of *all possible states* cannot be made precise). Thus from now on the state space S is a Polish space with its Borel sets as σ -algebra.

The set of all states possible for a probability μ on a Polish space X is captured through the support of a probability μ : Define $\text{supp}(\mu)$ as the smallest closed subset $F \subseteq X$ such that $\mu(F) = 1$; thus

$$\text{supp}(\mu) = \bigcap \{F \subseteq X \mid F \text{ is closed and } \mu(F) = 1\}.$$

It can be shown that $\mu(\text{supp}(\mu)) = 1$, and $x \in \text{supp}(\mu)$ iff $\mu(U) > 0$ for each neighborhood U of x ; this is exactly what we want.

PROPOSITION 5.4. *Let $\mathcal{K} = (S, (K_\Delta)_{\Delta \in O}, V)$ be a probabilistic τ -Kripke model. Define for the modal operator $\Delta \in O$ the set-valued map*

$$R_\Delta^{\mathcal{K}}(s) := \text{supp}(K_\Delta(s)).$$

Put

$$\mathcal{R}_{\mathcal{K}} := \left(S, (R_\Delta^{\mathcal{K}})_{\Delta \in O}, V \right);$$

then \mathcal{K} is a probabilistic refinement of $\mathcal{R}_{\mathcal{K}}$.

Proof. The proof proceeds by induction on the structure of the formulas. Assume that Δ is a modal operator and that we know that

$$\llbracket \varphi_i \rrbracket_{\mathcal{K}} \subseteq \llbracket \varphi_i \rrbracket_{\mathcal{R}_{\mathcal{K}}}$$

for $1 \leq i \leq \rho(\Delta)$. Now suppose

$$R_\Delta^{\mathcal{K}}, s \not\models \Delta_1(\varphi_1, \dots, \varphi_{\rho(\Delta)})$$

for some state s . Thus

$$R_\Delta^{\mathcal{K}}(s) \cap \llbracket \varphi_1 \rrbracket_{\mathcal{R}_{\mathcal{K}}} \times \cdots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{R}_{\mathcal{K}}} = \emptyset,$$

and, consequently, by the hypothesis,

$$R_{\Delta}^{\mathcal{K}}(s) \cap \llbracket \varphi_1 \rrbracket_{\mathcal{R}} \times \cdots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{R}} = \emptyset.$$

But this means

$$K_{\Delta}(s)(\llbracket \varphi_1 \rrbracket_{\mathcal{R}} \times \cdots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{R}}) < 1;$$

hence

$$\mathcal{K}, s \not\models \Delta_1(\varphi_1, \dots, \varphi_{\rho(\Delta)}). \quad \square$$

Thus each probabilistic Kripke model carries a nondeterministic one with it, and it refines this companion (one is tempted to perceive this as a *nondeterministic shadow*: a shadow as a coarser, black-and-white image of a probably more colorful, picturesque, and graphic original).

It will be shown now that the converse of Proposition 5.4 is also true: Given a nondeterministic Kripke model, there exists a stochastic one refining it. Intuitively, and in the finite case, one simply assigns a uniform weight as a probability to all possible outcomes. This is basically what we will do here, too, but we have to be a bit more careful since in an uncountable setting this idea requires some additional underpinning.

It is immediate that the support yields a measurable relation for a probabilistic relation $K : Y \rightsquigarrow Z$: put

$$R_K := \{\langle y, z \rangle \in Y \times Z \mid z \in \text{supp}(K(y))\}.$$

Then

$$(\forall R_K)(F) = \{y \in Y \mid K(y)(F) = 1\}$$

is true for the closed set $F \subseteq Z$, and

$$(\exists R_K)(G) = \{y \in Y \mid K(y)(G) > 0\}$$

holds for the open set $G \subseteq Z$. Both sets are measurable.

It is also plain that a representation of R through a stochastic relation K which is given by

$$(*) \forall y \in Y : R(y) = \text{supp}(K(y))$$

implies that R has to be a measurable relation.

Given a set-valued relation R , a probabilistic relation K with $(*)$ can be found. For this, R has to take closed values, and a condition of measurability is imposed. We obtain from [10] the following existential statement (which depends on the existence of a sufficient number of measurable selectors for a measurable relation; see Proposition 2.1).

LEMMA 5.5. *Let $R \subseteq Y \times Z$ be a measurable relation for Z Polish. There exists a probabilistic relation $K : Y \rightsquigarrow Z$ such that $R(y) = \text{supp}(K(y))$ holds for each $y \in Y$.*

Thus we can find a probabilistic Kripke structure refining a given nondeterministic one, provided we impose a measurability condition.

PROPOSITION 5.6. *Suppose $\mathcal{R} := (S, (R_{\Delta})_{\Delta \in O}, V)$ is a nondeterministic τ -Kripke model such that*

1. $V(p) \in \mathcal{B}(S)$ for all $p \in P$,
2. R_Δ is a measurable relation on $S \times S^{\rho(\Delta)}$ for each $\Delta \in O$.

Then there exists a probabilistic τ -Kripke model $\mathcal{K} = (S, (K_\Delta)_{\Delta \in O}, V)$ with $\mathcal{K} \vdash \mathcal{R}$.

Proof. Applying Lemma 5.5, find for each modal operator $\Delta \in O$ a transition probability $K_\Delta : S \rightsquigarrow S^{\rho(\Delta)}$ such that

$$\forall s \in S : R_\Delta(s) = \text{supp}(K_\Delta(s))$$

holds. The argumentation in the proof of Lemma 5.4 establishes the claim. \square

It is clear that the probabilistic τ -Kripke model is underspecified by merely requiring to be a refinement to a nondeterministic one. This is supported through the following corollary.

COROLLARY 5.7. *Let \mathcal{R} be a nondeterministic τ -Kripke model satisfying the conditions of Proposition 5.6. Assume that $\mathcal{K}_i = (S, (K_{\Delta,i})_{\Delta \in O}, V)$ is a probabilistic τ -Kripke model with $\mathcal{K}_i \vdash \mathcal{R}$ for each $i \in \mathbb{N}$. Let $(\alpha_i)_{i \in \mathbb{N}}$ be a sequence of positive real numbers such that $\sum_{i \in \mathbb{N}} \alpha_i = 1$, and define for $\Delta \in O$ the stochastic relation*

$$K_\Delta(s) := \sum_{i \in \mathbb{N}} \alpha_i \cdot K_{\Delta,i}(s).$$

Then

$$(S, (K_\Delta)_{\Delta \in O}, V) \vdash \mathcal{R}.$$

Proof. 1. Let $(\mu_i)_{i \in \mathbb{N}}$ be a sequence of probability measures. Since all α_i are positive, the definition of the support function yields that

$$\text{supp} \left(\sum_{i \in \mathbb{N}} \alpha_i \cdot \mu_i \right) = \left(\bigcup_{i \in \mathbb{N}} \text{supp}(\mu_i) \right)^{\text{cl}}$$

holds, $(\cdot)^{\text{cl}}$ denoting topological closure. Thus R_Δ equals $\text{supp}(K_\Delta)$.

2. The assertion now follows from Proposition 5.6. \square

Thus we know not only that a probabilistic τ -Kripke model is the refinement of a probabilistic one, but also that refinements offer a considerable degree of freedom, because they are closed under countable convex combinations (in fact, it can also be shown that it is closed under integration as the generalization of convex combinations). This supports the intuitive feeling that a probabilistic model conveys much more information than a nondeterministic one, but that it is also much harder to obtain.

6. Bisimulations for Kripke models. This section investigates morphisms for stochastic τ -Kripke models; we want to know whether bisimilarity and mutually identical theories are equivalent also for this general case. To this end we first discuss morphisms that are based on morphisms for stochastic relations (after all, a τ -Kripke model contains a family of stochastic relations), indicate that this notion of morphism is not adequate for our purposes, and propose the notion of a strong morphism. We show that strong morphisms are suitable for our purposes.

Fix the modal similarity type $\tau = (O, \rho)$ again. Assume first that the set P of propositional letters is empty, rendering the initial discussion a bit less technical. Then a stochastic τ -Kripke model $\mathcal{K} := (S, (K_\Delta)_{\Delta \in O})$ is determined through the

Polish state space S and the family $K_\Delta : S \rightsquigarrow S^{\rho(\Delta)}$ of stochastic relations. A morphism

$$\Phi : (S, (K_\Delta)_{\Delta \in O}) \rightarrow (S', (K'_\Delta)_{\Delta \in O})$$

for stochastic τ -Kripke models is then a family

$$\Phi = ((\phi_\Delta, \psi_\Delta)_{\Delta \in O})$$

of morphisms

$$(\phi_\Delta, \psi_\Delta) : (S, S^{\rho(\Delta)}, K_\Delta) \rightarrow (S', (S')^{\rho(\Delta)}, K'_\Delta)$$

for the associated relations.

Consider a modal operator Δ . The σ -algebra \mathcal{A}_Δ generated by

$$\{[\![\varphi_1]\!]_{\mathcal{K}} \times \cdots \times [\![\varphi_{\rho(\Delta)}]\!]_{\mathcal{K}} \mid \varphi_1, \dots, \varphi_{\rho(\Delta)} \in \mathfrak{Mod}_s(\tau, P)\}$$

is evidently countably generated, thus giving rise to a smooth equivalence relation β_Δ on $S^{\rho(\Delta)}$, and the relation

$$s\alpha_\Delta s' \Leftrightarrow \forall B \in \mathcal{A}_\Delta : K_\Delta(s)(B) = K_\Delta(s')(B)$$

is smooth due to \mathcal{A}_Δ being countably generated. Consequently, $(\alpha_\Delta, \beta_\Delta)$ is a congruence for $K_\Delta : S \rightsquigarrow S^{\rho(\Delta)}$, and if \mathcal{K} is nondegenerate, this congruence is nontrivial.

Let $\mathcal{K}' = (S', (K'_\Delta)_{\Delta \in O})$ be another τ -Kripke model which is equivalent to the first one in the sense that for the states the corresponding theories mutually coincide; the following definition will be more precise.

DEFINITION 6.1. *The stochastic τ -Kripke models \mathcal{K} and \mathcal{K}' are said to be equivalent ($\mathcal{K} \sim \mathcal{K}'$) iff given $s \in S$ there exists $s' \in S'$ such that $Th_{\mathcal{K}}(s) = Th_{\mathcal{K}'}(s')$ and vice versa.*

Assume both \mathcal{K} and \mathcal{K}' are nondegenerate. Construct for \mathcal{K}' the congruence $(\alpha'_\Delta, \beta'_\Delta)$ for each modal operator Δ as above; then it can be shown that $\mathcal{K} \sim \mathcal{K}'$ implies that the congruences $(\alpha_\Delta, \beta_\Delta)$ and $(\alpha'_\Delta, \beta'_\Delta)$ are equivalent. From Proposition 4.5 we see that K_Δ and K'_Δ are bisimilar for each modal operator Δ , so that there exists a span of morphisms

$$(S, S^{\rho(\Delta)}, K_\Delta) \xleftarrow{(\phi_\Delta, \psi_\Delta)} (A_\Delta, B_\Delta, M_\Delta) \xrightarrow{(\phi'_\Delta, \psi'_\Delta)} (S', (S')^{\rho(\Delta)}, K'_\Delta).$$

This is rather satisfying from the point of view of stochastic relations, but not when considering stochastic τ -Kripke models. This is so since in general $((A_\Delta, B_\Delta, M_\Delta)_{\Delta \in O})$ fails to be such a model because there is no way to guarantee that all A_Δ coincide with, say, a Polish space T , and so that B_Δ equals $T^{\rho(\Delta)}$.

Consequently, we have to strengthen the requirements for a morphism in order to achieve some uniformity. This will be done now, and we admit propositional letters again.

The basic idea is to have just one map ϕ between the state spaces so that

$$K'_\Delta(\phi(s))(A) = K_\Delta(s)(\{\langle s_1, \dots, s_{\rho(\Delta)} \rangle \mid \langle \phi(s_1), \dots, \phi(s_{\rho(\Delta)}) \rangle \in A\})$$

holds for each state $s \in S$ and each Borel set $A \subseteq (S')^{\rho(\Delta)}$, making the diagram

$$\begin{array}{ccc} S & \xrightarrow{\phi} & S' \\ K_{\Delta} \downarrow & & \downarrow K'_{\Delta} \\ \mathfrak{S}(S^{\rho(\Delta)}) & \xrightarrow{\mathfrak{S}(\phi^{\rho(\Delta)})} & \mathfrak{S}((S')^{\rho(\Delta)}) \end{array}$$

commutative (where $\phi^n : \langle x_1, \dots, x_n \rangle \mapsto \langle \phi(x_1), \dots, \phi(x_n) \rangle$ distributes ϕ into the components), and we want to have $s \in V(p)$ iff $\phi(s) \in V'(p)$ for each propositional letter. This leads to the following definition.

DEFINITION 6.2. Let $\mathcal{K} := (S, (K_{\Delta})_{\Delta \in O}, V)$ and $\mathcal{K}' := (S', (K'_{\Delta})_{\Delta \in O}, V')$ be stochastic τ -Kripke models. A strong morphism $\phi : \mathcal{K} \rightarrow \mathcal{K}'$ is determined through a measurable and surjective map $\phi : S \rightarrow S'$ so that these conditions are satisfied:

1. $\forall p \in P : V(p) = \phi^{-1}[V'(p)]$,
2. for each modal operator Δ ,

$$K'_{\Delta} \circ \phi = \mathfrak{S}(\phi^{\rho(\Delta)}) \circ K_{\Delta}$$

holds.

Thus, if $\phi : \mathcal{K} \rightarrow \mathcal{K}'$ is a strong morphism, then

$$(\phi, \phi^{\rho(\Delta)}) : (S, S^{\rho(\Delta)}, K_{\Delta}) \rightarrow (S', (S')^{\rho(\Delta)}, K'_{\Delta})$$

is a morphism between the corresponding stochastic relations for each modal operator $\Delta \in O$. Note that we also take the propositional letters into account.

It is clear that stochastic τ -Kripke models over general measurable spaces form a category **pKripke** with this notion of morphism, because the composition of strong morphisms is again a strong morphism, and because the identity is a strong morphism, too. Furthermore, each modal operator Δ induces a functor $F_{\Delta} : \mathbf{pKripke} \rightarrow \mathbf{Stoch}$ which forgets all but K_{Δ} . We will below make (rather informal) use of this functor.

Because we work on the safe grounds of a category, we have bisimulations at our disposal, which can be defined again as spans of strong morphisms.

DEFINITION 6.3. The stochastic τ -Kripke models \mathcal{K}_1 and \mathcal{K}_2 are called strongly bisimilar iff

1. there exist a mediating stochastic τ -Kripke model \mathcal{M} and strong morphisms

$$\mathcal{K}_1 \xleftarrow{\phi_1} \mathcal{M} \xrightarrow{\phi_2} \mathcal{K}_2,$$

2. the σ -algebra

$$\phi_1^{-1}[\mathcal{B}(S_1)] \cap \phi_2^{-1}[\mathcal{B}(S_2)]$$

is nontrivial (here S_i is the state space of \mathcal{K}_i , $i = 1, 2$).

Since the product σ -algebra is the smallest σ -algebra which contains all the measurable rectangles, it is not difficult to see that

$$\phi_1^{-1}[\mathcal{B}(S_1)] \cap \phi_2^{-1}[\mathcal{B}(S_2)]$$

is nontrivial iff for each modal operator $\Delta \in O$ the σ -algebra

$$\bigotimes_{i=1}^{\rho(\Delta)} \phi_1^{-1} [\mathcal{B}(S_1)] \cap \bigotimes_{i=1}^{\rho(\Delta)} \phi_2^{-1} [\mathcal{B}(S_2)]$$

is nontrivial. Thus condition 2 in Definition 6.3 will imply that this notion of bisimilarity is compatible to the one used for stochastic relations in general.

We will show that $\mathcal{K} \sim \mathcal{K}'$ iff \mathcal{K} and \mathcal{K}' are strongly bisimilar, provided the models are based on Polish spaces. Fix the stochastic τ -Kripke models $\mathcal{K} := (S, (K_\Delta)_{\Delta \in O}, V)$ and $\mathcal{K}' := (S', (K'_\Delta)_{\Delta \in O}, V')$.

It is well known that morphisms preserve theories for the Hennessy–Milner logic [6]. This is also true for stochastic relations.

LEMMA 6.4. *If $\phi : \mathcal{K} \rightarrow \mathcal{K}'$ is a strong morphism, then*

$$Th_{\mathcal{K}}(s) = Th_{\mathcal{K}'}(\phi(s))$$

holds for all states $s \in S$.

Proof. 1. We show by induction on the formula $\varphi \in \mathfrak{Mod}_s(\tau, P)$ that

$$\mathcal{K}, s \models \varphi \Leftrightarrow \mathcal{K}', \phi(s) \models \varphi$$

holds; putting it slightly differently, we want to show that

$$(*) \llbracket \varphi \rrbracket_{\mathcal{K}} = \llbracket \varphi \rrbracket_{\mathcal{K}'}$$

for all these φ .

2. If $\varphi = p \in P$, this follows from $V(p) = \phi^{-1}[V'(p)]$. The interesting case in the induction step is the application of an n -ary modal operator Δ_q with rational q . Suppose the assertion is true for $\llbracket \varphi_1 \rrbracket_{\mathcal{K}}, \dots, \llbracket \varphi_n \rrbracket_{\mathcal{K}}$; then

$$\begin{aligned} \mathcal{K}, s \models \Delta_q(\varphi_1, \dots, \varphi_n) &\Leftrightarrow K_\Delta(s)(\llbracket \varphi_1 \rrbracket_{\mathcal{K}} \times \dots \times \llbracket \varphi_n \rrbracket_{\mathcal{K}}) \geq q \\ &\Leftrightarrow K_\Delta(s)((\phi^n)^{-1}[\llbracket \varphi_1 \rrbracket_{\mathcal{K}'} \times \dots \times \llbracket \varphi_n \rrbracket_{\mathcal{K}'}]) \geq q \quad (\dagger) \\ &\Leftrightarrow (\mathfrak{S}(\phi^n) \circ K_\Delta)(s)(\llbracket \varphi_1 \rrbracket_{\mathcal{K}'} \times \dots \times \llbracket \varphi_n \rrbracket_{\mathcal{K}'})) \geq q \\ &\Leftrightarrow K'_\Delta(\phi(s))(\llbracket \varphi_1 \rrbracket_{\mathcal{K}'} \times \dots \times \llbracket \varphi_n \rrbracket_{\mathcal{K}'}) \geq q \quad (\ddagger) \\ &\Leftrightarrow \mathcal{K}', \phi(s) \models \Delta_q(\varphi_1, \dots, \varphi_n). \end{aligned}$$

In (\dagger) we use reformulation $(*)$ for the induction hypothesis, and in (\ddagger) we make use of the defining equation of a (strong) morphism. \square

Define the equivalence relation α on state space S through

$$s_1 \alpha s_2 \Leftrightarrow Th_{\mathcal{K}}(s_1) = Th_{\mathcal{K}}(s_2);$$

thus two states are α -equivalent iff they satisfy exactly the same formulas in $\mathfrak{Mod}_s(\tau, P)$; in a similar way α' is defined on S' . Because we have at most countably many formulas, α and α' are smooth equivalence relations. Define the equivalence relation β_Δ on $S^{\rho(\Delta)}$ through

$$\langle s_1, \dots, s_{\rho(\Delta)} \rangle \beta_\Delta \langle t_1, \dots, t_{\rho(\Delta)} \rangle \Leftrightarrow s_1 \alpha t_1 \wedge \dots \wedge s_{\rho(\Delta)} \alpha t_{\rho(\Delta)};$$

then β_Δ is smooth, and we know that the σ -algebra of β -invariant sets can be written in terms of the α -invariant sets, viz., $\mathcal{INV}(\mathcal{B}(S^{\rho(\Delta)}), \beta_\Delta) = \bigotimes_{i=1}^{\rho(\Delta)} \mathcal{INV}(\mathcal{B}(S), \alpha)$ (see Lemma 3.3). The relation β'_Δ is defined in the same way for α' .

The equivalence of \mathcal{K} and \mathcal{K}' makes these relations into equivalent congruences.

LEMMA 6.5. *If $\mathcal{K} \sim \mathcal{K}'$ for the nondegenerate Kripke models \mathcal{K} and \mathcal{K}' , then (α, β_Δ) and (α', β'_Δ) are equivalent and nontrivial congruences on the stochastic relations $F_\Delta(\mathcal{K})$ and $F_\Delta(\mathcal{K}')$.*

Proof. 1. The equivalence relations involved are all smooth, so it first has to be demonstrated that each pair indeed forms a congruence. Assume that $s_1 \alpha s_2$ holds; then

$$K_\Delta(s_1)(\llbracket \varphi_1 \rrbracket_{\mathcal{K}} \times \cdots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{K}}) = K_\Delta(s_2)(\llbracket \varphi_1 \rrbracket_{\mathcal{K}} \times \cdots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{K}})$$

follows (otherwise we could find a rational number q with $\mathcal{K}, s_1 \models \Delta_q(\varphi_1, \dots, \varphi_{\rho(\Delta)})$ but $\mathcal{K}, s_2 \not\models \Delta_q(\varphi_1, \dots, \varphi_{\rho(\Delta)})$ or vice versa). Because

$$\mathcal{B}_0 := \{\llbracket \varphi_1 \rrbracket_{\mathcal{K}} \times \cdots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{K}} \mid \varphi_1, \dots, \varphi_{\rho(\Delta)} \in \mathfrak{Mod}_s(\tau, P)\}$$

forms a generator for $\mathcal{INV}(\mathcal{B}(S^{\rho(\Delta)}), \beta_\Delta)$, we see that (α, β_Δ) is a congruence for $F_\Delta(\mathcal{K})$. The same arguments show that also (α', β'_Δ) is a congruence for $F_\Delta(\mathcal{K}')$.

2. $\mathcal{A}_0 := \{\llbracket \varphi \rrbracket_{\mathcal{K}} \mid \varphi \in \mathfrak{Mod}_s(\tau, P)\}$ is a countable generator of the σ -algebra $\mathcal{INV}(\mathcal{B}(S), \alpha)$, and since the logic is closed under conjunction, \mathcal{A}_0 is closed under finite intersections. Given $s \in S$ there exists $s' \in S'$ such that $Th_{\mathcal{K}}(s) = Th_{\mathcal{K}'}(s')$ holds; define $\Upsilon([s]_\alpha) := [s']_{\alpha'}$, and then $\Upsilon : S/\alpha \rightarrow S'/\alpha'$ is well defined, and $\Upsilon_{\llbracket \varphi \rrbracket_{\mathcal{K}}} = \llbracket \varphi \rrbracket_{\mathcal{K}'}$ holds. Consequently, $\{\Upsilon_A \mid A \in \mathcal{A}_0\}$ generates $\mathcal{INV}(\mathcal{B}(S'), \alpha')$, and the construction implies that

$$\bigcap \{\Upsilon_A \mid s \in A \in \mathcal{A}_0\} \cap \bigcap \{S' \setminus \Upsilon_A \mid s \notin A \in \mathcal{A}_0\} = [s']_{\alpha'}.$$

Hence α spawns α' via $(\Upsilon, \mathcal{A}_0)$.

3. The construction of β_Δ implies that

$$\langle [s_1, \dots, s_{\rho(\Delta)}] \rangle_{\beta_\Delta} = [s_1]_\alpha \times \cdots \times [s_{\rho(\Delta)}]_\alpha$$

holds. An argument very similar to that used above shows that β_Δ spawns β'_Δ via (Θ, \mathcal{B}_0) , where

$$\Theta : \langle [s_1, \dots, s_{\rho(\Delta)}] \rangle_{\beta_\Delta} \mapsto \Upsilon([s_1]_\alpha) \times \cdots \times \Upsilon([s_{\rho(\Delta)}]_\alpha),$$

and \mathcal{B}_0 is defined above.

4. An argumentation very close to the first part of the proof shows that $Th_{\mathcal{K}}(s) = Th_{\mathcal{K}'}(s')$ for $s \in S, s' \in S'$ implies for all formulas $\varphi_1, \dots, \varphi_{\rho(\Delta)}$ that

$$K_\Delta(s)(\llbracket \varphi_1 \rrbracket_{\mathcal{K}} \times \cdots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{K}}) = K'_\Delta(s')(\llbracket \varphi_1 \rrbracket_{\mathcal{K}'} \times \cdots \times \llbracket \varphi_{\rho(\Delta)} \rrbracket_{\mathcal{K}'})$$

(see part 2 of the proof of Lemma 6.4). Thus $(\alpha, \beta_\Delta) \times (\alpha', \beta'_\Delta)$, and in the same way, interchanging the roles of \mathcal{K} and \mathcal{K}' , we infer $(\alpha', \beta'_\Delta) \times (\alpha, \beta_\Delta)$.

5. Because \mathcal{K} is nondegenerate, the σ -algebra

$$\mathcal{INV}(\mathcal{B}(S), \alpha) = \sigma(\{\llbracket \varphi \rrbracket_{\mathcal{K}} \mid \varphi \in \mathfrak{Mod}_s(\tau, P)\})$$

is nontrivial. Because

$$\mathcal{INV}(\mathcal{B}(S^{\rho(\Delta)}), \beta_\Delta) = \bigotimes_{i=1}^{\rho(\Delta)} \mathcal{INV}(\mathcal{B}(S), \alpha),$$

we see that $\mathcal{I}NV(\mathcal{B}(S^{\rho(\Delta)}), \beta_\Delta)$ contains a set of the form $B^{\rho(\Delta)}$ for some B with $\emptyset \neq B \neq S$. Thus we may conclude that β_Δ is not the universal relation. Thus (α, β_Δ) is a nontrivial congruence. Replacing \mathcal{K} by \mathcal{K}' , this is also established for the congruence (α', β'_Δ) . This completes the proof. \square

Accordingly, we know from Proposition 4.5 that for equivalent Kripke models \mathcal{K} and \mathcal{K}' and for each modal operator Δ the stochastic relations $F_\Delta(\mathcal{K})$ and $F_\Delta(\mathcal{K}')$ are bisimilar. All the mediating relations can be collected to form a mediating Kripke model. This requires, however, that we have introductory knowledge of the internal structure of the semipullback which is constructed along the way, as we will see now in the proof of the following main result, the Hennessy–Milner theorem for stochastic τ -Kripke models.

THEOREM 6.6. *Assume that \mathcal{K} and \mathcal{K}' are nondegenerate stochastic τ -Kripke models over Polish spaces; then the following statements are equivalent:*

1. \mathcal{K} and \mathcal{K}' are strongly bisimilar,
2. $\mathcal{K} \sim \mathcal{K}'$.

Proof. 1. Since “1 \Rightarrow 2” follows from Lemma 6.4, we may concentrate on the proof for “2 \Rightarrow 1.”

2. Since $\mathcal{K} \sim \mathcal{K}'$, we know from Lemma 6.5 that the congruences (α, β_Δ) and (α', β'_Δ) are equivalent for each modal operator Δ . Let $\mathcal{M}_\Delta = (M_\Delta, N_\Delta, L_\Delta)$ be the mediating stochastic relation, which exists by Proposition 4.5. Theorem 2.2 shows that ($n := \rho(\Delta)$)

$$\begin{aligned} M_\Delta &= \{ \langle s, s' \rangle \in S \times S' \mid \langle s, \alpha + \alpha' \rangle s' \}, \\ N_\Delta &= \{ \langle s_1, s'_1, \dots, s_n, s'_n \rangle \in (S \times S')^n \mid s_i (\alpha + \alpha') s'_i \text{ for } 1 \leq i \leq n \}. \end{aligned}$$

These may be made into Polish spaces. Note that $S'' := M_\Delta$ does not depend at all on the modal operator, and that N_Δ depends only on its arity. Furthermore, we may infer for the **P** – **Stoch**-morphisms

$$F_\Delta(\mathcal{K}) \xleftarrow{f_\Delta} \mathcal{M}_\Delta \xrightarrow{f'_\Delta} F_\Delta(\mathcal{K}')$$

that

$$f_\Delta = (\pi_{1,S}, \pi_{1,S}^n), f'_\Delta = (\pi_{2,S'}, \pi_{2,S'}^n)$$

holds, where the π denote the projections. Now define for the propositional letter $p \in P$

$$W(p) := \{ \langle s, s' \rangle \in M_\Delta \mid s \in V(p), s' \in V'(p) \}.$$

Then it is immediate that the equations $W(p) = \pi_1^{-1}[V(p)] = \pi_2^{-1}[V'(p)]$ hold. Consequently, $\mathcal{M} := (S'', (L_\Delta)_{\Delta \in \mathcal{O}}, W)$ is a stochastic τ -Kripke model with

$$\mathcal{K} \xleftarrow{\pi_{1,S}} \mathcal{M} \xrightarrow{\pi_{2,S'}} \mathcal{K}'$$

in **pKripke**.

3. Finally, we need to show that the σ -algebra $\pi_{1,S}^{-1}[\mathcal{B}(S)] \cap \pi_{2,S'}^{-1}[\mathcal{B}(S')]$ is non-trivial. This is essentially the same argument as the one used in the third part of the proof of Proposition 4.5. Since \mathcal{K} is nondegenerate, we can find a formula φ with $\emptyset \neq \llbracket \varphi \rrbracket_{\mathcal{K}} \neq S$. The set $\llbracket \varphi \rrbracket_{\mathcal{K}}$ is an α -invariant Borel subset of S . We know from

the proof of Lemma 6.5 that α spawns α' via $(\Upsilon, \{\llbracket \varphi \rrbracket_{\mathcal{K}} \mid \phi \in \mathfrak{Mod}_{\mathfrak{s}}(\tau, P)\})$ for some suitably chosen Υ . Thus

$$\pi_{1,S}^{-1} [\llbracket \varphi \rrbracket_{\mathcal{K}}] = \pi_{2,S'}^{-1} [\Upsilon_{\llbracket \varphi \rrbracket_{\mathcal{K}}}] .$$

Consequently, we see that

$$\pi_{1,S}^{-1} [\llbracket \varphi \rrbracket_{\mathcal{K}}] \in \pi_{1,S}^{-1} [\mathcal{B}(S)] \cap \pi_{2,S'}^{-1} [\mathcal{B}(S')] .$$

Since $\emptyset \neq \llbracket \varphi \rrbracket_{\mathcal{K}} \neq S$ we conclude that $\emptyset \neq \pi_{1,S}^{-1} [\llbracket \varphi \rrbracket_{\mathcal{K}}] \neq M_{\Delta}$, and hence the σ -algebra in question is indeed not trivial. \square

Looking back at the development, it may be noted that Theorem 6.6 is derived from Proposition 4.5, hence from a condition that arose from the consideration of stochastic relations alone. This is in marked contrast to the proofs proposed in [6, 9] which start from the logic and develop the properties of equivalent congruences implicitly.

7. Related work. The investigation of congruences and their relationship to bisimilarity is new. Factoring stochastic relations has been introduced and studied in [11]. Special cases were considered in [6] and in [9] mainly in the realm of labeled Markov transition systems.

The research reported in [6] takes as a basic scenario an analytic state space and considers universally measurable transition functions. A Hennessy–Milner theorem is proved; the proof’s idea is to produce a cospan of morphisms through injections into a suitably factored sum. This idea has left its traces in various parts of the present paper. But the situation considered here is structurally subtly different: universal measurability, as assumed in [6], requires a somewhat elaborate completion process using all finite measures on that space. The present paper requires as a measurable structure merely the Borel sets of an analytic space. They are structurally much simpler and do not need additional considerations, since they are given through the morphisms of measurable spaces and nothing else (so one could work with them even if one would want to do without the real numbers). This more general approach has become possible through the observation that semipullbacks exist on analytic spaces with their Borel sets (a result that was not yet available for [6]). Desharnais and Panangaden [8] use an interplay between bisimulations (which are called here congruences) for showing that the logic *continuous time stochastic logic* which is discussed in [2] for model checking has also a property similar to the one discussed in Theorem 6.6: two states in a Markov process for the language satisfy the same formula from a given closed set F of formulas iff they are F -bisimilar [8, Theorem 6.3]. This is proved directly, without the benefit of a general criterion for bisimilarity.

In [9] a generalization of [6] is established for those labeled Markov transition systems which work over a Polish (rather than an analytic) state space and which have a certain smallness property. Technically, this property makes sure that the factor space is well behaved again. This technical condition is lifted in the present paper. This is so since general analytic spaces are considered, and the technique of factoring stochastic relations is better understood. Apart from a much wider class of modal logics which can be dealt with now (as witnessed in section 5.1), the present paper proposes a more general technical approach.

A stochastic relation $S \rightsquigarrow S$ may be considered as a coalgebra for the subprobability functor \mathfrak{S} on the category of analytic spaces; hence there are some ties to coalgebras. In [20] the probability functor \mathfrak{P} is considered on measurable spaces

that are endowed with the initial σ -algebra for the evaluation mapping $\mu \mapsto \mu(E)$. Given a discrete space I , final coalgebras for a functor derived from \mathfrak{P} yielding a type space over category \mathbf{Meas}^I are discussed, where \mathbf{Meas} is the category of measurable spaces with measurable maps as morphisms. Besides establishing the existence of a final coalgebra for the functor through satisfied theories, the main result states that functors polynomial in the original type functor have final coalgebras, too. In [5] coalgebraic simulation is considered, and one of the application areas for the discussion is probabilistic transition systems. They are modeled as coalgebras for the functor that assigns each set its discrete probability measures.

8. Conclusion and further work. The main technical result of this paper is the characterization of bisimilarity through suitable congruences, and through isomorphic factors. It bears fruit in establishing a Hennessy–Milner theorem for stochastic interpretations of modal logic. This paper proposes these contributions.

1. The notion of equivalent congruences is introduced and studied. Stochastic relations having equivalent congruences are shown to be bisimilar. As a corollary it is shown that isomorphic factors imply bisimilarity, too. It is shown that bisimilar relations also have isomorphic factor spaces, but this depends on a rather strong topological condition. We conjecture that the existence of isomorphic factor spaces and bisimilarity are equivalent for generic analytic spaces.

2. Stochastic Kripke models are introduced as a generalization of the well-known labeled Markov transition systems for general modal logics. A refinement relation between these models and their nondeterministic counterparts is investigated.

3. For stochastic Kripke models we propose the notion of a strong morphism, and, correspondingly, of strong bisimulations. A stochastic version of the Hennessy–Milner theorem of the equivalence of bisimilarity and mutually identical theories is established.

Examples show how some popular logics are interpreted through a stochastic Kripke model, and this opens the avenue for further research. It should be interesting to see how other modal logics are interpreted. A prime candidate is propositional dynamic logic (PDL) with its rich interaction among the modal operators that would have to be reflected in a suitable structure for the stochastic relations interpreting it. Investigating the interrelationship among a probabilistic interpretation, Kozen’s semantics of probabilistic programs [16], and probabilistic predicate transformers [19] is expected to give new insights into PDL as well as probabilistic program semantics and, incidentally, the algebraic properties of stochastic relations.

As the work in [2, 8] witnesses, that there are interesting links among stochastic relations, Markov processes, and model checking. It will be most helpful for model checking, and for a better understanding of probabilistic processes, to study this link closely.

Acknowledgments. The author appreciates and wants to thank the referees for providing insightful comments and suggestions which helped improve the paper.

SUBLINEAR GEOMETRIC ALGORITHMS*

BERNARD CHAZELLE[†], DING LIU[†], AND AVNER MAGEN[‡]

Abstract. We initiate an investigation of sublinear algorithms for geometric problems in two and three dimensions. We give optimal algorithms for intersection detection of convex polygons and polyhedra, point location in two-dimensional triangulations and Voronoi diagrams, and ray shooting in convex polyhedra, all of which run in expected time $O(\sqrt{n})$, where n is the size of the input. We also provide sublinear solutions for the approximate evaluation of the volume of a convex polytope and the length of the shortest path between two points on the boundary.

Key words. sublinear algorithms, approximate shortest paths, polyhedral intersection

1. Introduction. As an outgrowth of the recent work on property testing, the study of sublinear algorithms has emerged as a field unto itself, and great strides have been made in the context of graph and combinatorial problems [30]. Large geometric datasets often call for algorithms that examine only a small fraction of the input, but it is fair to say that sublinear computational geometry is still largely uncharted territory. If preprocessing is allowed, then, of course, this is an entirely different story [3, 23]. For example, checking whether a point lies in a convex 3-polyhedron can be done in logarithmic time with linear preprocessing. However, little of this technology is of any use with massive datasets, since examining the whole input—let alone preprocessing it—is out of the question. Sublinear algorithms have been given for dynamic problems [17] or in situations where a full multidimensional data structure is available [10]. There has also been work on geometric property testing, both in an approximate [11, 12, 18] and exact [24] setting.

In this paper, sublinearity is understood differently. The input is taken to be in any standard representation with no extra assumptions. For example, a planar subdivision or a polyhedron is given in classical edge-based fashion (e.g., doubly connected edge list (DCEL), winged-edge), with *no extra preprocessing*. This implies that we can pick an edge at random in constant time, but we cannot sample randomly among the neighbors of a given vertex in constant time. Our motivation is twofold: (i) we seek the minimal set of computational assumptions under which sublinearity is achievable; (ii) the assumptions should be realistic and nonrestrictive. Note, for example, that sublinear separation algorithms for convex objects are known [6, 15], but all of them require preprocessing, so they fall outside our model. Under these conditions one might ask whether there exist any interesting “offline” problems that can be solved in sublinear time. The answer is yes. Note that randomization is a necessity be-

cause, in a deterministic setting, most problems in computational geometry require looking at the entire input. There has been some (but little) previous work on sub-linear geometric algorithms as we define them, specifically point location in two- and three-dimensional Delaunay triangulations of sets of random points [14, 27]. As far as we know, however, these are the only works that fall inside our model. Here is a summary of our results. In all cases, n denotes the input size, and all polyhedra are understood to be in \mathbf{R}^3 :

- an optimal $O(\sqrt{n})$ time algorithm for checking whether two convex polyhedra intersect, reporting an intersection point if they do and a separating plane if they do not;
- optimal $O(\sqrt{n})$ time algorithms for point location in planar convex subdivisions with $O(1)$ maximum face size and two-dimensional Voronoi diagrams, finding the nearest neighbor on a convex polyhedron, and ray shooting-type problems in convex polyhedra.

In contrast with property testing, it is important to note that our algorithms never err. All the algorithms are of Las Vegas type, and randomization affects the running time but not the correctness of the output.¹ Devroye, Mücke, and Zhu [14] showed that a simple technique for point location in two-dimensional Delaunay triangulations, namely random sampling then walking from the nearest sample to the query, has expected running time (roughly) $O(n^{1/3})$ for n random input points and a random query. This does not contradict the optimality of our $O(n^{1/2})$ bound because the points must be chosen randomly in [14].

We also consider optimization problems for which approximate solutions are sought. We give

- an $O(\varepsilon^{-1}\sqrt{n})$ time algorithm for approximating the volume of a convex polytope with arbitrary relative error $\varepsilon > 0$;
- an $O(\varepsilon^{-5/4}\sqrt{n}) + f(\varepsilon^{-5/4})$ time algorithm for approximating the length of the shortest path between two points on the boundary of a convex polyhedron with arbitrary relative error $\varepsilon > 0$. Here, $f(n)$ denotes the complexity of the exact version of problem. This implies that the complexity of our algorithm is $O(\sqrt{n})$ for any fixed $\varepsilon > 0$.

The shortest path problem for polyhedral surfaces has been extensively studied, drawing its motivation from applications in route planning, injection molding, and computer assisted surgery [1, 21, 26]. In the convex case (the one at hand), an $O(n^3 \log n)$ algorithm was given by Sharir and Schorr [32], later improved by Mitchell, Mount, and Papadimitriou [25] to $O(n^2 \log n)$ and by Chen and Han [7] to $O(n^2)$; therefore, it is known that $f(n) = O(n^2)$. More recently, Kapoor [22] has announced a proof that $f(n) = O(n \log^2 n)$, which would make our algorithm run in time $O(\varepsilon^{-5/4}\sqrt{n})$. This improves on Agarwal et al.'s algorithm [2], which runs in $O(n \log \varepsilon^{-1} + \varepsilon^{-3})$ time for any $\varepsilon > 0$.

Our method makes progress on an important geometric problem of independent interest.

- Given a convex polytope P of n vertices, how many vertices must an enclosing polytope Q have if it is to approximate any (large enough) shortest path on ∂P with relative error at most ε ? We reduce to $O(\varepsilon^{-5/4})$ the best previous bound of $O(\varepsilon^{-3/2})$, due to Agarwal et al. [2].

¹Throughout this paper, unless specified otherwise, the running times are understood in the expected sense.

A Flavor of the Techniques. As a warmup exercise, consider the classical *successor searching* problem: Given a sorted (doubly linked) list of n keys and a number x , find the smallest key $y \geq x$ (the *successor* of x) in the list or report that none exists. It is well known that this smallest key can be found in $O(\sqrt{n})$ expected time [19]. For this, we choose \sqrt{n} list elements at random and find the predecessor and successor of x among those. (Perhaps only one exists.) This provides an entry point into the list, from which a naive search takes us to the successor. To make random sampling possible, we may assume that the list elements are stored in consecutive locations (say, in a table). However—and this is the key point—no assumption is made on the ordering of the elements in the table. (Otherwise we could do a binary search.)

LEMMA 1.1. *Successor searching can be done in $O(\sqrt{n})$ expected time per query, which is optimal.*

Proof. For $i \geq 1$, let Q_i be the set of all elements that are at distance at most i away from the answer on the list (in either direction). Let $P_{>i}$ be the probability of not hitting Q_i after \sqrt{n} random choices of the list elements. The expected distance of the answer to its nearest neighbor in the random sample is $\sum_{i \geq 1} i(P_{>i-1} - P_{>i}) = \sum_{i \geq 0} P_{>i}$. This sum is upper bounded by $\sqrt{n} \sum_{c \geq 0} P_{>c\sqrt{n}} \leq \sqrt{n} \sum_{c \geq 0} (1 - c/\sqrt{n})^{\sqrt{n}} = \sqrt{n} \sum_{c \geq 0} 2^{-\Omega(c)} = O(\sqrt{n})$. This immediately implies that the expected time of the algorithm is $O(\sqrt{n})$.

For the lower bound, we use Yao’s minimax principle [33]. We fix a distribution on the input, and we lower-bound the expected complexity of any deterministic algorithm. We then have the same lower bound for randomized algorithms. The input is a linked list containing the numbers 1 through n in sorted order. In our model, the list is represented by a table $T[1 \dots n]$, with the i th element in the list stored in location $\sigma(i)$ of the table; hence, $T[\sigma(i)] = i$. The input distribution is formed by choosing the permutation σ uniformly from the symmetric group on n elements. In other words, all permutations are equally likely. The query is set to be n . In other words, the problem is to locate the last element in the list. A deterministic algorithm can be modeled as a sequence of steps of the following form: (A) pick a location $T[k]$ already visited and look up the next (or previous) item, i.e., $T[\sigma(i \pm 1)]$, where $k = \sigma(i)$; (B) compute a new index k and look up $T[k]$. Each step may involve the consideration of every piece of information gathered so far. In particular, in a B-step we may not consult either one of the adjacent items in the list before computing k (unless, of course, these items were visited earlier). In this way, $\sigma^{-1}(k)$ of a B-step is equally likely to lie anywhere in the portion of the list still unvisited. For this reason, after a A-steps and b B-steps, there is a probability at least $(1 - \frac{\sqrt{n+a+b}}{n})^b$ that none of the last \sqrt{n} elements in the list has been visited in a B-step. Right after the last B-step, either the total number of A- and B-steps exceeds \sqrt{n} or, with constant nonzero probability, at least \sqrt{n} A-steps (some of which may have already been taken) are required to reach the last element in the list. This immediately implies that the expected time of any deterministic algorithm is $\Omega(\sqrt{n})$. \square

We can generalize these ideas to polygon intersection. Given two convex polygons P and Q , with n vertices each, determine whether they intersect or not and, if they do, report one point in the intersection. We assume that P and Q are given by their doubly linked lists of vertices (or edges) such that each vertex points to its predecessor and successor in clockwise order. As in successor searching, we assume that the two lists are stored in two tables to allow random sampling.

Choose a random sample of r vertices from each polygon, and let $R_p \subseteq P$ and $R_q \subseteq Q$ denote the two corresponding convex hulls. By two-dimensional linear pro-

FIG. 1. *Intersecting two convex polygons.*

gramming, we can test R_p and R_q for intersection without computing them explicitly. This can be done probabilistically (or even deterministically) in linear time. There are many ways of doing that (see [5] for references). It is easy to modify the algorithm (of, say, [31]) so that in $O(r)$ time it reports a point in the intersection of R_p and R_q if there is one (in which case we are done) and a bitangent separating line \mathcal{L} otherwise (Figure 1). Let p be the vertex of R_p in \mathcal{L} , and let p_1, p_2 be its two adjacent vertices in P . We define a polygon C_p as follows. If neither p_1 nor p_2 is on the R_q side of \mathcal{L} , then C_p is the empty polygon. Otherwise, by convexity exactly one of them is (say, p_1). We walk along the boundary of P starting at p_1 , away from p , until we cross \mathcal{L} again. This portion of the boundary, clipped by the line \mathcal{L} , forms the convex polygon C_p . A similar construction for Q leads to C_q .

It is immediate that $P \cap Q \neq \emptyset$ if and only if P intersects C_q or Q intersects C_p . We check the first condition and, if it fails, check the second one. We restrict our explanation to the case of $P \cap C_q$. First, we check whether R_p and C_q intersect, again using a linear time algorithm for a linear program (LP), and return with an intersection point if they do. Otherwise, we find a line \mathcal{L}' that separates R_p and C_q and, using the same procedure as described above, we compute the part of P , denoted C'_p , on the C_q side of \mathcal{L}' . Finally, we test C'_p and C_q for intersection in time linear on their sizes, using an LP or any other straightforward linear-time algorithm for intersection detection of convex polygons. Correctness is immediate. The running time is $O(r + |C_p| + |C'_p| + |C_q| + |C'_q|)$. We can prove that $\mathbf{E}|C_p| = O(n/r)$. (The three-dimensional case discussed below will subsume this result, so there is no need for a proof now.) Similarly, $\mathbf{E}|C'_p| = \mathbf{E}|C_q| = \mathbf{E}|C'_q| = O(n/r)$. The overall complexity of the algorithm is $O(r + n/r)$, and choosing $r = \lfloor \sqrt{n} \rfloor$ gives the desired bound of $O(\sqrt{n})$.

To show optimality, consider the following distributions on pairs of polygons. One polygon is fixed, convex, and nondegenerate with one vertex in the origin and all other vertices below the x -axis. The other polygon (also convex and nondegenerate) has $n-1$ vertices above the x -axis, and one vertex, p , in the origin or in $(0, \delta)$, where δ is a positive number small enough so that p is the lowest vertex of the polygon. Moreover, the edges of this polygon are randomly ordered in the edge table. Clearly, these two polygons intersect if and only if p is in the origin. Since nothing in the structure of the input except the geometry of p reveals whether it is indeed the origin, any algorithm that detects intersection must have access to p . Now recall that the only operations allowed are the random sampling of edges and edge-traversing via links, which means

that, as in Lemma 1.1, an expected time of $\Omega(\sqrt{n})$ is needed to access p . Optimality of subsequent results follows these lines very closely and shall not be proved again. We have the following.

THEOREM 1.2. *To check whether two convex n -gons intersect can be done in $O(\sqrt{n})$ time, which is optimal.*

To put Theorem 1.2 in perspective, recall that the intersection of two convex polygons can be determined in logarithmic time if the vertices are stored in an array in cyclic order [6]. The key point of our result is that, in fact, a linked list is sufficient for sublinearity. Similarly, if polyhedra are preprocessed à la Dobkin and Kirkpatrick, then fast intersection detection is possible [15]. What we show below is that sublinearity is achievable even with no preprocessing at all. Again, we use a two-stage process: In the first stage we break up the problem into r subproblems of size roughly n/r and then identify which ones actually need to be solved; in the second stage we solve these subproblems in standard (i.e., nonsublinear) fashion. Their number is constant, and hence the square root complexity. What prevents us from solving these subproblems recursively is the model’s restriction to *global* random sampling. In other words, one can sample efficiently for the main problem but *not* for the subproblems.

2. Convex polyhedral intersections. Given two n -vertex convex polyhedra P and Q in \mathbf{R}^3 , the problem is to determine whether or not they intersect: If they do, then we should report a point in the intersection; otherwise, we should report a plane that separates them. We assume that a convex polyhedron is given in any classical edge-based fashion (e.g., DCEL, winged-edge) but with no extra preprocessing. The main structure is a table of edges that allows us to pick an edge at random in constant time. There are also two tables for vertices and faces. Moreover, these tables are interconnected via pointers to make various local operations possible. For example, each edge points to its two vertices and two adjacent faces. It also points to its predecessor and successor edges in its two adjacent faces. Such a structure is a standard representation for convex polyhedra in computational geometry. It allows us to traverse a portion of a convex polyhedron in a local fashion and in time linear in the number of edges visited.

Choose a random sample of $r = \lfloor \sqrt{n} \rfloor$ edges from P and Q , and let R_p and R_q denote the convex hulls of these random edges in P and Q , respectively. We do not compute R_p and R_q explicitly but merely use their vertices to get an LP as described in the last section for the case of polygons. We use this LP to detect the intersection of R_p and R_q in $O(r)$ time by invoking a linear-time algorithm for low-dimensional linear programming. We stop with a point of intersection if there is one. Otherwise, we find a separating plane \mathcal{L} that is tangent to both R_p and R_q . It is important to choose the plane \mathcal{L} in a canonical fashion. To do that, we set up the LP so as to maximize, say, the coefficient α in the equation² $\alpha x + \beta y + \gamma z = 1$ of \mathcal{L} .

Next, choose a plane π normal to \mathcal{L} and consider projecting P and Q onto it. (Of course, we do not actually do it.) Let p be a vertex of R_p in \mathcal{L} (there could be two of them, but not more, if we assume general position between P and Q), and let p^* be its projection onto π . We also project the neighbors of p in P onto π and get $p_1^*, p_2^*, \dots, p_k^*$. In other words, they are the set of vertices adjacent to p^* in the projection of P onto π . We test to see if any of them is on the R_q side of \mathcal{L} and identify one such point, p_1 , if the answer is yes (more on that below). If none of them

²With perturbation techniques, we can always assume general position, and hence avoid having a solution passing through the origin. We will also assume that the relative position of P and Q is general.

FIG. 2. The edges of P incident to p ; the thick lines form the random sample.

is on the R_q side, then we define C_p to be the empty polyhedron. This is because in this case, P is completely on the other side of \mathcal{L} . Otherwise, we construct the portion of P , denoted C_p , that lies on the R_q side of \mathcal{L} . Note that C_p is a convex polytope, not just the boundary of P cut off by \mathcal{L} . We compute C_p by using a standard flooding mechanism. Beginning at p_1 , we perform a depth-first search through the facial structure of P , restricted to the relevant side of \mathcal{L} . Because C_p is convex, the edges form a single connected component, so we never need to leave C_p . This allows us to build the entire facial representation of C_p in time proportional to its number of edges. From then on, the algorithm has the same structure as its polygonal counterpart; i.e., we compute C_p, C'_p, C_q, C'_q and perform the same sequence of tests.

The question is now, How do we find p_1 (if it exists)? To simplify the analysis, once we have p , we resample by picking r edges in P at random; let E be the subset of those incident to p . To find p_1 , we project on π all of the edges of E . If there exists an edge of E that is on the R_q side of \mathcal{L} , then we identify its endpoint as p_1 . Otherwise, all the edges of E lie on one side of \mathcal{L} . We then identify the two extreme ones (e and f in Figure 2); being extreme means that all the other projected edges of E lie in the wedge between e and f in π . Assume that e and f are well defined and distinct. Consider the cyclic list V of edges of P incident to p . The edges of E break up V into blocks of consecutive edges. It is not hard to prove that pp_1 lies in a block starting or ending with e or f if such a p_1 (as defined above) exists. So, we examine each of these relevant blocks (at most four) exhaustively. If e and f are not both distinct and well defined, we may simply search for p_1 by checking every edge of P incident to p .

THEOREM 2.1. *Two convex n -vertex polyhedra in \mathbf{R}^3 can be tested for intersection in $O(\sqrt{n})$ time; this is optimal.*

Proof. Optimality was already discussed in the polygonal case, and correctness follows from elementary convex geometry, so we limit our discussion to the complexity of the algorithm. Because of the resampling, the expected sizes of the blocks next to e and f (or, alternatively, the expected size of the neighborhood of p if the blocks are not distinct) are $O(n/r)$, so the running time is $O(r + n/r + \mathbf{E}(|C_p| + |C_q|))$, where $|C_p|$ (resp., $|C_q|$) denotes the number of edges of C_p (resp., C_q). We may exclude the other two terms $|C'_p|$ and $|C'_q|$, since our upper bound on $\mathbf{E}(|C_p| + |C_q|)$ will apply to them as well. Here is how to bound $\mathbf{E}(|C_p| + |C_q|)$ by $O(n/r)$.

We modify the sampling distribution a little. Then we argue that reverting back to the original setting does not change the asymptotic value of the upper bound. The modification is twofold: (i) we view $P \cup Q$ as a multiset M where each vertex appears as

many times as its number of incident edges; (ii) R_p and R_q are formed by picking each point of M independently with probability r/n and assigning points of P to R_p and points of Q to R_q . With respect to the modified distribution, $|C_p|+|C_q|$ is proportional to the number of constraints in M that violate the LP $\mathcal{P}(R_p, R_q)$ used to define \mathcal{L} (with each point of R_p and R_q defining a linear constraint). For technical reasons, we need to perturb M slightly to make it in general position. Specifically, we move each point of M away from its corresponding vertex in P or Q by an infinitesimal random amount, along the corresponding edge of P or Q . After this random perturbation, the size of the violation set of $\mathcal{P}(R_p, R_q)$ can only increase. To see this, note that constraints in M that violate $\mathcal{P}(R_p, R_q)$ before the perturbation continue to do so because the perturbation is infinitesimal; and constraints in M that lie on \mathcal{L} before the perturbation may violate the LP after the perturbation.

To bound the expected size of the violation set, we apply a result proved by Gärtner and Welzl [19] (and also by Clarkson [9]). Following the notation of the “Sampling Lemma” in [19], we let the ground set S be the (perturbed) set M . After sampling a set of points R from M randomly, we set up an LP $\alpha x + \beta y + \gamma z = 1$ that separates R_p and R_q . Note that in this LP, $\alpha, \beta,$ and γ are variables and (x, y, z) is a point in R . This LP is set up so as to maximize the variable α , whose optimum value is a function of R . We set the function ϕ in [19] to be α . Under this setting, the extreme elements of R_p and R_q are their vertices on the optimum separating plane (as implied by the above LP). Since M is in general position, any R_p and R_q have three extreme elements. The Sampling Lemma in [19] then implies that the expected size of the violation set is at most $3(n - r)/(r + 1) = O(n/r)$.

Let \mathcal{D} be the original distribution (the one used by the actual algorithm) with r replaced by $13r$. Of course, this scaling has no asymptotic effect on the upper bound for $\mathbf{E}(|C_p| + |C_q|)$. We define an intermediate distribution \mathcal{D}_1 by going through each edge (u, v) of $P \cup Q$ twice, selecting it with probability r/n , and then throwing into the sample both u and v , provided that the edge (u, v) has not yet been selected. (Note that this implies that u and v are kept out with probability $(1 - r/n)^2$.) There are at most $6n$ edges in P and Q , so the probability that a sample from \mathcal{D}_1 is of size less than $13r$ is overwhelmingly high. Since all equal-size subsets of edges are equally likely to be chosen, $\mathbf{E}_{\mathcal{D}}(|C_p| + |C_q|)$ is nonincreasing with the sample size, and so $\mathbf{E}_{\mathcal{D}}(|C_p| + |C_q|) = O(\mathbf{E}_{\mathcal{D}_1}(|C_p| + |C_q|))$. Let \mathcal{D}_2 denote the modified distribution used in the calculations. Observe that \mathcal{D}_2 is derived from \mathcal{D}_1 by picking only u if (u, v) is chosen the first time it is considered for selection and then only v if it is picked the second time around. By monotonicity, we then have $\mathbf{E}_{\mathcal{D}_1}(|C_p| + |C_q|) = O(\mathbf{E}_{\mathcal{D}_2}(|C_p| + |C_q|))$. This proves that the $O(n/r)$ bound holds in the original distribution used by the algorithm.

Recall that the running time is $O(r + n/r + \mathbf{E}(|C_p| + |C_q|))$, which is $O(r + n/r)$ by the above analysis. For $r = \lfloor \sqrt{n} \rfloor$ it is $O(\sqrt{n})$. \square

When the two convex polyhedra intersect, the algorithm reports a point in the intersection. On the other hand, when they are disjoint, we can report a plane that separates them. Here is a brief description on how to do that. Note that we cannot simply return a separating plane for C_p and C'_q (or C'_p and C_q) because it is not necessarily separating for P and Q . Instead, we resort to geometric duality to compute the desired plane in expected $O(\sqrt{n})$ time. In a standard geometric duality transform, a vertex in the primal space is mapped to a plane in the dual space and vice versa. Moreover, the upper (resp., lower) hull of a convex polyhedron is transformed to a lower (resp., upper) envelope [13]. When P and Q are disjoint, at least one of the following must be true: (1) there exists a plane above the upper hull of P and below

the lower hull of Q ; (2) there exists a plane below the lower hull of P and above the upper hull of Q . Since they are symmetric, it suffices to consider the first one. By duality, such a plane dualizes to a point in the common intersection of an upper and a lower envelope, which is itself a convex polyhedron. Although this polyhedron is not available explicitly, we have access to its geometric features (vertices, edges, etc.) in constant time via the corresponding features in the primal space. Hence we can apply the above algorithm to find, in $O(\sqrt{n})$ time, an intersection point which is the dual of a separating plane for P and Q .

It is important to note that an alternative to the above approach can be found in a general scheme to solve the constant-dimensional LP in linear time due to Clarkson [9]. Clarkson suggested a randomized algorithm that finds a set of constraints of expected size $O(\sqrt{n})$ (or, in general, $O(d\sqrt{n})$, where d is the dimension) that contains a “basis,” that is, a minimal set of constraints that determines the problem. Our approach is somewhat similar to that schema. Of course, there are details to be filled as to how exactly this set may be computed in time $O(\sqrt{n})$. (Clarkson’s algorithm as it is would be a linear time algorithm.) In particular, an $O(\sqrt{n})$ -time method of finding the violating subpolyhedron (like the one we proposed) must still be used in order to implement the alternative approach of Clarkson efficiently enough.

3. Ray shooting applications. Given a convex polyhedron P with n vertices and a directed line ℓ in \mathbf{R}^3 , the ray shooting problem asks for the point on (the boundary of) P hit by ℓ if it exists. We apply essentially the same techniques as in convex polyhedral intersection to ray shooting and solve it in expected $O(\sqrt{n})$ time. Choose a random sample of $\lfloor \sqrt{n} \rfloor$ edges from P , and let R_p denote the convex hull of these edges. We first use an LP to detect intersection of R_p and ℓ in time $O(\sqrt{n})$. There are two cases. If R_p and ℓ do not intersect, we get a plane \mathcal{L} that separates them and passes through a vertex q of R_p . Starting from q we construct the intersection C_p of P with the halfspace bounded by \mathcal{L} that contains ℓ . We already explained how to do that in the previous section. Finally, we solve ray shooting for C_p and ℓ . Now suppose that R_p and ℓ intersect. We first find the point p on R_p hit by ℓ in time $O(\sqrt{n})$. We cannot afford to compute an explicit representation of R_p in time $\Omega(\sqrt{n} \log n)$. To find p we again use an LP. We can assume that ℓ is the positive x -axis by rotating the coordinate system. Of course, we do not rotate the whole polytope P . Instead, we maintain such a rotation transform implicitly. In other words, whenever we need a geometric feature (vertex, edge, etc.) of P after the rotation, we compute it from its corresponding feature on the original input in constant time. Finding p is equivalent to finding a plane \mathcal{L} such that (1) all vertices of R_p are on one side of \mathcal{L} (the side that contains $(+\infty, 0, 0)$); (2) the intersection point of \mathcal{L} with the x -axis has its x -coordinate as large as possible. In fact, p is that intersection point. It is straightforward to formulate this problem as a three-dimensional LP and solve it in time $O(\sqrt{n})$. In particular, to ensure (2) above we minimize the coefficient α in the equation $\alpha x + \beta y + \gamma z = 1$ for \mathcal{L} . Once we have \mathcal{L} and p , we construct C_p as before and solve the problem for C_p and ℓ . Essentially the same analysis as the proof of Theorem 2.1 shows that the expected size of C_p is $O(\sqrt{n})$. We thus have the following.

THEOREM 3.1. *Given a convex polyhedron with n vertices and a directed line, we can compute their intersection explicitly in optimal $O(\sqrt{n})$ time.*

This sublinear time algorithm for ray shooting towards a convex polyhedron gives us useful ammunition for all sorts of location problems.

Given the Delaunay triangulation \mathcal{T} of a set S of n points in the plane and a

query point q , consider the problem of locating q , i.e., retrieving the triangle of \mathcal{T} that contains it. The Delaunay triangulation can be given in any classical edge-based data structure (e.g., DCEL), as long as it supports $O(1)$ time access to a triangle from a neighboring triangle. We use the close relationship between Delaunay triangulations and convex hulls given by the mapping $h : (x, y) \mapsto (x, y, x^2 + y^2)$. As is well known, the Delaunay triangulation of S is facially isomorphic to the lower hull of $h(S)$ (i.e., the part of the convex hull that sees $z = -\infty$). In this way, point location in \mathcal{T} is equivalent to ray shooting towards the convex hull, where the ray originates from the query point q and shoots in the positive z -direction. Obviously, any facial feature of the convex hull can be retrieved in constant time from its corresponding feature in the Delaunay triangulation. (The one exception is the set of faces outside the lower hull: we can simplify matters by adding a dummy vertex to the hull at $z = \infty$.)

The same argument can be used for point location in Voronoi diagrams. Recall that each point (p_x, p_y) is now lifted to the plane $Z = 2p_xX + 2p_yY - (p_x^2 + p_y^2)$, which is tangent to the paraboloid $Z = X^2 + Y^2$. The Voronoi diagram of S is isomorphic to the lower envelope of the arrangement formed by the n tangent planes. Note that any vertex (resp., edge) of the envelope can be derived in constant time from the three (resp., two) faces incident to the corresponding vertex (resp., edge).

THEOREM 3.2. *Point location in the Delaunay triangulation or Voronoi diagram of n points in the plane can be done in optimal $O(\sqrt{n})$ time.*

Observe that algorithms for computing a Delaunay triangulation or a Voronoi diagram often supply an efficient point location data structure as a by-product, and thus sublinear time point location in Delaunay triangulations or Voronoi diagrams may be of lesser interest. However, our algorithm is still useful when the triangulation/diagram is huge and we cannot afford to store it together with the point location structure. Our algorithm for point location in Delaunay triangulations also has its limitations: It works only because of the known correspondence between a Delaunay triangulation and a special convex polyhedron. It cannot perform point location in arbitrary planar triangulations. In the next section, we use a different method to achieve sublinear time point location in arbitrary triangulations or convex subdivisions with $O(1)$ maximum face size.

We consider the following problem, which will arise in our subsequent discussion of volume approximation and shortest path algorithms. Given a convex polyhedron P with n vertices and a point q , let $n_P(q)$ denote the (unique) point of P that is closest to q . Of course, we can assume that q does not lie inside P , which we can test by using the previous algorithm. To compute $n_P(q)$ we extract a sample polyhedron R_p of size \sqrt{n} (as we did before) and find $n_{R_p}(q)$. Since we just have a collection of vertices of R_p instead of its full facial representation, it is not obvious how to find $n_{R_p}(q)$ in time $O(\sqrt{n})$. For this purpose, we express this problem as an *LP-type* problem and solve it using the method in [5] (see Chapter 8). A reformulation of the problem would be to seek the plane \mathcal{L} that separates q from the vertices of R_p and maximizes the distance from q to it. To apply the method in [5], we view each vertex of R_p as a constraint. We also check that all the assumptions (i.e., monotonicity, locality, violation test, and range space oracle) needed to solve this problem efficiently hold. See [5] for details. Thus we get \mathcal{L} in time $O(\sqrt{n})$: it is tangent to R_p at $n_{R_p}(q)$ and normal to the segment $qn_{R_p}(q)$. Next, we compute the intersection C_p of P with the halfspace bounded by \mathcal{L} that contains q . Again, a similar analysis shows that the expected size of C_p is $O(\sqrt{n})$. Obviously, $n_P(q) = n_{C_p}(q)$, so we can finish the work by exhaustive search in C_p .

THEOREM 3.3. *Given a convex polyhedron P with n vertices and a point q , the nearest neighbor of q in P can be found in $O(\sqrt{n})$ time.*

We can compute a related function by similar means. Given a directed line ℓ , consider an orthogonal system of coordinates with ℓ as one of its axes (in the positive direction), and define $\xi_P(\ell)$ to be any point of P with maximum ℓ -coordinate. If we choose a point q at infinity on ℓ , then $\xi_P(\ell)$ can be chosen as $n_P(q)$, and so we can apply Theorem 3.3.

Another function we can compute in this fashion maps a plane \mathcal{L} and a direction ℓ in \mathcal{L} to the furthest point of P in \mathcal{L} along ℓ : in other words, $\xi_P(\mathcal{L}, \ell) = \xi_{P \cap \mathcal{L}}(\ell)$. Again, the nonobvious part is computing $\xi_{R_p}(\mathcal{L}, \ell)$ in time $O(\sqrt{n})$ for a sample polytope R_p . As in the case of ray shooting, we can assume without loss of generality that \mathcal{L} is the xy -plane and ℓ is the positive x -direction. Finding $\xi_{R_p}(\mathcal{L}, \ell)$ is the same as finding a plane \mathcal{L}' such that (1) all vertices of R_p are on one side of \mathcal{L}' (the side that contains $(-\infty, 0, 0)$); (2) \mathcal{L}' is parallel to the y -axis; (3) the intersection point of \mathcal{L}' with the x -axis has its x -coordinate as small as possible. We solve this problem in time $O(\sqrt{n})$ by formulating it as a three-dimensional LP. Other parts of the algorithm (e.g., constructing C_p) and its analysis are similar to other problems discussed in this section. We summarize our results.

THEOREM 3.4. *Given a convex polyhedron P with n vertices, a directed line ℓ , and a plane π , the points $\xi_P(\ell)$ and $\xi_P(\pi, \ell)$ can be found in $O(\sqrt{n})$ time.*

4. Point location in convex subdivisions. Given a convex planar subdivision \mathcal{S} with n edges and a query point q , the point location problem asks for the face of \mathcal{S} that contains q . In the previous section, we provided an $O(\sqrt{n})$ -time point location algorithm where \mathcal{S} is a Delaunay triangulation or a Voronoi diagram. Devroye, Mücke, and Zhu [14] also showed that a simple “walk-through” technique locates a query point in the Delaunay triangulation of n random points in the plane in expected (roughly) $O(n^{1/3})$ time. Here we show that a slight variation of the walk-through technique actually locates a query point in *any* planar triangulation (not necessarily Delaunay or formed by random points) in expected $O(\sqrt{n})$ time, which is optimal. Our algorithm generalizes to planar subdivisions with $O(1)$ maximum face size. We also give a simple argument showing an $\Omega(n)$ lower bound for point location in subdivisions with large faces.

THEOREM 4.1. *Point location in an n -edge convex planar subdivision with $O(1)$ maximum face size can be done in optimal $O(\sqrt{n})$ time.*

Proof. First, we consider the case of a triangulation. For an edge e in the triangulation and a query point q , we use q_e to denote the nearest neighbor of q on e . It is natural to define the Euclidean distance between q and e as $|qq_e|$. We start by sampling \sqrt{n} edges of the triangulation at random. Let e be the edge in the random sample that has the smallest Euclidean distance to q . We walk from q_e toward³ q by traversing all triangles crossed by qq_e one by one. Given any edge-based representation of the triangulation (such as DCEL), it takes constant time to traverse from one triangle to the next. We stop at the triangle that contains q and output it as the answer.

The running time (besides the sampling stage) is proportional to the number of triangles crossed by qq_e . Thus it suffices to show that the expected number of

³It is important to walk towards q from its nearest neighbor on the nearest edge. In contrast, previous algorithms [27] either walk from an endpoint (or the midpoint) of the nearest edge or sample by vertices and walk from the nearest sample vertex. These algorithms do not have sublinear expected running time for arbitrary triangulations.

triangulation edges crossed by qq_e is $O(\sqrt{n})$. For this, we rank each edge according to its Euclidean distance to q . Since the rank of every edge crossed by qq_e is smaller than that of e , the number of edges crossed by qq_e is at most the rank of e . The claimed time bound then follows from the fact that the smallest rank of \sqrt{n} random edges has expectation $O(\sqrt{n})$. It is straightforward to generalize this algorithm to planar subdivisions with $O(1)$ maximum face size. \square

What if the subdivision has large faces: Is sublinear time point location still possible? The answer is no.

THEOREM 4.2. *There exists an n -edge planar subdivision such that any randomized algorithm for point location in this subdivision has expected running time $\Omega(n)$.*

Proof. Consider the following problem first: We are given a doubly linked list of numbers. We know exactly one of them is nonzero and want to find out that special number. We can use an argument similar to the proof of Lemma 1.1 to show that any randomized algorithm has to spend $\Omega(n)$ expected time on this problem. Returning to point location, consider a rectangle with corners $(-1, 0)$, $(-1, n + 1)$, $(1, 0)$, and $(1, n + 1)$. By breaking its two vertical sides into $n + 1$ unit length segments, we get a face with $2n + 4$ edges. Finally, we pick an integer i from 1 to n and add a horizontal edge from $(-1, i)$ to $(1, i)$. This gives us a two-face subdivision. Given the query point $(0, (n + 1)/2)$, a deterministic algorithm must find the horizontal edge in the middle to locate the query correctly, and the only way to do that is through a visit to one of its four adjacent edges. This is similar in spirit to the list-checking problem considered above. In other words, in both problems we try to find one of $O(1)$ special elements in a list⁴ of size $\Theta(n)$. We thus get the same lower bound of $\Omega(n)$. \square

5. Volume approximation. We seek to approximate the volume of a convex polytope P . We proceed in two stages. First, we compute a large enough enclosed ellipsoid, which we use to rescale P affinely. This is intended to make P round enough so that good Hausdorff distance approximation yields good volume approximation. Second, we use a standard construction of Dudley [16] to find, via the methods of the previous section, an enclosing polytope of $O(1/\varepsilon)$ vertices whose boundary is at Hausdorff distance at most ε from P .

STAGE 1. We begin by computing, in $O(\sqrt{n})$ time, a polytope $P' \subseteq P$, such that $\text{vol}(P') \geq c_0 \text{vol}(P)$ for some constant $c_0 > 0$. Compute the six points $\xi_P(\ell)$ for $\ell = \pm x, \pm y, \pm z$. These points come in pairs, so let w_1, w_2 be the pair forming the largest distance. Given a point w on the line \mathcal{L} passing through w_1 and w_2 , let P_w denote the intersection of P with the plane through w that is orthogonal to \mathcal{L} . Let w_0 be the midpoint of $w_1 w_2$ (Figure 3). We first show that if S is a set of points in P_{w_0} such that

$$(1) \quad \text{area}(\text{conv}(S)) \geq c_1 \text{area}(P_{w_0})$$

for some constant $c_1 > 0$, then $\text{vol}(\text{conv}(S \cup \{w_1, w_2\})) \geq c_2 \text{vol}(P)$ for some other constant $c_2 > 0$. Therefore, we can take $P' = \text{conv}(S \cup \{w_1, w_2\})$ to achieve our goal. Indeed, assume we have such a set S . As a straightforward consequence of Pythagorean theorem, we find that $\text{diam}(P) \leq \sqrt{3} d(w_1, w_2)$; therefore, the orthogonal projection of P on \mathcal{L} is a segment $v_1 v_2 \supseteq w_1 w_2$ of length at most $\sqrt{3} d(w_1, w_2)$. This implies that, for any w in \mathcal{L} , $\text{area}(P_w) \leq 12 \text{area}(P_{w_0})$. To see why, observe that if, say, $w \in v_1 w_0$, then, by convexity, P_w is enclosed in the cone with apex w_2 and base

⁴In the point location problem there are two lists of vertical edges instead of one. This requires only a small modification of the argument.

FIG. 3. Approximating P from within.

P_{w_0} . Therefore, P_w lies in a copy of P_{w_0} scaled by at most $d(w, w_2)/d(w_0, w_2) \leq 2\sqrt{3}$, which proves our claimed upper bound on $\mathbf{area}(P_w)$. Of course, the same argument can be repeated if $w \in w_0v_2$. Since $\mathbf{vol}(P) = \int_{v_1}^{v_2} \mathbf{area}(P_w) dw$, we can conclude that the four quantities

$$\mathbf{vol}(P), \quad \mathbf{vol}(\mathbf{conv}(P_{w_0} \cup \{v_1, v_2\})),$$

$$\mathbf{vol}(\mathbf{conv}(P_{w_0} \cup \{w_1, w_2\})), \quad \mathbf{vol}(\mathbf{conv}(S \cup \{w_1, w_2\}))$$

are all equal up to within constant factors.

We now show how to find a set S satisfying (1). We essentially repeat in two dimensions what we did so far in three dimensions. Specifically, we take a, b to be two mutually orthogonal vectors both normal to \mathcal{L} , and let π be the plane spanned by a and b . We compute the four points (two pairs) $\xi_P(\pi, \ell)$ for $\ell = a, -a, b, -b$. Let y_1, y_2 be the more distant pair (analogous to w_1, w_2 before). Let y_0 be the midpoint of y_1, y_2 , and let segment ℓ_{y_0} be the intersection of P with the line in π orthogonal to y_1y_2 . We can find the two endpoints z_1, z_2 of ℓ_{y_0} using ray shooting. Using almost the same argument as the one showing that $\mathbf{conv}(P_{w_0} \cup \{w_1, w_2\})$ has a volume proportional to $\mathbf{vol}(P)$, we get that the quadrilateral with vertex set $S = \{y_1, y_2, z_1, z_2\}$ has an area proportional to $\mathbf{area}(P_{w_0})$, and thus satisfies (1). We comment that a similar approach to the one we described above was used by Barequet and Har-Peled [4]. The difference is that they approximate the volume of a convex polytope from outside by a bounding box, whereas we approximate it from within.

Let \mathcal{E} be the largest ellipsoid enclosed in $P' = \mathbf{conv}(\{y_1, y_2, z_1, z_2, w_1, w_2\})$, also known as the Löwner–John ellipsoid. It is computable in constant time within any fixed relative error by solving a constant-size quadratic program [20]. As is well known, its volume is at least $(1/\dim)^2$ times that of the enclosing polytope; therefore,

$$\mathbf{vol}(\mathcal{E}) \geq \frac{1}{9} \mathbf{vol}(P') \geq c \cdot \mathbf{vol}(P)$$

for some constant $c > 0$. Make the center of the ellipsoid the origin of the system of coordinates and use the ellipsoid's positive semidefinite matrix to rescale P . To do that, we consider the linear transformation that takes the ellipsoid into a ball of the same volume. Specifically, if $x^T A^T A x \leq 1$ is the equation of the ellipsoid, then we consider the transformation $T = A/(\det A)$. The polytope TP has the same volume as P , but it is *round*; namely, it contains a ball B of volume $\Omega(\mathbf{vol}(TP))$. Thus, we might as well assume that P has this property to begin with. Note that P is also

enclosed in a concentric ball B' that differs from B by only a constant-factor scaling. (If not, then TP would contain a point p so far away from B that the convex hull of p and B , although contained in P , would have volume much larger than $\text{vol}(B)$, and hence $\text{vol}(P)$, which would give a contradiction.) Finally, by rescaling we can also assume that P is enclosed in the unit ball and its volume is bounded below by a positive constant. By Theorems 3.1 and 3.4, all of the work in Stage 1 can be done in $O(\sqrt{n})$ time.

STAGE 2. We implement Dudley’s construction [16] of a convex polytope Q such that (i) $Q \supseteq P$; (ii) $Q \subset P_\varepsilon$, where P_ε is the Minkowski sum of P with a ball of radius ε ; (iii) Q has $O(1/\varepsilon)$ vertices. Dudley’s result was used constructively in [2]. The difference here is that our implementation is sublinear. We compute an $\sqrt{\varepsilon}$ -net on the unit sphere,⁵ and project this net down to ∂P , using the nearest neighbor function n_P as a projection map. Finally, we form Q as the intersection of the $O(1/\varepsilon)$ halfspaces bounded by the appropriate tangent planes passing through the vertices of the projected net. With suitable use of the nearest neighbor algorithm of Theorem 3.3, we can implement the entire construction in time $O(\varepsilon^{-1}\sqrt{n})$ for the projection construction (since the facial representations of P and TP are the same, the algorithm can use TP as though it had its full facial representation at its disposal) and $O(\varepsilon^{-1} \log \varepsilon^{-1})$ for intersecting the halfspaces needed to form Q . Since we can obviously assume that Q does not have more vertices than P , there is no need for ε to be smaller than, say, $1/n^2$. This implies that the entire construction time is dominated by $O(\varepsilon^{-1}\sqrt{n})$. (In fact, we can further reduce this running time to roughly $O(\varepsilon^{-1/2}\sqrt{n})$ by exploiting the fact that the $O(\varepsilon^{-1})$ nearest neighbor queries can be answered in a more efficient batch mode. Similarly, we can also get a slight improvement on the running time in Theorem 6.2.)

We now show that $\text{vol}(Q) = (1 + O(\varepsilon))\text{vol}(P)$. Recall that P is “sandwiched” between two concentric balls B and B' such that $\text{rad}(B') = 1$ and $\text{rad}(B) = \Omega(1)$. We may assume that B and B' are centered at the origin. Since $Q \subset P_\varepsilon$, we have $\text{vol}(Q - P) \leq \text{vol}(P_\varepsilon - P) \leq \text{area}(P_\varepsilon) \cdot 2\varepsilon \leq \text{area}(B_{1+2\varepsilon}) \cdot 2\varepsilon = O(\varepsilon)$, where $B_{1+2\varepsilon}$ is a ball centered at the origin with radius $1 + 2\varepsilon$. The upper bound on $\text{vol}(P_\varepsilon - P)$ is obtained by integration over thin shells of increasing area from ∂P to ∂P_ε . Since $\text{vol}(P) = \Omega(1)$, we then have $\text{vol}(Q) = (1 + O(\varepsilon))\text{vol}(P)$.

THEOREM 5.1. *Given any $\varepsilon > 0$, it is possible to approximate the volume of an n -vertex convex polytope with arbitrary relative error $\varepsilon > 0$ in time $O(\varepsilon^{-1}\sqrt{n})$.*

6. Approximate shortest paths. Given a convex polyhedron P with n vertices and two points s and t on its boundary ∂P , the problem is to find the shortest path between s and t outside the interior of P . It is well known that the shortest path lies on the boundary ∂P . In fact, it is easy to construct instances where any reasonable approximation of the shortest path on ∂P involves $\Omega(n)$ edges. This rules out sublinear algorithms, unless we are willing to follow paths outside of P . We show how to compute a path between s and t whose length exceeds the minimum by a factor of at most $1 + \varepsilon$ for any $\varepsilon > 0$.

Our algorithm relies on a new result of independent interest. Let $d_P(s, t)$ denote the length of the shortest path between s and t in ∂P . Given a point $v \in \partial P$, let H_v be the supporting plane of P at v (or any such plane if v is a vertex), and let H_v^+ denote the halfspace bounded by H_v that contains P . Given $\varepsilon > 0$, we say that a

⁵This is a collection of $O(\varepsilon^{-1})$ points on the sphere such that any spherical cap of radius $\sqrt{\varepsilon}$ contains at least one of the points.

convex polytope Q is an ε -wrapper of P if (c_0 is an absolute constant discussed below)

- (i) Q encloses P ;
- (ii) the Hausdorff distance between ∂P and ∂Q is at most $\varepsilon \operatorname{diam}(P)$;
- (iii) given any $s, t \in \partial P$ such that $d_P(s, t) \geq c_0 \operatorname{diam}(P)$, $d_{\widehat{Q}}(s, t) \leq (1 + \varepsilon)d_P(s, t)$,
where $\widehat{Q} = Q \cap H_s^+ \cap H_t^+$.

LEMMA 6.1. *Any convex 3-polytope has an ε -wrapper of size $O(1/\varepsilon)^{5/4}$ for any $\varepsilon > 0$.*

This result improves on the $O(1/\varepsilon)^{3/2}$ bound of Agarwal et al. [2]. The use of a wrapper is self-evident. First, we clip the polytope to ensure that $d_P(s, t) \geq c_0 \operatorname{diam}(P)$ (section 6.1). Next, we compute an ε -wrapper (section 6.2) and approximate the shortest path between s and t by computing the shortest path between the two points in $\partial \widehat{Q}$. This can be done in quadratic time by using an algorithm by Chen and Han [7]. The resulting path, which is of length $(1 + O(\varepsilon))d_P(s, t)$, can be shortened to $(1 + \varepsilon)d_P(s, t)$ by rescaling ε suitably. Note that in (iii) the condition on s and t being sufficiently far apart is essential. It is a simple exercise to show that no variant of a wrapper can accommodate all pairs (s, t) simultaneously. If $f(n)$ denotes the complexity of the *exact* version of problem, then we have the following.

THEOREM 6.2. *Given any $\varepsilon > 0$ and two points s, t on the boundary of a convex polytope P of n vertices, it is possible to find a path between s and t outside P of length at most $(1 + \varepsilon)d_P(s, t)$ in time $O(\varepsilon^{-5/4}\sqrt{n}) + f(\varepsilon^{-5/4})$.*

We refer the reader back to the introduction for a discussion of the implication of this result in view of the state-of-the-art on the function $f(n)$.

6.1. Computing short paths. Given two points $s, t \in \partial P$, our first task is to ensure that $d_P(s, t) \geq c_0 \operatorname{diam}(P)$ for some constant $c_0 > 0$. To do this, we first compute a value δ such that $\delta \leq d_P(s, t) \leq 8\delta$. We will substitute for P the intersection P' of P with a clipping box centered at s of side length 16δ . Obviously, the shortest paths between s and t relative to P and P' are identical. The only computational primitive we need is the nearest neighbor function of Theorem 3.3. Note that we need only this function relative to P (not to P'). In fact, we first use this function to compute a few sample points on ∂P (see section 6.2). We then discard sample points that are outside of the clipping box. The remaining points together with the clipping box are used to compute an ε -wrapper of P' .

To compute a constant-factor approximation for $d_P(s, t)$, we adapt an algorithm of Har-Peled [21] to our sublinear setting. All that is needed is an implementation of the following primitive: Given two rays r_1, r_2 from a fixed point $p \in P$, let H be the plane spanned by these two rays, and let C denote the two-dimensional cone in H wedged between r_1 and r_2 . Given an additional query ray $r \in H$ (not necessarily emanating from p), we need to compute $\xi_{C \cap P}(H, r)$. By Theorem 3.4, this can be done in $O(\sqrt{n})$ time.

6.2. The ε -wrapper construction. Assuming without loss of generality that $\operatorname{diam}(P) = 1$, it suffices to prove the following.

THEOREM 6.3. *Given any $\varepsilon > 0$ and a convex polytope P of n vertices with diameter 1, there exists a convex polytope Q with $O(\varepsilon^{-5/4})$ vertices such that (i) $Q \supseteq P$; (ii) the Hausdorff distance between ∂P and ∂Q is $O(\varepsilon)$; and (iii) given any $s, t \in \partial P$ such that $d_P(s, t) \geq c_0$ for some constant c_0 , $d_{\widehat{Q}}(s, t) \leq (1 + O(\varepsilon))d_P(s, t)$, where $\widehat{Q} = Q \cap H_s^+ \cap H_t^+$.*

We first show how to construct Q . Let S be a sphere of radius 2 centered at some arbitrary point in P . Draw a grid G of longitudes and latitudes on S , so that

FIG. 4. The grid G .

FIG. 5. The path σ .

each cell is of length $\sqrt{\epsilon}$ by $\sqrt{\epsilon}$ (with an exception made for the last latitude and longitude if $\sqrt{\epsilon}$ does not divide π). All lengths in this discussion are Euclidean, *except* in this case where the length of a circular arc refers to its corresponding angle. We choose a parameter $\lambda = \epsilon^{3/4}$ and subdivide each side of a cell into subarcs of length λ (Figure 4). In this way each cell has $O(\sqrt{\epsilon}/\lambda)$ vertices, and the whole construction defines a set V of $O(1/\lambda\sqrt{\epsilon})$ vertices. For each point $v \in V$, we compute $n_P(v)$, its nearest neighbor in ∂P , and define

$$(2) \quad Q = \bigcap \{ H_{n_P(v)}^+ \mid v \in V \}.$$

It is immediate from our choice of λ that Q has $O(\epsilon^{-5/4})$ vertices.⁶ Every point of the sphere S has at least one vertex of G at distance $O(\sqrt{\epsilon})$. By a result of Dudley [16], this implies part (ii) of Theorem 6.3. Since (i) is obvious, it remains for us to prove (iii).

Borrowing terminology from Agarwal et al. [2], we say that a pair (σ, \mathcal{H}) forms a *supported path* of P if $\sigma = p_1, q_1, p_2, q_2, \dots, q_{m-1}, p_m$ is a polygonal line disjoint from the interior of P and $\mathcal{H} = H_{p_1}, \dots, H_{p_m}$ is a sequence of supporting planes of P , such that $q_{i-1}p_i$ and p_iq_i both lie in H_{p_i} , with $q_0 = p_1$ and $q_m = p_m$ (Figure 5). For $0 < i < m$, the *folding angle* α_i at q_i is the dihedral angle of the wedge between H_{p_i} and $H_{p_{i+1}}$ (the one that does not contain P). The folding angle of σ is defined as $\alpha(\sigma) = \sum_{0 < i < m} \alpha_i$.

LEMMA 6.4 (Agarwal et al. [2]). *Given $s, t \in \partial P$, there exists a supported path σ of P with $O(1/\epsilon)$ edges, joining s and t , such that*

$$d_P(s, t) \leq |\sigma| \leq (1 + \epsilon)d_P(s, t) \quad \text{and} \quad \alpha(\sigma) = O(\epsilon^{-1/2}).$$

⁶To be precise, we actually want to compute an ϵ -wrapper for P' instead of P . For this, we need to remove from the point set V all vertices whose nearest neighbors in ∂P fall outside of the clipping box in section 6.1. We also need to clip Q by that box. We omit these minor details.

To help build intuition for the remainder of our discussion, it is useful to sketch the proof of the lemma. Mapping the grid G to P via the nearest neighbor function n_P creates a grid $n_P(G)$ on ∂P (with curved, possibly degenerate edges). It is convenient to think of P as a smooth manifold by infinitesimally rounding the vertices and edges. It does not much matter how we do that, as long as the end result endows each point $p \in \partial P$ with an (outward) unit normal vector η_p that is a continuous function of p . Note that in this way, for any $u \in S$, the vectors $un_P(u)$ and $\eta_{n_P(u)}$ are collinear, and the function n_P is a bijection. The fundamental property of the nearest neighbor function is that it is nonexpansive. We need only a weak version of that fact, which follows directly from Lemmas 4.3 and 4.4 in [16].

LEMMA 6.5 (Dudley [16]). *Given two points $p, q \in \partial P$, $|pq|$ and $\angle(\eta_p, \eta_q)$ are both in $O(|n_P^{-1}(p)n_P^{-1}(q)|)$.*

This implies that, for any two points $p, q \in \partial P$ in the same cell of the mapped grid $n_P(G)$, both $|pq|$ and $\angle(\eta_p, \eta_q)$ are in $O(\sqrt{\varepsilon})$. We shortcut the shortest path on ∂P from s to t to form a supported path σ that passes through each cell at most once. In this manner, we identify $O(1/\varepsilon)$ points p_1, \dots, p_m on ∂P , where p_i (resp., p_{i+1}) is the entry (resp., exit) point of the path through the i th cell in the sequence. The points p_i lie on the edges of $n_P(G)$. There are two exceptions, $p_1 = s$ and $p_m = t$, which might lie in the interior of the cell. Next, we connect each pair (p_i, p_{i+1}) by taking the shortest path on $H_{p_i} \cup H_{p_{i+1}}$. The path intersects $H_{p_i} \cap H_{p_{i+1}}$ at a point denoted q_i . (Note that q_i might be infinitesimally close to p_i .) This forms a supported path σ with $O(1/\varepsilon)$ vertices $s = p_1, q_1, p_2, q_2, \dots, q_{m-1}, p_m = t$. The only real difference from the proof in [2] is that we skip the final “trimming” step and keep the points p_i unchanged. We mention two useful, immediate consequences of Lemma 6.5.

- The folding angle at q_i is $O(\sqrt{\varepsilon})$.
- For each $1 \leq i \leq m$, the point p_i belongs to ∂P and, for $i \neq 1, m$, there exists a point $w_i = n_P(v_i)$, where $v_i \in V$, such that both $|p_i w_i|$ and $\angle(\eta_{p_i}, \eta_{w_i})$ are in $O(\lambda)$.

From σ we build a curve σ' of length $(1 + O(\varepsilon))|\sigma|$ that joins s and t outside the interior of \widehat{Q} . The classical result below shows that the shortest path on $\partial \widehat{Q}$ from s to t cannot be longer than σ' , which proves Theorem 6.3.

THEOREM 6.6 (Pogorelov [29]). *Given a convex body C , let γ be a curve joining two points $s, t \in \partial C$ outside the interior of C . Then the length of γ is at least that of the shortest path joining s and t on ∂C .*

We now explain how to construct σ' . For $0 < i < m$, let (p_i, η_{p_i}) and (q_i, η_{p_i}) be the rays emanating from p_i and q_i , respectively, in the direction normal to H_{p_i} away from P . Together with the segments $p_i q_i$ and $q_i p_{i+1}$, the four rays (p_i, η_{p_i}) , (q_i, η_{p_i}) , $(q_i, \eta_{p_{i+1}})$, and $(p_{i+1}, \eta_{p_{i+1}})$ define a polyhedral surface Σ_i , which consists of two unbounded rectangles, Σ_i^1 and Σ_i^3 , joined together at q_i by an unbounded triangle, Σ_i^2 (Figure 6). Note that the surface is in general nonplanar, but Σ_i^2 is always normal to the line $H_{p_i} \cap H_{p_{i+1}}$. Out of Σ_i we carve a polyhedral strip S_i as follows. Fix a large enough constant $c > 0$, and let K_i denote the plane $H_{p_i} + c\lambda^2 \eta_{p_i}$. In other words, K_i is a parallel copy of H_{p_i} translated by $c\lambda^2$ away from P . As usual, the superscripted K_i^+ denotes the halfspace enclosing P . Recall that w_i is the nearest neighbor of v_i defined earlier. We need to consider

$$S_i = \Sigma_i \cap \left\{ (K_i^+ \cap K_{i+1}^+) \cup (H_{w_i}^+ \cap H_{w_{i+1}}^+) \right\}.$$

Again, we have two exceptions for $i = 1, m - 1$, where we use $H_{p_1}^+$ instead of $H_{w_1}^+$ and

FIG. 6. The curve σ'_i .

FIG. 7. How H_p intersects the xz plane.

$H_{p_m}^+$ instead of $H_{w_m}^+$.

Let $p_i p'_i$ be the edge of S_i incident to p_i collinear with η_{p_i} . We denote by σ'_i the portion of ∂S_i between p'_i and p'_{i+1} and define σ' as $\bigcup_{0 < i < m} \sigma'_i$. To provide a connection to s and t , we also add to σ' the segments $p_1 p'_1$ and $p_m p'_m$. To show that σ' is a connected curve outside the interior of \hat{Q} of length $(1 + O(\varepsilon))|\sigma|$ requires a simple technical lemma.

LEMMA 6.7 (Figure 7). *Given an orthogonal system of reference (O, xyz) , assume that P is tangent to the xy -plane at O and lies below it. Given a point p on ∂P , if $|n_P^{-1}(O)n_P^{-1}(p)| < \delta$, for some small enough $\delta > 0$, then the intersection of H_p with the xz -plane has for an equation $Z = aX + b$, where $|a| = O(\delta)$ and $0 \leq b = O(\delta^2)$.*

Proof. By Lemma 6.5, the normal to H_p forms a small angle $\theta = O(\delta)$ with the z -axis, so the plane H_p , being nonparallel to the z -axis, can be expressed as $Z = aX + cY + b$. The cross product between the normal $(a, c, -1)$ and the z -axis vector is the vector $(c, -a, 0)$. By the cross product formula, its length, which is $\sqrt{a^2 + c^2}$, is also equal to $\sqrt{a^2 + c^2 + 1} \sin \theta$. It follows that $a^2 + c^2 = O(a^2 + c^2 + 1)\delta^2$; therefore,

$$(3) \quad a^2 + c^2 = \frac{O(\delta^2)}{1 - O(\delta^2)} = O(\delta^2),$$

and hence $|a| = O(\delta)$. By convexity of P , the plane H_p intersects the nonnegative part of the z -axis, and p_z , the z -coordinate of p , is nonpositive. By (3) and $|Op| = O(\delta)$, it follows that

$$0 \leq b = p_z - ap_x - cp_y \leq \sqrt{a^2 + c^2} \sqrt{p_x^2 + p_y^2} = O(\delta^2). \quad \square$$

We examine each σ'_i separately, omitting the cases $i = 1, m - 1$, which are trivial

modifications of the general case $1 < i < m - 1$. The curve σ'_i lies outside the interior of $H_{w_i}^+ \cap H_{w_{i+1}}^+$, and hence of \widehat{Q} . It is naturally broken up into three parts, $\sigma_i^j \subset \Sigma_i^j$ ($j = 1, 2, 3$), each one of them being a polygonal curve whose edges lie in any one of four planes: K_i, K_{i+1}, H_{w_i} , and $H_{w_{i+1}}$. Applying Lemma 6.7 with $(p_i, \overrightarrow{p_i q_i}, \overrightarrow{p_i p'_i})$ in the role of (O, x, z) and w_i in the role of p , we find that H_{w_i} intersects the segment $p_i p'_i$ for c large enough (note that this c is the one in the definition of K_i); similarly, $H_{w_{i+1}}$ intersects $p_{i+1} p'_{i+1}$. This shows that p'_i is the intersection of the ray (p_i, η_{p_i}) with the plane K_i ; therefore, p'_i is *the same point* in the definition of σ'_i and σ'_{i-1} , thus proving that the curve σ' is, indeed, connected. (The danger was having p'_i defined by $H_{w_{i+1}}$.) We now bound the length of σ'_i .

- By Lemma 6.7 the slopes of the edges of σ_i^1 are chosen among 0 for K_i ; $O(\sqrt{\varepsilon})$ for K_{i+1} ; $O(\lambda)$ for H_{w_i} ; and $O(\sqrt{\varepsilon})$ for $H_{w_{i+1}}$. It follows that $|\sigma_i^1| \leq |p_i q_i| / \cos \theta$, where $\theta = O(\sqrt{\varepsilon})$; therefore, $|\sigma_i^1| = (1 + O(\varepsilon)) |p_i q_i|$. The same argument shows that $|\sigma_i^3| = (1 + O(\varepsilon)) |q_i p_{i+1}|$.
- Let q'_i, q''_i be the endpoints of the curve σ_i^2 (Figure 6), and let a, a', b, b' be the distances along the ray (q_i, η_{p_i}) from q_i to K_i, K_{i+1}, H_{w_i} , and $H_{w_{i+1}}$, respectively. By definition of S_i ,

$$|q_i q'_i| = \max \left\{ \min \{a, a'\}, \min \{b, b'\} \right\}.$$

Obviously, $a = c\lambda^2$ and, by Lemma 6.7, $b = O(\lambda |p_i q_i| + \lambda^2)$. This implies that $|q_i q'_i| = O(\lambda |p_i q_i| + \lambda^2)$ and, by the same argument,

$$|q_i q'_i| + |q_i q''_i| = O(\lambda (|p_i q_i| + |q_i p_{i+1}|) + \lambda^2).$$

Within Σ_i^2 , the curve σ_i^2 is a polygonal line consisting of at most a constant number of edges. It is not difficult to see that for any vertex v of σ_i^2 (including q'_i and q''_i), the angle between $q_i v$ and edges of σ_i^2 incident to v is $\pi/2 \pm O(\sqrt{\varepsilon})$. This follows from a simple geometric observation: given any plane H whose normal makes with $q_i v$ an angle at most α , the angle formed by $q_i v$ and any line on H lies in the range $[\pi/2 - \alpha, \pi/2 + \alpha]$. Since any of the edges of σ_i^2 lies on one of four planes, K_i, K_{i+1}, H_{w_i} , and $H_{w_{i+1}}$, and the normal of each of them makes an angle of $O(\sqrt{\varepsilon})$ with $q_i v$, the claim follows. Because the folding angle of $O(\sqrt{\varepsilon})$ can be assumed to be less than, say, $\pi/2$, this implies that the curve σ_i^2 lies entirely at a distance $O(|q_i q'_i| + |q_i q''_i|)$ from q_i . It follows that $|\sigma_i^2| = O(|q_i q'_i| + |q_i q''_i|) \sqrt{\varepsilon}$.

Putting everything together we find that

$$|\sigma'_i| = (1 + O(\varepsilon) + O(\lambda \sqrt{\varepsilon})) (|p_i q_i| + |q_i p_{i+1}|) + O(\lambda^2 \sqrt{\varepsilon}).$$

In view of the fact that $|p_1 p'_1| = |p_m p'_m| = c\lambda^2$, summing up over all $|\sigma'_i|$'s (there are $O(1/\varepsilon)$ of them),

$$\begin{aligned} |\sigma'| &= (1 + O(\varepsilon) + O(\lambda \sqrt{\varepsilon})) |\sigma| + O(\lambda^2 / \sqrt{\varepsilon}) \\ &= (1 + O(\varepsilon)) |\sigma| + O(\varepsilon) \\ &= (1 + O(\varepsilon)) |\sigma|, \end{aligned}$$

which completes the proof of Theorem 6.3. Note that the setting of λ is made to ensure that the additive term $O(\lambda^2 / \sqrt{\varepsilon})$ is $O(\varepsilon)$.

Acknowledgments. We wish to thank Pankaj Agarwal, Funda Ergun, Sariel Har-Peled, Joe Mitchell, and Ronitt Rubinfeld for several helpful discussions. We also wish to thank the anonymous referees for their comments and suggestions.

LOWNESS FOR THE CLASS OF SCHNORR RANDOM REALS*

BJØRN KJOS-HANSEN[†], ANDRÉ NIES[‡], AND FRANK STEPHAN[§]

Abstract. We answer a question of Ambos-Spies and Kučera in the affirmative. They asked whether, when a real is low for Schnorr randomness, it is already low for Schnorr tests.

Key words. lowness, randomness, Schnorr randomness, Turing degrees, recursion theory, computability theory

AMS subject classifications. 68Q30, 03D25, 03D28

DOI. 10.1137/S0097539704446323

1. Introduction. In an influential 1966 paper [9], Martin-Löf proposed an algorithmic formalization of the intuitive notion of randomness for infinite sequences of 0's and 1's. His formalization was based on an effectivization of a test concept from statistics, by means of uniformly recursively enumerable (r.e.) sequences of open sets. Martin-Löf's proposal addressed some insufficiencies in an earlier algorithmic concept of randomness proposed by Church [3], who had formalized a notion now called computable stochasticity. However, Schnorr [13] criticized Martin-Löf's notion as too strong, because it was based on an r.e. test concept rather than a computable notion of tests. He suggested that one should base a formalization of randomness on computable betting strategies (also called martingales), in a way that would still overcome the problem that Church's concept was too weak. In present terminology, a real Z is computably random if no computable betting strategy succeeds along Z ; that is, for each computable betting strategy there is a finite upper bound on the capital that it reaches. The real Z is Schnorr random if no martingale succeeds *effectively*. Here effective success means that the capital at $Z \upharpoonright n$ exceeds $f(n)$ infinitely often, for some unbounded computable function f . See [1] for more on the history of these ideas.

We recall some definitions. The Cantor space 2^ω is the set of infinite binary sequences; these are called *reals* and are identified with a set of integers, i.e., subsets of ω . If $\sigma \in 2^{<\omega}$, that is, σ is a finite binary sequence, then we denote by $[\sigma]$ the set of reals that extend σ . These form a basis of clopen sets for the usual discrete topology on 2^ω . Write $|\sigma|$ for the length of $\sigma \in 2^{<\omega}$. The Lebesgue measure μ on 2^ω is defined by stipulating that $\mu[\sigma] = 2^{-|\sigma|}$. With every set $U \subseteq 2^{<\omega}$ we associate the open set $[U]^\preceq = \bigcup_{\sigma \in U} [\sigma]$. The empty sequence is denoted λ . If $\sigma, \tau \in 2^{<\omega}$ and σ is a prefix of τ , then we write $\sigma \preceq \tau$. If $\sigma \in 2^{<\omega}$ and $i \in \{0, 1\}$, then σi denotes the string of length $|\sigma| + 1$ extending σ whose final entry is i . The concatenation of two strings σ

and τ is denoted $\sigma\tau$. The empty set is denoted \emptyset , and inclusion of sets is denoted by \subseteq . If A is a real and $n \in \omega$, then $A \upharpoonright n$ is the prefix of A consisting of the first n bits of A . Letting $A(n)$ denote bit n of A , we have $A \upharpoonright n = A(0)A(1) \cdots A(n-1)$.

Given $\alpha \in 2^{<\omega}$ and a measurable set $C \subseteq 2^\omega$, we let $\mu_\alpha C = \frac{\mu(C \cap [\alpha])}{\mu[\alpha]}$. For an open set W we let

$$W|\sigma = \bigcup \{[\tau] : \tau \in 2^{<\omega}, [\sigma\tau] \subseteq W\}.$$

Note in particular that $\mu_\sigma W = \mu(W|\sigma)$ and $\mu_\lambda W = \mu W$.

Fixing some effective correspondence between the set of finite subsets of ω and ω , we let D_e be the e th finite subset of ω under this correspondence. In other words, e is a strong, or canonical, index for the finite set D_e . Similarly, we let S_e be the e th finite subset of $2^{<\omega}$ under a suitable correspondence. Thus S_e is a finite set of strings, and $[S_e]^\preceq = \bigcup_{\sigma \in S_e} [\sigma]$ is then the clopen set coded by $e \in \omega$. We use the Cantor pairing function, namely the bijection $p : \omega^2 \rightarrow \omega$ given by $p(n, s) = \frac{(n+s)^2 + 3n + s}{2}$, and write $\langle n, s \rangle = p(n, s)$.

A *Martin-Löf test* is a set $U \subseteq \omega \times 2^\omega$ such that $\mu U_n \leq 2^{-n}$, where U_n denotes the n th section of U , and U_n is a Σ_1^0 class, uniformly in n . If, in addition, μU_n is a computable real, uniformly in n , then U is called a *Schnorr test*. Z is *Martin-Löf random* if for each Martin-Löf test U there is an n such that $Z \notin U_n$, and *Schnorr random* if for each Schnorr test U there is an n such that $Z \notin U_n$. The notion of Schnorr randomness is unchanged if we instead define a Schnorr test to be a Martin-Löf test for which $\mu U_n = 2^{-n}$ for each $n \in \omega$.

Concepts encountered in computability theory are usually based on some notion of computation, and therefore have relativized forms. For instance, we may relativize the tests and randomness notions above to an oracle A . If $\mathcal{C} = \{X : X \text{ is Martin-Löf random}\}$, then the relativization is $\mathcal{C}^A = \{X : X \text{ is Martin-Löf random relative to } A\}$ (meaning that Σ_1^0 classes are replaced by $\Sigma_1^{0,A}$ classes). In general, if \mathcal{C} is such a relativizable class, we say that A is *low for \mathcal{C}* if $\mathcal{C}^A = \mathcal{C}$. If \mathcal{C} is a randomness notion, more computational power means a smaller class, namely $\mathcal{C}^A \subseteq \mathcal{C}$ for any A . Being low for \mathcal{C} means having small computational power (in a sense that depends on \mathcal{C}). In particular, the low-for- \mathcal{C} reals are closed downward under Turing reducibility.

The randomness notions for which lowness was first considered are Martin-Löf and Schnorr randomness. Kučera and Terwijn [8] constructed a noncomputable r.e. set of integers A which is low for Martin-Löf randomness, answering a question of Zambella [16]. In the paper [14] it is shown that there are continuously many reals that are low for Schnorr randomness.

An important difference between the two randomness notions is that for Martin-Löf randomness, but not for Schnorr randomness, there is a universal test R . Thus, Z is not Martin-Löf random iff $Z \in \bigcap_{b \in \omega} R_b$. Therefore, in the Schnorr case, an apparently stronger lowness notion is being *low for Schnorr tests*, or *S_0 -low* in the terminology of [1]: A is low for Schnorr tests if for each Schnorr test U^A relative to A there is an unrelativized Schnorr test V such that $\bigcap_n U_n^A \subseteq \bigcap_n V_n$. This implies that A is low for Schnorr randomness, or *S -low* in the terminology of [1]. Ambos-Spies and Kučera asked if the two notions coincide. We answer this question in the affirmative.

Terwijn and Zambella [14] actually constructed oracles A that are low for Schnorr tests. They first gave a characterization of this lowness property via a notion of traceability, a restriction on the possible sequence of values of the functions computable from A . They showed that A is low for Schnorr tests iff A is computably traceable

(see formal definition in the next section). Then they constructed continuously many computably traceable reals. We answer the question of Ambos-Spies and Kučera by showing that each real which is low for Schnorr randomness is in fact computably traceable.

Towards this end, it turns out to be helpful to have a more general view of lowness. We consider lowness for any pair of randomness notions \mathcal{C}, \mathcal{D} with $\mathcal{C} \subseteq \mathcal{D}$.

DEFINITION 1.1. *A is in $\text{Low}(\mathcal{C}, \mathcal{D})$ if $\mathcal{C} \subseteq \mathcal{D}^A$. We write $\text{Low}(\mathcal{C})$ for $\text{Low}(\mathcal{C}, \mathcal{C})$.*

Clearly, if $\mathcal{C} \subseteq \tilde{\mathcal{C}} \subseteq \tilde{\mathcal{D}} \subseteq \mathcal{D}$ are randomness notions, and the inclusions relativize (so $\tilde{\mathcal{D}}^A \subseteq \mathcal{D}^A$ for each real A), then $\text{Low}(\tilde{\mathcal{C}}, \tilde{\mathcal{D}}) \subseteq \text{Low}(\mathcal{C}, \mathcal{D})$. That is, we make the class $\text{Low}(\tilde{\mathcal{C}}, \tilde{\mathcal{D}})$ larger by decreasing \mathcal{C} or increasing \mathcal{D} . Let MR, CR, and SR denote the classes of Martin-Löf random, computably random (defined below), and Schnorr random reals, respectively. Thus, for instance, $\text{Low}(\text{MR}, \text{CR})$ is the class of oracles A such that each Martin-Löf random real is computably random in A . We will characterize lowness for any pair of randomness notions $\mathcal{C} \subseteq \mathcal{D}$ with $\mathcal{C}, \mathcal{D} \in \{\text{MR}, \text{CR}, \text{SR}\}$.

Recall that Ω denotes the halting probability of a universal prefix machine. Ω is a Martin-Löf random *r.e. real*, i.e., a real that can be effectively approximated from below. Given $\mathcal{D} \supseteq \text{MR}$, an interesting lowness notion obtained by weakening $\text{Low}(\text{MR}, \mathcal{D})$ is $\text{Low}(\{\Omega\}, \mathcal{D})$. That is, instead of $\text{MR} \subseteq \mathcal{D}^A$ one merely requires that $\Omega \in \mathcal{D}^A$. We denote this class by $\text{Low}(\Omega, \mathcal{D})$. In [12], the case $\mathcal{D} = \text{MR}$ is studied. The authors show that the class coincides with $\text{Low}(\text{MR})$ on the Δ_2^0 reals but not in general. In fact, a Martin-Löf random real is 2-random iff it is in $\text{Low}(\Omega, \text{MR})$.

Here we investigate the class $\text{Low}(\Omega, \text{SR})$. We show that A is $\text{Low}(\text{MR}, \text{SR})$ iff A is r.e. traceable. Moreover, the weaker assumption $\Omega \in \text{SR}^A$ still implies that A is array computable (there is a function $f \leq_{\text{wtt}} \emptyset'$ bounding all functions computable from A , on almost all inputs). Thus for r.e. sets of integers A , A being $\text{Low}(\text{MR}, \text{SR})$ is in fact equivalent to $\Omega \in \text{SR}^A$ by Ishmukhametov [5]. We also provide an example of a real A which is array computable but not $\text{Low}(\Omega, \text{SR})$.

2. Main concepts.

2.1. Martingales. For our purposes, a *martingale* is a function $M : 2^{<\omega} \mapsto \mathbb{Q}$ (where \mathbb{Q} is the set of rational numbers) such that (i) the domain of M is $2^{<\omega}$, or $2^{\leq n} = \{\sigma \in 2^{<\omega} : |\sigma| \leq n\}$ for some n , (ii) $M(\lambda) \leq 1$, and (iii) M has the martingale property $M(x0) + M(x1) = 2M(x)$ whenever the strings $x0, x1$ belong to the domain of M . A martingale M *succeeds* on a sequence $Z \in 2^\omega$ if

$$\limsup_{n \rightarrow \infty} M(Z \upharpoonright n) = \infty.$$

A real is *computably random* if no computable martingale succeeds on it.

A martingale M *effectively succeeds* on a sequence Z if there is a nondecreasing and unbounded computable function $h : \omega \rightarrow \omega$ such that

$$\limsup_{n \rightarrow \infty} M(Z \upharpoonright n) - h(n) > 0.$$

Equivalently (since we are considering integer-valued functions), $\exists^\infty n M(Z \upharpoonright n) > h(n)$. We can now state the characterization of Schnorr randomness in terms of martingales: a real Z is Schnorr random iff no computable martingale effectively succeeds on Z .

2.2. Traceability. Let W_e denote the e th r.e. set of integers in some standard list. A real A is *r.e. traceable* if there is a computable function p , called a *bound*, such that for every $f \leq_T A$ there is a computable function r such that for all x we have $|W_{r(x)}| \leq p(x)$ and $f(x) \in W_{r(x)}$.

The following is a stronger notion than r.e. traceability. A is *computably traceable* if there is a computable p such that for every $f \leq_T A$ there is a computable r such that for all x we have $|D_{r(x)}| \leq p(x)$ and $f(x) \in D_{r(x)}$.

It is interesting to notice that it does not matter what bound p one chooses as a witness for traceability; see the following.

PROPOSITION 2.1 (see Terwijn and Zambella [14]). *Let A be a real that is computably traceable with bound p . Then for any monotone and unbounded computable function p' , A is computably traceable with bound p' . The same holds for r.e. traceability.*

The result of Terwijn and Zambella is the following.

THEOREM 2.2 (see [14]). *A real A is low for Schnorr tests iff A is computably traceable.*

3. Statement of the main result.

THEOREM 3.1.

(I) *A is Low(MR, SR) iff A is r.e. traceable.*

(II) *A is Low(CR, SR) iff A is Low(SR) iff A is computably traceable.*

We make some remarks about the proofs and fill in the details in the next section. We obtain Theorem 3.1(I) by modifying the methods in [14] to the case of r.e. traces instead of computable ones.

As for Theorem 3.1(II), by Theorem 2.2 if A is computably traceable, then A is low for Schnorr tests. Hence A is certainly Low(SR), and therefore also Low(CR, SR). It remains only to show that each real $A \in \text{Low}(\text{CR}, \text{SR})$ is computably traceable. To see that this is so, take the following three steps:

1. Recall that A is *hyperimmune-free* if for each $g \leq_T A$ there is a computable f such that for all x we have $g(x) \leq f(x)$. As a first step towards proving Theorem 3.1(II), Bedregal and Nies [2] showed that each $A \in \text{Low}(\text{CR}, \text{SR})$ is hyperimmune-free (see Lemma 4.9 below). To see this, assume that A is not, so there is a function $g \leq_T A$ not dominated by any computable function f . Define a martingale $L \leq_T A$ which succeeds in the sense of Schnorr, with the computable lower bound $h(n) = n/4$, on some $Z \in \text{CR}$. One uses here that g is infinitely often above the running time of each computable martingale. (Special care has to be taken with the partial martingales, which results in a real Z that is only Δ_3^0 .)

2. If A is hyperimmune-free and r.e. traceable, then A is computably traceable. If we let $g \leq_T A$, then the first stage where $g(x)$ appears in a given trace for g can be computed relative to A .

3. Now each A in Low(CR, SR) is r.e. traceable by Theorem 3.1(I), and hence by the above is computably traceable, and Theorem 3.1(II) follows.

We discuss lowness for the remaining pairs of randomness notions. Nies has shown that A is Low(MR, CR) iff A is Low(MR) iff A is K -trivial, where A is K -trivial if for all n $K(X \upharpoonright n) \leq K(n) + O(1)$ (see [11]). Here $K(\sigma)$ denotes the prefix-free Kolmogorov complexity of $\sigma \in 2^{<\omega}$. Finally, he shows that a real A which is Low(CR) is computable; namely, A is both K -trivial and hyperimmune-free. Since all K -trivial reals are Δ_2^0 , and all hyperimmune-free Δ_2^0 reals are computable, the conclusion follows.

4. Proof of the main result. We first need to develop a few useful facts from measure theory.

DEFINITION 4.1. *A measurable set A has density d at a real X if*

$$\lim_{n \rightarrow \infty} \mu_{(X|n)}A = d.$$

A basic result is the following.

THEOREM 4.2 (Lebesgue density theorem). *Let $\Xi(A) = \{X : A \text{ has density } 1 \text{ at } X\}$. If A is a measurable set, then so is $\Xi(A)$, and the measure of the symmetric difference of A and $\Xi(A)$ is zero.*

COROLLARY 4.3. *Let C be a measurable subset of 2^ω , with $\mu C > 0$. Then for each $\delta < 1$ there is an $\alpha \in 2^{<\omega}$ such that $\mu_\alpha C \geq \delta$.*

We will use the following consequence of Corollary 4.3.

LEMMA 4.4. *Let $0 < \epsilon \leq 1$. If $U_n, n \in \omega$, and V are open subsets of 2^ω with $\bigcap_{n \in \omega} U_n \subseteq V$ and $\mu V < \epsilon$, then there exist σ and n such that $\mu_\sigma(U_n - V) = 0$ and $\mu_\sigma V < \epsilon$.*

Proof. Suppose otherwise; we shall obtain a contradiction by constructing a real in $\bigcap_{n \in \omega} U_n - V$. Let $\sigma_0 = \lambda$ and assume we have defined σ_n such that $\mu_{\sigma_n} V < \epsilon$. By hypothesis, $\mu_{\sigma_n}(U_n - V) > 0$, and thus there is a $[\tau] \subseteq U_n$ such that $\mu_{\sigma_n}([\tau] - V) > 0$. In particular, $\tau \succeq \sigma_n$ and $\mu_\tau V < 1$. Let $C = 2^\omega - V$, a closed and hence measurable set. By Corollary 4.3 applied to C (and with 2^ω replaced by $[\tau]$), there exists $\sigma_{n+1} \succeq \tau$ such that $\mu_{\sigma_{n+1}} V < \epsilon$. Let X be the real that extends all σ_n 's constructed in this way. Since $[\sigma_{n+1}] \subseteq U_n$ for all n , we have that $X \in \bigcap_{n \in \omega} U_n$. However, $[\sigma_n] \not\subseteq V$ for every n , so, since V is open, $X \notin V$. This contradiction completes the proof. \square

We now get to the proof of Theorem 3.1. First we show Theorem 3.1(I), namely, that A is Low(MR, SR) iff A is r.e. traceable. We start with the “ \Leftarrow ” direction.

LEMMA 4.5. *If A is r.e. traceable, then A is Low(MR, SR).*

Proof. Assume that A is r.e. traceable and that U^A is a Schnorr test relative to A . Let $U_{n,s}^A, n, s \in \omega$, be clopen sets, $U_{n,s}^A \subseteq U_{n,s+1}^A, U_n^A = \bigcup_{s \in \omega} U_{n,s}^A$, such that the $U_{n,s}^A$ are $\Delta_1^{0,A}$ classes uniformly in n and s . As $\mu U_n^A = 2^{-n}$, we may assume that $\mu U_{n,s}^A > 2^{-n}(1 - 2^{-s})$. Let f be an A -computable function such that $[S_{f(\langle n,s \rangle)}]^\preceq = U_{n,s}^A$. Since A is r.e. traceable and $f \leq_T A$, we can let T be an r.e. trace of f . By Proposition 2.1, we may choose T such that in addition $|T_x| \leq x$ for each $x > 0$.

We now want to define a subtrace \hat{T} of T , i.e., $\hat{T}_{\langle n,s \rangle} \subseteq T_{\langle n,s \rangle}$ for each n, s . The intent is that the open sets defined via \hat{T} are small enough to give us a Martin-Löf test containing $\bigcap_{n \in \omega} U_n^A$, and nothing important is in $T_{\langle n,s \rangle} - \hat{T}_{\langle n,s \rangle}$. Thus let $\hat{T}_{\langle n,s \rangle}$ be the set of $e \in T_{\langle n,s \rangle}$ such that $2^{-n}(1 - 2^{-s}) \leq \mu[S_e]^\preceq \leq 2^{-n}$ and $[S_e]^\preceq \supseteq [S_d]^\preceq$ for some $d \in \hat{T}_{\langle n,s-1 \rangle}$, where $\hat{T}_{\langle n,-1 \rangle} = \omega$. Let

$$V_n = \bigcup \left\{ [S_e]^\preceq : e \in \hat{T}_{\langle n,s \rangle}, s \in \omega \right\}.$$

Then $\mu V_n \leq 2^{-n}|\hat{T}_{\langle n,0 \rangle}| + \sum_{s \in \omega} 2^{-s}2^{-n}|\hat{T}_{\langle n,s \rangle}|$. Since $|\hat{T}_{\langle n,s \rangle}| \leq |T_{\langle n,s \rangle}| \leq \langle n, s \rangle$ for $\langle n, s \rangle \neq 0$, and $\langle n, s \rangle$ has only polynomial growth in n and s , it is clear that $\sum_{s \in \omega} 2^{-s}2^{-n}|\hat{T}_{\langle n,s \rangle}|$ is finite and goes effectively to 0 as $n \rightarrow \infty$; hence the same can be said of μV_n . Thus there is a recursive function f such that $\mu V_{f(n)} \leq 2^{-n}$. Let $\tilde{V}_n = V_{f(n)}$. Then \tilde{V} is a Martin-Löf test and $\bigcap_n U_n^A \subseteq \bigcap_n \tilde{V}_n$. That is, each Schnorr test relative to A is contained in a Martin-Löf test. It follows that each real that is Martin-Löf random is Schnorr random relative to A , and the proof is complete. \square

Next we will show the “ \Rightarrow ” direction of Theorem 3.1(I). The proof is similar to the “ \Rightarrow ” of Theorem 2.2.

DEFINITION 4.6. For $k, l \in \omega$ define the clopen set

$$B_{k,l} = \bigcup \{[\tau 1^k] : \tau \in 2^{<\omega}, |\tau| = l\},$$

where 1^k is a string of 1’s of length k .

Note that $\mu B_{k,l} = 2^{-k}$ for all l .

LEMMA 4.7. If $A \in 2^\omega$ is Low(MR, SR), then A is r.e. traceable.

Proof. Note that A is Low(MR, SR) iff for every Schnorr test U^A relative to A , $\bigcap_{n \in \omega} U_n^A \subseteq \bigcap_{b \in \omega} R_b$ (recall that R is a universal Martin-Löf test).

Oversimplifying a bit, one can say that the proof below goes as follows. We code a given $g \leq_T A$ into a Schnorr test U^g relative to A . Then, by hypothesis, $\bigcap_n U_n^g \subseteq \bigcap_n R_n$; in fact we will use only the fact that $\bigcap_n U_n^g \subseteq R_3$. We then define an r.e.trace T ; namely, T_k is the set of l such that $B_{k,l} - R_3$ has small measure in some sense. Since R_3 has rather small measure, $B_{k,l} - R_3$ will tend to have big measure, which means that there will be only a few l for which $B_{k,l} - R_3$ has small measure; in other words, T_k has small size. Moreover, we make sure T is a trace for g so that A is r.e. traceable.

We now give the proof details. Suppose that we want to find a trace for a given function $g \leq_T A$. We define the test U^g by stipulating that

$$U_n^g = \bigcup_{k > n} B_{k,g(k)}.$$

It is easy to see that μU_n^g can be approximated computably in A , so after taking a subsequence of U_n^g , $n \in \omega$, we may assume that U^g is a Schnorr test relative to A . Hence, by assumption, $\bigcap U^g \subseteq \bigcap_{b \in \omega} R_b$. Thus $V = R_3$ contains $\bigcap U^g$ and $\mu V < \frac{1}{4}$. We may assume throughout that $g(k) \geq k$ for every k because from a trace for $g(k) + k$ one can obtain a trace for g with the same bound. By Lemma 4.4, there exist σ and n such that $\mu_\sigma(U_n^g - V) = 0$ and $\mu_\sigma V < 1/4$. As $U_0^g \supseteq U_1^g \supseteq \dots$, we can choose σ and n with the additional property $n \geq |\sigma|$. Hence for each $k > n$, we have $g(k) \geq k > n \geq |\sigma|$ and hence $g(k) \geq |\sigma|$.

Let $\tilde{V} = V|\sigma$, let $\tilde{g}(k) = \max\{0, g(k) - |\sigma|\}$, and take

$$T_k = \left\{ l : \mu(B_{k,l} - \tilde{V}) < 2^{-(l+3)} \right\}.$$

Note that for each $l \in \omega$, if $l \geq |\sigma|$, then $B_{k,l}|\sigma = B_{k,l-|\sigma|}$. Thus, since $g(k) \geq |\sigma|$,

$$U_n^g|\sigma = \bigcup_{k > n} B_{k,g(k)}|\sigma = \bigcup_{k > n} B_{k,g(k)-|\sigma|} = U_n^{\tilde{g}},$$

and so $\mu(U_n^{\tilde{g}} - \tilde{V}) = \mu_\sigma(U_n^g - V) = 0$. Hence $\tilde{g}(k) \in T_k$ for all $k > n$.

Since \tilde{V} is a Σ_1^0 class, it is evident that T is an r.e. set of integers; indeed $B_{k,l} - \tilde{V}$ is a Π_1^0 class, and thus we can enumerate the fact that certain basic open sets $[\sigma]$ are disjoint from it, until the measure remaining is as small as required. A trace for g is obtained as follows:

$$G_k = \begin{cases} \{l + |\sigma| : l \in T_k\} & \text{if } k > n, \\ \{g(k)\} & \text{if } k \leq n. \end{cases}$$

We now show that G is a trace for g ; i.e., for all $k \in \omega$, $g(k) \in G_k$. If $k \leq n$, then this holds by definition of G_k ; thus suppose $k > n$. Then $g(k) > k > n > |\sigma|$, so $\tilde{g}(k) = g(k) - |\sigma|$, so $g(k) = \tilde{g}(k) + |\sigma|$. As $k > n$, $\tilde{g}(k) \in T_k$ and hence $g(k) \in G_k$.

Clearly G is r.e.; thus it remains to show that $|G_k|$ is computably bounded, independently of g . As $|G_k| = |T_k|$ for $k > n$ and $|G_k| = 1$ for $k \leq n$, this is a consequence of Lemma 4.8 below. \square

LEMMA 4.8. *If \tilde{V} is a measurable set with $\mu\tilde{V} < \frac{1}{4}$, and $T_k = \{l : \mu(B_{k,l} - \tilde{V}) < 2^{-(l+3)}\}$, then for $k \geq 1$, $|T_k| < 2^k k$.*

Proof. Observe that, by definition of T_k ,

$$\sum_{l \in T_k} \mu(B_{k,l} - \tilde{V}) < \sum_{l \in T_k} 2^{-(l+3)} \leq \frac{1}{8} \sum_{l \in \omega} 2^{-l} = \frac{1}{4},$$

so

$$\mu \bigcup_{l \in T_k} B_{k,l} - \mu\tilde{V} \leq \mu \bigcup_{l \in T_k} (B_{k,l} - \tilde{V}) \leq \frac{1}{4}.$$

As $\mu\tilde{V} < \frac{1}{4}$, we obtain that

$$\mu \bigcup_{l \in T_k} B_{k,l} < \frac{1}{2}.$$

As observed above, $\mu B_{k,l} = 2^{-k}$. Moreover, for k fixed, the $B_{k,l}$'s are mutually independent as soon as the l 's are taken sufficiently far apart. In fact, sufficiently far here means a distance of k . So for $k \geq 1$ we let T_k^* be a subset of T_k consisting of $\lfloor \frac{|T_k|}{k} \rfloor$ elements, all of which are sufficiently far apart. (Here $\lfloor a \rfloor$ is the greatest integer $\leq a$.) To show that such a set exists we may assume we are in the worst case, where the elements of T_k are closest together: say, $T_k = \{0, \dots, |T_k| - 1\}$. Then let $T_k^* = \{mk : 0 \leq m \leq \lfloor \frac{|T_k|}{k} \rfloor - 1\}$. As $(\lfloor \frac{|T_k|}{k} \rfloor - 1)k \leq |T_k| - k \leq |T_k| - 1 \in T_k$, this makes $T_k^* \subseteq T_k$. Write $\alpha = \lfloor \frac{|T_k|}{k} \rfloor$. We now have

$$\mu \bigcap_{l \in T_k} (2^\omega - B_{k,l}) \leq \mu \bigcap_{l \in T_k^*} (2^\omega - B_{k,l}) = (1 - 2^{-k})^\alpha$$

and hence

$$\begin{aligned} 1 - (1 - 2^{-k})^\alpha &\leq 1 - \mu \bigcap_{l \in T_k} (2^\omega - B_{k,l}) = \mu 2^\omega - \mu \bigcap_{l \in T_k} (2^\omega - B_{k,l}) \\ &\leq \mu \left(2^\omega - \bigcap_{l \in T_k} (2^\omega - B_{k,l}) \right) = \mu \bigcup_{l \in T_k} B_{k,l} < \frac{1}{2}. \end{aligned}$$

From the inequality above we obtain, letting $m = 2^k - 1$,

$$\left(1 - \frac{1}{m+1} \right)^\alpha = (1 - 2^{-k})^\alpha > \frac{1}{2}$$

or $\left(\frac{m+1}{m}\right)^\alpha < 2$. Now suppose $\alpha \geq m$. Then $\left(\frac{m+1}{m}\right)^\alpha \geq \left(\frac{m+1}{m}\right)^m \geq 2$ as $(m+1)^m \geq m^m + m^{m-1} \binom{m}{1} = 2m^m$. Thus we conclude $\alpha < m = 2^k - 1$. Now, by the definition of α , we have $\frac{|T_k|}{k} \leq \alpha + 1 < 2^k$ and so $|T_k| < 2^k k$; this completes the proof. \square

In order to prove Theorem 3.1(II), recall that, by Theorem 2.2, each computably traceable real is Low(SR). Thus it suffices to show that each Low(CR, SR) real is computably traceable. The first ingredient for showing this is the following result from [2].

LEMMA 4.9. *If A is Low(CR, SR), then A is hyperimmune-free.*

Proof. Suppose A is not hyperimmune-free, so that there is a function $g \leq_T A$ not dominated by any computable function. Thus, for each computable f , $\exists^\infty x f(x) \leq g(x)$. We will define a computably random real X and an A -computable martingale L that succeeds on X in the sense of Schnorr, so that A is not Low(CR, SR). In the following, α, β, γ denote finite subsets of ω , and $n_\alpha = \sum_{i \in \alpha} 2^i$ (here $n_\emptyset = 0$).

Let $\{M_e\}_{e \in \omega}$ be an effective listing of all partial computable martingales with range included in $[1/2, \infty)$. At stage t , we have a finite portion $M_e[t]$, whose domain is a subset of some set of the form $2^{\leq n}$ for some n . If X is not computably random, then $\lim_{n \rightarrow \infty} M_e(X \upharpoonright n) = \infty$ for some total M_e by [13]. Let

$$TMG = \{e : M_e \text{ is total}\}.$$

For finite sets α, β , let us in this proof say that α is a *strong subset* of β (denoted $\alpha \subseteq^+ \beta$) if $\alpha \subseteq \beta$ and moreover for each $i \in \omega$, if $i \in \beta - \alpha$, then $i > \max(\alpha)$. Thus the possibility that β contains an element smaller than some element of α is ruled out.

For certain α , and all those included in TMG , we will define strings x_α in such a way that $\alpha \subseteq^+ \beta \Rightarrow x_\alpha \preceq x_\beta$. We choose the strings in such a way that $M_e(x_\alpha)$ is bounded by a fixed constant (depending on e) for each total M_e and each α containing e . Then the set of integers

$$X = \bigcup_{e \in \omega} x_{TMG \cap [0, e]}$$

is a computably random real. On the other hand, we are able to define an A -computable martingale L which Schnorr succeeds on X . We give an inductive definition of the strings x_α , “scaling factors” $p_\alpha \in \mathbb{Q}^+$ (positive rationals) (we do not define p_\emptyset), and partial computable martingales M_α such that if x_α is defined, then

$$(1) \quad M_\alpha(x_\alpha) \text{ converges in } g(|x_\alpha|) \text{ steps and } M_\alpha(x_\alpha) < 2.$$

It will be clear that A can decide if $y = x_\alpha$, given inputs y and α .

Let $x_\emptyset = \lambda$, and let M_\emptyset be the constant zero function. (We may assume that g is such that $M_\emptyset(\lambda)$ converges in $g(0)$ steps.) Now suppose $\alpha = \beta \cup \{e\}$, where $e > \max(\beta)$, and inductively suppose that (1) holds for β . Let

$$p_\alpha = \frac{1}{2} 2^{-|x_\beta|} (2 - M_\beta(x_\beta)),$$

and let $M_\alpha = M_\beta + p_\alpha M_e$. Since M_e is a martingale on its domain, $M_e(z) \leq 2^{|z|}$ for any z . So, writing $b = M_\beta(x_\beta)$, we have $M_\alpha(x_\beta) = b + p_\alpha M_e(x_\beta) < b + p_\alpha 2^{|x_\beta|} = b + \frac{1}{2}(2 - b) = 1 + \frac{b}{2} < 1 + \frac{2}{2} = 2$ if $M_\alpha(x_\beta)$ is defined.

To define x_α , we look for a sufficiently long $x \succeq x_\beta$ such that M_α does not increase from x_β to x and $M_\alpha(x)$ converges in $g(|x|)$ steps. In detail, for larger and larger $m > |x_\beta|$, $m \geq 4n_\alpha$, if no string y , $|y| < m$, has been designated to be x_α as yet, and if $M_\alpha(z)$ (i.e., each $M_e(z), e \in \alpha$) converges in $g(m)$ steps, for each string z

of length $\leq m$, then choose x_α of length m , $x_\beta \prec x_\alpha$ such that M_α does not increase anywhere from x_β to x_α .

CLAIM 4.10. *If $\alpha \subseteq TMG$, then x_α and p_α (the latter only if $\alpha \neq \emptyset$) are defined.*

Proof. The claim is trivial for $\alpha = \emptyset$. Suppose that it holds for β , and $\alpha = \beta \cup \{e\} \subseteq TMG$, where $e > \max(\beta)$. Since the function

$$f(m) = \mu s \quad \forall e \in \alpha, \forall x \quad [|x| \leq m \Rightarrow M_e(x) \text{ converges in } s \text{ steps}]$$

is computable, there is a least $m \geq 4n_\alpha$, $m > |x_\beta|$ such that $g(m) \geq f(m)$. Since there is a path down the tree starting at x_β , where M_α does not increase, the choice of x_α can be made. \square

CLAIM 4.11. *If $\beta \subseteq^+ \alpha$ are finite sets, then $M_\beta(x) \leq M_\alpha(x)$ for all x .*

Proof. This is clear by induction from the case $\alpha = \beta \cup \{e\}$, i.e., the case where $\alpha - \beta$ has only one element. \square

CLAIM 4.12. *X is computably random.*

Proof. Suppose that M_e is total. Let $\alpha = TMG \cap [0, e]$. Suppose $\alpha \subseteq \gamma$, $\gamma' = \gamma \cup \{i\}$, $\max(\gamma) < i$, and $\gamma' \subseteq TMG$. Then $\alpha \subseteq^+ \gamma \subseteq^+ \gamma'$. Hence by Claim 4.11, for each x with $x_\gamma \preceq x \preceq x_{\gamma'}$, we have

$$p_\alpha M_e(x) \leq M_\alpha(x) \leq M_{\gamma'}(x) \leq M_{\gamma'}(x_\gamma) < 2,$$

and hence $M_e(x) < 2/p_\alpha$ for each $x \prec X$, and so the capital of M_e on X is bounded. \square

CLAIM 4.13. *There is a martingale $L \leq_T A$ which effectively succeeds on X . In fact,*

$$\exists^\infty x \prec X \quad L(x) \geq \left\lfloor \frac{|x|}{4} \right\rfloor.$$

Proof. For a string z , let $r(z) = \lfloor |z|/2 \rfloor$. We let $L = \sum_\alpha L_\alpha$, where L_α is a martingale with initial capital $L_\alpha(\lambda) = 2^{-n_\alpha}$, which bets everything along x_α from $x_\alpha \upharpoonright r(x_\alpha)$ on. More precisely, if x_α is undefined, then L_α is constant with value 2^{-n_α} . Otherwise, for convenience we let $x = x_\alpha \upharpoonright 2r(x_\alpha)$ and work with x instead of x_α ; we define L_α on a string y as follows:

- If y does not contain “half of x ,” i.e., if $x \upharpoonright r(x) \not\preceq y$, then just let $L_\alpha(y) = 2^{-n_\alpha}$.
- If y does contain “half of x ” but y and x are incompatible, then let $L_\alpha(y) = 0$.
- If y contains “half of x ” and x and y are compatible, then let $L_\alpha(y) = 2^{-n_\alpha} 2^{\min(|y|-r(x), r(x))}$.

Thus if y contains x , then $L_\alpha(y) = 2^{r(x)-n_\alpha}$, so we make no more bets once we extend x_α , and if x contains y , then $L_\alpha(y) = 2^{|y|-r(x)-n_\alpha}$; i.e., we double the capital for each correct bit of x beyond $x \upharpoonright r(x)$.

Note that $L(\lambda) = \sum_\alpha 2^{-n_\alpha}$, and, as each $k \in \omega$ has a unique binary expansion and hence is equal to n_α for a unique finite set α , we have $L(\lambda) = \sum_{k \in \omega} 2^{-k} = 2$. Moreover, it is clear that each L_α satisfies the martingale property $L_\alpha(x0) + L_\alpha(x1) = 2L_\alpha(x)$, and hence so does L .

L effectively succeeds on X . Indeed, as $|x_\alpha| \geq 4n_\alpha$, we have $L_\alpha(x_\alpha) = 2^{r(x_\alpha)-n_\alpha} \geq 2^{\lfloor |x_\alpha|/2 \rfloor - \lfloor |x_\alpha|/4 \rfloor} \geq 2^{\lfloor |x_\alpha|/4 \rfloor} \geq \lfloor |x_\alpha|/4 \rfloor$ since $2^q \geq q$ for each $q \in \omega$.

Finally, we show that $L \leq_T A$. Given input y , we use g to see if some string x , $|x| \leq 2|y|$, is x_α . If not, $L_\alpha(y) = 2^{-n_\alpha}$. Else we determine $L_\alpha(y)$ from x using the definition of L_α . \square

The second ingredient to the proof of Theorem 3.1(II) is the following fact of independent interest.

PROPOSITION 4.14. *If A is hyperimmune-free and r.e. traceable, then A is computably traceable.*

Proof. Let $f \leq_T A$, and let h be as in the definition of r.e. traceability. Let $g(x) = \mu s(f(x) \in W_{h(x),s})$ (where $W_{e,s}$ is the approximation at stage s to the r.e. set W_e). Then $g \leq_T A$, and so since A is hyperimmune-free, g is dominated by a computable function r . Thus if we replace $W_{h(x)}$ by $W_{h(x),r(x)}$, we obtain a computable trace for f . \square

Lemma 4.9 and Proposition 4.14 together establish Theorem 3.1(II): if A is Low(CR,SR), then A is r.e. traceable by Theorem 3.1(I), and hyperimmune-free by Lemma 4.9. Thus by Proposition 4.14, A is computably traceable.

As a corollary, we obtain an answer to the question of Ambos-Spies and Kučera.

COROLLARY 4.15. *A real A is S -low iff it is S_0 -low.*

Proof. This follows by Theorem 2.2 and Theorem 3.1(II), since each computably traceable real is S_0 -low. \square

5. Lowness notions related to Chaitin's halting probability. Recall that A is array computable if there is a function $f \leq_{wtt} \emptyset'$ bounding all functions computable from A on almost all inputs.

THEOREM 5.1. *If $\Omega \in \text{SR}^A$, then A is array computable.*

Proof. We show that the function $\beta(x) = \mu s \Omega_s \upharpoonright 3x = \Omega \upharpoonright 3x$ dominates each function $\alpha \leq_T A$. Since $\beta \leq_{wtt} \Omega \leq_{wtt} \emptyset'$, this shows that A is array computable.

Given $\alpha \leq_T A$, consider the A -computable martingale $M = \sum_p M_p$, where M_p is the martingale which has the value 2^{-p} on all strings of length up to p and then doubles the capital along the string $y = \Omega_{\alpha(p)} \upharpoonright 3p$, so that $M_p(y) = 2^p$. Note that $M(z)$ is rational for each z . If $\alpha(p) > \beta(p)$ for infinitely many p , then M Schnorr succeeds on Ω , a contradiction. \square

COROLLARY 5.2. *If A is r.e., then $\Omega \in \text{SR}^A$ iff A is r.e. traceable.*

Proof. For an r.e. set A , array computable implies r.e. traceable by the work of Ishmukhametov [5]. \square

In [6] it is shown that r.e. traceable degrees do not contain diagonally noncomputable functions, and hence, by a result of Kučera [7], the r.e. traceable degrees have measure zero. On the other hand, every real A which is Martin-Löf random relative to Ω satisfies that Ω is MR^A , by van Lambalgen's theorem [15], and hence the measure of the set of A such that Ω is SR^A is one; thus A r.e. traceable is not equivalent to $\Omega \in \text{SR}^A$. Also, $\Omega \in \text{SR}^A$ is not equivalent to A being array computable, as we now show.

The following notion of forcing appears implicitly in [4].

DEFINITION 5.3. *A tree T is a set of strings $\sigma \in 2^{<\omega}$ such that if $\sigma \in T$ and τ is a substring of σ , then $\tau \in T$. A tree T is full on a set $F \subseteq \omega$ if whenever $\sigma \in T$ and $|\sigma| \in F$, then $\sigma 0 \in T$ and $\sigma 1 \in T$. Let F_n , $n \in \omega$, be finite sets such that each F_n is an interval of ω , $|F_{n+1}| > |F_n|$, and $\bigcup_n F_n = \omega$. The sequence F_n , $n \in \omega$, is called a very strong array. Let P be the set of computable perfect trees T such that T is full on F_n for infinitely many n . Order P by $T_1 \leq_P T_2$ if $T_1 \subseteq T_2$. The partial order (P, \leq_P) is a notion of forcing that we call very strong array forcing.*

THEOREM 5.4. *For each real X there is a hyperimmune-free real A such that no real computable from X is in SR^A . In particular, as hyperimmune-free implies array computable, there is an array computable real A such that $\Omega \notin \text{SR}^A$.*

Proof. Let A be sufficiently generic for very strong array forcing. Then A is hyperimmune-free, as may be proved by modifying the standard construction of a hyperimmune-free degree [10] to work with trees that are full on infinitely many F_n , $n \in \omega$.

Moreover, for each real B computable from X , there is an n (hence infinitely many n) such that A agrees with B on F_n . Indeed, given a condition T , a condition extending T and ensuring the existence of such an n is obtained as a full subtree of T .

Hence no real B computable from X is Schnorr random relative to A . Indeed the measure of the set of those oracles B that agree with A on infinitely many F_n is zero, and it is easy to see that the measure of those B such that, for some $k > n$, A and B agree on F_k , goes to zero effectively as $n \rightarrow \infty$. Hence there is a Schnorr test relative to A which is failed by any such B , as desired. \square

QUESTION 5.5. *Characterize the (r.e.) sets of integers A such that Ω is computably random relative to A . Does this depend on the version of Ω used?*

AN EFFICIENT ALGORITHM FOR COMPUTING OPTIMAL DISCRETE VOLTAGE SCHEDULES*

MINMING LI[†] AND FRANCES F. YAO[‡]

Abstract. We consider the problem of job scheduling on a variable voltage processor with d discrete voltage/speed levels. We give an algorithm which constructs a minimum energy schedule for n jobs in $O(dn \log n)$ time. Previous approaches solve this problem by first computing the optimal continuous solution in $O(n^3)$ time and then adjusting the speed to discrete levels. In our approach, the optimal discrete solution is characterized and computed directly from the inputs. We also show that $O(n \log n)$ time is required; hence the algorithm is optimal for fixed d .

1. Introduction. Advances in processor, memory, and communication technologies have enabled the development and widespread use of portable electronic devices. As such devices are typically powered by batteries, energy efficiency has become an important issue. With dynamic voltage scaling (DVS) techniques, processors are able to operate at a range of voltages and frequencies. Since energy consumption is at least a quadratic function of the supply voltage (hence CPU speed), it saves energy to execute jobs as slowly as possible while still satisfying all timing constraints.

We refer to the associated scheduling problem as the min-energy DVS scheduling problem (or DVS problem for short); the precise formulation will be given in section 2. The problem is different from classical scheduling on fixed-speed processors, and it has received much attention from both theoretical and engineering communities in recent years. One of the earliest theoretical models for DVS was introduced in [1]. They gave a characterization of the min-energy DVS schedule and an $O(n^3)$ algorithm¹ for computing it. No special assumption was made on the power consumption function except convexity. This optimal schedule has been referenced widely, since it provides a main benchmark for evaluating other scheduling algorithms in both theoretical and simulation work.

In the min-energy DVS schedule mentioned above, the processor must be able to run at *any* real-valued speed s in order to achieve optimality. In practice, variable voltage processors run only at a finite number of speed levels chosen from specific points on the power function curve. For example, the Intel *SpeedStep* technology [2] currently used in Intel's notebooks supports only 3 speed levels, although the new *Foxon* technology will soon enable Intel server chips to run at as many as 64 speed

¹The complexity of the algorithm was said to be further reducible in [1], but that claim has since been withdrawn.

grades. Thus, an accurate model for min-energy scheduling should capture the discrete, rather than continuous, nature of the available speed scale. This consideration has motivated our present work.

In this paper we consider the discrete version of the DVS scheduling problem. Denote by $s_1 > s_2 > \dots > s_d$ the clock speeds corresponding to d given discrete voltage levels. The goal is to find, under the restriction that only these speeds are available for job execution, a schedule that consumes as little energy as possible. (It is assumed that the highest speed s_1 is fast enough to guarantee a feasible schedule for the given jobs.) This problem was considered in [3] for a single job (i.e., $n = 1$), where they observed that minimum energy is achieved by using the immediate neighbors s_i, s_{i+1} of the ideal speed s in appropriate proportions. It was later extended in [4] to give an optimal discrete schedule for n jobs, obtained by first computing the optimal continuous DVS schedule and then individually adjusting the speed of each job appropriately to adjacent levels as done in [3].

The following question naturally arises: Is it possible to find a direct approach for solving the optimal discrete DVS scheduling problem without first computing the optimal continuous schedule? We answer the question in the affirmative. For n jobs with arbitrary arrival-time/deadline constraints and d given discrete supply voltages (speeds), we give an algorithm that finds an optimal discrete DVS schedule in $O(dn \log n)$ time. We also show that this complexity is optimal for any fixed d . We remark that the $O(n^3)$ algorithm for finding the continuous DVS schedule (cf. section 2) computes the highest speed, second highest speed, etc. for execution in a strictly sequential manner and may use up to n different speeds in the final schedule. Therefore it is unclear a priori how to find shortcuts to solve the discrete problem. Our approach is different from that of [4], which is based on the continuous version and therefore requires $O(n^3)$ time.

Our algorithm for optimal discrete DVS proceeds in two stages. In stage 1, the jobs in J are partitioned into d disjoint groups J_1, J_2, \dots, J_d , where J_i consists of all jobs whose execution speeds in the continuous optimal schedule S_{opt} lie between s_i and s_{i+1} . We show that this multilevel partition can be obtained without determining the exact optimal execution speed of each job. In stage 2, we proceed to construct an optimal schedule for each group J_i using two speeds s_i and s_{i+1} . Both the separation of each group J_i in stage 1, and the subsequent scheduling of J_i using two speed levels in stage 2, can be accomplished in time $O(n \log n)$ per group. Hence this two-stage algorithm yields an optimal discrete voltage schedule for J in total time $O(dn \log n)$. The algorithm admits a simple implementation, although its proof of correctness and complexity analysis are nontrivial. Aside from its theoretical value, we also expect our algorithm to be useful in generating optimal discrete DVS schedules for simulation purposes as in the continuous case.

We briefly mention some additional theoretical results on DVS, although they are not directly related to the problem considered in this paper. In [1], two on-line heuristics, average rate (AVR) and optimal available (OPA), were introduced for the case that jobs arrive one at a time. AVR was shown to have a competitive ratio of at most 8 in [1]; recently a tight competitive ratio of 4 was proven for OPA in [5]. For jobs with fixed priority, the scheduling problem was shown to be NP-hard, and an FPTAS was given in [6]. In addition, [7] gave efficient algorithms for computing the optimal schedule for job sets structured as trees. (The interested reader can find further references in these papers.)

The remainder of the paper is organized as follows. We give the problem formu-

lation and review the optimal continuous schedule in section 2. Section 3 discusses some mathematical properties associated with earliest deadline first (EDF) scheduling under different speeds. Sections 4 and 5 give details of the two stages of the algorithm as outlined above. The combined algorithm and a lower bound are presented in section 6. Finally, some concluding remarks are given in section 7.

2. Problem formulation. Each job j_k in a job set J over $[0, 1]$ is characterized by three parameters: arrival time a_k , deadline b_k , and required number of CPU cycles R_k . A schedule S for J is a pair of functions $(s(t), job(t))$ defining the processor speed and the job being executed at time t . Both functions are piecewise constant with finitely many discontinuities. A *feasible* schedule must give each job its required number of cycles between arrival time and deadline (with perhaps intermittent execution). We assume that the power P , or energy consumed per unit time, is a convex function of the processor speed. The total energy consumed by a schedule S is $E(S) = \int_0^1 P(s(t))dt$. The goal of the min-energy scheduling problem is to find, for any given job set J , a feasible schedule that minimizes $E(S)$. We refer to this problem as *DVS* scheduling (or sometimes *continuous DVS* scheduling to distinguish it from the discrete version below).

In the discrete version of the problem, we assume d discrete voltage levels are given, enabling the processor to run at d clock speeds $s_1 > s_2 > \dots > s_d$. The goal is to find a min-energy schedule for a job set using only these speeds. We may assume that, in each problem instance, the highest speed s_1 is always fast enough to guarantee a feasible schedule for the given jobs. We refer to this problem as *discrete DVS* scheduling.

For the continuous DVS scheduling problem, the optimal schedule S_{opt} can be characterized based on the notion of a *critical interval* for J , which is an interval I in which a group of jobs must be scheduled at maximum constant speed $g(I)$ in any optimal schedule for J . The algorithm proceeds by identifying such a critical interval I , scheduling those “critical” jobs at speed $g(I)$ over I and then constructing a subproblem for the remaining jobs and solving it recursively. The optimal $s(t)$ is in fact unique, whereas $job(t)$ is not always so. The details are given below.

DEFINITION 2.1. *Define the intensity of an interval $I = [z, z']$ to be*

$$g(I) = \frac{\sum R_j}{z' - z},$$

where the sum is taken over all jobs j_ℓ with $[a_\ell, b_\ell] \subseteq [z, z']$.

The interval $[c, d]$ achieving the maximum $g(I)$ will be the critical interval chosen for the current job set. All jobs $j_\ell \in J$ satisfying $[a_\ell, b_\ell] \subseteq [c, d]$ can be feasibly scheduled at speed $g([c, d])$ by the EDF principle. The interval $[c, d]$ is then removed from $[0, 1]$; all remaining intervals $[a_j, b_j]$ are updated (compressed) accordingly, and the algorithm recurses. The complete algorithm is given in Algorithm 1.

Let $CI_i \subseteq [0, 1]$ be the i th critical interval of J . Denote by Cs_i the execution speed during CI_i and by CJ_i those jobs executed in CI_i . We take note of a basic property of critical intervals which will be useful in later discussions.

LEMMA 2.2. *A job $j_\ell \in J$ belongs to $\bigcup_{k=1}^i CJ_k$ if and only if the interval $[a_\ell, b_\ell]$ of j_ℓ satisfies $[a_\ell, b_\ell] \subseteq \bigcup_{k=1}^i CI_k$.*

Proof. The “if” direction is straightforward. For the “only if” part, it can be proven by induction on i that $j_\ell \in CJ_i$ implies $[a_\ell, b_\ell] \subseteq \bigcup_{k=1}^i CI_k$, based on the way critical intervals are successively chosen. \square

3. EDF with variable speeds. The EDF principle defines an ordering on the jobs according to their deadlines. At any time t , among jobs j_k that are available for execution, that is, j_k satisfying $t \in [a_k, b_k)$ and j_k not yet finished by t , it is the job with minimum b_k that will be executed during $[t, t + \epsilon]$. EDF is a natural scheduling principle, and many optimal schedules (such as the continuous min-energy schedule described above) in fact conform to it. All schedules considered in the remainder of this paper are EDF schedules. Hence we assume the jobs in $J = \{j_1, \dots, j_n\}$ are indexed by their deadlines.

We introduce an important tool for solving the discrete DVS scheduling problem: an EDF schedule that runs at some constant speed s (except for periods of idleness).

DEFINITION 3.1. *An s -schedule for J is a schedule which conforms to the EDF principle and uses constant speed s in executing any job of J .*

As long as there are unfinished jobs available at time t , an s -schedule will select a job by the EDF principle and execute it at speed s . An s -schedule may contain periods of idleness when there are no jobs available for execution. An s -schedule may also yield an unfeasible schedule for J since the speed constraint may leave some jobs unfinished by their deadlines.

DEFINITION 3.2. *In any schedule S , a maximal subinterval of $[0, 1]$ devoted to executing the same job j_k is called an execution interval (for j_k with respect to S). Denote by $I_k(S)$ the collection of all execution intervals for j_k with respect to S . With respect to the s -schedule for J , any execution interval will be called an s -execution interval, and the collection of all s -execution intervals for job j_k will be denoted by I_k^s .*

Notice that for any EDF schedule S , it is always true that $I_i(S) \subseteq [a_i, b_i] - \cup_{k=1}^{i-1} I_k(S)$. For a given J , we observe some interesting monotone relations that exist among the EDF schedules of J with respect to different speed functions. These relations will be exploited by our algorithms later. They may also be of independent interest in studying other types of scheduling problems.

LEMMA 3.3. *Let S_1 and S_2 be two EDF schedules whose speed functions satisfy $s_1(t) > s_2(t)$ for all t whenever S_1 is not idle.*

(1) *For any t and any job j_k , the workload of j_k executed by time t under S_1 is*

always no less than that under S_2 .

(2) $\cup_{k=1}^i I_k(S_1) \subseteq \cup_{k=1}^i I_k(S_2)$ for any i , $1 \leq i \leq n$.

(3) Any job of J that can be finished under S_2 is always finished strictly earlier under S_1 .

(4) If S_2 is a feasible schedule for J , then so is S_1 .

Proof. We prove (1) and (2) by induction on i . When $i = 1$, since both S_1 and S_2 start executing j_1 at time a_1 , it is easy to see that induction hypotheses (1) and (2) are both true. Assume that they hold for jobs j_1, \dots, j_{i-1} ; we will prove (1) and (2) for j_i . The time V_1 available for executing j_i under S_1 is $V_1 = [a_i, b_i] - \cup_{k=1}^{i-1} I_k(S_1)$, which satisfies $V_1 \supseteq V_2$ for the corresponding available time under S_2 because of induction hypothesis (2). This together with the assumption $s_1(t) > s_2(t)$ proves (1); that is, the execution of j_i by S_1 will always be ahead of that by S_2 . Assuming that S_2 finishes j_i at time t , then we have $I_i(S_1) \subseteq [a_i, t] \subseteq \cup_{k=1}^i I_k(S_2)$ from which (2) follows inductively. \square

Note that as a special case, Lemma 3.3 holds when we substitute s_1 -schedule and s_2 -schedule, with $s_1 > s_2$, for S_1 and S_2 , respectively.

LEMMA 3.4. *The s -schedule for J contains at most $2n$ s -execution intervals and can be computed in $O(n \log n)$ time if the arrival times and deadlines are already sorted.*

Proof. The end of an execution interval corresponds to the moment when either a job is finished or a new job arrives. There can be at most $2n$ such endpoints, and hence at most $2n$ s -execution intervals. If the arrival times and deadlines are already sorted, then generating one s -execution interval costs $O(\log n)$ time, and the entire schedule can be computed in $O(n \log n)$ time. This completes the proof. \square

4. Partition of jobs by speed level. We will consider the first stage of the algorithm for optimal discrete DVS in this section. Clearly, to get an $O(dn \log n)$ -time partition of J into d groups corresponding to d speed levels, it suffices to give an $O(n \log n)$ algorithm which can properly separate J into two groups according to any given speed s .

DEFINITION 4.1. *Given a job set J and any speed s , let $J^{\geq s}$ and $J^{< s}$ denote the subset of J consisting of jobs whose executing speeds are $\geq s$ and $< s$, respectively, in the (continuous) optimal schedule of J . We refer to the partition $\langle J^{\geq s}, J^{< s} \rangle$ as the s -partition of J .*

Let $T^{\geq s} \subseteq [0, 1]$ be the union of all critical intervals CI_i with $Cs_i \geq s$. By Lemma 2.2, a job i is in $J^{\geq s}$ if and only if its interval $[a_i, b_i] \subseteq T^{\geq s}$. Thus $J^{\geq s}$ is uniquely determined by $T^{\geq s}$, and we can focus on computing $T^{\geq s}$ instead. Let $T^{< s} = [0, 1] - T^{\geq s}$, and we refer to $\langle T^{\geq s}, T^{< s} \rangle$ as the s -partition of time for J .

An example of J with 11 jobs is given in Figure 1, together with the optimal speed function $S_{opt}(t)$. The portion of $S_{opt}(t)$ lying above the horizontal line $Y = s$ projects to $T^{\geq s}$ on the time axis. In general, $T^{\geq s}$ may consist of a number of connected components.

In the remainder of this section, we will show that certain features existing in the s -schedule of J can be used for identifying connected components of $T^{< s}$. This then leads to an efficient algorithm for computing the s -partition of time $\langle T^{\geq s}, T^{< s} \rangle$.

DEFINITION 4.2. *In the s -schedule for J , we say a deadline b_i is tight if job j_i is either unfinished at time b_i or is finished just on time at b_i . An idle interval $g = [t, t']$ in the s -schedule is called a gap.*

Figure 2 depicts the s -schedule for the sample job set J considered in Figure 1. All tight deadlines and gaps have been marked along the time axis. By overlaying the

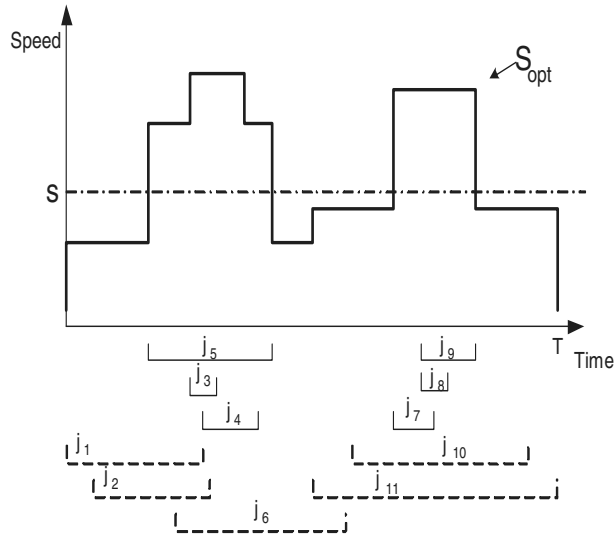

FIG. 1. The s -partition for a sample J . The jobs are represented by their intervals only and indexed according to deadline. Solid intervals represent jobs belonging to $J^{\geq s}$, while dashed intervals represent jobs belonging to $J^{< s}$.

FIG. 2. The s -execution intervals for the same J in Figure 1 are illustrated, where the number indicates which job is being executed. Shaded blocks correspond to gaps (idle time), while arrows point to tight deadlines.

s -partition of time $\langle T^{\geq s}, T^{< s} \rangle$ for J , we notice that (1) tight deadlines exist only in $T^{\geq s}$, and (2) each connected component of $T^{\geq s}$ ends with a tight deadline. We prove below that these properties always hold for any job set.

LEMMA 4.3. (1) *Tight deadlines in an s -schedule can exist only in $T^{\geq s}$.*

(2) *The rightmost point of each connected component of $T^{\geq s}$ must be a tight deadline.*

Proof. As observed before, the only jobs available for execution during $T^{< s}$ are those from $J^{< s}$. Furthermore, by property (3) of Lemma 3.3, all jobs of $J^{< s}$ will be finished strictly before their deadlines under the s -schedule, thus yielding no tight

deadlines in $T^{<s}$. This proves property (1). For property (2), we argue that it is a consequence of property (1) in Lemma 3.3. Let b_i be the end of a connected component of $T^{\geq s}$. Job j_i , being the last executed job of a critical interval, is finished exactly on time under S_{opt} (which runs at speed at least s throughout $T^{\geq s}$). Therefore, job j_i must have a tight deadline under the s -schedule. \square

Property (2) of Lemma 4.3 gives a necessary condition for identifying the right boundary of each connected component of $T^{\geq s}$. The corresponding left boundary of such a component can also be identified through left-right symmetry of the scheduling problem with respect to time.

DEFINITION 4.4. *Given a job set J , the reverse job set J^{rev} consists of jobs with the same workload but time intervals $[1 - b_i, 1 - a_i]$. The s -schedule for J^{rev} is called the reverse s -schedule for J . We call an arrival time a_i (for the original job set J) tight if $1 - a_i$ corresponds to a tight deadline in the reverse s -schedule for J .*

One may also view the reverse s -schedule as a schedule which runs backwards: starting from time 1 and executing jobs of J by the latest arrival time first principle at constant speed s whenever possible. Lemma 4.5 is the symmetric analogue of Lemma 4.3.

LEMMA 4.5. (1) *Tight arrival times in an s -schedule can exist only in $T^{\geq s}$.*

(2) *The leftmost point of each connected component of $T^{\geq s}$ must be a tight arrival time.*

Lemmas 4.3 and 4.5 are not sufficient by themselves to enable an efficient separation of $T^{\geq s}$ from $T^{<s}$. Fortunately, we have an additional useful property related to $T^{<s}$. Observe that in Figure 2 all gaps of the s -schedule fall within $T^{<s}$. This is in fact true in general, and, furthermore, a gap must exist in $T^{<s}$ as we prove next.

LEMMA 4.6. *Gaps in an s -schedule can exist only in $T^{<s}$; furthermore, a gap must exist in $T^{<s}$.*

Proof. Suppose a gap in an s -schedule occurs at some time $t \in T^{\geq s}$; that is, all jobs $J(t)$ in J whose intervals overlap t have been finished. In particular, no jobs belonging to $J(t) \cap J^{\geq s}$ are available. Since the schedule s_{opt} runs at higher speed than s over $T^{\geq s}$ in executing $J^{\geq s}$, it must also finish all jobs of $J(t) \cap J^{\geq s}$ before time t by Lemma 3.3. In other words, s_{opt} would have a gap at time t which is not possible. This proves that gaps can exist only in $T^{<s}$. For the second part, we note that the total workload of $J^{<s}$, which is executed over $T^{<s}$, is less than $s \cdot |T^{<s}|$; hence a gap must exist. \square

Finally, we collect the properties that will be used by the partition algorithm in the following theorem. We first give a definition.

DEFINITION 4.7. *Given a gap $[x, y]$ in an s -schedule, we define the expansion of $[x, y]$ to be the smallest interval $[b, a]$ satisfying (1) $[b, a] \supseteq [x, y]$, and (2) b and a are tight deadline and tight arrival time, respectively, of the s -schedule. (Note: we adopt the convention that 0 is considered a tight deadline, while 1 is considered a tight arrival time.) See Figure 3.*

THEOREM 4.8. (1) *A gap always exists in an s -schedule if $T^{<s} \neq \emptyset$.*

(2) *The expansion $[b, a]$ of a gap $[x, y]$ defines the connected component in $T^{<s}$ containing $[x, y]$.*

Proof. Property (1) comes from Lemma 4.6, while property (2) follows from Lemmas 4.3 and 4.5. \square

Notice that although Theorem 4.8 guarantees that one can always find a gap and then use it to identify a connected component C of $T^{<s}$ (provided $T^{<s} \neq \emptyset$), it is not true that *all* connected components of $T^{<s}$ must contain gaps and can be identified

FIG. 3. Gap expansion: the indicated gap will be expanded into $[b, a]$, a connected component of $T^{<s}$.

simultaneously. However, once a component C is found, by deleting the s -execution intervals of all jobs whose interval $[a_i, b_i]$ intersects with C , gaps can surely be found (provided $T^{<s} - C \neq \emptyset$), and the process can continue. This is true because, by reasoning similar to that of Lemma 4.6, the total workload of the remaining jobs in $J^{<s}$ over $T^{<s} - C$ is less than $s \cdot |T^{<s} - C|$; hence a gap must exist.

The detailed algorithm for generating the s -partition is given in Algorithm 2 below.

THEOREM 4.9. *Algorithm 2 finds the s -partition $\langle J^{\geq s}, J^{<s} \rangle$ for a job set J in $O(n \log n)$ time.*

Proof. The correctness of the algorithm is based on Theorem 4.8 and the discussions following the theorem. For the complexity part, sorting and generating s -schedules take $O(n \log n)$ time. We now analyze individual steps inside the for loop. For step 1, finding the expansion of a gap takes only $O(\log n)$ time by binary search; with at most n expansions (to find at most n connected components) the total cost is $O(n \log n)$. Step 2 can be done, with standard data structures such as interval trees, in time $O(\log n) + |J_{new}^{<s}|$, which amounts to total time $O(n \log n)$ since $\sum |J_{new}^{<s}| = O(n)$. It remains to consider steps 7 and 8. Since each individual gap is added to and deleted from the sorted list $Gaps$ only once, and since there are at most $2n$ s -execution intervals (hence gaps), the cost is at most $O(n \log n)$. This shows that the total running time of Algorithm 2 is $O(n \log n)$. \square

We next use Algorithm 2 as a subroutine to obtain Algorithm 3.

THEOREM 4.10. *Algorithm 3 partitions job set J into d subsets corresponding to d speed levels in time $O(dn \log n)$.*

5. Two-level schedule. After Algorithm 3 completes the multilevel partition of J into subsets J_1, \dots, J_d , we can proceed to schedule the jobs in each subset J_i with two appropriate speed levels s_i and s_{i+1} . We will present a two-level scheduling algorithm whose complexity is $O(n \log n)$ for a set of n jobs. For this purpose, it suffices to describe how to schedule the subset J_1 with two available speeds s_1 and

s_2 , where $s_1 > s_2 > 0$. We will schedule each connected component of J_1 separately. Thus, the two-level scheduler deals only with “eligible” input job sets, i.e., those with a continuous optimal schedule speed $s_{opt}(t)$ satisfying $s_1 \geq s_{opt}(t) \geq s_2$ for all t . (Clearly, this condition is satisfied by each connected component of $J_1 = J^{\geq s_2}$ output from Algorithm 3.) We give an alternative and equivalent definition of “eligibility” in the following. This definition does not make reference to $s_{opt}(t)$, and hence is more useful for the purpose of deriving a two-level schedule directly.

DEFINITION 5.1. For a job set J over $[0, 1]$, a two-level schedule with speeds s_1 and s_2 (or (s_1, s_2) -schedule for short) for J is a feasible schedule $s(t)$ for J , which is piecewise constant over $[0, 1]$ with either $s(t) = s_1$ or $s(t) = s_2$ for any t .

In other words, an (s_1, s_2) -schedule for J is a schedule using only speeds s_1 and s_2 which finishes every job and leaves no idle time.

LEMMA 5.2. For a job set J over $[0, 1]$, an (s_1, s_2) -schedule exists if and only if (1) the s_1 -schedule for J is a feasible schedule, and

(2) the s_2 -schedule for J contains no idle time in $[0, 1]$.

Proof. The “only if” direction is easy to see. Suppose a two-level schedule $s(t)$ exists with $s_1 \geq s(t) \geq s_2$ for all $t \in [0, 1]$. It follows from Lemma 3.3 that with speed s_1 the processor can finish all jobs just as with speed $s(t)$, while with speed s_2 the processor will not finish any job earlier than with speed $s(t)$, and hence will never be idle. This proves (1) and (2). For the “if” direction, suppose (1) and (2) both hold. Because the s_1 -schedule generates a feasible schedule, the optimal continuous schedule $s_{opt}(t)$ must satisfy $s_{opt}(t) \leq s_1$ for all $t \in [0, 1]$. On the other hand, (2) implies $J = J^{\geq s_2}$ by Lemma 4.6; that is, $s_{opt}(t) \geq s_2$ for all $t \in [0, 1]$. Using the result in [4], we can first calculate the continuous optimal schedule $s_{opt}(t)$ for J and then adjust the execution speed s of each job to be a combination of s_1 or s_2 in the right proportion to achieve the same average speed s . This results in a two-level schedule for J with speeds s_1 and s_2 . \square

In view of the preceding lemma, we give the following definition of eligibility for input job sets to two-level scheduling.

DEFINITION 5.3. A job set J over $[0, 1]$ is said to be eligible for (s_1, s_2) -scheduling if

- (1) the s_1 -schedule for J is a feasible schedule, and
- (2) the s_2 -schedule for J contains no idle time in $[0, 1]$.

We will consider only eligible job sets in discussing two-level scheduling in the remainder of this section. An (s_1, s_2) -schedule for J is said to be *optimal* if it consumes minimum energy among all (s_1, s_2) -schedules for J .

LEMMA 5.4. All (s_1, s_2) -schedules for an eligible job set J consume the same amount of energy, and hence are optimal.

Proof. The energy consumption is determined by the total amount of time the processor runs at speeds s_1 and s_2 , respectively. Suppose, in an optimal schedule for J , that α time is devoted to speed s_1 and β time is devoted to speed s_2 . An optimal schedule will not contain any idle period; hence the following equations are satisfied:

$$\begin{cases} \alpha s_1 + \beta s_2 = \sum R_i, \\ \alpha + \beta = 1. \end{cases}$$

Clearly, any (s_1, s_2) -schedule for J will also satisfy the above two equations. Since these equations uniquely determine α and β , the lemma follows. \square

The two-level schedule as described in the proof of Lemma 5.2, which first computes the continuous optimal schedule and then rounds the execution speed of each job up and down appropriately [4], requires $O(n^3)$ computation time. We now describe a more efficient algorithm which directly outputs a two-level schedule without first computing the continuous optimal schedule. The algorithm runs in $O(n)$ time if the input jobs are already sorted by deadline (as obtained via Algorithm 3) and $O(n \log n)$ time in general.

The two-level scheduling algorithm (Algorithm 4) proceeds as follows. It first computes the s_2 -schedule for J which in general does not provide a feasible schedule. We then transform it into a feasible schedule by suitably adjusting the execution speed of each job from s_2 to s_1 and possibly extending its execution interval if necessary. These adjustments are done in an orderly and systematic manner to ensure overall feasibility. The algorithm needs to consult the corresponding s_1 -schedule of J in making the transformation. An (s_1, s_2) -schedule for J is produced at the end which by Lemma 5.4 is an optimal two-level schedule.

Algorithm 4 Two-Level Schedule**Input:**

speeds s_1, s_2 , where $s_1 > s_2$

An eligible job set J for (s_1, s_2) -scheduling

Variables:

Committed: the list of allocated time intervals.

Committed(i): the time intervals allocated to job j_i .

Output:

Optimal (s_1, s_2) -schedule for J

Compute s_1 -schedule for J to obtain $I_k^{s_1}$ for $k = 1, \dots, n$.

Compute s_2 -schedule for J to obtain $I_k^{s_2}$ for $k = 1, \dots, n$.

$Committed \leftarrow \emptyset$

for $i = n$ **downto** 1 **do**

1. $I = I_i^{s_2} - Committed$

2. Take $I' \subseteq I_i^{s_1}$ of appropriate length (possibly 0) from the right end of $I_i^{s_1}$ to obtain an (s_1, s_2) -schedule for j_i over $I \cup I'$

3. $Committed(i) = I \cup I'$

4. $Committed \leftarrow Committed \cup Committed(i)$

end for

5.1. Correctness of two-level scheduling algorithm. Let J be an eligible job set for (s_1, s_2) -scheduling. We will show that Algorithm 4 indeed outputs an (s_1, s_2) -schedule for J .

The jobs in J are sorted in increasing order by their deadlines as j_1, j_2, \dots, j_n . After computing the s_1 -schedule and s_2 -schedule for J , the algorithm then allocates appropriate execution time and speed for each job j_i in the order $i = n, \dots, 1$. Step 2 of the for loop carries out the allocation for job j_i . We examine this step in more detail in the following lemma.

LEMMA 5.5. *In step 2 of the for loop, by choosing an appropriate interval $I' \subseteq I_i^{s_1}$ (assuming $I_i^{s_1} \cap Committed = \emptyset$), an (s_1, s_2) -schedule for job j_i over $I \cup I'$ can be found where $I = I_i^{s_2} - Committed$.*

Proof. There are two cases to consider when step 2 is encountered. Suppose job j_i can be feasibly scheduled with speed s_1 over $I = I_i^{s_2} - Committed$. Since the s_2 -schedule of j_i over I clearly has no idle time, Lemma 5.2 ensures that an (s_1, s_2) -schedule exists for job j_i over I . Suppose j_i cannot be feasibly scheduled at s_1 over I . Under the assumption $I_i^{s_1} \cap Committed = \emptyset$, we can take sufficient length of time I' from $I_i^{s_1}$ so that j_i can be finished at s_1 over $I \cup I'$. Therefore one can always find an (s_1, s_2) -schedule for job j_i over $I \cup I'$. \square

We next prove that the assumption $I_i^{s_1} \cap Committed = \emptyset$ in Lemma 5.5 is indeed satisfied when step 2 is encountered in the i th iteration (see property (3) below). In fact, we show by induction on i that the following induction hypotheses are maintained by the algorithm at the start of the i th iteration for $i = n, \dots, 1$.

LEMMA 5.6. *At the beginning of the i th iteration of the for loop, the following are true:*

- (1) $Committed(i+1) \subseteq I_{i+1}^{s_1} \cup I_{i+1}^{s_2}$.
- (2) $\cup_{k=i+1}^n I_k^{s_2} \subseteq Committed \subseteq (\cup_{k=i+1}^n I_k^{s_1}) \cup (\cup_{k=i+1}^n I_k^{s_2})$.
- (3) $Committed \cap (\cup_{k=1}^i I_k^{s_1}) = \emptyset$.

Proof. It is easy to verify that all three induction hypotheses hold initially for $i = n$. Now assume that they hold for iterations $i+1, \dots, n$; we will prove them for the i th iteration. Property (1) is a result of how $Committed(i+1)$ is selected as discussed in Lemma 5.5. For property (2), the right side follows from (1) since $Committed = \cup_{k=i+1}^n Committed(k)$. The left side follows from the fact that, by Lemma 5.5, each $Committed(k)$ always uses up all remaining time in $I_k^{s_2}$ not already committed to previous jobs. To prove (3), let $V = \cup_{k=1}^i I_k^{s_1}$. First, note that V is disjoint from $\cup_{k=i+1}^n I_k^{s_1}$. Next, V is contained in $\cup_{k=1}^i I_k^{s_2}$ by property (2) of Lemma 3.3; hence V is disjoint from $\cup_{k=i+1}^n I_k^{s_2}$. Thus it follows from (2) that $Committed \cap V = \emptyset$. \square

THEOREM 5.7. *Given an eligible job set J for (s_1, s_2) -scheduling, Algorithm 4 generates an (s_1, s_2) -schedule for J .*

Proof. Each job j_i is feasibly executed, with no idle time, over $Committed(i)$ at speeds $\{s_1, s_2\}$ as specified in Lemma 5.5. By the time the algorithm terminates, $Committed = \cup_{k=1}^n Committed(k) \supseteq \cup_{k=1}^n I_k^{s_2} = [0, 1]$ by property (2) of Lemma 5.6. Hence there is no idle time in $[0, 1]$. The resulting schedule thus satisfies the requirements of an (s_1, s_2) -schedule for J . \square

5.2. Complexity of two-level scheduling algorithm. We will show that the cost of Algorithm 4 is $O(n \log n)$. The algorithm first computes the s_1 -schedule and s_2 -schedule for J in $O(n \log n)$ time. The resulting list L_{s_1} with at most $2n$ s_1 -execution intervals is already sorted, and similarly for the list L_{s_2} of s_2 -execution intervals. A sorted list L_{s_1, s_2} , of size at most $4n$, representing $L_{s_1} \cap L_{s_2}$ can be obtained with cost $O(n)$. Using appropriate pointers from lists L_{s_1} , L_{s_2} , and $Committed$ into L_{s_1, s_2} , each step of the for loop can be carried out in constant time plus the number of intervals visited. Execution of step 2 may cause a splitting of some interval in L_{s_1} (to represent interval I') and corresponding splitting in L_{s_1} , L_{s_1, s_2} , and $Committed$. As only a single split can be introduced in each iteration, the overall effect is only $O(n)$. Also each subinterval in L_{s_1} , L_{s_2} , and L_{s_1, s_2} needs to be visited only once. Hence the total running time of the algorithm is $O(n)$ if the input jobs are sorted (as output by Algorithm 3). We have proved the following theorem.

THEOREM 5.8. *Algorithm 4 computes an optimal two-level schedule for J in $O(n \log n)$ time.*

Algorithm 5 Optimal Discrete DVS Schedule

Input:

job set J

speed levels: $s_1 > s_2 > \dots > s_d > s_{d+1} = 0$

Output:

Optimal Discrete DVS Schedule for J

Generate J_1, J_2, \dots, J_d by Algorithm 3

for $i = 1$ to d **do**

Schedule jobs in J_i using Algorithm 4 with speeds s_i and s_{i+1}

end for

The union of the schedules give the optimal Discrete DVS schedule for J

6. Optimal discrete voltage schedule.

THEOREM 6.1. *Algorithm 5 generates a min-energy discrete DVS (MDDVS) schedule with d voltage levels in time $O(dn \log n)$ for n jobs.*

Proof. This is a direct consequence of Theorems 4.10, 5.7, and 5.8. \square

We next show that the running time of Algorithm 5 is optimal by proving an $\Omega(n \log n)$ lower bound in the algebraic decision tree model.

THEOREM 6.2. *Any deterministic algorithm for computing an MDDVS schedule with $d \geq 2$ voltage levels will require $\Omega(n \log n)$ time for n jobs.*

Proof. The integer element uniqueness (IEU) problem is known to have $\Omega(n \log n)$ computational complexity in the algebraic decision tree model [8]. We now make a linear reduction from IEU to MDDVS. Suppose the given instance of IEU consists of n positive integers $\{x_1, x_2, \dots, x_n\}$. First, compute $N = \max\{x_i\}$ in linear time. We construct a job set $J = \{j_1, j_2, \dots, j_n\}$ over time span $[0, N]$ with $[a_i, b_i] = [x_i - 1, x_i]$ and $R_i = 1$. (The time span can be normalized to $[0, 1]$ by scaling all numbers appropriately.) Thus the time intervals of all the jobs are disjoint if and only if the integers x_i are distinct. Set the available speed levels to be $s_1 = n$ (to guarantee feasibility) and $s_d = 1$, while s_2, \dots, s_{d-1} may be any values in between. It is easy to see that the answer to the IEU problem is yes (all integers x_i are distinct) if and only if $MDDVS \leq n$ (by executing every job at speed $s_d = 1$). This completes the reduction. \square

7. Conclusion. In this paper we considered the problem of job scheduling on a variable voltage processor with d discrete voltage/speed levels. We give an algorithm which constructs a minimum energy schedule for n jobs in $O(dn \log n)$ time, which is optimal for fixed d . The min-energy discrete schedule is obtained without first computing the continuous optimal solution. Our algorithm consists of two stages: a multilevel partition of J into d disjoint groups J_i , followed by finding a two-level schedule for each J_i using speeds s_i and s_{i+1} . The individual modules in our algorithm, such as the multilevel partition and two-level scheduling, may be of interest in and of themselves aside from the main result. Our algorithm admits a simple implementation, although its proof of correctness and complexity analysis are nontrivial. We have also discovered some nice fundamental properties associated with EDF scheduling under variable speeds. Some of these properties are stated as lemmas in section 3 for easy reference. Our results may provide some new insights and tools for the problem of min-energy job scheduling on variable voltage processors. Aside from the theoretical value, we also expect the algorithm to be useful in generating optimal discrete schedules for simulation purposes as in the continuous case.

A COMBINATORIAL LOGARITHMIC APPROXIMATION ALGORITHM FOR THE DIRECTED TELEPHONE BROADCAST PROBLEM*

MICHAEL ELKIN[†] AND GUY KORTSARZ[‡]

Abstract. Consider a synchronous network of processors, modeled by directed or undirected graph $G = (V, E)$, in which in each round every processor is allowed to choose one of its neighbors and to send a message to this neighbor. Given a processor $s \in V$ and a subset $T \subseteq V$ of processors, the *telephone multicast* problem requires computing the shortest schedule (in terms of the number of rounds) that delivers a message from s to all the processors of T . The particular case $T = V$ is called the *telephone broadcast* problem.

These problems have multiple applications in distributed computing. Several approximation algorithms with polylogarithmic ratio, including one with logarithmic ratio, for the *undirected* variants of these problems are known. However, all these algorithms involve solving large linear programs. Devising a polylogarithmic approximation algorithm for the directed variants of these problems is an open problem, posed by Ravi in [*Proceedings of the 35th Annual IEEE Symposium on Foundations of Computer Science* (FOCS '94), 1994, pp. 202–213].

We devise a *combinatorial logarithmic* approximation algorithm for these problems that applies also for the *directed broadcast* problem. Our algorithm has significantly smaller running time and seems to reveal more information about the combinatorial structure of the solution than the previous algorithms that are based on linear programming.

We also improve the lower bounds on the approximation threshold of these problems. Both problems are known to be $3/2$ -inapproximable. For the undirected (resp., directed) broadcast problem we show that it is NP-hard (resp., impossible unless $NP \subseteq DTIME(n^{O(\log n)})$) to approximate it within a ratio of $3 - \epsilon$ for any $\epsilon > 0$ (resp., $\Omega(\sqrt{\log n})$).

1. Introduction. Consider a network of processors modeled by a directed or undirected n -vertex graph $G = (V, E)$. Assume that the communication in the network is synchronous, i.e., occurs in discrete “rounds,” and in every round every processor is allowed to pick one of its neighbors and to send a message to this neighbor. The *telephone broadcast* problem requires computing a schedule with a minimal number of rounds that delivers a message from a given single processor, which generates the message, to all the remaining processors in the network. A more general *telephone k -multicast* problem accepts as input also a set of terminals $T \subseteq V$ of size $|T| = k$ and requires computing the shortest schedule that delivers the message to all the processors of T , whereas the processors of $V \setminus T$ may be left uninformed.

The telephone broadcast and multicast are basic primitives in distributed computing and computer communication theory, and they are used as building blocks for various more complicated tasks in these areas (see, e.g., [HHL88]). The optimization

variants of the broadcast and multicast primitives were intensively studied during the last decade [BGN+98, KP95, R94, S00, F01].

Kortsarz and Peleg [KP95] devised the first approximation algorithm for the *undirected broadcast* problem. Their algorithm constructs schedules that can be longer than the optimal schedule by $\Theta(\sqrt{n})$ for the instance at hand. In a breakthrough paper [R94], Ravi devised an algorithm that provides an $O(\frac{\log^2 k}{\log \log k})$ -approximation for the *undirected multicast* problem. This result obviously implies an $O(\frac{\log^2 n}{\log \log n})$ -approximation for the undirected broadcast problem. Bar-Noy et al. [BGN+98] improved this result and devised an algorithm that provides logarithmic approximation guarantees for the *undirected* multicast and broadcast problems.

Note that all these algorithms do not apply for the *directed* versions of these problems. The importance of designing algorithms for telephone broadcast on directed graphs was realized already some 10 years ago by Ravi, who placed this problem in the first place in the list of open problems in the Conclusion section of [R94].

Also, both known approximation algorithms that provide polylogarithmic guarantees for these problems [R94, BGN+98] use large linear programming (LP). To the best of our knowledge, the worst-case running time for solving the linear program of [BGN+98] is no smaller than $\Omega(n^6)$. The algorithm of [R94] is significantly faster (even though it is also an LP-based algorithm) and requires $\tilde{O}(|E||V|^2)$ expected time¹ or $\tilde{O}(|E||V|^3)$ deterministic time. However, its approximation guarantee is superlogarithmic.

In this paper we devise a deterministic *combinatorial* $O(\log n)$ ratio algorithm for the telephone broadcast problem that applies to the *directed broadcast* problem as well. For the undirected case, the algorithm has $O(\log k)$ ratio for the k -multicast problem. The worst-case running time of our algorithm is $\tilde{O}(|E||V|)$, which is a significant improvement over the worst-case running times of [BGN+98] and [R94].

We also study the more general *heterogeneous postal model* (see [BGN+98]). In this model each vertex v has a delay $0 \leq \rho(v) \leq 1$. The vertex that sends a message is “busy” at the first ρ time units starting from its sending time. In addition, every arc e has a delay $l(e)$ representing the time required to send the message over e . The broadcast problem in the heterogeneous postal model was studied in [BGN+98], where the authors have shown that their algorithm (based on LP) can be adapted to this model, and provides a logarithmic approximation guarantee for the corresponding broadcast problem. We show that our combinatorial algorithm also can be adapted to give an $O(\log n)$ ratio broadcast algorithm for the directed case, and an $O(\log k)$ ratio algorithm for the multicast variant on undirected graphs, within the heterogeneous postal model. The running time of the adapted version of our algorithm is $\tilde{O}(|E||V|)$. In addition, we generalize the heterogeneous postal model and introduce the *arc-dependent heterogeneous postal model*, in which the delay of a vertex v depends on the arc it uses to send the message. We believe that this model captures modern communication networks, in which the major components (links and processors) are not homogeneous, more truthfully than the heterogeneous postal model of [BGN+98] and than all the other models that were previously considered in the literature (such as the *postal model* of [BK94] and the *logP model* of [CKP+96]). We adapt our algorithm to the arc-dependent heterogeneous postal model and show that it provides a logarithmic approximation guarantee for the *directed* and *undirected* versions of the corresponding broadcast problem. However, this most general version of our algorithm

¹We use the notation $\tilde{O}(f(n))$ to denote $O(f(n) \cdot \text{polylog}(f(n)))$.

does use LP and has a slightly higher running time of $\tilde{O}(|V|^3)$. No approximation algorithm was previously known for this version of the problem.

From the point of view of the hardness of approximation, the best known lower bound on the approximation threshold for the (directed and undirected) telephone broadcast problems is $3/2$ [S00]. In this paper we show that it is NP-hard to approximate the undirected broadcast problem within a ratio of $3 - \epsilon$ for any $\epsilon > 0$ and that the directed telephone broadcast problem is $\Omega(\sqrt{\log n})$ -inapproximable unless $NP \subseteq DTIME(n^{O(\log n)})$.

Implications for network design. A large body of research deals with network design problems in which the objective is to optimize more than one optimization criterion simultaneously (see, e.g., [MRR+01]). Such optimization problems are called *bicriteria optimization* problems. Consider the problem of constructing a spanning tree of the input graph that optimizes the maximum degree and the depth of the tree simultaneously. We call this problem the “*degree-depth* problem.” Ravi [R94] has shown that this problem is closely related to the telephone broadcast problem and has designed the first bicriteria approximation algorithm for it that provides simultaneous polylogarithmic approximation to both the maximum degree and the depth. Defining *poise* of a tree to be the sum between its maximum degree and its depth, this result implies directly a polylogarithmic approximation guarantee for the problem of constructing a spanning tree with minimum poise (henceforth, the *poise* problem). The algorithm of [BGN+98] can be adapted to provide a logarithmic bicriteria approximation for the degree-depth problem, implying, consequently, a logarithmic approximation algorithm for the poise problem.

Our algorithm for the telephone broadcast problem can also be adapted to the degree-depth and poise problems, and it provides logarithmic bicriteria approximation for the former and logarithmic approximation for the latter. As in the case with the telephone broadcast problem, our algorithm is the first to apply to the *directed* versions of both problems, and it is the first combinatorial algorithm for these problems. The discussion above about the worst-case running times of the three different approximation algorithms (those of [R94], [BGN+98], and ours) for the telephone broadcast problem is applicable for the degree-depth and poise problems as well.

Consequent developments. After a preliminary version of this paper was published in STOC 2002 [EK02], we published two more papers [EK03a, EK03b] on this subject. In [EK03a] we have shown that the techniques developed in the current paper can be employed to devise a *sublogarithmic* approximation algorithm for the *undirected* versions of the telephone broadcast and multicast problems, as well as for the undirected degree-depth and poise problems. Specifically, the approximation guarantee that is achieved in [EK03a] for the telephone multicast problem is $O(\frac{\log k}{\log \log k})$. In [EK03b] we studied the *directed multicast* problem and devised an approximation algorithm with multiplicative approximation guarantee of $O(\log n)$ and additive approximation guarantee of $O(\sqrt{k})$.

2. Preliminaries.

2.1. Graphs and trees. Let $G = (V, E)$ be a directed graph (henceforth, digraph). Given a subset W of V , let $G(W) = (W, E(W))$, $E(W) = \{\langle u, w \rangle \in E \mid u, w \in W\}$ denote the subgraph *induced* by W .

The distance $dist(u, v)$ between u and v is the number of arcs in the shortest path between u and v . For a pair of subsets A, B of vertices, the distance from A to B is the minimum distance from a vertex $u \in A$ to a vertex $w \in B$.

The outdegree $outdeg(v)$ of a node v is the number of arcs leaving v .

For a vertex $u \in V$, let $N(u) = \{v \mid \langle u, v \rangle \in E\}$ denote the set of *neighbors* of u .

For a digraph $G = (V, E)$, let $G' = (V, E')$, $E' = \{(u, w) \mid \langle u, w \rangle \in E\}$ denote the undirected *underlying graph* of G .

Let T be a digraph whose underlying graph is a tree, i.e., an acyclic and connected graph.

DEFINITION 2.1. *A digraph T as above is called an arborescence if there is a vertex $r \in V$ (called root) such that for any other vertex $v \in V$ there exists a unique directed path from r to v . The vertex r is called the root of the arborescence.*

The depth of an arborescence T , denoted as $h(T)$, is defined by $h(T) = \max_{v \in V'} \text{dist}_T(r, v)$. The degree of an arborescence T , denoted $\text{deg}(T)$, is the maximum out-degree of a vertex in T , i.e., $\max_{v \in V'} \text{outdeg}(v)$. The set of leaves of T , denoted $L(T)$, is the set of the vertices with no outgoing arcs in the directed case and with degree 1 in the undirected case.

A collection of vertex-disjoint arborescences is called *forest*. The *height* (resp., *degree*) of the forest F , denoted $h(F)$ (resp., $\text{deg}(F)$), is defined by $h(F) = \max_{T \in F} h(T)$ (resp., $\text{deg}(F) = \max_{T \in F} \text{deg}(T)$).

2.2. Schedules. At any given moment, the vertices are split into the set of *informed* vertices I and the set of *uninformed* vertices $U = V \setminus I$. At the beginning, $I = \{s\}$. Further, U' denotes the subset of U that contains vertices that still need to be informed; in the broadcast case $U' = U$, while in the multicast case U' may be much smaller.

The message transmission is performed in *rounds*, each requiring one time unit. A round is a matching between the subsets I and U with all the arcs of the matching oriented from a vertex in I to a vertex in U . In other words, in each round vertices that belong to a subset of the set of informed vertices send the message through this matching to a subset of vertices from the set U . Let I_i, U_i denote the subsets of informed and uninformed vertices, respectively, at the beginning of round i . The vertices of U that participate in the round (i.e., belong to the vertex set of the matching) become *informed* and, consequently, are removed from the subset U and are added to the subset I .

A *proper* schedule is a collection of matchings M_1, M_2, M_3, \dots , such that M_i is a matching between the subsets I_i and U_i , and $I = \{s\}$ when the schedule starts and $I = V$ when the schedule ends.

The *length* of a schedule is the number of rounds it uses.

The optimum value. Let opt be the minimum number of rounds required for broadcasting from s on the instance at hand. Since the size of I can at most double in each round, it follows that $\text{opt} \geq \lceil \log n \rceil$. In addition, $\text{opt} \leq n - 1$ since at least one additional vertex becomes informed in each round. (Otherwise, the instance is infeasible.) Our algorithm is provided with a guess opt' of the correct value of opt , and the algorithm distinguishes between the case when no schedule of length at most opt' exists and the case when there exists a schedule of length at most $\text{opt}' \cdot \log n$. This enables us to figure out the correct value of opt up to a logarithmic factor via binary search.

The optimum tree. Consider the optimum schedule. This schedule defines a directed tree denoted by T^* . The parent of u in the tree is the vertex that sent the message to the vertex u . Without loss of generality, it can be assumed that such a vertex is unique.

The following observation is immediate.

Observation 1. $h(T^*), \text{deg}(T^*) \leq \text{opt}$.

Nonlazy schedules. A schedule is called *nonlazy* [BGN+98] if in each round a maximal matching M_i between I and U is used. A schedule of this type uses a simple greedy rule that ensures that the only idle informed vertices will be those that satisfy that each of their neighbors either is in I or is informed in the current round by some other vertex from I .

2.3. Spiders. Spiders were shown to be useful for telephone broadcast in [BGN+98].

A set of directed paths $S = \{P_1, \dots, P_q\}$ all starting at the same vertex v is called a *spider* if the paths are *vertex-disjoint* except for sharing v . The vertex v is called the *head* of the spider.

The *length* of the spider S , denoted $\ell(S)$, is $\max_{P \in S} |P|$.

The *degree* of the spider S , denoted $\deg(S)$, is $|S| = q$, i.e., the number of paths in the spider.

The *value* of the spider S , denoted $\text{val}(S)$, is $\deg(S) + \ell(S) - 1$.

The following observation is immediate.

Observation 2. Using a nonlazy schedule, the head of a spider S can deliver the message to the other spider vertices in $\text{val}(S)$ rounds.

3. Overview of the algorithm. The algorithm is given for the more general problem of multicasting to a subset $\mathcal{T} \subseteq V$ of *terminals*. The analysis of the upper bound is identical, but since performance is evaluated in terms of *opt*, the minimum number of rounds required for broadcast, instead of the minimum number of rounds for multicasting to \mathcal{T} , we obtain logarithmic upper bounds on the approximation thresholds of the directed broadcast problem, the undirected broadcast problem, and the undirected multicast problem but not on the threshold of the directed multicast problem. (In the case of the *undirected* multicast problem, there is an easy way to modify the analysis so that the upper bound would be obtained in terms of the multicast optimum. Analogous modification, however, fails in the case of the *directed multicast* problem.)

An important combinatorial structure that will be used in this paper is called a *fork*. Informally, a fork is a pair of “short” vertex-disjoint paths starting with the same vertex v and ending at two uninformed vertices u, w . A path is short if its length is at most *opt*, the minimum number of rounds required for completing broadcast. The vertex v is called the *head* of the fork. As the paths are short and there are only two paths, it is easy to see that if v is informed, then it can quickly inform both u and w .

Our algorithm iteratively finds as many vertex-disjoint forks as possible. It maintains a set U corresponding to the set of vertices that are uninformed and have not yet been covered by forks, as well as a set U' of uninformed terminals not covered by forks. The set U' is called a *packing* if the graph contains no forks. A useful property that our algorithm utilizes is that vertices of a packing can be informed very efficiently.

We next provide a high-level description of the algorithm.

- *The extraction step:* Extract a maximal collection of vertex-disjoint forks from $G(U)$; i.e., keep extracting until $G(U)$ contains no more forks.
- *The recursion step:* Recursively inform the set of the fork heads.
- *The forking step:* Inform the vertices of the forks, now that the heads have been informed. Since the forks are vertex-disjoint and are short, this can be done in parallel.
- *The packing step:* It remains to inform the vertices of U' that remain in U , which now form a packing. This is done by a reduction to a minimal

maximum-degree set-cover problem in a bipartite graph. The latter graph has the set of informed vertices on one side and the set U' on the other side. The cover is then found by a single computation of maximum flow.

4. Packing and short schedules.

4.1. Packing. In this section, we describe one of the main tools of our algorithm. Let $U' \subseteq U$ be a subset of the uninformed vertices. We say that the vertices of U' are *dispersed*, or form a *packing* in $G(U)$, if for any two vertices $v, u \in U'$, every vertex $w \in U$ is of distance more than opt from either u or v in $G(U)$.

Formally, we have the following definition.

DEFINITION 4.1. *Let $G = (V, E)$ be a digraph, $U' \subseteq U$ be a subset of vertices, and opt be an integer. Then a (U, U') -fork triple is a triple (u, t_1, t_2) with $t_1, t_2 \in U'$ and $u \in U$, such that $u \neq t_2$ and $dist_{G(U)}(u, t_1), dist_{G(U)}(u, t_2) \leq opt$. Also, U' is called a packing with respect to the set U if no (U, U') -fork exists.*

Observe that if no (U, U') -fork triple exists, then for each vertex w in U there may exist at most one descendant in the tree T^* that belongs to the subset U' . If we think of w as “covering” its descendants, then U' is a packing in the sense that each vertex of U' is covered by a different unique vertex of U .

A straightforward way for testing the existence of a (U, U') -fork triple in an n -vertex digraph $G = (V, E)$ is to examine all breadth-first-search (BFS) trees in $G(U)$. Such an examination requires $O(|E||V|)$ time.

4.2. Mentor vertices. Consider a packing U' with respect to the subset U . We assign to each vertex u of U' a *mentor* vertex $m(u)$, which is the *last* vertex along the directed path between s and u in T^* belonging to I . The definition is valid since such a path starts with $s \in I$ and ends at $u \in U$. Observe that the path in T^* from $m(u)$ to u contains only vertices from the subset U (except $m(u)$.) Intuitively, the mentors aid in fast transmission of the message to the vertices of the subset U' .

Let $P^*(m(u), u)$ denote the arcs of the path from $m(u)$ to u in T^* . Then the following lemma holds.

LEMMA 4.2. *The graph induced by the set $\bigcup_{u \in U'} P^*(m(u), u)$ is a collection of vertex-disjoint spiders. The spider heads belong to I , while other spider vertices belong to U . The value of the forest is at most $2 \cdot opt$.*

Proof. By the definition of $m(u)$, all the vertices that belong to the unique path in T^* from $m(u)$ to u , except $m(u)$, belong to the set U . We show that no two paths $P^*(m(z), z)$ and $P^*(m(u), u)$, $z \neq u$, can intersect unless $m(z) = m(u)$. In the latter case, $m(u) = m(z)$ is the only vertex common to the two paths.

For the sake of contradiction, suppose that some $v \in U$ is contained in paths $P^*(m(u), u)$ and $P^*(m(z), z)$. By the definition of a mentor, the path from v to u and the path from v to z both belong to $G(U)$. In addition, the paths $P^*(m(u), u)$, $P^*(m(z), z)$ are of length at most opt (see Observation 1). It follows that the distance to u from v in $G(U)$, and also the distance from v to z in $G(U)$, is at most opt . This contradicts the assumption that U' is a packing.

Finally, note that both the depth and the maximum degree of the tree T^* are at most opt . Hence, $|P^*(m(u), u)| \leq opt$ for every vertex $u \in U'$, and the degree of each spider (which is a subgraph of T^*) is, consequently, at most opt . Hence, the value of this forest of spiders is at most $2 \cdot opt$. \square

It can now be seen that if U' is a packing, not too many vertices can have v as their mentor. Let $\nu(v) = \{u \mid v = m(u)\}$ denote the number of vertices with v as a mentor for $v \in I$.

FIG. 1. Computing a cover with minimal maximum degree via maximum flow.

LEMMA 4.3. *If U' is a packing, then $\nu(v) \leq \text{opt}$ for all $v \in I$.*

Proof. Observe that $\nu(v)$ is precisely the degree of the appropriate spider from the forest $\bigcup_{u \in U'} P^*(m(u), u)$. Hence, by Lemma 4.2, $\nu(v) \leq \text{opt}$. \square

4.3. Informing a packing.

Set covers of low degree. Let $B = (V_1, V_2, A)$ be a bipartite graph. We say that $S \subseteq V_1$ covers V_2 if every vertex $v_2 \in V_2$ has a neighbor in S .

DEFINITION 4.4. *We say that a cover S of V_2 has degree d if there exists a mapping $\psi : V_2 \mapsto S$ so that for every $v_2 \in V_2$, $\psi(v_2) \in S \cap N(v_2)$ and so that each vertex in S is assigned at most d vertices of V_2 , namely, for each $v \in S$, $|\{v_2 \in V_2 \mid \psi(v_2) = v\}| \leq d$.*

We next present a reduction from the problem of determining whether there exists a cover for V_2 of degree at most L to the maximum flow problem. Orient the edges of the bipartite graph B from V_1 to V_2 and assign unit capacity to each of them. Add a source s with arcs of capacity L to each vertex of V_1 and a sink t with an arc of unit capacity from each vertex of V_2 . There exists a cover for V_2 of degree at most L if and only if there exists a flow of capacity $|V_2|$. By the integrality of the maximum flow, this flow directly translates to a cover (see Figure 1).

To find a cover of minimum degree, we perform binary search for the value of L . Thus, a cover for V_2 with minimal maximum degree can be found in time $O(\log |V|)T(|E|, |V|)$, where $T(|E|, |V|) = O(|E| \cdot |V| \cdot \log |V|)$ is the time complexity of computing the maximum flow [GT88].

The graph H . Consider the graph $H(I, U', \hat{E})$ that describes all pairs $v \in I$ and $u \in U'$, with v being a potential mentor for u . Formally, we have the following definition.

DEFINITION 4.5. *The bipartite graph $H(I, U', \hat{E})$ has $I \cup U'$ as its vertex set. Two vertices $v \in I$ and $u \in U'$ are connected by an undirected edge in \hat{E} if $\text{dist}_{G(U \cup \{v\})}(v, u) \leq \text{opt}$. In other words, this condition means that there exists a path of length at most opt from v to u that uses only vertices from the set U (except v).*

Low-degree covers for H . Our goal is to show that every packing U' has a low-degree cover in H . Consider the assignment ψ from U' to I defined by $\psi(u) = m(u)$,

where $m(u)$ is the mentor of the vertex u . Note that the arc $\langle u, m(u) \rangle$ belongs to \hat{E} , and thus the assignment ψ defines a cover. In other words, $M = \{m(u) \mid u \in U'\}$ is a subset of I so that each $u \in U'$ has a neighbor in M (where the neighborhood is with respect to the graph H). By Lemma 4.3, $\nu(v) = |\{u \mid \psi(u) = v\}| \leq \text{opt}$. We have proven the following corollary.

COROLLARY 4.6. *There exists a cover of U' in $H(I, U', \hat{E})$ of maximum degree at most opt , and such a cover can be found in time $O(\log |V| \cdot T(|E|, |V|))$, where $T(|E|, |V|) = O(|E| \cdot |V| \cdot \log |V|)$ is the time required for computing a maximum flow.*

Using a low-degree cover to inform U' . Given a cover S of U' with maximum degree at most opt , consider the shortest path $P(\psi(u), u)$ from $\psi(u)$ to u in the graph $G(\{\psi(u)\} \cup U)$. The proof of the following lemma is similar to the one of Lemma 4.2.

LEMMA 4.7. *The union of the paths $P(\psi(u), u)$ induces a collection of vertex-disjoint spiders, whose heads belong to the cover S and whose values are at most $2 \cdot \text{opt}$.*

Proof. The paths $P(\psi(u), u)$ can only intersect at their start vertices, as otherwise a fork triple can be extracted (see the proof of Lemma 4.2). The number of paths in each spider is at most the degree of the cover, which is at most opt . In addition, the length of each path in the spider is at most opt , by the definition of the graph $H(I, U', \hat{E})$. Hence, the value of each spider is at most $2 \cdot \text{opt}$. \square

Since all the spiders have small values, the following procedure informs a packing U' using a small number of rounds.

ALGORITHM 1. *Inform-Packing(I, U, U')*

1. *Construct the graph $H(I, U', \hat{E})$.*
2. *Find an assignment $\psi : U' \mapsto I$ of degree at most opt that covers H using flow computation.*
3. *For each $u \in U$, let $P(\psi(u), u)$ be the shortest path from $\psi(u)$ to u in $G(\{\psi(u)\} \cup U)$.*
4. *Each spider head informs all the vertices that belong to the spider using a nonlazy schedule.*

LEMMA 4.8. *Let \mathcal{P} be the spider collection induced by the union of the paths $P(\psi(u), u)$, $u \in U'$. Any nonlazy schedule broadcasts over \mathcal{P} in at most $2 \cdot \text{opt}$ rounds, informing all the remaining vertices of the set U' .*

Proof. By Lemma 4.7, \mathcal{P} is a union of vertex-disjoint spiders, each of value at most $2 \cdot \text{opt}$. Since the spiders are vertex-disjoint, the lemma now follows from Observation 2. \square

4.4. Transforming U' into a packing: The extraction step. The following algorithm accepts as input a subset U of V and the subset U' and deletes vertices from U , so that for the resulting set U at the end of the extraction, no fork triple is left; U' is a packing. The collection of extracted forks is denoted by \mathcal{F} and their heads by \mathcal{R} .

In the following algorithm, it is assumed for simplicity that when a fork is found from $u \in U$ to t_1, t_2 in U' , the two paths used from u to t_1 and from u to t_2 are found by the BFS procedure (i.e., they are shortest paths). These two paths may intersect.

ALGORITHM 2. *Extract-forks (G, U, U')*

1. $\mathcal{F} \leftarrow \emptyset$.
2. **While** there exists a (U, U') -fork triple F **do**:
 3. Add F into \mathcal{F} .
 4. $U \leftarrow U \setminus V(F)$, $U' \leftarrow U' \setminus V(F)$, where $V(F)$ is the set of vertices in F .
5. **return** (U, U', \mathcal{F}) .

It is easy to see that the resulting forks in \mathcal{F} are vertex-disjoint and that the returned set U' is a packing with respect to the returned set U .

Say that we establish (via a BFS computation) that no two distinct terminals have a short distance from u in $G(U)$. In such a case the vertex u cannot serve as a head of a fork triple. Therefore, the number of BFS explorations is at most $|V|$, and hence extracting the fork triples can be accomplished in time $\tilde{O}(|E| \cdot |V|)$.

5. The algorithm: Combining the pieces. The input to the algorithm is the directed graph G , source vertex s , and a set U' of terminals. The algorithm accepts a guess of opt as part of its input.

5.1. The algorithm. Initially invoked as $ApproximateBroadcast(G, s, V)$, then the algorithm invokes itself recursively with different subsets serving as third parameter. The sequence of these subsets is a monotone decreasing one with respect to containment.

ALGORITHM 3. $ApproximateBroadcast(G(V, E), s, U')$

1. $U \leftarrow V \setminus s, I \leftarrow \{s\}$.
2. /* Transforming U' into a packing */
If U' is not a (U, U') -packing **then**
 - (a) /* The extraction step */
 $Let (U, U', \mathcal{F}) \leftarrow Extract-forks(G, U)$.
 $Let \mathcal{R}$ be the set of heads of \mathcal{F} .
 - (b) /* The recursive step */
 $Recursively\ invoke\ ApproximateBroadcast(G, s, \mathcal{R})$.
 - (c) /* The forking step */
 $Use\ a\ nonlazy\ schedule\ to\ inform\ the\ forks\ in\ \mathcal{F}$.
 $Let\ I \leftarrow I \cup V(\mathcal{F})$.
3. /* The packing step */
 $Invoke\ Inform-Packing(I, U, U')$.

5.2. Analysis of the number of rounds. The following observation follows from the fact that each fork triple contains at most $2 \cdot opt + 1$ vertices.

Observation 3. Each invocation of the forking step (line 2(c) in Algorithm $ApproximateBroadcast$) requires at most $2 \cdot opt$ rounds.

LEMMA 5.1. *The number of rounds used by Algorithm $ApproximateBroadcast$ for broadcasting to an arbitrary set U' is at most $4 \cdot (\log_2(|U'|) + 1) \cdot opt$.*

Proof. We first show that each time lines 2 and 3 of Algorithm $ApproximateBroadcast$ are executed, the number of rounds required is at most $4opt$. The two steps that perform the actual broadcast are the fork-extracting and packing steps. The bound of $4 \cdot opt$ per iteration follows from Lemma 4.8 and Observation 3.

We now analyze the depth of the recursion. Let U'_i (resp., \mathcal{R}_i) be the set of terminals (resp., roots of the forks) on iteration i . Since the forks are vertex-disjoint, and since $|U'_{i+1}| \leq |\mathcal{R}_i|$, the depth of the recursion is at most $\log_2 |U'| + 1$. Hence, overall, the number of rounds of the constructed broadcast is at most $4 \cdot (\log_2(|U'|) + 1) \cdot opt$. \square

To summarize, we have the following theorem.

THEOREM 5.2. *Algorithm $ApproximateBroadcast$ is an $O(\log n)$ -approximation algorithm for the directed telephone broadcast problem.*

Note that the main obstacle to generalizing Algorithm $ApproximateBroadcast$ to the multicast problem is the fact that the set \mathcal{R} is not necessarily contained in the set U' . In the undirected case this obstacle can be overcome by using *fork pairs* instead of fork triples. Intuitively, a fork pair is a pair of nearby terminals of U' that

are still not used for other fork pairs. From each fork pair, precisely one terminal is inserted to \mathcal{R} , guaranteeing both $|\mathcal{R}| \leq |U'|/2$ and $\mathcal{R} \subseteq U'$. This results in an $O(\log k)$ -approximation for the *undirected k -multicast problem*.

5.3. The running time of the algorithm. The most time-consuming computational tasks in each iteration are extractions of forks and computations of maximum flow. Recall that the extraction step can be completed with at most $|V|$ BFS computations, in time $O(|V||E|)$, while the time for finding a low-degree cover is $O(|V||E|\log|V|)$ [GT88]. Since each iteration reduces the number of target terminals by a factor of at least 2, the depth of the recursion is $O(\log n)$. Hence, the time complexity of the algorithm is $O(|V||E|\log^2|V|)$. Finding the optimal value of opt via binary search adds one more logarithmic factor.

5.4. The postal and arc-dependent postal models. In this section we consider some generalized versions of telephone communication.

The heterogeneous postal model. We start with the *heterogeneous postal model*, introduced in [BGN+98], in which each vertex v has a delay $0 \leq \rho(v) \leq 1$. The vertex that sends a message is “busy” at the first ρ time units starting from its sending time. In addition, every arc e has a delay $l(e)$ representing the time required to send the message over e . (Note that in the context of these generalized models one has to consider a continuous time scale instead of a discrete one, and hence the notion of “round” becomes obsolete.)

To adapt Algorithm ApproximateBroadcast to the heterogeneous postal model, the paths in forks should be weighted (with weight function determined by the delay function l). In addition, when computing a low-degree cover of U' , the delay $\rho(v)$ for $v \in I$ has to be taken into account. A vertex v can have up to $\lfloor opt/\rho(v) \rfloor$ children in the tree T^* (that is, possibly more than opt). Hence, the capacities of the arcs that are adjacent to the source s_1 in the flow graph $H(I, U', \hat{E})$ (see section 4.3) should be set as $opt/\rho(v)$. Finally, when constructing the arc set \hat{E} , the distances between $v \in I$ and $u \in U'$ in the graph $G(\{v\} \cup U)$ should take into account the length of the arcs (i.e., they are weighted distances).

The rest of the proof can be carried out in an analogous way. Particularly, the cover with bounded degree gives rise to a collection of “narrow” spiders. A vertex v that heads one of these spiders and has degree at most $opt/\rho(v)$ in the spider can deliver the message to all its children in the spider in at most opt time units.

The arc-dependent postal model. We next generalize our algorithm even further. Consider the *arc-dependent heterogeneous postal model*, in which the delay of a vertex v depends on the arc through which it chooses to send the message.

Consider again the construction of the flow graph $H(I, U', \hat{E})$. Observe that despite the assumption that the set U' is a packing, even in the standard telephone model for a given pair of vertices $v \in I$, $u \in U'$, there might be more than one shortest path from v to u in the graph $G(U \cup \{v\})$. Let $N(v)$ denote the set of neighbors of v . For each vertex $z \in N(v)$, let P_z denote the shortest path from v to u that passes through the vertex z . Let $\omega(P_z) = \sum_{e \in P_z} l(e)$ denote the *weight* of the path P_z . The edge (v, u) is added to the flow graph $H(I, U', \hat{E})$ if for some $z \in N(v)$, the weight of the path P_z plus the delay $\rho(\langle v, z \rangle)$ incurred by the vertex v while sending a message through the arc $\langle v, z \rangle$ is at most opt . (Observe that this is a direct generalization of the construction for the heterogeneous postal model.)

Let $C_u(v) \subseteq N(v)$ be the subset of $N(v)$ that contains only those neighbors z of $N(v)$ for which $\omega(P_z) + \rho(\langle v, z \rangle) \leq opt$. Suppose that for every vertex $u \in U'$ that is connected to v in \hat{E} we would pick an arbitrary vertex $z_u \in C_u(v)$ for serving as a relay

station for broadcasting the message from v to u . (This is exactly what is implicitly done in the telephone and heterogeneous postal models.) The weighted degree of the vertex v in the spider $\bigcup\{P_{z_u} \mid u \in U', (v, u) \in \hat{E}\}$ would be $\deg(v) = \sum\{\rho(\langle v, z_u \rangle) \mid u \in U', (v, u) \in \hat{E}\}$. Note that unlike the telephone and heterogeneous postal models, in the arc-dependent model $\deg(v)$ depends on the choice of the vertices z_u . To tackle this difficulty, we assign to each edge $(v, u) \in \hat{E}$ capacity $\rho(\langle v, z_u \rangle)$, where z_u is the vertex of $C_u(v)$ that minimizes $\rho(\langle v, z_u \rangle)$. We need to choose a cover $S \subseteq I$ and an assignment $\psi : U' \rightarrow I$ that minimizes $\max_{v \in S}\{\deg_\psi(v)\}$, where $\deg_\psi(v)$ is given by $\sum\{\rho(\langle v, z_u \rangle) \mid u \text{ such that } \psi(u) = v\}$.

We claim that the set $S = \{\psi(u) \mid u \in U'\}$, for $\psi(u) = m(u)$, is a cover of U' of weighted degree at most opt . Indeed, let $v = m(u)$. Consider the path $P^*(v, u)$ from v to u in T^* . Let w be the neighbor of v in this path.

Note that $w \in C_u(v)$. Hence the delay in sending the message from v to w is $\rho(v, w) \geq \rho(v, z_u)$. Therefore, the weighted degree of the assignment defined by T^* is a lower bound on the optimum broadcast time. Thus, this weighted degree cannot be larger than opt . It follows that the assignment $\psi(u) = m(u)$ yields a cover assignment for U' with maximum weighted degree at most opt .

We want to find a cover S and an assignment ψ that minimizes (or almost minimizes) $\max_{v \in S}\{\deg_\psi(v)\}$. The problem of finding the best weighted degree assignment is known in the literature as the problem of *scheduling of independent parallel machines*. This problem is NP -hard and, in fact, is $3/2$ -inapproximable [LST90].

For our purposes, any constant approximation for this problem is sufficient. Unfortunately, we are not aware of a combinatorial algorithm that provides a constant approximation ratio for this problem. We use the 2-approximation algorithm of [LST90] that formulates the problem as an integer linear program, relaxes it to allow fractional solutions, finds a basic feasible solution, and uses a standard rounding technique.

Hence, this way we find a (weighted) cover for the set U' of degree at most $2 \cdot \text{opt}$. It follows that the value of the resulting spiders is at most $3 \cdot \text{opt}$. The rest of the analysis can be carried through in a straightforward way. To summarize, our algorithm can be adapted to provide a logarithmic approximation guarantee for the directed and undirected versions of broadcast problem in the arc-dependent heterogeneous postal model. The approximation guarantee of the generalized algorithm is only by a constant factor greater than the approximation guarantee of our algorithm for the telephone broadcast problem; i.e., it is $O(\log n)$. Note, however, that for this most general version of our algorithm we do use LP. The particular linear programs that are used in the algorithm are solvable via Lagrangian relaxation in time $\tilde{O}(|V|^3)$ [LST90], and so the overall running time of the generalized algorithm is at most $\tilde{O}(|V|^3)$ as well.

5.5. Implications for network design.

A bicriteria approximation for depth and outdegree. Our algorithm provides a bicriteria approximation for the depth-degree problem. In other words, given a digraph for which there exists a spanning arborescence of height h and maximum degree d , our algorithm constructs a spanning arborescence of maximum depth $O(\log n) \cdot h$ and maximum degree $O(\log n) \cdot d$.

The tree is built “backwards” (from the leaves to the root). Throughout the algorithm we maintain a forest. The number of trees in the forest gradually decreases until they merge into a single spanning arborescence.

We show how to build this arborescence recursively. The collection of forks \mathcal{F} that is computed by our algorithm on the first level of the recursion forms the initial forest. The heads \mathcal{R} need now to be recursively connected to the root s . Let T' be the

arborescence connecting s to \mathcal{R} that was computed by the recursion. By the inductive hypothesis, the set T' is indeed an arborescence, and, in particular, each arc appears in T' at most once. However, observe that T' may not be arc- or vertex-disjoint with the forest \mathcal{F} . We need to unite T' and \mathcal{F} in order get a single spanning arborescence. This is done by taking the graph induced by $\mathcal{F} \cup T'$ and computing the shortest path arborescence from s to all the vertices $v \neq s$ in $G(\mathcal{F} \cup T')$.

Clearly, the resulting shortest path arborescence T'' has depth $O(\log n) \cdot h$, because each recursive iteration can add at most h to the depth of the arborescence. Similarly, on each recursive invocation, for every vertex v at most d arcs that are adjacent to v are added to the arborescence. Hence, the upper bound of $O(\log n) \cdot d$ on the maximum degree follows.

Hence, our algorithm provides an $(O(\log n), O(\log n))$ -bicriteria approximation for both the directed and undirected versions of the degree-depth problem. The algorithm is combinatorial, and its running time is $\tilde{O}(|E| \cdot |V|)$. Note that the same algorithm provides a logarithmic approximation for the directed and undirected poise problems.

6. Hardness results. In this section we present some lower bounds on the approximation thresholds of the (undirected and directed) telephone broadcast problems.

DEFINITION 6.1. *Given an undirected bipartite graph $G = (V_1, V_2, E)$, a subset of vertices $S \subseteq V_1$ is a set cover for G if for any $v_2 \in V_2$ there exists $v_1 \in S$ such that $(v_1, v_2) \in E$.*

Let $V = V_1 \cup V_2$. Let $|V| = n$.

Given a constant $0 < c \leq 1$ and an integer-valued function $t = t(n)$, the YES-instance of the set-cover $(t(n), c)$ -promise problem is an undirected bipartite graph G for which there exists a set cover S of size $|S| \leq t(n)$. The NO-instance of the set-cover $(t(n), c)$ -promise problem is an undirected bipartite graph G for which any set cover S has size $|S| \geq c \log n \cdot t(n)$.

The set-cover $(t(n), c)$ -promise problem is given either a YES-instance or a NO-instance of the problem, and the goal is to determine whether it is a YES-instance or a NO-instance.

It is known [LY95] that there exists a constant c such that the set-cover $(t(n), c)$ -promise problem is NP-hard for $t(n) = \lceil \sqrt{n} \rceil$.

Given an instance of the set-cover $(t(n), c)$ -promise problem, an undirected bipartite n -vertex graph $G = (V_1, V_2, E)$, $|V_1| = |V_2| = n/2$, we construct a graph \bar{G} in the following way. Insert into \bar{G} an isomorphic copy of G . For $j = 1, 2$, let \bar{V}_j be the image of V_j under the isomorphism, and, more generally, for a subset $X \subseteq V$ of vertices, let \bar{X} be the image of X under the isomorphism. Add a new vertex s and connect it with all the vertices of \bar{V}_1 via outgoing arcs. In addition, add a directed path of length $\lceil (c/2)t(n) \log n \rceil$ that starts in s and contains $\lceil (c/2)t(n) \log n \rceil$ new vertices. Denote by s' the tail of the path. Construct a complete binary arborescence T of depth $\lceil \log n \rceil$, rooted at s' , with the set of leaves that contains \bar{V}_1 and (maybe) some new vertices, and such that all the remaining vertices of T are new vertices. Finally, replace each star $(\bar{V}_1, \bar{V}_2^1), (\bar{V}_1, \bar{V}_2^2), \dots, (\bar{V}_1, \bar{V}_2^r)$, with $\bar{V}_1 \in \bar{V}_1, \bar{V}_2^1, \bar{V}_2^2, \dots, \bar{V}_2^r \in \bar{V}_2$, by a complete binary arborescence of depth $\lceil \log r \rceil$ rooted at \bar{V}_1 and whose set of leaves $L(T)$ contains the set $\{\bar{V}_2^1, \bar{V}_2^2, \dots, \bar{V}_2^r\}$ and (maybe) some new vertices. All the other vertices of the tree T are new vertices.

This completes the description of \bar{G} (see Figure 2). Its construction is very similar to the reduction of [S00] that proves the hardness of $3/2$ for the problem. We next use \bar{G} as a building block in our reduction that shows the hardness of $\Omega(\sqrt{\log n})$ for

FIG. 2. The first level of the graph \bar{G}^i . The path from s to s' is of length $\Theta(t(n) \cdot \log n)$. The vertex s' is connected via a complete binary arborescence to the vertex set \bar{V}_1 . The vertices of \bar{V}_1 are connected via complete binary arborescences to their neighbors in \bar{V}_2 . In turn, the vertices of the set \bar{V}_2 serve as sources of the next level of the recursive construction.

the directed broadcast problem and then, via a similar reduction, a hardness of $3 - \epsilon$ for any $\epsilon > 0$ for the undirected broadcast problem.

We first analyze the properties of the graph \bar{G} .

LEMMA 6.2. *If G is a YES-instance of the set-cover $(t(n), c)$ -promise problem, then there exists an $(\{s\}, \bar{V}_2)$ -schedule Π of length $|\Pi| = O(t(n))$ for the instance (\bar{G}, s) of the directed telephone broadcast problem.*

Proof. We describe the schedule Π that satisfies the assertion of the lemma. Let $S \subseteq V_1$ be an optimal set cover of the instance G . The schedule starts with delivering the message from the vertex s to all the vertices of the set \bar{S} . Note that as s is connected via outgoing arcs to all the vertices of \bar{V}_1 , it follows that all the vertices of the set \bar{S} will be informed within $|S|$ rounds. By assumption, G is a YES-instance of the set-cover $(t(n), c)$ -promise problem, and hence $|S| \leq t(n)$. Hence, this step requires at most $t(n)$ rounds.

Next, the schedule delivers the message from \bar{S} to all the vertices of the set \bar{V}_2 . Observe that since the set S is a set cover for the set V_2 , only $O(\log n)$ rounds will be required to deliver the message to all the vertices of \bar{V}_2 through the auxiliary arborescences that connect the sets \bar{V}_1 and \bar{V}_2 . Hence, altogether, the length of this schedule is at most $t(n) + \log n = O(t(n))$ (since $t(n) = \lceil \sqrt{n} \rceil$), and it informs all the vertices of the set \bar{V}_2 . \square

LEMMA 6.3. *If G is a NO-instance of the set-cover $(t(n), c)$ -promise problem, then any $(\{s\}, \bar{V}_2)$ -schedule Π for the instance (\bar{G}, s) of the directed telephone broadcast problem has length $|\Pi| = \Omega(t(n) \log n)$.*

Proof. By construction, the only way to inform the vertices of the set \bar{V}_2 is to inform all the vertices of a subset $\bar{S} \subseteq \bar{V}_1$ for some set cover S of V_1 .

There are two possible ways to inform such a subset \bar{S} : either using the arcs that connect s to the vertices of \bar{V}_1 , or through the path between s and s' , and via the complete binary arborescence T (or by combining these two ways).

Note that as G is a NO-instance, it follows that $|S| = |\bar{S}| = \Omega(t(n) \cdot \log n)$. Therefore, the first way requires $\Omega(t(n) \cdot \log n)$ rounds of telephone broadcast. Also, recall that the length of the path from s to s' is $\Omega(t(n) \cdot \log n)$, and hence informing even a single vertex $v \in \bar{V}_1$ using the second way would require $\Omega(t(n) \cdot \log n)$ rounds. Hence, any schedule that informs a subset $\bar{S} \subseteq \bar{V}_1$ of size $\Omega(t(n) \cdot \log n)$ requires $\Omega(t(n) \cdot \log n)$ rounds of telephone broadcast, proving the claim. \square

Note that Lemmata 6.2 and 6.3 imply $\Omega(\log n)$ -inapproximability of the *directed multicast problem*, that was known [F01].

However, since for both the YES and NO-instance of the set cover, informing \bar{V}_1 requires $\Omega(t(n) \log n)$ rounds, this reduction by itself may provide only a constant hardness of approximation for the *broadcast problems*. Indeed, by a careful choice of parameters and some modifications to \bar{G} , it is shown in [S00] that this reduction yields a hardness of $3/2$ for the undirected broadcast problem.

Consider the following recursive construction of a triple $(\bar{G}^i = (\bar{V}^i, \bar{E}^i), s^i, \bar{V}_2^i)$, where (\bar{G}^i, s^i) is an instance of the directed broadcast problem, and $\bar{V}_2^i \subseteq \bar{V}^i$. Let $(\bar{G}^1, s^1, \bar{V}_2^1) = (\bar{G}, s, \bar{V}_2)$. Let also $Z(\bar{G}^1)$ denote the set \bar{V}_2^1 . Given a construction of $(\bar{G}^i, s^i, \bar{V}_2^i)$, the triple $(\bar{G}^{i+1}, s^{i+1}, \bar{V}_2^{i+1})$ is constructed in the following way.

Insert an isomorphic copy of \bar{G}^1 into \bar{G}^{i+1} . Set $s^{i+1} = s^1$. For $j = 1, 2$, let \bar{V}_j^1 be an image of \bar{V}_j under the isomorphism. Insert the set \bar{V}_2^1 into \bar{V}_2^{i+1} . For every vertex $\bar{V}_2^1 \in \bar{V}_2^1$, construct a triple $(\bar{G}^i(\bar{V}_2^1), \bar{V}_2^1, \bar{V}_2^i(\bar{V}_2^1))$, where $\bar{G}^i(\bar{V}_2^1)$ is an isomorphic copy of \bar{G}^i such that the isomorphism takes s^i to \bar{V}_2^1 . All the other vertices of $\bar{G}^i(\bar{V}_2^1)$ are new vertices. Insert the set $\bar{V}_2^i(\bar{V}_2^1)$ into \bar{V}_2^{i+1} . Form the set $Z(\bar{G}^{i+1})$ to be the union of the isomorphic copies of the sets $Z(\bar{G}^i(\bar{V}_2^1))$ for all the different vertices $\bar{V}_2^1 \in \bar{V}_2$.

This completes the construction of $(\bar{G}^{i+1} = (\bar{V}^{i+1}, \bar{E}^{i+1}), s^{i+1}, \bar{V}_2^{i+1})$.

First, we provide an estimate of the number of vertices of the graph \bar{G}^i .

LEMMA 6.4. $|\bar{V}^i| = n^{O(i)}$, $i = 1, 2, \dots$

Proof. The proof follows by a straightforward induction on the number of levels i . \square

Next, we analyze the graph \bar{G}^i that is obtained by the reduction that was described above from a YES-instance G of the set-cover $(t(n), c)$ -promise problem.

LEMMA 6.5. *If G is a YES-instance of the set-cover $(t(n), c)$ -promise problem, then for any $i = 1, 2, \dots$, there exists an $(\{s^i\}, \bar{V}_2^i)$ -schedule Π for the instance (\bar{G}^i, s^i) of the directed broadcast problem of length $|\Pi| = O(i \cdot t(n))$.*

Proof. The proof is by induction on i . The induction base follows from Lemma 6.2.

For the induction step consider the instance (\bar{G}^{i+1}, s^{i+1}) . Note that by Lemma 6.2, all the vertices of the set \bar{V}_2^1 can be informed within $O(t(n))$ rounds. After that point every vertex $\bar{V}_2^1 \in \bar{V}_2^1$ needs to relay the message to all the vertices of the set $\bar{V}_2^i(\bar{V}_2^1)$ through an isomorphic copy of the graph \bar{G}^i . Since the different copies share no vertices, these broadcasts can be conducted in parallel and, by the induction hypothesis, can be completed within $O(i \cdot t(n))$ rounds. \square

LEMMA 6.6. *For any $i = 1, 2, \dots$, there exists a $(\{s^i\} \cup \bar{V}_2^i, \bar{V}^i \setminus \bar{V}_2^i)$ -schedule Π of length $O(t(n) \cdot \log n)$.*

Proof. Consider the graph \bar{G}^i , and suppose that for every isomorphic copy of the graph \bar{G} that is contained in \bar{G}^i , the vertex that corresponds to s is informed.

Consider some single copy of the graph \bar{G} . Observe that delivering the message from s to all the vertices of the set \bar{V}_1 through the path from s to s' and from s' through the complete binary arborescence to all the vertices of the set \bar{V}_1 requires only $O(t(n) \cdot \log n)$ rounds. This is because the distance between s and s' is $O(t(n) \cdot \log n)$, and after s' gets the message only $O(\log n)$ additional rounds are required to relay the message from s' to the vertices of the set \bar{V}_1 .

Since once \bar{V}_1 are informed only $O(\log n)$ more rounds are required to inform \bar{V}_2 , altogether $O(t(n) \cdot \log n)$ rounds are required to deliver the message from s to all the other vertices of the copy \bar{G} , and, furthermore, these deliveries can be conducted in parallel in different copies. \square

COROLLARY 6.7. *If G is a YES-instance of the set-cover $(t(n), c)$ -promise problem, then for any $i = 1, 2, \dots$, there exists an $(\{s^i\}, \bar{V}^i)$ -schedule of length $O(t(n) \cdot (i + \log n))$.*

Next, we turn to analyzing the graph \bar{G}^i that is obtained by the reduction that was described above from a NO-instance G of the set-cover $(t(n), c)$ -promise problem.

LEMMA 6.8. *If G is a NO-instance of the set-cover $(t(n), c)$ -promise problem, then for any $i = 1, 2, \dots$, any $(\{s^i\}, \bar{V}^i)$ -schedule Π for the instance (\bar{G}^i, s^i) of the directed broadcast problem is of length $|\Pi| = \Omega(t(n) \cdot \log n \cdot i)$.*

Proof. The proof is by induction on i . The induction base follows directly from Lemma 6.3.

For the induction step, consider the graph \bar{G}^{i+1} , and consider the isomorphic copy of \bar{G}^1 that has the vertex s^{i+1} as the image of the vertex s^1 under the isomorphism. For every schedule Π , by Lemma 6.3, there exists a vertex $\bar{V}_2^1 \in \bar{V}_2^1$ in this copy that is informed only after $\Omega(t(n) \cdot \log n)$ rounds. Consider the copy $\bar{G}^i(\bar{V}_2^1)$ of the graph \bar{G}^i . Recall that by construction, this copy of \bar{G}^i is a subgraph of the graph \bar{G}^{i+1} . Also, no vertex of this copy $\bar{G}^i(\bar{V}_2^1)$ can be informed before the vertex \bar{V}_2^1 is informed. By the induction hypothesis, delivering the message from the vertex \bar{V}_2^1 to all the other vertices of the copy $\bar{G}^i(\bar{V}_2^1)$ requires $\Omega(i \cdot t(n) \cdot \log n)$ rounds. The assertion of the lemma follows. \square

Substituting $i = \log n$ into Corollary 6.7 we get a broadcast time of $O(\log n) \cdot t(n)$ for a YES-instance. By substituting $i = \log n$ into Lemma 6.8 we get a broadcast time of $\Omega(\log^2 n \cdot t(n))$ for a NO-instance. Hence the gap is $\Theta(\log n)$.

We now compare the gap to the number of vertices in the broadcast instance. For $i = \log n$, the number N of vertices in the broadcast instance is $N = n^{\log n}$. Hence, $\log n = \sqrt{\log N}$. Hence, we get a gap which equals the square of the log of the size of the instance.

THEOREM 6.9. *The directed broadcast problem is $\Omega(\sqrt{\log n})$ -inapproximable unless $NP \subseteq DTIME(n^{O(\log n)})$.*

Next, we establish inapproximability of $3 - \epsilon$ for any $\epsilon > 0$ for the undirected broadcast problem. This is done via a similar reduction.

Specifically, the graph \bar{G} is modified in the following way. The distance between s and s' vertices is changed to $c \cdot t(n) \cdot \log n$. (In the directed construction it was half this value.) Insert into \bar{G} an isomorphic copy of \bar{G} , with all the directed arcs replaced by undirected edges. For $j = 1, 2$ let \bar{V}_j be the image of \bar{V}_j under the isomorphism, and, more generally, for a subset $X \subseteq V$, let \bar{X} denote its image under

the isomorphism. Second, for every star $(v_1, v_2^1), (v_1, v_2^2), \dots, (v_1, v_2^r)$ in G with $v_1 \in V_1, v_2^1, v_2^2, \dots, v_2^r \in V_2$ (or, in other words, for every complete binary tree rooted at \bar{V}_1 and with the set of leaves that contains the set $\{\bar{V}_2^1, \dots, \bar{V}_2^r\}$ in \bar{G}), insert a path of length $\lceil \log n \cdot c/2 \cdot t(n) \rceil$ that connects \bar{V}_1 with a vertex \bar{V}'_1 , where all the vertices of this path except of \bar{V}_1 are new. Now construct a complete binary tree rooted in \bar{V}'_1 and with the set of leaves that contains $\{\bar{V}_2^1, \dots, \bar{V}_2^r\}$, and all the other vertices of the tree are new. This completes the construction of \bar{G} .

Now the construction of the graph \bar{G}^i for $i = 1, 2, \dots$, given the graph \bar{G} , is identical to the construction of \bar{G}^i out of \bar{G} .

LEMMA 6.10. *If G is a YES-instance of the set-cover $(t(n), c)$ -promise problem, then there exists an $(\{s\}, \bar{V}_2)$ -schedule Π of length $|\Pi| \leq (c/2 + o(1))t(n) \log n$ for the instance (\bar{G}, s) of the undirected telephone broadcast problem.*

Proof. As G is a YES-instance of the set-cover problem, there exists a set cover $S \subseteq V_1$ for V_2 of size at most $t(n)$. Using the edges of the star that connect between the copy of the vertex s in \bar{G} and the copies of the vertices of S , it is possible to inform the latter vertices using $|S| \leq t(n)$ rounds. Since S is a set cover for V_2 , and since the distance between the sets \bar{S} and \bar{V}_2 in the graph \bar{G} is $\frac{c}{2} \cdot \log n \cdot t(n) + O(\log n)$, it follows that it is possible to relay the message from the vertices of the set \bar{S} to all the vertices of the set \bar{V}_2 in $(\frac{c}{2} + o(1)) \cdot \log n \cdot t(n)$ rounds. \square

LEMMA 6.11. *If G is a NO-instance of the set-cover $(t(n), c)$ -promise problem, then any $(\{s\}, \bar{V}_2)$ -schedule Π for the instance (\bar{G}, s) of the undirected telephone broadcast problem has length $|\Pi| \geq 3/2 \cdot c \cdot t(n) \log n$.*

Proof. The proof of this lemma is analogous to that of Lemma 6.3. As in that proof, it is easy to see that for informing all the vertices of the set \bar{V}_2 it is necessary to inform a subset $\bar{S} \subseteq \bar{V}_1$ that satisfies that the subset S is a set cover for V_2 . Informing the set \bar{S} via the edges that connect the vertex s to the vertices of \bar{V}_1 requires at least $|\bar{S}| \geq c \cdot t(n) \cdot \log n$ rounds (because G is a NO-instance). Informing a single vertex from the set \bar{V}_2 using the path that connects s to s' and using the complete binary tree T rooted in s' requires at least $c \cdot t(n) \cdot \log n$ rounds, because the length of this path between s and s' is $c \cdot t(n) \cdot \log n$. Hence, at least $c \cdot t(n) \cdot \log n$ rounds are required to inform a set \bar{S} , where S is a set cover for V_2 . Finally, since the distance between the sets \bar{V}_1 and \bar{V}_2 in the graph \bar{G} is at least $\frac{c}{2} \cdot t(n) \cdot \log n$, it follows that informing the vertices of the set \bar{V}_2 once all the vertices of the subset \bar{S} are informed would require at least $\frac{c}{2} \cdot t(n) \cdot \log n$ additional rounds. Hence, altogether, at least $\frac{3}{2}c \cdot t(n) \cdot \log n$ rounds are required to relay the message from s to all the vertices of the set \bar{V}_2 . \square

Note that Lemmata 6.10 and 6.11 imply that $(3 - o(1))$ -inapproximability of the undirected multicast problem with the multicast task is informing V_2 . However, since for both the YES and NO-instance of the set-cover problem, informing the subset \bar{V}_1 in the instance (\bar{G}, s) of the undirected telephone broadcast problem requires $t(n) \cdot \log n(c + o(1))$ rounds, the reduction that uses only \bar{G} yields only $(3/2 - o(1))$ -inapproximability for the undirected broadcast problem. This is, essentially, the reduction of [S00].

In the following lemmata we show that the construction of \bar{G}^i yields the desired $(3 - \epsilon)$ -inapproximability.

LEMMA 6.12. $|\bar{V}^i| = n^{O(i)}, i = 1, 2, \dots$

Proof. Similarly to Lemma 6.4, the proof can be derived by a straightforward induction on i . \square

The proof of the following lemma is analogous to the proofs of Lemmata 6.5 and 6.6.

LEMMA 6.13.

1. If G is a YES-instance of the set-cover $(t(n), c)$ -promise problem, then for any $i = 1, 2, \dots$, there exists an $(\{s^i\}, \bar{V}_2^i)$ -schedule Π for the instance (\bar{G}^i, s^i) of the undirected broadcast problem of length $|\Pi| \leq i \cdot t(n)(c/2 + o(1)) \log n$.
2. For any $i = 1, 2, \dots$, there exists a $(\{s^i\} \cup \bar{V}_2^i, \bar{V} \setminus \bar{V}_2^i)$ -schedule Π of length $|\Pi| \leq t(n) \log n(c/2 + o(1))$.

The following corollary is immediate, given Lemma 6.13.

COROLLARY 6.14. If G is a YES-instance of the set-cover $(t(n), c)$ -promise problem, then for any $i = 1, 2, \dots$, there exists an $(\{s^i\}, \bar{V}^i)$ -schedule Π for the instance (\bar{G}^i, s^i) of the undirected broadcast problem of length $|\Pi| \leq (i+1)t(n) \log n(c/2 + o(1))$.

We next turn to the analysis of the NO-instance.

LEMMA 6.15. If G is a NO-instance of the set-cover $(t(n), c)$ -promise problem, for any $i = 1, 2, \dots$, any $(\{s^i\}, \bar{V}^i)$ -schedule for the instance (\bar{G}^i, s^i) of the undirected broadcast problem is of length $|\Pi| \geq 3 \cdot t(n) \log n(c/2 + o(1)) \cdot i$.

Proof. The proof of this lemma is analogous to that of Lemma 6.8. The only difference is that Lemma 6.11 is used instead of Lemma 6.3. \square

It follows that the undirected broadcast problem is $(3 - O(1/i))$ -inapproximable unless $NP \subseteq DTIME(n^{O(i)})$.

THEOREM 6.16. For any $\epsilon > 0$, it is NP-hard to approximate the undirected broadcast problem within a ratio of $3 - \epsilon$.

7. Discussion. We demonstrated that the approximation threshold of the directed telephone broadcast problem is between $O(\log n)$ and $\Omega(\sqrt{\log n})$. Bridging this gap is a challenging open problem. Determining the approximation threshold of the directed multicast problem is another important open problem. Here the gap is between an additive approximation of $O(\sqrt{k})$ (that comes together with a logarithmic multiplicative factor) [EK03b] and a lower bound of $\Omega(\log n)$ [F01].

Acknowledgments. We are grateful to Magnus M. Halldorsson for his help in writing this manuscript and for helpful discussions and comments. We are also grateful to Zvika Lotker for helpful and motivating discussions, particularly about the reduction of [S00]. Finally, we thank two anonymous referees for helpful comments.

THE COMPUTATIONAL COMPLEXITY OF TUTTE INVARIANTS FOR PLANAR GRAPHS*

DIRK VERTIGAN†

Abstract. For each pair of algebraic numbers (x, y) , the complexity of computing the Tutte polynomial $T(G; x, y)$ of a planar graph G is determined. This computation is found to be $\#\overline{P}$ -complete except when $(x - 1)(y - 1) = 1, 2$ or when (x, y) is one of $(1, 1)$, $(-1, -1)$, (j, j^2) , or (j^2, j) , where $j = e^{2\pi i/3}$, in which case it is polynomial time computable. A corollary gives the computational complexity of various enumeration problems for planar graphs.

Key words. Tutte polynomial, knot polynomials, planar graphs, computational complexity, polynomial time, $\#\overline{P}$ -complete, enumeration, reliability, percolation, Potts model

1. Introduction. The main result of this paper is Theorem 5.1, which states the complexity of computing the Tutte polynomial $T(G; x, y)$ of a planar graph G at any fixed algebraic point or algebraic curve in the (x, y) -plane. It is $\#\overline{P}$ -complete (“computationally hard”) almost everywhere, that is, except when $(x - 1)(y - 1) = 1, 2$ or when (x, y) is one of $(1, 1)$, $(-1, -1)$, (j, j^2) , or (j^2, j) , where $j = e^{2\pi i/3}$, in which case it is polynomial time computable (“computationally easy”).

The corresponding result was done for the input class of general graphs in Proposition 1 of [8], where the complexity differed only on the curve $(x - 1)(y - 1) = 2$. Strengthening the result to the smaller input class of planar graphs requires that some novel, and more intricate, techniques be combined with those already used in [8].

One motivation for examining the planar graph case is that many interesting graph invariants are obtained as evaluations of the Tutte polynomial, giving the complexity of computing these invariants for planar graphs as an immediate corollary. For instance, for the input class of planar graphs, it is $\#\overline{P}$ -complete to count any one of the following: k -colorings, k -flows (for any fixed $k \in \{3, 4, \dots\}$), independent sets (forests), spanning sets, or acyclic orientations. And there is an equivalent complexity for one-variable polynomials such as the (all terminal) connectedness reliability polynomial, the percolation probability polynomial, the q -state Potts model polynomial (for any fixed $q \in \{3, 4, \dots\}$), as well as, of course, the full two-variable Tutte polynomial, and almost all specializations of these.

Another motivation is that the planar graph result is an important step toward answering the analogous question for the Homfly and Kauffman polynomials for knots and links; see [19].

The paper is arranged with the following sections, some of which have self-explanatory titles: 1. Introduction, 2. The Tutte polynomial, 3. Computational complexity, 4. Tutte invariants, 5. The main results, 6. Pointed Tutte polynomials, 7. The radial construction, 8. Some $4 \cdot k$ -tiles, 9. The radial construction using just T_{\setminus} and

T_{\succ} , 10. Some useful combinatorial identities, 11. The main constructions, 12. The remainder of the proofs, and 13. Conclusions.

As a historical note, this work was done in 1989 and appeared in the author’s DPhil thesis [17].

2. The Tutte polynomial. For graph and matroid theory terminology and notation, we follow [21] or [12]. The Tutte polynomial is a two-variable polynomial invariant defined originally for graphs [15, 23] but later extended to matroids [2, 3].

A *matroid* M consists of a pair $M = (E, \rho)$ with finite *ground set* E and *rank function* $\rho : 2^E \rightarrow \mathbb{Z}$ satisfying certain axioms; see [21]. With any graph G we associate its *cycle matroid* $M(G) = (E(G), \rho_G)$ as follows.

Let $G = (V, E)$ be a graph. For $A \subseteq E$ let $V(A)$ be the set of vertices incident with edges in A . Let $G|A$ (respectively, $G||A$) be the subgraph of G consisting of the edges in A and the vertices in $V(A)$ (respectively, V). (Thus $G||A$ may contain isolated vertices which are deleted to obtain $G|A$.) Let $c(G)$ denote the number of components of G . The *rank*, $\rho(G)$, of G is given by

$$(2.1) \quad \rho(G) = |V(G)| - c(G).$$

The *cycle matroid*, $M(G)$, of G is defined to be $M(G) = (E(G), \rho_G)$, where for $A \subseteq E$,

$$(2.2) \quad \rho_G(A) = \rho(G|A) = |V(A)| - c(G|A) = \rho(G||A) = |V| - c(G||A).$$

If the graph is directed, then the associated matroid is independent of the orientation of edges. A matroid of the form $M(G)$ is a *graphic matroid*. Let \mathbb{G} and \mathbb{PG} denote the classes of (cycle matroids of) graphs and planar graphs, respectively.

The *Tutte polynomial* of a matroid $M = (E, \rho)$, with ground set E and rank function $\rho : 2^E \rightarrow \mathbb{Z}$, is defined to be

$$(2.3) \quad T(M; x, y) = \sum_{A \subseteq E} (x - 1)^{\rho(E) - \rho(A)} (y - 1)^{|A| - \rho(A)}.$$

The Tutte polynomial of a graph G is the same as that of the matroid $M(G)$. We sometimes abuse notation by writing G instead of $M(G)$.

A matroid has a unique partition into *connected components*, and for a graph G the components of $M(G)$ are the edge sets of blocks. In particular, G is 2-connected if and only if $M(G)$ is connected. If a matroid $M = (E, \rho)$ has connected components $(E_i : i \in I)$, then

$$(2.4) \quad T(M; x, y) = \prod_{i \in I} T(M|E_i; x, y);$$

see [21] for more information. In particular, for a graph, its Tutte polynomial is simply the product of the Tutte polynomial of its blocks. Because of this simple formula we can almost always restrict attention to 2-connected graphs.

3. Computational complexity. For terminology and notation in computational complexity, we follow [5, 16]; see also [6, 17, 22]. Every complexity class we consider will be a class of *functions* $f : \{0, 1\}^* \rightarrow \{0, 1\}^*$, where $\{0, 1\}^*$ is the set of binary strings. Denote the *size* (or *length*) of a string $w \in \{0, 1\}^*$ by $\|w\|$. We assume that the objects we consider, such as graphs, matrices, rationals, polynomials, etc., are all encoded as binary strings in a standard way.

Let FP denote the class of *polynomial time computable functions*. Thus $f \in \text{FP}$ means there is a deterministic algorithm such that for every $w \in \{0, 1\}^*$, the algorithm outputs $f(w)$ with the number of steps taken bounded by a polynomial in $\|w\|$.

For functions f, g , we let $f \leq_T g$ denote that the function f is *polynomial time Turing reducible to g* . That is, there is a deterministic *g -oracle* algorithm to compute f in polynomial time. A *g -oracle* algorithm is an algorithm which is allowed to use the function g at a cost of only one step per use. Loosely speaking, if $f \leq_T g$, then f being (computationally) hard implies g is hard, while g being (computationally) easy implies f is easy.

For a class of functions \mathcal{F} , we let $\text{FP}^{\mathcal{F}}$ denote $\{f : f \leq_T g \text{ for some } g \in \mathcal{F}\}$. Also g is \mathcal{F} -complete if $g \in \mathcal{F}$ and $\text{FP}^{\mathcal{F}} = \text{FP}^{\{g\}}$; that is, $f \leq_T g$ for every $f \in \mathcal{F}$.

The class $\#\text{P}$ was first defined in [16]. A function $g : A \times B \rightarrow \{0, 1\}$ is *polynomially balanced* if, for any $(a, b) \in A \times B$ such that $g(a, b) \neq 0$, the size of b is polynomially bounded in the size of a (in particular, for each $a \in A$, there are only finitely many such b). A function $f : A \rightarrow \mathbb{N}$ is in $\#\text{P}$ if there exists a function

$$(3.1) \quad g : A \times B \rightarrow \{0, 1\}$$

which is polynomially balanced and polynomial time computable, and is such that for any $a \in A$,

$$(3.2) \quad f(a) = |\{b : b \in B, g(a, b) = 1\}| = \sum_{b \in B} g(a, b);$$

that is, on input a , f counts the number of b 's such that $g(a, b) = 1$. For example, counting the number of circuits in a graph is in $\#\text{P}$ since, given a graph a and a subset of its edges b , it is easy to check in polynomial time whether the set of edges is a circuit.

The two main classes we consider are FP and $\#\text{P}$. Actually, since most evaluations of the Tutte polynomial are not literally counting problems, we often use the class $\text{FP}^{\#\text{P}}$, the class of functions polynomial time Turing reducible to a function in $\#\text{P}$. We abbreviate $\text{FP}^{\#\text{P}}$ to $\overline{\#\text{P}}$.

The relation \leq_T is a quasi order; that is, it is reflexive and transitive. Within $\overline{\#\text{P}}$, the \leq_T -minimal elements are the functions in FP , while the \leq_T -maximal elements are the $\overline{\#\text{P}}$ -complete functions. All the functions considered in this paper are shown either to be $\overline{\#\text{P}}$ -complete or to be in FP .

Note that $\overline{\#\text{P}}$ -complete functions are NP-hard but are in Pspace.

4. Tutte invariants. Let \mathcal{C} be a class of matroids. Assume that any matroid M in \mathcal{C} can be encoded as a string in such a way that the size of the encoding of $M = (E, \rho) \in \mathcal{C}$ is polynomially bounded in $|E|$ (so that the input size can be taken to be $|E|$) and that the rank of any $A \subseteq E$ can be determined in time polynomially bounded in $|E|$. This assumption applies to all the classes of matroids mentioned in this paper (but not to the class of all matroids since there are too many of any given size).

Define the function

$$(4.1) \quad \tau^2(\mathcal{C}) : \mathcal{C} \rightarrow \mathbb{Z}[x, y], \text{ where } M \mapsto T(M; x, y).$$

This function determines the Tutte polynomial of each matroid $M \in \mathcal{C}$ on the whole (x, y) -plane.

Let \mathbb{A} denote the set of algebraic numbers. For any algebraic point $(x_0, y_0) \in \mathbb{A}^2$ define the function

$$(4.2) \quad \tau^0(\mathcal{C}, x_0, y_0) : \mathcal{C} \rightarrow \mathbb{Q}(x_0, y_0), \text{ where } M \mapsto T(M; x_0, y_0).$$

This function determines the Tutte polynomial of each matroid $M \in \mathcal{C}$ at a single point (x_0, y_0) .

It is also of interest to consider the Tutte polynomial of a matroid “along” an algebraic curve in the (x, y) -plane. Here is a formal definition (which will soon be made less formal). Let $p \in \mathbb{Q}[x, y]$ be an irreducible polynomial, let $\langle p(x, y) \rangle$ be the ideal generated by $p(x, y)$, and let $K = \langle (x, y) : p(x, y) = 0 \rangle$ be the corresponding algebraic curve. Define the function

$$(4.3) \quad \tau^1(\mathcal{C}, K) : \mathcal{C} \rightarrow \mathbb{Q}[x, y]/\langle p(x, y) \rangle, \text{ where } M \mapsto T(M; x, y) + \langle p(x, y) \rangle.$$

This function gives $T(M; x, y)$ reduced modulo $p(x, y)$ (in some predetermined canonical form). If the curve is expressed as a rational curve $\langle (x(s), y(s)) : s \in \mathbb{A} \rangle$, where x and y are rational functions of s , we can alternatively state

$$(4.4) \quad \tau^1(\mathcal{C}, K) \text{ sends } M \in \mathcal{C} \text{ to } T(M; x(s), y(s)),$$

the latter being a rational function of s . Thus, strictly speaking, the definition of $\tau^1(\mathcal{C}, K)$ depends on the representation of the curve K . However, it is easily shown that one can translate between any two of these representations in polynomial time, so that the computational complexity of $\tau^1(\mathcal{C}, K)$ is independent of the representation of K .

The polynomial time bounds on the algorithms and reductions presented in this paper will be fairly evident to those readers familiar with computational complexity except possibly for algebraic manipulations with the outputs of the Tutte invariants. But note, for example, that the outputs of $\tau^0(\mathcal{C}, x_0, y_0)$ are not arbitrary algebraic numbers but are elements of $\mathbb{Q}(x_0, y_0)$, which is a finite degree extension of \mathbb{Q} and whose elements can be represented as rational vectors of a fixed finite dimension. More generally, outputs of $\tau^1(\mathcal{C}, K)$ and $\tau^2(\mathcal{C})$ can be expressed as rational vectors of a dimension that is polynomially bounded in input size. In all cases, the rationals themselves have a polynomially bounded encoding as strings. And finally, considering the types of issues addressed in [6], these bounds remain true with all the algebraic manipulations done, primarily solving linear equations, as is needed for Lagrange interpolation.

Observe that if (x_0, y_0) is an algebraic point and K is an algebraic curve containing (x_0, y_0) , then trivially,

$$(4.5) \quad \tau^0(\mathcal{C}, x_0, y_0) \leq_T \tau^1(\mathcal{C}, K) \leq_T \tau^2(\mathcal{C}).$$

In certain cases (see Theorems 4.2 and 4.3 below) these reducibilities can be reversed, motivating the following definitions and terminology.

DEFINITION 4.1. *For each $q \in \mathbb{A}$ define the curves $H_q = \langle (x, y) : (x - 1)(y - 1) = q \rangle$ and define $H_0^x = \langle (x, y) : x = 1 \rangle$ and $H_0^y = \langle (x, y) : y = 1 \rangle$. The curves H_0^x , H_0^y , and H_q for $q \in \mathbb{A} - \{0\}$ are called special curves. Let $j = e^{2\pi i/3}$. The points $(1, 1)$, $(0, 0)$, $(-1, -1)$, $(0, -1)$, $(-1, 0)$, $(i, -i)$, $(-i, i)$, (j, j^2) , (j^2, j) are called special points.*

The following results come from [8]. It is assumed that the class of matroids \mathcal{C} satisfies certain natural technical conditions given in [8] and addressed in detail in

[17]. All the classes of matroids in this paper easily satisfy these conditions, allowing the use of Theorems 4.2 and 4.3 below.

The following is Theorem 1 from [8]. (This was proved only when the curve is expressed as a rational curve, but it is straightforward to extend this, though this extension is not used here.)

THEOREM 4.2. *If K is an algebraic curve, then $\tau^2(\mathcal{C}) \leq_T \tau^1(\mathcal{C}, K)$ unless K is a special curve.*

The following is Theorem 2 from [8].

THEOREM 4.3. *If K is a special curve and $(x, y) \in K$, then $\tau^1(\mathcal{C}, K) \leq_T \tau^0(\mathcal{C}, x, y)$ unless (x, y) is a special point.*

The following is Proposition 1 of [8]. The above two theorems are very useful for proving this proposition, as well as the main Theorem 5.1. But while Proposition 4.4 and Theorem 5.1 look quite similar—in changing the input class from \mathbb{G} to $\mathbb{P}\mathbb{G}$, the computational complexity changes only on the special curve H_2 —the proofs have significant differences, and Theorem 5.1 makes essentially no use of Proposition 4.4.

PROPOSITION 4.4.

- (i) *The function $\tau^2(\mathbb{G})$ is $\overline{\#\mathbb{P}}$ -complete.*
- (ii) *If K is an algebraic curve, then $\tau^1(\mathbb{G}, K)$ is $\overline{\#\mathbb{P}}$ -complete unless $K = H_1$, in which case $\tau^1(\mathbb{G}, K)$ is in FP.*
- (iii) *If $(x, y) \in \mathbb{A}^2$ is an algebraic point, then $\tau^0(\mathbb{G}, x, y)$ is $\overline{\#\mathbb{P}}$ -complete unless $(x, y) \in H_1$ or (x, y) is a special point, in which case $\tau^0(\mathbb{G}, x, y)$ is in FP.*

Note that for a graph G the Ising partition function of G (see [4, 11, 9, 22]) is given (up to an easily computable factor) by the Tutte polynomial of $M(G)$ along the curve H_2 (see, for example, [22]). By [9], this is $\overline{\#\mathbb{P}}$ -complete for graphs, whereas by [4, 11], this is polynomial time computable for planar graphs.

5. The main results. The main computational complexity result, proved in section 12, is the following.

THEOREM 5.1.

- (i) *The function $\tau^2(\mathbb{P}\mathbb{G})$ is $\overline{\#\mathbb{P}}$ -complete.*
- (ii) *If K is an algebraic curve, then $\tau^1(\mathbb{P}\mathbb{G}, K)$ is $\overline{\#\mathbb{P}}$ -complete unless $K = H_1$ or $K = H_2$, in which case $\tau^1(\mathbb{P}\mathbb{G}, K)$ is in FP.*
- (iii) *If $(x, y) \in \mathbb{A}^2$ is an algebraic point, then $\tau^0(\mathbb{P}\mathbb{G}, x, y)$ is $\overline{\#\mathbb{P}}$ -complete unless $(x, y) \in H_1 \cup H_2$ or (x, y) is a special point, in which case $\tau^0(\mathbb{P}\mathbb{G}, x, y)$ is in FP.*

Observe that the only special points not on H_1 or H_2 are $(1, 1)$, $(-1, -1)$, (j, j^2) , and (j^2, j) .

The paper [8] and the book [22] list many well-known quantities associated with graphs which are obtained (up to an easily computable factor) by evaluating the Tutte polynomial at certain points and curves. The above theorem shows that most of these calculations are $\overline{\#\mathbb{P}}$ -complete even for planar graphs. Some examples are given in the following corollary.

COROLLARY 5.2. *The following evaluations are $\overline{\#\mathbb{P}}$ -complete.*

$\tau^0(\mathbb{P}\mathbb{G}, 1 - k, 0)$: counting the number of k -colorings of a planar graph for any fixed $k \in \{3, 4, \dots\}$. Note that, by the four-color theorem, the corresponding decision problem is trivial for $k \geq 4$.

$\tau^0(\mathbb{P}\mathbb{G}, 0, 1 - k)$: counting the number of k -flows of a planar graph for any fixed $k \in \{3, 4, \dots\}$. As above, the corresponding decision problem is trivial for $k \geq 4$.

$\tau^0(\mathbb{P}\mathbb{G}, 2, 1)$ or $\tau^0(\mathbb{P}\mathbb{G}, 1, 2)$: counting the number of independent sets (forests) or spanning sets in a planar graph (shown independently by Jerrum [10]).

$\tau^1(\mathbb{P}\mathbb{G}, H_0^x)$ or $\tau^0(\mathbb{P}\mathbb{G}, 1, (1 - p)^{-1})$: “(all terminal) connectedness reliability” or “percolation probability” for planar graphs for any fixed $p \in \mathbb{A} - \{0, 1\}$. (Compare this to the “two-terminal connectedness reliability,” which is given (up to an easily computable factor) by the *pointed* Tutte polynomial T_L along the curve H_1 (see section 6 and (6.9)). This was shown to be $\overline{\#P}$ -complete in [13].)

$\tau^0(\mathbb{P}\mathbb{G}, 2, 0)$: counting the number of acyclic orientations of a planar graph.

$\tau^1(\mathbb{P}\mathbb{G}, H_q)$ or $\tau^0(\mathbb{P}\mathbb{G}, 1 + \frac{q}{x-1}, x)$: the “ q -state Potts model” for planar graphs, for any fixed $q \in \{3, 4, \dots\}$, $x \in \mathbb{A} - \{1\}$, $(q, x) \notin \{(3, j), (3, j^2), (4, -1)\}$ ($j = e^{2\pi i/3}$).

Moreover, Theorem 5.1 yields some immediate corollaries about the computational complexity of certain knot and link invariants (using connections in [7, 14]), while more comprehensive results are obtained with extra work which nevertheless has Theorem 5.1 as an essential foundation; see [19].

6. Pointed Tutte polynomials. The pointed Tutte polynomials [1] have important uses in [8, 18, 17]. In those works they appear in conjunction with the *matroid tensor product* operation [1], which we do not define here, although we note that it is crucial for Theorems 4.2 and 4.3, which we certainly use.

We primarily need pointed Tutte polynomials, and the sets defined in (6.1) below, in various places such as Lemmas 9.1, 11.2, 12.1, and 12.6. They are needed to fill what would otherwise be a “gap” as discussed preceding Lemma 11.2.

For $M = (E, \rho)$ and $g \in E$ define

$$(6.1) \quad \begin{aligned} C(M, g) &= \{A : g \in A, A \subseteq E, \rho(A) = \rho(A - \{g\}) + 1\}, \\ L(M, g) &= \{A : A \subseteq E - \{g\}, \rho(A \cup \{g\}) = \rho(A)\}. \end{aligned}$$

The *pointed* Tutte polynomials [1] are defined by

$$(6.2) \quad T_C(M, g; x, y) = \sum_{A \in C(M, g)} (x - 1)^{\rho(E) - \rho(A)} (y - 1)^{|A| - \rho(A)},$$

$$(6.3) \quad T_L(M, g; x, y) = \sum_{A \in L(M, g)} (x - 1)^{\rho(E) - \rho(A)} (y - 1)^{|A| - \rho(A)}.$$

Let \mathcal{C} be a class of matroids, and let $\overline{\mathcal{C}} = \{(M, g) : M = (E, \rho) \in \mathcal{C}, g \in E\}$. Let (x, y) be an algebraic point and let K be an algebraic curve. Define the function

$$(6.4) \quad \tau_L^2(\mathcal{C}) : \overline{\mathcal{C}} \rightarrow \mathbb{Z}[x, y], \text{ where } (M, g) \mapsto T_L(M, g; x, y),$$

and define the functions $\tau_L^1(\mathcal{C}, K)$, $\tau_L^0(\mathcal{C}, x, y)$, $\tau_C^2(\mathcal{C})$, $\tau_C^1(\mathcal{C}, K)$, $\tau_C^0(\mathcal{C}, x, y)$ in the obvious way (analogous to (4.1)–(4.4)).

When x, y, M, g are known from the context, it is convenient to abbreviate $T(M; x, y)$, $T(M \setminus g; x, y)$, $T(M/g; x, y)$, $T_C(M, g; x, y)$, and $T_L(M, g; x, y)$ to T, T', T'', T_C , and T_L , respectively. These are related by various identities [1] (or [17]). For instance, if g is not a loop or coloop, then

$$(6.5) \quad \begin{pmatrix} T' \\ T'' \end{pmatrix} = \begin{pmatrix} (x - 1) & 1 \\ 1 & (y - 1) \end{pmatrix} \begin{pmatrix} T_C \\ T_L \end{pmatrix}.$$

Note that the 2×2 matrix in (6.5) is nonsingular if and only if $(x, y) \neq 1$, that is, $(x, y) \notin H_1$. Using this and sundry other facts, it is easily shown that if $(x, y) \notin H_1$ and

\mathcal{C} is closed under *minors* (see [21]), then $\tau_L^0(\mathcal{C}, x, y)$ and $\tau_C^0(\mathcal{C}, x, y)$ are computationally equivalent to $\tau^0(\mathcal{C}, x, y)$, and similarly for τ^1 and τ^2 .

However, if $(x, y) \in H_1$, then $\tau^0(\mathcal{C}, x, y)$ is in FP since for $M = (E, \rho) \in \mathcal{C}$, $T(M; x, y)$ is simply $(x - 1)^{\rho(E)}y^{|E|}$. But, for example, if $(x, y) \in H_1 - \{(0, 0)\}$, then $\tau_L^0(\mathbb{P}\mathbb{G}, x, y)$ and $\tau_C^0(\mathbb{P}\mathbb{G}, x, y)$ are $\overline{\#P}$ -complete by the following reasoning. It is clear from (6.3) that

$$(6.6) \quad T_L(M, g; 2, 2) = |L(M, g)|.$$

Consider a graph $G = (V, E)$, edge $g \in E$, and subset $A \subseteq E - \{g\}$. Now $A \in L(M(G), g)$ if and only if $G|A$ contains a path between the ends of g , by the equivalence (1) \iff (4) in Lemma 9.1. Provan [13] shows that, given a planar graph G and edge g , determining the number of such subsets is $\overline{\#P}$ -complete. Since this number is $T_L(M(G), g; 2, 2)$, it follows that

$$(6.7) \quad \tau_L^0(\mathbb{P}\mathbb{G}, 2, 2) \text{ is } \overline{\#P}\text{-complete.}$$

Also $\tau_C^0(\mathbb{P}\mathbb{G}, 2, 2)$ is $\overline{\#P}$ -complete since $T_C(M(G), g; 2, 2) = 2^{|E|-1} - T_L(M(G), g; 2, 2)$. Using an argument similar to that in the proof of Theorem 4.3, it follows that $\tau_L^0(\mathbb{P}\mathbb{G}, x, y)$ and $\tau_C^0(\mathbb{P}\mathbb{G}, x, y)$ are $\overline{\#P}$ -complete whenever $(x, y) \in H_1 - \{(0, 0)\}$.

The following polynomial, related to the *2-terminal connectedness reliability*, is defined in [13] (where s and t are the ends of edge g):

$$(6.8) \quad R(G, s, t; p) = \sum_{A \in L(M(G), g)} p^{|A|}(1 - p)^{|E-A|}.$$

Using (6.3), it follows that

$$(6.9) \quad R(G, s, t; p) = p^{\rho(E)}(1 - p)^{|E|-\rho(E)}T_L(M(G), g; p^{-1}, (1 - p)^{-1}).$$

Observe that $(p^{-1}, (1 - p)^{-1}) \in H_1$ for all $p \in \mathbb{A} - \{0, 1\}$. Thus finding 2-terminal connectedness reliability is $\overline{\#P}$ -complete even for any fixed $p \in \mathbb{A} - \{0, 1\}$.

Finally note that since $\tau_L^2(\mathbb{P}\mathbb{G}) \leq_T \tau^2(\mathbb{P}\mathbb{G})$ (see comments following (6.5)) and $\tau_L^0(\mathbb{P}\mathbb{G}, 2, 2) \leq_T \tau_L^2(\mathbb{P}\mathbb{G})$ (similarly to (4.5)), it follows that

$$(6.10) \quad \tau_L^0(\mathbb{P}\mathbb{G}, 2, 2) \leq_T \tau^2(\mathbb{P}\mathbb{G}).$$

7. The radial construction. In what follows we regard plane graphs as being drawn on the 2-sphere. We describe a construction to piece together pieces of plane graphs. This construction is also important in [19].

Let G be a 2-connected directed plane graph, with vertex, edge, and face sets $V = V(G)$, $E = E(G)$, and $F = F(G)$. The *radial graph* of G , denoted G° , is a simple bipartite plane graph constructed as follows. It is instructive to regard the two graphs as being drawn simultaneously on the same 2-sphere. The vertex set of G° is $V \cup F$, with each vertex $f \in F$ of G° drawn in the face $f \in F$ of G . There is an edge, drawn in the obvious way, of G° between vertices $v \in V$ and $f \in F$ of G° if and only if vertex $v \in V$ is incident with face $f \in F$ in graph G . Note that every face of G° is a square, that is, it is bounded by four edges (regardless of actual shape in a drawing), and we identify the face set $F(G^\circ)$ of G° with the edge set $E = E(G)$ of G .

Figure 7.1 depicts a particular four-edge graph G (thick directed edges) and its radial graph G° (thin edges) with its corresponding four square faces. The three

FIG. 7.1. Graph G (thick edges) and radial graph G^\diamond (thin edges).

vertices and three faces of G correspond to the six vertices of G^\diamond , which are depicted, respectively, as triangular and square dots.

We use the orientation of G to add some extra labelling. Define functions $h, t : E \rightarrow V$, where $h(e)$ and $t(e)$ are, respectively, the *head* and *tail* of the directed edge $e \in E$. Also define functions $r, l : E \rightarrow F$, where $r(e)$ and $l(e)$ are, respectively, the *right(face)* and *left(face)* of the directed edge $e \in E$, when viewing e as pointing *up* (toward the head). Thus, the vertices of G^\diamond incident with face $e \in F(G^\diamond)$ are $h(e)$, $r(e)$, $t(e)$, $l(e)$ in clockwise order.

When G and G^\diamond are drawn simultaneously on the same 2-sphere, then edge $e \in E$ of G appears as the diagonal of face $e \in F(G^\diamond)$, which connects $h(e)$ and $t(e)$ (see Figure 7.1 again). Observe that we can also draw simultaneously the *plane dual* G^* of G with vertex, edge, and face sets $V(G^*) = F(G)$, $E(G^*) = E(G)$, $F(G^*) = V(G)$, and with each edge $e \in E(G^*) = E(G)$ appearing as the diagonal of face $e \in F(G^\diamond)$, which connects $l(e)$ and $r(e)$.

A *disk graph* H with *boundary vertex set* $B \subseteq V(H)$ is a plane graph drawn on a (closed) disk D , such that the drawing intersects the boundary of D precisely in vertex set B . The vertices in $V(H) - B$ are called the *internal* vertices. We wish to glue disk graphs together into larger disk graphs or plane graphs; for this purpose the labelling of the boundary vertices is important, and we do not equate a disk graph with its rotations or reflections.

For a positive integer k , a $4 \cdot k$ -*tile* is a disk graph with B, D as above, together with a distinguished set of four *boundary points* P (that is $|P| = 4$) on the boundary of D , with $P \cap B = \emptyset$, where there are exactly $|B| = 4k$ boundary vertices in four groups of k separated by the four points in P . We will typically label the four boundary points h, r, t, l in clockwise order, or use related names. We treat the disk as a square with corner points h, r, t, l and call the sides hr, rt, tl, lh in the natural way. The $4k$ boundary vertices are labelled hr^i, rt^i, tl^i, lh^i for $i = 1, \dots, k$, and they appear with the four boundary points h, r, t, l in clockwise order as follows:

$$(7.1) \quad h, hr^1, \dots, hr^k, r, rt^k, \dots, rt^1, t, tl^1, \dots, tl^k, l, lh^k, \dots, lh^1.$$

For each $i = 1, \dots, k$, the boundary vertices hr^i, rt^i, tl^i, lh^i are said to be of *type* i . Observe that boundary vertices of type 1 are consecutive with boundary points h and t , while boundary vertices of type k are consecutive with boundary points r and l .

Figure 7.2 depicts the boundary labelling in the $k = 3$ case. Boundary vertices are

depicted as round dots, while boundary points are depicted as triangular dots (h and t) and square dots (r and l). Figures 8.1, 8.2, and 11.1(a), with $k = 3, 3, 2$, respectively, depict $4 \cdot k$ -tiles with boundary labels and boundary “diamond” omitted from the drawing, with the understanding that these omitted features are to be deduced in the obvious way.

FIG. 7.2. Boundary labelling for a $4 \cdot k$ -tile ($k = 3$).

In the *radial construction* we place a $4 \cdot k$ -tile in each face of a radial graph and join them as we now detail. For visualization one may refer to Figures 7.1 and 7.2. Let G be a plane graph. Let k be a positive integer. For each $e \in E(G) = F(G^\circ)$ let T_e be a $4 \cdot k$ -tile drawn on a disk D_e with boundary points h_e, r_e, t_e, l_e in clockwise order. Other features of the $4 \cdot k$ -tile T_e also have an “ e ” incorporated into the notation where necessary.

DEFINITION 7.1. Given plane graph G , k , and $(T_e : e \in E)$ as above, where $E = E(G) = F(G^\circ)$, the radial construction produces a plane graph denoted

$$(7.2) \quad \Theta_G(T_e : e \in E)$$

by gluing the graphs T_e as follows. For each $e \in E$, place tile T_e in face $e \in F(G^\circ)$ of G° so that the boundary of disk D_e coincides with the boundary of face $e \in F(G^\circ)$. The boundary points h_e, r_e, t_e, l_e of T_e are identified with vertices $h(e), r(e), t(e), l(e)$ of G° . For each edge of G° incident with faces $e, g \in F(G^\circ)$, the appropriate k vertices of T_e are identified with the appropriate k vertices of T_g in the natural way.

Observe that only boundary vertices of the same *type* are identified.

We emphasize that $\Theta_G(T_e : e \in E)$ consists only of graphs $(T_e : e \in E)$ joined together as specified and does not include G° , or G or G^* , but instead these graphs determine *how* the T_e ’s are joined together. Nevertheless, it is instructive to visualize all four graphs as superimposed on the same 2-sphere.

This construction was called the *medial* construction in [17], but it is exactly the same construction. (The medial graph is the plane dual of the radial graph.) We remark that the vertices that are called $hr_e^i, rt_e^i, tl_e^i, lh_e^i$ in this paper are denoted in [17, 19] as $(e, h, a, i), (e, t, c, i), (e, t, a, i), (e, h, c, i)$, respectively.

FIG. 8.1. (a) $T_{\#}^k$, (b) $T_{(c)}^k$, (c) T_{\geq}^k ($k = 3$).

8. Some $4 \cdot k$ -tiles. We now describe some $4 \cdot k$ -tiles, which we shall need in various constructions and arguments. For convenience we initially define some as being drawn in the coordinate (X, Y) -plane with the X - and Y -axes being, respectively, horizontal and vertical. Let k be a positive integer. Let the disk D^k be the \diamond -shaped region of the (X, Y) -plane:

$$(8.1) \quad D^k = \{(X, Y) : |X| + |Y| \leq 2k\}.$$

The four distinguished boundary points of D^k are called h, r, t, l and have (X, Y) -coordinates $(0, 2k), (2k, 0), (0, -2k), (-2k, 0)$, respectively.

Let G_{\square}^{∞} be the infinite square grid in the (X, Y) -plane such that the vertices have coordinates (X, Y) , where X and Y are odd integers. The edges are parallel to the axes and have length 2. Call the edges *horizontal* and *vertical* in the obvious way.

Let $T_{\#}^k$ be the $4 \cdot k$ -tile on disk D^k with boundary points as above, where $T_{\#}^k$ is the intersection of G_{\square}^{∞} with D^k . See Figure 8.1(a) for the $k = 3$ case. The $4k$ boundary vertices are those which lie on the boundary of D^k , that is, the vertices with coordinates (X, Y) , where X and Y are odd integers and $|X| + |Y| = 2k$. For example, vertex hr^i has coordinates $(2i - 1, 2k - 2i + 1)$ for $i = 1, \dots, k$.

Observe that $T_{\#}^k$ has $4k^2$ edges and $2k(k+1)$ vertices, namely, $4k$ degree-2 boundary vertices and $2k(k-1)$ degree-4 internal vertices.

DEFINITION 8.1. Let T_{\langle}^k be the $4 \cdot k$ -tile obtained from $T_{\#}^k$ by restricting to the vertical edges. That is, T_{\langle}^k consists purely of vertex disjoint paths connecting boundary vertices hr^i to rt^i and tl^i to lh^i for $i = 1, \dots, k$.

Let T_{\geq}^k be the $4 \cdot k$ -tile obtained from $T_{\#}^k$ by restricting to the horizontal edges. That is, T_{\geq}^k consists purely of vertex disjoint paths connecting boundary vertices hr^i to lh^i and tl^i to rt^i for $i = 1, \dots, k$.

For our purposes the path lengths will generally not matter and we may use the notations T_{\langle}^k and T_{\geq}^k as long as boundary vertices are joined pairwise as above, regardless of (nonzero) path lengths. Figure 8.1(b)–(c) depicts T_{\langle}^k and T_{\geq}^k with $k = 3$ and with (internal) degree-2 vertices suppressed.

For a graph G , a *decontraction* at vertex v by new edge e yields a graph G' such that $G'/e = G$ and edge e in G' has endpoints, say v_1 and v_2 , in G' that are shrunk to v when contracting e . To uniquely specify G' we need to specify G , v , e together with a partition of the edges incident with v into two parts, specifying which of these edges are to be incident with v_1 or v_2 in G' . A degree d vertex can be decontracted into vertices of degree d_1 and d_2 provided $d = d_1 + d_2 - 2$. If G is drawn on a surface, then we can locally modify this drawing to obtain a drawing of G' on the surface provided the abovementioned partition is appropriately compatible with the cyclic ordering of edges around v . Thus there are three ways to decontract a degree-4 vertex into two degree-3 vertices, but only two are compatible with a surface drawing.

DEFINITION 8.2. We obtain a $4 \cdot k$ -tile $\tilde{T}_{\#}^k$ by decontracting at all of the $2k(k+1)$ vertices of $T_{\#}^k$, as follows. For future reference we will color the edges of $T_{\#}^k$ blue, while the new edges in $\tilde{T}_{\#}^k$ arising from decontraction are colored red. We require that the following hold.

- (a) Each of the $4k$ degree-2 boundary vertices of $T_{\#}^k$ is decontracted into a degree-1 boundary vertex and a degree-3 internal vertex in a unique way.
- (b) Each of the $2k(k-1)$ degree-4 internal vertices of $T_{\#}^k$ is decontracted into two degree-3 internal vertices in one of the two ways compatible with the plane drawing.
- (c) The decontractions in (b) are chosen such that the $4k^2$ blue edges form a single circuit.

Readers can verify that (c) can be satisfied in many ways, for instance, by doing one way of decontracting at the degree-4 internal vertices with coordinates (X, Y) satisfying $Y - X = 2k - 2$ (so that the corresponding red edges are roughly parallel to sides hr and tl), and the other way of decontracting at the rest (so that the corresponding red edges are roughly parallel to sides rt and lh). See Figure 8.2 for $\tilde{T}_{\#}^k$ with $k = 3$, and with this choice of decontraction. A fully explicit description of $\tilde{T}_{\#}^k$ (under a different name) is given in [17]. For the purposes of this paper, any choice in (b) that satisfies (c) will work for the constructions in which it appears. The blue edges retain the “vertical” or “horizontal” labelling they inherit from $T_{\#}^k$. (The red edges are just red.)

The (X, Y) -coordinates were convenient for the above definitions but we now no longer need them. We now ignore these coordinates and treat our graphs and tiles topologically or combinatorially.

FIG. 8.2. $\tilde{T}_{\#}^k$ with $k = 3$, and with a valid choice of decontractions as described in the text. Thick edges are blue. Thin edges are red. See Definition 8.2.

9. The radial construction using just T_{\langle}^k and T_{\succ}^k . We first consider the radial construction when all tiles are of the form T_{\langle}^k and T_{\succ}^k . Let G be a directed plane graph, as above. For $A \subseteq E$ and a positive integer k , construct the plane graph G_A^k as follows. Suppose

$$(9.1) \quad G_A^k = \Theta_G(T_e : e \in E), \text{ where } T_e = \begin{cases} T_{\langle}^k & \text{for } e \in A, \\ T_{\succ}^k & \text{for } e \in E - A. \end{cases}$$

Actually this means each T_e is a copy of T_{\langle}^k or T_{\succ}^k .

Let E_A^k be the edge set of G_A^k , and for $g \in E$ let $E_{A,g}^k$ be the set of edges in T_g .

Clearly G_A^k consists of some number, say $m_G(A, k)$ or $m(A, k)$, of vertex disjoint circuits. Moreover, for any $g \in E$, the boundary vertices of $4 \cdot k$ -tile T_g will be pairwise joined by vertex disjoint paths outside its disk in a way that can be specified depending on A . The next lemma provides more detail of this. This lemma highlights one crucial idea toward the main theorem, as well as in the connection between the Tutte polynomial for planar graphs and various invariants of link diagrams [19]; see also [7, 14].

Let $c(A)$ denote $c(G||A)$, which need not equal $c(G|A)$. For statements (4), (5), (6), (4'), (5'), (6') in Lemma 9.1 below, it does not matter whether we use “|” or “||”.

LEMMA 9.1. *Let G be a 2-connected plane graph, and let $M(G) = (E, \rho)$ be its cycle matroid. Let k be a positive integer. Let $A \subseteq E$. Let*

$$(9.2) \quad G_A^k = \Theta_G(T_e : e \in E), \text{ where } T_e = \begin{cases} T_{\cup}^k & \text{for } e \in A, \\ T_{\cap}^k & \text{for } e \in E - A. \end{cases}$$

Then G_A^k consists of $m_G(A, k) = m(A, k)$ vertex disjoint circuits, where

$$(9.3) \quad m_G(A, k) = m(A, k) = k(|V| - 2\rho(A) + |A|).$$

Moreover, if $g \in E$ and $A \subseteq E - \{g\}$, then the following conditions (1)–(7) are equivalent:

- (1) $A \in L(M(G), g)$.
- (2) $\rho(A \cup \{g\}) = \rho(A)$.
- (3) $c(A \cup \{g\}) = c(A)$.
- (4) *The ends of g are joined by a path in $G|A$.*
- (5) *The ends of g are not joined by a path in $G^*|A$.*
- (6) *In $G_A^k|(E_A^k - E_{A,g}^k)$ there are vertex disjoint paths between hr_g^i and rt_g^i and between tl_g^i and lh_g^i for $i = 1, \dots, k$.*
- (7) $m(A \cup \{g\}, k) - m(A, k) = k$.

If $g \in E$ and $A \subseteq E - \{g\}$, then the following conditions (1')–(7') are equivalent and are the negation of (1)–(7):

- (1') $A \in 2^{E-\{g\}} - L(M(G), g) = \{A \in 2^{E-\{g\}} : A \cup \{g\} \in C(M(G), g)\}$.
- (2') $\rho(A \cup \{g\}) = \rho(A) + 1$.
- (3') $c(A \cup \{g\}) = c(A) - 1$.
- (4') *The ends of g are not joined by a path in $G|A$.*
- (5') *The ends of g are joined by a path in $G^*|A$.*
- (6') *In $G_A^k|(E_A^k - E_{A,g}^k)$ there are vertex disjoint paths between hr_g^i and lh_g^i and between tl_g^i and rt_g^i for $i = 1, \dots, k$.*
- (7') $m(A \cup \{g\}, k) - m(A, k) = -k$.

Proof. As noted in section 7, only vertices of the same type are joined, and thus G_A^k consists of k disjoint subgraphs (one corresponding to each $i = 1, \dots, k$), each isomorphic to G_A^1 . Therefore $m(A, k) = k \times m(A, 1)$, and it suffices to prove the case $k = 1$.

Clearly $m(\emptyset, 1) = |V|$, since $\Theta_G(T_{\cap})$ consists of one circuit per vertex of G . Then (9.3) will follow by induction on $|A|$ once we have shown that (2) \iff (7) and (2') \iff (7').

Now (1) \iff (2) by (6.1) and (2) \iff (3) by (2.2). Clearly (3) \iff (4), since they hold exactly when the ends of g are in the same connected component of $G|A$. Similarly (1') \iff (2') \iff (3') \iff (4'). We show (3) \iff (5) and (3') \iff (5') by negating, dualizing, and changing A to $E - A - g$ in (3') \iff (4') and (3) \iff (4), respectively. Clearly (1') is the negation of (1).

Now (6) and (6') give the only ways that the boundary vertices of T_g can be joined by paths outside the disk for T_g , given that we are using only tiles T_{\cup}^k and T_{\cap}^k . If we regard G_A^k, G°, G , and G^* as being drawn simultaneously on the same 2-sphere, then by drawing edges $e \in E$ of G and G^* as “diagonals” of squares as discussed in section 7, we may easily arrange that edges $e \in A$ of G and edges $e \in E - A$ of G^* miss all the edges of G_A^k . Since exactly one of (4) or (5') must hold, then to miss these paths, this forces the connections as in (6) or (6'), respectively. Thus (4) \iff (6) and (5') \iff (6').

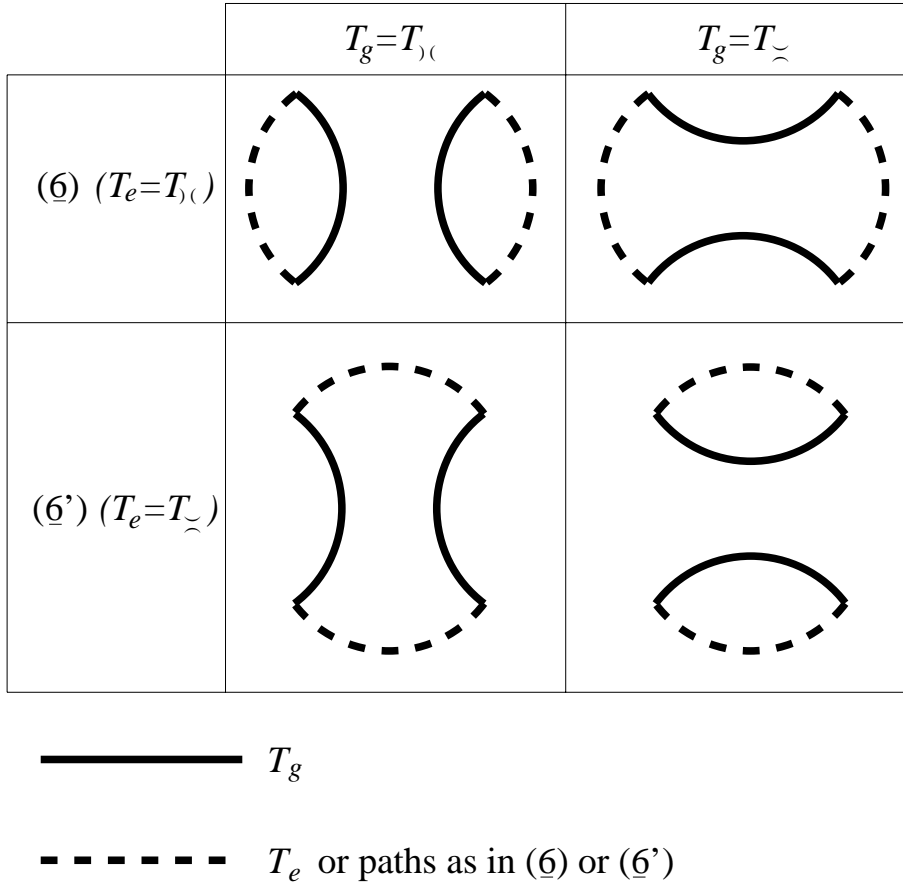

FIG. 9.1. How path routing relates to number of circuits.

To understand the remaining equivalences, with the help of Figure 9.1, first consider the special case where graph $G = G_{U12}$ consists of two parallel edges $E = \{e, g\}$ and $k = 1$. In that case, we can easily verify that (9.3) holds, that is,

$$(9.4) \quad m_{G_{U12}}(A, 1) = \begin{cases} 2 & \text{for } |A| = 0, 2, \\ 1 & \text{for } |A| = 1, \end{cases}$$

by considering all the appropriate ways of joining T_e and T_g , where each is either T_{\lrcorner} or T_{\sphericalangle} . Since, for the special case for $G = G_{U12}$, $e \in A \iff (1) - (6)$, we easily check that (6) \iff (7) and (6') \iff (7'). These equivalences follow for general G , since we need only consider path routings exactly as for the special case $G = G_{U12}$; that is, we need only consider how the boundary vertices of T_g are pairwise connected by vertex disjoint paths *internally* depending on whether T_g is T_{\lrcorner} or T_{\sphericalangle} , and how they are pairwise connected *externally* depending on whether (6) or (6') holds.

Figure 9.1 depicts the simple concept relating path routing to number of circuits. The same picture works for $G = G_{U12}$ (where dashed curves depict T_e being T_{\lrcorner} or T_{\sphericalangle}) and for general G (where dashed curves depict the paths referred to in (6) or (6')).

The general k case merely introduces a factor of k as noted above, and the proof is complete. \square

Remark 1. The above results hold regardless of the path lengths appearing in the T_{\subset} and T_{\supset} . Conditions (1)–(6) and (1′)–(6′) apply just as well when T_g is allowed to be an arbitrary $4 \cdot k$ -tile. The above results can also be restated for mathematical objects represented by curves in the plane such as *tangles* and *links* of topology; see [19].

10. Some useful combinatorial identities. We consider some useful combinatorial identities.

Lemma 10.1 below is central in the proof of Theorem 5.1. Let $M = (E, \rho)$ and $A \subseteq E$. The matroid M restricted to A , denoted $M|A$, is defined by $M|A = (A, \rho_A)$, where $\rho_A(B) = \rho(B)$ for all $B \subseteq A$.

LEMMA 10.1. *The following identity holds:*

$$(10.1) \quad \sum_{A \subseteq E} z^{|A|} (x-1)^{\rho(E)-\rho(A)} T(M|A; x, y) \\ = (1+z)^{|E|-\rho(E)} z^{\rho(E)} T\left(M; 1+(x-1)\frac{1+z}{z}, 1+(y-1)\frac{z}{1+z}\right).$$

Proof. By (2.3) the left-hand side of (10.1) is

$$(10.2) \quad \sum_{A \subseteq E} z^{|A|} (x-1)^{\rho(E)-\rho(A)} \sum_{B \subseteq A} (x-1)^{\rho(A)-\rho(B)} (y-1)^{|B|-\rho(B)}.$$

Rearranging the summation signs gives

$$(10.3) \quad \sum_{B \subseteq E} (x-1)^{\rho(E)-\rho(B)} (y-1)^{|B|-\rho(B)} \sum_{\substack{A \\ B \subseteq A \subseteq E}} z^{|A|},$$

which equals

$$(10.4) \quad \sum_{B \subseteq E} (x-1)^{\rho(E)-\rho(B)} (y-1)^{|B|-\rho(B)} z^{|B|} (1+z)^{|E|-|B|}.$$

Rearranging terms yields

$$(10.5) \quad (1+z)^{|E|-\rho(E)} z^{\rho(E)} \sum_{B \subseteq E} \left((x-1)\frac{1+z}{z} \right)^{\rho(E)-\rho(B)} \left((y-1)\frac{z}{1+z} \right)^{|B|-\rho(B)},$$

which, by (2.3), gives the right-hand side of (10.1), as required. \square

Observe that for fixed $(x, y) \neq (1, 1)$ and variable $z \notin \{0, -1\}$, the right-hand side of (10.1) gives an expression for the Tutte polynomial along the special curve containing (x, y) . Equation (10.1) is used in sections 11 and 12 in the case $x = 0$.

Now the *flow polynomial* [21] of a matroid $N = (E, \mu)$ is defined to be

$$(10.6) \quad \text{Flow}(N; q) = (-1)^{|E|-\mu(E)} T(N; 0, 1-q).$$

So the left-hand side of (10.1), with $(x, y) = (0, 1-q)$, can be rewritten as

$$(10.7) \quad \sum_{A \subseteq E} z^{|A|} (-1)^{\rho(E)-|A|} \text{Flow}(M|A; q).$$

Substituting $v = -z$ and multiplying by $(-1)^{\rho(E)}$ gives

$$(10.8) \quad \sum_{A \subseteq E} v^{|A|} \text{Flow}(M|A; q) = v^{\rho(E)}(1 - v)^{|E| - \rho(E)} T \left(M; \frac{1}{v}, 1 + \frac{qv}{1 - v} \right),$$

so that the Tutte polynomial of M along the special curve H_q (or H_0^y for $q = 0$) is given, up to an easily computable factor, by the left-hand side of (10.8).

For a positive integer q and a graph G with $N = M(G)$, the flow polynomial counts the number of *nowhere-zero \mathbb{Z}_q -flows* of G , but here we actually need only a few very basic facts. First, $e \in E$ is a *loop* of N if it is contained in no circuit. In the graph case, e is also called a *bridge* or *cut-edge*. An edge with a degree-1 endpoint is certainly a coloop. If **loop** and **coloop** are single edge graphs (or matroids) consisting of a loop and coloop, respectively, then

$$(10.9) \quad \text{Flow}(\mathbf{loop}; q) = q - 1, \quad \text{Flow}(\mathbf{coloop}; q) = 0.$$

As a consequence of (2.4) and (10.6), if a matroid $N = (E, \mu)$ has connected components $(E_i : i \in I)$, then

$$(10.10) \quad \text{Flow}(N; x, y) = \prod_{i \in I} \text{Flow}(N|E_i; x, y).$$

Hence by (10.9) and (10.10), the following holds:

$$(10.11) \quad \text{If } N \text{ has a coloop, then for all } q, \text{Flow}(N; q) = 0.$$

Two graphs G, H are *homeomorphic*, denoted $G \simeq H$, if one can be obtained from the other, up to isomorphism, by subdividing edges and suppressing degree-2 vertices. Another basic property is the following:

$$(10.12) \quad \text{If } G \simeq H, \text{ then } \text{Flow}(G; q) = \text{Flow}(H; q).$$

Hence by (10.9), (10.10), (10.12), if $\dot{\cup}_{i=1}^p C_i$ denotes a graph that is a vertex disjoint union of p circuits (of any length), then

$$(10.13) \quad \text{Flow}(\dot{\cup}_{i=1}^p C_i; q) = (q - 1)^p.$$

Another type of useful identity arises from the radial construction and the results in Lemma 9.1. In some constructions and computations in sections 11 and 12, we will produce the quantity on the left-hand side of the equation

$$(10.14) \quad \sum_{A \subseteq E} a^{|A|} b^{|E| - |A|} d^{m_G(A, k)} = a^{\rho(E)} b^{|E| - \rho(E)} d^{k(|V| - \rho(E))} T \left(G; 1 + \frac{b}{a} d^k, 1 + \frac{a}{b} d^k \right),$$

which readers can verify by using (2.3) and (9.3). Setting $a = b = 1$, a simpler useful identity is

$$(10.15) \quad \sum_{A \subseteq E} d^{m_G(A, k)} = d^{k(|V| - \rho(E))} T(G; 1 + d^k, 1 + d^k).$$

11. The main constructions. In this section we examine two constructions and related combinatorial quantities that form the bulk of the proofs of Lemmas 12.3 and 12.6, which in turn are the largest steps toward proving Theorem 5.1.

Let k be a positive integer, and recall the $4 \cdot k$ -tile $\tilde{T}_\#^k$ with its blue and red edges as in Definition 8.2. For a positive integer m , we obtain a $4 \cdot k$ -tile $\tilde{T}_\#^{k,m}$ by subdividing every red edge of $\tilde{T}_\#^k$ into a path of m edges. The blue edges are not subdivided. See Figure 8.2 again, now viewing red (thin) lines as paths of m edges.

Let $G = (V, E)$ be a 2-connected plane directed graph with $n = |E|$ edges. Let k be a positive integer and let $m = 4k^2|E| = 4k^2n$. Construct the graph

$$(11.1) \quad G_\#^k = \Theta_G(T_e : e \in E), \text{ where } T_e = \tilde{T}_\#^{k,m}.$$

As with (9.1), this actually means each T_e is a copy of $\tilde{T}_\#^{k,m}$.

Let $E_\#^k$ be the edge set of $G_\#^k$. The edges of $G_\#^k$ are colored red and blue just as they are in each T_e . Recalling the discussion in section 8, we note that $G_\#^k$ has $2k(k+1)nm$ red edges and $m = 4k^2n$ blue edges, so that

$$(11.2) \quad |E_\#^k| = 2k(k+1)nm + 4k^2n = 2k(k+1)nm + m.$$

For a polynomial $p(v)$ let $\text{coeff}_{v^\delta}(f(v))$ denote the coefficient of v^δ in $p(v)$.

We will show that, for $q \in \mathbb{A}$, if we find the Tutte polynomial of $G_\#^k$ along curve H_q as per (10.8) and extract a particular coefficient, we will be able to use Lemma 9.1 and (10.15) to find $T(G; 1 + (q-1)^k, 1 + (q-1)^k)$. This is the key construction and computation for the reducibilities (12.1) and (12.2) in Lemma 12.3.

LEMMA 11.1. *Let $q \in \mathbb{A}$. Let k be a positive integer. Let $G = (V, E)$ and $n = |E|$ be as above. Let $m = 4k^2|E| = 4k^2n$. Construct $G_\#^k$ as above. Let $\delta = 2k(k+1)nm + 2k^2n = 2k(k+1)nm + m/2 = |E_\#^k| - m/2$. Then*

$$(11.3) \quad \text{coeff}_{v^\delta} \left(\sum_{B \subseteq E_\#^k} v^{|B|} \text{Flow}(G_\#^k|B; q) \right) = (q-1)^{k(|V| - \rho_G(E))} T(G; 1 + (q-1)^k, 1 + (q-1)^k).$$

Proof. The vertices in $G_\#^k$ all have degree 2 or 3. Consider the paths in $G_\#^k$ which join degree-3 vertices without going through any other degree-3 vertex. There are $m = 4k^2n$ degree-3 vertices and hence $6k^2n$ such paths, namely $4k^2n$ paths of length 1, $2k(k-1)n$ paths of length m , and $2kn$ paths of length $2m$. (The length- $2m$ paths arise from joining two length- m paths when “gluing” the $\tilde{T}_\#^{k,m}$ ’s together using the radial construction. These length- $2m$ paths could have been replaced by length- m paths, but it is not necessary and would be more inconvenient to define.) Any mention of length-1, length- m , or length- $2m$ paths during this proof refers only to the paths mentioned here. Note also that the length-1 paths are colored blue while the others are colored red.

Of course, the left-hand side of (11.3) can be written as

$$(11.4) \quad \sum_{\substack{B \subseteq E_\#^k \\ |B| = \delta}} \text{Flow}(G_\#^k|B; q),$$

and we can further eliminate terms for which $\text{Flow}(G_{\#}^k|B; q) = 0$, which by (10.11) certainly holds if $G_{\#}^k|B$ has a coloop, or in particular, a degree-1 vertex. Call B *essential* if $B \subseteq E_{\#}^k$, $|B| = \delta$, and $G_{\#}^k|B$ has no degree-1 vertex.

The graph $G_{\#}^k$ has been constructed so that any essential B must take a special form, as we now argue. Suppose B is essential. The choice of m and δ ensures that B must contain all the (red) paths of length m and $2m$ and exactly $2k^2n$ of the $4k^2n$ (blue) length-1 paths, since otherwise $G_{\#}^k|B$ would have a degree-1 vertex. In other words, B must contain all of the red edges and exactly half of the blue edges of $G_{\#}^k$.

In $G_{\#}^k$ every degree-3 vertex is an end of exactly two length-1 paths, and each length-1 path joins two degree-3 vertices. Since B contains all the length- m and length- $2m$ paths, each vertex with degree 3 in $G_{\#}^k$ has degree at least 1, and hence at least 2, in $G_{\#}^k|B$. Thus, each vertex with degree 3 in $G_{\#}^k$ is adjacent to at least one, and hence by the choice of δ , exactly one length-1 path in $G_{\#}^k|B$.

For each $e \in E$, in each copy T_e of $\tilde{T}_{\#}^{k,m}$ the $4k^2$ blue edges form a single circuit by condition (c) of Definition 8.2, and this condition will be crucial in what follows. Thus there are $n = |E|$ vertex disjoint blue circuits, one in each T_e . By the above discussion, every second edge of each blue circuit must be in an essential B . Thus for each $e \in E$ there are two choices, namely, the blue edges of T_e that are in B are precisely all the vertical edges or precisely all the horizontal edges. Therefore B must be of the form $B(A)$ for some $A \subseteq E$, where $B(A)$ contains all the red edges, $B(A)$ contains all the vertical blue edges in T_e for $e \in A$, and $B(A)$ contains all the horizontal blue edges in T_e for $e \notin A$.

Thus the quantity in (11.4) can now be written as

$$(11.5) \quad \sum_{A \subseteq E} \text{Flow}(G_{\#}^k|B(A); q).$$

Each $G_{\#}^k|B(A)$ simply consists of some number of vertex disjoint circuits that together meet every vertex of $G_{\#}^k$. If we examine the intersection $(G_{\#}^k|B(A)) \cap T_e$ regarded as a $4 \cdot k$ -tile, we find that each is essentially $T_{\{ \}$ or $T_{\{ \}$ (according to whether the vertical or horizontal blue edges are used), except that the paths in these $4 \cdot k$ -tiles are lengthened by the red edges. These lengthenings are inconsequential here, due to (10.12). For each $e \in E$, $A \subseteq E$,

$$(11.6) \quad (G_{\#}^k|B(A)) \cap T_e \simeq \begin{cases} T_{\{ \} }^k & \text{for } e \in A, \\ T_{\{ \} }^k & \text{for } e \in E - A, \end{cases}$$

where the \simeq signifies that the red edges merely lengthen the paths in each $T_{\{ \} }^k$ or $T_{\{ \} }^k$. Thus, recalling (9.2),

$$(11.7) \quad G_{\#}^k|B(A) \simeq G_A^k = \Theta_G(T_e : e \in E), \text{ where } T_e = \begin{cases} T_{\{ \} }^k & \text{for } e \in A, \\ T_{\{ \} }^k & \text{for } e \in E - A. \end{cases}$$

Considering Remark 1 we can apply Lemma 9.1 to find that $G_{\#}^k|B(A)$ consists of exactly $m_G(A, k) = k(|V| - 2\rho_G(A) + |A|)$ vertex disjoint circuits. Using (10.13), the quantity in (11.5) is

$$(11.8) \quad \sum_{A \subseteq E} (q - 1)^{m_G(A, k)},$$

and using (10.15) with $d = q - 1$ gives

$$(11.9) \quad (q - 1)^{k(|V| - \rho_G(E))} T(G; 1 + (q - 1)^k, 1 + (q - 1)^k)$$

as required. \square

The above is the key to proving Lemma 12.3, which is the major new idea beyond Theorems 4.2 and 4.3 that is needed to prove Theorem 5.1. However, the above idea still leaves a gap. Lemmas 12.2–12.5 deal with all points (x, y) except where $q = (x - 1)(y - 1) = 0$, leaving a gap, namely the special curves H_0^y and H_0^x (that is, the curves $y = 1$ and $x = 1$, respectively; see section 4). This gap requires an additional new idea which we now describe, leading to Lemma 11.2 below. A corresponding situation is also encountered in [19].

Recall the comments after (10.8). In this case, with $q = 0$, (12.1) in Lemma 12.3 gives only the useless reducibilities $\tau^0(\mathbb{P}\mathbb{G}, 0, 0) \leq_T \tau^1(\mathbb{P}\mathbb{G}, H_0^y)$ and $\tau^0(\mathbb{P}\mathbb{G}, 2, 2) \leq_T \tau^1(\mathbb{P}\mathbb{G}, H_0^y)$, depending on whether we use k odd or even. They are useless since the left-hand sides are functions in FP, giving no information about the right-hand sides.

Recall section 6. The trick is to modify the above ideas to show instead that $\tau_L^0(\mathbb{P}\mathbb{G}, 2, 2) \leq_T \tau^1(\mathbb{P}\mathbb{G}, H_0^y)$, considering (6.7). The modification is simply to use the construction similar to (11.1) except that one $4 \cdot k$ -tile, say T_g , will be chosen differently.

Let $G = (V, E)$ be a 2-connected plane directed graph with $n = |E|$ edges. Let $g \in E$. Fix $k = 2$ and let $m = 4k^2(n - 1) = 16(n - 1)$.

Define a $4 \cdot 2$ -tile T_\star (see Figure 11.1(a)) with the eight boundary vertices named as in section 7 (see also (7.1)), two internal vertices called vh and vt , and nine edges: one from vh to vt called the *central edge*, one each from vh to hr^i and lh^i , $i = 1, 2$, and one each from vt to rt^i and tl^i , $i = 1, 2$. Color these nine edges red.

Obtain the $4 \cdot 2$ -tile T_\star^m (see Figure 11.1(a) again) by subdividing each of the nine edges of T_\star into a path of m edges, so that T_\star^m has $9m$ edges. Again these $9m$ edges are red.

FIG. 11.1. (a) T_\star or T_\star^m where, respectively, each thin line depicts a red edge or a path of m red edges. (b) and (c) are graphs appearing in the proof of Lemma 11.2; see text.

Instead of $G_{\#\#}^k$ we will construct the graph $G_{\#\#}^{2gm}$:

$$(11.10) \quad G_{\#\#}^{2gm} = \Theta_G(T_e : e \in E), \text{ where } T_e = \begin{cases} \tilde{T}_{\#\#}^{2,m} & \text{for } e \neq g, \\ T_\star^m & \text{for } e = g. \end{cases}$$

Let $E_{\star\#\#}^{2gm}$ be the edge set of $G_{\star\#\#}^{2gm}$. The edges of $G_{\star\#\#}^{2gm}$ are colored red and blue just as they are in each T_e . This time we note that $G_{\star\#\#}^{2gm}$ has $(9 + 2k(k+1)(n-1))m = (9 + 12(n-1))m$ red edges and $m = 4k^2(n-1) = 16(n-1)$ blue edges, so that

$$(11.11) \quad |E_{\star\#\#}^{2gm}| = (9 + 12(n-1))m + 16(n-1) = (9 + 12(n-1))m + m.$$

In place of Lemma 11.1, we have Lemma 11.2 below.

LEMMA 11.2. *Set $q = 0$ and $k = 2$. Let $G = (V, E)$ and $n = |E|$ be as above. Let $g \in E$. Let $m = 16(n-1)$. Construct $G_{\star\#\#}^{2gm}$ as above. Let $\delta = (9 + 12(n-1))m + 8(n-1) = (9 + 12(n-1))m + m/2 = |E_{\star\#\#}^{2gm}| - m/2$. Then*

$$(11.12) \quad \text{coeff}_{v^\delta} \left(\sum_{B \subseteq E_{\star\#\#}^{2gm}} v^{|B|} \text{Flow}(G_{\star\#\#}^{2gm}|B; 0) \right) = 4T_L(G; 2, 2).$$

Proof. There are many similarities to the previous proof. Call B essential if $B \subseteq E_{\star\#\#}^{2gm}$, $|B| = \delta$, and $G_{\star\#\#}^{2gm}|B$ has no degree-1 vertex. By the choice of δ and the construction of $G_{\star\#\#}^{2gm}$ we find similarly as before that an essential B must be of the form $B(A)$ for some $A \subseteq E - g$, where $B(A)$ contains all the red edges (including all of T_g), $B(A)$ contains all the vertical blue edges in T_e for $e \in A$, and $B(A)$ contains all the horizontal blue edges in T_e for $e \in E - A - g$.

Similarly as before, the left-hand side of (11.12) can be written as

$$(11.13) \quad \sum_{A \subseteq E-g} \text{Flow}(G_{\star\#\#}^{2gm}|B(A); 0).$$

Also, similarly as before,

$$(11.14) \quad G_{\star\#\#}^{2gm}|B(A) \simeq \Theta_G(T_e : e \in E), \text{ where } T_e = \begin{cases} T_{\star}^k & \text{for } e \in A, \\ T_{\star}^k & \text{for } e \in E - A - g, \\ T_{\star}^m & \text{for } e = g. \end{cases}$$

Recall Lemma 9.1 and Remark 1. Either (1)–(7) all hold or (1′)–(7′) all hold, but not both. The graph $G_{\star\#\#}^{2gm}|B(A)$ will consist of the $4 \cdot 2$ -tile $T_g = T_{\star}^m$ with its eight boundary vertices pairwise joined by paths as in (6) or (6′), together with an even number $p = m_G(A, 2) - 2$ of vertex disjoint circuits. Considering (10.10) and (10.13) with $q = 0$ and p even, these vertex disjoint circuits contribute a factor of $(q-1)^p = 1$ to $\text{Flow}(G_{\star\#\#}^{2gm}|B(A); 0)$ and can be ignored.

If $A \in L(M(G), g)$, then in $G_{\star\#\#}^{2gm}|B(A)$ the boundary vertices of $T_g = T_{\star}^m$ are joined as in (6) of Lemma 9.1, giving a graph that is a subdivision of a graph consisting of just five parallel edges; see Figure 11.1(b). This graph has flow polynomial at $q = 0$ equaling 4.

If $A \notin L(M(G), g)$, then in $G_{\star\#\#}^{2gm}|B(A)$ the boundary vertices of $T_g = T_{\star}^m$ are joined as in (6′) of Lemma 9.1, giving a graph that has coloops, namely, those edges in the subdivided central edge; see Figure 11.1(c). This graph has flow polynomial at $q = 0$ equaling 0.

In summary, for $A \subseteq E - g$,

$$(11.15) \quad \text{Flow}(G_{\star\#\#}^{2gm}|B(A); 0) = \begin{cases} 4 & \text{for } A \in L(M(G), g), \\ 0 & \text{for } A \notin L(M(G), g). \end{cases}$$

Combining (6.6), (11.13), and (11.15), the result follows. \square

12. The remainder of the proofs. Theorem 5.1 is proved in a series of lemmas. Of course, significant portions of the proof are already presented in earlier sections.

Since by (2.4) any Tutte invariant of a graph is simply the product of that Tutte invariant of each of its blocks, we may restrict attention without further comment to 2-connected graphs.

LEMMA 12.1. *All of the functions mentioned in Theorem 5.1 are in $\overline{\#P}$. The function $\tau^2(\mathbb{P}\mathbb{G})$ is $\overline{\#P}$ -complete.*

Proof. By a simple observation in [17], $\tau^2(\mathbb{P}\mathbb{G}) \in \overline{\#P}$. Therefore all of the functions mentioned in Theorem 5.1 are in $\overline{\#P}$, by (4.5). Combining this with (6.7) and (6.10), the function $\tau^2(\mathbb{P}\mathbb{G})$ is $\overline{\#P}$ -complete. \square

LEMMA 12.2. *The functions claimed in Theorem 5.1 to be in FP are indeed so.*

Proof. If $(x - 1)(y - 1) = 1$ and $M = (E, \rho)$, then $T(M; x, y) = (x - 1)^{\rho(E)} y^{|E|}$ (in particular $T(M; 0, 0) = 0$) so that $\tau^1(\mathbb{P}\mathbb{G}, H_1)$ is in FP as are $\tau^0(\mathbb{P}\mathbb{G}, x, y)$ for all $(x, y) \in H_1$.

For a graph G the *Ising partition function* of G (see [4, 11, 9, 22]) is given (up to an easily computable factor) by the Tutte polynomial of $M(G)$ along the curve H_2 (see, for example, [22]). By [4, 11], this is polynomial time computable for planar graphs so that $\tau^1(\mathbb{P}\mathbb{G}, H_2)$ is in FP as are $\tau^0(\mathbb{P}\mathbb{G}, x, y)$ for all $(x, y) \in H_2$.

If $(x, y) \in \{(-1, -1), (0, -1), (-1, 0), (i, -i), (-i, i), (j, j^2), (j^2, j)\}$, then as shown in [18], $\tau^0(\mathbb{M}_q, x, y)$ is in FP, where \mathbb{M}_q is the class of matroids representable over the field of $q = (x - 1)(y - 1) = 4, 2, 2, 2, 2, 3, 3$ elements, respectively. Each of these classes contains $\mathbb{P}\mathbb{G}$ (and there is a polynomial time function sending each directed plane graph G to the appropriate representation of $M(G)$ for the above classes) so that $\tau^0(\mathbb{P}\mathbb{G}, x, y)$ is in FP for these (x, y) . Also $\tau^0(\mathbb{P}\mathbb{G}, 1, 1)$ is in FP since for any graph G , $T(M(G); 1, 1)$ is the number of spanning trees of G , and this can be computed in polynomial time using Kirchoff's determinantal formula. \square

By (4.5), it now suffices to show that $\tau^0(\mathbb{P}\mathbb{G}, x, y)$ is $\overline{\#P}$ -complete for every algebraic point (x, y) which is not special or on H_1 or H_2 (since every algebraic curve other than H_1 and H_2 contains such a point).

LEMMA 12.3. *If $q \in \mathbb{A}$, $q \neq 1$, and k is a positive integer, then*

$$(12.1) \quad \tau^0(\mathbb{P}\mathbb{G}, 1 + (q - 1)^k, 1 + (q - 1)^k) \leq_T \tau^1(\mathbb{P}\mathbb{G}, H_q).$$

If $q \in \mathbb{A}$ and $q - 1$ is not zero or a root of unity and “ $x = y$ ” is the nonspecial curve $\langle (x, y) | x, y \in \mathbb{A}, x = y \rangle$, then

$$(12.2) \quad \tau^1(\mathbb{P}\mathbb{G}, x = y) \leq_T \tau^1(\mathbb{P}\mathbb{G}, H_q).$$

Proof. For fixed k , the reduction of $\tau^0(\mathbb{P}\mathbb{G}, 1 + (q - 1)^k, 1 + (q - 1)^k)$ to $\tau^1(\mathbb{P}\mathbb{G}, H_q)$ is as follows. Suppose the input is the directed plane graph G with edge set E and $n = |E|$. Construct $G_{\#}^k$. Apply $\tau^1(\mathbb{P}\mathbb{G}, H_q)$ to $G_{\#}^k$ and multiply by a simple factor to get $v^{\rho_{G_{\#}^k}(E_{\#}^k)} (1 - v)^{|E_{\#}^k| - \rho_{G_{\#}^k}(E_{\#}^k)} T(G_{\#}^k; \frac{1}{v}, 1 + \frac{qv}{1-v})$, which by (10.8) equals $\sum_{B \subseteq E_{\#}^k} v^{|B|} \text{Flow}(G_{\#}^k | B; q)$. With δ as in Lemma 11.1, take the coefficient of v^{δ} and divide by $(q - 1)^{k(|V| - \rho_G(E))}$ (which is nonzero since $q \neq 1$) to obtain $T(G; 1 + (q - 1)^k, 1 + (q - 1)^k)$ by Lemma 11.1, as required.

Note that all of the above can be done in time polynomial in both n and k . Note also that the degree of $T(G; x, x)$ is at most $2n$. For the second reducibility (12.2) do as above for $k = 1, \dots, 2n + 1$ (in time polynomial in n) to obtain $T(G; x, x)$ at $2n + 1$ distinct points, namely, $x = 1 + (q - 1)^k$ for $k = 1, \dots, 2n + 1$. Here we

have used the assumption that $q - 1$ is not zero or a root of unity. This one variable polynomial, with degree at most $2n$, can then be obtained in polynomial time by Lagrange interpolation. \square

LEMMA 12.4. *If $q, x, y \in \mathbb{A}$, $q - 1$ is not zero or a root of unity and $(x, y) \in H_q$, where (x, y) is not special, then $\tau^0(\mathbb{P}\mathbb{G}, x, y)$ is $\overline{\#P}$ -complete.*

Proof. By Lemma 12.1 $\tau^2(\mathbb{P}\mathbb{G})$ is $\overline{\#P}$ -complete. By Theorem 4.2, $\tau^2(\mathbb{P}\mathbb{G}) \leq_T \tau^1(\mathbb{P}\mathbb{G}, x = y)$. By Lemma 12.3, $\tau^1(\mathbb{P}\mathbb{G}, x = y) \leq_T \tau^1(\mathbb{P}\mathbb{G}, H_q)$. By Theorem 4.3, $\tau^1(\mathbb{P}\mathbb{G}, H_q) \leq_T \tau^0(\mathbb{P}\mathbb{G}, x, y)$. Therefore $\tau^0(\mathbb{P}\mathbb{G}, x, y)$ is $\overline{\#P}$ -complete. \square

LEMMA 12.5. *If $q, x, y \in \mathbb{A}$, $q \notin \{0, 1, 2\}$, $q - 1$ is a root of unity, and $(x, y) \in H_q$, where (x, y) is not special, then $\tau(\mathbb{P}\mathbb{G}, x, y)$ is $\overline{\#P}$ -complete.*

Proof. Since $q - 1 \neq 0$, then by Lemma 12.3 $\tau^0(\mathbb{P}\mathbb{G}, 1 + (q - 1)^k, 1 + (q - 1)^k) \leq_T \tau^1(\mathbb{P}\mathbb{G}, H_q)$ for each fixed $k \in \{1, 2, \dots\}$ and by Lemma 12.4, the left-hand side is $\overline{\#P}$ -complete unless [i] $(q - 1)^{2k} - 1$ is zero or a root of unity (since $(1 + (q - 1)^k, 1 + (q - 1)^k) \in H_{(q-1)^{2k}}$), or [ii] $(1 + (q - 1)^k, 1 + (q - 1)^k)$ is a special point. In case [ii], $(q - 1)^k = 0, -1, -2$. Now $(q - 1)^k = 0, -2$ contradicts $q - 1$ being a root of unity, and $(q - 1)^k = -1$ implies $(q - 1)^{2k} - 1$ is zero, so that both cases [i] and [ii] are covered by the following assumption. Suppose that $(q - 1)^{2k} - 1$ is zero or a root of unity for all $k \in \{1, 2, \dots\}$. Since $(q - 1)^{2k}$ is a root of unity, $(q - 1)^{2k}$ must be one of $1, -j, -j^2$ for all $k \in \{1, 2, \dots\}$. But if $(q - 1)^2 \in \{-j, -j^2\}$, then $(q - 1)^6 = -1 \notin \{1, -j, -j^2\}$, and if $(q - 1)^2 = 1$, then $q \in \{0, 2\}$, a contradiction. Thus $\tau^0(\mathbb{P}\mathbb{G}, 1 + (q - 1)^k, 1 + (q - 1)^k)$, and hence $\tau^1(\mathbb{P}\mathbb{G}, H_q)$, is $\overline{\#P}$ -complete. By Theorem 4.3, $\tau^1(\mathbb{P}\mathbb{G}, H_q) \leq_T \tau^0(\mathbb{P}\mathbb{G}, x, y)$ and since the left-hand side is $\overline{\#P}$ -complete, so is the right-hand side. \square

Only the case $(x, y) \in H_0$ remains.

LEMMA 12.6. $\tau_L^0(\mathbb{P}\mathbb{G}, 2, 2) \leq_T \tau^1(\mathbb{P}\mathbb{G}, H_0^y)$.

Proof. The reduction of $\tau_L^0(\mathbb{P}\mathbb{G}, 2, 2)$ to $\tau^1(\mathbb{P}\mathbb{G}, H_0^y)$ is as follows. Suppose the input is the directed plane graph G with edge set E and $n = |E|$. Construct $G_{*\#}^{2gm}$. Abbreviate $G_{*\#}^{2gm}$ and $E_{*\#}^{2gm}$ to G' and E' , respectively.

Apply $\tau^1(\mathbb{P}\mathbb{G}, H_0^y)$ to G' , and multiply by a simple factor to get $v^{\rho_{G'}(E')} (1 - v)^{|E'| - \rho_{G'}(E')} T(G'; \frac{1}{v}, 1)$, which by (10.8) with $q = 0$ equals $\sum_{B \subseteq E'} v^{|B|} \text{Flow}(G'|B; q)$.

With δ as in Lemma 11.2, take the coefficient of v^δ and divide by 4 to obtain $T_L(G; 2, 2)$ by Lemma 11.2, as required. \square

LEMMA 12.7. *If $x, y \in \mathbb{A}$, $(x, y) \in H_0 - \{(1, 1)\}$ (so that $x = 1$ or $y = 1$ but $(x, y) \neq (1, 1)$), then $\tau^0(\mathbb{P}\mathbb{G}, x, y)$ is $\overline{\#P}$ -complete.*

Proof. By Lemma 12.6, $\tau_L^0(\mathbb{P}\mathbb{G}, 2, 2) \leq_T \tau(\mathbb{P}\mathbb{G}, H_0^y)$. By Theorem 4.3, $\tau(\mathbb{P}\mathbb{G}, H_0^y) \leq_T \tau(\mathbb{P}\mathbb{G}, x, 1)$ for all $x \in \mathbb{A} - \{1\}$. Since $\tau_L^0(\mathbb{P}\mathbb{G}, 2, 2)$ is $\overline{\#P}$ -complete by (6.7), so is $\tau^0(\mathbb{P}\mathbb{G}, x, 1)$. Also $\tau^0(\mathbb{P}\mathbb{G}, x, 1) \leq_T \tau^0(\mathbb{P}\mathbb{G}, 1, x)$ (and vice versa) since for any plane graph G , its plane dual G^* can be constructed in polynomial time and $T(M(G^*); x, y) = T(M(G); y, x)$ (see [21]). Hence $\tau^0(\mathbb{P}\mathbb{G}, 1, y)$ is $\overline{\#P}$ -complete for all $y \in \mathbb{A} - \{1\}$. \square

We are finally in a position to prove Theorem 5.1.

Proof. All the cases have been covered, and Theorem 5.1 is proved. \square

13. Conclusions. For evaluations of the Tutte polynomial at a fixed algebraic point or curve, the computational complexity is the same for planar graphs (Theorem 5.1) as for graphs (Proposition 4.4), except along the curve H_2 (the ‘‘Ising model’’) and at the nonspecial points on H_2 . It is natural to consider the computational complexity of these evaluations for smaller (interesting) classes of graphs. For the class $3\mathbb{P}\mathbb{G}$, say, of planar graphs with vertex degree at most 3, the result is the

same as Theorem 5.1 (substituting $3\mathbb{P}\mathbb{G}$ for $\mathbb{P}\mathbb{G}$) except that $\tau^0(3\mathbb{P}\mathbb{G}, 0, -2)$ (which counts 3-flows) is polynomial time computable [20].

It is also natural to examine the computational complexity of Tutte invariants for larger classes of matroids. This examination leads to connections between computational complexity, representability over finite fields, and uniqueness of bicycle dimension; see [18].

The Tutte polynomial of planar graphs is closely related to the Homfly and Kauffman polynomials for knots and links. Theorem 5.1 forms part of the argument determining the complexity of computing Homfly and Kauffman invariants; see [19].

Acknowledgment. I would like to thank my wife, Jilyana Cazaran, for help with the drawing of figures, typesetting, and proofreading.

A POLYNOMIAL TIME APPROXIMATION SCHEME FOR THE MULTIPLE KNAPSACK PROBLEM*

CHANDRA CHEKURI[†] AND SANJEEV KHANNA[‡]

Abstract. The *multiple knapsack problem* (MKP) is a natural and well-known generalization of the single knapsack problem and is defined as follows. We are given a set of n items and m bins (knapsacks) such that each item i has a profit $p(i)$ and a size $s(i)$, and each bin j has a capacity $c(j)$. The goal is to find a subset of items of maximum profit such that they have a feasible packing in the bins. MKP is a special case of the *generalized assignment problem* (GAP) where the profit and the size of an item can vary based on the specific bin that it is assigned to. GAP is APX-hard and a 2-approximation, for it is implicit in the work of Shmoys and Tardos [*Math. Program. A*, 62 (1993), pp. 461–474], and thus far, this was also the best known approximation for MKP. The main result of this paper is a polynomial time approximation scheme (PTAS) for MKP.

Apart from its inherent theoretical interest as a common generalization of the well-studied knapsack and bin packing problems, it appears to be the strongest special case of GAP that is not APX-hard. We substantiate this by showing that slight generalizations of MKP are APX-hard. Thus our results help demarcate the boundary at which instances of GAP become APX-hard. An interesting aspect of our approach is a PTAS-preserving reduction from an arbitrary instance of MKP to an instance with $O(\log n)$ distinct sizes and profits.

1. Introduction. We study the following natural generalization of the classical knapsack problem.

Multiple knapsack problem (MKP).

INSTANCE: A pair $(\mathcal{B}, \mathcal{S})$ where \mathcal{B} is a set of m bins (knapsacks) and \mathcal{S} is a set of n items. Each bin $j \in \mathcal{B}$ has a capacity $c(j)$, and each item i has a size $s(i)$ and a profit $p(i)$.

OBJECTIVE: Find a subset $U \subseteq \mathcal{S}$ of maximum profit such that U has a feasible packing in \mathcal{B} .

The decision version of MKP is a generalization of the decision versions of both the knapsack and bin packing problems and is strongly NP-complete. Moreover, it is an important special case of the *generalized assignment problem* where both the size and the profit of an item are a function of the bin.

*Generalized assignment problem (GAP).*¹

INSTANCE: A pair $(\mathcal{B}, \mathcal{S})$ where \mathcal{B} is a set of m bins (knapsacks) and \mathcal{S} is a set of n items. Each bin $j \in \mathcal{B}$ has a capacity $c(j)$, and for each item i and bin j , we are given a size $s(i, j)$ and a profit $p(i, j)$.

¹GAP has also been defined in the literature as a (closely related) minimization problem (see [28]). In this paper, following [26], we refer to the maximization version of the problem as GAP and to the minimization version as Min GAP.

OBJECTIVE: Find a subset $U \subseteq \mathcal{S}$ that has a feasible packing in \mathcal{B} and maximizes the profit of the packing.

GAP and its restrictions capture several fundamental optimization problems and have many practical applications in computer science, operations research, and related disciplines. The special case of MKP with uniform sizes and profits is also important; the book on knapsack variants by Martello and Toth [26] has a chapter devoted to MKP. Also referred to as the loading problem in operations research, it models the problem of loading items into containers of different capacities such that container capacities are not violated. In many practical settings items could be more complex geometric objects; however, the one-dimensional case (MKP) is useful in its own right and has been investigated extensively [14, 11, 12, 23, 24, 25, 4].

Knapsack, bin packing, and related problems have attracted much theoretical attention for their simplicity and elegance, and their study has been instrumental in the development of the theory of approximation algorithms. Though knapsack and bin packing have a fully polynomial-time approximation scheme (FPTAS; asymptotic for bin packing), GAP, a strong generalization of both, is APX-hard, and only a 2-approximation exists. In fact, some very special cases of GAP can be shown to be APX-hard. In particular we can show that for arbitrarily small $\delta > 0$ (which can even be a function of n) the problem remains APX-hard on the following very restricted set of instances: bin capacities are identical, and for each item i and machine j , $p(i, j) = 1$, and $s(i, j) = 1$ or $s(i, j) = 1 + \delta$. The complementary case, where item sizes do not vary across bins but profits do, can also be shown to be APX-hard for a similar restricted setting. In light of this, it is particularly interesting to understand the complexity of MKP where profits and sizes of an item are independent of the bin, but the item sizes and profits as well as bin capacities may take arbitrary values. Establishing a PTAS shows a very fine separation between cases that are APX-hard and those that have a PTAS. Until now, the best known approximation ratio for MKP was a factor of 2 derived from the approximation for GAP.

Results. In this paper we resolve the approximability of MKP by obtaining a PTAS for it. It can be easily shown via a reduction from the Partition problem that MKP does not admit an FPTAS even if $m = 2$ (see Proposition 2.1). A special case of MKP is when all bin capacities are equal. It is relatively straightforward to obtain a PTAS for this case using ideas from approximation schemes for knapsack and bin packing [13, 3, 17]. However, the problem with *different* bin capacities is more challenging. Our paper contains two new technical ideas. Our first idea concerns the set of items to be packed in a knapsack instance. We show how to guess, in polynomial time, *almost all* the items that are packed by an optimal solution. More precisely, we can identify a polynomial number of subsets such that one of the subsets has a *feasible* packing and profit at least $(1 - \epsilon)\text{OPT}$. This is in contrast to earlier schemes for variants of knapsack [13, 1, 7], where only the $1/\epsilon$ most profitable items are guessed. An easy corollary of our strategy is a PTAS for the identical bin capacity case, the details of which we point out later. Even with the knowledge of the right subsets, the problem remains nontrivial since we need to verify for each subset if it has a feasible packing. Checking for feasibility is of course at least as hard as bin packing. To get around this difficulty we make crucial use of additional properties satisfied by the subsets that we guess. In particular, we show that each subset can be transformed such that the number of *distinct* size values of the items in the subset is $O(\epsilon^{-2} \log n)$. An immediate consequence of this is a dynamic programming-based quasi-polynomial time algorithm to pack all of the items into bins. Our second set of ideas shows that we can exploit the restriction on the number of distinct sizes

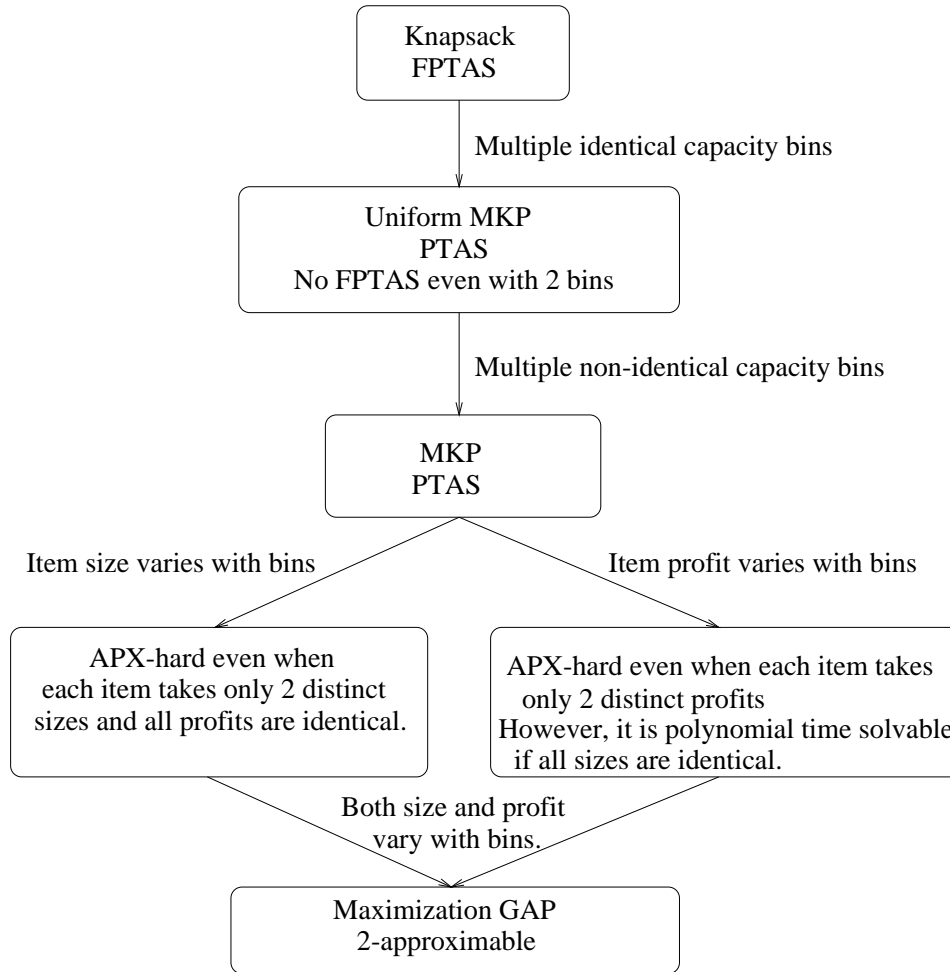

FIG. 1.1. Complexity of various restrictions of GAP.

to pack, in *polynomial* time, a subset of the item set that has at least a $(1 - \epsilon)$ fraction of the profit. Approximation schemes for number problems are usually based on rounding instances to have a fixed number of distinct values. In contrast, MKP appears to require a logarithmic number of values. We believe that our techniques to handle logarithmic number of distinct values will find other applications. Figure 1.1 summarizes the approximability of various restrictions of GAP.

Related work. MKP is closely related to knapsack, bin packing, and GAP. A very efficient FPTAS exists for the knapsack problem; Lawler's [19], based on ideas from [13], achieves a running time of $O(n \log 1/\epsilon + 1/\epsilon^4)$ for a $(1 + \epsilon)$ approximation. An asymptotic FPTAS is known for bin packing [3, 17]. Kellerer [18] has independently developed a PTAS for the special case of the MKP where all bins have *identical* capacity. As mentioned earlier, this case is much simpler than the general case and falls out as a consequence of our first idea. We defined the generalized assignment problem as a maximization problem. This is natural when we relate it to the knapsack problem (see [26]). There is also a minimization version, which we refer to as Min GAP (also known as the cost assignment problem), where the objective is to assign all the

items while *minimizing* the sum of the costs of assigning items to bins. In this version, item i when assigned to bin j incurs a *cost* $w(i, j)$ instead of obtaining a profit $p(i, j)$. Even without costs, deciding the feasibility of assigning all items without violating the capacity constraints is an NP-complete problem; therefore, capacity constraints need to be relaxed. An (α, β) bicriteria approximation algorithm for Min GAP is one that gives a solution with cost at most αC and with bin capacities violated by a factor of at most β , where C is the cost of an optimal solution that does not violate any capacity constraints. The work of Lin and Vitter [22] yields a $(1 + \epsilon, 2 + 1/\epsilon)$ bicriteria approximation for Min GAP. Shmoys and Tardos [28], building on the work of Lenstra, Shmoys, and Tardos [21], give an improved $(1, 2)$ bicriteria approximation. Implicit in this approximation is also a 2-approximation for the profit maximization version which we sketch later. Lenstra, Shmoys, and Tardos [21] also show that it is NP-hard to obtain a bicriteria approximation of the form $(1, \beta)$ for any $\beta < 3/2$. The hardness relies on an NP-completeness reduction from the decision version of the 3-dimensional matching problem. Our APX-hardness for the maximization version, mentioned earlier, is based on a similar reduction but instead relies on APX-hardness of the optimization version of the 3-dimensional matching problem [16].

MKP is also related to two variants of variable-size bin packing. In the first variant we are given a set of items and set of bin capacities \mathcal{C} . The objective is to find a feasible packing of items using bins with capacities restricted to be from \mathcal{C} so as to minimize the sum of the capacities of the bins used. A PTAS for this problem was provided by Murgolo [27]. The second variant is based on a connection to multiprocessor scheduling on uniformly related machines [20]. The objective is to assign a set of jobs with given processing times to machines with different speeds so as to minimize the makespan of the schedule. Hochbaum and Shmoys [10] gave a PTAS for this problem using a *dual*-based approach where they convert the scheduling problem into the following bin packing problem. Given items of different sizes and bins of different capacities, find a packing of all the items into the bins such that maximum relative violation of the capacity of any bin is minimized. Bicriteria approximations, where both capacity and profit can be approximated simultaneously, have been studied for several problems (Min GAP being an example mentioned above), and it is usually the case that relaxing both makes the task of approximation somewhat easier. In particular, relaxing the capacity constraints allows rounding of item sizes into a small number of distinct size values. In MKP, the constraint on the bin capacities and the constraint on the number of bins are both inviolable, and this makes the problem harder.

Organization. Section 2 describes our PTAS for MKP. In section 3, we show that GAP is APX-hard on very restricted classes of instances. We also indicate here a 2-approximation for GAP. In section 4, we discuss a natural greedy algorithm for MKP and show that it gives a $(2 + \epsilon)$ -approximation even when item sizes vary with bins.

2. A PTAS for the multiple knapsack problem. We first show that MKP does not admit an FPTAS even for $m = 2$.

PROPOSITION 2.1. *If MKP with two identical bins has an FPTAS, then the Partition problem can be solved in polynomial time. Hence there is no FPTAS for MKP even with $m = 2$ unless $P = NP$.*

Proof. An instance of the Partition problem consists of $2n$ numbers a_1, a_2, \dots, a_{2n} , and the goal is to decide if the numbers can be partitioned into two sets S_1 and S_2 such that the sum of numbers in each set add up to exactly $A = \frac{1}{2} \sum_{i=1}^{2n} a_i$. We can

reduce the Partition problem to MKP with two bins as follows. We set the capacity of the bins to be A . We have $2n$ items, one for each number in the Partition problem: the size of item i is a_i and the profit of item i is 1. If the Partition problem has a solution, the profit of an optimum solution to the corresponding MKP problem is $2n$; otherwise it is at most $2n - 1$. Thus, an FPTAS for MKP can be used to distinguish between these two situations in polynomial time. \square

We start with a remark on guessing. When we *guess* a quantity in polynomial time, we mean that we can identify, in polynomial time, a polynomial size set of values among which the correct value of the desired quantity resides. Coupled with the guessing procedure is a polynomial time checking procedure which can verify whether a feasible solution with a given value exists. We can run the checking procedure with each of the values in the guessed set and will be guaranteed to obtain a solution with the correct value. We will be using this standard idea several times in this section and implicitly assume that the above procedure is invoked to complete the algorithm.

We denote by OPT the value of an optimal solution to the given instance. Given a set Y of items, we use $p(Y)$ to denote $\sum_{y \in Y} p(y)$. The set of integers $0, 1, \dots, k$ is denoted by $[k]$. We will assume throughout this section that $\epsilon < 1$; when $\epsilon \geq 1$ we can use the 2-approximation for GAP from section 3. In the rest of the paper we assume, for simplicity of notation, that $1/\epsilon$ and $\ln n$ are integers. Further, we also assume that $\epsilon > 1/n$, for otherwise we can use an exponential time algorithm to solve the problem exactly. In several places in the paper, to simplify expressions, we use the inequality $\ln(1 + \epsilon) \geq \epsilon - \epsilon^2/2 \geq \epsilon/2$.

Our problem is related to both the knapsack problem and the bin packing problem, and some ideas used in approximation schemes for those problems will be useful to us. Our approximation scheme conceptually has the following two steps.

1. Guessing Items: Identify a set of items $U \subseteq \mathcal{S}$ such that $p(U) \geq (1 - \epsilon)\text{OPT}$ and U has a feasible packing in \mathcal{B} .
2. Packing Items: Given a set U of items that has a feasible packing in \mathcal{B} , find a feasible packing for a set $U' \subseteq U$ such that $p(U') \geq (1 - \epsilon)p(U)$.

The overall scheme is more involved since there is interaction between the two steps. The guessed items have some additional properties that are exploited in the packing step. We observe that both of the above steps require new ideas. For the regular single knapsack problem, the second step is trivial once we accomplish the first step. This is, however, not the case for MKP. Before we proceed with the details we show how our guessing step immediately gives a PTAS for the identical bin capacity case.

2.1. MKP with identical bin capacities. Suppose we can guess an item set as in our first step above. We show that the packing step is very simple if the bin capacities are identical. There are two cases to consider, depending on whether m , the number of bins, is less than or equal to $1/\epsilon$ or not. If $m \leq 1/\epsilon$, the number of bins can be treated as a constant, and a PTAS for this case exists even for instances of GAP (implicit in earlier work [7]). Now suppose $m > 1/\epsilon$. Bin packing has an asymptotic PTAS. In particular, there is an algorithm [3] that packs the items into $(1 + \epsilon)\text{OPT} + 1$ bins in polynomial time for any fixed $\epsilon > 0$. We can thus use this algorithm to pack *all* the guessed items using at most $(1 + \epsilon)m + 1$ bins. We find a feasible solution by simply picking the m largest profit bins and discarding the rest along with their items. Here we use the fact that $m\epsilon \geq 1$ and that the bins are identical. It is easily seen that we get a $(1 + O(\epsilon))$ approximation. We note that a different PTAS, one that does not rely on our guessing step, can be obtained for this case by directly adapting

the ideas used in approximation schemes for bin packing. The trick of using extra bins does not have a simple analogue when bin capacities are different and we need more sophisticated ideas for the general case.

2.2. Guessing items. Consider the case when all items have the same profit; without loss of generality assume it is 1. Thus the objective is to pack as many items as possible. For this case, it is easily seen that OPT is an integer in $[n]$. Further, given a guess \mathcal{O} for OPT , we can pick the *smallest* (in size) \mathcal{O} items to pack. Thus knowing \mathcal{O} allowed us to fix the item set as well. Therefore there are only a polynomial number of guesses for the set of items to pack. In the following we build on this useful insight.

Let p_{\max} denote the largest value among item profits. For the general case the first step involves massaging the given instance into a more structured one that has few distinct profits. This is accomplished as follows.

1. Guess a value \mathcal{O} such that $\max\{p_{\max}, (1 - \epsilon)\text{OPT}\} \leq \mathcal{O} \leq \text{OPT}$ and discard all items y where $p(y) < \epsilon\mathcal{O}/n$.
2. Divide all profits by $\epsilon\mathcal{O}/n$ such that after scaling each profit is at most n/ϵ .
3. Round *down* the profits of items to the nearest power of $(1 + \epsilon)$.

It is easily seen that only an $O(\epsilon)$ fraction of the optimal profit is lost by our transformation. Since we do not know OPT , we need to establish an upper bound on the number of values of \mathcal{O} that we will try out. We make use of the following easy bounds on OPT : $p_{\max} \leq \text{OPT} \leq n \cdot p_{\max}$.

Therefore, one of the values in $\{p_{\max} \cdot (1 + \epsilon)^i \mid 0 \leq i \leq 2\epsilon^{-1} \ln n\}$ is guaranteed to satisfy the desired properties for \mathcal{O} . Summarizing, we obtain the following lemma.

LEMMA 2.2. *Given an instance $I = (\mathcal{B}, \mathcal{S})$ with n items and a value \mathcal{O} such that $(1 - \epsilon)\text{OPT}(I) \leq \mathcal{O} \leq \text{OPT}(I)$, we can obtain in polynomial time another instance $I' = (\mathcal{B}, \mathcal{S}')$ such that*

- $\mathcal{S}' \subseteq \mathcal{S}$;
- for every $y \in \mathcal{S}'$, $p(y) = (1 + \epsilon)^i$ for some $i \in [4\epsilon^{-1} \ln n]$;
- $(1 - \epsilon)\text{OPT}(I) \leq \frac{n}{\epsilon\mathcal{O}}\text{OPT}(I') \leq \text{OPT}(I)$.

For the bound in the second item above we upper bound n/ϵ by n^2 . The above lemma allows us to work with instances with $O(\epsilon^{-1} \ln n)$ distinct profits. We now show how we can use this information to guess the items to pack. Let $h \leq 4\epsilon^{-1} \ln n + 1$ be the number of distinct profits in our new instance. We partition \mathcal{S} into h sets S_1, \dots, S_h with items in each set having the same profit. Let U be the items chosen in some optimal solution and let $U_i = S_i \cap U$. Recall that we have an estimate \mathcal{O} of the optimal value. If $p(U_i) \leq \epsilon\mathcal{O}/h$ for some i , we ignore the set S_i ; no significant profit is lost. Hence we can assume that $\epsilon\mathcal{O}/h \leq p(U_i) \leq \mathcal{O}$ and approximately guess the value $p(U_i)$ for $1 \leq i \leq h$. More precisely, for each i we guess a value $k_i \in [h/\epsilon^2]$ such that $k_i(\epsilon^2\mathcal{O}/h) \leq p(U_i) \leq (k_i + 1)(\epsilon^2\mathcal{O}/h)$.

A naive way of guessing the values k_1, \dots, k_h requires $n^{\Omega(\ln n/\epsilon^2)}$ time. We first show how the numbers k_i enable us to identify the items to pack and then show how the values k_1, \dots, k_h can in fact be guessed in polynomial time. Let a_i denote the profit of an item in S_i . Consider an index i such that $a_i \leq \epsilon\mathcal{O}/h$. Given the value k_i we order the items in S_i in increasing size values and pick the largest number of items from this ordered set whose cumulative profit does not exceed $k_i(\epsilon^2\mathcal{O}/h)$. If $a_i > \epsilon\mathcal{O}/h$ we pick the smallest number of items, again in order of increasing size, whose cumulative profit exceeds $k_i(\epsilon^2\mathcal{O}/h)$. The asymmetry is for technical reasons. The choice of items is thus completely determined by the choice of the k_i . For a tuple of values k_1, \dots, k_h , let $U(k_1, \dots, k_h)$ denote the set of items picked as described above.

LEMMA 2.3. *There exists a valid tuple (k_1, \dots, k_h) with each $k_i \in [h/\epsilon^2]$ such that $U(k_1, \dots, k_h)$ has a feasible packing in \mathcal{B} and $p(U(k_1, \dots, k_h)) \geq (1 - \epsilon)\mathcal{O}$.*

Proof. Let U be the items in some optimal solution and let $U_i = S_i \cap U$. Define k_i to be $\lfloor p(U_i)h/(\epsilon^2\mathcal{O}) \rfloor$. The tuple so obtained satisfies the required properties. \square

As remarked earlier, a naive enumeration of all integer h -tuples takes quasi-polynomial time. The crucial observation is that the k_i 's are not independent. They must satisfy the additional constraint that $\sum_i k_i \leq h/\epsilon^2$ since the total profit from all the sets S_1, \dots, S_h cannot exceed OPT . This constraint limits the number of tuples of relevance. We make use of the following claims.

CLAIM 2.4. *Let f be the number of g -tuples of nonnegative integers such that the sum of tuple coordinates is equal to d . Then $f = \binom{d+g-1}{g-1}$. If $d + g < \alpha g$, then $f = O(e^{\alpha g})$.*

Proof. The first part of the claim is elementary counting. If $d + g < \alpha g$, then $f \leq \binom{\alpha g}{g-1} \leq (\alpha g)^{g-1}/(g-1)!$. Using Stirling's formula we can approximate $(g-1)!$ by $\sqrt{2\pi(g-1)}((g-1)/e)^{g-1}$. Thus $f = O((e\alpha)^{g-1}) = O(e^{\alpha g})$. \square

CLAIM 2.5. *Let $h \in [4\epsilon^{-1} \ln n]$. Then the number of h -tuples (k_1, \dots, k_h) such that $k_i \in [h/\epsilon^2]$ and $\sum_i k_i \leq h/\epsilon^2$ is $O(n^{O(1/\epsilon^3)})$.*

Proof. The number of tuples satisfying the claim is easily seen to be $\binom{h/\epsilon^2+h}{h}$. We now apply the bound from Claim 2.4; we have $\alpha = (1 + 1/\epsilon^2)$ and $g = 4\epsilon^{-1} \ln n + 1$ and hence we get an upper bound of $e^{(4\epsilon^{-3} \ln n + 1 + \epsilon^{-2})}$. The claim follows. \square

Using the restricted number of distinct profit values we can also reduce the number of *distinct sizes* in the given instance to $O(\ln n)$. This property will be crucial in packing the items. The basic idea is *shifting*, an idea that is used in approximation schemes for bin packing [3]. Let A be a set of g items with identical profit but perhaps differing sizes. We order items in A in nondecreasing order of sizes and divide them into $t = (1 + 1/\epsilon)$ groups A_1, \dots, A_t with A_1, \dots, A_{t-1} containing $\lfloor g/t \rfloor$ items each and A_t containing $(g \bmod t)$ items. We discard the items in A_{t-1} , and for each $i < t - 1$ we increase the size of every item in A_i to the size of the smallest item in A_{i+1} . Since A is ordered by size, no item in A_i is larger than the smallest item in A_{i+1} for each $1 \leq i < t$. It is easy to see that if A has a feasible packing, then the modified instance also has a feasible packing. We discard at most an ϵ fraction of the profit and the modified sizes have at most $2/\epsilon$ distinct values. Applying this to each profit class we obtain an instance with $O(\epsilon^{-2} \ln n)$ distinct size values.

LEMMA 2.6. *Given an instance $I = (\mathcal{B}, \mathcal{S})$ with n items we can obtain in polynomial time $v = n^{O(1/\epsilon^3)}$ instances I_1, \dots, I_v such that*

- for $1 \leq j \leq v$, $I_j = (\mathcal{B}, \mathcal{S}_j)$;
- for $1 \leq j \leq v$, items in \mathcal{S}_j have $O(\epsilon^{-1} \ln n)$ distinct profit values;
- for $1 \leq j \leq v$, items in \mathcal{S}_j have $O(\epsilon^{-2} \ln n)$ distinct size values;
- there is an index ℓ , $1 \leq \ell \leq v$, such that \mathcal{S}_ℓ has a feasible packing in \mathcal{B} and $p(\mathcal{S}_\ell) \geq (1 - O(\epsilon))\text{OPT}(I)$.

Proof. As indicated earlier, we can guess a value \mathcal{O} such that $(1 - \epsilon)\text{OPT} \leq \mathcal{O} \leq \text{OPT}$ from $O(\epsilon^{-1} \ln n)$ values. For each guess for \mathcal{O} we round profits of items to geometric powers (see Lemma 2.2) and guess the partition of \mathcal{O} among the profit classes. The number of guesses for the partition is $n^{O(1/\epsilon^3)}$. Therefore the distinct number of instances is $n^{O(1/\epsilon^3)}$. Each instance is modified to reduce the number of distinct sizes. Each step potentially loses a $(1 - \epsilon)$ factor, so overall we lose a $(1 - O(\epsilon))$ factor in the profit. \square

We will assume for the next section that we have guessed the correct set of items and that they are partitioned into $O(\epsilon^{-2} \ln n)$ sets, with each set containing items

of the same size. We denote by U_i the items of the i th size value and by n_i the quantity $|U_i|$.

2.3. Packing items. From Lemma 2.6 we obtain a restricted set of instances in terms of item profits and sizes. We also need some structure in the bins and we start by describing the necessary transformations.

2.3.1. Structuring the bins. Assume without loss of generality that the smallest bin capacity is 1. We order the bins in increasing order of their capacity and partition them into *blocks* B_0, B_1, \dots, B_ℓ such that block B_i consists of all bins x with $(1 + \epsilon)^i \leq c(x) < (1 + \epsilon)^{i+1}$. Let m_i denote the number of bins in block B_i .

DEFINITION 2.7 (small and large blocks). *A block B_i of bins is called a small bin block if $m_i \leq 1/\epsilon$; it is called large otherwise.*

Let Q be the set of indices i such that B_i is small. Define Q' to be the set of $t = 1/\epsilon + \lceil 4\epsilon^{-1} \ln 1/\epsilon \rceil$ largest indices in the set Q . Note that we are choosing from Q the blocks with the largest indices and not the blocks with the most number of bins. Let B_Q and $B_{Q'}$ be the sets of all bins in the blocks specified by the index sets Q and Q' , respectively. The following lemma makes use of the property of geometrically increasing bin capacities.

LEMMA 2.8. *Let U be a set of items that can be packed in the bins B_Q . There exists a set $U' \subseteq U$ such that U' can be packed into the bins $B_{Q'}$, and $p(U') \geq (1 - \epsilon) \cdot p(U)$.*

Proof. Fix some packing of U in the bins B_Q . Consider the largest $1/\epsilon$ bins in B_Q . One of these bins has a profit less than $\epsilon p(U)$. Without loss of generality, assume its capacity is 1. We will remove the items packed in this bin and use it to pack items from smaller bins. Let B_i be the block containing this bin. Let j be the largest index in Q such that $j < i - 4\epsilon^{-1} \ln 1/\epsilon$. If no such j exists, $Q' = Q$ and there is nothing to prove. For any $k \leq j$, a bin in block B_k has capacity at most $1/(1 + \epsilon)^{i-k}$ since the bin from B_i had capacity 1 and the bin capacities decrease geometrically with index. Thus the bin capacity in B_k is at most $(1 + \epsilon)^{j-i+1}/(1 + \epsilon)^{j-k+1} \leq \epsilon^2/(1 + \epsilon)^{j-k+1}$. The latter inequality follows from the fact that $j - i + 1 \leq -4\epsilon^{-1} \ln 1/\epsilon$ and $(1 + \epsilon)^{-4\epsilon^{-1} \ln 1/\epsilon} \leq \epsilon^2$. Since B_k is a small bin block, it has no more than $1/\epsilon$ bins; therefore the total capacity of all bins in B_k is at most $\epsilon/(1 + \epsilon)^{j-k+1}$. Hence, the total capacity of bins in small bin blocks with indices less than or equal to j is $\sum_{k \leq j} \epsilon/(1 + \epsilon)^{j-k+1}$, which is at most 1. Therefore, we can pack all the items in blocks B_k with $k \in B_Q, k \leq j$ in the bin we picked. The total number of blocks in Q between i and j is $4\epsilon^{-1} \ln 1/\epsilon$. Each of the $1/\epsilon$ largest bins in B_Q could be in their own blocks. Hence the largest t indices from Q would contain all these blocks. From the above, we conclude that bins of blocks with indices in Q' are sufficient to pack a set $U' \subseteq U$ such that $p(U') \geq (1 - \epsilon) \cdot p(U)$. \square

Therefore we can retain the t small bin blocks from Q' and discard the blocks with indices in $Q \setminus Q'$. Hence from here on we assume that the given instance is modified to satisfy $|Q| \leq t$, and it follows that the total number of bins in small bin blocks is at most t/ϵ . When the number of bins is fixed, a PTAS is known (implicit in earlier work) even for the GAP. The basic idea in this PTAS will be useful to us in handling small bin blocks. For large bin blocks, the advantage, as we shall see later, is that we can exceed the number of bins used by an ϵ fraction. The main task is to integrate the allocation and packing of items between the different sets of bins. We do this in three steps that are outlined below.

For the rest of the section we assume that we have a set of items that can be feasibly packed in the given set of bins. We implicitly refer to some fixed feasible packing as the *optimal* solution.

2.3.2. Packing the most profitable items into small bin blocks. We guess, for each bin b in B_Q , the $1/\epsilon$ most profitable items that are packed in b in the optimal solution. The number of guesses needed is $n^{O(\ln(1/\epsilon)/\epsilon^3)}$.

2.3.3. Packing large items into large bin blocks. The second step is to select items and pack them in large bin blocks. We say that an item is packed as a *large item* if its size is at least ϵ times the capacity of the bin in which it is packed. Since the capacities of the blocks are increasing geometrically, an item can be packed as a large item in at most $f = \lceil 2\epsilon^{-1} \ln 1/\epsilon \rceil$ different blocks. Our goal is to guess all the items that are packed as large and also to which blocks they are assigned. We do this approximately as follows.

Let n_i be the number of items of the i th size class U_i , and let ℓ_i be the number packed as large in some optimal solution. Let $f_i \leq f$ be the number of blocks in which items of U_i can be packed as large. Let ℓ_i^j , $1 \leq j \leq f_i$, be the number of items packed in each of those blocks. If $\ell_i^j \leq \frac{\epsilon}{f_i} n_i$, we can discard those items, overall losing at most an ϵ fraction of the profit from U_i . Our objective is to guess a number h_i^j such that $(1 - \epsilon)\ell_i^j \leq h_i^j \leq \ell_i^j$. The number of guesses required to obtain a single h_i^j is bounded by $g = 2\epsilon^{-1} \ln f_i/\epsilon$, and therefore the total number of guesses for all h_i^j is bounded by g^f . Using f as an upper bound for f_i and simplifying we claim an upper bound of $2^{O(1/\epsilon^3)}$. Therefore the total number of guesses required for all the $O(\epsilon^{-2} \ln n)$ size classes is bounded by $n^{O(1/\epsilon^5)}$. Here is where we take advantage of the fact that the number of distinct sizes is small (logarithmic).

Suppose we have correctly assigned all large items to their respective bin blocks. We describe now a procedure for finding a feasible packing of these items. Here we ignore the potential interaction between items that are packed as large and those packed as small. We can focus on a specific block since the large items are now partitioned between the blocks. Note that even within a single block the large items could contain $\Omega(\ln n)$ distinct sizes. The abstract problem that we have is the following. Given a collection of m bins with capacities in the range $[1, 1 + \epsilon)$, and a set of n items with sizes in the range $(\epsilon, 1 + \epsilon)$, decide if there is a feasible packing for them. We do not know if this problem can be solved in polynomial time when the number of distinct sizes is $O(\ln n)$. Here we take a different approach. We obtain a relaxation by allowing use of *extra* bins to pack the items. However, we restrict the capacity of the extra bins to be 1. We give an algorithm that either decides that the instance is infeasible or gives a packing with at most an additional ϵm bins of capacity 1.

The first step in the algorithm is to pack the items of size strictly greater than 1. Let L be these set of items. Consider items of L in nondecreasing order of their sizes. When considering an item of size s , find the smallest size bin available that can accommodate it. If no such bin exists we declare that the items cannot be packed. Otherwise we pack the item into the bin and remove the bin from the available set of bins.

LEMMA 2.9. *If the algorithm fails, then there is no feasible packing for L . Further, if there is a feasible packing for all the items, then there is one that respects the packing of L produced by the above algorithm.*

Proof. In our instance, each bin's capacity is at most $1 + \epsilon$ and every item is of size strictly larger than ϵ . Therefore each item of L is packed in a bin by itself.

Suppose there are two bins x and y and an item from L of size s such that $c(x) > c(y) \geq s$. Consider any feasible packing of the items into the bins in which s is packed into x , and y does not contain any item from L . Then it is easy to see that we

can swap s to y and the items in y into x without affecting feasibility. Similarly, we can argue that if s_1 and s_2 are two items from L such that $s_1 > s_2$, then s_1 occupies a larger bin than s_2 . Using these swapping arguments we can see that the properties described in the lemma are satisfied. \square

From the above lemma, we can restrict ourselves to packing items with sizes in $(\epsilon, 1]$ into the bins that remain after packing L . Let m' be the number of bins that remain. If a feasible packing exists, the shifting technique for bin packing [3] can be adapted in a direct fashion to pack the items using $\epsilon m'$ additional bins of size 1 each. We briefly describe the algorithm. Let n' be the number of items to be packed. We observe that each bin can accommodate at most $1/\epsilon + 1$ items. Thus $m'(1/\epsilon + 1) \geq n'$. If $m' \leq 1/\epsilon$ we can check for a feasible packing by brute force enumeration. Otherwise let $t = 2/\epsilon^2$. The items are arranged in nonincreasing order of their sizes and grouped into sets $H_1, H_2, \dots, H_t, H_{t+1}$ such that $|H_1| = |H_2| = \dots = |H_t| = n'/t$ and $H_{t+1} = n' \pmod{t}$. Items in the first group H_1 that contains the largest items are each assigned to a separate bin of size 1. For $2 \leq i \leq t + 1$, the sizes of the items in H_i are uniformly set to be the size of the smallest item in H_{i-1} . It is clear that the rounded up items have a packing in the m' bins if the original items had a packing. The rounded up items have only t distinct sizes, and dynamic programming can be applied to test the feasibility of packing these items in the given m' bins in $O(n^{O(t)})$ time. Note that the number of extra bins we use is $|H_1| = n'/t = \epsilon^2 n'/2 \leq \epsilon m'$ since $m'(1/\epsilon + 1) \geq n'$. Thus we obtain the following lemma.

LEMMA 2.10. *Given $m \geq 1/\epsilon$ bins of capacities in the range $[1, 1 + \epsilon)$ and items of sizes in the range $(\epsilon, 1 + \epsilon)$, there is an $n^{O(1/\epsilon^2)}$ -time algorithm that either decides that there is no feasible packing for the items or returns a feasible packing using at most ϵm extra bins of capacity 1.*

We eliminate the extra bins later by picking the m most profitable among them and discarding the items packed in the rest. The restriction on the size and number of extra bins is motivated by the elimination procedure. In order to use extra bins the quantity ϵm needs to be at least 1. This is the reason to distinguish between small and large bin blocks. For a large bin block B_i let E_i be the *extra* bins used in packing the large items. We note that $|E_i| \leq \epsilon m' \leq \epsilon m_i$.

2.3.4. Packing the remaining items. The third and last step of the algorithm is to pack the remaining items, which we denote by R . At this stage we have a packing of the $1/\epsilon$ most profitable items in each of the bins in B_Q (bins in small bin blocks) and a feasible packing of the large items in the rest of the bins. For each bin $b_j \in \mathcal{B}$ let Y_j denote the set of items already packed into b_j in the first two steps. The item set R is packed via a linear programming (LP) approach. In particular, we use the generalized assignment formulation with the following constraints.

1. Each remaining item must be assigned to some bin.
2. An item y can be assigned to a bin b_j in a large bin block B_i only if $s(y) \leq \epsilon \cdot (1 + \epsilon)^i$. In other words, y should be small for all bins in B_i .
3. An item y can be assigned to a bin b_j in a small bin block only if $p(y) \leq \frac{\epsilon}{1+\epsilon} p(Y_j)$ and $|Y_j| \geq 1/\epsilon$.

Constraints 2 and 3 are based on the assumption that we have correctly guessed in the first two steps of the packing procedure. We make the formulation more precise now. Note that we only check for feasibility. The variable x_{ij} denotes the fraction of item i that is assigned to bin j . Let V be the set of item-bin pairs (i, j) such that i cannot be packed into b_j due to constraints 2 and 3. The precise LP formulation is

given below:

$$\begin{aligned} \sum_j x_{ij} &= 1, && \text{item } i, \\ \sum_i s(y_i) \cdot x_{ij} &\leq c(b_j), && \text{bin } j, \\ x_{ij} &= 0, && (i, j) \in V, \\ x_{ij} &= 1, && i \in Y_j, \\ x_{ij} &\geq 0, && (i, j) \in V. \end{aligned}$$

LEMMA 2.11. *The LP formulation above has a feasible solution if the guesses for the item set, the items packed as large, and those packed in small bin blocks are correct.*

Proof. Consider a feasible integral packing of the items in the bins (which by assumption exists) and let \bar{x} denote that solution. We will use \bar{x} to construct a feasible fractional solution x for the LP above. Note that \bar{x} need not satisfy the constraints imposed by V and the Y_j 's in the LP above.

Let $\text{blk}(j)$ denote the block that contains the bin b_j . We ensure the following constraint: if $\bar{x}_{ij} = 1$, then $\sum_{\{l|\text{blk}(l)=\text{blk}(j)\}} x_{il} = 1$. In other words, we fractionally assign each item to the same block that the optimal solution does. We treat the small and large bin blocks separately.

For a j where $\text{blk}(j)$ is small we set $x_{ij} = \bar{x}_{ij}$. If we had correctly guessed the largest profit items in small bin blocks, this assignment is consistent with V and Y_j .

Consider a large bin block B_k . By our assumption, we already have an integral assignment for the set of large items that \bar{x} assigns to B_k . Let S_k be the small items that are assigned by \bar{x} to B_k . We claim that S_k can be packed fractionally in B_k irrespective of the assignment of the large items. Clearly, there is enough fractional capacity. Since the sizes of the items do not change with the bins, any greedy fractional packing that does not waste capacity gives a feasible packing. \square

Let x_{ij} be a feasible fractional solution to the above formulation. Lenstra, Shmoys, and Tardos [21] and Shmoys and Tardos [28] show how a basic feasible solution to the linear program for GAP can be transformed into an integral solution that violates the capacities only slightly. We apply their transformation to x_{ij} and obtain a 0-1 solution \bar{x}_{ij} with the following properties.

1. If $x_{ij} = 0$, then $\bar{x}_{ij} = 0$, and if $x_{ij} = 1$, then $\bar{x}_{ij} = 1$.
2. For each bin b_j , either $\sum_i \bar{x}_{ij} \leq c(b_j)$ or there is an item $k(j)$ such that $\sum_{i \neq k(j)} \bar{x}_{ij} \leq c(b_j)$ and $x_{ik(j)} < 1$. We call this item $k(j)$ the *violating* item for bin b_j .

Thus we can find an integral solution where each bin's capacity is exceeded by at most one item. Further the items assigned to the bins satisfy the constraints specified by V ; that is, $\bar{x}_{ij} = 0$ if $(i, j) \in V$. The integral solution to the LP also defines an allocation of items to each block. Let P_i be the total profit associated with all items assigned to bins in block B_i . Then clearly $\mathcal{O} = \sum_{i \geq 0} P_i$. However, we have an infeasible solution since bin capacities are violated in the rounded solution \bar{x}_{ij} . We modify this solution to create a feasible solution such that in each block we obtain a profit of at least $(1 - 3\epsilon)P_i$.

Large bin blocks. Let B_i be a large bin block, and without loss of generality assume that bin capacities in B_i are in the range $[1, 1 + \epsilon)$. By constraint 2 on the

assignment, the size of any violating item in B_i is less than ϵ and there are at most m_i of them. For all $\epsilon < 1/2$ we conclude that at most $2\epsilon m_i$ extra bins of capacity 1 each are sufficient to pack all the violating items of B_i . Recall from Lemma 2.10 that we may have used ϵm_i extra bins in packing the large items as well. Thus the total number of extra bins of capacity 1, denoted by E'_i , is at most $3\epsilon m_i$. Thus all items assigned to bins in B_i have a feasible integral assignment in the set $E'_i \cup B_i$. Now clearly the m_i most profitable bins in the collection $E'_i \cup B_i$ must have a total associated profit of at least $P_i/(1 + 3\epsilon)$. Moreover, it is easy to verify that all the items in these m_i bins can be packed in the bins of B_i itself.

Small bin blocks. Consider now a small bin block B_i . By constraint 3 on the assignment, we know that the profit associated with the violating item in any bin b_j of B_i is at most $\frac{\epsilon}{(1+\epsilon)}p(Y_j)$. Thus we can simply discard all the violating items assigned to bins in B_i , and we obtain a feasible solution of profit value at least $P_i/(1 + \epsilon)$.

This gives a feasible integral solution with total profit value at least $\sum_{i \geq 0} P_i/(1 + 3\epsilon)$. Putting together the guessing and packing steps we obtain our main result.

THEOREM 2.12. *There is a PTAS for the multiple knapsack problem.*

3. Generalized assignment problem (GAP). We start by showing that even highly restricted cases of GAP are APX-hard. Then we sketch a 2-approximation algorithm for GAP that easily follows from the work of Shmoys and Tardos [28] on the Min GAP problem.

3.1. APX-hardness of restricted instances. We reduce the maximum 3-bounded 3-dimensional matching (3DM) problem [8, 16] (defined formally below) in an approximation-preserving manner to highly restricted instances of GAP.

DEFINITION 3.1 (3-bounded 3DM (3DM-3)). *We are given a set $T \subseteq X \times Y \times Z$, where $|X| = |Y| = |Z| = n$. A matching in T is a subset $M \subseteq T$ such that no elements in M agree in any coordinate. The goal is to find a matching in T of largest cardinality. A 3-bounded instance is one in which the number of occurrences of any element of $X \cup Y \cup Z$ in T is at most 3.*

Kann [16] showed that 3DM-3 is APX-hard; that is, there exists an $\epsilon_0 > 0$ such that it is NP-hard to decide whether an instance has a matching of size n or if every matching has size at most $(1 - \epsilon_0)n$. In what follows, we denote by m the number of hyperedges in the set T .

THEOREM 3.2. *GAP is APX-hard even on instances of the following form for all positive δ .*

- $p(i, j) = 1$ for all items i and bins j .
- $s(i, j) = 1$ or $s(i, j) = 1 + \delta$ for all items i and bins j .
- $c(j) = 3$ for all bins j .

Proof. Given an instance I of 3DM-3, we create an instance $I' = (\mathcal{B}, \mathcal{S})$ of GAP as follows. In I' we have m bins b_1, \dots, b_m of capacity 3 each, one for each of the edges e_1, \dots, e_m in T . For each element i of X we have an item x_i in I' and similarly y_j for $j \in Y$ and z_k for $k \in Z$. We also have an additional $2(m - n)$ items in I' , $u_1, \dots, u_{2(m-n)}$. We set all profits to be 1. It remains to set up the sizes. For each item u_h and bin b_ℓ we set $s(u_h, b_\ell) = (1 + \delta)$. For an item x_i and bin b_ℓ we set $s(x_i, b_\ell) = 1$ if $i \in e_\ell$ and $(1 + \delta)$ otherwise. The sizes of items y_j and z_k are set similarly.

We claim that 3 items can fit in a bin b_ℓ if and only if they are the elements of the edge e_ℓ . Thus bins with 3 items correspond to a matching in T . It then follows that if I has a matching of size n , then I' has a solution of value $3n + 2(m - n)$. Otherwise,

every solution to I' has value at most $3n - \epsilon_0 \cdot n + 2(m - n)$. The APX-hardness now follows from the fact that $m = O(n)$ for bounded instances. \square

A similar result can be stated if only profits are allowed to vary.

THEOREM 3.3. *GAP is APX-hard even on instances of the following form:*

- each item takes only two distinct profit values,
- each item has an identical size across all bins and there are only two distinct item sizes, and
- all bin capacities are identical.

Proof. The reduction is once again from 3DM-3. Given an instance I of 3DM-3, we create an instance $I' = (\mathcal{B}, \mathcal{S})$ of GAP as follows. In I' we have m bins b_1, \dots, b_m of capacity 3 each, one for each of the edges e_1, \dots, e_m in T . For each element i of X we have an item x_i in I' and similarly y_j for $j \in Y$ and z_k for $k \in Z$. We also have an additional $m - n$ items u_1, \dots, u_{m-n} where $s(u_h, b_\ell) = 3$ and $p(u_h, b_\ell) = 4$ for any additional item u_h and a bin b_ℓ . Fix a positive constant $\delta < 1/3$. For an item x_i and bin b_ℓ we set $p(x_i, b_\ell) = 1 + \delta$ if $i \in e_\ell$ and 1 otherwise. The profits of items y_j and z_k are set similarly. The sizes of items $x_i, y_j,$ and z_k are all set to 1 each.

It is now easy to verify that if I has a matching of size n , there exists a solution to I' of value $4(m - n) + 3n(1 + \delta)$. Otherwise, every solution to I' has value at most $4(m - n) + 3n(1 + \delta) - n\epsilon_0 \cdot \delta$. As above, the APX-hardness now follows from the fact that $m = O(n)$. \square

Notice that Theorem 3.3 is not a symmetric analogue of Theorem 3.2. In particular, we use items of two different sizes in Theorem 3.3. This is necessary as the special case of GAP where all item sizes are identical across the bins (but the profits can vary from bin to bin) is equivalent to minimum cost bipartite matching.

PROPOSITION 3.4. *There is a polynomial time algorithm to solve GAP instances where all items have identical sizes across the bins.*

3.2. A 2-approximation for GAP. Shmoys and Tardos [28] give a (1, 2) bi-criteria approximation for Min GAP. A paraphrased statement of their precise result is as follows.

THEOREM 3.5 (Shmoys and Tardos [28]). *Given a feasible instance for the cost assignment problem, there is a polynomial time algorithm that produces an integral assignment such that*

- cost of solution is no more than OPT,
- each item i assigned to a bin j satisfies $s(i, j) \leq c(j)$, and
- if a bin's capacity is violated, then there exists a single item that is assigned to the bin whose removal ensures feasibility.

We now indicate how the above theorem implies a 2-approximation for GAP. The idea is to simply convert the maximization problem to a minimization problem by turning profits into costs by setting $w(i, j) = L - p(i, j)$, where $L > \max_{i,j} p(i, j)$ is a large enough number to make all costs positive. To create a feasible instance we have an additional bin b_{m+1} of capacity 0 and for all items i we set $s(i, m + 1) = 0$ and $w(i, m + 1) = L$ (in other words $p(i, m + 1) = 0$). We then use the algorithm for cost assignment and obtain a solution with the guarantees provided in Theorem 3.5. It is easily seen that the profit obtained by the assignment is at least the optimal profit. Now we show how to obtain a feasible solution of at least half the profit. Let j be any bin whose capacity is violated by the assignment, and let i_j be the item guaranteed in Theorem 3.5. If $p(i_j, j)$ is at least half the profit of bin j , then we retain i_j and leave out the rest of the items in j . In the other case we leave out i_j . This results in a feasible solution of at least half the profit given by the LP solution. We get the following result.

PROPOSITION 3.6. *There is a 2-approximation for GAP.*

The algorithm in [28] is based on rounding an LP relaxation. For MKP an optimal solution to the linear program can be easily constructed in $O(n \log n)$ time by first sorting items by their profit to size ratio and then greedily filling them in the bins. Rounding takes $O(n^2 \log n)$ time. It is an easy observation that the integrality gap of the natural LP relaxation for GAP is 2 even on instances of MKP with identical bin capacities.

4. A greedy algorithm. We now analyze a natural greedy strategy: pack bins one at a time by applying the FPTAS for the single knapsack problem on the remaining items. Greedy(ϵ) refers to this algorithm with ϵ parameterizing the error tolerance used in the knapsack FPTAS.

CLAIM 4.1. *For instances of MKP with bins of identical capacity, the algorithm Greedy(ϵ) gives a $(\frac{e-1}{\epsilon} - O(\epsilon))$ -approximation.*

Proof. Let X be the set of items packed by some optimal solution. Let X_j denote the set of items in X that remain after Greedy packs the first $(j-1)$ bins, and let Y_j be the items packed by Greedy in the j th bin. Since the bin capacities are identical, by a simple averaging argument it is easy to see that $p(Y_j) \geq (1-\epsilon)p(X_j)/m$. Simple algebra gives the result. \square

CLAIM 4.2. *For MKP, the algorithm Greedy(ϵ) gives a $(2+\epsilon)$ -approximation.*

Proof. Let X_j denote the set of items that some fixed optimal solution assigns to the j th bin and which do not appear anywhere in Greedy's solution. Also, let Y_j denote the items that Greedy packs in the j th bin. Then we claim that $p(Y_j) \geq (1-\epsilon)p(X_j)$ since X_j was available to be packed when Greedy processed bin j . This follows from the greedy packing. Thus we obtain $\sum_{j=1}^m p(Y_j) \geq (1-\epsilon)\sum_{j=1}^m p(X_j)$. If $\sum_{j=1}^m p(X_j) \geq \text{OPT}/2$ we are done. Otherwise by definition of the X_j 's, Greedy must have packed the other half of the profit. This implies the claimed $(2+\epsilon)$ -approximation. \square

Claim 4.2 is valid even if the item sizes (but not profits) are a function of the bins, an important special case of GAP that is already APX-hard. The running time of Greedy(ϵ) is $O(mn \log 1/\epsilon + m/\epsilon^4)$ using the algorithm of Lawler [19] for the knapsack problem. Claim 4.2 has been independently observed in [2, 15].

We show an instance on which Greedy's performance is no better than 2. There are two items with sizes 1 and $\alpha < 1$ and each has a profit of 1. There are two bins with capacities 1 and α each. Greedy packs the smaller item in the big bin and obtains a profit of 1 while $\text{OPT} = 2$. This also shows that ordering bins in nonincreasing capacities does not help improve the performance of Greedy.

5. Conclusions. An interesting aspect of our guessing strategy is that it is completely independent of the number of bins and their capacities. This might prove to be useful in other variants of the knapsack problem. One application is in obtaining a PTAS for the stochastic knapsack problem with Bernoulli variables [9].

The Min GAP problem has a $(1, 2)$ bicriteria approximation, and it is NP-hard to obtain a $(1, 3/2 - \epsilon)$ -approximation. In contrast, GAP has a 2-approximation, but the known hardness of approximation is $(1 + \epsilon_0)$ for a very small but fixed ϵ_0 . Closing this gap is an interesting open problem. An $e/(e-1) + \epsilon \simeq 1.582 + \epsilon$ approximation for GAP has been obtained recently using an LP formulation [5]. Also in recent work, it has been observed that GAP is a special case of constrained submodular set function maximization, and using the results in [6], a greedy algorithm yields a $(2 + \epsilon)$ -approximation algorithm.

Another interesting problem is to obtain a PTAS for MKP with an improved running time. Though an FPTAS is ruled out even for the case of two identical bins, a PTAS with a running time of the form $f(1/\epsilon)\text{poly}(n)$ might be achievable. Such an algorithm is not known even for instances in which all bins have the same capacity.

THE RECTILINEAR STEINER ARBORESCENCE PROBLEM IS NP-COMPLETE*

WEIPING SHI[†] AND CHEN SU[‡]

Abstract. Given a set of points in the first quadrant, a rectilinear Steiner arborescence (RSA) is a directed tree rooted at the origin, containing all points, and composed solely of horizontal and vertical edges oriented from left to right, or from bottom to top. The complexity of finding an RSA with the minimum total edge length for general planar point sets has been a well-known open problem in algorithm design and VLSI routing. In this paper, we prove the problem is NP-complete in the strong sense.

1. Introduction. Let $P = \{p_1, p_2, \dots, p_n\}$ be a set of points in the first quadrant of E^2 , where $p_i = (x_i, y_i)$. A rectilinear Steiner arborescence (RSA) for P is a directed Steiner tree T rooted at the origin, containing all points in P , and composed solely of horizontal and vertical line segments oriented from left to right, or from bottom to top. A rectilinear Steiner minimum arborescence (RSMA) for P is an RSA for P that has the shortest possible total edge length.

The difference between an RSA and the traditional rectilinear Steiner tree is that an RSA is also a shortest distance tree with respect to the origin. Figure 1.1 shows a Steiner minimum arborescence, a Steiner minimum tree, and a minimum spanning tree for the same set of points with p_1 being the origin. For an introduction on Steiner trees, see the book by Hwang, Richards, and Winter [9].

FIG. 1.1. A rectilinear Steiner arborescence (a), a rectilinear Steiner tree (b), and a rectilinear spanning tree (c).

The rectilinear Steiner arborescence problem was first studied by Nastansky, Selkow, and Stewart [13] in 1974. They proposed an integer programming formulation, which has exponential time complexity. In 1979 Laderia de Matos [10] proposed

[‡]Inet Technologies, Richardson, TX 75081.

an exponential time dynamic programming algorithm. In 1985, Trubin [15] claimed the RSA problem can be solved in polynomial time. In 1992, Rao, Sadayappan, Hwang, and Shor [14] showed that Trubin's algorithm is incorrect and presented an $O(n \log n)$ time approximation algorithm that produces an RSA of length at most 2 times the optimal [14]. In 1994, Córdova and Lee [6] extended the heuristic to points in all four quadrants with the same time complexity. In 1997, Cho [3] again claimed that the RSA problem can be solved in polynomial time using a min-cost max-flow approach. Soon after, Erzin and Kahng showed Cho's claim is wrong [7]. In 2000, Lu and Ruan [12], motivated by the polynomial time approximation scheme (PTAS) of Arora [2], designed a PTAS for the RSA problem. Their PTAS runs in time $O(n^{O(c)} \log n)$ and produces an RSA of length at most $(1 + 1/c)$ times the optimal. However, whether there exists a polynomial time algorithm for the RSA problem remains open.

Because an RSMA is a shortest distance tree of minimum total length, it has important applications in VLSI routing. Cong, Leung, and Zhou [5] showed that routing trees based on RSMAs may have significantly less delay than those based on the traditional Steiner trees. Many researchers proposed efficient heuristics and exponential time exact algorithms for the RSA problem [1, 4].

2. NP-completeness.

2.1. Overall strategy. We assume that readers have the general knowledge of NP-completeness [8]. The decision version of the RSA problem is as follows:

Instance: A set of points $P = \{p_1, p_2, \dots, p_n\}$ in the plane, and a positive integer k .

Question: Is there an RSA of total edge length k or less?

The proof is a reduction from planar 3SAT, which was proven to be NP-complete in the strong sense by Lichtenstein [11]:

Instance: A set of variables $V = \{v_1, v_2, \dots, v_n\}$ and a set of clauses $C = \{c_1, c_2, \dots, c_m\}$. Each clause contains at most 3 literals. Furthermore, the bipartite graph $G = (V \cup C, E)$ is planar, where $E = \{(v_i, c_j) \mid v_i \in c_j \text{ or } \bar{v}_i \in c_j\}$.

Question: Is there an assignment for the variables so that all clauses are satisfied?

For example, Figure 2.1 is the graph of a planar 3SAT instance $c_1 = v_1 \vee v_2 \vee \bar{v}_3$ and $c_2 = \bar{v}_1 \vee \bar{v}_4$. We will use this example throughout the paper.

FIG. 2.1. Graph G of a planar 3SAT instance.

The reduction is through component design. For a given planar 3SAT instance, we first convert its planar graph G to a planar graph H . Then we embed H in a grid and let the embedded graph be R . Finally we replace each vertex of R by a tile. We

will use *basic tiles* to represent variables, *NOT tiles* to negate variables, *OR tiles* to compute the OR of two variables, and *clause tiles* to check if the clauses are satisfied. The length of the RSMA for the set of points so constructed will tell us whether the planar 3SAT has a satisfying solution.

2.2. Embedding. We first convert G of the given planar 3SAT instance to a planar graph H with maximum degree 3.

For each variable v_i in G , let $d(v_i)$ be the degree of v_i . Replace v_i by a path of $d(v_i)$ *variable vertices* for v_i in H : $u_{i1}, \dots, u_{id(v_i)}$ and edges $(u_{i1}, u_{i2}), \dots, (u_{id(v_i)-1}, u_{id(v_i)})$. See Figure 2.2 for an example. Each variable vertex will be connected to a clause vertex defined next.

FIG. 2.2. Vertex v_i of degree 4 is replaced by a path of 4 vertices.

For each clause c_j in G that contains two variables, if $c_j = v_i \vee \overline{v_k}$, then H will contain a *clause vertex* c_j and two edges (c_j, u_i) and (c_j, u_k) , where u_i and u_k are variable vertices for v_i and v_k , respectively. Since the transformation in Figure 2.2 produced $d(v_i)$ variable vertices for each v_i , we make each edge connect to a unique variable vertex. If c_j is not in the right form, say, $c_j = \overline{v_i} \vee \overline{v_k}$, then in H we insert a *NOT vertex* w_{ij} between c_j and the variable vertex for v_i . In other words, we will have a new vertex w_{ij} and edges (c_j, w_{ij}) , (w_{ij}, u_i) , and (c_j, u_k) .

For each clause c_j in G that contains three variables, let $c_j = v_i \vee \overline{v_k} \vee \overline{v_l} = (v_i \vee \overline{v_k}) \vee \overline{v_l} = c'_j \vee \overline{v_l}$. In H , there will be an *OR vertex* c'_j that connects the variable vertices for v_i and v_k , and a *clause vertex* c_j that connects c'_j and the variable vertex for v_l . Similarly, if c_j is not in the right form, we will insert *NOT vertices* as needed.

Now H is a planar graph with maximum degree 3. Figure 2.3 shows the converted planar graph H .

FIG. 2.3. Planar graph H converted from G .

Valiant [16] showed that any planar graph $G = (V, E)$ of maximum degree 3 has a planar embedding in a rectilinear grid of area $O(|V|^2)$. Therefore, graph H can be embedded in a rectilinear grid of area of $O((n + m)^2)$, where n and m are the number of variables and clauses. We further require the following in the grid embedding.

- (1) Vertices share an edge if and only if they are distance 1 apart.

(2) For each clause vertex $c_j = v_i \vee \overline{v_k}$, or $c_j = c'_j \vee \overline{v_k}$, the path from v_i , or c'_j , enters from the left, and the path from v_k enters from below.

(3) Each OR vertex $c'_j = v_i \vee \overline{v_k}$ occupies two horizontally adjacent vertices in the embedding, the path from v_i enters from the left, the path from v_k enters from below, and the path leading to c_j exits to the right.

These requirements can be satisfied by locally rearranging the grid embedding, increasing the size of the grid by a constant factor, and adding additional vertices and edges. For requirement (2), since v_i , c_j , and v_k is a path with no connection to other vertices in planar graph H , it is always possible to swirl the path to any direction. Figure 2.4 shows the embedding of an example clause vertex $c_j = v_i \vee \overline{v_k}$. For requirement (3), the same idea can be used. For an OR vertex $c'_j = v_i \vee \overline{v_k}$, we first swirl the path to c_j to the right. Then if v_k and v_i are in clockwise order from the path to c_j , then v_k and v_i can be swirled into proper positions. If v_k and v_i are in counterclockwise order from the path to c_j , then a crossing may occur. To avoid the crossing, note that $v_i \vee \overline{v_k} = \overline{v_k} \vee \overline{\overline{v_i}}$. Therefore we can add NOT vertices to paths for v_i and v_k and then route $\overline{v_k}$ to enter from the left and $\overline{\overline{v_i}}$ to enter from below, thereby maintaining the planarity.

FIG. 2.4. A clause vertex with incoming paths (a). Requirement (2) is satisfied by swirling (b).

Figure 2.5 shows the grid embedding R . There are two auxiliary vertices t_1 and t_2 introduced in order to meet the above requirements.

2.3. Component design. The most important building block of our design is the *quadruped* in Figure 2.6. A quadruped consists of 4 white points q_1, \dots, q_4 , and 4 black points b_1, \dots, b_4 . The distances between the points are given in Figure 2.6, where $\alpha, \beta, \delta_1, \delta_2 > 0$. In addition, $\beta + \delta_1 > \alpha$, meaning that the Y-coordinate of q_3 is less than the Y-coordinate of q_4 , and $\alpha > \delta_1 + \delta_2$, meaning that the rectilinear distance between q_2 and q_4 is $\beta - \delta_2 + \alpha - \delta_1 > \beta$. There is no other point on or inside the region enclosed by the solid, dashed, and dotted lines, i.e., three triangles and one rectangle. We call the region the *forbidden region*.

DEFINITION 2.1. For a set of points Q that contains white points and black points, a minimum forest of Q is a set of RSAs that contains all white points in Q . Furthermore, the root of each RSA is a black point in Q , and the total edge length is minimum.

LEMMA 2.2. For a quadruped, there are only two minimum forests, shown as solid edges and dashed edges in Figure 2.6. The edge length of both minimum forests is $2(\alpha + \beta)$.

FIG. 2.5. *Embedded graph R.*

FIG. 2.6. *A quadruped and its forbidden region. The two minimum forests both have total edge length $2\alpha + 2\beta$.*

Proof. To connect q_4 , we need a path of length at least α . To connect q_1 , we also need a path of length at least α , even with the help of the path for q_4 . Similarly, to connect q_2 and q_3 , we need two paths each of length at least β . Hence, the lower bound is $2(\alpha + \beta)$.

On the other hand, to connect q_1, q_2, \dots, q_4 with the minimum edge length $2(\alpha + \beta)$, each point must use a path that equals the lower bound. Starting with q_2 , we can use either the horizontal edge or the vertical edge, both of length β . If we use the vertical edge, then we must connect q_3 with the horizontal edge, q_4 with the vertical edge, and q_1 with the horizontal edge. This gives a total length of $2(\alpha + \beta)$ shown as the solid edges. If we use the horizontal edge for q_2 , we will end up with the dashed edges, also of length $2(\alpha + \beta)$. \square

We are now ready to define the tiles. The height and width of all tiles, except for the OR tile, are both 96. The height of the OR tile is 96, and the width is 192, twice the width of other tiles.

A basic tile is made of overlapping quadrupeds as shown in Figure 2.7.

FIG. 2.7. A basic tile made of overlapping quadrupeds, where $\alpha = \beta = 20$ and $\delta_1 = \delta_2 = 4$.

LEMMA 2.3. *There are only two minimum forests for a basic tile, one shown as dashed edges and one shown as solid edges.*

Proof. Since the basic tile consists of overlapping quadrupeds, from Lemma 2.2, the minimum forest for one quadruped will force the minimum forests for the rest of the quadrupeds. \square

Define the *parity* π of a minimum forest of a basic tile to be 1 if the rightmost white point is connected by a horizontal edge, and 0 otherwise. In Figure 2.7, since the rightmost white point q is connected by a solid horizontal edge, the minimum forest that uses all solid edges has parity 1, and the minimum forest that uses all dashed edges has parity 0.

A set of overlapping quadrupeds such as a basic tile has the important property that once we choose the connection of any point to be solid or dashed, then the entire minimum forest must be solid or dashed. Therefore, if we insist on the connection being a minimum forest, then our choice of any point is propagated left, right, top, and bottom, by overlapping quadrupeds such as basic tiles.

Figure 2.8 shows how to place two horizontally adjacent basic tiles by deleting b_1 and b_2 of the right tile. To place two vertically adjacent basic tiles, we delete b_3 and b_4 of the top tile. Clearly, we have the following result.

LEMMA 2.4. *For two horizontally or vertically adjacent basic tiles, their minimum forests must have the same parity.*

Now we explain the NOT tile, which is used to change the parity. A horizontal NOT tile is shown in Figure 2.9. It is easy to check that a horizontal NOT tile can be placed between two basic tiles, according to the dimension specified in the figure. A vertical NOT tile is symmetric and can be obtained by reflecting a horizontal NOT tile with respect to line $y = x$. The parity of a minimum forest of a horizontal (vertical, respectively) NOT tile is 1 if the rightmost white point is connected by a horizontal (vertical, respectively) edge, and 0 otherwise. In Figure 2.9, since the rightmost white point q is connected by a solid vertical edge, the minimum forest that uses all solid edges has parity 0.

LEMMA 2.5. *If a horizontal NOT tile is placed between two basic tiles in a row (see Figure 2.10), then in the minimum forest, the parities of the two basic tiles must*

FIG. 2.8. Two adjacent basic tiles have the same parity.

FIG. 2.9. A horizontal NOT tile, where $\alpha = \beta = 25$, $\delta_1 = 5$, and $\delta_2 = 4$.

be different. The same is true for the vertical case.

Proof. By observation, see Figures 2.9 and 2.10. It is easy to check that the interfaces between the basic tiles and the NOT tile satisfy the requirements of the quadruped. \square

A clause tile is shown in Figure 2.11. It has the same interface to the left and below as a basic tile.

LEMMA 2.6. *The length of the minimum forest of a clause tile is 108, which is achievable only if the tile to the left has parity 1, or the tile below has parity 0.*

Proof. Note that q_1, q_2, q_3 , and q_4 each requires an edge of length $\alpha = 20$. There are two ways to connect q_5 and q_6 : through edge (q_2, q_5) and edge (q_3, q_6) of length $20 + 20 = 40$ (shown as dashed edges in Figure 2.11) or through a Steiner point of length $24 + 4 = 28$ (shown as solid edges in Figure 2.11).

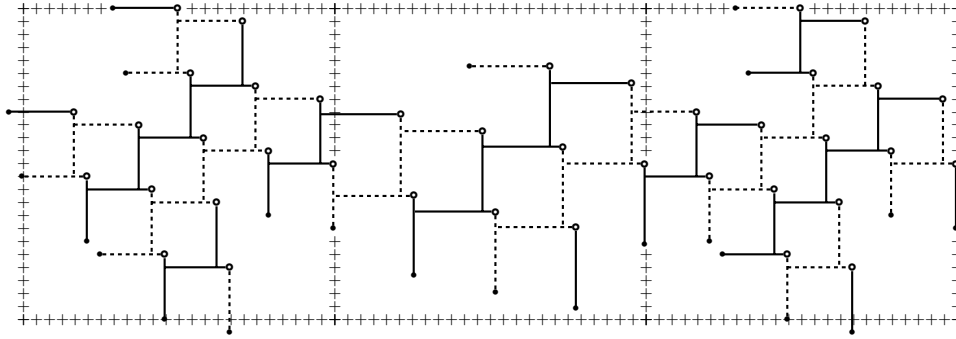

FIG. 2.10. The parity of the left basic tile is different from the parity of the right basic tile due to the NOT tile in the middle.

FIG. 2.11. A clause tile, where $\alpha = \beta = 20$ and $\delta_1 = \delta_2 = 4$, unless marked otherwise.

Therefore, the minimum forest has length 108, which is achievable only if q_2 or q_3 is connected by a solid edge. This in turn requires q_1 or q_4 to be connected by a solid edge. In order for q_1 to be connected by a solid edge, the parity of the forest on the left must be 1. In order for q_4 to be connected by a solid edge, the parity of the forest below must be 0. \square

Finally, we show the OR tile in Figure 2.12. There are two parts in the OR tile: The left part acts like a clause tile, and the right part adjusts the total width to 192. The parity of a minimum forest of a OR tile is 1 if the rightmost white point q is connected by a horizontal edge, and 0 otherwise.

Note that an OR tile can always have a minimum forest of parity 0. In Figure 2.12, all white points starting with q_5 and q_6 to the right can be connected by dashed edges, regardless of what happens to the left and below. However, for the OR tile to have a minimum forest of parity 1, either q_1 or q_4 must be connected by the solid edge. Since the right side of an OR tile is always a clause tile, the OR tile will try to have parity 1 if possible in order to reduce the cost of the clause tile on the right.

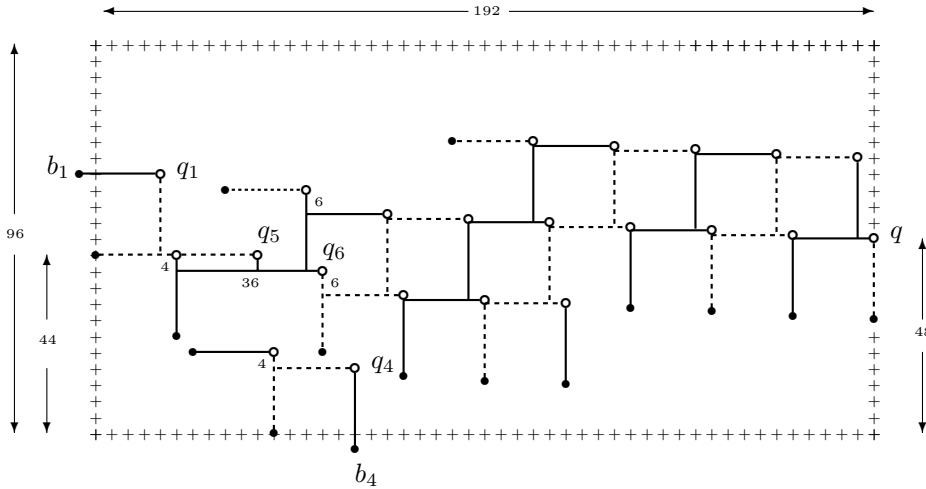

FIG. 2.12. An OR tile, where $\alpha = \beta = 20$, $\delta_1 = 1$, and $\delta_2 = 4$, unless marked otherwise.

LEMMA 2.7. *If the parity of a minimum forest of an OR tile is 1, then either the minimum forest to the left has parity 1 or the minimum forest below has parity 0. On the other hand, if either the minimum forest to the left has parity 1 or the minimum forest below has parity 0, then the parity of the OR tile can be 1.*

Proof. The proof is similar to the proof for the clause tile. In order for the OR tile to have parity 1, q_5 and q_6 cannot be connected by the dashed edges, which requires q_1 or q_4 to be connected by solid edges. Therefore, the minimum forest on the left must have parity 1 or the minimum forest below must have parity 0. \square

2.4. Main theorem. We construct an RSA instance from the 3SAT instance as follows. Each variable vertex and auxiliary vertex is replaced by a basic tile, each NOT vertex is replaced by a NOT tile, each pair of OR vertices is replaced by an OR tile, and each clause vertex is replaced by a clause tile.

To connect the black points without affecting any minimum forests for the white points, we need to add additional points. From Definition 2.1 and Lemma 2.2, if there is no point in the forbidden regions, then the properties of all tiles discussed above will not be affected. Therefore we add additional black points as follows: For each black point b_i in a basic, NOT, OR, or clause tile, we add a trail of additional black points distance 1 apart to connect b_i to the nearest black/white points to the left or below, provided that the trail does not enter any forbidden region. Such a trail always exists since any forbidden region must have a white point at the upper right corner. Figure 2.13 shows how to add trails of black points to connect some black points in a basic tile.

Since the newly added black points are not in any forbidden region, these black points will not affect the minimum forests for the quadrupeds. Furthermore, since the black points have exactly one closest neighbor to the left and below, of distance 1, all black points will be connected with a fixed edge length independent of how the white points are connected. Figure 2.14 shows the RSA instance from Figure 2.5.

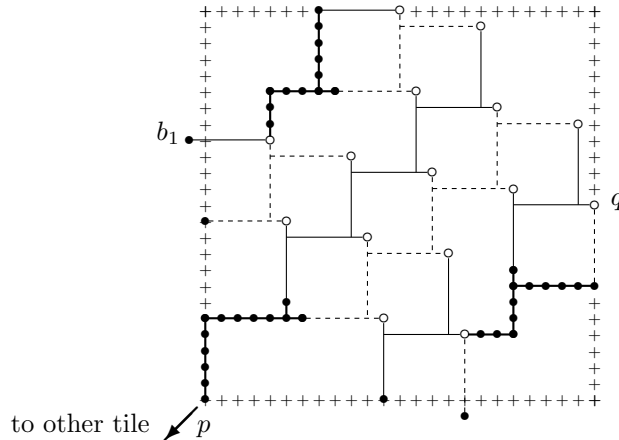

FIG. 2.13. *Trials of additional black points are added. The additional points are distance 1 apart and are not in any forbidden region. Therefore the black points will not affect how white points are connected.*

Some readers may wonder if graph G , H , or R contains a cycle, then whether the corresponding construction and connection will also contain a cycle. From Figure 2.13, it is easy to see that a cycle in G , H , or R does not correspond to a cycle in the connection. In the figure, the effect of the connection for q is propagated to b_1 , but q is not directly connected to b_1 in the Steiner tree in this tile.

THEOREM 2.8. *The RSA problem is NP-complete in the strong sense.*

Proof. It was shown in [14] that the RSA problem has the Hanan property; hence it is in NP.

For the transformed RSA instance, let L be the sum of minimum edge lengths for connecting all black points, and for the minimum forest of each basic tile, OR tile, and NOT tile. Then we claim that the set of points has an RSA of length $L + 108m$ if and only if the planar 3SAT instance has a satisfying assignment, where m is the number of clauses.

If the 3SAT is satisfiable, then for each variable v_i we make the minimum forest for the basic tiles corresponding to v_i have parity 1 if $v_i = 1$, or parity 0 if $v_i = 0$. From Lemmas 2.3 and 2.4, the parities of the basic tiles will force the parity of other tiles. Since all clauses are satisfied, from Lemmas 2.5 and 2.6, we can use the correct minimum forest for each OR tile and clause tile. Since every clause tile has edge length 108, we will have an RSA of total edge length $L + 108m$.

On the other hand, assume there is an RSA of total edge length $L + 108m$. From Lemmas 2.2, 2.3, 2.4, and 2.5, each tile must use either the dashed edges or the solid edges, the parities of adjacent tiles must match, and all clause tiles must have length 108. From Lemma 2.6, at least one variable in each clause is true. Therefore the RSA corresponds to a true assignment.

The RSA problem is strongly NP-complete because the planar 3SAT problem is strongly NP-complete, and the coordinates used in our construction are of polynomial size. \square

MAPPING CYCLES AND TREES ON WRAP-AROUND BUTTERFLY GRAPHS*

MEGHANAD D. WAGH[†] AND OSMAN GUZIDE[‡]

Abstract. We give a new algebraic representation for the wrap-around butterfly interconnection network. This new representation is based on the direct product of groups and finite fields and allows an algebraic expression of the network connectivity. The abstract algebraic tools may then be employed to explore the structural properties of the butterfly. In this paper we exploit this model to map guest graphs on the butterfly. In particular, we provide designs of unit dilation mappings of all possible length cycles on butterflies. We also map the largest possible binary trees on butterfly networks with a dilation 2 if the network degree is less than 16, 3 if it is less than 32, and 4 if it is less than 64. This is a great improvement over previous results.

1. Introduction. Distributed memory parallel architectures rely upon interconnection networks to communicate data and intermediate results between processors. With the rapid advances in semiconductor technology, the computational speeds of processors have far surpassed the improvements in communication speeds. Consequently, communication between processors is threatening to become a bottleneck in parallel processing.

Improving the communication characteristics of a parallel machine is a challenging problem because of the many conflicting demands on the interconnection networks. For example, scalability and cost issues force one to have a small (and, if possible, fixed) node degree and a small number of total edges. On the other hand, performance demands a large number of processors, a small network diameter, symmetry, and the possibility of mapping of common parallel algorithm skeletons on the architecture.

The *wrap-around butterfly network* represents a good trade-off between the cost and the performance of a parallel machine. It has a large number of processors, fixed node degree, low diameter, symmetry, and ability to support a variety of parallel algorithms. A *wrap-around butterfly network* of degree $n \geq 3$, B_n , is a graph with node set $Z_n \times \{0, 1\}^n$ [7]. A node (m, V) of B_n is connected to the four nodes shown in Figure 1.1. Note that in this figure, since $m \in Z_n$, $m + 1$ and $m - 1$ are evaluated modulo n . V is an n -bit binary vector $v_{n-1}, v_{n-2}, \dots, v_0$, and 2^m refers to a length n vector with 1 in position m and 0's everywhere else. Thus an exclusive OR operation with 2^m alters exactly the m th bit of vector V . B_n is often visualized as an $n \times 2^n$ array of nodes with node (m, V) located in the m th row and V th column of the array. Each node is connected only to nodes in the neighboring rows (except for the *wrap-around* links between the nodes of the 0th and the $(n - 1)$ th rows). The edges between nodes in the same row (same m) are often called *straight edges*, and those between nodes in different rows are the *diagonal edges*.

FIG. 1.1. Connections from node (m, V) in the butterfly network.

The edges in a butterfly network are bidirectional, i.e., corresponding to an edge from (m_1, V_1) to (m_2, V_2) , there is also an edge from (m_2, V_2) to (m_1, V_1) . B_n is node symmetric and has $n2^n$ nodes and $n2^{n+1}$ edges. Its node degree is 4 and its diameter is $\lfloor 3n/2 \rfloor$. The degree 4 Cayley graph, proposed recently [13], is identical to B_n [3]. Cube connected cycles are a subgraph of B_n [4]. B_n supports many parallel algorithms well [7, 5, 8, 9, 10, 12]. It is shown that one can map cycles and trees on B_n with relatively low dilation [11, 6, 2].

This paper provides a new model for the wrap-around butterfly graph using a direct product of groups and finite fields. In this model, node connectivity can be expressed as an algebraic relationship between the node labels. This allows one to explore the structural properties of the butterfly network in much more direct fashion using powerful algebraic techniques. This paper investigates the mapping of guest graphs of cycles and trees to the butterfly host graph with the help of this new model. All our mappings have unit *load*; i.e., each vertex of a guest graph is mapped to a unique butterfly node. Our mappings also have a low *dilation*; i.e., neighboring vertices of the guest graphs are mapped either to neighboring butterfly nodes (unit dilation) or on nodes between whom paths of relatively small length exists. Unit load and low dilation characterize an efficient mapping. In the case of constant node degree networks such as the wrap-around butterflies, unit load and constant dilation imply a constant congestion. Further, a unit load and unit dilation mapping is a subgraph of the host graph of butterfly.

The rest of this paper is organized as follows. In section 2, we provide the details of our new representation of B_n and prove its isomorphism to the binary node labels. Section 3 is devoted to mapping of cycles to B_n . We enumerate cycles which can *never* be subgraphs of a wrap-around butterfly graph and then provide simple procedures to design all the remaining cycle subgraphs. In particular, we show that barring a few exceptions, it is possible to map (with unit dilation) an arbitrary length cycle to B_n when n is odd, and any even length cycle when n is even. Section 4 deals with mapping trees to B_n . We show that when n is less than 16, one can map the maximal binary balanced tree to B_n with a dilation of 2. Results for larger size networks are also provided. Finally, section 5 presents our conclusions.

2. Alternate representation of the butterfly. This section presents a new model of the wrap-around butterfly using the direct product of finite groups and fields. We show that in this model, network connectivity is expressed as a simple algebraic relationship (Theorem 2.1), thereby providing powerful algebraic tools to investigate its structural properties.

In the proposed representation, nodes of B_n are labeled with the elements of $Z_n \times GF(2^n)$.¹ Thus the new node labels would be (m, X) , where $m \in Z_n$ and $X \in GF(2^n)$. Integer m and the field element X would be referred to as the first and second indices of the node, respectively. We will provide the exact equivalence between the new node labels and the ones using the binary notation later, but first we summarize important properties of finite fields used in this paper. Reader is referred to [1] for detailed description of the algebraic notions used here.

The finite field $GF(2^n)$ is an extension of $GF(2)$. Similar to $GF(2)$, it uses modulo 2 addition; i.e., for any $X \in GF(2^n)$, $X + X = 0$. Elements of $GF(2^n)$ may be enumerated as $\{0, 1, \alpha, \alpha^2, \dots, \alpha^{2^n-2}\}$, where the element α is known as the *primitive element*. $\alpha^{2^n-1} = 1$ and thus the elements of $GF(2^n)$ are closed under multiplication. The minimum degree polynomial (over $GF(2)$) of which α is a root, is called the *primitive polynomial*. Primitive polynomial has degree n and plays a central role in the design of $GF(2^n)$. Because α is a root of this degree n polynomial, elements of $GF(2^n)$ may also be expressed as polynomials (of degree at most $n - 1$) in α over $GF(2)$. One can therefore view $GF(2^n)$ as a vector space over $GF(2)$ with basis $\langle \alpha^{n-1}, \alpha^{n-2}, \dots, \alpha, 1 \rangle$.

Fields $GF(2^4)$ and $GF(2^5)$ are illustrated in Tables 2.1 and 2.2, respectively. Expressing each element of $GF(2^n)$ in basis $\langle \alpha^{n-1}, \alpha^{n-2}, \dots, \alpha, 1 \rangle$ is fairly straightforward. For example, in Table 2.1, elements 1, α , α^2 , and α^3 are already the basis elements. α^4 can be expressed using lower powers of α using the fact that α is the root of the primitive polynomial $x^4 + x + 1$. Thus $\alpha^4 + \alpha + 1 = 0$, or $\alpha^4 = \alpha + 1$. (Recall that $GF(2^n)$ uses modulo 2 additions.) The expressions for successive higher powers of α are obtained by multiplying the expressions for lower powers by α and replacing any α^4 , thus created, by $\alpha + 1$. Tables 2.1 and 2.2 are important to simplify additions between field elements. For example, using Table 2.1, one may easily add α^{10} and α^{11} in $GF(2^4)$ as $\alpha^{10} + \alpha^{11} = (\alpha^2 + \alpha + 1) + (\alpha^3 + \alpha^2 + \alpha) = \alpha^3 + \alpha = \alpha^{14}$.

Alternately, the elements of $GF(2^n)$ can be expressed over $GF(2)$ using the *dual basis* $\langle \beta_{n-1}, \beta_{n-2}, \dots, \beta_0 \rangle$. The dual basis is unique and its component β_i is defined as that element of $GF(2^n)$ which satisfies

$$(2.1) \quad \text{Tr}(\alpha^j \beta_i) = \begin{cases} 1 & \text{if } j = i, \\ 0 & \text{otherwise,} \end{cases}$$

where the *Trace* function $\text{Tr}(\cdot) : GF(2^n) \rightarrow GF(2)$ is computed as [1]

$$\text{Tr}(x) = x + x^2 + x^{2^2} + x^{2^3} + \dots + x^{2^{n-1}}.$$

$\text{Tr}(\cdot)$ is a linear function over $GF(2)$, i.e.,

$$\text{Tr}(aX + bY) = a\text{Tr}(X) + b\text{Tr}(Y), \quad a, b \in GF(2), \quad X, Y \in GF(2^n).$$

Structure of the primitive polynomial governs the relationships between the dual basis elements. For the purposes of this paper, we will need only the relationship

$$(2.2) \quad \beta_{n-1} = \alpha\beta_0.$$

¹Here, Z_n denotes the set of integers $\{0, 1, \dots, n - 1\}$ under the operation of addition modulo n and $GF(2^n)$ denotes the finite field of 2^n elements with characteristic 2.

TABLE 2.1
Structure of $GF(2^4)$.

Primitive polynomial: $x^4 + x + 1$ Elements and their relationships:	
0	$\alpha^7 = \alpha^3 + \alpha + 1$
1	$\alpha^8 = \alpha^2 + 1$
α	$\alpha^9 = \alpha^3 + \alpha$
α^2	$\alpha^{10} = \alpha^2 + \alpha + 1$
α^3	$\alpha^{11} = \alpha^3 + \alpha^2 + \alpha$
$\alpha^4 = \alpha + 1$	$\alpha^{12} = \alpha^3 + \alpha^2 + \alpha + 1$
$\alpha^5 = \alpha^2 + \alpha$	$\alpha^{13} = \alpha^3 + \alpha^2 + 1$
$\alpha^6 = \alpha^3 + \alpha^2$	$\alpha^{14} = \alpha^3 + 1$
Dual base $\langle \beta_3, \beta_2, \beta_1, \beta_0 \rangle = \langle 1, \alpha, \alpha^2, \alpha^{14} \rangle$	

TABLE 2.2
Structure of $GF(2^5)$.

Primitive polynomial: $x^5 + x^4 + x^3 + x^2 + 1$ Elements and their relationships:	
0	$\alpha^{15} = \alpha^4 + \alpha^3 + \alpha + 1$
1	$\alpha^{16} = \alpha^3 + \alpha + 1$
α	$\alpha^{17} = \alpha^4 + \alpha^2 + \alpha$
α^2	$\alpha^{18} = \alpha^4 + 1$
α^3	$\alpha^{19} = \alpha^4 + \alpha^3 + \alpha^2 + \alpha + 1$
α^4	$\alpha^{20} = \alpha + 1$
$\alpha^5 = \alpha^4 + \alpha^3 + \alpha^2 + 1$	$\alpha^{21} = \alpha^2 + \alpha$
$\alpha^6 = \alpha^2 + \alpha + 1$	$\alpha^{22} = \alpha^3 + \alpha^2$
$\alpha^7 = \alpha^3 + \alpha^2 + \alpha$	$\alpha^{23} = \alpha^4 + \alpha^3$
$\alpha^8 = \alpha^4 + \alpha^3 + \alpha^2$	$\alpha^{24} = \alpha^3 + \alpha^2 + 1$
$\alpha^9 = \alpha^2 + 1$	$\alpha^{25} = \alpha^4 + \alpha^3 + \alpha$
$\alpha^{10} = \alpha^3 + \alpha$	$\alpha^{26} = \alpha^3 + 1$
$\alpha^{11} = \alpha^4 + \alpha^2$	$\alpha^{27} = \alpha^4 + \alpha$
$\alpha^{12} = \alpha^4 + \alpha^2 + 1$	$\alpha^{28} = \alpha^4 + \alpha^3 + 1$
$\alpha^{13} = \alpha^4 + \alpha^2 + \alpha + 1$	$\alpha^{29} = \alpha^3 + \alpha^2 + \alpha + 1$
$\alpha^{14} = \alpha^4 + \alpha + 1$	$\alpha^{30} = \alpha^4 + \alpha^3 + \alpha^2 + \alpha$
Dual base $\langle \beta_4, \beta_3, \beta_2, \beta_1, \beta_0 \rangle = \langle \alpha^{20}, \alpha^9, \alpha^{26}, \alpha^{18}, \alpha^{19} \rangle$	

In order to establish the equivalence between the binary labels used in section 1 and the new labels, we use the mapping $\psi : Z_n \times \{0, 1\}^n \rightarrow Z_n \times GF(2^n)$,

$$(2.3) \quad \psi(m, v_{n-1}v_{n-2} \dots v_1v_0) = \left(m, \sum_{i=0}^{n-1} v_{(i+m) \bmod n} \beta_i \right).$$

Mapping ψ is one-to-one and onto because $\langle \beta_{n-1}, \beta_{n-2}, \dots, \beta_0 \rangle$ is a basis of $GF(2^n)$. We will show in Theorem 2.1 that ψ also preserves the connectivity of B_n .

Further, using the properties of β_i 's one can show the inverse of ψ to be

$$\psi^{-1}(m, X) = (m, v_{n-1}v_{n-2} \dots v_1v_0),$$

where

$$(2.4) \quad v_i = \text{Tr}(\alpha^{(i-m) \bmod n} X).$$

Table 2.3 provides the mapping ψ between the two representations of B_5 . In

order to illustrate the entries in this table, consider mapping of a butterfly node $(0, 01011) \in Z_n \times \{0,1\}^n$ to its new algebraic setting. The dual basis of $GF(2^5)$ given in Table 2.2 is $\langle \alpha^{20}, \alpha^9, \alpha^{26}, \alpha^{18}, \alpha^{19} \rangle$. Thus

$$\begin{aligned} \psi(0, 01011) &= (0, \alpha^9 + \alpha^{18} + \alpha^{19}) \\ &= (0, (\alpha^2 + 1) + (\alpha^4 + 1) + (\alpha^4 + \alpha^3 + \alpha^2 + \alpha + 1)) \\ &= (0, \alpha^3 + \alpha + 1) = (0, \alpha^{16}). \end{aligned}$$

Thus the butterfly node with binary label $(0, 01011)$ is renamed in the new algebraic notation as $(0, \alpha^{16})$.

We now state the central result of this section which expresses the connectivity of B_n through algebraic relationships between node labels.

THEOREM 2.1 (connectivity). *In B_n , a graph node (m, X) is connected to the four nodes $(m+1, \alpha X)$, $(m-1, \alpha^{-1}X)$, $(m+1, \alpha X + \beta_{n-1})$, and $(m-1, \alpha^{-1}X + \beta_0)$.*

Proof. Let

$$\begin{aligned} \psi(m, v_{n-1}v_{n-2} \dots v_1v_0) &= (m, X) \quad \text{and} \\ \psi(m+1, v'_{n-1}v'_{n-2} \dots v'_1v'_0) &= (m+1, \alpha X). \end{aligned}$$

Components v_i of the binary vector are related to m and X as in (2.4). Similar equation for v'_i gives

$$(2.5) \quad v'_i = \text{Tr}(\alpha^{(i-m-1) \bmod n} \alpha X).$$

Now, if $i \neq m$, then $(i-m-1) \bmod n < n-1$ and consequently $\alpha^{(i-m-1) \bmod n} \alpha = \alpha^{(i-m) \bmod n}$. On the other hand, if $i = m$, then $\alpha^{(i-m-1) \bmod n} \alpha = \alpha^n$. Using this in (2.5) gives the values of v'_i as

$$(2.6) \quad v'_i = \begin{cases} \text{Tr}(\alpha^{(i-m) \bmod n} X) & \text{if } i \neq m, \\ \text{Tr}(\alpha^n X) & \text{if } i = m. \end{cases}$$

Comparing (2.4) and (2.6) one now gets

$$(2.7) \quad v'_i = \begin{cases} v_i & \text{if } i \neq m, \\ v_m \text{ or } v_m \oplus 1 & \text{if } i = m. \end{cases}$$

The second line of (2.7) is obtained by noting that the $\text{Tr}(\alpha^n X)$ is either 0 or 1, and therefore equals either v_m or $v_m \oplus 1$. Since the binary vectors $(v_{n-1}v_{n-2} \dots v_1v_0)$ and $(v'_{n-1}v'_{n-2} \dots v'_1v'_0)$ are equal, except possibly in the m th bit, Figure 1.1 shows that nodes $(m, v_{n-1}v_{n-2} \dots v_1v_0)$ and $(m+1, v'_{n-1}v'_{n-2} \dots v'_1v'_0)$ are connected. Thus (m, X) is connected to $(m, \alpha X)$.

To show that $(m+1, \alpha X + \beta_{n-1})$ is connected to (m, X) , suppose

$$\psi(m+1, v'_{n-1}v'_{n-2} \dots v'_1v'_0) = (m+1, \alpha X + \beta_{n-1}).$$

In this case, v'_i is obtained as

$$(2.8) \quad v'_i = \text{Tr}(\alpha^{(i-m-1) \bmod n} (\alpha X + \beta_{n-1})).$$

As before, if $i \neq m$, $(i-m-1) \bmod n < n-1$. Using this and the linearity of the trace function in (2.8) gives

$$(2.9) \quad v'_i = \begin{cases} \text{Tr}(\alpha^{(i-m) \bmod n} X) + \text{Tr}(\alpha^{i-m-1 \bmod n} \beta_{n-1}) & \text{if } i \neq m, \\ \text{Tr}(\alpha^n X) + \text{Tr}(\alpha^{n-1} \beta_{n-1}) & \text{if } i = m. \end{cases}$$

FIG. 2.1. Connections from node $(m, X) \in Z_n \times GF(2^n)$ in the butterfly network.

Employing the definition of β_{n-1} , (see (2.1)), this becomes

$$v'_i = \begin{cases} v_i & \text{if } i \neq m, \\ v_m \text{ or } v_m \oplus 1 & \text{if } i = m. \end{cases}$$

As before, $\text{Tr}(\alpha^n X) + 1$ in the second line of (2.9) is replaced by v_m or $v_m \oplus 1$ because it is either 0 or 1. Therefore from Figure 1.1, (m, X) is connected to $(m, \alpha X + \beta_{n-1})$.

The other two connections specified in the theorem can be proved similarly by substituting α^{-1} and β_0 in place of α and β_{n-1} , respectively. \square

The four edges from $(m, X) \in Z_n \times GF(2^n)$ are shown in Figure 2.1. Because of (2.2), these edges are bidirectional. It should be pointed out here that even though the four edges in Figure 2.1 map to the four edges in Figure 1.1, the exact correspondence between them is dependent upon the source node (m, X) and, in particular, on the equality of $\text{Tr}(\alpha^n X)$ and the bit v_m of binary vector V . An edge from node (m, X) to $(m+1, \alpha X)$ is sometimes a *straight edge* and sometimes a *diagonal edge*. For example, as can be seen from Table 2.3, the edge between nodes $(1, \alpha^{22})$ and $(2, \alpha^{23})$ in B_5 is a straight edge since the binary labels of these nodes are $(0, 01100)$ and $(1, 01100)$, respectively. On the other hand, the edge between nodes $(1, \alpha^{23})$ and $(2, \alpha^{24})$ is a diagonal edge since the binary labels of these nodes are $(1, 01100)$ and $(2, 01110)$, respectively. Thus the correspondence between the binary labels and their algebraic counterparts is more intricate than one might initially suppose.

Redefining B_n in the new algebraic notation allows use of simple but powerful algebraic techniques to study its structure. Also, unlike the binary representation (Figure 1.1), in the new algebraic notation (Figure 2.1) the two indices of a node change independently between connected nodes. This independence further simplifies our investigation.

3. Mapping cycles on the butterfly. This section provides comprehensive results about cycles as subgraphs of B_n . We first prove exactly which cycles are *not* subgraphs of B_n (Theorem 3.1). Then we provide simple procedures to map to B_n all the permissible cycles, i.e., those that are not enumerated in Theorem 3.1 (Theorems 3.3, 3.6, and 3.7). Earlier, Rosenberg [11] has given mappings of cycles of lengths $L = n$ or $L = n2^n - (n - 2)c$, $1 \leq k \leq n$, $0 \leq c \leq 2^k$, on B_n . His results map at most $n + 2^{n+1} - 1$ cycles of different lengths on B_n when n is even and exactly $n + 2^{n+1} - 1$ cycles when n is odd. On the other hand, we give constructions of all the cycle subgraphs of B_n that are ever possible. Thus our methods map as many as

$n2^n - (n + 5)/2$ cycles of different lengths on B_n when n is odd and at least $n2^{n-1} - 3$, when n is even.

We begin by specifying which cycles can *never* be subgraphs of B_n .

THEOREM 3.1 (impossible cycles). *Simple cycles (i.e., cycles with distinct nodes) of the following lengths L are never subgraphs of B_n :*

- (a) *odd L when n is even,*
- (b) *odd L less than n ,*
- (c) *$L = 6$ when $n = 5$ or $n \geq 7$,*
- (d) *$L = 10$ when $n = 7, n = 9, \text{ or } n \geq 11$.*

Proof. (a). From Figure 2.1, if n is even and (m, X) is connected to (m', X') , then exactly one of m and m' is odd and the other is even. This implies that for even n , B_n is a *bipartite graph*, and therefore an odd-length cycle cannot be its subgraph.

(b). Note that because of the connectivity described in Figure 2.1, the first indices of all the nodes in the cycle may be translated by the same amount to get another equivalent cycle. Thus when $L < n$, the solution can be embedded on a butterfly *without* using any wrap-around edges. But an unwrapped butterfly is a bipartite graph and therefore cannot have an odd-length cycle subgraph.

(c) and (d). These cases may be proved by enumerating all possibilities of mapping the cycle and then illustrating contradictions in each case. First note that it is impossible to have the first indices of any five consecutive nodes in a cycle to be $m, m + 1, m, m + 1$, and m . Because if $(m, X) \rightarrow (m + 1, X_1) \rightarrow (m, X_2) \rightarrow (m + 1, X_3) \rightarrow (m, X_4)$ are the five connected nodes, then from Figure 2.1, $X_1 = \alpha X + c\beta_{n-1}$, $c \in \{0, 1\}$. This gives $X_2 = X + \beta_0$. Clearly, the only choices for X_3 are $\alpha X + \beta_{n-1}$ and αX , giving X_4 equal to $X + \beta_0$ or X . Thus node (m, X_4) is not distinct and the assumed chain of five nodes does not exist.

We can now demonstrate the impossibility of cycle mapping for $L = 6$. The case of $L = 10$ can be proved similarly. Let, if possible,

$$(m_0, X_0) \rightarrow (m_1, X_1) \rightarrow (m_2, X_2) \rightarrow (m_3, X_3) \rightarrow (m_4, X_4) \rightarrow (m_5, X_5) \rightarrow (m_0, X_0)$$

denote the length 6 cycle which is a subgraph of B_n , $n \geq 7$. Clearly, the first index of all cycle nodes can be increased or decreased by the same amount, or the direction of the cycle traversal may be reversed without disturbing the connectivity. Therefore, without loss of generality, one may choose $m_0 = 0$ and $m_1 = 1$. Clearly $m_5 = 1$ as well, because one cannot go from $m_1 = 1$ to $m_5 = n - 1$ in only 4 hops since $n \geq 7$. Indices m_2, m_3 , and m_4 should satisfy two conditions: (1) cyclically successive values in the sequence $(m_0, m_1, m_2, m_3, m_4, m_5)$ change only by 1; (2) no five cyclically consecutive values in the sequence are $(m, m + 1, m, m + 1, m)$. It can be verified that under these conditions, the only possible set of values for m_0 through m_5 are $(0, 1, 2, 3, 2, 1)$. Without loss of generality, let $X_0 = X$, $X_1 = \alpha X$, and $X_5 = \alpha X + \beta_{n-1}$. Then for $c_i \in \{0, 1\}$, following successive links, one gets $X_2 = \alpha^2 X + c_1\beta_{n-1}$, $X_3 = \alpha^3 X + c_1\alpha\beta_{n-1} + c_2\beta_{n-1}$, $X_4 = \alpha^2 X + c_1\beta_{n-1} + c_2\alpha^{-1}\beta_{n-1} + c_3\beta_0$, and $X_5 = \alpha X + c_1\alpha^{-1}\beta_{n-1} + c_2\alpha^{-2}\beta_{n-1} + c_3\alpha^{-1}\beta_0 + c_4\beta_0$. Equating the two values of X_5 and then using $\beta_{n-1} = \alpha\beta_0$ give

$$\alpha^2 + (c_1 + c_4)\alpha + (c_2 + c_3) = 0.$$

But this is impossible since α cannot satisfy an equation of degree smaller than n .

When $L = 6$ and $n = 5$, the only possible set of values of m_0 through m_5 that need to be considered are $(0, 1, 2, 3, 2, 1)$, $(0, 1, 0, 4, 3, 4)$, $(0, 1, 2, 1, 0, 4)$, and $(0, 4, 3, 2, 3, 4)$. Note that if all the indices in any set are increased by a constant amount, then the

set transforms into a rotated version of the first set. For example, by adding 2 to each index of the second set, one gets set (2, 3, 2, 1, 0, 1), which is simply the first set rotated left twice. Thus by dealing with only the first set, no generality is lost. But we demonstrated earlier that this first set does not produce a valid cycle of length 6. Therefore it is impossible to have a length 6 cycle as a subgraph of B_n when $n \geq 7$ or $n = 5$. \square

To obtain cycle mappings for lengths not specified in Theorem 3.1 we proceed as follows. Theorem 3.3 gives the mappings when the cycle length L is divisible by n .² This also includes the Hamiltonian cycle. For other lengths that may be expressed as $L = Kn + 2t \leq n2^n$, for some $K > 0$ and $0 \leq t < n$, Theorem 3.6 shows that one can first design a cycle of length Kn and then attach t pairs of new nodes to it. Finally, an alternate procedure to map cycles of lengths less than $4n$ (except 6 and 10) is provided in Theorem 3.7.

In order to prove the existence of cycles in butterfly networks, we need the following lemma.

LEMMA 3.2. $n \nmid (2^n - 1)$ for any integer $n > 1$.

Proof. The lemma is obvious when n is an even integer. Further, when n is an odd prime, according to *Fermat's little theorem*, $2^n = 2 \pmod n$ which shows that for prime n , $n \nmid (2^n - 1)$. If possible, let n be the smallest odd integer such that $n \mid (2^n - 1)$. Clearly n must be composite. Let p denote the largest odd prime in n , i.e., $n = p^t p_1^{t_1} p_2^{t_2} \dots$, where p, p_1, p_2, \dots are distinct primes, $p > p_1, p_2, \dots$. Consider the group G of integers less than n and relatively prime to n under the operation of multiplication modulo n . The Euler phi-function $\phi(n)$ which represents the number of elements in G is given by

$$(3.1) \quad \phi(n) = (p - 1)p^{t-1}(p_1 - 1)p_1^{t_1-1}(p_2 - 1)p_2^{t_2-1} \dots$$

As $2 \in G$, it satisfies

$$(3.2) \quad 2^{\phi(n)} = 1 \pmod n.$$

Now, if $n \mid (2^n - 1)$, then

$$(3.3) \quad 2^n = 1 \pmod n.$$

Equations (3.2) and (3.3) imply that

$$(3.4) \quad 2^{\gcd(\phi(n), n)} = 1 \pmod n.$$

Since p is the largest prime in n , the power of p in $\phi(n)$ according to (3.1) is $t - 1$. Therefore

$$(3.5) \quad \gcd(\phi(n), n) \mid (n/p).$$

From (3.4) and (3.5) one gets

$$2^{(n/p)} = 1 \pmod n,$$

and consequently,

$$(3.6) \quad 2^{(n/p)} = 1 \pmod{(n/p)}.$$

²We use the notation $n|L$ to indicate that L is a multiple of n , and $n \nmid L$ to indicate that L is not a multiple of n .

But this is contradictory to the assumption that n is the smallest integer satisfying $n \mid (2^n - 1)$. Hence there is no such n . \square

We can now state the theorems on cycles in butterfly networks.

THEOREM 3.3 (cycles of length divisible by n). *Suppose L is an arbitrary multiple of n and $L \leq n2^n$. Then cycle of length L can be mapped to B_n with dilation 1.*

Proof. Let $g = \gcd(n, 2^n - 1)$. From Lemma 3.2, one gets $n/g \geq 2$. We consider the following two cases based on the magnitude of L .

Case 1. $L \leq n(2^n - 1)/g$. If $L = n(2^n - 1)/g$, choose any nonzero $X \in GF(2^n)$. Otherwise, $\alpha^L \neq 1$ in $GF(2^n)$; choose X as

$$(3.7) \quad X = \beta_{n-1}(1 + \alpha^L)^{-1}.$$

The required cycle may then be constructed as

$$(3.8) \quad (0, X) \rightarrow (1, \alpha X) \rightarrow (2, \alpha^2 X) \rightarrow \dots \rightarrow ((L - 1) \bmod n, \alpha^{L-1} X) \rightarrow (0, X).$$

From the graph connectivity described earlier, each node on this cycle is connected to the next. Observe that (3.7) implies that $\alpha^L X = X + \beta_{n-1}$, so the last edge in (3.8) also is valid. Further, the first component of the node label repeats with periodicity of n and the second, with periodicity $(2^n - 1)$. Therefore the same label will repeat only with a periodicity of $n(2^n - 1)/g$. Thus for $L \leq n(2^n - 1)/g$, all the nodes in the cycle are distinct.

Case 2. $L > n(2^n - 1)/g$. Partition L as

$$(3.9) \quad L = n + L_1 + L_2 + \dots + L_t, \quad \text{where } (2^n - 1) \leq L_i \leq n(2^n - 1)/g \text{ and } n \mid L_i.$$

One way to achieve this partition is to choose

$$(3.10) \quad t = \left\lceil \frac{g(L - n)}{n(2^n - 1)} \right\rceil,$$

set $L_i = n(2^n - 1)/g$ for $1 \leq i < t$, and adjust L_t to make up the total to L . If this $L_t < 2^n - 1$, then reduce L_{t-1} by some amount and increase L_t by the same amount. Since $n/g \geq 2$, $L_{t-1} \geq 2(2^n - 1)$. Therefore, one can always find an appropriate amount to shift from L_{t-1} to L_t so as to make both $L_{t-1}, L_t \geq 2^n - 1$.

To build the required cycle, first obtain t disjoint cycles C_i of lengths L_i as in Case 1. Cycles of length $n(2^n - 1)/g$ may be constructed by starting from arbitrary nonzero nodes not used in previous cycles and always going from (m, x) to $(m+1, \alpha x)$. To create cycles of length less than $n(2^n - 1)/g$, compute the second index X of the starting node according to (3.7). Use a first index such that the node has not appeared in previous cycles. Note that this is possible because a node with the same second index repeats in a cycle only with a period of $2^n - 1$. In each cycle of length less than or equal to $n(2^n - 1)/g$, such labels occur at most n/g times. Since the number of cycles, t , is at most g (see (3.10)), unused labels (m, X) will be available to start new cycles.

Finally, build a cycle C_0 of length n as

$$(0, 0) \rightarrow (1, 0) \rightarrow (2, 0) \rightarrow \dots \rightarrow (n - 1, 0) \rightarrow (0, 0).$$

It is easy to see that the neighboring nodes in C_0 are connected and are distinct from those in the previous t cycles.

These $t + 1$ cycles can be merged together to form a single cycle as follows. Since each $L_i \geq 2^n - 1$, each cycle C_i , $1 \leq i \leq t$, contains consecutive elements

FIG. 3.1. Merging C_0 and C_i 's into a single cycle.

(m_i, β_0) and $(m_i + 1, \beta_{n-1})$ for some $0 \leq m_i < n$. To combine C_i and C_0 , add edges $(m_i, \beta_0) \rightarrow (m_i + 1, 0)$ and $(m_i + 1, \beta_{n-1}) \rightarrow (m_i, 0)$ and remove edges $(m_i, \beta_0) \rightarrow (m_i + 1, \beta_{n-1})$ and $(m_i, 0) \rightarrow (m_i + 1, 0)$. Since the m_i for each C_i is different, each C_i can be joined with C_0 at a different place. This process of cycle merging is sketched in Figure 3.1. The resultant cycle thus has the desired length L . \square

Note that for most values of n , we have $g = 1$. In fact, for $n \leq 20$, the only values of n for which $g > 1$ are 6, 12, and 18. Case 2 of Theorem 3.3 is mostly useful for these n 's. Using techniques similar to those of Theorem 3.3, it is also possible to map many disjoint cycles to B_n simultaneously. This is shown in the following corollary.

COROLLARY 3.4 (multiple cycles). *If $n|L$ and $L \leq t(2^n - 1)$ for some t , $0 < t < (n/g)$, one can map $g\lfloor n/(gt) \rfloor$ disjoint cycles of length L to B_n with dilation 1.*

Proof. Obtain X from (3.7) corresponding to the given L . Let h represent $(2^n - 1) \bmod n$. Begin the required cycles from

$$(3.11) \quad (hti_1 + i_2, X), \quad 0 \leq i_1 < \lfloor n/(tg) \rfloor, \quad 0 \leq i_2 < g,$$

and use the edges $(m, x) \rightarrow (m + 1, \alpha x)$ repeatedly until each cycle is complete.

From Theorem 3.3, it is clear that length of each cycle is L . We need only to prove that the nodes used in each cycle are distinct. Assume that, if possible, the i th node of the cycle beginning at $(hti_1 + i_2, X)$ is the same as the i' th node of the cycle beginning at $(hti'_1 + i'_2, X)$, i.e.,

$$(3.12) \quad (hti_1 + i_2 + i, \alpha^i X) = (hti'_1 + i'_2 + i', \alpha^{i'} X).$$

We will show that this implies that the two starting nodes are identical, i.e., $i_1 = i'_1$ and $i_2 = i'_2$. This being contradictory to the construction described above, we conclude that the cycles are disjoint.

By comparing the second indices of the nodes in (3.12) we get

$$(3.13) \quad i - i' = q(2^n - 1) \quad \text{for some integer } q.$$

Note that since $0 \leq i, i' < L = t(2^n - 1)$, one has $q < t$. Comparison of the first indices in (3.12) yields

$$ht(i_1 - i'_1) + (i_2 - i'_2) + q(2^n - 1) \equiv 0 \pmod{n}$$

or

$$(3.14) \quad h(t(i_1 - i'_1) + q) + (i_2 - i'_2) \equiv 0 \pmod{n}.$$

Note now from the definition of h that

$$(3.15) \quad g = \gcd(2^n - 1, n) = \gcd((2^n - 1) \bmod n, n) = \gcd(h, n).$$

By reducing each term in (3.14) modulo g (a factor of n and h), one gets

$$i_2 \equiv i'_2 \pmod{g}.$$

But since each $i_2, i'_2 < g$,

$$(3.16) \quad i_2 = i'_2.$$

Combining this with (3.14) and using (3.15) give

$$(3.17) \quad i_1 t + q \equiv i'_1 t \pmod{(n/g)}.$$

However, because of the bounds on i_1, i'_1, t , and q , one can verify that $i_1 t + q < (n/g)$ as well as $i'_1 t < (n/g)$. Therefore,

$$i_1 t + q = i'_1 t.$$

Since $q < t$, this gives

$$i_1 = i'_1. \quad \square$$

Corollary 3.4 allows one to efficiently utilize the butterfly architectures for concurrent computation of multiple algorithms, each having a cyclic communication structure. Thus, for example, in the case of B_6 , one can have 6 disjoint cycles of any length (divisible by 6) up to 60, or 3 disjoint cycles of any length (divisible by 6) up to 126.

We illustrate the construction by mapping four length 12 cycles to B_4 . To do this, we compute X from (3.7) in field $GF(2^4)$ as (refer to Table 2.1)

$$X = 1 \cdot (1 + \alpha^{12})^{-1} = \alpha^4.$$

The four disjoint cycles are then directly given by

$$\begin{aligned} &(0, \alpha^4) \rightarrow (1, \alpha^5) \rightarrow (2, \alpha^6) \rightarrow (3, \alpha^7) \rightarrow (0, \alpha^8) \rightarrow (1, \alpha^9) \rightarrow (2, \alpha^{10}) \\ &\quad \rightarrow (3, \alpha^{11}) \rightarrow (0, \alpha^{12}) \rightarrow (1, \alpha^{13}) \rightarrow (2, \alpha^{14}) \rightarrow (3, 1) \rightarrow (0, \alpha^4). \\ &(3, \alpha^4) \rightarrow (0, \alpha^5) \rightarrow (1, \alpha^6) \rightarrow (2, \alpha^7) \rightarrow (3, \alpha^8) \rightarrow (0, \alpha^9) \rightarrow (1, \alpha^{10}) \\ &\quad \rightarrow (2, \alpha^{11}) \rightarrow (3, \alpha^{12}) \rightarrow (0, \alpha^{13}) \rightarrow (1, \alpha^{14}) \rightarrow (2, 1) \rightarrow (3, \alpha^4). \\ &(2, \alpha^4) \rightarrow (3, \alpha^5) \rightarrow (0, \alpha^6) \rightarrow (1, \alpha^7) \rightarrow (2, \alpha^8) \rightarrow (3, \alpha^9) \rightarrow (0, \alpha^{10}) \\ &\quad \rightarrow (1, \alpha^{11}) \rightarrow (2, \alpha^{12}) \rightarrow (3, \alpha^{13}) \rightarrow (0, \alpha^{14}) \rightarrow (1, 1) \rightarrow (2, \alpha^4). \\ &(1, \alpha^4) \rightarrow (2, \alpha^5) \rightarrow (3, \alpha^6) \rightarrow (0, \alpha^7) \rightarrow (1, \alpha^8) \rightarrow (2, \alpha^9) \rightarrow (3, \alpha^{10}) \\ &\quad \rightarrow (0, \alpha^{11}) \rightarrow (1, \alpha^{12}) \rightarrow (2, \alpha^{13}) \rightarrow (3, \alpha^{14}) \rightarrow (0, 1) \rightarrow (1, \alpha^4). \end{aligned}$$

There is also another simple configuration of multiple cycles on B_n when $g = 1$. A cycle of length $L < n(2^n - 1)$, $n|L$, is given by

$$(0, X) \rightarrow (1, \alpha X) \rightarrow (2, \alpha^2 X) \rightarrow \dots \rightarrow ((L - 1), \alpha^{L-1} X) \rightarrow (0, X),$$

FIG. 3.2. Two cases of adding a pair of outside nodes to a cycle.

where

$$X = \beta_{n-1}(1 + \alpha^L)^{-1}.$$

It is easy to verify that all but n of the remaining nodes in B_n are also linked as a cycle. This *complementary cycle* of length $n2^n - n - L$ is given by

$$\begin{aligned} (L, \alpha^L X) &\rightarrow (L + 1, \alpha^{L+1} X) \rightarrow (L + 2, \alpha^{L+2} X) \rightarrow \dots \\ &\rightarrow (n(2^n - 1) - 1, \alpha^{n(2^n - 1) - 1} X) \rightarrow (L, \alpha^L X). \end{aligned}$$

One should also note that the only nodes which are not part of either the cycle of length L or its complementary cycle form a third cycle C_0 described earlier in Figure 3.1. Thus, when $g = 1$, the nodes of B_n can be partitioned into three cycles of lengths n , L , and $n2^n - L - n$ with the only condition on L being that it should be a multiple of n .

When $g > 1$ and cycle length $L \leq (2^n - 1)n/g$ is a multiple of n , one can similarly show that the nodes of B_n may be partitioned into g cycles of length L , g cycles of length $(2^n - 1)n/g - L$, and one cycle of length n .

We now present the result about mapping cycles of lengths that are *not* multiples of n . Our methodology is rather simple. We first form a cycle of a smaller length which is a multiple of n . Then we attach appropriately chosen pairs of outside nodes to this cycle. This process is illustrated in Figure 3.2. As shown in the figure, if the cycle link shown by the dashed line is removed and three new links are added, then the outside pair of nodes can be incorporated in the cycle. We will refer to this process as *attaching a node pair at (m, x)* . Further, the pair of nodes, (m, x) and $(m, x + \beta_0)$, which plays a crucial role in this process, will be called the pair of *companion nodes*. Note that the companion node labels have the same first index, and their second indices differ by β_0 .

For this method to succeed, it is necessary to find enough nodes in the cycle with their companion nodes outside the cycle. Lemma 3.5, to be presented later, will help us count (or in some cases, bound) the number of companion node pairs. This lemma will then be used to prove Theorem 3.6, which guarantees that there are, indeed, the required number of companion node pairs to construct cycles of any length.

For any $(m, X) \in Z_n \times GF(2^n)$, $X \neq 0$, define a *chain* starting from (m, X) to mean a set of distinct nodes

$$\{(m, X), (m + 1, \alpha X), (m + 2, \alpha^2 X), \dots, (m + T - 1, \alpha^{T-1} X)\}.$$

The number of nodes in the chain, T , will be called the length of the chain. The maximum value of T is $(2^n - 1)n/g$. Butterfly connectivity described in Figure 2.1 shows that the consecutive nodes in a chain are connected.

Let (m, α^i) be any node of B_n . We refer to the quantity $(i - m) \bmod g$ as the *partition index* of that node. Clearly, all the nodes (m_i, α^i) of a chain have the same partition index. This is because from one node to the next, m_i increases by 1 mod n and the power of α , by 1 mod $(2^n - 1)$. The $n(2^n - 1)$ nodes of B_n with nonzero second index may be separated into g partitions based on their partition index. Each partition has exactly $n(2^n - 1)/g$ nodes. Each chain is confined to a single partition. Chains of length $n(2^n - 1)/g$ occupy a complete partition.

In the light of this new terminology, one can see that when $g = 1$, a cycle formed as in (3.8) is also a chain. Further, for $g \neq 1$, cycles C_1, C_2, \dots, C_t described in Theorem 3.3 can also be viewed as chains in distinct partitions. Therefore, the number of companion node pairs that may be used to extend the cycle length can be obtained by studying companion node pairs in relation to chains. We call a companion node pair to be *within a chain* if both its nodes are in the same chain. If the two nodes are in different chains, we call that companion node pair to be *across chains*. The following lemma explores the bounds on these numbers.

LEMMA 3.5 (companion node pairs within and across chains).

(a) *The number of companion node pairs, $\Gamma(T)$, confined to a chain of length T satisfies*

$$(3.18) \quad \Gamma(T) \leq \begin{cases} \lfloor (T - 1)/n \rfloor & \text{if } T \leq 2^n - 1, \\ \lfloor (T - 1)/n \rfloor + \Gamma(T - (2^n - 1)) & \text{otherwise.} \end{cases}$$

(b) *The number of companion node pairs across two disjoint chains of lengths $T_1, T_2 \leq 2^n - 1$ is at most $\lfloor (T_1 + T_2)/n \rfloor + 1$.*

(c) *The number of companion pairs across the two chains (not necessarily disjoint) of lengths $T_1 = 2^n - 1$ and $T_2 = (2^n - 1)n/g$, is exactly $(2^n - 1)/g$ or $\lfloor (2^n - 1)/g \rfloor - 1$.*

Proof. (a) Let the chain begin at (m, X) . Consider a companion pair $(m + i, \alpha^i X)$ and $(m + j, \alpha^j X)$, $i < j$. By distance between the nodes of a companion pair we will mean the quantity $j - i$. Because these nodes are companions,

$$(3.19) \quad i \equiv j \pmod{n}$$

and

$$(3.20) \quad \alpha^i X + \alpha^j X = \beta_0.$$

From (3.20) one gets

$$(3.21) \quad \alpha^{j-i} X + X = \alpha^{-i} \beta_0.$$

Consider now another distinct companion node pair $(m + i', \alpha^{i'} X)$ and $(m + j', \alpha^{j'} X)$, $i' < j'$. For this pair, one could similarly show that

$$(3.22) \quad \alpha^{j'-i'} X + X = \alpha^{-i'} \beta_0.$$

If $i, i' < 2^n - 1$, then (3.21) and (3.22) imply that the distance $j' - i'$ must be different from $j - i$; or else α^i would equal $\alpha^{i'}$, which is impossible for $i, i' < 2^n - 1$. Further, from (3.19), the distances must always take values that are multiples of n . Therefore there are at most $\lfloor (T - 1)/n \rfloor$ companion node pairs when $T \leq 2^n - 1$.

For larger values of T , either the first node of the pair is within the first $2^n - 1$ nodes of the chain, or the pair is entirely confined to the last $T - (2^n - 1)$ elements of

the chain. Since the number of companion node pairs of these two kinds are at most $\lfloor (T - 1)/n \rfloor$ and $\Gamma(T - (2^n - 1))$, respectively, we get the stated bound.

(b) Let the two chains begin at (m, X) and (m', X') . Consider a companion pair $(m + i, \alpha^i X)$ and $(m' + j, \alpha^j X')$ across the chains. By arguments similar to part (a), $j - i$ must be a multiple of n . Since $-T_1 \leq j - i \leq T_2$, we get the specified bound on the number of pairs.

(c) Let $T_1 = 2^n - 1$ and $T_2 = (2^n - 1)n/g$. Denote by g_1 and g_2 , the partition indices of the nodes in the two chains. Let (m, α^i) be a typical node of the first chain, $0 \leq i \leq 2^n - 2$. We want to determine if its companion (m, α^j) is in the second chain. Since the second chain occupies a whole partition, the companion will belong to it if its partition index is g_2 . When $\alpha^i = \beta_0$, the companion, $(m, 0)$, is clearly not a member of the second chain. When $\alpha^i \neq \beta_0$, from the companion relationship between nodes (m, α^i) and (m, α^j) , one gets $\alpha^{j-i} = 1 + \alpha^{-i}\beta_0$. Thus for each of the $2^n - 2$ values of i (excluding the one corresponding to $\alpha^i = \beta_0$), $j - i \pmod{(2^n - 1)}$ takes a different value. Consequently it assumes all the values from 0 to $2^n - 2$ except one. Now, one has

$$\begin{aligned} \text{partition index of } (m, \alpha^j) &= j - m \pmod{g} \\ &= ((j - i) \pmod{(2^n - 1)} + g_1) \pmod{g}. \end{aligned}$$

Since $(j - i) \pmod{(2^n - 1)}$ takes all values from 0 to $2^n - 2$ except one, the partition index of (m, α^j) will assume value g_2 exactly $(2^n - 1)/g$ or $\lfloor (2^n - 1)/g \rfloor - 1$ times, showing that there exist exactly these many companion node pairs between the two chains. \square

Note that the two chains of part (c) of Lemma 3.5 may overlap, unlike those of part (b).

We now state Theorem 3.6 relating to mapping cycles of all allowed lengths larger than $2n$ to B_n . (Actually, odd lengths between n and $2n$ are also covered by this result.) Because of Lemma 3.5, this theorem only needs to prove the existence of sufficient number of external node pairs to attach to the cycle constructed as per Theorem 3.3.

THEOREM 3.6 (arbitrary length cycles of lengths $\geq n$).

(a) For odd n , a cycle of any length L , $n \leq L \leq n2^n$, excluding even values of L less than $2n$, can be mapped to B_n with dilation 1.

(b) For even n , a cycle of any even length L , $n \leq L \leq n2^n$, can be mapped to B_n with dilation 1.

Proof. If $n|L$, the desired cycle is already addressed in Theorem 3.3. For other L values, first form a cycle of length Kn using Theorem 3.3, where K is the largest possible number such that $Kn < L$ and $L - Kn$ is even. We will call this cycle the primary cycle. By adding up to $n - 1$ pairs of outside nodes to the primary cycle we get the required cycle of length L . (If $K = 2^n - 1$, one needs to add only up to $\lfloor n/2 \rfloor$ pairs to get the largest required length.)

We will show that there are sufficient number of nodes in the primary cycle without their companion nodes. Following the method of Figure 3.2, one can attach a pair of external nodes at each of these nodes. We first prove the theorem when $g = 1$ (Case 1). Cases 2, 3, and 4 deal with $g > 1$, and assume $n \geq 6$ since it is the smallest n for which $g \neq 1$. The parameter that distinguishes these cases is t , the number of smaller cycles C_1, C_2, \dots, C_t that are merged as in Theorem 3.3 to obtain the primary cycle.

Case 1. $g = 1$. If $K = 1$, then each node of the primary cycle is without its companion node, and each new added node pair is distinct. The first part of this is true because companion node pairs must have a distance of at least n . To see the second part, compare the pairs added at two consecutive cycle nodes, say, (m, X) and $(m + 1, \alpha X)$. The outside pair added at the first node is $(m, X + \beta_0) \rightarrow (m + 1, \alpha X + \beta_{n-1})$, and the one added at the second node is $(m + 1, \alpha X + \beta_0) \rightarrow (m + 2, \alpha^2 X + \beta_{n-1})$. Clearly all these four new nodes are distinct. In a similar fashion, one can show that up to $n - 1$ new distinct pairs of nodes may be added to the cycle.

When $K = 2^n - 1$, the primary cycle consists of all the nodes (m, X) , $0 \leq m < n$, $X \in GF(2^n)$, $X \neq 0$. In this case, at each node (m, β_0) in the cycle, one can attach an outside pair $(m, 0) \rightarrow (m + 1, 0)$. Distinctness of the new pairs can be ensured by using only even values of m . In this manner, up to $\lfloor n/2 \rfloor$ pairs of outside nodes may be attached to the cycle to achieve the required length.

Unfortunately, when $2 \leq K \leq 2^n - 2$, the second node of a pair may, at times, turn out to be the same as the first node of another pair. We therefore would not be able to add both these pairs to the cycle at the same time. However, if we have $2(n - 1)$ nodes without their companion nodes, we can guarantee adding at least half of the outside node pairs, i.e., $(n - 1)$ pairs. We will now show that the primary cycle, indeed, contains $2(n - 1)$ nodes without their companion nodes. We will prove this for $Kn \leq n(2^n - 1)/2$ only. For larger Kn values, one may consider the complementary cycle of length $n(2^n - 1) - Kn$ and prove similarly the existence of at least $2(n - 1)$ nodes therein, which have their companion nodes outside, i.e., in the original cycle of length Kn .

Using Lemma 3.5(a) we can find the maximum number of companion node pairs within the cycle of length Kn . Subtracting these nodes from the total number of nodes in the cycle, we find that at least

$$(3.23) \quad Kn - 2\Gamma(Kn)$$

cycle nodes have companion nodes outside the cycle. For $Kn \leq 2^n - 1$, use of Lemma 3.5(a) in (3.23) gives

$$\begin{aligned} \text{number of nodes with external companions} &\geq Kn - 2(K - 1) \\ &= (2n - 2) + (n - 2)(K - 2) \\ &> 2n - 2. \end{aligned}$$

This proves that there are sufficient number of companion node pairs in the primary cycle where new node pairs may be attached.

To prove the result for $Kn > 2^n - 1$ by mathematical induction, assume its truth for length $Kn - (2^n - 1)$; i.e., assume that

$$[Kn - (2^n - 1)] - 2\Gamma(Kn - (2^n - 1)) \geq 2n - 2.$$

Recall that we need only to prove the result for $Kn \leq n(2^n - 1)/2$. One now gets for the primary cycle of length Kn ,

$$\begin{aligned} \text{no. of nodes with external companions} &\geq Kn - 2[\lfloor (Kn - 1)/n \rfloor + \Gamma(Kn - (2^n - 1))] \\ &\geq (2n - 2) + (2^n - 1) - 2(K - 1) \\ &\geq (2n - 2) + 2 \\ &> 2n - 2. \end{aligned}$$

Case 2. $g > 1$ and $t < g$. If the primary cycle length $Kn \leq 2^n - 1$, the situation is similar to that of Case 1. For $Kn > 2^n - 1$, we proceed as follows. Since $t < g$, at least one partition representing a chain of length $n(2^n - 1)/g$ is not used in the primary cycle. Consider this chain and a chain of length $2^n - 1$ in C_1 of nodes used in the primary cycle. From Lemma 3.5(c), there are at least $\lfloor (2^n - 1)/g \rfloor - 1$ companion node pairs across them. But note that for $n \geq 6$, $2^n - 1 > n^2$. Further, $g \leq n/2$. Therefore $\lfloor (2^n - 1)/g \rfloor - 1 > 2n - 2$ showing that at least $2n - 2$ companion node pairs exist between the primary cycle and the remaining nodes.

Case 3. $g > 1$, $t = g$ and cycles C_1, C_2, \dots, C_{t-1} have lengths $n(2^n - 1)/g$. If the number of nodes left out of the primary cycle is less than or equal to $2^n - 1$, then one can prove this case in a manner similar to Case 1 except that the focus will now be on the nodes that are *not* in the cycle rather than those that are part of the cycle. But the final consequence is the same: there are enough companion pairs between the nodes in the cycle and those outside. If the number of nodes outside the primary cycle is more than $2^n - 1$, then a chain of length $2^n - 1$ of these outside elements will have at least $\lfloor (2^n - 1)/g \rfloor - 1$ companion nodes within C_1 . (Lemma 3.5(c)). This number is greater than $2n - 2$ (for $n \geq 6$) showing that there are enough companion node pairs between the primary cycle and the outside nodes.

Case 4. $g > 1$, $t = g$ and cycles C_1, C_2, \dots, C_{t-2} have lengths $n(2^n - 1)/g$. First note that because g is odd, when $g \neq 1$, $g \geq 3$. Thus, in this case, cycle C_1 of $n(2^n - 1)/g$ nodes is part of the primary cycle. Further, from the construction in Theorem 3.3, for this case to exist, the number of unused nodes in partitions of C_{t-1} and C_t —call them R_1 and R_2 , respectively—must satisfy

$$(3.24) \quad R_1 + R_2 > (2^n - 1)(n/g - 1).$$

Without loss of generality, let $R_1 \leq R_2$. Clearly, both these sets of unused elements form chains. If either of these chains has at least $2^n - 1$ elements, then at least $(2^n - 1)/g$ of them will have companion nodes in C_1 . Thus as in Case 3, there are enough companion node pairs between the nodes of the companion cycle and those outside. On the other hand, if both $R_1, R_2 < 2^n - 1$, then from Lemma 3.5(a) and (b), one can see that there are at most $\lfloor (R_1 - 1)/n \rfloor$ and $\lfloor (R_2 - 1)/n \rfloor$ companion node pairs within these chains and $\lfloor (R_1 + R_2)/n \rfloor + 1$ across the two chains. Since there are a total of $R_1 + R_2$ nodes in these two chains, the rest of their nodes must have companions in the primary cycle. Since R_1 and R_2 are multiples of n , $\lfloor (R_1 - 1)/n \rfloor = (R_1/n) - 1$ and $\lfloor (R_2 - 1)/n \rfloor = (R_2/n) - 1$. Using (3.24) one thus gets that the number of companion node pairs between the primary cycle and those outside to be at least

$$(3.25) \quad \begin{aligned} (R_1 + R_2) - 2[R_1/n - 1 + R_2/n - 1 + (R_1 + R_2)/n + 1] &= (R_1 + R_2)(1 - 4/n) + 2 \\ &> (2^n - 1)(n/g - 1)(1 - 4/n) + 2 \\ &\geq (2^n - 1)/3 + 2 \\ &> (2n - 2). \end{aligned}$$

The simplification in the third line of (3.25) is based on the fact that $(n/g) \geq 2$ and $(1 - 4/n) \geq 1/3$ for $n \geq 6$, while last line of (3.25) is true for any $n \geq 6$. \square

Theorem 3.6 proves that there are sufficient number of nodes in the primary cycle where one can attach outside node pairs to obtain any desired length cycle as long as this length can be expressed as $Kn + 2t$. Construction of such a cycle is rather straightforward; once the primary cycle is obtained as per Theorem 3.3, one only needs to identify the required number of cycle nodes whose companions are outside

FIG. 3.3. A length 12 cycle mapped to $Z_5 \times GF(2^5)$ with dilation 1.

FIG. 3.5. Cycles of length 12 and 21 in B_5 .

the cycle. Finding a small number of these nodes is a relatively simple process. New node pairs may be attached at these nodes as in Figure 3.2 to get the desired cycle.

We illustrate this process by constructing length 12 and 21 cycles in B_5 . The final construction is shown in Figures 3.3 and 3.4. To construct the cycle of length 12, one first uses Theorem 3.3 to create a primary cycle of length 10 (beginning at $(0, \alpha^4)$). Since $(0, \alpha^9)$ belongs to the cycle, but not its companion $(0, \alpha^9 + \beta_0) = (0, \alpha^{25})$, we add the indicated pair to get length 12 cycle. (Note that companions of none of the nodes in this length 10 cycle are present in it. Thus one could have added a new node pair at any of these nodes.) Similarly, a length 21 cycle is obtained by first creating a primary cycle of length 15 (beginning at $(0, \alpha^{26})$) and then adding pairs of new nodes at $(1, \alpha^6)$, $(2, \alpha^7)$, and $(3, \alpha^8)$. These cycles translated to binary notation using Table 2.3 are shown in Figure 3.5.

$$\begin{aligned}
 (0, 0) & \qquad \qquad \qquad \rightarrow (1, 0) & \qquad \qquad \qquad \cdots \rightarrow (K, 0) & \qquad \qquad \rightarrow \\
 (K - 1, \beta_0) & \qquad \qquad \rightarrow (K - 2, \beta_0(\alpha^{-1} + 1)) & \qquad \cdots \rightarrow (0, \beta_0 \sum_{i=0}^{K-1} \alpha^{-i}) & \rightarrow \\
 (1, \beta_0 \sum_{i=-1}^{K-2} \alpha^{-i}) & \qquad \rightarrow (2, \beta_0 \sum_{i=-2}^{K-3} \alpha^{-i}) & \qquad \cdots \rightarrow (K, \beta_0 \sum_{i=-K}^{-1} \alpha^{-i}) & \rightarrow \\
 (K - 1, \beta_0 \sum_{i=-(K-1)}^{-1} \alpha^{-i}) & \rightarrow (K - 2, \beta_0 \sum_{i=-(K-2)}^{-1} \alpha^{-i}) & \cdots \rightarrow (1, \beta_0 \sum_{i=-1}^{-1} \alpha^{-i}) & \rightarrow (0, 0)
 \end{aligned}$$

FIG. 3.6. Length $4K$ cycle mapping to B_n ($K < n$).

Unfortunately, Theorem 3.6 does not cover all the cycles that can possibly be mapped to B_n . Particularly, when n is odd, Theorem 3.6 does not provide constructions of cycles of even lengths less than $2n$ and when n is even, it excludes even lengths less than n . We now illustrate a technique to cover these cases. Using this technique, one can easily map cycles of even lengths less than $4n$ (except possibly lengths 6 and 10) to B_n with dilation 1. This implies that all the cycles that are not proved to be impossible in Theorem 3.1 can indeed be mapped to B_n . This final result about cycles is stated in Theorem 3.7.

THEOREM 3.7 (comprehensive cycle mapping). *One can map to B_n all cycles, except those identified in Theorem 3.1, with dilation 1.*

Proof. Because of Theorem 3.6, the only cycles we need to map to B_n are those with even lengths less than $2n$. We can use the following construction for even lengths less than $4n$.

If $L = 4K$, $K < n$, construct the cycle as follows.

Start from node $(0, 0)$. Let (m, X) denote the current node on the cycle. Use K times link $(m, X) \rightarrow (m+1, \alpha X)$. Then use K times link $(m, X) \rightarrow (m-1, \alpha^{-1}X + \beta_0)$. Follow it K times with link $(m, X) \rightarrow (m + 1, \alpha X)$. Finally, K times, travel along $(m, X) \rightarrow (m - 1, \alpha^{-1}X + \beta_0)$. This will bring you back to the starting node $(0, 0)$. Figure 3.6 shows this length $4K$ cycle.

One can see from the connectivity of B_n , shown in Figure 2.1, that the consecutive nodes in the cycle above are indeed connected. We need only to show that they are distinct. The only two nodes in the cycle with the first index of the label 0 are $(0, 0)$ and $(0, \beta_0 \sum_{i=0}^{K-1} \alpha^{-i})$. Clearly these are not the same since $K < n$. For the same reason, the two nodes with the first index of label being K , $(K, 0)$ and $(K, \beta_0 \sum_{i=-K}^{-1} \alpha^{-i})$ are distinct. The four cycle nodes with the same first index m , $0 < m < K$, are $(m, 0)$, $(m, \beta_0 \sum_{i=0}^{K-1-m} \alpha^{-i})$, $(m, \beta_0 \sum_{i=-m}^{K-1-m} \alpha^{-i})$, and $(m, \beta_0 \sum_{i=-m}^{-1} \alpha^{-i})$. One can see that the second indices of these four nodes are distinct because $K < n$ and α , being a primitive element of $GF(2^n)$, cannot satisfy any equation of degree less than n . Thus one can map all cycles of length $4K$, $K < n$, to B_n with dilation 1.

If $L = 4K + 2$ and $K > 2$, one can add a pair $(2, \beta_{n-1}) \rightarrow (1, \beta_0)$ of new nodes between the cycle nodes $(1, 0) \rightarrow (2, 0)$ as in Figure 3.2. Thus, replacing the first three elements in the cycle of Figure 3.6 by the five elements: $(0, 0) \rightarrow (1, 0) \rightarrow (2, \beta_{n-1}) \rightarrow (1, \beta_0) \rightarrow (2, 0)$, one gets a new cycle of length $4K + 2$. It is easy to verify that the new elements were indeed absent from the original cycle when $K > 2$. Thus one can map all cycles of length $4K + 2$, $2 < K < n$, to B_n with dilation 1. The only even-length cycles less than $4n$ excluded by this procedure have lengths 6 and 10. \square

The construction of Theorem 3.7 may be illustrated by mapping a cycle of length 14 to B_5 . Since $14 = 12 + 2$, we first construct a cycle of length 12 and then add a new pair to it. The final cycle and its binary translation are shown in Figures 3.7 and 3.8.

FIG. 3.7. A length 14 cycle mapped to $Z_5 \times GF(2^5)$.

$$\begin{aligned}
 (0, 00000) &\rightarrow (1, 00000) \rightarrow (2, 00010) \rightarrow (1, 00010) \rightarrow (2, 00000) \rightarrow \\
 (3, 00000) &\rightarrow (2, 00100) \rightarrow (1, 00110) \rightarrow (0, 00110) \rightarrow (1, 00111) \rightarrow \\

 \end{aligned}$$

FIG. 3.8. A length 14 cycle in B_5 .

4. Mapping binary trees on the butterfly. This section presents two results about mapping trees to B_n . We first show that it is possible to map multiple nonoverlapping balanced binary trees with dilation 1 to this network (Theorem 4.1). Next, by combining these trees, we show that one can map the largest possible binary tree to B_n with a slightly higher dilation (Theorem 4.3). With the new model for B_n , both these tasks are relatively simple.

In the discussion that follows, we restrict ourselves to balanced binary trees. By level of a node in the tree we will mean its distance from the root. An m -level tree has nodes in levels $0, 1, \dots, m - 1$. Each parent has exactly two children. Thus the m -level tree has 2^{m-1} leaves and $2^m - 1$ total nodes. All the logarithms are assumed to be base 2.

THEOREM 4.1 (multiple trees). *One can map n nonoverlapping n -level binary trees to B_n with dilation 1.*

Proof. Choose node (i, β_{n-1}) to be the root of the i th tree, $0 \leq i < n$. Construct each tree by the simple rule that the children of any node (j, x) are nodes $(j + 1, \alpha x)$ and $(j + 1, \alpha x + \beta_{n-1})$.

Clearly, both the children in each tree node are connected to the parent by a direct edge (see Figure 2.1). We need only to prove that all the nodes in these trees are distinct. Note that, because of the way the trees are constructed, the nodes in level j of i th tree have labels $((i + j) \bmod n, \beta_{n-1} f(\alpha))$ where $f(\alpha)$ are distinct binary polynomials of α of degree j . Clearly, nodes on different levels of a tree are distinct since their first indices are unequal. Similarly, all nodes on the same level of a tree are also distinct; otherwise, their second indices, $\beta_{n-1} f_1(\alpha)$ and $\beta_{n-1} f_2(\alpha)$ will be equal, implying that $f_1(\alpha) - f_2(\alpha)$, a polynomial in α of degree less than n , equals zero. This is impossible since α is a primitive element of $GF(2^n)$. Finally, suppose a node $((i_1 + j_1) \bmod n, \beta_{n-1} f_1(\alpha))$ of tree i_1 is identical to the node $((i_2 + j_2) \bmod n, \beta_{n-1} f_2(\alpha))$ of a different tree i_2 . Since the first indices of the two nodes are the same, $j_1 \neq j_2$. Thus, equality of the second index implies two polynomials

FIG. 4.1. Four nonoverlapping 4-level trees mapped to B_4 with dilation 1.

$f_1(\alpha)$ and $f_2(\alpha)$ of unequal degrees (and each less than n) are equal. This is again impossible in $GF(2^n)$. Therefore all nodes in all trees are distinct. \square

Bhatt et al. [2] have previously proved the same result stated in Theorem 4.1. However, our construction is based on the butterfly modeled as $Z_n \times GF(2^n)$ and is necessary to obtain the mapping of the largest tree as given in Theorem 4.3.

Note that the mapping given in Theorem 4.1 is optimum in the sense that it describes the maximum number of nonoverlapping n -level binary trees that may be mapped to B_n . Clearly the unused n nodes, $\{(i, 0) \mid 0 \leq i < n\}$, do not support another n -level tree. Figure 4.1 shows mapping of four disjoint trees to B_4 .

We now focus on mapping the single largest binary tree to B_n . Such a tree would have $n + \lceil \log n \rceil$ levels and would use $2^{\lceil \log n \rceil} 2^n - 1$ nodes of B_n . For n values which are powers of 2, such a tree would span all but one node of B_n . For other values of n , this is the largest tree that may be mapped to B_n , because increasing the number of tree levels even by 1 will imply more nodes than the number of nodes of B_n .

We create this tree by first designing the top $\lceil \log n \rceil$ levels using nodes unused in Theorem 4.1. Then two n -level trees generated as in Theorem 4.1 are attached at each leaf of this tree. Since a $\lceil \log n \rceil$ -level tree has at most $n/2$ leaves, the n nonoverlapping trees obtained in Theorem 4.1 suffice. The top tree, however, needs to be designed carefully since its leaves should be able to connect (with low dilation) to the roots of the lower n -level trees which are very specific. Recall that the only nodes unused in Theorem 4.1 are $(i, 0)$, $0 \leq i < n$. Lemma 4.2 provides the required mapping of the $\lceil \log n \rceil$ -level tree to these nodes.

LEMMA 4.2. *One can map a $\lceil \log n \rceil$ -level binary tree to nodes $(i, 0)$, $0 \leq i < n$, of B_n such that all its leaves are mapped to $(i, 0)$ with odd i . Further, the dilation of this mapping is $2^{\lceil \log n \rceil} / 4$.*

Proof. Let n' denote $\lceil \log n \rceil$. Number the tree levels 0 through $\lceil \log n \rceil - 1$ with the root at level 0. Map the tree root to node $(2^{n'-1}, 0)$. Map the children of a parent $(i, 0)$ at level l of the tree to nodes $(i - 2^{n'-2-l}, 0)$ and $(i + 2^{n'-2-l}, 0)$.

One can verify that this procedure maps 2^l tree vertices at level l to nodes $(2^{n'-1-l}p, 0)$, with odd p , $1 \leq p \leq 2^{l+1} - 1$. Thus all tree nodes are mapped to distinct nodes of B_n . The leaves of this tree are mapped to $(p, 0)$ as specified.

FIG. 4.2. The top of the tree in B_n , $8 \leq n < 16$ (with dilation marked on each edge). The last row contains the roots of n -level trees. (For brevity, a root (i, β_{n-1}) is shown only as (i) . Further, $(8)^*$ denotes root $(0, \beta_{n-1})$ when $n = 8$.)

Further, the paths from the image of a parent at level l to images of its children are of length $2^{n'-2-l}$. The longest of these paths gives the specified dilation of the mapping. \square

The mapping of Lemma 4.2 exhibits a congestion of $(n' - 1)$; i.e., $(n' - 1)$ paths corresponding to tree edges pass through a single edge B_n . To see this, first note that all the paths in B_n corresponding to edges of any single tree level are disjoint. Thus the congestion cannot exceed $(n' - 1)$. One can also show that the B_n edge between nodes $(\lfloor 2^{n'}/3 \rfloor, 0)$ and $(\lfloor 2^{n'}/3 \rfloor + 1, 0)$ carries paths corresponding to a tree edge at every level. Thus this B_n edge has a congestion of $(n' - 1)$.

We now combine Theorem 4.1 and Lemma 4.2 to derive the central result of this section.

THEOREM 4.3 (tree mapping). *One can map a binary tree of $n + \lfloor \log n \rfloor$ levels to B_n with dilation 2 if $n < 16$, 3 if $16 \leq n < 32$, 4 if $32 \leq n < 64$, and $2^{\lfloor \log n \rfloor} / 4$ if $n \geq 64$.*

Proof. We map the top $\lfloor \log n \rfloor$ levels of the tree as in Lemma 4.2. Note that the leaves of this $\lfloor \log n \rfloor$ -level tree are mapped to $(i, 0)$ for odd i . At each leaf $(i, 0)$ we attach two n -level trees generated according to Theorem 4.1 with roots at (i, β_{n-1}) and $(i + 1, \beta_{n-1})$. Obviously all the nodes in the resultant $(n + \lfloor \log n \rfloor)$ -level tree are distinct.

Further, the roots of the n -level tree are at distances 2 and 1 from the corresponding leaves of the $\lfloor \log n \rfloor$ -level tree. The dilation within the lower n -level trees is 1. Therefore the overall dilation of the tree is dictated by the dilation within the top $\lfloor \log n \rfloor$ levels which, according to Lemma 4.2, is $2^{\lfloor \log n \rfloor} / 4$.

As an example, the $\lfloor \log n \rfloor$ -level tree for $8 \leq n < 16$ is shown in Figure 4.2. The top three levels of this tree are generated from Lemma 4.2, and the fourth level shows the roots of n -level trees. When $16 \leq n < 64$, one can use the top trees shown in Figures 4.3 and 4.4 rather than the ones obtained from Lemma 4.2. These trees are obtained by shuffling certain nodes of the tree obtained from Lemma 4.2 to reduce the dilation. Since in the new $\lfloor \log n \rfloor$ -level trees the leaves are not necessarily at $(i, 0)$ with odd i 's, the choice of the n -level trees attached to each leaf is also different. The last rows of these figures specify the roots of the n -level trees to be attached to each leaf. \square

The tree mapping strategy presented here is interesting because of its extreme simplicity. The bottom n levels of the tree using $2^{\lfloor \log n \rfloor} (2^n - 1)$ nodes are mapped in a very systematic manner. The top $\lfloor \log n \rfloor$ levels of the tree using fewer than n nodes may also be algorithmically created using Lemma 4.2. The overall dilation is decided

FIG. 4.3. A better top for a tree in B_n , $16 \leq n < 32$ (with dilation marked on each edge). The last row contains the roots of the n -level trees. (For brevity, a root (i, β_{n-1}) is shown only as (i) . Further, $(16)^*$ denotes root $(0, \beta_{n-1})$ when $n = 16$.)

FIG. 4.4. A better top for a tree in B_n , $32 \leq n < 64$ (with dilation marked on each edge). The last row contains the roots of the n -level trees. (For brevity, a root (i, β_{n-1}) is shown only as (i) . Further, $(32)^*$ denotes root $(0, \beta_{n-1})$ when $n = 32$.)

by the dilation within these top levels. The dilation may be reduced by modifying the top tree. Fortunately, for every set of n values between two consecutive powers of 2, one needs to design a single top tree. We have altered the top tree to limit dilation to 3 when $16 \leq n < 32$ and to 4 when $32 \leq n < 64$. Such alterations may sometimes increase the congestion. The congestions of the top trees of Figures 4.2 and 4.3 are 2 and 3, respectively. These values are identical to the congestions of the same size top trees built using Lemma 4.2. But for the range $16 \leq n < 32$, the congestion of the top tree in Figure 4.4 is 6 as against the congestion of 4 for the top tree built using Lemma 4.2. Note that this increase in congestion yields a decrease of dilation from 8 to 4.

5. Conclusion. This paper has given a new model for the wrap-around butterfly networks and has demonstrated its utility to obtain mappings of cycles and trees.

Our results about cycle mappings are presented in Table 5.1. We have identified all cycles that could be subgraphs of butterfly networks and have provided their

mappings. We give two procedures for mapping cycles to B_n : one that is applicable to cycles of even lengths less than $4n$ and the other for larger lengths. In the first case, the cycle is established directly. In the second, one sets up a cycle of length divisible by n and then augments it with a small number of node pairs to make up the required length. Earlier results [11] about cycle mappings on B_n had identified $O(2^n)$ cycle subgraphs each with a different length, whereas we provide $O(n2^n)$ cycle subgraphs of different lengths.

Our results about tree mappings are listed in Table 5.2. Using our methods one can map the largest possible balanced binary tree to B_n , $n < 16$, with a small dilation of 2. One may note that B_{15} , the biggest butterfly network to which this result applies, has almost half a million nodes. We also give maximal tree mappings in larger butterflies with bounded dilation. For $16 \leq n < 32$, the dilation is 3, and for $32 \leq n < 64$, it is 4. Thus even though the tree mapping results presented here are asymptotically poor as compared to the earlier work [2, 6] (dilation and congestion $O(n)$ as against $O(1)$), for practical network sizes of up to $n = 64$, they have low dilation and congestion. Further, unlike the earlier mappings, ours does not require a larger size butterfly to ensure the one-to-one (load = 1) mapping. Thus to map the same tree, we use a butterfly with at most half the nodes as before. Our trees have unit dilation in their lower n levels. A larger dilation may be present only within the top $\lfloor \log n \rfloor + 1$ levels that employ fewer than n nodes.

The simplicity of the mappings obtained here is essentially due to our identification of the butterfly network with the direct product of a group and a finite field. We have shown that in the context of this model, the network connectivity may be expressed as an algebraic relationship between the node labels. One may then employ the powerful tools of abstract algebra to explore the structural properties of the network. Even though we have limited our investigation here to certain mappings, we

believe that these methods hold a lot of promise for other aspects of these networks as well.

Acknowledgment. The authors wish to thank anonymous referees for comments and suggestions that improved the paper tremendously.

WDM SWITCHING NETWORKS, REARRANGEABLE AND NONBLOCKING $[w, f]$ -CONNECTORS*

HUNG Q. NGO[†]

Abstract. We propose a framework to analyze and compare wavelength division multiplexed (WDM) switching networks qualitatively and quantitatively. The framework not only helps analyze and compare the complexity of WDM switching networks but also explains interesting properties of different designs. Then several important problems arising from this idea are addressed, and complexity bounds are derived. We also give several applications of the proposed model, including explicit constructions of nonblocking WDM switching fabrics.

Key words. wavelength division multiplexing, switching networks, $[w, f]$ -connectors

AMS subject classifications. 05C75, 05C90, 05C35

DOI. 10.1137/S0097539704442714

1. Introduction. With the advances in dense wavelength division multiplexing (DWDM) technology [21, 32, 38], the number of wavelengths in a wavelength division multiplexed (WDM) network increases to hundreds or more per fiber, and each wavelength operates at 10Gbps (OC-192) or higher [17, 18, 19]. While raw bandwidth has increased by more than four orders of magnitude over the last decade or so, capacity of switches has only been up by a factor of ten. Switching speed is the bottleneck at the core of optical network infrastructure [37]. Consequently, a challenge is to design cost-effective WDM cross-connects (WXC) that can scale in size beyond one hundred inputs and outputs and, at the same time, switch fast (e.g., tens of nanoseconds or less).

The notion of “cost-effectiveness” is difficult to capture. One can analyze and compare WDM switches both qualitatively and quantitatively.

Qualitatively, we need to know if a design is strictly nonblocking (SNB), rearrangeably nonblocking (RNB), and/or wide-sense nonblocking (WSNB) under different request models [20, 24, 25, 31, 33, 34, 39, 41, 42] and different traffic patterns (unicast [24, 25, 42], multicast [22, 26, 43]). A design can also be blocking as long as its blocking probability is below a certain threshold [15, 31]. There are various other qualitative features, such as small cross-talk [39], small number of limited-range wavelength converters [42], or fault tolerance [4]. Presumably each new design is guided by a particular qualitative feature. For example, one might come up with an RNB design under one request model, which may or may not be SNB under another request model. One might also have an intuitively good design, and hence need to know what qualitative feature the design possesses. This question is challenging in general. We will see later that the graph models introduced in this paper help, in several ways, answer these types of questions.

Quantitatively, comparing different designs, or asking how close to be optimal a new design is, are very important questions. This is a multidimensional problem, as there are many factors affecting the “cost” of a switch. Some factors, such as actual

*Received by the editors March 31, 2004; accepted for publication (in revised form) July 13, 2005; published electronically February 17, 2006.

[†]Department of Computer Science and Engineering, 201 Bell Hall, State University of New York at Buffalo, Amherst, NY 14260 (hungngo@cse.buffalo.edu).

cost in dollars, are business matters. Other factors include the numbers of different types of switching components, such as (de)multiplexors (MUXs/DEMUXs), full and limited wavelength converters (FWCs and LWCs), semiconductor optical amplifiers (SOAs), optical add-drop multiplexors (OADMs), directional couplers (DCs), etc; or signal and switch quality parameters, such as cross-talk, power consumption and attenuation, integratability and scalability, blocking probabilities, etc.

It should be apparent that we cannot hope to have a cost model that fits all needs. However, one can devise cost models which give good approximated measures on how “complex” a construction is. The notion of complexity should roughly capture as many practical parameters as possible.

In this paper, we outline an intriguing approach to model switch complexity which not only helps analyze WDM switches quantitatively and qualitatively but also suggests interesting generalizations of classical switching network theory [2, 29]. Then we address several important problems arising from the framework.

We consider two dominant request models in this paper. The following phenomena are samples of what our model suggests:

- (a) Designing WXC’s in the so-called $(\lambda, F, \lambda', F')$ -request model is basically the same as designing a circuit switch. Hence, many old ideas on circuit switching can be readily reused (section 4.1).
- (b) Two SNB switches in two models are equivalent topologically, even though one request model is much less restrictive than the other (section 5.1).
- (c) There is an inherent trade-off between a WXC’s “depth” (which is proportional to signal attenuation, cross-talk) and its “size” (which approximates the WXC’s complexity) (section 5.2).
- (d) Different designs of WXC’s which make use of different optical components can now be viewed in a unified manner. We can tell if two different-looking designs are equivalent topologically, for example (section 7).

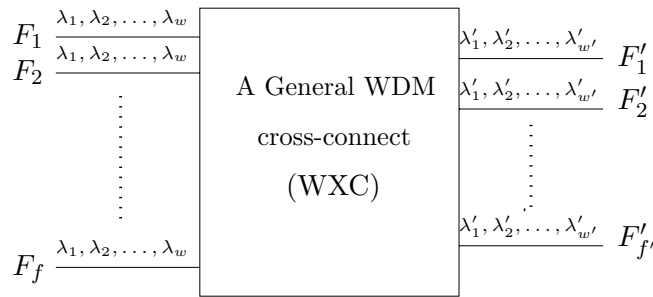

We will also derive several complexity bounds and give a generic construction which can be used to construct RNB switches (section 6).

The framework proposed here gives rise to interesting mathematical and networking problems, many of which are generalized versions of the well-studied circuit switching problems. We address several of these problems in later sections of the paper.

The rest of the paper is organized as follows. Section 2 introduces basic settings of WXC’s, request models, and nonblocking concepts. Section 3 motivates the graph models which will be rigorously defined in section 4. Section 5 addresses several key complexity problems arising from the framework. Section 6 explicitly constructs graphs with low complexity. The ideas in this section can be used to construct WXC’s of low cost. Section 7 discusses several applications of our framework. Last, section 8 concludes the paper with a few remarks and discussions on future works.

2. WXC’s, request models, and nonblockingness. A general WXC consists of f input fibers, each of which can carry a set $\Lambda = \{\lambda_1, \dots, \lambda_w\}$ of w wavelengths, and f' output fibers, each of which can carry a set $\Lambda' = \{\lambda'_1, \dots, \lambda'_{w'}\}$ of w' wavelengths, where $fw = f'w'$ (See Figure 1). This setting is referred to as the *heterogeneous* case [34], which is needed to connect subnetworks from different manufacturers. Henceforth, let $n = fw = f'w'$, unless specified otherwise.

Let $\mathcal{F} = \{F_1, \dots, F_f\}$ and $\mathcal{F}' = \{F'_1, \dots, F'_{f'}\}$ denote the set of input and output fibers, respectively. There are two common types of request models [24, 41]. In the (λ, F, F') -request model, a connection request is of the form (λ, F, F') , where $\lambda \in \Lambda$,

FIG. 1. *Heterogeneous WXC.*

$F \in \mathcal{F}$, and $F' \in \mathcal{F}'$. The request asks to establish a connection from wavelength λ in input fiber F to any free wavelength in output fiber F' . In the (λ, F, F') -request model, the difference is that the output wavelength λ' in F' is also specified.

In the next sections, we will define the concepts of SNB, WSNB, and RNB for both request models. We will be somewhat informal in our definitions. However, the idea should be clear to readers who have been exposed to switching theory [2, 13, 29, 23].

Consider a WXC with a few connections already established. Under the (λ, F, F') -model, a new request (λ, F, F') is said to be *valid* iff λ is a free wavelength in fiber F , and there are at most $w' - 1$ existing connections to F' . Under the $(\lambda, F, \lambda', F')$ -model, a new request $(\lambda, F, \lambda', F')$ is *valid* iff λ is free in F and λ' is free in F' .

A *request frame* under the (λ, F, F') -model is a set of requests such that no two requests are from the same wavelength in the same input fiber and that there are at most w' requests to any output fiber. A *request frame* under the $(\lambda, F, \lambda', F')$ -model is a set of requests such that no two requests are *from* the same input wavelength/fiber pair or *to* the same output wavelength/fiber pair.

The following definitions hold for both request models. A request frame is *realizable* by a WXC if all requests in the frame can be routed simultaneously. A WXC is *RNB* iff any request frame is realizable by the WXC. A WXC is *SNB* iff a new valid request can always be routed through the WXC without disturbing existing connections. A WXC is *WSNB* iff a new valid request can always be routed through the WXC without disturbing existing connections, provided that new requests are routed according to some routing algorithm. When the routing algorithm is known, we say that the WXC is WSNB with respect to the algorithm.

Henceforth, for any positive integer p , let $[p]$ denote the set $\{1, \dots, p\}$ and S_p denote the set of all permutations on $[p]$. The graph theoretic terminologies and notation we use here are fairly standard (see [40], for instance).

3. Motivations. Main known results on the constructions of (different types of) nonblocking WXCs can be found in [20, 22, 24, 25, 26, 31, 33, 34, 39, 41, 42]. (Note that we are not discussing multicast switching in this paper.) The constructions from these references made use of various different types of optical components, such as arrayed waveguide grating routers (AWGRs) and LWCs in [24], SOAs and LWCs in [42], OADMs and FWCs in [41], wavelength selective cross-connects (WSCs) and wavelength interchangers (WIs) in [33, 34], and DCs in [39]. It is clear that the task of comparing different designs is not easy. Different designs make use of different optical switching components which oftentimes are trade-offs. For instance, the designs in [42] made use of SOAs and LWCs which have a lower wavelength conversion cost than

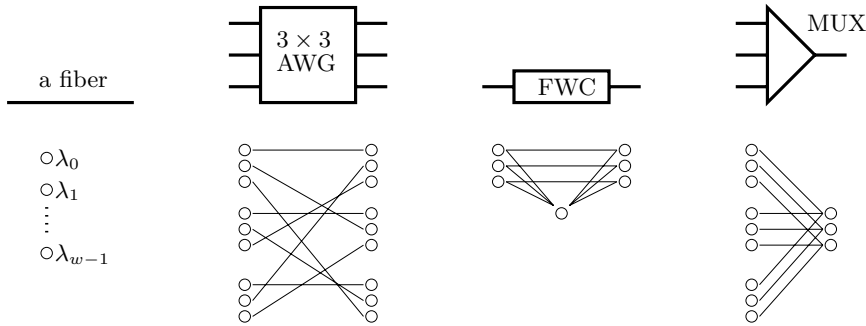

FIG. 2. Turning optical components into parts of a graph. A fiber is replaced by a set of vertices representing the wavelengths it can carry. Other components define edges connecting input wavelengths to output wavelengths. For the AWGR, MUX, and FWC, we illustrate with $w = 3$. Edges are directed from left to right.

FIG. 3. A WDM switch design and its corresponding DAG.

those in [24]. On the other hand, the ones in [24] preferred AWGRs over SOAs since AWGRs consume virtually no power.

We now propose an approach to uniformly model all designs by graphs and then discuss switch complexity from the graphs' standpoint.

We classify optical switching components into fibers and other switching components. For any switch design, we apply the following procedure to construct a directed acyclic graph (DAG) from the design: (a) each fiber is replaced by a set of vertices $\Lambda \cup \Lambda'$, which represents all possible wavelengths which can be carried on the fiber; (b) the edges of the DAG are defined according to the capacity of switching components in the design. The edges connect wavelengths (i.e., vertices) on the inputs of each switching component to the wavelengths on the outputs in accordance with the functionality of the switching component.

We shall be somewhat brief on this construction. However, the reader will undoubtedly understand the basic idea. As an example, Figure 2 shows how to turn an AWGR, an FWC, and a MUX into edges. Figure 3 shows a complete construction of the DAG from the design on the left.

The key point is that a set of compatible routes from input wavelengths to output wavelengths correspond to a set of vertex disjoint paths from the inputs to the outputs of the DAG.

There are two main parameters of the DAG, which capture the notion of "switch complexity" discussed earlier. The number of edges of the DAG, called the size of the

DAG, is roughly proportional to the total cost of various components in the design. For example, an FWC corresponds to $3w$ edges, while an WI [34] corresponds to w^2 edges; a $w \times w$ AWGR corresponds to w^2 edges, while a $w \times w$ WDM crossbar corresponds to w^4 edges; etc. As WIs and WDM crossbars are more expensive than FWCs and AWGRs, this model makes sense. Other components follow the same trend.

The reader might have noticed that different components contribute different “weights” to the total cost; hence summing up the number of edges may not give the “right” cost. To answer this doubt, we make three points. First, as argued earlier one cannot hope to have a perfect model which fits all needs, and part of the notion of cost is a business matter. Our first aim is at a more theoretical level. Second, this is the first step toward a good cost model. One certainly can envision weighted graphs as the next step. Third, we surely can and should still use more traditional cost functions, such as the direct counts of the number of each components, and compare them individually.

The second measure on the DAG is its *depth*, i.e., the length of a longest path from any input to any output. As signals pass through different components of a design, they lose some power. The depth of the DAG hence reflects power loss or in some cases even the signal delay. Again, different components impose different power loss factors. Hence, other information needs to be taken into account to estimate power loss. However, it is clear that network depth is an important measure.

Last but not least, this DAG model provides a nice bridge between classical switching theory and WDM switching theory. As we shall see in later sections, this model helps us tremendously in answering qualitative questions about a particular construction. For example, if an wf -input wf -output DAG must have size $\Omega(f^2w^2)$ to be SNB, then we know for certain that a construction of cost $o(f^2w^2)$ (reflected by the DAG’s size) cannot be SNB (for sufficiently large values of fw .)

4. Rigorous settings. An (n_1, n_2) -network is a DAG $\mathcal{N} = (V, E; A, B)$, where V is the set of vertices, E is the set of edges, A is a set of n_1 nodes called *inputs*, and B , disjoint from A , is a set of n_2 nodes called *outputs*. The vertices in $V - A \cup B$ are *internal* vertices. The indegrees of the inputs and the outdegrees of the outputs are 0. The *size* of a network is its number of edges. The *depth* of a network is the maximum length of a path from an input to an output. An n -network is an (n, n) -network.

An n -network is meant to represent the DAG from the previous section under the $(\lambda, F, \lambda', F')$ -request model. (Recall $n = wf = w'f'$.) Later on, we shall define $[w, f]$ -networks which represent the DAG under the (λ, F, F') -request model.

4.1. The $(\lambda, F, \lambda', F')$ -request model. Given an n -network $\mathcal{N} = (V, E; A, B)$, a pair $D = (a, b)$ in $A \times B$ is called a *request* (or *demand*) for \mathcal{N} . A set \mathcal{D} of requests is called a *request frame* iff no two requests share an input or an output. A request $D = (a, b)$ is *compatible* with a request frame \mathcal{D} iff $\mathcal{D} \cup \{D\}$ is also a request frame. A *route* R for a request $D = (a, b)$ is a (directed) path from a to b . We also say R *realizes* D . A *state* of \mathcal{N} is a set \mathcal{R} of vertex disjoint routes. Each state of \mathcal{N} realizes a request frame, one route per request in the frame. A request frame \mathcal{D} is *realizable* iff there is a network state realizing it.

An *RNB n -connector* (or just n -connector for short) is an n -network in which the request frame $\mathcal{D} = \{(a, \pi(a)) \mid a \in A\}$ is realizable for any one-to-one correspondence $\pi : A \rightarrow B$.

An *SNB n -connector* is an n -network \mathcal{N} in which given any network state \mathcal{R} realizing a request set \mathcal{D} , and given a new request D compatible with \mathcal{D} , there exists a route R such that $\mathcal{R} \cup \{R\}$ is a network state realizing $\mathcal{D} \cup \{D\}$.

As requests come and go, a strategy to pick new routes for new requests is called a *routing algorithm*. An n -network \mathcal{N} is called a *WSNB n -connector* with respect to a routing algorithm \mathbf{A} if \mathbf{A} can always pick a new route for a new request compatible with the current network state. We can also replace \mathbf{A} by a class of algorithms \mathcal{A} . In general, an n -network \mathcal{N} is WSNB iff it is WSNB with respect to *some* algorithm.

We often consider two classes of functions on each network type: (a) the minimum size of a network and (b) the minimum size of a network with a given depth. The main theme of research on classical switching networks is to investigate the trade-off between size and depth [23, 29].

Let $rc(n)$, $wc(n)$, and $sc(n)$ denote the minimum size of an RNB, WSNB, and SNB n -connector, respectively. Let $rc(n, k)$, $wc(n, k)$, and $sc(n, k)$ denote the minimum size of an RNB, WSNB, and SNB n -connector with depth k , respectively. Note that $rc(n) \leq wc(n) \leq sc(n)$, and $rc(n, k) \leq wc(n, k) \leq sc(n, k)$. These classes of functions are well studied in the context of circuit switching networks (see, e.g., [23, 29] for nice surveys).

Two key conclusions arise from this formulation:

- Studying WDM switches under the $(\lambda, F, \lambda', F')$ -request model is in a sense the same as studying classical switching networks. A lot of results can be readily reused. For example, using our DAG construction, it is easy to see that all of the constructions (under this request model) in [24, 33, 34, 42] made use of various forms of the Clos network [5, 27], banyan, butterfly, and base line networks [11, 12], Cantor network [3], etc. In fact, under this request model, we do not know of any design which is not topologically isomorphic to some classical circuit design.
- The situation under the (λ, F, F') -model is different, however. The RNB design in [24] and the designs presented in this paper require several new themes. Particularly, this is because the (λ, F, F') -model is not equivalent to the classical switching case, as we shall see in the next section.

4.2. The (λ, F, F') -request model. In this request model, each pair (λ, F) with $\lambda \in \Lambda$, $F \in \mathcal{F}$ can still be thought of as an “input” to our graphs as in the previous request model. However, on the output side we do have to indicate the number f of fibers and the number of wavelengths w on each fiber.

Set $n = wf$. A $[w, f]$ -network is an n -network $\mathcal{N} = (V, E; A, B)$ in which the set B of outputs is further partitioned into f subsets B_1, \dots, B_f of size w each. Each set B_i represents an output fiber in the WDM switch. We implicitly assume the existence of the partition in a $[w, f]$ -network, in order to simplify notation. (There is a slightly subtle point to be noticed here. The inputs are not distinguishable in this request model, while we do care which fiber an output wavelength is from. The parameters w and f in the above sentence and henceforth should be thought of as w' and f' in the original discussion.)

Given a $[w, f]$ -network \mathcal{N} , a pair $D = (a, k) \in A \times [f]$ is called a (connection) *request* for \mathcal{N} . The number k is called the *output fiber number* of D . A set \mathcal{D} of requests is called a *request frame* iff no two requests share an input, and for any $k \in [f]$, we have $|\{a \mid (a, k) \in \mathcal{D}\}| \leq w$. A request $D = (a, k)$ is *compatible* with a request frame \mathcal{D} iff $\mathcal{D} \cup \{D\}$ is also a request frame.

A *route* R for a request $D = (a, k)$ is a path from a to some vertex b in B_k . We also say R *realizes* D . A *state* of \mathcal{N} is a set \mathcal{R} of vertex disjoint routes. Each state of \mathcal{N} realizes a request frame. A request frame \mathcal{D} is *realizable* iff there is a network state realizing it.

We are interested in (WSNB, SNB, RNB) connectors under this request model. A (rearrangeable) $[w, f]$ -connector is a $[w, f]$ -network in which the request frame

$$\mathcal{D} = \{(a, \sigma(a)) \mid a \in A\}$$

is realizable for any mapping $\sigma : A \rightarrow [f]$ such that

$$|\{a \mid \sigma(a) = k\}| = w \quad \forall k \in [f].$$

A SNB $[w, f]$ -connector is an $[w, f]$ -network \mathcal{N} in which given any network state \mathcal{R} realizing a request set \mathcal{D} , and given a new request D compatible with \mathcal{D} , there exists a route R such that $\mathcal{R} \cup \{R\}$ realizes $\mathcal{D} \cup \{D\}$. As requests come and go, a strategy to pick new routes for new requests is called a *routing algorithm*. An $[w, f]$ -network \mathcal{N} is called a WSNB $[w, f]$ -connector with respect to a routing algorithm \mathbf{A} if \mathbf{A} can always pick a new route for a new request compatible with the current network state. We can also replace \mathbf{A} by a class of algorithms \mathcal{A} . In general, an $[w, f]$ -network \mathcal{N} is WSNB iff it is WSNB with respect to *some* algorithm.

The different $[w, f]$ -networks are generalized versions of the corresponding n -networks.

PROPOSITION 4.1. *A network is an SNB, WSNB, RNB $[1, f]$ -connector iff it is an SNB, WSNB, RNB f -connector, respectively.*

Let $\overline{rc}(w, f)$, $\overline{wc}(w, f)$, and $\overline{sc}(w, f)$ denote the minimum sizes of an RNB, WSNB, and SNB $[w, f]$ -connector, respectively. Similarly, for a fixed depth k , we define $\overline{rc}(w, f, k)$, $\overline{wc}(w, f, k)$, and $\overline{sc}(w, f, k)$. These functions have not been studied before. Some trivial bounds can be summarized as follows.

PROPOSITION 4.2. *Let $n = wf$; then the following hold:*

- (i) $\overline{rc}(w, f) \leq \overline{wc}(w, f) \leq \overline{sc}(w, f)$.
- (ii) $\overline{rc}(w, f, k) \leq \overline{wc}(w, f, k) \leq \overline{sc}(w, f, k)$.
- (iii) *An RNB, WSNB, SNB n -connector is also an RNB, WSNB, SNB $[w, f]$ -connector, respectively. Consequently, $\overline{rc}(\cdot) \leq rc(\cdot)$, $\overline{wc}(\cdot) \leq wc(\cdot)$, and $\overline{sc}(\cdot) \leq sc(\cdot)$, where the dots on the left-hand sides can be replaced by (w, f) or (w, f, k) and the dots on the right-hand sides by (n) or (n, k) , correspondingly.*

5. Complexity bounds.

5.1. SNB $[w, f]$ -connectors. We study SNB $[w, f]$ -connectors in this section. For $f = 1$, it is easy to see that $\overline{sc}(w, 1, k) = w + k - 1$. We assume $f \geq 2$ from here on.

Intuitively, an optimal SNB $[w, f]$ -connector might have (strictly) smaller size than an optimal SNB wf -connector, since the $(\lambda, F, \lambda', F')$ -request model is more restrictive than the (λ, F, F') -request model. However, the following theorem shows a somewhat surprising result: we can do no better than an SNB wf -connector when $f \geq 2$. This theorem explains rigorously why the authors in [24] could not construct SNB designs under the (λ, F, F') -model with a lower cost than the ones under the other model.

THEOREM 5.1. *Let $n = wf$, where n, w, f are positive integers, and $f \geq 2$. An n -network $\mathcal{N} = (V, E; A, B)$ is an SNB n -connector iff it is an SNB $[w, f]$ -connector.*

Proof. An SNB n -connector is also an SNB $[w, f]$ -connector, no matter how the fiber partitioning is done. For the converse, let \mathcal{N} be an SNB $[w, f]$ -connector. Let $B = B_1 \cup \dots \cup B_f$ be the partition of B . (Recall, by definition, that $|B_i| = w \quad \forall i \in [f]$ and that $|A| = wf$.)

Consider a state \mathcal{R} of this network. We shall show that if a is a free input and b is a free output, then there exists a route R from a to b such that $\mathcal{R} \cup \{R\}$ is a network state.

Let X be the set of free inputs and Y the set of free outputs. Note that $a \in X$, $b \in Y$, and $|X| = |Y|$.

Suppose $b \in B_k$ for some $k \in [f]$. Without loss of generality, we assume that there is no free output in any B_j for $j \neq k$. This can be accomplished by creating as many requests of the form (x, j) as possible, where $x \in X - \{a\}$ and $j \neq k$, until there is no more free outputs at the B_j with $j \neq k$. Then let \mathcal{R} be the new network state (which satisfies all new requests and also contains the old network state). An (a, b) -route compatible with \mathcal{R} is certainly compatible with the old network state.

We can now assume $Y \subseteq B_k$. Create $|X|$ requests of the form (x, k) , one for each $x \in X$. Since \mathcal{N} is a $[w, f]$ -connector, there is a route R_x for each x in X satisfying the following: (i) R_x starts from x and ends at some vertex in B_k , and (ii) $\mathcal{R} \cup \{R_x \mid x \in X\}$ is a network state.

If R_a is an (a, b) -route, then we are done. Moreover, if $|X| = |Y| = 1$, then R_a must be an (a, b) -route. Consequently, we can assume the following:

- $|X| = |Y| \geq 2$.
- R_a goes from a to some vertex $y \in B_k - \{b\}$.
- There is some $x \in X - \{a\}$ such that R_x ends at b .
- There is some vertex $a' \notin X$ and a route

$$R' = (a', v_1, \dots, v_p, b') \in \mathcal{R}$$

which goes from a' to a vertex $b' \in B_j$, where $j \neq k$. (The route $R' \in \mathcal{R}$ exists since we assumed that the vertices in $B_j, j \neq k$, are all busy.)

To this end, let

$$\mathcal{R}' = \mathcal{R} \cup \{R_t \mid t \in X\} - \{R_a, R_x, R'\}.$$

We shall show that there exists an (a, b) -route R for which $\mathcal{R}' \cup \{R', R\}$ is a state. The route R is then the route we are looking for, because $\mathcal{R} \subseteq \mathcal{R}' \cup \{R'\}$.

We first claim that there exists an (x, y) -route R_{xy} compatible with \mathcal{R}' . Consider the state $\mathcal{R}' \cup \{R_a\}$. The request (a', k) is valid (i.e., compatible with the request frame realized by $\mathcal{R}' \cup \{R_a\}$), and b is the only free output in B_k ; hence, there is an (a', b) -route $R_{a'b}$ such that $\mathcal{R}' \cup \{R_a, R_{a'b}\}$ is a state. Now in the state $\mathcal{R}' \cup \{R_{a'b}\}$ the request (x, k) is valid, and y is the only free output in B_k . Hence, there is an (x, y) -route R_{xy} such that $\mathcal{R}' \cup \{R_{a'b}, R_{xy}\}$ is a state. Consequently, there is an (x, y) -route R_{xy} compatible with \mathcal{R}' as claimed.

Now consider two cases as follows.

Case 1. Among all the (x, y) -routes which are compatible with \mathcal{R}' , there is some R_{xy} which is also vertex disjoint from R' . Then in the state $\mathcal{R}' \cup \{R', R_{xy}\}$ the request (a, k) is valid, and b is the only free output in B_k . Hence, there is an (a, b) -path compatible with $\mathcal{R}' \cup \{R'\}$ as desired.

Case 2. Every (x, y) -route compatible with \mathcal{R}' intersects R' at some point. Let R_{xy} be such an (x, y) -route whose last intersection vertex on (v_1, \dots, v_p) has the largest index, say v_j , for some $j \in [p]$. Then R_{xy} is composed of two parts: the part from x to v_j and the part from v_j to y .

Let $R_{a'y}$ be an (a', y) -path consisting of the part (a', v_1, \dots, v_j) of R' and the (v_j, y) -part of R_{xy} . Then certainly $R_{a'y}$ is compatible with \mathcal{R}' . In the state $\mathcal{R}' \cup \{R_{a'y}\}$

the request (a, k) is valid, and b is the only free output in B_k . Hence, there is an (a, b) -path R_{ab} compatible with $\mathcal{R}' \cup \{R_{a'y}\}$.

If R_{ab} does not intersect R' , then we are done. Otherwise, R_{ab} must intersect R' at some $v_{j'}$ for which $j' > j$. Similar to the previous paragraph, we can form an (a', b) -path $R_{a'b}$ compatible with \mathcal{R}' consisting of $(a', v_1, \dots, v_{j'})$ and the part of R_{ab} from $v_{j'}$ to b . Now consider the state $\mathcal{R}' \cup \{R_{a'b}\}$ in which y is the only free vertex in B_k . The request (x, k) is valid; hence there is some (x, y) -path compatible with $\mathcal{R}' \cup \{R_{a'b}\}$. This (x, y) -path must then intersect R' (since we are in Case 2) at some vertex after $v_{j'}$ (for compatibility with $R_{a'b}$), contradicting our choice of R_{xy} earlier. \square

COROLLARY 5.2. *The following hold for $f \geq 2$:*

- (i) $\overline{sc}(w, f, 1) = w^2 f^2$.
- (ii) $\overline{sc}(w, f, k) = \Omega((wf)^{1+1/(k-1)})$ and $\overline{sc}(w, f, k) = O((wf)^{1+1/\lfloor \frac{k+1}{2} \rfloor})$.
- (iii) $\overline{sc}(w, f) = \Theta(wf \lg(wf))$.

Proof. Let $n = wf$; then $\overline{sc}(w, f, k) = sc(n, k)$ by Theorem 5.1. The first equality is obvious. The fact that $sc(n, k) = O(n^{1+1/\lfloor \frac{k+1}{2} \rfloor})$ can be seen from the constructions in [3, 5, 27]. The lower bound $\Omega((wf)^{1+1/(k-1)})$ was shown in [8]. The fact that $sc(n) = \Theta(n \lg n)$ can be found in [1, 36]. The reader is referred to the surveys [23, 29] for more details on what is known about these functions. \square

5.2. Rearrangeable $[w, f]$ -connectors. In this section, we first devise lower bounds for the optimal size of RNB $[w, f]$ -connectors and connectors of a fixed depth. The upper bounds follow from explicit constructions presented in section 6.

An idea of Pippenger [28] can be used to show the following theorem.

THEOREM 5.3. *Every rearrangeable $[w, f]$ -connector must have size at least*

$$\frac{45}{7} wf \log_6 f + O(f) - O(f \lg w).$$

In particular, $\overline{rc}(w, f) = \Omega(wf \lg f)$.

Proof. The proof is completely similar to that of Pippenger's theorem and thus will not be repeated here. The only difference is that the number of valid request frames is no longer $n!$, as in the case of an n -connector. In our case, the total number of different request frames for \mathcal{N} is the multinomial coefficient

$$(1) \quad \underbrace{\binom{wf}{w, \dots, w}}_{f \text{ times}} = \frac{(wf)!}{(w!)^f} \geq \frac{\sqrt{2\pi wf} (wf/e)^{wf}}{e^{\frac{f}{12w}} (2\pi w)^{f/2} (w/e)^{wf}} = (2\pi w)^{1-\frac{f}{2}} e^{-\frac{f}{12w}} f^{wf+\frac{1}{2}},$$

where the inequality follows from Stirling's approximation [35]. \square

The bound $\Omega(wf \lg f)$ implies that for $w \leq f$, $[w, f]$ -connectors must have size at least $\Omega(wf \lg(wf))$, which is asymptotically no better than a wf -connector. This confirms our intuition that for small values of w , $[w, f]$ -connectors are almost the same as wf -connectors.

Fortunately, in WDM networks it is often the case that $w \geq f$; i.e., the number of wavelengths per fiber (in the hundreds) is often much larger than the number of fibers (in the tens). The next section shows that we can construct $[w, f]$ -connectors that are asymptotically less expansive than all known constructions of wf -connectors.

We next give lower bounds for fixed depth $[w, f]$ -connectors.

THEOREM 5.4. *The optimal size of a depth-1 $[w, f]$ -connector is $wf(wf - w + 1)$, namely $\overline{rc}(w, f, 1) = wf(wf - w + 1)$.*

Proof. In the next section, we shall construct depth-1 $[w, f]$ -connectors of size $wf(wf - w + 1)$, which proves the upper bound $\bar{rc}(w, f, 1) \leq wf(wf - w + 1)$.

For the lower bound, let $\mathcal{N} = (A \cup B, E; A, B)$ be a depth-1 $[w, f]$ -connector. Then \mathcal{N} is a (directed) bipartite graph where $|A| = wf$, $|B| = wf$, and B has a partition into $B_1 \cup \dots \cup B_f$, such that $|B_i| = w \forall i$. The network \mathcal{N} is a $[w, f]$ -connector iff for every partition of A into A_1, \dots, A_f with $|A_i| = w \forall i$, there exist f complete matchings from each A_i to each B_i .

It follows that each vertex $b \in B$ must have a neighbor in every w -subset of A . Consequently, each vertex $b \in B$ must be of degree at least $|A| - w + 1$. Hence, the number of edges of \mathcal{N} is at least $|B|(|A| - w + 1) = wf(wf - w + 1)$. \square

For $k \geq 2$, we can use an idea by Pippenger and Yao [30] on n -shifters to find a lower bound for depth- k $[w, f]$ -connectors. The proof is similar and is left as an exercise.

THEOREM 5.5. *Let $k \geq 2$ be an integer; then a depth- k $[w, f]$ -connector must have size at least $kwf^{1+1/k}$. Specifically, $\bar{rc}(w, f, k) = \Omega(kwf^{1+1/k})$.*

Noting that the function $kwf^{1+1/k}$ is minimized at $k = \ln f$, we get the result $\bar{rc}(w, f) = \Omega(wf \lg f)$ from the previous theorem (with a worse constant than $45/7$).

COROLLARY 5.6. *For $k \geq 2$, $\bar{rc}_2(w, f) \geq ewf \ln f$, where e is the base of the natural log.*

6. Explicit constructions. For any network \mathcal{N} , let $A(\mathcal{N})$ and $B(\mathcal{N})$ denote the set of inputs and outputs of \mathcal{N} , respectively. For any $[w, f]$ -network \mathcal{N} , we shall always use $B_1(\mathcal{N}), \dots, B_f(\mathcal{N})$ to denote the partition of $B(\mathcal{N})$. An important fact to notice is that all presumably “theoretic” constructions presented in this section can easily be converted to practical constructions. We shall not elaborate on this point due to space limitation.

6.1. Atomic networks. Let $\mathcal{B}(x, y) = (A \cup B; E)$ denote the complete $x \times y$ directed bipartite graph; i.e., $|A| = x$, $|B| = y$, and $E = A \times B$. The (x, y) -network $\mathcal{B}(x, y)$ is called an (x, y) -crossbar. When $x = y$, we use the shorter notation $\mathcal{B}(x)$ and call it the x -crossbar. For any positive integer m , let $\mathcal{M}(m) = (A \cup B; E)$ denote a perfect matching of size m from A into B . (Therefore, $|A| = |B| = m$.) An (n, m) -concentrator is an (n, m) -network where $n \geq m$, such that for any subset S of m inputs there exists a set of m vertex disjoint paths connecting S to the outputs.

6.2. Union networks and optimal depth-1 connectors. Let $\mathcal{N}_1, \dots, \mathcal{N}_f$ be (wf, w) -networks with input sets A_1, \dots, A_f and output sets B_1, \dots, B_f , respectively. For each $i = 1, \dots, f - 1$, let $\phi_i : A_i \rightarrow A_{i+1}$ be some one-to-one mapping. A *left union* or \triangleleft -union of $\mathcal{N}_1, \dots, \mathcal{N}_f$ is a $[w, f]$ -network \mathcal{N} constructed by identifying each vertex $a \in A_1$ with all vertices $\phi_1(a), \phi_2 \circ \phi_1(a), \dots, \phi_{f-1} \circ \dots \circ \phi_1(a)$ (to become an input of \mathcal{N}), and let B_1, \dots, B_f be, naturally, the partition of the outputs of \mathcal{N} (see Figure 4.) We denote \mathcal{N} as $\mathcal{N} = \triangleleft(\mathcal{N}_1, \dots, \mathcal{N}_f)$.

Let $\mathcal{N}_1, \dots, \mathcal{N}_k$ be (m, n) -networks. An (mk, n) -network $\mathcal{N} = \triangleright(\mathcal{N}_1, \dots, \mathcal{N}_k)$ constructed by identifying outputs of the \mathcal{N}_i in some one-to-one manner is called a *right union* (or \triangleright -union) of the \mathcal{N}_i . The picture is virtually symmetrical to the left union picture.

The next theorem summarizes a few important properties of the union constructions. The proof is simple and thus omitted. Note that part (iii) completes the proof of Theorem 5.4.

THEOREM 6.1 (optimal depth-1 construction). *Let w, f be positive integers; then the following hold:*

FIG. 4. The left union \mathcal{N} of f (wf, w) -networks is a $[w, f]$ -network.

- (i) Suppose $\mathcal{N}_1, \dots, \mathcal{N}_f$ are (wf, w) -concentrators; then the network $\triangleleft(\mathcal{N}_1, \dots, \mathcal{N}_f)$ is a $[w, f]$ -connector.
- (ii) The network $\mathcal{C}_1(w, f) = \triangleright(\mathcal{B}(wf - w, w), \mathcal{M}(w))$ is a depth-1 (wf, w) -concentrator of size $wf - w + 1$.
- (iii) Let $\mathcal{S}_1(w, f)$ be a left union of f copies of $\mathcal{C}_1(w, f)$. Then $\mathcal{S}_1(w, f)$ is a depth-1 $[w, f]$ -connector of size $wf(wf - w + 1)$, which is optimal.

6.3. Constructions of product networks and $[w, f]$ -connectors of depth 2.

DEFINITION 6.2 (the $\times \times$ -product). Let \mathcal{N}_1 be an m -network and \mathcal{N}_2 be a $[w, f]$ -network; then define the ordered product (for lack of a better term) $\mathcal{N} = \mathcal{N}_1 \times \times \mathcal{N}_2$ as follows. We shall “connect” wf copies of \mathcal{N}_1 , denoted by $\mathcal{N}_1^{(1)}, \dots, \mathcal{N}_1^{(wf)}$, to m copies $\mathcal{N}_2^{(1)}, \dots, \mathcal{N}_2^{(m)}$ of \mathcal{N}_2 . For each $i \in \{1, \dots, wf\}$ and $j \in \{1, \dots, m\}$, we identify the j th output of $\mathcal{N}_1^{(i)}$ with the i th input of $\mathcal{N}_2^{(j)}$. The output partition for \mathcal{N} is defined by

$$B_k(\mathcal{N}) = \bigcup_{j=1}^m B_k(\mathcal{N}_2^{(j)}).$$

Naturally, $A(\mathcal{N}) = \cup_{i=1}^{wf} A(\mathcal{N}_1^{(i)})$. Figure 5 illustrates the construction.

The following proposition summarizes a few trivial properties of the product network.

PROPOSITION 6.3. Let \mathcal{N}_1 be an m -network of size s_1 and depth d_1 and \mathcal{N}_2 a $[w, f]$ -network of size s_2 and depth d_2 . Then the network $\mathcal{N} = \mathcal{N}_1 \times \times \mathcal{N}_2$ is an $[mw, f]$ -network of size $s = wf s_1 + m s_2$ and depth $d = d_1 + d_2$.

Before proving a crucial property of this construction, we need a simple yet important lemma.

LEMMA 6.4. Let $G = (X \cup Y; E)$ be a bipartite multigraph where the degree of each vertex $x \in X$ is m and the degree of each vertex $y \in Y$ is mw . Then there is an edge coloring for G with exactly m colors such that vertices in X are incident to different colors, and vertices in Y are incident to exactly w edges of each color.

Proof. Split each vertex $y \in Y$ into w copies $y^{(1)}, \dots, y^{(w)}$ such that each copy has degree m . The resulting graph is an m -regular bipartite graph, which can be m -edge-colored, by König’s line coloring theorem [16]. This induces a coloring of G as desired. \square

The following lemma is the point of the ordered-product construction.

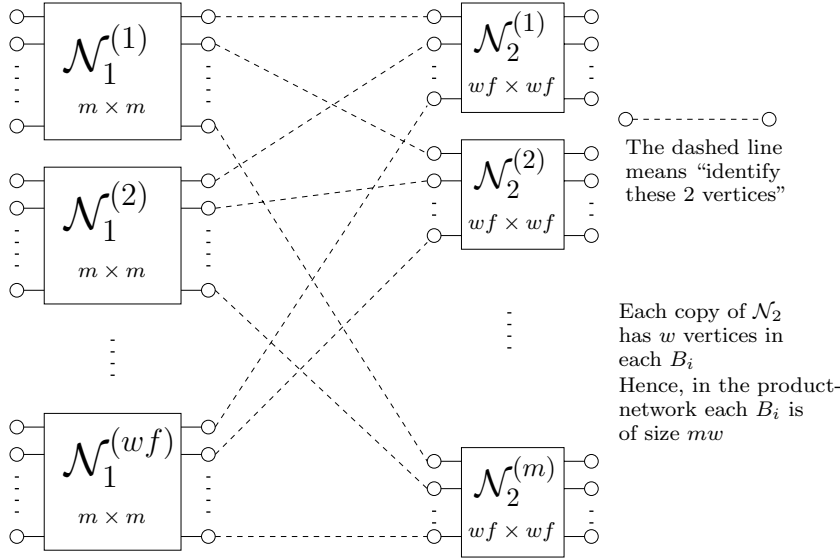

FIG. 5. Product of two networks: \mathcal{N}_1 is an m -network and \mathcal{N}_2 is a $[w, f]$ -network.

LEMMA 6.5. If \mathcal{N}_2 is a rearrangeable $[w, f]$ -connector and \mathcal{N}_1 is a rearrangeable m -connector, then $\mathcal{N} = \mathcal{N}_1 \times \times \mathcal{N}_2$ is a rearrangeable $[mw, f]$ -connector.

Proof. Consider a request frame \mathcal{D} for \mathcal{N} . We use $(a^{(i)}, k)$ to denote a request $(a, k) \in \mathcal{D}$ if $a \in A(\mathcal{N}_1^{(i)})$. This is to signify the fact that the request was from the a th input of $\mathcal{N}_1^{(i)}$ to B_k . By definition of a request frame, $|\{(a^{(i)}, k) \mid (a^{(i)}, k) \in \mathcal{D}\}| = m$ for a fixed i . We shall find vertex disjoint routes realizing requests in \mathcal{D} .

Construct a bipartite graph $G = (X \cup Y; E)$, where $X = \{\mathcal{N}_1^{(1)}, \dots, \mathcal{N}_1^{(wf)}\}$ is the set of all copies of \mathcal{N}_1 , and $Y = \{B_1, \dots, B_f\}$. There is (a copy of) an edge of G between $\mathcal{N}_1^{(i)}$ and B_k for each request $(a^{(i)}, k)$. Clearly, G is a bipartite graph satisfying the conditions of Lemma 6.4.

As each edge of G represents a request $D \in \mathcal{D}$, Lemma 6.4 implies that there is an m -coloring of all the requests such that, for a fixed i , requests of the form $(a^{(i)}, k)$ get different colors. Moreover, for a fixed k , requests of the form $(a^{(i)}, k)$ can be partitioned into m classes, where each class consists of exactly w requests of the same color.

Let $C = \{1, \dots, m\}$ be the set of colors. Let $c(a, k)$ denote the color of request $(a, k) \in \mathcal{D}$. Without loss of generality, we number the m outputs of $\mathcal{N}_1^{(i)}$ with numbers from 1 to m , i.e., $B(\mathcal{N}_1^{(i)}) = C, \forall i \in \{1, \dots, wf\}$.

Fix an $i \in \{1, \dots, wf\}$. As the m requests coming out of $\mathcal{N}_1^{(i)}$ have different colors, the correspondence $a^{(i)} \leftrightarrow c(a^{(i)}, k)$, where $(a^{(i)}, k) \in \mathcal{D}$, is a one-to-one correspondence between the inputs and the outputs of $\mathcal{N}_1^{(i)}$. Hence, for the m requests $(a^{(i)}, k)$, there exist m vertex disjoint routes $R_1(a^{(i)}, k)$ connecting input $a^{(i)}$ to the output numbered $c(a^{(i)}, k)$ of $\mathcal{N}_1^{(i)}$.

Fix a $j \in \{1, \dots, m\}$. The i th input of $\mathcal{N}_2^{(j)}$ is the j th output of $\mathcal{N}_1^{(i)}$, which is the endpoint of some route $R_1(a^{(i)}, k)$ for which $c(a^{(i)}, k) = j$. Let $k(i, j)$ be the number k such that the request $(a^{(i)}, k) \in \mathcal{D}$ has color $c(a^{(i)}, k) = j$. Then, for the fixed j and any $k \in \{1, \dots, f\}$, Lemma 6.4 ensures that there are exactly w of the $k(i, j)$ with

value k , namely $|\{i : k(i, j) = k\}| = w$. Thus, $\mathcal{D}' = \{(i, k(i, j)) \mid 1 \leq i \leq wf\}$ is a valid request frame for the rearrangeable $[w, f]$ -connector $\mathcal{N}_2^{(j)}$. Consequently, we can find vertex disjoint routes $R_2(i, k(i, j))$ connecting input i to some output in $B_{k(i, j)}$ of $\mathcal{N}_2^{(j)}$.

The concatenation of $R_1(a^{(i)}, k)$ and $R_2(i, k)$ completes a route realizing request $(a^{(i)}, k)$. These routes are vertex disjoint as desired. \square

We now illustrate the use of the Lemma 6.5 by a simple construction of depth-2 $[w, f]$ -connectors.

THEOREM 6.6 (depth-2 constructions). *Let w, f be positive integers; then*

- (i) *for $w \leq f - 1$, we can construct depth-2 $[w, f]$ -connectors of size $wf(w + f)$;*
- (ii) *for $w \geq f$, we can construct depth-2 $[w, f]$ -connectors of size $wf(2\sqrt{w(f - 1)} + 1)$.*

Proof. We ignore the issue of integrality for the sake of a clean presentation.

Write $w = mx$. By Theorem 6.1, $\mathcal{S}_1(x, f)$ is an $[x, f]$ -connector of depth 1 and size $xf(xf - x + 1)$. By Proposition 6.3 and Lemma 6.5, the network $\mathcal{B}(m) \times \times \mathcal{S}_1(x, f)$ is a $[w, f]$ -connector of depth-2 and size

$$s(x) = xfm^2 + mx f(xf - x + 1) = wf(w/x + (f - 1)x + 1).$$

Minimizing $s(x)$ as a function of x , with $1 \leq x \leq w$, we get the desired results. We pick $x = 1$ in case (i) and $x = \sqrt{w/(f - 1)}$ in case (ii). \square

6.4. Recursive constructions. Toward the constructions of $[w, f]$ -connectors, we need a few more definitions and properties.

DEFINITION 6.7. *Let w_0, w_1, \dots, w_k and f be positive integers and G be any $[w_0, f]$ -network. Let $\mathcal{N}(w_k, \dots, w_1; G)$ denote the recursively constructed network defined as follows:*

$$\begin{aligned} \mathcal{N}(\cdot; G) &= G, \\ \mathcal{N}(w_k, \dots, w_1; G) &= \mathcal{B}(w_k) \times \times \mathcal{N}(w_{k-1}, \dots, w_1; G). \end{aligned}$$

LEMMA 6.8. *Given positive integers w_0, w_1, \dots, w_k and f , let $w = \prod_{i=0}^k w_i$ and G be any $[w_0, f]$ -connector of size $s(G)$ and depth $d(G)$. Then the network $\mathcal{N} = \mathcal{N}(w_k, \dots, w_1; G)$ is a $[w, f]$ -connector of size*

$$s(\mathcal{N}) = w_0 \dots w_k f \cdot (w_1 + \dots + w_k) + w_1 \dots w_k \cdot s(G)$$

and depth $d(\mathcal{N}) = (k + d(G))$. (We set $s(\mathcal{N}) = s(G)$ when $k = 0$.)

Proof. This follows from Proposition 6.3 and Lemma 6.5. \square

PROPOSITION 6.9. *For any positive integers w and f , the following hold:*

- (i) *Let \mathcal{N} be any wf -connector. The $[w, f]$ -network \mathcal{N}' obtained by partitioning the outputs of \mathcal{N} arbitrarily into f subsets of size w is a $[w, f]$ -connector.*
- (ii) *$\mathcal{B}(f)$ is an f -connector and also a $[1, f]$ -connector.*

Basically, Proposition 6.9 implies that one can use good w_0f -networks to serve as the network G in Lemma 6.8. A general $[w, f]$ -network can then be constructed by decomposing $w = w_0, \dots, w_k$ with the right set of divisors w_0, \dots, w_k . As $[w, f]$ -networks of depth 2 have been constructed, we shall attempt to construct good networks of general depth and networks of a fixed depth at least 3.

Pippenger [27] has constructed a rearrangeable n -network, which we shall call $\mathcal{P}(n)$, of size $6n \log_3 n + O(n)$. He also constructed rearrangeable n -networks of depth $2i + 1$, $i \geq 1$, and size $2(i + 1)n \left(\frac{n}{2}\right)^{1/(i+1)} + O(n)$. An n -connector of depth $2i + 2$ can be

constructed by concatenating an n -matching with a depth- $(2i+1)$ n -connector. Hence, we can construct an n -connector of depth $j \geq 3$ and size $2\lceil j/2 \rceil n \left(\frac{n}{2}\right)^{1/\lceil j/2 \rceil} + O(n)$. We denote this network by $\mathcal{P}_j(n)$. For $j = 2$, a construction of size $O(n^{5/3})$ was given in [7] and [14]. Abusing notation, we shall also use $\mathcal{P}_2(n)$ to denote an n -connector of depth 2 and size $O(n^{5/3})$.

In the following results, we ignore the issue of integrality for the sake of clarity. We first address the general depth case.

THEOREM 6.10. *We can construct rearrangeable $[w, f]$ -connectors of size*

$$e \cdot wf \ln w + \frac{6}{\ln 3} wf \ln f + O(fw).$$

Proof. Let $w = xw_1 \dots w_k$. By Lemma 6.8 the network

$$\mathcal{N} = \mathcal{N}(w_k, \dots, w_1; \mathcal{P}(xf))$$

is a $[w, f]$ -connector of size

$$\begin{aligned} s(\mathcal{N}) &= wf(w_1 + \dots + w_k) + 6fx \log_3(fx) + O(fx) \\ &\geq wf \cdot k \cdot \left(\frac{w}{x}\right)^{1/k} + 6fx \log_3(fx) + O(fx). \end{aligned}$$

The right-hand side is minimized at $x = 1$ and $k = \ln w$. Equality can be obtained by setting $w_i = w^{1/k} \forall i$. \square

We now consider the fixed depth case. The networks $\mathcal{P}_j(n)$ are to be used. The following three theorems apply Lemma 6.8 with $G = \mathcal{P}_1, \mathcal{P}_2$, or \mathcal{P}_j with $j \geq 3$. Depending on the relative values between f, w , and k , one theorem may be better than the others.

THEOREM 6.11. *Let w, f , and $k \geq 3$ be positive integers.*

(i) *If $w < (f - 1)^{k-1}$, then we can construct a $[w, f]$ -connector of depth k and size*

$$(2) \quad (k - 1)fw^{1+\frac{1}{k-1}} + wf^2 = O(kwf^2).$$

(ii) *If $w \geq (f - 1)^{k-1}$, then we can construct a $[w, f]$ -connector of depth k and size*

$$(3) \quad wf(k - 1)[w(f - 1)]^{\frac{1}{k}} + w^{1+\frac{1}{k}}f(f - 1)^{\frac{1}{k}} + wf\Theta\left(k(wf)^{1+\frac{1}{k}}\right).$$

Proof. Write $w = xw_1 \dots w_{k-1}$. Then Lemma 6.8 implies that

$$\mathcal{N}(w_{k-1}, \dots, w_1; \mathcal{S}_1(x, f))$$

is a $[w, f]$ -network of depth k and size

$$(4) \quad \begin{aligned} s &= wf(w_1 + \dots + w_{k-1}) + w_1 \dots w_{k-1} \cdot xf(xf - x + 1) \\ &\geq wf(k - 1)(w/x)^{1/(k-1)} + wf(x(f - 1) + 1). \end{aligned}$$

Minimizing the right-hand side with respect to x , we get the desired results.

In case (i), equality can be obtained when $w_i = w^{1/(k-1)} \forall i$, and $x = 1$. In case (ii), equality can be obtained when $w_i = w^{1/(k-1)} \forall i$, and $x = \left(\frac{w}{(f-1)^{k-1}}\right)^{1/k}$. \square

We omit the proofs of the next two theorems due to the similarity to the above proof.

THEOREM 6.12. *Let w, f , and $k \geq 3$ be positive integers. Then there are positive real constants c_1, c_2 , and c_3 such that the following hold:*

(i) *If $w < c_1 f^{\frac{2}{3}(k-2)}$, then we can construct a $[w, f]$ -connector of depth k and size*

$$(5) \quad (k-2)f \cdot w^{1+\frac{1}{k-2}} + c_2 w f^{\frac{5}{3}} = O\left(k w f^{\frac{5}{3}}\right).$$

(ii) *If $w \geq c_1 f^{\frac{2}{3}(k-2)}$, then we can construct a $[w, f]$ -connector of depth k and size*

$$(6) \quad (k-2) \cdot (w f)^{1+\frac{1}{k-\frac{3}{2}}} + c_3 w^{1+\frac{1}{k-\frac{3}{2}}} f^{\frac{6k-7}{6k-9}} = O\left(k(w f)^{1+\frac{1}{k-\frac{3}{2}}}\right).$$

The following result can be improved by finer analysis. We give a somewhat “cleaner” version.

THEOREM 6.13. *Let w, f , and $k \geq 4$ be positive integers.*

(i) *If $w < f$, then we can construct a $[w, f]$ -connector of depth k and size*

$$(7) \quad O\left(k w^{1+\frac{1}{(k+1)}} f^{1+\frac{2}{(k+1)}}\right).$$

(ii) *If $w \geq f$, then we can construct a $[w, f]$ -connector of depth k and size*

$$(8) \quad O\left(k(w f)^{1+\frac{3}{2(k+1)}}\right).$$

7. Applications of our framework. In this section, we outline several practical applications coming from our theoretical formulation presented earlier. We will present only representative results. The reader should be able to see the main line of thoughts, nevertheless.

The applications fall into two main categories: (a) explicit constructions of WXCs and (b) complexity comparisons of known constructions.

7.1. Explicit constructions of WXC. The ideas for explicit constructions come from the physical realizations of atomic networks (section 6.1), the union of networks (section 6.2), the \times -product of networks (section 6.3), and the recursive construction (section 6.4).

There are several ways to physically realize an (x, y) -crossbar $\mathcal{B}(x, y)$. Figure 6(a) shows one possibility, and it is self-explanatory. The one thing to notice is that each fiber is aimed to carry one wavelength only. Another possibility to realize $\mathcal{B}(x, y)$ is to use a combination of an AWGR of dimension $\max\{x, y\}$ and the same number of LWCs as was done in [24]. The advantage of using AWGRs over SOAs is that AWGRs consume virtually no power.

Our second atomic component is a depth-1 $(w f, w)$ -concentrator $\mathcal{C}_1(w, f)$, which can be constructed by taking the left union of a $\mathcal{B}(w f - w, w)$ and a perfect matching $\mathcal{M}(w)$ as illustrated in Figure 6(b).

Given the aforementioned two atomic networks, we readily have a construction of a one-stage RNB WXC as shown in Figure 7. There is one column of tunable input—fixed output LWCs at the end to ensure no wavelength conflict. This one column of LWCs is needed in all realizations of the theoretical constructions shown in section 6.

This construction has a cost a little higher than that of Theorem 6.1 because of the LWCs, which are of total cost $w^2 f$. Asymptotically, however, $w^2 f \ll w f(w f - w + 1)$;

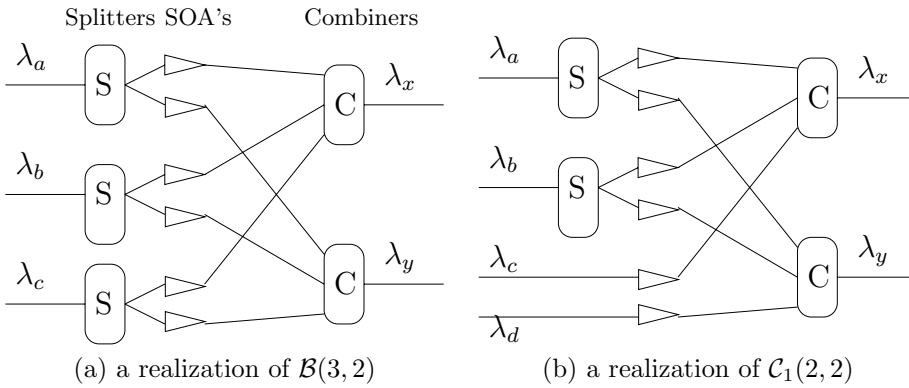

FIG. 6. Sample realizations of atomic networks.

FIG. 7. A realization of the one-stage construction $\mathcal{S}_1(2, 3)$. The LWCs are wavelength converters with tunable inputs and a fixed output.

hence we did not create too much of a gap between the theoretical construction and the physical realization. Another interesting point to notice is that the WXC RNB-1 construction of [24] is a special case of this idea. The only difference is that they use AWGRs and LWCs to realize the crossbars.

The same idea can be used to realize the generic product network of Lemma 6.5. The proof of the lemma also gives an efficient routing algorithm. (Efficient algorithms

TABLE 1

Cost comparisons of different constructions under the two request models. SNB/RNB-1 refers to the (λ, F, F') -request model. SNB/RNB-2 refers to the $(\lambda, F, \lambda', F')$ -request model.

	Type	Depth	Size	Cond
[41]/CBC	SNB-1	$2 \lg f$	$\Theta(wf(w + \lg f) \lg f)$	-
Corollary 5.2(ii)	SNB-1	k	$O((wf)^{1+1/\lfloor \frac{k+1}{2} \rfloor})$	-
Corollary 5.2(iii)	SNB-1	$\lg(wf)$	$\Theta(wf \lg(wf))$	-
[41]/WI-Cantor	RNB-1	$2 \lg f$	$\Theta(wf(w + \lg^2 f))$	-
[41]/WI-Beneš	RNB-1	$2 \lg f$	$\Theta(wf(w + \lg f))$	-
[24]/WXC-RNB-1	RNB-1	2	$2(wf)^{3/2}$	$f < w$
Theorem 6.6(i)	RNB-1	2	$wf(w + f)$	$f > w$
Theorem 6.6(ii)	RNB-1	2	$2(wf)^{3/2}$	$f \leq w$
Theorem 6.10	RNB-1	$\lg(wf)$	$ewf \ln w + \frac{6}{\ln 3} wf \ln f + O(wf)$	-
Theorem 6.11	RNB-1	$k \geq 3$	$(k-1)fw^{1+\frac{1}{k-1}} + wf^2$	$w < (f-1)^{k-1}$
Theorem 6.11	RNB-1	$k \geq 3$	$\Theta\left(k(wf)^{1+\frac{1}{k}}\right)$	$w \geq (f-1)^{k-1}$
Theorem 6.12	RNB-1	$k \geq 3$	$(k-2)f \cdot w^{1+\frac{1}{k-2}} + c_2 wf^{5/3}$	$w < c_1 f^{\frac{2}{3}(k-2)}$
Theorem 6.12	RNB-1	$k \geq 3$	$O\left(k(wf)^{1+\frac{1}{k-3/2}}\right)$	$w \geq c_1 f^{\frac{2}{3}(k-2)}$
Theorem 6.13	RNB-1	$k \geq 4$	$O\left(kw^{1+\frac{1}{k+1}} f^{1+\frac{2}{k+1}}\right)$	$w < f$
Theorem 6.13	RNB-1	$k \geq 4$	$O\left(k(wf)^{1+\frac{3}{2(k+1)}}\right)$	$w < f$
[33, 34]	SNB-2	3	$2w^2(2f + w)$	-
[24]/WXC-SNB-2	SNB-2	3	$4\sqrt{2}(wf)^{3/2}$	$f < w$
[42]/2S/P/N	SNB-2	3	$4(wf)^{3/2}$	$f < w$
[42]/3S/P/N	SNB-2	4	$4\sqrt{2}(wf)^{3/2}$	-
[24]/WXC-RNB-2	RNB-2	3	$2(wf)^{3/2}$	$f < w$
[42]/2S/P/R	RNB-2	3	$2(wf)^{3/2}$	$f < w$
[42]/3S/P/R	RNB-2	4	$2\sqrt{2}(wf)^{3/2}$	-
[42]/B/P/R	RNB-2	$\Theta(\lg(wf))$	$\Theta(wf \lg wf)$	$f < w$

for bipartite graph edge coloring can be found in [6, 9, 10].) Thus, we readily have constructions of a depth-2 RNB WXC as in Theorem 6.6 and several different recursive constructions as reported in Theorems 6.10, 6.11, 6.12, and 6.13. Depending on the relationship between w and f , we pick the best one to use.

7.2. Complexity comparisons of known constructions. Table 1 summarizes the costs of various recent constructions (including some of the ones in this paper). The costs are assessed in terms of architectural depths and sizes. From the table, we see the following:

- For the $(\lambda, F, \lambda', F')$ -request model (SNB-1, RNB-1), the various constructions have costs asymptotically the same as those of their circuit switching counterparts. This was expected, since our formulation in section 4.1 has indicated that the WXC under this request model and the corresponding circuit switches are equivalent topologically.

(This is not to say that there is nothing to study in this request model. Our cost model does not capture precisely more practical criteria such as cross-talks, attenuation, and wavelength conversion costs.)

- For the (λ, F, F') -request model (SNB-1, RNB-1), there is much room for improvement.

In the SNB case, our construction of Corollary 5.2 is already better than the existing construction CBC. However, since SNB in this request model is the same as the other, we cannot expect much more improvement.

In the RNB case, our constructions of Theorems 6.10, 6.11, 6.12, and 6.13 are better than all known constructions. However, there are still gaps between the constructions and theoretical lower bounds of Theorems 5.3 and 5.5. We expect that both the lower bounds and the constructions can be improved until they are asymptotically equal.

8. Conclusions and future works. There are several benefits of the proposed graph models: they help analyze the switches qualitatively and quantitatively, they can be used to compare switch complexity, and they give rise to interesting mathematical problems relating to many areas, such as classical switching theory, graph theory, and algebraic graph theory. Some of these points were not discussed in the paper. It would be interesting, for instance, to investigate the use of expanders for constructing $[w, f]$ -connectors.

We have addressed several important problems arising from this framework, including studying optimal networks and their constructions, the trade-off between network depth and size, and the equivalence of networks under different request models. Some practical applications have also been pointed out.

Many problems remain open. In particular, we have not touched upon the WSNB case much. The multicast switch complexity was not considered. The asymptotic bounds of various complexity functions are still not optimal.

**SPECIAL ISSUE: THE THIRTY-SIXTH ANNUAL ACM
SYMPOSIUM ON THEORY OF COMPUTING (STOC 2004)**

This volume comprises the polished and fully refereed versions of a selection of papers presented at the Thirty-Sixth Annual ACM Symposium on Theory of Computing (STOC 2004), held in Chicago, Illinois, June 13–15, 2004. Unrefereed preliminary versions of the papers presented at the symposium appeared in the proceedings of the meeting, published by ACM. The symposium was sponsored by the ACM Special Interest Group on Algorithms and Computation Theory (SIGACT).

The STOC 2004 Program Committee consisted of Andris Ambainis, László Babai (chair), Boaz Barak, Moses Charikar, Irit Dinur, Herbert Edelsbrunner, Sandy Irani, Adam Klivans, Vladlen Koltun, Robert Krauthgamer, Satya Lokam, Tal Malkin, Oded Regev, Alexander Russell, Éva Tardos, Mikkel Thorup, D. Sivakumar, Chris Umans, and Eric Vigoda.

Out of 271 “Extended Abstracts” submitted to the STOC 2004 Program Committee, 70 were selected for presentation at the symposium. Sixteen out of those 70 papers were selected for inclusion in this volume. The authors of 5 of the invited papers declined, and the remaining 11 accepted the invitation. One of the 11 papers was not completed by the deadline; one other paper was found to fall short of *SICOMP* standards. The present volume includes the remaining 9 papers.

This collection of papers encompasses a wide variety of questions and methods in theoretical computer science, often shedding new light on entire areas with a fresh approach. The topics include fundamental questions of complexity theory and algorithms as well as foundational mathematical problems. Several papers use methods of “continuous mathematics” to attack discrete optimization problems. Of the areas represented in this volume that have relatively recently gained prominence in the theory of computing, I should mention quantum computing and the theory of metric embeddings.

This issue includes the journal versions of the two papers that shared the 2004 Danny Lewin Best Student Paper award. One of them, by Scott Aaronson, shows how quantum arguments inspire new results in a classical model; the other, by Jonathan Kelner, demonstrates the relevance of conformal geometry to the algorithmic question of partitioning graphs into clusters.

All papers were refereed in accordance with *SICOMP*’s stringent standards, and most of them were substantially updated in the process. We take this opportunity to thank all the referees whose anonymous work has significantly contributed to the value of this volume.

* * * * *

Special issues dedicated to STOC have a distinguished history; a brief review of this history seems to be in order.

SIGACT, the premier U.S.-based organization of theoretical computer science, has sponsored the publication of special issues to its annual STOC conferences since the second STOC held in 1970; the *Journal of Computer and System Sciences (JCSS)* was designated the venue of the publication. *JCSS* published 34 STOC special issues, starting with the 2nd STOC (*JCSS* 5:3, June 1971) and ending with the 35th STOC (*JCSS* 69:3, November 2004). The volumes from 1978 onward are accessible to subscribers on the Elsevier website at <http://www.sciencedirect.com/>.

It was an honor to edit the present special issue for the *SIAM Journal on Computing*.¹

APPROXIMATING THE CUT-NORM VIA GROTHENDIECK'S INEQUALITY*

NOGA ALON[†] AND ASSAF NAOR[‡]

Abstract. The *cut-norm* $\|A\|_C$ of a real matrix $A = (a_{ij})_{i \in R, j \in S}$ is the maximum, over all $I \subset R$, $J \subset S$, of the quantity $|\sum_{i \in I, j \in J} a_{ij}|$. This concept plays a major role in the design of efficient approximation algorithms for dense graph and matrix problems. Here we show that the problem of approximating the cut-norm of a given real matrix is MAX SNP hard, and we provide an efficient approximation algorithm. This algorithm finds, for a given matrix $A = (a_{ij})_{i \in R, j \in S}$, two subsets $I \subset R$ and $J \subset S$, such that $|\sum_{i \in I, j \in J} a_{ij}| \geq \rho \|A\|_C$, where $\rho > 0$ is an absolute constant satisfying $\rho > 0.56$. The algorithm combines semidefinite programming with a rounding technique based on Grothendieck's inequality. We present three known proofs of Grothendieck's inequality, with the necessary modifications which emphasize their algorithmic aspects. These proofs contain rounding techniques which go beyond the random hyperplane rounding of Goemans and Williamson [*J. ACM*, 42 (1995), pp. 1115–1145], allowing us to transfer various algorithms for dense graph and matrix problems to the sparse case.

DOI. 10.1137/S0097539704441629

1. Introduction. The *cut-norm* $\|A\|_C$ of a real matrix $A = (a_{ij})_{i \in R, j \in S}$ with a set of rows indexed by R and a set of columns indexed by S is the maximum, over all $I \subset R$, $J \subset S$, of the quantity $|\sum_{i \in I, j \in J} a_{ij}|$. This concept plays a major role in the work of Frieze and Kannan [8] on efficient approximation algorithms for dense graph and matrix problems (see also [2] and the references therein). The techniques in [8] enabled the authors to approximate efficiently the cut-norm of an n by m matrix with entries in $[-1, 1]$ up to an *additive* error of ϵnm . However, prior to the present paper no polynomial time algorithm was known for approximating the cut-norm of a general real matrix within a constant multiplicative factor.

Let CUT NORM denote the computational problem of computing the cut-norm of a given real matrix. Here we first observe that the CUT NORM problem is MAX SNP hard, and then provide an efficient approximation algorithm for the problem. This algorithm finds, for a given matrix $A = (a_{ij})_{i \in R, j \in S}$, two subsets $I \subset R$ and $J \subset S$, such that $|\sum_{i \in I, j \in J} a_{ij}| \geq \rho \|A\|_C$, where $\rho > 0$ is an absolute constant. We first describe a deterministic algorithm that supplies a rather poor value of ρ , and then describe a randomized algorithm that provides a solution of expected value greater than 0.56 times the optimum.

The algorithm combines semidefinite programming with a rounding technique based on (the proofs of) Grothendieck's inequality. This inequality, first proved in [11],

is a fundamental tool in functional analysis and has several interesting applications in this area. We will actually use the matrix version of Grothendieck's inequality, formulated in [20]. In order to apply semidefinite programming to the study of the cut-norm of an n by m matrix $A = (a_{ij})$, it is convenient to first study another norm,

$$\|A\|_{\infty \rightarrow 1} = \max \sum_{i=1}^n \sum_{j=1}^m a_{ij} x_i y_j,$$

where the maximum is taken over all $x_i, y_j \in \{-1, 1\}$.

It is not difficult to show (see section 3) that for every matrix A ,

$$4\|A\|_C \geq \|A\|_{\infty \rightarrow 1} \geq \|A\|_C,$$

and hence a constant approximation of any of these norms provides a constant approximation of the other.

The value of $\|A\|_{\infty \rightarrow 1}$ is given by the following quadratic integer program:

$$(1.1) \quad \begin{aligned} & \text{Maximize} && \sum_{ij} a_{ij} x_i y_j \\ & \text{subject to} && x_i, y_j \in \{-1, 1\} \quad \text{for all } i, j. \end{aligned}$$

The obvious semidefinite relaxation of this program is

$$(1.2) \quad \begin{aligned} & \text{Maximize} && \sum_{ij} a_{ij} u_i \cdot v_j \\ & \text{subject to} && \|u_i\| = \|v_j\| = 1, \end{aligned}$$

where here $u_i \cdot v_j$ denotes the inner product of u_i and v_j , which are now vectors of (Euclidean) norm 1 that lie in an arbitrary Hilbert space. Clearly we may assume, without loss of generality, that they lie in an $(n+m)$ -dimensional space.

This semidefinite program can be solved, using well-known techniques (see [10]) within an additive error of ϵ , in polynomial time (in the length of the input and in the logarithm of $1/\epsilon$). The main problem is the task of rounding this solution into an integral one. A first possible attempt is to imitate the technique of Goemans and Williamson in [12]; that is, given a solution u_i, v_j to the above program, pick a random vector z and define $x_i = \text{sign}(u_i \cdot z)$ and $y_j = \text{sign}(v_j \cdot z)$. It is easy to check that the expected value of $x_i y_j$ satisfies $E(x_i y_j) = \frac{2}{\pi} \arcsin(u_i \cdot v_j)$, and as $\arcsin(t)$ and t differ only in constant factors for all $-1 \leq t \leq 1$, one could hope that this will provide an integral solution whose value is at least some absolute constant fraction of the value of the optimal solution. This reasoning is, unfortunately, incorrect, as some of the entries a_{ij} may be positive and some may be negative. (In fact, the problem is interesting only if this is the case, since otherwise either $x_i = y_j = 1$ or $x_i = -y_j = 1$ for all i, j supplies the required maximum.) Therefore, even if each single term $a_{ij} u_i \cdot v_j$ is approximated well by its integral rounding $a_{ij} x_i y_j$, there is no reason to expect the sum to be well approximated, due to cancellations. We thus have to compare the value of the rounded solution to that of the semidefinite program on a global basis. Nesterov [22] obtained a result of this form for the problem of approximating the maximum value of a quadratic form $\sum_{ij} b_{ij} x_i x_j$, where $x_i \in \{-1, 1\}$, but only for the special case in which the matrix $B = (b_{ij})$ is positive semidefinite. While his estimate is global, his rounding is the same simple rounding technique of [12] described above.

As explained before, some new ideas are required in our case in order to get any nontrivial result.

Luckily, there is a well-known inequality of Grothendieck, which asserts that the value of the semidefinite program (1.2) and that of the integer program (1.1) can differ only by a constant factor. The precise value of this constant, called *Grothendieck's constant* and denoted by K_G , is not known, but it is known that its value is at most $\frac{\pi}{2 \ln(1+\sqrt{2})} = 1.782\dots$ (see [18]) and at least $\frac{\pi}{2} = 1.570\dots$ (see [11]). Stated in other words, the integrability gap of the problem is at most K_G . (Krivine mentions in [18] that he can improve the lower bound, but such an improvement has never been published.)

It follows that the value of the semidefinite program (1.2) provides an approximation of $\|A\|_{\infty \rightarrow 1}$ up to a constant factor. This, however, still does not tell us how to round the solution of the semidefinite program into an integral one with a comparable value. Indeed, this task requires more work and is carried out in the following sections.

We describe three rounding techniques. The first one is a deterministic procedure, which combines Grothendieck's inequality with some facts about four-wise independent random variables in a manner that resembles the technique used in [4] to approximate the second frequency moment of a stream of data under severe space constraints. The second rounding method is based on Rietz's proof of Grothendieck's inequality [24]. This proof supplies a better approximation guarantee for the special case of positive semidefinite matrices A , where the integrality gap can be shown to be precisely $\pi/2$, and implies that Nesterov's analysis for the problem he considers in [22] is tight.

The third technique, which supplies the best approximation guarantee, is based on Krivine's proof of Grothendieck's inequality. Here we use the vectors u_i, v_j which form a solution of the semidefinite program (1.2) to construct some other unit vectors u'_i, v'_j , which are first shown to exist in an infinite-dimensional Hilbert space and are then found, using another instance of semidefinite programming, in an $(n+m)$ -dimensional space. These vectors can now be rounded to $\{-1, 1\}$ in order to provide an integral solution for the original problem (1.1) in a rather simple way. We note that there are several known techniques for modifying the solution of a semidefinite program before rounding it; see [28], [19], [9]. Here, however, the modification seems more substantial.

We believe that the techniques presented here will have further applications, as they provide a method for handling problems in which there is a possible cancellation between positive and negative terms. It seems that there are additional interesting problems of this type. Approximation algorithms based on semidefinite programming for MAX CUT, MAX 2SAT, and related problems have been initiated in the seminal paper of Goemans and Williamson [12] and further developed in many subsequent papers. Unlike these problems, prior to the present paper there was no known polynomial time constant approximation algorithm for the problem considered here. Indeed, in this case, the semidefinite programming and its rounding appear to be essential in order to obtain any constant approximation guarantee, and not only in order to improve the constants ensured by appropriate combinatorial algorithms.

The rest of this paper is organized as follows. In section 2 we present the (relatively simple) proof that the problem of approximating the cut-norm $\|A\|_C$, as well as the related problem of approximating $\|A\|_{\infty \rightarrow 1}$, are both MAX SNP hard. In section 3 we describe a deterministic procedure that approximates the cut-norm of a given

matrix up to a constant factor. Two other methods, providing better constants, are described in section 4, where we also consider the special case of positive semidefinite matrices. Section 5 presents some examples which illustrate the relevance of the cut-norm to certain graph and matrix problems and shows how the results of this paper improve various known algorithms. We conclude with section 6, which includes some concluding remarks and open problems.

2. Hardness of approximation. As usual, we say that an approximation algorithm for a maximization problem has *performance ratio* or *performance guarantee* ρ for some real $\rho \leq 1$, if it always delivers a solution with objective function value at least ρ times the optimum value. Such an approximation algorithm is then called a ρ -*approximation algorithm*. Similarly, a randomized approximation algorithm is a ρ -approximation algorithm if it always produces a solution with expected value at least ρ times the optimum.

In this section we observe that the problem of approximating the cut-norm $\|A\|_C$ of a given input matrix is MAX SNP hard, and so is the related problem of approximating $\|A\|_{\infty \rightarrow 1}$. This implies, by the results in [23], [6], that there exists some $\rho < 1$ such that the existence of a ρ -approximation, polynomial time algorithm for any of these problems would imply that $P = NP$. The proof is by a reduction of the MAX CUT problem to the CUT NORM problem, and to the problem of computing $\|A\|_{\infty \rightarrow 1}$. We need the following simple observation.

LEMMA 2.1. *For any real matrix $A = (a_{ij})$,*

$$\|A\|_C \leq \|A\|_{\infty \rightarrow 1} \leq 4\|A\|_C.$$

Moreover, if the sum of each row and the sum of each column of A is zero, then $\|A\|_{\infty \rightarrow 1} = 4\|A\|_C$.

Proof. For any $x_i, y_j \in \{-1, 1\}$,

$$\sum_{i,j} a_{ij} x_i y_j = \sum_{\substack{i: x_i=1 \\ j: x_j=1}} a_{ij} - \sum_{\substack{i: x_i=1 \\ j: x_j=-1}} a_{ij} - \sum_{\substack{i: x_i=-1 \\ j: x_j=1}} a_{ij} + \sum_{\substack{i: x_i=-1 \\ j: x_j=-1}} a_{ij}.$$

The absolute value of each of the four terms in the right-hand side is at most $\|A\|_C$, implying, by the triangle inequality, that

$$(2.1) \quad \|A\|_{\infty \rightarrow 1} \leq 4\|A\|_C.$$

Suppose, say, that $\|A\|_C = \sum_{i \in I, j \in J} a_{ij}$ (the computation in the case where it equals $-\sum_{i \in I, j \in J} a_{ij}$ is essentially the same). Define $x_i = 1$ for $i \in I$ and $x_i = -1$ otherwise, and similarly, $y_j = 1$ if $j \in J$ and $y_j = -1$ otherwise. Then

$$\begin{aligned} \|A\|_C &= \sum_{i,j} a_{ij} \frac{1+x_i}{2} \frac{1+y_j}{2} \\ &= \frac{1}{4} \sum_{i,j} a_{ij} + \frac{1}{4} \sum_{i,j} a_{ij} x_i \cdot 1 + \frac{1}{4} \sum_{i,j} a_{ij} 1 \cdot y_j + \frac{1}{4} \sum_{i,j} a_{ij} x_i y_j. \end{aligned}$$

The absolute value of each of the four terms in the right-hand side is at most $\|A\|_{\infty \rightarrow 1}/4$, implying that $\|A\|_{\infty \rightarrow 1} \geq \|A\|_C$. If the sum of each row and the sum of each column of A is zero, then the right-hand side is precisely $\frac{1}{4} \sum_{i,j} a_{ij} x_i y_j$, implying that in this case $\|A\|_{\infty \rightarrow 1} \geq 4\|A\|_C$, which, in view of (2.1), shows that the above holds as an equality. \square

PROPOSITION 2.2. *Given a (weighted or unweighted) graph $G = (V, E)$, there is an efficient way to construct a real $2|E|$ by $|V|$ matrix A , such that*

$$\text{MAXCUT}(G) = \|A\|_C = \|A\|_{\infty \mapsto 1} / 4.$$

Therefore, the CUT NORM problem and the problem of computing $\|A\|_{\infty \mapsto 1}$ are both MAX SNP hard.

Proof. We describe the construction for the unweighted case. The weighted case is similar. Given $G = (V, E)$, orient it in an arbitrary manner. Let $V = \{v_1, v_2, \dots, v_n\}$ and $E = \{e_1, e_2, \dots, e_m\}$, and let $A = (a_{ij})$ be the $2m$ by n matrix defined as follows. For each $1 \leq i \leq m$, if e_i is oriented from v_j to v_k , then $a_{2i-1,j} = a_{2i,k} = 1$ and $a_{2i-1,k} = a_{2i,j} = -1$. The rest of the entries of A are all 0. It is not difficult to check that $\text{MAXCUT}(G) = \|A\|_C$. In addition, since the sum of entries in each row and in each column of A is zero, it follows by Lemma 2.1 that $\|A\|_{\infty \mapsto 1} = 4\|A\|_C$. As it is known [23], [14] that the MAX CUT problem is MAX SNP hard, the desired result follows. \square

Håstad [14] has shown that if $P \neq NP$, then there is no polynomial-time approximation algorithm for the MAX CUT problem with approximation ratio exceeding $16/17$. Thus, this is an upper bound for the best possible approximation guarantee of a polynomial algorithm for approximating $\|A\|_C$ or $\|A\|_{\infty \mapsto 1}$. Similarly, our reduction above can be easily modified to construct, for any given directed graph D , a matrix B with vanishing row sums and column sums, so that the value of the maximum directed cut of D is equal to $\|B\|_C$. Håstad [14] has shown that if $P \neq NP$, then there is no polynomial-time approximation algorithm for the MAX DICUT problem with approximation ratio exceeding $12/13$. Thus, this is an upper bound for the best possible approximation guarantee of a polynomial approximation algorithm for $\|B\|_C$ or $\|B\|_{\infty \mapsto 1}$.

3. Approximating the cut-norm. In this section we describe an efficient, deterministic, ρ -approximation algorithm for the CUT NORM problem, where $\rho > 0$ is an absolute constant. We make no attempt here to optimize the value of ρ : this will be done (in a different way) in section 4. We believe, however, that although the value of ρ obtained in this section is rather poor, the method, which is motivated by the proof of Grothendieck’s inequality in [7, p. 15] and [16, p. 68], is interesting and may lead to similar results for related problems.

Given a real n by m matrix $A = (a_{ij})$, our objective is to find $x_i, y_j \in \{-1, 1\}$, such that

$$\sum_{i,j} a_{ij} x_i y_j \geq \rho \|A\|_{\infty \mapsto 1},$$

where ρ is an absolute positive constant. The discussion in section 1 and the proof of Lemma 2.1 imply that this will yield a similar procedure for finding I and J such that $|\sum_{i \in I, j \in J} a_{ij}| \geq \rho' \|A\|_C$.

We start by solving the semidefinite program (1.2). We can thus compute, for any positive δ , unit vectors $u_i, v_j \in R^p$, where $p = n + m$, such that the sum $\sum_{i,j} a_{ij} u_i \cdot v_j$ is at least the maximum value of the program (1.2) (which is clearly at least $\|A\|_{\infty \mapsto 1}$) minus δ . Since the value of the above norm of A is at least the maximum absolute value of an entry of A , we can make sure that the δ term is negligible. The main part of the algorithm is the rounding phase, that is, the phase of finding, using the vectors

u_i, v_j , reals $x_i, y_j \in \{-1, 1\}$, such that

$$\sum_{i,j} a_{ij} x_i y_j \geq \rho \sum_{i,j} a_{ij} u_i \cdot v_j.$$

This is done as follows. Let V be an explicit set of $t = O(p^2)$ vectors $\epsilon = (\epsilon_1, \epsilon_2, \dots, \epsilon_p) \in \{-1, 1\}^p$ in which the values ϵ_j are four-wise independent and each of them attains the two values -1 and 1 with equal probability. This means that for every four distinct coordinates $1 \leq i_1 < \dots < i_4 \leq n$ and every choice of $\epsilon_1, \dots, \epsilon_4 \in \{-1, 1\}$, exactly a $(1/16)$ -fraction of the vectors have ϵ_j in their coordinate number i_j for $j = 1, \dots, 4$. As described, for example, in [1] or [5] such sets (also known as *orthogonal arrays of strength 4*) can be constructed efficiently using the parity check matrices of BCH codes.

Let $M > 0$ be a fixed real, to be chosen later. Consider V as a sample space in which all t points ϵ have the same probability. For any unit vector $q = (q_1, q_2, \dots, q_p) \in R^p$, let $H(q)$ denote the random variable defined on the sample space V by putting $[H(q)](\epsilon) = \sum_{j=1}^p \epsilon_j q_j$. Since the entries ϵ_j are four-wise (and hence pairwise) independent, it follows that for any two vectors q, q' , the expectation of $H(q)H(q')$ is precisely the inner product $q \cdot q'$. In particular, the expectation of $[H(q)]^2$ is $q \cdot q = 1$. Similarly, four-wise independence implies that the expectation of $[H(q)]^4$ satisfies

$$E([H(q)]^4) = \sum_{j=1}^p q_j^4 + 6 \sum_{1 \leq j < j' \leq p} q_j^2 q_{j'}^2 \leq 3 \left(\sum_j q_j^2 \right)^2 = 3.$$

The M -truncation of $H(q)$, denoted $H^M(q)$, is defined as follows: $[H^M(q)](\epsilon) = [H(q)](\epsilon)$ if $|[H(q)](\epsilon)| \leq M$, $[H^M(q)](\epsilon) = M$ if $[H(q)](\epsilon) > M$, and $[H^M(q)](\epsilon) = -M$ if $[H(q)](\epsilon) < -M$.

By Markov's inequality, for every positive real m ,

$$\text{Prob}[|H(q)| \geq m] \cdot m^4 \leq E([H(q)]^4) \leq 3,$$

implying that $\text{Prob}[|H(q)| \geq m] \leq \frac{3}{m^4}$. This implies the following.

CLAIM 3.1. *The expectation $E(|H(q) - H^M(q)|^2)$ satisfies*

$$E(|H(q) - H^M(q)|^2) \leq \frac{1}{M^2}.$$

Proof. For every nonnegative random variable X we have that $EX^2 = 2 \int_0^\infty u \cdot \text{Prob}(X \geq u) du$. Hence,

$$\begin{aligned} E(|H(q) - H^M(q)|^2) &= 2 \int_0^\infty u \cdot \text{Prob}(|H(q)| \geq M + u) du \\ &\leq \int_0^\infty \frac{6u}{(M + u)^4} du = \frac{1}{M^2}. \quad \square \end{aligned}$$

Each random variable $H(q)$ can be associated with a vector $h(q) \in R^t$ by defining $[h(q)](\epsilon) = \frac{1}{\sqrt{t}} [H(q)](\epsilon)$. The truncation $h^M(q) = H^M(q)/\sqrt{t}$ is defined analogously. The above discussion thus implies the following.

LEMMA 3.2. *For each unit vector $q \in R^p$, $h(q) \in R^t$ is a unit vector. The norm of $h^M(q)$ is at most 1, and that of $h(q) - h^M(q)$ is at most $1/M$. If $q' \in R^p$ is another vector, then $h(q) \cdot h(q') = q \cdot q'$.*

Returning to our semidefinite program (1.2) and its solution (up to δ) given by the vectors $u_i, v_j \in R^p$, let B denote the value of the program. Since $h(q) \cdot h(q') = q \cdot q'$ for all unit vectors q, q' , it follows that

$$\begin{aligned} B - \delta &\leq \sum_{ij} a_{ij} u_i \cdot v_j \\ &= \sum_{ij} a_{ij} h(u_i) \cdot h(v_j) \\ &= \sum_{ij} a_{ij} h^M(u_i) \cdot h^M(v_j) + \sum_{ij} a_{ij} (h(u_i) - h^M(u_i)) \cdot h^M(v_j) \\ &\quad + \sum_{ij} a_{ij} h(u_i) \cdot (h(v_j) - h^M(v_j)). \end{aligned}$$

By the convexity of the program, and since the norm of each vector $h^M(v_j), h(u_i)$ is at most 1 and the norm of each vector $h(u_i) - h^M(u_i)$ and each vector $h(v_j) - h^M(v_j)$ is at most $1/M$, it follows that

$$\sum_{ij} a_{ij} (h(u_i) - h^M(u_i)) \cdot h^M(v_j) + \sum_{ij} a_{ij} h(u_i) \cdot (h(v_j) - h^M(v_j)) \leq \frac{2}{M} B.$$

Here we have used, crucially, the fact that as B is the maximum value of the semidefinite program, its value on the vectors $h(u_i) - h^M(u_i)$ and the vectors $h(v_j)$ does not exceed $B \frac{1}{M}$, and so does its value on the vectors $h(u_i)$ and $h(v_j) - h^M(v_j)$. Therefore,

$$B \left(1 - \frac{2}{M}\right) - \delta \leq \sum_{ij} a_{ij} h^M(u_i) \cdot h^M(v_j).$$

It follows that there is a coordinate $\epsilon \in V$ such that

$$\sum_{ij} a_{ij} h^M(u_i)(\epsilon) \cdot h^M(v_j)(\epsilon) \geq \frac{1}{t} \left(B \left(1 - \frac{2}{M}\right) - \delta \right).$$

By the definition of the vectors h , this implies

$$\sum_{ij} a_{ij} H^M(u_i)(\epsilon) \cdot H^M(v_j)(\epsilon) \geq B \left(1 - \frac{2}{M}\right) - \delta.$$

Choose $M = 3$ and define $x_i = \frac{H^M(u_i)(\epsilon)}{M}, y_j = \frac{H^M(v_j)(\epsilon)}{M}$. Then x_i, y_j are reals, each having an absolute value at most 1, and

$$\sum_{ij} a_{ij} x_i y_j \geq B \left(\frac{M-2}{M^3}\right) - \frac{\delta}{M^2} = \frac{B}{27} - \frac{\delta}{9}.$$

Fixing all x_i, y_j but, say, x_1 , the left-hand side is a linear form in x_1 , and thus we can shift x_1 to either -1 or 1 , without any decrease in the value of the sum. Proceeding in this way with the other variables, each one in its turn, we obtain $x_i, y_j \in \{-1, 1\}$ such that the value of the sum $\sum_{ij} a_{ij} x_i y_j$ is at least $\frac{B}{27} - \frac{\delta}{9}$. As δ is arbitrarily small, we have thus proved the following.

THEOREM 3.3. *There is a deterministic polynomial-time algorithm that finds, for a given real matrix $A = (a_{ij})$, integers $x_i, y_j \in \{-1, 1\}$ such that the value of the sum $\sum_{ij} a_{ij} x_i y_j$ is at least $0.03 B$, where B is the value of the semidefinite program (1.2) (which is at least $\|A\|_{\infty \rightarrow 1}$).*

4. Improving the constant. The constant obtained in the previous section can be improved by replacing the space V of four-wise independent $\{-1, 1\}$ variables with a space of $2k$ -wise independent $\{-1, 1\}$ variables (or with a space of independent standard normal random variables). This, however, will not provide a ρ -approximation algorithm with $\rho > \frac{1}{5}$.

In fact, we can do much better. In this section we describe two randomized ρ -approximation algorithms for approximating $\|A\|_{\infty \rightarrow 1}$. For the first algorithm, $\rho = \frac{4}{\pi} - 1 > 0.27$, while for the second $\rho = \frac{2 \ln(1+\sqrt{2})}{\pi} > 0.56$. We further show that these yield randomized ρ -approximation algorithms for the CUT NORM problem, with the same values of ρ (without losing the factor of 4 that appears in Lemma 2.1). It should be possible to derandomize these algorithms using the techniques of [21].

4.1. Averaging with a Gaussian measure: Rietz’s method. The main idea here, based on [24], is to round the solution $u_i, v_j \in R^p$ of the semidefinite program (1.2) by averaging over R^p with normalized Gaussian measure. We proceed with the details.

Let g_1, g_2, \dots, g_p be standard, independent, Gaussian random variables, and consider the random Gaussian vector $G = (g_1, \dots, g_p)$. The following identity holds for every two unit vectors $b, c \in \ell_2^p$:

$$(4.1) \quad \frac{\pi}{2} E [\text{sign}(b \cdot G) \cdot \text{sign}(c \cdot G)] \\ = b \cdot c + E \left\{ \left[b \cdot G - \sqrt{\frac{\pi}{2}} \text{sign}(b \cdot G) \right] \cdot \left[c \cdot G - \sqrt{\frac{\pi}{2}} \text{sign}(c \cdot G) \right] \right\}.$$

This is a simple exercise, using rotation invariance. Indeed, the fact that

$$(4.2) \quad E [(b \cdot G)(c \cdot G)] = b \cdot c$$

follows from the fact that the random variables g_i are uncorrelated; if $b = (b_1, \dots, b_p)$ and $c = (c_1, \dots, c_p)$, then

$$E [(b \cdot G)(c \cdot G)] = E \left[\sum_{i=1}^p b_i g_i \sum_{i=1}^p c_i g_i \right] = \sum_{i,j} b_i c_j E [g_i g_j] = \sum_{i=1}^p b_i c_i = b \cdot c.$$

To compute $E [(b \cdot G)\text{sign}(c \cdot G)]$ we may assume, by rotation invariance, that $c = (1, 0, \dots, 0)$ and $b = (b_1, b_2, 0, \dots, 0)$. Hence $b \cdot c = b_1$ and

$$\begin{aligned} E [(b \cdot G)\text{sign}(c \cdot G)] &= E [(b_1 g_1 + b_2 g_2)\text{sign}(g_1)] \\ &= E [b_1 g_1 \text{sign}(g_1)] + E [b_2 g_2] E [\text{sign}(g_1)] \\ &= E [b_1 g_1 \text{sign}(g_1)] \\ &= 2 \int_0^\infty \frac{1}{\sqrt{2\pi}} b_1 x e^{-x^2/2} dx = \sqrt{\frac{2}{\pi}} b_1. \end{aligned}$$

Thus

$$(4.3) \quad E [(b \cdot G)\text{sign}(c \cdot G)] = \sqrt{\frac{2}{\pi}} b \cdot c.$$

The identity above follows from (4.2) and (4.3) by linearity of expectation.

Suppose now that the vectors $u_i, v_j \in R^p$ supply a solution of (1.2), which can be found efficiently. (We assume, for simplicity, that this is a precise solution.) Let B denote the value of the solution. By (4.1),

$$(4.4) \quad \frac{\pi}{2} E \left\{ \sum_{i,j} a_{ij} [\text{sign}(u_i \cdot G) \cdot \text{sign}(v_j \cdot G)] \right\} \\ = B + \sum_{i,j} a_{ij} E \left\{ \left[u_i \cdot G - \sqrt{\frac{\pi}{2}} \cdot \text{sign}(u_i \cdot G) \right] \cdot \left[v_j \cdot G - \sqrt{\frac{\pi}{2}} \cdot \text{sign}(v_j \cdot G) \right] \right\}.$$

Note that each term of the form

$$E \left\{ \left[u_i \cdot G - \sqrt{\frac{\pi}{2}} \cdot \text{sign}(u_i \cdot G) \right] \cdot \left[v_j \cdot G - \sqrt{\frac{\pi}{2}} \cdot \text{sign}(v_j \cdot G) \right] \right\},$$

which multiplies a_{ij} in (4.4), is the inner product of two vectors in a Hilbert space. Moreover, the square of the norm of each of these vectors is easily seen to be $\frac{\pi}{2} - 1$ by substituting $b = c = u_i$ (or $b = c = v_j$) in (4.1). Therefore, as B is the maximum possible value of the program (1.2), it follows that the last sum in (4.4) is bounded, in absolute value, by $(\frac{\pi}{2} - 1)B$. Thus, by (4.4),

$$\frac{\pi}{2} E \left\{ \sum_{i,j} a_{ij} [\text{sign}(u_i \cdot G) \cdot \text{sign}(v_j \cdot G)] \right\} \geq \left(2 - \frac{\pi}{2} \right) B,$$

implying that by choosing the normal random variables g_i randomly and by defining

$$x_i = \text{sign}(u_i \cdot G), \quad y_j = \text{sign}(v_j \cdot G)$$

we get a solution for (1.1) whose expected value is at least $\frac{2}{\pi}(2 - \frac{\pi}{2})B = (\frac{4}{\pi} - 1)B$. As B is at least the value of the optimal solution of (1.1), this supplies a randomized ρ -approximation algorithm for estimating $\|A\|_{\infty \rightarrow 1}$, where $\rho = \frac{4}{\pi} - 1$.

Remark. The above algorithm is based only on the basic idea in the proof of [24], and it is in fact possible to improve its performance guarantee by modifying it according to the full proof. This suggests rounding $u_i \cdot G$ to $x_i = \text{sign}(u_i \cdot G)$ if it is “large” and rounding it to some multiple of $u_i \cdot G$ if it is not, where the definition of “large” and the precise multiple are chosen optimally. We can then further round the fractional values of x_i to integral ones with no loss. This resembles some of the ideas used in several recent papers, including [28], [19], and [9]. We do not include the details here, as we can get a better approximation guarantee by using another method described in subsection 4.3.

4.2. Positive semidefinite matrices. In this section we observe that when $A = (a_{ij})$ is positive semidefinite, then the approximation ratio can be improved to $2/\pi$. This follows from the work of Nesterov [22], but the short argument we describe here is based on Riesz’s proof that for such an A the constant in Grothendieck’s inequality can be improved to $\pi/2$. Grothendieck himself showed in [11] (in a somewhat different language) that $\pi/2$ is a lower bound for the constant in this case; we sketch a proof of this fact below.

We first show that if $A = (a_{ij})$ is a positive semidefinite n by n matrix, then the maximum of the semidefinite program (1.2) is obtained for some vectors u_i, v_j

satisfying $u_i = v_i$ for all i (though, of course, it may also be obtained for some vectors that do not satisfy this property). This is not really required for getting the $2/\pi$ -approximation algorithm, but we include this proof as it shows that the integrality gap of the problem is at most $\pi/2$.

Suppose thus that the maximum value of (1.2), denoted by B , is obtained by some p -dimensional vectors, where $p \leq 2n$ and A is positive semidefinite. Let $D = A \otimes I$ be the tensor product of A with a p by p identity matrix. This is simply the np by np matrix consisting of p blocks along the diagonal, each being a copy of A , so that, in particular, D is positive semidefinite. Given $u_1, \dots, u_n \in \ell_2^p$, where $u_i = (u_{i1}, u_{i2}, \dots, u_{ip})$, let $u^{(j)} = (u_{1j}, u_{2j}, \dots, u_{nj})$ be the vector consisting of the j th coordinates of all vectors u_i ($1 \leq j \leq p$). Let $u = (u^{(1)}, u^{(2)}, \dots, u^{(p)}) \in \ell_2^{np}$ and note that $Du = (Au^{(1)}, Au^{(2)}, \dots, Au^{(p)})$. Thus D is positive semidefinite and for $u_1, \dots, u_n, v_1, \dots, v_n \in \ell_2^p$, with v defined analogously to u ,

$$\sum_{i,j} a_{ij} u_i \cdot v_j = Du \cdot v = D^{1/2}u \cdot D^{1/2}v \leq \|D^{1/2}u\| \cdot \|D^{1/2}v\|,$$

with equality when $u = v$.

Therefore, if the maximum B of the quantity $\sum_{i,j} a_{ij} u_i \cdot v_j$ is obtained for the unit vectors $u_i, v_j \in \ell_2^p$, then, as $\|D^{1/2}u\|$ cannot exceed $B^{1/2}$, it follows that $\|D^{1/2}u\| = \|D^{1/2}v\| = B^{1/2}$. Thus the maximum is also equal to $\sum_{i,j} a_{ij} u_i \cdot u_j$ (and to $\sum_{i,j} a_{ij} v_i \cdot v_j$).

The fact that for positive semidefinite matrices A we can get a ρ -approximation algorithm with $\rho = \frac{2}{\pi}$ is now an easy consequence of (4.4). We first solve the semidefinite program (1.2) to get vectors u_i, v_j optimizing it. By the above discussion, the vectors $u_i = v_i$ for all i also give an optimal solution. (Alternatively, we can solve the variant of (1.2) in which $u_i = v_i$ for all i directly, and proceed from there.) By (4.4),

$$\begin{aligned} & \frac{\pi}{2} E \left\{ \sum_{i,j} a_{ij} [\text{sign}(u_i \cdot G) \cdot \text{sign}(u_j \cdot G)] \right\} \\ &= B + \sum_{i,j} a_{ij} E \left\{ \left[u_i \cdot G - \sqrt{\frac{\pi}{2}} \cdot \text{sign}(u_i \cdot G) \right] \cdot \left[u_j \cdot G - \sqrt{\frac{\pi}{2}} \cdot \text{sign}(u_j \cdot G) \right] \right\} \geq B, \end{aligned}$$

where here we have used the fact that A is positive semidefinite. The algorithm now simply chooses G at random, and computes $x_i = y_i = \text{sign}(u_i \cdot G)$.

We conclude this subsection with a sketch of (a modified version of) the argument of Grothendieck that shows that the integrality gap of (1.1) for the positive semidefinite case is indeed precisely $\pi/2$. We need the following.

Fact. If b and c are two random, independent vectors on the unit sphere in R^p , then

$$(4.5) \quad E[(b \cdot c)^2] = \frac{1}{p}$$

and

$$(4.6) \quad E[|b \cdot c|] = \left(\sqrt{\frac{2}{\pi}} + o(1) \right) \frac{1}{\sqrt{p}},$$

where the $o(1)$ term tends to zero as p tends to infinity.

Indeed, the computation of the first expectation is very simple; by rotation invariance we may assume that $c = (1, 0, 0, \dots, 0)$ and then $E[(b \cdot c)^2] = E[b_1^2]$, where we write $b = (b_1, b_2, \dots, b_p)$. However, by symmetry $E[b_1^2] = \frac{1}{p}E[b_1^2 + b_2^2 + \dots + b_p^2] = \frac{1}{p}$, implying (4.5). By the same reasoning, $E[|b \cdot c|] = E[|b_1|]$ which can now either be computed directly by integrating along the sphere or be estimated by noticing that it is well approximated by $E[|\frac{g}{\sqrt{p}}|]$, where g is a standard Gaussian random variable. The simple computation for this case appears before the derivation of (4.3).

Armed with the above fact, we now define an n by n positive semidefinite matrix $A = (a_{ij})$ for which the ratio between the value of (1.1) and that of (1.2) is (nearly) $\pi/2$. Fix a large integer p , and let n be much larger. Let v_1, v_2, \dots, v_n be n independent random vectors chosen uniformly in the unit sphere in R^p . Let A be the Gram matrix of the vectors $\frac{v_i}{n}$, that is, $a_{ij} = \frac{1}{n^2}v_i \cdot v_j$. Obviously A is positive semidefinite. Moreover, if we substitute the unit vectors v_i in the program (1.2) we get

$$\sum_{i,j} a_{ij}v_i \cdot v_j = \frac{1}{n^2} \sum_{ij} (v_i \cdot v_j)^2.$$

When n tends to infinity, this converges to the average value of the square of the inner product between two random vectors on the unit sphere of R^p , which is, by (4.5), $1/p$. Therefore, the optimal value of the program (1.2) for A is at least $1/p$.

Consider, now, the optimal value of the integer program (1.1) for A . Let $x_i \in \{-1, 1\}$ be a sign vector. Then

$$\sum_{i,j} a_{ij}x_i \cdot x_j = \left\| \frac{1}{n} \sum_{i=1}^n x_i v_i \right\|^2.$$

Therefore, the value of the integer program is the square of the maximum possible norm of a vector $\frac{1}{n} \sum_{i=1}^n x_i v_i$, where $x_i \in \{-1, 1\}$ for all i . If the direction of this optimal vector is given by the unit vector c , then, knowing c , it is clear how to choose x_i for each i ; it simply has to be $\text{sign}(v_i \cdot c)$. With this choice of the signs x_i , the quantity

$$\frac{1}{n} \sum_{i=1}^n x_i v_i \cdot c = \left\| \frac{1}{n} \sum_{i=1}^n x_i v_i \right\|$$

converges, when n tends to infinity, to the average value of $|v \cdot c|$, where v is a random vector on the sphere. By (4.6) this value is $(\sqrt{2/\pi} + o(1))\frac{1}{\sqrt{p}}$, where the $o(1)$ term tends to zero as p tends to infinity. Since n can be chosen to be arbitrarily large with respect to p , and as we do not have to consider all the infinitely many possible directions c but can consider an appropriate ϵ -net of directions on the sphere, we conclude that if p is large and n is huge, then, with high probability, the value of the integer program (1.1) for A is at most

$$\left[\left(\sqrt{\frac{2}{\pi}} + o(1) \right) \frac{1}{\sqrt{p}} \right]^2 = \left(\frac{2}{\pi} + o(1) \right) \frac{1}{p}.$$

It follows that the integrality gap is at least $\pi/2 - o(1)$, implying, by the discussion in the beginning of this subsection, that it is $\pi/2 + o(1)$.

4.3. Constructing new vectors: Krivine’s argument. The approach in this subsection is based on a simplified version of Krivine’s proof, presented in [18], of Grothendieck’s inequality as described in [15]. We need the following simple lemma, which has already been mentioned briefly in the introduction, and which has been applied in Grothendieck’s original proof as well.

LEMMA 4.1 (Grothendieck’s identity). *For every two unit vectors u, v in a finite-dimensional Euclidean space, if z is chosen randomly and uniformly from the unit sphere of the space, then*

$$\frac{\pi}{2} \cdot E([\text{sign}(u \cdot z)] \cdot [\text{sign}(v \cdot z)]) = \arcsin(u \cdot v).$$

Using this lemma, we prove the following.

LEMMA 4.2. *For any set $\{u_i : 1 \leq i \leq n\} \cup \{v_j : 1 \leq j \leq m\}$ of unit vectors in a Hilbert space H , and for $c = \sinh^{-1}(1) = \ln(1 + \sqrt{2})$, there is a set $\{u'_i : 1 \leq i \leq n\} \cup \{v'_j : 1 \leq j \leq m\}$ of unit vectors in a finite-dimensional Hilbert space H' , such that if z is chosen randomly and uniformly in the unit sphere of H' , then*

$$\frac{\pi}{2} \cdot E([\text{sign}(u'_i \cdot z)] \cdot [\text{sign}(v'_j \cdot z)]) = c u_i \cdot v_j$$

for all $1 \leq i \leq n, 1 \leq j \leq m$.

Proof. Fix c as above, a Hilbert space H , and $u, v \in H$. By Taylor’s expansion,

$$\sin(c u \cdot v) = \sum_{k=0}^{\infty} (-1)^k \frac{c^{2k+1}}{(2k+1)!} (u \cdot v)^{2k+1}.$$

For every vector w and integer j denote by $w^{\otimes j}$ the j th tensor power $w \otimes w \otimes \dots \otimes w$ (j terms). Then the above expansion becomes

$$\sin(c u \cdot v) = \sum_{k=0}^{\infty} (-1)^k \frac{c^{2k+1}}{(2k+1)!} u^{\otimes(2k+1)} \cdot v^{\otimes(2k+1)}.$$

Consider the following vectors in the direct sum $\bigoplus_{k=0}^{\infty} H^{\otimes(2k+1)}$, whose k th “coordinates” are given by

$$T(u)_k = (-1)^k \sqrt{\frac{c^{2k+1}}{(2k+1)!}} \cdot u^{\otimes(2k+1)} \quad \text{and} \quad S(v)_k = \sqrt{\frac{c^{2k+1}}{(2k+1)!}} \cdot v^{\otimes(2k+1)}.$$

Then the above expansion boils down to $\sin(c u \cdot v) = T(u) \cdot S(v)$, or

$$c u \cdot v = \arcsin(T(u) \cdot S(v)).$$

Moreover,

$$\|T(u)\|^2 = \sinh(c \cdot \|u\|^2) \quad \text{and} \quad \|S(v)\|^2 = \sinh(c \cdot \|v\|^2).$$

Given the unit vectors u_i, v_j , recall that $c = \sinh^{-1}(1)$ and define $u'_i = T(u_i)$ and $v'_j = S(v_j)$. Note that all the vectors u'_i, v'_j are unit vectors (in the huge direct sum of tensor products we constructed). Let H' be the span of u'_i, v'_j . It is an $(m+n)$ -dimensional Hilbert space. Let z be a random vector chosen uniformly on its unit sphere. By Grothendieck’s identity (Lemma 4.1), for every i, j ,

$$\frac{\pi}{2} \cdot E([\text{sign}(T(u_i) \cdot z)] \cdot [\text{sign}(S(v_j) \cdot z)]) = \arcsin(T(u_i) \cdot S(v_j)) = c u_i \cdot v_j$$

as needed. \square

THEOREM 4.3. *There is a randomized polynomial-time algorithm that, given an input n by m matrix $A = (a_{ij})$ and unit vectors u_i, v_j in R^{n+m} , finds $x_i, y_j \in \{-1, 1\}$ such that the expected value of the sum $\sum_{ij} a_{ij} x_i y_j$ is*

$$\frac{2 \ln(1 + \sqrt{2})}{\pi} \sum_{ij} a_{ij} u_i \cdot v_j.$$

Therefore, there is a polynomial randomized ρ -approximation algorithm for computing $\|A\|_{\infty \mapsto 1}$, where $\rho = \frac{2 \ln(1 + \sqrt{2})}{\pi} > 0.56$.

Proof. By Lemma 4.2 there are vectors u'_i, v'_j satisfying the conclusion of the lemma. We can thus find such vectors in an $(m+n)$ -dimensional space, using semidefinite programming. (This step can in fact be performed in a more efficient way either by using enough coordinates of the infinite-dimensional vectors $T(u_i), S(v_j)$ defined in the proof of Lemma 4.2 or by finding a root of the Gram matrix of the vectors u'_i, v'_j whose terms can be computed by the same proof. This, however, will not change the total running time by more than a constant factor, as we still have to solve one semidefinite programming problem for finding the vectors u_i, v_j .) By linearity of expectation, with $c = \sinh^{-1}(1)$ as above,

$$c \cdot \sum_{i,j} a_{ij} u_i \cdot v_j = \frac{\pi}{2} \cdot E \left(\sum_{i,j} a_{ij} [\text{sign}(u'_i \cdot z)] \cdot [\text{sign}(v'_j \cdot z)] \right).$$

We can now simply pick a random z and define $x_i = \text{sign}(u'_i \cdot z)$ and $y_j = \text{sign}(v'_j \cdot z)$. \square

4.4. The cut-norm. In this short subsection we observe that the same approximation ratio guaranteed in any approximation algorithm for $\|A\|_{\infty \mapsto 1}$ can be obtained for the CUT NORM problem as well. Given an n by m matrix $A = a_{ij}$, augment it to an $(n+1)$ by $(m+1)$ matrix $A' = (a'_{ij})$ by defining $a'_{ij} = a_{ij}$ for all $1 \leq i \leq n, 1 \leq j \leq m, a'_{i,m+1} = -\sum_{j=1}^m a_{ij}$ for all $1 \leq i \leq n, a'_{n+1,j} = -\sum_{i=1}^n a_{ij}$ for all $1 \leq j \leq m$, and $a'_{n+1,m+1} = 0$. We claim that $\|A'\|_C = \|A\|_C$. Indeed, obviously $\|A'\|_C \geq \|A\|_C$, as A is a submatrix of A' . Conversely, let $I \subset \{1, 2, \dots, n+1\}, J \subset \{1, 2, \dots, m+1\}$ satisfy $\|A'\|_C = |\sum_{i \in I, j \in J} a'_{ij}|$. If $n+1 \in I$, replace it by its complement $\{1, 2, \dots, n+1\} \setminus I$, and similarly, if $m+1 \in J$, replace it by its complement $\{1, 2, \dots, m+1\} \setminus J$. As the sum of each row and the sum of each column of A' is zero, the absolute value of the sum $\sum_{i \in I, j \in J} a'_{ij}$ with the new sets I, J is still equal to $\|A'\|_C$. This is, however, the sum of elements of a submatrix of A , implying that in fact $\|A'\|_C = \|A\|_C$ as claimed.

By the last part of Lemma 2.1, $\|A'\|_{\infty \mapsto 1} = 4\|A'\|_C$, and thus we can simply apply any algorithm for ρ -approximating $\|A'\|_{\infty \mapsto 1}$ to obtain a similar ρ -approximation of $\|A'\|_C = \|A\|_C$.

5. Examples and motivation. In order to explain the motivation for finding approximation algorithms for the cut-norm, in this section we present a few illustrative examples showing how the cut-norm occurs naturally in algorithmic contexts.

Let $G = (V, E)$ be an undirected graph, and let A and B be two disjoint nonempty subsets of V . Let $e(A, B)$ denote the number of edges of G with an endpoint in A and an endpoint in B , and define the *density of edges* between A and B by $d(A, B) = \frac{e(A, B)}{|A||B|}$. For $\epsilon > 0$, the pair (A, B) is called ϵ -regular if for every $X \subset A$ and $Y \subset B$

satisfying $|X| \geq \epsilon|A|$ and $|Y| \geq \epsilon|B|$, we have

$$|d(A, B) - d(X, Y)| < \epsilon.$$

The regularity lemma of Szemerédi [25] is a fundamental result that asserts that any graph can be partitioned in a certain regular way. An algorithmic version of this lemma appears in [3], together with several algorithmic applications. The main step in [3] is a polynomial-time algorithm that, given two disjoint subsets $A, B \subset V$ in a graph G , where $|A| = |B| = n$ and given $\epsilon > 0$, either decides that the pair (A, B) is ϵ -regular or finds two subsets $X \subset A$ and $Y \subset B$, each of size at least $\frac{\epsilon}{16}n$, such that $|d(A, B) - d(X, Y)| \geq \epsilon^4$. Given $G = (V, E)$, $\epsilon > 0$, and A, B as above, denote $d = d(A, B)$. Let $F = (f_{ab})_{a \in A, b \in B}$ be the n by n matrix defined by $f_{ab} = 1 - d$ if $ab \in E$ and $f_{ab} = -d$ if $ab \notin E$. Note that if (A, B) is not ϵ -regular, then there are $I \subset A$, $J \subset B$ satisfying $|I| \geq \epsilon n$, $|J| \geq \epsilon n$ such that

$$\left| \sum_{a \in I, b \in J} f_{ab} \right| \geq \epsilon|I||J| \geq \epsilon^3 n^2,$$

that is, the cut-norm of F is at least $\epsilon^3 n^2$. Therefore, in this case the algorithm presented in this paper will find efficiently $X \subset A$, $Y \subset B$ such that

$$\left| \sum_{a \in X, b \in Y} f_{ab} \right| \geq 0.56\epsilon^3 n^2.$$

Obviously this implies, say, that $|X| \geq 0.5\epsilon^3 n$, $|Y| \geq 0.5\epsilon^3 n$, and $|d(X, Y) - d(A, B)| \geq 0.5\epsilon^3$.

If the algorithm does not find such sets, it can report that the pair (A, B) is ϵ -regular. This can be used instead of Corollary 3.3 in [3] to obtain efficiently a regular partition of any given graph with less parts than the ones ensured by the algorithm in [3]. (But the number will still be huge; a tower of height polynomial in $1/\epsilon$, the degree of this polynomial will be smaller than the one in [3]. By being a bit careful this height can be shown to be $O(1/\epsilon^7)$, whereas the height obtained in [3] is $\Theta(1/\epsilon^{20})$.) Moreover, our algorithm actually finds subsets $I \subset A$, $J \subset B$ maximizing (approximately) the value of $|e(I, J)| \cdot |A| \cdot |B| - e(A, B)|I| \cdot |J|$, while the algorithm in [3] relies on the fact that this maximum is of order n^2 (i.e., that the problem is “dense”).

The rounding techniques described in section 3 or in subsection 4.1 (but not the one described in subsection 4.3) can be used to find efficiently, for any given square n by n matrix $A = (a_{ij})$, a vector $(x_1, \dots, x_n) \in \{-1, 1\}$, such that the value of $|\sum_{ij} a_{ij} x_i x_j|$ is at least a ρ -fraction of the maximum possible value of this quantity (or even the quantity $|\sum_{ij} a_{ij} u_i \cdot u_j|$, where u_i, u_j are unit vectors in a Hilbert space). Note that here we do not assume that A is positive semidefinite (but we try to maximize the absolute value of the quadratic form, not the quadratic form itself). By applying this approximation algorithm to a matrix defined from a graph G as above, we can find an induced subgraph that approximates the maximum possible deviation of the total number of edges from its expected value among all induced subgraphs of the graph.

In [8] Frieze and Kannan describe an efficient algorithm for finding what they call a *cut-decomposition* of a given n by m real matrix A , and apply it to obtain efficient approximation algorithms for various dense graph and matrix problems.

Consider matrices with a set of rows indexed by R and a set of columns indexed by S . For $I \subset R$ and $J \subset S$, and for a real d , the *cut matrix* $D = CUT(I, J, d)$ is the matrix $(d_{ij})_{i \in R, j \in S}$ defined by $d_{ij} = d$ if $i \in I, j \in J$ and $d_{ij} = 0$ otherwise. A *cut-decomposition* of A expresses it in the form

$$A = D^{(1)} + \dots + D^{(s)} + W,$$

where the matrices $D^{(i)}$ are cut matrices, and the matrix $W = (w_{kl})$ has a relatively small cut-norm.

The authors of [8] describe an efficient algorithm that produces, for any given n by m matrix A with entries in $[-1, 1]$, a cut-decomposition in which the number of cut matrices is $O(1/\epsilon^2)$, and the cut-norm of the matrix W is at most ϵnm . This is done as follows. Starting with $W^{(0)} = A$, suppose that the first i cut matrices $D^{(1)}, \dots, D^{(i)}$ have already been defined, and consider the difference $W^{(i)} = A - \sum_{j=1}^i D^{(j)}$. If the cut-norm of this difference is already smaller than ϵnm , we are done. Otherwise, let I, J be sets of rows and columns such that

$$(5.1) \quad \left| \sum_{k \in I, l \in J} w_{kl}^{(i)} \right| \geq \rho \epsilon nm,$$

where $\rho > 0$ is an absolute positive constant. Let d be the average value of the entries $w_{kl}^{(i)}$ for $k \in I, l \in J$, and define $D^{(i+1)} = CUT(I, J, d)$, $W^{(i+1)} = W^{(i)} - D^{(i+1)}$. A simple computation, described in [8], shows that the sum of squares of the entries of the new matrix $W^{(i+1)}$ is at most the sum of squares of the entries of the matrix $W^{(i)}$ minus $\rho^2 \epsilon^2 nm$. Therefore, this process must terminate after at most $\frac{1}{\rho^2 \epsilon^2}$ steps. The main step in the algorithm is clearly that of finding the sets I, J that satisfy (5.1), and the authors are able to do it efficiently only when the cut-norm is at least a constant fraction of nm . Our algorithm here enables us to perform this task efficiently (even if ϵ is, say, $1/n^{0.001}$, which is not feasible using the approach of [8], as the running time of their algorithm is exponential in $1/\epsilon^2$).

Another possible application of our approximation algorithm appears in computational molecular biology. While trying to identify groups of genes with statistically significant correlated behavior across diverse experiments, it is desirable to solve a certain biclustering problem; see [27], [26]. The basic computational problem here is to find efficiently, in a given matrix whose entries are the logarithms of certain probabilities, a submatrix of (approximately) maximum total sum. Our algorithm supplies such a procedure in case the sum of entries in every row (or every column) of the given matrix is zero.

6. Concluding remarks.

- There is a lot known about Grothendieck’s inequality in the case of complex scalars [13], [17], and it may be interesting to find algorithmic or combinatorial applications of these results.
- We believe that the methods described in this paper will find further applications, as they provide a rounding technique that can, at least in the cases considered here, handle cancellations between positive and negative terms.
- It will be interesting to improve the approximation guarantee of the algorithms presented here. It will also be interesting to find a ρ -approximation algorithm for the CUT NORM problem (for any positive absolute constant ρ) which does not apply semidefinite programming and/or can be analyzed without relying on Grothendieck’s inequality.

Acknowledgments. Part of this work was carried out during a visit by the first author to Microsoft Research, Redmond, WA, and he thanks his hosts at Microsoft for their hospitality. The authors also thank L. Babai and M. Goemans for helpful comments.

LOWER BOUNDS FOR LOCAL SEARCH BY QUANTUM ARGUMENTS*

SCOTT AARONSON†

Abstract. The problem of finding a local minimum of a black-box function is central for understanding local search as well as quantum adiabatic algorithms. For functions on the Boolean hypercube $\{0, 1\}^n$, we show a lower bound of $\Omega(2^{n/4}/n)$ on the number of queries needed by a quantum computer to solve this problem. More surprisingly, our approach, based on Ambainis’s quantum adversary method, also yields a lower bound of $\Omega(2^{n/2}/n^2)$ on the problem’s *classical* randomized query complexity. This improves and simplifies a 1983 result of Aldous. Finally, in both the randomized and quantum cases, we give the first nontrivial lower bounds for finding local minima on grids of constant dimension $d \geq 3$.

Key words. quantum computing, query complexity, decision trees, local search, local optima, polynomial local search, random walks

1. Introduction. This paper deals with the following problem.

LOCAL SEARCH. *Given an undirected graph $G = (V, E)$ and a function $f : V \rightarrow \mathbb{N}$, find a local minimum of f —that is, a vertex v such that $f(v) \leq f(w)$ for all neighbors w of v .*

We are interested in the number of *queries* that an algorithm needs to solve this problem, where a query just returns $f(v)$ given v . We consider deterministic, randomized, and quantum algorithms. Section 2 motivates the problem theoretically and practically; this section explains our results.

We start with some simple observations. If G is the complete graph of size N , then clearly $\Omega(N)$ queries are needed to find a local minimum (or $\Omega(\sqrt{N})$ with a quantum computer [8]). At the other extreme, if G is a line of length N , then even a deterministic algorithm can find a local minimum in $O(\log N)$ queries, using binary search: query the middle two vertices, v and w . If $f(v) \leq f(w)$, then search the line of length $(N - 2)/2$ connected to v ; otherwise search the line connected to w . Continue recursively in this manner until a local minimum is found.

So the interesting case is when G is a graph of “intermediate” connectedness: for example, the Boolean hypercube $\{0, 1\}^n$, with two vertices adjacent if and only if they have Hamming distance 1. For this graph, Llewellyn, Tovey, and Trick [18, 19] showed an $\Omega(2^n/\sqrt{n})$ lower bound on the number of queries needed by any deterministic algorithm, using a simple adversary argument. Intuitively, until the set of vertices queried so far comprises a *vertex cut* (that is, splits the graph into two or more connected components), an adversary is free to return a descending sequence of f values: $f(v_1) = 2^n$ for the first vertex v_1 queried by the algorithm, $f(v_2) = 2^n - 1$ for the second vertex queried, and so on. Moreover, once the set of queried vertices

†University of Waterloo, Waterloo, ON, N2L 3G1, Canada (scott@scottaaronson.com).

does comprise a cut, the adversary can choose the largest connected component of unqueried vertices and restrict the problem recursively to that component. So to lower-bound the deterministic query complexity, it suffices to lower-bound the size of any cut that splits the graph into two reasonably large components.¹ For the Boolean hypercube, Llewellyn, Tovey, and Trick showed that the best one can do is essentially to query all $\Omega(2^n/\sqrt{n})$ vertices of Hamming weight $n/2$.

The argument of Llewellyn, Tovey, and Trick fails completely in the case of randomized algorithms. By Yao's minimax principle, what we want here is a fixed *distribution* \mathcal{D} over functions $f : \{0, 1\}^n \rightarrow \mathbb{N}$, such that any deterministic algorithm needs many queries to find a local minimum of f , with high probability if f is drawn from \mathcal{D} . Taking \mathcal{D} to be uniform will not do, since a local minimum of a uniform random function is easily found. However, Aldous [3] had the idea of defining \mathcal{D} via a *random walk*, as follows. Choose a vertex $v_0 \in \{0, 1\}^n$ uniformly at random; then perform an unbiased walk² v_0, v_1, v_2, \dots starting from v_0 . For each vertex v , set $f(v)$ equal to the first hitting time of the walk at v —that is, $f(v) = \min\{t : v_t = v\}$. Clearly any f produced in this way has a unique local minimum at v_0 , since for all $t > 0$, if vertex v_t is visited for the first time at step t , then $f(v_t) > f(v_{t-1})$. Using sophisticated random walk analysis, Aldous managed to show a lower bound of $2^{n/2-o(n)}$ on the expected number of queries needed by any randomized algorithm to find v_0 .³ (As we will see in section 3, this lower bound is close to tight.) Intuitively, since a random walk on the hypercube mixes in $O(n \log n)$ steps, an algorithm that has not queried a v with $f(v) < 2^{n/2}$ has almost no useful information about where the unique minimum v_0 is, so its next query will just be a “stab in the dark.”

However, Aldous's result leaves several questions about LOCAL SEARCH unanswered. What if the graph G is a three-dimensional (3-D) cube, on which a random walk does *not* mix very rapidly? Can we still lower-bound the randomized query complexity of finding a local minimum? More generally, what parameters of G make the problem hard or easy? Also, what is the quantum query complexity of LOCAL SEARCH?

This paper presents a new approach to LOCAL SEARCH, which we believe points the way to a complete understanding of its complexity. Our approach is based on the *quantum adversary method*, introduced by Ambainis [4] to prove lower bounds on quantum query complexity. Surprisingly, our approach yields new and simpler lower bounds for the problem's *classical* randomized query complexity, in addition to quantum lower bounds. Thus, along with recent work by Kerenidis and de Wolf [15] and Aharonov and Regev [2] among others, this paper illustrates how quantum ideas can help to resolve classical open problems.

Our results are as follows. For the Boolean hypercube $G = \{0, 1\}^n$, we show that any quantum algorithm needs $\Omega(2^{n/4}/n)$ queries to find a local minimum on G , and any randomized algorithm needs $\Omega(2^{n/2}/n^2)$ queries (improving the $2^{n/2-o(n)}$ lower bound of Aldous [3]). Our proofs are elementary and do not require random walk analysis. By comparison, the best known upper bounds are $O(2^{n/3}n^{1/6})$ for a quantum algorithm and $O(2^{n/2}\sqrt{n})$ for a randomized algorithm. If G is a d -

¹Llewellyn, Tovey, and Trick actually give a tight characterization of deterministic query complexity in terms of vertex cuts.

²Actually, Aldous used a continuous-time random walk, so the functions would be from $\{0, 1\}^n$ to \mathbb{R} .

³Independently and much later, Droste, Jansen, and Wegener [11] showed the weaker bound $2^{g(n)}$ for any $g(n) = o(n)$.

dimensional grid of size $N^{1/d} \times \dots \times N^{1/d}$, where $d \geq 3$ is a constant, then we show that any quantum algorithm needs $\Omega(\sqrt{N^{1/2-1/d}/\log N})$ queries to find a local minimum on G , and any randomized algorithm needs $\Omega(N^{1/2-1/d}/\log N)$ queries. No nontrivial lower bounds (randomized or quantum) were previously known in this case.⁴ For any graph with N vertices and degree δ , we also show an upper bound of $O(N^{1/3}\delta^{1/6})$ on the quantum query complexity.

The paper is organized as follows. Section 2 motivates lower bounds on LOCAL SEARCH, pointing out connections to simulated annealing, quantum adiabatic algorithms, and the complexity class TFNP of total function problems. Section 3 defines notation and reviews basic facts about LOCAL SEARCH, including the $O(N^{1/3}\delta^{1/6})$ upper bound. In section 4 we give an intuitive explanation of Ambainis’s quantum adversary method, then state and prove a classical analogue of Ambainis’s main lower bound theorem. Section 5 introduces *snakes*, a construction by which we apply the two adversary methods to LOCAL SEARCH. We show there that to prove lower bounds for any graph G , it suffices to upper-bound a combinatorial parameter ε of a “snake distribution” on G . Section 6 applies this framework to specific examples of graphs: the Boolean hypercube in section 6.1 and the d -dimensional grid in section 6.2.

1.1. Current status. In an earlier version of this paper, we raised as our “most ambitious” conjecture that the deterministic and quantum query complexities of LOCAL SEARCH are polynomially related for *every* family of graphs. At the time, it was not even known whether deterministic and *randomized* query complexities were polynomially related, not even for simple examples such as the two-dimensional (2-D) square grid. Subsequently Santha and Szegedy [23] spectacularly resolved our conjecture, by showing that for every family of graphs, the quantum query complexity of LOCAL SEARCH is at least the 19th root (!) of the deterministic query complexity. They also showed that the quantum query complexity is $\Omega(N^{1/8})$ for the 2-D square grid.

So, like the King in the story of Rumpelstiltskin, we now feel emboldened to make a stronger conjecture: *for every family of graphs, the randomized query complexity of LOCAL SEARCH is at least the square root of the deterministic query complexity, the quantum query complexity is at least the square root of the randomized query complexity, and the quantum query complexity is at least the cube root of the deterministic query complexity.* Intuitively, there is “never anything better to do” than some combination of Grover’s algorithm with the classical steepest descent and divide-and-conquer heuristics.

Recent progress on specific graph families lends some support to our conjecture. For the Boolean hypercube $\{0, 1\}^n$, Zhang [27] has shown that the known algorithms are exactly optimal—that is, the randomized query complexity of LOCAL SEARCH is $\Theta(2^{n/2}\sqrt{n})$, and the quantum query complexity is $\Theta(2^{n/3}n^{1/6})$. Zhang has also shown the following lower bounds for the d -dimensional grid of size $N^{1/d} \times \dots \times N^{1/d}$:

Dimension	Randomized	Quantum
$d = 2$	$\Omega(N^{1/3})$	$\Omega(N^{1/6})$
$d = 3$	$\Omega\left((N/\log N)^{1/2}\right)$	$\Omega(N^{1/4})$
$d = 4$	$\Omega(N^{1/2})$	$\Omega(N^{3/10})$
$d = 5$	$\Omega(N^{1/2})$	$\Omega\left((N/\log N)^{1/3}\right)$
$d \geq 6$	$\Omega(N^{1/2})$	$\Omega(N^{1/3})$

⁴A lower bound on deterministic query complexity was known for such graphs [17].

Note that Zhang’s randomized lower bound is tight when $d \geq 4$, and his quantum lower bound is tight when $d \geq 6$. Finally, in the $d = 2$ case, Zhang has given a quantum upper bound of $O(N^{1/4} (\log \log N)^2)$, which Verhoeven [25] very recently improved to $O(N^{1/4} \log \log N)$ and generalized to all planar and bounded-genus graphs. Currently, no randomized upper bound better than $O(\sqrt{N})$ is known when $d \geq 2$, and no quantum upper bound better than $O(N^{1/3})$ is known when $d \geq 3$.

In a different direction, Laplante and Magniez [16] proposed a variant of Ambainis’s adversary method based on Kolmogorov complexity and showed that their variant also allows randomized and quantum query complexity to be lower-bounded in a unified way. Subsequently, Špalek and Szegedy [26] showed that Laplante and Magniez’s variant is equivalent to a weighted generalization of Ambainis’s original adversary method.

2. Motivation. Local search is the most effective weapon ever devised against hard optimization problems. For many real applications, neither backtrack search, nor approximation algorithms, nor even Grover’s algorithm (assuming we had a quantum computer) can compare. Furthermore, along with quantum computing, local search (broadly defined) is one of the most interesting links between computer science and Nature. It is related to evolutionary biology via genetic algorithms and to the physics of materials via simulated annealing. Thus it is both practically and scientifically important to understand its performance.

The conventional wisdom is that, although local search performs well in practice, its central (indeed defining) flaw is a tendency to get stuck at local optima. If this were correct, one corollary would be that the reason local search performs so well is that the problem it really solves—finding a local optimum—is intrinsically easy. It would thus be unnecessary to seek further explanations for its performance. Another corollary would be that, for *unimodal* functions (which have no local optima besides the global optimum), the global optimum would be easily found.

However, the conventional wisdom is false. The results of Llewellyn, Tovey, and Trick [18, 19] and Aldous [3] show that even if f is unimodal, any classical algorithm that treats f as a black box needs exponential time to find the global minimum of f in general. Our results extend this conclusion to quantum algorithms. In our view, the practical upshot of these results is that they force us to confront the question, what is it about “real-world” problems that makes it easy to find a local optimum? That is, why do exponentially long chains of descending values, such as those used for lower bounds, almost never occur in practice (even in functions with large range sizes)? One possibility is that the functions that occur in practice look “globally” like random functions, but we do not know whether that is true in any meaningful sense.

Our results are also relevant for physics. Many physical systems, including folding proteins and networks of springs and pulleys, can be understood as performing “local search” through an energy landscape to reach a locally minimal energy configuration. A key question is, how long will the system take to reach its ground state (that is, a globally minimal configuration)? Of course, if there are local optima, the system might *never* reach its ground state, just as a rock in a mountain crevice does not roll to the bottom by going up first. But what if the energy landscape is unimodal? And moreover, what if the physical system is quantum? Our results show that, for certain energy landscapes, even a quantum system would take exponential time to reach its ground state, regardless of what Hamiltonian is applied to it. So, in particular, the quantum adiabatic algorithm proposed by Farhi et al. [13], which can be seen as a quantum analogue of simulated annealing, needs exponential time to find a local

minimum in the worst case.

Finally, our results have implications for so-called *total function problems* in complexity theory. Megiddo and Papadimitriou [20] defined a complexity class⁵ TFNP, consisting (informally) of those NP search problems for which a solution always exists. For example, we might be given a function $f : \{0, 1\}^n \rightarrow \{0, 1\}^{n-1}$ as a Boolean circuit and asked to find any distinct x, y pair such that $f(x) = f(y)$. This particular problem belongs to a subclass of TFNP called PPP (Polynomial Pigeonhole Principle). Notice that no promise is involved: the combinatorial nature of the problem itself forces a solution to exist, even if we have no idea how to find it. In a recent talk, Papadimitriou [22] asked broadly whether such “nonconstructive existence problems” might be good candidates for efficient quantum algorithms. In the case of PPP problems, the collision lower bound of Aaronson [1] (improved by Shi [24] and others) implies a negative answer in the black-box setting. For other subclasses of TFNP, such as PODN (polynomial odd-degree node), a quantum black-box lower bound follows easily from the optimality of Grover’s search algorithm.

However, there is one important subclass of TFNP for which no quantum lower bound was previously known. This is PLS (polynomial local search), defined by Johnson, Papadimitriou, and Yannakakis [14] as a class of optimization problems whose cost function f and neighborhood function η (that is, the set of neighbors of a given point) are both computable in polynomial time. Given such a problem, the task is to output any local minimum of the cost function: that is, a v such that $f(v) \leq f(w)$ for all $w \in \eta(v)$. The lower bound of Llewellyn, Tovey, and Trick [18, 19] yields an oracle A relative to which $\text{FP}^A \neq \text{PLS}^A$, by a standard diagonalization argument along the lines of Baker, Gill, and Solovay [6]. Likewise, the lower bound of Aldous [3] yields an oracle relative to which $\text{PLS} \not\subseteq \text{FBPP}$, where FBPP is simply the function version of BPP. Our results yield the first oracle relative to which $\text{PLS} \not\subseteq \text{FBQP}$. In light of this oracle separation, we raise an admittedly vague question, is there a nontrivial “combinatorial” subclass of TFNP that we can show *is* contained in FBQP?

3. Preliminaries. In the LOCAL SEARCH problem, we are given an undirected graph $G = (V, E)$ with $N = |V|$ and oracle access to a function $f : V \rightarrow \mathbb{N}$. The goal is to find any *local minimum* of f , defined as a vertex $v \in V$ such that $f(v) \leq f(w)$ for all neighbors w of v . Clearly such a local minimum exists. We want to find one using as few queries as possible, where a query returns $f(v)$ given v . Queries can be adaptive; that is, they can depend on the outcomes of previous queries. We assume G is known in advance, so that only f needs to be queried. Since we care only about query complexity, not computation time, there is no difficulty in dealing with an infinite range for f —though for our lower bounds, it will turn out that a range of size $O(|V|)$ suffices.

Our model of query algorithms is the standard one; see [9] for a survey. Given a graph G , the deterministic query complexity of LOCAL SEARCH on G , which we denote $\text{DLS}(G)$, is $\min_{\Gamma} \max_f T(\Gamma, f, G)$ where the minimum ranges over all deterministic algorithms Γ , the maximum ranges over all f , and $T(\Gamma, f, G)$ is the number of queries made to f by Γ before it halts and outputs a local minimum of f (or ∞ if Γ fails to do so). The randomized query complexity $\text{RLS}(G)$ is defined similarly, except that now the algorithm has access to an infinite random string R and must only output a local minimum with probability at least $2/3$ over R . For simplicity, we assume that the number of queries T is the same for all R ; clearly this assumption changes the

⁵See www.complexityzoo.com for details about the complexity classes mentioned in this paper.

complexity by at most a constant factor.

In the quantum model, an algorithm's state has the form $\sum_{v,z,s} \alpha_{v,z,s} |v, z, s\rangle$, where v is the label of a vertex in G , and z and s are strings representing the answer register and workspace, respectively. The $\alpha_{v,z,s}$'s are complex amplitudes satisfying $\sum_{v,z,s} |\alpha_{v,z,s}|^2 = 1$. Starting from an arbitrary (fixed) initial state, the algorithm proceeds by an alternating sequence of *queries* and *algorithm steps*. A query maps each $|v, z, s\rangle$ to $|v, z \oplus f(v), s\rangle$, where \oplus denotes bitwise exclusive-OR. An algorithm step multiplies the vector of $\alpha_{v,z,s}$'s by an arbitrary unitary matrix that does not depend on f . Letting \mathcal{M}_f denote the set of local minima of f , the algorithm succeeds if at the end $\sum_{v,z,s : v \in \mathcal{M}_f} |\alpha_{v,z,s}|^2 \geq \frac{2}{3}$. Then the bounded-error quantum query complexity, or $\text{QLS}(G)$, is defined as the minimum number of queries used by a quantum algorithm that succeeds on every f .

It is immediate that $\text{QLS}(G) \leq \text{RLS}(G) \leq \text{DLS}(G) \leq N$. Also, letting δ be the maximum degree of G , we have the following trivial lower bound.

PROPOSITION 3.1. $\text{RLS}(G) = \Omega(\delta)$ and $\text{QLS}(G) = \Omega(\sqrt{\delta})$.

Proof. Let v be a vertex of G with degree δ . Choose a neighbor w of v uniformly at random, and let $f(w) = 1$. Let $f(v) = 2$, and $f(u) = 3$ for all neighbors u of v other than w . Let S be the neighbor set of v (including v itself); then for all $x \notin S$, let $f(x) = 3 + \Delta(x, S)$, where $\Delta(x, S)$ is the minimum distance from x to a vertex in S . Clearly f has a unique local minimum at w . However, finding y requires exhaustive search among the δ neighbors of v , which takes $\Omega(\sqrt{\delta})$ quantum queries by Bennett et al. [8]. \square

A corollary of Proposition 3.1 is that classically, zero-error randomized query complexity is equivalent to bounded-error up to a constant factor. For given a candidate local minimum v , one can check using $O(\delta)$ queries that v is indeed a local minimum. Since $\Omega(\delta)$ queries are needed anyway, this verification step does not affect the overall complexity.

As pointed out by Aldous [3], a classical randomized algorithm can find a local minimum of f with high probability in $O(\sqrt{N\delta})$ queries. The algorithm just queries $\sqrt{N\delta}$ vertices uniformly at random, and lets v_0 be a queried vertex for which $f(v)$ is minimal. It then follows v_0 to a local minimum by steepest descent. That is, for $t = 0, 1, 2, \dots$, it queries all neighbors of v_t , halts if v_t is a local minimum, and otherwise sets v_{t+1} to be the neighbor w of v_t for which $f(w)$ is minimal (breaking ties by lexicographic ordering). A similar idea yields an improved quantum upper bound.

THEOREM 3.2. For any G , $\text{QLS}(G) = O(N^{1/3}\delta^{1/6})$.

Proof. The algorithm first chooses $N^{2/3}\delta^{1/3}$ vertices of G uniformly at random, then uses Grover search to find a chosen vertex v_0 for which $f(v)$ is minimal. By a result of Dürr and Høyer [12], this can be done with high probability in $O(N^{1/3}\delta^{1/6})$ queries. Next, for $t = 0, 1, 2, \dots$, the algorithm performs Grover search over all neighbors of v_t , looking for a neighbor w such that $f(w) < f(v_t)$. If it finds such a w , then it sets $v_{t+1} := w$ and continues to the next iteration. Otherwise, it repeats the Grover search $\log(N/\delta)$ times before finally giving up and returning v_t as a claimed local minimum.

The expected number of u such that $f(u) < f(v_0)$ is at most $N / (N^{2/3}\delta^{1/3}) = (N/\delta)^{1/3}$. Since $f(v_{t+1}) < f(v_t)$ for all t , clearly the number of such u provides an upper bound on t . Furthermore, assuming there exists a w such that $f(w) < f(v_t)$, the expected number of repetitions of Grover's algorithm until such a w is found is $O(1)$. Since each repetition takes $O(\sqrt{\delta})$ queries, by linearity of expectation the total

expected number of queries used by the algorithm is therefore

$$O\left(N^{1/3}\delta^{1/6} + (N/\delta)^{1/3}\sqrt{\delta} + \log(N/\delta)\sqrt{\delta}\right)$$

or $O(N^{1/3}\delta^{1/6})$. To see that the algorithm finds a local minimum with high probability, observe that for each t the probability of not finding a w such that $f(w) < f(v_t)$, given that one exists, is at most $c^{-\log(N/\delta)} \leq (\delta/N)^{1/3}/10$ for a suitable constant c . So by the union bound, the probability that the algorithm returns a “false positive” is at most $(N/\delta)^{1/3} \cdot (\delta/N)^{1/3}/10 = 1/10$. \square

4. Relational adversary method. We know essentially two methods for proving lower bounds on quantum query complexity: the polynomial method of Beals et al. [7], and the quantum adversary method of Ambainis [4].⁶ For a few problems, such as the collision problem [1, 24], the polynomial method succeeded where the adversary method failed. However, for problems that lack permutation symmetry (such as LOCAL SEARCH), the adversary method has proven more effective.⁷

How could a quantum lower bound method possibly be applied classically? When proving randomized lower bounds, the tendency is to attack “bare-handed”: fix a distribution over inputs, and let x_1, \dots, x_t be the locations queried so far by the algorithm. Show that for small t , the posterior distribution over inputs, *conditioned* on x_1, \dots, x_t , is still “hard” with high probability—so that the algorithm knows almost nothing even about which location x_{t+1} to query next. This is essentially the approach taken by Aldous [3] to prove a $2^{n/2-o(n)}$ lower bound on RLS $(\{0, 1\}^n)$.

In the quantum case, however, it is unclear how to specify what an algorithm “knows” after a given number of queries. So we are almost *forced* to step back and identify general combinatorial properties of input sets that make them hard to distinguish. Once we have such properties, we can then try to exhibit them in functions of interest.

We will see, somewhat surprisingly, that this “gloved” approach is useful for classical lower bounds as well as quantum ones. In our *relational adversary method*, we assume there exists a T -query randomized algorithm for function F . We consider a set \mathcal{A} of 0-inputs of F , a set \mathcal{B} of 1-inputs, and an arbitrary real-valued *relation function* $R(A, B) \geq 0$ for $A \in \mathcal{A}$ and $B \in \mathcal{B}$. Intuitively, $R(A, B)$ should be large if A and B differ in only a few locations. We then fix a probability distribution \mathcal{D} over inputs; by Yao’s minimax principle, there exists a T -query deterministic algorithm Γ^* that succeeds with high probability on inputs drawn from \mathcal{D} . Let W_A be the set of 0-inputs and W_B the set of 1-inputs on which Γ^* succeeds. Using the relation function R , we define a *separation measure* S between W_A and W_B and show that (1) initially $S = 0$, (2) by the end of the computation S must be large, and (3) S increases by only a small amount as the result of each query. It follows that T must be large.

The advantage of the relational method is that it converts a “dynamic” opponent—an algorithm that queries adaptively—into a relatively static one. It thereby makes it easier to focus on what is unique about a problem and ignore aspects of query complexity that are common to all problems. Furthermore, one does not need to know anything about quantum computing to understand and apply the method. On the other hand, it is not clear how one would come up with it in the first place, without

⁶We are thinking here of the hybrid method [8] as a cousin of the adversary method.

⁷Indeed, Ambainis [5] has given problems for which the adversary method provably yields a better lower bound than the polynomial method.

Ambainis’s *quantum* adversary method [4] and the reasoning about entanglement that led to it.

Our starting point is the “most general” adversary theorem in Ambainis’s original paper (Theorem 6 in [4]), which he introduced to prove a quantum lower bound for the problem of inverting a permutation. Here the input is a permutation $\sigma(1), \dots, \sigma(N)$, and the task is to output 0 if $\sigma^{-1}(1) \leq N/2$ and 1 otherwise. To lower-bound this problem’s query complexity, what we would like to say is the following.

Given any 0-input σ and any location x , if we choose a random 1-input τ that is “related” to σ , then the probability $\theta(\sigma, x)$ over τ that $\sigma(x)$ does not equal $\tau(x)$ is small. In other words, the algorithm is unlikely to distinguish σ from a random neighbor τ of σ by querying x .

Unfortunately, the above claim is false. Letting $x = \sigma^{-1}(1)$, we have that $\sigma(x) \neq \tau(x)$ for every 1-input τ , and thus $\theta(\sigma, x) = 1$. Ambainis resolves this difficulty by letting us take the maximum, over all 0-inputs σ and 1-inputs τ that are related and differ at x , of the *geometric mean* $\sqrt{\theta(\sigma, x)\theta(\tau, x)}$. Even if $\theta(\sigma, x) = 1$, the geometric mean is still small provided that $\theta(\tau, x)$ is small. More formally, we have the following theorem.

THEOREM 4.1 (Ambainis). *Let $\mathcal{A} \subseteq F^{-1}(0)$ and $\mathcal{B} \subseteq F^{-1}(1)$ be sets of inputs to function F . Let $R(A, B) \geq 0$ be a real-valued function, and for $A \in \mathcal{A}$, $B \in \mathcal{B}$, and location x , let*

$$\theta(A, x) = \frac{\sum_{B^* \in \mathcal{B} : A(x) \neq B^*(x)} R(A, B^*)}{\sum_{B^* \in \mathcal{B}} R(A, B^*)},$$

$$\theta(B, x) = \frac{\sum_{A^* \in \mathcal{A} : A^*(x) \neq B(x)} R(A^*, B)}{\sum_{A^* \in \mathcal{A}} R(A^*, B)},$$

where the denominators are all nonzero. Then the number of quantum queries needed to evaluate F with at least 9/10 probability is $\Omega(1/v_{\text{geom}})$, where

$$v_{\text{geom}} = \max_{A \in \mathcal{A}, B \in \mathcal{B}, x : R(A, B) > 0, A(x) \neq B(x)} \sqrt{\theta(A, x)\theta(B, x)}.$$

The best way to understand Theorem 4.1 is to see it used in an example.

PROPOSITION 4.2 (Ambainis). *The quantum query complexity of inverting a permutation is $\Omega(\sqrt{N})$.*

Proof. Let \mathcal{A} be the set of all permutations σ such that $\sigma^{-1}(1) \leq N/2$, and \mathcal{B} be the set of permutations τ such that $\tau^{-1}(1) > N/2$. Given $\sigma \in \mathcal{A}$ and $\tau \in \mathcal{B}$, let $R(\sigma, \tau) = 1$ if σ and τ differ only at locations $\sigma^{-1}(1)$ and $\tau^{-1}(1)$, and $R(\sigma, \tau) = 0$ otherwise. Then given σ, τ with $R(\sigma, \tau) = 1$, if $x \leq N/2$ then $\theta(\tau, x) \leq 2/N$, and if $x > N/2$ then $\theta(\sigma, x) \leq 2/N$. So $\max_x : \sigma(x) \neq \tau(x) \sqrt{\theta(\sigma, x)\theta(\tau, x)} \leq \sqrt{2/N}$. \square

The only difference between Theorem 4.1 and our relational adversary theorem is that in the latter, we take the *minimum* of $\theta(A, x)$ and $\theta(B, x)$ instead of the geometric mean. Taking the reciprocal then gives up to a quadratically better lower bound: for example, we obtain that the randomized query complexity of inverting a permutation is $\Omega(N)$. However, the proofs of the two theorems are quite different.

THEOREM 4.3. *Let $\mathcal{A}, \mathcal{B}, R, \theta$ be as in Theorem 4.1. Then the number of randomized queries needed to evaluate F with at least 9/10 probability is $\Omega(1/v_{\text{min}})$, where*

$$v_{\text{min}} = \max_{A \in \mathcal{A}, B \in \mathcal{B}, x : R(A, B) > 0, A(x) \neq B(x)} \min\{\theta(A, x), \theta(B, x)\}.$$

Proof. Let Γ be a randomized algorithm that, given an input A , returns $F(A)$ with at least $9/10$ probability. Let T be the number of queries made by Γ . For all $A \in \mathcal{A}$, $B \in \mathcal{B}$, define

$$\begin{aligned} M(A) &= \sum_{B^* \in \mathcal{B}} R(A, B^*), \\ M(B) &= \sum_{A^* \in \mathcal{A}} R(A^*, B), \\ M &= \sum_{A^* \in \mathcal{A}} M(A^*) = \sum_{B^* \in \mathcal{B}} M(B^*). \end{aligned}$$

Now let \mathcal{D}_A be the distribution over $A \in \mathcal{A}$ in which each A is chosen with probability $M(A)/M$; and let \mathcal{D}_B be the distribution over $B \in \mathcal{B}$ in which each B is chosen with probability $M(B)/M$. Let \mathcal{D} be an equal mixture of \mathcal{D}_A and \mathcal{D}_B . By Yao's minimax principle, there exists a deterministic algorithm Γ^* that makes T queries and succeeds with at least $9/10$ probability given an input drawn from \mathcal{D} . Therefore Γ^* succeeds with at least $4/5$ probability given an input drawn from \mathcal{D}_A alone or from \mathcal{D}_B alone. In other words, letting W_A be the set of $A \in \mathcal{A}$ and W_B the set of $B \in \mathcal{B}$ on which Γ^* succeeds, we have

$$\sum_{A \in W_A} M(A) \geq \frac{4}{5}M, \quad \sum_{B \in W_B} M(B) \geq \frac{4}{5}M.$$

Define a predicate $P^{(t)}(A, B)$, which is true if Γ^* has distinguished $A \in \mathcal{A}$ from $B \in \mathcal{B}$ by the t th query and false otherwise. (To distinguish A from B means to query an index x for which $A(x) \neq B(x)$, given either A or B as input.) Also, for all $A \in \mathcal{A}$, define a score function

$$S^{(t)}(A) = \sum_{B^* \in \mathcal{B} : P^{(t)}(A, B^*)} R(A, B^*).$$

This function measures how much "progress" has been made so far in separating A from \mathcal{B} inputs, where the \mathcal{B} inputs are weighted by $R(A, B)$. Similarly, for all $B \in \mathcal{B}$ define

$$S^{(t)}(B) = \sum_{A^* \in \mathcal{A} : P^{(t)}(A^*, B)} R(A^*, B).$$

It is clear that for all t ,

$$\sum_{A \in \mathcal{A}} S^{(t)}(A) = \sum_{B \in \mathcal{B}} S^{(t)}(B).$$

So we can denote the above sum by $S^{(t)}$ and think of it as a global progress measure. We will show the following about $S^{(t)}$:

- (i) $S^{(0)} = 0$ initially.
- (ii) $S^{(T)} \geq 3M/5$ by the end.
- (iii) $\Delta S^{(t)} \leq 3v_{\min}M$ for all t , where $\Delta S^{(t)} = S^{(t)} - S^{(t-1)}$ is the amount by which $S^{(t)}$ increases as the result of a single query.

It follows from (i)–(iii) that

$$T \geq \frac{3M/5}{3v_{\min}M} = \frac{1}{5v_{\min}},$$

which establishes the theorem. Part (i) is obvious. For part (ii), observe that for every pair (A, B) with $A \in W_A$ and $B \in W_B$, the algorithm Γ^* must query an x such that $A(x) \neq B(x)$. Thus

$$\begin{aligned} S^{(T)} &\geq \sum_{A \in W_A, B \in W_B} R(A, B) \\ &\geq \sum_{A \in W_A} M(A) - \sum_{B \notin W_B} M(B) \\ &\geq \frac{4}{5}M - \frac{1}{5}M. \end{aligned}$$

It remains only to show part (iii). Suppose $\Delta S^{(t)} > 3v_{\min}M$ for some t ; we will obtain a contradiction. Let

$$\Delta S^{(t)}(A) = S^{(t)}(A) - S^{(t-1)}(A),$$

and let C_A be the set of $A \in \mathcal{A}$ for which $\Delta S^{(t)}(A) > v_{\min}M(A)$. Since

$$\sum_{A \in \mathcal{A}} \Delta S^{(t)}(A) = \Delta S^{(t)} > 3v_{\min}M,$$

it follows by Markov's inequality that

$$\sum_{A \in C_A} \Delta S^{(t)}(A) \geq \frac{2}{3} \Delta S^{(t)}.$$

Similarly, if we let C_B be the set of $B \in \mathcal{B}$ for which $\Delta S^{(t)}(B) > v_{\min}M(B)$, we have

$$\sum_{B \in C_B} \Delta S^{(t)}(B) \geq \frac{2}{3} \Delta S^{(t)}.$$

In other words, at least $2/3$ of the increase in $S^{(t)}$ comes from (A, B) pairs such that $A \in C_A$, and at least $2/3$ comes from (A, B) pairs such that $B \in C_B$. Hence, by a ‘‘pigeonhole’’ argument, there exists an $A \in C_A$ and $B \in C_B$ with $R(A, B) > 0$ that are distinguished by the t th query. In other words, there exists an x with $A(x) \neq B(x)$, such that the t th index queried by Γ^* is x whether the input is A or B . Then since $A \in C_A$, we have $v_{\min}M(A) < \Delta S^{(t)}(A)$, and hence

$$\begin{aligned} v_{\min} &< \frac{\Delta S^{(t)}(A)}{M(A)} \\ &\leq \frac{\sum_{B^* \in \mathcal{B} : A(x) \neq B^*(x)} R(A, B^*)}{\sum_{B^* \in \mathcal{B}} R(A, B^*)}, \end{aligned}$$

which equals $\theta(A, x)$. Similarly $v_{\min} < \theta(B, x)$ since $B \in C_B$. This contradicts the definition

$$v_{\min} = \max_{A \in \mathcal{A}, B \in \mathcal{B}, x : R(A, B) > 0, A(x) \neq B(x)} \min \{ \theta(A, x), \theta(B, x) \},$$

and we are done. \square

5. Snakes. For our lower bounds, it will be convenient to generalize random walks to arbitrary distributions over paths, which we call *snakes*.

DEFINITION 5.1. *Given a vertex h in G and a positive integer L , a snake distribution $\mathcal{D}_{h,L}$ (parameterized by h and L) is a probability distribution over paths (x_0, \dots, x_{L-1}) in G , such that each x_t is either equal or adjacent to x_{t+1} , and $x_{L-1} = h$. Let $D_{h,L}$ be the support of $\mathcal{D}_{h,L}$. Then an element of $D_{h,L}$ is called a snake; the part near $x_{L-1} = h$ is the head and the part near x_0 is the tail.*

Given a snake X and integer t , we use $X[t]$ as shorthand for $\{x_0, \dots, x_t\}$.

DEFINITION 5.2. *We say a snake $X \in D_{h,L}$ is ε -good if the following holds. Choose j uniformly at random from $\{0, \dots, L-1\}$, and let $Y = (y_0, \dots, y_{L-1})$ be a snake drawn from $\mathcal{D}_{h,L}$ conditioned on $x_t = y_t$ for all $t > j$. Then*

- (i) *letting $S_{X,Y}$ be the set of vertices v in $X \cap Y$ such that $\min\{t : x_t = v\} = \min\{t : y_t = v\}$, we have*

$$\Pr_{j,Y} [X \cap Y = S_{X,Y}] \geq \frac{9}{10};$$

- (ii) *for all vertices v ,*

$$\Pr_{j,Y} [v \in Y[j]] \leq \varepsilon.$$

The procedure above—wherein we choose a j uniformly at random and then draw a Y from $\mathcal{D}_{h,L}$ consistent with X on all steps later than j —will be important in what follows. We call it *the snake X flicking its tail*. Intuitively, a snake is good if it is spread out fairly evenly in G —so that when it flicks its tail, (1) with high probability the old and new tails do not intersect, and (2) any particular vertex is hit by the new tail with probability at most ε .

We now explain our “snake method” for proving lower bounds for LOCAL SEARCH. Given a snake X , we define an input f_X with a unique local minimum at x_0 , and f values that decrease along X from head to tail. Then, given inputs f_X and f_Y with $X \cap Y = S_{X,Y}$, we let the relation function $R(f_X, f_Y)$ be proportional to the probability that snake Y is obtained by X flicking its tail. (If $X \cap Y \neq S_{X,Y}$ we let $R = 0$.) Let f_X and g_Y be inputs with $R(f_X, g_Y) > 0$, and let v be a vertex such that $f_X(v) \neq g_Y(v)$. Then if all snakes were good, there would be two mutually exclusive cases: (1) v belongs to the tail of X or (2) v belongs to the tail of Y . In case (1), v is hit with small probability when Y flicks its tail, so $\theta(f_Y, v)$ is small. In case (2), v is hit with small probability when X flicks its tail, so $\theta(f_X, v)$ is small. In either case, then, the *geometric mean* $\sqrt{\theta(f_X, v)\theta(f_Y, v)}$ and *minimum* $\min\{\theta(f_X, v), \theta(f_Y, v)\}$ are small. So even though $\theta(f_X, v)$ or $\theta(f_Y, v)$ could be large individually, Theorems 4.1 and 4.3 yield a good lower bound, as in the case of inverting a permutation (see Figure 1).

One difficulty is that not all snakes are good; at best, a large fraction of them are. We could try deleting all inputs f_X such that X is not good, but that might ruin some remaining inputs, which would then have fewer neighbors. So we would have to delete *those* inputs as well, and so on ad infinitum. What we need is basically a way to replace “all inputs” by “most inputs” in Theorems 4.1 and 4.3.

Fortunately, a simple graph-theoretic lemma can accomplish this. The lemma (see Diestel [10, p. 6], for example) says that any graph with average degree at least k contains an induced subgraph with *minimum* degree at least $k/2$. Here we prove a weighted analogue of the lemma.

FIG. 1. For every vertex v such that $f_X(v) \neq f_Y(v)$, either when snake X flicks its tail v is not hit with high probability, or when snake Y flicks its tail v is not hit with high probability.

LEMMA 5.3. Let $p(1), \dots, p(m)$ be positive reals summing to 1. Also let $w(i, j)$ for $i, j \in \{1, \dots, m\}$ be nonnegative reals satisfying $w(i, j) = w(j, i)$ and $\sum_{i,j} w(i, j) \geq r$. Then there exists a nonempty subset $U \subseteq \{1, \dots, m\}$ such that for all $i \in U$, $\sum_{j \in U} w(i, j) \geq rp(i)/2$.

Proof. If $r = 0$, then the lemma trivially holds, so assume $r > 0$. We construct U via an iterative procedure. Let $U(0) = \{1, \dots, m\}$. Then for all t , if there exists an $i^* \in U(t)$ for which

$$\sum_{j \in U(t)} w(i^*, j) < \frac{r}{2} p(i^*),$$

then set $U(t+1) = U(t) \setminus \{i^*\}$. Otherwise halt and return $U = U(t)$. To see that the U so constructed is nonempty, observe that when we remove i^* , the sum $\sum_{i \in U(t)} p(i)$ decreases by $p(i^*)$, while $\sum_{i,j \in U(t)} w(i, j)$ decreases by at most

$$\sum_{j \in U(t)} w(i^*, j) + \sum_{j \in U(t)} w(j, i^*) < rp(i^*).$$

So since $\sum_{i,j \in U(t)} w(i, j)$ was positive to begin with, it must still be positive at the end of the procedure; hence U must be nonempty. \square

We can now prove the main result of the section.

THEOREM 5.4. Suppose a snake drawn from $\mathcal{D}_{h,L}$ is ε -good with probability at least $9/10$. Then

$$\text{RLS}(G) = \Omega(1/\varepsilon), \quad \text{QLS}(G) = \Omega(\sqrt{1/\varepsilon}).$$

Proof. Given a snake $X \in \mathcal{D}_{h,L}$, we construct an input function f_X as follows. For each $v \in X$, let $f_X(v) = \min \{t : x_t = v\}$; and for each $v \notin X$, let $f_X(v) = \Delta(v, h) + L$, where $\Delta(v, h)$ is the distance from v to h in G . Clearly f_X so defined has a unique local minimum at x_0 . To obtain a decision problem, we stipulate that querying x_0 reveals an answer bit (0 or 1) in addition to $f_X(x_1)$; the algorithm's goal is then to return the answer bit. Obviously a lower bound for the decision problem implies a corresponding lower bound for the search problem.

Let us first prove the theorem in the case that all snakes in $D_{h,L}$ are ε -good. Let $p(X)$ be the probability of drawing snake X from $\mathcal{D}_{h,L}$. Also, given snakes X, Y and $j \in \{0, \dots, L-1\}$, let $q_j(X, Y)$ be the probability that $X^* = Y$, if X^* is drawn from $\mathcal{D}_{h,L}$ conditioned on agreeing with X on all steps later than j . Then define

$$w(X, Y) = \frac{p(X)}{L} \sum_{j=0}^{L-1} q_j(X, Y).$$

Our first claim is that w is symmetric; that is, $w(X, Y) = w(Y, X)$. It suffices to show that

$$p(X) q_j(X, Y) = p(Y) q_j(Y, X)$$

for all j . We can assume X agrees with Y on all steps later than j , since otherwise $q_j(X, Y) = q_j(Y, X) = 0$. Given an $X^* \in D_{h,L}$, let A denote the event that X^* agrees with X (or equivalently Y) on all steps later than j , and let B_X (resp., B_Y) denote the event that X^* agrees with X (resp., Y) on steps 1 to j . Then

$$\begin{aligned} p(X) q_j(X, Y) &= \Pr[A] \Pr[B_X|A] \cdot \Pr[B_Y|A] \\ &= p(Y) q_j(Y, X). \end{aligned}$$

Now let $E(X, Y)$ denote the event that $X \cap Y = S_{X,Y}$, where $S_{X,Y}$ is as in Definition 5.2. Also, let f_X be the input obtained from X that has answer bit 0, and g_X be the input that has answer bit 1. To apply Theorems 4.1 and 4.3, take $\mathcal{A} = \{f_X : X \in D_{h,L}\}$ and $\mathcal{B} = \{g_X : X \in D_{h,L}\}$. Then take $R(f_X, g_Y) = w(X, Y)$ if $E(X, Y)$ holds, and $R(f_X, g_Y) = 0$ otherwise. Given $f_X \in \mathcal{A}$ and $g_Y \in \mathcal{B}$ with $R(f_X, g_Y) > 0$, and letting v be a vertex such that $f_X(v) \neq g_Y(v)$, we must then have either $v \notin Y$ or $v \notin X$. Suppose the former case; then

$$\sum_{f_{X^*} \in \mathcal{A} : f_{X^*}(v) \neq g_Y(v)} R(f_{X^*}, g_Y) \leq \sum_{f_{X^*} \in \mathcal{A} : f_{X^*}(v) \neq g_Y(v)} \frac{p(Y)}{L} \sum_{j=0}^{L-1} q_j(Y, X^*) \leq \varepsilon p(Y),$$

since Y is ε -good. Thus $\theta(g_Y, v)$ equals

$$\frac{\sum_{f_{X^*} \in \mathcal{A} : f_{X^*}(v) \neq g_Y(v)} R(f_{X^*}, g_Y)}{\sum_{f_{X^*} \in \mathcal{A}} R(f_{X^*}, g_Y)} \leq \frac{\varepsilon p(Y)}{9p(Y)/10}.$$

Similarly, if $v \notin X$, then $\theta(f_X, v) \leq 10\varepsilon/9$ by symmetry. Hence

$$\begin{aligned} v_{\min} &= \max_{f_X \in \mathcal{A}, g_Y \in \mathcal{B}, v : R(f_X, g_Y) > 0, f_X(v) \neq g_Y(v)} \min\{\theta(f_X, v), \theta(g_Y, v)\} \leq \frac{\varepsilon}{9/10}, \\ v_{\text{geom}} &= \max_{f_X \in \mathcal{A}, g_Y \in \mathcal{B}, v : R(f_X, g_Y) > 0, f_X(v) \neq g_Y(v)} \sqrt{\theta(f_X, v) \theta(g_Y, v)} \leq \sqrt{\frac{\varepsilon}{9/10}}, \end{aligned}$$

the latter since $\theta(f_X, v) \leq 1$ and $\theta(g_Y, v) \leq 1$ for all f_X, g_Y , and v .

We now turn to the general case, in which a snake drawn from $\mathcal{D}_{h,L}$ is ε -good with probability at least $9/10$. Let $G(X)$ denote the event that X is ε -good. Take $\mathcal{A}^* = \{f_X \in \mathcal{A} : G(X)\}$ and $\mathcal{B}^* = \{g_Y \in \mathcal{B} : G(Y)\}$, and take $R(f_X, g_Y)$ as before. Now note that

$$\sum_{X, Y} w(X, Y) = \sum_{X, Y} p(X) p(Y) = 1,$$

so we can consider a distribution \mathcal{W} over (X, Y) pairs, in which $\Pr [(X, Y)] = w(X, Y)$. Then by the assumption of the theorem and the definition of ε -goodness,

$$\begin{aligned} \Pr_{(X,Y) \in \mathcal{W}} [G(X)] &\geq \frac{9}{10}, \\ \Pr_{(X,Y) \in \mathcal{W}} [G(Y)] &\geq \frac{9}{10}, \\ \Pr_{(X,Y) \in \mathcal{W}} [E(X, Y) \mid G(X)] &\geq \frac{9}{10}. \end{aligned}$$

Hence

$$\begin{aligned} &\sum_{f_X \in \mathcal{A}^*, g_Y \in \mathcal{B}^*} R(f_X, g_Y) \\ &= \sum_{X, Y : G(X) \wedge G(Y) \wedge E(X, Y)} w(X, Y) \\ &= \Pr_{(X,Y) \in \mathcal{W}} [G(X) \wedge G(Y) \wedge E(X, Y)] \\ &\geq 1 - \Pr_{(X,Y) \in \mathcal{W}} [\neg G(X)] - \Pr_{(X,Y) \in \mathcal{W}} [\neg G(Y)] - \Pr_{(X,Y) \in \mathcal{W}} [\neg E(X, Y) \wedge G(X)] \\ &\geq 1 - \Pr_{(X,Y) \in \mathcal{W}} [\neg G(X)] - \Pr_{(X,Y) \in \mathcal{W}} [\neg G(Y)] - \Pr_{(X,Y) \in \mathcal{W}} [\neg E(X, Y) \mid G(X)] \\ &\geq 1 - \frac{1}{10} - \frac{1}{10} - \frac{1}{10} \\ &= \frac{7}{10}, \end{aligned}$$

where the third line follows from the union bound.

So by Lemma 5.3, there exist subsets $\tilde{\mathcal{A}} \subseteq \mathcal{A}^*$ and $\tilde{\mathcal{B}} \subseteq \mathcal{B}^*$ such that for all $f_X \in \tilde{\mathcal{A}}$ and $g_Y \in \tilde{\mathcal{B}}$,

$$\begin{aligned} \sum_{g_{Y^*} \in \tilde{\mathcal{B}}} R(f_X, g_{Y^*}) &\geq \frac{7p(X)}{20}, \\ \sum_{f_{X^*} \in \tilde{\mathcal{A}}} R(f_{X^*}, g_Y) &\geq \frac{7p(Y)}{20}. \end{aligned}$$

It follows that for all f_X, g_Y with $R(f_X, g_Y) > 0$, and all v such that $f_X(v) \neq g_Y(v)$, either $\theta(f_X, v) \leq 20\varepsilon/7$ or $\theta(g_Y, v) \leq 20\varepsilon/7$. Hence $v_{\min} \leq 20\varepsilon/7$ and $v_{\text{geom}} \leq \sqrt{20\varepsilon/7}$. \square

6. Specific graphs. In this section we apply the “snake method” developed in section 5 to specific examples of graphs: the Boolean hypercube in section 6.1, and the d -dimensional cubic grid (for $d \geq 3$) in section 6.2.

6.1. Boolean hypercube. Abusing notation, we let $\{0, 1\}^n$ denote the n -dimensional Boolean hypercube—that is, the graph whose vertices are n -bit strings, with two vertices adjacent if and only if they have Hamming distance 1. Given a vertex $v \in \{0, 1\}^n$, we let $v[0], \dots, v[n-1]$ denote the n bits of v , and let $v^{(i)}$ denote the neighbor obtained by flipping bit $v[i]$. In this section we lower-bound RLS ($\{0, 1\}^n$) and QLS ($\{0, 1\}^n$).

Fix a “snake head” $h \in \{0,1\}^n$ and take $L = 2^{n/2}/100$. We define the snake distribution $\mathcal{D}_{h,L}$ via what we call a *coordinate loop*, which starts at the head $x_{L-1} = h$, and works backward to the tail x_0 as follows. For each $t \in \{L-2, \dots, 0\}$, we set $x_t := x_{t+1}$ with 1/2 probability, and $x_t := x_{t+1}^{(t \bmod n)}$ with 1/2 probability. The following is a basic fact about this distribution.

PROPOSITION 6.1. *The coordinate loop mixes completely in n steps, in the sense that if $t^* \leq t - n$, then x_{t^*} is a uniform random vertex conditioned on x_t .*

Proof. Once we reach x_{t^*} , each of the n coordinates of x_t has been replaced by a uniform random coordinate. \square

We could also use the random walk distribution, following Aldous [3]. However, not only is the coordinate loop distribution easier to work with (since it produces fewer self-intersections), it also yields a better lower bound (since it mixes completely in n steps, as opposed to approximately in $n \log n$ steps).

We first upper-bound the probability, over X, j , and $Y[j]$, that $X \cap Y \neq S_{X,Y}$ (where $S_{X,Y}$ is as in Definition 5.2).

LEMMA 6.2. *Suppose X is drawn from $\mathcal{D}_{h,L}$, j is drawn uniformly at random from $\{0, \dots, L-1\}$, and $Y[j]$ is drawn from $\mathcal{D}_{x_j,j}$. Then*

$$\Pr_{X,j,Y[j]} [X \cap Y = S_{X,Y}] \geq 0.9999.$$

Proof. We claim that for all indices $t, t^* \in \{0, \dots, L-1\}$ with $t \neq t^*$, we have

$$\Pr_{X,j,Y[j]} [x_t = y_{t^*}] \leq \frac{1}{2^n}.$$

Let us first see why the lemma follows from this claim. If there are no “collisions” of the form $x_t = y_{t^*}$ with $t \neq t^*$, then clearly

$$\min \{t : x_t = v\} = \min \{t^* : y_{t^*} = v\}$$

for all vertices v , and hence $X \cap Y = S_{X,Y}$. It follows by the union bound that

$$\begin{aligned} \Pr_{X,j,Y[j]} [X \cap Y \neq S_{X,Y}] &\leq \sum_{t \neq t^*} \Pr_{X,j,Y[j]} [x_t = y_{t^*}] \\ &\leq \sum_{t \neq t^*} \frac{1}{2^n} \\ &\leq \frac{L^2}{2^n} \\ &= 0.0001. \end{aligned}$$

It remains only to prove the claim. There are two cases. First, if $t > j - n$ and $t^* > j - n$, then $x_t \neq y_{t^*}$ for all $t \neq t^*$, and hence $\Pr_{X,j,Y[j]} [x_t = y_{t^*}] = 0$. This follows from the definition of the coordinate loop $\mathcal{D}_{h,L}$. Second, if $t \leq j - n$ or $t^* \leq j - n$, then Proposition 6.1 implies that for all vertices $v, w \in \{0,1\}^n$,

$$\Pr_{X,j,Y[j]} [x_t = v \wedge y_{t^*} = w] = \frac{1}{2^{2n}}.$$

In other words, y_{t^*} is uniformly random conditioned on x_t , and x_t is uniformly random conditioned on y_{t^*} . Therefore

$$\Pr_{X,j,Y[j]} [x_t = y_{t^*}] = \frac{1}{2^n},$$

and we are done. \square

We now argue that, unless X spends a “pathological” amount of time in one part of the hypercube, the probability of any vertex v being hit when X flicks its tail is small. To prove this, we define a notion of *sparseness*, and then show that (1) almost all snakes drawn from $\mathcal{D}_{h,L}$ are sparse (Lemma 6.4), and (2) sparse snakes are unlikely to hit any given vertex v (Lemma 6.5).

DEFINITION 6.3. *Given vertices v, w and $i \in \{0, \dots, n - 1\}$, let $\Delta(x, v, i)$ be the number of steps needed to reach v from x by first setting $x[i] := v[i]$, then setting $x[i - 1] := v[i - 1]$, and so on. (After we set $x[0]$ we wrap around to $x[n - 1]$.) Then X is sparse if there exists a constant c such that for all $v \in \{0, 1\}^n$ and all k ,*

$$|\{t : \Delta(x_t, v, t \bmod n) = k\}| \leq cn \left(n + \frac{L}{2^{n-k}} \right).$$

LEMMA 6.4. *If X is drawn from $\mathcal{D}_{h,L}$, then X is sparse with probability $1 - o(1)$.*

Proof. For each $i \in \{0, \dots, n - 1\}$, the number of $t \in \{0, \dots, L - 1\}$ such that $t \equiv i \pmod{n}$ is at most L/n . For such a t , let $E_t^{(v,i,k)}$ be the event that $\Delta(x_t, v, i) \leq k$; then $E_t^{(v,i,k)}$ holds if and only if

$$x_t[i + 1] = v[i + 1], \dots, x_t[i - k] = v[i - k]$$

(where we wrap around to $x_t[0]$ after reaching $x_t[n - 1]$). This occurs with probability $1/2^{n-k}$ over X . So let

$$\mu_k = \frac{L}{n} \cdot \frac{1}{2^{n-k}}.$$

Then for fixed v, i, k , the expected number of t 's for which $E_t^{(v,i,k)}$ holds is at most μ_k . Furthermore, by Proposition 6.1, the $E_t^{(v,i,k)}$ events for different t 's are independent. Thus by a Chernoff bound (see Motwani and Raghavan [21], for example), if $\mu_k \geq 1$, then

$$\Pr_X \left[\left| \{t : E_t^{(v,i,k)}\} \right| > cn \cdot \mu_k \right] < \left(\frac{e^{cn-1}}{(cn)^{cn}} \right)^{\mu_k} < \frac{1}{2^{2n}}$$

for sufficiently large c . Similarly, if $\mu_k < 1$, then

$$\Pr_X \left[\left| \{t : E_t^{(v,i,k)}\} \right| > cn \right] < \left(\frac{e^{cn/\mu_k-1}}{(cn/\mu_k)^{cn/\mu_k}} \right)^{\mu_k} < \frac{1}{2^{2n}}$$

for sufficiently large c . By the union bound, then,

$$\begin{aligned} \left| \{t : E_t^{(v,i,k)}\} \right| &\leq cn \cdot (1 + \mu_k) \\ &= c \left(n + \frac{L}{2^{n-k}} \right) \end{aligned}$$

for every v, i, k triple *simultaneously* with probability at least $1 - n^2 2^n / 2^{2n} = 1 - o(1)$. Summing over all i 's produces the additional factor of n . \square

LEMMA 6.5. *Let X be sparse. Suppose j is drawn uniformly from $\{0, \dots, L - 1\}$, and then $Y[j]$ is drawn from $\mathcal{D}_{x_j,j}$. Then for every $v \in \{0, 1\}^n$,*

$$\Pr_{j,Y} [v \in Y[j]] = O\left(\frac{n^2}{L}\right).$$

Proof. By assumption, for every $k \in \{0, \dots, n\}$,

$$\begin{aligned} \Pr_j [\Delta(x_j, v, j \bmod n) = k] &\leq \frac{|\{t : \Delta(x_t, v, t \bmod n) = k\}|}{L} \\ &\leq \frac{cn}{L} \left(n + \frac{L}{2^{n-k}} \right). \end{aligned}$$

Consider the probability that $v \in Y[j]$ in the event that $\Delta(x_j, v, j \bmod n) = k$. Clearly

$$\Pr_Y [v \in \{y_{j-n+1}, \dots, y_j\}] = \frac{1}{2^k}.$$

Also, Proposition 6.1 implies that for every $t \leq j - n$, the probability that $y_t = v$ is 2^{-n} . So by the union bound,

$$\Pr_Y [v \in \{y_0, \dots, y_{j-n}\}] \leq \frac{L}{2^n}.$$

Then $\Pr_{j,Y} [v \in Y[j]]$ equals

$$\sum_{k=0}^n \Pr_j [\Delta(x_j, v, j \bmod n) = k] \cdot \Pr_Y [v \in Y[j] \mid \Delta(x_j, v, j \bmod n) = k],$$

which is at most

$$\sum_{k=0}^n \frac{cn}{L} \left(n + \frac{L}{2^{n-k}} \right) \left(\frac{1}{2^k} + \frac{L}{2^n} \right) = O\left(\frac{cn^2}{L}\right),$$

as can be verified by breaking the sum into cases and doing some manipulations. \square

The main result follows easily.

THEOREM 6.6.

$$\text{RLS}(\{0, 1\}^n) = \Omega\left(\frac{2^{n/2}}{n^2}\right),$$

$$\text{QLS}(\{0, 1\}^n) = \Omega\left(\frac{2^{n/4}}{n}\right).$$

Proof. Take $\varepsilon = n^2/2^{n/2}$. Then by Theorem 5.4, it suffices to show that a snake X drawn from $\mathcal{D}_{h,L}$ is $O(\varepsilon)$ -good with probability at least $9/10$. First, since

$$\Pr_{X,j,Y[j]} [X \cap Y = S_{X,Y}] \geq 0.9999$$

by Lemma 6.2, Markov's inequality shows that

$$\Pr_X \left[\Pr_{j,Y[j]} [X \cap Y = S_{X,Y}] \geq \frac{9}{10} \right] \geq \frac{19}{20}.$$

Second, by Lemma 6.4, X is sparse with probability $1 - o(1)$, and by Lemma 6.5, if X is sparse, then

$$\Pr_{j,Y} [v \in Y[j]] = O\left(\frac{n^2}{L}\right) = O(\varepsilon)$$

for every v . So both requirements of Definition 5.2 hold simultaneously with probability at least $9/10$. \square

FIG. 2. In $d = 3$ dimensions, a snake drawn from $\mathcal{D}_{h,L}$ moves a random distance left or right, then a random distance up or down, then a random distance inward or outward, etc.

6.2. Constant-dimensional grid graph. In the Boolean hypercube case, we defined $\mathcal{D}_{h,L}$ by a “coordinate loop” instead of the usual random walk mainly for convenience. When we move to the d -dimensional grid, though, the drawbacks of random walks become more serious: first, the mixing time is too long, and second, there are too many self-intersections, particularly if $d \leq 4$. Our snake distribution will instead use straight lines of randomly chosen lengths attached at the endpoints, as in Figure 2. Let $G_{d,N}$ be a d -dimensional grid graph with $d \geq 3$. That is, $G_{d,N}$ has N vertices of the form $v = (v[0], \dots, v[d-1])$, where each $v[i]$ is in $\{1, \dots, N^{1/d}\}$ (we assume for simplicity that N is a d th power). Vertices v and w are adjacent if and only if $|v[i] - w[i]| = 1$ for some $i \in \{0, \dots, d-1\}$, and $v[j] = w[j]$ for all $j \neq i$ (so $G_{d,N}$ does not wrap around at the boundaries).

We take $L = \sqrt{N}/100$, and define the snake distribution $\mathcal{D}_{h,L}$ as follows. We start from the head $x_{L-1} = h$. Then for all t of the form $L - 1 - \tau N^{1/d}$, where τ is a positive integer, we set x_t identical to $x_{t+N^{1/d}}$, but with the $(\tau \bmod d)$ th coordinate $x_t[\tau \bmod d]$ replaced by a uniform random value in $\{1, \dots, N^{1/d}\}$. We then take the vertices $x_{t+N^{1/d}-1}, \dots, x_t$ to lie along the shortest path from $x_{t+N^{1/d}}$ to x_t , “stalling” at x_t once that vertex has been reached. We call

$$\Phi_\tau = (x_{t+N^{1/d}}, \dots, x_t)$$

a *line* of vertices, whose *direction* is $\tau \bmod d$. As in the Boolean hypercube case, we have the following proposition.

PROPOSITION 6.7. *$\mathcal{D}_{h,L}$ mixes completely in $dN^{1/d}$ steps, in the sense that if $t^* \leq t - d$, then $x_{t^*N^{1/d}}$ is a uniform random vertex conditioned on $x_{tN^{1/d}}$.*

Proof. Once we reach $x_{t^*N^{1/d}}$, each of the d coordinates of $x_{tN^{1/d}}$ has been replaced by a uniform random coordinate. \square

Lemma 6.2 in section 6.1 goes through essentially without change.

DEFINITION 6.8. *Let $\Delta(x, v, i)$ be the number of steps needed to reach v from x by first setting $x[i] := v[i]$, then setting $x[i+1] := v[i+1]$, and so on. (After we set $x[d-1]$ we wrap around to $x[0]$.) Also, let $\tau(t) = \lceil (L-1-t)/N^{1/d} \rceil$ be the value of τ corresponding to t . Then we say X is sparse if there exists a constant c (possibly dependent on d) such that for all vertices v and all k ,*

$$|\{t : \Delta(x_t, v, \tau(t) \bmod d) = k\}| \leq (c \log N) \left(N^{1/d} + \frac{L}{N^{1-k/d}} \right).$$

LEMMA 6.9. *If X is drawn from $\mathcal{D}_{h,L}$, then X is sparse with probability $1 - o(1)$.*

Proof. The proof is similar to Lemma 6.4. Let Φ_τ be a line of vertices with direction $i = \tau \bmod d$, and notice that $\Delta(x_t, v, i)$ is the same for every vertex x_t in Φ_τ . Let $E_\tau^{(v,i,k)}$ denote the event that $\Delta(x_t, v, i) \leq k$ for the x_t 's in Φ_τ . Then $E_\tau^{(v,i,k)}$ occurs with probability $N^{k/d}/N$ over X . Thus, let

$$\mu_k = \frac{L}{N^{1/d}} \cdot \frac{N^{k/d}}{N}.$$

Then for fixed v, i, k , the expected number of lines for which $E_\tau^{(v,i,k)}$ holds is at most μ_k . Furthermore, if $|\tau - \tau^*| \geq d$, then $E_\tau^{(v,i,k)}$ and $E_{\tau^*}^{(v,i,k)}$ are independent events. Thus, by a Chernoff bound, if $\mu_k \geq 1$, then

$$\Pr_X \left[\left| \left\{ \tau : E_\tau^{(v,i,k)} \right\} \right| > c \log N \cdot \mu_k \right] < \left(\frac{e^{c \log N - 1}}{(c \log N)^{c \log N}} \right)^{\mu_k}$$

which is at most $1/N^2$ for sufficiently large c . Similarly, if $\mu_k < 1$, then letting $m = (c \log N) / \mu_k$,

$$\Pr_X \left[\left| \left\{ \tau : E_\tau^{(v,i,k)} \right\} \right| > c \log N \right] < \left(\frac{e^{m-1}}{m^m} \right)^{\mu_k} < \frac{1}{N^2}$$

for sufficiently large c . So if we let $\tau(t) = \lceil (L - 1 - t) / N^{1/d} \rceil$ as before, then with probability $1 - o(1)$ it holds that for all v, k ,

$$\begin{aligned} |\{t : \Delta(x_t, v, \tau(t) \bmod d) = k\}| &\leq c \log N \cdot (1 + \mu_k) \cdot N^{1/d} \\ &= (c \log N) \left(N^{1/d} + \frac{L}{N^{1-k/d}} \right). \quad \square \end{aligned}$$

LEMMA 6.10. *If X is sparse, then for every $v \in G_{d,N}$,*

$$\Pr_{j,Y} [v \in Y[j]] = O\left(\frac{N^{1/d} \log N}{L}\right),$$

where the big O hides a constant dependent on d .

Proof. As in Lemma 6.5, setting $\tau(j) = \lceil (L - 1 - j) / N^{1/d} \rceil$ we obtain that

$$\begin{aligned} \Pr_{j,Y} [v \in Y[j]] &= \sum_{k=1}^d \Pr_j [\Delta(x_j, v, \tau(j) \bmod d) = k] \Pr_Y [v \in Y[j] \mid \Delta(x_j, v, \tau(j) \bmod d) = k] \\ &\leq \sum_{k=1}^d \frac{c \log N}{L} \left(N^{1/d} + \frac{L}{N^{1-k/d}} \right) \left(\frac{1}{N^{(k-1)/d}} + \frac{L}{N} \right) \\ &= O\left(\frac{N^{1/d} \log N}{L}\right). \quad \square \end{aligned}$$

Taking $\varepsilon = (\log N) / N^{1/2-1/d}$ we get, by the same proof as for Theorem 6.6, the following theorem.

THEOREM 6.11. *Neglecting a constant dependent on d , for all $d \geq 3$,*

$$\text{RLS}(G_{d,N}) = \Omega\left(\frac{N^{1/2-1/d}}{\log N}\right),$$

$$\text{QLS}(G_{d,N}) = \Omega\left(\sqrt{\frac{N^{1/2-1/d}}{\log N}}\right).$$

Acknowledgments. I thank Andris Ambainis for suggesting an improvement to Theorem 3.2; David Aldous, Christos Papadimitriou, Yuval Peres, and Umesh Vazirani for discussions during the early stages of this work; and Ronald de Wolf and the anonymous reviewers for helpful comments.

APPROXIMATING FRACTIONAL PACKINGS AND COVERINGS IN $O(1/\epsilon)$ ITERATIONS*

D. BIENSTOCK[†] AND G. IYENGAR[†]

Abstract. We adapt a method proposed by Nesterov [*Math. Program. Ser. A*, 103 (2005), pp. 127–152] to design an algorithm that computes ϵ -optimal solutions to fractional packing problems by solving $O(\epsilon^{-1}\sqrt{Kn\ln(m)})$ separable convex quadratic programs, where n is the number of variables, m is the number of constraints, and K is the maximum number of nonzero elements in any constraint. We show that the quadratic program can be approximated to any degree of accuracy by an appropriately defined piecewise-linear program. For the special case of the maximum concurrent flow problem on a graph $G = (V, E)$ with rational capacities and demands, we obtain an algorithm that computes an ϵ -optimal flow by solving shortest path problems, i.e., problems in which the number of shortest paths computed grows as $O(\epsilon^{-1}\log(\epsilon^{-1}))$ in ϵ and polynomially in the size of the problem. In contrast, previous algorithms required $\Omega(\epsilon^{-2})$ iterations. We also describe extensions to the maximum multicommodity flow problem, the pure covering problem, and mixed packing-covering problem.

Key words. approximation algorithms, packing problems, multicommodity flows

1. Packing problems. The prototypical example of the problems considered in this paper is the *maximum concurrent flow* problem defined as follows. Given a graph $G = (V, E)$, where each edge $e \in E$ has a positive capacity u_e , and K commodities with associated demands $d_k \in \mathbf{R}^{|V|}$, $k = 1, \dots, K$, solve

$$\begin{aligned} \min \quad & \max_{e \in E} \left\{ \frac{\sum_{k=1}^K f_{k,e}}{u_e} \right\} \\ \text{s.t.} \quad & Nf_k = d_k, \quad k = 1, \dots, K, \\ & f_k \geq 0, \quad k = 1, \dots, K, \end{aligned}$$

where $N \in \mathbf{R}^{|V| \times |E|}$ is the node-arc incidence of the graph. Here and below we will assume that commodities are grouped by source; i.e., for each k there is one vertex $s(k)$ with $d_{k,s(k)} > 0$. We will call a nonnegative vector $f_k \in \mathbf{R}^{|E|}$ a *flow* vector for commodity k if $Nf_k = d_k$, i.e., it routes the corresponding demand d_k . A nonnegative vector $f = (f_1, f_2, \dots, f_K) \in \mathbf{R}^{K|E|}$ is called a *flow* if f_k is a flow vector for commodity k , $k = 1, \dots, K$. For a given flow f , the quantity $(\sum_k f_{k,e})/u_e$ is called the *load* or *congestion* on the edge $e \in E$. Thus, the maximum concurrent flow problem computes a flow that minimizes the maximum congestion. Problems of this nature arise in the context of routing in capacitated networks. Furthermore, many network design algorithms solve maximum concurrent flow problems as subroutines in order to find a feasible routing.

The maximum concurrent flow problem is a special case of the *fractional packing* problem. Let $A \in [a_1, \dots, a_m]^T \in \{0, 1\}^{m \times n}$, and let $Q \subseteq \mathbf{R}_+^n$ be a polyhedron. For $x \in Q$, let $\lambda(x) \triangleq \max_{1 \leq i \leq m} \{a_i^T x\}$. Then the fractional packing problem $\text{PACK}(A, Q)$ is given by

$$(1) \quad \lambda_{A,Q}^* \triangleq \min_{x \in Q} \lambda(x).$$

The fractional packing problem is itself a special case of the *generalized packing* problem, where each entry a_{ij} of the matrix A is assumed to be nonnegative, rather than $a_{ij} \in \{0, 1\}$.

A special case of the generalized packing problem of particular interest is the so-called *block-angular* problem. In such problems, there exist positive integers $k > 0$, and $n_i, i = 1, \dots, k$, with $\sum_i n_i = n$, such that the set $Q = Q^1 \times Q^2 \times \dots \times Q^k$, $Q^i \subseteq \mathbf{R}^{n_i}, i = 1, \dots, k$. When Q is a polyhedron this simply says that the nonzeros in the constraint matrix defining Q are arranged, without loss of generality, into a block-diagonal structure with k blocks. The maximum concurrent flow problem is clearly a block-angular problem with each block corresponding to a commodity; the constraints in a given block describe flow conservation and nonnegativity of the flow variables for the corresponding commodity.

Generalized packing problems are linear programs, and therefore can be solved to optimality in polynomial time. Nevertheless, these problems—and in particular the maximum concurrent flow problem—have long been recognized as extremely challenging. State-of-the-art implementations of the simplex method and also of interior point methods, running on fast machines, can require an inordinate amount of time to solve maximum concurrent flow problems on networks with a few thousand nodes, even when physical memory is adequate. Frequently, these codes can also consume an extremely large amount of memory. Consequently, they often prove unusable. For more background see [3].

It is not clear, from a theoretical standpoint, why traditional linear programming methods tend to require a large number of iterations to solve maximum concurrent flow problems. However, it is fairly clear why such methods tend to require a large running *time*. This is due to very expensive matrix computations, e.g., matrix inversions or Cholesky factorizations, that must be repeatedly carried out. As an example, consider a maximum concurrent flow problem on a network with $|V|$ vertices, $|E|$ edges, and K commodities. The overall constraint matrix for the linear program will have $|E| + K|V|$ rows and $K|E|$ variables. Even when the graph is very sparse ($|E| = \theta(|V|)$), if we have $K = \theta(|V|)$ the numerical linear algebra will be over matrices of dimension $\theta(|V|^2)$. Further, even though the constraint matrix may be very sparse, the matrix computations will usually experience “fill-in.”

These facts were recognized early on, in the context of block-angular linear programs, and were a motivating factor for some of the earliest decomposition ideas in mathematical programming, such as the Dantzig–Wolfe decomposition and Lagrangian relaxation. See [15, 3] for further background. The goal of these methods was to try to reduce the solution of the linear program $\min\{c^T x : Ax \leq b, x \in Q\}$ to a set of linear programs over Q . For a block-angular problem, a linear program over Q reduces to a set of linear programs over the blocks; therefore, when there are many blocks and each block is small relative to the overall Q , each iteration becomes cheap, while direct solution of the complete problem using a standard method may be impossible. For the concurrent flow problem, a linear program over Q reduces to

a set of shortest path problems for each commodity. In essence, this approach leads to a model of computation in which optimization over Q is viewed as the building block of more complex algorithms; the critical theoretical issue then becomes that of minimizing the number of iterations needed to achieve convergence.

This model of computation is perhaps not as precise as one would like it to be—we need to clearly state what can be done in addition to optimization over Q . Nevertheless, the model does capture the notion that we want to avoid matrix algebra over large matrices. In this paper we will adopt this model (an algorithm that fits the model will be called a *decomposition method*), and achieving low iteration counts will be a central goal in the design of our algorithms.

1.1. Modern results. The difficulty of the maximum concurrent flow problem, and its practical relevance, have long provided strong motivation for developing fast algorithms that can provide provably good, if not optimal, solutions.

Shahrokhi and Matula [26] developed the first approximation algorithm for the maximum concurrent flow problem. They considered the special case in which the capacity on all edges are equal. The method in [26] considers an exponential potential function of the form

$$\sum_{e \in E} e^{\alpha(\sum_k f_{k,e})}.$$

We will call a flow f with maximum load at most $(1 + \epsilon)$ times the optimal maximum load an ϵ -optimal flow. It is shown in [26] that, given $\epsilon \in (0, 1)$, one can choose $\alpha = \alpha(\epsilon)$ such that ϵ -optimal flow can be computed by minimizing the potential function to within an appropriate *absolute* error. The algorithm employed in [26] is, roughly, a first-order procedure to minimize the potential function, i.e., a procedure that approximates the potential function by its gradient, and the number of iterations required is $O(\epsilon^{-3})$ times a polynomial in the number of nodes and edges. In addition, the algorithm maintains a list of $O(\epsilon^{-2})$ paths so that the dependence of the running time on ϵ is $O(\epsilon^{-5})$. Each iteration consists of a shortest path computation or a single-commodity minimum-cost flow problem; thus, this algorithm is a decomposition method.

The Shahrokhi–Matula result spurred a great deal of research that generalized the techniques to broader packing and covering problems, gradually reducing the dependence of the iteration count on ϵ to finally obtain ϵ^{-2} , reducing the overall complexity to $O(\epsilon^{-2})$ times a polynomial in the size of the graph, and also simplifying the overall approach. See [15, 19, 9, 10, 24, 25, 8, 5] for details; [25, 8, 5] attain the best bounds for the maximum concurrent flow problem. All of these algorithms rely, sometimes implicitly, on the exponential potential function, and can be viewed as first-order methods. Villavicencio and Grigoriadis [30] use a logarithmic potential function. Bienstock and Raskin [4] show that the “flow deviation” algorithm for the maximum concurrent flow problem in [7] yields an $O(\epsilon^{-2})$ algorithm—this time using a rational barrier function.

A natural issue is that of proving lower bounds on the number of iterations needed to obtain an ϵ -optimal solution to a packing problem, and, in particular, the dependence of the iteration count on ϵ . Klein and Young [16] studied the complexity of $\text{PACK}(A, Q)$, assuming that there exists an oracle that, given $c \in \mathbf{R}^n$, returns an optimal *extreme point* for the linear program $\min\{c^T x : x \in Q\}$. The main result in [16] is that (under appropriate assumptions) the number of oracle calls needed to find an ϵ -optimal solution to a packing problem can be as large as $\Omega(\rho\epsilon^{-2} \log m)$. Here

$\rho = \max_{x \in Q} \max_{1 \leq i \leq m} a_i^T x$ (known as the *width* of the problem). This result applies when $\rho \epsilon^{-2} = O(m^{0.5-\delta})$ for some $\delta > 0$. Thus, in essence, the result amounts to an $\Omega(m^{0.5})$ lower bound on the iteration count. The dependence on ϵ implied by the bound is striking, and it raises the question of whether ϵ^{-2} is indeed a lower bound on the dependence on ϵ for the number of iterations required by a decomposition method. We note here that the assumption that the optimization oracle returns an *extreme point* of Q is critical in the proof in [16].

For some time, a parallel line of research has been followed in the nondifferentiable optimization community. Roughly stated, the focus of the work has been to produce solutions with small *absolute* error, rather than a small *relative* error as has been the focus of the algorithms community. This line of work has produced a number of interesting ideas and results (see [3] for references). Among them are decomposition algorithms that solve the generalized packing problem within an additive error of ϵ in $O(\epsilon^{-2})$ iterations; however, these are not polynomial-time algorithms, even for fixed ϵ , in that the $O()$ notation hides constants that depend on the matrix A and the set Q . Recently Nesterov [22] (also see [21]) obtained a major result: a decomposition algorithm that solves min-max problems to within an additive error of ϵ in $O(\epsilon^{-1})$ iterations. Again, this algorithm is, in general, not a polynomial-time algorithm, even for fixed ϵ . The algorithm combines, in a novel way, the (essentially folkloric) idea of making use of old iterate information with that of an approximate second-order approximation of the exponential potential function. In section 2.2 we present a streamlined analysis of the key ideas in [22].

1.2. New results. We show how to adapt the technique in [22] to obtain an ϵ -optimal solution (i.e., a solution with a *relative* error ϵ) to $\text{PACK}(A, Q)$ by solving at most

$$O\left(\epsilon^{-1} \sqrt{Kn \log m}\right)$$

convex, separable quadratic programs (QPs) over sets of the form

$$(2) \quad Q(\lambda_u) \triangleq \{x \in Q : 0 \leq x_j \leq \lambda_u, 1 \leq j \leq n\},$$

where $\lambda_u > 0$, and K denotes the maximum number of nonzero terms in any row of A . While some of the key ideas in this paper are derived from those in [22], our paper is self-contained. We also adapt a binary search technique from [9]. It is quite possible that in our iteration bound some of the constants and the dependency on m , n , and K can be improved with a somewhat more complex analysis. Also note that in the block-angular case each optimization over $Q(\lambda)$ breaks up into a separate problem over each block.

It is known that convex QPs can be solved in polynomial time (for some of the earliest references, see [17, 18]). But there is more that can be said here. Let S be a closed convex body in \mathbf{R}^n . Given $c \in \mathbf{R}^n$, the *linear optimization problem* over S consists of finding $\hat{x} \in S$ such that $c^T \hat{x} = \min \{c^T x : x \in S\}$. Also, given $y \in \mathbf{R}^n$, the *separation problem* over S consists of either showing that $y \in S$ or finding a violated inequality, e.g., a vector $d \in \mathbf{R}^n$ and a scalar d_0 such that $d^T y < d_0$ but $d^T x \geq d_0$ for all $x \in S$. It is well known (see [12, 13]) that the linear optimization problem and the separation problem over S are polynomially equivalent under appropriate (technical) assumptions regarding S ; i.e., any instance of the linear optimization (resp., separation) problem can be reduced to a polynomial number of instances of the separation (resp., linear optimization) problem.

Returning to our problem, suppose that Q is given by a (linear) optimization oracle, i.e., a subroutine that solves the linear optimization problem over Q for any objective vector c . For example, if Q describes the set of feasible flows in a network that correspond to sending one unit of flow from a certain vertex s to another vertex t , the subroutine would consist of an s - t shortest path algorithm. It follows that the separation problem over $Q(\lambda)$ can be solved by performing at most a polynomial number of oracle calls: the conditions $0 \leq x_j \leq \lambda_u$ can be checked directly, producing a violated inequality when not satisfied, and the condition $x \in Q$ is handled by using the aforementioned polynomial equivalence between linear optimization and separation. Under appropriate assumptions [27] (see also [17], which was also published as [18]) this implies that a convex QP over $Q(\lambda)$ can be solved by making a polynomial number of calls to the (linear) optimization oracle for Q .

The generalized packing problem can be reduced to a fractional packing problem as follows. Let N be the number of nonzeros in A . For each entry $a_{ij} > 0$, introduce a new variable y_{ij} and a new constraint

$$(3) \quad y_{ij} - a_{ij}x_{ij} = 0.$$

Let

$$P = \{y \in \mathbf{R}^N : \exists x \in Q \text{ such that (3) holds } \forall a_{ij} > 0\}.$$

It follows that

$$(4) \quad \lambda_{A,Q}^* = \min_{y \in P} \max_{1 \leq i \leq m} \sum_{j : a_{ij} > 0} y_{ij}.$$

Furthermore, P is closed convex, and because of (3), a convex separable QP over P reduces to one over Q . Hence, our result for fractional packing problems implies that, for any $\epsilon \in (0, 1)$, the number of iterations required to compute an ϵ -optimal solution for the generalized packing problem is

$$O\left(\epsilon^{-1} \sqrt{KN \log m}\right).$$

Using ideas derived from [20], we show how the QPs can be approximated by piecewise-linear programs. For the special case of maximum concurrent flows, this leads to an algorithm that computes ϵ -optimal flow by solving

$$O^* \left(\epsilon^{-1} K^2 E^{\frac{1}{2}} \left(L_U + |E| \lceil \log D \rceil + |E| \log \left(\frac{1}{\epsilon} \right) \right) + \epsilon^{-1} |V| |E| \right)$$

shortest path problems, where L_U denotes the number of bits needed to store the capacities, D is the sum of all demands, and K is the number of commodities grouped by source.

This paper is organized as follows. Section 2 presents our results on packing problems. Section 3 specializes our results to the maximum concurrent flow problem with rational capacities and demands. Section 4 describes the application of our techniques to the maximum multicommodity flow algorithms. Section 5 considers covering problems, and section 6 considers mixed packing and covering problems.

1.3. Comparison with previous results. First, we note that our results appear to violate the Klein–Young lower bound of $\Omega(\epsilon^{-2})$. This is not a contradiction since our algorithms bypass the requirements needed for the analysis in [16] to hold; in particular, we dynamically change the bounds on the variables. This feature will, in general, result in iterates in the *interior* of the set Q . In addition, some of our algorithms solve QPs over Q , again leading to interior solutions.

The previous fastest algorithms for finding ϵ -optimal solutions to generalized packing problems have a worst-case complexity that grows in proportion to ϵ^{-2} . Our methods improve on this, but at the cost of increasing the dependence on n and m . Hence, for ϵ fixed or moderately small, our algorithms are *not* the fastest. Note that, for example, the algorithm for maximum concurrent flows in [5] has complexity $O^*(\epsilon^{-2}|E|(K + |E|))$, where K is the number of origin-destination commodity pairs. See also [25, 8] for similar bounds.

Another class of algorithms worthy of comparison consists of the standard interior point polynomial-time algorithms for linear programming. Even though these are certainly not decomposition methods, their respective running times have a dependence on ϵ that grows like $\log(\epsilon^{-1})$, and hence for very small ϵ these algorithms are certainly faster than ours. Within this class, the algorithms proposed by Kapoor and Vaidya [14] and Vaidya [28, 29] deserve special attention. These algorithms are *not* decomposition algorithms, and when applied to a packing problem, Vaidya [29] computes, as a subroutine, the inverse of $n \times n$ matrices ([15] restates this as $m \times m$). In spite of this, it is possible that the algorithms in [14, 28, 29] are faster than ours even for moderate ϵ .

In summary, the primary contribution of this paper is to show that there exist decomposition methods for which the iteration count for computing ϵ -optimal solutions to generalized packing problems (among others) grows like $O(\epsilon^{-1})$ and is polynomial in n and m . We expect that the actual running *time* of our algorithms can be improved by using ideas such as those in [25, 8, 5] and, possibly, by using randomization as in [15].

1.4. Notation. In this paper, an ϵ -optimal solution will denote a solution that has a *relative* error at most ϵ . We also compute solutions with a given *absolute* error. We use the $O(\cdot)$ notation to denote the leading term in ϵ and the $O^*(\cdot)$ notation to suppress polylog factors in parameters such as m , n , and K . Also, since our focus in this paper is on designing decomposition algorithms with improved dependence on ϵ , we will occasionally state $O(\cdot)$ and $O^*(\cdot)$ bounds in terms of their dependence on ϵ , while suppressing polynomial factors in m , n , and K .

2. Fractional packing problems $\text{PACK}(A, Q)$. In this section we present our algorithm for $\text{PACK}(A, Q)$. As with many of the previous algorithms, our algorithm consists of an outer binary search procedure for refining an estimate for $\lambda_{A,Q}^*$ and an inner procedure that is a potential reduction algorithm.

2.1. Outer loop: Binary search. In this section we abbreviate $\lambda_{A,Q}^*$ as λ^* . We assume that $\lambda^* > 0$ and that we are given bounds $0 < \lambda_l \leq \lambda^* \leq \lambda_u$ such that $\lambda_u \leq O(\min\{m, K\})\lambda_l$. Such bounds can be computed by solving a polynomial (and independent of ϵ) number of linear programs over sets $Q(\lambda)$; see [3, 9] for details. Next, these bounds are refined using a binary search procedure introduced in [9] (see [3] for an alternate derivation). In the binary search procedure below, $\text{ABSOLUTE}(Q, A, \lambda_u, \delta)$ denotes any algorithm that returns an $x \in Q$ such that $\lambda(x) \leq \lambda^* + \delta$, i.e., an x that has an *absolute* error less than δ .

BINARY SEARCH

```

Input: values  $(\lambda_l, \lambda_u)$  with  $\lambda_l \leq \lambda^* \leq \lambda_u \leq 2 \min\{m, K\}\lambda_l$ 
Output:  $\hat{y} \in Q$  such that  $\lambda(y) \leq (1 + \epsilon)\lambda^*$ 
while  $(\lambda_u - \lambda_l) \geq \epsilon\lambda_l$  do
    set  $\delta = \frac{1}{3}(\lambda_u - \lambda_l)$ 
    set  $\hat{x} \leftarrow \text{ABSOLUTE}(Q, A, \lambda_u, \delta)$ 
    if  $\lambda(\hat{x}) \geq \frac{1}{3}\lambda_l + \frac{2}{3}\lambda_u$ , set  $\lambda_l \leftarrow \frac{2}{3}\lambda_l + \frac{1}{3}\lambda_u$ 
    else set  $\lambda_u \leftarrow \frac{1}{3}\lambda_l + \frac{2}{3}\lambda_u$ 
return  $\hat{x}$ 
    
```

In section 2.2 we construct an algorithm ABSOLUTE with the following properties.

THEOREM 1. *There exists an algorithm $\text{ABSOLUTE}(A, Q, \lambda_u, \delta)$ that computes, for any $\delta \in (0, \lambda_u)$, an $\hat{x} \in Q$ with $\lambda(\hat{x}) \leq \lambda^* + \delta$ by solving $O(\sqrt{Kn \log m} \frac{\lambda_u}{\delta})$ separable convex QPs over $Q(\lambda_u)$.*

As a consequence, we have the following complexity bound for the above binary search procedure.

COROLLARY 2. *The complexity of the binary search procedure is*

$$O\left(\epsilon^{-1} C_q \sqrt{Kn \log m}\right),$$

where C_q is the cost of solving a convex separable QP over $Q(\lambda_u)$.

Proof of Corollary 2. Consider first the iterations, where $\lambda_u > 2\lambda_l$. Since initially

$$\lambda_u \leq O(\min\{m, K\})\lambda_l,$$

there are at most $O(\log \min\{m, K\})$ iterations of this sort. In each such iteration we have $\frac{\lambda_u}{\delta} < 6$; thus by Theorem 1 the total number of QPs over sets $Q(\lambda_u)$ that are solved during these iterations is polynomial in K, n , and m .

Now consider the remaining iterations, i.e., those where $\lambda_u \leq 2\lambda_l$. Denoting by H the number of such iterations, we have $H = O(\log(1/\epsilon))$. Further, it is easy to check that in each iteration the ratio λ_u/δ increases by at most a factor of $3/2$. Now, again by Theorem 1, the number of QPs solved during the remaining iterations is, up to constants,

$$\sqrt{Kn \log m} \sum_{h=0}^H \left(\frac{3}{2}\right)^h = 2\sqrt{Kn \log m} \left(\left(\frac{3}{2}\right)^H - 1\right).$$

Thus, the result follows. \square

2.2. Inner loop: ABSOLUTE(A, Q, λ_u, δ). In this section we describe the ABSOLUTE(A, Q, λ_u, δ) algorithm. We construct this algorithm using techniques from [22].

Define $\bar{Q} \in \mathbf{R}^{2n}$ as

$$\bar{Q} \triangleq \{(x, y) \in \mathbf{R}^{2n} : x \in Q, x_j = \lambda_u y_j, y_j \leq 1, j = 1, \dots, n\}.$$

Since $\lambda^* \leq \lambda_u$, $\bar{Q} \neq \emptyset$. Let P denote the projection of \bar{Q} onto the space of the y variables, i.e.,

$$P = \{y \in \mathbf{R}^n : \exists x \text{ s.t. } (x, y) \in \bar{Q}\}.$$

If the feasible set Q in (1) is a polyhedron, so are \bar{Q} and P . Moreover, $P \subseteq [0, 1]^n$. Define

$$\lambda_P^* \triangleq \min \left\{ \lambda(y) = \max_{1 \leq i \leq m} \{a_i^T y\} : y \in P \right\}.$$

Then it follows that $\lambda_P^* = \lambda^*/\lambda_u \leq 1$.

In this section we describe an algorithm that, for any $\gamma \in (0, 1)$, computes $\hat{y} \in P$, with $\lambda(\hat{y}) \leq \lambda_P^* + \gamma$, by solving $O(\gamma^{-1}\sqrt{Kn \log m})$ separable convex QPs over P . Note that these programs reduce to separable convex QPs over $Q(\lambda_u)$, and, in the case of multicommodity flow problems, break up into separable convex quadratic min-cost flow problems over each commodity. Choosing $\gamma = \frac{\delta}{\lambda_u}$ will accomplish the objective of this section.

2.2.1. Potential reduction algorithm. For the purposes of this section, we assume that we are given a matrix $A \in \{0, 1\}^{m \times n}$ with at most K nonzeros per row, a (nonempty) closed convex set $P \subseteq [0, 1]^n$, and a constant $\gamma \in (0, 1)$. Furthermore, it is known that $\lambda_P^* \leq 1$.

Define the *potential function* $\Phi(x)$ as follows [9, 24]:

$$\Phi(x) \triangleq \frac{1}{|\alpha|} \ln \left(\sum_i e^{\alpha a_i^T x} \right), \quad \alpha \neq 0.$$

It is easy to show (see [9] for details) that for $\alpha > 0$,

$$(5) \quad \lambda(x) \leq \Phi(x) \leq \lambda(x) + \frac{\ln m}{\alpha} \quad \forall x \in P.$$

Let $\Phi^* \triangleq \min\{\Phi(x) : x \in P\}$ and choose $\alpha = \frac{2 \ln m}{\gamma}$. Then, for all $x \in P$ such that $\phi(x) \leq \Phi^* + \gamma/2$, the bound (5) implies that

$$\lambda(x) \leq \Phi(x) \leq \Phi^* + \frac{\gamma}{2} \leq \Phi(x^*) + \frac{\gamma}{2} \leq \lambda^* + \frac{\ln m}{\alpha} + \frac{\gamma}{2} = \lambda^* + \gamma.$$

Thus, our task reduces to computing $x \in P$ satisfying $\Phi(x) \leq \Phi^* + \gamma/2$.

In what follows, the notation $\langle x, y \rangle$ will denote the usual Euclidean inner product $x^T y$.

ALGORITHM QP

Input: $P \subseteq [0, 1]^n$, $\frac{0}{1}$ matrix A , $\alpha = \frac{\ln m}{\gamma}$, $L = \gamma^{-1}\sqrt{8Kn \ln(m)}$
Output: $\hat{y} \in P$ such that $\lambda(\hat{y}) \leq \lambda_P^* + \gamma$
choose $x^{(0)} \in P$. **set** $t \leftarrow 0$.
while ($t \leq L$) **do**

$g^{(t)} \leftarrow \nabla \Phi(x^{(t)})$

$y^{(t)} \leftarrow \operatorname{argmin}_{x \in P} \left\{ \frac{K|\alpha|}{2} \sum_{j=1}^n (x_j - x_j^{(t)})^2 + \langle g^{(t)}, x - x^{(t)} \rangle \right\}$

$S_t(x) \leftarrow \frac{2}{(t+1)(t+2)} \left\{ K|\alpha| \sum_{j=1}^n (x_j - x_j^0)^2 + \sum_{h=0}^t (h+1) [\Phi(x^{(h)}) + \langle g^{(h)}, x - x^{(h)} \rangle] \right\}$

$z^{(t)} \leftarrow \operatorname{argmin}_{x \in P} \{S_t(x)\}$

$x^{(t+1)} \leftarrow \left(\frac{2}{t+3} \right) z^{(t)} + \left(\frac{t+1}{t+3} \right) y^{(t)}$

$t \leftarrow t + 1$

return $y^{(L)}$

The following result is established in section 2.2.2.

THEOREM 3. For any $t \geq 0$, $\Phi(y^{(t)}) \leq S_t(z^{(t)})$.

Theorem 3 implies the following corollary.

COROLLARY 4. $\Phi(y^{(L)}) \leq \Phi^* + \gamma/2$.

Proof. Fix $t \geq 0$. Let $x^* = \operatorname{argmin}_{x \in P} \{\Phi(x)\}$. By definition,

$$\begin{aligned} S_t(z^t) &\leq S_t(x^*), \\ &= \frac{2}{(t+1)(t+2)} \left\{ K\alpha \sum_{j=1}^n (x_j^* - x_j^{(0)})^2 + \sum_{h=0}^t (h+1) [\Phi(x^{(h)}) + \langle g^{(h)}, x^* - x^{(h)} \rangle] \right\} \\ (6) \quad &\leq \frac{2Kn\alpha}{(t+1)(t+2)} + \Phi^*, \end{aligned}$$

where (6) follows from the following facts:

$$\begin{aligned} 0 \leq x_i^*, x_i^{(0)} \leq 1 &\Rightarrow (x_i^* - x_i^{(0)}) \leq 1, \\ \Phi \text{ convex} &\Rightarrow \Phi(x^{(h)}) + \langle g^{(h)}, x^* - x^{(h)} \rangle \leq \Phi(x^*). \end{aligned}$$

Theorem 3 implies that $\Phi(y^{(t)}) \leq S_t(z^{(t)})$. Thus,

$$\Phi(y^{(t)}) - \Phi^* \leq \frac{\gamma}{2m}, \quad t \geq L = \frac{\sqrt{8Kn \ln m}}{\gamma}. \quad \square$$

2.2.2. Proof of Theorem 3. The following result is a refinement of the Taylor series bound in [9] (see also [3, 23]). The proof is provided in section 7.1.

LEMMA 5. For all $x, y \in P$, we have $\Phi(y) \leq \Phi(x) + \langle \nabla \Phi(x), y - x \rangle + \frac{K|\alpha|}{2} \sum_j (y_j - x_j)^2$.

The rest of the proof of Theorem 3 closely mirrors the development in section 3 of [22]. The proof is by induction on t . To establish the base case $t = 0$, note that

$$\begin{aligned} S_0(z^{(0)}) &= K|\alpha| \sum_{j=1}^n (z_j^{(0)} - x_j^0)^2 + \Phi(x^0) + \langle g_0, z^{(0)} - x^0 \rangle \\ &\geq \frac{K|\alpha|}{2} \sum_{j=1}^n (z_j^{(0)} - x_j^0)^2 + \Phi(x^0) + \langle g_0, z^{(0)} - x^0 \rangle \\ (7) \quad &\geq \frac{K|\alpha|}{2} \sum_{j=1}^n (y_j^{(0)} - x_j^0)^2 + \Phi(x^0) + \langle g_0, y^{(0)} - x^0 \rangle \\ (8) \quad &\geq \Phi(y^{(0)}), \end{aligned}$$

where (7) follows from the definition of $y^{(0)}$ and (8) follows from Lemma 5.

To establish the induction step, assume that $\Phi(y^{(t)}) \leq S_t(z^{(t)})$. By definition, we have

$$\begin{aligned} S_{t+1}(x) &= \left(\frac{t+1}{t+3}\right) S_t(x) \\ &\quad + \left(\frac{2}{t+3}\right) [\Phi(x^{t+1}) + \langle g^{(t+1)}, x - x^{(t+1)} \rangle]. \end{aligned}$$

Since $\nabla^2 S_t = \frac{4K|\alpha|}{(t+1)(t+2)}I$, and S_t is minimized at z_t , we obtain

$$\begin{aligned}
 S_{t+1}(x) &\geq \left(\frac{t+1}{t+3}\right)S_t(z^{(t)}) + \frac{2K|\alpha|}{(t+2)(t+3)} \sum_j (x_j - z_j^{(t)})^2 \\
 (9) \qquad &+ \frac{2}{t+3} [\Phi(x^{(t+1)}) + \langle g^{(t+1)}, x - x^{(t+1)} \rangle].
 \end{aligned}$$

By the induction hypothesis and the convexity of Φ , it follows that $S_t(z^{(t)}) \geq \Phi(y^{(t)}) \geq \Phi(x^{(t+1)}) + \langle g^{(t+1)}, y^{(t)} - x^{(t+1)} \rangle$. Substituting this bound in (9) and rearranging terms, we get

$$\begin{aligned}
 S_{t+1}(x) &\geq \Phi(x^{(t+1)}) + \frac{2K|\alpha|}{(t+2)(t+3)} \sum_j (x_j - z_j^{(t)})^2 \\
 &+ \left\langle g^{(t+1)}, \left(\frac{2}{t+3}\right)x + \left(\frac{t+1}{t+3}\right)y^{(t)} - x^{(t+1)} \right\rangle \\
 &\geq \Phi(x^{(t+1)}) + \frac{2K|\alpha|}{(t+3)^2} \sum_j (x_j - z_j^{(t)})^2 \\
 &+ \left\langle g^{(t+1)}, \left(\frac{2}{t+3}\right)x + \left(\frac{t+1}{t+3}\right)y^{(t)} - x^{(t+1)} \right\rangle \\
 &= \Phi(x^{(t+1)}) \\
 &+ \frac{K|\alpha|}{2} \sum_j \left(\left(\frac{2}{t+3}\right)x_j + \left(\frac{t+1}{t+3}\right)y_j^{(t)} - x_j^{(t+1)} \right)^2 \\
 (10) \qquad &+ \left\langle g^{(t+1)}, \left(\frac{2}{t+3}\right)x + \left(\frac{t+1}{t+3}\right)y^{(t)} - x^{(t+1)} \right\rangle,
 \end{aligned}$$

where (10) is obtained by substituting $\left(\frac{2}{t+3}\right)z^{(t)} = x^{(t+1)} - \left(\frac{t+1}{t+3}\right)y^{(t)}$. Note that for $x \in P$, $\left(\frac{2}{t+3}\right)x + \left(\frac{t+1}{t+3}\right)y^{(t)} \in P$ as well. Thus, the expression in (10) is lower bounded by

$$S_{t+1}(x) \geq \Phi(x^{(t+1)}) + \min_{y \in P} \left\{ \frac{K|\alpha|}{2} \sum_j (y_j - x_j^{(t+1)})^2 + \langle g^{(t+1)}, y - x^{(t+1)} \rangle \right\}$$

$$(11) \qquad = \Phi(x^{(t+1)}) + \frac{K|\alpha|}{2} \sum_j (y_j^{t+1} - x_j^{(t+1)})^2 + \langle g^{(t+1)}, y^{t+1} - x^{(t+1)} \rangle$$

$$(12) \qquad \geq \Phi(y^{(t+1)}),$$

where (11) follows from the definition of $y^{(t+1)}$ and (12) follows from Lemma 5.

Remark. Note that the proofs of Corollary 4, Lemma 5, and Theorem 3 do not require $\alpha > 0$.

2.2.3. Notes on Algorithm QP. Having proved the correctness of Algorithm QP, we now give an intuitive motivation for the main algorithmic ideas behind it. The first step is to approximate the piecewise-linear function $\lambda(x)$ by the smooth potential function $\Phi(x)$. In all previous work on fractional packing problems, the next steps have been to construct the first-order Taylor series approximation to $\Phi(x)$ and minimize this linear approximation over the feasible set Q . The main bottleneck with the first-order methods is that the approximation is a *lower* bound; therefore,

one has to tightly control the step size to ensure that the improvement in the linear approximation is close to that in the potential function itself. As a direct consequence, the first-order methods yield algorithms whose complexity is $\mathcal{O}(\frac{1}{\epsilon^2})$.

The obvious next step is to consider the second-order approximation to $\Phi(x)$. Unfortunately, the Hessian of $\Phi(x)$ is dense and, therefore, the associated QP is relatively expensive. In [22], Nesterov proposed approximating the Hessian by its largest eigenvalue, i.e., replacing the Hessian with an identity matrix scaled by the largest eigenvalue. This immediately yields a second-order *upper* bound for $\Phi(x)$ that is easy to optimize. (An upper bound is superior to the lower bound since the improvement in $\Phi(x)$ is guaranteed to be more than the upper bound; consequently, one can set an aggressive step length.) Unfortunately, approximating the Hessian by its largest eigenvalue yields a very weak approximation, particularly when the iterate $x^{(t)}$ is far from the global minimum x^* . Algorithm QP corrects for this by computing two iterates: $y^{(t)}$ is a “local” iterate that uses only the “local” gradient information, i.e., the gradient at the current iterate $x^{(t)}$, and $z^{(t)}$ is a “global” iterate that uses a suitably weighted combination of the gradients at all the previous iterates. The next iterate, $x^{(t+1)}$, is a convex combination of the iterates $y^{(t)}$ and $z^{(t)}$. As iteration count t increases, the weight on the “local” iterate $y^{(t)}$ increases to 1, i.e., the algorithm becomes a Newton method, where the Hessian is approximated by its largest eigenvalue. The intuition of combining gradients at previous iterates to improve the approximation has also been previously proposed in the literature—Nesterov’s contribution showed that a particular combination leads to a worst-case bound on the complexity. It should be mentioned that this idea was also employed by Nemirovski [21] in a very different manner so as to obtain similar results.

Directly applying the technique proposed in [22] to the maximum concurrent flow problem does *not* yield a polynomial-time algorithm. Next, we discuss a particular scaling that we introduced in section 2.2 to construct a polynomial-time algorithm. When defining the set \bar{Q} in section 2.2 we impose the bounds $y_j \leq 1$ for all j . This bounding technique is essential in that it effectively reduces the width to at most n . This technique can be read in the approach used in [9] and [15]. More recent algorithms, such as those in [8] and [5], do not directly rely on this technique (arguably, their method for controlling width is *similar* in that they directly control the magnitudes of the solution variables) and potentially our overall scheme could be improved along the lines of [8] and [5]. The scaling technique in section 2.2 is essential for the analysis of Algorithm QP to go through; the scaling methods implicit in [9] and [15] will not work in this context.

2.3. Piecewise-linear approximation. Algorithm QP requires one to solve a sequence of separable QPs over P . In this section we describe a general method for approximating the separable convex quadratic function by piecewise-linear function with arbitrarily small error. This method is derived from one given in Minoux [20].

Fix $\sigma > 0$ and $w \geq 0$. Define a continuous convex piecewise-linear approximation $\mathcal{L}_{\sigma,w}(v)$ to the quadratic function $\frac{1}{2}(v - w)^2 : \mathbf{R}_+ \mapsto \mathbf{R}_+$ as

$$\mathcal{L}_{\sigma,w}(v) \triangleq \frac{1}{2}q^2\sigma^2 + \frac{w^2}{2} - wv + \left(q + \frac{1}{2}\right)\sigma(v - q\sigma), \quad v \in [q\sigma, (q + 1)\sigma), \quad q \in \mathbf{Z}_+.$$

For $q \in \mathbf{Z}_+$, the derivative $\mathcal{L}'_{\sigma,w}(q\sigma)$ is not defined. The *left-derivative* $\mathcal{L}^-_{\sigma,w}(q\sigma) = (q - \frac{1}{2})\sigma - w$ and the *right-derivative* $\mathcal{L}^+_{\sigma,w}(q\sigma) = (q + \frac{1}{2})\sigma - w$. For $v \in (q\sigma, (q + 1)\sigma)$, $q \in \mathbf{Z}$, the derivative $\mathcal{L}'_{\sigma,w}(v)$ exists and $\mathcal{L}'_{\sigma,w}(v) = \mathcal{L}^+_{\sigma,w}(v) = \mathcal{L}^-_{\sigma,w}(v) = (q + \frac{1}{2})\sigma - w$. The following properties are easy to obtain.

LEMMA 6. *The following hold for any $\sigma > 0$ and $w \in \mathbf{R}_+$.*

- (i) *For $q \in \mathbf{Z}_+$, $\mathcal{L}_{\sigma,w}(q\sigma) = \frac{1}{2}(q\sigma - w)^2$.*
- (ii) *For $v \in \mathbf{R}_+$, $\frac{1}{2}(v - w)^2 \leq \mathcal{L}_{\sigma,w}(v) \leq \frac{1}{2}(v - w)^2 + \frac{\sigma^2}{8}$.*
- (iii) *For $v \in \mathbf{R}_+$, $v - w - \frac{\sigma}{2} \leq \mathcal{L}_{\sigma,w}^-(v) \leq v - w \leq \mathcal{L}_{\sigma,w}^+(v) \leq v - w + \frac{\sigma}{2}$.*

2.4. Algorithm QP $_{\sigma}$. Algorithm QP $_{\sigma}$ approximates each convex quadratic term $\frac{1}{2}(x_j - \bar{x}_j)^2$ by the piecewise-linear $\mathcal{L}_{\sigma_j, \bar{x}_j}(x_j)$ with possibly different $\sigma_j \in (0, 1)$ for each variable x_j . Thus, each optimization problem in the course of Algorithm QP $_{\sigma}$ minimizes a piecewise-linear function over the convex set P .

ALGORITHM QP $_{\sigma}$

Input: $P \subseteq [0, 1]^n$, A , $\alpha = \frac{\ln m}{\gamma}$, $L = \gamma^{-1} \sqrt{16Kn \ln(m)}$, $\sigma_j \leq 2^{-p}$, $p = \lceil 3 \ln(L) \rceil = \lceil \frac{3}{2} \ln(16Kn \ln(m)) + 3 \ln(\frac{1}{\gamma}) \rceil$

Output: $\hat{y} \in P$ such that $\lambda(\hat{y}) \leq \lambda_P^* + \gamma$

choose $\hat{x}^0 \in P$. **set** $t \leftarrow 0$.

while ($t \leq L$) **do**

$g^{(t)} = \nabla \Phi(\hat{x}^{(t)})$

$\hat{y}^{(t)} \leftarrow \operatorname{argmin}_{x \in P} \left\{ K|\alpha| \sum_{j=1}^n \mathcal{L}_{\sigma_j, \hat{x}_j^{(t)}}(x_j) + \langle g^{(t)}, x - \hat{x}^{(t)} \rangle \right\}$

$\hat{S}_t(x) \leftarrow \frac{2}{t^2 + 3t + 2} \left\{ 2K|\alpha| \sum_{j=1}^n \mathcal{L}_{\sigma_j, \hat{x}_j^{(0)}}(x_j) + \sum_{h=0}^t (h+1) [\Phi(\hat{x}^h) + \langle g_h, x - \hat{x}^h \rangle] \right\}$

$\hat{z}^{(t)} \leftarrow \operatorname{argmin}_{x \in P} \{ \hat{S}_t(x) \}$

$\hat{x}^{(t+1)} \leftarrow \left(\frac{2}{t+3} \right) \hat{z}^{(t)} + \left(\frac{t+1}{t+3} \right) \hat{y}^{(t)}$

$t \leftarrow t + 1$

return $y^{(L)}$

In view of Lemma 6, we would expect that Algorithm QP $_{\sigma}$ successfully emulates Algorithm QP if the σ_j are small enough. In section 7.2 we provide a proof of the following fact.

THEOREM 7. *For any $t \geq 0$,*

$$\Phi(\hat{y}^{(t)}) \leq \hat{S}_t(\hat{z}^{(t)}) + \left(\frac{5K|\alpha|}{2} \right) \left(\sum_{h=1}^t \frac{1}{h^2} + t \right) \left(\sum_k \sigma_j \right).$$

This theorem implies the correctness of Algorithm QP $_{\sigma}$.

COROLLARY 8. *The output $y^{(L)}$ of Algorithm QP $_{\sigma}$ satisfies $\Phi(y^{(L)}) \leq \Phi^* + \gamma/2$.*

Proof. Suppose $\sigma_j \leq 2^{-p}$. Using Theorem 7 and Lemma 6(ii), we obtain

$$\begin{aligned} \Phi(\hat{y}^{(t)}) - \Phi^* &\leq \frac{2Kn|\alpha|}{(t+1)(t+2)} \left(1 + \frac{1}{4}(2^{-2p}) \right) \\ &\quad + \left(\frac{5K|\alpha|n}{2} \right) \left(\sum_{h=1}^t \frac{1}{h^2} + t \right) 2^{-p} \\ &< K|\alpha|n \left(\frac{2 + 2^{-(2p+1)}}{t^2} + \frac{5}{2}(2+t)2^{-p} \right). \end{aligned}$$

Suppose $t \geq 2$ and choose $p \geq 3 \ln t$. Then $\Phi(\hat{y}^{(t)}) - \Phi^* \leq \frac{8K|\alpha|n}{t^2}$. A simple calculation now establishes the result. \square

3. Concurrent flows with rational capacities and demands. In this section we discuss the special case of maximum concurrent flow with rational capacities and show that the piecewise-linear approximation introduced in section 2.3 can be solved efficiently for this special case.

Suppose we have a network $G = (V, E)$ with $|V|$ nodes, $|E|$ edges, and K commodities. We assume that the capacity u_e of every edge e is a positive rational. The demand vector d_k of every commodity k is also assumed to be a rational vector. Since scaling capacities and demands by a common positive constant does not change the value of the problem, we assume that all capacities and demands are integers. Let $f_{k,e}$ denote the flow associated with commodity k on edge e and let f_k denote the $|E|$ -vector with entries $f_{k,e}$. Then the maximum concurrent flow problem is given by

$$\begin{aligned} \lambda^* = \min \quad & \lambda \\ \text{s.t.} \quad & \sum_{k=1}^K f_{k,e} \leq \lambda u_e \quad \forall k, e, \\ & Nf_k = d_k, \quad f_k \geq 0, \quad k = 1, \dots, K, \end{aligned}$$

where N denotes the node-edge incidence matrix of the network. Let $\mathcal{F} = \{f : Nf_k = d_k, f_k \geq 0, k = 1, \dots, K\}$ denote the polyhedron of feasible flows.

In order to describe our piecewise-linear approach, in the following steps we review how the procedures we described in the prior sections would apply to the concurrent flow problem.

STEP 1. Define new, scaled variables $g_{k,e} = f_{k,e}/u_e$. This scaling leaves the objective unchanged, and the constraints are transformed into

$$\begin{aligned} \sum_k g_{k,e} &\leq \lambda, \quad e = 1, \dots, |E|, \\ g \in Q &= \{g \in \mathbf{R}^{K \times |E|} : \exists f \in \mathcal{F} \text{ with } g_{k,e} = f_{k,e}/u_e \forall k, e\}. \end{aligned}$$

The problem is now in the canonical form (1), with $m = |E|$ and $n = K|E|$.

STEP 2. After i iterations of BINARY SEARCH (see section 2.1), we get lower and upper bounds λ_l and λ_u with

$$(13) \quad \frac{\lambda_u - \lambda_l}{\lambda_l} \leq \left(\frac{2}{3}\right)^i O(\min\{m, K\}).$$

Let $\delta = \frac{1}{3}(\lambda_u - \lambda_l)$. We seek a vector g with $\max_e \sum_k g_{k,e} \leq \lambda^* + \delta$. Upon computing g , we reset either $\lambda_l \leftarrow \lambda_l + \delta$ or $\lambda_u \leftarrow \lambda_u - \delta$.

STEP 3. Let $P(\lambda_u) \triangleq \{z : \exists g \in Q \text{ with } z = g/\lambda_u, 0 \leq z \leq 1\}$. Procedure ABSOLUTE computes the vector g needed in Step 2 by approximately solving the scaled optimization problem

$$\begin{aligned} \min \quad & \lambda \\ \text{s.t.} \quad & \sum_{k=1}^K x_{k,e} \leq \lambda, \quad e = 1, \dots, |E|, \\ & x \in P(\lambda_u). \end{aligned}$$

The value of this problem is $\lambda^*/\lambda_u \leq 1$, and ABSOLUTE computes a feasible x with $\max_e \sum_k x_{k,e} \leq \lambda^*/\lambda_u + \gamma$, where $\gamma = \delta/\lambda_u$.

In section 2.2.1 we showed that in order to achieve the goal of procedure ABSOLUTE it is sufficient that x satisfy $\Phi(x) \leq \Phi^* + \gamma/2$. Corollary 8 in section 2.4 establishes that the output $\hat{y}^{(t)}$ produced by Algorithm QP_σ will satisfy this condition, provided

- (a) $\sigma_{k,e} \leq 2^{-p} \forall k, \forall e$,
- (b) $p \geq \bar{p} \triangleq \lceil \frac{3}{2} \ln(16Kn \ln(m)) + 3 \ln(\frac{1}{\gamma}) \rceil$,
- (c) $t \geq \frac{\sqrt{16Kn \ln m}}{\gamma}$.

Next we describe how to achieve (a)–(c) in the particular framework of the maximum concurrent flow problem. Note that in terms of the initial flow variables $f_{k,e}$, we have $x_{k,e} = \frac{1}{\lambda_u u_e} f_{k,e}$. We apply the framework developed in section 2.3 to the concurrent flow problem as follows:

- (i) We set $p = \bar{p} + \lceil \log D \rceil$, where D is the sum of all demands, and

$$(14) \quad \sigma_{k,e} = \frac{2^{-p}}{u_e} \quad \forall k, e.$$

This satisfies requirement (a) of Step 3.

- (ii) We modify BINARY SEARCH as follows. Every time a new upper bound λ_u is computed, we replace it with a *relaxed* bound $\hat{\lambda}_u \geq \lambda_u$, chosen so that $\frac{2^p}{\hat{\lambda}_u} = \lfloor \frac{2^p}{\lambda_u} \rfloor$. Note that $\lambda_u \leq D$, and so $\hat{\lambda}_u \leq \frac{\lambda_u}{1 - \lambda_u 2^{-p}} \leq \lambda_u (1 + O(2^{-p}))$. Since $\bar{p} = \frac{3}{2} \ln(Kn \ln(m)) + 3 \ln(\frac{1}{\gamma})$, where $\gamma = \frac{\delta}{\lambda_u}$, we have that

$$\frac{\hat{\lambda}^U - \lambda_l}{\lambda_u - \lambda_l} \leq 1 + \frac{\lambda_u O(2^{-\bar{p}})}{\lambda_u - \lambda_l} \leq 1 + O\left(\frac{2^{-\bar{p}}}{3\gamma}\right) = 1 + o(1).$$

Thus, up to constants, the complexity bound in Corollary 2 remains unchanged. For simplicity, in what follows we will use the notation λ_u to refer to the relaxed upper bound.

3.1. Solving the piecewise-linear problems. In this section we show how the modifications (i) and (ii) above allow one to efficiently solve the piecewise-linear problems encountered in Algorithm QP_σ .

The generic piecewise-linear problem that we need to solve is of the form

$$(15) \quad \begin{aligned} \min \quad & \sum_{k,e} \bar{\mathcal{L}}_{k,e}(x_{k,e}) \\ \text{s.t.} \quad & x \in P(\lambda_u), \end{aligned}$$

where $\bar{\mathcal{L}}_{k,e}(\cdot) = \mathcal{L}_{\sigma_{k,e}, \bar{x}_{k,e}}(\cdot)$ is a continuous convex piecewise-linear function with breakpoints at the integer multiples of $\frac{2^{-p}}{u_e}$ and with pieces of strictly increasing slope.

For every k and e , define $r_{k,e} = 2^p u_e x_{k,e}$. In terms of the initial flow variables $f_{k,e}$, we have $r_{k,e} = \frac{2^p}{\lambda_u} f_{k,e}$. Thus, after the change of variables the optimization problem is of the form

$$(16) \quad \begin{aligned} \min \quad & \sum_{k,e} \mathcal{L}_{k,e}(r_{k,e}) \\ \text{s.t.} \quad & Nr_k = \frac{2^p}{\lambda_u} d_k \quad \forall k, \\ & r_{k,e} \leq 2^p u_e \quad \forall k, e, \end{aligned}$$

where $\mathcal{L}_{k,e}$ is a continuous convex piecewise-linear function with breakpoints at the integers and pieces of strictly increasing slope. The optimization problem (16) is just a min-cost flow problem, with integral demands and capacities. In summary, as discussed in the previous section, given λ_u we will have to solve $2t$ problems of the form (16), where t is as in Step 3(c).

We solve each such problem using an approach similar to that described in [20] and in [1, Chap. 14]. This approach is reminiscent of the cost-scaling (or capacity-scaling) method for solving standard (linear) minimum-cost flow problems. Our algorithm is described in section 7.3. The algorithm assumes that a feasible, integral solution to (16) has been already computed (we will account for this work separately). Given such a solution, the algorithm solves problem (16) by performing

$$O\left(\sum_k \sum_e (p + \log u_e)\right) = O(K|E|p + KL_U)$$

shortest path computations, where L_U is the number of bits needed to represent the largest capacity. Since $p = \bar{p} + \lceil \log D \rceil$, over all iterations of Algorithm QP_σ the total number of shortest path computations incurred in calls to the algorithm in section 7.3 is

$$\begin{aligned} &O\left(\frac{\sqrt{Kn \ln(m)}}{\epsilon} (K|E|(\bar{p} + \lceil \log D \rceil) + KL_U)\right) \\ &= O^*\left(\epsilon^{-1} K^2 |E|^{\frac{1}{2}} \left(L_U + |E| \lceil \log D \rceil + |E| \log\left(\frac{1}{\epsilon}\right)\right)\right), \end{aligned}$$

plus lower-order complexity terms.

Finally, we account for the complexity of computing a feasible integral solution to (16). Note that all the problems of the form (16) arising in a given call to Algorithm QP_σ make use of the same value of λ_u and p ; consequently, the feasible integral flows need to be computed once per commodity, per call to QP_σ . In total, there will be $O^*(\epsilon^{-1})$ feasible flow computations per commodity. Each such computation essentially amounts to a maximum flow problem. We can solve such a problem using, e.g., any augmenting path algorithm (which essentially relies on shortest path computations). The simplest such algorithm (see [1]) performs $O(|V||E|)$ shortest path computations.

In summary, we now have the following result.

THEOREM 9. *An ϵ -optimal solution to a maximum concurrent flow problem, on a graph $G = (V, E)$ with $|V|$ nodes, $|E|$ edges, and K commodities, can be computed by solving*

$$O^*\left(\epsilon^{-1} K^2 E^{\frac{1}{2}} \left(L_U + |E| \lceil \log D \rceil + |E| \log\left(\frac{1}{\epsilon}\right)\right) + \epsilon^{-1} |V||E|\right)$$

shortest path problems, plus lower complexity steps, where L_U denotes the number of bits needed to store the capacities and D is the sum of demands.

4. Maximum multicommodity flows. In this section we extend the techniques developed in the previous section to the maximum multicommodity flow problem (see [2]; see also [8, 5]).

Let (s_k, t_k) , $k = 1, \dots, K$, denote a set of source-sink node pairs. The goal of the maximum multicommodity flow problem is to find a feasible multicommodity flow

(one that satisfies the capacity constraints on any edge) that maximizes the sum, over all k , of the amount of flow sent from s_k to t_k . Our approach will be to reduce this problem into an equivalent maximum concurrent flow problem.

Given a multicommodity flow, we will denote the total flow sent from s_k to t_k by F_k , $k = 1, \dots, K$. We denote by F^* the optimal value of the maximum multicommodity flow problem. Finally, let

$$(17) \quad F^L = \max_{k=1, \dots, K} \{\text{maxflow for commodity } k \text{ alone}\}.$$

Then $F^L \leq F^* \leq F^U = KF^L$. Moreover, for any feasible flow and any k , we have $F_k \leq F^L$. Suppose we introduce new variables $G_k = F^L - F_k \geq 0$. Then the maximum multicommodity flow problem is equivalent to

$$(18) \quad \begin{aligned} G^* \triangleq \min & \sum_{k=1}^K G_k \\ \text{s.t.} & F_k + G_k = F^L, \quad k = 1, \dots, K, \end{aligned}$$

$$(19) \quad \begin{aligned} & \sum_{k=1}^K f_{k,e} \leq u_e, \quad e \in E, \\ & f_k \text{ nonnegative and satisfies flow conservation,} \quad k = 1, \dots, K. \end{aligned}$$

Clearly, $\sum_k G_k \leq G^U \triangleq (K - 1)F^L$, and $F^* + G^* = F^U$. We assume that $F^L > 0$, or else the problem is trivial. Further, let $\delta = \min\{\frac{\epsilon}{K}, \frac{1}{2}\}$, and suppose $(\hat{f}_k, \hat{F}_k, \hat{G}_k)$, $k = 1, \dots, K$, is a vector satisfying

- (i) $\sum_{k=1}^K f_{k,e} \leq (1 + \delta)u_e \quad \forall e$,
- (ii) constraints (18) and (19), and
- (iii) $\sum_k \hat{G}_k \leq (1 + \delta)G^*$.

Then $\sum_k \hat{F}_k = F^U - \sum_k \hat{G}_k = F^* + G^* - \sum_k \hat{G}_k$, and consequently,

$$\frac{\sum_k \hat{F}_k}{F^*} \geq 1 - \delta \frac{G^*}{F^*} \geq 1 - \delta \frac{G^U}{F^L} = 1 - (K - 1)\delta.$$

As a result, the vector $((1 + \delta)^{-1}\hat{f}_k)$, $k = 1, \dots, K$, is an ϵ -optimal solution to the maximum multicommodity flow problem.

In order to find a vector satisfying conditions (i)–(iii), we first establish a nonzero lower bound for G^* . Consider the packing problem

$$(20) \quad \begin{aligned} \min & \max_{e \in E} \left\{ \frac{\sum_{k=1}^K f_{k,e}}{u_e} \right\} \\ \text{s.t.} & F_k = (1 - \delta/2)F^L \quad \forall k, \\ & f_k \text{ satisfies flow conservation} \quad \forall k. \end{aligned}$$

Note that (20) is a maximum concurrent flow problem. Let $\lambda(f)$ denote the maximum load of a flow f , and let \hat{f} denote any $(\delta/4)$ -optimal solution for (20). Consider the following two cases:

- (a) $\lambda(\hat{f}) \leq 1 + \delta/2$. In this case, $\hat{f}/(1 + \delta/2)$ is a feasible flow with total flow $(\sum_k F_k)/(1 + \delta/2) \geq (1 - \delta)KF^L = (1 - \delta)F^U$; i.e., $\hat{f}/(1 + \delta/2)$ is a δ -optimal multicommodity flow.

(b) $\lambda(\hat{f}) > 1 + \delta/2$. In this case, the packing problem (20) is infeasible. Thus, for any multicommodity flow satisfying the capacity constraints and flow conservation, we have $F_k < (1 - \delta/2)F^L$, i.e., $G^k > \delta F^L/2$ for at least one k .

Hence, $G^L \stackrel{\Delta}{=} \delta F^L/2$ is a valid lower bound for G^* .

We next describe the procedure that computes a vector satisfying (i)–(iii). The procedure maintains two bounds, $0 < G^L \leq G^* \leq G^U$, and a flow vector, \hat{f} . The bound G^L is initialized as indicated above and $G^U = (K - 1)F^L$. The flow vector \hat{f} is initialized as follows. Let \bar{k} denote the commodity attaining the maximum in (17). Then $\hat{f}_{\bar{k}}$ is set equal to any flow vector sending F^L units from $s_{\bar{k}}$ to $t_{\bar{k}}$, while for all other k , the flow vector \hat{f}_k is the zero vector. Thus, the flow \hat{f} attains G^U .

In any iteration of the procedure, we set $G = \frac{G^L + G^U}{2}$ and compute a $(\delta/8)$ -approximate solution to the packing problem

$$(21) \quad \lambda_G^* = \min \max \left\{ \max_{e \in E} \left\{ \frac{\sum_{k=1}^K f_{k,e}}{u_e} \right\}, \frac{\sum_k G_k}{G} \right\}$$

$$\text{s.t. } F_k + G_k = F^L \quad \forall k,$$

$$f_k \text{ satisfies flow conservation} \quad \forall k.$$

Note that (21) is a concurrent flow problem in the graph $G' = (V', E')$, $V' = V \cup \{S, T\}$, $E' = E \cup \{(S, T)\} \cup \{(s_k, S), (T, t_k) : k = 1, \dots, K\}$, $u_{(s_k, S)} = u_{(T, t_k)} = \infty$, and $u_{(S, T)} = G$ (the flows on edges (s_k, S) and (T, t_k) are both equal to G_k). Consequently, this task can be accomplished in $O^*(\frac{1}{\delta} \log(\frac{1}{\delta}))$ iterations of Algorithm QP $_{\sigma}$, where each iteration solves a piecewise-linear program that reduces to a sequence of shortest path problems.

Let λ_G denote the congestion of any $(\delta/8)$ -optimal solution. There are two cases as follows:

- (a) $\lambda_G > (1 + \delta/8)$. Then we reset to $G^L \leftarrow G$.
- (b) $\lambda_G \leq (1 + \delta/8)$. In this case we reset $G^U \leftarrow (1 + \delta/8)G$ and update \hat{f} to be the solution we computed to the packing problem.

The above procedure is repeated until $G^U - G^L \leq (\delta/2)G^L$. At the start of the procedure, $G^L = \delta F^L/2 \geq \delta G^U/2K$, and thus the number of bisection steps is bounded above by $O(\log(\frac{1}{\delta}))$ (neglecting polynomial factors in n , m , and K). To validate the procedure, note that each time that G^L is reset, i.e., case (a) holds, we have that $\lambda_G^* > 1$, which implies that $G \leq G^*$, and thus G^L is always a lower bound for G^* . When case (b) applies, the flow vector obtained in that iteration satisfies (i), (ii), and $\sum_k \hat{G}_k \leq (1 + \delta)G \leq (1 + \delta/8)G^U$. We conclude that at termination the vector \hat{f} is as desired.

In summary, the number of iterations of Algorithm QP $_{\sigma}$ needed to find an ϵ -optimal maximum multicommodity flow is bounded above by $O(\frac{1}{\epsilon} \log^2(\frac{1}{\epsilon}))$, again neglecting polynomial factors in n , m , and K .

5. Pure covering problems. The basic covering problem has the following structure:

$$(22) \quad \mu^* = \max_{x \in Q} \min_{1 \leq i \leq m} \{a_i^T x\},$$

where $Q \subseteq \mathbf{R}_+^n$ is a compact, convex set, $A = [a_1, \dots, a_m]^T \in \mathbf{R}_+^{m \times n}$, and each positive a_{ij} has value at least 1. For a given $x \in Q$, let $\mu(x) = \min_{1 \leq i \leq m} \{a_i^T x\}$. As in the packing problems, we will let K denote the maximum number of nonzero terms in any row of the A matrix.

5.1. Upper and lower bounds. In order to start our procedure, we need polynomially separated upper and lower bounds for μ^* . The following technique is used in [24]. For $i = 1, \dots, m$, define

$$(23) \quad \mu_i = \max_{x \in Q} \{a_i^T x\}, \quad \bar{x}_i = \operatorname{argmax}_{x \in Q} \{a_i^T x\}.$$

Then, it is clear that

$$(24) \quad \mu^* \leq \mu_u \triangleq \min_{1 \leq i \leq m} \{\mu_i\}.$$

Let $\bar{x} = \frac{1}{m} \sum_{k=1}^m \bar{x}_k$. Then

$$(25) \quad \begin{aligned} \mu(\bar{x}) &= \min_{1 \leq i \leq m} \{a_i^T \bar{x}\} = \frac{1}{m} \min_{1 \leq i \leq m} \left\{ \sum_{k=1}^m a_i^T \bar{x}_k \right\} \geq \frac{1}{m} \min_{1 \leq i \leq m} \{a_i^T \bar{x}_i\} = \frac{1}{m} \mu_u, \\ \mu_l &\triangleq \frac{1}{m} \mu_u \leq \mu^* \leq \mu_u. \end{aligned}$$

5.2. Refinement of bounds. In order to approximately compute μ^* , we would like to use a binary search procedure similar to that described in section 2.1. In the covering case, however, we need further elaboration. Given any $\mu_u > 0$, define

$$(26) \quad C(\mu_u) \triangleq \{y \in [0, 1]^n : \exists x \in Q \text{ s.t. } x \geq \mu_u y\}$$

and

$$(27) \quad \mu_u^* = \max_{y \in C(\mu_u)} \min_{1 \leq i \leq m} \{a_i^T y\}.$$

Then we have the following result.

LEMMA 10. *For any upper bound $\mu_u \geq \mu^*$, we have that $\mu_u^* = \frac{\mu^*}{\mu_u}$.*

Proof. Let $y^* = \operatorname{argmax}\{\mu(y) : y \in C(\mu_u)\}$. Since $y \in C(\mu_u)$, there exists $\hat{x} \in Q$ such that $\hat{x} \geq \mu_u y^*$. Thus,

$$\mu_u^* = \mu(y^*) \leq \frac{\mu(\hat{x})}{\mu_u} \leq \frac{\mu^*}{\mu_u}.$$

To prove the bound in the other direction, let $x^* = \operatorname{argmax}_{x \in Q} \mu(x)$. Define

$$\hat{y}_j = \frac{\min\{x_j^*, \mu_u\}}{\mu_u}, \quad j = 1, \dots, n.$$

Then $\hat{y} \in C(\mu_u)$, and to complete the proof it will suffice to show that, for any $1 \leq i \leq m$, $\sum_j a_{ij} \hat{y}_j \geq \frac{\mu^*}{\mu_u}$. To see that this is the case, fix i , and note that if $x_h^* > \mu_u$ for some h with $a_{ih} > 0$, then by the assumption on A , $\sum_j a_{ij} \hat{y}_j \geq \hat{y}_h = 1 \geq \frac{\mu^*}{\mu_u}$ (since $\mu_u \geq \mu^*$). If, on the other hand, $x_j^* \leq \mu_u$ for all j with $a_{ij} > 0$, then

$$\sum_j a_{ij} \hat{y}_j = \frac{\sum_j a_{ij} x_j^*}{\mu_u} \geq \frac{\mu^*}{\mu_u},$$

as desired. \square

The rest of the algorithm mirrors that for the packing case, in that we will use a potential function method to implement each step of the binary search. However, unlike in the packing case, the QPs solved in the course of approximately minimizing the potential function are defined over the sets $C(\mu_u)$, rather than over Q itself. At the end of this section we comment on why our approach needs the sets $C(\mu_u)$.

Consider a typical step of the binary search. We are given a lower bound μ_l and an upper bound μ_u on μ^* . Setting $\delta = \frac{\mu_u - \mu_l}{3}$, the outcome of the binary search step is an $x \in Q$ with $\mu(x) \geq \mu^* - \delta$; if $\mu(x) \geq \mu_l + 2\delta$, then we reset $\mu_l \leftarrow \mu_l + \delta$, while in the other case we reset $\mu_u \leftarrow \mu_l + 2\delta$, thereby improving the gap between the two bounds by a factor of $\frac{2}{3}$. In view of Lemma 10, we equivalently seek a $y \in C(\mu_u)$ with $\mu(y) \geq \mu_{P(\mu_u)}^* - \gamma$, where $\gamma = \frac{\delta}{\mu_u}$, and we will compare $\mu(y)$ with $\frac{\mu_l}{\mu_u} + 2\gamma$.

The computation of such a y is accomplished through the use of a potential function. For the covering case, we now use

$$\Phi(x) = \frac{1}{\beta} \ln \left(\sum_{i=1}^m e^{-\beta a_i^T x} \right)$$

for a suitably chosen $\beta > 0$. We have the following analogue of (5):

$$(28) \quad -\mu(x) \leq \Phi(x) \leq -\mu(x) + \frac{\ln m}{\beta}.$$

Thus, given $\gamma > 0$, in order to compute $y \in C(\mu_u)$ with $\mu(y) \geq \mu_u^* - \gamma$, we set $\beta = \frac{2 \ln m}{\gamma}$ and compute $y \in C(\mu_u)$ with $\Phi(y) \leq \Phi^* + \frac{\gamma}{2}$, where $\Phi^* \triangleq \min_{y \in P(\mu_u)} \Phi(y)$. For this purpose we can use Algorithm QP, given in section 2, verbatim. To see that this is a valid approach, recall that the proofs in section 2 that involve α and that of Lemma 5 are all valid for negative values of α . Thus, we have the following result.

THEOREM 11. *An ϵ -optimal solution to the covering problem can be computed by solving $O(\epsilon^{-1} \sqrt{Kn \ln m})$ convex separable QPs over the set $C(\mu_u)$ defined in (26).*

We conclude this section by listing some special cases, where convex separable QPs over the set $C(\mu_u)$ reduce to an optimization problem over Q or a simple modification of Q .

- (a) Q block angular: It is clear that $C(\mu_u)$ is also block angular. Moreover, $y \in C(\mu_u)$ if and only if there exists $s \geq 0$ such that $\mu_u y + s \in Q$. In other words, if we are given a linear inequality description of Q , then we obtain one for $C(\mu_u)$ with twice as many variables but with the same general structure.
- (b) Q “downwards closed”: Q is said to be “downwards closed” if $x \in Q$ implies that $\{x' : 0 \leq x' \leq x\} \subseteq Q$. Therefore, it follows that $C(\mu) = \{x \in Q : 0 \leq x_j \leq \mu \text{ for all } j\}$.
- (c) Q described by a linear optimization oracle: In this case, under appropriate assumptions, a convex QP over $C(\mu_u)$ reduces to a polynomial number of linear programs over Q [27]. The key ingredient here is that the separation problem over $C(\mu_u)$ can be solved by making a polynomial number of calls to the optimization oracle over Q . To see that this is the case, recall that we assumed $Q \subseteq \mathbf{R}_+^n$. Let

$$Q^{\leq}(\mu_u) = \{y \geq 0 : \exists x \in Q \text{ s.t. } x \geq \mu_u y\}.$$

Then, for any $c \in \mathbf{R}^n$, we have that

$$(29) \quad \max \left\{ \sum_j c_j y_j : y \in Q^{\leq}(\mu_u) \right\} = \max \left\{ \sum_j c_j^+ y_j : y \in Q^{\leq}(\mu_u) \right\},$$

where $r^+ \triangleq \max\{r, 0\}$. Since the objective vector on the right-hand side of (29) is nonnegative, it follows that this term is equal to

$$(\mu_u)^{-1} \max \left\{ \sum_j c_j^+ y_j : y \in Q \right\}.$$

Thus, a linear optimization problem over $Q^{\leq}(\mu_u)$ reduces to an equivalent linear optimization problem over Q . Consequently, the separation problem over $Q^{\leq}(\mu_u)$ requires a polynomial number of oracle calls (to the optimization oracle over Q). Since

$$C(\mu_u) = Q^{\leq}(\mu_u) \cap \{y \in R^n : y_j \leq 1 \ \forall j\},$$

we can conclude that the same holds for $C(\mu_u)$, as desired.

5.3. Why do covering problems require solving QPs over $C(\mu_u)$? In order to motivate our use of the sets $C(\mu_u)$, it is worth revisiting some of our techniques used for packing problems, in particular, the use of the potential function, which we adapted from the packing case in a straightforward manner in order to handle covering problems (essentially, by changing the sign of the exponent).

To understand the difference between packing and covering problems, let us examine the role of the sets P in packing problems. In the context of a fractional packing problem $\text{PACK}(A, Q)$ with $A \in \{0, 1\}^{m \times n}$, the critical observation is that $\lambda^* \leq \lambda_u$ implies that $x_j \leq \lambda_u$ for all $j = 1, \dots, n$. In this setting, the set P is given by $P = \lambda_u^{-1}Q \cap [0, 1]^n$. Next, consider a generalized packing problem with a nonnegative matrix A . We show that by introducing new variables this problem can be reduced to a packing problem $\text{PACK}(A, Q)$ with $A \in \{0, 1\}^{m \times n}$. The combined effect of adding variables and of scaling by λ_u^{-1} is the following: If $a_{ij} > 0$, then we generate a new variable of the form $\frac{a_{ij}}{\lambda_u} x_j$. The fact $\lambda^* \leq \lambda_u$ implies that, without loss of generality, we can place an upper bound of 1 on this new variable; equivalently, $\lambda^* \leq \lambda_u$ implies that the set $\bar{Q} = \{x \in Q : \frac{a_{ij}}{\lambda_u} x_j \leq 1 \text{ for all } a_{ij} > 0\}$ is nonempty, and $\lambda(x) \leq \lambda_u$ if and only if $x \in \bar{Q}$. For any $A \in \{0, 1\}^{m \times n}$ and $x \in P$, we have $\sum_j a_{ij} x_j \leq K$ for all i , where K denotes the maximum number of nonzero terms in any row of A . This bound is instrumental in the proofs of Corollary 4 and Lemma 5, both of which are critical in the analysis of the algorithm. In particular, the iteration count depends on K and not on the “width” [24] of the problem.

However, when dealing with a covering problem, this approach fails. Given an upper bound μ_u on μ^* , and a coefficient $a_{ij} > 0$, we cannot assume that $\frac{\mu_u}{a_{ij}}$ is an upper bound on x_j . The reason for this is that there might be a different row i' with $0 < a_{i'j} < a_{ij}$. Instead, we can assume only that $x_j \leq \frac{\mu_u}{a_{kj}}$, where a_{kj} is the smallest positive coefficient in column j of A . However, when we use this bound, the arguments in Corollary 4 and Lemma 5 do not follow through—instead of obtaining a dependence on K we obtain a dependence on the maximum ratio between positive entries in any given column j of A . Finally, we may be unable to place a (simple) upper bound on some x_j , even when $A \in \{0, 1\}^{m \times n}$ and there is a known upper bound $\mu_u \geq \mu^*$, because the structure of the set Q may simply prevent us from doing so—in other words, a set of the form $Q \cap \{x_j \leq \mu_u\}$ may be empty, in contrast with what happens in the packing case.

6. Algorithms for mixed packing and covering. In this section we consider the mixed packing-covering problem

$$(30) \quad \begin{aligned} \lambda^* \triangleq \min \quad & \lambda(x) \triangleq \max_{1 \leq i \leq m_p} \{p_i^T x\} \\ \text{s.t.} \quad & \min_{1 \leq i \leq m_c} \{c_i^T x\} \geq 1, \\ & x \geq 0, \end{aligned}$$

where $x \in \mathbf{R}^n$, and the vectors $p_i \in \mathbf{R}^n$, $i = 1, \dots, m_p$, and $c_i \in \mathbf{R}^n$, $i = 1, \dots, m_c$, are all assumed to be nonnegative. We present an algorithm that computes, for any $\epsilon > 0$, an ϵ -approximation to λ^* in $O^*(\frac{1}{\epsilon})$ steps. As before, each basic step consists of solving a separable, convex QP. As we will show, in this instance the QPs are particularly simple and can be solved in $O(nK_p)$ time.

6.1. Computing initial polynomially separated upper and lower bounds. The analysis in this section is identical to the one in [31]. Define $p = \frac{1}{m_p} \sum_{i=1}^{m_p} p_i$. For each $k = 1, \dots, m_c$, let

$$(31) \quad \lambda_k = \min \{p^T x : c_k^T x \geq 1, x \geq 0\} = \min_{1 \leq j \leq n} \left\{ \frac{p_j}{c_{kj}} \right\}.$$

Let $x^{(k)}$ denote the vector that achieves the minimum in (31), i.e.,

$$x_j^{(k)} = \begin{cases} \frac{1}{c_{kj}}, & j = \operatorname{argmin}_{1 \leq j' \leq n} \left\{ \frac{p_{j'}}{c_{kj'}} \right\}, \\ 0 & \text{otherwise.} \end{cases}$$

Then, it is clear that

$$\lambda^* \geq \lambda_l = \max_{1 \leq k \leq m_c} \{\lambda_k\}.$$

Let $\bar{x} = \sum_{k=1}^{m_c} x^{(k)}$. Then, for all $i = 1, \dots, m_c$,

$$c_i^T \bar{x} = \sum_{k=1}^{m_c} c_i^T x^{(k)} \geq c_i^T x^{(i)} \geq 1,$$

i.e., \bar{x} is feasible for (30), and

$$\max_{1 \leq i \leq m_p} \{p_i^T \bar{x}\} \leq \sum_{i=1}^{m_p} p_i^T \bar{x} = m_p p^T \bar{x} = m_p \sum_{k=1}^{m_c} \lambda_k \leq m_c m_p \lambda_l \triangleq \lambda_u.$$

Thus, we have a lower bound λ_l and an upper bound λ_u such that $\lambda_u \leq m_c m_p \lambda_l$.

6.2. Binary search to refine bounds. As with all other problems considered in this paper, we next refine the bounds using a binary search technique. In the general step of the binary search, we have the bounds $0 < \lambda_l \leq \lambda_u$. As before, set $\delta = \lambda_u - \lambda_l$ and $\gamma = \delta/\lambda_u$.

For $i = 1, \dots, m_p$, define $S_i = \{j : p_{ij} > 0\}$. Since $\lambda^* \leq \lambda_u$, it follows that for all $j \in S_i$ we can restrict $x_j \leq \lambda_u/p_{ij}$ without any loss in optimality. Thus, (30) is

equivalent to

$$(32) \quad \begin{aligned} \frac{\lambda^*}{\lambda_u} = \min \quad & \max_{1 \leq i \leq m_p} \left\{ \sum_{j \in S_i} y_{ij} \right\} \\ \text{s.t.} \quad & \sum_j c_{ij} x_j \geq 1, \quad i = 1, \dots, m_c, \\ & y_{ij} - \frac{p_{ij}}{\lambda_u} x_j = 0, \quad j \in S_i, \quad i = 1, \dots, m_p, \\ & y_{ij} \leq 1, \quad j \in S_i, \quad i = 1, \dots, m_p, \\ & x \geq 0. \end{aligned}$$

To refine the bounds we change variables by setting $z_{ij} = 1 - y_{ij}$ ($j \in S_i, i = 1, \dots, m_p$) and solve the following pure covering problem:

$$(33) \quad \begin{aligned} \mu^* = \max \quad & \mu \\ \text{s.t.} \quad & \sum_{j \in S_i} z_{ij} \geq \mu(|S_i| - (1 - 0.5\gamma)), \quad i = 1, \dots, m_p, \\ & \sum_j c_{ij} x_j \geq \mu, \quad i = 1, \dots, m_c, \\ & (x, z) \in Q, \end{aligned}$$

where the set Q consist of all pairs (x, z) satisfying

$$(34) \quad \begin{aligned} z_{ij} + \frac{p_{ij}}{\lambda_u} x_j &= 1, \quad j \in S_i, \quad i = 1, \dots, m_p, \\ z_{ij} &\geq 0, \quad j \in S_i, \quad i = 1, \dots, m_p, \\ x &\geq 0. \end{aligned}$$

Let $K_p = \max_{1 \leq i \leq m_p} \{|S_i|\}$, and let (\bar{x}, \bar{z}) denote any $(\frac{\gamma}{3K_p})$ -optimal solution for the pure covering problem (33). Consider the following two cases:

- (a) $\mu(\bar{x}, \bar{z}) < (1 - \frac{\gamma}{6K_p})$. In this case we claim that $1 - 0.5\gamma$ is a lower bound on $\frac{\lambda^*}{\lambda_u}$. Otherwise, there exists (\hat{x}, \hat{y}) feasible for (32) with $\sum_{j \in S_i} \hat{y}_{ij} \leq 1 - 0.5\gamma$ for each $1 \leq i \leq m_p$. Then it follows that $\mu^* \geq 1$, and a $(\frac{\gamma}{6K_p})$ -optimal solution to (33) must have $\mu \geq (1 - \frac{\gamma}{6K_p})$, a contradiction. Therefore $\lambda_l \leftarrow (1 - 0.5\gamma)\lambda_u$ is a valid lower bound for λ^* , and the gap $\delta = \lambda_u - \lambda_l$ decreases by half.
- (b) $\mu(\bar{x}, \bar{z}) \geq (1 - \frac{\gamma}{6K_p})$. Then $\sum_j c_{ij} \bar{x}_{ij} \geq 1 - \frac{\gamma}{6K_p}$, and

$$\sum_{j \in S_i} \bar{z}_{ij} \geq \left(1 - \frac{\gamma}{6K_p}\right) (|S_i| - (1 - 0.5\gamma)) \geq |S_i| - (1 - \gamma/3), \quad i = 1, \dots, m_p.$$

Define $\tilde{y}_{ij} = 1 - \bar{z}_{ij}, j \in S_i, i = 1, \dots, m_p$, and $(\tilde{x}, \tilde{y}) = \frac{1}{1 - \frac{\gamma}{6K_p}}(\bar{x}, \bar{y})$. Then it follows that $\sum_j c_{ij} \tilde{x}_{ij} \geq 1$ for all $i = 1, \dots, m_c$. Thus, (\tilde{x}, \tilde{y}) is feasible for (32). Further, for each $i = 1, \dots, m_p$, we have $\sum_{j \in S_i} \tilde{y}_{ij} \leq \frac{1 - \frac{\gamma}{3}}{1 - \frac{\gamma}{6K_p}} \leq 1 - \frac{\gamma}{6}$, or equivalently, $\sum_{j \in S_i} p_{ij} \tilde{x}_{ij} \leq (1 - \gamma/6)\lambda_u$. Consequently, $\lambda^* \leftarrow (1 - \gamma/6)\lambda_u$ is a valid upper bound, and the gap $\delta = \lambda_u - \lambda_l$ decreases by a factor of $5/6$.

In conclusion, in either case the gap is decreased by at least a factor of $5/6$. Therefore, it follows that we can compute an ϵ -optimal solution for the mixed packing-covering problem by solving $O(\ln(\epsilon^{-1} m_c m_p))$ covering problems of the form (33).

6.3. Overall complexity bound. In this section we compute a complexity bound for the pure covering problem (33) by exploiting the special structure of the set Q defined in (34).

Let $K_c = \max_{i=1}^{m_c} |\{j : c_{ij} > 0\}|$ denote the maximum number of nonzero entries in the covering constraints in the mixed packing-covering problem (30). Since the number of variables in the pure covering problem (33) is at most $n(1 + K_p)$, the number of constraints is $m_p + m_c$ and the maximum number of nonzero elements in the covering constraints is $\max\{K_p, K_c\}$, and $\gamma/K_p \geq \epsilon/n$. The results in section 5 imply that we can compute an $(\frac{\gamma}{3S})$ -optimal solution for (33) in

$$O\left(\frac{n}{\epsilon} \sqrt{\max\{K_c, K_p\}(1 + K_p)n \log(m_c + m_p)}\right)$$

iterations, where each iteration involves solving a convex separable QP over the set

$$C(\mu) = \left\{ (v, w) \in [0, 1]^{n+K_p} : \exists (x, z) \in Q \text{ s.t. } x \geq \mu v, z \geq \mu w \right\}.$$

See (26) for details. For Q defined in (34), the set $C(\mu)$ is given by

$$C(\mu) = \left\{ (v, w) \in [0, 1]^{n+K_p} : \mu v_j \leq \min \left\{ \min\{p_{ij}^{-1} \lambda_u : j \in S_i\}, 1 \right\}, \mu w_{ij} \leq (1 - \lambda_u \mu v_j / p_{ij}) \right\}.$$

A separable convex QP over $C(\mu)$ can be decomposed into n convex QPs in the variables (v, w) of the form

$$(35) \quad \begin{aligned} \min \quad & \alpha v - \frac{1}{2} \beta v^2 + \sum_{i:j \in S} \left(\eta_i w_i - \frac{1}{2} \kappa_i w_i^2 \right) \\ \text{s.t.} \quad & 0 \leq \mu w_i \leq (1 - \lambda_u \mu v / p_i), \quad i \in S, \\ & 0 \leq \mu v \leq \bar{v}. \end{aligned}$$

Fix v . Let $\bar{w}_i = \frac{\eta_i}{\kappa_i}$. If $\bar{w}_i \leq 0$, the optimal solution w_i^* of the one-dimensional QP in w_i variable is $w_i^* = 0$ and this variable can be removed from further consideration. When $\bar{w}_i > 0$, the optimal solution $w_i^* = \min\{\bar{w}_i, 1 - \frac{\lambda_u \mu v}{p_i}\}$. Thus, each index $i \in S$ partitions the interval $[0, \bar{v}/\mu]$ into two subintervals, one where $w_i^* = \bar{w}_i$ and the other where $w_i^* = 1 - \frac{\lambda_u \mu v}{p_i}$. Thus, the optimal value of the variable v can be computed in solving at most $|S| (\leq n)$ one-dimensional QPs. Thus, the computational effort required to compute an optimal solution of a convex separable QP over $C(\mu)$ is $O(nK_p)$. Combining this with our bound on the iteration count, we have the following result.

THEOREM 12. *The complexity of computing an ϵ -approximate solution for the mixed packing-covering problem (30) is*

$$O\left(\left(n^2 K_p \sqrt{\max\{K_c, K_p\}(1 + K_p)n \log(m_c + m_p)}\right) \frac{1}{\epsilon} \ln\left(\frac{m_c m_p}{\epsilon}\right)\right),$$

where K_p (resp., K_c) denote the maximum number of nonzeros in the packing (resp., covering) constraints.

7. Technical proofs.

7.1. Improved Taylor expansion. The derivative of $\nabla\Phi(x) = A^T\pi(x)$, where

$$\pi_i(x) = \frac{e^{\alpha a_i^T x}}{\sum_{j=1}^m e^{\alpha a_j^T x}}, \quad i = 1, \dots, m.$$

We want to show that $\|A^T(\pi(x) - \pi(y))\|_2 \leq K\alpha\|x - y\|_2$.

The construction of the bound will proceed in two steps as follows.

(a) \mathcal{L}_1 -bound on A^T : Since $\pi(x) \geq 0$ and $\sum_{i=1}^m \pi_i(x) = 1$ for all x , we endow the π -space with the \mathcal{L}_1 -norm. Define $\|A\|_{1,2}$ as

$$\begin{aligned} \|A\|_{1,2} &= \max \{ \|A^T\pi\|_2 : \|\pi\|_1 = 1 \} \\ &= \max \left\{ \left\| \sum_{i=1}^m \pi_i a_i \right\|_2 : \|\pi\|_1 = 1 \right\} \\ &= \max_{1 \leq i \leq m} \{ \|a_i\|_2 \} = \sqrt{K}, \end{aligned}$$

where the first equality in the last step follows from the fact that $\|a\|_2$ is a convex function and achieves its maximum at the extreme points of the feasible set, and the final bound follows from the fact that number of 1's in the vectors a_i is bounded above by K . Thus, we have that

$$(36) \quad \begin{aligned} \|A^T(\pi(x) - \pi(y))\|_2^2 &\leq \|A\|_{1,2}^2 \|\pi(x) - \pi(y)\|_1^2 \\ &\leq K \|\pi(x) - \pi(y)\|_1^2. \end{aligned}$$

(b) Strong convexity of the entropy function: The next step is to show an upper bound of the form $\|\pi(x) - \pi(y)\|_1 \leq C\|x - y\|_2$ for an appropriate C . Since we need an upper bound on a norm, one way to achieve this is to bound it above by a strongly convex function.

Define $H(\pi) = \sum_{i=1}^m \pi_i \log(\pi_i)$ for π such that $\pi \geq 0$ and $\sum_{i=1}^m \pi_i = 1$. Then, $\nabla^2 H = \text{diag}(1/\pi_i)$, and

$$y^T(\nabla^2 H)y = \sum_{i=1}^m \frac{y_i^2}{\pi_i}.$$

The right-hand side is a convex function and, on minimizing this function over π in the simplex, we obtain that

$$(37) \quad y^T(\nabla^2 H)y \geq \left(\sum_{i=1}^m |y_i| \right)^2.$$

Thus, we have that

$$\begin{aligned} &(\nabla H(\pi(x)) - \nabla H(\pi(y)))^T (\pi(x) - \pi(y)) \\ &= (\nabla^2 H(\pi_\theta)(\pi(x) - \pi(y)))^T (\pi(x) - \pi(y)) \geq \|\pi(x) - \pi(y)\|_1^2, \end{aligned}$$

where $\pi_\theta = \theta\pi(x) + (1 - \theta)\pi(y)$, $\theta \in [0, 1]$, the first equality follows from the

mean value theorem, and the second inequality follows from (37). Substituting the values of $\nabla H(\pi(x))$ and $\nabla H(\pi(y))$, it follows that

$$\begin{aligned}
 \|\pi(x) - \pi(y)\|_1^2 &\leq \sum_{i=1}^m (\log(\pi_i(x)) - \log(\pi_i(y))) (\pi_i(x) - \pi_i(y)) \\
 &= \sum_{i=1}^m \left(\alpha(a_i^T x) - \log \left(\sum_j e^{\alpha a_j^T x} \right) \right) (\pi_i(x) - \pi_i(y)) \\
 &\quad - \sum_{i=1}^m \left(\alpha(a_i^T y) + \log \left(\sum_j e^{\alpha a_j^T y} \right) \right) (\pi_i(x) - \pi_i(y)) \\
 &= \alpha \sum_{i=1}^m (a_i^T(x - y)) (\pi_i(x) - \pi_i(y)) \\
 &\quad - \log \left(\sum_j e^{\alpha a_j^T y} \right) \sum_{i=1}^m (\pi_i(x) - \pi_i(y)) \\
 (38) \quad &\quad + \log \left(\sum_j e^{\alpha a_j^T x} \right) \sum_{i=1}^m (\pi_i(x) - \pi_i(y)) \\
 &= \alpha \sum_{i=1}^m (a_i^T(x - y)) (\pi_i(x) - \pi_i(y)) \\
 &= \alpha(x - y)^T (A^T(\pi(x) - \pi(y))) \\
 (39) \quad &\leq |\alpha| \|x - y\|_2 \|A^T(\pi(x) - \pi(y))\|_2,
 \end{aligned}$$

where (38) follows from the fact that $\pi(x), \pi(y)$ are both elements of the simplex, and (39) follows from the Cauchy–Schwartz inequality.

Combining (36) and (39) we get

$$\begin{aligned}
 \|A^T(\pi(x) - \pi(y))\|_2 &\leq |\alpha| \|A\|_{1,2}^2 \|x - y\|_2, \\
 &\leq K |\alpha| \|x - y\|_2.
 \end{aligned}$$

7.2. Proof of Theorem 7. We begin with the approximate version of the Taylor expansion (see Lemma 5).

LEMMA 13. *At any iteration t of Algorithm QP_σ , we have that for any $x \in P$,*

$$\hat{S}_t(x) - \hat{S}_t(\hat{z}^{(t)}) \geq \frac{2K|\alpha|}{(t+1)(t+2)} \left\{ \sum_{j=1}^n (x_j - \hat{z}_j^{(t)})^2 - \sum_{j=1}^n \left(\sigma_j + \frac{1}{4}\sigma_j^2 \right) \right\}.$$

Proof. Fix $x \in P$. Recall that the function $\hat{S}_t(x)$ is defined as

$$\hat{S}_t(x) = \frac{2}{(t+1)(t+2)} \left\{ 2K|\alpha| \sum_{j=1}^n \mathcal{L}_{\sigma_j, \hat{x}_j^{(0)}}(x_j) + \sum_{h=0}^t (h+1) [\Phi(\hat{x}^h) + \langle g_h, x - \hat{x}^h \rangle] \right\}.$$

Define

$$\bar{S}_t(x) = \frac{2}{(t+1)(t+2)} \left\{ K|\alpha| \sum_{j=1}^n (x_j - \hat{x}_j^{(0)})^2 + \sum_{h=0}^t (h+1) [\Phi(\hat{x}^{(h)}) + \langle \hat{g}^{(h)}, x - \hat{x}^{(h)} \rangle] \right\}.$$

Then, by Lemma 6(ii),

$$(40) \quad \hat{S}_t(x) - \hat{S}_t(\hat{z}^{(t)}) \geq \bar{S}_t(x) - \bar{S}_t(\hat{z}^{(t)}) - \frac{2K|\alpha|}{(t+1)(t+2)} \left\{ \sum_{j=1}^n \frac{1}{4} \sigma_j^2 \right\}.$$

Since \bar{S}_t is a quadratic function, it follows that

$$(41) \quad \bar{S}_t(x) - \bar{S}_t(\hat{z}^{(t)}) = \frac{2K|\alpha|}{(t+1)(t+2)} \sum_{j=1}^n (x_j - \hat{z}_j^{(t)})^2 + \langle \nabla \bar{S}_t(\hat{z}^{(t)}), x - \hat{z}^{(t)} \rangle.$$

Consider the function \hat{S}_t restricted to the one-dimensional segment between $\hat{z}^{(t)}$ and x . \hat{S}_t is convex, piecewise-linear, and minimized at $\hat{z}^{(t)}$ (by definition of $\hat{z}^{(t)}$). Hence, as we traverse the segment from $\hat{z}^{(t)}$ to x , the slope of the first piece of the piecewise-linear function must be nonnegative. In other words,

$$(42) \quad \frac{2}{(t+1)(t+2)} \left\{ \sum_{j=1}^n \left[K|\alpha| \lambda_j + \sum_{h=0}^t (h+1) g_j^{(h)} \right] (x_j - \hat{z}_j^{(t)}) \right\} \geq 0,$$

where for $1 \leq j \leq n$,

$$\lambda_j = \begin{cases} \mathcal{L}_{\sigma_j, \hat{x}_j^{(0)}}^+(\hat{z}_j^{(t)}), & x_j \geq \hat{z}_j^{(t)}, \\ \mathcal{L}_{\sigma_j, \hat{x}_j^{(0)}}^-(\hat{z}_j^{(t)}), & \text{otherwise,} \end{cases}$$

and $g_j^{(h)}$ is the j th coordinate of $g^{(h)}$, $j = 0, \dots, t$. Since $P \subseteq [0, 1]^n$, by Lemma 6(iii) the second term in the right-hand side of (41) is at least $-\frac{2K|\alpha|}{(t+1)(t+2)} \sum_{j=1}^n \sigma_j$; consequently,

$$\bar{S}_t(x) - \bar{S}_t(\hat{z}^{(t)}) \geq \frac{2K|\alpha|}{(t+1)(t+2)} \left\{ \sum_{j=1}^n (x_j - \hat{z}_j^{(t)})^2 - \sum_{j=1}^n \sigma_j \right\}.$$

Together with equation (40) this implies the desired result. \square

Theorem 7 is established by induction on t . By definition, we have that

$$\begin{aligned} \hat{S}_0(\hat{z}^{(0)}) &= 2K|\alpha| \sum_{j=1}^n \mathcal{L}_{\sigma_j, \hat{x}_j^{(0)}}(\hat{z}_j^{(0)}) + \Phi(\hat{x}^0) + \langle \hat{g}^{(0)}, z^{(0)} - x^0 \rangle \\ &\geq K|\alpha| \sum_{j=1}^n \mathcal{L}_{\sigma_j, \hat{x}_j^0}(\hat{z}_j^{(0)}) + \Phi(\hat{x}^0) + \langle \hat{g}^{(0)}, z^{(0)} - x^0 \rangle \\ &\geq K|\alpha| \sum_{j=1}^n \mathcal{L}_{\sigma_j, \hat{x}_j^0}(\hat{y}_j^{(0)}) + \Phi(\hat{x}^0) + \langle \hat{g}^{(0)}, y^{(0)} - x^0 \rangle \\ (43) \quad &\geq \frac{K|\alpha|}{2} \sum_{j=1}^n (y_j^{(0)} - x_j^0)^2 + \Phi(x^0) + \langle g^{(0)}, y^{(0)} - x^0 \rangle \\ (44) \quad &\geq \Phi(y^{(0)}), \end{aligned}$$

where (43) follows from Lemma 6(ii) and (44) follows from the definition of $y^{(0)}$.

Next, we establish the inductive step. Let $x \in P$. By Lemma 13, we have

$$\begin{aligned} \hat{S}_t(x) &\geq \hat{S}_t(\hat{z}^{(t)}) + \frac{2K|\alpha|}{(t+1)(t+2)} \left\{ \sum_{j=1}^n (\hat{z}_j^{(t)} - \hat{x}_j^0)^2 - \sum_{j=1}^n \left(\sigma_j + \frac{1}{4}\sigma_j^2 \right) \right\} \\ &\geq \hat{S}_t(\hat{z}^{(t)}) + \frac{2K|\alpha|}{(t+1)(t+2)} \sum_{j=1}^n (\hat{z}_j^{(t)} - \hat{x}_j^0)^2 - \frac{5K|\alpha|}{2(t+1)^2} \left(\sum_{j=1}^n \sigma_j \right). \end{aligned}$$

Applying the induction hypothesis, and continuing as in the proof of Theorem 3, we obtain the following analogue of the inequality following (11):

$$\begin{aligned} \hat{S}_{t+1}(x) &\geq \Phi(\hat{x}^{(t+1)}) \\ &\quad + \min_{y \in P} \left\{ \frac{K|\alpha|}{2} \sum_j (y_j - \hat{x}_j^{(t+1)})^2 + \langle \hat{g}^{(t+1)}, y - \hat{x}^{(t+1)} \rangle \right\} \\ &\quad - \left(\frac{5K|\alpha|}{2} \right) \left(\sum_{h=1}^{t+1} \frac{1}{h^2} + t \right) \left(\sum_{j=1}^n \sigma_j \right). \end{aligned}$$

Applying Lemma 6 again, we obtain

$$\begin{aligned} \hat{S}_{t+1}(x) &\geq \Phi(\hat{x}^{(t+1)}) + K|\alpha| \sum_j \mathcal{L}_{\sigma_j, \hat{x}_j^{(t+1)}}(\hat{y}_j^{t+1}) + \langle \hat{g}^{(t+1)}, \hat{y}^{t+1} - \hat{x}^{(t+1)} \rangle \\ &\quad - \left(\frac{5K|\alpha|}{2} \right) \left(\sum_{h=1}^{t+1} \frac{1}{h^2} + t + 1 \right) \left(\sum_{j=1}^n \sigma_j \right) \\ &\geq \Phi(\hat{x}^{(t+1)}) + \frac{K|\alpha|}{2} \sum_j (\hat{y}_j^{t+1} - \hat{x}_j^{(t+1)})^2 + \langle \hat{g}^{(t+1)}, \hat{y}^{t+1} - \hat{x}^{(t+1)} \rangle \\ &\quad - \left(\frac{5K|\alpha|}{2} \right) \left(\sum_{h=1}^{t+1} \frac{1}{h^2} + t + 1 \right) \left(\sum_{j=1}^n \sigma_j \right) \\ &\geq \Phi(\hat{y}^{t+1}) - \left(\frac{5K|\alpha|}{2} \right) \left(\sum_{h=1}^{t+1} \frac{1}{h^2} + t + 1 \right) \left(\sum_{j=1}^n \sigma_j \right), \end{aligned}$$

where the last inequality follows from Lemma 5.

7.3. Piecewise-linear min-cost flow problems. We are given an optimization problem of the form described in section 3.1,

$$(45) \quad \begin{aligned} \min \quad &\sum_{k,e} \mathcal{L}_{k,e}(r_{k,e}) \\ \text{s.t.} \quad &Nr_k = \hat{d}_k, \quad 0 \leq r_k \leq \hat{u}_k, \quad k = 1, \dots, K, \end{aligned}$$

where, for every k and e , $\mathcal{L}_{k,e}$ is a continuous, convex, piecewise-linear function with breakpoints at the integers and with pieces of strictly increasing slope; \hat{d}_k and \hat{u}_k are integral; and $u_{k,e} \leq 2^q$ for an appropriate integer $q > 0$. For each k and each vertex i , denote by $\hat{d}_{k,i}$ the i th component of \hat{d}_k .

We assume that for each k we have an integral flow that satisfies the constraints of (45). Thus, we can convert (45) into an equivalent *circulation form*. Then we will have a problem of the form

$$(46) \quad \begin{aligned} \min \quad & \sum_{k,e} \mathcal{L}_{k,e}(r_{k,e}) \\ \text{s.t.} \quad & Nr_k = 0, \quad -a_k \leq r_k \leq b_k, \quad k = 1, \dots, K, \end{aligned}$$

where, for every k and e , the parameters $a_{k,e}$ and $b_{k,e}$ are integral and satisfy $0 \leq a_{k,e}, b_{k,e} \leq 2^q$, and again $\mathcal{L}_{k,e}$ is a convex, continuous, piecewise-linear function with breakpoints at the integers (the $\mathcal{L}_{k,e}$ in (46) equal those in (45), shifted by appropriate amounts).

We solve (46) by solving a sequence of circulation problems—our approach is similar to [20]. For all integers $h \in [0, q]$, $k = 1, \dots, K$, and $e \in E$, let $\mathcal{L}_{k,e}^{(h)}$ denote the continuous, convex, piecewise-linear function that has breakpoints at the integer multiples of 2^h and that agrees with $\mathcal{L}_{k,e}$ at each breakpoint.

Further, define $a_{k,e}^{(h)} = \lceil 2^{-h} a_{k,e} \rceil$ and $b_{k,e}^{(h)} = \lceil 2^{-h} b_{k,e} \rceil$. Then, the *level- h* problem is

$$(47) \quad \begin{aligned} \min \quad & \sum_{k,e} \mathcal{L}_{k,e}^{(h)}(r_{k,e}) \\ \text{s.t.} \quad & Nr_k = 0, \quad -b_k^{(h)} \leq r_k \leq a_k^{(h)} \quad \forall k. \end{aligned}$$

Thus, the level-0 problem is (46). We solve it by first solving the level- q problem, then the level- $(q - 1)$ problem, and so on. Note that for $0 \leq h \leq q$, the function $\mathcal{L}_{k,e}^{(h)}$ has 2^{q-h} breakpoints in the range of the level- h problem. Hence, the level- h problem can be seen as an ordinary (e.g., linear) minimum-cost circulation problem, on the graph $\hat{G}^{(h)}$ obtained from the original graph G , by replacing each edge e with 2^{q-h} parallel arcs, each with capacity 2^h and appropriate cost. (To avoid confusion, we use the term *arc*, rather than *edge*, which we reserve for G .) We stress that our algorithm will *only implicitly* work with \hat{G}^h .

Inductively, suppose we have solved the level- h problem. We can assume, without loss of generality, that all the entries of optimal circulation $r_k^{(h)}$ are integer multiples of 2^h . Let π_k^h denote the node potentials (see [20] or [1] for details). Our task is to refine $r_k^{(h)}$ into an optimal circulation for the level- $(h - 1)$ problem.

Note that by definition, for any k and e ,

- (a) the functions $\mathcal{L}_{k,e}^{(h)}$ and $\mathcal{L}_{k,e}^{(h-1)}$ agree at integer multiples of 2^{h-1} ,
- (b) we let $q \in \mathbf{Z}_+$. Then the slope of $\mathcal{L}_{k,e}^{(h-1)}$ is less (resp., more) than the slope of $\mathcal{L}_{k,e}^{(h)}$ in the interval $[2^h q, 2^h q + 2^{h-1})$ (resp., in the interval $[2^h q + 2^{h-1}, 2^h(q + 1))$),
- (c) either $a_{k,e}^{(h-1)} = a_{k,e}^{(h)}$ or $a_{k,e}^{(h-1)} = a_{k,e}^{(h)} - 2^{h-1}$, and similarly with the pair $(b_{k,e}^{(h-1)}, b_{k,e}^h)$.

Thus, it is easy to see that $r_k^{(h)}$, together with the potentials $\pi_k^{(h)}$, *nearly* satisfies the optimality conditions for the level- $(h - 1)$ problem. More precisely, suppose we convert $r_{k,e}^h$ into a circulation on the graph $\hat{G}^{(h-1)}$ by following the “greedy” rule: for any k and e , we “fill” the parallel arcs corresponding to k, e in increasing order of cost (and thus, at most one arc will have flows strictly between bounds). We may need an additional, “overflow” arc, also of capacity 2^{h-1} , in the case that $r_{k,e}^{(h)} = a_{k,e}^{(h)} > a_{k,e}^{(h-1)}$ and similarly for the case when $r_{k,e}^{(h)} = b_{k,e}^{(h)}$.

Denote by $\hat{r}_{k,e}^{(h)}$ the resulting circulation in \hat{G}^{h-1} . Then by properties (a)–(c) above, it follows that at most *one* of the parallel arcs corresponding to a pair (k, e) either fails to satisfy the optimality conditions with respect to the potentials $\pi_k^{(h)}$ or is an overflow arc. Consequently, we can obtain an optimal circulation in $\hat{G}^{(h-1)}$ in at most $O(|E|)$ flow pushes (each pushing $2^{(h-1)}$ units of flow) or computations of node potentials, and each such step requires the solution of a shortest path problem. It is clear that (again because of (a)–(c) above) all of this can be done without explicitly considering the graph $\hat{G}^{(h-1)}$: instead, we always keep a single flow value for commodity k on any edge e , which is always an integral multiple of $2^{(h-1)}$; if we wish to use one of the parallel arcs corresponding to k, e in a push (or when searching for an augmenting path), then it takes $O(1)$ time to determine *which* of the arcs we will use. This completes the description of the inductive step.

In summary, we have the following.

LEMMA 14. *Problem (45) can be solved by performing $O(\sum_k \sum_e \log u_{k,e})$ shortest path computations.*

TYPICAL PROPERTIES OF WINNERS AND LOSERS IN DISCRETE OPTIMIZATION*

RENE BEIER[†] AND BERTHOLD VÖCKING[‡]

Abstract. We present a probabilistic analysis of a large class of combinatorial optimization problems containing all *binary optimization problems* defined by linear constraints and a linear objective function over $\{0, 1\}^n$. Our analysis is based on a semirandom input model that preserves the combinatorial structure of the underlying optimization problem by parameterizing which input numbers are of a stochastic and which are of an adversarial nature. This input model covers various probability distributions for the choice of the stochastic numbers and includes *smoothed analysis* with Gaussian and other kinds of perturbation models as a special case. In fact, we can exactly characterize the smoothed complexity of binary optimization problems in terms of their worst-case complexity: A binary optimization problem has polynomial smoothed complexity if and only if it admits a (possibly randomized) algorithm with pseudo-polynomial worst-case complexity.

Our analysis is centered around structural properties of binary optimization problems, called *winner*, *loser*, and *feasibility gap*. We show that if the coefficients of the objective function are stochastic, then the gap between the best and second best solution is likely to be of order $\Omega(1/n)$. Furthermore, we show that if the coefficients of the constraints are stochastic, then the slack of the optimal solution with respect to this constraint is typically of order $\Omega(1/n^2)$. We exploit these properties in an adaptive rounding scheme that increases the accuracy of calculation until the optimal solution is found. The strength of our techniques is illustrated by applications to various NP-hard optimization problems from mathematical programming, network design, and scheduling for which we obtain the first algorithms with polynomial smoothed/average-case complexity.

Key words. optimization problems, average-case analysis, smoothed analysis

1. Introduction. Many combinatorial optimization problems have an objective function or constraints specified in terms of real numbers representing natural quantities such as time, weight, distance, or utility. This includes some well-studied optimization problems such as traveling salesperson, shortest path, minimum spanning tree as well as various scheduling and packing problems. When analyzing the complexity of algorithms for such problems, we usually assume that these numbers are integers or rational numbers with a finite length representation. The hope is that it suffices to measure and compute with some bounded precision in order to identify an optimal or close to optimal solution. In fact, if real numbers occur only in the objective function and if this objective function is well behaved (e.g., a linear function), then calculating with reasonable approximations of the input numbers yields a feasible solution whose objective value is at least close to the optimal objective value. More problematically, however, if the constraints are defined by real numbers, then calculating with rounded input numbers might miss relevant solutions or might even produce infeasible solutions.

How can one solve optimization problems (efficiently) on a computer when not even the input numbers can be specified exactly? In practice, optimization problems in which real numbers occur in the input are solved by simply rounding the real numbers more or less carefully. Fortunately, this approach seems to yield reasonable results. We seek a theoretically founded explanation why this rounding approach usually works. Studying this issue under worst case assumptions does not make very much sense as, in the worst case, the smallest inaccuracy might lead to an infeasible or utterly suboptimal solution. This question needs to be studied in a stochastic model. In the following probabilistic analysis, we will show that, under some reasonable and quite general stochastic assumptions, one can usually round real-valued input numbers after only a logarithmic number of bits without changing the optimal solution. In fact, our probabilistic analysis goes far beyond the point of explaining phenomena occurring in practice. We are able to provide algorithms with polynomial average-case complexity (more precisely, polynomial smoothed complexity) for a quite general class of discrete optimization problems. Our analysis covers various well-studied NP-hard discrete optimization problems from mathematical programming, network design, and scheduling such as multidimensional knapsack, constrained spanning tree, or scheduling to minimize the weighted number of tardy jobs.

1.1. A semirandom input model for discrete optimization problems.

We consider optimization problems defined over a vector of n binary variables $x = (x_1, \dots, x_n)$. The set of feasible solutions is described by the intersection of a ground set of solutions $\mathcal{S} \subseteq \{0, 1\}^n$ and solutions that satisfy linear constraints of the form $w^T x \leq t$ or $w^T x \geq t$. The ground set \mathcal{S} of solutions can be specified arbitrarily. While the part that specifies \mathcal{S} is adversarial, we assume that the coefficients in the additional linear constraints are random or randomly perturbed real numbers. The reason for distinguishing a stochastic and an adversarial part of the input is that we do not want the randomization destroying the combinatorial structure of the underlying optimization problem. A similar choice between stochastic and adversarial applies to the objective function. If it is chosen to be adversarial, then our model covers arbitrary functions $f : \mathcal{S} \rightarrow \mathbb{R}$. Our probabilistic analysis, however, can also handle stochastic objective functions that are linear, that is, the objective is of the form *minimize* (or *maximize*) $c^T x$, where c is a vector of random or randomly perturbed real valued coefficients c_1, \dots, c_n . In the following, we use the phrase *stochastic expression* as a generic term for the linear expressions $c^T x$ and $w^T x$ occurring in the objective function and the constraints, respectively. The number of stochastic expressions is denoted by $k \geq 1$ and the number of stochastic constraints by $k' \in \{k - 1, k\}$, depending on whether or not the objective function is stochastic. For $k' \geq 1$ let \mathcal{B}_j denote the set of solutions that satisfy the j th constraint for all $j \in [k']$. The set of feasible solutions for a given problem instance is then $\mathcal{S} \cap \mathcal{B}_1 \cap \dots \cap \mathcal{B}_{k'}$.

The coefficients in the stochastic expressions are specified by independent continuous probability distributions with domain \mathbb{R} . Different coefficients might be drawn according to different distributions. The only restriction on these distributions is that their density is bounded from above. Assuming bounded densities is necessary, as otherwise worst-case instances could be approximated arbitrarily well by specifying distributions with very high density. At this point, let us remark that the density of a continuous random variable is not uniquely defined. In fact, the density function can be changed on any set of points of measure 0 without affecting the distribution function. As usual, we ignore this trifling indeterminacy; that is, when saying that the density of a variable is bounded we mean that the variable admits a bounded

density function. For a given variable, the supremum of its density function is called its *density parameter*. We will see that the maximum density parameter over the distributions of the different coefficients plays an important role in our analysis. This parameter is denoted by ϕ . Intuitively, ϕ can be seen as a measure specifying the concentration of random instances around the worst case. A worst-case instance can be interpreted as a stochastic instance in which the probability measure for each stochastic number is mapped to a single point. Thus, the larger ϕ , the closer we are to a worst-case analysis.

In our probabilistic analysis we assume that the objective function defines a unique ranking among all solutions in $\{0, 1\}^n$ according to the objective function. Observe that, if the objective function is stochastic, then the coefficients are continuous random variables. Hence, the probability that there exist solutions with the same objective function value is 0. In other words, a unique ranking is given with probability 1. Recall that the objective function does not have to be linear if it is adversarial, but if it is linear, i.e., of the form $c^T x$, $c \in \mathbb{Q}^n$, then a unique ranking can always be enforced by encoding the lexicographical order among the solutions into the less significant bits of the objective function without changing the computational complexity of the underlying optimization problem by more than a polynomial factor. In fact, most of the algorithmic problems that we will study have algorithms that implicitly realize a unique ranking. In this case, one does not even need an explicit encoding. Given a unique ranking, we aim at finding the *winner*, i.e., the highest ranked solution in $\mathcal{S} \cap \mathcal{B}_1 \cap \dots \cap \mathcal{B}_k$. In the following, optimization problems satisfying all the conditions above are called *binary optimization problems with stochastic expressions* or, for short, *binary optimization problems*.

Smoothed analysis. The framework of smoothed analysis was introduced by Spielman and Teng in [29]. They assume that first an adversary specifies all coefficients w in the constraint matrix such that the norm of each row vector is at most 1. Then these adversarial numbers are slightly perturbed by adding an independent random number drawn according to a Gaussian distribution with mean 0 and a specified standard deviation $\sigma > 0$. Spielman and Teng prove a running time for the simplex algorithm under the shadow vertex pivot rule that is polynomial in the number of variables and constraints as well as in $\frac{1}{\sigma}$. Similar results have been obtained for other problems [2, 4, 5, 7, 30]. Our probabilistic analysis is not restricted to the model of smoothed analysis, but we use this nice framework to illustrate our results.

We generalize smoothed analysis as follows. At first, we do not necessarily perturb all input numbers but only the coefficients in the stochastic expressions. Initially, an adversary chooses all input numbers. The adversarial choice for the coefficients that shall be stochastic is restricted to real numbers from $[0, 1]$ or $[-1, 1]$, depending on whether the domain should be nonnegative or also include negative numbers. Then a random perturbation slightly changes the coefficients in the stochastic constraints by adding an independent random number to each of them. These random numbers are drawn according to a specified family of probability distributions satisfying the following conditions. Let $f : \mathbb{R} \rightarrow \mathbb{R}_{\geq 0}$ be any density function such that $\sup_s (f(s)) = 1$ and $\int |s|f(s)ds$ is finite, that is, the random variable described by f has a finite expected absolute value. Function f is called the *perturbation model*. For $\phi \geq 1$, we define f_ϕ by scaling f , that is, $f_\phi(s) = \phi f(s/\phi)$, for every $s \in \mathbb{R}$. This way, the density parameter of f_ϕ is ϕ . We obtain a ϕ -*perturbation* according to the perturbation model f by adding an independent random variable with density function f_ϕ to each stochastic input number. For example, one obtains the Gaussian perturbation model from [29] by choosing f to be the Gaussian density with standard deviation $(2\pi)^{-1/2}$.

A nonnegative domain can be obtained, e.g., by choosing f to be the density of the uniform distribution over $[0, 1]$. In [29] the running time is described in terms of the standard deviation σ . In contrast, we describe the running time in terms of the density parameter ϕ . For the Gaussian and the uniform distribution these two parameters are closely related; in both cases, ϕ is proportional to $\frac{1}{\sigma}$.

Let us illustrate our semirandom input model by an example. The minimum spanning tree problem is to find a spanning tree in a given graph that has minimum weight. In the binary program formulation of this problem there is a variable x_e for each edge $e \in E$. Thus, n corresponds to the number of edges. A 0/1 solution x is feasible if the edges in the set $\{e \in E \mid x_e = 1\}$ form a spanning tree. Let \mathcal{S} denote the set of all solutions satisfying this condition. The combinatorial structure described by \mathcal{S} should not be touched by our randomization. It makes sense, however, to assume that the objective function is stochastic as its coefficients describe measured quantities. So we may assume that these coefficients are perturbed with uniform ϕ -perturbations, that is, each of these coefficients correspond to the sum of an adversarial number from $[0, 1]$ and an independent random number drawn uniformly from $[0, \phi^{-1}]$. In the constrained minimum spanning tree problem [12], each edge does not only have weights but additionally a cost c_e . Now one seeks for the minimum weight spanning tree satisfying the linear cost constraint $\sum_e c_e x \leq T$. This additional constraint corresponds to a subset $\mathcal{B}_1 \subseteq \{0, 1\}^{|E|}$ so that $\mathcal{B}_1 \cap \mathcal{S}$ is the set of feasible solutions. Due to the additional constraint, the problem becomes NP-hard. We will see, however, that the problem has “polynomial smoothed complexity” assuming that either the objective function or the additional constraint is stochastic.

1.2. How accurately do we need to calculate?. More precisely, we ask how many bits of each stochastic input number do we need to reveal in order to determine the winner? We say that the winner is *determined* by revealing some number of the bits, when there is only one possible candidate for the winner regardless of the outcomes of the unrevealed bits.

THEOREM 1. *Consider any instance of a binary optimization problem Π . Let $n \geq 1$ denote the number of binary variables and $k \geq 1$ the number of stochastic expressions.*

- (a) *Suppose the expected absolute value $\mathbf{E}[|w|]$ of every stochastic coefficient w is bounded from above by $\mu > 0$. The number of bits in front of the floating point of any stochastic coefficient w is bounded by $O(\max\{1, \log(k\mu n/p)\})$, with probability at least $1 - p$, for any $0 < p < 1$.*
- (b) *Let $\phi \geq 1$ denote the maximum density parameter, that is, all density functions are upper-bounded by ϕ . The winner is determined when revealing $O(\log(k\phi n/p))$ bits after the binary point of each stochastic coefficient, with probability at least $1 - p$, for any $0 < p < 1$.*

One can always decrease ϕ or μ without changing the problem by scaling the appropriate stochastic expression (and the respective bound, where applicable) by some factor $\gamma > 0$. As the corresponding distribution has mean $\gamma\mu$ and density parameter ϕ/γ , this kind of scaling does not change the overall number of bits that need to be revealed as $\log(\mu nk) + \log(\phi nk) = \log(\gamma\mu nk) + \log(\frac{1}{\gamma}\phi nk)$. The scaling transfers only significant bits from positions before the binary points to a position after the binary point. One can eliminate one parameter by normalizing the distributions such that one parameter becomes 1. In case of a smoothed analysis, the right way to scale the input numbers is already built into the model. According to our definitions, the density function f specifying the perturbation model has to have a finite expected

absolute value. For any fixed model of perturbation, $\int |s|f(s)ds = O(1)$. In particular, the expected absolute value of the density function f_ϕ is $O(\phi^{-1})$. Taking into account that the domain of the initial adversarial choices for the stochastic coefficients is $[-1, 1]$ or $[0, 1]$, we observe that ϕ -perturbations yield coefficients with an expected absolute value of at most $\mu = O(1 + \frac{1}{\phi})$. In order to simplify the notation, our model of smoothed analysis is restricted to density parameters $\phi \geq 1$. This leads to the following result on the overall number of bits that need to be revealed per stochastic input number.

COROLLARY 2. *For any fixed perturbation model f and any density parameter $\phi > 1$, the winner is determined when revealing $O(\log(k\phi n/p))$ bits of each stochastic coefficient, with probability at least $1 - p$, for any $0 < p < 1$.*

Let us explain the concepts and ideas behind the analysis for Theorem 1. Part (a) of the theorem follows simply by applying the Markov inequality to the expected absolute values of the individual coefficients. The interesting part of the theorem is stated in (b). In order to identify the winner one needs to *isolate* the winner from other feasible solutions having a worse objective value. Furthermore, one needs to *separate* the winner from those infeasible solutions that have a better objective value than the winner. Our analysis is based on a *generalized isolating lemma*—i.e., a generalization of the well-known isolating lemma by Mulmuley, Vazirani, and Vazirani [22]—and a novel *separating lemma*.

The isolating lemma was originally presented in an article about RNC algorithms for perfect matchings [22]. It is known, however, that the lemma does not only apply to the matching problem but to general binary optimization problems with a linear objective function. The lemma states that the optimal solution of a binary optimization problem is unique with a probability of at least $\frac{1}{2}$ when choosing the coefficients of the objective function independently, uniformly at random from the set $\{1, 2, \dots, 2n\}$. This is a very surprising and counterintuitive result as there might be an exponential number of feasible solutions whose objective values all fall into a polynomially large set, namely the set $\{1, 2, \dots, 2n^2\}$, so that one can expect that an exponential number of solutions are mapped to the same objective value. The reason why the winner nevertheless is isolated is that the objective values of different solutions are not independent but the solutions represent subsets over a ground set of only n random numbers, and one of these numbers will be part of the best but not the second best solution. We adapt the isolating lemma toward our continuous setting and generalize it toward continuous probability distributions with bounded density as described in section 1.1. In particular, different coefficients may follow different continuous probability distributions. Suppose only the objective function is stochastic, and the feasible region is fixed arbitrarily. Let ϕ denote the maximum density parameter over all coefficients in the objective functions. Define the *winner gap* to be the difference between the objective value of the best and the second-best feasible solution, provided there are at least two feasible solutions. The generalized isolating lemma states that, for every $\epsilon \in [0, 1]$, the winner gap is lower bounded by $\frac{\epsilon}{2\phi n}$ with probability at least $1 - \epsilon$, and this bound is tight. As a consequence, it suffices to reveal only $O(\log(\phi n))$ bits of each coefficient of the objective function in order to identify the winner, with high probability.

We accompany the isolating lemma with a novel separating lemma, enabling us to separate the winner from infeasible solutions with better objective value than the winner. For the time being, consider any binary optimization problem in which a single constraint is stochastic. The difficulty in checking the feasibility with respect to this constraint is that it might be likely that there are many solutions that are

exponentially close to the constraint hyperplane. Nevertheless, we will see that the optimal solution can be identified by inspecting only a logarithmic number of bits per input number, with high probability. The reason is that we do not need to check the feasibility of all solutions but only of some particular solutions. The *losers* are those solutions that have a rank higher than the winner, but they are infeasible because of the stochastic constraint. The *loser gap* is defined to be the minimal amount by which a loser (except for the solution 0^n) exceeds the constraint threshold. The separating lemma shows that, for every $\epsilon \in [0, 1]$, the loser gap is larger than $\frac{\epsilon}{\phi n^2}$ with a probability of at least $1 - \epsilon$. Let us try to give some intuition about this result. If there are only a few losers, then one can imagine that none of them comes very close to a random or randomly perturbed hyperplane. However, there might be an exponential number of losers. In this case, however, the winner has a relatively low rank as there is an exponential number of solutions better than the winner; but this is very unlikely if the constraint hyperplane is likely to come very close to the good solutions which correspond to the losers. Seeing it the other way around, if there are many losers, then the hyperplane is likely to be relatively far away from the losers, which might intuitively explain the phenomenon described by the separating lemma. Besides the loser gap, we study the so-called *feasibility gap* corresponding to the slack of the optimal solution with respect to the stochastic constraint. We can show that the lower bound for the loser gap holds also for the feasibility gap. In fact, our analysis for loser and feasibility gaps is heavily based on symmetry properties between them.

When analyzing the winner gap, we assume that the objective function is random and the feasible region is fixed. In contrast, when we study the loser and feasibility gaps, we assume that the feasible region is determined by random constraints and that the objective function is fixed. In other words, the random expressions defining the objective function and the constraints are assumed to be stochastically independent. In fact, if the feasible region and the objective function are correlated, then winner, loser, and feasibility cannot be lower bounded by the reciprocal of a polynomial. The optimization variant of the subset-sum problem (i.e., knapsack with profits equal to weights) is a simple counterexample. Lueker [19] proved that random instances of the subset-sum problem have usually exponentially small gaps.

2. Analysis of the gap properties. In this section, we formally define the winner, loser, and feasibility gap and prove lower bounds for their size. We begin with an analysis of the winner gap. Afterwards we study the loser and the feasibility gap; first for a single constraint and then for multiple constraints. Finally, we apply these results to prove Theorem 1.

2.1. The winner gap. We consider an instance of a discrete optimization problem whose solutions are described by n binary variables x_1, \dots, x_n . The set of feasible solutions (ground set intersected with the constraints) is now denoted by $\mathcal{S} \subseteq \{0, 1\}^n$. Fix some arbitrary set \mathcal{S} with at least two solutions. The objective function is denoted by $c^T x$. The numbers $c_i \in \mathbb{R}$, $i = 1, \dots, n$, are assumed to be stochastic, that is, they are treated as independent random variables following possibly different continuous probability distributions with bounded density. Without loss of generality, we consider a maximization problem. Let $x^* = \operatorname{argmax}\{c^T x \mid x \in \mathcal{S}\}$ denote the winner and $x^{**} = \operatorname{argmax}\{c^T x \mid x \in \mathcal{S} \setminus \{x^*\}\}$ the second best solution. The *winner gap* Δ is defined to be the difference between the objective values of a best and second best solution, that is, $\Delta = c^T x^* - c^T x^{**}$.

LEMMA 3 (generalized isolating lemma). *Fix the feasible region \mathcal{S} . Let ϕ_i denote the density parameter of c_i , for $1 \leq i \leq n$, and $\phi = \max_i \phi_i$. For every $\epsilon \geq 0$,*

$\Pr [\Delta < \epsilon] \leq 2\epsilon \sum_{i \in [n]} \phi_i \leq 2\epsilon \phi n.$

Proof. At first we observe, if there is a variable x_i that takes the same value in all feasible solutions, then this variable does not affect the winner gap and it can be ignored. Thus, without loss of generality, for every $i \in [n]$, there are at least two feasible solutions whose vectors differ in the i th bit, i.e., with respect to the i th variable. Under this assumption, we can define the winner gap with respect to bit position $i \in [n]$ by

$$(1) \quad \Delta_i = c^T x^* - c^T y,$$

where $x^* = \operatorname{argmax}\{c^T x \mid x \in \mathcal{S}\}$, $y = \operatorname{argmax}\{c^T x \mid x \in \mathcal{S}, x_i \neq x_i^*\}$. In other words, Δ_i is the difference between the objective value of the winner x^* and the value of a solution y that is best among those solutions that differ in the i th bit from x^* , i.e., the best solution in $\{x \in \mathcal{S} \mid x_i \neq x_i^*\}$.

Clearly, the best solution, $x^* = (x_1^*, \dots, x_n^*)$, and the second best solution, $x^{**} = (x_1^{**}, \dots, x_n^{**})$, differ in at least one bit, that is, there exists $i \in [n]$ such that $x_i^* \neq x_i^{**}$. If the best and second best solution differ in the i th bit, then $\Delta = \Delta_i$. Thus, Δ is guaranteed to take a value also taken by at least one of the variables $\Delta_1, \dots, \Delta_n$. In the following, we will prove $\Pr [\Delta_i < \epsilon] \leq 2\epsilon \phi_i$, for $1 \leq i \leq n$. Thus,

$$\Pr [\Delta < \epsilon] \leq \Pr [\exists i \in [n] : \Delta_i < \epsilon] \leq \sum_{i \in [n]} \Pr [\Delta_i < \epsilon] \leq 2\epsilon \sum_{i \in [n]} \phi_i,$$

which implies the lemma.

Let us fix an index $i \in [n]$. It remains to show $\Pr [\Delta_i < \epsilon] \leq 2\epsilon \phi_i$. We partition \mathcal{S} , the set of feasible solutions, into two disjoint subsets $\mathcal{S}_0 = \{x \in \mathcal{S} \mid x_i = 0\}$ and $\mathcal{S}_1 = \{x \in \mathcal{S} \mid x_i = 1\}$. Now suppose all random variables $c_k, k \neq i$ are fixed arbitrarily. Under this assumption, we can identify a winner among the solutions in \mathcal{S}_0 as the objective values of the solutions in \mathcal{S}_0 do not depend on c_i . Although the objective values of the solutions in \mathcal{S}_1 are not fixed, we can nevertheless identify a winner of \mathcal{S}_1 because the unknown outcome of the random variable c_i does not affect the order among the solutions in \mathcal{S}_1 . For $j \in \{0, 1\}$, let $x^{(j)}$ denote a winner among the solutions in \mathcal{S}_j . We observe $\Delta_i = |c^T x^{(1)} - c^T x^{(0)}|$ because the solutions x^* and y as defined in (1) cannot be contained in the same set $\mathcal{S}_j, j \in \{0, 1\}$. Consider the random variable $Z = c^T x^{(1)} - c^T x^{(0)}$. We have shown $\Delta_i = |Z|$. Observe that the random variable c_i appears as a simple additive term in Z . Hence, the density function of Z is a shifted variant of the density function of c_i . In particular, ϕ_i is an upper bound for the density of Z , as it is for the density of c_i . Hence, $\Pr [\Delta_i < \epsilon] = \Pr [Z \in (-\epsilon, \epsilon)] \leq 2\epsilon \phi_i$. This completes the proof of the generalized isolating lemma. \square

Next we show that the given bound in the generalized isolating lemma is tight.

LEMMA 4. *Suppose $\mathcal{S} = \{0, 1\}^n$. Let $\phi_1, \dots, \phi_n > 0$ denote an arbitrary collection of density parameters. Fix any $\alpha < \sum_{i \in [n]} \phi_i$. There is a way to define continuous probability distributions for the coefficients c_1, \dots, c_n with density parameters ϕ_1, \dots, ϕ_n , respectively, such that there exists $\epsilon > 0$ with $\Pr [\Delta < \epsilon] > 2\alpha\epsilon$.*

Proof. As $\mathcal{S} = \{0, 1\}^n$, the optimal solution x^* satisfies $x_i^* = 1 \Leftrightarrow c_i > 0$. Let $k = \operatorname{argmin}_i(|c_i|)$. The second best solution x^{**} satisfies $x_i^{**} = x_i^*$, for all $i \neq k$, and $x_k^{**} = 1 - x_k^*$. Thus, $\Delta = \min_i(|c_i|)$. Assume the density functions of c_1, \dots, c_n are continuous and take their maximum value ϕ_i at 0. We study the density of the random variable Δ at 0,

$$\lim_{\substack{\epsilon \rightarrow 0 \\ \epsilon > 0}} \frac{\Pr [\Delta < \epsilon]}{\epsilon} = \lim_{\substack{\epsilon \rightarrow 0 \\ \epsilon > 0}} \frac{\Pr [\exists i \in [n] : |c_i| < \epsilon]}{\epsilon} = \sum_{i \in [n]} \lim_{\substack{\epsilon \rightarrow 0 \\ \epsilon > 0}} \frac{\Pr [|c_i| < \epsilon]}{\epsilon},$$

where the last equality is due to the fact that for any $S \subset \mathcal{S}$ with $|S| > 1$,

$$\lim_{\substack{\epsilon \rightarrow 0 \\ \epsilon > 0}} \frac{\Pr [\bigwedge_{i \in S} |c_i| < \epsilon]}{\epsilon} = 0.$$

Now

$$\lim_{\substack{\epsilon \rightarrow 0 \\ \epsilon > 0}} \frac{\Pr [|c_i| < \epsilon]}{\epsilon} = \lim_{\substack{\epsilon \rightarrow 0 \\ \epsilon > 0}} \frac{\Pr [c_i \in (-\epsilon, \epsilon)]}{\epsilon} = 2\phi_i.$$

As a consequence,

$$\lim_{\substack{\epsilon \rightarrow 0 \\ \epsilon > 0}} \frac{\Pr [\Delta < \epsilon]}{\epsilon} = 2 \sum_{i \in [n]} \phi_i,$$

so that, for any $\alpha < \sum_{i \in [n]} \phi_i$, there exists $\epsilon > 0$ with $\Pr [\Delta < \epsilon] > 2\alpha\epsilon$. \square

2.2. Loser and feasibility gaps for a single constraint. We consider an instance of an optimization problem over n binary variables. The objective function can be fixed arbitrarily; we rank all solutions (feasible and infeasible) according to their objective value in nonimproving order. Solutions with the same objective values are ranked in an arbitrary but fixed fashion. The feasible region is described by a subset $\mathcal{S} \subseteq \{0, 1\}^n$ intersected with the half space \mathcal{B} described by an additional linear constraint. Without loss of generality, the constraint is of the form $w^T x \leq t$. The set \mathcal{S} and the threshold t are assumed to be fixed. The coefficients w_1, \dots, w_n correspond to independent random variables following possibly different continuous probability distributions with bounded density. The *winner*, denoted by x^* , is the solution with highest rank in $\mathcal{S} \cap \mathcal{B}$. The *feasibility gap* is defined by

$$\Gamma = \begin{cases} t - w^T x^* & \text{if } \mathcal{S} \cap \mathcal{B} \neq \emptyset, \text{ and} \\ \perp & \text{otherwise.} \end{cases}$$

In other words, Γ corresponds to the slack of the winner with respect to the constraint $w^T x \leq t$. Observe that x^* might be undefined if there is no feasible solution. In this case, the random variable Γ takes the value \perp (*undefined*).

A solution in \mathcal{S} is called a *loser* if it has a higher rank than x^* , that is, the losers are those solutions from \mathcal{S} that have a better rank than the winner, but they are cut off by the constraint $w^T x \leq t$. The set of losers is denoted by \mathcal{L} . If there is no winner, as there is no feasible solution, then we define $\mathcal{L} = \mathcal{S}$. The *loser gap* is defined by

$$\Lambda = \begin{cases} \min\{w^T x - t \mid x \in \mathcal{L}\} & \text{if } \mathcal{L} \neq \emptyset, \text{ and} \\ \perp & \text{otherwise.} \end{cases}$$

In case $\mathcal{L} \neq \emptyset$, the loser that determines Λ , i.e., $\operatorname{argmin}_{x \in \mathcal{L}} \{w^T x\}$, is called *minimal loser*. Figure 1 illustrates these definitions.

Our goal is to lower bound Γ and Λ . Observe that the solution 0^n is different from all other solutions in \mathcal{S} , as its feasibility does not depend on the outcome of the random coefficients w_1, \dots, w_n . Suppose $0^n \in \mathcal{S}$ and 0^n has the highest rank among all solutions in \mathcal{S} . Then one can enforce $\Gamma = 0$ by setting $t = 0$. Similarly, one can enforce $\Lambda \rightarrow 0$ for $t \rightarrow 0$. For this reason, we need to exclude the solution 0^n from our analysis.

FIG. 1. Loser and feasibility gap: Solutions are listed from left to right according to the ranking. The height of the bars correspond to the weight $w^T x$. The winner is the first solution whose weight satisfies the threshold t . The feasibility gap Γ is the slack of the winner with respect to the constraint $w^T x \leq t$. All solutions left of the winner are losers. The loser gap Λ is the smallest amount by which any loser violates the threshold t .

LEMMA 5 (separating lemma). Let ϕ_i denote the density parameter of w_i , for all $i \in [n]$, and define $\phi = \max_{i \in [n]} \phi_i$. Suppose $0^n \notin \mathcal{S}$. For every $\epsilon \geq 0$, $\Pr[\Gamma < \epsilon] \leq \epsilon n \sum_{i \in [n]} \phi_i \leq \epsilon \phi n^2$ and $\Pr[\Lambda < \epsilon] \leq \epsilon n \sum_{i \in [n]} \phi_i \leq \epsilon \phi n^2$.

Proof. We will heavily use symmetry properties between the two gaps. First, we will prove $\Pr[\Lambda < \epsilon] \leq \epsilon \sum_{i \in [n]} \phi_i$ under the assumption that the ranking satisfies a certain monotonicity property. Next, we will show that any probabilistic lower bound of this kind that holds for the loser gap with respect to any given threshold $t \in \mathbb{R}$ transfers to the feasibility gap and vice versa. Because of this symmetry property, the probability that the loser gap is smaller than ϵ is also at most $\epsilon \sum_{i \in [n]} \phi_i$ under the same monotonicity assumption. Afterwards, we will show that the monotonicity assumption for the feasibility gap can be dropped at the cost of an extra factor n , thereby achieving an upper bound of $\epsilon n \sum_{i \in [n]} \phi_i$ on the probability that the feasibility gap is smaller than ϵ . Finally, by applying the symmetry argument in the other direction, we obtain the same result for the loser gap.

A ranking of the solutions is called *monotone* if all pairs of solutions $x, y \in \mathcal{S}$, x having a higher rank than y , satisfy that there exists $i \in [n]$ with $x_i > y_i$. When considering the binary solution vector as subsets of $[n]$, a ranking is *monotone* if each subset S is ranked higher than all its proper subsets $T \subset S$. This property is naturally satisfied for maximization problems having a linear objective function with positive coefficients, but also if all solutions in \mathcal{S} have the same number of ones.

LEMMA 6. Suppose $0^n \notin \mathcal{S}$ and the ranking is monotone. Then $\Pr[\Lambda < \epsilon] \leq \epsilon \sum_{i \in [n]} \phi_i$.

Proof. Fix $t \in \mathbb{R}$ arbitrarily. As in the proof for the winner gap, we define n random variables $\Lambda_1, \dots, \Lambda_n$ with maximum densities ϕ_1, \dots, ϕ_n such that at least one of them takes the value of Λ . For $i \in [n]$, define $\mathcal{S}_i = \{x \in \mathcal{S} \mid x_i = 1\}$ and $\bar{\mathcal{S}}_i = \mathcal{S} \setminus \mathcal{S}_i$. Let $\bar{x}^{(i)}$ denote the winner from $\bar{\mathcal{S}}_i$, i.e., the solution with the highest rank in $\bar{\mathcal{S}}_i \cap \mathcal{B}$. Now let \mathcal{L}_i denote the set of losers from \mathcal{S}_i when assuming that $\bar{x}^{(i)}$ is the winner, that is, $\mathcal{L}_i = \{x \in \mathcal{S}_i \mid x \text{ has a higher rank than } \bar{x}^{(i)}\}$. If $\bar{x}^{(i)}$ does not exist, then we set $\mathcal{L}_i = \mathcal{S}_i$. Now define the minimal loser of \mathcal{L}_i , $x_{\min}^{(i)} = \operatorname{argmin}\{w^T x \mid x \in \mathcal{L}_i\}$, and

$$\Lambda_i = \begin{cases} w^T x_{\min}^{(i)} - t & \text{if } \mathcal{L}_i \neq \emptyset, \text{ and} \\ \perp & \text{otherwise.} \end{cases}$$

Observe that \mathcal{L}_i is not necessarily a subset of \mathcal{L} , as $\bar{x}^{(i)}$ can have a lower rank than x^* .

In fact, $x_{\min}^{(i)}$ can be feasible so that Λ_i can take negative values. The reason for this “wasteful” definition is that it yields some kind of independence that we will exploit in the following arguments.

Claim A. $\Pr[\Lambda_i \in [0, \epsilon)] \leq \epsilon\phi_i$. This claim can be seen as follows. The definitions above ensure $\mathcal{L}_i \subseteq \mathcal{S}_i$ while $\bar{x}^{(i)} \in \bar{\mathcal{S}}_i$. Suppose all variables $w_j, j \neq i$ are fixed arbitrarily. The winner $\bar{x}^{(i)}$ can be determined without knowing the outcome of w_i as $\bar{x}^{(i)} \in \bar{\mathcal{S}}_i$ and for all solutions in $\bar{\mathcal{S}}_i$ the i th entry is zero. Observe that \mathcal{L}_i is fixed as soon as $\bar{x}^{(i)}$ is fixed, and so is $x_{\min}^{(i)}$, as the i th bit of all losers in \mathcal{L}_i is one. Hence, w_i is not affected by fixing $x_{\min}^{(i)}$. As the i th bit of $x_{\min}^{(i)}$ is one, the random variable Λ_i can be rewritten as $\Lambda_i = w^T x_{\min}^{(i)} - t = \kappa + w_i$, where κ depends on only the fixed coefficients $w_j, j \neq i$, and w_i is a random variable with density at most ϕ_i . Consequently, the density of Λ_i is bounded from above by ϕ_i . (The same is true if $\bar{x}^{(i)}$ does not exist so that $\mathcal{L}_i = \mathcal{S}_i$.) This upper bound on the density of Λ_i immediately implies $\Pr[\Lambda_i \in [0, \epsilon)] \leq \epsilon\phi_i$.

Claim B. If $\Lambda \neq \perp$, then there exists $i \in [n]$ such that Λ takes the value of Λ_i . To prove this claim, let us first assume that x^* exists and $\mathcal{L} \neq \emptyset$. Let $x_{\min} \in \mathcal{L}$ denote the *minimal loser*, i.e., $x_{\min} = \operatorname{argmin}\{w^T x \mid x \in \mathcal{L}\}$. By definition, x_{\min} has a higher rank than x^* . Because of the monotonicity of the ranking, there exists $i \in [n]$ such that $x^* \in \bar{\mathcal{S}}_i$ and $x_{\min} \in \mathcal{S}_i$. From $x^* \in \bar{\mathcal{S}}_i$, we conclude $x^* = \bar{x}^{(i)}$. Consequently, $x_{\min} \in \mathcal{L} \cap \mathcal{S}_i = \mathcal{L}_i$ so that $x_{\min} = x_{\min}^{(i)}$. Hence, $\Lambda = \Lambda_i$. Now suppose x^* does not exist. Then $\mathcal{L} = \mathcal{S}$ and $\mathcal{L}_i = \mathcal{S}_i$, for all $i \in [n]$. Thus, there exists $i \in [n]$ with $x_{\min} = x_{\min}^{(i)}$ because $\mathcal{S} = \bigcup_{i \in [n]} \mathcal{S}_i$ as $0^n \notin \mathcal{S}$. Finally, if $\mathcal{L} = \emptyset$, then the claim follows immediately as $\Lambda = \perp$.

Combining the claims with the union bound gives

$$\Pr[\Lambda < \epsilon] \leq \Pr[\exists i \in [n] : \Lambda_i \in [0, \epsilon)] \leq \sum_{i \in [n]} \Pr[\Lambda_i < \epsilon] \leq \sum_{i \in [n]} \epsilon\phi_i. \quad \square$$

Next we present a symmetry property that allows the transfer of lower bounds on the loser gap to the feasibility gap and vice versa. Observe that the lower bound above holds for any given threshold $t \in \mathbb{R}$. This is important for the application of our symmetry argument. In the following, let $\Lambda(t)$ and $\Gamma(t)$ denote loser and feasibility gap with respect to threshold t , respectively.

LEMMA 7. *Suppose $0^n \notin \mathcal{S}$. For any $t \in \mathbb{R}$ and $\epsilon \geq 0$,*

$$\Pr[\Gamma(t) < \epsilon] = \Pr[\Lambda(t - \epsilon) < \epsilon].$$

Proof. We take an alternative view on the given optimization problem. We interpret the problem as a bicriteria problem. The feasible region is then the whole set \mathcal{S} . The first criterion is the rank which is to be minimized (high ranks are small numbers). The second criterion is the weight, defined by the linear function $w^T x$, which is to be minimized as well. A solution $x \in \mathcal{S}$ is called *Pareto-optimal* if there is no higher ranked solution $y \in \mathcal{S}$ with smaller (or equal) weight. For simplicity assume that no two solutions have the same weight. This assumption is justified as the probability that there are two solutions with the same weight is 0.

Next we show that winners and minimal losers of the original optimization problem correspond to Pareto-optimal solutions of the bicriteria problem. First, let us observe that the winner x^* with respect to any given weight threshold t is a Pareto-optimal solution for the bicriteria problem because there is no other solution with

a higher rank and weight at most $t \geq w^T x^*$. Moreover, for every Pareto-optimal solution x there is also a threshold t such that x is a winner, i.e., $t = w^T x$.

The same kind of characterization holds for minimal losers as well. Recall, for a given threshold t , the minimal loser is defined to be $x_{\min} = \operatorname{argmin}\{w^T x \mid x \in \mathcal{L}\}$. We claim that there is no other solution $y \in \mathcal{S}$ that simultaneously achieves a higher rank and smaller weight than x_{\min} . This can be seen as follows. Suppose $y \in \mathcal{S}$ is a solution with higher rank than x_{\min} . If $w^T y \leq t$, then $y \in \mathcal{B}$ and, hence, x_{\min} would not be a loser. However, if $w^T y \in (t, w^T x_{\min})$, then y and x_{\min} would both be losers, but y instead of x_{\min} would be minimal. Furthermore, for every Pareto-optimal solution x there is also a threshold t such that x is a loser. This threshold can be obtained by setting $t \rightarrow w^T x$, $t < w^T x$.

Now let us describe winner and loser gap in terms of Pareto-optimal solutions. Let $\mathcal{P} \subseteq \mathcal{S}$ denote the set of Pareto-optimal solutions with respect to the fixed ranking and the random weight function $w^T x$. Then feasibility and loser gaps for any given threshold $t \in \mathbb{R}$ satisfy

$$\begin{aligned} \Gamma(t) &= \min\{t - w^T x \mid x \in \mathcal{P}, w^T x \leq t\}, \\ \Lambda(t) &= \min\{w^T x - t \mid x \in \mathcal{P}, w^T x > t\}. \end{aligned}$$

For a better intuition, we can imagine that all Pareto-optimal solutions are mapped onto a horizontal line such that $x \in \mathcal{P}$ is mapped to the point $w^T x$. Then $\Gamma(t)$ is the distance from the point t on this line to the closest Pareto point *left* of t (i.e., less than or equal to t), and $\Lambda(t)$ is the distance from t to the closest Pareto point *strictly right* of t (i.e., larger than t). As a consequence, $\Gamma(t) < \epsilon$ if and only if $\Lambda(t - \epsilon) \leq \epsilon$ and, hence,

$$\Pr[\Gamma(t) < \epsilon] = \Pr[\Lambda(t - \epsilon) \leq \epsilon] = \Pr[\Lambda(t - \epsilon) < \epsilon]. \quad \square$$

Combining Lemmas 6 and 7 yields that the probability that the feasibility gap is smaller than ϵ is at most $\epsilon \sum_{i \in [n]} \phi_i$ as well, provided that the ranking is monotone and $0^n \notin \mathcal{S}$. Next we extend this result toward general rankings by breaking the original problem into suitable subproblems. We partition \mathcal{S} into the sets $\mathcal{S}^{(k)} = \{x \in \mathcal{S} \mid \sum_i x_i = k\}$, for $1 \leq k \leq n$. Observe that each of these sets contains only solutions with the same number of ones, and hence, satisfies the monotonicity condition. Let $\Gamma^{(k)}(t)$ denote the feasibility gap over the set $\mathcal{S}^{(k)}$. By our arguments above, $\Pr[\Gamma^{(k)}(t) < \epsilon] \leq \epsilon \sum_{i \in [n]} \phi_i$. Furthermore, $\Gamma(t)$ takes the value of one of the variables $\Gamma^{(k)}(t)$, $1 \leq k \leq n$, because the winner of one of the subproblems is the winner of the original problem. Applying the union bound gives $\Pr[\Gamma(t) < \epsilon] \leq \epsilon n \sum_{i \in [n]} \phi_i$. Let us remark that such a kind of argument cannot be applied directly to the loser gap. By applying Lemma 7, however, the bound for the feasibility gap holds for the loser gap as well. This completes the proof of the separating lemma. \square

2.3. Loser and feasibility gap for multiple constraints. Assume there are $k \geq 2$ stochastic constraints. Without loss of generality, these constraints are of the form $w_j^T x \leq t_j$, for $j \in [k]$, and the sets of solutions satisfying these constraints are $\mathcal{B}_1, \dots, \mathcal{B}_k$, respectively. We generalize the definition of feasibility and loser gap as follows. Given a set of solutions $\mathcal{S} \subseteq \{0, 1\}^n$ and a ranking, the *winner* x^* is the highest ranked solution in $\mathcal{S} \cap \mathcal{B}_1 \cap \dots \cap \mathcal{B}_k$. The *feasibility gap for multiple constraints* is the minimal slack of x^* over all stochastic constraints, that is, $\Gamma = \min_{j \in [k]} \{t_j - w_j^T x^*\}$, if x^* exists, and $\Gamma = \perp$, otherwise.

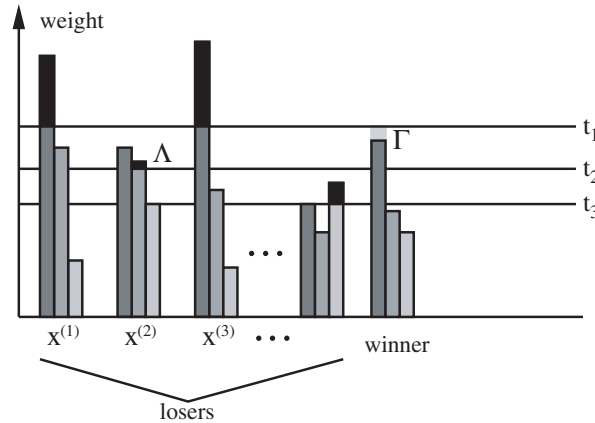

FIG. 2. Loser and feasibility gap for three constraints: Solutions are listed from left to right according to the ranking. For each solution three bars are shown representing three different weight functions. The thresholds t_1, t_2 , and t_3 apply to the first, second, and third weight function (bar), respectively. The winner is the first solution satisfying all three thresholds. The feasibility gap Γ is the smallest slack of the winner over the different constraints. All solutions left of the winner are losers. The loser gap for an individual loser is the largest amount by which this loser violates a threshold (given in black). The loser gap Λ is the minimum of the individual loser gaps over all losers.

A solution in \mathcal{L} is called a loser if it has a higher rank than x^* . Observe that a loser needs only to be infeasible with respect to one of the k constraints. In particular, it is not true that the weight values of each loser are likely to be far away from the corresponding thresholds $t_j, j \in [k]$; not even if we consider only those constraints for which the respective loser is infeasible. Fortunately, however, we do not need such a property in the application of the loser gap. For every loser, one needs only a single constraint that renders the loser infeasible. Therefore, we define the *loser gap for k constraints* by

$$\Lambda = \begin{cases} \min_{x \in \mathcal{L}} \max_{j \in [k]} \{w_j^T x - t_j\} & \text{if } \mathcal{L} \neq \emptyset, \text{ and} \\ \perp & \text{otherwise.} \end{cases}$$

Figure 2 illustrates this definition.

LEMMA 8. Let ϕ denote the maximum density parameter of all coefficients in the stochastic constraints. Suppose $0^n \notin \mathcal{S}$. For every $\epsilon \geq 0$, $\Pr[\Gamma < \epsilon] \leq \epsilon k \phi n^2$ and $\Pr[\Lambda < \epsilon] \leq \epsilon k \phi n^2$.

Proof. First we show the bound for the feasibility gap. Let x^* denote the winner and suppose $\Gamma \leq \epsilon$, for some $\epsilon \in \mathbb{R}_{\geq 0}$. Then there exists $j \in [k]$ with $t_j - w_j^T x^* \leq \epsilon$. Thus,

$$\Pr[\Gamma \leq \epsilon] \leq \sum_{j \in [k]} \Pr[t_j - w_j^T x^* \leq \epsilon].$$

For each individual $j \in [k]$, we can apply the separating lemma assuming that the set of feasible solutions with respect to all other constraints is fixed, as the coefficients in this constraint are stochastically independent from the other constraints. This way, we obtain $\Pr[\Gamma \leq \epsilon] \leq k \cdot \epsilon \phi n^2$.

Next, we turn our attention to the loser gap. Unfortunately, we cannot generalize the bound on the loser gap from one to multiple constraints in the same way as

we generalized the feasibility gap, as the loser gap for multiple constraints does not correspond to the minimal loser gap over the individual constraints. Instead we will make use of the result for the feasibility gap established above. Assume $\Lambda \leq \epsilon$, for some $\epsilon \in \mathbb{R}_{\geq 0}$. Then there exists a loser x satisfying for all $j \in [k] : w_j^T x - t_j \leq \epsilon$. Let x_L denote the loser with this property that is ranked highest. Consider a relaxed variant Π' of the given optimization problem Π where the thresholds of all stochastic constraints are increased by ϵ , i.e., we have constraints $w_j^T x \leq t_j + \epsilon, j \in [k]$. Observe that x_L is feasible in the relaxed problem Π' and, by the definition of x_L , no higher ranked solution is feasible. Thus, x_L is the winner of Π' . Since $t_j < w_j^T x_L \leq t_j + \epsilon$ for some $j \in [k]$, the feasibility gap Γ' of the relaxed problem is smaller than ϵ . Hence, $\Lambda \leq \epsilon$ implies $\Gamma' \leq \epsilon$. Finally, applying the bound $\Pr[\Gamma' \leq \epsilon] \leq \epsilon k \phi n^2$ derived in the first part of the proof yields $\Pr[\Lambda \leq \epsilon] \leq \epsilon k \phi n^2$. \square

2.4. Proof of Theorem 1. First we prove part (a) of the theorem. The probability that the absolute value of any of the kn stochastic coefficients $w_{i,j}$, ($i \in [k], j \in [n]$), is larger than $\mu nk/p$, for any $0 < p < 1$, is

$$\Pr \left[\exists(i, j) : |w_{i,j}| > \frac{\mu nk}{p} \right] \leq \sum_{i,j} \Pr \left[|w_{i,j}| > \frac{\mu nk}{p} \right] \leq \sum_{i,j} \frac{p}{kn} = p.$$

Hence, the maximum number of bits in front of the floating point over all stochastic coefficients is $O(\max\{1, \log(\mu nk/p)\})$, with a probability of at least $1 - p$.

Next we prove part (b) of the theorem. First, suppose that the objective function is the only stochastic expression. We reveal b bits after the binary point of each coefficient c_i ($1 \leq i \leq n$). Then we know the value of each c_i up to a absolute error of 2^{-b} . We will deal with this lack of precise information in terms of rounding, that is, we will think of rounding down all c_i to the next multiple of 2^{-b} causing a “rounding error” of less than 2^{-b} for each number.

LEMMA 9. *Let ϕ denote the maximum density parameter over the coefficients c_1, \dots, c_n in the objective function. When revealing b bits after the binary point of each coefficient then the winner is determined with a probability of at least $1 - 2n^2\phi/2^b$.*

Proof. Let $\lfloor c \rfloor$ be the vector that is obtained by rounding each entry c_i of vector c down to the next multiple of 2^{-b} . Consider any two solutions $x, x' \in \mathcal{S}$. Rounding changes the difference of the objective values of x and x' by

$$|(c^T x - c^T x') - (\lfloor c \rfloor^T x - \lfloor c \rfloor^T x')| = |(c - \lfloor c \rfloor)^T (x - x')| < n2^{-b},$$

as $c_i - \lfloor c_i \rfloor < 2^{-b}$, for all $i \in [n]$. Hence, if the winner gap Δ (with respect to the exact coefficients c_1, \dots, c_n) is at least $n2^{-b}$, then the winner is sufficiently isolated and the rounding cannot affect the optimality of the winner. In this case the winner is determined by revealing only b bits of each coefficient c_i . Applying the generalized isolating lemma with $\epsilon = n2^{-b}$ we obtain $\Pr[\Delta < n2^{-b}] \leq \frac{2n^2\phi}{2^b}$ and the lemma follows. \square

Next suppose only some of the constraints are stochastic and the objective function is fixed arbitrarily. Let k' denote the number of stochastic constraints. Without loss of generality, the constraints are of the form $w_j^T x \leq t_j, j \in [k']$. Assume we reveal b bits after the binary point of each coefficient in the k' constraints. We will think of it as rounding down each coefficient to the next multiple of 2^{-b} .

LEMMA 10. *Let ϕ denote the maximum density parameter over all coefficients in the stochastic constraints. When revealing b bits after the binary point of each coefficient, the winner is determined with a probability of at least $1 - k'n^3\phi/2^b$.*

Proof. As we round down, infeasible solutions might become feasible whereas feasible solutions stay feasible. (For constraints of the form $w_j^T x \geq t_j$ one would need to round up to the next multiple of 2^{-b} .) To ensure that the winner is determined it suffices to upper bound the maximum possible error in each constraint caused by the rounding of the coefficients. If this error is smaller than the loser gap, then rounding cannot change the feasibility status of any loser, i.e., all infeasible solutions that have rank higher than the winner stay infeasible.

In order to apply the bound on the loser gap given in Lemma 8, let us first assume $0^n \notin \mathcal{S}$. The rounding error in each expression is at most $n2^{-b}$. The definition of the loser gap for multiple stochastic constraints states that for every loser x there is a constraint $j \in [k']$ such that $w_j^T x - t_j \geq \Gamma$. Therefore, if $\Gamma > n2^{-b}$, then every loser stays infeasible with respect to at least one constraint after rounding. Applying Lemma 8, the probability for this event is at least $1 - k'\phi n^3/2^b$.

Including 0^n to the set of solutions \mathcal{S} can influence our analysis in two ways. First, 0^n can be a loser and might decrease the loser gap. However, rounding the coefficients w_i does not change the feasibility of this solution and the winner is not affected by 0^n . Second, 0^n can become the winner and might thereby change the set of losers. In this case, adding 0^n to \mathcal{S} can only remove solutions from \mathcal{L} and, hence, can only increase the loser gap. Thus, the above bound holds even if $0^n \in \mathcal{S}$. \square

Now suppose some constraints as well as the objective function are stochastic. We can combine the results for the winner gap and the feasibility gap as the coefficients of the objective function and the random constraints are assumed to be independent. Let $k = k' + 1$ denote the number of stochastic expressions. The probability that the winner and loser gap are sufficiently large, as described in the proofs of the two lemmas above, is $1 - k'\phi n^3/2^b - 2\phi n^2/2^b \geq 1 - k\phi n^3/2^b$, for $n \geq 2$.

This implies that the winner is determined when revealing $b = O(\log(k\phi n/p))$ bits, with a probability of at least $1 - p$, for any $0 < p < 1$. This completes the proof of Theorem 1. \square

3. Characterizing polynomial smoothed complexity. Based on the gap properties, we aim at characterizing which discrete optimization problems have polynomial time algorithms under random perturbations. We formalize this as follows. Fix any binary optimization problem Π and any perturbation model f . Let \mathcal{I}_N denote the set of all unperturbed instances of length N that an adversary may specify. The definition of the input length N needs some clarification as the coefficients in the stochastic expressions are assumed to be real numbers. We define that each of these numbers has a virtual length of one. (This way, we ensure $N \geq kn$.) The bits of the stochastic numbers can be accessed by asking an oracle in time $O(1)$ per bit. The bits after the binary point of each coefficient are revealed one by one from left to right. The deterministic part of the input can be encoded in an arbitrary fashion. For an instance $I \in \mathcal{I}_N$, let $I + f_\phi$ denote the random instance that is obtained by a ϕ -perturbation of I . We say that Π has *smoothed polynomial complexity* if and only if it admits an algorithm \mathcal{A} whose running time T satisfies

$$\exists \alpha, \beta > 0 : \text{for all } \phi \geq 1 : \text{for all } N \in \mathbb{N} : \max_{I \in \mathcal{I}_N} \mathbf{E}[(T(I + f_\phi))^\alpha] \leq \beta \phi N.$$

This definition of polynomial smoothed complexity follows more or less the way in which polynomial complexity is defined in average-case complexity theory, adding the requirement that the running time should be polynomially bounded not only in N but also in ϕ . It is not difficult to show that the assumption on the running time of \mathcal{A} is

equivalent to requiring that there exists a polynomial $P(N, \phi, \frac{1}{\epsilon})$ such that for every $N \in \mathbb{N}, \phi \geq 1, \epsilon \in [0, 1]$, the probability that the running time of \mathcal{A} exceeds $P(N, \phi, \frac{1}{\epsilon})$ is at most ϵ . Observe that this does not imply that the expected running time is polynomially bounded. To enforce expected polynomial running time, the exponent α in the definition of polynomial smoothed complexity should have been placed outside instead of inside the expectation. The reason for not defining polynomial smoothed complexity based on the expected running time is that this is not a sufficiently robust notion. For example, an algorithm with expected polynomial running time on one machine model might have expected exponential running time on another machine model. In contrast, the above definition yields a notion of polynomial smoothed complexity that does not vary among classes of machines admitting polynomial time simulations among each other. Although polynomial smoothed complexity does not always imply polynomial bounds on the expected running time, we will show that several of our algorithmic results yield expected polynomial running time on a random access machine (RAM).

We show that the smoothed complexity of a binary optimization problem Π can be characterized in terms of the worst-case complexity of Π . Theorem 1 shows that one usually needs to reveal only a logarithmic number of bits per real-valued input number. This suggests a connection between pseudo-polynomial worst-case running time and polynomial average-case complexity. For a binary optimization problem Π , let Π_u denote the corresponding optimization problem in which all numbers in the stochastic expression are assumed to be integers in unary representation instead of randomly chosen real-valued numbers. The following theorem holds for any fixed perturbation model f .

THEOREM 11. *A binary optimization problem Π has polynomial smoothed complexity if and only if $\Pi_u \in \text{ZPP}$.*

In other words, Π has polynomial smoothed complexity if it admits a (possibly randomized) algorithm whose (expected) running time for all instances is pseudo-polynomial in the stochastic constraints and polynomial in the remaining input. Notice that the expectation is over the randomization of the algorithm, not over the instances. This characterization immediately shows that strongly NP-hard optimization problems do not have polynomial smoothed complexity, unless $\text{ZPP} = \text{NP}$. This observation might not sound very surprising, as the hardness of strongly NP-hard problems does not rely on large or precisely specified input numbers. Observe, however, that the strong NP-hardness of a problem does not immediately rule out the possibility of a polynomial average-case complexity. For example, the TSP problem (on a complete graph) with edge lengths drawn uniformly at random from $[0, 1]$ might have a polynomial average-case complexity. Our theorem, however, shows that it does not have a polynomial smoothed complexity, unless $\text{ZPP} = \text{NP}$. The more sophisticated part of the theorem is the other direction stating that every binary optimization problem admitting a pseudo-polynomial time algorithm has polynomial smoothed complexity. This result is based on the generalized isolating lemma and the separating lemma. The idea is as follows. We design efficient verifiers checking whether a solution computed with a certain precision is actually the optimal solution of Π . The success probability of these verifiers is analyzed with the help of the gap properties. Using an adaptive rounding procedure, we increase the precision until we can certify that the computed solution is optimal. The overall running time of this meta-algorithm is polynomial if the algorithm computing solutions with bounded precision has pseudo-polynomial running time.

Proof. At first, we prove that the existence of a randomized pseudo-polynomial time algorithm for a binary optimization problem Π implies polynomial smoothed complexity for Π . We design an algorithm with polynomial smoothed complexity calling the pseudo-polynomial algorithm with higher and higher precision until the solution found is certified to be optimal. We describe verifiers that, based on the first b bits after the binary point of each coefficient in the stochastic expressions, either certify optimality or report FAILURE, stating that they have not sufficient information to ensure optimality. So the algorithm has access to the first b bits only, which corresponds to rounding down the numbers to the next multiple of 2^{-b} . Again we will interpret the lack of precise information as a rounding error. In the following, $\lfloor w \rfloor$ denotes the value of w rounded down to the next multiple of 2^{-b} .

Certifying optimality. For a moment assume that only the objective function is stochastic. Without loss of generality, consider a maximization problem with an objective function $c^T x$. At first, we compute an optimal solution x' for the problem with the rounded coefficients $\lfloor c_1 \rfloor, \dots, \lfloor c_n \rfloor$. To check whether x' is optimal with respect to the original cost vector c , we generate another vector \bar{c} of rounded coefficients. This time the rounding depends on the computed solution x' . For all i with $x'_i = 1$, we set $\bar{c}_i := \lfloor c_i \rfloor$ and for all i with $x'_i = 0$, we set $\bar{c}_i := \lceil c_i \rceil = \lfloor c_i \rfloor + 2^{-b}$. Observe that the function $\delta(x) = c^T x - \bar{c}^T x$ is maximal for $x = x'$. Next we compute an optimal solution x'' for the problem with the vector \bar{c} . If $x' = x''$, then x' simultaneously maximizes $\delta(x)$ and $\bar{c}^T x$. Consequently, it maximizes $\bar{c}^T x + \delta(x) = c^T x$ as well and, hence, x' corresponds to the true winner x^* . Thus, the algorithm outputs x' as a certified winner if $x' = x''$ and reports FAILURE otherwise. If the winner gap is large enough so that the winner is determined in the sense of Lemma 9, then the algorithm will always compute a certified winner. Hence, the probability that the algorithm is successful is at least $1 - 2n^2\phi/2^b$, corresponding to the bound given in Lemma 9. Observe that $\Gamma \geq n2^{-b}$ is a sufficient but not a necessary condition to certify the optimality of the winner with b revealed bits per coefficient. So the verifier might verify optimality of the computed solution even if $\Gamma < n2^{-b}$.

Certifying feasibility. Now we show how to deal with stochastic constraints. Without loss of generality, we assume that all stochastic constraints are of the form $w_j^T x \leq t_j$, $1 \leq j \leq k'$. For constraints of the form $w^T x \geq t$, we would need to round up instead of round down. First, we compute a certified winner, denoted by x' , using the rounded coefficients in the stochastic constraints. If the objective function is not stochastic, then there is no need to certify the winner. As we round down all coefficients in the stochastic constraints, we ensure that feasible solutions stay feasible. However, we have to detect infeasible solutions that become feasible due to the rounding and displace the true winner. Hence, we need to check whether x' is indeed feasible with respect to the original constraints. This would be trivial if the exact values of all constraint vectors w_1, \dots, w_k were available. However, we want to check the feasibility using only the knowledge of the first b bits after the binary point of each coefficient. Assume the solution x is infeasible with respect to the j th constraint and becomes feasible due to rounding. Then $\lfloor w_j \rfloor^T x \leq t_j < w_j^T x$ and hence $t_j - \lfloor w_j \rfloor^T x < w_j^T x - \lfloor w_j \rfloor^T x \leq n2^{-b}$, i.e., the slack of x in the j th constraint is less than $n2^{-b}$ with respect to the rounded vector $\lfloor w_j \rfloor$. Our verifier will use this property and classifies x' as possibly infeasible if it has slack less than $n2^{-b}$ for any of the k constraints with respect to the rounded coefficients. This way, we have two failure sources. First, there might be a loser that becomes feasible because of rounding. As seen in the proof of Lemma 10, this can happen only if the loser gap is smaller than $n2^{-b}$. Second, the true winner can be rejected since its slack is less than $n2^{-b}$.

This happens only if the feasibility gap is smaller than $n2^{-b}$. Due to Lemma 8, the probability that one of these events happens is at most $2k'\phi n^3/2^b$.

Adaptive rounding procedure. Consider a binary optimization problem Π with n binary variables and k stochastic expressions. Assume there exists an algorithm \mathcal{A} for the special variant of Π , where the domain of the coefficients in the stochastic expressions is restricted to \mathbb{Z} . Furthermore, assume that the worst-case running time of \mathcal{A} is bounded by some polynomial in W, n, k , and N , where W denotes the largest absolute value of any coefficient in the stochastic expressions. Recall that N specifies the size of the deterministic part of the input. We use the following adaptive rounding scheme. We start by revealing $b = \log(k\phi n^3)$ bits of each coefficient in the stochastic expressions. We obtain integer coefficients by scaling these numbers by 2^b . Now we use the algorithm \mathcal{A} to obtain a solution and use the verifiers to test for optimality. In case of FAILURE we increment b by one and iterate until the verifiers conclude optimality of the computed solution.

To analyze the running time of \mathcal{A} we need to estimate W , the largest absolute value of any integer in the stochastic expressions. It is the product of two factors. The first factor, $W_1 = 2^b$, is due to the scaling and depends on the number of revealed bits after the binary point of each coefficient. The second factor, W_2 , corresponds to the integer part of the largest absolute value of any coefficient. This way, $W = W_1W_2$. We have to show that there exists a polynomial $P(N, \phi, \frac{1}{p})$ such that for every $N \in \mathbb{N}, \phi > 0, p \in [0, 1] : \Pr \left[T > P(N, \phi, \frac{1}{p}) \right] \leq p$. The running time of \mathcal{A} is polynomial in W, n, k , and N . As n, k , and N do not depend on the random choice for the coefficients, it suffices to show such a polynomial bound for W . Let us first prove an upper bound on W_2 . Let $r_{j,i}$ be the random variable that is added to the i th coefficient in the j th stochastic expression when perturbing the instance. Recall that the mean of the absolute values of the probability distribution that defines the perturbation model is a constant, denoted by E . It then holds that $W_2 \leq \max_{j \in [k], i \in [n]} |r_{j,i}| + 1$. For every $\alpha \geq 1$,

$$\Pr \left[\max_{j,i} |r_{j,i}| > \alpha E \right] \leq \sum_{j,i} \Pr [|r_{j,i}| > \alpha E] \leq \frac{nk}{\alpha},$$

where the last inequality uses the Markov inequality. Thus, $\Pr [W_2 > \alpha E + 1] \leq nk/\alpha$. Setting $\alpha = 2nk/p$, it holds that $W_2 \leq \frac{2nkE}{p} + 1$ with a probability of at least $1 - p/2$, for every $0 < p < 1$. Next consider the term $W_1 = 2^b$. There are two reasons the certifier can declare the computed solutions suboptimal or infeasible. First, the random instance happens to have a small winner gap or a small loser gap such that the winner is not uniquely determined. By Theorems 9 and 10, the probability for this event is at most $k\phi n^3/2^b$. Second, the feasibility checker reports false negatives due to a small feasibility gap. This happens with a probability of at most $k'\phi n^3/2^b$. Allowing a failure probability of $p/4$ for each event, we obtain $W_1 = 2^b = \frac{k\phi n^3 4}{p}$. Therefore, with a probability of at least $1 - p$, none of these bad events occur and it holds that $W = W_1W_2 \leq \left(\frac{2nkE}{p} + 1 \right) \frac{k\phi n^3 4}{p}$. As E is assumed to be constant and $kn \leq N$, there exists a polynomial $P(N, \phi, \frac{1}{p})$ such that for all $N \in \mathbb{N}, \phi > 0, p \in [0, 1] : \Pr \left[W > P(N, \phi, \frac{1}{p}) \right] \leq p$.

From polynomial smoothed complexity to pseudo-polynomial running time. Finally, we need to show that polynomial smoothed complexity of a binary

optimization problem Π implies the existence of a randomized pseudo-polynomial algorithm for Π . Since we are aiming for a pseudo-polynomial time algorithm, we can assume that all numbers in the stochastic expressions are integers. Let M denote the largest absolute value of these numbers. The idea is to perturb all numbers only slightly such that the perturbation changes the value of each expression by at most $\frac{1}{2}$. To ensure that the set of feasible solutions is not changed by the perturbation, we relax all constraints by $\frac{1}{2}$, i.e., we replace $w^T x \leq t$ by $w^T x \leq t + \frac{1}{2}$ for all stochastic constraints. We then use an algorithm with polynomial smoothed complexity to compute an optimal solution x^* for the perturbed problem. By bounding the error due to the random perturbation, x^* can be shown to be optimal for the original problem as well.

Let us describe the proof in more detail. Our smoothed analysis framework assumes that all numbers in the stochastic expressions fall into the interval $[-1, 1]$ (or $[0, 1]$) before they are perturbed. To adapt our problem to this framework, we first scale all input numbers in the stochastic expressions by M^{-1} and adapt the thresholds accordingly, i.e., $w_1 x_1 + w_2 x_2 + \dots + w_n x_n \leq t$ is replaced by $(w_1/M)x_1 + (w_2/M)x_2 + \dots + (w_n/M)x_n \leq t/M$. Consequently, we have to ensure that the perturbation changes the value of an expression by at most $1/(2M)$. In particular, we will allow only perturbations that change each individual number by at most $1/(2Mn)$. We call such a perturbation *proper*. For the uniform distribution, we could simply set $\phi = 2Mn$. However, we have to deal with arbitrary families of distributions, as defined in our smoothed analysis framework, and they do not necessarily have a finite domain. The idea is to choose ϕ large enough so that a random perturbation is proper with a probability of at least $1/2$. Recall that the perturbation model is described by the density function f with density parameter $\phi = 1$. For other values of ϕ , we scale f appropriately. By our assumptions on f , it holds that $\int |t| f_\phi(t) dt = E/\phi$ for some fixed $E \in \mathbb{R}$. Let r be a random variable following f_ϕ . Setting $\phi = 4n^2 k E M$ and applying the Markov inequality yields $\Pr [|t| > \frac{1}{2nM}] = \Pr [|t| > \frac{2nkE}{\phi}] \leq \frac{1}{2nk}$. Our perturbation draws kn of these random variables. The probability that the perturbation is proper, i.e., the probability that their absolute values are at most $\frac{1}{2nM}$, is $1/2$.

Consider any binary optimization problem Π with polynomial smoothed complexity. Polynomial smoothed complexity implies that the problem admits an algorithm \mathcal{A} whose running time can be bounded polynomially in n and ϕ , with arbitrary large constant probability strictly less than 1. In particular, there exists a polynomial $P(n, \phi)$ such that the probability that the running time exceeds $P(n, \phi)$ is at most $\frac{1}{4}$. We use \mathcal{A} as a subroutine in order to obtain a pseudo-polynomial algorithm. This algorithm works as follows. At first, it generates a perturbation and checks whether it is *proper*. If it is proper, then it runs \mathcal{A} for at most $P(n, \phi)$ time steps. If \mathcal{A} has not finished within this time bound, the algorithm returns FAILURE. Let Q be the event that the perturbation is proper. Observe that for every two events A and B it holds that $\Pr [A \wedge B] \geq \Pr [A] + \Pr [B] - 1$. Therefore, the success probability of our algorithm is

$$\Pr [Q \wedge (T \leq P(n, \phi))] \geq \Pr [Q] - \Pr [T > P(n, \phi)] \geq \frac{1}{4}.$$

The running time of this algorithm is pseudo-polynomial because $\phi = O(Mn^2k)$. Hence, $\Pi_u \in \text{ZPP}$. This completes the proof of Theorem 11. \square

4. Algorithmic applications. Let us illustrate the strength of Theorem 11 by giving algorithmic applications to some well-known optimization problems and comparing these results with previous work on the probabilistic analysis of optimization problems. There has been substantial effort to analyze random instances of the knapsack problem; see, e.g., [5, 6, 13, 17, 18]. The knapsack problem can be seen as the simplest nontrivial binary optimization problem as its feasible region is described by only a single linear constraint. The problem belongs to the class of packing problems, that is, the constraint is of the form $w^T x \leq t$ and the coefficients are assumed to be nonnegative. To our knowledge, the knapsack problem is the only NP-hard optimization problem that was previously known to have polynomial smoothed complexity [5]. The multidimensional knapsack problem is a natural generalization in which there are multiple packing constraints instead of only one. Dyer and Frieze [10] proved that, with constant probability, this problem can be solved in polynomial time if the number of constraints is constant and the coefficients in the constraints as well as in the objective function are chosen uniformly at random from $[0, 1]$. Their result, however, does not yield polynomial average-case complexity as the dependence of the running time on the failure probability is not bounded by a polynomial. The multiple knapsack problem with a constant number of constraints admits a pseudo-polynomial algorithm [15]. Hence, Theorem 11 implies polynomial smoothed and, therefore, also polynomial average-case complexity for this problem. Moreover, the pseudo-polynomial algorithm also works for general 0/1 integer programming with any fixed number of constraints, i.e., when extending the domain of the coefficients to negative numbers. Therefore, this class of problems has polynomial smoothed complexity as well. This holds even if one constraint or the objective function is assumed to be adversarial. Furthermore, it follows from Theorem 11 that, unless $ZPP = NP$, general 0/1 integer programming as well as the multiple knapsack problem with an unbounded number of constraints have no polynomial smoothed complexity as they are strongly NP-hard.

It is important to interpret this result in the right way. It does not prove that all problems that can be formulated as a 0/1-integer program (with a constant number of constraints) have polynomial smoothed complexity. When expressing a problem as a 0/1 integer program, some numbers of the input usually appear in more than one constraint. Furthermore, the constraint matrix is usually sparse, containing many zero entries. Perturbing the constraints independently, as assumed by our smoothed analysis framework, destroys the structure of the problem. So instead of averaging over “similar” instances of the given problem, we would average over instances of some more general problem that might be easier to solve on average. We will see in section 6 how to strengthen our analysis by allowing zero entries in the constraints which are explicitly not perturbed. This way we are able to extend our analysis to problems with sparse constraint vectors.

4.1. Scheduling problems. The problem of scheduling to minimize the weighted number of tardy jobs is defined by n jobs each of which has a processing time p_i , a due date d_i , and a penalty c_i , which has to be paid if job i has not been finished at due date d_i . The jobs shall be scheduled on a single machine such that the sum of the penalties is minimized. In terms of n binary variables x_1, \dots, x_n , the objective is to minimize $c^T x$, where $x_i = 1$ if job i is not finished in time. Observe that the problem is essentially solved once these binary variables are determined as we can assume without loss of generality that an optimal schedule executes the selected jobs in the order of nondecreasing due dates. Notice that the feasible region is completely

determined by the processing times and the due dates. The objective, however, is a linear function $c^T x$. Using dynamic programming, the problem can be solved in time $O(n^2C)$, where C denotes the largest penalty for any job [24]. Hence, the problem has polynomial smoothed complexity for stochastic penalties.

4.2. Multicriteria optimization problems. If several criteria shall be optimized simultaneously, then usually one of them is declared to be the objective function, and the others are formulated in the form of a constraint with a given threshold. Often when a single-criteria optimization problem is polynomial, the problem becomes NP-hard when adding another criteria in the form of a linear constraint; examples for such problems are shortest path, spanning tree, or matching [21, 12, 23]. Theorem 11 enables us to prove polynomial smoothed complexity for such multicriteria problems as follows. The problems listed above have algorithms with pseudo-polynomial running time [23, 3, 22] solving the “exact version” of these problems, i.e., given an integer k and an instance of these problems, one can compute a solution with objective value exactly k in pseudo-polynomial time. Using standard coding techniques (see, e.g., [28]) a pseudo-polynomial algorithm for the exact single-criteria decision problem implies a pseudo-polynomial algorithm for its multicriteria optimization variant. Combining this observation with Theorem 11 yields the following result.

COROLLARY 12. *Let Π be a binary optimization problem with a single linear objective function. Suppose the exact version of Π admits an algorithm with pseudo-polynomial running time. Assume we deal with multicriteria variants of Π by choosing one criterion as the objective function and bounding the remaining criteria by appropriate thresholds. Then any multicriteria variant of Π with a constant number of criteria has polynomial smoothed complexity, provided that all criteria are stochastic.*

A similar approach was used in [23] to derive approximation schemes for multiobjective optimization problems. The corollary implies polynomial smoothed complexity for the multicriteria variants of shortest path, spanning tree, and matching. One does not always need to assume that all criteria are of stochastic nature. For example, the bicriteria variant of the shortest path problem, i.e., the constrained shortest path problem, can be solved in pseudo-polynomial time with respect to the objective function or with respect to the additional constraint. By Theorem 11, the constrained shortest path problem has polynomial smoothed complexity even if only the objective function or only the additional constraint is stochastic.

5. Expected polynomial running time. The main advantage of our definition of polynomial smoothed complexity is its robustness under different machine models. Besides, it allows a nice characterization of binary optimization problems under random inputs in terms of the problems’ worst-case complexity. However, the guarantee on the running time provided by polynomial smoothed/average-case complexity is weaker than the guarantee that the expected running time is polynomial. Making additional assumptions, we can use our analysis to conclude expected polynomial running time for certain binary optimization problems.

We use again our adaptive rounding scheme, which increases the precision of the stochastic input numbers until the computed solution is certified to be optimal. We assume that the running time of the last iteration of this meta-algorithm dominates the cumulative running time of all previous iterations. In fact, it suffices if all previous iterations have cumulative running time of at most a factor n^l larger than the running time of the last iteration, for some constant $l \in \mathbb{R}$. In order to obtain expected polynomial running time under random perturbations, one needs an algorithm whose

running time is “pseudo-linear” instead of only pseudo-polynomial with respect to the stochastic coefficients, i.e., the running time must be bounded linearly in the size of the unary encoding length of the integer coefficients. The only parameter in our running time bound that depends on the random perturbations is W , the largest absolute value of any (rounded and scaled) coefficient appearing in a stochastic expression.

We use the notation from the proof of Theorem 11. We divide W into two parts $W = W_1W_2$, where W_1 is due to the scaling by factor $2^b = W_1$ and depends on b , the number of revealed bits after the binary point of each coefficient. The second factor W_2 corresponds to the integer part of the largest absolute value of any coefficient. In the proof of Theorem 11 we have shown the following bounds on the random variables W_1 and W_2 :

$$\begin{aligned} \Pr [W_1 > 2^b] &\leq 2k\phi n^3/2^b, & \text{for any } b \in \mathbb{N}, \text{ and} \\ \Pr [W_2 > \alpha E + 1] &\leq nk/\alpha, & \text{for any } \alpha \in \mathbb{R}_{>0}. \end{aligned}$$

Since 2^b as well as α can grow linearly with the reciprocal of the failure probability, $W \approx 2^b\alpha E$ can grow quadratically. Hence, these bounds do not allow one to conclude a polynomial expected running time. Therefore, we will restrict the choice for the perturbation model by allowing only probability distributions whose tail function exhibits an exponential decay. More precisely, we assume that if X is drawn according to perturbation model f , then there exists some $E \in \mathbb{R}_{\geq 0}$, such that $\Pr [|X| > \alpha E] \leq 2^{-\alpha}$, for every $\alpha \geq 2$. For example, the Gaussian and exponential distribution have this property as well as all distributions with finite domain.

In the following analysis we exploit the fact that it is very unlikely that any of the coefficients in the stochastic expressions is much larger than E . Define event \mathcal{E} by $(W_2 \leq n \log(nk)E + 1) \wedge (W_1 \leq 2^n)$. As $\Pr [W_1 > 2^n] \leq 2k\phi n^3/2^n$ and $\Pr [W_2 > n \log(nk)E + 1] \leq kn \Pr [\max_{j,i} |r_{i,j}| > n \log(nk)E] \leq 2^{-n}$, it follows that $\Pr [-\mathcal{E}] \leq O(k\phi n^3/2^n)$. Assume that there exists an algorithm with pseudo-linear running time bound of $T \leq N^l W$, for some constant $l \in \mathbb{R}$. In case of $-\mathcal{E}$, we use a brute force enumeration of all 2^n possible 0/1-vectors which takes time $2^n P(N)$ for some polynomial $P(N)$. Additionally, we contribute the time for the unsuccessful adaptive rounding scheme, which is at most $N^l 2^n (n \log(nk)E + 1)$, to the enumeration process. Hence, the total running time is $O(2^n P(N))$ for some other polynomial $P(N)$. Next define random variable

$$W'_1 = \begin{cases} W_1 & \text{in case of } \mathcal{E}, \\ 0 & \text{otherwise.} \end{cases}$$

The expectation of W'_1 is

$$\mathbf{E} [W'_1] = \sum_{i=0}^n \Pr [W'_1 = 2^i] 2^i \leq \sum_{i=0}^n \Pr [W_1 \geq 2^i] 2^i \leq \sum_{i=0}^n \frac{4\phi kn^3}{2^i} 2^i = O(\phi kn^4).$$

Let T denote the running time of our algorithm. As $\mathbf{E} [W'_1] = \Pr [\mathcal{E}] \mathbf{E} [W'_1 | \mathcal{E}]$,

$$\begin{aligned} \mathbf{E} [T] &\leq \Pr [\mathcal{E}] \cdot \mathbf{E} [N^l W_1 W_2 | \mathcal{E}] + \Pr [-\mathcal{E}] \cdot 2^n P(N) \\ &\leq N^l (n \log(nk)E + 1) \cdot \Pr [\mathcal{E}] \mathbf{E} [W'_1 | \mathcal{E}] + \Pr [-\mathcal{E}] \cdot 2^n P(N) \\ &\leq N^l (n \log(nk)E + 1) \mathbf{E} [W'_1] + O(k\phi n^3/2^n) \cdot 2^n P(N) \\ &= O(N^l (n \log(nk)E + 1) \phi kn^4 + k\phi n^3 P(N)). \end{aligned}$$

COROLLARY 13. *Assume the perturbation model f satisfies $\Pr[|X| > \alpha E] \leq 2^{-\alpha}$, for some $E \in \mathbb{R}_{\geq 0}$ and all $\alpha \geq 2$. If a binary optimization problem has pseudo-polynomial running time $O(\text{poly}(N)W)$, then this problem allows an algorithm with expected polynomial running time.*

Such pseudo-linear algorithms exist on a uniform RAM, e.g., for the knapsack problem [8], the problem of scheduling to minimize weighted tardiness [24] or the constrained shortest path problem [16]. Hence, assuming the uniform RAM model, all these problems admit algorithms with expected polynomial running time under random perturbations. Observe, however, that the requirement of a pseudolinear running time is a strong restriction for binary optimization problems with $k > 1$ stochastic constraints, as standard approaches usually exhibit a running time of $\text{poly}(n)W^k$. In case of dynamic programming, for example, every additional constraint will add another dimension to the dynamic programming table.

6. Zero-preserving perturbations. One criticism of the smoothed analysis of the simplex algorithm is that the additive perturbations destroy the zero structure of an optimization problem, as it replaces zeros with small values; see also the discussion in [29]. The same criticism applies to the zero structure in binary programs. It turns out, however, that our probabilistic analysis in section 2 is robust enough to allow the preservation of zero entries. In particular, we can extend our semirandom input model introduced in section 1.1 by allowing the coefficients in the stochastic expressions to be fixed to zero instead of being a random variable. In the model of smoothed analysis, this corresponds to strengthening the adversary by avoiding the perturbation of these zero coefficients.

Consider the expression $w^T x$ and let Z be the set of indices i with w_i fixed to zero. We call two solutions $x, x' \in \mathcal{S} \subseteq \{0, 1\}^n$ equivalent if they differ only in positions contained in Z , e.g., if $x_i \neq x'_i \Rightarrow i \in Z$ holds. This way, Z defines equivalence classes on \mathcal{S} with respect to the expression $w^T x$. Clearly, $w^T x$ evaluates to the same value for all solutions within the same equivalence class.

First we consider the separation lemma. Observe that only the highest ranked solution in each equivalence class is relevant for the loser and feasibility gap. This is because the winner and the minimal loser are Pareto optimal solutions. As all solutions within an equivalence class have the same weight, only the highest ranked solution of this class can become Pareto optimal. For the purpose of analysis, we can remove virtually all solutions from \mathcal{S} that are not ranked highest within its equivalence class. This way, we can ignore variables x_i with $i \in Z$ and apply the separation lemma as before.

A similar argument can be used to show that the generalized isolating lemma stays valid with respect to equivalence classes, that is, the winner gap is defined to be the difference in objective value between the best and the second best equivalence class. However, it might be very likely that there are many optimal solutions, as the winning equivalence class might have many solutions. Notice that this affects the procedure that certifies optimality for stochastic objective functions which is described in the proof of Theorem 11. In particular, the two solutions x' and x'' , which are optimal with respect to the rounded cost vectors $\lfloor c \rfloor$ and \bar{c} , only have to be in the same equivalence class to certify optimality, which can be checked easily.

6.1. Algorithmic application. Using zero-preserving perturbations, we can apply our analysis to the general assignment problem (GAP), which is defined as follows:

$$\begin{aligned} \max \quad & \left(\sum_{i=1}^k \sum_{j=1}^n p_{ij} x_{ij} \right) \quad \text{subject to} \quad \sum_{j=1}^n w_{ij} x_{ij} \leq c_i, \quad i = 1, \dots, k, \\ & \sum_{i=1}^k x_{ij} = 1, \quad j = 1, \dots, n, \\ & x_{ij} \in \{0, 1\} \quad \text{for all } i \in [k], j \in [n]. \end{aligned}$$

Intuitively, the goal is to pack n items into k bins with capacities c_1, \dots, c_k . Packing item $j \in [n]$ into bin $i \in [k]$ occupies w_{ij} units of the capacity of bin i and yields a profit of p_{ij} . Even for two bins, the GAP problem does not allow a fully polynomial time approximation scheme (FPTAS), unless $P = NP$ [20]. In fact, the problem is strongly NP-hard for an unbounded number of bins. If, however, the number of bins is a constant, then the GAP can be solved in pseudo-polynomial time using standard dynamic programming as follows. Let $T(j, W_1, \dots, W_k)$ denote the maximum profit over solutions that use only items $\{1, \dots, j\}$ such that the cumulative weight of all items in bin i is exactly W_i , for all $i \in [k]$. All nontrivial entries can be computed by the following recursion:

$$T(j, W_1, \dots, W_k) = \max_{i \in [k]} \{T(j-1, V_1, \dots, V_k) + p_{ij} \mid V_i = W_i - w_{ij}, V_l = W_l \forall l \neq i\}.$$

Let W denote the largest weight of the instance, i.e., $W = \max_{j \in [n]} \max_{i \in [k]} w_{ij}$. Then the size of the dynamic programming table is at most $n(nW)^k$. Hence, the running time is at most $kn(nW)^k$.

How does the GAP problem fit into our framework? We have a vector of kn binary variables $(x_{11}, x_{12}, \dots, x_{1n}, x_{21}, x_{22}, \dots, x_{2n}, \dots, x_{k1}, x_{k2}, \dots, x_{kn})$ and the corresponding vector of profits. The weight constraint for bin $l \in [k]$ uses the weight vector with all entries w_{ij} , $i \neq l$, set to zero. These entries are declared to be fixed to zero, so they are not touched by the perturbation. This way, each w_{ij} appears in just one constraint and a perturbation of the profit and the constraint vectors has the same effect as perturbing each p_{ij} and w_{ij} individually. This yields the following corollary.

COROLLARY 14. *The general assignment problem with a constant number of constraints/bins has polynomial smoothed complexity if weights and profits are randomly perturbed.*

The discussion above reveals a limitation of our analysis. For this purpose, consider the multiple knapsack problem, a special case of the GAP problem, where the weight of an item is the same for all bins, i.e., $w_{ij} = w_j$ for all $i \in [k]$. Using the program formulation of the GAP problem, the weights w_j reoccur in the different constraints for the different knapsacks. The perturbation of the constraints, however, have to be independent such that the perturbed instance is, in general, not a multiple knapsack instance any more. We observe that for a sensible application of our analysis, each variable that describes the problem instance must appear at most once in the stochastic constraints of the linear program formulation. Or, seeing it another way, the coefficients in the stochastic constraints must allow independent perturbations without destroying the structure of the problem.

7. Other aspects.

7.1. Smoothed complexity and approximation schemes. If a binary optimization problem Π has polynomial smoothed complexity when perturbing only the coefficients in the objective function, then Π also admits an absolute fully polynomial

randomized approximation scheme. The idea is to perturb the instance only slightly, resulting in a very similar optimal objective function value. The set of feasible solutions is not affected by the perturbation. In order to bound the running time, we can exploit the positive influence of the added randomness. Let us give some more details.

Given a (worst-case) instance of Π , the coefficients in the objective function are normalized such that the largest absolute value is 1. Subsequently, the normalized coefficients are perturbed using the uniform perturbation model with parameter ϕ . As each coefficient changes by at most $1/\phi$, the difference in the objective value of any two solutions can change by at most n/ϕ due to this perturbation. Hence, the optimal solution of the perturbed instance is, with respect to the unperturbed objective function, at most n/ϕ away from the optimum. According to the definition of polynomial smoothed complexity, we can fix some polynomial bound B such that the running time of the algorithm is smaller than B with a probability of at least $1/2$. In order to obtain polynomial expected running time we generate perturbations and run the algorithm for at most B time steps. If the algorithm has not finished, we generate a new perturbation and try again. As the perturbations are independent, one needs 2 iterations on average until a solution is found. Hence, the expected running time is $2B$.

The approximation scheme allows only one to bound the absolute error. If, however, the optimum of the normalized instance can be lower bounded by some polynomial in $1/n$, then we obtain a randomized FPTAS.

The opposite direction works as well. Suppose Π is a binary optimization problem admitting a fully polynomial approximation scheme. It is well known that such an approximation scheme can be transformed into a pseudo-polynomial algorithm [11]. The running time of this algorithm is pseudo-polynomial only with respect to the coefficients in the objective function. Thus, Theorem 11 shows that Π has polynomial smoothed complexity when perturbing only the objective function.

This shows that for the class of problems considered, there exists a correlation between problems that allow an FPTAS and problems with polynomial smoothed complexity for stochastic linear objective functions.

Observe that these results rely solely on the analysis of the winner gap. The results based on the loser and feasibility gaps yield polynomial smoothed complexity for problems for which no fully polynomial approximation scheme is known, such as the constrained spanning tree problem, or even for problems that cannot be approximated within any polynomial-time computable factor, such as 0/1 programming with a constant number of constraints. In fact, the problems to which these gaps apply are exactly those problems admitting a bicriteria approximation scheme. In other words, our results show that the impact of randomly perturbing the objective function and/or the constraints on the computational complexity of a problem is comparable with the impact of relaxing the same set of expressions. The advantage of smoothed analysis over (bicriteria) approximation schemes, however, is that it yields optimal and feasible instead of almost optimal and almost feasible solutions.

7.2. Euclidean optimization problems. Upon first view, the Euclidean variants of TSP and Steiner tree might look like interesting candidates for problems with polynomial smoothed complexity. Karp [14], in a seminal work on the probabilistic analysis of algorithms, studied the TSP problem in a model in which n points are drawn uniformly and independently from the unit square. A natural extension of this model would be to assume that first an adversary chooses points in the unit cube

or ball, and then one applies a multidimensional Gaussian perturbation. We claim, however, that neither Euclidean TSP nor Steiner tree do have polynomial smoothed complexity, since the perturbation does not change the set of feasible solutions. The change in the objective function due to the perturbation depends at most linearly on the magnitude of the perturbation. Since the optimal objective value is $\Omega(1)$, we could obtain a fully polynomial randomized approximation scheme for worst-case instances, which is widely believed not to exist. Thus, one needs to give up either the requirement that the running time is polynomial in $1/\epsilon$ or the requirement that the running time is polynomial in ϕ . Under the first relaxation the problem has been solved by Arora [1]. The question whether there exist polynomial time algorithms for Euclidean TSP or the Steiner tree under perturbations with a fixed density parameter ϕ or in the uniform input model of Karp [14] is open.

7.3. Relationship to condition numbers. In order to obtain a finer analysis of algorithms than that provided by worst-case complexity, one might seek to find a way for distinguishing hard problem instances from easy ones. A natural approach is to find a quantity indicating the difficulty of solving a problem instance. In numerical analysis and operations research it is common to bound the running time of an algorithm in terms of a *condition number* of its input. The condition number is typically defined to be the sensitivity of the solution for a problem instance to slight perturbations of the input. For example, Renegar [25, 26, 27] presents a variant of the primal interior point method and describes its running time as a function of the condition number. Remarkably, his running time bound depends only logarithmically on the condition number. Dunagan, Spielman, and Teng [9] study this condition number in the smoothed analysis framework. Assuming Gaussian ϕ -perturbations, Renegar's condition number can be bounded by a function that is polynomial in ϕ . Thus, the running time of Renegar's interior point method depends only logarithmically on the density parameter ϕ . In contrast, the running time bound of the simplex algorithm presented by Spielman and Teng in [29] is polynomial in ϕ .

In [30], Spielman and Teng propose to extend the condition number concept toward discrete optimization problems in order to assist the smoothed analysis of such problems. As a natural definition for the condition number of a discrete function, they suggest *the reciprocal of the minimum distance of an input to one on which the function has a different value*. In fact, the minimum of winner, loser, and feasibility gap is a lower bound on the amount by which the coefficients of a binary optimization problem need to be altered so that the winner, i.e., the solution taking the optimal value, changes. Let us define the reciprocal of this minimum to be the *condition number for binary optimization problems*. This allows us to summarize our analysis in an alternative way. Our probabilistic analysis in section 2 shows that the condition number is bounded polynomially in the density parameter ϕ . Furthermore, in section 3, we proved that a problem with pseudo-polynomial worst-case complexity admits an algorithm whose running time is bounded polynomially in the condition number. Combining these results, we obtained algorithms whose smoothed complexity depends upon a polynomial fashioned on the density parameter ϕ . Let us remark that this kind of dependence on ϕ is best possible for NP-hard optimization problems, unless there is a subexponential time algorithm for NP-complete problems. In particular, a running time bound logarithmic in ϕ for an NP-hard optimization problem such as the knapsack problem would imply a randomized algorithm with polynomial worst-case complexity: Perturb all input numbers using a suitable distribution with sufficiently small density such that the identity of the optimal solution is not affected and com-

pute the optimal solution for the perturbed instance. For example, perturbing the profit values of the knapsack problem with a uniform distribution with exponentially small density parameter ϕ , the optimal solution of the perturbed instance is optimal for the original instance as well. Obviously, a smoothed analysis with running time logarithmic in ϕ would thus imply a polynomial running time for the NP-hard knapsack problem.

Acknowledgments. We thank Uriel Feige for helpful comments on an early version of this manuscript and an anonymous reviewer for several suggestions that improved the presentation of our analysis.

SPECTRAL PARTITIONING, EIGENVALUE BOUNDS, AND CIRCLE PACKINGS FOR GRAPHS OF BOUNDED GENUS*

JONATHAN A. KELNER[†]

Abstract. In this paper, we address two long-standing questions about finding good separators in graphs of bounded genus and degree:

1. It is a classical result of Gilbert, Hutchinson, and Tarjan [*J. Algorithms*, 5 (1984), pp. 391–407] that one can find asymptotically optimal separators on these graphs if given both the graph *and* an embedding of it onto a low genus surface. Does there exist a simple, efficient algorithm to find these separators, given only the graph and not the embedding?
2. In practice, spectral partitioning heuristics work extremely well on these graphs. Is there a theoretical reason why this should be the case?

We resolve these two questions by showing that a simple spectral algorithm finds separators of cut ratio $O(\sqrt{g/n})$ and vertex bisectors of size $O(\sqrt{gn})$ in these graphs, both of which are optimal. As our main technical lemma, we prove an $O(g/n)$ bound on the second smallest eigenvalue of the Laplacian of such graphs and show that this is tight, thereby resolving a conjecture of Spielman and Teng. While this lemma is essentially combinatorial in nature, its proof comes from continuous mathematics, drawing on the theory of circle packings and the geometry of compact Riemann surfaces.

Key words. bounded genus, circle packing, graph separators, Laplacian, partitioning, spectral partitioning

1. Introduction. Spectral methods have long been used as a heuristic in graph partitioning. They have had tremendous experimental and practical success in a wide variety of scientific and numerical applications, including mapping finite element calculations on parallel machines [24, 29], solving sparse linear systems [7, 8], partitioning for domain decomposition [8], and VLSI circuit design and simulation [6, 16, 3]. However, it is only recently that people have begun to supply formal justification for the efficacy of these methods [15, 25]. In [25], Spielman and Teng used the results of Mihail [22] to show that the quality of the partition produced by the application of a certain spectral algorithm to a graph can be established by proving an upper bound on the Fiedler value of the graph (i.e., the second smallest eigenvalue of its Laplacian). They then provided an $O(1/n)$ bound on the Fiedler value of a *planar* graph with n vertices and bounded maximum degree. This showed that spectral methods can produce a cut of ratio $O(\sqrt{1/n})$ and a vertex bisector of size $O(\sqrt{n})$ in a bounded degree planar graph.

In this paper, we use the theory of circle packings and conformal mappings of compact Riemann surfaces to generalize these results to graphs of positive genus. We prove that the Fiedler value of a genus g graph of bounded degree is $O(g/n)$ and demonstrate that this is asymptotically tight, thereby resolving a conjecture of Spielman and Teng. We then apply this result to obtain a spectral partitioning algorithm that finds separators whose cut ratios are $O(\sqrt{g/n})$ and vertex bisectors of size $O(\sqrt{gn})$, both of which are optimal. To our knowledge, this provides the only

[†]Computer Science and Artificial Intelligence Laboratory, Massachusetts Institute of Technology, Cambridge, MA 02139 (kelner@mit.edu).

truly practical algorithm for finding such separators and vertex bisectors for graphs of bounded genus and degree. While there exist other asymptotically fast algorithms for this, they all rely on being given an embedding of the graph in a genus g surface (e.g., [14]). It is not always the case that we are given such an embedding, and computing one is quite difficult. (In particular, computing the genus of a graph is NP-hard [27], and the best known algorithms for constructing such an embedding are either $n^{O(g)}$ [12] or polynomial in n but doubly exponential in g [11]. Mohar has found an algorithm that depends only linearly on n [21], but it has an uncalculated and very large dependence on g .) The excluded minor algorithm of Alon, Seymour, and Thomas [2] does not require an embedding of the graph, but the separators that it produces are not asymptotically optimal.

The question of whether there exists an efficient algorithm for providing asymptotically optimal cuts without such an embedding was first posed twenty years ago by Gilbert, Hutchinson, and Tarjan [14].¹ We resolve this question here, as our algorithm proceeds without any knowledge of an embedding of the graph, instead relying only on simple matrix manipulations of the adjacency matrix of the graph. While the analysis of the algorithm requires some somewhat involved mathematics, the algorithm itself is quite simple, and it can be implemented in just a few lines of Matlab code. In fact, the algorithm is only a slight modification of the spectral heuristics for graph partitioning that are widely deployed in practice without any theoretical guarantees.

We believe that the techniques that we employ to obtain our eigenvalue bounds are of independent interest. To prove these bounds, we make what is perhaps the first real use of the theory of circle packings and conformal mappings of positive genus Riemann surfaces in the computer science literature. This is a powerful theory, and we believe that it will be useful for addressing other questions in spectral and topological graph theory.

The structure of the paper is as follows. In section 2, we provide the necessary background in graph theory and spectral partitioning, and we state our main results. In section 3, we provide a brief outline of our proof techniques. In section 4, we review the basic theory of circle packings on compact Riemann surfaces. We then use this theory in sections 5 and 6 to prove our main results.

2. Background in graph theory and spectral partitioning. In this section we provide the basic definitions and results from graph theory and spectral partitioning that we shall require in what follows.

2.1. Graph theory definitions. Throughout the remainder of this paper, let $G = (V, E)$ be a finite, connected, undirected graph with n vertices, m edges, and no loops. In this section, we shall define two objects associated with G : its *Laplacian* and its *genus*.

Let the *adjacency matrix* $A(G)$ be the $n \times n$ matrix whose (i, j) th entry equals 1 if $(i, j) \in E$ and equals 0 otherwise. Let $D(G)$ be the $n \times n$ diagonal matrix whose i th diagonal entry equals the degree of the i th vertex of G .

DEFINITION 2.1. *The Laplacian $L(G)$ is the $n \times n$ matrix given by*

$$L(G) = D(G) - A(G).$$

Since $L(G)$ is symmetric, it is guaranteed to have an orthonormal basis of real eigenvectors and exclusively real eigenvalues. Let $\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_n$ be the eigenval-

¹Djidjev claimed in a brief note to have such an algorithm [10], but it has never appeared in the literature.

ues of $L(G)$, and let v_1, \dots, v_n be a corresponding orthonormal basis of eigenvectors. For any G , the all-ones vector will be an eigenvector of eigenvalue 0. It is not difficult to see that all of the other eigenvalues will always be nonnegative, so that $v_1 = (1, \dots, 1)^T$ and $\lambda_1 = 0$.

There has been a great deal of work relating the eigenvalues of $L(G)$ to the structure of G . In the present paper, we shall concern ourselves exclusively with λ_2 , also known as the *algebraic connectivity* or *Fiedler value* of G . We call the vector v_2 the *Fiedler vector* of G . As we shall see in section 2.2, the Fiedler value of a graph is closely related to how well connected the graph is.

A different measure of the connectivity of a graph is provided by its *genus*, which measures the complexity of the simplest orientable surface on which the graph can be embedded so that none of its edges cross. Standard elementary topology provides a full classification of the orientable surfaces without boundary. Informally, they are all obtained by attaching finitely many “handles” to the sphere, and they are fully topologically classified (i.e., up to homeomorphism) by the number of such handles. This number is called the *genus* of the surface. The genus 0, 1, 2, and 3 surfaces are shown in Figure 2.1.

FIG. 2.1. *The surfaces of genus 0, 1, 2, and 3.*

DEFINITION 2.2. *The genus g of a graph G is the smallest integer such that G can be embedded on a surface of genus g without any of its edges crossing one another.*

In particular, a planar graph has genus 0. By making a separate handle for each edge, it is easy to see that $g = O(m)$, where m is the number of edges in G .

Using these definitions, we can now state our main technical result, as follows.

THEOREM 2.3. *Let G be a graph of genus g and bounded degree. Its Fiedler value obeys the inequality*

$$\lambda_2 \leq O\left(\frac{g}{n}\right),$$

and this is asymptotically tight.

The constant in this bound depends on the degree of the graph. The proof that we provide yields a polynomial dependence on the degree, but no effort is made to optimize this polynomial. Finding the optimal such dependence is an interesting open question.

2.2. Spectral partitioning. We recall that a *partition* of a graph G is a decomposition $V = A \cup \bar{A}$ of the vertices of G into two disjoint subsets. For such a partition, we let $\delta(A)$ be the set of edges (i, j) such that $i \in A$ and $j \in \bar{A}$, and we call $|\delta(A)|$ the *cut size* of our partition. The *ratio* of our partition is defined to be

$$\phi(A) = \frac{|\delta(A)|}{\min(|A|, |\bar{A}|)}.$$

If our partition splits the graph into two sets that differ in size by at most one, we call it a *bisection*.

Spectral methods aim to use the Fiedler vector to find a partition of the graph with a good ratio. A theorem that begins to address why these work was proven by Mihail and restated in a more applicable form by Spielman and Teng, as follows.

THEOREM 2.4 (see [22, 25]). *Let G have maximum degree Δ . For any vector x that is orthogonal to the all-ones vector, there is a value s so that the partition of G into $\{i : x_i \leq s\}$ and $\{i : x_i > s\}$ has ratio at most*

$$\sqrt{2\Delta \frac{x^T L(G)x}{x^T x}}.$$

If x is an eigenvector of $L(G)$, the fraction $\frac{x^T L(G)x}{x^T x}$ is equal to its eigenvalue. So, if we find the eigenvector with eigenvalue λ_2 , we will thus quickly be able to find a partition of ratio $\sqrt{2\Delta\lambda_2}$. By Theorem 2.3, finding the second eigenvector of the Laplacian thus allows us to find a partition of ratio $O(\sqrt{g/n})$ for a graph of bounded degree. There is no guarantee that this partition has a similar number of vertices in each of the two sets. However, a theorem of Lipton and Tarjan [19] implies that a simple method based on repeated application of this algorithm can be used to give a bisection of size $O(\sqrt{gn})$.

For every g , Gilbert, Hutchinson, and Tarjan exhibited a class of bounded degree graphs that have no bisections smaller than $O(\sqrt{gn})$ [14]. This implies that our algorithm gives the best results possible, in general. Furthermore, it establishes the asymptotic tightness of our eigenvalue bound, as a smaller bound would show that every genus g graph has a partition of size $o(\sqrt{gn})$.

Putting all of this together yields our main algorithmic result, the following.

THEOREM 2.5. *Let G be a genus g graph of bounded maximum degree. There is a polynomial time algorithm that produces cuts of ratio $O(\sqrt{g/n})$ and vertex bisections of size $O(\sqrt{gn})$ in G , and both of these values are optimal.*

All that remains of the proof of Theorem 2.5 is the eigenvalue bound set forth in Theorem 2.3, which is the goal of the remainder of this paper.

3. Outline of the proof of Theorem 2.3. The proof of Theorem 2.3 necessitates the introduction of a good deal of technical machinery. Before launching into several pages of definitions and background theorems, we feel that a brief roadmap of where we're going will be helpful.

The basic motivation for our approach comes from an observation made by Spielman and Teng [25]. They noted that one can obtain bounds on the eigenvalues of a graph G from a nice representation of G on the unit sphere in \mathbb{R}^3 , known as a *circle packing* for G . This is a presentation of the graph on the sphere so that the vertices are the centers of a collection of circles, and the edges between vertices correspond to tangencies of their respective circles, as shown in Figure 4.1. Only planar graphs can be embedded as such if we require that the circles have disjoint interiors. However, if we allow the circles to overlap, as shown in Figure 4.2, we can represent nonplanar graphs as well. This will give rise to a weaker bound in which the eigenvalue bound is multiplied by the maximum number of circles containing a given point (i.e., the number of layers of circles on the sphere).

There is a well developed theory of circle packings, both on the sphere and on higher genus surfaces. The portions of it that we shall use will tell us two main things:

1. We can realize our graph as a circle packing of circles with disjoint interiors on some genus g surface.
2. The theory of discrete circle packings can be thought of as a discrete analogue of classical complex function theory, and many of the results of the latter carry

over to the former.

In classical complex analysis, you can put a complex analytic structure on a genus g surface to obtain a Riemann surface. Any genus g Riemann surface has a map to the sphere that is almost everywhere k -to-one for $k = O(g)$, with only $O(g)$ bad points at which this fails. With this as motivation, we shall try to use the representation of G as a circle packing on a genus g surface to obtain a representation of it as a circle packing on the sphere with $O(g)$ layers.

Unfortunately, the discrete theory is more rigid than the continuous one, and finding such a representation will turn out to be impossible. Instead, we shall actually pass to the continuous theory to prove our result. To do this, we shall provide a subdivision lemma that shows that it suffices to prove Theorem 2.3 for graphs that have circle packings with very small circles. We shall then show that the smooth map that we have from the Riemann surface to the sphere will take *almost* all of the circles of our circle packing to curves on the sphere that are *almost* circles. We will then show that this representation of our graph as an approximate circle packing is enough to provide our desired bounds.

4. Introduction to circle packings. Our proof of Theorem 2.3 operates by obtaining a nice geometric realization of G . We obtain this realization using the theory of circle packings. In this section, we shall review the basics of circle packing theory and quote the main results that our proof will employ. For a more comprehensive treatment of this theory and a historical account of its origins, see [26].

Loosely speaking, a circle packing is a collection of circles on a surface with a given pattern of tangencies. We remark at the outset that the theory that we are discussing *is not the same* as the classical theory of sphere packing. Our theory is concerned with the combinatorics of the tangency patterns, *not* with the maximum number of circles that one can fit in a small region. The coincidence of nomenclature is just an unfortunate historical accident.

FIG. 4.1. A univalent circle packing with its associated graph.

4.1. Planar circle packings. For simplicity, we begin by discussing circle packings in the plane.

DEFINITION 4.1. A planar circle packing \mathcal{P} is a finite collection of (possibly overlapping) circles C_1, \dots, C_n of respective radii r_1, \dots, r_n in the complex plane \mathbb{C} . If all of the C_i have disjoint interiors, we say that \mathcal{P} is univalent.

The associated graph $A(\mathcal{P})$ of \mathcal{P} is the graph obtained by assigning a vertex v_i to each circle C_i and connecting v_i and v_j by an edge if and only if C_i and C_j are mutually tangent.

This is illustrated in Figures 4.1 and 4.2.

We thus associate a graph with every circle packing. It is clear that every graph

FIG. 4.2. A nonunivalent circle packing with its associated graph.

associated with a univalent planar circle packing is planar. A natural question to ask is whether every planar graph can be realized as the associated graph of some planar circle packing. This is answered in the affirmative by the Koebe–Andreev–Thurston theorem [18, 1, 28].

THEOREM 4.2 (Koebe–Andreev–Thurston). *Let G be a planar graph. There exists a planar circle packing \mathcal{P} such that $A(\mathcal{P}) = G$.*

This theorem also contains a uniqueness result, but we have not yet developed the machinery to state it. We shall generalize this theorem in section 4.3, at which point we shall have the proper terminology to state the uniqueness part of the theorem.

We note that if we map the plane onto the sphere by stereographic projection, circles in the plane will be sent to circles on the sphere, so this theorem can be interpreted as saying that every genus 0 graph can be represented as a circle packing on the surface of a genus 0 surface. This suggests that we attempt to generalize this theorem to surfaces of higher genus. The theory of circle packings on surfaces of arbitrary genus acts in many ways like a discrete analogue of classical Riemann surface theory. As such, a basic background in Riemann surfaces is necessary to state or motivate many of its results. It is to this that we devote the next section.

4.2. A very brief introduction to Riemann surface theory. In this section, we provide an informal introduction to Riemann surface theory. Our goal is to provide geometric intuition, not mathematical rigor. We assume some familiarity with the basic concept of a manifold, as well as with the basic definitions of complex analysis. For a more complete exposition of the theory, see [13].

We recall that an n -dimensional manifold is a structure that looks locally like \mathbb{R}^n . More formally, we write our manifold M as a topological union of open sets S_i , each endowed with a homeomorphism $\varphi_i : S_i \rightarrow B_n$, where B_n is the ball $\{|x| < 1 \mid x \in \mathbb{R}^n\}$. Furthermore, we require a compatibility among these maps to avoid cusps and such. To this end, we mandate that the compositions $\varphi_j \circ \varphi_i^{-1} : \varphi_i(S_i \cap S_j) \rightarrow \varphi_j(S_i \cap S_j)$ be diffeomorphisms. The orientable 2-dimensional manifolds are precisely the genus g surfaces described above.

An n -dimensional complex manifold is the natural complex analytic generalization of this. We write our manifold M as a union of open sets S_i and endow each such set with a homeomorphism $\varphi_i : S_i \rightarrow B_{\mathbb{C}^n}$, where $B_{\mathbb{C}^n}$ is the complex unit ball $\{|x| < 1 \mid x \in \mathbb{C}^n\}$. Now, instead of requiring that the compositions of these functions obey a smooth compatibility condition, we require that they obey an analytic one: we demand that the compositions $\varphi_i \circ \varphi_j^{-1}$ be biholomorphic maps.

As such, an n -dimensional complex manifold M is a $2n$ -dimensional real manifold with additional complex analytic structure. This structure allows us to transfer over many of the definitions from standard complex analysis. The basic idea is that we

define these notions as before on the S_i , and the compatibility condition allows them to make sense as global definitions. In particular, if $M = (S_i^M, \phi_i^M)$ and $N = (S_j^N, \phi_j^N)$ are complex manifolds of the same dimension, we say that a function $f : M \rightarrow N$ is holomorphic if its restriction to a map $f_{ij} : S_i^M \rightarrow S_j^N$ is holomorphic for all i and j . Since the compositions $\varphi_i^M \circ (\varphi_j^M)^{-1}$ and $\varphi_i^N \circ (\varphi_j^N)^{-1}$ are holomorphic, this notion makes sense where the regions overlap.

DEFINITION 4.3. *A Riemann surface is a 1-dimensional complex manifold.*

In this paper, we shall take all of our Riemann surfaces to be compact. Since there is a natural way to orient the complex plane, we note that the complex structure can be used to define an orientation on the manifold. As such, all complex manifolds, and in particular all Riemann surfaces, are orientable. Compact Riemann surfaces are thus, topologically, 2-dimensional orientable real manifolds. Every compact Riemann surface is therefore topologically one of the genus g surfaces discussed above. The complex structure imposed by the φ_i , however, varies much more widely, and there are many different such structures that have the same underlying topological space.

Nothing in the definition of a Riemann surface supplies a metric on the surface. Indeed, there is no requirement that the different ϕ_i agree in any way about the distance between two points in their intersection. One can assign many different metrics to the surface. However, it turns out that there is way to single out a unique metric on the surface, called the *metric of constant curvature*. This allows us to supply an intrinsic notion of distance on any Riemann surface. In particular, this allows us to define a circle on our Riemann surface to be a simple closed curve that is contractible on the surface and all of whose points lie at a fixed distance from some center.

One particularly important Riemann surface that we shall consider is the Riemann sphere, which we denote $\widehat{\mathbb{C}}$. It is topologically a sphere. It should be thought of as being obtained by taking the complex plane and adjoining a single point called ∞ . One way of visualizing its relation to \mathbb{C} is to consider the stereographic projection away from the North Pole of a sphere onto a plane. The North Pole corresponds to ∞ , and the rest of the sphere corresponds to \mathbb{C} .

We recall from single variable complex analysis that the requirement that a map be analytic is quite a stringent one, and that it imposes a significant amount of local structure on the map. Let $f : \mathbb{C} \rightarrow \mathbb{C}$ be nonconstant and analytic in a neighborhood of the origin, and assume without loss of generality that $f(0) = 0$. There is some neighborhood of the origin in which f can be expressed as a power series $f(z) = a_1z + a_2z^2 + a_3z^3 + \dots$. If $a_1 \neq 0$, $f(z)$ is analytically invertible in some neighborhood of the origin, and thus it is locally an isomorphism. In particular, it is *conformal*—it preserves the angles between intersecting curves, and the image of an infinitesimal circle is another infinitesimal circle.

If $a_1 = 0$ and a_n is the first nonzero coefficient in its power series, f has a *branch point of order n* at the origin. In this case, f operates, up to a scale factor and lower order terms, like the function $f(z) = z^n$. This function is n -to-one on a small neighborhood of the origin, excluding the origin itself. It sends only 0 to 0, however. The preimages of the points in this small neighborhood thus trace out n different “sheets” that all intersect at 0. This confluence of sheets is the only sort of singularity that can appear in an analytic map. We note that the angles between curves intersecting at the branch point are not preserved, but they are instead divided by n .

This local behavior is identical for Riemann surfaces. From this, we can deduce that if $f : M \rightarrow N$ is an analytic map of Riemann surfaces, it has some well-defined

degree k . For all but finitely many points p in N , $\#f^{-1}(p) = k$. The preimage of each of these points looks like a collection of k sheets, and f has nonzero derivative at all of them. There exist some points $q \in M$ at which $f'(q) = 0$. At each such point there is a branch point, so the sheets intersect, and $f(q)$ has fewer than k preimages.

However, the global structure of Riemann surfaces provides further constraints on maps between them, and there are, generally speaking, very few functions $f : M \rightarrow N$ of a given degree. For example, topological arguments, using the local form of analytic maps described above, show that there are no degree 1 maps from the torus to the sphere, and no degree 2 maps from the genus 2 surface to the sphere.

There is a deep theory of maps of Riemann surfaces that describes rather precisely when a map of a given degree exists between two Riemann surfaces, and, if it exists, where and how such a map must branch. Of this theory we shall require only one main result, which is a direct corollary of the celebrated Riemann–Roch theorem.

THEOREM 4.4. *Let M be a Riemann surface of genus g . There exists an analytic map $f : M \rightarrow \widehat{\mathbb{C}}$ of degree $O(g)$ and with $O(g)$ branch points.*

4.3. Circle packings on surfaces of arbitrary genus. We now have the machinery in place to deal with general circle packings. Throughout this section, let G be a graph of genus g , and suppose that it is embedded on a genus g surface S so that none of its edges cross. The graph G divides S into faces. We say that G is a *fully triangulated* graph if all of these faces are triangles, in which case we say that it gives a *triangulation* of S . If G is not fully triangulated, one can clearly add edges to it to make it so. It will follow immediately from (5.2) in section 5 that this will only increase $\lambda_2(G)$, so we shall assume for convenience that G gives a triangulation of S . We are now ready to define our primary objects of study, as follows.

DEFINITION 4.5. *Let S be a compact Riemann surface endowed with its metric of constant curvature. A circle packing \mathcal{P} on S is a finite collection of (possibly overlapping) circles C_1, \dots, C_n of respective radii r_1, \dots, r_n on the surface of S . If all of the C_i have disjoint interiors, we say that \mathcal{P} is univalent.*

The associated graph $A(\mathcal{P})$ of \mathcal{P} is the graph obtained by assigning a vertex v_i to each circle C_i and connecting v_i and v_j by an edge if and only if C_i and C_j are mutually tangent. Alternatively, we say that \mathcal{P} is a circle packing for $A(\mathcal{P})$ on S .

The main result on circle packings that we shall use is the circle packing theorem, which is the natural extension of the Koebe–Andreiev–Thurston theorem to this more general setting. It was originally proven in a restricted form by Beardon and Stephenson [4] and then proven in full generality by He and Schramm [17].

THEOREM 4.6 (circle packing theorem). *Let G be a triangulation of a surface of genus g . There exists a Riemann surface S of genus g and a univalent circle packing \mathcal{P} such that \mathcal{P} is a circle packing for G on S . This packing is unique up to automorphisms of S .*

If G is embedded in a surface of genus g but is not fully triangulated, the Riemann surface and circle packing guaranteed by the theorem still exist, but they need not be unique.

The complex structure on the Riemann surface allows us to define the angle at which two edges of a face meet. If the points u , v , and w are the vertices of a face, we denote the angle between the edges \overline{uv} and \overline{vw} at v by $\langle uvw \rangle$. We can thus define the angle sum at a vertex to be $\sum \langle uvw \rangle$, where the sum is taken over all faces containing v . If \mathcal{P} is a univalent sphere packing, the angle sum at any vertex of $A(\mathcal{P})$ is clearly 2π .

In a nonunivalent circle packing, it is possible for the circles at a point to wrap around the point more than once. In the case of a nonunivalent circle packing, the

edges of its associated graph may intersect, but we can still define an associated triangulation of the surface—there just may be more than one triangle covering a given point. We can therefore compute the angle sum at a point. In this case, it need not be 2π . However, the circles must wrap around the vertex an integral number of times, so it must be some multiple $2\pi k$. (See Figure 4.2.) We then say that the vertex is a *discrete branch point of order k* .

These discrete branch points behave very much like the continuous branch points present on Riemann surfaces. In fact, there is an extensive theory that shows that a large portion of the theory of Riemann surfaces has an analogue in the discrete realm of circle packing. One can define maps of circle packings, just as one can define maps of Riemann surfaces. They consist of a correspondence of the circles on one surface to those on another in a way that commutes with tangency. While analytic maps send infinitesimal circles to infinitesimal circles, maps of circle packings send finite circles to finite circles. The analogue of branched covering maps in Riemannian geometry takes univalent circle packings and places them as nonunivalent circle packings on other surfaces. Unfortunately, these maps are somewhat rarer than their continuous analogues.

In particular, if we have a circle packing on a genus g surface S , there is no known analogue of the Riemann–Roch theorem, and thus no analogue of Theorem 4.4. We are therefore not guaranteed that there is a nonunivalent circle packing on the sphere carrying the same associated graph. Intuitively, this comes from the fact that the analytic maps from S to $\widehat{\mathbb{C}}$ are required to be branched over a very restricted locus of points. The discrete maps, however, can only be branched over the centers of circles. If there does not exist an admissible set of branch points among the centers of the circles, we will have difficulty constructing a discrete analytic map. This will lie at the root of many of the technical difficulties that we shall face in the remainder of this paper.

5. An eigenvalue bound. In this section, we prove Theorem 2.3. The proof will assume a technical lemma whose proof we shall postpone until section 6.

We begin by recalling the expression of the Fiedler value of G as a so-called *Rayleigh quotient*:

$$(5.1) \quad \lambda_2 = \min_{x \perp (1, \dots, 1)^T} \frac{x^T L(G)x}{x^T x}.$$

A straightforward calculation shows that for $x = (x_1, \dots, x_n)^T \in \mathbb{R}^n$,

$$x^T L(G)x = \sum_{(i,j) \in E} (x_i - x_j)^2,$$

so that (5.1) becomes

$$(5.2) \quad \lambda_2 = \min_{x \perp (1, \dots, 1)^T} \frac{\sum_{(i,j) \in E} (x_i - x_j)^2}{x^T x}.$$

As noted by Spielman and Teng [25], it follows easily from (5.2) that we can replace the scalar values x_i with vectors $v_i \in \mathbb{R}^k$, so that

$$(5.3) \quad \lambda_2 = \min \frac{\sum_{(i,j) \in E} \|v_i - v_j\|^2}{\sum_{i=1}^n \|v_i\|^2},$$

where the minimum is taken over all sets of n -vectors such that $\sum v_i = (0, \dots, 0)^T$ and such that at least one of the v_i is nonzero.

The general goal is thus to find a set of v_i that gives a small value for this quotient. The v_i that we use will almost be the centers of a nonunivalent circle packing on the unit sphere $S^2 \subseteq \mathbb{R}^3$. The efficacy of this follows from the following theorem, which follows easily from the work of Spielman and Teng [25].

THEOREM 5.1. *Let \mathcal{P} be a circle packing on the sphere $S^2 = \{x \in \mathbb{R}^3 \mid \|x\|^2 = 1\}$ so that the graph $A(\mathcal{P})$ has no vertex of degree greater than Δ . Suppose further that the packing is of degree k , so that no point on the sphere is contained in the interior of more than k circles, and that the centroid of the centers of the circles is the origin. Then the Fiedler value*

$$\lambda_2(A(\mathcal{P})) \leq O\left(\frac{\Delta k}{n}\right).$$

Proof. The proof follows from (5.3). Let the circles be C_1, \dots, C_n , and let the corresponding radii be r_1, \dots, r_n . Let $v_i \in \mathbb{R}^3$ be the x, y , and z coordinates of the center of the i th circle. The sum $\sum v_i = 0$ by assumption, so λ_2 is less than or equal to the fraction in (5.3). Since all of the v_i are on the unit sphere, we have $\sum \|v_i\|^2 = n$, so it just remains to bound the numerator. If there is an edge (i, j) , the two circles C_i and C_j must be mutually tangent, so that $\|v_i - v_j\|^2 \leq (r_i + r_j)^2 \leq 2(r_i^2 + r_j^2)$. It thus follows that

$$\sum_{(i,j) \in E} \|v_i - v_j\|^2 \leq \sum_{(i,j) \in E} 2(r_i^2 + r_j^2) \leq 2\Delta \sum_{i=1}^n r_i^2.$$

However, the total area of all of the circles is less than or equal to k times the area of the sphere, since the circle packing is of degree k . We thus have that $\sum_{i=1}^n r_i^2 \leq O(k)$, from which the desired result follows. \square

This suggests that we use the circle packing theorem (Theorem 4.6) to embed our graph on a genus g surface and then try to use some analogue of Theorem 4.4 to obtain a branched circle packing on the sphere of degree $O(g)$. Unfortunately, as previously noted, such a circle packing need not exist, due to the restrictiveness of the discrete theory. Thus, we shall instead show that a certain subdivision process on our graph does not significantly decrease $n\lambda_2$. We shall then show that performing this subdivision enough times causes our discrete circle packing to approximate a continuous structure on the Riemann surface, at which point we can use the continuous theory in addition to the discrete one.

The refinement procedure that we shall use is called “hexagonal refinement.” It operates on a triangulation of a surface by replacing each triangle with four smaller triangles, as shown in Figure 5.1. This process produces another triangulation of the same surface, so we can iterate it arbitrarily many times.

LEMMA 5.2. *Let G be a graph with n vertices, m edges, and maximum degree Δ that triangulates some surface without boundary, and let G' be the graph with n' vertices and m' edges obtained by performing k successive hexagonal refinements on G . Then*

$$n\lambda_2(G) \leq C(\Delta)n'\lambda_2(G').$$

For the sake of continuity, we defer this proof to section 6.

FIG. 5.1. The hexagonal subdivision procedure applied to a triangulation with two triangles.

The refinement process replaces each triangle in our graph with four smaller triangles. If all of the original triangles remained the same size and shape, this would imply that performing enough hexagonal refinements would give rise to a circle packing whose circles have arbitrarily small radii. However, it is possible for the original triangles to change size and shape as we refine, so this is no longer obvious. Nevertheless, it remains true, as shown by the following lemma.

LEMMA 5.3. *Let G be a graph that triangulates a genus g Riemann surface without boundary, and let $G^{(k)}$ be the graph obtained by performing k hexagonal refinements on G . For every $\epsilon > 0$, there exists some k_ϵ so that for all $\ell \geq k_\epsilon$ every circle in $G^{(\ell)}$ has radius less than ϵ .*

Proof. This was essentially proven by Rodin and Sullivan [23]; their proof, however, was stated for only the genus 0 case. The precise statement above was proven by Bowers and Stephenson [5]. \square

We get a new Riemann surface for each iteration of the refinement procedure. It is intuitive that, as the number of iterations grows and the circles in the refined graph get arbitrarily small, the Riemann surfaces will somehow converge, and the embedding of the graph on these Riemann surfaces will somehow stabilize. This can be made formal by the following lemma.

LEMMA 5.4. *Let G be a graph that triangulates a genus g compact Riemann surface without boundary, let $G^{(k)}$ be the result of performing k hexagonal refinements on G , and let $S^{(k)}$ be the Riemann surface on which $G^{(k)}$ is realized as a circle packing. Further, let $h_k : S^{(k)} \rightarrow S^{(k+1)}$ be the map that takes a triangle to its image under the subdivision procedure by the obvious piecewise-linear map. The sequence of surfaces $\{S^{(k)}\}$ converges in the moduli space of genus g surfaces, and the sequence of maps $\{h_k\}$ converges to the identity.*

Proof. This has been shown by Bowers and Stephenson [5]. \square

We shall also require one last definition, as follows.

DEFINITION 5.5. *Let $f : X \rightarrow Y$ be a map between two locally Euclidean metric spaces. The quantity*

$$H_f(x, r) = \frac{\max_{|x-y|=r} |f(x) - f(y)|}{\min_{|x-y|=r} |f(x) - f(y)|} - 1$$

is called the radius r distortion of f at x .

We are now finally ready to prove Theorem 2.3.

Proof of Theorem 2.3. Using the circle packing theorem (Theorem 4.6), realize the graph $G = G^{(0)}$ as a circle packing on some Riemann surface S of genus g . Let $G^{(k)}$ be the result of performing k hexagonal refinements on G , and let $S^{(k)}$ be the Riemann surface on which it can be realized as a circle packing. By Theorem 4.4, there exists an analytic map $f^{(k)}$ from $S^{(k)}$ to the Riemann sphere of degree $O(g)$

and with $O(g)$ branch points. Embed the Riemann sphere as the unit sphere in \mathbb{R}^3 using the conformal map given by inverse stereographic projection. By the work of Spielman and Teng (Theorem 9 of [25]), postcomposing with a Möbius transformation allows us to assume, without loss of generality, that the centroid of the images of the vertices of each $G^{(k)}$ under $f^{(k)}$ is the origin. By Lemma 5.4, the $S^{(k)}$ converge to some surface $S^{(\infty)}$, and the $f^{(k)}$ can be chosen so as to converge to some continuous limit map $f^{(\infty)}$.

By Lemma 5.2, it suffices to prove the theorem for an arbitrarily fine hexagonal refinement of the original graph. Away from its branch points, a map of Riemann surfaces is conformal, meaning it sends infinitesimal circles to infinitesimal circles. In particular, given a map $f : S \rightarrow \widehat{\mathbb{C}}$, the compactness of S guarantees that for every $\epsilon, \kappa > 0$ there exists a $\delta > 0$ so that the radius δ' distortion $H_f(x, \delta')$ is less than ϵ for every x that is at least distance κ from any branch point and any $\delta' \leq \delta$. In fact, by the convergence results of the last paragraph, there exist some N and δ such that this holds for every $f^{(k)}$ with $k > N$. Fix ϵ and κ , and let δ and N be chosen so that this is true. By possibly increasing N if necessary, we can assume by Lemma 5.3 that all of the circles on $S^{(k)}$ have radius at most δ for all $k > N$.

Let k be at least N . We shall break $S^{(k)}$ into two parts, $S^{(k)} = S_1^{(k)} \cup S_2^{(k)}$, as follows. Construct a ball of radius κ around each branch point of $f^{(k)}$, and let $S_2^{(k)}$ be the union of these balls. Let $S_1^{(k)}$ be the complement $S^{(k)} \setminus S_2^{(k)}$.

We can now use (5.3) to bound λ_2 , just as in the proof of Theorem 5.1. Let $G^{(k)}$ have n_k vertices. The denominator of (5.3) is equal to n_k , so it suffices to bound the numerator. We shall separately consider the circles contained entirely in $S_1^{(k)}$ and those that intersect $S_2^{(k)}$.

We begin with the circles contained in $S_1^{(k)}$. Every circle of the packing gets mapped by f to some connected region on $\widehat{\mathbb{C}}$, and there are at most $O(g)$ such regions covering any point of the sphere. Let C be a circle in $S_1^{(k)}$, let D be the diameter function, which takes a region to the length of the longest geodesic it contains, and let A be the area function. Since the radius δ distortion of f inside of $S_1^{(k)}$ is at most ϵ , and the radius of C is at most δ , the ratio $D^2(f(C))/A(f(C))$ is at most $O(1 + \epsilon)$. Using the same argument as in the proof of Theorem 5.1, the vertex at the center of a circle C cannot contribute more than $O(dD^2(f(C)))$ to the sum, and the total area of the regions from $S_1^{(k)}$ cannot exceed $O(g)$, so the total contribution to the numerator of the vertices in $S_1^{(k)}$ cannot be more than $O(dg(1 + \epsilon))$.

If this were the only term in the numerator, we could complete the proof by setting ϵ to be a constant. It thus remains to show that the contribution from the circles intersecting $S_2^{(k)}$ can be made small. To do this, we need only show that the contribution $\theta^{(k)}(x)$ to the numerator per unit area at a point x from these circles remains bounded as we subdivide, since we can make the area of $S_2^{(k)}$ arbitrarily small by sending κ to zero, and thus the area of the circles intersecting $S_2^{(k)}$ will go to zero as k goes to infinity and the circles get arbitrarily small. Our argument is similar to one used by McCaughan to analyze the recurrence of random walks on circle packings [20].

Let $x_i, i = 1, \dots, 3$, be the coordinate functions on \mathbb{R}^3 , and let $f^{(k)*}x_i$ be their pullbacks along $f^{(k)}$ to $S^{(k)}$. (That is, if y is a point on $S^{(k)}$, $f^{(k)*}x_i(y) = x_i(f^{(k)}(y))$.) In addition, let $C_1^{(k)}$ and $C_2^{(k)}$ be a pair of adjacent circles in $S_2^{(k)}$ with respective radii $r_1^{(k)}$ and $r_2^{(k)}$ and respective centers $c_1^{(k)}$ and $c_2^{(k)}$. The contribution of the correspond-

ing edge in $G^{(k)}$ to the numerator of (5.3) will be

$$(5.4) \quad \left\| \left(f^{(k)*} x_i(c_1^{(k)}) \right)_{i=1}^3 - \left(f^{(k)*} x_i(c_2^{(k)}) \right)_{i=1}^3 \right\|^2 = \sum_{i=1}^3 \left(f^{(k)*} x_i(c_1^{(k)}) - f^{(k)*} x_i(c_2^{(k)}) \right)^2.$$

The distance between $c_1^{(k)}$ and $c_2^{(k)}$ equals $r_1^{(k)} + r_2^{(k)}$. As k goes to infinity, the radii $r_1^{(k)}$ and $r_2^{(k)}$ both go to zero, by Lemma 5.3. By the smoothness of the $f^{(k)}$, their convergence to $f^{(\infty)}$, and the compactness of their domains, we can approximate each term on the right-hand side of (5.4) arbitrarily well by its first order approximation, so that

$$(5.5) \quad \left(f^{(k)*} x_i(c_1^{(k)}) - f^{(k)*} x_i(c_2^{(k)}) \right)^2 \leq (1 + o(1))(r_1^{(k)} + r_2^{(k)})^2 \|\nabla f^{(k)*} x_i(c_1^{(k)})\|^2$$

as k goes to infinity and the distance between $c_1^{(k)}$ and $c_2^{(k)}$ shrinks to zero.

The right-hand side of (5.5) is bounded above by

$$(5.6) \quad (2 + o(1))[(r_1^{(k)})^2 + (r_2^{(k)})^2] \|\nabla f^{(k)*} x_i(c_1^{(k)})\|^2 = O(1)[(r_1^{(k)})^2 \|\nabla f^{(k)*} x_i(c_1^{(k)})\|^2 + (r_2^{(k)})^2 \|\nabla f^{(k)*} x_i(c_2^{(k)})\|^2].$$

The degree of our graph is bounded, so every vertex appears in at most a constant number of edges. If we sum the right-hand side of (5.6) over all of the edges in our graph, the total contribution of terms involving a fixed circle of radius r centered at c is thus bounded above by

$$O(1)r^2 \|\nabla f^{(k)*} x_i(c)\|^2,$$

so the contribution per unit area is bounded above by

$$O(1) \|\nabla f^{(k)*} x_i(c)\|^2.$$

This clearly remains bounded as k goes to infinity and $f^{(k)}$ approaches $f^{(\infty)}$. It thus follows that the contribution to the numerator of (5.3) of the vertices in $S_2^{(k)}$ tends to zero as k goes to infinity and κ is made arbitrarily small. By setting ϵ to be a constant and sending κ to zero, Theorem 2.3 follows. \square

6. The proof of Lemma 5.2. In this section, we shall prove Lemma 5.2. In proving this bound, it will be convenient to consider the following weighted form of the Laplacian.

DEFINITION 6.1. *The weighted Laplacian $\mathcal{L}^W(G)$ of a graph G is the matrix*

$$\mathcal{L}^W(G) = W^{-1/2}L(G)W^{-1/2},$$

where $L(G)$ is the Laplacian of G , and W is a diagonal matrix whose i th diagonal entry w_i is strictly positive for all i .

We shall denote the eigenvalues of $\mathcal{L}^W(G)$ by $\tilde{\lambda}_1^W(G) \leq \dots \leq \tilde{\lambda}_n^W(G)$ and the corresponding eigenvectors by $\tilde{v}_1^W(G) \dots \tilde{v}_n^W(G)$. A straightforward calculation shows

that the weighted Laplacian has $\tilde{\lambda}_1^W = 0$ and $\tilde{v}_1^W = W^{1/2}\mathbf{1}$. Our main quantity of interest will be $\tilde{\lambda}_2^W(G)$, which we can compute using a weighted analogue of the Rayleigh quotient:

$$(6.1) \quad \tilde{\lambda}_2^W = \min_{x \perp W\mathbf{1}} \frac{\sum_{(i,j) \in E} (x_i - x_j)^2}{\sum_i x_i^2 w_i}.$$

The second eigenvector $\tilde{v}_2^W(G)$ equals $W^{1/2}x$, where x is the vector that achieves the minimum in (6.1).

If all of the weights are $\Theta(1)$, standard linear algebra shows that $\lambda_2(G)$ and $\tilde{\lambda}_2^W(G)$ differ by at most a constant factor, so proving a bound on one implies a bound on the other. (See Chung’s book [9] for detailed proofs of the above facts and for other foundational information about the weighted Laplacian.)

Before we can proceed to the body of the proof of Lemma 5.2, we require two fairly general technical lemmas about independent random variables.

LEMMA 6.2. *Let a_1, \dots, a_n be independent real-valued random variables, possibly drawn from different probability distributions. Let $w_1, \dots, w_n \in \mathbb{R}^+$ be strictly positive constants. If the expectation $\mathbb{E}[\sum_i w_i a_i] = 0$, then*

$$\mathbb{E} \left[\left(\sum_j w_j a_j \right)^2 \right] \leq \mathbb{E} \left[\sum_j w_j^2 a_j^2 \right].$$

Proof. This follows by expanding the left-hand side:

$$\begin{aligned} \mathbb{E} \left[\left(\sum_j w_j a_j \right)^2 \right] &= \mathbb{E} \left[\sum_i w_i^2 a_i^2 \right] + \mathbb{E} \left[\sum_i w_i a_i \left(\sum_{j \neq i} w_j a_j \right) \right] \\ &= \mathbb{E} \left[\sum_i w_i^2 a_i^2 \right] + \sum_i -(\mathbb{E}[w_i a_i])^2 \\ &\leq \mathbb{E} \left[\sum_j w_j^2 a_j^2 \right], \end{aligned}$$

where the second equality follows from the independence of the variables and the fact that the sum of their expectations is zero. \square

We shall now use this lemma to establish our second lemma, which is the one that will actually appear in our main proof.

LEMMA 6.3. *Let a_1, \dots, a_n be independent real-valued random variables, possibly drawn from different probability distributions, and let $w_1, \dots, w_n \in \mathbb{R}^+$ be strictly positive constants such that $\mathbb{E}[\sum_i w_i a_i] = 0$. Let $a = (a_1, \dots, a_n)$, and let $w_{\max} = \max_i w_i$. Further let*

$$b = \left(\frac{1}{\sum_i w_i} \sum_i w_i a_i \right) \mathbf{1} \quad \text{and} \quad c = a - b.$$

Then

$$\mathbb{E} \left[\sum_i w_i c_i^2 \right] \geq \left(1 - \frac{w_{\max}}{\sum_i w_i} \right) \mathbb{E} \left[\sum_i w_i a_i^2 \right].$$

Proof. This follows by direct calculation:

$$\begin{aligned}
\mathbb{E} \left[\sum_i w_i c_i^2 \right] &= \mathbb{E} \left[\sum_i w_i \left(a_i - \frac{1}{\sum_j w_j} \left(\sum_j w_j a_j \right) \right)^2 \right] \\
&= \mathbb{E} \left[\sum_i w_i a_i^2 \right] + \frac{1}{(\sum_i w_i)^2} \mathbb{E} \left[\sum_i w_i \left(\sum_j w_j a_j \right)^2 \right] \\
&\quad - \frac{2}{\sum_i w_i} \mathbb{E} \left[\sum_i w_i a_i \left(\sum_j w_j a_j \right) \right] \\
&= \mathbb{E} \left[\sum_i w_i a_i^2 \right] + \frac{1}{\sum_i w_i} \mathbb{E} \left[\left(\sum_j w_j a_j \right)^2 \right] - \frac{2}{\sum_i w_i} \mathbb{E} \left[\left(\sum_j w_j a_j \right)^2 \right] \\
&= \mathbb{E} \left[\sum_i w_i a_i^2 \right] - \frac{1}{\sum_i w_i} \mathbb{E} \left[\left(\sum_j w_j a_j \right)^2 \right] \\
&\geq \mathbb{E} \left[\sum_i w_i a_i^2 \right] - \frac{1}{\sum_i w_i} \mathbb{E} \left[\sum_j w_j^2 a_j^2 \right] \\
&= \mathbb{E} \left[\sum_i \left(1 - \frac{w_i}{\sum_j w_j} \right) w_i a_i^2 \right] \\
&\geq \left(1 - \frac{w_{\max}}{\sum_i w_i} \right) \mathbb{E} \left[\sum_i w_i a_i^2 \right],
\end{aligned}$$

where second-to-last inequality follows from Lemma 6.2. \square

We are now prepared to prove Lemma 5.2.

Proof of Lemma 5.2. Let $G = (V_G, E_G)$ be the original graph, and let $G' = (V_{G'}, E_{G'})$ be the graph that results from performing k successive hexagonal refinements on G . The embeddings into surfaces endow both G and G' with triangulations; let T_G and $T_{G'}$ be the respective sets of triangles in these triangulations. There is a natural inclusion $\iota : V_G \hookrightarrow V_{G'}$, since the subdivision procedure only adds vertices to the original set. There is also a map $\eta : T_{G'} \rightarrow T_G$ that takes a triangle from the subdivided graph to the one in the original graph from which it arose. For a vertex v in either graph, let $N(v)$ be the set of triangles containing it. For a vertex $w \in V_G$, let $P(w) = \eta^{-1}(N(w))$ be the set of triangles in $T(G')$ taken by η to elements of $N(w)$. (See Figure 6.1.)

Our proof will proceed by producing a randomized construction of a subgraph H of G' . Given a vector that assigns a value to every vertex of G' , we can obtain such a vector on H by restriction. We shall also show how to use such a vector on H to construct such a vector on G . The vectors on the different graphs will give rise to Rayleigh quotients on the graphs (some of which will be weighted), where the Rayleigh quotients for G and H will depend on the random choices made in the construction of H . By relating the terms in the different Rayleigh quotients, we shall then provide a probabilistic proof that there exists an H that gives rise to a small Rayleigh quotient

FIG. 6.1. A subdivided graph, with $P(w)$ and $N(w)$ shaded for a vertex w .

on G , which will suffice to prove our desired bound.

H will be produced by randomly choosing a representative in $V_{G'}$ for each vertex in V_G and representing every edge in E_G by a randomly chosen path in G' between the representatives of its endpoints.

We first construct the map $\pi_V : V_G \rightarrow V_{G'}$ that chooses the representatives of the vertices. For each $v \in V_G$ we choose $\pi_V(v)$ uniformly at random from the vertices contained in $P(v)$ that are at least as close to $\iota(v)$ as to $\iota(w)$ for any other $w \in V_G$. Vertices in $P(v)$ that are equally close to $\iota(v)$ and $\iota(w)$ should be arbitrarily assigned to either v or w , but not both.

We now construct π_E , which maps edges in E_G to paths in G' . Let $e = (v_1, v_2)$ be an edge in G , and let w_1 and w_2 equal $\pi_V(v_1)$ and $\pi_V(v_2)$, respectively. The two neighborhoods in G , $N(v_1)$ and $N(v_2)$, share exactly two triangles, t_1 and t_2 . Let x be a vertex randomly chosen from the vertices in $\eta^{-1}(t_1 \cup t_2)$. We shall construct a path from each w_i ($i = 1, 2$) to x , so that their composition gives a path from w_1 to w_2 . We shall use the same construction for each, so, without loss of generality, we shall just construct the path from w_1 to x .

Both w_1 and x are in $P(v_1)$, and we give a general procedure for constructing a path between any two such vertices. The images under the inclusion ι of the triangles in $N(v_1)$ encircle $\iota(v_1)$. Suppose w_1 is contained in T_1 , and x is contained in T_2 . Traversing the triangles in a clockwise order from T_1 to T_2 gives one list of triangles, and traversing in a counterclockwise order gives another. Let $T_1, Q_1, \dots, Q_\ell, T_2$ be the shorter of these two lists, with a random choice made if the two lists are the same length. Choose a random vertex a_i in each Q_i , and let $a_0 = w_1$ and $a_{\ell+1} = x$. We thus have a vertex representing each triangle in the list. Our path will consist of a sequence of segments from each representative to the next.

Note that all of the triangles are distinct, except if $T_1 = T_2$ and the list is of length 2. We suppose for now that we have two vertices a_i and a_{i+1} in distinct triangles, and we deal with the degenerate case later. The two triangles in question

FIG. 6.2. An illustration of how the grid graph exists as a subgraph of the union of two adjacent subdivided triangles.

FIG. 6.3. The entire construction illustrated for a given edge of the original graph.

are adjacent, and their union contains a grid graph as a subgraph. (See Figure 6.2.) Given two vertices in a grid, there is a unique path between them that one obtains by first moving horizontally and then vertically, and another that one obtains by moving vertically and then horizontally. (These two coincide if there is a line connecting the two points.) Randomly choose one of these two paths. This is the path connecting a_i to a_{i+1} . If a_i and a_{i+1} lie in the same triangle, randomly choose one of the two adjacent triangles to form a grid, and then use the above construction. Composing the paths between each a_i and a_{i+1} completes the construction of π_E . The entire construction is illustrated in Figure 6.3.

We now consider the Rayleigh quotients for the three graphs that we have con-

structed. After k hexagonal refinements, every edge in G is split into $r = 2^k$ pieces, every triangle gets replaced with r^2 smaller triangles, and the number of vertices grows quadratically in r . A vector $y \in \mathbb{R}^{|V_{G'}|}$ that assigns a value to each vertex in G' gives the Rayleigh quotient

$$R(G') = \frac{\sum_{(i,j) \in E_{G'}} (y_i - y_j)^2}{y^T y}.$$

This induces a vector on the vertices of H by restriction. The probability, taken over the random choices in the construction of π_V and π_E , that a given edge of G' appears on the path representing a given edge e of G is zero if it is not in $P(\alpha)$ with α equal to one of the endpoints of e , and at most $O(1/r)$ otherwise. Since the maximum degree of a vertex in G is assumed constant, the expected number of times that a given edge of G' occurs in H is $O(1/r)$. Every vertex in G' is selected as a representative of a vertex in G with probability $\Theta(1/r^2)$. It thus follows that

$$(6.2) \quad \mathbb{E} \left[\sum_{(i,j) \in E_H} (y_i - y_j)^2 \right] \leq O\left(\frac{1}{r}\right) \sum_{(i,j) \in E_{G'}} (y_i - y_j)^2$$

and

$$(6.3) \quad \mathbb{E} \left[\sum_{i \in V_G} w_i y_{\pi_V(i)}^2 \right] = \Theta\left(\frac{1}{r^2}\right) \sum_{i \in V_{G'}} y_i^2,$$

where the expectations are taken over the random choices in the construction of (π_V, π_E) , and the w_i are any weights that are bounded above and below by positive constants.

Let \bar{y} be the vector in $\mathbb{R}^{|V_G|}$ whose i th coordinate is $y_{\pi_V(i)}$. Each coordinate \bar{y}_i of \bar{y} is chosen independently from a distinct set S_i of the coordinates of y , and every coordinate is contained in one of these sets. Let $s_i = |S_i|$, let $s_{\min} = \min_i s_i$, and take W to be the diagonal matrix whose i th diagonal entry w_i equals s_i/s_{\min} . The probability that a given vertex in S_i is selected equals $1/s_i$, so we have that

$$\mathbb{E} \left[\sum_{j \in V_G} w_j \bar{y}_j \right] = \sum_{k \in V_{G'}} y_k = 0.$$

(The need to weight the terms on the left-hand side of this expression by the w_i is what will necessitate the use of the weighted Laplacian in our proof.) The size of each S_i is approximately proportional to the degree of the i th vertex of G , so the w_i are all bounded above by a constant, and they are all at least one by definition. The eigenvalue $\tilde{\lambda}_2^W(G)$ of the weighted Laplacian is thus within a constant factor of the standard Fiedler value $\lambda_2(G)$.

Let z be the vector

$$z = \bar{y} - \left(\frac{\sum_i w_i \bar{y}_i}{\sum_i w_i} \right) \mathbf{1},$$

so that z differs from \bar{y} by a multiple of the all-ones vector and is orthogonal to $W\mathbf{1}$. By applying Lemma 6.3 to (6.3), we obtain

$$(6.4) \quad \mathbb{E} \left[\sum_{i \in V_G} w_i z_i^2 \right] \geq \left(1 - \frac{w_{\max}}{\sum_i w_i} \right) \mathbb{E} \left[\sum_{i \in V_G} w_i \bar{y}_i^2 \right] = \Theta\left(\frac{1}{r^2}\right) \sum_{i \in V_{G'}} y_i^2.$$

Multiplying the inequalities in (6.2) and (6.4) by the appropriate factors and combining them yields

$$(6.5) \quad O(r) \left(\sum_{(i,j) \in E_{G'}} (y_i - y_j)^2 \right) \cdot \mathbb{E} \left[\sum_{i \in V_G} w_i z_i^2 \right] \geq \left(\sum_{i \in V_{G'}} y_i^2 \right) \cdot \mathbb{E} \left[\sum_{(i,j) \in E_H} (y_i - y_j)^2 \right].$$

This implies that there exists some choice of (π_V, π_E) for which the left-hand side of (6.5) is greater than or equal to the right-hand side, in which case we would have

$$(6.6) \quad \frac{\sum_{(i,j) \in E_H} (y_i - y_j)^2}{\sum_{i \in V_G} w_i z_i^2} \leq O(r) \frac{\sum_{(i,j) \in E_{G'}} (y_i - y_j)^2}{\sum_{i \in V_{G'}} y_i^2} = O(r)R(G').$$

Now suppose that we assign to each vertex $v \in V_G$ the value assumed by y at $\pi_V(v)$. Using the fact that the maximum degree of a vertex is bounded, so that there are $O(1)$ triangles surrounding any vertex in G , we see that every path representing an edge is of length $O(r)$. We note that if i_1, \dots, i_s is a sequence of vertices,

$$(y_{i_s} - y_{i_1})^2 \leq s \sum_{a=1}^{s-1} (y_{i_{a+1}} - y_{i_a})^2.$$

As such, we have

$$(6.7) \quad \sum_{(i,j) \in E_G} (y_{\pi_V(i)} - y_{\pi_V(j)})^2 \leq O(r) \sum_{(i,j) \in E_H} (y_i - y_j)^2.$$

Since z is obtained from \bar{y} by subtracting a multiple of the all-ones vector,

$$z_i - z_j = y_{\pi_V(i)} - y_{\pi_V(j)}$$

for any i and j . Plugging this into (6.7) gives

$$\sum_{(i,j) \in E_G} (z_i - z_j)^2 \leq O(r) \sum_{(i,j) \in E_H} (y_i - y_j)^2,$$

and applying this to the inequality in (6.6) yields

$$\frac{\sum_{(i,j) \in E_G} (z_i - z_j)^2}{\sum_{i \in V_G} w_i z_i^2} \leq O(r^2)R(G').$$

We have thus constructed an assignment of values to the vertices of G that is orthogonal to the vector $W\mathbf{1}$ and produces a weighted Rayleigh quotient of $O(r^2)R(G')$. If we choose the y_i to be the values that give the Fiedler value of G' , we thus obtain, by (6.1) and the fact that the w_i are $\Theta(1)$,

$$\lambda_2(G) = \Theta(1)\tilde{\lambda}_2^W(G) \leq O(r^2)\lambda_2(G').$$

Since the number of vertices in G' grows as r^2 times the number of vertices in G , this completes the proof of Lemma 5.2. \square

USING NONDETERMINISM TO AMPLIFY HARDNESS*

ALEXANDER HEALY[†], SALIL VADHAN[†], AND EMANUELE VIOLA[†]

Abstract. We revisit the problem of hardness amplification in \mathcal{NP} , as recently studied by O’Donnell [*J. Comput. System Sci.*, 69 (2004), pp. 68–94]. We prove that if \mathcal{NP} has a balanced function f such that any circuit of size $s(n)$ fails to compute f on a $1/\text{poly}(n)$ fraction of inputs, then \mathcal{NP} has a function f' such that any circuit of size $s'(n) = s(\sqrt{n})^{\Omega(1)}$ fails to compute f' on a $1/2 - 1/s'(n)$ fraction of inputs. In particular,

1. if $s(n) = n^{\omega(1)}$, we amplify to hardness $1/2 - 1/n^{\omega(1)}$;
2. if $s(n) = 2^{n^{\Omega(1)}}$, we amplify to hardness $1/2 - 1/2^{n^{\Omega(1)}}$;
3. if $s(n) = 2^{\Omega(n)}$, we amplify to hardness $1/2 - 1/2^{\Omega(\sqrt{n})}$.

Our results improve those of O’Donnell, which amplify to $1/2 - 1/\sqrt{n}$. O’Donnell also proved that no construction of a certain general form could amplify beyond $1/2 - 1/n$. We bypass this barrier by using both *derandomization* and *nondeterminism* in the construction of f' .

We also prove impossibility results demonstrating that both our use of nondeterminism and the hypothesis that f is balanced are necessary for “black-box” hardness amplification procedures (such as ours).

Key words. average-case complexity, hardness amplification, pseudorandom generators for space-bounded computation, noise stability

AMS subject classifications. 68Q01, 68Q17

DOI. 10.1137/S0097539705447281

1. Introduction. *Average-case complexity* is a fundamental topic in complexity theory, whose study has at least two distinct motivations. On the one hand, it may provide more meaningful explanations than worst-case complexity about the intractability of problem instances actually encountered in practice. On the other hand, it provides us with methods for generating hard instances, allowing us to harness intractability for useful ends such as cryptography and derandomization.

One of the goals of this area is to establish connections between average-case complexity and worst-case complexity. While this has been accomplished for high complexity classes such as $\#\mathcal{P}$ and $\mathcal{EXPTIME}$ (e.g., [2, 4, 7, 8, 25, 33, 35, 37]), it remains a major open question for \mathcal{NP} . In fact, there are results showing that such connections for \mathcal{NP} are unlikely to be provable using the same kinds of techniques used for the high complexity classes [6, 9, 37, 38].

A more modest goal is “hardness amplification,” where we seek to establish connections between “mild” average-case complexity and “strong” average-case complexity. That is, given a problem for which a nonnegligible fraction of inputs are “hard,” can we obtain a problem for which almost all inputs are hard? To make this precise, let us define “hard.”

DEFINITION 1.1. For $\delta \in [0, 1/2]$, a function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ is δ -hard for size s if every circuit of size s fails to compute f on at least a δ fraction of inputs.

Note that the maximum value of the hardness parameter δ is $1/2$ because f is Boolean (and so can trivially be computed with error probability at most $1/2$). This notion of hardness is fairly standard (e.g., in the literature on derandomization starting from [30]), but we remark that it differs from Levin’s notion of average-case complexity [24] in several ways. Most importantly, Levin’s formulation corresponds to algorithms that always either give the correct answer or say “don’t know,” whereas we consider even “heuristic” algorithms that can make arbitrary errors. (See Impagliazzo’s survey [19].)

The *hardness amplification problem* is to convert a function f that is δ -hard for size s into a function f' that is $(1/2 - \epsilon)$ -hard for size polynomially related to s . Commonly, $\delta = 1/\text{poly}(n)$, and the aim is to make $\epsilon = \epsilon(n)$ vanish as quickly as possible.

The standard approach to hardness amplification employs Yao’s XOR lemma [39] (see [15]): Given a mildly hard-on-average function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, we define $f' : \{0, 1\}^{n \cdot k} \rightarrow \{0, 1\}$ by

$$f'(x_1, \dots, x_k) \stackrel{\text{def}}{=} f(x_1) \oplus f(x_2) \oplus \dots \oplus f(x_k).$$

The XOR Lemma says that the hardness of f' approaches $1/2$ exponentially fast with k . More precisely, this can be stated as follows.

YAO’S XOR LEMMA. If f is δ -hard for size $s(n) \geq n^{\omega(1)}$ and $k \leq \text{poly}(n)$, then f' is $(1/2 - 1/2^{\Omega(\delta k)} - 1/s')$ -hard for size $s'(n \cdot k) = s(n)^{\Omega(1)}$.

In particular, taking $k = \Theta(n/\delta)$, the amplified hardness is dominated by the $1/s'$ term. That is, we can amplify to hardness $(1/2 - \epsilon)$, where ϵ is polynomially related to the (reciprocal of the) circuit size for which f was hard. (Note, however, that we should measure $\epsilon = \epsilon(n')$ as a function of the new input length $n' = n \cdot k$, so when $k = n$, the hardness is actually $1/2 - 1/s(\sqrt{n'})^{\Omega(1)}$.)

However, if we are interested in hardness amplification within \mathcal{NP} (i.e., f and f' are characteristic functions of languages in \mathcal{NP}), we cannot use the XOR lemma; it does not ensure that f' is in \mathcal{NP} when f is in \mathcal{NP} . Hardness amplification within \mathcal{NP} was first addressed in a recent paper of O’Donnell [31], which is the starting point for our work.

1.1. O’Donnell’s hardness amplification. To ensure that the new function f' is in \mathcal{NP} when f is in \mathcal{NP} , O’Donnell [31] was led to study constructions of the form

$$(1) \quad f'(x_1, \dots, x_k) \stackrel{\text{def}}{=} C(f(x_1), f(x_2), \dots, f(x_k)),$$

where C is an efficiently computable *monotone* function. The monotonicity of C ensures that f' is in \mathcal{NP} when f is in \mathcal{NP} . However, we are left with the task of choosing such a function C and proving that it indeed amplifies hardness.

Remarkably, O’Donnell was able to precisely characterize the amplification properties of construction (1) in terms of a combinatorial property of the combining function C , called its *expected bias*. (The actual definition is not needed for this discussion, but can be found in section 3.) By finding a monotone combining function in which this expected bias is small, he obtained the first positive result on hardness amplification in \mathcal{NP} , given next.

O'DONNELL'S THEOREM (see [31]). *If \mathcal{NP} contains a balanced function that is $1/\text{poly}(n)$ -hard for polynomial-size circuits, then \mathcal{NP} contains a function that is $(1/2 - 1/n^{1/2-\alpha})$ -hard for polynomial-size circuits (where α is an arbitrarily small positive constant).*

However, the amplification provided by O'Donnell's theorem is not as strong as what the XOR lemma gives. It is limited to $1/2 - 1/\sqrt{n}$, regardless of the circuit size s for which the original function is hard, even if s is exponentially large. The XOR lemma, on the other hand, amplifies to $1/2 - 1/s^{\Omega(1)}$. O'Donnell showed that this difference is inherent—no construction of the form (1) with a monotone combining function C can always amplify hardness to better than $1/2 - 1/n$.¹

1.2. Our result. In this paper, we manage to amplify hardness within \mathcal{NP} beyond the $1/2 - 1/n$ barrier, as described in the following.

THEOREM 1.2 (main theorem). *If \mathcal{NP} contains a balanced function that is $1/\text{poly}(n)$ -hard for circuits of size $s(n)$, then \mathcal{NP} contains a function that is $(1/2 - 1/s'(n))$ -hard for circuits of size $s'(n)$ for some function² $s'(n) = s(\sqrt{n})^{\Omega(1)}$. In particular,*

1. *if $s(n) = n^{\omega(1)}$, we amplify to hardness $1/2 - 1/n^{\omega(1)}$;*
2. *if $s(n) = 2^{n^{\Omega(1)}}$, we amplify to hardness $1/2 - 1/2^{n^{\Omega(1)}}$;*
3. *if $s(n) = 2^{\Omega(n)}$, we amplify to hardness $1/2 - 1/2^{\Omega(\sqrt{n})}$.*

Items 1–3 match the parameters of the Yao's XOR lemma. However, subsequent “derandomizations” of the XOR lemma [18, 20] actually amplify up to $1/2 - 1/2^{\Omega(n)}$ rather than just $1/2 - 1/2^{\Omega(\sqrt{n})}$ in the case $s(n) = 2^{\Omega(n)}$. This gap is *not* inherent in our approach and, as mentioned below, would be eliminated given a corresponding improvement in one of the tools we employ.

Of course, our construction cannot be of the form in construction (1). Below we describe our two main points of departure.

1.3. Techniques. To explain how we bypass it, we first look more closely at the source of the $1/2 - 1/n$ barrier. The actual barrier is $1/2 - 1/k$, where k is the input length of the monotone combining function C . (This is based on a result of [22]; see [31].) Since in construction (1), f' has input length $n' = n \cdot k \geq k$, it follows that we cannot amplify beyond $1/2 - 1/n'$.

Derandomization. Given the above, our first idea is to break the link between the input length of f' and the input length of the combining function C . We do this by *derandomizing* O'Donnell's construction. That is, the inputs x_1, \dots, x_k are no longer taken independently (as in construction (1)), but are generated pseudorandomly from a short seed of length $n' \ll k$, which becomes the actual input to f' . Our method for generating the x_i 's is based on combinatorial designs (as in the Nisan–Wigderson generator [30]) and Nisan's pseudorandom generator for space-bounded computation [29]; it reduces the input length of f' from $n \cdot k$ to $n' = O(n^2 + \log^2 k)$. We stress that this derandomization is unconditional, i.e., requires no additional complexity assumption. We also remark that it is the quadratic seed length of Nisan's generator that limits our amplification to $1/2 - 1/2^{\Omega(\sqrt{n})}$ rather than $1/2 - 1/2^{\Omega(n)}$ in part 3 of our main

¹The gap between O'Donnell's positive result of $1/2 - 1/\sqrt{n}$ and his negative result of $1/2 - 1/n$ is not significant for what follows, and in particular it will be subsumed by our improvements.

²In the rest of the paper, we more compactly write “for circuits of size $s'(n) = s(\sqrt{n})^{\Omega(1)}$,” where the $\Omega(1)$ is to be interpreted as a fixed constant (possibly depending on previously quantified constants).

theorem, and thus any improvement in Nisan’s generator would yield a corresponding improvement in our result.

Similar derandomizations have previously been achieved for Yao’s XOR lemma by Impagliazzo [18] and Impagliazzo and Wigderson [20]. The analysis of such derandomizations is typically tailored to a particular proof, and indeed [18, 20] each gave a new proof of the XOR lemma for that purpose. In our case, we do not know how to derandomize O’Donnell’s original proof, but instead manage to derandomize a different proof due to Trevisan [34].

Our derandomization allows for k to be larger than the input length of f' , and hence we can go beyond the $1/2 - 1/n'$ barrier. Indeed, by taking k to be a sufficiently large polynomial, we amplify to $1/2 - 1/(n')^c$ for any constant c .

Using nondeterminism. To amplify further, it is tempting to take k superpolynomial in the input length of f' . But then we run into a different problem: how do we ensure that f' is in \mathcal{NP} ? The natural algorithm for f' requires running the algorithm for f on k inputs.

To overcome this difficulty, we observe that we need only give an efficient *nondeterministic* algorithm for f' . Each nondeterministic path may involve only polynomially many evaluations of f , while the global outcome $f'(x)$ depends on exponentially many evaluations. To implement this idea, we exploit the specific structure of the combining function C . Namely, we (like O’Donnell) use the Tribes function of Ben-Or and Linial [5], which is a monotone DNF with clauses of size $O(\log k)$. Thus, the nondeterministic algorithm for f' can simply guess a satisfied clause and (nondeterministically) evaluate f on the $O(\log k)$ corresponding inputs.

1.4. Other results. We also present some complementary negative results:

- We show that the assumption that the original hard function is balanced is necessary, in the sense that no monotone “black-box” hardness amplification can amplify unbalanced functions of unknown bias (or even improve their bias).³
- We show that our use of nondeterminism is necessary, in the sense that any “black-box” hardness amplification in which each evaluation of f' is a monotone function of at most k evaluations of f can amplify hardness to at most $1/2 - 1/k$.

Informally, a “black-box” hardness amplification is one in which the construction of the amplified function f' from f utilizes f only as an oracle and is well defined for any function f (regardless of whether or not it is in \mathcal{NP}). Moreover, the correctness of the construction is proved by a generic reduction that converts any *oracle* A (regardless of its circuit size) that computes f' well on average (e.g., with probability $1/2 + \epsilon$ over random choice of input) into one that computes f much better on average (e.g., with probability $1 - o(1)$ over random input). (A formal definition is given in section 7.1.) We note that most results on hardness amplification against circuits, including ours, are black-box (though there have been some recent results using non-black-box techniques in hardness amplification against *uniform* algorithms; see [21, 35]).

Our framework also gives a new proof of the hardness amplification by Impagliazzo and Wigderson [20]. Our proof is simpler, and in particular its analysis does not employ the Goldreich–Levin [14] step.

³We note that there do exist balanced \mathcal{NP} -complete problems, as observed by Barak and reported in [10], but this has no direct implication for us because we are studying the average-case complexity of \mathcal{NP} .

1.5. Organization. The rest of the paper is organized as follows. In section 2, we discuss some preliminaries. In section 3, we review existing results on hardness amplification in \mathcal{NP} . In section 4, we present our main results and new techniques. In section 5 we treat the details of the proof of our main theorem. In section 6 we show how we could amplify to $1/2 - 1/2^{\Omega(n)}$, given an improvement in the pseudorandom generator we use, and we also give a new proof of the hardness amplification by Impagliazzo and Wigderson [20]. In section 7 we discuss some limitations of monotone hardness amplification; in particular we show a sense in which the hypothesis that the starting function is balanced is necessary, and also that the use of nondeterminism is necessary.

2. Preliminaries. We denote the uniform distribution on $\{0, 1\}^n$ by U_n . If U_n occurs more than once in the same expression, it is understood that these all represent the same random variable; for example, $U_n \cdot f(U_n)$ denotes the random variable obtained by choosing X uniformly at random in $\{0, 1\}^n$ and outputting $X \cdot f(X)$ (where \cdot means concatenation).

DEFINITION 2.1. *Let X and Y be two random variables taking values over the same set S . Then the statistical difference between X and Y is*

$$\Delta(X, Y) \stackrel{\text{def}}{=} \max_{T \subseteq S} \left| \Pr[X \in T] - \Pr[Y \in T] \right|.$$

We view probabilistic functions as functions of two inputs, e.g., $h(x; r)$, the first being the input to the function and the second being the randomness. (Deterministic functions may be thought of as probabilistic functions that ignore the randomness.) For notational convenience, we will often omit the second input to a probabilistic function, e.g., writing $h(x)$ instead of $h(x; r)$, in which case we view $h(x)$ as the random variable $h(x; U_{|r|})$.

DEFINITION 2.2. *The bias of a 0-1 random variable X is*

$$\text{Bias}[X] \stackrel{\text{def}}{=} \left| \Pr[X = 0] - \Pr[X = 1] \right| = 2 \cdot \Delta(X, U_1).$$

Analogously, the bias of a probabilistic function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ is

$$\text{Bias}[f] \stackrel{\text{def}}{=} \left| \Pr[f(U_n) = 0] - \Pr[f(U_n) = 1] \right|,$$

where the probabilities are taken over both the input chosen according to U_n and the coin tosses of f . We say that f is balanced when $\text{Bias}[f] = 0$.

Note that the bias of a random variable is a quantity between 0 and 1.

We say that the random variables X and Y are ϵ -indistinguishable for size s if for every circuit C of size s ,

$$\left| \Pr_X[C(X) = 1] - \Pr_Y[C(Y) = 1] \right| \leq \epsilon.$$

We will routinely use the following connection between hardness and indistinguishability.

LEMMA 2.3 (see [39]). *Let $h : \{0, 1\}^n \rightarrow \{0, 1\}$ be any probabilistic function. If the distributions $U_n \cdot h(U_n)$ and $U_n \cdot U_1$ are ϵ -indistinguishable for size s , then h is $(1/2 - \epsilon)$ -hard for size $s - O(1)$. Conversely, if h is $(1/2 - \epsilon)$ -hard for size s , then the distributions $U_n \cdot h(U_n)$ and $U_n \cdot U_1$ are ϵ -indistinguishable for size $s - O(1)$.*

Finally, whenever we amplify the hardness of a function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ that is hard for circuits of size $s(n)$, we assume that $s(n)$ is well behaved in the sense that

it is computable in time $\text{poly}(n)$ and $s(cn) = s(n)^{O(1)}$, for all constants $c > 0$. Most natural functions smaller than 2^n , such as $n^k, 2^{\log^k n}, 2^{n^\epsilon}, 2^{\epsilon n}$, are well behaved in this sense.

3. Overview of previous hardness amplification in \mathcal{NP} . In this section we review the essential components of existing results on hardness amplification in \mathcal{NP} . We then discuss the limitations of these techniques. By the end of this section, we will have sketched the main result of O’Donnell [31], following the approach of Trevisan [34]. We outline this result in a way that will facilitate the presentation of our results in subsequent sections.

Let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be an average-case hard function, and let $C : \{0, 1\}^k \rightarrow \{0, 1\}$ be any function. In [31], O’Donnell studies the hardness of functions of the form

$$C \circ f^{\otimes k} : (\{0, 1\}^n)^k \rightarrow \{0, 1\},$$

where $f^{\otimes k}(x_1, \dots, x_k) \stackrel{\text{def}}{=} (f(x_1), \dots, f(x_k))$ and \circ denotes composition. That is,

$$(C \circ f^{\otimes k})(x_1, \dots, x_k) \stackrel{\text{def}}{=} C(f(x_1), \dots, f(x_k)).$$

In order to ensure that $C \circ f^{\otimes k} \in \mathcal{NP}$ whenever $f \in \mathcal{NP}$, O’Donnell chooses C to be a polynomial-time computable *monotone* function. (Indeed, it is not hard to see that a monotone combination of \mathcal{NP} functions is itself in \mathcal{NP} .)

O’Donnell characterizes the hardness of $C \circ f^{\otimes k}$ in terms of a combinatorial property of the combining function C , called its *expected bias* (which we define later). We will now review the key steps in establishing this characterization and O’Donnell’s final amplification theorem.

Step 1: Impagliazzo’s hardcore sets. An important tool for establishing this connection is the hardcore set lemma of Impagliazzo [18], which allows us to pass from computational hardness to information-theoretic hardness.

DEFINITION 3.1. *We say that a (probabilistic) function $g : \{0, 1\}^n \rightarrow \{0, 1\}$ is δ -random if g is balanced and there exists a subset $H \subseteq \{0, 1\}^n$ with $|H| = 2\delta 2^n$ such that $g(x) = U_1$ (i.e., a coin flip) for $x \in H$ and $g(x)$ is deterministic for $x \notin H$.*

Thus, a δ -random function has a set of relative size 2δ on which it is information-theoretically unpredictable. Note that in the above definition we require g to be balanced. This will be convenient when dealing with functions f that are balanced.

The following version of the Impagliazzo hardcore set lemma says that any balanced δ -hard function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ has a hardcore set $H \subseteq \{0, 1\}^n$ of density $\approx 2\delta$ such that f is very hard on average on H . Thus, f looks like a δ -random function to small circuits (cf. Lemma 2.3). (Following subsequent works, our formulation of Impagliazzo’s lemma differs from the original in several respects.)

LEMMA 3.2 (see [18, 23, 33, 31]). *For any function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ that is balanced and δ -hard for size s , there exists a δ' -random function $g : \{0, 1\}^n \rightarrow \{0, 1\}$ such that $X \cdot f(X)$ and $X \cdot g(X)$ are ϵ -indistinguishable for size $\Omega(s\epsilon^2 / \log(1/\delta))$, with $\delta/2 \leq \delta' \leq \delta$, where $X \equiv U_n$.*

In particular, by a standard hybrid argument (see, e.g., [13]),

$$X_1 \cdots X_k \cdot f(X_1) \cdots f(X_k) \quad \text{and} \quad X_1 \cdots X_k \cdot g(X_1) \cdots g(X_k)$$

are $k\epsilon$ -indistinguishable for size $\Omega(s\epsilon^2 / \log(1/\delta))$, where the X_i ’s are uniform and independent.

Step 2: expected bias. By the above, proving the computational hardness of $C \circ f^{\otimes k}$ reduces to calculating the information-theoretic hardness of $C \circ g^{\otimes k}$ for some δ' -random g . It turns out that information-theoretic hardness can be characterized by the following quantity.

DEFINITION 3.3. *Let $h : \{0, 1\}^n \rightarrow \{0, 1\}$ be any probabilistic function. We define the expected bias of h by*

$$\text{ExpBias}[h] \stackrel{\text{def}}{=} \mathbb{E}_{x \leftarrow U_n} [\text{Bias}[h(x)]],$$

where $\text{Bias}[h(x)]$ is taken over the coin tosses of h .

It turns out that for any function $C : \{0, 1\}^k \rightarrow \{0, 1\}$ and any δ -random g , the quantity $\text{ExpBias}[C \circ g^{\otimes k}]$ does not depend on the particular choice of the δ -random function g ; indeed, it turns out to equal the quantity that O'Donnell [31] calls the ‘‘expected bias of C with respect to noise 2δ ’’ and denotes by $\text{ExpBias}_{2\delta}(C)$ in [31]. However, the more general notation we use will be useful in presenting our improvements.

The next lemma shows that information-theoretic hardness is equivalent to expected bias.

LEMMA 3.4. *For any probabilistic function $h : \{0, 1\}^n \rightarrow \{0, 1\}$,*

$$\Delta(U_n \cdot h(U_n), U_n \cdot U_1) = \frac{1}{2} \text{ExpBias}[h].$$

Proof. $\Delta(U_n \cdot h(U_n), U_n \cdot U_1) = \mathbb{E}_{x \leftarrow U_n} [\Delta(h(x), U_1)] = \mathbb{E}_{x \leftarrow U_n} [\text{Bias}[h(x)]/2] = \text{ExpBias}[h]/2.$ \square

In particular, for any circuit C (regardless of its size) we have $|\Pr[C(U_n \cdot h(U_n)) = 1] - \Pr[C(U_n \cdot U_1) = 1]| \leq \text{ExpBias}[h]/2$, and thus by Lemma 2.3, h is $(1/2 - \text{ExpBias}[h]/2)$ -hard for circuits of any size.

Now we characterize the hardness of $C \circ f^{\otimes k}$ in terms of expected bias. Specifically, by taking, say, $\epsilon = 1/s^{1/3}$ in Lemma 3.2 and using Lemmas 2.3 and 3.4, one can prove the following (we defer the details until the proof of the more general Lemma 5.2).

LEMMA 3.5 (see [31]). *Let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be balanced and δ -hard for size s , and let $C : \{0, 1\}^k \rightarrow \{0, 1\}$ be any function. Then there exists a δ' -random function $g : \{0, 1\}^n \rightarrow \{0, 1\}$, with $\delta/2 \leq \delta' \leq \delta$, such that $C \circ f^{\otimes k} : (\{0, 1\}^n)^k \rightarrow \{0, 1\}$ has hardness*

$$\frac{1}{2} - \frac{\text{ExpBias}[C \circ g^{\otimes k}]}{2} - \frac{k}{s^{1/3}}$$

for circuits of size $\Omega(s^{1/3}/\log(1/\delta)) - \text{size}(C)$, where $\text{size}(C)$ denotes the size of a smallest circuit computing C .

What makes this lemma so useful is that, as noted above, the quantity $\text{ExpBias}[C \circ g^{\otimes k}]$ is independent of the choice of the δ -random function g (using the fact that g is balanced, by definition of δ -random); hence the hardness of $C \circ f^{\otimes k}$ depends only on the combining function C and the hardness parameter δ . Thus, understanding the hardness of $C \circ f^{\otimes k}$ is reduced to analyzing a combinatorial property of the combining function C .

Step 3: noise stability. Unfortunately, it is often difficult to analyze the expected bias directly. However, the expected bias is closely related to the *noise stability*, a quantity that is more amenable to analysis and better studied (see, e.g., [31, 27]). The

noise stability of a function is (up to normalization) the probability that the value of the function is the same on two correlated inputs x and $x + \eta$, where x is a random input and η a random vector of noise.

DEFINITION 3.6. *The noise stability of C with respect to the noise δ , denoted $\text{NoiseStab}_\delta[C]$, is defined by*

$$\text{NoiseStab}_\delta[C] \stackrel{\text{def}}{=} 2 \cdot \Pr_{x,\eta}[C(x) = C(x \oplus \eta)] - 1,$$

where x is random, η is a vector whose bits are independently one with probability δ , and \oplus denotes bitwise XOR.

The following lemma from [31] bounds the expected bias of $C \circ g^{\otimes k}$ (and hence the hardness in Lemma 3.5) in terms of the noise stability of C .

LEMMA 3.7. *Let $g : \{0, 1\}^n \rightarrow \{0, 1\}$ be δ -random. Then*

$$\text{ExpBias}[C \circ g^{\otimes k}] \leq \sqrt{\text{NoiseStab}_\delta[C]}.$$

Combining this with Lemma 3.5, we find that the hardness of $C \circ f^{\otimes k}$ is at least (roughly) $1/2 - \sqrt{\text{NoiseStab}_\delta[C]}/2$. The next step is to exhibit a combining function C with a small noise stability (to ensure that the hardness of $C \circ f^{\otimes k}$ is as close to $1/2$ as possible). The following is shown in [31].

LEMMA 3.8 (see [31]). *For all $\delta > 0$, there exists a $k = \text{poly}(1/\delta)$ and a polynomial-time computable monotone function $C : \{0, 1\}^k \rightarrow \{0, 1\}$ with $\text{NoiseStab}_\delta[C] \leq 1/k^{\Omega(1)}$.*

Finally, by combining Lemmas 3.5, 3.7, and 3.8, we obtain the following weaker version of O’Donnell’s hardness amplification within \mathcal{NP} . (While in the introduction we mentioned a stronger version of O’Donnell’s result, which amplifies up to hardness $1/2 - 1/m^{1/2-\alpha}$ for every constant $\alpha > 0$, the following version will suffice as a starting point for our work. The loss in the amplification in this version comes from the fact that we did not specify the constants in Lemma 3.8.)

THEOREM 3.9 (see [31]). *If there is a balanced function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ in \mathcal{NP} that is $1/\text{poly}(n)$ -hard for size $s(n)$, then there is a function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ in \mathcal{NP} that is $(1/2 - 1/m^{\Omega(1)})$ -hard for size $s(m^{\Omega(1)})^{\Omega(1)}$.*

Limitations of direct product constructions. O’Donnell also showed that Theorem 3.9 is essentially the best result that one can obtain using the techniques that we have described thus far. He showed that for all monotone combining functions C there is a δ -hard function f such that the hardness of $C \circ f^{\otimes k}$ is not much better than $1/2 - \text{NoiseStab}_\delta[C]/2$ (assuming that C is easily computable). This is problematic because the noise stability of monotone functions cannot become too small. Specifically, by combining a result from [22] with a Fourier characterization of noise stability, O’Donnell [31] proves the following theorem.

THEOREM 3.10 (see [22, 31]). *For every monotone function $C : \{0, 1\}^k \rightarrow \{0, 1\}$ and every $\delta > 0$,*

$$\text{NoiseStab}_\delta[C] \geq (1 - 2\delta) \cdot \Omega\left(\frac{\log^2 k}{k}\right).$$

Therefore, for any monotone $C : \{0, 1\}^k \rightarrow \{0, 1\}$ there is a δ -hard f such that $C \circ f^{\otimes k}$ does not have hardness $1/2 - \text{NoiseStab}_\delta[C]/2 \leq 1/2 - \Omega(1/k)$. Since $C \circ f^{\otimes k}$ takes inputs of length $m = n \cdot k \geq k$, this implies that we must employ a new technique to amplify beyond hardness $1/2 - \Omega(1/m)$.

4. Main theorem and overview. In this paper, we obtain the following improvement upon Theorem 3.9.

THEOREM 4.1 (main theorem, restated). *If there is a balanced function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ in \mathcal{NP} that is $1/\text{poly}(n)$ -hard for size $s(n)$, then there is a function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ in \mathcal{NP} that is $(1/2 - 1/s(\sqrt{m})^{\Omega(1)})$ -hard for size $s(\sqrt{m})^{\Omega(1)}$.*⁴

We also show that the assumption that we start with a *balanced* function f is essential for a large class of hardness amplifications. Specifically, we show (section 7.1) that no monotone black-box hardness amplification can amplify the hardness of functions whose bias is unknown. Most hardness amplifications, including the one in this paper, are black-box.

We now elaborate on the two main techniques that allow us to prove Theorem 4.1. As explained in the introduction, these two techniques are derandomization and nondeterminism.

4.1. Derandomization. As in the previous section, let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be our hard function, and let $C : \{0, 1\}^k \rightarrow \{0, 1\}$ be a (monotone) combining function.

We will derandomize O’Donnell’s construction using an appropriately “pseudo-random” generator.

DEFINITION 4.2. *A generator is a function $G : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$. We call l the seed length of G , and we often write $G(\sigma) = X_1 \cdots X_k$, with each $X_i \in \{0, 1\}^n$. G is explicitly computable if, given σ and $1 \leq i \leq k$, we can compute X_i in time $\text{poly}(l, \log k)$, where $G(\sigma) = X_1 \cdots X_k$.*

Instead of using the function $C \circ f^{\otimes k} : (\{0, 1\}^n)^k \rightarrow \{0, 1\}$, we take a generator $G : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ (where $l \ll nk$) and use $(C \circ f^{\otimes k}) \circ G : \{0, 1\}^l \rightarrow \{0, 1\}$, i.e.,

$$(C \circ f^{\otimes k}) \circ G(\sigma) = C(f(X_1), \dots, f(X_k)),$$

where $(X_1, \dots, X_k) \in (\{0, 1\}^n)^k$ is the output of $G(\sigma)$. This reduces the input length of the function to l . Therefore, if G is a “good” pseudorandom generator, we would expect $(C \circ f^{\otimes k}) \circ G$ to be harder (with respect to its input length) than $C \circ f^{\otimes k}$. We will show that this is indeed the case, provided that the generator G satisfies the following requirements:

1. *G is indistinguishability-preserving.* Analogously to Lemma 3.5, the generator G should be such that the computational hardness of $(C \circ f^{\otimes k}) \circ G$ is at least the information-theoretic hardness of $(C \circ g^{\otimes k}) \circ G$ for some δ -random function g —that is, at least $1/2 - \text{ExpBias}[(C \circ g^{\otimes k}) \circ G]$. We will see that this can be achieved, provided that G is *indistinguishability-preserving*; that is (analogously to the last part of Lemma 3.2),

$$\sigma \cdot f(X_1) \cdots f(X_k) \quad \text{and} \quad \sigma \cdot g(X_1) \cdots g(X_k)$$

should be indistinguishable, for some δ -random g , when $\sigma \stackrel{\text{R}}{\leftarrow} \{0, 1\}^l$ and $(X_1, \dots, X_k) \in (\{0, 1\}^n)^k$ is the output of G on input σ .

2. *G fools the expected bias.* G should be such that for any δ -random g $\text{ExpBias}[(C \circ g^{\otimes k}) \circ G]$ is approximately $\text{ExpBias}[C \circ g^{\otimes k}]$, and thus, by Lemma 3.7,

$$(2) \quad \text{ExpBias} [(C \circ g^{\otimes k}) \circ G] \leq \sqrt{\text{NoiseStab}_\delta[C] + \epsilon}$$

⁴A comment is in order about the input lengths for which f' is hard. As it turns out, the hardness of f' on inputs of length m is related to the hardness of the original function f on inputs of length $\Theta(\sqrt{m})$. Thus if f is hard for all sufficiently large input lengths, then so is f' . Alternatively, if f is hard only infinitely often, then we may still conclude that f' is hard infinitely often.

for a suitably small ϵ . Actually, we will not show that G fools the expected bias directly but instead will work with a related quantity (the expected collision probability), which will still suffice to show inequality (2).

Informally, the effect of the two above requirements on the generator G is that the hardness of $(C \circ f^{\otimes k}) \circ G$ is roughly the hardness of $C \circ f^{\otimes k}$, while the input length is dramatically reduced from nk to l (the seed length of G). More precisely, the first requirement allows us to relate the hardness of $(C \circ f^{\otimes k}) \circ G$ to the information-theoretic hardness of $(C \circ g^{\otimes k}) \circ G$ (where g is a δ -random function); the second allows us to relate this information-theoretic hardness to the noise stability of the combining function C . In particular, if we employ the combining function from Lemma 3.8, we obtain hardness $1/2 - 1/k^{\Omega(1)}$. Thus, by choosing $k \gg l$, we bypass the barrier discussed at the end of the previous section.

Now we briefly describe how the above requirements on G are met. The first requirement is achieved through a generator that outputs *combinatorial designs*. This construction is essentially from Nisan [28] and Nisan and Wigderson [30] and has been used in many places, e.g., [20, 33].

The second requirement is achieved as follows. We show that if G is pseudorandom against space-bounded algorithms and the combining function C is computable in small space (with one-way access to its input), then inequality (2) holds. We then use Nisan's *unconditional* pseudorandom generator against space-bounded algorithms [29], and show that combining functions with low noise stability can in fact be computed in small space.⁵ Note that we use the pseudorandomness of the generator G only to relate the expected bias with respect to G to a combinatorial property of the combining function C . In particular, it is *not* used to fool the circuits trying to compute the hard function. This is what allows us to use an unconditional generator against a relatively weak model of computation.

Our final generator, Γ , is the generator obtained by XORing a generator that is indistinguishability-preserving and a generator that fools the expected bias, yielding a generator that has both properties. The approach of XORing two generators in this way appeared in [20] and was subsequently used in [33].

4.2. Using nondeterminism. The derandomization described above gives hardness amplification up to $1/2 - 1/n^c$ for any constant c . This already improves upon the best previous result, namely Theorem 3.9. However, to go beyond this new techniques are required. The problem is that if we want C to be computable in time $\text{poly}(n)$, we must take $k = \text{poly}(n)$, and thus we amplify to at most $1/2 - 1/k = 1/2 - 1/\text{poly}(n)$.

We solve this problem by taking full advantage of the power of \mathcal{NP} , namely nondeterminism. This allows us to use a function $C : \{0, 1\}^k \rightarrow \{0, 1\}$ which is computable in *nondeterministic* time $\text{poly}(n, \log(k))$; thus, the amplified function will still be in \mathcal{NP} for k as large as 2^n .

Conversely, in section 7.2 we show that any nonadaptive monotone black-box hardness amplification that amplifies to hardness $1/2 - 1/n^{\omega(1)}$ cannot be computed in \mathcal{P} ; i.e., the use of nondeterminism is essential.

We proceed by discussing the details of the derandomization (sections 5.1, 5.2, and 5.3) and the use of nondeterminism (section 5.4). The results obtained in these sections are summarized in Table 1. For clarity of exposition, we focus on the case where the original hard function f is balanced and is $1/3$ -hard. Hardness amplification

⁵The same approach also works using the unconditional pseudorandom generator against constant-depth circuits of [28] and showing that the combining function is computable by a small constant-depth circuit; however, the space generator gives us slightly better parameters.

TABLE 1
Hardness amplification within \mathcal{NP} .

Functions : $\{0, 1\}^n \rightarrow \{0, 1\}$		
Amplification up to	Technique	Reference
$1/2 - 1/\sqrt{n}$	Direct product	[31]
$1/2 - 1/n^c$, for every c	Derandomized direct product	Theorem 5.8
$1/2 - 1/2^{\Omega(\sqrt{n})}$	Derandomized direct product & nondeterminism	Theorem 5.13

from hardness $1/\text{poly}(n)$ is discussed in section 5.5, and hardness amplification of unbalanced functions is discussed in section 7.1.

5. Proof of main theorem. In this section we prove our main theorem (i.e., Theorem 4.1).

5.1. Preserving indistinguishability. The main result in this subsection is that if G is pseudorandom in an appropriate sense, then the hardness of $(C \circ f^{\otimes k}) \circ G$ is roughly

$$1/2 - \text{ExpBias} [(C \circ g^{\otimes k}) \circ G]$$

for some δ -random function g . As we noted in the previous section, it will be sufficient for G to be *indistinguishability-preserving*. We give the definition of indistinguishability-preserving and then our main result.

DEFINITION 5.1. A generator $G : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ is said to be indistinguishability-preserving for size t if for all (possibly probabilistic) functions $f_1, \dots, f_k, g_1, \dots, g_k$ the following holds: If for every $i, 1 \leq i \leq k$, the distributions

$$U_n \cdot f_i(U_n) \quad \text{and} \quad U_n \cdot g_i(U_n)$$

are ϵ -indistinguishable for size s , then

$$\sigma \cdot f_1(X_1) \cdots f_k(X_k) \quad \text{and} \quad \sigma \cdot g_1(X_1) \cdots g_k(X_k)$$

are $k\epsilon$ -indistinguishable for size $s - t$, where σ is a random seed of length l and $X_1 \cdots X_k$ is the output of $G(\sigma)$.

The fact that in the above definition we consider k f_i 's and k g_i 's implies that an *indistinguishability-preserving* generator stays *indistinguishability-preserving* when XORed with any other generator (cf. the proof of item 1 in Lemma 5.12). We will use this property in the proof of our main result.

LEMMA 5.2. Let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be δ -hard for size s , let $G : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ be a generator that is *indistinguishability-preserving* for size t , and let $C : \{0, 1\}^k \rightarrow \{0, 1\}$ be any function. Then there exists a δ' -random g , with $\delta/2 \leq \delta' \leq \delta$ such that the function $(C \circ f^{\otimes k}) \circ G : \{0, 1\}^l \rightarrow \{0, 1\}$ has hardness

$$\frac{1}{2} - \frac{\text{ExpBias} [(C \circ g^{\otimes k}) \circ G]}{2} - \frac{k}{s^{1/3}}$$

for circuits of size $\Omega(s^{1/3}/\log(1/\delta)) - t - \text{size}(C)$, where $\text{size}(C)$ denotes the size of a smallest circuit computing C .

Proof. By Lemma 3.2, there exists a δ' -random function g with $\delta/2 \leq \delta' \leq \delta$ such that $U_n \cdot f(U_n)$ and $U_n \cdot g(U_n)$ are ϵ -indistinguishable for size $\Omega(s\epsilon^2/\log(1/\delta))$. Since G is indistinguishability-preserving for size t by assumption, this implies that

$$\sigma \cdot f(X_1) \cdots f(X_k) \quad \text{and} \quad \sigma \cdot g(X_1) \cdots g(X_k)$$

are $k\epsilon$ -indistinguishable for size $\Omega(s\epsilon^2/\log(1/\delta)) - t$, where here and below σ denotes a uniform random seed in $\{0, 1\}^l$ and $X_1 \cdots X_k$ will denote the output of $G(\sigma)$. This in turn implies that

$$\sigma \cdot C(f(X_1) \cdots f(X_k)) \quad \text{and} \quad \sigma \cdot C(g(X_1) \cdots g(X_k))$$

(i.e., $\sigma \cdot (C \circ f^{\otimes k}) \circ G(\sigma)$ and $\sigma \cdot (C \circ g^{\otimes k}) \circ G(\sigma)$) are $k\epsilon$ -indistinguishable for size $\Omega(s\epsilon^2/\log(1/\delta)) - t - \text{size}(C)$. By Lemma 3.4,

$$\sigma \cdot (C \circ g^{\otimes k}) \circ G \quad \text{and} \quad \sigma \cdot U_1$$

are $(\text{ExpBias}[(C \circ g^{\otimes k}) \circ G]/2)$ -indistinguishable for any size. Therefore, we have that

$$\sigma \cdot (C \circ f^{\otimes k}) \circ G \quad \text{and} \quad \sigma \cdot U_1$$

are $(\text{ExpBias}[(C \circ g^{\otimes k}) \circ G]/2 + k\epsilon)$ -indistinguishable for size $\Omega(s\epsilon^2/\log(1/\delta)) - t - \text{size}(C)$. The result follows by setting $\epsilon = 1/s^{1/3}$ and applying Lemma 2.3. \square

In particular, we note that the *identity generator* $G : \{0, 1\}^{nk} \rightarrow (\{0, 1\}^n)^k$, i.e., $G(x) = x$, is indistinguishability-preserving for size 0 (by a hybrid argument, see, e.g., [13]), and thus Lemma 3.5 is a corollary of Lemma 5.2. However, the identity generator has seed length nk and is therefore a very poor pseudorandom generator. Fortunately, there are indistinguishability-preserving pseudorandom generators with much shorter seeds which will allow us to use Lemma 5.2 to obtain much stronger hardness amplifications.

LEMMA 5.3. *There is a constant c such that for every $n \geq 2$ and every $k = k(n)$ there is an explicitly computable generator $NW_k : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ with seed length $l = c \cdot n^2$ that is indistinguishability-preserving for size k^2 .*

Proof. The generator is the main component of the generator by Nisan [28] and Nisan and Wigderson [30] and is based on combinatorial designs. Specifically, we let $S_1, \dots, S_k \subseteq [l]$ be an explicit family of sets such that $|S_i| = n$ for all i , and $|S_i \cap S_j| \leq \log k$ for all $i \neq j$. Nisan [28] gives an explicit construction of such sets with $l = O(n^2)$. Then the generator $NW_k : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ is defined by

$$NW_k(\sigma) := (\sigma|_{S_1}, \dots, \sigma|_{S_k}),$$

where $\sigma|_{S_i} \in \{0, 1\}^n$ denotes the projection of σ onto the coordinates indexed by the set S_i .

The proof that this generator is indistinguishability-preserving for size k^2 follows the arguments in [30, 33]. For completeness, we sketch the proof here. Suppose that we have a circuit C of size $s - k^2$ distinguishing the distributions $\sigma \cdot f_1(\sigma|_{S_1}) \cdots f_k(\sigma|_{S_k})$ and $\sigma \cdot g_1(\sigma|_{S_1}) \cdots g_k(\sigma|_{S_k})$ with advantage greater than $k \cdot \epsilon$. For $i = 0, \dots, k$, let H_i be the hybrid distribution

$$H_i = \sigma \cdot g_1(\sigma|_{S_1}) \cdots g_i(\sigma|_{S_i}) \cdot f_{i+1}(\sigma|_{S_{i+1}}) \cdots f_k(\sigma|_{S_k}).$$

Then there must exist an $i \in \{0, \dots, k\}$ such that C distinguishes H_i from H_{i+1} with advantage greater than ϵ . The only difference between H_i and H_{i+1} is that H_i has the component $f_{i+1}(\sigma|_{S_{i+1}})$, while H_{i+1} has $g_{i+1}(\sigma|_{S_{i+1}})$. By averaging, we may fix all the bits of σ outside of S_{i+1} (as well as the randomness of f_j, g_j for $j \neq i + 1$ if they are probabilistic functions) while preserving the advantage of C . Thus C distinguishes between two distributions of the form

$$\tau \cdot h_1(\tau)h_2(\tau) \cdots h_i(\tau)f_{i+1}(\tau)h_{i+2}(\tau) \cdots h_k(\tau)$$

and

$$\tau \cdot h_1(\tau)h_2(\tau) \cdots h_i(\tau)g_{i+1}(\tau)h_{i+2}(\tau) \cdots h_k(\tau),$$

where τ is uniform in $\{0, 1\}^n$ and each h_j is a function of at most $|S_j \cap S_{i+1}|$ bits of τ . Then each h_j can be computed by a circuit of size smaller than $2^{|S_j \cap S_{i+1}|} \leq k$. Combining these $k - 1$ circuits with C , we get a distinguisher between $\tau \cdot f_{i+1}(\tau)$ and $\tau \cdot g_{i+1}(\tau)$ of size $|C| + (k - 1) \cdot k < s$ and advantage greater than ϵ . \square

5.2. Fooling the expected bias. In this subsection we prove a derandomized version of Lemma 3.7. Informally, we show that if C is computable in a restricted model of computation and G “fools” that restricted model of computation, then for any δ -random function g ,

$$\text{ExpBias} [(C \circ g^{\otimes k}) \circ G] \leq \sqrt{\text{NoiseStab}_\delta[C] + \epsilon}.$$

The restricted model of computation we consider is that of nonuniform space-bounded algorithms that make one pass through the input, reading it in blocks of length n . These are formally modeled by the following kind of branching programs.

DEFINITION 5.4. *A (probabilistic, read-once, oblivious) branching program of size s with block-size n is a finite state machine with s states, over the alphabet $\{0, 1\}^n$ (with a fixed start state and an arbitrary number of accepting states). Each edge is labeled with a symbol in $\{0, 1\}^n$. For every state a and symbol $\alpha \in \{0, 1\}^n$, the edges leaving a and labeled with α are assigned a probability distribution. Then computation proceeds as follows. The input is read sequentially, one block of n bits at a time. If the machine is in state a and it reads α , then it chooses an edge leaving a and labeled with α according to its probability, and moves along it.*

Now we formally define pseudorandom generators against branching programs.

DEFINITION 5.5. *A generator $G : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ is ϵ -pseudorandom against branching programs of size s and block-size n if for every branching program B of size s and block-size n :*

$$|\Pr[B(G(U_l)) = 1] - \Pr[B(U_{nk}) = 1]| \leq \epsilon.$$

In [29], Nisan builds an unconditional pseudorandom generator against branching programs. Its parameters (specialized for our purposes) are given in the following theorem.

THEOREM 5.6 (see [29]). *For every n and $k \leq 2^n$, there exists a generator*

$$N_k : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$$

such that

- N_k is 2^{-n} -pseudorandom against branching programs of size 2^n and block-size n ,

- N_k has seed length $l = O(n \log k)$,
- N_k is explicitly computable.

Note that Nisan [29] does not mention *probabilistic* branching programs. However, if there is a probabilistic branching program distinguishing the output of the generator from uniform, then by a fixing of the coin tosses of the branching program there is a *deterministic* branching program that distinguishes the output of the generator from uniform.

We now state the derandomized version of Lemma 3.7.

LEMMA 5.7. *Let*

1. $g : \{0, 1\}^n \rightarrow \{0, 1\}$ be a δ -random function,
2. $C : \{0, 1\}^k \rightarrow \{0, 1\}$ be computable by a branching program of size t and block-size 1,
3. $G : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ be $\epsilon/2$ -pseudorandom against branching programs of size t^2 and block-size n .

Then $\text{ExpBias}[(C \circ g^{\otimes k}) \circ G] \leq \sqrt{\text{NoiseStab}_\delta[C] + \epsilon}$.

Proof. We will not show that G fools the expected bias, but rather the following related quantity. For a probabilistic Boolean function $h(x; r)$ we define its (normalized) *expected collision probability* as

$$\text{ExpCP}[h] \stackrel{\text{def}}{=} \mathbb{E}_x \left[2 \cdot \Pr_{r, r'} [h(x; r) = h(x; r')] - 1 \right].$$

The same reasoning that proves Lemma 3.7 also shows that for every probabilistic Boolean function h ,

$$(3) \quad \text{ExpBias}[h] \leq \sqrt{\text{ExpCP}[h]}.$$

More specifically, inequality (3) holds because

$$\begin{aligned} \text{ExpBias}[h] &= \mathbb{E}_{x \leftarrow U_n} [\text{Bias}[h(x)]] \\ &\leq \sqrt{\mathbb{E}_{x \leftarrow U_n} [\text{Bias}[h(x)]^2]} \quad (\text{by Cauchy-Schwarz}) \\ &= \sqrt{\text{ExpCP}[h]}. \end{aligned}$$

Let $h(x; r) : (\{0, 1\}^n)^k \rightarrow \{0, 1\}$ be the probabilistic function $C \circ g^{\otimes k}$. Even though h is defined in terms of g , it turns out that its expected collision probability is the same for all δ -random functions g . Specifically, for $x = (x_1, \dots, x_k)$, the only dependence of the collision probability $\Pr_{r, r'} [h(x; r) = h(x; r')]$ on x_i comes from whether $g(x_i)$ is a coin flip (which occurs with probability δ over the choice of x_i), $g(x_i) = 1$ (which occurs with probability $(1 - \delta)/2$), or $g(x_i) = 0$ (which occurs with probability $(1 - \delta)/2$). In the case where $g(x_i)$ is a coin flip, then the i th bits of the two inputs fed to C (i.e., $g(x_i; r)$ and $g(x_i; r')$) are random and independent, and otherwise they are equal and fixed (according to $g(x_i)$). It can be verified that this corresponds precisely to the definition of noise stability, so that we have

$$(4) \quad \text{ExpCP}[h] = \text{NoiseStab}_\delta[C].$$

Now we construct a probabilistic branching program $M : (\{0, 1\}^n)^k \rightarrow \{0, 1\}$ of size t^2 and block-size n such that for every $x \in (\{0, 1\}^n)^k$:

$$\Pr[M(x) = 1] = \Pr_{r, r'} [h(x; r) = h(x; r')].$$

To do this, we first note that, using the branching program for C , we can build a probabilistic branching program of size t with block-size n which computes $C \circ g^{\otimes k}$: The states of the branching program are the same as those of the branching program for C , and we define the transitions as follows. Upon reading symbol $\alpha \in \{0, 1\}^n$ in state s , if $g(\alpha) = 0$ (resp. $g(\alpha) = 1$), we deterministically go to the state given by the 0-transition (resp., 1-transition) of C from state s , and if $g(\alpha)$ is a coin flip, then we put equal probability on these two transitions.

Then, to obtain M , run two *independent* copies of this branching program (i.e., using independent choices for the probabilistic state transitions) and accept if and only if both of them accept or both of them reject. Now,

$$\begin{aligned} & \left| \text{ExpCP}[(C \circ g^{\otimes k}) \circ G] - \text{NoiseStab}_\delta[C] \right| \\ &= \left| \text{ExpCP}[(C \circ g^{\otimes k}) \circ G] - \text{ExpCP}[C \circ g^{\otimes k}] \right| \quad (\text{by (4)}) \\ &= 2 \cdot \left| \Pr[M \circ G(U_l) = 1] - \Pr[M(U_{n \cdot k}) = 1] \right| \\ &\leq \epsilon. \quad (\text{by pseudorandomness of } G) \end{aligned}$$

The lemma follows, combining this with (3). \square

5.3. Amplification up to $1/2 - 1/\text{poly}$. In this subsection we sketch our hardness amplification up to $1/2 - 1/n^c$, for every c , as follows.

THEOREM 5.8. *If there is a balanced function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ in \mathcal{NP} that is $(1/3)$ -hard for size $s(n) \geq n^{\omega(1)}$, then for every $c > 0$ there is a function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ in \mathcal{NP} that is $(1/2 - 1/m^c)$ -hard for size $(s(\sqrt{m}))^{\Omega(1)}$.*

To amplify we use the Tribes function of Ben-Or and Linial [5], a monotone read-once DNF.

DEFINITION 5.9. *The Tribes function on k bits is*

$$\begin{aligned} \text{Tribes}_k(x_1, \dots, x_k) &\stackrel{\text{def}}{=} \\ &(x_1 \wedge \dots \wedge x_b) \vee (x_{b+1} \wedge \dots \wedge x_{2b}) \vee \dots \vee (x_{k-b+1} \wedge \dots \wedge x_k) \end{aligned}$$

where there are k/b clauses each of size b , and b is the largest integer such that $(1 - 2^{-b})^{k/b} \geq 1/2$. Note that this makes $b = O(\log k)$.

The Tribes DNF has very low noise stability when perturbed with constant noise.

LEMMA 5.10 (see [31, 27]). *For every constant $\delta > 0$,*

$$\text{NoiseStab}_\delta[\text{Tribes}_k] \leq \frac{1}{k^{\Omega(1)}}.$$

A key step in our result is that Tribes_k is easily computable by a branching program of size $O(k)$, and therefore we can use Lemma 5.7 to fool its expected bias.

We now define the generator that we will use in our derandomized direct product construction.

DEFINITION 5.11. *Given n and $k \leq 2^n$, define the generator $\Gamma_k : \{0, 1\}^m \rightarrow (\{0, 1\}^n)^k$ as follows:*

$$\Gamma_k(x, y) \stackrel{\text{def}}{=} NW_k(x) \oplus N_k(y),$$

where \oplus denotes bitwise XOR.

We recall the properties of Γ that we are interested in, as follows.

LEMMA 5.12. *The following hold:*

1. Γ_k is indistinguishability-preserving for size k^2 .
2. Γ_k is 2^{-n} -pseudorandom against branching programs of size 2^n and block-size n .
3. Γ_k has seed length $m = O(n^2)$.
4. Γ_k is explicitly computable (see Definition 4.2 for the definition of explicit).

Proof. . Item 1 follows from Lemma 5.3 and the fact that an indistinguishability-preserving generator XORed with any fixed string is still indistinguishability-preserving. More specifically, suppose, for the sake of contradiction, that $\Gamma_k(x, y) = NW_k(x) \oplus N_k(y)$ is not indistinguishability-preserving. Then there are functions f_1, \dots, f_k and g_1, \dots, g_k such that for every i the distributions $U_n \cdot f_i(U_n)$ and $U_n \cdot g_i(U_n)$ are indistinguishable, yet the distributions

$$(x, y) \cdot f_1(NW_1(x) \oplus N_1(y)) \cdots f_k(NW_k(x) \oplus N_k(y))$$

and

$$(x, y) \cdot g_1(NW_1(x) \oplus N_1(y)) \cdots g_k(NW_k(x) \oplus N_k(y))$$

are distinguishable (for random x, y). Then, by averaging, they are distinguishable for some fixed value of $y = \tilde{y}$. Thus, we obtain that

$$x \cdot f'_1(NW_1(x)) \cdots f'_k(NW_k(x))$$

and

$$x \cdot g'_1(NW_1(x)) \cdots g'_k(NW_k(x))$$

are distinguishable (for random x), where $f'_i(z) = f_i(z \oplus N_i(\tilde{y}))$, $g'_i(z) = g_i(z \oplus N_i(\tilde{y}))$. (Note that we hardwire the fixed part of the seed \tilde{y} in the distinguisher.) Now observe that the indistinguishability of $U_n \cdot f_i(U_n)$ and $U_n \cdot g_i(U_n)$ implies the indistinguishability of $U_n \cdot f'_i(U_n)$ and $U_n \cdot g'_i(U_n)$, because the mapping $T(u \cdot v) = (u \oplus N_i(\tilde{y})) \cdot v$ transforms the latter pair of distributions to the former. (There is no loss in the circuit size, assuming that circuits have input gates for both the input variables and their negations.) But this is a contradiction because NW is indistinguishability-preserving.

Item 2 follows from Theorem 5.6 and the fact that XORing with any fixed string (in particular, $NW_k(x)$ for any x) preserves pseudorandomness against branching programs.

Item 3 is an immediate consequence of the seed lengths of NW_k (Lemma 5.3) and N_k (Theorem 5.6).

Item 4 follows from the facts that NW_k is explicit (Lemma 5.3) and N_k is explicit (Theorem 5.6). \square

Proof of Theorem 5.8. Given $f : \{0, 1\}^n \rightarrow \{0, 1\}$ that is δ -hard for size $s(n)$ (for $\delta = 1/3$) and a constant c , let $k = n^{c'}$ for $c' = O(c)$ to be determined later. Consider the function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ defined by

$$f' \stackrel{\text{def}}{=} (\text{Tribes}_k \circ f^{\otimes k}) \circ \Gamma_k.$$

Note that $f' \in \mathcal{NP}$ since $f \in \mathcal{NP}$, Tribes is monotone, and both Γ and Tribes are efficiently computable.

We now analyze the hardness of f' . Since Γ_k is indistinguishability-preserving for size k^2 by Lemma 5.12, Lemma 5.2 implies that there is a δ' -random function g (for $\delta/2 \leq \delta' \leq \delta$) such that f' has hardness

$$(5) \quad \frac{1}{2} - \frac{\text{ExpBias}[(\text{Tribes}_k \circ g^{\otimes k}) \circ \Gamma_k]}{2} - \frac{k}{s(n)^{1/3}}$$

for circuits of size $\Omega(s(n)^{1/3}) - k^2 - \text{size}(\text{Tribes}_k)$. Next we bound the hardness. By Lemma 5.12, we know that Γ_k is 2^{-n} -pseudorandom against branching programs of size 2^n and block-size n . In particular, since $k = \text{poly}(n)$, Γ_k is $1/k$ -pseudorandom against branching programs of size $9k$ and block-size n . Since, as we noted before, Tribes_k is easily computable by a branching program of size $O(k)$, we can apply Lemma 5.7 (noting that $O(k)^2 = \text{poly}(n) \ll 2^n$) in order to bound $\text{ExpBias}[(\text{Tribes}_k \circ g^{\otimes k}) \circ \Gamma_k]$ by $\sqrt{\text{NoiseStab}_{\delta'}[\text{Tribes}_k] + 2/k}$. And the noise stability inside the square root is at most $1/k^{\Omega(1)}$ by Lemma 5.10. Since $k = \text{poly}(n)$ and $s(n) = n^{\omega(1)}$, the $k/s^{1/3}$ term in the hardness (5) is negligible, and we obtain hardness at least $1/2 - 1/k^{\Omega(1)}$.

We now bound the circuit size: Since Tribes_k is computable by circuits of size $O(k)$, and since $s(n) = n^{\omega(1)}$, the size is at least $s(n)^{\Omega(1)}$.

Now note that f' has input length $m = m(n) = O(n^2)$ by Lemma 5.12. Strictly speaking, we have defined f' only for certain input lengths; however, it is easy to extend the function to every input length simply by defining $f'(x) \stackrel{\text{def}}{=} f'(x')$, where x' consists of the first $m(n)$ bits of x and n is the largest integer such that $m(n) \leq |x|$. It is easy to check that f' still has hardness $1/2 - 1/k^{\Omega(1)} = 1/2 - 1/n^{\Omega(c')}$. The result then follows by an appropriate choice of $c' = O(c)$. \square

5.4. Using nondeterminism. In this subsection we discuss how to use nondeterminism to get the following theorem.

THEOREM 5.13. *If there is a balanced function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ in \mathcal{NP} that is $(1/3)$ -hard for size $s(n)$, then there is a function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ in \mathcal{NP} that is $(1/2 - 1/s(\sqrt{m})^{\Omega(1)})$ -hard for size $s(\sqrt{m})^{\Omega(1)}$.*

Our main observation is that Tribes_k is a DNF with clause size $O(\log k)$, and therefore it is computable in nondeterministic time $\text{poly}(n)$ even when k is superpolynomial in n .

LEMMA 5.14. *Let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be in \mathcal{NP} , and let $G_k : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ be any explicitly computable generator (see Definition 4.2) with $l \geq n$. Then the function $f' \stackrel{\text{def}}{=} (\text{Tribes}_k \circ f^{\otimes k}) \circ G_k$ is computable in \mathcal{NP} for every $k = k(n) \leq 2^n$.*

Proof. We compute $f'(\sigma)$ nondeterministically as follows. Guess a clause $v_i \wedge v_{i+1} \wedge \dots \wedge v_j$ in Tribes_k . Accept if for every h such that $i \leq h \leq j$ we have $f(X_h) = 1$, where $G(\sigma) = (X_1, \dots, X_k)$ and the values $f(X_h)$ are computed using the \mathcal{NP} algorithm for f .

It can be verified that this algorithm has an accepting computation path on input σ iff $f'(\sigma) = 1$. Note that the clauses have size logarithmic in k , which is polynomial in n . Moreover, G is explicitly computable. The result follows. \square

Now the proof of Theorem 5.13 proceeds along the same lines as the proof of Theorem 5.8, setting $k \stackrel{\text{def}}{=} s(n)^{\Omega(1)}$.

5.5. Amplifying from hardness $1/\text{poly}$. Our amplification from hardness $\Omega(1)$ to $1/2 - \epsilon$ (Theorem 5.8) can be combined with O'Donnell's amplification from hardness $1/\text{poly}$ to hardness $\Omega(1)$ to obtain an amplification from $1/\text{poly}$ to $1/2 - \epsilon$.

However, since O’Donnell’s construction blows up the input length polynomially, we would obtain only $\epsilon = 1/s(n^{\Omega(1)})$ (where the hidden constant depends on the initial polynomial hardness) rather than $\epsilon = 1/s(\sqrt{n})^{\Omega(1)}$ (as in Theorem 5.8). Thus we show here how to amplify directly from $1/\text{poly}$ to $1/2 - \epsilon$ using our approach. For this we need a combining function C that is more involved than the Tribes function. The properties of C that are needed in the proof of Theorem 4.1 are captured by the following lemma.

LEMMA 5.15. *For every $\delta(n) = 1/n^{O(1)}$, there is a sequence of functions $C_k : \{0, 1\}^k \rightarrow \{0, 1\}$ such that for every $k = k(n)$ with $n^{\omega(1)} \leq k \leq 2^n$ the following hold:*

1. $\text{NoiseStab}_\delta[C_k] \leq 1/k^{\Omega(1)}$.
2. For every $f : \{0, 1\}^n \rightarrow \{0, 1\}$ in \mathcal{NP} and every explicitly computable generator (see Definition 4.2) $G_k : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ with $l \geq n$, the function $(C_k \circ f^{\otimes k}) \circ G_k$ is in \mathcal{NP} .
3. C_k can be computed by a branching program of size $\text{poly}(n) \cdot k$ and also by a circuit of size $\text{poly}(n) \cdot k$.

Before proving Lemma 5.15, let us see how it can be used to prove our main theorem.

THEOREM 5.16 (Theorem 4.1, restated). *If there is a balanced function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ in \mathcal{NP} that is $1/\text{poly}(n)$ -hard for size $s(n)$, then there is a function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ in \mathcal{NP} that is $(1/2 - 1/s(\sqrt{m})^{\Omega(1)})$ -hard for size $s(\sqrt{m})^{\Omega(1)}$.*

Proof. Let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be a balanced function in \mathcal{NP} that is $\delta = \delta(n)$ -hard for size $s(n)$, where $\delta \geq 1/n^{O(1)}$. Let $k = k(n) \stackrel{\text{def}}{=} s(n)^{1/7}$, and let C_k be the function guaranteed by Lemma 5.15. Let Γ_k be the generator from Definition 5.11. Consider the function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ defined by $f' \stackrel{\text{def}}{=} (C_k \circ f^{\otimes k}) \circ \Gamma_k$. Note that $f' \in \mathcal{NP}$, by item 2 in Lemma 5.15.

We now analyze the hardness of f' . Since Γ_k is indistinguishability-preserving for size k^2 (by Lemma 5.12), Lemma 5.2 implies that there is a δ' -random function g (for $\delta/2 \leq \delta' \leq \delta$) such that f' has hardness

$$(6) \quad \alpha(m) = \frac{1}{2} - \frac{\text{ExpBias}[(C_k \circ g^{\otimes k}) \circ \Gamma_k]}{2} - \frac{k}{s(n)^{1/3}}$$

for circuits of size

$$s'(m) = \Omega\left(\frac{s(n)^{1/3}}{\log(1/\delta)}\right) - k^2 - \text{size}(C_k).$$

We first bound the hardness $\alpha(m)$. By Lemma 5.12, we know that Γ_k is 2^{-n} -pseudorandom against branching programs of size 2^n and block-size n . Since the branching program for computing C_k has size $\text{poly}(n) \cdot k$, and $(\text{poly}(n) \cdot k)^2 \ll 2^n$ (by our choice of $k(n)$), we may apply Lemma 5.7 in order to bound $\text{ExpBias}[(C_k \circ g^{\otimes k}) \circ \Gamma_k]$ by $\sqrt{\text{NoiseStab}_{\delta'}[C_k]} + 2/2^n$. This noise stability is at most $1/k^{\Omega(1)}$ by item 1 in Lemma 5.15. Using the fact that $k = s(n)^{1/7}$, we have

$$\alpha(m) \geq \frac{1}{2} - \frac{\sqrt{1/k^{\Omega(1)} - 2/2^n}}{2} - \frac{k}{s(n)^{1/3}} = \frac{1}{2} - \frac{1}{s(n)^{\Omega(1)}}.$$

We now bound the circuit size $s'(m)$. Since C_k is computable by a circuit of size $\text{poly}(n) \cdot k$ (by item 3 in Lemma 5.15) and $\log(1/\delta) = O(\log n)$ and $s(n) = n^{\omega(1)}$, we have

$$s'(m) = \Omega\left(\frac{s(n)^{1/3}}{\log n}\right) - s(n)^{2/7} - \text{poly}(n) = s(n)^{\Omega(1)}.$$

To conclude, we note that f' has input length $m = O(n^2)$ by Lemma 5.12, so $s(n) = s(\Omega(\sqrt{m})) = s(\sqrt{m})^{\Omega(1)}$, and we indeed obtain hardness $\alpha(m) = 1/2 - 1/s(\sqrt{m})^{\Omega(1)}$ for size $s'(m) = s(\sqrt{m})^{\Omega(1)}$. Strictly speaking, we have defined f' only for certain input lengths; however, it is easy to extend the function to every input length; cf. the end of the proof of Theorem 5.8. \square

The rest of this subsection is devoted to the proof of Lemma 5.15. Recall that amplification from hardness $\Omega(1)$ (Theorem 5.8) relies on the fact that the Tribes DNF has low noise stability with respect to noise parameter $\delta = \Omega(1)$ (i.e., Lemma 5.10). Similarly, to amplify from hardness $1/\text{poly}(n)$ we need to employ a combining function that has low noise stability with respect to noise $1/\text{poly}(n)$. To this end, following [31], we employ the recursive-majorities function, RMaj_r . Let Maj denote the majority function.

DEFINITION 5.17. *The RMaj_r function on 3^r bits is defined recursively by*

$$\begin{aligned} \text{RMaj}_1(x_1, x_2, x_3) &\stackrel{\text{def}}{=} \text{Maj}(x_1, x_2, x_3), \\ \text{RMaj}_r(x_1, \dots, x_{3^r}) &\stackrel{\text{def}}{=} \text{RMaj}_{r-1}(\text{Maj}(x_1, x_2, x_3), \dots, \text{Maj}(x_{3^{r-2}}, x_{3^{r-1}}, x_{3^r})). \end{aligned}$$

The following lemma quantifies the noise stability of RMaj_r .

LEMMA 5.18 (see [31, Proposition 11]). *There is a constant c such that for every $\delta > 0$ and every $r \geq c \cdot \log(1/\delta)$ we have*

$$\text{NoiseStab}_\delta[\text{RMaj}_r] \leq \frac{1}{4}.$$

Note that if $r = O(\log n)$, then RMaj_r is a function of $3^r = \text{poly}(n)$ bits.

However, when $r = O(\log n)$, RMaj_r does not have sufficiently low noise stability to be used on its own. For this reason, we will combine RMaj with Tribes. (The same combination of RMaj and Tribes is employed by O'Donnell [31], albeit for a different setting of parameters.)

Proof of Lemma 5.15. Given n and $\delta = \delta(n) \geq 1/n^{O(1)}$, let $r \stackrel{\text{def}}{=} c \cdot \log(1/\delta)$ for a constant c to be chosen later. Assume, without loss of generality, that r and $k/3^r$ are integers. The function $C_k : \{0, 1\}^k \rightarrow \{0, 1\}$ is defined as

$$C_k \stackrel{\text{def}}{=} \text{Tribes}_{k/3^r} \circ \text{RMaj}_r^{\otimes k/3^r}.$$

We now prove that C_k satisfies the required properties.

Item 1. We will use the following result from [31].

LEMMA 5.19 (see [31, Proposition 8]). *If h is a balanced Boolean function and $\varphi : \{0, 1\}^\ell \rightarrow \{0, 1\}$ is any Boolean function, then*

$$\text{NoiseStab}_\delta[\varphi \circ h^{\otimes \ell}] = \text{NoiseStab}_{\frac{1}{2} - \frac{\text{NoiseStab}_\delta[h]}{2}}[\varphi].$$

Letting c be a sufficiently large constant (recall that $r = c \cdot \log(1/\delta)$), by Lemma 5.18 we have that $\text{NoiseStab}_\delta[\text{RMaj}_r]/2 \geq 1/2 - 1/8 \geq 3/8$. Now note that RMaj_r is balanced because taking the bitwise complement of an input x also negates the value of $\text{RMaj}_r(x)$. Hence, by Lemma 5.19,

$$\begin{aligned} \text{NoiseStab}_\delta[\text{Tribes}_{k/3^r} \circ \text{RMaj}_r^{\otimes k/3^r}] &= \text{NoiseStab}_{3/8}[\text{Tribes}_{k/3^r}] \\ &\leq \frac{1}{(k/3^r)^{\Omega(1)}} = \frac{1}{k^{\Omega(1)}}, \end{aligned}$$

where the last two equalities use Lemma 5.10 and the fact that $k = n^{\omega(1)}$ and $r = O(\log n)$.

The proof of item 2 is similar to the proof of Lemma 5.14. To compute $(\text{Tribes}_{k/3^r} \circ \text{RMaj}_r^{\otimes k/3^r} \circ f^{\otimes k}) \circ G_k$, we guess a clause of the $\text{Tribes}_{k/3^r}$ and verify that all the RMaj_r evaluations feeding into it are satisfied (using the \mathcal{NP} algorithm for f). The only additional observation is that each of the recursive majorities depends on only $3^r = \text{poly}(n)$ bits of the input and hence can be computed in time polynomial in n .

Item 3. As noted earlier, $\text{Tribes}_{k/3^r}$ is easily computable by a branching program of size $O(k)$. RMaj_r , on the other hand, can be computed by a branching program of size $\text{poly}(n)$. Indeed, $\text{Maj}(x_1, x_2, x_3)$ is clearly computable by a branching program of constant size c , and therefore $\text{RMaj}_r = \text{RMaj}_{r-1}(\text{Maj}(x_1, x_2, x_3), \dots, \text{Maj}(x_{3^{r-2}}, x_{3^{r-1}}, x_{3^r}))$ can be computed by a branching program whose size is at most c times the size of RMaj_{r-1} . By induction it follows that RMaj_r can be computed in size $c^r = \text{poly}(n)$.

By composing the branching program of size $O(k)$ for Tribes with the branching program of size $\text{poly}(n)$ for RMaj , we can compute C_k by a branching program of size $\text{poly}(n) \cdot k$. \square

A natural question is whether one can amplify from hardness $1/n^{\omega(1)}$. A modification of the [37] negative result about hardness amplification given in [26] shows that this task cannot be achieved by any black-box hardness amplification computable in the polynomial-time hierarchy (and thus in particular cannot be achieved by any black-box hardness amplification computable in \mathcal{NP}). (See Definition 7.2 for the definition of black-box hardness amplification.)

6. Extensions.

6.1. On the possibility of amplifying hardness up to $1/2 - 1/2^{\Omega(n)}$. Even when starting from a function that is δ -hard for size $2^{\Omega(n)}$, our results (Theorem 4.1) amplify hardness only up to $1/2 - 1/2^{\Omega(\sqrt{n})}$ (rather than $1/2 - 1/2^{\Omega(n)}$). In this section we discuss the possibility of amplifying hardness in \mathcal{NP} up to $1/2 - 1/2^{\Omega(n)}$ when starting with a function that is δ -hard for size $2^{\Omega(n)}$. The problem is that the seed length of our generator in Lemma 5.12 is *quadratic* in n , rather than linear. To amplify hardness up $1/2 - 1/2^{\Omega(n)}$ we need a generator (for every $k = 2^{\Omega(n)}$) with the same properties of the one in Lemma 5.12, but with linear seed length.

Recall that our generator is the XOR of an indistinguishability-preserving generator and a generator that is pseudorandom against branching programs. While it is an open problem to exhibit a generator with linear seed length that is pseudorandom against branching programs, an indistinguishability-preserving generator with linear seed length is given by the following lemma.

LEMMA 6.1. *For every constant γ , $0 < \gamma < 1$, there is a constant c such that for every n there is an explicitly computable generator $NW'_{2^{n/c}} : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^{2^{n/c}}$ with seed length $l = c \cdot n$ that is indistinguishability-preserving for size $2^{\gamma \cdot n}$.*

The generator is due to Nisan and Wigderson [30] and Impagliazzo and Wigderson [20]. The approach is the same as for the generator used in Lemma 5.3, except we now require a design consisting of $2^{\Omega(n)}$ sets of size n in a universe of size $O(n)$, with pairwise intersections of size at most $\gamma n/2$. An explicit construction of such a design is given in [16].⁶

⁶Alternatively, we can use the randomized algorithm described in [20], which computes such sets S_1, \dots, S_M with probability exponentially close to 1 using $O(n)$ random bits. This is sufficient for constructing an indistinguishability-preserving generator.

THEOREM 6.2. *Suppose that there exists an explicit generator $N'_{2^n} : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^{2^n}$ that is 2^{-n} -pseudorandom against branching programs of size 2^n and block-size n and that has seed length $l = O(n)$. Then the following holds: If there is a balanced function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ in \mathcal{NP} that is $1/\text{poly}(n)$ -hard for size $2^{\Omega(n)}$, then there is a function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ in \mathcal{NP} that is $(1/2 - 1/2^{\Omega(n)})$ -hard for size $2^{\Omega(n)}$.*

A slightly more careful analysis shows that all the branching programs considered in our constructions have *width*⁷ much smaller than their size (specifically, the branching program for Tribes has constant width, and the one for the function in Lemma 5.15, i.e., Tribes composed with RMaj, has width $\text{poly}(n)$ independent of k). Thus to prove the conclusion in the statement of Theorem 6.2 it would suffice to exhibit an explicit pseudorandom generator that fools such restricted branching programs.

For amplifying from constant hardness, it suffices instead to have a generator fooling *constant-depth circuits* of size 2^n with seed length $O(n)$. (The generator of Nisan [28] has seed length $\text{poly}(n)$.) The reason is that our proof that generators against branching programs “fool” the expected bias also works for generators against constant-depth circuits, provided that the combining function is computable in constant depth. The Tribes function is depth 2 by definition (but the recursive majorities RMaj is not constant-depth, and hence this would only amplify from constant hardness).

More generally, we only need, for every constant $\gamma > 0$, a generator $G : \{0, 1\}^{O(n)} \rightarrow (\{0, 1\}^n)^k$, where $k = 2^{\gamma n}$, such that for every δ -random function g ,

$$\text{ExpBias} [(C_k \circ g^{\otimes k}) \circ G] = 2^{-\Omega(n)},$$

where, for example, $C_k = \text{Tribes}_k$ (when δ is constant). As in the proof of Lemma 3.7, in proving such a statement it may be convenient to work instead with the (polynomially related) expected collision probability. An important property of $C_k = \text{Tribes}_k$ used in bounding the expected bias with respect to G is that it gives expected bias $2^{-\Omega(n)}$ if G is replaced with a truly random generator (i.e., using seed length $n \cdot k$) and δ is constant. One might try to use a different monotone combining function with this property, provided that it can also be evaluated in nondeterministic time $\text{poly}(n)$.

6.2. Impagliazzo and Wigderson’s hardness amplification. Our framework gives a new proof of the hardness amplification by Impagliazzo and Wigderson [20]. Impagliazzo and Wigderson showed that if $\mathcal{E} \stackrel{\text{def}}{=} \text{DTIME}(2^{O(n)})$ contains a function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ that requires (in the worst-case) circuits of size $2^{\Omega(n)}$, then \mathcal{E} contains a function f' that is $(1/2 - 1/2^{\Omega(n)})$ -hard for circuits of size $2^{\Omega(n)}$. The main contribution in [20] is amplification from constant hardness, e.g., $1/3$, to $(1/2 - 1/2^{\Omega(n)})$ (amplification from worst-case hardness and constant hardness was essentially already established in [3, 18]). The improvement over the standard Yao XOR lemma is that the input length of the amplified function increases by only a constant factor. In this section, we sketch a simple proof of this result using the framework developed in earlier sections. While other, more recent hardness amplifications achieving the same result for \mathcal{E} are known [33, 32, 36], the original one by Impagliazzo and Wigderson is still interesting because it can be implemented in “low” complexity classes, such as the polynomial-time hierarchy, while the others cannot (due to the fact that they actually amplify from worst-case hardness [37]).

⁷The width of a branching program is the maximum, over i , of the number of states that are reachable after reading i symbols.

The construction of [20] uses an *expander-walk* generator $W_k : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$, which uses its seed of length $l = n + O(k)$ to do a random walk of length k (started at a random vertex) in a constant-degree expander graph on 2^n vertices. More background on such generators can be found in [12, section 3.6.3]. The construction of [20] XORs the expander-walk generator with the (first k outputs of the) indistinguishability-preserving generator from Lemma 6.1, as follows.

DEFINITION 6.3. *Let $k = c \cdot n$ for a constant $c > 1$. Let $NW''_k : \{0, 1\}^{O(n)} \rightarrow (\{0, 1\}^n)^k$ be a generator that is indistinguishability-preserving for size $2^{n/c}$, as given by Lemma 6.1. The generator $IW_k : \{0, 1\}^l \rightarrow (\{0, 1\}^n)^k$ is defined as*

$$IW_k(x, y) \stackrel{\text{def}}{=} NW''_k(x) \oplus W_k(y).$$

The seed length of IW_k is $l = O(n)$.

Given a function f that is $1/3$ -hard for size $s = 2^{\Omega(n)}$, the Impagliazzo–Wigderson amplification defines

$$f' \stackrel{\text{def}}{=} (XOR \circ f^{\otimes k}) \circ IW_k : \{0, 1\}^{O(n)} \rightarrow \{0, 1\},$$

where $k = c \cdot n$ for a constant c that depends on the hidden constant in the $s = 2^{\Omega(n)}$. They prove the following about this construction.

THEOREM 6.4 (after [20]). *If there is a function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ in \mathcal{E} that is $1/3$ -hard for size $2^{\Omega(n)}$, then there is a function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ in \mathcal{E} that is $(1/2 - 2^{-\Omega(m)})$ -hard for size $2^{\Omega(m)}$.*

Proof. By Theorem 5.2 there exists a δ' -random function $g : \{0, 1\}^n \rightarrow \{0, 1\}$, where δ' is a constant, such that the hardness of $f' : \{0, 1\}^{O(n)} \rightarrow \{0, 1\}$ is $1/2 - \text{ExpBias}[(XOR \circ g^{\otimes k}) \circ IW_k] - 2^{-\Omega(n)}$ for circuits of size $2^{\Omega(n)}$.

We now bound the hardness. Whenever some $IW_i(x)$ falls in the set of inputs of density $2 \cdot \delta'$, where the output of g is a coin flip, the bias of $(XOR \circ g^{\otimes k}) \circ IW_k$ is 0. Therefore

$$\text{ExpBias}[(XOR \circ g^{\otimes k}) \circ IW_k] \leq \Pr_x[\forall i : IW_i(x) \notin H] \leq 2^{-\Omega(n)},$$

where in the last inequality we use standard hitting properties of expander walks (see, e.g., [11] for a proof) and take c to be a sufficiently large constant. \square

7. Limitations of monotone hardness amplification.

7.1. On the hypothesis that f is balanced. The hardness amplification results in the previous sections start from balanced functions. In this section we study this hypothesis. Our main finding is that, while this hypothesis is not necessary for hardness amplification within \mathcal{NP}/poly (i.e., nondeterministic polynomial size circuits), it is likely to be necessary for hardness amplification within \mathcal{NP} .

To see that this hypothesis is not necessary for amplification within \mathcal{NP}/poly , note that if the quantity $\Pr_x[f(x) = 1]$ of the original hard function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ is known, then we can easily pad f to obtain a balanced function $\bar{f} : \{0, 1\}^{n+1} \rightarrow \{0, 1\}$:

$$\bar{f}(x, p) \stackrel{\text{def}}{=} \begin{cases} f(x) & \text{if } p = 0, \\ 0 & \text{if } p = 1 \text{ and } x \leq \Pr_x[f(x) = 1] \cdot 2^n, \\ 1 & \text{if } p = 1 \text{ and } x > \Pr_x[f(x) = 1] \cdot 2^n. \end{cases}$$

It is easy to see that \bar{f} is $1/\text{poly}(n)$ -hard if f is. Since a circuit can (nonuniformly) depend on $\Pr_x[f(x) = 1]$, the following hardness amplification within \mathcal{NP}/poly is a corollary to the proof of Theorem 4.1.

COROLLARY 7.1. *If there is a function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ in \mathcal{NP}/poly that is $1/\text{poly}(n)$ -hard for size $s(n)$, then there is a function $f' : \{0, 1\}^m \rightarrow \{0, 1\}$ in \mathcal{NP}/poly that is $(1/2 - 1/s(\sqrt{m})^{\Omega(1)})$ -hard for size $s(\sqrt{m})^{\Omega(1)}$.*

Now we return to hardness amplification within \mathcal{NP} . First we note that, in our results, to amplify the hardness of $f : \{0, 1\}^n \rightarrow \{0, 1\}$ up to $1/2 - \epsilon$ it is necessary only that $\text{Bias}[f] \leq \epsilon^c$ for some universal constant c . The argument is standard and can be found, for example, in [34].

Combining this observation with the above padding technique, O'Donnell constructs several candidate hard functions, one for each “guess” of the bias of the original hard function. He then combines them in a single function using a different input length for each candidate; this gives a function that is very hard on average for infinitely many input lengths. However, this approach, even in conjunction with derandomization and nondeterminism, cannot give better hardness than $1/2 - 1/n$. (Roughly speaking, if we want to amplify to $1/2 - \epsilon$, then we will have at least $1/\epsilon$ different candidates, and thus the “hard” candidate may have input length $n \geq 1/\epsilon$, which means $1/2 - \epsilon \leq 1/2 - 1/n$.)

To what extent can we amplify the hardness of functions whose bias is *unknown*? Nonmonotone hardness amplifications, such as Yao’s XOR lemma, work regardless of the bias of the original hard function. However, in the rest of this section we show that, for hardness amplifications that are *monotone* and *black-box*, this is impossible. In particular, we show that black-box monotone hardness amplifications cannot amplify the hardness beyond the bias of the original function.

We now formalize the notion of black-box monotone hardness amplification and then state our negative result.

DEFINITION 7.2. *An oracle algorithm $\text{Amp} : \{0, 1\}^l \rightarrow \{0, 1\}$ is a black-box β -bias $[\delta \mapsto (1/2 - \epsilon)]$ -hardness amplification for length n and size s if for every $f : \{0, 1\}^n \rightarrow \{0, 1\}$ such that $\text{Bias}[f] \leq \beta$ and for every $A : \{0, 1\}^l \rightarrow \{0, 1\}$ such that*

$$\Pr[A(U_l) \neq \text{Amp}^f(U_l)] \leq \frac{1}{2} - \epsilon$$

there is an oracle circuit C of size at most s such that

$$\Pr[C^A(U_n) \neq f(U_n)] \leq \delta.$$

Amp is monotone if, for every x , $\text{Amp}^f(x)$ is a monotone function of the truth table of f .

Note that if Amp is as in Definition 7.2, and if f is δ -hard for size s' and $\text{Bias}[f] \leq \beta$, then Amp^f is $(1/2 - \epsilon)$ -hard for size s'/s : If there were a circuit A of size s'/s computing Amp^f with error probability at most $1/2 - \epsilon$, then C^A would be a circuit of size $s \cdot (s'/s) = s'$ computing f with error probability at most δ , contradicting the hardness of f . The term “black box” refers to the fact that the definition requires this to hold for *every* f and A , regardless of whether f is in \mathcal{NP} or A is a small circuit.

The following theorem shows that any *monotone* black-box hardness amplification up to $1/2 - \epsilon$ must start from functions of bias $\beta \approx \epsilon$.

THEOREM 7.3. *For any constant $\gamma > 0$, if Amp is a monotone black-box β -bias $[\delta \mapsto (1/2 - \epsilon)]$ -hardness amplification for length n and size $s \leq 2^{n/3}$ such that $1/2 - 4\epsilon > \delta + \gamma$, then $\beta \leq 8\epsilon + O(2^{-n})$.*

The main ideas for proving this bound are the same as in the negative result for black-box hardness amplification in [37]: First we show that the above kind of hardness amplification satisfies certain coding-like properties. Roughly, Amp can be seen as a kind of list-decodable code, where the distance property is guaranteed only for δ -distant messages with bias at most β (cf. [34]). Then we show that monotone functions fail to satisfy these properties. The limitation we prove on monotone functions relies on the following corollary to the Kruskal–Katona theorem (see [1, Theorem 7.3.1]).

LEMMA 7.4. *Let $\mathcal{S} = \{S_1, \dots, S_m\}$ be a collection of m subsets $S_i \subseteq \{1, \dots, N\}$, where $|S_i| = t$. If $m \geq \binom{N-1}{t} = (1 - \frac{t}{N}) \binom{N}{t}$, then for every integer $t' < t$*

$$|\{S : |S| = t', S \subseteq S_i \text{ for some } i\}| \geq \binom{N-1}{t'} = \left(1 - \frac{t'}{N}\right) \binom{N}{t'}.$$

Let \mathcal{F}_p be the uniform distribution on functions f whose truth tables have relative Hamming weight exactly p , i.e., $\Pr_x[f(x) = 1] = p$. We use the above Lemma 7.4 to prove the following fact.

LEMMA 7.5. *Let $A : \{0, 1\}^l \rightarrow \{0, 1\}$ be an oracle function such that, for every $x \in \{0, 1\}^l$, $A^f(x)$ is a monotone function of the truth table of $f : \{0, 1\}^n \rightarrow \{0, 1\}$. (For example, any monotone black-box hardness amplification Amp satisfies this condition.) Let τ be an integer multiple of $1/2^n$. Then there is $p \in \{1/2 - \tau, 1/2 + \tau\}$ such that*

$$\mathbb{E}_{U_l} [\text{Bias}_{F \leftarrow \mathcal{F}_p}[A^F(U_l)]] \geq \tau.$$

Proof. We show that for every fixed $x \in \{0, 1\}^l$ there is a $p \in \{1/2 - \tau, 1/2 + \tau\}$ such that $\text{Bias}_{F \leftarrow \mathcal{F}_p}[A^F(x)] \geq 2\tau$. The theorem then follows easily. Fix x . For every p define S_p as the set of functions f in \mathcal{F}_p such that $A^f(x) = 0$. Note that

$$\text{Bias}_{F \leftarrow \mathcal{F}_p}[A^F(x)] = \left|1 - \frac{2|S_p|}{|\mathcal{F}_p|}\right|.$$

If $|S_{1/2+\tau}| < (1/2 - \tau) \cdot |\mathcal{F}_{1/2+\tau}|$, then $\text{Bias}_{F \leftarrow \mathcal{F}_{1/2+\tau}}[A^F(x)] > 2\tau$ and we are done. Otherwise,

$$|S_{1/2+\tau}| \geq \left(\frac{1}{2} - \tau\right) \cdot |\mathcal{F}_{1/2+\tau}| = \left(1 - \left(\frac{1}{2} + \tau\right)\right) \cdot \binom{2^n}{(1/2 + \tau)2^n}.$$

View the elements $f \in S_p$ as subsets of $\{1, \dots, 2^n\}$ of size exactly $p2^n$ in the natural way; i.e., the subset associated with f is the set of inputs x such that $f(x) = 1$. Note that if $f' \subseteq f \subseteq \{1, \dots, 2^n\}$ and $A^f(x) = 0$, then by the monotonicity of A , $A^{f'}(x) = 0$. Therefore, by Lemma 7.4,

$$|S_{1/2-\tau}| \geq \left(1 - \left(\frac{1}{2} - \tau\right)\right) \cdot \binom{2^n}{(1/2 - \tau)2^n} = \left(\frac{1}{2} + \tau\right) \cdot |\mathcal{F}_{1/2-\tau}|,$$

and so $\text{Bias}_{F \leftarrow \mathcal{F}_{1/2-\tau}}[A^F(x)] \geq 2\tau$. \square

The following lemma captures the coding-like properties of monotone, black-box hardness amplifications—it shows that it is very unlikely that Amp^f for a “random f ” will land in any fixed Hamming ball of radius $1/2 - \epsilon$. For two functions f_1, f_2 , let

$Dist$ denote the relative Hamming distance of their truth tables, i.e., $Dist(f_1, f_2) \stackrel{\text{def}}{=} \Pr_x[f_1(x) \neq f_2(x)]$.

LEMMA 7.6. *Let $\gamma > 0$ be any fixed constant. Let Amp be a monotone black-box 8ϵ -bias $[\delta \mapsto (1/2 - \epsilon)]$ -hardness amplification for length n and size $s \leq 2^{n/3}$, where $1/2 - 4\epsilon > \delta + \gamma$, and let $\epsilon > 0$ be an integer multiple of $1/2^n$. Then for both p in $\{1/2 - 4\epsilon, 1/2 + 4\epsilon\}$ and every function G ,*

$$\Pr_{F \leftarrow \mathcal{F}_p} \left[Dist(G, Amp^F) \leq \frac{1}{2} - \epsilon \right] \leq 2^{-\Omega(2^n)}.$$

Proof. Let $N \stackrel{\text{def}}{=} 2^n$. For every function f of bias at most 8ϵ such that $Dist(G, Amp^f) \leq 1/2 - \epsilon$, there must exist a circuit of size s , with oracle access to G , that computes f with error at most δ . Therefore, since there are $2^{O(s \log s)}$ circuits of size s and no more than $2^{H(\delta)N}$ functions that are at distance at most δ from f , there are at most $2^{O(s \log s)} 2^{H(\delta)N}$ such functions. Thus, when we restrict our attention to the $\binom{N}{pN}$ functions in \mathcal{F}_p (for $p \in \{1/2 - 4\epsilon, 1/2 + 4\epsilon\}$), we have

$$\begin{aligned} \Pr_{F \leftarrow \mathcal{F}_p} \left[Dist(G, Amp^F) \leq \frac{1}{2} - \epsilon \right] &\leq \frac{2^{O(s \log s)} \cdot 2^{H(\delta)N}}{\binom{N}{pN}} \\ &\leq 2^{O(s \log s)} \cdot (N + 1) \cdot 2^{(H(\delta) - H(p))N} \\ &\leq 2^{O(s \log s)} \cdot (N + 1) \cdot 2^{(H(\delta) - H(1/2 - 4\epsilon))N} \\ &\leq 2^{-\Omega(N)}, \end{aligned}$$

where the second inequality follows from the fact that $\binom{N}{pN} \geq 2^{H(p)N} / (N + 1)^8$ and the last inequality uses the fact that $1/2 - 4\epsilon > \delta + \gamma$ implies $H(1/2 - 4\epsilon) > H(\delta) + \Omega(1)$. \square

Proof of Theorem 7.3. We assume that ϵ is a positive integer multiple of $1/2^n$ and show that $\beta \leq 8\epsilon$. The theorem then follows for general ϵ by rounding it up to the next integer multiple of $1/2^n$. We show that $\beta = 8\epsilon$ is impossible, and therefore that $\beta < 8\epsilon$ (because any β' -bias hardness amplification is clearly also a β -bias hardness amplification for every $\beta \leq \beta'$).

Suppose, for the sake of contradiction, that $\beta = 8\epsilon$.

By Lemma 7.5, we may choose $p \in \{1/2 - 4\epsilon, 1/2 + 4\epsilon\}$ such that

$$\mathbb{E}_{U_l} [\text{Bias}_{F \leftarrow \mathcal{F}_p}[Amp^F(U_l)]] \geq 4\epsilon.$$

Define the function $G(x) \stackrel{\text{def}}{=} \text{Maj}_{F \leftarrow \mathcal{F}_p} Amp^F(x)$, and consider

$$(7) \quad \Pr_{U_l, F \leftarrow \mathcal{F}_p} [Amp^F(U_l) \neq G(U_l)].$$

⁸Actually, $\binom{N}{pN}$ is asymptotically $\Theta(2^{H(p)N} / \sqrt{N})$, but for our purposes the easier estimate stated suffices.

We have

$$\begin{aligned}
 & \Pr_{U_l, F \leftarrow \mathcal{F}_p} [Amp^F(U_l) \neq G(U_l)] \\
 &= \mathbb{E}_{U_l} \left[\Pr_{F \leftarrow \mathcal{F}_p} [Amp^F(U_l) \neq G(U_l)] \right] \\
 &= \mathbb{E}_{U_l} \left[\frac{1}{2} - \frac{\text{Bias}_{F \leftarrow \mathcal{F}_p}[Amp^F(U_l)]}{2} \right] \quad (\text{by def. of bias and } G) \\
 &= \frac{1}{2} - \frac{\mathbb{E}_{U_l} [\text{Bias}_{F \leftarrow \mathcal{F}_p}[Amp^F(U_l)]]}{2} \\
 &\leq \frac{1}{2} - 2\epsilon. \quad (\text{by the choice of } p)
 \end{aligned}$$

On the other hand, Lemma 7.6 implies that quantity (7) is at least $1/2 - \epsilon - 2^{-\Omega(2^n)}$ (note that the hypothesis of the lemma is satisfied by our assumption that $1/2 - 4\epsilon \geq \delta + \gamma$).

Combining the two bounds, we have that

$$\frac{1}{2} - 2\epsilon \geq \Pr_{U_l, F \leftarrow \mathcal{F}_p} [Amp^F(U_l) \neq G(U_l)] \geq \frac{1}{2} - \epsilon - 2^{-\Omega(2^n)},$$

which is a contradiction for sufficiently large n (by the assumption that ϵ is a positive multiple of $1/2^n$). \square

7.2. Nondeterminism is necessary. In this subsection we show that *deterministic*, monotone, nonadaptive, black-box hardness amplifications cannot amplify hardness beyond $1/2 - 1/\text{poly}(n)$. Thus, the use of *nondeterminism* in our results (section 5.4) seems necessary. Note that most hardness amplifications, including the one in this paper, are black-box and nonadaptive.

O’Donnell [31] proves that any monotone “direct product construction” (i.e., $f'(x_1, \dots, x_k) = C(f(x_1), \dots, f(x_k))$, as in (1)) cannot amplify to hardness better than $1/2 - 1/n$, assuming that the amplification works for all functions f (not necessarily in \mathcal{NP}). We relax the assumption that the hardness amplification is a direct product construction (allowing any monotone nonadaptive oracle algorithm $f' = Amp^f$). On the other hand, we require that the reduction proving its correctness also be black-box (as formalized in Definition 7.2).

We prove our bound even for hardness amplifications that amplify only balanced functions (i.e., $\beta = 0$ in Definition 7.2).

THEOREM 7.7. *For every constant $\delta < 1/2$, if Amp is a black-box 0-bias $[\delta \mapsto (1/2 - \epsilon)]$ -hardness amplification for length n and size $s \leq 2^{n/3}$ such that, for every x , $Amp^f(x)$ is a monotone function of $k \leq 2^{n/3}$ values of f , then*

$$\epsilon \geq \Omega\left(\frac{\log^2 k}{k}\right).$$

The proof of this result follows closely the proof of the negative result on hardness amplification in [37]. The main difference is that here we use bounds on the noise stability of monotone functions rather than constant depth circuits.

By a Chernoff bound, a $2^{-\epsilon^2 N}$ fraction of 2^N strings are ϵ -unbalanced. But it is impossible to kill this fraction with noise bounded away from $1/2$. (This will only give min entropy $2^{-\epsilon N}$, which will not kill $2^{-\epsilon^2 N + N}$.)

The following lemma is similar to Lemma 7.6. The only difference is in considering functions F at distance η from f ; this will correspond to perturbing the monotone amplification function with noise having parameter η .

LEMMA 7.8. *Let Amp be as in Definition 7.2 with $\beta = 0$ and $s \leq 2^{n/3}$. Then for any constant $\delta < 1/2$ there is a constant $\eta < 1/2$ such that, for sufficiently large n , the following holds: If $f : \{0, 1\}^n \rightarrow \{0, 1\}$ is any fixed balanced function and $F : \{0, 1\}^n \rightarrow \{0, 1\}$ is a random balanced function such that $\text{Dist}(f, F) = \eta$, then*

$$\Pr_F \left[\text{Dist}(\text{Amp}^f, \text{Amp}^F) \leq \frac{1}{2} - \epsilon \right] \leq \epsilon.$$

Proof. Let $N \stackrel{\text{def}}{=} 2^n$. It is easy to see that F is uniform on a set of size $\binom{N/2}{\eta N/2}^2$. The rest of the proof is like the proof of Lemma 7.6:

$$\begin{aligned} \Pr \left[\text{Dist}(\text{Amp}^f, \text{Amp}^F) \leq \frac{1}{2} - \epsilon \right] &\leq \frac{2^{O(s \log s)} 2^{H(\delta)N}}{\binom{N/2}{\eta N/2}^2} \\ &\leq 2^{O(s \log s)} \cdot \left(\frac{N}{2} + 1 \right)^2 \cdot 2^{(H(\delta) - H(\eta))N} \\ &\leq \epsilon, \end{aligned}$$

where the last inequality holds for a suitable choice of $\eta < 1/2$, using the fact that $\delta < 1/2$ is a constant and that $s \leq 2^{n/3}$. \square

Proof of Theorem 7.7. Let η be the constant in Lemma 7.8. The idea is to consider

$$(8) \quad \Pr_{U_l, F, F'} [\text{Amp}^F(U_l) \neq \text{Amp}^{F'}(U_l)],$$

where F is a random balanced function and F' is a random balanced function such that $\text{Dist}(F, F') = \eta$.

By the above lemma, the probability (8) is at least $1/2 - 2\epsilon$.

On the other hand, for every fixed x , $\text{Amp}^F(x)$ is a monotone function depending only on k bits of the truth table of the function F . Since k is small compared to 2^n , the distribution (F, F') induces on the input of $\text{Amp}^F(x)$ a distribution very close to $(U_k, U_k \oplus \mu)$, where μ is a noise vector with parameter η . Specifically, it can be verified that the statistical difference between these two distributions is at most $O(k^2/(\eta 2^n))$. Because this value is dominated by $\log^2 k/k$ when $k \leq 2^{n/3}$, and because $\text{Amp}^F(x)$ is a *monotone* function of k bits, we may apply Theorem 3.10 to conclude that the probability (8) is at most $1/2 - O(\log^2 k/k)$.

Combining the two bounds, we have that $1/2 - O(\log^2 k/k) \geq 1/2 - 2\epsilon$, and the results follows. \square

Acknowledgments. We thank Ryan O’Donnell and Rocco Servedio for an email exchange about noise stability. We thank Richard Stanley for pointing out the Kruskal–Katona theorem. We also thank Oded Goldreich, Luca Trevisan, Avi Wigderson, and the anonymous reviewers for helpful suggestions.

LOGARITHMIC LOWER BOUNDS IN THE CELL-PROBE MODEL*

MIHAI PĂTRAȘCU[†] AND ERIK D. DEMAINÉ[†]

Abstract. We develop a new technique for proving cell-probe lower bounds on dynamic data structures. This technique enables us to prove an amortized randomized $\Omega(\lg n)$ lower bound per operation for several data structural problems on n elements, including partial sums, dynamic connectivity among disjoint paths (or a forest or a graph), and several other dynamic graph problems (by simple reductions). Such a lower bound breaks a long-standing barrier of $\Omega(\lg n / \lg \lg n)$ for any dynamic language membership problem. It also establishes the optimality of several existing data structures, such as Sleator and Tarjan’s dynamic trees. We also prove the first $\Omega(\log_B n)$ lower bound in the external-memory model without assumptions on the data structure (such as the comparison model). Our lower bounds also give a query-update trade-off curve matched, e.g., by several data structures for dynamic connectivity in graphs. We also prove matching upper and lower bounds for partial sums when parameterized by the word size and the maximum additive change in an update.

Key words. cell-probe complexity, lower bounds, data structures, dynamic graph problems, partial-sums problem

1. Introduction. The cell-probe model is perhaps the strongest model of computation for data structures, subsuming in particular the common word-RAM model. We suppose that the memory is divided into fixed-size cells (words), and the cost of an operation is just the number of cells it reads or writes. Typically we think of the cell size as being around $\lg n$ bits long, so that a single cell can address all n elements in the data structure. (Refer to section 4 for a precise definition of the model.) While the cell-probe model is unrealistic as a model of computation for actual data structures, its generality makes it an important model for lower bounds on data structures.

Previous cell-probe lower bounds for data structures fall into two categories of approaches. The first approach is based on communication complexity. Lower bounds for the predecessor problem [Ajt88, MNSW98, BF02, SV] are perhaps the most successful application of this idea. Unfortunately, this approach can be applied only to problems that are hard even in the static case. It also requires queries to receive a parameter of $\omega(\lg n)$ bits, which is usually interpreted as requiring cells to have $\omega(\lg n)$ bits. For problems that are hard only in the dynamic case, all lower bounds have used some variation of the chronogram method of Fredman and Saks [FS89]. By design, this method cannot prove a trade-off between the query time t_q and the update time t_u better than $t_q \lg t_u = \Omega(\lg n)$, which was achieved for the marked-ancestor problem (and consequently many other problems) in [AHR98]. This limitation on trade-off lower bounds translates into an $\Omega(\lg n / \lg \lg n)$ limitation on lower bounds for both queries and updates provable by this technique. The $\Omega(\lg n / \lg \lg n)$ barrier

has been recognized as an important limitation in the study of data structures and was proposed as a major challenge for future research in a recent survey [Mil99].

This paper introduces a new technique for proving cell-probe lower bounds on dynamic data structures. With this technique we establish an $\Omega(\lg n)$ lower bound for either queries or updates in several natural and well-studied problems, in particular, maintaining partial (prefix) sums in an array and dynamic connectivity among disjoint paths (or a forest or a graph). (We detail the exact problems we consider, and all results we obtain, in section 2; we summarize relevant previous results on these problems in section 3.) These lower bounds establish the optimality of several data structures, including the folkloric $O(\lg n)$ balanced tree data structure for partial sums, and Sleator and Tarjan's dynamic trees data structure (which in particular maintains dynamic connectivity in a forest).

We also prove a trade-off lower bound of $t_q \lg \frac{t_u}{t_q} = \Omega(\lg n)$.¹ This trade-off turns out to be the right answer for our problems, and implies the $\Omega(\lg n)$ bound on the worst of queries and updates. In addition, we can prove a symmetric trade-off $t_u \lg \frac{t_q}{t_u} = \Omega(\lg n)$. As mentioned above, it is fundamentally impossible to achieve such a trade-off using the previous techniques.

We also refine our analysis of the partial-sums problem beyond the dependence on n . Specifically, we parameterize by n , the number b of bits in a word, and the number δ of bits in an update. Naturally, $\delta \leq b$, but in some applications, δ is much smaller than b . We prove tight upper and lower bounds of $\Theta(\frac{\lg n}{\lg(b/\delta)})$ on the worst of queries and updates. This result requires improvements in both the upper bounds and the lower bounds. In addition, we give the tight query/update trade-off $t_q(\lg \frac{b}{\delta} + \lg \frac{t_u}{t_q}) = \Theta(\lg n)$. The tightness of this characterization is particularly unusual given its dependence on five variables.

The main idea behind our lower bound technique is to organize time (the sequence of operations performed on the data structure) into a complete tree. The heart of the analysis is an encoding/decoding argument that bounds the amount of information transferred between disjoint subtrees of the tree: if few cells are read and written, then little information can be transferred. The nature of the problems of interest requires at least a certain amount of information transfer from updates to queries, providing a lower bound on the number of cells read and written. This main idea is developed first in section 5 in the context of the partial-sums problem, where we obtain a short proof of an $\Omega(\lg n)$ lower bound for partial sums. Compared to the lower bounds based on previous techniques, our technique leads to relatively clean proofs with minimal combinatorial calculation.

We generalize this basic approach in several directions to obtain our further lower bounds. In section 6, we show how our technique can be extended to handle queries with binary answers (such as dynamic connectivity) instead of word-length answers (such as partial sums). In particular, we obtain an $\Omega(\lg n)$ lower bound for dynamic connectivity in disjoint paths. We also show how to use our lower bound technique in the presence of nondeterminism or Monte Carlo randomization. In section 7, we show how our technique can be further extended to handle updates asymptotically smaller than the word size, in particular obtaining lower bounds for the partial-sums problem when $\delta < b$ and for dynamic connectivity in the external-memory model. This section develops the most complicated form of our technique.

The final sections contain complementary results to this main flow of the lower

¹Throughout this paper, $\lg x$ denotes $\log_2(2+x)$, which is positive for all $x \geq 0$ (an important property in this bound and several others).

bound technique. In section 8, we give tight upper bounds for the partial-sums problem. The data structure is based on a few interesting ideas that enable us to eliminate the precomputed tables from previous approaches. In section 9, we prove some easy reductions from dynamic connectivity to other dynamic graph problems, transferring our lower bounds to these problems. Finally, we conclude in section 10 with a list of open problems.

2. Results. In this section we give precise descriptions of the problems we consider, our results, and a brief synopsis of how these results compare to previous work. (Section 3 gives a more detailed historical account.)

2.1. The partial-sums problem. This problem asks to maintain an array $A[1..n]$ of n integers subject to the following operations:

UPDATE(k, Δ): modify $A[k] \leftarrow \Delta$.

SUM(k): returns the partial sum $\sum_{i=1}^k A[i]$.

SELECT(σ): returns an index i satisfying $\text{SUM}(i-1) < \sigma \leq \text{SUM}(i)$. To guarantee uniqueness of the answer, we require that $A[i] > 0$ for all i .

Besides n , the problem has several interesting parameters. One parameter is b , the number of bits in a cell (word). We assume that every array element and sum fits in a cell. Also, we assume that $b = \Omega(\lg n)$. Another parameter is δ , the number of bits needed to represent an argument Δ to **UPDATE**. Naturally, δ is bounded above by b ; however, it is traditional (see, e.g., [RRR01]) to consider a separate parameter δ because it is smaller in many applications. We write t_u for the running time of **UPDATE**, t_q for the running time of **SUM**, and t_s for the running time of **SELECT**.

We first study the unrestricted case when $\delta = \Omega(b)$.

THEOREM 2.1. *Consider any cell-probe data structure for the partial-sums problem that may use amortization and Las Vegas randomization. If $\delta = \Omega(b)$, then the following trade-offs hold:*

$$\begin{aligned} t_q \lg(t_u/t_q) &= \Omega(\lg n); & t_u \lg(t_q/t_u) &= \Omega(\lg n); \\ t_s \lg(t_u/t_s) &= \Omega(\lg n); & t_u \lg(t_s/t_u) &= \Omega(\lg n). \end{aligned}$$

The trade-off curves are identical for the **SELECT** and **SUM** operations. The first branch of each trade-off is relevant when queries are faster than updates, while the second branch is relevant when updates are faster. The trade-offs imply the long-sought logarithmic bound for the partial-sums problem: $\max\{t_u, t_q\} = \Omega(\lg n)$. The best previous bound, by Fredman and Saks [FS89], was $t_q \lg(bt_u) = \Omega(\lg n)$, implying $\max\{t_u, t_q\} = \Omega(\lg n / \lg b)$. The trade-off curves between t_u and t_q also hold in the group model of computation, where elements of the array come from a black-box group and time is measured as the number of algebraic operations. The best previous bound for this model was $\Omega(\lg n / \lg \lg n)$, also by Fredman and Saks [FS89].

A classic result achieves $t_u = t_q = t_s = O(\lg n)$. For the **SUM** query, our entire trade-off curve can be matched (again, this is folklore; see the next section on previous work). For **SELECT**, the trade-offs cannot be tight for the entire range of parameters because, even for polynomial update times, there is a superconstant lower bound on the query time for the predecessor problem [Ajt88, SV].

We also analyze the case $\delta = o(b)$. We first give the following lower bounds.

THEOREM 2.2. *Consider any cell-probe data structure for the partial-sums problem using amortization and Las Vegas randomization. The following trade-offs hold: $t_q(\lg \frac{b}{\delta} + \lg \frac{t_u}{t_q}) = \Omega(\lg n)$ and $t_s(\lg \frac{b}{\delta} + \lg \frac{t_u}{t_s}) = \Omega(\lg n)$.*

In this case, we cannot prove a reverse trade-off (when updates are faster than queries). This trade-off implies the rather interesting lower bound $\max\{t_u, t_q\} = \Omega(\frac{\lg n}{\lg(b/\delta)})$, and similarly for t_s . When $\delta = \Theta(b)$, this gives the same $\Omega(\lg n)$ as before. We give new matching upper bounds as follows.

THEOREM 2.3. *There exists a data structure for the partial-sums problem achieving $t_u = t_q = t_s = O(\frac{\lg n}{\lg(b/\delta)})$. The data structure runs on a RAM, is deterministic, and achieves worst-case bounds.*

Our upper bounds can handle a slightly harder version of the problem, where **UPDATE**(i, Δ) has the effect $A[i] \leftarrow A[i] + \Delta$. Thus, we are not restricting each $A[i]$ to δ bits, but just mandate that they don't grow by more than a δ -bit term at a time. Several previous results [Die89, RRR01, HSS03] achieved $O(\lg n / \lg \lg n)$ bounds for $\delta = O(\lg \lg n)$. None of these solutions scale well with δ or b because they require large precomputed tables.

This result not only matches the previous lower bound on the hardest operation but also actually helps match the entire trade-off of Theorem 2.2. Indeed, the trade-off lower bound shows that there is effectively no interesting trade-off when $\delta = o(b)$: when $\frac{b}{\delta} \geq \frac{t_u}{t_q}$, the tight bound is $t_q = \Theta(\frac{\lg n}{\lg(b/\delta)})$, matched by our structure; when $\frac{b}{\delta} < \frac{t_u}{t_q}$, the tight bound is $t_q = \Theta(\frac{\lg n}{\lg(t_u/t_q)})$, matched by the classic result, which does not depend on δ . Thus, we obtain an unusually precise understanding of the problem, having a trade-off that is tight in all five parameters.

2.2. Dynamic connectivity. This problem asks to maintain an undirected graph with a fixed set of n vertices subject to the following operations:

INSERT(u, v): insert an edge (u, v) into the graph.

DELETE(u, v): delete the edge (u, v) from the graph.

CONNECTED(u, v): test whether u and v lie in the same connected component.

We write t_q for the running time of **CONNECTED** and t_u for the running times of **INSERT** and **DELETE**. It makes the most sense to study this problem in the cell-probe model with $O(\lg n)$ bits per cell because every quantity in the problem occupies $O(\lg n)$ bits.

We prove the following lower bound.

THEOREM 2.4. *Any cell-probe data structure for dynamic connectivity satisfies the following trade-offs: $t_q \lg(t_u/t_q) = \Omega(\lg n)$ and $t_u \lg(t_q/t_u) = \Omega(\lg n)$. These bounds hold under amortization, nondeterministic queries, and Las Vegas randomization, or under Monte Carlo randomization with error probability $n^{-\Omega(1)}$. These bounds hold even if the graph is always a disjoint union of paths.*

This lower bound holds under very broad assumptions. It allows for nondeterministic computation or Monte Carlo randomization (with polynomially small error) and holds even for paths (and thus for trees, plane graphs, etc.). The trade-offs we obtain are identical to the partial-sums problem. In particular, we obtain that $\max\{t_u, t_q\} = \Omega(\lg n)$.

An upper bound of $O(\lg n)$ for trees is given by the famous dynamic trees data structure of Sleator and Tarjan [ST83]. In addition, the entire trade-off curve for $t_u = \Omega(t_q)$ can be matched for trees. For general graphs, Thorup [Tho00] gave an almost-matching upper bound of $O(\lg n (\lg \lg n)^3)$. For any $t_u = \Omega(\lg n (\lg \lg n)^3)$, his data structure can match our trade-off.

Dynamic connectivity is perhaps the most fundamental dynamic graph problem. It is relatively easy to show by reductions that our bounds hold for several other dynamic graph problems. Section 9 describes such reductions for deciding connectivity of the entire graph, minimum spanning forest, and planarity testing. Many

data structural problems on undirected graphs have polylogarithmic solutions, so our bound is arguably interesting for these problems. Some problems have logarithmic solutions for special cases (such as plane graphs), and our results prove optimality of those data structures.

We also consider dynamic connectivity in the external-memory model. Let B be the page (block) size, i.e., the number of $(\lg n)$ -bit cells that fit on one page. We prove the following lower bound.

THEOREM 2.5. *A data structure for dynamic connectivity in the external-memory model with page size B must satisfy $t_q(\lg B + \lg \frac{t_u}{t_q}) = \Omega(\lg n)$. This bound allows for amortization, Las Vegas randomization, and nondeterminism, and holds even if the graph is always a disjoint union of paths.*

Thus we obtain a bound of $\max\{t_u, t_q\} = \Omega(\log_B n)$. Although bounds of this magnitude are ubiquitous in the external-memory model, our lower bound is the first that holds in a general model of computation, i.e., allowing data items to be manipulated arbitrarily and just counting the number of page transfers. Previous lower bounds have assumed the comparison model or indivisibility of data items.

It is possible to achieve an $O(\log_B n)$ upper bound for a forest by combining Euler tour trees with buffer trees [Arg03]. As with the partial-sums problem, this result implies that our entire trade-off is tight for trees: for $B \geq t_u/t_q$, this solution is optimal; if the term in t_u/t_q dominates, we use the classic trade-off, which foregoes the benefit of memory pages.

3. Previous work. In this section we detail the relevant history of cell-probe lower bounds in general and the specific problems we consider.

3.1. Cell-probe lower bounds. Fredman and Saks [FS89] were the first to prove cell-probe lower bounds for dynamic data structures. They developed the chronogram technique and used it to prove a lower bound of $\Omega(\lg n / \lg b)$ for the partial-sums problem in $\mathbb{Z}/2\mathbb{Z}$ (integers modulo 2, where elements are bits and addition is equivalent to binary exclusive-or). This bound assumes $b \geq \lg n$ so that an index into the n -element array fits in a word; for the typical case of $b = \Theta(\lg n)$, it implies an $\Omega(\lg n / \lg \lg n)$ lower bound. Fredman and Saks also obtain a trade-off of $t_q = \Omega(\frac{\lg n}{\lg b + \lg t_u})$.

There has been considerable exploration of what the chronogram technique can offer. Ben-Amram and Galil [BAG01] reprove the lower bounds of Fredman and Saks in a more formalized framework built around the concepts of problem and output variability. Using these ideas, they show in [BAG02] that the lower bound holds even if cells have infinite precision, but the set of operations is restricted.

Miltersen et al. [MSVT94] observe that there is a trivial reduction from the partial-sums problem in $\mathbb{Z}/2\mathbb{Z}$ to dynamic connectivity, implying an $\Omega(\lg n / \lg \lg n)$ lower bound for the latter problem. Independently, Fredman and Henzinger [FH98] observe the same reduction, as well as more complex reductions applied to connectivity in plane graphs and dynamic planarity testing. Husfeldt and Rauhe [HR03] show slightly stronger results using the chronogram technique. They prove that the lower bound holds even for nondeterministic algorithms, and even in a promise version of the problem in which the algorithm is told the requested sum to ± 1 precision. These improved results make it possible to prove reductions to various other problems [HR03, HRS96].

Alstrup, Husfeldt, and Rauhe [AHR98] give the only previous improvement to the bounds of Fredman and Saks by proving a stronger trade-off of $t_q \lg t_u = \Omega(\lg n)$. This

bound is the best trade-off provable by the chronogram technique. However, it still cannot improve beyond $\max\{t_u, t_q\} = \Omega(\lg n / \lg \lg n)$. The problem they considered was the partial-sums problem generalized to trees, where a query asks for the sum of a root-to-leaf path. (This is a variation of the more commonly known marked-ancestor problem.) Their bound is tight for balanced trees; for arbitrary trees, our lower bound shows that $\Theta(\lg n)$ is the best possible.

Miltersen [Mil99] surveys the field of cell-probe complexity and advocates “dynamic language membership” problems as a standardized framework for comparing lower bounds. Given a language L that is polynomial-time decidable, the *dynamic language membership problem* for L is defined as follows. For any given n (the problem size), maintain a string $w \in \{0, 1\}^n$ under two operations: flip the i th bit of w , and report whether $w \in L$. Through its minimalism, this framework avoids several pitfalls in comparing lower bounds. For instance, it is possible to prove very high lower bounds in terms of the number of cells in the problem representation (which, misleadingly, is often denoted n), if the cells are large [Mil99]. However, these lower bounds are not very interesting because they assume exponential-size cells. In terms of the number of bits in the problem representation, all known lower bounds do not exceed $\Omega(\lg n / \lg \lg n)$.

Miltersen proposes several challenges for future research, two of which we solve in this paper. One such challenge was to prove an $\Omega(\lg n)$ lower bound for the partial-sums problem. Another such challenge, listed as one of three “big challenges,” was to prove a lower bound of $\omega(\lg n / \lg \lg n)$ for a dynamic language membership problem. We solve this problem because dynamic connectivity can be phrased as a dynamic language membership problem [Mil99].

3.2. The partial-sums problem in other models. The partial-sums problem has been studied since the dawn of data structures and has served as the prototypical problem for the study of lower bounds. Initial efforts concentrated on algebraic models of computation. In the semigroup or group models, the elements of the array come from a black-box (semi)group. The algorithm can manipulate the Δ inputs only through additions and, in the group model, subtractions; all other computations in terms of the indices touched by the operations are free.

In the semigroup model, Fredman [Fre81] gives a tight logarithmic bound. However, this bound is generally considered weak, because updates have the form $A[i] \leftarrow \Delta$. Because additive inverses do not exist, such an update invalidates all memory cells storing sums containing the old value of $A[i]$. For the case when updates have the form $A[i] \leftarrow A[i] + \Delta$, Yao [Yao85] proved a lower bound of $\Omega(\lg n / \lg \lg n)$. Finally, Hampapuram and Fredman [HF98] proved an $\Omega(\lg n)$ lower bound for this version of the problem; their bound holds even for the offline problem. In higher dimensions, Chazelle [Cha97] gives a lower bound of $\Omega((\lg n / \lg \lg n)^d)$, which also holds even for the offline problem.

In the group model, the best previous lower bound of $\Omega(\lg n / \lg \lg n)$ is by Fredman and Saks [FS89]. A tight logarithmic bound (including the lead constant) was given by [Fre82] for the restricted class of “oblivious” algorithms, whose behavior can be described by matrix multiplication. For the offline problem, Chazelle [Cha97] gives a lower bound of $\Omega(\lg \lg n)$ per operation; this is exponentially weaker than the best known upper bound. No better lower bounds are known in higher dimensions.

3.3. Upper bounds for the partial-sums problem. An easy $O(\lg n)$ upper bound for partial sums is to maintain a balanced binary tree with the elements of A in the leaves, augmented to store partial sums for each subtree. A

simple variation of this scheme yields an implicit data structure occupying exactly n memory locations [Fen94]. For the **SUM** query, it is easy to obtain good trade-offs. Using trees with branching factor B , one can obtain $t_q = O(\log_B n)$ and $t_u = O(B \log_B n)$, or $t_q = O(B \log_B n)$ and $t_u = O(\log_B n)$. These bounds can be rewritten as $t_q \lg \frac{t_u}{t_q} = O(\lg n)$, or $t_u \lg \frac{t_u}{t_q} = O(\lg n)$, respectively, which matches our lower bound for the case $\delta = \Theta(b)$ and for the group model. For **SELECT** queries, one cannot expect to achieve the same trade-offs because, even for a polynomial update time, there is a superconstant lower bound on the predecessor problem [BF02]. Exactly what trade-offs are possible remains an open problem.

Dietz [Die89] considers the partial-sums problem with **SUM** queries on a RAM, when $\delta = o(b)$. He achieves $O(\lg n / \lg \lg n)$ running times provided that $\delta = O(\lg \lg n)$. Raman, Raman, and Rao [RRR01] show how to support **SELECT** in $O(\lg n / \lg \lg n)$, again if $\delta = O(\lg \lg n)$. For $t_u = \Omega(\lg n / \lg \lg n)$, the same δ , and **SUM** queries, they give a trade-off of $t_q = O(\log_{t_u} n)$. They achieve the same trade-off for **SELECT** queries, when $\delta = 1$. Hon, Sadakane, and Sung [HSS03] generalize the trade-off for **SELECT** when $\delta = O(\lg \lg n)$. All of these results do not scale well with b or δ because of their use of precomputed tables.

3.4. Upper bounds for dynamic connectivity. For forests, Sleator and Tarjan's classic data structure for dynamic trees [ST83] achieves an $O(\lg n)$ upper bound for dynamic connectivity. A simpler solution is given by Euler tour trees [HK99]. This data structure can achieve a running time of $t_q = O(\frac{\lg n}{\lg(t_u/t_q)})$, matching our lower bound.

For general graphs, the first to achieve polylogarithmic time per operation were Henzinger and King [HK99]. They achieve $O(\lg^3 n)$ per update, and $O(\lg n / \lg \lg n)$ per query, using randomization and amortization. Henzinger and Thorup [HT97] improve the update bound to $O(\lg^2 n)$. Holm, de Lichtenberg, and Thorup [HdLT01] give a simple deterministic solution with the same amortized running time: $O(\lg^2 n)$ per update and $O(\lg n / \lg \lg n)$ per query. The best known result in terms of updates is by Thorup [Tho00], achieving nearly logarithmic running times: $O(\lg n (\lg \lg n)^3)$ per update and $O(\lg n / \lg \lg \lg n)$ per query. This solution is only a factor of $(\lg \lg n)^3$ away from our lower bound. Interestingly, all of these solutions are on our trade-off curve. In fact, for any $t_u = \Omega(\lg n (\lg \lg n)^3)$, Thorup's solution can achieve $t_q = O(\frac{\lg n}{\lg(t_u/t_q)})$, showing that our trade-off curve is optimal for this range of t_u .

For plane graphs, Eppstein et al. [EIT⁺92] give a logarithmic upper bound. Plane graphs are planar graphs with a given topological planar embedding, specified by the order of the edges around each vertex. Our lower bound holds for such graphs, proving the optimality of this data structure.

4. Models. The cell-probe model is a nonuniform model of computation. The memory is represented by a collection of cells. Operations are handled by an algorithm which can read and write cells from the memory; all computation is free, and the internal state is unbounded. However, the state is lost at the end of an operation. Because the state is not bounded, it can be assumed that all writes happen at the end of the operation. If cells have b bits, we restrict the number of cells to 2^b , ensuring that a pointer can be represented in one cell. This restriction is a version of the standard *transdichotomous assumption* frequently made in the context of the word RAM, and is therefore natural in the cell-probe model as well.

We extend the model to allow for nondeterministic computation, in the spirit of [HR03]. Boolean queries can spawn any number of independent execution threads;

the overall result is an accept (“yes” answer) if and only if at least one thread accepts. The running time of the operation is the running time of the longest thread. Rejecting threads may not write any cells; accepting threads may, as long as all accepting threads write exactly the same values. Because of this restriction, and because updates are deterministic, the state of the data structure is always well defined.

All lower bounds in this paper hold under Las Vegas randomization, i.e., zero-error randomization. We consider a model of randomization that is particularly easy to reason about in the case of data structures. When the data structure is created, a fixed subset of, say, 2^{b-1} cells is initialized to uniformly random values; from that point on, everything is deterministic. This model can easily simulate other models of randomization, as long as the total running time is at most 2^{b-1} (which is always the case in our lower bounds); the idea is that the data structure maintains a pointer to the next random cell and increments the pointer upon use. For nondeterministic computation, all accepting threads increment the pointer by the largest number of coins that could be used by a thread (bounded by the running time). Using this model, one can immediately apply the easy direction of Yao’s minimax principle [Yao77]. Thus, for any given distribution of the inputs, there is a setting of the random coins such that the amortized running time, in expectation over the inputs, is the same as the original algorithm, in expectation over the random coins. Using the nonuniformity in the model, we can hardwire the fixed setting of the coins into the algorithm.

We also consider Monte Carlo randomization, i.e., randomization with a two-sided error. Random coins are obtained in the same way, but now the data structure is allowed to make mistakes. We do not allow the data structure to be nondeterministic. In this paper, we are concerned only with error probabilities of $n^{-\Omega(1)}$; that is, the data structure should be correct with high probability. Note that by holding a constant number of copies of the data structure and using independent coins, we can increase the exponent of n to any desired constant. In the data-structures world, it is natural to require that data structures be correct with high probability, as opposed to the bounded-error restriction that is usually considered in complexity theory. This is because we want to guarantee correctness over a large sequence of operations. In addition, boosting the error from constant to n^{-c} requires $O(\lg n)$ repetitions, which is usually not significant for an algorithm, but is a significant factor in the running time of a data-structure operation.

5. Lower bounds, take one. In this section, we give the intuition behind our approach and detail a simple form of it that allows us to prove an $\Omega(\lg n)$ lower bound on the partial-sums problem when $\delta = \Theta(b)$, which is tight in this case. This proof serves as a warmup for the more complicated results in sections 6 and 7.

5.1. General framework. We begin with the framework for our lower bounds in general terms. Consider a sequence of data-structure operations A_1, A_2, \dots, A_m , where each A_i incorporates all information characterizing operation i , i.e., the operation type and any parameters for that type of operation. Upon receiving request A_i , the data structure must produce an appropriate response. The information gathered by the algorithm during a query (by probing certain cells) must uniquely identify the correct answer to the query, and thus must encode sufficient information to do so.

To establish the lower bounds of this paper, we establish lower bounds for a simpler type of problem. Consider two adjacent intervals of operations: A_i, \dots, A_{j-1} and A_j, \dots, A_k . At all times, conceptually associate with each memory cell a *chronogram* [FS89], i.e., the index t of the operation A_t during which the memory cell was last modified. Now consider all read instructions executed by the data structure during

operations A_j, \dots, A_k that access cells with a chronogram in the interval $[i, j - 1]$. In other words, we consider the set of cells written during the time interval $[i, j - 1]$ and read during the interval $[j, k]$ before they are overwritten. All *information transfer* from time interval $[i, j - 1]$ to time interval $[j, k]$ must be encoded in such cells and must be executed by such cell writes and reads. If the queries from the interval $[j, k]$ depend on updates from the interval $[i, j - 1]$, all the information characterizing this dependency must come from these cell probes, because an update happening during $[i, j - 1]$ cannot be reflected in a cell written before time i . The main technical part of our proofs is to establish a lower bound on the amount of information that must be transferred between two time intervals, which implies a corresponding lower bound on the number of cells that must be written and read to execute such a transfer. Such bounds will stem from an encoding argument, in conjunction with a simple information-theoretic analysis.

Next we show how to use such a lower bound on the information transfer between two adjacent intervals of operations to prove a lower bound on the data-structure problems we consider. Consider a binary tree whose leaves represent the entire sequence of operations in time order. Each node in the tree has an associated time interval of operations, corresponding to the subtree rooted at that node. We can obtain two adjacent intervals of operations by, for example, considering the two nodes with a common parent. For every node in the tree, we define the *information transfer through that node* to be the number of read instructions executed in the subtree of the node's right child that read data written by (i.e., cells last written by) operations in the subtree of the node's left child. The lower bound described above provides a lower bound on this information transfer for every node. We combine these bounds into a lower bound on the number of cell probes performed during the entire execution by simply summing over all nodes.

To show that this sum of individual lower bounds is indeed an overall lower bound, we make two important points. First, we claim that we are not double counting any read instructions. Any read instruction is characterized by the time when it occurs and the time when the location was last written. Such a read instruction is counted by only one node, namely, the lowest common ancestor of the read and write times, because the write must happen in the left subtree of the node, and the read must happen in the right subtree. The second point concerns the correctness of summing up individual lower bounds. This approach works for the arguments in this paper, because all lower bounds hold in the average case under the same probability distribution for the operations. Therefore, we can use linearity of expectation to break up the total number of read instructions performed on average into these distinct components. Needless to say, worst-case lower bounds could not be summed in this way.

The fact that our lower bounds hold in the average case of an input distribution has another advantage: the same lower bound holds in the presence of Las Vegas randomization. The proofs naturally allow the running time to be a random variable, depending on the input. By the easy direction of the minimax principle, a Las Vegas randomized data structure can be converted into a deterministic data structure that, on a given random distribution of the inputs, achieves the same expected running time.

This line of argument has an important generalization that we use for proving trade-off lower bounds. Instead of considering a binary tree, we can consider a tree of arbitrary degree. Then we may consider the information transfer either between any node and all its left siblings, or between any node and all its right siblings. Neither of these strategies double counts read instructions, because a read instruction is counted

only for a node immediately below the lowest common ancestor of the read and write times.

5.2. An initial bound for the partial-sums problem. We are now ready to describe an initial lower bound for the partial-sums problem, which gives a clear and concise materialization of the general approach from the previous section. We will prove a lower bound of $\Omega(\frac{\delta}{b} \lg n)$, which is tight (logarithmic) for the special case of $\delta = \Theta(b)$. The bound from this section considers only `SUM` queries and does not allow nondeterminism.

It will be useful to analyze the partial-sums problem over an arbitrary group with at least 2^δ elements. Our proof will not use any knowledge about the group, except the quantity δ . Naturally, the data structure is allowed to know the group; in fact, the data structure need only work for one arbitrary choice of group. In particular, the lower bound will hold for the group $\mathbb{Z}/2^\delta\mathbb{Z}$, the group of δ -bit integers with addition modulo 2^δ . A solution to the original partial-sums problem also gives a solution to the problem over this group, as long as we can avoid overflowing a cell in the original problem. To guarantee this, it suffices that $\delta + \lg n < b$. By definition of the model, we always have $\lg n \leq b$ and $\delta \leq b$, so we can avoid overflow by changing only constant factors.

We consider a sequence of $m = \Omega(\sqrt[3]{n})$ operations, where m is a power of 2. Operations alternate between updates and queries. We choose the index in the array touched by the operation uniformly at random. If the operation is an update, we also choose the value Δ uniformly at random. This notion of random updates and queries remains unchanged in our subsequent lower bounds, but the pattern of alternating updates and queries changes. Our lemmas do not assume anything about which operations are updates or queries, making it possible to reuse them later.

Our lower bound is based on the following lemma analyzing intervals of operations.

LEMMA 5.1. *Consider two adjacent intervals of operations such that the left interval contains L updates, the right interval contains L queries, and overall the intervals contain $O(\sqrt[3]{n})$ operations. Let c be the number of read instructions executed during the second interval that read cells last written during the first interval. Then $E[c] = \Omega(\frac{\delta}{b}L)$.*

Before we embark on a proof of the lemma, we show how it implies our logarithmic lower bound. As in the framework discussion, we consider a complete binary tree with one leaf per operation. For every node v , we analyze the information transfer through v , i.e., the read instructions executed in the subtree of v 's right child that access cells with a chronogram in the subtree of v 's left child. If v is on the $\frac{1}{3} \lg n$ bottommost levels, the conditions of the lemma are satisfied, with L being a quarter of the number of leaves under v . Then, the information transfer through v is $\Omega(L\frac{\delta}{b})$ on average. As explained in the framework discussion, we can simply sum these bounds for all nodes to get a lower bound for the execution time. The information transfer through all nodes on a single level is $\Omega(m\frac{\delta}{b})$ in expectation (because these subtrees are disjoint). Over $\frac{1}{3} \lg n$ levels, the lower bound is $\Omega(m\frac{\delta}{b} \lg n)$, or amortized $\Omega(\frac{\delta}{b} \lg n)$ per operation.

5.3. Interleaving between two intervals. The lower bound for two adjacent intervals of operations depends on the interleaving between the indices updated and queried in the two intervals. More precisely, we care about the indices a_1, a_2, \dots touched by updates during the left interval of time, and the indices b_1, b_2, \dots queried during the right interval. By relabeling, assume that $a_1 \leq a_2 \leq \dots$ and $b_1 \leq b_2 \leq \dots$.

We define the *interleaving number* l to be the number of indices i such that, for some index j , $a_i < b_j \leq a_{i+1}$. In other words, the interleaving number counts transitions from runs of a 's to runs of b 's when merging the two sorted lists of indices.

LEMMA 5.2. *Consider two adjacent intervals of operations such that the left interval contains L updates, the right interval contains L queries, and overall the intervals contain $O(\sqrt[3]{n})$ operations. Then the interleaving between the two intervals satisfies $E[l] = \Theta(L)$ and, with probability $1 - o(1)$, no index is touched by more than one operation.*

Proof. By the birthday paradox, the expected number of indices touched more than once is at most $O((\sqrt[3]{n})^2) \cdot \frac{1}{n} = O(n^{-1/3})$. By Markov's inequality, all indices are unique with probability $1 - O(n^{-1/3})$. Because $l \leq L$, it suffices to prove the lower bound. We show $E[l \mid \text{all indices are unique}] = \Omega(L)$. Because the condition is met with $\Omega(1)$ probability, $E[l] = \Omega(L)$. Fix the set S of $2L$ relevant indices arbitrarily. It remains to randomly designate L of these to be updates from the left interval, and the rest of S to be queries from the right interval. Then l is the number of transitions from updates to queries, as we read S in order. The probability that a transition happens on any fixed position is $\frac{1}{4}$, so by linearity of expectation, $E[l \mid S] = \Omega(L)$. Because this bound holds for any S , we can remove the conditioning. \square

The following information-theoretic lemma will be used throughout the paper by comparing the lower bound it gives with upper bounds given by various encoding algorithms. For an introduction to information theory, we refer the reader to [CT91]. Remember that we are considering the partial-sums problem over an arbitrary group with at least 2^δ elements.

LEMMA 5.3. *Consider two adjacent intervals of operations such that the left interval contains L updates, the right interval contains L queries, and overall the intervals contain $O(\sqrt[3]{n})$ operations. Let G be the random variable giving the indices touched by every operation, and giving the Δ values for all updates except those in the left interval. Let S be the random variable giving all partial sums queried in the right interval. Then $H(S \mid G) = \Omega(L\delta)$.*

Proof. Fix $G = g$ to an arbitrary value such that no index is touched twice in the two intervals. Let l be the interleaving between the two intervals (l is a function of g). Let U denote the set of indices updated in the left interval. By the definition of the interleaving number, there must exist l queries in the right interval to indices $q_1 < q_2 < \dots < q_l$ such that $U \cap [q_{t-1} + 1, q_t] \neq \emptyset$ for each $t \geq 1$, where q_0 is taken to be $-\infty$. Now let us consider the partial sums queried by these l queries, which we denote S_1, S_2, \dots, S_l . The terms of these sums are elements of the array $A[1..n]$ at the time the query is made. Some elements were set by updates before the first interval, or during the second interval, so they are constants for $G = g$. However, each S_t contains a random term in $[q_{t-1} + 1, q_t]$, which comes from an update from the first interval. This element was not overwritten by a fixed update from the second interval because, by assumption, no index was updated twice. Then each S_t will be a random variable uniformly distributed in the group: even if we condition on arbitrary values for all but one of the random terms, the sum remains uniformly random in the group because of the existence of inverses. Furthermore, the random variables will be independent, because S_t contains at least one random term that was not present in any S_r with $r < t$ (namely, the term in $[q_{t-1} + 1, q_t]$). Then $H((S_1, \dots, S_l) \mid G = g) = l\delta$. The variable S entails S_1, \dots, S_l , so $H(S \mid G = g) \geq l\delta$. By Lemma 5.2, $E[l] = \Omega(L)$. Furthermore, with probability $1 - o(1)$, a random G leads to no index being updated twice in the two intervals, so the above analysis applies. Then $H(S \mid G) = \Omega(L\delta)$. \square

5.4. Proof of Lemma 5.1. We consider two adjacent intervals of time, the first spanning operations $[i, j - 1]$ and the second spanning operations $[j, k]$. We propose an encoding for the partial sums queried in $[j, k]$ given the value of G and compare its size to the $\Omega(L\delta)$ lower bound of Lemma 5.3. Our encoding is simply the list of addresses and contents of the cells probed in the right interval that were written in the left interval. Thus, we are proposing an encoding of expected size $E[c] \cdot 2b$ bits, proving that $E[c] = \Omega(L\frac{\delta}{b})$. It should be noted that c is a random variable, because the algorithm can make different cell probes for different update parameters.

To recover the partial sums from this encoding, we begin by running the algorithm for the time period $[1, i - 1]$; this is possible because all operations before time i are known given G . We then skip the time period $[i, j - 1]$ and run the algorithm for the time period $[j, k]$, which will return the partial sums queried during this time. To see why this is possible, notice that a read instruction issued during time period $[j, k]$ falls into one of the following three categories, depending on the time t_w when the cell was written:

- $t_w \geq j$: We can recognize this case by maintaining a list of memory locations written during the simulation; the data is immediately available.
- $i \leq t_w < j$: The contents of the memory location are available as part of our encoding; we can recognize this case by examining the set of addresses in the encoding.
- $t_w < i$: This is the default case, if we failed to satisfy the previous conditions. The contents of the cell are determined from the state of the memory upon finishing the first simulation up to time $i - 1$.

5.5. Obtaining trade-off lower bounds. We now show how our framework can be used to derive trade-off lower bounds. In a nutshell, we consider instances when the cheaper operation is performed more frequently, so that the total cost of queries matches the total cost of updates. Then, we analyze the sequence of operations by considering a tree with a higher branching factor.

Assume there exists a data structure with amortized expected running times bounded by t_u for updates and t_q for queries. Our hard instance consists of blocks of $t_u + t_q$ operations. Each block contains t_q updates and t_u queries; the order inside a block is irrelevant. We generate the arguments to updates and queries randomly as before. Let $B = 2 \cdot \max\{\frac{t_u}{t_q}, \frac{t_q}{t_u}\}$. We prove below that the expected amortized cost of a block is $\Omega(\max\{t_u, t_q\} \frac{\delta}{b} \log_B n)$. On the other hand, the expected amortized cost of a block is at most $2t_u t_q$. This implies $\frac{t_u t_q}{\max\{t_u, t_q\}} = \Omega(\frac{\delta}{b} \log_B n)$, so $\min\{t_u, t_q\} \cdot \lg \frac{\max\{t_u, t_q\}}{\min\{t_u, t_q\}} = \Omega(\frac{\delta}{b} \lg n)$. This is the desired trade-off, which is tight when $\delta = \Theta(b)$.

To prove the lower bound on blocks, consider a balanced B -ary tree in which the leaves correspond to blocks. We let the total number of blocks be $m = \Theta(\sqrt[b]{n})$. If $\max\{t_u, t_q\} = \Omega(\sqrt[b]{n})$, our lower bound states that $\min\{t_u, t_q\} = \Omega(1)$, so there is nothing to prove. Thus, we can assume $t_u + t_q = O(\sqrt[b]{n})$, which bounds the number of operations in a block. Then, the total number of operations is $O(\sqrt[b]{n})$, satisfying one of the conditions of Lemma 5.1.

For the case $t_u \geq t_q$, we are interested in the information transfer between each node and its left siblings. The subtree of the node defines the right interval of operations, and the union of the subtrees of all left siblings defines the left interval. Let L be the number of blocks in the right interval. We make a claim only regarding nodes that are in the right half of their parent's children. In this case, the number of blocks in the left interval is at least $\frac{B}{2}L$. Then, the number of queries in the right interval

is Lt_u , while the number of updates in the left interval is at least $L \frac{t_u}{t_q} t_q = Lt_u$. We can then apply Lemma 5.1; having more updates in the left interval cannot decrease the bound, because moving the beginning of the left interval earlier can only increase the number of cell probes that are counted. Therefore, the expected number of cell probes associated with this node is $\Omega(Lt_u \frac{\delta}{b})$. Now we sum the lower bounds for all nodes on a level and obtain that the number of cell probes associated with that level is $\Omega(mt_u \frac{\delta}{b})$. Summing over all levels, we get an amortized lower bound of $\Omega(t_u \frac{\delta}{b} \log_B n)$ per block, as desired.

For the case $t_u < t_q$, we apply a symmetric argument. We analyze the information transfer between any node, giving the left interval, and all its right siblings, giving the right interval. For nodes in the first half of their parent's children, the left interval contains Lt_q updates, while the right interval contains at least Lt_q queries. By Lemma 5.1, the expected number of cell probes associated with this node is $\Omega(Lt_q \frac{\delta}{b})$. Thus, the number of cell probes associated with a level is $\Omega(mt_q \frac{\delta}{b})$, and the amortized bound per block is $\Omega(t_q \frac{\delta}{b} \log_B n)$.

5.6. Refinements. First, note that our lower bounds so far depend only on randomness in the update parameters Δ , and not on randomness in the update or query indices. Indeed, the value of G is irrelevant, except for the interleaving number that it yields. It follows that the logarithmic lower bound and the trade-off lower bound are also true for sequences of operations in which we fix everything except the Δ parameters, as long as such sequences have a high sum of the interleaving numbers of each node. Our application of Lemma 5.2 can be seen as a probabilistic proof that such bad sequences exist.

The prototypical deterministic sequence with high total interleaving is the bit-reversal permutation. For any n that is a power of 2, consider the permutation $\pi : \{0, \dots, n-1\} \rightarrow \{0, \dots, n-1\}$ that takes i to the integer obtained by reversing i 's $\log_2 n$ bits. The corresponding access sequence consists of n pairs of **UPDATE** and **SUM**, the i th pair touching index $\pi(i)$. The bit-reversal permutation underlies the fast Fourier transform algorithm. It also gives an access sequence that takes $\Omega(\lg n)$ amortized time for any binary search tree [Wil89]. Finally, it was used to prove an $\Omega(\lg n)$ bound for the partial-sums problem in the semigroup model [HF98]. To see why this permutation has high total interleaving, consider the following recursive construction. The permutation π' of order $2n$ is obtained from a permutation π of order n by the rules $\pi'(i) = 2 \cdot \pi(i)$, $\pi'(i+n) = 2 \cdot \pi(i) + 1$, for $i \in \{0, 1, \dots, n-1\}$. Each level of the recursion adds an interleaving of n between the left and right halves, so the total interleaving is $\Theta(n \lg n)$.

The fact that our lower bound holds for fixed sequences of operations implies the same lower bound in the group model. A solution in the group model handles every **UPDATE** and **SUM** by executing a sequence of additions on cells containing abstract elements from the group. The cells touched by these additions depend only on the indices touched by queries and updates, because the data structure treats the group as a black box and cannot examine the Δ 's. So if we know a priori the sequence of indices touched by queries and updates, we can implement the same solution in the cell-probe model for the group $\mathbb{Z}/2^b\mathbb{Z}$; because the Δ 's are unrestricted elements of the group, $\delta = b$. The group additions can be hardwired into our solution for the cell-probe model through nonuniformity, and cell probes are needed only to execute the actual additions.

5.7. Duality of lower and upper bounds. Recall the classic upper bound for the partial-sums problem. We maintain a tree storing the elements of the array in

order in the leaves. Each node stores the sum of all leaves in its subtree. An update adds Δ to the subtree sums along the root-to-leaf path of the touched element. A query traverses the root-to-leaf path of the element and reports the sum of all subtrees to the left of the path.

Our lower bound can be seen as a dual of this natural algorithm. To see this, we describe what happens when we apply the lower bound analysis to the algorithm. We argue informally. Consider two intervals of 2^k operations. The information transfer between the intervals is associated with a node of height k in the lower bound tree. On the other hand, the indices of the operations will form a relatively uniformly spaced set of $O(2^k)$ indices. Thus, the distance in index space between a query from the right interval and the closest update from the left interval will usually be around $n/2^k$. The algorithm's tree passes information between the update and the query through the lowest common ancestor of the two indices. Because of the separation between the indices, this will usually be a node at level around $\lg n - k$. Thus, we can say that our lower bound is roughly an upside-down view of the upper bound. The information passed through the k th level from the bottom of one tree is roughly associated with the k th level from the top of the other tree.

6. Handling queries with low output entropy. The lower bound technique as presented so far depends crucially on the query answers having high entropy: the information transfer through a node is bounded from below by the entropy of all queries from the right subtree of the node. However, in order to prove lower bounds for dynamic language membership problems (such as dynamic connectivity), we need to be able to handle queries with binary answers. To prove lower bounds for a pair of adjacent intervals, it is tempting to consider the communication complexity between a party holding the updates from the left interval and a party holding the queries from the right interval. Many bounds for communication complexity hold even for decision problems, so queries with binary output should not be a problem. However, a solution for the data structure does not really translate well into the communication-complexity setting. The query algorithm probes many cells, only a few of which (a logarithmic fraction) are in the left interval. If the party with the right interval communicates all these addresses, just to get back the answer “not written in the left interval” for most of them, the communication complexity blows up considerably. One could also imagine a solution based on approximate dictionaries, where the party holding the left interval sends a sketch of the cells that were written, allowing the other party to eliminate most of the uninteresting cell probes. However, classic lower bounds for approximate dictionaries [CFG⁺78] show that it is impossible to send a sketch that is small enough for our purposes. The solution developed in this section is not based on communication complexity, although it can be rephrased in terms of nondeterministic communication complexity. While this solution is not particularly hard, we find it to be quite subtle.

6.1. Setup for the lower bound. Our approach is to construct hard sequences of operations that will have a fixed response, and the data structure need only confirm that the answer is correct. Such predictable answers do not trivialize the problem: the data structure has no guarantee about the sequence of operations, and the information it gathers during a query (by probing certain cells) must provide a certificate stating that the predicted answer is correct. In other words, the probed cells must uniquely identify the answer to the query, and thus must encode sufficient information to do so. As a consequence, our lower bounds hold even if the algorithm makes nondeterministic cell probes, or if an all-powerful prover reveals a minimal set of cells sufficient to show

FIG. 6.1. Our graphs can be viewed as a sequence of permutation boxes (dashed). The horizontal edges between boxes are in fact contracted in the actual graphs.

that a certain answer to a query is correct.

The machinery developed in this section is also necessary in the case of the partial-sums problem if we want a lower bound for sequences of **UPDATE** and **SELECT** operations. Even though **SELECT** returns an index in the array, i.e., $\lg n$ bits, it is not clear how more than one bit of information can be used for a lower bound argument. Instead, we consider a **VERIFY-SUM** operation, which is given a sum Σ and an index i , and tests whether the partial sum up to i is equal to Σ . In principle, this operation can be implemented by two calls to **SELECT**, namely, by testing that $i = \text{SELECT}(\Sigma) = \text{SELECT}(\Sigma - 1) + 1$.

Below we give a single lower bound proof that applies to both the partial-sums problem with verify and dynamic connectivity. We accomplish this by giving a proof for the partial-sums problem over any group G with at least 2^δ elements and then specializing G for the two problems we consider.

For the partial-sums problem with **SELECT**, we use $G = \mathbb{Z}/2^\delta\mathbb{Z}$. This introduces a slight complication, because **VERIFY-SUM** in modulo arithmetic can no longer be implemented by a constant number of calls to **SELECT**. To work around this issue, remember that our lower bound for **VERIFY-SUM** also holds for nondeterministic computation. To implement **VERIFY-SUM**(i, Σ) nondeterministically, we guess a b -bit quantity Σ' such that $\Sigma' \bmod 2^\delta = \Sigma$, and verify the old condition $i = \text{SELECT}(\Sigma') = \text{SELECT}(\Sigma' - 1) + 1$. We have implicitly assumed that **SELECT** is deterministic, which is natural because **SELECT** does not return a binary answer. Note that only one thread accepts, so there is no problem if **SELECT** updates memory cells (the updates made by the sole accepting thread are the ones that matter).

For the dynamic-connectivity problem, we use $G = S_{\sqrt{n}}$, i.e., the permutation group on \sqrt{n} elements. Notice that now we have $\delta = \sqrt{n} \lg \sqrt{n} - \Theta(\sqrt{n})$, a very large quantity, unlike in the partial-sums problem, where it was implied that $\delta < b$. Our proof never actually assumes any particular relation between δ and b .

To understand the relation between this problem and dynamic connectivity, refer to Figure 6.1. We consider a graph whose vertices form an integer grid of size \sqrt{n} by \sqrt{n} . Edges only connect vertices from adjacent columns. Each vertex is incident to at most two edges, one edge connecting to a vertex in the previous column and one edge connecting to a vertex in the next column. These edges do not exist only when the vertex is in the first or last column. The edges between two adjacent columns of vertices thus form a perfect matching in the complete bipartite graph $K_{\sqrt{n}, \sqrt{n}}$, describing a permutation of order \sqrt{n} . More precisely, point (x, y_1) in the grid is connected to point $(x + 1, y_2)$ exactly when $\pi_x(y_1) = y_2$ for a permutation π_x .

Another way to look at the graph is in terms of permutation networks. We can imagine that the graph is formed by \sqrt{n} horizontal wires, going between permutation boxes. Inside each box, the order of all wires is changed arbitrarily.

Our graph is always the disjoint union of \sqrt{n} paths. This property immediately implies that the graph is plane, because any embedding maintains planarity (though the edges may have to be routed along paths with several bends).

The operations required by the partial-sums problem need to be implemented in terms of many elementary operations, so they are actually “macro-operations.” Macro-operations are of two types, **UPDATE** and **VERIFY-SUM**, and all receive as parameters a permutation and the index x of a permutation box. To perform an update, all the edges inside the named permutation box are first deleted and then reconstructed according to the new permutation. This translates to \sqrt{n} **DELETE**’s and \sqrt{n} **INSERT**’s in the dynamic-connectivity world. Queries on box x test that point $(1, y)$ is connected to point $(x + 1, \pi(y))$ for all $y \in \{1, 2, \dots, \sqrt{n}\}$. This requires \sqrt{n} connectivity queries. The conjunction of these tests is equivalent to testing that the composition of $\pi_1, \pi_2, \dots, \pi_x$ (the permutations describing the boxes to the left) is identical to the given permutation π —the **VERIFY-SUM** in the partial-sums world.

As stated before, the lower bound we obtain is $\Omega(\frac{\delta}{b} \lg n)$. For dynamic connectivity, we are interested in $b = \Theta(\lg n)$, which is the natural word size for this problem. As we saw already, $\delta = \Theta(\sqrt{n} \lg n)$. Thus, our lower bound translates into $\Omega(\sqrt{n} \lg n)$. This is a lower bound for the macro-operations, though, which are implemented through $O(\sqrt{n})$ elementary operations. Therefore, the lower bound for dynamic connectivity is $\Omega(\lg n)$, as desired. The same calculation applies to the trade-off expressions, which essentially means that the $\frac{\delta}{b}$ term should be dropped to obtain the true bound for dynamic connectivity.

6.2. Proof of the lower bound. As before, the sequence of operations alternates between **UPDATE** and **VERIFY-SUM**. The index queried or updated is chosen uniformly at random. If the operation is an **UPDATE**, we select a random element of G for the value Δ . If the operation is **VERIFY-SUM**, we give it the composition of the elements before the queried index. This means that the data structure will be asked to prove a tautology, involving the partial sum up to that index.

Because of this construction of the hard sequence, at least one nondeterministic thread for each query should accept. For every random input, let us fix one accepting thread for each operation. When we mention cells that are “read,” we mean cells read in this chosen execution path; by definition of the model, writes are the same for all accepting threads. As in the framework discussion, we are interested in lower bounds for the information transfer between adjacent intervals of operations. The following lemma is an analogue of Lemma 5.1.

LEMMA 6.1. *Consider two adjacent intervals of operations such that the left interval contains L updates, the right interval contains L queries, and overall the intervals contain $O(\sqrt[3]{n})$ operations. Let w be the number of write instructions executed during the first interval, and let r be the number of read instructions executed during the second interval. Also, let c be the number of read instructions executed during the second interval that read cells last written during the first interval. Then $E[c] = \Omega(L \frac{\delta}{b}) - O(\frac{E[s]}{b})$, where $s = \lg \binom{r+w}{r}$.*

Note that the lower bound of this lemma is weaker than that of Lemma 5.1, because of the additional term $\frac{E[s]}{b}$. Before we prove this lemma (in the next section), let us show that this term is inconsequential, and the lemma implies the same bounds and trade-offs.

Consider a sequence of $m = \Theta(\sqrt[3]{n})$ operations, and let T be the total running time of the data structure. We construct a complete binary tree over these operations. Consider a node v that is a right child, and let L be the number of leaves in its subtree. By Lemma 6.1, we have $E[c] = \Omega(L \frac{\delta}{b}) - O(\frac{E[s]}{b})$, where c is the number of cell probes associated with v . Note that $s = \lg \binom{r+w}{r} \leq r + w$; thus, s is bounded by the number of read instructions in v 's subtree, plus the number of write instructions in the subtree of v 's left sibling. Summing for all nodes on a level, s counts all read and write instructions at most once, so we obtain $E[\sum c_i] = \Omega(m \cdot \frac{\delta}{b}) - O(\frac{E[T]}{b})$. We sum up the lower bounds for each level to obtain a lower bound on $E[T]$. We obtain that $E[T] = \Omega(m \cdot \frac{\delta}{b} \lg n) - O(\lg n \cdot \frac{E[T]}{b})$. Because $\lg n \leq b$, this means that $E[T] = \Omega(m \cdot \frac{\delta}{b} \lg n)$. This result implies an average-case amortized lower bound per operation of $\Omega(\frac{\delta}{b} \lg n)$.

To obtain trade-off lower bounds, we apply the same reasoning as in section 5.5. The only thing we have to do is verify that the new term depending on $E[s]$ does not affect the end result. When we sum the lower bounds for one level in the tree, we lose a term of $O(\sum \frac{E[s_i]}{b})$, compared to the old bound. Here i ranges over all nodes at that level. We must understand $\sum s_i = \lg \prod \binom{r_i+w_i}{r_i}$ in terms of T , the total running time for the entire sequence of operations.

The quantity $\prod \binom{r_i+w_i}{r_i}$ counts the total numbers of ways to choose r_i elements from a set $r_i + w_i$, where we have a different set for each i . This is bounded from above by the number of ways to choose $\sum r_i$ elements from a single set of $\sum (r_i + w_i)$ objects. Thus, $\sum s_i \leq \lg \binom{\sum (r_i+w_i)}{\sum r_i}$. Assume we have upper bounds $\sum r_i \leq U_r$ and $\sum w_i \leq U_w$. Then, we can write $\binom{\sum (r_i+w_i)}{\sum r_i} \leq \binom{U_r+U_w}{\sum r_i} \leq \binom{2(U_r+U_w)}{\sum r_i} \leq \binom{2(U_r+U_w)}{U_r}$. The last inequality holds because $\binom{n}{k}$ increases with k for $k \leq \frac{n}{2}$. We entered this regime by artificially doubling $U_r + U_w$. Because r_i and w_i are symmetric, we also have $\binom{\sum (r_i+w_i)}{\sum r_i} = \binom{\sum (r_i+w_i)}{\sum w_i} \leq \binom{2(U_r+U_w)}{U_r}$.

Now we need to develop the upper bounds U_r and U_w . For the case $t_u \leq t_q$, our proof considered intervals formed by a node and all its left siblings. Thus, $\sum r_i$ counts each read instruction once, for the node it is under; so $\sum r_i \leq T$. On the other hand, $\sum w_i \leq B \cdot T$, because a write instruction is counted for every right sibling of its ancestor on the current level. For the case $t_u > t_q$, we consider intervals formed by a node and all its right siblings. Thus, $\sum w_i \leq T$ and $\sum r_i \leq B \cdot T$.

Using these bounds, we see that $\sum s_i \leq \lg \binom{2(B+1)T}{T} = O(T \lg B)$. Because this upper bound holds in any random instance, it also holds in expectation: $E[\sum s_i] = O(E[T] \lg B)$. So our lower bound loses $O(\frac{E[T] \lg B}{b})$ per level, which, over all levels, sums to $O(\frac{E[T] \lg B}{b} \log_B n) = O(E[T] \frac{\lg n}{b})$. Because $\lg n \leq b$, our lower bound on $E[T]$ is equal to the old lower bound minus $O(E[T])$. Thus, we lose only a constant factor in the lower bound, and the results of section 5.5 continue to hold.

6.3. Proof of Lemma 6.1. The proof is an encoding argument, which is similar in spirit to the proof of Lemma 5.1 but requires a few significant new ideas. The difference from the previous proof is that the partial sums that we want to encode are no longer returned by queries, but rather they are given as parameters. Our strategy is to recover the partial sums by simulating each query for all possible parameters and see which one leads to an accept. However, these simulations may read a large number of cells, which we cannot afford in the encoding. Instead, we add a new part to the encoding which enables us to stop simulations that try to read cells we don't know. The difficulty is making this new component of the encoding small enough.

As before, we consider two adjacent intervals of operations, the first spanning $[i, j - 1]$ and the second $[j, k]$. We propose an encoding for the partial sums passed to the **VERIFY-SUM** operations during $[j, k]$, given the variable G defined in Lemma 5.3. By this lemma, such an encoding must have size $\Omega(L\delta)$ bits.

The encoder first simulates the entire execution of the data structure. Each query is given the correct partial sum, so it must accept. We choose arbitrarily one of the accepting threads. Consider the following sets of cells, based on this computation history:

- W = cells which are updated by the data structure during the interval of time $[i, j - 1]$, and never read during $[j, k]$.
- R = cells which are read by the data structure during $[j, k]$ and their last update before the read happened before time i .
- C = cells which are read by the data structure during $[j, k]$ and their last update before the read happened during $[i, j - 1]$.

These are simple sets, so, for example, cells written multiple times during $[i, j - 1]$ are included only once in W . We have $|C| = c$, $|W| \leq w$, $|R| \leq r$. Note that all of c , $|W|$, w , $|R|$, and r are random variables, because the data structure can behave differently depending on the Δ 's passed to the updates. We will give an encoding for the queried partial sums that uses $O(b) + c \cdot 2b + O(s)$ bits, where $s = \lg \binom{r+w}{r}$. Because the expected size of our encoding must be $\Omega(L\delta)$, we obtain that $E[c] + \frac{E[s]}{\Theta(b)} = \Omega(L\frac{\delta}{b})$, and therefore $E[c] = \Omega(L\frac{\delta}{b}) - O(\frac{E[s]}{b})$.

Our encoding consists of two parts. The first encodes all information about the interesting cell probes (the information transfer): for each cell in C , we encode the address of the cell and its contents at time j . This uses $O(b)$ bits to write the size of C , and $c \cdot 2b$ for the information about the cells. The second part is concerned with the “uninteresting” cell probes, i.e., those in R . This accounts for a covert information transfer: the fact that a cell was *not* written during $[i, j - 1]$ is a type of information transmitted to $[j, k]$. The part certifies that W and R are disjoint, by encoding a set S , such that $R \subset S$ and $W \subset \bar{S}$. We call S a separator between R and W . To efficiently encode a separator, we need the following result.

LEMMA 6.2. *For any integers a, b, u with $a + b \leq u$, there exists a system of sets \mathbb{S} with $\lg |\mathbb{S}| = O(\lg \lg u + \lg \binom{a+b}{a})$ such that, for all $A, B \subset \{1, 2, \dots, u\}$ with $|A| \leq a$, $|B| \leq b$, $A \cap B = \emptyset$, there exists an $S \in \mathbb{S}$ satisfying $A \subset S$ and $B \subset \bar{S}$.*

Proof. It suffices to prove the lemma for $|A| = a$ and $|B| = b$, because we can simply add some elements from $\{1, 2, \dots, u\} \setminus (A \cup B)$ to pad the sets to the right size. We use the probabilistic method to show that a good set system exists. Select a set S randomly by letting every element $x \in \{1, 2, \dots, u\}$ be in the set with probability $p = \frac{a}{a+b}$. Then, for any pair A, B , the probability that $A \subset S$ and $B \subset \bar{S}$ is $p^a(1 - p)^b$. The system \mathbb{S} will be formed of sets chosen independently at random, so the probability that there is no good S for some A and B is $(1 - p^a(1 - p)^b)^{|\mathbb{S}|} \leq \exp(-p^a(1 - p)^b|\mathbb{S}|)$. The number of choices for A and B is $\binom{u}{a} \binom{u-a}{b} \leq u^{a+b}$. So the probability that there is no good set in \mathbb{S} for any A, B is at most $u^{a+b} \exp(-p^a(1 - p)^b|\mathbb{S}|) = \exp((a + b) \ln u - p^a(1 - p)^b|\mathbb{S}|)$. As long as this probability is less than 1, such a system \mathbb{S} exists. So we want $(a + b) \ln u < p^a(1 - p)^b|\mathbb{S}| = (\frac{a}{a+b})^a (\frac{b}{a+b})^b |\mathbb{S}|$. We want to choose a system of size greater than $\frac{(a+b)^{a+b+1} \ln u}{a^a b^b}$. Then $\lg |\mathbb{S}| = \Theta((a + b + 1) \log_2(a + b) + \lg \lg u - a \log_2 a - b \log_2 b)$. Assume by symmetry that $a \leq b$. Then $\lg |\mathbb{S}| = \Theta(\lg \lg u + a \lg \frac{b}{a} + a \cdot \frac{b}{a} \log_2(1 + \frac{a}{b}))$. Let $t = \frac{b}{a}$; then $t \log_2(1 + \frac{1}{t}) = \log_2((1 + \frac{1}{t})^t) \rightarrow \log_2 e$ as $t \rightarrow \infty$. We then have

$\frac{b}{a} \log_2(1 + \frac{a}{b}) = \Theta(1)$, so our result simplifies to $\lg |\mathbb{S}| = \Theta(\lg \lg u + a \lg(b/a))$. It is well known that $a \lg(b/a) = \Theta(\lg \binom{a+b}{a})$ for $a \leq b$. \square

We apply this lemma with parameters r , w , and 2^b . First, we encode r and w , using $O(b)$ bits. The encoding and decoding algorithms can simply iterate over all possible systems \mathbb{S} for the given r and w , and choose the first good one (in the sense of the lemma). Given this unique choice of a system, a separator between R and W is the index of an appropriate set in the system. This index will occupy $O(\lg \lg(2^b) + \lg \binom{r+w}{r}) = O(\lg b + s)$ bits.

It remains to show that this information is enough to encode the sequence of queried partial sums. We simulate the data structure for the interval $[j, k]$, and prove by induction on time steps that all cell writes made by these operations are correctly determined, and all partial sums appearing in `VERIFY-SUM`'s are recovered. Updates are easy to handle, because their parameters are known given G , and they are deterministic. Thus, we can simply simulate the update algorithm. We are guaranteed that all cells that are read and have a chronogram in $[i, j-1]$ appear in C , so we can identify these cells and recover their contents. All other cells have a known content given G , so we can correctly simulate the update.

In the case of `VERIFY-SUM`, we do not actually know the sum passed to it, so we cannot simply simulate the algorithm. Instead, we try all partial sums that could be passed to the query, and for each one try all possible execution paths that the data structure can explore through nondeterminism. The cell probes made while simulating such a thread fall in one of the following cases:

- The cell was written by the data structure after time j . This case can be identified by looking at the set of cells written during the simulation. By the induction hypothesis, we have correctly determined the cell's contents.
- The cell is in C . We recover the contents from the encoding.
- The cell is on R 's side of the separator between R and W . Then, it was not written during $[i, j-1]$, and thus it has the old value before time i . Given G , everything is fixed before time i , so we know the cell's contents.
- The cell is on W 's side of the separator. Then this thread of execution cannot be in the computation history chosen by the encoding algorithm. We abort the thread.

For each query, there exists a unique partial sum for which it should accept. Furthermore, one accepting thread is included in the computation history of the encoder. Thus, we identify at least one thread which accepts and is not aborted because of the last case above. Because the data structure is correct, all accepting threads must be for the same partial sum, so we correctly identify the sum. By definition of the nondeterministic model, the cell writes are identical for all accepting threads, so we correctly determine the cell writes, as well.

It should be noted that, even though the size of the encoding depends only on the characteristics of one accepting thread per query, the separator allows us to handle an arbitrary number of rejecting threads. All such threads (including all threads for incorrect partial sums) are either simulated until they reject, or they are aborted.

6.4. Handling Monte Carlo randomization. This section shows that the logarithmic lower bound for dynamic connectivity is also true if we allow Monte Carlo randomization with two-sided error probability at most n^{-c} , for constant c (that is, the data structure must be correct with high probability). The idea is to make the decoding algorithm from the previous section use only a polynomial number of calls to data-structure operations.

Assume for now that the data structure is deterministic. The previous decoding algorithm simulates a large number of primitive connectivity operations for every query. A partial sum is recovered by simulating **VERIFY-SUM** for all possible sums. Remember that a partial sum in the dynamic-connectivity problem is a permutation in $S_{\sqrt{n}}$, obtained by composition of the permutations up to a certain column k . Thus, there are $(\sqrt{n})!$ partial sums to try—a huge quantity. However, we can recover the partial-sum permutation by simulating at most $(\sqrt{n})^2$ **CONNECTED** queries: it suffices to test connectivity of every point in the first column with every point on the k th column. First, the decoder simulates **CONNECTED** queries between the first node in column one and every node in column k . Exactly one of these queries was executed by the encoder so that query should accept. The other queries will reject or be aborted. Now the writes made by the accepting query are incorporated in the data structure. The decoder continues to simulate query calls between the second node in column one and all nodes in column k , and so on.

Now assume that the data structure makes an error with probability at most n^{-c} for a sufficiently large constant c . We make the encoding randomized; the random bits are those used to initialize the memory of the data structure. We assume both the encoder and the decoder receive the same random bits, so both can simulate the same behavior of the data structure. By the minimax principle, we can fix those random bits if we are interested only in the expected size of the encoding for a known input distribution (which is the case).

The decoding algorithm described above will work if all correct queries accept, *and* all incorrect queries would reject if they were executed instead of the correct one. We can simulate the execution of any query, or abort it only if it is not one of the correct queries. So if all incorrect queries reject, their simulation will either reject or be aborted. Because we consider only polynomial sequences of operations, we simulate at most $\text{poly}(n)$ queries (including the incorrect ones). The probability that any of them will fail is at most $n^{-c'}$ for some arbitrarily large constant c' (depending on c). Because the decoder has the same coins as the encoder, the encoder can predict whether the decoder will fail. Thus, it can simply add one bit saying whether the old encoding is used (when the decoder works), or the entire input is simply included in the encoding (if the old decoder would fail). The expected size of the encoding grows by at most $1 + n^{-c'} \cdot \text{poly}(n) < 2$ for sufficiently large c' . So the bounds of Lemma 6.1 remain the same. Then, the bounds and trade-offs derived for dynamic connectivity hold even if the data structure answers correctly with high probability.

7. Handling a higher word size. For the partial-sums problem, it is natural and traditional to consider the case $\delta = o(b)$. For ease of notation, we will let $B = \frac{b}{\delta}$. For dynamic connectivity, our motivation comes from external-memory models. For this problem, a “memory cell” is actually an entire page, because that is the unit of memory that can be accessed in constant time. In this case, B is what is usually referred to as “page size”; the number of bits in a page is $b = B \cdot \lg n$. For both problems, the lower bound we obtain is $\Omega(\log_B n)$.

We note that the analysis from the previous sections gives a tight bound on the number of bits that must be communicated: $\Omega(\delta \lg n)$. Given that we can pack b bits into a word, it is straightforward to conclude that $\Omega(\frac{\delta}{b} \lg n) = \Omega(\frac{\lg n}{B})$ read instructions must be performed. Our strategy for achieving $\Omega(\frac{\lg n}{\lg B})$ is to argue that an algorithm cannot make efficient use of all b bits of a word if future queries are sufficiently unpredictable. Intuitively speaking, if we need δ bits of information from a certain time epoch to answer a query, and there are $t \cdot \frac{b}{\delta}$ possible future queries

that would also need δ bits of information from the same epoch ($t > 1$), a cell probe cannot be very effective. No matter what information the cell probe gathers, we have a probability of at most $1/t$ that it has gathered all the information necessary for a random future query, so with constant probability the future query will need another cell probe. The reader will recognize the similarity, at an intuitive level, with the round-elimination lemma from communication complexity [MNSW98, SV]. Also note that our proof strategy hopelessly fails with any deterministic sequence of indices, such as the bit-reversal permutation. Thus, we are identifying another type of hardness hidden in our problems.

Unfortunately, there are two issues that complicate our lower bounds. The first is that, for dynamic connectivity, we need to go beyond the **VERIFY-SUM** abstraction, and deal with **CONNECTED** queries directly. To see why, remember that a **VERIFY-SUM** macro-query accesses a lot of information ($\Theta(\sqrt{n} \lg n)$ bits) in a very predictable fashion, depending on just one query parameter. Thus, we do not have the unpredictability needed by our lower bound. The second complication is that, for the partial-sums problem, we can handle **VERIFY-SUM** only when $\delta = \Omega(b)$. When $\delta = o(\lg n)$, the information per query is not enough to hide the cost of the separators from Lemma 6.2. However, we can still obtain lower bounds for **SUM** and **SELECT**, without nondeterminism, using a rather simple hack.

In section 7.1, we describe a new analysis for adjacent intervals of operations, which is the gist of our new lower bounds. In section 7.2, we show how this new lower bound can be used for the partial-sums problems, whereas in section 7.3, we show how to apply it to dynamic connectivity.

7.1. A new lower bound for adjacent intervals. We now consider an abstract data-structure problem with two operations, **UPDATE** and **QUERY**. We do not specify what **UPDATE** does, except that it receives some parameters and behaves deterministically based on those. A query receives two parameters i and q and returns a Boolean answer. We refer to i as an index. For any admissible i , there exists a unique q which makes the query accept. The parameter q is a δ -bit value, where δ is a parameter of the problem; we let $B = b/\delta$. The implementation of **QUERY** can be nondeterministic. We assume that the hard instance of the problem comes from some random distribution, but that the pattern of updates and queries is deterministic. In the hard instance, each **QUERY** receives the q which makes it accept. We will assume that the random features of each operation are chosen by the distribution independently of the choices for other operations. Though we do not really need this assumption, it is true in both problems we consider and, assuming independence, simplifies exposition.

Now consider two intervals of operations $[i, j - 1]$ and $[j, k]$, and let L be the number of queries in the second interval. We make an information-theoretic assumption, which we will later prove for both the partial-sums and dynamic-connectivity problems. To describe this assumption, pick a random $t \in [j, k]$ such that the t th operation is a query. Also pick a set Q of BL random queries that could have been generated as query t . Now, imagine simulating each such query starting with the state of the data structure at time $t - 1$. Our assumption is essentially that the correct q 's for all original queries from $[j, k]$, plus the simulated queries in Q , have high entropy. More specifically, let Z be the random variable specifying all updates outside $[i, j - 1]$ and the indices for all queries, including those in Q . We assume that the vector of q 's has entropy $\Omega(BL\delta)$ given Z .

Let w be the number of write instructions executed during the first interval, and

let r be the number of read instructions executed during the second interval. Also let c be the number of read instructions executed during the second interval that read cells last written during the first interval. Under the assumptions above, we prove $E[c] = \Omega(L) - O(\frac{s}{b})$, where $s = (B \cdot E[r]) \log_2(1 + \frac{E[w]}{B \cdot E[r]})$.

We now outline the proof strategy. The probability that query t reads at least one cell from $[i, j - 1]$ is at most $\frac{E[c]}{L}$. If $E[c]$ were small, so would this probability. That would mean that a large fraction of the queries from Q (random queries that could be executed at time t) would not need to read any cell written during $[i, j]$. On the other hand, the queries recover $\Omega(BL\delta) = \Omega(Lb)$ bits of information about the updates in the left interval. Because most queries don't need to read another cell, most of this information must have already been recovered by the cell probes made in $[j, t - 1]$. There are at most $E[c]$ probes in expectation, each reading b bits, so the recovered information is not enough when $E[c]$ is small.

Encoding algorithm. As the first step of the formal proof, we describe the algorithm encoding the correct q 's. First, simulate the entire execution of the data structure, with the real query at time t . For each query, include an arbitrary accepting thread in the computation history. Based on this computation history, consider the following sets:

- C = cells that are written during $[i, j - 1]$ and read during $[j, k]$.
- W = cells that are written during $[i, j - 1]$ but not read during $[j, k]$.
- R_1 = cells that are read during $[j, k]$, but never written during $[i, j - 1]$.

Now simulate the queries in Q starting from the state of the data structure at time $t - 1$. As before, we only pass correct parameters to these queries. Call *easy queries* the queries for which there exists an accepting thread which does not read any cell in W ; call such a thread a *good thread*. The rest of the queries are *hard queries*; let h be the number of hard queries. Let R_2 be the union of the cells read by an arbitrary good thread of every easy query, from which we exclude the cells in C . By the definition of easy queries, R_2 is disjoint from W . Let $R = R_1 \cup R_2$; R is also disjoint from W .

The encoding has four parts as follows:

1. Encode c and, for each cell in C , the address and contents of the cell;
2. a separator (as given by Lemma 6.2) between R and W ;
3. encode h , and the set of hard queries. The set takes $\lg \binom{|Q|}{h} = \lg \binom{BL}{h}$ bits;
4. the correct q for each hard query, as an array of size h . This takes $h\delta$ bits.

The third part of the encoding could be avoided for our current problem, because the separator can be used to recognize hard queries. However, we will later consider a variation in which we discard the separator, and then encoding which queries are hard could no longer be avoided.

Decoding algorithm. We now describe how to recover the correct q 's given Z and the previous encoding. By definition, a separator of R and W is also a separator for R_1 and W . Given this separator and complete information about C , we can simulate the real operations in the second interval, as argued in Lemma 6.1, and recover their correct q 's. Now we have to recover the correct parameters for the queries in Q . For hard queries, this is included in the encoding. For each easy query, each possible q , and all threads, we try to simulate the thread starting with what we know about the data structure at time $t - 1$. Each cell that is probed falls into one the following cases:

- The cell was written during $[j, t - 1]$. Because we simulated the data structure in this interval, we can identify this condition and recover the cell contents.
- The cell is in C . We recover the contents from the encoding.

- The cell is on R 's side of the separator between R and W . Then, it was not written during $[i, j - 1]$, and we can recover the cell contents because Z includes perfect information before time i .
- The cell is on W 's side of the separator. Then, this thread of execution cannot be among the chosen good threads for the easy queries, so we abort it.

For the chosen good thread of an easy query, the encoder included its probes outside of C in the set R_2 , so simulation of this thread is never aborted. Thus, for each easy query, we find at least one accepting thread, and recover the correct q .

Analysis. We want to bound the size of the separator. We have $|W| \leq w$, $|R_1| \leq r$, so it remains to bound $|R_2|$. In expectation over a random t and a random choice of the queries in the second interval, the number of cells read by query t is at most $\frac{E[r]}{L}$. We are simulating a set of BL queries as if they happened at time t . In expectation, the total number of cell probes performed by these is at most $BL \frac{E[r]}{L} = B \cdot E[r]$, which also bounds $E[|R_2|]$. Then $E[|R|] \leq E[|R_1|] + E[|R_2|] = O(B)E[r]$. To specify the separator, we need $O(b)$ bits to write $|W|$ and $|R|$, and then, by Lemma 6.2, $O(\lg b + \log_2 \binom{|W|+|R|}{|R|})$ bits for the index into the system of separators. The total size is $O(b + |R| \log_2(1 + \frac{|W|}{|R|}))$ bits. The function $(x, y) \mapsto x \log_2(1 + \frac{y}{x})$ is concave, so the expected size is upper bounded by moving expectations inside. Then, the expected size of the separator is $O(b + (B \cdot E[r]) \lg(1 + \frac{E[w]}{B \cdot E[r]})) = O(b + s)$.

To analyze the rest of the encoding, we need to bound h . For a random t , the expected number of cell probes from the first interval that are made by query t is at most $\frac{E[c]}{L}$. This means that a random query at position t is bad with probability at most $\frac{E[c]}{L}$. Thus, $E[h] = BL \frac{E[c]}{L} = B \cdot E[c]$. Explicitly encoding the correct q 's for the hard queries takes $E[h]\delta = b \cdot E[c]$ bits in expectation. This is the same as the space taken to encode the contents of cells in C . Encoding which queries are hard takes space $O(b) + \lg \binom{BL}{h} = O(b + h \lg \frac{BL}{h})$. The function $x \rightarrow x \lg \frac{\gamma}{x}$ is concave for constant γ , so the expected size is at most $O(b + E[h] \lg \frac{BL}{E[h]}) = O(b + B \cdot E[c] \lg \frac{L}{E[c]})$.

We have shown an upper bound of $O(E[c]b + s + B \cdot E[c] \lg \frac{L}{E[c]})$ on the expected total size of the encoding. Let $\varepsilon > 0$ be an absolute constant to be determined. If $E[c] \geq \varepsilon L$, there is nothing to prove. Otherwise, observe that $x \mapsto x \log_2(2 + \frac{\gamma}{x})$ grows with x for constant γ , so the last term of the encoding size becomes $O(B\varepsilon L \lg \frac{1}{\varepsilon})$. The assumed lower bound on the size of the encoding is $\Omega(BL\delta) = \Omega(bL)$, so we obtain $E[c] = \Omega(L) - O(\frac{\varepsilon}{\delta} L \lg \frac{1}{\varepsilon}) - O(\frac{s}{b})$. Note that $\varepsilon \lg \frac{1}{\varepsilon}$ goes to zero as ε goes to zero. Then, assuming $\delta \geq 2$, there is an absolute constant ε such that the second term of the lower bound is a constant fraction of the first term. We thus obtain $E[c] = \Omega(L) - O(\frac{s}{b})$.

Deterministic queries. Now we consider a variation of our original problem, in which queries are deterministic, and they return q , as opposed to verifying a given q . The only change in our analysis is that we do not need the separator. Indeed, each query can be simulated unambiguously, because it only receives a known index, and it is deterministic. Then, the separator term in our lower bound disappears, and we obtain $E[c] = \Omega(L)$.

7.2. The partial-sums problem. Our hard instance is the same as in section 5.5: we consider blocks of t_q random updates and t_u queries to random indices. We begin by showing a lower bound for two intervals based on the analysis from the previous section. Let c, r, w be as defined in the previous section.

LEMMA 7.1. *Consider two adjacent intervals of operations such that the left interval contains $B \cdot L$ updates, the right interval contains L queries, and overall the intervals contain $O(\sqrt[3]{n})$ operations. The following lower bounds hold:*

- In the case of **SUM** queries, $E[c] = \Omega(L)$.
- In the case of **VERIFY-SUM** queries, $E[c] = \Omega(L) - O(\frac{s}{b})$, where we define $s = (B \cdot E[r]) \log_2(1 + \frac{E[w]}{B \cdot E[r]})$.

Proof. This follows from the analysis in the previous section, as long as we can show the information-theoretic assumption made there. Specifically, we pick a query from the second interval, and imagine simulating BL random queries in its place. We need to show that the partial sums of the original queries and these virtual queries have entropy $\Omega(BL\delta)$, given the indices of all queries, and the indices and Δ values for all queries outside the left interval (the variable Z from the previous section). To prove this, we apply Lemma 5.3. Because that lemma deals only with the partial sums (a feature of the problem instance) and not with computation, it doesn't matter that we are simulating the BL queries at the same time. The partial sums would be the same if the queries ran consecutively. Then, the lemma applies and shows our entropy lower bound. Note that the variable G in Lemma 5.3 describes all queries, including the simulated ones (which the lemma thinks are consecutive). This is exactly the variable Z . \square

We now show how to use this lemma to derive our lower bounds. Our analysis is similar to that of section 6.2, with two small exceptions. The first is that there is an inherent asymmetry between the left and right intervals in Lemma 7.1. Because of this, we can handle only the case $t_q = O(t_u)$. The second change is that the definition of s is somewhat different from that in Lemma 6.1; roughly, s is larger because $E[r]$ is multiplied by B . We will show lower bounds of the form $t_q(\lg B + \lg \frac{t_u}{t_q}) = \Omega(\lg n)$.

We consider a balanced tree with branching factor $\beta = 2B \frac{t_u}{t_q}$ over $m = \Theta(\sqrt[n]{n})$ blocks. Because, for $\max\{t_q, t_u\} = \Omega(\sqrt[n]{n})$, our trade-off states $\min\{t_q, t_u\} = \Omega(1)$, we may assume $t_u + t_q = O(\sqrt[n]{n})$. Then there are $O(\sqrt[n]{n})$ operations in total, as needed. We will consider right intervals formed by a node of the tree, and left intervals formed by all its left siblings. The choice of β gives the right proportion of updates in the left interval, compared to queries in the right interval, for any node which is in the right half of its siblings. Then, we can apply Lemma 7.1.

First, consider the case of **SUM** queries, so there is no term depending on s . Note that the $\Omega(L)$ term is linear in the number of queries, so summing it over the entire tree yields a lower bound on the total time of $E[T] = \Omega(mt_u \log_\beta n)$. By the definition of the blocks, $E[T] = m \cdot 2t_u t_q$, so $t_q = \Omega(\log_\beta n)$, which is equivalent to $t_q(\lg B + \lg \frac{t_u}{t_q}) = \Omega(\lg n)$.

Now we consider nondeterministic **VERIFY-SUM** queries, assuming $\delta = \Omega(\lg n)$. There is a new term in the lower bound on $E[T]$, given by the sum of the s terms over all nodes. First, consider the sum for all nodes on one level: $\sum s_i = \sum (B \cdot E[r_i]) \log_2(1 + \frac{E[w_i]}{B \cdot E[r_i]})$. We have $\sum r_i \leq T$, because each read is counted for the node it is under, and $\sum w_i \leq \beta T$, because each write is counted for the siblings of the node it is under. These inequalities must also hold in expectation, so $\sum B \cdot E[r_i] \leq B \cdot E[T]$ and $\sum E[w_i] \leq \beta E[T]$. Because the function $(x, y) \mapsto x \log_2(1 + \frac{y}{x})$ is concave, $\sum s_i$ is maximized when $E[r_i]$ and $E[w_i]$ are equal. Then $\sum s_i \leq B \cdot E[T] \log_2(1 + \frac{\beta E[T]}{B \cdot E[T]}) = O(E[T] B \lg(t_u/t_q))$. When we sum this over $O(\log_\beta n)$ levels, we obtain $E[T] \cdot O(B \lg(t_u/t_q) \frac{\lg n}{\lg(B t_u/t_q)}) = E[T] \cdot O(B \lg n)$.

Thus, our overall lower bound becomes $E[T] = \Omega(mt_u \log_\beta n) - O(\frac{1}{b} E[T] B \lg n)$. Expanding B , $E[T] = \Omega(mt_u \log_\beta n) - O(E[T] \frac{\lg n}{\delta})$. For $\delta = \Omega(\lg n)$, we obtain $E[T] = \Omega(mt_u \log_\beta n)$, which is the same lower bound as for **SUM** queries. This bound holds for **VERIFY-SUM** queries, even with nondeterminism, and, as shown in section 6.1,

also for **SELECT** queries.

For the case $\delta = O(\lg n)$, we can obtain the same lower bound on **SELECT** by a relatively simple trick. This means that the trade-off lower bound for **SELECT** holds for any δ , though we cannot prove it in general for **VERIFY-SUM**. The trick is to observe that for small δ (e.g., $\delta < \frac{1}{3} \lg n$), we can stretch (polynomially) an instance of **SUM** into an instance of **SELECT**. Because we already have a lower bound for **SUM**, a lower bound for **SELECT** follows by reduction.

Consider the **SUM** problem on an array $A[0.. \sqrt[3]{n} - 1]$, where each element has δ bits. This implies $0 \leq A[i] < \sqrt[3]{n}$, and any partial sum is less than $n^{2/3}$. Now we embed A into an array $A'[0.. n-1]$ by $A'[i \cdot n^{2/3}] = A[i]$. The $n^{2/3} - 1$ spacing positions between elements from A are set to 1 in the initialization phase, and never changed later. An update in A translates into an update in A' in the appropriate position. Now assume we want to find $\sigma = \sum_{i=0}^k A[i]$. We run **SELECT** $((k+1)(n^{2/3} - 1))$ in A' . We have $\sum_{j=0}^{t+k \cdot n^{2/3}} A[j] = t + \sigma + k(n^{2/3} - 1)$, for any $t < n^{2/3}$. Then, if **SELECT** returns $t + k \cdot n^{2/3}$, we know that $t + \sigma = n^{2/3} - 1$, so we find σ .

7.3. Dynamic connectivity. The graph used in the hard sequence is the same as the one before (Figure 6.1): \sqrt{n} permutation boxes, each permuting \sqrt{n} “wires.” Let t_u be the running time of an update (edge insertion or deletion) and t_q the running time of a query. We handle only $t_q \leq t_u$. Our hard sequence consists of blocks of operations. Each block begins with a macro-update: for an index k (chosen as described below), remove all edges in the k th permutation box, and insert edges for a random permutation. Then, the block contains $\frac{t_u}{t_q} \sqrt{n}$ **CONNECTED** queries. Each query picks a random node in the first column and a random index k , and calls **CONNECTED** on the node in the first column and the node on the k th column which is on the same path. This means that all queries should be answered in the affirmative; the information is contained in the choice of the node from the k th column.

We still have to specify the sequence of indices of the macro-updates. We use a deterministic sequence to ensure that updates which occur close in time touch distant indices. This significantly simplifies the information-theoretic analysis. Our hard sequence consists of exactly \sqrt{n} blocks. Each macro-update touches a different permutation box; the order of the boxes is given by the bit-reversal permutation (see section 5.6) of order \sqrt{n} . Now consider a set of indices $S = \{i_1, i_2, \dots\}$ sorted by increasing i_j . We say S is *uniformly spaced* if $i_{j+1} - i_j = \sqrt{n}/(|S| - 1)$ for every j .

LEMMA 7.2. *Consider two adjacent intervals of operations such that the second one contains L queries, and the indices updated in the first interval contain a uniformly spaced subset of cardinality $\Theta(BL/\sqrt{n})$. Then $E[c] = \Omega(L) - O(\frac{s}{b})$, where $s = B \cdot E[r] \lg(1 + \frac{E[w]}{B \cdot E[r]})$.*

Proof. This lemma follows from section 7.1, if we show the information-theoretic assumption used there. For our problem, $\delta = \Theta(\lg n)$. Imagine picking a random query from the right interval and simulating BL random queries in its place. The variable Z denotes the random choices for all queries and for updates outside the left interval. We need to show that the entropy of the correct parameters for all queries in the right interval, including the simulated ones, given Z , is $\Omega(BL \lg n)$.

Remember that all updates are to different boxes, so an update is never overwritten. For this reason, our proof is not concerned with the precise order of updates and queries in the right interval, and there will be no difference between the real and simulated queries. Let the uniformly spaced set of update indices be $S = \{i_1, i_2, \dots\}$. We let B_j be the set of queries from the right interval (either real or simulated) whose

random column is in $[i_j, i_{j+1} - 1]$. For notational convenience, we write $H(B_j)$ for the entropy of the correct parameters to the set of queries B_j . Basic information theory states that $H(\bigcup_j B_j \mid Z) = \sum_j H(B_j \mid B_1, \dots, B_{j-1}, Z)$. Thus, to prove our lower bound, it suffices to show $H(B_j \mid B_1, \dots, B_{j-1}, Z) = \Omega(\sqrt{n} \lg n)$ for all j .

Let Z_j be a random variable describing Z and, in addition, the random permutations for all updates in the left interval with indices below i_j . Also, if there are any updates with indices in $[i_j + 1, i_{j+1} - 1]$, include their permutation in Z_j (these are updates outside the uniformly spaced set). Note that $H(B_j \mid B_1, \dots, B_{j-1}, Z) \geq H(B_j \mid Z_j)$, because conditioning on Z_j also fixes the correct parameters for queries in B_1, \dots, B_{j-1} .

Now let us look at a query from B_j . The query picks a random node in the first column. All permutations before column i_j are fixed through Z_j , so we can trace the path of the random node until it enters box i_j . Assume we have the correct parameter of the query, i.e., the node from column k to which the initial node is connected. Permutations between column i_j and i_{j+1} are also fixed by Z_j , so we can trace back this node until the exit of box i_j . Thus, knowing the correct parameter is equivalent to knowing some point values of the permutation i_j . As long as the nodes chosen in the first column are distinct, we will learn new point values. If we query d distinct point values of the random permutation, the entropy of the correct parameters is $\Omega(d \lg n)$, for any d .

Now imagine an experiment choosing the queries sequentially. This describes a random walk for d . In each step, d may remain constant or it may be incremented. Because of the uniform spacing, the probability that a query ends up in B_j is $\Omega(\frac{\sqrt{n}}{BL})$. If $d \leq \sqrt{n}/2$, with probability at least half, the node chosen in the first column is new. Then, for $d \leq \sqrt{n}/2$, the probability that d is incremented is $\Omega(\frac{\sqrt{n}}{BL})$. We do BL independent random steps, and we are interested in the expected value of d at the end. The waiting time until d is incremented is $O(\frac{BL}{\sqrt{n}})$. For a sufficiently small constant ε , the expected time until d reaches $\varepsilon\sqrt{n}$ is $\frac{1}{2}BL$. Then, with probability at least half, $d \geq \varepsilon\sqrt{n}$ after BL steps. This implies the expected value of d after BL steps is $\Omega(\sqrt{n})$, so $H(B_j \mid Z_j) = \Omega(\sqrt{n} \lg n)$. \square

To use this lemma, we construct a tree with a branching factor $\beta \geq 2B \frac{t_u}{t_q}$, rounded to the next power of 2. The right interval is formed by a node, and the left interval by the node's left siblings. We consider only the case when the node is among the right half of its siblings. Now we argue there is a uniformly spaced subset among the indices updated in the left interval. Note that these include all indices from the first half of siblings. Because β is a power of 2, a root-to-leaf path in the tree is tracing a bit representation of the leaf's index, in chunks of $\log_2 \beta$ bits. Because update indices are the reverse of the leaf's index, all the leaves in the subtrees of the first half of the children have the same low order bits in the indices. On the other hand, the high order bits assume all possible values. So the indices from the first half of the children are always a uniformly spaced subset of indices.

Now we can apply Lemma 7.2, and we sum over all nodes of the tree to obtain our lower bound. By the analysis in the previous section, the sum of the s terms only changes the bound by a constant factor. The $\Omega(L)$ term of the lower bound is linear in the number of queries, so by summing over all levels we obtain $E[T] = \Omega(\sqrt{n} \cdot \frac{t_u}{t_q} \sqrt{n} \cdot \log_\beta n)$. Because $E[T] = \sqrt{n}(t_u \sqrt{n} + t_q \frac{t_u}{t_q} \sqrt{n}) = O(\sqrt{n} \cdot t_u \sqrt{n})$, we obtain $t_q = \Omega(\log_\beta n)$, which is our desired lower bound.

8. Upper bounds for the partial-sums problem. As mentioned before, our partial-sums data structure can support a harder variant of updates. We will allow the $A[i]$'s to be arbitrary b -bit integers, while $\text{UPDATE}(i, \Delta)$ implements the operation $A[i] \leftarrow A[i] + \Delta$, where Δ is a δ -bit (signed) integer.

Our data structure is based on a balanced tree of branching factor B (to be determined) with the elements of the array $A[1..n]$ in the leaves. Assume we pick B such that we can support constant-time operations for the partial-sums problem in an array of size B . Then, we can hold an array of size B in every node, where each element is the total of the leaves in one of the B subtrees of our node. All three operations in the large data structure translate into a sequence of operations on the small data structures of the nodes along a root-to-leaf path. Thus, the running time is $O(\log_B n)$. We will show how to handle $B = \Theta(\min\{b/\delta, b^{1/5}\})$. Then $\lg B = \Theta(\lg(b/\delta))$, which implies our upper bound.

It remains to describe the basic building block, i.e., a constant-time solution for arrays of B elements. We now give a simple solution for UPDATE and SUM . In the next section, we develop the ideas necessary to support SELECT . We will conceptually maintain an array of partial sums $S[1..B]$, where $S[k] = \sum_{i=1}^k A[i]$. To make it possible to support UPDATE in constant time, we maintain the array as two separate components, $V[1..B]$ and $T[1..B]$, such that $S[i] = V[i] + T[i]$. The array V will hold values of S that were valid at some point in the past, while more recent updates are reflected only in T . We can use Dietz's incremental rebuilding scheme [Die89] to keep every element of B relatively up to date: on the t th UPDATE , we set $V[t \bmod B] \leftarrow V[t \bmod B] + T[t \bmod B]$ and $T[t \bmod B] \leftarrow 0$. This scheme guarantees that every element in T is affected by at most B updates, and thus is bounded in absolute value by $B \cdot 2^\delta$.

The key idea is to pack T in a machine word. We represent each $T[i]$ by a range of $O(\delta + \lg n)$ bits from the word, with one zero bit of padding between elements. Elements in T also can be negative; in this case, each value will be represented in the standard two's complement form on its corresponding range of bits. Packing T in a word is possible as long as $B = O(\frac{b}{\delta + \lg b})$. We can read and write an element of T using a constant number of standard RAM operations (bitwise Boolean operations and shift operations).

To complete our solution, we need to implement UPDATE in constant time. Using the packed representation, we can add a given value to all elements $V[i]$, $i \geq k$, in constant time. Refer to Table 8.1. First, we create a word with the value to be added appearing in all positions corresponding to the elements of V that need to be changed. We can compute this word using a multiplication by an appropriate binary pattern. The result is then added to the packed representation of V ; all the needed additions are performed in one step, using word-level parallelism. Because we are representing negative quantities in two's complement, additions may carry over, and set the padding bits between elements; we therefore force these buffer bits to zero using a bitwise AND with an appropriate constant mask.

8.1. Selecting in small arrays. To support SELECT , we use the classic result of Fredman and Willard [FW93] that forms the basis of their fusion-tree data structure. Their result has the following black-box functionality: for $B = O(b^{1/5})$, we can construct a data structure that can answer successor queries on a static array of B integers in constant time. As demonstrated in [AMT99], the lookup tables used by the original data structure can be eliminated if we perform a second query in the sketch representation of the array. The data structure then can be constructed in $O(B^4)$ time.

TABLE 8.1
Performing UPDATE(2, Δ) at the word level. Here V has 5 elements, each 5 bits long.

V[4] 0 V[3] 0 V[2] 0 V[1] 0 V[0]	old packed representation of V
00001 0 00001 0 00001 0 00001 0 00001	constant pattern
00001 0 00001 0 00001 0 00000 0 00000	shift right, then left by same amount
Δ	argument given to UPDATE
Δ 0 Δ 0 Δ 0 00000 0 00000	multiply the last two values
V'[4] ? V'[3] ? V'[2] ? V'[1] ? V'[0]	add to the packed representation of V
11111 0 11111 0 11111 0 11111 0 11111	constant cleaning pattern
V'[4] 0 V'[3] 0 V'[2] 0 V'[1] 0 V'[0]	final value of V, obtained by bitwise AND

As before, we break partial sums into the arrays V and T . We store a fusion structure that can answer successor queries in V . Because the fusion structure is static, we abandon the incremental rebuilding of V in favor of periodic global rebuilding. By the standard deamortization of global rebuilding [dBSvKO00], we can then obtain worst-case bounds. Our strategy is to rebuild the data structure completely every B^4 operations: we set $V[i] \leftarrow V[i] + T[i]$ and $T[i] \leftarrow 0$, for all i , and rebuild the fusion structure over V . While servicing a **SELECT** that doesn't occur immediately after a rebuild, the successor in V found by the fusion structure might not be the appropriate answer to the **SELECT** query, because of recent updates. We will describe shortly how the correct answer can be computed by also examining the array T ; the key realization is that the real successor must be close to the successor in V in terms of their partial sums.

Central to our solution is the way we rebuild the data structure every n^4 operations. We begin by splitting S into runs of elements satisfying $S[i + 1] - S[i] < B^4 \cdot 2^\delta$; recall that we must have $S[i] < S[i + 1]$ for the **SELECT** problem. We denote by $\text{rep}(i)$ the first element of the run containing i (the representative of the run); also let $\text{len}(i)$ be the length of the run containing i . Each of these arrays can be packed in a word, because we already limited ourselves to $B = O(b^{1/5})$. Finally, we let every $V[i] \leftarrow V[\text{rep}(i)]$ and $T[i] \leftarrow S[i] - V[\text{rep}(i)]$. Conveniently, T can still be packed in a word. Indeed, the value stored in an element after a rebuild is at most $B \cdot (B^4 \cdot 2^\delta)$, and it can subsequently change by less than $B^4 \cdot 2^\delta$. Therefore, it takes $O(\lg B + \delta)$ bits to represent an element of C , so we need only impose the condition that $B = O(\min\{b/\delta, b^{1/5}\})$.

It remains to show how **SELECT**(σ) can be answered. Let k denote the successor in V identified by the fusion structure; we have $V[k - 1] < \sigma \leq V[k]$. We know that k is the representative of a run, because all elements of a run have equal values in V . By construction, runs are separated by gaps of at least $B^4 \cdot 2^\delta$, which cannot be closed by B^4 updates. Thus, the answer to the query must be either an index in the run starting at k , or an index in the run ending at $k - 1$, or exactly equal to $k + \text{len}(k)$. We can distinguish between these cases in constant time, using two calls to **SUM** followed by comparisons. If we identify the correct answer as exactly $k + \text{len}(k)$, we are done.

Otherwise, assume by symmetry that the answer is an index in the run starting at k . Because elements of a run have equal values of V , our task is to identify the unique index i in the run satisfying $T[i - 1] < \sigma - V[k] \leq T[i]$. Now we can employ word-level parallelism to compare all elements in T with $\sigma - V[k]$ in constant time. This is similar to a problem discussed by Fredman and Willard [FW93], but we must also handle negative quantities. The solution is to subtract $\sigma - V[k]$ in parallel from all elements in T ; if elements of T are oversized by 1 bit, we can avoid overflow. The

sign bits of every element then give the results of the comparisons. The answer to the query can be found by summing up the sign bits corresponding to elements in our run, which indicates how many elements in the run were smaller than $\sigma - V[k]$. Because these bits are separated by more than $\lg b$ zeros, we can sum them up using a multiplication with a constant pattern, as described in [FW93].

9. Reductions to other dynamic graph problems. It is relatively easy to dress up dynamic connectivity as other dynamic graph problems, obtaining logarithmic lower bounds for these. Most problems on undirected graphs admit polylogarithmic solutions, so such lower bounds are interesting. The problems discussed in this section are meant only as examples and not as an exhaustive list of possible reductions.

9.1. Connectivity of the entire graph. The problem is to maintain a dynamic graph along with the answer to the question, “Is the entire graph connected?”. We obtain a lower bound of $\Omega(\lg n)$ even for plane graphs, which implies the same lower bound for counting connected components. The dynamic-connectivity algorithms mentioned in the introduction also can maintain the number of connected components, so the same almost-tight upper bounds hold for this problem.

We use the same graph as in the dynamic-connectivity lower bound, except that we add a new vertex s which is connected to all nodes from the first column. The updates in the connectivity problem translate into identical updates in our current problem. The hard instance of connectivity asks queries between a vertex u on the first column, and an arbitrary vertex v . To simulate these, we disconnect u from s , connect v to s , and ask whether the entire graph is connected; after this, we undo the two changes to the graph. If u and v were on distinct paths, u 's path will now be disconnected from the rest of the graph. Otherwise, the edge (v, s) will reconnect the path to the rest of the graph.

The graph we consider is a tree, so it is plane regardless of the embedding of the vertices. During a query, if u and v are on the same path, we create an ephemeral cycle. However, the (v, s) edge can simply be routed along the old path $s \rightarrow u \rightsquigarrow v$, so the graph remains plane.

9.2. Dynamic MSF. The problem is to maintain the cost of the MSF (minimum spanning forest) in a weighted dynamic graph. The problem can be solved in $O(\lg^4 n)$ time per operation [HdLT01]. In plane graphs, the problem admits a solution in time $O(\lg n)$ [EIT⁺92]. We obtain a lower bound of $\Omega(\lg n)$, which holds even for plane graphs with unit weights. Our bound follows immediately from the previous bound. If all edges have unit weight and the graph is connected, the weight of the MSF is $n - 1$. If the graph is disconnected, the weight of the MSF is strictly smaller.

9.3. Dynamic planarity testing. The problem is to maintain a dynamic plane graph, and test whether inserting a given edge would destroy planarity. Actual insertions always maintain planarity; an edge (u, v) is given along with an order inside the set of edges adjacent to u and v . The problem can be solved in $O(\lg^2 n)$ time per operation [IPH93]. A lower bound of $\Omega(\lg n / \lg \lg n)$ appears in [FH98]. We obtain a lower bound of $\Omega(\lg n)$.

Because the graph from our lower bound proof is always a collection of disjoint paths, it is plane under any embedding. Consider the complete bipartite graph $K_{3,3}$, from which an edge (s, t) is removed. Without that edge, this annex graph is also planar. To implement connectivity queries between two nodes u and v , we first insert the edge (u, s) temporarily and then query whether inserting the edge (v, t) would

destroy planarity. If u and v are on distinct paths, the graph created by adding (u, s) and (v, t) is planar and can be embedded for any relative order of these two edges (the edges of $K_{3,3} \setminus \{(s, t)\}$ can simply go around the two paths containing u and v). If u and v are on the same path, we would be creating a subdivision (graph expansion) of $K_{3,3}$, so the graph would no longer be planar (by Kuratowski's theorem).

10. Open problems. This paper provides powerful techniques for understanding problems which have complexity around $\Theta(\lg n)$. The chronogram technique had already proven effective for problems with complexity $\Theta(\frac{\lg n}{\lg \lg n})$. However, current techniques seem ineffective either below or above these thresholds. Below this regime, we have integer search problems, such as priority queues. Looking at higher complexities, we find many important problems which seem to have polylogarithmic complexity (such as range queries in higher dimensions) or even $n^{\Omega(1)}$ complexity (dynamic problems on directed graphs). It is also an important complexity theoretic challenge to obtain an $\omega(\lg n)$ lower bound for a dynamic language membership problem.

It is also worth noting that our bounds do not bring a complete understanding of the partial-sums problem when $\delta = o(b)$. First, we cannot prove a tight bound for **VERIFY-SUM**. A bound of $\Omega(\lg n / \lg b)$, for any δ , is implicit in [HR03] and also can be reproved using our technique. Second, we do not have a good understanding of the possible trade-offs. For **SELECT**, this seems a thorny issue, because of the interaction with the predecessor problem. Even for **SUM**, we do not know what bounds are possible in the range $t_u < t_q$. It is tempting to think that the right bound is $t_u(\lg \frac{t_q}{t_u} + \lg \frac{b}{\delta}) = \Theta(\lg n)$, by symmetry with the case $t_u > t_q$. However, buffer trees [Arg03] give better bounds for some choices of parameters, e.g., when $b = \Omega(\lg^{1+\varepsilon} n)$. This problem seems to touch on a fundamental issue: a good lower bound apparently needs to argue that the data structure has to recover a lot of information about the indices of updates, in addition to the Δ values.

It would be very interesting to obtain a logarithmic upper bound for dynamic connectivity matching our lower bound. It also would be interesting to determine the complexity of decremental connectivity. For this problem, at least our trade-off lower bound cannot hold, because [HK99] gave a solution with polylogarithmic updates and constant query time.

ON SUMS OF INDEPENDENT RANDOM VARIABLES WITH UNBOUNDED VARIANCE AND ESTIMATING THE AVERAGE DEGREE IN A GRAPH*

URIEL FEIGE†

Abstract. We prove the following inequality: for every positive integer n and every collection X_1, \dots, X_n of nonnegative independent random variables, each with expectation 1, the probability that their sum remains below $n+1$ is at least $\alpha > 0$. Our proof produces a value of $\alpha = 1/13 \simeq 0.077$, but we conjecture that the inequality also holds with $\alpha = 1/e \simeq 0.368$.

As an example for the use of the new inequality, we consider the problem of estimating the average degree of a graph by querying the degrees of some of its vertices. We show the following threshold behavior: approximation factors above 2 require far fewer queries than approximation factors below 2. The new inequality is used in order to get tight (up to multiplicative constant factors) relations between the number of queries and the quality of the approximation. We show how the degree approximation algorithm can be used in order to quickly find those edges in a network that belong to many shortest paths.

Key words. Markov inequality, shortest paths

1. A new inequality. For a random variable X , its typical value may be very different from its mean. In particular, the probability that X exceeds its mean may be arbitrarily close to 1. In some special cases (e.g., when X is symmetric around its mean), the probability that X exceeds its mean is at most $1/2$. The purpose of this manuscript is to investigate the probability that X exceeds its mean when X is the sum of n independent random variables. We show that for nonnegative random variables, this probability is bounded away from 1, provided that we give ourselves a little slack in exceeding the mean.

THEOREM 1. *Let X_1, \dots, X_n be arbitrary nonnegative independent random variables, with expectations μ_1, \dots, μ_n , respectively, where $\mu_i \leq 1$ for every i . Let $X = \sum_{i=1}^n X_i$, and let μ denote the expectation of X (hence, $\mu = \sum_{i=1}^n \mu_i$). Then for every $\delta > 0$,*

$$(1) \quad \Pr[X < \mu + \delta] \geq \min[\delta/(1 + \delta), 1/13].$$

The term $\delta/(1+\delta)$ in Theorem 1 is best possible, as X_1 might be a random variable that has value $1 + \delta$ with probability $1/(1 + \delta)$ and value 0 with probability $\delta/(1 + \delta)$, and every other X_i might be a random variable whose value is 1 with probability 1. This gives $\mu_i = 1$ for every i . For this case, $\Pr[X < \mu + \delta] = \Pr[X_1 = 0] = \delta/(1 + \delta)$. For large δ (e.g., $\delta = 1$), it is not true that $\Pr[X \leq \mu + \delta] \geq \delta/(1 + \delta)$. One can take for every i , $X_i = n + \delta$, with probability $1/(n + \delta)$ and 0 otherwise. This gives $\mu_i = 1$ for every i , implying $\mu = n$. For this case, $\Pr[X < n + \delta] = (1 - 1/(n + \delta))^n$, which is roughly $1/e$ for large n .

Based on the two examples above we make the following conjecture.

CONJECTURE 2. *In the setting of Theorem 1, for every value of δ and n , one of the two examples above is the worst case for $\Pr[X < \mu + \delta]$.*

Conjecture 2, if true, would allow us to replace the constant $1/13$ with $1/e$ in Theorem 1. A conjecture very similar in nature to Conjecture 2 is the following conjecture that was suggested by Samuels in [6].

CONJECTURE 3. *Let X_1, \dots, X_n be arbitrary nonnegative independent random variables, with expectations μ_1, \dots, μ_n , respectively, where $\mu_1 \geq \dots \geq \mu_n$. Then for every $\lambda > \sum_{j=1}^n \mu_j$ there is some $1 \leq i \leq n$ such that $\Pr[\sum_{j=1}^n X_j < \lambda]$ is minimized when the random variables X_j are distributed as follows:*

- For $j > i$, $X_j = \mu_j$ with probability 1.
- For $j \leq i$, $X_j = \lambda - \sum_{k=i+1}^n \mu_k$ with probability $\frac{\mu_j}{\lambda - \sum_{k=i+1}^n \mu_k}$, and $X_j = 0$ otherwise.

The difference between the settings of the two conjectures is that in Conjecture 3 all means are given, whereas in Conjecture 2 only an upper bound on the means is given. The difference in the conclusions of the conjectures is that in Conjecture 3 we may have an arbitrary $i \in \{1, \dots, n\}$, whereas Conjecture 2 effectively states that i is restricted to one of two values, $i \in \{1, n\}$.

Samuels (see [6, 7] and the references therein) proves Conjecture 3 when n (the number of random variables) is at most 4. The case $n = 2$ was proved earlier in [2]. When $n \geq 5$, Samuels shows that Conjecture 3 is true when $\lambda \geq (n - 1) \sum_{j=1}^n \mu_j$. In contrast, in the current paper we are interested in the case (that when put in the framework of Conjecture 3 corresponds to) $\lambda = \delta + \sum_{j=1}^n \mu_j$ with δ fairly small (e.g., $\delta = \mu_1$).

It may be instructive to consider how some standard probabilistic tools relate to Theorem 1. Consider the case that the X_i are identically distributed. Then the central limit theorem implies that when n is large enough, X approaches the normal distribution, and hence $\Pr[X < \mu]$ approaches $1/2$. However, in Theorem 1 the variables X_i may depend on n , and hence n cannot be thought of as being “large enough” with respect to the X_i (even if they are independently and identically distributed (i.i.d.)). This relates to the fact that we place no bounds on the variance of the X_i , and hence standard bounds on deviations of random variables from their expectation (such as Chebyshev’s bound or Chernoff’s bound) are not applicable. The only restriction on the random variables (other than being independent) is their nonnegativity. In particular, this means that X is nonnegative and that Markov’s inequality can be used to show that $\Pr[X \leq \mu + \delta] \geq \delta/(\mu + \delta)$. For the sum of i.i.d. random variables, this bound tends to 0 as n grows (unlike the bound in Theorem 1).

In addition to the work by Samuels mentioned above, the author is aware of some other work of nature similar to Theorem 1. There are results surveyed and developed by Siegel [8] that show that under certain conditions the median of the sum of random variables does not exceed the mean. This holds, for example, for the sum of Bernoulli random variables (if the mean is an integer). The book by Dubins and Savage [4] analyzes strategies for gambling when the goal is to maximize the probability of ending up with a net profit of δ . There the strategies are adaptive (the next gamble may depend on outcomes of previous gambles), and the gambler may quit once a net profit of δ is achieved. One of the main findings of [4] is a set of sufficient conditions under which the strategy of “playing boldly” is optimal. Informally, this strategy tries to reach a net profit of δ (also taking into account previous losses) in one gamble. A simple example is the repeated doubling approach to gain one dollar when

there are 50/50 odds, in which the gambler first gambles one dollar and then doubles the gamble until the first win (or until he/she runs out of money). The scenario in Theorem 1 can be viewed as a version of “how to gamble in parallel,” in which n unbiased gambles with independent outcomes can be placed in parallel in an attempt to reach a net profit of δ units, where each gamble is allowed to risk at most one unit. Our results show that when δ is small (specifically, $\delta \leq 1/12$), having $n > 1$ does not lead to higher probability of achieving a net profit of δ compared to the case that $n = 1$. For larger values of δ , there is an advantage to having $n > 1$, but regardless of the value of n , the probability of achieving a net profit of δ is bounded away from 1. Regardless of the value of δ , it appears to us (though our proof does not actually show this when $\delta > 1/12$) that similar to the “play boldly” principle, the optimal strategy is based on hoping for one successful gamble. (Namely, when δ is small, only one gamble is nonzero, and when δ is large, all gambles are identical, and it suffices for one successful gamble to both reach a profit of δ and cover for all the losses in the other gambles.) Despite similarities in the nature of the results, the proof techniques from [4] and [8] do not appear to be applicable to the setting of Theorem 1.

Theorem 1 can in principle be used whenever one is interested in bounding the probability that the sum of independent random variables significantly exceeds its expectation. However, in many contexts the random variables are known to have some additional properties (e.g., bounded variance), and useful results can also be derived by other means. The application that motivated the development of the inequality (1) is described in section 2.

2. Estimating the average degree. Let $G(V, E)$ be a graph with n vertices. A *degree query* specifies a vertex $v \in V$ and gets in reply d_v , the degree of v in G . We are interested in estimating $m = |E|$ by making only degree queries. Equivalently, we wish to estimate the average degree $d = 2m/n$. We say that an algorithm provides a ρ estimation if its output d^* satisfies

$$d^* \leq d \leq \rho d^*.$$

Naturally, we limit our interest to $\rho \geq 1$. As our sampling-based algorithms are randomized, there is some probability that their output fails to be a ρ estimation. We require this failure probability to be at most $1/3$. We note that the failure probability can be reduced to an arbitrarily small value δ by repeating the estimation algorithm $O(\log 1/\delta)$ times independently and outputting the median of all estimates. Our goal is for given ρ to design ρ estimation algorithms with as few queries as possible and with failure probability at most $1/3$.

Let us note here an observation that helps us to drastically reduce the number of queries in our algorithms. Consider first the case where rather than having an actual graph as input, the input is simply a sequence of integers d_1, \dots, d_n , with the only restriction that for every i , $0 \leq d_i \leq n$. (For simplicity of presentation we allow values here to range up to n , even though degrees can range only up to $n - 1$.) Let $d = \frac{1}{n} \sum_{i=1}^n d_i$. We wish to estimate d . It is not hard to see that for any value d_0 (which one may think of as a large constant independent of n), $\Omega(n/d_0)$ queries are required in order to distinguish between the cases $d = 0$ and $d \geq d_0$. The reason is that it may happen that there are d_0 numbers with value n , and all other numbers have value 0. If we perform less than $n/2d_0$ queries, most likely we always get the 0 answer, which is exactly the answer that we would get if $d = 0$.

To get estimation algorithms with fewer queries, we shall use the fact that not every sequence d_1, \dots, d_n is a degree sequence of graphs. For example, if $d_1 = n - 1$,

then necessarily $d_i \geq 1$ for all i . Still, the bad example given above can be modified to show that $\Omega(n/d_0)$ queries are required in order to distinguish between the cases $d \leq d_0$ and $d \geq 2d_0 - O((d_0)^2/n)$. In the first of these two cases we can have all $d_i = d_0$. In the second of these two cases we can have $d_i = d_0$ for all vertices except for d_0 vertices of degree $n - 1$. Hence if we wish to have estimation algorithms with a sublinear (in n) number of queries, we need to restrict ourselves to $\rho \geq 2$.

There is one more restriction that we introduce. Observe that if G contains only one edge, one needs $\Omega(n)$ queries to distinguish this case from $d = 0$. To avoid the problem of handling such very sparse graphs (which are often not interesting anyway), we shall assume that $d \geq d_0$ for some d_0 that will be a parameter of our estimation algorithms. The reader may think of d_0 as typically having value at least 1. Hence the estimation algorithm is allowed to output $d^* = 0$ as an estimation of d for very sparse graphs, even though the ratio between d and d^* is in this case infinite. (The assumption that $d \geq d_0$ can be replaced by allowing the estimation algorithm to have an additive error of d_0 in addition to the multiplicative error of ρ .)

As noted above, for $\rho < 2$ and $d_0 = 1$, the number of queries needed by an estimation algorithm might be $\Omega(n)$. Our main observation is that for $\rho > 2$ and for $d_0 = 1$, the number of queries in the estimation algorithm drops dramatically, from $\Omega(n)$ to $O(\sqrt{n})$. This result is stated in more technical terms in the following theorem.

THEOREM 4. *For any $d_0 > 0$, $\epsilon > 0$, and $\rho = 2 + \epsilon$, there is a ρ estimation algorithm for the average degree of a graph that uses $O(\frac{1}{\epsilon}\sqrt{n/d_0})$ queries, and it is applicable to all graphs of average degree at least d_0 .*

In terms of the application of estimating the average degree in the graph, the more interesting part of our upper bound on the number of queries is the term $\sqrt{n/d_0}$. The dependency on ϵ may be less interesting, especially if one is satisfied with large values of ϵ , such as $\epsilon = 1$. However, achieving a linear dependency in $1/\epsilon$ (rather than some polynomial dependency) is the part that uses Theorem 1.

In section 4 we prove Theorem 4. In section 5 we show how Theorem 4 can be used in order to obtain Theorem 5, addressing a problem that is studied in [3].

THEOREM 5. *There is a randomized algorithm that runs in time $O(\frac{mn \log n}{\epsilon\sqrt{c}})$ on graphs with n vertices and m edges and outputs a list of edges that with high probability satisfies the following:*

1. *Every edge that is on at least c shortest paths is on the list.*
2. *No edge that is on less than $(1/2 - \epsilon)c$ shortest paths is on the list.*

3. Proof of Theorem 1. In this section we prove Theorem 1. Let us first try to clarify our proof plan. It is based on a sequence of transformations whose goal is to simplify the random variables until a case analysis becomes manageable. Known arguments (the *reduce support* operation that will be explained in our proof) show that we may assume that every random variable by itself is “simple” in the sense that it has small support. Hence it is reasonable to expect that if the number of random variables is a small constant, then the theorem (if true) can be proven by a “brute force” case analysis. For example, Samuels [6] mentions 25 cases that are to be considered if one is to prove Conjecture 3 for the case $n = 4$. In our proof we describe a merge operation that replaces two random variables with one random variable. However, we do not perform this merge operation until the number of random variables becomes small, because this operation might create random variables whose mean is larger than 1. After rescaling the random variables, this corresponds to decreasing δ in the statement of Theorem 1 to be arbitrarily small and drives the bound $\delta/(1 + \delta)$ to 0. Instead, we perform the merge operation until a step in which many random variables

may still remain, but they have nice properties. Namely, all random variables, except for perhaps one, have roughly the same mean and, moreover, have small “surplus” (to be defined in the proof). Thereafter, case analysis becomes possible through the use of Proposition 10, which allows us to analyze many such random variables as if they were just one random variable. It is interesting to note that even though our proof plan does not seem to allow us to prove tight bounds (due to the fact that we generate random variables with mean above 1), it does in fact provide optimal bounds when δ is small ($\delta < 1/12$). We shall comment more on our proof in section 3.2, and now we present the proof itself.

Proof. Fix n , δ , and arbitrary nonnegative random variables X_1, \dots, X_n with means at most 1. We prove that inequality (1) holds. We assume without loss of generality that the support of every random variable is composed of a finite set of values. (This is a standard argument, but we sketch it for completeness. Any value larger than $\mu + \delta$ in the support of a random variable can be lowered to $\mu + \delta$ without increasing the probability that $X < \mu + \delta$. Thereafter, any continuous random variable can be approximated by a discrete random variable with the same mean and whose support includes only multiples of ϵ , where ϵ is chosen to be much smaller than δ/n . For these new random variables, X'_1, \dots, X'_n , the event $X' < \mu + \delta'$, where $\delta' = \delta - \epsilon n$, implies that for the original variables, $X < \mu + \delta$. By making ϵ arbitrarily small, we can make δ' arbitrarily close to δ .)

Our proof of inequality (1) consists of a sequence of transformations on the variables X_i . We may view these transformations as occurring in discrete time steps, and in our notation, superscripts will denote time steps. Hence, after time step t , random variables are denoted by X_i^t , their sum by X^t , and the expectation of X^t by μ^t . For $t = 0$, we have the original random variables. All our transformations will have the property that for every $t \geq 0$,

$$(2) \quad \Pr[X^{t+1} < \mu^{t+1} + \delta] \leq \Pr[X^t < \mu^t + \delta].$$

Some properties of the random variables may change by the transformations. In particular, the reduce support transformation (to be defined shortly) when applied to two random variables that were originally identically distributed might transform them to new random variables that are not identically distributed. Moreover, the merge transformation might generate random variables whose mean is larger than 1, even though all original random variables have mean at most 1. We now describe the transformations.

Remove constant. This transformation is applied whenever there is a random variable X_i^t that is constant, that is, $\Pr[X_i^t = \mu_i^t] = 1$. Such a random variable is removed, and $\mu^{t+1} = \mu^t - \mu_i^t$. Clearly, *remove constant* satisfies inequality (2).

Reduce support. This transformation is applied to every random variable whose support has at least three values, and replaces it with a new random variable with the same mean, and whose support includes at most two values from the original support.

LEMMA 6. *Let X_i^t be a random variable whose support includes at least three values. Then X_i^t can be replaced with a new variable X_i^{t+1} with $\mu_i^{t+1} = \mu_i^t$ and whose support includes only two values from the original support of X_i^t . This can be done in a way that satisfies inequality (2).*

Proof. Let $\{v_1, \dots, v_k\}$ be the support of X_i^t , and for $1 \leq j \leq k$, let q_j denote the conditional probability of the event $[X^t < \mu^t + \delta^t]$, conditioned on the event $[X_i^t = v_j]$. For X_i^{t+1} and for $1 \leq j \leq k$, we wish to select $p_j = \Pr[X_i^{t+1} = v_j]$ under the restrictions that the mean of X_i^{t+1} is the same as the mean of X_i^t and that

inequality (2) is satisfied. This can be expressed by the following linear program over the variables p_j :

Minimize $\sum_{j=1}^k q_j p_j$

subject to

- $\sum_{j=1}^k p_j = 1,$
- $\sum_{j=1}^k p_j v_j = \mu_i^t,$
- $p_j \geq 0$ for every $j.$

The above linear program is feasible (as the probabilities associated with the original X_i^t satisfy the constraints). By the theory of linear programming, there is a *basic* optimal solution in which at most two p_j are nonzero. \square

We remark that Lemma 6 has several alternative proofs and in general does not require X_t to have finite support. A similar lemma (with a functional analytic proof) is used in [6].

Align with 0. This transformation is applied to every random variable whose support has two values and these values are greater than 0 (say X_i^t has value v_1 with probability p and v_2 with probability $(1 - p)$, with $0 < v_1 < v_2$) and replaces it with a random variable X_i^{t+1} that has value $v_1 - v_1 = 0$ with probability p and has value $v_2 - v_1$ with probability $(1 - p)$. Hence $\mu_i^{t+1} = \mu_i^t - v_1$, and $\mu^{t+1} = \mu^t - v_1$. Clearly, *align with 0* satisfies inequality (2).

Merge. This transformation takes the two random variables with smallest mean (say X_i^t and X_j^t) and replaces them with a new random variable in three steps. First, replace X_i^t and X_j^t with a new random variable that is distributed like their sum $X_i^t + X_j^t$. Then apply *reduce support* to this new random variable. Finally, apply *align with 0* or *remove constant* to the new random variable (if applicable).

It is easy to see that the transformation *merge* satisfies inequality (2).

The sequence of transformations that we perform is partitioned into two stages. We now describe the first stage.

Stage 1:

1. Whenever possible, apply *remove constant*.
2. Apply *reduce support* until all random variables have support of size at most two. (Different variables may have different support.)
3. Apply *align with 0* to all variables.
4. Apply *merge* until either the number of random variables is reduced to one, or all random variables have mean at least $1/2$ (whichever happens first).

Stage 1 must end because with each application of *merge*, the number of random variables decreases. Let t denote the step after which Stage 1 ends, and let $X_1^t, \dots, X_{n'}^t$ be the random variables that remain. We assume that they are sorted in order of decreasing μ_i^t . Their number n' may be smaller than n , because some of the transformations remove random variables. These are not arbitrary random variables, as each of them has a support of two values, one of which is 0, and the stopping condition for the merge transformations has been reached. For a random variable X_i^t as above, let μ_i^t denote its mean, let $\{0, v_i^t\}$ denote its support, and let $s_i^t = v_i^t - \mu_i^t$ denote its *surplus*. Let $s^t = \sum_{i=1}^{n'} s_i^t$ denote the total surplus.

PROPOSITION 7. *If the total surplus satisfies $s^t < \delta$, then $\Pr[X^t \geq \mu^t + \delta] = 0$.*

Proof. X^t is maximized when $X_i^t = v_i^t$ for all i . In this case,

$$X^t = \sum_{i=1}^{n'} (\mu_i^t + s_i^t) = \mu^t + s^t < \mu^t + \delta. \quad \square$$

Hence we may assume without loss of generality that $s^t \geq \delta$.

LEMMA 8. *If Stage 1 ended with a random variable with mean below 1/2, then $\Pr[X^t < \mu^t] \geq \delta/(1/2 + \delta)$.*

Proof. In this case, exactly one random variable remains. Let X_1^t be the random variable left, with mean $\mu_1^t < 1/2$ and support $\{0, v_1 = \mu_1^t + s^t\}$. Note that the event $X_1^t = 0$ implies $X^t < \mu^t$. Now $\Pr[X_1^t = 0] = s^t/(\mu_1^t + s^t) \geq \delta/(1/2 + \delta)$, because $s^t \geq \delta$ and $\mu_1^t < 1/2$. \square

Observe that Lemma 8 offers a conclusion that is even stronger than that required by Theorem 1, as is illustrated by the following sequence of inequalities:

$$\Pr[X < \mu + \delta] \geq \Pr[X^t < \mu^t + \delta] \geq \Pr[X^t < \mu^t] \geq \frac{\delta}{1/2 + \delta} > \frac{\delta}{1 + \delta}.$$

Hence we may also assume that Stage 1 ended with all random variables having mean at least 1/2. The following property will be used in this case.

PROPOSITION 9. *If Stage 1 ended with all random variables having mean at least 1/2, then $\mu_1^t/2 \leq \mu_{n'}^t \leq \mu_1^t < 3/2$.*

Proof. Recall that the random variables are assumed to be sorted with μ_1^t being the largest mean and $\mu_{n'}^t$ being the smallest mean.

If no random variable has mean greater than 1, then we are done. Hence consider the first time that a random variable with mean greater than 1 is created. This happens by merging two random variables, say at time step r (shortly we will see that in fact it must hold that $r = t - 1$), with the random variables being X_i^r and X_j^r . Let $\mu_i^r \geq \mu_j^r$ be their means before the merge. By the definition of *merge*, no other variable had mean smaller than μ_i^r . By the stopping rule for Stage 1, $\mu_j^r < 1/2$. To get a variable with mean greater than 1, we must have $\mu_i^r > 1/2$. Note that Stage 1 ends after the merge, because no variable with mean below 1/2 is left. Hence the new variable created becomes X_1^{r+1} with $1 < \mu_1^{r+1} < 1 + 1/2 = 3/2$. But as $\mu_1^{r+1} \leq 2\mu_i^r$ and $\mu_{n'}^{r+1} \geq \mu_i^r$, it follows that $\mu_{n'}^{r+1} \geq \mu_1^{r+1}/2$. \square

Let us pause at this point and explain what remains to be proved. All random variables can be assumed to be 2-valued, with one of the values being 0 and with all means μ_i^t satisfying $\mu_1^t/2 \leq \mu_i^t \leq \mu_1^t$. Moreover, the total surplus s^t satisfies $s^t \geq \delta$. For random variables as above we in fact will bound $\Pr[X^t < \mu^t]$ rather than $\Pr[X^t < \mu^t + \delta]$. Lemma 11 (its first part) and Lemma 12 will show that $\Pr[X^t < \mu^t] \geq \min[\delta/(\mu_1^t + \delta), 1/13]$. This almost proves Theorem 1, except that it might happen that at the end of Stage 1, $\mu_1^t > 1$. This possibility is handled in the second part of Lemma 11 by showing that one merge operation before the end of Stage 1 we had $\Pr[X^{t-1} < \mu^{t-1} + \delta] \geq \delta/(1 + \delta)$.

The following proposition is used several times in the proofs of Lemmas 11 and 12. It is most effective when $s < \mu_n$, and μ_n is not much smaller than μ_1 .

PROPOSITION 10. *Let X_1, \dots, X_n be independent random variables with means $\mu_1 \geq \dots \geq \mu_n$ and supports $\{0, \mu_1 + s_1\}, \dots, \{0, \mu_n + s_n\}$, and let $X = \sum_{i=1}^n X_i$, $\mu = \sum_{i=1}^n \mu_i$, and $s = \sum_{i=1}^n s_i$. Then*

$$\Pr[X < \mu - \mu_n + s] \geq \frac{s}{\mu_1 + s}.$$

Proof. It suffices that one random variable comes up 0 to imply $X < \mu + s - \mu_n$. (The inequality is strict because only a variable with $s_i > 0$ may come up 0.) Hence

$$\Pr[X \geq \mu + s - \mu_n] = \prod_{i=1}^n \frac{\mu_i}{\mu_i + s_i} \leq \prod_{i=1}^n \frac{\mu_1}{\mu_1 + s_i}.$$

Given that $\sum_{i=1}^n s_i = s$ and that $s_i \geq 0$, the above product is maximized when $s_1 = s$ and $s_i = 0$ for all $i > 1$, giving $\mu_1/(\mu_1+s)$. Hence $\Pr[X < \mu - \mu_n + s] \geq s/(\mu_1+s)$. \square

The following lemma illustrates the desired outcome of Stage 1.

LEMMA 11.

1. If Stage 1 ended with all random variables having mean at least $1/2$, and if $s^t < \mu_n^t$, then

$$\Pr[X^t < \mu^t] \geq \frac{\delta}{\mu_1^t + \delta} \geq \frac{\delta}{3/2 + \delta}.$$

2. If in addition $\delta \leq 1/12$, then either $\Pr[X^t < \mu^t] < \delta/(1 + \delta)$ or one merge operation before the end of Stage 1 it must have been the case that

$$\Pr[X^{t-1} < \mu^{t-1} + \delta] \geq \delta/(1 + \delta).$$

Remark. The choice of $\delta \leq 1/12$ in the second part of Lemma 11 is made because $\delta/(1 + \delta) = 1/13$ for $\delta = 1/12$. The limiting factor for improving beyond $1/13$ is Lemma 12 rather than Lemma 11. For $\delta > 1/12$ the second part of Lemma 11 simply implies that $\Pr[X^{t-1} < \mu^{t-1} + \delta] \geq \Pr[X^{t-1} < \mu^{t-1} + 1/12] \geq 1/13$.

Proof. The surplus s^t is smaller than the mean of any of the random variables. Using Proposition 10 we then have $\Pr[X^t < \mu^t] \geq \frac{s^t}{\mu_1^t + s^t}$. Using the assumption that $s^t \geq \delta$ and the fact that $\mu_1^t \leq 3/2$ (Proposition 9), we have that $\Pr[X^t < \mu^t] \geq \delta/(3/2 + \delta)$.

To prove the second part of the lemma, note that if it happens that $\mu_1^t \leq 1$, then we have $\Pr[X^t < \mu^t] \geq \delta/(1 + \delta)$. Hence we may assume that $\mu_1^t > 1$, implying in particular that X_1^t is the result of the last merge operation (see the proof of Proposition 9). Let $s' = s^t - s_1^t$ be the surplus of all variables except for X_1^t . If $s' > 0$ (which implies $\mu_2^t \geq 1/2 > 0$), then analysis as in the proof of the first part of the lemma implies that

$$\Pr[X^t \geq \mu^t] \leq \frac{\mu_2^t}{\mu_2^t + s'} \leq \frac{1}{1 + s'}.$$

Hence if $s' \geq \delta$, then $\Pr[X^t < \mu^t] \geq \delta/(1 + \delta)$. So we can assume that $s' < \delta$ (also including the possibility that $s' = 0$).

Let us backtrack to the last merge operation. Hence instead of X_1^t we have two variables X_i^{t-1} and X_j^{t-1} that were merged to give X_1^t . Let their means be $\mu_i^{t-1} \geq \mu_j^{t-1}$ and their surpluses be s_i^{t-1} and s_j^{t-1} . Observe that necessarily $\mu_j^{t-1} < 1/2$ (otherwise the merge operation would not have been performed), and then the assumption that $\mu_1^t > 1$ implies that $\mu_i^{t-1} > 1/2$. As the total surplus of all random variables except for X_i^{t-1} and X_j^{t-1} is $s' < \delta$, we must have $X_i^{t-1} + X_j^{t-1}$ come up larger than $\mu_i^{t-1} + \mu_j^{t-1}$ for $X^{t-1} \geq \mu^{t-1} + \delta$. We consider now two cases.

Case 1. $s_i^{t-1} > 2\delta$. Then $\Pr[X_i^{t-1} = 0] = \frac{s_i^{t-1}}{\mu_i^{t-1} + s_i^{t-1}} \geq \frac{2\delta}{\mu_i^{t-1} + 2\delta}$. If $X_i^{t-1} = 0$, then in order to have $X_i^{t-1} + X_j^{t-1} > \mu_i^{t-1} + \mu_j^{t-1}$ we must have $X_j^{t-1} > \mu_i^{t-1} + \mu_j^{t-1}$. But this happens with probability at most $\frac{\mu_j^{t-1}}{\mu_i^{t-1} + \mu_j^{t-1}} \leq \frac{1/2}{\mu_i^{t-1} + 1/2}$. Hence

$$\Pr[X^{t-1} < \mu^{t-1} + \delta] \geq \frac{2\delta}{\mu_i^{t-1} + 2\delta} \cdot \frac{\mu_i^{t-1}}{\mu_i^{t-1} + 1/2} \geq \frac{\delta}{1 + \delta},$$

where the last inequality holds for $\delta \leq 1/2$ because $1/2 \leq \mu_i^{t-1} \leq 1$.

Case 2. $s_i^{t-1} \leq 2\delta$. Define $s'' = s' + s_i^{t-1}$ as the surplus of all random variables except for s_j^{t-1} , and observe that $s'' < 3\delta \leq 1/4$, the last inequality holding for $\delta \leq 1/12$. We now consider several subcases.

- $s'' < \delta$ and $s_j^{t-1} \geq 1/2$. The fact that $s'' < \delta$ implies that it suffices for X_j^{t-1} to come up 0 to ensure $X^{t-1} < \mu^{t-1} + \delta$. This happens with probability at least $s_j^{t-1}/(\mu_j^{t-1} + s_j^{t-1}) \geq 1/2$.
- $s'' < \delta$ and $s_j^{t-1} < 1/2$. The fact that all random variables except for X_j^{t-1} have mean at least $1/2$ implies that it suffices for one random variable to come up 0 to ensure $X^{t-1} < \mu^{t-1} + \delta$. As necessarily $s'' + s_j^{t-1} \geq \delta$ and $\mu_k^{t-1} \leq 1$ for all k , this happens with probability at least $\delta/(1 + \delta)$ by Proposition 10.
- $\delta \leq s'' < \delta + \mu_j^{t-1}$ and $s_j^{t-1} \geq \delta$. It suffices for X_j^{t-1} to come up 0 to ensure $X^{t-1} < \mu^{t-1} + \delta$. This happens with probability at least $\delta/(1/2 + \delta)$.
- $\delta \leq s'' < \delta + \mu_j^{t-1}$ and $s_j^{t-1} < \delta$. It suffices for some random variable other than X_j^{t-1} to come up 0 to ensure $X^{t-1} < \mu_{t-1} - 1/2 + s'' + \delta < \mu^{t-1} + \delta$. (We used the fact that every random variable except for X_j^{t-1} has mean at least $1/2$ and that $s'' \leq 1/4$.) This happens with probability at least $\delta/(1 + \delta)$ by Proposition 10.
- $s'' \geq \delta + \mu_j^{t-1}$. By Proposition 10, there is probability of at least $\frac{\delta + \mu_j^{t-1}}{1 + \delta + \mu_j^{t-1}}$ for a random variable other than X_j^{t-1} to come up 0. Thereafter X_j^{t-1} must come up at least $\mu_j^{t-1} + \delta + 1/2 - s'' \geq \mu_j^{t-1} + \delta + 1/4$ for $X^{t-1} \geq \mu^{t-1} + \delta$ to hold. The probability of this is at most $\mu_j^{t-1}/(\mu_j^{t-1} + 1/4 + \delta) \leq \mu_j^{t-1}/(\mu_j^{t-1} + 1/4)$. Hence

$$\Pr[X^{t-1} < \mu^{t-1} + \delta] \geq \frac{\delta + \mu_j^{t-1}}{1 + \delta + \mu_j^{t-1}} \cdot \frac{1/4}{\mu_j^{t-1} + 1/4} \geq \frac{\delta}{1 + \delta},$$

where the last inequality holds when $4(\delta + \delta^2 + \mu_j^{t-1}\delta) \leq 1$, which is true for our parameters of $\mu_j^{t-1} \leq 1/2$ and $\delta \leq 1/12$. \square

Summarizing, Lemmas 8 and 11 prove Theorem 1, except for the case that Stage 1 ended with $\mu_1^t/2 \leq \mu_{n'}^t \leq \mu_1^t$ and $s^t \geq \mu_{n'}^t$. We now address this last case. For this case we shall not use the extra slack offered by δ , but rather we shall show the stronger inequality $\Pr[X^t < \mu^t] \geq 1/13$. To prove this last inequality, we perform Stage 2 of our sequence of transformations. It is composed of a modified form of the merge operations, which we call *modified merge*. The modification will allow us to deal with the event $X^t < \mu^t$ rather than $X^t < \mu^t + \delta$. Recall that the *reduce support* operation was based on a linear program that minimized $\Pr[X^{t+1} < \mu^{t+1} + \delta]$ (via the definition of the q_j in the proof of Lemma 6). Modify the *reduce support* operation by modifying the objective function of the linear program to be $\Pr[X^{t+1} < \mu^{t+1}]$ (by making the respective change in the definition of q_j). Use this *modified reduce support* rather than the original *reduce support* as the second step of *modified merge*. Now *modified merge* maintains the inequality

$$(3) \quad \Pr[X^{t+1} < \mu^{t+1}] \leq \Pr[X^t < \mu^t].$$

Note that an application of *modified merge* cannot increase the total surplus. (This was also true for *merge*.) This works in our favor, because as the proof of Lemma 11 demonstrates, it is easier to perform case analysis when the total surplus is small. However, an application of modified merge may result in a random variable

whose mean is smaller than $\mu_1^{t+1}/2$. (For simplicity of notation, we assume that after every step the variables are renamed so as to keep μ_1^{t+1} the largest mean.) This will complicate our case analysis. But note that even with repeated applications of *modified merge*, there will be at most one such random variable. Let us define $s' = \sum s_i$, where the sum is taken over all random variables whose mean is at least $\mu_1/2$. In particular, at the time when Stage 1 ends we may assume that $s' = s^t$ by Proposition 9.

Stage 2. Apply *modified merge* (on the two random variables with currently lowest mean) until a step (that we shall denote by r) after which either the number of remaining (nonconstant) random variables is one or the condition $s' \leq \alpha\mu_1^r$ has been reached for some constant $0 < \alpha < 1/2$ that will be determined later. Stage 2 must eventually end, because with each application of *modified merge* the number of random variables decreases.

LEMMA 12. *Let $\alpha = 1/3$, and let r denote the time step at which Stage 2 ends. Then either $\Pr[X^r < \mu^r] \geq 1/13$ or one modified merge operation before Stage 2 ends $\Pr[X^{r-1} < \mu^{r-1}] \geq 1/13$.*

Proof. The proof of Lemma 12 is based on a case analysis. Some of the details in the case analysis are included so as to get the explicit bound of $1/13$. Those readers who are just interested in verifying that the lemma holds for some universal constant (though perhaps much smaller than $1/13$) may simply think of α as some small constant (say $\alpha = 1/10$) and β (to be introduced shortly) as a much smaller constant (say $\beta = 1/100$) and read each case only up to the point where it becomes clear that under this setting of the parameters; the case in question gives a probability bounded away from 0.

LEMMA 13. *If Stage 2 ends without the condition $s' \leq \alpha\mu_1^r$ being reached, then $\Pr[X^r < \mu^r] > \alpha/(1 + \alpha)$.*

Proof. In this case we have only one nonconstant random variable, X_1^r , with support $\{0, \mu_1^r + s'\}$:

$$\Pr[X^r < \mu^r] = \Pr[X_1^r = 0] = \frac{s'}{\mu_1^r + s'} > \frac{\alpha}{1 + \alpha}. \quad \square$$

LEMMA 14. *If Stage 2 ends with $\beta\mu_1^r \leq s' \leq \alpha\mu_1^r$, where $0 \leq \beta \leq \alpha$ is some constant that will be optimized later, then*

$$\Pr[X^r < \mu^r] \geq \min \left[\left(\frac{\alpha - 2\alpha^2}{1 + \alpha} \right), \left(\frac{\beta - 2\beta^2}{1 + \beta} \right) \right].$$

Proof. Consider first only the random variables with mean at least $\mu_1^r/2$, let X' be their sum, and let μ' be the expectation of X' . Over these random variables, the surplus is $s' = \gamma\mu_1^r$, with $\beta \leq \gamma \leq \alpha < 1/2$. By Proposition 10,

$$\Pr \left[X' < \mu' - \left(\frac{1}{2} - \gamma \right) \mu_1^r \right] \geq \frac{s'}{\mu_1^r + s'} = \frac{\gamma}{1 + \gamma}.$$

The event $X' < \mu' - (1/2 - \gamma)\mu_1^r$ does not yet imply that $X^r < \mu^r$. There still might be one variable $X_{n''}^r$ with $\mu_{n''}^r < \mu_1^r/2$. If $X_{n''}^r$ turns out $\mu_{n''}^r + s_{n''}^r$ and $s_{n''}^r \geq (1/2 - \gamma)\mu_1^r$, then it still may hold that $X^r \geq \mu^r$.

Let us first assume that $\mu_{n''}^r \leq s' = \gamma\mu_1^r$. Then by Markov's inequality,

$$\Pr[X_{n''}^r = \mu_{n''}^r + s_{n''}^r] = \frac{\mu_{n''}^r}{\mu_{n''}^r + s_{n''}^r} \leq \frac{\gamma\mu_1^r}{\gamma\mu_1^r + (1/2 - \gamma)\mu_1^r} = 2\gamma.$$

Hence

$$\Pr[X^r < \mu^r] \geq \frac{\gamma}{1 + \gamma} \cdot (1 - 2\gamma) = \frac{\gamma - 2\gamma^2}{1 + \gamma}.$$

For $0 < \beta \leq \gamma \leq \alpha < 1/2$, the expression above is minimized when $\gamma \in \{\alpha, \beta\}$.

We are left with the case that $\mu_{n''} > s'$. But then we have

$$\Pr[X^r < \mu^r] \geq \Pr[X_{n''}^r = 0] = \frac{s_{n''}^r}{\mu_{n''}^r + s_{n''}^r} \geq \frac{1/2 - \gamma}{1 - \gamma},$$

where we have used the fact that $\mu_{n''}^r < \mu_1^r/2$ and $s_{n''}^r \geq (1/2 - \gamma)\mu_1^r$. As $\gamma \leq \alpha$, we have that $\Pr[X^r < \mu^r] \geq (1/2 - \alpha)/(1 - \alpha)$. But this probability is larger than $(\alpha - 2\alpha^2)/(1 + \alpha)$ of the previous case, and hence can be ignored. \square

LEMMA 15. *If Stage 2 ends with $s' < \beta\mu_1^r$, and $0 < \beta < \alpha/2$, then one merge prior to the end of Stage 2 it must have been the case that $\Pr[X^{r-1} < \mu^{r-1}]$ was at least the minimum of the following expressions:*

1. $\frac{\alpha - \beta}{1/2 + \alpha - \beta} \cdot \frac{1/2 - \beta}{1 - \beta}$.
2. $\frac{\alpha - 3\beta/2}{1 + \alpha - 3\beta/2} \cdot \frac{1 - 3\beta/2}{3/2 - 3\beta/2}$.
3. $\frac{\alpha - 2\beta}{1 + \alpha - 2\beta}$.
4. $\left(\frac{1/2 - \beta}{1 - \beta}\right)^2$.
5. $\frac{1/2 - 3\beta/2}{3/2 - 3\beta/2} \cdot \frac{1 - 3\beta/2}{3/2 - 3\beta/2}$.

The proof of Lemma 15 involves a detailed case analysis and appears in section 3.1.

Summing up, Lemmas 14 and 15 imply that after Stage 2, either $\Pr[X^r < \mu^r]$ or $\Pr[X^{r-1} < \mu^{r-1}]$ is at least the smallest of the following quantities (where $0 < \beta < \alpha/2 < 1/4$):

- $\frac{\alpha - 2\alpha^2}{1 + \alpha}$;
- $\frac{\beta - 2\beta^2}{1 + \beta}$;
- $\frac{\alpha - \beta}{1/2 + \alpha - \beta} \cdot \frac{1/2 - \beta}{1 - \beta}$;
- $\frac{\alpha - 3\beta/2}{1 + \alpha - 3\beta/2} \cdot \frac{1 - 3\beta/2}{3/2 - 3\beta/2}$;
- $\frac{\alpha - 2\beta}{1 + \alpha - 2\beta}$;
- $\left(\frac{1/2 - \beta}{1 - \beta}\right)^2$;
- $\frac{1/2 - 3\beta/2}{3/2 - 3\beta/2} \cdot \frac{1 - 3\beta/2}{3/2 - 3\beta/2}$.

Choosing (suboptimally) $\alpha = 1/3$ and $\beta = 1/8$ gives at least $1/13$ in all cases.

This completes the proof of Lemma 12. \square

We can now summarize the proof of Theorem 1. We have the original random variables for which we wish to prove $\Pr[X < \mu + \delta] \geq \min[\delta/(1 + \delta), 1/13]$. The proof proceeds in two stages. In Stage 1 we apply a sequence of transformations maintaining the inequality (2) until a step t in which all random variables have mean at least $1/2$ (or only one random variable remains, which is an easy case to handle). Then Lemma 11 implies the theorem whenever the total surplus s^t is small ($s^t < \mu_{n'}^t$). To handle the case that the surplus is large, we perform a sequence of transformations in Stage 2, this time maintaining the inequality (3), until a step r in which the surplus of all variables (except for the variable with smallest mean) is no longer large compared to the maximum mean (namely, $s' \leq \alpha\mu_1^r$). Then Lemma 12 implies that also in this case (corresponding to the case that s^t was greater than $\mu_{n'}^t$) the theorem holds. Note

that, overall, depending on which case is considered, Lemmas 11 and 12 do not prove inequality (1) on the original random variables but on transformed random variables that appear after one of the steps $t - 1, t, r - 1$, or r . But this implies inequality (1) on the original random variables, because of the inequalities (2) and (3). \square

3.1. Remaining analysis for Stage 2. We prove here Lemma 15, whose proof was the only part omitted from the proof of Theorem 1.

Proof. Consider the last two random variables to have been merged, say X_i^{r-1} and X_j^{r-1} , with means $\mu_i^{r-1} \geq \mu_j^{r-1}$, and let μ_1^{r-1} be the largest mean at time $r - 1$. After the *modified merge* of X_i^{r-1} and X_j^{r-1} , the largest mean μ_1^r may still have been μ_1^{r-1} , but it could also be as high as $\mu_i^{r-1} + \mu_j^{r-1}$ if this happens to be higher than μ_1^{r-1} . In fact, μ_1^r may also be lower than μ_1^{r-1} if only one variable is left at the end of Stage 2 and this variable underwent an *align with 0* operation. However, in this case the bounds that we get for $X^{r-1} < \mu^{r-1}$ are much stronger than what we get otherwise (details omitted), so we shall ignore this case.

We analyze the situation one merge operation before the end of Stage 2. Note that we know that at that time, $s' \geq \alpha\mu_1^{r-1}$, because otherwise Stage 2 would have ended earlier. Likewise, the sum $\sum s_i^{r-1}$ taken over all variables except X_i^{r-1} and X_j^{r-1} is at most $\max[\beta\mu_1^{r-1}, \beta(\mu_i^{r-1} + \mu_j^{r-1})]$, because otherwise we could not have had $s' < \beta\mu_1^r$ at the end of Stage 2. We consider now two cases.

Case 1. $\mu_j^{r-1} < \mu_1^{r-1}/2$. Hence X_j^{r-1} did not contribute to s' at time step $r - 1$. Note that $\mu_i^{r-1} \geq \mu_1^{r-1}/2$, and hence X_i^{r-1} did contribute to s' at time step $r - 1$. It follows that $s_i^{r-1} \geq \alpha\mu_1^{r-1} - \beta\mu_1^r$. (This last expression is positive, because Lemma 15 assumes that $\beta < \alpha/2$, and $\mu^r \leq 2\mu^{r-1}$.) Hence,

$$\Pr[X_i^{r-1} = 0] \geq \frac{\alpha\mu_1^{r-1} - \beta\mu_1^r}{\mu_i^{r-1} + \alpha\mu_1^{r-1} - \beta\mu_1^r}.$$

If $X_i^{r-1} = 0$, then in order to have $X^{r-1} \geq \mu^{r-1}$, X_j^{r-1} must contribute at least $\mu_j^{r-1} + \mu_i^{r-1} - \beta\mu_1^r$ to X^{r-1} . (The expression $\mu_i^{r-1} - \beta\mu_1^r$ is positive because $\beta < 1/4$ and $\mu_i^{r-1} \geq \mu_1^{r-1}/2 \geq \mu_1^r/4$.) This may happen with probability at most $\mu_j^{r-1}/(\mu_j^{r-1} + \mu_i^{r-1} - \beta\mu_1^r)$. We then have

$$\Pr[X^{r-1} < \mu^{r-1}] \geq \frac{\alpha\mu_1^{r-1} - \beta\mu_1^r}{\mu_i^{r-1} + \alpha\mu_1^{r-1} - \beta\mu_1^r} \cdot \frac{\mu_i^{r-1} - \beta\mu_1^r}{\mu_j^{r-1} + \mu_i^{r-1} - \beta\mu_1^r}.$$

The above expression is minimized when μ_j^{r-1} is maximized, namely, when $\mu_j^{r-1} = \mu_1^{r-1}/2$. As $\mu_i^{r-1} \geq \mu_1^{r-1}/2$, it follows that $\mu_i^{r-1} + \mu_j^{r-1} \geq \mu_1^{r-1}$. The expression above is minimized when μ_1^r is maximized, namely, $\mu_1^r = \mu_j^{r-1} + \mu_i^{r-1}$. Normalizing μ_1^{r-1} to 1 and using the notation μ_i to denote μ_i^{r-1}/μ_1^{r-1} , we have after some rearrangements

$$\Pr[X^{r-1} < \mu^{r-1}] \geq \frac{\alpha - \beta/2 - \beta\mu_i}{(1 - \beta)\mu_i + \alpha - \beta/2} \cdot \frac{(1 - \beta)\mu_i - \beta/2}{(1 - \beta)\mu_i + 1/2 - \beta/2}.$$

The expression above is defined for all $\mu_i \geq 0$. It equals 0 for $\mu_i \in \{\beta/2(1 - \beta), (\alpha - \beta/2)/\beta\}$ and is positive in between. Moreover, there are at most two points where the derivative with respect to μ_i of this expression vanishes (as it is a ratio of two nonproportional quadratics), and for $\beta < 2\alpha/3$ the expression is positive in the allowed

range of $1/2 \leq \mu_i \leq 1$. It follows that the expression is minimized when $\mu_i \in \{1/2, 1\}$, giving

$$\Pr[X^{r-1} < \mu^{r-1}] \geq \min \left[\frac{\alpha - \beta}{1/2 + \alpha - \beta} \cdot \frac{1/2 - \beta}{1 - \beta}, \frac{\alpha - 3\beta/2}{1 + \alpha - 3\beta/2} \cdot \frac{1 - 3\beta/2}{3/2 - 3\beta/2} \right].$$

This gives items 1 and 2 in the statement of Lemma 15.

Case 2. $\mu_j^{r-1} \geq \mu_1^{r-1}/2$. Hence both s_i^{r-1} and s_j^{r-1} did contribute to s' (before the last merge), and moreover, $\mu_i^{r-1} + \mu_j^{r-1} \geq \mu_1^{r-1}$. This, together with the inequality $\mu_1^r \leq \max[\mu_1^{r-1}, \mu_i^{r-1} + \mu_j^{r-1}]$, implies that we may use $\mu_i^{r-1} + \mu_j^{r-1}$ as an upper bound on μ_1^r . To simplify notation and without loss of generality we may assume that $\mu_1^{r-1} = 1$, and then $1/2 \leq \mu_j^{r-1} \leq \mu_i^{r-1} \leq 1$. We have that $s_i^{r-1} + s_j^{r-1} > \alpha - \beta(\mu_i^{r-1} + \mu_j^{r-1}) \geq \alpha - 2\beta$. Recall (from the paragraph prior to Case 1) the sum $\sum s_i^{r-1}$ taken over all variables except X_i^{r-1} and X_j^{r-1} is at most $\beta(\mu_i^{r-1} + \mu_j^{r-1})$. Hence if $X_i^{r-1} + X_j^{r-1} < \mu_i^{r-1} + \mu_j^{r-1} - \beta(\mu_i^{r-1} + \mu_j^{r-1})$, then necessarily $X^{r-1} < \mu^{r-1}$. We let B denote the event $[X_i^{r-1} + X_j^{r-1} < (1 - \beta)(\mu_i^{r-1} + \mu_j^{r-1})]$ and perform a subcase analysis for $\Pr[B]$. The subcases are partitioned according to which of X_i^{r-1} and X_j^{r-1} (or both, or either one) needs to come up 0 in order for B to hold.

1. It suffices that either $X_i^{r-1} = 0$ or $X_j^{r-1} = 0$ for B to hold. In this case, using $\mu_i^{r-1} \leq 1$ and $s_i^{r-1} + s_j^{r-1} \geq \alpha - 2\beta$, Proposition 10 implies that

$$\Pr[B] \geq \frac{\alpha - 2\beta}{1 + \alpha - 2\beta}.$$

This gives item 3 in the statement of Lemma 15.

2. B holds iff $X_i^{r-1} = 0$. In this subcase, necessarily $\mu_i^{r-1} + s_i^{r-1} \geq (1 - \beta)(\mu_i^{r-1} + \mu_j^{r-1})$. Using the fact that $\mu_i^{r-1} \leq 1$ and $\mu_j^{r-1} \geq 1/2$ we have that $s_i^{r-1} \geq \mu_j^{r-1} - \beta\mu_i^{r-1} - \beta\mu_j^{r-1} \geq 1/2 - 3\beta/2$, and therefore

$$\Pr[B] = \Pr[X_i^{r-1} = 0] = \frac{s_i^{r-1}}{\mu_i^{r-1} + s_i^{r-1}} \geq \frac{1/2 - 3\beta/2}{3/2(1 - \beta)}.$$

This subcase is dominated by the subcase above, and hence can be ignored.

3. B holds iff $X_j^{r-1} = 0$. This subcase is analogous to and dominated by the subcase above, and hence can be ignored.
4. B holds only if both $X_i^{r-1} = 0$ and $X_j^{r-1} = 0$. Then necessarily $\mu_i^{r-1} + s_i^{r-1} \geq (1 - \beta)(\mu_i^{r-1} + \mu_j^{r-1})$ and $\mu_j^{r-1} + s_j^{r-1} \geq (1 - \beta)(\mu_i^{r-1} + \mu_j^{r-1})$. We have

$$\Pr[B] \geq \left(\frac{(1 - \beta)(\mu_i^{r-1} + \mu_j^{r-1}) - \mu_i^{r-1}}{(1 - \beta)(\mu_i^{r-1} + \mu_j^{r-1})} \right) \cdot \left(\frac{(1 - \beta)(\mu_i^{r-1} + \mu_j^{r-1}) - \mu_j^{r-1}}{(1 - \beta)(\mu_i^{r-1} + \mu_j^{r-1})} \right).$$

For fixed $\mu_i^{r-1} + \mu_j^{r-1}$ this expression is minimized when $\mu_i^{r-1} - \mu_j^{r-1}$ is maximized. Hence either $\mu_i^{r-1} = 1$ or $\mu_j^{r-1} = 1/2$. Thereafter, it can

be verified that the expression is minimized when the other mean is either maximized or minimized, giving us three possible local minimum points, $\mu_i^{r-1}, \mu_j^{r-1} \in \{1/2, 1\}$, $\mu_j^{r-1} \leq \mu_i^{r-1}$. Two of these give identical values (the cases that $\mu_i^{r-1} = \mu_j^{r-1}$); hence we obtain

$$\Pr[B] \geq \min \left[\left(\frac{1/2 - \beta}{1 - \beta} \right)^2, \left(\frac{1/2 - 3\beta/2}{3/2 - 3\beta/2} \cdot \frac{1 - 3\beta/2}{3/2 - 3\beta/2} \right) \right].$$

This gives items 4 and 5 in the statement of Lemma 15. \square

3.2. Some comments. It is straightforward to modify inequality (1) so that there is no formal requirement that the random variables are nonnegative or that their mean is bounded by 1. Let w be the maximum over all random variables X_1, \dots, X_n of the respective $\mu_i - l_i$, where l_i is the lowest value in the support of X_i . Then

$$(4) \quad \Pr[X \leq \mu + \delta w] \geq \min[\delta/(1 + \delta), 1/13].$$

The constant 1/13 in Theorem 1 is not best possible and can be improved with more detailed case analysis. We suspect that the true constant should be $1/e$. Presumably, the way to prove a tight result is to find a sequence of transformations on the random variables that does not increase $\Pr[X < \mu + \delta]$ and that gradually brings them to the conjectured worst case for $[X < \mu + \delta]$. The sequence of transformations performed in our proof of Theorem 1 manages to achieve this only when $\delta \leq 1/12$ (or some other constant not far from 1/12). However, it fails to characterize the worst case for the perhaps more interesting $\delta = 1$. The idea in the proof is to transform the random variables into a situation where a case analysis becomes manageable, at the possible cost of giving up the tightness of the bound. The main principles used are reducing the support of every random variable to two values, getting all random variables (perhaps except one) to have roughly the same mean, reducing the surplus to be of order of magnitude comparable to this mean, and extracting from arbitrarily many random variables a single event of interest, as done in Proposition 10. It should be clear to the reader that more detailed case analysis would provide tighter results. But let us point out some limitations that relate to Lemma 12. As long as one chooses α not larger than $\mu_1/2$ (and, in fact, not larger than $3\mu_1/2$) and analyzes only the situation at the end of Stage 2 or one step earlier, one cannot obtain a bound better than $\Pr[X < \mu] \geq 2/9$. For example, assume that during Stage 2 we are left with three variables, each with support $\{0, \mu\}$ and mean $\mu/3$. At this point, $\Pr[X < \mu] = (2/3)^3 = 8/27 < 1/e$. After a merge operation, this probability decreases further to $(1/3) \cdot (2/3) = 2/9$. One merge operation later, Stage 2 ends. Hence to get (nearly) tight results using the current approach, one may need to modify the definition of Stage 2 and perform much more extensive (possibly computer assisted) case analysis.

4. Proof of Theorem 4. The reader is assumed to be familiar with elementary methods in probability (such as the use of Markov’s inequality, Chebyshev’s inequality, and Chernoff bounds). If needed, see details in [1], for example.

We query random t vertices and obtain their degrees. Let d_i be the degree returned by the i th query. Basically, our estimator for d will be $d^* = \frac{1}{t} \sum_{i=1}^t d_i$. In section 4.3 we shall modify this estimator so as to improve its quality. For simplicity of analysis, we assume that sampling is done with replacement. (The same vertex might be queried more than once.) This is insignificant when t is small (e.g., $t \leq \sqrt{n}$),

though note that for large values of t (and, in particular, when $t = n$) sampling without replacement gives better estimates than sampling with replacement.

Note that the expectation of our estimate satisfies

$$(5) \quad E[d^*] = d.$$

Hence the estimator is *unbiased*. In deviations from the expectation, we will analyze separately the events $d^* > d$ and $d^* < d$, or rather, $d^* < d/2$.

4.1. The estimate is not too high. Here we shall use Theorem 1. As an immediate consequence of this theorem (taking $\delta = 1$ and using the fact that the degree of a sampled vertex is a nonnegative random variable with expectation d) we have the following corollary.

COROLLARY 16. *There is some universal constant $\alpha > 0$ such that for every graph with average degree d , by querying t random vertices (with replacement) for their degree, the average d^* satisfies $\Pr[d^* \leq (1 + 1/t)d] \geq \alpha$.*

We can take $\alpha = 1/13$ in Corollary 16, and we conjecture that the corollary is also true with $\alpha = 1/e$.

4.2. The estimate is not too low. We assume that the average degree in the graph is at least d_0 . Our sampling algorithm queries $t = k\sqrt{n/d_0}$ vertices at random and reports the sum of the degrees. Here k is a parameter that will later be chosen to be of order $1/\epsilon$.

Let X_i be the random variable that denotes the degree of the i th query, and let $X = \sum_{i=1}^t X_i$. Then $E[X] = t \cdot d$. The following lemma shows that the typical value of X is not much smaller than $E[X]/2$.

LEMMA 17. *For arbitrary $\delta > 0$ (that will later be fixed to $50\sqrt{2}/\alpha$, where α is as in Corollary 16), with probability at least $1 - 4\sqrt{2}/\delta - 2^{-\Omega(\delta)}$,*

$$X \geq \frac{E[X]}{2} \left(1 - \frac{\delta}{k}\right).$$

Proof. Essentially, the proof of the lemma is based on Chebyshev's inequality. To apply Chebyshev's inequality directly, one would need the variance of X to be small compared to $(E[X])^2$. Unfortunately, vertices of very high degree may cause the variance to exceed $(E[X])^2$. To overcome this problem we observe (and will soon show formally) that in every graph, the vertices of very high degree contain at most slightly more than half the endpoints of the edges. The contribution to X of vertices whose degree is not very high is concentrated around its mean, because for them the variance is small. This explains why the value of X is likely to be not much smaller than $E[X]/2$. We now present our proof of the lemma, based on the above principles.

Partition the set of vertices of G into two sets, H (for high) and L (for low). For a constant c (independent of n, d, k) that will be determined later, the set H contains the $c\sqrt{nd}/k$ vertices of highest degree (breaking ties arbitrarily). The set L contains the other vertices. Every edge has two endpoints. Let us partition the endpoints of edges into the following four sets:

- $E_{H,L}$ (the endpoints in H of edges between H and L);
- $E_{L,H}$ (the endpoints in L of edges between H and L);
- $E_{H,H}$ (the endpoints in H of edges between H and H);
- $E_{L,L}$ (the endpoints in L of edges between L and L).

Observe that $|E_{H,H}| \leq |H|^2 = c^2 nd/k^2$. It will be the case that c is a universal constant, whereas $k \geq \Omega(1/\epsilon)$, and hence $|E_{H,H}| = O(\epsilon^2 nd)$. Moreover, we allow an

error of $\epsilon \cdot nd$ in our estimation of nd . Hence, $E_{H,H}$ has only a low order effect on the accuracy of the estimation. So as to simplify notation and the presentation, we shall simply assume that $|E_{H,H}| = 0$. We shall not give a rigorous proof that this assumption has only a low order effect on our analysis but merely note here that formalists may redo the analysis without assuming that $|E_{H,H}| = 0$, and at worst this will affect some constants that are eventually hidden by the O notation.

Let $m_1 = |E_{H,L}|$, $m_2 = |E_{L,H}|$, and $m_3 = |E_{L,L}|$. Hence $m_1 + m_2 + m_3 = dn$. Note that $m_2 = m_1$, because $|E_{L,H}| = |E_{H,L}|$. Let us break the random variable X into the sum of three random variables, $X = Y_1 + Y_2 + Y_3$, according to the contribution to X from m_1 , m_2 , and m_3 , respectively. Let h denote the minimum degree of a vertex in H .

PROPOSITION 18. *With probability $1 - 2^{-\Omega(c)}$,*

$$Y_1 \geq ch/2.$$

Proof. The expected number of vertices queried from H is $t|H|/n = k\sqrt{n/d_0} \cdot c\sqrt{d_0n}/kn = c$. With probability $1 - 2^{-\Omega(c)}$, the actual number of vertices queried from H is at least $c/2$. Each such vertex contributes at least h to Y_1 . \square

PROPOSITION 19. *A vertex in L can cover at most $|H| = c\sqrt{nd_0}/k$ endpoints in $E_{L,H}$.*

Proof. For every endpoint in $E_{L,H}$ covered by a vertex in L , the other endpoint of the respective edge is in H . As the original graph is a simple graph with no parallel edges, the proof follows. \square

PROPOSITION 20. *For $\lambda > 0$, with probability at least $1 - 1/\lambda^2$,*

$$Y_2 \geq E[Y_2] - \lambda\sqrt{cdn/2}.$$

Proof. The variance of Y_2 is maximized if the endpoints of $E_{L,H}$ are concentrated on $m_2/|H|$ vertices (each covering $|H|$ endpoints). Hence

$$\text{var}[Y_2] \leq |H|^2 \frac{m_2}{n|H|} t = cm_2 \leq cdn/2.$$

The proof now follows from Chebyshev's inequality. \square

PROPOSITION 21. *For $\lambda > 0$, with probability at least $1 - 1/\lambda^2$,*

$$Y_3 \geq E[Y_3] - \lambda\sqrt{\frac{hkm_3}{\sqrt{d_0n}}}.$$

Proof. The maximum degree of any vertex in L is h . Hence the graph induced by the edges $E_{L,L}$ also has maximum degree at most h . Thus

$$\text{var}[Y_3] \leq h^2 \frac{m_3}{h} \frac{t}{n} = hm_3k/\sqrt{d_0n}.$$

The proof now follows from Chebyshev's inequality. \square

PROPOSITION 22. *With probability at least $1 - 2/\lambda^2 - 2^{-\Omega(c)}$,*

$$X \geq \frac{E[X]}{2} + \frac{ch}{2} - \lambda\sqrt{\frac{cdn}{2}} - \lambda\sqrt{\frac{hkm_3}{\sqrt{d_0n}}} + \frac{km_3}{2\sqrt{d_0n}}.$$

Proof. $X = Y_1 + Y_2 + Y_3$. By Propositions 18, 20, and 21 we have that with probability at least $1 - 2/\lambda^2 - 2^{-\Omega(c)}$,

$$X \geq E[Y_2] + E[Y_3] + \frac{ch}{2} - \lambda\sqrt{\frac{cdn}{2}} - \lambda\sqrt{\frac{hkm_3}{\sqrt{d_0n}}}.$$

As $E[Y_1] = E[Y_2]$, we have that $E[X]/2 = E[Y_2] + E[Y_3]/2$. Using $E[Y_3] = m_3t/n = km_3/\sqrt{d_0n}$, the proof follows. \square

Fix $c = 4\lambda^2$. Then

$$\frac{ch}{2} \cdot \frac{km_3}{2\sqrt{d_0n}} \geq \left(\lambda\sqrt{\frac{hkm_3}{\sqrt{d_0n}}} \right)^2,$$

implying

$$\frac{ch}{2} - \lambda\sqrt{\frac{hkm_3}{\sqrt{d_0n}}} + \frac{km_3}{2\sqrt{d_0n}} \geq 0.$$

Hence for $c = 4\lambda^2$, the inequality in Proposition 22 can be replaced with

$$X \geq \frac{E[X]}{2} - \lambda\sqrt{\frac{cdn}{2}}.$$

The term $\lambda\sqrt{\frac{cdn}{2}} = \lambda^2\sqrt{2dn}$ is at most $\frac{E[X]}{2}2\lambda^2\sqrt{2}/k$, because $E[X] = dt = k\sqrt{nd}\sqrt{d/d_0}$. Renaming $2\sqrt{2}\lambda^2$ by δ , Lemma 17 is proved. \square

4.3. Combining the upper and lower bound. Let us set $k = 3\delta/\epsilon$ (where ϵ is taken from Theorem 4), and hence from Lemma 17 we have that with probability at least $1 - 4\sqrt{2}/\delta - 2^{-\Omega(\delta)}$,

$$X \geq \frac{E[X]}{2} \left(1 - \frac{\epsilon}{3} \right).$$

By Corollary 16, we have that with probability at least α , $X \leq E[X](1 + 1/t)$. The ratio between the upper bound on X and the lower bound on X is $2(1+1/t)/(1-\epsilon/3) \leq 2 + \epsilon$. This last inequality holds when ϵ is sufficiently small (which implies Theorem 4 also for larger values of ϵ) and t is sufficiently large compared to $1/\epsilon$ (which is true in our context because t is a parameter that grows with the number of vertices n , and the O notation in the statement of Theorem 4 implies that it suffices to prove the theorem when n is sufficiently large).

An *unbiased estimate* consists of taking t samples and returning their sum X . Perform $2/\alpha$ independent unbiased estimates for X , where α is taken to be as in the discussion following Corollary 16. Our estimation procedure returns X_{\min} , the minimum of these estimates. (Equivalently, we set $d^* = X_{\min}/t$.)

$$\Pr \left[X_{\min} \leq E[X] \left(1 + \frac{1}{t} \right) \right] \geq 1 - (1 - \alpha)^{2/\alpha} \geq 1 - \frac{1}{e^2} \geq \frac{5}{6},$$

$$\Pr \left[X_{\min} \geq \frac{E[X]}{2} \left(1 - \frac{\epsilon}{3} \right) \right] \geq 1 - \frac{2}{\alpha} \left(\frac{4\sqrt{2}}{\delta} + 2^{-\Omega(\delta)} \right) \geq \frac{5}{6},$$

where the last inequality uses $\delta = 50\sqrt{2}/\alpha$. This gives $k = 3\delta/\epsilon < 220/\alpha\epsilon$. The total number of queries used in our estimation procedure is $2t/\alpha$. This gives the following corollary.

COROLLARY 23. *For some universal constant β , using*

$$\beta \frac{\sqrt{n/d_0}}{\epsilon}$$

queries, one can estimate the average degree d of an n node graph within a ratio of $(2 + \epsilon)$, provided that $d > d_0$.

Proof. Setting $\beta = (\frac{2}{\alpha})(\frac{220}{\alpha}) = 440/\alpha^2$, we perform $2/\alpha$ unbiased estimates, each with $t = 220\sqrt{n/d_0}\alpha^{-1}\epsilon^{-1}$ queries, and take the minimum of the estimations that they give. \square

Let us note here the role of Corollary 16. It allows us to substitute a universal constant for α (which is shown to be at least $1/13$ in Theorem 1, though we conjecture that $1/e$ also works). If not for Theorem 1, we could have used Markov's inequality in a proof of a modified Corollary 16, showing (for example) that $\Pr[d^* \leq (1+\epsilon/3)d] \geq \epsilon/4$. This would have been equivalent to replacing α in the proof of Corollary 23 with $\epsilon/4$, which would require the number of queries used by the estimation procedure to be $\beta\sqrt{n/d_0}\epsilon^{-3}$ (for some constant β). This a factor of ϵ^{-2} worse than the bounds that we get through the use of Theorem 1.

4.4. Optimality of sample size. The sample size in Corollary 23 is essentially best possible, as the following proposition shows.

PROPOSITION 24. *For every (reasonable) n, d, ϵ , one can construct a graph G_1 with $(1 + \epsilon)nd$ edges and a graph G_2 with $dn/2$ edges, such that $\Omega(\frac{1}{\epsilon}\sqrt{n/d})$ vertices need to be queried in order to have probability above $2/3$ of distinguishing between them.*

Proof. Graph G_1 has a set A of $\epsilon\sqrt{nd}$ vertices of degree $(1 + \epsilon)\sqrt{nd}/\epsilon$ and a set B of $(1 + \epsilon)\sqrt{nd}/\epsilon$ vertices of degree $\epsilon\sqrt{nd}$ (e.g., arranged as a complete bipartite subgraph between A and B). The other vertices have degree 0. Graph G_2 has a set C of \sqrt{nd}/ϵ vertices of degree $\epsilon\sqrt{nd}$.

We sketch the proof of why $\Omega(\sqrt{\frac{n}{d}}\epsilon^{-1})$ queries are necessary. Assume that the number of queries is $\sqrt{\frac{n}{d}}\epsilon^{-1}$. Then there is constant probability that no vertex from A is queried, and the expected number of vertices queried from B is $\epsilon^{-2} + \epsilon^{-1}$. The expected vertices queried from C is ϵ^{-2} . As the standard deviation is of order $\sqrt{\epsilon^{-2}} = \epsilon^{-1}$, there is constant probability that G_1 and G_2 will be confused. \square

The optimality of the sample size was proved under the assumption that the only information used by the estimation algorithm is the degree of the queried vertices. More generally, one may think of randomized estimation algorithms that make use of additional information. For example, when querying a vertex of positive degree, the next vertex to query may be chosen at random from the list of neighbors of the current vertex. The use of a more general class of random estimation algorithms may allow either quicker or more accurate estimation of the average degree in a graph. See [5], for example. However, let us explain here some of the advantages of “degree only” sampling, advantages that might be lost by other estimation algorithms.

1. All queries can be made in parallel, which in some contexts results in saving time.
2. Sampling can be done anonymously. The estimation algorithm need not know the identity of queried vertices nor the identity of their neighbors. Privacy issues may sometimes require that this be the case. For example, vertices of

a graph may represent persons in some community, and an edge may represent some sort of interaction that took place between the respective persons. Persons may be willing to fill out an anonymous questionnaire stating with how many different persons they had interaction (namely, their degree) but may not be willing to disclose with whom they had interaction.

3. In section 5 there are several different graphs G_e defined on the same set of vertices, and in a single degree query one gets the degrees of the respective vertex in all graphs simultaneously. In order to efficiently estimate the average degree in all graphs, it is useful to have an estimation algorithm for which the choice of which vertex to query does not depend on the graph in question.

5. Quickly estimating the load on a network. We have seen how to estimate the average degree in a graph using a relatively small number of degree queries. Graph problems are often abstractions of other more concrete problems. As an example (which motivated this study), consider the following problem motivated and studied in [3].

The input is a connected network G with n vertices and m edges (namely, a graph). Between every two vertices there is a shortest path (a path that crosses the smallest number of edges). We assume here that shortest paths are unique, a point that we shall return to later. For an integer parameter c (that may depend on n), we wish to find all edges that are members of at least c shortest paths. In the terminology of [3], these edges are called “weakest links,” apparently because these are the edges where failure may cause the largest amount of damage to the performance of the network. Finding all weakest links can be done in time $O(nm)$ using an algorithm for all pairs’ shortest paths. The goal in [3] is to do better. They propose a randomized algorithm that with high probability has the following guarantees:

- *Finds weakest links.* It outputs all edges that belong to at least c shortest paths.
- *Avoids false alarms.* It does not output any edge that is a member of less than $(1 - \epsilon)c$ shortest paths.

The running time of the algorithm in [3] is $O(\frac{mn^2 \log n}{c\epsilon^2})$, which is better than that of all pairs’ shortest paths when $c \gg n \log n$. The basic idea in this algorithm is to choose $k \simeq \frac{n^2 \log n}{c\epsilon^2}$ pairs of vertices at random and for each pair to perform a shortest path computation (taking $O(m)$ operations per pair). Using the collection of k shortest paths that are found, one estimates in how many shortest paths each edge participates.

Here we present a faster algorithm for finding the weakest links. It is based on two observations. One is that the cost of performing single source shortest path computations (namely, that of finding the shortest paths from one vertex to all other vertices) is $O(m)$, similar to that of finding the shortest path between one pair of vertices. The other observation is that the estimation problem that this gives rise to can be cast as that of estimating the average degree in a graph or, more precisely, in m different graphs simultaneously. The improved running time comes at a cost of a somewhat weaker guarantee in terms of false alarms:

- *Avoids false alarms.* The algorithm does not output any edge that is a member of less than $(1/2 - \epsilon)c$ shortest paths.

As in [3] we assume that shortest paths are unique. This requires a convention for breaking ties between paths of equal length. We shall use the same convention that is proposed in [3], namely, to take the lexicographically first such path. This convention assumes that vertices are labelled and that there is a total ordering on the labels. For

example, the labels can be 1 to n . A path can be viewed as a sequence of vertices in a natural way. Hence a path is a sequence of labels. In fact, two sequences correspond to the same path, depending on which of its two endpoints is considered to be the head of the path and which is considered to be the tail. The name of the path is taken to be the lexicographically smaller of the two. Given two different paths that connect the same pair of vertices, if they are of equal length we use the convention that the one with the lexicographically smaller name is considered to be shorter.

PROPOSITION 25. *Under the tiebreaking convention specified above, there is an $O(m)$ -time algorithm that does the following. Given a connected graph G with n vertices and m edges and an arbitrary vertex v , it simultaneously counts for every edge e in how many vertices u edge e participates in the shortest path connecting u and v .*

Proof. We assume a model of computation in which algorithms such as single source shortest path take $O(m)$ time. In particular, some basic operations (such as comparison between two $O(\log n)$ -bit words) take unit time.

Given a starting vertex v , the distances to all other vertices in G can be computed in $O(m)$ time using breadth first search (BFS). The BFS tree rooted at v also gives shortest paths from v to all vertices. It is quite straightforward to also count for each edge in the BFS tree (starting from edges furthest from the root and moving towards the root) in how many shortest paths (starting from v) it participates. The counting requires only $O(n)$ operations, as there are only $n - 1$ edges in the BFS tree.

In general, several different BFS trees can be constructed starting at the same vertex v , because a vertex at distance i from v may have more than one neighbor at distance $i - 1$ from v . We shall need to construct two such trees. For both trees, we may scan the vertices of the graph in the following order, starting at v : within a level of the BFS tree, vertices are scanned in the order under which they were first discovered, and every vertex scans its neighbors in order of increasing labels. The *forward tree* rooted at v (which gives the lexicographically first shortest paths when v is the first vertex of the path) is constructed using the following rule: for every vertex discovered at level i keep a pointer to its level $i - 1$ neighbor that was first to be discovered (according to the scanning order described above). The *backward tree* rooted at v (which gives the lexicographically first shortest paths when v is the last vertex of the path) is constructed using the following rule: for every vertex discovered at level i keep a pointer to its level $i - 1$ neighbor of smallest label. Both the forward tree and the backward tree can be constructed in $O(m)$ time.

Given both the forward tree and the backward tree for a vertex v , and using the convention that for vertices with a label smaller than v one uses the backward tree and for vertices with a label larger than v one uses the forward tree, one can simultaneously count in $O(n)$ time how many shortest paths with an endpoint at v pass through every edge. (Note that this count is 0 for all but at most $2n - 2$ edges of the two BFS trees.) \square

We now consider m different graphs, one for every edge e . We denote the graph that we associate with edge e by G_e . The vertices of G_e are the vertices of G . Two vertices are connected by an edge in G_e iff e is on their unique shortest path in G . It follows that edge e is on c shortest paths in G iff the average degree in G_e is at least $2c/n$. Hence to find all weakest links, it suffices to find (or estimate) the average degrees of all graphs G_e . We shall now combine two facts.

1. By Theorem 4, $O(\sqrt{n/d_0}/\epsilon)$ degree queries suffice in order to estimate the average degree in a graph with average degree at least d_0 . To make the prob-

ability of error in this estimation below $1/n^2$, one can repeat the estimation procedure $O(\log n)$ times and take the median of the estimations. We shall set $d_0 = (1 - \epsilon)c/n$.

2. For any vertex v , Proposition 25 implies that in time $O(m)$ one can simultaneously obtain the degree of v in all graphs G_e .

Hence using $k = O\left(\frac{\log n \sqrt{n/(c/n)}}{\epsilon}\right) = O\left(\frac{n \log n}{\epsilon \sqrt{c}}\right)$ single source shortest path computations one can with high probability simultaneously estimate the average degree in all graphs G_e , and thus find all weakest links (edges that are on more than c shortest paths) while avoiding any false alarms (by edges that are on less than $(1/2 - \epsilon)c$ shortest paths). This proves Theorem 5.

Theorem 5 offers a savings of roughly n/\sqrt{c} in the running time compared to the running time of $O\left(\frac{mn^2 \log n}{c\epsilon^2}\right)$ in [3]. (Note, however, that ϵ has different meanings in the two bounds. Hence the savings comes at the cost of allowing more false alarms.)

Acknowledgments. I thank Johan Hastad, Michael Langberg, Eran Ofek, Gideon Schechtman, Benjy Weiss, and Avi Wigderson for their interest and involvement in various stages of this work, Assaf Naor for bringing to my attention the work of Samuels, and the anonymous referees for their detailed and useful comments.

HIT-AND-RUN FROM A CORNER*

LÁSZLÓ LOVÁSZ† AND SANTOSH VEMPALA‡

Abstract. We show that the hit-and-run random walk mixes rapidly starting from any interior point of a convex body. This is the first random walk known to have this property. In contrast, the ball walk can take exponentially many steps from some starting points. The proof extends to sampling an exponential density over a convex body.

Key words. sampling, random walks, isoperimetric inequalities

1. Introduction. Consider a random walk in \mathbb{R}^n . It starts somewhere and at each step moves to a randomly chosen “neighboring” point (which could be the current point). With a suitable choice of the “neighbor” transition, the steady state distribution of such a walk can be the uniform distribution over a convex body or, indeed, any reasonable distribution in \mathbb{R}^n . For example, to sample uniformly from a convex body K , the *ball walk* at a point x chooses a point y uniformly in a ball of fixed radius centered at x and then goes to y if y is in K ; else, the step is wasted and it stays at x .

In the last decade and a half, there has been much progress in analyzing these walks [1, 2, 4, 6, 8, 9, 11, 12]. In [8] it was shown that the ball walk mixes in $O^*(n^3)$ steps from a *warm* start after appropriate preprocessing. (A warm start means that the starting point is chosen from a distribution that already is not too far from the target in the sense that its density at any point is at most twice the density of the target distribution. The O^* notation suppresses logarithmic factors and dependence on other parameters like error bounds.) While this result is sufficient to get polynomial-time algorithms for important applications, it is rather cumbersome to generate a warm start and increases the complexity substantially. Kannan and Lovász [6] have shown that the ball walk mixes in $O^*(n^3)$ time from any starting point if wasted steps are not counted. However, the ball walk can take an exponential number of (mostly wasted) steps to mix from some starting points, e.g., a point close to the apex of a rotational cone. (This is because most of the volume of the ball around the start is outside the cone.) Moreover, even starting from a fairly deep point (i.e., the distance to the boundary is much larger than the ball radius), the mixing time can be exponential.¹ The only known way to avoid this problem is to invoke a warm start; it has been an open question as to whether there is a random walk that mixes rapidly starting from, say, the center of gravity of the convex body.

¹Random walks on a discrete subset of \mathbb{R}^n (e.g., the lattice walk) avoid this local conductance problem but have other complications that make their convergence less efficient, although still polynomial. Also, one is sampling from a discrete subset, which might be acceptable for applications but is a bit unsatisfactory.

Is there a random walk that mixes rapidly starting from a(ny) single point? *Hit-and-run*, introduced by Smith [15], is defined as follows:

- Pick a uniformly distributed random line ℓ through the current point.
- Move to a uniform random point along the chord $\ell \cap K$.

It was proved in [15] that the stationary distribution of the hit-and-run walk is the uniform distribution π_K over K . In [10], it was shown that hit-and-run mixes in $O^*(n^3)$ steps from a warm start after appropriate preprocessing; i.e., it is no worse than the ball walk. In this paper, we show that it actually mixes rapidly from *any* interior starting point.

To be more precise, the mixing time *can* be big if we start from a very tight corner. But our bound will be logarithmic in the distance; thus, if, e.g., the convex body is described by a system of linear inequalities with rational coefficients, and the starting point is given by rational coordinates, then the mixing time will be polynomial in the input data.

To derive this mixing result, we prove the following theorem that still assumes a bound on the density of the starting distribution.

THEOREM 1.1. *Let K be a convex body that contains a ball of radius r and is contained in a ball of radius R . Let σ be a starting distribution and let σ^m be the distribution of the current point after m steps of hit-and-run in K . Let $\varepsilon > 0$, and suppose that the density function $d\sigma/d\pi_K$ is bounded by M except on a set S with $\sigma(S) \leq \varepsilon/2$. Then for*

$$m > 10^{10} \frac{n^2 R^2}{r^2} \ln \frac{M}{\varepsilon},$$

the total variation distance of σ^m and π_K is less than ε .

The condition on the starting density captures the case when the L_2 distance of σ and π is bounded (as shown in section 5). The theorem improves on existing bounds by reducing the dependence on M and ε from polynomial (which is unavoidable for the ball walk) to logarithmic, while maintaining the optimal dependence on r , R , and n . To bound the convergence to stationarity when starting from a specific point at distance d from the boundary, we do one step and then (if this is not too short) we apply Theorem 1.1 with the starting distribution obtained this way.

COROLLARY 1.2. *Under the conditions of Theorem 1.1, suppose that the starting distribution σ is concentrated on a single point in K at distance d from the boundary. Then for*

$$m > 10^{11} \frac{n^3 R^2}{r^2} \ln \frac{R}{d\varepsilon},$$

the total variation distance of σ^m and π_K is less than ε .

At the heart of this theorem is a bound of $\Omega(r/nR)$ on the conductance of every subset (see Theorem 4.2). (For the ball walk, the conductance of small sets can be arbitrarily small; therefore the need for a warm start.) As we discuss in section 5, the condition that K is contained in a ball of radius R can be replaced by the weaker condition that its second moment is at most R^2 , i.e., $\mathbf{E}_K(|x - z_K|^2) \leq R^2$, where z_K is the centroid of K . The mixing time goes up by a factor of $O(\ln^2(M/\varepsilon))$. For a body in near-isotropic position, $R/r = O(\sqrt{n})$ and so the number of steps required is $O(n^3 \ln^3(M/\varepsilon))$. It follows that hit-and-run mixes in $O(n^4 \ln^3(n/d))$ steps starting from a point at distance d from the boundary. Such a guarantee is not possible for the ball walk.

Our main tool is a new isoperimetric inequality (section 2). To formulate an isoperimetric inequality, one considers a partition of a convex body K into three sets S_1, S_2, S_3 such that S_1 and S_2 are “far” from each other and the inequality bounds the minimum possible volume of S_3 relative to the volumes of S_1 and S_2 . All previous inequalities have viewed the distance between S_1 and S_2 as the *minimum* distance between points in S_1 and points in S_2 . For example, if $d(S_1, S_2)$ is the minimum Euclidean distance between S_1 and S_2 , then

$$\text{vol}(S_3) \geq \frac{2d(S_1, S_2)}{D} \min\{\text{vol}(S_1), \text{vol}(S_2)\},$$

where D is the diameter of K [3, 7]. One can get a similar inequality using the cross-ratio distance (see section 2) instead of the Euclidean distance [10]:

$$\text{vol}(S_3) \geq d_K(S_1, S_2) \frac{\text{vol}(S_1)\text{vol}(S_2)}{\text{vol}(K)}.$$

In this paper, by means of a weight function $h(x)$ on K that measures the distance between S_1 and S_2 as a certain average distance, we obtain a more general inequality that can be much stronger. We formulate it for general logconcave functions in Theorem 2.1. For a convex body, it says that

$$\text{vol}(S_3) \geq \mathbf{E}_K(h(x)) \min\{\text{vol}(S_1), \text{vol}(S_2)\}.$$

The weight $h(x)$ at a point x is restricted only by the cross-ratio distance between pairs u, v from S_1, S_2 , respectively, for which $x \in [u, v]$. In general, the weight $h(x)$ can be much higher than the minimum cross-ratio distance between S_1 and S_2 .

Hit-and-run can be extended to sampling general densities f in \mathbb{R}^n as follows:

- Pick a uniformly distributed random line ℓ through the current point.
- Move to a random point y along the line ℓ chosen from the distribution induced by f on ℓ .

The stationary distribution of this walk is π_f , the probability measure with density f . It has been shown that it is efficient for any logconcave density from a warm start [13]. (Similar results are also known for the ball walk with a Metropolis filter [13].) It is natural to ask if hit-and-run is rapidly mixing from any starting point even for arbitrary logconcave functions. There are some technical problems with extending the results of this paper to arbitrary logconcave functions; but we make some progress in this direction by showing that this is indeed the case for an exponential density over a convex body. This class of density functions is interesting for other reasons as well—these are the functions used in “simulated annealing” and in the fastest volume algorithm [14]. We prove the following theorem in section 6. The condition on the starting density captures the case of bounded L_2 -norm; the proof uses the same isoperimetric inequality (see Theorem 2.1).

THEOREM 1.3. *Let $K \subseteq \mathbb{R}^n$ be a convex body and let f be a density supported on K which is proportional to $e^{-a^T x}$ for some vector $a \in \mathbb{R}^n$. Assume that the level set of f of probability $1/8$ contains a ball of radius r and that $\mathbf{E}_f(|x - z_f|^2) \leq R^2$, where z_f is the centroid of f . Let σ be a starting distribution and let σ^m be the distribution of the current point after m steps of hit-and-run applied to f . Let $\varepsilon > 0$, and suppose that the density function $d\sigma/d\pi_f$ is bounded by M except on a set S with $\sigma(S) \leq \varepsilon/2$. Then for*

$$m > 10^{30} \frac{n^2 R^2}{r^2} \ln^5 \frac{MnR}{r\varepsilon},$$

the total variation distance of σ^m and π_f is less than ε .

1.1. Overview of analysis. We wish to bound the rate of convergence of the Markov chain underlying hit-and-run to the uniform distribution π_K on the convex body K . For this we use the notion of *conductance*, which is defined as follows: For any measurable subset $S \subseteq K$ and $x \in K$, we denote by $P_x(S)$ the probability that a step from x goes to S . If $0 < \pi_K(S) < 1$, then the conductance $\phi(S)$ is defined as

$$\phi(S) = \frac{\int_{x \in S} P_x(K \setminus S) d\pi_K}{\min\{\pi_K(S), \pi_K(K \setminus S)\}}.$$

The minimum value over all subsets S is the conductance, ϕ , of the Markov chain. Lovász and Simonovits [12], extending a result of Jerrum and Sinclair [5], have shown that the mixing rate (roughly, the number of steps needed to halve the distance to the stationary distribution) is bounded by $O(1/\phi^2)$ (and is at least $1/\phi$).

The main part of our proof shows that the conductance of the hit-and-run Markov chain is $\Omega(r/nR)$. All previous attempts to bound the conductance of geometric random walks could prove only that the conductance of “large” subsets is large, namely, that the conductance bound for a subset S was proportional to $\pi_K(S)$. For this reason, one had to limit the probability that we start in one of bad small sets, which leads to the use of a warm start. As mentioned earlier, the example of starting at a point x near the apex of a rotational cone shows that the ball walk can in fact take exponentially many steps from some starting points: Most points of a ball around x are outside the cone, and hence most steps from x are wasted.

Hit-and-run, on the contrary, exhibits a sizable (inverse polynomial) drift toward the base of the cone. Thus, although the initial steps are tiny, they quickly get larger and the current point moves away from the apex. By bounding the conductance, we show that this phenomenon is general; i.e., hit-and-run mixes rapidly starting from any interior point of a convex body. To prove this, we use the new isoperimetric inequality. Besides the inequality, a key observation in the proof is that the “median” step length from points in K is a concave function.

2. A weighted isoperimetric inequality. To analyze the walk, we use a non-Euclidean notion of distance [10]. Let u, v be two distinct points in K , let $\ell(u, v)$ denote the line through u and v , and let p, q be the endpoints of the segment $\ell(u, v) \cap K$, so that the points appear in the order p, u, v, q along $\ell(u, v)$. Then,

$$d_K(u, v) = \frac{|u - v||p - q|}{|p - u||v - q|}.$$

For two subsets S_1, S_2 of K , we define

$$d_K(S_1, S_2) = \min_{u \in S_1, v \in S_2} d_K(u, v).$$

Theorem 2.5 from [13] asserts the following: If f is a logconcave function on a convex set K , $\varepsilon > 0$ and $S_1 \cup S_2 \cup S_3$ is a partition of K into three measurable sets such that for any $u \in S_1$ and $v \in S_2$ we have $d_K(u, v) \geq \varepsilon$, then

$$(1) \quad \int_K f(x) dx \int_{S_3} f(x) dx \geq \varepsilon \int_{S_1} f(x) dx \int_{S_2} f(x) dx.$$

We prove the following related result.

THEOREM 2.1. *Let K be a convex body in \mathbb{R}^n . Let $f : K \rightarrow \mathbb{R}_+$ be a logconcave function and let $h : K \rightarrow \mathbb{R}_+$ be an arbitrary function. Let S_1, S_2, S_3 be any partition*

of K into measurable sets. Suppose that for any pair of points $u \in S_1$ and $v \in S_2$ and any point x on the chord of K through u and v ,

$$h(x) \leq \frac{1}{3} \min(1, d_K(u, v)).$$

Then

$$\frac{\int_{S_3} f(x) dx}{\min \left\{ \int_{S_1} f(x) dx, \int_{S_2} f(x) dx \right\}} \geq \frac{\int_K h(x)f(x) dx}{\int_K f(x) dx}.$$

Remark. For a logconcave density function f and corresponding distribution π_f , the conclusion of the theorem can be stated as

$$\pi_f(S_3) \geq E_f(h(x)) \min\{\pi_f(S_1), \pi_f(S_2)\}.$$

Proof. We can assume that $\int_{S_1} f(x) dx \leq \int_{S_2} f(x) dx$. Suppose that the conclusion is false. Then there exists an $A \leq 1/2$ such that

$$\int_K f(x) dx = \frac{1}{A} \int_{S_1} f(x) dx$$

and

$$\int_{S_3} f(x) dx < A \int_K h(x)f(x) dx.$$

Now we invoke the localization lemma, specifically the version given in Corollary 2.4 of [7]. This implies that there exist two points $a, b \in K$ and a linear function $\ell : [0, 1] \rightarrow \mathbb{R}_+$ with the following properties. Set

$$F(t) = \ell(t)^{n-1} f(ta + (1-t)b), \quad G(t) = h(ta + (1-t)b),$$

and

$$J_i = \{t \in [0, 1] : ta + (1-t)b \in S_i\} \quad (i = 1, 2, 3);$$

then

$$\begin{aligned} \int_0^1 F(t) dt &= \frac{1}{A} \int_{J_1} F(t) dt, \\ \int_{J_3} F(t) dt &< A \int_0^1 G(t)F(t) dt, \end{aligned}$$

and hence

$$\int_0^1 F(t) dt \int_{J_3} F(t) dt < \int_{J_1} F(t) dt \int_0^1 G(t)F(t) dt.$$

For $u, v \in K$, let M_{uv} denote the maximum of $h(x)$ over the chord through u and v ; then

$$\int_0^1 G(t)F(t) dt \leq M_{ab} \int_0^1 F(t) dt,$$

and so

$$(2) \quad \int_{J_3} F(t) dt < M_{ab} \int_{J_1} F(t) dt.$$

We also have

$$(3) \quad \int_{J_1} F(t) dt = A \int_0^1 F(t) dt \leq \frac{1}{2} \int_0^1 F(t) dt.$$

Let $u \in J_1$ and $v \in J_2$, and (say) $u < v$. Then by hypothesis,

$$\frac{v - u}{u(1 - v)} \geq d_K(ua + (1 - u)b, va + (1 - v)b) \geq 3M_{ab},$$

and hence by the one-dimensional case of (1), we have

$$\int_0^1 F(t) dt \int_{J_3} F(t) dt \geq 3M_{ab} \int_{J_1} F(t) dt \int_{J_2} F(t) dt.$$

Comparing this with (2), we get

$$\int_0^1 F(t) dt > 3 \int_{J_2} F(t) dt.$$

Using this and (3), it follows that

$$\begin{aligned} \int_{J_3} F(t) dt &= \int_0^1 F(t) dt - \int_{J_1} F(t) dt - \int_{J_2} F(t) dt \\ &> \left(1 - \frac{1}{2} - \frac{1}{3}\right) \int_0^1 F(t) dt \\ &= \frac{1}{6} \int_0^1 F(t) dt. \end{aligned}$$

But then (2) and (3) imply that $M_{ab} > 1/3$, a contradiction. \square

3. Bounding the step size. For $x \in K$, let y be a random step from x . Following [10], we define $F(x)$ as

$$(4) \quad \mathbb{P}(|x - y| \leq F(x)) = \frac{1}{8}.$$

Roughly speaking, this is the “median” step length from x . The goal of this section is to bound this function from below by a concave function.

For $x \in K$, let

$$\lambda(x, t) = \frac{\text{vol}(K \cap (x + tB))}{\text{vol}(tB)}$$

denote the fraction of a ball of radius t around x that intersects K . For a fixed $\gamma \geq 0$, define $s : K \rightarrow \mathbb{R}_+$ as

$$s(x) = \sup\{t \in \mathbb{R}_+ : \lambda(x, t) \geq \gamma\}.$$

The value $s(x)$ is a measure of how close x is to the boundary of K . Its somewhat complicated definition guarantees some useful properties.

LEMMA 3.1. *For any $\gamma > 0$, $s(x)$ is a concave function.*

Proof. Let $x_1, x_2 \in K$ with $s(x_1) = r_1$ and $s(x_2) = r_2$. Let $A_i = K \cap (x_i + r_i B)$ ($i = 1, 2$). Let $x = (x_1 + x_2)/2$ and consider $A = (A_1 + A_2)/2$. By convexity, $A \subseteq K$. Further, any point $y \in A$ can be written as

$$y = \frac{1}{2}(x_1 + z_1 + x_2 + z_2) = x + \frac{z_1 + z_2}{2}$$

for some z_1, z_2 such that $|z_1| \leq r_1$ and $|z_2| \leq r_2$. Thus,

$$A \subseteq K \cap \left(x + \frac{r_1 + r_2}{2} B \right).$$

Next, by the Brunn–Minkowski inequality,

$$\begin{aligned} \text{vol}(A)^{\frac{1}{n}} &\geq \frac{1}{2} \left(\text{vol}(A_1)^{\frac{1}{n}} + \text{vol}(A_2)^{\frac{1}{n}} \right) \\ &\geq \frac{1}{2} \gamma^{\frac{1}{n}} \text{vol}(B)^{\frac{1}{n}} (r_1 + r_2) \\ &= \gamma^{\frac{1}{n}} \text{vol} \left(\frac{r_1 + r_2}{2} B \right)^{\frac{1}{n}}. \end{aligned}$$

It follows that

$$\text{vol} \left(K \cap \left(x + \frac{r_1 + r_2}{2} B \right) \right) \geq \text{vol}(A) \geq \gamma \text{vol} \left(\frac{r_1 + r_2}{2} B \right)$$

and thus $s(x) \geq (r_1 + r_2)/2$. \square

LEMMA 3.2. *If $\gamma \geq 63/64$, then for all $x \in K$,*

$$F(x) \geq \frac{s(x)}{32}.$$

Proof. Set $s = s(x)$. Let p denote the fraction of the surface of the ball $x + (s/2)B$ that is not in K . Then

$$\text{vol}((x + sB) \setminus K) \geq p \text{vol}(sB) - \text{vol}((s/2)B).$$

By the definition of s ,

$$\text{vol}((x + sB) \setminus K) \leq (1 - \gamma) \text{vol}(sB),$$

and hence

$$p \leq 1 - \gamma + 2^{-n} \leq \frac{1}{32}.$$

Take a random line ℓ through x ; then with probability at least $1 - 2p$, $\ell \cap (x + (s/2)B) \subseteq K$. If this happens, then for the point y chosen uniformly from $\ell \cap K$, we have

$$\mathbb{P} \left(|y - x| \leq \frac{s}{32} \mid \ell \right) \leq \frac{1}{16},$$

and so

$$P\left(|y - x| \leq \frac{s}{32}\right) \leq \frac{1}{16} + \frac{15}{16} \cdot \frac{1}{16} < \frac{1}{8}.$$

This proves the lemma. \square

Let us quote Corollary 4.6 in [8] as the following lemma.

LEMMA 3.3. *Suppose K contains a ball of radius r . Then,*

$$\int_K \int_{y \in x+tB \setminus K} dy dx \leq \frac{t\sqrt{n}}{2r} \text{vol}(K) \text{vol}(tB).$$

This lemma can be used to bound the average value of $s(x)$ from below, as follows.

LEMMA 3.4. *Suppose K contains a unit ball. Then,*

$$\int_K s(x) dx \geq \frac{1-\gamma}{\sqrt{n}} \text{vol}(K).$$

Proof. From Lemma 3.3,

$$\int_K \lambda(x, t) dx \geq \left(1 - \frac{t\sqrt{n}}{2}\right) \text{vol}(K).$$

On the other hand,

$$\int_K \lambda(x, t) dx \leq \gamma \text{vol}(K) + (1-\gamma) \text{vol}(\{x \in K : \lambda(x, t) \geq \gamma\})$$

and so

$$\text{vol}(\{x \in K : \lambda(x, t) \geq \gamma\}) \geq \left(1 - \frac{t\sqrt{n}}{2(1-\gamma)}\right) \text{vol}(K).$$

Using this,

$$\begin{aligned} \int_K s(x) dx &= \int_0^\infty \text{vol}(\{x \in K : \lambda(x, t) \geq \gamma\}) dt \\ &\geq \text{vol}(K) \int_0^\infty \left(1 - \frac{t\sqrt{n}}{2(1-\gamma)}\right)^+ dt \\ &= \frac{1-\gamma}{\sqrt{n}} \text{vol}(K). \quad \square \end{aligned}$$

4. A scale-free bound on the conductance. For a point $u \in K$, let P_u be the distribution obtained by taking one hit-and-run step from u . Then (as shown in [10]),

$$(5) \quad P_u(A) = \frac{2}{\text{vol}_{n-1}(\partial B)} \int_A \frac{dx}{\ell(u, x)|x - u|^{n-1}},$$

where $\ell(u, x)$ is the length of the chord through u and x .

Let $d_{tv}(P, Q)$ denote the total variation distance between distributions P and Q . The following lemma from [10] connects the geometric distance of two points to the variation distance of the distributions obtained by taking one hit-and-run step.

LEMMA 4.1 (see [10]). *Let $u, v \in K$. Suppose that*

$$d_K(u, v) < \frac{1}{8} \text{ and } |u - v| < \frac{2}{\sqrt{n}} \max\{F(u), F(v)\}.$$

Then

$$d_{tv}(P_u, P_v) < 1 - \frac{1}{500}.$$

The main theorem of this section is the following.

THEOREM 4.2. *Let K be a convex body in \mathbb{R}^n of diameter D , containing a unit ball. Then the conductance of hit-and-run in K is at least $\frac{1}{2^{24}nD}$.*

Proof. Let $K = S_1 \cup S_2$ be a partition into measurable sets. We will prove that

$$(6) \quad \int_{S_1} P_x(S_2) dx \geq \frac{1}{2^{24}nD} \min\{\text{vol}(S_1), \text{vol}(S_2)\}.$$

We can read the left-hand side as follows: We select a random point X from the uniform distribution and make one step to get Y . What is the probability that $X \in S_1$ and $Y \in S_2$? It is well known that this quantity remains the same if S_1 and S_2 are interchanged.

Consider the points that are deep inside these sets, i.e., unlikely to jump out of the set:

$$S'_1 = \left\{ x \in S_1 : P_x(S_2) < \frac{1}{1000} \right\}$$

and

$$S'_2 = \left\{ x \in S_2 : P_x(S_1) < \frac{1}{1000} \right\}.$$

Let S'_3 be the rest, i.e., $S'_3 = K \setminus S'_1 \setminus S'_2$.

Suppose $\text{vol}(S'_1) < \text{vol}(S_1)/2$. Then

$$\int_{S_1} P_x(S_2) dx \geq \frac{1}{1000} \text{vol}(S_1 \setminus S'_1) \geq \frac{1}{2000} \text{vol}(S_1),$$

which proves (6).

So we can assume that $\text{vol}(S'_1) \geq \text{vol}(S_1)/2$ and, similarly, that $\text{vol}(S'_2) \geq \text{vol}(S_2)/2$. For any $u \in S'_1$ and $v \in S'_2$,

$$d_{tv}(P_u, P_v) \geq 1 - P_u(S_2) - P_v(S_1) > 1 - \frac{1}{500}.$$

Thus, by Lemma 4.1, either

$$(7) \quad d_K(u, v) \geq \frac{1}{8}$$

or

$$(8) \quad |u - v| \geq \frac{2}{\sqrt{n}} \max\{F(u), F(v)\}.$$

We want to apply Theorem 2.1 to the partition S'_1, S'_2, S'_3 and the function $h(x) = s(x)/(48D\sqrt{n})$, where $s(x)$ is as defined in section 3 with $\gamma = 63/64$. To verify the condition, let $u \in S'_1, v \in S'_2$, and x be any point on the chord pq through u and v (where p is the endpoint closer to u than v). Clearly $h(x) \leq 1/3$. If (7) holds, then $h(x) \leq d_K(u, v)/3$ is trivial. Then suppose that (8) holds. Let, e.g., x be between u and q . Then, using the concavity of s (Lemma 3.1), we have

$$\begin{aligned} s(x) &\leq \frac{|x-p|}{|u-p|}s(u) \leq 32\frac{|q-p|}{|u-p|}F(u) \quad (\text{using Lemma 3.2}) \\ &\leq 16\frac{|q-p|}{|u-p|}\sqrt{n}|u-v| \quad (\text{using (8) above}) \\ &= 16d_K(u, v)\sqrt{n}|q-v| \\ &\leq 16d_K(u, v)D\sqrt{n}, \end{aligned}$$

and hence $h(x) \leq d_K(u, v)/3$ follows again. Thus, Theorem 2.1 applies with f being the uniform density and we get

$$\begin{aligned} \frac{\text{vol}(S'_3)}{\min\{\text{vol}(S'_1), \text{vol}(S'_2)\}} &\geq \frac{1}{48D\sqrt{n}} \cdot \frac{1}{\text{vol}(K)} \int_K s(x) dx \\ &> \frac{1}{4000nD}. \end{aligned}$$

Here we have used Lemma 3.4 with $\gamma = 63/64$. Therefore,

$$\begin{aligned} \int_{S_1} P_x(S_2) dx &\geq \frac{1}{2} \cdot \frac{1}{1000} \text{vol}(S'_3) \\ &\geq \frac{1}{2^{23}nD} \min\{\text{vol}(S'_1), \text{vol}(S'_2)\} \\ &\geq \frac{1}{2^{24}nD} \min\{\text{vol}(S_1), \text{vol}(S_2)\}, \end{aligned}$$

which again proves (6). \square

5. Proof of the mixing bound. First note that hit-and-run is invariant under a scaling of space (i.e., there is a 1-1 mapping between the random walk in K and cK) and thus the conductance bound of $\Omega(r/nR)$ follows by considering K/r . Next, suppose we start with an M -warm distribution σ ; i.e., for any subset S of K , $\sigma(S) \leq M\pi_K(S)$. Then using Corollary 1.5 of [12], the distribution σ^m obtained after m steps satisfies

$$d_{tv}(\sigma^m, \pi_K) \leq \sqrt{M} \left(1 - \frac{\phi^2}{2}\right)^m$$

and thus after $m > Cn^2 \frac{R^2}{r^2} \ln \frac{M}{\epsilon}$ steps (C is a constant), the total variation distance of σ^m and π_K is less than ϵ .

If we know only that $\sigma \leq M\pi_K$ except for the subsets of a set S with $\sigma(S) < \epsilon/2$, then we think of a random point of K as being generated with probability $1 - \epsilon/2$ from a distribution σ' that is $(2M)$ -warm with respect to π_K and with probability $\epsilon/2$ from some other distribution. After m steps, we have

$$d_{tv}(\sigma^m, \pi_K) \leq \frac{\epsilon}{2} + \left(1 - \frac{\epsilon}{2}\right) \sqrt{\frac{2M}{\epsilon}} \left(1 - \frac{\phi^2}{2}\right)^m,$$

which implies Theorem 1.1.

In some applications, the L_2 -norm of σ w.r.t. π is bounded; i.e., suppose that

$$\int_K \left(\frac{d\sigma}{d\pi}\right)^2 d\pi \leq M.$$

This will also be sufficient for mixing. The set

$$S = \left\{x : \frac{d\sigma}{d\pi} > \frac{2M}{\varepsilon}\right\}$$

has measure $\pi(S)$ of at most $\varepsilon/2$. So we can apply the mixing theorem with $2M/\varepsilon$ in place of M .

As mentioned in the introduction, Theorem 1.1 can be strengthened to require only that $\mathbb{E}_K(\|x - z_K\|^2) \leq R^2$ with a small increase in the mixing time. It is well known that the volume of K outside a ball of radius $R \ln(2/\delta)$ is at most a $\delta/2$ fraction. Thus the conductance of any subset of measure x is at least

$$\phi(x) = \frac{cr}{nR \ln(2/x)}$$

for some constant c . Then the average conductance theorem of [6] implies that after $m > C(n^2 R^2 / r^2) \ln^3(M/\varepsilon)$ steps (where C is a constant), we get that $d_{tv}(\sigma^m, \pi_K) \leq \varepsilon$.

Finally, Corollary 1.2 follows by bounding M for the distribution obtained after one step of hit-and-run.

6. Exponential density over a convex body. Here we extend the main theorem to sample an exponential density over a convex body. We will use the following notation. Let f be a density function in \mathbb{R}^n . For any line ℓ in \mathbb{R}^n , let $\mu_{\ell, f}$ be the measure induced by f on ℓ , i.e.,

$$\mu_{\ell, f}(S) = \int_{p+tu \in S} f(p+tu) dt,$$

where p is any point on ℓ and u is a unit vector parallel to ℓ . We abbreviate $\mu_{\ell, f}$ by μ_ℓ if f is understood, and also $\mu_\ell(\ell)$ by μ_ℓ . The probability measure $\pi_\ell(S) = \mu_\ell(S)/\mu_\ell$ is the restriction of f to ℓ .

For two points $u, v \in \mathbb{R}^n$, let $\ell(u, v)$ denote the line through them. Let $[u, v]$ denote the segment connecting u and v , and let $\ell^+(u, v)$ denote the semiline in ℓ starting at u and not containing v . Furthermore, let

$$\begin{aligned} f^+(u, v) &= \mu_{\ell, f}(\ell^+(u, v)), \\ f^-(u, v) &= \mu_{\ell, f}(\ell^+(v, u)), \\ f(u, v) &= \mu_{\ell, f}([u, v]). \end{aligned}$$

For any $T > 0$, let $L(T) = \{x : f(x) \geq T\}$ be the level set of function value T . It will be convenient to let π_n denote the volume of the unit ball in \mathbb{R}^n .

6.1. Distance. The following “distance” was used in [13]:

$$d_f(u, v) = \frac{f(u, v)f(\ell(u, v))}{f^-(u, v)f^+(u, v)}.$$

(This quantity is not really a distance, since it does not satisfy the triangle inequality. To get a proper distance function, one could consider $\ln(1 + d_f(u, v))$; but it will be more convenient to work with d_f .)

Note that when f is the uniform distribution over a convex set K , then $d_f(u, v) = d_K(u, v)$. The next lemma describes how the two are related in general.

LEMMA 6.1. *Let f be a logconcave density function in \mathbb{R}^n whose support is a convex body K . Let $G = \max_K f(x)/\min_K f(x)$.*

1. $d_f(u, v) \geq d_K(u, v)$.
- 2.

$$d_K(u, v) \geq \frac{\min\{3, d_f(u, v)\}}{6(1 + \ln G)}.$$

The first inequality is Lemma 5.9 in [13], and the second inequality is a direct implication of Lemma 5.11 in [13].

6.2. Step size. Let f be a density function whose support is a convex body K . We define three parameters that all measure the local smoothness of f . First, for a fixed β and γ , we define

$$\lambda(x, t) = \frac{\text{vol}((x + tB) \cap L(\beta f(x)))}{\text{vol}(tB)} \quad \text{and} \quad s(x) = \sup\{t \in \mathbb{R}_+ : \lambda(x, t) \geq \gamma\}.$$

Second, we define $F(x)$ by

$$\mathbb{P}(|x - y| \leq F(x)) = \frac{1}{8},$$

where y is a random step from x . Third, we define $\alpha(x)$ (as in [13]) as the smallest $s \geq 3$ for which a hit-and-run step y from x satisfies

$$\mathbb{P}(f(y) \geq sf(x)) \leq \frac{1}{16}.$$

We will shortly fix $\beta = 3/4$ and $\gamma = 63/64$. Note that $\lambda(x, t)$, $s(x)$, and $F(x)$ as defined here are generalizations of the definitions in section 3 (where $f(x)$ was the uniform density over K).

The following lemma was proved in [13].

LEMMA 6.2 (see [13, Lemma 6.10]).

$$\pi_f(u : \alpha(u) \geq t) \leq \frac{16}{t}.$$

Our next lemma extends a crucial property of $s(x)$ to exponential functions (it does not hold for general logconcave functions).

LEMMA 6.3. *Suppose $f(x)$ is proportional to $e^{-a^T x}$ in a convex body K and zero outside. Then for any fixed $\beta, \gamma > 0$, the function $s(x)$ is concave.*

Proof. Let $x_1, x_2 \in K$ with $s(x_1) = r_1$ and $s(x_2) = r_2$. Define

$$A_1 = \{y \in x_1 + r_1B : f(y) \geq \beta f(x_1)\} \quad \text{and} \quad A_2 = \{y \in x_2 + r_2B : f(y) \geq \beta f(x_2)\}.$$

Now let $x = (x_1 + x_2)/2$ and consider $A = (A_1 + A_2)/2$. Any point $y \in A$ can be written as

$$y = x + \frac{z_1 + z_2}{2}$$

for some z_1, z_2 such that $z_1 \in r_1 B$ and $z_2 \in r_2 B$. Thus

$$A \subseteq x + \frac{r_1 + r_2}{2} B.$$

Also, since $f(x)$ is proportional to $e^{-a^T x}$, we have $f((x + y)/2) = \sqrt{f(x)f(y)}$ and so for any $y \in A$,

$$f(y) = f\left(\frac{y_1 + y_2}{2}\right) = \sqrt{f(y_1)f(y_2)},$$

where $y_1 \in A_1$ and $y_2 \in A_2$. By the definition of these subsets, $f(y_1) \geq \beta f(x_1)$ and $f(y_2) \geq \beta f(x_2)$. Thus

$$f(y) \geq \beta \sqrt{f(x_1)f(x_2)} = \beta f\left(\frac{x_1 + x_2}{2}\right) = \beta f(x)$$

and so

$$A \subseteq \left\{y \in x + \frac{r_1 + r_2}{2} B : f(y) \geq \beta f(x)\right\}.$$

Finally, by the Brunn–Minkowski inequality,

$$\begin{aligned} \text{vol}(A)^{\frac{1}{n}} &\geq \frac{1}{2} \left(\text{vol}(A_1)^{\frac{1}{n}} + \text{vol}(A_2)^{\frac{1}{n}}\right) \\ &\geq \frac{1}{2} (\gamma \pi_n)^{\frac{1}{n}} (r_1 + r_2) \\ &= \gamma^{\frac{1}{n}} \text{vol}\left(\frac{r_1 + r_2}{2} B\right)^{\frac{1}{n}}. \end{aligned}$$

It follows that $s(x) \geq (r_1 + r_2)/2$. \square

Next, we bound the expected value of $s(x)$.

LEMMA 6.4. *Let f be any logconcave density such that the level set of f of measure $1/8$ contains a ball of radius r . Then with $\beta = 3/4$ and $\gamma = 63/64$,*

$$\mathbb{E}_f(s(x)) \geq \frac{r}{2^{10} \sqrt{n}}.$$

Proof. Let L_0 be the level set

$$L_0 = \{x : f(x) \geq f_0\},$$

such that the measure of L_0 is $1/8$. For $i = 1, 2, \dots$, consider the level sets

$$L_i = \left\{x : f(x) \geq \left(\frac{3}{4}\right)^i f_0\right\}.$$

Note that since f is logconcave, each L_i is a convex body. We will first bound $\mathbb{E}_f(1 - \lambda(x, t))$ as follows:

$$\begin{aligned}
 \int_{\mathbb{R}^n} f(x) \int_{y \in x+tB: f(y) < 3f(x)/4} \frac{dy}{\text{vol}(tB)} dx & \\
 & \leq \frac{1}{8} + \sum_{i>0} \frac{f_0}{(4/3)^{i-1}} \int_{x \in L_i \setminus L_{i-1}} \int_{y \in x+tB \setminus L_i} \frac{dy}{\text{vol}(tB)} dx \\
 & \leq \frac{1}{8} + \sum_i \frac{f_0}{(4/3)^{i-1}} \int_{x \in L_i} \int_{y \in x+tB \setminus L_i} \frac{dy}{\text{vol}(tB)} dx \\
 & \leq \frac{1}{8} + \frac{t\sqrt{n}}{2r} \sum_i \frac{f_0}{(4/3)^{i-1}} \text{vol}(L_i).
 \end{aligned}$$

In the last step, we applied Lemma 3.3 to the convex set L_i which contains a ball of radius r by assumption. Now for any $x \in L_i \setminus L_{i-1}$,

$$\frac{f_0}{(4/3)^i} \leq f(x) < \frac{f_0}{(4/3)^{i-1}}.$$

Using this,

$$\begin{aligned}
 \sum_i \frac{f_0}{(4/3)^{i-1}} \text{vol}(L_i) & \leq \sum_i \frac{4f_0}{(4/3)^{i-1}} \text{vol}(L_i \setminus L_{i-1}) \\
 & \leq \frac{16}{3} \int_{\mathbb{R}^n} f(x) dx < 6.
 \end{aligned}$$

Thus,

$$\mathbb{E}_f(1 - \lambda(x, t)) \leq \frac{1}{8} + \frac{3t\sqrt{n}}{r}.$$

Next, since $\lambda(x, t)$ can be at most 1, we get

$$\int_{x: \lambda(x, t) \geq 3/4} f(x) dx \geq \frac{1}{2} - \frac{12t\sqrt{n}}{r}.$$

We will use the following claim to complete the proof: If $\lambda(x, t) \geq 3/4$, then for $c > 1$,

$$\lambda(x, t/c) \geq 1 - e^{-(\frac{c}{4}-1)^2/2}.$$

To see the claim, note that since $\lambda(x, t) \geq 3/4$, there must be a ball of radius $t/2\sqrt{n}$ inside K centered at x . The claim then follows by applying Lemma 4.4 in [13].

Setting $c = 16$ above, we get $\lambda(x, t/16) \geq 1 - e^{-9/2} > 63/64$. Using this,

$$\begin{aligned}
 \int_{\mathbb{R}^n} s(x)f(x) dx & \geq \frac{1}{16} \int_{t=0}^\infty \int_{x: \lambda(x, t) \geq 3/4} f(x) dx dt \\
 & \geq \frac{1}{16} \int_{t=0}^\infty \left(\frac{1}{2} - \frac{12t\sqrt{n}}{r} \right)^+ dt \\
 & \geq \frac{r}{2^{10}\sqrt{n}}. \quad \square
 \end{aligned}$$

We can also relate the maximum value of $s(x)$ to the diameter D .

LEMMA 6.5. Let $G = \frac{\max_K f(x)}{\min_K f(x)}$, where f is proportional to $e^{-a^T x}$ with support K . Suppose K has diameter D . Then,

$$\max_K s(x) \leq \min \left\{ \frac{2\sqrt{n}D}{\ln G}, D \right\}.$$

Proof. Let $t = 1/|a|$. Then along the direction of a , the function value drops by $1/e$ each time we move distance t . Hence,

$$t \leq \frac{D}{\ln G}.$$

On the other hand, for any point x , we claim that

$$s(x) \leq 2t\sqrt{n}.$$

To see this, consider the nearest point y along the line through x in the direction of a with $f(y) \leq f(x)/2$. This point satisfies $|x - y| \leq t$. Now the portion of the ball $x + s(x)B$ in the half-space $\{z : a^T z \geq a^T y\}$ must have volume at most $1/4$ of the volume of $s(x)B$ by the definition of $s(x)$ (in a ball of radius $2t\sqrt{n}$, a half-space at distance t from the center cuts off at least $1/4$ of the volume of the ball). This implies the inequality. The lemma follows. \square

The next lemma is about the step size along a given line.

LEMMA 6.6. Let f be logconcave and ℓ be any line through a point x . Let p, q be intersection points of ℓ with the boundary of $L(F/8)$, where F is the maximum value of f along ℓ , and let $s = \max\{|x - p|/32, |x - q|/32\}$. Choose a random point y on ℓ from the distribution π_ℓ . Then

$$P(|x - y| > s) > \frac{3}{4}.$$

Proof. We will use the following observation. For any logconcave function g that is nonincreasing on an interval $[a, b]$

$$\int_{[a,b]} g(x) dx \geq |a - b| \frac{g(a) - g(b)}{\ln g(a) - \ln g(b)}.$$

The proof is by noting that the exponential function with value $g(a)$ at a and $g(b)$ at b is a lower bound on any such function.

In our case, suppose f attains its maximum at a point $z \in [p, q]$. Then, applying the observation separately to the intervals $[p, z]$ and $[z, q]$, we get

$$\int_{[p,q]} f(x) dx \geq \frac{7F}{8 \ln 8} |p - q|.$$

Also, by Lemma 3.5(a) in [13] (whose proof uses a similar reduction to the exponential function), $P(y \in [p, q]) \geq 7/8$. We now consider two cases. If $x \in [p, q]$, then $s \leq |p - q|/32$ and thus

$$P(|x - y| \leq s) \leq \frac{2sF}{\int_{[p,q]} f(x) dx} \leq \frac{\ln 8}{14} < \frac{1}{4}.$$

Suppose $x \notin [p, q]$. Let u be the unit vector along $p - q$. Then,

$$|[x - su, x + su] \cap [p, q]| \leq \frac{|p - q|}{32},$$

and thus

$$\mathbb{P}(|x - y| \leq s) \leq \frac{1}{8} + \frac{F|p - q|/32}{7F|p - q|/8 \ln 8} < \frac{1}{4}. \quad \square$$

Finally, $s(x)$ gives a lower bound on $F(x)$ as in section 3.

LEMMA 6.7. *If $\gamma \geq 63/64$ and $\beta \geq 3/4$, then*

$$F(x) \geq \frac{s(x)}{64}.$$

Proof. We need to prove the following: If $x \in \mathbb{R}^n$ and $s > 0$ satisfies

$$\text{vol}((x + sB) \cap \{f \leq \beta f(x)\}) \leq (1 - \gamma)\text{vol}(x + sB),$$

then for a hit-and-run step y from x ,

$$(9) \quad \mathbb{P}\left(|x - y| \leq \frac{s}{64}\right) \leq \frac{1}{8}.$$

Let p denote the fraction of the surface of $x + (s/2)B$ in the set $\{f \leq \beta f(x)\}$. Clearly

$$\begin{aligned} \text{vol}((x + sB) \cap \{f \leq \beta f(x)\}) &\geq p\text{vol}(x + sB) - \text{vol}(x + (s/2)B) \\ &= (p - 2^{-n})\text{vol}(x + sB), \end{aligned}$$

and by our hypothesis on s ,

$$p \leq 1 - \gamma + 2^{-n} \leq \frac{1}{32}.$$

Thus if we choose a random line through x , with probability at least $15/16$ it will intersect the surface of $x + (s/2)B$ in points z_1, z_2 with $f(z_i) \geq \beta f(x)$.

Suppose that we have chosen such a line, and let u be a unit vector parallel to this line. Then we have

$$f(x + tu) \geq \beta f(x) \quad \left(-\frac{s}{2} \leq t \leq \frac{s}{2}\right)$$

and also (by logconcavity)

$$f(x + tu) \leq \beta^{-2|t|/s} f(x) \quad (-\infty < t < \infty).$$

We have

$$\mathbb{P}(|x - y| \leq s/64) = \int_{-s/64}^{s/64} f(x + tu) dt \Big/ \int_{-\infty}^{\infty} f(x + tu) dt.$$

Here

$$\int_{-\infty}^{\infty} f(x + tu) dt \geq \int_{-s/2}^{s/2} f(x + tu) dt \geq s\beta f(x),$$

while

$$\int_{-s/64}^{s/64} f(x + tu) dt \leq \frac{s}{32} \beta^{-1/32} f(x),$$

and thus

$$\mathbb{P}\left(|x - y| \leq \frac{s}{64}\right) \leq \frac{1}{32} \beta^{-33/32} < \frac{1}{16}.$$

Thus the probability that $|x - y| \leq s/64$ is bounded by $2p + 1/16 \leq 1/8$. This proves the lemma. \square

6.3. Conductance. For a point $u \in K$, let P_u be the distribution obtained by taking one hit-and-run step from u . Let $\mu_f(u, x)$ be the integral of f along the line through u and x . Then,

$$(10) \quad P_u(A) = \frac{2}{n\pi_n} \int_A \frac{f(x) dx}{\mu_f(u, x)|x - u|^{n-1}}.$$

The next lemma is analogous to Lemma 4.1. It holds for any logconcave density f , although we know how to use it only for the exponential density. Its proof is closely related to that of Lemma 7.2 in [13].

LEMMA 6.8. *Let $u, v \in K$. Suppose that*

$$d_f(u, v) < \frac{1}{128 \ln(3 + \alpha(u))} \quad \text{and} \quad |u - v| < \frac{1}{4\sqrt{n}} \max\{F(u), F(v)\}.$$

Then

$$d_{tv}(P_u, P_v) < 1 - \frac{1}{500}.$$

Proof. We will show that there exists a set $A \subseteq K$ such that $P_u(A) \geq \frac{1}{2}$ and for any subset $A' \subset A$,

$$P_v(A') \geq \frac{1}{200} P_u(A').$$

To this end, we define certain “bad” lines through u . Let σ be the uniform probability measure on lines through u .

Let B_1 be the set of lines that are not almost orthogonal to $u - v$, in the sense that for any point $x \neq u$ on the line,

$$|(x - u)^T(u - v)| > \frac{2}{\sqrt{n}}|x - u||u - v|.$$

The measure of this subset can be bounded as $\sigma(B_1) \leq 1/8$.

Next, let B_2 be the set of all lines through u which contain a point y with $f(y) > 2\alpha(u)f(u)$ (see section 6.2 for the definition of α). By Lemma 3.5(a) in [13], if we select a line from B_2 , then with probability at least $1/2$, a random step along this line takes us to a point x with $f(x) \geq \alpha(u)f(u)$. From the definition of $\alpha(u)$, this can happen with probability at most $1/16$, which implies that $\sigma(B_2) \leq 1/8$.

Let A be the set of points x in K which are not on any of the lines in $B_1 \cup B_2$, and which are far from u in the sense of Lemma 6.6:

$$|x - u| \geq \frac{1}{32} \max\{|u - p|, |u - q|\}.$$

Applying Lemma 6.6 to each such line, we get

$$P_u(A) \geq \left(1 - \frac{1}{8} - \frac{1}{8}\right) \frac{3}{4} > \frac{1}{2}.$$

We will show that for any subset $A' \subseteq A$,

$$P_v(A') \geq \frac{1}{200} P_u(A')$$

using the next two claims.

Claim 1. For every $x \in A$,

$$|x - v| \leq \left(1 + \frac{1}{n}\right) |x - u|.$$

Claim 2. For every $x \in A$,

$$\mu_f(v, x) < 64 \frac{|x - v|}{|x - u|} \mu_f(u, x).$$

Claim 1 is easy to prove (cf. [10]), and the proof of Claim 2 is identical to that given in [13]. Thus, for any $A' \subset A$,

$$\begin{aligned} P_v(A') &= \frac{2}{n\pi_n} \int_{A'} \frac{f(x) dx}{\mu_f(v, x) |x - v|^{n-1}} \\ &\geq \frac{2}{64n\pi_n} \int_{A'} \frac{|x - u| f(x) dx}{\mu_f(u, x) |x - v|^n} \\ &\geq \frac{2}{64en\pi_n} \int_{A'} \frac{f(x) dx}{\mu_f(u, x) |x - u|^{n-1}} \\ &\geq \frac{1}{64e} P_u(A'). \end{aligned}$$

The lemma follows. \square

We are now ready to state and prove the main theorem.

THEOREM 6.9. *Let f be a density in \mathbb{R}^n proportional to $e^{-\alpha^T x}$ whose support is a convex body K of diameter D . Assume that any level set of measure $1/8$ contains a ball of radius r . Then for any subset S , with $\pi_f(S) = p \leq 1/2$, the conductance of hit-and-run satisfies*

$$\phi(S) \geq \frac{r}{10^{13} n D \ln \frac{nD}{rp}}.$$

Proof. The proof has the same structure as that of Theorem 4.2.

Let $K = S_1 \cup S_2$ be a partition into measurable sets, where $S_1 = S$ and $p = \pi_f(S_1) \leq \pi_f(S_2)$. We will prove that

$$(11) \quad \int_{S_1} P_x(S_2) dx \geq \frac{r}{10^{13} n D \ln \frac{nD}{rp}} \pi_f(S_1).$$

Consider the points that are deep inside these sets:

$$S'_1 = \left\{ x \in S_1 : P_x(S_2) < \frac{1}{1000} \right\} \quad \text{and} \quad S'_2 = \left\{ x \in S_2 : P_x(S_1) < \frac{1}{1000} \right\}.$$

Let S'_3 be the rest, i.e., $S'_3 = K \setminus S'_1 \setminus S'_2$.

Suppose $\pi_f(S'_1) < \pi_f(S_1)/2$. Then

$$\int_{S_1} P_x(S_2) dx \geq \frac{1}{1000} \pi_f(S_1 \setminus S'_1) \geq \frac{1}{2000} \pi_f(S_1),$$

which proves (11).

So we can assume that $\pi_f(S'_1) \geq \pi_f(S_1)/2$ and, similarly, that $\pi_f(S'_2) \geq \pi_f(S_2)/2$.

Next, define the exceptional subset W as the set of points u for which $\alpha(u)$ is very large.

$$W = \left\{ u \in S : \alpha(u) \geq \frac{2^{27}nD}{rp} \right\}.$$

By Lemma 6.2,

$$\pi_f(W) \leq \frac{rp}{2^{23}nD}.$$

Next, for any $u \in S'_1 \setminus W$ and $v \in S'_2 \setminus W$,

$$d_{tv}(P_u, P_v) \geq 1 - P_u(S_2) - P_v(S_1) > 1 - \frac{1}{500}.$$

Thus, by Lemma 6.8, either

$$d_f(u, v) \geq \frac{1}{128 \ln(3 + \alpha(u))} \geq \frac{1}{2^{12} \ln \frac{nD}{rp}}$$

or

$$|u - v| \geq \frac{1}{4\sqrt{n}} \max\{F(u), F(v)\}.$$

But by Lemmas 6.1 and 6.7, this implies that either

$$(12) \quad d_K(u, v) \geq \frac{1}{2^{15} \ln \frac{nD}{rp} (1 + \ln G)}$$

or

$$(13) \quad |u - v| \geq \frac{1}{2^8 \sqrt{n}} \max\{s(u), s(v)\}$$

holds. Now, by Lemma 6.5, condition (12) implies that

$$(14) \quad d_K(u, v) \geq \frac{1}{2^{17} \ln \frac{nD}{rp}} \frac{\max s(x)}{\sqrt{n}D}.$$

Next, we define

$$h(x) = \frac{s(x)}{2^{19} D \sqrt{n} \ln \frac{nD}{rp}}$$

and apply Theorem 2.1 to the partition $S'_1 \setminus W$, $S'_2 \setminus W$ and the rest. If (14) holds, then clearly $h(x) \leq d_K(u, v)/3$. Otherwise, (13) holds. Let x be a point on the chord pq of K , say between u and q . Then, using the concavity of s (Lemma 6.3),

$$\begin{aligned} s(x) &\leq \frac{|x - p|}{|u - p|} s(u) \leq 2^8 \frac{|q - p|}{|u - p|} \sqrt{n} |u - v| \\ &\leq 2^8 d_K(u, v) D \sqrt{n} \end{aligned}$$

and hence $h(x) \leq d_K(u, v)/3$ again. Thus,

$$\begin{aligned} \pi_f(S'_3) &\geq \mathbb{E}_f(h)\pi_f(S'_1 \setminus W)\pi_f(S'_2 \setminus W) - \pi_f(W) \\ &\geq \frac{r}{2^{30}nD \ln \frac{nD}{ra}}\pi_f(S_1). \end{aligned}$$

Here we have used Lemma 6.4 and the bound on $\pi_f(W)$. Therefore,

$$\begin{aligned} \int_{S_1} P_x(S_2) dx &\geq \frac{1}{2} \cdot \frac{1}{1000}\pi_f(S'_3) \\ &\geq \frac{r}{10^{13}nD \ln \frac{nD}{rp}}\pi_f(S_1), \end{aligned}$$

which again proves (11). \square

6.4. Mixing time. Since f satisfies $\mathbb{E}_f(|x - z_f|^2) \leq R^2$, we consider the restriction of f to the ball of radius $R \ln(4e/a)$ around z_f and then by Lemma 5.17 in [13], the measure of f outside this ball is at most $a/4$. In the proof of the conductance bound, we can consider the restriction of f to this set. In the bound on the conductance for a set of measure a , the diameter D is effectively replaced by $R \ln(4e/a)$.

The bound on the mixing time then follows by applying Theorem 6.9 along with either Corollary 1.6 in [12] or the average conductance theorem of [6]. For the latter, we have that for any subset of measure x , the conductance is at least

$$\phi(x) \geq \frac{cr}{nR \ln(nR/rx) \ln(4e/x)} \geq \frac{cr}{nR \ln^2(nR/rx)}.$$

Then the theorem of [6] implies that after $m > C(n^2R^2/r^2) \ln^5(MnR/r\varepsilon)$ steps, we have $d_{tv}(\sigma^m, \pi_f) < \varepsilon$.

FUNCTION MATCHING*

AMIHOOD AMIR[†], YONATAN AUMANN[†], MOSHE LEWENSTEIN[†], AND ELY PORAT[†]

Abstract. We present problems in the following three application areas: identifying similar codes in which global register reallocation and spill code minimization were done (programming languages); protein threading (computational biology); and searching for color icons under different color maps (image processing).

We introduce a new search model called *function matching* that enables us to solve the above problems. The *function matching problem* has as its input a text T of length n over alphabet Σ_T and a pattern $P = P[1]P[2] \cdots P[m]$ of length m over alphabet Σ_P . We seek all text locations i , where the m -length substring that starts at i is equal to $f(P[1])f(P[2]) \cdots f(P[m])$, for some function $f : \Sigma_P \rightarrow \Sigma_T$.

We give a randomized algorithm that solves the function matching problem in time $O(n \log n)$ with probability $\frac{1}{n}$ of declaring a false positive. We give a deterministic algorithm whose time is $O(n|\Sigma_P| \log m)$ and show that it is optimal in the convolutions model. We use function matching to efficiently solve the problem of two-dimensional parameterized matching.

Key words. pattern matching, parameterized matching, function matching, color maps

1. Introduction. The last few decades have prompted the evolution of pattern matching from a combinatorial solution of the exact string matching problem [19, 20] to an area concerned with approximate matching of various relationships motivated by computational molecular biology, computer vision, and complex searches in digitized and distributed multimedia libraries [18, 9]. We will describe a number of important applications in various diverse areas that necessitate the introduction of a new generalized matching paradigm, that of *function matching*.

Programming languages. The *parameterized matching* problem was introduced by Baker [11]. Her main motivation lay in software maintenance, where program fragments are considered “identical” even if variable names are different. Therefore, strings under this model are comprised of symbols from two disjoint sets Σ and Π containing fixed symbols and parameter symbols, respectively. In this paradigm, one seeks *parameterized occurrences*, i.e., occurrences up to renaming of the parameter symbols, of one string in another. This renaming is a bijection $b : \Pi \rightarrow \Pi$.

Important topics in compiler design are global register allocation and spill code minimization (see, e.g., [23, 22]). The idea is to minimize the number of used registers by reusing the same register for several purposes.

Unfortunately, the parameterized matching paradigm will not identify similar codes with different levels of optimizing reusable global variables because of the bijection requirement on the parameter alphabet Π . In this application, it is sufficient that $f : \Pi \rightarrow \Pi$ is a function.

Computational biology. The Grand Challenge *protein folding* problem is one of the most important problems in computational biology (see, e.g., [24]). It consists of determining the protein's tertiary structure from its linear arrangement of peptides.

This problem is still open, which leads to the myriad of extremely active research methods used in the attempt to solve it. One possible technique that is being investigated is *threading* (see, e.g., [12, 31]). The idea is to try to “thread” a given protein sequence into a known structure. A possible way of viewing this idea is to consider subsequences that are known to fold in a particular way. These sequences can be used as patterns in subsequent given sequences with unknown secondary or tertiary structure. However, a subsequence of different peptides that bond in the same way as the pattern peptides may still fold in a similar way. This cannot be detected by exact matching, yet a function matching (under a careful reduction) will detect such a match.

Image Processing. One of the interesting problems in Web searching is searching for color images (see, e.g., [27, 10, 4]). Assume, for example, that we are seeking a given icon in any possible color map. If the colors were fixed, then this is exact two-dimensional pattern matching [3]. However, if the color map is changed the exact matching algorithm would not find the pattern. A parameterized two-dimensional search is precisely what is needed. If, in addition, we are also willing to lose resolution, then we would use a two-dimensional function matching search.

The above examples are just a sample of diverse application areas encountering search problems that are not solved by state-of-the-art methods in pattern matching. This has led us to introduce, in this paper, the *function matching* model, and to explore the *two-dimensional parameterized matching* problem. We start with an intuitive description of the function matching model.

In the traditional pattern matching model, one seeks exact occurrences of a given pattern in a text, i.e., text locations where every text symbol is *equal* to its corresponding pattern symbol. In parameterized matching, one seeks occurrences of a pattern image achieved by a bijection on the alphabet symbols. We seek text locations where there exists a bijection f on the alphabet for which every text symbol is equal to $f(a)$, where a is the corresponding pattern symbol. In the applications we described, f cannot be a bijection. Rather, it should be just a function. P matches T at location i if, for every element $a \in \Pi$, all occurrences of a have the same corresponding symbol in T . In other words, unlike in parameterized matching, there may be *several* different symbols in the pattern which are mapped to the same text symbol.

Relaxing the bijection restriction introduces nontrivial technical difficulties. Many powerful pattern matching techniques such as automata methods [20, 13], subword trees [30, 14], dueling [28, 3], and deterministic sampling [29] assume transitivity of the matching relation. For any pattern matching relation where transitivity does not exist, the above methods do not help.

Examples of pattern matching with nontransitive matching relation are string matching with “don't cares” [19], less-than matching [6], pattern matching with mismatches [1, 21], and swapped matching [25, 2, 5]. It is interesting to note that the efficient algorithms for solving the above problems all use convolutions as their main tool. Convolutions were introduced by Fischer and Paterson [19] as a technique for solving pattern matching problems where the match relation is not transitive.

It turns out that many such problems can be solved by a “standard” application of convolutions (e.g., matching with “don't cares,” matching with mismatches in bounded finite alphabets, and swapped matching). Muthukrishnan and Palem were the first to identify this application method as the *convolutions model* [26]. The con-

volution model provides an excellent tool for solving many nonstandard matching problems efficiently using an off-the-shelf method. Even more important, a rigorous formal definition of such a model can be very useful in proving lower bounds. While such bounds do not restrict the solution complexity in a general RAM, they do help in understanding the limits of the convolution method, hitherto the only powerful tool for nonstandard pattern matching. Unfortunately, we have not found in the literature a formal definition of the convolutions model.

There are three main contributions in this paper as follows:

1. *A solution to a number of search problems in diverse fields.* This is achieved by the introduction of a new type of generalized pattern matching, called function matching.
2. *A formalization of the convolutions model.* This leads to a deterministic solution. We prove that this solution is *tight* in the convolutions model. We also present an efficient randomized solution of the function matching problem.
3. *A solution to the problem of exact search in color images with different color maps.* This is done via efficient randomized and deterministic algorithms for two-dimensional parameterized and function matching.

This paper is organized in the following way. In section 2 we give basic definitions. In sections 3 and 4 we present progressively more efficient deterministic solutions, culminating in an $O(n|\Sigma_P| \log m)$ algorithm, where $|\Sigma_P|$ is the pattern alphabet size. In section 5 we present a Monte Carlo algorithm that solves the function matching problem in time $O(n \log n)$ with failure probability no larger than $\frac{1}{n}$. In section 6 we formalize the convolutions model. We then show a lower bound proving that our deterministic algorithm is tight in the convolutions model and discuss the limitations of that model. Finally, in section 7 we present a randomized algorithm that solves the two-dimensional parameterized matching problem in time $O(n^2 \log n)$ with probability of false positives no larger than $\frac{1}{n^2}$. We also present a deterministic algorithm that solves the two-dimensional parameterized matching problem in time $O(n^2 m \log^2 m \log \log m)$.

2. Problem definition. Formally, *function pattern matching* is defined as follows.

DEFINITION. *Let s_1 and s_2 be arrays of the same dimensions and sizes over alphabets Σ_1 and Σ_2 , respectively. Array s_1 is said to function-match array s_2 if there exists a function $f : \Sigma_1 \rightarrow \Sigma_2$, such that $f(s_1) = s_2$, where $f(s_1)$ is the array obtained by replacing every occurrence of $x \in \Sigma_1$ with $f(x)$. (Note that this implies that such an f is always a surjection.) If f is a bijection, then s_1 is said to parameterize-match.*

Given two arrays $P = P[i, j]$, $i, j = 0, \dots, m - 1$, a pattern of size m^2 over alphabet Σ_P , and $T = T[i, j]$, $i, j = 0, \dots, n - 1$, a text of size n^2 over alphabet Σ_T , there is a *function occurrence* (*parameterized occurrence*, respectively) of P in T at location $[i, j]$ if P function-matches (*parameterize-matches*, respectively) the $m \times m$ subarray of T that begins at the $[i, j]$ th position ($T[i + k, j + \ell]$, $k, \ell = 0, \dots, m - 1$).

The problem in which the pattern and text are strings, i.e., one-dimensional arrays, is a special case of the above.

The problem of function matching (parameterized matching) is the following:

INPUT: Pattern P and text T .

OUTPUT: All function (parameterized, respectively) occurrences of P in T .

The parameterized matching definition above differs from Baker's original definition, since her motivation called for two types of alphabet. Our simpler definition

follows the definition of Amir, Farach, and Muthukrishnan, who also proved in [7] that the two definitions are mutually linearly reducible.

Observation 1 establishes the connection between function matching and parameterized matching.

OBSERVATION 1. *Let s_1 and s_2 be strings of the same length over alphabet Σ , and assume that string s_1 function-matches string s_2 . Then s_1 parameterize-matches s_2 iff $|\Sigma_1| = |\Sigma_2|$.*

Proof. By the definition of cardinality, two sets have the same cardinality iff there is a bijection between them. \square

3. Naive algorithm for function matching. The function matching problem can be trivially solved in time $O(nm)$ simply by checking if there exists a match for every location (for unbounded alphabets, there is also a $\log m$ multiplicative factor).

Convolutions can be used in a standard fashion to improve the time for finite fixed alphabets.

DEFINITION. *Let $P[0], \dots, P[m-1]$ and $T[0], \dots, T[n-1]$ be arrays of natural numbers. The discrete convolution (polynomial multiplication) of T and P is R , where*

$$R[j] = \sum_{i=0}^{m-1} T[j-i]P[i],$$

where $j = 0, \dots, n-m$. We denote R as $T * P$.

The convolution can be computed in time $O(n \log m)$, in a computational model with word size $O(\log m)$, by using the fast Fourier transform (FFT) [17].

Similarly to R , we can define the following array M :

$$M[j] = \sum_{i=0}^{m-1} T[j+i]P[i],$$

where $j = 0, \dots, n-m+1$. We denote M as $T \otimes P$. It is easy to see that computing R and M can easily reduce them to each other by reversing P .

Notations. For $\sigma \in \Sigma$, let

$$\chi_\sigma(x) = \begin{cases} 1 & \text{if } x = \sigma, \\ 0 & \text{if } x \neq \sigma. \end{cases}$$

If $X = x_1, \dots, x_n$ then $\chi_\sigma(X) = \chi_\sigma(x_1), \dots, \chi_\sigma(x_n)$.

Let $a \in \Sigma_T$, $b \in \Sigma_P$. Then $\chi_a(T) \otimes \chi_b(P)[i]$ is precisely the number of times that an a in the text matches a b in the pattern when the pattern is matched starting at text location i . Formally, $\chi_a(T) \otimes \chi_b(P)[i] = |\{\ell \in \{0, \dots, m-1\} \mid T[i+\ell] = a \text{ and } P[\ell] = b\}|$. If that number is equal to the number of b 's in the pattern, then we know that in text location i all pattern b 's are mapped to a in the text.

This leads to the following algorithm for the function matching problem.

ALGORITHM A.
 For all $b \in \Sigma_P$ do
 $c_b \leftarrow$ the number of b 's in P
 For all $a \in \Sigma_T$, $b \in \Sigma_P$ do
 $F_{a,b} \leftarrow (\chi_a(T) \otimes \chi_b(P))$
 endfor
 endfor
 Announce a function occurrence of P at every location i for which $\forall b \in \Sigma_P \exists a \in \Sigma_T$ such that $F_{a,b}[i] = c_b$. END

Time. There are $|\Sigma_T||\Sigma_P|$ convolutions and each convolution requires $O(n \log m)$ steps. Hence the total time is $O(n|\Sigma_T||\Sigma_P| \log m)$.

For fixed finite alphabets this algorithm is quite efficient. For unbounded alphabets, the time may be $O(n^2 m \log m)$, which is significantly worse than the naive algorithm.

4. Deterministic improvements. In this section we reduce the $|\Sigma_T|$ factor to $\log |\Sigma_T|$. We use a standard observation allowing text size reduction and use an interesting lemma that allows text alphabet size reduction for the function matching problem.

The following observation is commonly used in pattern matching papers (see, e.g., [6, 2]).

OBSERVATION 2. *To assume that the text size is $n \leq 2m$ does not limit the algorithm's generality. The reason is that if a matching problem can be deterministically solved in time $O(f(m))$ for text of size $n \leq 2m$, then it can be solved in time $O(\frac{n}{m} f(m))$ for any n -length strip. Simply divide the text into $2\frac{n}{2m}$ overlapping $2m$ -length segments and solve the matching problem separately for each. Clearly, all locations are covered.*

From this point on our paper assumes that the text size $n \leq 2m$.

DEFINITION. A binary alphabet reduction function is a function $f : \Sigma \rightarrow \{0, 1\}$.

LEMMA 1. *Let P and T be a pattern and text over alphabets Σ_P and Σ_T , respectively. Then there exist $\log |\Sigma_T|$ binary alphabet reduction functions $\{f_1, \dots, f_{\log |\Sigma_T|}\}$ such that, for every text location i of T , there is a function occurrence of P iff, for all $f \in \{f_1, \dots, f_{\log |\Sigma_T|}\}$, there is a function occurrence of P at location i of $f(T)$.*

Proof. For $a \in \Sigma_T$, let $f_i(a)$ be the i th bit of a 's binary representation, $i = 1, \dots, \log |\Sigma_T|$.

(\Rightarrow) This follows immediately from the function matching definition.

(\Leftarrow) If there is no function occurrence of P at location i of T , it means that there exist two indices j and k , $j, k \in \{0, \dots, m-1\}$, for which $P[j] = P[k]$ but $T[i+j] \neq T[i+k]$. However, $T[i+j] \neq T[i+k]$ means that there is some bit in their binary representation, where $T[i+j]$ and $T[i+k]$ are different. Let that bit be the ℓ th bit. Then $f_\ell(T[i+j]) \neq f_\ell(T[i+k])$, and therefore there is no function occurrence of P at location i of $f_\ell(T)$. \square

COROLLARY 1. *The function matching problem can be solved in time $O(n|\Sigma_P| \log^2 m)$.*

Proof. Construct the $O(\log |\Sigma_T|)$ binary alphabet reduction functions and use Algorithm A to solve the function matching problem of P in $f_\ell(T)$ for all $\ell = 1, \dots, \log |\Sigma_T|$. Each run of Algorithm A takes time $O(n|\Sigma_P| \log m)$, and there are $\log |\Sigma_T|$ applications of Algorithm A. Since the text length is $n \leq 2m$, it follows that $|\Sigma_T| \leq 2m$, and hence $\log |\Sigma_T| = O(\log m)$ bits. Therefore the total time is $O(n|\Sigma_P| \log^2 m)$. \square

The following number theoretic lemma allows for the removal of yet another logarithmic factor. The lemma is folklore. Nevertheless, we include a proof for the sake of completeness.

LEMMA 2. *Let a_1, \dots, a_k be natural numbers. Then $k \sum_{i=1}^k (a_i)^2 = (\sum_{i=1}^k a_i)^2$ iff $a_i = a_j$, $i, j = 1, \dots, k$.*

Proof. If $a_i = a_j$, $i, j = 1, \dots, k$ then it is easily seen that the equations are equal. Conversely, we show a stronger claim, $k \sum_{i=1}^k (a_i)^2 \geq (\sum_{i=1}^k a_i)^2$, and show that $k \sum_{i=1}^k (a_i)^2 > (\sum_{i=1}^k a_i)^2$ iff there exists i such that $a_i \neq a_k$. The proof is by induction.

The base case is easily verified. Assume that $k \sum_{i=1}^k (a_i)^2 \geq (\sum_{i=1}^k a_i)^2$ and

prove for $k + 1$. We have $(k + 1) \sum_{i=1}^{k+1} (a_i)^2 = k \sum_{i=1}^k (a_i)^2 + \sum_{i=1}^k (a_i)^2 + (k + 1)(a_{k+1})^2$ and $(\sum_{i=1}^{k+1} a_i)^2 = (\sum_{i=1}^k a_i + a_{k+1})^2 = (\sum_{i=1}^k a_i)^2 + a_{k+1}^2 + 2a_{k+1}(\sum_{i=1}^k a_i)$. By induction, $k \sum_{i=1}^k (a_i)^2 \geq (\sum_{i=1}^k a_i)^2$, and hence it is sufficient to show that $\sum_{i=1}^k (a_i)^2 + k(a_{k+1})^2 \geq 2a_{k+1}(\sum_{i=1}^k a_i)$, which is equivalent to $\sum_{i=1}^k a_i(a_i - a_{k+1}) - \sum_{i=1}^k a_{k+1}(a_i - a_{k+1}) \geq 0$ and can be shortened to $\sum_{i=1}^k (a_i - a_{k+1})^2 \geq 0$, which is obviously true. Moreover, it is easily seen that $\sum_{i=1}^k (a_i - a_{k+1})^2 > 0$ only if there is an i such that $a_i \neq a_{k+1}$. \square

For every $a \in \Sigma_P$ and for every location i in the text, we are interested in finding out if there is indeed a single symbol that appears in every text location that matches a in the occurrence beginning at text location i . Lemma 2 allows us to do that with a constant number of convolutions.

The convolutions are defined as follows: Assume that $\Sigma_T = \{1, \dots, |\Sigma_T|\}$. If the alphabet is not of this form, it can be turned into $\{1, \dots, |\Sigma_T|\}$ by sorting the alphabet and renaming the characters. This can always be accomplished in time $O(m \log m)$. Let $k = |\Sigma_P|$. Let T_2 be the array of length n , where $T_2[i] = (T[i])^2$, $i = 0, \dots, n - 1$, where $(T[i])^2$ is the square of the number $T[i]$.

The locations i , where $k(T_2 \otimes \chi_a(P))[i] = (T \otimes (\chi_a(P)))[i]^2$, are precisely the locations where all a 's are matched to a single text symbol.

COROLLARY 2. *The function matching problem can be solved in time $O(n|\Sigma_P| \log m)$.*

Proof. Because of Lemma 2, our algorithm requires only $O(|\Sigma_P|)$ convolutions. \square

5. Randomized improvements. In this section we present a randomized Monte Carlo algorithm that solves the function matching problem in time $O(n \log n)$. Our probability of declaring a function occurrence when it does not exist is $\frac{1}{n}$.

We have shown reductions that minimized the text alphabet size as well as the text size. Next we attempt to reduce the number of *occurrences* of an alphabet symbol in the pattern. Note that a symbol that appears only once in the pattern does not have any effect on the function matching, since it can be matched to any text symbol without ever causing a contradiction. In particular, a pattern that consists of m different symbols function-matches every text location. However, the following lemma shows that the crucial number of character occurrences is 2.

DEFINITION. *A pattern is called a paired pattern if no symbol in the pattern appears more than twice.*

LEMMA 3. *Let P and T be text and pattern over Σ_P and Σ_T , respectively. Then there exist paired patterns P_{even} and P_{odd} such that there is a function occurrence of P in location i of T iff there are function occurrences of both P_{even} and P_{odd} in location i of T .*

Proof. For every $a \in \Sigma$, let c_a be the number of times a appears in the pattern, and let those appearances be in locations $\ell_0^a, \dots, \ell_{c_a-1}^a$. Let $s_0^a, \dots, s_{\lfloor c_a/2 \rfloor}^a$ be new symbols. P_{even} is constructed from P by replacing $P[\ell_i^a]$ with $s_{\lfloor i/2 \rfloor}^a$. P_{odd} is constructed from P by replacing $P[\ell_i^a]$ with $s_{\lfloor i/2 \rfloor}^a$.

In P_{even} we have replaced the first pair of occurrences of every letter with a new symbol, the second pair by a new symbol, and so on. In P_{odd} we shift the starting point of the pairs by 1. The first occurrence of a symbol is replaced by a new symbol, each symbol of the next pair is replaced by the next new symbol, and so on.

Example. Let $P = a a a b a b a b b a a b b$. Then

$$P_{even} = s_0^a s_0^a s_1^a s_0^b s_1^a s_0^b s_2^a s_1^b s_1^b s_2^a s_3^a s_2^b s_2^b,$$

$$P_{odd} = s_0^a s_1^a s_1^a s_0^b s_2^a s_1^b s_2^a s_1^b s_2^b s_3^a s_3^a s_2^b s_3^b.$$

(\Rightarrow) If there is a function occurrence of P in location i of T , then breaking up symbol occurrences into pairs cannot make matters worse and there will be function occurrences of both P_{even} and P_{odd} in location i of T .

(\Leftarrow) If there is no function occurrence of P in location i of T , then there must be a pair ℓ_j^a, ℓ_{j+1}^a where the corresponding symbols do not match, i.e., $T[i+\ell_j^a] \neq T[i+\ell_{j+1}^a]$. This pair will cause a function mismatch either at P_{even} , if j is even, or at P_{odd} , if j is odd. \square

Lemma 3 implies that if we find an efficient algorithm for solving the function matching problem for paired patterns, we are done. Our randomized algorithm will do just that. The idea behind our algorithm is to make sure that every pair is matched with the same symbol. We will measure it by assigning the text and pattern numerical values and by assigning a positive number to the first element of a pattern pair and the negation of that number to the second element of a pattern pair. Thus if a pair of pattern symbols $x, -x$ matches the same text symbol y , then $xy + -xy = 0$. We need to discuss the conditions under which the probability of a false positive is small.

ALGORITHM B.
 Let $f_T : \Sigma_T \rightarrow \{1, \dots, n^2\}$, where $f_T(\sigma)$ is chosen uniformly at random.
 Let $g_P : \Sigma_P \rightarrow \{1, \dots, n^2\}$, where $g_P(\sigma)$ is chosen uniformly at random, with the exception that any symbol appearing only once in the pattern is always mapped to 0.
 Let $f_P : \Sigma_P \times \{\text{first}, \text{second}\} \rightarrow \{-n^2, \dots, n^2\}$, where $f_P(\sigma, \text{first}) = g_P(\sigma)$ and $f_P(\sigma, \text{second}) = -g_P(\sigma)$.
 $M \leftarrow f_T(T) \otimes f_P(P)$
 For $i = 0$ to $n - 1$:
 If $M[i] = 0$, then declare function matching in location i
 endfor
 END

Time. The algorithm performs one convolution, so its time is $O(n \log m)$ word operations for words of size $O(\log n)$ bits. If we stay within the $O(\log m)$ bit-word computation model, the time is $O(n \log n)$.

We need to show that our algorithm gives the correct answer with high probability.

THEOREM 1. *If there is a function occurrence of P in location i of T , then Algorithm B will announce it. Conversely, the probability that Algorithm B will incorrectly announce a function occurrence at some location is $\frac{1}{n}$.*

Proof. If there is a function occurrence of P in location i of T , then for every pair in P , the corresponding text symbols are equal. Consider a pair in locations j and k of the pattern $f_P(P[j]) = x, f_P(P[k]) = -x, f_T(t[i+j]) = y$, and $f_T(t[i+k]) = y$. The contribution of this pair to a convolution result at location i is thus $xy - xy = 0$. Because there is a function occurrence, this is true for every pair. The single pattern elements were mapped to 0. Therefore the value of the convolution in location i is 0.

Conversely, if Algorithm B wrongly announces a function occurrence at position i , it is because the convolution result at location i was 0. Consider a pair j, k , where the corresponding text elements are not equal, i.e., $P[j] = P[k] = a$ and $T[i+j] = b$ and $T[i+k] = c$.

By definition, $Pr(f_T(T) \otimes f_P(P)[i] = 0) = Pr(\sum_{l=1}^m f_T(T[i+l]) \cdot f_P(P[l]) = 0)$.

Hence,

$$\begin{aligned} & Pr(f_T(T) \otimes f_P(P)[i] = 0) \\ = & Pr\left(\sum_{l=1}^m f_T(T[i+l]) \cdot f_P(P[l]) - (f_T(T[i+j]) \cdot f_P(P[j]) + f_T(T[i+k]) \cdot f_P(P[k]))\right) \\ = & (f_T(T[i+j]) \cdot f_P(P[j]) + f_T(T[i+k]) \cdot f_P(P[k])) \end{aligned}$$

Denote with p_0 the following:

$$\begin{aligned} & \sum_{l=1}^m f_T(T[i+l]) \cdot f_P(P[l]) - (f_T(b) \cdot f_P(a, first) + f_T(c) \cdot f_P(a, second)) \\ & = \sum_{l=1}^m f_T(T[i+l]) \cdot f_P(P[l]) - (g_P(a) \cdot [f_T(b) - f_T(c)]). \end{aligned}$$

We will show that $Pr((g_P(a) \cdot [f_T(b) - f_T(c)]) = p_0) \leq \frac{1}{n^2}$.

Note that $f_T(b)$ and $f_T(c)$ were chosen randomly from $\{1, \dots, n^2\}$ and are independent of each other. Hence, for any constant z_0 , $Pr([f_T(b) - f_T(c)] = z_0) \leq \frac{1}{n^2}$. For any $z_0 \neq 0$, $Pr(g_P(a) \cdot z_0) \leq \frac{1}{n^2}$ since $g_P(a)$ was chosen randomly from $\{1, \dots, n^2\}$. Moreover, for $z_0 = 0$, $g_P(a) \cdot z_0 = 0$, and for $z_0 \neq 0$, $g_P(a) \cdot z_0 \neq 0$. Hence, for $z_0 = 0$, $Pr(g_P(a) \cdot z_0) \leq \frac{1}{n^2}$. Since $P[h] \neq a$, for each $h \notin \{j, k\}$, it follows that $Pr((g_P(a) \cdot [f_T(b) - f_T(c)]) = p_0) \leq \frac{1}{n^2}$, i.e., $Pr(f_T(T) \otimes f_P(P)[i] = 0) \leq \frac{1}{n^2}$.

It follows that over all n locations, $Pr(\exists i, f_T(T) \otimes f_P(P)[i] = 0) \leq \frac{1}{n}$. \square

6. Lower bounds in the convolutions model. In this section we give compelling evidence that an efficient deterministic solution to the function matching problem, if such a solution exists, may be difficult. We do so by showing an $\Omega(nm)$ lower bound for the problem in the *convolutions model*. This model, which we formally define shortly, captures the modus operandi of pattern matching algorithms that use convolutions as their key computational tool. We note that this model is different from the convolution model of [26], which is defined in combinatorial terms, unlike our computational model.

6.1. The convolutions model. We begin by defining the type of problems that are solved by the convolutions model. For a string T , denote by T_i the suffix of T starting at position i and by T_i^j the substring from T from location i to j inclusive.

DEFINITION 1. A pattern matching problem is defined as follows:

- *Match relation:* a binary relation $M(a, b)$, where $a \in \Sigma_P^*$ and $b \in \Sigma_T^*$;
- *Input:* a pattern $P = P[0], \dots, P[m - 1]$ and a text $T = T[0], \dots, T[n - 1]$, $P[i] \in \Sigma_P, T[j] \in \Sigma_T$.
- *Output:* the set of indices $S \subseteq \{0, \dots, n - 1\}$, where the pattern P matches to T according to M , i.e., all indices i such that $M(P, T_i)$ (where T_i is the suffix of T starting at location i).

As the name suggests, the convolutions model uses convolutions as the key operation for computing the output for a pattern matching problem. In most cases the convolutions are not performed directly between the original text and the original pattern, but rather between different *transformations* thereof. Thus, the first step is to compute a sequence of transformation $T^{(1)}, \dots, T^{(c)}$ for the text and $P^{(1)}, \dots, P^{(c)}$ for the pattern. Then, for each k , one computes the *convolution* $C^{(k)} = T^{(k)} \otimes P^{(k)}$.

Given these convolutions, for each location i the decision on whether there is a match at i is determined based on the values $C^{(1)}[i], \dots, C^{(c)}[i]$.

A computation in the convolution model is thus composed of the following three phases:

1. Preprocessing: producing the transformations $T^{(1)}, \dots, T^{(c)}$ and $P^{(1)}, \dots, P^{(c)}$.
2. Convolutions: computing $C^{(k)} = T^{(k)} \otimes P^{(k)}$ for $k = 1, \dots, c$.
3. Postprocessing: for each $i = 0, \dots, n - 1$ deciding if there is a match at location i based on $C^{(1)}[i], \dots, C^{(c)}[i]$.

The convolution phase is the key computational tool in the convolution model on the total number of steps of the entire process. Thus, we must determine what operations are permitted in the pre- and postprocessing phases (or else the entire solution to the problem may be “hidden” in these phases). For $k = 1, \dots, c$, let $\tau_P^{(k)}$ be the transformation that produces $P^{(k)}$ from P , and let $\tau_T^{(k)}$ be the transformation that produces $T^{(k)}$ from T . We assume that $\tau_P^{(k)}$ gets as input only the array P , and that it can perform any computation on P . Formally, $\tau_P^{(k)}$ is a function $\tau_P^{(k)} : \Sigma_P^* \rightarrow N^*$. For the text preprocessing transformations we further allow the transformations $\tau_T^{(k)}$ to be dependent on the pattern P . Thus, $\tau_T^{(k)} : \Sigma_T^* \times \Sigma_P^* \rightarrow N^*$. However, we require that the transformation be *local*, in the sense that for any location i , the value $T^{(k)}[i]$ at that location is dependent only on the value of $T[i]$ and not on other locations of T . Formally, the function $\tau_T^{(k)}$ is *local* if for each i there exists a function f_i such that for any T and P , $\tau_T^{(k)}(T, P)[i] = f_i(T[i], P)$. Clearly, we also require that $\tau_T^{(k)}$ be *length preserving*, in the sense that for any T, P , the number of elements in the array $\tau_T^{(k)}(T, P)$ is equal to that in T .

For the postprocessing phase, we allow any computation on values $C^{(1)}[i], \dots, C^{(c)}[i]$ for each i .

We are now ready to formally define the convolutions model.

DEFINITION 2. An algorithm in the convolution model is a quadruplet $A = (c, \tau_P, \tau_T, D)$ where

1. $c = c(m, n)$ is an integer function (where $m = |P|$ and $n = |T|$, the sizes of P and T , respectively),
2. $\tau_P = (\tau_P^{(1)}, \tau_P^{(2)}, \dots)$ is the sequence of pattern preprocessing functions, $\tau_P^{(k)} : \Sigma_P^* \rightarrow N^*$,
3. $\tau_T = (\tau_T^{(1)}, \tau_T^{(2)}, \dots)$ is the sequence of local, length preserving text preprocessing functions, $\tau_T^{(k)} : \Sigma_T^* \times \Sigma_P^* \rightarrow N^*$.
4. $D = D_0, D_2, \dots$ is the sequence of decision criteria, $D_i : N^* \rightarrow \{0, 1\}$.

Given an algorithm A in the convolution model, text T , and pattern P , with $|T| = n$ and $|P| = m$, a computation in the convolutions model is composed on the following three phases:

1. Preprocessing: for each $k = 1, \dots, c$, compute $T^{(k)} = \tau_T^{(k)}$ and $P^{(k)} = \tau_P^{(k)}$.
2. Convolution: for each $k = 1, \dots, c$, compute $C^{(k)} = T^{(k)} \otimes P^{(k)}$.
3. Decide: for each $i = 0, \dots, n - 1$, compute $d_i = D_i(C^{(1)}[i], \dots, C^{(c)}[i])$.

Example. Consider the problem of exact string matching with “don’t cares.” The input to the problem is a pattern array $P \in \{0, 1, \phi\}^m$ and a text array $T \in \{0, 1\}^n$. There is a match at location i if, for $j = 0, \dots, m - 1$, either $P[j] = T[i + j]$ or $P[j] = \phi$. Fischer and Paterson [19] provide the following convolution-based solution to this matching problem. First, compute the following two convolutions:

$$\begin{aligned} C^{(1)} &\leftarrow \chi_0(T) \otimes \chi_1(P), \\ C^{(2)} &\leftarrow \chi_1(T) \otimes \chi_0(P) \end{aligned}$$

(where for $b = 0, 1$, $\chi_b(A)$ is the characteristic function of b). The text locations i , where $C^{(1)}[i] = C^{(2)}[i] = 0$, are those where there is a match with “don’t cares.”

In order to cast this algorithm into the structure defined in Definition 2 set

- $c(m, n)$ is the constant function 2.
- $\tau_P^{(1)} = \chi_1$ and $\tau_P^{(2)} = \chi_0$.
- $\tau_T^{(1)}(T, P) = \chi_0(T)$ and $\tau_T^{(2)}(T, P) = \chi_1(T)$, for all T and P . Note that these functions are indeed local and length preserving.
- for each i ,

$$D_i(C^{(1)}[i], C^{(2)}[i]) = \begin{cases} 1, & C^{(1)}[i] = C^{(2)}[i] = 0, \\ 0, & \text{otherwise.} \end{cases}$$

Our solutions in sections 3 and 4 are all algorithms in the convolutions model.

6.2. The lower bound. We wish to bound the amount of work necessary for solving the function matching problem in the convolution model. We do so by providing a bound on the total number of bits produced in the convolution phase. For a variable x , let $sizeof(x)$ be the number of bits used to represent x (e.g., a bit, a byte, a word).

CLAIM 1. *Let $A = (c, \tau_P, \tau_T, D)$ be an algorithm that solves the function matching problem in the convolutions model. Then, for any m (even) and any n , there exists a pattern P and text T , with $|P| = m$ and $|T| = n$, such that the following holds. For text location i set $s(i) = \sum_{k=1}^c sizeof(C^{(k)}[i])$ ($s(i)$ is the total number of bits in the convolution results for location i). Then, for any $i < n - m$, $s(i) \geq m/2$.*

Proof. Consider the algorithm A from Claim 1 above for computing the function matching in the convolution model. We show how to use A in order to solve the *word equality problem* in the communication complexity setting. We then use known bounds from communication complexity to bound $s(i)$. Suppose that Alice has string $w_1 \in \{0, 1\}^\ell$ and Bob has string $w_2 \in \{0, 1\}^\ell$, and that they wish to determine whether $w_1 = w_2$. Let $w = w_1 w_2$ (the concatenation of the two) and consider the pattern $P = (1, 2, \dots, \ell, 1, 2, \dots, \ell)$. Then, P function-matches with w iff $w_1 = w_2$. Consider a location i . For any k ,

$$C^{(k)}[i] = \left(\sum_{j=i}^{i+\ell-1} T^{(k)}[j] \cdot P^{(k)}[j] \right) + \left(\sum_{j=i+\ell}^{i+2\ell-1} T^{(k)}[j] \cdot P^{(k)}[j] \right).$$

Denote $C_A^{(k)}[i] = \sum_{j=i}^{i+\ell-1} T^{(k)}[j] \cdot P^{(k)}[j]$ (the first summand) and $C_B^{(k)} = \sum_{j=i+\ell}^{i+2\ell-1} T^{(k)}[j] \cdot P^{(k)}[j]$ (the second summand). Since the transformation $T^{(k)}$ is *local*, the value of $C_A^{(k)}[i]$ depends only on the values $T[j]$ with $i \leq j < i + \ell$ and possibly on P , while $C_B^{(k)}[i]$ depends only on the values $T[j]$ with $i + \ell \leq j < i + 2\ell$ and possibly on P . Thus, setting $T_i^{i+\ell-1} = w_1$, $T_{i+\ell}^{i+2\ell-1} = w_2$ and fixing $P = (1, 2, \dots, \ell, 1, 2, \dots, \ell)$, we get that Alice can compute *on her own* $C_A^{(k)}[i]$ (for all k), and similarly Bob can compute *on his own* $C_B^{(k)}[i]$ (for all k). Now, in order to determine if $w_1 = w_2$, we must determine if there is a function match at location i . To this end, Bob sends Alice $C_B^{(k)}[i]$ for all k . Alice then computes $C_A^{(k)}[i]$ and $C^{(k)}[i] = C_A^{(k)}[i] + C_B^{(k)}[i]$, for

$k = 1, \dots, c$, and finally $d = D_i(C^{(1)}[i], \dots, C^{(c)}[i])$ to obtain the result. Thus, the total communication is

$$\sum_{j=1}^c \text{sizeof}(C_B^{(k)}[i]) \leq \sum_{k=1}^c \text{sizeof}(C^{(k)}[i]) = s(i).$$

However, it is known that any protocol for solving the word equality problem for ℓ -bit words in the communication complexity model requires at least ℓ bits [32]. Thus, $s(i) \geq \ell = m/2$. \square

We obtain the following.

THEOREM 2. *Any algorithm for solving the function matching problem in the convolution model requires $\Omega(mn)$ bit operations.*

Proof. By Claim 1, for each $i < n - m$ at least $m/2$ bits must be produced. Thus, in total at least $(n - m)m/2 = \Omega(mn)$ bits must be produced. Producing a bit requires at least one bit operation. \square

The reader is cautioned that the above lower bound does not provide a deterministic lower bound for the function matching problem in the RAM model, but rather only in the convolutions model. While convolutions seem to be the only known effective tool in pattern matching for solving generalized problems such as the function matching problem, the convolutions model is very restrictive. The lower bound does indicate, however, that using convolutions in the way defined in the convolutions model is a direction one should *not follow* when seeking an efficient algorithm for the function matching problem.

7. Two-dimensional parameterized matching. The one-dimensional parameterized matching problem was efficiently solved in [7]. However, as discussed in [4], the move to two dimensions implies a possible computational difficulty if no separable attributes exist. Parameterized matching is not separable—if all columns (or rows) parameterize-match, it does not necessarily imply that the entire matrix parameterize-matches. Thus we are forced to seek other approaches.

Our problem.

INPUT: Two-dimensional pattern P of size $m \times m$ and two-dimensional text T of size $2m \times 2m$.

OUTPUT: All locations $[i, j]$ in T where there is a parameterized occurrence of the pattern.

We may assume the text size $n^2 \leq 4m^2$ because of an argument similar to the one in Observation 2.

Solution idea. We will do a function matching of the pattern in the text. Following that, because of Observation 1 we discard all locations where the number of symbols in the text submatrix is different from $|\Sigma_P|$.

The solution's implementation uses a well-established two-dimensional linearization technique (see, e.g., [8]). Construct a text string T' of length n^2 and a pattern string P' of length m^2 such that a P' occurrence in T' will indeed mean a P occurrence in T .

String T' is taken as the concatenation of all rows of T . P' needs to be constructed more carefully since an occurrence of P in T means that each row of P occurs in T at a distance $n - m$ from its previous row. We can make this happen by introducing a new symbol, ϕ , that does not appear in the alphabets. This symbol's semantics is different from the other alphabet symbols in that it *matches every symbol*. This symbol is called the *don't care* or *wildcard* symbol. Fischer and Paterson [19] used

convolutions to solve the *pattern matching with “don’t cares”* problem. Recall that our algorithms for function matching are convolutions-based.

We have reduced the two-dimensional parameterized matching problem to the *string function matching problem with “don’t cares” in the pattern*.

DEFINITION. *The string function matching problem with “don’t cares” in the pattern is the following:*

INPUT: *Pattern string $P = P[0], \dots, P[m - 1]$ over alphabet $\Sigma_P \cup \{\phi\}$ and text string $T = T[0], \dots, T[n - 1]$ over alphabet Σ_T .*

OUTPUT: *All locations i in T where there is a function occurrence of P , where the symbol ϕ matches everything.*

7.1. Randomized two-dimensional parameterized matching. The only change necessary for Algorithm B to solve the function matching with “don’t cares” in the pattern problem is in the f_P function. Currently every symbol that appears more than once was mapped to a random number between 1 and n^2 . Symbols that appear in the pattern once were always mapped to 0 so they have no effect on the results. The “don’t care” symbol behaves the same way—it is allowed to match every symbol. Therefore for every mapping f_P that we randomly construct, we always have $f_P(\phi) = 0$.

Time. $O(n \log n)$.

COROLLARY 3. *Two-dimensional function matching can be done in time $O(n^2 \log n)$ and with probability $\frac{1}{n^2}$ of false positive matches.*

We still need to count the number of different symbols in the $m \times m$ submatrix at every location where there is a function matching. The problem we need to solve is the following.

SUBMATRIX CHARACTER COUNT problem.

INPUT: *Two-dimensional $n \times n$ array T of symbols over alphabet Σ and a natural number m .*

OUTPUT: *For every $i, j \in \{1, \dots, n - m + 1\}$, the number of different alphabet symbols occurring in the submatrix $T[k, \ell]$, $k = i, \dots, i + m - 1$, $\ell = j, \dots, j + m - 1$.*

Amir, Church, and Dar [4] show that the submatrix character count problem can be solved deterministically in time $O(n^2 \log m)$. We conclude with the following.

COROLLARY 4. *Two-dimensional function matching can be done in time $O(n^2 \log n)$ and with probability $\frac{1}{n^2}$ of false positive matches.*

7.2. Deterministic two-dimensional parameterized matching. It is sufficiently efficient to solve the string function matching problem with “don’t cares” in the pattern. Unfortunately, we do not know how to compute string function matching for general alphabets in $o(nm)$ time. However, our real aim is two-dimensional *parameterized* matching. Therefore our algorithm will make use of both these facts. The result of our algorithm is a set of locations that is a superset of the parameterized match and a subset of the function match. We narrow it down to the parameterized match by counting the number of different symbols.

Recall, then, that we have a linearized T and P , where the length of T is $4m^2$ and the length of P is $2m^2$ (caused by the addition of the “don’t cares” padding).

The algorithm’s idea is to treat symbols that appear many times in the text and pattern (and thus are few in number) differently from the possibly numerous alphabet symbols that appear rarely. The thinking is that convolutions can be used on a small number of symbols (the frequent ones) while some other technique will be effective on the rare symbols, even though they are many.

DEFINITION. *An alphabet symbol $a \in \Sigma_T$ or $a \in \Sigma_P$ is frequent if it appears in*

T or P , respectively, at least m times. Otherwise the symbol is rare.

Our algorithm will treat separately the following three types of symbols: the frequent in the pattern symbols versus the text; the frequent in the text versus the pattern; and then the rare symbols in both text and pattern. For ease of description, we will henceforth say that symbol a function-matches the text at location i , by which we mean that starting at location i for the length of $2m^2$ elements, all text symbols corresponding to an occurrence of a in the pattern are equal. In other words, if there is no function occurrence at location i , then it is not because of the symbol a . We are now ready to provide the outline of the algorithm for two dimensional parameterized matching.

ALGORITHM C

1. Find all text locations where the symbols that are frequent in the pattern function-match.
2. Find all text locations where the symbols that are frequent in the text parameterize-match.
3. Find all text locations where symbols that are rare in the pattern function-match the symbols that are rare in the text.
4. Retain only the text locations where the number of different symbols is precisely equal to the number of different symbols in the pattern.

END

The submatrix character count (step C.4) can be done in time $O(n^2 \log m)$ [4]. The next three subsections show efficient implementations to steps C.1.–C.3.

7.2.1. Frequent pattern symbols. For every frequent symbol a in the pattern, Lemma 2 allows us to find all text location where a function-matches in the manner described in section 4 using a constant number of convolutions. Mark all text location where there was no function-matching, i.e., where a corresponds to at least two distinct text alphabet symbols.

At the end of this stage, replace all frequent pattern symbols with ϕ .

Time. Since there are $O(m)$ frequent pattern symbols, the time for this stage is $O(n^2 m \log m)$.

7.2.2. Frequent text symbols. We desire to find the locations i of the linearized text (corresponding to text locations (l, j)) where the pattern parameterize-matches on the frequent symbols. To do so, remember that the padded pattern is of length $2m^2$ and that we need to find out whether the frequent text symbols in the $2m^2$ substring, of the linearized text, starting at i parameterize-match the pattern. In other words, no frequent text symbol corresponds to more than one pattern symbol. Again, we would like to use Lemma 2. However, now the roles of T and P are reversed. Additional complications are that the number of elements in the sum is different for every location (this number is dependent on the distribution of elements in the text substring) and that there are “don’t cares” in the pattern. Both these problems are solved via a single convolution.

Assume that $\Sigma_P = \{1, \dots, |\Sigma_P|\}$. If it does not, this can always be obtained in time $O(m^2 \log m)$. Let P_2 be the array of length $2m^2$, where $P_2[i] = (P[i])^2$, $i = 0, \dots, 2m^2 - 1$.

Let $K \leftarrow (\chi_a(T) \otimes \chi_{\bar{\phi}}(P))$, where

$$\chi_{\bar{\phi}}(x) = \begin{cases} 1 & \text{if } x \neq \phi, \\ 0 & \text{if } x = \phi. \end{cases}$$

The number of non- ϕ pattern elements that correspond to frequent text symbol a at location i is $K[i]$.

Let $SA \leftarrow \chi_a(T) \otimes P$. By Lemma 2, the locations i , where $(SA[i])^2 = K[i]P_2[i]$, are precisely the locations where all text a 's are matched to a single pattern alphabet symbol.

Note that it may still be the case that one pattern symbol matches the two frequent text symbols a_1 and a_2 . We need to discard these locations as well. This is done as follows. For every location i where all occurrences of a correspond to a single parameter alphabet symbol, find that symbol. This can be found by two convolutions.

Let $N_a \leftarrow \chi_a(T) \otimes \chi_{\bar{\phi}}(P)$. $N_a[i]$ is precisely the number of a 's in the substring of length sm^2 starting at location i that do not correspond to ϕ in the pattern. Assume that $\Sigma_P = \{1, \dots, |\Sigma_P|\}$. If it does not, this can always be obtained in time $O(m \log m)$. Let $C_a \leftarrow \chi_a(T) \otimes P$. For every undiscarded location i , $C_a[i]/N_a[i]$ is the pattern symbol that corresponds to all occurrences of a in the $O(sm^2)$ substring beginning at i .

For every location i where a parameterize-matches with a corresponding pattern symbol b_a , insert b_a in a data structure D_i that holds all different symbols that parameterize-match a frequent text symbol in the substring starting at i . If b_a already appears in the data structure (i.e., it parameterize-matched some other symbol), then mark i as a nonmatch location.

D_i 's size is at most $O(m)$ since there are no more than $O(m)$ frequent symbols. We use a data structure, e.g., balanced trees, that supports *insert* and *search* in time $O(\log m)$. Therefore this stages adds a cost of $O(m \log m)$ for every text location, for a total cost of $O(n^2 m \log m)$.

After all frequent text symbols are handled, mark them all as ϕ . At the end of this stage, all locations where there was no parameterized match of the frequent text symbols are marked.

Time. The time for this stage is dominated by the function matching over the binary alphabets, making the total time $O(n^2 m \log^2 m)$.

7.2.3. Symbols rare in both text and pattern. At this point the only cases we have not handled are correspondences of rare pattern symbols and rare text symbols. There may be many such elements, but each of them appears less than m times. We use *subset matching*, defined by Cole and Hariharan [15], to solve this case.

We construct a new pattern P' and a new text T' in which every element P' and T' is a subset of Z , where Z is the set of integers. In this case, the lengths of P' and T' are the same as the lengths of P and T , respectively.

$P'[i] = \phi$ (the empty set) if $P[i] = \phi$ (the “don't care” symbol).

$T'[i] = Z$ (the universal set) if $T[i] = \phi$ (the “don't care” symbol).

Assume $P[i] = a$ (a rare symbol). Further, assume that a occurs at locations $i_0, i_1, \dots, i_j = i, \dots, i_k$. Then the set $P'[i]$ is $\{i_0 - i, i_1 - i, \dots, i_{j-1} - i, i_{j+1} - i, \dots, i_k - i\}$. In other words, we consider i as the center and write the distance between it and every other occurrence of a in the pattern. The distance to the a occurrences that precede i is negative, and the distance to the a occurrences that follow i is positive.

If $T[i]$ is a rare symbol, then we construct $T'[i]$ in a manner identical to the construction of P' .

P' and T' can be constructed in time $O(n^2 m)$.

Recall that P and T now include only rare symbols. All frequent symbols previously handled and replaced by “don't care” symbols.

DEFINITION. *There is a function occurrence of a rare symbol a of P with the*

rare symbols of T at location i , if one of two conditions hold:

1. Every occurrence of a corresponds to ϕ .
2. Every occurrence of a corresponds to b_a , where b_a is a rare text symbol.

THEOREM 3. *There is a function match of the rare symbols of P in the rare symbols of T iff there is a subset matching of P' in T' .*

Proof. The rare symbols of P function-match the rare symbols of T iff, at every text location i , every occurrence of pattern alphabet symbol a corresponds either to the same text alphabet symbol or to ϕ . If the corresponding text symbol everywhere is ϕ , then it is replaced by Z (the universal set) and thus the subset that replaces a in P' is clearly a subset of the corresponding universal set Z . Otherwise, the alphabet symbol b_a is a rare symbol. a function-matches T at i iff every location where there is an a corresponds to the same b_a . This precisely means that the relative locations of a are a subset of the relative location of b_a , which means that the set in P' that replaces a is a subset of the set in T' that replaces b_a .

Note that the cases where some occurrences of a match a ϕ in the text and the rest match a single b_a in the text are not defined as a function match of rare symbols in rare symbols. The definition follows our problem's requirement since a matching both ϕ and b_a means that some occurrences of a match a frequent text symbol and some match a nonfrequent symbol, and thus it is not a function matching). However, in this case there is not a subset matching either because the text subset of the rare symbols will *not* include the indices of the occurrences corresponding to the Z sets, and thus they will not match. \square

The only thing left for us to do now is analyze the time it takes for subset matching with “don't cares.”

Cole, Hariharan, and Indyk [16] showed that subset matching, in which the pattern has m sets, the text has n sets, and the size of the sets is bound globally by z , can be achieved deterministically in time $O(nz \log^2 m \log \log m)$. This was done by creating a code of size $z \log m \log \log m$. An empty set in the pattern is always easily handled, since it means there are no elements at all. However, in the case of bounded size sets, a universal set is also easily implementable, since it means we have a set of all 1's in those text locations during all convolutions, forcing always a match.

We conclude with the following.

COROLLARY 5. *The time for computing the function-matching of the rare elements is $O(n^2 m \log^2 m \log \log m)$.*

FINDING FOUR INDEPENDENT TREES*

SEAN CURRAN[†], ORLANDO LEE[‡], AND XINGXING YU[§]

Abstract. Motivated by a multitree approach to the design of reliable communication protocols, Itai and Rodeh gave a linear time algorithm for finding two independent spanning trees in a 2-connected graph. Cheriyan and Maheshwari gave an $O(|V|^2)$ algorithm for finding three independent spanning trees in a 3-connected graph. In this paper we present an $O(|V|^3)$ algorithm for finding four independent spanning trees in a 4-connected graph. We make use of chain decompositions of 4-connected graphs.

1. Introduction. We consider simple graphs only. For a graph G , we use $V(G)$ and $E(G)$ to denote the vertex set and edge set of G , respectively.

For a tree T and $x, y \in V(T)$, let $T[x, y]$ denote the unique path from x to y in T . A *rooted tree* is a tree with a specified vertex called the *root* of T . Let G be a graph, let $r \in V(G)$, and let T and T' be trees of G rooted at r . We say that T and T' are *independent* if for every $x \in V(T) \cap V(T')$, the paths $T[r, x], T'[r, x]$ have no vertex in common except r and x .

The study of independent spanning trees started with Itai and Rodeh [11], where they proposed a multitree approach to reliability in distributed networks (see also [5]). They developed a linear time algorithm that, given any vertex r in a 2-connected graph G , finds two independent spanning trees of G rooted at r . Later, Cheriyan and Maheshwari [1] proved that for any vertex r in a 3-connected graph G , there exist three independent spanning trees of G rooted at r . Furthermore, they gave an $O(|V(G)|^2)$ algorithm for finding these trees.

Itai and Zehavi [12] also proved that every 3-connected graph contains three independent spanning trees (rooted at any vertex), and they conjectured that for any k -connected graph G and for any $r \in V(G)$, there exist k independent spanning trees of G rooted at r . According to Schrijver [14], the Itai-Zehavi conjecture is part of a more general conjecture by Frank [6]. Huck [9] proved this conjecture for planar 4-connected graphs. Later, Miura et al. [13] gave a linear time algorithm for finding four independent rooted spanning trees in a planar 4-connected graph.

Our main result is the following.

THEOREM 1.1. *Let G be a 4-connected graph, and let $r \in V(G)$. Then there exist four independent spanning trees of G rooted at r . Moreover, such trees can be found in $O(|V(G)|^3)$ time.*

To provide motivation for our method, we first describe Itai and Rodeh's method for constructing two independent spanning trees rooted at a vertex r in a 2-connected graph. Let G be a 2-connected graph, and let r and t be two adjacent vertices of G . An r - t numbering is a function $g : V(G) \mapsto \{1, \dots, n\}$ with $n \geq |V(G)|$ satisfying the following properties:

- (i) $g(r) = 1$ and $g(t) = n$.
- (ii) Every vertex $v \in V(G) - \{r, t\}$ has a neighbor u with $g(u) < g(v)$ and a neighbor w with $g(w) > g(v)$.

An r - t numbering can be produced from an ear decomposition of G . From an r - t numbering g , Itai and Rodeh define two independent spanning trees T_1 and T_2 of G rooted at r as follows. For each vertex $v \in V(G) - \{r\}$, specify its parent in each tree. In tree T_1 , for each $v \in V(G) - \{r\}$, the parent of v is a neighbor u for which $g(u) < g(v)$. In tree T_2 , the parent of t is r and, for each $v \in V(G) - \{r, t\}$, the parent of v is a neighbor w for which $g(w) > g(v)$. It is not hard to show that T_1 and T_2 are independent spanning trees in G rooted at r .

The idea for constructing four independent spanning trees in a 4-connected graph is inspired by the 2-connected case. The main difference is that we need to use two numberings instead of one. This idea can be roughly described as follows. Let G be a 4-connected graph, and let $r \in V(G)$. First, we compute a decomposition of G into "planar chains," a generalization of ear decomposition, which we describe in section 2. From this decomposition, we find two numberings g and f . We then construct these trees from these numberings.

The main difficulty with this idea lies in the fact that it is not possible to number all vertices of G , because the "chains" in our decomposition need not be paths. Fortunately, the nonpath part of the chains are planar, and we can compute four independent spanning trees in each one of these planar parts using the algorithm of Miura et al. [13] mentioned above. These trees are then used to number every vertex in the planar parts that has neighbors outside its chain. Once these numberings are computed, we can construct four independent spanning trees.

The rest of this paper is organized as follows. The remainder of this section is devoted to notation and terminology. In section 2 we describe chain decomposition of a graph and state the main decomposition result from [4] (also see [3]). In section 3 we describe known results for the planar case and give some auxiliary lemmas. In section 4 we give algorithms for constructing the required numberings. In section 5 we describe an algorithm for constructing four independent spanning trees in a 4-connected graph, and we prove its correctness in section 6.

Throughout this paper, we use $A := B$ to rename B as A or to define A as B . We use the notation xy (or yx) to represent an edge with ends x and y . Let G be a graph. For any $S \subseteq V(G)$, let $G[S]$ denote the subgraph of G with $V(G[S]) = S$ and $E(G[S])$ consisting of the edges of G with both ends in S ; we say that $G[S]$ is the subgraph of G induced by S . Let $G - S := G[V(G) - S]$. A subgraph H of G is an induced subgraph of G if $G[V(H)] = H$. We also say that H is induced in G . For any $H \subseteq G$ and $S \subseteq V(G) \cup E(G)$, $H + S$ denotes the graph with vertex set $V(H) \cup (S \cap V(G))$ and edge set $E(H) \cup \{uv \in S : \{u, v\} \subseteq V(H) \cup (S \cap V(G))\}$.

A graph G is k -connected, where k is a positive integer, if $|V(G)| \geq k + 1$ and, for any $S \subseteq V(G)$ with $|S| \leq k - 1$, $G - S$ is connected. A subgraph H of G is nonseparating in G if $G - V(H)$ is connected.

FIG. 1. Example of a chain.

Let G be a graph. For $S \subseteq V(G)$, let $N_G(S) := \{x \in V(G) - S : xy \in E(G) \text{ for some } y \in S\}$. For a subgraph H of G , let $N_G(H) := N_G(V(H))$. When $S = \{x\}$, we let $N_G(x) := N_G(\{x\})$. When there exists no ambiguity, we may simply use $N(S), N(H)$, and $N(x)$, instead of $N_G(S), N_G(H)$, and $N_G(x)$, respectively.

We describe a *path* in G as a sequence $P = (v_1, v_2, \dots, v_k)$ of distinct vertices of G such that $v_i v_{i+1} \in E(G)$, $1 \leq i \leq k - 1$. The vertices v_1 and v_k are called the *ends* of the path P , and the vertices in $V(P) - \{v_1, v_k\}$ are called the *internal vertices* of P . For $1 \leq i \leq j \leq k$, let $P[v_i, v_j] := (v_i, \dots, v_j)$, and for $1 \leq i < j \leq k$, let $P(v_i, v_j) := P[v_{i+1}, v_{j-1}]$. For $A, B \subseteq V(G)$, we say that a path P is an A - B path if one end of P is in A , the other end is in B , and no internal vertex of P is in $A \cup B$. If P is a path with ends a and b , we say that P is a *path from a to b* , or P is an a - b path. Two paths P and Q are *disjoint* if $V(P) \cap V(Q) = \emptyset$. Two paths are *internally disjoint* if no internal vertex of one path is contained in the other. Given a path P in G and a set $S \subseteq V(G)$ (respectively, a subgraph S of G), we say that P is *internally disjoint from S* if no internal vertex of P is contained in S (respectively, $V(S)$). We also describe a *cycle* in G as a sequence $C = (v_1, v_2, \dots, v_k, v_1)$ such that the vertices v_1, \dots, v_k are distinct, $v_i v_{i+1} \in E(G)$, for $1 \leq i \leq k - 1$, and $v_k v_1 \in E(G)$.

2. Chain decomposition. In order to prove Theorem 1.1, we rely on the existence of a *nonseparating chain decomposition* of a 4-connected graph, proved in [4] (also see [3]). Such a decomposition is similar to an ear decomposition. An *ear decomposition* of a graph G is a sequence (P_0, P_1, \dots, P_t) such that (i) P_0 is a cycle in G , (ii) P_1, \dots, P_t are paths in G , (iii) $\bigcup_{i=0}^t P_i = G$, and (iv) for each $0 \leq i \leq t - 1$, $G_i := \bigcup_{j=0}^i P_j$ is 2-connected and $P_{i+1} \cap G_i$ consists of the ends of P_{i+1} . In a nonseparating chain decomposition, the P_i 's will be chains and cycle chains, which may be thought of as a generalization of paths and cycles.

DEFINITION 2.1. A connected graph H is a chain if its blocks can be labeled as B_1, \dots, B_k , where $k \geq 1$ is an integer, and its cut vertices can be labeled as v_1, \dots, v_{k-1} such that

- (i) $V(B_i) \cap V(B_{i+1}) = \{v_i\}$ for $1 \leq i \leq k - 1$, and
- (ii) $V(B_i) \cap V(B_j) = \emptyset$ if $|i - j| \geq 2$ and $1 \leq i, j \leq k$.

We let $H := B_1 v_1 B_2 v_2 \dots v_{k-1} B_k$ denote this situation. If $k \geq 2$, let $v_0 \in V(B_1) - \{v_1\}$ and $v_k \in V(B_k) - \{v_{k-1}\}$, or, if $k = 1$, let $v_0, v_k \in V(B_1)$ with $v_0 \neq v_k$; then we say that H is a v_0 - v_k chain, and we denote this by $H := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$. We usually fix v_0 and v_k , and we refer to them as the ends of H_i . See Figure 1 for an example with $k = 5$.

DEFINITION 2.2. A connected graph H is a cyclic chain if for some integer $k \geq 2$, there exist subgraphs B_1, \dots, B_k of H and vertices v_1, \dots, v_k of H such that

- (i) for $1 \leq i \leq k$, B_i is 2-connected or B_i is induced by an edge of H ,
- (ii) $V(H) = \bigcup_{i=1}^k V(B_i)$ and $E(H) = \bigcup_{i=1}^k E(B_i)$,
- (iii) if $k = 2$, then $V(B_1) \cap V(B_2) = \{v_1, v_2\}$ and $E(B_1) \cap E(B_2) = \emptyset$, and
- (iv) if $k \geq 3$, then $V(B_i) \cap V(B_{i+1}) = \{v_i\}$ for $1 \leq i \leq k$, where $B_{k+1} := B_1$, and $V(B_i) \cap V(B_j) = \emptyset$ for $1 \leq i < i + 2 \leq j \leq k$ and $(i, j) \neq (1, k)$.

FIG. 2. Example of a cyclic chain.

FIG. 3. A planar chain $H := v_0B_1v_1B_2v_2B_3v_3B_4v_4B_5v_5$ in a graph G .

For notational convenience, we usually fix one of the vertices v_1, \dots, v_k as the root of H , say v_k , and write $H := v_0B_1v_1 \dots v_{k-1}B_kv_k$ to indicate that H is a cyclic chain rooted at $v_0 (= v_k)$. Each subgraph B_i is called a piece of H . We sometimes write $I(H) := V(H)$. See Figure 2 for an example with $k = 6$.

In the chain decompositions we will work with, the blocks and pieces have a planar structure. Let G be a graph with distinct vertices a, b, c , and d . We say that the quintuple (G, a, b, c, d) is planar if G can be drawn in a closed disc in the plane with no pair of edges crossing such that a, b, c, d occur in cyclic order on the boundary of the disc. For a graph G and $x, y \in V(G)$, we use $G - xy$ to denote the graph with vertex set $V(G)$ and edge set $E(G) - \{xy\}$ (note that xy need not be an edge of G).

DEFINITION 2.3. Let G be a graph, and let $H := v_0B_1v_1 \dots v_{k-1}B_kv_k$ be a chain (respectively, cyclic chain). If H is an induced subgraph of G , then we say that H is a chain in G (respectively, cyclic chain in G). We say that H is planar in G if, for each $1 \leq i \leq k$ with $|V(B_i)| \geq 3$ (or equivalently, B_i is 2-connected), there exist distinct vertices $x_i, y_i \in V(G) - V(H)$ such that $(G[V(B_i) \cup \{x_i, y_i\}] - x_iy_i, x_i, v_{i-1}, y_i, v_i)$ is planar, and $B_i - \{v_{i-1}, v_i\}$ is a component of $G - \{x_i, y_i, v_{i-1}, v_i\}$. We also say that H is a planar v_0 - v_k chain (respectively, planar cyclic chain). See Figure 3 for two drawings of an example with $k = 5$. The dashed edges may or may not exist, but they are not part of H .

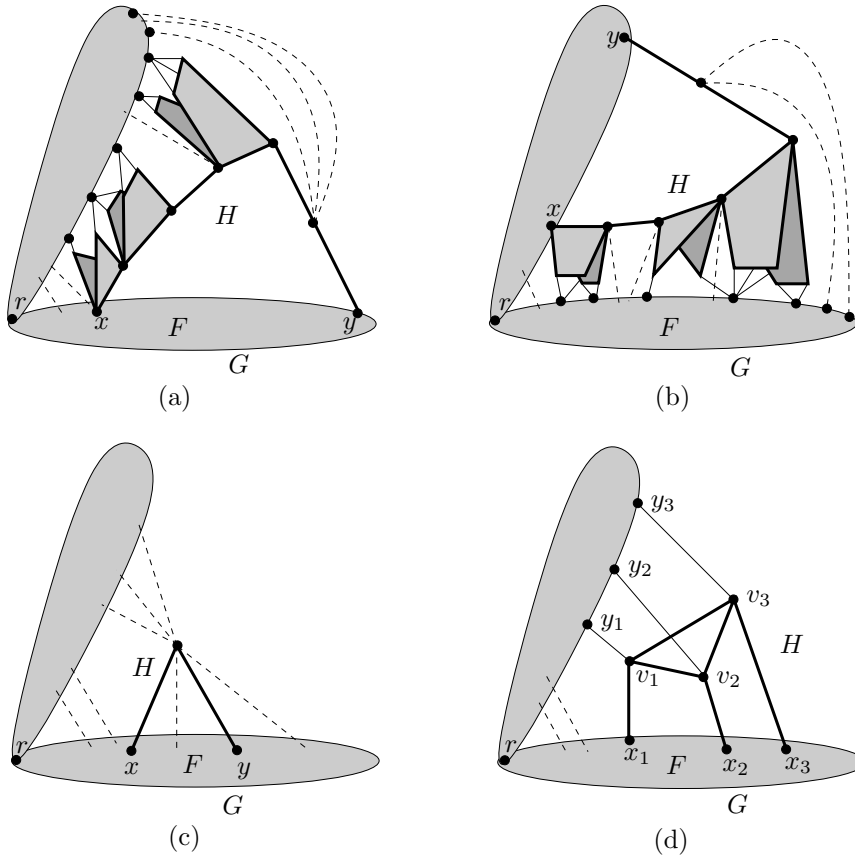

FIG. 4. (a) An up F -chain, (b) a down F -chain, (c) an elementary F -chain, and (d) a triangle F -chain. The dashed edges need not exist.

We can now describe the chains in nonseparating chain decompositions. See Figure 4 for illustrations.

DEFINITION 2.4. Let G be a graph, let F be a subgraph of G , and let $r \in V(F)$. Let H be a planar x - y chain in G such that $V(H) - \{x, y\} \subseteq V(G) - V(F)$. We say that

- (i) H is an up F -chain if $\{x, y\} \subseteq V(F)$ and $N_G(H - \{x, y\}) \subseteq (V(G) - V(F - r)) \cup \{x, y\}$,
- (ii) H is a down F -chain if $\{x, y\} \subseteq V(G) - V(F - r)$ and $N_G(H - \{x, y\}) \subseteq V(F - r) \cup \{x, y\}$, and
- (iii) H is an elementary F -chain if $\{x, y\} \subseteq V(F)$ and H is an x - y path of length two.

In any of the three cases we say that H is a planar x - y F -chain in G (or simply a planar F -chain). Let $I(H) := V(H) - \{x, y\}$.

DEFINITION 2.5. Let G be a graph, let F be a subgraph of G , and let $r \in V(F)$. Suppose that $\{v_1, v_2, v_3\} \subseteq V(G) - V(F)$ induces a triangle T in G and, for each $1 \leq i \leq 3$, v_i has exactly one neighbor x_i in $V(F - r)$ and exactly one neighbor y_i in $V(G) - (V(F) \cup V(T))$, and each v_i has degree four in G . Moreover, assume that x_1, x_2, x_3 are distinct and y_1, y_2, y_3 are distinct. Then we say that $H := T + \{x_1, x_2, x_3, v_1x_1, v_2x_2, v_3x_3\}$ is a triangle F -chain in G . We let $I(H) := \{v_1, v_2, v_3\}$.

Note that Definitions 2.4 and 2.5 depend on the choice of r and F , but in spite of this, whenever we use these concepts in this paper, it should be clear which pair r, F we refer to.

DEFINITION 2.6. *Let G be a graph, let F be a subgraph of G , and let $r \in V(F)$. By a good F -chain in G , we mean an up F -chain or a down F -chain, or an elementary F -chain or a triangle F -chain.*

We are now ready to describe a chain decomposition, which is similar to an ear decomposition.

DEFINITION 2.7. *Let G be a graph, let $r \in V(G)$, and let H_1, \dots, H_t be chains in G , where $t \geq 2$. We say that (H_1, \dots, H_t) is a nonseparating chain decomposition of G rooted at r if the following conditions hold:*

- (i) H_1 is a planar cyclic chain in G rooted at r .
- (ii) For each $i = 2, \dots, t - 1$, H_i is a good $G[\bigcup_{j=1}^{i-1} I(H_j)]$ -chain in G .
- (iii) $H_t := G - (\bigcup_{j=1}^{t-1} I(H_j) - \{r\})$ is a planar cyclic chain in G rooted at r .
- (iv) For each $i = 1, \dots, t - 1$, both $G[\bigcup_{j=1}^i I(H_j)]$ and $G - ((\bigcup_{j=1}^i I(H_j)) - \{r\})$ are 2-connected.

The chains H_2, \dots, H_{t-1} are called internal chains of the nonseparating chain decomposition. If ra is a piece of H_1 , then we say that H_1, \dots, H_t is a nonseparating chain decomposition of G starting at ra .

The following result is proved in [4] (also see [3]).

THEOREM 2.8. *Let G be a 4-connected graph, let $r \in V(G)$, and let $ra \in E(G)$. Then G has a nonseparating chain decomposition rooted at r and starting at ra , and such a decomposition can be found in $O(|V(G)|^2|E(G)|)$ time.*

The basic idea for constructing four independent spanning trees (rooted at r) can be described as follows. By Theorem 2.8, G has a nonseparating chain decomposition (H_1, \dots, H_t) rooted at r . For $1 \leq i \leq t$, let $G_i := G[\bigcup_{j=1}^i I(H_j)]$. We compute two numberings g, f defined on $V(G)$ which resemble r - t numberings. From g we compute two independent spanning trees T_1, T_2 such that for each $i = 1, \dots, t$, the restriction of T_1 and T_2 to G_i are independent spanning trees in G_i rooted at r . Similarly, from f we compute two spanning trees T_3, T_4 such that for each $i = 1, \dots, t$, the restriction of T_3 and T_4 to $G - (V(G_i) - r)$ are independent spanning trees rooted at r .

3. Planar graphs. Let G be a 4-connected graph, and let $r \in V(G)$. To use a nonseparating chain decomposition of G for constructing four independent spanning trees rooted at r , we must be able to find four independent spanning trees in the planar blocks and pieces. Unlike the original problem, these trees are not rooted at the same vertex, but they are rooted at four distinct vertices. Before we describe this result, we introduce some definitions.

DEFINITION 3.1. *Let T and T' be two trees in a graph G with roots r and r' , respectively. We say that T and T' are independent if, for each $x \in V(T) \cap V(T')$, the paths $T[r, x]$ and $T'[r', x]$ have no vertex in common except x (and r if $r = r'$).*

Let G be a graph, and let $S := \{t_1, \dots, t_4\}$ be a set of vertices of G . A 4-tuple $\mathcal{T} := \{T_1, \dots, T_4\}$ is an S -system of G if, for $1 \leq i \leq 4$, T_i is a tree of G rooted at t_i , $V(T_i) \subseteq V(G) - (S - \{t_i\})$, and $t_i \in V(T_i)$. An S -system $\mathcal{T} := \{T_1, \dots, T_4\}$ is independent if the trees in the system are pairwise independent, and an S -system \mathcal{T} is spanning if $V(T_i) = V(G) - (S - \{t_i\})$ for $1 \leq i \leq 4$. See Figure 5 for an example, where the darkened edges are in the trees.

Let G be a graph, let $S \subseteq V(G)$, and let k be a positive integer. We say that G is (k, S) -connected if $|V(G)| \geq |S| + 1$, G is connected, and for any $T \subseteq V(G)$ with $|T| \leq k - 1$, every component of $G - T$ contains an element of S .

FIG. 5. Four independent trees in a plane graph forming an independent spanning system.

THEOREM 3.2. *Let (G, a, b, c, d) be a planar graph, and suppose that G is $(4, \{a, b, c, d\})$ -connected. Then there exists an independent spanning $\{a, b, c, d\}$ -system of G . Moreover, one can find such a system in linear time.*

The existence of an independent system in Theorem 3.2 was proved by Huck [9]. Huck’s proof is not based on a decomposition of a planar graph, but through a careful analysis of his proof, one can extract an $O(|V(G)|^3)$ algorithm. Miura et al. [13] gave a linear algorithm for finding such a system based on a decomposition of 4-connected planar graphs. In fact, the decomposition they obtained can be viewed as a special case of a nonseparating chain decomposition.

Before we proceed, let us recall that the problem of finding an embedding of a planar graph can be solved in linear time [7, 8]. Moreover, the following problem can be solved in linear time: find a drawing of a planar quintuple (G, a, b, c, d) in a closed disc in the plane with no pair of edges crossing such that a, b, c, d occur in cyclic order on the boundary of the disc. We make no further mention of this fact, but it is implicitly used throughout this section.

In what follows we will use Theorem 3.2 to prove some results concerning “orderings” of certain vertices of a planar graph (G, a, b, c, d) . These results correspond to Lemmas 3.4, 3.5, 3.6, and 3.7. They will be used in the next section to compute two numberings of subsets of $V(G)$.

DEFINITION 3.3. *Let (G, a, b, c, d) be a planar graph, and let $\{T_a, T_b, T_c, T_d\}$ be an independent spanning $\{a, b, c, d\}$ -system of G , where T_v is rooted at v for each $v \in \{a, b, c, d\}$. Let $U \subseteq (N_G(b) \cup N_G(d)) - \{a, c\}$. We say that a permutation u_1, \dots, u_p of the elements of U is a (T_a, T_c) -ordering of U if, for $i, j \in \{1, \dots, p\}$ with $i < j$, $T_a[a, u_i]$ and $T_c[c, u_j]$ are (vertex) disjoint. We also say that u_1, \dots, u_p is (T_a, T_c) -ordered.*

Our first lemma concerns (T_a, T_c) -orderings restricted to elements in $N_G(b) - \{a, c\}$. In this case, this ordering corresponds to a total order.

LEMMA 3.4. *Let (G, a, b, c, d) be a planar graph, and let $\{T_a, T_b, T_c, T_d\}$ be an independent spanning $\{a, b, c, d\}$ -system of G , where T_v is rooted at v for each $v \in \{a, b, c, d\}$. Then there exists a unique (T_a, T_c) -ordering of $N_G(b) - \{a, c\}$. Moreover, such an ordering can be found in $O(|V(G)|)$ time.*

FIG. 6. u_1, \dots, u_p is the unique (T_a, T_c) -ordering of $N_G(b) - \{a, c\}$.

Proof. Let $G' := G - \{ab, bc\}$. If b has at most one neighbor in G' , then the result follows immediately. So assume b has at least two neighbors in G' . Take an embedding of G' in a closed disc such that a, b, c, d occur in clockwise order on the boundary of the disc (such an embedding for G can be computed in linear time). Let u_1, \dots, u_p ($p \geq 2$) denote the neighbors of b in G' in that cyclic order around b such that a, u_1, b, u_p, c, d occur in clockwise order on the boundary of the disc (see Figure 6). Since T_a, T_c are independent, we have that for each $i \in \{1, \dots, p\}$, $T_a[a, u_i]$ and $T_c[c, u_i]$ are internally disjoint. Then by planarity one can see that, for every $i, j \in \{1, \dots, p\}$ with $i \neq j$, $T_a[a, u_i]$ and $T_c[c, u_j]$ are disjoint if and only if $i < j$. Thus, u_1, \dots, u_p is the unique (T_a, T_c) -ordering of $N_G(b) - \{a, c\}$. Clearly, such an ordering can be computed in $O(|V(G)|)$ time. \square

In the next lemma we show that it is possible to extend a (T_a, T_c) -ordering of $N_G(b) - \{a, c\}$ and a (T_a, T_c) -ordering of $N_G(d) - \{a, c\}$ to a (T_a, T_c) -ordering of $(N_G(b) \cup N_G(d)) - \{a, c\}$.

LEMMA 3.5. *Let (G, a, b, c, d) be a planar graph, and let $\{T_a, T_b, T_c, T_d\}$ be an independent spanning $\{a, b, c, d\}$ -system of G , where T_v is rooted at v for each $v \in \{a, b, c, d\}$. Then there exists a (T_a, T_c) -ordering of $(N_G(b) \cup N_G(d)) - \{a, c\}$. Moreover, such an ordering can be found in $O(|V(G)|^2)$ time.*

Proof. Take an embedding of G in a closed disc such that a, b, c, d occur in clockwise order on the boundary of the disc. Consider the following relation. For $u, v \in (N_G(b) \cup N_G(d)) - \{a, c\}$, we say that $u \prec v$ if either one of the following holds:

- (i) $u \in N_G(b)$ and $T_a[a, u] \cap T_c[c, v] = \emptyset$.
- (ii) $u \in N_G(d)$, $T_a[a, u] \cap T_c[c, v] = \emptyset$, and $T_a[a, v] \cap T_c[c, u] \neq \emptyset$.

See Figure 7 for an illustration of conditions (i) and (ii). The bold lines denote the paths in T_a and the dashed lines denote the paths in T_c . Next, we show that \prec defines a total order on $(N_G(b) \cup N_G(d)) - \{a, c\}$.

First, we show that for any distinct $x, y \in (N_G(b) \cup N_G(d)) - \{a, c\}$, either $x \prec y$, or $y \prec x$, but not both. If $x, y \in N_G(b)$ or $x, y \in N_G(d)$, then by planarity, either $T_a[a, x] \cap T_c[c, y] = \emptyset$ and $T_a[a, y] \cap T_c[c, x] \neq \emptyset$, or $T_a[a, x] \cap T_c[c, y] \neq \emptyset$ and $T_a[a, y] \cap T_c[c, x] = \emptyset$. So by (i) or (ii), either $x \prec y$, or $y \prec x$, but not both. Thus, we may assume that $x \in N_G(b)$ and $y \in N_G(d)$. If $T_a[a, x] \cap T_c[c, y] = \emptyset$, then x, y satisfy (i) (as u, v) but not (ii) (as v, u), and we have $x \prec y$ and $y \not\prec x$. So assume $T_a[a, x] \cap T_c[c, y] \neq \emptyset$. Then x, y does not satisfy (i) (as u, v), and hence, $x \not\prec y$. Since T_a and T_c are independent, $T_a[a, y]$ and $T_c[c, y]$ are internally disjoint, and $T_a[a, x]$ and $T_c[c, x]$ are internally disjoint. By planarity, $T_a[a, y] \cap T_c[c, x] = \emptyset$. Therefore, $y \prec x$.

FIG. 7. $u \prec v$ and $u \prec w$.

It remains to show that \prec is transitive. Let $x, y, z \in (N_G(b) \cup N_G(d)) - \{a, c\}$, and assume that $x \prec y$ and $y \prec z$. We will show that $x \prec z$. We have eight cases by considering which of x, y, z are in $N_G(b)$.

- (1) $x, y, z \in N_G(b)$. Since $x \prec y$ and $y \prec z$, it follows from (i) that $T_a[a, x] \cap T_c[c, y] = \emptyset$ and $T_a[a, y] \cap T_c[c, z] = \emptyset$. So by planarity, $T_a[a, x] \cap T_c[c, z] = \emptyset$, and by (i), $x \prec z$.
- (2) $x, y, z \in N_G(d)$. Since $x \prec y$ and $y \prec z$, it follows from (ii) that $T_a[a, x] \cap T_c[c, y] = \emptyset$, $T_a[a, y] \cap T_c[c, x] \neq \emptyset$, $T_a[a, y] \cap T_c[c, z] = \emptyset$, and $T_a[a, z] \cap T_c[c, y] \neq \emptyset$. So by planarity, $T_a[a, x] \cap T_c[c, z] = \emptyset$ and $T_a[a, z] \cap T_c[c, x] \neq \emptyset$. By (ii), $x \prec z$.
- (3) $y, z \in N_G(b)$ and $x \in N_G(d)$. Since T_a and T_c are independent, $P := T_a[a, y] \cup T_c[c, y]$ is an a - c path in $G - \{b, d\}$. Note that P divides the disc into two closed regions, say B and D , with b in B and d in D . Since $x \prec y$ and $x \in N_G(d)$, it follows from (ii) that $T_a[a, x] \cap T_c[c, y] = \emptyset$ and $T_a[a, y] \cap T_c[c, x] \neq \emptyset$. Since $y \prec z$ and $y \in N_G(b)$, it follows from (i) that $T_a[a, y] \cap T_c[c, z] = \emptyset$. So $T_c[c, z]$ lies in B and $T_a[a, x]$ lies in D . Therefore, by planarity, $T_a[a, x] \cap T_c[c, z] = \emptyset$. Since $T_a[a, y] \cap T_c[c, x] \neq \emptyset$, it follows by planarity that $T_a[a, z] \cap T_c[c, x] \neq \emptyset$. Therefore, $x \prec z$.
- (4) $y, z \in N_G(d)$ and $x \in N_G(b)$. Since T_a and T_c are independent, $P := T_a[a, y] \cup T_c[c, y]$ is an a - c path in $G - \{b, d\}$, and P divides the disc into two closed regions B and D , with b in B and d in D . Since $x \prec y$ and $x \in N_G(b)$, it follows from (i) that $T_a[a, x] \cap T_c[c, y] = \emptyset$, and since $y \prec z$ and $y \in N_G(d)$, it follows from (ii) that $T_a[a, y] \cap T_c[c, z] = \emptyset$. So $T_c[c, z]$ lies in D and $T_a[a, x]$ lies in B . By planarity, $T_a[a, x] \cap T_c[c, z] = \emptyset$, and hence by (i), $x \prec z$.
- (5) $x, y \in N_G(d)$ and $z \in N_G(b)$. Since T_a and T_c are independent, $P := T_a[a, y] \cup T_c[c, y]$ is an a - c path in $G - \{b, d\}$, and P divides the disc into two closed regions B and D , with b in B and d in D . Since $x \prec y$ and $x \in N_G(d)$, it follows from (ii) that $T_a[a, x] \cap T_c[c, y] = \emptyset$, and since $y \prec z$ and $y \in N_G(d)$, it follows from (ii) that $T_a[a, y] \cap T_c[c, z] = \emptyset$. Thus, $T_a[a, x]$ lies in D and $T_c[c, z]$ lies in B . By planarity, $T_a[a, x] \cap T_c[c, z] = \emptyset$. Moreover, since $y \prec z$ and $y \in N_G(d)$, it follows from (ii) that $T_a[a, z] \cap T_c[c, y] \neq \emptyset$. By planarity, $T_a[a, z] \cap T_c[c, x] \neq \emptyset$. Therefore by (ii), $x \prec z$.
- (6) $x, y \in N_G(b)$ and $z \in N_G(d)$. Since T_a and T_c are independent, $P := T_a[a, y] \cup T_c[c, y]$ is an a - c path in $G - \{b, d\}$, and P divides the disc into two closed

FIG. 8. Two disjoint paths, one in T_a and the other in T_d .

regions B and D , with b in B and d in D . Since $x \prec y$ and $x \in N_G(b)$, it follows from (i) that $T_a[a, x] \cap T_c[c, y] = \emptyset$, and since $y \prec z$ and $y \in N_G(b)$, it follows from (i) that $T_a[a, y] \cap T_c[c, z] = \emptyset$. So $T_a[a, x]$ lies in B and $T_c[c, z]$ lies in D . By planarity $T_a[a, x] \cap T_c[c, z] = \emptyset$. Therefore by (i), $x \prec z$.

- (7) $x, z \in N_G(b)$ and $y \in N_G(d)$. We have shown that either $x \prec z$ or $z \prec x$. Suppose for a contradiction that $z \prec x$. Then by (i), $T_a[a, z] \cap T_c[c, x] = \emptyset$, and by planarity, $T_a[a, x] \cap T_c[c, z] \neq \emptyset$. Since $y \prec z$ and $y \in N_G(d)$, $T_a[a, z] \cap T_c[c, y] \neq \emptyset$. But then, by planarity, $T_a[a, x] \cap T_c[c, y] \neq \emptyset$, which is a contradiction to (i) since $x \prec y$ and $x \in N_G(b)$. Therefore, $x \prec z$.
- (8) $x, z \in N_G(d)$ and $y \in N_G(b)$. We have shown that either $x \prec z$ or $z \prec x$. Suppose for a contradiction that $z \prec x$. Then by (ii), $T_a[a, z] \cap T_c[c, x] = \emptyset$ and $T_a[a, x] \cap T_c[c, z] \neq \emptyset$. Since $x \prec y$ and $x \in N_G(d)$, $T_a[a, y] \cap T_c[c, x] \neq \emptyset$. But then, by planarity, $T_a[a, y] \cap T_c[c, z] \neq \emptyset$, which is a contradiction to (i) since $y \prec z$ and $y \in N_G(b)$. Therefore, $x \prec z$.

Thus, \prec defines a total order on $(N_G(b) \cup N_G(d)) - \{a, c\}$. Hence, the required (T_a, T_c) -ordering exists.

Furthermore, this ordering can be found as follows. Let b_1, \dots, b_p be the (T_a, T_c) -ordering of $N_G(b) - \{a, c\}$, and let d_1, \dots, d_q be the (T_a, T_c) -ordering of $N_G(d) - \{a, c\}$. Both exist by Lemma 3.4. These sequences are ordered under \prec . We can decide in $O(|V(G)|)$ time whether $b_i \prec d_j$ or $d_j \prec b_i$ (by checking which of (i) or (ii) holds) for any pair b_i, d_j , $1 \leq i \leq p$, $1 \leq j \leq q$. Thus, using the so-called merge technique in [2], we can merge the two sequences to obtain a sequence ordered under \prec in $O(|V(G)|^2)$ time. \square

The last two lemmas of this section will also be needed in section 5. Figure 8 illustrates Lemma 3.6, and Figure 9 illustrates Lemma 3.7.

LEMMA 3.6. *Let (G, a, b, c, d) be a planar graph, and let $\{T_a, T_b, T_c, T_d\}$ be an independent spanning $\{a, b, c, d\}$ -system of G , where T_v is rooted at v for each $v \in \{a, b, c, d\}$. Assume that b has at least two neighbors in $V(G) - \{a, c\}$. Then for any (T_a, T_c) -ordered pair $x, y \in N_G(b) - \{a, c\}$, $T_a[a, x] \cap T_d[d, y] = \emptyset$.*

Proof. Take an embedding of G in a disc such that a, b, c, d occur in clockwise order on the boundary of the disc. Let $x, y \in N_G(b) - \{a, c\}$ such that x, y is (T_a, T_c) -ordered (see Figure 8). Hence, $T_a[a, x] \cap T_c[c, y] = \emptyset$. Since T_a and T_d are independent, $P := T_a[a, x] \cup T_d[d, x]$ is an a - d path in $G - \{a, c\}$, and P divides the disc into two closed regions B and C , with b in B . By planarity and since $T_a[a, x] \cap T_c[c, y] = \emptyset$, $T_d[d, y]$ lies in B . Then by planarity, $T_a[a, x] \cap T_d[d, y] = \emptyset$. \square

LEMMA 3.7. *Let (G, a, b, c, d) be a planar graph, and let $\{T_a, T_b, T_c, T_d\}$ be an independent spanning $\{a, b, c, d\}$ -system of G , where T_v is rooted at v for each $v \in$*

FIG. 9. Three disjoint paths contained in $T_a, T_c,$ and $T_d,$ respectively.

$\{a, b, c, d\}$. Assume that b has at least three neighbors in $V(G) - \{a, c\}$. Then for any (T_a, T_c) -ordered triple $x, y, z \in N_G(b) - \{a, c\}$, $T_a[a, x], T_d[d, y]$, and $T_c[c, z]$ are pairwise disjoint.

Proof. Take an embedding of G in a disc such that a, b, c, d occur in clockwise order on the boundary of the disc. Let $x, y, z \in N_G(b)$ such that x, y, z is (T_a, T_c) -ordered (see Figure 9). Hence, $T_a[a, x] \cap T_c[c, y] = \emptyset$ and $T_a[a, y] \cap T_c[c, z] = \emptyset$.

By Lemma 3.4, $T_a[a, x] \cap T_c[c, z] = \emptyset$. Hence, the path $P := T_d[d, y] + \{b, yb\}$ divides the disc into closed regions A and C , with $T_a[a, x]$ in A and $T_c[c, z]$ in C . By Lemma 3.6, $T_a[a, x] \cap T_d[d, y] = \emptyset$. By applying a mirror image version of Lemma 3.6, we can show that $T_d[d, y] \cap T_c[c, z] = \emptyset$. \square

4. Numberings. By Theorem 2.8, G has a nonseparating chain decomposition rooted at r . In this section we will combine this decomposition with Theorem 3.2 to produce a numbering of a subset of $V(G)$. This numbering will be used in the next section to construct four independent spanning trees rooted at r .

In the rest of this section we fix the following notation.

Notation 4.1. Let G be a 4-connected graph, and let $r \in V(G)$. Fix a nonseparating chain decomposition of G rooted at r , say $\mathcal{C} := (H_1, \dots, H_t)$, $t \geq 2$. Define the sequences $G_0, \bar{G}_1, \dots, \bar{G}_t$ as follows:

- (i) $G_0 := \bar{G}_t := (\{r\}, \emptyset)$.
- (ii) For $i = 1, \dots, t - 1$, $G_i := G[\bigcup_{j=1}^i I(H_j)]$ and $\bar{G}_i := G - (V(G_i) - \{r\})$.

Notation 4.2. Suppose that H_i ($1 \leq i \leq t$) is an up G_{i-1} -chain in G or a down G_{i-1} -chain in G . Let $H_i := v_0 B_1 v_1 B_2 v_2 \dots v_{k-1} B_k v_k$. For each 2-connected B_j there exist u_j, w_j (both on $V(G_{i-1})$ or both on $V(\bar{G}_i)$) such that $B_j - \{v_{j-1}, v_j\}$ is a component of $G - \{v_{j-1}, v_j, u_j, w_j\}$, and $(B_j^+, v_{j-1}, u_j, v_j, w_j)$ is planar, where $B_j^+ := G[V(B_j) \cup \{u_j, w_j\}] - u_j w_j$. We refer to each such B_j^+ as a *planar section* in C . The vertices v_{j-1}, v_j, u_j, w_j are the *terminals* of B_j^+ . See Figure 10 for an illustration. Note that the notation above depends on i . For the sake of clarity we will not make it explicit in the notation, but whenever we use this we will make clear which i we refer to. Furthermore, the algorithms we will describe deal with each H_i separately, and thus no confusion should arise.

DEFINITION 4.3. Suppose that H_i ($1 \leq i \leq t$) is a triangle G_{i-1} -chain in G . See Figure 4. Let $I(H_i) := \{v_1, v_2, v_3\}$, let $V(H_i) - I(H_i) := \{x_1, x_2, x_3\}$, and suppose that $x_j v_j \in E(G)$ for $j = 1, 2, 3$. We say that $v_j x_j$ ($j = 1, 2, 3$) are the *legs* of H_i .

DEFINITION 4.4. Let $D \subseteq V(G)$. A numbering of D is a function from D to $\{1, \dots, |D|\}$. Let g be a numbering of D , let v_1, \dots, v_k be a sequence of distinct vertices in $V(G) - D$, and let $v_0 \in D$. The extension g' of g to v_1, \dots, v_k from v_0 is defined as follows:

FIG. 10. v_2, v_3, u_3, w_3 are the terminals of B_3^+ .

- (i) for $1 \leq i \leq k$, let $g'(v_i) := g(v_0) + i$;
- (ii) for each $v \in D$ with $g(v) \leq g(v_0)$ let $g'(v) = g(v)$; and
- (iii) for each $v \in D$ with $g(v) > g(v_0)$ let $g'(v) := g(v) + k$.

Note that g' is a numbering of $D \cup \{v_1, \dots, v_k\}$. For convenience, if $D \subseteq V(G)$ and σ denotes a sequence v_1, \dots, v_k of vertices in $V(G) - D$, we let $D \cup \{\sigma\} := D \cup \{v_1, \dots, v_k\}$.

In order to compute the desired numberings g and f from a nonseparating chain decomposition, we need to find independent spanning systems in the planar sections in \mathcal{C} .

Assumption 4.5. For each planar section B_j^+ in \mathcal{C} , with terminals v_{j-1}, v_j, u_j, w_j , we compute an independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ . By Theorem 3.2, such a system can be computed in $O(|V(B_j^+)| + |E(B_j^+)|)$ time. Since two distinct planar sections are edge-disjoint, the overall time consumed in this phase (for all planar sections in \mathcal{C}) is $O(|V(G)| + |E(G)|)$.

Next, we describe the algorithm for computing a numbering g of a subset of $V(G)$. It also computes a sequence $\{r\} = D_0 \subset D_1 \subset \dots \subset D_{t-1}$ of subsets of $V(G)$ such that for $i = 1, \dots, t$, $N_G(H_i) \cap V(G_{i-1}) \subseteq D_{i-1}$. When the algorithm stops, g is a numbering of D_{t-1} . We note that keeping track of this sequence is not necessary for computing g , but its inclusion will make proofs easier in section 6.

ALGORITHM NUMBERING g .

Description. The algorithm executes $t - 1$ iterations, where t is the number of chains in \mathcal{C} . At the beginning of the first iteration, we have $i = 1$, $D_0 := \{r\}$, and $g(r) := 1$. At the beginning of each iteration, we have an integer i with $1 \leq i \leq t - 1$, a subset $D_{i-1} \subseteq V(G_{i-1})$ such that $N_G(H_i) \cap V(G_{i-1}) \subseteq D_{i-1}$, and a numbering g of D_{i-1} .

Each iteration consists of the following: update g and define D_i according to the following cases (depending on the type of H_i), and, if $i < t - 1$, then set $i \leftarrow i + 1$ and start a new iteration.

Case 1. H_i is an elementary G_{i-1} -chain in G .

Let $H_i := v_0 B_1 v_1 B_2 v_2$, and assume that v_0, v_2 are labeled so that $g(v_0) < g(v_2)$.

Extend g to v_1 from v_0 , and let $D_i := D_{i-1} \cup \{v_1\}$.

Case 2. $i = 1$, or H_i is an up G_{i-1} -chain in G but not an elementary G_{i-1} -chain.

Let $H_i := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$, and suppose that v_0, \dots, v_k and B_1, \dots, B_k are labeled so that $v_0 = v_k = r$ when $i = 1$ and $g(v_0) < g(v_k)$ when $i \neq 1$. For each 2-connected B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j . Let $T_{v_{j-1}}^j, T_{v_j}^j$ denote the trees rooted, respectively, at v_{j-1}, v_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5.

FIG. 11. Extending the numbering g to an up G_{i-1} -chain.

FIG. 12. Extending the numbering g to a down G_{i-1} -chain.

For each $j = 1, \dots, k$, compute a sequence σ_j as follows. If B_j is 2-connected, then let σ_j be a $(T_{v_{j-1}}^j, T_{v_j}^j)$ -ordering of $N_{B_j^+}(\{u_j, w_j\}) - \{v_{j-1}, v_j\}$ (the existence of this ordering is guaranteed by Lemma 3.5). If B_j is trivial, then let σ_j denote the empty sequence.

Extend g to $\sigma := \sigma_1, v_1, \sigma_2, v_2, \dots, v_{k-1}, \sigma_k$ from v_0 , and let $D_i := D_{i-1} \cup \{\sigma\}$. See Figure 11 for an illustration.

Case 3. H_i is a down G_{i-1} -chain in G but not an elementary G_{i-1} -chain.

Let $H_i := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$. For each 2-connected block B_j let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j with $g(u_j) < g(w_j)$. Let $T_{u_j}^j, T_{w_j}^j$ denote trees rooted, respectively, at u_j, w_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5.

Let $D_i := D_{i-1} \cup N_{B_1}(v_0) \cup N_{B_k}(v_k)$. See Figure 12 for an illustration. Extend g according to the following three subcases.

Subcase 3.1. $k = 1$ (thus, B_1 is 2-connected).

Let σ denote a $(T_{u_1}^1, T_{w_1}^1)$ -ordering of $N_{B_1^+}(\{v_0, v_1\}) - \{u_1, w_1\} = N_{B_1}(v_0) \cup N_{B_k}(v_k)$ (the existence of this ordering is guaranteed by Lemma 3.5). Extend g to σ from u_1 .

Subcase 3.2. $k = 2$, and B_1 or B_2 is trivial.

Note that since H_i is not an elementary G_{i-1} -chain, B_1 or B_2 is nontrivial.

Assume then (renaming B_1 and B_2 if necessary) that B_1 is 2-connected and B_2 is trivial. Extend g according to the following cases.

- (i) v_1 has no neighbor in $V(G_{i-1})$. Let q_1, q_2, q_3 be neighbors of v_1 in B_1 (they exist since G is 4-connected), and assume that q_1, q_2, q_3 is $(T_{u_1}^1, T_{w_1}^1)$ -ordered (this is possible by Lemma 3.4). By Lemma 3.7, $T_{u_1}^1[u_1, q_1], T_{v_0}^1[v_0, q_2]$, and $T_{w_1}^1[w_1, q_3]$ are disjoint. Let $H := B_1^+ \cup B_2$ (note that $H - \{v_0, v_2, u_1, w_1\}$ is a component of $G - \{v_0, v_2, u_1, w_1\}$). Then (H, v_0, u_1, v_2, w_1) is planar, and $\{T_{v_0}^1 + \{v_1, v_1q_2\}, T_{v_1}^1 + \{v_2, v_1v_2\}, T_{u_1}^1 + \{v_1, v_1q_1\}, T_{w_1}^1 + \{v_1, v_1q_3\}\}$ forms an independent spanning $\{v_0, u_1, v_2, w_1\}$ -system of H .

Let σ denote a $(T_{u_1}^1 + \{v_1, v_1q_1\}, T_{w_1}^1 + \{v_1, v_1q_3\})$ -ordering of $N_H(\{v_0, v_2\}) - \{u_1, w_1\}$ (the existence of this ordering is guaranteed by Lemma 3.5). Extend g to σ from u_1 .

Comment: we also keep track of q_1, q_2, q_3 for the construction of the independent spanning trees.

- v_1 has a neighbor in $V(G_{i-1})$. Let $x \in N_G(v_1) \cap V(G_{i-1})$ with $g(x)$ minimum, and let σ denote a $(T_{u_1}^1, T_{w_1}^1)$ -ordering of $N_{B_1^+}(v_0) - \{u_1, w_1\}$ (the existence of this ordering is guaranteed by Lemma 3.4). If $g(x) > g(u_1)$, then extend g to σ, v_1 from u_1 , where σ, v_1 is the sequence obtained from σ by adding v_1 at the end. If $g(x) \leq g(u_1)$, then extend g to v_1, σ from x , where v_1, σ is the sequence obtained from σ by adding v_1 in the front.

Subcase 3.3. $k \geq 3$, or $k = 2$ and both B_1, B_2 are 2-connected.

Extend g to $N_{B_1}(v_0)$ according to the following cases.

- B_1 is 2-connected. Let σ denote a $(T_{u_1}^1, T_{w_1}^1)$ -ordering of $N_{B_1^+}(v_0) - \{u_1, w_1\} = N_{B_1}(v_0)$ (the existence of this ordering is guaranteed by Lemma 3.4). Extend g to σ from u_1 .
- Both B_1 and B_2 are trivial. Let $x \in N_G(v_1) \cap V(G_{i-1})$ with $g(x)$ minimum. Extend g to v_1 from x .
- B_1 is trivial and B_2 is 2-connected.
 - If v_1 has no neighbor in $V(G_{i-1})$, extend g to v_1 from u_2 .
 - If v_1 has a neighbor in $V(G_{i-1})$, let $x \in N_G(v_1) \cap V(G_{i-1})$ with $g(x)$ minimum. If $g(x) > g(u_2)$, then extend g to v_1 from u_2 . If $g(x) \leq g(u_2)$, then extend g to v_1 from x .

Extend (the resulting) g to $N_{B_k}(v_k)$ according to the following cases.

- B_k is 2-connected. Let σ be a $(T_{u_k}^k, T_{w_k}^k)$ -ordering of $N_{B_k^+}(v_k) - \{u_k, w_k\} = N_{B_k}(v_k)$ (the existence of this ordering is guaranteed by Lemma 3.4). Extend g to σ from u_k .
- Both B_k and B_{k-1} are trivial. Let $x \in N_G(v_{k-1}) \cap V(G_{i-1})$ with $g(x)$ minimum. Extend g to v_{k-1} from x .
- B_k is trivial and B_{k-1} is 2-connected.
 - If v_{k-1} has no neighbor in $V(G_{i-1})$, extend g to v_{k-1} from u_{k-1} .
 - If v_{k-1} has a neighbor in $V(G_{i-1})$, let $x \in N_G(v_{k-1}) \cap V(G_{i-1})$ with $g(x)$ minimum. If $g(x) > g(u_{k-1})$, then extend g to v_{k-1} from u_{k-1} . If $g(x) \leq g(u_{k-1})$, then extend g to v_{k-1} from x .

Case 4. H_i is a triangle G_{i-1} -chain in G .

Let $I(H_i) := \{v_1, v_2, v_3\}$, and let $v_j x_j$ ($j = 1, 2, 3$) be the legs of H_i . Suppose that v_1, v_2, v_3 are labeled so that $g(x_1) < g(x_2) < g(x_3)$. Let $D_i := D_{i-1} \cup \{v_1, v_2, v_3\}$. Extend g to v_1, v_2, v_3 from x_2 .

This concludes the description of the algorithm for computing g .

LEMMA 4.6. *Algorithm Numbering g runs in $O(|V(G)|^3)$ time.*

Proof. Observe that at the i th iteration, Algorithm Numbering g extends the current numbering g^i to a sequence σ from a previously numbered vertex $v \in D_{i-1}$. Clearly, given g^i, σ , and v , this extension can be computed in $O(|V(G)|)$ time. We now analyze the time spent at each iteration of Algorithm Numbering g according to Cases 1–4. We use the same notation as in the algorithm.

If Case 1 occurs (H_i is an elementary G_{i-1} -chain in G), then Algorithm Numbering g extends g to v_1 . This can be done in $O(|V(G)|)$ time.

If Case 2 occurs (H_i is an up G_{i-1} -chain but not an elementary G_{i-1} -chain), then Algorithm Numbering g computes sequences $\sigma_1, \dots, \sigma_k$, where σ_j denotes the empty sequence when B_j is trivial, and σ_j is a $(T_{v_{j-1}}^j, T_{v_j}^j)$ -ordering of $N_{B_j^+}(\{u_j, w_j\}) - \{v_{j-1}, v_j\}$ when B_j is 2-connected. In the latter case, by Lemma 3.5 the sequence σ_j can be computed in $O(|V(B_j^+)|^2)$ time. Thus, the algorithm spends $O(|V(G)|^2)$ time to compute $\sigma_1, \dots, \sigma_k$. After that, the algorithm extends g to $v_0, \sigma_1, v_1, \dots, v_{k-1}, \sigma_k, v_k$, which can be done in $O(|V(G)|)$ time. Therefore, the algorithm spends $O(|V(G)|^2)$ time if Case 2 occurs.

If Case 3 occurs (H_i is a down G_{i-1} -chain but not an elementary G_{i-1} -chain), then Algorithm Numbering g considers three cases.

- If Subcase 3.1 occurs ($k = 1$), then the algorithm computes a $(T_{u_1}^1, T_{w_1}^1)$ -ordering σ of $N_{B_1^+}(\{v_0, v_1\}) - \{u_1, w_1\}$ and extends g to σ from u_1 . The sequence σ can be computed in $O(|V(G)|^2)$ time by Lemma 3.5, and the extension of g can be computed in $O(|V(G)|)$ time, resulting in $O(|V(G)|^2)$ time for this iteration.
- If Subcase 3.2 occurs ($k = 2$, and B_1 or B_2 is trivial), then the algorithm considers two subcases, according to whether or not v_1 has a neighbor in $V(G_{i-1})$.
 - If v_1 has no neighbor in $V(G_{i-1})$, the algorithm chooses neighbors q_1, q_2, q_3 of v_1 in B_1 and computes a $(T_{u_1}^1 + \{v_1, v_1 q_1\}, T_{w_1}^1 + \{v_1, v_1 q_3\})$ -ordering σ of $N_{B_1}(v_0) \cup N_{B_k}(v_k) = N_H(\{v_0, v_2\}) - \{u_1, w_1\}$ as in Subcase 3.1 and extends g to σ from u_1 . Thus, the algorithm spends $O(|V(G)|^2)$ time in this case.
 - If v_1 has a neighbor in $V(G_{i-1})$, then the algorithm computes a $(T_{u_1}^1, T_{w_1}^1)$ -ordering σ of $N_{B_1^+}(v_0) - \{u_1, w_1\}$, and it performs an extension on g . The sequence σ can be computed in $O(|V(G)|)$ time by Lemma 3.4, and the extension can be computed in $O(|V(G)|)$ time. Thus, the algorithm spends $O(|V(G)|)$ time in this case.
- If Subcase 3.3 occurs ($k \geq 3$, or $k = 2$ and both B_1, B_2 are 2-connected), then the algorithm extends g to $N_{B_1}(v_0)$ and extends g to $N_{B_k}(v_k)$. The algorithm may need to compute a $(T_{u_1}^1, T_{w_1}^1)$ -ordering of $N_{B_1^+}(v_0) - \{u_1, w_1\}$ and a $(T_{u_k}^k, T_{w_k}^k)$ -ordering of $N_{B_k^+}(v_k) - \{u_k, w_k\}$, but both can be done in $O(|V(G)|)$ time by Lemma 3.4. It is not hard to check that the algorithm spends $O(|V(G)|)$ time in this case.

If Case 4 occurs (H_i is a triangle chain), then Algorithm Numbering g extends g to v_1, v_2, v_3 . This can be done in $O(|V(G)|)$ time.

From the analysis above, it follows that Algorithm Numbering g spends $O(|V(G)|^2)$ time in each iteration. Since the number of iterations is $t < n \rightarrow t < |V(G)|$, the numbering g can be computed in $O(|V(G)|^3)$ time. \square

Note that the extension operation does not affect the order of the vertices previously numbered, although their actual g values may have changed. Thus, at each iteration the algorithm orders the vertices in $D_i - D_{i-1}$ without affecting the order of the vertices in D_{i-1} . In fact, it does not affect the order of the vertices in D_j for every $1 \leq j \leq i - 1$.

The numbering g will be used to construct *two* independent spanning trees rooted at r from $\mathcal{C} = (H_1, \dots, H_t)$ in order from H_1 to H_t . For constructing the other two spanning trees we compute a numbering f by examining the chains of \mathcal{C} in reverse order.

The algorithm for computing f is analogous to Algorithm Numbering g when it deals with an up G_{i-1} -chain or a down G_{i-1} -chain or elementary G_{i-1} -chain. The differences appear when it deals with a triangle G_{i-1} -chain. The algorithm also computes a sequence $\{r\} = D'_{t+1} \subset D'_t \subset \dots \subset D'_2$ of subsets of $V(G)$ such that for $t \geq i \geq 1$, $N_G(H_i) \cap V(\bar{G}_i) \subseteq D'_{i+1}$.

ALGORITHM NUMBERING f .

Description. The algorithm executes $t - 1$ iterations, where t is the number of chains in $\mathcal{C}' := (H_1, \dots, H_t)$. At the beginning of the first iteration, we have $i = t$, $D'_{t+1} := \{r\}$, and $f(r) := 1$. At the beginning of each iteration, we have an integer i with $t \geq i \geq 2$, a subset $D'_{i+1} \subseteq V(\bar{G}_i)$ such that $N_G(H_i) \cap V(\bar{G}_i) \subseteq D'_{i+1}$, and a numbering f of D'_{i+1} .

Each iteration consists of the following: update f and define D'_i according to the following cases (depending on the chain type of H_i), and, if $i > 2$, then set $i \leftarrow i - 1$ and start a new iteration.

Case 1. H_i is an elementary G_{i-1} -chain in G .

Let $H_i := v_0 B_1 v_1 B_2 v_2$, and let v'_0, v'_2 be neighbors of v_1 in $V(\bar{G}_i)$ with $f(v'_0) < f(v'_2)$. Extend f to v_1 from v'_0 , and let $D'_i := D'_{i+1} \cup \{v_1\}$.

Case 2. $i = t$, or H_i is a down G_{i-1} -chain in G but not an elementary G_{i-1} -chain.

Let $H_i := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$, and suppose that v_0, \dots, v_k and B_1, \dots, B_k are labeled so that $v_0 = v_k = r$ when $i = t$ and $f(v_0) < f(v_k)$ when $i \neq t$. For each 2-connected B_j , let u_j, w_j be the terminals of B_j^+ other than v_{j-1}, v_j . Let $T^j_{v_{j-1}}, T^j_{v_j}$ denote the trees rooted, respectively, at v_{j-1}, v_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5.

For each $j = 1, \dots, k$ compute a sequence σ_j as follows. If B_j is 2-connected, then let σ_j be a $(T^j_{v_{j-1}}, T^j_{v_j})$ -ordering of $N_{B_j^+}(\{u_j, w_j\}) - \{v_{j-1}, v_j\}$ (the existence of this ordering is guaranteed by Lemma 3.5). If B_j is trivial, then let σ_j denote the empty sequence.

Extend f to $\sigma := \sigma_1, v_1, \sigma_2, v_2, \dots, v_{k-1}, \sigma_k$ from v_0 , and let $D'_i := D'_{i+1} \cup \{\sigma\}$. See Figure 13 for an illustration.

Case 3. H_i is an up G_{i-1} -chain in G but not an elementary G_{i-1} -chain in G .

Let $H_i := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$. For each 2-connected B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $f(u_j) < f(w_j)$. Let $T^j_{u_j}, T^j_{w_j}$ denote the trees rooted, respectively, at u_j, w_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5.

Let $D'_i := D'_{i+1} \cup N_{B_1}(v_0) \cup N_{B_k}(v_k)$. See Figure 14 for an illustration. Extend f according to the following three subcases.

Subcase 3.1. $k = 1$ (thus, B_1 is 2-connected).

FIG. 13. Extending the numbering f to a down G_{i-1} -chain.

FIG. 14. Extending the numbering f to an up G_{i-1} -chain.

Let σ denote a $(T_{u_1}^1, T_{w_1}^1)$ -ordering of $N_{B_1^+}(\{v_0, v_1\}) - \{u_1, w_1\} = N_{B_1}(v_0) \cup N_{B_k}(v_k)$ (the existence of this ordering is guaranteed by Lemma 3.5). Extend f to σ from u_1 .

Subcase 3.2. $k = 2$, and B_1 or B_2 is trivial.

Note that since H_i is not an elementary chain, B_1 or B_2 is nontrivial.

Assume then (renaming B_1 and B_2 if necessary) that B_1 is 2-connected and B_2 is trivial. Extend f according to the following cases.

- v_1 has no neighbor in $V(\bar{G}_i)$. Let q_1, q_2, q_3 be distinct neighbors of v_1 in B_1 (they exist since G is 4-connected), and assume that q_1, q_2, q_3 is $(T_{u_1}^1, T_{w_1}^1)$ -ordered (this is possible by Lemma 3.4). By Lemma 3.7, $T_{u_1}^1[u_1, q_1], T_{v_0}^1[v_0, q_2]$, and $T_{w_1}^1[w_1, q_3]$ are disjoint. Let $H := B_1^+ \cup B_2$. Note that $H - \{v_0, v_2, u_1, w_1\}$ is a component of $G - \{v_0, v_2, u_1, w_1\}$, (H, v_0, u_1, v_2, w_1) is planar, and $\{T_{v_0}^1 + \{v_1, v_1q_2\}, T_{v_1}^1 + \{v_2, v_1v_2\}, T_{u_1}^1 + \{v_1, v_1q_1\}, T_{w_1}^1 + \{v_1, v_1q_3\}\}$ is an independent spanning $\{v_0, v_2, u_1, w_1\}$ -system of H .
Let σ denote a $(T_{u_1}^1 + \{v_1, v_1q_1\}, T_{w_1}^1 + \{v_1, v_1q_3\})$ -ordering of $N_H(\{v_0, v_2\}) - \{u_1, w_1\} = N_{B_1}(v_0) \cup N_{B_k}(v_k)$ (the existence of this ordering is guaranteed by Lemma 3.5). Extend f to σ from u_1 .

Comment: we also keep track of q_1, q_2, q_3 for the construction of the independent spanning trees.

- v_1 has a neighbor in $V(\bar{G}_i)$. Let $x \in N_G(v_1) \cap V(\bar{G}_i)$ with $f(x)$ minimum, and let σ denote a $(T_{u_1}^1, T_{w_1}^1)$ -ordering of $N_{B_1}(v_0) = N_{B_1^+}(v_0) - \{u_1, w_1\}$ (the existence of this ordering is guaranteed by Lemma 3.4). If $f(x) > f(u_1)$, then extend f to σ, v_1 from u_1 . If $f(x) \leq f(u_1)$, then extend f to v_1, σ from x .

Subcase 3.3. $k \geq 3$, or $k = 2$ and both B_1, B_2 are 2-connected.

Extend f to $N_{B_1}(v_0)$ according to the following cases.

- B_1 is 2-connected. Let σ denote a $(T_{u_1}^1, T_{w_1}^1)$ -ordering of $N_{B_1}(v_0) = N_{B_1^+}(v_0) - \{u_1, w_1\}$ (the existence of this ordering is guaranteed by Lemma 3.4). Extend f to σ from u_1 .
- Both B_1 and B_2 are trivial. Let $x \in N_G(v_1) \cap V(\bar{G}_i)$ with $f(x)$ minimum. Extend f to v_1 from x .
- B_1 is trivial and B_2 is 2-connected.
 - If v_1 has no neighbor in $V(\bar{G}_i)$, extend f to v_1 from u_2 .
 - If v_1 has a neighbor in $V(\bar{G}_i)$, let $x \in N_G(v_1) \cap V(\bar{G}_i)$ with $f(x)$ minimum. If $f(x) > f(u_2)$, then extend f to v_1 from u_2 . If $f(x) \leq f(u_2)$, then extend f to v_1 from x .

Extend (the resulting) f to $N_{B_k}(v_k)$ according to the following cases.

- B_k is 2-connected. Let σ denote a $(T_{u_k}^k, T_{w_k}^k)$ -ordering of $N_{B_k}(v_k) = N_{B_k^+}(v_k) - \{u_k, w_k\}$ (the existence of this ordering is guaranteed by Lemma 3.4). Extend f to σ from u_k .
- Both B_k and B_{k-1} are trivial. Let $x \in N_G(v_{k-1}) \cap V(\bar{G}_i)$ with $f(x)$ minimum. Extend f to v_{k-1} from x .
- B_k is trivial and B_{k-1} is 2-connected.
 - If v_{k-1} has no neighbor in $V(\bar{G}_i)$, extend f to v_{k-1} from u_{k-1} .
 - If v_{k-1} has a neighbor in $V(\bar{G}_i)$, let $x \in N_G(v_{k-1}) \cap V(\bar{G}_i)$ with $f(x)$ minimum. If $f(x) > f(u_{k-1})$, then extend f to v_{k-1} from u_{k-1} . If $f(x) \leq f(u_{k-1})$, then extend f to v_{k-1} from x .

Case 4. H_i is a triangle G_{i-1} -chain in G .

Let $I(H_i) := \{v_1, v_2, v_3\}$, let $v_j x_j$ ($j = 1, 2, 3$) be the legs of H_i , and let $y_1, y_2, y_3 \in V(\bar{G}_i)$ such that $y_1 v_1, y_2 v_2, y_3 v_3 \in E(G)$. Assume that v_1, v_2, v_3 are labeled so that $g(x_1) < g(x_2) < g(x_3)$. Let $D'_i := D'_{i+1} \cup \{v_1, v_2, v_3\}$.

- If $f(y_1) < f(y_2)$ and $f(y_1) < f(y_3)$, then extend f to v_1, v_2, v_3 from y_1 .
- If $f(y_2) < f(y_1)$ and $f(y_2) < f(y_3)$, then extend f to v_2, v_1, v_3 from y_2 .
- If $f(y_3) < f(y_1) < f(y_2)$, then extend f to v_3 from y_3 and extend (the resulting) f to v_1, v_2 from y_1 .
- If $f(y_3) < f(y_2) < f(y_1)$, then extend f to v_3 from y_3 and extend (the resulting) f to v_2, v_1 from y_2 .

This concludes the description of the algorithm for computing f . The proof of the next lemma is similar to the proof of Lemma 4.6, and we omit it.

LEMMA 4.7. *Algorithm Numbering f runs in $O(|V(G)|^3)$ time.*

5. Construction of spanning trees. We now describe how to use Theorem 3.2 and the two numberings of the last section to produce four independent spanning trees. This will follow from Algorithm Trees. The proof of its correction and analysis of its complexity will be given in the next section.

ALGORITHM TREES.

Description. Let G be a 4-connected graph, let $r \in V(G)$, and let $\mathcal{C} = (H_1, \dots, H_t)$ be a nonseparating chain decomposition of G rooted at r . Let $G_0 = \bar{G}_t = (\{r\}, \emptyset)$,

and for $1 \leq i \leq t - 1$, let $G_i := G[\bigcup_{j=1}^i I(H_j)]$ and $\bar{G}_i = G - (V(G_i) - \{r\})$. The algorithm executes t iterations, where t is the number of chains in \mathcal{C} . At the first iteration, we have $i = 1$ and $T_1 = T_2 = T_3 = T_4 = G_0$. At the beginning of each iteration, we have an integer i with $1 \leq i \leq t$, spanning trees T_1, T_2 in G_{i-1} and spanning forests T_3, T_4 in $G_{i-1} - r$.

Each iteration consists of the following: update T_1, T_2, T_3, T_4 by adding certain vertices and edges of H_i to T_1, T_2, T_3, T_4 according to the following four cases (depending on the type of H_i), and, if $i < t$, then set $i \leftarrow i + 1$ and start a new iteration. After t iterations, T_1, T_2, T_3, T_4 will be independent spanning trees in G rooted at r .

Case 1. H_i is an elementary G_{i-1} -chain in G .

Let $H_i := v_0 B_1 v_1 B_2 v_2$ with $g(v_0) < g(v_2)$. Let v'_0, v'_2 be neighbors of v_1 in $V(\bar{G}_i)$ with $f(v'_0) < f(v'_2)$.

Set $T_1 \leftarrow T_1 + \{v_1, v_0 v_1\}, T_2 \leftarrow T_2 + \{v_1, v_1 v_2\}, T_3 \leftarrow T_3 + \{v'_0, v_1, v'_0 v_1\}$, and $T_4 \leftarrow T_4 + \{v'_2, v_1, v'_2 v_1\}$.

Case 2. $i = 1$, or H_i is an up G_{i-1} -chain in G but not an elementary G_{i-1} -chain in G .

Let $H_i := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$, with $v_0 = v_k = r$ when $i = 1$, and $g(v_0) < g(v_k)$ when $i \neq 1$.

For each 2-connected block B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j with $f(u_j) < f(w_j)$, and let $T_{v_{j-1}}^j, T_{v_j}^j, T_{u_j}^j, T_{w_j}^j$ denote the trees rooted, respectively, at v_{j-1}, v_j, u_j, w_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5.

Let $J := \{j : 1 \leq j \leq k, B_j \text{ is 2-connected}\}$, and let $\bar{J} := \{1, \dots, k\} - J$.

First, set

$$\begin{aligned}
 T_1 &\leftarrow T_1 \cup \left(\bigcup_{j \in \bar{J} - \{k\}} B_j \right) \cup \left(\bigcup_{j \in J} T_{v_{j-1}}^j \right), \\
 T_2 &\leftarrow T_2 \cup \left(\bigcup_{j \in \bar{J} - \{1\}} B_j \right) \cup \left(\bigcup_{j \in J} T_{v_j}^j \right), \\
 T_3 &\leftarrow T_3 \cup \left(\bigcup_{j \in J} T_{u_j}^j \right), \text{ and} \\
 T_4 &\leftarrow T_4 \cup \left(\bigcup_{j \in J} T_{w_j}^j \right).
 \end{aligned}$$

Now for each $j = 1, \dots, k - 1$ add v_j and edges incident to v_j to T_1, T_2, T_3, T_4 according to the following cases (at this stage, $v_0, v_k \notin V(T_3 \cup T_4)$).

Subcase 2.1. B_j and B_{j+1} are trivial.

Let p_3, p_4 be neighbors of v_j in $V(\bar{G}_i)$ with $f(p_3)$ minimum (hence $f(p_3) < f(p_4)$). Set $T_3 \leftarrow T_3 + \{v_j, p_3, v_j p_3\}$ and $T_4 \leftarrow T_4 + \{v_j, p_4, v_j p_4\}$.

Subcase 2.2. B_j is 2-connected and B_{j+1} is trivial.

- If v_j has no neighbor in $V(\bar{G}_i)$, then let p_1, p_3, p_4 be neighbors of v_j in B_j (they exist since G is 4-connected), and assume that p_3, p_1, p_4 is $(T_{u_j}^j, T_{w_j}^j)$ -ordered (this is possible by Lemma 3.4). By Lemma 3.7, $T_{u_j}^j[u_j, p_3], T_{v_{j-1}}^j[v_{j-1}, p_1]$,

and $T_{w_j}^j[w_j, p_4]$ are disjoint. If $k = 2$, then we also require that p_3, p_1, p_4 be the vertices q_1, q_2, q_3 , respectively, chosen in Subcase 3.2 of Algorithm Numbering f .

Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}$, $T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.

- If v_j has a neighbor in $V(\bar{G}_i)$, then let $x \in N_G(v_j) \cap V(\bar{G}_i)$ with $f(x)$ minimum.
 - If $f(x) > f(u_j)$, then let p_1, p_3 be neighbors of v_j in B_j such that the paths $T_{v_{j-1}}^j[v_{j-1}, p_1]$ and $T_{u_j}^j[u_j, p_3]$ are disjoint (they exist by Lemma 3.6).
Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}$, $T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$, and $T_4 \leftarrow T_4 + \{v_j, x, v_j x\}$.
 - If $f(x) \leq f(u_j)$, then let p_1, p_4 be neighbors of v_j in B_j such that the paths $T_{v_{j-1}}^j[v_{j-1}, p_1]$ and $T_{w_j}^j[w_j, p_4]$ are disjoint (they exist by Lemma 3.6).
Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}$, $T_3 \leftarrow T_3 + \{v_j, x, v_j x\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.

Subcase 2.3. B_j is trivial and B_{j+1} is 2-connected.

- If v_j has no neighbor in $V(\bar{G}_i)$, then let p_2, p_3, p_4 be neighbors of v_j in B_{j+1} (they exist since G is 4-connected), and assume that p_3, p_2, p_4 is $(T_{u_{j+1}}^{j+1}, T_{w_{j+1}}^{j+1})$ -ordered (this is possible by Lemma 3.4). By Lemma 3.7, $T_{u_{j+1}}^{j+1}[u_{j+1}, p_3]$, $T_{v_{j+1}}^{j+1}[v_{j+1}, p_2]$, and $T_{w_{j+1}}^{j+1}[w_{j+1}, p_4]$ are disjoint. If $k = 2$, then we also require that p_3, p_2, p_4 be the vertices q_1, q_2, q_3 , respectively, chosen in Subcase 3.2 of Algorithm Numbering f .
Set $T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$, $T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.
- If v_j has a neighbor in $V(\bar{G}_i)$, then let $x \in N_G(v_j) \cap V(\bar{G}_i)$ with $f(x)$ minimum.
 - If $f(x) > f(u_{j+1})$, then let p_2, p_3 be neighbors of v_j in B_{j+1} such that the paths $T_{v_{j+1}}^{j+1}[v_{j+1}, p_2]$ and $T_{u_{j+1}}^{j+1}[u_{j+1}, p_3]$ are disjoint (they exist by Lemma 3.6).
Set $T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$, $T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$, and $T_4 \leftarrow T_4 + \{v_j, x, v_j x\}$.
 - If $f(x) \leq f(u_{j+1})$, then let p_2, p_4 be neighbors of v_j in B_{j+1} such that the paths $T_{v_{j+1}}^{j+1}[v_{j+1}, p_2]$ and $T_{w_{j+1}}^{j+1}[w_{j+1}, p_4]$ are disjoint (they exist by Lemma 3.6).
Set $T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$, $T_3 \leftarrow T_3 + \{v_j, x, v_j x\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.

Subcase 2.4. B_j and B_{j+1} are 2-connected.

Note that $f(u_j) < f(w_{j+1})$ or $f(u_{j+1}) < f(w_j)$.

- If $f(u_j) < f(w_{j+1})$, then let p_1, p_3 be neighbors of v_j in B_j such that the paths $T_{v_{j-1}}^j[v_{j-1}, p_1]$ and $T_{u_j}^j[u_j, p_3]$ are disjoint (they exist by Lemma 3.6), and let p_2, p_4 be neighbors of v_j in B_{j+1} such that the paths $T_{v_{j+1}}^{j+1}[v_{j+1}, p_2]$ and $T_{w_{j+1}}^{j+1}[w_{j+1}, p_4]$ are disjoint (they exist by Lemma 3.6).
Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}$, $T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$, $T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.
- If $f(u_j) \geq f(w_{j+1})$, then $f(u_{j+1}) < f(w_j)$. Let p_1, p_4 be neighbors of v_j in B_j such that the paths $T_{v_{j-1}}^j[v_{j-1}, p_1]$ and $T_{w_j}^j[w_j, p_4]$ are disjoint (they exist by Lemma 3.6), and let p_2, p_3 be neighbors of v_j in B_{j+1} such that the paths $T_{v_{j+1}}^{j+1}[v_{j+1}, p_2]$ and $T_{u_{j+1}}^{j+1}[u_{j+1}, p_3]$ are disjoint (they exist by Lemma 3.6).
Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}$, $T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$, $T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.

Case 3. $i = t$, or H_i is a down G_{i-1} -chain in G .

Let $H_i := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$, with $v_0 = v_k = r$ when $i = t$, and $f(v_0) < f(v_k)$ when $i \neq t$.

For each 2-connected block B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $g(u_j) < g(w_j)$, and let $T_{v_{j-1}}^j, T_{v_j}^j, T_{u_j}^j, T_{w_j}^j$ denote the trees rooted, respectively, at v_{j-1}, v_j, u_j, w_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5.

Let $J := \{j : 1 \leq j \leq k, B_j \text{ is 2-connected}\}$, and let $\bar{J} := \{1, \dots, k\} - J$.

First, set

$$\begin{aligned} T_1 &\leftarrow T_1 \cup \left(\bigcup_{j \in J} T_{u_j}^j \right), \\ T_2 &\leftarrow T_2 \cup \left(\bigcup_{j \in J} T_{w_j}^j \right), \\ T_3 &\leftarrow T_3 \cup \left(\bigcup_{j \in \bar{J} - \{k\}} B_j \right) \cup \left(\bigcup_{j \in J} T_{v_{j-1}}^j \right), \text{ and} \\ T_4 &\leftarrow T_4 \cup \left(\bigcup_{j \in \bar{J} - \{1\}} B_j \right) \cup \left(\bigcup_{j \in J} T_{v_j}^j \right). \end{aligned}$$

Now for each $j = 1, \dots, k - 1$ add v_j and edges incident to v_j to T_1, T_2, T_3, T_4 according to the following cases (at this stage $v_0, v_k \notin V(T_1 \cup T_2)$).

Subcase 3.1. B_j and B_{j+1} are trivial blocks.

Let p_1, p_2 be neighbors of v_j in $V(G_{i-1})$ with $g(p_1)$ minimum (hence $g(p_1) < g(p_2)$).

Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}$ and $T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$.

Subcase 3.2. B_j is 2-connected and B_{j+1} is trivial.

- If v_j has no neighbor in $V(G_{i-1})$, then let p_1, p_2, p_3 be neighbors of v_j in B_j (they exist since G is 4-connected), and assume that p_1, p_3, p_2 is $(T_{u_j}^j, T_{w_j}^j)$ -ordered (this is possible by Lemma 3.4). By Lemma 3.7, $T_{u_j}^j[u_j, p_1]$, $T_{v_{j-1}}^j[v_{j-1}, p_3]$, and $T_{w_j}^j[w_j, p_2]$ are disjoint. If $k = 2$, then we also require that p_1, p_3, p_2 be the vertices q_1, q_2, q_3 , respectively, chosen in Subcase 3.2 of Algorithm Numbering g .

Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}$, $T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$, and $T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$.

- If v_j has a neighbor in $V(G_{i-1})$, then let $x \in N_G(v_j) \cap V(G_{i-1})$ with $g(x)$ minimum.
 - If $g(x) > g(u_j)$, then let p_1, p_3 be neighbors of v_j in B_j such that the paths $T_{u_j}^j[u_j, p_1]$ and $T_{v_{j-1}}^j[v_{j-1}, p_3]$ are disjoint (they exist by Lemma 3.6). Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}$, $T_2 \leftarrow T_2 + \{v_j, v_j x\}$, and $T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$.
 - If $g(x) \leq g(u_j)$, then let p_2, p_3 be neighbors of v_j in B_j such that the paths $T_{w_j}^j[w_j, p_2]$ and $T_{v_{j-1}}^j[v_{j-1}, p_3]$ are disjoint (they exist by Lemma 3.6). Set $T_1 \leftarrow T_1 + \{v_j, v_j x\}$, $T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$, and $T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$.

Subcase 3.3. B_j is trivial and B_{j+1} is 2-connected.

- If v_j has no neighbor in $V(G_{i-1})$, then let p_1, p_2, p_4 be neighbors of v_j in B_{j+1} (they exist since G is 4-connected), and assume that p_1, p_4, p_2 is $(T_{u_{j+1}}^{j+1}, T_{w_{j+1}}^{j+1})$ -ordered (this is possible by Lemma 3.4). By Lemma 3.7, $T_{u_{j+1}}^{j+1}[u_{j+1}, p_1]$, $T_{v_{j+1}}^{j+1}[v_{j+1}, p_4]$, and $T_{w_{j+1}}^{j+1}[w_{j+1}, p_2]$ are disjoint. If $k = 2$, then

we also require that p_1, p_4, p_2 be the vertices q_1, q_2, q_3 , respectively, chosen in Subcase 3.2 of Algorithm Numbering g .

Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}, T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.

- If v_j has a neighbor in $V(G_{i-1})$, then let $x \in N_G(v_j) \cap V(G_{i-1})$ with $g(x)$ minimum.
 - If $g(x) > g(u_{j+1})$, then let p_1, p_4 be neighbors of v_j in B_{j+1} such that the paths $T_{u_{j+1}}^{j+1}[u_{j+1}, p_1]$ and $T_{v_{j+1}}^{j+1}[v_{j+1}, p_4]$ are disjoint (they exist by Lemma 3.6).
Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}, T_2 \leftarrow T_2 + \{v_j, v_j x\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.
 - If $g(x) \leq g(u_{j+1})$, then let p_2, p_4 be neighbors of v_j in B_{j+1} such that the paths $T_{w_{j+1}}^{j+1}[w_{j+1}, p_2]$ and $T_{v_{j+1}}^{j+1}[v_{j+1}, p_4]$ are disjoint (they exist by Lemma 3.6).
Set $T_1 \leftarrow T_1 + \{v_j, v_j x\}, T_2 \leftarrow T_2 + \{v_j, v_j p_2\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.

Subcase 3.4. B_j and B_{j+1} are 2-connected.

Note that $g(u_j) < g(w_{j+1})$ or $g(u_{j+1}) < g(w_j)$.

- If $g(u_j) < g(w_{j+1})$, then let p_1, p_3 be neighbors of v_j in B_j such that the paths $T_{u_j}^j[u_j, p_1]$ and $T_{v_{j-1}}^j[v_{j-1}, p_3]$ are disjoint (they exist by Lemma 3.6), and let p_2, p_4 be neighbors of v_j in B_{j+1} such that the paths $T_{w_{j+1}}^{j+1}[w_{j+1}, p_2]$ and $T_{v_{j+1}}^{j+1}[v_{j+1}, p_4]$ are disjoint (they exist by Lemma 3.6).
Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}, T_2 \leftarrow T_2 + \{v_j, v_j p_2\}, T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.
- If $g(u_j) \geq g(w_{j+1})$, then $g(u_{j+1}) < g(w_j)$. Let p_2, p_3 be neighbors of v_j in B_j such that the paths $T_{w_j}^j[w_j, p_2]$ and $T_{v_{j-1}}^j[v_{j-1}, p_3]$ are disjoint (they exist by Lemma 3.6), and let p_1, p_4 be neighbors of v_j in B_{j+1} such that the paths $T_{u_{j+1}}^{j+1}[u_{j+1}, p_1]$ and $T_{v_{j+1}}^{j+1}[v_{j+1}, p_4]$ are disjoint (they exist by Lemma 3.6).
Set $T_1 \leftarrow T_1 + \{v_j, v_j p_1\}, T_2 \leftarrow T_2 + \{v_j, v_j p_2\}, T_3 \leftarrow T_3 + \{v_j, v_j p_3\}$, and $T_4 \leftarrow T_4 + \{v_j, v_j p_4\}$.

Case 4. H_i is a triangle G_{i-1} -chain in G .

Let $I(H_i) := \{v_1, v_2, v_3\}$, let $v_j x_j$ ($j = 1, 2, 3$) be the legs of H_i , and let $y_1, y_2, y_3 \in V(\bar{G}_i)$ such that $y_1 v_1, y_2 v_2, y_3 v_3 \in E(G)$. Assume that v_1, v_2, v_3 are labeled so that $g(x_1) < g(x_2) < g(x_3)$.

Update T_1, T_2, T_3, T_4 according to the following four possibilities.

- If $f(y_1) < f(y_2)$ and $f(y_1) < f(y_3)$ then set
 $T_1 \leftarrow T_1 + \{v_1, v_2, v_3, x_1 v_1, x_2 v_2, v_2 v_3\}, T_2 \leftarrow T_2 + \{v_1, v_2, v_3, x_3 v_3, v_3 v_1, v_3 v_2\},$
 $T_3 \leftarrow T_3 + \{v_1, v_2, v_3, y_1 v_1, v_1 v_2, v_1 v_3\}, T_4 \leftarrow T_4 + \{v_1, v_2, v_3, y_2 v_2, v_2 v_1, y_3 v_3\}.$
- If $f(y_2) < f(y_1)$ and $f(y_2) < f(y_3)$ then set
 $T_1 \leftarrow T_1 + \{v_1, v_2, v_3, x_1 v_1, x_2 v_2, v_1 v_3\}, T_2 \leftarrow T_2 + \{v_1, v_2, v_3, x_3 v_3, v_3 v_1, v_3 v_2\},$
 $T_3 \leftarrow T_3 + \{v_1, v_2, v_3, y_2 v_2, v_2 v_1, v_2 v_3\}, T_4 \leftarrow T_4 + \{v_1, v_2, v_3, y_1 v_1, v_1 v_2, y_3 v_3\}.$
- If $f(y_3) < f(y_1) < f(y_2)$ then set
 $T_1 \leftarrow T_1 + \{v_1, v_2, v_3, x_1 v_1, x_2 v_2, v_1 v_3\}, T_2 \leftarrow T_2 + \{v_1, v_2, v_3, x_3 v_3, v_3 v_1, v_3 v_2\},$
 $T_3 \leftarrow T_3 + \{v_1, v_2, v_3, y_1 v_1, v_1 v_2, y_3 v_3\}, T_4 \leftarrow T_4 + \{v_1, v_2, v_3, y_2 v_2, v_2 v_1, v_2 v_3\}.$
- If $f(y_3) < f(y_2) < f(y_1)$ then set
 $T_1 \leftarrow T_1 + \{v_1, v_2, v_3, x_1 v_1, x_2 v_2, v_2 v_3\}, T_2 \leftarrow T_2 + \{v_1, v_2, v_3, x_3 v_3, v_3 v_1, v_3 v_2\},$
 $T_3 \leftarrow T_3 + \{v_1, v_2, v_3, y_2 v_2, v_2 v_1, y_3 v_3\}, T_4 \leftarrow T_4 + \{v_1, v_2, v_3, y_1 v_1, v_1 v_2, v_1 v_3\}.$

6. Correctness of Algorithm Trees. In this section we will prove Theorem 1.1. More precisely, we will show that the subgraphs T_1, T_2, T_3, T_4 returned by Algorithm Trees are independent spanning trees of G rooted at r , and they can be computed in $O(|V(G)|^3)$ time.

Notation 6.1. Let G be a 4-connected graph, let $r \in V(G)$, and let $\mathcal{C} = (H_1, \dots, H_t)$ be a nonseparating chain decomposition of G rooted at r . Let $G_0 = \bar{G}_t = (\{r\}, \emptyset)$, and for $1 \leq i \leq t - 1$, let $G_i := G[\bigcup_{j=1}^i I(H_j)]$ and $\bar{G}_i = G - (V(G_i) - \{r\})$. Let T_1, T_2, T_3, T_4 denote the subgraphs returned by Algorithm Trees. Let D, D' denote the sets of vertices returned by Algorithm Numbering g and Algorithm Numbering f , respectively.

We start with a series of seven simple lemmas which follow from the cases of Algorithm Trees. The first lemma follows immediately by inspecting Case 1 of Algorithm Trees.

LEMMA 6.2. *Let $H_i := v_0B_1v_1B_2v_2$ be an elementary G_{i-1} -chain in G , with $g(v_0) < g(v_2)$. Then v_1 has neighbors v'_0, v'_2 in $V(\bar{G}_i)$, with $f(v'_0) < f(v'_2)$, such that*

- (1) $E(T_1 \cap H_i) = \{v_0v_1\}$ and $E(T_2 \cap H_i) = \{v_1v_2\}$, and
- (2) $E(T_3 \cap H'_i) = \{v'_0v_1\}$ and $E(T_4 \cap H'_i) = \{v_1v'_2\}$, where $H'_i = v'_0B'_1v_1B'_2v'_2$ is an elementary \bar{G}_i -chain in G .

The next lemma follows by inspecting Case 2 (for $i = 1$) of Algorithm Trees.

LEMMA 6.3. *Let $H_1 := v_0B_1v_1 \dots v_{k-1}B_kv_k$, with $v_0 = v_k = r$, and for each 2-connected B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $f(u_j) < f(w_j)$. Let H_1^+ be the graph obtained from H_1 by adding $N_G(H_1 - r) - \{r\}$ and the edges of G from $V(H_1)$ to $N_G(H_1 - r) - \{r\}$. Then*

- (1) $T_1 \cap H_1$ is a spanning tree of H_1 rooted at r and contains no edge from r to $N_{B_k}(r)$,
- (2) $T_2 \cap H_1$ is a spanning tree of H_1 rooted at r and contains no edge from r to $N_{B_1}(r)$,
- (3) $T_3 \cap (H_1^+ - r)$ is a spanning forest of $H_1^+ - r$, and each component of $T_3 \cap (H_1^+ - r)$ either is a tree in $B_j^+ - w_j$ rooted at u_j for some $j \in \{1, \dots, k\}$ or is induced by a single edge with one end in $V(\bar{G}_1)$ and the other in $\{v_1, \dots, v_{k-1}\}$, and
- (4) $T_4 \cap (H_1^+ - r)$ is a spanning forest of $H_1^+ - r$, and each component of $T_4 \cap (H_1^+ - r)$ either is a tree in $B_j^+ - u_j$ rooted at w_j for some $j \in \{1, \dots, k\}$ or is induced by a single edge with one end in $V(\bar{G}_1)$ and the other in $\{v_1, \dots, v_{k-1}\}$.

By inspecting Case 2 (for $i \neq 1$) of Algorithms Trees, we have the following lemma.

LEMMA 6.4. *Let $H_i := v_0B_1v_1 \dots v_{k-1}B_kv_k$ be an up G_{i-1} -chain in G ($2 \leq i \leq t - 1$), with $g(v_0) < g(v_k)$, and for each 2-connected block B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $f(u_j) < f(w_j)$. Let H_i^+ be the graph obtained from H_i by adding $N_G(H_i - \{v_0, v_k\}) - \{v_0, v_k\}$ and the edges of G from $V(H_i)$ to $N_G(H_i - \{v_0, v_k\}) - \{v_0, v_k\}$. Then*

- (1) $T_1 \cap (H_i - v_k)$ is a spanning tree of $H_i - v_k$ rooted at v_0 , and T_1 contains no edge from v_k to $N_{B_k}(v_k)$,
- (2) $T_2 \cap (H_i - v_0)$ is a spanning tree of $H_i - v_0$ rooted at v_k , and T_2 contains no edge from v_0 to $N_{B_1}(v_0)$,
- (3) $T_3 \cap (H_i^+ - \{v_0, v_k\})$ is a spanning forest of $H_i^+ - \{v_0, v_k\}$, and each component of $T_3 \cap (H_i^+ - \{v_0, v_k\})$ either is a tree in $B_j^+ - w_j$ rooted at u_j for some $j \in \{1, \dots, k\}$ or is induced by a single edge with one end in $V(\bar{G}_i)$ and the other in $\{v_1, \dots, v_{k-1}\}$, and
- (4) $T_4 \cap (H_i^+ - \{v_0, v_k\})$ is a spanning forest of $H_i^+ - \{v_0, v_k\}$, and each component of $T_4 \cap (H_i^+ - \{v_0, v_k\})$ either is a tree in $B_j^+ - u_j$ rooted at w_j for some $j \in \{1, \dots, k\}$ or is induced by a single edge with one end in $V(\bar{G}_i)$ and the other in $\{v_1, \dots, v_{k-1}\}$.

By a simple inspection of Case 3 (for $i = t$) of Algorithm Trees, we have the following lemma.

LEMMA 6.5. *Let $H_t := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$, with $v_0 = v_k = r$, and for each 2-connected B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $g(u_j) < g(w_j)$. Let H_t^+ be the graph obtained from H_t by adding $N_G(H_t - r) - \{r\}$ and the edges of G from $V(H_t)$ to $N_G(H_t - r) - \{r\}$. Then*

- (1) $T_1 \cap (H_t^+ - r)$ is a spanning forest of $H_t^+ - r$, and each component of $T_1 \cap (H_t^+ - r)$ either is a tree in $B_j^+ - w_j$ rooted at u_j for some $j \in \{1, \dots, k\}$ or is induced by a single edge with one end in $V(G_{t-1})$ and the other in $\{v_1, \dots, v_{k-1}\}$,
- (2) $T_2 \cap (H_t^+ - r)$ is a spanning forest of $H_t^+ - r$, and each component of $T_2 \cap (H_t^+ - r)$ either is a tree in $B_j^+ - u_j$ rooted at w_j for some $j \in \{1, \dots, k\}$ or is induced by a single edge with one end in $V(G_{t-1})$ and the other in $\{v_1, \dots, v_{k-1}\}$,
- (3) $T_3 \cap H_t$ is a spanning tree of H_t rooted at r and contains no edge from r to $N_{B_k}(r)$, and
- (4) $T_4 \cap H_t$ is a spanning tree of H_t rooted at r and contains no edge from r to $N_{B_1}(r)$.

The next lemma follows from a simple inspection of Case 3 (for $i \neq t$) of Algorithm Trees.

LEMMA 6.6. *Let $H_i := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$ be a down G_{i-1} -chain in G ($2 \leq i \leq t-1$), with $f(v_0) < f(v_k)$, and for each 2-connected block B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $g(u_j) < g(w_j)$. Let H_i^+ be the graph obtained from H_i by adding $N_G(H_i - \{v_0, v_k\}) - \{v_0, v_k\}$ and the edges of G from $V(H_i)$ to $N_G(H_i - \{v_0, v_k\}) - \{v_0, v_k\}$. Then*

- (1) $T_1 \cap (H_i^+ - \{v_0, v_k\})$ is a spanning forest of $H_i^+ - \{v_0, v_k\}$, and each component of $T_1 \cap (H_i^+ - \{v_0, v_k\})$ either is a tree in $B_j^+ - w_j$ rooted at u_j for some $j \in \{1, \dots, k\}$ or is induced by a single edge with one end in $V(G_{i-1})$ and the other in $\{v_1, \dots, v_{k-1}\}$,
- (2) $T_2 \cap (H_i^+ - \{v_0, v_k\})$ is a spanning forest of $H_i^+ - \{v_0, v_k\}$, and each component of $T_2 \cap (H_i^+ - \{v_0, v_k\})$ either is a tree in $B_j^+ - u_j$ rooted at w_j for some $j \in \{1, \dots, k\}$ or is induced by a single edge with one end in $V(G_{i-1})$ and the other in $\{v_1, \dots, v_{k-1}\}$,
- (3) $T_3 \cap (H_i - v_k)$ is a spanning tree of $H_i - v_k$ rooted at v_0 , and T_3 contains no edge from v_k to $N_{B_k}(v_k)$, and
- (4) $T_4 \cap (H_i - v_0)$ is a spanning tree of $H_i - v_0$ rooted at v_k , and T_4 contains no edge from v_0 to $N_{B_1}(v_0)$.

Finally, by a simple inspection of Case 4 of Algorithm Trees, we have the following lemma.

LEMMA 6.7. *Let H_i be a triangle G_{i-1} -chain in G ($2 \leq i \leq t-1$). Let $I(H_i) := \{v_1, v_2, v_3\}$, let $y_1, y_2, y_3 \in V(\bar{G}_i)$ such that $y_1 v_1, y_2 v_2, y_3 v_3 \in E(G)$, and let $v_j x_j$ ($j = 1, 2, 3$) be the legs of H_i , with $g(x_1) < g(x_2) < g(x_3)$. Let $H_i^+ := H_i + \{y_1, y_2, y_3, y_1 v_1, y_2 v_2, y_3 v_3\}$.*

- *If $f(y_1) < f(y_2)$ and $f(y_1) < f(y_3)$, then*
 $E(T_1 \cap H_i^+) = \{x_1 v_1, x_2 v_2, v_2 v_3\}$, $E(T_2 \cap H_i^+) = \{x_3 v_3, v_3 v_1, v_3 v_2\}$,
 $E(T_3 \cap H_i^+) = \{y_1 v_1, v_1 v_2, v_1 v_3\}$, and $E(T_4 \cap H_i^+) = \{y_2 v_2, v_2 v_1, y_3 v_3\}$.
- *If $f(y_2) < f(y_1)$ and $f(y_2) < f(y_3)$, then*
 $E(T_1 \cap H_i^+) = \{x_1 v_1, x_2 v_2, v_1 v_3\}$, $E(T_2 \cap H_i^+) = \{x_3 v_3, v_3 v_1, v_3 v_2\}$,
 $E(T_3 \cap H_i^+) = \{y_2 v_2, v_2 v_1, v_2 v_3\}$, and $E(T_4 \cap H_i^+) = \{y_1 v_1, v_1 v_2, y_3 v_3\}$.

- If $f(y_3) < f(y_1) < f(y_2)$, then
 $E(T_1 \cap H_i^+) = \{x_1v_1, x_2v_2, v_1v_3\}$, $E(T_2 \cap H_i^+) = \{x_3v_3, v_3v_1, v_3v_2\}$,
 $E(T_3 \cap H_i^+) = \{y_1v_1, v_1v_2, y_3v_3\}$, and $E(T_4 \cap H_i^+) = \{y_2v_2, v_2v_1, v_2v_3\}$.
- If $f(y_3) < f(y_2) < f(y_1)$, then
 $E(T_1 \cap H_i^+) = \{x_1v_1, x_2v_2, v_2v_3\}$, $E(T_2 \cap H_i^+) = \{x_3v_3, v_3v_1, v_3v_2\}$,
 $E(T_3 \cap H_i^+) = \{y_2v_2, v_2v_1, y_3v_3\}$, and $E(T_4 \cap H_i^+) = \{y_1v_1, v_1v_2, v_1v_3\}$.

We can now show that T_1, T_2, T_3 , and T_4 are spanning trees of G .

LEMMA 6.8. For every $i = 1, \dots, t$, $T_1 \cap G_i$ and $T_2 \cap G_i$ are spanning trees of G_i .

Proof. Note that every $v \in V(G) - \{r\}$ is an internal vertex of some chain H_i in \mathcal{C} . The result follows by induction on i with the help of (1) of Lemma 6.2, (1) and (2) of Lemma 6.3, (1) and (2) of Lemma 6.4, (1) and (2) of Lemma 6.5, (1) and (2) of Lemma 6.6, and Lemma 6.7. \square

LEMMA 6.9. For every $i = t, \dots, 1$, $T_3 \cap \bar{G}_i$ and $T_4 \cap \bar{G}_i$ are spanning trees of \bar{G}_i .

Proof. The result follows by induction on $t - i$ with the help of (2) of Lemma 6.2, (3) and (4) of Lemma 6.3, (3) and (4) of Lemma 6.4, (3) and (4) of Lemma 6.5, (3) and (4) of Lemma 6.6, and Lemma 6.7. \square

Lemmas 6.8 and 6.9 imply the following.

COROLLARY 6.10. T_1, T_2, T_3, T_4 are spanning trees of G .

Now we proceed to show that T_1, T_2, T_3, T_4 are independent spanning trees of G rooted at r . The proof consists of several lemmas.

LEMMA 6.11. For any $1 \leq i \leq t$ and for any $v \in I(H_i) - \{r\}$, there exist vertices z_1, z_2, z_3, z_4 such that

- (1) $z_1, z_2 \in V(G_{i-1})$, and either $z_1 = z_2 = r$ or $g(z_1) < g(z_2)$ (and $g(z_1) < g(v) < g(z_2)$ if $v \in D$),
- (2) $z_3, z_4 \in V(\bar{G}_i)$, and either $z_3 = z_4 = r$ or $f(z_3) < f(z_4)$ (and $f(z_3) < f(v) < f(z_4)$ if $v \in D'$), and
- (3) $T_i[z_i, v]$, $i = 1, 2, 3, 4$, are internally disjoint paths in G , and $V(T_i[z_i, v]) - z_i \subseteq I(H_i)$.

Proof. Let $1 \leq i \leq t$ and $v \in I(H_i) - \{r\}$. We consider the four cases of Algorithm Trees.

Case 1. H_i is an elementary G_{i-1} -chain in G .

In this case, $2 \leq i \leq t - 1$. Let $H_i := v_0B_1v_1B_2v_2$, with $g(v_0) < g(v_2)$. This is the same as in Case 1 of Algorithm Trees. Then $v_0, v_2 \in V(G_{i-1})$, $v = v_1$, and by Case 1 of Algorithm Numbering g , we have $g(v_0) < g(v_1) < g(v_2)$. By Lemma 6.2, there exist $v'_0, v'_2 \in V(\bar{G}_i)$, with $f(v'_0) < f(v'_2)$, such that $v_0v \in E(T_1)$, $v_2v \in E(T_2)$, $v'_0v \in E(T_3)$, and $v'_2v \in E(T_4)$. By Case 1 of Algorithm Numbering f , $f(v'_0) < f(v_1) < f(v'_2)$. Thus, the result follows by taking $z_1 := v_0$, $z_2 := v_2$, $z_3 := v'_0$, and $z_4 := v'_2$.

Case 2. $i = 1$, or H_i is an up G_{i-1} -chain in G but not an elementary G_{i-1} -chain.

Let $H_i := v_0B_1v_1 \dots v_{k-1}B_kv_k$, with $v_0 = v_k = r$ when $i = 1$, and $g(v_0) < g(v_k)$ when $i \neq 1$. For each 2-connected B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $f(u_j) < f(w_j)$, and let $T_{v_{j-1}}^j, T_{v_j}^j, T_{u_j}^j, T_{w_j}^j$ denote the trees rooted, respectively, at v_{j-1}, v_j, u_j, w_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5. This is the same as in Case 2 of Algorithm Trees.

Let $j \in \{1, \dots, k - 1\}$. If $i = 1$, then by (1) and (2) of Lemma 6.3, $T_1[r, v_j] \subseteq \bigcup_{l=1}^j B_l$ and $T_2[r, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. If $i \neq 1$, then v_j is a cut vertex of H_i , and hence, by (1) and (2) of Lemma 6.4, $T_1[v_0, v_j] \subseteq \bigcup_{l=1}^j B_l$ and $T_2[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$.

First, let us consider the case when $v \neq v_j$ for $j = 1, \dots, k - 1$. Thus, there exists some j , $1 \leq j \leq k$, such that B_j is 2-connected and $v \in V(B_j) - \{v_{j-1}, v_j\}$. By Case 2 of Algorithm Numbering g , we know that $g(v_0) \leq g(v_{j-1}) < g(v_j) \leq$

$g(v_k)$, and if $v \in D$, then $g(v_0) \leq g(v_{j-1}) < g(v) < g(v_j) \leq g(v_k)$. Furthermore, $T_{v_{j-1}}^j[v_{j-1}, v]$, $T_{v_j}^j[v_j, v]$, $T_{u_j}^j[u_j, v]$, and $T_{w_j}^j[w_j, v]$ are internally disjoint, because $\{T_{v_{j-1}}^j, T_{v_j}^j, T_{u_j}^j, T_{w_j}^j\}$ is an independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ . By the construction in Case 2 of Algorithm Trees, $T_1[v_{j-1}, v] = T_{v_{j-1}}^j[v_{j-1}, v]$, $T_2[v_j, v] = T_{v_j}^j[v_j, v]$, $T_3[u_j, v] = T_{u_j}^j[u_j, v]$, and $T_4[w_j, v] = T_{w_j}^j[w_j, v]$. By Case 3 of Algorithm Numbering f , if $v \in D'$, then $f(u_j) < f(v) < f(w_j)$. Moreover, $T_1[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_2[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. Let $z_1 := v_0, z_2 := v_k, z_3 := u_j$, and $z_4 := w_j$. Clearly, (1)–(3) hold.

So assume that $v = v_j$ for some $j, 1 \leq j \leq k-1$. Let $z_1 := v_0$ and $z_2 := v_k$. Then by Case 2 of Algorithm Numbering g , $g(z_1) < g(v) < g(z_2)$. We will define z_3 and z_4 and prove that (1)–(3) hold. We do this by analyzing how Algorithm Trees chooses the neighbors p_3, p_4 of v_j in the trees T_3, T_4 , respectively.

Subcase 2.1. B_j and B_{j+1} are trivial (Subcase 2.1 in Algorithm Trees).

Then Algorithm Trees chooses neighbors p_3, p_4 of v_j in $V(\bar{G}_i)$ with $f(p_3)$ minimum (and hence $f(p_3) < f(p_4)$). If $v_j \in D'$, then by Case 3 of Algorithm Numbering f , we have $f(p_3) < f(v_j) < f(p_4)$. Let $z_3 := p_3$ and $z_4 := p_4$. Clearly, (1)–(3) hold.

Subcase 2.2. B_j is 2-connected and B_{j+1} is trivial (Subcase 2.2 in Algorithm Trees).

- If v_j has no neighbor in $V(\bar{G}_i)$, then Algorithm Trees chooses three neighbors p_1, p_3, p_4 of v_j in B_j such that $T_{v_{j-1}}^j[v_{j-1}, p_1]$, $T_{u_j}^j[u_j, p_3]$, and $T_{w_j}^j[w_j, p_4]$ are disjoint. By construction, $T_1[v_{j-1}, v_j] = T_{v_{j-1}}^j[v_{j-1}, p_1] + \{v_j, v_j p_1\}$, $T_3[u_j, v_j] = T_{u_j}^j[u_j, p_3] + \{v_j, v_j p_3\}$, and $T_4[w_j, v_j] = T_{w_j}^j[w_j, p_4] + \{v_j, v_j p_4\}$. Moreover, $T_1[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_2[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. Therefore, $T_1[v_0, v_j]$, $T_2[v_k, v_j]$, $T_3[u_j, v_j]$, and $T_4[w_j, v_j]$ are internally disjoint. If $v_j \in D'$, then by Case 3 of Algorithm Numbering f , we have $f(u_j) < f(v) < f(w_j)$. Let $z_3 := u_j$ and $z_4 := w_j$. Clearly, (1)–(3) hold.
- If v_j has a neighbor in $V(\bar{G}_i)$, then Algorithm Trees chooses a vertex $x \in N_G(v_j) \cap V(\bar{G}_i)$ with $f(x)$ minimum.
 - If $f(x) > f(u_j)$, then the algorithm chooses neighbors p_1, p_3 of v_j in B_j such that $T_{v_{j-1}}^j[v_{j-1}, p_1]$ and $T_{u_j}^j[u_j, p_3]$ are disjoint. By construction, $T_1[v_{j-1}, v_j] = T_{v_{j-1}}^j[v_{j-1}, p_1] + \{v_j, v_j p_1\}$, $T_3[u_j, v_j] = T_{u_j}^j[u_j, p_3] + \{v_j, v_j p_3\}$, and $T_4[x, v_j]$ is induced by the edge xv_j . Moreover, $T_1[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_2[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. Therefore, $T_1[v_0, v_j]$, $T_2[v_k, v_j]$, $T_3[u_j, v_j]$, and $T_4[x, v_j]$ are internally disjoint. If $v_j \in D'$, then by Case 3 of Algorithm Numbering f , we have $f(u_j) < f(v) < f(x)$. Let $z_3 := u_j$ and $z_4 := x$. Clearly, (1)–(3) hold.
 - If $f(x) \leq f(u_j)$, then Algorithm Trees chooses neighbors p_1, p_4 of v_j in B_j such that $T_{v_{j-1}}^j[v_{j-1}, p_1]$ and $T_{w_j}^j[w_j, p_4]$ are disjoint. By construction, $T_1[v_{j-1}, v_j] = T_{v_{j-1}}^j[v_{j-1}, p_1] + \{v_j, v_j p_1\}$, $T_4[w_j, v_j] = T_{w_j}^j[w_j, p_4] + \{v_j, v_j p_4\}$, and $T_3[x, v_j]$ is induced by the edge xv_j . Moreover, $T_1[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_2[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. Therefore, $T_1[v_0, v_j]$, $T_2[v_k, v_j]$, $T_3[x, v_j]$, and $T_4[w_j, v_j]$ are internally disjoint. If $v_j \in D'$, then by Case 3 of Algorithm Numbering f , we have $f(x) < f(v) < f(w_j)$. Let $z_3 := x$ and $z_4 := w_j$. Clearly, (1)–(3) hold.

Subcase 2.3. B_j is trivial and B_{j+1} is 2-connected (Subcase 2.3 in Algorithm Trees).

In this case, if $v_j \in D'$, then $j = 1$ by Case 3 of Algorithm Numbering f . The arguments for the proof are similar to Subcase 2.2, and we indicate only the choice of

z_3 and z_4 . In each case below, one can show that (1)–(3) hold for the corresponding choice of z_3, z_4 .

- If v_j has no neighbor in $V(\bar{G}_i)$, then let $z_3 := u_{j+1}$ and $z_4 := w_{j+1}$.
- If v_j has a neighbor in $V(\bar{G}_i)$, then Algorithm Trees chooses a vertex $x \in N_G(v_j) \cap V(\bar{G}_i)$ with $f(x)$ minimum.
 - If $f(x) > f(u_{j+1})$, then let $z_3 := u_{j+1}$ and $z_4 := x$.
 - If $f(x) \leq f(u_{j+1})$, then let $z_3 := x$ and $z_4 := w_{j+1}$.

Subcase 2.4. Both B_j and B_{j+1} are 2-connected (Subcase 2.4 in Algorithm Trees).

Since G is 4-connected and $(B_j^+, v_{j-1}, u_j, v_j, w_j)$ and $(B_{j+1}^+, v_j, u_{j+1}, v_{j+1}, w_{j+1})$ are both planar, $v_j \notin N_{B_j}(v_{j-1}) \cup N_{B_{j+1}}(v_{j+1})$. Hence, $v_j \notin D'$ by Case 3 of Algorithm Numbering f . Note that $f(u_j) < f(w_{j+1})$ or $f(u_{j+1}) < f(w_j)$.

- If $f(u_j) < f(w_{j+1})$, then Algorithm Trees chooses neighbors p_1, p_3 of v_j in B_j such that $T_{v_{j-1}}^j[v_{j-1}, p_1], T_{u_j}^j[u_j, p_3]$ are disjoint and neighbors p_2, p_4 of v_j in B_{j+1} such that $T_{v_{j+1}}^j[v_{j+1}, p_2], T_{w_{j+1}}^j[w_{j+1}, p_4]$ are disjoint. By construction, $T_1[v_{j-1}, v_j] = T_{v_{j-1}}^j[v_{j-1}, p_1] + \{v_j, v_j p_1\}$, $T_3[u_j, v_j] = T_{u_j}^j[u_j, p_3] + \{v_j, v_j p_3\}$, $T_2[v_{j+1}, v_j] = T_{v_{j+1}}^{j+1}[v_{j+1}, p_2] + \{v_j, v_j p_2\}$, and $T_4[w_{j+1}, v_j] = T_{w_{j+1}}^{j+1}[w_{j+1}, p_4] + \{v_j, v_j p_4\}$. Moreover, $T_1[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_2[v_k, v_{j+1}] \subseteq \bigcup_{l=j+2}^k B_l$. Thus, $T_1[v_0, v_j], T_2[v_k, v_j], T_3[u_j, v_j]$, and $T_4[w_{j+1}, v_j]$ are internally disjoint. Let $z_3 := u_j$ and $z_4 := w_{j+1}$. Clearly, (1)–(3) hold.
- If $f(u_j) \geq f(w_{j+1})$, then $f(u_{j+1}) < f(w_j)$, and Algorithm Trees chooses neighbors p_1, p_4 of v_j in B_j such that $T_{v_{j-1}}^j[v_{j-1}, p_1]$ and $T_{w_j}^j[w_j, p_4]$ are disjoint and neighbors p_2, p_3 of v_j in B_{j+1} such that $T_{v_{j+1}}^{j+1}[v_{j+1}, p_2]$ and $T_{u_{j+1}}^{j+1}[u_{j+1}, p_3]$ are disjoint. Let $z_3 := u_{j+1}$ and $z_4 := w_j$. One can show as in the above paragraph that $T_1[v_0, v_j], T_2[v_k, v_j], T_3[u_{j+1}, v_j]$, and $T_4[w_j, v_j]$ are internally disjoint and (1)–(3) hold.

Case 3. $i = t$, or H_i is a down G_{i-1} -chain in G but not an elementary G_{i-1} -chain.

Let $H_i := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$, with $v_0 = v_k = r$ when $i = t$, and $f(v_0) < f(v_k)$ when $i \neq t$. For each 2-connected B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $g(u_j) < g(w_j)$, and let $T_{v_{j-1}}^j, T_{v_j}^j, T_{u_j}^j, T_{w_j}^j$ denote the trees rooted, respectively, at v_{j-1}, v_j, u_j, w_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5. This is the same as in Case 3 of Algorithm Trees.

Let $j \in \{1, \dots, k-1\}$. If $i = t$, then by (3) and (4) of Lemma 6.5, $T_3[v_0, v_j] \subseteq \bigcup_{l=1}^j B_l$ and $T_4[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. If $i \neq t$, then v_j is a cut vertex of H_i , and hence, by (3) and (4) of Lemma 6.6, $T_3[v_0, v_j] \subseteq \bigcup_{l=1}^j B_l$ and $T_4[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$.

First, let us consider the case when $v \neq v_j$ for $j = 1, \dots, k-1$. Thus, there exists some j , $1 \leq j \leq k$, such that B_j is 2-connected and $v \in V(B_j) - \{v_{j-1}, v_j\}$. By Case 2 of Algorithm Numbering f , we know that $f(v_0) \leq f(v_{j-1}) < f(v_j) \leq f(v_k)$, and if $v_j \in D'$, then $f(v_0) \leq f(v_{j-1}) < f(v) < f(v_j) \leq f(v_k)$. Furthermore, $T_{v_{j-1}}^j[v_{j-1}, v], T_{v_j}^j[v_j, v], T_{u_j}^j[u_j, v]$, and $T_{w_j}^j[w_j, v]$ are internally disjoint because $\{T_{v_{j-1}}^j, T_{v_j}^j, T_{u_j}^j, T_{w_j}^j\}$ is an independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ . By the construction in Case 3 of Algorithm Trees, $T_1[u_j, v] = T_{u_j}^j[u_j, v]$, $T_2[w_j, v] = T_{w_j}^j[w_j, v]$, $T_3[v_{j-1}, v] = T_{v_{j-1}}^j[v_{j-1}, v]$, and $T_4[v_j, v] = T_{v_j}^j[v_j, v]$. Moreover, $T_3[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_4[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. Let $z_1 := u_j, z_2 := w_j, z_3 := v_0$, and $z_4 := v_k$. Clearly, (1)–(3) hold.

So assume that $v = v_j$ for some j , $1 \leq j \leq k-1$. Let $z_3 := v_0$ and $z_4 := v_k$. By Case 2 of Algorithm Numbering f , we have $f(z_2) < f(v) < f(z_4)$. We will define z_1 and z_2 and prove that (1)–(3) hold. We do this by analyzing how Algorithm Trees chooses the neighbors p_1, p_2 of v_j in the trees T_1, T_2 , respectively.

Subcase 3.1. B_j and B_{j+1} are trivial (Subcase 3.1 in Algorithm Trees).

Then Algorithm Trees chooses neighbors p_1, p_2 of v_j in $V(G_{i-1})$ with $g(p_1)$ minimum (and so $g(p_1) < g(p_2)$). By Subcase 3.3 of Algorithm Numbering g , we have $g(p_1) < g(v) < g(p_2)$. Let $z_1 := p_1$ and $z_2 := p_2$. Clearly, (1)–(3) hold.

Subcase 3.2. B_j is 2-connected and B_{j+1} is trivial (Subcase 3.2 in Algorithm Trees).

- If v_j has no neighbor in $V(G_{i-1})$, then Algorithm Trees chooses three neighbors p_1, p_2, p_3 of v_j in B_j such that $T_{u_j}^j[u_j, p_1]$, $T_{w_j}^j[w_j, p_2]$, and $T_{v_{j-1}}^j[v_{j-1}, p_3]$ are disjoint. By construction, $T_1[u_j, v_j] = T_{u_j}^j[u_j, p_1] + \{v_j, v_j p_1\}$, $T_2[w_j, v_j] = T_{w_j}^j[w_j, p_2] + \{v_j, v_j p_2\}$, and $T_3[v_{j-1}, v_j] = T_{v_{j-1}}^j[v_{j-1}, p_3] + \{v_j, v_j p_3\}$. Moreover, $T_3[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_4[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. Therefore, $T_1[u_j, v_j]$, $T_2[w_j, v_j]$, $T_3[v_0, v_j]$, and $T_4[v_k, v_j]$ are internally disjoint. In this case, if $v_j \in D$, then by Case 3 of Algorithm Numbering g , we have $j = k - 1$ and $g(u_j) < g(v) < g(w_j)$. Let $z_1 := u_j$ and $z_2 := w_j$. Clearly, (1)–(3) hold.
- If v_j has a neighbor in $V(G_{i-1})$, then Algorithm Trees chooses a vertex $x \in N_G(v_j) \cap V(G_{i-1})$ with $g(x)$ minimum.
 - If $g(x) > g(u_j)$, then the algorithm chooses neighbors p_1, p_3 of v_j in B_j such that $T_{u_j}^j[u_j, p_1]$ and $T_{v_{j-1}}^j[v_{j-1}, p_3]$ are disjoint. By construction, $T_1[u_j, v_j] = T_{u_j}^j[u_j, p_1] + \{v_j, v_j p_1\}$, $T_3[v_{j-1}, v_j] = T_{v_{j-1}}^j[v_{j-1}, p_3] + \{v_j, v_j p_3\}$, and $T_2[x, v_j]$ is induced by the edge xv_j . Moreover, $T_3[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_4[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. Therefore, $T_1[u_j, v_j]$, $T_2[x, v_j]$, $T_3[v_0, v_j]$, and $T_4[v_k, v_j]$ are internally disjoint. If $v_j \in D$, then by Case 3 of Algorithm Numbering g , we have $j = k - 1$ and $g(u_j) < g(v) < g(x)$. Let $z_1 := u_j$ and $z_4 := x$. Clearly, (1)–(3) hold.
 - If $g(x) \leq g(u_j)$, then Algorithm Trees chooses neighbors p_2, p_3 of v_j in B_j such that $T_{w_j}^j[w_j, p_2]$ and $T_{v_{j-1}}^j[v_{j-1}, p_3]$ are disjoint. By construction, $T_2[w_j, v_j] = T_{w_j}^j[w_j, p_2] + \{v_j, v_j p_2\}$, $T_3[v_{j-1}, v_j] = T_{v_{j-1}}^j[v_{j-1}, p_3] + \{v_j, v_j p_3\}$, and $T_1[x, v_j]$ is induced by the edge xv_j . Moreover, $T_3[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_4[v_k, v_j] \subseteq \bigcup_{l=j+1}^k B_l$. Therefore, $T_1[x, v_j]$, $T_2[w_j, v_j]$, $T_3[v_0, v_j]$, and $T_4[v_k, v_j]$, are internally disjoint. If $v_j \in D$, then by Case 3 of Algorithm Numbering g , we have $j = k - 1$ and $g(x) < g(v) < g(w_j)$. Let $z_1 := x$ and $z_2 := w_j$. Clearly, (1)–(3) hold.

Subcase 3.3. B_j is trivial and B_{j+1} is 2-connected (Subcase 3.3 in Algorithm Trees).

In this case, if $v_j \in D$, then $j = 1$ by Case 3 of Algorithm Numbering g . The arguments for this case are similar to Subcase 3.2, and we indicate only the choice of z_1 and z_2 . In each case below, one can show that (1)–(3) hold for the corresponding choice of z_1, z_2 .

- If v_j has no neighbor in $V(G_{i-1})$, then let $z_1 := u_{j+1}$ and $z_2 := w_{j+1}$.
- If v_j has a neighbor in $V(G_{i-1})$, then Algorithm Trees chooses a vertex $x \in N_G(v_j) \cap V(G_{i-1})$ with $g(x)$ minimum.
 - If $g(x) > g(u_{j+1})$, then let $z_1 := u_{j+1}$ and $z_2 := x$.
 - If $g(x) \leq g(u_{j+1})$, then let $z_1 := x$ and $z_2 := w_{j+1}$.

Subcase 3.4. B_j and B_{j+1} are 2-connected (Subcase 3.4 in Algorithm Trees).

Since G is 4-connected and $(B_j^+, v_{j-1}, u_j, v_j, w_j)$ and $(B_{j+1}^+, v_j, u_{j+1}, v_{j+1}, w_{j+1})$ are both planar, $v_j \notin N_{B_j}(v_{j-1}) \cup N_{B_{j+1}}(v_{j+1})$. So by Case 3 of Algorithm Numbering g , $v_j \notin D$. Note that $g(u_j) < g(w_{j+1})$ or $g(u_{j+1}) < g(w_j)$.

- If $g(u_j) < g(w_{j+1})$, then Algorithm Trees chooses neighbors p_1, p_3 of v_j in B_j such that $T_{u_j}^j[u_j, p_1]$ and $T_{v_{j-1}}^j[v_{j-1}, p_3]$ are disjoint and neighbors

p_2, p_4 of v_j in B_{j+1} such that $T_{w_{j+1}}^{j+1}[w_{j+1}, p_2]$ and $T_{v_{j+1}}^{j+1}[v_{j+1}, p_4]$ are disjoint. By construction, $T_1[u_j, v_j] = T_{u_j}^j[u_j, p_1] + \{v_j, v_j p_1\}$, $T_3[v_{j-1}, v_j] = T_{v_{j-1}}^j[v_{j-1}, p_3] + \{v_j, v_j p_3\}$, $T_2[w_{j+1}, v_j] = T_{w_{j+1}}^{j+1}[w_{j+1}, p_2] + \{v_j, v_j p_2\}$, and $T_4[v_{j+1}, v_j] = T_{v_{j+1}}^{j+1}[v_{j+1}, p_4] + \{v_j, v_j p_4\}$. Moreover, $T_3[v_0, v_{j-1}] \subseteq \bigcup_{l=1}^{j-1} B_l$ and $T_4[v_k, v_{j+1}] \subseteq \bigcup_{l=j+2}^k B_l$. Thus, $T_1[u_j, v_j], T_2[w_{j+1}, v_j], T_3[v_0, v_j]$, and $T_4[v_k, v_j]$ are internally disjoint. Let $z_1 := u_j$ and $z_2 := w_{j+1}$. Clearly, (1)–(3) hold.

- If $g(u_j) \geq g(w_{j+1})$, then $g(u_{j+1}) < g(w_j)$, and Algorithm Trees chooses neighbors p_2, p_3 of v_j in B_j such that $T_{w_j}^j[w_j, p_2]$ and $T_{v_{j-1}}^j[v_{j-1}, p_3]$ are disjoint and neighbors p_1, p_4 of v_j in B_{j+1} such that $T_{u_{j+1}}^{j+1}[u_{j+1}, p_1]$ and $T_{v_{j+1}}^{j+1}[v_{j+1}, p_4]$ are disjoint. Let $z_1 := u_{j+1}$ and $z_2 := w_j$. One can show as in the above paragraph that $T_1[u_{j+1}, v_j], T_2[w_j, v_j], T_3[v_0, v_j]$, and $T_4[v_k, v_j]$ are internally disjoint and (1)–(3) hold.

Case 4. H_i is a triangle G_{i-1} -chain in G .

Let $I(H_i) := \{v_1, v_2, v_3\}$, let $y_1, y_2, y_3 \in V(\bar{G}_i)$ such that $y_1 v_1, y_2 v_2, y_3 v_3 \in E(G)$, and let $v_j x_j$ ($j = 1, 2, 3$) be the legs of H_i . Assume that v_1, v_2, v_3 are labeled so that $g(x_1) < g(x_2) < g(x_3)$.

The proof can be done by inspecting a small number of cases (Case 4 in Algorithm Trees) and using Lemma 6.7 and Case 4 of Algorithm Numbering g and Algorithm Numbering f . For the sake of completeness, we list for each case the choice for z_1, z_2, z_3 , and z_4 . The verification that they satisfy (1)–(3) is straightforward, and we omit it.

- If $f(y_1) < f(y_2)$ and $f(y_1) < f(y_3)$, then let $z_2 := x_3$ and $z_3 := y_1$.
 If $v = v_1$, then let $z_1 := x_1$ and $z_4 := y_2$.
 If $v = v_2$, then let $z_1 := x_2$ and $z_4 := y_2$.
 If $v = v_3$, then let $z_1 := x_2$ and $z_4 := y_3$.
- If $f(y_2) < f(y_1)$ and $f(y_2) < f(y_3)$, then let $z_2 := x_3$ and $z_3 := y_2$.
 If $v = v_1$, then let $z_1 := x_1$ and $z_4 := y_1$.
 If $v = v_2$, then let $z_1 := x_2$ and $z_4 := y_1$.
 If $v = v_3$, then let $z_1 := x_1$ and $z_4 := y_3$.
- If $f(y_3) < f(y_1) < f(y_2)$, then let $z_2 := x_3$ and $z_4 := y_2$.
 If $v = v_1$, then let $z_1 := x_1$ and $z_3 := y_1$.
 If $v = v_2$, then let $z_1 := x_2$ and $z_3 := y_1$.
 If $v = v_3$, then let $z_1 := x_1$ and $z_3 := y_3$.
- If $f(y_3) < f(y_2) < f(y_1)$, then let $z_2 := x_3$ and $z_4 := y_1$.
 If $v = v_1$, then let $z_1 := x_1$ and $z_3 := y_2$.
 If $v = v_2$, then let $z_1 := x_2$ and $z_3 := y_2$.
 If $v = v_3$, then let $z_1 := x_2$ and $z_3 := y_3$.

This completes the proof of Lemma 6.11. \square

LEMMA 6.12. Let $i \in \{1, \dots, t - 1\}$. Then for any $u, v \in D_i$, with $g(u) < g(v)$, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

Proof. We will prove the lemma by induction on i . The basis of induction is $i = 0$ with $D_0 := \{r\}$ and $G_0 := (\{r\}, \emptyset)$. So assume that $i > 0$ and the lemma holds for $i - 1$. We consider the four cases of Algorithm Numbering g .

Case 1. H_i is an elementary G_{i-1} -chain in G .

Let $H_i := v_0 B_1 v_1 B_2 v_2$, with $g(v_0) < g(v_2)$. By (1) of Lemma 6.2, $E(T_1 \cap H_i) = \{v_0 v_1\}$ and $E(T_2 \cap H_i) = \{v_1 v_2\}$. Recall that $D_i = D_{i-1} \cup \{v_1\}$.

If $u, v \in D_{i-1}$ and $g(u) < g(v)$, then by the induction hypothesis, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_{i-1} . Thus, it suffices to prove the following:

for any $u, v \in D_i$, with $g(u) < g(v)$ and $v_1 \in \{u, v\}$, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

Assume first that $u = v_1$. Then $v = v \in D_{i-1}$. Since $g(v_0) < g(v_1) < g(v)$, it follows from the induction hypothesis that $T_1[r, v_0]$ and $T_2[r, v]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, v_1] = T_1[r, v_0] + \{v_1, v_1v_0\}$ and $T_2[r, v]$ are internally disjoint paths in G_i .

Now suppose $v = v_1$. Then $u \in D_{i-1}$. Since $g(u) < g(v_1) < g(v_2)$, it follows from the induction hypothesis that $T_1[r, u]$ and $T_2[r, v_2]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v_1] = T_2[r, v_2] + \{v_1, v_1v_2\}$ are internally disjoint paths in G_i .

Case 2. $i = 1$, or H_i is an up G_{i-1} -chain in G but not an elementary G_{i-1} -chain in G .

Let $H_i := v_0B_1v_1 \dots v_{k-1}B_kv_k$, with $v_0 = v_k = r$ when $i = 1$, and $g(v_0) < g(v_k)$ when $i \neq 1$. For each 2-connected B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $f(u_j) < f(w_j)$, and let $T_{v_{j-1}}^j, T_{v_j}^j, T_{u_j}^j, T_{w_j}^j$ denote the trees rooted, respectively, at v_{j-1}, v_j, u_j, w_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5. This is the same as in Case 2 of Algorithm Trees. Let $u, v \in D_i$ with $g(u) < g(v)$.

If $u, v \in D_{i-1}$, then by the induction hypothesis, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_{i-1} .

If $u \in D_i - D_{i-1}$ and $v \in D_{i-1}$, then by the construction in Case 2 of Algorithm Numbering g , $g(v_0) < g(u) < g(v)$. By the induction hypothesis, $T_1[r, v_0]$ and $T_2[r, v]$ are internally disjoint paths in G_{i-1} . Since $T_1[v_0, u]$ is a path in $H_i - v_k$ by (1) of Lemma 6.3 when $i = 1$, or by (1) of Lemma 6.4 when $i \neq 1$, $T_1[r, v]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

If $u \in D_{i-1}$ and $v \in D_i - D_{i-1}$, then by the construction in Case 2 of Algorithm Numbering g , $g(u) < g(v) < g(v_k)$. By the induction hypothesis, $T_1[r, u]$ and $T_2[r, v_k]$ are internally disjoint paths in G_{i-1} . Since $T_2[v_k, v]$ is a path in $H_i - v_0$ by (2) of Lemma 6.3 when $i = 1$, or by (2) of Lemma 6.4 when $i \neq 1$, $T_1[r, v]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

So we may assume that $u, v \in D_i - D_{i-1}$. Let g^i denote the function g at the start of iteration i of Algorithm Numbering g (when it examines H_i in Case 2). Recall that for each $j = 1, \dots, k$ the algorithm computes a sequence σ_j as follows. If B_j is 2 connected, then σ_j is a $(T_{v_{j-1}}^j, T_{v_j}^j)$ -ordering of $N_{B_j^+}(\{u_j, w_j\}) - \{v_{j-1}, v_j\}$. If B_j is trivial, then σ_j is the empty sequence. Moreover, the algorithm extends g^i to $\sigma := \sigma_1, v_1, \sigma_2, \dots, v_{k-1}, \sigma_k$ from v_0 and set $D_i := D_{i-1} \cup \{\sigma\}$. Thus, $u, v \in \{\sigma\}$. Note that since $g(u) < g(v)$, u precedes v in the sequence σ .

First, suppose that there exists no $j \in \{1, \dots, k-1\}$ such that $u, v \in \{\sigma_j\}$. Hence, there is some $j \in \{1, \dots, k-1\}$ such that either

- u appears in the sequence $\sigma_1, v_1, \dots, \sigma_j, v_j$ and v appears in the sequence $\sigma_{j+1}, v_{j+1}, \dots, v_{k-1}, \sigma_k$ or
- u appears in the sequence $\sigma_1, v_1, \dots, \sigma_j$ and v appears in the sequence $v_j, \sigma_{j+1}, v_{j+1}, \dots, v_{k-1}, \sigma_k$.

By (1) and (2) of Lemma 6.3 when $i = 1$ or by (1) and (2) of Lemma 6.4 when $i \neq 1$, $T_1[v_0, u]$ and $T_2[v_k, v]$ are internally disjoint paths in H_i , and by the induction hypothesis, $T_1[r, v_0]$ and $T_2[r, v_k]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

So, we may assume that there exists some $j \in \{1, \dots, k-1\}$ such that u, v are in the sequence σ_j . Since the sequence σ_j is $(T_{v_{j-1}}^j, T_{v_j}^j)$ -ordered and u precedes v in

$\sigma_j, T_{v_{j-1}}^j[v_{j-1}, u]$ and $T_{v_j}^j[v_j, v]$ are disjoint. By the construction in Algorithm Trees, $T_1[v_{j-1}, u] = T_{v_{j-1}}^j[v_{j-1}, u]$ and $T_2[v_j, v] = T_{v_j}^j[v_j, v]$. By (1) and (2) of Lemma 6.3 when $i = 1$, or by (1) and (2) of Lemma 6.4 when $i \neq 1$, $T_1[v_0, v_{j-1}]$ and $T_2[v_k, v_j]$ are internally disjoint paths in H_i . Moreover, by the induction hypothesis, $T_1[r, v_0]$ and $T_2[r, v_k]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

Case 3. $i = t$, or H_i is a down G_{i-1} -chain in G but not an elementary G_{i-1} -chain in G .

Let $H_i := v_0 B_1 v_1 \dots v_{k-1} B_k v_k$, with $v_0 = v_k = r$ when $i = t$, and $f(v_0) < f(v_k)$ when $i \neq t$. For each 2-connected B_j , let u_j, w_j denote the terminals of B_j^+ other than v_{j-1}, v_j , with $g(u_j) < g(w_j)$, and let $T_{v_{j-1}}^j, T_{v_j}^j, T_{u_j}^j, T_{w_j}^j$ denote the trees rooted, respectively, at v_{j-1}, v_j, u_j, w_j in the independent spanning $\{v_{j-1}, v_j, u_j, w_j\}$ -system of B_j^+ computed in Assumption 4.5. This is the same as in Case 3 of Algorithm Trees. Let $u, v \in D_i$ with $g(u) < g(v)$. Recall that $D_i = D_{i-1} \cup N_{B_1}(v_0) \cup N_{B_k}(v_k)$.

If $u, v \in D_{i-1}$, then by the induction hypothesis, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in $G_{i-1} \subset G_i$.

If $u \in D_i - D_{i-1}$ and $v \in D_{i-1}$, then $u \in N_{B_1}(v_0) \cup N_{B_k}(v_k)$. By (1) and (3) of Lemma 6.11, there exists $z_1 \in V(G_{i-1})$ such that $g(z_1) < g(u)$ and $V(T_1[z_1, u] - z_1) \subseteq I(H_i)$. Since $z_1, v \in D_{i-1}$ and $g(z_1) < g(u) < g(v)$, it follows from the induction hypothesis that $T_1[r, z_1]$ and $T_2[r, v]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

If $u \in D_{i-1}$ and $v \in D_i - D_{i-1}$, then $v \in N_{B_1}(v_0) \cup N_{B_k}(v_k)$. By (1) and (3) of Lemma 6.11, there exists $z_2 \in V(G_{i-1})$ such that $g(v) < g(z_2)$ and $V(T_2[z_2, v] - z_2) \subseteq I(H_i)$. Since $z_2, u \in D_{i-1}$ and $g(u) < g(v) < g(z_2)$, it follows from the induction hypothesis that $T_1[r, u]$ and $T_2[r, z_2]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

So, we need only to prove the case when $u, v \in D_i - D_{i-1}$. Let g^i denote the function g at the start of iteration i of Algorithm Numbering g (when it examines H_i in Case 3). Now we consider the three subcases of Case 3 of Algorithm Numbering g .

Subcase 3.1. $k = 1$ (thus, B_1 is 2-connected).

Since $(B_1^+, v_0, u_1, v_1, w_1)$ is planar and G is 4-connected, $v_0, v_1 \notin N_{B_1}(v_0) \cup N_{B_1}(v_1)$. Hence, in this case, $D_i - D_{i-1} = N_{B_1^+}(\{v_0, v_1\}) - \{u_1, w_1\} = N_{B_1}(v_0) \cup N_{B_1}(v_1)$. Moreover, Algorithm Numbering g produces a $(T_{u_1}^1, T_{w_1}^1)$ -ordering σ of $N_{B_1^+}(\{v_0, v_1\}) - \{u_1, w_1\}$ and extends g^i to σ from u_1 .

Let $u, v \in D_i - D_{i-1}$, with $g(u) < g(v)$. Then both u and v are in the sequence σ , and u precedes v in σ . Since σ is $(T_{u_1}^1, T_{w_1}^1)$ -ordered, $T_{u_1}^1[u_1, u]$ and $T_{w_1}^1[w_1, v]$ are disjoint. By the construction in Case 3 of Algorithm Trees, $T_1[u_1, u] = T_{u_1}^1[u_1, u]$ and $T_2[w_1, v] = T_{w_1}^1[w_1, v]$. By the induction hypothesis, $T_1[r, u_1]$ and $T_2[r, w_1]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

Subcase 3.2. $k = 2$, and B_1 or B_2 is trivial.

By symmetry we assume that B_2 is trivial (the arguments are analogous if B_1 is trivial). Note that B_1 is 2-connected because H_i is not an elementary G_{i-1} -chain in G . Thus, $D_i - D_{i-1} = N_{B_1}(v_0) \cup \{v_1\}$.

- If v_1 has no neighbor in $V(G_{i-1})$, then Algorithm Numbering g chooses neighbors q_1, q_2, q_3 of v_1 in B_1 such that $T_{u_1}^1[u_1, q_1], T_{v_0}^1[v_0, q_2]$, and $T_{w_1}^1[w_1, q_3]$ are disjoint and then computes a $(T_{u_1}^1 + \{v_1, v_1 q_1\}, T_{w_1}^1 + \{v_1, v_1 q_3\})$ -ordering σ of $N_{B_1}(v_0) \cup \{v_1\}$ in $B_1^+ \cup B_2$ (recall that $(B_1^+ \cup B_2, v_0, u_1, v_2, w_1)$ is planar). Then Algorithm Numbering g extends g^i to σ from u_1 .

Let $u, v \in D_i - D_{i-1}$, with $g(u) < g(v)$. Then both u and v are in the sequence σ , and u precedes v in σ .

Let us consider first the case when $u \neq v_1$ and $v \neq v_1$. Thus, $u, v \in N_{B_1}(v_0)$. Since σ is $(T_{u_1}^1 + \{v_1, v_1q_1\}, T_{w_1}^1 + \{v_1, v_1q_3\})$ -ordered and u precedes v in σ , $T_{u_1}^1[u_1, u]$ and $T_{w_1}^1[w_1, v]$ are disjoint. By construction (Case 3 of Algorithm Trees), $T_1[u_1, u] = T_{u_1}^1[u_1, u]$ and $T_2[w_1, v] = T_{w_1}^1[w_1, v]$. By the induction hypothesis, $T_1[r, u_1]$ and $T_2[r, w_1]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

Now suppose that $u = v_1$. Since σ is $(T_{u_1}^1 + \{v_1, v_1q_1\}, T_{w_1}^1 + \{v_1, v_1q_3\})$ -ordered and u precedes v in σ , $T_{u_1}^1[u_1, q_1] + \{v_1, v_1q_1\}$ and $T_{w_1}^1[w_1, v]$ are disjoint. By construction (Case 3 of Algorithm Trees), $T_1[u_1, v_1] = T_{u_1}^1[u_1, q_1] + \{v_1, v_1q_1\}$ and $T_2[w_1, v] = T_{w_1}^1[w_1, v]$. By the induction hypothesis, $T_1[r, u_1]$ and $T_2[r, w_1]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

So assume $v = v_1$. Since σ is $(T_{u_1}^1 + \{v_1, v_1q_1\}, T_{w_1}^1 + \{v_1, v_1q_3\})$ -ordered and u precedes v in σ , $T_{u_1}^1[u_1, u]$ and $T_{w_1}^1[w_1, q_3] + \{v_1, v_1q_3\}$ are disjoint. By construction (Case 3 of Algorithm Trees), $T_1[u_1, u] = T_{u_1}^1[u_1, u]$ and $T_2[w_1, v_1] = T_{w_1}^1[w_1, q_3] + \{v_1, v_1q_3\}$. By the induction hypothesis, $T_1[r, u_1]$ and $T_2[r, w_1]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

- If v_1 has a neighbor in $V(G_{i-1})$, then Algorithm Numbering g chooses a vertex $x \in (N_G(v_1) \cap V(G_{i-1}))$ with $g^i(x)$ minimum and computes a $(T_{u_1}^1, T_{w_1}^1)$ -ordering σ of $N_{B_1^+}(v_0) - \{u_1, w_1\}$.

Let $u, v \in D_i - D_{i-1}$, with $g(u) < g(v)$.

Let us consider first the case when $u \neq v_1$ and $v \neq v_1$. Then both u and v are in σ , and u precedes v in σ . Since σ is $(T_{u_1}^1, T_{w_1}^1)$ -ordered and u precedes v in σ , $T_{u_1}^1[u_1, u]$ and $T_{w_1}^1[w_1, v]$ are disjoint. By construction (Case 3 of Algorithm Trees), $T_1[u_1, u] = T_{u_1}^1[u_1, u]$ and $T_2[w_1, v] = T_{w_1}^1[w_1, v]$. By the induction hypothesis, $T_1[r, u_1]$ and $T_2[r, w_1]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

Now suppose that $u = v_1$. Thus, v is in the sequence σ . Recall how Algorithm Numbering g extends g^i in Subcase 3.2 of Algorithm Numbering g .

If $g(x) > g(u_1)$, then $g^i(x) > g^i(u_1)$, and Algorithm Numbering g extends g^i to σ, v_1 from u_1 . But then $g(v) < g(v_1) = g(u)$, contradicting the assumption that $g(u) < g(v)$.

If $g(x) \leq g(u_1)$, then $g^i(x) \leq g^i(u_1)$, and Algorithm Numbering g extends g^i to v_1, σ from x . By construction (Subcase 3.2 of Algorithm Trees with $j = 1$), $xv_1 \in E(T_1)$ and $T_2[w_1, v] = T_{w_1}^1[w_1, v]$. Since $g(x) < g(w_1)$, by the induction hypothesis, $T_1[r, x]$ and $T_2[r, w_1]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, v_1]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

The case $v = v_1$ can be treated analogously ($g(x) \leq g(u_1)$ cannot occur).

Subcase 3.3. $k \geq 3$, or $k = 2$ and both B_1, B_2 are 2-connected.

In this case, $D_i - D_{i-1} = N_{B_1}(v_0) \cup N_{B_k}(v_k)$. Let $u, v \in D_i - D_{i-1}$ with $g(u) < g(v)$.

Let us consider first the case when $u, v \in N_{B_1}(v_0)$. Thus, B_1 is 2-connected, and Algorithm Numbering g (Subcase 3.3) computes a $(T_{u_1}^1, T_{w_1}^1)$ -ordering σ of $N_{B_1^+}(v_0) - \{u_1, w_1\} = N_{B_1}(v_0)$ and extends g^i to σ from u_1 . Thus, $g(u_1) < g(u) < g(v)$. Since σ is $(T_{u_1}^1, T_{w_1}^1)$ -ordered and u precedes v in σ , $T_{u_1}^1[u_1, u]$ and $T_{w_1}^1[w_1, v]$ are disjoint. By construction (Case 3 of Algorithm trees), $T_1[u_1, u] = T_{u_1}^1[u_1, u]$ and

$T_2[w_1, v] = T_{w_1}^1[w_1, v]$. Since $g(u_1) < g(w_1)$ and by the induction hypothesis, $T_1[r, u_1]$ and $T_2[r, w_1]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

Suppose, now, that $u, v \in N_{B_k}(v_k)$. Then B_k is 2-connected, and Algorithm Numbering g (Subcase 3.3) computes a $(T_{u_k}^k, T_{w_k}^k)$ -ordering of $N_{B_k^+}(v_k) - \{u_k, w_k\} = N_{B_k}(v_k)$ and extends g^i to σ from u_k . Thus, $g(u_k) < g(u) < g(v)$. Since σ is $(T_{u_k}^k, T_{w_k}^k)$ -ordered and u precedes v in σ , $T_{u_k}^k[u_k, u]$ and $T_{w_k}^k[w_k, v]$ are disjoint. By construction (Case 3 of Algorithm Trees), $T_1[u_k, u] = T_{u_k}^k[u_k, u]$ and $T_2[w_k, v] = T_{w_k}^k[w_k, v]$. Since $g(u_k) < g(w_k)$ and by the induction hypothesis, $T_1[r, u_k]$ and $T_2[r, w_k]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

So we may assume that $u \in N_{B_1}(v_0)$ and $v \in N_{B_k}(v_k)$, or $u \in N_{B_k}(v_k)$ and $v \in N_{B_1}(v_0)$. By symmetry, assume that $u \in N_{B_1}(v_0)$ and $v \in N_{B_k}(v_k)$. We will prove that there exist vertices $z_1, z_2 \in V(G_{i-1})$, with $g(z_1) < g(z_2)$, such that $T_1[z_1, u]$ and $T_2[z_2, v]$ are internally disjoint paths in G , $V(T_1[z_1, u] - z_1) \subseteq I(H_i)$, and $V(T_2[z_2, v] - z_2) \subseteq I(H_i)$.

Consider the following cases for u and B_1 .

- B_1 is 2-connected. Then, by construction in Algorithm Trees, $T_1[u_1, u] = T_{u_1}^1[u_1, u]$, and let $z_1 := u_1$.
- B_1 is trivial. Thus, $u = v_1$. If B_2 is trivial, then by construction in Subcase 3.1 of Algorithm Trees (with $j = 1$), there exists a neighbor p_1 of v_1 in $V(G_{i-1})$ such that $g(p_1)$ is minimum and $p_1v_1 \in E(T_1)$. In this case, let $z_1 := p_1$.

So assume that B_2 is 2-connected.

- If v_1 has no neighbor in $V(G_{i-1})$, then by construction in Subcase 3.3 (with $j = 1$) of Algorithm Trees, there exists a neighbor p_1 of v_1 in B_2 such that $T_1[u_2, v_1] = T_{u_2}^2[u_2, p_1] + \{v_1, v_1p_1\}$. In this case, let $z_1 := u_2$.
- If v_1 has a neighbor in $V(G_{i-1})$, then Algorithm Trees in Subcase 3.3 (with $j = 1$) chooses $x \in N_G(v_1) \cap V(G_{i-1})$ with $g(x)$ minimum. If $g(x) > g(u_2)$, then by construction there exists a neighbor p_1 of v_1 in B_2 such that $T_1[u_2, v_1] = T_{u_2}^2[u_2, p_1] + \{v_1, v_1p_1\}$. In this case, let $z_1 := u_2$. If $g(x) \leq g(u_2)$, then $xv_1 \in E(T_1)$. In this case, let $z_1 := x$.

Consider the analogous cases for v and B_k .

- B_k is 2-connected. Then by construction in Algorithm Trees, $T_2[w_k, v] = T_{w_k}^k[w_k, v]$, and let $z_2 := w_k$.
- B_k is trivial. Thus, $v = v_{k-1}$. If B_{k-1} is trivial, then by construction in Subcase 3.1 of Algorithm Trees (with $j = k - 1$), there exists a neighbor p_2 of v_{k-1} in $V(G_{i-1})$ such that $g(p_2)$ is not minimum and $p_2v_{k-1} \in E(T_2)$. In this case, let $z_2 := p_2$.

So assume that B_{k-1} is 2-connected.

- If v_{k-1} has no neighbor in $V(G_{i-1})$, then by construction in Subcase 3.2 (with $j = k - 1$) of Algorithm Trees, there exists a neighbor p_2 of v_{k-1} in B_{k-1} such that $T_2[w_{k-1}, v_{k-1}] = T_{w_{k-1}}^{k-1}[w_{k-1}, p_2] + \{v_{k-1}, v_{k-1}p_2\}$. In this case, let $z_2 := w_{k-1}$.
- If v_{k-1} has a neighbor in $V(G_{i-1})$, then Algorithm Trees in Subcase 3.2 chooses $x \in N_G(v_{k-1}) \cap V(G_{i-1})$ with $g(x)$ minimum. If $g(x) > g(u_{k-1})$, then $xv_{k-1} \in E(T_2)$. In this case, let $z_2 := x$. If $g(x) \leq g(u_{k-1})$, then by construction there exists a neighbor p_2 of v_{k-1} in B_{k-1} such that $T_2[w_{k-1}, v_{k-1}] = T_{w_{k-1}}^{k-1}[w_{k-1}, p_2] + \{v_{k-1}, v_{k-1}p_2\}$. In this case, let $z_2 := w_{k-1}$ (this is the same as in the previous paragraph).

So $T_1[z_1, u]$ either is contained in B_1^+ , or is contained in B_2^+ , or is induced by a single edge. Hence, $g(z_1) < g(u)$. Similarly, $T_2[z_2, v]$ either is contained in B_k^+ , or is contained in B_{k-1}^+ , or is induced by a single edge. So $g(v) < g(z_2)$. Since $g(u) < g(v)$, $g(z_1) < g(z_2)$.

Note that if $k = 3$, B_2 is 2-connected, and both paths $T_1[z_1, u]$ and $T_2[z_2, v]$ are contained in B_2^+ , then $u = v_1, v = v_2 = v_{k-1}, T_1[u_2, u] = T_{u_2}^2[u_2, p_1] + \{v_1, v_1 p_1\}$ for some neighbor p_1 of v_1 in B_2 , and $T_2[w_2, v] = T_{w_2}^2[w_2, p_2] + \{v_2, v_2 p_2\}$ for some neighbor p_2 of v_2 in B_2 . In this case, since u, v are $(T_{u_2}^2, T_{w_2}^2)$ -ordered, $T_1[u_2, u]$ and $T_2[w_2, v]$ are disjoint.

Therefore, since $k \geq 3$, it is not hard to see that $T_1[z_1, u]$ and $T_2[z_2, v]$ are disjoint paths in $G, V(T_1[z_1, u] - z_1) \subseteq I(H_i)$, and $V(T_2[z_2, v] - z_2) \subset I(H_i)$.

Since $g(z_1) < g(z_2)$, by the induction hypothesis, $T_1[r, z_1]$ and $T_2[r, z_2]$ are internally disjoint paths in G_{i-1} . Therefore, $T_1[r, u]$ and $T_2[r, v]$ are internally disjoint paths in G_i .

Case 4. H_i is a triangle G_{i-1} -chain in G .

By Algorithm Numbering $g, D_i - D_{i-1} = \{v_1, v_2, v_3\}$ and $g(v_1) < g(v_2) < g(v_3)$. Thus, it suffices to show that the following pairs are internally disjoint: $T_1[r, v_1]$ and $T_2[r, v_2], T_1[r, v_2]$ and $T_2[r, v_3],$ and $T_1[r, v_1]$ and $T_2[r, v_3]$. This can be done by inspecting Case 4 of Algorithm Trees. \square

Recall that Algorithm Numbering f with input $\mathcal{C} := (H_1, \dots, H_t)$ computes a numbering f and sets $D'_{t+1}, D'_t, D'_{t-1}, \dots, D'_2$. The next lemma can be proved, analogously to Lemma 6.12. We give only some detail for Case 4, as f and g are not symmetric in that case.

LEMMA 6.13. *Let $i \in \{1, \dots, t\}$. Then for any $u, v \in D'_i$ with $f(u) < f(v)$, $T_3[r, u]$ and $T_4[r, v]$ are internally disjoint paths in \bar{G}_i .*

Proof. We use the notation in the proof of Lemma 6.12 and assume H_i is a triangle G_{i-1} -chain in G . By inspecting Case 4 of Algorithm Numbering f and Algorithm Trees, we have the following.

- If $f(y_1) < f(y_2)$ and $f(y_1) < f(y_3)$, then $f(v_1) < f(v_2) < f(v_3)$. So we can show that $T_3[r, v_1]$ and $T_4[r, v_2]$ are internally disjoint, $T_3[r, v_1]$ and $T_4[r, v_3]$ are internally disjoint, and $T_3[r, v_2]$ and $T_4[r, v_3]$ are internally disjoint.
- If $f(y_2) < f(y_1)$ and $f(y_2) < f(y_3)$, then $f(v_2) < f(v_1) < f(v_3)$. So we can show that $T_3[r, v_2]$ and $T_4[r, v_1]$ are internally disjoint, $T_3[r, v_2]$ and $T_4[r, v_3]$ are internally disjoint, and $T_3[r, v_1]$ and $T_4[r, v_3]$ are internally disjoint.
- If $f(y_3) < f(y_1) < f(y_2)$, then $f(v_3) < f(v_1) < f(v_2)$. So we can show that $T_3[r, v_3]$ and $T_4[r, v_1]$ are internally disjoint, $T_3[r, v_3]$ and $T_4[r, v_2]$ are internally disjoint, and $T_3[r, v_1]$ and $T_4[r, v_2]$ are internally disjoint.
- If $f(y_3) < f(y_2) < f(y_1)$, then $f(v_3) < f(v_2) < f(v_1)$. So we can show that $T_3[r, v_3]$ and $T_4[r, v_2]$ are internally disjoint, $T_3[r, v_3]$ and $T_4[r, v_1]$ are internally disjoint, and $T_3[r, v_2]$ and $T_4[r, v_1]$ are internally disjoint. \square

THEOREM 6.14. *Given a 4-connected graph $G, r \in V(G)$, and a nonseparating chain decomposition $\mathcal{C} := (H_1, \dots, H_t)$ of G rooted at r , Algorithm Trees computes four independent spanning trees rooted at r .*

Proof. By Corollary 6.10, T_1, T_2, T_3, T_4 are spanning trees of G . Let us prove that they are independent with r as root. Let $v \in V(G) - \{r\}$. Suppose that v is an internal vertex of a good chain H_i in the decomposition \mathcal{C} . By Lemma 6.11 there exist $z_1, z_2, z_3, z_4 \in V(G)$ such that

- (i) $z_1, z_2 \in V(G_{i-1})$, and either $g(z_1) < g(z_2)$ or $z_1 = z_2 = r$,
- (ii) $z_3, z_4 \in V(\bar{G}_i)$, and either $f(z_3) < f(z_4)$ or $z_3 = z_4 = r$, and

- (iii) $T_i[z_i, v]$, $i = 1, 2, 3, 4$, are internally disjoint paths and $V(T_i[z_i, v] - z_i) \subseteq I(H_i)$.

By Lemma 6.12, if $g(z_1) < g(z_2)$, then $T_1[r, z_1]$ and $T_2[r, z_2]$ are internally disjoint paths in G_{i-1} . Obviously, the same holds if $z_1 = z_2 = r$. Similarly, by Lemma 6.13, if $f(z_3) < f(z_4)$, then $T_3[r, z_3]$ and $T_4[r, z_4]$ are internally disjoint paths in \bar{G}_i , and the same holds if $z_3 = z_4 = r$. Therefore, $T_1[r, v], T_2[r, v], T_3[r, v]$, and $T_4[r, v]$ are internally disjoint. Hence, T_1, T_2, T_3 , and T_4 are independent spanning trees of G rooted at r . \square

LEMMA 6.15. *Algorithm Trees runs in $O(|V(G)|^3)$ time.*

Proof. By Lemmas 4.6 and 4.7, given \mathcal{C} we can compute numberings g and f in $O(|V(G)|^3)$ time. By Theorem 3.2 we can compute independent spanning systems for all planar sections in \mathcal{C} in $O(|V(G)| + |E(G)|)$ time.

We will show that at each iteration the time spent by Algorithm Trees is $O(|V(G)|^2)$ time. Since the number of iterations is at most $|V(G)|$, this implies the result.

Suppose we are at iteration i of Algorithm Trees.

One can see easily that if Case 1 or Case 4 occurs, then Algorithm Trees uses constant time. Thus, we may assume that Case 2 or Case 3 occurs.

Suppose that Case 2 occurs. The initial updating of T_1, T_2, T_3, T_4 (before Subcases 2.1–2.4 are dealt with) can be done in $O(|V(G)|)$ time. Then for each $j \in \{1, \dots, k\}$ the algorithm inserts v_j into the subgraphs T_1, T_2, T_3, T_4 according to Subcases 2.1–2.4. One can see that Subcase 2.1 can be executed in $O(1)$ time. In the other cases, the algorithm has to solve one of the following problems (at most twice).

- (1) Given a planar graph (B, v', u, v, w) and an independent spanning $\{v', u, v, w\}$ -system $\{T_{v'}, T_u, T_v, T_w\}$ of B (with $T_{v'}, T_u, T_v, T_w$ rooted, respectively, at v', u, v, w), find three neighbors p_1, p_2, p_3 of v in B such that $T_{v'}[v', p_1], T_u[u, p_2]$, and $T_w[w, p_3]$ are disjoint.
- (2) Given a planar graph (B, v', u, v, w) and an independent spanning $\{v', u, v, w\}$ -system $\{T_{v'}, T_u, T_v, T_w\}$ of B (with $T_{v'}, T_u, T_v, T_w$ rooted, respectively, at v', u, v, w), find two neighbors p_1, p_2 of v in B such that $T_{v'}[v', p_1]$ and $T_u[u, p_2]$ are disjoint.

By Lemmas 3.6 and 3.7, both problems can be solved in $O(|V(B)|)$ time. Thus, it is not hard to see that the time spent by Algorithm Trees in Case 2 is $O(|V(G)|^2)$.

Case 3 is analogous to Case 2, and by an argument similar to the last paragraph, one can show that Algorithm Trees uses $O(|V(G)|^2)$ time in this case as well. \square

Now we are almost ready to prove Theorem 1.1, except that if we apply Theorem 2.8 directly to a 4-connected graph G to find a nonseparating chain decomposition of G , we spend $O(|V(G)|^2|E(G)|)$ time. We can obtain an $O(|V(G)|^3)$ algorithm by using the following result of Ibaraki and Nagamochi [10].

THEOREM 6.16. *Let G be a k -connected graph for some integer $k \geq 1$. Then one can find in $O(|V(G)| + |E(G)|)$ time a spanning k -connected subgraph of G with $O(|V(G)|)$ edges.*

Proof of Theorem 1.1. Let G be a 4-connected graph, and let $r \in V(G)$. Apply Theorem 6.16 to G , and let G' be the resulting spanning 4-connected subgraph of G .

Applying Theorem 2.8 to G' , we can find a nonseparating chain decomposition \mathcal{C} of G' in $O(|V(G')|^3)$ time (and hence in $O(|V(G)|^3)$ time).

Finally, apply Theorem 6.14 to G, \mathcal{C} and find four independent spanning trees T_1, T_2, T_3, T_4 of G' rooted at r . By Lemma 6.15, this is done in $O(|V(G')|^3)$ time, and hence in $O(|V(G)|^3)$ time. Clearly, T_1, T_2, T_3, T_4 are independent spanning trees of G rooted at r . \square

EFFICIENT SIMULATIONS BY QUEUE MACHINES*

HOLGER PETERSEN[†] AND JOHN MICHAEL ROBSON[‡]

Abstract. The following simulations by machines equipped with a one-way input tape and additional queue storage are shown:

- Every nondeterministic single-tape Turing machine (no separate input-tape) with time bound $t(n)$ can be simulated by one queue in $O(t(n))$ time.
- Every deterministic machine with a one-turn pushdown store can be simulated deterministically by one queue in $O(n\sqrt{n})$ time.
- Every Turing machine with several multidimensional tapes accepting with time bound $t(n)$ can be simulated by two queues in $O(t(n)\log^2 t(n))$ time.
- Every deterministic Turing machine with several linear tapes accepting with time bound $t(n)$ can be simulated deterministically in time $O(t(n)\log t(n))$ by a queue and a pushdown store.

The first two results appear to be the first subquadratic simulations of other storage devices by one queue.

Key words. pushdown automata, grammars, multiqueue machines, multitape machines, simulation, upper bounds

AMS subject classification. 68Q05

DOI. 10.1137/S0097539799350608

1. Introduction. A classical result, essentially due to Post, says that a machine with a single queue is able to perform any computation a Turing machine can; see, e.g., [12]. Turing machines with auxiliary storage devices like pushdowns or stacks are well studied, and the complexity of simulations between machines with such storages and tapes has been thoroughly investigated. In contrast, fewer results have been obtained for the storage device queue. It is known that one-queue machines can simulate several tapes, pushdowns, and queues with quadratic slowdown [9, Theorem 3.1]. Nondeterministic two-queue machines can simulate any number of queues in linear time [9, Theorem 4.2].

For deterministic devices with several queues Hühne [8] gives a simulation of $t(n)$ time-bounded multistorage Turing machines on $O(t(n)\sqrt[k]{t(n)})$ time-bounded machines with $k \geq 2$ queues. He also reports almost matching lower bounds for online simulations of these storage devices.

Li and Vitányi [10] report lower bounds for simulating one queue on other storages without the online restriction.

In the framework of formal languages, machines with one or more queues have been investigated, e.g., in [16, 2].

Hartmanis and Stearns [5] showed that a k -dimensional tape machine with time bound $t(n)$ could be simulated by a linear tape machine in time $O(t^2(n))$. Pippenger and Fischer [14] improved the time to $O(t^{2-1/k}(n))$, and the result of Hennie [6] (with

the correction from [3]) shows that this is optimal, at least for online deterministic simulation. Grigor'ev [4] and Loui [11] showed how to reduce the time when the simulating machine uses m -dimensional tapes ($m > 1$); they used nondeterministic and deterministic machines, respectively. Monien [13] improved the result in case of nondeterministic simulation to use only linear tapes and time $O(t(n) \log^2 t(n))$. We show that this bound also holds for nondeterministic simulation by two queues. Rosenberg [15] presented an $O(n \log n)$ time algorithm for context free language recognition on a machine with two queues. Rosenberg's proof—being based on context free grammars—does not seem to generalize to the simulation of storage devices other than a single pushdown.

We also give a self-contained simulation of multistorage machines by machines with a queue and a pushdown.

2. Preliminaries. We adopt the concepts from [10, 9]. The simulated devices will be introduced below. Unless stated otherwise our simulating machines are nondeterministic and are equipped with a single one-way head on a read-only input tape. The machines can determine end-of-input, have access to one or more first-in-first-out queues storing symbols, and are able to signal acceptance of their input. Depending on the symbols read by the input head and at the front of the queues, a finite control determines one or more of the following operations:

- advance the input head to the next cell,
- dequeue the first symbols of some queues,
- enqueue at most one symbol per queue.

After these operations, control is transferred to the next state.

A machine accepts in time $t(n)$ if, for all accepted inputs of length n , the machine admits a computation that ends with acceptance after at most $t(n)$ steps.

Simulation will be understood in the most general sense; i.e., machine A simulates B if both machines accept the same set of inputs. Note that other concepts of simulation are frequently used, notably step-by-step simulation or simulation of a specified retrieval function of a storage unit (e.g., a two-dimensional array with one point of access which can be moved one row or column at a time).

3. Results.

THEOREM 1. *Every nondeterministic bi-infinite single-tape Turing machine accepting in $t(n)$ steps can be simulated by a nondeterministic one-queue machine in $O(t(n))$ steps.*

Proof. We call the Turing machine to be simulated S and the queue machine Q . Let the tape cells of S be labeled with consecutive integers; the first symbol of the input is labeled with 0. We assume without loss of generality that S moves its head in every step, that there is a single final state, and that the head movement in every step reaching this final state is to the right.

Recall that a crossing sequence at the boundary between two adjacent tape cells consists of the chronological sequence of states to which the finite control of S transfers control as the head crosses the boundary. Here we will denote by c_i the crossing sequence occurring in a computation between cell $i - 1$ and i , and we will also encode the direction when going to state q by \vec{q} (right movement) and \overleftarrow{q} (left movement). We adopt the convention that c_0 starts with the initial state of S moving to the right.

The computation of S in terms of crossing sequences can be divided into three stages:

1. involving cells to the left of the input ($i \leq 0$),
2. involving cells within the input w ($0 < i \leq |w|$),

3. involving cells to the right of the input ($i > |w|$).

Queue machine Q simulates the behavior of S on every tape cell used by S , from left to right, i.e., generally not in chronological sequence. During a cycle corresponding to a tape cell, Q keeps the symbol x currently in the cell in its finite control. The symbol x is initialized with a blank in stage 1 and stage 3 and with the actual input symbol in stage 2. This symbol is available to Q from Q 's own input tape.

The idea of the simulation is to have a crossing sequence c_i on the queue and to guess c_{i+1} (which is separated from c_i by $\$$) in a manner consistent with S 's finite control. More specifically, if the remaining suffix of c_i on the queue is c , we have the following cases, which are nonexclusive (c' is the part of the crossing sequence not affected by the step currently simulated):

- $c = \overrightarrow{q_1} \overleftarrow{q_2} c'$ and there is a transition from q_1 to q_2 reading x , writing some symbol y , and moving the head left. Then Q dequeues $\overrightarrow{q_1} \overleftarrow{q_2}$ and replaces x with y .
- $c = \overrightarrow{q_1} c'$ and there is a transition from q_1 to q_2 reading x , writing some symbol y , and moving the head right. Then Q dequeues $\overrightarrow{q_1}$, enqueues $\overrightarrow{q_2}$, and replaces x with y .
- $c = \overleftarrow{q_2} c'$ and there is a transition from q_1 to q_2 reading x , writing some symbol y , and moving the head left. Then Q dequeues $\overleftarrow{q_2}$, enqueues $\overleftarrow{q_1}$, and replaces x with y .
- There is a transition from q_1 to q_2 reading x , writing some symbol y , and moving the head right. Then Q enqueues $\overleftarrow{q_1} \overrightarrow{q_2}$ and replaces x with y .

If the last symbol of the current crossing sequence has been processed and no further operations according to the last case above occur, the marker symbol $\$$ is dequeued, enqueued, and the next cycle starts.

Should the final state be reached, then no successor state is stored on the queue, but the fact that it has been encountered is recorded in the finite control of Q .

The simulation is initiated by guessing zero or more pairs of states according to the last case to be inserted into the queue with the initial tape symbol being a blank. It proceeds in stage 1 until Q guesses that tape cell -1 has just been processed, c_{-1} is stored on the queue, and stage 2 of the simulation is about to start. At this moment, S 's initial state is inserted into the queue as the first element of c_0 . After c_0 has been assembled, the input is read in every cycle, until the last symbol is consumed and $c_{|w|}$ has been formed. The simulation continues in stage 3 until the queue contains no symbol except $\$$. The machine Q eventually accepts when S 's final state has been encountered during the simulation.

Suppose S accepts input w . We fix an accepting computation C on w using tape cells only between positions ℓ and r . To each cell i with $\ell + 1 \leq i \leq r$ we associate the crossing sequence c_i arising from C . By its definition, Q can first guess $c_{\ell+1}$ and then inductively generate c_{i+1} from c_i in a nondeterministic way. When stage 2 starts, Q begins to read input symbols until stage 3 starts. In this way Q can execute an accepting computation (the final state of S is encountered, since C is accepting).

Conversely, if Q accepts an input w , then the contents of the queue after a full cycle of the accepting computation of Q can be assembled into an accepting computation of S . This is done by starting at the step when Q reads the first symbol of w and picking the first entry of the queue. Then we follow the arrows and always choose "fresh" queue entries, resulting in an accepting computation of S .

The number of steps executed by S is equal to the sum of the lengths of all crossing sequences. For every element of a crossing sequence, Q executes a number of

steps bounded by a constant. This shows the claimed time bound. \square

A converse of the above simulation is not possible, showing that queue machines are stronger than single-tape Turing machines.

OBSERVATION 1. *The language $D^\# = \{w\#w \mid w \in \{0,1\}^*\}$ can be accepted in real time by a deterministic one-queue machine but not by any nondeterministic single-tape Turing machine working in $o(n^2)$ time.*

Proof. Techniques due to Hennie and Barzdin show that $D^\#$ cannot be accepted in $o(n^2)$ time by a single-tape machine; see [17, Theorem 8.13]. On the other hand, a queue machine stores all symbols up to the first $\#$ on the queue and compares them to the string following $\#$. The input is rejected if a mismatch is detected or no separator $\#$ is found; otherwise it is accepted. \square

In the following we present a simulation of a pushdown automaton by a machine with a single queue. It will help to first recall the trivial simulation of one pushdown store by a queue, a special case of [9, Theorem 3.1]. Every push operation can be simulated in constant time by enqueueing a symbol, while pop operations are simulated by cycling through the entire queue contents, locating the top symbol, and removing it. Since the size of the queue is linearly bounded by the number of operations being simulated, this results in a quadratic overhead. Notice that after simulating one pushdown operation, this trivial approach encodes the pushdown contents verbatim. The key to a more efficient simulation is a different encoding and processing of the information stored.

The next machine to be simulated has a one-turn pushdown. (In any computation the machine may switch from pushing to popping at most once.) Machines in this class accept exactly the deterministic linear context free languages.

THEOREM 2. *Every deterministic machine with a one-turn pushdown store can be simulated by a deterministic machine with one queue in $O(n\sqrt{n})$ time.*

Proof. Let P be a deterministic one-turn pushdown machine. Note that if P accepts, it does so in linear time.

Let Q be the queue machine with queue alphabet $X \cup \{\#, *, \$\}$, where X is the pushdown alphabet of P , the union is disjoint, and the length of the input is n .

The idea of the simulation is to divide Q 's computation into three stages. In the first stage, Q simulates push operations of P by writing the pushed symbols into its queue in the same way as in the trivial simulation outlined above. When P switches to popping the pushdown contents, the approach deviates from the trivial one.

After stage 1, queue machine Q suspends the simulation and prepares its storage in order to speed up the access to pushdown symbols. The main observation is that each section of the queue contents eventually has to be read in a reversed fashion. Therefore we would like to form mirror images of the sections. This will be fast if the sections are short since we can process one symbol of *each* section in one round, reading the queue contents once. On the other hand, if the sections are short, there will be many of them. Because the sections are reversed as well, access time during stage 3 depends on exactly how many. A compromise between speed of preprocessing and access leads to a size of the sections proportional to \sqrt{n} .

In stage 3 of the simulation, Q simulates the pop operations of P , from time to time rearranging the queue contents. A more detailed description of the second and third stages follows.

Suppose that v is the queue contents of Q when P reverses its access to the pushdown and stage 2 starts, $|v| \in O(n)$. First Q divides v into strings v_i with $|v_i| \in \Theta(\sqrt{|v|})$ except for the last string, which may be shorter. To do this, Q marks

the end of the queue with \$ and in one pass writes the string *# after every symbol from X . As long as the number of *'s in the queue exceeds one, Q deletes every second * starting with the first one, and in every second pass also deletes every second #, except the one immediately before \$. Thus Q makes $\lfloor \log |v| \rfloor$ passes in $O(|v| \log |v|)$ steps and $\lfloor \lfloor \log |v| \rfloor / 2 \rfloor$ times approximately divides the number of #'s by 2. After these operations, v is divided into k blocks v_i terminated by #. We have

$$|v_i| \leq 2^{\lfloor \frac{\lfloor \log |v| \rfloor}{2} \rfloor} \leq \sqrt{|v|}$$

and

$$k \leq \frac{|v|}{2^{\lfloor \frac{\lfloor \log |v| \rfloor}{2} \rfloor}} \leq 2\sqrt{2}\sqrt{|v|}.$$

Next, Q in one pass inserts a symbol * before every #. Then it starts to reverse the blocks v_i by deleting a symbol $x \in X$ from the beginning of each block that is not yet completely reversed, keeping x in its finite control and inserting it after the * in the same block. This process is repeated until all blocks start with *, and then the *'s are deleted in one pass. Each block $v_i\#$ has been transformed into $v_i^R\#$ in a total of $O(|v|\sqrt{|v|})$ steps.

The third stage of Q 's operation requires a preparation that speeds up Q 's access to the last block on the queue. In k cycles Q inserts a * in front of every block that already contains a * and of the first block that has not received a * up to that point, until every block has received at least one *. The effect of these operations is that the blocks contain $k, k-1, \dots, 1$ symbols *. The preparation is $O(n\sqrt{n})$ time bounded. Now Q enters the third stage and simulates P 's pushdown-reading operations by repeatedly rotating blocks to the rear of the queue until it finds the unique block with a single *. It deletes * and reads this block of pushdown symbols while processing the next input segment until it encounters the trailing #, deletes this symbol, and rewrites \$ at the rear of the queue. Then in one cycle it deletes a single * in every block. It repeats this sequence of operations until the input is exhausted. Emptiness of the pushdown store can easily be detected since then the \$ is the first symbol in the queue. Each rotation takes $O(|v|)$ time, and there are $k \in O(\sqrt{|v|})$ blocks; therefore this stage is $O(|v|\sqrt{|v|})$ time-bounded. \square

We remark that the previous simulation applies to the language $L = \{w\#w^R \mid w \in \{0,1\}^*\}$ investigated in [9, section 3.2]. Our upper bound almost matches the lower bound $\Omega(n^{4/3}/\log n)$ from [9].

The proof of the next result uses ideas from [13].

THEOREM 3. *Every nondeterministic Turing machine with several multidimensional work tapes accepting with time bound $t(n)$ can be simulated by two queues in $O(t(n)\log^2 t(n))$ time.*

Proof. For convenience we will describe a simulator that is equipped with a large number of queues. The linear-time simulation of machines with several queues with two queues [9, Theorem 4.2] will give the result.

Let the m work tapes of machine M that is to be simulated be d -dimensional. For tape i our simulator Q has $d+1$ queues. Queue $i(d+1)$ records the read-write operations on tape i ; queues $i(d+1)+1$ through $i(d+1)+d$ contain binary counters that store the distance of M 's head from its initial head position on tape i . More precisely, for a distance k , the reversal of the binary representation of k is written into the corresponding queue followed by a separator symbol #. For each counter,

Q 's finite control records whether the stored value is positive or negative. All counters are initially zero.

The simulation of M is divided into stages. In the first stage Q guesses step-by-step a computation of M , reading input symbols if necessary, and guessing a corresponding step of M . Let the symbol read by this step on tape i be x_i and the symbol written be y_i . The current distances for tape i are k_1, \dots, k_d . Then Q writes a record containing x_i, y_i , and k_1, \dots, k_d (including signs) into queue $i(d+1)$. The distances are copied by rotating the binary representations stored in queues $i(d+1)+1, \dots, i(d+1)+d$. Now Q updates the distances as indicated by the head move on tape i by adding or subtracting one if necessary. These operations are carried out for every tape and take $O(t(n) \log t(n))$ time. If eventually the simulation reaches an accepting state of M , the second stage is started.

In the second stage the consistency of the guessed computation is checked. For every tape i the simulator uses queues $i(d+1)$ and $i(d+1)+1$ for sorting the records according to distances in a stable way. A suitable method is to use radix sort on their binary representations, starting with the least significant bits and marking off used bits. First a new marker is appended to queue $i(d+1)$. Records containing 0 at the current position are put into queue $i(d+1)+1$; the others are moved to the rear of queue $i(d+1)$. If the marker is encountered, the queues are appended, and the next bit position is considered. In case all digits of a number are exhausted while there are still bits to be processed, the symbol # is interpreted as a string of leading zeros. If all bits have been handled, a final pass sorts according to signs. Sorting is done for all dimensions. Then Q checks for every run of records with equal distances that the first symbol read is a blank and that the symbol written by record j is equal to the symbol read by record $j+1$. If it detects an inconsistency, it aborts the simulation; otherwise it accepts.

The number of records is $O(t(n))$, the length of every record is $O(\log t(n))$, and the total number of passes is $O(\log t(n))$. We obtain the required time bound $O(t(n) \log^2 t(n))$. \square

We remark that tapes can simulate queues in linear time; see [17, Lemma 19.9].

Hühne [8] pointed out that his deterministic simulation of multistorage Turing machines in time $O(t(n)\sqrt{t(n)})$ can be performed on a deterministic machine with a queue and a pushdown store. He also mentions an $\Omega(t(n)\sqrt[4]{\log t(n)})$ lower bound.

In the nondeterministic case a queue and a pushdown simulate any number of pushdown stores (and hence tapes) in linear time by adapting the following technique of Book and Greibach [1]. Guess a sequence of partial configurations containing the state of the simulated machine, the topmost symbols of each pushdown store, the input symbol currently scanned, and the operations on input head and storage. This sequence is written onto the queue. Then the simulator checks that the sequence corresponds to a valid computation for each of the pushdown stores and the input.

We give a deterministic simulation of an arbitrary number of tapes on a queue and a pushdown store that almost matches the lower bound.

THEOREM 4. *Any deterministic $t(n)$ -time-bounded multitape Turing machine can be simulated by a deterministic Turing machine accessing a queue and a pushdown store which is $O(t(n) \log t(n))$ -time-bounded.*

Proof. We first note that a tape can be simulated by two pushdown stores with a linear overhead in a straightforward manner. We may thus restrict our attention to an efficient simulation of several pushdown storages with the help of a single pushdown and a queue.

The idea of the simulation is to store the contents of several pushdown stores on separate tracks of the single pushdown store of the simulator. Each storage cell on these tracks may be empty or contain information stored in the simulated pushdown. The concatenation of all nonempty cells on track k from top to bottom constitutes the string stored on the k th simulated pushdown. We point out that the distribution of empty cells may vary between these tracks, depending on the sequence of accesses to the pushdown stores. Bottom markers of the simulated pushdowns are treated in the same way as other symbols in the pushdown alphabet.

In order to simplify the description of our simulation we concentrate on one pushdown and describe the modification of the track corresponding to this pushdown during the simulation of pop and push operations. The contents of other tracks are left unchanged, except for the introduction of additional empty cells above the bottom marker of the simulator.

Each track is divided into a special topmost cell and a potentially infinite sequence of frames of increasing size, where frame i contains 2^{i+1} cells. Each frame is divided into two blocks of equal size. We assume that this structure is easily recognizable, e.g., by marking the borders between frames and blocks. An invariant maintained by the phases of the simulation is that a frame either is empty, has block 0 empty and block 1 full, or has both blocks full. The number of frames is the same for each track, and the bottom symbol of the simulator's pushdown marks the last frame.

The simulation starts with an empty pushdown, except for the topmost symbol and the bottom marker, and an empty queue.

We will first describe the simulation of a pop. Let the i th frame be the first nonempty one; recall that it has block 1 full, and block 0 may be full or empty. The state of the pushdown is described by Figure 1.

Phase 1 (unloading). The simulator unloads the pushdown onto the queue until it has read the first nonempty frame. We assume that the structure imposed on the pushdown is still visible after unloading.

Phase 2 (redistribution). In this phase the simulator uses the pushdown as a scratch memory, separating the contents of the pushdown at the start of this phase from the operations carried out within the phase. It can do so by storing a marker on top of the pushdown. In this way the contents of the pushdown at the end of the redistribution phase are identical to the contents at the start of the phase.

The current state of the queue before the redistribution phase is shown in Figure 2.

First the simulator rotates the queue until it reaches the string previously stored in the nonempty frame and copies the contents of block 0, if it is nonempty, or else block 1 onto the pushdown. Then in another round it overwrites this portion of the queue with the mirror-image of its initial contents, emptying the pushdown (see Figure 3).

The simulator again copies the reversed string onto the pushdown, this time erasing the cells read. Then it puts one symbol into the position of the first cell on the queue and, now rotating the queue contents, 2^i symbols from the top of the pushdown into the first blocks of each of the frames currently on the queue. Since $2^i = 1 + \sum_{k=0}^{i-1} 2^k$, there are just enough cells to accommodate all symbols and completely empty the pushdown by putting 2^k symbols into block 1 of frame k . Each block receiving symbols from the pushdown is full. Therefore the invariant remains true (see Figure 4).

Finally the simulator transforms the entire track into its mirror-image.

Phase 3 (loading). The simulator removes the marker that separated the sections

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

not involved in the simulation of the pop operation from the pushdown. Then it empties the queue and stores its contents onto the pushdown. Note that the initial sequence of frames is restored by forming the mirror-image of the contents of the queue at the end of the previous phase. We thus obtain the situation shown in Figure 5.

This completes the simulation of a pop operation.

For a push operation the situation is slightly more complicated, since the current number of frames stored on the pushdown might not suffice for storing another symbol. In the following we describe the simulation of a push operation again in three phases, referring to the corresponding phases in a pop operation if there are common sections.

Phase 1 (unloading). The simulator checks whether the topmost cell is empty. If so, it fills this position with the new symbol and skips the remaining phases. Otherwise it unloads the pushdown onto the queue until it has read a frame that is not completely full or the pushdown becomes empty. In the latter case it allocates a new frame on the queue. This is done by counting the current length ℓ of the queue on the pushdown and adding $\ell + 1$ (for each track) empty cells.

Phase 2 (redistribution). The remaining contents of the pushdown are protected from the forthcoming operations in the same way as described in the simulation of pop operations. Let frame i be the one that is not completely full. The simulator collects the $2^{i+1} - 1$ symbols from the topmost cell and the frames that are full and reverses this string as described above. Then it enters 2^k symbols into block 1 of frame k for each $0 \leq k < i$ and the remaining 2^i symbols into block 1 of frame i if it is empty. Otherwise it uses block 0. Finally the new symbol is written into the topmost cell.

After each operation involving frame i there are 2^i symbols and $2^i - 1$ empty cells above this frame in the pushdown. At most one access to frame i can thus occur within 2^i steps. The number of operations in the simulation described above is proportional to the maximum length of the frames involved. We can therefore bound the time complexity of simulating $t(n)$ steps of the multitape machine by

$$\sum_{k=0}^{\lfloor \log t(n) \rfloor} c2^k \cdot \lfloor t(n)/2^k \rfloor = O(t(n) \log t(n))$$

for some constant factor c . Since the number of tracks is fixed for a given machine, the time complexity of the simulation is also $O(t(n) \log t(n))$. \square

The simulation employed in the preceding proof is based on the idea of using memory blocks of exponentially increasing size from the multitape simulation due to

FIG. 5.

Hennie and Stearns [7]. It is known that the latter simulation can be done with a tape and a pushdown store, and the same is true for our simulation by replacing the queue by a tape and modifying the appropriate steps in the simulation. A direct adaption of the simulation from [7] to a machine with queue and pushdown does not, however, seem to be possible, since keeping the majority of memory accesses close to the “home” square in that simulation does not work if the information is stored on a queue. Instead the entire contents would have to be rotated, resulting in a quadratic slow-down.

4. Open problems. A gap remains between the upper bound $O(n\sqrt{n})$ from Theorem 2 and the lower bound $\Omega(n^{4/3}/\log n)$ from [9] for the simulation of a push-down by one queue. The optimality of the bounds in Theorems 3 and 4 are further open problems.

Acknowledgments. The first author would like to thank Jeff Shallit and Pierre McKenzie for comments on an earlier draft of this paper. We also thank Franz-Josef Brandenburg and the anonymous referees for useful remarks.

THE COMPLEXITY OF THE LOCAL HAMILTONIAN PROBLEM*

JULIA KEMPE[†], ALEXEI KITAEV[‡], AND ODED REGEV[§]

Abstract. The k -LOCAL HAMILTONIAN problem is a natural complete problem for the complexity class QMA, the quantum analogue of NP. It is similar in spirit to MAX- k -SAT, which is NP-complete for $k \geq 2$. It was known that the problem is QMA-complete for any $k \geq 3$. On the other hand, 1-LOCAL HAMILTONIAN is in P and hence not believed to be QMA-complete. The complexity of the 2-LOCAL HAMILTONIAN problem has long been outstanding. Here we settle the question and show that it is QMA-complete. We provide two independent proofs; our first proof uses only elementary linear algebra. Our second proof uses a powerful technique for analyzing the sum of two Hamiltonians; this technique is based on perturbation theory and we believe that it might prove useful elsewhere. Using our techniques we also show that adiabatic computation with 2-local interactions on qubits is equivalent to standard quantum computation.

Key words. quantum computation, local Hamiltonian problem, complete problems, adiabatic computation

1. Introduction. Quantum complexity theory has emerged alongside the first efficient quantum algorithms in an attempt to formalize the notion of an *efficient* algorithm. In analogy to classical complexity theory, several new quantum complexity classes have appeared. A major challenge today consists in understanding their structure and the interrelation between classical and quantum classes.

One of the most important classical complexity classes is NP—nondeterministic polynomial time. This class comprises languages that can be *verified* in polynomial time by a deterministic verifier. The celebrated Cook–Levin theorem (see, e.g., [17]) shows that this class has *complete* problems. More formally, it states that SAT is NP-complete; i.e., it is in NP and any other language in NP can be reduced to it with polynomial overhead. In SAT we are given a set of clauses (disjunctions) over n variables and asked whether there is an assignment that satisfies all clauses. One can consider the restriction of SAT in which each clause consists of at most k literals.

This is known as the k -SAT problem. It is known that 3-SAT is still NP-complete while 2-SAT is in P, i.e., has a polynomial time solution. We can also consider the MAX- k -SAT problem: here, given a k -SAT formula and a number m we are asked whether there exists an assignment that satisfies at least m clauses. It turns out that MAX-2-SAT is already NP-complete; MAX-1-SAT is clearly in P.

The class QMA is the quantum analogue of NP in a probabilistic setting, i.e., the class of all languages that can be probabilistically verified by a quantum verifier in polynomial time (the name is derived from the classical class MA, which is the randomized analogue of NP). This class, which is also called BQNP, was first studied in [13, 12]; the name QMA was given to it by Watrous [20]. Several problems in QMA have been identified [20, 12, 9]. For a good introduction to the class QMA, see the book by Kitaev, Shen, and Vyalvi [12] and the paper by Watrous [20].

Kitaev, inspired by ideas due to Feynman, defined the quantum analogue of the classical SAT problem, the LOCAL HAMILTONIAN problem [12].¹ An instance of k -LOCAL HAMILTONIAN can be viewed as a set of local constraints on n qubits, each involving at most k of them. We are asked whether there is a state of the n qubits such that the expected number of violated constraints is either below a certain threshold or above another, with a promise that one of the two cases holds and both thresholds are at least a constant apart. More formally, we are to determine whether the *groundstate* energy of a given k -local Hamiltonian is below one threshold or above another.

Kitaev proved [12] that the 5-LOCAL HAMILTONIAN problem is QMA-complete. Later, Kempe and Regev showed that even 3-LOCAL HAMILTONIAN is complete for QMA [11]. In addition, it is easy to see that 1-LOCAL HAMILTONIAN is in P. The complexity of the 2-LOCAL HAMILTONIAN problem was left as an open question in [2, 21, 11, 7]. It is not hard to see that the k -LOCAL HAMILTONIAN problem contains the MAX- k -SAT problem as a special case.² Using the known NP-completeness of MAX-2-SAT, we obtain that 2-LOCAL HAMILTONIAN is NP-hard; i.e., any problem in NP can be reduced to it with polynomial overhead. But is it also QMA-complete? Or perhaps it lies in some intermediate class between NP and QMA? Some special cases of the problem were considered by Bravyi and Vyalvi [7]; however, the question still remained open.

In this paper we settle the question of the complexity of 2-LOCAL HAMILTONIAN and show that the following theorem holds.

THEOREM 1.1. *The 2-LOCAL HAMILTONIAN problem is QMA-complete.*

In [12] it was shown that the k -LOCAL HAMILTONIAN problem is in QMA for any constant k (and in fact even for $k = O(\log n)$, where n is the total number of qubits). Hence, our task in this paper is to show that any problem in QMA can be reduced to the 2-LOCAL HAMILTONIAN problem with a polynomial overhead. We give two self-contained proofs for this.

Our first proof is based on a careful selection of gates in a quantum circuit and several applications of a lemma called the *projection lemma*. The proof is quite involved; however, it uses only elementary linear algebra and hence might appeal to some readers.

¹For a survey of the LOCAL HAMILTONIAN problem, see [2].

²The idea is to represent the n variables by n qubits and represent each clause by a Hamiltonian. Each Hamiltonian is diagonal and acts on the k variables that appear in its clause. It “penalizes” the assignment that violates the clause by increasing its eigenvalue. Therefore, the lowest eigenvalue of the sum of the Hamiltonians corresponds to the maximum number of clauses that can be satisfied simultaneously.

Our second proof is based on perturbation theory—a collection of techniques that are used to analyze sums of Hamiltonians. This proof is more mathematically involved. Nevertheless, it might give more intuition as to why the 2-LOCAL HAMILTONIAN problem is QMA-complete. Unlike the first proof, which shows how to represent any QMA circuit by a 2-local Hamiltonian, the second proof shows a reduction from the 3-LOCAL HAMILTONIAN problem (which is already known to be QMA-complete [11]) to the 2-LOCAL HAMILTONIAN problem. To the best of our knowledge, this is the first reduction *inside* QMA (i.e., not from the circuit problem). This proof involves what is known as *third order* perturbation theory (interestingly, the projection lemma used in our first proof can be viewed as an instance of *first order* perturbation theory). We are not aware of any similar application of perturbation theory in the literature and we hope that our techniques will be useful elsewhere.

Adiabatic computation. It has been shown in [3] that the model of adiabatic computation with 3-local interactions is equivalent to the standard model of quantum computation (i.e., the quantum circuit model).³ We strengthen this result by showing that 2-local interactions suffice.⁴ Namely, the model of adiabatic computation with 2-local interactions is equivalent to the standard model of quantum computation. We obtain this result by applying the technique of perturbation theory, which we develop in the second proof of the main theorem.

Recent work. After a preliminary version of our paper appeared [10], Oliveira and Terhal [16] generalized our results and have shown that the 2-LOCAL HAMILTONIAN problem remains QMA-complete even if the Hamiltonians are restricted to nearest neighbor interactions between qubits on a two-dimensional grid. Similarly, they show that the model of adiabatic computation with 2-local Hamiltonians between nearest neighbor qubits on a two-dimensional grid is equivalent to standard quantum computation. Their proof applies the perturbation theory techniques that we develop in this paper and introduces several novel “perturbation gadgets” akin to our three-qubit gadget in section 6.2.

Structure. We start by describing our notation and some basics in section 2. Our first proof is developed in sections 3, 4, and 5. The main tool in this proof, which we name the projection lemma, appears in section 3. Using this lemma, we rederive in section 4 some of the previously known results. Then we give the first proof of our main theorem in section 5. In section 6 we give the second proof of our main theorem. This proof does not require the projection lemma and is in fact independent of the first proof. Hence, some readers might choose to skip sections 3, 4, and 5 and go directly to section 6. In section 7 we show how to use our techniques to prove that 2-local adiabatic computation is equivalent to standard quantum computation. Some open questions are mentioned in section 8.

2. Preliminaries. QMA is naturally defined as a class of promise problems: A promise problem L is a pair (L_{yes}, L_{no}) of disjoint sets of strings corresponding to YES and NO instances of the problem. The problem is to determine, given a string $x \in L_{yes} \cup L_{no}$, whether $x \in L_{yes}$ or $x \in L_{no}$. Let \mathcal{B} be the Hilbert space of a qubit.

DEFINITION 2.1 (QMA). Fix $\varepsilon = \varepsilon(|x|)$ such that $\varepsilon = 2^{-\Omega(|x|)}$. Then, a promise problem L is in QMA if there exists a quantum polynomial time verifier V and a polynomial p such that

³Interestingly, their proof uses ideas from the proof of QMA-completeness of the LOCAL HAMILTONIAN problem.

⁴The main result of [3] is that 2-local adiabatic computation on *six-dimensional particles* is equivalent to standard quantum computation. This result is incomparable to ours since the particles in [3] are set on a two-dimensional grid and all 2-local interactions are between closest neighbors.

- $\forall x \in L_{yes} \exists |\xi\rangle \in \mathcal{B}^{\otimes p(|x|)}$ such that $\Pr(V(|x\rangle, |\xi\rangle) = 1) \geq 1 - \varepsilon$,
- $\forall x \in L_{no} \forall |\xi\rangle \in \mathcal{B}^{\otimes p(|x|)}$ such that $\Pr(V(|x\rangle, |\xi\rangle) = 1) \leq \varepsilon$,

where $\Pr(V(|x\rangle, |\xi\rangle) = 1)$ denotes the probability that V outputs 1 given $|x\rangle$ and $|\xi\rangle$.

We note that in the original definition ε was defined to be $2^{-\Omega(|x|)} \leq \varepsilon \leq 1/3$. By using amplification methods, it was shown in [12] that for any choice of ε in this range the resulting classes are equivalent. Hence our definition is equivalent to the original one. In a related result, Marriott and Watrous [14] showed that exponentially small ε can be achieved without amplification with a polynomial overhead in the verifier’s computation.

A natural choice for the quantum analogue of SAT is the LOCAL HAMILTONIAN problem. As we will see later, this problem is indeed a complete problem for QMA.

DEFINITION 2.2. We say that an operator $H : \mathcal{B}^{\otimes n} \rightarrow \mathcal{B}^{\otimes n}$ on n qubits is a k -local Hamiltonian if H is expressible as $H = \sum_{j=1}^r H_j$ where each term is a Hermitian operator acting on at most k qubits.

DEFINITION 2.3. The (promise) problem k -LOCAL HAMILTONIAN is defined as follows. We are given a k -local Hamiltonian on n qubits $H = \sum_{j=1}^r H_j$ with $r = \text{poly}(n)$. Each H_j has a bounded operator norm $\|H_j\| \leq \text{poly}(n)$, and its entries are specified by $\text{poly}(n)$ bits. In addition, we are given two constants a and b with $a < b$. In YES instances, the smallest eigenvalue of H is at most a . In NO instances, it is larger than b . We should decide which one is the case.

We will frequently refer to the lowest eigenvalue of some Hamiltonian H .

DEFINITION 2.4. Let $\lambda(H)$ denote the lowest eigenvalue of the Hamiltonian H . Another important notion that will be used in this paper is that of a restriction of a Hamiltonian.

DEFINITION 2.5. Let H be a Hamiltonian and let Π be a projection on some subspace \mathcal{S} . Then we say that the Hamiltonian $\Pi H \Pi$ on \mathcal{S} is the restriction of H to \mathcal{S} . We denote this restriction by $H|_{\mathcal{S}}$.

3. Projection lemma. Our main technical tool is the *projection lemma*. This lemma (in a slightly different form) was already used in [11] and [3] but not as extensively as it is used in this paper (in fact, we apply it four times in the first proof of our main theorem). The lemma allows us to successively *cut out* parts of the Hilbert space by giving them a large *penalty*. More precisely, assume we work in some Hilbert space \mathcal{H} and let H_1 be some Hamiltonian. For some subspace $\mathcal{S} \subseteq \mathcal{H}$, let H_2 be a Hamiltonian with the property that \mathcal{S} is an eigenspace of eigenvalue 0 and \mathcal{S}^\perp has eigenvalues at least J for some large $J \gg \|H_1\|$. In other words, H_2 gives a very high penalty to states in \mathcal{S}^\perp . Now consider the Hamiltonian $H = H_1 + H_2$. The projection lemma says that $\lambda(H)$, the lowest eigenvalue of H , is very close to $\lambda(H_1|_{\mathcal{S}})$, the lowest eigenvalue of the restriction of H_1 to \mathcal{S} . The intuitive reason for this is the following. By adding H_2 we give a very high penalty to any vector that has even a small projection in the \mathcal{S}^\perp direction. Hence, all eigenvectors with low eigenvalue (and in particular the one corresponding to $\lambda(H)$) have to lie very close to \mathcal{S} . From this it follows that these eigenvectors correspond to the eigenvectors of $H_1|_{\mathcal{S}}$.

The strength of this lemma comes from the following fact. Even though H_1 and H_2 are local Hamiltonians, $H_1|_{\mathcal{S}}$ is not necessarily so. In other words, the projection lemma allows us to approximate a nonlocal Hamiltonian by a local Hamiltonian.

LEMMA 3.1. Let $H = H_1 + H_2$ be the sum of two Hamiltonians operating on some Hilbert space $\mathcal{H} = \mathcal{S} + \mathcal{S}^\perp$. The Hamiltonian H_2 is such that \mathcal{S} is a zero eigenspace

and the eigenvectors in \mathcal{S}^\perp have eigenvalue at least $J > 2\|H_1\|$. Then,

$$\lambda(H_1|_{\mathcal{S}}) - \frac{\|H_1\|^2}{J - 2\|H_1\|} \leq \lambda(H) \leq \lambda(H_1|_{\mathcal{S}}).$$

Notice that with, say, $J \geq 8\|H_1\|^2 + 2\|H_1\| = \text{poly}(\|H_1\|)$ we have $\lambda(H_1|_{\mathcal{S}}) - 1/8 \leq \lambda(H) \leq \lambda(H_1|_{\mathcal{S}})$.

Proof. First, we show that $\lambda(H) \leq \lambda(H_1|_{\mathcal{S}})$. Let $|\eta\rangle \in \mathcal{S}$ be the eigenvector of $H_1|_{\mathcal{S}}$ corresponding to $\lambda(H_1|_{\mathcal{S}})$. Using $H_2|\eta\rangle = 0$,

$$\langle \eta | H | \eta \rangle = \langle \eta | H_1 | \eta \rangle + \langle \eta | H_2 | \eta \rangle = \lambda(H_1|_{\mathcal{S}})$$

and hence H must have an eigenvector of eigenvalue at most $\lambda(H_1|_{\mathcal{S}})$.

We now show the lower bound on $\lambda(H)$. We can write any unit vector $|v\rangle \in \mathcal{H}$ as $|v\rangle = \alpha_1|v_1\rangle + \alpha_2|v_2\rangle$ where $|v_1\rangle \in \mathcal{S}$ and $|v_2\rangle \in \mathcal{S}^\perp$ are two unit vectors, $\alpha_1, \alpha_2 \in \mathbb{R}$, $\alpha_1, \alpha_2 \geq 0$ and $\alpha_1^2 + \alpha_2^2 = 1$. Let $K = \|H_1\|$. Then we have

$$\begin{aligned} \langle v | H | v \rangle &\geq \langle v | H_1 | v \rangle + J\alpha_2^2 \\ &= (1 - \alpha_2^2)\langle v_1 | H_1 | v_1 \rangle + 2\alpha_1\alpha_2\text{Re}\langle v_1 | H_1 | v_2 \rangle + \alpha_2^2\langle v_2 | H_1 | v_2 \rangle + J\alpha_2^2 \\ &\geq \langle v_1 | H_1 | v_1 \rangle - K\alpha_2^2 - 2K\alpha_2 - K\alpha_2^2 + J\alpha_2^2 \\ &= \langle v_1 | H_1 | v_1 \rangle + (J - 2K)\alpha_2^2 - 2K\alpha_2 \\ &\geq \lambda(H_1|_{\mathcal{S}}) + (J - 2K)\alpha_2^2 - 2K\alpha_2, \end{aligned}$$

where we used $\alpha_1^2 = 1 - \alpha_2^2$ and $\alpha_1 \leq 1$. Since $(J - 2K)\alpha_2^2 - 2K\alpha_2$ is minimized for $\alpha_2 = K/(J - 2K)$, we have

$$\langle v | H | v \rangle \geq \lambda(H_1|_{\mathcal{S}}) - \frac{K^2}{J - 2K}. \quad \square$$

4. Kitaev’s construction. In this section we reprove Kitaev’s result that $O(\log n)$ -LOCAL HAMILTONIAN is QMA-complete. The difference between our version of the proof and the original one in [12] is that we do not use the authors’ geometrical lemma to obtain the result, but rather apply our Lemma 3.1. This paves the way to the later proof that 2-LOCAL HAMILTONIAN is QMA-complete.

As mentioned before, the proof that $O(\log n)$ -LOCAL HAMILTONIAN is in QMA appears in [12]. Hence, our goal is to show that any problem in QMA can be reduced to $O(\log n)$ -LOCAL HAMILTONIAN. Let $V_x = V(|x\rangle, \cdot) = U_T \cdots U_1$ be a quantum verifier circuit of size $T = \text{poly}(|x|)$ operating on $N = \text{poly}(|x|)$ qubits.⁵ Here and in what follows we assume without loss of generality that each U_i is either a one-qubit gate or a two-qubit gate. We further assume that $T \geq N$ and that initially, the first $m = p(|x|)$ qubits contain the proof and the remaining ancillary $N - m$ qubits are zero (see Definition 2.1). Finally, we assume that the output of the circuit is written into the first qubit (i.e., it is $|1\rangle$ if the circuit accepts). See Figure 4.1.

⁵For ease of notation we hardwire the dependence on the input x into the circuit.

FIG. 4.1. A circuit with $T = 11$, $N = 4$, and $m = 2$.

The constructed Hamiltonian H operates on a space of $n = N + \log(T + 1)$ qubits. The first N qubits represent the computation and the last $\log(T + 1)$ qubits represent the possible values $0, \dots, T$ for the clock:

$$H = H_{out} + J_{in}H_{in} + J_{prop}H_{prop}.$$

The coefficients J_{in} and J_{prop} will be chosen later to be some large polynomials in N . The terms are given by

$$(4.1) \quad \begin{aligned} H_{in} &= \sum_{i=m+1}^N |1\rangle\langle 1|_i \otimes |0\rangle\langle 0|, & H_{out} &= (T + 1)|0\rangle\langle 0|_1 \otimes |T\rangle\langle T|, \\ H_{prop} &= \sum_{t=1}^T H_{prop,t}, \end{aligned}$$

and

$$(4.2) \quad H_{prop,t} = \frac{1}{2} \left(I \otimes |t\rangle\langle t| + I \otimes |t-1\rangle\langle t-1| - U_t \otimes |t\rangle\langle t-1| - U_t^\dagger \otimes |t-1\rangle\langle t| \right)$$

for $1 \leq t \leq T$, where $|\alpha\rangle\langle \alpha|_i$ denotes the projection on the subspace in which the i th qubit is $|\alpha\rangle$. It is understood that the first part of each tensor product acts on the space of the N computation qubits and the second part acts on the clock qubits. U_t and U_t^\dagger in $H_{prop,t}$ act on the same computational qubits as U_t does when it is employed in the verifier’s circuit V_x . Intuitively, each Hamiltonian “checks” a certain property by increasing the eigenvalue if the property does not hold: The Hamiltonian H_{in} checks that the input of the circuit is correct (i.e., none of the last $N - m$ computation qubits is 1), H_{out} checks that the output bit indicates acceptance, and H_{prop} checks that the propagation is according to the circuit. Notice that these Hamiltonians are $O(\log n)$ -local since there are $\log(T + 1) = O(\log n)$ clock qubits.

To show that a problem in QMA reduces to the $O(\log n)$ -LOCAL HAMILTONIAN problem with H chosen as above, we prove the following lemma.

LEMMA 4.1. *If the circuit V_x accepts with probability more than $1 - \varepsilon$ on some input $|\xi, 0\rangle$, then the Hamiltonian H has an eigenvalue smaller than ε . If the circuit V_x accepts with probability less than ε on all inputs $|\xi, 0\rangle$, then all eigenvalues of H are larger than $\frac{3}{4} - \varepsilon$.*

Proof. Assume the circuit V_x accepts with probability more than $1 - \varepsilon$ on some $|\xi, 0\rangle$. Define

$$|\eta\rangle = \frac{1}{\sqrt{T + 1}} \sum_{t=0}^T U_t \cdots U_1 |\xi, 0\rangle \otimes |t\rangle.$$

It can be seen that $\langle \eta | H_{prop} | \eta \rangle = \langle \eta | H_{in} | \eta \rangle = 0$ and that $\langle \eta | H_{out} | \eta \rangle < \varepsilon$. Hence, the smallest eigenvalue of H is less than ε . It remains to prove the second part of

the lemma. So now assume the circuit V_x accepts with probability less than ε on all inputs $|\xi, 0\rangle$.

Let \mathcal{S}_{prop} be the groundspace of the Hamiltonian H_{prop} . It is easy to see that \mathcal{S}_{prop} is a 2^N -dimensional space whose basis is given by the states

$$(4.3) \quad |\eta_i\rangle = \frac{1}{\sqrt{T+1}} \sum_{t=0}^T U_t \cdots U_1 |i\rangle \otimes |t\rangle,$$

where $i \in \{0, \dots, 2^N - 1\}$ and $|i\rangle$ represents the i th vector in the computational basis on the N computation qubits. These states have eigenvalue 0. The states in \mathcal{S}_{prop} represent the correct propagation from an initial state on the N computation qubits according to the verifier's circuit V_x .

We would like to apply Lemma 3.1 with the space \mathcal{S}_{prop} . For that, we need to establish that $J_{prop}H_{prop}$ gives a sufficiently large ($\text{poly}(N)$) penalty to states in \mathcal{S}_{prop}^\perp . In other words, the smallest nonzero eigenvalue of H_{prop} has to be lower bounded by some inverse polynomial in N . This has been shown in [12], but we wish to briefly recall it here, as it will apply in several instances throughout this paper.

CLAIM 4.2 ([12]). *The smallest nonzero eigenvalue of H_{prop} is at least c/T^2 for some constant $c > 0$.*

Proof. We first apply the change of basis

$$W = \sum_{t=0}^T U_t \cdots U_1 \otimes |t\rangle\langle t|,$$

which transforms H_{prop} to

$$W^\dagger H_{prop} W = \sum_{t=1}^T I \otimes \frac{1}{2} (|t\rangle\langle t| + |t-1\rangle\langle t-1| - |t\rangle\langle t-1| - |t-1\rangle\langle t|).$$

The eigenspectrum of H_{prop} is unchanged by this transformation. The resulting Hamiltonian is block-diagonal with 2^N blocks of size $T + 1$:

$$(4.4) \quad W^\dagger H_{prop} W = I \otimes \begin{pmatrix} \frac{1}{2} & -\frac{1}{2} & 0 & \cdots & 0 \\ -\frac{1}{2} & 1 & -\frac{1}{2} & 0 & \ddots & \vdots \\ 0 & -\frac{1}{2} & 1 & -\frac{1}{2} & 0 & \ddots & \vdots \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \\ \vdots & & 0 & -\frac{1}{2} & 1 & -\frac{1}{2} & 0 \\ 0 & \cdots & & 0 & -\frac{1}{2} & 1 & -\frac{1}{2} \\ & & & & & & \frac{1}{2} \end{pmatrix}.$$

Using standard techniques, one can show that the smallest nonzero eigenvalue of each $(T + 1) \times (T + 1)$ block matrix is bounded from below by c/T^2 for some constant $c > 0$. \square

Hence any eigenvector of $J_{prop}H_{prop}$ orthogonal to \mathcal{S}_{prop} has eigenvalue at least $J = cJ_{prop}/T^2$. Let us apply Lemma 3.1 with

$$H_1 = H_{out} + J_{in}H_{in}, \quad H_2 = J_{prop}H_{prop}.$$

Note that $\|H_1\| \leq \|H_{out}\| + J_{in}\|H_{in}\| \leq T + 1 + J_{in}N \leq \text{poly}(N)$ since H_{in} and H_{out} are sums of orthogonal projectors and $J_{in} = \text{poly}(N)$. Lemma 3.1 implies that we can choose $J_{prop} = JT^2/c = \text{poly}(N)$, such that $\lambda(H)$ is lower bounded by $\lambda(H_1|_{\mathcal{S}_{prop}}) - \frac{1}{8}$. With this in mind, let us now consider the Hamiltonian $H_1|_{\mathcal{S}_{prop}}$ on \mathcal{S}_{prop} .

Let $\mathcal{S}_{in} \subset \mathcal{S}_{prop}$ be the groundspace of $H_{in}|_{\mathcal{S}_{prop}}$. Then \mathcal{S}_{in} is a 2^m -dimensional space whose basis is given by states as in (4.3) with $|i\rangle = |j, 0\rangle$, where $|j\rangle$ is a computational basis state on the first m computation qubits. We apply Lemma 3.1 again inside \mathcal{S}_{prop} with

$$H_1 = H_{out}|_{\mathcal{S}_{prop}}, \quad H_2 = J_{in}H_{in}|_{\mathcal{S}_{prop}}.$$

This time, $\|H_1\| \leq \|H_{out}\| = T + 1 = \text{poly}(N)$. Any eigenvector of H_2 orthogonal to \mathcal{S}_{in} inside \mathcal{S}_{prop} has eigenvalue at least $J_{in}/(T + 1)$. Hence, there is a $J_{in} = \text{poly}(N)$ such that $\lambda(H_1 + H_2)$ is lower bounded by $\lambda(H_{out}|_{\mathcal{S}_{in}}) - \frac{1}{8}$.

Since the circuit V_x accepts with probability less than ε on all inputs $|\xi, 0\rangle$, we have that all eigenvalues of $H_{out}|_{\mathcal{S}_{in}}$ are larger than $1 - \varepsilon$. Hence the smallest eigenvalue of H is larger than $1 - \varepsilon - \frac{2}{8} = \frac{3}{4} - \varepsilon$, proving the second part of the lemma. \square

5. The 2-local construction.

Previous constructions. Let us give an informal description of ideas used in previous improvements on Kitaev’s construction; these ideas will also appear in our proof. The first idea is to represent the clock register in *unary notation*. Then, the clock register consists of T qubits, and time step $t \in \{0, \dots, T\}$ is represented by $|1^t 0^{T-t}\rangle$. The crucial observation is that clock terms that used to involve $\log(T + 1)$ qubits can now be replaced by 3-local terms that are essentially equivalent. For example, a term like $|t-1\rangle\langle t|$ can be replaced by the term $|100\rangle\langle 110|_{t-1,t,t+1}$. Since the gates U_t involve at most two qubits, we obtain a 5-local Hamiltonian. This is essentially the way 5-LOCAL HAMILTONIAN was shown to be QMA-complete in [12]. The only minor complication is that we need to get rid of illegal clock states (i.e., ones that are not a unary representation). This is done by the addition of a (2-local) Hamiltonian H_{clock} that penalizes a clock state whenever 1 appears after 0.

This result was further improved to 3-LOCAL HAMILTONIAN in [11]. The main idea there is to replace a 3-local clock term like $|100\rangle\langle 110|_{t-1,t,t+1}$ by the 1-local term $|0\rangle\langle 1|_t$. These one-qubit terms are no longer equivalent to the original clock terms. Indeed, it can be seen that they have unwanted transitions into illegal clock states. The main idea in [11] was that by giving a large penalty to illegal clock states (i.e., by multiplying H_{clock} by some large number) and applying the projection lemma, we can essentially project these one-qubit terms to the subspace of legal clock states. Inside this subspace, these terms become the required clock terms.

The 2-local construction. Most of the terms that appear in the construction of [11] are already 2-local. The only 3-local terms are terms as in (4.2) that correspond to two-qubit gates (those corresponding to one-qubit gates are already 2-local). Hence, in order to prove our main theorem, it is enough to find a 2-local Hamiltonian that checks for the correct propagation of two-qubit gates. This seems difficult because the Hamiltonian must somehow couple two computation qubits to a clock qubit. We circumvent this problem in the following manner. First, we isolate from the propagation Hamiltonian those terms that correspond to one-qubit gates and we multiply these terms by some large factor. Using the projection lemma, we can project the remaining Hamiltonians into a space where the one-qubit-gate propagation is correct. In other words, at this stage we can assume that our space is spanned by states that correspond to legal propagation according to the one-qubit gates. This allows us to couple clock qubits *instead* of computation qubits. To see this, consider the circuit in

Figure 5.1 at time t and at time $t + 2$. A Z gate flips the phase of a qubit if its state is $|1\rangle$ and leaves it unchanged otherwise. Hence, the phase difference between time t and time $t + 2$ corresponds to the parity of the two qubits. This phase difference can be detected by a 2-local term such as $|00\rangle\langle 11|_{t+1,t+2}$. The crucial point here is that by using a term involving only two clock qubits, we are able to check the state of two computation qubits (in this case, their parity) at a certain time. This is the main idea in our proof.

We now present the proof of the main theorem in detail. We start by making some further assumptions on the circuit V_x , all without loss of generality. First, we assume that in addition to one-qubit gates, the circuit contains only the controlled phase gate, C_ϕ . This two-qubit gate is diagonal in the computational basis and flips the sign of the state $|11\rangle$,

$$C_\phi = C_\phi^\dagger = |00\rangle\langle 00| + |01\rangle\langle 01| + |10\rangle\langle 10| - |11\rangle\langle 11|.$$

It is known [5, 15] that quantum circuits consisting of one-qubit gates and C_ϕ gates are universal⁶ and can simulate any other quantum circuit with only polynomial overhead. Second, we assume that each C_ϕ gate is both preceded and followed by two Z gates, one on each qubit, as in Figure 5.1. The Z gate is defined by $|0\rangle\langle 0| - |1\rangle\langle 1|$; i.e., it is a diagonal one-qubit gate that flips the sign of $|1\rangle$. Since both the Z gate and the C_ϕ gate are diagonal, they commute and the effect of the Z -gates cancels out. This assumption makes the circuit at most five times bigger. Finally, we assume that the C_ϕ gates are applied at regular intervals. In other words, if T_2 is the number of C_ϕ gates and L is the interval length, then a C_ϕ gate is applied at steps $L, 2L, \dots, T_2L$. Before the first C_ϕ gate, after the last C_ϕ gate, and between any two consecutive C_ϕ gates we have $L - 1$ one-qubit gates. This makes the total number of gates in the resulting circuit $T = (T_2 + 1)L - 1$.

FIG. 5.1. A modified C_ϕ gate applied at step t .

We construct a Hamiltonian H that operates on a space of $N + T$ qubits. The first N qubits represent the computation and the last T qubits represent the clock. We think of the clock as represented in unary,

$$(5.1) \quad |\hat{t}\rangle \stackrel{def}{=} |\underbrace{1\dots 1}_t \underbrace{0\dots 0}_{T-t}\rangle.$$

Let T_1 be the time steps in which a one-qubit gate is applied. Namely, $T_1 = \{1, \dots, T\} \setminus \{L, 2L, \dots, T_2L\}$. Then

$$H = H_{out} + J_{in}H_{in} + J_2H_{prop2} + J_1H_{prop1} + J_{clock}H_{clock},$$

⁶The original universal gate set in [5] consists of one-qubit gates and CNOT gates. It is, however, easy to see that a CNOT gate can be obtained from a C_ϕ gate by conjugating the second qubit with Hadamard gates (see [15]).

where

$$H_{in} = \sum_{i=m+1}^N |1\rangle\langle 1|_i \otimes |0\rangle\langle 0|_1, \quad H_{out} = (T+1)|0\rangle\langle 0|_1 \otimes |1\rangle\langle 1|_T,$$

$$H_{clock} = \sum_{1 \leq i < j \leq T} I \otimes |01\rangle\langle 01|_{ij}.$$

The terms H_{prop1} and H_{prop2} , which represent the correct propagation according to the one-qubit gates and two-qubit gates, respectively, are defined as

$$H_{prop1} = \sum_{t \in T_1} H_{prop,t}, \quad H_{prop2} = \sum_{l=1}^{T_2} (H_{qubit,lL} + H_{time,lL})$$

with

$$H_{prop,t} = \frac{1}{2} \left(I \otimes |10\rangle\langle 10|_{t,t+1} + I \otimes |10\rangle\langle 10|_{t-1,t} - U_t \otimes |1\rangle\langle 0|_t - U_t^\dagger \otimes |0\rangle\langle 1|_t \right)$$

for $t \in T_1 \cap \{2, \dots, T-1\}$ and

$$H_{prop,1} = \frac{1}{2} \left(I \otimes |10\rangle\langle 10|_{1,2} + I \otimes |0\rangle\langle 0|_1 - U_1 \otimes |1\rangle\langle 0|_1 - U_1^\dagger \otimes |0\rangle\langle 1|_1 \right),$$

$$H_{prop,T} = \frac{1}{2} \left(I \otimes |1\rangle\langle 1|_T + I \otimes |10\rangle\langle 10|_{T-1,T} - U_T \otimes |1\rangle\langle 0|_T - U_T^\dagger \otimes |0\rangle\langle 1|_T \right)$$

and, with f_t and s_t being the first and second qubits of the C_ϕ gate at time t ,

$$H_{qubit,t} = \frac{1}{2} \left(-2|0\rangle\langle 0|_{f_t} - 2|0\rangle\langle 0|_{s_t} + |1\rangle\langle 1|_{f_t} + |1\rangle\langle 1|_{s_t} \right) \otimes (|1\rangle\langle 0|_t + |0\rangle\langle 1|_t),$$

$$H_{time,t} = \frac{1}{8} I \otimes \left(|10\rangle\langle 10|_{t,t+1} + 6|10\rangle\langle 10|_{t+1,t+2} + |10\rangle\langle 10|_{t+2,t+3} \right. \\ \left. + 2|11\rangle\langle 00|_{t+1,t+2} + 2|00\rangle\langle 11|_{t+1,t+2} \right. \\ \left. + |1\rangle\langle 0|_{t+1} + |0\rangle\langle 1|_{t+1} + |1\rangle\langle 0|_{t+2} + |0\rangle\langle 1|_{t+2} \right. \\ \left. + |10\rangle\langle 10|_{t-3,t-2} + 6|10\rangle\langle 10|_{t-2,t-1} + |10\rangle\langle 10|_{t-1,t} \right. \\ \left. + 2|11\rangle\langle 00|_{t-2,t-1} + 2|00\rangle\langle 11|_{t-2,t-1} \right. \\ \left. + |1\rangle\langle 0|_{t-2} + |0\rangle\langle 1|_{t-2} + |1\rangle\langle 0|_{t-1} + |0\rangle\langle 1|_{t-1} \right).$$

At this point, these last two expressions might look strange. Let us say that later, when we consider their restriction to a smaller space, the reason for this definition should become clear. Note that all the above terms are at most 2-local. We will later choose $J_{in} \ll J_2 \ll J_1 \ll J_{clock} \leq \text{poly}(N)$. As in section 4, we have to prove the following lemma.

LEMMA 5.1. *Assume that the circuit V_x accepts with probability more than $1 - \varepsilon$ on some input $|\xi, 0\rangle$. Then H has an eigenvalue smaller than ε . If the circuit V_x accepts with probability less than ε on all inputs $|\xi, 0\rangle$, then all eigenvalues of H are larger than $\frac{1}{2} - \varepsilon$.*

Proof. If the circuit V_x accepts with probability more than $1 - \varepsilon$ on some input $|\xi, 0\rangle$, then the state

$$|\eta\rangle = \frac{1}{\sqrt{T+1}} \sum_{t=0}^T U_t \cdots U_1 |\xi, 0\rangle \otimes |\hat{t}\rangle$$

satisfies $\langle \eta | H | \eta \rangle \leq \varepsilon$. In order to see this, one can check that

$$\langle \eta | H_{clock} | \eta \rangle = \langle \eta | H_{prop1} | \eta \rangle = \langle \eta | H_{prop2} | \eta \rangle = \langle \eta | H_{in} | \eta \rangle = 0$$

and $\langle \eta | H_{out} | \eta \rangle \leq \varepsilon$. However, verifying that $\langle \eta | H_{prop2} | \eta \rangle = 0$ can be quite tedious. Later in the proof, we will mention an easier way to see this.

In the following, we will show that if the circuit V_x accepts with probability less than ε on all inputs $|\xi, 0\rangle$, then all eigenvalues of H are larger than $\frac{1}{2} - \varepsilon$. The proof of this is based on four applications of Lemma 3.1. Schematically, we proceed as follows:

$$\mathcal{H} \supset \mathcal{S}_{legal} \supset \mathcal{S}_{prop1} \supset \mathcal{S}_{prop} \supset \mathcal{S}_{in},$$

where \mathcal{S}_{legal} corresponds to states with *legal* clock states written in unary, and \mathcal{S}_{prop1} is spanned by states in the legal clock space whose propagation at time steps corresponding to *one-qubit* gates (that is, in T_1) is correct. Finally, \mathcal{S}_{prop} and \mathcal{S}_{in} are defined in almost the same way as in section 4. These spaces will be described in more detail later.

Norms. Note that all relevant norms, as needed in Lemma 3.1, are polynomial in N . Indeed, we have $\|H_{out}\| = T + 1$ and $\|H_{in}\| \leq N$ as in section 4, $\|H_{prop1}\| \leq \sum_{t \in T_1} \|H_{prop,t}\| \leq 2T$ (each term in H_{prop1} has norm at most 2), and $\|H_{prop2}\| \leq \sum_{t=1}^{T_2} (\|H_{qubit,t}\| + \|H_{time,t}\|) \leq O(T_2) \leq O(T)$.

1. *Restriction to legal clock states in \mathcal{S}_{legal} .* Let \mathcal{S}_{legal} be the $(T+1)2^N$ -dimensional space spanned by states with a legal unary representation on the T clock qubits, i.e., by states of the form $|\tilde{\xi}\rangle \otimes |\hat{t}\rangle$ with $|\hat{t}\rangle$ as in (5.1). In this first stage we apply Lemma 3.1 with

$$H_1 = H_{out} + J_{in}H_{in} + J_2H_{prop2} + J_1H_{prop1}, \quad H_2 = J_{clock}H_{clock}.$$

Notice that \mathcal{S}_{legal} is an eigenspace of H_2 of eigenvalue 0 and that states orthogonal to \mathcal{S}_{legal} have eigenvalue at least J_{clock} . Lemma 3.1 implies that we can choose $J_{clock} = \text{poly}(\|H_1\|) = \text{poly}(N)$ such that $\lambda(H)$ can be lower bounded by $\lambda(H_1|_{\mathcal{S}_{legal}}) - \frac{1}{8}$. Hence, in the remainder of the proof, it is enough to study $H_1|_{\mathcal{S}_{legal}}$ inside the space \mathcal{S}_{legal} . This can be written as

$$H_{out}|_{\mathcal{S}_{legal}} + J_{in}H_{in}|_{\mathcal{S}_{legal}} + J_2H_{prop2}|_{\mathcal{S}_{legal}} + J_1H_{prop1}|_{\mathcal{S}_{legal}}$$

with

$$\begin{aligned} H_{in}|_{\mathcal{S}_{legal}} &= \sum_{i=m+1}^N |1\rangle\langle 1|_i \otimes |\hat{0}\rangle\langle \hat{0}|, & H_{out}|_{\mathcal{S}_{legal}} &= (T+1)|0\rangle\langle 0|_1 \otimes |\hat{T}\rangle\langle \hat{T}|, \\ H_{prop,t}|_{\mathcal{S}_{legal}} &= \frac{1}{2} \left(I \otimes |\hat{t}\rangle\langle \hat{t}| + I \otimes |\hat{t-1}\rangle\langle \hat{t-1}| - U_t \otimes |\hat{t}\rangle\langle \hat{t-1}| - U_t^\dagger \otimes |\hat{t-1}\rangle\langle \hat{t}| \right), \\ H_{qubit,t}|_{\mathcal{S}_{legal}} &= \frac{1}{2} \left(-2|0\rangle\langle 0|_{f_t} - 2|0\rangle\langle 0|_{s_t} + |1\rangle\langle 1|_{f_t} + |1\rangle\langle 1|_{s_t} \right) \otimes \left(|\hat{t}\rangle\langle \hat{t-1}| + |\hat{t-1}\rangle\langle \hat{t}| \right), \\ H_{time,t}|_{\mathcal{S}_{legal}} &= \frac{1}{8} I \otimes \left(|\hat{t}\rangle\langle \hat{t}| + 6|\hat{t+1}\rangle\langle \hat{t+1}| + |\hat{t+2}\rangle\langle \hat{t+2}| \right. \\ &\quad + 2|\hat{t+2}\rangle\langle \hat{t}| + 2|\hat{t}\rangle\langle \hat{t+2}| + |\hat{t+1}\rangle\langle \hat{t}| + |\hat{t}\rangle\langle \hat{t+1}| + |\hat{t+2}\rangle\langle \hat{t+1}| + |\hat{t+1}\rangle\langle \hat{t+2}| \\ &\quad + |\hat{t-3}\rangle\langle \hat{t-3}| + 6|\hat{t-2}\rangle\langle \hat{t-2}| + |\hat{t-1}\rangle\langle \hat{t-1}| \\ &\quad \left. + 2|\hat{t-1}\rangle\langle \hat{t-3}| + 2|\hat{t-3}\rangle\langle \hat{t-1}| + |\hat{t-2}\rangle\langle \hat{t-3}| + |\hat{t-3}\rangle\langle \hat{t-2}| + |\hat{t-1}\rangle\langle \hat{t-2}| + |\hat{t-2}\rangle\langle \hat{t-1}| \right). \end{aligned}$$

The above was obtained by noting that the projection of a term like, say, $|10\rangle\langle 10|_{t,t+1}$ on \mathcal{S}_{legal} is exactly $|\hat{t}\rangle\langle \hat{t}|$. Similarly, the projection of the term $|1\rangle\langle 0|_{t+1}$ is $|\widehat{t+1}\rangle\langle \hat{t}|$.⁷ By rearranging terms, $H_{time,t}|_{\mathcal{S}_{legal}}$ can be written as a sum of projectors:

$$\begin{aligned}
 & \frac{1}{8}I \otimes \left\{ 2 \left(|\hat{t}\rangle + |\widehat{t+1}\rangle \right) \left(\langle \hat{t}| + \langle \widehat{t+1}| \right) + 2 \left(|\widehat{t+1}\rangle + |\widehat{t+2}\rangle \right) \left(\langle \widehat{t+1}| + \langle \widehat{t+2}| \right) \right. \\
 & \quad + \left(|\hat{t}\rangle - |\widehat{t+1}\rangle \right) \left(\langle \hat{t}| - \langle \widehat{t+1}| \right) + \left(|\widehat{t+1}\rangle - |\widehat{t+2}\rangle \right) \left(\langle \widehat{t+1}| - \langle \widehat{t+2}| \right) \\
 & \quad - 2 \left(|\hat{t}\rangle - |\widehat{t+2}\rangle \right) \left(\langle \hat{t}| - \langle \widehat{t+2}| \right) \\
 & \quad + 2 \left(|\widehat{t-3}\rangle + |\widehat{t-2}\rangle \right) \left(\langle \widehat{t-3}| + \langle \widehat{t-2}| \right) + 2 \left(|\widehat{t-2}\rangle + |\widehat{t-1}\rangle \right) \left(\langle \widehat{t-2}| + \langle \widehat{t-1}| \right) \\
 & \quad + \left(|\widehat{t-3}\rangle - |\widehat{t-2}\rangle \right) \left(\langle \widehat{t-3}| - \langle \widehat{t-2}| \right) + \left(|\widehat{t-2}\rangle - |\widehat{t-1}\rangle \right) \left(\langle \widehat{t-2}| - \langle \widehat{t-1}| \right) \\
 & \quad \left. - 2 \left(|\widehat{t-3}\rangle - |\widehat{t-1}\rangle \right) \left(\langle \widehat{t-3}| - \langle \widehat{t-1}| \right) \right\}.
 \end{aligned}
 \tag{5.2}$$

Notice that the above expression is symmetric around $t - \frac{1}{2}$ (i.e., switching $t - 1$ with t , $t - 2$ with $t + 1$, and $t - 3$ with $t + 2$ does not change the expression). Let us also mention that the fact that we have terms like $|\hat{t}\rangle - |\widehat{t+2}\rangle$ is crucial in our proof. They allow us to compare the state at time t to the state at time $t + 2$.

2. *Restriction to \mathcal{S}_{prop1} .* We now apply Lemma 3.1 inside \mathcal{S}_{legal} with

$$H_1 = (H_{out} + J_{in}H_{in} + J_2H_{prop2})|_{\mathcal{S}_{legal}}, \quad H_2 = J_1H_{prop1}|_{\mathcal{S}_{legal}}.$$

Let \mathcal{S}_{prop1} be the $2^N(T_2 + 1)$ -dimensional space given by all states that represent correct propagation on all one-qubit gates. More precisely, let

$$|\eta_{l,i}\rangle \stackrel{def}{=} \frac{1}{\sqrt{L}} \sum_{t=lL}^{(l+1)L-1} U_t \cdots U_1 |i\rangle \otimes |\hat{t}\rangle,
 \tag{5.3}$$

where $l \in \{0, \dots, T_2\}$, $i \in \{0, \dots, 2^N - 1\}$, and $|i\rangle$ represents the i th vector in the computational basis. Then these states form a basis of \mathcal{S}_{prop1} . It is easy to see that each $|\eta_{l,i}\rangle$ is an eigenvector of H_{prop1} of eigenvalue 0. Hence, \mathcal{S}_{prop1} is an eigenspace of eigenvalue 0 of $H_{prop1}|_{\mathcal{S}_{legal}}$. Furthermore, $H_{prop1}|_{\mathcal{S}_{legal}}$ decomposes into $T_2 + 1$ invariant blocks, with the l th block spanned by states of the form $U_t \cdots U_1 |i\rangle \otimes |\hat{t}\rangle$ for $t = lL, \dots, (l + 1)L - 1$. Inside such a block $H_{prop1}|_{\mathcal{S}_{legal}}$ corresponds exactly to H_{prop} of section 4, equations (4.1), (4.2). By Claim 4.2, its nonzero eigenvalues are at least $c/L^2 \geq c/T^2$ for some constant $c > 0$ and hence the smallest nonzero eigenvalue of $H_{prop1}|_{\mathcal{S}_{legal}}$ is also at least c/T^2 . Therefore, all eigenvectors of H_2 orthogonal to \mathcal{S}_{prop1} have eigenvalue at least $J = J_1c/T^2$ and Lemma 3.1 implies that for $J_1 \geq \text{poly}(N)$, $\lambda(H_1 + H_2)$ can be lower bounded by $\lambda(H_1|_{\mathcal{S}_{prop1}}) - \frac{1}{8}$.

Hence, in the remainder of the proof, it is enough to study

$$H_{out}|_{\mathcal{S}_{prop1}} + J_{in}H_{in}|_{\mathcal{S}_{prop1}} + J_2H_{prop2}|_{\mathcal{S}_{prop1}}.$$

Let us find $H_{prop2}|_{\mathcal{S}_{prop1}}$. Let $t = lL$ be the time at which the l th C_ϕ gate is applied and consider the projection of a state $|\eta_{l,i}\rangle$ onto the space spanned by the computation

⁷Notice that we do not have terms like $|1\rangle\langle 1|_t$; its projection on \mathcal{S}_{legal} is not $|\hat{t}\rangle\langle \hat{t}|$ but rather $|\hat{t}\rangle\langle \hat{t}| + \cdots + |\widehat{T}\rangle\langle \widehat{T}|$.

qubits and $|\widehat{t}\rangle, |\widehat{t+1}\rangle, |\widehat{t+2}\rangle$. Since at time $t + 1$ (resp., $t + 2$) a Z gate is applied to qubit f_t (resp., s_t), this projection is a linear combination of the following four states:

$$\begin{aligned} & |00\rangle_{f_t, s_t} |\xi_{00}\rangle \otimes \left(|\widehat{t}\rangle + |\widehat{t+1}\rangle + |\widehat{t+2}\rangle \right), \\ & |01\rangle_{f_t, s_t} |\xi_{01}\rangle \otimes \left(|\widehat{t}\rangle + |\widehat{t+1}\rangle - |\widehat{t+2}\rangle \right), \\ & |10\rangle_{f_t, s_t} |\xi_{10}\rangle \otimes \left(|\widehat{t}\rangle - |\widehat{t+1}\rangle - |\widehat{t+2}\rangle \right), \\ & |11\rangle_{f_t, s_t} |\xi_{11}\rangle \otimes \left(|\widehat{t}\rangle - |\widehat{t+1}\rangle + |\widehat{t+2}\rangle \right), \end{aligned}$$

where $|\xi_{b_1 b_2}\rangle$ is an arbitrary state on the remaining $N - 2$ computation qubits. This implies that the restriction to \mathcal{S}_{prop1} of the projector on, say, $|\widehat{t}\rangle + |\widehat{t+1}\rangle$ from (5.2) is essentially the same as the restriction to \mathcal{S}_{prop1} of the projector on $|0\rangle_{f_t} |\widehat{t}\rangle$. More precisely, for all l_1, l_2, i_1, i_2 we have

$$\frac{1}{4} \langle \eta_{l_1, i_1} | \left(I \otimes (|\widehat{t}\rangle + |\widehat{t+1}\rangle) \right) (\langle \widehat{t} | + \langle \widehat{t+1} |) | \eta_{l_2, i_2} \rangle = \langle \eta_{l_1, i_1} | \left(|0\rangle \langle 0|_{f_t} \otimes |\widehat{t}\rangle \langle \widehat{t}| \right) | \eta_{l_2, i_2} \rangle.$$

Similarly, the term involving $|\widehat{t}\rangle - |\widehat{t+2}\rangle$ satisfies

$$\begin{aligned} & \frac{1}{4} \langle \eta_{l_1, i_1} | \left(I \otimes (|\widehat{t}\rangle - |\widehat{t+2}\rangle) \right) (\langle \widehat{t} | - \langle \widehat{t+2} |) | \eta_{l_2, i_2} \rangle \\ & = \langle \eta_{l_1, i_1} | \left((|01\rangle \langle 01|_{f_t, s_t} + |10\rangle \langle 10|_{f_t, s_t}) \otimes |\widehat{t}\rangle \langle \widehat{t}| \right) | \eta_{l_2, i_2} \rangle. \end{aligned}$$

Observe that the right-hand side involves two computation qubits and the clock register. Being able to obtain such a term from 2-local terms is a crucial ingredient in this proof.

Following a similar calculation, we see that from the terms involving $|\widehat{t-1}\rangle, |\widehat{t-2}\rangle, |\widehat{t-3}\rangle$ we obtain projectors involving $|\widehat{t-1}\rangle$. To summarize, instead of considering $H_{time, t} |_{\mathcal{S}_{prop1}}$ we can equivalently consider the restriction to \mathcal{S}_{prop1} of

$$\begin{aligned} & \frac{1}{2} \left(2|0\rangle \langle 0|_{f_t} + 2|0\rangle \langle 0|_{s_t} + |1\rangle \langle 1|_{f_t} + |1\rangle \langle 1|_{s_t} - 2|01\rangle \langle 01|_{f_t, s_t} - 2|10\rangle \langle 10|_{f_t, s_t} \right) \\ & \otimes \left(|\widehat{t-1}\rangle \langle \widehat{t-1}| + |\widehat{t}\rangle \langle \widehat{t}| \right). \end{aligned}$$

We now add the terms in $H_{qubit, t}$. A short calculation shows that the restriction to \mathcal{S}_{prop1} of $(H_{time, t} + H_{qubit, t})$ is the same as the restriction to \mathcal{S}_{prop1} of

$$\begin{aligned} & |00\rangle \langle 00|_{f_t, s_t} \otimes 2 \left(|\widehat{t-1}\rangle - |\widehat{t}\rangle \right) \left(\langle \widehat{t-1} | - \langle \widehat{t} | \right) + \\ & |01\rangle \langle 01|_{f_t, s_t} \otimes \frac{1}{2} \left(|\widehat{t-1}\rangle - |\widehat{t}\rangle \right) \left(\langle \widehat{t-1} | - \langle \widehat{t} | \right) + \\ & |10\rangle \langle 10|_{f_t, s_t} \otimes \frac{1}{2} \left(|\widehat{t-1}\rangle - |\widehat{t}\rangle \right) \left(\langle \widehat{t-1} | - \langle \widehat{t} | \right) + \\ & |11\rangle \langle 11|_{f_t, s_t} \otimes \left(|\widehat{t-1}\rangle + |\widehat{t}\rangle \right) \left(\langle \widehat{t-1} | + \langle \widehat{t} | \right). \end{aligned}$$

At this point, let us mention how one can show that for the state $|\eta\rangle$ described in the beginning of this proof, $\langle \eta | H_{prop2} | \eta \rangle = 0$. First, observe that $|\eta\rangle \in \mathcal{S}_{prop1}$ (its propagation is correct at all time steps). Next, since $|\eta\rangle$ has a C_ϕ propagation at time t , the above Hamiltonian shows that $\langle \eta | H_{prop2} | \eta \rangle = 0$.

Let us return now to the main proof. Recall that we wish to show a lower bound on the lowest eigenvalue of

$$(5.4) \quad H_{out}|_{\mathcal{S}_{prop1}} + J_{in}H_{in}|_{\mathcal{S}_{prop1}} + J_2H_{prop2}|_{\mathcal{S}_{prop1}}.$$

In the following, we show a lower bound on the lowest eigenvalue of the Hamiltonian

$$(5.5) \quad H_{out}|_{\mathcal{S}_{prop1}} + J_{in}H_{in}|_{\mathcal{S}_{prop1}} + J_2H'$$

on \mathcal{S}_{prop1} , where H' satisfies that $H' \leq H_{prop2}|_{\mathcal{S}_{prop1}}$, i.e., $H_{prop2}|_{\mathcal{S}_{prop1}} - H'$ is positive semidefinite. Hence, any lower bound on the lowest eigenvalue of the Hamiltonian in (5.5) implies the same lower bound on the lowest eigenvalue of the Hamiltonian in (5.4). We define H' as the sum over $t \in \{L, 2L, \dots, T_2L\}$ of the restriction to \mathcal{S}_{prop1} of

$$\begin{aligned} &|00\rangle\langle 00|_{f_t, s_t} \otimes \frac{1}{2} \left(|\widehat{t-1}\rangle - |\widehat{t}\rangle \right) \left(\langle \widehat{t-1}| - \langle \widehat{t}| \right) + \\ &|01\rangle\langle 01|_{f_t, s_t} \otimes \frac{1}{2} \left(|\widehat{t-1}\rangle - |\widehat{t}\rangle \right) \left(\langle \widehat{t-1}| - \langle \widehat{t}| \right) + \\ &|10\rangle\langle 10|_{f_t, s_t} \otimes \frac{1}{2} \left(|\widehat{t-1}\rangle - |\widehat{t}\rangle \right) \left(\langle \widehat{t-1}| - \langle \widehat{t}| \right) + \\ &|11\rangle\langle 11|_{f_t, s_t} \otimes \frac{1}{2} \left(|\widehat{t-1}\rangle + |\widehat{t}\rangle \right) \left(\langle \widehat{t-1}| + \langle \widehat{t}| \right). \end{aligned}$$

Equivalently, H' is the sum over $t \in \{L, 2L, \dots, T_2L\}$ of

$$\frac{1}{2} \left(I \otimes |\widehat{t}\rangle\langle \widehat{t}| + I \otimes |\widehat{t-1}\rangle\langle \widehat{t-1}| - C_\phi \otimes |\widehat{t}\rangle\langle \widehat{t-1}| - C_\phi^\dagger \otimes |\widehat{t-1}\rangle\langle \widehat{t}| \right) \Big|_{\mathcal{S}_{prop1}},$$

which resembles (4.2). Note that this term enforces correct propagation at time step $t = lL$. We claim that

$$(5.6) \quad H' = \frac{1}{2L} \sum_{i=0}^{2^N-1} \sum_{l=1}^{T_2} (|\eta_{l-1,i}\rangle - |\eta_{l,i}\rangle) (\langle \eta_{l-1,i}| - \langle \eta_{l,i}|).$$

The intuitive reason for this is the following. For any i , $|\eta_{l-1,i}\rangle + |\eta_{l,i}\rangle$ can be seen as a correct propagation at time $t = lL$. In other words, consider the projection of $|\eta_{l,i}\rangle$ on clock $|\widehat{t}\rangle$ and the projection of $|\eta_{l-1,i}\rangle$ on clock $|\widehat{t-1}\rangle$. Then the first state is exactly the second state after applying the l th C_ϕ gate. This means that inside \mathcal{S}_{prop1} , checking correct propagation from time $t-1$ to time t is equivalent to checking correct propagation from $|\eta_{l-1,i}\rangle$ to $|\eta_{l,i}\rangle$.

More precisely, fix some l and $t = lL$. Then, using (5.3), we get that for all l_1, l_2, i_1, i_2 such that either $l_1 \neq l$, $l_2 \neq l$, or $i_1 \neq i_2$,

$$\langle \eta_{l_1, i_1} | (I \otimes |\widehat{t}\rangle\langle \widehat{t}|) | \eta_{l_2, i_2} \rangle = 0.$$

Otherwise, $l_1 = l_2 = l$ and $i_1 = i_2 = i$ for some i and we have

$$\langle \eta_{l,i} | (I \otimes |\widehat{t}\rangle\langle \widehat{t}|) | \eta_{l,i} \rangle = \frac{1}{L}.$$

Hence we obtain

$$I \otimes |\widehat{t}\rangle\langle \widehat{t}| \Big|_{\mathcal{S}_{prop1}} = \frac{1}{L} \sum_{i=0}^{2^N-1} |\eta_{l,i}\rangle\langle \eta_{l,i}|$$

and similarly,

$$I \otimes |\widehat{t-1}\rangle\langle\widehat{t-1}|_{\mathcal{S}_{prop1}} = \frac{1}{L} \sum_{i=0}^{2^N-1} |\eta_{l-1,i}\rangle\langle\eta_{l-1,i}|.$$

For the off-diagonal terms we see that

$$\langle\eta_{l_1,i_1}| \left(C_\phi \otimes |\widehat{t}\rangle\langle\widehat{t-1}| \right) |\eta_{l_2,i_2}\rangle = 0$$

if $l_1 \neq l$ or $l_2 \neq l - 1$. If $l_1 = l$ and $l_2 = l - 1$, then using $C_\phi = U_{lL}$, we get

$$\langle\eta_{l,i_1}| \left(C_\phi \otimes |\widehat{t}\rangle\langle\widehat{t-1}| \right) |\eta_{l-1,i_2}\rangle = \frac{1}{L} \langle i_1 | (U_{lL} \cdots U_1)^\dagger C_\phi U_{lL-1} \cdots U_1 | i_2 \rangle = \frac{1}{L} \langle i_1 | i_2 \rangle,$$

which is 0 if $i_1 \neq i_2$ and $\frac{1}{L}$ otherwise. Hence $C_\phi \otimes |\widehat{t}\rangle\langle\widehat{t-1}|_{\mathcal{S}_{prop1}} = \frac{1}{L} \sum_{i=0}^{2^N-1} |\eta_{l,i}\rangle\langle\eta_{l-1,i}|$ and similarly for its Hermitian adjoint. This establishes (5.6).

3. *Restriction to \mathcal{S}_{prop} .* Let \mathcal{S}_{prop} be the 2^N -dimensional space whose basis is given by the states

$$|\eta_i\rangle = \frac{1}{\sqrt{T+1}} \sum_{t=0}^T U_t \cdots U_1 |i\rangle \otimes |\widehat{t}\rangle = \frac{1}{\sqrt{T_2+1}} \sum_{l=0}^{T_2} |\eta_{l,i}\rangle$$

for $i \in \{0, \dots, 2^N - 1\}$. Equation (5.6) shows that \mathcal{S}_{prop} is an eigenspace of H' of eigenvalue 0. Moreover, H' is block-diagonal with 2^N blocks of size $T_2 + 1$. Each block is a matrix as in (4.4), multiplied by $1/L$. As in Claim 4.2 we see that the smallest nonzero eigenvalue of this Hamiltonian is $c/LT_2^2 \geq c/T^2$ for some constant c . Now we can apply Lemma 3.1. This time, we apply it inside \mathcal{S}_{prop1} with

$$H_1 = (H_{out} + J_{in}H_{in})|_{\mathcal{S}_{prop1}}, \quad H_2 = J_2H'.$$

Eigenvectors of H_2 orthogonal to \mathcal{S}_{prop} have eigenvalue at least $J = J_2c/T^2$. As before, we can choose $J_2 = \text{poly}(N)$ such that $\lambda(H_1 + H_2)$ is lower bounded by $\lambda(H_1|_{\mathcal{S}_{prop}}) - \frac{1}{8}$. Hence, in the remainder we consider

$$H_{out}|_{\mathcal{S}_{prop}} + J_{in}H_{in}|_{\mathcal{S}_{prop}}.$$

4. *Restriction to \mathcal{S}_{in} .* The rest of the proof proceeds in the same way as in section 4. Indeed, the subspace \mathcal{S}_{prop} is isomorphic to the one in section 4 and both $H_{out}|_{\mathcal{S}_{prop}}$ and $H_{in}|_{\mathcal{S}_{prop}}$ are the same Hamiltonians. So by another application of Lemma 3.1 we get that the lowest eigenvalue of $H_{out}|_{\mathcal{S}_{prop}} + J_{in}H_{in}|_{\mathcal{S}_{prop}}$ is lower bounded by $\lambda(H_{out}|_{\mathcal{S}_{in}}) - \frac{1}{8}$. As in section 4, we have that $\lambda(H_{out}|_{\mathcal{S}_{in}}) > 1 - \varepsilon$ if the circuit accepts with probability less than ε . Hence $\lambda(H)$, the lowest eigenvalue of the original Hamiltonian H , is larger than $1 - \varepsilon - \frac{4}{8} = \frac{1}{2} - \varepsilon$. \square

6. Perturbation theory proof. In this section we give an alternative proof of our main theorem. In section 6.1, we develop our perturbation theory technique. Since this technique might constitute a useful tool in other Hamiltonian constructions, we keep the presentation as general as possible. Then, in section 6.2, we present a specific application of our technique, the three-qubit gadget. Finally, in section 6.3, we use this gadget to complete the proof of the main theorem.

6.1. Perturbation theory. The goal in perturbation theory is to analyze the spectrum of the sum of two Hamiltonians $\tilde{H} = H + V$ in the case that V has a small norm compared to the spectral gap of H . One setting was described in the projection lemma. Specifically, assume H has a zero eigenvalue with the associated eigenspace \mathcal{S} , whereas all other eigenvalues are greater than $\Delta \gg \|V\|$. The projection lemma shows that in this case, the lowest eigenvalue of \tilde{H} is close to that of $V|_{\mathcal{S}}$. In this section we find a better approximation to $\text{Spec } \tilde{H}$ by considering certain correction terms that involve higher powers of V . It turns out that these higher order correction terms include interesting interactions, which will allow us to create an effective 3-local Hamiltonian from 2-local terms. We remark that the projection lemma (for the entire lower part of the spectrum) can be obtained by following the development done in this section up to the first order.

Before giving a more detailed description of the technique, we need to introduce a certain amount of notation. For two Hermitian operators H and V , let $\tilde{H} = H + V$. We refer to H as the *unperturbed Hamiltonian* and to V as the *perturbation Hamiltonian*. Let $\lambda_j, |\psi_j\rangle$ be the eigenvalues and eigenvectors of H , whereas the eigenvalues and eigenvectors of \tilde{H} are denoted by $\tilde{\lambda}_j, |\tilde{\psi}_j\rangle$. In case of multiplicities, some eigenvalues might appear more than once. We order the eigenvalues in a nondecreasing order

$$\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_{\dim \mathcal{H}}, \quad \tilde{\lambda}_1 \leq \tilde{\lambda}_2 \leq \dots \leq \tilde{\lambda}_{\dim \mathcal{H}}.$$

In general, everything related to the perturbed Hamiltonian is marked with a tilde.

An important component in our proof is the *resolvent* of \tilde{H} , defined as

$$(6.1) \quad \tilde{G}(z) = (zI - \tilde{H})^{-1} = \sum_j (z - \tilde{\lambda}_j)^{-1} |\tilde{\psi}_j\rangle \langle \tilde{\psi}_j|.$$

It is a meromorphic⁸ operator-valued function of the complex variable z with poles at $z = \tilde{\lambda}_j$. In fact, for our purposes, it is sufficient to consider real z .⁹ Its usefulness comes from the fact that poles can be preserved under projections (while eigenvalues are usually lost). Similarly, we define the resolvent of H as $G(z) = (zI - H)^{-1}$.¹⁰

Let $\lambda_* \in \mathbb{R}$ be some cutoff on the spectrum of H .

DEFINITION 6.1. Let $\mathcal{H} = \mathcal{L}_+ \oplus \mathcal{L}_-$, where \mathcal{L}_+ is the space spanned by eigenvectors of H with eigenvalues $\lambda \geq \lambda_*$ and \mathcal{L}_- is spanned by eigenvectors of H of eigenvalue $\lambda < \lambda_*$. Let Π_{\pm} be the corresponding projection onto \mathcal{L}_{\pm} . For an operator X on \mathcal{H} define the operator $X_{++} = X|_{\mathcal{L}_+} = \Pi_+ X \Pi_+$ on \mathcal{L}_+ and similarly $X_{--} = X|_{\mathcal{L}_-}$. We also define $X_{+-} = \Pi_+ X \Pi_-$ as an operator from \mathcal{L}_- to \mathcal{L}_+ , and similarly X_{-+} .

With these definitions, in a representation of $\mathcal{H} = \mathcal{L}_+ \oplus \mathcal{L}_-$ both H and G are block-diagonal and we will omit one index for their blocks, i.e., $H_+ \stackrel{\text{def}}{=} H_{++}$,

⁸A meromorphic function is analytic in all but a discrete subset of \mathbb{C} , and these singularities must be poles and not essential singularities.

⁹The resolvent is the main tool in abstract spectral theory [19]. In physics, it is known as the *Green's function*. Physicists actually use slightly different Green's functions that are suited for specific problems.

¹⁰We can express \tilde{G} in terms of G (where we omit the variable z): $\tilde{G} = (G^{-1} - V)^{-1} = G(I - VG)^{-1} = G + GVG + GVGVG + GVGVGVG + \dots$. This expansion of \tilde{G} in powers of V may be represented by Feynman diagrams [1].

$G_+ \stackrel{\text{def}}{=} G_{++}$ and so on. Note that $G_{\pm}^{-1} = zI_{\pm} - H_{\pm}$. To summarize, we have

$$\begin{aligned} \tilde{H} &= \begin{pmatrix} \tilde{H}_{++} & \tilde{H}_{+-} \\ \tilde{H}_{-+} & \tilde{H}_{--} \end{pmatrix}, \quad V = \begin{pmatrix} V_{++} & V_{+-} \\ V_{-+} & V_{--} \end{pmatrix}, \quad H = \begin{pmatrix} H_+ & 0 \\ 0 & H_- \end{pmatrix}, \\ \tilde{G} &= \begin{pmatrix} \tilde{G}_{++} & \tilde{G}_{+-} \\ \tilde{G}_{-+} & \tilde{G}_{--} \end{pmatrix}, \quad G = \begin{pmatrix} G_+ & 0 \\ 0 & G_- \end{pmatrix}. \end{aligned}$$

We similarly write $\mathcal{H} = \tilde{\mathcal{L}}_+ \oplus \tilde{\mathcal{L}}_-$ according to the spectrum of \tilde{H} and the cutoff λ_* . Finally, we define

$$\Sigma_-(z) = zI_- - \tilde{G}_{--}^{-1}(z).$$

This operator-valued function is called *self-energy*.¹¹

With these notations in place, we can now give an overview of what follows. Our goal is to approximate the spectrum of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$. We will do this by showing that in some sense, the spectrum of $\Sigma_-(z)$ gives such an approximation. To see why this arises, notice that by definition of $\Sigma_-(z)$, we have $\tilde{G}_{--}(z) = (zI_- - \Sigma_-(z))^{-1}$. In some sense, this equation is the analogue of (6.1), where $\Sigma_-(z)$ plays the role of a Hamiltonian for the projected resolvent $\tilde{G}_{--}(z)$. However, $\Sigma_-(z)$ is in general z -dependent and not a fixed Hamiltonian. Nonetheless, for certain choices of H and V , $\Sigma_-(z)$ is nearly constant in a certain range of z so we can choose an *effective Hamiltonian* H_{eff} that approximates $\Sigma_-(z)$ in this range. Our main theorem relates the spectrum of H_{eff} to that of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$.

THEOREM 6.2. *Assume H has a spectral gap Δ around the cutoff λ_* ; i.e., all its eigenvalues are in $(-\infty, \lambda_-] \cup [\lambda_+, +\infty)$, where $\lambda_+ = \lambda_* + \Delta/2$ and $\lambda_- = \lambda_* - \Delta/2$. Assume, moreover, that $\|V\| < \Delta/2$. Let $\varepsilon > 0$ be arbitrary. Assume there exists an operator H_{eff} such that $\text{Spec } H_{\text{eff}} \subseteq [c, d]$ for some $c < d < \lambda_* - \varepsilon$ and, moreover, the inequality*

$$\|\Sigma_-(z) - H_{\text{eff}}\| \leq \varepsilon$$

holds for all $z \in [c - \varepsilon, d + \varepsilon]$. Then each eigenvalue $\tilde{\lambda}_j$ of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$ is ε -close to the j th eigenvalue of H_{eff} .

The usefulness of the theorem comes from the fact that $\Sigma_-(z)$ has a natural series expansion, which can be truncated to obtain H_{eff} . This series may give rise to interesting terms; for example, in our application, 2-local terms in H and V lead to 3-local terms in H_{eff} . To obtain this expansion, we start by expressing \tilde{G} in terms of G as

$$\tilde{G} = (G^{-1} - V)^{-1} = \begin{pmatrix} G_+^{-1} - V_{++} & -V_{+-} \\ -V_{-+} & G_-^{-1} - V_{--} \end{pmatrix}^{-1}.$$

Then, using the block matrix identity

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix}^{-1} = \begin{pmatrix} (A - BD^{-1}C)^{-1} & -A^{-1}B(D - CA^{-1}B)^{-1} \\ -D^{-1}C(A - BD^{-1}C)^{-1} & (D - CA^{-1}B)^{-1} \end{pmatrix}$$

¹¹As we will see later, this definition includes an H_- term. This term is usually not considered part of self-energy, but we have included it for notational convenience.

we conclude that

$$\tilde{G}_{--} = \left(G_{-}^{-1} - V_{--} - V_{-+}(G_{+}^{-1} - V_{++})^{-1}V_{+-} \right)^{-1}.$$

Finally, we can represent $\Sigma_{-}(z)$ using the series expansion $(I-X)^{-1} = I+X+X^2+\dots$,

$$\begin{aligned} \Sigma_{-}(z) &= H_{-} + V_{--} + V_{-+}(G_{+}^{-1} - V_{++})^{-1}V_{+-} \\ (6.2) \quad &= H_{-} + V_{--} + V_{-+}G_{+}(I_{+} - V_{++}G_{+})^{-1}V_{+-} \\ &= H_{-} + V_{--} + V_{-+}G_{+}V_{+-} + V_{-+}G_{+}V_{++}G_{+}V_{+-} \\ &\quad + V_{-+}G_{+}V_{++}G_{+}V_{++}G_{+}V_{+-} + \dots \end{aligned}$$

Proof of Theorem 6.2. We start with an overview of the proof. We first notice that, by definition, the eigenvalues of $\tilde{H}|_{\tilde{\mathcal{L}}_{-}}$ appear as poles in \tilde{G} . In Lemma 6.4, we show that these poles also appear as poles of \tilde{G}_{--} . As mentioned before, this is the reason we work with resolvents. In Lemmas 6.5 and 6.6 we relate these poles to the eigenvalues of Σ_{-} by showing that z is a pole of \tilde{G}_{--} if and only if it is an eigenvalue of $\Sigma_{-}(z)$. In other words, these are values of z for which $\Sigma_{-}(z)$ has z as an eigenvalue. Finally, we complete the proof of the theorem by using the assumption that $\Sigma_{-}(z)$ is close to H_{eff} , and thus any eigenvalue of $\Sigma_{-}(z)$ must be close to an eigenvalue of H_{eff} . This situation is illustrated in Figure 6.1.

FIG. 6.1. The spectrum of $\Sigma_{-}(z)$ as a function of z is indicated with solid curves. The boxes correspond to the spectrum of $\tilde{H}|_{\tilde{\mathcal{L}}_{-}}$; they are those eigenvalues of $\Sigma_{-}(z)$ that lie on the dashed line $z = \text{e.v.}$ The dots indicate the spectrum of H_{eff} , which approximates the spectrum of $\tilde{H}|_{\tilde{\mathcal{L}}_{-}}$.

We start with a simple lemma that says that if two Hamiltonians H_1, H_2 are close, their spectra must also be close. It is a special case of Weyl’s inequalities (see, e.g., section III.2 in [6]).

LEMMA 6.3. *Let H_1, H_2 be two Hamiltonians with eigenvalues $\mu_1 \leq \mu_2 \leq \dots$ and $\sigma_1 \leq \sigma_2 \leq \dots$. Then, for all j , $|\mu_j - \sigma_j| \leq \|H_1 - H_2\|$.*

Proof. We will use a fact from the theory of Hermitian forms: If $X \leq Y$ (i.e., if $Y - X$ is positive semidefinite), then the operator Y has at least as many positive and nonnegative eigenvalues as X . Let $\varepsilon = \|H_1 - H_2\|$; then

$$(\mu_j - \varepsilon)I - H_2 \leq \mu_j I - H_1 \leq (\mu_j + \varepsilon)I - H_2.$$

The operator $\mu_j I - H_1$ has at most $j - 1$ positive and at least j nonnegative eigenvalues. Hence $(\mu_j - \varepsilon)I - H_2$ has at most $j - 1$ positive eigenvalues, and $(\mu_j + \varepsilon)I - H_2$ has at least j nonnegative eigenvalues. It follows that $\sigma_j \in [\mu_j - \varepsilon, \mu_j + \varepsilon]$. \square

The next lemma asserts that the poles of \tilde{G}_{--} in the range $(-\infty, \lambda_*)$ are in one-to-one correspondence with the eigenvalues of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$. Hence we can recover the eigenvalues of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$ from the poles of \tilde{G}_{--} .

LEMMA 6.4. *Let $\tilde{\lambda}$ be in $(-\infty, \lambda_*)$ and let $m \geq 0$ be its multiplicity as an eigenvalue of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$. Then around $\tilde{\lambda}$, \tilde{G}_{--} is of the form $(z - \tilde{\lambda})^{-1}A + O(1)$, where A is a rank m operator.*

Proof. We first show that $\tilde{\mathcal{L}}_- \cap \mathcal{L}_+ = \{0\}$. Suppose the contrary; i.e., there is a nonzero vector $|\xi\rangle \in \tilde{\mathcal{L}}_- \cap \mathcal{L}_+$. Without loss of generality, $\langle \xi | \xi \rangle = 1$. Then we have $\langle \xi | (H + V) | \xi \rangle \leq \lambda_*$ (since $|\xi\rangle \in \tilde{\mathcal{L}}_-$) and $\langle \xi | H | \xi \rangle \geq \lambda_+$ (since $|\xi\rangle \in \mathcal{L}_+$). Hence $\langle \xi | V | \xi \rangle \leq \lambda_* - \lambda_+ = -\Delta/2$. But this is impossible because $\|V\| < \Delta/2$.

Now, since $\tilde{\mathcal{L}}_- \cap \mathcal{L}_+ = \{0\}$, we have that $\Pi_- |\xi\rangle \neq 0$ for all nonzero vectors $|\xi\rangle \in \tilde{\mathcal{L}}_-$. From (6.1) we obtain

$$\tilde{G}_{--} = \Pi_- \tilde{G} \Pi_- = \sum_j (z - \tilde{\lambda}_j)^{-1} \Pi_- |\tilde{\psi}_j\rangle \langle \tilde{\psi}_j | \Pi_-.$$

If the multiplicity of $\tilde{\lambda}$ is m , then the matrix $\sum |\tilde{\psi}_j\rangle \langle \tilde{\psi}_j |$ of the corresponding eigenvectors has rank m . This implies that the matrix $\sum \Pi_- |\tilde{\psi}_j\rangle \langle \tilde{\psi}_j | \Pi_-$ also has rank m . Indeed, if there is some linear combination of $\Pi_- |\tilde{\psi}_j\rangle$ that sums to zero, then taking the same linear combination of $|\tilde{\psi}_j\rangle$ must also sum to zero. \square

The next two lemmas relate the spectrum of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$ to the operator $\Sigma_-(z)$.

LEMMA 6.5. *For any $z < \lambda_*$, the multiplicity of z as an eigenvalue of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$ is equal to the multiplicity of z as an eigenvalue of $\Sigma_-(z)$.*

Proof. Fix some $z < \lambda_*$ and let m be its multiplicity as an eigenvalue of \tilde{H} (in particular, $m = 0$ if z is not an eigenvalue of \tilde{H}). In the neighborhood of z the function $\tilde{G}_{--}(w)$ has the form

$$\tilde{G}_{--}(w) = (w - z)^{-1}A + B + O(|w - z|),$$

where by Lemma 6.4, A is an operator of rank m . We now consider $\tilde{G}_{--}^{-1}(w)$. For any $w < \lambda_+ - \|V\|$ the norm of $G_+(w)$ is strictly less than $1/\|V\|$. Hence, by (6.2) we see that all the poles of $\Sigma_-(w)$ lie on the interval $[\lambda_+ - \|V\|, +\infty)$; in particular $\tilde{G}_{--}^{-1}(w) = wI_- - \Sigma_-(w)$ is analytic for $w \in (-\infty, \lambda_*)$. Hence we can write

$$\tilde{G}_{--}^{-1}(w) = wI_- - \Sigma_-(w) = C + D(w - z) + O(|w - z|^2).$$

We claim that the dimension of the null-space of C is exactly m . Notice that this implies that z is an m -fold eigenvalue of $\Sigma_-(z) = zI_- - C$. By multiplying the two equations above, we obtain

$$I_- = \tilde{G}_{--}^{-1}(w)\tilde{G}_{--}(w) = (w - z)^{-1}CA + (DA + CB) + O(|w - z|).$$

By equating coefficients, we obtain $CA = 0$ and $DA + CB = I_-$. On one hand, $CA = 0$ implies that the null-space of C has dimension at least m . On the other hand, the rank of DA is at most $\text{rank}(A) = m$. Since I_- has full rank, the dimension

of the null-space of CB must be at most m . This implies that the dimension of the null-space of C must also be at most m . \square

We observe that the function $\Sigma_-(z)$ is monotone decreasing in the operator sense (i.e., if $z_1 \leq z_2$, then $\Sigma_-(z_1) - \Sigma_-(z_2)$ is positive semidefinite):

$$\begin{aligned} \frac{d\Sigma_-(z)}{dz} &= \frac{d}{dz} \left(H_- + V_{--} + V_{-+}(zI_+ - H_+ - V_{++})^{-1}V_{+-} \right) \\ &= -V_{-+}(zI_+ - H_+ - V_{++})^{-2}V_{+-} \leq 0. \end{aligned}$$

LEMMA 6.6. *Let $\tilde{\lambda}_j$ be the j th eigenvalue of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$. Then it is also the j th eigenvalue of $\Sigma_-(\tilde{\lambda}_j)$.*

Proof. For any $z \in \mathbb{R}$, let $f_1(z)$ (resp., $f_2(z)$) be the number of eigenvalues not greater than z of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$ (resp., $\Sigma_-(z)$). When $z \rightarrow -\infty$, $f_1(z)$ is clearly 0. By the monotonicity of Σ_- we see that $f_2(z)$ is also 0. Using Lemma 6.5 we see that as z increases, both numbers increase together by the same amount m whenever z hits an eigenvalue of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$ of multiplicity m (here we used again the monotonicity of Σ_-). Hence, for all z , $f_1(z) = f_2(z)$ and the lemma is proven. \square

We can now complete the proof of the theorem. By Lemma 6.3 and our assumption on H_{eff} , we have that for any $z \in [c - \varepsilon, d + \varepsilon]$, $\text{Spec } \Sigma_-(z)$ is contained in $[c - \varepsilon, d + \varepsilon]$. From this and the monotonicity of Σ_- , we obtain that there is no $z \in (d + \varepsilon, \lambda_*]$ that is an eigenvalue of $\Sigma_-(z)$. Similarly, there is no $z < c - \varepsilon$ that is an eigenvalue of $\Sigma_-(z)$. Hence, using Lemma 6.5 we see that $\text{Spec } \tilde{H}|_{\tilde{\mathcal{L}}_-}$ is contained in $[c - \varepsilon, d + \varepsilon]$. Now let $\tilde{\lambda}_j \in [c - \varepsilon, d + \varepsilon]$ be the j th eigenvalue of $\tilde{H}|_{\tilde{\mathcal{L}}_-}$. By Lemma 6.6 it is also the j th eigenvalue of $\Sigma_-(\tilde{\lambda}_j)$. By Lemma 6.3 it is ε -close to the j th eigenvalue of H_{eff} . \square

6.2. The three-qubit gadget. In this section we demonstrate how Theorem 6.2 can be used to transform a 3-local Hamiltonian into a 2-local one. The complete reduction will be shown in the next section. From now we try to keep the discussion more specialized to our QMA problem rather than presenting it in full generality as was done in section 6.1.

Let Y be some arbitrary 2-local Hamiltonian acting on a space \mathcal{M} of N qubits. Also, let B_1, B_2, B_3 be positive semidefinite Hamiltonians each acting on a different qubit (so they commute). We think of these four operators as having constant norm. Assume we have the 3-local Hamiltonian

$$(6.3) \quad Y - 6B_1B_2B_3.$$

The factor 6 is added for convenience. Recall that in the LOCAL HAMILTONIAN problem we are interested in the lowest eigenvalue of a Hamiltonian. Hence, our goal is to find a 2-local Hamiltonian whose lowest eigenvalue is very close to the lowest eigenvalue of (6.3).

We start by adding three qubits to our system. For $j = 1, 2, 3$, we denote the Pauli operators acting on the j th qubit by σ_j^α . Let $\delta > 0$ be a sufficiently small constant. Our 2-local Hamiltonian is $\tilde{H} = H + V$, where

$$\begin{aligned} H &= -\frac{\delta^{-3}}{4} I \otimes (\sigma_1^z \sigma_2^z + \sigma_1^z \sigma_3^z + \sigma_2^z \sigma_3^z - 3I), \\ V &= X \otimes I - \delta^{-2} (B_1 \otimes \sigma_1^x + B_2 \otimes \sigma_2^x + B_3 \otimes \sigma_3^x), \\ X &= Y + \delta^{-1} (B_1^2 + B_2^2 + B_3^2). \end{aligned}$$

The unperturbed Hamiltonian H has eigenvalues 0 and $\Delta \stackrel{def}{=} \delta^{-3}$. Associated with the zero eigenvalue is the subspace

$$\mathcal{L}_- = \mathcal{M} \otimes \mathcal{C}, \quad \text{where } \mathcal{C} = (|000\rangle, |111\rangle).$$

In the orthogonal subspace \mathcal{C}^\perp we have the states $|001\rangle, |010\rangle$, etc. We may think of the subspace \mathcal{C} as an effective qubit (as opposed to the three physical qubits); the corresponding Pauli operators are denoted by $\sigma_{\text{eff}}^\alpha$.

To obtain H_{eff} , we now compute the self-energy $\Sigma_-(z)$ using the power expansion in (6.2) up to the third order. There is no zeroth order term, i.e., $H_- = 0$. For the remaining terms, notice that $G_+ = (z - \Delta)^{-1} I_{\mathcal{C}_+}$. Hence, we can write $\Sigma_-(z)$ as

$$V_{--} + (z - \Delta)^{-1} V_{-+} V_{+-} + (z - \Delta)^{-2} V_{-+} V_{++} V_{+-} + (z - \Delta)^{-3} V_{-+} V_{++} V_{+-} + \dots$$

The first term is $V_{--} = X \otimes I_{\mathcal{C}}$ because a σ^x term takes any state in \mathcal{C} to \mathcal{C}^\perp . The expressions in the following terms are of the form

$$\begin{aligned} V_{-+} &= -\delta^{-2} (B_1 \otimes |000\rangle \langle 100| + B_2 \otimes |000\rangle \langle 010| + B_3 \otimes |000\rangle \langle 001| + \\ &\quad B_1 \otimes |111\rangle \langle 011| + B_2 \otimes |111\rangle \langle 101| + B_3 \otimes |111\rangle \langle 110|), \\ V_{++} &= X \otimes I_{\mathcal{C}^\perp} - \delta^{-2} (B_1 \otimes (|001\rangle \langle 101| + |010\rangle \langle 110| + |101\rangle \langle 001| + |110\rangle \langle 010|) + \\ &\quad B_2 \otimes (\dots) + B_3 \otimes (\dots)), \end{aligned}$$

where the dots denote similar terms for B_2 and B_3 . Now, in the second term of $\Sigma_-(z)$, V_{+-} flips one of the physical qubits, and V_{-+} must return it to its original state in order to return to the space \mathcal{C} . Hence we have $V_{-+} V_{+-} = \delta^{-4} (B_1^2 + B_2^2 + B_3^2) \otimes I_{\mathcal{C}}$. The third term is slightly more involved. Here we have two possible processes. In the first process, V_{+-} flips a qubit, V_{++} acts with $X \otimes I_{\mathcal{C}^\perp}$, and finally V_{-+} flips the qubit back. In the second process, V_{+-} , V_{++} , and V_{-+} flip all three qubits in succession. Thus,

$$\begin{aligned} (6.4) \quad \Sigma_-(z) &= X \otimes I_{\mathcal{C}} + (z - \Delta)^{-1} \delta^{-4} (B_1^2 + B_2^2 + B_3^2) \otimes I_{\mathcal{C}} \\ &\quad + (z - \Delta)^{-2} \delta^{-4} (B_1 X B_1 + B_2 X B_2 + B_3 X B_3) \otimes I_{\mathcal{C}} \\ &\quad - (z - \Delta)^{-2} \delta^{-6} \\ &\quad \quad (B_3 B_2 B_1 + B_2 B_3 B_1 + B_3 B_1 B_2 + B_1 B_3 B_2 + B_2 B_1 B_3 + B_1 B_2 B_3) \otimes \sigma_{\text{eff}}^x \\ &\quad + O(\|V\|^4 (z - \Delta)^{-3}). \end{aligned}$$

We now focus on the range $z = O(1) \ll \Delta$. In this range we have

$$(z - \Delta)^{-1} = -\frac{1}{\Delta} \left(1 - \frac{z}{\Delta}\right)^{-1} = -\frac{1}{\Delta} + O\left(\frac{z}{\Delta^2}\right) = -\delta^3 + O(\delta^6).$$

Simplifying, we obtain

$$\Sigma_-(z) = \underbrace{Y \otimes I_{\mathcal{C}} - 6B_1 B_2 B_3}_{H_{\text{eff}}} \otimes \sigma_{\text{eff}}^x + O(\delta).$$

Notice that $\|H_{\text{eff}}\| = O(1)$ and hence we obtain that for all z in, say, $[-2\|H_{\text{eff}}\|, 2\|H_{\text{eff}}\|]$ we have

$$\|\Sigma_-(z) - H_{\text{eff}}\| = O(\delta).$$

We may now apply Theorem 6.2 with $c = -\|H_{\text{eff}}\|$, $d = \|H_{\text{eff}}\|$, and $\lambda_* = \Delta/2$ to obtain the following result: Each eigenvalue $\tilde{\lambda}_j$ from the lower part of $\text{Spec } \tilde{H}$ is $O(\delta)$ -close to the j -th eigenvalue of H_{eff} . In fact, for our purposes, it is enough that the lowest eigenvalue of \tilde{H} is $O(\delta)$ -close to the lowest eigenvalue of H_{eff} . It remains to notice that the spectrum of H_{eff} consists of two parts that correspond to the effective spin states $|+\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ and $|-\rangle = \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$. Since $B_1 B_2 B_3$ is positive semidefinite, the smallest eigenvalue is associated with $|+\rangle$. Hence, the lowest eigenvalue of \tilde{H} is equal to the lowest eigenvalue of (6.3), as required.

6.3. Reduction from 3-Local Hamiltonian to 2-Local Hamiltonian.

In this section we reduce the 3-LOCAL HAMILTONIAN problem to the 2-LOCAL HAMILTONIAN problem. By the QMA-completeness of the 3-LOCAL HAMILTONIAN problem [11], this establishes Theorem 1.1.

THEOREM 6.7. *There is a polynomial time reduction from the 3-LOCAL HAMILTONIAN problem to the 2-LOCAL HAMILTONIAN problem.*

Proof. Recall that in the 3-LOCAL HAMILTONIAN problem (see Definition 2.3) we are given two constants a and b and a local Hamiltonian $H^{(3)} = \sum_j H_j$ such that each H_j is a three-qubit term whose norm is at most $\text{poly}(n)$. Our goal in this proof is to transform $H^{(3)}$ into a 2-local Hamiltonian $H^{(2)}$ whose lowest eigenvalue is close to that of $H^{(3)}$. We do this in two steps. The first is a somewhat technical step where we bring $H^{(3)}$ into a convenient form. In the second step, we replace each 3-local term with 2-local terms by using the gadget construction of the previous section. Before we continue with the proof, let us mention that it is crucial that we apply the gadget construction to all 3-local terms *simultaneously*. If instead we tried to apply the gadget construction sequentially, we would end up with an exponential blowup in the norms (since each application of the three-qubit gadget increases the norm by a multiplicative factor).

LEMMA 6.8. *The 3-local Hamiltonian $H^{(3)}$ can be represented as*

$$H^{(3)} = c_r \left(Y - 6 \sum_{m=1}^M B_{m1} B_{m2} B_{m3} \right),$$

where Y is a 2-local Hamiltonian with $\|Y\| = O(1/n^6)$, $M = O(n^3)$, each B_{mi} is a one-qubit term of norm $O(1/n^3)$ that satisfies $B_{mi} \geq \frac{1}{n^3} I$, and c_r is a rescaling factor satisfying $1 \leq c_r \leq \text{poly}(n)$.¹²

Proof. First, we can assume without loss of generality that each H_j acts on a different triple of qubits, and hence there are at most n^3 such terms. Recall that any three-qubit Hermitian operator can be written as a linear combination with real coefficients of the basis elements $\sigma^\alpha \otimes \sigma^\beta \otimes \sigma^\gamma$, where each of $\sigma^\alpha, \sigma^\beta, \sigma^\gamma$ ranges over the four possible Pauli matrices $\{I, \sigma^x, \sigma^y, \sigma^z\}$. Hence, for $M = O(n^3)$, we can write

$$H^{(3)} = c_r \left(-6 \sum_{m=1}^M c_m \cdot \sigma^{m,\alpha} \otimes \sigma^{m,\beta} \otimes \sigma^{m,\gamma} \right),$$

where each $\sigma^{m,\alpha}$ is a Pauli matrix acting on one of the qubits, and $c_r \leq \text{poly}(n)$ is chosen to be large enough so that $|c_m| \leq \frac{1}{n^9}$ for all $m = 1, \dots, M$.

¹²For the proof of Theorem 6.7 we need only the property $B_{mi} \geq 0$. The stronger property $B_{mi} \geq \frac{1}{n^3} I$ will be used in section 7.

We finish the proof by writing each $c_m \sigma^{m,\alpha} \otimes \sigma^{m,\beta} \otimes \sigma^{m,\gamma}$ as

$$\underbrace{\left(\frac{2}{n^3}I + n^6 c_m \sigma^{m,\alpha}\right)}_{B_{m1}} \otimes \underbrace{\left(\frac{2}{n^3}I + \frac{1}{n^3} \sigma^{m,\beta}\right)}_{B_{m2}} \otimes \underbrace{\left(\frac{2}{n^3}I + \frac{1}{n^3} \sigma^{m,\gamma}\right)}_{B_{m3}} + D_m,$$

where D_m is 2-local. Since $|c_m| \leq 1/n^9$ we have that $B_{mi} \geq \frac{1}{n^3}I$ and $\|D_m\| = O(1/n^9)$. \square

We now replace each term $-6B_{m1}B_{m2}B_{m3}$ by a three-qubit gadget. More specifically, let δ be a sufficiently small inverse polynomial in n to be chosen later. We consider the Hamiltonian $H^{(2)} = c_r \tilde{H}$, $\tilde{H} = H + V$, acting on a system of $n + 3M$ qubits, where

$$\begin{aligned} H &= -\frac{\delta^{-3}}{4} \sum_{m=1}^M I \otimes (\sigma_{m1}^z \sigma_{m2}^z + \sigma_{m1}^z \sigma_{m3}^z + \sigma_{m2}^z \sigma_{m3}^z - 3I), \\ V &= Y \otimes I + \delta^{-1} \sum_{m=1}^M (B_{m1}^2 + B_{m2}^2 + B_{m3}^2) \otimes I \\ (6.5) \quad &\quad - \delta^{-2} \sum_{m=1}^M (B_{m1} \otimes \sigma_{m1}^x + B_{m2} \otimes \sigma_{m2}^x + B_{m3} \otimes \sigma_{m3}^x). \end{aligned}$$

As before, let $\Delta = \delta^{-3}$ be the spectral gap of H . Notice that the spectrum of H includes not only 0 and Δ but also $2\Delta, 3\Delta, \dots, M\Delta$. Associated with the zero eigenvalue is the subspace spanned by all the zero-subspaces of the gadgets. Using $\|B_{mi}\| \leq O(1/n^3)$ and $M = O(n^3)$ we get $\|V\| = O(\delta^{-2}) < \Delta/2$.

The calculation of Σ_- is quite similar to the one-gadget case (cf. (6.4)). Each gadget contributes an independent term. Terms up to the third order can include only processes that involve one gadget. Indeed, in order to involve two gadgets, one has to flip a qubit from one gadget and from another gadget, and then flip both qubits back. Moreover, since only one gadget is involved, G_+ can be replaced by $(z - \Delta)^{-1} I_{\mathcal{L}_+}$ as before. From the fourth order onwards, processes start to include cross-terms between different gadgets. However, we claim that their contribution is only $O(\delta)$, as long as $|z| = O(1)$. Indeed, in this range, the eigenvalues of G_+ , which are $(z - \Delta)^{-1}, (z - 2\Delta)^{-1}, \dots$, are all at most $O(\delta^3)$ in absolute value, while the norm of each of the V terms is at most $O(\delta^{-2})$. To summarize, for $|z| = O(1)$,

$$(6.6) \quad \Sigma_-(z) = Y \otimes I_C - \underbrace{6 \sum_{m=1}^M B_{m1} B_{m2} B_{m3} \otimes (\sigma_m^x)_{\text{eff}}}_{H_{\text{eff}}} + O(\delta).$$

Since $\|H_{\text{eff}}\| \leq O(1)$, we can apply Theorem 6.2 with $c = -\|H_{\text{eff}}\|$, $d = \|H_{\text{eff}}\|$, and $\lambda_* = \Delta/2$. We obtain that the smallest eigenvalue of \tilde{H} is $O(\delta)$ -close to that of H_{eff} . The spectrum of H_{eff} consists of 2^M parts, corresponding to subspaces spanned by setting each effective spin state to either $|+\rangle$ or $|-\rangle$. Since $B_{m1}B_{m2}B_{m3} \geq 0$, the smallest eigenvalue of H_{eff} is achieved in the subspace where all effective spin states are in the $|+\rangle$ state. In this subspace, H_{eff} is identical to $H^{(3)}/c_r$. Hence, the smallest eigenvalue of $H^{(2)} = c_r \tilde{H}$ is $O(c_r \delta)$ -close to that of $H^{(3)}$. We complete the proof by choosing $\delta = c'/c_r$ for some small enough constant c' . \square

7. 2-local universal adiabatic computation. In this section we show that adiabatic computation with 2-local Hamiltonians is equivalent to “standard” quantum computation in the circuit model. In order to prove such an equivalence, one has to show that each model can simulate the other. One direction is already known: it is not too hard to show that any polynomial time adiabatic computation can be efficiently simulated by a quantum circuit [8]. Hence, it remains to show that adiabatic computation with 2-local Hamiltonians can efficiently simulate any quantum circuit. In [3] it is shown that adiabatic computation with 3-local Hamiltonians can efficiently simulate any quantum circuit. We obtain our result by combining their result with the techniques in our second proof.

Let us briefly mention the main ideas behind adiabatic computation. For more details see [3] and the references therein. In adiabatic computation, we consider a time-dependent Hamiltonian $H(s)$ for $s \in [0, 1]$ acting on a quantum system. We initialize the system in the groundstate of the initial Hamiltonian $H(0)$. This groundstate is required to be some simple quantum state that is easy to create. We then slowly modify the Hamiltonian from $s = 0$ to $s = 1$. We say that the adiabatic computation is *successful* if the final state of the system is close to the groundstate of $H(1)$. The adiabatic theorem (see, e.g., [18, 4]) says that if the Hamiltonian is modified slowly enough, the adiabatic computation is successful. In other words, it gives an upper bound on the running time of an adiabatic computation. For our purposes, it is enough to know that this bound is polynomial if for any $s \in [0, 1]$, the norm of $H(s)$, as well as those of its first and second derivatives, is bounded by a polynomial, and the spectral gap of $H(s)$ is larger than some inverse polynomial.

In [3] it is shown how to transform an arbitrary quantum circuit into an efficient 3-local adiabatic computation. To establish this, they define a 3-local time-dependent Hamiltonian $H^{(3)}(s)$ with the following properties. First, the Hamiltonian acts on a system of n qubits, where n is some constant times the number of gates in the circuit. Second, the groundstate of $H^{(3)}(0)$ is very easy to create (namely, it is the all zero state), and the groundstate of $H^{(3)}(1)$ is some state that encodes the result of the quantum circuit. Third, for all $s \in [0, 1]$, the spectral gap of $H^{(3)}(s)$ is bounded from below by an inverse polynomial in n , and the norm of $H^{(3)}(s)$, as well as those of its first and second derivatives, is bounded by some polynomial in n . Together with the adiabatic theorem, these properties imply that adiabatic computation according to $H^{(3)}(s)$ is efficient. Finally, let us mention that $H^{(3)}(s)$, as defined in [3], is linear in s ; that is, $H^{(3)}(s) = (1 - s)H^{(3)}(0) + sH^{(3)}(1)$. This property will be useful in our proof.

The following is the main theorem of this section.

THEOREM 7.1. *Any quantum computation can be efficiently simulated by an adiabatic computation with 2-local Hamiltonians.*

Proof. Given a quantum circuit, let $H^{(3)}(s)$ be the time-dependent Hamiltonian of [3] as described above. The idea of the proof is to apply the gadget construction of section 6.3 to $H^{(3)}(s)$ for any $s \in [0, 1]$, thereby creating a 2-local time-dependent Hamiltonian $H^{(2)}(s)$. Some care needs to be taken to ensure that the resulting time-dependent Hamiltonian is smooth enough as a function of s . We therefore describe how this is done in more detail.

We start by writing $H^{(3)}(s)$ in a form similar to that given by Lemma 6.8. Since $H^{(3)}(s)$ is linear in s , we can write

$$H^{(3)}(s) = c_r \left(-6 \sum_{m=1}^M c_m(s) \cdot \sigma^{m,\alpha} \otimes \sigma^{m,\beta} \otimes \sigma^{m,\gamma} \right),$$

where $M = O(n^3)$, each $c_m(s)$ is a linear function of s , and $c_r \leq \text{poly}(n)$ is chosen to be large enough so that $|c_m(s)| \leq \frac{1}{n^9}$ for all m and all $s \in [0, 1]$. Notice that c_r is a fixed scaling factor used for all $s \in [0, 1]$. Following the proof of Lemma 6.8, we write

$$H^{(3)}(s) = c_r \left(Y(s) - 6 \sum_{m=1}^M B_{m1}(s)B_{m2}B_{m3} \right),$$

where by our construction, $Y(s)$ and $B_{m1}(s)$ are linear in s , whereas B_{m2} and B_{m3} are independent of s . Finally, we define $H^{(2)}(s) = c_r \tilde{H}(s)$, where $\tilde{H}(s) = H + V(s)$ and the Hamiltonians H and $V(s)$ are defined as in (6.5). The parameter δ will be chosen later to be some small enough inverse polynomial in n .

In the rest of the proof, we show that adiabatic computation according to $H^{(2)}(s)$ can be used to simulate the given quantum circuit. We start by proving two lemmas that, together with the adiabatic theorem, imply that the running time of the adiabatic computation is polynomial in n .

LEMMA 7.2. *For any $s \in [0, 1]$, $\|H^{(2)}(s)\|$, $\|\frac{d}{ds}H^{(2)}(s)\|$, and $\|\frac{d^2}{ds^2}H^{(2)}(s)\|$ are upper bounded by a polynomial in n .*

Proof. Recall that $Y(s)$ and $B_{m1}(s)$ are linear in s . Together with the definition of $H^{(2)}$, this implies that $H^{(2)}(s)$ is a degree-two polynomial in s , i.e., we can write $H^{(2)}(s) = A + sB + s^2C$ for some Hermitian matrices A, B, C . It is not hard to see that the norm of each of these matrices is bounded by some polynomial in n . This implies that the norms of $H^{(2)}(s)$, its first derivative $B + 2sC$, and its second derivative $2C$ are bounded by some polynomial in n . \square

LEMMA 7.3. *For any $s \in [0, 1]$, the spectral gap of $H^{(2)}(s)$ is lower bounded by an inverse polynomial in n .*

Proof. As shown in section 6.3, the lower part of the spectrum of $H^{(2)}(s)$ is $O(c_r\delta)$ -close to the spectrum of $c_r H_{\text{eff}}(s)$. Hence, by choosing δ to be a small enough inverse polynomial in n , we see that it is enough to show that the spectral gap of $c_r H_{\text{eff}}(s)$ is at least some inverse polynomial in n .

The spectrum of $c_r H_{\text{eff}}(s)$ consists of 2^M parts, corresponding to all possible settings for the effective qubits. The part corresponding to the subspace in which all effective qubits are in the $|+\rangle$ state is identical to the spectrum of $H^{(3)}(s)$. Hence, we know that in this subspace the spectral gap is at least some inverse polynomial in n . We now claim that the lowest eigenvalue in all other $2^M - 1$ subspaces is greater than that in the all $|+\rangle$ subspace by at least some inverse polynomial in n . Indeed, the restriction of $c_r H_{\text{eff}}(s)$ to any such subspace is given by $H^{(3)}(s)$ plus a nonzero number of terms of the form $12c_r B_{m1}(s)B_{m2}B_{m3}$. The claim follows from the fact that $B_{m1}(s)B_{m2}B_{m3} \geq \frac{1}{n^9}I$. \square

To complete the proof, we need to argue about the groundstate of $H^{(2)}(0)$ and that of $H^{(2)}(1)$. To this end, we use the following lemma, which essentially says that if H_{eff} has a spectral gap, then Theorem 6.2 not only implies closeness in spectra but also in the groundstates.

LEMMA 7.4. *Assume that H, V, H_{eff} satisfy the conditions of Theorem 6.2 with some $\varepsilon > 0$. Let $\lambda_{\text{eff},i}$ denote the i th eigenvalue of H_{eff} and $|\tilde{v}\rangle$ (resp., $|v_{\text{eff}}\rangle$) denote the groundstate of \tilde{H} (resp., H_{eff}). Then, under the assumption $\lambda_{\text{eff},2} > \lambda_{\text{eff},1}$,*

$$|\langle \tilde{v} | v_{\text{eff}} \rangle| \geq 1 - \frac{2\|V\|^2}{(\lambda_+ - \lambda_{\text{eff},1} - \varepsilon)^2} - \frac{4\varepsilon}{\lambda_{\text{eff},2} - \lambda_{\text{eff},1}}.$$

Before we prove the lemma, let us complete the proof of the theorem. Recall that in our case $\varepsilon = O(\delta)$, $\|V\| = O(\delta^{-2})$, $\lambda_+ = \delta^{-3}$, $|\lambda_{\text{eff},1}| \leq O(1)$, and $\lambda_{\text{eff},2} - \lambda_{\text{eff},1} = 1/\text{poly}(n)$. Hence, the first error term in the above bound is $O(\delta^2)$ while the second is $O(\delta \cdot \text{poly}(n))$. Therefore, by choosing δ to be a small enough inverse polynomial in n , we can guarantee that the groundstate of $H^{(2)}(s)$ is close to the groundstate of $H_{\text{eff}}(s)$. In particular, the groundstate of $H^{(2)}(1)$, which is the output of the adiabatic computation, is close to the groundstate of $H_{\text{eff}}(1)$. The latter is $|v_1\rangle \otimes |+\rangle^{\otimes M}$, where $|v_1\rangle$ is the groundstate of $H^{(3)}(1)$. By simply tracing out the $3M$ gadget qubits, we can recover $|v_1\rangle$ from this groundstate and therefore obtain the output of the quantum circuit. Similarly, the groundstate of $H^{(2)}(0)$, which is the state to which the system should be initialized, is close to the groundstate of $H_{\text{eff}}(0)$. The latter is $|v_0\rangle \otimes |+\rangle^{\otimes M}$, where $|v_0\rangle$ is the groundstate of $H^{(3)}(0)$. We therefore initialize the system by setting the original n qubits to $|v_0\rangle$ and the M gadgets to the effective $|+\rangle$ state. This state is close to the groundstate of $H^{(2)}(0)$, and since the adiabatic computation is unitary, this approximation does not affect the output by much.

It remains to prove the lemma.

Proof of Lemma 7.4. Let $|\tilde{v}_-\rangle = \Pi_- |\tilde{v}\rangle / \|\Pi_- |\tilde{v}\rangle\|$ be the normalized projection of $|\tilde{v}\rangle$ on the space \mathcal{L}_- . We first show that $|\tilde{v}_-\rangle$ is close to $|\tilde{v}\rangle$. By Theorem 6.2, we know that $\tilde{\lambda}_1 \leq \lambda_{\text{eff},1} + \varepsilon$. Hence,

$$\|\Pi_+ \tilde{H} |\tilde{v}\rangle\| = \tilde{\lambda}_1 \|\Pi_+ |\tilde{v}\rangle\| \leq (\lambda_{\text{eff},1} + \varepsilon) \|\Pi_+ |\tilde{v}\rangle\|$$

and

$$\|\Pi_+ \tilde{H} |\tilde{v}\rangle\| = \|\Pi_+ H |\tilde{v}\rangle + \Pi_+ V |\tilde{v}\rangle\| \geq \|\Pi_+ H |\tilde{v}\rangle\| - \|V\| \geq \lambda_+ \|\Pi_+ |\tilde{v}\rangle\| - \|V\|.$$

By combining the two inequalities we obtain

$$\|\Pi_+ |\tilde{v}\rangle\| \leq \frac{\|V\|}{\lambda_+ - \lambda_{\text{eff},1} - \varepsilon},$$

from which we see that

$$\alpha \stackrel{\text{def}}{=} |\langle \tilde{v} | \tilde{v}_- \rangle| = \|\Pi_- |\tilde{v}\rangle\| \geq \|\Pi_- |\tilde{v}\rangle\|^2 \geq 1 - \frac{\|V\|^2}{(\lambda_+ - \lambda_{\text{eff},1} - \varepsilon)^2}.$$

Our next step is to show that $|\tilde{v}_-\rangle$ is close to $|v_{\text{eff}}\rangle$. For this we need to consider the proof of Theorem 6.2. We start by taking Lemma 6.4 with $\tilde{\lambda} = \tilde{\lambda}_1$. The lemma says that A is a matrix of rank 1. By looking at the proof, it is easy to see that A is in fact $\Pi_- |\tilde{v}\rangle \langle \tilde{v} | \Pi_-$. Next, Lemma 6.5 implies that $\tilde{\lambda}_1$ is an eigenvalue of multiplicity 1 of $\Sigma_-(\tilde{\lambda}_1)$. In fact, from the proof it follows that the corresponding eigenvector is exactly $\Pi_- |\tilde{v}\rangle$ (since the null space of C is equal to the span of A). By normalizing, this is exactly $|\tilde{v}_-\rangle$. But by our assumption, $\|\Sigma_-(z) - H_{\text{eff}}\| \leq \varepsilon$ for all $z \in [c - \varepsilon, d + \varepsilon]$ and in particular

$$\|\Sigma_-(\tilde{\lambda}_1) - H_{\text{eff}}\| \leq \varepsilon.$$

From this we obtain that

$$|\langle \tilde{v}_- | (\Sigma_-(\tilde{\lambda}_1) - H_{\text{eff}}) | \tilde{v}_- \rangle| \leq \varepsilon$$

and hence

$$\langle \tilde{v}_- | H_{\text{eff}} | \tilde{v}_- \rangle \leq \tilde{\lambda}_1 + \varepsilon \leq \lambda_{\text{eff},1} + 2\varepsilon,$$

where we again used that $\tilde{\lambda}_1 \leq \lambda_{\text{eff},1} + \varepsilon$. Since H_{eff} has a spectral gap, this indicates that $|\tilde{v}_-\rangle$ must be close to $|v_{\text{eff}}\rangle$. Indeed, let $\beta = |\langle \tilde{v}_- | v_{\text{eff}} \rangle|$. Then,

$$\langle \tilde{v}_- | H_{\text{eff}} | \tilde{v}_- \rangle \geq \beta^2 \lambda_{\text{eff},1} + (1 - \beta^2) \lambda_{\text{eff},2} = \lambda_{\text{eff},1} + (1 - \beta^2)(\lambda_{\text{eff},2} - \lambda_{\text{eff},1}).$$

By combining the two inequalities we obtain

$$1 - \beta^2 \leq \frac{2\varepsilon}{\lambda_{\text{eff},2} - \lambda_{\text{eff},1}}.$$

Summarizing,

$$\begin{aligned} |\langle \tilde{v} | v_{\text{eff}} \rangle| &= |\langle \tilde{v} | \tilde{v}_- \rangle \langle \tilde{v}_- | v_{\text{eff}} \rangle + \langle \tilde{v} | (I - |\tilde{v}_-\rangle \langle \tilde{v}_-|) | v_{\text{eff}} \rangle| \\ &\geq \alpha \cdot \beta - \sqrt{(1 - \alpha^2)(1 - \beta^2)} \geq \alpha \cdot \beta - \frac{1}{2}((1 - \alpha^2) + (1 - \beta^2)) \\ &\geq (1 - (1 - \alpha) - (1 - \beta)) - ((1 - \alpha) + (1 - \beta)) = 1 - 2(1 - \alpha) - 2(1 - \beta) \\ &\geq 1 - \frac{2\|V\|^2}{(\lambda_+ - \lambda_{\text{eff},1} - \varepsilon)^2} - \frac{4\varepsilon}{\lambda_{\text{eff},2} - \lambda_{\text{eff},1}}. \quad \square \end{aligned}$$

8. Conclusion. Some interesting open questions remain. First, perturbation theory has allowed us to perform the first reduction *inside* QMA. What other problems can be solved using this technique? Second, there exists an intriguing class between NP (in fact, MA) and QMA known as QCMA. It is the class of problems that can be verified by a quantum verifier with a *classical* proof. Can one show a separation between QCMA and QMA, or perhaps show that they are equal? Third, Kitaev's original 5-local proof has the following desirable property: For any YES instance produced by the reduction there exists a state such that each individual 5-local term is very close to its groundstate. Note that this is a stronger property than the one required in the LOCAL HAMILTONIAN problem. Using a slight modification of Kitaev's original construction, one can show a reduction to the 4-LOCAL HAMILTONIAN problem that has the same property. However, we do not know if this property can be achieved for the 3-local or the 2-local problem.

ALGORITHMS FOR COMBINING ROOTED TRIPLETS INTO A GALLED PHYLOGENETIC NETWORK*

JESPER JANSSON[†], NGUYEN BAO NGUYEN[†], AND WING-KIN SUNG^{†‡}

Abstract. This paper considers the problem of determining whether a given set \mathcal{T} of rooted triplets can be merged without conflicts into a galled phylogenetic network and, if so, constructing such a network. When the input \mathcal{T} is dense, we solve the problem in $O(|\mathcal{T}|)$ time, which is optimal since the size of the input is $\Theta(|\mathcal{T}|)$. In comparison, the previously fastest algorithm for this problem runs in $O(|\mathcal{T}|^2)$ time. We also develop an optimal $O(|\mathcal{T}|)$ -time algorithm for enumerating all simple phylogenetic networks leaf-labeled by L that are consistent with \mathcal{T} , where L is the set of leaf labels in \mathcal{T} , which is used by our main algorithm. Next, we prove that the problem becomes NP-hard if extended to nondense inputs, even for the special case of simple phylogenetic networks. We also show that for every positive integer n , there exists some set \mathcal{T} of rooted triplets on n leaves such that any galled network can be consistent with at most $0.4883 \cdot |\mathcal{T}|$ of the rooted triplets in \mathcal{T} . On the other hand, we provide a polynomial-time approximation algorithm that always outputs a galled network consistent with at least a factor of $\frac{5}{12}$ (> 0.4166) of the rooted triplets in \mathcal{T} .

1. Introduction. A *rooted triplet* is a binary, rooted, unordered tree with three distinctly labeled leaves. Aho et al. [1] introduced the problem of determining whether a given set of rooted triplets can be combined without conflicts into a distinctly leaf-labeled tree which contains each of the given rooted triplets as an embedded subtree, and, if so, returning one. The original motivation for this problem came from an application in the theory of relational databases (see [1] for details), but it has since been studied further and generalized because of its applications to phylogenetic tree construction [2, 6, 7, 10, 13, 14, 17, 20, 21, 23, 25]. Here, we study an extension of the problem in which the objective is to determine if a given set \mathcal{T} of rooted triplets can be merged into a more complex structure known as a *galled phylogenetic network*.

A *phylogenetic network* is a type of distinctly leaf-labeled, directed acyclic graph that can be used to model nontreelike evolution. A number of methods for inferring phylogenetic networks under various assumptions and using different kinds of data have been proposed recently [8, 12, 15, 19, 22, 24]. A *galled phylogenetic network*, or *galled network* for short, is an important, biologically motivated structural restriction of a phylogenetic network (see section 1.2) in which all cycles in the underlying undirected graph are node-disjoint.¹

¹Without the node-disjoint constraint, our problem becomes trivial to solve since then a solution always exists and, furthermore, can be obtained in polynomial time using a simple sorting network-based construction [15].

We present several new results for the problem of inferring a galled network consistent with a given set \mathcal{T} of rooted triplets. Denote the set of leaf labels in \mathcal{T} by L . If \mathcal{T} contains at least one rooted triplet for each cardinality-three subset of L , then \mathcal{T} is called *dense*. We first give an exact algorithm named *FastGalledNetwork* for dense inputs whose running time is $O(|\mathcal{T}|)$. In comparison, the previously fastest known algorithm for this case runs in $O(|\mathcal{T}|^2)$ time [15]. Since the size of the input is $\Theta(|\mathcal{T}|)$ when \mathcal{T} is dense and any algorithm that solves the problem must look at the entire input, the asymptotic running time of our new algorithm is optimal. The improvement in running time is due to two observations: first, that the so-called *SN*-sets employed in [15] do not have to be explicitly computed but can be represented using a tree (the *SN*-tree) which we can construct in $O(|\mathcal{T}|)$ time, and second, that the *SN*-tree can be expanded into a galled network consistent with \mathcal{T} (if one exists) in $O(|\mathcal{T}|)$ time by replacing each internal node of degree 3 or higher with a special kind of network found by applying an algorithm called *SimpleNetworks*.

Next, we show that the problem becomes NP-hard when \mathcal{T} is not required to be dense by giving a polynomial-time reduction from Set Splitting. Finally, we consider approximation algorithms. We present an $O(|L| \cdot |\mathcal{T}|^3)$ -time algorithm that always outputs a galled network consistent with at least a factor of $\frac{5}{12}$ (> 0.4166) of the rooted triplets in \mathcal{T} for any \mathcal{T} . (Our approximation algorithm can also be applied in the dense case when the input cannot be combined into a galled network without conflicts.) On the negative side, we show that there exist inputs for which any galled network can be consistent with at most a factor of 0.4883 of the rooted triplets. It is interesting to note that for *trees*, the corresponding bounds are known to be tight [7]; that is, there is a polynomial-time approximation algorithm which always constructs a tree consistent with at least $\frac{1}{3} \cdot |\mathcal{T}|$ of the rooted triplets in \mathcal{T} , and there exist some inputs for which no tree can achieve a factor higher than $\frac{1}{3} \cdot |\mathcal{T}|$.

1.1. Definitions and notation. A *phylogenetic tree* is a binary, rooted, unordered tree whose leaves are distinctly labeled. A *phylogenetic network* is a generalization of a phylogenetic tree formally defined as a rooted, connected, directed acyclic graph in which (1) exactly one node has indegree 0 (the *root*), and all other nodes have indegree 1 or 2; (2) all nodes with indegree 2 (referred to as *hybrid nodes*) have outdegree 1, and all other nodes have outdegree 0 or 2; and (3) all nodes with outdegree 0 (the *leaves*) are distinctly labeled. For any phylogenetic network N , let $\mathcal{U}(N)$ be the undirected graph obtained from N by replacing each directed edge by an undirected edge. N is said to be a *galled phylogenetic network* (*galled network*, for short) if all cycles in $\mathcal{U}(N)$ are node-disjoint. Galled networks are also known in the literature as *topologies with independent recombination events* [24], *galled-trees* [8], *gt-networks* [19], and *level-1 phylogenetic networks* [4, 15].

A phylogenetic tree with exactly three leaves is called a *rooted triplet*. The unique rooted triplet on a leaf set $\{x, y, z\}$ in which the lowest common ancestor of x and y is a proper descendant of the lowest common ancestor of x and z (or, equivalently, where the lowest common ancestor of x and y is a proper descendant of the lowest common ancestor of y and z) is denoted by $(\{x, y\}, z)$. For any phylogenetic network N , a rooted triplet $t = (\{x, y\}, z)$ is said to be *consistent with N* if t is an embedded subtree of N (i.e., if a lowest common ancestor of x and y in N is a proper descendant of a lowest common ancestor of x and z in N), and a set \mathcal{T} of rooted triplets is said to be *consistent with N* if every rooted triplet in \mathcal{T} is consistent with N .

Denote the set of leaves in any phylogenetic network N by $\Lambda(N)$ and for any set \mathcal{T} of rooted triplets, define $\Lambda(\mathcal{T}) = \bigcup_{t_i \in \mathcal{T}} \Lambda(t_i)$. A set \mathcal{T} of rooted triplets is *dense* if

FIG. 1. A dense set \mathcal{T} of rooted triplets with leaf set $\{a, b, c, d\}$ and a galled phylogenetic network which is consistent with \mathcal{T} . Note that this solution is not unique.

for each $\{x, y, z\} \subseteq \Lambda(\mathcal{T})$, at least one of $(\{x, y\}, z)$, $(\{x, z\}, y)$, and $(\{y, z\}, x)$ belongs to \mathcal{T} . If \mathcal{T} is dense, then $|\mathcal{T}| = \Theta(|\Lambda(\mathcal{T})|^3)$. Furthermore, for any set \mathcal{T} of rooted triplets and $L' \subseteq \Lambda(\mathcal{T})$, define $\mathcal{T}|L'$ as the subset of \mathcal{T} consisting of all rooted triplets t with $\Lambda(t) \subseteq L'$. The problem we consider here is the following: Given a set \mathcal{T} of rooted triplets, output a galled network N with $\Lambda(N) = \Lambda(\mathcal{T})$ such that N and \mathcal{T} are consistent if such a network exists; otherwise, output *null*. See Figure 1 for an example. Throughout this paper, we write $L = \Lambda(\mathcal{T})$ and $n = |L|$.

To describe our algorithms, we need the following additional terminology. Let N be a phylogenetic network. We call nodes with indegree 2 *hybrid nodes* and their parent edges *hybrid edges*. Let h be a hybrid node in N . Every ancestor s of h such that h can be reached using two disjoint directed paths starting at the children of s is called a *split node of h* . If s is a split node of h , then any path starting at s and ending at h is called a *merge path of h* , and any path starting at a child of s and ending at a parent of h is called a *clipped merge path of h* . From the above, it follows that in a galled network, each split node is a split node of exactly one hybrid node, and each hybrid node has exactly one split node.

Let N be a galled network. For any node u in N , $N[u]$ denotes the subnetwork of N rooted at u , i.e., the minimal subgraph of N which includes all nodes and directed edges of N reachable from u . $N[u]$ is called a *side network* of N if there exists a merge path P in N such that u does not belong to P but u is a child of a node belonging to P . In this case, $N[u]$ is also said to be *attached to P* . N is called a *simple phylogenetic network* (or *simple network*) if N has exactly one hybrid node h , the root node of N is the split node of h , and every side network of N is a leaf. For example, the galled network on the right in Figure 1 is a simple network. For any simple network N , denote the leaf attached to the hybrid node in N by $hl(N)$.

1.2. Motivation. Phylogenetic networks are used by scientists to describe evolutionary relationships that do not fit the traditional models in which evolution is assumed to be treelike. Evolutionary events such as horizontal gene transfer or hybrid speciation (often referred to as *recombination events*) cannot be adequately represented in a single tree [8, 9, 19, 22, 24] but can be modeled in a phylogenetic network as internal nodes having more than one parent. Galled networks are an important type of phylogenetic network and have attracted special attention in the

literature [4, 8, 19, 24] due to their biological significance (see [8] for a discussion) and their simple, almost treelike, structure. When the number of recombination events is limited and most of them have occurred recently, a galled network may suffice to accurately describe the evolutionary process under study [8].

A challenge in the field of phylogenetics is to develop efficient and reliable methods for constructing and comparing phylogenetic networks. For example, to construct a meaningful phylogenetic network for a large subset of the human population (which may subsequently be used to help locate regions in the genome associated with some observable trait indicating a particular disease) in the future, efficient algorithms are crucial because the input can be expected to be very large. The motivation behind the rooted triplet approach taken in this paper is that a highly accurate tree for each cardinality-three subset of the leaf set can be obtained through maximum likelihood-based methods such as [3] or Sibley–Ahlquist-style DNA–DNA hybridization experiments (see [17]). Hence, the algorithms presented in [15] and here can be used as the merging step in a divide-and-conquer approach for constructing phylogenetic networks analogous to the quartet method paradigm for inferring unrooted phylogenetic trees [16, 18] and other supertree methods (see [10, 21] and the references therein). We consider dense input sets in particular since this case can be solved in polynomial time.

1.3. Related work. Aho et al. [1] gave an $O(|\mathcal{T}| \cdot n)$ -time algorithm for determining whether a given set \mathcal{T} of rooted triplets on n leaves is consistent with some rooted, distinctly leaf-labeled tree, and, if so, returning such a tree. Henzinger, King, and Warnow [10] improved its running time to $\min\{O(|\mathcal{T}| \cdot n^{0.5}), O(|\mathcal{T}| + n^2 \log n)\}$; in fact, replacing the deterministic algorithm for dynamic graph connectivity employed by Henzinger, King, and Warnow, with a more recent one due to Holm, de Lichtenberg, and Thorup [11] yields a running time of $\min\{O(|\mathcal{T}| \cdot \log^2 n), O(|\mathcal{T}| + n^2 \log n)\}$ [14]. Gąsieniec et al. [6] studied a variant of the problem for *ordered* trees. Ng and Wormald [21] considered the problem of constructing *all* rooted, unordered trees distinctly leaf-labeled by $\Lambda(\mathcal{T})$ that are consistent with \mathcal{T} .

If two or more of the rooted triplets are in conflict, i.e., contain contradicting branching information, the algorithm of Aho et al. returns a null tree. However, this is not very practical in certain applications. For example, in the context of constructing a phylogenetic tree from a set of rooted triplets, some errors may occur in the input when the rooted triplets are based on data obtained experimentally, yet a nonnull tree is still required. In this case, one can try to construct a tree consistent with the maximum number of rooted triplets in the input [2, 6, 7, 13, 25], or a tree with as many leaves from $\Lambda(\mathcal{T})$ as possible which is consistent with all input rooted triplets involving these leaves only [14]. Although the former problem is NP-hard [2, 13, 25], Gąsieniec et al. [7] showed that it has a polynomial-time approximation algorithm that outputs a distinctly leaf-labeled tree consistent with at least $\frac{1}{3}$ of the given rooted triplets, which is a tight bound in the sense that there exist inputs \mathcal{T} such that any distinctly leaf-labeled tree can be consistent with at most $\frac{1}{3}$ of the rooted triplets in \mathcal{T} .²

The problem studied in this paper was introduced in [15]. The main result of [15] is an exact $O(|\mathcal{T}|^2)$ -time algorithm for the dense case. Reference [15] also showed that if no restrictions are placed on the structure of the output phylogenetic network (i.e., if nongalled networks are allowed), then the problem always has a solution which

²On the other hand, if the optimal solution contains a large fraction of the input rooted triplets, another approximation presented in [7] (based on minimum cuts in the auxiliary graph introduced by Aho et al. [1]) gives a better approximation factor.

can be easily obtained from any given sorting network for n elements. Nakhleh et al. [19] gave an $O(n^2)$ -time algorithm for the related problem of determining if two given phylogenetic trees T_1 and T_2 with identical leaf sets can be combined into a galled network containing both T_1 and T_2 as embedded subtrees and, if so, constructing one with the smallest possible number of hybrid nodes, where n is the number of leaves (in fact, this is equivalent to inferring a galled network consistent with the set of all rooted triplets which are embedded subtrees of T_1 or T_2). They also studied the case where T_1 and T_2 may contain errors but only one hybrid node is allowed. Huson et al. [12] considered a similar problem for constructing an *unrooted* phylogenetic network from a set of unrooted, distinctly leaf-labeled trees.

1.4. Organization of the paper. In section 2, we present a new algorithm called *SimpleNetworks* for computing all simple phylogenetic networks consistent with a given dense set \mathcal{T} of rooted triplets in $O(n^3)$ time. This algorithm is used by our main algorithm *FastGalledNetwork* in section 3 to construct a galled network consistent with a given dense set \mathcal{T} of rooted triplets, if one exists, in optimal $O(n^3)$ time. In section 4, we prove that the problem becomes NP-hard if we remove the requirement that \mathcal{T} forms a dense set. Next, in section 5.1, we show that for every positive integer n , there exists some set \mathcal{T} of rooted triplets with $|\Lambda(\mathcal{T})| = n$ such that any galled network can be consistent with at most $0.4883 \cdot |\mathcal{T}|$ of the rooted triplets in \mathcal{T} . On the other hand, we give an $O(n \cdot |\mathcal{T}|^3)$ -time algorithm in section 5.2 that constructs a galled network guaranteed to be consistent with at least a factor of $\frac{5}{12}$ (> 0.4166) of the rooted triplets in \mathcal{T} for any input \mathcal{T} .

2. Constructing all simple phylogenetic networks when \mathcal{T} is dense. In this section, we describe an algorithm called *SimpleNetworks* for inferring all simple phylogenetic networks consistent with a given dense set \mathcal{T} of rooted triplets in $O(n^3)$ time, where $L = \Lambda(\mathcal{T})$ and $n = |L|$. This algorithm is later used by our main algorithm in section 3. Below, for any $L' \subseteq L$, $\mathcal{G}(L')$ denotes *the auxiliary graph for L'* (originally defined by Aho et al. [1]), which is the undirected graph with vertex set L' and edge set $E(L')$, where for each $(\{i, j\}, k) \in \mathcal{T} \mid L'$, the edge $\{i, j\}$ is included in $E(L')$.

SimpleNetworks assumes that $n \geq 3$, \mathcal{T} is dense, and $\mathcal{G}(L)$ is connected.

For any simple network N , define $A(N)$ and $B(N)$ to be the sets of leaves attached to the two clipped merge paths in N , where we require without loss of generality that $A(N)$ is nonempty. If both $A(N)$ and $B(N)$ are nonempty, then N is called *nonskew*; if $A(N)$ is nonempty and $B(N)$ is empty, then N is called *skew*.

Algorithm *SimpleNetworks* is listed in Figure 2. It calls two procedures named *Non-SkewSimpleNetworks* and *SkewSimpleNetworks* that find all valid nonskew simple networks and all valid skew simple networks, respectively. Then it returns their union. In the next two subsections, we show how to implement each of these two procedures to run in $O(n^3)$ time. We thus obtain Theorem 1.

THEOREM 1. *The set of all simple networks consistent with a given dense set of rooted triplets and leaf-labeled by L can be constructed in $O(n^3)$ time.*

The next two lemmas are used in sections 2.1 and 2.2. A *caterpillar tree* is a rooted tree such that every internal node has at most one child which is not a leaf (see, e.g., [2]). Recall that for any simple network N , we denote the leaf attached to the hybrid node in N by $hl(N)$.

LEMMA 1. *Suppose N is a simple phylogenetic network that is consistent with a set \mathcal{T} of rooted triplets. Let N' be the graph obtained from N by deleting the root node of N , the hybrid node of N , and $hl(N)$ together with all their incident edges, and then, for every node with outdegree 1 and indegree less than 2, contracting its*

Algorithm *SimpleNetworks*

Input: A dense set \mathcal{T} of rooted triplets with a leaf set L such that $\mathcal{G}(L)$ consists of one connected component.

Output: The set of all simple phylogenetic networks with leaf set L which are consistent with \mathcal{T} .

- 1 Let $\mathcal{N}_1 = \text{Non-SkewSimpleNetworks}(\mathcal{T})$.
- 2 Let $\mathcal{N}_2 = \text{SkewSimpleNetworks}(\mathcal{T})$.
- 3 **return** $\mathcal{N}_1 \cup \mathcal{N}_2$.

End *SimpleNetworks*

FIG. 2. Constructing all simple phylogenetic networks.

outgoing edge. If N is nonskew, then N' consists of two binary caterpillar trees which are consistent with $\mathcal{T} \upharpoonright A(N)$ and $\mathcal{T} \upharpoonright B(N)$, respectively; if N is skew, then N' is a binary caterpillar tree which is consistent with $\mathcal{T} \upharpoonright A(N)$.

LEMMA 2. [15] Let \mathcal{T} be a dense set of rooted triplets and let L be the leaf set of \mathcal{T} . There is at most one rooted, unordered tree distinctly leaf-labeled by L which is consistent with \mathcal{T} . Furthermore, if such a tree exists, then it must be binary.

2.1. Constructing all nonskew simple phylogenetic networks. Let U be an undirected, connected graph. Any partition (X, Y, Z) of the vertex set of U is called a *nonskew leaf partition in U* if $|X| \geq 1$, $|Y| = 1$, $|Z| \geq 1$, and in U the following holds: (1) X and Z form two cliques, and (2) there is no edge between a vertex in X and a vertex in Z . Any two nonskew leaf partitions of the form (X, Y, Z) and (Z, Y, X) are considered to be equivalent.

LEMMA 3. Let \mathcal{T} be a dense set of rooted triplets and let L be the leaf set of \mathcal{T} . If N is a nonskew simple phylogenetic network with leaf set L that is consistent with \mathcal{T} , then $(A(N), hl(N), B(N))$ forms a nonskew leaf partition in $\mathcal{G}(L)$.

Proof. Consider any $a_i, a_j \in A(N)$ with $i \neq j$ and let b be an arbitrary element in $B(N)$. N is consistent with \mathcal{T} , implying that $(\{a_i, b\}, a_j) \notin \mathcal{T}$ and $(\{a_j, b\}, a_i) \notin \mathcal{T}$. Since \mathcal{T} is dense, $(\{a_i, a_j\}, b)$ must belong to \mathcal{T} ; i.e., there is an edge (a_i, a_j) in $\mathcal{G}(L)$. Hence, $A(N)$ forms a clique in $\mathcal{G}(L)$. In the same way, $B(N)$ forms a clique in $\mathcal{G}(L)$. Moreover, \mathcal{T} cannot contain any rooted triplet of the form $(\{a, b\}, x)$ where $a \in A(N)$, $b \in B(N)$, $x \in L$, and thus there are no edges in $\mathcal{G}(L)$ between leaves in $A(N)$ and leaves in $B(N)$. However, $\mathcal{G}(L)$ is connected, which means that there must be at least one edge from $A(N)$ to the leaf $hl(N)$ and at least one edge from $B(N)$ to $hl(N)$. By definition, $(A(N), hl(N), B(N))$ forms a nonskew leaf partition in $\mathcal{G}(L)$. \square

By Lemmas 1 and 3, if N is a nonskew simple network with leaf set L that is consistent with \mathcal{T} , then $(A(N), hl(N), B(N))$ forms a nonskew leaf partition in $\mathcal{G}(L)$ and $\mathcal{T} \upharpoonright A(N)$ and $\mathcal{T} \upharpoonright B(N)$ are consistent with two binary caterpillar trees. Algorithm *Non-SkewSimpleNetworks*, shown in Figure 3, uses these implications to efficiently construct all nonskew simple networks with leaf set L that are consistent with \mathcal{T} . The algorithm enumerates all nonskew leaf partitions in $\mathcal{G}(L)$, and for each such leaf partition P , tries to build binary caterpillar trees for subsets of L induced by P (Lemma 2 ensures that for any dense subset \mathcal{T}' of \mathcal{T} , if \mathcal{T}' is consistent with a caterpillar tree, then it is uniquely determined, and so the algorithm of Aho et al. [1] can find it) and if successful, then combines the caterpillar trees in accordance with Lemma 1 to obtain all possible valid simple networks. Lemmas 1 and 3 guarantee that this approach will discover every valid simple network. However, it may also yield some simple networks which are not consistent with \mathcal{T} ; hence, before including any

<p>Algorithm <i>Non-SkewSimpleNetworks</i></p> <p>Input: A dense set \mathcal{T} of rooted triplets with a leaf set L such that $\mathcal{G}(L)$ consists of one connected component.</p> <p>Output: The set of all nonskew simple phylogenetic networks with leaf set L which are consistent with \mathcal{T}.</p> <ol style="list-style-type: none"> 1 Set $\mathcal{N}_1 = \emptyset$. 2 Construct $\mathcal{G}(L)$ and compute all nonskew leaf partitions in $\mathcal{G}(L)$. 3 for every nonskew leaf partition (X, Y, Z) in $\mathcal{G}(L)$ do 3.1 Let $T_X = \text{BuildTree}(\mathcal{T} X)$ and $T_Z = \text{BuildTree}(\mathcal{T} Z)$. 3.2 if T_X and T_Z are binary caterpillar trees then Make the roots of T_X and T_Z children of a new root node, create a new hybrid node H with a child labeled by the leaf in Y, and construct at most four nonskew simple networks by attaching H to one of T_X's bottommost leaves' parent edges and one of T_Z's bottommost leaves' parent edges in all possible ways. --

FIG. 3. Constructing all nonskew simple phylogenetic networks.

constructed network N in the final solution set \mathcal{N}_1 , *Non-SkewSimpleNetworks* verifies if N is consistent with \mathcal{T} .

For any $L' \subseteq L$ with $|L'| \geq 3$, $\text{BuildTree}(\mathcal{T} | L')$ refers to the fast implementation of the algorithm of Aho et al. applied to $\mathcal{T} | L'$ (we may assume it returns *null* if it fails). For $|L'| < 3$, the set $\mathcal{T} | L'$ is empty and we simply let $\text{BuildTree}(\mathcal{T} | L')$ return a tree with the one or two leaves in L' . The running time of $\text{BuildTree}(\mathcal{T} | L')$ is $\min\{O(|\mathcal{T}| \cdot \log^2 n), O(|\mathcal{T}| + n^2 \log n)\}$ (see section 1.3).

We now derive an upper bound on the running time of *Non-SkewSimpleNetworks*.

LEMMA 4. *For any undirected, connected graph U with n vertices, all nonskew leaf partitions in U can be computed in $O(n^3)$ time.*

Proof. To find all nonskew leaf partitions in U , test each of the n vertices to see if its removal divides U into two disjoint, nonempty cliques. Each test can be done in $O(n^2)$ time by depth-first search; thus this takes a total of $O(n^3)$ time. \square

LEMMA 5. *Any undirected, connected graph U has at most two nonskew leaf partitions.*

Proof. First observe that for any two different nonskew leaf partitions $(X, \{h\}, Z)$ and $(X', \{h'\}, Z')$ in U , we have $h \neq h'$. Moreover, h and h' are neighbors in U (otherwise, for any two neighbors x', z' of h' such that $x' \in X'$ and $z' \in Z'$, we have $x' \neq h$ and $z' \neq h$, and then all of h', x', z' must belong to one of X and Z while there is no edge between x' and z' , which is a contradiction).

Now, suppose $(X, \{h\}, Z)$ is a nonskew leaf partition in U and consider any other nonskew leaf partition $(X', \{h'\}, Z')$ in U . Either $h' \in X$ or $h' \in Z$. If $h' \in X$, then h can have no neighbors in X other than h' (otherwise, there would be an edge between X' and Z') and, furthermore, U cannot have any nonskew leaf partition of the form $(X'', \{h''\}, Z'')$ where $h'' \in Z$ because h' and h'' are not neighbors. This also holds in the case $h' \in Z$. This proves that U has at most two nonskew leaf partitions. \square

Algorithm *SkewSimpleNetworks*

Input: A dense set \mathcal{T} of rooted triplets with a leaf set L such that $\mathcal{G}(L)$ consists of one connected component.

Output: The set of all skew simple phylogenetic networks with leaf set L which are consistent with \mathcal{T} .

- 1 Set $\mathcal{N}_2 = \emptyset$.
- 2 Construct \mathcal{D} .
- 3 **for** every $x \in L$ **do**
- 3.1 Let $Q = \text{BuildCaterpillar}(\mathcal{D} | L')$, where $L' = L \setminus \{x\}$.
- 3.2 **if** $Q \neq \text{null}$ **then**
- Make the root of Q a child of a new root node r , create a new hybrid node H with a child labeled by x , add an edge from r to H , and construct two skew simple networks by attaching H to each one of Q 's two bottommost edges.
- For each obtained network N , if N is consistent with all rooted triplets in \mathcal{T} involving x then let $\mathcal{N}_2 = \mathcal{N}_2 \cup \{N\}$.
- endif**
- 4 **return** \mathcal{N}_2 .

End *SkewSimpleNetworks*

FIG. 4. Constructing all skew simple phylogenetic networks.

Next, if N is any galled network with n leaves, then the total number of nodes in N is $O(n)$ by Lemma 3 in [4]. By traversing the $O(n)$ nodes in N in a bottom-up order while keeping track of each node's $O(n)$ descendants and updating a table containing all $O(n^2)$ node pairs' lowest common ancestors, we obtain the following.

LEMMA 6. *Let N be a galled network with n leaves. After $O(n^2)$ time preprocessing, we can check if any given rooted triplet is consistent with N in $O(1)$ time.*

THEOREM 2. *The time complexity of Algorithm Non-SkewSimpleNetworks is $O(n^3)$.*

Proof. Steps 1 and 4 require $O(1)$ time. Step 2 can be performed in $O(n^3)$ time by a single scan of \mathcal{T} and by applying Lemma 4. Moreover, $\mathcal{G}(L)$ has at most two nonskew leaf partitions according to Lemma 5. Therefore, steps 3.1 and 3.2 are carried out at most two times each. Step 3.1 takes $O(|\mathcal{T}| + n^2 \log n) = O(n^3)$ time with the fast implementation of *BuildTree* by Henzinger, King, and Warnow [10]. Every time step 3.2 is performed, the algorithm constructs at most four nonskew simple networks and tests each of them for inclusion in \mathcal{N} , which after $O(n^2)$ time preprocessing takes $O(n^3)$ time using Lemma 6 since $|\mathcal{T}| = O(n^3)$. Hence, the total running time is $O(n^3)$. \square

2.2. Constructing all skew simple phylogenetic networks. To obtain all skew simple networks with leaf set L consistent with \mathcal{T} , Algorithm *SkewSimpleNetworks* in Figure 4 tries all ways to remove one leaf x from L and construct a binary caterpillar tree consistent with all rooted triplets not involving x using a procedure named *BuildCaterpillar*. For each such caterpillar Q , it forms two candidate skew simple networks by letting the root of Q be a child of a new split node with a hybrid node H such that H has a child labeled by x and H is attached to one of Q 's two bottommost edges. (By Lemma 1, every skew simple network with leaf set L that is consistent with \mathcal{T} must have this structure.) Then, each candidate skew simple network is checked to see if it is consistent with all rooted triplets in \mathcal{T} involving x (by the above, it is always consistent with the rest); if yes, then it is included in the solution set \mathcal{N}_2 .

The procedure *BuildCaterpillar* uses a graph \mathcal{D} , defined as follows. Given a set \mathcal{T} of rooted triplets with leaf set L , let \mathcal{D} be the directed graph with vertex set L such that there is a directed edge (x, y) if and only if \mathcal{T} contains at least one rooted triplet of the form $(\{y, z\}, x)$, where $z \in L$. For any $L' \subseteq L$, let $\mathcal{D}|L'$ be the subgraph of \mathcal{D} in which all vertices not in L' and their incident edges have been deleted. $\mathcal{D}|L'$ is acyclic if and only if there exists a binary caterpillar tree consistent with $\mathcal{T}|L'$.

For any $L' \subseteq L$, *BuildCaterpillar*($\mathcal{D}|L'$) returns a binary caterpillar tree with leaf set L' which is consistent with $\mathcal{T}|L'$ if such a tree exists, and *null* otherwise, by the following method. If $\mathcal{D}|L'$ has a cycle, then return *null*. Else, do a topological sort of $\mathcal{D}|L'$ to find a linear ordering \mathcal{O} of L' and return a binary caterpillar tree whose leaves are labeled in order of increasing distance from the root according to \mathcal{O} . Since \mathcal{T} is dense, \mathcal{O} is uniquely determined except for its last two elements which may be interchanged arbitrarily.

THEOREM 3. *The time complexity of Algorithm *SkewSimpleNetworks* is $O(n^3)$.*

Proof. Steps 1 and 4 require $O(1)$ time, and step 2 can be performed in $O(n^3)$ time by a single scan of \mathcal{T} . Steps 3.1 and 3.2 are carried out n times. Each call to *BuildCaterpillar* in step 3.1 takes $O(n^2)$ time since a topological sort can be done in $O(n^2)$ time. In step 3.2, to construct two networks and test them against the $O(n^2)$ rooted triplets involving x takes $O(n^2)$ time by Lemma 6. Hence, the total running time is $O(n^3)$. \square

3. An exact algorithm for inferring a galled phylogenetic network from a dense set of rooted triplets with optimal running time. Here, we present our algorithm *FastGalledNetwork* for constructing a galled network consistent with a given dense set \mathcal{T} of rooted triplets if such a network exists. Its running time is $O(n^3)$, where $n = |L|$ and L denotes the leaf set of \mathcal{T} , which is optimal since the size of the input is $\Theta(n^3)$ when \mathcal{T} is dense.

In section 3.1, we give an algorithm named *ComputeSNTree* which computes the so-called *SN-tree* for \mathcal{T} in $O(n^3)$ time. Then, in section 3.2, we describe *FastGalledNetwork*. It uses *ComputeSNTree* as well as *SimpleNetworks* from section 2 to construct a galled network consistent with \mathcal{T} (if one exists) from the *SN-tree* for \mathcal{T} . In sections 3.1 and 3.2 below, we assume \mathcal{T} is dense.

3.1. Computing the *SN-tree*. For any $X \subseteq L$, the set $SN(X)$ is defined recursively as $SN(X \cup \{c\})$ if there exist some $x, x' \in X$ and $c \in L \setminus X$ such that $(\{x, c\}, x') \in \mathcal{T}$, and as X otherwise. *SN-sets* were introduced in [15]. Intuitively, each *SN-set* is a subset of L which will form the leaf set of one subnetwork in the final solution. The *SN-sets* satisfy the following important property.

LEMMA 7 (see [15]). *If \mathcal{T} is dense, then for any $A, B \subseteq L$, $SN(A) \cap SN(B)$ equals \emptyset , $SN(A)$, or $SN(B)$.*

Reference [15] showed how to compute $SN(\{a, b\})$ for any $a, b \in L$ in $O(n^3)$ time; that approach therefore takes $O(n^5)$ time to compute $SN(\{a, b\})$ for all $a, b \in L$. This section presents a faster method for implicitly computing all *SN-sets* of this form when \mathcal{T} is dense, which requires only $O(n^3)$ time. The algorithm (*ComputeSNTree*) is listed in Figure 5. Given a dense \mathcal{T} , it builds a rooted tree called *the SN-tree for \mathcal{T}* which encodes all *SN-sets* so that $SN(X)$ for any $X \subseteq L$ can be retrieved efficiently.

In the first step, *ComputeSNTree* constructs a directed graph $G_{\mathcal{T}}$ with vertex set $V(G_{\mathcal{T}})$ and edge set $E(G_{\mathcal{T}})$. $V(G_{\mathcal{T}})$ is defined as $\{v_{\{a,b\}} \mid a, b \in L\}$, where $v_{\{a,a\}}$ for any $a \in L$ is denoted by $v_{\{a\}}$ for short, and $E(G_{\mathcal{T}})$ is $\{(v_{\{a,c\}}, v_{\{a,b\}}), (v_{\{a,c\}}, v_{\{b,c\}}), (v_{\{b,c\}}, v_{\{a,b\}}), (v_{\{b,c\}}, v_{\{a,c\}}) \mid (\{a, b\}, c) \in \mathcal{T}\} \cup \{(v_{\{a,b\}}, v_{\{a\}}), (v_{\{a,b\}}, v_{\{b\}}) \mid a, b \in L\}$.

Algorithm *ComputeSNTree*
Input: A dense set \mathcal{T} of rooted triplets with a leaf set L .
Output: The SN -tree $R_{\mathcal{T}}$ for \mathcal{T} .

- 1 Construct the directed graph $G_{\mathcal{T}}$.
- 2 Compute the set \mathcal{C} of strongly connected components of $G_{\mathcal{T}}$ and then construct $G'_{\mathcal{T}}$ for \mathcal{T} .
- 3 Construct the SN -tree $R_{\mathcal{T}}$ and **return** $R_{\mathcal{T}}$.

End *ComputeSNTree*

FIG. 5. Computing the SN -tree for a dense set \mathcal{T} .

L }. Note that $|V(G_{\mathcal{T}})| = O(n^2)$ and $|E(G_{\mathcal{T}})| = O(n^3)$. Before describing the remaining steps of *ComputeSNTree*, we first investigate the structure of $G_{\mathcal{T}}$ and the relationship between $G_{\mathcal{T}}$ and the SN -sets of the form $SN(\{a, b\})$.

LEMMA 8. For every $a, b, y, z \in L$, if $G_{\mathcal{T}}$ contains a path from $v_{\{a,b\}}$ to $v_{\{a,y\}}$ and a path from $v_{\{a,b\}}$ to $v_{\{a,z\}}$, then $G_{\mathcal{T}}$ has a path from $v_{\{a,b\}}$ to $v_{\{y,z\}}$.

Proof. If $|\{a, y, z\}| < 3$, then the lemma follows from the construction of $G_{\mathcal{T}}$. Otherwise, since \mathcal{T} is dense, we have one of the following cases for $\{a, y, z\}$:

- Case (1): $(\{y, z\}, a) \in \mathcal{T}$ or $(\{a, z\}, y) \in \mathcal{T}$. Then $(v_{\{a,y\}}, v_{\{y,z\}}) \in E(G_{\mathcal{T}})$, and thus there is a path from $v_{\{a,b\}}$ to $v_{\{a,y\}}$ and then to $v_{\{y,z\}}$.
- Case (2): $(\{a, y\}, z) \in \mathcal{T}$. Then $(v_{\{a,z\}}, v_{\{y,z\}}) \in E(G_{\mathcal{T}})$, and thus there is a path from $v_{\{a,b\}}$ to $v_{\{a,z\}}$ and then to $v_{\{y,z\}}$. \square

LEMMA 9. For every $a, b, c \in L$, if $c \in SN(\{a, b\})$, then there exists a directed path from $v_{\{a,b\}}$ to $v_{\{a,c\}}$ in $G_{\mathcal{T}}$.

Proof. Define $SN_0(\{a, b\}) = \{a, b\}$ and for $\ell = 1, 2, \dots, n$, define $SN_{\ell} = \{x \in L \mid (\{y, x\}, z) \in \mathcal{T} \text{ for some } y, z \in SN_{\ell-1}(\{a, b\})\}$. Note that $SN(\{a, b\}) = \bigcup_{i=0}^n SN_i(\{a, b\})$. We prove by induction that the following statement $P(\ell)$ is true for $\ell \in \{0, 1, 2, \dots, n\}$.

$P(\ell)$: For every $x \in SN_{\ell}(\{a, b\})$, there exists a path from $v_{\{a,b\}}$ to $v_{\{a,x\}}$ in $G_{\mathcal{T}}$.

When $\ell = 0$ (the base case), the statement follows trivially by the construction of $G_{\mathcal{T}}$.

Next, when $\ell > 0$, suppose the statement $P(\ell - 1)$ is true; i.e., for every $w \in SN_{\ell-1}(\{a, b\})$, there exists a path from $v_{\{a,b\}}$ to $v_{\{a,w\}}$ in $G_{\mathcal{T}}$. Consider any $x \in SN_{\ell}(\{a, b\})$. By the definition of SN_{ℓ} , there exist $y, z \in SN_{\ell-1}(\{a, b\})$ such that $(\{y, x\}, z) \in \mathcal{T}$. Then $P(\ell - 1)$ implies that there is a path from $v_{\{a,b\}}$ to $v_{\{a,y\}}$ and a path from $v_{\{a,b\}}$ to $v_{\{a,z\}}$, which means there exists a path from $v_{\{a,b\}}$ to $v_{\{y,z\}}$ according to Lemma 8. Moreover, $(v_{\{y,z\}}, v_{\{x,y\}}) \in E(G_{\mathcal{T}})$ because $(\{y, x\}, z) \in \mathcal{T}$. Now, if $x = a$ or $y = a$, then $P(\ell)$ follows directly; therefore assume $x \neq a$ and $y \neq a$. Since \mathcal{T} is dense, for the set $\{a, x, y\}$, there are two cases:

- Case (1): $(\{a, y\}, x) \in \mathcal{T}$ or $(\{a, x\}, y) \in \mathcal{T}$. Then $(v_{\{x,y\}}, v_{\{a,x\}}) \in E(G_{\mathcal{T}})$.
- Case (2): $(\{x, y\}, a) \in \mathcal{T}$. Then $(v_{\{a,y\}}, v_{\{a,x\}}) \in E(G_{\mathcal{T}})$.

In both cases, there exists a path from $v_{\{a,b\}}$ to $v_{\{a,x\}}$, and thus $P(\ell)$ holds.

By induction, $P(\ell)$ is true for every $\ell \in \{0, 1, 2, \dots, n\}$. Since c belongs to at least one set SN_{ℓ} , the lemma follows. \square

LEMMA 10. For every $a, b, c, d \in L$, if there is a directed path from $v_{\{a,b\}}$ to $v_{\{c,d\}}$ in $G_{\mathcal{T}}$, then $SN(\{c, d\}) \subseteq SN(\{a, b\})$.

Proof. For any $e \in SN(\{c, d\})$, there is a directed path from $v_{\{c,d\}}$ to $v_{\{c,e\}}$ by Lemma 9. Since $E(G_{\mathcal{T}})$ contains the directed edge $(v_{\{c,e\}}, v_{\{e\}})$, and since there is a directed path from $v_{\{a,b\}}$ to $v_{\{c,d\}}$, this means there is a directed path from $v_{\{a,b\}}$ to

$v_{\{e\}}$. Without loss of generality, let the path be $v_{\{x_0,x_1\}}, v_{\{x_1,x_2\}}, v_{\{x_2,x_3\}}, \dots, v_{\{x_{p-1},x_p\}}, v_{\{x_p\}}$, where $\{x_0, x_1\} = \{a, b\}$, and $x_p = e$. Then, based on the rooted triplets in \mathcal{T} for the sets $\{x_0, x_1, x_2\}, \{x_1, x_2, x_3\}, \dots, \{x_{p-2}, x_{p-1}, x_p\}$, we can deduce that $x_p \in SN(\{a, b\})$. Thus, $e \in SN(\{a, b\})$, so we have just shown that $SN(\{c, d\}) \subseteq SN(\{a, b\})$. \square

COROLLARY 1. *For any two nodes $v_{\{a,b\}}$ and $v_{\{c,d\}}$ on a directed cycle in $G_{\mathcal{T}}$, $SN(\{a, b\}) = SN(\{c, d\})$.*

By the above, computing $SN(\{a, b\})$ for any $a, b \in L$ is equivalent to finding all nodes of the form $v_{\{c\}}$ reachable from $v_{\{a,b\}}$. Let the set of all strongly connected components of $G_{\mathcal{T}}$ be $\mathcal{C} = \{C_1, C_2, \dots, C_m\}$. By Corollary 1, $SN(\{a, b\}) = SN(\{c, d\})$ if $v_{\{a,b\}}$ and $v_{\{c,d\}}$ are in the same C_i . So, we define $SN(C_i)$ as $SN(\{a, b\})$ for any $v_{\{a,b\}} \in C_i$. The set \mathcal{C} has the following properties.

LEMMA 11. *For every $c \in L$, $\{v_{\{c\}}\} \in \mathcal{C}$. Moreover, for every $i \neq j$, $SN(C_i) \neq SN(C_j)$.*

Proof. Since $v_{\{c\}}$ has no outgoing edge, $\{v_{\{c\}}\}$ is a strongly connected component in $G_{\mathcal{T}}$ and therefore belongs to \mathcal{C} .

To prove the second statement, suppose for the sake of contradiction that there exist strongly connected components C_i, C_j with $i \neq j$ such that $SN(C_i) = SN(C_j)$. Take any $v_{\{w,x\}} \in C_i$ and $v_{\{y,z\}} \in C_j$. Since $y, z \in SN(C_j) = SN(C_i) = SN(\{w, x\})$, it follows from Lemma 9 that $G_{\mathcal{T}}$ has a path from $v_{\{w,x\}}$ to $v_{\{w,y\}}$ and a path from $v_{\{w,x\}}$ to $v_{\{w,z\}}$, and hence a path from $v_{\{w,x\}}$ to $v_{\{y,z\}}$ by Lemma 8. Symmetrically, $G_{\mathcal{T}}$ contains a path from $v_{\{y,z\}}$ to $v_{\{w,x\}}$. But then $C_i \cup C_j$ must be a strongly connected component of $G_{\mathcal{T}}$, and we have arrived at a contradiction. \square

In the second step of *ComputeSNTree*, we compute \mathcal{C} and then let $G'_{\mathcal{T}}$ be the directed graph with vertex set $V(G'_{\mathcal{T}}) = \mathcal{C}$ and edge set $E(G'_{\mathcal{T}}) = \{(C_i, C_j) \mid \text{there exists some } (v_{\{w,x\}}, v_{\{y,z\}}) \in E(G_{\mathcal{T}}) \text{ where } v_{\{w,x\}} \in C_i \text{ and } v_{\{y,z\}} \in C_j\}$. Note that $G'_{\mathcal{T}}$ is a directed acyclic graph. From $G'_{\mathcal{T}}$, construct a graph $R_{\mathcal{T}}$ with $V(R_{\mathcal{T}}) = \mathcal{C}$ and $E(R_{\mathcal{T}}) = \{(C_i, C_j) \in E(G'_{\mathcal{T}}) \mid \text{there exists no path of length at least 2 from } C_i \text{ to } C_j \text{ in } G'_{\mathcal{T}}\}$. Finally, return $R_{\mathcal{T}}$. The next two lemmas show that $R_{\mathcal{T}}$ is indeed a tree.

LEMMA 12. *There is only one node in $G'_{\mathcal{T}}$ with indegree 0.*

Proof. Suppose $G'_{\mathcal{T}}$ has two different nodes r, s with indegree 0. Denote the two strongly connected components in $G_{\mathcal{T}}$ which correspond to r and s in $R_{\mathcal{T}}$ by C_r and C_s , respectively. Let $v_{\{a,b\}}$ be any node in C_r and let $v_{\{c,d\}}$ be any node in C_s . Clearly, $a \neq b$ and $c \neq d$ since any node of the form $v_{\{a\}}$ belongs to a strongly connected component consisting only of $v_{\{a\}}$ and therefore cannot have indegree 0 by the construction of $G_{\mathcal{T}}$. Consider the three possible rooted triplets with leaf set $\{a, b, c\}$ (of which at least one belongs to \mathcal{T} since \mathcal{T} is dense). By the definition of $E(G_{\mathcal{T}})$, there will always be at least one edge ending at $v_{\{a,b\}}$. Since r has indegree 0 in $G'_{\mathcal{T}}$, this implies that (1) at least one of $v_{\{a,c\}}$ and $v_{\{b,c\}}$ must be in C_r . In the same way, we see that (2) at least one of $v_{\{a,d\}}$ and $v_{\{b,d\}}$ is in C_r ; (3) at least one of $v_{\{a,c\}}$ and $v_{\{a,d\}}$ is in C_s ; and (4) at least one of $v_{\{b,c\}}$ and $v_{\{b,d\}}$ is in C_s .

Assume without loss of generality that $v_{\{a,c\}} \in C_r$. Then (3) yields $v_{\{a,d\}} \in C_s$, and thus we have $v_{\{b,d\}} \in C_r$ by (2), and then $v_{\{b,c\}} \in C_s$ by (4). There are three cases:

- Case (1): $(\{a, b\}, c) \in T$. Then the two edges $(v_{\{a,c\}}, v_{\{b,c\}})$ and $(v_{\{b,c\}}, v_{\{a,c\}})$ in $E(G_{\mathcal{T}})$ imply that C_r is reachable from C_s in $G'_{\mathcal{T}}$ and vice versa.
- Case (2): $(\{a, c\}, b) \in T$. Then $(v_{\{a,b\}}, v_{\{b,c\}}), (v_{\{b,c\}}, v_{\{a,b\}}) \in E(G_{\mathcal{T}})$ imply that C_r is reachable from C_s in $G'_{\mathcal{T}}$ and vice versa.
- Case (3): $(\{b, c\}, a) \in T$. Then $(v_{\{a,b\}}, v_{\{b,c\}}) \in E(G_{\mathcal{T}})$, and thus C_s is reachable from C_r in $G'_{\mathcal{T}}$. Next, by considering all possible rooted triplets on

$\{a, c, d\}$, we see that $(v_{\{c,d\}}, v_{\{a,c\}}) \in E(G_{\mathcal{T}})$; $(v_{\{a,c\}}, v_{\{c,d\}}), (v_{\{c,d\}}, v_{\{a,c\}}) \in E(G_{\mathcal{T}})$; or $(v_{\{a,c\}}, v_{\{a,d\}}), (v_{\{a,d\}}, v_{\{a,c\}}) \in E(G_{\mathcal{T}})$, which means that C_r is always reachable from C_s in $G'_{\mathcal{T}}$.

Every case contradicts that C_r and C_s are disjoint strongly connected components. Hence, $G'_{\mathcal{T}}$ can only have one node with indegree 0. \square

LEMMA 13. $R_{\mathcal{T}}$ is a tree with no nodes having outdegree 1. Its set of leaves is $\{\{v_{\{c\}}\} \mid c \in L\}$.

Proof. From Lemma 12 and by the construction of $R_{\mathcal{T}}$, it follows that $R_{\mathcal{T}}$ has only one node with indegree 0, i.e., only one root node.

Now, suppose $R_{\mathcal{T}}$ is not a tree. Then there exists a node C_j in $R_{\mathcal{T}}$ with at least two parents, say C_i and $C_{i'}$. By definition, $(C_i, C_j), (C_{i'}, C_j) \in E(G'_{\mathcal{T}})$ and by Lemma 10, $SN(C_j) \subseteq SN(C_i)$ as well as $SN(C_j) \subseteq SN(C_{i'})$. Next, by Lemmas 7 and 11, we have either $SN(C_i) \subsetneq SN(C_{i'})$ or $SN(C_{i'}) \subsetneq SN(C_i)$. Without loss of generality, assume $SN(C_i) \subsetneq SN(C_{i'})$. Then, by Lemmas 8 and 9, we have a path in $G'_{\mathcal{T}}$ from $C_{i'}$ to C_i and then to C_j . But this implies that $(C_{i'}, C_j) \notin E(R_{\mathcal{T}})$, which is a contradiction. Thus, $R_{\mathcal{T}}$ must be a tree.

Next, suppose some node C_i in $R_{\mathcal{T}}$ has a single child C_j . By Lemma 10, $SN(C_j) \subseteq SN(C_i)$. Observe that for any $c \in SN(C_i)$, there is a path from C_i to $v_{\{c\}}$ in $G'_{\mathcal{T}}$ according to Lemma 9, and since this path passes through C_j , we also have $c \in SN(C_j)$ by Lemma 10. This means that $SN(C_i) \subseteq SN(C_j)$, giving us $SN(C_i) = SN(C_j)$. But this contradicts Lemma 11. Thus, $R_{\mathcal{T}}$ has no nodes with outdegree 1.

Finally, for every $c \in L$, $\{v_{\{c\}}\}$ is of outdegree 0 in $G'_{\mathcal{T}}$ and is therefore a leaf in $R_{\mathcal{T}}$. The lemma follows. \square

COROLLARY 2. $|\mathcal{C}| = O(n)$.

Proof. By the definition of $R_{\mathcal{T}}$, we have $V(R_{\mathcal{T}}) = \mathcal{C}$. Lemma 13 states that $R_{\mathcal{T}}$ is a tree with n leaves and no nodes with outdegree 1. Hence, $|\mathcal{C}| = |V(R_{\mathcal{T}})| = O(n)$. \square

In the rest of the paper, $R_{\mathcal{T}}$ is called the *SN-tree for \mathcal{T}* . This is because $SN(\{a, b\})$ for any $a, b \in L$ can be obtained from $R_{\mathcal{T}}$ using the following theorem.

THEOREM 4. Given any $a, b \in L$, let u be the lowest common ancestor of $v_{\{a\}}$ and $v_{\{b\}}$ in $R_{\mathcal{T}}$. Then, $SN(\{a, b\}) = \{c \in L \mid v_{\{c\}} \text{ is a descendant of } u \text{ in } R_{\mathcal{T}}\}$.

Proof. We first prove that for any $c \in L$, if $v_{\{c\}}$ is a descendant of the lowest common ancestor u of $v_{\{a\}}$ and $v_{\{b\}}$ in $R_{\mathcal{T}}$, then $c \in SN(\{a, b\})$. Let $v_{\{y,z\}}$ be any node in the strongly connected component in $G_{\mathcal{T}}$ which corresponds to u in $R_{\mathcal{T}}$. Then $a \in SN(\{y, z\})$ by Lemma 10. Since also $a \in SN(\{a, b\})$, Lemma 7 implies that either (1) $SN(\{a, b\}) \subsetneq SN(\{y, z\})$ or (2) $SN(\{y, z\}) \subseteq SN(\{a, b\})$. If (1) holds, then there is a path in $G_{\mathcal{T}}$ from $v_{\{y,z\}}$ to $v_{\{a,b\}}$ by Lemma 9, but then u cannot be the lowest common ancestor of $v_{\{a\}}$ and $v_{\{b\}}$ in $R_{\mathcal{T}}$, which is a contradiction. Thus, (2) must hold, which means that $y, z \in SN(\{a, b\})$, so there is a path in $G_{\mathcal{T}}$ from $v_{\{a,b\}}$ to $v_{\{y,z\}}$ as can be seen by applying Lemma 9 two times and then Lemma 8. Now, since $v_{\{c\}}$ is a descendant of u in $R_{\mathcal{T}}$, there is a path in $G_{\mathcal{T}}$ from $v_{\{y,z\}}$ to $v_{\{c\}}$. This shows that $v_{\{c\}}$ is reachable from $v_{\{a,b\}}$ in $G_{\mathcal{T}}$, i.e., that $c \in SN(\{a, b\})$ by Lemma 10.

Next, we prove that if $c \in SN(\{a, b\})$, then $v_{\{c\}}$ is a descendant of u in $R_{\mathcal{T}}$. Take any $c \in SN(\{a, b\})$, and suppose that $v_{\{c\}}$ is not a descendant of u in $R_{\mathcal{T}}$. Then $v_{\{b\}}$ is a descendant of the lowest common ancestor u' of $v_{\{a\}}$ and $v_{\{c\}}$ in $R_{\mathcal{T}}$, so $b \in SN(\{a, c\})$ by the preceding paragraph and, similarly, $a \in SN(\{b, c\})$. But then, $SN(\{a, b\}) = SN(\{a, c\}) = SN(\{b, c\})$ by Lemma 9 and Corollary 1, which is impossible since this would imply that u and u' coincide. Therefore, $v_{\{c\}}$ must be a descendant of u in $R_{\mathcal{T}}$. \square

Thus, the *SN-tree* has the properties we want. The next theorem shows that the

SN -tree for \mathcal{T} can be constructed efficiently.

THEOREM 5. *The time complexity of Algorithm `ComputeSNTree` is $O(n^3)$.*

Proof. By scanning all rooted triplets in \mathcal{T} , we can construct $G_{\mathcal{T}}$ in step 1 in $O(|\mathcal{T}|) = O(n^3)$ time. For step 2, the time complexity is $O(|V(G_{\mathcal{T}})| + |E(G_{\mathcal{T}})|) = O(n^3)$. To build the SN -tree $R_{\mathcal{T}}$ in step 3, we need two substeps. First, for each node $C_i \in V(G'_{\mathcal{T}})$, we compute the set of all nodes that are reachable from C_i in $G'_{\mathcal{T}}$. By Corollary 2, $|V(G'_{\mathcal{T}})| = O(n)$ and thus $|E(G'_{\mathcal{T}})| = O(n^2)$, so this takes $O(n^2)$ time for each C_i using depth-first search, so $O(n^3)$ time in total. Next, we check, for each $(C_i, C_j) \in E(G'_{\mathcal{T}})$, if there is a path of length at least 2 from C_i to C_j . If the answer is no, then (C_i, C_j) is an edge in $R_{\mathcal{T}}$. Each such check can be performed in $O(n)$ time by asking if C_j is reachable from any of the children (except C_j itself) of C_i . Since there are $O(n^2)$ edges, we can check all edges in $O(n^3)$ time. Thus, the algorithm's total running time is $O(n^3)$. \square

3.2. Algorithm `FastGalledNetwork`. The main algorithm of this section, Algorithm `FastGalledNetwork`, is listed in Figure 6. The key observation is that a galled network consistent with \mathcal{T} (if one exists) can be obtained from the SN -tree for \mathcal{T} by replacing each internal node of degree 3 or higher with a subnetwork whose structure is inferred by Algorithm `SimpleNetworks`.

Recall that for any node u in a rooted, leaf-labeled tree R , $R[u]$ is the subtree of R rooted at u , and $\Lambda(R[u])$ denotes the set of leaves in $R[u]$. Below, $\mathcal{T} \upharpoonright u$ is shorthand for the set $\mathcal{T} \upharpoonright \Lambda(R[u])$.

In step 1, `FastGalledNetwork` computes the SN -tree R for \mathcal{T} using Algorithm `ComputeSNTree` from section 3.1. Then, in steps 2 and 3, it tries to construct a galled network N_u consistent with all rooted triplets in $\mathcal{T} \upharpoonright u$ for each node u in R in bottom-up order. If successful, it returns N_r , where r is the root of R (note that $\mathcal{T} = \mathcal{T} \upharpoonright r$); otherwise, it returns *null*. To obtain N_u for any node u in R , `FastGalledNetwork` proceeds as follows. Let q be the degree of u and denote the children of u by $\{u_1, u_2, \dots, u_q\}$. If $q = 0$, then let N_u be a network consisting of one leaf, labeled by u . If $q = 2$, then form N_u by joining the roots of N_{u_1} and N_{u_2} to a new root node. Otherwise, $q \geq 3$ by Lemma 13. In this case, let $\alpha_1, \alpha_2, \dots, \alpha_q$ be q new symbols not in L , and define a function f as follows. For every $x \in \Lambda(R[u])$, let $f(x) = \alpha_i$, where $x \in \Lambda(R[u_i])$. Next, define \mathcal{T}' as the set $\{(\{f(x), f(y)\}, f(z)) : (\{x, y\}, z) \in (\mathcal{T} \upharpoonright u) \text{ and } f(x), f(y), f(z) \text{ all differ}\}$, and apply Algorithm `SimpleNetworks` from section 2 to \mathcal{T}' . If there is a simple phylogenetic network N' consistent with \mathcal{T}' , then replace each α_i in N' with N_{u_i} and let N_u be the resulting network; otherwise, terminate and output *null*.

The correctness of this method follows from the next two lemmas.

LEMMA 14. *For any node u in R , if $\mathcal{T} \upharpoonright u$ is consistent with a galled network with leaf set $\Lambda(R[u])$ and if $q \geq 3$, then there exists a simple network consistent with \mathcal{T}' .*

Proof. Let M be a galled network with leaf set $\Lambda(R[u])$ consistent with $\mathcal{T} \upharpoonright u$. First we show that if $q \geq 3$, then the root r of M must be a split node. Suppose r is not a split node and let A and B be the disjoint sets of leaves in the two subnetworks rooted at the children of r . For every child u_i of u , we have either $\Lambda(R[u_i]) \subseteq A$ or $\Lambda(R[u_i]) \subseteq B$ (otherwise, let a, b be two leaves in $\Lambda(R[u_i])$ such that $a \in A$ and $b \in B$; for each $x \in \Lambda(R[u]) \setminus \{a, b\}$, at least one of $(\{a, x\}, b)$ and $(\{b, x\}, a)$ belongs to $\mathcal{T} \upharpoonright u$ since \mathcal{T} is dense, so $x \in \Lambda(R[u_i])$, i.e., $\Lambda(R[u_i]) = \Lambda(R[u])$, which is not possible). Since $q \geq 3$, there exist i, j, k where i, j, k differ such that both $\Lambda(R[u_i])$ and $\Lambda(R[u_j])$ are subsets of one of A and B , and $\Lambda(R[u_k])$ is a subset of the other. Assume without loss of generality that $\Lambda(R[u_i]), \Lambda(R[u_j]) \subseteq A$ and $\Lambda(R[u_k]) \subseteq B$.

Algorithm *FastGalledNetwork*
Input: A dense set \mathcal{T} of rooted triplets with a leaf set L .
Output: A galled network consistent with \mathcal{T} , if one exists; otherwise, *null*.

- 1 Let $R = \text{ComputeSNTree}(\mathcal{T})$.
- 2 Define N_u for every leaf u in R to be a single node labeled by u .
- 3 **for** each nonleaf node u in R , in bottom-up order **do**
 /* Construct a galled network N_u for the set of leaves in $\Lambda(R[u])$. */
 3.1 Denote the set of children of u in R by $\{u_1, u_2, \dots, u_q\}$.
 3.2 If $q = 2$, let N_u be a network with a root node joined to N_{u_1} and N_{u_2} .
 3.3 Otherwise ($q \geq 3$), build \mathcal{T}' from $\mathcal{T} \upharpoonright u$, compute $\mathcal{N} = \text{SimpleNetworks}(\mathcal{T}')$, and check if \mathcal{N} is empty; if yes then **return** *null*, else select any $N' \in \mathcal{N}$ and form a network N_u by replacing each α_i in N' with N_{u_i} .
 endfor

FIG. 6. Constructing a galled phylogenetic network consistent with a dense set \mathcal{T} of rooted triplets.

For any $x, y \in A$ and $b_k \in \Lambda(R[u_k])$, \mathcal{T} cannot contain $(\{x, b_k\}, y)$ or $(\{y, b_k\}, x)$, so $SN(\{a_i, a_j\})$ is a proper subset of $SN(\{a_i, b_k\})$ for every $a_i \in \Lambda(R[u_i])$, $a_j \in \Lambda(R[u_j])$. However, u is the lowest common ancestor in R of $\{a_i, a_j\}$ as well as of $\{a_i, b_k\}$, so $SN(\{a_i, a_j\}) = SN(\{a_i, b_k\})$ by Theorem 4, which is a contradiction. Hence, r is a split node.

Next, observe that each side network of M can contain leaves from only one $R[u_i]$. To see this, let $M[v]$ be a side network of M . For any i, j with $i \neq j$, if $M[v]$ contains a leaf $a \in \Lambda(R[u_i])$ and a leaf $b \in \Lambda(R[u_j])$, then since \mathcal{T} is dense, $\Lambda(R[u_i]) \subsetneq SN(\{a, b\})$ and $\Lambda(R[u_j]) \subsetneq SN(\{a, b\})$ by Lemma 7 while $SN(\{a, b\}) \neq \Lambda(R[u])$ (otherwise, $M[v]$ cannot be a side network of M), contradicting the maximality of $\Lambda(R[u_i])$ and $\Lambda(R[u_j])$ in $\Lambda(R[u])$.

By the preceding two paragraphs, the root of M is a split node of some hybrid node h , and each side network attached to a merge path of h contains leaves from only one $\Lambda(R[u_i])$. We now show that there exists a galled network M^* consistent with $\mathcal{T} \upharpoonright u$ such that for every i , all leaves in $\Lambda(R[u_i])$ belong to only one side network of M^* attached to a merge path of h . Suppose M has two side networks $M[v]$ and $M[w]$ attached to merge paths of h such that both $M[v]$ and $M[w]$ contain leaves from the same $\Lambda(R[u_i])$. $M[v]$ and $M[w]$ must be attached to the same merge path p of h (otherwise, $\Lambda(R[u_i]) = \Lambda(R[u])$, which is impossible), and, furthermore, all side networks attached to p between $M[v]$ and $M[w]$ contain leaves from $\Lambda(R[u_i])$ only. Thus, all side networks containing leaves from the same $\Lambda(R[u_i])$ are consecutively ordered along one merge path of h and can therefore be concatenated into one side network in such a way that all rooted triplets involving $\Lambda(R[u_i])$ are still consistent with it (note that \mathcal{T} does not contain any rooted triplet of the form $(\{a, x\}, b)$ where $a, b \in \Lambda(R[u_i])$ and x is located in a side tree of M below the side trees leaf-labeled by $\Lambda(R[u_i])$). Let M^* be the resulting galled network consistent with $\mathcal{T} \upharpoonright u$ such that each side network M_i^* attached to a merge path of h is bijectively leaf-labeled by one $\Lambda(R[u_i])$.

Finally, construct a simple phylogenetic network M' from M^* by replacing each M_i^* by a leaf labeled by α_i . M' is consistent with \mathcal{T}' , which can be seen as follows. Let t' be any rooted triplet in \mathcal{T}' and write $t' = (\{\alpha_i, \alpha_j\}, \alpha_k)$. Then there exists some rooted triplet $t = (\{x, y\}, z)$ in \mathcal{T} such that $x \in \Lambda(R[u_i])$, $y \in \Lambda(R[u_j])$, and

$z \in \Lambda(R[u_k])$, where i, j, k all differ. t is consistent with M^* , so t' is consistent with M' by the construction of M' . Hence, \mathcal{T}' and M' are consistent. \square

LEMMA 15. *Let u be any node in R and suppose each $\mathcal{T}|_{u_i}$ is consistent with a galled network N_{u_i} . If $q = 2$, then the galled network obtained by joining the roots of N_{u_1} and N_{u_2} to a new root node is consistent with $\mathcal{T}|_u$. If $q \geq 3$ and \mathcal{T}' is consistent with a simple network N' with leaf set $\{\alpha_1, \alpha_2, \dots, \alpha_q\}$, then the galled network N_u obtained from N' by replacing each α_i by N_{u_i} is consistent with $\mathcal{T}|_u$.*

Proof (analogous to the proof of Lemma 8 in [15]). Consider any rooted triplet t in $\mathcal{T}|_u$ and write $t = (\{x, y\}, z)$. If $x \in \Lambda(R[u_i])$, $y \in \Lambda(R[u_j])$, and $z \in \Lambda(R[u_k])$, where i, j, k all differ, then t is consistent with N_u (otherwise, $t' = (\{f(x), f(y)\}, f(z)) = (\{\alpha_i, \alpha_j\}, \alpha_k)$ cannot be consistent with N' which is a contradiction since $t' \in \mathcal{T}'$). If $x, y \in \Lambda(R[u_i])$ and $z \in \Lambda(R[u_j])$ with $i \neq j$, then t is consistent with N_u by the construction of N_u . The case $x, z \in \Lambda(R[u_i])$ and $y \in \Lambda(R[u_j])$ (or symmetrically, $y, z \in \Lambda(R[u_i])$ and $x \in \Lambda(R[u_j])$) with $i \neq j$ is not possible because then y would not belong to $SN(\{x, z\})$ by Theorem 4, contradicting that $y \in SN(\{x, z\})$ according to the definition of SN -sets. Finally, if x, y, z belong to the same $\Lambda(R[u_i])$, then t is consistent with N_{u_i} and therefore with N_u . In all possible cases, t is consistent with N_u . \square

We now analyze the running time of *FastGalledNetwork*.

THEOREM 6. *The time complexity of Algorithm *FastGalledNetwork* is $O(n^3)$.*

Proof. Step 1 takes $O(n^3)$ by Theorem 5. For every node u in R with $\deg(u) < 3$, N_u can be constructed in $O(1)$ time. The total time for constructing all networks N_u with $\deg(u) \geq 3$ is given by the total time needed to build all the \mathcal{T}' -sets plus the total time taken by all calls to *SimpleNetworks*; both of these are shown below to be $O(n^3)$. Thus, the theorem follows.

First note that to construct \mathcal{T}' for a node u , we need to consider only rooted triplets in \mathcal{T} whose three leaves belong to subtrees rooted at three different children of u . For this purpose, we may create a list $T(u)$ for each node u in R containing all rooted triplets in \mathcal{T} of the form $(\{x, y\}, z)$ such that u is the lowest common ancestor in R of x, y , and z . All the $T(u)$ -lists can be constructed using an additional $O(n^3)$ time after computing the SN -tree R in step 1 by doing a bottom-up traversal of R . Then, when constructing \mathcal{T}' in step 3.3, check each rooted triplet in $T(u)$ to see if its leaves belong to three different subtrees, and if so, update \mathcal{T}' accordingly. This way, each rooted triplet in \mathcal{T} is considered for one \mathcal{T}' -set only, so the total time required to build all \mathcal{T}' -sets is bounded by $O(n^3)$.

Next, note that each constructed \mathcal{T}' has $\deg(u)$ leaves. Running *SimpleNetworks* on \mathcal{T}' therefore takes $O((\deg(u))^3)$ time by Theorem 1. Summing over all nodes, the calls to *SimpleNetworks* take a total of $\sum_{u \in R} O((\deg(u))^3) = O((\sum_{u \in R} \deg(u))^3) = O(n^3)$ time. \square

Finally, we remark that *FastGalledNetwork* can be modified to return *all* galled networks consistent with \mathcal{T} by utilizing all simple networks computed in step 3.3. However, this may take exponential time.

4. NP-hardness of the nondense case. We now prove that the problem of inferring a galled phylogenetic network which is consistent with a given set of \mathcal{T} rooted triplets, if one exists, is NP-hard when \mathcal{T} is not required to be dense. Our proof consists of a polynomial-time reduction from the NP-complete problem Set Splitting (see, e.g., [5]) to the decision version of our problem. We use the same reduction to prove that the closely related problem of inferring a *simple* phylogenetic network which is consistent with a given (nondense) set of rooted triplets is also NP-hard.

Set Splitting. Given a set $S = \{s_1, s_2, \dots, s_n\}$ and a collection $\mathcal{C} = \{C_1, C_2, \dots, C_m\}$ of subsets of S , where $|C_j| = 3$ for every $C_j \in \mathcal{C}$, does (S, \mathcal{C}) have a set splitting; i.e., can S be partitioned into two disjoint subsets S_1, S_2 such that for every $C_j \in \mathcal{C}$ it holds that C_j is not a subset of S_1 and C_j is not a subset of S_2 ?

First, we describe the reduction from Set Splitting. Given an instance (S, \mathcal{C}) , where we assume without loss of generality that $\bigcup_{C_j \in \mathcal{C}} C_j = S$, construct a nondense set \mathcal{T} of rooted triplets having a leaf set L with $L = \{h, x, y\} \cup \{s_i^j \mid s_i \in S, 1 \leq j \leq m\}$, where h, x, y , and all elements of the form s_i^j are new elements not belonging to S . Initially, let \mathcal{T} consist of the two rooted triplets $(\{x, h\}, y)$ and $(\{y, h\}, x)$. Next, for each $C_j \in \mathcal{C}$, write $C_j = \{s_a, s_b, s_c\}$ with $a < b < c$ and include three rooted triplets $(\{s_a^j, h\}, s_b^j)$, $(\{s_b^j, h\}, s_c^j)$, and $(\{s_c^j, h\}, s_a^j)$ in \mathcal{T} . Finally, for each $s_i \in S$, add m rooted triplets $(\{s_i^1, s_i^2\}, h)$, $(\{s_i^2, s_i^3\}, h), \dots, (\{s_i^{m-1}, s_i^m\}, h)$, $(\{s_i^m, s_i^1\}, h)$ and $2m$ rooted triplets $(\{s_i^1, h\}, x)$, $(\{y, h\}, s_i^1)$, $(\{s_i^2, h\}, x)$, $(\{y, h\}, s_i^2), \dots, (\{s_i^m, h\}, x)$, $(\{y, h\}, s_i^m)$ to \mathcal{T} . (The main idea in the reduction is to encode \mathcal{C} by rooted triplets of the form $(\{s_a^j, h\}, s_b^j)$ and use other rooted triplets to force any galled network N consistent with \mathcal{T} to have a special structure; see Lemma 17. Then, for each $C_j = \{s_a, s_b, s_c\} \in \mathcal{C}$, at most two of s_a^j, s_b^j, s_c^j can descend from the same clipped merge path from the root in N , inducing a set splitting of S .)

LEMMA 16. *If (S, \mathcal{C}) has a set splitting, then there exists a simple phylogenetic network which is consistent with \mathcal{T} .*

Proof. Let (S_1, S_2) be a set splitting of (S, \mathcal{C}) . Define $S_1^* = \{s_i^j \mid s_i \in S_1, 1 \leq j \leq m\}$ and $S_2^* = \{s_i^j \mid s_i \in S_2, 1 \leq j \leq m\}$. Note that $S_1^* \cup S_2^* \cup \{h, x, y\} = L$. Let O_1 be any ordering of $S_1^* \cup \{x\}$ in which x is the first element, and for every pair of elements of the form s_a^j and s_b^j in S_1^* , if there exists a C_j in \mathcal{C} with $C_j = \{s_a, s_b, s_c\}$ and either $b < a < c$, $a < c < b$, or $c < b < a$, then s_a^j precedes s_b^j . (Except for this requirement, the elements may be ordered arbitrarily in O_1 .) Define an ordering O_2 of $S_2^* \cup \{y\}$ analogously, letting y be the last element in O_2 , respectively. Next, build a simple phylogenetic network N having a root node r and a hybrid node whose child is a leaf labeled by h , where (1) $|S_1^*| + 1$ leaves distinctly labeled by $S_1^* \cup \{x\}$ are attached to the left clipped merge path in order according to O_1 , and $|S_2^*| + 1$ leaves distinctly labeled by $S_2^* \cup \{y\}$ are attached to the right clipped merge path in order according to O_2 . See Figure 7 for an example. It is easy to verify that N and \mathcal{T} are consistent. \square

To prove the other direction (i.e., that a galled network consistent with \mathcal{T} yields a set splitting of (S, \mathcal{C})), we need the following lemma.

LEMMA 17. *Suppose N is a galled network with leaf set L which is consistent with \mathcal{T} . Then (1) the root r of N is a split node, (2) one side network attached to a merge path of r contains h but no other leaves, and (3) h is a descendant of the hybrid node for r .*

Proof. (1) Suppose r is not a split node. Then L can be partitioned into two disjoint, nonempty subsets U and V such that every path between a leaf in U and a leaf in V passes through r . It follows that for any rooted triplet $(\{a, b\}, c)$ which is consistent with N , if $a \in U$, then $b \in U$, and if $a \in V$, then $b \in V$. Now consider any element of the form s_i^j in L . If $s_i^j \in U$, then $h, x, y \in U$ because N is consistent with $(\{s_i^j, h\}, x)$, $(\{x, h\}, y)$, and $(\{y, h\}, s_i^j)$. But then also $s_z^k \in U$ for every s_z^k in L by $(\{s_z^k, h\}, x) \in \mathcal{T}$, contradicting that V is nonempty. The case $s_i^j \in V$ is analogous. Hence, r must be a split node.

(2) Let N' be the side network attached to a merge path of r such that $h \in \Lambda(N')$.

FIG. 7. Let $C_1 = \{s_1, s_2, s_3\}$, $C_2 = \{s_1, s_3, s_4\}$, and $C_3 = \{s_2, s_3, s_4\}$, and suppose $S_1 = \{s_1, s_3\}$ and $S_2 = \{s_2, s_4\}$. The construction described in Lemma 16 yields a simple phylogenetic network N as shown above.

If $x \in \Lambda(N')$, then $\Lambda(N') = L$ because $y \in \Lambda(N')$ by $(\{y, h\}, x) \in \mathcal{T}$ and for every element of the form s_i^j in L , it holds that $s_i^j \in \Lambda(N')$ by $(\{s_i^j, h\}, x) \in \mathcal{T}$. If $y \in \Lambda(N')$, then $\Lambda(N') = L$ because of $x \in \Lambda(N')$ by $(\{x, h\}, y) \in \mathcal{T}$ and the above. If $\Lambda(N')$ contains an element of the form s_i^j , then $\Lambda(N') = L$ because of $y \in \Lambda(N')$ by $(\{y, h\}, s_i^j) \in \mathcal{T}$ and the above. Thus, if $\Lambda(N')$ contains any element in addition to h , then $\Lambda(N') = L$, which is not possible. Therefore, $\Lambda(N') = \{h\}$.

(3) By (1), r is a split node of N . Let $hn(r)$ be the hybrid node for r and let N' be the subnetwork of N rooted at $hn(r)$. Suppose, on the contrary, that h is not contained in N' . Take any $C_j \in \mathcal{C}$ and write $C_j = \{s_a, s_b, s_c\}$ with $a < b < c$. Since $(\{s_a^j, h\}, s_b^j)$, $(\{s_b^j, h\}, s_c^j)$, and $(\{s_c^j, h\}, s_a^j)$ are in \mathcal{T} and $h \notin \Lambda(N')$, exactly one of s_a^j , s_b^j , and s_c^j belongs to $\Lambda(N')$. Assume without loss of generality that $s_a^j \in \Lambda(N')$. Next, neither x nor y can belong to the same side network as h by (2), and since $(\{x, h\}, y)$ and $(\{y, h\}, x)$ are consistent with N , we have either $x \in \Lambda(N')$ and $y \notin \Lambda(N')$ or $x \notin \Lambda(N')$ and $y \in \Lambda(N')$. If $x \in \Lambda(N')$, then $(\{s_a^j, h\}, x)$ is not consistent with N , and if $y \in \Lambda(N')$, then $(\{y, h\}, s_a^j)$ is not consistent with N , which is a contradiction in both cases. Therefore, $h \in \Lambda(N')$. \square

LEMMA 18. *If there exists a galled network which is consistent with \mathcal{T} , then (S, \mathcal{C}) has a set splitting.*

Proof. Let N be a galled network with leaf set L that is consistent with \mathcal{T} . By Lemma 17, the root r of N is a split node. Also by Lemma 17, the subnetwork of N rooted at the child of $hn(r)$, where $hn(r)$ denotes the hybrid node for r , consists of a single leaf which is labeled by h . Let P_1 and P_2 be the two clipped merge paths of $hn(r)$, and define L_1 and L_2 as the set of all leaves except x , y , and h which are descendants of nodes on P_1 and P_2 , respectively. We now show that (L_1, L_2) induces a set splitting (S_1, S_2) of (S, \mathcal{C}) . For every $s_i \in S$, if s_i^1 belongs to L_1 , then all elements in $\{s_i^k \mid 1 \leq k \leq m\}$ belong to L_1 because $(\{s_i^1, s_i^2\}, h)$, $(\{s_i^2, s_i^3\}, h)$, \dots , $(\{s_i^{m-1}, s_i^m\}, h)$, $(\{s_i^m, s_i^1\}, h) \in \mathcal{T}$. Similarly, if $s_i^1 \in L_2$, then $\{s_i^k \mid 1 \leq k \leq m\} \subseteq L_2$. Define $S_1 = \{s_i \mid s_i^1 \in L_1\}$ and $S_2 = \{s_i \mid s_i^1 \in L_2\}$. Clearly, $S_1 \cup S_2 = S$ and $S_1 \cap S_2 = \emptyset$. Moreover, for every $C_j \in \mathcal{C}$, it holds that $C_j \not\subseteq S_1$ and $C_j \not\subseteq S_2$ (to

see this, write $C_j = \{s_a, s_b, s_c\}$ with $a < b < c$ and note that if all of $s_a, s_b,$ and s_c belonged to just one of S_1 and S_2 , then $s_a^j, s_b^j,$ and s_c^j would be descendants of nodes on the same clipped merge path of $hn(r)$, and then all three rooted triplets $(\{s_a^j, h\}, s_b^j), (\{s_b^j, h\}, s_c^j),$ and $(\{s_c^j, h\}, s_a^j)$ could never be consistent with N , which is a contradiction). Thus, (S_1, S_2) is a set splitting of (S, \mathcal{C}) . \square

THEOREM 7. *Given any nondense set \mathcal{T} of rooted triplets, it is NP-hard to determine if there exists a galled network which is consistent with \mathcal{T} . It is also NP-hard to determine if there exists a simple network which is consistent with \mathcal{T} .*

Proof. If (S, \mathcal{C}) has a set splitting, then there exists a simple network which is consistent with \mathcal{T} according to Lemma 16. Next, Lemma 18 shows that if there exists a galled network consistent with \mathcal{T} , then (S, \mathcal{C}) has a set splitting. Since a simple phylogenetic network is always a galled network, and the reduction can be carried out in polynomial time, the theorem follows. \square

5. Approximating the maximum number of consistent rooted triplets.

This section studies the problem of constructing a galled network consistent with the maximum number of rooted triplets in \mathcal{T} for any (not necessarily dense) given \mathcal{T} . Section 5.2 presents a polynomial-time approximation algorithm for this problem which always outputs a galled network consistent with at least a factor of $\frac{5}{12}$ (> 0.4166) of the rooted triplets in \mathcal{T} . On the negative side, section 5.1 shows that there exist inputs for which any galled network can be consistent with at most a factor of 0.4883 of the rooted triplets in \mathcal{T} .

5.1. Inapproximability result. Given any positive integer n , fix \mathcal{T} to contain all possible rooted triplets for a leaf set L of size n , that is, $\mathcal{T} = \{(\{a, b\}, c), (\{a, c\}, b), (\{b, c\}, a) \mid a, b, c \in L\}$. For any phylogenetic network N , let $\#N$ denote the number of rooted triplets from \mathcal{T} that are consistent with N .

LEMMA 19. *Let N be a galled network with $\Lambda(N) = L$. If N contains a nonsplit node u with two children u_1, u_2 such that u is the root node or a child of a hybrid node, then making u into a split node by removing the edges (u, u_1) and (u, u_2) , adding two new nodes v and w , and inserting the edges $(u, v), (u, w), (v, u_1), (w, u_2),$ and (v, w) yields a galled network N' with $\#N' = \#N$.*

LEMMA 20. *Let N be a galled network with $\Lambda(N) = L$. Suppose N contains a merge path P of a hybrid node h, c is the child of $h, N[u]$ is a side network attached to $P, u \neq c,$ and u has two children u_1, u_2 . Then one of the following holds:*

- *If $|\Lambda(N[u])| > |\Lambda(N[c])|,$ then N can be transformed into a galled network N' with $\#N' > \#N$ by letting $N[u]$ and $N[c]$ trade places.*
- *Else, if $|\Lambda(N[u])| \leq |\Lambda(N[c])|,$ then N can be transformed into a galled network N' with $\#N' > \#N$ as follows: First, in case u is a split node in $N,$ delete a hybrid edge descending from u (and contract all edges from vertices with outdegree 1) so that $N[u_1]$ and $N[u_2]$ become disjoint. Second, remove $N[u]$ and instead attach the resulting disjoint $N[u_1]$ and $N[u_2]$ to P .*

Proof. Let s be the split node corresponding to $h,$ and define $L_u = \Lambda(N[u]), L_c = \Lambda(N[c]), L_m = \Lambda(N[s]) \setminus (L_u \cup L_c),$ and $L_{rest} = L \setminus (L_u \cup L_c \cup L_m)$. First consider the case $|\Lambda(N[u])| > |\Lambda(N[c])|.$ For any subset $\{x, y, z\}$ of $L,$ we have the following possibilities:

- When at least one of $\{x, y, z\}$ belongs to $L_{rest},$ it is easy to see that N and N' are consistent with exactly the same rooted triplets labeled by $\{x, y, z\}.$
- When $\{x, y, z\}$ contains at least two leaves from L_u or at least two leaves from $L_c,$ or when $\{x, y, z\}$ contains three leaves from $L_m,$ then N and N' are

again consistent with exactly the same rooted triplets labeled by $\{x, y, z\}$.

- When $\{x, y, z\}$ contains one leaf from L_u , one leaf from L_c , and one leaf from L_m , then each of N and N' is consistent with exactly two rooted triplets labeled by $\{x, y, z\}$.
- When $\{x, y, z\}$ contains one leaf from L_u and two leaves from L_m , then N is consistent with one rooted triplet labeled by $\{x, y, z\}$, whereas N' is consistent with two.
- When $\{x, y, z\}$ contains one leaf from L_c and two leaves from L_m , then N is consistent with two rooted triplets labeled by $\{x, y, z\}$, whereas N' is consistent with one.

Since $|L_u| > |L_c|$, the difference in number of consistent rooted triplets is given by $\#N' - \#N = |L_u| \cdot \binom{|L_m|}{2} - |L_c| \cdot \binom{|L_m|}{2} > 0$.

Next consider the case $|\Lambda(N[u])| \leq |\Lambda(N[c])|$. If u is a split node in N , then delete a hybrid edge e descending from u so that the resulting $\Lambda(N[u_1])$ and $\Lambda(N[u_2])$ are disjoint; assume without loss of generality that e is a descendant of u_2 . In addition to the above, define $L_{u_1} = \Lambda(N[u_1])$ and $L_{u_2} = \Lambda(N[u]) \setminus \Lambda(N[u_1])$. For any subset $\{x, y, z\}$ of L , we have the following possibilities:

- When at least one of $\{x, y, z\}$ belongs to L_{rest} , then N and N' are consistent with exactly the same rooted triplets labeled by $\{x, y, z\}$.
- When $\{x, y, z\}$ does not contain at least one leaf from L_{u_1} and at least one leaf from L_{u_2} , then N and N' are consistent with the same number of rooted triplets labeled by $\{x, y, z\}$.
- When $\{x, y, z\}$ contains one leaf from L_{u_1} , one leaf from L_{u_2} , and one leaf from L_m , then each of N and N' is consistent with one rooted triplet labeled by $\{x, y, z\}$.
- When $\{x, y, z\}$ contains one leaf from L_{u_1} , one leaf from L_{u_2} , and one leaf from L_c , then N is consistent with one rooted triplet labeled by $\{x, y, z\}$, whereas N' is consistent with two.
- When $\{x, y, z\}$ contains two leaves from L_{u_1} and one leaf from L_{u_2} , or one leaf from L_{u_1} and two leaves from L_{u_2} , then N is consistent with one or two rooted triplets labeled by $\{x, y, z\}$, whereas N' is consistent with one.

Since $|L_c| \geq |L_u|$, $|L_u| \geq |L_{u_1}|$, and $|L_u| \geq |L_{u_2}|$, the difference in number of consistent rooted triplets satisfies $\#N' - \#N \geq |L_{u_1}| \cdot |L_{u_2}| \cdot |L_c| - \binom{|L_{u_1}|}{2} \cdot |L_{u_2}| - |L_{u_1}| \cdot \binom{|L_{u_2}|}{2} \geq \frac{1}{2} \cdot |L_{u_1}| \cdot |L_{u_2}| \cdot (2 \cdot |L_u| - |L_{u_1}| - |L_{u_2}| + 2) > 0$. \square

By repeatedly applying Lemmas 19 and 20, the next lemma concludes that for any fixed n , at least one of the galled networks N for a set of n leaves that maximizes $\#N$ must be a *caterpillar network*. A galled network N is called a caterpillar network if (1) the root of N and every nonleaf child of a hybrid node are split nodes and (2) for every merge path P in N , all side networks attached to P except for the one at the hybrid node are leaves.

LEMMA 21. *For any galled network N , there is a caterpillar network N' with $\Lambda(N') = \Lambda(N)$ and $\#N' \geq \#N$.*

Now, we are ready to show the bound on the approximation ratio. Let $S(n)$ be the maximum value of $\#N$ taken over all galled networks N with n leaves.

LEMMA 22. $S(n) = \max_{1 \leq a \leq n} \left\{ \binom{a}{3} + 2 \cdot \binom{a}{2} \cdot (n - a) + a \cdot \binom{n-a}{2} + S(n - a) \right\}$.

Proof. By Lemma 21, there is a caterpillar network N that maximizes $\#N$ among all galled networks with n leaves. The recurrence for $S(n)$ counts the maximum number of rooted triplets in \mathcal{T} consistent with a caterpillar network with n leaves because if such a network contains a set A of a leaves attached to the two merge

paths starting at the root, then it must be consistent with

- $\binom{a}{3}$ rooted triplets labeled by three elements in A ;
- $2 \cdot \binom{a}{2} \cdot (n - a)$ rooted triplets labeled by two elements in A and one element in $L \setminus A$;
- $a \cdot \binom{n-a}{2}$ rooted triplets labeled by one element in A and two elements in $L \setminus A$;
- $S(n - a)$ rooted triplets labeled by three elements in $L \setminus A$. \square

THEOREM 8. *There is no approximation algorithm with approximation ratio larger than 0.4883.*

Proof. Define $T(n) = |\mathcal{T}|$ for any given positive integer n , i.e., $T(n) = 3 \cdot \binom{n}{3}$. Note that the approximation ratio can be at most $\min_{n \in \mathbb{Z}^+} \frac{S(n)}{T(n)}$. By inserting $n = 1000$ into the recurrence in Lemma 22, we obtain $S(1000) = 243383298$. Hence, the approximation ratio must be less than or equal to $\frac{S(1000)}{T(1000)} < 0.4883$. \square

5.2. A polynomial-time $\frac{5}{12}$ -approximation algorithm. Given any set \mathcal{T} of rooted triplets, our approximation algorithm called *Approximate* (shown in Figure 8) infers a galled network which is consistent with at least $\frac{5}{12}$ of the rooted triplets in \mathcal{T} . We first describe the algorithm and then present the analysis.

Initially, *Approximate* partitions the set of leaves L into three subsets A, B, C so that none of them equals L using an algorithm named *LeafPartition* (also listed in Figure 8 and described in detail below). Then, for each $X \in \{A, B, C\}$, it recursively infers a galled network K_X by calling *Approximate*($\mathcal{T}|X$). Next, for each $X \in \{A, B, C\}$, it generates a galled network $Network_X$ such that the root node is a split node whose hybrid node is the parent of K_X , and the other two networks in $\{K_A, K_B, K_C\} \setminus \{K_X\}$ are side networks. Finally, it returns the best network among $Network_A, Network_B,$ and $Network_C$.

We now explain the algorithm *LeafPartition*. It divides L into the three subsets A, B, C in such a way that a special condition $5N_1 + 8N_2 + 12N_3 \geq 5 \cdot |\mathcal{T}|$ holds, where for $i \in \{0, 1, 2, 3\}$, we define $N_i = |Z_i(A, B, C)|$ and where $Z_i(A, B, C)$ is the set defined as follows:

- $Z_0(A, B, C) = \{(\{x, y\}, z) \in \mathcal{T} \mid x \text{ and } z \text{ are in one of the subsets } A, B, C \text{ and } y \text{ is in another}\};$
- $Z_1(A, B, C) = \{(\{x, y\}, z) \in \mathcal{T} \mid x, y, \text{ and } z \text{ are in one of the subsets } A, B, C\};$
- $Z_2(A, B, C) = \{(\{x, y\}, z) \in \mathcal{T} \mid x, y, \text{ and } z \text{ are in three different subsets among } A, B, C\};$
- $Z_3(A, B, C) = \{(\{x, y\}, z) \in \mathcal{T} \mid x \text{ and } y \text{ are in one of the subsets } A, B, C \text{ and } z \text{ is in another}\}.$

Note that $Z_0(A, B, C) \cup Z_1(A, B, C) \cup Z_2(A, B, C) \cup Z_3(A, B, C) = \mathcal{T}$. As shown below, any A, B, C which imply $5N_1 + 8N_2 + 12N_3 \geq 5 \cdot |\mathcal{T}|$ guarantee a good approximation ratio for *Approximate*. Algorithm *LeafPartition* is a greedy algorithm which first divides L into the three subsets arbitrarily and then moves leaves (one at a time) from one subset to another until $score(A, B, C)$ cannot be further improved, where we define $score(A, B, C) = 4N_1 + 7N_2 + 12N_3$. If one of the subsets, say A , equals L after finishing moving the leaves, then it selects a leaf u that maximizes $\frac{p(u)}{c(u)}$, where $p(u) = |\{(\{x, y\}, u) \in \mathcal{T}\}|$ and $c(u) = |\{(\{u, x\}, y) \in \mathcal{T}\}|$, and moves u from A to either B or C . (This step is to ensure that none of the three subsets equals L .) The next lemma shows that this extra move does not reduce the value of $score(A, B, C)$. Since $score$ keeps increasing by at least 1 as long as the while-loop iterates and $score(A, B, C) \leq 12 \cdot |\mathcal{T}|$, step 2.1 is performed at most $12 \cdot |\mathcal{T}|$ times in total; i.e., the algorithm is guaranteed to terminate.

Algorithm *LeafPartition***Input:** A set \mathcal{T} of rooted triplets with a leaf set L .**Output:** A partition of L into three subsets A, B, C such that none of them equals L and such that $5N_1 + 8N_2 + 12N_3 \geq 5 \cdot |\mathcal{T}|$.1 Arbitrarily partition L into three subsets A, B, C .2 **while** moving a leaf m from one subset to another increases $score(A, B, C) = 4N_1 + 7N_2 + 12N_3$ **do**2.1 Move m accordingly.**endwhile**3 **if** one of the subsets A, B, C equals L **then**3.1 Choose a leaf u that maximizes $\frac{p(u)}{c(u)}$ and move u to another subset. Go to Step 2.
endif4 **return** A, B, C .**End** *LeafPartition***Algorithm** *Approximate***Input:** A set \mathcal{T} of rooted triplets with a leaf set L .**Output:** A galled network that is consistent with at least $\frac{5}{12} \cdot |\mathcal{T}|$ of the rooted triplets in \mathcal{T} .1 Partition L into A, B, C using *LeafPartition*.2 For $X \in \{A, B, C\}$, let $K_X = \text{Approximate}(\mathcal{T}|X)$.3 For $X \in \{A, B, C\}$, generate a galled network $Network_X$ in which the root node is a split node whose hybrid node h is the parent of K_X , and the other two networks in $\{K_A, K_B, K_C\} \setminus \{K_X\}$ are side networks attached to the merge paths of h .4 **return** the $Network_X$ among $X \in \{A, B, C\}$ that is consistent with the most rooted triplets in \mathcal{T} .**End** *Approximate*FIG. 8. An approximation algorithm for computing a galled network consistent with as many rooted triplets in \mathcal{T} as possible.

LEMMA 23. *Algorithm LeafPartition partitions L into three subsets A, B, C so that $score(A, B, C)$ cannot be further improved by moving a single element from one subset to another.*

Proof. If none of A, B, C equals L after step 2 in Algorithm *LeafPartition* is done, the lemma follows. Hence, assume that one of the subsets, say A , equals L after step 2. We only need to show that step 3.1 does not decrease $score(A, B, C)$. When u is moved from A , all rooted triplets in \mathcal{T} of the form $(\{x, y\}, u)$ are moved from $Z_1(A, B, C)$ to $Z_3(A, B, C)$ and all rooted triplets in \mathcal{T} of the form $(\{u, x\}, y)$ are moved from $Z_1(A, B, C)$ to $Z_0(A, B, C)$. The difference in $score$ is equal to $score(A \setminus \{u\}, \{u\}, \emptyset) - score(A, \emptyset, \emptyset) = p(u) \cdot (12 - 4) - c(u) \cdot 4 \geq 0$, where the last inequality follows since $p(u) \geq \frac{1}{2} \cdot c(u)$ by the choice of u . Thus, step 3.1 will not decrease $score(A, B, C)$. \square

The next two lemmas are needed to analyze the approximation ratio of *Approximate*.

LEMMA 24. *When Algorithm LeafPartition terminates, we have $5N_1 + 8N_2 + 12N_3 \geq 5 \cdot |\mathcal{T}|$.*

Proof. Write $score(A, B, C) = x \cdot N_1 + y \cdot N_2 + z \cdot N_3$. For any $U, V, W \in \{A, B, C\}$, denote by $(\{U, V\}, W)$ the set of all rooted triplets in \mathcal{T} of the form $(\{u, v\}, w)$ where $u \in U$, $v \in V$, and $w \in W$. Similarly, for any $m \in L$ and $U, V \in \{A, B, C\}$, let

$(\{m, U\}, V)$ and $(\{U, V\}, m)$ denote the set of all rooted triplets in \mathcal{T} of the form $(\{m, u\}, v)$ and $(\{u, v\}, m)$, respectively, where $u \in U$ and $v \in V$. For each of the six possible ways of moving a leaf m from one of the subsets A, B, C to another, we can derive a formula to express how *score* is affected, as described next.

First, suppose m is moved from A to B . Then, for every element t in $(\{m, A\}, A)$, since t will be moved from $Z_1(A, B, C)$ to $Z_0(A, B, C)$, the corresponding change in *score* is $-x$. In the same way, we can calculate the change in *score* for each element in $(\{m, U\}, V)$ and $(\{U, V\}, m)$ for every $U, V \in \{A, B, C\}$ when m is moved from A to B . After *LeafPartition* is done, moving m will not increase the value of *score*, so $score(A \setminus \{m\}, B \cup \{m\}, C) - score(A, B, C) \leq 0$. Thus, we have $-x|(\{m, A\}, A)| - z|(\{m, A\}, B)| + (y - z)|(\{m, A\}, C)| + z|(\{m, B\}, A)| + x|(\{m, B\}, B)| + (z - y)|(\{m, B\}, C)| + y|(\{m, C\}, A)| - y|(\{m, C\}, B)| + 0 \cdot |(\{m, C\}, C)| + (z - x)|(\{A, A\}, m)| + 0 \cdot |(\{A, B\}, m)| + y|(\{A, C\}, m)| + (x - z)|(\{B, B\}, m)| - y|(\{B, C\}, m)| + 0 \cdot |(\{C, C\}, m)| \leq 0$.

Next, by summing over all $m \in A$, we obtain the following inequality I_{AB} :

$$I_{AB}: -2x|(\{A, A\}, A)| - 2z|(\{A, A\}, B)| + 2(y - z)|(\{A, A\}, C)| + z|(\{A, B\}, A)| + x|(\{A, B\}, B)| + (z - y)|(\{A, B\}, C)| + y|(\{A, C\}, A)| - y|(\{A, C\}, B)| + (z - x)|(\{A, A\}, A)| + y|(\{A, C\}, A)| + (x - z)|(\{B, B\}, A)| - y|(\{B, C\}, A)| \leq 0.$$

In the summation, each element of the form $(\{a_1, a_2\}, x)$ where $a_1, a_2 \in A$ is counted twice; therefore, the coefficient of each $|(\{A, A\}, x)|$ is multiplied by 2.

We derive five inequalities $I_{AC}, I_{BA}, I_{BC}, I_{CA}$, and I_{CB} analogously. Finally, we add $I_{AB}, I_{AC}, I_{BA}, I_{BC}, I_{CA}$, and I_{CB} together, and use $N_0 = |(\{A, B\}, A)| + |(\{A, B\}, B)| + |(\{A, C\}, A)| + |(\{A, C\}, C)| + |(\{B, C\}, B)| + |(\{B, C\}, C)|$, $N_1 = |(\{A, A\}, A)| + |(\{B, B\}, B)| + |(\{C, C\}, C)|$, $N_2 = |(\{A, B\}, C)| + |(\{A, C\}, B)| + |(\{B, C\}, A)|$, and $N_3 = |(\{A, A\}, B)| + |(\{A, A\}, C)| + |(\{B, B\}, A)| + |(\{B, B\}, C)| + |(\{C, C\}, A)| + |(\{C, C\}, B)|$ to obtain $(z + 2y + x) \cdot N_0 + (2z - 6x) \cdot N_1 + (2z - 6y) \cdot N_2 + (2y + x - 5z) \cdot N_3 \leq 0$. By substituting $N_0 = |\mathcal{T}| - N_1 - N_2 - N_3$ and replacing $x = 4, y = 7, z = 12$, we get $5N_1 + 8N_2 + 12N_3 \geq 5 \cdot |\mathcal{T}|$. \square

Let $m(\mathcal{T})$ be the number of rooted triplets in \mathcal{T} consistent with the network returned by *Approximate*(\mathcal{T}).

LEMMA 25. *If $m(\mathcal{T}|Z) \geq q \cdot |\mathcal{T}|Z|$ for every $Z \in \{A, B, C\}$, then $m(\mathcal{T}) \geq q \cdot N_1 + \frac{2}{3} \cdot N_2 + N_3$.*

Proof. Every rooted triplet in $Z_2(A, B, C)$ is consistent with two of $Network_A, Network_B$, and $Network_C$, and every rooted triplet in $Z_3(A, B, C)$ is consistent with all of these three networks. Thus, $Network_X$ returned by *Approximate* must be consistent with at least $\frac{2}{3} \cdot N_2 + N_3$ of the rooted triplets in $Z_2(A, B, C) \cup Z_3(A, B, C)$. Also, each of $Network_A, Network_B$, and $Network_C$ is consistent with $m(\mathcal{T}|A) + m(\mathcal{T}|B) + m(\mathcal{T}|C) \geq q \cdot (|\mathcal{T}|A| + |\mathcal{T}|B| + |\mathcal{T}|C|) = q \cdot N_1$ of the rooted triplets in $Z_1(A, B, C)$. Thus, in total, $Network_X$ is consistent with at least $q \cdot N_1 + \frac{2}{3} \cdot N_2 + N_3$ rooted triplets in \mathcal{T} . \square

THEOREM 9. $m(\mathcal{T}) \geq \frac{5}{12} \cdot |\mathcal{T}|$.

Proof. By induction on $|L|$. Base case ($|L| = 3$): Steps 3 and 4 of Algorithm *Approximate* construct a network consistent with at least $2/3$ of the rooted triplets in \mathcal{T} ; i.e., $m(\mathcal{T}) \geq \frac{5}{12} \cdot |\mathcal{T}|$. Inductive case ($|L| > 3$) Step 2 of *Approximate* recursively constructs three networks K_A, K_B, K_C for $\mathcal{T}|A, \mathcal{T}|B$, and $\mathcal{T}|C$, respectively. By the induction assumption, $m(\mathcal{T}|X) \geq \frac{5}{12} \cdot |\mathcal{T}|X|$ for each $X \in \{A, B, C\}$. By Lemmas 24 and 25, $m(\mathcal{T}) \geq \frac{5}{12} \cdot N_1 + \frac{2}{3} \cdot N_2 + N_3 \geq \frac{5}{12} \cdot |\mathcal{T}|$. \square

Finally, the algorithm's running time is given by the following theorem.

THEOREM 10. *The time complexity of Algorithm Approximate is $O(n \cdot |\mathcal{T}|^3)$.*

Proof. Denote by $t(\mathcal{T})$ and $f(\mathcal{T})$ the running times of *Approximate*(\mathcal{T}) and *LeafPartition*(\mathcal{T}), respectively. We have $t(\mathcal{T}) = f(\mathcal{T}) + t(\mathcal{T}|A) + t(\mathcal{T}|B) + t(\mathcal{T}|C)$.

In *LeafPartition*, step 2 is performed at most $12 \cdot |\mathcal{T}|$ times in total. Every time, the algorithm needs to compute $O(n)$ values of *score*, and each *score* can be computed in $O(|\mathcal{T}|)$ time. Steps 1 and 3 can easily be implemented in $O(|\mathcal{T}|)$ time. Therefore, $f(\mathcal{T}) = O(n \cdot |\mathcal{T}|^2)$.

Furthermore, $|\mathcal{T}|A + |\mathcal{T}|B + |\mathcal{T}|C < |\mathcal{T}|$. Solving the recurrence for $t(\mathcal{T})$ gives us $t(\mathcal{T}) = O(n \cdot |\mathcal{T}|^3)$. \square

CERTIFYING POLYNOMIAL TIME AND LINEAR/POLYNOMIAL SPACE FOR IMPERATIVE PROGRAMS*

KARL-HEINZ NIGGL[†] AND HENNING WUNDERLICH[†]

Abstract. In earlier work of Kristiansen and Niggl the polynomial-time computable functions were characterized by stack programs of μ -measure 0, and the linear-space computable functions by loop programs of μ -measure 0. Until recently, an open problem was how to extend these characterizations to programs with user-friendly basic instructions, such as assignment statements, and with mixed data structures.

It is shown how to strengthen the above characterizations to imperative programs built from arbitrary basic instructions by sequencing and by if-then-else and for-do statements. These programs operate on variables, each of which may represent any data structure such as stacks, registers, trees, or graphs.

The paper presents a new method of certifying “polynomial size boundedness” of such imperative programs under the natural assumption that the basic instructions used are polynomially size bounded, too. The certificate for a program P with variables among X_1, \dots, X_n will be an $(n+1) \times (n+1)$ matrix $M(P)$ over the finite set $\{0, 1, \infty\}$.

It is shown that certified string programs (i.e., stack programs, but with any polynomial-time computable basic instructions) exactly compute the functions in $FPTIME$. Accordingly, certified general loop programs (using any linear-space computable basic instructions) exactly compute the functions in $FLINSPACE$.

Furthermore, it is shown that certified power string programs (i.e., string programs, but built from polynomial-space computable basic instructions and extended by power loop statements) exactly compute the polynomial-space computable functions in $FPSPACE$.

In addition, examples of certified “natural” (implementations of) algorithms, such as insertion-sort or binary addition and multiplication, are given.

1. Introduction. In recent research [16], [29] the polynomial-time computable functions are characterized by stack programs of μ -measure 0, and loop programs of μ -measure 0 exactly compute the linear-space computable functions. Loop programs are a slight modification of the LOOP programs of Meyer and Ritchie [25], and stack programs are essentially loop programs that operate with stacks instead of registers, supporting a suitable loop concept over stacks. The measure μ is a conceptually simple, purely syntactical method of analyzing the impact of nesting loops on the running time, and it associates to each program a natural number such that programs of μ -measure $n \geq 1$ exactly compute those functions computed by a Turing machine whose running time is in Grzegorzcyk class \mathcal{E}_{n+2} [12].

From a programming perspective, these findings might not be practically appealing, for unlike modern programming languages, those programs support neither user-friendly basic instructions nor mixed data structures.

Although it is no problem to extend the measure μ to programs with any nonsize-increasing basic instructions (cf. [16]), until recently, an open problem was how to

extend the above characterizations to programs with arbitrary size-increasing basic instructions or vital instructions, such as assignment statements, without losing too many programs that could be certified as, e.g., running in polynomial time.

In this paper, we show how to strengthen the above characterizations to *imperative programs* built from arbitrary basic instructions by sequencing and by if-then-else and for-do statements. Each of those programs operates on finitely many variables X_1, \dots, X_n , each of which may represent any data structure such as stacks, registers, trees, or graphs, and is equipped implicitly with a notion of *size* of an object stored in X_i , denoted by $|X_i|$. For example, if X_i serves as a register, then $|X_i|$ might be the unary or the binary length of the number stored in X_i , and if X_i serves as a stack, $|X_i|$ is, as usual, the length of the word stored in X_i .

The paper presents a new method of certifying “polynomial size boundedness” for such programs under the natural assumption that all basic instructions are *polynomially size bounded*, too. Expressed in Hoare-like sentences $\{A\} P \{B\}$, for programs P in variables X_1, \dots, X_n , that means there exist polynomials p_1, \dots, p_n satisfying

$$\{s_1 = |X_1|, \dots, s_n = |X_n|\} P \{|X_i| \leq p_i(s_1, \dots, s_n)\} \text{ for } i = 1, \dots, n.$$

Thus, unlike the measure μ , the new method abstracts from the concrete form of basic instructions and focuses on their impact on the polynomial size bounds on the variables involved. As we shall see, polynomial size bounds provide all information on the “control” of one variable over another in a much more subtle way than the measure μ does. Central to the method is that we store and process only a finite amount of information on the class of possible polynomial size bounds for programs. For each polynomial size bound p on X_i with respect to a program P , say $p(\vec{X}) = c_0 + \dots + c_j \cdot X_1^{j_1} \cdot \dots \cdot X_n^{j_n} + \dots$, that information is just an $(n + 1)$ -tuple $\langle p \rangle$ over $\{0, 1, \infty\}$, where for $j = 1, \dots, n$,

$$\langle p \rangle[j] = \begin{cases} 0 & \text{if } p \text{ is a polynomial in } \vec{X} \setminus X_j, \\ 1 & \text{if } p = X_j + q \text{ for some polynomial } q \text{ in } \vec{X} \setminus X_j, \\ \infty & \text{else,} \end{cases}$$

$$\langle p \rangle[n + 1] = \begin{cases} c_0 & \text{if } c_0 \leq 1, \\ \infty & \text{else.} \end{cases}$$

Thus, the certificate for a program P in variables X_1, \dots, X_n will be an $(n + 1) \times (n + 1)$ matrix $M(P)$ over $\{0, 1, \infty\}$, where for technical reasons the last row $M(P)[n + 1]$ is always the $(n + 1)$ -tuple $(0, \dots, 0, 1)$.

Altogether that results in a *matrix calculus for program certificates*. In particular, that calculus provides criteria on the certificate for the body of a loop which guarantee the existence of a certificate for the loop statement itself. We investigate two forms of loop statements, $\text{loopI } X_h [Q]$ and $\text{loopII } X_h [Q]$, the intuition being that for *loopI statements* the body is executed $|X_h|$ times, while the body of *loopII statements* is executed $2^{|X_h|} - 1$ times.

Strengthening the results for μ -measure 0 programs, the following theorems are obtained.

THEOREM A. *Certified string programs (stack programs built from any polynomial-time computable basic instructions) exactly compute the functions in FPTIME.*

THEOREM B. *Certified general loop programs (loop programs built from any linear-space computable basic instructions) precisely compute the functions in FLINSPACE.*

Extending string programs by power loop statements and admitting any polynomial-space computable basic instructions, we obtain the following result.

THEOREM C. *Certified power string programs exactly compute the polynomial-space computable functions FPSPACE.*

Thus, the novelty of the present certification method is that for a significantly large class of imperative programs very close to those in programming practice, with no restrictions on the basic instructions or the data structures involved (cf. section 8 for examples), programs can be certified so as to run in polynomial time or in linear/polynomial space.

The present paper continues research in implicit computational complexity as initiated by Simmons [33], Bellantoni and Cook [4], and Leivant [18], [19], [20], which has led to resource-free, purely functional characterizations of many complexity classes, such as FPTIME [4], [21], [23], [5], [28], FLINSPACE [2], [20], [5], [28], NP and the polynomial-time hierarchy [3], the Kalmár-elementary functions [30] and FPSPACE [15], [31], the exponential-time functions of linear growth [9], and the Grzegorzcyk hierarchy at and above the linear-space level [5], [28], [16], [17], among many others. As well, implicit characterizations through higher-type recursion have been given for the Kalmár-elementary functions [22], [15], [1], for polynomial space [24], and for FPTIME [6], [13].

There are several groups which work on program verification and property testing, e.g., the MRG group [27], the CRISS group [11], or the “Nancy group” (cf. [8], [7], and [26]). There might be some connection between the present work and those interesting approaches, but due to the different frameworks an exact comparison has not been made.

The paper is organized as follows. In section 2, all basic notions involved in the design of certificates for the class of imperative programs under consideration are introduced. Section 3 is concerned with constructing certificates for composed imperative programs, resulting in the certification method. In section 4, stack and loop programs and the measure μ are reviewed, and it is shown that all programs of μ -measure 0 are certified, too. Section 5 introduces string programs and establishes Theorem A. In section 6, general loop programs are introduced, and a proof of Theorem B is given. Section 7 presents power string programs and the proof of Theorem C. In section 8 “natural” implementations of INSERTION-SORT, BINARY ADDITION, MULTIPLICATION, and EXPONENTIATION are given and certified, except for the latter, where the method correctly fails.

2. Preliminaries. Each program we consider uses finitely many variables X_1, \dots, X_n , each of which may represent any data structure such as stacks, registers, trees, or graphs, and is equipped implicitly with a notion of *size* of an object stored in X_i , denoted by $|X_i|$. For example, if X_i serves as a stack (over a given alphabet), $|X_i|$ is the length of the word stored in X_i .

All we require from the primitives that those programs are built from is that they are polynomially size bounded.

DEFINITION 2.1. *A program P with variables among X_1, \dots, X_n is polynomially size bounded (psb) iff there exist polynomials $p_1(\vec{X}), \dots, p_n(\vec{X})$ such that (expressed in Hoare notation)*

$$\{s_1 = |X_1|, \dots, s_n = |X_n|\} P \{|X_i| \leq p_i(s_1, \dots, s_n)\} \text{ for } i = 1, \dots, n.$$

Any such list of polynomials is called a polynomial bound on P.

The imperative programs under consideration are built from arbitrary psb *basic instructions* $\text{imp}(\vec{X})$ by sequencing $P_1; P_2$, conditionals $\text{if (cond) then } P_1 \text{ else } P_2$, and two forms of *loops*, $\text{loopI } X_h [Q]$ and $\text{loopII } X_h [Q]$.

We do not specify the particular form of the condition (cond) in a conditional. All we require is that any instance of (cond) be evaluated in polynomial time (in the size of the variables involved). Along these lines, we do not specify the particular form of the two loop statements, but we do specify that the body of loopI is executed $|X_h|$ times, while the body of loopII is executed $2^{|X_h|} - 1$ times. Furthermore, we require that during the execution of a loop statement the contents of its *control variable* X_h remain unchanged.

Throughout this paper, *polynomials* $p(\vec{X})$ in variables X_1, \dots, X_n are expressions

$$p(\vec{X}) = c_0 + \dots + c_i \cdot X_1^{i_1} \dots X_n^{i_n} + \dots$$

with coefficients $c_i \in \mathbb{N}$, and we write $\kappa(p)$ for the *constant* coefficient c_0 . For convenience, we use the same variable names for both polynomials and programs but, no doubt, for polynomials those variables range over natural numbers only.

Given another polynomial $q(\vec{X}) = d_0 + \dots + d_i \cdot X_1^{i_1} \dots X_n^{i_n} + \dots$, the coefficientwise *maximum* of p and q , denoted by $p \sqcup q$, is defined by

$$p \sqcup q := \max(c_0, d_0) + \dots + \max(c_i, d_i) \cdot X_1^{i_1} \dots X_n^{i_n} + \dots$$

Furthermore, we write $X_i \in p$ ($X_i \notin p$) if X_i occurs in p (if p is a polynomial in $\vec{X} \setminus X_i$), and we say that X_i *occurs simple* in p , denoted by $X_i \in s(p)$, if p can be written as

$$p(X_1, \dots, X_n) = X_i + q(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_n).$$

As pointed out in the introduction, all that we store and process about polynomials $p(X_1, \dots, X_n)$ is whether $X_i \notin p$ (represented by 0) or $X_i \in s(p)$ (represented by 1) or otherwise (represented by ∞), resulting into the *forgetting set* $A := \{0, 1, \infty\}$. This set is ordered by $0 < 1 < \infty$, and the binary operations $+$, \bullet , and \sqcup on A are defined as follows:

$+$	0	1	∞	\bullet	0	1	∞	\sqcup	0	1	∞
0	0	1	∞	0	0	0	0	0	0	1	∞
1	1	∞	∞	1	0	1	∞	1	1	1	∞
∞	∞	∞	∞	∞	0	∞	∞	∞	∞	∞	∞

One can easily verify that these operations are commutative, associative, and distributive (for $+$, \bullet only), and $0, 1, 0$ are the neutral elements of $+$, \bullet , \sqcup , respectively.

DEFINITION 2.2. For $n \geq 1$, let $\mathcal{M}_n[A]$ denote the set of all $n \times n$ matrices M over A , and let $\tilde{\mathcal{M}}_n[A]$ denote the set of all $M \in \mathcal{M}_{n+1}[A]$ with last row $M[n+1] = 0^n 1$.

As usual, one defines a *matrix multiplication* \otimes on $\mathcal{M}_n[A]$, which is associative and has the *identity matrix* 1_n as the neutral element. Let $+$, \bullet , \sqcup denote the componentwise extension of these operations to A^m and $\mathcal{M}_n[A]$, and $<$ the componentwise extension of $<$ to A^m .

3. Constructing certificates for imperative programs. In this section we will define and construct certificates for essentially composed programs.

DEFINITION 3.1. For any polynomial $p(X_1, \dots, X_n)$, let $\langle p \rangle \in A^{n+1}$ be defined by

$$\langle p \rangle[i] := \begin{cases} 0 & \text{if } X_i \notin p, \\ 1 & \text{if } X_i \in s(p), \\ \infty & \text{else,} \end{cases}$$

$$\langle p \rangle[n+1] := \begin{cases} \kappa(p) & \text{if } \kappa(p) \leq 1, \\ \infty & \text{else,} \end{cases}$$

where $i \in \{1, \dots, n\}$. $\langle p \rangle$ is called the representation of p .

DEFINITION 3.2. For $n \geq 0$ and $\vec{a} \in A^{n+1}$, the set of polynomials of bound \vec{a} is

$$\text{POLY}(\vec{a}) := \{p(\mathbf{X}_1, \dots, \mathbf{X}_n) \mid \langle p \rangle \leq \vec{a}\}.$$

To verify that a polynomial belongs to $\text{POLY}(\vec{a})$, one can use the following fact.

COROLLARY 3.3 (POLY explicit). Let $p(\vec{\mathbf{X}})$ be any polynomial, and let $\vec{a} \in A^{n+1}$. Then

$$\begin{aligned} p \in \text{POLY}(\vec{a}) \iff & \forall i \in \{1, \dots, n\}: (a_i = 0 \Rightarrow \mathbf{X}_i \notin p) \wedge \\ & (a_i = 1 \Rightarrow \mathbf{X}_i \in s(p) \vee \mathbf{X}_i \notin p) \\ & \wedge (a_{n+1} = 0 \Rightarrow \mathbf{K}(p) = 0) \\ & \wedge (a_{n+1} = 1 \Rightarrow \mathbf{K}(p) \leq 1). \end{aligned}$$

DEFINITION 3.4 (certificate). Let \mathbf{P} be any program in variables $\mathbf{X}_1, \dots, \mathbf{X}_n$. A certificate for \mathbf{P} is any matrix $Z \in \tilde{\mathcal{M}}_n[A]$ such that there exists a polynomial bound $p_1 \in \text{POLY}(Z[1]), \dots, p_n \in \text{POLY}(Z[n])$ on \mathbf{P} (cf. Definition 2.1).

NOTE 3.5. If \vec{p} is a polynomial bound on the program \mathbf{P} , the matrix $\langle \mathbf{P}, \vec{p} \rangle$ is a certificate for \mathbf{P} , where

$$\langle \mathbf{P}, \vec{p} \rangle := \begin{pmatrix} \langle p_1 \rangle \\ \vdots \\ \langle p_n \rangle \\ 0^n 1 \end{pmatrix}.$$

This is exactly how certificates for basic instructions $\text{imp}(\vec{\mathbf{X}})$ with polynomial bound \vec{p} are constructed (cf. sections 5–8 for examples).

In the following, we tacitly assume that all programs \mathbf{P} have variables among $\mathbf{X}_1, \dots, \mathbf{X}_n$.

DEFINITION 3.6. For $u \in \{0, 1\}^{n+1}$, let q_u be the polynomial induced by u , i.e.,

$$q_u := u[n+1] + \sum_{i=1}^n u[i] \cdot \mathbf{X}_i.$$

LEMMA 3.7 (structure). Let u, v be in A^{n+1} .

(a) If $u \leq v$, then $\text{POLY}(u) \subseteq \text{POLY}(v)$.

(b) If $\infty \notin u$, then $p \leq q_u$ for all $p \in \text{POLY}(u)$.

Proof. (a) is obvious from Def. 3.2; (b) follows from $\langle q_u \rangle = u$ for $u \in \{0, 1\}^{n+1}$. \square

LEMMA 3.8 (conditional). Let v_1, v_2 be in A^{n+1} .

(a) If $p_1 \in \text{POLY}(v_1)$ and $p_2 \in \text{POLY}(v_2)$, then $p_1 \sqcup p_2 \in \text{POLY}(v_1 \sqcup v_2)$.

(b) If Z_1, Z_2 are certificates for $\mathbf{P}_1, \mathbf{P}_2$, respectively, then

- $Z_1 \sqcup Z_2$ is a certificate for the conditional **if** (cond) **then** \mathbf{P}_1 **else** \mathbf{P}_2 ;
- $Z_1 \sqcup 1_{n+1}$ is a certificate for the conditional **if** (cond) **then** \mathbf{P}_1 .

Proof. (b) follows from (a), and (a) follows from $\langle p_1 \rangle \leq v_1 \wedge \langle p_2 \rangle \leq v_2 \Rightarrow \langle p_1 \sqcup p_2 \rangle \leq v_1 \sqcup v_2$. \square

Note that $\sqcup 1_{n+1}$ takes into account the case where \mathbf{P}_1 is not executed.

LEMMA 3.9 (sequence). Let u, v_1, \dots, v_n be in A^{n+1} .

- (a) Let p, q_1, \dots, q_n be polynomials in $\text{POLY}(u), \text{POLY}(v_1), \dots, \text{POLY}(v_n)$, respectively. Then $r \in \text{POLY}(w)$, where $r(\vec{X}) := p(q_1(\vec{X}), \dots, q_n(\vec{X}))$ and

$$w := u \otimes \begin{pmatrix} v_1 \\ \vdots \\ v_n \\ 0^n 1 \end{pmatrix}.$$

- (b) If Z_1, Z_2 are certificates for P_1, P_2 , respectively, then $Z_2 \otimes Z_1$ is a certificate for $P_1; P_2$.

Proof. Part (b) follows from (a). As for the proof of (a), we use Corollary 3.3 and distinguish several cases, where t, t_0, j range over numbers in $\{1, \dots, n\}$.

Case $w[n+1] = 0$. In other words, $u[n+1] \bullet 1 + \sum_{t=1}^n u[t] \bullet v_t[n+1] = 0$; hence $u[n+1] = 0$, and $u[t] = 0$ or $v_t[n+1] = 0$ for all t . By the hypothesis, that implies $\kappa(p) = 0$, and $(X_t \notin p \text{ or } \kappa(q_t) = 0)$ for all t . Thus, $\kappa(r) = 0$ by definition of r .

Case $w[n+1] = 1 = u[n+1] \bullet 1 + \sum_{t=1}^n u[t] \bullet v_t[n+1]$. We distinguish two subcases.

Subcase $u[n+1] = 1$ and $(u[t] = 0 \text{ or } v_t[n+1] = 0)$ for all t . By the hypothesis, that implies $\kappa(p) \leq 1$, and $(X_t \notin p \text{ or } \kappa(q_t) = 0)$ for all t . Hence $\kappa(r) \leq 1$ by definition of r .

Subcase $u[n+1] = 0$, and $u[t_0] = 1 = v_{t_0}[n+1]$ for some t_0 , and $(u[t] = 0 \text{ or } v_t[n+1] = 0)$ for all $t \neq t_0$. By the hypothesis, that yields $\kappa(p) = 0$, $X_{t_0} \in s(p)$ or $X_{t_0} \notin p$, $\kappa(q_{t_0}) \leq 1$, and $(X_t \notin p \text{ or } \kappa(q_t) = 0)$ for all $t \neq t_0$. Hence $\kappa(r) \leq 1$ by definition of r .

Case $w[j] = 0$. We have $\sum_{t=1}^n u[t] \bullet v_t[j] = 0$, implying $u[t] = 0$ or $v_t[j] = 0$ for all t . By the hypothesis, we obtain $X_t \notin p$ or $X_j \notin q_t$ for all t , implying $X_j \notin r$ as required.

Case $w[j] = 1$. We have $\sum_{t=1}^n u[t] \bullet v_t[j] = 1$, implying $u[t_0] = 1 = v_{t_0}[j]$ for some t_0 , and $(u[t] = 0 \text{ or } v_t[j] = 0)$ for all $t \neq t_0$. The hypothesis yields $X_{t_0} \in s(p)$ or $X_{t_0} \notin p$, $X_j \in s(q_{t_0})$ or $X_j \notin q_{t_0}$, and $(X_t \notin p \text{ or } X_j \notin q_t)$ for all $t \neq t_0$. That implies $X_j \in s(r)$ or $X_j \notin r$ as required. \square

Preparing the construction of certificates for loop statements, suppose that Y is a certificate for the body Q of a loop statement. Clearly, by Lemma 3.9 the k -fold iteration of Q , that is, $Q^k := Q; \dots; Q$ (k -times) for $k \geq 1$, has certificate Y^k , where, as usual, for $M \in \mathcal{M}_n[A]$ we write M^l for the l th iterate of M , that is, $M^0 := 1_n$ and $M^{l+1} := M \otimes M^l$.

Therefore, to obtain a certificate for all k -fold iterations of Q , it is natural to look at the limit Y^+ of all Y^k as defined below. Obviously, Y^+ is finite and efficiently computable. However, in order to verify the then constructed certificate for the given loop, we also consider the monotonic variant \hat{Y}^* of Y^+ .

DEFINITION 3.10 (limit forms). For $M \in \mathcal{M}_n[A]$, the limit forms M^+, M^* , and \hat{M}^* are

$$M^+ := \bigsqcup_{k=1}^{\infty} M^k, \quad M^* := 1_n \sqcup M^+, \quad \text{and} \quad \hat{M}^* := \bigsqcup_{k=0}^{\infty} \hat{M}^k, \quad \text{where} \quad \hat{M} := 1_n \sqcup M.$$

Observe that if M is a matrix in $\tilde{\mathcal{M}}_n[A]$, then so are M^+, M^* , and \hat{M}^* .

At some point in the construction of certificates for loop statements, we will proceed by induction on the partial ordering induced by the control of the certificate for the body of a given loop. According to the two forms of loop statements, there are two versions of the following partial ordering lemma.

DEFINITION 3.11 (control of M). For $M \in \mathcal{M}_n[A]$, the binary relation \rightarrow_M on

$\{1, \dots, n\}$, where $j \rightarrow_M i$ reads j controls i in M , is defined by

$$j \rightarrow_M i : \iff M[i][j] \geq 1.$$

Of course, given a certificate Z for a program P , $j \rightarrow_Z i$ means that the variable X_j may occur in $p_i \in \text{POLY}(Z[i])$ for a polynomial bound \vec{p} on P , and in that sense may control X_i in Z .

LEMMA 3.12 (partial ordering I). *Let M be in $\mathcal{M}_n[A]$ such that $\infty \notin \text{Diag}(\hat{M}^*)$. Then $\rightarrow_{\hat{M}^*}$ is a partial ordering of $\{1, \dots, n\}$.*

Proof. Reflexivity follows from $\hat{M}^* = \bigsqcup_{m \geq 0} (1_n \sqcup M)^m$. As for transitivity, suppose that $j \rightarrow_{\hat{M}^*} i$ and $i \rightarrow_{\hat{M}^*} k$. Then there exist $a, b \geq 0$ such that $\hat{M}^a[i][j] \geq 1$ and $\hat{M}^b[k][i] \geq 1$. We obtain $j \rightarrow_{\hat{M}^*} k$ as follows:

$$\begin{aligned} \hat{M}^* [k][j] &\geq \hat{M}^{b+a} [k][j] = (\hat{M}^b \otimes \hat{M}^a) [k][j] \\ &= \hat{M}^b [k][i] \bullet \hat{M}^a [i][j] + \sum_{d \neq i} \hat{M}^b [k][d] \bullet \hat{M}^a [d][j] \\ &\geq 1 \bullet 1 = 1. \end{aligned}$$

As for antisymmetry, we argue indirectly and assume $j \rightarrow_{\hat{M}^*} i$, $i \rightarrow_{\hat{M}^*} j$, and $i \neq j$. Thus, $\hat{M}^a [i][j] \geq 1$ and $\hat{M}^b [j][i] \geq 1$ for some $a, b \in \mathbb{N}$. As $i \neq j$, we know $a, b \geq 1$, since, e.g., $a = 0$ implied $\hat{M}^a [i][j] = 1_n [i][j] = 0$. By reflexivity of $\rightarrow_{\hat{M}^*}$, $\hat{M}^m [k][k] = (1_n \sqcup M)^m [k][k] \geq 1$ for any k , and $\infty \notin \text{Diag}(\hat{M}^*)$, we obtained as above the following contradiction:

$$1 = \hat{M}^* [j][j] \geq \hat{M}^b [j][i] \bullet \hat{M}^a [i][j] + \hat{M}^b [j][j] \bullet \hat{M}^a [j][j] \geq 1 + 1 = \infty. \quad \square$$

LEMMA 3.13 (partial ordering II). *Let M be any matrix in $\mathcal{M}_n[A]$ such that*

$$M^+ [i] = 1_n [i] \text{ or } M^+ [i][i] = 0 \text{ for } i = 1, \dots, n.$$

Then \rightarrow_{M^} is a partial ordering of $\{1, \dots, n\}$.*

Proof. Reflexivity of \rightarrow_{M^*} follows from $M^* = 1_n \sqcup M^+$, and transitivity follows as above, since $j \rightarrow_{M^*} i$ implies $M^a [i][j] \geq 1$ for some $a \geq 0$.

For antisymmetry, we argue indirectly and assume $j \rightarrow_{M^*} i$, $i \rightarrow_{M^*} j$, and $i \neq j$. As above, there exist $a, b \geq 1$ such that $M^a [i][j] \geq 1$ and $M^b [j][i] \geq 1$. That implied

$$M^+ [j][j] \geq (M^b \otimes M^a) [j][j] \geq M^b [j][i] \bullet M^a [i][j] \geq 1,$$

and thus $M^+ [j][j] \geq 1$, $M^+ [j][i] \geq 1$ with $i \neq j$, contradicting the hypothesis on M^+ . \square

Note that each $q \in \text{POLY}(\vec{a})$ is a polynomial in those variables X_i for which $a_i \geq 1$.

LEMMA 3.14 (certificate for loopI). *Let $P \equiv \text{loopI } X_h [Q]$ be any program, and let Y be a certificate for Q such that $\infty \notin \text{Diag}(\hat{Y}^*)$. Then the matrix Z with rows*

$$(z_1 \sqcup 1_{n+1} [1]), \dots, (z_n \sqcup 1_{n+1} [n]), 0^n 1$$

is a certificate for P , where z_1, \dots, z_n are defined as follows:

$$z_i := \begin{cases} Y^+ [i] & \text{if } \infty \notin Y^+ [i] \quad (\text{variable assignment}), \\ Y^+ [i] & \text{if } Y^+ [i] = 0^n \infty \quad (\text{constant assignment}), \\ 1_{n+1} [i] \sqcup 0^{h-1} Y [i][n+1] 0^{n+1-h} & \text{if } Y^+ [i] = 0^{i-1} 10^{n-i} \infty \quad (\text{push/inc}), \\ \text{else}(z_i) & \text{else} \quad (\text{else}), \end{cases}$$

where for $i \neq h$ (case $i = h$ falls under variable assignment) $\text{else}(z_i)$ is defined by

$$\text{else}(z_i)[j] := \begin{cases} \infty \bullet \hat{Y}^*[i][j] & \text{if } j \neq i, h, n+1, \\ 1 & \text{if } j = i, \\ \infty & \text{if } j = h, \\ 0 & \text{if } j = n+1. \end{cases}$$

Comments. The parts $\sqcup 1_{n+1}[i]$ in the i th row of Z take into account that P is not executed. Furthermore, the names of the first three cases in the above definition of z_i are not meant to cover the general situation but only refer to typical ones. In the variable assignment case, there exists a bounding polynomial on $|X_i|$ with simple variable occurrences only. As for the constant assignment case, there exists a constant bound on $|X_i|$. The push/inc case deals with the situation where each execution of Q increases $|X_i|$ by a constant ≥ 1 . In the else case, the idea is that because of $\infty \notin \text{Diag}(\hat{Y}^*)$ there exists a bounding polynomial of the form $X_i + X_h \cdot q(X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_n)$, resulting in the definition of $\text{else}(z_i)$.

Proof. By Lemma 3.12 we can define a strict partial ordering of $\{1, \dots, n\}$ by setting

$$i \sqsubset_{\hat{Y}^*} j \iff i \rightarrow_{\hat{Y}^*} j \text{ and } i \neq j.$$

Thus, preparing the *else case* for z_i , we first proceed by induction on $\sqsubset_{\hat{Y}^*}$ showing the following.

CLAIM. *There exist polynomials $q_1(m, \vec{X}), \dots, q_n(m, \vec{X})$ such that for $i = 1, \dots, n$,*

- (A) $\{|\vec{X}| = \vec{s}\} Q^m \{|X_i| \leq s_i + q_i(m, \vec{s})\}$ for all $m \geq 0$.
- (B) $X_i + q_i(X_h, \vec{X}) \in \text{POLY}(\infty \bullet \hat{Y}^*[i] \sqcup H)$, where $H := 0^{h-1} \infty 0^{n+1-h}$.
- (C) $X_i \notin q_i$ and $\kappa(q_i) = 0$.

Proof of the claim. Consider any $i \in \{1, \dots, n\}$, and let i_1, \dots, i_l be those $i_j \neq i$ for which $i_j \rightarrow_{\hat{Y}^*} i$ holds. As Y is a certificate for Q with $\infty \notin \text{Diag}(\hat{Y}^*)$, there exists a polynomial $X_i + q'_i \in \text{POLY}(\hat{Y}[i])$ such that $X_i \notin q'_i$ and

$$(1) \quad \{|\vec{X}| = \vec{s}\} Q \{|X_i| \leq s_i + q'_i(\vec{s})\}.$$

Subcase $l = 0$. We have that $Y[i] \leq \hat{Y}^*[i] \leq 0^{i-1} 10^{n-i} \infty$; hence q'_i is a constant. Thus,

$$q_i(m, \vec{X}) := m \cdot q'_i$$

yields a polynomial clearly satisfying (C) and (A), the latter by (1), and (B) holds because $X_i + X_h \cdot q'_i \in \text{POLY}(1_{n+1}[i] \sqcup H) \subseteq \text{POLY}(\infty \bullet \hat{Y}^*[i] \sqcup H)$ by Lemma 3.7.

Subcase $l \geq 1$. We have that $i \neq h$, because the requirement on loop statements and Lemma 4.5 imply that Q is nonsize-increasing w.r.t. X_h , that is, $Y[h] \leq 1_{n+1}[h]$, implying $\hat{Y}^*[h] = 1_{n+1}[h]$. Now, the induction hypothesis yields polynomials r_{i_1}, \dots, r_{i_l} such that for $j = 1, \dots, l$,

- (IHA) $\{|\vec{X}| = \vec{s}\} Q^m \{|X_{i_j}| \leq s_{i_j} + r_{i_j}(m, \vec{s})\}$ for all $m \geq 0$.
- (IHB) $X_{i_j} + r_{i_j}(X_h, \vec{X}) \in \text{POLY}(\infty \bullet \hat{Y}^*[i_j] \sqcup H)$.
- (IHC) $X_{i_j} \notin r_{i_j}$ and $\kappa(r_{i_j}) = 0$.

Let j_1, \dots, j_k be those indices $j_s \neq i$ for which $j_s \rightarrow_Y i$ holds. As $Y[i] \leq \hat{Y}^*[i]$, all of those indices are among i_1, \dots, i_l . As q'_i is a polynomial in X_{j_1}, \dots, X_{j_k} , we set

$$q_i(m, \vec{X}) := m \cdot q'_i(\dots, X_{i_j} + r_{i_j}(m, \vec{X}), \dots),$$

where $X_{i_j} + r_{i_j}(m, \vec{X})$ is substituted for X_{i_j} just in case i_j is among j_1, \dots, j_k .

As for (C), clearly $\kappa(q_i) = 0$. To see $\mathbf{X}_i \notin q_i$, we argue indirectly, assuming $\mathbf{X}_i \in q_i$. Then $\mathbf{X}_i \in r_{i_j}$ for some i_j ; hence $\mathbf{X}_i \in \text{POLY}(\infty \bullet \hat{Y}^*[i_j] \sqcup H)$ by (IHB). As $i_j \neq i$ and $i \neq h$, that implied $i \rightarrow_{\hat{Y}^*} i_j \rightarrow_{\hat{Y}^*} i$. Thus, $i = i_j$ by antisymmetry of $\rightarrow_{\hat{Y}^*}$, contradicting $i \notin \{i_1, \dots, i_l\}$.

As for the proof of (A), we proceed by induction on $m \geq 0$, where *base case* $m = 0$ is obvious. For the *step case* $m \rightarrow m + 1$, let \vec{u} be the output size of $\vec{\mathbf{X}}$ after m rounds of \mathbf{Q} on input of size \vec{s} , and let \vec{v} be the output size of $\vec{\mathbf{X}}$ after another round of \mathbf{Q} on input of size \vec{u} . Then, by using monotonicity of polynomials, we conclude the step case as follows:

$$\begin{aligned} v_i &\leq u_i + q'_i(\vec{u}) && \text{by (1),} \\ &\leq s_i + q_i(m, \vec{s}) + q'_i(\dots, s_{i_j} + r_{i_j}(m, \vec{s}), \dots) && \text{by the I.H. for } m \text{ and (IHA),} \\ &\leq s_i + (m + 1) \cdot q'_i(\dots, s_{i_j} + r_{i_j}(m + 1, \vec{s}), \dots) && \text{by definition of } q_i(m, \vec{s}), \\ &= s_i + q_i(m + 1, \vec{s}). \end{aligned}$$

As for (B), we know $q'_i \in \hat{Y}[i]$, and $\mathbf{X}_{i_j} + r_{i_j}(\mathbf{X}_h, \vec{\mathbf{X}}) \in \text{POLY}(\infty \bullet \hat{Y}^*[i_j] \sqcup H)$ by (IHB). As the zero polynomial belongs to each class $\text{POLY}(\vec{a})$, Lemma 3.9 yields $r \in \text{POLY}(w)$, where $w := \hat{Y}[i] \otimes (\infty \bullet \hat{Y}^* \sqcup \hat{H})$, \hat{H} denotes the matrix in $\tilde{\mathcal{M}}_n[A]$ with rows $H, \dots, H, 0^{n-1}1$ (recall $H = 0^{h-1}10^{n+1-h}$), and

$$r(\mathbf{X}_h, \vec{\mathbf{X}}) := q'_i(\dots, \mathbf{X}_{i_j} + r_{i_j}(\mathbf{X}_h, \vec{\mathbf{X}}), \dots).$$

Thus, for the proof of (B), it suffices to show $(*) \text{POLY}(w) \subseteq \text{POLY}(\infty \bullet \hat{Y}^*[i] \sqcup H)$, because then (B) follows from $\mathbf{X}_i + q_i(\mathbf{X}_h, \vec{\mathbf{X}}) = \mathbf{X}_i + \mathbf{X}_h \cdot r(\mathbf{X}_h, \vec{\mathbf{X}})$, and $\mathbf{X}_i \notin q_i$, $i \neq h$. To see $(*)$, we argue using Lemma 3.7. First, observe that $\hat{Y}^* = \hat{Y}^e = \hat{Y}^{e+1}$ for some $e \geq 0$, implying $\hat{Y}[i] \otimes (\infty \bullet \hat{Y}^*) = \infty \bullet (\hat{Y}[i] \otimes \hat{Y}^*) = \infty \bullet \hat{Y}^*[i]$. Now consider any $j \in \{1, \dots, n+1\}$. If $j \neq h$, then $w[j] = (\hat{Y}[i] \otimes (\infty \bullet \hat{Y}^*)) [j] = \infty \bullet \hat{Y}^*[i][j] = (\infty \bullet \hat{Y}^*[i] \sqcup H)[j]$. Otherwise, if $j = h$, then $(\infty \bullet \hat{Y}^*[i] \sqcup H)[j] = \infty \bullet \hat{Y}^*[i][j] \sqcup \infty = \infty \geq w[j]$. Thus, in either case, $w[j] \leq (\infty \bullet \hat{Y}^*[i] \sqcup H)[j]$ as required. This completes the proof of the above claim. \square

Turning to the proof of the lemma, recall that we must prove the existence of polynomials $p_1 \in \text{POLY}(Z_1), \dots, p_n \in \text{POLY}(Z_n)$ such that

$$(2) \quad \{|\vec{\mathbf{X}}| = \vec{s}\} \mathbf{P} \{|\mathbf{X}_i| \leq p_i(\vec{s})\} \quad \text{for } i = 1, \dots, n.$$

Consider any $i \in \{1, \dots, n\}$. As Y is a certificate for \mathbf{Q} , there exists a polynomial $q_i \in \text{POLY}(Y[i])$ such that

$$(3) \quad \{|\vec{\mathbf{X}}| = \vec{s}\} \mathbf{Q} \{|\mathbf{X}_i| \leq q_i(\vec{s})\}.$$

According to the definition of z_i , we consider four cases.

Variable assignment case $\infty \notin Y^+[i]$. We have that $z_i = Y^+[i]$, and we conclude from (3) and Lemma 3.7 that $q_{z_i} \in \text{POLY}(z_i)$ satisfies $\{|\vec{\mathbf{X}}| = \vec{s}\} \mathbf{Q}^m \{|\mathbf{X}_i| \leq q_{z_i}(\vec{s})\}$ for all $m \geq 1$. Thus, $p_i := \mathbf{X}_i \sqcup q_{z_i}$ is a polynomial in $\text{POLY}(Z[i])$ such that (2) is true of p_i .

Constant assignment case $Y^+[i] = 0^n \infty$. We have that $z_i = Y^+[i]$, and by (3) there exists a constant polynomial c in $\text{POLY}(z_i)$ such that $\{|\vec{\mathbf{X}}| = \vec{s}\} \mathbf{Q} \{|\mathbf{X}_i| \leq c\}$. Thus, $p_i := \mathbf{X}_i + c$ is a polynomial in $\text{POLY}(Z[i])$ which satisfies (2).

Push/inc case $Y^+[i] = 0^{i-1}10^{n-i} \infty$. We have that $z_i = 1_{n+1}[i] \sqcup 0^{h-1}Y[i][n+1]0^{n+1-h}$, and by (3) and Lemma 3.7 there exists a polynomial $\mathbf{X}_i + b \in \text{POLY}(Y^+[i])$

such that $\{|\vec{X}| = \vec{s}\} \mathbf{Q} \{|\mathbf{X}_i| \leq s_i + b\}$. We conclude that $\{|\vec{X}| = \vec{s}\} \mathbf{Q}^m \{|\mathbf{X}_i| \leq s_i + b \cdot m\}$ for $m \geq 0$. Thus, $p_i := \mathbf{X}_i + b \cdot \mathbf{X}_h$ is a polynomial in $\text{POLY}(Z_i)$ for which (2) holds.

Else case $\infty \in Y^+[i] \neq 0^n \infty$ and $Y^+[i] \neq 0^{i-1}10^{n-i} \infty$. Then $i \neq h$, because the requirement on loop statements and Lemma 4.5 imply that \mathbf{Q} is nonsize-increasing w.r.t. \mathbf{X}_h , that is, $Y[h] \leq 1_{n+1}[h]$; hence $Y^+[h] \leq 1_{n+1}[h]$ and $\infty \notin Y^+[h]$. Thus, the case $i=h$ is appropriately treated in the variable assignment case. Now, let q_i be the polynomial obtained from the above Claim, satisfying (A), (B), (C). The current case is then completed by setting

$$p_i(\vec{X}) := \mathbf{X}_i + q_i(\mathbf{X}_h, \vec{X}).$$

Obviously, (2) is true of p_i by (A). To see $p_i \in \text{POLY}(Z[i]) = \text{POLY}(\text{else}(z_i))$, we argue using Corollary 3.3. If $Z[i][j] = 1$, then $j = i$; hence $\mathbf{X}_i \in s(p_i)$ by (C) and $i \neq h$. If $Z[i][j] = 0$, then $j \neq i, h$, and as $\kappa(p_i) = 0$, it suffices to consider the case $j \in \{1, \dots, n\} \setminus \{i, h\}$. Then $0 = Z[i][j] = \infty \bullet \hat{Y}^*[i][j] = (\infty \bullet \hat{Y}^*[i] \sqcup H)[j]$; hence (B) implies $\mathbf{X}_j \notin p_i$ as required. \square

LEMMA 3.15 (certificate for loopII). *Let $\mathbf{P} \equiv \text{loopII } \mathbf{X}_h \mathbf{Q}$ be any program, and let Y be a certificate for \mathbf{Q} satisfying*

$$(I) \quad Y^+[i] = 1_{n+1}[i] \text{ or } Y^+[i][i] = 0 \text{ for } i = 1, \dots, n + 1.$$

Then Y^ is a certificate for \mathbf{P} .*

Proof. First, we define polynomials $q_{1,m}, \dots, q_{n,m}$ for $m \geq 0$ s.t. for $i = 1, \dots, n$,

(A) $\{|\vec{X}| = \vec{s}\} \mathbf{Q}^m \{|\mathbf{X}_i| \leq q_{i,m}(\vec{s})\}$ for all $m \geq 0$.

(B) $q_{i,m} \in \text{POLY}(Y^m[i])$.

(C) There exists an $m_i \geq 0$ such that $\bigsqcup_{s \leq m} q_{i,s} \leq \bigsqcup_{s \leq m_i} q_{i,s}$ for all $m \geq 0$.

The proof that Y^* is a certificate for \mathbf{P} is then completed by setting (for $i = 1, \dots, n$)

$$p_i := \bigsqcup_{s \leq m_i} q_{i,s}$$

since (B) and Lemmas 3.8(a) and 3.7(a) imply $p_i \in \text{POLY}(\bigsqcup_{s \leq m_i} Y^s[i]) \subseteq \text{POLY}(Y^*[i])$, and from (A), (C) we obtain $\{|\vec{X}| = \vec{s}\} \mathbf{P} \{|\mathbf{X}_i| \leq q_{i,2^{\lceil s_h \rceil}}(\vec{s}) \leq p_i(\vec{s})\}$ as required.

As for the proof of (A) and (B), consider any $i \in \{1, \dots, n\}$. Since Y is a certificate for \mathbf{Q} , there exist polynomials $q'_1 \in \text{POLY}(Y[1]), \dots, q'_n \in \text{POLY}(Y[n])$ such that

$$(4) \quad \{|\vec{X}| = \vec{s}\} \mathbf{Q} \{|\mathbf{X}_j| \leq q'_j(\vec{s})\} \quad \text{and} \quad q'_i = \mathbf{X}_i \text{ whenever } Y[i] = 1_{n+1}[i]$$

for $j = 1, \dots, n$. Let i_1, \dots, i_l be those i_j such that $i_j \rightarrow_{Y^+} i$, and let $j_1 < \dots < j_k$ be those indices j_s such that $j_s \rightarrow_Y i$. Then $j_1, \dots, j_k \in \{i_1, \dots, i_l\}$, as $Y[i] \leq Y^+[i]$. We inductively define $q_{i,m}$ by

$$q_{i,0} := \mathbf{X}_i, \\ q_{i,m+1} := q'_i(r_1, \dots, r_n), \quad \text{where } r_{j_s} := q_{j_s,m} \text{ for } s = 1, \dots, k, \text{ and } r_t := 0 \text{ else.}$$

One easily verifies (A) by induction on $m \geq 0$, using (4). To see that (B) is true of $q_{i,m}$, observe that $q_{i,0} \in \text{POLY}(Y^0[i])$, and inductively $r_1, \dots, r_n \in \text{POLY}(Y^m[i])$, the hypothesis $q'_i \in \text{POLY}(Y[i])$, and Lemma 3.9(a) imply $q_{i,m+1} \in \text{POLY}(Y \otimes Y^m[i]) = \text{POLY}(Y^{m+1}[i])$.

For (C), we associate to each $q_{i,m}$ a *control tree* $\text{CT}_{i,m}$ with root (ℓ) and labels i, \perp :

$$\begin{aligned} \text{CT}_{i,0} &:= (i), \\ \text{CT}_{i,m+1} &:= \begin{cases} (\perp) & \text{if } l = 0 \ (Y^+[i] \in \{0\}^n A), \\ (i) & \text{if } l \geq 1, \ i \in \{j_1, \dots, j_k\} \ (Y^+[i] = 1_{n+1}[i]), \\ \langle (i), \text{CT}_{j_1,m}, \dots, \text{CT}_{j_k,m} \rangle & \text{if } l \geq 1, \ i \notin \{j_1, \dots, j_k\}. \end{cases} \end{aligned}$$

By Lemma 3.13, \rightarrow_{Y^*} is a partial ordering of $\{1, \dots, n\}$, and $Y \leq Y^+$. Therefore, for every path in any $\text{CT}_{i,m}$ from the root to a leaf, each label can occur at most once. Hence each such path is of length at most n , implying that there are only finitely many control trees. Thus, to prove (C), it suffices to show that the mapping $q_{i,m} \mapsto \text{CT}_{i,m}$ is injective, that is, for all $m, m' \geq 0$, and for $i = 1, \dots, n$,

(D) if $\text{CT}_{i,m} = \text{CT}_{i,m'}$ then $q_{i,m} = q_{i,m'}$.

The proof is by induction on the *depth* N of $\text{CT}_{i,m}$, assuming (H) $\text{CT}_{i,m} = \text{CT}_{i,m'}$.

Case $N = 0$. We have that $\text{CT}_{i,m} \in \{(i), (\perp)\}$. If $\text{CT}_{i,m} = (i)$, then $q_{i,m} = \mathbf{X}_i = q_{i,m'}$, because, e.g., $q_{i,0} = \mathbf{X}_i$, and $m > 0$ implies $k = 1$, $j_1 = i$, $r_i = q_{i,m-1} = \mathbf{X}_i$, and $q'_i = \mathbf{X}_i$; hence $q_{i,m} = \mathbf{X}_i$ by construction. Otherwise if $\text{CT}_{i,m} = (\perp)$, then $m, m' > 0$, and q'_i is a constant, implying $q_{i,m} = c = q_{i,m'}$ by construction.

Case $N > 0$. We have that (H) implies $m, m' > 0$ and $\text{CT}_{j_s,m-1} = \text{CT}_{j_s,m'-1}$ for $s = 1, \dots, k$. Thus, the I.H. yields $q_{j_s,m-1} = q_{j_s,m'-1}$ for $s = 1, \dots, k$, implying $q_{i,m} = q_{i,m'}$. \square

Now that we know how to construct certificates for psb basic instructions (see Note 3.5) and for composed programs (see Lemmas 3.8, 3.9, 3.14, 3.15), all ingredients are at hand to set up the *method* of certifying the psb property for the class of programs under consideration.

More precisely, we will define a *certification method* which assigns to each program P a value $M(P)$, which is either the *undefined value* \perp or a certificate $M(P)$ for P . As usual, we write $M(P) \downarrow$ for $M(P) \neq \perp$. Furthermore, we say that a program P is *certified* iff $M(P) \downarrow$.

DEFINITION 3.16 (certification method). *For any program P with variables among $\vec{X} = X_1, \dots, X_l$, $M(P)$ is defined inductively as follows:*

- $M(\text{imp}(\vec{X})) := \langle \text{imp}(\vec{X}), \vec{p} \rangle$ for psb basic instructions $\text{imp}(\vec{X})$ with polynomial bound \vec{p} .
- If $M(P_1) \downarrow$ and $M(P_2) \downarrow$, then $M(P_1; P_2) := M(P_2) \otimes M(P_1)$.
- If $M(P_1) \downarrow$ and $M(P_2) \downarrow$, then $M(\text{if}(\text{cond}) \text{ then } P_1 \text{ else } P_2)$ is defined as $M(P_1) \sqcup M(P_2)$.
- If $M(Q) \downarrow$, then $M(\text{if top}(X_k) \equiv a \text{ then } Q) := M(Q) \sqcup 1_{n+1}$.
- If P is $\text{loopI } X_h [Q]$ and $Y := M(Q)$ is a certificate for Q with $\infty \notin \text{Diag}(\hat{Y}^*)$, then $M(P) := Z$ as defined in Lemma 3.14.
- If P is $\text{loopII } X_h [Q]$ and $Y := M(Q)$ is a certificate for Q such that $Y^+[i] = 1_{n+1}[i]$ or $Y^+[i][i] = 0$ for $i = 1, \dots, n+1$, then $M(P) := Y^*$.
- In all other cases of P , $M(P) := \perp$.

THEOREM 3.17 (soundness). *For every program P with psb basic instructions only, if $M(P) \downarrow$, then $M(P)$ is a certificate for P ; in other words, P is psb, too.*

Proof. Following the cases of $M(P) \downarrow$, the statement of the theorem follows from Note 3.5 and Lemmas 3.8, 3.9, 3.14, and 3.15. \square

For reasons similar to those elaborated on in [16], it is an undecidable problem whether a given program is psb. As a consequence, there is no limit to refining the above certification method so as to recognize more and more psb programs. We give three examples.

Suppose that P is a sequence $P_1; P_2$ such that P_2 is a loop with body Q and control variable X_h , and $M(P_1) \downarrow$. If $M(P_1)[h] = 0^{n+1}$, then Q will never be executed; thus

P_2 can be ignored when computing $M(P)$. Furthermore, if $M(P)[h] = 0^n 1$, then Q is executed at most once. In that case, we obtain $(M(Q) \sqcup 1_{n+1}) \otimes M(P_1)$ as a certificate for P whenever $M(Q) \downarrow$.

Moreover, for nonsize-increasing basic instructions (cf. Definition 4.4) one obtains a certificate $\leq 1_{n+1}$. Those instructions can be ignored when computing $M(P)$. However, it would be wiser to keep basic instructions like $\text{nil}(X)$, for they can lead to better bounding polynomials.

4. Embedding stack and loop programs of μ -measure 0. In this section, we will show that all stack and loop programs of μ -measure 0 [16] are certified by the present method. That embedding will be used only to facilitate the proof of the characterization theorems below. The strength of the present method, however, is not based on the measure μ . First we review stack programs and the measure μ .

Stack programs operate on stacks X, Y, Z, \dots over a fixed but arbitrary alphabet. Such programs are built from the usual basic instructions $\text{push}(a, X)$, $\text{pop}(X)$, $\text{nil}(X)$ by sequencing $P_1; P_2$, conditional statements $\text{if } \text{top}(X) \equiv a \text{ then } Q$, and loopI statements $\text{foreach } X [Q]$ (read *for each symbol in X do Q*) provided that no push , pop , or nil instruction with respect to the control stack X occurs in Q . The operational semantics of stack programs is standard, except possibly for loop statements $\text{foreach } X [Q]$: they are executed *call-by-value* such that during the execution, every symbol in X can be inspected while preserving its contents.

Central to the design of the measure μ is the notion of control.

DEFINITION 4.1 (control). *Let P be any stack program, and let $\text{PUSH}(P)$ be the set of all Y appearing as $\text{push}(a, Y)$ in P . The control of P is the transitive closure \rightarrow_P of the following governance relation \rightarrow_P :*

- X governs Y in P ($X \rightarrow_P Y$) if P contains a loop statement $\text{foreach } X [R]$ such that $Y \in \text{PUSH}(R)$.

Thus, X controls Y in P ($X \rightarrow_P Y$) iff $X \rightarrow_P Z_1 \rightarrow_P \dots \rightarrow_P Z_l \rightarrow_P Y$ for some Z_1, \dots, Z_l .

Observe that $Z \rightarrow_Q Z$ is precluded by the syntactic restrictions on loop statements.

DEFINITION 4.2 (measure μ). *For stack programs P , the μ -measure of P , denoted by $\mu(P)$, is inductively defined (and streamlined) as follows:*

- $\mu(\text{imp}(\vec{X})) := 0$ for every basic instruction $\text{imp}(\vec{X})$.
- $\mu(\text{if } \text{top}(X) \equiv a \text{ then } Q) := \mu(Q)$.
- $\mu(P_1; P_2) := \max\{\mu(P_1), \mu(P_2)\}$.
- $\mu(\text{foreach } X [Q]) := \begin{cases} \mu(Q) + 1 & \text{if } Q \text{ has a top circle,} \\ \mu(Q) & \text{else,} \end{cases}$

where Q has a top circle if it contains a loop $T := \text{foreach } Y [R]$ such that $\mu(T) = \mu(Q)$ and $Z \rightarrow_Q Y$ for some $Z \in \text{PUSH}(R)$.

One obtains $\mu(\text{foreach } X [\text{foreach } X [Q]]) = \mu(\text{foreach } X [Q])$, and furthermore, if Q is a sequence $Q_1; \dots; Q_k$ with a top circle, then some component Q_i contains a loop $T := \text{foreach } Y [R]$ such that $\mu(T) = \mu(Q)$ and $Z \rightarrow_Q Y$ for some $Z \in \text{PUSH}(R)$. The latter clearly shows that this measure μ admits more programs at any higher level than the original version in [16] does, for it requires the existence of a component Q_i such that $\mu(Q_i) = \mu(Q)$ and $U \rightarrow_{Q_i} V$ and $V \rightarrow_{Q^{-i}} U$ for some U, V , where Q^{-i} is Q without component Q_i .

The measure μ on loop programs is defined in the same way, except that the size-increasing instruction $\text{suc}(X)$ plays the role of the push operation.

Loop programs are built from the basic instructions $\text{suc}(X)$ (increment the number stored in X by one), $\text{nil}(X)$ (set X to zero), and $\text{pred}(X)$ (decrement the number stored in X by one) by sequencing $P_1; P_2$ and loopI statements $\text{loop } X [Q]$ (execute Q x times

whenever x is stored in \mathbf{X}), provided that no instruction $\text{succ}(\mathbf{X})$, $\text{nil}(\mathbf{X})$, or $\text{pred}(\mathbf{X})$ occurs in \mathbf{Q} . Here variables serve as registers, storing natural numbers.

As shown in [16], stack programs of μ -measure 0 compute precisely the functions in FPTIME , and loop programs of μ -measure 0 exactly compute the functions of the Grzegorzczuk class \mathcal{E}_2 which is identical to the class FLINSPACE of the linear-space computable functions [32].

To show that $\mu(\mathbf{P})=0$ implies $M(\mathbf{P}) \downarrow$, we need to embed the analysis of control inherent in the measure μ in the certification method. Some technical lemmata are needed beforehand.

LEMMA 4.3 (iteration). *Let M be in $\tilde{\mathcal{M}}_n[A]$ such that $j \rightarrow_{M^m} i$ for some $m \geq 1$, where $i, j \in \{1, \dots, n\}$. Then there exist $i_1 = j, i_2, \dots, i_k = i \in \{1, \dots, n\}$ such that*

$$j = i_1 \rightarrow_M i_2 \rightarrow_M \dots \rightarrow_M i_k = i$$

and i_1, \dots, i_k are pairwise distinct, except for i_1, i_k .

Proof. We proceed by induction on $m \geq 1$. The base case $m = 1$ holds by the hypothesis on M . For the step case $m \rightarrow m + 1$, note that $M[n + 1] = 0^n 1$ implies

$$M^{m+1}[i][j] = \sum_{d=1}^n M[i][d] \bullet M^m[d][j],$$

and hence $M[i][e], M^m[e][j] \geq 1$ for some $e \in \{1, \dots, n\}$ by the hypothesis on M^{m+1} . The I.H. yields $i_1 = j, i_2, \dots, i_k = e$ such that $j = i_1 \rightarrow_M i_2 \rightarrow_M \dots \rightarrow_M i_k = e$, and i_1, \dots, i_k are pairwise distinct, except for i_1, i_k .

Subcase $j \neq e$. If $i \notin \{i_1, \dots, i_k\}$, then we are done, as $e \rightarrow_M i$. Otherwise let l be minimal such that $i_l = i$. If $j \neq i$, we are done; otherwise $i \rightarrow_M i_2 \rightarrow_M \dots \rightarrow_M i_k \rightarrow_M i$ will do.

Subcase $j = e$. In this case, we are done, since $e \rightarrow_M i$. \square

DEFINITION 4.4. *A program \mathbf{P} with certificate $M(\mathbf{P})$ is nonsize-increasing w.r.t. \mathbf{X}_i iff $M(\mathbf{P})[i] \leq 1_{n+1}[i]$.*

Obviously, $\text{pop}(\mathbf{X}_i)$ and $\text{nil}(\mathbf{X}_i)$ are nonsize-increasing w.r.t. \mathbf{X}_i (cf. section 5).

LEMMA 4.5 (nonsize-increasing). *If a certified program \mathbf{P} contains only nonsize-increasing basic instructions w.r.t. \mathbf{X}_i , then \mathbf{P} is also nonsize-increasing w.r.t. \mathbf{X}_i .*

Proof. The proof is by induction on the structure of \mathbf{P} with $Z = M(\mathbf{P})$. The case where \mathbf{P} is a basic instruction follows from the hypothesis on \mathbf{P} .

Case $\mathbf{P} \equiv \mathbf{P}_1; \mathbf{P}_2$. Then $Z = Y_2 \otimes Y_1$, where $Y_k = M(\mathbf{P}_k)$ for $k = 1, 2$, and the induction hypothesis yields $Y_k[i] \leq 1_{n+1}[i]$ for $k = 1, 2$. Thus, for $j = 1, \dots, n + 1$ we obtain

$$Z[i][j] = (Y_2 \otimes Y_1)[i][j] = \sum_{d=1}^{n+1} Y_2[i][d] \bullet Y_1[d][j] \leq Y_1[i][j] \leq 1_{n+1}[i][j].$$

Case $\mathbf{P} \equiv \text{if}(\text{cond}) \text{ then } \mathbf{P}_1 \text{ else } \mathbf{P}_2$. Then $Z = Y_1 \sqcup Y_2$, where $Y_k = M(\mathbf{P}_k)$ for $k = 1, 2$. The I.H. yields $Y_k[i] \leq 1_{n+1}[i]$ for $k = 1, 2$, and hence $Z[i] \leq 1_{n+1}[i]$.

Case $\mathbf{P} \equiv \text{loopI } \mathbf{X}_h[\mathbf{Q}]$. Then $\infty \notin \text{Diag}(\hat{Y}^*)$ for $Y = M(\mathbf{Q})$, and $Y[i] \leq 1_{n+1}[i]$ by the I.H. on \mathbf{Q} . We conclude $\hat{Y}[i] = 1_{n+1}[i]$; hence $Y^+[i] \leq 1_{n+1}[i]$ and $Z[i] = Y^+[i] \sqcup 1_{n+1}[i] = 1_{n+1}[i]$ as required. Note that $Z[i]$ falls under the variable assignment case of Lemma 3.14.

Case $\mathbf{P} \equiv \text{loopII } \mathbf{X}_h[\mathbf{Q}]$. Then $Z = Y^*$, where $Y = M(\mathbf{Q})$, and $Y[i] \leq 1_{n+1}[i]$ by the I.H. on \mathbf{Q} . From the above we conclude that $Y^+[i] \leq 1_{n+1}[i]$; hence $Z[i] \leq 1_{n+1}[i]$. \square

LEMMA 4.6 (control embedding). *For any stack or loop program P with certificate $Z = M(P)$, and for all $i, j \in \{1, \dots, n\}$,*

- *if $Z[i][j] \geq 1$ and $i \neq j$, then $X_j \rightarrow_P X_i$;*
- *if $Z[i][i] = \infty$, then $X_i \rightarrow_P X_i$.*

NOTE. *To see that the two cases above are distinct, consider the stack program $P \equiv \text{foreach } X_h [\text{pop}(X_i)]$. As $M(\text{pop}(X_i)) = 1_{n+1}$, we obtain $M(P) = 1_{n+1}$, in particular $M(P)[i][i] = 1$, but $\neg(X_i \rightarrow_P X_i)$.*

Proof. The proof is by induction on the structure of P with $Z = M(P)$. We treat only stack programs, as the proof for loop programs is almost identical. The case where P is a basic instruction holds by pure logic, since the hypothesis fails for $M(P)$.

Case P is if $\text{top}(X_k) \equiv a$ then Q. Then $Z = M(Q) \sqcup 1_{n+1}$, and the claim follows from the I.H., as $Z[i][j] = M(Q)[i][j]$ for $i \neq j$, and $Z[i][i] = \infty$ implies $M(Q)[i][i] = \infty$.

Case $P \equiv P_1; P_2$. Then $Z = Y_2 \otimes Y_1$, where $Y_k = M(P_k)$. As $Y_1[n+1][j] = 0$, we get

$$(*) \quad Z[i][j] = \sum_{d=1}^n Y_2[i][d] \bullet Y_1[d][j].$$

First consider the case where $Z[i][j] \geq 1$ and $i \neq j$. Then (*) implies $Y_2[i][e], Y_1[e][j] \geq 1$ for some $e \in \{1, \dots, n\}$. Then either i, j, e are distinct or $e \in \{i, j\}$. In either case, the I.H. yields $X_e \rightarrow_{P_2} X_i$ and $X_j \rightarrow_{P_1} X_e$, implying $X_j \rightarrow_P X_i$ as required.

Consider the case $Z[i][i] = \infty$. By (*) for $i = j$, we can consider two subcases.

Subcase $Y_2[i][e] \bullet Y_1[e][i] = \infty$ for some $e \in \{1, \dots, n\}$. Then each factor is ≥ 1 , and one is ∞ . If $e = i$, then $X_i \rightarrow_P X_i$ follows from the I.H. on an ∞ factor. Otherwise the I.H. yields $X_e \rightarrow_{P_2} X_i$ and $X_i \rightarrow_{P_1} X_e$, implying $X_i \rightarrow_P X_i$ as required.

Subcase $Y_2[i][e] \bullet Y_1[e][i] = 1$ and $Y_2[i][d] \bullet Y_1[d][i] = 1$ for some $e \neq d$. We may assume $i \neq e$. As each factor is 1, the I.H. yields $X_e \rightarrow_{P_2} X_i$ and $X_i \rightarrow_{P_1} X_e$. This implies $X_i \rightarrow_P X_i$, concluding the current case $P \equiv P_1; P_2$.

Case $P \equiv \text{foreach } X_h [Q]$. Suppose that $Y = M(Q)$. Then case $Z[i][i] = \infty$ is ruled out by construction and $\infty \notin \text{Diag}(\hat{Y}^*)$. Suppose that $Z[i][j] \geq 1$ and $i \neq j$. We consider several subcases according to the definition of $Z = M(P)$.

Subcase $\infty \notin Y^+[i]$ or $Y^+[i] = 0^n \infty$. Then $Z[i] = Y^*[i]$, and $Z[i][j] \geq 1$ implies $Y^m[i][j] \geq 1$ for some $m \geq 1$, as $i \neq j$. Lemma 4.3 yields pairwise distinct $j = i_1, i_2, \dots, i_k = i$ such that

$$j = i_1 \rightarrow_Y i_2 \rightarrow_Y \dots \rightarrow_Y i_k = i.$$

Therefore, the I.H. yields $X_{i_1} \rightarrow_Q X_{i_2} \rightarrow_Q \dots \rightarrow_Q X_{i_k}$, implying $X_j \rightarrow_P X_i$.

Subcase $Y^+[i] = 0^{i-1}10^{n-i}\infty$. Then $Z[i] = 1_{n+1}[i] \sqcup 0^{h-1}Y[i][n+1]0^{n+1-h}$, and $i \neq j$ and $Z[i][j] \geq 1$ imply $j = h$ and $Y[i][n+1] \geq 1$. Thus, we must show $X_h \rightarrow_P X_i$. It suffices to show that Q contains a push operation on X_i . If Q contained no such operation, then Q would be nonsize-increasing w.r.t. X_i by Lemma 4.5; hence $Y[i] \leq 1_{n+1}[i]$. But that implied $Y^+[i] \leq 1_{n+1}[i]$, contradicting the subcase assumption.

Subcase $\infty \in Y^+[i]$ and $Y^+[i] \neq 0^n \infty, 0^{i-1}10^{n-i}\infty$. Now $i \neq j$ and $Z[i][j] \geq 1$ imply $j = h$ or $\hat{Y}^*[i][j] \geq 1$. If $j = h$ then, as $\infty \in Y^+[i]$, we argue as above that Q contains a push operation on X_i , implying $X_h \rightarrow_P X_i$. Otherwise $\hat{Y}^*[i][j] \geq 1$ and

$i \neq j$ imply $\hat{Y}^m[i][j] \geq 1$ for some $m \geq 1$; hence Lemma 4.3 yields pairwise distinct $j = i_1, i_2, \dots, i_k = i$ such that

$$j = i_1 \rightarrow_{\hat{Y}} i_2 \rightarrow_{\hat{Y}} \dots \rightarrow_{\hat{Y}} i_k = i.$$

Now observe that $\hat{Y}[d][e] \geq 1$ and $d \neq e$ imply $Y[d][e] \geq 1$. Thus, the I.H. yields $X_{i_1} \rightarrow_{\mathbb{Q}} X_{i_2} \rightarrow_{\mathbb{Q}} \dots \rightarrow_{\mathbb{Q}} X_{i_k}$, implying $X_j \rightarrow_{\mathbb{P}} X_i$ as required. \square

THEOREM 4.7 (embedding). *All stack/loop programs of μ -measure 0 are certified.*

Proof. The proof is by induction on the structure of \mathbb{P} with $\mu(\mathbb{P}) = 0$. We treat only stack programs, as the proof for loop programs is almost identical. The case where \mathbb{P} is a basic instruction `push`, `pop`, or `nil` is obvious.

Case \mathbb{P} is `if top(X_k) \equiv a then \mathbb{Q} .` Then $\mu(\mathbb{Q}) = 0$, and the I.H. yields $M(\mathbb{P}) = M(\mathbb{Q}) \sqcup 1_{n+1}$.

Case $\mathbb{P} \equiv \mathbb{P}_1; \mathbb{P}_2$. Then $\mu(\mathbb{P}_1) = \mu(\mathbb{P}_2) = 0$, and the I.H. yields $M(\mathbb{P}) = M(\mathbb{P}_2) \otimes M(\mathbb{P}_1)$.

Case $\mathbb{P} \equiv \text{foreach } X_h \text{ [} \mathbb{Q} \text{].}$ Then $\mu(\mathbb{Q}) = 0$ and \mathbb{Q} contains no (top) circle; that is, \mathbb{Q} contains no variable X_i such that $X_i \rightarrow_{\mathbb{Q}} X_i$. By the I.H., $Y := M(\mathbb{Q})$ is defined, and we must show $\infty \notin \text{Diag}(\hat{Y}^*)$. We argue indirectly and assume $\hat{Y}^*[i][i] = \infty$ for some $i \in \{1, \dots, n\}$. Note that $i \neq h$, since \mathbb{Q} contains no `push` operation on the control stack X_h of \mathbb{P} , and hence \mathbb{Q} is nonsize-increasing w.r.t. X_h by Lemma 4.5.

From the assumption, we obtain $\hat{Y}^m[i][i] = \infty$ for some $m \geq 1$. We show by induction on $m \geq 1$ that this implies $X_i \rightarrow_{\mathbb{Q}} X_i$, contradicting $\mu(\mathbb{P}) = 0$. In the *base case* $m = 1$, $\hat{Y}[i][i] = \infty$ implies $Y[i][i] = \infty$, and hence $X_i \rightarrow_{\mathbb{Q}} X_i$ by Lemma 4.6.

For the *step case* $m \rightarrow m+1$, observe that $\hat{Y}[n+1] = 0^n 1$ and $i \in \{1, \dots, n\}$ imply

$$\hat{Y}^{m+1}[i][i] = \sum_{d=1}^n \hat{Y}[i][d] \bullet \hat{Y}^m[d][i] = \infty.$$

Subcase $\hat{Y}[i][e] \bullet \hat{Y}^m[e][i] = \infty$ for some $e \in \{1, \dots, n\}$. If $e = i$ and $\hat{Y}[i][i] = \infty$, then $Y[i][i] = \infty$, implying $X_i \rightarrow_{\mathbb{Q}} X_i$ by Lemma 4.6. If $e = i$ and $\hat{Y}^m[i][i] = \infty$, then $X_i \rightarrow_{\mathbb{Q}} X_i$ follows from the induction hypothesis. Otherwise $e \neq i$ and $\hat{Y}[i][e], \hat{Y}^m[e][i] \geq 1$. In that case, Lemmas 4.3 and 4.6 imply $X_e \rightarrow_{\mathbb{Q}} X_i$ and $X_i \rightarrow_{\mathbb{Q}} X_e$; hence $X_i \rightarrow_{\mathbb{Q}} X_i$.

Subcase $\hat{Y}[i][e] \bullet \hat{Y}^m[e][i] = 1$ and $\hat{Y}[i][d] \bullet \hat{Y}^m[d][i] = 1$ for some $e \neq d$. In that case, we may assume $e \neq i$, and we argue as in the previous subcase to show $X_i \rightarrow_{\mathbb{Q}} X_i$. \square

5. String programs and FPTIME. This section is concerned with showing that certified “string programs” exactly compute the functions in FPTIME.

DEFINITION 5.1 (string programs). *A basic instruction $\text{imp}(\vec{X})$ is admissible if it can be simulated on a Turing machine in polynomial time.*

String programs are stack programs that have arbitrary admissible basic instructions and are extended by the following conditional with expected operational semantics:

$$\text{if top}(X_i) \equiv a \text{ then } \mathbb{P}_1 \text{ else } \mathbb{P}_2.$$

Observe that admissible basic instructions are psb.

Examples. The following are examples of admissible basic instructions, where w is any word over Σ :

- The *no operation*: $\{\vec{X} = \vec{v}\} \text{nop } \{\vec{X} = \vec{v}\}$.
- The *swap operation*: $\{X_i, X_j = v_i, v_j\} \text{swap}(X_i, X_j) \{X_i, X_j = v_j, v_i\}$.

- The *constant assignment statement*: $\{X_i = v_i\} X_i = w \{X_i = w\}$.
- The *assignment statement*: $\{X_i, X_j = v_i, v_j\} X_i = X_j \{X_i, X_j = v_j, v_j\}$.
- The *constant concatenation*: $\{X_i = v_i\} X_i += w \{X_i = v_i w\}$.
- The *concatenation statement*: $\{X_i, X_j = v_i, v_j\} X_i += X_j \{X_i, X_j = v_i v_j, v_j\}$.

We use the following notation for simple certificates.

DEFINITION 5.2 ($Z_{i,j,a}$, $A_{i,j,a}$, and F). For programs in variables X_1, \dots, X_n , let

- $Z_{i,j,a}$ result from 1_{n+1} by replacing row i with $0^{j-1} a 0^{n+1-j}$, and
- $A_{i,j,a}$ result from 1_{n+1} by replacing row i with $1_{n+1}[i] + 0^{j-1} a 0^{n+1-j}$.

The forgetting function $F: \mathbb{N} \rightarrow A$ is defined by $F(0) := 0$, $F(1) := 1$, $F(n+2) := \infty$.

Certificates. The following are certificates for some admissible basic instructions with variables among X_1, \dots, X_n :

- 1_{n+1} is a certificate for both $\text{pop}(X_i)$ and nop .
- One obtains a certificate $S_{i,j}$ for $\text{swap}(X_i, X_j)$ by swapping in 1_{n+1} row i with row j .
- Using the notation in Definition 5.2,

$Z_{i,i,0}$	is a certificate for $\text{nil}(X_i)$,
$Z_{i,n+1,F(w)}$	is a certificate for $X_i = w$,
$Z_{i,j,1}$	is a certificate for $X_i = X_j$,
$A_{i,n+1,1}$	is a certificate for $\text{push}(a, X_i)$,
$A_{i,n+1,F(w)}$	is a certificate for $X_i += w$,
$A_{i,j,1}$	is a certificate for $X_i += X_j$.

Observe that, in the presence of the conditionals, $\text{if } \text{top}(X_i) \equiv a \text{ then } P_1 \text{ else } P_2$ and nop , conditionals of the form $\text{if } \text{top}(X_i) \equiv a \text{ then } P_1$ can be dispensed with, because they can be defined by $\text{if } \text{top}(X_i) \equiv a \text{ then } P_1 \text{ else nop}$ with an identical certificate, if any.

DEFINITION 5.3 (sharp form). For $X \in \tilde{\mathcal{M}}_n[A]$ and any choice of $*_1, \dots, *_{n+1} \in \{0, 1, \infty\}$, a sharp form $X^\#$ of X is a matrix in $\tilde{\mathcal{M}}_{n+1}[A]$ defined as follows:

$$X = \begin{pmatrix} X_1 & \cdots & X_n & X_{n+1} \\ 0 & \cdots & 0 & 1 \end{pmatrix} \implies X^\# = \begin{pmatrix} X_1 & \cdots & X_n & \mathbf{0} & X_{n+1} \\ *_1 & \cdots & *_n & 1 & *_{n+1} \\ 0 & \cdots & 0 & 0 & 1 \end{pmatrix}.$$

DEFINITION 5.4. An accumulator of X_1, \dots, X_n is any string program in variables X_1, \dots, X_n, X_{n+1} such that $C \in \tilde{\mathcal{M}}_{n+1}[A]$ is a certificate for that program, where C is obtained from 1_{n+2} by replacing row $n+1$ with $1^{n+1}0$.

Note that the certificate of an accumulator of X_1, \dots, X_n is a sharp form of 1_{n+1} . The following program ADD is a typical example of an accumulator of X_1, \dots, X_n :

$$\text{ADD} := X_{n+1} += X_1; \dots; X_{n+1} += X_n.$$

LEMMA 5.5 (sharp forms and accumulators). Let ACC be any accumulator of $\vec{X} := X_1, \dots, X_n$, and let P be any string program in variables \vec{X} such that $M(P) \downarrow$.

- If $X, Y \in \tilde{\mathcal{M}}_n[A]$, then $Y^\# \otimes X^\#$ is a sharp form $(Y \otimes X)^\#$, and $Y^\# \sqcup X^\#$ is a sharp form $(Y \sqcup X)^\#$.
- $M(P; \text{ACC})$ is a sharp form $M(P)^\#$.
- If $P^\#$ is obtained from P by replacing each admissible basic instruction $\text{imp}(\vec{X})$ with the sequence $\text{imp}(\vec{X}); \text{ACC}$, then $M(P^\#)$ is a sharp form $M(P)^\#$.

Proof. Part (a) holds by pure matrix multiplication. Part (b) holds by pure matrix multiplication together with the fact that if $Y \in \tilde{\mathcal{M}}_n[A]$ is a certificate for P ,

then

$$Y' = \begin{pmatrix} Y_1 \cdots Y_n \mathbf{0} Y_{n+1} \\ 0 \cdots 0 \ 1 \ 0 \\ 0 \cdots 0 \ 0 \ 1 \end{pmatrix}$$

is a certificate for P as a program with variables among \vec{X}, X_{n+1} . The proof of (c) is by induction on the structure of P , where the case $P \equiv \text{imp}(\vec{X})$ follows from (b).

If P is a sequence $P_1; P_2$ or a conditional $\text{if } \text{top}(X_i) \equiv a \text{ then } P_1 \text{ else } P_2$, then $P^\#$ is $P_1^\#; P_2^\#$ or $\text{if } \text{top}(X_i) \equiv a \text{ then } P_1^\# \text{ else } P_2^\#$, and the claim follows from the I.H., part (a), and Definition 3.16.

Consider the case $P \equiv \text{foreach } X_h [Q]$. Then $P^\# \equiv \text{foreach } X_h [Q^\#]$, and by the I.H. $M(Q^\#)$ is a sharp form $Y^\#$ of $Y := M(Q)$. Furthermore, as $\infty \notin \text{Diag}(\hat{Y}^*)$, and as $\widehat{Y^\#}^*$ is a sharp form $(\hat{Y}^*)^\#$ by (a), we conclude that $\infty \notin \text{Diag}(\widehat{Y^\#}^*)$, too. Thus, $M(P^\#)$ is defined, and inspecting all cases in the construction of $M(P^\#)$ in Lemma 3.14, we see that $M(P^\#)$ is a sharp form $M(P)^\#$. \square

THEOREM 5.6 (characterization of FPTIME). *Certified string programs exactly compute the functions in FPTIME.*

Proof. For the implication $\boxed{\Leftarrow}$, consider any f in FPTIME. By [16] and Theorem 4.7, f can be computed by a stack program of μ -measure 0 such that $M(P) \downarrow$.

As for $\boxed{\Rightarrow}$, let P be a certified string program with variables among $\vec{X} := X_1, \dots, X_n$. Then let $\text{TIME}_P(\vec{w})$ denote the number of steps in a run of P on input \vec{w} , where a *step* is the execution of any admissible basic instruction $\text{imp}(\vec{X})$. Observe that there is a polynomial $q_{\text{time}}(\vec{n})$ such that each step $\text{imp}(\vec{X})$ can be simulated by a Turing machine in time $q_{\text{time}}(|\vec{X}|)$. Then let $P^\#$ result from P by replacing each basic instruction $\text{imp}(\vec{X})$ with the sequence $\text{imp}(\vec{X}); \text{ADD}$, where ADD is the accumulator of \vec{X} defined above.

By Lemma 5.5 we obtain that $M(P^\#)$ is a sharp form $M(P)^\#$. Thus, by soundness (Theorem 3.17) there exists a polynomial $q \in \text{POLY}(M(P^\#)[n+1])$ such that

$$\{\vec{X}, X_{n+1} = \vec{w}, v\} P^\# \{ |X_{n+1}| \leq q(|\vec{w}|, |v|) \}.$$

By the construction of $P^\#$ we see that $\text{TIME}(P) := \text{nil}(X_{n+1}); \text{ADD}; P^\#$ satisfies

$$\{\vec{X} = \vec{w}\} \text{TIME}(P) \{ |X_{n+1}| \geq \text{TIME}_P(\vec{w}) \}$$

and that $p(|\vec{w}|) := q(|\vec{w}|, \sum_i |w_i|)$ bounds the size of each stack at any time during the execution of P on input \vec{w} . Thus, every step $\text{imp}(\vec{X})$ in a run of P on input \vec{w} can be simulated on a Turing machine in time $q_{\text{time}}(p(|\vec{w}|), \dots, p(|\vec{w}|))$. Referring to standard simulations of string programs on Turing machines (e.g., cf. section 7), the existence of a Turing machine which simulates P on input \vec{w} in time $O(p(|\vec{w}|) \cdot q_{\text{time}}(p(|\vec{w}|), \dots, p(|\vec{w}|)))$ follows. \square

6. General loop programs and FLINSPACE. In this section we will show that certified “general loop programs” exactly compute the functions in FLINSPACE.

DEFINITION 6.1 (general loop programs). *A basic instruction $\text{imp}(\vec{X})$ is admissible if it can be simulated on a Turing machine in linear space.*

General loop programs are loop programs that have arbitrary admissible basic instructions and are extended by the following conditional with expected operational semantics:

$$\text{if } X_i \leq X_j \text{ then } P_1 \text{ else } P_2.$$

Examples. The following are examples of admissible basic instructions, where p is any polynomial in \vec{X} :

- the basic instructions $\text{nil}(X_i)$, $\text{pred}(X_i)$, $\text{suc}(X_i)$ of loop programs, just as nop and $\text{swap}(X_i, X_j)$, bearing in mind that now \vec{X} serve as *registers*.
- the *assignment statement* $X_i = p$ satisfying $\{\vec{X} = \vec{x}\} X_i = p \{X_i = p(\vec{x})\}$.
- the *increase statement* $X_i += p$ satisfying $\{\vec{X} = \vec{x}\} X_i += p \{X_i = x_i + p(\vec{x})\}$.

In particular, the instructions $X_i = c$ and $X_i = X_j$, as well as $X_i += c$ and $X_i += X_j$, are admissible basic instructions, where c is any constant.

Certificates. The following are certificates for some admissible basic instructions with variables among X_1, \dots, X_n :

- The certificates for $\text{nil}(X_i)$, $\text{pred}(X_i)$, $\text{suc}(X_i)$, nop , and $\text{swap}(X_i, X_j)$ are just those for $\text{nil}(X_i)$, $\text{pop}(X_i)$, $\text{push}(a, X_i)$, nop , and $\text{swap}(X_i, X_j)$ as given in section 6.
- One obtains a certificate for $X_i = p$ from 1_{n+1} by replacing row i with $\langle p \rangle$.
- By replacing in 1_{n+1} row i with $1_{n+1}[i] + \langle p \rangle$, one obtains a certificate for $X_i += p$.

THEOREM 6.2 (characterization of FLINSPACE). *Certified general loop programs exactly compute the functions in FLINSPACE.*

Proof. For the implication $\boxed{\Leftarrow}$, consider any f in FLINSPACE. By [16] and Theorem 4.7, f can be computed by a loop program of μ -measure 0 such that $M(P) \downarrow$.

As for $\boxed{\Rightarrow}$, let P be any certified general loop program. By soundness (Theorem 3.17), every f computed by P has a polynomial bound. Thus, by closure of \mathcal{E}_2 under bounded simultaneous primitive recursion, we obtain inductively that every f computed by P is in $\mathcal{E}_2 = \text{FLINSPACE}$. \square

7. Power string programs and FPSPACE. This section concerns an extension of string programs we call power string programs such that certified power string programs exactly compute the functions in FPSPACE.

DEFINITION 7.1 (power string programs). *A basic instruction is ps-admissible if it can be simulated on a Turing machine in polynomial space.*

Power string programs are string programs that are built from ps-admissible basic instructions and are extended by the following loopII statement we call power loop:

$$\text{repeat Pow}(X_h) [Q],$$

which executes the body $2^{|w|}-1$ times whenever w is initially stored in the control stack X_h .

An example of a ps-admissible basic instruction used in the proof of the characterization theorem above is the *truncate instruction* $\text{truncate}(X_i, X_j)$ satisfying

$$\{X_i, X_j = w_i, w_j\} \text{truncate}(X_i, X_j) \{X_j = w_j \text{ and } X_i = \text{trunc}(w_i, w_j)\},$$

where $\text{trunc}(u, v) := u$ if $|u| \leq |v|$, and $\text{trunc}(u, v) := u'$ if $u = u'u''$ and $|u'| = |v|$.

Using the notation of Definition 5.2, we obtain $Z_{i,j,1}$ as a certificate for $\text{truncate}(X_i, X_j)$.

If the method certifies a power string program P , then every function computed by P will be polynomially size bounded. However, when simulating P on a Turing machine $\text{sim}(P)$, the space used by $\text{sim}(P)$ might exceed the polynomial bounds provided by $M(P)$. Therefore, to prove that power string programs with certificate $M(P)$ can be simulated on a Turing machine $\text{sim}(P)$ in polynomial space, we first *standardize* those simulations.

Given a power string program P with variables among X_1, \dots, X_n , the simulation $\text{sim}(P)$ has an *input/output tape*, a *working tape* $T(X_i)$ for each X_i , and a *reference tape* $R(X_i)$ for each occurrence of a loop controlled by X_i .

Every run of $\text{sim}(\text{P})$ on input $w_{i_1} \# \dots \# w_{i_n}$ is divided into three phases, where phase 1 or 3 can be skipped, depending on the use of $\text{sim}(\text{P})$ as a subprogram of another program: the *initialization* phase, in which each component w_{i_j} is copied to the corresponding working tape $T(\mathbf{X}_{i_j})$, the *step-by-step simulation* phase, and the *output preparation* phase.

All cases of $\text{sim}(\text{P})$ are obvious, except possibly the case where P is a loop statement **foreach** $\mathbf{X}_h[\text{Q}]$ or **repeat** $\text{Pow}(\mathbf{X}_h)[\text{Q}]$. Given $\text{sim}(\text{Q})$, let $\text{sim}(\text{Q})^*$ result from $\text{sim}(\text{Q})$ by modifying its transition function such that every move w.r.t. $T(\mathbf{X}_h)$ becomes a move w.r.t. $R(\mathbf{X}_h)$.

$\text{sim}(\text{foreach } \mathbf{X}_h[\text{Q}])$ works on input \vec{w} as follows: After the initialization phase, the contents of tape $T(\mathbf{X}_h)$ is copied to the reference tape $R(\mathbf{X}_h)$, leaving its tape head on the top symbol of \mathbf{X}_h . Then for each inspected symbol on $R(\mathbf{X}_h)$ distinct from B , first call $\text{sim}(\text{Q})^*$, then delete the actual “top symbol” of tape $R(\mathbf{X}_h)$, and move its tape head one cell to the left.

$\text{sim}(\text{repeat } \text{Pow}(\mathbf{X}_h)[\text{Q}])$ works on input \vec{w} as follows: After the initialization phase, write $y := |w_h|$ ones (the binary representation of $2^{|w_h|} - 1$) or $y := 0$ (in case of $w_h = \varepsilon$) on the reference tape $R(\mathbf{X}_h)$. Then in an obvious loop of $2^{|w_h|} - 1$ rounds, first call $\text{sim}(\text{Q})$, and then compute the new $y := \text{bin}((y)_2 - 1)$ on tape $R(\mathbf{X}_h)$ from the actual y .

THEOREM 7.2 (characterization of FPSPACE). *Certified power string programs exactly compute the functions in FPSPACE .*

Proof. As for $\boxed{\Rightarrow}$, we proceed by induction on the structure of certified power string programs P , showing $S_{\text{sim}(\text{P})}(n) \leq p(n)$ for some polynomial $p(n)$.

The base case where P is a ps-admissible basic instruction holds by the fact that if a power string program can be simulated on a Turing machine in polynomial space, then it can also be simulated on a standardized Turing machine in polynomial space.

The cases where P is a sequence or a conditional easily follow by the I.H. and closure of polynomials under composition.

*Remaining cases, where P is a loop statement **foreach** $\mathbf{X}_h[\text{Q}]$ or **repeat** $\text{Pow}(\mathbf{X}_h)[\text{Q}]$.* By the I.H. there exists a polynomial $q(n)$ such that $S_{\text{sim}(\text{Q})}(n) \leq q(n)$. Furthermore, since $M(\text{P})$ is a certificate for P , there exists a polynomial b , built from those polynomials obtained in Lemma 3.14 or Lemma 3.15, respectively, such that

$$\{s_1 = |\mathbf{X}_1|, \dots, s_n = |\mathbf{X}_n|\} \text{P} \{|\mathbf{X}_i| \leq b(\max\{s_1, \dots, s_n\})\} \text{ for } i = 1, \dots, n.$$

Then a straightforward induction on s_h shows that $S_{\text{sim}(\text{P})}(n) \leq (b \sqcup q \circ b)(n)$.

As for the proof of $\boxed{\Leftarrow}$, let f be any function in FPSPACE computed by a one-tape Turing machine $M := (Q, \Gamma, \Sigma, q_0, \delta)$ such that $S_M(n) \leq p(n)$ for some polynomial $p(n)$. As M halts on every input, one can find another polynomial $q(n)$ such that $T_M(n) \leq 2^{q(n)}$. Let b be the polynomial $p \sqcup q$. To obtain a certified power string program P that simulates M , we follow [16], [29] and modify the given stack program simulation of M as follows.

The required program P satisfying $\{\mathbf{X} = w\} \text{P} \{0 = f_M(w)\}$ uses stacks $\mathbf{X}, \mathbf{Y}, \mathbf{Z}, \mathbf{L}, \mathbf{R}, 0, \dots$, and is of the form

$$\begin{array}{ll} \text{P} ::= \text{COMPUTE-SPACE-BOUND}(\mathbf{Y}); & (* \text{ of } \mu\text{-measure } 0 *) \\ \text{INITIALIZE}(\mathbf{L}, \mathbf{Z}, \mathbf{R}); & (* \text{ of } \mu\text{-measure } 0 *) \\ \text{repeat Pow}(\mathbf{Y}) [\text{SIMULATE-MOVES}; \text{TRUNCATE-ALL}]; & (* ? *) \\ \text{OUTPUT}(\mathbf{R}; 0) & (* \text{ of } \mu\text{-measure } 0 *) \end{array}$$

where $\text{TRUNCATE-ALL} ::= \text{truncate}(\mathbf{X}_1, \mathbf{Y}); \dots; \text{truncate}(\mathbf{X}_n, \mathbf{Y})$, and $\vec{\mathbf{X}} = \text{Var}(\text{P})$. Let INIT be the initial part $\text{COMPUTE-SPACE-BOUND}(\mathbf{Y}); \text{INITIALIZE}(\mathbf{L}, \mathbf{Z}, \mathbf{R})$, and let Q be

the body of the power loop. Then the simulation of M is such that for each configuration $\alpha(\mathbf{q}, \mathbf{a})\beta$ obtained after m steps of M on w , that is, $\text{init}_M(w) \vdash^m \alpha(\mathbf{q}, \mathbf{a})\beta$, we have

$$\{\mathbf{X} = w\} \text{INIT}; \mathbf{Q}^m \{\mathbf{L} = \alpha, \text{reverse}(\mathbf{R}) = \mathbf{a}\beta, \mathbf{Z} = \mathbf{q}\}.$$

Observe that, apart from the use of the power loop and `truncate`, everything else in \mathbf{P} belongs to the stack program world. In particular, the stack program `COMPUTE-SPACE-BOUND(Y)` computes in stack \mathbf{Y} a word of size $b(|w|)$, bounding the space that M uses on input w . As well, `SIMULATE-MOVES` is a stack program of μ -measure 0. Hence by Theorem 4.7, all of the components `INIT`, `Q`, and `OUTPUT(R; 0)` are certified. Thus, to obtain a certificate $M(\mathbf{P})$, it remains to verify that the certificate for `Q` satisfies the hypothesis of Lemma 3.15, that is,

$$(I) \quad M(\mathbf{Q})^+[i] = 1_{n+1}[i] \text{ or } M(\mathbf{Q})^+[i][i] = 0 \text{ for } i = 1, \dots, n + 1.$$

First observe that `TRUNCATE-ALL` is the only place in \mathbf{P} where `truncate` is used, and where \mathbf{Y} appears in `Q`. Furthermore, by construction of the bound b , none of those truncate operations changes the contents of any \mathbf{X}_i . However, assuming $\mathbf{X}_n = \mathbf{Y}$ (w.l.o.g.), and bearing in mind that $Z_{i,n,1}$ is the certificate of `truncate(Xi, Xn)`, the effect of `TRUNCATE-ALL` is that

$$M(\mathbf{Q}) = \begin{pmatrix} 0 \cdots 010 \\ \cdots \\ 0 \cdots 010 \\ 0 \cdots 001 \end{pmatrix},$$

whatever the certificate of `SIMULATE-MOVES`. Thus (I) is true of $M(\mathbf{Q})$. \square

Inspecting again the certificate $M(\mathbf{Q})$ above, we see that for the proof of $\boxed{\Leftarrow}$, a trivialized hypothesis on the certificate of a loopII-body in Lemma 3.15 would have sufficed. But note again that the focus here is not on characterization theorems but on certifying as many programs as possible, and that is why the hypothesis (I) in Lemma 3.15 is so valuable.

8. Applications. In this section, examples of certified natural algorithms are given, some of which are considered benchmark algorithms [14] in implicit computational complexity. Furthermore, one algorithm is given where the certification method correctly fails.

8.1. Basic arithmetical operations. For legibility, we write

$$\text{prog}(\vec{\mathbf{X}}_1, \dots, \mathbf{X}_r; \mathbf{Y}_1, \dots, \mathbf{Y}_s)$$

for *subprograms*, where $\vec{\mathbf{X}}$ act as *read-only input parameters*, and $\vec{\mathbf{Y}}$ as *output parameters*. All variables of the subprogram not appearing among $\vec{\mathbf{X}}, \vec{\mathbf{Y}}$ are *local variables* and must be discharged at the end of the subprogram. That allows us to suppress in subprogram certificates all rows and columns corresponding to local variables.

The following programs are straightforward implementations of elementary methods of basic arithmetical operations, and it is natural to use stacks of bits here. Accordingly, we use the following two kinds of variables:

- variables `A, B, S, ...` of data type “`stack < bit >`” with `bit := {0, 1}`. As usual, the *size* of a stack is the length of the word stored in it.
- variables `carry, sum_bit` of data type `bit`. The *size* of a bit is 1.

In addition to those admissible basic instructions and their certificates as shown in section 5, we use the following admissible basic instructions, where \mathbf{b} , \mathbf{S} are aliases for X_i, X_j and $\langle \text{BE} \rangle$ is any polynomial-time computable Boolean expression:

$\mathbf{b} = \langle \text{BE} \rangle$	assigns the value of $\langle \text{BE} \rangle$ to \mathbf{b}	certificate: $Z_{i,n+1,1}$,
$\text{push}(\mathbf{b}, \mathbf{S})$	pushes the bit stored in \mathbf{b} on \mathbf{S}	certificate: $A_{j,n+1,1}$,
$\text{reverse}(\mathbf{S})$	reverses the word stored in \mathbf{S}	certificate: 1_{n+1} .

Alternatively, using Lemma 3.14 and the above convention of suppressing local variables, one could implement $\text{reverse}(\mathbf{S})$ with certificate 1_{n+1} .

BINARY ADDITION. This procedure uses $\mathbf{A}, \mathbf{B}, \mathbf{S}, \mathbf{A}', \mathbf{B}', \text{carry}$, and sum_bit as aliases for X_1, \dots, X_7 .

```

1: procedure BIN_ADD( $\mathbf{A}, \mathbf{B}; \mathbf{S}$ )
2:    $\mathbf{A}' = \mathbf{A}; \mathbf{B}' = \mathbf{B};$                                 ▷ Creates local copies of  $\mathbf{A}, \mathbf{B}$ 
3:   if ( $\text{len}(\mathbf{B}') < \text{len}(\mathbf{A}')$ ) then
4:      $\mathbf{S} = \mathbf{B}';$ 
5:      $\mathbf{B}' = \mathbf{A}';$ 
6:      $\mathbf{A}' = \mathbf{S};$                                         ▷ Sets the control variable  $\mathbf{B}'$ 
7:    $\text{nil}(\mathbf{S});$                                           ▷ Initializes the result stack
8:    $\text{carry} = 0;$                                         ▷ Initializes the carry
9:   foreach  $\mathbf{B}'$  do
10:     $\text{sum\_bit} = \text{top}(\mathbf{A}') \text{ xor } \text{top}(\mathbf{B}') \text{ xor } \text{carry};$ 
11:     $\text{push}(\text{sum\_bit}, \mathbf{S});$ 
12:     $\text{carry} = \text{top}(\mathbf{A}') \text{ and } \text{top}(\mathbf{B}');$ 
13:     $\text{pop}(\mathbf{A}');$ 
14:   if ( $\text{carry}$ ) then
15:      $\text{push}(1, \mathbf{S});$                                   ▷ Now  $\mathbf{S}$  holds the result string in reverse order
16:    $\text{reverse}(\mathbf{S});$ 
17:    $\text{nil}(\mathbf{A}'); \text{nil}(\mathbf{B}')$                             ▷ Discharges local copies

```

To compute the certificate, we refer to the following parts of the algorithm: P_1 for lines 2–8, P_2 for the loop with body Q , and P_3 for lines 14–17. For those parts, the method yields

$$\begin{aligned}
M(P_1) &= Z_{6,8,1} \otimes Z_{3,3,0} \otimes ((Z_{4,3,1} \otimes Z_{5,4,1} \otimes Z_{3,5,1}) \sqcup 1_8) \otimes Z_{5,2,1} \otimes Z_{4,1,1}, \\
M(P_3) &= Z_{5,5,0} \otimes Z_{4,4,0} \otimes 1_8 \otimes (A_{3,8,1} \sqcup 1_8), \\
Y &:= M(Q) = 1_8 \otimes Z_{6,8,1} \otimes A_{3,8,1} \otimes Z_{7,8,1}.
\end{aligned}$$

Thus, we obtain

$$M(P_1) = \begin{pmatrix} 10000000 \\ 01000000 \\ 00000000 \\ 11000000 \\ 11000000 \\ 00000001 \\ 00000010 \\ 00000001 \end{pmatrix}, \quad M(P_3) = \begin{pmatrix} 10000000 \\ 01000000 \\ 00100001 \\ 00000000 \\ 00000000 \\ 00000100 \\ 00000010 \\ 00000001 \end{pmatrix}, \quad \text{and } Y = \begin{pmatrix} 10000000 \\ 01000000 \\ 00100001 \\ 00010000 \\ 00001000 \\ 00000001 \\ 00000001 \\ 00000001 \end{pmatrix}.$$

Application of Lemma 3.14 yields the following certificate $M(P_2)$ for the loop:

$$\text{As } \hat{Y}^* = \begin{pmatrix} 1000000 0 \\ 0100000 0 \\ 0010000 \infty \\ 0001000 0 \\ 0000100 0 \\ 0000010 \infty \\ 0000001 \infty \\ 0000000 1 \end{pmatrix}, Y^+ = \begin{pmatrix} 1000000 0 \\ 0100000 0 \\ 0010000 \infty \\ 0001000 0 \\ 0000100 0 \\ 0000000 1 \\ 0000000 1 \\ 0000000 1 \end{pmatrix}, \text{ we get } M(P_2) = \begin{pmatrix} 1000000 0 \\ 0100000 0 \\ 0010\boxed{1}00\boxed{0} \\ 0001000 0 \\ 0000100 0 \\ 0000010 1 \\ 0000001 1 \\ 0000000 1 \end{pmatrix}.$$

Altogether, we obtain the following certificate for binary addition:

$$M(\text{bin_add}(A, B; S)) = M(P_3) \otimes M(P_2) \otimes M(P_1) = \begin{pmatrix} 1000000 0 \\ 0100000 0 \\ 1100000 1 \\ 0000000 0 \\ 0000000 0 \\ 0000000 \infty \\ 0000001 1 \\ 0000000 1 \end{pmatrix}.$$

BINARY MULTIPLICATION. This procedure uses $A, B, C,$ and tmp as aliases for $X_1, \dots, X_4.$

```

1: procedure BIN_MULT(A,B; C)
2:   nil(C);                                ▷ Initializes the result stack
3:   foreach B do
4:     push(0, C);                            ▷ Performs a shift-left of C
5:     if (top(B) ≡ 1) then
6:       bin_add(A, C; tmp);
7:       C = tmp;
8:       nil(tmp);

```

To compute the certificate, let Q denote the loop body (lines 4–8). As binary addition is called as a subprogram, we can use the certificate obtained above, but suppressing local variables and mapping arguments A, C, tmp to the parameters A, B, S of bin_add , that is,

$$M(\text{bin_add}(A, C; \text{tmp})) = \begin{pmatrix} 10000 \\ 01000 \\ 00100 \\ 10101 \\ 00001 \end{pmatrix}.$$

First, for the certificate $Y := M(Q)$ of the loop body Q we obtain

$$Y = ((Z_{4,4,0} \otimes Z_{3,4,1} \otimes M(\text{bin_add}(A, C; \text{tmp}))) \sqcup 1_5) \otimes A_{3,5,1}.$$

To obtain $M(\text{foreach } B[Q])$, we need to compute \hat{Y}^* and Y^+ . Since $Y = \hat{Y}$, this simplifies the calculations of the limit forms:

$$Y = \begin{pmatrix} 1000 0 \\ 0100 0 \\ 1010 \infty \\ 0001 0 \\ 0000 1 \end{pmatrix} \quad \text{and} \quad Y^+ = \hat{Y}^* = \begin{pmatrix} 1 000 0 \\ 0 100 0 \\ \infty 010 \infty \\ 0 001 0 \\ 0 000 1 \end{pmatrix}.$$

As $\infty \notin \text{Diag}(\hat{Y}^*)$, Lemma 3.14 can be applied, yielding

$$M(\text{foreach } B [Q]) = \begin{pmatrix} 1 & 0 & 000 \\ 0 & 1 & 000 \\ \infty & \infty & 100 \\ 0 & 0 & 010 \\ 0 & 0 & 001 \end{pmatrix}. \text{ Thus, } M(\text{bin_mult}(A, B; C)) = \begin{pmatrix} 1 & 0 & 000 \\ 0 & 1 & 000 \\ \infty & \infty & 000 \\ 0 & 0 & 010 \\ 0 & 0 & 001 \end{pmatrix}.$$

BINARY EXPONENTIATION. This procedure, which on input n computes 2^n , uses A, B, aux , and tmp as aliases for X_1, \dots, X_4 .

```

1: procedure BIN_EXP(A; B)
2:   B = 1;                                ▷ Initializes the result stack
3:   aux = 10;                              ▷ Initializes the auxiliary stack
4:   foreach A do
5:     bin_mult(aux, B; tmp);
6:     B = tmp

```

Clearly, as `bin_exp` cannot run in polynomial time, the certification method must fail. Let Q denote the loop body (lines 5–6). As `bin_mult` is called as a subprogram, we can use the certificate obtained above, again suppressing local variables and mapping arguments $\text{aux}, B, \text{tmp}$ to the parameters A, B, C of `bin_mult`:

$$M(\text{bin_mult}(\text{aux}, B; \text{tmp})) = \begin{pmatrix} 1 & 0 & 0 & 00 \\ 0 & 1 & 0 & 00 \\ 0 & 0 & 1 & 00 \\ 0 & \infty & \infty & 00 \\ 0 & 0 & 0 & 01 \end{pmatrix} \text{ and } Y := M(Q) = \begin{pmatrix} 1 & 0 & 0 & 00 \\ 0 & \infty & \infty & 00 \\ 0 & 0 & 1 & 00 \\ 0 & \infty & \infty & 00 \\ 0 & 0 & 0 & 01 \end{pmatrix}.$$

As $\infty \in \text{Diag}(\hat{Y}^*)$, Lemma 3.14 is not applicable; hence the method correctly fails.

8.2. Insertion-sort. The previous examples demonstrate that our certification method appropriately processes size-increasing programs; the following certification of insertion-sort exemplifies that the method applies to nonsize-increasing programs, too. To our knowledge, no implicit description of `FPTIME` includes a natural implementation of insertion-sort—Leivant’s first-order tiered systems typically involve needing a second copy of the list to be sorted; Hofmann’s [14] nonsize-increasing “coin” types require higher-type functionals. By contrast, our implementation, modeled after [10, p. 8] stays in the realm of imperative programming, and in that way, some nontrivial headway has been made.

For simplicity, the `INSERTION_SORT` algorithm sorts arrays of natural numbers. Accordingly, we use the following two kinds of variables:

- Variables i, j, k, \dots of data type “`Nat`” store natural numbers, with logarithmic *size measure* $|i| := \lceil \log_2(n + 1) \rceil$ whenever n is stored in i .
- Variables A, \dots of data type “`array(Nat)`” store sequences (of length $\text{len}(A)$) of natural numbers, with logarithmic *size measure*

$$|A| := \text{len}(A) \cdot \max_{1 \leq i \leq \text{len}(A)} \{|n_i| + 1\}$$

whenever $(n_1, \dots, n_{\text{len}(A)})$ is stored in A .

The implementation of `INSERTION_SORT` uses the following admissible basic instructions (cf. Definition 5.2 for the notation of certificates), where i, j, A are aliases for

X_i, X_j, X_k :

<code>dec(i)</code>	decrements any $n > 0$ stored in i by 1	certificate: 1_{n+1} ,
<code>inc(i)</code>	increments any n stored in i by 1	certificate: $A_{i,n+1,1}$,
<code>i = c</code>	assigns any constant $c \geq 0$ to i	certificate: $Z_{i,n+1,F(c)}$,
<code>i = j</code>	assigns the storage of j to i	certificate: $Z_{i,j,1}$,
<code>i = ones(len(A))</code>	assigns $2^{\text{len}(A)} - 1$ to i	certificate: $Z_{i,k,1}$,
<code>i = len(A)</code>	assigns $\text{len}(A)$ to i	certificate: $Z_{i,k,1}$,
<code>A[i] = A[j]</code>	assigns $A[j]$ to $A[i]$, $1 \leq i, j \leq \text{len}(A)$	certificate: 1_{n+1} .

For the certificate of `i = ones(len(A))`, observe that $|2^{\text{len}(A)} - 1| = \text{len}(A) \leq |A|$.

The INSERTION_SORT algorithm sorts an array A of type `array(Nat)`. As $A[1]$ is sorted, in each round the algorithm inserts the current *key* $A[i+1]$ into the sorted array $A[1 \dots i]$ (cf. [10, p. 8]). In the absence of while statements in the given framework, a natural implementation could appear as shown below, where INSERTION_SORT(A) sorts $A[1 \dots n]$, using $A[n+1]$ to buffer the current key.

```

1: procedure INSERTION_SORT(A)
2:   len = len(A);
3:   rounds = ones(len(A));
4:   j = 2;                                ▷ Prepares the for loop starting with 2
5:   loop rounds
6:     if (j < len) then
7:       i = j;
8:       dec(i);                            ▷ Prepares the downto loop starting with  $j - 1$ 
9:       A[len] = A[j];                    ▷ Buffers the current key  $A[j]$ 
10:      loop rounds
11:        if (i > 0 and A[i] > A[len]) then
12:          i_tmp = i;
13:          inc(i_tmp);
14:          A[i_tmp] = A[i];              ▷ Shifts  $A[i]$  one component to the right
15:          i_tmp = 0;
16:          dec(i);                          ▷ Prepares the next round of the downto loop
17:          i_tmp = i;                        ▷ Treats the cases  $\text{key} < A[1]$  or  $A[i] \leq \text{key}$ 
18:          inc(i_tmp);
19:          A[i_tmp] = A[len];
20:          i_tmp = 0;
21:          inc(j)                            ▷ Prepares the next round of the for loop

```

In order to compute the certificate for this algorithm, we refer to the variables A , len , rounds , j , i , and i_tmp as X_1, \dots, X_6 , respectively, and to the following parts of the algorithm:

P_1 \equiv the body `if (j < len) then [P2;P3;P4]` of the outer loop,
 P_2 \equiv `i = j ; dec(i); A[len]=A[j]`,
 P_3 \equiv the inner loop with body P_5 ,
 P_4 \equiv lines 17–21,
 P_5 \equiv the body of the conditional `if (i > 0 and A[i] > A[len]) then [P6]`.

According to the method, we obtain the following certificates:

$$\begin{aligned} M(\mathbf{P}_6) &= 1_7 \otimes Z_{6,7,0} \otimes 1_7 \otimes A_{6,7,1} \otimes Z_{6,5,1} = Z_{6,7,0}, \\ M(\mathbf{P}_5) &= M(\mathbf{P}_6) \sqcup 1_7 = 1_7, \\ M(\mathbf{P}_4) &= A_{4,7,1} \otimes Z_{6,7,0} \otimes 1_7 \otimes A_{6,7,1} \otimes Z_{6,5,1} = A_{4,7,1} \otimes Z_{6,7,0}, \\ M(\mathbf{P}_3) &= 1_7. \end{aligned}$$

$$\begin{aligned} M(\mathbf{P}_2) &= 1_7 \otimes 1_7 \otimes Z_{5,4,1} = Z_{5,4,1}, \\ Y := M(\mathbf{P}_1) &= (M(\mathbf{P}_4) \otimes M(\mathbf{P}_3) \otimes M(\mathbf{P}_2)) \sqcup 1_7 = A_{4,7,1} \sqcup A_{5,4,1}, \\ \hat{Y}^* &= \bigsqcup_{i=1}^{\infty} (\hat{Y})^i = A_{4,7,\infty} \sqcup A_{5,7,\infty} \sqcup A_{5,4,\infty}. \end{aligned}$$

As $\infty \notin \text{Diag}(\hat{Y}^*)$, Lemma 3.14 yields $M(\text{loopI rounds } [\mathbf{P}_1]) = A_{4,3,1} \sqcup A_{5,3,\infty} \sqcup A_{5,4,\infty}$. Thus, we obtain $M(\text{INSERTION_SORT}) = (A_{4,3,1} \sqcup A_{5,3,\infty} \sqcup A_{5,4,\infty}) \otimes Z_{4,7,\infty} \otimes Z_{3,1,1} \otimes Z_{2,1,1}$.

9. Conclusion. We have presented a new method of certifying polynomial size boundedness for imperative programs under the natural assumption that the basic instructions are polynomially size bounded, too. Apart from that, there are no restrictions on the data structures involved. We proved that certified string programs exactly compute the FPTIME functions, certified general loop programs precisely compute the FLINSPACE functions, and finally, that certified power string programs exactly compute the FPSPACE functions. We also gave examples of certified “natural” implementations of algorithms such as insertion-sort. Altogether, this can be considered a major step towards applicability of research in the evolving field of implicit computational complexity to daily programming practice. It seems that the future will see further work in this area.

Acknowledgments. We would like to thank Martin Dietzfelbinger for both his precious comments and suggestions concerning the presentation of the material. Along these lines, we are also grateful to the referees for their thorough reports. Furthermore, we are greatly indebted to Jan Mehler for pointing out various misprints in the paper, and in particular for his contribution to the proof of Lemma 3.15.

FAST CONSTRUCTION OF NETS IN LOW-DIMENSIONAL METRICS AND THEIR APPLICATIONS*

SARIEL HAR-PELED[†] AND MANOR MENDEL[‡]

Abstract. We present a near linear time algorithm for constructing hierarchical nets in finite metric spaces with constant doubling dimension. This data-structure is then applied to obtain improved algorithms for the following problems: approximate nearest neighbor search, well-separated pair decomposition, spanner construction, compact representation scheme, doubling measure, and computation of the (approximate) Lipschitz constant of a function. In all cases, the running (pre-processing) time is near linear and the space being used is linear.

Key words. doubling dimension, nearest neighbor search, approximate distance oracle, quadtree, metric nets, doubling measure, distance labeling

1. Introduction. Given a data set, one frequently wants to manipulate it and quickly compute some properties of it. For example, one would like to cluster the data into similar clusters, or measure similarity of items in the data, etc. One possible way to do this is to define a distance function (i.e., metric) on the data items and perform the required task using this metric. Unfortunately, in general, the metric might be intrinsically complicated (“high-dimensional”), and various computational tasks on the data might require high time and space complexity. This is known in the literature as “the curse of dimensionality.”

One approach receiving considerable attention recently is that of defining a notion of dimension on a finite metric space and developing efficient algorithms for this case. An example of this approach is the notion of doubling dimension [2, 27, 23]. The *doubling constant* of metric space \mathcal{M} is the maximum, over all balls \mathbf{b} in the metric space \mathcal{M} , of the minimum number of balls needed to cover \mathbf{b} , using balls with half the radius of \mathbf{b} . The logarithm of the doubling constant is the *doubling dimension* of the space. The doubling dimension can be thought of as a generalization of the Euclidean dimension, as \mathbb{R}^d has $\Theta(d)$ doubling dimension. Furthermore, the doubling dimension extends the notion of growth restricted metrics of Karger and Ruhl [30].

Understanding the structure of such spaces (or similar notions) and how to manipulate them efficiently received considerable attention in the last few years [14, 30, 23, 28, 34, 33, 44].

The low doubling metric approach can be justified at the following two levels:

1. Arguably, non-Euclidean, low (doubling) dimensional metric data appear in practice and deserve an efficient algorithmic treatment. Even high-dimensional Euclidean data may have some low doubling dimension structure, which makes it amenable to this approach.

This view seems to be shared by many recent algorithmic papers on doubling metrics, but it still awaits convincing empirical and/or theoretical support.

2. Even if one is only interested in questions on Euclidean point sets, it makes sense to strip the techniques being used to their bare essentials, obtaining a better understanding of the problems and conceptually simpler solutions.

More arguments along these lines can be found in [14], where the author advocates this approach.

In general, it is impossible to directly apply algorithmic results developed for fixed dimensional Euclidean space to doubling metrics, since there exist doubling metrics that cannot be embedded in Hilbert space with low distortion of the distances [41, 35]. Hence, some of the aforementioned works apply notions and techniques from fixed dimensional computational geometry and extend them to finite metric spaces.

In particular, Talwar [44] showed that one can extend the notion of *well-separated pairs decomposition* (WSPD) of [11] to spaces with low doubling dimension. Specifically, he shows that for every set P of n points having doubling dimension \dim , and every $\varepsilon > 0$, there exists WSPD, with separation $1/\varepsilon$ and $O(n\varepsilon^{-O(\dim)} \log \Phi)$ pairs, where \dim is the doubling dimension of the finite metric space, and Φ is the *spread* of the point set, which is the ratio between the diameter of P and the distance between the closest pair of points in P . This is weaker than the result of Callahan and Kosaraju [11] for Euclidean space, which does not depend on the spread of the point set.

Krauthgamer and Lee [34] showed a data structure for answering $(1 + \varepsilon)$ -approximate nearest neighbor queries on point set P with spread Φ . Their data structure supports insertions in $O(\log \Phi \log \log \Phi)$ time. The preprocessing time is $O(n \log \Phi \log \log \Phi)$ (this is by inserting the points one by one), and the query time is $O(\log \Phi + \varepsilon^{-O(\dim)})$. In \mathbb{R}^d for fixed d , one can answer such queries in $O(\log \log(\Phi/\varepsilon))$ time, using near linear space; see [24] and references therein. (In fact, it is possible to achieve constant query time using slightly larger storage [26].) Note, however, that the latter results strongly use the Euclidean structure. Recently, Krauthgamer and Lee [33] overcame the restriction on the spread, presenting a data-structure with nearly quadratic space, and logarithmic query time.

Underlining all those results is the notion of hierarchical nets. Intuitively, hierarchical nets are sequences of larger and larger subsets of the underlining set P , such that in a given resolution, there is a subset in this sequence that represents well the structure of P in this resolution (a formal definition is given in section 2). Currently, the known algorithms for constructing those nets require running time which is quadratic in n .

An alternative way of constructing those nets is by the clustering algorithm of Gonzalez [20]. The algorithm of Gonzalez computes 2-approximate k -center clustering by repeatedly picking the point furthest away from the current set of centers. Setting $k = n$, this results in a permutation of the points in the metric space. It is easy to verify that, by taking different prefixes of this permutation, one gets hierarchical nets for the metric. However, the running time of Gonzalez's algorithm in this case is still quadratic. Although in fixed dimensional Euclidean space the algorithm of Gonzalez was improved to $O(n \log k)$ time by Feder and Greene [17], and to linear time by Har-Peled [25], those algorithms require specifying k in advance, they do not generate the permutation of the points, and as such they cannot be used in this case.

Our results. In this paper, we present for the aforementioned applications improved algorithms having near linear preprocessing time and linear space. We also remove the dependency on the spread. As such, we (almost) match the known results

in computational geometry for low-dimensional Euclidean spaces.

We assume that the input is given via a black box that can compute the distance between any two points in the metric space in constant time. Since the matrix of all $\binom{n}{2}$ distances has quadratic size, this means that in some sense our algorithms have sublinear running time. This is not entirely surprising since subquadratic time algorithms exist for those problems in fixed dimensional Euclidean space. Thus, our paper can be interpreted as further strengthening the perceived connection between finite spaces of low doubling dimensions and Euclidean space of low dimension. Furthermore, we believe that our algorithms for the well-separated pair decomposition and approximate nearest neighbor are slightly cleaner and simpler than the previous corresponding algorithms for the Euclidean case.

Net-tree. In section 3 we present a $2^{O(\dim)}n \log n$ expected time randomized algorithm for constructing the hierarchical nets data-structure, which we call a net-tree.

Approximate nearest neighbor (ANN). In section 4 we show a new data-structure for the $(1 + \varepsilon)$ -approximate nearest neighbor query. The expected preprocessing time is $2^{O(\dim)}n \log n$, the space used is $2^{O(\dim)}n$, and the query time is $2^{O(\dim)} \log n + \varepsilon^{-O(\dim)}$.

This query time is almost optimal in the oracle model since there are examples of point sets in which the query time is $2^{\Omega(\dim)} \log n$ [34], and examples in which the query time is $\varepsilon^{-\Omega(\dim)}$.¹

Our result also matches the results of Arya et al. [1] in Euclidean settings. Furthermore, our result improves upon the recent work of Krauthgamer and Lee, which either assumes bounded spread [34] or requires quadratic space [33]. The algorithms in [1, 34, 33] are deterministic, in contrast to ours.

WSPD. In section 5 we show that one can construct an ε^{-1} WSPD of P in near linear time. The number of pairs is $n\varepsilon^{-O(\dim)}$. The size of the WSPD is tight, as there are examples of metrics in which the size of the WSPD is $n\varepsilon^{-\Omega(\dim)}$. Our result improves upon Talwar’s work [44] and matches the results of Callahan and Kosaraju (the algorithms of both [11, 44] are deterministic, though).

Spanners. A t -spanner of a metric is a sparse weighted graph whose vertices are the metric’s points and in which the graph metric is a t -approximation to the original metric. Spanners were first defined and studied in [40]. Construction of $(1 + \varepsilon)$ -spanners for points in low-dimensional Euclidean space is considered in [31, 10]. Using Callahan’s technique [10], the WSPD construction also implies a near linear time construction of $(1 + \varepsilon)$ -spanners having linear number of edges for such metrics. Independently of our work, Chan et al. [12] show a construction of a $(1 + \varepsilon)$ -spanner for doubling metrics with a linear number of edges. Their construction is stronger in the sense that the degrees in their spanner graph are bounded by constant. However, they do not specify a bound on the running time of their construction.

Compact representation scheme (CRS). In section 6 we construct in near linear time a data-structure of linear size that can answer approximate distance queries between pairs of points in essentially constant time. CRSs were coined “approximate distance oracles” in [45]. Our result extends recent results of Gudmunsson et al. [21, 22], who showed the existence of CRSs with similar parameters for metrics that are “nearly” fixed dimensional Euclidean (and that are a subclass of fixed dou-

¹Consider the set \mathbb{Z}_m^n with the ℓ_∞ norm, where $m = \lceil \varepsilon^{-1}/2 \rceil$, $n = \lceil \dim \rceil$. Consider a query at point q satisfying $\exists x_0 \in \mathbb{Z}_m^n$ such that $d(q, x_0) = m - 1$, and for all $x \in \mathbb{Z}_m^n$, $x \neq x_0 \Rightarrow d(q, x) = m$. Since x_0 can be chosen in an adversarial way, any randomized $(1 + \varepsilon)$ -ANN query algorithm would have to make $\Omega(m^n)$ distance queries before hitting x_0 .

bling dimension metrics). We also mention in passing that our CRS technique can be applied to improve and unify two recent results [44, 43] on distance labeling.

Doubling measure. A doubling measure μ is a measure on the metric space with the property that for every $x \in P$ and $r > 0$, the ratio $\mu(\mathbf{b}(x, 2r))/\mu(\mathbf{b}(x, r))$ is bounded, where $\mathbf{b}(x, r) = \{y : d(x, y) \leq r\}$. Vol'berg and Konyagin [47] proved that for finite metrics (and in fact for complete metrics [36]) the existence of a doubling measure is quantitatively equivalent to the metric being doubling. This measure has found some recent algorithmic applications [43], and we anticipate more applications. Following the proof of Wu [48], we present in section 7 a near linear time algorithm for constructing a doubling measure.

Lipschitz constant of a mapping. In section 8 we study the problem of computing the Lipschitz constant of a mapping $f : P \rightarrow B$. In particular, we show how using WSPD makes it possible to approximate the Lipschitz constant of f in near linear time (in $|P|$) when P has a constant doubling dimension (and B is an arbitrary metric). We also obtain efficient exact algorithms, with near linear running time, for the case where P is a set of points in one- or two-dimensional Euclidean space.

Computing the doubling dimension. Although not stated explicitly in what follows, we assume in sections 2–8 that the doubling dimension of the given metric is either known a priori or given as part of the input. This assumption is removed in section 9, where we remark that a constant approximation of the doubling dimension of a given metric \mathcal{M} can be computed in $2^{O(\dim)} n \log n$ time. It is therefore possible to execute the algorithms of sections 2–8 with the same asymptotic running time, using the approximation of the doubling dimension. (In all the cases where the doubling dimension is needed, any upper bound on it will do, with accordingly degraded running time.)

Most of the algorithms in this paper are randomized. However, our use of randomness is confined to Lemma 2.4 (except for section 8.1). This means that the algorithms always return the desired result, with bounds on the *expected* running time. This also gives the same asymptotic bound with constant probability, using Markov inequality. Furthermore, in the ANN and CRS schema, randomness is used only in the preprocessing, and the query algorithms are deterministic. Lemma 2.4 can be easily derandomized in $O(n^2)$ time, thus giving $n^2 \text{polylog}(n)$ deterministic algorithms for all problems discussed here. We do not know whether a nontrivial derandomization is possible.

2. Preliminaries. Denote by \mathcal{M} a metric space and by P a finite subset $P \subset \mathcal{M}$. The *spread* of P , denoted by $\Phi(P)$, is the ratio of the diameter of P and the distance between the closest pair of points in P . For a point $p \in \mathcal{M}$ and a number $r \geq 0$, we denote by $\mathbf{b}(p, r) = \{q \in \mathcal{M} \mid d_{\mathcal{M}}(p, q) \leq r\}$ the ball of radius r around p . The *doubling constant* λ of P , defined as the minimum over $m \in \mathbb{N}$ such that every ball \mathbf{b} in P , can be covered by at most m balls of at most half the radius. The doubling dimension of the metric space is defined as $\log_2 \lambda$. A slight variation of the doubling constant is that any subset can be covered by λ' subsets of at most half the diameter. It is not hard to see that $\log_2 \lambda$ and $\log_2 \lambda'$ approximate each other up to a factor of 2. Since we will ignore constant factors in the dimension, these two definitions are interchangeable. It is clear that $\log_2 \lambda'(P) \leq \log_2 \lambda'(\mathcal{M})$, and thus the doubling dimension of P is “approximately” at most that of \mathcal{M} .

A basic fact about the λ doubling metric \mathcal{M} that will be used repeatedly is that if $P \subset \mathcal{M}$ has spread at most Φ , then $|P| \leq \lambda^{O(\log_2 \Phi)}$.

2.1. Hierarchy of nets. An r -net in a metric space \mathcal{M} is a subset $\mathcal{N} \subset \mathcal{M}$ of points such that $\sup_{x \in \mathcal{M}} d_{\mathcal{M}}(x, \mathcal{N}) \leq r$ and $\inf_{x, y \in \mathcal{N}; x \neq y} d_{\mathcal{M}}(x, y) \geq r/\alpha$ for some constant $\alpha \geq 1$. r -nets are useful “sparse” object that approximately capture the geometry of the metric space at scales larger than $3r$. In this paper we will rely heavily on the following notion of hierarchical nets.

DEFINITION 2.1 (net-tree). Let $P \subset \mathcal{M}$ be a finite subset. A net-tree of P is a tree T whose set of leaves is P . We denote by $P_v \subset P$ the set of leaves in the subtree rooted at a vertex $v \in T$. Associate with each vertex v a point $\text{rep}_v \in P_v$. Internal vertices have at least two children. Each vertex v has a level $\ell(v) \in \mathbb{Z} \cup \{-\infty\}$. The levels satisfy $\ell(v) < \ell(\bar{p}(v))$, where $\bar{p}(v)$ is the parent of v in T . The levels of the leaves are $-\infty$. Let τ be some large enough constant, say $\tau = 11$.

We require the following properties from T :

Covering property: For every vertex $v \in T$,

$$\mathbf{b}\left(\text{rep}_v, \frac{2\tau}{\tau-1} \cdot \tau^{\ell(v)}\right) \supset P_v.$$

Packing property: For every nonroot vertex $v \in T$,

$$\mathbf{b}\left(\text{rep}_v, \frac{\tau-5}{2(\tau-1)} \cdot \tau^{\ell(\bar{p}(v))-1}\right) \cap P \subset P_v.$$

Inheritance property: For every nonleaf vertex $u \in T$, there exists a child $v \in T$ of u such that $\text{rep}_u = \text{rep}_v$.

The net-tree can be thought of as a representation of nets from all scales in the following sense.

PROPOSITION 2.2. Given a net-tree, let

$$\mathcal{N}_C(l) = \{\text{rep}_u \mid \ell(u) < l \leq \ell(\bar{p}(u))\}.$$

Then the points in $\mathcal{N}_C(l)$ are pairwise $\tau^{l-1}/4$ separated; that is, for any $p, q \in \mathcal{N}_C(l)$, we have $d_{\mathcal{M}}(p, q) \geq \tau^{l-1}/4$. In addition, $P \subseteq \cup_{p \in \mathcal{N}_C(l)} \mathbf{b}(p, 4 \cdot \tau^l)$.

Proof. Let $p, q \in \mathcal{N}_C(l)$, and let u and v be the corresponding nodes in the net-tree, respectively. Consider the balls $\mathbf{b}_p = \mathbf{b}(p, r_p)$ and $\mathbf{b}_q = \mathbf{b}(q, r_q)$, where $r_p = \frac{\tau-5}{2(\tau-1)} \cdot \tau^{\ell(\bar{p}(u))-1}$ and $r_q = \frac{\tau-5}{2(\tau-1)} \cdot \tau^{\ell(\bar{p}(v))-1}$. The sets $\mathbf{b}_p \cap P$ and $\mathbf{b}_q \cap P$ are fully contained in P_u and P_v , respectively, by the definition of the net-tree. Since u and v are on different branches of the net-tree, P_u and P_v are disjoint. But then $d_{\mathcal{M}}(p, q) \geq \max\{r_p, r_q\} \geq \frac{\tau-5}{2(\tau-1)} \cdot \tau^{l-1} \geq \tau^{l-1}/4$ by the definition of $\mathcal{N}_C(l)$ and since $\tau = 11$.

Similarly, consider the set of nodes $V_C(l) = \{u \mid \ell(u) < l \leq \ell(\bar{p}(u))\}$ realizing $\mathcal{N}_C(l)$. For any $v \in V_C(l)$, we have $P_v \subseteq \mathbf{b}(\text{rep}_v, \frac{2\tau}{\tau-1} \cdot \tau^{\ell(v)}) \subseteq \mathbf{b}(\text{rep}_v, \frac{2\tau^l}{\tau-1}) \subseteq \mathbf{b}(\text{rep}_v, \tau^l)$ since $\tau \geq 3$. Thus, $P \subseteq \cup_{v \in V_C(l)} \mathbf{b}(\text{rep}_v, \tau^l) = \cup_{p \in \mathcal{N}_C(l)} \mathbf{b}(p, \tau^l)$, as required. \square

Although $\mathcal{N}_C(\cdot)$ are quantitatively weaker nets compared with the greedy approach,² they are stronger in the sense that the packing and the covering properties respect the hierarchical structure of the net-tree.

The packing and covering properties easily imply that each vertex has at most $\lambda^{O(1)}$ children. Net-trees are roughly equivalent to compressed quadtrees [1]. The

²We have made no attempt to optimize the ratio between the packing and covering radii, and the one reported here can be (substantially) improved. However, some degradation in this ratio seems to be unavoidable.

net-tree is also similar to the sb data-structure of Clarkson [15], but our analysis and guaranteed performance are new.

2.2. The computational model. The model of computation we use is the “unit cost floating-point word RAM model.” More precisely, for a given input consisting of $\text{poly}(n)$ real numbers at the range $[-\Phi, -\Phi^{-1}] \cup [\Phi^{-1}, \Phi]$, and given an accuracy parameter $t \in \mathbb{N}$, the RAM machine has words of length $O(\log n + \log \log \Phi + t)$. These words can accommodate floating-point numbers from the set

$$\left\{ \pm(1+x)2^y \mid x \in [0, 1], x2^{-t} \in \mathbb{N}, y \in [-n^{O(1)} \log^{O(1)} \Phi, n^{O(1)} \log^{O(1)} \Phi] \cap \mathbb{Z} \right\}$$

and integers from the set $\{-(2^t n \log \Phi)^{O(1)}, \dots, 0, \dots, (2^t n \log \Phi)^{O(1)}\}$. For simplicity, we assume that the input given in this way is *exact*. All the problems discussed in this paper have an accuracy parameter of $\varepsilon > 0$. We assume that $\varepsilon^{O(1)} > 2^{-t}$ to avoid rounding problems. The space used by an algorithm (or a scheme) is the number of *words* being used. The machine allows arithmetic, floor, ceiling, conversion from integer to floating point, logarithm, and exponent operations in unit time. We further assume that the machine is equipped with a random number generator.

Floating-point computation is a very well studied topic; see [32, Chap. 4] and references therein. However, we were unable to trace a citation that explicitly defines an asymptotic floating-point computational model. We choose this model for the following two related reasons:

1. The algorithms in this paper are supposed to output only an approximate solution. Therefore it makes sense to try to use approximate numbers since they use less resources.
2. An important theme in this paper is developing algorithms that are independent of the spread of the given metrics. Most algorithms that have an explicit dependence on the spread in their time or space complexity have some form of $\text{polylog}(\Phi)$ dependence. An algorithm that has no dependence on the spread Φ , but relies on words of length $O(\log \Phi)$, may be considered suspicious at best.

Having stated these reasons, for the most part in what follows we will ignore numerical and accuracy issues in our algorithms. The algorithms are simple enough that it is evidently clear that no numerical stability issues arise. A notable exception is Assouad’s embedding discussed in section 6.2. There we have to explicitly add another ingredient (Lemma 6.7) to the algorithm in order to adapt it to the floating-point word RAM model. Indeed, that section is the catalyst for the current discussion.

2.3. Finding a separating ring. We next present a simple argument that helps to overcome the dependence on the spread in the running time.

PROPOSITION 2.3. *Denote by $r_{\text{opt}}(P, m)$ the radius of the smallest ball in P (whose center is also in P) containing m points. Then in a metric space with doubling constant λ , any ball of radius $2r$, where $r \leq 2r_{\text{opt}}(P, m)$, contains at most $\lambda^2 m$ points.*

Proof. By the doubling property, the ball of radius $2r$ can be covered by λ^2 balls of radius $r_{\text{opt}}(P, m)$. Each such ball contains at most m points. \square

LEMMA 2.4. *Given an n -point metric space P with doubling constant λ , one can compute a ball $\mathbf{b} = \mathbf{b}(p, r)$, such that \mathbf{b} contains at least $m = n/(2\lambda^3)$ points of P , and $\mathbf{b}(p, 2r)$ contains at most $n/2$ points of P . The expected running time of this algorithm is $O(\lambda^3 n)$.*

Proof. Pick randomly a point p from P , and compute the ball $\mathbf{b}(p, r)$ of smallest radius around p containing at least $n/(2\lambda^3)$ points. Next, consider the ball of radius

$\mathbf{b}(p, 2r)$. If it contains $\leq n/2$ points, we are done. Otherwise, we repeat this procedure until we succeed.
