To see why this algorithm succeeds with constant probability in each iteration, consider the smallest ball $Q = P \cap \mathbf{b}(q, r_{\text{opt}})$ that contains at least m points of P . Observe that any ball of radius $r_{\text{opt}}/2$ contain less than m points. With probability $1/(2\lambda^3)$ our sample is from Q . If $p \in Q$, then $r \leq 2r_{\text{opt}}$, and by the doubling property the ball $\mathbf{b}(p, 4r_{\text{opt}})$ can be covered by at most λ^3 balls of radius $r_{\text{opt}}/2$. Hence it holds that $|P \cap \mathbf{b}(p, 2r)| < \lambda^3 m \leq n/2$.

Thus, the algorithm succeeds with probability $1/(2\lambda^3)$ in each iteration, and with probability $\geq 1/3$ after $2\lambda^3$ iterations, implying the result, as each iteration takes $O(n)$ time. \square

Lemma 2.4 enables us to find a sparse ring of radius “not much larger” than its width. For example, by using it we can find an empty ring of width h and radius at most $2nh$ in linear time.

3. Computing nets efficiently.

In this section we prove the following theorem.
THEOREM 3.1. *Given a set P of n points in \mathcal{M} , one can construct a net-tree for P in $2^{O(\dim)} n \log n$ expected time.*

The outline of the proof is as follows. In section 3.1 we show how to construct the Gonzalez sequence in $2^{O(\dim)} n \log(n + \Phi)$ time. We then eliminate the dependence of the running time on the spread Φ in section 3.3 by using a tool developed in section 3.2. In section 3.4 we conclude the proof of Theorem 3.1 by showing how to construct the net-tree from the Gonzalez sequence. We end by mentioning in section 3.5 a few data structures for efficient searching on the net-tree.

3.1. Computing greedy clustering quickly. Gonzalez [20] presented a greedy algorithm, denoted by **GreedyCluster**, that when applied to a set of points P computes a permutation of the points $\Pi = \langle p_1, p_2, \dots, p_m \rangle$, such that p_1, \dots, p_k are good centers for P , for any $k \geq 1$. We refer to Π as the *greedy permutation* of P . Formally, there are numbers r_1, \dots, r_n , such that $P \subseteq \cup_{i=1}^k \mathbf{b}(p_i, r_k)$. Furthermore, $\min_{1 \leq i < j \leq k} d_{\mathcal{M}}(p_i, p_j) = r_{k-1}$.

GreedyCluster works by picking an arbitrary point in P to be p_1 and setting r_1 to be the distance of the furthest point in P to p_1 . For every point $q \in P$, **GreedyCluster** stores its distance to the closest center picked so far; namely, in the beginning of the k th iteration, for all $q \in P$ we have $\alpha_q^k = \min_{i=1}^{k-1} d_{\mathcal{M}}(q, p_i)$. The algorithm sets the k th center to be $p_k = \arg \max_{p \in P} \alpha_p^k$ (namely, p_k is the point in P furthest away from the centers picked so far). Clearly, $r_{k-1} = \alpha_{p_k}^k$. By implementing this naively, one can compute the first k points p_1, \dots, p_k in $O(nk)$ time. Thus, this leads to a 2-approximation to k -center clustering in $O(nk)$ time.

Feder and Greene [17] improved the running time to $O(n \log k)$ time (this was further improved to linear time by Har-Peled [25]). Feder and Greene’s main observation was that when updating α_q^{k+1} , one needs to update this value only for points of P , which are in distance $\leq r_{k-1}$ away from p_k , since for points q further away, the addition of p_k cannot change α_q^k .

This suggests the following natural approach for computing the greedy permutation: Associate with each center in $\{p_1, \dots, p_k\}$ the points of P that it serves (namely, points that are closer to the given center than to any other center). Furthermore, each center p_i maintains a *friends list* that contains all the centers that are a distance of at most $4r_k$ from it. An “old” center will trim a point from its friends list only when its distance is larger than $8r_k$. Specifically, the friends list of p_i at the k th iteration

($k \geq i$) contains all the centers at a distance of at most $\min\{8r_k, 4r_i\}$ from p_i . Because of the constant doubling dimension property, this list is of size $\lambda^{O(1)}$.

We further maintain a max-heap in which every center p_i , $i < k$, maintains the point p'_i furthest away from p_i in its cluster along with its current $\alpha_{p'_i} = d_{\mathcal{M}}(p_i, p'_i)$ value.

At the k th iteration, the algorithm extracts the maximum value from the heap. It sets p_k to be the corresponding point. Denote by c_{p_k} the closest point among $\{p_1, \dots, p_{k-1}\}$ to p_k (i.e., the cluster's center of p_k at the end of the $(k-1)$ th round). Next, the algorithm scans all the points currently served by the same cluster as c_{p_k} , or by clusters containing points from friends list of c_{p_k} , and updates the α value of those points. Furthermore, it moves all the relevant points to the newly formed cluster. In the process, it also update the points p'_i (of maximum distance from p_i in its cluster) for all p_i in the friends list of c_{p_k} . It also computes the friends list of p_k (how exactly this is done will be described in detail shortly).

We next bound the running time. To this end, a phase starting at the i th iteration of the algorithm terminates at the first $j > i$ such that $r_{j-1} \leq r_{i-1}/2$. A ball of radius $4r_{j-1}$ around each point $q \in P$ contains at most λ^3 points of p_1, \dots, p_j , and as such every point of P is being scanned at most λ^3 times at each phase of the algorithm. Thus, if the spread of the point set is Φ , the number of phases is $O(\log \Phi)$, and scanning takes $\lambda^{O(1)}n \log \Phi$ time overall. Maintaining the max-heap costs an additional $\lambda^{O(1)}n \log n$ time, since in each iteration only $\lambda^{O(1)}$ values in the head are changed.

The only remaining hurdle is the computation of the friends list of a newly formed center p_k . This can be done by maintaining, for every point p_l , $l \in \{1, \dots, n\}$, the serving center $p_{l'}$ two phases ago (at the end of that phase). The friends list of p_k is constructed by scanning the friends list of $p_{k'}$ and picking those points that are at distance at most $4r_k$ from p_k . This costs $\lambda^{O(1)}$ time for p_k and $O(\lambda^{O(1)}n)$ time overall. To see that this search suffices, note that the set $\{p_i | i < k, d_{\mathcal{M}}(p_i, p_k) \leq 4r_k\}$ is scanned. Indeed, fix p_{i_0} , having $i_0 < k$, and $d_{\mathcal{M}}(p_{i_0}, p_k) \leq 4r_k$. Let $p_{k'}$ be the center of p_k two phases ago. From the definition, $2r_k \leq r_{k'} \leq 4r_k$, and thus $d_{\mathcal{M}}(p_k, p_{k'}) \leq 4r_k$. The current (at the end of the $(k-1)$ th iteration) friends list of $p_{k'}$ contains all the current centers at a distance of at most $\min\{8r_k, 4r_{k'}\} = 8r_k$ from $p_{k'}$. Furthermore,

$$d_{\mathcal{M}}(p_{i_0}, p_{k'}) \leq d_{\mathcal{M}}(p_{i_0}, p_k) + d_{\mathcal{M}}(p_k, p_{k'}) \leq 8r_k.$$

We are therefore guaranteed that p_{i_0} will be scanned.

Of course, as the algorithm progresses it needs to remove nonrelevant elements from the friends list as the current clustering radius r_i shrinks. However, this can be done in a lazy fashion whenever the algorithm scans such a list.

THEOREM 3.2. *Let P be an n -point metric space with doubling constant λ and spread Φ . Then the greedy permutation for P can be computed in $O(\lambda^{O(1)}n \log(\Phi n))$ time and $O(\lambda^{O(1)}n)$ space.*

3.2. Low quality approximation by HST. Here we present an auxiliary tool that will be used in section 3.3 to extend the net-tree construction of section 3.1 to metric spaces with large spread.

We will use the following special type of metric spaces.

DEFINITION 3.3. *A hierarchically well-separated tree (HST) is a metric space defined on the leaves of a rooted tree T . Associated with each vertex $u \in T$ is a label $\Delta_u \geq 0$ such that $\Delta_u = 0$ if and only if u is a leaf of T . The labels are such that if a vertex u is a child of a vertex v , then $\Delta_u \leq \Delta_v$. The distance between two leaves x*

and y of T is defined as $\Delta_{lca(x,y)}$, where $lca(x,y)$ is the least common ancestor of x and y in T .

The class of HSTs coincides with the class of finite ultrametrics. For convenience, we will assume that the underlying tree is binary (any HST can be converted into a binary HST in linear time, while retaining the underlying metric). We will also associate with every vertex $u \in T$ an arbitrary leaf rep_u of the subtree rooted at u . We also require that $\text{rep}_u \in \{\text{rep}_v \mid v \text{ is a child of } u\}$.

A metric N is called a t -approximation of the metric \mathcal{M} if N and \mathcal{M} are defined on the same set of points and $\forall u, v \in \mathcal{M}, d_{\mathcal{M}}(u, v) \leq d_N(u, v) \leq t \cdot d_{\mathcal{M}}(u, v)$.

It is not hard to see that any n -point metric is $(n - 1)$ -approximated by some HST (see, e.g., Lemma 3.6). Here we show the following.

LEMMA 3.4. *For an n -point metric space \mathcal{M} with doubling constant λ , it is possible to construct in $O(\lambda^6 n \log n)$ expected time an HST which is a $3n^2$ approximation of \mathcal{M} .*

This low quality HST will help us later in eliminating the dependence on the spread of the construction time of the net-tree and in distance queries.

We begin proving Lemma 3.4 by constructing a sparse graph that approximates the original metric (this is sometimes called a *spanner*).

LEMMA 3.5. *Given an n -point metric space P with doubling constant λ , one can compute a weighted graph G that $3n$ -approximates P in $O(\lambda^6 n \log n)$ expected time. The graph G contains $O(\lambda^3 n \log n)$ edges.*

Proof. The construction is recursive. If $n = O(1)$, we just add all the pairs from P as edges. Otherwise, we compute, using Lemma 2.4, a ball $\mathbf{b}(c, r)$ containing at least $m = n/(2\lambda^3)$ points of P with the additional property that $\mathbf{b}(c, 2r)$ contains at most $n/2$ points of P .

As such, there exists two numbers r', h such that $r \leq r' \leq 2r$, $h \geq r/n$, and $P \cap \mathbf{b}(c, r') = P \cap \mathbf{b}(c, r' + h)$ (namely, the ring with outer radius $r' + h$ and inner radius r' around c is empty of points of P). Computing r' and h is done by computing the distance of each point from c and partitioning the distance range $[r, 2r]$ into $2n$ segments of equal length. In each segment, we register the point with minimum and maximum distance from c in this range. This can be easily done in $O(n)$ time using the floor function. Next, scan those buckets from left to right. Clearly, the maximum length gap is realized by a maximum of one bucket together with a consecutive nonempty minimum of another bucket. Thus, the maximum length interval can be computed in linear time, and it yields r and h .

Let $P_{\text{in}} = \mathbf{b}(c, r') \cap P$ and let $P_{\text{out}} = P \setminus P_{\text{in}}$. Observe that $d_{\mathcal{M}}(P_{\text{in}}, P_{\text{out}}) = \min_{p \in P_{\text{in}}, q \in P_{\text{out}}} d_{\mathcal{M}}(p, q) \geq h \geq r/n$. Next, we build recursively a spanner for P_{in} and a spanner for P_{out} . We then add the edges between c and all the points of P to the spanner. Let G denote the resulting graph.

Since there are $n/2 \geq |P_{\text{in}}| \geq n/2\lambda^3$ points of P , the running time of the algorithm is $T(|P|) = T(|P_{\text{in}}|) + T(|P_{\text{out}}|) + O(\lambda^3 n) = O(\lambda^6 n \log n)$. Similarly, the number of edges in G is $O(\lambda^3 n \log n)$.

Remaining is the task of proving that G provides a $3n$ -approximation to the distances of P . Let G_{in} and G_{out} be the graphs computed for P_{in} and P_{out} , respectively. Consider any two points $u, v \in P$. If u and v are both in P_{in} or both in P_{out} , then the claim follows by induction. Thus, consider the case that $u \in P_{\text{in}}$ and $v \in P_{\text{out}}$. Observe that $d_{\mathcal{M}}(u, v) \geq h \geq r/n$. On the other hand,

$$\begin{aligned} r/n \leq d_{\mathcal{M}}(u, v) &\leq d_G(u, v) \leq d_{\mathcal{M}}(c, u) + d_{\mathcal{M}}(c, v) \\ &\leq r + r + d_{\mathcal{M}}(u, v) \leq (2n + 1)d_{\mathcal{M}}(u, v), \end{aligned}$$

since $d_{\mathcal{M}}(c, v) \leq d_{\mathcal{M}}(c, u) + d_{\mathcal{M}}(u, v) \leq r + d_{\mathcal{M}}(u, v)$. Clearly, this implies that $d_G(u, v) \leq 3nd_{\mathcal{M}}(u, v)$, as claimed. \square

We will later obtain in Theorem 5.3 a near linear time construction of spanners that $(1 + \varepsilon)$ -approximate the original metric and have a linear number of edges.

LEMMA 3.6. *Given a weighted connected graph G on n vertices and m edges, it is possible to construct in $O(n \log n + m)$ time an HST H that $(n - 1)$ -approximates the shortest path metric on G .*

Proof. Compute the minimum spanning tree of G in $O(n \log n + m)$ time, and let T denote this tree.

Sort the edges of T in nondecreasing order, and add them to the graph one by one. The HST is built from the bottom up. At each point we have a collection of HSTs, each of which corresponds to a connected component of the current graph. When an added edge merges two connected components, we merge the two corresponding HSTs into one by adding a new common root for the two HSTs and labeling this root with the edge’s weight times $n - 1$. This algorithm is only a slight variation on the Kruskal algorithm and has the same running time.

We next estimate the approximation factor. Let x and y be two vertices of G . Denote by e the first edge that was added in the process above that made x and y to be in the same connected component C . Note that at that point in time, e is the heaviest edge in C , so $w(e) \leq d_G(x, y) \leq (|C| - 1)w(e) \leq (n - 1)w(e)$. Since $d_H(x, y) = (n - 1)w(e)$, we are done. \square

The proof of Lemma 3.4 now follows by applying Lemma 3.6 on the spanner from Lemma 3.5.

Note that by applying Lemma 3.6 on the spanner from Theorem 5.3, one can obtain a near linear time construction of an HST which $O(n)$ -approximates that original metric.

3.3. Extending greedy clustering to metrics of large spread. The main idea in removing the dependence of the running time on the spread is to apply the algorithm of section 3.1 to a *dynamic* set of points that will correspond to a level of the HST. In more detail, the set of points will correspond to the representatives rep_v , where $\Delta_v \leq r_{\text{curr}}/n^4 \leq \Delta_{\bar{p}(v)}$, where r_{curr} is the current greedy radius, Δ_v is the HST label of v (i.e., the diameter of the subtree rooted at v), and $\bar{p}(v)$ is the parent of v in the HST. The algorithm now needs to handle another type of event since, as the algorithm proceeds, the greedy radius decreases to a level in which $\Delta_v \geq r_{\text{curr}}/n^4$. In this case, v should be replaced with its two children u, w . Specifically, if v belongs to a cluster of a point p_i , we remove rep_v from the list of points associated with the cluster of p_i and add rep_u and rep_w to this list (the case where p_i is equal to rep_v is handled in a similar fashion). Next, we need to compute for the new point its nearest center; namely, compute α_{rep_u} and α_{rep_w} (in fact, since $\text{rep}_v = \text{rep}_u$ or $\text{rep}_v = \text{rep}_w$, we need to compute only one of those values). To this end, we scan the friends list of p_i and compute α_{rep_u} and α_{rep_w} from it. This takes $\lambda^{O(1)}$ time. We also need to insert $\{\text{rep}_u, \text{rep}_w\} \setminus \{\text{rep}_v\}$ into the max-heap.

Thus, the algorithm has two heaps. One is a max-heap maintaining the points according to their distances to the nearest center; that is, for every point $p \in P$ we maintain the values of α_p in a max-heap. The second max-heap maintains the nodes of the HST sorted by their diameters Δ (multiplied by a factor of n^4 for normalization). At every point, the algorithm extracts the larger of two heaps and handles it accordingly. One important technicality is that the algorithm is no longer generating the same permutation as **GreedyCluster**, since we are not always picking the furthest

point to add as the next center. Rather, we add the furthest active point. We refer to the new algorithm as **NetPermutAlg**.

LEMMA 3.7. *Let $\pi = \langle p_1, \dots, p_n \rangle$ be the permutation of P generated by **NetPermutAlg**. Furthermore, let $r_k = \alpha_{p_{k+1}}^{k+1} = \min_{i=1}^k d_{\mathcal{M}}(q, p_i)$. Then, $P \subseteq \cup_{i=1}^k \mathbf{b}(p_i, (1 + n^{-2})r_k)$ and for any $u, v \in \{p_1, \dots, p_k\}$ we have $d_{\mathcal{M}}(u, v) \geq (1 - n^{-2})r_k$.*

Proof. Clearly, the balls of radius r_k around p_1, \dots, p_k cover all the active points when p_{k+1} was created. However, every active point might represent points which are a distance of r_k/n^2 from it. Thus, by expanding the radius by $(1 + 1/n^2)$, those balls cover all the points.

Observe, that this implies that for any $i < j$ we have $(1 + n^{-2})r_i \geq r_j$. In particular, let $\alpha \leq k$ be the minimum number such that $u, v \in \{p_1, \dots, p_\alpha\}$. Clearly, $d_{\mathcal{M}}(u, v) \geq r_{\alpha-1} \geq r_\alpha/(1 + n^{-2}) \geq (1 - n^{-2})r_\alpha$. \square

LEMMA 3.8. *The expected running time of **NetPermutAlg** is $O(\lambda^{O(1)}n \log n)$.*

Proof. Constructing the HST takes $\lambda^{O(1)}n \log n$ expected time, using Lemma 3.4. As in the bounded spread case, we conceptually divide the execution of the algorithm into phases. In the i th phase, the algorithm handles new clusters with radii in the ranges $\text{diam}(P)/2^{i-1}$ and $\text{diam}(P)/2^i$. Consider a point $p \in P$: It is inserted into the point-set when a node v in the HST is “split” at phase i (since p is the representative point for one of the children of v). Let p and q be the two representative points of the two children of v . We charge v for any work done with p and q for the next $L = 10 \log n$ phases. Consider any work done on p before it undergoes another split event. If p is at most L phases away from the split event of v , the vertex v pays for it.

Otherwise, consider p at $> L$ phases away from its latest split event that happened at v . Let r_{curr} be the current clustering radius, and observe that p represents a set of points which has a diameter $\leq r_{\text{curr}}/n^2$ and that $r_{\text{curr}} \leq \Delta_v/n^{10}$. In particular, this implies that $P \cap \mathbf{b}(p, r_{\text{curr}} \cdot n^2) \subset P \cap \mathbf{b}(p, \Delta_v/n^4) \subset P \cap \mathbf{b}(p, r_{\text{curr}}/n^2)$. Namely, all the points that p represents are very far from the rest of the points of P , in terms of r_{curr} . In particular, it cannot be that the cluster that p represents is in any updated friends list in the current stage. (It can be in a friends list that was not updated lately, since we use lazy evaluation. However, when this friends list is used, it will be updated and p will disappear from it. Note that the work required to update the friends lists is $\lambda^{O(1)}n$ overall; see section 3.1.) Thus, p does not require any work from the algorithm until it undergoes another split event.

Thus, every node in the HST is charged with $\lambda^{O(1)} \log n$ work. It follows that the overall running time of the algorithm is $\lambda^{O(1)}n \log n$. \square

3.4. Constructing the net-tree. In this section we conclude the description of the algorithm for constructing the net-tree and prove Theorem 3.1.

The construction of the net-tree T is done by adding the points of P according to the permutation of **NetPermutAlg**. As mentioned before, the construction algorithm and the resulting tree are similar to the data-structure of Clarkson [15] (our analysis and the guaranteed performance are new, however). The tree constructed for p_1, \dots, p_k is denoted by $T^{(k)}$ and $T = T^{(n)}$. We obtain $T^{(k)}$ from $T^{(k-1)}$ as follows.

During the construction, we maintain for every vertex $u \in T^{(k)}$ a set of “close by” vertices $\text{Rel}(u)$. Namely, the set $\text{Rel}(u)$ would be in fact the set

$$\overline{\text{Rel}}(u) = \left\{ v \in T^{(k)} \mid \ell(v) \leq \ell(u) < \ell(\overline{p}(v)), \text{ and } d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v) \leq 13 \cdot \tau^{\ell(u)} \right\},$$

where τ is the packing constant associated with the net-tree; see Definition 2.1. (Since we compute $\text{Rel}(u)$ indirectly, the fact that $\text{Rel}(u) = \overline{\text{Rel}}(u)$ requires a formal proof;

see Lemma 3.9(v).) The set $\text{Rel}(u)$ is of size $\lambda^{O(1)}$ throughout the algorithm's execution.

We denote $\bar{r}_i = \min \{r_j \mid 1 \leq j \leq i\}$.

The algorithm. The k th point in the permutation, p_k , will be added as a leaf to the tree $T^{(k-1)}$ to form the tree $T^{(k)}$. As such, we fix $\ell(p_k) = -\infty$ and $\text{rep}_{p_k} = p_k$. Let $l = \lceil \log_\tau \bar{r}_{k-1} \rceil$.

Let h be the largest index such that $\log_\tau \bar{r}_{h-1} > l$ (i.e., p_h is the last added center in the previous phase). Let $q \in \{p_1, \dots, p_h\}$ be the closest point to p_k among $\{p_1, \dots, p_h\}$; namely, q is the nearest neighbor to p_k in all the centers present in the previous phase. Identifying q with the unique leaf of $T^{(k-1)}$ whose representative is q , let $u = \bar{p}(q)$. We obtain $T^{(k)}$ as follows:

- (a) If $\ell(u) > l$, then we make a new vertex v and set $\ell(v) = l$ and $\text{rep}_v = q$. We then connect q and p_k as children of v and make v a child of u .
- (b) Otherwise, connect p_k as another child of u .

Finding q . Let c_{p_k} be the closest point among $\{p_1, \dots, p_{k-1}\}$ to p_k (this information is computed by `NetPermutAlg`; see section 3.1 for details). Denote $\hat{u} = \bar{p}(c_{p_k})$. We consider the following two cases:

- (1) If $\ell(\hat{u}) > l$, then $q = \hat{u}$; see Lemma 3.9(i) for a proof.
- (2) Otherwise, $\ell(\hat{u}) = l$. In this case, q must be in the set $\{\text{rep}_w \mid w \in \text{Rel}(\hat{u})\}$; see Lemma 3.9(i) for a proof. Thus, we just pick q to be the nearest neighbor to p_k in $\{\text{rep}_w \mid w \in \text{Rel}(\hat{u})\}$.

Updating $\text{Rel}(\cdot)$. For each new vertex x added we do the following. Let $y = \bar{p}(x)$. For each $z \in \text{Rel}(y)$, and for each child z' of z , we traverse *part* of the tree rooted at z' in the following way: When visiting a vertex u , we check whether u should be added to $\text{Rel}(x)$ and whether x should be added to $\text{Rel}(u)$ according to the $\overline{\text{Rel}}(\cdot)$ definition, and update $\text{Rel}(x)$ and $\text{Rel}(u)$ accordingly. If x has been added to $\text{Rel}(u)$, then we continue by traversing the children of u . Otherwise, we skip them.

Note that this might require scanning a large fraction of the net-tree, as x might appear in a large number of $\text{Rel}()$ lists.

LEMMA 3.9. *For any $k \in [1, \dots, n]$, the tree $T^{(k)}$ has the following properties:*

- (i) *The part of the algorithm that finds q indeed finds it.*
- (ii) *If v is a child of u , then $d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v) \leq 2 \cdot \tau^{\ell(u)}$.*
- (iii) *For every $t \in \mathfrak{R}$, every pair of points in $\mathcal{N}_C(t)$ is at least τ^{t-1} far apart.*
- (iv) *$T^{(k)}$ is a net-tree of $\{p_1, \dots, p_k\}$.*
- (v) *For any $u \in T$, $\text{Rel}(u) = \overline{\text{Rel}}(u)$.*

Since the proof of Lemma 3.9 is tedious, we defer it to the appendix. We next analyze the running time.

LEMMA 3.10. *Given the (approximate) greedy permutation $\langle p_1, \dots, p_n \rangle$ with its "current" cluster's center $\langle c_{p_2}, \dots, c_{p_n} \rangle$, the algorithm for constructing the net-tree runs in $\lambda^{O(1)}n$ time.*

Proof. By the definition of $\text{Rel}(\cdot)$, the size of each such list is at most $\lambda^{O(1)}$. Assuming the tree is implemented reasonably (with pointers from a vertex to its children and parent), constructing the tree clearly takes $O(\lambda^{O(1)})$ time per new point.

Next we estimate the time to construct $\text{Rel}(\cdot)$. For each vertex x added, we first charge $\lambda^{O(1)}$ visits for visiting the children of $\text{Rel}(\bar{p}(x))$. All the other visits are charged to the parent of the visited vertex. Each vertex has at most $\lambda^{O(1)}$ children, and its children are visited only if a new entry was inserted into its $\text{Rel}()$. As the total size of the $\text{Rel}(\cdot)$ lists is at most $\lambda^{O(1)}n$, we have just bounded the number of visits of vertices during the update process of $\text{Rel}(\cdot)$ to $\lambda^{O(1)}n$. Thus the time spent is $\lambda^{O(1)}n$. \square

3.5. Augmenting the net-tree. In order to efficiently search on the net-tree, we will need the following three auxiliary data structures.

The first one, given a vertex v of level l , allows us to find all the vertices of “roughly the same level” that are nearby, i.e., those with a representative at a distance of at most $O(\tau^l)$ from the representative of v . More accurately, we need fast access to $\overline{\text{Rel}}(v)$, as defined in section 3.4. We have seen in that section how to construct it in near linear time such that the whole list can be accessed in $O(\lambda^4)$ time.

The second data-structure enables the following seek operation: Given a leaf x and a level l , find the ancestor y of x such that $\ell(\overline{p}(y)) > l \geq \ell(y)$. Bender and Farach-Colton [5] present a data-structure \mathcal{D} that can be constructed in linear time over a tree T such that, given a node x and depth d , it outputs the ancestor of x at depth d at x . This takes constant time per query. Thus, performing the seek operation just requires performing a binary search using \mathcal{D} over the net-tree, and this takes $O(\log n)$ time.

Our third data-structure supports a restricted version of the above seek operation: Given a leaf x , an ancestor z of x , and a level l : If $l \notin [\ell(z) - c \log n, \ell(z)]$, return “don’t know.” Otherwise, return an ancestor y of x satisfying $\ell(\overline{p}(y)) > l \geq \ell(y)$ (here $c > 0$ is an absolute constant). The data-structure has $O(n)$ space and $O(n \log n)$ preprocessing time, and the queries can be answered in *constant time*.

As a first step, observe that if for every internal vertex z and a descendant leaf x we add vertices to the tree so as to fill all levels between $\ell(z)$ and $\ell(x) - c \log n$ on the path between z and x , then queries to the l level ancestor, $l \in [\ell(x) - c \log n, \ell(z)]$, can be answered by using the data-structure \mathcal{D} as above to find an ancestor of x at depth $\overline{d}(z) - (\ell(z) - l)$. This construction, however, may blow up the number of vertices in the net-tree (and hence the space) by a $\log n$ factor.

To obtain linear space we do the following: In the preprocessing step we enumerate all the possible patterns of existence/nonexistence of vertices in $0.5 \log_2 n$ consecutive levels. For each given pattern and each given level in the pattern, we write the number of actual vertices above this level. Preparing this enumeration takes only $O(\sqrt{n} \log n)$ time. Now, for each vertex u of the net-tree, we hold $2c$ pointers to such patterns that together map the vertices in the $c \log n$ level below v on the path to u , where v is an ancestor of u at depth $\overline{d}(u) - c \log n$, if such v exists (note that v is $c \log n$ edges above u in the net-tree, but u holds the pattern of only the first $c \log n$ levels below v). This data-structure can be clearly computed in $O(n \log n)$ time using top-down dynamic programming on the net-tree.

Given a query (with x , z , and l as above), we do as follows: Let u be an ancestor of x at depth $\max\{\overline{d}(z) + c \log n, \overline{d}(x)\}$. Vertex u can be accessed in $O(1)$ time using the data-structure \mathcal{D} . Using the patterns pointed out by u , we can find the depth of the relevant vertex whose level is just below l in $O(1)$ time, and now using \mathcal{D} again we can access this vertex in constant time.

4. Approximate nearest neighbor search. In the following, ANN stands for approximate nearest neighbor. In this section, we present an ANN scheme that preprocesses a given set of points P in near linear time and produces a linear space data-structure which answers queries of the form “given point q , find $p \in P$ such that $d(q, p) \leq (1 + \epsilon)d(q, P)$ ” in logarithmic time. See section 1 for more details.

In section 4.1, we present a variant of Krauthgamer and Lee’s [34] net navigation algorithm for the net-tree. This algorithm allows us to boost an A -ANN solution to a $(1 + \epsilon)$ -ANN solution in $O(\log n + \log A + \epsilon^{O(\dim)})$ query time. In section 4.2 we present a fast construction of a variant of the ring separator tree [29, 33] which

supports fast $2n$ -ANN queries. We conclude in section 4.3 with the general scheme which is a combination of the previous two.

4.1. The low spread case.

LEMMA 4.1. *We are given a net-tree T of P , a query point $q \in \mathcal{M}$, and a vertex $u \in T$ at level $l = \ell(u)$ such that $d_{\mathcal{M}}(\text{rep}_u, q) \leq 5 \cdot \tau^l$ or $\widehat{p} \in P_u$, where \widehat{p} is the nearest neighbor to q in P . Then there is an algorithm that traverses T from u downward such that for any $t \in \mathbb{N}$, after $t + 4$ steps, the algorithm reaches a vertex s for which rep_s is a $(1 + \tau^{l-f-t})$ -ANN, where $f = \log_{\tau} d_{\mathcal{M}}(\widehat{p}, q)$. The running time of this search is $\lambda^{O(1)} \min\{t, l - f\} + \lambda^{O(\max\{t-(l-f), 0\})}$.*

Proof. The query algorithm works as follows. It constructs sets A_i of vertices in T with the following properties:

1. For each $v \in A_i$, $\ell(\overline{p}(v)) > i \geq \ell(v)$.
2. $\widehat{p} \in \cup_{v \in A_i} P_v \subset \mathbf{b}(q, d_{\mathcal{M}}(q, \widehat{p}) + (13 + \frac{2\tau}{\tau-1}) \cdot \tau^i)$.

The algorithm starts by setting $A_l = \text{Rel}(u)$. If $\widehat{p} \in P_u$, then A_l clearly satisfies the two properties above. If $d_{\mathcal{M}}(\text{rep}_u, q) \leq 5 \cdot \tau^l$, then $d_{\mathcal{M}}(\text{rep}_u, \widehat{p}) \leq 10\tau^l$. Suppose for the sake of contradiction that $\widehat{p} \notin \cup_{v \in A_l} P_v$; then $\exists v'$ such that $\ell(v') \leq l$, $d_{\mathcal{M}}(\text{rep}_u, \text{rep}_{v'}) > 13\tau^l$, and $\widehat{p} \in P_{v'}$. But then from the covering property, $d_{\mathcal{M}}(\text{rep}_{v'}, \widehat{p}) \leq \frac{2\tau}{\tau-1} \tau^l$, which means that $d_{\mathcal{M}}(\text{rep}_u, \widehat{p}) > (13 - \frac{2\tau}{\tau-1})\tau^l > 10\tau^l$, a contradiction.

The set A_{i-1} is constructed from A_i as follows. Let $v \in A_i$ be the closest vertex in A_i to q , i.e., $d_{\mathcal{M}}(\text{rep}_v, q) = \min_{w \in A_i} d_{\mathcal{M}}(\text{rep}_w, q)$. Let B be the set obtained from A_i by replacing every vertex of level i with its children. The set A_{i-1} is obtained from B by throwing out any vertex w for which $d_{\mathcal{M}}(q, \text{rep}_w) > d_{\mathcal{M}}(q, \text{rep}_v) + \frac{2\tau}{\tau-1} \cdot \tau^{i-1}$. It is easily checked that A_{i-1} has the required properties.

The running time is clearly dominated by $\lambda^{O(1)}$ times the sum of the A_i 's sizes. For $i > f$, $d_{\mathcal{M}}(q, \text{rep}_v)$ is at most $\frac{2\tau}{\tau-2} \cdot \tau^i$, and therefore $|A_i| \leq \lambda^{O(1)}$. For $i \leq f$, we have only a weak bound of $|A_i| \leq \lambda^{O(f-i)}$. Thus the running time of the algorithm for t steps follows. Notice that any point in A_{l-i} is $(1 + \tau^{l-f-i+4})$ -ANN. \square

For a set P with spread Φ , by applying the algorithm of Lemma 4.1 with u the root of T , and $t = \lceil \log_{\tau}(\Phi/\varepsilon) - f \rceil$, Lemma 4.1 gives a $(1 + \varepsilon)$ -approximate nearest neighbor scheme with $O(n \log n)$ expected construction time and $O(\log \Phi + \varepsilon^{-O(\dim)})$ query time. (Note that the algorithm does not need to know t (and thus f) in advance—it can estimate the current approximation by comparing $d_{\mathcal{M}}(q, \text{rep}_v)$ to τ^i .) This gives an alternative to the data-structure of Krauthgamer and Lee [34], with a slightly faster construction time. Their construction time is $O(n \log \Phi \log \log \Phi)$ if one uses the insertion operation for their data-structure (note that in the constant doubling dimension setting, $\log n = O(\log \Phi)$). In fact, in this case, the $\text{Rel}()$ data-structure is not needed since $\text{Rel}(\text{root}) = \{\text{root}\}$. Therefore the storage for this ANN scheme is $O(n)$, with no dependency on the dimension. A similar construction was obtained independently in [8]. However, its construction time is $O(n^2)$.

4.2. Low quality ring separator tree.

LEMMA 4.2. *One can construct a data-structure which supports $2n$ -ANN queries in $2^{O(\dim)} \log n$ time. The construction time is $2^{O(\dim)} n \log n$, and the data-structure uses $2^{O(\dim)} n$ space.*

Proof. The data structure is a binary search tree S , in which each vertex of the tree v is associated with a point $p_v \in P$ and radius r_v . We are guaranteed that $n/2\lambda^3 \leq |\mathbf{b}(p_v, r_v)| \leq (1 - 1/2\lambda^3)n$ and that $(\mathbf{b}(p_v, (1 + 1/2n)r_v) \setminus \mathbf{b}(p_v, (1 - 1/2n)r_v)) \cap P = \emptyset$. The left subtree is recursively constructed on the set $P \cap \mathbf{b}(p_v, r_v)$, and the right

subtree is recursively constructed on $P \setminus \mathbf{b}(p_v, r_v)$. The depth of S is clearly at most $O(\lambda^3 \log n)$.

The construction of S is similar to the construction of the low quality spanner (section 3.2) and uses Lemma 2.4 as follows. Apply Lemma 2.4 to find $p \in P$ and r such that $|\mathbf{b}(p, r)| \geq n/(2\lambda^3)$, whereas $|\mathbf{b}(p, 2r)| \leq n/2$. From the pigeonhole principle, there exists $r' \in [(1 + 1/2n)r, 2r - r/2n)$ for which $\mathbf{b}(p, (1 + 1/2n)r') \setminus \mathbf{b}(p, (1 - 1/2n)r') = \emptyset$. We now make a root v for the ring separator tree, set $p_v = p$ and $r_v = r'$, and recurse on $\mathbf{b}(p_v, r_v)$ as the left subtree and $P \setminus \mathbf{b}(p_v, r_v)$ as the right subtree. The construction time $T(n)$ obeys the recursive formula $T(n) = T(n_1) + T(n_2) + O(n)$, where $n_1 + n_2 = n$, $n/2\lambda^3 \leq n_1 \leq n/2$.

Once we have this data-structure, $2n$ -ANN can be found in $O(\lambda^3 \log n)$ time as follows. Let the root of the ring separator tree be u . Given a query point q , check its distance to p_u . If $d_{\mathcal{M}}(q, p_u) \leq r_u$, then recurse on the left subtree. Otherwise, recurse on the right subtree. At the end, return the nearest point to q among p_v , where v is on the path traversed by the algorithm.

The running time of this procedure is clearly dominated by the height of the tree which is $O(\lambda^3 \log n)$.

To see that this is indeed $2n$ -ANN, let a be the vertical path in the tree traversed by the algorithm, and let b be the vertical path in the tree connecting the root to the nearest neighbor of q in P . Let v be the lowest common vertex of a and b . Suppose that a continued on the left subtree of v while b continued on the right subtree. In this case the distance from q to the nearest neighbor is at least $r_v/2n$, while $d_{\mathcal{M}}(p_v, q) \leq r_v$. Thus p_v is $2n$ -ANN.

If a continued on the right subtree of v while b continued on the left subtree of v , then the distance from the nearest neighbor is at least $r_v/2n + (d_{\mathcal{M}}(p_v, q) - r_v)$, while p_v is at distance $d_{\mathcal{M}}(p_v, q)$. The ratio between these two quantities is clearly at most $2n$. \square

Remark 1. As is pointed out in [29, 33], it is possible to duplicate points in the ring for the two subtrees. Hence we can actually partition the $\mathbf{b}(p, 2r) \setminus \mathbf{b}(p, r)$ into $t \leq n$ subrings and choose to duplicate a “light” ring. When $t = 1$, we obtain the ring separator tree from [33] that supports $O(1)$ -ANN queries, but requires $n^{2^{O(\dim)}}$ storage. For general $t \leq n$ we obtain a data-structure that supports $O(t)$ -ANN queries, and that by choosing the right ring to duplicate, consumes only $n^{(3 \log 2\lambda)^{1/t}}$ storage. To see this, we set $\beta = (3 \log 2\lambda)^{1/t}$ and prove by induction on n that it is possible to find a ring such that the number of leaves in the tree is at most n^β . Denote $\eta_i = |\mathbf{b}(p, (1 + i/t)r)|/n$. Note that $(2\lambda)^{-3} \leq \eta_0 \leq \eta_1 \leq \dots \eta_t \leq n/2$, and therefore there exists $i \leq t$ for which $\eta_{i-1} \geq \eta_i^\beta$; otherwise $(2\lambda)^{-3} < \eta_0^{\beta^t} \leq (1/2)^{\beta^t}$ which is a contradiction. Thus by duplicating the i th ring, and by applying the inductive hypothesis on the number of leaves in the subtrees, the resulting tree will have at most $(\eta_i n)^\beta + ((1 - \eta_{i-1})n)^\beta \leq (\eta_{i-1} + (1 - \eta_{i-1}))n^\beta$ leaves.

Thus, setting $t = O(\log \log \lambda \cdot \log n)$, we obtain a linear space ring separator tree that supports $O(t)$ -ANN queries in $O(\log n)$ time.

4.3. ANN algorithm for arbitrary spread. The algorithm for arbitrary spread is now pretty clear. During the preprocessing we construct the augmented net-tree from section 3. We also construct the low quality ring separator tree. The construction time is $2^{O(\dim)} n \log n$, and the space used is $2^{O(\dim)} n$.

Given a query point $q \in \mathcal{M}$, and the approximation parameter $\varepsilon > 0$, the query algorithm consists of the following three steps:

1. First, find $2n$ -ANN p_1 using the low quality ring separator tree of section 4.2.
2. Next, find a vertex u in the net-tree that is an ancestor for p_1 and that satisfies

$$\ell(\bar{p}(u)) - 1 \geq \lceil \log_\tau(16 \cdot d_{\mathcal{M}}(p_1, q)) \rceil \geq \ell(u).$$

Hence

$$d_{\mathcal{M}}(\text{rep}_u, q) \leq d_{\mathcal{M}}(\text{rep}_u, p_1) + d_{\mathcal{M}}(p_1, q) \leq 2.5 \cdot \tau^{\ell(u)} + \frac{1}{16} \tau^{\ell(\bar{p}(u))-1}.$$

3. We now split the analysis into two cases as follows:
 - (a) If $2.5 \cdot \tau^{\ell(u)} \geq \frac{1}{16} \tau^{\ell(\bar{p}(u))-1}$, then clearly $d_{\mathcal{M}}(\text{rep}_u, q) \leq 5\tau^{\ell(u)}$, and thus u satisfies the conditions of Lemma 4.1.
 - (b) If, on the other hand, $2.5 \cdot \tau^{\ell(u)} < \frac{1}{16} \tau^{\ell(\bar{p}(u))-1}$, then the packing property of the net-tree implies that

$$\begin{aligned} P \cap \mathbf{b}(q, d_{\mathcal{M}}(q, \text{rep}_u)) &\subset P \cap \mathbf{b}(\text{rep}_u, 2d_{\mathcal{M}}(q, \text{rep}_u)) \\ &\subset P \cap \mathbf{b}\left(\text{rep}_u, \frac{1}{4} \cdot \tau^{\ell(\bar{p}(u))-1}\right) \subset P_u, \end{aligned}$$

and therefore $\hat{p} \in P_u$. Thus, in this case u also satisfies the conditions of Lemma 4.1.

4. Set $l = \ell(u)$. Using the notation of Lemma 4.1, the fact that p_1 is a $2n$ -ANN implies that $f \geq l - (1 + \log n)$, thus by setting the number of steps to $t = \lceil \log(n/\varepsilon) \rceil$, and applying the algorithm of Lemma 4.1, we obtain $(1 + \varepsilon)$ -ANN.

The running time of the query is

$$\lambda^{O(1)} \log n + O(\log n) + \lambda^{O(1)} \log n + \varepsilon^{-O(\dim)} \leq \lambda^{O(1)} \log n + \varepsilon^{-O(\dim)}.$$

We summarize as follows.

THEOREM 4.3. *Given a set P of n points of bounded doubling dimension \dim in a metric space \mathcal{M} , one can construct a data-structure for answering ANN queries (where the quality parameter ε is provided together with the query). The query time is $2^{O(\dim)} \log n + \varepsilon^{-O(\dim)}$, the expected preprocessing time is $2^{O(\dim)} n \log n$, and the space used is $2^{O(\dim)} n$.*

Theorem 4.3 compares quite favorably with the result of Krauthgamer and Lee [33], which solves the same problem with the same (tight) query time but uses $O(2^{O(\dim)} n^2 \text{polylog}(n))$ space.

5. Fast construction of WSPD and spanners. Let P be an n -point subset of a metric space \mathcal{M} with doubling dimension \dim and a parameter $1/4 > \varepsilon > 0$. Denote by $A \otimes B$ the set $\{\{x, y\} \mid x \in A, y \in B\}$. A WSPD with parameter ε^{-1} of P is a set of pairs $\{\{A_1, B_1\}, \dots, \{A_s, B_s\}\}$ such that

1. $A_i, B_i \subset P$ for every i .
2. $A_i \cap B_i = \emptyset$ for every i .
3. $\cup_{i=1}^s A_i \otimes B_i = P \otimes P$.
4. $d_{\mathcal{M}}(A_i, B_i) \geq \varepsilon^{-1} \cdot \max\{\text{diam}(A_i), \text{diam}(B_i)\}$.

The notion of WSPD was defined by Callahan and Kosaraju [11] for Euclidean spaces. Talwar [44] have shown that this notion transfers to constant doubling metrics. In particular, he proves that any n -point metric with doubling dimension \dim admits WSPD in which the number of pairs is $n\varepsilon^{-O(\dim)} \log \Phi$. We improve this result.

LEMMA 5.1. For $1 \geq \varepsilon > 0$, one can construct an ε^{-1} -WSPD of size $n\varepsilon^{-O(\dim)}$, and the expected construction time is $2^{O(\dim)}n \log n + n\varepsilon^{-O(\dim)}$.

Furthermore, the pairs of the WSPD correspond to (P_u, P_v) , where u, v are vertices of a net-tree of P , and for any pair (P_u, P_v) in WSPD, $\text{diam}(P_u), \text{diam}(P_v) \leq \varepsilon d_P(\text{rep}_u, \text{rep}_v)$.

Proof. We compute the net-tree T using Theorem 3.1. For concreteness of the WSPD, assume also that some weak linear order \preceq is defined on the vertices of T . The WSPD is constructed by calling $\text{genWSPD}(u_0, u_0)$, where u_0 is the root of the net-tree T , and $\text{genWSPD}(u, v)$ is defined recursively as follows:

```

genWSPD(u, v)
  Assume  $\ell(u) > \ell(v)$  or  $(\ell(u) = \ell(v)$  and  $u \preceq v)$ 
    (otherwise exchange  $u \leftrightarrow v$ ).
  If  $8 \frac{2\tau}{\tau-1} \cdot \tau^{\ell(u)} \leq \varepsilon \cdot d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v)$ , then
    return  $\{\{u, v\}\}$ 
  else
    Denote by  $u_1, \dots, u_r$  the children of  $u$ 
    return  $\bigcup_{i=1}^r \text{genWSPD}(u_i, v)$ .
```

For any node $u \in T$, we have $\text{diam}(P_u) \leq 2 \frac{2\tau}{\tau-1} \cdot \tau^{\ell(u)}$ (see Definition 2.1). In particular, for every output pair $\{u, v\}$, it holds that

$$\begin{aligned} \max\{\text{diam}(P_u), \text{diam}(P_v)\} &\leq 2 \frac{2\tau}{\tau-1} \cdot \max\{\tau^{\ell(u)}, \tau^{\ell(v)}\} \leq \frac{\varepsilon}{4} d_P(\text{rep}_u, \text{rep}_v) \\ &\leq \frac{\varepsilon}{4} (d_P(P_u, P_v) + \text{diam}(P_u) + \text{diam}(P_v)), \end{aligned}$$

and so $\max\{\text{diam}(P_u), \text{diam}(P_v)\} \leq \frac{\varepsilon}{4(1-\varepsilon/2)} d_P(P_u, P_v) \leq \varepsilon d_P(P_u, P_v)$, since $\varepsilon \leq 1$. Similarly, for any $x \in P_u$ and $y \in P_v$, we have

$$d_P(\text{rep}_u, \text{rep}_v) \leq d_P(x, y) + \text{diam}(P_u) + \text{diam}(P_v) \leq (1 + \varepsilon) d_P(x, y).$$

One can verify that every pair of points is covered by a pair of subsets $\{P_u, P_v\}$ output by the genWSPD algorithm.

We are left to argue about the size of the output (the running time is clearly linear in the output size). Let $\{u, v\}$ be an output pair and assume that the call to $\text{genWSPD}(u, v)$ was issued by $\text{genWSPD}(u, \bar{p}(v))$. We charge this call to $\bar{p}(v)$, and we will prove that each vertex is charged at most $\varepsilon^{-O(\dim)}$ times.

Fix $v' \in T$. It is charged by pairs of the form $\{u, v\}$ in which $\bar{p}(v) = v'$, and which were issued inside $\text{genWSPD}(u, v')$. This implies that $\ell(\bar{p}(u)) \geq \ell(v') \geq \ell(u)$.

Since the pair (u, v') was not generated by genWSPD , we conclude that $d_P(\text{rep}_{v'}, \text{rep}_u) \leq (8 \frac{2\tau}{\tau-1} \cdot \tau^{\ell(v')})/\varepsilon$. The set

$$U = \left\{ w \mid \ell(\bar{p}(w)) \geq \ell(v') \geq \ell(w) \text{ and } d_P(\text{rep}_{v'}, \text{rep}_w) \leq 8 \frac{2\tau}{\varepsilon(\tau-1)} \cdot \tau^{\ell(v')} \right\}$$

contains u , and U is a subset of $\mathcal{N}_C(\ell(v'))$. By Proposition 2.2, for every $u_1, u_2 \in U$, if $u_1 \neq u_2$, then $d_P(P_{u_1}, P_{u_2}) \geq \tau^{\ell(v')-1}/4$. By the doubling property, we have $|U| \leq \varepsilon^{-O(\dim)}$. We therefore infer that v' can be charged only by pairs in $U \times C_{v'}$, where $C_{v'}$ is the set of children of v' . We conclude that v' might be charged at most $|U| \cdot |C_{v'}| \leq (2/\varepsilon)^{O(\dim)} = \varepsilon^{-O(\dim)}$ times. Thus, the total number of pairs generated by the algorithm is $n\varepsilon^{-O(\dim)}$. \square

5.1. Spanners.

DEFINITION 5.2. *A t -spanner of a finite metric space P is a weighted graph G whose vertices are the points of P , and for any $x, y \in P$,*

$$d_P(x, y) \leq d_G(x, y) \leq t \cdot d_P(x, y),$$

where d_G is the metric of the shortest path on G .

THEOREM 5.3. *Given an n -point metric P with doubling dimension \dim and parameter $1 \geq \varepsilon > 0$, one can compute a $(1 + \varepsilon)$ -spanner of P with $n\varepsilon^{-O(\dim)}$ edges, in $2^{O(\dim)}n \log n + n\varepsilon^{-O(\dim)}$ expected time.*

Proof. Let $c \geq 16$ be an arbitrary constant, and set $\delta = \varepsilon/c$. Compute a δ^{-1} WSPD decomposition using the algorithm of the previous section. For every pair $\{u, v\} \in \text{WSPD}$, add an edge between $\{\text{rep}_u, \text{rep}_v\}$ with weight $d_P(\text{rep}_u, \text{rep}_v)$. Let G be the resulting graph; clearly, the resulting shortest path metric d_G dominates the metric d_P .

The upper bound on the stretch is proved by induction on the length of pairs in the WSPD. Fix a pair $x, y \in P$; by our induction hypothesis, we have that for every pair $z, w \in P$ such that $d_P(z, w) < d_P(x, y)$, it holds that $d_G(z, w) \leq (1 + c\delta)d_P(z, w)$.

The pair x, y must appear in some pair $\{u, v\} \in \text{WSPD}$, where $x \in P_u$ and $y \in P_v$. Thus $d_P(\text{rep}_u, \text{rep}_v) \leq (1 + 2\delta)d_P(x, y)$ and $d_P(x, \text{rep}_u), d_{\mathcal{M}}(y, \text{rep}_v) \leq \delta d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v)$ by Lemma 5.1. By the inductive hypothesis

$$\begin{aligned} d_G(x, y) &\leq d_G(x, \text{rep}_u) + d_G(\text{rep}_u, \text{rep}_v) + d_G(\text{rep}_v, y) \\ &\leq (1 + c\delta)d_P(x, \text{rep}_u) + d_P(\text{rep}_u, \text{rep}_v) + (1 + c\delta)d_P(\text{rep}_v, y) \\ &\leq 2(1 + c\delta) \cdot \delta \cdot d_P(\text{rep}_u, \text{rep}_v) + d_P(\text{rep}_u, \text{rep}_v) \\ &\leq (1 + 2\delta + 2c\delta^2)(1 + 2\delta)d_P(x, y) \\ &\leq (1 + \varepsilon)d_P(x, y), \end{aligned}$$

since $\delta c \leq \varepsilon \leq 1$ and $16\delta \leq 1$ and $c \geq 11$. \square

6. Compact representation scheme. A CRS of a finite metric space P is a “compact” data-structure that can answer distance queries for pairs of points. We measure the performance of a CRS using four parameters $(P, S, Q, \bar{\kappa})$, where P is the preprocessing time of the distance matrix, S is the space used by the CRS (in terms of words), Q is the query time, and $\bar{\kappa}$ is the approximation factor.

The distance matrix by itself is a $(P = O(1), S = O(n^2), Q = O(1), \bar{\kappa} = 1)$ -CRS. The ε^{-1} -WSPD as well as the $(1 + \varepsilon)$ -spanner are representations of $(1 + O(\varepsilon))$ -approximation of the metric that consumes only $\varepsilon^{-O(\dim)}n$ space. However, naively it takes $\Omega(n)$ time to answer approximate distance queries in these data-structures.

In this section, we obtain the following theorem.

THEOREM 6.1. *For any n point metric with doubling dimension \dim , the following exist:*

- (a) A ($P = 2^{O(\dim)}n \log^2 n + \varepsilon^{-O(\dim)}n, S = \varepsilon^{-O(\dim)}n, Q = 2^{O(\dim)}, \bar{\kappa} = 1 + \varepsilon$)-CRS.
- (b) A ($P = 2^{O(\dim)} \cdot \text{poly}(n) + \varepsilon^{-O(\dim)}n, S = \varepsilon^{-O(\dim)}n, Q = O(\dim), \bar{\kappa} = 1 + \varepsilon$)-CRS.

For general n -point metrics, Thorup and Zwick [45] obtained a $(kn^{1+1/k}, kn^{1+1/k}, O(k), 2k - 1)$ -CRS, where $k \in \mathbb{N}$ is a prescribed parameter. The trade-off between the

approximation and the space is essentially tight for general metrics. Closer in spirit to our setting, Gudmunsson et al. [21, 22] considered metrics that are t -approximated by Euclidean distances in \mathbb{R}^d , where both d and t are (possibly large) constants. They showed that such metrics have $(O(n \log n), O(n), O(1), 1 + \varepsilon)$ -CRS (the O notation here hides constants that depend on ε , d , and t). Our scheme strictly extends³ their result since metrics that are t -approximated by a set of points in the d -dimensional Euclidean space have doubling dimension at most $O(d \log(2t))$. We further discuss previous work on a special type of CRS, called *distance labeling*, in section 6.3.

Our scheme is naturally composed of two parts. In section 6.1 we show that by using the net-tree it is possible to convert an A -approximate CRS into a $(1 + \varepsilon)$ -approximate CRS in essentially $O(\log A)$ query time (and even $O(\log \log A)$ query time). We then show in section 6.2 how to obtain an $O(1)$ -approximate CRS using Assouad's embedding. In section 6.3 we observe that Assouad's embedding can be used in distance labeling schema.

6.1. Approximation boosting lemma. Assume we are given a data-structure \mathcal{A} , which is a $(P, S, Q, \bar{\kappa})$ -CRS of a set $P \subset \mathcal{M}$, where $\bar{\kappa} \leq 3n^2$. In this section, we derive a CRS with improved approximation. Besides storing the data-structure of \mathcal{A} , we also need the following data-structures:

1. The net-tree T , augmented so that it supports the following operations:
 - (a) $O(\log n)$ time access for ancestors of a given level as defined in section 3.5.
 - (b) Constant time access for an ancestor at a given level l of a given vertex x , when $l + 6 \log n$ is at least the level of a given ancestor z of x .
 - (c) A constant time access for the lca of two vertices in T [4].
2. An ε^{-1} -WSPD W on the net-tree T , with support for fast membership queries. For each pair we also store the distance between its representatives. By using hashing membership, queries can be answered in constant time.
3. The $(3n^2)$ -approximation HST H of section 3.2. The HST H should be augmented with the following features:
 - (a) A constant time access to lca queries, after a linear time preprocessing [4].
 - (b) Each vertex u of H contains pointers to the following set of vertices in T :

$$K_u = \{x \in T : d_{\mathcal{M}}(\text{rep}_x, \text{rep}_u) \leq 4\Delta_u \text{ and } \ell(x) < \log \Delta_u \leq \ell(\bar{p}(x))\}.$$

Note that $|K_u| \leq \lambda^{O(1)}$, and computing all these sets can be accomplished in $\lambda^{O(1)} n \log n$ time by finding the level $\lceil \log \Delta_u \rceil$ ancestor z of rep_u in T in $O(\log n)$ time, and then scanning $\text{Rel}(z)$.

All these data-structures can be created in $2^{O(\dim)} n \log n + \varepsilon^{-O(\dim)} n$ time and $\varepsilon^{-O(\dim)} n$ space.

Assuming Query- $\mathcal{A}(x, y)$ returns a value η , such that $d_{\mathcal{M}}(x, y)/\bar{\kappa} \leq \eta \leq d_{\mathcal{M}}(x, y)$, the query algorithm is as follows:

³Caveat: They use a weaker model of computation.

```

Query- $\mathcal{B}(x, y \in P)$ 
   $z \leftarrow \text{lca}_H(x, y)$ .
   $u' \leftarrow$  ancestor of  $x$  in  $T$  among  $K_z$ ,  $v' \leftarrow$  ancestor of  $y$  in  $T$  among  $K_z$ .
   $\eta \leftarrow \text{Query-}\mathcal{A}(x, y)$ .
   $u_0 \leftarrow$  ancestor of  $x$  in level  $\lfloor \log(\varepsilon\eta) \rfloor$ ,  $v_0 \leftarrow$  ancestor of  $y$  in level  $\lfloor \log(\varepsilon\eta) \rfloor$ .
   $u \leftarrow u_0$ ,  $v \leftarrow v_0$ .
  while  $\{u, v\} \notin W$  do
    if  $\ell(\bar{p}(u)) < \ell(\bar{p}(v))$  or  $(\ell(\bar{p}(u)) = \ell(\bar{p}(v)) \text{ and } \bar{p}(v) \preceq \bar{p}(u))$  then
       $u \leftarrow \bar{p}(u)$ 
    else
       $v \leftarrow \bar{p}(v)$ .
  return  $d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v)$ .
    
```

Implementation details. u' is found by scanning all vertices in K_z (there are only $\lambda^{O(1)}$ such vertices) and checking which one of them is an ancestor of x in T (ancestorship can be checked using the lca operation on T). Note that an ancestor of x must be contained in K_z , since $d_{\mathcal{M}}(\text{rep}_z, x) \leq \Delta_z$, and thus the ancestor of the level immediately below $\log \Delta_z$ must be in K_z . A similar thing happens with v' . Both η and Δ_z are $3n^2$ -approximations to $d_{\mathcal{M}}(x, y)$, and therefore $\ell(u') - \ell(u_0) \leq 4 \log n + 3$; hence u_0 can be accessed in constant time. The same goes for v_0 .

The following lemma is an immediate consequence of the way in which the WSPD algorithm works.

LEMMA 6.2. *For a pair $\{s, t\} \in W$ (the ε^{-1} -WSPD), and $\ell(s) \leq \ell(t)$, one of the following conditions must be satisfied:*

1. $\ell(s) \leq \ell(t) < \ell(\bar{p}(s))$ and $\frac{2\tau}{\tau-1} \cdot \tau^{\ell(\bar{p}(s))} > \varepsilon \cdot d_{\mathcal{M}}(\text{rep}_{\bar{p}(s)}, \text{rep}_t)$, and $\frac{2\tau}{\tau-1} \cdot \tau^{\ell(s)} \leq \varepsilon \cdot d_{\mathcal{M}}(\text{rep}_s, \text{rep}_t)$.
2. $\ell(s) < \ell(t) = \ell(\bar{p}(s))$, and $\bar{p}(s) \preceq t$, and $\frac{2\tau}{\tau-1} \cdot \tau^{\ell(\bar{p}(s))} > \varepsilon \cdot d_{\mathcal{M}}(\text{rep}_{\bar{p}(s)}, \text{rep}_t)$.
 $\frac{2\tau}{\tau-1} \cdot \tau^{\ell(s)} \leq \varepsilon \cdot d_{\mathcal{M}}(\text{rep}_s, \text{rep}_t)$.

PROPOSITION 6.3. *The while loop finds a pair in W after $O(\log \bar{\kappa})$ steps.*

Proof. Denote by $\{u_0, v_0\}$ the pair with which the loop begins. It is straightforward to see that the loop climbs through all ancestor pairs $\{u, v\}$ of $\{u_0, v_0\}$ that satisfy either (i) $\ell(u) \leq \ell(v) < \ell(\bar{p}(u))$, or (ii) $\ell(u) < \ell(v) = \ell(\bar{p}(u))$ and $\bar{p}(u) \preceq v$.

Thus, if an ancestor pair exists in W , it will be found by the loop. As we argue in Lemma 5.1, there exists an ancestor pair $\{\bar{u}, \bar{v}\}$ of $\{x, y\}$ in W . Our choice $\{u_0, v_0\}$ ensures that u_0 is a descendant of \bar{u} at most $O(\log \bar{\kappa})$ levels down T , and the same goes for v_0 and \bar{v} . \square

Combining the above claims, implies the following.

LEMMA 6.4. *Let P be an n -point metric. Assume we are given a $(P, S, Q, \bar{\kappa})$ -CRS \mathcal{A} of a set P , where $\bar{\kappa} \leq 3n^2$. Then, one can obtain $(P', S', Q', 1 + \varepsilon)$ -CRS \mathcal{B} of P , where $P' = P + 2^{O(\dim)} n \log n + \varepsilon^{O(\dim)} n$, $S' = S + \varepsilon^{-O(\dim)} n$, $Q' = Q + O(\log \bar{\kappa})$.*

Remark 2. The dependence of the query time on $\bar{\kappa}$ can be improved from $O(\log \bar{\kappa})$ to $O(\log \log \bar{\kappa})$ without sacrificing any other parameter. The idea is to replace the “ladder climbing” in the algorithm above (the while loop) with a binary search on the $\log \bar{\kappa}$ levels. To do so we change the WSPD procedure to output *all* pairs it encounters. This clearly does not change asymptotically the size of W . We do a binary search on the $\log \bar{\kappa}$ relevant levels to find the lowest level pairs which still appear in the WSPD, and this gives the relevant pairs. We do not pursue this improvement rigorously, since in the CRS that we develop in the next section, the query time Q dominates $\bar{\kappa}$ anyway, and thus this would lead to no asymptotic savings in the query time.

6.2. Assouad embedding. To quickly obtain a constant approximation of the distance, we will use a theorem due to Assouad [2] (see also [27, 23]). The following is a variant of the original statement, tailored for our needs, and its proof is provided for the sake of completeness.

THEOREM 6.5. *Any metric space \mathcal{M} with doubling dimension \dim can be embedded in ℓ_∞^d , where $d \leq \varepsilon^{-O(\dim)}$, such that the metric $(\mathcal{M}, \sqrt{d_{\mathcal{M}}})$ is distorted by a factor of $1 + \varepsilon$.*

Proof. Fix $r > 0$. We begin by constructing an embedding $\phi^{(r)} : \mathcal{M} \rightarrow \mathbb{R}^{d_1}$, where $d_1 = \varepsilon^{-O(\dim)}$ with the following properties for every $x, y \in \mathcal{M}$:

1. $\|\phi^{(r)}(x) - \phi^{(r)}(y)\|_\infty \leq \min\{r, d_{\mathcal{M}}(x, y)\}$.
2. If $d_{\mathcal{M}}(x, y) \in [(1 + \varepsilon)r, 2r]$, then $\|\phi^{(r)}(x) - \phi^{(r)}(y)\|_\infty \geq (1 - \varepsilon)r$.

We take an εr -net $\mathcal{N}^{(r)}$ of \mathcal{M} and color it such that every pair $x, y \in \mathcal{N}^{(r)}$ for which $d_{\mathcal{M}}(x, y) \leq 4r$ is colored differently. Clearly, $d_1 = \varepsilon^{-O(\dim)}$ colors suffice. Associate with every color i a coordinate, and for $x \in \mathcal{M}$ define $\phi_i^{(r)}(x) = \max\{0, r - d_{\mathcal{M}}(x, C_i)\}$, where $C_i \subset \mathcal{N}^{(r)}$ is the set of points of color i .

We next check that the two properties above are satisfied. As $\phi_i^{(r)}(x) \in [0, r]$, it is clear that $|\phi_i^{(r)}(x) - \phi_i^{(r)}(y)| \leq r$ for every color i . The 1-Lipschitz property easily follows from the triangle inequality.

Next, assume that $d_{\mathcal{M}}(x, y) \in [(1 + \varepsilon)r, 2r]$. Since $d_{\mathcal{M}}(x, \mathcal{N}^{(r)}) \leq \varepsilon r$, there exists a color i for which $d_{\mathcal{M}}(x, C_i) \leq \varepsilon r$. This implies (by the triangle inequality) that $d_{\mathcal{M}}(y, C_i) \geq r$, and hence $|\phi_i^{(r)}(x) - \phi_i^{(r)}(y)| \geq (1 - \varepsilon)r$. Thus, the concatenation of all these coordinates, $\phi^{(r)} = \oplus_i \phi_i^{(r)}$, satisfies the condition above.

Let $d_2 = 8\varepsilon^{-1} \log(\varepsilon^{-1})$. The final embedding $\phi : \mathcal{M} \rightarrow \mathbb{R}^{d_2 d_1}$ is done by combining a weighted sum of $\phi^{(r)}$ as follows. Let $M_l(x)$ denote the matrix of size $d_2 \times d_1$, such that it is all zero, except the $(l \pmod{d_2})$ th row, which is $M_l(x) = \phi^{((1+\varepsilon)^l)}(x)$. Then

$$\phi(x) = \sum_{l \in \mathbb{Z}} \frac{M_l(x)}{(1 + \varepsilon)^{l/2}}.$$

To see that the embedding is a $1 + O(\varepsilon)$ -approximation of $\sqrt{d_{\mathcal{M}}}$, fix a pair of points $x, y \in \mathcal{M}$, and let $l_0 \in \mathbb{Z}$ such that $d_{\mathcal{M}}(x, y) \in [(1 + \varepsilon)^{l_0+1}, (1 + \varepsilon)^{l_0+2})$. Then in the relevant coordinates the ℓ_∞ distance between x and y is

$$\begin{aligned} \left\| \sum_{k \in \mathbb{Z}} (\psi_{l_0+d_2k}(x) - \psi_{l_0+d_2k}(y)) \right\|_\infty &\geq \|\psi_{l_0}(x) - \psi_{l_0}(y)\|_\infty - \sum_{k < 0} \|\psi_{l_0+d_2k}(x) - \psi_{l_0+d_2k}(y)\|_\infty \\ &\quad - \sum_{k > 0} \|\psi_{l_0+d_2k}(x) - \psi_{l_0+d_2k}(y)\|_\infty \\ &\geq (1 - \varepsilon)(1 + \varepsilon)^{l_0/2} - \sum_{k < 0} \frac{(1 + \varepsilon)^{2+l_0+d_2k}}{(1 + \varepsilon)^{(l_0+d_2k)/2}} - \sum_{k > 0} \frac{(1 + \varepsilon)^{2+l_0}}{(1 + \varepsilon)^{(l_0+d_2k)/2}} \\ &\geq (1 - \varepsilon) \cdot (1 + \varepsilon)^{l_0/2} - \varepsilon \cdot (1 + \varepsilon)^{l_0/2} - \varepsilon \cdot (1 + \varepsilon)^{l_0/2} \geq (1 - O(\varepsilon))\sqrt{d_{\mathcal{M}}(x, y)}. \end{aligned}$$

On the other hand, for each $j \in \{0, \dots, d_2 - 1\}$,

$$\begin{aligned} & \left\| \sum_{k \in \mathbb{Z}} (\psi_{l_0+j+d_2k}(x) - \psi_{l_0+j+d_2k}(y)) \right\|_{\infty} \\ & \leq \sum_{k \leq 0} \|\psi_{l_0+j+d_2k}(x) - \psi_{l_0+j+d_2k}(y)\|_{\infty} + \sum_{k > 0} \|\psi_{l_0+j+d_2k}(x) - \psi_{l_0+j+d_2k}(y)\|_{\infty} \\ & \leq \sum_{k \leq 0} \frac{(1 + \varepsilon)^{2+l_0+j+d_2k}}{(1 + \varepsilon)^{(l_0+j+d_2k)/2}} + \sum_{k > 0} \frac{(1 + \varepsilon)^{2+l_0}}{(1 + \varepsilon)^{(l_0+j+d_2k)/2}} = (1 + O(\varepsilon))\sqrt{d_{\mathcal{M}}(x, y)}. \end{aligned}$$

Hence $\|\phi(x) - \phi(y)\|_{\infty}$ is a $1 + O(\varepsilon)$ -approximation to $\sqrt{d_{\mathcal{M}}(x, y)}$. \square

The relevance of Assouad’s embedding to compact representations is clear: Intuitively, $\phi(x)$ is short, and given $\phi(x)$ and $\phi(y)$, we can compute the square of the ℓ_{∞} norm of the difference and obtain a $(1 + \varepsilon)$ -approximation to $d_{\mathcal{M}}(x, y)$. Note, however, that in order to be able to do this, we need to store $\Theta(\log(\Phi/\varepsilon))$ bits for each real number, which may require many words to be represented in our computation model (see section 2). We solve this issue in Lemma 6.7 by reducing the problem for metrics with arbitrary spread to a set of similar problems on metrics with only polynomial spread, on which Assouad’s embedding can be applied.

LEMMA 6.6. *Given an n -point metric M with a polynomially bounded spread Φ and doubling dimension dim , an Assouad embedding (with parameter ε) of M can be computed in $\varepsilon^{-O(\text{dim})}n \log^2 n$ time.*

Proof. We follow closely the proof of Theorem 6.5. For each scale $(1 + \varepsilon)^l$, we find in $O(n)$ time an $\varepsilon(1 + \varepsilon)^l$ -net $\mathcal{N}^{((1+\varepsilon)^l)}$ from the net-tree. We define a graph on this net: two points are connected by an edge if they are at a distance of at most $4(1 + \varepsilon)^l$. This can be done in $\varepsilon^{-O(\text{dim})}n$ time using a variant of $\text{Rel}()$ sets (basically, we compute sets like $\text{Rel}()$ that contain points at a distance of at most $O(\varepsilon^{-1})$ times the current scale, instead of 13 times the current scale). We then partition $\mathcal{N}^{((1+\varepsilon)^l)}$ to color-classes using the greedy algorithm. Implemented with hashing, it works in expected $O(n)$ steps. Next, for each color-class we construct a $(1 + \varepsilon/2)$ -ANN data-structure, and thus we can compute a $(1 + \varepsilon/2)$ -approximation to $d_{\mathcal{M}}(x, C_i)$. Note that in the proof of Theorem 6.5, by enlarging the constants a little bit, a $(1 + \varepsilon/2)$ -approximation suffices. We repeat this construction for the $\log_{1+\varepsilon} \Phi$ levels in the metric. The rest of the embedding calculation is straightforward.

The running time of the algorithm is therefore $\varepsilon^{-O(\text{dim})}n \log n \log \Phi$. \square

Remark 3. We believe that for $\varepsilon = 100$, a similar embedding can be constructed directly on the net-tree in $2^{O(\text{dim})}n$ time. The construction seems, however, much more complicated than the one described in Lemma 6.6. We have therefore decided that the slight gain in preprocessing time (overall, a factor of $\log n$, since the running time for constructing the net-tree is $2^{O(\text{dim})}n \log n$) is not worth the complications.

LEMMA 6.7. *If there exists a $(P, S, Q, \bar{\kappa})$ -CRS \mathcal{A} for every n -point metric with doubling dimension dim and spread $\leq 3(n/\varepsilon)^{12}$, and if P is concave, then there exists a $(P(4n) + 2^{O(\text{dim})}n \log n, S + O(n), Q + O(1), (1 + \varepsilon)\bar{\kappa})$ -CRS \mathcal{B} for every n -point metric with doubling dimension dim (without any assumption on the spread).*

Proof. Denote by H the low quality HST of section 3.2 which is a $3n^2$ -approximation to the given metric \mathcal{M} .

Set $a_1 = 0$ and $a_2 = \lceil 5(\log(\varepsilon^{-1}) + \log_2 n) \rceil$. Apply the following procedure on H to obtain two HSTs, H_1 and H_2 . Scan H from the top down. Retain the root, the leaves, and all internal vertices $u \in H$ with the following property: There exists $b > 0$ such that $\log_2 b \equiv a_i \pmod{\lceil 10(\log(\varepsilon^{-1}) + \log_2 n) \rceil}$ and $\Delta_{\bar{p}(u)} > b \geq \Delta_u$. The HST H_i is constructed naturally on the retained vertices: A retained vertex u is connected

to a parent v in H_i if v is the lowest retained ancestor of u in H .

Next, for each nonleaf vertex $u \in H_i$, $i \in \{1, 2\}$, denote by $C(u)$ the set of children of u . We observe that $R(C(u)) = \{\text{rep}_u \mid u \in C(u)\}$ has a spread of at most $3(n/\varepsilon)^{12}$. To see this, note that $\text{diam}(R(C(u))) \leq \Delta_u$, and, on the other hand, let b the largest real number such that $b < \Delta_u$ and $\log b \equiv a_i \pmod{\lceil 10(\log(\varepsilon^{-1}) \log_2 n) \rceil}$. Obviously $b \geq \Delta_u/(n/\varepsilon)^{10}$ and for every $x, y \in C(u)$, $\Delta_{\text{lca}_H(x,y)} \geq b$, and therefore $d_{\mathcal{M}}(x, y) \geq b/(3n^2)$. Thus, for each internal vertex $u \in H_i$ we can construct a $\bar{\kappa}$ -approximate CRS \mathcal{A} to $R(C(u))$. The whole construction time is therefore $2^{O(\text{dim})}n \log n + \sum_k P(n_k) \leq 2^{O(\text{dim})}n \log n + P(4n)$.

We equip H , H_1 , and H_2 with a data-structure for handling queries for lca and finding an ancestor at a given depth, both in constant time.

A distance query for the pair $x, y \in \mathcal{M}$ is processed as follows. Let $u_i = \text{lca}_{H_i}(x, y)$. let x_i be a child of u_i which is an ancestor of x in H_i , and similarly y_i . Note that u_i, x_i, y_i can be computed in constant time using the lca and depth ancestor queries.

Further observe that $\exists i \in \{1, 2\}$ for which $\max\{\Delta_{x_i}, \Delta_{y_i}\} \leq \Delta_{\text{lca}_H(x,y)}/(n/\varepsilon)^5$, and finding this i is an easy task.

We next query the CRS \mathcal{A} of $R(C(u_i))$ for an approximation of $d_{\mathcal{M}}(\text{rep}_{x_i}, \text{rep}_{y_i})$. From the above we deduce that

$$\max\{d_{\mathcal{M}}(x, \text{rep}_{x_i}), d_{\mathcal{M}}(y, \text{rep}_{y_i})\} \leq \frac{3\varepsilon^5}{n^3} \cdot \frac{\Delta_{\text{lca}_H(x,y)}}{3n^2} \leq \frac{3\varepsilon^5}{n^3} d_{\mathcal{M}}(x, y),$$

and therefore we have obtained a $\bar{\kappa}(1 + \varepsilon)$ -approximation to $d_{\mathcal{M}}(x, y)$. \square

COROLLARY 6.8. *Every n -point metric with doubling dimension dim has a $(P = \varepsilon^{-O(\text{dim})}n \log^2 n, S = \varepsilon^{-O(\text{dim})}n, Q = \varepsilon^{-O(\text{dim})}, \bar{\kappa} = 1 + \varepsilon)$ -CRS.*

Proof. For the proof, combine Lemmas 6.7 and 6.6. \square

Note that in Corollary 6.8 the query time depends on ε , in contrast to the claim in Theorem 6.1(a). This can be remedied using Lemma 6.4.

Proof of Theorem 6.1(a). Use the CRS of Corollary 6.8 with constant $\varepsilon_0 = 0.1$ as the bootstrapping CRS in Lemma 6.4. \square

Proof of Theorem 6.1(b). In [23], an alternative proof for the Assouad theorem is given with a much improved bound on the dimension of the host space: They prove that for any metric $(\mathcal{M}, d_{\mathcal{M}})$ with doubling dimension dim , it is possible to embed $(\mathcal{M}, d_{\mathcal{M}}^{1/2})$ in $\ell_{\infty}^{O(\text{dim})}$ with distortion $O(\text{dim}^2)$.⁴

This embedding can be done in polynomial time. Using it as a replacement for Lemma 6.6, we therefore obtain the claimed CRS. \square

Remark 4. The distortion of embedding into $\text{poly}(\text{dim})$ dimensional normed space cannot be improved below 1.9, since such an embedding gives a 1.9 approximate CRS which uses only $O(n \text{poly}(\text{dim}) \log \phi)$ bits of storage with label length which are polynomially dependent on dim (see section 6.3), but Talwar [44] have shown that such a CRS necessarily uses at least $n2^{\Omega(\text{dim})}$ bits, which is impossible for $\text{dim} = \Omega(\log \log n)$. In this sense the embedding technique of [23] cannot replace Assouad’s original technique.

It is still open whether the construction time in Theorem 6.1(b) can be improved to near linear. The difficulty lies in the algorithmic version of the Lovász local lemma. As discussed in Remark 2, distortions as high as $2^{2^{O(\text{dim})}}$ are tolerable in this context.

⁴If one wants to optimize the distortion using their technique, then it is possible to obtain $O(\text{dim})$ distortion when embedding into $\ell_p^{O(\text{dim} \log \text{dim})}$.

6.2.1. Lower bound. We next argue that beating the $\Omega(\dim)$ query time using schema similar to the one presented above is unlikely.

For given reals $d_1, D, d_2 > 1$, we say that a (d_1, D, d_2) -Assouad-type-scheme (ATS) exists if there is a monotone increasing bijection $f : [0, \infty) \rightarrow [0, \infty)$, such that for all finite metric spaces $(P, d_{\mathcal{M}})$, with doubling dimension at most d_1 , there exists $\phi : P \rightarrow \mathbb{R}_{\|\cdot\|_X}^{d_2}$, such that for $x, y \in P$, we have

$$\frac{d_{\mathcal{M}}(x, y)}{D} \leq f(\|\phi(x) - \phi(y)\|_X) \leq d_{\mathcal{M}}(x, y).$$

For example, the embedding of [23] cited above is a $(d_1, O(d_1^2), O(d_1))$ -ATS for any $d_1 > 1$, and it uses $f(x) = x^2$.

PROPOSITION 6.9. *If $d_2 \leq d_1/5$, then for any $D > 1$, no (d_1, D, d_2) -ATS exists.*

Proof. The argument distinguishes between two essential cases: ‘‘Concave’’ function f cannot be used in any ATS since it causes a violation of the triangle inequality. For ‘‘convex’’ functions f we slightly generalize an argument from [9] that uses topological considerations (Borsuk–Ulam theorem) to conclude the impossibility.

Indeed, fix a (d_1, D, d_2) -ATS with a function f , where $d_2 \leq d_1/5$. Denote $g : [0, \infty) \rightarrow [0, \infty)$, where $g = f^{-1}$.

Suppose first that $\sup_{0 < a \leq b < \infty} \frac{g(b)/b}{g(a)/a} = \infty$ (‘‘concave f ’’). Fix a and b such that $0 < a < b < \infty$ and $\frac{g(b)/b}{g(a)/a} \geq 100D$. Let $n = \lceil 2Db/a \rceil$, and let P be the line metric on $\{0, \dots, n\}$ such that $d_{\mathcal{M}}(i, j) = a|i - j|$. By the assumption, there exists $\phi : P \rightarrow \mathbb{R}_{\|\cdot\|_X}^{d_1}$ such that $\|\phi(i) - \phi(i + 1)\|_X \leq g(d_{\mathcal{M}}(i, i + 1)) = g(a)$, while on the other hand,

$$g(b) \leq g\left(\frac{\lceil 2Db/a \rceil a}{D}\right) = g\left(\frac{d_{\mathcal{M}}(0, n)}{D}\right) \leq \|\phi(0) - \phi(n)\|_X,$$

since g is monotone increasing, as f is monotone increasing. Then by the triangle inequality,

$$g(b) \leq \|\phi(0) - \phi(n)\|_X \leq \sum_{i=1}^n \|\phi(i - 1) - \phi(i)\|_X \leq n g(a) \leq 4D \frac{b g(a)}{a},$$

which implies that $\frac{g(b)/b}{g(a)/a} \leq 4D$, which is a contradiction.

Next, assume that there exists $C > 1$ such that $\sup_{0 < a \leq b < \infty} \frac{g(b) \cdot a}{g(a) \cdot b} \leq C$ (‘‘convex f ’’). Then, for any $a \leq b$ we have $\frac{g(b)a}{Cb} \leq g(a)$. In particular, we have $\frac{g(d_{\mathcal{M}}(x, y))(d_{\mathcal{M}}(x, y)/D)}{C d_{\mathcal{M}}(x, y)} \leq g(d_{\mathcal{M}}(x, y)/D)$. Namely,

$$\frac{g(d_{\mathcal{M}}(x, y))}{C \cdot D} \leq g\left(\frac{d_{\mathcal{M}}(x, y)}{D}\right) \leq \|\phi(x) - \phi(y)\|_X \leq g(d_{\mathcal{M}}(x, y)).$$

Since $\|\cdot\|_X$ is d_2 -dimensional, by John’s theorem (see [3, Chap. V]) it can be approximated by $\|\cdot\|_2$ up to a $\sqrt{d_2}$ factor. We thus have a $C' > 1$ such that for any d_1 -dimensional finite metric $(P, d_{\mathcal{M}})$, there exists $\phi' : (P, d_{\mathcal{M}}) \rightarrow \mathfrak{H}_{\|\cdot\|_2}^{d_2}$ satisfying

$$(6.1) \quad \frac{g(d_{\mathcal{M}}(x, y))}{C'} \leq \|\phi'(x) - \phi'(y)\|_2 \leq g(d_{\mathcal{M}}(x, y)).$$

We next estimate how much $g \circ d_{\mathcal{M}}$ distorts $d_{\mathcal{M}}$ as a function of the spread of P . Assume that $\min_{x \neq y \in P} d_{\mathcal{M}}(x, y) = a_1$ and $\max_{x \neq y \in P} d_{\mathcal{M}}(x, y) = b_1$, that is, $\Phi(P) = b_1/a_1$. Then

$$\begin{aligned} \max_{a_1 \leq t} \frac{g(t)}{t} &= \frac{g(a_1)}{a_1} \cdot \max_{a_1 \leq t} \frac{g(t)a_1}{tg(a_1)} \leq C \frac{g(a_1)}{a_1}, \\ \max_{s \leq b_1} \frac{s}{g(s)} &= \frac{b_1}{g(b_1)} \cdot \max_{s \leq b_1} \frac{g(b_1)s}{b_1g(s)} \leq C \frac{b_1}{g(b_1)}. \end{aligned}$$

Thus, considering the “distortion” of g , we have

$$\frac{\max_{x \neq y \in P} \frac{g(d_{\mathcal{M}}(x, y))}{d_{\mathcal{M}}(x, y)} \cdot \max_{x \neq y \in P} \frac{d_{\mathcal{M}}(x, y)}{g(d_{\mathcal{M}}(x, y))}}{\Phi(P)} \leq \frac{C \frac{g(a_1)}{a_1} \cdot C \frac{b_1}{g(b_1)}}{b_1/a_1} = C^2 \frac{g(a_1)}{g(b_1)}.$$

As $g(0) = 0$ and $\lim_{x \rightarrow \infty} g(x) = \infty$, we conclude that this ratio tends to 0 as the spread $\Phi(P)$ tends to ∞ . Combining it with (6.1), we conclude that for $\widehat{\phi} : (P, d_{\mathcal{M}}) \rightarrow \mathfrak{R}_{\|\cdot\|_2}^{d_2}$, defined as $\widehat{\phi}(x) = \phi'(x)$, we have $\text{dist}(\widehat{\phi}) = o(\Phi(P))$. We will next show that this is impossible when P is a sufficiently dense net of \mathbb{S}^{d_2} .

Let $0 < \eta \leq 0.1$. We take $P = P_{\eta}$ to be an η -net of $\mathbb{S}_{\|\cdot\|_2}^{d_2}$. The finite metric P_{η} has doubling dimension at most d_1 . From the above we can embed $\phi' : P_{\eta} \rightarrow \mathfrak{R}_{\|\cdot\|_2}^{d_2}$ with distortion $o(\Phi(P)) = o(\eta^{-1})$. By scaling we may assume that this embedding is 1-Lipschitz. By Kirszbraun’s theorem (see [7, Chap. 1]), the embedding ϕ' can be extended to the whole sphere $\widehat{\phi}' : \mathbb{S}_{\|\cdot\|_2}^{d_2} \rightarrow \mathbb{R}_{\|\cdot\|_2}^{d_2}$ without increasing the Lipschitz constant. The Borsuk–Ulam theorem (cf. [37]) states that there exists $x \in \mathbb{S}^k$ such that $\widehat{\phi}'(x) = \widehat{\phi}'(-x)$. Note that $\exists y, z \in P_{\eta}$ such that $\|x - y\|_2 \leq \eta$, and $\|(-x) - z\|_2 \leq \eta$. Since $\widehat{\phi}'$ is 1-Lipschitz, we have

$$\|\phi'(y) - \phi'(z)\|_2 = \|\widehat{\phi}'(y) - \widehat{\phi}'(z)\|_2 \leq \|\widehat{\phi}'(y) - \widehat{\phi}'(x)\|_2 + \|\widehat{\phi}'(-x) - \widehat{\phi}'(z)\|_2 \leq 2\eta.$$

On the other hand, $\|y - z\|_2 \geq 1 - 2\eta$, which means that the Lipschitz constant of ϕ'^{-1} , and thus the distortion of ϕ' , is at least $\Omega(\eta^{-1})$. This is a contradiction when η is a sufficiently small positive number, since we argued above that the distortion must be $o(\Phi(P)) = o(\eta^{-1})$. \square

6.3. Distance labeling. An approximate distance labeling scheme (ADLS) seeks to compute for each point in the metric a short label such that given the labels of a pair of points, it is possible to compute efficiently an approximation of the pairwise distance. Thus, ADLS is a stricter notion of compact representation.⁵ This notion was studied, for example, in [19, 18, 45].

In the constant doubling dimension setting, Gupta et al. [23] have shown a $(1 + \varepsilon)$ -embedding of the metric in $\ell_{\infty}^{O(\log n)}$. This implies a $(1 + \varepsilon)$ -ADLS with $O(\log n \log \Phi)$ bits for each label (the O notation here hides constants that depend on ε and dim). Talwar [44] has shown an improved $(1 + \varepsilon)$ -ADLS with only $\varepsilon^{-O(\text{dim})} \log \Phi$ bits per label. Slivkins [43] has shown a $(1 + \varepsilon)$ -ADLS with $\varepsilon^{-O(\text{dim})} \log^2 n \log \log \Phi$ bits per label. Their techniques seem to be very different from each other.

⁵When comparing the storage of ADLSs to that of the CRSs from the previous sections, note that here we count *bits*, whereas in the rest of the paper we count *words* of length $O(\log n + \log \log \Phi + \log \varepsilon^{-1})$.

Here we improve Slivkins’ result and unify it with Talwar’s result under the same technique.

PROPOSITION 6.10. *Given a finite metric space, one can build a $(1 + \varepsilon)$ -ADLS with*

$$\min \left\{ \varepsilon^{-O(\dim)} \log \Phi, \varepsilon^{-O(\dim)} \log n(\log n + \log \log \Phi) \right\}$$

bits per label.

Furthermore, there exist one-dimensional finite metric spaces of size n , and spread $\Phi \geq 2^{2n}$ for which any 1.9-ADLS requires labels of size $\Omega(\log n \log \log \Phi)$ bits per label.

Proof (sketch). First, labels of length $\varepsilon^{-O(\dim)} \log \Phi$ follow directly from Theorem 6.5: We have $\varepsilon^{-O(\dim)}$ coordinates, and, as discussed after the proof of Theorem 6.5, we need only $O(\log(\Phi/\varepsilon))$ bits of accuracy for each coordinate.

We next show a $(1 + \varepsilon)$ -ADLS using $\varepsilon^{-O(\dim)} \log n(\log n + \log \log \Phi)$ bits per label. We do so by presenting a “distributed implementation” of the data-structure used to prove Corollary 6.8. That data-structure consists of two trees (HSTs) H_1, H_2 on the same set of leaves: the points of the metric. Given two points x^1, x^2 , we compute $u_i = \text{lca}_{H_i}(x^1, x^2)$, and x_i^j is the ancestor of x^j in H_i which is the child of u_i . We then apply an Assouad embedding $A(x_i^j)$ that uses $O(\log n + \log \log \Phi + \log(\varepsilon^{-1}))$ bits. We define an identifier $I(v)$ of vertex $v \in H_i$ to be $A(v)$ concatenated with the Δ_v (encoded with $O(\log \log \Phi)$ bits). Hence, given two points x^1, x^2 , using the identifiers $I(x_1^1), I(x_1^2), I(x_2^1), I(x_2^2), I(u_1), I(u_2)$, we can compute a $(1 + \varepsilon)$ -approximation of $d_{\mathcal{M}}(x_1, x_2)$. We now use (the proof of) a result of Peleg [39]: Given an n -vertex rooted tree with identifiers $I(v)$ of maximum length s on the vertices, it is possible to efficiently compute labels $L(v)$ of length $O(\log n(\log n + s))$ to the vertices, such that given $L(x)$ and $L(y)$ one can efficiently decode $I(u)$, where $u = \text{lca}(x, y)$.

Unfortunately, we need a little bit more, namely, access to the children of u which are the ancestors of x and y . In order to obtain it we tinker with the construction of Peleg: In his Definition 3.2 from [39], we extend the tuple $Q_i(v)$ to be

$$Q_i(v) = \left\langle \langle i - 1, I(\gamma_{i-1}(v)) \rangle, \langle i, I(\gamma_i(v)) \rangle, \langle i + 1, I(\gamma_{i+1}(v)) \rangle, \underline{\langle i, I(\text{hs}(\gamma_i(v))) \rangle} \right\rangle,$$

where $\text{hs}(u)$ is the *heavy sibling* of u (the underlined part is our extension). By studying Peleg’s construction, it is easy to verify that this extension suffices.

The above construction is asymptotically optimal in terms of n and Φ when $\Phi \geq 2^{2n}$, as we now prove. In [19] there is a family of n -vertex weighted rooted binary trees, such that any exact distance labeling scheme of the *leaves* requires labels of length $\Omega(\log n \log M)$ bits, where the edge weight is in the range $\{0, \dots, M - 1\}$. A further property of that family of trees is that the depth $h = M \log_2 n$ (i.e., the distance from the root) of all the leaves is the same. We next transform each tree T in that family into an HST H by giving every vertex v a label $2^{-\text{depth}_T(v)}$. For any two leaves x and y , let $d_T(x, y) = 2(h + \log_2 d_H(x, y))$. Furthermore, even a 1.9 approximation of $d_H(x, y)$ allows us to recover the exact value of $d_H(x, y)$, since this value is an integral power of 2. Let us summarize: Given a 1.9 approximation of the distance in H allows us to obtain the exact distance in T . Therefore by setting $M = (\log_2 \Phi)/n$, it proves a lower bound of $\Omega(\log n \log \log \Phi)$ on the average label’s length for a 1.9-ADLS for this family of HSTs. Since these HSTs are binary, their doubling dimension is 1. \square

After a preliminary version of this paper appeared, Slivkins [42] managed to produce an ADLS with labels of length $\varepsilon^{-O(\dim)} \log n \log \log \Phi$, which improves upon our construction in the range $n^{\log \log n} \ll \Phi \ll 2^n$.

7. Doubling measure. A measure μ on a metric space \mathcal{M} is called η -doubling if, for any $x \in \mathcal{M}$ and $r \geq 0$, $\mu(\mathbf{b}(x, 2r)) \leq \eta \cdot \mu(\mathbf{b}(x, r))$. *Doubling measure* is already a useful notion in the analysis of metric spaces (see [27]) and has recently been used in some algorithmic applications [43]. Vol'berg and Konyagin [47] proved that any compact λ -doubling metric space has a $\lambda^{O(1)}$ -doubling measure. Wu's proof of this theorem [48] can be implemented in linear time on the net-tree.

We assume that the net-tree T is already given. Denote by $\deg(v)$ the number of children of $v \in T$. Let $\gamma = \max_{v \in T} \deg(v)$ be the maximum degree in T . As we have seen before, $\gamma \leq 2^{O(\dim)}$. The probability measure μ is computed by calling $\text{Partition}(\text{root}, 1)$, where Partition is defined recursively as follows.

```

Partition( $u \in T, p_u \in [0, 1]$ ).
  if  $u$  is a leaf then
    Set  $\mu(\{\text{rep}_u\}) \leftarrow p_u$ .
  else
    for each child  $v$  of  $u$  with  $\text{rep}_v \neq \text{rep}_u$  do
      Set  $p_v \leftarrow p_u / \gamma$ .
      Call Partition( $v, p_v$ ).
    Let  $v_0$  be the unique child of  $u$  such that  $\text{rep}_{v_0} = \text{rep}_u$ .
    Set  $p_{v_0} \leftarrow p_u(1 - (\deg(u) - 1) / \gamma)$ .
    Call Partition( $v_0, p_{v_0}$ ).
    
```

PROPOSITION 7.1. *For any $u \in T$, we have $p_u = \mu(P_u)$.*

Proof. The proof is by straightforward induction on the height of T . □

PROPOSITION 7.2. *Fix $l \in \mathbb{N}$, and two vertices u and v in T , such that $\max\{\ell(u), \ell(v)\} < l \leq \min\{\ell(\bar{p}(u)), \ell(\bar{p}(v))\}$ and $d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v) \leq 40\tau^l$. Then $p_u \leq \gamma^{O(1)}p_v$.*

Proof. Denote $w = \text{lca}_T(u, v)$, and denote by $w = u_0, u_1, \dots, u_a = u$ the path in T from w to u , and by $w = v_0, v_1, \dots, v_b = v$ the path in T from w to v .

We claim that for any $i \geq 1$, if $\ell(u_i) > l + 3$, then $\text{rep}_{u_i} \neq \text{rep}_{u_{i+1}}$. Indeed, otherwise

$$\begin{aligned}
 d_{\mathcal{M}}(\text{rep}_{u_i}, \text{rep}_v) &\leq d_{\mathcal{M}}(\text{rep}_{u_{i+1}}, \text{rep}_u) + d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v) \\
 &\leq \frac{2\tau}{\tau - 1} \cdot \tau^{\ell(u_{i+1})} + 40\tau^l \leq \frac{2}{\tau - 1} \tau^{\ell(u_i)} + 40\tau^{-4} \cdot \tau^{\ell(u_i)} \leq \frac{\tau^{\ell(u_i)}}{4},
 \end{aligned}$$

but this is a contradiction to the packing property of Definition 2.1, since $v \notin P_{u_i}$ (note that for this argument to work, τ needs to be a large enough constant, say 11).

Next, we claim that for any $i \geq 1$ for which $\ell(u_i) > l + 3$, $\ell(u_{i-1}) = \ell(u_i) + 1$. Otherwise, $\ell(u_{i-1}) - 1 \geq \ell(u_i) + 1$, implying

$$\begin{aligned}
 d_{\mathcal{M}}(\text{rep}_{u_i}, \text{rep}_v) &\leq d_{\mathcal{M}}(\text{rep}_{u_{i+1}}, \text{rep}_u) + d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v) \leq \frac{2\tau}{\tau - 1} \cdot \tau^{\ell(u_i)} + 40\tau^{-4} \cdot \tau^{\ell(u_i)} \\
 &= \left(\frac{2\tau}{\tau(\tau - 1)} + \frac{40}{\tau^5} \right) \cdot \tau^{\ell(u_i)+1} \leq \frac{\tau^{\ell(u_{i-1})-1}}{4} = \frac{\tau^{\ell(\bar{p}(u_i))-1}}{4},
 \end{aligned}$$

contradicting the packing property of Definition 2.1, since $v \notin P_{u_i}$.

Thus, the path between u and w is full, containing vertices on all levels, except maybe the last three levels. Furthermore, the representatives are different in each level. We therefore conclude that $p_u \leq p_w/\gamma^{\ell(w)-l-4}$. On the other hand, $p_v \geq p_w\gamma^{\ell(w)-l+1}$. Therefore $p_u \leq \gamma^5 p_v$. \square

THEOREM 7.3. *For any n -point metric space having doubling dimension dim , it is possible to construct a $2^{O(\text{dim})}$ -doubling measure in $2^{O(\text{dim})}n \log n$ time.*

Proof. The running time of Partition is clearly linear and is dominated by the time to construct the net-tree.

We are left to prove that μ is a $\lambda^{O(1)}$ -doubling measure. Let $x \in P$ and $r > 0$. Denote $N = \{u \in T \mid \ell(u) \leq \log_\tau(r/8) < \ell(\bar{p}(u))\}$. As we have seen in Proposition 2.2, the representatives of the vertices of N forms a net in the right scale. In particular, there exists $\hat{x} \in N$ such that $d_{\mathcal{M}}(x, \text{rep}_{\hat{x}}) \leq 3r/8$ and $P_{\hat{x}} \subset \mathbf{b}(\text{rep}_{\hat{x}}, 3r/8) \subset \mathbf{b}(x, r)$. Hence $p_{\hat{x}} \leq \mu(\mathbf{b}(x, r))$. On the other hand, any two different representatives of vertices from N are at least $r/40$ separated, and therefore, for $X = N \cap \{u \in T \mid \text{rep}_u \in \mathbf{b}(x, 3r)\}$, we have $|X| \leq \lambda^{O(1)}$. Note that $\mathbf{b}(x, 2r) \subset \cup_{u \in X} P_u$, and therefore

$$\mu(\mathbf{b}(x, 2r)) \leq \sum_{u \in X} p_u \leq |X| \max_{u \in X} p_u.$$

By Proposition 7.2, $\max_{u \in X} p_u \leq \lambda^{O(1)} p_{\hat{x}}$. We conclude that $\mu(\mathbf{b}(x, 2r)) \leq \lambda^{O(1)} \mu(\mathbf{b}(x, r))$. \square

We note in passing that algorithm Partition can be programmed in our computational model since every point gets at least a $2^{-O(n \log n)}$ measure, which can be easily represented in a floating-point word of length $O(\log n)$. Moreover, the algorithm has a “built in” mechanism to handle rounding error: instead of dividing by γ , we can divide by, say, 2γ , and now rounding errors are automatically offset in the measure given to v_0 .

8. Lipschitz constant of mappings.

DEFINITION 8.1. *A function $f : (P, \nu) \rightarrow (M, \rho)$ is K -Lipschitz if for any $x, y \in P$, we have $\rho(f(x), f(y)) \leq K \cdot \nu(x, y)$.*

A point $x \in P$ is K -Lipschitz if, for any $y \in P$, we have $\rho(f(x), f(y)) \leq K \cdot \nu(x, y)$.

Thus, given a set of points $P \subseteq \mathbb{R}^d$, and a mapping $f : P \rightarrow \mathbb{R}^d$, it is natural to ask how quickly we can compute the Lipschitz constant for f on the set P , and more specifically, to compute it for every point of P .

8.1. The low-dimensional Euclidean case. Here, we consider a mapping $f : P \rightarrow (M, \rho)$, where $P \subseteq \mathbb{R}$ is of size n , and (M, ρ) is an arbitrary metric space given as a matrix.

PROPOSITION 8.2. *Computing the Lipschitz constant for f on P can be done in $O(n \log n)$ time.*

Proof. Indeed, let a, b, c be three numbers in P such that $a < b < c$. Observe that

$$\frac{\rho(f(c), f(a))}{c - a} \leq \frac{\rho(f(c), f(b)) + \rho(f(b), f(a))}{c - b + b - a} \leq \max\left(\frac{\rho(f(c), f(b))}{c - b}, \frac{\rho(f(b), f(a))}{b - a}\right),$$

since for any p, q, r, s positive numbers such that $p/q \leq r/s$, we have $p/q \leq (p + r)/(q + s) \leq r/s$. Thus, the Lipschitz constant is realized by a consecutive pair of points in P . We can therefore sort P and compute the slope for every consecutive pair. Clearly, the maximum is the Lipschitz constant of f . \square

PROPOSITION 8.3. *Let P be a set of n numbers on the real line, and let $f : P \rightarrow \mathfrak{R}$ be a given mapping. One can compute the Lipschitz constant of f on every point of P in $O(n \log^2 n)$ time.*

Proof. Consider the set $Q = \{(p, f(p)) \mid p \in P\}$. Let p be a point in P , and let L_p be the set of points of Q strictly to the left of p (according to the x -order), and let R_p be the set of points to its right. Denote by $\mathcal{CH}(A)$ the convex hull of $A \subset \mathfrak{R}^2$. If we know the tangents to $\mathcal{CH}(L_p)$ and $\mathcal{CH}(R_p)$ that pass through p , then we can compute the Lipschitz constant of p in constant time (i.e., it is the slope of the tangent with the largest slope).

Here, one can use the data-structure of Overmars and van Leeuwen [38], which supports the maintenance of the convex hull under insertions, deletions, and tangent queries in $O(\log^2 n)$ per operation. Indeed, sort the points of P from left to right. Let p_1, \dots, p_n be the sorted points. Clearly, given $\mathcal{CH}(L_{p_i})$ and $\mathcal{CH}(R_{p_i})$ stored in the dynamic convex hull data-structure, we can compute $\mathcal{CH}(L_{p_{i+1}})$ and $\mathcal{CH}(R_{p_{i+1}})$ by deleting p_{i+1} from $\mathcal{CH}(R_{p_i})$ and inserting p_i into $\mathcal{CH}(L_{p_i})$. Thus, we can compute all the relevant convex hulls in $O(n \log^2 n)$ time. Furthermore, when we have $\mathcal{CH}(L_{p_i})$ and $\mathcal{CH}(R_{p_i})$, we perform tangent queries to compute the Lipschitz constant of p_i . Thus, the overall running time is $O(n \log^2 n)$. \square

THEOREM 8.4. *Given a set P of n points in the plane, and a mapping $f : P \rightarrow \mathfrak{R}$, one can compute the Lipschitz constant of f in $O(n \log^2 n)$ expected time.*

Proof. Assume that we know that f is K -Lipschitz on a set $Q \subseteq P$, and we would like to verify that it is K -Lipschitz on $\{q\} \cup Q$, where $q \in P \setminus Q$. This can be visualized as follows: From every point $p \in P$, there is an associated point in \mathfrak{R}^3 , which is $\hat{p} = (p_x, p_y, f(p))$. Being K -Lipschitz, as far as p is concerned, implies that q must lie below the upper cone of slope K emanating from \hat{p} and above the lower cone of slope K emanating from \hat{p} . Thus, if we collect all those upper cones, then q must lie below their lower envelope. However, since the upper cones all have the same slope, their lower envelope is no more than a (scaled) version of an additive weighted Voronoi diagram in the plane. Such a diagram can be computed in $O(n \log n)$ time for n points, and a point-location query in it can be performed in $O(\log n)$ time.

In fact, using the standard Bentley–Saxe technique [6], one can build a data-structure, where one can insert such upper cones in $O(\log^2 n)$ amortized time, given a query point q in the plane, and decide in $O(\log^2 n)$ time which of the cones inserted lies on the lower envelope vertically above q . Similar data-structures can be built for the upper envelope of the lower cones.

Thus, if we conjecture that the Lipschitz constant is K , then we can verify it for P in $O(n \log^2 n)$ time by inserting the points of P into the upper and lower envelope data-structure described above. However, let us assume that K is too small. Then, after inserting a subset Q of points into the data-structure, we will try to verify that the Lipschitz constant for a point $p \in P$ is K and fail. Then, it must be that the Lipschitz constant of f on $Q \cup \{p\}$ is realized by p . Thus, we can compute the Lipschitz constant of p in $Q \cup \{p\}$ in $O(|Q|)$ time, update our guess K , and rebuild the upper and lower data-structures for $Q \cup \{p\}$.

Of course, in the worst case, this would required $O(n^2 \log^2 n)$ running time (i.e., we would fail on every point). However, it is well known that if we randomly permute the points, and handle the points according to this ordering, then the value of the Lipschitz constant on every prefix would change $O(\log n)$ times in expectation. Thus, this would lead to $O(n \log^3 n)$ expected running time. Moreover, a slightly more careful analysis shows that the expected running time is $O(n \log^2 n)$. See [16] for details of such analysis. \square

8.2. Constant doubling dimension to arbitrary metric.

THEOREM 8.5. *We are given a metric (P, ν) of n points having doubling dimension d , and a mapping $f : P \rightarrow (\mathcal{M}, \rho)$, where \mathcal{M} is an arbitrary metric space. Then one can compute a $(1 + \varepsilon)$ -approximation of the Lipschitz constant of f in $n\varepsilon^{-O(d)} \log^2 n$ expected time.*

Proof. The algorithm is as follows:

1. Compute ε^{-1} -WSPD of P according to section 5.
2. Set $K \leftarrow 0$.
3. For every pair $(A, B) \in \varepsilon^{-1}$ -WSPD do:
 - (a) Obtain *some* pair of points $a \in A$ and $b \in B$.
 - (b) Compute $K \leftarrow \max\{K, \frac{\rho(f(a), f(b))}{\nu(a, b)}\}$.

Obviously the value K computed by the algorithm above is not larger than the Lipschitz constant of f . We next show that it is not much smaller. Let $x, y \in P$ be a pair in which f obtains its Lipschitz constant, i.e., $\frac{\rho(f(x), f(y))}{\nu(x, y)} = \max_{a \neq b} \frac{\rho(f(a), f(b))}{\nu(a, b)}$. Let $\{A, B\} \in \text{WSPD}$ be a pair such that $x \in A, y \in B$. Our algorithm chooses some pair $a \in A, b \in B$. Using the triangle inequality we have

$$\begin{aligned} \frac{\rho(f(a), f(b))}{\nu(a, b)} &\geq \frac{\rho(f(x), f(y)) - \text{diam}(f(A)) - \text{diam}(f(B))}{\nu(x, y) + \text{diam}(A) + \text{diam}(B)} \\ &\geq \frac{\rho(f(x), f(y)) - \text{diam}(f(A)) - \text{diam}(f(B))}{(1 + 2\varepsilon)\nu(x, y)}. \end{aligned}$$

If $\max\{\text{diam}(f(A)), \text{diam}(f(B))\} \leq \varepsilon \cdot \rho(f(x), f(y))$ then we conclude that

$$\frac{\rho(f(a), f(b))}{\nu(a, b)} \geq \frac{(1 - 2\varepsilon)\rho(f(x), f(y))}{(1 + 2\varepsilon)\nu(x, y)}$$

and we are done. Otherwise, assume that $\text{diam}(f(A)) > \varepsilon \cdot \rho(f(x), f(y))$. Then there exists $f(a_1), f(a_2) \in f(A)$ for which $\rho(f(a_1), f(a_2)) > \varepsilon \cdot \rho(f(x), f(y))$, whereas

$$\nu(a_1, a_2) \leq \text{diam}(A) \leq \varepsilon \cdot \nu(A, B) \leq \varepsilon \cdot \nu(x, y).$$

Thus,

$$\frac{\rho(f(a_1), f(a_2))}{\nu(a_1, a_2)} > \frac{\varepsilon \cdot \rho(f(x), f(y))}{\varepsilon \cdot \nu(x, y)},$$

which is a contradiction to the maximality of the pair $\{x, y\}$. □

9. Fast approximation of the doubling dimension.

THEOREM 9.1. *Given a metric space \mathcal{M} with n points, one can approximate the doubling dimension dim of \mathcal{M} , up to a constant factor, in $2^{O(\text{dim})} n \log n$ expected time.*

Notice that this theorem, apart from its intrinsic interest, also removes the need to specify dim together with the input for the other algorithms in this paper.

The algorithm suggested in Theorem 9.1 naturally uses the net-tree.

PROPOSITION 9.2. *Given a net-tree T of a metric \mathcal{M} , denote by λ_T the maximum out degree in T . Then $\log \lambda_T$ is a constant approximation to $\text{dim}(\mathcal{M})$.*

Proof. Let $v \in T$ be the vertex with the maximum number of children λ_T . By Definition 2.1, any covering of $\mathbf{b}(\text{rep}_v, \frac{2\tau}{\tau-1}\tau^{\ell(v)})$ by balls of radius $\frac{\tau-5}{4\tau(\tau-1)}$ requires at least λ_T such balls. This means that $\text{dim}(\mathcal{M}) = \Omega(\log \lambda_T)$.

The upper bound $\dim(\mathcal{M}) = O(\log \lambda_T)$ follows easily from the arguments of section 7. There, we actually prove the existence of a $\lambda_T^{O(1)}$ -doubling measure in \mathcal{M} , and it is easy to prove that the existence of an α doubling measure in \mathcal{M} implies that $\dim(\mathcal{M}) \leq \alpha$. \square

Proof of Theorem 9.1. By Proposition 9.2 it is enough to show an implementation of the algorithm for constructing the net-tree that is oblivious to the doubling dimension of the metric. Checking the algorithm in section 3, we observe that the algorithms in sections 3.1, 3.3, and 3.4 are indeed oblivious to the doubling dimension. We are therefore left with describing a doubling-dimension-oblivious algorithm for constructing HST that $O(n^2)$ -approximates the given metric. More specifically, the only part that needs to be changed is the use of Lemma 2.4 in Lemma 3.5. To this end, instead of knowing λ , we “guess” the doubling constant to be 2^i , increasing i until we “succeed.” More accurately, in the i th iteration, we apply the following sampling step 2^{3i} times: Pick randomly a point p from P , and compute the ball $\mathbf{b}(p, r)$ of smallest radius around p containing at least $n/(2 \cdot 2^{3i})$ points. Next, consider the ball of radius $\mathbf{b}(p, 2r)$. If it contains $\leq n/2$ points, the algorithm succeeded, and it stops. The algorithm is guaranteed to stop when $i \geq \lceil \log n \rceil$. Denote by $\delta = \delta(X)$ the random value, which is the value of 2^i when the algorithm stopped, when applied to a point set $X \subset \mathcal{M}$.

The resulting spanner is a $3n$ -approximation *regardless* of the random bits, and thus the correctness of the net-tree algorithm is guaranteed. We need only argue about the expected running time for constructing the HST. The running time of the HST constructed is dominated by the spanner construction and the number of edges in it (see Lemma 3.5). Denote by λ the doubling constant of the metric \mathcal{M} .

PROPOSITION 9.3. *For any $X \subset \mathcal{M}$,*

1. $\mathbf{E}[\delta(X)^{-3}] \geq \lambda^{-3}/16$.
2. $\mathbf{E}[\delta(X)^3] = O(\lambda^3)$.

Proof. Consider the algorithm above for computing $\delta(X)$. Once i reaches the value $k = \lceil \log_2 \lambda \rceil$, the probability of success on each point sampled is at least 2^{-3k} (by the argument in Lemma 2.4). Hence the probability of success in the i th round, $i \geq k$, conditioned on a failure in all previous rounds is at least $1 - (1 - 2^{-3k})^{2^{3i}}$, which means that

$$\mathbf{E}[\delta(X)^{-3}] \geq 1 - (1 - 2^{-3k})^{2^{3k}} 2^{-3k} \geq (1 - 1/e)\lambda^{-3}/8.$$

It also means that $\Pr[\delta \geq 2^{k+i}] \leq (1 - 2^{-3k})^{2^{3(k+i-1)}} \leq \exp(-\binom{i}{2})$, and therefore

$$\mathbf{E}[\delta^3] = \sum_{t=1}^{\infty} \Pr[\delta^3 \geq t] \leq 2\lambda^3 + \sum_{t=2^{3k}}^{\infty} \exp\left(-\binom{\log t - 3k}{2}\right) \leq 2\lambda^3 + O(1). \quad \square$$

We prove only an upper bound on the running time. Bounding the number of edges is similar. Denote by $f(X)$ the running time of the algorithm when applied to $X \subseteq \mathcal{M}$, and let $g(X) = \mathbf{E}[f(X)]$ and $g(n) = \sup_{X \subseteq \mathcal{M}, |X|=n} g(X)$.

The spanner construction algorithm of Lemma 3.5 satisfies

$$(9.1) \quad g(X) \leq \mathbf{E}\left[\max_{\delta(X)^{-3} \leq \alpha \leq 1/2} (g(\alpha|X|) + g((1 - \alpha)|X|) + c'\delta(X)^3 n)\right].$$

We now prove by induction that $g(n) \leq c\lambda^3 n \ln n$ for some $c > 0$. Fix Y to be a

subset of \mathcal{M} of size n such that $g(Y) = g(n)$. We have

$$\begin{aligned}
 g(n) &\leq \mathbf{E} \left[\max_{\delta(Y)^{-3} \leq \alpha \leq 1/2} (\mathbf{E}[g(\alpha|Y)] + \mathbf{E}[g((1-\alpha)|Y)]) + c'\delta^3 n \right] \\
 &\leq \mathbf{E} \left[\max_{\delta(Y)^{-3} \leq \alpha \leq 1/2} (c\lambda^3 \alpha |Y| \ln(\alpha|Y|) + c\lambda^3 (1-\alpha) |Y| \ln((1-\alpha)|Y|) + c'\delta^3 n) \right] \\
 &\leq \mathbf{E} [c\lambda^3 \delta^{-3} n \ln(\delta^{-3} n) + c\lambda^3 (1-\delta^{-3}) n \ln((1-\delta^{-3}) n) + c'\delta^3 n] \\
 &\leq c\lambda^3 n \cdot \mathbf{E} [\delta^{-3} \ln(\delta^{-3} n) + (1-\delta^{-3}) \ln((1-\delta^{-3}) n)] + (c''\lambda^3 + d')n \\
 &\leq c\lambda^3 n \cdot \mathbf{E} [\ln((1-\delta^{-3}) n)] + (c''\lambda^3 + d')n \\
 &\leq c\lambda^3 n \ln n + c\lambda^3 n \cdot \mathbf{E} [\ln(1-\delta^{-3})] + (c''\lambda^3 + d')n \\
 &\leq c\lambda^3 n \ln n - c\lambda^3 n \cdot \mathbf{E} [\delta^{-3}] + (c''\lambda^3 + d')n \\
 &\leq c\lambda^3 n \ln n - c\lambda^3 n \cdot (\lambda^{-3}/16) + (c''\lambda^3 + d')n \\
 &\leq c\lambda^3 n \ln n,
 \end{aligned}$$

since $\ln(1-\delta^{-3}) \leq -\delta^{-3}$, by Proposition 9.3, and for $c > 0$ large enough. \square

10. Concluding remarks. In this paper, we show how to efficiently construct hierarchical nets for finite spaces with low doubling dimension and use this construction in several applications. We believe that this result will have further applications.

Among other things, our fast construction of WSPD implies a near linear time construction of an approximate minimum spanning tree of the space. Our fast construction of net-tree implies that one can do 2-approximate k -center clustering in $O(n \log n)$ expected time.

Further, transfer of problems and techniques from low-dimensional Euclidean space to low-dimensional metrics seems to be interesting. A plausible example of such problems is the construction of $(1 + \varepsilon)$ -spanners with some additional properties (such as low total weight or small hop-diameter). Results of this flavor exist in low-dimensional Euclidean spaces.

It is easy to verify that, for a general metric, no HST can be constructed without inspecting all $\binom{n}{2}$ edges. Indeed, consider the uniform metric over n points, and change in an adversarial fashion a single edge to have length 0.

10.1. All nearest neighbors. The *all nearest neighbor problem* is to compute for a set P of n points the (exact) nearest neighbor for each point of $p \in P$ in the set $P \setminus \{p\}$. It is known that in low-dimensional Euclidean space this can be done in $O(n \log n)$ time [13, 46, 11]. One can ask if a similar result can be attained for finite metric spaces with low doubling dimensions. Below we show that this is impossible.

Consider the points p_1, \dots, p_n , where the distance between p_i and p_j , for $i < j$, is either 2^j or $2^j + \varepsilon$, for $\varepsilon < 0.1$. It is easy to verify that this metric has doubling constant at most three. We now show that for any deterministic algorithm for computing all nearest neighbors, there is a metric in the family of the metrics described above for which the algorithm performs $\binom{n}{2}$ distance queries.

This claim is proved using an adversarial argument: When the adversary is queried about the distance between p_i and p_j , for $i < j$, if not all the distances between p_1, \dots, p_{j-1} and p_j were specified, the adversary will always return the distance to be $2^j + \varepsilon$. The distances 2^j would be returned only for the last pair among the $j - 1$ pairs in this set. In particular, for the algorithm to know what is the closest point to p_j , it must perform $j - 1$ queries. Thus, overall, an algorithm doing all nearest neighbors for p_1, \dots, p_n will have to perform $\binom{n}{2}$ queries.

A similar asymptotic lower bound can be proved for randomized algorithms using Yao’s principle (here the adversary selects for each j one index $i_j < j$ at random for which $d(p_{i_j}, p_j) = 2^j$, and for the rest of $i \neq i_j, i < j, d(p_i, j) = 2^j + \varepsilon$).

At this point, it is natural to ask whether one can achieve running time of $O(n \log(n\Phi(P)))$ for the all nearest neighbor problem. This, however, is straightforward. Indeed, compute a 4-WSPD of P . Clearly, if q is a nearest neighbor for p , then there is a pair in the WSPD such that p is the only point on one side, and the other side contains q . Thus, we scan all such unbalanced pairs (one point on one side, and many points on the other side) and compute the nearest neighbor for each point. Thus, this computes all nearest neighbors. As for the running time analysis, consider all such pairs in distance range l to $2l$, and observe that by a packing argument, for any node u in the net-tree, the number of such WSPD pairs with u in them is $2^{O(\dim)}$. In fact, along a path in the net-tree, only a constant number of nodes might participate in such pairs. Thus, every point is being scanned $2^{O(\dim)}$ times, implying that scanning all such pairs takes $2^{O(\dim)}n$ time. There are $\lceil \lg(\Phi(P)) \rceil$ resolutions, so the overall running time is $2^{O(\dim)}n \log(n\Phi(P))$.

Appendix. Proof of Lemma 3.9. Notice that Lemma 3.7 implies that $(\bar{r}_i)_{i \geq 1}$ is a monotone nonincreasing sequence and that $r_i \geq \bar{r}_i \geq r_i/(1 + n^{-2}) \geq \frac{4}{5}r_i$.

Proof of Lemma 3.9. We prove by induction on k all five assertions together. The base case is obvious. Assume by the induction hypothesis that $T^{(k-1)}$ satisfies all the properties above. We prove it for $T^{(k)}$.

Property (i). Every point inserted during the l th phase (i.e., a point p_i for which $\lceil \log_\tau \bar{r}_i \rceil = l$) must have its current parent (in $T^{(k)}$) at level l . Thus, if $\ell(\hat{u}) > l$, this means that c_{p_k} was inserted before the current phase, which means that it is indeed the closest point to p_k among $\{p_1, \dots, p_h\}$. Otherwise, if $\ell(\hat{u}) = l$, then

$$\begin{aligned} d_{\mathcal{M}}(\hat{u}, q) &\leq d_{\mathcal{M}}(\hat{u}, c_{p_k}) + d_{\mathcal{M}}(c_{p_k}, p_k) + d_{\mathcal{M}}(p_k, q) \\ &\leq 2 \cdot \tau^l + (1 + n^{-2})\tau^l + (1 + n^{-2})\tau^l \leq 13 \cdot \tau^l. \end{aligned}$$

Since q appears before the level l began, either $\ell(\bar{p}(q)) > l$ and then $q \in \overline{\text{Rel}}(\hat{u})$, or $\ell(\bar{p}(q)) = l$; but then it must be that $\text{rep}_{\bar{p}(q)} = q$, so $\bar{p}(q) \in \overline{\text{Rel}}(\hat{u})$. Either case q is a representative of a vertex in $\overline{\text{Rel}}(\hat{u})$ which is the same as $\text{Rel}(\hat{u})$ (in $T^{(k-1)}$).

Property (ii). We shall prove it for both p_k and the new internal vertex (in case (a) of the construction). Consider first case (a) of the construction:

$$d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v) = d_{\mathcal{M}}(\text{rep}_u, q) \leq \tau^{\ell(u)},$$

where the last inequality follows from the induction hypothesis. Also,

$$d_{\mathcal{M}}(\text{rep}_v, p_k) \leq 2 \cdot \tau^{\ell(v)},$$

and we are done with the first case of the construction.

Case (b) of the construction follows from the definition of q and since, as argued above, for $u = \bar{p}(q)$, $\text{rep}_u = q$.

Property (iii). Fix some $t \in \mathfrak{R}$, and let x and y be two vertices for which $\max\{\ell(x), \ell(y)\} < t \leq \min\{\ell(\bar{p}(x)), \ell(\bar{p}(y))\}$. If both x and y are not p_k , then the claim follows from the inductive hypothesis (even for the newly formed internal vertex, since it inherits its parent and representative from a previously established vertex). Otherwise, assume $x = p_k$. As p_k is the latest addition of a leaf to T , $d_{\mathcal{M}}(p_k, \text{rep}_y) \geq \bar{r}_{k-1} \geq \tau^{t-1}$. Note that $\ell(\bar{p}(p_k)) = l$, so $t \leq l$, and we conclude that $d_{\mathcal{M}}(\text{rep}_x, \text{rep}_y) \geq \tau^{t-1}$.

Property (iv). We next prove that $T^{(k)}$ is a net-tree. The only nonstraightforward claims are the packing and covering properties. The covering property follows from Property (ii) of this lemma: Let $u = u_1$ be a vertex, $v = u_m$ a descendant, and $\langle u_1, \dots, u_m \rangle$ the path between them in T ; then

$$\begin{aligned} d_{\mathcal{M}}(\text{rep}_u, \text{rep}_v) &\leq \sum_{i=1}^{m-1} d_{\mathcal{M}}(\text{rep}_{u_i}, \text{rep}_{u_{i+1}}) \leq 2 \sum_{i=1}^{m-1} \tau^{\ell(u_i)} \\ &\leq 2 \sum_{i=1}^{m-1} \tau^{\ell(u_1) - (i-1)} \leq \frac{2\tau}{\tau - 1} \cdot \tau^{\ell(u)}. \end{aligned}$$

The packing property is more delicate. Let w be an arbitrary vertex in $T^{(k)}$, and let $x \notin P_w$ be a point. We want to prove that $d_{\mathcal{M}}(x, \text{rep}_w) \geq \frac{\tau-5}{2(\tau-1)} \tau^{\ell(\bar{p}(w))-1}$. Let $\hat{x} \in T^{(k)}$ be an ancestor of x such that $\ell(\hat{x}) \leq \ell(\bar{p}(w)) - 1 < \ell(\bar{p}(\hat{x}))$. Applying Property (iii) with $t = \ell(\bar{p}(w))$, we get that $d_{\mathcal{M}}(\text{rep}_{\hat{x}}, \text{rep}_w) \geq \tau^{\ell(\bar{p}(w))-1}$.

If $x = \hat{x}$, we are done. Otherwise, if $\ell(\hat{x}) < \ell(\bar{p}(w)) - 1$, then, by Property (ii), we have

$$\begin{aligned} d_{\mathcal{M}}(\text{rep}_w, x) &\geq d_{\mathcal{M}}(\text{rep}_w, \text{rep}_{\hat{x}}) - d_{\mathcal{M}}(\text{rep}_{\hat{x}}, x) \\ &\geq \tau^{\ell(\bar{p}(w))-1} - \frac{2\tau}{\tau - 1} \cdot \tau^{\ell(\bar{p}(w))-2} = \frac{\tau - 3}{\tau - 1} \cdot \tau^{\ell(\bar{p}(w))-1}, \end{aligned}$$

and we are done.

Otherwise, let $\bar{x} \in T^{(k)}$ be an ancestor of x which is the child of \hat{x} ($\bar{p}(\bar{x}) = \hat{x}$). If $\text{rep}_{\bar{x}} = \text{rep}_{\hat{x}}$, then the preceding argument (where $\ell(\hat{x}) < \ell(\bar{p}(w)) - 1$) also applies here, and we are done.

Otherwise, we get the following situation: $\ell(\bar{p}(\bar{x})) = \ell(\bar{p}(w)) - 1$ and $\text{rep}_{\bar{x}} \neq \text{rep}_{\bar{p}(\bar{x})}$. But this can happen only if \bar{x} was inserted during level $\ell(\bar{p}(w)) - 1$. Recall that the algorithm connects $\text{rep}_{\bar{x}}$ as a child of a vertex in level $\ell(\bar{p}(w)) - 1$ whose representative is the closest point among those appearing during the levels greater than $\ell(\bar{p}(w)) - 1$. Note that both $\text{rep}_{\bar{p}(\bar{x})}$ and rep_w are inserted in a level greater than $\ell(\bar{p}(w)) - 1$. We conclude that $d_{\mathcal{M}}(\text{rep}_{\bar{x}}, \text{rep}_{\bar{p}(\bar{x})}) \leq d_{\mathcal{M}}(\text{rep}_{\bar{x}}, \text{rep}_w)$. Therefore

$$\begin{aligned} d_{\mathcal{M}}(\text{rep}_{\bar{x}}, \text{rep}_w) &\geq \max \left\{ d_{\mathcal{M}}(\text{rep}_{\bar{x}}, \text{rep}_{\bar{p}(\bar{x})}), d_{\mathcal{M}}(\text{rep}_w, \text{rep}_{\bar{p}(\bar{x})}) - d_{\mathcal{M}}(\text{rep}_{\bar{x}}, \text{rep}_{\bar{p}(\bar{x})}) \right\} \\ &\geq \frac{d_{\mathcal{M}}(\text{rep}_w, \text{rep}_{\bar{p}(\bar{x})})}{2} \geq 0.5 \cdot \tau^{\ell(\bar{p}(w))-1}. \end{aligned}$$

Hence, by the covering property,

$$\begin{aligned} d_{\mathcal{M}}(x, \text{rep}_w) &\geq d_{\mathcal{M}}(\text{rep}_{\bar{x}}, \text{rep}_w) - d_{\mathcal{M}}(\text{rep}_{\bar{x}}, x) \geq 0.5 \cdot \tau^{\ell(\bar{p}(w))-1} - \frac{2\tau}{\tau - 1} \cdot \tau^{\ell(\bar{p}(w))-2} \\ &= \frac{\tau - 5}{2(\tau - 1)} \cdot \tau^{\ell(\bar{p}(w))-1}, \end{aligned}$$

and we are done.

Property (v). Assume that a new vertex x is attached as a child to a vertex y . We shall prove that our traversing algorithm visits all vertices w for which either $w \in \overline{\text{Rel}}(x)$ or $x \in \overline{\text{Rel}}(w)$. Suppose first that $x \in \overline{\text{Rel}}(w)$. Thus, $\ell(w) < \ell(y)$. Let z be an ancestor of w for which $\ell(z) \leq \ell(y) < \ell(\bar{p}(z))$. Let $\langle z = z_1, \dots, z_m = w \rangle$ be the

path between them in T . Then, for any $1 \leq i \leq m-1$, it holds that

$$\begin{aligned} d_{\mathcal{M}}(\text{rep}_x, \text{rep}_{z_i}) &\leq d_{\mathcal{M}}(\text{rep}_x, \text{rep}_w) + d_{\mathcal{M}}(\text{rep}_{z_i}, \text{rep}_w) \\ &\leq 13 \cdot \tau^{\ell(z_m)} + \frac{2\tau}{\tau-1} \cdot \tau^{\ell(z_i)} \leq 13 \cdot \tau^{\ell(z_i)}. \end{aligned}$$

Thus $x \in \overline{\text{Rel}}(z_i)$ for any $2 \leq i \leq m$. Thus, if $z = z_1 \in \text{Rel}(y)$, we are assured that $w = z_m$ will be visited. Indeed, $z \in \overline{\text{Rel}}(y)$, since

$$\begin{aligned} d_{\mathcal{M}}(\text{rep}_y, \text{rep}_z) &\leq d_{\mathcal{M}}(\text{rep}_y, \text{rep}_x) + d_{\mathcal{M}}(\text{rep}_x, \text{rep}_w) + d_{\mathcal{M}}(\text{rep}_w, \text{rep}_z) \\ &\leq 2 \cdot \tau^{\ell(y)} + 13 \cdot \tau^{\ell(w)} + \frac{2\tau}{\tau-1} \cdot \tau^{\ell(z)} \\ &\leq 2 \cdot \tau^{\ell(y)} + 13 \cdot \tau^{\ell(y)-1} + \frac{2\tau}{\tau-1} \cdot \tau^{\ell(y)} \\ &\leq 13 \cdot \tau^{\ell(y)}. \end{aligned}$$

This means that $z \in \text{Rel}(y)$ by the inductive hypothesis.

Next, we consider the case when $w \in \overline{\text{Rel}}(x)$. In this case, $\ell(w) \leq \ell(x) < \ell(\overline{\text{p}}(w))$ and

$$d_{\mathcal{M}}(\text{rep}_w, \text{rep}_y) \leq d_{\mathcal{M}}(\text{rep}_w, \text{rep}_x) + d_{\mathcal{M}}(\text{rep}_x, \text{rep}_y) \leq 13 \cdot \tau^{\ell(x)} + 2 \cdot \tau^{\ell(y)} \leq 13 \cdot \tau^{\ell(y)}.$$

Hence, if $\ell(\overline{\text{p}}(w)) > \ell(y)$, then $w \in \overline{\text{Rel}}(y)$ which implies that $w \in \text{Rel}(y)$ by the inductive hypothesis, and we are done.

If $\ell(\overline{\text{p}}(w)) = \ell(y)$, then

$$\begin{aligned} d_{\mathcal{M}}(\text{rep}_{\overline{\text{p}}(w)}, \text{rep}_y) &\leq d_{\mathcal{M}}(\text{rep}_{\overline{\text{p}}(w)}, \text{rep}_w) + d_{\mathcal{M}}(\text{rep}_w, \text{rep}_x) + d_{\mathcal{M}}(\text{rep}_x, \text{rep}_y) \\ &\leq 2 \cdot \tau^{\ell(y)} + 13 \cdot \tau^{\ell(y)-1} + 2 \cdot \tau^{\ell(y)} \leq 13 \cdot \tau^{\ell(y)}. \end{aligned}$$

Thus, in this case $\overline{\text{p}}(w) \in \overline{\text{Rel}}(y)$, and using the inductive hypothesis, we are done.

We are left with the case $\ell(\overline{\text{p}}(w)) < \ell(y)$. In this case

$$\begin{aligned} d_{\mathcal{M}}(\text{rep}_{\overline{\text{p}}(w)}, \text{rep}_x) &\leq d_{\mathcal{M}}(\text{rep}_{\overline{\text{p}}(w)}, \text{rep}_w) + d_{\mathcal{M}}(\text{rep}_w, \text{rep}_x) \\ &\leq 2 \cdot \tau^{\ell(\overline{\text{p}}(w))} + 13 \cdot \tau^{\ell(\overline{\text{p}}(w))-1} \leq 13 \cdot \tau^{\ell(\overline{\text{p}}(w))}. \end{aligned}$$

Thus, we have that $x \in \text{Rel}(\overline{\text{p}}(w))$. As was proved above, this means that $\overline{\text{p}}(w)$ will be visited, and since x is added to $\text{Rel}(\overline{\text{p}}(w))$, the algorithm also visits the children of $\overline{\text{p}}(w)$, and in particular, w . \square

Acknowledgments. We thank James Lee, Ken Clarkson, and Alex Slivkins for helpful correspondence regarding the content of this paper. James Lee pointed us to some recent related papers and suggested the construction of a doubling measure as an application of the net-tree. The observations about the all nearest neighbors problem rose from discussions with Ken Clarkson. Alex Slivkins pointed out to us an error in a preliminary version of this paper. Finally, the authors would like to thank the anonymous referees for their useful comments.

EXTRACTING RANDOMNESS VIA REPEATED CONDENSING*

OMER REINGOLD[†], RONEN SHALTIEL[‡], AND AVI WIGDERSON[§]

Abstract. Extractors (as defined by Nisan and Zuckerman) are procedures that use a *small* number of truly random bits (called the seed) to extract *many* (almost) truly random bits from arbitrary distributions as long as distributions have sufficient (min)-entropy. A natural weakening of an extractor is a *condenser*, whose output distribution has a higher entropy rate than the input distribution (without losing much of the initial entropy). An extractor can be viewed as an ultimate condenser because it outputs a distribution with the maximal entropy rate.

In this paper we construct explicit condensers with short seed length. The condenser constructions combine (variants of or more efficient versions of) ideas from several works, including the block extraction scheme of [N. Nisan and D. Zuckerman, *J. Comput. System Sci.*, 52 (1996), pp. 43–52], the observation made in [A. Srinivasan and D. Zuckerman, *SIAM J. Comput.*, 28 (1999), pp. 1433–1459; N. Nisan and A. Ta-Shma, *J. Comput. System Sci.*, 58 (1999), pp. 148–173] that a failure of the block extraction scheme is also useful, the recursive “win-win” case analysis of [R. Impagliazzo, R. Shaltiel, and A. Wigderson, *Near-optimal conversion of hardness into pseudo-randomness*, in Proceedings of the 40th Annual IEEE Symposium on Foundations of Computer Science, IEEE, Los Alamitos, CA, 1999, pp. 181–190; R. Impagliazzo, R. Shaltiel, and A. Wigderson, *Extractors and pseudo-random generators with optimal seed length*, in Proceedings of the 32nd Annual ACM Symposium on Theory of Computing, ACM, New York, 2000, pp. 1–10], and the error correction of random sources used in [L. Trevisan, *J. ACM*, 48 (2001), pp. 860–879].

As a by-product (via repeated iterating of condensers), we obtain new extractor constructions. The new extractors give significant qualitative improvements over previous ones for sources of arbitrary min-entropy; they are nearly optimal *simultaneously* in the two main parameters of seed length and output length. Specifically, our extractors can make any one of these two parameters optimal (up to a constant factor) only at a *polylogarithmic* loss in the other. Previous constructions require *polynomial* loss in both cases for general sources.

We also give a simple reduction converting “standard” extractors (which are good for an average seed) into “strong” ones (which are good for most seeds), with essentially the same parameters. With this reduction, all the above improvements apply to strong extractors as well.

Key words. randomness extractors, randomness condensers, derandomization

1. Introduction.

1.1. Extractors. One of the most successful ideas in modern computer science is that of probabilistic algorithms and protocols. These are procedures that use random coin tosses when performing computational tasks. A natural problem in these procedures is how computers can obtain truly random bits.

A line of research initiated by [1, 20, 28] was motivated by the question of availability of truly random bits. The idea behind this question is to make truly random bits available by refining the (imperfect) randomness found in some natural physical processes, with the ultimate goal of designing procedures called “randomness extractors” that, given a sample from an arbitrary source of randomness, produce truly random bits. It was shown by [20] that this goal cannot be achieved by deterministic algorithms, even for some randomness sources that have a simple and “nice” structure. In light of this, the goal became to “spend” as few as possible truly random bits in order to extract as many as possible (almost) truly random bits from arbitrary imperfect random sources which contain sufficient randomness.

The most general definition of weak random sources and the formal definition of extractors emerged from the works of [3, 30, 31, 13]. The definition of extractors [13] requires quantifying two notions: the first is the amount of randomness in probability distributions, which is measured using a variant of the entropy function called *min-entropy*.

DEFINITION 1.1. *A distribution X is called a k -source if the probability it assigns to every element in its range is bounded above by 2^{-k} . The min-entropy of X (denoted by $H_\infty(X)$) is the maximal k such that X is a k -source.*

The second notion is the quality of the extracted bits, which is measured using the statistical distance between the extracted bits and truly uniform ones.

DEFINITION 1.2. *Two distributions P, Q (over the same domain Ω) are ϵ -close if they have a statistical distance of at most ϵ . (For every event $A \subseteq \Omega$, the probability that both distributions assign to A differs by at most ϵ).*

Extractors are functions that use *few* truly random bits to extract *many* (almost) truly random bits from arbitrary distributions which “contain” sufficient randomness. A formal definition follows. We use U_m to denote the uniform distribution on m bit strings.

DEFINITION 1.3 (see [13]). *A function $Ext : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ is a (k, ϵ) -extractor if for every k -source X the distribution $Ext(X, U_d)$ (obtained by running the extractor on an element sampled from X and a uniformly chosen d bit string, which we call the seed) is ϵ -close to U_m . The entropy-loss of an extractor is defined to be $k + d - m$.*

Informally, we will say that an extractor uses a seed of length d in order to extract m bits from distributions on n bits which contain k random bits. We refer to the ratio between m and k as the fraction of the randomness which the extractor extracts, and to the ratio between k and n as the entropy rate of the source.

Apart from their original application of obtaining random bits from natural sources, extractors turned out to be useful in many areas in complexity theory and combinatorics, with examples being construction of pseudorandom generators for space bounded computation; deterministic amplification; oblivious sampling; constructive leader election; and explicit constructions of expander graphs, superconcentrators, and sorting networks. The reader is referred to the excellent survey articles [11, 12]. (A more recent survey article that complements the aforementioned ones is [21].)

1.2. Extractor constructions: Goals and previous work. We now survey some of the goals of extractor constructions and the previous research done towards achieving these goals. Extractor constructions are measured by viewing d and m as functions of the source parameters (n and k) and the required error ϵ . A recent result of [16] enables us to rid ourselves of ϵ and concentrate on the case that ϵ is

TABLE 1

Extracting a constant fraction: $m = (1 - \alpha)k$ for arbitrary $\alpha > 0$.

[32]	$k = \Omega(n)$	$O(\log n)$
[24]	any k	$O(\log^9 n)$
[7]	$k = 2^{O(\sqrt{\log n})}$	$O(\log n \cdot \log \log \log n)$
[17]	any k	$O(\log^2 n)$
Thm. 1.4	any k	$O(\log n \cdot (\log \log n)^2)$
optimal	any k	$O(\log n)$

some fixed small constant.¹ We maintain this convention throughout the introduction.

When constructing extractors, there are two possible objectives: minimizing the seed length d and maximizing the output size m . It should be noted that the existence of an optimal extractor (which optimizes both parameters simultaneously, and matches the known lower bounds due to [14]) can be easily proven using the probabilistic method. Thus, the goal is to match this performance with explicit constructions. A (family of) extractors is *explicit* if it can be computed in polynomial time.²

In the remainder of this subsection we survey the currently known explicit extractors constructions known for the two objectives. (The reader is also referred to [21] for a more recent survey that covers some subsequent work [25, 26, 22, 9].) Tables 1 and 2 contain some extractor constructions but are far from complete in their coverage of the mass of work done in this area. In the following paragraphs we focus on extractors which work for arbitrary min-entropy threshold k .

1. *Minimizing the seed length.* A lower bound of $\Omega(\log n)$ on the seed length was given in [13, 14]. In contrast to the (nonexplicit) optimal extractor, which uses a seed of length $O(\log n)$ to extract *all* the randomness from the source, explicit constructions of extractors can optimize the seed length only at the cost of extracting a small fraction of the randomness. For large k ($k = \Omega(n)$) the extractor of [32] uses a seed of length $O(\log n)$ to extract a constant fraction of the initial randomness. However, for smaller k , explicit constructions can extract only a polynomial fraction of the initial randomness ($m = k^{1-\alpha}$ for an arbitrary constant α). This result was first achieved in [27] for $k = n^{\Omega(1)}$ and later extended for any k in [7].

2. *Maximizing the output size.* Current constructions of explicit extractors can extract large fractions of the randomness only at the cost of enlarging the seed length. A general method for increasing the fraction extracted at the cost of enlarging the seed length was given in [29]. The best extractors that extract *all* the randomness out of random sources are constructed this way from extractors which extract a constant fraction of the randomness. In light of this, we focus our attention on extractors which extract a constant fraction. The best such explicit extractor is that in [17], which uses a seed of length $O(\log^2 n)$.

¹Raz, Reingold, and Vadhan [16] give a general explicit transformation that transforms an extractor with constant error into an extractor with arbitrary small error while harming the other parameters only slightly more than is necessary. The exact dependence of our results on ϵ is presented in section 7.

²More formally, a family $E = \{E_n\}$ of extractors is defined given polynomially computable integer functions $d(n), m(n), k(n), \epsilon(n)$ such that for every n , $E_n : \{0, 1\}^n \times \{0, 1\}^{d(n)} \rightarrow \{0, 1\}^{m(n)}$ is a $(k(n), \epsilon(n))$ -extractor. The family is explicit in the sense that E_n can be computed in time polynomial in $n + d(n)$.

TABLE 2

Optimizing the seed length: $d = O(\log n)$. All the results are stated for constant ϵ . α is an arbitrary small constant.

Reference	min-entropy k	Output length m
[32]	$k = \Omega(n)$	$(1 - \alpha)k$
[27]	$k = n^{\Omega(1)}$	$k^{1-\alpha}$
[7]	$k = 2^{O(\sqrt{\log n})}$	$\Omega(\frac{k}{\log \log \log n})$
[7]	any k	$k^{1-\alpha}$
Thm. 1.6	any k	$\Omega(\frac{k}{\log n})$
optimal	any k	k

Concluding this presentation, we stress that while there are explicit constructions which are optimal in any one of the above two parameters (for arbitrary k), the cost is a polynomial loss in the other.

1.3. New results. We give two constructions, each optimal in one of the parameters and losing only a *polylogarithmic* factor in the other. Thus, both come closer to simultaneously optimizing both parameters. (We remark that a subsequent work [9] gives constructions that lose only a *constant* factor in the other parameter.) The results are stated for constant ϵ (see section 7 for the exact dependence on ϵ). In the first construction we extract any constant fraction of the initial randomness using a seed of length $O(\log n \cdot (\log \log n)^2)$. This improves the best previous such result, found in [17], which uses a seed of length $O(\log^2 n)$.

THEOREM 1.4. *For every n, k , and constant ϵ , there are explicit (k, ϵ) -extractors $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^{O(\log n \cdot (\log \log n)^2)} \rightarrow \{0, 1\}^{(1-\alpha)k}$, where $\alpha > 0$ is an arbitrary constant.³*

Using [29], we get the following corollary,⁴ which also improves the previous best construction which extract all the randomness by [17].

COROLLARY 1.5. *For every n, k , and constant ϵ , there are explicit (k, ϵ) -extractors $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^{O(\log n \cdot (\log \log n)^2 \cdot \log k)} \rightarrow \{0, 1\}^k$.*

Our second construction uses the optimal seed length (that is, $O(\log n)$) to extract $m = \Omega(k/\log n)$ bits; this improves the best previous result of [7] which could only extract $m = k^{1-\alpha}$ bits.

THEOREM 1.6. *For every n, k , and constant ϵ , there are explicit (k, ϵ) -extractors $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^{O(\log n)} \rightarrow \{0, 1\}^{\Omega(k/\log n)}$.*

Using [7], we get the following corollary (in which the “loss” depends only on k).⁵

COROLLARY 1.7. *For every n, k , and constant ϵ , there are explicit (k, ϵ) -extractors $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^{O(\log n)} \rightarrow \{0, 1\}^{\Omega(k/(\log k \cdot \log \log k))}$.*

³We remark that our construction requires $k \geq 8 \log^5 n$. Nevertheless, theorem 1.4 follows as stated because the case of $k < 8 \log^5 n$ was already covered in [7]. This is also the case in the next theorems.

⁴In fact, the version of Theorem 1.4 stated above does not suffice to conclude the corollary. To use the method of [29], we need a version in which the error is $1/\text{polylog} n$, which follows from our analysis; see section 7.

⁵Impagliazzo, Shaltiel, and Wigderson [7] show that an extractor $\text{Ext} : \{0, 1\}^{k^{O(1)}} \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ can be used to construct an extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^{d+O(\log n)} \rightarrow \{0, 1\}^{\Omega(m/\log \log k)}$ for any n .

1.4. Condensers. The main technical contribution of this paper consists of constructions of various “condensers.”⁶ A condenser is a generalization of an extractor.

DEFINITION 1.8. *A (k, k', ϵ) -condenser is a function $Con : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^{n'}$ such that for every k -source X of length n , the distribution $Con(X, U_d)$ is ϵ -close to a k' -source.*

Note that an extractor is a special case of a condenser when $n' = k'$. Condensers are most interesting when $k'/n' > k/n$ (that is, when the entropy rate of the output distribution is larger than that of the initial distribution). Such condensers can be used to construct extractors via repeatedly condensing the source until an entropy rate 1 is achieved. In this paper we give a new construction of condensers. One possible setting of the parameters gives that, for constant $\epsilon > 0$ and every n and k with $k \geq 8 \log^5 n$, there is an explicit $(k, \Omega(k), \epsilon)$ -condenser $Con : \{0, 1\}^n \times \{0, 1\}^{O(\log n \cdot \log \log n)} \rightarrow \{0, 1\}^{k \log n}$. The exact parameters can be found in section 5.

Somewhat surprisingly, an important component in the construction of the condenser above is a condenser that does not condense at all! That is one in which the entropy rate of the output distribution is *smaller* than that of the initial distribution. The usefulness of such objects in constructing extractors is demonstrated in [13] (see also [23, 32]). We refer to such condensers as “block extraction schemes” and elaborate on their role in extractor (and condenser) constructions in section 1.6. In this paper we give a construction of a block extraction scheme that uses a seed of length $O(\log \log n)$. The exact parameters can be found in section 3.

1.5. Transforming general extractors into strong extractors. Speaking informally, a strong extractor is an extractor in which the output distribution is independent of the seed.⁷ In some applications of extractors, it is beneficial to have the strong version. Most extractor constructions naturally lead to strong extractors, yet some (with examples being the constructions of [24, 7] and this paper) are not strong or are difficult to analyze as strong. We solve this difficulty by giving a general explicit transformation which transforms any extractor into a strong extractor with essentially the same parameters. Exact details are given in section 8.

1.6. Technique. In this section we attempt to explain the main ideas in this paper without delving into technical details.

High level overview. In contrast to the latest papers on extractors [27, 17, 7] we do not use Trevisan’s paradigm. Instead, we revisit [13] and attempt to construct block-sources (a special kind of source which allow very efficient extraction). Following [23, 12], we observe that, when failing to produce a block-source, the method of [13] “condenses” the source. This enables us to use a “win-win” case analysis, as in [6, 7], which eventually results in a construction of a condenser. Our extractors are then constructed by repeated condensing. A critical component in obtaining improved parameters is derandomizing the construction of block-sources of [13].

Block-sources. We begin by describing a special kind of source called block-sources (a precise definition appears in Definition 2.3) that allow for the construction of extractors with very efficient parameters. Consider a source distribution X that

⁶The notion of condensers was also used in [15]. While similar in spirit, that paper deals with a completely different set of parameters and uses different techniques. The notion of condensers also comes up in subsequent work [25, 2, 9] as a tool for constructing extractors and expander graphs.

⁷In the original paper [13] strong versions of extractors were initially defined and constructed, and the notion of a “nonstrong” extractor was later given by Ta-Shma [24].

is composed of two independent concatenated distributions $X = (X_1, X_2)$, where X_1 is a k_1 -source and X_2 is a k_2 -source. Extractors for this special scenario (which are called block-source extractors) can be constructed by composing two extractors. An extractor with optimal seed length can be used to extract random bits from X_2 , and these bits (being independent of X_1), can be used as seed to extract all the randomness from X_1 using an extractor with large output. (Note that with today's best extractors this construction uses the optimal seed length to extract all the randomness from X_1 , as long as k_2 is at least $\text{polylog}(n)$.) The requirement that X_1 and X_2 be independent could be relaxed in the following way (which was suggested in [3]). Intuitively, it is sufficient that X_1 "contains" k_1 random bits, and X_2 "contains" k_2 random bits even conditioned on X_1 . Such sources are called block-sources.⁸ Thus, extracting randomness from general sources can be achieved by giving a construction which uses few random bits to transform a general source into a block-source and by using a block-source extractor.

This approach was suggested by Nisan and Zuckerman in [13]. They constructed a "block extraction scheme." That is a condenser that given an arbitrary source X , uses few random bits to produce a new source B (called a block) which is shorter than the initial source, and contains a large fraction of the initial randomness. This means that the distribution (B, X) meets the first requirement of block-sources, i.e., the first block contains randomness. Intuitively, to meet the second requirement one should give an upper bound on the amount of randomness contained in B , and conclude that there is some randomness in X which is not contained in B . However, in the construction of Nisan and Zuckerman such an upper bound can be achieved only "artificially" by setting the parameters so that the length of B is smaller than k . This indeed gives that B does not "steal all the entropy" in the source. However, this approach has a costly effect. In the analysis of Nisan and Zuckerman the amount of randomness that is guaranteed to be in B is proportional to its length. Thus, decreasing the length of B reduces the amount of entropy that can be guaranteed. In particular, when $k < \sqrt{n}$ and the length of B is chosen in the way explained above, it may be the case that B contains no randomness. As a result, the extractors of [13] do not work when $k < \sqrt{n}$.

Condensing by a "win-win" analysis. A way to get around this problem was suggested in [23, 12]. We now explain a variant of the argument in [12] that we use in our construction. Recall that we want to obtain a large block B that does not "steal all the entropy." An important observation is that the case in which the block extraction scheme fails to produce such a block is also good in the sense that it means that B "stole all the entropy from the source." As B is shorter than the initial source, it follows that it is more condensed. We now explain this approach in more detail.

Suppose we use the block extraction scheme to produce a large block B (say, of length $n/2$) and consider the distribution (B, X) . Recall that, for our purposes, to get a useful block-source it suffices that X contains very few random bits that are not contained in B . An important observation is that when the procedure above fails to construct a block-source, this happens because (almost) all the randomness "landed" in B . In this case, we obtained a block that is more condensed than the initial source X . (It has roughly the same amount of randomness and half the length.)

Using this idea repeatedly, at each step either we construct a block-source (from which we can extract randomness) or we condense the source. There is a limit to

⁸More precisely, a (k_1, k_2) -block-source is a distribution $X = (X_1, X_2)$ such that X_1 is a k_1 -source, and for every possible value x_1 of X_1 , the distribution of X_2 , conditioned on the event that $X_1 = x_1$, is a k_2 -source.

how much we can condense the source. Certainly, when the length reduces below the original entropy k , no further condensing is possible. This means that by running this procedure repeatedly enough times we eventually obtain a block-source.

The outcome of the procedure above consists of several “candidate” distributions, where one of them is a block-source. Not knowing which is the “right one,” we run block-source extractors on all of them (using the same seed). We know that one of the distributions we obtain is close to uniform. It turns out that the number of candidate distributions is relatively small (about $\log(n/k)$). Consider the distribution obtained by concatenating the output distributions of the block-source extractors. This distribution contains a portion which is (close to being) uniformly distributed on roughly k bits and thus has entropy close to that of the initial source. Moreover, the distribution is on strings of length not much larger than k (the length is roughly $k \log(n/k)$). We conclude that the aforementioned distribution is more condensed than the initial source and that the procedure described above is a condenser!

We can now obtain an extractor construction by repeatedly condensing the source (using fresh randomness in each iteration) until it becomes close to uniform. However, it turns out that the parameters of the constructed condenser are not good enough to yield a good extractor. Our actual construction of condensers is achieved by using the procedure above with an improved version of the block extraction scheme of Nisan and Zuckerman.

Improved block extraction. Let us delve into the parameters. The block extraction scheme of Nisan and Zuckerman spends $O(\log n)$ random bits when producing a block B of length $n/2$ and guarantees that B is an $\Omega(k/\log(n/k))$ -source. This turns out to be too costly and we cannot run our condenser construction.

One problem is that the number of random bits used by the block extraction scheme is too large for our purposes. Note that the block extraction scheme already spends $O(\log n)$ random bits. Using the strategy described above, we will need to run it roughly $\log(n/k)$ times, which results in a large seed length ($\log n \cdot \log(n/k)$). We overcome this problem by derandomizing the construction of Nisan and Zuckerman. We reduce the number of random bits used from $\log n$ to $\log \log n$, which allows us to run it a larger number of times while still obtaining short seed length.

A second problem is that we want the block B to contain a constant fraction of the initial randomness k . The analysis of Nisan and Zuckerman guarantees only that the block B contains $\Omega(k/\log(n/k))$ random bits. Note that while this quantity is smaller than we want, it does achieve the goal when k is a constant fraction of n . We introduce another modification to the construction of Nisan and Zuckerman in order to increase the randomness in B . The idea is to reduce the case of $k = o(n)$ to the case of $k = \Omega(n)$. This is done by error correcting the source prior to using the block extraction scheme. We give a nonconstructive argument to show that every error corrected random source has a “piece” of length k which is an $\Omega(k)$ -source. When analyzing the scheme, we use the analysis of Nisan and Zuckerman on this piece. Intuitively, this enables the analysis of the block extraction scheme to be carried out on the condensed piece, where it performs best.

1.7. Organization of the paper. Section 2 includes some preliminaries. In section 3 we construct a block extraction scheme. In section 4 we use the method of [12] to show that when using the block extraction scheme either we get a block-source or we condense the source. In section 5 we run the block extraction scheme recursively and obtain condensers. In section 6 we use the condensers to construct extractors. Section 7 gives the exact dependence of our extractors on the error parameter ϵ . In

section 8 we show how to transform arbitrary extractors into strong extractors.

2. Preliminaries.

2.1. Probability distributions. Given a probability distribution P , we use the notation $\Pr_P[\cdot]$ to denote the probability of the relevant event according to the distribution P . We sometimes fix some probability space (namely, a set Ω and a distribution over Ω) and then use the notation $\Pr[\cdot]$ to denote the probability of events in this probability space. We use $\Pr[E_1, E_2]$ to denote $\Pr[E_1 \cap E_2]$.

We need the following notion of “collision probability.”

DEFINITION 2.1. *For a distribution P over Ω , define $C(P) = \sum_{\omega \in \Omega} P(\omega)^2$. In other words, $C(P)$ is the probability that two independent samples from P give the same outcome. We refer to $C(P)$ as the collision probability of P .*

We need the following useful lemma.

LEMMA 2.2. *Let V be ρ -close to a k -source. Define $L = \{v \mid \Pr[V = v] > 2^{-(k-1)}\}$. It follows that $\Pr(V \in L) < 2\rho$.*

Proof. Let V' be a k -source such that V and V' are ρ -close. We have that $|\Pr_V(L) - \Pr_{V'}(L)| < \rho$. However, V' assigns small probability to all elements in L , whereas V assigns large probability to these elements. This gives that $\Pr_V(L) - \Pr_{V'}(L) > \Pr_{V'}(L)$, which means that $\Pr_{V'}(L) < \rho$. Using the inequality above, we get that $\Pr_V(L) < 2\rho$. \square

2.2. Block-sources. Block-sources are random sources which have a special structure. The notion of block-sources was defined in [3].

DEFINITION 2.3 (see [3]). *Two random variables (X_1, X_2) form a (k_1, k_2) -block-source if X_1 is a k_1 -source, and for every possible value x_1 of X_1 , the distribution of X_2 , given that $X_1 = x_1$, is a k_2 -source.*

Block-source extractors are extractors which work on block-sources.

DEFINITION 2.4. *A (k, t, ϵ) -block-source extractor is a function $\text{Ext} : \{0, 1\}^{n_1} \times \{0, 1\}^{n_2} \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ such that for every (k, t) -block-source (X_1, X_2) (where X_1, X_2 are of length n_1, n_2 , respectively), the distribution $\text{Ext}(X_1, X_2, U_d)$ is ϵ -close to U_m .*

Block-sources allow the following composition of extractors.

LEMMA 2.5 (implicit in [13]; also appears in [23]). *If there exist an explicit (k, ϵ_1) -extractor $\text{Ext}_1 : \{0, 1\}^{n_1} \times \{0, 1\}^{d_1} \rightarrow \{0, 1\}^m$, and an explicit (t, ϵ_2) -extractor $\text{Ext}_2 : \{0, 1\}^{n_2} \times \{0, 1\}^{d_2} \rightarrow \{0, 1\}^{d_1}$, then there exists an explicit $(k, t, \epsilon_1 + \epsilon_2)$ -block-source extractor $\text{Ext} : \{0, 1\}^{n_1} \times \{0, 1\}^{n_2} \times \{0, 1\}^{d_2} \rightarrow \{0, 1\}^m$, where $\text{Ext}(x_1, x_2; y) = \text{Ext}_1(x_1, \text{Ext}_2(x_2, y))$.*

Following [13, 23, 32], we can use the above theorem to compose two extractors: one which optimizes the seed length and another which optimizes the output length. The resulting block-source extractor will “inherit” the nice properties of both its component extractors. Particularly, taking Ext_1 to be the extractor of [17] and Ext_2 to be the extractor of [7], we get the following block-source extractor.

COROLLARY 2.6. *For all integers $n_1 \leq n_2$, k , and $t \geq \log^4 n_1$, there is an explicit $(k, t, \frac{1}{n_1} + \frac{1}{n_2})$ -block-source extractor $BE : \{0, 1\}^{n_1} \times \{0, 1\}^{n_2} \times \{0, 1\}^{O(\log n_2)} \rightarrow \{0, 1\}^k$.*

Thus, to construct extractors which achieve short seed length and large output simultaneously, it suffices to use few random bits and convert any k -source into a $(k', \log^4 n)$ -block-source such that k' is not much smaller than k .

This turns out to be a tricky problem. No such scheme (efficient in terms of random bits spent) is known when $k < \sqrt{n}$.

2.3. Error correcting codes. Our construction uses error correcting codes.

DEFINITION 2.7. *An error correcting code with distance d is a function $EC : \{0, 1\}^n \rightarrow \{0, 1\}^{\bar{n}}$ such that for every $x_1, x_2 \in \{0, 1\}^n$ such that $x_1 \neq x_2$, $d_{\text{Hamming}}(EC(x_1), EC(x_2)) \geq d$. (Here $d_{\text{Hamming}}(z_1, z_2)$ denotes the Hamming distance between z_1, z_2). An error correcting code is explicit if EC can be computed in polynomial time.*

We use the following construction of error correcting codes.

THEOREM 2.8 (see [8]). *There exist constants $0 < b < a$ and an explicit error correcting code $EC : \{0, 1\}^n \rightarrow \{0, 1\}^{an}$ with distance bn .*

2.4. Almost l -wise independent distributions. We use the following notion of efficiently constructible distributions.

DEFINITION 2.9. *Call a distribution P on n bits, polynomially constructible using $u(n)$ bits,⁹ if there exists an algorithm $A : \{0, 1\}^{u(n)} \rightarrow \{0, 1\}^n$ which runs in time polynomial in n such that the distribution $A(Y)$, where Y is chosen uniformly from $\{0, 1\}^{u(n)}$, is identical to P .*

Naor and Naor [10] defined “almost l -wise independent distribution.”

DEFINITION 2.10 (see [10]). *A distribution (P_1, \dots, P_n) over $\{0, 1\}^n$ is said to be (ϵ, l) -wise dependent with mean p if for every subset $\{i_1, \dots, i_l\}$ of $[n]$, the distribution $(P_{i_1}, \dots, P_{i_l})$ is ϵ -close to the distribution over l bit strings, where all bits are independent and each of them takes the value 1 with probability p .*

Naor and Naor showed that almost l -wise independent distributions can be constructed using very few random bits.

THEOREM 2.11 (see [10]). *For every n, l , and ϵ , an (ϵ, l) -wise dependent distribution with mean $1/2$ is polynomially constructible using $O(\log \log n + l + \log(1/\epsilon))$ bits.*

We require distributions that are almost l -wise independent with mean different than $1/2$. Nevertheless, it is very easy to construct such distributions from Theorem 2.11.

COROLLARY 2.12. *For every n, ϵ , and q , an $(\epsilon, 2)$ -wise dependent distribution with mean 2^{-q} is polynomially constructible using $O(\log \log n + q + \log(1/\epsilon))$ bits.*

Proof. We use Theorem 2.11 to construct a distribution that is $(\epsilon, 2q)$ -wise dependent with mean $1/2$ over qn bits. Note that this costs $O(\log \log(qn) + q + \log(1/\epsilon)) = O(\log \log n + q + \log(1/\epsilon))$ bits. We denote these bits by P_1, \dots, P_{qn} . We divide them into n blocks of length q and define n bits P'_1, \dots, P'_n as follows: P'_i is set to “one” if and only if all the bits in the i th block are “one.” In particular, each P'_i is a function of the bits in the i th block. It follows that the distribution P'_1, \dots, P'_n is $(\epsilon, 2)$ -wise dependent. \square

Given (X_1, \dots, X_n) that form a $(0, 2)$ -wise dependent distribution, Chebyshev’s inequality gives that for every $0 < \lambda < 1$,

$$\Pr \left(\left| \sum_{1 \leq i \leq n} X_i - pn \right| > \lambda pn \right) < \frac{1}{\lambda^2 pn}.$$

The same argument can be applied to $(\epsilon, 2)$ -wise dependent distributions and gives the following.

⁹Naturally, one should speak about a sequence $P = \{P_n\}$ of distributions for this to make sense.

LEMMA 2.13 (see [10]). *If (X_1, \dots, X_n) is an $(\epsilon, 2)$ -wise dependent distribution with mean p , then for every $0 < \lambda < 1$,*

$$\Pr \left(\left| \sum_{1 \leq i \leq n} X_i - pn \right| > \lambda pn \right) < O \left(\frac{1}{\lambda^2 pn} + \sqrt{\epsilon} \right)$$

as long as $\epsilon < \frac{\lambda^4 p^4}{25}$.

3. Improved block extraction. Some constructions of block-sources from general sources [13, 23, 32] rely on a building block called a “block extraction scheme.” In our terminology a block extraction scheme is a condenser. Nevertheless, we choose to redefine this notion, as it is more convenient to present the parameters in a different way.

DEFINITION 3.1. *Let n, k , and r be integers and ρ, γ be numbers. A function $B : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^{n/r}$ is a (k, ρ, γ) -block extraction scheme if it is a $(k, \gamma \cdot (\frac{k}{r}), \rho)$ -condenser.*

In other words, a block extraction scheme takes a k -source of length n and uses a seed to produce a distribution (which we call a block) of length n/r . The parameter γ measures the entropy rate of the new distribution in terms of the entropy rate of the initial distribution. For example, when $\gamma = 1$ this means that the two distributions have the same rate and the block extraction scheme “preserves” the entropy rate in the source. In this section, we discuss constructions in which $\gamma < 1$, meaning that the entropy rate in the output distribution is *smaller* than that of the initial distribution.

Using this notation, Nisan and Zuckerman proved the following theorem.

LEMMA 3.2 (see [13]). *There exists a constant $c > 0$ such that for every n, k, r , and $\rho \geq 2^{-ck/r}$ there is an explicit $(k, \rho, \Omega(\frac{1}{\log n/k}))$ -block extraction scheme $B : \{0, 1\}^n \times \{0, 1\}^{O(\log n \log 1/\rho)} \rightarrow \{0, 1\}^{n/r}$.*

We prove the following lemma, which improves Lemma 3.2 for some choice of parameters, namely, for $1 < r \leq \log n$ and $\rho = 1/\log^{O(1)} n$.

LEMMA 3.3. *There exists a constant $c > 0$ such that for every n, k, r , and $\rho \geq c\sqrt{\frac{\rho}{k}}$ there is an explicit $(k, \rho, \Omega(1))$ -block extraction scheme $B : \{0, 1\}^n \times \{0, 1\}^{O(\log \log n + \log(1/\rho) + \log r)} \rightarrow \{0, 1\}^{n/r}$.*

Lemma 3.3 improves Lemma 3.2 in the following two respects (as long as one settles for small $r \leq \log n$ and large $\rho > 1/\log^{O(1)} n$):

1. We reduce the number of random bits spent by the block extraction scheme.

In [13] the number of random bits is logarithmic in n , whereas in Lemma 3.3 the number of random bits is double logarithmic in n .

This is achieved by derandomizing the proof of Nisan and Zuckerman using almost l -wise independent distributions. In section 3.1 we describe the property that a distribution needs to have to allow for the Nisan–Zuckerman analysis, and we construct a small sample space with this property.

2. We increase the amount of randomness guaranteed in the output block. In [13] the amount of randomness guaranteed in the output block B is $\Omega(\frac{k}{r \log(n/k)})$.

Lemma 3.3 guarantees that B contains $\Omega(\frac{k}{r})$ random bits.

Note that the two quantities are the same when $k = \Omega(n)$. Indeed, our improvement is achieved by reducing the case of $k = o(n)$ to that of $k = \Omega(n)$.

We start from a k -source with $k = o(n)$. In section 3.3 we show that once a random source is error corrected, there are some k indices (to the error corrected source) which induce an $\Omega(k)$ -source. This induced source has a

constant entropy rate. When applying the argument of Nisan and Zuckerman, our analysis concentrates on this source which allows us to guarantee that the block contains more randomness. The exact analysis is given in section 3.4. The remainder of this section is devoted to proving Lemma 3.3.

3.1. The analysis of Nisan and Zuckerman. The block extraction scheme of Nisan and Zuckerman is obtained by restricting the source to some subset of the indices which is selected using few random bits. More precisely, they construct a small sample space of subsets of $[n]$ (having a property that we immediately describe) and prove that the distribution obtained by sampling an element from a k -source and restricting it to the indices in a random set from the sample space contains a large fraction of the initial randomness. In this section we construct a smaller such sample space which enables us to spend less random bits to construct a block extraction scheme. We now describe the property used by Nisan and Zuckerman. Intuitively, a k -source has k random bits “hidden” somewhere.

DEFINITION 3.4. *Let n, k, r , and δ be parameters. A distribution S over subsets of $[n]$ is called r -intersecting for sets of size k with error probability δ if for every $G \subseteq [n]$ with $|G| \geq k$, $\Pr_S(|S \cap G| < \frac{k}{8r}) < \delta$.*

The following is implicit in [13].

LEMMA 3.5 (see [13]). *There exists some constant $c > 0$ such that if X is a k -source on $\{0, 1\}^n$ and S is a distribution over subsets of $[n]$ which is r -intersecting for sets of size $\frac{ck}{\log(n/k)}$ with error probability δ , then the distribution $X|_S$ (obtained by sampling x from X and s from S and computing $x|_s$) is $(4\sqrt{\delta} + 2^{-\Omega(k)})$ -close to an $\Omega(\frac{k}{r \log(n/k)})$ -source.*

Nisan and Zuckerman use a construction based on $O(\log(1/\delta))$ -wise independence to prove the following lemma.

LEMMA 3.6 (see [13]). *For every n, k, r , and $\delta > 2^{-O(k/r)}$ there is a distribution over subsets of $[n]$ that are of size n/r and this distribution is r -intersecting for sets of size k with error probability δ . Furthermore, the distribution is polynomially constructible using $O(\log n \cdot \log(1/\delta))$ bits.*

Using Lemma 3.5, this immediately implies the block extraction scheme of Lemma 3.2. We will be mostly interested in the case when r is small (say $r \leq \log n$) and δ is large, (say $\delta \geq \log^{-O(1)} n$). For this setup we can save random bits and make the dependence on n double logarithmic.

LEMMA 3.7. *There exists a constant $c > 0$ such that for every n, k, r , and $\delta > cr/k$, there is a distribution over subsets of $[n]$ that are of size n/r and this distribution is r -intersecting for sets of size k with error probability $\delta > 0$. Furthermore, the distribution is polynomially constructible using $O(\log \log n + \log r + \log(1/\delta))$ bits.*

We prove this lemma in the following subsection.

3.2. A small sample space for intersecting large sets. We now prove Lemma 3.7. We view distributions over n bit strings as distributions over subsets of $[n]$. More specifically, we identify the n bit values (W_1, \dots, W_n) with the set $\{i | W_i = 1\}$. We construct random variables (W_1, \dots, W_n) with the following properties:

- For every $1 \leq i \leq n$, $\Pr(W_i = 1) \approx 1/2r$.
- For every set $G \subseteq [n]$ with $|G| \geq k$, the probability that the sum of the W_i 's for $i \in G$ is far from the expected $|G|/2r$ is small. (It is important to note that we allow the “small probability” to be quite large, since we are shooting for large δ .)

Note that the second condition gives both the intersecting property and the fact that the selected sets are rarely of size larger than n/r (by considering $G = [n]$). We are interested in constructing such a distribution using as few random bits as possible. A pairwise independent distribution has these properties but takes $\log n$ random bits to construct. We can do better by using the “almost l -wise independent” distributions of [10].

CONSTRUCTION 3.8. *Let q be an integer such that $1/4r < 2^{-q} \leq 1/2r$ and $\epsilon = \min(c\delta^2, c/r^4)$, where $c > 0$ is a constant that will be determined later. Let $W = (W_1, \dots, W_n)$ be the $(\epsilon, 2)$ -wise dependent distribution with mean 2^{-q} guaranteed in Corollary 2.12. Note that this requires $O(\log \log n + \log r + \log(1/\epsilon))$ random bits.*

The next lemma follows.

LEMMA 3.9. *There exist constants $c, c' > 0$ such that when using construction 3.8 with the constant c , for every $\delta > c' \cdot r/k$ the distribution W has the following properties:*

1. *For every set $G \subseteq [n]$ such that $|G| \geq k$, $\Pr(\sum_{i \in G} W_i < \frac{k}{8r}) < \frac{\delta}{3}$.*
2. $\Pr(\sum_{1 \leq i \leq n} W_i > \frac{n}{r}) < \frac{\delta}{3}$.

Proof. We use Lemma 2.13 to deduce both parts of the lemma and we use the fact that the W_i 's are $(\epsilon, 2)$ dependent with mean $p = 1/2^q$, where $1/4r < p \leq 1/2r$. We start by proving the first part. For this part, we set $\lambda = 1/2$ and assume without loss of generality that $|G| = k$. Note that

$$\left\{ \sum_{i \in G} W_i < \frac{k}{8r} \right\} \subseteq \left\{ \sum_{i \in G} W_i < \frac{k}{2 \cdot 2^q} \right\} \subseteq \left\{ \left| \sum_{i \in G} W_i - \frac{k}{2^q} \right| > \frac{\lambda k}{2^q} \right\}.$$

Thus, it suffices to bound the probability of the latter event. To meet the condition in Lemma 2.13 we need to make sure that $\epsilon < \frac{\lambda^4 p^4}{25} = \Theta(\frac{1}{r^4})$. The requirement that $\epsilon < c/r^4$ takes care of this condition by choosing a sufficiently small constant $c > 0$. Applying Lemma 2.13, we get that the probability of deviation from the mean is bounded by $O(r/k + \delta\sqrt{c})$. We have that $r/k \leq \delta/c'$. We can set c' to be large enough so that $O(r/k + \delta\sqrt{c}) \leq \delta/6 + O(\delta\sqrt{c})$. This is bounded from above by $\delta/3$ for small enough $c > 0$.

The proof of the second item is similar. We choose $\lambda = 1$ and note that

$$\left\{ \sum_{1 \leq i \leq n} W_i > \frac{n}{r} \right\} \subseteq \left\{ \sum_{1 \leq i \leq n} W_i > \frac{2n}{2^q} \right\} \subseteq \left\{ \left| \sum_{1 \leq i \leq n} W_i - \frac{n}{2^q} \right| > \frac{\lambda n}{2^q} \right\}.$$

Using the fact that $n \geq k$, we can repeat the computations above and conclude that the probability of this event is also bounded by $O(\delta\sqrt{c})$. The lemma follows by choosing a sufficiently small $c > 0$. \square

We are ready to prove Lemma 3.7.

Proof of Lemma 3.7. The first item of Lemma 3.9 shows that W is a distribution over subsets of $[n]$ that is r -intersecting for sets of size k with error probability $\delta/3$. The second item shows that W could be transformed into a distribution over subsets of size exactly n/r without changing it by much. This change is done by adding arbitrary indices to the set if its size is smaller than n/r and deleting arbitrary indices if its size is larger than n/r . Adding indices will not spoil the intersecting property, and the probability that we need to delete indices is bounded by $\delta/3$. The lemma follows. \square

3.3. Error corrected random sources. In this subsection we develop another tool required for the proof of Lemma 3.3 and show that if we apply an error correcting

code to an arbitrary k -source, we obtain a k -source which has k indices which induce an $\Omega(k)$ -source.

In the remainder of this section we fix a, b , and EC to be as in Theorem 2.8. For a vector $x \in \{0, 1\}^n$ and a set $T \subseteq [n]$, we use $x|_T$ to denote the restriction of x to T .

LEMMA 3.10. *Let X be a k -source on $\{0, 1\}^n$. There exists a set $T \subseteq [an]$ of size k such that $EC(X)|_T$ is an $\Omega(k)$ -source.*

Lemma 3.10 is an immediate corollary of Lemma 3.11 which was mentioned to us by Russell Impagliazzo. A very similar argument also appears in [23].

LEMMA 3.11 (see [5]). *Let X be a k -source on $\{0, 1\}^n$. For every v , there exists a set $T \subseteq [an]$ of size v such that $EC(X)|_T$ is a $\frac{1}{2} \cdot \log 1/(2^{-k} + (1 - \frac{b}{a})^v)$ -source.*

The following fact states that if a distribution has low collision probability, then it has high min-entropy. This follows because a distribution with low min-entropy has an element which gets large probability. This element has a large chance of appearing in two consecutive independent samples.

FACT 3.12. *If $C(P) \leq 2^{-k}$, then P is a $(k/2)$ -source.*

Our goal is to show that there exists a subset of $[an]$ on which the error corrected source has low collision probability. We will show that a random (multi-) set has this property.

Proof of Lemma 3.11. Consider the following probability space: X_1, X_2 are independently chosen from the distribution X , and $T = (I_1, \dots, I_v)$ is chosen independently, where each I_j is uniformly distributed in $[an]$. Consider the following event: $B = \{EC(X_1)|_T = EC(X_2)|_T\}$. We first show that the probability of B is small:

$$(3.1) \quad \Pr(B) = \Pr(B|X_1 = X_2) \Pr(X_1 = X_2) + \sum_{a_1 \neq a_2} \Pr(B|X_1 = a_1, X_2 = a_2) \Pr(X_1 = a_1, X_2 = a_2).$$

X is a k -source, and therefore $\Pr(X_1 = X_2) \leq 2^{-k}$. For given $a_1 \neq a_2$, we know that the distance between $EC(a_1)$ and $EC(a_2)$ is at least bn . Thus, any of the I_j 's has a chance of $\frac{b}{a}$ to "hit" a coordinate where $EC(a_1)$ and $EC(a_2)$ disagree. Having chosen v such coordinates, the probability that none of them differentiate between $EC(a_1)$ and $EC(a_2)$ is bounded by $(1 - \frac{b}{a})^v$. Plugging this into (3.1) we get that

$$\Pr(B) \leq 2^{-k} + \left(1 - \frac{b}{a}\right)^v.$$

In the sample space we considered, T was chosen at random. Still, by averaging there exists a fixed value T' of the random variable T for which the above inequality holds. For this T' we have that the probability that independently chosen X_1 and X_2 have $EC(X_1)|_{T'} = EC(X_2)|_{T'}$ is small. In other words, we have that

$$C(EC(X)|_{T'}) \leq 2^{-k} + \left(1 - \frac{b}{a}\right)^v.$$

The lemma immediately follows from Fact 3.12. \square

3.4. Construction of the block extraction scheme. In this subsection we put everything together and prove Lemma 3.3. We are ready to define our block extraction scheme. Recall that EC is the error correcting code from Theorem 2.8 and a and b are the constants whose existence is guaranteed by that theorem.

CONSTRUCTION 3.13 (block extraction scheme). *Given n, k, r, ρ , and a constant e (which will be fixed later), let $d = O(\log \log n + \log r + \log(1/\rho))$ be the number of bits used by Lemma 3.7 to construct a distribution over subsets of $[an]$ that is ar -intersecting for sets of size ek with error probability $(\frac{\rho}{4})^2$. For $y \in \{0, 1\}^u$, let S_y be the set defined by y in the intersecting distribution. We now define*

$$B(x, y) = EC(x)|_{S_y}.$$

We are finally ready to prove Lemma 3.3.

Proof of Lemma 3.3. Let V denote the distribution $EC(X)$. Lemma 3.10 implies that there exists a set $T \subseteq [an]$ of size k such that $V|_T$ is an ηk -source (for some constant $\eta > 0$). Consider the distribution $S \cap T$ (the restriction of the intersecting distribution to the coordinates of T). Note that the distribution $S \cap T$ is a distribution over subsets of T . We claim that it has the same intersecting properties of S , namely, that $S \cap T$ is ar -intersecting for sets of size ek with error probability $(\frac{\rho}{4})^2$. (This follows from the definition, as every subset $G \subseteq T$ is in particular a subset of $[n]$.) We now use Lemma 3.5 on the source $V|_T$ using the intersecting distribution $S \cap T$. Let us first check that the conditions of Lemma 3.5 are met. We fix the constant e of Construction 3.13, setting $e = (c\eta)/(-\log \eta)$, where c is the constant from Lemma 3.5. The conditions of Lemma 3.5 are met since $V|_T$ is an ηk -source of length k and we have a distribution consisting of intersecting sets of size $ek = \frac{c(\eta k)}{\log(k/(\eta k))}$. We conclude from the lemma that $V|_{S \cap T}$ is ρ -close to an $\Omega(k/r)$ -source. We now claim that $V|_S$ is ρ -close to an $\Omega(k/r)$ -source. This is because adding more coordinates cannot reduce the entropy. The lemma follows, as we have shown that $B(X, U_d) = V|_S$ is ρ -close to an $\Omega(k/r)$ -source. \square

4. Partitioning to two “good” cases. Let B be the block extraction scheme constructed in the previous section and let X be a k -source. We consider the distribution $(B(X, Y), X)$ (where Y is a random seed that is independent of X). Following the intuition explained in section 1.6, we would like to argue that for every k -source X , at least one of the following good cases occurs:

- $(B(X, Y), X)$ is (close to) a block-source.
- $B(X, Y)$ is (close to) having a higher entropy rate than X ; that is, $B(X, Y)$ is more condensed than X .

In this section we show that, although the statement above does not hold as stated, we can prove a more technical result with the same flavor.

Remark 4.1. Here is a counterexample for the statement above assuming $k \leq n/2$. To make the example more simple, we assume that the block extraction scheme does not error correct the source prior to choosing a subset. Consider a source X which tosses a random bit b and, depending on the outcome, decides whether to sample from a distribution X_1 , in which the first k bits are random and the remaining $n - k$ bits are fixed, or from a distribution X_2 that is k -wise independent. X_1 corresponds to the first good case (and yields a block-source), as B is expected to hit about $k/2$ random bits. X_2 corresponds to the second (and yields a condensed block), as the block that B outputs contains $n/2$ bits and thus “steals all the randomness.” However, the “combination distribution” X does not satisfy any of the two good cases.

A way of getting around this problem was devised in [12]. The idea is to argue that the example in the remark above is the “worst possible” and show that any source X can be partitioned into two sources, where for each of them one of the good cases holds. To make this formal, we introduce the following notation.

DEFINITION 4.2 (conditioning random variables). *Fix some probability space. Let X be a random variable and E be an event with positive probability. We define the probability distribution of X conditioned on E , which we denote by $P_{(X|E)}$ as follows: For every possible value x in the range of X ,*

$$P_{(X|E)}(x) = \begin{cases} \Pr(X = x|E) & \Pr(X = x, E) > 0 \\ 0 & \Pr(X = x, E) = 0 \end{cases}$$

- For a random variable X and an event E we say that X is a k -source in E if $P_{(X|E)}$ is a k -source.
- For two random variables A, B and an event E , we say that the pair (A, B) is a (k_1, k_2) -block-source in E if $P_{((A,B)|E)}$ is a (k_1, k_2) -source.

We use the convention that if E has zero probability, then any random variable is a k -source (or (k_1, k_2) -block-source) in E .

With this notation, the precise statement is that, given some k -source X and uniformly distributed seed Y for the block extraction scheme, we can partition this probability space into three sets: The first has negligible weight and can be ignored. In the second, the block extraction scheme produces a block-source, and in the third, the block extraction scheme condenses the source. We now state this precisely.

For the remainder of this section we fix the following parameters:

- a k -source X over n bit strings,
- an (k, ρ, γ) block extraction scheme $B : \{0, 1\}^n \times \{0, 1\}^u \rightarrow \{0, 1\}^{n/r}$ for $r \geq 2$,
- a parameter t . (Intuitively, t measures how much randomness we want the second block of a block-source to contain.)

We now fix the following probability space that will be used in the remainder of this section. The probability space is over the set $\Omega = \{0, 1\}^n \times \{0, 1\}^u$ and consists of two independent random variables: X (the given k -source) and Y (uniformly distributed over $\{0, 1\}^u$).

LEMMA 4.3. *There exists a partition of $\{0, 1\}^n \times \{0, 1\}^u$ into three sets, BAD , BLK , CON , with the following properties:*

1. $\Pr(BAD) \leq 2(\rho + 2^{-t})$.
2. $(B(X, Y), X)$ is a $(\frac{\gamma k}{r} - t, t)$ -block-source in BLK .
3. $B(X, Y)$ is a $(k - 2t)$ -source in CON .

In the remainder of this section we use an idea similar to that in [12] to prove Lemma 4.3. This idea is to partition the elements in the probability space into three sets according to their “weight”: The “small weight” elements form the set CON . Intuitively the small weight elements induce a source of high min-entropy. The “medium-weight” elements form the set BLK . Intuitively the medium weight elements induce a source of medium min-entropy. Thus, they contain some (but not all!) of the min-entropy of the initial source. The fraction of “large weight” elements is bounded by ρ (the error parameter of the block extraction scheme). These elements form the set BAD and can be ignored because of their small fraction.

The following definition is motivated by the intuition above. (The partition of Lemma 4.3 will be based on the following partition.)

DEFINITION 4.4. *We partition $\Omega = \{0, 1\}^n \times \{0, 1\}^u$ according to the “weight” of the elements:*

$$\begin{aligned} LRG &= \{(x, y) \in \Omega \mid 2^{-(\frac{\gamma k}{r}-1)} < \Pr(B(X, Y) = B(x, y))\} \\ MED &= \{(x, y) \in \Omega \mid 2^{-(k-t)} < \Pr(B(X, Y) = B(x, y)) \leq 2^{-(\frac{\gamma k}{r}-1)}\} \\ SML &= \{(x, y) \in \Omega \mid \Pr(B(X, Y) = B(x, y)) \leq 2^{-(k-t)}\}. \end{aligned}$$

We prove the following lemma.

LEMMA 4.5. *The sets LRG, MED, and SML have the following properties:*

1. $\Pr(LRG) \leq 2\rho$.
2. $(B(X, Y), X)$ is a $(\frac{\gamma k}{r} - \log \frac{1}{\Pr(MED)} - 1, t)$ -block-source in MED.
3. $B(X, Y)$ is a $(k - (t + \log \frac{1}{\Pr(SML)}))$ -source in SML.

Proof of Lemma 4.5.

Proof of first item. We apply Lemma 2.2, choosing $V = B(X, Y)$. Note that V is guaranteed to be ρ -close to a $(\gamma k/r)$ -source and therefore, by the lemma, $\Pr(LRG) \leq 2\rho$.

Proof of second item. Note that we need to prove the following:

- For every $(x, y) \in MED$, $\Pr(B(X, Y) = B(x, y) | MED) \leq 2^{-(\frac{\gamma k}{r} - \log \frac{1}{\Pr(MED)} - 1)}$.
- For every $(x, y) \in MED$, $\Pr(X = x | B(X, Y) = B(x, y), MED) \leq 2^{-t}$.

For the first statement, we use the following inequality: For every two events E_1, E_2 ,

$$(4.1) \quad \Pr(E_1 | E_2) = \frac{\Pr(E_1 \cap E_2)}{\Pr(E_2)} \leq \frac{\Pr(E_1)}{\Pr(E_2)}.$$

Applying this rule on the first statement gives

$$\begin{aligned} \Pr(B(X, Y) = B(x, y) | MED) &\leq \frac{\Pr(B(X, Y) = B(x, y))}{\Pr(MED)} \\ &\leq \frac{2^{-(\frac{\gamma k}{r} - 1)}}{\Pr(MED)} \leq 2^{-(\frac{\gamma k}{r} - \log \frac{1}{\Pr(MED)} - 1)}. \end{aligned}$$

Here we used the definition of MED.

We now prove the second statement:

$$\Pr(X = x | B(X, Y) = B(x, y), MED) = \frac{\Pr(X = x, B(X, Y) = B(x, y), MED)}{\Pr(B(X, Y) = B(x, y), MED)}.$$

Note that whether a given pair (x, y) is in the set MED depends only on the value $B(x, y)$. Thus, $\{B(X, Y) = B(x, y), MED\} = \{B(X, Y) = B(x, y)\}$ because when $B(X, Y) = B(x, y)$ for $(x, y) \in MED$, we already know that $(X, Y) \in MED$. Thus,

$$= \frac{\Pr(X = x, B(X, Y) = B(x, y))}{\Pr(B(X, Y) = B(x, y))} \leq \frac{\Pr(X = x)}{\Pr(B(X, Y) = B(x, y))} \leq \frac{2^{-k}}{2^{-(k-t)}} = 2^{-t},$$

where the last inequality follows from the fact that X is a k -source and from the definition of MED.

Proof of the third item. We need to prove that for $(x, y) \in SML$,

$$\Pr(B(X, Y) = B(x, y) | SML) \leq 2^{-(k - (t + \log \frac{1}{\Pr(SML)}))}.$$

The proof is similar to the proof of the first part in the second item. More precisely, we use the rule (4.1) above. We argue that

$$\begin{aligned} \Pr(B(X, Y) = B(x, y) | SML) &\leq \frac{\Pr(B(X, Y) = B(x, y))}{\Pr(SML)} \\ &\leq \frac{2^{-(k-t)}}{\Pr(SML)} \leq 2^{-(k - (t + \log \frac{1}{\Pr(SML)}))} \quad \square \end{aligned}$$

We are now ready to prove Lemma 4.3.

Proof of Lemma 4.3. We need to slightly change the partition above. The sets LRG, MED , and SML are almost the partition we want. We need only avoid a setup in which the sets MED or SML are too small, since in this case the effect of conditioning is too costly. Still, if one of the sets is very small, we can safely add it to the “bad” elements and ignore it. This is the intuition behind the following partition, which partitions $\{0, 1\}^n \times \{0, 1\}^u$ into three sets:

1. The set BAD will contain all $(x, y) \in LRG$. It will also contain all $(x, y) \in SML$ if $\Pr(SML) < 2^{-t}$, and all $(x, y) \in MED$ if $\Pr(MED) < 2^{-t}$.
2. The set BLK (which corresponds to the set MED) contains all $(x, y) \in MED$ if $\Pr(MED) \geq 2^{-t}$. (Thus, BLK is empty if $\Pr(MED) < 2^{-t}$.)
3. The set CON (which corresponds to the set SML) contains all $(x, y) \in SML$ if $\Pr(SML) \geq 2^{-t}$. (Thus, BLK is empty if $\Pr(SML) < 2^{-t}$.)

Lemma 4.3 follows from Lemma 4.5. \square

5. Constructing condensers. In this section we use a win-win analysis as outlined in section 1.6 to construct a condenser. The main theorem of this section is the following.

THEOREM 5.1. *For every n and k such that $k \geq 8 \log^5 n$ and $2 \leq r \leq \log^2 n$, there is an explicit $(k, \Omega(k/r), 1/\log^2 n)$ -condenser $Con : \{0, 1\}^n \times \{0, 1\}^{O(\frac{\log(n/k) \cdot \log \log n}{\log r} + \log n)} \rightarrow \{0, 1\}^{\frac{k \log(n/k)}{r \log r}}$.*

It is helpful to consider two particular corollaries. For the first one, we choose $r = 2$. This gives that the condenser maintains a constant fraction of the initial randomness.

COROLLARY 5.2. *For every n and k such that $k \geq 8 \log^5 n$, there is an explicit $(k, \Omega(k), 1/\log^2 n)$ -condenser $Con : \{0, 1\}^n \times \{0, 1\}^{O(\log(n/k) \log \log n + \log n)} \rightarrow \{0, 1\}^{O(k \log(n/k))}$.*

For the second condenser, we choose $r = \Theta(\log n)$. This gives a condenser with seed $O(\log n)$ that maintains a $(1/\log n)$ -fraction of the initial randomness.

COROLLARY 5.3. *For every n and k such that $k \geq 8 \log^5 n$, there is an explicit $(k, \Omega(k/\log n), 1/\log^2 n)$ -condenser $Con : \{0, 1\}^n \times \{0, 1\}^{O(\log n)} \rightarrow \{0, 1\}^{k/2}$.*

In the remainder of this section we prove Theorem 5.1.

5.1. Getting a block-source. We now implement the idea presented in the introduction, namely, that running the block extraction scheme recursively eventually produces a block-source. In the next definition we recursively run the block extraction scheme. That is, given an n bit string x we use a fresh random seed y of length $O(\log \log n)$ to obtain $x' = B(x, y)$ and continue this process recursively on x' .

DEFINITION 5.4. *Let n, k , and r be parameters such that $k \geq 8 \log^5 n$ and $1 < r \leq \log^2 n$. Let l be a number that will be determined later. Let $t = \log^4 n$ and $\rho = 1/\log^4 n$.*

We first define sequences of numbers n_0, \dots, n_l and k_0, \dots, k_l as follows: $n_i = n/r^i$ and $k_i = k - 2ti$. Let l be the smallest integer such that $n_i < k_i$. We soon show that such an l exists and $l = O(\log_r(n/k))$.

By Lemma 3.3 there exists a universal constant $\gamma > 0$ such that for every i there is a (k_i, ρ, γ) -block extraction scheme $B^i : \{0, 1\}^{n_i} \times \{0, 1\}^{u_i} \rightarrow \{0, 1\}^{n_i/r}$. Furthermore, note that $u_0 \geq u_i$ for every $1 \leq i \leq l$. Let $u = u_0$, and observe that for this choice of parameters, $u = O(\log \log n)$.

For every $0 \leq i \leq l$, we define a function $D_i : \{0, 1\}^n \times (\{0, 1\}^u)^l \rightarrow \{0, 1\}^{n/r^i}$ in the following manner:

- $D_0(x; y_1 \cdots y_l) = x$.
- For $i > 0$, $D_i(x; y_1, \dots, y_l) = B^i(D_{i-1}(x; y_1, \dots, y_l), y_i)$.

It is easy to see that D_i does not depend on y_{i+1}, \dots, y_l , and that for each i , computing D_i takes polynomial time.

Let X be some k -source over n bit strings. Consider the following probability space over $\Omega = \{0, 1\}^n \times (\{0, 1\}^u)^l$. It consists of the random variable X and an independent random variable $Y = (Y_1, \dots, Y_l)$ that is uniformly distributed over $(\{0, 1\}^u)^l$. We also define random variables B_0, \dots, B_l by $B_i = D_i(X, Y)$. Following the intuition in section 1.6, we want to argue that there exists a small l and an $1 \leq i \leq l$ such that (B_i, B_{i-1}) is a block-source. This does not hold. However, we can use the machinery developed in section 4 to show a result with the same flavor.

LEMMA 5.5. *Let $t = \log^4 n$. If $k \geq 8 \log^5 n$, then there exists a partition of $\{0, 1\}^n \times (\{0, 1\}^u)^l$ into $l + 1$ sets: BLK_1, \dots, BLK_l and BAD with the following properties:*

1. $\Pr(BAD) \leq 2l(\rho + 2^{-t})$.
2. (B_i, B_{i-1}) is a (k', t) -block-source in BLK_i , (where $k' \geq \frac{\gamma(k-2lt)}{r}$).
3. $l = O(\log_r(n/k))$.

The remainder of this section is devoted to proving Lemma 5.5. The proof is just a recursive application of Lemma 4.3 and the reader is encouraged to skip it on a first reading.

Proof of Lemma 5.5. For $0 \leq i \leq l$, we recursively define sets $BAD_i, BLK_i, CON_i \subseteq \{0, 1\}^n \times (\{0, 1\}^u)^l$ and a distribution X_i that is defined over strings of length n_i . We define $BAD_0 = BLK_0 = \emptyset$, $CON_0 = \{0, 1\}^n \times (\{0, 1\}^u)^l$, and $X_0 = X$. For $i > 0$, suppose that sets $BAD_{i-1}, BLK_{i-1}, CON_{i-1}$ have already been defined; that the distribution of X_{i-1} is $P_{(B_{i-1}|CON_{i-1})}$; and that X_{i-1} is a (k_{i-1}) -source. (Note that this holds for $i = 1$.) We now recursively define sets BAD_i, BLK_i, CON_i that are a partition of CON_{i-1} and a distribution X_i .

We first apply Lemma 4.3 on the i th application of the block extraction scheme B^i on X_{i-1} and Y_i . It follows that $\{0, 1\}^{n_{i-1}} \times \{0, 1\}^u$ can be partitioned into three sets BAD, BLK, CON as in the lemma.

We “pull these events back to the original probability space.” That is, we want to see these sets as a partition of CON_{i-1} . More precisely, we define

$$BAD_i = \{(x, y_1, \dots, y_l) \in CON_{i-1} : D_{i-1}(x, y_1, \dots, y_l) \in BAD\},$$

$$BLK_i = \{(x, y_1, \dots, y_l) \in CON_{i-1} : D_{i-1}(x, y_1, \dots, y_l) \in BLK\},$$

$$CON_i = \{(x, y_1, \dots, y_l) \in CON_{i-1} : D_{i-1}(x, y_1, \dots, y_l) \in CON\}.$$

Note that this is a partition of CON_{i-1} . Recall that $B_i = D_i(X, Y) = B^i(D_{i-1}(X, Y), Y_i)$. Thus, the distribution $P_{(B_i|CON_i)}$ is exactly the same as $P_{(B^i(X_{i-1}, Y_i)|CON)}$. Similarly, $P_{(B_i|BLK_i)}$ is exactly the same as $P_{(B^i(X_{i-1}, Y_i)|BLK)}$. We conclude that the guarantees of Lemma 4.3 give the following:

1. $\Pr(BAD_i) \leq 2(\rho + 2^{-t})$.
2. (B_i, B_{i-1}) is a $(\frac{\gamma k_{i-1}}{r} - t, t)$ -block-source in BLK_i .
3. B_i is a k_i -source in CON_i .

We now define X_i to be the distribution $P_{(B_i|CON_i)}$ that is over n_i bits. Indeed, we have that X_i is a k_i -source. Thus, we can successfully define sets BAD_i, BLK_i, CON_i such that for each $i > 0$, these sets are a partition of CON_{i-1} and the three properties above hold.

We now show that at some step i , $CON_i = \emptyset$. After i steps, the length of the i th block is $n_i = n/r^i$ and $k_i = k - 2it$. Thus, after $l = \log_r(4n/k)$ steps we have that the i th block is of length at most $k/4$. At this point, $k_l = k - 2lt \geq k - 2\log^5 n \geq k/2$. It follows that $n_l < k_l$ and that there is some $i \leq l$ for which $CON_i = \emptyset$, as otherwise the third item above cannot hold (simply because it is impossible to have a distribution with more entropy than length).

We define $BAD = \cup_{1 \leq i \leq l} BAD_i$. It follows that BLK_1, \dots, BLK_l and BAD are a partition of $\Omega = \{0, 1\}^n \times (\{0, 1\}^l)^u$ and the lemma follows. \square

5.2. Getting a condenser. In the previous section we showed how to get $\ell = O(\log_r(n/k))$ pairs of distributions such that (at least in some sense) one of them is a block-source. Had we been able to construct a single block-source, we could have used the block-source extractor of Corollary 2.6 to get an extractor. At this point, however, we have many candidates (pairs B_i, B_{i-1}). We now run block-source extractors on all pairs (using the same seed). It follows that one of the outputs is close to uniform, and therefore the concatenation of the outputs gives a condenser. We now formalize this intuition.

CONSTRUCTION 5.6. *We use the parameters of Definition 5.4. Let n, k , and r be parameters such that $k \geq 8 \log^5 n$ and $1 < r \leq \log^2 n$. Let $l = \log_r(4n/k)$, $t = \log^4 n$, and $\rho = 1/\log^4 n$. Let $u = O(\log \log n)$ be the seed length for the block extraction scheme as determined in Definition 5.4. Let $k' = \frac{\gamma(k-2lt)}{r}$.*

We define a function $Con : \{0, 1\}^n \times \{0, 1\}^{ul+O(\log n)} \rightarrow \{0, 1\}^{n'}$, where n' is determined later. Given inputs $x \in \{0, 1\}^n$ and $y \in \{0, 1\}^{ul+O(\log n)}$, Con interprets its second argument as l strings $y_1, \dots, y_l \in \{0, 1\}^u$ and an additional string s of length $O(\log n)$. For $0 \leq i \leq l$ it computes $b_i = D_i(x; y_1, \dots, y_l)$ (where D_i is taken from Definition 5.4) and $o_i = BE(b_i, b_{i-1}, s)$ (where BE is the block-source extractor of Corollary 2.6 using output length k'). The final output is (o_1, \dots, o_l) (which makes $n' = lk'$).

We now prove Theorem 5.1.

Proof of Theorem 5.1. Let X be a k -source. For this proof we fix a probability space consisting of independent random variables X, Y , and Z , where $Y = (Y_1, \dots, Y_l)$ is uniformly distributed over $(\{0, 1\}^u)^l$ and $Z = (Z_1, \dots, Z_l)$ is uniformly distributed over $(\{0, 1\}^{k'})^l$. We now define more random variables as a function of the initial random variables. We define random variables B_1, \dots, B_l as before by $B_i = D_i(X, Y)$. We also define random variables O_1, \dots, O_l by $O_i = BE(B_{i-1}, B_i)$. Note that $CON(X, Y) = (O_1, \dots, O_l)$. We also define random variables (R_1, \dots, R_l) over $(\{0, 1\}^{k'})^l$ as follows: Let BLK_1, \dots, BLK_l and BAD be the sets of Lemma 5.5. If $(X; Y_1, \dots, Y_l) \in BAD$, we set $R = Z$. Otherwise, $(X; Y_1, \dots, Y_l)$ belong to a unique BLK_i . In this case we set $R_i = Z_i$ and $R_j = O_j$ for $j \neq i$. Note that R is a k' -source. To complete the proof we now show that (R_1, \dots, R_l) is $(2l(\rho + 2^{-t}) + 2/\log^4 n)$ -close to (O_1, \dots, O_l) . This suffices, as $2l(\rho + 2^{-t}) + 2/\log^4 n \leq 1/\log^2 n$.

By Lemma 5.5 we have that (B_i, B_{i-1}) is close to a block-source in BLK_i . The block-source extractor BE has error $\epsilon' = 1/|B_2| + 1/|B_1|$. Recall that the length of all blocks B_i is at least $k' \geq \log^4 n$. It follows that $\epsilon' < 2/\log^4 n$ and that O_i is ϵ' -close to uniform in BLK_i . We conclude that for every i , (R_1, \dots, R_l) is ϵ' -close to (O_1, \dots, O_l) in BLK_i . This gives that (R_1, \dots, R_l) is ϵ' -close to (O_1, \dots, O_l) in the complement of BAD . By Lemma 5.5 the probability of BAD is at most $2l(\rho + 2^{-t})$. Thus, (R_1, \dots, R_l) is $2l(\rho + 2^{-t}) + \epsilon'$ close to (O_1, \dots, O_l) . \square

Let us compare the entropy rates of the new source and the initial source. The new source has min-entropy k' , which is approximately k , and length approximately

$k \cdot \log \frac{n}{k}$, whereas the initial source had length $n = k \cdot \frac{n}{k}$. Note that $\log(n/k) < n/k$, and thus Con indeed improves the entropy rate and is a $(k, k', 2l(\rho + 2^{-t}) + \epsilon')$ -condenser.

Remark 5.7. Actually, the distribution (O_1, \dots, O_l) is a source of a special kind called a “somewhere random source” by Ta-Shma in [24], where it was shown that extracting randomness from such sources is easier using special extractors, which are called “somewhere random mergers.” At this point we could have used Ta-Shma’s “somewhere random mergers” to extract the randomness from (o_1, \dots, o_l) . Instead, we use different methods, which exploit the fact that l is relatively small, to obtain better results.

6. Constructing extractors. In this section we use the condensers constructed in the previous section to prove the two main theorems (Theorems 1.4 and 1.6).

For Theorem 1.4 we use the condenser of Corollary 5.2 repeatedly (with fresh seeds) to condense the source until we achieve constant entropy rate. (This is guaranteed to happen after no more than $\log^* n$ iterations.) For constant entropy rate, Zuckerman’s extractor [32] (see Table 2) uses the optimal seed length to extract a constant fraction. This procedure loses some randomness in the iteration process and results in an extractor which extracts a subconstant fraction of the initial randomness. We then use the method of [29] to increase this fraction to an arbitrary constant. This informal argument is made precise in the following proof.

Proof of Theorem 1.4. Without loss of generality, we assume that $k \geq 8 \log^5 n$ as the extractor of [7] achieves the required result for $k < 8 \log^5 n$. It is easy to check that, given a (k, k', ϵ) -condenser $Con_1 : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^{n'}$ and a (k', k'', ϵ') -condenser $Con_2 : \{0, 1\}^{n'} \times \{0, 1\}^{d'} \rightarrow \{0, 1\}^{n''}$, composing the condensers produces a $(k, k'', \epsilon + \epsilon')$ -condenser $Con : \{0, 1\}^n \times \{0, 1\}^{d+d'} \rightarrow \{0, 1\}^{n''}$.

Let us denote the entropy rate of a source by $R(X) = k/n$ and let $R'(X) = n/k = 1/R(X)$. The condenser of Corollary 5.2 produces a source X' that is close to an $\Omega(k)$ source over $k \log(n/k)$ bits. Thus, $R(X') = \Theta(1/\log(1/R(X)))$ or, in other words, we have that $R'(X') = \Theta(\log(R'(X)))$. We now apply the condenser recursively on X' using a fresh seed. After $\log^* R'(X) \leq \log^* n$ iterations, the entropy rate becomes constant. Once the ratio is constant, Zuckerman’s extractor [32] (see Table 1) can be used to extract a constant fraction (say, half) of the randomness using a fresh seed of length $O(\log n)$ and error $1/\log^2 n$. Overall, we have used at most $\log^* n$ iterations, where in each of them we required a seed of length at most $O(\log n \cdot \log \log n)$ and the final application of Zuckerman’s extractor requires an additional $O(\log n)$ bits. Thus, the strategy described above gives an extractor that uses seed length $O(\log n \cdot \log \log n \cdot \log^* n)$ bits. Recall that our condenser loses a constant fraction of the randomness in every iteration. Thus, after $\log^* n$ iterations we extract only $k/2^{O(\log^* n)}$ random bits from the source and produce an extractor which extracts $1/2^{O(\log^* n)}$ of the initial randomness. To get to a constant fraction we use the method of Wigderson and Zuckerman [29].¹⁰ Implementing the technique of Wigderson and Zuckerman multiplies the seed and error by $2^{O(\log^* n)}$. Thus, the total number of random bits is $\log n \cdot \log \log n \cdot \log^* n \cdot 2^{O(\log^* n)} = O(\log n \cdot (\log \log n)^2)$ as required. Furthermore the final extractor has error smaller than $1/\log n$. \square

In the case of Theorem 1.6, we are shooting for the optimal seed length and cannot afford the condenser of Corollary 5.2 or repeated condensing. Instead we use

¹⁰Wigderson and Zuckerman suggested to repeatedly extract randomness from the source (using fresh seeds) until one extracts the desired fraction. This gives that if $m = k/p$, then m could be increased to $(1 - \alpha)k$ (where α is an arbitrary constant) at the cost of multiplying d by $O(p)$. (An exact formulation of the Wigderson and Zuckerman technique can be found, for example, in [11, 12].)

the condenser of Corollary 5.3, interpreting it as a block extraction scheme. Viewed this way, the condenser extracts a block B of length $k/2$, and therefore the distribution $(B(X, Y), X)$ forms a block-source, since B is too short to “steal” all the randomness from X . (This intuition is formalized in the next lemma.) All that is left is to use the block-source extractor of Corollary 2.6. The precise details follow.

LEMMA 6.1. *Let Con be the condenser of Corollary 5.3. If X is a k -source for $k \geq 8 \log^5 n$, then the distribution $(Con(X, U_{O(\log n)}), X)$ is $O(1/\log^2 n)$ -close to an $(\Omega(k/\log n), \log^4 n)$ -block-source.*

Proof. Fix some n and $k \geq 8 \log^5 n$, and let $Con : \{0, 1\}^n \times \{0, 1\}^{u=O(\log n)} \rightarrow \{0, 1\}^{k/2}$ be the $(k, \Omega(k/\log n), 1/\log^2 n)$ -condenser of Corollary 5.3. For this proof we view Con as a block extraction scheme $B : \{0, 1\}^n \times \{0, 1\}^u \rightarrow \{0, 1\}^{n/r}$ for $r = 2n/k$. It follows that B is a (k, ρ, γ) -block extraction scheme for $\rho = 1/\log^2 n$ and $\gamma = \Omega(r/\log n)$. We remark that, in particular, $\gamma \gg 1$.

We now consider the probability space of section 4. The probability space is over the set $\Omega = \{0, 1\}^n \times \{0, 1\}^u$ and consists of two independent random variables X (the given k -source) and Y (that is uniformly distributed over $\{0, 1\}^u$). We set $t = \log^4 n$ and apply Lemma 4.3 and let BAD, BLK, CON be the sets guaranteed by the lemma. We claim that $CON = \emptyset$.

We make this claim because the lemma guarantees that $(B(X, Y))$ is a $(k - 2t)$ -source in CON . Note that the output length of B is $k/2$, whereas $k - 2t > k/2$ because $k \geq 8 \log^5 n$. Thus, the lemma says that in CON there is a random variable which has min-entropy larger than its length. This statement is true only if $CON = \emptyset$.

Lemma 4.3 also gives that

- $\Pr(BAD) \leq 2(\rho + 2^{-t})$.
- $(B(X, Y), X)$ is a $(\frac{\gamma k}{r} - t, t)$ -block-source in BLK .

Thus, $(B(X, Y), X)$ is $O(\rho + 2^{-t})$ -close to a $(\frac{\gamma k}{r} - t, t)$ -block-source. Using again that $k \geq 8 \log^5 n$, we conclude that the distribution $(Con(X, U_{O(\log n)}), X)$ is $O(1/\log^2 n)$ -close to an $(\Omega(k/\log n), \log^4 n)$ -block-source as required. \square

We now prove Theorem 1.6.

Proof of Theorem 1.6. As in the proof of Theorem 1.4, without loss of generality we can assume that $k \geq 8 \log^5 n$ because the extractor of [7] achieves the required result for $k < 8 \log^5 n$. Given a k -source, we use Lemma 6.1 to get a distribution that is close to a block-source and use the block-source extractor of Corollary 2.6. \square

7. Achieving small error. The statements of Theorems 1.4 and 1.6 are for constant error ϵ . The analysis provided in this paper gives a slightly better result and allows us to replace the requirement that ϵ be a constant with $\epsilon = 1/(\log n)^c$ for any constant c . Still, our technique does not give good dependence of the seed length on the error. We get better dependence on ϵ using the error reduction transformation of [16], which transforms an extractor with large (say, constant) error into an extractor with arbitrary small error, while losing only a little bit in the other parameters. More precisely, after undergoing the transformation, a factor of $O(\log m(\log \log m)^{O(1)} + \log(1/\epsilon))$ is added to d , and the fraction extracted decreases by a constant. The latter loss makes no difference from our point of view since we are only able to extract constant fractions. The first loss is not significant in the case of Theorem 1.4, since the seed size is already larger than the optimal one by a multiplicative $\text{polyloglog}(n)$ factor. However, it completely spoils Theorem 1.6 and makes it inferior to Theorem 1.4. Following is Theorem 1.4 rephrased using the error reduction transformation of [16].

THEOREM 7.1 (*Theorem 1.4 rephrased for nonconstant ϵ*). *For every n, k , and $\epsilon > \exp(\frac{-n}{(\log^* n)^{O(\log^* n)}})$, there are explicit (k, ϵ) -extractors*

$$\text{Ext} : \{0, 1\}^n \times \{0, 1\}^{O(\log n \cdot (\log \log n)^{O(1)} + \log(1/\epsilon))} \rightarrow \{0, 1\}^{(1-\alpha)k},$$

where $\alpha > 0$ is an arbitrary constant.

8. Transforming arbitrary extractors into strong extractors. It is sometimes helpful to have a stronger variant of extractors, called a *strong* extractor. A strong extractor is required to extract randomness “only from the source” and not “from the seed.”

DEFINITION 8.1. *A (k, ϵ) -extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ is strong if for every k -source X the distribution $(\text{Ext}(X, U_d) \circ U_d)$ (obtained by concatenating the seed to the output of the extractor) is ϵ -close to a U_{m+d} .*

Intuitively, this is helpful since a strong extractor has the property that, for any source, a $1 - \epsilon$ fraction of the seeds extracts randomness from that source. It is interesting to note that the concept of strong extractors preceded that of nonstrong extractors, and the strong version was the one which was defined in the seminal paper [13]. Several extractors constructions (with examples being the constructions of [24, 7] and this paper) are nonstrong or difficult to analyze as strong.

The following theorem shows that every nonstrong extractor can be transformed into a strong one with essentially the same parameters.

THEOREM 8.2. *Any explicit (k, ϵ) -extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ can be transformed into an explicit strong $(k, O(\sqrt{\epsilon}))$ -extractor $\text{Ext}' : \{0, 1\}^n \times \{0, 1\}^{d+d'} \rightarrow \{0, 1\}^{m-(d+L+1)}$ for $d' = \text{polylog}(d/\epsilon)$ and $L = 2 \log(1/\epsilon) + O(1)$.*

Let us consider the parameters of Ext' compared to that of Ext . The seed length of Ext' is longer than that of Ext by a factor that is only polylogarithmic (for large ϵ). The output length of Ext' is shorter than that of Ext by $d + L + 1$. The loss of d bits is unavoidable, as the output of Ext may contain d bits of randomness from the seed. The additional loss of $L + 1$ bits can sometimes be recovered (at the cost of increasing the seed length). Exact details are given in Remark 8.3.

Remark 8.3. In [17] it was shown that any strong extractor which has seed length d and entropy-loss Δ can be transformed into a strong extractor with seed length $d + O(\Delta)$ and an optimal entropy loss of $2 \log(1/\epsilon) + O(1)$. Thus, if the initial extractor Ext had an entropy loss of Δ , we can use our construction to get an extractor Ext' with the parameters mentioned above, and then use [17] to construct a strong extractor Ext'' with seed length $d'' = d + d' + O(\Delta)$ and optimal entropy-loss. This addition is affordable if Δ is small.

The intuition above also gives a hint for the construction. The output of Ext may contain d bits of randomness which “belong” to the seed. Still, it contains roughly $m - d$ bits which *do not* depend on the seed. Thus, fixing the seed, the output of Ext is a random source of length m which contains roughly $m - d$ random bits. We can now use another extractor to extract this randomness and “dismantle” the correlation between the seed and the output. The extractor we need is one that works well when the source lacks only a very small amount of randomness. Such a construction was given by [4] and improved by [19].

THEOREM 8.4 (see [19]). *There are explicit strong (k, ϵ) -extractors $\text{RVW} : \{0, 1\}^n \times \{0, 1\}^{d'} \rightarrow \{0, 1\}^{k-L}$ for $d' = \text{polylog}((n - k)/\epsilon)$ and $L = 2 \log(1/\epsilon) + O(1)$.*

CONSTRUCTION 8.5. *Given a (k, ϵ) -extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$, we construct Ext' as follows. Let $\text{RVW} : \{0, 1\}^m \times \{0, 1\}^{d' = \text{polylog}(d/\epsilon)} \rightarrow \{0, 1\}^{m-d-1-L}$*

be an $(m - d - 1, \epsilon)$ -extractor guaranteed by Theorem 8.4. Then,

$$\text{Ext}'(x; (y, z)) = \text{RVW}(\text{Ext}(x, y), z).$$

The actual proof that Ext' has the desired properties is slightly more complicated than the above presentation. This is mainly because the above presentation ignores the error of Ext . We now give the formal proof.

Proof of Theorem 8.2. We now describe a probability space for this proof. It consists of three independent random variables: an arbitrary k -source X over n bit strings, a uniformly chosen string Y of length d , and a uniformly chosen string Z of length d' .

Given strings $x \in \{0, 1\}^n$ and $y \in \{0, 1\}^d$ we define the *weight* of (x, y) , denoted $w(x, y)$, in the following way:

$$w(x, y) = \Pr(\text{Ext}(X, Y) = \text{Ext}(x, y)).$$

In other words, this is the weight of the string $\text{Ext}(x, y)$ according to the distribution $\text{Ext}(X, Y)$. We say that a pair (x, y) is heavy if $w(x, y) > 2^{-(m-1)}$. We first claim that only few pairs are heavy.

CLAIM 1. $\Pr((X, Y) \text{ are heavy}) < 2\epsilon$.

Proof. Let V denote the distribution $\text{Ext}(X, Y)$. We now use Lemma 2.2. We have that V is ϵ -close to an m -source (the uniform distribution). Therefore the probability under V of hitting an element v such that $\Pr_V(V = v) > 2^{-(m-1)}$ is bounded by 2ϵ and the claim follows. \square

Call a seed $y \in \{0, 1\}^d$ *bad* if $\Pr((X, y) \text{ is heavy}) > \sqrt{2\epsilon}$. That is, if for many choices of x , the output element is heavy. We now claim that there are few bad seeds.

CLAIM 2. *The fraction of bad seeds is at most $\sqrt{2\epsilon}$.*

Proof. The proof is a Markov argument. If the fraction of bad seeds is more than $\sqrt{2\epsilon}$, then $\Pr((X, Y) \text{ is heavy}) > 2\epsilon$. \square

The following claim shows that running the extractor with a good seed produces a source which lacks very few random bits.

CLAIM 3. *For a good seed y , $\text{Ext}(X, y)$ is $\sqrt{2\epsilon}$ -close to an $(m - d - 1)$ -source.*

Proof. For a good y we know that $\Pr((X, y) \text{ is heavy}) < \sqrt{2\epsilon}$. That is, at least a $1 - \sqrt{2\epsilon}$ fraction of the x 's has $w(x, y) \leq 2^{-(m-1)}$. For such an x ,

$$\begin{aligned} \Pr(\text{Ext}(X, y) = \text{Ext}(x, y)) &= \Pr(\text{Ext}(X, Y) = \text{Ext}(x, y) | Y = y) \\ &\leq \frac{w(x, y)}{2^{-d}} \leq 2^{-(m-d-1)}. \quad \square \end{aligned}$$

We have that Ext' runs RVW on the source $\text{Ext}(X, Y)$ using a fresh seed Z . Using the fact that, for a good seed y , $\text{Ext}(X, y)$ is close to a high entropy source, we derive the following claim.

CLAIM 4. *Given $y \in \{0, 1\}^d$, let D_y denote $(\text{Ext}'(X; (y, Z)) \circ Z)$. For every good y , D_y is $(2\sqrt{\epsilon} + \epsilon)$ -close to uniform.*

Proof. Note that $\text{Ext}'(X; (y, Z)) = \text{RVW}(\text{Ext}(X, y), Z)$. The claim follows immediately from Claim 3 and the fact that RVW is a strong extractor. \square

We now complete the proof of the theorem. Let D denote $(\text{EXT}'(X; (Y, Z)) \circ Z)$. We need to show that $(D \circ Y)$ is $O(\sqrt{\epsilon})$ -close to uniform. Note that $D = D_Y$ (that is, D is a convex combination of the distributions D_y). As the fraction of bad seeds is at most $O(\sqrt{\epsilon})$, it is sufficient to show that for any good seed y , $(D_y \circ Y)$ is $O(\sqrt{\epsilon})$ -close to uniform. Note that as Y is independent of D_y , it is sufficient to show that D_y is $O(\sqrt{\epsilon})$ -close to uniform, which follows from Claim 4. \square

9. Discussion. In a subsequent work, Lu et al. [9] achieve extractors with better parameters than those constructed here. Namely, for constant error $\epsilon > 0$ they achieve a (k, ϵ) -extractor $E : \{0, 1\}^n \times \{0, 1\}^{O(\log n)} \rightarrow \{0, 1\}^{\Omega(k)}$ for every choice of k . Their construction uses some of the ideas of this paper (condensers, win-win analysis) as well as additional ideas.

The next milestone in extractor constructions seems to be achieving seed length $d = O(\log n)$ and output length $m = k + d - O(1)$. (We remark that the difference between output length $\Omega(k)$ and k is significant in some applications of extractors.) This has already been achieved by [25] for small values of k ($k = 2^{\log n / \log \log n}$) in a subsequent work.

Another important goal is to achieve the “correct dependence” of the seed length on ϵ for nonconstant ϵ , namely, to achieve an extractor with seed length $d = O(\log(n/\epsilon))$ and output length (say) $m = \Omega(k)$. We remark that both our approach and the approach of [9] do not give this dependence.

Acknowledgments. We thank Russel Impagliazzo and Amnon Ta-Shma for helpful discussions, and particularly for bringing to our attention their insights on error correcting random sources. We are also grateful to the anonymous referees for helpful comments.

WORD PROBLEMS AND MEMBERSHIP PROBLEMS ON COMPRESSED WORDS*

MARKUS LOHREY†

Abstract. We consider a compressed form of the word problem for finitely presented monoids, where the input consists of two compressed representations of words over the generators of a monoid \mathcal{M} , and we ask whether these two words represent the same monoid element of \mathcal{M} . Words are compressed using straight-line programs, i.e., context-free grammars that generate exactly one word. For several classes of finitely presented monoids we obtain completeness results for complexity classes in the range from P to EXPSPACE. As a by-product of our results on compressed word problems we obtain a fixed deterministic context-free language with a PSPACE-complete compressed membership problem. The existence of such a language was open so far. Finally, we will investigate the complexity of the compressed membership problem for various circuit complexity classes.

Key words. grammar-based compression, word problems for monoids, context-free languages, complexity

1. Introduction. During the last decade, the massive increase in the volume of data has motivated the investigation of algorithms on *compressed data*, e.g., compressed strings, trees, or pictures. The general goal is to develop algorithms that directly work on compressed data without prior decompression. Let us mention here the work on compressed pattern matching; see, e.g., [19, 23, 49, 60].

In this paper we investigate two classes of computational problems on compressed data that have been of central importance in theoretical computer science since its very beginning: the *word problem* and the *membership problem*.

In its most general form, the word problem asks whether two terms over an algebraic structure represent the same element of the structure. Here we restrict ourselves to the word problem for *finitely presented monoids*, i.e., monoids that are given by a finite set of generators and defining relations. In this case the input consists of two finite words over the set of generators, and we ask whether these two words represent the same monoid element. The undecidability results concerning the word problem for finitely presented monoids [47, 56] and finitely presented groups [12, 51] are among the first undecidability results that touched “real mathematics.” Moreover, these negative results motivated a still ongoing investigation of decidable subclasses of word problems and their computational complexity. In particular, monoids that can be presented by *terminating and confluent semi-Thue systems* (i.e., string rewriting systems where every word can be rewritten in a finite number of steps to a unique irreducible word; see [11, 33]) received a lot of attention: these monoids have decidable word problems, and if the restriction to terminating systems is suitably sharpened, then precise complexity bounds can be deduced [10, 41, 42]. All relevant definitions concerning semi-Thue systems and finitely presented monoids are collected in section 3.3.

In its compressed variant, the input to the word problem for a (finitely presented) monoid consists of two compressed representations of words over the generators. Here we choose *straight-line programs*, or equivalently context-free grammars that generate exactly one word, for compression—this approach is also known as *grammar-based compression*. See section 3.4 for a formal definition of straight-line programs. Recently, straight-line programs turned out to be a very flexible compressed representation of strings. Several other compressed representations, e.g., Lempel–Ziv factorizations [73], can be efficiently converted into straight-line programs and vice versa [55], which implies that most of our complexity results will also hold for Lempel–Ziv factorizations. An algorithmic application of this efficient transformation to and into straight-line programs is given in [23], where the pattern matching problem for Lempel–Ziv compressed texts is solved efficiently via reduction to straight-line programs. Finally, by using straight-line programs for representing inputs, the compressed word problem becomes equivalent to the well-known circuit equivalence problem (a generalization of the circuit evaluation problem), where we ask whether two circuits over a finitely presented monoid \mathcal{M} (i.e., acyclic directed graphs with leaves labeled by generators of \mathcal{M} and internal nodes labeled by the monoid operation) evaluate to the same element of \mathcal{M} . This problem was mainly investigated for finite structures (e.g., finite monoids [7]) and integer circuits [48] so far. From this perspective, the compressed word problem highlights the classical circuit versus formula evaluation problem in the context of finitely presented monoids.

In sections 4–7 we study the complexity of compressed word problems for several subclasses of monoids presented by terminating and confluent semi-Thue systems. For this we will distinguish semi-Thue systems with respect to the syntactical form of the rewriting rules. In sections 4 and 5 we will consider confluent and *2-homogeneous* semi-Thue systems, which are confluent systems where all rules are of the form $w \rightarrow \varepsilon$ with w of length 2. For confluent and 2-homogeneous systems that satisfy a further syntactical restriction (which we call *N-freeness*) we prove that the presented monoid has a polynomial time solvable compressed word problem (Theorem 4.5). For all other confluent and 2-homogeneous systems, the compressed word problem becomes coNP-hard (Corollary 5.9) and is contained in P^{NP} (Theorem 5.1). In section 6 we show that the complexity of the compressed word problem increases to PSPACE-completeness if we allow also rules of the form $u \rightarrow v$, where again u has length 2 but v may have length 0 or 1 (Theorem 6.6)—the resulting semi-Thue systems are called *2-monadic*. The largest class of semi-Thue systems that is considered in this paper consists of confluent and *weight-reducing* systems. It is briefly studied in section 7, where it is shown that the compressed word problem for a monoid which is presented by a confluent and weight-reducing semi-Thue system is in EXPSPACE and is EXPSPACE-hard for some specific system (Theorem 7.1).

As a by-product of our investigation of compressed word problems we obtain several new results concerning compressed membership problems. Here the problem is to decide for a fixed language L (e.g., a regular or context-free language) whether a given straight-line compressed word w belongs to L [55]. Using Theorem 6.6 concerning 2-monadic semi-Thue systems, we show that there exists a fixed deterministic context-free (even deterministic linear) language with a PSPACE-complete compressed membership problem (Corollary 6.7), which solves an open problem from [23, 55]. Corollary 6.7 should be compared with a result from [24], stating that given a straight-line compressed word w and a nondeterministic hierarchical automaton A (see [24] for a precise definition) it is PSPACE-complete to decide whether $w \in L(A)$. It is straightforward to transform a hierarchical automaton in logspace

into an equivalent nondeterministic pushdown automaton of the same size. Corollary 6.7 improves the result of [24] in two aspects: (i) the context-free language in Corollary 6.7 is deterministic and (ii) it is fixed; i.e., it does not belong to the input. Another result related to Corollary 6.7 was recently shown in [50]: it is PSPACE-complete to decide for two given *nonrecursive* context-free grammars G_1 and G_2 whether $L(G_1) \cap L(G_2) \neq \emptyset$. Nonrecursive context-free grammars generate finite languages; in particular, a straight-line program is a nonrecursive context-free grammar. Thus, in comparison to the result of [50], we sharpen the condition on the grammar G_1 (it has to be a straight-line program) but relax the condition on G_2 (it generates an infinite language). One should also note that for the result of [50] it is crucial that both G_1 and G_2 are part of the input.

Compressed membership problems for context-free languages are also interesting in light of recent attempts to use straight-line programs for the compressed representation of control flow traces of procedural programming languages [36, 72]. At a certain level of abstraction, the set of all valid control flow traces of a procedural programming language is a context-free language.

In section 8 we will investigate the complexity of the compressed membership problem for various circuit complexity classes. We show that the levels of the logtime hierarchy [63] correspond in a compressed setting to the levels of the polynomial time hierarchy. This is another instance of a general phenomenon that we observe: in the worst case there is an exponential jump with respect to computational complexity when moving from the (uncompressed) word/membership problem to its compressed variant. This exponential jump is well known also from other work on the complexity of succinct problems [21, 66, 68, 69], where Boolean circuits/formulas are used for the succinct representation of graphs. But whereas for these formalisms general upgrading theorems can be shown, which roughly state that completeness of problem for a complexity class C implies completeness of the compressed variant for the exponentially harder version of C , such an upgrading theorem fails for straight-line programs: The compressed membership problem for a language may be of the same complexity as the language itself (Proposition 8.5). Thus, the relationship between a computational problem and its straight-line compressed variant is quite loose. A similar phenomenon was observed in the context of hierarchical graph descriptions [38], which can be seen as graph generating straight-line programs.

An extended abstract of this paper appeared in [43].

2. Related work. One of the most intensively studied problems on compressed strings is the pattern matching problem; see, e.g., [19, 23, 49, 60]. In these papers, strings are compressed using either a variant of Lempel–Ziv encoding or straight-line programs. Compressed membership problems for straight-line compressed words were investigated for the first time in [23, 55, 59]; see also [62] for a recent survey.

The problem of checking whether for a given input string s and a given integer n there exists a straight-line program of size at most n that generates s is NP-complete [37]. A smallest straight-line program generating a given input string is even hard to approximate up to some constant factor unless $P = NP$ [37]. Practical algorithms for generating a small straight-line program that produces a given input string were proposed and analyzed with respect to their approximation ratios in [16, 37, 61].

Algorithmic problems on compressed data were also investigated for more general structures than only strings. Complexity theoretical investigations of computational problems on compressed graphs can be found in [13, 20, 21, 38, 44, 53, 66, 67, 68, 69]. In [13, 21, 53, 68, 69] (resp., [66]) Boolean circuits (resp., formulas) are used for

compression, in [20, 67] OBBDs are used, and in [38, 44] graphs are represented via hierarchical graph descriptions. The latter formalism can be seen as an adaptation of the idea of grammar-based compression to the context of graphs. Recently, grammar-based compression was also used in the context of XML in order to obtain succinct representations of large XML documents [14, 45, 46, 71]. Here context-free tree grammars are used as a compact representation of XML skeletons.

3. Preliminaries.

3.1. General notation. For a binary relation \rightarrow on some set, we denote by $\xrightarrow{+}$ ($\xrightarrow{*}$) the transitive (reflexive and transitive) closure of \rightarrow . For sets A , B , and C , we write $A = B \uplus C$ if A is the disjoint union of B and C (B or C may be empty). Let Γ be a finite alphabet. The *empty word* over Γ is denoted by ε . Let $s = a_1 a_2 \cdots a_n \in \Gamma^*$ be a word over Γ , where $a_i \in \Gamma$ for $1 \leq i \leq n$. We define $w^{\text{rev}} = a_n a_{n-1} \cdots a_1$. The *alphabet of s* is $\text{alph}(s) = \{a_1, \dots, a_n\}$. The *length* of s is $|s| = n$. Furthermore, for $a \in \Gamma$ we define $|s|_a = |\{i \mid a_i = a\}|$. For $1 \leq i \leq n$ let $s[i] = a_i$ and for $1 \leq i \leq j \leq n$ let $s[i, j] = a_i a_{i+1} \cdots a_j$. If $i > j$, we set $s[i, j] = \varepsilon$. For a subalphabet $\Sigma \subset \Gamma$ we define the projection morphism $\pi_\Sigma : \Gamma^* \rightarrow \Sigma^*$ by $\pi_\Sigma(a) = \varepsilon$ if $a \notin \Sigma$ and $\pi_\Sigma(a) = a$ if $a \in \Sigma$. For a language $L \subseteq \Gamma^*$ we define the language $\text{Pref}(L) = \{w \in \Gamma^* \mid w \text{ is a prefix of some } u \in L\}$. An *involution* $\bar{}$ on Γ is a function $\bar{} : \Gamma \rightarrow \Gamma$ such that $\overline{\overline{a}} = a$ for all $a \in \Gamma$. It may have fixed points; i.e., $\overline{a} = a$ for some $a \in \Gamma$. The involution $\bar{} : \Gamma \rightarrow \Gamma$ can be extended to an involution on Γ^* by setting $\overline{a_1 \cdots a_n} = \overline{a_n} \cdots \overline{a_1}$. By $\overline{\Gamma} = \{\overline{a} \mid a \in \Gamma\}$ we will always denote a disjoint copy of the alphabet Γ . Then we can define an involution $\bar{}$ on $\Delta = \Gamma \cup \overline{\Gamma}$ by setting $\overline{\overline{a}} = a$; this involution will be extended to Δ^* in the above way. A *weight-function* is a homomorphism $f : \Gamma^* \rightarrow \mathbb{N}$ from the free monoid Γ^* with concatenation to the natural numbers with addition such that $f(s) = 0$ if and only if $s = \varepsilon$. Given a linear order \succ on the alphabet Γ , we extend \succ to a linear order on Γ^* , called the *lexicographic extension of \succ* , as follows: $u \succ v$ if either v is a prefix of u or there exist factorizations $u = w a u'$ and $v = w b v'$ with $a, b \in \Gamma$ and $a \succ b$. For two monoids \mathcal{M}_1 and \mathcal{M}_2 we write $\mathcal{M}_1 \cong \mathcal{M}_2$ if \mathcal{M}_1 and \mathcal{M}_2 are isomorphic.

3.2. Complexity theory. We assume that the reader is familiar with standard complexity classes such as P, coNP, PSPACE, and EXPSPACE; see, e.g., [52] for more details. All hardness results in this paper refer to logspace reductions unless some stronger form of reductions is mentioned explicitly. Several times we will use the fact that addition and multiplication of integers with $n^{O(1)}$ many bits can be done in space $O(\log(n))$. In section 8 we will make use of *alternating Turing-machines* with logarithmic running times. An alternating Turing-machine is a nondeterministic Turing-machine, where the set of states is partitioned into existential and universal states [15]. A configuration with a universal (resp., existential) state is accepting if every (resp., some) successor state is accepting. An alternation in a computation of an alternating Turing-machine is a transition from a universal state to an existential state or vice versa. Following [15], we add a random access mechanism to the ordinary Turing-machine model when dealing with sublogarithmic time bounds: There exists a special address tape that contains a binary coded number p . If the machine enters a special query state, then it has random access to the p th symbol of the input. This mechanism allows a Turing-machine to reach every input position in logarithmic time. If the address tape contains a position which is larger than the length of the input, then querying the input yields some distinguished special symbol. With *DLOGTIME* (resp., *ALOGTIME*) we denote the class of languages that can be recognized on a

deterministic (resp., alternating) Turing-machine in time $O(\log(n))$. It is known that ALOGTIME is equal to uniform NC^1 [3], which is the class of all languages that can be recognized by a uniform family of polynomial-size, logarithmic-depth, fan-in 2 Boolean circuits. Functions computable in uniform NC^1 are defined analogously by allowing circuits with more than one output. For the considerations in this paper, it is not necessary to go into the quite technical details of the precise definition of uniformity. We just remark that Ruzzo's U_{E^*} -uniformity of circuit families [58] would be suitable for all purposes in this paper. A language $L \subseteq \{0, 1\}^*$ is NC^1 -many-one reducible to a language $K \subseteq \{0, 1\}^*$, briefly $L \leq_{\text{NC}^1} K$, if there exists a function f which is computable in uniform NC^1 such that for all $x \in \{0, 1\}^*$, $x \in L$ if and only if $f(x) \in K$.

3.3. Semi-Thue systems and finitely presented monoids. Presentations for monoids are the basic concept of this work. In this section we will introduce the necessary definitions. For more details and references see [11, 33].

Let Γ be a finite alphabet. A *semi-Thue system* R over Γ is a finite subset $R \subseteq \Gamma^* \times \Gamma^*$, whose elements are called rules. A rule $(s, t) \in R$ will be also written as $s \rightarrow t$. The pair (Γ, R) is called a *monoid presentation*. The sets $\text{dom}(R)$ of all left-hand sides and $\text{ran}(R)$ of all right-hand sides are defined by $\text{dom}(R) = \{s \mid \exists t : (s, t) \in R\}$ and $\text{ran}(R) = \{t \mid \exists s : (s, t) \in R\}$, respectively. We define two binary relations \rightarrow_R and \leftrightarrow_R on Γ^* as follows:

- $s \rightarrow_R t$ if there exist $u, v \in \Gamma^*$ and $(\ell, r) \in R$ with $s = u\ell v$ and $t = urv$ (the *one-step rewrite relation*).
- $s \leftrightarrow_R t$ if $(s \rightarrow_R t$ or $t \rightarrow_R s)$.

We also write $t_R \leftarrow s$ in case $s \rightarrow_R t$. Let $\text{RED}(R) = \Gamma^* \cdot \text{dom}(R) \cdot \Gamma^*$ be the set of *reducible words* and $\text{IRR}(R) = \Gamma^* \setminus \text{RED}(R)$ be the set of *irreducible words* (with respect to R). The presentation (Γ, R) is *terminating* if there does not exist an infinite chain $s_1 \rightarrow_R s_2 \rightarrow_R s_3 \rightarrow_R \dots$ in Γ^* . The presentation (Γ, R) is *confluent* if for all $s, t, u \in \Gamma^*$ with $t_R \leftarrow^* s \xrightarrow^* u$ there exists $v \in \Gamma^*$ with $t \xrightarrow^* v_R \leftarrow^* u$. It is well known that (Γ, R) is confluent if and only if (Γ, R) is *Church-Rosser*; i.e., for all $s, t \in \Gamma^*$, if $s \leftrightarrow_R^* t$, then $s \xrightarrow^* u_R \leftarrow^* t$ for some $u \in \Gamma^*$. The presentation (Γ, R) is *locally confluent* if for all $s, t, u \in \Gamma^*$ with $t_R \leftarrow s \rightarrow u$ there exists $v \in \Gamma^*$ with $t \xrightarrow^* v_R \leftarrow^* u$. By Newman's lemma, a terminating presentation is confluent if and only if it is locally confluent. Moreover, if (Γ, R) is terminating and confluent, then for every $s \in \Gamma^*$ there exists a unique *normal form* $\text{NF}_R(s) \in \text{IRR}(R)$ such that $s \xrightarrow^* \text{NF}_R(s)$. It is undecidable whether a given presentation is terminating, confluent, or locally confluent, respectively. On the other hand, for a terminating presentation, local confluence (and hence by Newman's lemma also confluence) can be checked using *critical pairs*, which result from overlapping left-hand sides.

The relation \xrightarrow^* is a congruence relation with respect to the concatenation of words; it is called the *Thue-congruence* generated by (Γ, R) . Hence we can define the quotient monoid $\Gamma^* / \xrightarrow^*$, which we denote by $\mathcal{M}(\Gamma, R)$. It is called a *finitely presented monoid*, and we say that $\mathcal{M}(\Gamma, R)$ is the *monoid presented by* (Γ, R) .

A decision problem that is of fundamental importance in the theory of monoid presentations is the word problem. Let (Γ, R) be a fixed presentation. The *word problem* for (Γ, R) is the following decision problem:

INPUT: Two words $s, t \in \Gamma^*$.

QUESTION: Does $s \xrightarrow^* t$ hold; i.e., do s and t represent the same element of the monoid $\mathcal{M}(\Gamma, R)$?

Here the input size is $|s| + |t|$.

If (Γ, R) and (Σ, S) are presentations such that $\mathcal{M}(\Gamma, R) \cong \mathcal{M} \cong \mathcal{M}(\Sigma, S)$, then for every $a \in \Gamma$ there exists a word $w_a \in \Sigma^*$ such that a and w_a represent the same element of \mathcal{M} . If we define the homomorphism $h : \Gamma^* \rightarrow \Sigma^*$ by $h(a) = w_a$, then for all $s, t \in \Gamma^*$ we have $s \stackrel{*}{\leftrightarrow}_R t$ if and only if $h(s) \stackrel{*}{\leftrightarrow}_S h(t)$. Thus, the word problem for (Γ, R) can be reduced to the word problem for (Σ, S) and vice versa. Moreover, this reduction can be realized in deterministic logspace (even in uniform TC^0 [35]). Thus, the decidability and complexity of the word problem do not depend on the chosen presentation. Since we are interested only in decidability and complexity questions for word problems, we may just speak of the word problem for the monoid \mathcal{M} .

It is well known that in case (Γ, R) is a terminating and confluent presentation, then the word problem for $\mathcal{M}(\Gamma, R)$ is decidable: in order to check whether $u \stackrel{*}{\leftrightarrow}_R v$ it suffices to verify whether $\text{NF}_R(u) = \text{NF}_R(v)$. On the other hand, this algorithm does not yield any upper bound on the computational complexity of the word problem [5]. Complexity results on word problems for restricted classes of finitely presented monoids can be found, for instance, in [10, 41, 42].

3.4. Grammar-based compression. Following [55], a *straight-line program* (SLP) (over the terminal alphabet Γ) is a restricted context-free grammar $G = (V, \Gamma, S, P)$ (where V is the set of nonterminals, Γ is the set of terminals, $S \in V$ is the initial nonterminal, and $P \subseteq V \times (V \cup \Gamma)^*$ is the set of productions) such that

- for every $X \in V$ there exists exactly one production of the form $(X, \alpha) \in P$ for $\alpha \in (V \cup \Gamma)^*$, and
- there exists a linear order \prec on the set of nonterminals V such that $X \prec Y$ whenever there exists a production of the form $(X, \alpha) \in P$ with $Y \in \text{alph}(\alpha)$.¹

Clearly, the language generated by the SLP G consists of exactly one word that is denoted by $\text{eval}(G)$. More generally, from every nonterminal $X \in V$ we can generate exactly one word that is denoted by $\text{eval}_G(X)$ (thus $\text{eval}(G) = \text{eval}_G(S)$). We omit the index G if the underlying SLP is clear from the context. We also write $P(G)$ for the set of productions P . The size of G is $|G| = \sum_{(X, \alpha) \in P} |\alpha|$. Note that every SLP can be transformed in polynomial time into an equivalent SLP in *Chomsky normal form*; i.e., all productions have the form (A, a) with $a \in \Gamma$ or (A, BC) with $B, C \in V$.

Example 3.1. Consider the SLP G_7 over the terminal alphabet $\{a, b\}$ that consists of the following productions:

$$X_i \rightarrow X_{i-1}X_{i-2} \text{ for } 3 \leq i \leq 7, \quad X_2 \rightarrow a, \quad X_1 \rightarrow b.$$

X_7 is the start nonterminal. Then $\text{eval}(G_7) = \text{abaababaabaab}$, which is the 7th Fibonacci word. The SLP G_7 is in Chomsky normal form and $|G_7| = 12$.

Sometimes we will also allow exponential expressions of the form A^i for $A \in V$ and $i \in \mathbb{N}$ in the right-hand sides of productions. Here the number i is coded binary. Such an expression can be replaced by a sequence of ordinary productions, where the length of that sequence is bounded polynomially in the length of the binary coding of i . The following lemma collects several simple algorithmic properties of SLPs that will be used several times in this paper.

¹The term “straight-line program” is used for such a context-free grammar, because a production $A \rightarrow \alpha$ corresponds to a definition $A := \alpha$. Thus, the whole context-free grammar can be interpreted as a linear sequence of instructions, i.e., a straight-line program. Usually one also allows instructions in straight-line programs, where the defined variable appears on the right-hand side (e.g., $x := x + 1$). But instructions of this kind can be easily eliminated by introducing additional variables.

LEMMA 3.2. *The following tasks can be easily solved in polynomial time:*

1. *Given an SLP G , calculate $|\text{eval}(G)|$ and $\text{alph}(\text{eval}(G))$.*
2. *Given an SLP G and a number $i \in \{1, \dots, |\text{eval}(G)|\}$, calculate $\text{eval}(G)[i]$.*
3. *Given an SLP G over the terminal alphabet Γ and a homomorphism $\rho : \Gamma^* \rightarrow \Sigma^*$, calculate an SLP H such that $\text{eval}(H) = \rho(\text{eval}(G))$ (this is in fact possible in logspace).*

The proofs of these statements are straightforward. The following result from [30, 54] is much harder to obtain.

LEMMA 3.3 (see [30, 54]). *For two given SLPs G_1 and G_2 , we can decide in polynomial time whether $\text{eval}(G_1) = \text{eval}(G_2)$.*

It is open whether this problem is P-complete. In this work, we will consider the following generalization: Let (Γ, R) be a fixed monoid presentation. The *compressed word problem* for the monoid $\mathcal{M}(\Gamma, R)$ is the following problem:

INPUT: Two SLPs G_1 and G_2 over the terminal alphabet Γ .

QUESTION: Does $\text{eval}(G_1) \overset{*}{\leftrightarrow}_R \text{eval}(G_2)$ hold?

Here the input size is $|G_1| + |G_2|$. Analogously to the uncompressed word problem, the complexity of the compressed word problem does not depend on the chosen presentation (for this, Lemma 3.2, statement 3, can be used). For a fixed language $L \subseteq \Gamma^*$ we will also consider the *compressed membership problem* for the language L , which is the following problem:

INPUT: An SLP G over the terminal alphabet Γ .

QUESTION: Does $\text{eval}(G) \in L$ hold?

We can view the compressed word problem also from another perspective. A *circuit* \mathcal{C} over $\mathcal{M}(\Gamma, R)$ is a finite directed acyclic graph with exactly one node of outdegree 0. The nodes of indegree 0 are labeled with elements from Γ . All nodes of indegree greater than zero are labeled with the multiplication of the monoid $\mathcal{M}(\Gamma, R)$. Such a circuit computes in a natural way an element of $\mathcal{M}(\Gamma, R)$. Then the compressed word problem for $\mathcal{M}(\Gamma, R)$ is equivalent to the question of whether two given circuits over $\mathcal{M}(\Gamma, R)$ compute the same monoid element. This question has been considered in [7] for the case of finite monoids. Clearly, for a finite monoid, the compressed word problem can be solved in polynomial time. In [7], it was shown that for a finite nonsolvable monoid the compressed word problem is P-complete, whereas for every finite solvable monoid the compressed word problem belongs to DET (the class of all problems that are NC¹-reducible to the calculation of an integer determinant [17]) and hence to NC². Due to the tight correspondence between finite monoids and regular languages, every compressed word problem for a finite monoid is equivalent to the compressed membership problem for a specific regular language and vice versa. Thus, [7] gives a complete classification of the complexity of the compressed membership problem for regular languages. Our work can be seen as a first step of an extension of the work from [7] to finitely presented infinite monoids.

Finally, let us remark that most of our complexity results can be transferred to other compression schemes, e.g., Lempel–Ziv 77, briefly LZ77 [73]. If w is a string and G is an SLP of size n with $\text{eval}(G) = w$, then $\text{LZ}(w)$ (the LZ77-compressed representation of w) has size $O(n)$ and can be constructed in polynomial time [55, 61]. On the other hand, if n is the size of $\text{LZ}(w)$, then we can construct in polynomial time an SLP of size $O(n^2 \cdot \log(n))$ that generates w [55]. Thus, if we allow polynomial time reductions, all our hardness results for complexity classes above P also hold if we use LZ77 for compression. Since the transformation from an SLP to the

LZ77-compressed representation might be P-hard, we cannot transfer directly P-hardness results for SLPs to LZ77.

4. Compressed word problems in P. As already mentioned in the previous section, for every finite monoid the compressed word problem is solvable in polynomial time. In this section we will present a class of infinite monoids with polynomial time solvable compressed word problems. This class contains all free groups. We will also prove that the compressed word problem for every free group of rank at least 2 is P-complete.

A presentation (Γ, R) is called 2-homogeneous if, for every $(\ell, r) \in R$, $|\ell| = 2$ and $r = \varepsilon$ [9]. In [42] it was shown that for every 2-homogeneous presentation the (uncompressed) word problem is in logspace. Moreover, the uniform variant of the word problem for 2-homogeneous presentations, where the presentation is part of the input, is complete for symmetric logspace [42].

The following result was shown by Book [9].

PROPOSITION 4.1 (see [9]). *For every 2-homogeneous presentation (Γ, R) there exists a 2-homogeneous and confluent presentation (Σ, S) with $\mathcal{M}(\Gamma, R) \cong \mathcal{M}(\Sigma, S)$.*

For further consideration let us fix a 2-homogeneous presentation (Γ, R) . By Proposition 4.1 we may assume that (Γ, R) is confluent. The following lemma is easy to prove.

LEMMA 4.2. *Let $u, v \in \text{IRR}(R)$. Then there exist factorizations $u = u_1u_2$ and $v = v_1v_2$ such that $\text{NF}_R(uv) = u_1v_2$, $|u_2| = |v_1|$, and $u_2v_1 \xrightarrow{*}_R \varepsilon$.*

The following lemma was shown in [42].

LEMMA 4.3 (see [42]). *There exists a partition $\Gamma = \Sigma_\ell \uplus \Sigma_r \uplus \Delta$ and an involution $\bar{\cdot} : \Delta \rightarrow \Delta$ with $\{(a\bar{a}, \varepsilon) \mid a \in \Delta\} \subseteq R \subseteq \{(a\bar{a}, \varepsilon) \mid a \in \Delta\} \cup \{(ab, \varepsilon) \mid a \in \Sigma_\ell, b \in \Sigma_r\}$.*

We say that (Γ, R) is *N-free* if there do not exist $a, b \in \Sigma_\ell$ and $c, d \in \Sigma_r$ (where Σ_ℓ and Σ_r result from Lemma 4.3) such that $ac, ad, bc \in \text{dom}(R)$ but $bd \notin \text{dom}(R)$. *N-freeness* means that the bipartite graph $(\Sigma_\ell \cup \Sigma_r, \{(a, b) \in \Sigma_\ell \times \Sigma_r \mid (ab, \varepsilon) \in R\})$ does not contain an *N-shaped* induced subgraph; i.e., it is a disjoint union of complete bipartite graphs.

Example 4.4. Let $\Gamma = \{a, \bar{a}, b, \bar{b}\}$ and $R = \{(a\bar{a}, \varepsilon), (\bar{a}a, \varepsilon), (b\bar{b}, \varepsilon), (\bar{b}b, \varepsilon)\}$. Then (Γ, R) is 2-homogeneous, confluent, and *N-free*. In fact, we have $\Delta = \Gamma$ and $\Sigma_\ell = \Sigma_r = \emptyset$. The monoid $\mathcal{M}(\Gamma, R)$ is the free group of rank 2; see also the paragraph before Theorem 4.9. If $\Gamma = \{a, b, c, d\}$ and $R = \{(ac, \varepsilon), (ad, \varepsilon), (bc, \varepsilon)\}$, then (Γ, R) is 2-homogeneous and confluent but not *N-free*. In fact, (Γ, R) is contained in every 2-homogeneous and confluent presentation, which is not *N-free*.

THEOREM 4.5. *If (Γ, R) is 2-homogeneous, confluent, and N-free, then the compressed word problem for $\mathcal{M}(\Gamma, R)$ is in P.*

In the next section we will see that Theorem 4.5 cannot be extended to non-*N-free* presentations unless $\text{P} = \text{NP}$.

The proof of Theorem 4.5 will be presented after introducing *composition systems* [23]—a generalization of SLPs. A composition system $G = (V, \Gamma, S, P)$ is defined analogously to an SLP, but in addition to productions of the form $A \rightarrow \alpha$ ($A \in V$, $\alpha \in (V \cup \Gamma)^*$) it may also contain productions of the form $A \rightarrow B[i, j]$ for $B \in V$ and $i, j \in \mathbb{N}$. For such a production we define $\text{eval}_G(A) = \text{eval}_G(B)[i, j]$; i.e., we select from $\text{eval}_G(B)$ the subword from position i to position j .² We also allow more general

²In [23], a slightly more restricted formalism, where only productions of the form $A \rightarrow B[j, \text{eval}_G(B)]C[1, i]$ are allowed, was introduced. But this definition is easily seen to be equivalent to our formalism.

rules, e.g., $A \rightarrow B[i, j]C[k, \ell]$; of course this does not lead to higher compression rates. As for SLPs we define $\text{eval}(G) = \text{eval}_G(S)$. The following result from [23] generalizes Lemma 3.3.

LEMMA 4.6 (see [23]). *For two given composition systems G_1 and G_2 , we can decide in polynomial time whether $\text{eval}(G_1) = \text{eval}(G_2)$.*

The following result was shown in [29, Ch. 8].

LEMMA 4.7 (see [29]). *A given composition system can be transformed in polynomial time into an SLP that generates the same word.*

Lemma 4.7 leads to an alternative proof of Lemma 4.6: transform the two given composition systems in polynomial time into equivalent SLPs and apply Lemma 3.3. Moreover, Lemma 4.7 implies that all statements from Lemma 3.2 also hold for composition systems.

LEMMA 4.8. *Assume that (Γ, R) is 2-homogeneous, confluent, and N -free. Then the following problem belongs to P :*

INPUT: *Composition systems G_1 and G_2 with $\text{eval}(G_1), \text{eval}(G_2) \in \text{IRR}(R)$, and $|\text{eval}(G_1)| = |\text{eval}(G_2)|$.*

QUESTION: *Does $\text{eval}(G_1)\text{eval}(G_2) \xrightarrow{*}_R \varepsilon$ hold?*

Proof. Let $\Gamma = \Sigma_\ell \uplus \Sigma_r \uplus \Delta$ be the partition resulting from Lemma 4.3 and $\bar{-} : \Delta \rightarrow \Delta$ be the corresponding involution on Δ . Note that $\text{eval}(G_1), \text{eval}(G_2) \in \text{IRR}(R)$ and $\text{eval}(G_1)\text{eval}(G_2) \xrightarrow{*}_R \varepsilon$ implies that $\text{eval}(G_1) \in (\Sigma_\ell \cup \Delta)^*$ and $\text{eval}(G_2) \subseteq (\Sigma_r \cup \Delta)^*$. Thus, we first check in polynomial time whether this is true; if not, we can reject. Next, from G_2 we can easily construct (by reversing productions) a composition system G'_2 with $\text{eval}(G'_2) = \text{eval}(G_2)^{\text{rev}}$. Since (Γ, R) is N -free, we can find partitions $\Sigma_\ell = \uplus_{i=1}^k \Sigma_{\ell,i}$ and $\Sigma_r = \uplus_{i=1}^k \Sigma_{r,i}$ such that

$$R = \{(a\bar{a}, \varepsilon) \mid a \in \Delta\} \cup \bigcup_{i=1}^k \{(ab, \varepsilon) \mid a \in \Sigma_{\ell,i}, b \in \Sigma_{r,i}\}.$$

Let us take new symbols a_1, \dots, a_k and define homomorphisms ρ_1 and ρ_2 by $\rho_1(a) = \rho_2(a) = a_i$ for all $a \in \Sigma_{\ell,i} \cup \Sigma_{r,i}$, $1 \leq i \leq k$, $\rho_1(a) = a$ for all $a \in \Delta$, and $\rho_2(a) = \bar{a}$ for all $a \in \Delta$. From G_1 and G'_2 we can construct in polynomial time composition systems H_1, H_2 such that $\text{eval}(H_1) = \rho_1(\text{eval}(G_1))$ and $\text{eval}(H_2) = \rho_2(\text{eval}(G'_2))$. By construction, we have $\text{eval}(G_1)\text{eval}(G_2) \xrightarrow{*}_R \varepsilon$ if and only if $\text{eval}(H_1) = \text{eval}(H_2)$. The latter identity can be verified in polynomial time by Lemma 4.6. \square

Proof of Theorem 4.5. Let (Γ, R) be a fixed 2-homogeneous, confluent, and N -free presentation. Given SLPs G_1 and G_2 over the terminal alphabet Γ , we have to verify in polynomial time whether $\text{NF}_R(\text{eval}(G_1)) = \text{NF}_R(\text{eval}(G_2))$. By Lemma 4.6, it suffices to prove that given an SLP G in Chomsky normal form over the terminal alphabet Γ , we can construct in polynomial time a composition system H such that $\text{eval}(H) = \text{NF}_R(\text{eval}(G))$. We construct H inductively by adding more and more rules. Initially, we put into $P(H)$ all productions from $P(G)$ of the form $A \rightarrow a$ with $a \in \Gamma$. Now assume that $A \rightarrow BC$ belongs to $P(G)$ and that H already contains enough productions such that $\text{eval}_H(B) = \text{NF}_R(\text{eval}_G(B))$ and $\text{eval}_H(C) = \text{NF}_R(\text{eval}_G(C))$. We first calculate the largest i such that

$$(4.1) \quad \text{eval}_H(B) = u_1v_2, \quad \text{eval}_H(C) = v_1v_2, \quad |u_2| = |v_1| = i, \quad u_2v_1 \xrightarrow{*}_R \varepsilon.$$

Lemma 4.2 implies that $\text{NF}_R(\text{eval}_G(A)) = u_1v_2$. For a given $i \in \mathbb{N}$, we can check condition (4.1) in polynomial time by Lemma 4.8. Since i is bounded exponentially

in the input size, the largest i satisfying (4.1) can be calculated in polynomial time by doing a binary search. For this largest i we add to the current H the production $A \rightarrow B[1, |\text{eval}_H(B)| - i]C[i + 1, |\text{eval}_H(C)|]$. This concludes the proof of Theorem 4.5. \square

For a finite alphabet Γ , the *free group* $F(\Gamma)$ generated by Γ is defined as

$$(4.2) \quad F(\Gamma) = \mathcal{M}(\Gamma \cup \bar{\Gamma}, \{(c\bar{c}, \varepsilon) \mid c \in \Gamma \cup \bar{\Gamma}\}).$$

Recall from section 3.1 that we define an involution on $\Gamma \cup \bar{\Gamma}$ by setting $\bar{\bar{a}} = a$. Clearly, $F(\Gamma)$ is indeed a group. In case $|\Gamma| = n$ we also write F_n instead of $F(\Gamma)$ and call it the *free group of rank n* . It is known that the (uncompressed) word problem for a free group is in logspace [40]. Moreover, the word problem for F_2 is hard for uniform NC¹ [57]. By Theorem 4.5, the compressed word problem for every free group F_n is in P (we have $\Sigma_\ell = \Sigma_r = \emptyset$ for the presentation in (4.2)). This upper bound is also sharp.

THEOREM 4.9. *The compressed word problem for F_2 is P-complete.*

Proof. It suffices to prove P-hardness, which will be done by a reduction from the monotone circuit value problem, i.e., the problem of whether a Boolean circuit consisting of AND and OR gates evaluates to TRUE [25]. We will use the following result, which is proved in [57]: Let $\Gamma = \{a, b\}$ and $x, y \in (\Gamma \cup \bar{\Gamma})^*$ such that $|x| = |y| = k$ and $|x|_a - |x|_{\bar{a}} = |y|_a - |y|_{\bar{a}} = 0$. Then, if we interpret x and y as elements from F_2 , the following holds, where 1 denotes the neutral element of F_2 :

$$\begin{aligned} (x = 1) \vee (y = 1) &\Leftrightarrow \bar{a}^{3k} x a^{3k} y \bar{a}^{3k} \bar{x} a^{3k} \bar{y} = 1, \\ (x = 1) \wedge (y = 1) &\Leftrightarrow \bar{a}^{3k} x a^{3k} y \bar{a}^{3k} x a^{3k} y = 1. \end{aligned}$$

Note that the words on the right of these equivalences have length $16k$ and that the number of a 's minus the number of \bar{a} 's is again 0.

Now let C be a monotone Boolean circuit. Without loss of generality we can assume that C is layered; i.e., the gates of C are partitioned into n layers and a gate in layer $i > 1$ receives its inputs from layer $i - 1$; see, e.g., [28, Problem A.1.6]. Layer 1 contains the input gates and layer n contains the unique output gate. We now construct an SLP $G(C)$ as follows. For every gate z of C , G contains two nonterminals A_z and $A_{\bar{z}}$. The nonterminal A_z will evaluate to a string that represents the 1 of F_2 if and only if gate z of the circuit evaluates to TRUE. The nonterminal $A_{\bar{z}}$ evaluates to the inverse of $\text{eval}_{G(C)}(A_z)$ in F_2 . Moreover, we will have $|\text{eval}_{G(C)}(A_z)| = |\text{eval}_{G(C)}(A_{\bar{z}})| = 2 \cdot 16^{i-1}$ if z is located in the i th layer of the circuit ($1 \leq i \leq n$).

For every input gate x in layer 1 we introduce the productions

$$\begin{aligned} A_x &\rightarrow \begin{cases} a\bar{a} & \text{if input gate } x \text{ is TRUE,} \\ b^2 & \text{if input gate } x \text{ is FALSE,} \end{cases} \\ A_{\bar{x}} &\rightarrow \begin{cases} a\bar{a} & \text{if input gate } x \text{ is TRUE,} \\ \bar{b}^2 & \text{if input gate } x \text{ is FALSE.} \end{cases} \end{aligned}$$

If z is an OR gate in the i th layer ($i \geq 2$) with input gates x and y from the $(i - 1)$ th layer, then the productions for A_z and $A_{\bar{z}}$ are

$$\begin{aligned} A_z &\rightarrow \bar{a}^{6 \cdot 16^{i-2}} A_x a^{6 \cdot 16^{i-2}} A_y \bar{a}^{6 \cdot 16^{i-2}} A_{\bar{x}} a^{6 \cdot 16^{i-2}} A_{\bar{y}} \text{ and} \\ A_{\bar{z}} &\rightarrow A_y \bar{a}^{6 \cdot 16^{i-2}} A_x a^{6 \cdot 16^{i-2}} A_{\bar{y}} \bar{a}^{6 \cdot 16^{i-2}} A_{\bar{x}} a^{6 \cdot 16^{i-2}}. \end{aligned}$$

Note that the binary codings of the exponents $6 \cdot 16^{i-2}$ have polynomial length, and hence each of the above productions can be replaced by a sequence of ordinary productions. Moreover, if $|\text{eval}(A_u)| = 2 \cdot 16^{i-2}$ for $u \in \{x, \bar{x}, y, \bar{y}\}$ (which is true if x

and y are located in the first layer, i.e., $i = 2$), then $|\text{eval}(A_z)| = |\text{eval}(A_{\bar{z}})| = 2 \cdot 16^{i-1}$. If z is an AND gate in the i th layer ($i \geq 2$) with input gates x and y , then the productions for A_z and $A_{\bar{z}}$ are

$$A_z \rightarrow \bar{a}^{6 \cdot 16^{i-2}} A_x a^{6 \cdot 16^{i-2}} A_y \bar{a}^{6 \cdot 16^{i-2}} A_x a^{6 \cdot 16^{i-2}} A_y \text{ and}$$

$$A_{\bar{z}} \rightarrow A_y \bar{a}^{6 \cdot 16^{i-2}} A_{\bar{x}} a^{6 \cdot 16^{i-2}} A_{\bar{y}} \bar{a}^{6 \cdot 16^{i-2}} A_{\bar{x}} a^{6 \cdot 16^{i-2}}.$$

Once again, these productions can be replaced by a sequence of ordinary productions. Let o be the unique output gate of the circuit C . Then, by the result from [57], the circuit C evaluates to TRUE if and only if $\text{eval}_{G(C)}(A_o) = 1$ in F_2 . \square

5. Compressed word problems between P and PSPACE. In this section we will consider 2-homogeneous and confluent presentations that are not necessarily N -free. Recall that P^{NP} is the class of all languages that can be accepted by a deterministic polynomial time machine that has additional access to an NP-oracle [64]. P^{NP} is also denoted by Δ_2^P in the literature; it is contained in the second level of the polynomial time hierarchy and hence in PSPACE. Several complete problems for P^{NP} can be found in [34].

THEOREM 5.1. *If (Γ, R) is 2-homogeneous and confluent (but not necessarily N -free), then the compressed word problem for $\mathcal{M}(\Gamma, R)$ is in P^{NP} .*

Proof. The key observation is that for a 2-homogeneous and confluent (but not necessarily N -free) presentation (Γ, R) the problem from Lemma 4.8 is in coNP ; i.e., the complementary condition is in NP: If $\text{eval}(G_1), \text{eval}(G_2) \in \text{IRR}(R)$ and $|\text{eval}(G_1)| = |\text{eval}(G_2)|$, then

$$\text{eval}(G_1)\text{eval}(G_2) \xrightarrow{*}_R \varepsilon \text{ does not hold}$$

if and only if there exists $1 \leq i \leq |\text{eval}(G_1)|$ with

$$\text{eval}(G_1)[i] \text{eval}(G_2)[|\text{eval}(G_2)| - i + 1] \notin \text{dom}(R).$$

For a given i , the latter condition can be checked in polynomial time. Now the decision procedure from the proof of Theorem 4.5 in section 4 gives us a P^{coNP} -, i.e., P^{NP} -,algorithm in the present situation. \square

By the next result, coNP -hardness can be obtained for every 2-homogeneous presentations that is not N -free.

THEOREM 5.2. *Let $\Gamma = \{a, b, c, d\}$ and $R = \{(ac, \varepsilon), (ad, \varepsilon), (bc, \varepsilon)\}$. The compressed word problem for $\mathcal{M}(\Gamma, R)$ is coNP -hard.*

Proof. The following problem is the complementary problem to SUBSETSUM [22, Problem SP13], and hence is coNP -complete:

INPUT: Binary coded integers $w_1, \dots, w_n, t \geq 0$.

QUESTION: For all $x_1, \dots, x_n \in \{0, 1\}$, does $\sum_{i=1}^n x_i \cdot w_i \neq t$ hold?

Let us fix binary coded integers $w_1, \dots, w_n, t \geq 0$. Let $\bar{w}_k = (w_1, \dots, w_k)$, and $\bar{w} = \bar{w}_n$. Let $\bar{1}_k = (1, \dots, 1)$ be the k -dimensional vector with all entries equal to 1. For vectors $\bar{x} = (x_1, \dots, x_m)$ and $\bar{y} = (y_1, \dots, y_m)$ we define $\bar{x} \cdot \bar{y} = x_1 y_1 + \dots + x_m y_m$. Finally, let $s_k = \bar{1}_k \cdot \bar{w}_k = w_1 + \dots + w_k$, and $s = s_n = w_1 + \dots + w_n$.

We construct two SLPs G_1 and G_2 over the terminal alphabets $\{a, b\}$ and $\{c, d\}$, respectively, such that $\text{eval}(G_1)\text{eval}(G_2) \xrightarrow{*}_R \varepsilon$ (i.e., $\text{eval}(G_1)\text{eval}(G_2) \xleftrightarrow{*}_R \varepsilon$ since R

is confluent and hence Church–Rosser) if and only if $\bar{x} \cdot \bar{w} \neq t$ for all $\bar{x} \in \{0, 1\}^n$. This will prove the theorem. First, let us construct G_1 :

$$\begin{aligned} S_1 &\rightarrow ba^{s+w_1}b, \\ S_{k+1} &\rightarrow S_k a^{s-s_k+w_{k+1}}S_k. \end{aligned}$$

Let S_n be the start nonterminal of G_1 .

*Claim.*³

$$\text{eval}_{G_1}(S_k) = \left(\prod_{\bar{x} \in \{0,1\}^k \setminus \{\bar{1}_k\}} a^{\bar{x} \cdot \bar{w}_k} b a^{s - \bar{x} \cdot \bar{w}_k} \right) a^{s_k} b.$$

We prove the claim by induction on k . The case $k = 1$ is clear, since $\text{eval}_{G_1}(S_1) = ba^{s+w_1}b = ba^s a^{s_1} b = a^0 b a^{s-0} a^{s_1} b$. For $k + 1 \leq n$ we obtain the following:

$$\begin{aligned} &\left(\prod_{\bar{x} \in \{0,1\}^{k+1} \setminus \{\bar{1}_{k+1}\}} a^{\bar{x} \cdot \bar{w}_{k+1}} b a^{s - \bar{x} \cdot \bar{w}_{k+1}} \right) a^{s_{k+1}} b \\ &= \underbrace{\left(\prod_{\bar{x} \in \{0,1\}^k} a^{\bar{x} \cdot \bar{w}_k} b a^{s - \bar{x} \cdot \bar{w}_k} \right)}_{\text{eval}(S_k) a^{s-s_k}} \underbrace{\left(\prod_{\bar{x} \in \{0,1\}^k \setminus \{\bar{1}_k\}} a^{\bar{x} \cdot \bar{w}_k + w_{k+1}} b a^{s - \bar{x} \cdot \bar{w}_k - w_{k+1}} \right)}_{a^{w_{k+1}} \text{eval}(S_k)} a^{w_{k+1}} a^{s_k} b \\ &= \text{eval}_{G_1}(S_k) a^{s-s_k+w_{k+1}} \text{eval}_{G_1}(S_k) = \text{eval}_{G_1}(S_{k+1}), \end{aligned}$$

which proves the claim.

For $k = n$ we get

$$\text{eval}(G_1) = \text{eval}_{G_1}(S_n) = \prod_{\bar{x} \in \{0,1\}^n} a^{\bar{x} \cdot \bar{w}} b a^{s - \bar{x} \cdot \bar{w}}.$$

Now let G_2 be an SLP such that $\text{eval}(G_2) = (c^{s-t} d c^t)^{2^n}$, which is easy to construct. Let us give an example before we continue with the proof.

Example 5.3. Assume that $w_1 = 2$, $w_2 = 5$, $w_3 = 8$, and $t = 9$. Thus, $s = 2 + 5 + 8 = 15$ and

$$\begin{aligned} \text{eval}(G_1) &= ba^{15} a^2 b a^{13} a^5 b a^{10} a^7 b a^8 a^8 b a^7 a^{10} b a^5 a^{13} b a^2 a^{15} b \\ &= ba^{17} b a^{18} b a^{17} b a^{16} b a^{17} b a^{18} b a^{17} b \\ \text{eval}(G_2) &= (c^6 d c^9)^8 = c^6 d c^{15} d c^{15} d c^{15} d c^{15} d c^{15} d c^{15} d c^9. \end{aligned}$$

For this example, we have $\text{eval}(G_1) \text{eval}(G_2) \xrightarrow{*}_R \varepsilon$, because, while reducing the word $\text{eval}(G_1) \text{eval}(G_2)$, in the middle of the current word the factor bd (which cannot be replaced by ε) will never occur.

Note that $\text{eval}(G_1) \in \{a, b\}^*$, $\text{eval}(G_2) \in \{c, d\}^*$, and $|\text{eval}(G_1)| = |\text{eval}(G_2)| = 2^n \cdot (s + 1)$. Thus, since bd is the only factor from $\{ac, ad, bc, bd\}$ that cannot be

³The \prod -expression on the right-hand side of this production denotes the concatenation of the corresponding words, where the order of concatenation is given by the lexicographic order on the set of vectors $\{0, 1\}^k$, where the last position has the highest significance.

rewritten to ε , we have $\text{eval}(G_1)\text{eval}(G_2) \xrightarrow{*}_R \varepsilon$ if and only if a b does not meet a d in the unique R -derivation that starts from $\text{eval}(G_1)\text{eval}(G_2)$. Hence, by construction of G_1 and G_2 , we have $\text{eval}(G_1)\text{eval}(G_2) \xrightarrow{*}_R \varepsilon$ if and only if $\bar{x} \cdot \bar{w} \neq t$ for all $\bar{x} \in \{0, 1\}^n$. This concludes the proof. \square

The precise complexity of the compressed word problem for a 2-homogeneous but not N -free presentation remains open; it is located somewhere between coNP and P^{NP} . On the other hand, by the previous proof, it is already coNP -hard to decide whether $\text{eval}(G) \xleftrightarrow{*}_R \varepsilon$ for a given SLP G , in case R is 2-homogeneous and confluent but not N -free. For this restricted variant of the compressed word problem we can also prove an upper bound of coNP .

THEOREM 5.4. *For every 2-homogeneous and confluent (but not necessarily N -free) presentation (Γ, R) , the following problem belongs to coNP :*

INPUT: An SLP over the terminal alphabet Γ .

QUESTION: Does $\text{eval}(G) \xleftrightarrow{}_R \varepsilon$ (i.e., $\text{eval}(G) \xrightarrow{*}_R \varepsilon$) hold?*

For the proof of Theorem 5.4 we first introduce some notation.

Let us fix a 2-homogeneous and confluent (but not necessarily N -free) presentation (Γ, R) for the rest of this section. Recall that by Lemma 4.3, there exist a partition $\Gamma = \Sigma_\ell \uplus \Sigma_r \uplus \Delta$ and an involution $\bar{\cdot} : \Delta \rightarrow \Delta$ such that $\{(a\bar{a}, \varepsilon) \mid a \in \Delta\} \subseteq R \subseteq \{(a\bar{a}, \varepsilon) \mid a \in \Delta\} \cup \{(ab, \varepsilon) \mid a \in \Sigma_\ell, b \in \Sigma_r\}$. Let $S = \{(a\bar{a}, \varepsilon) \mid a \in \Delta\} \subseteq R$, which is also 2-homogeneous and confluent but in addition N -free. Thus, by Theorem 4.5, the compressed membership problem for the language $\{w \in \Delta^* \mid w \xrightarrow{*}_S \varepsilon\}$ can be solved in polynomial time.

Let us take two bracket symbols “ \langle ” and “ \rangle ” and define the morphism $\rho : \Gamma^* \rightarrow \{\langle, \rangle\}^*$ by $\rho(a) = \langle$ for $a \in \Sigma_\ell$, $\rho(b) = \rangle$ for $b \in \Sigma_r$ and $\rho(c) = \varepsilon$ for $c \in \Delta$. Let D_1 be the set of all well-bracketed words over $\{\langle, \rangle\}$; i.e., D_1 is the Dyck language over one bracket pair. If P is the semi-Thue system that contains the single rule $\langle \rangle \rightarrow \varepsilon$, then $D_1 = \{w \in \{\langle, \rangle\}^* \mid w \xrightarrow{*}_P \varepsilon\}$. Since P is 2-homogeneous, confluent, and N -free, Theorem 4.5 implies that the compressed membership problem for D_1 can be solved in polynomial time.

Now assume that $w \in \Gamma^*$ is a word such that $\rho(w) \in D_1$. We say that two positions $i, j \in \{1, \dots, |w|\}$ are *corresponding brackets*, briefly $\text{match}(i) = j$, if $w[i] \in \Sigma_\ell$, $w[j] \in \Sigma_r$, $i < j$, $\rho(w[i, j]) \in D_1$, and $\rho(w[i, k]) \notin D_1$ for all k with $i < k < j$.

Example 5.5. Let $\Gamma = \{a, b, c, d, x, y, \bar{x}, \bar{y}\}$ and

$$R = \{(ac, \varepsilon), (ad, \varepsilon), (bc, \varepsilon), (x\bar{x}, \varepsilon), (\bar{x}x, \varepsilon), (y\bar{y}, \varepsilon), (\bar{y}y, \varepsilon)\}.$$

Thus, $\Delta = \{x, y, \bar{x}, \bar{y}\}$, $\Sigma_\ell = \{a, b\}$, and $\Sigma_r = \{c, d\}$. Consider the word $w = x a \bar{y} y c y \bar{x} b a x \bar{x} d x c \bar{y} \bar{x}$. Then $\rho(w) = \langle \rangle \langle \langle \rangle \rangle \in D_1$ and, for instance, $\text{match}(8) = 14$.

LEMMA 5.6. *The following problem can be solved in polynomial time:*

INPUT: An SLP G over the terminal alphabet Γ such that $\rho(\text{eval}(G)) \in D_1$ and a position $1 \leq i \leq |\text{eval}(G)|$ such that $\text{eval}(G)[i] \in \Sigma_\ell$.

OUTPUT: The unique position $j = \text{match}(i)$ in $\text{eval}(G)$.

Proof. In a first step we will reduce the problem to the alphabet $\{\langle, \rangle\}$. Let $1 \leq i \leq |\text{eval}(G)|$ such that $\text{eval}(G)[i] \in \Sigma_\ell$. First, we calculate in polynomial time the unique number k such that i is the position of the k th symbol from $\Sigma_\ell \cup \Sigma_r$ in $\text{eval}(G)$. Formally, $k = |\pi_{\Sigma_\ell \cup \Sigma_r}(\text{eval}(G)[1, i])|$ (by Lemma 4.7 we can calculate in polynomial time an SLP H that generates $\text{eval}(G)[1, i]$; then $|\pi_{\Sigma_\ell \cup \Sigma_r}(\text{eval}(H))|$ can be calculated in polynomial time using Lemma 3.2). Now assume for a moment that we can calculate the position ℓ of the bracket “ \rangle ” that corresponds to the bracket “ \langle ” at position k in $\rho(\text{eval}(G))$ —we also call this position $\text{match}(k)$. Then we just calculate

FIG. 5.1.

the position j of the ℓ th symbol from $\Sigma_\ell \cup \Sigma_r$ in $\text{eval}(G)$ and have $\text{match}(i) = j$ in $\text{eval}(G)$. Formally, j is the unique number with $\ell = |\pi_{\Sigma_\ell \cup \Sigma_r}(\text{eval}(G)[1, j])|$ and $\text{eval}(G)[j] \in \Sigma_\ell \cup \Sigma_r$. In order to calculate j from ℓ in polynomial time, we calculate bottom-up $|\pi_{\Sigma_\ell \cup \Sigma_r}(\text{eval}_G(A))|$ as well as $|\text{eval}_G(A)|$ for every nonterminal A of the SLP G . Then we can walk top-down in G in order to calculate j from ℓ .

Thus, we may assume that G is an SLP with $\text{eval}(G) \in D_1$ and $1 \leq i \leq |\text{eval}(G)|$ is a position with $\text{eval}(G)[i] = \langle$. We compute in polynomial time the unique matching position $\text{match}(i)$ in $\text{eval}(G)$. Consider the language

$$K = \text{Pref}(D_1) \setminus [(D_1 \setminus \{\varepsilon\}) \cdot \text{Pref}(D_1)];$$

i.e., K is the set of all prefixes of words from D_1 that do not contain a nonempty prefix from D_1 . Then

$$\text{match}(i) = \max\{j > i \mid \text{eval}(G)[i, j] \in K\} + 1.$$

Since K is prefix-closed, it suffices to show that the compressed membership problem for the language K is solvable in polynomial time, because then we can find the largest $j > i$ with $\text{eval}(G)[i, j] \in K$ using a binary search.

Thus, let H be an SLP in Chomsky normal form. We want to check whether $\text{eval}(H) \in K = \text{Pref}(D_1) \setminus [(D_1 \setminus \{\varepsilon\}) \cdot \text{Pref}(D_1)]$. Recall that the semi-Thue system P consists of the single rule $\langle \rangle \rightarrow \varepsilon$. Clearly, for a word $w \in \{\langle, \rangle\}^*$, we have $\text{NF}_P(w) \in \rangle^* \langle^*$. We represent a word $\rangle^n \langle^m$ by the binary coding of n and m . Using this representation, we can calculate bottom-up in polynomial time for every nonterminal A of H the normal form $\text{NF}_P(\text{eval}_H(A)) \in \rangle^* \langle^*$. Clearly, for every word $w \in \{\langle, \rangle\}^*$, $w \in \text{Pref}(D_1)$ if and only if $\text{NF}_P(w) \in \langle^*$. Using this, we can first check whether $\text{eval}(H) = \text{eval}_H(S) \in \text{Pref}(D_1)$. If this is not the case, we reject. Thus, assume that $\text{eval}(H) \in \text{Pref}(D_1)$. We have to check in polynomial time whether or not $\text{eval}(H) \in (D_1 \setminus \{\varepsilon\}) \cdot \text{Pref}(D_1)$.

Consider the unique path of nonterminals $S = A_0, A_1, \dots, A_m$ such that $A_m \rightarrow \langle$ and for all $i \leq 0 < m$, $A_i \rightarrow A_{i+1}B_{i+1}$ are productions of H . This path is shown in Figure 5.1 (left) for $m = 4$. Since every prefix of $\text{eval}(H)$ also belongs to $\text{Pref}(D_1)$, we have $\text{NF}_P(\text{eval}_H(A_i)) = \langle^{k_i}$ for some numbers $k_i \geq 0$. Assume that $\text{NF}_P(\text{eval}_H(B_i)) = \rangle^{m_i} \langle^{n_i}$ for $m_i, n_i \geq 0$; see the right tree in Figure 5.1. We claim that $\text{eval}(H) \in (D_1 \setminus \{\varepsilon\}) \cdot \text{Pref}(D_1)$ if and only if there exists $1 \leq i \leq m$ such that $k_i \leq m_i$, which can be checked in polynomial time. If $k_i \leq m_i$ for some $1 \leq i \leq m$, i.e., $\text{NF}_P(\text{eval}_H(B_i)) = \rangle^{k_i} \langle^\ell \langle^{n_i}$ for some ℓ , then there exists a prefix u of $\text{eval}_H(B_i)$ such that $\text{NF}_P(u) = \rangle^{k_i}$ and thus $\text{eval}_H(A_i)u \in D_1$ (we may have $u = \varepsilon$ in case $k_i = 0$, i.e.,

$\text{eval}_H(A_i) \in D_1$). The word $\text{eval}_H(A_i)u$ is a nonempty prefix of $\text{eval}(H)$ that belongs to D_1 . On the other hand, if there exists a nonempty prefix $v \in D_1$ of $\text{eval}(H)$, then let i be maximal such that v is a prefix of $\text{eval}_H(A_i)$. Clearly, $i < m$, since $\text{eval}_H(A_m) = \langle$. Thus, $v = \text{eval}_H(A_{i+1})u$ for some prefix u of $\text{eval}_H(B_{i+1})$. Since $\text{NF}_P(\text{eval}_H(A_{i+1})) = \langle^{k_{i+1}}$ and $\text{eval}_H(A_{i+1})u \in D_1$, it follows that $\text{NF}_P(u) = \rangle^{k_{i+1}}$. Since $\text{NF}_P(\text{eval}_H(B_{i+1})) = \rangle^{m_{i+1}}\langle^{n_{i+1}}$ and u is a prefix of $\text{eval}_H(B_{i+1})$, we obtain $m_{i+1} \geq k_{i+1}$. This proves the lemma. \square

Let us again take a word $w \in \Gamma^*$ such that $\rho(w) \in D_1$. Then we can factorize w uniquely as $w = s_0 w[i_1, j_1] s_1 \cdots w[i_n, j_n] s_n$, where $n \geq 0$, $\text{match}(i_k) = j_k$ for all $k \in \{1, \dots, n\}$, and $s_k \in \Delta^*$ for all $k \in \{0, \dots, n\}$. We define $\mathcal{F}(w) = s_0 s_1 \cdots s_n \in \Delta^*$.

Example 5.7. Take Γ, R , and the word $w \in \Gamma^*$ from Example 5.5. Then we have $\mathcal{F}(w) = x y \bar{x} \bar{y} \bar{x}$.

LEMMA 5.8. *The following problem can be solved in polynomial time:*

INPUT: An SLP G over the terminal alphabet Γ such that $\rho(\text{eval}(G)) \in D_1$ and two positions i and j such that $\text{match}(i) = j$ in $\text{eval}(G)$.

OUTPUT: An SLP that generates $\mathcal{F}(\text{eval}(G)[i + 1, j - 1])$.

Proof. Let $\Theta = \Delta \cup \{\langle, \rangle\}$ and consider the infinite semi-Thue system

$$T = \{\langle w \rangle \rightarrow \varepsilon \mid w \in \Delta^*\}$$

over the alphabet Θ . This system is clearly terminating and confluent (T has no overlapping left-hand sides); hence every word $w \in \Theta^*$ has a unique normal form $\text{NF}_T(w)$. Note that $\text{IRR}(T) = (\Delta^*)\Delta^*(\Delta^*\langle\Delta^*)^*$. Let $\mu : \Gamma \rightarrow \Theta$ be the morphism with $\mu(a) = \langle$ for all $a \in \Sigma_\ell$, $\mu(a) = \rangle$ for all $a \in \Sigma_r$, and $\mu(a) = a$ for all $a \in \Delta$.

In a first step we construct in polynomial time an SLP G' such that $\text{eval}(G') = \mu(\text{eval}(G)[i + 1, j - 1])$. Then $\text{NF}_T(\text{eval}(G')) = \mathcal{F}(\text{eval}(G)[i + 1, j - 1])$. Hence, it suffices to calculate a composition system H that generates $\text{NF}_T(\text{eval}(G))$ for a given SLP G with $\text{eval}(G) \in \Theta^*$; this composition system can be transformed in polynomial time into an equivalent SLP by Lemma 4.7. We construct H analogously to the proof of Theorem 4.5. Assume that $A \rightarrow BC$ is a production from G and assume that H already contains enough rules such that $\text{eval}_H(X) = \text{NF}_T(\text{eval}_G(X)) =: w_X \in (\Delta^*)\Delta^*(\Delta^*\langle\Delta^*)^*$ for $X \in \{B, C\}$. We then calculate the numbers $n_B = |w_B|_\langle$ and $n_C = |w_C|_\rangle$, i.e., the number of opening (closing) brackets in w_B (w_C). Assume that $n_C \geq n_B$; the other case is analogous. Then we calculate the position i_B of the n_B th opening bracket \langle in w_B as well as the position i_C of the n_C th closing bracket \rangle in w_C . It follows that $\text{NF}_T(\text{eval}_G(A)) = w_B[1, i_B - 1]w_C[i_C + 1, |w_C|]$. Thus, we add to the current H the production $A \rightarrow B[1, i_B - 1]C[i_C + 1, |w_C|]$. \square

Proof of Theorem 5.4. We use all notation from the previous discussion. The following statement was shown in [42]: For $w \in \Gamma^*$ it holds that $w \stackrel{*}{\leftrightarrow}_R \varepsilon$ if and only if $\rho(w) \in D_1$, $\mathcal{F}(w) \stackrel{*}{\rightarrow}_S \varepsilon$, and for all $i, j \in \{1, \dots, |w|\}$ with $\text{match}(i) = j$ it holds that $w[i]w[j] \in \text{dom}(R)$ and $\mathcal{F}(w[i + 1, j - 1]) \stackrel{*}{\rightarrow}_S \varepsilon$.

This leads to the following NP-algorithm for testing $\text{eval}(G) \stackrel{*}{\leftrightarrow}_R \varepsilon$ for a given SLP G , and hence to a coNP-algorithm for testing $\text{eval}(G) \stackrel{*}{\leftrightarrow}_R \varepsilon$:

1. Produce an SLP G' such that $\text{eval}(G') = \rho(\text{eval}(G))$ and check whether $\text{eval}(G') \in D_1$. This is possible in polynomial time by Theorem 4.5. If $\text{eval}(G') \notin D_1$, then accept; otherwise continue.
2. Guess a position $1 \leq i \leq |\text{eval}(G)|$ (this is the only nondeterministic step) such that $\text{eval}(G)[i] \in \Sigma_\ell$, calculate in polynomial time (by Lemma 5.6) the unique position $j = \text{match}(i)$ in $\text{eval}(G)$, and check whether $\text{eval}(G)[i]\text{eval}(G)[j] \notin \text{dom}(R)$. If this is true, then accept; otherwise continue.

3. Calculate in polynomial time (by Lemma 5.8) an SLP G'' that generates $\mathcal{F}(\text{eval}(G)[i+1, j-1])$ and test in polynomial time (by Theorem 4.5) whether $\text{eval}(G'') \xrightarrow{*}_S \varepsilon$. If this is true, then accept; otherwise reject.

This concludes the proof of Theorem 5.4. \square

From Theorems 4.5, 5.2, and 5.4 we obtain the following corollary.

COROLLARY 5.9. *Let (Γ, R) be a 2-homogeneous and confluent presentation.*

Consider the following computational problem:

INPUT: A word $s \in \Gamma^$.*

QUESTION: Does $w \xrightarrow{}_R \varepsilon$ hold?*

If (Γ, R) is N -free, then this problem can be solved in polynomial time; otherwise this problem is coNP-complete.

6. Compressed word problems in PSPACE. In the previous two sections we have investigated 2-homogeneous systems, where every rule is of the form $ab \rightarrow \varepsilon$. In this section we consider a slightly more general class of presentations, where we also allow rules of the form $ab \rightarrow c$. We show that this generalization leads to PSPACE-complete compressed word problems. As a corollary we obtain a fixed deterministic context-free language with a PSPACE-complete compressed word problem, which solves an open problem from [23, 55].

Our PSPACE upper bounds rely all on the following simple fact.

PROPOSITION 6.1. *If the membership problem for the language L (the word problem for a finitely presented monoid \mathcal{M}) belongs to $\bigcup_{c>0} \text{NSPACE}(\log^c(n))$, then the compressed membership problem for L (the compressed word problem for \mathcal{M}) belongs to PSPACE.*

Proof. Assume that the language L belongs to $\text{NSPACE}(\log^c(n))$. Let us fix an SLP G . We decide $\text{eval}(G) \in L$ by simulating the $\text{NSPACE}(\log^c(n))$ algorithm for the membership problem for L on words of length $|\text{eval}(G)|$. Note that a number less than $|\text{eval}(G)|$ can be stored in polynomial space and that for a given position $i \in \{1, \dots, |\text{eval}(G)|\}$ we can calculate $\text{eval}(G)[i]$ in polynomial time. Thus, the simulation gives us a PSPACE-algorithm for the compressed membership problem for L . \square

A presentation (Γ, R) is *weight-reducing* if there exists a weight-function $f : \Gamma^* \rightarrow \mathbb{N}$ such that $f(s) > f(t)$ for all $(s, t) \in R$. Typical examples of weight-reducing presentations are *length-reducing presentations* (i.e., $|s| > |t|$ for all $(s, t) \in R$).

PROPOSITION 6.2. *For every weight-reducing and confluent presentation (Γ, R) , the compressed word problem for $\mathcal{M}(\Gamma, R)$ is in PSPACE.*

Proof. In [41] we have shown that for every fixed weight-reducing and confluent presentation (Γ, R) , the (uncompressed) word problem for $\mathcal{M}(\Gamma, R)$ is in LOGCFL, which is the logspace closure of the class of context-free languages [65]. The class LOGCFL is known to be contained in $\text{NSPACE}(\log^2(n))$ [39]. Thus, membership in PSPACE follows from Proposition 6.1. \square

In the rest of this section, we will show that PSPACE-hardness can be shown already for a quite small subclass of weight-reducing and confluent presentations.

A presentation (Γ, R) is called *monadic* if, for every $(\ell, r) \in R$, $|\ell| > |r|$ and $|r| \leq 1$. A *2-monadic* presentation is a monadic presentation (Γ, R) such that, moreover, $|\ell| = 2$ for every $\ell \in \text{dom}(R)$. In the following, we present a construction that reduces the reachability problem for directed forests to the (uncompressed) word problem of a fixed 2-monadic and confluent presentation (Γ, R) . Later in this section, we will use this construction in order to prove that the compressed word problem for $\mathcal{M}(\Gamma, R)$ is PSPACE-complete.

Let $\Gamma = \{b_0, b_1, c_0, c_1, c_2, \#, \$, \triangleright, 0\}$ and let R be the 2-monadic semi-Thue system consisting of the following rules:

(1) $b_0x \rightarrow \varepsilon$ for all $x \in \{\$, c_0, c_1, c_2\}$	(2) $b_1c_0 \rightarrow \varepsilon$
(3) $b_1\$ \rightarrow \triangleright$	(4) $\triangleright c_i \rightarrow \triangleright$ for all $i \in \{0, 1, 2\}$
(5) $\triangleright\$ \rightarrow \$$	(6) $\#\$ \rightarrow \varepsilon$
(7) $b_1c_2 \rightarrow 0$	
(8) $0x \rightarrow 0$ for all $x \in \Gamma$	(9) $x0 \rightarrow 0$ for all $x \in \Gamma$

Only the rules involving the absorbing symbol 0 produce overlappings. In the resulting critical pairs, both words can be reduced to 0. Thus, R is confluent.

A *directed forest* is a directed acyclic graph (V, E) (where V is the finite set of nodes and $E \subseteq V \times V$ is the edge relation) such that, moreover, for every $u \in V$, $|\{v \in V \mid (u, v) \in E\}| \leq 1$; i.e., every node has at most one outgoing edge. Assume now that (V, E) is a directed forest, where $V = \{v_1, \dots, v_n\}$ and $(v_i, v_j) \in E$ implies $i < j$. Let $v_\alpha \in V$ be a distinguished start node ($1 \leq \alpha \leq n$) and $U \subseteq V$ be a set of final nodes such that every node in U has outdegree 0 (there may be also nodes in $V \setminus U$ without outgoing edges). For $i \leq j$ we define the interval $I_{i,j} = \{v_k \mid i \leq k \leq j\}$. Thus, $I_{1,n} = V$. If $i > j$, we set $I_{i,j} = \emptyset$. We will construct a word $w(v_\alpha, U) \in \Gamma^*$ such that $(v_\alpha, v_i) \in E^*$ for some $v_i \in U$ (i.e., there is a path from the start node to some final node) if and only if $w(v_\alpha, U) \xrightarrow{*}_R 0$, i.e., $w(v_\alpha, U) \xrightarrow{*}_R 0$. For every $i \in \{1, \dots, n\}$ define the word δ_i as follows:

$$\delta_i = \begin{cases} c_0^{n-j+i+1} & \text{if } (v_i, v_j) \text{ is the unique outgoing edge at node } v_i, \\ c_1 & \text{if } v_i \in V \setminus U \text{ and } v_i \text{ has no outgoing edge,} \\ c_2 & \text{if } v_i \in U \text{ (and thus has no outgoing edge).} \end{cases}$$

Note that $\triangleright \delta_i \xrightarrow{*}_R \triangleright$ for all $1 \leq i \leq n$ using the rules in (4). For an interval $I_{i,j}$ ($i \leq j$) we define $\sigma[I_{i,j}] = \delta_i \$ \delta_{i+1} \$ \dots \delta_j \$$. We set $\sigma[\emptyset] = \varepsilon$. Note that $\triangleright \sigma[I_{i,j}] \xrightarrow{*}_R \$ \sigma[I_{i+1,j}]$ if $i \leq j$ using the rules in (4) and (5). Let $\beta = |\sigma[I_{1,\alpha-1}]|$. Finally, define

$$w(v_\alpha, U) = (\#b_1^n)^\beta b_0^\beta \sigma[I_{1,n}].$$

LEMMA 6.3. *We have $w(v_\alpha, U) \xrightarrow{*}_R 0$ if and only if $(v_\alpha, v_i) \in E^*$ for some $v_i \in U$.*

Before we prove Lemma 6.3 let us first consider an example.

Example 6.4. Let (V, E) be the following directed forest (see Figure 6.1). The set U contains only the node v_6 . Let $\alpha = 2$; i.e., v_2 is the start node.

FIG. 6.1.

Then $w(v_\alpha, U) = (\#b_1^7)^7 b_0^5 c_0^4 c_0^5 c_0^4 c_0^5 c_0^7 c_2 c_1$. We obtain the following derivation:

$$\begin{aligned}
& (\#b_1^7)^7 b_0^5 c_0^4 c_0^5 c_0^4 c_0^5 c_0^7 c_2 c_1 \xrightarrow{*}_R && \text{(rules in (1))} \\
& (\#b_1^7)^7 c_0^5 c_0^4 c_0^5 c_0^7 c_2 c_1 \xrightarrow{*}_R && \text{(rule (2))} \\
& (\#b_1^7)^6 \#b_1^2 c_0^4 c_0^5 c_0^7 c_2 c_1 \rightarrow_R && \text{(rule (3))} \\
& (\#b_1^7)^6 \#b_1 \triangleright c_0^4 c_0^5 c_0^7 c_2 c_1 \xrightarrow{*}_R && \text{(rules in (4))} \\
& (\#b_1^7)^6 \#b_1 \triangleright c_0^5 c_0^7 c_2 c_1 \rightarrow_R && \text{(rule (5))} \\
& (\#b_1^7)^6 \#b_1 c_0^5 c_0^7 c_2 c_1 \rightarrow_R && \text{(rule (3))} \\
& (\#b_1^7)^6 \# \triangleright c_0^5 c_0^7 c_2 c_1 \xrightarrow{*}_R && \text{(rules in (4))} \\
& (\#b_1^7)^6 \# \triangleright c_0^7 c_2 c_1 \rightarrow_R && \text{(rule (5))} \\
& (\#b_1^7)^6 \# c_0^7 c_2 c_1 \xrightarrow{*}_R && \text{(rule (6))} \\
& (\#b_1^7)^6 c_0^7 c_2 c_1 \xrightarrow{*}_R && \text{(rule (2))} \\
& (\#b_1^7)^5 \# c_2 c_1 \rightarrow_R && \text{(rule (6))} \\
& (\#b_1^7)^5 c_2 c_1 \xrightarrow{*}_R && \text{(rule (7))} \\
& (\#b_1^7)^4 \#b_1^6 c_1 \xrightarrow{*}_R && \text{(rules in (8) and (9))} \\
& 0.
\end{aligned}$$

Indeed, there exists a path from v_2 to a node in U . If U would consist only of the node v_7 instead of v_6 , then $w(v_\alpha, U) = (\#b_1^7)^7 b_0^5 c_0^4 c_0^5 c_0^4 c_0^5 c_0^7 c_1 c_2$. In this case we obtain a similar derivation showing $w(v_\alpha, U) \xrightarrow{*}_R (\#b_1^7)^5 c_1 c_2$. But the latter word is irreducible. Since R is confluent, $w(v_\alpha, U) \xrightarrow{*}_R 0$ cannot hold.

Proof of Lemma 6.3. First, note that using the rules in (1) we obtain

$$w(v_\alpha, U) = (\#b_1^n)^n b_0^\beta \sigma[I_{1, \alpha-1}] \sigma[I_{\alpha, n}] \xrightarrow{*}_R (\#b_1^n)^n \sigma[I_{\alpha, n}].$$

Claim. For every $v_i \in V$, if $(v_\alpha, v_i) \in E^*$, then there exists $k \geq n - i + \alpha$ such that $w(v_\alpha, U) \xrightarrow{*}_R (\#b_1^n)^k \sigma[I_{i, n}]$.

We prove this claim by induction over the length of the unique path from v_α to v_i . The case $i = \alpha$ is clear. Thus, assume that $(v_\alpha, v_j) \in E^*$ and $(v_j, v_i) \in E$. Then $j < i$ and by induction we have

$$w(v_\alpha, U) \xrightarrow{*}_R (\#b_1^n)^k \sigma[I_{j, n}] = (\#b_1^n)^{k-1} \#b_1^n c_0^{n-i+j+1} \sigma[I_{j+1, n}],$$

where $k \geq n - j + \alpha$, i.e., $k - 1 \geq n - i + \alpha$. We obtain

$$\begin{aligned}
& (\#b_1^n)^{k-1} \#b_1^n c_0^{n-i+j+1} \sigma[I_{j+1, n}] \xrightarrow{*}_R && \text{(rule (2))} \\
& (\#b_1^n)^{k-1} \#b_1^{i-j-1} \sigma[I_{j+1, n}] \rightarrow_R && \text{(rule (3))} \\
& (\#b_1^n)^{k-1} \#b_1^{i-j-2} \triangleright \sigma[I_{j+1, n}] \xrightarrow{*}_R && \text{(rules in (4) and (5))} \\
& (\#b_1^n)^{k-1} \#b_1^{i-j-2} \sigma[I_{j+2, n}] \xrightarrow{*}_R \\
& \quad \vdots \\
& (\#b_1^n)^{k-1} \#b_1^0 \sigma[I_{i, n}] \\
& = (\#b_1^n)^{k-1} \# \sigma[I_{i, n}] \rightarrow_R && \text{(rule (6))} \\
& (\#b_1^n)^{k-1} \sigma[I_{i, n}].
\end{aligned}$$

This proves the claim.

Thus, if $(v_\alpha, v_i) \in E^*$ for some $v_i \in U$, then by the above claim

$$\begin{aligned} w(v_\alpha, U) &\xrightarrow*_R (\#b_1^n)^k \sigma[I_{i,n}] \\ &= (\#b_1^n)^{k-1} \#b_1^{n-1} b_1 c_2 \$\sigma[I_{i+1,n}] \rightarrow_R \quad (\text{rule (7)}) \\ &(\#b_1^n)^{k-1} \#b_1^{n-1} 0 \$\sigma[I_{i+1,n}] \xrightarrow*_R 0 \quad (\text{rules in (8) and (9)}) \end{aligned}$$

for some $k > 0$. On the other hand, if there does not exist $v_i \in U$ with $(v_\alpha, v_i) \in E^*$, then there exists $v_i \in V \setminus U$ with outdegree 0 and $(v_\alpha, v_i) \in E^*$. Thus,

$$w(v_\alpha, U) \xrightarrow*_R (\#b_1^n)^k \sigma[I_{i,n}] = (\#b_1^n)^k c_1 \$\sigma[I_{i+1,n}] \in \text{IRR}(R).$$

Since (Γ, R) is confluent, $w(v_\alpha, U) \xrightarrow*_R 0$ cannot hold. This proves Lemma 6.3. \square

Lemma 6.3 yields the following result that is of independent interest; see section 3.2 for the definition of NC^1 -reductions.

THEOREM 6.5. *There exists a fixed 2-monadic and confluent presentation (Γ, R) such that the word problem for $\mathcal{M}(\Gamma, R)$ is L-hard under NC^1 -reductions.*

Proof. By [18], the reachability problem for directed forests that are ordered (i.e., the set of nodes is $\{1, \dots, n\}$ for some n and $i < j$ whenever there is an edge from i to j) is L-complete under NC^1 -reductions. Moreover, one can assume that 1 is the initial node. It remains to show that for such a forest $G = (V, E)$ and $U \subseteq V$ the word $w(1, U)$ can be constructed in NC^1 from G and U . We leave the details to the reader. \square

The existence of a fixed monadic and confluent presentation with an L-hard word problem was also shown in [6].

Now let us consider the compressed word problem for 2-monadic and confluent presentations.

THEOREM 6.6. *For every 2-monadic and confluent presentation (Γ, R) , the compressed word problem for $\mathcal{M}(\Gamma, R)$ is in PSPACE. There exists a fixed 2-monadic and confluent presentation (Γ, R) such that the compressed word problem for $\mathcal{M}(\Gamma, R)$ is PSPACE-complete.*

Proof. The upper bound follows from Proposition 6.2. For the lower bound we will show that the compressed word problem for the 2-monadic presentation (Γ, R) from the previous discussion is PSPACE-hard. For this we repeat a construction from [41]. Let $\mathcal{A} = (Q, \Sigma, \delta, q_0, q_f)$ be a fixed deterministic linear bounded automaton (Q is the set of states, Σ is the tape alphabet, q_0 (resp., q_f) is the initial (resp., final) state, and $\delta : Q \setminus \{q_f\} \times \Sigma \rightarrow Q \times \Sigma \times \{\text{left}, \text{right}\}$ is the transition function) such that the question of whether a word $w \in \Sigma^*$ is accepted by \mathcal{A} is PSPACE-complete. Such a linear bounded automaton exists; see, e.g., [5]. The one-step transition relation between configurations of \mathcal{A} is denoted by $\Rightarrow_{\mathcal{A}}$. Let $w \in \Sigma^*$ be an input for \mathcal{A} with $|w| = N$. We may assume that \mathcal{A} operates in phases, where a single phase consists of a sequence of $2 \cdot N$ transitions of the form $q_1 \gamma_1 \xrightarrow*_A \gamma_2 q_2 \xrightarrow*_A q_3 \gamma_3$, where $\gamma_1, \gamma_2, \gamma_3 \in \Sigma^N$ and $q_1, q_2, q_3 \in Q$. During the transition sequence $q_1 \gamma_1 \xrightarrow*_A \gamma_2 q_2$, only right-moves are made, whereas during the sequence $\gamma_2 q_2 \xrightarrow*_A q_3 \gamma_3$, only left-moves are made. The automaton \mathcal{A} accepts if it reaches the final state q_f . Otherwise \mathcal{A} does not terminate. There exists a constant $c > 0$ such that if w is accepted by \mathcal{A} , then \mathcal{A} , started on w , reaches the final state q_f after at most $2^{c \cdot N}$ phases. Let $\widehat{\Sigma} = \{\widehat{a} \mid a \in \Sigma\}$ be a disjoint copy of Σ and similarly for \widehat{Q} . Let $\Delta = \Sigma \cup \widehat{\Sigma} \cup \{\langle, 0, 1, \ell\}$ and $\Theta = Q \cup \widehat{Q} \cup \Delta$. We simulate \mathcal{A} by the following semi-Thue system S over the alphabet Θ :

$0\widehat{q} \rightarrow \widehat{q}\mathcal{L}$ for all $q \in Q \setminus \{q_f\}$	$qa \rightarrow \widehat{b}p$ if $\delta(q, a) = (p, b, \text{right})$
$1\widehat{q} \rightarrow 0q$ for all $q \in Q \setminus \{q_f\}$	$\widehat{a}\widehat{q} \rightarrow \widehat{p}b$ if $\delta(q, a) = (p, b, \text{left})$
$q\mathcal{L} \rightarrow 1q$ for all $q \in Q \setminus \{q_f\}$	$q\triangleleft \rightarrow \widehat{q}\triangleleft$ for all $q \in Q \setminus \{q_f\}$

(Θ, S) is length-preserving and if \succ is any linear order on the alphabet Θ that satisfies $Q \succ 1 \succ 0 \succ \widehat{\Sigma} \succ \widehat{Q}$, then $s \succ t$ for every rule $(s, t) \in S$; i.e., S is lexicographic (recall from section 3.1 that we identify an order \succ on the alphabet Θ with its lexicographic extension to Θ^*). Let us choose such a linear order on Θ that, moreover, satisfies $Q \succ \Delta \succ \widehat{Q}$. In [41] we have argued that w is accepted by \mathcal{A} if and only if $1q_0\mathcal{L}^{c \cdot N - 1}w\triangleleft \xrightarrow{*}_S v$ for some word v with $\text{alph}(v) \cap \{q_f, \widehat{q}_f\} \neq \emptyset$. We briefly repeat the arguments: First, note that $1q_0\mathcal{L}^{c \cdot N - 1}w\triangleleft \xrightarrow{*}_S 1^{c \cdot N}q_0w\triangleleft$. From the word $1^{c \cdot N}q_0w\triangleleft$ we can simulate $2^{c \cdot N}$ phases of \mathcal{A} . The crucial point is that the prefix from $\{0, 1\}^*$ acts as a binary counter: for every $u \in \{0, 1\}^i$ ($i < c \cdot N$) and every $q \in Q$ we have $u10^{c \cdot N - |u| - 1}\widehat{q} \xrightarrow{*}_S u1\widehat{q}\mathcal{L}^{c \cdot N - |u| - 1} \rightarrow_S u0q\mathcal{L}^{c \cdot N - |u| - 1} \xrightarrow{*}_S u01^{c \cdot N - |u| - 1}q$. Thus, if \mathcal{A} accepts w , then we can derive from $1q_0\mathcal{L}^{c \cdot N - 1}w\triangleleft$ a word v with $\text{alph}(v) \cap \{q_f, \widehat{q}_f\} \neq \emptyset$. On the other hand, if \mathcal{A} does not accept w and hence does not terminate, then we can derive from $1q_0\mathcal{L}^{c \cdot N - 1}w\triangleleft$ a word of the form $\widehat{q}\mathcal{L}^{c \cdot N}u\triangleleft$ for some $u \in \Sigma^N$ and $q \neq q_f$. Since S is confluent (the left-hand sides of S do not overlap) and $\widehat{q}\mathcal{L}^{c \cdot N}u\triangleleft \in \text{IRR}(S)$, we cannot reach a word v with $\text{alph}(v) \cap \{q_f, \widehat{q}_f\} \neq \emptyset$ from $1q_0\mathcal{L}^{c \cdot N - 1}w\triangleleft$.

To simplify the following construction, we will next expand all rules from S in the following sense: The rule $q\mathcal{L} \rightarrow 1q$, for instance, is replaced by all rules of the form $xq\mathcal{L} \rightarrow x1q$ for all $x \in \Delta$, whereas the rule $0\widehat{q} \rightarrow \widehat{q}\mathcal{L}$ is replaced by all rules of the form $0\widehat{q}x \rightarrow \widehat{q}\mathcal{L}x$ for all $x \in \Delta$. Let us call the resulting system again S . Then S is still length-preserving and lexicographic and $\text{dom}(S) \subseteq \Delta(Q \cup \widehat{Q})\Delta$. The new system S is no longer confluent, but this is not important for the further arguments. It is only important that

$$(6.1) \quad \forall v, v_1, v_2 \in \Delta^*(Q \cup \widehat{Q})\Delta^* : (v_1 \xleftarrow{S} v \xrightarrow{S} v_2) \Rightarrow v_1 = v_2.$$

This is easy to see by inspection of the rules. Moreover, w is accepted by \mathcal{A} if and only if $1q_0\mathcal{L}^{c \cdot N - 1}w\triangleleft \xrightarrow{*}_S v$ for some word v with $\text{alph}(v) \cap \{q_f, \widehat{q}_f\}$. Let $m = (c + 1)N - 1$; thus $m + 3$ is the length of words in any derivation starting from $1q_0\mathcal{L}^{c \cdot N - 1}w\triangleleft$.

Let us now define the directed graph (V, E) , where $V = \bigcup_{i=1}^{m+1} \Delta^i(Q \cup \widehat{Q})\Delta^{m-i+2}$ and $E = \{(v, v') \in V \times V \mid v \xrightarrow{S} v'\}$. This graph is basically the transition graph of the automaton \mathcal{A} on configurations of length N . Since S is lexicographic, (V, E) is acyclic. Moreover, by (6.1), every node from V has at most one outgoing edge. Thus, (V, E) is a directed forest. If we order V lexicographically by \succ and write $V = \{v_1, \dots, v_n\}$ with $v_1 \succ v_2 \succ \dots \succ v_n$, then $(v_i, v_j) \in E$ implies $i < j$. Note that $n = |V| = 2(m + 1) \cdot |Q| \cdot |\Delta|^{m+2}$, which belongs to $2^{O(N)}$. Let U be those words in V that contain either q_f or \widehat{q}_f ; these words have outdegree 0 in the directed forest (V, E) . Let $v_\alpha = 1q_0\mathcal{L}^{c \cdot N - 1}w\triangleleft$. Thus, $\alpha - 1$ is the number of words from V that are lexicographically larger than $1q_0\mathcal{L}^{c \cdot N - 1}w\triangleleft$. The number α can be easily calculated in logarithmic space from the input word w using simple arithmetic. We now have available all the data in order to construct the word $w(v_\alpha, U) \in \Gamma^*$ from Lemma 6.3.

The automaton \mathcal{A} accepts w if and only if there is a path in (V, E) from v_α to a node in U . By Lemma 6.3 this holds if and only if $w(v_\alpha, U) \xleftarrow{*}_R 0$. Thus, it remains to show that the word $w(v_\alpha, U)$ can be generated by a small SLP. Recall the definition

of the words σ_i and $\sigma[I] \in \Gamma^*$, where $1 \leq i \leq n = |V|$ and I is an interval of (V, \succ) that we introduced before Lemma 6.3.

Note that for all $1 \leq i, j \leq n$, if $v_i = u_1 \ell u_2 \rightarrow_S u_1 r u_2 = v_j$ with $(\ell, r) \in S$, then $j - i$ (i.e., the number of words from V that are lexicographically between v_i and v_j) is a number that depends only on the rule (ℓ, r) (and thus ℓ) and $|u_2|$. We call this number $\lambda(\ell, |u_2|)$; it belongs to $2^{O(N)}$ and can be calculated in logarithmic space from ℓ and $|u_2|$ using simple arithmetic. We now describe a small SLP that generates the word $\sigma[V] \in \Gamma^*$. For this let us assume that $Q = \{p_1, \dots, p_{n_1}\}$ and $\Delta = \{a_1, \dots, a_{n_2}\}$ with $p_i \succ p_{i+1}$, $\widehat{p}_i \succ \widehat{p}_{i+1}$, and $a_i \succ a_{i+1}$ (note that the order \succ on the subalphabets Q, \widehat{Q} , and Δ , respectively, is arbitrary except that $1 \succ 0$). We introduce the following productions:⁴

$$\begin{aligned}
 A_i &\rightarrow \prod_{j=1}^{n_2} B_{i,j} A_{i+1} \widehat{B}_{i,j} \text{ for } 0 \leq i < m, \\
 A_m &\rightarrow \prod_{j=1}^{n_2} B_{m,j} \widehat{B}_{m,j}, \\
 B_{i,j} &\rightarrow \prod_{k=1}^{n_1} \prod_{\ell=1}^{n_2} (C_{i,j,k,\ell} \mathbb{S})^{|\Delta|^{m-i}} \text{ for } 0 \leq i \leq m, 1 \leq j \leq n_2, \\
 C_{i,j,k,\ell} &\rightarrow \begin{cases} c_0^{n-\lambda(a_j p_k a_\ell, m-i)+1} & \text{if } a_j p_k a_\ell \in \text{dom}(R), \\ c_1 & \text{if } a_j p_k a_\ell \notin \text{dom}(R) \text{ and } p_k \neq q_f, \\ c_2 & \text{if } p_k = q_f, \end{cases} \\
 \widehat{B}_{i,j} &\rightarrow \prod_{k=1}^{n_1} \prod_{\ell=1}^{n_2} (\widehat{C}_{i,j,k,\ell} \mathbb{S})^{|\Delta|^{m-i}} \text{ for } 0 \leq i \leq m, 1 \leq j \leq n_2, \\
 \widehat{C}_{i,j,k,\ell} &\rightarrow \begin{cases} c_0^{n-\lambda(a_j \widehat{p}_k a_\ell, m-i)+1} & \text{if } a_j \widehat{p}_k a_\ell \in \text{dom}(R), \\ c_1 & \text{if } a_j \widehat{p}_k a_\ell \notin \text{dom}(R) \text{ and } \widehat{p}_k \neq \widehat{q}_f, \\ c_2 & \text{if } \widehat{p}_k = \widehat{q}_f. \end{cases}
 \end{aligned}$$

The exponents that appear in the right-hand sides of the productions for the nonterminal $B_{i,j}$ and $\widehat{B}_{i,j}$, namely $|\Delta|^{m-i}$, are of size $2^{O(N)}$ and can therefore be replaced by sequences of ordinary productions. Note that $\text{eval}(C_{i,j,k,\ell}) = \delta_s$ for every node v_s from $\Delta^i a_j p_k a_\ell \Delta^{m-i}$, whereas $\text{eval}(\widehat{C}_{i,j,k,\ell}) = \delta_s$ for every node v_s from $\Delta^i a_j \widehat{p}_k a_\ell \Delta^{m-i}$. It follows that for all $0 \leq i \leq m$, all $u \in \Delta^i$, and all $1 \leq j \leq n_2$ we have (note that $ua_j Q \Delta^{m-i+1} \subseteq V$ is an interval of (V, \succ))

$$(6.2) \quad \text{eval}(B_{i,j}) = \sigma[ua_j Q \Delta^{m-i+1}] \quad \text{and} \quad \text{eval}(\widehat{B}_{i,j}) = \sigma[ua_j \widehat{Q} \Delta^{m-i+1}].$$

Claim. Let $0 \leq i \leq m$ and let $u \in \Delta^i$ be arbitrary. Then for the interval $I = \bigcup_{j=1}^{m-i+1} u \Delta^j (Q \cup \widehat{Q}) \Delta^{m-i-j+2}$ of the linear order (V, \succ) we have $\sigma[I] = \text{eval}(A_i)$.

The claim will be shown by induction on i (for $i = m$ down to 0). For $i = m$ the

⁴The expression $\prod_{i=1}^k w_i$ is an abbreviation for $w_1 w_2 \dots w_k$.

claim is true:

$$\begin{aligned} \text{eval}(A_m) &= \prod_{j=1}^{n_2} \text{eval}(B_{m,j})\text{eval}(\widehat{B}_{m,j}) \quad (\text{by (6.2)}) \\ &= \prod_{j=1}^{n_2} \sigma[ua_jQ\Delta]\sigma[ua_j\widehat{Q}\Delta] \quad (Q \succ \widehat{Q}) \\ &= \sigma[u\Delta(Q \cup \widehat{Q})\Delta]. \end{aligned}$$

Now let $i < m$ and $u \in \Delta^i$. The words from the interval $\bigcup_{j=1}^{m-i+1} u\Delta^j(Q \cup \widehat{Q})\Delta^{m-i-j+2}$ can be partitioned into the following decreasing sequence of consecutive intervals of (V, \succ) (recall that $Q \succ \Delta \succ \widehat{Q}$ and $a_1 \succ a_2 \succ \dots \succ a_{n_2}$):

$$\begin{aligned} ua_1Q\Delta^{m-i+1} &\succ \bigcup_{j=1}^{m-i} ua_1\Delta^j(Q \cup \widehat{Q})\Delta^{m-i-j+1} \succ ua_1\widehat{Q}\Delta^{m-i+1} \\ \succ ua_2Q\Delta^{m-i+1} &\succ \bigcup_{j=1}^{m-i} ua_2\Delta^j(Q \cup \widehat{Q})\Delta^{m-i-j+1} \succ ua_2\widehat{Q}\Delta^{m-i+1} \\ \succ \dots \succ ua_{n_2}Q\Delta^{m-i+1} &\succ \bigcup_{j=1}^{m-i} ua_{n_2}\Delta^j(Q \cup \widehat{Q})\Delta^{m-i-j+1} \succ ua_{n_2}\widehat{Q}\Delta^{m-i+1}. \end{aligned}$$

By induction, we have

$$\begin{aligned} &\sigma \left[\bigcup_{j=1}^{m-i} ua_1\Delta^j(Q \cup \widehat{Q})\Delta^{m-i-j+1} \right] \\ &= \dots = \sigma \left[\bigcup_{j=1}^{m-i} ua_{n_2}\Delta^j(Q \cup \widehat{Q})\Delta^{m-i-j+1} \right] = \text{eval}(A_{i+1}). \end{aligned}$$

Together with (6.2) we obtain

$$\sigma \left[\bigcup_{j=1}^{m-i+1} u\Delta^j(Q \cup \widehat{Q})\Delta^{m-i-j+2} \right] = \prod_{j=1}^{n_2} \text{eval}(B_{i,j})\text{eval}(A_{i+1})\text{eval}(\widehat{B}_{i,j}) = \text{eval}(A_i).$$

This proves the claim. By setting $i = 0$ we get

$$\text{eval}(A_0) = \sigma \left[\bigcup_{j=1}^{m+1} \Delta^j(Q \cup \widehat{Q})\Delta^{m-j+2} \right] = \sigma[V].$$

Let $\beta = |\sigma[I_{1,\alpha-1}]| \in 2^{O(N)}$. Arithmetic on numbers with $N^{O(1)}$ many bits allows us to compute β in logspace from the input word w . Using the above productions and the number β , we can construct an SLP G of size polynomial in the input size N with $\text{eval}(G) = (\#b_1^n)^n b_0^\beta \sigma[V] = w(v_\alpha, U)$. Recall that n is of size $2^{O(N)}$. Then our input word w is accepted by \mathcal{A} if and only if $\text{eval}(G) \stackrel{*}{\leftrightarrow}_R 0$. This proves the theorem. \square

The following corollary solves an open problem from [23, 55].

COROLLARY 6.7. *There exists a fixed deterministic context-free language L such that the compressed membership problem for L is PSPACE-complete.*

Proof. Since every context-free language is contained in $\text{DSPACE}(\log^2(n))$, the PSPACE upper bound can be deduced from Proposition 6.1. For the lower bound,

notice that the language $\{w \in \Gamma^* \mid w \xrightarrow{*}_R 0\}$ is deterministic context-free for every monadic and confluent presentation and every $0 \in \Gamma$; see, e.g., [11, Theorem 4.2.7]. If we choose the 2-monadic and confluent presentation from the proof of Theorem 6.5 for (Γ, R) , then the language $\{w \in \Gamma^* \mid w \xrightarrow{*}_R 0\}$ is PSPACE-hard by the proof of Theorem 6.6. \square

In [31] a language L is called *deterministic linear* if it is accepted by a deterministic 1-turn pushdown automaton.

COROLLARY 6.8. *There exists a fixed deterministic linear language L such that the compressed membership problem for L is PSPACE-complete.*

Proof. The language $\{w \in \Gamma^* \mid w \xrightarrow{*}_R 0\} \cap (\#b_1^+)^+ b_0^+ ((c_0^+ \cup c_1 \cup c_2)\$)^+$ is easily seen to be deterministic linear. Moreover, it contains a word of the form $w(v_\alpha, U)$ if and only if $w(v_\alpha, U) \xrightarrow{*}_R 0$. \square

7. Compressed word problems in EXPSPACE. The largest class of monoid presentations that we consider in this paper are weight-lexicographic and confluent presentations: A presentation (Γ, R) is *weight-lexicographic* if there exist a linear order \succ on the alphabet Γ and a weight-function $f : \Gamma^* \rightarrow \mathbb{N}$ such that for all $(s, t) \in R$ we have either $f(s) > f(t)$ or $(f(s) = f(t) \text{ and } s \succ t)$. If the weight-function f is the length-function, i.e., $f(w) = |w|$, then (Γ, R) is called *length-lexicographic*.

THEOREM 7.1. *For every weight-lexicographic and confluent presentation (Γ, R) , the compressed word problem for $\mathcal{M}(\Gamma, R)$ is in EXPSPACE. Moreover, there exists a fixed length-lexicographic and confluent presentation (Γ, R) such that the compressed word problem for $\mathcal{M}(\Gamma, R)$ is EXPSPACE-complete.*

Proof. For the upper bound we can use a result from [41]: for every fixed weight-lexicographic and confluent presentation (Γ, R) , the word problem for $\mathcal{M}(\Gamma, R)$ belongs to PSPACE. Thus, for two given SLPs G_1 and G_2 we can first generate the exponentially long words $\text{eval}(G_1)$ and $\text{eval}(G_2)$ and then check in space bounded polynomially in $|\text{eval}(G_1)| + |\text{eval}(G_2)|$ whether $\text{eval}(G_1) \xleftrightarrow{*}_R \text{eval}(G_2)$.

For the lower bound, let (Θ, S) be the presentation from the proof of Theorem 6.6, where this time the simulated machine \mathcal{A} is a fixed Turing-machine that accepts an EXPSPACE-complete language. Also for such a machine we may assume that it operates in alternating phases of left and right sweeps. The presentation (Θ, S) is length-lexicographic and confluent. Without loss of generality the space bound for an input of length n is 2^n . The number of phases can be bounded by $2^{c \cdot 2^n}$ for some constant $c > 0$. Add to Θ an absorbing symbol 0 and add to S the following rules: $q_f \rightarrow 0$, $\hat{q}_f \rightarrow 0$, $x0 \rightarrow 0$ for all $x \in \Theta$, and $0x \rightarrow 0$ for all $x \in \Theta$. We again call the resulting presentation (Θ, S) ; it is still length-lexicographic and confluent. Moreover, for an input word w of length n , w is accepted by \mathcal{A} if and only if $1q_0 \mathcal{L}^{c \cdot 2^n - 1} w \square^{2^n - |w|} \triangleleft \xleftrightarrow{*}_S 0$ (where q_0 is the initial state of \mathcal{A} and \square is the blank symbol); see also the proof of Theorem 6 in [41]. Finally, note that the word $1q_0 \mathcal{L}^{c \cdot 2^n - 1} w \square^{2^n - |w|} \triangleleft$ can be generated by an SLP of polynomial size in n . \square

The language $\{w \in \Theta^* \mid w \xrightarrow{*}_S 0\}$, where (Θ, S) is the presentation from the previous proof, is context-sensitive. Thus, we obtain the following result.

COROLLARY 7.2. *There exists a fixed context-sensitive language L such that the compressed membership problem for L is EXPSPACE-complete.*

8. Circuit complexity and compression. In this section we will investigate the compressed membership problem for languages from very low complexity classes. These classes are usually defined by uniform families of small depth Boolean circuit families. An equivalent and for our purpose more suitable definition is based on

alternating Turing-machines with logarithmic time bounds; see section 3.2. Recall that ALOGTIME denotes the class of all languages that can be recognized on an alternating Turing-machine in time $O(\log(n))$. Within ALOGTIME, we can define the logtime hierarchy: For $k \geq 1$ we denote by Σ_k^{\log} (resp., Π_k^{\log}) the class of all languages that can be decided by an alternating Turing-machine in time $O(\log(n))$ within $k - 1$ alternations (on every computation path) starting in an existential state (resp., universal state). In [4], $\Sigma_k^{\log} \cup \Pi_k^{\log}$ is proposed as a uniform version of AC_k^0 , which is the class of all languages that can be recognized by a polynomial-size, depth k family of unbounded fan-in Boolean circuits. The union $\bigcup_{k \geq 0} \Sigma_k^{\log} \cup \Pi_k^{\log}$ is also called the *logtime hierarchy* (LH). By [63], LH is a strict hierarchy.

The well-known *polynomial time hierarchy* [64] is defined similarly to the LH: For $k \geq 1$ we denote by Σ_k^p (resp., Π_k^p) the class of all languages that can be decided by an alternating Turing-machine in polynomial time within $k - 1$ alternations (on every computation path) starting in an existential state (resp., universal state).

For the further investigations we will need the following lemma.

LEMMA 8.1. *Incrementing a binary n -bit counter C (with arbitrary initial value) m times by 1 takes a total of $O(n + m)$ steps on a deterministic Turing-machine.*

Proof. Without loss of generality assume that m is a power of 2. We assume that after each increment, the read-write head moves back to the least significant bit of C . If the first i bits of C are $1^{i-1}0$ in that order, then we need $2i$ steps for the increment. For $i > \log(m)$, this will happen only once during the m increments. Thus, it suffices to show that incrementing a binary $\log(m)$ -bit counter m times by 1 takes a total of $O(m)$ steps. There are at most $2^{\log(m)-i} = \frac{m}{2^i}$ numbers $t \in \{0, \dots, m\}$ such that the first i bits of t are $1^{i-1}0$ in that order. Incrementing such a number by 1 takes $2i$ steps. Thus, incrementing the counter m times by 1 takes a total of $\sum_{i=1}^{\log(m)} 2i \cdot \frac{m}{2^i} \leq 2m \sum_{i=1}^{\infty} \frac{i}{2^i} = 4m$ steps. \square

Of course, an analogous statement for decrementing a counter is also true.

THEOREM 8.2. *For every language L in Σ_k^{\log} (resp., Π_k^{\log}) the compressed membership problem belongs to Σ_k^p (resp., Π_k^p). Moreover, there exists a fixed language L in Σ_k^{\log} (resp., Π_k^{\log}) such that the compressed membership problem for L is Σ_k^p -complete (resp., Π_k^p -complete).*

Proof. It suffices to prove the statement for Σ_k^p and Σ_k^{\log} , respectively, because Π_k^p and Π_k^{\log} are the corresponding complementary classes. Let us first show that the compressed membership problem for L belongs to Σ_k^p in case L belongs to Σ_k^{\log} . Assume that L belongs to Σ_k^{\log} . Given an SLP G we simulate the Σ_k^{\log} -algorithm on $\text{eval}(G)$. Since $|\text{eval}(G)| \in 2^{O(n)}$, this simulation takes $O(n)$ steps. Moreover, the number of alternations during the simulation is k and we start in an existential state. Finally, note that if the Σ_k^{\log} -machine has written a position $i \in \{1, \dots, |\text{eval}(G)|\}$ on its address tape and queries the i th position of $\text{eval}(G)$, then in the simulation we have to determine the symbol $\text{eval}(G)[i]$ which is possible in polynomial time (with respect to $|G|$).

Next, we will construct a language L in Σ_k^{\log} such that the compressed membership problem for L is Σ_k^p -complete. First, assume that k is odd. In this case the following restricted version of quantified Boolean satisfiability (QBF), called Q3SAT $_k$, is Σ_k^p -complete [70]:

INPUT: A quantified Boolean formula of the form

$$\Theta = \exists \bar{x}_1 \forall \bar{x}_2 \cdots \exists \bar{x}_k : \varphi(x_1, \dots, x_n).$$

Here $\bar{x}_i = (x_{\ell_i}, \dots, x_{\ell_{i+1}-1})$ (where $\ell_1 = 1$ and $\ell_{k+1} = n + 1$) is a sequence of Boolean variables and φ is a formula in 3-CNF (a conjunction of disjunctions, each containing exactly three literals) over the variables x_1, \dots, x_n .

QUESTION: Is Θ a true quantified Boolean formula?

Let us take an instance Θ of Q3SAT $_k$ of the above form. Assume that $\varphi = C_1 \wedge C_2 \wedge \dots \wedge C_m$ where every C_i is a disjunction of three literals. Note that there are 2^n truth assignments to the variables x_1, \dots, x_n and each of these truth assignments can be represented by the vector (b_1, \dots, b_n) where $b_i = 1$ if the variable x_i evaluates to true; otherwise $b_i = 0$. We order these vectors lexicographically, where the last position gets the highest significance, i.e., $(0, \dots, 0) < (1, 0, \dots, 0) < \dots < (1, \dots, 1)$. Thus, we can speak of the j th truth assignment ($0 \leq j \leq 2^n - 1$). For each disjunction C_i define the word $c_i = b_0 b_1 \dots b_{2^n-1}$, where $b_j \in \{0, 1\}$ is the truth value of C_i under the j th truth assignment. In [8] it is shown that the word c_i can be generated by an SLP of size $O(n)$. Let $d_i = \ell_{i+1} - \ell_i$; i.e., d_i is the number of variables in the i th block \bar{x}_i . Let $\Gamma = \{0, 1, \$, a_1, \dots, a_k\}$. Finally, we define the word $w(\Theta) \in \Gamma^*$ by

$$w(\Theta) = c_1 c_2 \dots c_m \$^{2^m} a_k^{d_k} \dots a_2^{d_2} a_1^{d_1}.$$

Since every c_i can be generated by an SLP of size $O(n)$, the word $w(\Theta)$ can be generated by an SLP of polynomial size with respect to the size of the formula Θ . Note that $|w(\Theta)| = m \cdot 2^n + 2^m + n$. Thus $n \leq \log(|w(\Theta)|)$ and also $m \leq \log(|w(\Theta)|)$. The only use of the padding-factor $\$^{2^m}$ is to ensure $m \leq \log(|w(\Theta)|)$. It remains to construct a Σ_k^{\log} -machine \mathcal{A} that accepts a given input word of the form $w(\Theta)$ if and only if Θ is true. The behavior of this machine on inputs that are not of the form $w(\Theta)$ is not important; it is important only that the logarithmic time bound is respected, independently of the form of the input. This will be ensured by a counter t . In the following, we write $w[i]$ ($i \in \{0, \dots, |w| - 1\}$), where i is the current content of the address tape, for the result of querying the input w via the random access mechanism. Note that in contrast to the definition in section 3.1, we number the first position of w with 0 and the last position with $|w| - 1$. The alternating Turing-machine \mathcal{A} is described in Figure 8.1. Let us consider an example before we continue analyzing the machine \mathcal{A} .

Example 8.3. Let Θ be the quantified Boolean formula

$$\exists x_1 \forall x_2 \exists x_3 : (x_1 \vee x_2 \vee \neg x_3) \wedge (\neg x_1 \vee x_2 \vee x_3),$$

which evaluates to true. We have $c_1 = 11110111$ and $c_2 = 10111111$ and thus

$$w(\Theta) = 1111011110111111\$^4 a_3 a_2 a_1.$$

Consider the truth assignment $x_1 = x_2 = 1, x_3 = 0$. This is the third assignment in lexicographic order (recall that we start with the 0th assignment). The fact that $(x_1 \vee x_2 \vee \neg x_3) \wedge (\neg x_1 \vee x_2 \vee x_3)$ is true under this assignment corresponds to the fact that $w(\Theta)[3] = 1$ and $w(\Theta)[3 + 2^m] = w(\Theta)[11] = 1$. This is verified by the machine \mathcal{A} in the second while-loop, where $p = 3$ is guessed in the for-loop.

Now let us analyze the behavior of the alternating Turing-machine \mathcal{A} on an input $w \in \Gamma^*$. All counters (t, s, n , and q) in this algorithm need only $\log(|w|)$ bits and are incremented (or decremented) only $O(\log(|w|))$ times. Thus, by Lemma 8.1 all increments and decrements for the various counters need $O(\log(|w|))$ total time. Hence, the counter t enforces a logarithmic time bound of the whole algorithm. Since the number of alternations is precisely k and \mathcal{A} starts in an existential state, the

```

input a string  $w \in \Gamma^*$ 
 $t := 2\lceil \log(|w|) \rceil$  (by [3, Lemma 6.1],  $t$  can be calculated in DLOGTIME)
 $s := |w| - 1$  (again, by [3, Lemma 6.1],  $s$  can be calculated in DLOGTIME)
 $p := 0; n := 0;$ 
for  $i = 1$  to  $k$  do
  while  $w[s] = a_i$  and  $t > 0$  do
     $t := t - 1; s := s - 1; n := n + 1;$ 
    Guess existentially (if  $i$  is odd) or universally (if  $i$  is even) the  $n$ th bit of
    the number  $p$ .
  endwhile
endfor
Copy the  $n$ -bit number  $p$  to the address tape, initialize a counter  $q$  to 0, and
append  $q$  to the  $n$  bits of the address tape. When querying the input tape
via the address tape, the machine  $\mathcal{A}$  will interpret the content of the address
tape (i.e., the concatenation of the  $n$  bits of  $p$  followed by the bits of  $q$ ) as the
number  $p + 2^n \cdot q$ .
while  $w[p + 2^n \cdot q] = 1$  and  $t > 0$  do
   $q := q + 1; t := t - 1;$ 
endwhile
if  $w[p + 2^n \cdot q] = 0$  then reject else accept

```

FIG. 8.1. *The alternating Turing-machine \mathcal{A} .*

machine \mathcal{A} is indeed a Σ_k^{\log} -machine. We claim that if the input w is of the form $w(\Theta)$ for an instance Θ of Q3SAT_k , then the counter t does not reach the value 0 if \mathcal{A} is started on $w(\Theta)$. Let us fix an instance Θ of Q3SAT_k with n variables and m clauses. Thus, $n \leq \log(|w(\Theta)|)$ and $m \leq \log(|w(\Theta)|)$. From the construction of $w(\Theta)$ it follows that \mathcal{A} decrements the counter t only $n + m \leq 2\lceil \log(|w(\Theta)|) \rceil$ times when \mathcal{A} runs on the input $w(\Theta)$. Thus, t does not reach the value 0. Using this observation, it is easy to see that \mathcal{A} accepts $w(\Theta)$ if and only if Θ is true. This finishes the presentation of a language in Σ_k^{\log} with a Σ_k^p -complete compressed membership problem for the case that k is odd. If k is even, one can argue analogously; one has to only replace the 3-CNF formula by a 3-DNF formula. The resulting variant of Q3SAT_k is Σ_k^p -complete [70]. \square

Let us remark that the logtime hierarchy LH can be also characterized using first-order logic (FO) with ordering and the BIT predicate: $\text{LH} = \text{FO}[<, \text{BIT}]$; see, e.g., [32] for definitions. Since, for instance, NP can be captured by existential second-order logic ($\text{NP} = \text{SO}\exists$), it follows from Theorem 8.2 that $\text{FO}[<, \text{BIT}]$ properties on strings cannot be translated into $\text{SO}\exists$ properties on SLPs unless the polynomial time hierarchy collapses. In a setting without the BIT predicate, similar definability issues are investigated in [1].

By Proposition 6.1, for every language in $\bigcup_{i \geq 0} \text{NSPACE}(\log^i(n))$ the compressed membership problem belongs to PSPACE. It turns out that we find languages with a PSPACE-complete compressed membership problem already in $\text{ALOGTIME} \subseteq \text{DSPACE}(\log(n))$.

THEOREM 8.4. *There exists a fixed language L in ALOGTIME such that the compressed membership problem for L is PSPACE-complete.*

Proof. We can reuse the construction from the previous proof, except that we start from an instance of QBF which is PSPACE-complete [52]. \square

One should note that it is *not* the case that for every ALOGTIME-complete language the compressed membership problem is PSPACE-complete (unless $P = PSPACE$): The word problem for the finite group S_5 is ALOGTIME-complete [2], but the compressed word problem for S_5 is in P ; in fact, it is P -complete [7]. Another example is the word problem for the free group F_2 of rank 2. Its compressed membership problem is P -complete by Theorem 4.9, whereas the word problem for F_2 is ALOGTIME-hard [57] but not even known to be in ALOGITME. Thus, in the framework of SLPs, a general upgrading theorem analogous to [68] does not hold. The next theorem states this fact in a more general context. For this, we introduce a parallel notion of reducibility that we call LOGDCFL-reducibility.

A deterministic logspace-bounded AuxPDA is a deterministic pushdown automaton that has an auxiliary read-write working tape of length $O(\log(n))$ for an input of length n [65]. It is known that a language can be recognized by a deterministic logspace-bounded AuxPDA in polynomial time if and only if it belongs to the class LOGDCFL, which is the class of all problems that are logspace reducible to a deterministic context-free language [65]. We say that a function $f : \Gamma^* \rightarrow \Sigma^*$ is computable in LOGDCFL if there exists a deterministic logspace-bounded AuxPDA with an output tape that computes for an input $x \in \Gamma^*$ the word $f(x)$ on the output tape in polynomial time. This leads to the notion of LOGDCFL-reductions. LOGDCFL-reducibility is denoted by \leq_{LOGDCFL} . It is easy to see that a LOGDCFL-computable function belongs to the functional class L^{LOGDCFL} of [27], which is the class of all functions that can be computed by a logspace transducer which has additional access to an oracle from LOGCFL. Since L^{LOGDCFL} is contained in functional NC^2 [27], we see that LOGDCFL-computable functions also belong to functional NC^2 .

If \mathcal{R} is any notion of reducibility, then we write $A \equiv_{\mathcal{R}} B$ for $A \leq_{\mathcal{R}} B \leq_{\mathcal{R}} A$. In the following proposition, we denote for a language K by $\mathcal{C}(K)$ the compressed membership problem for K .

PROPOSITION 8.5. *For every language L there exists a language K such that $L \equiv_{\text{NC}^1} K \equiv_{\text{LOGDCFL}} \mathcal{C}(K)$.*

Proof. Let us fix a language $L \subseteq \Gamma^*$, let $\# \notin \Gamma$ be a new symbol, and define

$$K = \{a_1 \# a_2 \#^2 a_3 \cdots \#^{n-1} a_n \mid a_1 a_2 \cdots a_n \in L, a_1, \dots, a_n \in \Gamma\}.$$

Then $L \equiv_{\text{NC}^1} K$ is easy to see.

That K is LOGDCFL-reducible to $\mathcal{C}(K)$ is trivial. Thus, it remains to show $\mathcal{C}(K) \leq_{\text{LOGDCFL}} K$. Note that if an SLP G generates a word $a_1 \# a_2 \#^2 a_3 \cdots \#^{n-1} a_n$ (which has length $\frac{n(n+1)}{2}$), then $|G| \geq n$. This is true, because if for a nonterminal A , $\text{eval}_G(A)$ contains more than one symbol from Γ , then A can occur only once in the whole derivation tree generated by G . Now a LOGDCFL-reduction from $\mathcal{C}(K)$ to K can be implemented as follows: For a given SLP G , a deterministic logspace-bounded AuxPDA generates the word $\text{eval}(G)$ on the pushdown in the same way as context-free languages are recognized on pushdown automata. Moreover, every time the AuxPDA pushes a terminal on the pushdown, it writes that terminal on the output tape, increments a counter by 1, and removes the terminal from the pushdown. If the counter reaches the value $\frac{|G|(|G|+1)}{2} + 1$ (which has $O(\log(|G|))$ many bits in its binary representation), then the AuxPDA terminates immediately (this ensures a polynomial running time) and writes, for instance, $\#\#$ on the output in order to ensure that the generated output does not belong to K . If the counter does not reach the value $\frac{m(m+1)}{2} + 1$, then the AuxPDA finally has produced the word $\text{eval}(G)$ on the output. We have described a LOGDCFL-reduction from $\mathcal{C}(K)$ to K . \square

From Proposition 8.5 it follows that if C is a complexity class that is closed under NC^1 -reductions and such that C has complete problems under some notion \mathcal{R} of reducibility that is weaker than LOGDCFL-reducibility (e.g., NC^2 -reducibility), then C contains a language L such that both L and $\mathcal{C}(L)$ are complete for C under \mathcal{R} -reducibility.

We remark that also for hierarchical graph descriptions [38] (which can be viewed as graph-generating SLPs) the correlation between the complexity of a problem in its compressed and uncompressed variant, respectively, is quite loose.

9. Uniform variants. Many of the decision problems in this paper can be also investigated in a uniform setting. For a class \mathcal{C} of monoid presentations define the *compressed uniform word problem* for the class \mathcal{C} as the following decision problem:

INPUT: A monoid presentation (Γ, R) and two SLPs G_1 and G_2 over the terminal alphabet Γ .

QUESTION: Does $\text{eval}(G_1) \stackrel{*}{\leftrightarrow}_R \text{eval}(G_2)$ hold?

Similarly we can define the *compressed uniform membership problem* for a class \mathcal{C} of languages. Here we have to specify the representation of a language from \mathcal{C} . For various representations of regular languages, the complexity of the uniform compressed membership problem was investigated in [55]. The upper bound in the following result was also stated in [55].

THEOREM 9.1. *The compressed uniform membership problem for the class of all context-free languages (represented by context-free grammars) is PSPACE-complete.*

Proof. The lower bound follows from Corollary 6.7. For the upper bound it was argued in [55] that one can use a $DSPACE(\log^2(n))$ algorithm for parsing context-free languages in the same way as in the proof of Corollary 6.7. But here, a problem arises: The uniform membership problem for context-free languages is P-complete, and thus probably not contained in $\bigcup_{c>0} DSPACE(\log^c(n))$. On the other hand, by [26] the uniform membership problem for context-free grammars in *Chomsky normal form* can be solved in $DSPACE(\log^2(|G| + |w|))$, where $|G|$ is the size of the input grammar and w is the word that has to be tested for membership. Since every context-free grammar can be transformed in polynomial time into Chomsky normal form, we can argue analogously to the proof of Proposition 6.1. \square

APPROXIMATION BOUNDS FOR A GENERAL CLASS OF PRECEDENCE CONSTRAINED PARALLEL MACHINE SCHEDULING PROBLEMS*

MAURICE QUEYRANNE[†] AND ANDREAS S. SCHULZ[‡]

Abstract. An important class of scheduling problems concerns parallel machines and precedence constraints. We consider precedence delays, which associate with each precedence constraint a certain amount of time that must elapse between the completion and start times of the corresponding jobs. Together with ordinary precedence constraints, release dates and delivery times can be modeled in this manner. We present a 4-approximation algorithm for the total weighted completion time objective for this general class of problems. The algorithm is a rather simple form of list scheduling. The list is in order of job midpoints derived from a linear programming relaxation. Our analysis unifies and simplifies that of a number of special cases heretofore separately studied, while actually improving many of the former approximation results.

Key words. approximation algorithm, linear programming relaxation, performance guarantee, precedence constraints, scheduling

1. Introduction. Scheduling problems with precedence constraints are among the most difficult problems in the area of machine and processor scheduling, in particular for the design of good approximation algorithms. Our understanding of the structure of these problems and our ability to generate near-optimal solutions remain limited. The following examples illustrate this point:

(i) The first approximation algorithm for $P|\text{prec}|C_{\max}$ by Graham (1969) with performance ratio $2 - 1/m$ is still the algorithm of choice for this problem. On the other hand, it is known only that no polynomial-time algorithm can have a better approximation ratio than $4/3$, unless $P = NP$ (Lenstra and Rinnooy Kan (1978)).

(ii) The computational complexity of the problem $Pm|\text{prec}, p_j = 1|C_{\max}$, open problem “OPEN8” from the original list of Garey and Johnson (1979), is still open.

(iii) No constant-factor approximation algorithms are known for machines running at different speeds. For the makespan and total weighted completion time objectives, Chudak and Shmoys (1999) only recently improved to $O(\log m)$ performance ratios of $O(\sqrt{m})$ due to Jaffe (1980) and Schulz (1996a), respectively.

(iv) Progress is also quite recent for the latter objective on a single machine or identical parallel machines. Until recently, no constant-factor approximation algorithms were known. Lately, the use of linear programming (LP) relaxations has led to 2- and 2.7183-approximation algorithms for $1|\text{prec}|\sum w_j C_j$ and $1|r_j, \text{prec}|\sum w_j C_j$, respectively (Schulz (1996b), Schulz and Skutella (1997)), and to a 5.3281-approximation algorithm for $P|r_j, \text{prec}|\sum w_j C_j$ (Chakrabarti et al. (1996)). (Since then, Chudak

and Hochbaum (1999), Chekuri and Motwani (1999), and Margot, Queyranne, and Wang (2003) have proposed various combinatorial 2-approximation algorithms for $1|\text{prec}|\sum w_j C_j$. Few deep negative results are known for these problems (Hoogeveen, Schuurman, and Woeginger (2001)).

We consider (a generalization of) the scheduling problem $P|r_j, \text{prec}|\sum w_j C_j$ and answer a question of Hall et al. (1997, page 530), which they raised in the context of a 7-approximation algorithm for this problem:

Unfortunately, we do not know how to prove a good performance guarantee for this model by using a simple list-scheduling variant.

We show that using a similar LP relaxation as Hall et al. (1997) and Chakrabarti et al. (1996) in a different way (reading the list order from the LP midpoints instead of LP completion times) yields a simple 4-approximation algorithm for $P|r_j, \text{prec}|\sum w_j C_j$. We actually obtain this result in the more general framework of precedence delays.

Let us describe the model in detail. We are given a set N of n jobs, and m identical parallel machines. Each job j has a nonnegative processing time p_j ; it must be processed uninterruptedly for that amount of time on any one of the machines. Each machine can process only one job at a time. An acyclic, directed graph $D = (N, A)$ specifies precedence constraints between jobs. A nonnegative precedence delay d_{ij} is associated with each precedence-constrained job pair $(i, j) \in A$, with the following meaning: in every feasible schedule, job j cannot start until d_{ij} time units after job i is completed. Precedence delays can be used to model ordinary precedence constraints ($d_{ij} = 0$), release dates $r_j \geq 0$ (by adding a dummy job 0 with zero processing time and precedence delays $d_{0j} = r_j$ for all other jobs), or delivery times $q_j \geq 0$, which must elapse between the end of a job's processing and its actual completion time.

Precedence delays were considered for project scheduling under the name of "finish-to-start lags," e.g., by Bartusch, Möhring, and Radermacher (1988) and Herroelen and Demeulemeester (1995), for one-machine scheduling by Wikum, Llewellyn, and Nemhauser (1994) under the name of "generalized precedence constraints," and by Balas, Lenstra, and Vazacopoulos (1995) under that of "delayed precedence constraints"; the latter authors used the L_{\max} minimization problem as a key relaxation in a modified version of the shifting bottleneck procedure for the classic job-shop scheduling problem. The one-machine problem $1|\text{prec. delays } d_{ij} = k, p_j = 1|C_{\max}$ corresponds to a basic pipeline scheduling problem; see Lawler et al. (1987) for a survey. Leung, Vornberger, and Witthoff (1984) showed that this problem is strongly NP-complete. Several other authors, including Bruno, Jones III, and So (1980), Bernstein and Gertner (1989), Palem and Simons (1993), Finta and Liu (1996), and Brucker and Knust (1999), derived polynomial-time algorithms for particular instances by utilizing well-known algorithms for special cases of the classical m -machine problem. In the context of approximation algorithms, Hall and Shmoys (1989, 1990, 1992) presented polynomial-time approximation schemes for the problems $1|r_j, q_j|C_{\max}$, $P|r_j, q_j|C_{\max}$, and $1|r_j, \text{prec. } q_j|C_{\max}$, respectively. Schuurman (1998) gave a fully polynomial-time approximation scheme for $1|\text{prec. delays } d_{ij}|C_{\max}$ when the partial order A has a special structure introduced by Wikum, Llewellyn, and Nemhauser (1994). Graham's list-scheduling algorithm (Graham (1969)) was extended to $P|\text{prec. delays } d_{ij} = k, p_j = 1|C_{\max}$ to yield a worst-case performance ratio of $2 - 1/(m(k + 1))$ (Lawler et al. (1987), Palem and Simons (1993)). This result was in turn extended by Munier to nonidentical precedence delays and processing times; see Munier, Queyranne, and Schulz (1998) for details. We refer to Brucker and Knust (1999) for an overview of complexity results for single-machine problems with precedence delays, including polynomially solvable cases with total completion time objective.

For given nonnegative job weights $w_j \geq 0$, we consider the objective of minimizing the weighted sum $\sum_{j \in N} w_j C_j$ of completion times. Here, C_j denotes the completion time of job j in the corresponding schedule. Even special cases of this problem P|prec. delays d_{ij} | $\sum w_j C_j$ are NP-hard;¹ we therefore discuss the quality of relaxations and approximation algorithms. An α -approximation algorithm is a polynomial-time algorithm that produces a solution with objective value at most α times the optimal value. Sometimes α is called the (worst-case) performance guarantee of the algorithm. Similarly, an α -relaxation is a relaxation with objective value at least $1/\alpha$ times the optimal value.

For P|prec. delays d_{ij} | $\sum w_j C_j$, we present in section 3 a new algorithm with a performance guarantee of 4. This algorithm is based on an LP relaxation of this problem, which is a direct extension of earlier LP relaxations proposed by Schulz (1996b) and Hall et al. (1997). The decision variables are the job completion times C_j ; in particular, this relaxation ignores the machine assignments. There are two sets of linear constraints: one represents the precedence delays in a straightforward fashion; the other set of constraints is a relatively simple way of enforcing the total capacity of the m machines. Although the machine assignments are ignored and the machine capacities are modeled in a simplistic way, this is sufficient to obtain the best relaxation and approximation bounds known so far for these problems and several special cases thereof. We show that using job midpoints (instead of completion times) derived from the LP relaxation leads to a performance ratio of 4 for the general problem described above. In a given schedule, the midpoint of a job is the earliest point in time at which half of its processing has been performed; if the schedule is nonpreemptive, then the midpoint of job j is simply $C_j - p_j/2$. Midpoints and more general notions of α -points have previously been used in the design and analysis of approximation algorithms for a variety of scheduling problems with the weighted sum of completion times objective; see, e.g., Phillips, Stein, and Wein (1998), Hall, Shmoys, and Wein (1996), Goemans (1997), Chekuri et al. (2001), Goemans et al. (2002), and Schulz and Skutella (2002a, 2002b).

In summary, the contributions of this paper are as follows:

(i) We shed further light on the relationship between two forms of list-scheduling algorithms: Graham's nonidling, machine-based list scheduling and job-driven list scheduling.² It is well known that the former is appropriate for optimizing objectives, such as the makespan C_{\max} , that are related to maximizing machine utilization, whereas they are inappropriate (leading to unbounded performance ratio) for job-oriented objectives, such as the weighted sum of completion times $\sum_j w_j C_j$. This difficulty was recognized by, among others, Chekuri et al. (2001), who proposed a variant of machine-based list scheduling that allows for insertion of idle time, using a mechanism for "charging" such idle time to jobs. This technique leads to a 5.8285-approximation algorithm for P| r_j , prec| $\sum w_j C_j$. We show that job-driven list-scheduling algorithms have bounded performance ratio for the $\sum_j w_j C_j$ objective if the priority list is sensibly chosen.

(ii) Using job completion times as a basis for job-driven list scheduling may yield very poor schedules for problems with parallel machines, precedence constraints, and a weighted sum of completion times objective. This may happen even if the completion

¹For example, P2| $\sum w_j C_j$, 1| r_j | $\sum w_j C_j$, and 1|prec| $\sum w_j C_j$ are NP-hard (Bruno, Coffman, Jr., and Sethi (1974), Lenstra, Rinnooy Kan, and Brucker (1977), Lawler (1978), Lenstra and Rinnooy Kan (1978)).

²Sometimes also called the parallel and serial methods; see Kolisch (1996) for a recent review in the context of resource-constrained project scheduling.

times are those of an optimal schedule. In contrast, we show that job-driven list scheduling according to job midpoints from an appropriate LP relaxation leads to job-by-job error bounds of at most 4 for a broad class of problems.

(iii) The general model of scheduling with precedence delays allows us to treat in a unified framework ordinary precedence constraints and release dates. In particular, this simplifies and unifies the analysis and proof techniques.

(iv) We present the best polynomial-time approximation bounds known so far for a broad class of parallel machine scheduling problems with precedence constraints or delays and a total weighted completion time objective. These approximation results are summarized in Table 1.1.

2. List-scheduling algorithms. List-scheduling algorithms, first analyzed by Graham (1966, 1969), are among the simplest and most commonly used approximate solution methods for parallel machine scheduling problems. These algorithms use priority rules, or job rankings. Whenever one of the m machines becomes idle, the next available job in the list is started on that machine. In the presence of precedence constraints, a job is available if all of its predecessors have completed processing. By their nonidling property, Graham's list-scheduling algorithms are appropriate when machine utilization is an important consideration. Indeed, Graham (1969) showed that list scheduling is a $(2 - 1/m)$ -approximation algorithm for P|prec| C_{\max} , no matter which priority order is used. In contrast, the two examples below show that the nonidling property may lead to poor performance ratios for a weighted sum of completion times objective $\sum_j w_j C_j$.

Example 2.1. Consider the following two-job instance of the single-machine non-preemptive scheduling problem 1| r_j | $\sum w_j C_j$ (a special case of a precedence delay problem, as discussed in the introduction). For a parameter $q \geq 2$, job 1 has $p_1 = q$, $r_1 = 0$, and $w_1 = 1$, whereas job 2 has $p_2 = 1$, $r_2 = 1$, and $w_2 = q^2$. The optimal strategy is to leave the machine idle during the time interval $[0, 1)$ so as to process job 2 first. The optimum objective value is $2q^2 + q + 2$. Any nonidling heuristic starts processing job 1 at time 0, leading to an objective value of $q^3 + q^2 + q$. The performance ratio is unbounded as q may be arbitrarily large. \square

The following example is of the same type but uses ordinary precedence constraints instead of release dates.

Example 2.2. Consider an instance with $m \geq 3$ machines and three types of jobs. Unit-time job 1 precedes jobs $a(1), a(2), \dots, a(m)$, each of which has processing time 1 as well. Jobs $b(1), b(2), \dots, b(m-1)$ are independent and have processing time m each. Job 1 and jobs $b(1), b(2), \dots, b(m-1)$ have zero weight, whereas $w_{a(h)} = 1$ for

$h = 1, 2, \dots, m$. The optimal schedule starts job 1 at time 0 on some machine and leaves $m - 1$ machines idle during the time interval $[0, 1)$ so as to complete all jobs $a(1), a(2), \dots, a(m)$ by time 2. Hence, its objective value is $2m$. Any form of Graham's machine-based list scheduling starts processing jobs $b(1), b(2), \dots, b(m - 1)$ at time 0. These jobs occupy their machines until time m , forcing jobs $a(1), a(2), \dots, a(m)$ onto the same machine as job 1, which results in an objective value of $(m + 1)(m + 2)/2 - 1$. Therefore, the performance ratio increases with m . \square

Evidently, the appropriate introduction of idle time is an important element in the design of approximation algorithms to minimize a weighted sum of completion times subject to precedence delays. As Examples 2.1 and 2.2 illustrate, idle time is needed to prevent large-weight jobs, which may soon become available, from being delayed by other, less important jobs.³ On the other hand, too much idle time is undesirable as well. The necessity to balance these two effects contributes to the difficulty of this problem. All former approximation algorithms for $P|r_j, \text{prec}|\sum w_j C_j$ with constant-factor performance ratios are based on variants of Graham's original list scheduling, which actually tries to avoid machine idle time. In fact, Hall et al. (1997) partitioned jobs into groups that are individually scheduled according to Graham's list-scheduling rule, and then these schedules are concatenated to obtain a solution for the original problem. To find a good partition, this scheme was enriched with randomness by Chakrabarti et al. (1996). Chekuri et al. (2001) presented a different variant of Graham's list scheduling by artificially introducing idle time whenever it seems that a further delay of the next available job in the list (if it is not the first) can be afforded. It is worth mentioning that these techniques, analyses, and approximation results also generalize to precedence delays.

Another, arguably simpler, strategy is to consider the jobs one by one, in the given list order, starting from an empty schedule. Each job is nonpreemptively inserted into the current schedule without altering the jobs already scheduled. Specific job-driven list-scheduling algorithms differ in how this principle is implemented. For definiteness, consider the version in Figure 2.1, whereby every job is considered in the list order and is scheduled at the earliest feasible time at the end of the current schedule on a machine. We assume that the given list is a linear extension of the partial order defined by the precedence constraints.

1. The list $L = (\ell(1), \ell(2), \dots, \ell(n))$ is given.
2. Initially, all machines are empty, with machine completion times $\Gamma_h := 0$ for $h = 1, 2, \dots, m$.
3. For $k = 1$ to n do:
 - 3.1 Let job $j = \ell(k)$; set its start time $S_j := \max(\max\{C_i + d_{ij} : (i, j) \in A\}, \min\{\Gamma_h : h = 1, 2, \dots, m\})$ and its completion time $C_j := S_j + p_j$.
 - 3.2 Assign job j to a machine h such that $\Gamma_h \leq S_j$. Update $\Gamma_h := C_j$.

FIG. 2.1. *Job-driven list-scheduling algorithm for $P|\text{prec. delays } d_{ij}|\sum w_j C_j$.*

Various rules may be used in step 3.2 for the choice of the assigned machine h , for example, one with largest completion time Γ_h (so as to reduce the idle time between Γ_h and S_j). Moreover, the above algorithm can be modified to allow the insertion of

³It is important to point out that this difficulty results from the nonpreemptive mode; Graham's list scheduling with jobs ordered according to LP completion times gives a 3-approximation for $P|r_j, \text{prec, pmtn}|\sum w_j C_j$ (Hall et al. (1997)).

a job in an idle period before time Γ_h . In effect, the observations below also apply to all these variants.

One method (e.g., Phillips, Stein, and Wein (1998) and Hall et al. (1997)) for defining the list L consists of sorting the jobs in nondecreasing order of their completion times in a relaxation of the scheduling problem under consideration. In the presence of ordinary precedence constraints, this works well for the case of a single machine (Schulz (1996b), Hall et al. (1997)), but Example 2.3 shows that this may produce very poor schedules for the case of identical parallel machines. This example uses the list which is produced by an optimal schedule, the tightest kind of relaxation that can be defined; moreover, this optimal schedule defines the same completion time order as the LP relaxation in section 3.1.

Example 2.3. For a fixed number $m \geq 2$ of identical parallel machines and a positive number ϵ , let the job set N consist of m sets J_h ($h = 1, 2, \dots, m$) of $m + 1$ jobs each, plus a “last job” n . (Thus $n = m(m + 1) + 1$.) Each set J_h consists of a “long job” $a(h)$, with processing time $p_{a(h)} = 1 + (h - 1)(m + 1)\epsilon$, and m “small jobs” $b(h, g)$ (for $g = 1, 2, \dots, m$), each with processing time $p_{b(h, g)} = \epsilon$ and subject to the precedence constraint $(a(h), b(h, g))$. In addition, there is a precedence constraint $(b(h, g), n)$ from each small job $b(h, g)$ (for $h = 1, 2, \dots, m$ and $g = 1, 2, \dots, m$) to the last job n , which has processing time ϵ . The objective is to minimize either the makespan or a weighted sum $\sum_j w_j C_j$ of job completion times with weights $w_j = 0$ for all $j \neq n$ and $w_n = 1$; due to the precedence constraints, these two objectives coincide for any feasible schedule. An optimal schedule has, for $h = 1, 2, \dots, m$, long job $a(h)$ starting at time $S_{a(h)}^* = 0$ on machine h , immediately followed by all small jobs $b(h, g)$ (for $g = 1, 2, \dots, m$) in the same set J_h , assigned as uniformly as possible to machines $1, 2, \dots, h$. Note that all the jobs in J_h are completed before the next long job $a(h + 1)$ completes. Job n is then processed last on any machine, so that the optimal objective value is $C_{\max}^* = C_n^* = 1 + (m^2 + 1)\epsilon$. On the other hand, any version of the job-driven list-scheduling algorithm with all jobs listed in order of their optimal completion times produces the following schedule: long job $a(1)$ is scheduled first, with start time $S_{a(1)}^L = 0$ and completion time $C_{a(1)}^L = 1$; the m small jobs $b(1, g)$ (for $g = 1, 2, \dots, m$) in J_1 are then scheduled, each with start time $S_{b(1, g)}^L = 1$ and completion time $C_{b(1, g)}^L = 1 + \epsilon$ on a different machine; this forces all subsequent jobs to be scheduled no earlier than date $1 + \epsilon$. Consequently, for $h = 1, 2, \dots, m$, long job $a(h)$ is scheduled with start time $S_{a(h)}^L = (h - 1) + (h - 1)(h - 1)(m + 1)/2\epsilon$, followed by all small jobs $b(h, g)$ (for $g = 1, 2, \dots, m$) in the same set J_h , each with start time $S_{b(h, g)}^L = S_{a(h)}^L + p_{a(h)}$ on a different machine. Finally, job n is scheduled last with $S_n^L = m + (m + m(m - 1)(m + 1)/2)\epsilon$, and thus the objective value is $C_{\max}^L = C_n^L = m + o(\epsilon)$, arbitrarily close to m times the optimal value C_{\max}^* when $\epsilon > 0$ is small enough. \square

3. LP-based approximation algorithms. In this section we present an LP relaxation for the problem of minimizing a weighted sum $\sum_j w_j C_j$ of job completion times subject to precedence delays, and use it to develop a 4-approximation algorithm for this problem. Thereafter, we refine the analysis to give improved bounds for various relevant special cases.

3.1. The LP relaxation. The decision variables are the job completion times C_j . The set of constraints is

$$(3.1) \quad C_j \geq p_j \quad \text{for all } j \in N,$$

$$(3.2) \quad C_j \geq C_i + d_{ij} + p_j \quad \text{for all } (i, j) \in A,$$

$$(3.3) \quad \sum_{j \in F} p_j C_j \geq \frac{1}{2m} \left(\sum_{j \in F} p_j \right)^2 + \frac{1}{2} \sum_{j \in F} p_j^2 \quad \text{for all } F \subseteq N.$$

This relaxation is an extension of a relaxation introduced by Hall et al. (1997) for $P|r_j, \text{prec}|\sum w_j C_j$: on the one hand, ordinary precedence constraints are replaced by inequalities (3.2), which model the precedence delays; on the other hand, inequalities (3.3) are stronger than the analogous class of inequalities used by Hall et al. (1997). Our analysis requires this strengthened class of inequalities, which was proposed by Schulz (1996b). For $m = 1$ (the single-machine case), they are identical to inequalities introduced by Wolsey (1985) to model the constraint that the machine can process at most one job at a time; see Queyranne (1993) for further details. Constraints (3.1) impose the trivial lower bounds on job completion times.

For a weighted sum of completion times objective, the LP formulation is simply

$$(3.4) \quad \text{minimize } \sum_{j \in N} w_j C_j \quad \text{subject to (3.1)–(3.3).}$$

Although there is an exponential number of constraints in (3.3), the separation problem for these inequalities can be solved in polynomial time (Schulz 1996a). It follows that this LP relaxation can be solved in polynomial time, using the ellipsoid method.

3.2. The approximation algorithm. Let C^{LP} denote any feasible solution to the constraint set (3.1)–(3.3) of this LP. We use this LP solution to define a feasible schedule with completion time vector C^{H} and analyze the job-by-job relationship between C_j^{H} and C_j^{LP} for every job $j \in N$. We define the LP midpoint as $M_j^{\text{LP}} := C_j^{\text{LP}} - p_j/2$. We now use the list-scheduling algorithm of Figure 2.1 with the LP midpoint list L defined by sorting the jobs in nondecreasing order of their midpoints M_j^{LP} . The next theorem contains our main result.

THEOREM 3.1. *Let C^{LP} denote any feasible solution to the constraint set (3.1)–(3.3), and let M^{LP} denote the corresponding vector of LP midpoints. Let S^{H} be the vector of start times of the feasible schedule constructed by the job-driven list-scheduling algorithm using the LP midpoint list. Then*

$$(3.5) \quad S_j^{\text{H}} \leq 4 M_j^{\text{LP}} \quad \text{for all jobs } j \in N.$$

Proof. Assume for simplicity that the jobs are indexed in the order of their LP midpoints; that is, $M_1^{\text{LP}} \leq M_2^{\text{LP}} \leq \dots \leq M_n^{\text{LP}}$. We fix job $j \in N$ and consider the schedule constructed by the list-scheduling heuristic using the LP midpoint list $L = (1, 2, \dots, n)$ up to and including the scheduling of job j , that is, up to the completion of step 3 with $k = j$. Let $[j] := \{1, 2, \dots, j\}$.

Let μ denote the total time between 0 and the start time S_j^{H} of job j when all m machines are busy at this stage of the algorithm. Since only jobs in $[j - 1]$ have been scheduled so far, $\mu \leq \sum_{i=1}^{j-1} p_i/m$. Let $\lambda := S_j^{\text{H}} - \mu$. To prove (3.5), we need only show that

$$(i) \quad \frac{1}{m} \sum_{i=1}^{j-1} p_i \leq 2M_j^{\text{LP}} \quad \text{and} \quad (ii) \quad \lambda \leq 2M_j^{\text{LP}}.$$

Inequality (i) follows from a straightforward variant of Lemma 1 in Schulz (1996b) or Lemma 3.2 in Hall et al. (1997). For this, first observe that the inequalities (3.3) are

equivalent to

$$\sum_{i \in F} p_i M_i \geq \frac{1}{2m} \left(\sum_{i \in F} p_i \right)^2 \quad \text{for all } F \subseteq N.$$

Since M^{LP} satisfies all these inequalities, letting $F = [j-1]$ and using $M_1^{\text{LP}} \leq M_2^{\text{LP}} \leq \dots \leq M_j^{\text{LP}}$, we obtain

$$\left(\sum_{i=1}^{j-1} p_i \right) M_j^{\text{LP}} \geq \sum_{i=1}^{j-1} p_i M_i^{\text{LP}} \geq \frac{1}{2m} \left(\sum_{i=1}^{j-1} p_i \right)^2,$$

implying (i).

To show (ii), let q denote the number of maximal intervals between dates 0 and S_j^{H} when at least one machine is idle (i.e., not processing a job in $[j-1]$) in the schedule C^{H} . Denote these idle intervals as $[a_h, b_h)$ for $h = 1, 2, \dots, q$, so that $0 \leq a_1, b_{h-1} < a_h < b_h$ for all $h = 2, \dots, q$, and $b_q \leq S_j^{\text{H}}$. Hence, $\lambda = \sum_{h=1}^q (b_h - a_h)$ and all machines are busy during the complementary intervals $[b_h, a_{h+1})$, including intervals $[0, a_1)$ and $[b_q, S_j^{\text{H}})$, if nonempty.

Consider the digraph $G^{[j]} = ([j], A^{[j]})$, where

$$A^{[j]} := \{(k, \ell) \in A : k, \ell \in [j] \text{ and } C_\ell^{\text{H}} = C_k^{\text{H}} + d_{k\ell} + p_\ell\}.$$

That is, $A^{[j]}$ is the set of precedence pairs in $[j]$ for which the precedence delay constraints (3.2) are tight for C^{H} . If $b_q > 0$, then a machine becomes busy at date b_q (or starts processing job j if $b_q = S_j^{\text{H}}$) and thus there exists a job $x(q) \in [j]$ with start time $S_{x(q)}^{\text{H}} = b_q$. Since $x(q) \in [j]$ we have $M_{x(q)}^{\text{LP}} \leq M_j^{\text{LP}}$. We repeat the following process for decreasing values of the interval index h , starting with $h = q$, until we reach the date 0 or the busy interval $[0, a_1)$. Let $(v(1), \dots, v(s))$ denote a maximal path in $G^{[j]}$ with last node (job) $v(s) = x(h)$. Note that we must have $b_g < S_{v(1)}^{\text{H}} \leq a_{g+1}$ for some busy interval $[b_g, a_{g+1})$ with $a_{g+1} < b_h$, for otherwise some machine is idle immediately before the start time $S_{v(1)}^{\text{H}}$ of job $v(1)$ and this job, not being constrained by any tight precedence delay constraint, should have started earlier than that date. (Unless $S_{v(1)}^{\text{H}} = 0$, of course. In this case, a_{g+1} is the first point in time at which some machine falls idle.) We have

$$(3.6) \quad b_h - a_{g+1} \leq S_{v(s)}^{\text{H}} - S_{v(1)}^{\text{H}} = \sum_{i=1}^{s-1} (S_{v(i+1)}^{\text{H}} - S_{v(i)}^{\text{H}}) = \sum_{i=1}^{s-1} (p_{v(i)} + d_{v(i)v(i+1)}).$$

On the other hand, the precedence delay constraints (3.2) imply

$$M_{v(i+1)}^{\text{LP}} \geq M_{v(i)}^{\text{LP}} + \frac{1}{2} p_{v(i)} + d_{v(i)v(i+1)} + \frac{1}{2} p_{v(i+1)}$$

for all $i = 1, 2, \dots, s-1$. Therefore,

$$M_{x(h)}^{\text{LP}} - M_{v(1)}^{\text{LP}} \geq \frac{1}{2} \sum_{i=1}^{s-1} (p_{v(i)} + d_{v(i)v(i+1)}) \geq \frac{1}{2} (b_h - a_{g+1}).$$

If $b_g > 0$, then let $x(g)$ be a job with $S_{x(g)}^{\text{H}} = b_g$. Because of the order of jobs in the priority list L , $S_{x(g)}^{\text{H}} < S_{v(1)}^{\text{H}}$ implies $M_{x(g)}^{\text{LP}} \leq M_{v(1)}^{\text{LP}}$. Therefore,

$$(3.7) \quad M_{x(h)}^{\text{LP}} - M_{x(g)}^{\text{LP}} \geq \frac{1}{2} (b_h - a_{g+1}).$$

We also have $(k, x(g)) \in A^{[j]}$ for some $k \in [j]$ with $S_k^H < b_g = S_{x(g)}^H$, for otherwise job $x(g)$ should have started processing on some idle machine before date b_g . We may thus repeat the above process with $h = g$ and job $x(h) = x(g)$. Since $g < h$ at each step, this whole process must terminate, generating a decreasing sequence of indices $q = H(1) > \dots > H(q') = 0$ such that every idle interval is contained in some interval $[a_{H(i+1)+1}, b_{H(i)}]$. Adding the corresponding inequalities (3.7), we obtain

$$(3.8) \quad \lambda \leq \sum_{i=1}^{q'-1} (b_{H(i)} - a_{H(i+1)+1}) \leq 2(M_{x(H(1))}^{LP} - M_{x(H(q'))}^{LP}) \leq 2(M_j^{LP} - 0).$$

This establishes (ii). The proof of Theorem 3.1 is complete. \square

The following example shows that the factor 4 in inequality (3.5) is (asymptotically) best possible, even for ordinary precedence constraints only.

Example 3.2. For a given number $m \geq 2$ of identical parallel machines, the job set N includes m sets J_h (for $h = 1, 2, \dots, m$) of $m + 1$ jobs each: a job $a(h)$ with processing time $p_{a(h)} = 2^{h-1-m}$, and m “small jobs” $b(h, g)$ (for $g = 1, 2, \dots, m$), each with processing time $p_{b(h,g)} = 0$ and subject to the ordinary precedence constraint $(a(h), b(h, g))$ (with zero delay). In addition, there are m “unit jobs” $u(i)$ (for $i = 1, 2, \dots, m$) with processing time $p_{u(i)} = 1$, and two jobs, $n - 1$ and n , with processing times $p_{n-1} = 2/m$ and $p_n = 0$ (thus $n = (m + 1)^2 + 1$). There are two additional (ordinary) precedence constraints: $a(m)$ precedes $n - 1$ and $n - 1$ precedes n .

For sufficiently large m , the following solution C^{LP} is feasible for constraints (3.1)–(3.3): $C_j^{LP} = p_{a(h)} = 2^{h-1-m}$ for all jobs $j \in J_h$, for $h = 1, 2, \dots, m$; $C_{u(i)}^{LP} = 1 + 2/m$ for all unit jobs $u(i)$; and $C_{n-1}^{LP} = C_n^{LP} = M_n^{LP} = p_{a(m)} + p_{n-1} = 1/2 + 2/m$. Therefore, an LP midpoint list starts with sets J_1, J_2, \dots, J_m (each with its medium job before all its small jobs), followed by job $n - 1$, all unit jobs $u(i)$, and finally job n . This LP midpoint list produces the following schedule. First schedule the sets J_h in sequence $h = 1, 2, \dots, m$, beginning with the medium job $a(h)$ on one machine (starting just after set $J(h - 1)$ is complete), immediately followed by the m small jobs in J_h , each on a different machine. All jobs j in J_h have completion time $C_j^H = \sum_{i=1}^h p_{a(i)} = 2^{h-m} - 2^{-m}$; since all machines are occupied at that date, this forces all subsequent jobs to start no earlier than that date. After the last set J_m is complete, schedule job $n - 1$ and $m - 1$ unit jobs $u(i)$, each on a different machine. After this, start the remaining unit job on the same machine as job $n - 1$. The first $m - 1$ unit jobs have completion time $C_{u(i)}^H = 2 - 2^{-m}$. Finally, start job n at date $S_n^H = 2 - 2^{-m}$. For m large enough, the latter expression is arbitrarily close to $4M_n^{LP} = 2 + 8/m$. \square

If C^{LP} is an optimal LP solution, Theorem 3.1 implies performance ratios of $1/4$ and 4 for the LP relaxation and the heuristic solution, respectively.

COROLLARY 3.3. *Let C^{LP} denote an optimal solution to the LP relaxation defined in (3.4) for the problem $P|\text{prec. delays } d_{ij}|\sum w_j C_j$. Let C^H denote the solution constructed from C^{LP} by the job-driven list-scheduling algorithm using the LP midpoint list, and let C^* denote an optimum schedule. Then,*

$$(3.9) \quad \sum_{j \in N} w_j C_j^{LP} \geq \frac{1}{4} \sum_{j \in N} w_j C_j^* \quad \text{and} \quad \sum_{j \in N} w_j C_j^H \leq 4 \sum_{j \in N} w_j C_j^*.$$

The following example shows that the latter bound is (asymptotically) tight, even for ordinary precedence constraints only, i.e., for problem $P|\text{prec. delays } d_{ij}|\sum w_j C_j$.

Example 3.4. In Example 3.2, let the weights be $w_n = 1$ and all other $w_j = 0$, so that the optimum solution has $\sum_{j \in N} w_j C_j^* = w_n(p_{a(m)} + p_{n-1} + p_n) = 1/2 + 2/m$. Since the precedence constraints (3.2) and the lower bounds (3.1) imply $C_n^{\text{LP}} \geq p_{a(m)} + p_{n-1} + p_n = 1/2 + 2/m$, the solution C^{LP} described in Example 3.2 is optimal for the LP relaxation (3.4); its objective value is $\sum_{j \in N} w_j C_j^{\text{LP}} = 1/2 + 2/m = \sum_{j \in N} w_j C_j^*$. Using the LP midpoint list produces the schedule described in the above example, with $\sum_{j \in N} w_j C_j^{\text{H}} = 2 - 2^{-m}$. For m large enough, the latter expression is arbitrarily close to $4 \sum_{j \in N} w_j C_j^*$. \square

We suspect that the first inequality in (3.9), bounding the performance ratio of the LP relaxation, is not tight. The worst instances we know arise actually for $m = 1$ and lead to a gap of 2; see Hall et al. (1997) for details.

3.3. Special cases. The analysis in Theorem 3.1 can be refined for some special cases, yielding tighter performance ratios. For the problem $\text{P|prec|} \sum w_j C_j$, observe that the list-scheduling algorithm will not allow all machines to be simultaneously idle at any date before the start time of any job $j \in N$. Therefore, in the proof of Theorem 3.1, all the idle intervals, with total length λ , contain some processing of some job(s) $i < j$; as a result the total work during the busy intervals is at most $\sum_{i=1}^{j-1} p_i - \lambda$. Hence, we obtain the following result.

COROLLARY 3.5. *Job-driven list scheduling by optimal LP midpoints is a $(4 - 2/m)$ -approximation algorithm for the scheduling problem $\text{P|prec|} \sum w_j C_j$.*

Note that for $m = 1$ we recover the performance ratio of 2 for $1|\text{prec}| \sum w_j C_j$ in Schulz (1996b), which is known to be tight for that special case (Hall et al. (1997)).

In the case of precedence delays and a single machine, the idle intervals that add up to λ time units cannot contain any processing. Therefore, in the proof of Theorem 3.1 replace inequality (3.6) with $b_h - a_{g+1} \leq S_{v(s)}^{\text{H}} - C_{v(1)}^{\text{H}} = \sum_{i=1}^{s-1} d_{v(i)v(i+1)}$. (Note that, if all processing times are positive, then $s = 2$ and the summation in the right-hand side consists of a single term $d_{v(1)v(2)}$.) Adding up the precedence delay constraints (3.2) for all $i = 1, 2, \dots, s - 1$ and omitting some processing times yields $M_{x(h)}^{\text{LP}} - M_{v(1)}^{\text{LP}} \geq \sum_{i=1}^{s-1} d_{v(i)v(i+1)} \geq b_h - a_{g+1}$. Therefore, we may replace (3.8) with $\lambda \leq \sum_{i=1}^{q'-1} (b_{H(i)} - a_{H(i+1)+1}) \leq M_{x(H(1))}^{\text{LP}} - M_{x(H(q'))}^{\text{LP}} \leq M_j^{\text{LP}}$ and thus inequality (ii) with $\lambda \leq M_j^{\text{LP}}$. This implies $S_j^{\text{H}} \leq 3M_j^{\text{LP}}$.

COROLLARY 3.6. *Job-driven list scheduling by optimal LP midpoints is a 3-approximation algorithm for the scheduling problem $1|\text{prec. delays } d_{ij}| \sum w_j C_j$.*

Note that for the special case $1|r_j, \text{prec}| \sum w_j C_j$ we recover the performance ratio of 3 in Schulz (1996b). The best approximation algorithm known for this problem, however, has a performance guarantee of $e \approx 2.7183$ (Schulz and Skutella (1997)).

In principle, we may use any LP α -point $C_j^{\text{LP}}(\alpha) := C_j^{\text{LP}} - (1 - \alpha)p_j$ for some $0 \leq \alpha < 1$ in section 3.2. Indeed, inequality (i) in the proof of Theorem 3.1 can be replaced with $\sum_{i=1}^{j-1} p_i/m \leq 2C_j^{\text{LP}}(\alpha)$, provided that $\alpha \geq 1/2$. On the other hand, inequality (ii) becomes $\lambda \leq (1 - \alpha)^{-1}C_j^{\text{LP}}(\alpha)$. While it turns out that using the midpoint $M_j^{\text{LP}} = C_j^{\text{LP}}(1/2)$ leads to the best bound for the general case, we can take advantage of this observation for some special cases.

For example, if the LP midpoint list coincides with the LP start-time list (which is the case, e.g., if $p_i = p_j$ for all $i, j \in N$), then we can apply inequality (i) in the proof of Theorem 3.1 with $\alpha = 1/2$ to bound the total busy time, whereas we can use inequality (ii) with $\alpha = 0$ to bound the total idle time λ by $S_j^{\text{LP}} = C_j^{\text{LP}}(0)$. We obtain the following result.

COROLLARY 3.7. Let C^{LP} denote an optimal solution to the LP relaxation (3.4). If $M_1^{\text{LP}} \leq M_2^{\text{LP}} \leq \dots \leq M_n^{\text{LP}}$ implies $S_1^{\text{LP}} \leq S_2^{\text{LP}} \leq \dots \leq S_n^{\text{LP}}$, then job-driven list scheduling by LP midpoints is a 3-approximation algorithm for the problem $P|\text{prec. delays } d_{ij}|\sum w_j C_j$.

Because the arguments leading to Corollary 3.5 apply here as well, Corollary 3.7 actually gives a $(3-1/m)$ -approximation algorithm for this special case of $P|\text{prec}|\sum w_j C_j$. Hall et al. (1997) had earlier proved these performance ratios for the special cases $P|r_j, \text{prec}, p_j = 1|\sum w_j C_j$ and $P|\text{prec}, p_j = 1|\sum w_j C_j$, respectively.

Let us finally consider “stiff” instances of $P|\text{prec}|\sum w_j C_j$. Margot, Queyranne, and Wang (2003) called an instance (of the single-machine problem $1|\text{prec}|\sum w_j C_j$) stiff if $w(I)/p(I) \leq w(N)/p(N)$ for all initial sets $I \subseteq N$. A set I is initial if $j \in I$ and $(i, j) \in A$ imply $i \in I$. Chekuri and Motwani (1999) and Margot, Queyranne, and Wang (2003) showed that the total weighted completion time of any feasible one-machine schedule of a stiff instance is within a factor 2 of that of an optimum. Given an instance of $P|\text{prec}|\sum w_j C_j$, we define a corresponding single-machine instance with processing times p_j/m , and we keep the original job weights and precedence constraints. The objective value of an optimal solution to this single-machine instance is a lower bound on the cost of an optimal schedule C^* for the original instance on m identical parallel machines (Chekuri et al. (2001)). Let us argue that job-driven list scheduling according to optimal LP start times $S_j^{\text{LP}} = C_j^{\text{LP}} - p_j$ is a $(3 - 1/m)$ -approximation for stiff instances of $P|\text{prec}|\sum w_j C_j$. In fact, it suffices when C^{LP} is an optimal solution to the LP with constraint set (3.1)–(3.2), which can be solved combinatorially using shortest-path computations. That is, inequalities (3.3) are not needed. So, let L be defined by $S_1^{\text{LP}} \leq S_2^{\text{LP}} \leq \dots \leq S_n^{\text{LP}}$. From the preceding discussion, we already know that we can use inequality (ii) in the proof of Theorem 3.1 with $\alpha = 0$ to bound the total idle time λ by S_j^{LP} . It remains to bound $\sum_{i=1}^j p_i/m$. This time, we do not give a job-by-job bound, but bound the entire contribution of busy periods to the objective function value of the heuristic schedule. Let C^1 be the completion time vector of an optimal schedule to the corresponding single-machine instance. Note that $\sum_{i=1}^j p_i/m$ is the completion time of job j in the single-machine schedule where jobs are sequenced according to L . Hence, as the instance is stiff, $\sum_{j=1}^n w_j \sum_{i=1}^j p_i/m \leq 2 \sum_{j=1}^n w_j C_j^1$. Overall, we obtain

$$\begin{aligned} \sum_{j=1}^n w_j C_j^{\text{H}} &\leq \sum_{j=1}^n w_j \left(\sum_{i=1}^j p_i/m + (1 - 1/m)(S_j^{\text{LP}} + p_j) \right) \\ &\leq 2 \sum_{j=1}^n w_j C_j^1 + (1 - 1/m) \sum_{j=1}^n w_j C_j^{\text{LP}} \\ &\leq (3 - 1/m) \sum_{j=1}^n w_j C_j^*. \end{aligned}$$

COROLLARY 3.8. Let C^{LP} denote an optimal solution to the LP relaxation defined over (3.1)–(3.2). Job-driven list scheduling by LP start times is a combinatorial $(3 - 1/m)$ -approximation algorithm for stiff instances of the scheduling problem $P|\text{prec}|\sum w_j C_j$.

Finally, let us point out that Corollaries 3.5, 3.6, and 3.7 also imply corresponding bounds on the quality of the LP relaxation (3.4) for these special cases.

Acknowledgments. The authors are grateful to Alix Munier for helpful discussions and to Maxim Sviridenko for useful comments on an earlier version of this paper. They also thank the organizers of the workshop on “Parallel Scheduling” held July 14–18, 1997, at Schloß Dagstuhl, Germany, where this work was initiated.

OBLIVIOUS POLYNOMIAL EVALUATION*

MONI NAOR[†] AND BENNY PINKAS[‡]

Abstract. Oblivious polynomial evaluation is a protocol involving two parties, a sender whose input is a polynomial P , and a receiver whose input is a value α . At the end of the protocol the receiver learns $P(\alpha)$ and the sender learns nothing. We describe efficient constructions for this protocol, which are based on new intractability assumptions that are closely related to noisy polynomial reconstruction. Oblivious polynomial evaluation can be used as a primitive in many applications. We describe several such applications, including protocols for private comparison of data, for mutually authenticated key exchange based on (possibly weak) passwords, and for anonymous coupons.

Key words. cryptography, secure computation, noisy polynomial reconstruction

1. Introduction. A secure computation protocol for a function $f(\cdot, \cdot)$ allows two parties, a receiver who knows x and a sender who knows y , to jointly compute the value of $f(x, y)$ in a way that does not reveal to each side more information than it can learn from $f(x, y)$. The fact that for every polynomially computable function $f(\cdot, \cdot)$ there exists such a (polynomially computable) protocol is one of the most remarkable achievements of research in foundations of cryptography. However, the resulting protocols are often not as efficient as one would desire, since the number of cryptographic operations that should be performed is proportional to the *size of the circuit computing $f(x, y)$* [60]. Even for relatively simple functions this may be prohibitively expensive. It is therefore interesting to investigate for which functions it is possible to come up with a protocol that does not emulate a circuit computing the function.

1.1. Oblivious polynomial evaluation. In the oblivious polynomial evaluation (OPE) problem the input of the sender is a polynomial P of degree k over some field \mathcal{F} . The receiver can learn the value $P(x)$ for any element $x \in \mathcal{F}$ without learning anything else about the polynomial P and without revealing to the sender any information about x (for the precise definition of “learning” and “information” see section 1.2). We find this problem to be a useful primitive. For example, as it can act as a cheap replacement for pseudorandom functions in case only k -wise independence is needed.

Strongly polynomial overhead The overhead of an algorithm is strongly polynomial if it is bounded by a polynomial function of the number of data items in the input,

rather than a function of the *size* of the input values (e.g., the number of bits of numerical input values). In combinatorial optimization it is common to look for strongly polynomial algorithms for different problems, for example, for linear programming.

The computational overhead of cryptographic protocols is usually measured as the number of *public key operations*. We use this term to denote cryptographic operations which we do not know how to implement based on the existence of one-way functions, and for which the best known constructions are based on trapdoor functions, or on similar primitives. (In the context of this paper we usually only measure the number of invocations of a 1-out-of-2 oblivious transfer protocol.) Counting only public key operations is justified since the overhead of public key operations depends on the length of their inputs, and is greater by orders of magnitude than the overhead of symmetric key operations (i.e., operations based on one-way functions). Furthermore, the separation result of Impagliazzo and Rudich [38], and subsequent work, hint that it is unlikely that these operations can be based on the existence of one-way functions.

We say that a cryptographic protocol is *strongly polynomial* if the following two properties hold: (1) the number of public key operations performed by the protocol is bounded by a polynomial function of a security parameter and of the number of inputs (but not their size), and (2) the length of the inputs to the public key operations is linear in the security parameter. Note that the number of *symmetric* key operations that the protocol performs can be polynomial in the size of its inputs.

Known methods of implementing oblivious polynomial evaluation include generic protocols for secure two-party computation (e.g., [60]), or using homomorphic encryption (e.g., using Paillier’s encryption system [56]). However, none of these methods is strongly polynomial in the sense defined above: the number of oblivious transfer operations in the generic construction, as well as the size of the input to the homomorphic encryption function, is linear in the size of the receiver’s input in the OPE protocol.

In contrast, the number of oblivious transfers (OT) used by the OPE protocols presented in this paper does not depend on the size of the underlying field: the length of the items transferred in the oblivious transfer protocols is of size $\log |\mathcal{F}|$, but they require only $O(1)$ public key operations per transfer. Namely, if $\log |\mathcal{F}|$ is longer than the length of the input of the OT protocol, then the items to be transferred in the OT protocol are encrypted using random keys, and the corresponding keys are transferred in the actual OT protocol.

An alternative formulation of the “strongly polynomial” requirement for cryptographic protocols is to allow only “black box” access to field operations, while hiding the underlying field from the parties. In addition, the number of invocations of the black box must be independent of the size of the inputs. Note that our construction satisfies this requirement, whereas generic constructions, or constructions based on homomorphic encryption, do not.

It is interesting to note that the work on randomizing polynomials [36] implies that any function which has an efficient branching program representation can be efficiently reduced to computing polynomials. We explain in section 4.3 how to reduce two-party secure computation of such functions to OPE. In particular, this implies strongly polynomial protocols for computing any function which has an efficient branching program representation.

Our protocols can also be readily applied to oblivious computation of $g^{P(x)}$, where P is a polynomial, with no increase in their overhead, as described in section 4.1. In comparison, binary circuits that evaluate this function must compute exponentiations and are very large, and the overhead of the resulting secure protocols is high.

(Protocols based on homomorphic encryption, however, can compute $g^{P(x)}$ without increasing their overhead.) Oblivious evaluation of $g^{P(x)}$ yields k -wise independent outputs that might be useful for distributed implementations of public key operations.

The noisy polynomial reconstruction problem. The protocols we describe are based on intractability assumptions related to the noisy polynomial reconstruction problem. While being related to other computational problems, this problem has not been used before as an intractability assumption in a cryptographic protocol. Section 2 describes in detail the assumptions and the background. Interestingly, following the publication of the conference version of our work [51] Kiayias and Yung designed different cryptographic primitives which are based on variants of the noisy polynomial reconstruction problem [40, 41].

Overhead independent of the degree of the polynomial. We describe a protocol (Protocol 3.4) whose computational overhead (as measured by the number of 1-out-of-2 oblivious transfers that are computed) is independent of the degree of the polynomial. That is, for any degree d , the number of oblivious transfers that are required for an oblivious evaluation of a polynomial of degree d is the same as for a linear polynomial. (Of course, the total computation overhead of the evaluation of the polynomial depends on the degree of the polynomial, but the number of public key operations is independent of the degree.)

Applications. We envision two types of applications for oblivious polynomial evaluation. One is whenever k -wise independence can replace full independence or pseudorandomness (i.e., oblivious evaluation of a pseudorandom function, as in [54]). Such property is required, for example, for the application of constructing anonymous coupons that enable anonymous usage of limited resources (e.g., for constructing an anonymous complaint box). The other type of application uses OPE for preserving anonymity when the receiver must compute the value of a polynomial at a certain point. Applications of this nature include a protocol that allows reliable and privacy preserving metering (described in section 4.4), a method for distributed generation of RSA keys, designed by Gilboa [26], and a protocol for private computation of the ID3 data mining algorithms [45] (in that case the polynomial is used for a Taylor approximation of the logarithm function).

1.2. Correctness and security definitions. We now get to the delicate business of defining the security of oblivious polynomial evaluation. The OPE functionality requires privacy for both receiver and sender. In an OPE protocol neither party learns anything more than is defined by the OPE functionality. The strongest way of formalizing this notion and ensuring simple composability of the protocols is through the definition of secure two-party computation (see, e.g., Goldreich [29] and papers on composability, e.g., [10, 11]). However, this definition is rather complex, while there are many applications that do not require the full power of the general definition and could use “non-ideal” protocols. We therefore prefer to use a relaxed definition for OPE, which ensures privacy for both parties but does not require the sender to commit to its input (i.e., to commit to the polynomial P). We call this definition *private computation*. The definition of private computation is relevant also to the case of malicious parties (and is therefore stronger than a definition for the semi-honest case only). It preserves the privacy of the clients, but does not require simulation of the joint distribution of the view of a malicious sender and the output of an honest receiver, as is required by the general definition of secure computation.

We claim that this relaxation is justified by efficiency considerations, in particular when constructing specific OPE protocols rather than black-box reductions of OPE

to other primitives. Furthermore, the definition of private computation is standard for related primitives such as oblivious transfer [58, 21, 53] or private information retrieval (PIR) [13, 43] (note that we present a reduction of OPE to oblivious transfer). Note also that the definition of private computation is equivalent to the definition of secure computation in the case of semi-honest parties. Furthermore, we deal with a receiver-sender (aka. client-server) scenario, where only one party, the receiver, has an output in the protocol. Therefore, the two definitions are equivalent with respect to a malicious *client*, as there is no issue of simulating the joint distribution of the client's view and the server's output.

The requirements of a private OPE protocol can be divided into *correctness*, *receiver privacy*, and *server privacy*. Let us first define these properties independently and then define a private OPE protocol as a protocol satisfying these three properties. In the definitions, the running time of polynomial time algorithms is polynomial in the size of their inputs, as well as in $\log |\mathcal{F}|$, where \mathcal{F} is the field in which the polynomial P is defined, and in a security parameter k . (Note that the length of representations of elements in \mathcal{F} must be polynomial in the security parameter since otherwise the cryptographic operations might be insecure given adversaries with poly- $\log |\mathcal{F}|$ running time.) We don't require in the definitions themselves that the number of public key operations is independent of \mathcal{F} . To simplify the notation we also omit any reference to auxiliary inputs.

We first define the input and output for the OPE functionality as a two party protocol run between a receiver and a sender over a field \mathcal{F} .

- Input:
 - Receiver: an input $x \in \mathcal{F}$.
 - Sender: a polynomial P defined over \mathcal{F} .
- Output:
 - Receiver: $P(x)$.
 - Sender: nothing.

DEFINITION 1.1 (correctness, or functionality). *At the end of the protocol the receiver obtains the output of the OPE functionality, namely, $P(x)$.*

The definition of the receiver's privacy is simplified by the fact that the sender gets no output. It is as follows.

DEFINITION 1.2 (receiver's privacy—indistinguishability). *For any probabilistic polynomial time \mathcal{B}' executing the sender's part, for any x and x' in \mathcal{F} , the views that \mathcal{B}' sees in case the receiver's input is x and in case the receiver's input is x' are computationally indistinguishable.*

The definition of sender's privacy is a bit trickier, since the receiver obtains some information, and we want to say that the receiver does not get more or different information than $P(x)$. We compare the protocol to the *ideal implementation*. In the ideal implementation there is a trusted third party Charlie, which gets the sender's polynomial P and the receiver's request x and gives $P(x)$ to the receiver. The privacy requirement is that the protocol does not leak to the receiver more information than in the ideal implementation.

DEFINITION 1.3 (sender's security—comparison with the ideal model). *For any probabilistic polynomial-time machine \mathcal{A}' substituting the receiver, there exists a probabilistic polynomial-time machine \mathcal{A}'' that plays the receiver's role in the ideal implementation, such that the view of \mathcal{A}' and the output of \mathcal{A}'' are computationally indistinguishable.*

DEFINITION 1.4 (private OPE protocol). *A two-party protocol satisfying Definitions 1.1, 1.2 and 1.3.*

Note that the definition of receiver privacy does *not* preclude the sender from cheating by using a polynomial of degree higher than the degree of P (and therefore it might not be possible to extract from the sender a degree k polynomial). We do not require that the sender be committed to a single polynomial, or that the receiver could verify that the value she receives corresponds to such a polynomial. Our construction allows such cheating; however, in many applications (including the ones described in this paper) this is immaterial.

As a side note we observe that a possible approach for ensuring correctness could use the verifiable secret sharing (VSS) schemes of Feldman and of Pedersen [23, 57], which let the sender commit to a single polynomial P before engaging in the OPE protocol. Since two polynomials of degree d agree in at most d locations, an OPE invocation in which the sender lets the user evaluate a different polynomial P' of the same degree is revealed with probability $1 - d/|\mathcal{F}|$ by a receiver that evaluates the polynomial at a *random* point. This approach does not work, however, if the sender has some information about the distribution of points in which the user might compute P .

Shared output OPE. A variant of OPE which might be useful in many applications (e.g., [26, 45]) is one where the output of the polynomial is shared between the two parties. As in the basic OPE protocol the input of the sender is a polynomial $P()$ and the input of the receiver is x . However, unlike the basic OPE protocol both parties have random outputs which sum up to $P(x)$. In other words, the sender and receiver have output y_S and y_R , respectively, such that each of these values is uniformly distributed in \mathcal{F} and it also holds that $y_S + y_R = P(x)$.

There is a simple reduction from shared output OPE to basic OPE. Namely, given an input polynomial $P()$, the sender chooses a random $y_S \in \mathcal{F}$ and defines $P'(x) = P(x) - y_S$. The parties then perform an OPE of $P'(x)$ and the receiver sets $y_R = P'(x)$.

1.3. Related work.

1.3.1. Oblivious transfer. The basic cryptographic primitive that is used by the protocols for oblivious polynomial evaluation is *oblivious transfer*. The notion of 1-out-of-2 oblivious transfer was suggested by Even, Goldreich and Lempel [21] as a generalization of Rabin's oblivious transfer [58]. A protocol for 1-out-of-2 OT involves a sender, which has two inputs x_0 and x_1 , and a receiver whose input is a single bit, $b \in \{0, 1\}$. At the end of the protocol the receiver learns x_b and nothing about x_{1-b} , while the sender learns nothing about b . More generally, a k -out-of- N OT functionality is defined in the following way.

DEFINITION 1.5. (k -out-of- N oblivious transfer functionality).

- *Parameters:* Integers $N > k \geq 1$.
- *Input:*
 - *Sender:* N inputs x_1, \dots, x_N .
 - *Receiver:* k inputs i_1, \dots, i_k which are integer values in the range $[1, N]$.
- *Output:*
 - *Sender:* nothing.
 - *Receiver:* x_{i_1}, \dots, x_{i_k} .

For a discussion of OT see Goldreich [29]. 1-out-of- N oblivious transfer was introduced by Brassard, Crépeau and Robert [8, 9] under the name ANDOS (all or nothing disclosure of secrets). They used information theoretic reductions to construct 1-out-of- N protocols from $N - 1$ invocations of a 1-out-of-2 protocol (it was later shown that such reductions must use at least $\Omega(N)$ invocations of 1-out-of-2 OT in order

to preserve the information theoretic security [17]). Goldreich and Vainish [33] and Kilian [42] showed that oblivious transfer enables general secure two-party computation, with no additional assumptions (with security against semi-honest and malicious adversaries, respectively).

This paper describes reductions of oblivious polynomial evaluation to an ideal implementation of the OT functionality of Definition 1.5. Based on composition theorems (see, e.g., [29, 10, 11]) the ideal functionality can be replaced with actual implementations of OT. Such constructions of OT can be based on physical assumptions, such as the use of a noisy channel (see, e.g., [15]), or on computational assumptions. Constructions of OT based on computational assumptions can be divided to different categories, as listed below, according to the security definitions that they satisfy. The OPE constructions can be based on OT protocols from any of these categories. (Of course, security depends on the security of the oblivious transfer protocol. In particular, all OT protocols we describe provide security against semi-honest adversaries. All but the first category provide *privacy* in the face of malicious parties.)

(i) OT protocols which provide security in the semi-honest model. These include basic protocols based on the EGL (Even–Goldreich–Lempel) paradigm [21], which are based on using a public key encryption system with the additional property that the distribution of ciphertexts is independent of the encryption key (the original EGL protocol uses trapdoor permutations with a special property, but its structure is similar). In these protocols the receiver sends two encryption keys PK_0 and PK_1 , while knowing only a single decryption key, corresponding to PK_b . The sender encrypts x_0 using the key PK_0 , and encrypts x_1 using the key PK_1 . The receiver then decrypts x_b but cannot decrypt x_{1-b} . Protocols based on this paradigm include the construction suggested by Bellare and Micali [4], and generic constructions based on the existence of trapdoor permutations.

OT protocols of this type can be made secure with respect to malicious parties by applying the GMW (Goldreich–Micali–Wigderson) [31] paradigm, i.e., “compiling” a semi-honest protocol using generic techniques to obtain a protocol which ensures that the operation of the parties follows the protocol. This is usually done by adding zero-knowledge proofs in which the parties prove that they operate according to the protocol. If the zero-knowledge proofs enable extraction then the protocols are simulatable, but only for a single invocation at a time, rather than for parallel or concurrent invocations of the protocol.

(ii) OT protocols which provide information-theoretic security for the sender with respect to a corrupt receiver, and computational security for the receiver (e.g., the two round protocols of [52, 1, 39]). Although these protocols provide information-theoretic security, they do not enable extraction of the receiver’s input. Therefore they do not enable easy simulation of the output that is obtained by the receiver. (The GMW paradigm can be applied to this type of protocol as well, but usually with considerable degradation in efficiency. In addition, the information-theoretic security might be lost.)

(iii) Fully simulatable OT protocols, in particular for parallel or concurrent invocations. These include the concurrent OT protocol of [24] (which assumes that the inputs are independent), the universally composable protocols of [11], and the universally composable committed OT of [25].

(iv) Protocols based on the random oracle model. In this model it is possible to design very efficient protocols based on the EGL or the Bellare–Micali paradigms. These protocols are secure against malicious parties and fully simulatable. Their security relies, however, on the random oracle model.

Most constructions of OT protocols that are described in the literature are of 1-out-of-2 OT. Efficient implementations of 1-out-of- N and k -out-of- N oblivious transfer protocols are described in [53]. These protocols are based on efficient computationally secure reductions to 1-out-of-2 oblivious transfer. A 1-out-of- N oblivious transfer is reduced to $\log N$ invocations of 1-out-of-2 OT, and the k -out-of- N protocol is considerably more efficient than k repetitions of 1-out-of- N oblivious transfer. Furthermore, more recent constructions [52] reduce the amortized overhead of oblivious transfer, if multiple invocations of this protocol should be run (as is the case in the OPE constructions). A direct implementation of 1-out-of- N OT, e.g., by the protocols which provide information-theoretic security for the sender [52, 1, 39], is quite efficient for the receiver which has to do only $O(1)$ work, while the sender has to perform $O(N)$ exponentiations.

It was recently shown how to extend oblivious transfer in the sense that two parties can execute a large number of OTs (a number polynomial in k , where k is a security parameter of a pseudorandom function), at the cost of running only k OTs and executing additional invocations of symmetric cryptographic functions for every OT [35] (this is an efficient realization of a generic construction of Beaver [2]). The security of this construction is based on a nonstandard assumption (or alternatively on the random oracle assumption), and security against malicious parties is obtained using a cut-and-choose method that involves running multiple invocations of the system.

In our work we measure the computational overhead by the number of OTs that are executed by the parties. The use of this criterion makes sense since all other operations are either arithmetic or are symmetric crypto operations, which are considerably more efficient. It is preferable to minimize the number of OT operations even given the recent work on extending oblivious transfer, since that construction depends on a new assumption, involves some additional constants, and requires a cut-and-choose solution against malicious parties.

We present a protocol that uses a minimal number of OTs in the sense that this number is independent of the size of the field and of the degree of the polynomial. We assume that each 1-out-of-2 OT operation is atomic and can accommodate an input of arbitrary size (this is justified since the OT can be used to transfer one of two keys whose length is equal to the security parameter, and these keys can be used to encrypt each of the two inputs, which can be of arbitrary size).

1.3.2. Secure two-party computation. The idea of secure two-party computation was introduced by Yao [60]. His construction enables one party, the sender, to define a function F and enable another party, the receiver, to compute the value of F at a single point x without learning anything else about F , and without disclosing to the sender any information about x . The construction is based on describing F as a binary circuit and evaluating the circuit. Its computational overhead is composed of running an oblivious transfer protocol for every input wire of the circuit, and computing a pseudorandom function for every gate. The bulk of the communication overhead is incurred by sending a table, of size linear in the security parameter of the pseudorandom function, for every gate. The overhead, therefore, strongly depends on the size of the representation of F as a binary circuit. In the case of a polynomial of degree d this circuit should compute x^d and its size is $O(|x|^2 \cdot \log d)$. In particular, the size of the circuit depends on the size of the field over which the polynomial is defined. (It is also possible to construct a circuit that uses an FFT approach for computing x^d . The size of this circuit, too, depends on the size of the field over which the polynomial is defined.)

In another generic construction, Naor and Nissim [49] show that any two-party protocol can be transformed into a secure protocol with the effect that a protocol with communication complexity of c bits is transformed to a secure protocol which performs c invocations of oblivious transfer (or SPIR) from a database of length 2^c . A simple (insecure) protocol for oblivious polynomial evaluation has a single round and a communication overhead of $\log |\mathcal{F}|$ bits (the receiver simply sends x to the sender). Applying the Naor–Nissim transformation to this protocol results in a secure protocol that executes an OT/SPIR out of a table of $|\mathcal{F}|$ elements. Namely, the server constructs a table of $|\mathcal{F}|$ items, containing the value of $P(x)$ for every $x \in \mathcal{F}$. The receiver then reads a single entry of this table using OT or SPIR. This protocol is definitely not strongly polynomial as its overhead is linear in $|\mathcal{F}|$.

2. Intractability assumptions. This section contains definitions of two new pseudorandomness assumptions. They are later used for constructing protocols for oblivious polynomial evaluation. The assumptions are closely related to the noisy polynomial reconstruction problem, or the list decoding problem of Reed–Solomon codes. We first describe this well-known problem, and then introduce the pseudorandomness assumptions.

2.1. The noisy polynomial reconstruction problem. The noisy polynomial reconstruction problem is described by the following definition.

DEFINITION 2.1 (polynomial reconstruction). *A polynomial reconstruction algorithm has the following functionality:*

- *Input: Integers k and t , and n points $\{(x_i, y_i)\}_{i=1}^n$, where $x_i, y_i \in \mathcal{F}$ (\mathcal{F} is a field).*
- *Output: Any univariate polynomial P of degree at most k such that $P(x_i) = y_i$ for at least t values $i \in [1, n]$.*

The noisy polynomial reconstruction problem is related to the list decoding problem, which is motivated by coding theory and was first defined by Elias [20] (and sometimes also termed as the bounded-distance decoding problem). The input to this problem is a received word, and the output is a list of all code words that are within some distance from the received word. For the case of Reed–Solomon codes the list decoding problem can be formulated as follows.

DEFINITION 2.2 (polynomial list reconstruction). *A polynomial list reconstruction algorithm has the following functionality.*

- *Input: Integers k and t , and n points $\{(x_i, y_i)\}_{i=1}^n$, where $x_i, y_i \in \mathcal{F}$ (\mathcal{F} is a field).*
- *Output: All univariate polynomials P of degree at most k such that $P(x_i) = y_i$ for at least t values $i \in [1, n]$.*

For given values of k and n , and in particular for a given message rate k/n , it is preferable to obtain solutions for minimal values of t . The classic algorithm of Berlekamp and Massey (see, e.g., [48]) solves the polynomial reconstruction problem in polynomial time for $t \geq \frac{n+k}{2}$ (in this range there is a unique solution). Sudan [59] presented a polynomial algorithm that works if $t \geq \sqrt{2kn}$, and later Guruswami and Sudan [34] presented a polynomial algorithm that solves the problem for $t \geq \sqrt{kn}$, and thus improves upon the Berlekamp–Massey algorithm for every value of the message rate k/n . (Later, Coppersmith and Sudan [14] showed an improved noisy interpolation algorithm which removes random errors applied to curves of the form $\langle x, p_1(x), p_2(x), \dots, p_c(x) \rangle$, where p_1, \dots, p_c are polynomials. We are interested in the case $c = 1$, for which this algorithm is not better than the Guruswami–Sudan algorithm.)

The “polynomial list reconstruction” problem is defined as a worst case problem regarding the *number* of polynomials that might appear in the solution list. In other words, the definition requires that all polynomials within a given distance be listed. Goldreich et al. [32] have shown that for $t > \sqrt{kn}$ the number of possible polynomials in the solution to the problem is bounded by a polynomial in n . We are more interested in the problem of finding just a single polynomial that fits t or more of the given n points, since our constructions use random instances for which it holds with high probability that the corresponding noisy polynomial reconstruction problem has a single solution.

We note that given an input to a noisy polynomial reconstruction problem it is possible to randomize it to obtain an input that corresponds to a random polynomial. Specifically, for parameters k and t and given n points $\{(x_i, y_i)\}_{i=1}^n$ the randomization is achieved by choosing a random polynomial R of degree k and constructing a new instance of the problem with input $\{(x_i, y_i + R(x_i))\}_{i=1}^n$. While this is by no means a reduction from the worst case problem to the average case (since it only randomizes the polynomial but not the noise), it might hint that solving the problem in the average case might not be much simpler than solving it in the worst case.

2.2. The intractability assumptions—pseudorandomness. We present two new intractability assumptions. The first assumption is equivalent to a conjecture that given a randomly chosen input to the polynomial list reconstruction problem the value of the polynomial at $x = 0$ is pseudorandom. The second assumption states that the value $P(0)$ is pseudorandom even given some additional hints about the location of the values of P . Section 3 describes OPE protocols that are based on the assumptions.

The intractability assumptions depend on the following parameters:

- (i) \mathcal{F} , the field over which the polynomial is defined.
- (ii) k , the degree of the hidden polynomial.
- (iii) n , the number of correct values of the polynomial, which is also the number of queries made in the oblivious evaluation protocol. (This parameter corresponds to t in the definition of the polynomial list reconstruction problem, Definition 2.2. We change the notation to agree with the notation used later in this paper.)
- (iv) m , the expansion ratio (namely, the ratio between the total number of points and n). This parameter corresponds to n/t in Definition 2.2.

Setting precise parameter sizes to satisfy the intractability assumptions is beyond the scope of this paper, and we therefore do not make any precise recommendations with regard to parameter sizes.

The first intractability assumption. This intractability assumption simply assumes that given an input to the polynomial list reconstruction problem, with all x_i being distinct, the value of the polynomial at $x = 0$ is pseudorandom. That is, it is infeasible to distinguish between two such inputs corresponding to polynomials with different values at $x = 0$. To define this more formally, we use the following notation:

Let $A_{n,m}^{k,\alpha}$ denote the probability distribution of sets generated in the following way:

1. Pick a random polynomial P over \mathcal{F} , of degree at most k , for which it holds that $P(0) = \alpha$.
2. Generate nm random values x_1, \dots, x_{nm} in \mathcal{F} subject to the constraint that all x_i values are distinct and different from 0.
3. Choose a random subset S of n different indices in $[1, nm]$, and set $y_i = P(x_i)$ for all $i \in S$. For every $i \notin S$ set y_i to be a random value in \mathcal{F} .
4. Output the set $\{(x_i, y_i)\}_{i=1}^{nm}$.

The pseudorandomness assumption is based on the notion of computationally indistinguishability, as defined by Goldreich in [28, page 104]. It sets the size of the parameters to be polynomial in a security parameter ℓ , and requires that the resulting probability ensembles are computationally indistinguishable.

Assumption 1 (first pseudorandomness assumption). Let ℓ be a security parameter, and let $n(\ell), m(\ell), k(\ell), F(\ell)$ be polynomially bounded functions that define the parameters n, m, k and the description of the field \mathcal{F} . Let $\alpha(\ell)$ and $\alpha'(\ell)$ be any polynomially bounded functions defining elements of the field \mathcal{F} , and define $\alpha = \alpha(\ell)$ and $\alpha' = \alpha'(\ell)$. Let $\mathcal{A}_{n,m}^{k,\alpha}$ and $\mathcal{A}_{n,m}^{k,\alpha'}$ be random variables that are chosen according to the distributions $A_{n,m}^{k,\alpha}$ and $A_{n,m}^{k,\alpha'}$, respectively.

The assumption is that the probability ensembles $\{\mathcal{A}_{n,m}^{k,\alpha}\}$ and $\{\mathcal{A}_{n,m}^{k,\alpha'}\}$ are computationally indistinguishable for adversaries whose running time is polynomial in the security parameter ℓ .

Pseudorandomness Assumption 1 is related to the assumption that polynomial list reconstruction is hard. Assumption 1 is stronger, since in addition to assuming that reconstructing the polynomial is hard, it assumes that all x_i are distinct and that it is even hard to learn information about the value of the polynomial at 0.

Assumption 1 is weaker than an assumption that states that it is hard to distinguish between any probability ensemble $\{\mathcal{A}_{n,m}^{k,\alpha}\}$ and a probability ensemble that generates sets with the same number of *random* (x, y) values. If the latter assumption is true, then so is Assumption 1. (Assume that Assumption 1 does not hold. Then there is a distinguisher such that the probability of its output being 1 given an input from $\{\mathcal{A}_{n,m}^{k,\alpha}\}$ has a nonnegligible difference from the probability of it having a 1 output given an input from $\{\mathcal{A}_{n,m}^{k,\alpha'}\}$. The probability of a 1 output given an input from the “random” ensemble must have a nonnegligible difference from at least one of these two probabilities.) The converse might not be true. It might be that it is easy to distinguish between an input from the “random” ensemble and an input from $\{\mathcal{A}_{n,m}^{k,\alpha}\}$, yet for all α values, the inputs from the different $\{\mathcal{A}_{n,m}^{k,\alpha}\}$ ensembles are indistinguishable.

The pseudorandomness assumption is of course false for any choice of parameters for which the polynomial list reconstruction problem is easy, e.g., when $m < n/k$. (This corresponds to the number of correct points, n , being more than the square root of the total number of points, nm , times the degree of polynomial, k . This equation therefore agrees with the threshold for which the noisy polynomial problem is easy.) In the other direction, it is an open problem to find a reduction from the polynomial list reconstruction to the assumption.

The second intractability assumption. The second assumption states that given n sets with m points in every set, such that a polynomial P agrees with at least one point in each set, the value of $P(0)$ is pseudorandom. Namely, the total number of points, and the number of correct points, are as in pseudorandomness Assumption 1, but in addition there is a partition into sets and it is promised that the polynomial P agrees with at least one point in each set. It is hard to come up with a reduction to this assumption from pseudorandomness Assumption 1 since the reduction must map each of the n points of P into a different set. The new assumption seems stronger than pseudorandomness Assumption 1 since the problem is easier. Namely, the adversary is given an additional hint—the partition into sets containing at least one correct value of the polynomial.

The definition of the assumption uses the following notation.

Let $C_{n,m}^{k,\alpha}$ denote the probability distribution of sets generated in the following way:

1. Pick a random polynomial P over \mathcal{F} , of degree at most k , for which it holds that $P(0) = \alpha$.
2. Generate nm random values x_1, \dots, x_{nm} in \mathcal{F} subject to the constraint that all x_i values are distinct and different from 0.
3. Choose a random subset S of n different indices in $[1, nm]$, and set $y_i = P(x_i)$ for all $i \in S$. For every $i \notin S$ set y_i to be a random value in \mathcal{F} .
4. Partition the nm (x_i, y_i) pairs to n random subsets subject to the following constraints:
 - (i) The subsets are disjoint.
 - (ii) Each subset contains exactly one pair whose index is in S (and therefore for this pair it holds that $y_i = P(x_i)$).
 - (iii) Each subset contains exactly $m-1$ pairs whose indices are not in S (and therefore have a random y_i value).

Output the resulting subsets.

The intractability assumption says that for any α, α' the two probability ensembles $\{C_{n,m}^{k,\alpha}\}, \{C_{n,m}^{k,\alpha'}\}$ are computationally indistinguishable. It depends on the parameters F, k, m , and n .

Assumption 2 (second pseudo-randomness assumption). Let ℓ be a security parameter, and let $n(\ell), m(\ell), k(\ell), F(\ell)$ be polynomially bounded functions that define the parameters n, m, k and the description of the field \mathcal{F} . Let $\alpha(\ell)$ and $\alpha'(\ell)$ be any polynomially bounded functions defining elements of the field \mathcal{F} , and define $\alpha = \alpha(\ell)$ and $\alpha' = \alpha'(\ell)$. Let $C_{n,m}^{k,\alpha}$ and $C_{n,m}^{k,\alpha'}$ be random variables that are chosen according to the distributions $C_{n,m}^{k,\alpha}$ and $C_{n,m}^{k,\alpha'}$, respectively.

The assumption is that the probability ensembles $\{C_{n,m}^{k,\alpha}\}$ and $\{C_{n,m}^{k,\alpha'}\}$ are computationally indistinguishable.

As with Assumption 1 there is an easy reduction from the problem of breaking this pseudorandomness assumption to the noisy polynomial reconstruction problem. In addition, if pseudorandomness Assumption 1 does not hold in the worst case, then pseudorandomness Assumption 2 does not hold in the worst case (since any input for the latter can be transformed to an input for the first assumption by simply ignoring the partition into subsets). This reduction is also true in the average case: consider all sets generated by the distributions $A_{n,m}^{k,\alpha}$ and $C_{n,m}^{k,\alpha}$ subject to the constraint that no more than n points in a set agree with the polynomial P (the probability that this property does not hold for a specific set is at most $n(m-1)/|\mathcal{F}|$, which we consider to be negligible). Denote the resulting collections of sets as $\hat{A}_{n,m}^{k,\alpha}$ and $\hat{C}_{n,m}^{k,\alpha}$. A set in $\hat{A}_{n,m}^{k,\alpha}$ is matched to a set in $\hat{C}_{n,m}^{k,\alpha}$ if they contain exactly the same points. Each of the sets in $\hat{A}_{n,m}^{k,\alpha}$ is therefore matched with the exactly same number of sets in $\hat{C}_{n,m}^{k,\alpha}$, and no two sets in $\hat{A}_{n,m}^{k,\alpha}$ are matched with the same set in $\hat{C}_{n,m}^{k,\alpha}$. Now, picking a random set in $\hat{C}_{n,m}^{k,\alpha}$ and removing the partition into subsets results in the matching set in $\hat{A}_{n,m}^{k,\alpha}$. Therefore, this procedure has the same probability of hitting any set in $\hat{A}_{n,m}^{k,\alpha}$.

It is an interesting open problem to provide a reduction to pseudorandomness Assumption 2 from pseudorandomness Assumption 1, or from the polynomial reconstruction problem. The problem with designing such a reduction is that its output should comply with the input distribution of pseudorandomness Assumption 2, namely, in each subset there should be (with high probability) a single value of the polynomial P .

Remark. The pseudorandomness assumption that was used in an earlier version of this work [51] was broken by Bleichenbacher and Nguyen [6] and by Boneh [7]. The assumption was similar to pseudorandomness Assumption 2, but with the additional requirement that in each subset of the sets generated by $C_{n,m}^{k,\alpha}$ all the points have the *same x coordinate*. This property enables reduction of this problem to an instance of the lattice shortest vector problem, and solving it using the LLL algorithm [44]. We remark that it is unknown how to employ this attack against pseudorandomness Assumption 2. Furthermore, the overhead of the oblivious evaluation scheme that is based on pseudorandomness Assumption 2 is not greater than that of the scheme that is based on the broken assumption.

3. Protocols for oblivious polynomial evaluation. This section describes protocols for oblivious evaluation of polynomials. The protocols reduce computing the OPE functionality to computing an OT functionality. We first describe a generic OPE protocol (Protocol 3.1), and then describe two instantiations of the generic protocol using each of the two pseudorandomness assumptions (Protocols 3.2 and 3.3, respectively). These protocols provide privacy against semi-honest or malicious senders, and against semi-honest receivers.

The protocols ensure that a malicious receiver learns at most a single linear equation of the coefficients of the polynomial, but this equation might not correspond to a legitimate value of the polynomial. We show that if the polynomial P that is evaluated is linear, then the protocols are secure even against malicious receivers, since the linear equation always corresponds to a value of the polynomial.

Security against malicious receivers, and improved efficiency. We then describe Protocol 3.4 which is secure against malicious receivers. Furthermore, Protocol 3.4, although a little more complicated conceptually, has computational overhead which is better than that of the previous protocols: the number of oblivious transfers is independent of the degree of the polynomial P and is equal to the number of oblivious transfers that are required in the case of a linear polynomial.

3.1. A generic protocol. All the protocols involve a receiver A and a sender B and have the following specifications:

- Input:
 - Sender: a polynomial $P(y) = \sum_{i=0}^{d_P} b_i y^i$ of degree d_P in the field \mathcal{F} .
 - Receiver: a value $\alpha \in \mathcal{F}$.
- Output:
 - Sender: nothing.
 - Receiver: $P(\alpha)$.
- Protocol security parameters: m, k , which are discussed below.

At the end of the protocol the parties learn nothing but their specified outputs. The generic protocol (Protocol 3.1) is described in Figure 1. It is based on the sender hiding P in a *bivariate* polynomial, and running oblivious transfer protocols with the receiver to reveal to her just enough information to enable the computation of $P(\alpha)$. (In this respect, the protocol is somewhat similar to the instance hiding construction of [3, 46].)

Note that the protocol uses a polynomial $Q(x, y)$ which is defined by $d + d_P + 1$ coefficients only, whereas a random bivariate polynomial of the same degrees is defined by $(d + 1)(d_P + 1)$ coefficients.

The only step that has to be further specified is step 3, in which the receiver learns $d_R + 1$ values of R . This is the only step that involves interaction between the two parties, and as such determines the overhead of the protocol. Below are descriptions

PROTOCOL 3.1 (a generic protocol for oblivious polynomial evaluation).

- The sender hides P in a bivariate polynomial:** (see Figure 2) The sender generates a random masking polynomial $P_x(x)$ of degree d , s.t. $P_x(0) = 0$. Namely, $P_x(x) = \sum_{i=1}^d a_i x^i$. The parameter d equals the degree of P multiplied by the security parameter k (i.e., $d = k \cdot d_P$).

The sender then defines a bivariate polynomial

$$Q(x, y) = P_x(x) + P(y) = \sum_{i=1}^d a_i x^i + \sum_{i=0}^{d_P} b_i y^i$$

for which it holds that $\forall y \ Q(0, y) = P(y)$.

- The receiver hides α in a univariate polynomial:** (see Figure 3) The receiver chooses a random polynomial S of degree k , such that $S(0) = \alpha$. The receiver's plan is to use the univariate polynomial $R(x) = Q(x, S(x))$ in order to learn $P(\alpha)$: it holds that $R(0) = Q(0, S(0)) = P(S(0)) = P(\alpha)$ and, therefore, if the receiver is able to interpolate R she can learn $R(0) = P(\alpha)$. The degree of R is $d_R = d = k \cdot d_P$.
- The receiver learns points of R :** The receiver learns $d_R + 1$ values of the form $(x_i, R(x_i))$.
- The receiver computes $P(\alpha)$:** The receiver uses the values of R that it learned to interpolate $R(0) = P(\alpha)$.

FIG. 1. A generic protocol for oblivious polynomial evaluation.

FIG. 2. The polynomial P embedded in the bivariate polynomial Q s.t. $Q(0, y) = P(y)$.

FIG. 3. The polynomial S defines a polynomial R s.t. $R(0) = Q(0, S(0)) = Q(0, \alpha) = P(\alpha)$.

FIG. 4. The receiver uses n -out-of- N OT to learn n values of R hidden between N values.

of two protocols for oblivious polynomial computation in which step 3 is based on each of the two pseudorandomness assumptions.

3.2. Detailed protocols. This section describes instantiations of Protocol 3.1 based on the two pseudorandomness assumptions.

3.2.1. A protocol based on pseudorandomness Assumption 1. The first instantiation is a reduction to an n -out-of- N oblivious transfer protocol (see, e.g., [53]), in which the receiver learns n of the N inputs of the sender while hiding these values from the sender.

PROTOCOL 3.2 (oblivious polynomial evaluation based on Assumption 1). *The protocol is the generic protocol (Protocol 3.1), where the third step is run as follows:*

1. The receiver sets $n = d_R + 1 = d + 1 = kd_P + 1$ and chooses $N = nm$ distinct random values $x_1, \dots, x_N \in \mathcal{F}$, all different from 0.
2. The receiver chooses a random set T of n distinct indices $1 \leq i_1, \dots, i_n \leq N$. She then defines N values y_i , for $1 \leq i \leq N$. The value y_i is defined as $S(x_i)$ if i is in T , and is a random value in \mathcal{F} otherwise.
3. The receiver sends the N points $\{(x_i, y_i)\}_{i=1}^N$ to the sender.
4. The receiver and sender execute an n -out-of- N oblivious transfer protocol for the N values $Q(x_1, y_1), \dots, Q(x_N, y_N)$ (see Figure 4). The receiver chooses to learn $\{Q(x_i, y_i)\}_{i \in T}$.

The correctness of the protocol is based on observing that the receiver learns $d_R + 1$ values of the polynomial R , and can, therefore, interpolate R and compute $R(0) = P(\alpha)$. We prove the security of the protocol in section 3.3 below.

3.2.2. A protocol based on pseudorandomness Assumption 2. The second protocol is based on using n sets of points, such that each set contains a point of the polynomial R . The receiver runs an independent oblivious transfer protocol for each set, in which it learns a value of R .

PROTOCOL 3.3 (oblivious polynomial evaluation based on Assumption 2). *The protocol is the generic protocol (Protocol 3.1), where the third step is run as follows:*

1. The receiver sets $n = d_R + 1 = kd_P + 1$, defines $N = nm$ and chooses N distinct random values $x_1, \dots, x_N \in \mathcal{F}$, all different from 0.
2. The receiver chooses a set T of n randomly-chosen distinct indices $1 \leq i_1, i_2, \dots, i_n \leq N$, subject to the constraint that $(j - 1)m + 1 \leq i_j \leq jm$ for $1 \leq j \leq n$.
3. The receiver defines N values y_i , for $1 \leq i \leq N$. The value y_i is defined as $S(x_i)$ if i is in T , and is random otherwise.
4. The receiver partitions the N pairs $\{(x_i, y_i)\}_{i=1}^N$ into n subsets B_1, \dots, B_n , where subset B_j contains the m pairs indexed $(j - 1)m + 1$ to jm . This means that each subset B_j contains exactly one pair from T .

5. The receiver sends the n subsets B_1, \dots, B_n to the sender.
6. The receiver and sender execute n protocols of 1-out-of- m oblivious transfer, one for each subset. The protocol for subset B_j enables the receiver to learn one of the values $Q(x_i, y_i)$ for the m points (x_i, y_i) in B_j . (The receiver should choose to learn $Q(x_i, y_i)$ for which $y_i = P(x_i)$.)

3.2.3. Properties of the protocols.

Correctness. It is straightforward to verify that both protocols enable the receiver to obtain any value $P(\alpha)$ she desires. She can do this by choosing a polynomial S for which $S(0) = \alpha$, learning $d_R + 1$ values of R , and interpolating $R(0) = P(\alpha)$.

Complexity. The main overhead of the protocols, in terms of both computation and communication, is the overhead of the oblivious transfer stage. The overhead depends on the degree of P and on the security parameters k and m . Namely, the overhead of each protocol is that of running the following primitives:

- (i) Protocol 3.2 (based on Assumption 1): running a single invocation of $(kd_P + 1)$ -out-of- $[(kd_P + 1) \cdot m]$ oblivious transfer.
- (ii) Protocol 3.3 (based on Assumption 2): running $(kd_P + 1)$ invocations of 1-out-of- m oblivious transfer.

The actual overhead of the protocol depends on the value that is set to the parameter m , as a function of k and d_P , in order for the relevant security assumption to hold (this value might be different in each of the protocols). It might seem that Protocol 3.3, which uses $(kd_P + 1)$ invocations of 1-out-of- m oblivious transfer, is always inferior to Protocol 3.2, which uses a single invocation of $(kd_P + 1)$ -out-of- $[(kd_P + 1) \cdot m]$ oblivious transfer. Also, the fact that in Protocol 3.3 each subset is known to contain a value of the polynomial S might make the task of attacking the receiver easier, and require the use of larger parameter m to ensure the security of the protocol. We describe both protocols since the choice of parameters k and m might be different in the two cases and result in Protocol 3.3 being the more efficient. Also, recent work on extending oblivious transfer [35] leads to more efficient implementation of multiple invocations of OT.

We note that the multiple invocations of the oblivious transfer protocol in Protocol 3.3 can be run in parallel. The protocol is secure if the specific oblivious transfer protocol which is used can be securely run in parallel with respect to the relevant adversary (i.e., with respect to either semi-honest or malicious adversaries).

3.2.4. A note on evaluating multiple polynomials with the same receiver input. The OPE protocols have a rather handy property: a *single* invocation of a protocol can be used to let the receiver compute the values of *several* polynomials at the *same* point x , with the same overhead (in terms of the number of oblivious transfers) as computing the value of a single polynomial. This can be done since the choices of the receiver in the OT protocols depend on its input x alone, and this input is the same in all invocations of the OPE protocol. The parallel invocation is done by the parties running a protocol in which the sender's input is n polynomials $\langle P_1, \dots, P_n \rangle$, the receiver's input is x , and the receiver's output is $\langle P_1(x), \dots, P_n(x) \rangle$. The sender defines appropriate polynomials $\langle Q_1, \dots, Q_n \rangle$ and in every step in which the sender transfers a single value $Q(i, j)$ in the original protocol, it transfers n values $\langle Q_1(i, j), \dots, Q_n(i, j) \rangle$ in the multipolynomial protocol. Note that this variant ensures that the receiver computes the values of all the polynomials at the *same point* x . This variant of the protocol is used in Protocol 3.4 in section 3.4, and is also used in [26] for distributed generation of RSA keys.

3.3. Security analysis for semi-honest behavior. In order to prove the security of the protocol one must show that the privacy of both parties is preserved. The privacy of the receiver is based on the pseudorandomness assumption which is used (namely, Assumption 1 or 2), while the privacy of the sender is independent of this assumption. The proof employs a hybrid model in which there is access to an ideal OT functionality, as is defined in Definition 1.5. Composition theorems (see, e.g., [29, 10, 11]) can then be used to replace the ideal OT functionality with a specific implementation of OT, as is described in section 1.3.1.

3.3.1. The receiver’s privacy. The privacy goal of the receiver is to hide the value $\alpha = S(0)$ from the sender. We only need to show this for a semi-honest sender, since the protocol includes a single message from the receiver to the sender, which does not depend on the operation of the sender (and our security definition does not require stimulation of the output of the receiver together with the view of the sender). This property is guaranteed by the pseudorandomness assumptions stated in section 2.2. We prove this result for Protocol 3.2, based on pseudorandomness Assumption 1. The proof for Protocol 3.3 is identical and is based on pseudorandomness Assumption 2.

THEOREM 3.1. *If the sender can distinguish between two different inputs of the receiver in Protocol 3.2, then pseudorandomness Assumption 1 does not hold (namely, there is a distinguisher between the two probability ensembles stated in the assumption).*

Proof. The sender’s view in the protocol contains the set of points that is given to him by the receiver, and the interaction between the two parties in the oblivious transfer protocol. Each instance of the sender’s view therefore contains nm points, and in addition his view in an oblivious transfer protocol in which the receiver chooses to learn values associated with a set of n of the nm points. Recall also that we assume that the protocol uses an ideal OT functionality.

Let α_0, α_1 be any two values in \mathcal{F} . Consider the following probability distributions of instances of the sender’s view in the protocol.

(i) $S_{OT,0}$: The set of nm points is chosen randomly from $A_{n,m}^{k,\alpha_0}$. The interaction of the receiver in the oblivious transfer protocol corresponds to it choosing to learn the n correct points of the polynomial among the nm points.

(ii) $S_{OT,1}$: Similar to $S_{OT,0}$, with the only difference being that the set of nm points is chosen randomly from $A_{n,m}^{k,\alpha_1}$.

(iii) $S_{R,0}$: The set of nm points is chosen randomly from $A_{n,m}^{k,\alpha_0}$. The interaction of the receiver in the oblivious transfer protocol corresponds to it choosing to learn n points sampled at random from the set of nm points.

(iv) $S_{R,1}$: Similar to $S_{R,0}$, with the only difference being that the set of nm points is chosen randomly from $A_{n,m}^{k,\alpha_1}$.

We would like to show that no algorithm D_{α_0,α_1} run by the sender can distinguish between an input sampled from $S_{OT,0}$ and an input sampled from $S_{OT,1}$. Define $D_{OT,0}$ as the probability that the output of D_{α_0,α_1} is 1 given an input sampled from $S_{OT,0}$. Similarly, define $D_{OT,1}$, $D_{R,0}$ and $D_{R,1}$. It holds that

$$|D_{OT,0} - D_{OT,1}| \leq |D_{OT,0} - D_{R,0}| + |D_{R,0} - D_{R,1}| + |D_{R,1} - D_{OT,1}|.$$

Assume to the contrary that $|D_{OT,0} - D_{OT,1}|$ is nonnegligible. In this case either the value $|D_{OT,0} - D_{R,0}| + |D_{R,1} - D_{OT,1}|$ is nonnegligible (option 1), or the value $|D_{R,0} - D_{R,1}|$ is nonnegligible (option 2).

If option 1 occurs, then either $|D_{R,0} - D_{OT,0}|$ or $|D_{R,1} - D_{OT,1}|$ is nonnegligible. This is a contradiction since in this case the sender can distinguish between different

inputs of the receiver to the oblivious transfer protocol. (It is possible to show a reduction that uses the fact that, e.g., $|D_{R,0} - D_{OT,0}|$ is nonnegligible, to distinguish between different inputs of the receiver.)

If option 2 occurs then we have a distinguisher between inputs sampled from $A_{n,m}^{k,\alpha_0}$ and from $A_{n,m}^{k,\alpha_1}$. The distinguisher operates by receiving its input, adding to it an interaction for the oblivious transfer protocol in which the receiver learns a random set of n values, and forwarding the combined input to D_{α_0,α_1} . Since $|D_{R,0} - D_{R,1}|$ is nonnegligible there will be a nonnegligible difference between the output being 1 given inputs from the two distributions. \square

3.3.2. The sender’s privacy—the case of a semi-honest receiver. We first assume a semi-honest receiver whose operation follows the behavior that it should take according to the protocol. This is a good model for the case of a truthful party that executes the protocol, but at a later stage falls prey to an adversary that might examine the information learned during the protocol execution. The proof for the case of a semi-honest receiver, as we show in section 3.4, is also sufficient for the case of *linear* polynomials, even if the receiver is malicious. Later we show how to provide privacy in the general case of malicious receivers.

The proof that the sender’s privacy is preserved against semi-honest receivers is identical for all protocols. The sender hides the polynomial P in a bivariate polynomial Q that is generated by adding to $P()$ a random polynomial in x , and the receiver obtains a system of $d_R + 1 = d + 1 = kd_P + 1$ values of Q , using different x values. Lemma 3.2 states that the receiver learns only a single linear combination of the coefficients of P . In particular this implies (Corollary 3.1) that a semi-honest receiver learns only a single value of the polynomial P .

LEMMA 3.2. *Let $Q(x, y)$ be a bivariate polynomial of the form*

$$Q(x, y) = P_x(x) + P(y) = \sum_{i=1}^d a_i x^i + \sum_{i=0}^{d_P} b_i y^i.$$

Then for any $d + 1$ values x_1, \dots, x_{d+1} , which are distinct and different from 0, and for any $d + 1$ values y_1, \dots, y_{d+1} , the distribution of $\{Q(x_j, y_j)\}_{j=1}^{d+1}$ is either independent of the coefficients b_0, \dots, b_{d_P} , or depends on a single linear equation of these coefficients.

Proof. The values of $Q(x_j, y_j)$ are equations of the form $Q(x_j, y_j) = \sum_{i=1}^d a_j \cdot (x_j)^i + \sum_{i=0}^{d_P} b_i \cdot (y_j)^i$. They correspond, therefore, to a set of $d + 1$ equations of the following form, with different x_j ’s:

$$\underbrace{\begin{pmatrix} (x_{j_1})^d & (x_{j_1})^{d-1} & \dots & x_{j_1} & y_{j_1}^{d_P} & \dots & 1 \\ (x_{j_2})^d & (x_{j_2})^{d-1} & \dots & x_{j_2} & y_{j_2}^{d_P} & \dots & 1 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ (x_{j_{d+1}})^d & (x_{j_{d+1}})^{d-1} & \dots & x_{j_{d+1}} & y_{j_{d+1}}^{d_P} & \dots & 1 \end{pmatrix}}_A \begin{pmatrix} a_d \\ \vdots \\ a_1 \\ b_{d_P} \\ \vdots \\ b_0 \end{pmatrix} = \begin{pmatrix} Q(x_{j_1}, y_{j_1}) \\ Q(x_{j_2}, y_{j_2}) \\ \vdots \\ Q(x_{j_{d+1}}, y_{j_{d+1}}) \end{pmatrix}.$$

It should be shown that regardless of the values of the points (x_j, y_j) , the rows of the matrix A do not span more than a single linear combination of the vectors

$$\{e_i = \underbrace{(0, \dots, 0, 1, 0, \dots, 0)}_i \mid d + 1 \leq i \leq d + d_P + 1\}.$$

The matrix A has $d + d_P + 1$ columns and $d + 1$ rows. Consider the matrix A' with $d + d_P + 1$ rows that is formed by taking the first d rows of A and appending to them the vectors $e_{d+1}, \dots, e_{d+d_P+1}$. The determinant of A' is different from 0, since its upper-left submatrix of size $d \times d$ is a Vandermonde matrix, and the lower-right submatrix of size $(d_P + 1) \times (d_P + 1)$ is an identity matrix. Therefore, the first d rows of A do not span any of $e_{d+1}, \dots, e_{d+d_P+1}$, and the matrix A that has just a single additional row cannot span more than a single linear combination of these vectors. \square

Note that we assume that the OT protocol implements an ideal functionality, and therefore the receiver (either semi-honest or malicious) learns $d + 1$ values from the set $\{Q(x_j, y_j)\}_{j=1}^{d+1}$. In the case of a semi-honest receiver these values are of the form $Q(x_j, P(x_j))$, whereas a malicious receiver can learn arbitrary values of $Q(x_j, y_j)$ subject to the constraint that the x coordinates are distinct and different from 0. Therefore Lemma 3.2 implies the following two corollaries.

COROLLARY 3.1. *A semi-honest receiver learns only a single value of the polynomial P .*

COROLLARY 3.2. *A malicious receiver learns only a single linear equation of the coefficients of the polynomial P .*

The latter corollary is used in section 3.4 to construct an OPE protocol which is secure against malicious adversaries.

3.4. Security against malicious behavior. As described in section 3.3.1, we should only consider a semi-honest server since the only message sent by the receiver is sent before it receives any information from the server. On the other hand, a malicious adversary that plays the receiver’s role might run the protocol and ask to learn values $Q(x, y)$ that do not correspond to a polynomial $S(x)$, i.e., are not of the form $Q(x, S(x))$. By doing so it might learn a linear combination of the coefficients of P which does not correspond to any value of $P(x)$. Lemma 3.2 shows that the adversary can only learn a single such linear combination. This might be sufficient for some applications, but to conform to the “ideal model” security definition, or, in general, to security against malicious behavior, the protocol must limit the information that the receiver can learn to a linear combination corresponding to a value of the polynomial P . This is achieved by the Protocol 3.4 that is described in what follows.

Improved efficiency. Another advantage of Protocol 3.4 is that its computational overhead, as measured by the number of oblivious transfers that are executed, is independent of the degree of P , and is equal to the overhead of Protocols 3.2 and 3.3 for the case of a linear polynomial P .

Before describing Protocol 3.4, we first note that if the polynomial P is linear, then Protocols 3.1, 3.2, and 3.3 allow the receiver to learn only a single value of P and no other information about the coefficients (regardless of whether the receiver is malicious or not). This is proved for Protocol 3.2 in the following lemma.

LEMMA 3.3. *When P is linear, the only information that the receiver can learn in Protocol 3.2 is a single value of $P(\cdot)$.*

Proof. Denote $P(x)$ as $P(x) = b_1x + b_0$. Corollary 3.2 implies that the receiver can only learn a single linear combination of the form $b_1 \cdot \gamma_1 + b_0 \cdot \gamma_0$, where the receiver knows γ_1 and γ_0 . If $\gamma_0 \neq 0$, then this is equivalent to the receiver learning $P(\gamma_1/\gamma_0) = b_1 \cdot (\gamma_1/\gamma_0) + b_0$.

We next claim that the adversary cannot learn any combination in which the coefficient γ_0 is 0. Consider the matrix A used in the proof of Theorem 3.2. The receiver can learn the scalar multiplication of the coefficient vector by a linear combination of

the rows of this matrix. In the case of a linear polynomial P , the matrix has $d+1$ rows and $d+2$ columns, where the last two columns correspond to the coefficients b_1 and b_0 of P . Note that the $(d+1) \times (d+1)$ matrix that is composed of the first d columns together with the last column, is a Vandermonde matrix. Therefore no linear combination of the $d+1$ rows of the original matrix can generate the row $(0, \dots, 0, 1, 0)$, which corresponds to the receiver learning a linear combination $b_1 \cdot \gamma_1 + b_0 \cdot \gamma_0$ in which the coefficient γ_0 is 0. \square

Using linearization to combat malicious receivers. Given Lemma 3.3 the major tool we use is a reduction from the OPE of a polynomial of degree z , to z OPEs of linear polynomials, due to Gilboa [27]. The reduction is stated in the following lemma, which is proven at the end of this section.

LEMMA 3.4 (see [27]). *For every polynomial P of degree z , there exist z linear polynomials P_1, \dots, P_z such that an OPE of P can be reduced to a parallel execution of an OPE of each of P_1, \dots, P_z , where all the linear polynomials are evaluated at the same point.*

We first describe Protocol 3.4 that uses this reduction to provide security against a malicious receiver. We then show that the privacy of the server is preserved and prove the lemma. Protocol 3.4 itself ensures that the receiver evaluates all linear polynomials at the same point. Furthermore, the overhead, in terms of oblivious transfers, is the same as that of a *single* OPE of a linear polynomial, since the choices of the receiver in the oblivious transfer invocations in all OPEs are the same, and therefore it is possible to use parallel executions of OPE as described in section 3.2.4.

PROTOCOL 3.4 (oblivious polynomial evaluation against malicious receivers). *The sender's input is P and the receiver's input is a polynomial α . The protocol is composed of the following steps:*

1. *The sender generates the d_P linear polynomials P_1, \dots, P_{d_P} that are used for reducing the OPE of the polynomial P to d_P OPEs of linear polynomials, by the method of Lemma 3.4.*
2. *The parties execute d_P instances of OPE in which the receiver evaluates the linear polynomials P_1, \dots, P_{d_P} at the point α , under the following constraints:*
 - (i) *The sender generates independent masking polynomials $P_{x,i}$, $1 \leq i \leq d_P$, and obtains the resulting bivariate polynomials $Q_i(x, y) = P_{x,i}(x) + P_i(y)$, one for each of the d_P OPEs. (step 1 of Protocol 3.1.)*
 - (ii) *The receiver generates a single polynomial S for use in all the OPEs (step 2 of Protocol 3.1). This step defines d_P polynomials $R_1(x) = Q_1(x, S(x)), \dots, R_{d_P}(x) = Q_{d_P}(x, S(x))$ such that for each i it holds that $R_i(0) = P_i(\alpha)$.*
 - (iii) *The receiver learns $d_R + 1$ tuples of the form $(x_j, R_1(x_j), \dots, R_{d_P}(x_j))$. These values enable it to interpolate $R_1(\alpha), \dots, R_{d_P}(\alpha)$ (steps 3 and 4 of Protocol 3.1).*
The implementation of this step is done by executing the same number of oblivious transfers as is required for a single OPE of a linear polynomial. In the protocol the receiver obtains values of all polynomials, namely, $(x_j, R_1(x_j), \dots, R_{d_P}(x_j))$, instead of a single value $(x_j, R(x_j))$.
3. *The receiver uses $P_1(\alpha), \dots, P_{d_P}(\alpha)$ to compute $P(\alpha)$ according to the method of Lemma 3.4.*

It follows from Lemma 3.4 and from the correctness of Protocol 3.1 that this protocol is correct. Namely, that it enables the receiver to compute $P(\alpha)$ for every value α . As for efficiency, we measure the computation overhead by the number of oblivious transfers that are executed. The protocol requires the same number of

oblivious transfers as is required by an OPE of a *linear* polynomial, regardless of the degree d_P .¹ It is therefore more efficient computationally than a direct OPE of the d_P degree polynomial P . The communication overhead is about $d_P + 1$ times larger than that of the OPE of a linear polynomial.

THEOREM 3.5. *Assuming the use of an ideal OT functionality, Protocol 3.4 is secure against malicious behavior. Namely,*

- (i) *The sender cannot distinguish between two different inputs of the receiver.*
- (ii) *The receiver learns only a single value of the polynomial P .*

Proof. The receiver’s privacy is an immediate corollary of the receiver’s privacy in the linear OPE protocol (Theorem 3.1), since the information that the receiver sends is the same as in a single OPE protocol where it asks to learn the value of a linear polynomial at $x = \alpha$. The sender’s privacy follows from Lemma 3.4 and from Lemma 3.3 (which guarantees the sender’s privacy against malicious receivers in the case of linear polynomials). \square

We now turn to the proof of Lemma 3.4.

Proof of Lemma 3.4. The lemma follows from the following three claims. \square

CLAIM 3.1. *For every polynomial P of degree z the server can define z linear polynomials P_1, \dots, P_z such that given $P_1(\alpha), \dots, P_z(\alpha)$, it is possible to compute the value of $P(\alpha)$.*

Proof. Denote the polynomial P as $P(x) = \sum_{i=0}^z b_i x^i$, where z denotes the degree of the polynomial. The Horner representation of this polynomial is the following:

$$P(x) = (((b_z x + b_{z-1}) \cdot x + b_{z-2}) \cdot x) + \dots + b_0.$$

The innermost linear polynomial of the Horner representation is $Q_z(x) = b_z x + b_{z-1}$. Define the linear polynomial $P_z(x) = b_z x + b_{z-1} - s_z$, where s_z is a random value chosen by the server. Of course, it holds that $P_z(x) + s_z = Q_z(x)$. Suppose that the client learns the value $P_z(\alpha)$ (say, by executing an OPE). Following this step, the client and server have two random shares, $P_z(\alpha)$ and s_z , that sum up to $Q_z(\alpha)$. Now, the innermost polynomial of degree 2 is the following:

$$Q_{z-1}(x) = Q_z(x) \cdot x + b_{z-2} = (P_z(x) + s_z) \cdot x + b_{z-2} = P_z(x) \cdot x + s_z \cdot x + b_{z-2}.$$

Define $P_{z-1}(x) = s_z \cdot x + b_{z-2} - s_{z-1}$, where s_{z-1} is randomly chosen by the server. Then,

$$Q_{z-1}(\alpha) = P_z(\alpha) \cdot \alpha + P_{z-1}(\alpha) + s_{z-1}.$$

Suppose now that the client learns $P_{z-1}(\alpha)$ (by executing an OPE). Now the parties know two random shares that sum up to $Q_{z-1}(\alpha)$: the client can compute the share $P_z(\alpha) \cdot \alpha + P_{z-1}(\alpha)$, and the server knows s_{z-1} .

In the general case, the inner polynomial of degree $z - i$ can be represented as

$$\begin{aligned} Q_i(x) &= Q_{i+1}(x) \cdot x + b_{i-1} \\ &= P_z(x) \cdot x^{z-i} + P_{z-1}(x) \cdot x^{z-i-1} + \dots + P_{i+1}(x) \cdot x + s_{i+1} \cdot x + b_{i-1}. \end{aligned}$$

¹The length of the inputs of the oblivious transfer protocols is likely to be larger than the security parameter. This fact does not increase the number of oblivious transfers: the sender encrypts the long inputs with random keys, uses oblivious transfer to let the receiver learn one of the keys, and sends all encrypted inputs to the receiver. The receiver then uses the key to decrypt one of the inputs.

The server chooses a random value s_i and defines the linear polynomial $P_i(x) = s_{i+1} \cdot x + b_{i-1} - s_i$. It now holds that $(P_z(\alpha) \cdot \alpha^{z-i} + P_{z-1}(\alpha) \cdot \alpha^{z-i-1} + \dots + P_{i+1}(\alpha) \cdot \alpha + P_i(\alpha))$ and s_i are two random shares, which can be computed by the client and the server, respectively, and which sum up to $Q_i(\alpha)$. This definition is used up to $P_2(x)$; for $P_1(x)$, the server defines $P_1(x) = s_2 \cdot x + b_0$ (without any random value m_1).

We get that $Q_1(x) = P(x)$, and therefore

$$(3.1) \quad P(\alpha) = P_z(\alpha) \cdot \alpha^{z-1} + P_{z-1}(\alpha) \cdot \alpha^{z-2} + \dots + P_1(\alpha). \quad \square$$

CLAIM 3.2. *The computation of the z linear polynomials of Claim 3.4 can be done by z OPEs that are executed in parallel.*

Proof. Note that the polynomials P_1, \dots, P_z do not depend on α . Therefore, the server can define them in advance (by defining the values s_2, \dots, s_z). This enables the parties to execute z parallel invocations of OPE, in which the client computes $P_1(\alpha), \dots, P_z(\alpha)$. At the end of this stage, the client is able to compute $P(\alpha)$ using (3.1).

It follows that for every $\alpha \in \mathcal{F}$, the client can compute $P(\alpha)$ by learning the values $P_1(\alpha), \dots, P_z(\alpha)$. If the parties use the OPE protocols described in this paper then the $z + 1$ OPEs can be implemented with the client sending the same message in all invocations, which is the same information as in a single OPE of a linear polynomial at the point α . The server responds with the relevant answer for each of the z polynomials. \square

In order to prove that the only information about P that can be computed given $P_1(\alpha), \dots, P_z(\alpha)$ is $P(\alpha)$ we prove the following claim.

CLAIM 3.3. *Given $P(\alpha)$ it is possible to simulate the client's output in the z invocations of the OPE protocols. (Namely, the only information about P that can be computed given $P_1(\alpha), \dots, P_z(\alpha)$ is $P(\alpha)$.)*

Proof. To prove the claim we show that for every $\langle P, \alpha \rangle$ it holds that the vector $\langle P_2(\alpha), \dots, P_z(\alpha) \rangle$ is uniformly distributed in \mathcal{F}^{z-1} given that $\langle s_2, \dots, s_z \rangle$ are uniformly distributed in \mathcal{F}^{z-1} .

For every $2 \leq i \leq z$, observe that we can write $P_i(\alpha) = C_i(P, \alpha, s_{i+1}, \dots, s_z) - s_i$, where $C_i(P, \alpha, s_{i+1}, \dots, s_z)$ is a function of the coefficients of P , of α , and of s_{i+1}, \dots, s_z . The claim is proved by induction, showing that $P_i(\alpha), \dots, P_z(\alpha)$ is random, with i going from z down to 2. The base case, $i = z$ is clear. In every step, we observe that s_i , which is chosen at random, is used to define $P_i(\alpha)$ alone and is not involved in defining $P_{i+1}(\alpha), \dots, P_z(\alpha)$. Therefore the vector $P_i(\alpha), \dots, P_z(\alpha)$ is randomly distributed given that $P_{i+1}(\alpha), \dots, P_z(\alpha)$ is randomly distributed.

Now, recall (3.1). $P_1(\alpha)$ is well defined given $\alpha, P(\alpha)$, and the values of $P_2(\alpha), \dots, P_z(\alpha)$. Therefore to simulate the client's view we choose random values for $P_2(\alpha), \dots, P_z(\alpha)$ and compute $P_1(\alpha)$ according to (3.1). \square

Realizing oblivious transfer. The security proofs show a reduction of security to that of an ideal OT functionality. All implementations of OT which are described in section 1.3.1 provide security against semi-honest adversaries. In the malicious case, the security provided by Protocol 3.4 depends on the security of the protocol which is used to realize the OT functionality. Universally composable OT protocols obviously result in a secure OPE protocol, since the choices of the receiver in the invocations of the OT protocol define a single point in which it can evaluate the polynomial. Invoking an information-theoretic OT protocol results in an OPE protocol which provides information-theoretic security for the sender. In this case the receiver cannot learn more than a single point of the polynomial, but it might not be possible to extract

it. Finally, it is also possible to use OT protocols that provide computational security for the sender, where the receiver's input is extractable if the OT invocations are done sequentially. In this case, however, the protocols must be invoked sequentially in order to enable extraction of the receiver's input from the OPE protocol.

4. Applications of oblivious evaluation of polynomials. There are two types of applications in which oblivious polynomial evaluation is useful. The first is where the receiver obtains a value from a k -wise independent space. For many applications such values are as good as truly random or pseudorandom values. The second type of application is of cryptographic protocols in which users must obtain a value of a polynomial held by another party without revealing their input. We give examples of both types of applications below. We also give a short description of applying the protocols of this paper to obviously computing $g^{P(x)}$, where P is a polynomial.

4.1. Obviously computing a polynomial in the exponent. In some scenarios it might be required to let the receiver compute the value of $g^{P(x)}$, where g is a generator of some group, P is known to the sender and x is known to the receiver. This computation is likely to be useful for cryptographic protocols that are based on the Diffie–Hellman assumption [19].

All the protocols described in this paper can be readily applied for this computation. The only change is for the sender to provide the receiver with values of $g^{R(x)} = g^{Q(x,S(x))}$, instead of values of $R(x) = Q(x,S(x))$. The receiver needs to interpolate these values to compute $g^{R(0)} = g^{P(\alpha)}$. She can do so by computing

$$g^{R(0)} = g \sum_{i=1}^{d_R+1} \lambda_i \cdot R(i) = \prod_{i=1}^{d_R+1} g^{\lambda_i \cdot R(i)} = \prod_{i=1}^{d_R+1} (g^{R(i)})^{\lambda_i},$$

where the values $\{\lambda_i\}_{i=1}^{d_R+1}$ are the appropriate Lagrange coefficients.

4.2. Comparing information without leaking it. Imagine two parties, A and B . Each of the parties holds a particular name (e.g., of a “suspect” from a small group of people). The two parties would like to check whether they both have the same input, under the condition that if the inputs are different they do not want to reveal any information about them (except for the fact that they are different). The main obstacle in designing a protocol for this problem is that the domain of inputs, e.g., names, is probably small enough to enable a brute force search over all possible inputs. This problem was thoroughly discussed by Fagin, Naor, and Winkler [22], with subsequent constructions by Crépeau and Salvail [16].

To specify the function more accurately, we require that if the parties' inputs are (α, β) , respectively, then their outputs are $(1, 1)$ if $\alpha = \beta$, and $(0, 0)$ otherwise. In the case of malicious parties we relax the requirement and say that while for $\alpha = \beta$ the outputs can be arbitrary (since a malicious party can always change its input or output), in the case of inputs $\alpha \neq \beta$, the output of the honest party must be 0. Namely, the malicious party cannot convince the honest party that the inputs are equal. (This requirement is natural in the context of password verification, discussed below, in which if one party does not provide the right password then the other party must reject.)

Since we cannot prevent a malicious party from choosing or guessing its input, we refer to the common security notion of simulation: for every behavior of the malicious party it should be possible to construct a simulator which has access to the trusted

third party (TTP) in the ideal model (but has no access to the input of the honest party) and can interact with the malicious party. The simulator should simulate the output distribution of the two parties, where the output of the honest party satisfies the requirement above. (In our case, the simulator will operate by extracting the input that the malicious party provides to the OPE and sending it as an input to the TTP.)

Oblivious evaluation of linear polynomials can be used to construct a very simple solution to the comparison of information problem.

PROTOCOL 4.1 (privacy preserving comparison of information).

- (i) *Input: Denote A 's input as α and B 's input as β .*
- (ii) *Party A generates a random linear polynomial $P_A(\cdot)$.*
- (iii) *Party B generates a random linear polynomial $P_B(\cdot)$.*
- (iv) *The parties execute the oblivious polynomial evaluation twice, switching roles.*

(i) *In the first invocation, A obviously learns a value of B 's polynomial (it should choose to learn $P_B(\alpha)$).*

(ii) *In the second invocation, B obviously learns a value of A 's polynomial (it should choose to learn $P_A(\beta)$).*

(iii) *The parties compute and compare the two values, $P_A(\alpha) + P_B(\alpha)$ (computed by A), and $P_A(\beta) + P_B(\beta)$ (computed by B).*

(iv) *If these values are equal then each party outputs 1. Otherwise the parties output 0. (If $\alpha = \beta$, then the two values are the same, otherwise they are different with probability $1/|\mathcal{F}|$, where \mathcal{F} is the field over which the polynomial is defined.)*

For semi-honest parties, privacy is preserved since the parties compare values of the function $P_A(x) + P_B(x)$ that has the following properties (which are trivial to prove):

- (i) The function is pairwise independent.
- (ii) Each party only computes $P_A(x) + P_B(x)$ once.
- (iii) Each party computes $P_A(x) + P_B(x)$ without revealing x to the other party.

In the case of malicious parties, the proof is simple if the protocol uses an OPE protocol which enables the extraction of the receiver's input. In this case, given a TTP which computes the function in the ideal model, we can simulate the joint distribution of the malicious party and the output of the other party: assume that Alice is malicious. We extract her input α from her invocations of the OPE protocol and provide α to the TTP. If the answer is 1, we continue the protocol by evaluating her polynomial at $\beta = \alpha$, sending the value $P_A(\alpha) + P_B(\alpha)$ to the comparison, and fixing Bob's output based on the result of the comparison. If the answer of the TTP is 0 then we provide a random value to the comparison. (Note that in the case of a malicious Bob, who computes a value of Alice's polynomial *after* letting her evaluate his, we cannot extract Bob's input before evaluating $P_B()$. We can, however, execute the OPE of Bob's polynomial twice in the simulation, learn $P_B()$ completely, and then be able to compute any value of $P_B()$ and use it to provide the right value to the comparison.)

Note that for all OPE protocols it holds that if the evaluation point does not match the input of the honest party, then with high probability the output of the protocol is 0. If the OPE protocol does not enable extraction, then we don't know, however, how to extract the evaluation point. (It might even be possible that the malicious party has some computational representation of the other party's input such that it can evaluate the OPE in the right point but does not have an explicit knowledge of the value of its input.)

Application to passwords. The protocol can serve as a basis for a mutually authenticated key exchange based on (possibly weak) passwords. Consider a user who wishes to log in to a remote server over an insecure network. She does not want to send her password in the clear, and is not even certain that the remote party is the required server. An additional problem is that the password might not have enough entropy and might therefore be susceptible to dictionary attacks. Assume that there is no PKI (public key infrastructure), and that the user does not carry with her a public key of the remote server. There have been several initial solutions to this problem (see, e.g., [5, 47]), for which it seems that a security proof must postulate the existence of a random oracle.

The most natural formulation of the scenario is as a “comparing information without leaking it” problem. If the right user contacts the right server they both should be “thinking” of the same password, and they can verify whether this is the case using Protocol 4.1. Therefore, if it is assumed that there is no active adversary, and an adversary only listens to the communication between the two parties and then tries to impersonate the user, then Protocol 4.1 can be used for password authentication. Furthermore, it can be used to generate a session key for the two parties, whose entropy does not depend on the entropy of the passwords.

In more detail, each of the parties, the user and the remote server, chooses a random linear polynomial and (obviously) computes the sum of the two polynomials at $x = \text{password}$. They use the first half of the output for authentication and the second half as a session key.

If the adversary can also be active, i.e., change the communication sent between the two parties, then the above protocol is insufficient. Although the adversary cannot decrypt the messages sent between the parties (e.g., in the invocations of the oblivious transfer protocol), it can change them and cause the output of the oblivious transfer protocol to be different, but related, to its legitimate output. The adversary can use this feature to attack different invocations of the protocol that are being executed in parallel. Our protocol can serve as a basis for a protocol that prevents such attacks, which must address delicate issues such as the nonmalleability [18] of the oblivious transfer protocols. Elaborate definitions and constructions of such protocols were given in subsequent work (see, e.g., [30, 55]).

4.3. Secure computation using randomizing polynomials. Ishai and Kushilevitz showed that secure evaluation of arbitrary functions can be reduced to secure evaluation of (perhaps several) degree-3 polynomials [36]. The inputs of these polynomials are the input variables of the original function and additional variables which must take random values. The size of the polynomials is quadratic in the size of a branching program computing the original function (therefore, this approach is efficient for functions that have an efficient branching program representation).

An examination of the structure of the polynomials generated by the constructions in [36] shows that each monomial is of the form $r_i x_j r_k$, where x_j is an original input variable and r_i and r_k are variables which must be assigned random values. Each of the variables is assigned to a party that must instantiate it with its corresponding input value (in the case of x_j) or with a random value (in the case of r_j and r_k). In the case of secure two-party computation, the computation of the randomizing polynomials can be easily reduced to OPE of *linear* polynomials. Namely, the sender assigns values to each of the variables that it controls and consequently each monomial becomes either a constant or a linear polynomial of an input known to the receiver. The two parties then do a shared output OPE for each of these polynomials and compute the sum of all the shares they learned.

The original work of [36] reduced the computation of the OPE to generic secure computation (the focus of that work was on information-theoretic security). However, a more efficient solution could use the linear OPE described in this paper. Furthermore, this results in a strongly polynomial secure computation protocol for a more general class of functions—namely, functions with efficient branching program representation.

4.4. Anonymous initialization for metering. A scheme for efficient and secure metering of clients' visits to servers was suggested in [50]. This scheme involves *clients* which send requests to *servers*, and a trusted, off-line, *audit authority*. Servers prove to the audit authority that they fulfilled requests (e.g., served web pages) of a certain number of clients. On a very high level, the operation of the scheme is as follows:

(i) The audit authority generates a random bivariate polynomial $P(x, y)$, where the degree of x is $k - 1$.

(ii) Each client u receives from the audit authority initialization data, which contains a univariate polynomial $P(u, \cdot)$.

(iii) When u sends a request to a server S (e.g., visits its web site), it sends it the value $P(u, S)$.

(iv) After k requests of different clients, S can interpolate the value $P(0, S)$ which serves as a proof for serving k requests.

A modification of this scheme described in [50] preserves the anonymity of clients towards servers. However, if the audit agency cooperates with a server S they are able to identify clients which access the server, since the audit agency knows which polynomial is owned by every client. Combining this scheme with oblivious polynomial evaluation enables the client to learn the initialization data from the audit agency without revealing to the agency which initialization value (i.e., polynomial) was learned by the client. If this method is employed, then even a coalition of the audit agency and a server is not able to identify the client.

4.5. Anonymous coupons. Consider the following scenario. An organization wants to set up an *anonymous* complaint box for its personnel, but would like to ensure that each person complains at most once (for example, if there are ten complaints about the quality of the coffee machine, they should be from ten different people and not ten complaints of the same person). A solution for this problem is to give each person an anonymous coupon that he or she should attach to any submitted complaint. When a complaint is received the coupon is checked for validity and freshness (namely, it is verified that it is a valid coupon that was not previously used).

Anonymous coupons can be constructed using oblivious polynomial evaluation.² The coupon manager sets up a polynomial P of degree d . Each person A obtains a coupon by choosing a random secret value R_A and obliviously computing $P(R_A)$, using an oblivious polynomial evaluation protocol in which the coupon manager is the sender. The coupon is the pair $\langle R_A, P(R_A) \rangle$. It is easy for the coupon manager to verify that a coupon $\langle X, Y \rangle$ is valid by simply testing whether $Y = P(X)$. The coupon manager also keeps a list of the coupons that were received and compares each new coupon to that list in order to verify that it was not used before.

²Another construction for this problem can be based on using blind signatures: Each user prepares in advance coupons by letting the central server sign them using a blind signature scheme (e.g., Chaum's scheme [12], or the scheme of Juels et al. that can be based on standard hardness assumptions [37]). A complaint must be accompanied by a signed coupon. The server verifies the signature, and also verifies that this coupon has not been used before.

The system is secure against a coalition of corrupt users that attempt to generate fake coupons, as long as the coalition has at most d different coupons. The degree of the polynomial, d , should therefore be set in accordance with the potential size of a corrupt coalition of users.

A corrupt coupon manager might attempt to identify the owners of coupons by using a different polynomial for each person. Namely, for every user A it might use a different polynomial P_A for the oblivious evaluation protocol. When it later receives a coupon $\langle X, Y \rangle$ it attempts to identify its owner by checking for which polynomials P_A it holds that $Y = P_A(X)$. This attack can be prevented by ensuring that the sender uses the same polynomial in all oblivious evaluation protocols, for example, using the verifiable secret sharing techniques of Feldman [23] or Pedersen [57].

Acknowledgments. We would like to thank Sanjeev Arora, Daniel Bleichenbacher, Dan Boneh, Oded Goldreich, Yuval Ishai, Amit Klein, Ronitt Rubinfeld, Madhu Sudan, and the anonymous referees that reviewed this paper.

AN ALGORITHM FOR COMPUTING FUNDAMENTAL SOLUTIONS*

KLAUS WEIHRAUCH[†] AND NING ZHONG[‡]

Abstract. For a partial differential operator $P = \sum_{|\alpha| \leq m} c_\alpha D^\alpha$ with constant coefficients, a generalized function u is a fundamental solution if $Pu = \delta$, where δ is the Dirac distribution. In this article, we provide an algorithm which computes a fundamental solution for every such differential operator P on a Turing machine if the input- and output-data are represented canonically.

Key words. computable analysis, partial differential equations, fundamental solution

AMS subject classifications. 03D80, 35D05, 68Q99

DOI. 10.1137/S0097539704446360

1. Introduction. In the theory of differential operators with constant coefficients, fundamental solutions have a central place. Let

$$(1) \quad P = P(D) = \sum_{|\alpha| \leq m} c_\alpha D^\alpha$$

be a partial differential operator with constant coefficients c_α , where $\alpha = (\alpha_1, \dots, \alpha_n)$ is a multi-index of order $|\alpha| = \alpha_1 + \dots + \alpha_n$, $D_j = (1/i)\partial/\partial x_j$ with $1 \leq j \leq n$ and $i = \sqrt{-1}$, $D = (D_1, \dots, D_n)$, and $D^\alpha = D_1^{\alpha_1} D_2^{\alpha_2} \dots D_n^{\alpha_n}$. A distribution is called a fundamental solution of the partial differential operator P if it is a solution of the point source problem

$$(2) \quad P(D)u = \sum_{|\alpha| \leq m} c_\alpha D^\alpha u = \delta,$$

where δ is the Dirac measure at 0. In 1954 Malgrange and Ehrenpreis proved that every partial differential operator with constant coefficients has a fundamental solution. Fundamental solutions are very useful tools in the theory of partial differential equations, for instance, in solving inhomogeneous equations and in providing information about the regularity and growth of solutions. In the case of solving inhomogeneous equations, if E is a fundamental solution of the partial differential operator $P = P(D)$ and if f is a distribution, then $E * f$ is a solution of the equation $P(D)u = f$ whenever the convolution is defined.

Many classical differential operators are known to have computable functions as fundamental solutions. For example, the Schwartz function

$$E_H(t, x) = (4\pi\nu t)^{-n/2} e^{-|x|^2/4\nu t},$$

which is a computable real function, is a fundamental solution of the heat equation

$$\frac{\partial u}{\partial t} = \nu \sum_{i=1}^n \frac{\partial^2 u}{\partial x_i^2}, \quad (t, x) \in \mathbb{R} \times \mathbb{R}^n.$$

In general, however, a fundamental solution is a distribution. Does every partial differential operator $P(D)$ with computable coefficients have a computable fundamental solution? In fact, this follows from the even more general result we prove in this note: There is a computable operator mapping every differential operator $P(D)$ (as in (1)) to a fundamental solution. We present an algorithm which in a well-defined realistic model of computation computes a fundamental solution of any given differential operator P from its coefficients, where abstract data are encoded canonically by, generally infinite, sequences of symbols and where computations are (can be) performed by Turing machines.

2. Preliminaries. In this note, we consider the representation approach as a model of computation for analysis [4]. Computable functions on Σ^* and Σ^ω (the set of finite and infinite sequences of symbols, respectively, from the finite alphabet Σ) are defined by Turing machines which can read and write finite and infinite sequences. A multifunction $f : \subseteq X \rightrightarrows Y$ is a function which assigns to every $x \in X$ a set $f(x) \subseteq Y$, the set of “acceptable” values ($f(x) = \emptyset$ if $x \notin \text{dom}(f)$). Any concrete computation will produce on input $a \in \text{dom}(f)$ some element $b \in f(a)$, but usually there is no method to select a specific one.

Computability on other sets is defined by using Σ^* and Σ^ω as codes or names. In some of our applications, a “name” $w \in \Sigma^*$ or $p \in \Sigma^\omega$ contains information about a point x , which is sufficient for certain computations but may not identify x . Therefore, we use multifunctions as naming systems. A *naming system* of a set M is a surjective multifunction $\nu : \subseteq \Sigma^* \rightrightarrows M$ (a *notation*) or $\gamma : \subseteq \Sigma^\omega \rightrightarrows M$ (a *representation*). For the natural numbers and the rational numbers we use canonical notations $\nu_{\mathbb{N}} : \subseteq \Sigma^* \rightarrow \mathbb{N}$ and $\nu_{\mathbb{Q}} : \subseteq \Sigma^* \rightarrow \mathbb{Q}$, respectively. For the real numbers we use the representation $\rho : \subseteq \Sigma^\omega \rightarrow \mathbb{R}$, where $\rho(p) = x$ if p encodes a sequence $(a_i)_i$ of rational numbers such that $|x - a_i| \leq 2^{-i}$. For a naming system $\gamma : \subseteq Y \rightarrow M$ ($Y \in \{\Sigma^*, \Sigma^\omega\}$) the representation $\gamma^k : \subseteq Y \rightarrow M^k$ is defined by $\gamma^k \langle y_1, \dots, y_k \rangle := (\gamma(y_1), \dots, \gamma(y_k))$, where $\langle \rangle$ is a tupling function. For the complex numbers we use the representation ρ^2 of \mathbb{R}^2 .

For naming systems $\gamma_i : \subseteq Y_i \rightrightarrows M_i$ a function $h : \subseteq Y_1 \rightarrow Y_2$ (on names) realizes a multifunction $f : \subseteq M_1 \rightrightarrows M_2$ if

$$\gamma_2 \circ h(p) \cap f(x) \neq \emptyset \quad \text{if } \gamma_1(p) \in \text{dom}(f);$$

that is, $h(p)$ is a name of some $y \in f(x)$ if p is a name of $x \in \text{dom}(f)$; see Figure 1.

The multifunction f is called (γ_1, γ_2) -computable if it has a computable realization.

Multifunctions occur naturally in computable analysis. As an example, there is an algorithm which maps every ρ -name p of $x \in \mathbb{R}$ (i.e., every sequence of rational numbers rapidly converging to x) to some $n \in \mathbb{N}$ such that $x < n$. This algorithm, however, might give another upper bound n' of x if fed with another ρ -name p' of x . The algorithm is not “ $(\rho, \nu_{\mathbb{N}})$ -extensional.” Nevertheless, the algorithm realizes the multifunction $f : \mathbb{R} \rightrightarrows \mathbb{N}$, defined by $n \in f(x) \iff x < n$. There is no $(\rho, \nu_{\mathbb{N}})$ -computable function $g : \mathbb{R} \rightarrow \mathbb{N}$ such that $x < g(x)$.

As generalizations of the “acceptable Gödel numbering $\varphi : \mathbb{N} \rightarrow P^{(1)}$ ” of the partial recursive functions, for any $a, b \in \{*, \omega\}$ there is a canonical representation $\eta^{ab} : \Sigma^\omega \rightarrow F^{ab}$ of continuous functions $f : \subseteq \Sigma^a \rightarrow \Sigma^b$ satisfying the “utm-theorem” and the “smn-theorem” [4] (abbreviation: $\eta_p^{ab} := \eta^{ab}(p)$). For naming systems $\gamma_1 : \subseteq \Sigma^a \rightarrow M_1$ and $\gamma_2 : \subseteq \Sigma^b \rightarrow M_2$ a *representation* $[\gamma_1 \rightarrow \gamma_2]$ of the *total* (γ_1, γ_2) -

FIG. 1. $h(p)$ is a name of some $y \in f(x)$ if p is a name of $x \in \text{dom}(f)$.

continuous functions is defined by

$$[\gamma_1 \rightarrow \gamma_2](p) = f : \iff \eta_p^{ab} \text{ realizes } f \text{ w.r.t. } (\gamma_1, \gamma_2),$$

and a *multirepresentation* $[\gamma_1 \rightarrow_p \gamma_2]$ of all partial (γ_1, γ_2) -continuous functions is defined by

$$f \in [\gamma_1 \rightarrow_p \gamma_2](p) : \iff \eta_p^{ab} \text{ realizes } f \text{ w.r.t. } (\gamma_1, \gamma_2).$$

Notice that $[\gamma_1 \rightarrow \gamma_2]$ is the “weakest” representation δ of the set of total (γ_1, γ_2) -continuous functions such that the evaluation $(f, x) \mapsto f(x)$ becomes $(\delta, \gamma_1, \gamma_2)$ -computable (Lemma 3.3.14 in [4]).

We will apply the following slight generalization of the type conversion theorem in [4].

LEMMA 2.1 (type conversion). *Let $\gamma_i : \subseteq Y_i \rightarrow M_i$ be representations ($i = 1, 2, 3$), let $f : \subseteq M_1 \times M_2 \rightarrow M_3$, and let $\tilde{f} : M_1 \rightarrow \tilde{M}$ be the total function to the partial (γ_2, γ_2) -continuous functions $h : \subseteq M_2 \rightarrow M_3$ defined by $\tilde{f}(x)(y) := f(x, y)$. Then*

$$f \text{ is } (\gamma_1, \gamma_2, \gamma_3)\text{-computable} \iff \tilde{f} \text{ is } (\gamma_1, [\gamma_2 \rightarrow_p \gamma_3])\text{-computable}.$$

For definitions and mathematical properties of distributions, see [1, 2]. In [6] computability on distributions over the real line is studied. The definitions and theorems can be generalized straightforwardly to distributions over \mathbb{R}^n ($n \geq 1$). For the space of continuous functions $f : \mathbb{R}^n \rightarrow \mathbb{C}$ we use the representation $[\rho^n \rightarrow \rho^2] : \subseteq \Sigma^\omega \rightarrow C(\mathbb{R}^n)$. For the space $C^\infty(\mathbb{R}^n)$ of infinitely differentiable functions $f : \mathbb{R}^n \rightarrow \mathbb{C}$ we use the representation $\delta_\infty : \subseteq \Sigma^\omega \rightarrow C^\infty(\mathbb{R}^n)$ defined by

$$\delta_\infty(\langle p_\alpha \rangle_{\alpha \in \mathbb{N}^n}) = f : \iff (\forall \alpha \in \mathbb{N}^n) D^\alpha f = [\rho^n \rightarrow \rho^2](p_\alpha)$$

(where $\langle p_\alpha \rangle_{\alpha \in \mathbb{N}^n} \in \Sigma^\omega$ is a canonical merging of the infinitely many infinite sequences $p_\alpha \in \Sigma^\omega$, $\alpha \in \mathbb{N}^n$). The topology of $C^\infty(\mathbb{R}^n)$ can be defined by the seminorms $f \mapsto |D^m f|_k = \sup_{|\alpha| \leq m} (\sup_{x \in K} |D^\alpha f(x)|)$ as m varies over the set of nonnegative integers and K varies over the family of compact subsets of \mathbb{R}^n .

A test function is a function $f \in C^\infty(\mathbb{R}^n)$ with compact support $\text{supp}(f) := \text{cls}\{x \in \mathbb{R}^n \mid f(x) \neq 0\}$. The set of test functions is denoted by $\mathcal{D}(\mathbb{R}^n)$, and its

topology is induced by $C^\infty(\mathbb{R}^n)$. We use the representation $\delta_D : \subseteq \Sigma^\omega \rightarrow \mathcal{D}(\mathbb{R}^n)$ defined by

$$\delta_D(0^k 1p) = f : \iff \delta_\infty(p) = f \text{ and } \text{supp}(f) \subseteq [-k; k]^n.$$

A Schwartz function is a function $f \in C^\infty(\mathbb{R}^n)$ such that $\sup_{x \in \mathbb{R}^n} (|x|^j |D^\alpha f(x)|) < \infty$ for all $j \in \mathbb{N}$ and $\alpha \in \mathbb{N}^n$. The set of Schwartz functions is denoted by $\mathcal{S}(\mathbb{R}^n)$. We use the representation $\delta_S : \subseteq \Sigma^\omega \rightarrow \mathcal{S}(\mathbb{R}^n)$ defined by

$$\delta_S(\langle p, q \rangle) = f : \iff \delta_\infty(p) = f \text{ and } q \text{ encodes a function } h : \mathbb{N}^{n+1} \rightarrow \mathbb{N} \text{ such that } (\forall j, \alpha) \sup_{x \in \mathbb{R}^n} (|x|^j |D^\alpha f|) \leq h(j, \alpha).$$

Of course, the above representations can be replaced by equivalent ones. Examples for the case $n = 1$ are discussed in [6].

A continuous linear map $T : \mathcal{D}(\mathbb{R}^n) \rightarrow \mathbb{C}$ (or $T : \mathcal{S}(\mathbb{R}^n) \rightarrow \mathbb{C}$) is called a distribution (tempered distribution). The set of all distributions (tempered distributions) is denoted as $\mathcal{D}'(\mathbb{R}^n)$ ($\mathcal{S}'(\mathbb{R}^n)$). For the set $\mathcal{D}'(\mathbb{R}^n)$ we use the representation $[\delta_D \rightarrow \rho^2]$ (restricted to the linear functions).

Recall that the evaluation function is computable; i.e., there is Type-2 Turing machine which computes a ρ^2 -name of $T(\phi)$ whenever given a $[\delta_D \rightarrow \rho^2]$ -name of T and a δ_D -name of ϕ as input. Usually $T(\phi)$ is written as $\langle T, \phi \rangle$.

We conclude this section by recalling some further definitions and facts [2]. The Dirac measure δ on \mathbb{R}^n at 0 is a tempered distribution defined by $\delta(\phi) = \langle \delta, \phi \rangle = \phi(0)$ for any Schwartz function $\phi \in \mathcal{S}(\mathbb{R}^n)$. The Dirac measure can be viewed as a point source. The Fourier transform of a Schwartz function $\phi \in \mathcal{S}(\mathbb{R}^n)$, denoted by $\hat{\phi}$ or $\mathcal{F}(\phi)$, is defined as

$$\mathcal{F}(\phi)(\xi) = \hat{\phi}(\xi) := (2\pi)^{-n/2} \int_{\mathbb{R}^n} e^{-ix\xi} \phi(x) dx,$$

where $x = (x_1, x_2, \dots, x_n)$, $\xi = (\xi_1, \xi_2, \dots, \xi_n)$, and $x\xi = x_1\xi_1 + x_2\xi_2 + \dots + x_n\xi_n$. The Fourier transform is a linear bijection of $\mathcal{S}(\mathbb{R}^n)$ to itself. For every partial derivative,

$$(3) \quad \mathcal{F}(D_j \phi) = \xi_j \mathcal{F}(\phi) \text{ and } D_j \mathcal{F}(\phi) = \mathcal{F}(-\xi_j \phi).$$

Therefore, for any partial differential operator $P(D)$ with constant coefficients

$$(4) \quad \langle \mathcal{F}(P(D)), \phi \rangle = P(\xi) \hat{\phi} \quad \forall \phi \in \mathcal{S}(\mathbb{R}^n).$$

Since $\mathcal{S}(\mathbb{R}^n)$ is sequentially dense in $\mathcal{S}'(\mathbb{R}^n)$, by a duality argument, \mathcal{F} and D_j can be uniquely extended from $\mathcal{S}(\mathbb{R}^n)$ to $\mathcal{S}'(\mathbb{R}^n)$ defined by the following formulae:

$$(5) \quad \langle \mathcal{F}T, \phi \rangle := \langle T, \mathcal{F}\phi \rangle,$$

$$(6) \quad \langle D_j T, \phi \rangle := \langle T, -D_j \phi \rangle$$

for any $T \in \mathcal{S}'(\mathbb{R}^n)$ and $\phi \in \mathcal{S}(\mathbb{R}^n)$. The Fourier transform $\hat{\delta}$ of the Dirac measure δ is a constant:

$$(7) \quad \mathcal{F}(\delta) = (2\pi)^{-n/2}.$$

Let \mathcal{R} be the reflexion operator on $\mathcal{S}(\mathbb{R}^n)$ defined by $\mathcal{R}(u)(x) := u(-x)$.

LEMMA 2.2. For any $E \in \mathcal{D}'(\mathbb{R}^n)$ let $\langle \tilde{E}, \phi \rangle := \langle E, \mathcal{R}\phi \rangle$. Then E is a fundamental solution of $P(D)$; that is, $P(D)E = \delta$ iff

$$\langle \tilde{E}, P(D)\phi \rangle = \phi(0) \quad \forall \phi \in \mathcal{D}(\mathbb{R}^n).$$

Proof. By (6), $\langle E, \mathcal{R}D_j\phi \rangle = \langle E, -D_j\mathcal{R}\phi \rangle = \langle D_jE, \mathcal{R}\phi \rangle$, and therefore,

$$\langle \tilde{E}, P(D)\phi \rangle = \langle E, \mathcal{R}P(D)\phi \rangle = \langle P(D)E, \mathcal{R}\phi \rangle.$$

We obtain $P(D)E = \delta$ iff $(\forall \phi)\langle P(D)E, \mathcal{R}\phi \rangle = \mathcal{R}\phi(0) = \phi(0)$ iff

$$(\forall \phi)\langle \tilde{E}, P(D)\phi \rangle = \phi(0). \quad \square$$

3. Computing a fundamental solution. Formally, the problem of constructing a fundamental solution of a partial differential operator $P(D)$ is very easy. Indeed, suppose that we have

$$P(D)E = \delta.$$

Since $\mathcal{F}D_jT = \xi_j\mathcal{F}T$ (from (3), (5), and (6)), by taking the Fourier transform we obtain $P(\xi)\mathcal{F}E = (2\pi)^{-n/2}$, hence

$$\mathcal{F}E = \frac{(2\pi)^{-n/2}}{P(\xi)},$$

and E should be defined as the inverse Fourier transform of $(2\pi)^{-n/2}/P(\xi)$. This is meaningful if $P(\xi)$ has no real zeros. In the general case, we will overcome the difficulty by selecting domains of integration which avoid the zeros of $P(\xi)$.

For $m \geq 1$ let $\mathcal{P}(m)$ be the linear space of all polynomials $P(\xi) = \sum_{|\alpha| \leq m} c_\alpha \xi^\alpha$, $c_\alpha \in \mathbb{C}$, in n variables of degree $\leq m$, where $\xi^\alpha = \xi_1^{\alpha_1} \cdots \xi_n^{\alpha_n}$ for $\alpha = (\alpha_1, \dots, \alpha_n)$ and $|\alpha| = \alpha_1 + \cdots + \alpha_n$. This space has dimension $N(m, n) := (m+n)!/m!n!$, and the monomials ξ^α , $|\alpha| \leq m$, can be considered as a basis. On $\mathcal{P}(m)$ we consider the norm $\|\sum_{|\alpha| \leq m} c_\alpha \xi^\alpha\|_m := \sqrt{\sum_{|\alpha| \leq m} |c_\alpha|^2}$.

LEMMA 3.1 (see [3]). From m a finite set $A_m = \{\nu_i \mid 1 \leq i \leq L(m, n)\} \subseteq \mathbb{Q}^n$ of vectors, $L(m, n) := (m+1)^{(n+1)}$, can be computed such that for all $P \in \mathcal{P}(m)$, $P \neq 0$,

$$(8) \quad (\exists \nu \in A_m)(\forall z \in \mathbb{C}, |z| = 1)P(z\nu) \neq 0.$$

A_m can be chosen as follows: $A_m = \{\frac{k}{m}\nu : \nu \in A', k = 0, 1, \dots, m\}$, where $A' = \{\xi \in \mathbb{R}^n : \xi_i \in \{0, 1, 2, \dots, m\}, 1 \leq i \leq n\}$. Observe that $|A_m| = (m+1)^{(n+1)} = L(m, n)$.

LEMMA 3.2. There is a Type-2 Turing machine which, for every polynomial $P \in \mathcal{P}(m)$ of degree $m > 0$, computes a number $l \in \mathbb{N}$ such that

$$(9) \quad 2^{-l} < \max_{\nu \in A_m} \inf_{|z|=1} |P(\xi + z\nu)| \quad \forall \xi \in \mathbb{R}^n.$$

More precisely, from the degree m and ρ^2 -names of the coefficients $c_\alpha \in \mathbb{C}$ ($|\alpha| \leq m$) of a polynomial $P(\xi) = \sum_{|\alpha| \leq m} c_\alpha \xi^\alpha$ the machine computes a number l such that (9) holds.

Proof. By Lemma 3.1 there is some $\nu \in A_m$ such that for all $z \in \mathbb{C}$, $P(z\nu) \neq 0$ if $|z| = 1$. Since $z \mapsto |P(z\nu)|$ is continuous,

$$(10) \quad 0 < \max_{\nu \in A_m} \inf_{|z|=1} |P(z\nu)|.$$

For every $\nu \in A_m$ the total function

$$(\tilde{c}, z) \mapsto |P(z\nu)| \text{ is } (\rho^{2N(m,n)}, \rho^2, \rho)\text{-computable}$$

($\tilde{c} := (c_\alpha)_{|\alpha| \leq m} \in \mathbb{C}^{N(m,n)}$). By Lemma 2.1 on type conversion, the function

$$\tilde{c} \mapsto (z \mapsto |P(z\nu)|) \text{ is } (\rho^{2N(m,n)}, [\rho^2 \rightarrow \rho])\text{-computable.}$$

Since $\{z \in \mathbb{C} \mid |z| = 1\}$ is a κ^2 -computable compact set (see Definition 5.2.1 in [4]) the function

$$f \mapsto \inf_{|z|=1} f(z) \text{ is } ([\rho^2 \rightarrow \rho], \rho)\text{-computable}$$

by Corollary 6.2.5 in [4]. Therefore, for each $\nu \in A_m$, the function

$$(11) \quad \tilde{c} \mapsto \inf_{|z|=1} |P(z\nu)| \text{ is } (\rho^{2N(m,n)}, \rho)\text{-computable.}$$

By Theorem 6.2.1 in [4], the total function

$$(12) \quad \tilde{c} \mapsto \max_{\nu \in A_m} \inf_{|z|=1} |P(z\nu)| \text{ is } (\rho^{2N(m,n)}, \rho)\text{-computable.}$$

Since $B_m := \{\tilde{c} \mid \sqrt{\sum_{|\alpha| \leq m} |c_\alpha|^2} = 1\}$ is compact and $\tilde{c} \mapsto \max_{\nu \in A_m} \inf_{|z|=1} |P(z\nu)|$ is continuous by (12), by (10)

$$\inf_{\|\tilde{c}\|_m=1} \max_{\nu \in A_m} \inf_{|z|=1} |P(z\nu)| > 0.$$

Since B_m is $\kappa^{2N(m,n)}$ -computable, by (12) and Corollary 6.2.5 in [4],

$$\inf_{\|\tilde{c}\|_m=1} \max_{\nu \in A_m} \inf_{|z|=1} |P(z\nu)| > 0 \text{ is } \rho\text{-computable.}$$

Since all the above computations are uniform in the degree m , a rational number $C_m > 0$ can be computed from m such that

$$(13) \quad C_m < \max_{\nu \in A_m} \inf_{|z|=1} |P(z\nu)| \text{ if } \|P\|_m = 1.$$

Now consider arbitrary polynomials $P(\xi) = \sum_{|\alpha| \leq m} c_\alpha \xi^\alpha$ of degree m . There is a Type-2 machine which on input m and the coefficients $(c_\alpha)_{|\alpha| \leq m}$ computes some rational number a_P such that $0 < a_P < |c_\beta|$ for some index β with $|\beta| = m$.

For fixed $\xi \in \mathbb{R}^n$, $P(\xi + \xi') = \sum c_\alpha (\xi + \xi')^\alpha = \sum d_\alpha(\xi) (\xi')^\alpha$, where the coefficients of the polynomials $d_\alpha(\xi)$ can be determined by algebraic computation. By an easy observation, $d_\beta(\xi) = c_\beta$ since $|\beta| = m$. Let $Q(\xi') := P(\xi + \xi')$. Then $a_P < |c_\beta| \leq \sqrt{\sum |d_\alpha(\xi)|^2} = \|Q\|_m$. Since $Q/\|Q\|_m$ has norm 1, by (13), $C_m < \max_{\nu \in A_m} \inf_{|z|=1} |Q(z\nu)|/\|Q\|_m$, and therefore

$$a_P \cdot C_m < \|Q\|_m \cdot C_m \leq \max_{\nu \in A_m} \inf_{|z|=1} |Q(z\nu)| = \max_{\nu \in A_m} \inf_{|z|=1} |P(\xi + z\nu)|.$$

Finally, some $l \in \mathbb{N}$ can be computed such that $2^{-l} \leq a_P C_m$. \square

In the following we denote, for any $(\xi_1, \dots, \xi_n) \in \mathbb{R}^n$, $|(\xi_1, \dots, \xi_n)| := \max_j |\xi_j|$. \overline{X} will denote the closure, and X° will denote the interior of a set X . For vectors in \mathbb{R}^n let $(x_1, \dots, x_n) < (y_1, \dots, y_n)$ iff $x_i < y_i$ for all i . For $a, b \in \mathbb{R}^n$ and $a < b$, let $(a; b]$ be the half-open interval (box) $\{x \in \mathbb{R}^n \mid a < x \leq b\}$. Let $\mathcal{B}_1 := \{(a; b] \mid a, b \in \mathbb{Q}^n \text{ and } a < b\}$ be the set of all half-open rational intervals with canonical notation ν_{B_1} . The set $\{I^\circ \mid I \in \mathcal{B}_1\}$ is a basis of the topology on \mathbb{R}^n . Let \mathcal{B} be the set of all finite unions of elements from \mathcal{B}_1 , and let ν_B be a standard notation of \mathcal{B} . Notice that $\emptyset \in \mathcal{B}$ and \mathcal{B} is closed under union, intersection, and difference $(I, J) \mapsto I \setminus J$ and that every $J \in \mathcal{B}$ is a finite union of pairwise disjoint half-open intervals from \mathcal{B}_1 . Union and difference are (ν_B, ν_B, ν_B) -computable.

Integration of total continuous functions over intervals is computable [4]. We need a generalization to partial functions. The following lemma generalizes Theorem 6.4.1 in [4]. It can be proved by using standard techniques.

LEMMA 3.3.

1. The partial function $f \mapsto \int_{|z|=1} f(z) dz$ for continuous $f : \subseteq \mathbb{C} \rightarrow \mathbb{C}$, which is defined if $\{z \mid |z| = 1\} \subseteq \text{dom}(f)$, is $([\rho^2 \rightarrow_p \rho^2], \rho^2)$ -computable.
2. The partial function $(f, I) \mapsto \int_I f(\xi) d\xi$ for continuous $f : \subseteq \mathbb{R}^n \rightarrow \mathbb{C}$ and $I \in \mathcal{B}$, which is defined if $\overline{I} \subseteq \text{dom}(f)$, is $([\rho^n \rightarrow_p \rho^2], \nu_B, \rho^2)$ -computable.

Since the boundary of every $I \in \mathcal{B}$ has measure 0, for every continuous function f ,

$$\int_{\overline{I}} f(\xi) d\xi = \int_I f(\xi) d\xi = \int_{I^\circ} f(\xi) d\xi$$

if $\overline{I} \subseteq \text{dom}(f)$. After these preparations we can prove our main theorem.

THEOREM 3.4. There is a Type-2 Turing machine which for every differential operator $P(D) = \sum_{|\alpha| \leq m} c_\alpha D^\alpha \neq 0$ computes a fundamental solution $E \in \mathcal{D}'(\mathbb{R}^n)$. More precisely, from m and ρ^2 -names of the $c_\alpha \in \mathbb{C}$ it computes a $[\delta_D \rightarrow \rho^2]$ -name of a fundamental solution E .

Proof. First, we assume that the degree m of the polynomial $P(\xi) = \sum_{|\alpha| \leq m} c_\alpha \xi^\alpha$ is fixed. Let $\tilde{c} := (c_\alpha)_{|\alpha| \leq m} \in \mathbb{C}^{N(m,n)}$ be the vector of coefficients of $P(\xi)$. Let $A_m = \{\nu_i \mid 1 \leq i \leq L(m,n)\}$ be any set satisfying Lemma 3.1. Let $l \in \mathbb{N}$ be some constant such that (9). For $1 \leq j \leq L(m,n)$, define

$$(14) \quad \Omega_j := \left\{ \xi \in \mathbb{R}^n \mid 2^{-l} < \inf_{|z|=1} |P(\xi + z\nu_j)| \right\}.$$

Notice that $\bigcup_{j=1}^{L(m,n)} \Omega_j = \mathbb{R}^n$.

Let $M_{-1} := M_0 := \emptyset \in \mathcal{B}$ and $M_k := ((-k, \dots, -k); (k, \dots, k)) \in \mathcal{B}$ for $k \geq 1$. For $k, j \in \mathbb{N}$, $1 \leq j \leq L(m,n)$, let $T_j^k \in \mathcal{B}$ be sets such that

$$(15) \quad T_j^k \subseteq \Omega_j, \quad T_i^k \cap T_j^k = \emptyset \text{ for } i \neq j, \text{ and } \bigcup_j T_j^k = M_k \setminus M_{k-1}.$$

We shall show below how such sets T_j^k can be computed. Since for each k the T_j^k ($1 \leq j \leq L(m,n)$) are a partition of $M_k \setminus M_{k-1}$, and since the $M_k \setminus M_{k-1}$ are a partition of \mathbb{R}^n , $T_j^k \cap T_{j'}^{k'} = \emptyset$ if $k \neq k'$ or $j \neq j'$. Define $T_j := \bigcup_k T_j^k$. Then

$$(16) \quad T_j \subseteq \Omega_j, \quad T_i \cap T_j = \emptyset \text{ for } i \neq j, \text{ and } \bigcup_j T_j = \mathbb{R}^n.$$

For any $u \in \mathcal{D}(\mathbb{R}^n)$ and $k \in \mathbb{N}$ define

$$(17) \quad \tilde{E}_k(u) := (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j^k} d\xi \frac{1}{2\pi i} \int_{|z|=1} \frac{\hat{u}(\xi + z\nu_j)}{P(\xi + z\nu_j)} \frac{1}{z} dz$$

and

$$(18) \quad \tilde{E}(u) := (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j} d\xi \frac{1}{2\pi i} \int_{|z|=1} \frac{\hat{u}(\xi + z\nu_j)}{P(\xi + z\nu_j)} \frac{1}{z} dz.$$

The integrals exist because $u \in \mathcal{D}(\mathbb{R}^n)$ and $P(\xi + z\nu_j) \neq 0$ for $|z| = 1$ and $\xi \in T_j$ by (14) and (16).

Define E by $\langle E, \phi \rangle := \langle \tilde{E}, \mathcal{R}\phi \rangle$ for all $\phi \in \mathcal{D}(\mathbb{R}^n)$. Then $\langle \tilde{E}, \phi \rangle = \langle \tilde{E}, \mathcal{R}^2\phi \rangle = \langle E, \mathcal{R}\phi \rangle$ for all $\phi \in \mathcal{D}(\mathbb{R}^n)$. We show in the following that E is a fundamental solution of $P(D)$. By Lemma 2.2, E is a fundamental solution of $P(D)$ iff $\tilde{E}(P(D)v) = v(0)$ for any $v \in \mathcal{D}(\mathbb{R}^n)$. For any $v \in \mathcal{D}(\mathbb{R}^n)$ and $u = P(D)v$,

$$\begin{aligned} \tilde{E}(u) &= \tilde{E}(P(D)v) \\ &= (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j} d\xi \frac{1}{2\pi i} \int_{|z|=1} \frac{\mathcal{F}(P(D)v)(\xi + z\nu_j)}{P(\xi + z\nu_j)} \frac{1}{z} dz \\ &= (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j} d\xi \frac{1}{2\pi i} \int_{|z|=1} \frac{P(\xi + z\nu_j)\hat{v}(\xi + z\nu_j)}{P(\xi + z\nu_j)} \frac{1}{z} dz \\ &= (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j} d\xi \frac{1}{2\pi i} \int_{|z|=1} \hat{v}(\xi + z\nu_j) \frac{1}{z} dz. \end{aligned}$$

We observe that

$$\begin{aligned} &\frac{1}{2\pi i} \int_{|z|=1} \hat{v}(\xi + z\nu_j) \frac{1}{z} dz \\ &= \frac{1}{2\pi i} \int_{|z|=1} (2\pi)^{-n/2} \int_{\mathbb{R}^n} e^{-ix(\xi+z\nu_j)} v(x) dx \frac{1}{z} dz \\ &= (2\pi)^{-n/2} \int_{\mathbb{R}^n} e^{-ix\xi} v(x) dx \frac{1}{2\pi i} \int_{|z|=1} \frac{e^{-ixz\nu_j}}{z} dz \\ &= (2\pi)^{-n/2} \int_{\mathbb{R}^n} e^{-ix\xi} v(x) e^{-ix0\nu_j} dx \quad (\text{Cauchy integral}) \\ &= (2\pi)^{-n/2} \int_{\mathbb{R}^n} e^{-ix\xi} v(x) dx \\ &= \hat{v}(\xi). \end{aligned}$$

Thus we obtain

$$\begin{aligned} \tilde{E}(P(D)v) &= (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j} \hat{v}(\xi) d\xi \\ &= (2\pi)^{-n/2} \int_{\mathbb{R}^n} \hat{v}(\xi) d\xi \\ &= (2\pi)^{-n/2} \int_{\mathbb{R}^n} e^{i0\xi} \hat{v}(\xi) d\xi \\ &= v(0). \end{aligned}$$

Next we determine an upper bound of $|\tilde{E}_k(u)|$. Since $\hat{u} \in \mathcal{S}(\mathbb{R}^n)$,

$$(19) \quad (\exists k' \in \mathbb{N}) \quad (|\hat{u}(\xi)| |\xi|^{n+2} \leq 1 \quad \text{if} \quad |\xi| \geq k').$$

Define $\bar{\nu} := \max_{\nu \in A_m} |\nu|$.

Let $k \geq k' + \bar{\nu} + 1$ and $k \geq 2\bar{\nu} + 2$. Then for $\xi \in \mathbb{R}^n$, $z \in \mathbb{C}$, and $1 \leq j \leq L(m, n)$,

$$(20) \quad |\xi + z\nu_j| \geq |\xi| - \bar{\nu} \geq k' \quad \text{if} \quad |\xi| \geq k - 1 \quad \text{and} \quad |z| = 1.$$

We obtain

$$\begin{aligned} |\tilde{E}_k(u)| &\leq (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j^k} d\xi \frac{1}{2\pi} \int_{|z|=1} \frac{|\hat{u}(\xi + z\nu_j)|}{|P(\xi + z\nu_j)|} \frac{1}{|z|} |dz| \\ &\leq 2^l (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j^k} d\xi \frac{1}{2\pi} \int_{|z|=1} |\hat{u}(\xi + z\nu_j)| |dz| \quad (\text{by (14), (15)}) \\ &\leq 2^l (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j^k} d\xi \frac{1}{2\pi} \int_{|z|=1} \frac{|\hat{u}(\xi + z\nu_j)| \cdot |\xi + z\nu_j|^{n+2}}{|\xi + z\nu_j|^{n+2}} |dz| \\ &\leq 2^l (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j^k} d\xi \frac{1}{2\pi} \int_{|z|=1} \frac{1}{|\xi + z\nu_j|^{n+2}} |dz| \\ &\quad (\text{by (19) and (20), since } |\xi| \geq k - 1 \text{ for } \xi \in T_j^k) \\ &\leq 2^l (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j^k} d\xi \frac{1}{2\pi} \int_{|z|=1} \frac{1}{(k - 1 - \bar{\nu})^{n+2}} |dz| \\ &\leq 2^l (2\pi)^{-n/2} \sum_{j=1}^{L(m,n)} \int_{T_j^k} d\xi \frac{1}{(k - 1 - \bar{\nu})^{n+2}} \\ &\leq 2^l (2\pi)^{-n/2} \frac{(2k)^n}{(k - 1 - \bar{\nu})^{n+2}} \quad (\text{by (15)}) \\ &\leq 2^l \cdot (2\pi)^{-n/2} \cdot 2^{2n+2} \frac{1}{k^2} \quad (\text{since } k \geq 2\bar{\nu} + 2). \end{aligned}$$

Since $\sum_{k>K} \frac{1}{k^2} \leq \frac{1}{K}$, we obtain for all $K \geq k' + 2\bar{\nu} + 2$,

$$\sum_{k=K+1}^{\infty} |\tilde{E}_k(u)| \leq 2^{l+2n+2} \cdot (2\pi)^{-n/2} \frac{1}{K},$$

and by (15)–(18),

$$(21) \quad \tilde{E}(u) = \sum_{k=0}^{\infty} \tilde{E}_k(u),$$

and for all $K \geq k' + 2\bar{\nu} + 2$,

$$(22) \quad \left| \tilde{E}(u) - \sum_{k=0}^K \tilde{E}_k(u) \right| \leq 2^{l+2n+2} \cdot (2\pi)^{-n/2} \frac{1}{K}.$$

It remains to prove that the fundamental solution E can be *computed* from the polynomial P . Concretely, a polynomial P of degree m is given by the list $\tilde{c} = (c_\alpha)_{|\alpha| \leq m}$, $c_\alpha \in \mathbb{C}$, of its coefficients represented by $\rho^{2N(m,n)}$. Let A_m be a set of vectors according to Lemma 3.1.

- (a) By Lemma 3.2, the multifunction $\tilde{c} \mapsto l$ such that (9) is $(\rho^{2N(m,n)}, \nu_{\mathbb{N}})$ -computable.
- (b) Next we compute the sets Ω_j defined in (14). For each number j the function $(l, \tilde{c}, \xi) \mapsto \inf_{|z|=1} |P(\xi + z\nu_j)| - 2^{-l}$ is $(\nu_{\mathbb{N}}, \rho^{2N(m,n)}, \rho^n, \rho)$ -computable. The proof is essentially that of (11). By Lemma 2.1 on type conversion, for each j the function

$$(l, \tilde{c}) \mapsto \left(\xi \mapsto \inf_{|z|=1} |P(\xi + z\nu_j)| - 2^{-l} \right)$$

is $(\nu_{\mathbb{N}}, \rho^{2N(m,n)}, [\rho^n \rightarrow \rho])$ -computable. For the open subsets of \mathbb{R}^n we use the representation $\theta_<$ defined by $\theta_<(p) = U$ iff $p \in \Sigma^\omega$ is (encodes) a list of all $I \in \mathcal{B}_1$ such that $\bar{I} \subseteq U$ (see Definition 5.1.15 in [4]). Notice that $U = \bigcup_{\bar{I} \subseteq U} I^\circ = \bigcup_{\bar{I} \subseteq U} \bar{I}$. Since the set $\{y \in \mathbb{R} \mid y > 0\}$ is reclusively enumerable (r.e.) open, by Theorem 6.2.4.1 in [4] for each j the function

$$(l, \tilde{c}) \mapsto \Omega_j \text{ is } (\nu_{\mathbb{N}}, \rho^{2N(m,n)}, \theta_<)\text{-computable.}$$

- (c) We describe how to compute sets T_j^k from sequences $p_j \in \Sigma^\omega$ such that $\theta_<(p_j) = \Omega_j$. Consider $k \in \mathbb{N}$. Simultaneously for all $j = 1, \dots, L(m, n)$ produce the lists of intervals $I \in \mathcal{B}_1$ encoded by the p_j . Halt as soon as a finite family $C \subseteq \mathcal{B}_1$ has been found such that $\overline{M_k \setminus M_{k-1}} \subseteq \bigcup_{I \in C} I^\circ$ (finite covering of a compact set). For each j let $C_j \subseteq C$ be the set of intervals from C so far listed by p_j . Let $T_0^k := \emptyset$ and determine the $T_j^k \subseteq \mathcal{B}$ successively by the rule

$$T_j^k := \left(\bigcup_{I \in C_j} I \cap (M_k \setminus M_{k-1}) \right) \setminus \bigcup_{j' < j} T_{j'}^k.$$

If (9) holds for the number l , then $\bigcup_j \Omega_j = \mathbb{R}^n$, a set C will be found by compactness of $\overline{M_k \setminus M_{k-1}}$, and (15) and (16) are true. As a summary, we have a multifunction

$$(l, \tilde{c}) \mapsto ((k, j) \mapsto T_j^k), \text{ which is } (\nu_{\mathbb{N}}, \rho^{2N(m,n)}, [\nu_{\mathbb{N}}^2 \rightarrow \nu_B])\text{-computable.}$$

- (d) Next we prove that $(\tilde{c}, k, u, ((k, j) \mapsto T_j^k)) \mapsto \tilde{E}_k(u)$ defined in (17) is $(\rho^{2N(m,n)}, \nu_{\mathbb{N}}, \delta_D, [\nu_{\mathbb{N}}^2 \rightarrow \nu_B], \rho^2)$ -computable. First let j be fixed. Since the identity from $\mathcal{D}(\mathbb{R}^n)$ to $\mathcal{S}(\mathbb{R}^n)$ is (δ_D, δ_S) -computable, the Fourier transform is (δ_S, δ_S) -computable [6], and the identity from $\mathcal{S}(\mathbb{R}^n)$ to $C(\mathbb{R}^n)$ is $(\delta_S, [\rho^n \rightarrow \rho^2])$ -computable, the partial function

$$(u, \tilde{c}, \xi, z) \mapsto \frac{\hat{u}(\xi + z\nu_j)}{P(\xi + z\nu_j)} \frac{1}{z} \text{ is } (\delta_D, \rho^{2N(m,n)}, \rho^n, \rho^2, \rho^2)\text{-computable.}$$

Therefore by type conversion (Lemma 2.1),

$$(u, \tilde{c}, \xi) \mapsto \left(z \mapsto \frac{\hat{u}(\xi + z\nu_j)}{P(\xi + z\nu_j)} \frac{1}{z} \right) \text{ is } (\delta_D, \rho^{2N(m,n)}, \rho^n, [\rho^2 \rightarrow_p \rho^2])\text{-computable.}$$

By Lemma 3.3 the function

$$(u, \tilde{c}, \xi) \mapsto \int_{|z|=1} \frac{\hat{u}(\xi + z\nu_j)}{P(\xi + z\nu_j)} \frac{1}{z} dz \quad \text{is } (\delta_D, \rho^{2N(m,n)}, \rho^n, \rho^2)\text{-computable.}$$

Again after type conversion by Lemma 3.3, the function

$$(I, u, \tilde{c}) \mapsto \int_I d\xi \int_{|z|=1} \frac{\hat{u}(\xi + z\nu_j)}{P(\xi + z\nu_j)} \frac{1}{z} dz \quad \text{is } (\nu_B, \delta_D, \rho^{2N(m,n)}, \rho^2)\text{-computable.}$$

Finally, since π is computable, we can conclude that

$$(\tilde{c}, k, u, ((k, j) \mapsto T_j^k)) \mapsto \tilde{E}_k(u)$$

is $(\rho^{2N(m,n)}, \nu_{\mathbb{N}}, \delta_D, [\nu_{\mathbb{N}}^2 \rightarrow \nu_B], \rho^2)$ -computable. By Theorem 3.1.7 in [4] on primitive recursion, the function

$$(\tilde{c}, K, u, ((k, j) \mapsto T_j^k)) \mapsto \sum_{k=0}^K \tilde{E}_k(u)$$

is $(\rho^{2N(m,n)}, \nu_{\mathbb{N}}, \delta_D, [\nu_{\mathbb{N}}^2 \rightarrow \nu_B], \rho^2)$ -computable.

- (e) As above, from $u \in \mathcal{D}(\mathbb{R}^n)$, $\hat{u} \in \mathcal{S}(\mathbb{R}^n)$ can be computed. By the definition of δ_S , a number k' can be computed from \hat{u} such that $|v(\xi)| |\xi|^{n+2} \leq 1$ if $|\xi| \geq k'$. From l, k' , and $L \in \mathbb{N}$, a number K can be computed such that $K \geq k' + 2\bar{\nu} + 2$ and $K \geq 2^{l+2n+2} \cdot (2\pi)^{-n/2} \cdot 2^{L+1}$. Then by (22),

$$\left| \tilde{E}(u) - \sum_{k=0}^K \tilde{E}_k(u) \right| \leq 2^{-L-1}.$$

By (d) above, from $\tilde{c}, K, u, ((k, j) \mapsto T_j^k)$ and L a rational $b_L \in \mathbb{C}$ can be computed such that

$$\left| b_L - \sum_{k=0}^K \tilde{E}_k(u) \right| \leq 2^{-L-1}.$$

From the sequence b_0, b_1, \dots we can compute a ρ^2 -name of $\tilde{E}(u)$. Therefore, after type conversion, the function

$$(\tilde{c}, l, ((k, j) \mapsto T_j^k)) \mapsto (u \mapsto \tilde{E}(u))$$

is $(\rho^{2N(m,n)}, \nu_{\mathbb{N}}, [\nu_{\mathbb{N}}^2 \rightarrow \nu_B], [\delta_D \rightarrow \rho^2])$ -computable.

From (a), (c), and (e), the multifunction $\tilde{c} \mapsto \tilde{E}$ is $(\rho^{2N(m,n)}, [\delta_D \rightarrow \rho^2])$ -computable. Since $\langle E, u \rangle = \langle \tilde{E}, \mathcal{R}u \rangle = \langle \mathcal{R}\tilde{E}, u \rangle$ and \mathcal{R} is computable on $\mathcal{D}'(\mathbb{R}^n)$ by Lemma 4.7 in [6], the operator $u \mapsto E$ mapping a polynomial of degree m to some fundamental solution is $(\rho^{2N(m,n)}, [\delta_D \rightarrow \rho^2])$ -computable.

So far we have assumed a fixed degree m of the polynomial. Since the set A_m can be computed from m (Lemma 3.1) and all the other computations are uniform also in m the proof is finished. \square

In the proof multivalued functions occur several times. A critical part is the computation of the sets T_j^k , which determines a partition of \mathbb{R}^n into (at most) $L(m, n)$

sets. The resulting distribution depends essentially on this partition. However, the function from $\mathbb{C}^{N(m,n)}$ to these sets cannot be computable (hence continuous) and single-valued at the same time, provided it is not trivial (Lemma 4.3.15 in [4]).

Problem. Is there a *single-valued* computable function mapping any polynomial of degree m to a fundamental solution?

As usual in recursion theory, we have not merely proved the *existence* of a computable function (from names of input objects to names of output objects), but also the proof is *constructive*; i.e., it explains how a concrete Turing machine or computer program can be constructed for computing this function. Of course, the algorithm is not trivial since subroutines for integration, for Fourier transform on Schwartz space, etc., have to be included. The presented algorithms can be improved, since, e.g., no derivatives of the Fourier transform \hat{u} of the input test function $u \in \mathcal{S}(\mathbb{R}^n)$ are needed for computing the $\tilde{E}_k(u)$ by integration. We finish the article with a question.

Problem. Can our informal algorithm be converted to a feasible numerical algorithm for computing fundamental solutions efficiently, or is the problem inherently difficult?

COMPACT LABELING SCHEME FOR ANCESTOR QUERIES*

SERGE ABITEBOUL[†], STEPHEN ALSTRUP[‡], HAIM KAPLAN[§],
TOVA MILO[§], AND THEIS RAUHE[‡]

Abstract. We consider the following problem. Given a rooted tree T , label the nodes of T in the most compact way such that, given the labels of two nodes u and v , one can determine in constant time, by looking only at the labels, whether u is ancestor of v . The best known labeling scheme is rather straightforward and uses labels of length at most $2\log_2 n$ bits each, where n is the number of nodes in the tree. Our main result in this paper is a labeling scheme with maximum label length $\log_2 n + O(\sqrt{\log n})$. Our motivation for studying this problem is enhancing the performance of web search engines. In the context of this application each indexed document is a tree, and the labels of all trees are maintained in main memory. Therefore even small improvements in the maximum label length are important.

Key words. ancestor queries, rooted tree, labeling algorithm, alphabetic codes

1. Introduction. The problem that we study in this paper is the following. Given a rooted tree T , what are the shortest labels that one can attach to the nodes of the tree such that, given the labels of two nodes v and w , it is possible to determine in constant time—by looking only at the labels—whether v is an ancestor of w ? When measuring the quality of a labeling scheme, we will look at the length of the maximal label, as a function of the size of the tree. We are interested in the *exact* function rather than its order of growth—constant factors do matter! (E.g., labels of length bounded by, say, $1.5 \log n$ bits will be considered significantly better than labels of length $2 \log n$ bits.¹) Note that clearly one cannot go below $\log n$ bits—if the maximal label has less than $\log n$ bits, there are not enough labels in the domain even to identify all nodes. But how much more is actually needed for answering ancestor queries? This somewhat abstract problem arises in optimizing web search engines.

Before presenting our results, let us consider a simple labeling scheme that we call the *DFS* labeling scheme. Let T be a tree of size n . To each internal node we assign a *first* and *last* value, and to a leaf we assign only a *first* value, as follows. Perform a depth first traversal [28] of the tree from the root r . Let $first(r) = counter = 0$. The first time a node v is visited, we set $first(v) = counter$ and increment the counter by 1. The last time an internal node v is visited, we set $last(v) = counter$ and increment the counter by 1. Now an internal node v is a proper ancestor of a node w if and only if $first(v) < first(w) < last(v)$. The standard binary representation of the numbers

FIG. 1. *The books catalog.*

first and *last* consists of $\log n + 2$ bits. Hence, this scheme uses at most $\log n + 2$ bits for a label of a leaf and at most $2 \log n + 4$ bits for a label of an internal node. Interestingly, although rather naive, the bound obtained by this simple scheme is in fact the tightest we could find in the existing literature. We present a labeling scheme that improves this bound to $\log n + O(\sqrt{\log n})$ bits.

We use the RAM model of computation and assume that the length of a computer word is $\Omega(\log n)$ bits (hence the basic operations on the labels can be performed in constant time). The algorithm uses only the basic and fast RAM operations as assignment, less-than comparison, bitwise AND, OR, and XOR. Our labeling scheme avoids the sometime more costly operations such as multiplication.

Motivation. Most of the data on the web today is written in HTML format [33]. An HTML document consists of text interspersed with tag fields such as `<I>...</I>` to describe the presentation of the page, the inclusion of pictures, hyperlinks, forms, etc. These tags do not provide, however, any information about the semantic nature of the document components, which makes the analysis of the content of documents difficult. To remedy this, a new web standard, the XML data exchange format [31], has been proposed. Just like HTML, XML documents feature tags. But rather than providing instructions on how the document is to be displayed,² they provide information on the logical structure of the document, with each semantic element starting with an `<itemname>` tag and ending with an `</itemname>` tag. To see an example, consider Figure 1, which shows a fragment of an XML document describing a books catalog. The `<Category>` and `</Category>` tags are used to delimit the information corresponding to one catalog category. Each category item consists of a sequence of tagged subitems such as `Category_Name`, `Book`, etc.

XML is being widely adopted as web standard, and it is believed that although a large portion of the web will remain unstructured or hidden behind interactive graphics and forms, a large and contentwise essential portion of the web will soon be available in XML [25, 31].

To retrieve data from the web, people use search engines like Alta vista [8] or Google [17]. Today these search engines support full-text queries; namely, the user

²This may be specified in a *style-sheet*.

gives a few words, and the engine returns documents containing these particular words. When querying XML data it is desired also to support queries that utilize the document structure to ask for more specific data. For example, it is desired to support structural queries like “find all book items containing “Fielding” as an author and a price less than \$12” [1, 12, 32].

Going back to the problem stated in the introduction, observe that an XML document can be viewed as a tree (essentially the parse tree of the document) whose nodes are the document items and whose edges correspond to the component-of relationship among data items. With this view, a query of the above form amounts to finding nodes with particular tags (book, author, price) having certain ancestor relationship between them. In our example we ask for documents containing book nodes that are ancestors of particular qualifying author and price nodes.

To understand how to implement such structural queries, consider the following rather typical implementation of a search engine. The engine’s heart is a big hash table containing all words occurring in the database, where for each word we keep the identifiers of the documents in which it appears. For XML documents we refine this structure as follows. First, in addition to the words that appear in text items, we also keep the tags of the nodes (like “book,” “author,” etc.) in the hash table. Second, to allow structural queries we give each node in the XML document (tree) a unique label and associate with each tag in the hash table the labels of all nodes with this tag in each particular document containing it.

Now if we give the nodes meaningful labels that reflect the hierarchical structure of the documents (namely, such that, given labels of two items, we can determine whether one is a descendant, i.e., component, of the other), queries of the above form can be answered by using the index only, without access to the actual document. We first use the hash table to retrieve the labels of the relevant nodes, and then iterate over the retrieved label sets and select those having the appropriate ancestor relationships.

To allow for good performance it is essential that the index structure (or at least a large part of it) reside in main memory. Observe that we are talking here about an extremely large structure. Experiments to evaluate the effect of adding the structural information to the index show that adding a label of just one integer (4 bytes) to each word occurrence almost doubles the index size [34]. Since the length of the node labels is a main factor for the index size, reducing this, even by a constant factor, is a critical issue, contributing directly to hardware cost reduction and performance improvement.

Consider now the actual physical representation of the labels in the index. In a fixed-length representation each label is allocated a fixed space, determined by the maximal potential label length. In a variable-length representation labels are allocated a variable size space (consisting of a fixed prefix stating the actual size of the label, followed by the label itself), and the size of the index is determined by the average label length plus the log of the maximum potential length of a label (the space allocated for the fixed prefix). We study here the case of fixed-length representation, aiming to improve the bound on the maximal label length. The case of variable-length representation is left for future research.

Related work. Variants of the *DFS* labeling scheme have been described in several papers including [11, 18, 23, 27, 30]. Implementations of such approaches are integrated in the Xyleme XML warehouse system [34]. As explained by Kannan, Naor, and Rudich [18], the names of the nodes in a graph³ typically convey no in-

³Typically the integers 1 to n .

formation about the graph itself, and so memory is wasted. Therefore [18] focus on labeling the nodes in such a way that various information can be, as in this paper, detected solely by looking at names of the nodes. Kannan, Naor, and Rudich [18] considered determining ancestor relationship, and to that end they suggested a variant of the *DFS* labeling scheme. They also considered the parent relation and other information.

Extracting local information from the node is helpful for some routing applications. In [29] Thorup and Zwick show how to assign short labels to a packet which is to be routed, such that one can determine the ancestor relationship between the packet's destination and the currently visited node, thus avoiding costly access to external memory. Specifically, after the work presented in [7], Thorup and Zwick [29], independently, obtained a labeling scheme for ancestor queries with labels of length $\log n + O(\log n / \log \log n)$. Recently, Alstrup, Bille, and Rauhe [3] established that labels which carry ancestor information for every tree must have length $\log n + \Omega(\log \log n)$ for some trees. An experimental comparison of different labeling schemes for testing ancestor relationships on real XML data can be found in [20].

Labeling schemes for other types of queries have recently received significant interest. Labeling schemes for various distance queries have been studied in [15, 19, 22, 26]. Alstrup et al. [4] studied a labeling scheme for computing nearest common ancestors in trees. Labels for vertex-connectivity and the adjacency relation are described in [9, 10, 18, 19, 21, 27]. In [14] one finds an extensive survey of labeling schemes and their applications.

The rest of this paper is organized as follows. Section 2 gives some definitions and background on labelings of trees, alphabetic codes, and partitions of trees. We present our labeling scheme in section 3. In section 4 we describe the algorithm that answers a query based on two labels. Section 5 analyzes the lengths of the labels. Finally, in section 6 we show how to implement our algorithm so that it runs in linear time.

2. Preliminaries. In this section we give a more formal definition of labeling scheme. Furthermore, we define an alphabetic code and subtree partition of a tree, and state the known results we use to construct our labeling.

Labeling schemes. An ancestor labeling scheme for a family \mathcal{F} of trees with n nodes consist of two mappings EC and DC . For a given tree $T \in \mathcal{F}$, the encoder EC labels the nodes of the tree; i.e., $EC_T = EC(T)$ maps the nodes from T into labels. The decoder DC maps a pair of labels into $\{0, 1\}$ such that for all T , $DC(EC_T(v), EC_T(w)) = 1$ if and only if v is an ancestor to w in T . Notice that DC is independent of the tree from which the pair of labels is taken; it depends only on the two labels. In different papers [18, 21] there are additional requirements, such as different time constraints on the function DC . The function DC presented in this paper can be computed in constant time on a RAM, assuming a standard set of operations as explained in the introduction.

Alphabetic codes. We denote by $\langle y \rangle_k$ a sequence of objects y_1, y_2, \dots, y_k (such as integers or binary strings). For binary strings $a, b \in \{0, 1\}^*$, $a <_{\text{lex}} b$ if and only if a precedes b in the lexicographic order on binary strings, i.e., a is prefix of b , or the first bit in which a and b differ is 0 in a and 1 in b . A sequence $\langle b \rangle_k$ of binary strings is *lexicographically ordered* if $b_i <_{\text{lex}} b_j$ for all $1 \leq i < j \leq k$. Let $|s|$ denote the length of a binary string $s \in \{0, 1\}^*$. Observe that, given machine words that contain $a, b, |a|$, and $|b|$ in their least significant bits, it is possible to determine whether $a <_{\text{lex}} b$ in a constant number of operations as follows. Assume $|a| \leq |b|$. We first align a and b by

shifting a to the left by $|b| - |a|$ bits. Then we use standard integer comparison on the resulting words and return the result of this integer comparison if these words differ. If the two words are equal—this will happen if b equals a followed by a sequence of zeros—we break the tie according to the lengths of a and b .

For a sequence of binary strings $\langle b \rangle_k$, we say it is *prefix-free* if no string is a prefix of another in the sequence. The following lemma due to Gilbert and Moore [16] states the existence of a lexicographically ordered prefix-free sequence of binary strings called an alphabetic code.

LEMMA 2.1 (see Gilbert and Moore [16]). *For any sequence $\langle y \rangle_k$ of positive integers with $n = \sum_{i=1}^k y_i$ there exists a prefix-free lexicographically ordered sequence $\langle b \rangle_k$, where $|b_i| \leq \log n - \log y_i + O(1)$ for all i .*

For the sake of completeness we show how to construct an alphabetic code for an integer sequence $\langle y \rangle_k$ in $O(k)$ time. Let $s_0 = 0$, $s_i = \sum_{j=1}^i y_j$ for $1 \leq i \leq k$, $I_i = [s_{i-1} + 1, s_{i-1} + y_i]$, and $f_i = \max\{0, \lfloor \log y_i \rfloor\}$. For each y_i we will find a number z_i in the interval I_i such that z_i can be represented in a word with $w = \lceil \log n \rceil$ bits, having the f_i less significant bits set to 0. Then we can let b_i be the bit string consisting of the $w - f_i$ most significant bits of z_i . Thus we get alphabetic codes where $1 \leq |b_i| \leq \log n - \log y_i + O(1)$. We choose z_i such that $z_i + 2^{f_i} - 1$ belongs to I_i to make the bit strings prefix-free. The computation can be done as follows. In the interval I_i there must be a number z_i such that $z_i \bmod 2^{f_i} = 0$. If $s_{i-1} + 1 \bmod 2^{f_i} = 0$, then $z_i = s_{i-1} + 1$. Otherwise $z_i = s_{i-1} + 1 - (s_{i-1} + 1 \bmod 2^{f_i}) + 2^{f_i}$.

The algorithm runs in $O(k)$ time if machine operations for shift, remainder in a division by a power of 2, and discrete logarithm on words of $O(\log n)$ bits are available. In a machine that does not support such operations we can construct a table representing these functions, using $O(n)$ time and space. This will only increase the preprocessing time of our labeling algorithm by a constant factor. Note that Mehlhorn [24] gives a somewhat more complicated algorithm that produces an *alphabetic code*, $\langle b \rangle_k$, for an arbitrary sequence $\langle y \rangle_k$ of positive real numbers with the same bound on the lengths. Mehlhorn’s algorithm can be implemented to run in $O(k)$ time.

Tree terminology. We denote the sets of nodes and edges in T by $V(T)$ and $E(T)$, respectively. We let $T(u)$ denote the subtree of T rooted at node $u \in V(T)$. If $w \in V(T(u))$, then u is an *ancestor* of w , and we write $u \prec w$. If $w \in V(T(u)) \setminus \{u\}$, then u is a *proper ancestor* of w . If u is a (proper) ancestor of w , then w is a (*proper*) *descendant* of u . For nodes u and v in T we denote the path between u and v including u and v by $u \rightsquigarrow v$.

We say that a rooted tree is a *binary tree* if all nodes in the tree have at most two children. If a tree T is not binary, it is straightforward to construct a binary tree T' such that $|V(T')| \leq 2|V(T)|$, and a mapping $f : V(T) \rightarrow V(T')$ such that for $v, w \in V(T)$ we have that $v \prec_T w$ if and only if $f(v) \prec_{T'} f(w)$. Hence, in the remainder of this paper we assume without loss of generality that T is a binary tree.

Clustering. Let T be a rooted tree of size $n = |V(T)| > 1$. Let C be a connected subgraph of T . A node x in $V(C)$ is a *boundary node* if either $x = r$, where r is the root of T , or x is adjacent to a node in $V(T) \setminus V(C)$. The boundary nodes of C are denoted by ∂C . A *cluster* is a connected subgraph of T , where $|\partial C| \leq 2$. Clusters are also used in [5, 6, 13].

Next we define a *cluster partition* of a tree T . If T is a single vertex, then its *cluster partition* consists of one cluster containing this vertex. Otherwise a set of

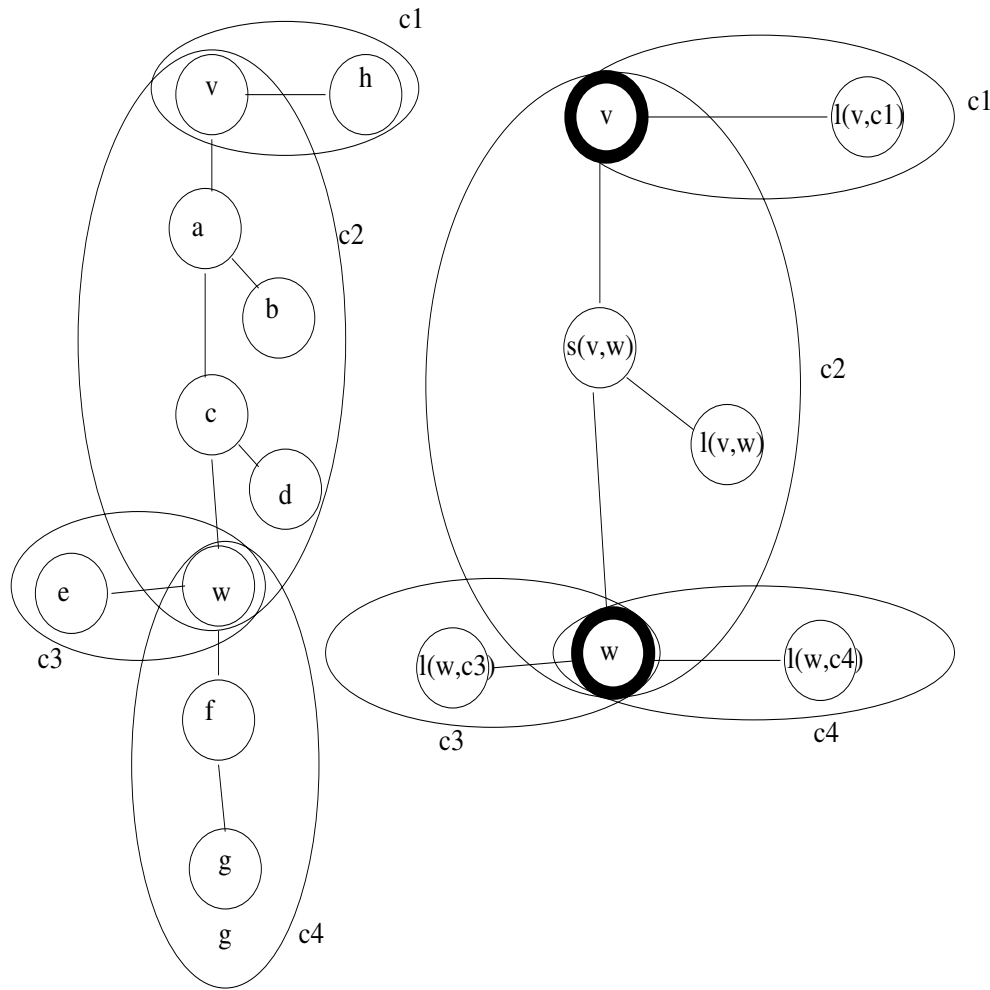

FIG. 2. *Left: a tree T decomposed into four clusters, where $V(c1) = \{v, h\}$, $\partial c1 = \{v\}$, $V(c2) = \{v, a, b, c, d, w\}$, $\partial c2 = \{v, w\}$, $V(c3) = \{w, e\}$, $\partial c3 = \{w\}$, $V(c4) = \{w, f, g\}$, and $\partial c4 = \{w\}$. Right: the tree T^m , illustrating from which clusters the nodes of T^m originate.*

clusters CS is a *cluster partition* of a tree T if the following conditions hold:

1. For every $C \in CS$, $|E(C)| \geq 1$.
2. $V(T) = \cup_{C \in CS} V(C)$, and $E(T) = \cup_{C \in CS} E(C)$.
3. For any $C_1, C_2 \in CS$, $E(C_1) \cap E(C_2) = \emptyset$.
4. If $v \in \partial C$ has two children a and b , then no cluster includes both a and b .

Note that the sets of edges of the different clusters form a partition of the set of edges of T . A vertex, on the other hand, may belong to more than one cluster. Figure 2 gives an example of a cluster partition. A variant of the following lemma was also used in [5, 6, 13].

LEMMA 2.2. *Given a tree T , $n > 1$, and a parameter x , where $\lceil n/x \rceil \geq 2$, it is possible to construct a cluster partition CS in linear time such that $|CS| \leq k \cdot x$ for a constant k , and $|V(C)| \leq \lceil n/x \rceil$ for every $C \in CS$.*

Proof. We describe an algorithm that constructs such a cluster partition. Let S be the set of boundary nodes picked until now; initially $S = \{r\}$. Now recursively

choose a node $v \in S$ not yet examined. Let the children of v be a and b . We treat the two children similarly; hence in the following we can assume $c = a$ (or $c = b$). If $|V(T(c))| + 1 \leq \lceil n/x \rceil$, we let the nodes $V(T(c))$ and v be a cluster, with the boundary node v . Otherwise, let $w \in V(T(c))$ be a maximal node such that $|V(T(c))| + 2 - |V(T(w))| \leq \lceil n/x \rceil$. (By *maximal* we mean that this inequality holds for w but does not hold for any of the children of w .) We let $V(T(c)) \setminus V(T(w)) \cup \{v, w\}$ be a cluster, with boundary nodes w and v , and add w to S . Finally, we remove v from S . It is easy to see that one can implement this algorithm to run in linear time.

Clearly we have $|V(C)| \leq \lceil n/x \rceil$ for every $C \in CS$. Notice that each node is a boundary node in at most three different clusters, and each cluster has at least one boundary node. Therefore the number of boundary nodes is within a constant factor of the number clusters. So to bound the number of clusters we will prove an upper bound on the number of boundary nodes.

To bound the number of boundary nodes, we consider separately those boundary nodes that have two children that are roots of subtrees of T of size $\geq \lceil n/x \rceil$, and those boundary nodes which have at least one child which roots a subtree of size $\leq \lceil n/x \rceil - 1$.

Consider first the set S of boundary nodes which have two children that are roots of subtrees of size $\geq \lceil n/x \rceil$. It is easy to see that, by the definition of our algorithm, if y and z are nodes in S , then their lowest common ancestor must be a boundary node and therefore belongs to S . Thus if we connect each node in S to its immediate descendants that are in S , we obtain a tree with all internal nodes having two children. Since the number of leaves in this tree is $O(x)$ (each roots a tree with at least $2\lceil n/x \rceil + 1$ nodes), we obtain that there are $O(x)$ boundary nodes in S .

Consider now a boundary node z that has one child y which roots a subtree of size $\leq \lceil n/x \rceil - 1$. By the definition of our algorithm, z and the subtree rooted by y form a cluster C . Assume that z is not the root. Then by the definition of our algorithm, the cluster C , and the other one or two clusters for which z is a boundary node, contain together at least $\lceil n/x \rceil$ nodes. (Otherwise z should not have been selected as a boundary node.) Therefore, if we charge each such boundary node evenly among the nodes of the clusters of which it is a boundary, each node in these clusters is charged by at most x/n . Since each node is charged by a constant number of boundary nodes, the total charge of a node is $O(x/n)$, and the total charge summed over all nodes is $O(x)$. Thus there are $O(x)$ boundary nodes with at most one child which roots a subtree of size $\leq \lceil n/x \rceil - 1$. \square

3. A $\log n + O(\sqrt{\log n})$ labeling scheme. Our labeling scheme is based on a particular tree decomposition technique. We define this tree decomposition in section 3.1 and characterize the ancestor relationship in terms of it. The labeling itself is defined in section 3.2.

3.1. Tree decomposition. Let T be a binary tree with root r . (As explained in section 2 when we defined our tree terminology, we assume that T is a binary tree.) Let CS be a cluster partition of T , as described in Lemma 2.2. We will fix the parameter x later. By the definition of a cluster partition we have that, if z is a boundary node in a cluster, it is a boundary node in every cluster that contains it. If z not is a boundary node, it belongs to a unique cluster, which we denote by $C(z)$. Furthermore, for $v, w \in \partial C$, either v or w is an ancestor in T of all nodes in $V(C)$. Let C be a cluster such that $\partial C = \{v, w\}$; we define the *spine path* of C to be the set of nodes on the path from v to w in T excluding v and w . We denote this path by $\mathcal{P}(v, w)$. In the example of Figure 2, $\mathcal{P}(v, w) = \{a, c\}$.

Given a cluster partition CS of T , we define a *macro tree* and denote it by T^m as follows. The vertex set of T^m consists of the boundary nodes of all clusters in CS , together with one or two new nodes for each cluster. For a cluster C with a single boundary node, say $\partial C = \{v\}$, we introduce one new node, denoted by $\ell(v, C)$. For a cluster C with two boundary nodes, say $\partial C = \{v, w\}$, where v is an ancestor of w , we introduce two new nodes denoted by $\ell(v, w)$ and $s(v, w)$. The edges of T^m consist of an edge $(v, \ell(v, C))$, for every cluster C with a single boundary node, and the three edges $(v, s(v, w))$, $(s(v, w), w)$, and $(s(v, w), \ell(v, w))$, for every cluster C with two boundary nodes. See Figure 2.

Since r is a boundary node, then $r \in V(T^m)$. Furthermore, since there is a path from r to every boundary node $v \in T$, there is a corresponding path from r to v in T^m , and therefore T^m is connected. We can obtain T^m by deleting the edges that do not belong to spine paths and then replacing each spine path $\mathcal{P}(v, w)$ by a path of two edges connecting v and w through $s(v, w)$. Finally for every cluster with a single boundary node we add a leaf $\ell(v, C)$ and connect it to v , and we also connect a leaf $\ell(v, w)$ to every node $s(v, w)$. From this description it is clear that T^m is indeed a tree. We define r to be the root of T^m . The properties of T^m that are summarized in the following lemma easily follow from Lemma 2.2 and the definition of T^m .

LEMMA 3.1. *Let T be a binary tree, and let T^m be the macro tree corresponding to a cluster partition of T . Then*

- T^m is a binary tree;
- $|V(T^m)| \leq 4kx$, where k is the constant given in Lemma 2.2;
- the leaves of T^m are the nodes $\ell(\cdot, \cdot)$;
- for two boundary nodes $v, w \in T$, $v \prec_T w$ if and only if $v \prec_{T^m} w$.

We classify each node of $v \in T$ into one of four different types as follows:

1. *Boundary node:* v is a boundary node of a cluster in the cluster partition.
2. *Spine node:* $C(v)$ has two boundary nodes, and v is on the spine path of $C(v)$.
3. *Leaf clustered node:* $C(v)$ has a single boundary node, and v is in $C(v) \setminus \partial C(v)$.
4. *Internal clustered node:* $C(v)$ has two boundary nodes, say u and w , and v is in $C(v) \setminus \{u, w\} \setminus \mathcal{P}(u, w)$.

With every node $v \in T$ we associate a *representative node* in T^m , which we denote by $a(v)$, as follows. If v is a boundary node, then $a(v) = v$. If v is a spine node, where $\partial C(v) = \{u, w\}$, then $a(v) = s(u, w)$. If v is a leaf clustered node, then $a(v) = \ell(v, C(v))$, and if v is an internal clustered node, then $a(v) = \ell(u, w)$, where u and w are the boundary nodes of $C(v)$. In the example of Figure 2, v and w are boundary nodes, a and c are spine nodes, b and d are internal clustered nodes, and e , f , g , and h are leaf clustered nodes.

Let $z \in T$ be a spine node. By the definition of a spine node, node z has a child w , which is either a boundary node or a spine node. We define $Isubtree(z)$ to be $T(z)$ from which we have removed the subtree $T(w)$ and the edge (w, z) . It follows that $V(Isubtree(z))$ consists of z and all the internal clustered nodes in $C(z)$ whose nearest node on the spine path is z . For $w \in V(Isubtree(z))$, we define $sub(w) = z$. Thus, the $sub()$ mapping maps each internal clustered node to its closest ancestor on the spine path of its cluster. For nodes v and w on the same spine path, we define an ordering $<_\alpha$ such that $v <_\alpha w$ if and only if $depth_T(v) < depth_T(w)$.

It would be instructive at this point to understand how the ancestor relationship between nodes in T relates to the classification of the nodes and their representatives in T^m . We summarize this relation in the following lemma.

LEMMA 3.2. *Letting $v \in T$, the followings cases give necessary and sufficient conditions for $v \prec_T w$ to hold, according to the type of v :*

1. *If v is a leaf clustered node, then $v \prec w$ if and only if w is also a leaf clustered node, $a(v) = a(w)$, and v is an ancestor of w in $C(v)$.*
2. *If v is an internal clustered node, then $v \prec w$ if and only if w is also an internal clustered node, $a(v) = a(w)$, $sub(v) = sub(w)$, and $v \prec_{Isubtree(sub(v))} w$.*
3. *If v is a spine node, then $v \prec w$ if and only if one of the following conditions holds:*
 - (a) $C(v) = C(w)$, w is also a spine node, and $v <_\alpha w$.
 - (b) $C(v) = C(w)$, w is an internal clustered node, and $v = sub(w)$ or $v <_\alpha sub(w)$.
 - (c) $C(v) \neq C(w)$ and $a(v)$ is an ancestor of $a(w)$ in T^m .
4. *If v is a boundary node, then $v \prec w$ if and only if $a(v)$ is an ancestor of $a(w)$ in T^m .*

Lemma 3.2 indicates that we can compute ancestor relationship in T by computing one of the following:

1. ancestor relationship in T^m ,
2. ancestor relationship in $Isubtree(v)$ for a spine node v ,
3. ancestor relationship in a cluster C with a single boundary node,
4. whether $v <_\alpha w$ for two spine nodes v and w .

We achieve 1 by using a DFS labeling of T^m . We achieve 2 and 3 by recursively decomposing clusters with a single boundary node and subtrees hanging off spine nodes. We achieve 4 by using an alphabetic code for the spine nodes on each spine path. The details of how exactly we construct the labels are in the next section.

3.2. The labels. Let $L^m : V(T^m) \rightarrow \{0, 1\}^*$ be the DFS labeling of T^m . Recall that this DFS labeling associates a label consisting of $|L^m(v)| \leq 2 \log x + O(1)$ bits with each internal node v in T^m , and a label of $|L^m(\ell)| \leq \log x + O(1)$ bits with each leaf ℓ in T^m . For binary strings b_1 and b_2 we denote the concatenation of b_1 and b_2 by $b_1 \cdot b_2$.

The label of each node starts with a prefix of constant length stating the type of the node. We denote the prefix corresponding to a boundary node, a spine node, an internal clustered node, and a leaf clustered node, by `boundary`, `spine`, `int_clustered`, and `leaf_clustered`, respectively. The bits following this constant length prefix depend on the type of the node v as follows.

Boundary node. In addition to the type bits, $L(v)$ contains the label of v in T^m .

That is,

$$L(v) = \text{boundary} \cdot L^m(a(v)).$$

It follows that in this case $|L(v)| \leq 2 \log x + O(1)$.

Spine node. Let $a(v) = s(v', w') \in T^m$, and let $SP = \mathcal{P}(v', w')$ be the spine path of $C(v)$. Let $k = |SP|$ be the number of nodes on this spine path, and let v_1, v_2, \dots, v_k be the nodes on SP ordered such that for $i < i'$, $depth_T(v_i) < depth_T(v_{i'})$. Clearly v is a node on this spine path, say $v = v_j$, for some $1 \leq j \leq k$. Let $T_i = Isubtree(v_i)$, and let $\langle c \rangle_k$ be an alphabetic code of the sequence $\langle |V(T_1)|, \dots, |V(T_k)| \rangle$ constructed according to Lemma 2.1. Hence, c_j is the string corresponding to $V(T_j)$ in $\langle c \rangle_k$. Note that $|c_j| \leq \log \sum_i |V(T_i)| - \log |V(T_j)| + O(1) \leq \log(n/x) - \log |V(T_j)| + O(1)$, since all nodes in T_i , $1 \leq i \leq k$, belong to the same cluster which contains no more

than n/x nodes. The label of v is defined to be

$$L(v) = \mathbf{spine} \cdot L^m(s(v', w')) \cdot c_j.$$

Thus, $|L(v)| \leq 2 \log x + \log(n/x) - \log |V(T_j)| + O(1) \leq \log x + \log n + O(1)$.
Internal clustered node. Let $a(v) = \ell(v', w')$, and let $v_j = \mathit{sub}(v)$ be the spine node associated with v . As in the previous case, let v_1, \dots, v_k be the nodes on the spine path $\mathcal{P}(v', w')$, and let $\langle c \rangle_k$ be an alphabetic code for the sequence $\langle |V(T_1)|, \dots, |V(T_k)| \rangle$, where $T_i = \mathit{Isubtree}(v_i)$. Thus c_j is the string corresponding to T_j in the code $\langle c \rangle_k$. By its definition the root of T_j has one child d in T_j . We define $T'_j = T_j(d)$ to be the subtree of T_j rooted by this child. We recursively apply the labeling algorithm to T'_j (with the same decomposition threshold x , which is not scaled relative to the size of T'_j). Let $L^b(v)$ denote the label of node v in the recursive labeling of T'_j . The label of v in the tree T is defined to be

$$L(v) = \mathbf{int_clustered} \cdot L^m(\ell(v', w')) \cdot c_j \cdot L^b(v).$$

Thus, $|L(v)| \leq \log x + \log(n/x) - \log |T_j| + |L^b(v)| + O(1) = \log n - \log |T_j| + |L^b(v)| + O(1)$, where $|L^b(v)|$ is the length of the recursive ancestor labeling of v in T'_j .

Leaf clustered node. Let c be the only child of the boundary node of $C(v)$ in $C(v)$. We recursively label the tree $T(c)$ (with the same decomposition threshold x , which is not scaled relative to the size of $T(c)$). Let $L^b(v)$ be the label of v in this labeling of $T(c)$. Also let $a(v) = \ell(v', C)$. The label of v is defined to be

$$L(v) = \mathbf{leaf_clustered} \cdot L^m(\ell(v', C)) \cdot L^b(v).$$

We obtain in this case that $|L(v)| \leq \log x + |L^b(v)| + O(1)$, where $|L^b(v)|$ is the length of $L^b(v)$.

We say that the prefix of $L(v)$ before the recursive labeling $L^b(v)$ is a *block* of the labeling $L(v)$. Similarly $L^b(v)$ consists of such recursive blocks, i.e., $L(v) = b_1 b_2, \dots, b_k$, where $b_i \in \{0, 1\}^*$ is a block of bits starting with the type bit information and ending just before the type bit information of block b_{i+1} . By the definition of the labels, the last block b_k is either a label of a spine node or a label of a boundary node.

The recursion ends when we get to label a tree of size no larger than x , in which case $\lceil |T|/x \rceil \leq 1$ and Lemma 2.2 does not apply.

In this case we consider all nodes as boundary nodes and take the macro tree T^m to be identical to T .

Consider a node $v \in V(T)$ and its label $L(v)$ with blocks b_1, \dots, b_k . We define subtrees of T relative to prefixes of this label. For the empty bitstring ϵ we let $T(\epsilon) = T$. The tree $T(b_1)$ is the subtree of T containing v , whose recursive labeling defined the suffix of the label of v to be b_2, \dots, b_k . In general for every $i < k$ we let $T(b_1 b_2, \dots, b_i)$ denote the subtree of T containing v whose recursive labeling defined the suffix of the label of v to be b_{i+1}, \dots, b_k .

In addition to the labeling defined above, we also keep the index of the first bit of the last block b_k , i.e., $|b_1, \dots, b_{k-1}|$, using $\log \log n$ bits. This index, which is of fixed length, is stored at a fixed position of the word storing the label. Note that each block b_i stores a DFS label of a node in the macro tree corresponding to $T(b_1 b_2, \dots, b_{i-1})$. This DFS label occupies a fixed number of bits at the beginning of the block. This

number of bits is either $2 \log x + O(1)$ in case of a boundary node or a spine node, or $\log x + O(1)$ in case of an internal clustered node or a leaf clustered node.

To parse the labels while answering a query, the decoder needs to know the length and the position of the field storing $|b_1, \dots, b_{k-1}|$. Furthermore, it also needs to know our decomposition threshold x . The decoder has this information if it knows n , the size of the tree, since both these lengths are functions of n : the first is $\log \log n$ and the second will be fixed to $2^{\sqrt{\log n}}$. Since both lengths change quite slowly with n , the decoder does not in fact have to know n exactly but just up to a precision that allows it to determine these values uniquely. For example, knowing $\log n$ certainly suffices. In case the value of $\log n$ is not available to the decoder, one can encode it within each label using $\log \log n$ bits.

4. Answering a query. Let v, w be two nodes in the tree T with labels $L(v) = a_1 a_2, \dots$ and $L(w) = b_1 b_2, \dots$, where a_i and b_i are the blocks of the labels of v and w , respectively, as defined in section 3.2. We now show how to decide based on $L(v)$ and $L(w)$ whether $v \prec_T w$. The test consists of two phases defined as follows.

Let j be the index of the last block of $L(v)$, and assume first that $j > 1$. (If $j = 1$, we do nothing in the first phase and jump directly to the second phase.) It follows from Lemma 3.2 that if $v \prec w$, then v and w must both be either leaf clustered nodes or internal clustered nodes in the same cluster of the cluster partition of $T_i = T(a_1, a_2, \dots, a_i)$ for every $i < j$. Furthermore, in each of these cluster partitions where they are internal clustered nodes then it must be the case that $sub(w) = sub(v)$. Therefore, if $v \prec w$ and $j > 1$, we must have that for every $i < j$, $a_i = b_i$. Thus in the first phase of the query algorithm we verify that for every $i < j$, $a_i = b_i$. If this test fails, we report that $v \not\prec_T w$, and otherwise we continue to the second phase.

To efficiently test that indeed $a_i = b_i$ for every $i < j$ without decomposing $L(v)$ and $L(w)$ into their components a_1, a_2, \dots, a_{j-1} and b_1, b_2, \dots, b_{j-1} , respectively, we use the fact that a_i cannot be a prefix of b_i and b_i cannot be a prefix of a_i . This follows from the fact that the part of a_i and b_i containing a DFS label of a node in $T_{i-1} = T(a_1, a_2, \dots, a_{i-1})$ is of fixed length, and in case v and w are internal clustered nodes of the same cluster in T_{i-1} also from the fact that the strings in an alphabetic code are prefix-free.

Since a_i is not a prefix of b_i and b_i is not a prefix of a_i , one can easily prove by induction that $a_1 a_2, \dots, a_{j-1}$ is a prefix of $b_1 b_2, \dots$ if and only if $a_i = b_i$ for every $1 \leq i \leq j - 1$. Thus we start the processing of the query by testing if $a_1 a_2, \dots, a_{j-1}$ is a prefix of $L(w)$. Note that we can extract $a_1 a_2, \dots, a_{j-1}$ from $L(v)$ since we store with $L(v)$ the index of the first bit of b_j . If $a_1 a_2, \dots, a_{j-1}$ is not a prefix of $L(w)$, then v is not an ancestor of w . Otherwise we proceed to the second phase of the algorithm, which is defined as follows.

Let $\bar{T} = T(a_1, a_2, \dots, a_{j-1})$. Next we check whether $v \prec w$ in \bar{T} since at this point we know that $v \prec w$ in T if and only if $v \prec w$ in \bar{T} . Since j is the index of the last block of $L(v)$, node v is either a spine node or a boundary node in the cluster partition of \bar{T} . Node w , on the other hand, may be of any type. We check whether v is an ancestor of w in \bar{T} according to Lemma 3.2. Let $dfs(v)$ and $dfs(w)$ be the DFS labels of $a(v)$ and $a(w)$, respectively, in the DFS labeling of \bar{T}^m . We extract $dfs(v)$ and $dfs(w)$ from the blocks a_j and b_j of $L(v)$ and $L(w)$, respectively. Then we can determine whether the representative $a(v)$ of v in \bar{T}^m and the representative $a(w)$ of w in \bar{T}^m are equal, and whether $a(v)$ is an ancestor of $a(w)$, by comparing $dfs(v)$ and $dfs(w)$.

If $dfs(v)$ is equal to $dfs(w)$, then $a(v)$ is the same node as $a(w)$. We know that

$a(v)$ is either a spine node or a boundary node. Since a boundary node v is not $a(w)$ for any $w \neq v$, and since $a(v) = a(w)$, it follows that v and w are spine nodes. Thus, by Lemma 3.2, $v \prec_T w$ if and only if w is a descendant of v on their spine path, i.e., if and only if $v <_\alpha w$. Let $c(v)$ and $c(w)$ be the alphabetic codes in blocks a_j and b_j of v and w , respectively. By the definition of an alphabetic code and the definition of the labels, we have that $v <_\alpha w$ if and only if $c(v) <_{\text{lex}} c(w)$. Thus in this case we answer that $v \prec_T w$ if and only if $c(v) <_{\text{lex}} c(w)$.

If $dfs(v)$ is not equal to $dfs(w)$, then $a(v)$ is not equal to $a(w)$. By Lemma 3.2, a necessary condition for v to be an ancestor of w is that $a(v)$ be an ancestor of $a(w)$ in \overline{T}^m , so we check that using $dfs(v)$ and $dfs(w)$. Furthermore, by Lemma 3.2, if $a(v)$ is indeed an ancestor of $a(w)$ in \overline{T}^m , then we can conclude that $v \prec_T w$ except when v and w are in the same cluster, v is a spine node, and w is an internal clustered node. In this case $a(v) = s(u_1, u_2)$ is the parent of $a(w) = \ell(u_1, u_2)$, where u_1 and u_2 are the boundary nodes of $C(v) = C(w)$. Fortunately, the DFS labeling scheme allows us to determine whether $a(w)$ is indeed a child of $a(v)$ and thereby identify this case where v is a spine node and w is an internal clustered node of the same cluster. First we check whether $a(w)$ is indeed a leaf, by verifying that $dfs(w)$ consists only of a single number. Assume this is indeed the case, let $k = dfs(w)$, and let $(first, last) = dfs(v)$. Then $a(v)$ is a leaf child of $a(w)$ if and only if $k = first + 1$ or $last = k + 1$.

If indeed v is a spine node and w is an internal clustered node of some cluster, then, by Lemma 3.2, $v \prec_T w$ if and only if $sub(w)$ is a descendant of v on v 's spine path. Let $c(v)$ and $c(w)$ be the alphabetic codes in blocks a_j and b_j of $L(v)$ and $L(w)$, respectively. By the definition of the labels and the definition of an alphabetic code, $sub(w)$ is a descendant of v on v 's spine path if and only if $c(v) = c(w)$ or $c(v) <_{\text{lex}} c(w)$.

Since the decoder does not know the length of $c(w)$ it cannot easily extract it. However, since $c(w)$ is not a proper prefix of $c(v)$ (as $c(w)$ and $c(v)$ are strings in an alphabetic code) we have that $c(v) \leq_{\text{lex}} c(w)$ if and only if $c(v)$ is lexicographically smaller than the suffix of the label of w starting from and including $c(w)$. Thus in case v is a spine node and w is an internal clustered node of some cluster of \overline{T} , the second phase concludes that $v \prec_T w$ if and only if $c(v)$ is lexicographically smaller than the suffix of the label of w starting from and including $c(w)$.

Note that the above test for the ancestor relation using the DFS labeling and alphabetic codes uses a constant number of basic and fast RAM operations, i.e., bit wise AND/OR, left/right shifts, and less-than comparisons. Our labeling scheme avoids the sometimes more costly operations such as multiplication, retrieval of the most significant bit, or nonstandard operations precomputed and stored in a pre-computed table.

5. The length of the labels. In this section we give an upper bound on the length of $L(v)$ for any $v \in T$. We first bound the length of any block which is not the last block.

LEMMA 5.1. *Let $L(v) = b_1 b_2, \dots, b_k$ for some $k \geq 2$. Then,*

$$b_1 \leq \log \left(\frac{n}{|T(b_1)|} \right) + O(1),$$

$$\text{and for } 1 < i < k, \quad |b_i| \leq \log \left(\frac{|T(b_1, \dots, b_{i-1})|}{|T(b_1, \dots, b_{i-1} b_i)|} \right) + O(1).$$

Proof. Since b_i is not the last block in $L(v)$, v is either an internal clustered node or a leaf clustered node in $T(b_1, \dots, b_{i-1})$ or in T in case $i = 1$. In case v is an

internal clustered node, the claim follows from the definition of the label of an internal clustered node and the definition of $|T(b_1, \dots, b_{i-1}b_i)|$ (see section 3.2). In case v is a leaf clustered node, then by the definition of the label we have that $|b_i| \leq \log x + O(1)$. But in this case we also have that $|T(b_1, \dots, b_{i-1}b_i)| \leq \lceil |T(b_1, \dots, b_{i-1})|/x \rceil$ by the definition of a cluster partition. \square

The following lemma gives a bound on the length of the last block.

LEMMA 5.2. *Let $L(v) = b_1b_2, \dots, b_k$. Then*

$$|b_k| \leq \log(|T(b_1, \dots, b_{k-1})|) + O(\log x) + O(1).$$

Proof. Since b_k is the last block, v is either a boundary node or a spine node in $T(b_1, \dots, b_{k-1})$. If v is a boundary node, then $|b_k| \leq 2 \log x + O(1)$. If v is a spine node, then $|b_k| \leq \log(|T(b_1, \dots, b_{k-1})|) + \log x + O(1)$. \square

Last we bound the number of blocks.

LEMMA 5.3. *Let $L(v) = b_1b_2, \dots, b_k$. Then $k \leq \frac{\log n}{\log x}$.*

Proof. By the definition of a cluster partition we have for $i < k$ that $|T(b_1, \dots, b_{i-1})|/|T(b_1, \dots, b_i)| \geq x$. Since $|T(\epsilon)| = |T| = n$ the lemma follows. \square

Now from these three lemma we immediately obtain the following result.

LEMMA 5.4. *For every $v \in T$, $|L(v)| \leq \log n + O(\log x) + O(\frac{\log n}{\log x})$.*

Hence, choosing $x = 2^{\sqrt{\log n}}$, we obtain the claimed bound of $\log n + O(\sqrt{\log n})$ for the worst-case length of a label in T .

6. Preprocessing time. It is rather straightforward to compute the labels in time $O(n\sqrt{\log n})$, spending linear time calculating the part of the labels in each of the $\sqrt{\log n}$ recursive levels. In each recursive level we calculate the cluster partition in each of the trees that get labeled in that level, and we also calculate alphabetic code for the nodes on every spine path.

We can improve this preprocessing time to linear by slightly changing the labeling scheme, while keeping the labels of length $\log n + O(\sqrt{\log n})$. We do that as follows. We obtain a cluster partition of T with $x = n/\sqrt{\log n}$, as described in section 2. Hence the clusters are of size at most $\sqrt{\log n}$. For this cluster partition we construct a tree T' that is similar to T^m defined in section 3.1. We define T' as follows. For each cluster with two boundary nodes v and w , we have in T' the nodes $v, w, s(v, w)$ and two edges $(v, s(v, w))$ and $(w, s(v, w))$. For each cluster C with one boundary node v , we have in T' the nodes v and $\ell(v, C)$ and the edge $(v, \ell(v, C))$. (In contrast with T^m , in T' we do not have a leaf $\ell(v, w)$ for a cluster with boundary nodes v and w .) By Lemma 3.1, the tree T' consists of $O(n/\sqrt{\log n})$ nodes. We label T' by the labeling scheme of section 3, using the naive labeling algorithm mentioned above. Since the size of T' is $O(n/\sqrt{\log n})$, computing this labeling of T' takes linear time. We denote the label of a node v in T' by $L'(v)$.

We also label the nodes of each cluster separately for ancestor queries using the *DFS* labeling scheme. This takes linear time for all clusters. We denote the label of v in its cluster by $CL(v)$.

For each node v in T we associate a node in T' , denoted by $b(v)$. (This mapping is similar to the mapping $a()$ from section 3.1.) If v is a boundary node, then $b(v) = v$. If v is a spine node or an internal clustered node in a cluster with two boundary nodes u, w , then $b(v) = s(u, w)$. If v is a leaf clustered node in a cluster C with boundary node w , then $b(v) = \ell(w, C)$.

We define the label of a node $v \in T$ to be $L(v) = Q(v) \cdot CL(v) \cdot L'(b(v))$, where $Q(v)$ are two bits that determine the type of the node with respect to the cluster partition

(see section 3.2). Since $|L'(b(v))| \leq \log n + O(\sqrt{\log n})$ and $|CL(v)| \leq O(\log \log n)$ we obtain that $|L(v)| \leq \log n + O(\sqrt{\log n})$.

To test whether v is an ancestor of w in T we proceed as follows. If v is a boundary node, we check whether $b(v)$ is an ancestor of $b(w)$. If v is a spine node and $b(v) \neq b(w)$, we test whether $b(v)$ is ancestor of $b(w)$. If v is a spine node and $b(v) = b(w)$, we use $CL(v)$ and $CL(w)$ to test whether v is ancestor of w . In the remaining cases, for v to be an ancestor of w , $b(v)$ must be equal to $b(w)$, and if that is indeed the case, then we check that v is an ancestor of w in their cluster using $CL(v)$ and $CL(w)$.

We conclude this section with the following theorem, which is the main result of this paper.

THEOREM 6.1. *We can label the nodes of a tree of size n in $O(n)$ time by labels of length at most $\log n + O(\sqrt{\log n})$ such that, given the labels of two nodes v and w , we can determine whether v is an ancestor of w in T in $O(1)$ time.*

7. Conclusions. We have described a labeling scheme for ancestor queries, where the length of each label is bounded by $\log n + O(\sqrt{\log n})$ bits. The labeling is computed in linear time, and an ancestor query takes $O(1)$ time. As we mentioned, Alstrup, Bille, and Rauhe [3] proved that for every labeling scheme there is a tree that requires a label of length $\log n + \Omega(\log \log n)$ bits. Closing this gap between the upper and the lower bounds is an intriguing open question.

QUANTUM QUERY COMPLEXITY OF SOME GRAPH PROBLEMS*

CHRISTOPH DÜRR[†], MARK HEILIGMAN[‡], PETER HØYER[§], AND MEHDI MHALLA[¶]

Abstract. Quantum algorithms for graph problems are considered, both in the adjacency matrix model and in an adjacency list-like array model. We give almost tight lower and upper bounds for the bounded error quantum query complexity of CONNECTIVITY, STRONG CONNECTIVITY, MINIMUM SPANNING TREE, and SINGLE SOURCE SHORTEST PATHS. For example, we show that the query complexity of MINIMUM SPANNING TREE is in $\Theta(n^{3/2})$ in the matrix model and in $\Theta(\sqrt{nm})$ in the array model, while the complexity of CONNECTIVITY is also in $\Theta(n^{3/2})$ in the matrix model but in $\Theta(n)$ in the array model. The upper bounds utilize search procedures for finding minima of functions under various conditions.

Key words. graph theory, quantum algorithm, lower bound, connectivity, minimum spanning tree, single source shortest paths

1. Introduction. A primary goal of the theory of quantum complexity is to determine when quantum computers may offer a computational speed-up over classical computers. Today there are only a few results which give a polynomial time quantum algorithm for some problem for which no classical polynomial time solution is known. We are interested in studying the potentials for speed-up for problems for which there already are efficient classical algorithms. Basic graph problems are interesting candidates.

We study the query complexity of these problems, meaning the minimal number of queries to the graph required for solving the problem. Throughout this paper, the symbol $[n]$ denotes the set $\{0, 1, \dots, n-1\}$. We consider two query models for directed graphs:

- *the adjacency matrix model*, where the graph is given as the adjacency matrix $M \in \{0, 1\}^{n \times n}$, with $M_{ij} = 1$ if and only if $(v_i, v_j) \in E$, and
- *the adjacency array model*, where we are given the out-degrees of the vertices d_1^+, \dots, d_n^+ and for every vertex u an array with its neighbors $f_i : [d_i^+] \rightarrow [n]$.

So $f_i(j)$ returns the j th neighbor of vertex i , according to some arbitrary but fixed numbering of the outgoing edges of i . In this paper the upper bounds for this model are all at least n , so we assume henceforth that the degrees are given as part of the input and we count only queries to the arrays f_i . In addition the arrays satisfy the *simple graph* promise

$$(1.1) \quad \forall i \in [n], j, j' \in [k], j \neq j' : f_i(j) \neq f_i(j')$$

ensuring the graph is not a multigraph, i.e., does not have multiple edges between any two vertices.

For undirected graphs we require an additional promise on the input, namely, that M is symmetric in the matrix model, and for the array model that for all $i, i' \in [n]$, if $\exists j \in [k] : f_i(j) = i'$, then $\exists j' \in [k] : f_{i'}(j') = i$. Note that in the matrix model this symmetry assumption does not create a promise problem on undirected graphs since we may assume that the input is upper triangular.

Weighted graphs are encoded by a weight matrix, where for convenience we set $M_{ij} = \infty$ if $(v_i, v_j) \notin E$. In the adjacency array model, the graph is encoded by a sequence of functions $f_i : [d_i^+] \rightarrow [n] \times \mathbb{N}$, such that if $f_i(j) = (i', w)$, then there is an edge $(v_i, v_{i'})$ and it has weight w .

We emphasize that the array model is different from the standard list model. In the latter, we have access to the neighbors of a given vertex only as a list, and thus querying the i th neighbor requires i accesses to the list. This is also true on a quantum computer, so its speed-up is quite restricted.

Many other query models are of course possible; for example, we could be given an array of edges $f : [m] \rightarrow [n] \times [n]$ or an ordered array (which is up to $O(n)$ preprocessing the same as the adjacency array model). For simplicity, we use the array model as presented above.

For the quantum query complexity of general monotone graph properties, a lower bound of $\Omega(\sqrt{n})$ is known in the matrix model, as shown by Buhrman et al. [9]. We are not aware of any quantum or classical lower bounds in the array model.

In this paper we show that the quantum query complexity of CONNECTIVITY is $\Theta(n^{3/2})$ in the matrix model and $\Theta(n)$ in the array model. The classical randomized query complexity of CONNECTIVITY in the matrix model is $\Omega(n^2)$ by a sensitivity argument: Distinguishing the graph consisting of two length $n/2$ paths from the graph consisting of those two paths, plus an additional edge connecting them, requires $\Omega(n^2)$ queries.

We study the complexity of three other problems; see Table 1.1. In STRONG CONNECTIVITY we are given a directed graph and have to decide if there is a directed path between every pair of vertices. In MINIMUM SPANNING TREE we are given a weighted graph and have to compute a spanning tree with minimal total edge weight. In SINGLE SOURCE SHORTEST PATHS we have to compute the shortest paths according to the total edge weight from a given source vertex to every other vertex. The quantum query complexity of these three problems is $\Omega(n^{3/2})$ in the matrix model and $\Omega(\sqrt{nm})$ in the array model. We give almost tight upper bounds.

We note that for graphs with a large number of edges ($m = \Theta(n^2)$), the complexities are (almost) the same in the matrix and array models for all problems but CONNECTIVITY. However, the models still differ in that case. For example, the test $(u, v) \in E$ costs a single query in the matrix model and $\Theta(\sqrt{\min\{d_u^+, d_v^+\}})$ queries in the array model since we do not assume any order on the arrays f_u and f_v .

TABLE 1.1
Quantum query complexity of some graph problems.

Problem	Matrix model	Array model
MINIMUM SPANNING TREE	$\Theta(n^{3/2})$	$\Theta(\sqrt{nm})$
CONNECTIVITY	$\Theta(n^{3/2})$	$\Theta(n)$
STRONG CONNECTIVITY	$\Theta(n^{3/2})$	$\Omega(\sqrt{nm}), O(\sqrt{nm \log n})$
SINGLE SRC. SHORT. PATHS	$\Omega(n^{3/2}), O(n^{3/2} \log^2 n)$	$\Omega(\sqrt{nm}), O(\sqrt{nm \log^2 n})$

The time complexities of the algorithms are the same as the query complexities up to log-factors. The algorithms given for CONNECTIVITY and STRONG CONNECTIVITY can be altered to also output the (strongly) connected components without increasing the asymptotic complexity. The space requirement is $O(\log n)$ qubits and $O(n \log n)$ classical bits. If we constrain the space (both classical and quantum) to $O(\log n)$ qubits, the problems may be solved by random walks. Quantum random walks have been the subject of several papers [1, 10, 15], in particular for the *st*-CONNECTIVITY problem [22].

Other work on the query complexity of graph problems has been done independently of us. For example, [4] shows that testing whether a given graph is bipartite needs $\Omega(n^{3/2})$ queries in the matrix model. Note that a graph is bipartite if and only if it does not contain an odd cycle. For the array model a lower bound can be constructed from our lower bound for connectivity, showing that $\Omega(\sqrt{nm})$ queries are necessary for any bounded error quantum algorithm which distinguishes a single even cycle from two disjoint odd cycles. Matching upper bounds follow from our connectivity algorithms: simply construct a spanning forest of the graph, color the nodes of each tree alternately black and white, and finally use the quantum search procedure to find an edge with endpoints of the same color. Such an edge creates an odd cycle and exists if and only if the graph contains an odd cycle.

2. Tools used in this paper. We use two fundamental tools. The first is amplitude amplification [7, 8], which we use when proving the upper bounds; the second is Ambainis’s lower bound technique [2].

Amplitude amplification is a generalization of Grover’s search algorithm [13]. Since it is the most important tool used in our algorithms, we restate the exact results we require. We are given a boolean function F defined on a domain of size n . The function is given as a black box so that the only way we can obtain information about F is via evaluating F on elements in the domain. The search problem considered by Grover is to find an element x for which $F(x) = 1$, provided one exists. We say that x is a *solution* to the search problem and that x is *good*. We use three generalizations of the search algorithm—all of which we refer to as “the search algorithm.”

- If there are t elements mapped to 1 under F , with $t > 0$, the search algorithm returns a solution after an expected number of at most $\frac{9}{10} \sqrt{n/t}$ queries to F . The output of the algorithm is chosen uniformly at random among the t solutions. The algorithm does not require prior knowledge of t [6].
- A second version uses $O(\sqrt{n})$ queries to F in the worst case and outputs a solution with probability at least a constant, provided there is one [6].
- A third version uses $O(\sqrt{n \log 1/\epsilon})$ queries to F and finds a solution with probability at least $1 - \epsilon$, provided there is one [9].

We note that for very sparse graphs given in the adjacency matrix model, it may for some applications be efficient to initially learn all entries of the matrix by reiterating the first version of the search algorithm, for instance, as formalized in

Fact 2.1.

FACT 2.1. *Let k be given. There is a quantum algorithm that takes as input an $n \times n$ boolean matrix M , uses $O(n\sqrt{k})$ queries to M , and outputs a set S of 1-entries of M so that with probability at least $\frac{1}{2}$, S is of cardinality at least k or contains all 1-entries of M in case M has less than k 1-entries.*

Our lower bounds use a technique introduced by Ambainis [2].

THEOREM 2.2 (see [2, Theorem 6]). *Let $L \subseteq \{0, 1\}^*$ be a decision problem. Let $X \subseteq L$ be a set of positive instances and $Y \subseteq \bar{L}$ a set of negative instances. Let $R \subseteq X \times Y$ be a relation between instances of the same size. Let values $m, m', \ell_{x,i}$, and $\ell'_{y,i}$ for $x, y \in \{0, 1\}^n$ and $x \in X, y \in Y, i \in [n]$ be so that*

- *for every $x \in X$ there are at least m different $y \in Y$ in relation with x ,*
- *for every $y \in Y$ there are at least m' different $x \in X$ in relation with y ,*
- *for every $x \in X$ and $i \in [n]$ there are at most $\ell_{x,i}$ different $y \in Y$ in relation with x which differ from x at entry i ,*
- *for every $y \in Y$ and $i \in [n]$ there are at most $\ell'_{y,i}$ different $x \in X$ in relation with y which differ from y at entry i .*

Then the quantum query complexity of L is $\Omega(\sqrt{mm'/\ell_{\max}})$, where ℓ_{\max} is the maximum of $\ell_{x,i}\ell'_{y,i}$ subject to xRy and $x_i \neq y_i$.

3. Minima finding. Many graph problems are optimization problems, as are finding a minimum spanning tree, single source shortest paths, and largest connected components. Most quantum algorithms for such optimization problems utilize the search algorithm discussed above. A very basic and abstract optimization problem is as follows. Suppose we are given a function f defined on a domain of size n , and we want to find an index i so that $f(i)$ is a minimum in the image of f . This minimization problem was considered in [11], which gives an optimal quantum algorithm that uses $O(\sqrt{n})$ queries to f and finds such an i with constant probability. Since it will make the rest of the section easier to understand, we include it here.

1. Initially let $j \in [N]$ be an index chosen uniformly at random.
2. Repeat forever
 - (a) Find an index $i \in [N]$ such that $f(i) < f(j)$.
 - (b) Set $j := i$.

The analysis of this minimization algorithm is straightforward.

THEOREM 3.1 (see [11]). *The expected number of queries to f , until j contains the index of a minimum in the image of f , is $O(\sqrt{N})$.*

Proof. Without loss of generality assume that f is injective. Every index $j \in [N]$ has a *rank*, which we define as the number of indices i such that $f(i) \leq f(j)$. Consider an iteration of the main loop, and suppose the rank of j is r in Step 2(a). Let t be a power of two such that $t \leq r < 2t$. After an expected number of at most $\frac{9}{10}\sqrt{N}/t$ queries, the algorithm finds an index i of rank $r_i < r$. Since the algorithm in Step 2(b) picks an index of rank smaller than j uniformly at random, $r_i < t$ with probability at least $\frac{1}{2}$. Thus after an expected number of at most $\frac{9}{5}\sqrt{N}/t$ queries, we have found an index of rank less than t .¹ Applying this argument repeatedly, the expected total number of queries is at most $\frac{9}{5} \sum_{k \geq 0} \sqrt{N}/2^k$. Since the geometric summation $\sum_{k \geq 0} \frac{1}{\sqrt{2^k}}$ is upper bounded by a constant, the expected total number of queries is $O(\sqrt{N})$. \square

¹In fact, the probability that the index of rank r is picked at some point during the run of the algorithm is exactly $\frac{1}{r}$.

Let $c'\sqrt{N}$ be the expected number of queries to f until j contains the index of a minimum. Stopping the algorithm after $2c'$ queries gives a quantum algorithm with error probability upper bounded by $\frac{1}{2}$.

For the purposes of this paper, we require the following generalizations of the minimum finding problem, illustrated in Figure 3.1.

PROBLEM 1 (find d smallest values of a function). *Let \mathbb{N}^* denote $\mathbb{N} \cup \{\infty\}$. Given a function $f : [N] \rightarrow \mathbb{N}^*$ and an integer $d \in [N]$, we wish to find d distinct indices mapping to smallest values, i.e., a subset $I \subseteq [N]$ of cardinality d such that for any $j \in [N] \setminus I$ we have that $f(i) \leq f(j)$ for all $i \in I$.*

In the rest of this section, we assume $d \leq N/2$. In the following problem we are given a different function $g : [N] \rightarrow \mathbb{N}$, such that $g(j)$ defines the *type* of j . Let $e = |\{g(j) : j \in [N]\}|$ be the number of different types.

PROBLEM 2 (find d elements of different type). *Given a function g and an integer d' we wish to find integer $d = \min\{d', e\}$ and a subset $I \subseteq [N]$ of cardinality d such that $g(i) \neq g(i')$ for all distinct $i, i' \in I$.*

Now we present a generalization of both problems.

PROBLEM 3 (find d smallest values of different type). *Given two functions f, g and an integer d' we wish to find integer $d = \min\{d', e\}$ and a subset $I \subseteq [N]$ of cardinality d such that $g(i) \neq g(i')$ for all distinct $i, i' \in I$ and such that for all $j \in [N] \setminus I$ and $i \in I$, if $f(j) < f(i)$, then $f(i') \leq f(j)$ for some $i' \in I$ with $g(i') = g(j)$.*

FIG. 3.1. Illustration of the three problems. Each index i is illustrated by a point with horizontal coordinate $g(i)$ and vertical coordinate $f(i)$.

It is clear that Problems 1 and 2 are special cases of Problem 3. In this section, we give an upper bound of $O(\sqrt{dN})$ for Problem 3. In section 8, we then show a lower bound of $\Omega(\sqrt{dN})$ for Problems 1 and 2, implying that all three problems are of complexity $\Theta(\sqrt{dN})$. We prove the upper bound by a simple greedy algorithm. Consider a subset $I \subseteq [N]$ of d indices of different types. We say an index $j \in [N]$ is good for I if

1. either $g(j) = g(i)$ and $f(j) < f(i)$ for some $i \in I$,
2. or $g(j) \notin g(I)$ and $f(j) < f(i)$ for some $i \in I$.

In the former case we say j is a good index of *known type* and in the latter that j is a good index of *unknown type*. In each iteration of the greedy algorithm, we find a good index j by the search algorithm and then improve I by replacing some index in I by j .

1. Initially, let $I = \{N + 1, \dots, N + d'\}$ be a set of artificial indices of unique different types and unique maximal value.
2. Repeat forever

- (a) Let t denote the number of good elements for I . (Note: This step is not required but is only included for the purpose of simplifying the analysis of the algorithm.)
- (b) Use the first version of the search algorithm to find a good element $j \in [N]$ for I .
- (c) Set $I = \text{improve}(I, j)$ where we improve I by replacing with j the element in I that has the same type as j if j is of known type, and by replacing with j some element in I with largest f -value if j is of unknown type.

The next lemma shows that we need only an expected number of $O(d)$ iterations of the main loop to eliminate a constant fraction of the remaining good elements.

LEMMA 3.2. *Let $I \subseteq [N]$ be any subset of d' indices of different types with $t > 0$ good elements of e types. After an expected number of $O(d)$ iterations of the main loop there are at most $\frac{3}{4}t$ good elements for I . Here $d = \min\{d', e\}$.*

Proof. For notational simplicity assume f is injective. Set $I_0 = I$ and let $T_0 = T$ be the set of good elements for I . Let T_j denote the set of good elements after j iterations of the main loop for $j > 0$. Similarly, let I_j denote the selected index set after j iterations for $j > 0$. Set $t_k = |T_k|$. In particular, $I_0 = I$ and $t_0 = t$. Let y_{mid} denote the $\lfloor t/2 \rfloor$ th smallest of the t elements according to f . For any subset $S \subseteq [N + d']$, let $\text{low}(S)$ denote the number of elements in S that are no bigger than y_{mid} according to f .

Note that initially

- $\text{low}(T_0) = \lfloor t/2 \rfloor$ and
- $\text{low}(I_0) < d$.

By the nature of the greedy algorithm, $\text{low}(T_{k+1}) \leq \text{low}(T_k)$ and $\text{low}(I_{k+1}) \geq \text{low}(I_k)$ for any $k \geq 0$. Note that

- if $\text{low}(T_k) < \frac{t}{4}$, then we have eliminated at least a fraction of $\frac{1}{4}$ of the initially t good elements for I , and similarly,
- if $\text{low}(I_k) = d$, then we have eliminated at least a fraction of $\frac{1}{2}$ of the initially t good elements for I .

We claim that in each iteration of the main loop, as long as $\text{low}(T_k) \geq \frac{t}{4}$, with probability at least $\frac{1}{32}$, at least one of the following two events happens:

- $\text{low}(T_{k+1}) \leq \text{low}(T_k) \left(1 - \frac{1}{32d}\right)$,
- $\text{low}(I_{k+1}) = \text{low}(I_k) + 1$.

Assume $\text{low}(T_k) \geq \frac{t}{4}$, since otherwise we are done. Consider the element j picked in Step 2(b). First suppose the majority of the $\text{low}(T_k)$ indices are of unknown type with respect to I_k . Then, with probability at least $\frac{1}{8}$, index j is among these, in which case $\text{low}(I_{k+1}) = \text{low}(I_k) + 1$.

Now suppose the majority of the $\text{low}(T_k)$ indices are of known type with respect to I_k . Then, with probability at least $\frac{1}{8}$, index j is among these. Conditioned on this happening, with probability at least $\frac{1}{2}$, there are at least $\frac{\text{low}(T_k)}{4d}$ good elements for I_k of the same type as j . With probability at least $\frac{1}{2}$, at least half of these are not good for I_{k+1} . Thus, with probability at least $\frac{1}{32}$, we have eliminated at least $\frac{t}{32d}$ of the remaining elements in T_j .

This proves the claim. It follows that after an expected number of $O(d)$ iterations of the main loop, we have eliminated at least a fraction of $\frac{1}{4}$ of the initially t good elements. \square

The above lemma implies that, for $t > 2d$, after an expected number of $O(d\sqrt{N/t})$ applications of function f , the number of good elements is at most $\frac{t}{2}$. Hence, for any

$t > 2d$, the expected number applications of function f required until we have that $t \leq 2d$ for the first time is on the order of

$$d \left(\sqrt{\frac{N}{d}} + \sqrt{\frac{N}{2d}} + \sqrt{\frac{N}{4d}} + \sqrt{\frac{N}{8d}} + \dots \right) \in O(\sqrt{dN}).$$

Once $t \leq 2d$ for the first time, the expected number of applications of f required before $t = 0$ for the first time is on the order of $\sum_{j=1}^{2d} \sqrt{N/j}$, which is $O(\sqrt{dN})$.

COROLLARY 3.3. *In the greedy algorithm given above, after an expected number of $O(\sqrt{dN})$ applications of function f , there are no good elements for I ; that is, $t = 0$.*

The next theorem follows immediately.

THEOREM 3.4. *The problem FIND d SMALLEST VALUES OF DIFFERENT TYPE has bounded error quantum query complexity $O(\sqrt{dN})$.*

Nayak and Wu give in [19] a bounded error quantum algorithm that, given a function $f : [N] \rightarrow \mathbb{N}$ and two integers d and Δ , outputs an index i such that the rank of $f(i)$ is between $d - \Delta$ and $d + \Delta$. The query complexity of their algorithm is $O(M \log M \log \log M)$, where $M = \sqrt{N/\Delta} + \sqrt{d(N-d)}/\Delta$. Setting $\Delta = \frac{1}{2}$, it would find the d th smallest element with $O(\sqrt{dN} \log N \log \log N)$ queries. Nayak [18] later improved this algorithm to $O(\sqrt{dN})$, matching the lower bound given in [19]. His method is different from ours.

Remark 1. The algorithm above uses $c\sqrt{dN}$ queries for some constant c and outputs the solution with probability at least $1/2$. In order to reduce the error probability to $1/2^k$ one could run the algorithm k times and, among the dk resulting indices, output the d smallest values of different type. However, starting each run with randomly chosen points of different type regardless of the previous outcome is a waste of information. So it is much more clever to run the algorithm only once and stop it after $kc\sqrt{dN}$ queries.

4. MINIMUM SPANNING TREE. In this section we consider undirected graphs with weighted edges. In MINIMUM SPANNING TREE we wish to compute a cycle-free edge set of maximal cardinality that has minimum total weight. To be precise, if the graph is not connected, this is actually a spanning forest.

Classically, there are a number of different approaches to finding minimum spanning trees efficiently, including the algorithms of Borůvka [5, 20], Kruskal [17], and Prim [21]. To construct an efficient quantum algorithm, we use Borůvka's algorithm since it is of a highly parallel nature. This allows us to use the minima finding algorithms given in section 3.

Borůvka's algorithm consists of at most $\log n$ iterations. In brief, initially it starts with a collection of n spanning trees, each tree containing a single vertex. In each iteration, it finds a minimum weight edge out of each tree in the collection, adds the edges to the trees, and merges them into larger and fewer trees. After at most $\log n$ iterations, there is only one tree left, which is a minimum spanning tree. The correctness of Borůvka's algorithm rests on the following simple fact about spanning trees.

FACT 4.1. *Let $U \subset V$ be a set of vertices of a connected graph $G = (V, E)$ and let e be a minimum weight edge of $(U \times \bar{U}) \cap E$. Then there is a minimum spanning tree containing e .*

In our quantum version of Borůvka's algorithm, we make a few adjustments to keep the overall error probability small without sacrificing the number of queries. We adjust it slightly so that the ℓ th iteration errs with probability at most $\frac{1}{2^{\ell+2}}$, ensuring

that the overall error is at most $\frac{1}{4}$. This increases the cost of the ℓ th iteration by a factor of ℓ , but since the cost of the first few iterations dominates, this is asymptotically negligible. The details follow.

1. Let T_1, T_2, \dots, T_k be a spanning forest. Initially, $k = n$ and each tree T_j contains a single vertex.
2. Set $\ell = 0$.
3. Repeat until there is only a single spanning tree (i.e., $k = 1$).
 - (a) Increment ℓ .
 - (b) Find edges e_1, e_2, \dots, e_k satisfying that e_j is a minimum weight edge leaving T_j . Interrupt when the total number of queries is $(\ell + 2)c\sqrt{km}$ for some appropriate constant c .
 - (c) Add the edges e'_j to the trees, merging them into larger trees.
4. Return the spanning tree T_1 .

To find the minimum edges e_1, \dots, e_k in Step 3(b), we use the following functions. In the array model, any edge (u, v) is coded twice, u appears as neighbor of v , but v also appears as neighbor of u . Enumerate the directed edges from 0 to $2m - 1$. Let $f : [2m] \rightarrow \mathbb{N}^*$ denote the function that maps every directed edge (u, v) to its weight if u and v belong to different trees of the current spanning forest and to ∞ otherwise. Let $g : [2m] \rightarrow [k]$ denote the function that maps every directed edge (u, v) to the index j of the tree T_j containing u . We then apply the algorithm for FIND k SMALLEST VALUES OF DIFFERENT TYPE, interrupting it after $(\ell + 2)c\sqrt{km}$ queries to obtain an error probability at most $1/2^{\ell+2}$ (see Remark 1 in section 3).

THEOREM 4.2. *Given an undirected graph with weighted edges, the algorithm above outputs a spanning tree that is minimum with probability at least $\frac{1}{4}$. The algorithm uses $O(\sqrt{nm})$ queries in the array model and $O(n^{3/2})$ queries in the matrix model.*

Proof. To simplify the proof, consider the matrix model an instance of the array model with $m = n(n - 1)$ edges.

At the beginning of the ℓ th iteration of the main loop, the number of trees k is at most $n/2^{\ell-1}$, and thus it uses at most $(\ell + 2)c\sqrt{nm}/2^{\ell-1}$ queries. Summing over all iterations, the total number of queries is at most $\sum_{\ell \geq 1} (\ell + 2)c\sqrt{nm}/2^{\ell-1}$, which is $O(\sqrt{nm})$.

The ℓ th iteration introduces an error with probability at most $\frac{1}{2^{\ell+2}}$. The overall error probability is thus upper bounded by $\sum_{\ell \geq 1} \frac{1}{2^{\ell+2}} \leq \frac{1}{4}$. \square

5. Connectivity. A special case of MINIMUM SPANNING TREE when all edge weights are equal is GRAPH CONNECTIVITY. The input is an *undirected* graph and the output is a spanning tree, provided the graph is connected.

For the matrix model, the algorithm for MINIMUM SPANNING TREE given in the previous section implies an $O(n^{3/2})$ upper bound for GRAPH CONNECTIVITY as well. Below, we give a somewhat simpler and arguably more natural quantum algorithm of query complexity $O(n^{3/2})$, which is optimal by the lower bound given in section 8 below.

For the array model, we give a quantum algorithm that uses only $O(n)$ queries. Both algorithms start with a collection of n connected components, one for each vertex, and greedily construct a spanning tree by repeatedly picking an edge that connects two of the components.

THEOREM 5.1. *Given the adjacency matrix M of an undirected graph G , the algorithm below outputs a spanning tree for G after an expected number of $O(n^{3/2})$*

queries to M , provided G is connected, and otherwise runs forever.

Proof. Consider the following algorithm.

1. Initially the edge set A is empty.
2. Repeat until A connects the graph.
 - (a) Search for a *good* edge, i.e., an edge that connects two different components in A , and add it to A . Use the version of the search algorithm that returns a solution in the expected $O(n^2/t)$ queries if there are $t > 0$ good edges and otherwise runs forever.
3. Return the edge set A .

Suppose the graph is connected and consider the expected total number of queries used by the algorithm. There are exactly $n-1$ iterations of the main loop. The number of good edges is at least $k-1$ when A consists of k components, and thus the expected total number of queries is on the order of $\sum_{k=2}^n \sqrt{n^2/(k-1)}$, which is $O(n^{3/2})$. \square

When implementing the above algorithm, we maintain an appropriate data structure containing information about the connected components in the graph induced by A . This introduces an additional $O(n \log n)$ term in the running time of the algorithm which is negligible compared to $O(n^{3/2})$. We may choose to stop the algorithm after twice the expected total number of queries, giving an $O(n^{3/2})$ query algorithm with bounded one-sided error.

5.1. The array model. As for the matrix model, we also solve CONNECTIVITY for the array model by constructing larger and larger connected components by merging components. Achieving an $O(n^{3/2})$ query algorithm is fairly easy but not optimal. To do better, we require an efficient routine for generating connected components as a first stage of the complete algorithm.

LEMMA 5.2. *Given an undirected graph G in the array model, we can in $O(n)$ classical queries partition vertex set V into a set of connected components $\{C_1, \dots, C_k\}$ for some integer k , so that for each component C , its total degree $m_C = \sum_{i \in C} d_i$ is no more than $|C|^2$.*

Proof. The algorithm is classical and is as follows.

1. Initially the edge set A is empty.
2. Let $S = V$ be the set of vertices not yet placed in some component.
3. Let $k = 0$ be the number of components constructed thus far.
4. While S is nonempty
 - (a) Take the vertex v of highest degree in S and set $D = \{v\}$.
 - (b) Go through v 's list of neighbors one by one, each time adding the neighbor w to D and the edge (v, w) to A , until one of two events happens: (1) We reach the end of the list, or (2) we reach a neighbor w already assigned to some component C_j with $j \leq k$.
 - (c) In case (1), set $k = k + 1$, $C_k = D$, and remove D from S . In case (2), add D to C_j , and remove D from S .
5. Output k , A , and C_1, C_2, \dots, C_k .

The algorithm uses $n - k$ queries in total, one query for each vertex but the first added to each component. Edge set A contains the union of spanning trees of the components C_1 through C_k .

To show correctness, let v be the vertex chosen in Step 4(a) and d its degree. Then $d \leq |C_j|$ for each component constructed so far, since the size of a freshly created component is the degree of one of its vertices, which by choice in Step 4(a) must be no less than d , and components can only grow. To show that the total degree of every component C_j is no more than $|C_j|^2$, consider the two cases in Step 4(b).

In case (1), D is the set of v and its neighbors, each neighbor having degree no larger than d , implying the total degree is at most $d(d + 1)$ which is strictly less than $(d + 1)^2 = |D|^2$. In case (2), let a be the size of the component C_j to which D is merged, and b the size of D . Then $b \leq d \leq a$. The total degree is no more than $a^2 + bd$ which is strictly less than $(a + b)^2$. \square

THEOREM 5.3. *Given an undirected graph G in the array model, the algorithm below outputs a spanning tree for G using an expected number of $O(n)$ queries, provided G is connected, and otherwise runs forever.*

Proof. Consider the following algorithm.

1. Construct the edge set A using the above lemma.
2. Repeat until A connects the graph.
 - (a) Pick a connected component C in A with smallest total degree, i.e., a component minimizing $m_C = \sum_{i \in C} d_i$.
 - (b) Search for an edge out of C , i.e., an edge that connects C to some other component in A , and add it to A . Use the version of the search algorithm that returns a solution in the expected $O(\sqrt{m_C})$ queries if there is at least one such edge and otherwise runs forever.
3. Return the edge set A .

Suppose the graph is connected and consider the expected total number of queries used by the algorithm.

We first construct k components, each component C having total degree m_C at most $|C|^2$. In each iteration of the main loop, we pick the component with smallest total degree and search for an edge out of C . The expected cost of finding such an edge is at most $\alpha\sqrt{m_C}$ for some constant α . We distribute this cost evenly among each of the m_C edge endpoints in C , each endpoint paying $\alpha/\sqrt{m_C}$.

Fix an arbitrary edge endpoint. Enumerate from 0 up to at most $\log m$ the successive components that were chosen by the algorithm for a search and that contain this fixed edge endpoint. Let m_i be the number of edge endpoints in the i th component. Then $m_{i+1} \geq 2m_i$. The total cost assigned to our fixed edge endpoint is upper bounded by

$$\sum_{i=0}^{\log m} \frac{\alpha}{\sqrt{m_i}} \leq \sum_{i=0}^{\log m} \frac{\alpha}{\sqrt{2^i m_0}} \leq \frac{4\alpha}{\sqrt{m_0}}.$$

Let C be any of the k components constructed in the first step. The total cost assigned over all edge endpoints in C is thus upper bounded by $4\alpha\sqrt{m_C}$, which is at most $4\alpha|C|$. Summing over all k components, the total cost assigned in the main loop is at most $4\alpha n$, which is linear in n . \square

6. STRONG CONNECTIVITY. We give two quantum algorithms for STRONG CONNECTIVITY, first one for the matrix model and then one for the array model. The input is a *directed* graph and the output is a set of at most $2(n - 1)$ edges that proves the graph is strongly connected, provided it is. It follows from the discussions below that such sets always exist.

For the matrix model, all we need is to construct an oriented tree, rooted at some vertex v_0 . We can then run the procedure again on the transposed adjacency matrix, which results in $2(n - 1)$ edges with the required property.

We now give a method for constructing such a tree with bounded error using an optimal number of queries. To keep the overall error small, we classify vertices covered by the current tree into sets T_0, \dots, T_q such that the *confidence* that vertices from T_i

have no new neighbors is increasing with i . Whenever a search for an edge (u, v) with $u \in R$ and $v \notin T_0 \cup \dots \cup T_i$ is successful for some subset $R \subseteq T_i$, the vertices R and v will be moved into T_0 ; otherwise R will be moved into T_{i+1} . We make this formal now.

1. Let S be the tree consisting of the single vertex v_0 .
Partition the vertex set covered by S into $T_0 = \{v_0\}$ and $T_1 = \dots = T_q = \{\}$ for $q = \lfloor \log_2(n) \rfloor + 1$.
2. While there is a set T_i with $|T_i| \geq 2^i$ do
 - (a) Let i be the smallest index such that $|T_i| \geq 2^i$.
 - (b) If $|T_i| < 2^{i+1}$, then $R = T_i$; otherwise R is an arbitrary subset of T_i with $|R| = 2^i$.
 - (c) Remove R from T_i .
 - (d) Search for an edge (u, v) with $u \in R$ and $v \notin S$ in a search space of size $O(2^i n)$ with the version of the quantum search procedure that uses $O(2^{3i/4} \sqrt{n})$ queries and finds a solution with probability $1 - c_0/2^{\sqrt{2^{i+2}}}$, provided such an edge exists, and where $c_0 > 0$ is some appropriately small constant.
 - (e) If the search is successful, add (u, v) to S and $R \cup \{v\}$ to T_0 ; otherwise add R to T_{i+1} .
3. Output S .

We now show some properties of the algorithm. For convenience we define $t_j = |T_0| + |T_1| + \dots + |T_j|$ for each $j = 0, \dots, q$.

LEMMA 6.1. *At the beginning and end of each iteration, the following invariants hold. Let k be the smallest and ℓ the largest index of a nonempty set T_j . Then*

$$(6.1) \quad |T_\ell| \geq 2^{\ell-1},$$

$$(6.2) \quad \forall k \leq j < \ell : t_j \geq 2^j.$$

Proof. The proof is by induction on the number of iterations of the algorithm. Initially, when T_0 is the unique nonempty set, the conditions (6.1) and (6.2) hold.

Assume both conditions hold at the beginning of an iteration. First observe that by the induction hypothesis (6.2) that if $k < \ell$, then $|T_k| \geq 2^k$, and so the index chosen by the algorithm is always $i = k$. Now if the search is successful, we have $t_0 \geq 2^k$ and thus $t_j \geq 2^k$ for all $0 \leq j \leq k$, while for all $j > k$, t_j increases by one, maintaining condition (6.2). If the search is not successful, then by the choice of R , after the iteration, either $t_k = 0$ or $t_k \geq 2^k$, while for all values $j > k$, t_j is not modified, and thus condition (6.2) holds for all $k \leq j < \ell$.

Consider condition (6.1). Whenever an empty set T_j becomes nonempty, it contains at least 2^{j-1} elements, and whenever elements are taken out of a set T_j , afterward it is either empty ($|T_j| = 0$) or $|T_j| \geq 2^j$. Thus in all cases, condition (6.1) is maintained. \square

As a consequence, when the algorithm stops, there is a unique nonempty set T_i and moreover $2^{i-1} \leq |T_i| < 2^i$. Also since at most $n - 1$ searches can be successful, the algorithm stops after $O(n^2)$ iterations.

LEMMA 6.2. *When the algorithm stops, S covers all vertices reachable from v_0 with probability at least $39/40$.*

Proof. First note that the algorithm never outputs a vertex that is not reachable from v_0 . Suppose the algorithm outputs a strict subset of the r vertices that are reachable from v_0 . Consider the probability of the event that the algorithm outputs a subset of size q with $q < r$. For this event to happen, in particular the very last run

of the search procedure fails in finding a new edge, which happens with probability at most $c_0/2^{\sqrt{2^i+2}}$, where i is such that $2^{i-1} \leq q < 2^i$. By summing over all $1 \leq q < r$, the probability that the algorithm fails in finding all reachable vertices is at most

$$\sum_{q \geq 1} \frac{c_0}{2^{\sqrt{q+2}}},$$

which is upper bounded by $\frac{1}{40}$ for some appropriately small constant $c_0 > 0$. \square

We now analyze the complexity of the algorithm.

LEMMA 6.3. *The expected number of queries made by the algorithm is $O(|S|\sqrt{n})$.*

Proof. To analyze the total number of queries made by the search procedures, we group the calls to the search procedures into sequences of unsuccessful searches ending with a success, plus the last sequence of unsuccessful searches.

For the first case, let (u, v) be an arbitrary edge found by the algorithm. Then the probability that it was found when $u \in T_i$ is upper bounded by the probability that it was not found when $u \in T_{i-1}$, which is at most $1/2^{\sqrt{2^i}}$. The cost of this search and the $i - 1$ unsuccessful searches over sets R containing u is of order

$$\sum_{j=0}^i 2^{3j/4} \sqrt{n} \in O(2^{3i/4} \sqrt{n}).$$

The expected cost of finding (u, v) is thus at most

$$\sum_{i \geq 0} \frac{2^{3i/4}}{2^{\sqrt{2^i}}} \sqrt{n} \in O(\sqrt{n}).$$

To complete the analysis we upper bound the total work of the $O(\log n)$ unsuccessful searches which were made after the last successful search. Let i be such that $2^{i-1} \leq |S| < 2^i$. There are at most $2^i/2^j$ searches for sets R with $|R| = 2^j$. Therefore the total work is of order

$$\sum_{j=0}^i 2^{i-j} 2^{3j/4} \sqrt{n} \in O(|S|\sqrt{n}).$$

This concludes the proof. \square

In conclusion we have an algorithm that outputs a directed tree T rooted at v_0 . With probability at least $39/40$, T covers all the vertices which are reachable from v_0 , and its expected number of queries to M is at most $O(n^{3/2})$. This can be turned into an algorithm with worst case query complexity $O(n^{3/2})$ and success probability at least $19/20$. Now running the algorithm again on the transposed adjacency matrix provides an edge set $T \cup T'$ which with probability at least $9/10$ is strongly connected, provided the input graph is strongly connected.

THEOREM 6.4. *There is an algorithm that, given the adjacency matrix M of a directed graph G , uses $O(n^{3/2})$ queries to M , outputs “strongly connected” with probability at least $9/10$ if G is strongly connected, and otherwise outputs “not strongly connected.”*

6.1. The array model. In the array model, we may try to apply an algorithm similar to the one given above for the matrix model. Doing so, we would reverse the edge orientations as part of the second stage, which would require m queries and

hence be of the same query complexity as the classical algorithm that initially queries every bit of the input. We now give another algorithm that is sublinear in m and works in two stages. The first stage computes an oriented spanning tree rooted at v_0 as we did for the matrix model, but this time by using a depth-first search algorithm. The second stage then uses desirable properties of a depth-first search tree to achieve an algorithm of complexity sublinear in m .

LEMMA 6.5. *Given the adjacency array of a directed graph G and a vertex v_0 , the algorithm below uses $O(\sqrt{nm \log n})$ queries to M and outputs a directed tree $A \subseteq E$ rooted at v_0 . With probability at least $\frac{9}{10}$, A is a depth-first tree spanning all of G , provided G is strongly connected.*

Proof. Consider the following simple algorithm.

1. Initially the edge set A is empty.
2. Let $S = \{v_0\}$ be a set of reachable vertices and $T = \{v_0\}$ a stack of vertices to be processed.
3. While $T \neq \{\}$ do
 - (a) Let u be the topmost vertex on stack T .
 - (b) Search for a neighbor v of u not in S . Use the version of the search algorithm that uses $O(\sqrt{d_u^+ \log n})$ queries and outputs a solution with probability at least $1 - \frac{1}{20n}$, provided one exists.
 - (c) If (3b) succeeds, add (u, v) to A , add v to S , and push v onto T .
 - (d) Otherwise, remove u from T .
4. Return edge set A .

For any vertex u let b_u^+ be its out-degree in the tree A produced by the algorithm. Then the total number of queries spent in finding the b_u^+ neighbors of u is on the order of $\sum_{t=1}^{b_u^+} \sqrt{d_u^+ / t} \sqrt{\log n}$ which is $O(\sqrt{b_u^+ d_u^+ \log n})$. Summing over all vertices u this gives

$$\sum_{u \in V} \sqrt{b_u^+ d_u^+ \log n} \leq \sqrt{\sum_u b_u^+} \sqrt{\sum_u d_u^+ \log n} \in O(\sqrt{nm \log n}),$$

where the first inequality follows from the Cauchy–Schwarz inequality and the second from the fact that a tree has only $O(n)$ edges. The algorithm spends in addition $O(\sum_u \sqrt{d_u^+ \log n})$ queries for the unsuccessful neighbor searches, but this is dominated by the previous cost.

The overall error probability is upper bounded by $\frac{1}{10}$ since each of the at most $2n - 1$ searches has error at most $\frac{1}{20n}$. \square

We show now, given a depth-first tree A , how to compute the remaining edge set B such that $A \cup B$ is strongly connected, provided G is strongly connected.

THEOREM 6.6. *Given the adjacency array of a directed graph $G = (V, E)$ and a vertex v_0 , there is an algorithm that uses $O(\sqrt{nm \log n})$ queries and outputs an edge set $E' \subseteq E$ of size at most $2n - 2$ covering v_0 . If G is strongly connected, then with probability at least $\frac{3}{4}$, (V, E') is strongly connected.*

Proof. We use the previous algorithm to construct a directed depth-first spanning tree $A \subseteq E$ rooted at v_0 . We label the vertices according to the order in which they are added to the tree A in Lemma 6.5.

Then in the second stage, for every vertex $v_i \in V$, we search for the neighbor v_j with smallest index. The result is a set of backward edges $B \subseteq E$. We claim that the graph $G = (V, E)$ is strongly connected if and only if its subgraph $G' = (V, A \cup B)$ is strongly connected.

Clearly if G' is strongly connected then so is G since $A \cup B \subseteq E$. Therefore to show the converse assume G is strongly connected. For a proof by contradiction let v_i be the vertex with smallest index for which there is no path from v_i to v_0 in G' . By assumption there is a path in G from v_i to v_0 . Let $(v_l, v_{l'})$ be its first edge with $l \geq i$ and $l' < i$. We use the following property of depth-first search.

Let v_i and v_l be two vertices in the graph G with $i \leq l$. If there is a path from v_i to v_l in G then v_l is in the subtree of $G'' = (V, A)$ that is rooted at v_i .

Therefore we can replace in the original path the portion from v_i to v_l by a path using only edges from A . Let $v_{l''}$ be the neighbor of v_l in G with smallest index. Clearly $l'' \leq l' < i$. By the choice of v_i , there exists a path from $v_{l''}$ to v_0 in G' . Together this gives a path from v_i to v_0 in G' , contradicting the assumption and therefore concluding the correctness of the algorithm.

Now we analyze the complexity. During the first stage, set A is computed in time $O(\sqrt{nm} \log n)$. The second stage can be done with $O(\sqrt{nm})$ queries using the minima finding for the mapping from an edge number in $[1, m]$ to the source-target vertex pair. Both stages can be made to succeed with probability at least $7/8$. \square

7. SINGLE SOURCE SHORTEST PATHS. Let G be a directed graph with nonnegative edge weights and let v_0 be a fixed vertex in G . We want to compute a shortest path from v_0 to every vertex $v \in V$. It may happen that the shortest path is not unique. Using, for example, the lexicographical ordering on vertex sequences, we choose to compute a single canonical shortest path. From now on assume that different paths have different lengths. As a result, the union over all vertices v of the shortest paths from v_0 to v is a *shortest path tree*. Let $\nu(u, v)$ be the weight of edge (u, v) and $\delta(v_0, v)$ the shortest path length from v_0 to v .

Classically SINGLE SOURCE SHORTEST PATHS may be solved by Dijkstra's algorithm. It maintains a subtree \mathcal{T} with the "shortest path subtree" invariant: for any vertex $v \in \mathcal{T}$, the shortest path from v_0 to v uses only vertices from \mathcal{T} . An edge (u, v) is called a *border edge* (of \mathcal{T}) if $u \in \mathcal{T}$ and $v \notin \mathcal{T}$, where u is the source vertex and v the target vertex. The *cost* of (u, v) is $\delta(v_0, u) + \nu(u, v)$. Dijkstra's algorithm starts with $\mathcal{T} = \{v_0\}$ and iteratively adds the cheapest border edge to it.

Our improvement lies in the selection of the cheapest border edge. We first give an algorithm for the array model. Setting $m = n^2$ gives the upper bound for the matrix model.

THEOREM 7.1. *The bounded error query complexity of SINGLE SOURCE SHORTEST PATHS in the array model is $O(\sqrt{nm} \log^2 n)$.*

Proof. As in Dijkstra's algorithm, we iteratively construct a tree T such that for every vertex $v \in T$, the shortest path from v_0 to v is in T . We maintain a partitioning of the vertices covered by T and store the partitioning as a sequence of sets. The length of the sequence is denoted by l .

1. Set $T = \{v_0\}$, $l = 1$, $P_1 = \{v_0\}$.
2. Repeat until T covers the graph
 - (a) For P_l compute up to $|P_l|$ cheapest border edges with disjoint target vertices. For this purpose set $N = \sum_{v \in P_l} d(v)$, and number all edges with source in P_l from 0 to $N - 1$. Define the functions $f : [N] \rightarrow \mathbb{N}^*$ and $g : [N] \rightarrow V$, where $g(i)$ is target vertex of the i th edge and $f(i)$ is its weight if $g(i) \notin T$ and ∞ otherwise. Apply the algorithm of section 3 on f and g with $d = |P_l|$ to find the d edges of smallest weight with distinct target vertices. Let A_l be the resulting edge set.

(b) Let (u, v) be the minimal weighted edge of $A_1 \cup \dots \cup A_l$ with $v \notin P_1 \cup \dots \cup P_l$. Set $T = T \cup \{(u, v)\}$, $P_{l+1} = \{v\}$, and $l = l + 1$.

(c) As long as $l \geq 2$ and $|P_{l-1}| = |P_l|$, merge P_l into P_{l-1} , and set $l = l - 1$.

All steps but 2(a) construct a vertex set sequence P_1, \dots, P_l , the cardinality of each being a power of two, and of strictly decreasing sizes. Figure 7.1 shows an example of this partitioning of the vertices in T .

FIG. 7.1. Left: Example of the set decomposition for $|T| = 7$ into powers of 2. Right: Example of corresponding edge sets. The closest border edge of T belongs to one of A_1, A_2, A_3 .

Therefore each set P_i is strictly larger than the union of all the following sets. Hence, if A_i contains $|P_i|$ edges, then at least one of them has its target vertex outside of P_1, \dots, P_l . Let (u, v) be the cheapest border edge of T . Let P_i be the vertex set containing u . Then A_i must contain this edge, and Step 2(b) selects it.

Only Step 2(a) generates queries to the graph. Consider the total number of queries related to sets P_i of some size s . There are at most n/s sets of this size s . Therefore the total work is of order $\sum_{j=1}^{n/s} \sqrt{sm_j}$, where m_j is the number of edges with source in the j th vertex set. We have $\sum_{j=1}^{n/s} m_j = m$. The worst case is when $m_i = sm/n$. In this case, the total work is $O(\sqrt{nm})$ for the fixed size s . There are $\log n$ different set sizes in the algorithm. We require that each of the $O(n \log n)$ queries to the minimum finding succeeds with probability at least $1 - 1/2n \log n$, which introduces an $O(\log n)$ factor (see also Remark 1 in section 3) and we obtain the claimed complexity. \square

8. The lower bounds. Finding the d smallest values of a function can be done in $O(\sqrt{dN})$ queries by Theorem 3.4. We now show this is tight.

THEOREM 8.1. *The problems FIND d SMALLEST VALUES OF A FUNCTION, FIND d ELEMENTS OF DIFFERENT TYPE, and FIND d SMALLEST VALUES OF DIFFERENT TYPE require $\Omega(\sqrt{dN})$ queries.*

Proof. For even k and odd d we consider $d \times k$ boolean matrices with a single 0 in every row. It is encoded by a function $f : [N] \rightarrow \{0, 1\}$ with $N = kd$, such that for every $i \in [d], j \in [k]$, $f(id + j)$ is the entry in row i and column j . Let function $g : [N] \rightarrow [d + 1]$ be such that $g(id + j)$ maps to i if $f(id + j) = 0$ and to d otherwise. By this construction, the problems of FIND $d + 1$ SMALLEST VALUES OF A FUNCTION or $d + 1$ ELEMENTS OF DIFFERENT TYPE or $d + 1$ SMALLEST VALUES OF DIFFERENT TYPE are all equivalent to finding the positions of the d zeros in the matrix.

Let X be the set of matrices such that exactly $\lfloor d/2 \rfloor$ rows have their 0 in the first $k/2$ columns. And let Y be the set of matrices such that this number is exactly $\lceil d/2 \rceil$. We show a lower bound for distinguishing X and Y . We say that matrix $A \in X$ is in relation with $B \in Y$ if and only if the matrices differ at exactly two entries. It follows that there are indices $i \in [d], 0 \leq j < k/2 \leq j' < k$ with $A_{ij} = B_{ij'} = 1$ and

$A_{ij'} = B_{ij} = 0$. The following example illustrates this definition.

$$(8.1) \quad A = \begin{pmatrix} \overbrace{011}^{k/2} \overbrace{111}^{k/2} \\ 111 \ 011 \\ 111 \ 101 \end{pmatrix}, \quad B = \begin{pmatrix} \overbrace{011}^{k/2} \overbrace{111}^{k/2} \\ 110 \ 111 \\ 111 \ 101 \end{pmatrix}.$$

Then the number of matrices which are in relation with a fixed matrix is at least $m = m' = \lceil d/2 \rceil k/2$. For fixed i, j the number of matrices in relation with M and differing at i, j is $k/2$ if $M_{ij} = 0$ and 1 if $M_{ij} = 1$. So $l_{\max} = k/2$ and, by Theorem 2.2, $\Omega(\sqrt{mm'}/l_{\max})$ gives the required lower bound. \square

We first consider lower bounds for CONNECTIVITY and STRONG CONNECTIVITY in the array model. By reducing from PARITY as done by Henzinger and Fredman for the on-line connectivity problem [14], one can show a simple lower bound of $\Omega(n)$ queries in the array model for both problems. For directed graphs, we can improve this to $\Omega(\sqrt{nm})$ queries in the array model.

THEOREM 8.2. STRONG CONNECTIVITY requires $\Omega(\sqrt{nm})$ queries in the array model.

Proof. Let m be such that $m = kn$ for some integer k , and assume $n - k$ is even. We construct the lower bound for regular graphs with out-degree k .

We use two kinds of vertices. The first $2p$ vertices are connected by two disjoint cycles or by a single cycle, as in the aforementioned reduction from PARITY. The other k vertices are used as a pool to collect most of the edges. See Figure 8.1. Let the vertex set be $V = \{v_0, \dots, v_{2p-1}, u_0, \dots, u_{k-1}\}$ for integer $p = (n - k)/2$. In the list model, the edges are defined by a function $f : V \times [k] \rightarrow V$. We consider only functions with the following restrictions:

For every $i \in [k]$ we have $f(u_i, 0) = v_0$ and for $j \in \{1, \dots, k - 1\}$ $f(u_i, j) = u_{i+j}$, where addition is modulo k .

For every $i \in [p]$ there exist $j_0, j_1 \in [k]$ and a bit b such that $f(v_{2i}, j_0) = v_{2i+2+b}$ and $f(v_{2i+1}, j_1) = v_{2i+3-b}$, where addition is modulo $2p$ this time. We call these edges the *forward edges*. The *backward edges* are for all $j \in [k]$ $f(v_{2i}, j) = u_j$ whenever $j \neq j_0$ and $f(v_{2i+1}, j) = u_j$ whenever $j \neq j_1$.

FIG. 8.1. A strongly connected graph.

Now all the vertices are connected to the k -clique, the clique is connected to v_0 , and the graph is strongly connected if and only if there is a path from v_0 to v_1 .

Let X be the set of functions which define a strongly connected graph and Y the set of functions which do not. Function $f \in X$ is in relation with $g \in Y$ if there are numbers $i \in [p], j_0, j_1, h_0, h_1 \in [k]$ with $j_0 \neq h_0, j_1 \neq h_1$ such that the only places where f and g differ are

$$\begin{aligned} g(v_{2i}, h_0) &= f(v_{2i+1}, j_1)g(v_{2i+1}, h_1) = f(v_{2i}, j_0), \\ g(v_{2i}, j_0) &= u_{j_0}g(v_{2i+1}, j_1) = u_{j_1}, \\ f(v_{2i}, h_0) &= u_{h_0}f(v_{2i+1}, h_1) = u_{h_1}. \end{aligned}$$

Informally f and g are in relation if there is a level, where the forward edges are exchanged between a *parallel* and *crossing* configuration and in addition the edge labels are changed.

Then $m = m' \in \Omega(nk^2), p \in \Omega(n)$, for the number of levels and $(k - 1)^2$ for the number of possible forward edge labels. We also have $l_{f,(v,j)} = k - 1$ if $f(v, j) \in \{u_0, \dots, u_{k-1}\}$ and $l_{f,(v,j)} = (k - 1)^2$ otherwise. The value $l'_{g,(v,j)}$ is the same. Since only one of $f(v, j), g(v, j)$ can be in $\{u_0, \dots, u_{k-1}\}$ we have $l_{\max} \in O(k^3)$ and the lower bound follows. \square

For the matrix model, there is a much simpler lower bound which works even for undirected graphs.

THEOREM 8.3. *CONNECTIVITY requires $\Omega(n^{3/2})$ queries in the matrix model.*

Proof. We use Ambainis’s method for the following special problem in a very simple manner. We are given a symmetric matrix $M \in \{0, 1\}^{n \times n}$ with the promise that it is the adjacency matrix of a graph with exactly one or two cycles, and we have to determine which is the case.

Let X be the set of all adjacency matrices of a unique cycle and Y the set of all adjacency matrices with exactly two cycles each of length between $n/3$ and $2n/3$. We define the relation $R \subseteq X \times Y$ as $M R M'$ if there exist $a, b, c, d \in [n]$ such that the only difference between M and M' is that $(a, b), (c, d)$ are edges in M but not in M' and $(a, c), (b, d)$ are edges in M' but not in M . See Figure 8.2. The definition of Y implies that in M the distance from a to c is between $n/3$ and $2n/3$.

FIG. 8.2. *Illustration of the relation.*

Then $m \in \Omega(n^2)$ since there are $n - 1$ choices for the first edge and $n/3$ choices for the second edge. Also $m' \in \Omega(n^2)$ since from each cycle one edge must be picked, and cycle length is at least $n/3$.

We have $l_{M,(i,j)} = 4$ if $M_{i,j} = 0$ since in M' we have the additional edge (i, j) and the endpoints of the second edge must be neighbors of i and j , respectively. Moreover $l_{M,(i,j)} \in O(n)$ if $M_{i,j} = 1$ since then (i, j) is one of the edges to be removed and there remain $n/3$ choices for the second edge.

The values $l'_{M',(i,j)}$ are similar, so in the product one factor will always be constant while the other is linear giving $l_{M,(i,j)}l'_{M',(i,j)} \in O(n)$, and the theorem follows. \square

We give a lower bound for both **MINIMUM SPANNING TREE** and **SINGLE SOURCE SHORTEST PATHS**.

THEOREM 8.4. MINIMUM SPANNING TREE *and* SINGLE SOURCE SHORTEST PATHS *each require* $\Omega(\sqrt{nm})$ *queries.*

Proof. The proof is a reduction from minima finding. Let $m = k(n + 1)$ for some integer k . Let M be a matrix with n rows and k columns and positive entries. The lower bound on minima finding, with $d = n, N = kn$, shows that $\Omega(\sqrt{kn^2})$ queries are required to find the minimum value in every row.

FIG. 8.3. Reduction from finding minima to MINIMAL SPANNING TREE.

We construct a weighted graph G from M like this: The vertices are $V(G) = \{s, v_1, \dots, v_k, u_1, \dots, u_n\}$. The edges are all (s, v_i) with weight 0 and all (v_i, u_j) with weight M_{ji} . (See Figure 8.3.) Then clearly a minimum spanning tree contains the 0-weight edges connecting s to all vertices v_i . And every vertex u_j will be connected to the rest of the graph only with the minimal weighted edge. \square

THE APPROXIMABILITY OF THREE-VALUED MAX CSP*

PETER JONSSON[†], MIKAEL KLASSON[†], AND ANDREI KROKHIN[‡]

Abstract. In the maximum constraint satisfaction problem (MAX CSP), one is given a finite collection of (possibly weighted) constraints on overlapping sets of variables, and the goal is to assign values from a given domain to the variables so as to maximize the number (or the total weight, for the weighted case) of satisfied constraints. This problem is **NP**-hard in general, and, therefore, it is natural to study how restricting the allowed types of constraints affects the approximability of the problem. It is known that every Boolean (that is, two-valued) MAX CSP with a finite set of allowed constraint types is either solvable exactly in polynomial time or else **APX**-complete (and hence can have no polynomial-time approximation scheme unless **P** = **NP**). It has been an open problem for several years whether this result can be extended to non-Boolean MAX CSP, which is much more difficult to analyze than the Boolean case. In this paper, we make the first step in this direction by establishing this result for MAX CSP over a three-element domain. Moreover, we present a simple description of all polynomial-time solvable cases of our problem. This description uses the well-known algebraic combinatorial property of supermodularity. We also show that every hard three-valued MAX CSP contains, in a certain specified sense, one of the two basic hard MAX CSPs which are the MAXIMUM k -COLORABLE SUBGRAPH problems for $k = 2, 3$.

Key words. maximum constraint satisfaction, approximability, dichotomy, supermodularity

1. Introduction and related work. Many combinatorial optimization problems are **NP**-hard, and the use of approximation algorithms is one of the most prolific techniques to deal with **NP**-hardness. However, hard optimization problems exhibit different behavior with respect to approximability, and complexity theory for approximation is now a well-developed area [1].

Constraint satisfaction problems (CSPs) have always played a central role in this direction of research, since the CSP framework contains many natural computational problems, for example, from graph theory and propositional logic. Moreover, certain CSPs were used to build foundations for the theory of complexity for optimization problems [21], and some CSPs provided material for the first optimal inapproximability results [16] (see also survey [25]). In a CSP, informally speaking, one is given a finite collection of constraints on overlapping sets of variables, and the goal is to decide whether there is an assignment of values from a given domain to the variables satisfying all constraints (decision problem) or to find an assignment satisfying the maximum number of constraints (optimization problem). In this paper we will focus on the optimization problems, which are known as *maximum constraint satisfaction* problems (MAX CSPs). The most well-known examples of such problems are MAX

k -SAT and MAX CUT. Let us now formally define these problems.

Let D denote a *finite* set with $|D| > 1$. Let $R_D^{(m)}$ denote the set of all m -ary predicates over D , that is, functions from D^m to $\{0, 1\}$, and let $R_D = \bigcup_{m=1}^{\infty} R_D^{(m)}$. Also, let \mathbb{Z}^+ denote the set of all nonnegative integers.

DEFINITION 1.1. *A constraint over a set of variables $V = \{x_1, x_2, \dots, x_n\}$ is an expression of the form $f(\mathbf{x})$ where*

- $f \in R_D^{(m)}$ is called the constraint predicate and
- $\mathbf{x} = (x_{i_1}, \dots, x_{i_m})$ is called the constraint scope.

The constraint f is said to be satisfied on a tuple $\mathbf{a} = (a_{i_1}, \dots, a_{i_m}) \in D^m$ if $f(\mathbf{a}) = 1$.

DEFINITION 1.2. *For a finite $\mathcal{F} \subseteq R_D$, an instance of MAX CSP(\mathcal{F}) is a pair (V, C) where*

- $V = \{x_1, \dots, x_n\}$ is a set of variables taking their values from the set D and
- C is a collection of constraints $f_1(\mathbf{x}_1), \dots, f_q(\mathbf{x}_q)$ over V , where $f_i \in \mathcal{F}$ for all $1 \leq i \leq q$.

The goal is to find an assignment $\varphi : V \rightarrow D$ that maximizes the number of satisfied constraints, that is, to maximize the function $f : D^n \rightarrow \mathbb{Z}^+$, defined by $f(x_1, \dots, x_n) = \sum_{i=1}^q f_i(\mathbf{x}_i)$. If the constraints have (positive integral) weights ϱ_i , $1 \leq i \leq q$, then the goal is to maximize the total weight of satisfied constraints, to maximize the function $f : D^n \rightarrow \mathbb{Z}^+$, defined by $f(x_1, \dots, x_n) = \sum_{i=1}^q \varrho_i \cdot f_i(\mathbf{x}_i)$.

Note that throughout the paper the values 0 and 1 taken by any predicate will be considered, rather unusually, as integers, not as Boolean values, and addition will always denote the addition of integers. It is easy to check that, in the Boolean case, our problem coincides with the MAX CSP considered in [9, 10, 19]. We say that a predicate is nontrivial if it is not identically 0. Throughout the paper, we assume that \mathcal{F} is finite and contains only nontrivial predicates.

Boolean constraint satisfaction problems (that is, when $D = \{0, 1\}$) are by far better studied [10] than the non-Boolean version. The main reason for this is, in our opinion, that Boolean constraints can be conveniently described by propositional formulas which provide a flexible and easily manageable tool, and which have been extensively used in complexity theory from its very birth. Moreover, Boolean CSPs suffice to represent a number of well-known problems and to obtain results clarifying the structure of complexity for large classes of interesting problems [10]. In particular, Boolean CSPs were used to provide evidence for one of the most interesting phenomena in complexity theory, namely, that interesting problems belong to a small number of complexity classes [10], which cannot be taken for granted due to Ladner's theorem. After the celebrated work of Schaefer [22] presenting a tractable versus NP-complete dichotomy for Boolean decision CSPs, many classification results have been obtained (see, e.g., [10]), most of which are dichotomies. In particular, a dichotomy in complexity and approximability for the Boolean MAX CSP has been obtained by Creignou [9], and it was slightly refined in [19] (see also [10]).

Many papers on various versions of Boolean CSPs mention studying non-Boolean CSPs as a possible direction of future research, and additional motivation for it, with an extensive discussion, was given by Feder and Vardi [14]. Non-Boolean CSPs provide a much wider variety of computational problems. Moreover, research in non-Boolean CSPs leads to new sophisticated algorithms (e.g., [3]) or to new applications of known algorithms (e.g., [7]). Dichotomy results on non-Boolean CSPs give a better understanding of what makes a computational problem tractable or hard, and they give a more clear picture of the structure of complexity of problems, since many facts

observed in Boolean CSPs appear to be special cases of more general phenomena. Notably, many appropriate tools for studying non-Boolean CSPs have not been discovered until recently. For example, universal algebra tools have proved to be very fruitful when working with decision and counting problems [2, 4, 5, 8] while ideas from combinatorial optimization and operational research have been recently suggested for optimization problems [7].

The MAX-CSP framework has been well studied in the Boolean case. Many fundamental results have been obtained, concerning both complexity classifications and approximation properties (see, e.g., [9, 10, 16, 18, 19, 28]). In the non-Boolean case, a number of results have been obtained that concern exact (superpolynomial) algorithms or approximation properties (see, e.g., [11, 12, 13, 17, 23]). The main research problem we will look at in this paper is the following.

PROBLEM 1. *Classify the problems $\text{MAX CSP}(\mathcal{F})$ with respect to approximability.*

It is known that, for any \mathcal{F} , $\text{MAX CSP}(\mathcal{F})$ is an **NP** optimization (**NPO**) problem that belongs to the complexity class **APX**. In other words, for any \mathcal{F} , there is a polynomial-time approximation algorithm for $\text{MAX CSP}(\mathcal{F})$ whose performance is bounded by a constant.

For the Boolean case, Problem 1 was solved in [9, 10, 19]. It appears that a Boolean $\text{MAX CSP}(\mathcal{F})$ also exhibits a dichotomy in that it either is solvable exactly in polynomial time or else does not admit a polynomial-time approximation scheme (PTAS) unless $\mathbf{P}=\mathbf{NP}$. These papers also describe the boundary between the two cases.

In this paper we solve the above problem for the case $|D| = 3$ by showing that $\text{MAX CSP}(\mathcal{F})$ is solvable exactly in polynomial time if, after removing redundant values, if there are any, from the domain (that is, taking the core), all predicates in \mathcal{F} are supermodular with respect to some linear ordering of the reduced domain (see definitions in section 2.2) or else the problem is **APX**-complete. Experience shows that non-Boolean constraint problems are much more difficult to classify, and hence we believe that the techniques used in this paper can be further extended to all finite domains D . A small technical difference between our result and that of [19] is that we allow repetitions of variables in constraints, as in [10]. Similarly to [10, 19], weights do not play much of a role, since the tractability part of our result holds for the weighted case, while the hardness part is true in the unweighted case even if repetitions of constraints in instances are disallowed. Our result uses a combinatorial property of supermodularity which is a well-known source of tractable optimization problems [6, 15, 24], and the technique of strict implementations [10, 19] which allows one to show that an infinite family of problems can express, in a regular way, one of a few basic hard problems. We remark that the idea to use supermodularity in the analysis of the complexity of $\text{MAX CSP}(\mathcal{F})$ is very new and has not been even suggested in the literature prior to [7]. Generally, it has been known for a while that the property of supermodularity allows one to solve many maximization problems in polynomial time [6, 15, 24]; however, our result is surprising in that supermodularity appears to be the *only* source of tractability for $\text{MAX CSP}(\mathcal{F})$. In the area of approximability, examples of other works where hardness results are obtained for large families of problems simultaneously include [20, 27].

The only other known complete dichotomy result on a non-Boolean constraint problem (that is, with *no* restrictions on \mathcal{F}) is the theorem of Bulatov [2], where the complexity of the standard decision problem CSP on a three-element domain is

classified. Despite the clear similarity in the settings and also in the outcomes (full dichotomy in both cases), we note that none of the universal-algebraic techniques used in [2] can possibly be applied in the study of MAX CSP because the main algebraic constructions which preserve the complexity of decision problems can be easily shown not to do this in the case of optimization problems. Another similarity between Bulatov's result and our theorem is that the proof is broken down to a (relatively) large number of cases. We believe that this is caused either by insufficiently general methods or, more likely, by significant variation in structure of the problems under consideration, where a large number of cases is probably an unavoidable feature of complete classifications.

The structure of the paper is as follows. Section 2 contains definitions of approximation complexity classes and reductions, descriptions of our reduction techniques, and the basics of supermodularity. Section 3 contains the proof of the main theorem of the paper. Finally, section 4 contains a discussion of the work we have done and of possible future work.

2. Preliminaries. This section is subdivided into two parts. The first one contains basic definitions on complexity of approximation and our reduction techniques, while the second one introduces the notion of supermodularity and discusses the relevance of this notion in the study of MAX CSP.

2.1. Approximability.

2.1.1. Definitions. A *combinatorial optimization problem* is defined over a set of *instances* (admissible input data); each instance \mathcal{I} has a finite set $\text{sol}(\mathcal{I})$ of *feasible solutions* associated with it. An *objective* function attributes an integer value to any feasible solution. The *goal* of an optimization problem is, given an instance \mathcal{I} , to find a solution $s \in \text{sol}(\mathcal{I})$ of *optimum* value. The optimal value is the largest one for *maximization* problems and the smallest one for *minimization* problems. A combinatorial optimization problem is said to be an **NP** optimization (**NPO**) problem if instances and solutions can be recognized in polynomial time, solutions are polynomial-bounded in input size, and the objective function can be computed in polynomial time. For a more formal definition, see, e.g., [1].

DEFINITION 2.1 (performance ratio). A solution s to an instance \mathcal{I} of an **NPO** problem Π is r -approximate if it has value Val satisfying

$$\max \left\{ \frac{Val}{Opt(\mathcal{I})}, \frac{Opt(\mathcal{I})}{Val} \right\} \leq r,$$

where $Opt(\mathcal{I})$ is the optimal value for a solution to \mathcal{I} . An approximation algorithm for an **NPO** problem Π has performance ratio $\mathcal{R}(n)$ if, given any instance \mathcal{I} of Π with $|\mathcal{I}| = n$, it outputs an $\mathcal{R}(n)$ -approximate solution.

DEFINITION 2.2 (complexity classes). **PO** is the class of **NPO** problems that can be solved (to optimality) in polynomial time. An **NPO** problem Π is in the class **APX** if there is a polynomial-time approximation algorithm for Π whose performance ratio is bounded by a constant.

Completeness in **APX** is defined using an appropriate reduction, called *AP*-reduction. Our definition of this reduction follows [10, 19].

DEFINITION 2.3 (*AP*-reduction, **APX**-completeness). An **NPO** problem Π_1 is said to be *AP*-reducible to an **NPO** problem Π_2 if two polynomial-time computable functions F and G and a constant α exist such that

1. for any instance \mathcal{I} of Π_1 , $F(\mathcal{I})$ is an instance of Π_2 ;

2. for any instance \mathcal{I} of Π_1 , and any feasible solution s' of $F(\mathcal{I})$, $G(\mathcal{I}, s')$ is a feasible solution of \mathcal{I} ;
3. for any instance \mathcal{I} of Π_1 , and any $r \geq 1$, if s' is an r -approximate solution of $F(\mathcal{I})$, then $G(\mathcal{I}, s')$ is a $(1 + (r - 1)\alpha + o(1))$ -approximate solution of \mathcal{I} where the o -notation is with respect to $|\mathcal{I}|$.

An **NPO** problem Π is **APX**-hard if every problem in **APX** is **AP**-reducible to it. If, in addition, Π is in **APX** then Π is called **APX**-complete.

It is a well-known fact (see, e.g., [1, section 8.2.1]) that **AP**-reductions compose. It is well known that $\text{MAX CSP}(\mathcal{F})$ belongs to **APX** for every \mathcal{F} (actually, it belongs to **MAX SNP** which is a subclass of **APX** [21]); a direct proof of this fact can be found in [7]. A complete classification of the complexity of $\text{MAX CSP}(\mathcal{F})$ for a two-element set D was obtained in [9, 19]; we will give it in subsection 2.2. We shall now give an example of an **APX**-complete problem which will be used extensively in this paper.

Example 2.4. Given a graph $G = (V, E)$, the **MAXIMUM k -COLORABLE SUBGRAPH** problem, $k \geq 2$, is the problem of maximizing $|E'|$, $E' \subseteq E$, such that the graph $G' = (V, E')$ is k -colorable. This problem is known to be **APX**-complete (it is Problem GT33 in [1]). Let neq_k denote the binary disequality predicate on $\{0, 1, \dots, k-1\}$, $k \geq 2$, that is, $neq_k(x, y) = 1 \Leftrightarrow x \neq y$. The problem $\text{MAX CSP}(\{neq_k\})$ is slightly more general than the **MAXIMUM k -COLORABLE SUBGRAPH** problem. To see this, think of vertices of a given graph as of variables, and apply the predicate to every pair of variables x, y such that (x, y) is an edge in the graph.

If we allow weights on edges in graphs and on constraints, then the problems coincide; the obtained problem is known as **MAX k -CUT**. For unweighted problems, the $\text{MAX CSP}(\{neq_k\})$ is slightly more general because, formally, one can have constraints $neq_k(x, y)$ and $neq_k(y, x)$ in the same instance. In any case, it follows that the problem $\text{MAX CSP}(\{neq_k\})$ is **APX**-complete.

Interestingly, the problems $\text{MAX CSP}(\{neq_k\})$, $k = 2, 3$, will be the only basic hard problems for the case $|D| \leq 3$. We will show that, for all other **APX**-complete problems $\text{MAX CSP}(\mathcal{F})$, the set \mathcal{F} can express, in a certain regular approximability-preserving way, one of the predicates neq_2, neq_3 .

2.1.2. Reduction techniques. The basic reduction technique in our **APX**-completeness proofs is based on *strict implementations*; see [10, 19], where this notion was defined and used for the Boolean case. We will give this definition in a slightly different form from that of [10, 19], but it can easily be checked that it is equivalent to the original one.

DEFINITION 2.5. Let $Y = \{y_1, \dots, y_m\}$ and $Z = \{z_1, \dots, z_n\}$ be two disjoint sets of variables. The variables in Y are called *primary* and the variables in Z *auxiliary*. The set Z may be empty. Let $g_1(\mathbf{y}_1), \dots, g_s(\mathbf{y}_s)$, $s > 0$, be constraints over $Y \cup Z$. If $g(y_1, \dots, y_m)$ is a predicate such that the equality

$$g(y_1, \dots, y_m) + (\alpha - 1) = \max_Z \sum_{i=1}^s g_i(\mathbf{y}_i)$$

is satisfied for all y_1, \dots, y_m , and some fixed $\alpha \in \mathbb{Z}^+$, then this equality is said to be a *strict α -implementation of g from g_1, \dots, g_s* .

We use $\alpha - 1$ rather than α in the above equality to ensure that this notion coincides with the original notion of a strict α -implementation for Boolean constraints [10, 19].

We say that a collection of predicates \mathcal{F} *strictly implements* a predicate g if, for some $\alpha \in \mathbb{Z}^+$, there exists a strict α -implementation of g using predicates only from

\mathcal{F} . In this case we write $\mathcal{F} \xrightarrow{s}_\alpha g$. It is not difficult to show that if g can be obtained from \mathcal{F} by a series of strict implementations then it can also be obtained by a single strict implementation. In this paper, we will use about 60 (relatively) short strict implementations for the case when $|D| = 3$. Each of them can be straightforwardly verified by hand, or (better still) by a simple computer program.¹

The following lemma is stated in [10] for the Boolean case, but it is immediately extendable to any finite domain.

LEMMA 2.6 (Lemma 5.18 in [10]). *If \mathcal{F} strictly implements a predicate f , and $\text{MAX CSP}(\mathcal{F} \cup \{f\})$ is **APX**-complete, then $\text{MAX CSP}(\mathcal{F})$ is **APX**-complete as well.*

As in [10], Lemma 2.6 will be the main tool in our **APX**-completeness proofs. It will be used as follows: if \mathcal{F}' is a fixed finite collection of predicates each of which can be strictly implemented by \mathcal{F} , then we can assume that $\mathcal{F}' \subseteq \mathcal{F}$. For example, if \mathcal{F} contains a binary predicate f , then we can assume, at any time when it is convenient, that \mathcal{F} also contains $f'(x, y) = f(y, x)$, since this equality is a strict 1-implementation of f' .

Example 2.7. The (SIMPLE) **MAX CUT** problem is the problem of partitioning the set of vertices of a given undirected graph into two subsets so as to maximize the number of edges with ends being in different subsets. This problem is the same as **MAXIMUM 2-COLORABLE SUBGRAPH** (see Example 2.4), and hence it is **APX**-complete (see Problem ND14 in [1]). As was mentioned in Example 2.4, this problem is essentially the same as $\text{MAX CSP}(\{neq_2\})$. Let f_{dicut} be the binary predicate on $\{0, 1\}$ such that $f_{dicut}(x, y) = 1 \Leftrightarrow x = 0, y = 1$. Then $\text{MAX CSP}(\{f_{dicut}\})$ is essentially the problem **MAX DICUT** (see problem ND16 in [1]), which is the problem of partitioning the vertices of a digraph into two subsets V_0 and V_1 so as to maximize the number of arcs going from V_0 to V_1 . This problem is known to be **APX**-complete as well, and this can be proved by exhibiting a strict 1-implementation from f to neq_2 . Here it is: $neq_2(x, y) = f_{dicut}(x, y) + f_{dicut}(y, x)$.

For a subset $D' \subseteq D$, let $u_{D'}$ denote the predicate such that $u_{D'}(x) = 1$ if and only if $x \in D'$. Let $\mathcal{U}_D = \{u_{D'} \mid \emptyset \neq D' \subseteq D\}$, that is, \mathcal{U}_D is the set of all nontrivial unary predicates on D . We will now give two more examples of strict implementations that will be used later in our proofs.

Example 2.8. Let $D = \{0, 1, 2\}$, and let g_i , $i = 0, 1, 2$, be the binary predicates on D defined by the following rule: $g_i(x, y) = 1 \Leftrightarrow (x = y = i \text{ or } x, y \in D \setminus \{i\})$. We will show that $\mathcal{F} = \{g_0, g_1, g_2\} \cup \mathcal{U}_D$ strictly implements the binary predicate $g(x, y)$ such that $g(x, y) = 1 \Leftrightarrow x = 0, y = 1$. Indeed, one can check that the following is a strict 5-implementation:

$$g(x, y) + 4 = \max_{z, w} [g_0(x, z) + g_1(y, w) + g_2(z, w) + u_{\{0\}}(z) + u_{\{1, 2\}}(w)].$$

Example 2.9. In this example, we will show that the predicate neq_3 can be strictly implemented from the binary equality predicate eq_3 and all unary predicates on $D = \{0, 1, 2\}$. We will use three additional binary predicates f_1, f_2, f_3 defined as follows:

$$\begin{aligned} f_1(x, y) &= 1 \Leftrightarrow x \leq y, \\ f_2(x, y) &= 1 \Leftrightarrow (x, y) = (1, 2), \\ f_3(x, y) &= 1 \Leftrightarrow (x, y) \in \{(1, 0), (1, 2), (2, 0)\}. \end{aligned}$$

¹An example of such a program can be obtained from the authors or anonymously downloaded from <http://www.ida.liu.se/~petej/supermodular.html>.

Then it can be checked that the following equalities hold:

$$\begin{aligned}
 f_1(x, y) + 3 &= \max_{z,w} [eq_3(z, w) + eq_3(z, y) + eq_3(w, x) + u_{\{2\}}(z) + u_{\{1\}}(w) + u_{\{0\}}(x)]; \\
 f_2(x, y) + 5 &= \max_{z,w} [f_1(z, w) + f_1(w, y) + f_1(x, z) + u_{\{0,1\}}(z) + u_{\{0,2\}}(w) + u_{\{1,2\}}(x)]; \\
 f_3(x, y) + 2 &= \max_{z,w} [f_2(z, w) + f_2(z, x) + f_2(w, z) + f_2(w, y) + f_2(x, w) + f_2(x, y) \\
 &\quad + f_2(y, z) + u_{\{0\}}(y)]; \\
 neq_3(x, y) &= f_3(x, y) + f_3(y, x).
 \end{aligned}$$

As mentioned above, any chain of strict implementations can be replaced by a single strict implementation. Since $\text{MAX CSP}(\{neq_3\})$ is **APX**-complete by Example 2.4, this and Lemma 2.6 imply that the problem $\text{MAX CSP}(\{eq_3\} \cup \mathcal{U}_D)$ is **APX**-complete as well. Note that this result was first proved in [7].

Another notion which we will use in our hardness proofs is the notion of a core for a set of predicates. In the case when \mathcal{F} consists of a single binary predicate h , this notion coincides with the usual notion of a core of the directed graph whose arcs are specified by h .

DEFINITION 2.10. *An endomorphism of \mathcal{F} is a unary operation π on D such that we have $f(a_1, \dots, a_m) = 1 \Rightarrow f(\pi(a_1), \dots, \pi(a_m)) = 1$ for all $f \in \mathcal{F}$ and all $(a_1, \dots, a_m) \in D^m$. We will say that \mathcal{F} is a core if every endomorphism of \mathcal{F} is injective (i.e., a permutation).*

If π is an endomorphism of \mathcal{F} with a minimal image $im(\pi) = D'$, then a core of \mathcal{F} , denoted $core(\mathcal{F})$, is the subset $\{f|_{D'} \mid f \in \mathcal{F}\}$ of $R_{D'}$.

The intuition here is that if \mathcal{F} is not a core, then it has a noninjective endomorphism π , which implies that, for every assignment φ , there is another assignment $\pi\varphi$ that satisfies all constraints satisfied by φ and uses only a restricted set of values, so the problem is equivalent to a problem over this smaller set. As in the case of graphs, all cores of \mathcal{F} are isomorphic, so one can speak about *the* core of \mathcal{F} . The following rather simple lemma will be frequently used in our proofs.

LEMMA 2.11. *If $\mathcal{F}' = core(\mathcal{F})$ and $\text{MAX CSP}(\mathcal{F}')$ is **APX**-complete, then so is $\text{MAX CSP}(\mathcal{F})$.*

Proof. We produce an *AP*-reduction from $\text{MAX CSP}(\mathcal{F}')$ to $\text{MAX CSP}(\mathcal{F})$. We may assume that the endomorphism $\pi : D \rightarrow D'$ is the identity on D' , since if it is not, then some power of π is such an endomorphism. We will now describe functions F and G necessary for the reduction. The function F takes an instance of $\text{MAX CSP}(\mathcal{F}')$ and replaces every predicate $f|_{D'}$ in it by f . If \mathcal{I} is an instance of $\text{MAX CSP}(\mathcal{F}')$, with the set V of variables, and s' is a feasible solution of $F(\mathcal{I})$ (that is, an assignment $V \rightarrow D$), then $G(F(\mathcal{I}), s') = s$ defined by $s(x) = \pi(s'(x))$ for all $x \in V$. It is easy to see that s is also a feasible solution for \mathcal{I} . Finally, note that, since π is an endomorphism, s satisfies every constraint satisfied by s' ; in particular, we have $Opt(\mathcal{I}) = Opt(F(\mathcal{I}))$. Hence, if s' is an r -approximate solution for $F(\mathcal{I})$, then s is an r -approximate solution for \mathcal{I} , so we can choose $\alpha = 1$ in the definition of *AP*-reducibility. \square

Example 2.12. Let f be the binary predicate on $\{0, 1\}$ considered in Example 2.7 and g the binary predicate on $\{0, 1, 2\}$ considered in Example 2.8. It is easy to see that $\{f\}$ is the core of $\{g\}$ where the corresponding endomorphism is given by $\pi(0) = 0, \pi(1) = \pi(2) = 1$. Since $\text{MAX CSP}(\{f\})$ is **APX**-complete, Lemma 2.11

implies that $\text{MAX CSP}(\{g\})$ is **APX**-complete as well. Now note that this also proves that the problem $\text{MAX CSP}(\{g_0, g_1, g_2\} \cup \mathcal{U}_{\{0,1,2\}})$, as considered in Example 2.8, is **APX**-complete.

2.2. Supermodularity. In this section we discuss the well-known combinatorial algebraic property of supermodularity [24], which will play a crucial role in classifying the approximability of MAX CSP problems.

A partial order on a set D is called a *lattice order* if, for every $x, y \in D$, there exists a greatest lower bound $x \sqcap y$ and a least upper bound $x \sqcup y$. The corresponding algebra $\mathcal{L} = (D, \sqcap, \sqcup)$ is called a *lattice*. For tuples $\mathbf{a} = (a_1, \dots, a_n)$, $\mathbf{b} = (b_1, \dots, b_n)$ in D^n , let $\mathbf{a} \sqcap \mathbf{b}$ and $\mathbf{a} \sqcup \mathbf{b}$ denote the tuples $(a_1 \sqcap b_1, \dots, a_n \sqcap b_n)$ and $(a_1 \sqcup b_1, \dots, a_n \sqcup b_n)$, respectively.

DEFINITION 2.13. *Let \mathcal{L} be a lattice on D . A function $f : D^n \rightarrow \mathbb{Z}^+$ is called supermodular on \mathcal{L} if*

$$f(\mathbf{a}) + f(\mathbf{b}) \leq f(\mathbf{a} \sqcap \mathbf{b}) + f(\mathbf{a} \sqcup \mathbf{b}) \text{ for all } \mathbf{a}, \mathbf{b} \in D^n,$$

and f is called submodular on \mathcal{L} if the inverse inequality holds.

We say that $\mathcal{F} \subseteq R_D$ is supermodular on \mathcal{L} if every $f \in \mathcal{F}$ has this property.

A finite lattice $\mathcal{L} = (D, \sqcap, \sqcup)$ is *distributive* if and only if it can be represented by subsets of a set A , where the operations \sqcap and \sqcup are interpreted as set-theoretic intersection and union, respectively. Totally ordered lattices, or *chains*, will be of special interest in this paper. Note that, for chains, the operations \sqcap and \sqcup are simply min and max. Hence, the supermodularity property for an n -ary predicate f on a chain is expressed as follows:

$$f(\mathbf{a}) + f(\mathbf{b}) \leq f(\min(a_1, b_1), \dots, \min(a_n, b_n)) + f(\max(a_1, b_1), \dots, \max(a_n, b_n))$$

for all $\mathbf{a} = (a_1, \dots, a_n)$ and $\mathbf{b} = (b_1, \dots, b_n)$.

Example 2.14. (1) The binary equality predicate eq_3 is not supermodular on any chain on $\{0, 1, 2\}$. Take, without loss of generality, the chain $0 < 1 < 2$. Then

$$eq_3(1, 1) + eq_3(0, 2) = 1 \not\leq 0 = eq_3(0, 1) + eq_3(1, 2).$$

(2) Reconsider the predicates neq_2 and f from Example 2.7. It is easy to check that neither of them is supermodular on any chain on $\{0, 1\}$.

(3) Fix a chain on D and let \mathbf{a}, \mathbf{b} be arbitrary elements of D^2 . Consider the binary predicates $f_{\mathbf{a}}$, $f^{\mathbf{b}}$, and $f_{\mathbf{a}}^{\mathbf{b}}$ defined by the rules

$$\begin{aligned} f_{\mathbf{a}}(x, y) &= 1 \Leftrightarrow (x, y) \leq \mathbf{a}, \\ f^{\mathbf{b}}(x, y) &= 1 \Leftrightarrow (x, y) \geq \mathbf{b}, \\ f_{\mathbf{a}}^{\mathbf{b}}(x, y) &= 1 \Leftrightarrow (x, y) \leq \mathbf{a} \text{ or } (x, y) \geq \mathbf{b}, \end{aligned}$$

where the order on D^2 is componentwise. It is easy to check that every predicate of the form $f_{\mathbf{a}}$, $f^{\mathbf{b}}$, or $f_{\mathbf{a}}^{\mathbf{b}}$ is supermodular on the chain. Note that such predicates were considered in [7], where they were called generalized 2-monotone. We will see later in this subsection that such predicates are generic supermodular binary predicates on a chain.

We will now make some very simple, but useful, observations.

h_1	h_2	h_3	h_4	h_5	h_6	h_7	h_8	h_9	h_{10}
$\begin{matrix} 000 \\ 000 \\ 001 \end{matrix}$	$\begin{matrix} 000 \\ 000 \\ 011 \end{matrix}$	$\begin{matrix} 000 \\ 011 \\ 011 \end{matrix}$	$\begin{matrix} 100 \\ 000 \\ 000 \end{matrix}$	$\begin{matrix} 100 \\ 000 \\ 001 \end{matrix}$	$\begin{matrix} 100 \\ 000 \\ 011 \end{matrix}$	$\begin{matrix} 100 \\ 011 \\ 011 \end{matrix}$	$\begin{matrix} 100 \\ 100 \\ 000 \end{matrix}$	$\begin{matrix} 100 \\ 100 \\ 001 \end{matrix}$	$\begin{matrix} 100 \\ 100 \\ 011 \end{matrix}$
$\begin{matrix} 100 & 110 & 110 \\ h_{11} 101 & h_{12} 110 & h_{13} 110 \\ 001 & 000 & 001 \end{matrix}$									

FIG. 2.1. A list of binary predicates on $\{0, 1, 2\}$ that are supermodular on the chain $0 < 1 < 2$. The predicates are represented by matrices, the order of indices being also $0 < 1 < 2$.

OBSERVATION 2.15.

1. Any chain is a distributive lattice.
2. Any lattice on a three-element set is a chain.
3. Any unary predicate on D is supermodular on any chain on D .
4. A predicate is supermodular on a chain if and only if it is supermodular on its dual chain (obtained by reversing the order).

The tractability part of our classification is contained in the following result.

THEOREM 2.16 (see [7]). *If \mathcal{F} is supermodular on some distributive lattice on D , then weighted MAX CSP(\mathcal{F}) is in **PO**.*

Given a binary predicate $f : D^2 \rightarrow \{0, 1\}$, we will often use a $|D| \times |D|$ 0/1-matrix M to represent f : $f(x, y) = 1$ if and only if $M_{xy} = 1$. Note that this matrix is essentially the table of values of the predicate. For example, some binary predicates on $D = \{0, 1, 2\}$ that are supermodular on the chain $0 < 1 < 2$ are listed in Figure 2.1. Matrices for all other binary predicates that are supermodular on $0 < 1 < 2$ can be obtained from those in the list or from the trivial binary predicate by transposing matrices (which corresponds to swapping arguments in a predicate) and by replacing some all-0 rows by all-1 rows, and the same for all-0 columns (but not for both rows and columns at the same time). This can be shown by using Lemma 2.3 [6] or by direct exhaustive (computer-assisted) search. Note that all predicates in Figure 2.1 have the form described in Example 2.14 (3). For example, h_2 is $f^{(2,1)}$ and h_9 is $f^{(2,2)}_{(1,0)}$.

The property of supermodularity can be used to classify the approximability of Boolean problems MAX CSP(\mathcal{F}) (though originally the classification was obtained and stated [9, 10, 19] without using this property). It is easy to see that $\mathcal{F} \subseteq R_{\{0,1\}}$ is not a core if and only if $f(a, \dots, a) = 1$ for some $a \in \{0, 1\}$ and all $f \in \mathcal{F}$, in which case MAX CSP(\mathcal{F}) is trivial.

THEOREM 2.17 (see [7, 10]). *Let $D = \{0, 1\}$ and $\mathcal{F} \subseteq R_D$ be a core. If \mathcal{F} is supermodular on some chain on D , then MAX CSP(\mathcal{F}) belongs to **PO**. Otherwise, MAX CSP(\mathcal{F}) is **APX**-complete.*

Remark 2.18. It was shown in Lemma 5.37 of [10] that, for $|D| = 2$, \mathcal{F} can strictly implement neg_2 whenever $\mathcal{F} \subseteq R_D$ is a core that is not supermodular on any chain on D .

Combining Theorem 2.17 with Lemma 2.11, we get the following corollary which will be used often in our **APX**-completeness proofs.

COROLLARY 2.19. *If g' is binary predicate on $\{0, 1, 2\}$ and $core(\{g'\})$ is $\{g\}$ where g is nonsupermodular predicate on a two-element subset of D , then MAX CSP($\{g'\}$) is **APX**-complete.*

Note that there are only two (up to swapping of arguments) binary predicates g on $\{0, 1\}$ such that $\{g\}$ is a core: the predicates neg_2 and f_{dicut} from Example 2.7. As mentioned above, these two predicates are nonsupermodular, and f_{dicut} strictly 1-implements neg_2 .

3. Main result. In this section we establish a generalization of Theorem 2.17 to the case of a three-element domain. Throughout this section, let $D = \{0, 1, 2\}$. Note that if $\mathcal{F} \subseteq R_D$ is not a core, then, by Lemma 2.11, the problem $\text{MAX CSP}(\mathcal{F})$ either is trivial (if \mathcal{F} has a constant endomorphism) or else reduces to a similar problem over a two-element domain, in which case Theorem 2.17 applies.

THEOREM 3.1. *Let $D = \{0, 1, 2\}$ and $\mathcal{F} \subseteq R_D$ be a core. If \mathcal{F} is supermodular on some chain on D , then weighted $\text{MAX CSP}(\mathcal{F})$ belongs to **PO**. Otherwise, unweighted $\text{MAX CSP}(\mathcal{F})$ is **APX**-complete even if repetitions of constraints in instances are disallowed.*

Proof. The tractability part of the proof follows immediately from Theorem 2.16 (see also Observation 2.15 (1)). Assume for the rest of this section that \mathcal{F} is a core and it is not supermodular on any chain on D . We will show that (at least) one of neg_2, neg_3 can be obtained from \mathcal{F} by using the following two operations:

1. replacing \mathcal{F} by $\mathcal{F} \cup \{f\}$ where f is a predicate that can be strictly implemented from \mathcal{F} ;
2. taking the core of a subset of \mathcal{F} .

By Example 2.4 and Lemmas 2.6 and 2.19, this will establish the result.

To improve readability, we divide the rest of the proof into three parts: in subsection 3.1, we establish **APX**-completeness for some small sets \mathcal{F} consisting of at most two binary and several unary predicates, and also for the case when \mathcal{F} contains an irreflexive nonunary predicate (see definition below). Subsection 3.2 establishes the result when all unary predicates are available, and subsection 3.3 finishes the proof. \square

Remark 3.2. Note that it can be checked in polynomial time whether a given \mathcal{F} is supermodular on some chain on D if the predicates in \mathcal{F} are given by full tables of values or only by tuples on which predicates take value 1.

3.1. Small cases and irreflexive predicates. We say that an n -ary predicate f on D is *irreflexive* if and only if $f(d, \dots, d) = 0$ for all $d \in D$. It is easy to check that any irreflexive nontrivial predicate f is not supermodular on any chain on D . For example, if f is binary and $f(a, b) = 1$ for some $a \neq b$, then $f(a, b) + f(b, a) \geq 1$, but $f(\min(a, b), \min(b, a)) + f(\max(a, b), \max(b, a)) = 0$ due to irreflexivity.

Since a predicate f is supermodular on a chain C if and only if f is supermodular on its dual, we can identify chains on the three-element set D with the same middle element: let C_i denote an arbitrary chain on D with i as its middle element. We also define the set \mathcal{Q}_i that consists of all binary predicates on D that are supermodular on C_i but on neither of the other two chains. For example, it is easy to check using Figure 2.1 that \mathcal{Q}_1 consists of predicates $h_2, h_5, h_6, h_8, h_9, h_{10}, h_{11}$ and the predicates obtained from them by using the following operations:

1. swapping the variables (this corresponds to transposing the tables);
2. adding a unary predicate $u(x)$ or $u(y)$ in such a way that the sum is also a predicate (this corresponds to replacing some all-0 rows/columns by all-1 rows/columns).

Recall that, for a subset $D' \subseteq D$, $u_{D'}$ denotes the predicate such that $u_{D'}(x) = 1$ if and only if $x \in D'$, and $\mathcal{U}_D = \{u_{D'} \mid \emptyset \neq D' \subseteq D\}$; that is, \mathcal{U}_D is the set of all nontrivial unary predicates on D .

LEMMA 3.3. *Let g be a binary predicate such that, for some $a \in D$, $g(x, a) = 1$ for all $x \in D$. Let $g'(x, y) = 0$ if $y = a$ and $g'(x, y) = g(x, y)$ otherwise. Then, the following hold:*

1. *for any chain on D , g and g' are supermodular (or not) on it simultaneously and*
2. *$\{g, u_{D \setminus \{a\}}\}$ strictly implements g' .*

Proof. The first statement can be straightforwardly verified by using the definition of supermodularity. To see that the second statement holds, we note that $g'(x, y) + 1 = g(x, y) + u_{D \setminus \{a\}}(y)$ is a strict 2-implementation of $g'(x, y)$. \square

We say that a predicate g contains an *all-one column* if there exists $a \in D$ such that $g(x, a) = 1$ for all $x \in D$, and we define *all-one rows* analogously. Clearly, the lemma above holds for both all-one rows and all-one columns. The lemma will be used in our hardness proofs as follows: if \mathcal{F} contains $g(x, y)$ and $u_{D \setminus \{a\}}(y)$, then, by Lemma 2.6, we may also assume that $g' \in \mathcal{F}$.

The following lemma contains more **APX**-completeness results for some problems MAX CSP(\mathcal{F}) where \mathcal{F} is a small set containing at most two binary and some unary predicates.

LEMMA 3.4. *Let f, h be binary predicates on D . The problem MAX CSP(\mathcal{F}) is **APX**-complete if one of the following holds:*

1. $\mathcal{F} = \{f\}$ where f is nontrivial and irreflexive;
2. $\mathcal{F} = \{f\} \cup \mathcal{U}_D$ where f is not supermodular on any chain on D ;
3. $\mathcal{F} = \{f, h_7\} \cup \mathcal{U}_D$ where $f \in \mathcal{Q}_0$ and h_7 is given in Figure 2.1;
4. $\mathcal{F} = \{f, h\} \cup \mathcal{U}_D$ where $f \in \mathcal{Q}_1$ and $h \in \mathcal{Q}_0$;
5. $\mathcal{F} = \{f, u_{\{0,1\}}\}$ where f is such that $f(0, 0) = f(1, 1) = 0$ and $f(2, 2) = f(0, 1) = 1$.

Proof. The lemma is proved by providing strict implementations, from \mathcal{F} , of the predicate neq_3 (see Example 2.4) or of a binary predicate whose core is a nonsupermodular predicate on a two-element subset of D (see Corollary 2.19). In total, we give 54 implementations.

We prove only case 1 here; the other cases are similar and can be found in the appendix. First, we make the list of predicates we need to consider. There are 63 irreflexive nontrivial predicates on D . We may skip all predicates whose cores are nonsupermodular predicates on a two-element subset of D , since we already have the result for them (Corollary 2.19). For every pair of predicates that can be obtained from each other by swapping the variables (that is, $f(x, y)$ and $f'(x, y) = f(y, x)$), we can skip one of them. By symmetry, we may skip any predicate obtained from some predicate already in the list by renaming the elements of D . Finally, we already know that the result is true for the disequality predicate neq_3 , so we skip that one too. All this can be done using a computer or by hand, and the resulting list contains only six predicates. Here are strict implementations for them.

$$\begin{array}{l}
 \begin{array}{ccc}
 & 011 & 011 \\
 1. \ f_1 := & \begin{array}{ccc} 001 & \xrightarrow{s} & 101 \\ 000 & & 110 \end{array} & = \ neq_3 \\
 \text{Implementation:} & \ neq_3 = f_1(x, y) + f_1(y, x) & \\
 & \begin{array}{ccc} 010 & & 011 \\
 2. \ f_2 := & \begin{array}{ccc} 001 & \xrightarrow{s} & 101 \\ 100 & & 110 \end{array} & = \ neq_3 \\
 \text{Implementation:} & \ neq_3(x, y) = f_2(x, y) + f_2(y, x) &
 \end{array}
 \end{array}$$

$$3. f_3 := \begin{array}{ccc} & 011 & 010 \\ & 101 \xrightarrow{s} & 001 = f_2 \\ & 100 & 100 \end{array}$$

Implementation: $f_2(x, y) + 2 = \max_z [f_3(z, x) + f_3(x, y) + f_3(y, z)]$

$$4. f_4 := \begin{array}{ccc} & 011 & 011 \\ & 101 \xrightarrow{s} & 101 = neq_3 \\ & 000 & 110 \end{array}$$

Implementation:

$neq_3(x, y) + 2 = \max_z [f_4(z, x) + f_4(z, y) + f_4(x, y) + f_4(y, x)]$

$$5. f_5 := \begin{array}{ccc} & 011 & 011 \\ & 100 \xrightarrow{s} & 101 = f_4 \\ & 000 & 000 \end{array}$$

Implementation:

$f_4(x, y) + 2 = \max_{z,w} [f_5(z, w) + f_5(z, y) + f_5(w, y) + f_5(x, w) + f_5(y, z)]$

$$6. f_6 := \begin{array}{ccc} & 011 & 011 \\ & 001 \xrightarrow{s} & 101 = f_3 \\ & 100 & 100 \end{array}$$

Implementation:

$f_3(x, y) + 3 = \max_{z,w} [f_6(z, y) + f_6(w, z) + f_6(w, x) + f_6(x, z) + f_6(x, y)] \quad \square$

PROPOSITION 3.5. *If $h \in R_D^{(n)}$, $n \geq 2$, is nontrivial and irreflexive, then $\text{MAX CSP}(\{h\})$ is **APX**-complete.*

Proof. The proof is by induction on n (the arity of h). The basis when $n = 2$ was proved in Lemma 3.4(1). Assume that the lemma holds for $n = k$, $k \geq 2$. We show that it holds for $n = k + 1$. Assume first that there exists $(a_1, \dots, a_{k+1}) \in D^{k+1}$ such that $h(a_1, \dots, a_{k+1}) = 1$ and $|\{a_1, \dots, a_{k+1}\}| \leq k$. We assume without loss of generality that $a_k = a_{k+1}$ and consider the predicate $h'(x_1, \dots, x_k) = h(x_1, \dots, x_k, x_k)$. Note that this is a strict 1-implementation of h' , that $h'(d, \dots, d) = 0$ for all $d \in D$, and that h' is nontrivial since $h'(a_1, \dots, a_k) = 1$. Consequently, $\text{MAX CSP}(\{h'\})$ is **APX**-complete by the induction hypothesis, and $\text{MAX CSP}(\{h\})$ is **APX**-complete, too.

Assume now that $|\{a_1, \dots, a_{k+1}\}| = k + 1$ whenever $h(a_1, \dots, a_{k+1}) = 1$. Consider the predicate $h'(x_1, \dots, x_k) = \max_y h(x_1, \dots, x_k, y)$, and note that this is a strict 1-implementation of h' . We see that $h'(d, \dots, d) = 0$ for all $d \in D$ (due to the condition above) and h' is nontrivial since h is nontrivial. We can once again apply the induction hypothesis and draw the conclusion that $\text{MAX CSP}(\{h'\})$ and $\text{MAX CSP}(\{h\})$ are **APX**-complete. \square

3.2. When all unary predicates are available. As the next step, we will prove that $\text{MAX CSP}(\mathcal{F} \cup \mathcal{U}_D)$ is **APX**-complete if \mathcal{F} is not supermodular on any chain. As a special case of Lemma 6.3 of [6], we have the following result (see also Observation 6.1 of [6]).

LEMMA 3.6. *An n -ary, $n \geq 2$, predicate f is supermodular on a fixed chain C if and only if the following holds: every binary predicate obtained from f by replacing any given $n - 2$ variables by any constants is supermodular on C .*

PROPOSITION 3.7. *The problem $\text{MAX CSP}(\mathcal{F} \cup \mathcal{U}_D)$ is **APX**-complete if \mathcal{F} is not supermodular on any chain.*

Proof. By our initial assumptions, \mathcal{F} is not supermodular on any chain. For $i = 0, 1, 2$, let $f_i \in \mathcal{F}$ be not supermodular on C_i . Recall that every unary predicate is supermodular on any chain. Therefore, f_i is n -ary where $n \geq 2$ (note that n depends on i). By Lemma 3.6, it is possible to substitute constants for some $n - 2$ variables of f_i to obtain a binary predicate f'_i which is not supermodular on C_i . Assume without loss

of generality that these variables are the last $n - 2$ variables, and the corresponding constants are d_3, \dots, d_n ; that is, $f'_i(x, y) = f_i(x, y, d_3, \dots, d_n)$. Then the following is a strict $(n - 1)$ -implementation of f'_i :

$$f'_i(x, y) + (n - 2) = \max_{z_3, \dots, z_n} [f_i(x, y, z_3, \dots, z_n) + u_{\{d_3\}}(z_3) + \dots + u_{\{d_n\}}(z_n)].$$

By Lemma 2.6, it now is sufficient to show the result for $\mathcal{F} = \{f'_0, f'_1, f'_2\}$. We can assume that \mathcal{F} consists of at most three binary predicates and it is minimal with the property of not being supermodular on any chain. In addition, we can assume that the binary predicates in \mathcal{F} do not contain any all-one columns or all-one rows (this is justified by Lemma 3.3). We need to consider three cases depending on the number of predicates in \mathcal{F} .

Case 1. $|\mathcal{F}| = 1$. The result is proved in Lemma 3.4 (2).

Case 2. $|\mathcal{F}| = 2$. Assume $\mathcal{F} = \{g, h\}$. We consider two subcases:

1. g is supermodular on C_1 and C_2 but not on C_0 ; this implies that $h \in \mathcal{Q}_0$ because otherwise $\mathcal{F} \cup \mathcal{U}_D$ is supermodular on C_1 or C_2 , or else h is not supermodular on any chain, contradicting the minimality of \mathcal{F} . By Lemma 3.3, we can assume that neither g nor h have an all-1 row or column. It can be easily checked by inspecting the list of binary predicates (see, e.g., Figure 2.1) that there exist only three such predicates g . These are predicates h_3, h_4 , and h_7 from Figure 2.1. We have that $h_4(x, y) + 1 = h_3(x, y) + u_{\{0\}}(x) + u_{\{0\}}(y)$ is a strict 2-implementation of h_4 from h_3 , $h_3(x, y) + 1 = h_4(x, y) + u_{\{1,2\}}(x) + u_{\{1,2\}}(y)$ is a strict 2-implementation of h_3 from h_4 , and $h_7(x, y) = h_3(x, y) + h_4(x, y)$ is a strict 1-implementation of h_7 . Hence, since all unary predicates are available, it is enough to show the result for $g = h_7$, which has already been obtained in Lemma 3.4(3).
2. None of the predicates g, h is supermodular on two distinct (that is, not mutually dual) chains. By symmetry, we may assume that $g \in \mathcal{Q}_1$ and $h \in \mathcal{Q}_0$. Then the result follows from Lemma 3.4(4).

Case 3. $|\mathcal{F}| = 3$. By the minimality of \mathcal{F} , it follows that $\mathcal{F} = \{g_0, g_1, g_2\}$ where each g_i is *not* supermodular on C_i but is supermodular on the other two chains. As argued in the previous case, we may assume that $g_0 = h_7$. By symmetry, we may assume that g_1 and g_2 have the following matrices, respectively:

$$\begin{matrix} 1 & 0 & 1 & & 1 & 1 & 0 \\ 0 & 1 & 0 & \text{and} & 1 & 1 & 0 \\ 1 & 0 & 1 & & 0 & 0 & 1 \end{matrix}$$

It remains to say that, for such \mathcal{F} , **APX**-completeness of MAX CSP($\mathcal{F} \cup \mathcal{U}_D$) was shown in Examples 2.8 and 2.12. \square

3.3. The last step. We will need one more auxiliary lemma. Let $\mathcal{C}_D = \{u_{\{d\}} \mid d \in D\}$.

LEMMA 3.8. *For any \mathcal{F} , if MAX CSP($\mathcal{F} \cup \mathcal{U}_D$) is **APX**-complete, then so is MAX CSP($\mathcal{F} \cup \mathcal{C}_D$).*

Proof. For any disjoint subsets S, T of D , $u_{S \cup T}(x) = u_S(x) + u_T(x)$ is a strict 1-implementation of $u_{S \cup T}$. Use this repeatedly and apply Lemma 2.6. \square

PROPOSITION 3.9. *Let \mathcal{F} be a core. If \mathcal{F} is not supermodular on any chain, then MAX CSP(\mathcal{F}) is **APX**-complete.*

Proof. If \mathcal{F} contains a nontrivial irreflexive predicate then the result follows from Proposition 3.5. Letting $r(f) = \{d \in D \mid f(d, \dots, d) = 1\}$ for a predicate f , we can now assume that $r(f) \neq \emptyset$ for all $f \in \mathcal{F}$. Let $r(\mathcal{F}) = \{r(f) \mid f \in \mathcal{F}\}$. If $r(f) = S$ then $u_S(x) = f(x, \dots, x)$ is a strict 1-implementation of $u_S(x)$. Hence, for each $S \in r(\mathcal{F})$, we can without loss of generality assume that $u_S \in \mathcal{F}$. Note that if, for some $d \in D$, we have $d \in r(f)$ for all $f \in \mathcal{F}$, then the operation sending all elements of D to d is an endomorphism of \mathcal{F} , contradicting the assumption that \mathcal{F} is a core. Hence, for every $d \in D$, there is a unary predicate $u_S \in \mathcal{F}$ (depending on d) such that $d \notin S$.

Note that if $\{a, b, c\} = D$, then $u_{\{b\}}(x) + 1 = u_{\{a,b\}}(x) + u_{\{b,c\}}(x)$ is a strict 2-implementation of $u_{\{b\}}(x)$. Hence, we may assume that, for any distinct two-element sets S_1, S_2 in $r(\mathcal{F})$, we also have $S_1 \cap S_2 \in r(\mathcal{F})$. It is easy to see that then $r(\mathcal{F})$ contains at least one of the following: (1) two distinct singletons, or (2) sets $\{a, b\}$ and $\{c\}$ such that $\{a, b, c\} = D$. We will consider these two cases separately.

Note that, by Proposition 3.7, $\text{MAX CSP}(\mathcal{F} \cup \mathcal{U}_D)$ is **APX**-complete. Then, by Lemma 3.8, $\text{MAX CSP}(\mathcal{F} \cup \mathcal{C}_D)$ is **APX**-complete as well. Hence, by Lemma 2.6, showing that \mathcal{F} can strictly implement every predicate in \mathcal{C}_D is sufficient to prove the proposition.

Case 1. $u_{\{a\}}, u_{\{b\}} \in \mathcal{F}$ and $a \neq b$. Assume without loss of generality that $a = 0$ and $b = 1$. We will show that \mathcal{F} can strictly implement $u_{\{2\}}$. Since \mathcal{F} is a core, let $f \in \mathcal{F}$ be an n -ary predicate witnessing that the operation π_1 such that $\pi_1(0) = 0$ and $\pi_1(1) = \pi_1(2) = 1$ is not an endomorphism of \mathcal{F} . Let $\mathbf{a} = (a_1, \dots, a_n)$ be a tuple such that $f(\mathbf{a}) = 1$, but $f(\pi_1(\mathbf{a})) = 0$ (where $\pi_1(\mathbf{a}) = (\pi_1(a_1), \dots, \pi_1(a_n))$). Note that at least one of the a_i 's must be equal to 2, since otherwise $\mathbf{a} = \pi_1(\mathbf{a})$. For each $1 \leq i \leq n$, let t_i be x if $a_i = 2$ and z_i otherwise. Denote by l the number of t_i 's that are of the form z_i . Now it is not difficult to verify that

$$g_1(x) + l = \max_{\{z_i \mid a_i \neq 2\}} \left[f(t_1, \dots, t_n) + \sum_{a_i \neq 2} u_{\{a_i\}}(z_i) \right]$$

is a strict $(l + 1)$ -implementation of a unary predicate $g_1(x)$ such that $g_1(2) = 1$ and $g_1(1) = 0$. That is, g_1 is either $u_{\{2\}}$ or $u_{\{0,2\}}$. If $g_1 = u_{\{2\}}$ then we have all predicates from \mathcal{C}_D , and we are done. So assume that $g_1 = u_{\{0,2\}}$.

Next, the operation π_2 such that $\pi_2(1) = 1$ and $\pi_2(0) = \pi_2(2) = 0$ is not an endomorphism of \mathcal{F} either. Acting as above, one can show that \mathcal{F} strictly implements a unary predicate $g_2(x)$ such that $g_2(2) = 1$ and $g_2(0) = 0$, which is either $u_{\{2\}}(x)$ or $u_{\{1,2\}}(x)$. Again, if $g_2 = u_{\{2\}}$ then we are done. Otherwise, $g_2 = u_{\{1,2\}}$ and $u_{\{2\}}(x) + 1 = g_1(x) + g_2(x)$ is strict 2-implementation of $u_{\{2\}}$.

Case 2. $u_{\{a,b\}}, u_{\{c\}} \in \mathcal{F}$ and $\{a, b, c\} = D$. Assume without loss of generality that $a = 0, b = 1$, and $c = 2$. Let $f \in \mathcal{F}$ be a predicate witnessing that the operation π such that $\pi(0) = \pi(1) = 1$ and $\pi(2) = 2$ is not an endomorphism of \mathcal{F} . If f is unary then $f = u_{\{0\}}$ or $f = u_{\{0,2\}}$. In the former case we go back to Case 1, and in the latter case $u_{\{0\}}(x) + 1 = u_{\{0,1\}}(x) + u_{\{0,2\}}(x)$ is a strict 2-implementation of $u_{\{0\}}$, so we can use Case 1 again.

Assume that f is n -ary, $n \geq 2$. Similarly to Case 1, let $\mathbf{a} = (a_1, \dots, a_n)$ be a tuple such that $f(\mathbf{a}) = 1$, but $f(\pi(\mathbf{a})) = 0$. For each $1 \leq i \leq n$, let t_i be x if $a_i = 0, y$ if $a_i = 1$, and z otherwise. Note that y or/and z may not appear among the t_i 's (unlike x which does appear). We consider the case when z does appear; the other case is very similar. If none of the t_i 's is y then $g_1(x) + 1 = \max_z [f(t_1, \dots, t_n) + u_{\{2\}}(z)]$ is a strict 2-implementation of a unary predicate g_1 which is either $u_{\{0\}}$ or $u_{\{0,2\}}$ (since

π is not its endomorphism). Hence we are done, as above. Assume now that some t_i is y . Now it is not difficult to verify that $g_2(x, y) + 1 = \max_z [f(t_1, \dots, t_n) + u_{\{2\}}(z)]$ is a strict 2-implementation of a binary predicate g_2 which satisfies $g_2(0, 1) = 1$ and $g_2(1, 1) = 0$. If $g_2(0, 0) = 1$, then the predicate $g_2(x, x)$ is either $u_{\{0\}}$ or $u_{\{0,2\}}$, and we are done. Otherwise, we have $g_2(0, 0) = 0$. Now apply Lemma 3.4 (1) if $g_2(2, 2) = 0$, and use Lemma 3.4 (5) otherwise. \square

4. Conclusion. We have proved a dichotomy result for maximum constraint satisfaction problems over a three-element domain. The property of supermodularity appears to be the dividing line: those sets of predicates whose cores have this property give rise to problems solvable exactly in polynomial time, while all other sets of predicates can implement, in a regular way, the disequality predicate on a two- or three-element set, and hence give rise to **APX**-complete problems. Interestingly, the description of polynomial cases is based on orderings of the domain, which is not suggested in any way by the formulation of the problem.

It can be shown using Theorem 2.16 that Theorem 3.1, as stated in the paper, does not hold for domains with at least four elements. The reason is that all lattices on at most three-element set are chains, but on larger sets there are other types of lattices (for example, a Boolean lattice on a four-element set). For $|D| \geq 4$, Theorem 2.16 can be used to construct examples of sets \mathcal{F} such that $\text{MAX CSP}(\mathcal{F})$ is tractable, and \mathcal{F} is supermodular on some distributive lattice which is not a chain, but not supermodular on any chain. Hence, more general lattices are required to make further progress in classifying the complexity of MAX CSPs, as is a better understanding of the supermodularity property on arbitrary lattices. We believe that the ideas from this paper can be further developed to obtain a complete classification of approximability of MAX CSP.

Notably, the hard problems of the form considered in this paper do not have a PTAS. It is possible that, as in Theorem 8.8 of [10], a restriction on the incidence graph of variables in instance can give rise to **NP**-hard problems that do have a PTAS.

Finally, techniques of [26] can probably be used to obtain better implementations and more precise (in)approximability results for non-Boolean problems MAX CSP. We leave this direction for future research.

Appendix. Proof of Lemma 3.4 (Cases 2–5).

In each case, we generate a list of all applicable predicates, and then optimize it as follows:

- skip a predicate $f(x, y)$ if $f'(x, y)$ is in the list, with $f(x, y) = f'(y, x)$;
- skip all predicates with an all-1 row or column.

By Lemma 3.3, it is sufficient to prove the result for the optimized lists.

Cases 2–5 follow in order, with a description and a list of strict implementations. Each strict implementation produces neq_3 or some binary predicate whose core is a nonsupermodular predicate on a two-element subset of D , or some other predicate for which an implementation has already been found.

Cases 2 and 3 will also use eq_3 —the binary equality predicate—as an implementation target. Note that it was shown in Example 2.9 that the set $\{eq_3\} \cup \mathcal{U}_D$ strictly implement neq_3 , and hence, $\text{MAX CSP}(\{eq_3\} \cup \mathcal{U}_D)$ is **APX**-complete.

If some implementation produces a predicate g , whose core is a nonsupermodular predicate on a two-element subset of D , then we write $([0, 1, 2] \mapsto [\pi(0), \pi(1), \pi(2)])$ to describe the endomorphism π leading to the core, and we also give a matrix for that nonsupermodular predicate.

In all strict implementations in this section, the variables x, y are primary, and z, w (when they appear) are auxiliary.

Case 2. $\mathcal{F} = \{f\} \cup \mathcal{U}_D$ and f is not supermodular on any chain on D . We further optimize the list of predicates for this case. We can assume that $f(d, d) = 1$ for some d , as the other predicates are handled in Case 1. By symmetry, we may skip a predicate if there is another predicate in the list by renaming the elements of D . We can also skip eq_3 , as we have handled it separately in Example 2.9.

$$\left\{ \begin{array}{l} f_1 := \\ 110 \\ 010 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 010 \\ 001 \end{array} =: g \quad g = eq_3$$

$$\text{Implementation: } g(x, y) + 1 = f_1(x, y) + f_1(y, x) + u_{\{2\}}(x) + u_{\{2\}}(y)$$

$$\left\{ \begin{array}{l} f_2 := \\ 101 \\ 101 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 000 \\ 000 \\ 010 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 00 \\ 10 \end{array} ([0, 1, 2] \mapsto [1, 1, 2])$$

$$\text{Implementation: } g(x, y) + 1 = f_2(x, y) + u_{\{2\}}(x) + u_{\{1\}}(y)$$

$$\left\{ \begin{array}{l} f_3 := \\ 110 \\ 001 \\ 100 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 000 \\ 001 \\ 010 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 01 \\ 10 \end{array} ([0, 1, 2] \mapsto [1, 1, 2])$$

$$\text{Implementation: } g(x, y) + 2 = f_3(x, y) + f_3(y, x) + u_{\{1,2\}}(x) + u_{\{1,2\}}(y)$$

$$\left\{ \begin{array}{l} f_4 := \\ 110 \\ 011 \\ 101 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 010 \\ 001 \end{array} =: g \quad g = eq_3$$

$$\text{Implementation: } g(x, y) + 1 = f_4(x, y) + f_4(y, x)$$

$$\left\{ \begin{array}{l} f_5 := \\ 101 \\ 100 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 000 \\ 101 \\ 000 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 00 \\ 10 \end{array} ([0, 1, 2] \mapsto [0, 1, 0])$$

$$\text{Implementation: } g(x, y) + 2 = \max_z [f_5(z, y) + f_5(x, z) + u_{\{2\}}(z) + u_{\{1,2\}}(x)]$$

$$\left\{ \begin{array}{l} f_6 := \\ 001 \\ 010 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 110 \\ 010 \\ 000 \end{array} =: g \quad g = f_1$$

$$\text{Implementation: } g(x, y) + 1 = \max_z [f_6(z, x) + f_6(y, z) + u_{\{0\}}(x)]$$

$$\left\{ \begin{array}{l} f_7 := \\ 011 \\ 010 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 110 \\ 010 \\ 000 \end{array} =: g \quad g = f_1$$

$$\text{Implementation: } g(x, y) + 2 = \max_z [f_7(z, x) + f_7(z, y) + f_7(y, z) + u_{\{2\}}(z) + u_{\{0\}}(x)]$$

$$\left\{ \begin{array}{l} f_8 := \\ 001 \\ 110 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 001 \\ 000 \\ 000 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 01 \\ 00 \end{array} ([0, 1, 2] \mapsto [0, 0, 2])$$

$$\text{Implementation: } g(x, y) + 3 = \max_z [f_8(z, y) + f_8(x, z) + u_{\{1,2\}}(z) + u_{\{0,2\}}(x) + u_{\{2\}}(y)]$$

$$\left\{ \begin{array}{l} f_9 := \\ 101 \\ 110 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 001 \\ 000 \\ 000 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 01 \\ 00 \end{array} ([0, 1, 2] \mapsto [0, 0, 2])$$

$$\text{Implementation: } g(x, y) + 3 = \max_z [f_9(z, y) + f_9(x, z) + u_{\{1\}}(z) + u_{\{0,2\}}(x) + u_{\{2\}}(y)]$$

$$\left\{ \begin{array}{l} f_{10} := \\ 011 \\ 110 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 001 \\ 010 \\ 000 \end{array} =: g \quad g = f_6$$

Implementation:

$$g(x, y) + 3 = \max_z [f_{10}(x, z) + f_{10}(x, y) + f_{10}(y, z) + u_{\{0,2\}}(z) + u_{\{2\}}(x) + u_{\{2\}}(y)]$$

$$\left\{ \begin{array}{l} f_{11} := \\ \end{array} \begin{array}{l} 001 \\ 010 \\ 100 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 010 \\ 001 \end{array} =: g \quad g = eq_3$$

Implementation: $g(x, y) + 1 = \max_z [f_{11}(z, x) + f_{11}(z, y)]$

$$\left\{ \begin{array}{l} f_{12} := \\ \end{array} \begin{array}{l} 011 \\ 010 \\ 100 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 110 \\ 010 \\ 000 \end{array} =: g \quad g = f_1$$

Implementation: $g(x, y) + 2 = \max_z [f_{12}(z, y) + f_{12}(x, z) + u_{\{1,2\}}(z)]$

$$\left\{ \begin{array}{l} f_{13} := \\ \end{array} \begin{array}{l} 011 \\ 110 \\ 100 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 011 \\ 010 \\ 000 \end{array} =: g \quad g = f_7$$

Implementation: $g(x, y) + 3 = \max_z [f_{13}(z, x) + f_{13}(z, y) + f_{13}(x, y) + u_{\{0\}}(z) + u_{\{0\}}(x)]$

$$\left\{ \begin{array}{l} f_{14} := \\ \end{array} \begin{array}{l} 110 \\ 011 \\ 100 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 000 \\ 000 \\ 110 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 00 \\ 10 \end{array} \quad ([0, 1, 2] \mapsto [0, 0, 2])$$

Implementation: $g(x, y) + 2 = \max_z [f_{14}(z, y) + f_{14}(x, z) + u_{\{2\}}(x)]$

$$\left\{ \begin{array}{l} f_{15} := \\ \end{array} \begin{array}{l} 101 \\ 011 \\ 100 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 110 \\ 010 \\ 000 \end{array} =: g \quad g = f_1$$

Implementation: $g(x, y) + 3 = \max_z [f_{15}(z, x) + f_{15}(z, y) + f_{15}(x, z) + u_{\{2\}}(z) + u_{\{1\}}(y)]$

$$\left\{ \begin{array}{l} f_{16} := \\ \end{array} \begin{array}{l} 011 \\ 011 \\ 100 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 000 \\ 000 \\ 100 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 00 \\ 10 \end{array} \quad ([0, 1, 2] \mapsto [0, 0, 2])$$

Implementation: $g(x, y) + 3 = \max_z [f_{16}(z, y) + f_{16}(x, z) + f_{16}(x, y) + u_{\{2\}}(z) + u_{\{2\}}(x)]$

$$\left\{ \begin{array}{l} f_{17} := \\ \end{array} \begin{array}{l} 110 \\ 010 \\ 001 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 110 \\ 010 \\ 000 \end{array} =: g \quad g = f_1$$

Implementation: $g(x, y) + 2 = \max_z [f_{17}(z, y) + f_{17}(x, z) + u_{\{0,1\}}(z)]$

$$\left\{ \begin{array}{l} f_{18} := \\ \end{array} \begin{array}{l} 101 \\ 110 \\ 001 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 110 \\ 010 \\ 000 \end{array} =: g \quad g = f_1$$

Implementation: $g(x, y) + 2 = \max_z [f_{18}(z, x) + f_{18}(y, z) + u_{\{0,1\}}(x)]$

$$\left\{ \begin{array}{l} f_{19} := \\ \end{array} \begin{array}{l} 110 \\ 100 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 000 \\ 101 \\ 000 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 00 \\ 10 \end{array} \quad ([0, 1, 2] \mapsto [0, 1, 0])$$

Implementation:

$g(x, y) + 4 = \max_{z,w} [f_{19}(z, w) + f_{19}(z, y) + f_{19}(w, x) + u_{\{1\}}(z) + u_{\{1\}}(w) + u_{\{1,2\}}(x) + u_{\{2\}}(y)]$

$$\left\{ \begin{array}{l} f_{20} := \\ \end{array} \begin{array}{l} 101 \\ 010 \\ 100 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 001 \\ 010 \\ 000 \end{array} =: g \quad g = f_6$$

Implementation:

$g(x, y) + 4 = \max_{z,w} [f_{20}(z, w) + f_{20}(z, y) + f_{20}(w, x) + u_{\{2\}}(z) + u_{\{1,2\}}(w) + u_{\{1,2\}}(y)]$

$$\left\{ \begin{array}{l} f_{21} := \\ \end{array} \begin{array}{l} 101 \\ 011 \\ 110 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 101 \\ 010 \\ 100 \end{array} =: g \quad g = f_{20}$$

Implementation: $g(x, y) + 3 = \max_z [f_{21}(z, x) + f_{21}(z, y) + f_{21}(x, y) + u_{\{0,2\}}(z)]$

Case 3. $\mathcal{F} = \{f, h_7\} \cup \mathcal{U}_D$ and $f \in \mathcal{Q}_0$. We further optimize the list of predicates for this case as follows. By symmetry, we can skip a predicate if there is another predicate in the list obtained by swapping the names of elements 1 and 2 of D .

$$\left\{ \begin{array}{l} f_1 := 000 \\ 000 \\ 101 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 010 \\ 001 \end{array} =: g \quad g = eq_3$$

Implementation: $g(x, y) + 2 = f_1(x, y) + f_1(y, x) + h_7(x, y) + u_{\{0,1\}}(x) + u_{\{0,1\}}(y)$

$$\left\{ \begin{array}{l} f_2 := 000 \\ 110 \\ 101 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 010 \\ 001 \end{array} =: g \quad g = eq_3$$

Implementation: $g(x, y) + 1 = f_2(x, y) + h_7(x, y) + u_{\{0\}}(y)$

$$\left\{ \begin{array}{l} f_3 := 000 \\ 010 \\ 001 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 000 \\ 110 \\ 101 \end{array} =: g \quad g = f_2$$

Implementation: $g(x, y) + 1 = \max_z [f_3(z, x) + f_3(z, y) + u_{\{0\}}(y)]$

$$\left\{ \begin{array}{l} f_4 := 001 \\ 110 \\ 001 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 000 \\ 000 \\ 101 \end{array} =: g \quad g = f_1$$

Implementation: $g(x, y) + 2 = \max_z [f_4(z, x) + f_4(y, z) + u_{\{2\}}(z)]$

$$\left\{ \begin{array}{l} f_5 := 000 \\ 010 \\ 101 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 000 \\ 110 \\ 101 \end{array} =: g \quad g = f_2$$

Implementation: $g(x, y) + 1 = \max_z [f_5(x, z) + f_5(y, z) + u_{\{0\}}(y)]$

Case 4. $\mathcal{F} = \{f, h\} \cup \mathcal{U}_D$ and $f \in \mathcal{Q}_1$ and $h \in \mathcal{Q}_0$. We show that $\{f\} \cup \mathcal{U}_D$ can strictly implement h_7 , whereby the result follows from Case 3.

$$\left\{ \begin{array}{l} f_1 := 100 \\ 000 \\ 011 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 011 \\ 011 \end{array} =: g \quad g = h_7$$

Implementation: $g(x, y) + 1 = \max_z [f_1(z, x) + f_1(z, y)]$

$$\left\{ \begin{array}{l} f_2 := 100 \\ 100 \\ 011 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 011 \\ 011 \end{array} =: g \quad g = h_7$$

Implementation: $g(x, y) + 1 = \max_z [f_2(z, x) + f_2(z, y)]$

$$\left\{ \begin{array}{l} f_3 := 100 \\ 100 \\ 000 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 000 \\ 011 \end{array} =: g \quad g = f_1$$

Implementation:
 $g(x, y) + 2 = \max_z [f_3(z, x) + f_3(z, y) + f_3(x, y) + u_{\{2\}}(z) + u_{\{2\}}(x) + u_{\{1,2\}}(y)]$

$$\left\{ \begin{array}{l} f_4 := 100 \\ 100 \\ 001 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 100 \\ 000 \end{array} =: g \quad g = f_3$$

Implementation: $g(x, y) + 3 = \max_z [f_4(z, y) + f_4(x, z) + u_{\{2\}}(z) + u_{\{0,1\}}(x) + u_{\{0,1\}}(y)]$

$$\left\{ \begin{array}{l} f_5 := 100 \\ 101 \\ 001 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 100 \\ 001 \end{array} =: g \quad g = f_4$$

Implementation: $g(x, y) + 3 = \max_z [f_5(z, x) + f_5(z, y) + f_5(x, z) + u_{\{0\}}(z) + u_{\{1,2\}}(x)]$

$$\left\{ \begin{array}{l} f_6 := 000 \\ 000 \\ 011 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 100 \\ 000 \end{array} =: g \quad g = f_3$$

Implementation: $g(x, y) + 1 = f_6(x, y) + u_{\{0,1\}}(x) + u_{\{0\}}(y)$

$$\left\{ \begin{array}{l} f_7 := 100 \\ 000 \\ 001 \end{array} \right\} \cup \mathcal{U}_D \xrightarrow{s} \begin{array}{l} 100 \\ 101 \\ 001 \end{array} =: g \quad g = f_5$$

Implementation: $g(x, y) + 1 = \max_z [f_7(z, x) + f_7(z, y) + u_{\{1\}}(x)]$

Case 5. $\mathcal{F} = \{f, u_{\{0,1\}}\}$ where f is such that $f(0, 0) = f(1, 1) = 0$ and $f(2, 2) = f(0, 1) = 1$.

$$\left\{ \begin{array}{l} 010 \\ f_1 := 001, u_{\{0,1\}} \\ 101 \end{array} \right\} \xrightarrow{s} \begin{array}{l} 010 \\ 100 \\ 000 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 01 \\ 10 \end{array} ([0, 1, 2] \mapsto [0, 1, 0])$$

$$\text{Implementation: } g(x, y) + 2 = f_1(x, y) + f_1(y, x) + u_{\{0,1\}}(x) + u_{\{0,1\}}(y)$$

$$\left\{ \begin{array}{l} 011 \\ f_2 := 000, u_{\{0,1\}} \\ 011 \end{array} \right\} \xrightarrow{s} \begin{array}{l} 010 \\ 100 \\ 000 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 01 \\ 10 \end{array} ([0, 1, 2] \mapsto [0, 1, 0])$$

$$\text{Implementation: } g(x, y) + 2 = f_2(x, y) + f_2(y, x) + u_{\{0,1\}}(x) + u_{\{0,1\}}(y)$$

$$\left\{ \begin{array}{l} 010 \\ f_3 := 101 \\ 101 \end{array} \right\} \xrightarrow{s} \begin{array}{l} 010 \\ 001 \\ 101 \end{array} =: g \quad g = f_1$$

$$\text{Implementation: } g(x, y) + 2 = \max_z [f_3(z, x) + f_3(x, y) + f_3(y, z)]$$

$$\left\{ \begin{array}{l} 010 \\ f_4 := 000, u_{\{0,1\}} \\ 001 \end{array} \right\} \xrightarrow{s} \begin{array}{l} 010 \\ 000 \\ 000 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 01 \\ 00 \end{array} ([0, 1, 2] \mapsto [0, 1, 0])$$

$$\text{Implementation: } g(x, y) + 3 = \max_{z,w} [f_4(z, w) + f_4(w, y) + f_4(x, z) + u_{\{0,1\}}(z) + u_{\{0,1\}}(w)]$$

$$\left\{ \begin{array}{l} 011 \\ f_5 := 000, u_{\{0,1\}} \\ 001 \end{array} \right\} \xrightarrow{s} \begin{array}{l} 011 \\ 000 \\ 011 \end{array} =: g \quad g = f_2$$

$$\text{Implementation: } g(x, y) + 2 = \max_{z,w} [f_5(z, y) + f_5(w, z) + f_5(x, w) + u_{\{0,1\}}(z)]$$

$$\left\{ \begin{array}{l} 010 \\ f_6 := 100, u_{\{0,1\}} \\ 001 \end{array} \right\} \xrightarrow{s} \begin{array}{l} 010 \\ 100 \\ 000 \end{array} =: g \quad g \text{ has core } \begin{array}{l} 01 \\ 10 \end{array} ([0, 1, 2] \mapsto [0, 1, 0])$$

BALANCED ALLOCATIONS: THE HEAVILY LOADED CASE*

PETRA BERENBRINK[†], ARTUR CZUMAJ[‡], ANGELIKA STEGER[§], AND
BERTHOLD VÖCKING[¶]

Abstract. We investigate balls-into-bins processes allocating m balls into n bins based on the multiple-choice paradigm. In the classical *single-choice* variant each ball is placed into a bin selected uniformly at random. In a *multiple-choice* process each ball can be placed into one out of $d \geq 2$ randomly selected bins. It is known that in many scenarios having more than one choice for each ball can improve the load balance significantly. Formal analyses of this phenomenon prior to this work considered mostly the lightly loaded case, that is, when $m \approx n$. In this paper we present the first *tight* analysis in the *heavily loaded* case, that is, when $m \gg n$ rather than $m \approx n$.

The best previously known results for the multiple-choice processes in the heavily loaded case were obtained using majorization by the single-choice process. This yields an upper bound of the maximum load of bins of $m/n + \mathcal{O}(\sqrt{m \ln n / n})$ with high probability. We show, however, that the multiple-choice processes are fundamentally different from the single-choice variant in that they have “*short memory*.” The great consequence of this property is that the deviation of the multiple-choice processes from the optimal allocation (that is, the allocation in which each bin has either $\lfloor m/n \rfloor$ or $\lceil m/n \rceil$ balls) does not increase with the number of balls as in the case of the single-choice process. In particular, we investigate the allocation obtained by two different multiple-choice allocation schemes, the greedy scheme due to Azar et al. and the always-go-left scheme due to Vöcking. We show that these schemes result in a maximum load of only $m/n + \mathcal{O}(\ln \ln n)$ with high probability. All our detailed bounds on the maximum load are tight up to an additive constant.

Furthermore, we investigate the two multiple-choice algorithms in a comparative study. We present a majorization result showing that the always-go-left scheme obtains a better load balancing than the greedy scheme for any choice of n , m , and d .

Key words. occupancy problems, balls-into-bins processes, randomized resource allocation

1. Introduction. One of the central topics in the area of randomized algorithms is the study of *occupancy problems* for *balls-into-bins processes*; see, e.g., [1, 2, 3, 5, 6, 8, 9, 10, 11, 12, 15, 17, 20, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 33]. We consider allocation processes in which a set of independent balls representing, e.g., tasks or jobs is assigned to a set of bins representing, e.g., servers or machines. Since the framework of balls-into-bins processes can be used to translate realistic problems into a formal mathematical model in a natural way, it has been frequently analyzed in probability theory [15, 17], random graph theory, and, most recently, in computer science. For example, in theoretical computer science, the balls-into-bins processes found many applications in hashing (see, e.g., [16]) or randomized rounding. They also

play a crucial role in load balancing and resource allocation in parallel and distributed systems (see, e.g., [1, 10, 18, 31, 32]). The goal of our study is to derive improved upper and lower bounds on the maximum load or even the entire distribution of the load in all bins for balls-into-bins processes in which each ball is placed in a load-adaptive fashion into one out of a small number of randomly chosen bins.

In the classical *single-choice process* (see, e.g., [15, 17, 30]), each ball is placed into a bin chosen *independently and uniformly at random (i.u.r.)*. For the case of n bins and $m \geq n \ln n$ balls it is well known that there exists a bin receiving $m/n + \Theta(\sqrt{m \ln n / n})$ balls (see, e.g., [30]). This result holds not only in expectation but even with high probability (w.h.p.).¹ Let the *maximum load* denote the number of balls in the fullest bin and let the *max height above average* denote the difference between the maximum load and the average number of balls per bin (which is m/n in our notation). Then the max height above average of the single choice algorithm is $\Theta(\sqrt{m \ln n / n})$, w.h.p. Observe that the deviation between the randomized single-choice allocation and the optimal allocation increases with the number of balls.

In this paper we investigate randomized multiple-choice allocation schemes (see, e.g., [1, 3, 11, 22, 23, 33]). The idea of *multiple-choice algorithms* is to reduce the maximum load by choosing a small subset of the bins for each ball at random and placing the ball into one of these bins. Typically, the ball is placed into a bin with a minimum number of balls among the d alternatives. It is well known that having more than one choice for each ball can improve the load balancing significantly [1, 33]. Previous analyzes, however, are only able to deal with the *lightly loaded case*, i.e., $m = \mathcal{O}(n)$; the bounds for $m \gg n$ are far off. Our *main contribution* is the first tight analysis for the *heavily loaded case*, i.e., when $m = \omega(n)$. We investigate two different kinds of well-known multiple-choice algorithms, the *greedy scheme* and the *always-go-left scheme*.

- Algorithm Greedy[d] was introduced and analyzed by Azar et al. in [1]. Greedy[d] chooses $d \geq 2$ locations for each ball i.u.r. from the set of bins. The m balls are inserted sequentially, one by one, and each ball is placed into the least loaded among its d locations (if several locations have the same minimum load, then the ball is placed into an arbitrary one among them). Azar et al. [1] show that the max height above average (and the maximum load) is $\ln \ln n / \ln d + \Theta(m/n)$, w.h.p.
- Algorithm Left[d] was introduced and analyzed by Vöcking in [33]. Let n be a multiple of $d \geq 2$. This algorithm partitions the set of bins into d groups of equal size. These groups are ordered from left to right. Left[d] chooses for each ball d locations: one location from each group is chosen i.u.r. The m balls are inserted one by one and each ball is placed into the least loaded among its d locations. If there are several locations having the same minimum load, the ball is always placed into the leftmost group containing one of these locations. Vöcking [33] proved, rather surprisingly, that the use of this unfair tie breaking mechanism leads to a better load balancing than a fair mechanism that resolves ties at random. In particular, the max height above average (and the maximum load) produced by Left[d] is only $\ln \ln n / (d \ln \phi_d) + \Theta(m/n)$, w.h.p., where $1.61 \leq \phi_d \leq 2$.

In the lightly loaded case, the bounds above are tight up to additive constants. In the heavily loaded case, however, these bounds are not even as good as the bounds

¹Throughout the entire paper we say an event A related to the process of allocating m balls into n bin occurs *with high probability (w.h.p.)* if $\Pr[A] \geq 1 - n^{-\kappa}$ for an arbitrarily chosen constant $\kappa \geq 0$. Notice that this probability does *not* depend on m , the number of balls.

known for the classical single-choice process. In fact, the best known bounds for the multiple-choice algorithms in the heavily loaded case are obtained using majorization from the single-choice process showing only that the multiple-choice algorithms do not behave worse than the single-choice process.

Unfortunately, the known methods for analyzing the multiple-choice algorithms do not allow us to obtain better results for the heavily loaded case. Both the techniques used in [1] (“layered induction”) and [33] (“witness trees”) inherently assume a load of $2m/n$ already in their base case and therefore they do not seem to be suitable to prove a bound better than $2m/n$. Alternative proof techniques using differential equations as suggested in [5, 22, 23, 34, 35] fail for the heavily loaded case, too. The reason is that the concentration results obtained by Kurtz’s theorem hold only for a limited number of balls. Therefore, the analysis of the heavily loaded case requires new ideas. Before we proceed with the detailed statement of our results we first provide some terminology.

1.1. Basic definitions and notation. We model the state of the system by *load vectors*. A load vector $u = (u_1, \dots, u_n)$ specifies that the number of balls in the i th bin (the *load* of the i th bin) is u_i . If u is *normalized*, then the entries in the vector are sorted in decreasing order so that u_i describes the number of balls in the i th fullest bin. In the case of Greedy[d], the order among the bins does not matter so that we can restrict the state space to normalized load vectors. In the case of Left[d], however, we need to consider general load vectors.

Suppose X_t denotes the load vector at time t , i.e., after inserting t balls using Greedy[d] or Left[d]. Then the stochastic process $(X_t)_{t \in \mathbb{N}}$ corresponds to a Markov chain $\mathfrak{M} = (\mathbf{X}_t)_{t \in \mathbb{N}}$ whose transition probabilities are defined by the respective allocation process. In particular, X_t is a random variable obeying some probability distribution $\mathcal{L}(X_t)$ defined by the allocation scheme. (Throughout the paper we use the standard notation to denote the probability distribution of a random variable U by $\mathcal{L}(U)$.) We use a standard measure of discrepancy between two probability distributions ϑ and ν on a space Ω , the *variation distance*, defined as

$$\|\vartheta - \nu\| = \frac{1}{2} \sum_{\omega \in \Omega} |\vartheta(\omega) - \nu(\omega)| = \max_{A \subseteq \Omega} (\vartheta(A) - \nu(A)).$$

A basic technique used in this paper is *coupling* (cf., e.g., [4, 7]). A coupling for two (possibly identical) Markov chains $\mathfrak{M}_X = (\mathbf{X}_t)_{t \in \mathbb{N}}$ with state space Ω_X and $\mathfrak{M}_Y = (\mathbf{Y}_t)_{t \in \mathbb{N}}$ with state space Ω_Y is a stochastic process $(X_t, Y_t)_{t \in \mathbb{N}}$ on $\Omega_X \times \Omega_Y$ such that each of $(X_t)_{t \in \mathbb{N}}$ and $(Y_t)_{t \in \mathbb{N}}$ is a faithful copy of \mathfrak{M}_X and \mathfrak{M}_Y , respectively.

Another basic concept that we use frequently is *majorization* (cf., e.g., [1]). We say that a vector $u = (u_1, \dots, u_n)$ is *majorized* by a vector $v = (v_1, \dots, v_n)$, written $u \leq v$, if for all $1 \leq i \leq n$ it holds that

$$\sum_{1 \leq j \leq i} u_{\pi(j)} \leq \sum_{1 \leq j \leq i} v_{\sigma(j)},$$

where π and σ are permutations of $1, \dots, n$ such that $u_{\pi(1)} \geq u_{\pi(2)} \geq \dots \geq u_{\pi(n)}$ and $v_{\sigma(1)} \geq v_{\sigma(2)} \geq \dots \geq v_{\sigma(n)}$. Given an allocation scheme \mathcal{X} defining a Markov chain $\mathfrak{M}_X = (\mathbf{X}_t)_{t \in \mathbb{N}}$ and an allocation scheme \mathcal{Y} defining a Markov chain $\mathfrak{M}_Y = (\mathbf{Y}_t)_{t \in \mathbb{N}}$, we say that \mathcal{X} is *majorized* by \mathcal{Y} if there is a coupling between the two Markov chains \mathfrak{M}_X and \mathfrak{M}_Y such that $X_t \leq Y_t$ for all $t \in \mathbb{N}$.

In order to express our results of the always-go-left scheme we use *d -ary Fibonacci numbers*. Define $F_d(k) = 0$ for $k \leq 0$, $F_d(1) = 1$, and $F_d(k) = \sum_{i=1}^d F_d(k-i)$ for $k \geq 2$.

Let $\phi_d = \lim_{k \rightarrow \infty} \sqrt[k]{F_d(k)}$. Then $F_d(k) = \Theta(\phi_d^k)$. Notice that ϕ_2 corresponds to the golden ratio. ϕ_d is called the *d-ary golden ratio*. In general $1.61 < \phi_2 < \phi_3 < \dots < 2$.

1.2. New results. Our main contribution is the first tight analysis for multiple-choice algorithms assuming an arbitrary number of balls. Our first result is a tight analysis of Greedy[d] in the heavily loaded case when the number of balls is upper-bounded by a polynomial in the number of bins.

LEMMA 1.1. *Let $\beta \geq 1$ be an arbitrary constant. Suppose we allocate m balls to n bins using Greedy[d] with $d \geq 2$ and $m \leq n^\beta$. Then the number of bins with load at least $\frac{m}{n} + i + \gamma$ is upper bounded by $n \cdot \exp(-d^i)$, w.h.p., where γ denotes a suitable constant, $\gamma = \gamma(\beta)$.*

Even if Lemma 1.1 may seem to be a simple extension of the analysis of the greedy algorithm with $m = \mathcal{O}(n)$ from [1], our analysis is significantly more complicated. The main idea behind the proof is similar to the layered induction approach from [1]. However, the fact that the number of balls is only bounded by a polynomial in the number of bins requires many additional tricks to be applied. In particular, unlike in [1], we have to consider the entire distribution of the bins in our analysis (while in [1] the bins with load smaller than the average could be ignored).

The techniques used to prove Lemma 1.1 cannot be extended to deal with the case when m is unbounded. This is because the analysis in the proof of Lemma 1.1 is based on an inductive argument showing that the bound given in the lemma holds after throwing *any* number $m' \leq m$ of the balls. Of course, this approach cannot work if m is unbounded, because in that case we expect that for some $m' \leq m$ there will be some bins having a huge load, even w.h.p. Therefore, to extend the result of Lemma 1.1 to all values of m we will need other techniques.

Our next result is the main technical contribution of this paper and is central for extending Lemma 1.1 to all values of m . It shows that the multiple-choice processes are fundamentally different from the classical single-choice process in that they have “short memory.”

LEMMA 1.2 (Short Memory Lemma). *Let $\varepsilon > 0$. Let $d \geq 2$ be any integer. Let X and Y be any two load vectors describing the allocation of m balls to n bins. Let X_t (Y_t) be the random variable that describes the load vector after allocating t further balls on top of X (Y , respectively) using protocol Greedy[d]. Then there is a $\tau = \mathcal{O}(m n^6 \ln^4(1/\varepsilon))$ such that $\|\mathcal{L}(X_\tau) - \mathcal{L}(Y_\tau)\| \leq \varepsilon$. In the special case when $d = 2$, this result holds even with $\tau = \mathcal{O}(m n^2 + n^4 \ln(m/\varepsilon))$.*

The proof of Lemma 1.2 is done by analyzing the mixing time of the underlying Markov chain describing the load distribution of the bins. Our study of the mixing time is via a new variant of the coupling method (called neighboring coupling (see Lemma 3.2 in section 3.1.2)) which may be of independent interest.

The Short Memory Lemma implies the following property of the Greedy[d] process (see Corollary 4.1 for a precise statement). Suppose that we begin in an arbitrary configuration with the load difference between any pair of bins being at most Δ . Then the Greedy[d] process “forgets” this unbalance in $\Delta \cdot \text{polylog}(\Delta) \cdot \text{poly}(n)$ steps. That is, the allocation after inserting further $\Delta \cdot \text{polylog}(\Delta) \cdot \text{poly}(n)$ balls is stochastically undistinguishable from an allocation obtained by starting from a totally balanced system. This is in contrast to the single-choice process that requires $\Delta^2 \cdot \text{poly}(n)$ steps to “forget” a load difference of Δ . We show that this property implies a fundamental difference between the allocation obtained by the multiple- and the single-choice algorithms. While the allocation of the single-choice algorithm deviates more and more from the optimal allocation with an increasing number of balls, the deviation between

the multiple-choice and the optimal allocation is independent of the number of balls. This allows us to concentrate the analysis for the large number of balls m on the case when m is only a polynomial of n .

Next, we show how to incorporate the results above, in Lemmas 1.1 and 1.2, to obtain our main result about the load distribution of Greedy[d].

THEOREM 1.3. *Let γ denote a suitable constant. Suppose we allocate m balls to n bins using Greedy[d] with $d \geq 2$. Then the number of bins with load at least $\frac{m}{n} + i + \gamma$ is upper bounded by $n \cdot \exp(-d^i)$, w.h.p.*

This result is tight up to additive constants in the sense that, for $m \geq n$, the number of bins with load at least $\frac{m}{n} + i \pm \Theta(1)$ is also bounded below by $n \cdot \exp(-d^i)$, w.h.p. In particular, Theorem 1.3 implies immediately the following corollary, which is tight up to a constant additive term.

COROLLARY 1.4. *If m balls are allocated into n bins using Greedy[d] with $d \geq 2$, then the number of balls in the fullest bin is $\frac{m}{n} + \frac{\ln \ln n}{\ln d} \pm \Theta(1)$, w.h.p. (that is, the max height above average is $\frac{\ln \ln n}{\ln d} \pm \Theta(1)$, w.h.p.).*

Next, we analyze the always-go-left scheme. The load distribution is described in terms of Fibonacci numbers defined in the previous section.

THEOREM 1.5. *Let γ denote a suitable constant. Suppose we allocate m balls into n bins using Left[d] with $d \geq 2$. Then the number of bins with load at least $\frac{m}{n} + i + \gamma$ is upper bounded by $n \cdot \exp(-\phi_d^{d^i})$, w.h.p.*

Also this bound is tight up to additive constants because the number of bins with load at least $\frac{m}{n} + i \pm \Theta(1)$ is lower-bounded by $n \cdot \exp(-\phi_d^{d^i})$, w.h.p., too. Similarly as in the case of the analysis of Greedy[d], Theorem 1.5 immediately implies a tight bound for the maximum load when using Left[d].

COROLLARY 1.6. *If m balls are allocated into n bins using Left[d] with $d \geq 2$, then the number of balls in the fullest bin is $\frac{m}{n} + \frac{\ln \ln n}{d \cdot \ln \phi_d} \pm \Theta(1)$, w.h.p. (that is, the max height above average is $\frac{\ln \ln n}{d \cdot \ln \phi_d} \pm \Theta(1)$, w.h.p.).*

In addition to these quantitative results, we investigate the relationship between the greedy and the always-go-left scheme directly.

THEOREM 1.7. *Left[d] is majorized by Greedy[d].*

In other words, we show that the always-go-left scheme produces a (stochastically) better load balancing than the greedy scheme for any possible choice of d , n , and m . We notice also that Theorem 1.7 is the key part of our analysis in Theorem 1.5.

1.3. Outline. In the first part of the paper we present the analysis of the greedy process. We begin in section 2 with the analysis of Greedy[d] for a polynomial number of balls (Lemma 1.1). Next, in section 3, we show that Greedy[d] has short memory (Lemma 1.2). Based on this property, we show in section 4 that our analysis for a polynomial number of balls can be extended to the analysis of the allocation for an arbitrary number of balls (Theorem 1.3).

In the second part of the paper we analyze the always-go-left process. Here we do not prove the short memory property explicitly. Instead, our main tool is majorization of Left[d] by Greedy[d]. In section 5, we show this majorization result, Theorem 1.7. In section 6, we analyze the allocation obtained by Left[d] based on the knowledge about the allocation of Greedy[d] to prove Theorem 1.5.

2. The behavior of Greedy[d] in the polynomially loaded case. In this section, we investigate the allocation obtained by Greedy[d] in the polynomially loaded case. In particular, we prove Lemma 1.1. In this theorem it is assumed that the number of balls is polynomially bounded by the number of bins, that is, $m \leq n^\delta$ with

$\delta > 0$ denoting an arbitrary constant. The theorem states that there exists a constant $\gamma \geq 0$ such that the number of bins with load at least $\frac{m}{n} + i + \gamma$ is at most $n \cdot \exp(-d^i)$, w.h.p. Recall that the term *w.h.p.* means that an event holds with probability at least $1 - n^{-\kappa}$ for any fixed $\kappa \geq 0$. Of course, the choice of γ has to depend on κ and δ . Observe that if $n < n_0$ for some constant n_0 , then the theorem is trivially satisfied by setting $\gamma = n_0^\delta$. We will use this observation at several points in our analysis at which certain inequalities hold only under the assumption $n \geq n_0$ for a suitable choice of n_0 . The choice of n_0 might depend only on δ and κ .

Without loss of generality, we assume that $m \leq n^\delta$ is a multiple of n . We prove the theorem by induction. For this purpose, we divide the set of balls into at most $n^{\delta-1}$ *batches* of size n each. The allocation *at time* t describes the number of balls in the bins after we have inserted the balls of the first t batches, i.e., after placing tn balls, starting with a set of empty bins at time 0. Our proof is by induction on $t \geq 0$. We provide several invariants characterizing a typical distribution of the balls among the bins at time t . We prove by induction that if these invariants hold before allocating a new batch, then they hold also after allocating the batch with probability at least $1 - n^{-\kappa}$ for any given $\kappa > 0$. This implies that the invariants hold with probability at least $1 - n^{-\kappa+(\delta-1)}$ after inserting the last batch because the number of batches is upper-bounded by $n^{\delta-1}$. In other words, we prove that each individual induction step holds w.h.p. which implies that the invariants hold w.h.p. over all steps because the number of induction steps is polynomially bounded.

2.1. Invariants for Greedy[d]. The average number of balls per bin at *time* t (that is, after allocating tn balls) is t . The bins with less than t balls are called *underloaded bins* and the bins with more than t balls are called *overloaded bins*. The *number of holes* at time t is defined as the minimal number of balls one would need to add to the underloaded bins so that each bin has load at least t . The *height* of a ball in a bin is defined such that the i th ball allocated to a bin has height i . We investigate the number of holes in the underloaded bins and the number of balls in the overloaded bins. In particular, we show that the following invariants hold w.h.p.

- $L(t)$: At time t , there are at most $0.74n$ holes.
- $H(t)$: At time t , there are at most $0.27n$ balls of height at least $t + 3$.

We prove these invariants by an interleaved induction; that is, the proof for $L(t)$ assumes $H(t-1)$ and the proof for $H(t)$ assumes $L(t)$. Notice that since t is the average number of balls per bin at time t , the number of holes at time t corresponds to the number of balls above height t . Thus, invariant $L(t)$ implies that there are at most $0.74n$ balls with height $t + 1$ or larger at time t . This property will enable us to show the upper bound on the number of balls with large height given in $H(t)$. In turn, we will see that there is a way to translate the upper bound on the number of balls with large height given in $H(t-1)$ into an upper bound on the number of holes, which will enable us to prove invariant $L(t)$.

Observe that the two invariants above do not directly imply Lemma 1.1. However, they will allow us to split the analysis into two parts: one for the underloaded bins and one for the overloaded bins. These two parts depend on each other only through the invariants L and H . In both of these parts we will specify further invariants. Finally, the invariants for the overloaded bins will imply Theorem 1.1.

Throughout the analysis, we use the following notation. For $i, t \geq 0$, $\alpha_i^{(t)}$ denotes the fraction of bins with load at most $t - i$ at time t , and $\beta_i^{(t)}$ denotes the fraction of bins with load at least $t + i$ at the same time. Figure 1 illustrates this notation.

FIG. 1. Illustration of the terms $\alpha_i^{(t)}$ and $\beta_i^{(t)}$.

2.2. Analysis of the underloaded bins. In this section, we analyze the number of holes in the underloaded bins. We prove the following two invariants for time $t \geq 0$. Let c_1 and c_2 denote suitable constants with $c_1 \leq c_2$.

- $L_1(t)$: For $1 \leq i \leq c_1 \ln n$, $\alpha_i^{(t)} \leq 1.3 \cdot 2.8^{-i}$.
- $L_2(t)$: For $i \geq c_2 \ln n$, $\alpha_i^{(t)} = 0$.

Observe that the invariants $L_1(t)$ and $L_2(t)$ imply the invariant $L(t)$ as the number of holes at time t is at most

$$\sum_{i=1}^{\lfloor c_2 \ln n \rfloor} 1.3 \cdot 2.8^{-\min(i, \lceil c_1 \ln n \rceil)} \cdot n \leq 0.74n,$$

where the last inequality holds if $n \geq n_0$ for suitably chosen constant term n_0 . In the following, we prove that $L_1(t)$ and $L_2(t)$ hold w.h.p. Our analysis is focused on Greedy[2]; that is, we explicitly prove that the invariants $L_1(t)$ and $L_2(t)$ hold for Greedy[2]. Given that the invariants hold for $d = 2$, a majorization argument [1, Theorem 3.5] implies that the same invariants hold for every $d \geq 2$. In fact, the same argument shows that the choice of the tie breaking mechanism of Greedy[2] is irrelevant. Therefore, without loss of generality, we can assume that Greedy[2] breaks ties among bins of the same height by flipping a fair coin. Under this assumption, we have the following lemma.

LEMMA 2.1. *Let ℓ be an arbitrary integer and assume that at some point in time there exist (at most) $a_\ell n$ bins with at most ℓ balls and (at most) $a_{\ell-1} n$ bins with at most $\ell - 1$ balls. Suppose that b is a bin with load exactly ℓ . Then, the probability that the next ball allocated by Greedy[2] will be placed into bin b is (at least) $(2 - a_\ell - a_{\ell-1})/n$.*

Proof. Since the term $(2 - a_\ell - a_{\ell-1})/n$ is decreasing in both a_ℓ and $a_{\ell-1}$, we can assume without loss of generality that there are exactly $a_\ell n$ bins with at most ℓ balls and exactly $a_{\ell-1} n$ bins with at most $\ell - 1$ balls. The probability that the ball goes to one of the bins with load ℓ is

$$(a_\ell - a_{\ell-1})^2 + 2(a_\ell - a_{\ell-1})(1 - a_\ell) = (a_\ell - a_{\ell-1}) \cdot (2 - a_\ell - a_{\ell-1}),$$

because this event happens if and only if either both random locations of the ball point to a bin with load ℓ or at least one of them points to a bin with load ℓ and the

other to a bin with load larger than ℓ . Now, since we assume a random tie breaking mechanism, each of the bins with load ℓ is equally likely to receive the ball. Thus, given that the ball falls into one of these bins, the probability that b receives the ball is $\frac{1}{(a_\ell - a_{\ell-1})n}$ because the number of bins with load ℓ is $(a_\ell - a_{\ell-1})n$. Multiplying the two probabilities yields the lemma. \square

Combining Lemma 2.1 with invariant L_1 , we can now analyze the probability that a ball from batch t falls into a fixed bin b with a given number of holes. Applying invariant $L_1(t - 1)$, there are at most $\alpha_i^{(t-1)}n \leq 1.3 \cdot 2.8^{-i} \cdot n$ bins with load at most $(t - 1) - i$ at time $t - 1$ for every $1 \leq i \leq c_1 \ln n$. This upper bound not only holds at the time immediately before the first ball of batch t is inserted but can be applied to any ball from this batch since the load of a bin is nondecreasing over time. Now, applying Lemma 2.1 yields that the probability that a ball from batch t is assigned to a bin with load at most $(t - 1) - i$ is at least

$$\frac{2 - \alpha_i^{(t-1)} - \alpha_{i+1}^{(t-1)}}{n} \geq \frac{2 - 1.3 \cdot 2.8^{-i} - 1.3 \cdot 2.8^{-(i+1)}}{n}.$$

For $i \geq 3$, this probability is larger than $1.9/n$, which yields the following observation.

OBSERVATION 2.2. *The probability that a ball from batch t goes to any fixed bin with load at most $t - 4$ at the ball's insertion time is at least $1.9/n$, unless invariant $L_1(t - 1)$ fails.*

Thus bins with load $t - 4$ or less have almost twice the probability of receiving a ball than the average. This might give an intuition as to why none of the bins falls far behind. The following analysis puts this intuition into formal arguments.

LEMMA 2.3. *Let $t \geq 0$. Suppose the probability that one of the invariants $L_1(0), \dots, L_1(t - 1)$ fails is at most $n^{-\kappa'}$ for $\kappa' \geq 1$. For any fixed $\kappa > 0$, there exist constants c_0, c_1, c_2, c_3 (solely depending on κ) such that*

- *there are at most $n \cdot 0.18 \cdot 3^{-i+2}$ bins containing at most $t - i$ balls, for $c_0 < i \leq c_1 \ln n$, and*
- *every bin contains at least $t - c_2 \ln n$ balls,*

with probability at least $1 - n^{-\kappa} - n^{-\kappa'}$, provided $n \geq c_3$.

Proof. Consider a bin b . For any integer $s \geq 0$, let ℓ_s denote the load of bin b at time s , and let q_s be the number of holes in bin b at time s ; that is, $q_s = s - \ell_s$. Now, suppose $q_t \geq i + 4$, for $i \geq 0$. Since the number of holes can increase by at most one during the allocation of a batch, there exists an integer t' , $0 \leq t' < t$, such that $q_{t'} = 4$ and for all $s \in \{t' + 1, \dots, t\}$ it holds that $q_s \geq 4$. Observe that by this definition of t' , the number of balls from the batches $t' + 1, \dots, t$ that are assigned to bin b is at most $t - t' - i$.

The definition of t' implies that the bin b has at least four holes at any time during the allocation of the batches $t' + 1, \dots, t$. More formally, at the insertion time of any ball from batch $s \in \{t' + 1, \dots, t\}$, the bin b contains at most $s - 4$ balls. Thus, by Observation 2.2, it follows that every ball from these batches has probability at least $1.9/n$ to be assigned to bin b or there exist $s < t$ such that invariant $L_1(s)$ fails. Ignoring the latter event, the number of balls from these batches that are placed into bin b is stochastically dominated by a binomially distributed random variable $B((t - t')n, 1.9/n)$. However, we cannot simply condition on $L_1(0, \dots, t - 1)$ as this gives an unwanted bias to the random experiments under consideration. Instead we explicitly exclude the event $\neg L_1(0, \dots, t - 1)$ from our considerations. This way, we

obtain

$$\begin{aligned} \Pr[(q_t \geq i + 4) \wedge L_1(0, \dots, t - 1)] &\leq \sum_{t'=0}^{t-1} \Pr[\mathbf{B}((t - t')n, 1.9/n) \leq t - t' - i] \\ &\leq \sum_{\tau=1}^{\infty} \Pr[\mathbf{B}(\tau n, 1.9/n) \leq \tau - i] \\ &= \sum_{\tau=1}^{\infty} \sum_{k=i}^{\tau} \Pr[\mathbf{B}(\tau n, 1.9/n) = \tau - k]. \end{aligned}$$

Next, for $0 \leq k < \tau$, we obtain

$$\begin{aligned} \Pr[\mathbf{B}(\tau n, 1.9/n) = \tau - k] &= \binom{\tau n}{\tau - k} \cdot \left(1 - \frac{1.9}{n}\right)^{\tau n - \tau + k} \cdot \left(\frac{1.9}{n}\right)^{\tau - k} \\ &\leq \frac{(1.9 e \tau)^{\tau - k}}{(\tau - k)!} e^{-(\tau n - \tau + k) 1.9/n} \\ &\leq \frac{(1.9 \tau)^{\tau - k}}{(\tau - k)^{\tau - k}} e^{-0.9 \tau - k + 1.9 \tau/n} \\ &\leq \left(\frac{1.9 \tau}{\tau - k}\right)^{\tau - k} e^{-0.89 \tau - k}, \end{aligned}$$

where the last inequality holds for $n \geq 190$. Now, set $z = \tau/k > 1$. Then, we obtain for $k > 0$

$$\begin{aligned} \Pr[\mathbf{B}(\tau n, 1.9/n) = \tau - k] &\leq \left(\frac{1.9 z k}{(z - 1) k}\right)^{(z-1)k} e^{-0.79 z k - 0.1 \tau - k} \\ &= \left(\frac{1.9 z}{z - 1}\right)^{(z-1)k} e^{-0.79 (z-1)k - 1.79 k - 0.1 \tau} \\ &= \left(e^{-1.79} \left(\frac{1.9 z}{e^{0.79} (z - 1)}\right)^{(z-1)k}\right)^k e^{-0.1 \tau}. \end{aligned}$$

The term $\left(\frac{1.9 z}{e^{0.79} (z - 1)}\right)^{(z-1)}$, $z \geq 1$, takes its maximum at $z = 2.22\dots$ and is bounded from above by 1.74. Therefore,

$$\Pr[\mathbf{B}(\tau n, 1.9/n) = \tau - k] \leq (1.74 \cdot e^{-1.79})^k \cdot e^{-0.1 \tau} \leq 3.4^{-k} \cdot e^{-0.1 \tau}$$

for $0 < k < \tau$. The same inequality also holds for $k = 0$, because for $n \geq 13$ it holds that

$$\begin{aligned} \Pr[\mathbf{B}(\tau n, 1.9/n) = \tau - 0] &= \Pr[\mathbf{B}(\tau n, 1.9/n) = \tau] \\ &= \binom{\tau n}{\tau} \cdot \left(1 - \frac{1.9}{n}\right)^{\tau(n-1)} \cdot \left(\frac{1.9}{n}\right)^{\tau} \\ &\leq \left(\frac{e \tau n}{\tau}\right)^{\tau} e^{1.9 \tau \frac{n-1}{n}} \cdot \left(\frac{1.9}{n}\right)^{\tau} \\ &= \left(\frac{1.9 e}{e^{1.9 \frac{n-1}{n}}}\right)^{\tau} \\ &\leq e^{-0.1 \tau}. \end{aligned}$$

Finally, we can obtain the same bound for $k = \tau$. In this case,

$$\begin{aligned} \Pr[\mathbf{B}(\tau n, 1.9/n) = \tau - k] &= \Pr[\mathbf{B}(\tau n, 1.9/n) = 0] \\ &= \left(1 - \frac{1.9}{n}\right)^{\tau n} \\ &\leq e^{-1.9\tau} \\ &\leq 3.4^{-k} \cdot e^{-0.1\tau}. \end{aligned}$$

Substituting this bound into the upper bound for $\Pr[q_t \geq i + 4]$ gives

$$\Pr[(q_t \geq i + 4) \wedge L_1(0, \dots, t - 1)] \leq \sum_{\tau \geq 1} \sum_{k \geq i} 3.4^{-k} \cdot e^{-0.1\tau} \leq 13.5 \cdot 3.4^{-i}.$$

Now let Q_t denote the maximum number of holes over all bins at time t . Recall that the probability for the event $\neg L_1(0, \dots, t - 1)$ is bounded from above by $n^{-\kappa'}$. Consequently,

$$\Pr[Q_t \geq i + 4] \leq n^{-\kappa'} + \Pr[(Q_t \geq i + 4) \wedge L_1(0, \dots, t - 1)] \leq n^{-\kappa'} + n \cdot 13.5 \cdot 3.4^{-i}.$$

It follows $Q_t = \mathcal{O}(\log n)$, w.h.p. More specifically, for every $\kappa \geq 0$, there exists a constant c_2 such that every bin contains at least $t - c_2 \ln n$ balls, with probability $1 - n^{-\kappa'} - \frac{1}{2}n^{-\kappa}$. This yields the second statement given in the lemma. In the following, we show that the first statement holds with probability at least $1 - \frac{1}{2}n^{-\kappa}$. In particular, we prove that for any given $\kappa > 0$, there are constants c_0, c_1, c_3 such that, for $c_0 < i \leq c_1 \ln n$ and $n \geq c_3$, there are at most $0.18 \cdot 3^{-i+2} \cdot n$ bins containing $t - i$ or less balls at time t , with probability at least $1 - n^{-\kappa-1} \geq 1 - (2c_1 n^\kappa \ln n)^{-1}$. This way, the probability that one of the statements listed in the lemma fails is at most $n^{-\kappa'} + n^{-\kappa}$, so that the lemma is shown.

Let $c_0 = 40$. For $i > c_0$, we obtain

$$\Pr[q_t \geq i] \leq n^{-\kappa'} + 13.5 \cdot 3.4^{-i+4} \leq n^{-1} + 0.65 \cdot 2.8^{-i}.$$

Now let X_b be an indicator random variable that is 1 if bin b holds at most $t - i$ balls, and that is 0, otherwise. Define $X = \sum X_b$. We have to prove that $X \leq 1.3 \cdot 2.8^{-i} \cdot n$, w.h.p.

Let us first notice that

$$\mathbf{E}[X] \leq n \cdot \Pr[q_t \geq i] \leq 0.65 \cdot 2.8^{-i} \cdot n + 1.$$

The random variables X_b are “negatively associated” in the sense of [14, Proposition 7]. Hence, we can apply a Chernoff bound to these variables: For every $\mu \geq \mathbf{E}[X]$, $\Pr[X \geq 2\mu] \leq e^{-\mu/2}$. We choose $\mu = 0.65 \cdot 2.8^{-i} \cdot n + 1$, set $c_1 = 0.5$, and assume that c_3 is sufficiently large so that $\mu \geq 2(\kappa + 1) \ln n$ for every $i \leq c_1 \ln n$ and $n \geq c_3$. This yields

$$\Pr[X \geq 1.3 \cdot 2.8^{-i} \cdot n + 2] \leq \Pr[X \geq 2\mu] \leq e^{-\mu/2} \leq e^{-(\kappa+1) \ln n} = n^{-\kappa-1}.$$

This completes the proof of Lemma 2.3. \square

The second part of the lemma corresponds to invariant $L_2(t)$, and the first part corresponds to invariant $L_1(t)$, but only for $i > c_0$. Thus, it remains to show invariant $L_1(t)$ for $1 \leq i \leq c_0$; that is, we have to show $\alpha_i^t \leq 1.3 \cdot 2.8^{-i}$. We will solve this

problem by specifying a recursive formula upper-bounding the term $\alpha_i^{(t)}$, $1 \leq i \leq c_0$, in terms of the vector $(\alpha_{i-1}^{(t-1)}, \dots, \alpha_{i+3}^{(t-1)})$.

LEMMA 2.4. *Let $\epsilon > 0$ and a_0, \dots, a_4 be constant reals with $0 < a_4 < \dots < a_0 < 1$. Let k be a constant integer. Let ℓ denote any integer. Suppose for $i = 0, \dots, 4$ there are at most $a_i n$ bins with load at most $\ell - i$ at time $t - 1$. Then, at time t , the number of bins with load at most ℓ is at most $g_k(0) \cdot n$, w.h.p., where the function g is defined by*

$$g_j(i) = \begin{cases} a_i & \text{if } j = 0 \text{ or } i = 4, \\ (1 + \epsilon) \cdot (g_{j-1}(i + 1) + (g_{j-1}(i) - g_{j-1}(i + 1)) \cdot E) & \text{otherwise,} \end{cases}$$

where

$$E = \exp\left(-\frac{2 - g_{j-1}(i + 1) - g_{j-1}(i)}{k}\right).$$

Proof. For the time being, let us assume that n is a multiple of k . We divide the allocation of the n balls into k phases, into each of which we insert n/k balls using Greedy[2]. For $0 \leq i \leq 4$ and $1 \leq j \leq k$, we show that $n \cdot g_j(i)$ is an upper bound on the number of bins with load at most $\ell - i$ after phase j . Observe that this claim is trivially satisfied for $i = 4$.

We perform an induction on j , the index of the phase. Observe that for $0 \leq i \leq 4$, $n \cdot g_0(i)$ is an upper bound on the number of bins with load at most $\ell - i$ at the beginning of phase 1. In the inductive hypothesis we assume that $n \cdot g_{j-1}(i)$ is an upper bound on the number of bins with load at most $\ell - i$ at the beginning of phase $j \geq 1$. Now consider the allocation of the n/k balls in phase j . Suppose b is a bin having load $\ell - i$ ($0 \leq i \leq 3$) at the beginning of that phase. Lemma 2.1 implies that the probability that b receives none of the next n/k balls is at most

$$\left(1 - \frac{2 - g_{j-1}(i) - g_{j-1}(i + 1)}{n}\right)^{n/k} \leq \exp\left(-\frac{2 - g_{j-1}(i + 1) - g_{j-1}(i)}{k}\right) = E.$$

Thus, the expected number of bins with load exactly $\ell - i$ not receiving a ball in this phase is at most

$$n \cdot (g_{j-1}(i) - g_{j-1}(i + 1)) \cdot E.$$

As a consequence, the expected fraction of bins containing at most $\ell - i$ balls at the end of phase k is upper-bounded by

$$g_{j-1}(i + 1) + (g_{j-1}(i) - g_{j-1}(i + 1)) \cdot E$$

for $0 \leq i \leq 3$. This term, however, by the definition, is equivalent to $g_j(i)/(1 + \epsilon)$, and hence the expected number of bins containing at most $\ell - i$ balls is upper-bounded by $n g_j(i)/(1 + \epsilon)$. Applying Azuma's inequality to this expectation, we can observe that the deviation is at most $o(n)$, w.h.p. Hence, since $n \cdot g_j(i) \geq a_4 \cdot n = \Theta(n)$, we conclude that the stochastic deviation can be bounded by a factor $(1 + \epsilon)$ for any $\epsilon > 0$, provided n is sufficiently large. We conclude that the fraction of bins containing at most $\ell - i$ balls at the end of phase k is at most $g_j(i)$, w.h.p.

Now let us consider the case that n is not a multiple of k . In this case, we can upper-bound the probability that b receives none of the at least $n/k - 1$ balls from the next batch by

$$\left(1 - \frac{2}{n}\right)^{-1} \cdot E$$

instead of E as before. Obviously the leading factor in front of the E can be made arbitrarily small by choosing n sufficiently large so that it is covered by the $1 + \epsilon$ factor that we already used above to cover stochastic deviations. This completes the proof of the lemma. \square

In the following, we apply the recursive formula given in Lemma 2.4 to prove that invariant $L_1(t)$ holds for every $i \in \{1, \dots, c_0 - 1\}$. The recursion gives an upper bound for $\alpha_i^{(t)}$ in terms of the vector $(a_0, \dots, a_4) = (\alpha_{i-1}^{(t-1)}, \dots, \alpha_{i+3}^{(t-1)})$. For $i \geq 2$, the terms $\alpha_{i-1}^{(t-1)}, \dots, \alpha_{i+3}^{(t-1)}$ can be estimated using invariant $L_1(t-1)$. Suppose this invariant is given. Fix any $i \in \{2, \dots, c_0 - 1\}$. For $i' = 0, \dots, 4$, we set $a_{i'} = 1.3 \cdot 2.8^{-(i+i'-1)}$. Then, $a_{i'}$ is an upper bound on the fraction of bins with load at most $i - i'$ at time $t - 1$. Now we choose $k = 20$ and $\epsilon = \frac{1}{1000}$, and we numerically calculate $g_k(0)$ using Maple. For such a choice of parameters, we obtain $g_k(0) \leq 1.3 \cdot 2.8^{-i}$. By Lemma 2.4, $g_k(0)$ is an upper bound on $\alpha_i^{(t)}$, w.h.p. Thus, invariant $L(t)$ is shown for $i \geq 2$. Unfortunately, this approach does not work for $i = 1$, because in that case a_0 corresponds to $\alpha_0^{(t-1)}$, which is not covered by invariant $L_1(t-1)$. In what follows, we prove another lemma that gives an upper bound on $\alpha_0^{(t-1)}$ based on invariant $H(t-1)$.

LEMMA 2.5. *Suppose $H(t-1)$ is fulfilled. Let $(a_0, \dots, a_4) := (\alpha_0^{(t-1)}, \dots, \alpha_4^{(t-1)})$. Then*

$$a_0 \leq 1 - \frac{a_1 + a_2 + a_3 + a_4 - 0.27}{2}.$$

Proof. At any time $\tau \geq 0$, the number of holes at time τ is $A_\tau = \sum_{j \geq 1} \alpha_j^{(\tau)} n$. Since the number of balls above the average height is equal to the number of holes, we can conclude that A_τ also corresponds to the number of balls with height at least $\tau + 1$ at time τ . Now, suppose invariant $H(\tau)$ holds. Then, there are at most $B_\tau = 0.27n$ balls of height at least $\tau + 3$ at time τ . Combining these two bounds, the number of balls with height either $\tau + 1$ or $\tau + 2$ is lower-bounded by $A_\tau - B_\tau$. This implies that at least $(A_\tau - B_\tau)/2$ bins contain more than τ balls at time τ . As a consequence, the number of bins containing at most τ balls is upper-bounded by $n - (A_\tau - B_\tau)/2$. Hence,

$$\alpha_0^{(\tau)} n \leq n - \frac{A_\tau - B_\tau}{2} \leq n \cdot \left(1 - \frac{\sum_{j=1}^4 \alpha_j^{(\tau)} - 0.27}{2} \right).$$

Finally, setting $\tau = t - 1$ and $\alpha_j^{(\tau)} = a_j$ gives the lemma. \square

Now, we are ready to prove invariant $L_1(t)$ by showing $g_k(0) \leq 1.3 \cdot 2.8^{-1}$ for all choices of $a_{i'} \in [0, 1.3 \cdot 2.8^{-i'}]$, $1 \leq i' \leq 4$, and $a_0 \in [0, 1 - \frac{1}{2}(a_1 + a_2 + a_3 + a_4 - 0.27)]$. Again, we check the condition on $g_k(0)$ numerically using Maple. For this purpose we need to discretize the domains of the a_i 's. For the discretization, we use the monotonicity of $g_k(0)$: the term $g_k(0)$ is monotonically increasing in each of the terms a_0, \dots, a_4 . Therefore, it suffices to check the parameters a_1, \dots, a_4 in discrete steps of a suitable size $\delta > 0$ while assuming

$$a_0 = 1 - \frac{a_1 + a_2 + a_3 + a_4 - 0.27 - 4\delta}{2}.$$

In fact, we choose $k = 20$, $\epsilon = \frac{1}{1000}$, and $\delta = \frac{1}{400}$. The numerical calculations with Maple show that the above condition on $g_k(0)$ is satisfied in all cases. Hence, the invariants $L_1(t)$, $L_2(t)$, and, thus, $L(t)$ are shown.

2.3. Analysis of the overloaded bins. In this section, we will analyze the distribution of load in the overloaded bins. In particular, we prove invariant $H(t)$ stating that the number of balls with height at least $t + 3$ is at most $0.27n$. Our analysis is based on invariant $L(t)$ which we proved in the previous section based on $H(t - 1)$. Thus $H(t - 1)$ yields $L(t)$ and, in turn, $L(t)$ yields $H(t)$.

Our analysis of invariant $H(t)$ is obtained by the analysis of two further invariants that will imply invariant $H(t)$ and will yield the proof of Lemma 1.1. These invariants are defined as follows. Let

$$h(i) = 0.7 \cdot 0.53^{d^{i-2}}.$$

Let ℓ denote the smallest integer i such that $h(i) \leq n^{-0.9}$. Let $b \geq 1$ denote a suitable constant, whose value will be specified later. For $i \geq 3$, define

$$f(i) = \begin{cases} h(i) & \text{for } 2 \leq i < \ell, \\ \max\{h(i), \frac{1}{4}n^{-0.9}\} & \text{for } i = \ell, \\ bn^{-1} & \text{for } i = \ell + 1. \end{cases}$$

We will prove that the following invariants hold w.h.p.

- $H_1(t)$: $\beta_i^{(t)} \leq f(i)$ for $2 \leq i \leq \ell$,
- $H_2(t)$: $\sum_{i>\ell} \beta_i^{(t)} \leq bn^{-1}$.

Roughly speaking, invariant H_1 states that the sequence $\beta_2, \beta_3, \dots, \beta_\ell$ decreases doubly exponentially, and the number of balls on layer ℓ is upper-bounded by $\frac{1}{4}n^{0.1}$. Furthermore, invariant H_2 states that there is only a constant number of balls with a height larger than ℓ . These two invariants imply the bounds given in Lemma 1.1. Furthermore, these invariants imply the invariant $H(t)$ as they upper-bound the number of balls above layer $t + 3$ by

$$\sum_{i=3}^{\ell-1} h(i)n + \frac{1}{4}n^{-0.1} + b \leq 0.26n + \frac{1}{4}n^{-0.1} + b \leq 0.27n,$$

where the last inequality holds for $n \geq 50b + 78$. We show the invariants H_1 and H_2 by induction. Our induction assumptions are $H_1(0), \dots, H_1(t - 1)$, $H_2(t - 1)$, and $L(t)$. We prove that these assumptions imply $H_1(t)$, $H_2(t)$, and $H(t)$, w.h.p. Our analysis starts by summarizing some properties of the function f . We assume that n is sufficiently large.

CLAIM 2.6.

- A1. $f(2) = 0.371$;
- A2. $f(i) \geq 0.53^{-2}f(i + 1)$ for $3 \leq i \leq \ell$;
- A3. $f(i) \geq 0.7^{-1}f(i - 1)^d$ for $3 \leq i \leq \ell$;
- A4. $f(i) \geq \frac{1}{4}n^{-0.9}$ for $3 \leq i \leq \ell$.

Proof. The properties A1 and A4 follow directly from the definition of f . Property A2 can be seen as follows. For $3 \leq i \leq \ell - 2$, $f(i) = h(i)$ as well as $f(i + 1) = h(i + 1)$. Thus,

$$f(i + 1) = 0.7 \cdot 0.53^{d^{i-1}} = 0.7 \cdot 0.53^{d^{i-2} \cdot d} \leq 0.7 \cdot 0.53^{d^{i-2} + 2} \leq 0.53^2 \cdot f(i).$$

If $i = \ell - 1$, then $f(i + 1) = h(i + 1)$ or $f(i + 1) = \frac{1}{4}n^{-0.9}$. In the former case, we can apply the same argument as before. In the latter case, we apply $f(i) \geq n^{-0.9}$ which immediately yields $f(i)/f(i + 1) > 4 \geq 0.53^{-2}$. Finally, in the case $i = \ell$, we need the

assumption that n is sufficiently large so that $f(\ell)/f(\ell + 1) \geq \frac{1}{4}n^{-0.9}/(bn) \geq 0.53^{-2}$. It remains to prove property A3. For $3 \leq i \leq \ell$,

$$f(i - 1)^d = (0.7 \cdot 0.53^{d^{i-3}})^d = 0.7^d \cdot 0.53^{d^{i-2}} \leq 0.7 \cdot f(i).$$

Now we use these properties to show $H_1(t)$ using a “layered induction” on the index i , similar to the analysis presented in [1]. For the base case, i.e., $i = 2$, we apply invariant $L(t)$. This invariant yields that, at time t , there exist at most $0.74n$ balls of height larger than t . Consequently, the number of bins with $t + 2$ or more balls is at most $0.74n/2 = 0.37n$. Applying property A1 yields $\beta_2^{(t)} \leq 0.37 \leq f(2)$. Thus, invariant $H_1(t)$ is shown for $i = 2$.

Next we prove $H_1(t)$ for $i \in \{3, \dots, \ell\}$. Fix i , $3 \leq i \leq \ell$. We assume that $H_1(t)$ holds for $i - 1$. Let q denote the number of bins that contain $t + i$ or more balls at time $t - 1$, i.e., immediately before batch t is inserted, and let p denote the number of balls from batch t that are placed into a bin containing at least $t + i - 1$ balls at time t . Observe that $\beta_i^{(t)} \cdot n \leq q + p$. Thus, it suffices to show $q + p \leq f(i) \cdot n$. Applying induction assumption $H_1(t - 1)$, we obtain

$$q \leq \beta_{i+1}^{(t-1)} \cdot n \leq f(i + 1) \cdot n \stackrel{(A2)}{\leq} 0.53^2 \cdot f(i) \cdot n.$$

Bounding p requires slightly more complex arguments. For $3 \leq i \leq \ell$, the probability that a fixed ball of batch t is allocated to height $t + i$ is at most $f(i - 1)^d$. This is because each of its locations has to point to one of the bins with $t + i - 1$ or more balls, and by our induction on i , the fraction of these bins is bounded from above by $f(i - 1)$. Taking into account all n balls of batch t , we obtain

$$\mathbf{E}[p] \leq f(i - 1)^d \cdot n \stackrel{(A3)}{\leq} 0.7 \cdot f(i) \cdot n.$$

Applying a Chernoff bound yields, for every $\epsilon \in (0, 1]$,

$$\begin{aligned} \Pr[p \geq (1 + \epsilon) \cdot 0.7 \cdot f(i) \cdot n] &\leq \exp\left(\frac{-0.7 \epsilon^2}{2} \cdot f(i) \cdot n\right) \\ &\stackrel{(A4)}{\leq} \exp\left(\frac{-0.7 \epsilon^2}{8} \cdot n^{0.1}\right) \\ &\leq n^{-\kappa}, \end{aligned}$$

where the last inequality holds for any given κ and $\epsilon > 0$, provided n is sufficiently large. Hence, $p \leq (1 + \epsilon) \cdot 0.7 \cdot f(i) \cdot n$, w.h.p. Consequently, $\beta_i^{(t)} \cdot n \leq q + p \leq (0.53^2 + 0.7 \cdot (1 + \epsilon)) \cdot f(i) \cdot n$, w.h.p. We set $\epsilon = 0.02$ so that $(0.53^2 + 0.7 \cdot (1 + \epsilon)) \leq 1$. This proves invariant $H_1(t)$ for $2 \leq i \leq \ell$.

Finally, we prove invariant $H_2(t)$. For $0 \leq \tau \leq t$, let x_τ denote a random variable which is one if at least one ball of batch τ is allocated into a bin with load larger than $\tau + \ell$, and zero, otherwise. Furthermore, let h_τ denote the number of balls from batch τ that are allocated into a bin with load larger than $\tau + \ell$. Because of the invariants $H_1(1), \dots, H_1(t)$, the probability that a fixed ball from batch τ will fall into a bin with more than $\tau + \ell$ balls is at most $f(\ell)^d \leq (n^{-0.9})^d \leq n^{-1.8}$. Therefore, $\Pr[x_\tau = 1] \leq n \cdot n^{-1.8} = n^{-0.8}$. In particular, for any integer $j \geq 1$,

$$\Pr[h_\tau \geq j] \leq \binom{n}{j} \left(\frac{1}{n^{1.8}}\right)^j \leq n^{-0.8j}.$$

In other words, $h_\tau = O(1)$, w.h.p. Thus, we can assume that there exists a suitable constant j so that $h_\tau \leq j$ for $1 \leq \tau \leq t$. A violation of $H_2(t)$ implies that the bins with load at least $t + \ell + 1$ contain more than b balls of height at least $t + \ell + 1$. Observe that these balls must have been placed during the last b rounds or one of the invariants $H_2(1), \dots, H_2(t-1)$ is violated. That is, if $H_2(1), \dots, H_2(t-1)$ hold, then a violation of $H_2(t)$ implies that $j \cdot \sum_{\tau=t-b}^t x_\tau \geq b$. The probability for this event is at most

$$\Pr \left[\sum_{\tau=t-b}^t x_\tau \geq b/j \right] \leq \binom{b}{b/j} \cdot \left(\frac{1}{n^{0.8}} \right)^{b/j} \leq \left(\frac{e j}{n^{0.8}} \right)^{b/j} \leq n^{-\kappa}$$

for any constant κ , provided that n is sufficiently large. Consequently, invariant H_2 holds, w.h.p., over all batches. This completes the proof of Lemma 1.1.

3. Greedy has short memory. The goal of this section is to prove the Short Memory Lemma, Lemma 1.2. We will study the performance of Greedy[d] by analyzing the underlying Markov chain describing the load distribution of the bins and our analysis uses a new variant of coupling approach (neighboring coupling (see section 3.1.2)) to study the convergence time of Markov chains.

Remark 1. It is well known that the Short Memory Lemma does not hold for $d = 1$, that is, for the single-choice algorithm. In that case, in order to claim that \mathcal{X}_τ has stochastically almost the same distribution as \mathcal{Y}_τ one must have $\tau = \Omega(m^2 \cdot \text{poly}(n))$.

3.1. Auxiliary lemmas. In this subsection we state some auxiliary results that will be used in order to prove Lemma 1.2.

3.1.1. A simple load estimation. We present here the following simple (and known) lemma (see, e.g., [15, 17, 30]) that we use in the proof of Lemma 3.9.

LEMMA 3.1. *Suppose that m balls are allocated in n bins using Greedy[2]. Let p be any positive real. Then with probability at least $1 - p$ the minimum load in any bin is larger than or equal to*

$$\frac{m}{n} - \sqrt{\frac{2m}{n} \cdot \ln \frac{n}{p}}.$$

Proof. The proof follows easily from the fact that the minimum load in Greedy[2] is (stochastically) not smaller than the minimum load in the process that allocates m balls in n bins i.u.r. (this follows, for example, from the majorization results presented in [1, Theorem 3.5]). The minimum load in the process that allocates m balls in n bins i.u.r. can be estimated by looking at each bin independently. Then, we apply the Chernoff bound² to estimate the probability that the load of the bin is smaller than the expected load (i.e., from $\frac{m}{n}$) by more than $\sqrt{\frac{2m}{n} \cdot \ln \frac{n}{p}}$. We apply the Chernoff bound to m independent random variables X_1, \dots, X_m with X_i indicating the event that the i th ball is allocated in the given bin. Then, we obtain for every $t \in \mathbb{N}$

$$\Pr \left[\text{given bin has load} \leq \frac{m}{n} - t \right] \leq \exp \left(\frac{-n t^2}{2m} \right).$$

²We use the following form of the Chernoff bound (see, e.g., [21, Theorem 2.3 (c)]): If X_1, \dots, X_m are binary independent random variables and if $X = \sum_{j=1}^m X_j$, then for any δ , $0 < \delta < 1$, it holds that $\Pr[X \leq (1 - \delta) \mathbf{E}[X]] \leq \exp(-\delta^2 \mathbf{E}[X]/2)$.

Therefore, by the union bound,

$$\Pr \left[\text{minimum load} \leq \frac{m}{n} - t \right] \leq n \cdot \exp \left(\frac{-nt^2}{2m} \right).$$

This implies our result by setting $t = \sqrt{\frac{2m}{n} \cdot \ln \frac{n}{p}}$. \square

3.1.2. Neighboring coupling. Our main tool in the analysis of the convergence of Markov chains is a new variant of the path coupling arguments that extends the results from [7, 13] and which is described in the following lemma.

LEMMA 3.2 (Neighboring Coupling Lemma). *Let $\mathfrak{M} = (\mathbf{Y}_t)_{t \in \mathbb{N}}$ be a discrete-time Markov chain with a state space Ω . Let $\Omega^* \subseteq \Omega$. Let Γ be any subset of $\Omega^* \times \Omega^*$ (elements $(X, Y) \in \Gamma$ are called neighbors). Suppose that there is an integer D such that for every $(X, Y) \in \Omega^* \times \Omega^*$ there exists a sequence $X = \Lambda_0, \Lambda_1, \dots, \Lambda_r = Y$, where $(\Lambda_i, \Lambda_{i+1}) \in \Gamma$ for $0 \leq i < r$, and $r \leq D$.*

If there exists a coupling $(X_t, Y_t)_{t \in \mathbb{N}}$ for \mathfrak{M} such that for some $T \in \mathbb{N}$, for all $(X, Y) \in \Gamma$, it holds that $\Pr[X_T \neq Y_T \mid (X_0, Y_0) = (X, Y)] \leq \frac{\varepsilon}{D}$, then

$$\|\mathcal{L}(X_T \mid X_0 = X) - \mathcal{L}(Y_T \mid Y_0 = Y)\| \leq \varepsilon$$

for every $(X, Y) \in \Omega^* \times \Omega^*$.

Proof. For any pair of neighbors $(\Lambda, \Lambda') \in \Gamma$,

$$\|\mathcal{L}(Z_T \mid Z_0 = \Lambda) - \mathcal{L}(Z_T \mid Z_0 = \Lambda')\| \leq \frac{\varepsilon}{D}$$

by the well-known Coupling Lemma (see, e.g., [4, Lemma 3.6]). As a consequence, we obtain

$$\begin{aligned} & \|\mathcal{L}(Z_T \mid Z_0 = X) - \mathcal{L}(Z_T \mid Z_0 = Y)\| \\ & \leq \sum_{i=1}^r \|\mathcal{L}(Z_T \mid Z_0 = \Lambda_i) - \mathcal{L}(Z_T \mid Z_0 = \Lambda_{i-1})\| \leq r \cdot \frac{\varepsilon}{D} \leq \varepsilon. \quad \square \end{aligned}$$

Thus, if we can find a neighboring coupling, we obtain immediately a bound on the total variation distance in terms of the tail probabilities of the coupling time, i.e., a random time \mathbb{T} for which $X_t = Y_t$ for all $t \geq \mathbb{T}$.

3.1.3. Random walks on \mathbb{N} . In this section we present some auxiliary results on the convergence rates of a random walk on the line \mathbb{N} with the starting point D , with the absorbing barrier at 0, and with a drift $\beta \geq 0$ toward 0. We feel that these results might be known, but since we have not seen them in forms needed in our paper, we decided to present them here in detail for the sake of completeness.

We begin with the following result which can be viewed as a bound on the number of steps needed by a random walk on the integer line with positive drift toward 0 until the “barrier” 0 is hit.

LEMMA 3.3 (random walk on \mathbb{N} —positive drift toward 0). *Let ϵ and β be any positive reals. Let D be an arbitrary natural number. Let $c \geq 1$ be an arbitrary constant. Let $(\mathcal{X}_t)_{t \in \mathbb{N}}$ be a sequence of (not necessarily independent) random variables such that*

- (1) $0 \leq \mathcal{X}_0 \leq D$,
- (2) for every $t \in \mathbb{N}$, $|\mathcal{X}_{t+1} - \mathcal{X}_t| \leq c$,
- (3) for every $t \in \mathbb{N}$, if $\mathcal{X}_t > 0$ then $\mathbf{E}[\mathcal{X}_{t+1} - \mathcal{X}_t \mid \mathcal{X}_0, \mathcal{X}_1, \dots, \mathcal{X}_t] \leq -\beta$, and

(4) for every $t \in \mathbb{N}$, if $\mathcal{X}_t \leq 0$ then $\mathcal{X}_{t+1} = 0$.

Then, for certain $T = \Theta(D/\beta + \ln(1/\epsilon)/\beta^2)$, if $\tau \geq T$ then $\Pr[\mathcal{X}_\tau > 0] \leq \epsilon$.

Proof. We eliminate the requirement that \mathcal{X}_t is never negative by introducing a new sequence of random variables $(\mathcal{Y}_t)_{t \in \mathbb{N}}$. If $\mathcal{X}_t > 0$ then we set $\mathcal{Y}_t = \mathcal{X}_t$, and otherwise we define $\mathcal{Y}_t = \mathcal{Y}_{t-1} - \beta$.

Then, conditions (1)–(2) still hold for sequence $(\mathcal{Y}_t)_{t \in \mathbb{N}}$, condition (3) holds for $(\mathcal{Y}_t)_{t \in \mathbb{N}}$ even without the assumption that $\mathcal{Y}_t > 0$, and we have a new condition (4*) such that for every $t \in \mathbb{N}$, if $\mathcal{Y}_t \leq 0$ then $\mathcal{Y}_{t+1} \leq 0$. Additionally, it is easy to see that for every $t \in \mathbb{N}$ it holds that $\Pr[\mathcal{Y}_t > 0] = \Pr[\mathcal{X}_t > 0]$.

Next, since for every t we have $\mathbf{E}[\mathcal{Y}_{t+1} - \mathcal{Y}_t \mid \mathcal{Y}_0, \dots, \mathcal{Y}_t] \leq -\beta$, we see that $\mathbf{E}[\mathcal{Y}_t] \leq D - \beta t$. Therefore, we can apply the Hoeffding–Azuma inequality (see, e.g., [21, Theorem 3.10]) to obtain that for every $\alpha > 0$ it holds that

$$\Pr[\mathcal{Y}_t > \alpha + \mathbf{E}[\mathcal{Y}_t]] \leq e^{-\alpha^2/(2tc)}.$$

Since for $\alpha = t\beta - D$ we have $\alpha + \mathbf{E}[\mathcal{Y}_t] \leq 0$, we can conclude that

$$\Pr[\mathcal{X}_t > 0] = \Pr[\mathcal{Y}_t > 0] \leq e^{-(t\beta - D)^2/(2tc)},$$

which yields the lemma. \square

Next, we investigate random walks on the integers with “balanced” drift, or a drift which is very small; that is, β in Lemma 3.3 is tiny and hence the bound at that lemma is weak.

LEMMA 3.4 (random walk on \mathbb{N} —balanced case). *Let ϵ be any positive real. Let D be an arbitrary natural number. Let $c \geq 1$ be an arbitrary constant. Let $(\mathcal{X}_t)_{t \in \mathbb{N}}$ be a sequence of (not necessarily independent) integer random variables such that the following properties hold:*

1. $0 \leq \mathcal{X}_t \leq D$ for every $t \in \mathbb{N}$,
2. for every $t \in \mathbb{N}$, $|\mathcal{X}_{t+1} - \mathcal{X}_t| \leq c$,
3. for every $t \in \mathbb{N}$, if $\mathcal{X}_t > 0$ then $\mathcal{X}_{t+1} \neq \mathcal{X}_t$ and $\mathbf{E}[\mathcal{X}_{t+1} - \mathcal{X}_t \mid \mathcal{X}_0, \mathcal{X}_1, \dots, \mathcal{X}_t] \leq 0$, and
4. for every $t \in \mathbb{N}$, if $\mathcal{X}_t = 0$ then $\mathcal{X}_{t+1} = 0$.

Then, for certain $T = \Theta(D^2 \cdot \ln(1/\epsilon))$, if $\tau \geq T$ then $\Pr[\mathcal{X}_\tau > 0] \leq \epsilon$.

Proof. We first observe that it is enough to prove the lemma only for $\mathbf{E}[\mathcal{X}_{t+1} - \mathcal{X}_t \mid \mathcal{X}_0, \dots, \mathcal{X}_t] = 0$. We follow here arguments given in [19, Lemma 4]. Recall that random variables $\mathcal{V}_0, \mathcal{V}_1, \dots$, form a *submartingale* with respect to a sequence $(\mathcal{W}_t)_{t \in \mathbb{N}}$ if $\mathbf{E}[\mathcal{V}_{t+1} - \mathcal{V}_t \mid \mathcal{W}_0, \mathcal{W}_1, \dots, \mathcal{W}_t] \geq 0$ for every $t \in \mathbb{N}$. A random variable τ is a *stopping time* for the submartingale if for each t one can determine if $\tau \geq t$. We shall use the optional stopping time theorem (due to Doob) for submartingales which says that if $(\mathcal{U}_t)_{t \in \mathbb{N}}$ is a submartingale $(\mathcal{U}_t)_{t \in \mathbb{N}}$ with bounded $|\mathcal{U}_{t+1} - \mathcal{U}_t|$ for every $t \in \mathbb{N}$ and τ is a stopping time with finite expectation, then $\mathbf{E}[\mathcal{U}_\tau] \geq \mathbf{E}[\mathcal{U}_0]$.

Fix \mathcal{X}_0 . Define the stochastic process $\mathcal{Z}_0, \mathcal{Z}_1, \dots$ such that for every $t \in \mathbb{N}$,

$$\mathcal{Z}_t = \begin{cases} (D - \mathcal{X}_t)^2 - t & \text{if either } t = 0 \text{ or } t > 0 \text{ and } \mathcal{X}_{t-1} > 0, \\ \mathcal{Z}_{t-1} & \text{if } t > 0 \text{ and } \mathcal{X}_{t-1} = 0. \end{cases}$$

Let us first observe that \mathcal{Z}_t is a submartingale with respect to the sequence $(\mathcal{X}_t)_{t \in \mathbb{N}}$. Indeed, conditioned on $\mathcal{X}_0, \mathcal{X}_1, \dots, \mathcal{X}_t$, if $\mathcal{X}_t = 0$ then $\mathcal{Z}_{t+1} - \mathcal{Z}_t = 0$. Otherwise, if $\mathcal{X}_t > 0$, then we obtain $\mathbf{E}[\mathcal{Z}_{t+1} - \mathcal{Z}_t] = \mathbf{E}[(D - \mathcal{X}_{t+1})^2 - (t + 1) - ((D - \mathcal{X}_t)^2 - t)] = \mathbf{E}[(\mathcal{X}_{t+1} - \mathcal{X}_t)^2 - 1 + 2 \cdot (\mathcal{X}_t - \mathcal{X}_{t+1}) \cdot (D - \mathcal{X}_t)] \geq \mathbf{E}[(\mathcal{X}_{t+1} - \mathcal{X}_t)^2] - 1 + 2 \cdot (D - \mathcal{X}_t) \cdot \mathbf{E}[\mathcal{X}_t -$

$\mathcal{X}_{t+1}] \geq 1 - 1 + 0 \geq 0$. Here, we used the fact that if $\mathcal{X}_t > 0$ then $\mathcal{X}_{t+1} \neq \mathcal{X}_t$, and therefore since each of \mathcal{X}_{t+1} and \mathcal{X}_t is an integer, it holds that $\mathbf{E}[(\mathcal{X}_{t+1} - \mathcal{X}_t)^2] \geq 1$.

Next, we notice that the differences $|\mathcal{Z}_{t+1} - \mathcal{Z}_t|$ are bounded for every $t \in \mathbb{N}$ and the random time $\mathfrak{T}_{\mathcal{X}_0} = \min\{t : \mathcal{X}_t = 0\}$ is a stopping time for \mathcal{Z}_t with finite expectation. Moreover, $\mathcal{Z}_0 = (D - \mathcal{X}_0)^2$ and $\mathcal{Z}_{\mathfrak{T}_{\mathcal{X}_0}} = D^2 - \mathfrak{T}_{\mathcal{X}_0}$. Since $\mathbf{E}[\mathcal{Z}_{\mathfrak{T}_{\mathcal{X}_0}}] \geq \mathbf{E}[\mathcal{Z}_0]$ by the optional stopping time theorem, we get $\mathbf{E}[\mathfrak{T}_{\mathcal{X}_0}] \leq \mathcal{X}_0 \cdot (2D - \mathcal{X}_0) \leq D^2$.

Take $t = e \cdot D^2$. The Markov inequality implies that $\Pr[\mathfrak{T}_{\mathcal{X}_0} \geq t] \leq e^{-1}$. If we run $\ln(1/\epsilon)$ independent trials of length t then for $T = t \cdot \ln(1/\epsilon)$ the probability that $\mathcal{X}_T \neq 0$ is at most ϵ^{-1} . \square

3.2. Greedy[d] has short memory: Analysis for $d=2$. In this section we prove Lemma 1.2 for $d = 2$. More precisely, we will prove various properties about Greedy[d]. For $d = 2$ these properties will immediately imply Lemma 1.2. For $d > 2$ we need some additional arguments which are then presented in section 3.3.

Throughout this section we deal only with *normalized* load vectors. For every $k \geq 0$, let Ω_k denote the set of normalized load vectors with k balls. In our analysis, we investigate the following Markov chain $\mathfrak{M}[d] = (\mathcal{M}_t)_{t \in \mathbb{N}}$, which models the behavior of protocol Greedy[d]:

Input: \mathcal{M}_0 is any load vector in Ω_m

Transitions $\mathcal{M}_t \Rightarrow \mathcal{M}_{t+1}$:

Pick $q \in [n]$ at random such that $\Pr[q = k] = \frac{k^d - (k-1)^d}{n^d}$

\mathcal{M}_{t+1} is obtained from \mathcal{M}_t by adding a new ball to the q th fullest bin

It is easy to see that the choice of q is equivalent to the choice obtained by the following simple randomized process: Pick $q_1, q_2, \dots, q_d \in [n]$ i.u.r. and set $q = \max\{q_i : 1 \leq i \leq d\}$. This in turn, is equivalent to the choice of q obtained by Greedy[d]: Pick d bins i.u.r. and let the least loaded among the chosen bins be the q th fullest bin in the system.

Our proof of Lemma 1.2 is via the *neighboring coupling* method discussed in detail in section 3.1.2. Let X and Y denote two vectors from Ω_m . We study the process by which we add new balls on the top of each of the allocations described by these vectors. We analyze how many balls one has to add until the two allocations are almost indistinguishable.

3.2.1. Neighboring coupling. In order to apply the Neighboring Coupling Lemma to analyze the Markov chain $\mathfrak{M}[d] = (\mathcal{M}_t)_{t \in \mathbb{N}}$, we must first define the notion of neighbors. Let us fix m and n . Let us define $\Omega^* = \Omega_m$ and let Γ be the set of pairs of those load vectors from Ω_m which correspond to the balls' allocations that differ in exactly one ball (cf. Figure 2). In that case, if X can be obtained from Y by moving a ball from the i th fullest bin into the j th fullest bin, then we write $X = Y - \mathbf{e}_i + \mathbf{e}_j$. Thus,

$$\Gamma = \{(X, Y) \in \Omega_m \times \Omega_m : X = Y - \mathbf{e}_i + \mathbf{e}_j \text{ for certain } i, j \in [n], i \neq j\}.$$

Clearly, for each $X, Y \in \Omega_m$ there exists a sequence $X = Z^{(0)}, Z^{(1)}, \dots, Z^{(l-1)}, Z^{(l)} = Y$, where l is the number of balls on which X and Y differ, $l \leq m$, and $(Z^{(i)}, Z^{(i+1)}) \in \Gamma$ for every i , $0 \leq i \leq l - 1$. Thus, we can apply the Neighboring Coupling Lemma with $D = m$.

FIG. 2. An example of neighboring load vectors X and Y with $X = Y - \mathbf{e}_1 + \mathbf{e}_5$ and $\Delta(X, Y) = 6$.

3.2.2. Short memory lemma using neighboring coupling. The main result of this section is the following technical lemma.

LEMMA 3.5. *Let $\varepsilon > 0$ and let $d \geq 2$ be integer. Let $X, Y \in \Omega_m$. There exists a coupling $(X_t, Y_t)_{t \in \mathbb{N}}$ for $\mathfrak{M}[d]$ and there is $\mathbb{T} = \Theta(m \cdot n^d + n^{2d} \cdot \ln(m/\varepsilon))$ such that for any $\tau \geq \mathbb{T}$ it holds that $\Pr[X_\tau \neq Y_\tau \mid (X_0, Y_0) = (X, Y)] \leq \varepsilon$.*

Let us first observe that for $d = 2$ Lemma 3.5 immediately implies the Short Memory Lemma for Greedy[2]. However, Lemma 3.5 yields a weaker bound for $d \geq 3$. Therefore, a more specialized analysis for the case $d \geq 3$ is postponed to section 3.3.

Notice that since for any pair $X, Y \in \Omega_m$ there exists a sequence $\Lambda_0, \Lambda_1, \dots, \Lambda_k$ such that $k \leq m$, $\Lambda_0 = X$, $\Lambda_k = Y$, and $(\Lambda_{i-1}, \Lambda_i) \in \Gamma$ for every $1 \leq i \leq k$, Lemma 3.5 follows immediately from the following lemma.

LEMMA 3.6. *Let $\varepsilon > 0$ and let $d \geq 2$ be integer. Let $X, Y \in \Gamma$. There exists a coupling $(X_t, Y_t)_{t \in \mathbb{N}}$ for $\mathfrak{M}[d]$ and there is $\mathbb{T} = \Theta(m \cdot n^d + n^{2d} \cdot \ln(m/\varepsilon))$ such that for any $\tau \geq \mathbb{T}$ it holds that $\Pr[X_\tau \neq Y_\tau \mid (X_0, Y_0) = (X, Y)] \leq \frac{\varepsilon}{m}$.*

The rest of this subsection is devoted to the proof of Lemma 3.6.

For any load vectors $X = (x_1, \dots, x_n)$ and $Y = (y_1, \dots, y_n)$ with $X = Y - \mathbf{e}_i + \mathbf{e}_j$, $i, j \in [n]$, let us define the *distance* function $\Delta(X, Y)$ (cf. Figure 2),

$$\Delta(X, Y) = \max\{|x_i - x_j|, |y_i - y_j|\}.$$

Observe that $\Delta(X, Y)$ is always a nonnegative integer, it is zero only if $X = Y$ and it never takes the value of 1. Let

$$\begin{aligned} \xi &= \min\{\Pr[\text{Greedy}[d] \text{ picks the } j\text{th fullest bin}] \\ &\quad - \Pr[\text{Greedy}[d] \text{ picks the } i\text{th fullest bin}] : i, j \in [n], i < j\}. \end{aligned}$$

Then, clearly, $\xi \geq 1/n^d$. The following lemma describes main properties of the desired coupling.

LEMMA 3.7. *If $(X, Y) \in \Gamma$ then there exists a coupling $(X_t, Y_t)_{t \in \mathbb{N}}$ for $\mathfrak{M}[d]$ that, conditioned on $(X_0, Y_0) = (X, Y)$, satisfies the following properties for every $t \in \mathbb{N}$:*

- if $X_t = Y_t$ then $X_{t+1} = Y_{t+1}$,
- if $X_t \neq Y_t$ then X_t and Y_t differ in at most one ball,
- $\Delta(X_{t+1}, Y_{t+1}) - \Delta(X_t, Y_t) \in \{-2, -1, 0, 1\}$, and
- if $X_t \neq Y_t$ then $\mathbf{E}[\Delta(X_{t+1}, Y_{t+1}) \mid X_t, Y_t] \leq \Delta(X_t, Y_t) - \xi$.

Proof. We use the following natural coupling: each time we increase the vectors X and Y by one ball, we use the same random choice. That is, in each step the obtained load vectors will be obtained from X and Y , respectively, by allocating a new ball to the q th fullest bin for certain $q \in [n]$.

FIG. 3. Illustration to the proof of Claim 3.8. In this case $X = Y - e_4 + e_9$, $\Delta(X, Y) = 4$, $l = 2$, $\alpha = 6$, $\beta = 8$, and $r = 11$.

The lemma now follows directly from the properties of the coupling described in Claim 3.8 below. \square

CLAIM 3.8. Let X, Y be two load vectors from Ω_m that differ in one ball with $X = Y - e_i + e_j$ for certain $i < j$. Let $X^{(q)}$ and $Y^{(q)}$ be obtained from X and Y , respectively, by allocating a new ball to the q th fullest bin. Then, either

1. $X^{(q)} = Y^{(q)}$ and $\Delta(X^{(q)}, Y^{(q)}) = \Delta(X, Y) - 2$, or
2. $X^{(q)}$ and $Y^{(q)}$ differ in one ball and

$$\Delta(X^{(q)}, Y^{(q)}) = \begin{cases} \Delta(X, Y) - 1 & \text{if and only if } q = j, \\ \Delta(X, Y) + 1 & \text{if and only if } q = i, \\ \Delta(X, Y) & \text{otherwise.} \end{cases}$$

Proof. The proof is by case analysis which is tedious but otherwise straightforward (see also Figure 3 for some intuition behind the coupling). We assume that $\Delta(X, Y) = y_i - y_j$; the case $\Delta(X, Y) = x_i - x_j$ can be done similarly. Let

$$\begin{aligned} l &= \min\{s \in [n] : y_s = y_i\}, \\ \alpha &= \max\{s \in [n] : x_i = x_s\}, \\ \beta &= \min\{s \in [n] : x_s = x_j\}, \\ r &= \max\{s \in [n] : y_j = x_s\}. \end{aligned}$$

Let us notice that $1 \leq l \leq i \leq \alpha$, $l < \alpha$, $\beta \leq j \leq r \leq n$, and $\beta < r$. We first consider six cases when either $1 \leq q \leq i$ or $j \leq q \leq n$.

Case (1) $1 \leq q < l$. Since $q < l$ the same happens for both processes. For certain s , $s \leq q$, we have $X^{(q)} = X + e_s$ and $Y^{(q)} = Y + e_s$. Therefore, after adding the ball to the q th fullest bin, we still have $X^{(q)} = Y^{(q)} - e_i + e_j$. Hence, $\Delta(X^{(q)}, Y^{(q)}) = y_i^{(q)} - y_j^{(q)} = y_i - y_j = \Delta(X, Y)$.

Case (2) $l \leq q < i$. After reordering of the bins, the load of the l th largest bin has increased by one for both load vectors (note that all load vectors between the l th largest and the $i - 1$ th largest bin have the same load in both processes). Hence, $X^{(q)} = X + e_l$ and $Y^{(q)} = Y + e_l$. Therefore, $X^{(q)} = Y^{(q)} - e_i + e_j$ and the rest of the case is similar to Case (1).

Case (3) $q = i$. In this case we have $X^{(q)} = X + e_i$. After reordering of the load vector of Y we have $Y^{(q)} = Y + e_l$ (see Case (2)). This yields $X^{(q)} = Y^{(q)} - e_l + e_j$ and $\Delta(X^{(q)}, Y^{(q)}) = y_l^{(q)} - y_j^{(q)} = (y_l + 1) - y_j = \Delta(X, Y) + 1$.

Case (4) $q = j$. The β th and the j th largest bins have the same number of elements after adding a ball to the j th largest bin of X . Hence, $X^{(q)} = X + e_\beta$ and

$Y^{(q)} = Y + \mathbf{e}_j$ (in the case of Y the bins do not have to be reordered). Therefore $X^{(q)} = Y^{(q)} - \mathbf{e}_i + \mathbf{e}_\beta$.

Now, there are two possibilities. First, if $\Delta(X, Y) = 2$, then $i = \beta$ and therefore $X^{(q)} = Y^{(q)}$. Otherwise, $\Delta(X, Y) > 2$ and hence $i \leq \alpha < \beta$, which implies that $\Delta(X^{(q)}, Y^{(q)}) = y_i^{(q)} - y_\beta^{(q)} = y_i - (y_j + 1) = \Delta(X, Y) - 1$.

Case (5) $j < q \leq r$. After reordering we have $X^{(q)} = X + \mathbf{e}_{j+1}$ and $Y^{(q)} = Y + \mathbf{e}_j$. We get $X^{(q)} = Y^{(q)} - \mathbf{e}_i + \mathbf{e}_{j+1}$ and $\Delta(X^{(q)}, Y^{(q)}) = y_i^{(q)} - y_{j+1}^{(q)} = y_i - y_j = \Delta(X, Y)$.

Case (6) $r < q \leq n$. This case is similar to Case (1). For certain $s, r < s \leq q$, it holds that $X^{(q)} = X + \mathbf{e}_s$ and $Y^{(q)} = Y + \mathbf{e}_s$. Therefore, $X^{(q)} = Y^{(q)} - \mathbf{e}_i + \mathbf{e}_j$ and $\Delta(X^{(q)}, Y^{(q)})$ does not change.

Now it remains to consider the case when $i < q < j$. We distinguish here two main cases.

Case (A) $x_i = x_j$. In this case we have $\Delta(X, Y) = 2$. After reordering we have $X^{(q)} = X + \mathbf{e}_i$ and $Y^{(q)} = Y + \mathbf{e}_{i+1}$. This means $X^{(q)} = Y^{(q)} - \mathbf{e}_{i+1} + \mathbf{e}_j$ and $\Delta(X^{(q)}, Y^{(q)}) = y_{i+1}^{(q)} - y_j^{(q)} = y_i - y_j = 2 = \Delta(X, Y)$.

Case (B) $x_i > x_j$. In this case $\alpha < \beta$ and we distinguish three subcases:

Case (B.1) $i < q \leq \alpha$. After reordering we get $X^{(q)} = X + \mathbf{e}_i$ and $Y^{(q)} = Y + \mathbf{e}_{i+1}$. Therefore, $X^{(q)} = Y^{(q)} - \mathbf{e}_{i+1} + \mathbf{e}_j$ and $\Delta(X^{(q)}, Y^{(q)}) = y_{i+1}^{(q)} - y_j^{(q)} = y_i - y_j = \Delta(X, Y)$.

Case (B.2) $\alpha < q < \beta$. Again, this case is similar to Case (1); for certain $s, \alpha < s \leq q < \beta$, we get $X^{(q)} = X + \mathbf{e}_s$ and $Y^{(q)} = Y + \mathbf{e}_s$. Hence, $\Delta(X, Y)$ does not change.

Case (B.3) $\beta \leq q < j$. In this case $X^{(q)} = X + \mathbf{e}_\beta$ and $Y^{(q)} = Y + \mathbf{e}_\beta$. Therefore, $X^{(q)} = Y^{(q)} - \mathbf{e}_i + \mathbf{e}_j$ and $\Delta(X, Y)$ does not change. \square

Now we are ready to present the proof of Lemma 3.6.

Proof. We use the coupling constructed in Lemma 3.7. Observe that if we define $\Delta_t = \Delta(X_t, Y_t), t \geq 0$, then from Lemma 3.7 the random variable Δ_t behaves like a random walk on \mathbb{N} with drift toward 0; see section 3.1.3. By our assumption, we can set $\xi = 1/n^d$. Given that, we can conclude the proof by applying Lemma 3.3 with $\mathcal{X}_t = \Delta(X_t, Y_t), c_t = 2$ for every $t \in \mathbb{N}$, and with $D = m$ and $\beta = \xi = 1/n^d$. \square

3.3. Short memory property of Greedy[d] for large d . The main problem with applying Lemma 3.7 for large d is that the value of ξ may be very small. Now we modify the analysis above to give a better bound for Greedy[d] than the one of Lemma 3.5 for all $d > 2$.

3.3.1. Load difference reduction in Greedy[d] for $d \geq 3$. For any load vector \mathcal{W} let us denote by $\text{LOW}(\mathcal{W})$ ($\text{UPP}(\mathcal{W})$) the minimum load (respectively, the maximum load) in \mathcal{W} . We prove that independently of the initial difference between $\text{LOW}(\mathcal{W})$ and $\text{UPP}(\mathcal{W})$ at some moment of the allocation process Greedy[d], after allocating some new balls, this difference will be kept small.

LEMMA 3.9. *Let n and M be any positive integers and let ε be any positive real. Let $d \geq 2$ be any integer. Let $X \in \Omega_M$. Let $\mathfrak{M}[d] = (X_t)_{t \in \mathbb{N}}$ with $X_0 = X$; that is, X_0, X_1, \dots is the sequence of random variables describing the Markov chain $\mathfrak{M}[d]$ conditioned on the event $X_0 = X$. Then, there exist a certain $\mathbb{T} = \Theta(Mn^2 + n^4 \cdot \ln(M/\varepsilon))$ and a constant $c > 0$ such that the following hold.*

(1) If $M = \mathcal{O}(n^3 \ln(n/\varepsilon))$, then the following two bounds hold:

$$\Pr \left[\text{LOW}(X_{\mathbb{T}}) \leq \frac{M + \mathbb{T}}{n} - c \cdot \sqrt{(M + n^2 \ln(M/\varepsilon)) \cdot n \cdot \ln(n/\varepsilon)} \right] \leq \varepsilon,$$

$$\Pr \left[\text{UPP}(X_{\mathbb{T}}) \geq \frac{M + \mathbb{T}}{n} + c \cdot \sqrt{(M + n^2 \ln(M/\varepsilon)) \cdot n \cdot \ln(n/\varepsilon)} \right] \leq \varepsilon.$$

(2) If $M = \Omega(n^3 \ln(n/\varepsilon))$, then the following two bounds hold:

$$\Pr \left[\text{LOW}(X_{\mathbb{T}}) \leq \frac{M + \mathbb{T}}{n} - c \cdot n^{1.25} \cdot M^{0.25} \cdot (\ln(n/\varepsilon))^{0.75} \right] \leq \varepsilon,$$

$$\Pr \left[\text{UPP}(X_{\mathbb{T}}) \geq \frac{M + \mathbb{T}}{n} + c \cdot n^{1.25} \cdot M^{0.25} \cdot (\ln(n/\varepsilon))^{0.75} \right] \leq \varepsilon.$$

Proof. We prove the lemma only for M being the multiple of n ; the general case can be handled similarly. Since the proofs for $\text{LOW}(\mathcal{W})$ and $\text{UPP}(\mathcal{W})$ are almost the same, we will deal only with $\text{LOW}(\mathcal{W})$. We also point out that our proof uses ideas similar to those discussed later in section 4.

Let Y_0, Y_1, \dots be the sequence of random variables (normalized load vectors) describing the Markov chain $\mathfrak{M}[2]$ conditioned on the event $Y_0 = X$. It is known that for every $l \in \mathbb{N}$ the normalized load vector X_l is majorized by the normalized load vector Y_l (see, e.g., [1, Theorem 3.5]). Therefore, in particular, $\text{LOW}(X_l)$ is stochastically larger than or equal to $\text{LOW}(Y_l)$ (the minimum load in Y_l). Hence, it is enough to prove the lemma only for the load vectors Y_0, Y_1, \dots .

Let ς be any positive real. Let Z be the ideally balanced load vector in Ω_M (i.e., the loads of all bins in Z are the same). Let Z_0, Z_1, \dots be the sequence of random variables (normalized load vectors) describing the Markov chain $\mathfrak{M}[2]$ conditioned on the event $Z_0 = Z$. Lemma 3.5 implies that for certain $T = \Theta(M n^2 + n^4 \cdot \ln(M/\varsigma))$, for any $t \geq T$ the load vectors Y_t and Z_t are almost indistinguishable (formally, $\|\mathcal{L}(Z_t) - \mathcal{L}(Y_t)\| \leq \varsigma$). In particular, this means that the random variables $\text{LOW}(Y_t)$ and $\text{LOW}(Z_t)$ are stochastically the same with probability at least $1 - \varsigma$. Furthermore, by Lemma 3.1, we know that for any $t \in \mathbb{N}$, it holds that

$$(1) \quad \Pr \left[\text{LOW}(Z_t) \leq \frac{M + t}{n} - \sqrt{\frac{2(M + t)}{n} \ln \frac{n}{\varsigma}} \right] \leq \varsigma.$$

Therefore, since for any $t \geq T$ we have $\|\mathcal{L}(Z_t) - \mathcal{L}(Y_t)\| \leq \varsigma$, we may conclude that for $t \geq T$ it holds that

$$(2) \quad \Pr \left[\text{LOW}(Y_t) \leq \frac{M + t}{n} - \sqrt{\frac{2(M + t)}{n} \ln \frac{n}{\varsigma}} \right] \leq 2\varsigma.$$

With inequality (2) we immediately obtain the first estimation for LOW by setting $\varepsilon = 2\varsigma$ and $\mathbb{T} = t = T$.

In order to obtain the second estimation, we first fix the smallest $\tau \geq T$ such that τ is a multiple of n . Let \mathcal{E} be the event that $\text{LOW}(Y_\tau) \geq \frac{M + \tau}{n} - \sqrt{\frac{2(M + \tau)}{n} \ln \frac{n}{\varsigma}}$. Let us condition on this event for a moment.

For any $t \geq \tau$, let Y_t^* be the load vector obtained from Y_t after removing $r = \lfloor \frac{M + \tau}{n} - \sqrt{\frac{2(M + \tau)}{n} \ln \frac{n}{\varsigma}} \rfloor$ balls from each bin in Y_t . Clearly, since $\text{LOW}(Y_t) \geq$

$\text{Low}(Y_\tau) \geq r$, Y_t^* is a proper normalized load vector in $\Omega_{t+M-r \cdot n}$. Notice further that there are $M^* = M + \tau - r \cdot n$ balls in the system described by Y_τ^* .

Now we apply once again a similar procedure as we did above for the first estimation. Let V be the ideally balanced load vector in Ω_{M^*} (i.e., each bin in V has the same load). Let V_0, V_1, \dots be the sequence of random variables (normalized load vectors) describing the Markov chain $\mathfrak{M}[2]$ conditioned on the event $V_0 = V$. Proceeding similarly as above, we want to compare $Y_{t+\tau}^*$ with V_t for $t \geq 0$.

Lemma 3.5 implies that for certain $T^* = \Theta(M^* n^2 + n^4 \cdot \ln(M^*/\varsigma))$, for any $t \geq T^*$ it holds that $\|\mathcal{L}(V_t) - \mathcal{L}(Y_{t+\tau}^*)\| \leq \varsigma$. Therefore, in particular, the random variables $\text{Low}(Y_{t+\tau}^*)$ and $\text{Low}(V_t)$ are stochastically the same with probability at least $1 - \varsigma$. Furthermore, by Lemma 3.1, we know that for any $t \in \mathbb{N}$ it holds that

$$\Pr \left[\text{Low}(V_t) \leq \frac{M^* + t}{n} - \sqrt{\frac{2(M^* + t)}{n} \ln \frac{n}{\varsigma}} \right] \leq \varsigma.$$

Therefore, since $\|\mathcal{L}(V_t) - \mathcal{L}(Y_{t+\tau}^*)\| \leq \varsigma$ for any $t \geq T^*$, we may conclude that for any $t \geq T^*$ it holds that

$$\Pr \left[\text{Low}(Y_{t+\tau}^*) \leq \frac{M^* + t}{n} - \sqrt{\frac{2(M^* + t)}{n} \ln \frac{n}{\varsigma}} \right] \leq 2\varsigma.$$

Furthermore, since the load vector $Y_{t+\tau}^*$ is obtained from the load vector $Y_{t+\tau}$ by removing r balls from each bin, we obtain that (conditioned on \mathcal{E}) for any $t \geq T^*$,

$$\Pr \left[\text{Low}(Y_{t+\tau}) \leq \frac{M + \tau + t}{n} - \sqrt{\frac{2(M^* + t)}{n} \ln \frac{n}{\varsigma}} \mid \mathcal{E} \right] \leq 2\varsigma.$$

Finally, since we have proved that event \mathcal{E} holds with probability at least $1 - 2\varsigma$ (see inequality (2)), we can conclude that for any $t \geq T^*$ it holds that

$$\Pr \left[\text{Low}(Y_{t+\tau}) \leq \frac{M + \tau + t}{n} - \sqrt{\frac{2(M^* + t)}{n} \ln \frac{n}{\varsigma}} \right] \leq 4\varsigma.$$

Now, it remains to resolve this bound with respect to n , M , and ς . We observe that

$$\tau = \Theta(M n^2 + n^4 \ln(M/\varsigma))$$

and

$$M^* = \Theta \left(\sqrt{\tau n \ln(n/\varsigma)} \right) = \Theta \left(n^{1.5} \sqrt{M \ln(n/\varsigma)} + n^{2.5} \sqrt{\ln(M/\varsigma) \ln(n/\varsigma)} \right).$$

Furthermore,

$$\begin{aligned} T^* &= \Theta(M^* n^2 + n^4 \cdot \ln(M^*/\varsigma)) \\ &= \Theta \left(n^{3.5} \sqrt{M \cdot \ln(n/\varsigma)} \quad n^{4.5} \sqrt{\ln(M/\varsigma) \ln(n/\varsigma)} \right. \\ &\quad \left. + n^4 \ln \left(\frac{n M \ln(n/\varsigma) \ln(M/\varsigma)}{\varsigma} \right) \right). \end{aligned}$$

Now, we use our assumption that $M = \Omega(n^3 \ln(n/\varsigma))$ for $\varsigma = \Theta(\varepsilon)$. In this case, the first term dominates the other one in the bounds for τ and for M^* and the first

term dominates the other two in the bound for T^* . Hence, $\tau = \Theta(Mn^2)$, $M^* = \Theta(n^{1.5} \sqrt{M \ln(n/\zeta)})$, $T^* = \Theta(n^{3.5} \sqrt{M \cdot \ln(n/\zeta)})$, and $\tau + T^* = \Theta(\tau)$. Therefore, we can conclude with the following claim: There exists a positive constant c such that for $\mathbb{T} = \tau + T^*$ it holds that

$$\Pr \left[\text{Low}(X_{\mathbb{T}}) \leq \frac{M + \mathbb{T}}{n} - c \cdot n^{1.25} \cdot M^{0.25} \cdot (\ln(n/\zeta))^{0.75} \right] \leq 4\zeta.$$

Now, the lemma follows by setting $\varepsilon = 4\zeta$. \square

3.3.2. Coupling arguments and the short memory lemma for $d > 2$.

Observe that a trivial implication of Lemma 3.9 is that if we start with any pair of normalized load vectors $X_0, Y_0 \in \Omega_M$, then for certain $\tau = \Theta(Mn^2 + n^4 \ln(M/\varepsilon))$, w.h.p. (depending on ε and κ), it holds that for any integer $\kappa > 0$, and for all t , $0 \leq t < \kappa$, the difference in the maximum load and the minimum load in $X_{\tau+t}$ (or $Y_{\tau+t}$) is upper-bounded by

$$\zeta = \begin{cases} \mathcal{O} \left(\sqrt{(M + n^2 \ln(M/\varepsilon)) n \ln(n/\varepsilon)} \right) & \text{for } M = \mathcal{O}(n^3 \ln(n/\varepsilon)), \\ \mathcal{O} \left(n^{1.25} M^{0.25} (\ln(n/\varepsilon))^{0.75} \right) & \text{for } M = \Omega(n^3 \ln(n/\varepsilon)). \end{cases}$$

From now on we shall fix τ and κ and shall condition on this event (which, by applying the union bound to Lemma 3.9, is satisfied with probability larger than $1 - 2\kappa\varepsilon$).

Now we proceed with coupling arguments. Let $X, Y \in \Gamma$. We use the same distance function $\Delta(\cdot, \cdot)$ as in section 3 and the same coupling as in Lemma 3.7 and Claim 3.8. Observe that by our discussion in section 3.2.2, for any $t \in \mathbb{N}$, either X_t and Y_t are identical or they differ by one ball.

Epochs. Let τ and κ be set as above. We divide the time into *epochs*. The 0th epoch starts at time step $l_0 = 0$ and ends in time step $r_0 = \tau$. Each following epoch corresponds to the time period when the value of Δ remains unchanged. That is, if the $(k - 1)$ st epoch, $k \geq 1$, ends in time step r_{k-1} , then, inductively, the k th epoch begins in time step $l_k = 1 + r_{k-1}$ and ends in the smallest time step $t \geq l_k$ for which $\Delta(X_{t-1}, Y_{t-1}) \neq \Delta(X_t, Y_t)$. Additionally, if $X_{r_{k-1}} = Y_{r_{k-1}}$, then we define $r_k = \infty$, and the k th epoch lasts until the infinity.

CLAIM 3.10. *Let μ be any positive integer. Let for every t , $\tau \leq t \leq \tau + \kappa$, the difference between the maximum load and the minimum load in each of X_t and Y_t be upper-bounded by μ . Then, for every $1 \leq k \leq \frac{\kappa}{2n\mu + 1}$, if $X_{r_{k-1}} \neq Y_{r_{k-1}}$, then the k th epoch lasts at most $2n\mu + 1$ time steps.*

Proof. Let $X_t = Y_t - \mathbf{e}_i + \mathbf{e}_j$ with $i < j$ and let $X_{t+1} = Y_{t+1} - \mathbf{e}_{i^*} + \mathbf{e}_{j^*}$, where X_{t+1} and Y_{t+1} are obtained from X_t and Y_t , respectively, by allocating a ball to bin q . By the case analysis (cf. also the proof of Claim 3.8) one can show that one of the following two cases must hold:

- $q = i$ or $q = j$ in the transition $(X_t, Y_t) \rightarrow (X_{t+1}, Y_{t+1})$ of the coupling.
- The load of the i^* th fullest bin in Y_{t+1} is the same as the load of the i th fullest bin in Y_t .

Consider a k th epoch and suppose that $X_{r_{k-1}} \neq Y_{r_{k-1}}$ with $X_{r_{k-1}} = Y_{r_{k-1}} - \mathbf{e}_{i^*} + \mathbf{e}_{j^*}$, $i^* < j^*$, in time r_{k-1} . Let ℓ be the load of the i^* th fullest bin in $Y_{r_{k-1}}$. Then, by the observation above and by Claim 3.8, for every t with $r_{k-1} \leq t \leq r_k - 1$, if $X_t = Y_t - \mathbf{e}_i + \mathbf{e}_j$ with $i < j$, then the load of the i th fullest bin in Y_t is ℓ .

Now, we want to use the assumption that for every t , $\tau \leq t \leq \tau + \kappa$, the difference between the maximum load and the minimum load in Y_t is upper-bounded by μ . Therefore, if $\tau \leq r_{k-1} \leq \tau + \kappa$, then in time r_{k-1} the value of ℓ (which is the load of

one of the bins in Y_{r_k-1}) is at most $\frac{r_k-1}{n} + \mu$. Furthermore, if $\tau \leq r_k \leq \tau + \kappa$, then in time $r_k - 1$ the value of ℓ (which is the load of one of the bins in Y_{r_k-1}) is at least $\frac{r_k-1}{n} - \mu$. Therefore, we obtain that

$$\frac{r_k-1}{n} + \mu \geq \ell \geq \frac{r_k-1}{n} - \mu.$$

This implies immediately that $r_k - l_k \leq 2n\mu$. This also yields inductively that if $1 \leq k \leq \kappa/(2n\mu + 1)$ and $X_{r_{k-1}} \neq Y_{r_{k-1}}$, then the k th epoch lasts at most $2n\mu + 1$ time steps. \square

Let Δ_k be the value of $\Delta(X_t, Y_t)$ for $t = r_k$, i.e., for t being the last time step of the k th epoch. Clearly, $\Delta_{k-1} \neq \Delta_k$. Furthermore, by Claim 3.8 the following holds:

- If $\Delta_{k-1} \geq 3$ then $\Delta_k \in \{\Delta_{k-1} - 1, \Delta_{k-1} + 1\}$ and $\mathbf{E}[\Delta_k - \Delta_{k-1}] < 0$.
- If $\Delta_{k-1} = 2$ then $\Delta_k \in \{0, 3\}$ and $\mathbf{E}[\Delta_k - \Delta_{k-1}] < 0$.

Therefore, similarly as in the proof of Lemma 3.5, we can model sequence $\Delta_0, \Delta_1, \dots$ as a random walk on the line \mathbb{N} with the starting point $D \leq \zeta$, the absorbing barrier in 0, and with a positive drift toward 0. This time, however, the drift is very small and therefore we use a weaker bound for the convergence of this random walk. From Lemma 3.4 we obtain that

$$\mathbf{Pr}[\Delta_k > 0] \leq 2\kappa\varepsilon \quad \text{for all } k \geq \gamma\zeta^2 \ln(2\kappa\varepsilon)^{-1},$$

where γ is some absolute positive constant. Now, since by Claim 3.10 each epoch k with $\Delta_{k-1} > 0$ lasts at most $2n\zeta + 1$ time steps, the last inequality implies the following. For all $t, t \geq \tau + \gamma\zeta^2 \ln(2\kappa\varepsilon)^{-1} \cdot (2n\zeta + 1)$, it holds that $\mathbf{Pr}[X_t \neq Y_t] \leq 2\kappa\varepsilon$. Since, by Lemma 3.9, we have proven that with probability larger than or equal to $1 - 2\kappa\varepsilon$, for every $t, \tau \leq t < \tau + \kappa$, the difference between the maximum load and the minimum load in each of X_t and Y_t is upper bounded by ζ , we can conclude with the following lemma.

LEMMA 3.11. *Let n and m be any positive integers and let ε be any positive real. Let $d \geq 2$ be any integer. Let $X_0, Y_0 \in \Omega_m$.*

- (1) *If $m = \mathcal{O}(n^3 \ln(n/\varepsilon))$, then there is a coupling $(X_t, Y_t)_{t \in \mathbb{N}}$ for $\mathfrak{M}[d]$ such that for certain \mathbb{T}^* ,*

$$\mathbb{T}^* = \Theta(n^{2.5} \cdot (m + n^2 \ln(n/\varepsilon))^{1.5} \cdot \ln(n/\varepsilon)^{1.5} \cdot \ln(1/\varepsilon));$$

it holds for any $t \geq \mathbb{T}^$ that*

$$\mathbf{Pr}[X_t \neq Y_t \mid (X_0, Y_0) = (X, Y)] \leq \varepsilon.$$

- (2) *If $m = \Omega(n^3 \ln(n/\varepsilon))$, then there is a coupling $(X_t, Y_t)_{t \in \mathbb{N}}$ for $\mathfrak{M}[d]$ such that for certain \mathbb{T}^* ,*

$$\mathbb{T}^* = \Theta(m \cdot n^2 + m^{0.75} \cdot n^{4.75} \cdot (\ln(m/\varepsilon))^{2.25} \cdot \ln(1/\varepsilon));$$

it holds for any $t \geq \mathbb{T}^$ that*

$$\mathbf{Pr}[X_t \neq Y_t \mid (X_0, Y_0) = (X, Y)] \leq \varepsilon.$$

Now, Lemma 3.11 directly implies the Short Memory Lemma, Lemma 1.2, for all values of d .

4. A reduction to a polynomial number of balls for Greedy[d]. In this section, we discuss our main use of the Short Memory Lemma which is a reduction of the analysis of the problem of allocating an arbitrary number m of balls into n bins to the case when m is upper-bounded by a polynomial of n . If we combine this analysis with the analysis for a polynomial number of balls in section 2, we will immediately obtain Theorem 1.3.

Our arguments are similar to those used in section 3.3. We begin with the following corollary which follows directly from Lemma 1.2.

COROLLARY 4.1. *Let X_0 be any normalized load vector describing an arbitrary allocation of some number m of balls to n bins. Let Δ be the difference between the maximum and the minimum load in X_0 . Let Y_0 be the normalized load vector describing the optimally balanced allocation of m balls into n bins (that is, each bin in Y_0 has either $\lfloor m/n \rfloor$ or $\lceil m/n \rceil$ balls). Let X_k and Y_k , respectively, denote the vectors obtained after inserting $k \geq 1$ further balls into both systems using Greedy[d]. For every constant α there is a constant c such that if $k \geq cn^7 \Delta \ln^4(n\Delta)$, then*

$$\|\mathcal{L}(X_k) - \mathcal{L}(Y_k)\| \leq k^{-\alpha}.$$

Proof. Let ℓ denote the minimum load of any bin in X_0 . We consider the scenario after removing ℓ balls from each bin in X_0 and Y_0 ; let X_0^* and Y_0^* be the respective load vectors. X_0^* and Y_0^* have an identical number of balls that we denote by m^* . Observe that since the maximum load in X_0 was $\ell + \Delta$, we have $m^* \leq n\Delta$.

Next, let X_t^* and Y_t^* , respectively, denote the vectors obtained after inserting $t \geq 1$ further balls to the systems corresponding to X_0^* and Y_0^* , where we use Greedy[d] to place the balls. We apply the Short Memory Lemma, Lemma 1.2, to the sequences X_t^* and Y_t^* to obtain that there is $\tau \leq c'm^* n^6 \ln^4(1/\varepsilon) \leq c'\Delta n^7 \ln^4(1/\varepsilon)$ for a suitable constant $c' > 0$, such that for every $t \geq \tau$ we have $\|\mathcal{L}(X_t^*) - \mathcal{L}(Y_t^*)\| \leq \varepsilon$. Therefore, if we set $\varepsilon = k^{-\alpha}$ and choose k such that it satisfies $k = c'\Delta n^7 \alpha \ln^4 k = O(n^7 \Delta \ln^4(n\Delta))$, we have $\|\mathcal{L}(X_k^*) - \mathcal{L}(Y_k^*)\| \leq k^{-\alpha}$.

Now, the claim follows from the fact that for every $t \geq 0$ the distributions of X_t and Y_t^* , and Y_t and Y_t^* , respectively, differ only in that every bin corresponding to X_t (Y_t) has ℓ less balls than the corresponding bin in X_t^* (Y_t^* , respectively). \square

Using Corollary 4.1, we present a general transformation which shows that the allocation obtained by an allocation process with “short memory” is more or less independent of the number of balls. The following theorem shows that the allocation (its distribution) is essentially determined after inserting a polynomial number of balls. In particular, this theorem together with Lemma 1.1 immediately imply Theorem 1.3. We assume that n is sufficiently large.

THEOREM 4.2. *Let us consider the process Greedy[d], $d \geq 2$, in which the balls are allocated into n bins. For any integer m , let $X_m = (x_1^{(m)}, \dots, x_n^{(m)})$ be a load vector obtained after allocating m balls with Greedy[d] and let $\tilde{X}_m = (x_1^{(m)} - \frac{m}{n}, \dots, x_n^{(m)} - \frac{m}{n})$. Let $N = n^{36}$. Then, for every M , $M \geq N$, that is a multiple of n ,*

$$\|\mathcal{L}(\tilde{X}_M) - \mathcal{L}(\tilde{X}_N)\| \leq N^{-\alpha},$$

where α denotes an arbitrary constant.

Proof. Let us first begin with the claim that if M and m are multiples of n with $M \geq n^{36}$ and $M \geq m \geq M^{0.8}$, then

$$(3) \quad \|\mathcal{L}(\tilde{X}_M) - \mathcal{L}(\tilde{X}_m)\| \leq M^{-\alpha}.$$

Let us set $m' = M - m$. We use the majorization from the single-choice process to estimate the distribution of the bins' loads after inserting m' balls. Since Greedy[d] is majorized by the single-choice process, each bin contains $\frac{m'}{n} \pm \mathcal{O}(\sqrt{m' \ln(n/p)/n})$ balls, with probability at least $1 - p$ for any $p \in [0, 1]$. We set $\Delta = M^{0.6}$ and $p = M^{-\alpha}/2$. Applying $M \geq m' \geq n$ yields that every bin contains between $\frac{m'}{n} - \Delta/2$ and $\frac{m'}{n} + \Delta/2$ balls, with probability at least $1 - p$, provided that n is sufficiently large. Let us now condition on this event and assume that the entries in $\tilde{X}_{m'}$ are in the Δ -range specified above.

Let Y describe another system in which the first m' balls are inserted in an optimal way; that is, $Y_{m'} = (\frac{m'}{n}, \dots, \frac{m'}{n})$. Now, we add m balls using protocol Greedy[d] on top of $X_{m'}$ and $Y_{m'}$, respectively. Now, applying Corollary 4.1, we obtain $\|\mathcal{L}(X_M) - \mathcal{L}(Y_M)\| \leq m^{-2\alpha} \leq M^{-\alpha}/2$ as $m \geq M^{0.8} \geq n^7 M^{0.6} \ln^4 M \geq c n^7 \Delta \ln^4(n \Delta)$, where c is the constant specified in the corollary. Thus, conditioned on the event that the values in $\tilde{X}_{m'}$ are in the interval $[\frac{m'}{n} - \Delta/2, \frac{m'}{n} + \Delta/2]$, we have $\mathcal{L}(\tilde{Y}_M) = \mathcal{L}(\tilde{X}_m)$, with probability at least $1 - M^{-\alpha}/2$. Therefore, since the condition is satisfied with probability at least $1 - M^{-\alpha}/2$ as well, we have

$$\|\mathcal{L}(\tilde{X}_M) - \mathcal{L}(\tilde{X}_m)\| \leq M^{-\alpha}/2 + \|\mathcal{L}(X_M) - \mathcal{L}(Y_M)\| \leq M^{-\alpha}/2 + M^{-\alpha}/2 = M^{-\alpha},$$

which completes the proof of inequality (3).

Finally, we use inequality (3) to prove Theorem 4.2. Observe first that if $M \leq N^{1/0.8}$, then (3) directly implies Theorem 4.2. Otherwise, we have to apply inequality (3) repeatedly as follows. Let m_0, m_1, \dots, m_k denote a sequence of integers such that $m_0 = N$, $m_k = M$, $m_i^{0.8} \leq m_{i-1}$, and $m_i^\alpha \geq 2m_{i-1}^\alpha$. Then

$$\|\mathcal{L}(\tilde{X}_M) - \mathcal{L}(\tilde{X}_N)\| \leq \sum_{i=1}^k \|\mathcal{L}(\tilde{X}_{m_i}) - \mathcal{L}(\tilde{X}_{m_{i-1}})\| \leq \sum_{i=1}^k m_i^{-\alpha} \leq N^{-\alpha},$$

where the last inequality follows from the fact that $m_i^{-\alpha} \leq 2^{-i} m_0^{-\alpha} = 2^{-i} N^{-\alpha}$. \square

Remark 2. It is easy to see that the proof above does not use any of the properties of Greedy[d] but the following two: Corollary 4.1 and the fact that Greedy[d] is majorized by the single-choice process. Therefore, Theorem 4.2 holds for any allocation protocol \mathcal{P} that has short memory (in the sense of Corollary 4.1) and that is majorized by the single-choice process.

5. Greedy[d] majorizes Left[d]. In this section, we will begin our analysis of the always-go-left allocation scheme and prove Theorem 1.7. Let $d \geq 2$, n be any multiple of d , and $m \geq 0$. We show that Left[d] is majorized by Greedy[d].

Our proof is by induction on the number of balls in the system. Let u denote the load vector obtained after inserting some number of balls with Left[d], and let v denote the load vector obtained after inserting the same number of balls with Greedy[d]. Without loss of generality, we assume that u and v are normalized, i.e., $u_1 \geq u_2 \geq \dots \geq u_n$ and $v_1 \geq v_2 \geq \dots \geq v_n$. Notice that the normalization of u jumbles the bins in the different groups used by Left[d] in some unspecified way so that it remains unclear which bin belongs to which group. Let u' and v' denote the load vectors obtained by adding another ball b with Left[d] and Greedy[d], respectively. To prove Theorem 1.7 by induction, we show that if $u \leq v$ then there is a coupling of Left[d] and Greedy[d] with respect to the allocation of b such that $u' \leq v'$, regardless of the unspecified mapping of the bins to the groups underlying u .

As a first step in the description of the coupling, we replace the original formulations of the allocation rules of the two random processes by alternative formulations that enable us to define an appropriate coupling.

- At first, we describe the alternative formulation of the allocation rules for Greedy[d]. For $1 \leq i \leq n$, let \mathbf{e}_i denote the i th unit vector, and define $b_i = \Pr[v' = v + \mathbf{e}_i]$. For $0 \leq i \leq n$, let $B_i = \sum_{j=1}^i b_j$; that is, B_i denotes the probability that the next ball is added to a bin with index at most i with respect to the considered order of bins. Without loss of generality, we assume that Greedy[d] gives the ball to the bin with larger index in case of a tie. Then $B_i = (i/n)^d$ because Greedy[d] places the ball b in a bin with index smaller than or equal to i if and only if all of the d locations of b point to bins whose indices are at most i . Instead of inserting the next ball using the rules of Greedy[d], we now choose a continuous random variable x uniformly at random from the interval $[0, 1]$ and allocate b in the i th bin if $B_{i-1} < x \leq B_i$. By our construction, this results in the same distribution.
- Now we turn our attention to Left[d]. Given any allocation of the balls to bins corresponding to the load vector u , define $a_i = \Pr[u' = u + \mathbf{e}_i]$ for $1 \leq i \leq n$ and $A_i = \sum_{j=1}^i a_j$ for $0 \leq i \leq n$. Observe that the probabilities a_i and A_i do not depend only on the index i (as in the case of Greedy[d]) or the vector u , but also on the hidden mapping of the bins to the groups. Consequently, we cannot specify these terms as a functional of i or u . Nevertheless, for any given mapping of the bins to groups, the terms A_0, \dots, A_n are well defined so that we can replace the original allocation rules by the following rule that results in the same distribution: Choose a random variable x uniformly at random from the interval $[0, 1]$ and allocate the ball b into the i th bin if $A_{i-1} < x \leq A_i$.

For the coupling, we now assume that Left[d] and Greedy[d] use the same random number x to assign the ball b . By our construction, this coupling is faithful. Under the coupling, we have to show $u' \leq v'$. Let $u' = u + \mathbf{e}_i$ and $v' = v + \mathbf{e}_j$ for some i and j ; that is, i and j specify the indices of the bins in the vectors u and v into which Left[d] and Greedy[d], respectively, put the ball b .

First, let us assume that the initial vectors u and v are equal. In this case, we have to show that $u + \mathbf{e}_i \leq u + \mathbf{e}_j$. Consider the plateaus of u , i.e., maximal index sets of bins with the same height. Suppose there are $k \geq 2$ plateaus U_1, \dots, U_k such that the load is decreasing from U_1 to U_k . Let I and J denote the indices of the plateaus that contain i and j , respectively. Observe that $I \geq J$ implies $u + \mathbf{e}_i \leq u + \mathbf{e}_j$ because adding a ball to different positions of the same plateau results in the same normalized vector. Thus, we have only to show that $J \leq I$. Let $\ell = \max\{U_I\}$. Since $i \leq \ell$, we have $x \leq A_\ell$. In the following lemma, we show that $A_\ell \leq (\ell/n)^d$. Above we have shown that $B_\ell = (\ell/n)^d$. Therefore, the lemma implies $x \leq B_\ell$, which shows that Greedy[d] places its ball in a bin with index at most ℓ ; that is, $j \leq \ell$ and, hence, $J \leq I$. Consequently, $u + \mathbf{e}_i \leq u + \mathbf{e}_j$.

LEMMA 5.1. *For any mapping of the bins to the groups underlying the vector u , $A_\ell \leq (\ell/n)^d$.*

Proof. Recall that A_ℓ corresponds to the probability that Left[d] places the ball b in a location with index (with respect to u) smaller than or equal to ℓ . Let ℓ_k for $0 \leq k < d$ denote the number of bins in group k with load greater than or equal to u_ℓ . Then $A_\ell = \prod_{k=0}^{d-1} \frac{\ell_k}{n/d}$ because the k th location of b must be one of those ℓ_k bins among the d/n bins in group k that have load at least u_ℓ . Since $\sum_{k=0}^{d-1} \ell_k = \ell$, A_ℓ is

maximized for $\ell_0 = \dots = \ell_{d-1} = \ell/d$. Consequently, $A_\ell \leq (\ell/n)^d$. \square

Until now we have analyzed only the case when $u = v$ and have shown $u + \mathbf{e}_i \leq u + \mathbf{e}_j$. This, however, can be easily generalized to arbitrary normalized load vectors. Indeed, for any two normalized load vectors w and w' , $w \leq w'$ implies $w + \mathbf{e}_i \leq w' + \mathbf{e}_i$, cf. [1, Lemma 3.4]. Consequently, we can conclude from $u + \mathbf{e}_i \leq u + \mathbf{e}_j$ that $u' = u + \mathbf{e}_i \leq u + \mathbf{e}_j \leq v + \mathbf{e}_j = v'$. Thus, Theorem 1.7 is shown.

6. Analysis of Left[d]. In this section, we investigate the allocation generated by Left[d]. In particular, we prove Theorem 1.5, that is, we show that the number of bins with load at least $\frac{m}{n} + i + \gamma$ is at most $n \cdot \exp(-\phi_d^{d \cdot i})$, w.h.p., where ϕ_d denotes the d -ary golden ratio (cf. section 1.1) and γ is a suitable constant. Similarly to the proof for Greedy[d], we divide the set of balls into batches of size n and we apply an induction on the number of batches. On one hand, the proof for Left[d] is slightly more complicated since we have to take into account that the set of bins is partitioned into d groups. On the other hand, we can avoid the detour through analyzing the holes below average height as we can instead make use of the majorization of Left[d] by Greedy[d].

For the time being, let us assume that $m \geq n \log_2 n$. We will use the majorization from Greedy[d] to estimate the allocation after allocating the first $m' = m - n \log_2 n$ balls. The special properties of Left[d] will only be taken into account for the remaining $n \log_2 n$ balls. Let us divide the set of these balls into $\log_2 n$ batches of size n each. Let time 0 denote the point of time before the first ball from batch 1 is inserted, that is, after inserting the first m' balls; and, for $1 \leq t \leq \log_2 n$, let time t denote the point of time after inserting the balls from batch t . Furthermore, set $\Gamma = \frac{m'}{n} + 7$ and, for $i \geq 0, 0 \leq j < d, 0 \leq t \leq \log_2 n$, let $\nu_{i,j}^{(t)}$ denote the number of bins with load at least $\Gamma + t + i$ in group j at time t . The following lemma gives an upper bound on the allocation of Left[d] obtained by the majorization from Greedy[d] at time 0. This upper bound is specified in terms of the function

$$h_0(i) = \frac{1}{4^i \cdot 64d}.$$

Later we will use the same lemma to estimate parts of the allocation also for other points of time, $t \geq 1$.

LEMMA 6.1. *Let ℓ denote the smallest integer such that $h_0(\ell) \leq n^{-0.9}$, i.e., $\ell = \lfloor 0.9 \log_4 n - \log_4 d \rfloor - 2$. For $0 \leq i < \ell, 0 \leq j < d, 0 \leq t \leq \log_2 n$, it holds $\nu_{i,j}^{(t)} \leq h_0(i) \cdot n/d$, w.h.p. For $i \geq \ell, \nu_{i,j}^{(t)} = 0$, w.h.p.*

Proof. Fix a time step t . Theorem 1.3 shows that, when using Greedy[d], the fraction of bins with load at least $\frac{m'}{n} + t + i$ is upper-bounded by a function that decreases doubly exponentially in i . Now, in order to simplify the subsequent calculations, we upper-bound this function by another function that decreases only exponentially in i , namely, the function h_0 . With lots of room to spare, the analysis in section 2.3 yields that the fraction of bins with load at least $\Gamma + t + i$ can be upper-bounded by $h_0(i)/(2d)$, w.h.p., provided n is sufficiently large. This result holds for Greedy[d], and we want to apply it to Left[d] via majorization. In order to make use of the majorization of Left[d] by Greedy[d], we need a bound on the number of balls above some given height rather than a bound on the number of bins with load above the height. However, since the bound given above on the number of bins decreases geometrically in i , the number of balls of height at least $\Gamma + t + i$ when using Greedy[d] is bounded from above by $h_0(i) \cdot n/d$. Now, because of the majorization, this result holds for Left[d], too. In turn, the number of balls above height $\Gamma + t + i$ upper-bounds

the number of bins with load at least $\Gamma + t + i$. Hence, when using $\text{Left}[d]$, the total number of bins with load at least $\Gamma + t + i$ is bounded from above by $h_0(i) \cdot n/d$. Of course, the same upper bound holds for the number of such bins in each individual group.

Finally, it remains to be shown that $\nu_{i,j}^{(t)} = 0$, w.h.p., for $i \geq \ell$ with $\ell = \lfloor 0.9 \log_4 n - \log_4 d \rfloor - 2$. Again this follows via majorization from $\text{Greedy}[d]$. Theorem 1.3 implies that the maximum load of $\text{Greedy}[d]$ and, hence, also of $\text{Left}[d]$ at time t is bounded from above by $\Gamma + t + O(\log_d \log n)$, w.h.p. Thus there is no ball with height $\Gamma + t + \ell$, w.h.p. \square

Before we turn to the technical details, let us explain the high-level idea behind the following analysis. We will use a function $f(k, t)$ as an upper bound for $\nu_{\lfloor k/d \rfloor, j \bmod d}^{(t)}$. For $t = 0$, $f(k, t)$ will be set equal to $h_0(\lfloor k/d \rfloor)$, and we will use the above lemma to show that $f(k, 0)$ upper-bounds $\nu_{\lfloor k/d \rfloor, k \bmod d}^{(0)}$. When increasing t , the function $f(k, t)$ will become more similar to the function $h_1(k)$ defined by

$$h_1(k) = \frac{\exp(-F_d(k - d + 1))}{64d},$$

where $F_d(k)$ denotes the k th d -ary Fibonacci number as defined in section 1.1. Let $i = \lfloor k/d \rfloor$ and $j = k \bmod d$. Then $h_1(k)$ will serve as an upper bound on the fraction of bins with height $\Gamma + t + i$ in group j . As explained in section 1.1, we use the d -ary golden ratio to upper-bound the d -ary Fibonacci numbers. This way,

$$h_1(k) = \frac{\exp(-\phi_d^{k \pm O(d)})}{64d} = \frac{\exp(-\phi_d^{(i \pm O(1))d})}{64d}.$$

Hence, for large t , the fraction of bins with some given height decreases ‘‘Fibonacci exponentially’’ with the height, exactly as described in Theorem 1.5.

Now we come to the technical details. We define

$$f(k, t) = \max\{h_0(\lfloor k/d \rfloor) \cdot 2^{-t}, h_1(k)\}.$$

Observe that f changes smoothly from h_0 into h_1 when increasing t . In particular, $f(k, 0) = h_0(\lfloor k/d \rfloor)$ and $f(k, \log_2 n) \leq h_1(k) + \frac{1}{n}$. We need to refine the function f slightly. Intuitively, we truncate the function when the function values become ‘‘too small.’’ Let c denote a sufficiently large constant term, whose value will be specified later. Let ℓ_t denote the smallest integer such that $f(\ell_t, t) \leq n^{-0.9}$. We set

$$f'(k, t) = \begin{cases} \max\left\{\frac{n^{-0.9}}{4}, f(k, t)\right\} & \text{if } 0 \leq k < \ell_t + d, \\ \frac{cd}{n} & \text{if } k \geq \ell_t + d. \end{cases}$$

The following properties of f' are crucial for our analysis. They hold only if n is sufficiently large.

LEMMA 6.2.

- B1. $f'(k, t) = h_0(0)$ for $0 \leq k < d, t \geq 0$;
- B2. $f'(k, t) \geq 2 \cdot f'(k + d, t - 1)$ for $d \leq k < \ell_t + d, t \geq 1$;
- B3. $f'(k, t) \geq (4d) \cdot \prod_{j=1}^d f'(k - j, t)$ for $d \leq k < \ell_t + d, t \geq 0$;
- B4. $f'(k, t) \geq n^{-0.9}/4$ for $d \leq k < \ell_t, t \geq 0$.

Proof. We start with the proof of property B1. First, let us check the property for f instead of f' . For $0 \leq k < d$, $F_d(k - d + 1) = 0$ so that $h_1(k) = 1/(64d) = h_0(0)$. Hence, for every $t \geq 0$,

$$f(k, t) = \max\{h_0(\lfloor k/d \rfloor) \cdot 2^{-t}, h_1(k)\} = h_0(0).$$

If n is sufficiently large then the same is true for f' .

Next we show property B2, first for f and then for f' . The function $f(k, t)$ is defined by the maximum of the two terms $h_0(\lfloor k/d \rfloor) \cdot 2^{-t}$ and $h_1(k)$. We study these terms one after the other. The definition of h_0 immediately implies

$$h_0(\lfloor k/d \rfloor) \cdot 2^{-t} = 4h_0(\lfloor (k + d)/d \rfloor) \cdot 2^{-t} = 2h_0(\lfloor (k + d)/d \rfloor) \cdot 2^{-(t-1)}.$$

Furthermore, for $k \geq d$,

$$h_1(k) = \frac{\exp(-F_d(k - d + 1))}{64d} \geq \frac{2 \exp(-F_d(k + 1))}{64d} = 2h_1(k + d).$$

As a consequence, $f(k, t) \geq 2f(k + d, t - 1)$, that is, B2 is shown for f . The refinement from f to f' might raise the right-hand side of the inequality from $2f(k + d, t - 1)$ to the value $2n^{-0.9}/4$, or the right-hand side might take the value $2cd/n$. At first, suppose $f'(k + d, t - 1) = n^{-0.9}/4$. Then $k < \ell_{t-1}$ so that $f(k, t - 1) \geq n^{-0.9}$. Now this implies $f(k, t) \geq n^{-0.9}/2$ as $f(k, t) \geq f(k, t - 1)/2$. Consequently,

$$f'(k, t) = \max \left\{ f(k, t), \frac{n^{-0.9}}{4} \right\} \geq \frac{n^{-0.9}}{2} = 2f'(k + d, t - 1).$$

In the second case, $f'(k + d, t - 1) = cd/n$. Observe that property B2 needs to be shown only for $k < \ell_t + d$. For this choice of k , $f'(k, t) \geq n^{-0.9}/4$ so that $f'(k, t) \geq 2f'(k + d, t - 1)$ if n is sufficiently large. Hence, B2 is shown.

Property B3 is shown as follows. Again we first show the property for f and then for f' . Fix $k \geq d$. Depending on the outcome of the terms $f(k - d, t), \dots, f(k - 1, t)$, we distinguish two cases. First, suppose there exists $\delta \in \{1, \dots, d\}$ such that $f(k - \delta, t) = h_0(\lfloor (k - \delta)/d \rfloor) \cdot 2^{-t}$. Observe that $h_0(\lfloor (k - \delta)/d \rfloor) \leq h_0(\lfloor k/d \rfloor - 1) = 4 h_0(\lfloor k/d \rfloor)$. We obtain

$$\begin{aligned} \prod_{j=1}^d f(k - j, t) &= h_0(\lfloor (k - \delta)/d \rfloor) \cdot 2^{-t} \cdot \prod_{\substack{j=1 \\ j \neq \delta}}^d f(k - j, t) \\ &\leq 4 h_0(\lfloor k/d \rfloor) \cdot 2^{-t} \cdot \left(\frac{1}{64d}\right)^{d-1} \\ &\leq \frac{h_0(\lfloor k/d \rfloor) \cdot 2^{-t}}{4d} \\ &\leq \frac{f(k, t)}{4d}. \end{aligned}$$

Second, suppose $f(k - \delta, t) = h_1(k - \delta)$ for all $\delta \in \{1, \dots, d\}$. Then

$$\begin{aligned} \prod_{j=1}^d f(k - j, t) &= \prod_{j=1}^d \frac{\exp(-F_d(k - j - d + 1))}{64d} \\ &= \frac{\exp\left(-\sum_{j=1}^d F_d(k - j - d + 1)\right)}{(64d)^d} \\ &\leq \frac{\exp(-F_d(k - d + 1))}{(4d)(64d)} \\ &= \frac{h_1(k)}{4d} \\ &\leq \frac{f(k, t)}{4d}. \end{aligned}$$

The refinement from f to f' affects the above proof only if $f'(k, t) \neq f(k, t)$, since otherwise, $f(k - \delta, t) = f'(k - \delta, t)$ for all $0 \leq \delta \leq d$, so that the above arguments hold. If $f'(k, t) \neq f(k, t)$ then $f'(k, t) = n^{-0.9}/4$. In this case, either $f'(k - 1, t)$ might take the value $n^{-0.9}/4$ as well or it takes the value $f(k - 1, t)$. In the latter case, B3 follows by the same arguments as before, if we additionally apply $f(k, t) \leq n^{-0.9}/4 = f'(k, t)$. If both $f'(k, t)$ and $f'(k - 1, t)$ take the value $n^{-0.9}/4$, then

$$\prod_{j=1}^d f(k - j, t) \leq \frac{n^{-0.9}}{4} \cdot \prod_{j=2}^d f(k - j, t) \leq \frac{n^{-0.9}}{4} \cdot \frac{1}{4d} = \frac{f(k, t)}{4d}.$$

Thus, B1, B2, and B3 hold for f and f' . B4 does not hold for f . However, our refinement explicitly ensures this property for f' . \square

Based on these properties we prove now that the following invariants hold w.h.p. for every $t \in \{0, \dots, \log_2 n\}$. We say that a ball has *index k at time t* if the ball belongs to one of the batches $1, \dots, t$ and it is placed in group $k \bmod d$ with height $\lfloor (\Gamma + t + k)/d \rfloor$.

- $H_1(t)$: $\nu_{i,j}^{(t)} \leq f'(id + j, t) \cdot n/d$ for $i \geq 0, 0 \leq j < d$.
- $H_2(t)$: The number of balls with index at least $\ell_t + d$ at time t is bounded from above by a constant term c .

Observe that these invariants imply the bounds given in Theorem 1.5 as the function $f'(i, \log_2 n)$ decreases ‘‘Fibonacci exponentially’’ in i as discussed above.

We show the invariants H_1 and H_2 by an induction on the number of rounds t . Lemma 6.1 gives that the invariants hold at time 0. In the following, we prove that $H_1(t)$ and $H_2(t)$ hold w.h.p. assuming that $H_1(t - 1)$ and $H_2(t - 1)$ are given. Fix $t \in \{1, \dots, \log_2 n\}$. First, we consider $H_1(t)$. We prove this invariant by a further induction on $k = id + j$. Observe that we need only to prove the invariant for $k < \ell_t + d$ as the upper bound given for $k \geq \ell_t + d$ is a direct consequence of invariant H_2 . For $k \in \{0, \dots, d - 1\}$, property B1 gives $f'(k, t) = h_0(0)$. Hence, for $k < d$, invariant H_1 follows again directly from Lemma 6.1.

Now assume $d \leq k < \ell_t + d$. Suppose $H_1(t)$ is shown for all $k' < k$. For $i = \lfloor k/d \rfloor$ and $j = k \bmod d$, let $q(k) = q(i, j)$ denote the number of bins of group j containing $\Gamma + t + i$ balls already at the beginning of round t , and let $p(k) = p(i, j)$ denote the number of balls from batch t that are placed into a bin of group j that contains at least $\Gamma + t + i - 1$ balls. Clearly,

$$\nu_{i,j}^{(t)} \leq q(k) + p(k).$$

In the following, we calculate upper bounds for $q(k)$ and $p(k)$.

Observe that $q(k) = q(i, j)$ corresponds to $\nu_{i+1,j}^{(t-1)}$. Hence, invariant $H_1(t-1)$ gives

$$q(k) \leq f'((i+1)d + j, t-1) \cdot \frac{n}{d} \leq f'(k+d, t-1) \cdot \frac{n}{d} \stackrel{\text{(B2)}}{\leq} 0.5 \cdot f'(k, t) \cdot \frac{n}{d}$$

for $d \leq k < \ell_t + d$.

The term $p(k) = p(i, j)$ can be estimated as follows. If a ball is placed into a bin of group j with $\Gamma + t + i - 1$ balls, the d possible locations for that ball fulfill the following conditions. The randomly picked location from group g , $0 \leq g < j$, points to a bin with load at least $\Gamma + t + i$. (Otherwise, the always-go-left scheme would assign the ball to that location instead of location j .) At the ball's insertion time the number of these bins is at most $\nu_{i,g}^{(t)}$. By the induction on k , $\nu_{i,g}^{(t)} \leq f'(i \cdot d + g, t) \cdot n/d$. Thus, the probability that the location points to a suitable bin is at most $f'(i \cdot d + g, t)$. Furthermore, the randomly picked location from group g , $j \leq g < d$, points to a bin with load at least $\Gamma + t + i - 1$. At the ball's insertion time, the number of these bins is at most $\nu_{i-1,g}^{(t)}$. Thus, the probability for this event is at most $f'((i-1) \cdot d + g, t)$. Now multiplying the probabilities for all d locations yields that the probability that a fixed ball is allocated to group j with height $\Gamma + t + i$ or larger is at most

$$\prod_{g=0}^{j-1} f'(i \cdot d + g, t) \cdot \prod_{g=j}^{d-1} f'((i-1) \cdot d + g, t) = \prod_{g=1}^d f'(k-g, t) \stackrel{\text{(B3)}}{\leq} \frac{f'(k, t)}{4d}$$

for $d \leq k < \ell_t + d$. Taking into account all n balls of batch t , we obtain $\mathbf{E}[p(k)] \leq n \cdot f'(k, t)/(4d)$. Applying a Chernoff bound yields

$$\Pr \left[p(k) \geq 2n \cdot \frac{f'(k, t)}{4d} \right] \leq \exp \left(-n \cdot \frac{f'(k, t)}{8d} \right) \stackrel{\text{(B4)}}{\leq} \exp \left(-\frac{n^{0.1}}{32d} \right).$$

As a consequence, $p(k) \leq 0.5f'(k, t) \cdot n/d$, w.h.p.

Combining the bounds on $q(k)$ and $p(k)$ gives

$$\nu_{i,j}^{(t)} \leq q(k) + p(k) \leq f'(k, t) \cdot \frac{n}{d} \leq f'(id + j, t) \cdot \frac{n}{d}$$

for $d \leq k = id + j < \ell_t + d$. Thus, invariant $H_1(t)$ is shown.

Now we turn to the proof of $H_2(t)$. For $s \geq 0$, let L_s denote the number of balls with index at least $\ell_s + d$ at time s . Using this notation, invariant $H_2(t)$ states that $L_t \leq c$. For $s \geq r \geq 1$, let $L_s(r)$ denote the number of balls from batch r with index at least $\ell_s + d$ at time s . We claim

$$L_t = \sum_{s=1}^t L_t(s) \leq \sum_{s=1}^t L_s(s).$$

The first equation follows directly from the definition. The second equation can be seen as follows. First, observe that ℓ_{s-1} might be larger than ℓ_s as the function f' decreases over time. However, property B2 combined with the fact that f' decreases by at most a factor of two from time $s-1$ to time s yields $\ell_{s-1} \leq \ell_s + d$ for every $s \geq 0$, which implies $L_s(r) \leq L_{s-1}(r)$ for every $r \leq s-1$. By induction, we obtain $L_t(r) \leq L_s(r)$ for $r \leq s \leq t$ and especially $L_t(s) \leq L_s(s)$.

Let us study the probability that a fixed ball from batch s has index at least $\ell_s + d$ at time s and, hence, contributes to $L_s(s)$. This event happens only if each of the d randomly selected locations of the ball points to a bin whose topmost ball has index at least $\ell_s + d - d = \ell_s$. Invariant $H_1(s)$ yields that the fraction of such bins in each group is at most $f(\ell_s, s) \leq n^{-0.9}$. Thus, the probability that a ball from batch s contributes to $L(s)$ is at least $n^{-0.9d} \leq n^{-1.8}$. Now let us estimate the probability that there exist c balls from the batches 1 to t that fulfill this condition. This probability is at most

$$\binom{tn}{c} \cdot \left(\frac{1}{n^{1.8}}\right)^c \leq \left(\frac{\log_2 n}{cn^{0.8}}\right)^c \leq n^{-c/2},$$

where the last inequality holds for sufficiently large n . Consequently, with probability at least $1 - n^{-c/2}$, $L_t \leq \sum_{s=1}^t L_s(s) \leq c$. Thus, we have shown that $H_1(0), \dots, H_1(t)$ imply $H_2(t)$, w.h.p. This completes the proof for the case $m \geq n \log_2 n$.

Finally, let us investigate the case $m < n \log_2 n$. We break the set of balls into at most $t \leq \log n$ batches. All batches except for the last one contain exactly n balls; only the last batch might contain less. We use a simplified variant of the above analysis. In particular, we define $f(k, t) = h_1(k)$ instead of $f(k, t) = \max\{h_0(\lfloor k/d \rfloor) \cdot 2^{-t}, h_1(k)\}$. The invariants H_1 and H_2 can be shown by the same arguments as before. The advantage is that the identity between $f(k, t)$ and $h_1(k)$ is given from the beginning on, so that one does not have to iterate for $\log_2 n$ batches until the two functions become similar. In other words, the invariants H_1 and H_2 imply the bounds described in the theorem already after the first batch as well as after all subsequent batches. This completes the proof of Theorem 1.5.

7. Conclusions. We have presented the first tight analysis of two balls-into-bins multiple-choice processes: the greedy protocol of Azar et al. [1] and the always-go-left scheme due to Vöcking [33]. We showed that these schemes result in a maximum load (w.h.p.) of only $\frac{m}{n} + \frac{\ln \ln n}{\ln d} + \Theta(1)$ and $\frac{m}{n} + \frac{\ln \ln n}{d \ln \phi_d} + \Theta(1)$, respectively. Both these bounds are tight up to additive constants. In addition, we have given upper bounds on the number of bins with any given load. Furthermore, we presented the first comparative study of the two multiple-choice algorithms and gave a majorization result showing that the always-go-left scheme obtains a stochastically better load balancing than the greedy scheme for any choice of d , n , and m .

Our important technical contribution is the Short Memory Lemma, which informally states that the multiple-choice processes quickly “forget” their initial distribution of balls. The great consequence of this property is that the deviation of the multiple-choice processes from the optimal allocation (that is, the allocation in which each bin has either $\lfloor m/n \rfloor$ or $\lceil m/n \rceil$ balls) does not increase with the number of balls as in the case of the single-choice process. This property played a fundamental role in our analysis. We also hope that it will find further applications in the analysis of allocation processes. In particular, we believe that the use of the Markov chain approach to estimate the mixing time of underlying stochastic processes will be an important tool in analyzing other balls-into-bins or similar processes.

Our calculations in section 2 use some help from computers; it would be interesting to come up with a more elegant analysis that would possibly provide more insight on the greedy process for a polynomial number of balls.

Acknowledgments. We thank anonymous referees for helpful suggestions. We are also grateful to Christian Scheideler for inspiring discussion about the paper.

LINEARIZATION AND COMPLETENESS RESULTS FOR TERMINATING TRANSITIVE CLOSURE QUERIES ON SPATIAL DATABASES*

FLORIS GEERTS[†], BART KUIJPERS[†], AND JAN VAN DEN BUSSCHE[†]

Abstract. We study queries to spatial databases, where spatial data are modeled as semi-algebraic sets, using the relational calculus with polynomial inequalities as a basic query language. We work with the extension of the relational calculus with terminating transitive closures. The main result is that this language can express the linearization of semialgebraic databases. We also show that the sublanguage with linear inequalities only can express all computable queries on semilinear databases. As a consequence of these results, we obtain a completeness result for topological queries on semialgebraic databases.

Key words. constraint databases, real algebraic geometry, transitive closure logics, query languages

1. Introduction. Spatial database systems [1, 8, 12, 24, 25, 42] are concerned with the representation and manipulation of data that have a geometric or topological interpretation. Conceptually, spatial databases store geometric figures, which are possibly infinite sets of points in a real space \mathbf{R}^n . The framework of constraint databases [34], introduced by Kanellakis, Kuper, and Revesz [27], provides an elegant and powerful model for spatial databases. In the setting of the constraint model, a geometric figure is finitely represented as a Boolean combination of polynomial equalities and inequalities over the real numbers. Such figures are known as semi-algebraic sets. Special cases of figures definable by linear polynomials are known as semilinear sets [6].

The relational calculus or first-order logic, expanded with polynomial equalities and inequalities and evaluated over the semialgebraic sets (viewed as relations over the reals) stored in the database, serves as a basic spatial query language and is denoted by FO+POLY. The special case of queries expressed using linear equalities and inequalities is denoted by FO+LIN. Several authors have argued that the restriction to linear polynomial constraints provides a sufficiently general framework for spatial database applications [21, 46, 47]. Indeed, in geographic information systems (GIS), which form one of the main application areas of spatial databases, linear representations are used to model spatial objects [34, Chapter 9]. Existing implementations of the constraint model, for instance, the work on the system DEDALE [19, 20, 21], are also restricted to linear polynomial constraints. Indeed, for these constraints, the evaluation of queries expressed in FO+LIN is conceptually easier and can be computed by numerous efficient algorithms for geometric operations on linear figures [38]. The computational complexity of evaluating an FO+LIN query on linear constraint

databases (NC^1) is also slightly lower than that of evaluating an $\text{FO}+\text{POLY}$ query on polynomial constraint databases (NC) [2, 22, 41].

Since the expressive power of the basic query languages $\text{FO}+\text{POLY}$ and $\text{FO}+\text{LIN}$ is rather limited [34, Chapters 5 and 6], it makes sense to consider more powerful extensions.

Various extensions with recursion have already been introduced and studied. Grumbach and Kuper [18] defined syntactic variants of DATALOG with linear constraints which capture exactly the queries on linear constraint databases in the plane, which have PTIME and PSPACE data complexity. Kreutzer [30] defines several recursive languages capturing PTIME and PSPACE on a restricted class of linear constraint databases. Termination properties of DATALOG with polynomial constraints are investigated by Kuijpers et al. [31] and Kuijpers and Smits [33].

In this paper, we study the expressive power of $\text{FO}+\text{POLY}$ (and $\text{FO}+\text{LIN}$) extended with the transitive closure operator (TC). Transitive closure is a simple form of recursion and we apply it only in a simple way; specifically, we do not apply TC to formulas with extra free variables (parameters), as is allowed in the standard definition of transitive closure logic [11].

In the first part of the paper, we show that when we extend the TC operator with explicit stop conditions, which we denote by TCS , the language $\text{FO}+\text{LIN}+\text{TCS}$ is computationally complete on the class of databases definable by linear polynomials with integer coefficients (\mathbf{Z} -linear databases). This means that for every partial computable query Q , there is a formula φ such that for every \mathbf{Z} -linear database D , the evaluation of φ on D terminates if and only if $Q(D)$ is defined and results in $Q(D)$. It remains an open problem whether $\text{FO}+\text{LIN}+\text{TC}$ (without explicit stop conditions) is also computationally complete in this sense. We point out that recently, Kreutzer [29] defined an extension of $\text{FO}+\text{LIN}$ with a different transitive closure operator and proved completeness on linear constraint databases as well (see the end of section 3 for more details).

In the second part of the paper, we investigate the expressive power of $\text{FO}+\text{POLY}+\text{TCS}$ on general polynomial constraint databases. In contrast to the linear case, we have not been able to establish the computational completeness. Yet, we will show that the language is complete as far as all Boolean topological queries are concerned.

In order to prove this result, we show that there is a formula of $\text{FO}+\text{POLY}+\text{TC}$ (no stop conditions are needed) that expresses *linearization*: when evaluated on an arbitrary semialgebraic set A , it results in a semilinear set \hat{A} topologically equivalent (i.e., homeomorphic) to A . Moreover, \hat{A} can be assumed to be a \mathbf{Z} -linear set.

Our linearization formula always terminates, in the sense that on any input A , every application of the TC operator in the formula converges after a finite number of stages. In the case when A is bounded, the linearization formula can be sharpened to produce a set \hat{A} that is arbitrarily close to the input set A .

The components of the linearization formula require a number of new geometric constructions in $\text{FO}+\text{POLY}$. More specifically, we introduce the uniform cone radius decomposition of semialgebraic sets. Using the result of Geerts [14], we show that this decomposition can be defined in $\text{FO}+\text{POLY}$. Also, we define the regular decomposition of semialgebraic sets and use the results of Rannou [39] to show that this decomposition is expressible in $\text{FO}+\text{POLY}$.

The linearization algorithm also implies that semialgebraic sets in \mathbf{R}^n can be linearized, a fact which has been known for a long time [7]. The standard constructive linearization (or triangulation) algorithm for semialgebraic sets, which is attributed

to Hardt [26], can be found in the standard textbook on real algebraic geometry [6, section 9.2] and in the more recent book on algorithms in real algebraic geometry [3, Chapter 5].

The difference of the existing linearization algorithm for semialgebraic sets is that the polynomials appearing in the description of the semialgebraic sets are used explicitly. This is not possible in our setting because we can only interact with the semialgebraic set using queries. Because of this, our algorithm is not likely to be as efficient as the existing algorithm (we did not compute the exact complexity though). Moreover, our linearization is based on the local conical behavior of semialgebraic sets, and the inductive construction based on these cones might be of interest in real algebraic geometry.

Finally, we use the linearization formula in the following two ways to show the expressibility in FO+POLY+TC of two common queries which are known to be not expressible in FO+POLY: (1) We show that the connectivity query on polynomial constraint databases is expressible by an always terminating formula in FO+POLY+TC; (2) we show that there is a formula in FO+POLY+TC that always has a terminating evaluation and that evaluates on a given bounded semialgebraic set A to a number that is arbitrarily close to the volume of A .

We remark that some of the above results were already described (in considerably less detail) for two dimensions [16] and arbitrary dimensions [13].

This paper is organized as follows. Section 2 gives the definition of polynomial constraint databases and defines the standard first-order query languages. Section 3 extends these languages with a transitive closure operator. Section 4 studies the computational completeness of these extensions and gives some inexpressibility results of the first-order query languages. Section 5 provides geometric tools necessary for the linearization construction. Section 6 presents the construction itself and discusses applications of linearization (testing connectivity and approximating the volume).

2. Preliminaries. We denote the set of real numbers by \mathbf{R} , the set of algebraic numbers by \mathbf{A} , the set of integers by \mathbf{Z} , and the set of natural numbers by \mathbf{N} .

A *semialgebraic set in \mathbf{R}^n* is a finite union of sets definable by conditions of the form

$$f_1(\vec{x}) = f_2(\vec{x}) = \dots = f_k(\vec{x}) = 0, \quad g_1(\vec{x}) > 0, \quad g_2(\vec{x}) > 0, \dots, g_\ell(\vec{x}) > 0,$$

where $\vec{x} = (x_1, \dots, x_n) \in \mathbf{R}^n$, and where $f_1(\vec{x}), \dots, f_k(\vec{x}), g_1(\vec{x}), \dots, g_\ell(\vec{x})$ are multivariate polynomials in the variables x_1, \dots, x_n with integer coefficients. A *\mathbf{Z} -linear (A-linear) set in \mathbf{R}^n* is a semialgebraic set which can be defined in terms of linear polynomials with *integer (algebraic)* coefficients.

A *database schema \mathcal{S}* is a finite set of relation names, each with a given arity. A *polynomial constraint database D over \mathcal{S}* assigns to each $S \in \mathcal{S}$ a semialgebraic set S^D in \mathbf{R}^k , where k is the arity of S . A *\mathbf{Z} -linear (A-linear) constraint database* assigns to each $S \in \mathcal{S}$ a \mathbf{Z} -linear (A-linear) set S^D in \mathbf{R}^k , where k is the arity of S . A *k -ary query over \mathcal{S}* is a partial function Q that maps each database D over \mathcal{S} to a k -ary relation $Q(D) \subseteq \mathbf{R}^k$.

First-order logic over the vocabulary $(+, \times, 0, 1, <)$ expanded with the database schema \mathcal{S} provides a basic query language which we denote by FO+POLY. The sublanguage of FO+POLY consisting of the formulas that do not use multiplication is denoted by FO+LIN.

Every formula $\varphi(x_1, \dots, x_k)$ in FO+POLY expresses a k -ary query as follows: Let D be a database over \mathcal{S} ; then

$$\varphi(D) = \{(a_1, \dots, a_k) \in \mathbf{R}^k \mid \langle \mathbf{R}, D \rangle \models \varphi(a_1, \dots, a_k)\}.$$

Here, by $\langle \mathbf{R}, D \rangle$ we mean the standard structure of the reals $\langle \mathbf{R}; +, \times, 0, 1, < \rangle$ expanded with the relations (semialgebraic sets) in D .

Example 2.1. Suppose that \mathcal{S} contains the binary relation name S . Then the FO+POLY formula

$$\varphi(x, y) \equiv \exists \varepsilon \forall x' \forall y' (\varepsilon > 0 \wedge ((x - x')^2 + (y - y')^2 < \varepsilon \rightarrow S(x', y')))$$

expresses the query that maps any database D over \mathcal{S} to the interior of S^D . \diamond

FO+POLY queries can be effectively evaluated as follows. Let $\varphi(x_1, \dots, x_k)$ be an FO+POLY formula over schema \mathcal{S} , and let D be a database over \mathcal{S} . For every $S \in \mathcal{S}$, we represent the set S^D by some quantifier-free polynomial constraint formula $\psi_S(y_1, \dots, y_k)$, where k is the arity of S , that defines S^D in the sense that $S^D = \{(a_1, \dots, a_k) \in \mathbf{R}^k \mid \mathbf{R} \models \psi_S(a_1, \dots, a_k)\}$. Now replace in φ every subformula of the form $S(z_1, \dots, z_k)$ with $\psi_S(z_1, \dots, z_k)$. Making these replacements for every $S \in \mathcal{S}$, we obtain a polynomial constraint formula which we denote by φ^D and which defines $\varphi(D)$ in the sense that $\varphi(D) = \{(a_1, \dots, a_k) \in \mathbf{R}^k \mid \mathbf{R} \models \varphi^D(a_1, \dots, a_k)\}$.

Because first-order logic over the reals admits quantifier elimination [43], we can rewrite φ^D in a quantifier-free form from which we can conclude that $\varphi(D)$ is always a semialgebraic set. This is called the closure principle. The reals without multiplication also admit quantifier elimination, so in the same way, if D is semilinear and φ is in FO+LIN, then $\varphi(D)$ is also semilinear. Thus, there is also a closure principle for FO+LIN provided we work with semilinear databases. For more information on FO+POLY and FO+LIN queries, we refer the reader to the literature [34].

3. Transitive closure logics. Many interesting spatial database queries are not expressible in the first-order query languages FO+POLY and FO+LIN, e.g., the query that asks whether a given set is topologically connected or not. Therefore, it makes sense to consider extensions of FO+POLY (or FO+LIN) with recursion to obtain more powerful query languages. We study one of the most simple recursion constructs in this context, i.e., the transitive closure operator TC.

An immediate observation is that TC cannot be added “just like that” with its standard mathematical semantics without losing the important closure principle.

Example 3.1. The transitive closure of the semialgebraic set $\{(x, y) \in \mathbf{R}^2 \mid y = 2x\}$ equals $\{(x, y) \in \mathbf{R}^2 \mid \exists i \in \mathbf{N} : y = 2^i x\}$, which is not a semialgebraic set. \diamond

Therefore, we look at the TC operator quite naturally as a programming construct with a purely operational semantics. For example, we will look at the transitive closure example just mentioned simply as a nonterminating computation. Almost all programming languages allow for the expression of nonterminating computations, and it is part of the programmer’s job to avoid writing such programs.

A formula in FO+POLY+TC is a formula built in the same way as an FO+POLY formula, but with the following extra formation rule: If $\psi(\vec{x}, \vec{y})$ is a formula with \vec{x}, \vec{y} k -tuples of variables, and \vec{s}, \vec{t} are k -tuples of terms, then

$$(3.1) \quad [\text{TC}_{\vec{x}; \vec{y}} \psi](\vec{s}, \vec{t})$$

is also a formula which has as free variables those in \vec{s} and \vec{t} . Since the only free variables in $\psi(\vec{x}, \vec{y})$ are those in \vec{x} and \vec{y} , we do not allow parameters in applications

of the TC operator, as are allowed in general transitive closure logic studied in finite model theory [11]. With parameters, it is not so clear how to preserve the simple and elegant operational semantics we define next.

The semantics of a subformula of the above form (3.1) evaluated on a database D is defined in the following operational manner:

1. Evaluate, recursively, $\psi(D)$.
2. Start computing the following iterative sequence of $2k$ -ary relations:

$$\begin{aligned} X_0 &:= \psi(D), \\ X_{i+1} &:= X_i \cup \{(\vec{x}, \vec{y}) \in \mathbf{R}^{2k} \mid \exists \vec{z}(X_i(\vec{x}, \vec{z}) \wedge X_0(\vec{z}, \vec{y}))\}. \end{aligned}$$

Stop as soon as an i has been found such that $X_i = X_{i+1}$.

3. The semantics of $[\text{TC}_{\vec{x};\vec{y}} \psi](\vec{s}, \vec{t})$ is now defined as the $2k$ -ary relation X_i .

Since every step in the above algorithm, including the test for $X_i = X_{i+1}$, is expressible in FO+POLY, every step is effective and the only reason why the evaluation may not be effective is that the computation does not terminate. In that case the semantics of the formula (3.1) (and any other formula in which it occurs as subformula) is undefined.

The language FO+LIN+TC consists of all FO+POLY+TC formulas that do not use multiplication.

Example 3.2. Let S be a relation name of arity n . Consider the following FO+POLY+TC formula:

$$\mathbf{connected} \equiv \forall \vec{s} \forall \vec{t} ((S(\vec{s}) \wedge S(\vec{t})) \rightarrow [\text{TC}_{\vec{x};\vec{y}} \mathbf{lineconn}](\vec{s}, \vec{t})),$$

where $\mathbf{lineconn}(\vec{x}, \vec{y})$ is the formula

$$\forall \lambda (0 \leq \lambda \leq 1 \wedge \forall \vec{t} (\vec{t} = \lambda \vec{x} + (1 - \lambda) \vec{y} \rightarrow S(\vec{t}))).$$

In section 6.5, we will prove that the TC-subformula in $\mathbf{connected}$ terminates on all linear constraint databases over \mathcal{S} . Note that a pair of points (\vec{p}, \vec{q}) belongs to the TC of $\mathbf{lineconn}(D)$ (with D semilinear) if and only if \vec{p} and \vec{q} belong to the same connected component of S^D . Hence, $\mathbf{connected}$ effectively expresses connectivity of semilinear sets. \diamond

We will sometimes want to be able to specify an explicit termination condition on transitive closure computations. To this end, we introduce the language FO+POLY+TCS.

Formulas in FO+POLY+TCS are again built in the same way as in FO+POLY but with the following extra formation rule: If $\psi(\vec{x}, \vec{y})$ is a formula with \vec{x}, \vec{y} k -tuples of variables; σ is an FO+POLY sentence (formula without free variables) over the schema \mathcal{S} expanded with a special $2k$ -ary relation name X ; and \vec{s}, \vec{t} are k -tuples of terms, then

$$(3.2) \quad [\text{TC}_{\vec{x};\vec{y}} \psi \mid \sigma](\vec{s}, \vec{t})$$

is also a formula which has as free variables those in \vec{s} and \vec{t} . We call σ the *stop condition* of this formula.

The semantics of a subformula of the above form (3.2) evaluated on databases D is defined in the same manner as in the case without stop condition, but now we stop not only in case an i is found such that $X_i = X_{i+1}$, but also in case an i is found such that $(D, X_i) \models \sigma$, whichever case occurs first.

FIG. 3.1. Illustration of the difference between transitive closure without stop condition (left) and with stop condition (right).

Example 3.3. Let S be a relation name of arity n in \mathcal{S} , and consider the FO+POLY+TCS formula

$$(3.3) \quad \varphi_1(s, t) \equiv [\text{TC}_{x;y} S](s, t)$$

and the formula

$$(3.4) \quad \varphi_2(s, t) \equiv [\text{TC}_{x;y} S \mid X(1, 8)](s, t).$$

On the database D over S , where $S^D = \{(x, y) \in \mathbf{R}^2 \mid y = 2x\}$, the evaluation of formula (3.3) does not terminate, but formula (3.4) evaluates in three iterations to $\{(s, t) \in \mathbf{R}^2 \mid t = 2s \vee t = 4s \vee t = 6s \vee t = 8s\}$. An illustration is given in Figure 3.1. \diamond

The language FO+LIN+TCS consists of all FO+POLY+TCS formulas that do not use multiplication.

An alternative way of controlling the computation of the transitive closure is provided by Kreutzer [29]. He allows a parametrized transitive closure operator in which the computation of the transitive closure can be restricted to certain paths (after specifying certain starting points).

It can be easily seen that any formula in FO+LIN+TC or FO+POLY+TC can be expressed by an equivalent formula in the corresponding logics of Kreutzer (see Geerts and Kuijpers [17]). Moreover, the transitive closure logic FO+LIN+KTC (the “K” stands for “Kreutzer”) is computationally complete on \mathbf{Z} -linear constraint databases [29]. As we will see in the next section, the same completeness result holds for FO+LIN+TCS. Hence, FO+LIN+KTC and FO+LIN+TCS are equally expressive on \mathbf{Z} -linear constraint databases. Despite this similarity, the way in which queries are expressed in each language is quite different. Indeed, FO+LIN+KTC has an “a priori” character because *starting* points have to be properly selected in order to obtain terminating formula. In FO+LIN+TCS, termination is forced by the *stop* conditions, which are of an “a posteriori” character.

We point out that termination properties of these logics on general polynomial constraint databases have already been studied [17]. However, a complete comparison of these logics on polynomial constraint databases is left open.

4. Expressivity results. In this section, we show a general result on the expressive power of FO+LIN+TCS. More specifically, we prove that FO+LIN+TCS is computationally complete on \mathbf{Z} -linear constraint databases (Theorem 4.4). The proof consists of three steps. In the first step, we show that any computable function on

the natural numbers can be simulated in FO+LIN+TCS (Lemma 4.1). In the second step, we show that there exists an encoding of \mathbf{Z} -linear constraint databases by finite sets of rational numbers, and show that both the encoding and the corresponding decoding are expressible in FO+LIN+TCS (Lemmas 4.2 and 4.3). This implies that FO+LIN+TCS is computationally complete on \mathbf{Z} -linear constraint databases.

For polynomial constraint databases, we show that FO+POLY+TCS is computationally complete for Boolean topological queries. This follows from the completeness on \mathbf{Z} -linear constraint databases and the existence of an FO+POLY+TC query that, given any polynomial constraint database as input, returns a \mathbf{Z} -linear constraint database which is topologically equivalent to the input. In this section we show that this “linearization query” is not expressible in FO+POLY. The FO+POLY+TC construction of the linearization query will be presented in section 6 (following preparations in section 5.1).

4.1. Recursive functions on the natural numbers. We first show that FO+LIN+TCS is computationally complete on the set of natural numbers \mathbf{N} .

LEMMA 4.1. *For every partial computable function $f : \mathbf{N}^k \rightarrow \mathbf{N}$, there exists a formula $\varphi_f(y)$ in FO+LIN+TCS over the schema $\mathcal{S} = \{S\}$, with S a k -ary relation, such that for any database D over \mathcal{S} with $S^D = \{(n_1, \dots, n_k)\}$, we have that $\varphi_f(D)$ is defined if and only if $f(n_1, \dots, n_k)$ is defined, and in this case $\varphi_f(D) = \{f(n_1, \dots, n_k)\}$.*

Proof. We show this by simulating the run of a nondeterministic p -counter machine M_f which computes f . Here $M_f = (Q, \delta, q_0, q_f)$, where Q is a finite set of internal states, $q_0 \in Q$ is the initial state, and $q_f \in Q$ is the final (halting) state. The set δ contains quadruples of the form $[q, i, s, q'] \in Q \times \{1, \dots, p\} \times \{Z, P\} \times Q$ or $[q, i, d, q'] \in Q \times \{1, \dots, p\} \times \{-, +\} \times Q$. The quadruple $[q, i, s, q']$ means that if M_f is in state q and the i th counter is equal to zero (when $s = Z$) or positive (when $s = P$), then change the state into q' . The quadruple $[q, i, d, q']$ means that if M_f is in state q , then increase the i th counter by one (when $d = +$), or decrease the i th counter by one (when $d = -$), and change the state into q' . We assume that $Q = \{0, 1, \dots, m-1, m\}$, $q_0 = 0$, and $q_f = m$. Moreover, we assume that $p \geq k$ and that the initial configuration of M_f when computing $f(n_1, \dots, n_k)$ has n_1, \dots, n_k as the values of the first k counters. When a halting state is reached, we assume that the first counter contains $f(n_1, \dots, n_k)$.

We define the first-order formula $\Psi_{\text{step}}(q, n_1, \dots, n_p, q', n'_1, \dots, n'_p)$, which describes a single step in a run of M_f . The formula Ψ_{step} is the disjunction of the following formulas for $[q, i, s, q']$ and $[q, i, d, q']$ in δ :

$$\Psi_{[q,i,Z,q']} \equiv Q(q) \wedge Q(q') \wedge n'_i = n_i = 0 \wedge \bigwedge_{j \in \{1, \dots, i-1, i+1, \dots, p\}} n_j = n'_j,$$

$$\Psi_{[q,i,P,q']} \equiv Q(q) \wedge Q(q') \wedge n'_i = n_i > 0 \wedge \bigwedge_{j \in \{1, \dots, i-1, i+1, \dots, p\}} n_j = n'_j,$$

$$\Psi_{[q,i,+,q']} \equiv Q(q) \wedge Q(q') \wedge n'_i = n_i + 1 \wedge \bigwedge_{j \in \{1, \dots, i-1, i+1, \dots, p\}} n_j = n'_j,$$

$$\Psi_{[q,i,-,q']} \equiv Q(q) \wedge Q(q') \wedge n'_i = n_i - 1 \wedge \bigwedge_{j \in \{1, \dots, i-1, i+1, \dots, p\}} n_j = n'_j.$$

We use the stop condition σ , which checks whether the final state has been reached starting from the initial state:

$$\sigma \equiv \exists y_1 \cdots \exists y_p \exists n_1 \cdots \exists n_k (S(n_1, \dots, n_k) \wedge X(0, n_1, \dots, n_k, \vec{0}_{p-k}, m, y_1, \dots, y_p)).$$

Here, $\vec{0}_\ell$ denotes the ℓ -tuple $(0, \dots, 0)$.

The desired formula $\varphi_f(y)$ extracts $f(n_1, \dots, n_k)$ from the first counter (represented by the variable y) when the stop condition is satisfied:

$$\begin{aligned} &\exists y_2 \cdots \exists y_p \exists n_1 \cdots \exists n_k (S(n_1, \dots, n_k) \\ &\quad \wedge [\text{TC}_{q, \vec{n}; q', \vec{n}'} \Psi_{\text{step}} \mid \sigma](0, n_1, \dots, n_k, \vec{0}_{p-k}, m, y, y_2, \dots, y_p)). \quad \square \end{aligned}$$

4.2. Finite representation of \mathbf{Z} -linear constraint databases.

LEMMA 4.2. *There exists an encoding of \mathbf{Z} -linear constraint databases into finite relational databases over the rationals, and a corresponding decoding, which are both expressible in FO+LIN+TCS.*

Proof. It was shown by Vandeurzen [46] and Vandeurzen, Gyssens, and Van Gucht [48] that any \mathbf{Z} -linear set in \mathbf{R}^n has a finite geometric representation by means of a finite set over \mathbf{Q} consisting of $(n + 1)^2$ -ary tuples. Basically, this geometric representation contains the projective coordinates¹ of a complete triangulation of the \mathbf{Z} -linear set. Moreover, this representation can be expressed in FO+POLY. Vandeurzen [46] and Vandeurzen, Gyssens, and Van Gucht [48] actually show that this representation can be expressed in an extension of FO+LIN with some limited amount of multiplicative power. Also, the corresponding decoding, which computes the \mathbf{Z} -linear constraint database given its finite geometric representation, can be expressed in this logic.

Hence, the lemma follows if we can show that FO+LIN+TCS can perform this limited amount of multiplication.

More specifically, we have to be able to express the multiplication of rationals q_i from a finite set $S = \{q_1, \dots, q_m\}$ with a real number x , i.e., $q_i x$ for $i = 1, \dots, m$. First, we express how integers n_i and d_i can be computed in FO+LIN+TCS such that $q_i = \frac{n_i}{d_i}$ for $i = 1, \dots, m$.

We assume that all rational numbers in the set S are positive. The case of all negative rational numbers is completely analogous. If both positive and negative rational numbers occur in the set, we separate the positive from the negative and treat both sets separately.

Consider the following enumeration $enum$ of pairs of natural numbers: $enum$ is a mapping from $\mathbf{N} \times \mathbf{N}$ to $\mathbf{N} \times \mathbf{N}$ defined by

$$enum : (i, j) \mapsto \begin{cases} (i + 1, j - 1) & \text{if } j > 0, \\ (0, i + 1) & \text{if } j = 0. \end{cases}$$

For every pair $(p, q) \in \mathbf{N} \times \mathbf{N}$, there clearly exists $k \in \mathbf{N}$ such that $enum^k(0, 0) = (p, q)$. We shall interpret (p, q) as the rational number $\frac{p}{q}$ in case $q \neq 0$ and as 0 otherwise.

Given a rational number q and two natural numbers n and d , we can test in FO+LIN+TCS whether $q = \frac{n}{d}$. This test can be performed as follows. Let $frac : \mathbf{R}^3 \rightarrow \mathbf{R}^3$ be the mapping defined as

$$frac : (q, j, v) \mapsto (q, j - 1, v + q).$$

¹Projective coordinates are used to deal with unbounded databases and the unbounded simplices in their triangulation.

Then for given $q \in \mathbf{Q}$ and $n, d \in \mathbf{N}$, we have that $q = \frac{n}{d}$ if and only if $\text{frac}^d(q, d, 0) = (q, 0, n)$.

To find the numerator and denominator of a rational number q , we will enumerate all pairs of natural numbers $(n, d) = \text{enum}^k(0, 0)$, $k = 0, 1, \dots$ and test for each pair whether $\text{frac}^d(q, d, 0) = (q, 0, n)$. For this, we combine *enum* and *frac* into a partial mapping $\text{tryall} : \mathbf{R}^5 \rightarrow \mathbf{R}^5$ defined as

$$(q, i, j, u, v) \mapsto \begin{cases} (q, i, j, u', v') & \text{with } (q, u', v') = \text{frac}(q, u, v) \quad \text{if } u \geq 1, \\ (q, i', j', j', 0) & \text{with } (i', j') = \text{enum}(i, j) \quad \text{if } u = 0. \end{cases}$$

We claim that $q = \frac{n}{d}$ for $n, d \in \mathbf{N}$ if and only if $\text{tryall}^k(q, 0, 0, 0, 0) = (q, n, d, 0, n)$. Indeed, starting from $(q, 0, 0, 0, 0)$ the iterates of *tryall* behave as follows. Suppose we are at the k th iterate. If the third coordinate of $\text{tryall}^k(q, 0, 0, 0, 0)$ is zero, a new pair of natural numbers is generated (using the *enum* mapping). Assume that $\text{tryall}^{k+1}(q, 0, 0, 0, 0) = (q, i, j, j, 0)$ and suppose that $j > 0$ (otherwise we jump to a new pair of natural numbers immediately). Then, using the *frac* mapping, we end up after j more iterations at $\text{tryall}^{k+j+1}(q, 0, 0, 0, 0) = \text{tryall}^j(q, i, j, j, 0) = (q, i, j, 0, jq)$ (*frac* reduces the fourth coordinate by one in each iteration). Note that if $i = jq$, then we have found a numerator i and denominator j of q . In any case, we move on to $\text{tryall}^{k+j+2}(q, 0, 0, 0, 0) = (q, i', j', j', 0)$, where (i', j') is the next pair of natural numbers, and the above process starts again. In this way, the iterates of *tryall* visit every pair of natural numbers starting from $(q, 0, 0, 0, 0)$; between two consecutive pairs, it is checked whether the first pair is a numerator/denominator pair for q . The mapping *tryall* can clearly be expressed by an FO+LIN formula,

$$\psi_{\text{tryall}}(q, i, j, u, v, q', i', j', u', v'),$$

expressing that $\text{tryall}(q, i, j, u, v) = (q', i', j', u', v')$.

Let $\Psi(q, i, j, u, v, q', i', j', u', v')$ be the formula

$$q \geq 0 \wedge i \geq 0 \wedge j \geq 0 \wedge i' \geq 0 \wedge j' \geq 0 \wedge u \geq 0 \wedge q = q' \wedge \psi_{\text{tryall}}(q, i, j, u, v, q', i', j', u', v').$$

Given a finite set of rational numbers $S = \{q_1, \dots, q_m\}$, we obtain a denominator and numerator for all these numbers by taking the transitive closure

$$(4.1) \quad [\text{TC}_{q,i,j,u,v;q',i',j',u',v'} \Psi \mid \sigma](\vec{s}, \vec{t}),$$

where \vec{s} and \vec{t} are 5-tuples of variables, and where

$$\sigma \equiv \forall q(S(q) \rightarrow \exists n \exists d X(q, 0, 0, 0, 0, q, n, d, 0, n)).$$

This condition stops the computation of the transitive closure of Ψ when, for each rational number q in S , there exists a k such that $\text{tryall}^k(q, 0, 0, 0, 0) = (q, n, d, 0, n)$, or in other words, when a pair of natural numbers (n, d) has been encountered such that $q = \frac{n}{d}$. If multiple pairs (n, d) represent the same rational number in S , we select the pair with the smallest value of n . Thus, we obtain for each $q \in S$ a unique denominator and numerator.

We are now ready to show how to express the multiplication of rational numbers from a finite set S with a real number. By what we just showed, we may assume that

the rational numbers are represented as numerator/denominator pairs; i.e., we may assume that $S = \{(n_1, d_1), \dots, (n_m, d_m)\}$.

Let \max be the largest natural number occurring in S . We first compute any multiplication of the form rn with $r \in \mathbf{R}$ and $n \in \{0, 1, \dots, \max\}$.

For this, we define the following formula $\mathbf{natmult}(x, y, z, x', y', z')$:

$$\begin{aligned} x &= x' \wedge y' = y - 1 \wedge z' \\ &= z + x \wedge \exists \max(\exists n(S(\max, n) \vee S(n, \max)) \\ &\quad \wedge \forall n \forall d(S(n, d) \rightarrow n \leq \max \wedge d \leq \max) \wedge 0 \leq y \wedge y \leq \max). \end{aligned}$$

Then the formula

$$\mathbf{mult}(a, b, c) \equiv [\mathbf{TC}_{x,y,z;x',y',z'} \mathbf{natmult}](a, b, 0, a, 0, c)$$

holds if and only if $ab = c$ for $a \in \mathbf{R}$, $b \in \mathbf{N}$ and $b \leq \max$. In this way, we can retrieve any multiple up to \max of any real number.

Finally, we define $\mathbf{ratmult}(z, y, n, d) \equiv \exists u(\mathbf{mult}(z, d, u) \wedge \mathbf{mult}(y, n, u))$. This formula holds for (z, y, n, d) if and only if $z = yq$ with $z, y \in \mathbf{R}$, and $q = \frac{n}{d}$ with $(n, d) \in S$. \square

4.3. Natural number representation.

LEMMA 4.3. *There exists an encoding of finite relations over the rational numbers into single natural numbers, and a corresponding decoding, which are both expressible in FO+LIN+TCS.*

Proof. We assume that the relation to be encoded involves positive rational numbers only. The general case can be dealt with by splitting the relation into “sign-homogeneous” pieces, dealing with each piece separately and encoding the tuple of natural numbers obtained for each piece again into a single natural number.

In the proof of Lemma 4.2, we have seen that in FO+LIN+TCS we can go from rational numbers (out of a finite set) to denominator/numerator pairs and back. Hence, we can actually assume that the relation to be encoded involves positive natural numbers only.

We will encode this in two steps. In the first step, we encode a finite relation over \mathbf{N} into a finite subset of \mathbf{N} . In the second step, we encode a finite subset of \mathbf{N} into a single natural number. Since queries can be composed, we can treat these two encoding steps (and their corresponding decoding steps) separately.

Encoding, first step. A finite k -ary relation s over \mathbf{N} can be encoded into a finite subset $\text{Enc}_1(s)$ of \mathbf{N} :

$$\text{Enc}_1(s) := \left\{ \prod_{i=1}^k p_i^{n_i} \mid (n_1, \dots, n_k) \in s \right\}.$$

Here, p_i denotes the i th prime number.

Now let S be a k -ary relation name. We will construct an FO+LIN+TC formula ϵ_1 over $\{S\}$ such that for any database D where S^D is finite and involves natural numbers only, $\epsilon_1(D) = \text{Enc}_1(S^D)$. For notational simplicity, we give the construction only for the case $k = 2$; the general case is analogous.

Consider the following formula $\psi(x_1, x_2, y, x'_1, x'_2, y')$:

$$\begin{aligned} \exists u_1 \exists u_2(S(u_1, u_2) \wedge x_1 \leq u_1 \wedge x_2 \leq u_2) \\ \wedge ((x_1 > 0 \wedge x'_1 = x_1 - 1 \wedge x'_2 = x_2 \wedge y' = 2y) \\ \vee (x_1 = 0 \wedge x_2 > 0 \wedge x'_1 = x_1 \wedge x'_2 = x_2 - 1 \wedge y' = 3y)). \end{aligned}$$

Here, $y' = 2y$ is an abbreviation for $y' = y + y$, and similarly for $y' = 3y$; note that 2 and 3 are the first two prime numbers.

We now define the mapping $p(x_1, x_2, y) = (x'_1, x'_2, y)$ if and only if $\psi(x_1, x_2, y, x'_1, x'_2, y')$. As long as $k \leq x_1$, we have that $p^k(x_1, x_2, y) = (x_1 - k, x_2, y2^k)$. As soon as $k > x_1$, $p^k(x_1, x_2, y)$ is undefined. If $k = x_1$, we can compute further iterates and have that $p^{k+\ell}(x_1, x_2, y) = p^\ell(0, x_2 - \ell, y2^{x_1}3^\ell)$ as long as $\ell \leq x_2$. Iterates again become undefined in case $\ell > x_2$. Finally, if $\ell = x_2$ then $p^{k+\ell}(x_1, x_2, y) = (0, 0, y2^{x_1}3^{x_2})$, and we obtain the encoding for (x_1, x_2) for $y = 1$. No further iterates are defined starting from $(0, 0, y')$.

We will compute the iterates of p using transitive closure and check for each (n_1, n_2) whether there exists a k such that $p^k(n_1, n_2, 1) = (0, 0, y)$. More specifically, the desired formula $\epsilon_1(y)$ is equal to

$$\exists n_1 \exists n_2 (S(n_1, n_2) \wedge [\text{TC}_{x_1, x_2, y; x'_1, x'_2, y'} \psi](n_1, n_2, 1, 0, 0, y)).$$

The discussion above shows that this formula gives the correct answer. The condition $S(u_1, u_2) \wedge x_1 \leq u_1 \wedge x_2 \leq u_2$ in ψ bounds the values of x_1 and x_2 , and hence ensures that the transitive closure computation always terminates.

Decoding, first step. Let S be a unary relation name. We will construct an FO+LIN+TC formula δ_1 over $\{S\}$ such that for any database D where S^D equals $\text{Enc}_1(r)$ for some r , we have $\delta_1(D) = r$. As above, we give the construction only for the case $k = 2$.

Consider now the following formula $\psi(x_1, x_2, y, x'_1, x'_2, y')$:

$$x_1 \geq 0 \wedge x_2 \geq 0 \wedge y \geq 1 \wedge ((x'_1 = x_1 + 1 \wedge x'_2 = x_2 \wedge y' = 2y) \vee (x'_1 = x_1 \wedge x'_2 = x_2 + 1 \wedge y' = 3y)) \wedge \exists u(S(u) \wedge y' \leq u).$$

An analysis similar to that for Enc_1 shows that when we define $q(x_1, x_2, y) = (x'_1, x'_2, y')$ if and only if $\psi(x_1, x_2, y, x'_1, x'_2, y')$, the iterates of q satisfy $q^k(0, 0, 1) = (n_1, n_2, u)$ if and only if $u = 2^{n_1}3^{n_2}$.

Then the desired formula $\delta_1(n_1, n_2)$ is

$$\exists u(S(u) \wedge [\text{TC}_{x_1, x_2, y; x'_1, x'_2, y'} \psi](0, 0, 1, n_1, n_2, u)).$$

The condition $\exists u(S(u) \wedge y' \leq u)$ in ψ bounds the value of y' , and hence ensures the termination of the computation of the transitive closure.

Encoding, second step. A finite ordered subset $s = \{n_1, \dots, n_\ell\}$ of \mathbf{N} can be encoded into a single natural number $\text{Enc}_2(s) := \prod_{i=1}^\ell p_i^{n_i}$.

Let S be a unary relation name. We will construct an FO+LIN+TCS formula ϵ_2 over $\{S\}$ such that for any database D where S^D is a finite subset of \mathbf{N} , we have $\epsilon_2(D) = \{\text{Enc}_2(S^D)\}$.

We will use the following auxiliary FO+LIN+TCS formulas; we will explain later how to get them (except for \min and \max , which are easy to get).

- Formulas card , \min , and \max over $\{S\}$, with the property that for any D where S^D is finite of cardinality ℓ , $\text{card}(D) = \{\ell\}$; $\min(D) = \{\min S^D\}$; and $\max(D) = \{\max S^D\}$.
- Formulas prime , mult , and nat , over $\{M\}$, with M a unary relation name, with the property that for any D where $M^D = \{m\}$ is a natural number singleton,
 - $\text{prime}(D) = \{p_m\}$;
 - $\text{mult}(D) = \{(x, y, z) \in \mathbf{R}^3 \mid xy = z \text{ and } y \in \mathbf{N} \text{ and } y \leq m\}$; and
 - $\text{nat}(D) = \{0, 1, 2, \dots, m\}$.

- Formula **pow** over $\{M, M_2\}$, with M, M_2 unary relation names, with the property that for any D where $M^D = \{m\}$ and $M_2^D = \{m_2\}$ are natural number singletons, $\text{pow}(D) = \{(x, y, z) \in \mathbf{R}^3 \mid x^y = z \text{ and } x \in \mathbf{N} \text{ and } x \leq m \text{ and } y \in \mathbf{N} \text{ and } y \leq m_2\}$.

Using composition, we also obtain that

- $\text{maxprime} \equiv \text{prime}(\text{card})$, defining p_ℓ where ℓ is the cardinality of S ;
- $\text{nat}' \equiv \text{nat}(\text{maxprime})$, defining $\{0, 1, 2, \dots, p_\ell\}$; and
- $\text{pow}' \equiv \text{pow}(\text{maxprime}, \text{max})$, defining exponentiation of natural numbers $\leq p_\ell$ by natural numbers $\leq \text{max } S$.

We furthermore construct the following formulas:

- mult' , obtained from mult by replacing each occurrence of a subformula $M(u)$ with

$$\exists p_\ell \exists m (\text{maxprime}(p_\ell) \wedge \text{max}(m) \wedge \text{pow}'(p_\ell, m, u)).$$

This formula defines multiplication by natural numbers $\leq p_\ell^{\text{max } S}$.

- $\text{isprime}(p)$, which defines $\{p_1, p_2, \dots, p_\ell\}$:

$$\text{nat}'(p) \wedge p > 1 \wedge \neg \exists u \exists v (\text{nat}'(u) \wedge \text{nat}'(v) \wedge u > 1 \wedge v > 1 \wedge \text{mult}'(u, v, p)).$$

- $\text{succ}(x, x')$, which specifies the next element after x in S (or $\text{max}(S) + 1$) and is given by the formula

$$\begin{aligned} & (\neg \text{max}(x) \wedge S(x') \wedge x < x' \\ & \wedge \neg \exists x'' (S(x'') \wedge x < x'' < x')) \vee (\text{max}(x) \wedge x' = x + 1). \end{aligned}$$

- $\text{next}(p, p')$, which specifies the next prime number greater than p and smaller than or equal to p_ℓ (or $p_\ell + 1$) and is given by the formula

$$\begin{aligned} & (\neg \text{maxprime}(p) \wedge \text{isprime}(p') \wedge p < p' \\ & \wedge \neg \exists p'' (\text{isprime}(p'') \wedge p < p'' < p')) \vee (\text{maxprime}(p) \wedge p' = p + 1). \end{aligned}$$

We need to compute the product $\prod_{i=1}^{\ell} p_i^{n_i}$. Consider now the following formula $\psi(x, p, y, x', p', y')$:

$$S(x) \wedge \text{succ}(x, x') \wedge \text{next}(p, p') \wedge \exists y'' (\text{pow}'(p, x, y'') \wedge \text{mult}'(y, y'', y')).$$

Note that the variables y and y' are related by $y' = p^x y$. In order to find the desired product, we have to compute the transitive closure of ψ and check which y' -value is in the transitive closure with $(n_1, 2, 1)$ and $(m + 1, p_\ell + 1, y')$. More explicitly, the desired formula $\epsilon_2(n)$ is

$$\begin{aligned} & \exists n_1 \exists m \exists p_\ell (\text{min}(n_1) \wedge \text{max}(m) \wedge \text{maxprime}(p_\ell) \\ & \wedge [\text{TC}_{x,p,y;x',p',y'} \psi](n_1, 2, 1, m + 1, p_\ell + 1, n)). \end{aligned}$$

It remains to show how the auxiliary formulas can be constructed. Formula $\text{card}(\ell)$ can be written as

$$\begin{aligned} & \exists n_1 \exists m (\text{min}(n_1) \wedge \text{max}(m) \\ & \wedge [\text{TC}_{x,c;x',c'} S(x) \wedge \text{succ}(x, x') \wedge c' = c + 1](n_1, 0, m + 1, \ell)), \end{aligned}$$

where $\text{succ}(x, x')$ is as above.

From the computationally completeness of FO+LIN+TCS (Lemma 4.1), we derive directly the formula **prime**.

For formula **mult**, consider the following formula $\psi(x, y, u, x', y', u')$:

$$x' = x \wedge y' = y - 1 \wedge u' = u + x \wedge 0 < y \wedge \exists m(M(m) \wedge y \leq m).$$

Then **mult**(x, y, z) is $[\text{TC}_{x,y,u;x',y',u'} \psi](x, y, 0, x, 0, z)$.

Formula **nat**(n) can be written as

$$n = 0 \vee [\text{TC}_{x;x'} (0 \leq x \wedge \exists m(M(m) \wedge x < m) \wedge x' = x + 1)](0, n).$$

Finally, for formula **pow**, consider the following formula $\psi(x, u, v; x', u', v')$:

$$\begin{aligned} \mathbf{nat}(x) \wedge \exists m(M(m) \wedge x < m) \wedge 0 \leq u \wedge \exists m_2(M_2(m_2) \wedge u < m_2) \wedge u' \\ = u + 1 \wedge \mathbf{mult}(v, x, v'). \end{aligned}$$

Then **pow**(x, y, z) is $(y = 0 \wedge z = 1) \vee [\text{TC}_{x,u,v;x',u',v'} \psi](x, 0, 1, x, y, z)$.

Decoding, second step. Let E be a unary relation name. We will construct an FO+LIN+TCS formula δ_2 over $\{E\}$ such that for any database D where E^D is a singleton $\{e\}$ such that e equals $\text{Enc}_2(s)$ for some s , we have $\delta_2(D) = s$.

By Lemma 4.1, we have formulas **highprime** and **highexp** over $\{E\}$ such that for any D as above, we have **highprime**(D) = $\{p_\ell\}$ and **highexp**(D) = $\{m\}$, where p_ℓ is the highest prime factor of e , and m is the highest exponent of a prime number in the prime factorization of n . Composing the formula **pow** of above with these two formulas, we obtain a formula defining exponentiation of natural numbers $\leq p_\ell$ by natural numbers $\leq m$, which we again denote by **pow'**. Also, analogously to the way we constructed the formula **isprime** above, we obtain a formula defining $\{p_1, p_2, \dots, p_\ell\}$, which we again denote by **isprime**.

We need a formula **divisor** that finds all divisors of a natural number. First, consider the following formula $\psi(u, v, u', v')$:

$$0 \leq u \wedge \exists e(E(e) \wedge u \leq e) \wedge v \geq 1 \wedge v' = v \wedge u' = u - v$$

and let **divisor**(d) be the formula

$$\exists e(E(e) \wedge [\text{TC}_{u,v;u',v'} \psi](e, d, 0, d)).$$

Then, the desired formula $\delta_2(n)$ is

$$\begin{aligned} \exists p(\mathbf{isprime}(p) \wedge \exists d(\mathbf{pow}'(p, n, d) \wedge \mathbf{divisor}(d)) \\ \wedge \neg \exists n' \exists d'(\mathbf{pow}'(p, n', d') \wedge \mathbf{divisor}(d') \wedge n' > n)). \quad \square \end{aligned}$$

4.4. Completeness result for \mathbf{Z} -linear constraint databases.

THEOREM 4.4. *For every partially computable query Q on \mathbf{Z} -linear constraint databases, there exists an FO+LIN+TCS formula φ such that for each database D , $\varphi(D)$ is defined if and only if $Q(D)$ is, and in this case $\varphi(D)$ and $Q(D)$ are equal.*

Proof. The proof follows directly from the lemmas above, as is illustrated in the following diagram. Let D be a \mathbf{Z} -linear constraint database over a schema

$\mathcal{S} = \{S_1, \dots, S_k\}$, and let Q be an arbitrary partially computable query:

$$\begin{array}{ccc}
 D & \xrightarrow{Q} & Q(D) \\
 \downarrow \text{(Lemma 4.2)} & & \uparrow \text{(Lemma 4.2)} \\
 \{S_{1,\text{fin}}, \dots, S_{k,\text{fin}}\} & & S_{\text{fin}} \\
 \downarrow \text{(Lemma 4.3)} & & \uparrow \text{(Lemma 4.3)} \\
 (n_1, \dots, n_k) \in \mathbf{N}^k & \xrightarrow[\text{(Lemma 4.1)}]{f_Q} & n_{Q(D)} \in \mathbf{N}
 \end{array}$$

First, each S_i^D , $i = 1, \dots, k$, is encoded in a finite relations $S_{i,\text{fin}}$, which in its turn is encoded in a natural number n_i . In this way, a k -tuple (n_1, \dots, n_k) is obtained. Since Q is computable, there exists a partial computable function f_Q which implements Q on these encodings. Let $n_{Q(D)}$ be the result of f_Q on input (n_1, \dots, n_k) . This integer is decoded into a finite relation S_{fin} which in its turn is decoded into a \mathbf{Z} -linear constraint database D' . This database is then the result of the query Q on the input database D , i.e., $D' = Q(D)$. \square

4.5. Implications for polynomial constraint databases. For polynomial constraint databases, we cannot prove completeness and have to settle for less. Although finite representations of polynomial constraint databases exist, it is not known whether a finite encoding can be expressed in FO+POLY+TCS.

Let A be a semialgebraic set in \mathbf{R}^n . An *algebraic linearization* of A is an \mathbf{A} -linear set \widehat{A} in \mathbf{R}^n such that A and \widehat{A} are topologically equivalent. A *rational linearization* of A is a \mathbf{Z} -linear set \widehat{A}_{rat} in \mathbf{R}^n such that A and \widehat{A}_{rat} are topologically equivalent.

For $\vec{x} \in \mathbf{R}^n$, we define $\|\vec{x}\| = \sqrt{x_1^2 + \dots + x_n^2}$. A linearization approximates the set A also from a metric point of view if the following condition is satisfied: for every point \vec{p} in A , $\|\vec{p} - h(\vec{p})\| < \varepsilon$ for a fixed $\varepsilon > 0$, where h is a homeomorphism of \mathbf{R}^n such that $h(A) = \widehat{A}$. If this condition is satisfied for a (rational) linearization, we call this linearization a *(rational) ε -approximation* of the set A . We will denote rational and algebraic ε -approximations, respectively, by $\widehat{A}_{\text{rat},\varepsilon}$ and \widehat{A}_ε .

Example 4.1. Consider the planar semialgebraic set $A = \{(x, y) \in \mathbf{R}^2 \mid x^2 + y^2 = 2\}$. Let $\varepsilon = \frac{1}{2}$. In Figure 4.1, we have drawn an algebraic ε -approximation $\widehat{A}_\varepsilon = \{(x, y) \in \mathbf{R}^2 \mid \max\{|x|, |y|\} = \sqrt{2}\}$, a rational ε -approximation $\widehat{A}_{\text{rat},\varepsilon} = \{(x, y) \in \mathbf{R}^2 \mid \max\{|x|, |y|\} = 1\}$, and a linearization \widehat{A} which is not an ε -approximation. \diamond

Algebraic and rational linearizations exist for any semialgebraic set. This is no longer true for ε -approximations, where the existence is guaranteed only for bounded semialgebraic sets. Consider, e.g., the semialgebraic set $\{(x, y) \in \mathbf{R}^2 \mid y = x^2\}$. It is easy to see that this parabola cannot be approximated by a finite number of line segments, and hence has no ε -approximation for any $\varepsilon > 0$.

Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. We define for any polynomial constraint database D over \mathcal{S} an *algebraic (rational) linearization query* Q_{lin} ($Q_{\text{rat-lin}}$) as a query such that $Q_{\text{rat}}(D)$ ($Q_{\text{rat-lin}}(D)$) is an algebraic (rational) linearization of S^D .

Similarly, for any $\varepsilon > 0$ and any polynomial constraint database D over \mathcal{S} such that S^D is a bounded semialgebraic set, we define an *algebraic (rational) ε -approximation query* Q_ε ($Q_{\text{rat},\varepsilon}$) as a query such that $Q_\varepsilon(D)$ ($Q_{\text{rat},\varepsilon}(D)$) is an algebraic (rational) ε -approximation of S^D .

FIG. 4.1. Let A be the circle (grey). Left: an algebraic ε -approximation. Middle: a rational ε -approximation. Right: an algebraic linearization.

It is an open question whether some algebraic or rational linearization query can be expressed in FO+POLY. With respect to the ε -approximation query, neither the algebraic nor the rational version can be expressed in FO+POLY.

PROPOSITION 4.5. Let $\varepsilon > 0$ be a real number. No ε -approximation query is expressible in FO+POLY.

Proof. Let $\mathcal{S} = \{S\}$, with S a binary relation name. Let D be a polynomial constraint database over \mathcal{S} . Consider the following FO+POLY formulas over \mathcal{S} :

- A formula `circle` such that for any database D over \mathcal{S} , `circle`(D) is either the circle through the points of S^D , if S^D consists of three noncollinear points, or `circle`(D) = \emptyset . This formula is easily seen to be in FO+POLY.
- A formula `cornerpoints` such that for any database D over \mathcal{S} , `cornerpoints`(D) is either the set of points in which S^D is not locally a straight line, in the case when S^D is semilinear, or `cornerpoints`(D) = \emptyset , otherwise. By a result of Dumortier et al. [10], it is expressible in FO+POLY whether a semialgebraic set is semilinear. Hence, `cornerpoints` is expressible in FO+POLY.

Assume that the query Q_ε (and similarly, $Q_{\text{rat},\varepsilon}$) is expressible in FO+POLY. Let ε -`approx` be the formula which expresses Q_ε . Then the formula

$$\varphi \equiv \text{cornerpoints}(\varepsilon\text{-approx}(\text{circle}))$$

is also in FO+POLY. However, the number of points in $\varphi(D)$, $|\varphi(D)|$ can be made arbitrarily large by choosing D such that S^D consist of three points far enough apart. This contradicts the dichotomy theorem of Benedikt and Libkin [4], which guarantees the existence of a polynomial p_φ such that $|\varphi(D)| < p_\varphi(|S^D|) = p_\varphi(3)$ in the case when $|\varphi(D)|$ is finite. \square

In contrast to the negative expressiveness result in Proposition 4.5, we will prove that all kinds of linearizations are expressible in FO+POLY+TC. Indeed, in section 6 we show that there exists

- an FO+POLY+TC expressible algebraic linearization query (Theorem 6.6);
- an FO+POLY+TC expressible rational linearization query (Theorem 6.9);
- an FO+POLY+TC expressible algebraic ε -approximation query (Theorem 6.7);
- an FO+POLY+TC expressible rational ε -approximation query (Theorem 6.10).

We shall denote the FO+POLY+TC formula, which expresses the rational linearization by ratlin . Let Q be a partially computable Boolean topological query. Since Q is partially computable, it is in particular partially computable on \mathbf{Z} -linear constraint databases, and therefore by Theorem 4.4 is expressible on these databases by a formula φ_Q in FO+LIN+TCS.

Because Q is topological, $Q(D)$ is true if and only if $\varphi_Q(\text{ratlin}(D))$ is true. Hence, we have proven the following theorem.

THEOREM 4.6. *For every partially computable Boolean topological query Q on polynomial constraint databases, there exists an FO+POLY+TCS formula φ such that for each database D , $\varphi(D)$ is defined if and only if $Q(D)$ is defined, and in this case $\varphi(D)$ and $Q(D)$ are equal.*

5. Geometrical properties of semialgebraic sets. In this section, we discuss a number of topological properties of spatial databases that can be expressed in first-order logic. They are used in the construction of the linearization of polynomial constraint databases in the next section.

We will use the following notation. Let $A \subseteq \mathbf{R}^n$; the closure of A is denoted by $\text{cl}(A)$, and $\text{int}(A)$ indicates the interior of A . We denote $\text{cl}(A) - \text{int}(A)$ (the boundary of A) by ∂A .

5.1. The cone radius. Let A be a semialgebraic set in \mathbf{R}^n , and let \vec{p} be a point in \mathbf{R}^n . We define the *cone with base A and top \vec{p}* as the union of all closed line segments between \vec{p} and points in A . Formally, this is the set $\{t\vec{b} + (1-t)\vec{p} \mid \vec{b} \in A, 0 \leq t \leq 1\}$ and we denote this set by $\text{Cone}(A, \vec{p})$.

For a point $\vec{p} \in \mathbf{R}^n$, and $\varepsilon > 0$, we denote the closed ball centered at \vec{p} with radius ε by $B^n(\vec{p}, \varepsilon)$, and we denote the sphere centered at \vec{p} with radius ε by $S^{n-1}(\vec{p}, \varepsilon)$.

The local conic structure of semialgebraic sets characterizes the local topology of semialgebraic sets.

THEOREM 5.1 (local conic structure; see Theorem 9.3.6 of [6]). *Let A be a semialgebraic set in \mathbf{R}^n and \vec{p} be a point of $\text{cl}(A)$. Then there is a real number $\varepsilon > 0$ such that intersection $B^n(\vec{p}, \varepsilon) \cap A$ is homeomorphic to the set $\text{Cone}(S^{n-1}(\vec{p}, \varepsilon) \cap A, \vec{p})$, in the case when $\vec{p} \in A$, and homeomorphic to $\text{Cone}(S^{n-1}(\vec{p}, \varepsilon) \cap A, \vec{p}) - \{\vec{p}\}$ otherwise.*

Before we can state a “box” version of this theorem, we need the following definitions. Consider a $2n$ -tuple $B = (a_1, b_1, \dots, a_n, b_n) \in \mathbf{R}^{2n}$ with $a_i \leq b_i$ for each i . One can associate with each such tuple an n -ary relation $|B|$ in \mathbf{R}^n :

$$|B| := \{(x_1, \dots, x_n) \in \mathbf{R}^n \mid (a_1 \leq x_1 \leq b_1) \wedge \dots \wedge (a_n \leq x_n \leq b_n)\}.$$

We call B a *box* in \mathbf{R}^n , and $|B|$ is the *geometric realization* of B . The *dimension* of a box is the number of pairs (a_i, b_i) with $a_i \neq b_i$. The *diameter* of a box B , $\text{diam}(B)$, equals $(\sum_{i=1}^n (b_i - a_i)^2)^{1/2}$. The *center* of B is the point $((a_1 + b_1)/2, \dots, (a_n + b_n)/2)$.

THEOREM 5.2 (see [14]). *Let A be a semialgebraic set in \mathbf{R}^n and \vec{p} a point of $\text{cl}(A)$. Then there is a real number $\varepsilon > 0$ such that for any n -dimensional box B in \mathbf{R}^n such that*

1. $\vec{p} \in \text{int}(|B|)$, and
2. $|B| \subseteq (p_1 - \varepsilon, p_1 + \varepsilon) \times \dots \times (p_n - \varepsilon, p_n + \varepsilon)$,

we have that the intersection $A \cap |B|$ is homeomorphic to the set $\text{Cone}(A \cap \partial|B|, \vec{p})$, in the case when $\vec{p} \in A$, and homeomorphic to the set $\text{Cone}(A \cap \partial|B|, \vec{p}) - \{\vec{p}\}$ otherwise.

Any positive real number ε as in Theorem 5.2 is called a *cone radius* of A in \vec{p} (see Figure 5.1).

FIG. 5.1. The local conic structure of semialgebraic sets.

Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. We define the *cone radius query* Q_{radius} as a query which maps any polynomial constraint database D over \mathcal{S} to a set of pairs $(\vec{p}, r) \in \mathbf{R}^n \times \mathbf{R}$ such that for every $\vec{p} \in \text{cl}(S^D)$ there exists at least one pair $(\vec{p}, r) \in Q_{\text{radius}}(D)$, and for every $(\vec{p}, r) \in Q_{\text{radius}}(D)$, r is a cone radius of S^D in \vec{p} .

THEOREM 5.3 (see [14]). *The cone radius query defined above is expressible in FO+POLY.*

The FO+POLY formula over \mathcal{S} , constructed in [14] and whose existence is referred to in Theorem 5.3, will be denoted by **radius**. The exact properties of this formula are not important (except for the fact that, for each point \vec{p} , it assigns an open interval $(0, r) \subset \mathbf{R}$ such that for each $r' \in (0, r)$, r' is a cone radius) until the proof of Claim 6.1. There we have to go back to the construction of **radius** for the cone radius query as presented in [14].

As observed above, for each point \vec{p} ,

$$\{r' \mid (\vec{p}, r') \in \text{radius}(D)\} = (0, r).$$

Define $r_{\vec{p}}$ to be the cone radius $r/2$. Moreover, let **uniqueradius** be the FO+POLY formula over \mathcal{S} such that for each point $\vec{p} \in \text{cl}(S^D)$, $(\vec{p}, r_{\vec{p}})$ is in **uniqueradius**(D). Basically, **uniqueradius** assigns a unique cone radius to each point.

For a given semialgebraic set A in \mathbf{R}^n , we now define the semialgebraic mapping² $\gamma_{\text{cone}, A}$ from $\text{cl}(A)$ to \mathbf{R} which maps each point $\vec{p} \in \text{cl}(A)$ to the unique cone radius $r_{\vec{p}} \in \mathbf{R}$ given by **uniqueradius**(D), where $S^D = A$.

5.2. The uniform cone radius decomposition. Although every point of a semialgebraic set has a cone radius which is strictly greater than zero (Theorem 5.2), we are now interested in finding a *uniform cone radius* for a semialgebraic set. We define a uniform cone radius of a semialgebraic set $A \subseteq \mathbf{R}^n$ as a real number $\varepsilon_A > 0$ such that ε_A is a cone radius of A in all points of A . For any $X \subseteq A \subseteq \mathbf{R}^n$, we define a uniform cone radius of X with respect to A as a real number $\varepsilon > 0$ such that ε is a cone radius of A in all points of X .

A first observation is that a uniform cone radius of a semialgebraic set does not always exist.

Example 5.1. Consider the set shown in Figure 5.2. We have drawn the maximal cone radius around the points $\vec{p}_1, \vec{p}_2, \vec{p}_3, \vec{p}_4$, and \vec{p}_5 . It is clear that the closer these points are to the point \vec{p} , the smaller their maximal cone radius is. Because we can make the maximal cone radius arbitrarily small by taking points very close to \vec{p} , we may conclude that the set shown in this figure has no uniform cone radius. \diamond

²A mapping is called semialgebraic if its graph is a semialgebraic set.

FIG. 5.2. Example of a semialgebraic set which does not have a uniform cone radius.

Let A be a semialgebraic set in \mathbf{R}^n . We define the ε -neighborhood of A as

$$A^\varepsilon := \{\vec{x} \in \mathbf{R}^n \mid \exists \vec{y} (\vec{y} \in A \wedge \|\vec{x} - \vec{y}\| < \varepsilon)\}.$$

We will frequently use the following notation. Let U_0, \dots, U_m be pairwise disjoint semialgebraic subsets of $\text{cl}(A)$, which satisfy the condition that for any m -tuple $(\varepsilon_0, \dots, \varepsilon_m)$ of positive real numbers, and for $i = 0, \dots, m$, the sets

$$(5.1) \quad \inf \left\{ \gamma_{\text{cone}, A} \left(U_i - \bigcup_{j=i+1}^m U_j^{\varepsilon_j} \right) \right\} > 0.$$

Note that these sets have a uniform cone radius with respect to A . Hence, we say that the sets U_0, \dots, U_m form a *uniform cone radius collection* of $\text{cl}(A)$.

When the sets U_0, \dots, U_m of a uniform cone radius collection of A form a decomposition of $\text{cl}(A)$, i.e.,

$$\text{cl}(A) = U_0 \cup \dots \cup U_m,$$

then we call U_0, \dots, U_m a *uniform cone radius decomposition* of $\text{cl}(A)$.

We now show how to construct such a uniform cone radius decomposition of $\text{cl}(A)$. For any closed subset $X \subseteq \text{cl}(A)$, we define

$$(5.2) \quad \Gamma_{\text{nc}}(X) := \{\vec{p} \in X \mid \gamma_{\text{cone}, A} \upharpoonright_X \text{ is not continuous in } \vec{p}\}.$$

Let $\Delta_0 := \text{cl}(A)$, and let $\Delta_{i+1} := \text{cl}(\Gamma_{\text{nc}}(\Delta_i)) \cap \Delta_i$. We define for $k = 0, 1, \dots$ the sets

$$(5.3) \quad C_k := \Delta_k - \Delta_{k+1}.$$

By taking $f = \gamma_{\text{cone}, A}$ in the following lemma, we obtain that $\Gamma_{\text{nc}}(X)$ is semialgebraic and $\dim(\Gamma_{\text{nc}}(X)) < \dim X$.

LEMMA 5.4. *For each semialgebraic set X in \mathbf{R}^n and each semialgebraic function $f : X \rightarrow \mathbf{R}$, the set $\Gamma(f) = \{\vec{p} \in X \mid f(\vec{p}) \text{ is not continuous in } \vec{p}\}$ is semialgebraic and $\dim(\Gamma(f)) < \dim X$.*

Proof. The set

$$\Gamma(f) = \{\vec{p} \in \mathbf{R}^n \mid (\exists \varepsilon > 0)(\forall \delta > 0)\exists \vec{q} \in \mathbf{R}^n (\vec{q} \in X \cap B^n(\vec{p}, \delta) \wedge |f(\vec{p}) - f(\vec{q})| > \varepsilon)\}$$

is clearly semialgebraic. This proves the first assertion.

FIG. 5.3. The points $\vec{p}_1, \vec{p}_2, \vec{p}_3, \vec{p}_4,$ and \vec{p}_5 form the part C_1 which has ε_1 as uniform cone radius. As can be seen, the set $C_0 = A - C_1^{\varepsilon_1}$ has a uniform cone radius ε_0 .

We prove the second assertion by contradiction. Let $d = \dim X$ and suppose that $\dim(\Gamma(f)) = d$. Then there exists a semialgebraic cell $V \subseteq \Gamma(f)$ of dimension d . By the cell decomposition theorem of semialgebraic sets [44, Theorem 2.11] there exists a semialgebraic cell decomposition of V into a finite number of semialgebraic cells,

$$V = V_1 \cup \dots \cup V_k \cup V_{k+1} \cup \dots \cup V_\ell,$$

with $\dim(V_i) = d$ for $i = 1, \dots, k$ and $\dim(V_j) < d$ for $j = k + 1, \dots, \ell$, such that

$$(5.4) \quad f|_{V_i} \text{ is continuous for every } i = 1, \dots, \ell.$$

Since $V_i \subseteq V$ has dimension d for $i = 1, \dots, k$, V_i is open in V , and V_i is also open in X for $i = 1, \dots, k$. From (5.4) we deduce that each V_i for $i = 1, \dots, k$ is included in $X - \Gamma(f)$, which is impossible since $V \subseteq \Gamma(f)$. Hence, $\dim(\Gamma(f)) < d$. \square

An immediate consequence of this lemma is that from $i = n + 1$ on, the C_i 's are all empty. Let us denote by m the latest index such that C_m is nonempty. Thus, $m \leq n$.

We now prove that for any tuple $(\varepsilon_0, \dots, \varepsilon_m)$ of positive real numbers, the sets

$$C_i - \bigcup_{j=i+1}^m C_j^{\varepsilon_j} \quad \text{for } i = 0, 1, \dots, m$$

have a uniform cone radius. Since $C_m = \Delta_m$ is closed, $\gamma_{\text{cone}, A}(C_m)$ is also closed and therefore has a minimum which is strictly positive. Hence, C_m has a uniform cone radius. For $i > 0$ there exists an $\eta < \min\{\varepsilon_0, \dots, \varepsilon_m\}$ such that

$$(5.5) \quad C_i - \bigcup_{j=i+1}^m C_j^{\varepsilon_j} \subseteq Z := \Delta_i - \Delta_{i+1}^\eta.$$

The set Z is closed and the restriction $\gamma_{\text{cone}, A}|_Z$ is continuous. Hence, $\gamma_{\text{cone}, A}(Z)$ is closed in \mathbf{R} and has a minimum which is strictly positive. We may conclude that Z has a uniform cone radius, and by (5.5), so has $C_i - \bigcup_{j=i+1}^m C_j^{\varepsilon_j}$. Thus, C_0, \dots, C_m is a uniform cone radius decomposition of $\text{cl}(A)$.

Example 5.2. In Figure 5.3, we have shown the uniform cone radius decomposition of the set depicted in Figure 5.2. \diamond

Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. We define the $n + 1$ queries Q_k^{uniform} such that for any polynomial constraint database D over \mathcal{S} ,

$$Q_k^{\text{uniform}}(D) := C_k$$

for $k = 0, 1, \dots, n$, with C_0, \dots, C_n being the uniform cone radius decomposition of $\text{cl}(S^D)$.

Because $\gamma_{\text{cone}, S^D}$ equals $\text{uniqueradius}(D)$, and by Theorem 5.3 the formula uniqueradius is in FO+POLY, the following lemma is immediate.

LEMMA 5.5. *The queries $Q_{k\text{-uniform}}$, $k = 0, 1, \dots, n$, are expressible in FO+POLY.*

5.3. The regular decomposition. In this section, we construct a decomposition of semialgebraic sets such that a certain regularity condition is satisfied on each part of the decomposition. In order to define this regularity condition, we need to define the tangent space to a semialgebraic set in a point. The following definitions are taken from Rannou [39].

Let A be a semialgebraic set in \mathbf{R}^n . The *secants limit set* of A in a point $\vec{p} \in A$ is defined as the set

$$\text{limsec}_{\vec{p}} A := \bigcap_{\eta > 0} \text{cl}(\{\lambda(\vec{u} - \vec{v}) \in \mathbf{R}^n \mid \lambda \in \mathbf{R} \text{ and } \vec{u}, \vec{v} \in A \cap B^n(\vec{p}, \eta)\}).$$

If $\text{limsec}_{\vec{p}} A$ is a vector space, then we define the *tangent space of A in \vec{p}* as $T_{\vec{p}} A := \vec{p} + \text{limsec}_{\vec{p}} A$. If $\text{limsec}_{\vec{p}} A$ is not a vector space, then the tangent space of A in \vec{p} is undefined.

Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. We define the query Q_{tangent} as the query such that for any polynomial constraint database D over \mathcal{S} ,

$$Q_{\text{tangent}}(D) := \{(\vec{x}, \vec{v}) \in S^D \times \mathbf{R}^n \mid T_{\vec{x}} S^D \text{ exists in } \vec{x} \text{ and } \vec{v} \in T_{\vec{x}} S^D\}.$$

LEMMA 5.6. *The query Q_{tangent} is expressible in FO+POLY.*

Proof. It is shown by Rannou [39, Lemma 2] that the definition of the secant limit set of a set in a point can be translated into a first-order formula over the reals. Since it is straightforward to check in FO+POLY whether a secant limit set is a vector space (i.e., we need to check whether, for all \vec{s}, \vec{t} in a secant limit set, the sum $\vec{s} + \vec{t}$ is also an element of this secant limit set), the lemma is immediate. \square

The set A is *regular in \vec{p}* if and only if $T_{\vec{p}} A$ exists and there exists a neighborhood U of \vec{p} such that the orthogonal projection of $A \cap U$ on $T_{\vec{p}} A$ is bijective. A set is *regular* if it is regular in all of its points.

A finite number of pairwise disjoint regular sets R_1, \dots, R_k is called a *regular decomposition of A* if $A = R_1 \cup \dots \cup R_k$.

We now show that every semialgebraic set A has a regular decomposition.

We denote the set of points where A is regular and where the local dimension of A is k by $\text{Reg}_k(A)$. Note that $\text{Reg}_k(A)$ is either empty or $\dim \text{Reg}_k(A) = k$.

Define inductively for $k = n, n - 1, \dots, 0$, the sets

$$(5.6) \quad R_k := \text{Reg}_k \left(A - \bigcup_{j=k+1}^n R_j \right).$$

These sets are pairwise disjoint and form a decomposition of A , i.e.,

$$(5.7) \quad A = R_n \cup R_{n-1} \cup \dots \cup R_0.$$

FIG. 5.4. The snowman A has no tangent space in \vec{p} , A has a tangent space in \vec{q} and \vec{r} but is not regular in these points, and A is regular in \vec{s} .

FIG. 5.5. The three-dimensional set A of Figure 5.4 is decomposed into four parts R_0 , R_1 , R_2 , and R_3 according to the construction of the regular decomposition.

Note that $n + 1$ parts are really sufficient because, for any semialgebraic set $X \subseteq \mathbf{R}^n$ of dimension d , $X - \text{Reg}_d(X)$ has a strictly lower dimension than X [45].

Moreover, by (5.6) each R_k is regular, and hence we define the *regular decomposition* of A as the $n + 1$ sets R_0, \dots, R_n .

Example 5.3. In Figure 5.4, we have illustrated the three possible cases: $T_{\vec{p}}A$ does not exist; $T_{\vec{q}}A$ and $T_{\vec{r}}A$ exist but A is not regular in \vec{q} and \vec{r} ; and finally, A is regular in \vec{s} . In Figure 5.5, we have drawn an example of the regular decomposition of a three-dimensional set in \mathbf{R}^3 . \diamond

Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. We define the $n + 1$ queries Q_k^{reg} as the queries such that for every polynomial constraint database D ,

$$Q_k^{\text{reg}}(D) := R_k$$

for $k = 0, \dots, n$, with R_0, \dots, R_n the regular decomposition of S^D .

It was proved by Rannou [39, Proposition 2] that checking whether a semi-algebraic set is regular in a point is first-order expressible. Hence the next lemma follows.

LEMMA 5.7. *The queries $Q_{k\text{-reg}}$, $k = 0, 1, \dots, n$ are expressible in FO+POLY.*

Regular decompositions of semilinear sets are fully treated by Dumortier et al. [10] and Vandeuren [46]. These authors showed that on semilinear databases, the $n + 1$

queries $Q_{k\text{-reg}}$ are already expressible in FO+LIN. There is, however, a great difference between the semilinear and semialgebraic cases. Indeed, in the semialgebraic case, regularity implies that the set is a C^1 -smooth algebraic variety, while in the semilinear case, regularity implies that the set is a C^∞ -smooth algebraic variety. One could ask if it is possible to define a regularity condition in first-order logic such that it also induces C^∞ -smoothness of semialgebraic sets, but this is impossible [49].

However, we still can generalize the regular decompositions defined above to C^k -regular decompositions by demanding C^k -smoothness instead of C^1 -smoothness (regularity). Using again results from Rannou [39, Proposition 3], we have first-order expressibility of the corresponding query in this case too.

An interesting question is which extensions of FO+POLY can express C^∞ -regular decompositions. A useful observation in this context might be that for every semialgebraic set, there exists a natural number K such that for all $k > K$, a C^k -regular decomposition is already a C^∞ -regular decomposition. Unfortunately, it is not known how to find K for a given semialgebraic set [40] and we might have to compute C^k -regular decompositions for increasing values of k until two consecutive decompositions are identical. This indicates that recursion is needed for the computation of C^∞ -regular decompositions. We leave open whether the recursion in FO+POLY+TC or FO+POLY+TCS is sufficient for this purpose.

5.4. Transversality. In computational geometry [9], a convenient assumption is the hypothesis of “general position,” which dispenses with the detailed consideration of special cases. In the description of our linearization algorithm in section 6, we would like to assume this hypothesis. However, we need to make precise what we will mean by general position and see if this hypothesis may indeed be assumed.

Let A and B be two regular semialgebraic sets in \mathbf{R}^n . From differential topology [23], we recall that A and B are said to *intersect transversally* at $\vec{p} \in A \cap B$ if³

$$(5.8) \quad T_{\vec{p}}A + T_{\vec{p}}B = \mathbf{R}^n.$$

The sets A and B are *in general position* if they intersect transversally in every point of $A \cap B$. We denote this by $A \pitchfork B$. This is illustrated in Figure 5.6 and Figure 5.7, where some examples of transversal and nontransversal intersections in \mathbf{R}^2 and \mathbf{R}^3 are depicted.

Let $\mathcal{A} = \{A_1, \dots, A_n\}$ and $\mathcal{B} = \{B_1, \dots, B_m\}$ be finite sets of regular semialgebraic sets in \mathbf{R}^n such that $A_i \cap A_j = \emptyset$ and $B_i \cap B_j = \emptyset$ for $i \neq j$. We say that \mathcal{A} and \mathcal{B} are in general position if A_i and B_j are in general position for every $i = 1, \dots, n$ and every $j = 1, \dots, m$. We denote this by $\mathcal{A} \pitchfork \mathcal{B}$.

Let $\mathcal{S} = \{S_1, S_2\}$, with S_1 and S_2 two n -ary relation names. We define the Boolean query Q_{\pitchfork} such that for every polynomial constraint database D over \mathcal{S} ,

$$Q_{\pitchfork}(D) = \text{true} \text{ if and only if } S_1^D \text{ and } S_2^D \text{ are regular and } S_1^D \pitchfork S_2^D.$$

Condition (5.8) can be readily expressed in FO+POLY, and by Lemma 5.7, regularity is expressible in FO+POLY. Hence Lemma 5.8 follows.

LEMMA 5.8. *The Boolean query Q_{\pitchfork} is expressible in FO+POLY.*

Given two arbitrary regular semialgebraic sets A and B in \mathbf{R}^n not in general position, we can ask how to force them to be in general position. The following

³Let U and V be two subspaces of a vector space X ; then the *sum* $U + V$ is the set of all vectors $\vec{u} + \vec{v}$, where $\vec{u} \in U$ and $\vec{v} \in V$. Besides, $U + V$ is a subspace of X .

FIG. 5.6. Curves in \mathbf{R}^2 .

FIG. 5.7. Curves and surfaces in \mathbf{R}^3 .

theorem answers this question. A translation of a set $X \subseteq \mathbf{R}^n$ is a set of the form $X + \tau := \{\vec{x} + \tau \in \mathbf{R}^n \mid \vec{x} \in X\}$, where $\tau \in \mathbf{R}^n$.

THEOREM 5.9. *Let A and B two regular semialgebraic sets in \mathbf{R}^n . For almost all $\tau \in \mathbf{R}^n$, we have that $A + \tau$ and B are in general position.*

Proof. This theorem is a direct consequence of the transversality theorem of differential topology. A proof of the transversality theorem given by Guillemin and Pollack [23] for C^∞ -smooth varieties in \mathbf{R}^n literally remains valid in this case, except that the C^1 -version of Sard’s theorem given by Wilkie [50] needs to be used instead of the standard C^∞ -smooth version. \square

Here, “almost all” means that the set of translation vectors τ for which $A + \tau$ and B are not in general position has *measure zero*.⁴ Since a set of measure zero cannot contain an open set in \mathbf{R}^n , the set of translation vectors τ for which $A + \tau$ and B are in general position is dense in \mathbf{R}^n .

Moreover, Theorem 5.9 can be easily generalized as follows.

COROLLARY 5.10. *Let $\mathcal{A} = \{A_1, \dots, A_n\}$ and $\mathcal{B} = \{B_1, \dots, B_m\}$ be sets of regular semialgebraic sets in \mathbf{R}^n such that $A_i \cap A_j = \emptyset$ ($B_i \cap B_j = \emptyset$) for $i \neq j$. Then for almost all $\tau \in \mathbf{R}^n$, $\mathcal{A} + \tau \pitchfork \mathcal{B}$.*

We mention three useful properties of sets in general position. Let \mathcal{A} and \mathcal{B} be as above; then if $\mathcal{A} \pitchfork \mathcal{B}$, there exists an $\varepsilon > 0$ such that $\mathcal{A} + \tau \pitchfork \mathcal{B}$ for any $\tau \in \mathbf{R}^n$ of norm less than ε . Therefore, one says that transversality is a *stable* property. A second useful property is that the intersection of two regular sets in general position is again regular. A third property is that the tangent space in a point of the intersection of two sets in general position is the intersection of the tangent spaces of these sets in this point [23].

⁴A set in \mathbf{R}^n has *measure zero* if it can be covered by a countable number of n -dimensional boxes with arbitrary small volume.

FIG. 5.8. A two-dimensional example of the construction of a box collection for two boxes in the \mathbf{R}^2 .

5.5. Box collections. We need one more ingredient before we can start explaining the linearization algorithm: box collections.

We define an n -dimensional box collection \mathcal{B} in \mathbf{R}^n as a finite set of n -dimensional boxes satisfying an intersection condition. Let B_1 and B_2 be two arbitrary boxes in \mathcal{B} . Then, if $|B_1|$ and $|B_2|$ intersect, the intersection is included in their boundaries $\partial|B_1|$ and $\partial|B_2|$. By the *geometric realization* $|\mathcal{B}|$ of \mathcal{B} , we mean the union of the geometric realizations of all boxes in \mathcal{B} . If $X \subseteq \mathbf{R}^n$ is a semialgebraic set and \mathcal{B} an n -dimensional box collection in \mathbf{R}^n , then $\mathcal{B} \cap X$ is the set of all boxes $B \in \mathcal{B}$ such that $B \cap X \neq \emptyset$.

Let D be a set of n -dimensional boxes, which does not necessarily satisfy the above intersection condition. In the following, we show how in FO+POLY to split the boxes in D into smaller boxes such that the collection of these smaller boxes is a box collection. We call this the *box collection of D* and denote it by \mathcal{D} . By construction, the geometric realization of each box in D is the union of the geometric realizations of certain boxes of \mathcal{D} .

We first give an example of the construction and then present the general construction more formally.

Example 5.4. Fix the dimension $n = 2$ and consider the set D consisting of two boxes $(0, 2, 0, 3)$ and $(1, 3, 1, 4)$. The geometric realization $|D|$ of D is depicted in Figure 5.8. In this figure, two sets of lines, $\mathcal{H}_{D,x} = \{H_1, H_2, H_3, H_4\}$ and $\mathcal{H}_{D,y} = \{V_1, V_2, V_3, V_4\}$, are drawn. Denote the intersection $\bigcup \mathcal{H}_{D,x} \cap \bigcup \mathcal{H}_{D,y}$ by I . In this example, I consists of 16 points $\{\bar{p}_1, \dots, \bar{p}_{16}\}$. From these points, we construct the set \mathcal{P} which contains the 9 two-dimensional boxes denoted by $B_i, i = 1, \dots, 9$. The geometric realizations of these boxes are shown in the figure. As can be seen, these boxes intersect only at their boundaries, and hence form a two-dimensional box collection. Finally, we define the box collection \mathcal{D} of D as the boxes included in $|D|$, i.e., $\mathcal{D} = \{B_1, B_2, B_4, B_6, B_8, B_9\}$. \diamond

In general, we define n unions of $(n - 1)$ -dimensional hyperplanes,

$$\mathcal{H}_{D,i} := \{(x_1, \dots, x_n) \in \mathbf{R}^n \mid \exists (a_1, b_1, \dots, a_n, b_n) \in D \wedge (x_i = a_i \vee x_i = b_i)\},$$

for $i = 1, \dots, n$. Let $I \subseteq \mathbf{R}^n$ be the set of points $\mathcal{H}_{D,1} \cap \dots \cap \mathcal{H}_{D,n}$.

It is easily shown that I is a finite set of points. Indeed, a proof by induction shows that $\dim(\mathcal{H}_{D,1} \cap \dots \cap \mathcal{H}_{D,k}) = n - k$ for any $k = 1, \dots, n$. In particular, $\dim(I) = n - n = 0$, or in other words, I is a finite set.

Next, we construct an n -dimensional box collection, which we denote by \mathcal{P} , such that the geometric realization of each box in D is the union of the geometric

FIG. 5.9. The set $|\mathcal{D}| - |\mathcal{D}|_2$ (left). The one-dimensional box collection $\mathcal{P}_x \cup \mathcal{P}_y$, where the line segment L_i is labeled with the number i (center). The set $|\mathcal{D}|_0$ (right).

realizations of boxes in \mathcal{P} . More specifically,

$$\mathcal{P} := \left\{ (a_1, b_1, \dots, a_n, b_n) \in \mathbf{R}^{2n} \mid \exists \vec{p}_1 \exists \vec{q}_1 \dots \exists \vec{p}_n \exists \vec{q}_n \in I \right. \\ \left. \bigwedge_{i=1}^n (a_i = (\vec{p}_i)_i \wedge b_i = (\vec{q}_i)_i \wedge a_i < b_i) \right. \\ \left. \wedge \left(\forall \vec{r} \in I \bigwedge_{i=1}^n \neg (a_i < (\vec{r})_i < b_i) \right) \right\}.$$

Finally, we define \mathcal{D} as those n -dimensional boxes B in \mathcal{P} such that $|B|$ is included in the geometric realization of any of the boxes in \mathcal{B} . By construction, \mathcal{D} is a box collection, and the geometric realization of any box in \mathcal{D} is the union of the geometric realizations of certain boxes in \mathcal{B} . The construction of \mathcal{D} for a given D can be expressed in FO+POLY, as is clear from the above expressions for $\mathcal{H}_{D,i}$ and \mathcal{P} .

Let $\mathcal{S} = \{S\}$, with S a $2n$ -ary relation name. We define the *box collection query* Q_{bc} such that for any polynomial constraint database D over \mathcal{S} representing a set of n -dimensional boxes in \mathbf{R}^n ,

$$Q_{bc}(D) = \mathcal{D},$$

where \mathcal{D} is the box collection of D . From the constructions above, the following result is immediate.

LEMMA 5.11. *The query Q_{bc} is expressible in FO+POLY.*

When applied to the union of two box collections D and D' , we will denote the box collection $Q_{bc}(D \cup D')$ by $\mathcal{D} \sqcup \mathcal{D}'$.

We next define a useful decomposition of box collections. We again give first an example.

Example 5.5 (see Figure 5.8 and Figure 5.9). Let us continue the previous example. Let $|\mathcal{D}|_2$ be the set in \mathbf{R}^2 defined by $\bigcup_{i \in \{1,2,4,5,6,8,9\}} \text{int}(|B_i|)$. Consider the set $|\mathcal{D}| - |\mathcal{D}|_2$ and define \mathcal{P}_x to be the set of horizontal line segments L_i , with $i = 1, \dots, 12$, and let \mathcal{P}_y be the set of vertical line segments L_i , with $i = 13, \dots, 24$. The line segments L_i can easily be defined from the points in I and from a one-dimensional box collection. We define \mathcal{D}^1 to be the box collection consisting of boxes in $\mathcal{P}_x \cup \mathcal{P}_y$, which are contained in $|\mathcal{D}|$. Next, define $|\mathcal{D}|_1$ to be the set $\bigcup_{i \in \{1, \dots, 24\} - \{3, 10, 22, 15\}} \text{int}(|L_i|)$. Here, when taking the interior, we regard each $|L_i|$ as a space on itself, so the result is an open line segment without the endpoints (as opposed to the empty set, where we would regard each $|L_i|$ as a set in \mathbf{R}^2). Now, $|\mathcal{D}| - |\mathcal{D}|_2 - |\mathcal{D}|_1$ is a subset of I , which we denote by $|\mathcal{D}|_0$. Hence, we have obtained a decomposition of $|\mathcal{D}|$. \diamond

This decomposition is important for two reasons. First, the geometric realization of each box of \mathcal{D} is the disjoint union of the interiors of the geometric realizations of certain boxes in \mathcal{D}^2 , \mathcal{D}^1 , and \mathcal{D}^0 . Second, the interiors of boxes in \mathcal{D} are open subsets of $Reg_2(|\mathcal{D}|)$, the interiors of boxes in \mathcal{D}^1 are open subsets of $Reg_1(|\mathcal{D}| - |\mathcal{D}|_2)$, and finally, $|\mathcal{D}|_0$ equals $Reg_0(|\mathcal{D}| - |\mathcal{D}|_2 - |\mathcal{D}|_1)$.

In general, the construction of this decomposition goes as follows. For $k = 0, 1, \dots, n$ and any combination of k different elements i_1, \dots, i_k in $\{1, \dots, n\}$, we define the following set of $(n - k)$ -dimensional boxes in \mathbf{R}^n :

$$(5.9) \quad \mathcal{P}_{\{i_1, \dots, i_k\}} := \left\{ (a_1, b_1, \dots, a_n, b_n) \in \mathbf{R}^{2n} \mid \exists \vec{p}_1 \exists \vec{q}_1 \dots \exists \vec{p}_n \exists \vec{q}_n \in I \right. \\ \left. \bigwedge_{i \in \{1, \dots, n\}} (a_i = (\vec{p}_i)_i \wedge b_i = (\vec{q}_i)_i) \wedge \forall \vec{r} \in I \bigwedge_{i=1}^n \neg(a_i < (\vec{r})_i < b_i) \right. \\ \left. \wedge \bigwedge_{i \in \{1, \dots, n\} - \{i_1, \dots, i_k\}} a_i < b_i \wedge \bigwedge_{i \in \{i_1, \dots, i_k\}} a_i = b_i \right\}.$$

Note that $\mathcal{P}_{\{1, \dots, n\}} = I$ and $\mathcal{P}_\emptyset = \mathcal{P}$. It is clear that these sets are expressible in FO+POLY. We also define for $k = 0, 1, \dots, n$ and any combination of k different elements i_1, \dots, i_k in $\{1, \dots, n\}$ the following $(n - k)$ -dimensional box collection in \mathbf{R}^n :

$$\mathcal{D}_{\{i_1, \dots, i_k\}} := \left\{ (a_1, b_1, \dots, a_n, b_n) \in \mathcal{P}_{\{i_1, \dots, i_k\}} \mid \exists (a'_1, b'_1, \dots, a'_n, b'_n) \in \mathcal{D} \right. \\ \left. \wedge \bigwedge_{i=1}^n (a'_i \leq a_i \wedge b_i \leq b'_i) \right\}.$$

We then define

$$\mathcal{D}^{n-k} := \bigcup_{\{i_1, \dots, i_k\}} \mathcal{D}_{\{i_1, \dots, i_k\}}.$$

Finally, for $k = 0, 1, \dots, n$, we define $|\mathcal{D}|_{n-k}$ as the union of the interiors of the geometric realizations of boxes in \mathcal{D}^{n-k} . Here, when taking the interior, we regard each geometric realization of a box as a space on itself, so the result is an open box. By construction, we have the following properties:

1.

$$(5.10) \quad |\mathcal{D}| = |\mathcal{D}|_n \cup \dots \cup |\mathcal{D}|_0;$$

2. each geometric realization of a box in \mathcal{D} is the union of the geometric realizations of boxes in $|\mathcal{D}|_k$ for $k = 0, 1, \dots, n$; and
3. the interiors of the geometric realizations of boxes in \mathcal{D}^k are open subsets of $Reg_k(|\mathcal{D}| - |\mathcal{D}|_n - \dots - |\mathcal{D}|_{k+1})$.

Let $\mathcal{S} = \{S\}$, with S a $2n$ -ary relation name. We define the $n + 1$ queries $Q_{k\text{-box}}$ such that for any polynomial constraint database D over \mathcal{S} representing a box collection \mathcal{D} ,

$$Q_{k\text{-box}}(D) = \mathcal{D}^i$$

for $k = 0, 1, \dots, n$ with \mathcal{D}^i the i -dimensional box collection in \mathbf{R}^n defined above. The following trivially holds.

LEMMA 5.12. *The queries $Q_{k\text{-box}}$, $k = 0, 1, \dots, n$, are expressible in FO+POLY.*

FIG. 5.10. The δ -cover of a semiopen annulus for $\delta = 1$.

5.6. Expressing the box covering query. Let $\delta > 0$ be a real number. We define the n -dimensional standard grid of size δ , called the δ -grid, as the n -dimensional box collection δ -grid consisting of all boxes of the form $(k_1\delta, (k_1 + 1)\delta, \dots, k_n\delta, (k_n + 1)\delta)$, where $k_1, \dots, k_n \in \mathbf{Z}$. We define the *box covering of size δ* of a semialgebraic set A , denoted by $\delta\text{-cover}(A)$, as those boxes in the δ -grid that intersect the closure of A (see Figure 5.10). Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. For each $\delta > 0$ we define the *box covering query* $Q_{\delta\text{-cover}}$ such that for every constraint database D over \mathcal{S} ,

$$Q_{\delta\text{-cover}}(D) := \delta\text{-cover}(S^D).$$

PROPOSITION 5.13. *Let $\delta > 0$. The query $Q_{\delta\text{-cover}}$ is not expressible in FO+POLY.*

Proof. Let $\mathcal{S} = \{S\}$, with S a binary relation name. We consider the following FO+POLY formula over \mathcal{S} : a formula `circle` such that for any database D over \mathcal{S} , either `circle`(D) is the circle through the points of S^D , if S^D consists of three noncollinear points, or `circle`(D) = S^D .

Assume that the query $Q_{\delta\text{-cover}}$ is expressible in FO+POLY. Let $\delta\text{-cover}$ be the formula which expresses $Q_{\delta\text{-cover}}$. Then the formula

$$\varphi \equiv \delta\text{-cover}(\text{circle})$$

is also expressible in FO+POLY. However, the number of 4-tuples in $\varphi(D)$ can be made arbitrarily large by choosing D to be a database over \mathcal{S} such that S^D consists of three points far enough apart. This contradicts the dichotomy theorem of Benedikt and Libkin [4], which guarantees the existence of a polynomial p_φ such that $|\varphi(D)| < p_\varphi(|S^D|) = p_\varphi(3)$ in the case when $|\varphi(D)|$ is finite. \square

However, in FO+POLY+TC we can express the box covering query as follows.

PROPOSITION 5.14. *For each $\delta > 0$, the query $Q_{\delta\text{-cover}}$ is expressible in FO+POLY+TC when restricted to bounded input databases.*

Proof. Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. We define the bounding box query Q_{bb} as the query such that for every polynomial constraint database D , such that S^D is bounded, $Q_{\text{bb}}(D) := \{M\}$, with M a real number such that $\text{cl}(S^D) \subseteq [-M, M]^n$. This query is clearly FO+POLY expressible by a formula over \mathcal{S} which we denote by `boundingbox`(x). Let

$$\begin{aligned} \text{grid}(u) \equiv & [\text{TC}_{x;x'} \exists M (\text{boundingbox}(M) \wedge x \geq 0 \\ & \wedge x' = x + \delta \wedge x' \leq M)](0, u) \vee u = 0. \end{aligned}$$

Let

$$\delta\text{-cover}(u_1, v_1, \dots, u_n, v_n) \equiv \bigwedge_{i=1}^n (v_i = u_i + \delta \wedge \text{grid}(u_i)) \\ \wedge \exists \vec{x} \left(\text{cl}(S)(\vec{x}) \wedge \bigwedge_{i=1}^n u_i < x_i < v_i \right).$$

Then $Q_{\delta\text{-cover}}(D) = \delta\text{-cover}(D)$ for any database D over \mathcal{S} such that S^D is bounded. \square

6. Linearization and approximation of semialgebraic sets. In this section, we give a construction of both an algebraic linearization and an ε -approximation of semialgebraic sets which are implementable in FO+POLY+TC. This implementation is based on the construction of a box collection satisfying some special properties.

More specifically, it is shown in section 6.1 how to construct such a box collection \mathcal{R} for a semialgebraic set A . In section 6.2 we derive a box collection \mathcal{U} from \mathcal{R} and take a closer look at A on the boundaries of \mathcal{U} . We show that we can apply the construction in section 6.1 again for A on the lower-dimensional box collections on the boundaries of \mathcal{U} . This inductive process is the basis of the algorithm LINEARIZE in section 6.3 which builds an algebraic linearization and an ε -approximation of bounded semi-algebraic sets. In the same section, we prove the correctness of the algorithm LINEARIZE and show that the algorithm can be expressed by a query in FO+POLY+TC.

We also show how to extend this algorithm such that it also builds algebraic linearizations of possibly unbounded semialgebraic sets. Finally, in section 6.4 we show that after some minor changes, the algorithm LINEARIZE can be used to build a rational linearization and an ε -approximation of semialgebraic sets.

6.1. Construction of a special box collection. Let \mathcal{B} be an n -dimensional box collection in \mathbf{R}^n , and let $\mathcal{X} = \{X_1, \dots, X_k\}$ be a finite set of pairwise disjoint semialgebraic sets in \mathbf{R}^n . We now define when \mathcal{B} and \mathcal{X} are in general position. We decompose $|\mathcal{B}|$ and \mathcal{X} into a finite number of regular sets and then define “being in general position” in terms of these decompositions as follows.

In (5.10), we defined a decomposition of a box collection into regular sets. Applied to $|\mathcal{B}|$, this results in the decomposition $|\mathcal{B}|_n, \dots, |\mathcal{B}|_0$, where $|\mathcal{B}|_i$ is a union of interiors of i -dimensional boxes in \mathbf{R}^n .

For each X_i , let R_{i0}, \dots, R_{in_i} be a regular decomposition of X_i . We say that \mathcal{B} and \mathcal{X} are in general position if and only if $\{|\mathcal{B}|_n, \dots, |\mathcal{B}|_0\}$ and $\{R_{1,0}, \dots, R_{1,n_1}, \dots, R_{k,0}, \dots, R_{k,n_k}\}$ are in general position.

We now describe the construction of an n -dimensional special box collection (the properties of this box collection will become clear later on). The construction takes as input

- a bounded semialgebraic set A in \mathbf{R}^n ;
- a uniform cone radius collection U_0, \dots, U_m of $\text{cl}(A)$ (as defined in section 5.2); and
- a fixed n -dimensional box collection \mathcal{F} in \mathbf{R}^n , which is in general position with $\{U_0, \dots, U_m\}$.

The result of the construction will be

- a set of box collections $\mathcal{R} = \{\mathcal{R}_0, \dots, \mathcal{R}_m\}$ and
- a positive real number δ

FIG. 6.1. Illustration of the construction of the box collection $\mathcal{B}_0^{\mathcal{R}}(\tau)$ for $\mathcal{R} = \{\mathcal{R}_0, \mathcal{R}_1\}$ and $U = U_0 \cup U_1$ as explained in Example 6.1. The picture shows $\mathcal{R} + \tau$ (right), the intermediate result $(\mathcal{R}_0 \sqcup \mathcal{R}_1) + \tau$ (middle), and the end result $\mathcal{B}_0^{\mathcal{R}}(\tau)$ (right).

satisfying some properties. Before we can state these properties, we need to define for $k = m, \dots, 0$ and $\tau \in \mathbf{R}^n$ the box collections

$$\mathcal{B}_k^{\mathcal{R}}(\tau) := (((\mathcal{R}_k \sqcup \dots \sqcup \mathcal{R}_m) + \tau \sqcup \mathcal{F}) \cap U_k) \setminus \{B' \in ((\mathcal{R}_k \sqcup \dots \sqcup \mathcal{R}_m) + \tau \sqcup \mathcal{F}) \cap U_k \mid |B'| \subseteq |\mathcal{B}_{k+1}^{\mathcal{R}}(\tau) \cup \dots \cup \mathcal{B}_m^{\mathcal{R}}(\tau)|\}.$$

In the following, we will write $\mathcal{B}_i^{\mathcal{R}}$ for $\mathcal{B}_i^{\mathcal{R}}(\mathbf{0})$ and let $U = U_0 \cup \dots \cup U_m$. The definition of $\mathcal{B}_k^{\mathcal{R}}(\tau)$ basically tells how to fit together all the box collections in \mathcal{R} and specifies which boxes should be disregarded. We illustrate the definition of $\mathcal{B}_k^{\mathcal{R}}$ by the following example.

Example 6.1. Assume we have a box collection $\mathcal{R} = \{\mathcal{R}_0, \mathcal{R}_1\}$ covering $U = U_0 \cup U_1$. In Figure 6.1 (left) we have depicted \mathcal{R}_0 and \mathcal{R}_1 with solid and dotted lines, respectively. Moreover, the set U_1 consists of the dotted curve, while U_0 is shown as a thick solid line. In this example, we assume that no fixed box collection \mathcal{F} is present.

Then by definition, $\mathcal{B}_1^{\mathcal{R}}(\tau) = (\mathcal{R}_1 + \tau) \cap U_1$. This box collection (in this example consisting of a single box only) corresponds to the large shaded box in Figure 6.1 (middle). For the construction of $\mathcal{B}_0^{\mathcal{R}}(\tau)$, we first compute the box collection $(\mathcal{R}_0 \sqcup \mathcal{R}_1) + \tau$, which consists of all the boxes shown in Figure 6.1 (middle). Solid-lined boxes intersect U_0 ; dotted-lined boxes do not. In order to obtain $\mathcal{B}_0^{\mathcal{R}}(\tau)$, all dotted-lined boxes are removed as well as those solid-lined boxes, which are included in $\mathcal{B}_1^{\mathcal{R}}(\tau)$ (the shaded area). The resulting box collection $\mathcal{B}_0^{\mathcal{R}}(\tau)$ is shown in Figure 6.1 (right). \diamond

We now continue with the statement of the desired properties of the box collection \mathcal{R} and real number δ . They must satisfy the properties

- (i) $\text{cl}(U)^\delta \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}}|)$;
- (ii) for all $i = 0, \dots, m$ and for all $\tau \in \mathbf{R}^n$ of norm less than δ , $(\mathcal{R}_i + \tau) \sqcup \mathcal{F} \pitchfork U_i$; and
- (iii) for all $i = 0, \dots, m$ and for all $\tau \in \mathbf{R}^n$ of norm less than δ , and for each n -dimensional box $B \in \mathcal{B}_i^{\mathcal{R}}(\tau)$, there exists a point $\vec{p} \in \text{int}(|B| \cap U_i)$ such that $\gamma_{\text{cone}, A}(\vec{p}) > \text{diam}(B)$.

Construction algorithm. The construction of the box collection is done inductively on the number of parts m in the uniform cone radius collection $\{U_0, \dots, U_m\}$.

For the base case, when the uniform cone radius collection is empty, we define

$\mathcal{R}_{-1} = \emptyset$ and take $\delta = \infty$. Properties (i), (ii), and (iii) are then trivially satisfied.

Suppose now that U is nonempty and consists of m parts. By the induction hypothesis, there exist n -dimensional box collections $\mathcal{R}' = \{\mathcal{R}'_1, \dots, \mathcal{R}'_m\}$ and a positive real number δ' such that

- (i)' $\text{cl}(U \setminus U_0)^{\delta'} \subseteq \text{int}(|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|)$;
- (ii)' for all $i = 1, \dots, m$ and for all $\tau \in \mathbf{R}^n$ of norm less than δ' , $(\mathcal{R}'_i + \tau) \sqcup \mathcal{F} \pitchfork U_i$; and
- (iii)' for all $i = 1, \dots, m$ and for all $\tau \in \mathbf{R}^n$ of norm less than δ' , and for each n -dimensional box $B \in \mathcal{B}_i^{\mathcal{R}'(\tau)}$, there exists a point $\vec{p} \in \text{int}(|B| \cap U_i)$ such that $\gamma_{\text{cone}, A}(\vec{p}) > \text{diam}(B)$.

The construction consists of two steps:

Step 1. Cover the part of U_0 which may become uncovered by translations of the box collection $\mathcal{R}' + \tau$, for $\|\tau\| < \delta'$, with a box covering of a certain size. This size is determined by the uniform cone radius of the part of U_0 possibly uncovered by the translates of \mathcal{R}' .

Step 2. Some of the boxes in the above box covering might be in a degenerate position and in this way prevent the box collection from satisfying the required properties. This can be easily resolved, however, by translating all boxes with a small translation vector τ . Lemma 6.3 shows that it is possible to bring all boxes into general position; Lemma 6.4 shows that translating the boxes indeed results in a box collection with the desired properties.

We describe the two steps now in more detail. An example of the construction can be seen in Figure 6.2 and is described in the following example.

Example 6.2. We consider the case that no fixed box collection \mathcal{F} is present. Let $\{A_0, A_1\}$ be the uniform cone radius decomposition of $\text{cl}(A)$ (see Figure 6.2(a)). The set A_1 consists of the horizontal circle and point \vec{p} in Figure 6.2(a). The set A_0 is equal to the remainder $\text{cl}(A) \setminus A_1$.

1. *Base case* (not shown in Figure 6.2): $U = \emptyset, U_0 = \emptyset$. By definition, $\mathcal{R}_{-1} = \{\emptyset\}$, $\delta = \infty$.
2. *Case $m = 1, U = A_1, U_0 = A_1$.*

Covering U_0 : Since in Step 1 nothing is yet constructed, we have that $V = U_0, W = \emptyset$, and $\zeta = \infty$. Hence, $\mathcal{R}'' = \frac{\varepsilon V}{4\sqrt{3}}\text{-cover}(V)$. This box covering is depicted by the dashed boxes in Figure 6.2(a). By definition, $\delta'' = \min\{\frac{\delta'}{3} = \infty, \eta, \zeta = \infty\} = \eta$, where η is such that $\text{cl}(V)^\eta \subseteq \text{int}(|\mathcal{R}''|)$.

Translating \mathcal{R}'' : As can be seen in Figures 6.2(a), (b), the point \vec{p} lies on a side of one of the boxes at the bottom. In other words, \vec{p} is not in general position with the box collection. A simple small translation, however, resolves this situation and brings \vec{p} into general position with the box collection (see Figure 6.2(b)) while keeping the other points U_0 in general position as well. The resulting box collection is denoted by \mathcal{R} .

From \mathcal{R} we get $\mathcal{B}_0^{\mathcal{R}}$, as shown in Figure 6.2(c), by removing, in this case, a single box which no longer intersect U_0 .

3. *Case $m = 2, U = A_0 \cup A_1, U_0 = A_0, \mathcal{R}''_1 = \mathcal{R}$, and $\delta' = \delta$ (obtained in Step 2).*

Covering U_0 : We focus on a region around the box B in \mathcal{R}''_1 containing \vec{p} (See Figure 6.2(d)). For expository reasons, the position of U with respect to B is slightly simplified.

We have depicted the set V (dark shaded area) of points in U_0 , which might be outside $|B|$ when B is slightly translated, and show the remaining set W

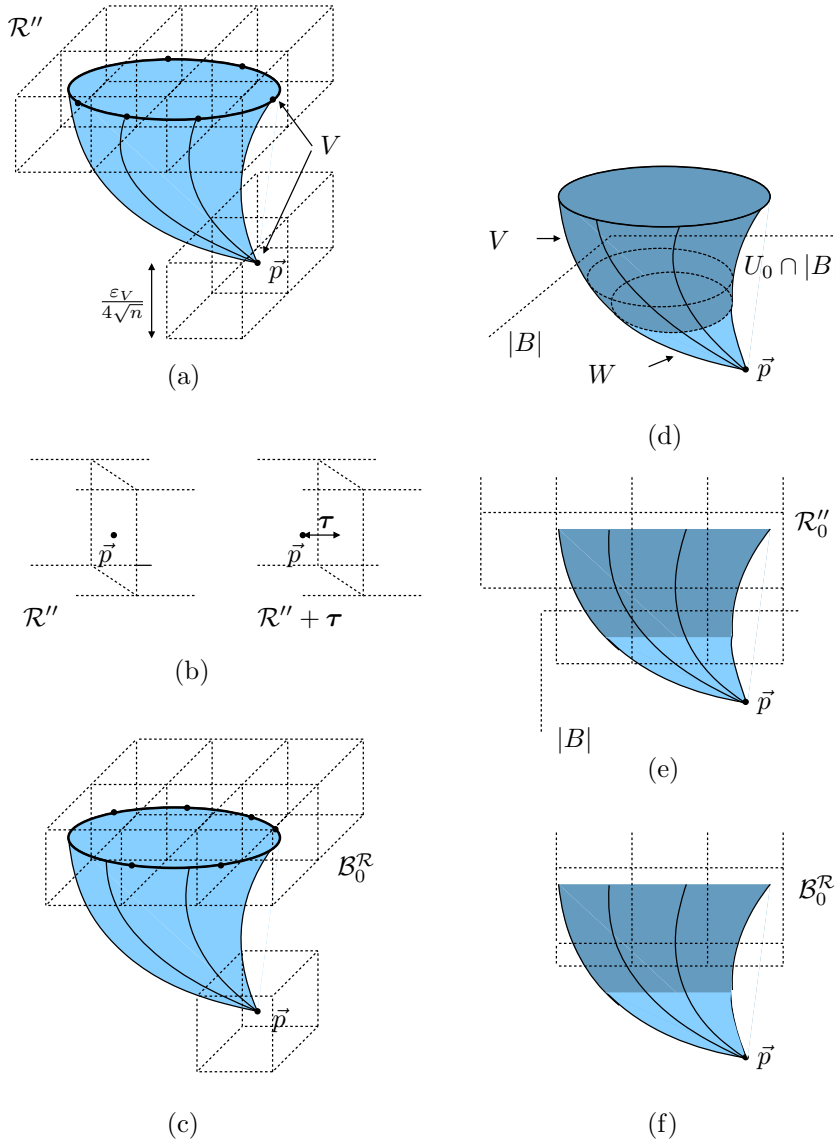

FIG. 6.2. Construction of the special box collection \mathcal{R} .

(light shaded area) as well. The new box collection \mathcal{R}_0'' will be $\frac{\varepsilon_V}{4\sqrt{3}}$ -cover(V). In order to not overload the figure, we have depicted the box collection from a sideways point of view (See Figure 6.2(e)). Let $\mathcal{R}'' = \{\mathcal{R}_0'', \mathcal{R}_1''\}$.

The constraint δ'' on the norm of translation vectors is given by $\delta'' = \min\{\frac{\delta'}{3}, \eta, \zeta\}$. It takes into account the distance between W and the boundary of the boxes constructed in Step 2 (ζ), the distance between V and the boundary of boxes in \mathcal{R}_0'' (η), and the constraint given in Step 2 (δ').

Translating \mathcal{R}'' : If necessary, slightly translate \mathcal{R}'' to bring it in general position such that it satisfies the desired properties. This results in the final box collection \mathcal{R} .

We also show part of $\mathcal{B}_0^{\mathcal{R}}$ (See Figure 6.2(f)). We refer to Example 6.1 for a discussion of its construction. The collection $\mathcal{B}_1^{\mathcal{R}}$ is equal to $\mathcal{B}_0^{\mathcal{R}}$ constructed in Step 2. \diamond

We now continue with the general description of the construction.

First step: Covering U_0 . We will define a set \mathcal{R}_0'' and define $\mathcal{R}_i'' = \mathcal{R}_i'$ for $i = 1, \dots, m$ such that for $\mathcal{R}'' = \{\mathcal{R}_0'', \dots, \mathcal{R}_m''\}$, $\text{cl}(U)\delta'' \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''}(\boldsymbol{\tau}) \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}(\boldsymbol{\tau})|)$ for some $\delta'' > 0$.

All points of U_0 that can become uncovered by varying the vector $\boldsymbol{\tau}$ in $|\mathcal{B}_1^{\mathcal{R}'}(\boldsymbol{\tau}) \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}(\boldsymbol{\tau})|$ with $\|\boldsymbol{\tau}\| < \frac{\delta'}{3}$ are included in the set

$$V := U_0 - (|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}| - (\partial|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|)^{\frac{\delta'}{3}}).$$

By (i)', the minimal distance from any point in $U \setminus U_0$ to the boundary $\partial(|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|)$ is greater than or equal to δ' . This implies that

$$\text{cl}(U \setminus U_0)^{\frac{\delta'}{3}} \subseteq |\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}| - (\partial|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|)^{\frac{\delta'}{3}},$$

and hence, because U_0, \dots, U_m is a uniform cone radius collection, there exists a uniform cone radius, ε_V , of A for the set V . Let \mathcal{R}_0'' be $\frac{\varepsilon_V}{4\sqrt{n}}$ -cover(V). Note that

$$(6.1) \quad \text{diam}(B) = \frac{\varepsilon_V}{2}$$

for any box $B \in \mathcal{R}_0''$. The reason why we take this specific box covering is that the box collection, which we are constructing, must satisfy property (iii).

We now show that there exists a positive real number δ'' such that (i) holds for $\mathcal{R}'' = \{\mathcal{R}_0'', \dots, \mathcal{R}_m''\}$ and δ'' .

We partition $U_0 \cup \dots \cup U_m$ into three parts: $U \setminus U_0$, V , and

$$W := U_0 \cap (|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}| - (\partial|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}|)^{\frac{\delta'}{3}}).$$

By (i)',

$$(6.2) \quad \text{cl}(U \setminus U_0)^{\frac{\delta'}{3}} \subseteq \text{int}(|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|) \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}|).$$

We shall need the following lemma, which is readily verified.

LEMMA 6.1. *Let X and Y be two sets in \mathbf{R}^n . If X is bounded, then $\text{cl}(X) \subseteq \text{int}(Y)$ implies that there exists a positive real number ε such that $\text{cl}(X)^\varepsilon \subseteq \text{int}(Y)$.*

By the definition of a box covering, $\text{cl}(V) \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''}|) \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}|)$. Since A is bounded, V is also bounded. By Lemma 6.1, there exists a positive real number η such that

$$(6.3) \quad \text{cl}(V)^\eta \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}|).$$

We now prove that Lemma 6.1 can also be used for W .

LEMMA 6.2. $\text{cl}(W) \subseteq \text{int}(|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|)$.

Proof of Lemma 6.2. Suppose that there exists a point $\vec{p} \in \text{cl}(W)$ such that $\vec{p} \notin \text{int}(|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|)$. Let (\vec{p}_m) for $m > 0$ be a sequence of points in W such that $\|\vec{p} - \vec{p}_m\| < 1/m$. By the definition of W , for all points in $\vec{r} \in \partial|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|$, $\|\vec{r} - \vec{p}_m\| \geq \frac{\delta'}{3}$ for every m .

Now, every line segment $\{\lambda\vec{p}_m + (1-\lambda)\vec{p} \mid 0 \leq \lambda \leq 1\}$, intersects $\partial|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|$ in a point \vec{r}_m . However, since $\|\vec{p}_m - \vec{p}\| < 1/m$, also $\|\vec{p}_m - \vec{r}_m\| < 1/m$. Thus, we obtain a contradiction for m large enough such that $\frac{1}{m} < \frac{\delta'}{3}$. \square

Hence, by Lemma 6.1 and Lemma 6.2 there exists a positive real number ζ such that

$$(6.4) \quad W^\zeta \subseteq \text{int}(|\mathcal{B}_1^{\mathcal{R}'} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}'}|) \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}|).$$

From the inclusions (6.2), (6.3), and (6.4), it follows that property (i) is satisfied for \mathcal{R}'' and δ'' , with $\delta'' = \min\{\frac{\delta'}{3}, \eta, \zeta\}$.

Second step: translating \mathcal{R}'' . The box collections in \mathcal{R}'' already satisfy property (i) for δ'' . However, properties (ii) and (iii) are not necessarily satisfied. This can be seen in Figure 6.2 (a), (b). We now show that a little translation of the box collection is all that is needed so that all properties are satisfied by the translated box collections.

LEMMA 6.3. *For each $i = 0, \dots, m$, there exists a translation $\tau \in \mathbf{R}^n$ of norm $\|\tau\| < \delta''$ such that*

$$(\mathcal{R}''_i + \tau) \sqcup \mathcal{F} \pitchfork U_i.$$

Proof of Lemma 6.3. Consider the decomposition of $|(\mathcal{R}''_i + \tau) \sqcup \mathcal{F}|$ into the sets $|(\mathcal{R}''_i + \tau) \sqcup \mathcal{F}|_j$ for $i = 0, \dots, m$ and for $j = 0, \dots, n$. Recall from section 5.5 that $|(\mathcal{R}''_i + \tau) \sqcup \mathcal{F}|_j$ is the union of the geometric realizations of boxes in $((\mathcal{R}''_0 + \tau) \sqcup \mathcal{F})^j$.

We need to prove that there exists a translation $\tau \in \mathbf{R}^n$, $\|\tau\| < \delta''$, such that for each $i = 0, \dots, m$, for each $r \in \{0, \dots, n_i\}$, for each $j \in \{0, \dots, n\}$, and for each $B \in ((\mathcal{R}''_i + \tau) \sqcup \mathcal{F})^j$, we have that

$$(6.5) \quad |B| \pitchfork R_{i,r}.$$

Let T denote the set of all possible translations: $T := \{\tau \in \mathbf{R}^n \mid \|\tau\| < \delta''\}$. Note that case $i > 0$ of (6.5) holds for any $\tau \in T$ by induction. Hence, we can focus on the case $i = 0$. Take an arbitrary B as in (6.5), take r arbitrary in $\{0, \dots, n\}$, and consider a point $\vec{x} \in |B| \cap R_{0,r}$. We are going to impose several conditions on T such that if $\tau \in T$ and τ satisfies these conditions, then (6.5) holds for τ . By definition of the union operator \sqcup , there exists a neighborhood W of \vec{x} such that one of the following three cases holds:

1. $|B| \cap W = |B'| \cap W$ for some $B' \in \mathcal{F}^p$ for some p . Note that

$$(6.6) \quad T_{\vec{x}}|B| = T_{\vec{x}}(|B| \cap W) = T_{\vec{x}}(|B'| \cap W) = T_{\vec{x}}|B'|.$$

Given that $\mathcal{F} \pitchfork U_0$, $|B'|$ and $R_{0,r}$ are transversal in \vec{x} for all $\tau \in T$. By (6.6), we may conclude that $|B|$ and $R_{0,r}$ are transversal in \vec{x} for all $\tau \in T$.

2. $|B| \cap W = |B''| \cap W$ for some $B'' \in (\mathcal{R}''_0 + \tau)^q$ for some q . Note that

$$(6.7) \quad T_{\vec{x}}|B| = T_{\vec{x}}(|B| \cap W) = T_{\vec{x}}(|B''| \cap W) = T_{\vec{x}}|B''|.$$

Suppose that

$$(T1) \quad (\mathcal{R}''_0 + \tau) \pitchfork U_0.$$

Then, $|B''| \pitchfork U_0$ and hence, $|B''|$ and $R_{0,r}$ are transversal in \vec{x} for all $\tau \in T$ such that condition (T1) is satisfied. By (6.7), we may conclude that $|B|$ and $R_{0,r}$ are transversal in \vec{x} for all $\tau \in T$ such that condition (T1) is satisfied.

3. $|B| \cap W = |B'| \cap |B''| \cap W$ for some $B' \in \mathcal{F}^p$ for some p , and for some $B'' \in (\mathcal{R}''_0 + \tau)^q$ for some q . Suppose that

$$(T2) \quad (\mathcal{R}''_0 + \tau) \pitchfork \mathcal{F}.$$

Because the intersection of regular sets in general position is regular, the tangent space $T_{\vec{x}}(|B'| \cap |B''|)$ exists. Note that

$$(6.8) \quad T_{\vec{x}}|B| = T_{\vec{x}}(|B| \cap W) = T_{\vec{x}}(|B'| \cap |B''| \cap W) = T_{\vec{x}}(|B'| \cap |B''|).$$

Furthermore, suppose that

$$(T3) \quad |B''| \pitchfork (|B'| \cap R_{0,r}).$$

When two regular sets intersect transversally in a point, the tangent space of the intersection in this point is the intersection of the tangent spaces of the regular sets in this point [23]. Hence, by (T2) and given that $\mathcal{F} \pitchfork U_0$, we have that $T_{\bar{x}}|B'| \cap T_{\bar{x}}|B''| = T_{\bar{x}}(|B'| \cap |B''|)$ and $T_{\bar{x}}|B'| \cap T_{\bar{x}}(R_{0,r}) = T_{\bar{x}}(|B'| \cap R_{0,r})$. Moreover, $T_{\bar{x}}(|B'| \cap R_{0,r}) \subseteq T_{\bar{x}}(R_{0,r})$. By (T3) we have that $T_{\bar{x}}(|B'| \cap |B''|) + T_{\bar{x}}(|B'| \cap R_{0,r}) = T_{\bar{x}}|B'|$. Hence,

$$\begin{aligned} T_{\bar{x}}|B| + T_{\bar{x}}(R_{0,r}) &= T_{\bar{x}}(|B'| \cap |B''|) + T_{\bar{x}}(R_{0,r}) \\ &= T_{\bar{x}}(|B'| \cap |B''|) + T_{\bar{x}}(|B'| \cap R_{0,r}) + T_{\bar{x}}(R_{0,r}) \\ &= T_{\bar{x}}(|B'|) + T_{\bar{x}}(R_{0,r}) \\ &= \mathbf{R}^n. \end{aligned}$$

Hence, we may conclude that $|B|$ and $R_{0,r}$ are transversal in \bar{x} for all $\tau \in T$ such that conditions (T2) and (T3) are satisfied.

We may conclude that $(\mathcal{R}_0'' + \tau) \sqcup \mathcal{F} \pitchfork U_0$ if $\tau \in T$ and if τ is such that, for each box $B \in ((\mathcal{R}_0'' + \tau) \sqcup \mathcal{F})^j$ for $j = 0, \dots, n$, either no extra condition holds, the condition (T1) holds, or both conditions (T2) and (T3) hold. Hence, we obtain a finite number of conditions on the translations in T . By Corollary 5.10, the set of translations $\tau \in T$ for which a single transversality condition, like (T1), (T2), or (T3), is not satisfied, has measure zero. Since a finite union of sets of measure zero also has measure zero, this implies that for almost all translations in T , all conditions can be satisfied simultaneously. This concludes the proof of the lemma. \square

Let τ_0 be a translation, as specified in Lemma 6.3. We now define for $i = 0, \dots, m$, $\mathcal{R}_i = \mathcal{R}_i'' + \tau_0$ and consider $\mathcal{R} = \{\mathcal{R}_0, \dots, \mathcal{R}_m\}$ and $\delta''' < \delta'' - \|\tau_0\|$.

LEMMA 6.4. *There exists a $\delta > 0$ such that $\mathcal{R}_0, \dots, \mathcal{R}_m$ and δ satisfy properties (i), (ii), and (iii).*

Proof of Lemma 6.4. We first prove that there exists a $\delta > 0$ such that property (ii) is satisfied. Indeed, the proof of Lemma 6.3 shows that for $i = 0, \dots, m$, $(\mathcal{R}_i'' + \tau) \sqcup \mathcal{F} \pitchfork U_i$ holds for any τ which satisfies a finite number of transversality conditions. Recall from section 5.4 that transversality is a stable property. Hence, if τ is a translation vector satisfying these transversality conditions, then there exists an $\varepsilon > 0$ such that any $\tau' \in \mathbf{R}^n$, for which $\|\tau' - \tau\| < \varepsilon$, also satisfies these transversality conditions.

Since $\mathcal{R}_i = \mathcal{R}_i'' + \tau_0$, and τ_0 is such that Lemma 6.3 holds, there exists a $\varepsilon > 0$ such that for $\tau \in \mathbf{R}^n$, $\|\tau\| < \varepsilon$,

$$(\mathcal{R}_i + \tau) \sqcup \mathcal{F} \pitchfork U_i$$

for $i = 0, \dots, m$. Hence, property (ii) is satisfied for $\mathcal{R}_0, \dots, \mathcal{R}_m$ and $\delta = \min\{\delta''', \varepsilon\}$.

We now prove that $\mathcal{R}_0, \dots, \mathcal{R}_m$ and δ also satisfy property (i). We will need the following properties which can be readily verified. Let X and Y be semialgebraic sets in \mathbf{R}^n . Then

- (1) $X^\varepsilon \subseteq Y \Rightarrow X \subseteq Y + \tau$ for any $\tau \in \mathbf{R}^n$ such that $\|\tau\| < \varepsilon$, and
- (2) $(X^{\varepsilon_1})^{\varepsilon_2} = X^{\varepsilon_1 + \varepsilon_2}$.

We already know $\text{cl}(U)^{\delta''} \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}|)$. Let $\varepsilon = \delta'' - \|\tau_0\| - \delta$. Since $\delta < \delta'' - \|\tau_0\|$, we have $\varepsilon > 0$, and by property (2),

$$\text{cl}(U)^{\delta''} = (\text{cl}(U)^\delta)^{\|\tau_0\| + (\delta'' - \|\tau_0\| - \delta)} \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}|).$$

By property (1), we have that

$$\text{cl}(U)^\delta \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}|) + \tau \quad \forall \tau : \|\tau\| < \|\tau_0\| + \varepsilon.$$

In particular, $\text{cl}(U)^\delta \subseteq \text{int}(|\mathcal{B}_0^{\mathcal{R}''} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}''}|) + \tau_0 = \text{int}(|\mathcal{B}_0^{\mathcal{R}} \cup \dots \cup \mathcal{B}_m^{\mathcal{R}}|)$, and property (i) is satisfied for \mathcal{R} and δ .

We now prove that property (iii) is satisfied. Let $B \in \mathcal{B}_i^{\mathcal{R}}(\tau)$ for any $\tau \in \mathbf{R}^n$, $\|\tau\| < \delta$. We distinguish between the following two cases:

1. $i > 0$. Since $\mathcal{B}_i^{\mathcal{R}}(\tau) \subseteq \mathcal{B}_i^{\mathcal{R}'}(\tau_0 + \tau)$ and $\|\tau - \tau_0\| < \delta'$, we have by induction that there exists a $\vec{p} \in \text{int}(|B|) \cap U_i$ such that $\gamma_{\text{cone},A}(\vec{p}) > \text{diam}(B)$.
2. $i = 0$. Since $|B| \cap U_0 \neq \emptyset$, we need to prove that there exists a $\vec{p} \in \text{int}(|B|) \cap U_0$ such that $\gamma_{\text{cone},A}(\vec{p}) > \text{diam}(B)$.

Thus, let $\vec{x} \in |B| \cap U_0$. If $\vec{x} \in \text{int}(|B|)$, we are done. If $\vec{x} \in \partial|B|$, then $\vec{x} \in |B'| \cap U_0$ for some $|B'| \in ((\mathcal{R}_0 \sqcup \dots \sqcup \mathcal{R}_m) + \tau) \sqcup \mathcal{F}^p$ and some p . Let $D = (x_1 - \varepsilon, x_1 + \varepsilon, \dots, x_n - \varepsilon, x_n + \varepsilon)$ be an n -dimensional box centered around \vec{x} , with $\varepsilon \in \mathbf{R}$. For ε sufficiently small, $|B'| \cap \text{int}(|D|)$ has the form

$$(x_1 - \varepsilon, x_1 + \varepsilon) \times \dots \times (x_p - \varepsilon, x_p + \varepsilon) \times \{x_{p+1}\} \times \dots \times \{x_n\},$$

or a permutation of this form, which is handled analogously. Hence, $\text{int}(|B|) \cap \text{int}(|D|)$ has the form

$$(x_1 - \varepsilon, x_1 + \varepsilon) \times \dots \times (x_p - \varepsilon, x_p + \varepsilon) \times (x_{p+1}, x_{p+1} + \varepsilon) \times \dots \times (x_n, x_n + \varepsilon),$$

or a permutation of this form, which is handled analogously, or even a variant of this form, where some of the $n - p$ intervals $(x_i, x_i + \varepsilon)$ are replaced by $(x_i - \varepsilon, x_i)$, which again is handled analogously.

By property (ii),

$$(6.9) \quad \mathbb{T}_{\vec{x}}|B'| + \mathbb{T}_{\vec{x}}U_0 = \mathbf{R}^n.$$

Now, any $\vec{v} \in \mathbb{T}_{\vec{x}}|B'|$ is of the form $\vec{v} = (v_1, \dots, v_p, x_{p+1}, \dots, x_n)$; hence, by (6.9) there exists a tangent vector $\vec{w} \in \mathbb{T}_{\vec{x}}U_0$ such that $x_{p+1} < w_{p+1}, \dots, x_n < w_n$. By definition of the tangent space, if $\|\vec{w} - \vec{x}\|$ is small enough, there exists a point \vec{q} in U_0 arbitrarily close to \vec{w} . This point \vec{q} is also arbitrarily close to \vec{x} and also has $n - p$ last coordinates, which are strictly greater than the $n - p$ last coordinates of \vec{x} . Hence, \vec{q} is in $\text{int}(|B|) \cap \text{int}(|D|)$, and we have found a point in $\text{int}(|B|) \cap U_0$.

We now show that for any $\vec{p} \in \text{int}(|B|) \cap U_0$, $\gamma_{\text{cone},A}(\vec{p}) > \text{diam}(B)$. Indeed, any box in $\mathcal{B}_0^{\mathcal{R}}(\tau)$ is included in a box in $\mathcal{R}_0'' + \tau_0 + \tau$. By (6.1), \mathcal{R}_0'' consists of boxes which have a diameter that is strictly smaller than the uniform cone radius of $\text{int}(|B|) \cap U_0$. Hence, $\gamma_{\text{cone},A}(\vec{p}) > \text{diam}(B)$ for any point $\vec{p} \in \text{int}(|B|) \cap U_0$.

As a result, property (iii) is satisfied for \mathcal{R} and δ . □

This concludes the construction of the box collection \mathcal{R} and $\delta > 0$.

6.2. A first glance at the linearization algorithm. In this section we describe how the special box collection \mathcal{R} , constructed in the previous section, helps us in achieving our goal of linearizing a semialgebraic set $A \subseteq \mathbf{R}^n$.

First, using the box collection \mathcal{R} , we define

$$(6.10) \quad \mathcal{U} = \mathcal{B}_0^{\mathcal{R}} \cup \dots \cup \mathcal{B}_n^{\mathcal{R}}.$$

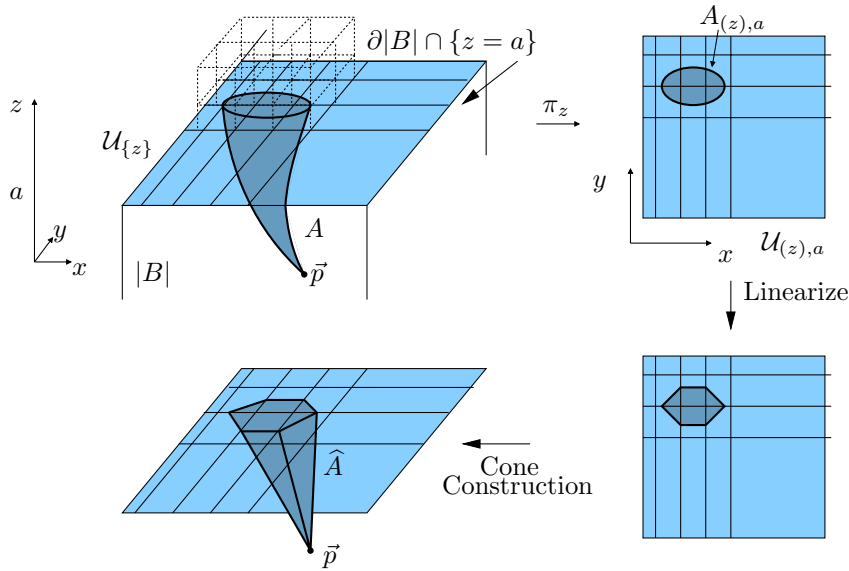

FIG. 6.3. Illustration of the linearization \widehat{A} inside $|B|$. The top side of $\partial|B|$ is shown together with that part of $\mathcal{U}_{(z)}$ and A lying on it. The top side has z -coordinate a (top left). The two-dimensional projected sets $\mathcal{U}_{(z),a}$ and $A_{(z),a}$ are shown (top right). The linearization algorithm is called inductively on these lower-dimensional sets (bottom right). The three-dimensional linearization consists of building a cone with top \vec{p} and base the previously constructed linearization on the boundary of B (bottom left).

Recall that $\mathcal{B}_i^{\mathcal{R}}$ stands for $\mathcal{B}_i^{\mathcal{R}}(\mathbf{0})$. Since each $\mathcal{B}_i^{\mathcal{R}}$ is a box collection and $\text{int}(|\mathcal{B}_i^{\mathcal{R}}|) \cap \text{int}(|\mathcal{B}_j^{\mathcal{R}}|) = \emptyset$ for any $i \neq j$, \mathcal{U} is a box collection too. It is clear that \mathcal{U} inherits some of the properties of \mathcal{R} . Indeed, by property (i) of \mathcal{R} , we know that \mathcal{U} is a box covering of $\text{cl}(A)$ and, by property (iii) of \mathcal{R} , we know that for each box $B \in \mathcal{U}$ there exists a point $\vec{p} \in \text{int}(|B|) \cap A$ such that $\gamma_{\text{cone},A}(\vec{p}) > \text{diam}(B)$.

The linearization algorithm, which will be described in more detail in section 6.3, works inductively on the boundaries of the boxes in \mathcal{U} . For each box $B \in \mathcal{U}$, the linearization algorithm replaces $|B| \cap A$ with a semilinear set in two steps. In the induction step, it replaces the intersection $\partial|B| \cap A$ with a semilinear set $\widehat{\partial|B| \cap A}$ on $\partial|B|$, which is homeomorphic to $\partial|B| \cap A$. Then, for each box $B \in \mathcal{U}$, it replaces $|B| \cap A$ with the semilinear set

$$\text{Cone}(\widehat{\partial|B| \cap A}, \vec{p}),$$

where $\vec{p} \in \text{int}(|B|) \cap A$ such that $\gamma_{\text{cone},A}(\vec{p}) > \text{diam}(B)$. It is shown in Lemma 6.5 that in this way we end up with a linearization of A . An illustration of the linearization algorithm is given in Figure 6.3.

In order to construct the linearization $\widehat{\partial|B| \cap A}$ on $\partial|B|$ of boxes $B \in \mathcal{U}$, we will need to construct again a box collection \mathcal{R} , but this time on the boundaries of the boxes in \mathcal{U} .

We will decompose the boundaries of the boxes in \mathcal{U} according to the direction of their supporting hyperplanes and according to the coordinate value of the fixed coordinate of these hyperplanes.

These coordinates can be computed as

$$\text{Coord}(\mathcal{U}_{\{i\}}) = \{a \in \mathbf{R} \mid \exists a_1, \exists b_1, \dots, \exists a_{i-1}, \exists b_{i-1}, \exists a_{i+1}, \exists b_{i+1}, \dots, \exists a_n, \exists b_n \\ (a_1, b_1, \dots, a_{i-1}, b_{i-1}, a, a, a_{i+1}, b_{i+1}, \dots, a_n, b_n) \in \mathcal{U}_{\{i\}}\}$$

for $i = 1, \dots, n$ and where $\mathcal{U}_{\{i\}}$ are the n -dimensional box collections defined in (5.9). Recall that $\mathcal{U}_{\{i\}}$ contains all n -dimensional boxes on the boundaries of boxes in \mathcal{U} , whose i th coordinates are all equal.

For each $a \in \text{Coord}(\mathcal{U}_{\{i\}})$, we will need all the points in $\text{cl}(A)$ with the i th coordinated fixed to a , i.e.,

$$\text{cl}(A)_{(i),a} := \{(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n) \in \mathbf{R}^{n-1} \mid \\ (x_1, \dots, x_{i-1}, a, x_{i+1}, \dots, x_n) \in \text{cl}(A)\}$$

for $i = 1, \dots, n$.

Similarly, we define the $(n - 1)$ -dimensional box collections

$$\mathcal{U}_{(i),a} := \{(a_1, b_1, \dots, b_{i-1}, a_{i+1}, \dots, a_n, b_n) \in \mathbf{R}^{2(n-1)} \mid \\ (a_1, b_1, \dots, b_{i-1}, a, a, a_{i+1}, \dots, a_n, b_n) \in \mathcal{U}_{\{i\}}\}$$

for $i = 1, \dots, n$.

Since $\text{cl}(A) = C_0 \cup \dots \cup C_m$, and $C_m = R_{m,n} \cup \dots \cup R_{m,0}$, we have that

$$\text{cl}(A)_{(i),a} = (C_0)_{(i),a} \cup \dots \cup (C_m)_{(i),a}, \\ (C_j)_{(i),a} = (R_{j,n})_{(i),a} \cup \dots \cup (R_{j,0})_{(i),a}.$$

For each $i = 0, \dots, n$ and each $a \in \text{Coord}(\mathcal{U}_{\{i\}})$, we now show that we can construct an $(n - 1)$ -dimensional box collection \mathcal{R} , as described in section 6.1, for $\text{cl}(A)_{(i),a}$ in the role of $\text{cl}(A)$, $(C_0)_{(i),a}, \dots, (C_m)_{(i),a}$ in the role of, respectively, U_0, \dots, U_m , and $\mathcal{U}_{(i),a}$ in the role of \mathcal{F} .

However, for the construction to be successful, we need to verify that we start with valid input data. In other words, we need to show that $(C_0)_{(i),a}$ is a uniform cone radius with a regular decomposition given by $(R_{j,n})_{(i),a}$ and that \mathcal{F} (which is $\mathcal{U}_{(i),a}$) is in general position with $(C_0)_{(i),a}$ for the regular decomposition $(R_{j,n})_{(i),a}$.

CLAIM 6.1. *The sets $(C_0)_{(i),a}, \dots, (C_m)_{(i),a}$ form a uniform cone radius decomposition of $\text{cl}(A)_{(i),a}$.*

Proof. By definition, the sets $(C_0)_{(i),a}, \dots, (C_m)_{(i),a}$ form a decomposition of $\text{cl}(A)_{(i),a}$, so we need only show that each of the sets $(C_0)_{(i),a}, \dots, (C_m)_{(i),a}$ form a uniform cone radius collection.

We will need the following property, which is readily verified. Let X and Y be semialgebraic sets in \mathbf{R}^n . Then

- (1) if Y is closed and bounded, then for all ε' there exists an ε such that $X^\varepsilon \cap Y \subseteq (X \cap Y)^{\varepsilon'}$.

Let $H_{(i),a} = \{\vec{x} \in \mathbf{R}^n \mid x_i = a\}$, and let $\pi_i : \mathbf{R}^n \rightarrow \mathbf{R}^{n-1}$ be defined by $\pi_i(x_1, \dots, x_n) = (x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n)$. Let $j \in \{0, \dots, m\}$, and let $\varepsilon'_0, \dots, \varepsilon'_m$ be positive real numbers. We have that

$$(C_j)_{(i),a} \setminus \bigcup_{k=j+1}^m ((C_k)_{(i),a})^{\varepsilon'_k} = \pi_i \left((C_j \cap H_{(i),a}) \setminus \bigcup_{k=j+1}^m (C_k \cap H_{(i),a})^{\varepsilon'_k} \right).$$

By property (1), there exist $\varepsilon_0 > 0, \dots, \varepsilon_m > 0$ such that

$$(6.11) \quad (C_j \cap H_{(i),a}) \setminus \bigcup_{k=j+1}^m (C_k \cap H_{(i),a})^{\varepsilon'_k} \subseteq (C_j \cap H_{(i),a}) \setminus \bigcup_{k=j+1}^m (C_k^{\varepsilon_k} \cap H_{(i),a}) \\ = \left(C_j \setminus \bigcup_{k=j+1}^m C_k^{\varepsilon_k} \right) \cap H_{(i),a}.$$

Moreover, we have that $\text{cl}(A) = C_0 \cup \dots \cup C_m$ and, since C_0, \dots, C_m is a uniform cone radius collection, from the inclusion (6.11), it follows that

$$0 < \inf \left\{ \gamma_{\text{cone},A} \left(\left(C_j \setminus \bigcup_{k=j+1}^m C_k^{\varepsilon_k} \right) \cap H_{(i),a} \right) \right\} \\ \leq \inf \left\{ \gamma_{\text{cone},A} \left((C_j \cap H_{(i),a}) \setminus \bigcup_{k=j+1}^m (C_k \cap H_{(i),a})^{\varepsilon'_k} \right) \right\}.$$

We will next show that the following inequality holds:

$$\inf \left\{ \gamma_{\text{cone},A} \left((C_j \cap H_{(i),a}) \setminus \bigcup_{k=j+1}^m (C_k \cap H_{(i),a})^{\varepsilon'_k} \right) \right\} \\ \leq \inf \left\{ \gamma_{\text{cone},A \cap H_{(i),a}} \left((C_j \cap H_{(i),a}) \setminus \bigcup_{k=j+1}^m (C_k \cap H_{(i),a})^{\varepsilon'_k} \right) \right\} \\ = \inf \left\{ \gamma_{\text{cone},\pi_i(A \cap H_{(i),a})} \left(\pi_i \left((C_j \cap H_{(i),a}) \setminus \bigcup_{k=j+1}^m (C_k \cap H_{(i),a})^{\varepsilon'_k} \right) \right) \right\}.$$

Hence,

$$0 < \inf \left\{ \gamma_{\text{cone},A_{(i),a}} \left((C_j)_{(i),a} \setminus \bigcup_{k=j+1}^m ((C_k)_{(i),a})^{\varepsilon'_k} \right) \right\},$$

which proves that $(C_0)_{(i),a}, \dots, (C_m)_{(i),a}$ is a uniform cone radius collection.

We still need to prove that for each $\vec{x} \in C_j \cap H_{(i),a}$,

$$\gamma_{\text{cone},A}(\vec{x}) \leq \gamma_{\text{cone},A \cap H_{(i),a}}(\vec{x}).$$

The proof is illustrated in Figure 6.4. The main ingredient is the construction of the cone radius, as described in the proof of Theorem 2 in [14]. As explained in the paragraph immediately following Theorem 5.3, the radius query produces for each point \vec{x} an interval $(0, r)$ of cone radii, where r is the minimal distance between \vec{x} and each $\vec{s} \in \mathcal{S} \subseteq \mathbf{R}^n$, where \mathcal{S} contains those points \vec{s} which have a tangent space that is orthogonal to $\vec{x} - \vec{s}$ or parallel to one of the axes-parallel hyperplanes. Here, the tangent spaces are taken with respect to a Whitney-decomposition \mathcal{Z} of A , which is compatible with the union of all axes-parallel hyperplanes (including $H_{i,a}$) through \vec{x} . An example of such a Whitney-decomposition is given in Figure 6.4 (top right). Also in this figure, we have depicted the set \mathcal{S} . The (maximal) cone radius of A in (a, b) is illustrated by the dashed circle centered around (a, b) .

Recall that we defined

$$\gamma_{\text{cone},A}(\vec{x}) = \frac{1}{2}r = \frac{1}{2} \min_{\vec{s} \in \mathcal{S}} d(\vec{x}, \vec{s}),$$

FIG. 6.4. Semialgebraic set A locally around (a, b) (top left). Whitney-decomposition \mathcal{Z} of A compatible with axes-parallel hyperplanes through (a, b) (top right). Intersection A' of A with horizontal hyperplane through (a, b) and projected on the x -axis (bottom left). Whitney-decomposition \mathcal{Z}' of A' (bottom right). The isolated points (top and bottom right) denote the critical points, i.e., points (c, d) with a horizontal or vertical tangent space, or a tangent space perpendicular to the vector $(c, d) - (a, b)$. Note that these tangent spaces are relative to the Whitney-decomposition. Moreover, by construction the set \mathcal{S} of critical points for A around (a, b) shown as the isolated points (top right) includes the set \mathcal{S}' of critical points of A' around a (bottom right). Consequently, $\gamma_{\text{cone}, A}(a, b) \leq \gamma_{\text{cone}, A'}(a)$.

where d denotes the ordinary distance function.

In the same way,

$$\gamma_{\text{cone}, A \cap H_{(i), a}}(\vec{x}) = \frac{1}{2} \min_{\vec{s} \in \mathcal{S}'} d(\vec{x}, \vec{s}),$$

where \mathcal{S}' contains those points \vec{s} which have a tangent space that is orthogonal to $\vec{x} - \vec{s}$ or parallel to one of the axes-parallel hyperplanes. Here, the tangent spaces are taken with respect to a Whitney-decomposition \mathcal{Z}' of $A \cap H_{(i), a}$. An example of such a Whitney-decomposition is given in Figure 6.4 (bottom right). Also in this figure we have depicted \mathcal{S}' . The (maximal) cone radius is illustrated by the interval bounded by the two dashed line segments centered around a .

Due to the requirement that \mathcal{Z} is compatible with the axes-parallel hyperplanes through \vec{x} , the Whitney-decomposition \mathcal{Z}' of $A \cap H_{(i), a}$ is equal to those strata $Z \in \mathcal{Z}$ such that $Z \subseteq H_{(i), a}$. In other words, $\mathcal{S}' \subseteq \mathcal{S}$, and hence,

$$\gamma_{\text{cone}, A}(\vec{x}) = \frac{1}{2} \min_{\vec{s} \in \mathcal{S}} d(\vec{x}, \vec{s}) \leq \frac{1}{2} \min_{\vec{s} \in \mathcal{S}'} d(\vec{x}, \vec{s}) = \gamma_{\text{cone}, A \cap H_{(i), a}}(\vec{x}),$$

as desired. \square

CLAIM 6.2. The sets $(R_{j,0})_{(i), a}, \dots, (R_{j,n_j})_{(i), a}$ form a regular decomposition of $(C_j)_{(i), a}$.

Proof. By definition, the sets $(R_{j,n})_{(i), a}, \dots, (R_{j,0})_{(i), a}$ form a decomposition of $(C_j)_{(i), a}$, so we need only show that each of the sets $(R_{j,k})_{(i), a}$, for $k = 0, \dots, n$, is regular. Let $H_{(i), a} = \{\vec{x} \in \mathbf{R}^n \mid x_i = a\}$, and let $\pi_i : \mathbf{R}^n \rightarrow \mathbf{R}^{n-1}$ be defined by $\pi_i(x_1, \dots, x_n) = (x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n)$.

It is sufficient to show that $R_{j,k}$ and $H_{(i), a}$ are in general position. Indeed, by the observation at the end of section 5.4, the intersection of two regular sets in general

position is again regular. Hence, $R_{j,k} \cap H_{(i),a}$ is regular. Thus, $(R_{j,k})_{(i),a} = \pi_i(R_{j,k} \cap H_{(i),a})$ is the image by the C^1 -diffeomorphism π_i of a regular set, and hence is regular itself.

We still need to show that $R_{j,k} \pitchfork H_{(i),a}$. By property (ii) of the constructed box collection \mathcal{U} , we know that $R_{j,k} \pitchfork \mathcal{U}$, and hence $R_{j,k} \pitchfork |\mathcal{U}|_\ell$. Let $\vec{x} \in R_{j,k} \cap H_{(i),a}$ and $B \in (\mathcal{U})^\ell$ such that $\vec{x} \in B \subset H_{(i),a}$. Note that such a B always exists because $a \in \text{Coord}(\mathcal{U}_{(i)})$ and \mathcal{U} covers A . Hence, $R_{j,k} \pitchfork |B|$ or, in other words, $T_{\vec{x}}R_{j,k} + T_{\vec{x}}|B| = \mathbf{R}^n$. Since $|B| \subset H_{(i),a}$, we have that $T_{\vec{x}}|B| \subseteq T_{\vec{x}}H_{(i),a}$, and hence also $T_{\vec{x}}R_{j,k} + T_{\vec{x}}H_{(i),a} = \mathbf{R}^n$. \square

CLAIM 6.3. *The box collections $\mathcal{U}_{(i),a}$ are in general position with $(C_0)_{(i),a}, \dots, (C_m)_{(i),a}$.*

Proof. We need to prove that $\{|\mathcal{U}_{(i),a}|_0, \dots, |\mathcal{U}_{(i),a}|_n\} \pitchfork \{(R_{j,k})_{(i),a} \mid j = 0, \dots, m, k = 0, \dots, n\}$. Let $H_{(i),a} = \{\vec{x} \in \mathbf{R}^n \mid x_i = a\}$, and let $\pi_i : \mathbf{R}^n \rightarrow \mathbf{R}^{n-1}$ be defined by $\pi_i(x_1, \dots, x_n) = (x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n)$.

We have that $|\mathcal{U}_{(i),a}|_\ell = \pi_i(|\mathcal{U}|_\ell \cap H_{(i),a})$. Thus, $B' \in (\mathcal{U}_{(i),a})^\ell$ if and only if $|B'| = \pi_i(|B|)$ with $B \in (\mathcal{U})^\ell$ and $|B| \subseteq H_{(i),a}$.

As already observed in the proof of Claim 6.2, $R_{j,k} \cap |\mathcal{U}|_\ell$ is a regular set. Hence, for $\vec{x} \in R_{j,k} \cap |\mathcal{U}|_\ell$ the tangent space $T_{\vec{x}}(R_{j,k} \cap |\mathcal{U}|_\ell)$ exists. Moreover, $T_{\vec{x}}(R_{j,k} \cap |\mathcal{U}|_\ell) = T_{\vec{x}}(R_{j,k} \cap |B|)$ for some $B \in (\mathcal{U})^\ell$ and $|B| \subseteq H_{(i),a}$.

Let $|B'| = \pi_i(|B|)$. We need to prove that

$$(6.12) \quad T_{\vec{x}_{(i),a}}|B'| + T_{\vec{x}_{(i),a}}((R_{j,k})_{(i),a}) = \mathbf{R}^{n-1}.$$

We have that

$$(6.13) \quad T_{\vec{x}_{(i),a}}|B'| = d\pi_i(T_{\vec{x}}|B|) \text{ and}$$

$$(6.14) \quad T_{\vec{x}_{(i),a}}((R_{j,k})_{(i),a}) = d\pi_i(T_{\vec{x}}(R_{j,k} \cap |B|)),$$

where $d\pi_i$ is the differential of π_i [23].

Moreover, because of property (ii) of the box collection \mathcal{U} and the remark at the end of section 5.4 on the intersection of tangent spaces, we have

$$(6.15) \quad T_{\vec{x}}|B| + T_{\vec{x}}(R_{j,k}) = \mathbf{R}^n \text{ and}$$

$$(6.16) \quad T_{\vec{x}}(R_{j,k} \cap |B|) = T_{\vec{x}}R_{j,k} \cap T_{\vec{x}}|B|.$$

Now, let $(v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n) \in \mathbf{R}^{n-1}$ and let $\vec{v} = (v_1, \dots, v_{i-1}, 0, v_{i+1}, \dots, v_n) \in \mathbf{R}^n$. By (6.15) there exists $\vec{b} \in T_{\vec{x}}|B|$ and $\vec{r} \in T_{\vec{x}}(R_{j,k})$ such that $\vec{v} = \vec{b} + \vec{r}$. Moreover, we may take $b_i = 0$ since vectors in $T_{\vec{x}}|B|$ have no component in the i th coordinate. Hence r_i has to be zero too. By (6.16), we have $\vec{r} \in T_{\vec{x}}(R_{j,k} \cap |B|)$. Let $\vec{b}' = d\pi_i(\vec{b})$ and $\vec{r}' = d\pi_i(\vec{r})$. Then by (6.13), $\vec{b}' \in T_{\vec{x}_{(i),a}}|B'|$, and by (6.14), $\vec{r}' \in T_{\vec{x}_{(i),a}}((R_{j,k})_{(i),a})$. By construction, $(v_1, \dots, v_{i-1}, v_{i+1}, \dots, v_n) = \vec{b}' + \vec{r}'$, proving (6.12). \square

6.3. Putting everything together: The linearization algorithm. The algorithm that constructs an \mathbf{A} -linear set, which is homeomorphic to a given semialgebraic set, works inductively on the dimension of the surrounding space in which the semialgebraic set is embedded.

6.3.1. The bounded case. The algorithm consists of two parts. The first part is a preprocessing step, which takes as input a bounded semialgebraic set A in \mathbf{R}^n and returns the regular decomposition of each part of the uniform cone radius decomposition of A .

Subroutine: PREPROCESS**Input:** A semialgebraic set A in \mathbf{R}^n .**Output:** A uniform cone radius decomposition C_0, \dots, C_k of A and for each C_i a regular decomposition $R_{i,0}, \dots, R_{i,i}$ of C_i .**Method:**

1. Compute the uniform cone radius decomposition of A :

$$A = C_0 \cup \dots \cup C_k.$$

2. Compute the regular decomposition of C_i , for $i = 0, \dots, k$:

$$C_i = R_{i,0} \cup \dots \cup R_{i,i}.$$

Subroutine: LINEARIZE-IN- n -DIMENSIONS**Input:** $(\{C_i\}, \{R_{i,r}\}, \mathcal{F})$ with C_0, \dots, C_k a uniform cone radius collection, $\{R_{i,r}\}$ a regular decomposition of C_i , and \mathcal{F} an n -dimensional box collection in \mathbf{R}^n which is in general position with C_0, \dots, C_k .**Output:** An \mathbf{A} -linear set \widehat{C} in \mathbf{R}^n which is homeomorphic to $C = C_0 \cup \dots \cup C_k$.**Method:**

- If $n > 1$, do the following:
 1. Compute the box collection \mathcal{U} constructed in section 6.2.
 2. Compute a $(3n+1)$ -ary relation \mathcal{P} consisting of pairs (B, \vec{p}_B, b) , where B is an n -dimensional box in \mathcal{U} , $\vec{p}_B \in \mathbf{R}^n$, and $b \in \{0, 1\}$ such that:
 - (a) $\vec{p}_B \in \text{cl}(C) \cap \text{int}(B)$ and is uniquely selected for each B ;
 - (b) $\gamma_{\text{cone}, C}(\vec{p}_B) > \text{diam}(B)$; and
 - (c) $b = 0$ in case $\vec{p}_B \in \text{cl}(C) \setminus C$ and $b = 1$ in case $\vec{p}_B \in C$.
 3. Compute all $\mathcal{U}_{(i),a}$ with $a \in \text{Coord}(\mathcal{U}_{\{i\}})$ and $i \in \{1, \dots, n\}$.
 4. Compute all $(C_j)_{(i),a} \subset \mathbf{R}^{n-1}$ with $a \in \text{Coord}(\mathcal{U}_{\{i\}})$ and $i \in \{1, \dots, n\}$.
 5. Compute all $(R_{i,r})_{(i),a} \subset \mathbf{R}^{n-1}$ with $a \in \text{Coord}(\mathcal{U}_{\{i\}})$ and $i \in \{1, \dots, n\}$.
 6. For all input triples $(\{(C_j)_{(i),a}\}, \{(R_{i,r})_{(i),a}\}, \mathcal{U}_{(i),a})$ with $a \in \text{Coord}(\mathcal{U}_{\{i\}})$ and $i \in \{1, \dots, n\}$, apply LINEARIZE-IN- $(n-1)$ -DIMENSIONS and embed the result in the corresponding hyperplane in \mathbf{R}^n , i.e., apply $(x_1, \dots, x_{n-1}) \mapsto (x_1, \dots, a, \dots, x_{n-1})$ where a appears in the i th position.
 7. Initialize \widehat{C} to the union of the results of the calls to LINEARIZE-IN- $(n-1)$ -DIMENSIONS of step 6.
- If $n = 1$, then do the following:
 1. Initialize \widehat{C} to $C_0 \cup \dots \cup C_k$.
- Output

$$\begin{aligned} \widehat{C} := & \widehat{C} \cup \{\text{Cone}(\widehat{C} \cap \partial B, \vec{p}_B) \mid (B, \vec{p}_B, b) \in \mathcal{P} \text{ and } b = 1\} \\ & \cup \{\text{Cone}(\widehat{C} \cap \partial B, \vec{p}_B) \setminus \{\vec{p}_B\} \mid (B, \vec{p}_B, b) \in \mathcal{P} \text{ and } b = 0\}. \end{aligned}$$

Algorithm: LINEARIZE

Input: A bounded semialgebraic set A in \mathbf{R}^n .

Output: An \mathbf{A} -linear set \widehat{A} in \mathbf{R}^n which is homeomorphic to A .

Method:

1. Call LINEARIZE-IN- n -DIMENSIONS(PREPROCESS(A), \emptyset).

Before we prove the correctness of the LINEARIZE algorithm, we want to point out the importance of the general position assumption made in the input of the algorithm. First of all, it allows us to treat all boxes in \mathcal{U} in the same way. More specifically, for every box B we are assured of having a point $\vec{p}_B \in \text{int}(|B|)$ as described in step 2 of the algorithm (see Lemma 6.4). The existence of these points is essential for the linearization, as is clear from the last step in the algorithm. Second, the general position assumption ensures that the lower-dimensional sets defined in steps 3–5 are nice and are again in general position (see the three claims in section 6.2). This implies that we can apply LINEARIZE on the lower-dimensional sets, which is a key feature for the algorithm.

LEMMA 6.5. *For any semialgebraic set A in \mathbf{R}^n , the set $\widehat{A} = \text{LINEARIZE}(A)$ is indeed a linearization of A .*

Proof. The linearity of \widehat{A} is immediate, so we focus on the existence of a homeomorphism $h : \mathbf{R}^n \rightarrow \mathbf{R}^n$, which maps A to \widehat{A} .

The existence proof (which is also a constructive proof) is an inductive proof. Before we can state the induction hypothesis, we need to define some box collections in \mathbf{R}^n .

We define $\mathcal{U}_{[n]}$ to be the n -dimensional box collection \mathcal{U} in \mathbf{R}^n constructed in step 1 when LINEARIZE-IN- n -DIMENSIONS is called.

Let $k < n$. With each call of LINEARIZE-IN- k -DIMENSIONS during the linearization of A we associate the pair $(i_{n-k}, a_{i-k}) \in \{1, \dots, n\} \times \mathbf{R}$ such that a_{n-k} is the value in $\text{Coord}(\mathcal{U}_{\{i_{n-k}\}})$ used in step 6. Note that \mathcal{U} is the box collection constructed in step 1 during the preceding call of LINEARIZE-IN- $(k + 1)$ -DIMENSIONS.

This sequence of pairs gives us a unique identifier for the box collection constructed in step 1 during each call of the algorithm. More specifically, we denote by $\mathcal{U}_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})}$ the box collection \mathcal{U} constructed in step 1 of the call LINEARIZE-IN- k -DIMENSIONS corresponding to (i_{n-k}, a_{n-k}) , which was called within LINEARIZE-IN- $(k + 1)$ -DIMENSIONS corresponding to (i_{n-k-1}, a_{n-k-1}) , and so forth until LINEARIZE-IN- $(n - 1)$ -DIMENSIONS is called with (i_1, a_1) within the initial call LINEARIZE-IN- n -DIMENSIONS. If $k = 1$, then no box collection \mathcal{U} is constructed, since step 1 is skipped in the algorithm. However, for the purpose of this proof, we define $\mathcal{U}_{(i_1, a_1), \dots, (i_{n-1}, a_{n-1})}$ to be $\mathcal{U}_{\{i_{n-1}\}, a_{n-1}}$, where \mathcal{U} is the box collection constructed in step 1 of the preceding call to LINEARIZE-IN-2-DIMENSIONS corresponding to (i_{n-2}, a_{n-2}) , and so forth.

At the same time, the sequence of pairs (i_j, a_j) tells us how to correctly embed $\mathcal{U}_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})}$ into \mathbf{R}^n . Indeed, the embedding simply maps $\vec{x} \in \mathbf{R}^k$ to the vector $\vec{x}' \in \mathbf{R}^n$ obtained by putting a_j at position i_j and filling up the k open slots with the values (in this order) x_1, \dots, x_k . We will denote this embedding by $\rho_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})}$.

We now define the k -dimensional box collection $\mathcal{U}_{[k]}$ in \mathbf{R}^n as

$$\mathcal{U}_{[k]} = \cup_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})} \rho_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})}(\mathcal{U}_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})}).$$

Let $\mathcal{U}_{[\leq k]}$ be the union of all boxes in $\mathcal{U}_{[k]}, \dots, \mathcal{U}_{[1]}$. We shall construct homeomorphisms $h_k : |\mathcal{U}_{[\leq k]}| \rightarrow |\widehat{A} \cap \mathcal{U}_{[\leq k]}|$, such that

- $h_k(A \cap |\mathcal{U}_{[\leq k]}|) = \widehat{A} \cap |\mathcal{U}_{[\leq k]}|$, and
- for all boxes B in $\mathcal{U}_{[k]}, \dots, \mathcal{U}_{[1]}$, $h_k|_{|B|} : |B| \rightarrow |B|$ is a homeomorphism.

We shall construct the homeomorphisms h_k by induction on k .

For the base case, $k = 1$, the linearization algorithm keeps A intact (see the case $n = 1$ in the description of the LINEARIZE-IN- n -DIMENSIONS algorithm). Hence, $\mathcal{U}_{[1]} \cap \widehat{A} = \mathcal{U}_{[1]} \cap A$ and we let h_k be the identity mapping on $\mathcal{U}_{[1]}$. Both conditions are trivially satisfied for h_1 .

Suppose we have constructed a homeomorphism $h_{k-1} : |\mathcal{U}_{[\leq k-1]}| \rightarrow |\widehat{A} \cap \mathcal{U}_{[\leq k-1]}|$ such that

- $h_{k-1}(A \cap |\mathcal{U}_{[\leq k-1]}|) = \widehat{A} \cap |\mathcal{U}_{[\leq k-1]}|$, and
- for all boxes B in $\mathcal{U}_{[k]}, \dots, \mathcal{U}_{[1]}$, $h_{k-1}|_{|B|} : |B| \rightarrow |B|$ is a homeomorphism.

Let $B' \in \mathcal{U}_{[k]}$; then we will define $h_k|_{|B'|} : |B'| \rightarrow |B'|$ as the composition of two homeomorphisms f and g . Let us first describe the homeomorphism g . By definition, $|B'| = \rho_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})}(|B|)$ with $B \in \mathcal{U}_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})}$.

Let \mathcal{P} be the relation computed in step 2 after $\mathcal{U}_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})}$ was computed. By the definition of the relation \mathcal{P} and by Theorem 5.2, there exists a homeomorphism $g|_{|B|} : |B| \rightarrow |B|$ such that $g|_{\partial|B|}$ is the identity, and either

1. $g|_{|B|}(|B| \cap A) = \text{Cone}(A \cap \partial|B|, \vec{p}_B)$ in case $(B, \vec{p}_B, 1) \in \mathcal{P}$, or
2. $g|_{|B|}(|B| \cap A) = \text{Cone}(A \cap \partial|B|, \vec{p}_B) \setminus \{\vec{p}_B\}$ in case $(B, \vec{p}_B, 0) \in \mathcal{P}$.

Since the second case is completely analogous to the first case, we assume that the first case holds for g . This concludes the description of the homeomorphism g .

Before we explain the construction of the second homeomorphism f , we show how to partition $|B|$ using the boundary of boxes $|B_t|$ parametrized by $t \in [0, 1]$. Suppose that $|B| = [a_1, b_1] \times \dots \times [a_n, b_n]$, and suppose $\vec{p}_B = (c_1, \dots, c_n)$ with $a_i < c_i < b_i$ for $i = 1, \dots, n$. Then the following sets for $0 \leq t \leq 1$ partition $|B|$ such that $|B| = \cup_{t \in [0, 1]} \partial|B_t|$:

$$|B_t| := [ta_1 + (1-t)c_1, tb_1 + (1-t)c_1] \times \dots \times [ta_n + (1-t)c_n, tb_n + (1-t)c_n] \quad 0 \leq t \leq 1.$$

Let $\vec{x} \in |B|$. To start with the construction of $f(\vec{x})$ for $\vec{x} \in |B|$, we define the unique t_0 such that $\vec{x} \in \partial|B_{t_0}|$. Then, let L be the halfline from \vec{p}_B to \vec{x} and define

$$\vec{y} = L \cap \partial|B|.$$

Next, let L' is the halfline from \vec{p}_B to $h_{k-1}(\vec{y})$. Note that $h_{k-1}(\vec{y})$ still lies on the boundary $\partial|B|$. Finally, define $f|_{|B|} : |B| \rightarrow |B|$ in \vec{x} as

$$f|_{|B|}(\vec{x}) = \partial|B_{t_0}| \cap L'.$$

The construction of f is illustrated in Figure 6.5. It can easily be verified that $f|_{|B|}$ is a homeomorphism from $|B|$ to $|B|$ such that

$$(6.17) \quad f|_{|B|}(\text{Cone}(A \cap \partial|B|, \vec{p}_B)) = \text{Cone}(h_{k-1}(A \cap \partial|B|), \vec{p}_B).$$

Finally, we define $h_k|_{|B'|} : |B'| \rightarrow |B'|$ using the composition of the two homeomorphisms $f|_{|B|}$ and $g|_{|B|}$, i.e.,

$$h_k|_{|B'|} = \rho_{(i_1, a_1), \dots, (i_{n-k}, a_{n-k})} \circ f|_{|B|} \circ g|_{|B|} \circ \pi_{i_1, \dots, i_{n-k}}.$$

FIG. 6.5. Construction of the homeomorphism $f : |B| \rightarrow |B|$. The figure shows the construction of $f(\vec{x})$ for a point $\vec{x} \in |B|$.

We now define $h_k : |\mathcal{U}_{[\leq k]}| \rightarrow |\mathcal{U}_{[\leq k]}|$ as

$$h_k := \bigcup_{B \in \mathcal{U}_{[k]}} h_k|_{|B|}$$

and show that it has the desired properties. First, we prove that h_k is a homeomorphism. By the gluing Lemma [35, Lemma 3.8], it is sufficient to show that for any two boxes B and B' in $\mathcal{U}_{[k]}$, we have that

$$h_k|_{|B| \cup |B'|} = h_k|_{|B|} \cup h_k|_{|B'|} : |B| \cup |B'| \rightarrow |B| \cup |B'|.$$

For this to hold, it is sufficient to show that for any k -dimensional box $B' \in \mathcal{U}_{[k]}$ in \mathbf{R}^n ,

$$(6.18) \quad (h_k|_{|B|})|_{|B'|} = (h_k|_{|B'|})|_{|B|}.$$

This holds indeed. If $|B| \cap |B'| = \emptyset$, then we are done. Suppose that $\vec{x} \in |B| \cap |B'|$. Then by the definition of a box collection, $\vec{x} \in \partial|B| \cap \partial|B'|$. Now, for every box $B'' \in \mathcal{U}_{[k]}$, we have $h_k|_{\partial|B''|}(\vec{x}) = f|_{\partial|B''|}(\vec{x}) = h_{k-1}(\vec{x})$. Hence,

$$\begin{aligned} (h_k|_{|B|})|_{|B'|}(\vec{x}) &= h_k|_{\partial|B| \cap \partial|B'|}(\vec{x}) \\ &= h_{k-1}(\vec{x}) \\ &= h_k|_{\partial|B'| \cap \partial|B|}(\vec{x}) \\ &= (h_k|_{|B'|})|_{|B|}(\vec{x}). \end{aligned}$$

Hence, $h_k : |\mathcal{U}_{[\leq k]}| \rightarrow |\mathcal{U}_{[\leq k]}|$ is a homeomorphism.

Second, we show that for all boxes B in $\mathcal{U}_{[k]}, \dots, \mathcal{U}_{[1]}$, $h_{k-1}|_{|B|} : |B| \rightarrow |B|$ is a homeomorphism. By construction, this holds for any box $B \in \mathcal{U}_{[k]}$. For boxes $B' \in \mathcal{U}_{[i]}$ for $i < k$, it is sufficient to observe that such boxes B' lie on the boundary of a box B in $\mathcal{U}_{[k]}$, and on these boundaries h_k coincides with h_{k-1} for which the desired property holds by induction.

Finally, we still need to verify that $h_k(A \cap |\mathcal{U}_{[\leq k]}|) = \widehat{A} \cap |\mathcal{U}_{[\leq k]}|$. It is sufficient to show that $h_k(A \cap |B|) = \widehat{A} \cap |B|$ for any $B \in \mathcal{U}_{[k]}$. By (6.17), the induction hypothesis,

and the definition of \widehat{A} in the algorithm LINEARIZE-IN- n -DIMENSIONS, we have

$$\begin{aligned} h_k(A \cap |B|) &= \text{Cone}(h_{k-1}(A \cap \partial|B|), \vec{p}_B) \\ &= \text{Cone}(\widehat{A} \cap \partial|B|, \vec{p}_B) \\ &= \widehat{A} \cap |B|. \end{aligned}$$

Since $|\mathcal{U}|$ is closed, a standard result from topology [36] implies that the final homeomorphism h_n can be extended to a homeomorphism $h : \mathbf{R}^n \rightarrow \mathbf{R}^n$. \square

We are now ready to state the main result of this section.

THEOREM 6.6. *For each n , there exists an FO+POLY+TC formula `linearize` over the schema $\mathcal{S} = \{S\}$, with S an n -ary relation name such that for any polynomial constraint database D over \mathcal{S} , `linearize`(D) is an algebraic linearization of S^D if S^D is bounded.*

Proof. The desired FO+POLY+TC formula `linearize` expresses the algorithm LINEARIZE described above. From Lemma 5.5 and Lemma 5.7, it follows that the algorithm PREPROCESS is FO+POLY-expressible.

Concerning the algorithm LINEARIZE-IN- n -DIMENSIONS, we have that in step 1, the box collection \mathcal{U} is computed. In the construction of this box collection in section 6.1, we need to compute the following:

- The computation of a uniform cone radius. This is FO+POLY-expressible by Theorem 5.3.
- The computation of a finite number of box coverings, i.e., the $\frac{\varepsilon V}{4\sqrt{n}}$ -cover(V) coverings of section 6.1. This is FO+POLY+TC-expressible by Proposition 5.14.
- A candidate $\tau \in \mathbf{R}^n$ as specified in Lemma 6.3 needs to be found. Since this is essentially checking a finite number of transversality conditions, this is FO+POLY-expressible by Lemma 5.8.

Hence, we may conclude that the computation of \mathcal{U} is in FO+POLY+TC. In step 2, the relation \mathcal{P} is constructed. Given the box collection \mathcal{U} , we know by property (iii) of this collection that in each $B \in \mathcal{U}$ there exists a point $\vec{p} \in \text{int}(|B|) \cap \text{cl}(C)$ such that $\gamma_{\text{cone}, C}(\vec{p}) > \text{diam}(B)$. The set of points in $\text{int}(|B|)$ with this property is FO+POLY-expressible by Theorem 5.3. Hence, we can also select in FO+POLY for each $B \in \mathcal{U}$ a unique representant among these points. This will be \vec{p}_B . Hence, we may conclude that the computation of the relation \mathcal{P} is FO+POLY-expressible. In steps 3, 4, and 5, we need to compute $\text{Coord}(\mathcal{U}_{\{i\}})$, $\mathcal{U}_{(i), a}$, $(C_j)_{(i), a}$, and $(R_{i, r})_{(i), a}$. By definition these are all FO+POLY-expressible. In step 6 we call the algorithm n times. We have to be careful of how the inductive step is translated in FO+POLY+TC. A straightforward translation would result in a parametrized call of the transitive closure operators in the computation of the box coverings in step 1. Observe, however, that the set of parameters $\text{Coord}(\mathcal{U}_{(i)})$ for $i = \{1, \dots, n\}$ can be computed inside the transitive closure operator and that these parameters can then be passed on outside the transitive closure operator by simply annotating the vectors inside the transitive closure with these parameters. Indeed, suppose that we want to compute the transitive closure of a parametrized set $X \in \mathbf{R}^{n+m}$, where the last m coordinates are the parameters. Suppose that the set of parameters is FO+POLY+TC-definable from the database by a formula φ . We now define $Y = [\text{TC}_{\vec{x}, \vec{a}; \vec{y}, \vec{b}} X \wedge \vec{a} = \vec{b} \wedge \varphi(\vec{a})]$. We can then uniquely identify the result of this transitive closure computation for each parameter value by asking for all $(\vec{x}, \vec{a}) \in Y$, for which $\varphi(\vec{a})$ holds. By adapting the box covering formula constructed in Proposition 5.14, we can compute the box coverings for the parameter

FIG. 6.6. A semialgebraic set (shaded area) is mapped onto the sphere $S^2(\vec{0}, 1)$, flipped vertically, and projected back onto the sphere $S^2(\vec{0}, 1)$. This brings the point at infinity \vec{p}_∞ to the origin $\vec{0}$.

set $\text{Coord}(\mathcal{U}_{(i)})$ in parallel and keep them apart afterwards. In this way, we do not need parametrized transitive closure, and hence step 6 is expressible in FO+POLY+TC.

In step 7 a simple union is performed (which is trivially in FO+POLY), and finally, the cones are constructed, which is also clearly expressible in FO+POLY.

Since the recursion depth is bounded by the dimension, we can write the complete execution of the algorithm as a single FO+POLY+TC formula. \square

If the linearization obtained in Theorem 6.6 also needs to be a good approximation from a metrical point of view, we can easily adapt the algorithms such that the approximation lies arbitrarily close to the original polynomial constraint database. Indeed, we can simply bound the diameter of the boxes used in the construction by a specified ε -value. We will see some applications of these ε -approximations in the next section.

THEOREM 6.7. *For each n there exists an FO+POLY+TC query ε -approx over the schema $\mathcal{S} = \{S\}$ with S an n -ary relation name such that for any polynomial constraint database D over \mathcal{S} such that S^D is bounded, the set ε -approx(D) is an algebraic ε -approximation of S^D .*

Proof. The proof follows at once from the fact that the homeomorphism h constructed in the proof of Theorem 6.6 maps $A \cap |B|$ to $\hat{A} \cap |B|$ for each box $B \in \mathcal{U}$. Thus, if $\vec{p} \in A \cap |B|$ then also $h(\vec{p}) \in |B|$. Because $\text{diam}(B) < \varepsilon$, the distance between \vec{p} and $h(\vec{p})$ is smaller than ε , so in this case \hat{A} will be an ε -approximation of A . \square

6.3.2. The general case. Let A be an unbounded semialgebraic set in \mathbf{R}^n . We reduce the construction of an algebraic linearization of A to the construction for bounded semialgebraic sets as follows.

First, we need to define the *cone radius of A in the point at infinity \vec{p}_∞* . Consider the embedding $i : \mathbf{R}^n \rightarrow \mathbf{R}^{n+1} : (x_1, \dots, x_n) \mapsto (x_1, \dots, x_n, 0)$. Let $\rho : \mathbf{R}^{n+1} \rightarrow \mathbf{R}^{n+1}$ be the reflection defined by $(x_1, \dots, x_{n+1}) \mapsto (x_1, \dots, x_n, -x_{n+1})$. Let $\mathbf{R}^n \cup \{\vec{p}_\infty\}$ be the one-point compactification of \mathbf{R}^n [35]. Finally, consider the stereographic projection $\sigma : S^n((0, \dots, 0), 1) \rightarrow i(\mathbf{R}^n) \cup \{\vec{p}_\infty\}$ defined by $\sigma(x_1, \dots, x_{n+1}) = \frac{(x_1, \dots, x_n)}{1-x_{n+1}}$ and $\sigma(0, \dots, 0, 1) = \vec{p}_\infty$.

We define a cone radius of A at \vec{p}_∞ as a cone radius of the semialgebraic set

$$i^{-1}(\sigma(\rho(\sigma^{-1}(i(A) \cup \{\vec{p}_\infty\}))))$$

in the origin of \mathbf{R}^n . Figure 6.6 illustrates the above transformation process. The local conic structure of semialgebraic sets implies that there exists an $m > 0$ such that $\{\vec{x} \in \mathbf{R}^n \mid \|\vec{x}\| \geq m\} \cap A$ is topologically equivalent to $\{\lambda \vec{x} \in \mathbf{R}^n \mid \vec{x} \in \partial([-m, m] \times \dots \times [-m, m]) \cap A \wedge \lambda \geq 1\}$.

We now present the unbounded version of the algorithm LINEARIZE.

Algorithm LINEARIZE'

Input: A semialgebraic set A in \mathbf{R}^n .

Output: An \mathbf{A} -linear set \widehat{A} in \mathbf{R}^n which is homeomorphic to A .

Method:

1. Compute a cone radius m of A in \vec{p}_∞ . Let $M = [-m, m] \times \cdots \times [-m, m]$.
2. Call $\text{Linearize}(A \cap M)$.
3. Output

$$\widehat{A} := (\widehat{A \cap M}) \cup \{\lambda \vec{x} \in \mathbf{R}^n \mid \vec{x} \in A \cap \partial M \wedge \lambda \geq 1\}.$$

We obtain the following generalization of Theorem 6.6.

THEOREM 6.8. *For each n there exists an FO+POLY+TC formula **linearize** over the schema $\mathcal{S} = \{S\}$, with S an n -ary relation name such that for any polynomial constraint database D over \mathcal{S} , $\text{linearize}(D)$ is an algebraic linearization of S^D .*

6.4. Rational linearizations. We now refine the previous theorems to *rational linearization*.

THEOREM 6.9. *For each n , there exists an FO+POLY+TC query **ratlin** over the schema $\mathcal{S} = \{S\}$, with S n -ary, such that for any polynomial constraint database D over \mathcal{S} such that S^D is bounded, $\text{ratlin}(D)$ is a rational linearization of S^D .*

Proof. We can obtain this result easily by modifying the construction of the special box collection in section 6.1 in the following way. When the box covering \mathcal{V} of size $\frac{\varepsilon \mathcal{V}}{\sqrt{n}}$ is computed in this construction, we compute a rational number that is smaller than $\frac{\varepsilon \mathcal{V}}{\sqrt{n}}$ and take this as the size of the box covering \mathcal{V} to be computed. By similar techniques as those in section 4, it is easy to show that there exists an FO+POLY+TC query, which returns a rational number smaller than the input number. In this way, all boxes in $\mathcal{R} \subset \mathbf{Q}^{2n}$. A second adaptation is that the relation \mathcal{P} is replaced by the following relation

$$\mathcal{P}' = \{(B, \vec{c}_B, b) \in \mathcal{U} \times \mathbf{Q}^n \times \{0, 1\} \mid \exists \vec{p}_B(B, \vec{p}_B, b) \in \mathcal{P}\},$$

where \vec{c}_B denote the center of the box B .

In this way the algorithm LINEARIZE-IN- n -DIMENSIONS will select points with rational coordinates. □

We also have a rational equivalent of Theorem 6.7.

THEOREM 6.10. *For each n there exists an FO+POLY+TC query ε -**ratlin** over the schema $\mathcal{S} = \{S\}$, with S an n -ary relation name, such that for any polynomial constraint database D over \mathcal{S} such that S^D is bounded, the set ε -**ratlin**(D) is a rational ε -approximation of S^D .*

6.5. The connectivity query. Although we know already that the connectivity query, which asks whether a polynomial constraint database is connected, is expressible in FO+POLY+TCS, we show in this section that the connectivity query is already expressible in FO+POLY+TC. Let A be a semialgebraic set in \mathbf{R}^n . For semialgebraic sets, expressing the connectivity query is the same as expressing whether any two points can be connected by a path lying entirely in A [6, Proposition 2.5.13]. One

can even choose the paths to be semialgebraic, in case of a semialgebraic set, and semilinear, in case of a semilinear set [44, Chapter 6, Proposition 3.2].

We now show that this query can be expressed in FO+POLY+TC using the formula `linearize` given in Theorem 6.8.

Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. Consider the FO+POLY+TC formula `lineconn`(\vec{r}, \vec{s}) over \mathcal{S} such that for any database D over \mathcal{S} , $(\vec{p}, \vec{q}) \in \text{lineconn}(D)$ if and only if

$$\forall \lambda (0 \leq \lambda \leq 1), \quad \lambda \vec{p} + (1 - \lambda) \vec{q} \in \text{linearize}(D).$$

Define now the FO+POLY+TC sentence `connected`, which tests for any database D over \mathcal{S} whether

$$\forall \vec{p} \in \text{linearize}(D), \forall \vec{q} \in \text{linearize}(D), \quad (\vec{p}, \vec{q}) \in [\text{TC}_{\vec{x}; \vec{y}} \text{lineconn}(D)].$$

PROPOSITION 6.11. *Let $\mathcal{S} = \{S\}$ with S an n -ary relation name. The FO+POLY+TC formula `connected` always terminates and expresses the connectivity query.*

Proof. Since `linearize`(D) is topologically equivalent to S^D , S^D is connected if and only if `linearize`(D) is. Since `linearize`(D) is semilinear, two points \vec{p} and \vec{q} belong to the same connected component of `linearize`(D) if and only if there exists a piecewise linear path from \vec{p} to \vec{q} lying entirely in `linearize`(D). The formula `connected` expresses that all points of `linearize`(D) belong to the same connected component, i.e., that `linearize`(D) is connected.

To conclude that the evaluation of the transitive closure in the formula `connected` ends in finitely many steps, we need to show that there exists an upper bound on the number of line segments in `linearize`(D), which is needed to connect any two points in the same connected component of `linearize`(D). Now, any semilinear set can be decomposed into a finite number of convex sets [44]. The finiteness of this decomposition yields the desired bound. \square

Since FO+POLY+TC is included in stratified DATALOG with polynomial constraints, Proposition 6.11 solves the question [15, 31, 33] of whether stratified DATALOG with polynomial constraints can express the connectivity query.

6.6. Volume approximation. In this section, we shall use the box covering and the ε -approximation to approximate the volume of semialgebraic sets with an FO+POLY+TC formula. We restrict our attention to bounded semialgebraic sets and require that the evaluation of this FO+POLY+TC formula is effective for all bounded semialgebraic inputs.

Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. Let D be a polynomial constraint database over \mathcal{S} .

The *volume* of a database D is defined as the Lebesgue-measure of the semialgebraic set $S^D \subseteq \mathbf{R}^n$ and is denoted by $\text{VOL}(D)$.

Since we want an FO+POLY+TC formula whose evaluation is effective on all databases, it is impossible to define the *exact* volume of polynomial constraint databases in FO+POLY+TC. Indeed, consider the database consisting of the unit disk D in \mathbf{R}^2 . The volume of D equals π . Since π is not algebraic, this value cannot be the output of an effective FO+POLY+TC query.

Hence, as suggested by Koiran [28] and Benedikt and Libkin [5], we consider for each $\varepsilon > 0$ an ε -*volume approximation query* VOL^ε , such that for any polynomial constraint database D over \mathcal{S} , such that if $v \in \text{VOL}^\varepsilon(D)$, then

$$|v - \text{VOL}(S^D)| < \varepsilon.$$

FIG. 6.7. A semialgebraic set A with $\kappa(A) = 12$.

It is known that volume approximation is not expressible in FO+POLY [5]. We show that it is expressible in FO+POLY+TC.

We will use the following result.

THEOREM 6.12 (see [28]). *Let A be a semialgebraic set in \mathbf{R}^n , and let δ -cover(A) be its box covering of size δ . Then*

$$(6.19) \quad |\text{VOL}(A) - \text{VOL}(\delta\text{-cover}(A))| < \frac{1}{\delta}(\text{diam}(A))^{n+1}\kappa(A)n,$$

where $\kappa(A)$ is the maximal number of connected components of the intersection of A with any axis-parallel line L (see Figure 6.7), and where $\text{diam}(A)$ is the diameter of A .⁵

THEOREM 6.13. *For each $\varepsilon > 0$, there exists an ε -volume approximation query in FO+POLY+TC.*

Proof. We first show that the number κ of Theorem 6.12 is expressible in FO+POLY+TC. Thereto, first we define n sets K_i which contain $(2n - 1)$ -tuples $(a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_n, \vec{p})$, where $a_j \in \mathbf{R}$ for $j = 1, \dots, i - 1, i + 1, \dots, n$, and where \vec{p} is either an isolated point on the intersection of A with $\{\vec{x} \mid \bigwedge_{j \neq i} x_j = a_j\}$, or in the middle of an interval in this intersection. Using similar techniques as in section 4, we compute for each $(a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_n)$ the number of points \vec{p} such that $(a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_n, \vec{p}) \in K_i$. We then obtain n sets K'_i consisting of n -tuples $(a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_n, N)$ with $N \in \mathbf{N}$, and we define M_i to be the maximum of all those N which are in K'_i for some $(a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_n)$. Finally, $\kappa = \max\{M_1, \dots, M_n\}$.

Let $\delta = \frac{1}{\varepsilon}(\text{diam}(S^D))^n \kappa(S^D)n + 1$. By Proposition 5.14, the box covering of S^D of size δ is expressible in FO+POLY+TC. By Theorem 6.12, $\text{VOL}(\delta\text{-cover}(S^D))$ approximates the volume of S^D within an ε -error margin.

Recall that $\delta\text{-cover}(S^D)$ is represented as a $2n$ -ary relation. Each $2n$ -tuple corresponds to an n -dimensional box of size δ (see section 5.5). Let $\mathbf{nrofboxes}(y)$ be the formula

$$[\text{TC}_{\vec{b},x;\vec{b}',x'} \text{lexicographic}(\vec{b}, \vec{b}') \wedge x' = x + 1](\vec{b}_{\min}, 1, \vec{b}_{\max}, y),$$

where $\text{lexicographic}(\vec{b}, \vec{b}')$ is an FO+POLY formula expressing that \vec{b} is less than \vec{b}' with respect to the lexicographical ordering on tuples in \mathbf{R}^n , and where $\vec{b}_{\min}, \vec{b}_{\max} \in \delta\text{-cover}(S^D)$ is the minimum (respectively, maximum) n -tuple in $\delta\text{-cover}(S^D)$ with respect to the lexicographical ordering. Finally, let $N \in \mathbf{R}$ such that $\mathbf{nrofboxes}(N)$ holds. Then we define $\text{VOL}^\varepsilon(v)$ to be the FO+POLY+TC formula which expresses that $v = N\delta^n$. \square

⁵For $X \subseteq \mathbf{R}^n$ bounded, the *diameter* of X is defined as the supremum of $\{\|\vec{x} - \vec{y}\| \mid \vec{x}, \vec{y} \in X\}$.

Since the δ -approximation of A is included in the box covering $\delta\text{-cover}(A)$, a better volume approximation can be obtained by using the volume of the δ -approximation instead of the volume of $\delta\text{-cover}(A)$. By the next theorem, this also gives an FO+POLY+TC expressible ε -approximation query.

It is known that taking the volume of a semilinear set does not take us out of the semialgebraic setting and that the volume of a semilinear set can be expressed in the aggregate language FO+POLY+SUM [5].

THEOREM 6.14. *Let $\mathcal{S} = \{S\}$, with S an n -ary relation name. There exists an FO+POLY+TC formula `volume` over \mathcal{S} such that `volume`(S^D) is the volume of S^D for any linear constraint database D over \mathcal{S} .*

Proof. If $\dim(S^D) < n$, then we define `volume`(x) $\equiv x = 0$. Suppose that $\dim(S^D) = n$. Since $\text{VOL}(S^D) = \text{VOL}(\text{cl}(\text{int}(S^D)))$, we actually may assume that S^D is closed and consists entirely of n -dimensional pieces.

It is well known that S^D is a finite union of convex sets c_1, \dots, c_r of a partition of \mathbf{R}^n induced by a finite number of $(n-1)$ -dimensional hyperplanes H_1, \dots, H_s [48]. Vandeurzen, Gyssens, and Van Gucht [48] show that there exists an FO+POLY formula `hyperplanes`(v_1, \dots, v_n, d) such that `hyperplanes`(D) consists of s tuples $(\vec{v}_1, d_1), \dots, (\vec{v}_s, d_s)$ such that $H_i = \{\vec{x} \in \mathbf{R}^n \mid \vec{v}_i \vec{x} = d_i\}$. Moreover, there exists an FO+POLY formula `points` such that `points`(D) is equal to the extremal points of the convex sets c_1, \dots, c_s . Recall that the *extremal points* of a convex set are those points which cannot be written as a linear combination of two other points of the convex set [51].

We now want to retrieve the extremal points of the convex sets c_1, \dots, c_r . In order to do so, we shall first select a unique point in the interior of each convex set. With each of these points we then associate all special points which are in the corresponding convex set. These will then be the extremal points.

We thus define an FO+POLY+TC formula `unique` over \mathcal{S} such that `unique`(D) consists of points $\vec{p}_1, \dots, \vec{p}_s$ such that $\vec{p}_i \in \text{int}(c_i)$ for $i = 1, \dots, s$. The formula `unique` makes use of the following formulas over \mathcal{S} :

- A formula over \mathcal{S} which computes the barycenter of any n -dimensional simplex obtained as the convex hull of an $(n+1)$ -tuple of points in `specialpoints`(D), i.e.,

$$\text{barycenter}(\vec{x}) \equiv \exists \vec{y}_1 \cdots \exists \vec{y}_{n+1} \left(\bigwedge_{i=1}^n \text{points}(\vec{y}_i) \wedge x_i = \frac{1}{n+1} ((\vec{y}_1)_i + \cdots + (\vec{y}_{n+1})_i) \right).$$

- A formula `interiors` over \mathcal{S} which computes the interiors of the sets c_1, \dots, c_s , i.e.,

$$\text{interiors}(\vec{x}) \equiv S(\vec{x}) \wedge \neg(\exists \vec{v} \exists d (\text{hyperplanes}(\vec{v}, d) \wedge \vec{v} \cdot \vec{x} = d)).$$

- A formula over \mathcal{S} which checks whether two barycenters are in the same convex set c_i for some i , i.e.,

$$\text{samecell}(\vec{x}, \vec{y}) \equiv \text{barycenter}(\vec{x}) \wedge \text{barycenter}(\vec{y}) \wedge \forall \lambda (0 \leq \lambda \leq 1 \rightarrow \text{interiors}(\lambda \vec{x} + (1 - \lambda) \vec{y})).$$

We then define the formula $\text{unique}(\vec{x})$ as

$$\forall \vec{z} \text{samecell}(\vec{x}, \vec{z}) \rightarrow \text{lexicographic}(\vec{x}, \vec{z}),$$

where $\text{lexicographic}(\vec{x}, \vec{z})$ is an FO+POLY formula expressing that \vec{x} is less than or equal to \vec{z} with respect to the lexicographical ordering on tuples in \mathbf{R}^n .

Define the formula

$$\begin{aligned} \text{extremal}(\vec{x}, \vec{y}) \equiv & \text{points}(\vec{x}) \wedge \text{unique}(\vec{y}) \\ & \wedge \forall \lambda (0 < \lambda \leq 1) \rightarrow \text{interiors}(\lambda \vec{y} + (1 - \lambda) \vec{x}). \end{aligned}$$

We can now identify each convex set c_1, \dots, c_r , so we may focus on a single convex set. We now show that, given the extremal points of a convex set c in \mathbf{R}^n , a decomposition of c in a finite number of n -simplices can be constructed in FO+POLY. The n -simplices will be represented by $n + 1$ independent points.

We first identify the hyperplanes which have an $(n - 1)$ -dimensional intersection with the boundary of the convex set c . Let $\vec{e}_1, \dots, \vec{e}_k$ be the extremal points of c . Let onboundary be the FO+POLY formula which selects the tuples in $\text{hyperplanes}(D)$ with this property. Next, let sameface be an FO+POLY formula such that $\text{face}(\vec{e}, \vec{v}, d)$ if and only if \vec{e} is an extremal point of c , $(\vec{v}, d) \in \text{onboundary}(\vec{e}_1, \dots, \vec{e}_k)$, and $\vec{e} \in \{\vec{x} \in \mathbf{R}^n \mid \vec{v} \cdot \vec{x} = d\}$. In this way, we can group the extremal points of c such that each group corresponds to a single face of the convex cell c .

For each face of c , we now project the extremal points corresponding to this face to \mathbf{R}^{n-1} such that they are the extremal points of a convex set in \mathbf{R}^{n-1} . Thus, if $\text{face}(\vec{x}_1, \vec{v}, d, \vec{e}_1, \dots, \vec{e}_k) \wedge \dots \wedge \text{face}(\vec{x}_\ell, \vec{v}, d, \vec{e}_1, \dots, \vec{e}_k)$, then we obtain extremal points of a convex set in \mathbf{R}^{n-1} as follows: Let $i \in \{1, \dots, n\}$ be such that $\{\vec{x} \in \mathbf{R}^n \mid x_i = 0\}$ is not perpendicular to $\{\vec{x} \in \mathbf{R}^n \mid \vec{v} \cdot \vec{x} = d\}$ (this can be easily expressed in FO+POLY). Then consider the projection $\pi_i : \mathbf{R}^n \rightarrow \mathbf{R}^{n-1}$ defined as $\pi_i(x_1, \dots, x_n) \mapsto (x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n)$ and apply this map on $\vec{x}_1, \dots, \vec{x}_\ell$.

Algorithm TRIANGULATE-IN- n -DIMENSIONS

Input: The extremal points $\vec{e}_1, \dots, \vec{e}_k$ of a convex set c in \mathbf{R}^n .
Output: A finite number of n -simplices forming a decomposition of c .
Method:

1. Compute the pairs $(\vec{v}, d) \in \text{onboundary}(\vec{e}_1, \dots, \vec{e}_k)$.
2. For each $(\vec{v}, d) \in \text{onboundary}(\vec{e}_1, \dots, \vec{e}_k)$ do the following:
 - (a) Compute $\text{face}(\vec{x}, \vec{v}, d, \vec{e}_1, \dots, \vec{e}_k)$.
 - (b) Find an i as described above and call TRIANGULATE-IN- $(n - 1)$ -DIMENSIONS($\pi_i(\text{face}(\vec{v}, d, \vec{e}_1, \dots, \vec{e}_k))$).
3. Select a point \vec{p}_{n+1} in the interior of c .
4. Output the $(n + 1)$ -tuples $(\vec{p}_1, \dots, \vec{p}_n, \vec{p}_{n+1})$, where $(\vec{p}_1, \dots, \vec{p}_n)$ is an n -tuple in the result of the calls of TRIANGULATE-IN- $(n - 1)$ -DIMENSIONS in step 2(b).

We now define the FO+POLY formula simplexdecomp over \mathcal{S} such that $\text{simplexdecomp}(D)$ is a decomposition into n -simplices of S^D for any polynomial constraint database D over $\{S\}$. Let triang be a formula which expresses the algorithm TRIANGULATE-IN- n -DIMENSIONS. Then

$$\begin{aligned} \text{simplexdecomp}(\vec{x}_1, \dots, \vec{x}_{n+1}) \equiv & \exists \vec{y} (\text{unique}(\vec{y}) \\ & \wedge \text{triang}(\text{extremal})(\vec{x}_1, \dots, \vec{x}_{n+1}, \vec{y})). \end{aligned}$$

Let $(\vec{p}_1, \dots, \vec{p}_{n+1})$ be an n -simplex points. Let $\vec{r}_i = \vec{p}_i - \vec{p}_1$ for $i = 2, \dots, n + 1$, and let G be the $n \times n$ matrix whose rows contain the coordinates of the vectors \vec{r}_j for $1 \leq j \leq n$. Then by the Gram determinant formula [37], the volume of $(\vec{p}_1, \dots, \vec{p}_{n+1})$ is equal to

$$\frac{|\det(GG^t)|^{\frac{1}{2}}}{n!},$$

where G^t is the transpose of G . Hence, the volumes of the simplices are expressible by an FO+POLY formula, which we will denote by `volsimplex`.

Finally, define

$$\begin{aligned} \Psi(y) \equiv & [\text{TC}_{x,s;x',s'} s = \exists \vec{p}_1, \dots, \exists \vec{p}_{n+1}, \exists \vec{q}_1, \dots, \exists \vec{q}_{n+1} \\ & \text{volsimplex}(\vec{p}_1, \dots, \vec{p}_{n+1}) \wedge s' = \text{volsimplex}(\vec{q}_1, \dots, \vec{q}_{n+1}) \\ & \wedge \text{successor}(\vec{q}_1, \dots, \vec{q}_{n+1}, \vec{p}_1, \dots, \vec{p}_{n+1}) \\ & \wedge \text{simplexdecomp}(\vec{p}_1, \dots, \vec{p}_{n+1}) \wedge \text{simplexdecomp}(\vec{q}_1, \dots, \vec{q}_{n+1}) \\ & \wedge x' = x + s](0, v_1, y, v_\ell), \end{aligned}$$

where `successor` is a successor relation defined on the n -simplices in the decomposition into simplices `simplexdecomp`(D), and where v_1 and v_ℓ are, respectively, the volume of the first and last simplex according to this successor relation. The total volume of S^D is then given by

$$\text{volume}(v) \equiv \exists y \Psi(y) \wedge v = y + v_\ell,$$

with v_ℓ as above. □

PARTIAL MATCH QUERIES IN RANDOM k -d TREES*

HUA-HUAI CHERN[†] AND HSIEN-KUEI HWANG[‡]

Abstract. We solve the open problem of characterizing the leading constant in the asymptotic approximation to the expected cost used for random partial match queries in random k -d trees. Our approach is new and of some generality; in particular, it is applicable to many problems involving differential equations (or difference equations) with polynomial coefficients.

Key words. k -d trees, partial match queries, differential equations, average-case analysis of algorithms, method of linear operators, asymptotic analysis

1. Introduction. Multidimensional binary search trees (abbreviated as k -d trees or simply kd trees, k being the dimensionality) were first proposed by Bentley [2] and represent extremely useful data structures for problems in diverse fields, especially those having to do with range queries; nearest neighbor search; or partial, exact, or approximate match queries. For example, they are useful in statistical learning, databases, data-mining, computer graphics, robotics, medical imaging, neural networks, multimedia, statistical computing, computer-aided design, astronomy, pattern recognition, geographic information systems, music information retrieval, computational biology, etc. For more information, see Bentley [3], Bentley and Friedman [4], Bertino et al. [5], Friedman, Bentley, and Finkel [19], Gray and Moore [21], Grother, Candela, and Blue [22], Nichol et al. [28], Omohundro [29], Preparata and Shamos [31], Reiss, Aucouturier, and Sandler [32], Samet [33, 34], and Schwarzer and Lotan [35]. According to the statistics collected in the Stony Brook Algorithm Repository, k -d trees were among the most popular algorithmic problems; see Skiena’s account in [37].

Despite the usefulness and diversity of k -d trees, their precise probabilistic analysis appears only sporadically in the literature (although many properties can be derived from those for random binary search trees); see [6, 11, 12, 13, 19, 20, 25, 26, 27]. We are concerned in this paper with the expected cost used by random partial match queries in random k -d trees. The growth order of this cost has been known since Flajolet and Puech’s work [17], but the characterization of the leading constant remains a very challenging problem. We propose a new approach to filling this gap.

The prototypes of k -d trees are binary search trees when there is a total ordering for the input keys or when $k = 1$. A binary search tree \mathcal{B} is a binary tree constructed from a given sequence of keys as follows. If the tree size is $n = 0$, then \mathcal{B} is empty. If $n \geq 1$, then the first key is placed at the root. The remaining keys are compared successively to the root key, which may be called a “discriminator,” and are directed to the left (or right) branch if they are smaller (or larger); keys directed to the same

branch are constructed recursively as a binary search tree. By construction, a query operation such as “ $x \in \mathcal{B}$?” can be easily carried out in binary search trees; hence the name “search tree.”

When given k -dimensional points or keys, $k \geq 2$, the simple idea of k -d trees is to use each coordinate cyclically, say, in the order from the first coordinate to the last, as the “discriminator” to direct points falling in the same subtree as in binary search trees (but using the $(\ell \bmod k) + 1$ st coordinate for a node at a distance of ℓ from the root); see Figure 1.1 for a plot of a simple 2-d tree.

In addition to exact match searches, as in binary search trees, k -d trees can also be used for *partial match queries* when some coordinates are either unspecified, don’t-cares, or wild cards. Thus the range search is continued in both subtrees when the unspecified coordinate is used as a discriminator in the k -d tree and in either the left or the right subtree (but not both) otherwise; see Bentley [2] for details. Two simple instances of a range search in 2-d trees are shown in Figure 1.2.

FIG. 1.1. The stepwise constructions of a 2-d tree of six points.

We consider the following probabilistic model for our average-case analysis. A sequence of n independently and identically distributed random points in $[0, 1]^k$ is given, where each coordinate is uniformly distributed over the unit interval and is independent of other coordinates. Then we construct the k -d tree \mathcal{T} , called a *random k -d tree*. For partial match queries, we then consider a query of the form $\mathcal{Y} = (Y_1, \dots, Y_k)$, where Y_j is either the unit interval (meaning don’t-care) or a random variable uniformly distributed over the unit interval ($Y_j = \text{Uniform}(0, 1)$), the number of specified coordinates s satisfying $0 \leq s \leq k$. We then perform the range search of

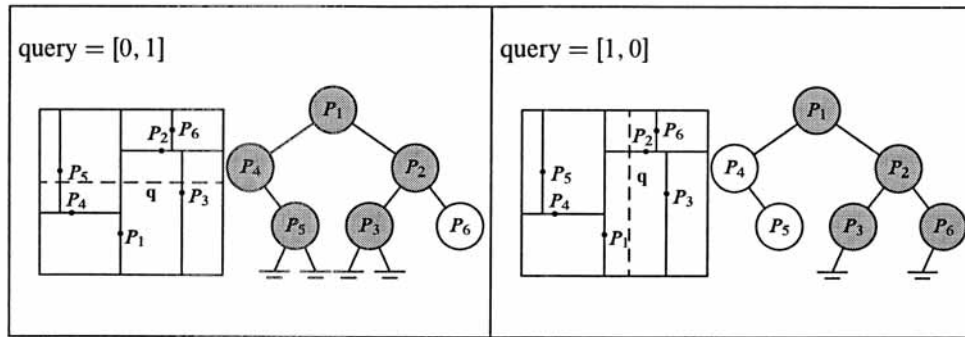

FIG. 1.2. Two instances of partial match queries (as marked by the dashed line) in a 2-d tree: visited nodes are the filled-in grey circles. Here the query pattern $[0, 1]$ means that the first coordinate is unspecified and the second is specified; the meaning of $[1, 0]$ is similar.

the query \mathcal{Y} in the tree \mathcal{T} . The number of nodes visited is a random variable, say, X_n . The main quantity of interest in this paper is the expected value $Q_n := \mathbb{E}(X_n)$, or simply the *expected cost of a random partial match query in random k -d trees of n nodes*.

While the uniform model we are considering may seem too idealized, it is simple yet mathematically tractable; also the asymptotics obtained under such a model usually subsists under more general ones; see [17] for more discussions.

For convenience, throughout this paper we write the query pattern as $\mathbf{q} := [q_1, \dots, q_k]$ since Q_n depends only on \mathbf{q} , where $q_j \in \{0, 1\}$ and $0 \leq q_1 + \dots + q_k \leq k$. Here $q_j = 0$ means that the j th coordinate is unspecified, and $q_j = 1$ means that it is specified. Flajolet and Puech [17] showed that

$$(1.1) \quad Q_n \sim Cn^{\alpha-1} \quad (1 \leq s < k),$$

where C is a constant and $\alpha > 1$ solves the equation

$$(\alpha + q_1) \cdots (\alpha + q_k) = 2^k,$$

or, equivalently, the equation $\alpha^{k-s}(\alpha + 1)^s = 2^k$, where $s = q_1 + \dots + q_k$ denotes the number of specified coordinates. Their result corrected the original claim of Bentley [2, p. 513] that $Q_n = O(n^{1-s/k})$ since α can be written as $\alpha = 1 - s/k + \varepsilon(s/k)$, where $\varepsilon(u) > 0$ for $0 < u < 1$; see [17] and [6].

The approach of Flajolet and Puech [17] is based on a linear differential system and starts from the generating function $y_1(z) := \sum_{n \geq 1} (n + 1)Q_n z^n$. Then

$$\frac{d}{dz} \mathbf{y}(z) = \Omega(z) \mathbf{y}(z) + \mathbf{b}(z),$$

where $\mathbf{y}(z) = (y_1(z), \dots, y_{2k-s}(z))^T$, $\mathbf{b}(z) = (b_1(z), \dots, b_{2k-s}(z))^T$, and $\Omega(z)$ is a $(2k - s) \times (2k - s)$ matrix. For example, when $\mathbf{q} = [0, 1, 1]$,

$$\frac{d}{dz} \begin{pmatrix} y_1(z) \\ y_2(z) \\ y_3(z) \\ y_4(z) \end{pmatrix} = \begin{pmatrix} \frac{1}{z(1-z)} & \frac{2}{1-z} & 0 & -\frac{1}{z^2(1-z)} \\ 0 & 0 & \frac{2}{1-z} & 0 \\ \frac{2}{1-z} & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} y_1(z) \\ y_2(z) \\ y_3(z) \\ y_4(z) \end{pmatrix} + \begin{pmatrix} \frac{1}{(1-z)^3} \\ \frac{2}{(1-z)^3} \\ \frac{2}{(1-z)^3} \\ 0 \end{pmatrix}.$$

From this system, they proved that the generating function $Q(z) := \sum_{n \geq 1} Q_n z^n$ satisfies

$$Q(z) \sim K(1 - z)^{-\alpha}$$

for some constant K and for z in some region in the z -plane. Then (1.1) follows from singularity analysis (see [16]). But as is often the case for linear systems, the constant K or C in (1.1) does not seem to have simple computable forms by this approach.

Chanzy, Devroye, and Zamora-Cura [6] proved (1.1) by a more combinatorial and probabilistic approach, but the calculation of C still remains open.

The recurrence for Q_n we are solving is of the form ($j_0 := n$)

$$(1.2) \quad \begin{aligned} Q_n = 1 + & \sum_{1 \leq i < k} 2^i \sum_{1 \leq j_i < \dots < j_1 < n} \prod_{1 \leq r \leq i} \frac{1 + q_r j_r}{j_{r-1}(1 + q_r j_{r-1})} \\ & + 2^k \sum_{1 \leq j_k < \dots < j_1 < n} Q_{j_k} \prod_{1 \leq r \leq k} \frac{1 + q_r j_r}{j_{r-1}(1 + q_r j_{r-1})} \end{aligned}$$

for $n \geq 1$, with $Q_0 := 0$. In particular (writing $Q_n = Q_n[q_1, \dots, q_k]$)

$$\begin{aligned} Q_n[0, 1] &= 3 - \frac{2}{n} + \frac{4}{n^2} \sum_{1 \leq j < n} (n - 1 - j) Q_j[0, 1], \\ Q_n[0, 0, 1] &= 7 - \frac{6}{n} - \frac{4}{n} H_{n-1} \\ &\quad + \frac{8}{n} \sum_{1 \leq j < n} \left(H_{n-1} - H_j - (j + 1) \left(H_{n-1}^{(2)} - H_j^{(2)} \right) \right) Q_j[0, 0, 1] \end{aligned}$$

for $n \geq 1$ with $Q_0 := 0$. Here $H_n^{(i)} := \sum_{1 \leq j \leq n} j^{-i}$ and $H_n = H_n^{(1)}$.

While the problem we are studying in this paper is similar to partial match queries in random quadtrees (see [14, 9]), the nature of the associated analytic problems is very different (although both problems can be written in terms of linear systems). Intuitively, random quadtrees seem to have more independence in subtrees, while the independence of k -d trees is somehow “bound” by the cyclic construction. For partial match queries in quadtrees, the dominant asymptotic approximation to the expected cost depends only on the number (but not the pattern) of specified coordinates; in contrast, the leading constant in the asymptotic approximation to the expected cost for k -d trees depends strongly on the query pattern, making the analytic problem harder.

We propose in the next section a more straightforward approach, which is based on translating the system of recurrences satisfied by Q_n into a *scalar differential equation with polynomial coefficients* for the generating function of Q_n . Some explicitly solvable cases of the differential equation are discussed in section 3. We then solve the general differential equation by using Mellin transforms (see Flajolet, Gourdon, and Dumas [15]) in section 4. This Mellin approach leads, by suitably changing the initial conditions, to a series form for K that is absolutely convergent. But the justification of the application of the Mellin inversion integrals is more delicate and requires stronger analytic estimates. We thus develop in section 5 a different approach based on extending our asymptotic theory for Cauchy–Euler differential equations (see [10]). Such an approach is very general and is mostly algebraic and elementary in nature, requiring little knowledge in differential equations as in [10]. It is also applicable to

other situations, where one has linear differential equations with polynomial coefficients. We briefly indicate the application to k -d- t trees in section 6, which are locally balanced versions of k -d trees; see [11]. The development of a general theory with many applications will be given elsewhere; see [7] for further exploration of the same approach to quadtrees.

Notation. Throughout this paper, $[q_1, \dots, q_k] \in \{0, 1\}^k$, $k \geq 2$, always denotes the query pattern with $s := q_1 + \dots + q_k$, where 0 means unspecified and 1 specified. We also introduce the symbol

$$\rho_{n,j}(q) := \frac{1 + qj}{1 + qn} \quad (q \in \{0, 1\}).$$

Finally, $\alpha > 1$ denotes the zero of the equation (except in section 6 on k -d- t trees)

$$(x + q_1) \cdots (x + q_k) - 2^k = x^{k-s}(x + 1)^s - 2^k = 0.$$

2. From recurrences to differential equations. In this section, we first show that the expected cost $Q_n = Q_n[q_1, \dots, q_k]$ satisfies a system of recurrences (of quick-sort type) and then derive a “normal form” for the differential equation satisfied by the generating function $Q(z) = Q[q_1, \dots, q_k](z) := \sum_{n \geq 1} Q_n z^n$.

Basic recurrences. By definition, $Q_0 = 0$ for all query patterns.

LEMMA 2.1. *The expected cost Q_n satisfies the recurrence*

$$(2.1) \quad Q_n[q_1, \dots, q_k] = 1 + \frac{2}{n} \sum_{1 \leq j < n} \rho_{n,j}(q_1) Q_j[q_2, \dots, q_k, q_1] \quad (n \geq 1),$$

with $Q_0 = 0$.

Proof. When the first coordinate is unspecified, the search is conducted in both subtrees. The probability that the left subtree is of size j is $1/n$ for $0 \leq j < n$. By cyclic construction of k -d trees, we then have

$$Q_n[q_1, \dots, q_k] = 1 + \frac{1}{n} \sum_{0 \leq j < n} (Q_j[q_2, \dots, q_k, q_1] + Q_{n-1-j}[q_2, \dots, q_k, q_1]);$$

thus (2.1) follows with $q_1 = 0$. On the other hand, if $q_1 = 1$, then the probability of going to the left subtree of the root (when it has j nodes) is $(j + 1)/(n + 1)$ since with probability 1 the query results in an unsuccessful search. Thus

$$Q_n[q_1, \dots, q_k] = 1 + \frac{1}{n} \sum_{0 \leq j < n} \left(\frac{j + 1}{n + 1} Q_j[q_2, \dots, q_k, q_1] + \frac{n - j}{n + 1} Q_{n-1-j}[q_2, \dots, q_k, q_1] \right).$$

This proves (2.1). \square

Write $Q_n^{[j]} := Q_n[q_j, \dots, q_k, q_1, \dots, q_{j-1}]$, $1 \leq j \leq k$.

COROLLARY 2.2. *The $Q_n^{[j]}$'s satisfy the system of recurrences*

$$(2.2) \quad \begin{cases} Q_n^{[1]} = 1 + \frac{2}{n} \sum_{1 \leq j < n} \rho_{n,j}(q_1) Q_j^{[2]}, \\ \vdots \\ Q_n^{[k]} = 1 + \frac{2}{n} \sum_{1 \leq j < n} \rho_{n,j}(q_k) Q_j^{[1]}, \end{cases} \quad (n \geq 1).$$

Proof. The proof follows from Lemma 2.1 and the cyclic relation of k -d trees. \square

The recurrence (1.2) then follows from (2.2).

COROLLARY 2.3. *If we assume that $Q_n^{[1]} \sim Cn^{\beta-1}$ for $\beta > 1$, then*

$$(2.3) \quad Q_n^{[j]} \sim \frac{2^{k-j+1}C}{(\beta + q_j) \cdots (\beta + q_k)} n^{\beta-1} \quad (j = 1, \dots, k),$$

and β solves the equation $(\beta + q_1) \cdots (\beta + q_k) = 2^k$.

Proof. From (2.2), we have

$$Q_n^{[k]} \sim \frac{2C}{n^{1+q_k}} \sum_{1 \leq j < n} j^{\beta-1+q_k} \sim \frac{2C}{\beta + q_k} n^{\beta-1}.$$

Then the asymptotics of $Q_n^{[k-j]}$ can be obtained one after another. On the other hand, since

$$Q_n^{[1]} \sim \frac{2^k C}{(\beta + q_1) \cdots (\beta + q_k)} n^{\beta-1} \sim Cn^{\beta-1},$$

β has to satisfy the equation $(\beta + q_1) \cdots (\beta + q_k) = 2^k$. Thus $\beta = \alpha$. \square

The corollary says that once we obtain the asymptotics of one of the $Q_n^{[j]}$'s, those of the others are all known. One can show that the number of distinct query patterns needed to be computed in order to derive Q_n for all 2^k possible queries is equal to (essentially the number of different types of necklaces with two distinct colors)

$$(2.4) \quad N_k := k^{-1} \sum_{d|k} \phi(d) 2^{k/d},$$

where $\phi(d)$ denotes Euler's totient function; see Flajolet and Sedgewick [18, p. 18]. For large k , $N_k \sim 2^k/k$.

We can rewrite and simplify (2.2) as follows.

COROLLARY 2.4. *For $n \geq 1$,*

$$(2.5) \quad \begin{pmatrix} Q_n^{[1]} \\ \vdots \\ Q_n^{[k]} \end{pmatrix} = \mathbf{M} \begin{pmatrix} Q_{n-1}^{[1]} \\ \vdots \\ Q_{n-1}^{[k]} \end{pmatrix} + \begin{pmatrix} \frac{1+q_1}{n+q_1} \\ \vdots \\ \frac{1+q_k}{n+q_k} \end{pmatrix},$$

where $\mathbf{M} = (a_{i,j})_{k \times k}$ with $a_{i,i} = (n-1)/(n+q_i)$, $a_{i,(i+1) \bmod k} = 2/(n+q_i)$, and all other entries are zeros.

Proof. Taking the difference $n(n+q_j)Q_n^{[j]} - (n-1)(n-1-q_j)Q_{n-1}^{[j]}$ gives

$$(n+q_j)Q_n^{[j]} = (n-1)Q_{n-1}^{[j]} + 2Q_{n-1}^{[j+1]} + 1 + q_j \quad (1 \leq j \leq k),$$

where $Q_n^{[k+1]} = Q_n^{[1]}$. \square

The nonhomogeneous matrix recurrence (2.5) can be converted into a homogeneous one by considering

$$\bar{Q}_n^{[j]} := Q_n^{[j]} + \frac{1 + \sum_{1 \leq \ell < k} (2 - q_1) \cdots (2 - q_\ell)}{2^s - 1};$$

then

$$\begin{pmatrix} \bar{Q}_n^{[1]} \\ \vdots \\ \bar{Q}_n^{[k]} \end{pmatrix} = \mathbf{M} \begin{pmatrix} \bar{Q}_{n-1}^{[1]} \\ \vdots \\ \bar{Q}_{n-1}^{[k]} \end{pmatrix},$$

with obvious initial conditions.

Integral equations. Lemma 2.1 is next translated into an integral equation for the generating function $Q(z)$. For convenience, we introduce two integral operators,

$$\begin{cases} I_0[\varphi](z) := \int_0^z \frac{\varphi(t)}{1-t} dt, \\ I_1[\varphi](z) := \frac{1-z}{z} \int_0^z \frac{t\varphi(t)}{(1-t)^2} dt. \end{cases}$$

Let $f_j(z) = Q[q_j, \dots, q_k, q_1, \dots, q_{j-1}](z)$, $1 \leq j \leq k$.

LEMMA 2.5. *The generating function f_1 satisfies the integral equation*

$$(2.6) \quad f_1(z) = \frac{z}{1-z} + 2I_{q_1}[f_2](z).$$

Proof. The proof for (2.6) with $q_1 = 0$ is straightforward. When $q_1 = 1$, (2.6) follows from

$$\begin{aligned} \sum_{n \geq 1} \frac{z^n}{n(n+1)} \sum_{0 \leq j < n} (j+1)Q_j &= \sum_{n \geq 1} \left(\frac{z^n}{n} - \frac{z^n}{n+1} \right) \sum_{0 \leq j < n} (j+1)Q_j \\ &= \int_0^z \frac{1}{1-t} (tQ(t))' dt - \frac{1}{z} \int_0^z \frac{t}{1-t} (tQ(t))' dt. \quad \square \end{aligned}$$

The form given in (2.6) for $q_1 = 1$ is the main diverging point on which our approach differs from that used in [17]. Roughly, we keep the inverse operator of I_1 to be of first order, so that the associated linear system is of degree k , instead of $2k - s$ as used in [17]; cf. also (2.5).

COROLLARY 2.6. *We have*

$$\begin{cases} f_1(z) = 2I_{q_1}[f_2](z) + \frac{z}{1-z}, \\ \vdots \\ f_k(z) = 2I_{q_k}[f_1](z) + \frac{z}{1-z}. \end{cases}$$

By composing the above integral equations, we obtain a single integral equation for $f_1(z) = Q(z)$.

COROLLARY 2.7. *The generating function of Q_n satisfies*

$$(2.7) \quad Q(z) - 2^k(I_{q_1} \circ \dots \circ I_{q_k})[Q](z) = G_0(z),$$

where $(I_{q_1} \circ \dots \circ I_{q_j})[f](z) := I_{q_1}[\dots[I_{q_j}[f]]\dots](z)$, $1 \leq j \leq k$, and

$$G_0(z) = \frac{z}{1-z} + \sum_{1 \leq j < k} 2^j(I_{q_1} \circ \dots \circ I_{q_j}) \left[\frac{z}{1-z} \right] (z).$$

Note that $Q_n = [z^n]G_0(z)$ for $1 \leq n < k$, where $[z^n]\varphi(z)$ denotes the coefficient of z^n in the Taylor expansion of φ . On the other hand, by (1.2),

$$Q_n = 1 + \sum_{1 \leq i \leq n} 2^i \sum_{1 \leq j_i < \dots < j_1 < n} \prod_{1 \leq r \leq i} \frac{1 + q_r j_r}{j_{r-1}(1 + q_r j_{r-1})} \quad (1 \leq n < k).$$

Differential equations. Define the differential operator $\vartheta := (1 - z)(d/dz)$. Then the inverse operator of I_q is

$$I_q^{-1} = \vartheta + \frac{q}{z} \quad (q \in \{0, 1\}),$$

and the integral equation (2.7) can be converted into a scalar differential equation

$$(2.8) \quad \left(\vartheta + \frac{q_k}{z}\right) \dots \left(\vartheta + \frac{q_1}{z}\right) Q(z) - 2^k Q(z) = \sum_{1 \leq j \leq k} 2^{j-1} \left(\vartheta + \frac{q_k}{z}\right) \dots \left(\vartheta + \frac{q_j}{z}\right) \frac{z}{1-z}.$$

If we multiply both sides by z^k , then the left-hand side can be written in the form $\sum_{0 \leq j \leq k} (1 - z)^j L_{k,j}(\vartheta) Q(z)$ for some polynomials $L_{k,j}$, all of degree k . But this approach does not lead to simpler solutions.

Two special cases are indicative of the general pattern for simplification.

(i) If all q_j 's are zeros, then (2.8) becomes

$$(2.9) \quad (\vartheta^k - 2^k) Q(z) = \frac{2^k - 1}{1 - z}.$$

(ii) If the q_j 's are all ones, then, by the relation

$$\left(\vartheta + \frac{1}{z}\right) \frac{\varphi(z)}{z^j} = \frac{1 - j(1 - z)}{z^{j+1}} \varphi(z) \quad (j = 0, 1, \dots),$$

we have

$$\left(\vartheta - 2^k + \frac{(\vartheta + 1)^k - \vartheta^k}{z}\right) Q(z) = z^{-1} \left(2 - 2^{k+1} + \frac{k2^k}{1 - z}\right),$$

which, by multiplying both sides by z , yields

$$(2.10) \quad ((\vartheta + 1)^k - 2^k) Q(z) - (1 - z) (\vartheta^k - 2^k) Q(z) = 2 - 2^{k+1} + \frac{k2^k}{1 - z}.$$

These observations suggest that we define a “minimum exponent” $\mu_{\mathbf{q}}$ as $k - v + 1$, where v denotes the last position of the first block of 1's (from left to right) and $\mu_{\mathbf{q}} := 0$ if $s = 0$. In symbols,

$$[q_1, \dots, q_k] = [0, \dots, 0, 1, \dots, \underbrace{1, 0, *, \dots, *}_{\mu_{\mathbf{q}}}] \quad (* \in \{0, 1\})$$

so that $\mu_{\mathbf{q}} := 1$ if $s = k$.

LEMMA 2.8. *Let $\mu_{\mathbf{q}}$ be defined as above. Then*

$$(2.11) \quad \begin{aligned} & z^{\mu_{\mathbf{q}}} \left(\left(\vartheta + \frac{q_k}{z}\right) \dots \left(\vartheta + \frac{q_1}{z}\right) - 2^k \right) Q(z) \\ & = P_{k,0}(\vartheta) Q(z) - \sum_{1 \leq \ell \leq \mu_{\mathbf{q}}} (1 - z)^\ell P_{k,\ell}(\vartheta) Q(z), \end{aligned}$$

where the $P_{k,\ell}$'s are polynomials of degree k defined by $P_{k,0}(x) = p_{k,0}(x) - 2^k$, and for $1 \leq \ell \leq \mu_{\mathbf{q}}$,

$$(2.12) \quad P_{k,\ell}(x) := p_{k,\ell}(x) + (-1)^\ell 2^k \binom{\mu_{\mathbf{q}}}{\ell},$$

with

$$\begin{cases} p_{k,1}(x) = (x + q_k - 1)p_{k-1,1}(x) + (x + \mu_{\mathbf{q}} - 1)p_{k-1,0}(x), \\ p_{k,\ell}(x) = (x + q_k - \ell)p_{k-1,\ell}(x) - (x + \mu_{\mathbf{q}} - \ell)p_{k-1,\ell-1}(x) \end{cases} \quad (2 \leq \ell < \mu_{\mathbf{q}}),$$

and the boundary values $p_{k,0}(x) = x^{k-s}(x+1)^s$ and $p_{k,\mu_{\mathbf{q}}}(x) = (-1)^{\mu_{\mathbf{q}}+1}x^k$ for $k \geq 1$.

Proof. The two cases of when $s = 0$ and when $s = k$ are easily checked by (2.9) and (2.10), respectively. We assume that $1 \leq s < k$.

For $k = 2$, there are two query patterns, $[0, 1]$ and $[1, 0]$. The differential equation for $[0, 1]$ is ($\mu_{\mathbf{q}} = 1$)

$$(2.13) \quad (\vartheta(\vartheta + 1) - 4 - (1 - z)(\vartheta^2 - 4)) Q(z) = 1 + \frac{6z}{1 - z},$$

and that for $[1, 0]$ is ($\mu_{\mathbf{q}} = 2$)

$$(2.14) \quad ((\vartheta(\vartheta + 1) - 4) - (1 - z)(2\vartheta^2 + \vartheta - 7) + (1 - z)^2(\vartheta^2 - 4)) Q(z) = \frac{4z^2}{1 - z}.$$

Thus (2.11) holds.

When the query is of the form

$$(2.15) \quad \underbrace{[0, \dots, 0]}_{k-s}, \underbrace{[1, \dots, 1]}_s \quad (1 \leq s < k),$$

we have $\mu_{\mathbf{q}} = 1$, and the left-hand side of (2.8) satisfies

$$z \left(\vartheta + \frac{1}{z} \right)^s \vartheta^{k-s} Q(z) = (\vartheta^{k-s}(\vartheta + 1)^s - 2^k - (1 - z)(\vartheta^k - 2^k)) Q(z);$$

thus (2.11) holds.

The remaining cases follow by induction on k . The proof is messy and omitted here. \square

Similarly, the right-hand side of (2.8) can be rewritten as

$$(2.16) \quad z^{\mu_{\mathbf{q}}} \sum_{1 \leq j \leq k} 2^{j-1} \left(\vartheta + \frac{q_k}{z} \right) \cdots \left(\vartheta + \frac{q_j}{z} \right) \frac{z}{1 - z} = \sum_{-1 \leq \ell < \mu_{\mathbf{q}}} \nu_{k,\ell} (1 - z)^\ell.$$

For the special query pattern (2.15), we have

$$(2.17) \quad \begin{cases} \nu_{k,-1} = (s + 1)2^k - 2^s, \\ \nu_{k,0} = -2^{k+1} + 2^{k-s} + 1. \end{cases}$$

For other cases, we obtain, by induction,

$$(2.18) \quad \nu_{k,\ell} := \begin{cases} (2^{k-1} + \nu_{k-1,-1})(q_k + 1), & \ell = -1, \\ 2^{k-1}(q_k + 1)(-1)^\ell \binom{\mu_{\mathbf{q}}}{\ell + 1} \\ \quad + ((\ell - \mu_{\mathbf{q}})\nu_{k-1,\ell-1} + (q_k - \ell)\nu_{k-1,\ell}), & 0 \leq \ell \leq \mu_{\mathbf{q}} - 2, \\ 2^{k-1}(q_k + 1)(-1)^{\mu_{\mathbf{q}}} - \nu_{k-1,\mu_{\mathbf{q}}-2}, & \ell = \mu_{\mathbf{q}} - 1, \end{cases}$$

with the initial values $\nu_{\tau+1,-1} = 2(2^{\tau+1} - 1)$ and $\nu_{\tau+1,0} = -3 \cdot 2^\tau + 1$, τ being the largest integer for which $q_1 = \dots = q_\tau = 0$ but $q_{\tau+1} = 1$. The proof is again lengthy and laborious, and thus omitted here.

Combining (2.11) and (2.16), we obtain the following “normal form” for Q .

PROPOSITION 2.9. *The generating function $Q(z)$ satisfies the initial value problem*

$$(2.19) \quad \begin{cases} P_{k,0}(\vartheta)Q(z) - \sum_{1 \leq \ell \leq \mu_q} (1-z)^\ell P_{k,\ell}(\vartheta)Q(z) = \sum_{-1 \leq \ell < \mu_q} \nu_{k,\ell}(1-z)^\ell, \\ Q(z) = z + Q_2 z^2 + \dots + Q_{k-1} z^{k-1} + \dots, \end{cases}$$

where the $P_{k,\ell}$'s are polynomials of degree k defined in (2.12) and the $\nu_{k,\ell}$'s are constants given in (2.17) and (2.18).

The exact solution for such a general problem is still not obvious and exists only for a few special cases to be discussed below.

3. Explicitly solvable cases. Exactly solvable cases of (2.19) include $s = 0$, $s = k$, and $k = 2$, where s is the number of specified coordinates.

None specified: $s = 0$. When no coordinate is specified, the search cost is obviously n . The associated differential equation is given by (2.9), with the initial conditions $Q(z) = z + 2z^2 + \dots + (k-1)z^{k-1} + \dots$. The solution is $Q(z) = z/(1-z)^2$ for all $k \geq 1$. This is a case when *the particular solution is itself the exact solution because all initial values coincide.*

All queries specified: $s = k$. In this case, the two Q_n 's on the two sides of the recurrence (2.1) are the same so that Q_n satisfies

$$Q_n = 1 + \frac{2}{n(n+1)} \sum_{1 \leq j < n} (j+1)Q_j \quad (n \geq 1),$$

with $Q_0 = 0$, which is easily solved to be

$$(3.1) \quad Q_n = 2(H_{n+1} - 1) \quad (n \geq 1).$$

The solution is invariant in k . This is nothing but the expected number of comparisons used for an unsuccessful search in random binary search trees; see [6, 23].

Note that $Q(z)$ satisfies the differential equation (2.10), with the initial values $Q(0) = 0$ and

$$Q_j = 1 + [z^{j-2}] \frac{1}{(1-z)^2} \left(1 - \frac{2\Gamma(j+2z)}{\Gamma(j+2)\Gamma(1+2z)} \right) \quad (1 \leq j < k),$$

Γ being the Gamma function. The differential equation (2.10) can be rewritten as

$$\left((\vartheta + 1)^k - 2^k \right) (zQ(z)) = 2 + (k-2)2^k + \frac{k2^k}{1-z} z,$$

which is indeed of Cauchy–Euler type (see [10]). The exact solution is

$$Q(z) = \frac{2}{z(1-z)} \log \left(\frac{1}{1-z} \right) - \frac{2}{1-z},$$

from which one derives (3.1). This is another case *when the particular solution is itself the exact solution.*

2-*d trees*. In this case, $Q[0, 1](z)$ satisfies (2.13) and $Q[1, 0](z)$ satisfies (2.14), both with the initial conditions $Q(0) = 0$ and $Q'(0) = 1$.

Let ${}_2F_1$ denote Gauss's hypergeometric function

$${}_2F_1 \left(\begin{matrix} a, b \\ c \end{matrix} \middle| z \right) = 1 + \sum_{j \geq 1} \frac{a^{\bar{j}} b^{\bar{j}}}{c^{\bar{j}} j!} z^j,$$

where $x^{\bar{j}} = x(x + 1) \cdots (x + j - 1)$ denotes the rising factorial.

LEMMA 3.1 (exact solutions for $Q(z)$). *The generating function of $Q_n[0, 1]$ satisfies*

$$(3.2) \quad Q[0, 1](z) = \frac{13}{2}(1 - z)^{-\alpha} {}_2F_1 \left(\begin{matrix} 2 - \alpha, -2 - \alpha \\ 1 \end{matrix} \middle| z \right) - \frac{7}{2} + 4z - \frac{3}{2}z^2 - \frac{3}{1 - z},$$

and that for $Q_n[1, 0]$

$$(3.3) \quad Q[1, 0](z) = \frac{13}{2}z(1 - z)^{-\alpha} {}_2F_1 \left(\begin{matrix} 3 - \alpha, -1 - \alpha \\ 3 \end{matrix} \middle| z \right) + 2 - \frac{7}{2}z + \frac{3}{2}z^2 - \frac{2}{1 - z},$$

where $\alpha = (\sqrt{17} - 1)/2$.

The corresponding recurrence relations have the forms

$$Q_n[0, 1] = 3 - \frac{2}{n} + \frac{4}{n^2} \sum_{1 \leq j < n} (n - 1 - j)Q_j[0, 1],$$

$$Q_n[1, 0] = 3 - \frac{2}{n} + \frac{4}{n(n + 1)} \sum_{1 \leq j < n} (n - 1 - j + H_{n-1} - H_j)Q_j[1, 0],$$

with $Q_0 = 0$ for both cases.

COROLLARY 3.2 (exact solutions for Q_n). *For $n \geq 3$,*

$$Q_n[0, 1] = \frac{13}{2} \sum_{0 \leq j \leq n} \binom{n - j + \alpha - 1}{n - j} \frac{(2 - \alpha)^{\bar{j}} (-2 - \alpha)^{\bar{j}}}{j! j!} - 3,$$

$$Q_n[1, 0] = 13 \sum_{0 \leq j < n} \binom{n - j + \alpha - 2}{n - 1 - j} \frac{(3 - \alpha)^{\bar{j}} (-1 - \alpha)^{\bar{j}}}{(j + 2)! j!} - 2.$$

Proof. The proof follows from taking coefficients of z^n on both sides of (3.2) and of (3.3). \square

COROLLARY 3.3 (asymptotics of Q_n).

$$Q_n[0, 1] = \frac{13(2\alpha - 3)}{2} \cdot \frac{\Gamma(2\alpha)}{\Gamma(\alpha)^3} n^{\alpha-1} - 3 + O(n^{\alpha-2}),$$

$$Q_n[1, 0] = \frac{13(8 - 5\alpha)}{2} \cdot \frac{\Gamma(2\alpha)}{\Gamma(\alpha)^3} n^{\alpha-1} - 2 + O(n^{\alpha-2}).$$

Proof. The proof follows from applying the exact solutions of Q_n or by applying singularity analysis to (3.2) and (3.3), and then using Gauss's identity (see [1, Eq. 15.1.20, p. 556]). \square

Numerically,

$$\frac{13(2\alpha - 3)}{2} \cdot \frac{\Gamma(2\alpha)}{\Gamma(\alpha)^3} \approx 2.55275, \quad \frac{13(8 - 5\alpha)}{2} \cdot \frac{\Gamma(2\alpha)}{\Gamma(\alpha)^3} \approx 1.99312,$$

which are to be compared with the asymptotic approximation

$$\frac{1}{2} \cdot \frac{\Gamma(2\alpha)}{\Gamma(\alpha)^3} n^{\alpha-1} \approx 1.59099 n^{\alpha-1}$$

for the expected cost of partial match queries in random two-dimensional quadrees; see [9, 14].

Proof of Lemma 3.1. Consider first the case when the query pattern is $[0, 1]$. In this case, the differential equation is

$$z(1-z)^2 Q''(z) + (1-z)^2 Q'(z) - 4zQ(z) = -5 + \frac{6}{1-z}.$$

To solve this equation, we first observe that the particular solution is given by

$$y_p(z) = -\frac{7}{2} + 4z - \frac{3}{2}z^2 - \frac{3}{1-z}.$$

Thus we consider $Q(z) = (1-z)^{-\alpha}y(z) + y_p(z)$, and we have

$$z(1-z)^2 y''(z) + (1-z)(1-z+2z\alpha)y'(z) + (\alpha+z\alpha^2-4z)y(z) = 0.$$

Since $\alpha(\alpha+1) - 4 = 0$, we can simplify the above equation and obtain

$$z(1-z)y''(z) + (1+(2\alpha-1)z)y'(z) + \alpha y(z) = 0.$$

This equation is then rewritten as a generalized hypergeometric differential equation

$$(\delta^2 - z(\delta^2 - 2\alpha\delta - \alpha))y(z) = 0,$$

where $\delta = z(d/dz)$. The differential equation has two fundamental solutions, and the only one that is regular at the origin is

$${}_2F_1\left(\begin{matrix} 2-\alpha, -2-\alpha \\ 1 \end{matrix} \middle| z\right).$$

Thus the solution is of the form

$$Q(z) = -\frac{7}{2} + 4z - \frac{3}{2}z^2 - 3(1-z)^{-1} + c_0(1-z)^{-\alpha}{}_2F_1\left(\begin{matrix} 2-\alpha, -2-\alpha \\ 1 \end{matrix} \middle| z\right),$$

and by matching the initial values, we conclude (3.2).

For the query pattern $[1, 0]$, the particular solution for (2.14) is

$$y_p(z) := 2 - \frac{7}{2}z + \frac{3}{2}z^2 - \frac{2}{1-z}.$$

The only different part of the above proof is considering $y(z) := (Q[1, 0](z) - y_p(z)) / z$; the remaining analysis is similar and omitted. \square

The approach we used for deriving (3.2) and (3.2) is similar to the one used in [14]. However, such an approach does not apply for $k \geq 3$. We need a different approach to solving (2.19).

4. Constants for general query patterns. We rewrite the differential equation (2.19) as

$$(4.1) \quad P_0(\vartheta)Q(z) = \sum_{1 \leq \ell \leq \mu} (1-z)^\ell P_\ell(\vartheta)Q(z) + \sum_{-1 \leq \ell < \mu} \nu_{k,\ell}(1-z)^\ell,$$

where, for simplicity, we write $P_\ell = P_{k,\ell}$ (defined in (2.12)) and $\mu = \mu_{\mathbf{q}}$.

Our main result in this paper is the following asymptotic estimate for Q_n .

THEOREM 4.1. *The expected cost of a random partial match query in a random k - d tree of n nodes satisfies*

$$(4.2) \quad Q_n \sim \frac{K}{\Gamma(\alpha)} n^{\alpha-1} \quad (1 \leq s < k),$$

where the constant K is defined in (4.6) below.

This theorem is proved in the next section by extending the asymptotic theory in [10] for Cauchy–Euler differential equations. The idea is roughly as follows. If the right-hand side of (4.1) is independent of Q , then the solution of Q would satisfy $Q(z) \sim c_1(1-z)^{-\alpha} + y_p(z)$ for some constant c_1 and particular solution $y_p(z)$; see [10]. But the intricate part here is that the right-hand side of (4.1), expected to have a smaller contribution to $Q(z)$, itself depends on Q .

In this section we give an approach to the proof of (4.2) based on Mellin-type integrals. The proof is almost complete, up to an estimate in the complex plane that is needed in justifying the Mellin inversion integrals. The advantage of this approach is that it quickly gives the right form for the constant.

Shifting the initial values. A minor but crucial step in our analysis is to consider the function $f(z) := Q(z) - \sum_{1 \leq j < k} Q_j z^j$. The differential equation for f remains the same, but all initial values become zero. Indeed, by the integral equation (2.7), we have

$$f(z) - 2^k(I_{q_1} \circ \dots \circ I_{q_k})[f](z) = G_1(z),$$

with $f(0) = \dots = f^{(k-1)}(0) = 0$, where

$$G_1(z) := G_0(z) - \sum_{1 \leq j < k} Q_j z^j - 2^k(I_{q_1} \circ \dots \circ I_{q_k}) \left[\sum_{1 \leq j < k} Q_j z^j \right] (z).$$

Note that $I_q[z^j] = z^{j+1}/(j+1+q) + \dots$, $q \in \{0, 1\}$. This, together with the relations $Q_j = [z^j]G_0(z)$ for $0 \leq j < k$, implies that $[z^j]G_1(z) = 0$ for $j < k$.

Now applying the inverse operators to the above integral equation, and then multiplying both sides by z^μ , we obtain

$$(4.3) \quad P_0(\vartheta)f(z) = \sum_{1 \leq \ell \leq \mu} (1-z)^\ell P_\ell(\vartheta)f(z) + g(z),$$

with $f^{(j)}(0) = 0$, $0 \leq j \leq k-1$, where

$$g(z) = z^\mu \sum_{1 \leq j \leq k} 2^{j-1} \left(\vartheta + \frac{q_k}{z} \right) \dots \left(\vartheta + \frac{q_j}{z} \right) \frac{z}{1-z} - z^\mu \left(\left(\vartheta + \frac{q_k}{z} \right) \dots \left(\vartheta + \frac{q_1}{z} \right) - 2^k \right) (Q_1 z + \dots + Q_{k-1} z^{k-1}).$$

By using the same arguments as in the proof of Proposition 2.9, we obtain the alternative form for g ,

$$g(z) = \frac{\nu_{k,-1}}{1-z} + \Pi(z),$$

with $\Pi(z)$ being a polynomial of degree $k + \mu - 1$. With this form, we can now define

$$(4.4) \quad g^*(w) := \int_0^1 (1-x)^{w-1} g(x) dx \quad (\Re(w) > 0).$$

Then g^* satisfies

$$g^*(w) = \frac{\nu_{k,-1}}{w-1} + \sum_{0 \leq j < k+\mu} \frac{(-1)^j \Pi^{(j)}(1)}{j!(w+j)};$$

see Table 5.2. The function g^* can be viewed either as the Mellin transform (see [15]) of $g(x)$ (defined to be zero for $x > 1$) or as the factorial series of the sequence $[z^j]g(z)$.

The following estimate is needed in proving the absolute convergence of the series representation (4.6) of K .

LEMMA 4.2. *The function g^* satisfies the estimate*

$$(4.5) \quad g^*(w) = O(|w|^{-\mu-1})$$

for large $|w|$ and $|\arg(w)| \leq \pi - \varepsilon$, $\varepsilon > 0$.

Proof. Observe first that by definition,

$$g(z) = z^\mu \left(\vartheta + \frac{q_k}{z}\right) \cdots \left(\vartheta + \frac{q_j}{z}\right) G_1(z),$$

and that $[z^j]G_1(z) = 0$ for $j < k$. Since each operator $\vartheta + q_k/z$ has the effect of decreasing the powers of monomials by 1 (from z^j to z^{j-1}), we can expand g as $g(z) = \sum_{j \geq \mu} g_j z^j$ for some coefficients g_j . By using this expansion and interchanging the summation and integral, we obtain

$$g^*(w) = \sum_{j \geq \mu} \frac{g_j j!}{w(w+1) \cdots (w+j)} \quad (\Re(w) > 1),$$

which is not only a factorial series but also an asymptotic expansion for large $|w|$. □

Characterization of K . Now we are ready to give an explicit form for the constant K in Theorem 4.1.

PROPOSITION 4.3. *The constant K in (4.2) is given by*

$$(4.6) \quad K = \frac{1}{P'_0(\alpha)} \sum_{j \geq 0} g^*(\alpha + j) B_j,$$

with the series being absolutely convergent, where

$$(4.7) \quad B_j = \sum_{1 \leq \ell \leq \mu} \frac{P_\ell(\alpha + j)}{P_0(\alpha + j)} B_{j-\ell} \quad (j \geq 1),$$

with the initial conditions $B_0 = 1$ and $B_j = 0$ for $j < 0$.

We defer the hard part of proving (4.6) to later sections and prove here only the absolute convergence, which is a direct consequence of the estimate (4.5) for g^* and the following lemma.

LEMMA 4.4. *Let $B(z) = \sum_{j \geq 0} B_j z^j$. Then $B(z)$ satisfies the differential equation*

$$(4.8) \quad (1 - z)^\mu \left(\left(\frac{q_1 - \mu z}{1 - z} + \alpha + z \mathbb{D}_z \right) \cdots \left(\frac{q_k - \mu z}{1 - z} + \alpha + z \mathbb{D}_z \right) - 2^k \right) B(z) = 0,$$

where $\mathbb{D}_z := d/dz$, and the sequence B_j satisfies

$$(4.9) \quad B_j = O(j^{\mu - q_k - 1}).$$

Proof. The proof is adapted from that of Lemma 3 in [7]. Define the operator

$$\Psi(q_1, \dots, q_k)[\vartheta] := \left(\vartheta + \frac{q_k}{z} \right) \cdots \left(\vartheta + \frac{q_1}{z} \right).$$

By the Cauchy integral representation,

$$B_j = \frac{1}{2\pi i} \oint (1 - z)^{-j-1} B(1 - z) dz \quad (j \geq 0),$$

where, here and throughout the proof, the integration contour is a sufficiently small circle around unity, we obtain

(4.10)

$$\begin{aligned} 0 &= \frac{1}{2\pi i} \oint B(1 - z)(1 - z)^{\alpha-1} \\ &\quad \times \left(P_0(j + \alpha) - \sum_{1 \leq \ell \leq \mu} (1 - z)^\ell P_\ell(j + \alpha) \right) (1 - z)^{-j-\alpha} dz \\ &= \frac{1}{2\pi i} \oint B(1 - z)(1 - z)^{\alpha-1} \left(P_0(\vartheta) - \sum_{1 \leq \ell \leq \mu} (1 - z)^\ell P_\ell(\vartheta) \right) (1 - z)^{-j-\alpha} dz \\ &= \frac{1}{2\pi i} \oint B(1 - z)(1 - z)^{\alpha-1} (z^\mu \Psi(q_1, \dots, q_k)[\vartheta] - 2^k z^\mu) (1 - z)^{-j-\alpha} dz \\ &= V_j - 2^k [z^j] B(z)(1 - z)^\mu, \end{aligned}$$

where

$$\begin{aligned} V_j &:= \frac{1}{2\pi i} \oint B(1 - z)(1 - z)^{\alpha-1} z^\mu \Psi(q_1, \dots, q_k)[\vartheta] (1 - z)^{-j-\alpha} dz \\ &= \frac{1}{2\pi i} \oint B(1 - z)(1 - z)^{\alpha-1} z^\mu \left(\vartheta + \frac{q_k}{z} \right) \Psi(q_1, \dots, q_{k-1})[\vartheta] (1 - z)^{-j-\alpha} dz. \end{aligned}$$

By an integration by parts (for the term corresponding to ϑ), we have

$$V_j = \frac{1}{2\pi i} \oint B_1(1 - z)(1 - z)^{\alpha-1} z^\mu \Psi(q_1, \dots, q_{k-1})[\vartheta] (1 - z)^{-j-\alpha} dz,$$

where

$$B_1(1 - z) := \left(\frac{q_k - \mu(1 - z)}{z} + \alpha - \vartheta \right) B(1 - z).$$

Repeating the same argument $k - 1$ times, we obtain

$$\begin{aligned} V_j &= \frac{1}{2\pi i} \oint (1 - z)^{-j-1} z^\mu \\ &\quad \times \left(\frac{q_1 - \mu(1 - z)}{z} + \alpha - \vartheta \right) \cdots \left(\frac{q_k - \mu(1 - z)}{z} + \alpha - \vartheta \right) B(1 - z) dz \\ &= [z^j] (1 - z)^\mu \left(\frac{q_1 - \mu z}{1 - z} + \alpha + z\mathbb{D}_z \right) \cdots \left(\frac{q_k - \mu z}{1 - z} + \alpha + z\mathbb{D}_z \right) B(z). \end{aligned}$$

From this and (4.10), the result (4.8) follows from multiplying both sides of (4.10) and summing over all $j \geq 0$.

According to the Frobenius method (see [24]), we seek solutions to the differential equation (4.8) of the form $B(z) = (1 - z)^\zeta \xi(1 - z)$ for some $\zeta \in \mathbb{C}$ and some function $\xi(z)$ analytic at the origin. Substituting this form into (4.8), we see that the indicial equation for (4.8) is given by

$$\prod_{1 \leq j \leq k} (-\mu - \zeta + k - j + q_j) = 0.$$

In particular, the dominant zero is $\zeta = -\mu + q_k$, which is a simple zero. This implies that

$$B(z) = O(|1 - z|^{-\mu + q_k}),$$

and, by singularity analysis (see [16]), proves (4.9). \square

Note that, by (4.7), $B(z)$ also satisfies the differential equation

$$P_0(\alpha + z\mathbb{D}_z)B(z) = \sum_{1 \leq \ell \leq \mu} (1 - z)^\ell P_\ell(\alpha + \ell + z\mathbb{D}_z)B(z),$$

but this form is less manageable than (4.8) for our purposes.

While the series form (4.6) may seem recursive, it is readily modified for numerical purposes; see Table 5.1.

We next give a formal proof of the formula (4.6) by Mellin integrals, which will be justified by a more algebraic procedure.

Factorial series and Mellin integrals. Define the factorial series

$$f^*(w) := \int_0^1 (1 - z)^{w-1} f(z) dz = \sum_{j \geq k} \frac{Q_j j!}{w(w + 1) \cdots (w + j)}.$$

Then $f^*(w)$ is well defined in the half-plane $\Re(w) > \alpha$.

By a Mellin inversion formula (or by a standard argument for the integral representation for factorial series), we have

$$(4.11) \quad f(z) = \frac{1}{2\pi i} \int_{\sigma - i\infty}^{\sigma + i\infty} f^*(w) (1 - z)^{-w} dw \quad (\sigma > \alpha).$$

Substituting this into (4.3) and using (4.4), we obtain

$$\begin{aligned} &\frac{1}{2\pi i} \int_{\sigma - i\infty}^{\sigma + i\infty} f^*(w) P_0(w) (1 - z)^{-w} dw \\ &= \frac{1}{2\pi i} \int_{\sigma - i\infty}^{\sigma + i\infty} f^*(w) \sum_{1 \leq \ell \leq \mu} P_\ell(w) (1 - z)^{-w + \ell} dw + \frac{1}{2\pi i} \int_{\sigma - i\infty}^{\sigma + i\infty} g^*(w) (1 - z)^{-w} dw. \end{aligned}$$

By absolute convergence and by the changes of variables $w \mapsto w + j$, we are led to the difference equation

$$(4.12) \quad f^*(w) = \sum_{1 \leq \ell \leq \mu} \frac{P_\ell(w + \ell)}{P_0(w)} f^*(w + \ell) + \frac{g^*(w)}{P_0(w)}$$

for $\Re(w) > \alpha$, with the additional property that $f^*(w) \rightarrow 0$ as $|w| \rightarrow \infty$ in the half-plane $|\arg(w)| < \pi$. But the right-hand side of (4.12) also gives a meromorphic continuation of $f^*(w)$ to the whole plane (up to the zeros of $P_0(w + \ell)$ for $\ell \geq 0$).

In particular, since α is a simple zero of $P_0(w)$ (see [9]),

$$(4.13) \quad f^*(w) \sim \frac{K'}{w - \alpha} \quad (w \sim \alpha),$$

where the residue K' can be computed by

$$(4.14) \quad \begin{aligned} K' &:= \lim_{w \rightarrow \alpha} (w - \alpha) f^*(w) \\ &= \frac{1}{P'_0(\alpha)} \left(\sum_{1 \leq \ell \leq \mu} P_\ell(\alpha + \ell) f^*(\alpha + \ell) + g^*(\alpha) \right). \end{aligned}$$

Mellin inversion and singularity analysis. Heuristically, the series form (4.6) results easily from (4.13) and the Mellin inversion formula (4.11) as follows. First, by (4.11) using (4.13), we expect that

$$f(z) \sim K'(1 - z)^{-\alpha},$$

by formally shifting the integration line to $\Re(w) = \alpha - \varepsilon$ and by taking into account the residue of the integrand at $w = \alpha$.

Then by a formal application of the singularity analysis, we anticipate the approximation

$$[z^n]Q(z) = [z^n]f(z) \sim \frac{K'}{\Gamma(\alpha)} n^{\alpha-1},$$

so that K' should equal K .

Justifying the above quick analysis requires an estimate of $|f^*(\sigma \pm iT)|$ for large T . On the other hand, because of the presence of the factor $(1 - z)^{-w}$, which can be exponentially large when $z \in \mathbb{C}$ lies near unity and when T grows, we need an estimate of $|f^*(\sigma \pm iT)|$ that decays at infinity at an exponential rate (in T). While this approach might be made rigorous, we prefer to develop another approach that is more general and does not rely on analytic properties but instead on algebraic manipulations of integrals.

Effective expressions for K . Iterating the right-hand side of (4.14) N times by the same difference equation (4.12), we deduce that

$$(4.15) \quad P'_0(\alpha)K = \sum_{1 \leq j \leq (\mu-1)N+1} A_{N,j} f^*(\alpha + N + j - 1) + K_N$$

for any $N \geq 1$, where $A_{1,j} := P_j(\alpha + j)$ for $1 \leq j \leq \mu$ and for $N \geq 2$,

$$(4.16) \quad A_{N,\ell} = \sum_{1 \leq i \leq \mu} \frac{P_i(\alpha + N + \ell - 1)}{P_0(\alpha + N + \ell - 1 - i)} A_{N-1,\ell+1-i} \quad (1 \leq \ell \leq N(\mu - 1) + 1),$$

and

$$\begin{aligned} K_N &= K_{N-1} + \sum_{1 \leq j \leq (N-1)(\mu-1)+1} \frac{g^*(\alpha + N + j - 2)}{P_0(\alpha + N + j - 2)} A_{N-1,j} \\ &= g^*(\alpha) + \sum_{1 \leq i \leq N-1} \sum_{1 \leq j \leq i(\mu-1)+1} \frac{g^*(\alpha + i + j - 1)}{P_0(\alpha + i + j - 1)} A_{i,j} \\ &= g^*(\alpha) + \sum_{1 \leq j \leq (N-1)\mu} \frac{g^*(\alpha + j)}{P_0(\alpha + j)} \sum_{1 \leq i \leq j} A_{i,j+1-i}. \end{aligned}$$

By induction and the recursive expression for P_j 's, we have $P_j(x) \asymp x^k$ for large x . From this and the estimate (4.5), we obtain

$$K = \frac{1}{P'_0(\alpha)} \lim_{N \rightarrow \infty} K_N = \frac{1}{P'_0(\alpha)} \left(g^*(\alpha) + \sum_{j \geq 1} \frac{g^*(\alpha + j)}{P_0(\alpha + j)} \sum_{1 \leq i \leq j} A_{i,j+1-i} \right).$$

Define

$$B_j := \frac{1}{P_0(\alpha + j)} \sum_{1 \leq i \leq j} A_{i,j+1-i}.$$

Then B_j is easily seen to satisfy (4.7) by using (4.16).

5. A Cauchy–Euler approach. In this section we develop a different approach to proving (4.6). The reason we write (4.3) in the form of a Cauchy–Euler differential equation is that if

$$(5.1) \quad f(z) = (1 - z)^{-\alpha} \xi(1 - z)$$

for $z \in \mathbb{C}$ near unity, where $\xi(z)$ is analytic at the origin, then

$$(5.2) \quad \sum_{1 \leq \ell \leq \mu} (1 - z)^\ell P_\ell(\vartheta) f(z) = O(|1 - z|^{-\alpha+1}),$$

and thus the dominant (asymptotic) solutions are expected to be determined by the left-hand side of (4.3), with the right-hand side behaving as if it is independent of f . We apply again the Frobenius method to prove (5.1). Once (5.1) is proved, (4.3) is then solved asymptotically by extending our approach of *iterative linear operators* developed in [10].

The growth order of f . By using the formula

$$\vartheta^j f(z) = \sum_{0 \leq \ell \leq j} (-1)^{j+\ell} S(j, \ell) (1 - z)^\ell f^{(\ell)}(z),$$

where the $S(j, \ell)$'s represent the Stirling numbers of the second kind, we can rewrite (4.3) in the form

$$\sum_{0 \leq j \leq k} L_j(z) (1 - z)^j f^{(j)}(z) = g(z)$$

for some polynomials L_j of degree k . In particular, $L_k(z) = z^\mu (1 - z)^k$. Therefore, the possible singularities of (4.3) are the two zeros $z = 0$ and $z = 1$ of the polynomial

$z^\mu(1 - z)^k$, $z = \infty$, and the singularities of $g(z)$ ($z = 1$ only). In particular, the singularity $z = 1$ is a *regular singular point*.

Before applying the Frobenius method (see [24]), we use suitable operators to convert the nonhomogeneous equation into a homogeneous one. We start from the relation

$$(\vartheta + j)(1 - z)^j = 0 \quad (j \in \mathbb{Z}).$$

Then we can annihilate the nonhomogeneous term in (4.3) by multiplying both sides by a sufficient number of the above annihilating operators, giving

$$(5.3) \quad \left(\prod_{-1 \leq j < k + \mu} (\vartheta + j) \right) \left(P_0(\vartheta)f(z) - \sum_{1 \leq \ell \leq \mu} (1 - z)^\ell P_\ell(\vartheta)f(z) \right) = 0.$$

This means that if $f(z)$ solves the nonhomogeneous equation (4.3), then it is also a solution of (5.3) since the dominant growth order of f near the singularity $z = 1$ is determined by the zero of the new indicial equation

$$\left(\prod_{-1 \leq j \leq d} (\vartheta + j) \right) P_0(\vartheta)$$

with the largest real part. By the Frobenius method (see [24]), we then deduce the required estimate (5.1), from which (5.2) follows.

Method of iterative linear operators. As in [10], let α_j , $1 \leq j \leq k$, be the zeros of $P_0(z)$ arranged in decreasing order of their real parts (see [9])

$$\alpha = \alpha_1 > \Re(\alpha_2) \geq \dots \geq \Re(\alpha_k).$$

Define

$$\mathbf{I}_\eta[f](z) = (1 - z)^{-\eta} \int_0^z (1 - x)^{\eta-1} f(x) dx.$$

To solve (4.3), we first factor $P_0(\vartheta)$ into linear operators

$$P_0(\vartheta)f(z) = (\vartheta - \alpha_1) \cdots (\vartheta - \alpha_k)f(z) = R(z),$$

where

$$R(z) := g(z) + \sum_{1 \leq j \leq \mu} (1 - z)^j P_j(\vartheta)f(z),$$

and then solve the linear equations one after another, giving (see [10])

$$f(z) = (\mathbf{I}_{\alpha_k} \circ \mathbf{I}_{\alpha_{k-1}} \circ \dots \circ \mathbf{I}_\alpha)[R](z).$$

By using successive integrations by parts (see [8]) or the inductive arguments used in [10], we deduce that

$$f(z) = \frac{1}{P'_0(\alpha)} \mathbf{I}_\alpha[R](z) + T_1(z),$$

where $[z^n]T_1(z) = o(n^{\alpha-1})$.
 Then (see [10])

$$\begin{aligned} Q_n &= [z^n]f(z) = \frac{1}{P'_0(\alpha)}[z^n]\mathbf{I}_\alpha[R](z) + o(n^{\alpha-1}) \\ &= \frac{1}{P'_0(\alpha)} \sum_{0 \leq \ell < n} \frac{[z^\ell]R(z)}{\ell + 1} \prod_{\ell+2 \leq j \leq n} \left(1 + \frac{\alpha - 1}{j}\right) + o(n^{\alpha-1}) \\ &= \frac{K''}{P'_0(\alpha)\Gamma(\alpha)} n^{\alpha-1} + o(n^{\alpha-1}), \end{aligned}$$

where

$$K'' = \int_0^1 (1-x)^{\alpha-1} R(x) dx = \sum_{\ell \geq 0} \frac{\ell! [z^\ell]R(z)}{\alpha(\alpha+1) \cdots (\alpha+\ell)}.$$

Iteration of the leading constant. We next “mimic” the operations of the Mellin approach and show that

$$K'' = P'_0(\alpha)K,$$

and this will complete the proof of Theorem 4.1.

LEMMA 5.1. *Let $\omega(x)$ and $\beta(x)$ be two polynomials of degree at most k . Let $h(x)$ be defined in the unit interval. If h satisfies*

- (i) $h^{(j)}(0) = 0$ for $0 \leq j < k$, and
- (ii) *the integral*

$$h^*(w) := \int_0^1 (1-x)^{\eta-1} h(x) dx$$

converges,

then for any $\eta \in \mathbb{C}$ for which $\beta(\eta) \neq 0$,

$$(5.4) \quad \int_0^1 (1-x)^{\eta-1} \omega(\vartheta_x) \beta(\vartheta_x)^{-1} h(x) dx = \frac{\omega(\eta)}{\beta(\eta)} h^*(\eta),$$

where $\beta(\vartheta_x)^{-1}$ represents the inverse operator of the differential operator $\beta(\vartheta_x)$ and $\vartheta_x := (1-x)(d/dx)$.

Proof. Obviously, (5.4) holds when $\omega(x) = \beta(x)$. It is also easily checked, by integration by parts, for the two fundamental cases $\omega(x) = x$, $\beta(x) = 1$ and $\omega(x) = 1$, $\beta(x) = x - \nu$ for $\nu \neq \eta$.

When $\omega(x)$ is a polynomial of degree at most k , we first write $\omega(x) = (x-\nu)\omega_1(x)$, where ν is a zero of $\omega(x)$. Then

$$\begin{aligned} \int_0^1 (1-x)^{\eta-1} \omega(\vartheta_x) h(x) dx &= \int_0^1 (1-x)^{\eta-1} (\vartheta_x - \nu) \omega_1(\vartheta_x) h(x) dx \\ &= (\eta - \nu) \omega_1(\vartheta_x) h^*(\eta). \end{aligned}$$

Repeating the same argument, we have

$$\int_0^1 (1-x)^{\eta-1} \omega(\vartheta_x) h(x) dx = \omega(\eta) h^*(\eta)$$

and

$$\int_0^1 (1-x)^{\eta-1} \beta(\vartheta_x)^{-1} h(x) dx = \frac{h^*(\eta)}{\beta(\eta)}.$$

Similarly, we derive (5.4). \square

Define

$$\Lambda_f(\alpha) := \int_0^1 (1-x)^{\alpha-1} P_0(\vartheta_x) f(x) dx.$$

Note that $\Lambda_f(\alpha) = K''$. By substituting (4.3) into the above integral and by applying (5.4), we have

$$(5.5) \quad \Lambda_f(\alpha) = g^*(\alpha) + \sum_{1 \leq \ell \leq \mu} \frac{P_\ell(\alpha + \ell)}{P_0(\alpha + \ell)} \Lambda_f(\alpha + \ell),$$

where $g^*(\alpha)$ is defined as in (4.4). By definition, we have

$$K'' = g^*(\alpha) + \sum_{1 \leq \ell \leq \mu} \frac{P_\ell(\alpha + \ell)}{P_0(\alpha + \ell)} \Lambda_f(\alpha + j).$$

It follows by (4.12) and the property $\Lambda_f(x) \rightarrow 0$ as $x \rightarrow \infty$ that $K'' = P'_0(\alpha)K$, as required.

More refined approximations. We can refine the above analysis and derive the effective approximation

$$(5.6) \quad Q_n = \frac{K}{\Gamma(\alpha)} n^{\alpha-1} - \frac{1}{2^k - 2^s} \sum_{1 \leq j \leq k} 2^{j-1+q_j+\dots+q_k} + O\left(n^{\alpha-2} + n^{\Re(\alpha_2)-1} (\log n)^{\kappa-1}\right),$$

where κ denotes the largest multiplicity of zeros with real parts equal to $\Re(\alpha_2)$ (see [10]).

Hypergeometric cases: $\mu = 1$. When the query pattern is of the form (2.15), we can obtain more explicit expressions. In this case, $\mu = 1$ and $P_1(x) = x^k - 2^k$. Then

$$K = \frac{1}{P'_0(\alpha)} \sum_{j \geq 0} g^*(\alpha + j) \prod_{1 \leq \ell \leq j} \frac{P_1(\alpha + \ell)}{P_0(\alpha + \ell)},$$

where, by a lengthy calculation,

$$g^*(w) := \frac{(s+1)2^k - 2^s}{w-1} + \frac{2^k \sigma_0 - 2^{k+1} + 2^{k-s} + 1}{w} - \sum_{1 \leq \ell \leq k} \frac{P_0(-\ell) \sigma_\ell - P_1(1-\ell) \sigma_{\ell-1}}{w+\ell},$$

with $\sigma_\ell := (-1)^\ell \sum_{\ell \leq j \leq k} \binom{j}{\ell} Q_j$. From this expression of g , we can further rewrite the above series form for K in terms of generalized hypergeometric functions.

$\mu \geq 2$. When $\mu \geq 2$, the solution to the recurrence (4.7) is, in general, less explicit. But there are special cases when $\mu > 1$ can be reduced to $\mu = 1$. These occur when the query patterns are of the form

$$\underbrace{[0, \dots, 0]}_{k-\mu-s+1}, \underbrace{[1, \dots, 1]}_s, [0, \dots, 0] \quad (1 \leq s \leq k - \mu + 1),$$

TABLE 5.1

Approximate numerical values of α and $Q_n/n^{\alpha-1}$ for all generating query patterns (up to cyclic rotations) for $k = 3, 4, 5$, and 6. Note that the periodic patterns $[0, 1, 0, 1]$, $[0, 1, 0, 1, 0, 1]$, $[0, 0, 1, 0, 0, 1]$ and $[0, 1, 1, 0, 1, 1]$ are not shown. The total number of different patterns (up to rotations) needed to cover all 2^k possible query forms is given by (2.4).

the expected cost of which can be computed via that of the special patterns (2.15) and the relations (2.3).

Tables. For concreteness, we give numerical approximations to $K/\Gamma(\alpha)$ in Table 5.1 and the expansions of $g^*(w)$ for $k \leq 5$ in Table 5.2.

Note that the general terms in (4.6) converge slowly; thus it is more efficient, for numerical purposes, to use the expression (4.15); see Table 5.1. The idea is roughly to take a sufficiently large N , say 1000, to compute the first N terms as precisely as we can, and then to estimate the errors by the values of $f^*(\alpha + N)$, which can be easily computed by

$$f^*(\alpha + N) = \sum_{j \geq k} \frac{Q_j j!}{(\alpha + N) \cdots (\alpha + N + j)},$$

the series itself being an asymptotic expansion.

6. k -d- t trees. In this section we extend our approach to k -d- t trees, $t \in \mathbb{N}$, which are locally balanced versions of k -d trees (in which all trees of sizes larger than $2t$ have both subtrees of sizes at least t); see [11]. For simplicity, trees of sizes $\leq 2t$ are not rearranged.

The probabilistic model for partial match queries remains the same as above. For convenience, we use the same set of notations as for k -d trees (indexed by t when ambiguity may arise). Let $Q_{n,t} = Q_n[q_1, \dots, q_k; t]$ stand for the expected number of nodes visited when performing the range search algorithm of a random partial match query in a random k -d- t tree of n nodes. Then $Q_{n,0} = Q_n$. Cunto, Lau, and Flajolet [11] showed that

$$Q_{n,t} \sim C_t n^{\alpha-1}$$

for some constant C_t , where $\alpha > 1$ solves the equation $P_0(\alpha) = 0$, with

$$(6.1) \quad P_0(x) := \left((x+t)^{\overline{t+1}} \right)^{k-s} \left((x+t+1)^{\overline{t+1}} \right)^s - \left((t+2)^{\overline{t+1}} \right)^k.$$

We show that C_t can be computed as above but with more complicated components.

LEMMA 6.1 (basic recurrences). *Define $\varpi_{n,j} := \binom{j}{t} \binom{n-1-j}{t} / \binom{n}{2t+1}$. The expected search cost $Q_{n,t}$ for fixed $t \in \mathbb{N}$ satisfies the system of recurrences*

$$(6.2) \quad \begin{cases} Q_n[q_1, \dots, q_k; t] = 1 + 2 \sum_{1 \leq j < n} \rho_{n,j}(q_1) \varpi_{n,j} Q_j[q_2, \dots, q_k, q_1; t], \\ \vdots \\ Q_n[q_k, q_1, \dots, q_{k-1}; t] = 1 + 2 \sum_{1 \leq j < n} \rho_{n,j}(q_k) \varpi_{n,j} Q_j[q_1, \dots, q_k; t] \end{cases}$$

for $n \geq 2t + 1$, with the initial values $Q_{n,t} \equiv Q_n$ for $n \leq 2t$.

Differential equations. Define the differential operator

$$J_q[\varphi](z) = \left((\vartheta + t) \cdots (\vartheta + 2t) + \frac{q(t+1)}{z} (\vartheta + t + 1) \cdots (\vartheta + 2t) \right) \varphi(z) \quad (q \in \{0, 1\}).$$

From (6.2), we derive a system of differential equations satisfied by the generating functions

$$f_j^{[t]}(z) := Q[q_j, \dots, q_k, q_1, \dots, q_{j-1}; t](z) := \sum_{n \geq 1} Q_{n,t} z^n.$$

LEMMA 6.2. Let $\lambda_t := (2t + 2)/(t + 1)!$. For any query pattern $[q_1, \dots, q_k]$,

$$\begin{cases} J_{q_1}[f_1^{[t]}] = J_{q_1}\left[\frac{z}{1-z}\right] + \lambda_t f_2^{[t]}, \\ \vdots \\ J_{q_k}[f_k^{[t]}] = J_{q_k}\left[\frac{z}{1-z}\right] + \lambda_t f_1^{[t]}. \end{cases}$$

Proof (sketch). When $q_j = 0$, we have

$$\vartheta^{\overline{2t+1}}\left(f_j^{[t]} - \frac{z}{1-z}\right) = \lambda_t \vartheta^{\bar{t}} f_{j+1}^{[t]} \quad (1 \leq j \leq k),$$

where $f_{k+1}^{[t]} := f_1^{[t]}$.

When $q_j = 1$, the differential equation becomes

$$\vartheta^{\overline{2t+2}}\left(z f_j^{[t]} - \frac{z^2}{1-z}\right) = \lambda_t \vartheta^{\overline{t+1}}(z f_{j+1}^{[t]}).$$

By applying the identity $\vartheta((1-z)\varphi(z)) = (1-z)(\vartheta-1)\varphi(z)$, we obtain

$$\left((\vartheta+t)\cdots(\vartheta+2t) + \frac{(t+1)}{z}(\vartheta+t+1)\cdots(\vartheta+2t)\right) f_j^{[t]} = \lambda_t f_{j+1}^{[t]}. \quad \square$$

COROLLARY 6.3.

$$(J_{q_k} \circ \dots \circ J_{q_1})[f_1^{[t]}] - \lambda_t^k f_1^{[t]} = \sum_{1 \leq j \leq k} \lambda_t^{j-1} (J_{q_k} \circ \dots \circ J_{q_j})\left[\frac{z}{1-z}\right].$$

Differential equations: Normal form. We multiply, as in the case of k -d trees, both sides by $z^{\mu_{\mathbf{q}}(t)}$, where $\mu_{\mathbf{q}}(t)$ denotes the “minimum exponent”

$$\mu_{\mathbf{q}}(t) := (k - v)(t + 1) + 1,$$

with v being the last position of the first block of 1’s (from left to right), and $\mu_{\mathbf{q}}(t) := 0$ if $s = 0$.

Then the generating function

$$f(z) := f_1^{[t]}(z) - \sum_{1 \leq j < k(t+1)} Q_j z^j$$

satisfies the differential equation

$$P_0(\vartheta)f = \sum_{1 \leq \ell \leq \mu_{\mathbf{q}}(t)} (1-z)^\ell P_\ell(\vartheta)f + g,$$

where the P_ℓ ’s are polynomials of degree $k(t + 1)$ and

$$\begin{aligned} g(z) = & z^{\mu_{\mathbf{q}}(t)} \sum_{1 \leq j \leq k} \lambda_t^{j-1} (J_k \circ \dots \circ J_j)\left[\frac{z}{1-z}\right](z) + z^{\mu_{\mathbf{q}}(t)} \lambda_t^k \sum_{1 \leq j < k(t+1)} Q_j z^j \\ & - z^{\mu_{\mathbf{q}}(t)} (J_k \circ \dots \circ J_1)\left[\sum_{1 \leq j < k(t+1)} Q_j z^j\right](z). \end{aligned}$$

In particular, $P_0(x)$ is as given in (6.1).

A series form for K_t . Following the same method of proof as for k -d trees, we can derive a series representation for K_t .

THEOREM 6.4. *The expected cost $Q_{n,t}$ satisfies the approximation*

$$Q_{n,t} \sim \frac{K_t}{\Gamma(\alpha)} n^{\alpha-1},$$

where

$$K_t = \frac{1}{P'_0(\alpha)} \sum_{j \geq 0} g^*(\alpha + j) B_j,$$

with the series being absolutely convergent. Here $g^*(w) := \int_0^1 g(x)(1-x)^{w-1} dx$ and B_j is defined recursively by

$$B_j = \sum_{1 \leq \ell \leq \mu_{\mathbf{q}}(t)} \frac{P_\ell(\alpha + j)}{P_0(\alpha + j)} B_{j-\ell} \quad (j \geq 1),$$

with the initial values $B_0 = 1$ and $B_j = 0$ for $j < 0$.

The method of proof is the same as that for k -d trees. In particular, the estimates $g^*(w) = O(|w|^{-\mu_{\mathbf{q}}(t)-1})$ and $B_j = O(|j|^{\mu_{\mathbf{q}}(t)-q_k-1})$ hold. Note that the generating function $B(z) := \sum_j B_j z^j$ satisfies the differential equation

$$\left(\prod_{t < \ell \leq 2t} \left(\ell + \alpha - \frac{\mu_{\mathbf{q}}(t)z}{1-z} + z\mathbb{D}_z \right) \right) \times \left(\frac{q_1(t+1)}{1-z} + t + \alpha - \frac{\mu_{\mathbf{q}}(t)z}{1-z} + z\mathbb{D}_z \right) \times \dots$$

$$\times \left(\prod_{t < \ell \leq 2t} \left(\ell + \alpha - \frac{\mu_{\mathbf{q}}(t)z}{1-z} + z\mathbb{D}_z \right) \right) \left(\frac{q_k(t+1)}{1-z} + t + \alpha - \frac{\mu_{\mathbf{q}}(t)z}{1-z} + z\mathbb{D}_z \right) B(z) = 0,$$

and the indicial equation is given by

$$\prod_{1 \leq j \leq k} \left((-\zeta - \mu + (q_{k-j+1} + j - 1)(t + 1)) \prod_{1 \leq \ell \leq t} (-\zeta - \mu + (j - 1)(t + 1) + \ell) \right),$$

with the dominant (simple) zero being $\zeta = -\mu + q_k$.

All coordinates specified: $s = k$. In this case, the two Q_n 's on both sides of (6.2) are the same; thus the k recurrences reduce to a single one. The associated differential equation is

$$\left(\vartheta^{2t+2} - \lambda_t \vartheta^{t+1} \right) (zf(z)) = \frac{(2t+2)!}{1-z},$$

with suitable initial conditions. Note that the polynomial $(x+t+1) \cdots (x+2t+1) - \lambda_t$ has 1 as the simple, largest zero (in real part). By applying [10, Theorem 1], we have

$$Q_n[1, \dots, 1; t] \sim \frac{\log n}{H_{2t+2} - H_{t+1}},$$

another well-known result; see [11, 30, 36].

Hypergeometric cases: $\mu_{\mathbf{q}}(t) = 1$. For query patterns of the form (2.15), we have $\mu_{\mathbf{q}}(t) = 1$, and

$$P_1(x) = \prod_{t \leq j \leq 2t} (x+j)^k - \lambda_t^k.$$

7. Conclusions. We derived an effective expression for the leading constant of the expected cost used for random partial match queries in random k -d trees. The proposed approach for solving linear differential equations with polynomial coefficients is very general, and its success relies on the close interplay between complex-analytic methods and elementary methods (without complex analysis).

Complex-analytic methods, when they apply, usually give efficient approximations and neat expressions, but at the cost that stronger analytic properties are needed. On the other hand, elementary methods are computationally less efficient but can provide more general results under weaker conditions. A combination of both (heuristically or rigorously) usually yields very powerful tools, as already shown by the problems studied in [7, 8, 9, 10] and in this paper.

POWER FROM RANDOM STRINGS*

ERIC ALLENDER[†], HARRY BUHRMAN[‡], MICHAL KOUCKÝ[§], DIETER VAN
MELKEBEEK[¶], AND DETLEF RONNEBURGER^{||}

Abstract. We show that sets consisting of strings of high Kolmogorov complexity provide examples of sets that are complete for several complexity classes under probabilistic and nonuniform reductions. These sets are provably not complete under the usual many-one reductions.

Let $R_C, R_{K_t}, R_{KS}, R_{KT}$ be the sets of strings x having complexity at least $|x|/2$, according to the usual Kolmogorov complexity measure C , Levin’s time-bounded Kolmogorov complexity K_t [L. Levin, *Inform. and Control*, 61 (1984), pp. 15–37], a space-bounded Kolmogorov measure KS , and a new time-bounded Kolmogorov complexity measure KT , respectively.

Our main results are as follows:

1. R_{KS} and R_{K_t} are complete for PSPACE and EXP, respectively, under P/poly-truth-table reductions. Similar results hold for other classes with PSPACE-robust Turing complete sets.
2. $EXP = NP^{R_{K_t}}$.
3. $PSPACE = ZPP^{R_{KS}} \subseteq P^{R_C}$.
4. The Discrete Log, Factoring, and several lattice problems are solvable in $BPP^{R_{KT}}$.

Our hardness result for PSPACE gives rise to fairly natural problems that are complete for PSPACE under \leq_T^P reductions, but not under \leq_m^{\log} reductions.

Our techniques also allow us to show that all computably enumerable sets are reducible to R_C via P/poly-truth-table reductions. This provides the first “efficient” reduction of the halting problem to R_C .

Key words. Kolmogorov complexity, completeness, reductions, randomness, derandomization

DOI. 10.1137/050628994

1. Introduction. Much recent work in derandomization can be viewed as an attempt to understand and exploit the interplay between the two common meanings of the phrase “random string”: a string picked at random (according to some distribution), and a string with high Kolmogorov complexity (in some sense). In this paper, we further investigate the relationship between these two notions. We apply recent advances in derandomization to obtain fundamentally new types of complete sets for several standard complexity classes. The sets consist of random strings with respect to various Kolmogorov measures.

We will focus on the set $R_C = \{x : C(x) \geq |x|/2\}$ of strings with high traditional Kolmogorov complexity, as well as various resource-bounded variants R_μ for $\mu = \text{KT}, \text{KS}, \text{Kt}$. See section 2 for the definitions of KT, KS , and Kt . The choice of $|x|/2$ as a quantification of “high complexity” is rather arbitrary. Our results hold for any reasonable bound ranging from $|x|$ to $|x|^\epsilon$ for any positive ϵ . In most cases, our results carry over to other notions of resource-bounded Kolmogorov complexity that have been considered in the literature.

The sets R_μ of Kolmogorov random strings are good examples of sets with a lot of information content that is difficult to access. There are many examples in the literature where sets consisting of strings with high resource-bounded Kolmogorov complexity have been studied as possible examples of intractable sets that are not complete for any of the standard complexity classes. We list a few of these results here.

1. Buhrman and Mayordomo [20] studied a time-bounded Kolmogorov complexity measure K^t for exponential time bounds $t(n) \geq 2^{n^2}$, and they showed that the set $R^t = \{x : K^t(x) \geq |x|\}$ lies in $\text{EXP} - \text{P}$ and is *not* complete for EXP under polynomial-time Turing reducibility $\leq_{\text{T}}^{\text{P}}$.

2. Ko [38] studied the measure K^t for *polynomial* time bounds $t(n)$ and showed that the questions of whether the set $\{x : K^t(x) \geq \epsilon|x|\}$ is in P or is coNP -complete (with respect to $\leq_{\text{T}}^{\text{P}}$ reductions) cannot be answered using relativizing techniques.

3. Kabanets and Cai [36] study the Minimum Circuit Size Problem (MCSP) defined as the set of all pairs (χ_f, s) where χ_f denotes a string of length 2^n that is the truth-table of a Boolean function f on n variables and s denotes an integer such that f can be computed by a Boolean circuit of size at most s . Because the circuit size of f is polynomially related to $\text{KT}(f)$ (see section 2), the MCSP can be seen to be related to R_{KT} . Kabanets and Cai present evidence that the MCSP is not in P but is also not likely to be NP -complete under $\leq_{\text{m}}^{\text{P}}$ reductions.

4. In the traditional setting of Kolmogorov complexity, where no resource bounds are present, the set of Kolmogorov random strings R_C is easily seen to be co-computably enumerable (co-c.e.) and not decidable, but the complement of the halting problem is *not* reducible to R_C via a many-one reduction. It was shown only within the last decade by Kummer that a truth-table reduction is sufficient to reduce the complement of the halting problem to R_C [40], although it had long been known [46] that Turing reductions can be used. It should be emphasized that Kummer’s reduction, which is in fact a disjunctive truth-table reduction, is *not* feasible and asks *many* queries. It can be shown that R_C is not complete for the co-c.e. sets under polynomial-time disjunctive truth-table reductions. (This was originally observed in [9]; a more general statement is proved in [8].)

These results suggest that the sets of resource-bounded random strings are not complete for the complexity class they naturally live in. Buhrman and Torenvliet [21] gave some evidence that this is not the complete picture. They showed that for the *conditional* version of space-bounded Kolmogorov complexity, the set of random strings is hard for PSPACE under NP reductions. However, their result had the major drawback that it needed conditional Kolmogorov complexity and used NP reductions, and, moreover, their proof technique could not be used beyond PSPACE .

Using very different techniques, we provide much stronger results in the same direction. We show that the set of random strings *can* be exploited by efficient reductions. For instance, we show that the set R_{Kt} of strings with high complexity using Levin’s time-bounded Kolmogorov notion Kt [43] is complete for EXP under truth-table reductions computable by polynomial-size circuits. Since this set is provably

not complete under polynomial-time many-one reductions, we obtain natural examples that witness the difference in power of various reducibilities.

It is significant that all of our completeness results are obtained via derandomization techniques. This provides a new paradigm for proving completeness in settings where more traditional methods provably are not applicable.

In some instances, we are also able to provide completeness results under uniform reductions. By making use of multiple-prover interactive proofs for EXP [13] we show that R_{Kt} is complete for EXP under NP-Turing reductions.

Of greater interest is the fact that the set R_{KS} of strings with high space-bounded Kolmogorov complexity is complete for PSPACE under ZPP-Turing reductions. Our proofs rely on the existence of complete sets for PSPACE that are both downward self-reducible and random self-reducible [57], and hence our proofs do not relativize. It remains unknown whether the results themselves hold relative to all oracles.

For the unbounded case we even show that PSPACE is reducible to R_{C} under *deterministic* polynomial-time Turing reductions. The main tool in proving this is a polynomial-time algorithm that constructs a string of high Kolmogorov complexity, using R_{C} as an oracle.

For R_{KT} , a set in coNP, we do not obtain completeness results but we show that R_{KT} is hard under BPP-reductions for some well-known candidate NP-intermediate problems: Discrete Log, Factoring, and several lattice problems. These hardness results also hold for the minimum circuit size problem (MCSP), thereby improving results of [36].

1.1. The connection to derandomization. There is an obvious connection between Kolmogorov complexity and derandomization. For any randomized algorithm \mathcal{A} having small error probability, and any input x , the coin flip sequences r resulting in a wrong answer are atypical and hence have short descriptions of some kind.

By considering different notions of Kolmogorov complexity, less obvious (and more useful) connections can be exposed. Assume that the coin flip sequences that result in wrong answers have small μ -complexity, for some Kolmogorov measure μ . If we can generate a coin flip sequence r belonging to the set R_{μ} of strings with high μ -complexity, then we obtain an upper bound on the complexity of \mathcal{A} , by running the randomized algorithm on (x, r) . Instead of generating a string in R_{μ} , if we assume only that we can check membership in R_{μ} , then we obtain a zero-error probabilistic algorithm by picking a coin flip sequence r at random until we get one in R_{μ} (of which there are many) and then running \mathcal{A} on (x, r) .

The first interesting application of this approach is due to Sipser [54]. His proof that BPP lies in the polynomial-time hierarchy uses $\mu = \text{KD}^t$, the $t(n)$ -time-bounded distinguishing complexity, for some polynomial t . The corresponding set R_{μ} lies in Π_2^p . The hardness versus randomness tradeoffs by Babai et al. [14] and by Impagliazzo and Wigderson [33] and the “easy witness technique” of [35, 32] can be cast as an application of this approach with $\mu = \text{KT}$. A survey of some derandomization results from this perspective can be found in [6]. The observation from [37] that the construction of [33] relativizes with respect to any oracle A can be viewed in terms of a Kolmogorov measure which we denote as KT^A . This interpretation plays a crucial role in Trevisan’s influential construction of extractors out of pseudorandom generators [56].

Our main technique is to use relativizing hardness versus randomness tradeoffs in the contrapositive. Such results state that if there exists a computational problem in a certain complexity class \mathcal{C} that is hard when given oracle access to A , then there exists

a pseudorandom generator secure against A that is computable within \mathcal{C} . However, we argue that no pseudorandom generator computable in \mathcal{C} can be secure against R_μ . Thus we conclude that every problem in \mathcal{C} is easy given oracle access to R_μ ; i.e., \mathcal{C} reduces to R_μ . For our results, we exploit the nonuniform hardness versus randomness tradeoffs in [14] and [33], as well as the uniform ones in [30] and [34].

1.2. The structure of complexity classes. The tools of reducibility and completeness are responsible for most of the success that complexity theory has had in proving (or providing evidence for) intractability of various problems. It has been known since the work of Ladner [41] that, if P is not equal to NP, then there are intractable problems in NP that are not NP-complete. There are not many interesting candidates for this status, though. Certainly the sets constructed in [41] are quite artificial; they are constructed by putting huge empty segments inside a standard complete problem such as SAT. Similarly, there are a great many notions of reducibility that have been considered and for many of these notions it is known that more powerful reducibilities provide more complete sets (at least for large complexity classes such as EXP) [61, 2]. However, almost all of the known constructions proceed by diagonalization and do not produce very “natural” languages.

We have already mentioned three notable examples that run counter to this trend [20, 36, 38]. Using the insight that circuit size is closely connected to a version of time-bounded Kolmogorov complexity, all of these examples can be seen to be variations on a single theme. Our results amplify and extend these earlier papers. For instance, the set R^t (for $t = 2^{n^2}$) was shown in [20] not to be complete for EXP under \leq_T^P reductions, but the authors presented no positive results showing how to reduce problems in EXP to R^t . In contrast, we show that this set is complete under $\leq_{tt}^{P/poly}$ and \leq_T^{NP} reductions. To the best of our knowledge, this is the first example of a “natural” set A with the property that $P^A \neq NP^A$. All previous examples of such sets have been explicitly constructed via diagonalization, to separate P and NP. For polynomial time bounds t , Ko raised the prospect that R^t might be complete for NP under \leq_T^{SNP} reductions, but he presented no unconditional results reducing supposedly intractable problems to R^t . In contrast, we show that factoring and various problems arising in cryptography are reducible to R^t (and in many cases we present \leq_T^{ZPP} reductions).

As an additional application of our techniques toward explicating the structure of complexity classes, we present natural examples of sets that witness the difference of \leq_{tt}^P and \leq_T^{\log} or \leq_T^P and \leq_m^P completeness notions in PSPACE.

1.3. Outline of the rest of the paper. In section 2 we present background and definitions regarding resource-bounded Kolmogorov complexity. In section 3 we present our results for R_{Kt} , R_{KS} , and R_C , and in section 4 those for R_{KT} . We conclude with open problems in section 5.

2. Resource-bounded Kolmogorov complexity. In this section, we present the notions of resource-bounded Kolmogorov complexity that we use in stating most of our results. Before presenting our definitions, it is necessary to give some justification for introducing new definitions, because it might seem to the reader that the literature has more than enough notions of resource-bounded Kolmogorov complexity already.

2.1. Motivation. Kolmogorov complexity provides a very useful and elegant tool for measuring the complexity of finite objects. We refer the reader to [44] for the standard theorems and notation related to Kolmogorov complexity. Since the Kolmogorov complexity $C(x)$ of a string x cannot be computed, many definitions have been proposed for computable approximations to $C(x)$.

One of the most useful of these was given by Levin [43]. Given a universal Turing machine U , Levin defined $\text{Kt}(x|y)$ to be $\min\{|d| + \log t : U(d, y) = x \text{ in at most } t \text{ steps}\}$ and $\text{Kt}(x)$ to be a shortcut for $\text{Kt}(x|\lambda)$, where λ denotes the empty string. Levin's Kt measure has many useful properties, among which is the fact that it provides a search strategy for finding accepting computations for nondeterministic Turing machines that provably is nearly optimal. Stated another way, suppose that you want to find satisfying assignments for Boolean formulae. Given a formula ϕ with n variables, you want to find a string $v \in \{0, 1\}^n$ that satisfies ϕ . If this problem can be solved in time $t(n)$, then it can be solved in time nearly $O(t(n))$ by a program that, on input ϕ , enumerates strings v in order of increasing value of $\text{Kt}(v|\phi)$. For details, see [44].

For reasons of ease of presentation, we will slightly change the formal definition of Kt in section 2.2. The modification affects the value of Kt by at most a logarithmic additive term and does not alter any of Kt 's desirable properties. The principal change is in the way the universal machine U uses the description d . In Levin's original definition, U uses the description d to output the entire string x . In the new definition, the description d allows U to compute each bit of x . That is, given d and i , U can compute the i th bit of x . Although this causes no substantial change to the measure Kt , it opens up the possibility of considering run times that are much smaller than the length of the string x . In turn, this allows us to introduce a new notion of time-bounded Kolmogorov complexity, denoted KT , which is very closely related to circuit complexity. More precisely, $\text{KT}(x)$ is polynomially related to the minimum circuit size of the function that has x as its truth-table (see Theorem 11).

Other notions of resource-bounded Kolmogorov complexity have been studied previously. One definition that one encounters fairly frequently [38, 45, 44, 20, 21] is the measure $\text{K}^t(x)$, in which one explicitly bounds the running time of the universal machine U by $t(|x|)$, where the function t is an additional parameter. In contrast to our notion KT , there is no known relationship between circuit size and K^t . The need to fix the running time t also makes the notion K^t less robust with respect to the choice of the underlying universal machine U . See section 2.2 for more details.

It turns out to be convenient to consider relativized measures KT^A where the universal machine is given access to an oracle A . This highlights some close connections with some previously studied Kolmogorov complexity measures. For instance,

1. Levin's measure $\text{Kt}(x)$ is linearly related to $\text{KT}^A(x)$, where A is a certain complete set for E ; and
2. the original Kolmogorov measure $\text{C}(x)$ is linearly related to $\text{KT}^H(x)$, where H is the halting problem.

The relationship between KT and circuit size also holds in the relativized setting. Thus Levin's measure Kt is roughly the same thing as circuit size on oracle circuits that have access to an E -complete set, and C is roughly the same thing as circuit size relative to the halting problem.

The computational model that we use throughout this paper is the multitape Turing machine with random access to its input tape. Our ideas work in any general model of computation. The main reason for providing random access to the input tape is that $\text{KT}(x|y)$ can be seen to be closely related to the circuit size of the function represented by x on circuits that have oracle access to the function represented by y . For this correspondence to hold, U must be able to access any bit of y quickly. Let us emphasize that all of our theorems in sections 3 and 4 hold verbatim for models such as Turing machines with sequential access to their input tapes or Turing machines that have random access to all their tapes.

2.2. Formal definitions. We begin by defining the models of computation used in this paper and by observing some basic properties relating them to one another.

DEFINITION 1. We consider circuits with AND, OR, and negation gates, as well as oracle gates for one or more oracles. An oracle gate for an oracle A has inputs z_1, \dots, z_r for some r ; it outputs the value 1 if the string $z = z_1, \dots, z_r$ is in A , and outputs 0 otherwise. We define the size of a circuit as the number of connections in the circuit.

We also associate circuit complexities with Boolean strings viewed as truth-tables of Boolean functions.

DEFINITION 2. Let x be a string in $\{0, 1\}^*$ of length n . Let $2^{k-1} < n \leq 2^k$ and let x' be the string of length 2^k of the form $x0^i$ for some i . Let f_x be the Boolean function on k variables, having x' as its truth-table. We define $\text{SIZE}(x)$ to be the size of a minimal-sized circuit with k input variables computing the function f_x . For any oracle A , $\text{SIZE}^A(x)$ denotes the circuit size required to compute f_x on circuits with oracle A . If $y \in \{0, 1\}^*$, then $\text{SIZE}^{A,y}(x)$ denotes the circuit size required to compute f_x on circuits with two kinds of oracle gates: oracle gates for A of arbitrary fan-in and oracle gates for f_y of fan-in $\lceil \log |y| \rceil$.

For a good overview of circuit complexity refer to [60].

We have already mentioned that we will be using a Turing machine with random access to its input tape; we now make more precise what we mean by this. We use essentially the same notion that was considered in [15]. The machine has one read-only input tape of length n , a constant number of read-write working tapes of infinite length, and a read-write input address tape. At every time step the machine can modify the content of its read-write tapes using the appropriate heads and move these heads left or right by one tape cell. It can also query the content of the input bit whose address is written on the input address tape. If there is no such input bit the reply to the query is the symbol “*.”

In the case where the machine is an oracle Turing machine, for each oracle the machine has one read-write oracle tape. At every step the machine can query any of its oracles whether the string written on the corresponding oracle tape belongs to the oracle set or not. We also allow finite oracles. For a finite oracle $y \in \{0, 1\}^*$, the machine obtains as an answer to its query i bit y_i if $i \leq |y|$ and “*” otherwise. Note that the input tape behaves like an oracle tape accessing a finite oracle.

As usual, the *running time* of a Turing machine on a particular input is the number of steps before a computation of the machine stops on that input, and the *space* used during the computation is the number of read-write tape cells visited during the computation.

As with ordinary Turing machines, running time on our machines is closely related to circuit size.

PROPOSITION 3 (simulation of circuits). Let $k \geq 0$ be an integer. There is a constant c and a two-tape oracle Turing machine M such that for every oracle A , finite oracles y_1, \dots, y_k , and circuit C^{A,y_1,\dots,y_k} of size m computing a function of n input bits, there is an encoding d_C of C of size $\leq cm(\log m + \log n)$, so that for any string x , if $|x| = n$ then $M^{A,d_C,y_1,\dots,y_k}(x)$ outputs $C^{A,y_1,\dots,y_k}(x)$ in time $\leq c(m^2 \log m + m \log n)$, and it outputs * in time $\leq c(\log n)$ otherwise.

PROPOSITION 4 (simulation by circuits). For every oracle Turing machine M there is a constant c_M such that if M^{A,y_1,\dots,y_k} runs in time $t = t(n, n_1, \dots, n_k)$ on inputs of length n with oracles y_1, \dots, y_k of length n_1, \dots, n_k , respectively, then for every n and n_1, \dots, n_k there is a circuit C_{n,n_1,\dots,n_k} of size $c_M t(t^2 + n + \log \sum_{i=1}^k n_i)$, such that $C^{A,y_1,\dots,y_k}(x) = M^{A,y_1,\dots,y_k}(x)$ for all inputs x of length n .

Using the technique of Hennie and Stearns [31] and Fürer [26, 27] we can establish the following proposition.

PROPOSITION 5 (minimal simulation overhead). *There is a Turing machine U with two work tapes, such that for any oracle Turing machine M there is a constant c_M so that for any oracle A and finite oracles d and y and input x , there is a finite oracle d' of length at most $|d| + c_M$ such that $U^{A,d',y}(x) = M^{A,d,y}(x)$. The computation time of U is at most $c_M t \log t$ and the space used is at most $c_M s$, where $M^{A,d,y}(x)$ runs for time t and uses space s . Furthermore, if M is a two-tape machine, then the running time of U is bounded by $c_M t$.*

We call any machine U that satisfies the previous proposition a *universal Turing machine*; note that we require our universal Turing machines to be efficient in simulating other machines.

DEFINITION 6. *A Turing machine U is universal if it satisfies all properties stated in Proposition 5.*

It is customary to define the Kolmogorov complexity function $C(x)$ to be the length of the shortest description $d \in \{0, 1\}^*$ such that $U(d) = x$, where U is a universal Turing machine. In order to present all of our definitions in a uniform framework, we give a slightly different definition below. We use the notation $x_{|x|+1} = *$ to denote the “end of string marker.”

DEFINITION 7 (Kolmogorov complexity). *Let U be a Turing machine and let A be an oracle. Define*

$$C_U^A(x|y) = \min\{|d| : \forall b \in \{0, 1, *\} \forall i \leq |x| + 1, \text{ the machine } U^{A,d,y}(i, b) \text{ accepts iff } x_i = b\}.$$

We let $C_U(x|y)$ denote $C_U^\emptyset(x|y)$, and we let $C_U(x)$ denote $C_U(x|\lambda)$.

Definition 7 deviates from the standard definition in two respects. First, the universal machine U gets the index i of a bit position of the string x as input and needs only to determine x_i , the i th bit of x . Since this mechanism alone does not encode the length of x , we stipulate that we obtain $*$ for bit position $i = |x| + 1$. As discussed in section 2.1, this change allows us to consider sublinear running times for U , which will be critical for the new Kolmogorov measure KT we introduce.

Second, the way we define the value of x_i is through a distinguishing process; i.e., the machine U needs only to recognize the correct value of x_i . For the results in our paper, we could as well use the traditional defining mechanism, which calls for the machine U to produce x_i . In fact, we used that convention in our original definition of the measure KT [6, 9]. However, it has subsequently been useful to consider new measures in this framework, where nondeterministic and alternating machines U are also taken into account [11, 7]. In order that all of these measures can be presented in a uniform framework, we adopt the convention that the machine U needs only to recognize the correct value of x_i . That is, given description d , index i , and $b \in \{0, 1, *\}$, U^d should accept (i, b) if and only if b equals x_i .

The reader can easily check that Definition 7 is exactly equivalent to the usual one. That is, if d is a description of x in the “traditional” definition, then d will also be a description of x in Definition 7, for a suitable machine U .

If U is a universal machine, we have the useful property that for any other machine U' there is a constant c such that $C_U^A(x|y) \leq C_{U'}^A(x|y) + c$ for all x, y , and A . Following convention (as in [44]), we pick one such universal machine U and define $C^A(x|y)$ to be equal to $C_U^A(x|y)$. $C(x|y)$ and $C(x)$ are defined similarly in terms of U .

Now we present a formal definition of Levin’s time-bounded Kolmogorov complexity measure K_t using this framework.

DEFINITION 8 (Kt). Let U be a Turing machine and let A be an oracle. Define the measure $\text{Kt}_U^A(x|y)$ of a string x as

$$\text{Kt}_U^A(x|y) = \min\{|d| + \log t : \forall b \in \{0, 1, *\} \forall i \leq |x| + 1, \text{ the machine } U^{A,d,y}(i, b) \text{ accepts in } t \text{ steps iff } x_i = b\}.$$

We use $\text{Kt}_U(x|y)$ to denote $\text{Kt}_U^\emptyset(x|y)$, and we use $\text{Kt}_U(x)$ to denote $\text{Kt}_U(x|\lambda)$.

Our definition is essentially equivalent to Levin's original one up to a logarithmic term. More precisely, for suitable choices of the underlying machines, Definition 8 yields a value that is between Levin's and Levin's plus $\log|x|$.¹

As in the case of resource-unbounded Kolmogorov complexity, the measure Kt_U is essentially invariant under the particular choice of universal machine U . Now, however, instead of an additive constant term, it seems that we must accept an additive logarithmic term. Universal Turing machines can simulate any other Turing machine M in time $O(t \log t)$ (Proposition 5), where t is the original time required for the computation of M . We pick one such universal machine U and define $\text{Kt}^A(x|y)$ to be equal to $\text{Kt}_U^A(x|y)$. $\text{Kt}(x|y)$ and $\text{Kt}(x)$ are defined similarly in terms of U .

Another Kolmogorov measure that has been studied before is K^t , where the running time of the underlying machine U is bounded by a parameter t .

DEFINITION 9 (K^t). Let U be a Turing machine and t a time bound. Define the measure $\text{K}_U^t(x)$ of a string x as

$$\text{K}_U^t(x) = \min\{|d| : \forall b \in \{0, 1, *\} \forall i \leq |x| + 1, \text{ the machine } U^d(i, b) \text{ accepts in } t(|x|) \text{ steps iff } x_i = b\}.$$

In contrast to all other Kolmogorov measures that we consider, changing the choice of universal Turing machine might cause a huge change in the value of $\text{K}^t(x)$. Nonetheless, we follow the usual convention [38, 45, 44, 20, 21] and pick some universal machine U and define $\text{K}^t(x)$ to be $\text{K}_U^t(x)$. Proposition 5 guarantees that for any other choice U' of universal machine, there is a constant c such that $\text{K}^{ct \log t}(x) \leq \text{K}_{U'}^t(x)$ (although we observe that $\text{K}^{ct \log t}(x)$ might be *much* less than $\text{K}_{U'}^t(x)$). (In this paper, we will consider neither $\text{K}^t(x|y)$ nor K^t relative to oracles A .)

It is now time to give the formal definition of the measure KT that will be one of our main objects of study. This definition can be seen as a variant on a definition introduced by Antunes, Fortnow, and van Melkebeek in [12].

DEFINITION 10 (KT). Let U be a Turing machine and A an oracle. Define the measure $\text{KT}_U^A(x|y)$ to be

$$\text{KT}_U^A(x|y) = \min\{|d| + t : \forall b \in \{0, 1, *\} \forall i \leq |x| + 1, \text{ the machine } U^{A,d,y}(i, b) \text{ accepts in } t \text{ steps iff } x_i = b\}.$$

We omit the superscript A if $A = \emptyset$, and the string y if $y = \lambda$.

¹As discussed briefly in [44], Levin's original definition of Kt was formulated in terms of "Kolmogorov-Uspensky machines." This model of computation is one of several that allow for the existence of universal machines that can simulate any other algorithm with at most a linear slow-down; see also [16]. This allows for a more elegant statement of certain theorems regarding Kt complexity. For instance, using this model of computation, one can show that for a universal machine U , for every machine M $\text{Kt}_U(x) \leq \text{Kt}_M(x) + O(1)$, and searching for satisfying assignments y to a Boolean formula ϕ in order of increasing $\text{Kt}(y|\phi)$ can be shown to be optimal up to a *linear* slow-down. However, Kolmogorov-Uspensky machines confer no special advantages when considering more refined measures such as KS and KT , and thus we choose to use the more familiar Turing machines in defining our measures.

Note that the only difference between KT and Levin’s measure Kt is that in KT the time bound is given exponentially more weight than in Kt. The capital “T” in the notation for KT reflects the fact that the time component weighs more strongly than in the Kt measure.

Along with the greater emphasis on running time, we unfortunately incur a greater sensitivity on the underlying machine U . Definition 6 implies that for any universal Turing machine U and any other machine U' , $\text{KT}_U^A(x|y) \leq c \cdot \text{KT}_{U'}^A(x|y) \log \text{KT}_{U'}^A(x|y)$. We pick one such universal Turing machine U (guaranteed to exist by Proposition 5) and define $\text{KT}^A(x|y)$ to be equal to $\text{KT}_U^A(x|y)$. $\text{KT}(x|y)$ and $\text{KT}(x)$ are defined similarly in terms of U .

If one views a given string x as the truth table of a function f_x , then $\text{KT}(x|y)$ roughly corresponds to circuit complexity of f_x on circuits that have oracle access to f_y . This is made precise below.

THEOREM 11. *There is a constant c such that for any oracle A and any strings x and y in $\{0, 1\}^*$,*

- (i) $\text{Size}^{A,y}(x) \leq c(\text{KT}^A(x|y))^2 ((\text{KT}^A(x|y))^2 + \log |x| + \log |y|)$; and
- (ii) $\text{KT}^A(x|y) \leq c(\text{Size}^{A,y}(x))^2 (\log \text{Size}^{A,y}(x) + \log \log |x|)$.

Proof. To prove (i), let c_1, c_2 be suitably large constants. Assume a given string x of length n has $\text{KT}^A(x|y) = m$. Thus there is a description d_x of length at most m , such that $U^{A,d_x,y}(i, b)$ accepts if and only if $b = x_i$ in at most m steps. By Proposition 4, there is a circuit $C_{n,m}^{A,d_x,y}$ of size $c_1 m(m^2 + \log n + \log(m + |y|))$ such that $C_{n,m}^{A,d_x,y}(i, b) = U^{A,d_x,y}(i, b)$ for all i and b . The finite oracle d_x can be replaced by a circuit of size $c_2 m$ to obtain a desired circuit for x of size $cm^2(m^2 + \log n + \log(m + |y|))$, provided that $c \geq c_1 c_2$.

To prove (ii), let c_1 and M be the constant and machine given by Proposition 3. Assume that there is a circuit C of size m with oracle gates for A and y , such that on input i (in binary) the circuit computes $C(i) = x_i$ for $i \leq |x|$. Denote $n = |x|$.

By Proposition 3 there is an encoding d_C of C of size $c_1 m(\log m + \log \log n)$ such that machine M , given oracle access to A, d_C , and y , outputs $C(i)$ in time $c_1 m^2 \log m + m \log \log n$. From M one can easily construct a two-tape machine M' such that $M'^{A,d_C,y}(i, b)$ accepts if $x_i = b$ and that runs in essentially the same time as M . Thus $\text{KT}_{M'}^A(x|y) \leq c_2 m^2(\log m + \log \log n)$ for some $c_2 \geq c_1$.

The theorem now follows by Definition 6 and the fact that the defining Turing machine U for KT is universal. \square

So far we have considered time-bounded Kolmogorov complexity measures. In section 3 we will see how these measures give rise to complete problems for time-bounded complexity classes. It is useful to define space-bounded notions that will yield complete problems for space-bounded complexity classes.

DEFINITION 12 (KS). *Let U be a Turing machine and A be an oracle. We define the following space-bounded complexity measure.*

$$\text{KS}_U^A(x|y) = \min\{ |d| + s : \forall b \in \{0, 1, *\} \forall i \leq |x| + 1, \text{ the machine } U^{A,d,y}(i, b) \text{ accepts in } s \text{ space iff } x_i = b \}.$$

We omit the superscript A if $A = \emptyset$, and the string y if $y = \lambda$.

As usual, we will fix a universal Turing machine U and then drop the subscript U when considering this space-bounded Kolmogorov complexity measure. Similar to the measure KT, the measure KS is somewhat sensitive to the exact choice of the

universal machine U . However, regardless of the particular choice of universal Turing machine, Proposition 5 implies that for any Turing machine U' , there is a constant c such that $\text{KS}^A(x|y) \leq c\text{KS}_{U'}^A(x|y)$.

As is the case with traditional Kolmogorov complexity, for each of these resource-bounded Kolmogorov complexity measures KT , KS , Kt , every string has a description that is not much longer than itself.

PROPOSITION 13. *There is a constant c , such that for all strings x : $\text{KT}(x) \leq |x| + c \log |x|$, $\text{KS}(x) \leq |x| + c \log |x|$, and $\text{Kt}(x) \leq |x| + c \log \log |x|$.*

It is useful to observe that the measures C , Kt , and KS can be approximated in terms of KT^A for appropriate choices of oracle A .

THEOREM 14. *Let H denote the halting problem. There exist a complete set A for E , a complete set B for $\text{DSPACE}(n)$, and a constant c such that*

- (i) $\frac{1}{c}\text{Kt}(x) \leq \text{KT}^A(x) \leq c \cdot \text{Kt}(x)$,
- (ii) $\frac{1}{c}\text{KS}(x) \leq \text{KT}^B(x) \leq c \cdot \text{KS}(x)$, and
- (iii) $\frac{1}{c}\text{C}(x) \leq \text{KT}^H(x) \leq c \cdot (\text{C}(x) + \log |x|)$.

Proof. Let us prove first the relation between Kt and KT^A . The proof for KS is similar. Then we will consider the claim for C .

Let $A \in \text{E}$ and let x be given, such that $\text{KT}^A(x) = m$. Thus, there is a description d_x of length $|d_x| \leq m$, such that $U^{A,d_x}(i, b)$ accepts if and only if $x_i = b$ in time at most m . During the computation, U can ask queries of length at most m , and since $A \in \text{E}$, each such query can be answered in time $2^{O(m)}$. If M denotes the algorithm that simulates the computation of $U^{A,d_x}(i, b)$ for every i by directly computing the answers to the oracle queries to A , then the description $d'_x = \langle M, d_x \rangle$ is sufficient for U to compute $U^{d'_x}(i, b)$ in time $2^{O(m)}$. As $|d'_x| = m + O(1)$, we can conclude that $\text{Kt}(x) \leq m + O(1) + \log(2^{O(m)}) = O(m)$.

For the other inequality, let $A = \{ \langle (1^r, d_x), i, b \rangle : U^{d_x}(i, b) \text{ accepts in } 2^r \text{ steps} \}$. (It is not hard to show that A is complete for $\text{DTime}(2^n)$ under linear-time many-one reductions.) Let x be given and let $\text{Kt}(x) = m$. Thus, there is a description d_x of length m , such that $U^{d_x}(i, b)$ accepts if and only if $x_i = b$ in at most 2^m steps. The following algorithm M (computable by a two-tape Turing machine) accepts the input (i, b) if and only if $x_i = b$ and runs in time $O(m)$ given oracle A and given finite oracle $(1^m, d_x)$. Given (i, b) , the machine M writes the query $q = \langle (1^m, d_x), i, b \rangle$ onto the query tape. If the oracle accepts q , then M accepts; else it rejects. Clearly, given finite oracle $(1^m, d_x)$, the machine M accepts (i, b) if and only if $b = x_i$. The time required for M is $O(m + |d_x| + |q|) = O(m)$. The length of $| \langle (1^m, d_x) |$ is $O(m)$. Thus, $\text{KT}_M^A(x) = O(m)$. By Definition 6, the first part of the theorem follows.

Now we show that $\text{C}(x) = O(\text{KT}^H(x))$. Let $\text{KT}^H(x) = m$. Thus there is a description d_x of length at most m , such that $U^{H,d_x}(i, b)$ accepts in time m if and only if $x_i = b$. Let r be the number of strings in H of length at most m . Note that r can be written using $O(m)$ bits. Let M be an algorithm with an oracle encoding d_x , r , and m that, given (i, b) , enumerates all the r elements of H that have length at most m and then simulates U^{H,d_x} on input (i, b) . It follows that $\text{C}_M(x) = O(m)$, which is sufficient to prove the claim.

It remains only to show that $\text{KT}^H(x) = O((\text{C}(x) + \log |x|) \log(\text{C}(x) + \log |x|))$. Let $\text{C}(x) = m$ and let d_x be a description of x . The set $L = \{ \langle d_x, i, b \rangle : U^{d_x}(i, b) \text{ accepts} \}$ is a c.e. set; thus it is reducible to H in linear time by a trivial reduction f . Hence there is a machine M that, on input (i, b) with oracle d_x , computes $f(d_x, i, b)$ and poses this question to the oracle H . The running time is $O(m + \log |x|)$. The claim follows by Definition 6. \square

In [11], the approach developed here has been extended to provide new measures of resource-bounded Kolmogorov complexity that are polynomially related to branching program size and formula size.

2.3. Sets of random strings. Our attention will be focused on sets containing strings of high complexity, for various measures of complexity. Specifically, we consider the following sets.

DEFINITION 15. For any Kolmogorov complexity measure μ (such as C, Kt, KS, KT, K^t), define $R_\mu = \{x : \mu(x) \geq |x|/2\}$.

The bound of $|x|/2$ in the definition of R_μ is arbitrary; all of our results hold for any reasonable bound in the range $|x|$ to $|x|^\epsilon$ for any positive ϵ . Essentially, apart from the mere fact that strings in R_μ do not have short descriptions of the appropriate type, all we need is that the set R_μ has polynomial density. We refer to the *density* of a language L as the fraction of all strings of length n that belong to L . L is said to have *polynomial density* if it contains at least $2^n/n^k$ strings of each length n , for some k . The set of μ -incompressible strings, i.e., the set of strings x with $\mu(x) \geq |x|$, is well known to have polynomial density for $\mu = C$ [44]. The same holds for $\mu \in \{\text{Kt}, \text{KS}, \text{KT}\}$ by a trivial counting argument: Since each of these measures μ involves a nontrivial additional cost on top of the length of the describing program d , μ -compressible strings of length n are defined by strings d of length less than $n - 1$, of which there are fewer than 2^{n-1} . We refer the reader to [39] for the detailed proofs of our main theorems in their full generality, for arbitrary ϵ .

PROPOSITION 16. The sets R_C , R_{K^t} , R_{K^t} for any t , and R_{KS} all have polynomial density.

Many of our results about Kt and KT complexity carry over to K^t complexity for certain values of t because of the following observation. A similar statement holds for K^t in relationship to C and for KS in relationship to Kt.

PROPOSITION 17. For some constant $c > 1$,

- (i) $C(x) \leq K^t(x)$ for any time bound t ,
- (ii) $K^t(x) < \text{KT}(x)$ for any time bound $t \geq n + c \log n$,
- (iii) $K^t(x) < \text{Kt}(x)$ for any time bound $t \geq (\log n)^c 2^n$, and
- (iv) $\text{Kt}(x) \leq c \text{KS}(x)$.

Proof. The first item follows directly from the definition. For the second statement, let $m = \text{KT}(x)$. Thus, there is a description d of length less than m such that each bit of x can be produced in time at most m . By Proposition 13, $m \leq n + c \log n$. Thus, the same description d shows that $K^t(x) < m$ for any $t \geq n + c \log n$. The proof for Kt is analogous. The last inequality follows from the fact that if a halting machine runs in time t and space s then $t \leq 2^{O(s)}$. \square

COROLLARY 18. For some constant c ,

- (i) $R_C \subseteq R_{K^t}$ for any time bound t ,
- (ii) $R_{K^t} \subseteq R_{\text{KT}}$ for $t \geq n + c \log n$, and
- (iii) $R_{K^t} \subseteq R_{\text{Kt}}$ for $t \geq n^c 2^n$.

PROPOSITION 19. If $\text{Kt}(x) \leq |x|^\epsilon$, then $K^{2^{n^\epsilon}}(x) \leq |x|^\epsilon$.

The following upper bounds on the complexity of the various sets of random strings are straightforward.

PROPOSITION 20. $R_C \in \text{co-c.e.}$, $R_{K^t} \in \text{E}$, $R_{KS} \in \text{DSPACE}(n)$, and $R_{\text{KT}} \in \text{coNP}$. Also, $R_{K^t} \in \text{EXP}$ for any constructible $t = 2^{n^{O(1)}}$, and $R_{K^t} \in \text{coNP}$ for any constructible $t = n^{O(1)}$.

We show in Corollary 32 that every c.e. set is reducible to R_C via a reduction computable by polynomial size circuits. It follows that R_C requires circuits of size at

least 2^{n^ϵ} for some $\epsilon > 0$. For the rest of these sets R_μ , the best unconditional circuit lower bound known is that none of these sets are in AC^0 .

THEOREM 21. *Let A be any set in AC^0 that contains at least $2^n/n^k$ strings of each length n . Then there is a constant c such that, for every length n , there is a string $x \in A \cap \{0, 1\}^n$ such that $KT(x) \leq \log^c n$.*

Proof. Nisan [48] showed that the Nisan–Wigderson generator can be used to derandomize any probabilistic AC^0 circuit. His construction presents a generator G that takes a seed of length $\log^c n$ and produces pseudorandom output of length n , with the property that any AC^0 circuit C of size n^l and depth d that accepts at least $2^n/n^k$ inputs of length n must accept some string in the range of G . (The constant c depends on the constants l, k , and d .) Furthermore, it was shown in [59] that there is a circuit (actually, even a formula) of size $\log^{O(1)} n$ that takes s and i as input and produces the i th bit of $G(s)$. It follows that, for any seed s , the pseudorandom string $G(s)$ has polylogarithmic KT complexity. \square

COROLLARY 22. *For $t = \Omega(n^2)$, none of the sets R_{Kt} , R_{Kt^t} , R_{KT} , and R_{KS} are in AC^0 .*

2.4. Nonhardness results for R_μ . As stated in the introduction, earlier results had indicated that sets of strings with high resource-bounded Kolmogorov complexity would *not* be complete for the complexity classes in which they reside. In this subsection, we present a few of these nonhardness results as they relate to the sets R_{KT} , R_{KS} , and R_{Kt} .

THEOREM 23.

- (i) R_{Kt} is not hard for EXP under \leq_{tt}^P reductions.
- (ii) R_{KS} is not hard for PSPACE under \leq_T^{\log} reductions.

Proof. We present the proof for R_{KS} . The proof for R_{Kt} is analogous. (The interested reader can consult [6].) Note first that \leq_T^{\log} reducibility coincides with \leq_{tt}^{\log} reducibility [42].

Let T be a subset of $\{0\}^*$ that is in PSPACE but not in L. Suppose $T \leq_{tt}^{\log} R_{KS}$, and let f be the query generator of such a reduction. Note that $KS(f(0^n)) = O(\log n)$. Thus each of the strings y that the reduction queries on input 0^n has $KS(y) = O(\log n)$. Hence, the only strings y for which the query can receive a “yes” answer are of length $O(\log n)$, and for such queries the answer is computable directly in space $O(\log n)$. Hence all of the queries can be answered in space $O(\log n)$ and it follows that $T \in L$, contrary to our choice of T . \square

An interesting picture emerges if we consider even more restrictive reducibilities than polynomial-time and logspace reductions. Most natural examples of NP-complete sets are complete even under many-one reductions computed by uniform AC^0 circuits. However, as the following theorem shows, uniform AC^0 reductions cannot reduce even some very small complexity classes to R_{KS} and R_{Kt} .

THEOREM 24. *R_{Kt} and R_{KS} are not hard for TC^0 under AC^0 many-one reductions.*

Proof. Let A be any set that is hard for TC^0 under AC^0 many-one reductions. Agrawal shows in [1] that A is also hard for TC^0 under length-increasing AC^0 reductions. Thus, there is a length-increasing AC^0 reduction f reducing 0^* to A . Since this reduction f is computable in logspace, it follows that $KS(f(0^n))$ and $Kt(f(0^n))$ are each $O(\log n)$. Since f is length-increasing, it follows that A must contain infinitely many strings of low KS and Kt complexity. \square

Unfortunately, we do *not* know how to argue that the strings $f(0^n)$ in the preceding proof have low KT complexity; in fact it follows easily from Lemma 25 below

that this happens if and only if every problem in the polynomial-time hierarchy has circuits of size $2^{n^{o(1)}}$.

The *linear-time hierarchy* is a subclass of the polynomial-time hierarchy consisting of the union of the classes Σ_k -time(n).

LEMMA 25. *Let s be a monotone nondecreasing function. Every problem in the linear-time hierarchy has circuits of size $s(n)^{O(1)}$ if and only if for each function f computable in AC^0 , $KT(f(0^n)) \leq s(\log n)^{O(1)}$.*

Proof. Suppose that every problem in the linear-time hierarchy has circuits of size $s(n)^{O(1)}$. Let f be computable in AC^0 . By a standard padding argument (see, for instance, [10]) it follows that the set $\{(n, i) : \text{the } i\text{th bit of } f(0^n) \text{ is } 1\}$ is in the linear-time hierarchy. It follows from our hypothesis that this set has circuits of size $s(\log n)^{O(1)}$, and therefore by Theorem 11 that $KT(f(0^n)) \leq s(\log n)^{O(1)}$.

For the other direction, suppose that each function f computable in AC^0 has the property that $KT(f(0^n)) \leq s(\log n)^{O(1)}$. Let A be any problem in the linear-time hierarchy, and consider the function f that maps 0^n for $n = 2^m$ to the characteristic string of A for inputs of length m . The function f is computable in AC^0 . It follows from the hypothesis and Theorem 11 that A on inputs of size m has circuits of size $s(\log 2^m)^{O(1)} = s(m)^{O(1)}$. \square

In particular, Lemma 25 states that SAT has polynomial-size circuits if and only if for every function f computable in uniform AC^0 , $KT(f(0^n))$ is polylogarithmic.

Based on Lemma 25, the best we can offer for R_{KT} is the following conditional nonhardness theorem. The hypothesis to this theorem is unlikely; thus the proper way to interpret this result is that it is unlikely that one will be able to prove that R_{KT} is hard for TC^0 under AC^0 reductions.

THEOREM 26. *If every problem in the polynomial-time hierarchy has circuits of size $2^{n^{o(1)}}$, then R_{KT} is not hard for TC^0 under AC^0 many-one reductions.²*

Proof. Let A and f be as in the proof of Theorem 24. Since f is computable in AC^0 , the hypothesis and Lemma 25 imply that $KT(f(0^n)) \leq n^{o(1)}$. Since f is length-increasing, this means that A has to contain infinitely many strings of low KT complexity. \square

On the other hand, if SAT requires large circuits, the proof of Lemma 25 ensures the existence of an AC^0 computable function f such that $f(0^n)$ has high KT complexity (for every large n that is a power of 2). By concatenating elements of SAT with $f(0^n)$, we obtain a set SAT' that is AC^0 -isomorphic to SAT but where each element of SAT' has large KT complexity. Combining the two directions, we see that SAT requiring large circuits is in fact equivalent to the existence of sets AC^0 -isomorphic to SAT containing only strings of high KT complexity.

The results of this section are related to the issue that was raised by Kabanets and Cai [36] in considering the question of whether or not MCSP is NP-complete under length-increasing reductions. They observed that if MCSP (or R_{KT}) is complete for coNP under length-increasing reductions, then there is a polynomial-time computable length-increasing function f such that each string $f(0^n)$ has high KT complexity, which implies that there is an efficient way to construct the truth tables of certain functions on $m = \Theta(\log n)$ bits that require circuits of size $2^{\epsilon m}$ for some $\epsilon > 0$. As Kabanets and Cai discuss (see also [6]), this implies $BPP = P$.

²In [6], it is asserted that the conclusion of this theorem follows from the weaker assumption that SAT has circuits of size $2^{n^{o(1)}}$. We do not know how to prove this stronger statement.

3. Complexity of R_{Kt} , R_{KS} , and R_{C} . Improving greatly the results in [21], we show that strings of high Kolmogorov complexity are very useful as oracles. Our main technique is to use relativizing hardness-randomness tradeoffs in the contrapositive. In particular we will argue that an appropriate set R_μ of Kolmogorov random strings can be used to distinguish the output of a pseudorandom generator G_f (based on a function f) from truly random strings. This in turn will enable us to efficiently reduce f to R_μ . In this section, we will exploit pseudorandom generators G_f that may take more time to compute than the randomized procedure they try to fool. They yield our hardness results for R_{Kt} , R_{KS} , and R_{C} . In the next section, we will use pseudorandom generators G_f that are more efficiently computable and obtain hardness results for R_{KT} .

We first describe the derandomization tools we will use. Then we present some hardness results in terms of nonuniform (P/poly) reductions that apply to many complexity classes. Finally, we consider some special cases where we are able to strengthen our results to provide uniform reductions.

3.1. Tools. It will be useful to recall the definition of PSPACE-robustness [14]. A language A is PSPACE-robust if $\text{PSPACE}^A = \text{P}^A$. (Here we assume that machines are allowed to ask oracle queries of only polynomial size.) The complete sets for many large complexity classes like PSPACE, EXP, and EXPSPACE, have this property, as well as the complete sets (under linear-time reductions) for classes like DSPACE(n) and E. It will be useful for us to observe that the halting problem is also PSPACE-robust.

THEOREM 27. *The halting problem H is PSPACE-robust.*

Proof. Let M be a PSPACE machine using space n^k . The set $A = \{(1^n, i) : \text{there are at least } i \text{ strings in } H \text{ of length at most } n\}$ is c.e., and thus it is reducible in linear time to H . Using binary search on calls to A , we can compute the number of strings in H of length at most n^k . Now consider the set $B = \{(M, x, r) : M^{H'}(x) \text{ accepts, where } H' \text{ is the set consisting of the first } r \text{ strings of length at most } |x|^k \text{ that show up in the enumeration of } H\}$. Deciding whether M^H accepts x boils down to computing the desired number r (using calls to A) and then making a single call to B . Since both A and B are efficiently reducible to H , the proof is complete. \square

We will use several related constructions that build a pseudorandom generator G_f out of a function f . They are all based on the Nisan–Wigderson paradigm [49]. The authors of [14] construct, for any $\epsilon > 0$, a variant $G_f^{\text{BFNW}} : \{0, 1\}^{n^\epsilon} \mapsto \{0, 1\}^n$ such that for any x of size n^ϵ , the function $G_f^{\text{BFNW}}(x)$ is computable in space $O(n^\epsilon)$ given access to the Boolean function f on inputs of size at most n^ϵ . Moreover, if f is PSPACE-robust, then there is a constant c independent of ϵ , such that each bit of $G_f^{\text{BFNW}}(x)$ is computable in time $n^{\epsilon c}$ with oracle access to f . The following hardness versus randomness tradeoff holds.

THEOREM 28 (see [14, 37]). *Let f be a Boolean function, let $\epsilon > 0$, and denote the pseudorandom generator described above as $G_f^{\text{BFNW}} : \{0, 1\}^{n^\epsilon} \mapsto \{0, 1\}^n$. Let T be a set and $p(n)$ a polynomial. If $|\Pr_{r \in U_n}[r \in T] - \Pr_{x \in U_{n^\epsilon}}[G_f^{\text{BFNW}}(x) \in T]| \geq 1/p(n)$ for all large n , then there exists a polynomial size oracle circuit family $\{C_n\}_{n \in \mathbb{N}}$ with oracle T that computes f and queries T nonadaptively.*

In fact, as observed in [11], close analysis of [14, 37] reveals that the circuit family $\{C_n\}$ can be constructed to be in TC^0 . Thus, in particular, we can also conclude that f is in L^T/poly .

In [34], Impagliazzo and Wigderson reexamine the approach of [14]. For any $\epsilon > 0$, their pseudorandom generator $G_f^{\text{IW98}} : \{0, 1\}^{n^\epsilon} \mapsto \{0, 1\}^n$ is also computable in space

$O(n^\epsilon)$ with oracle access to f on inputs of size at most n^ϵ . It satisfies the following uniform version of Theorem 28. Recall that a function f is *random self-reducible* if there exists a randomized polynomial-time reduction from f to itself such that each individual query the reduction makes on an input of length n is uniformly distributed among the inputs of length n . A function f is *downward self-reducible* if there exists a polynomial-time reduction from f to itself that makes only queries of length strictly less than the input.

THEOREM 29 (see [34]). *Let $f : \{0, 1\}^* \mapsto \{0, 1\}^*$ be a random and downward self-reducible function, $\epsilon > 0$, and $G_f^{\text{IW98}} : \{0, 1\}^{n^\epsilon} \mapsto \{0, 1\}^n$ be the pseudorandom generator described above. Let T be a set and $p(n)$ be a polynomial. If for all large enough n , $|\Pr_{r \in U_n}[r \in T] - \Pr_{x \in U_{n^\epsilon}}[G_f^{\text{IW98}}(x) \in T]| \geq 1/p(n)$, then there exists a probabilistic, polynomial-time Turing machine with oracle T that on input x outputs $f(x)$ with probability at least $2/3$.*

The preceding two theorems provide the key derandomization techniques that are required to prove our completeness results. They are stated in the contrapositive of their original formulations since that is the way we will use them. However, some of our completeness results (namely for EXP and PSPACE) involve uniform reductions that make use of randomness. These reductions can then be further derandomized by applying hardness versus randomness tradeoffs in the standard way. We will make use of the strengthening of the results of [14], as provided by Impagliazzo and Wigderson [33] (see also [55]). Given access to a Boolean function f , they show how to construct a pseudorandom generator $G_f^{\text{IW97}} : \{0, 1\}^{O(\log n)} \mapsto \{0, 1\}^n$ with the following property (see also [37]).

THEOREM 30 (see [33, 37]). *For any $\epsilon > 0$, there exist constants $c, c' > 0$ such that the following holds. Let A be a set and $n > 1$ be an integer. Let $f : \{0, 1\}^{c \log n} \mapsto \{0, 1\}$ be a Boolean function that cannot be computed by oracle circuits of size $n^{c\epsilon}$ with oracle A . Then $G_f^{\text{IW97}} : \{0, 1\}^{c' \log n} \mapsto \{0, 1\}^n$ satisfies the following for any oracle circuit C^A of size at most n : $|\Pr_{r \in U_n}[C^A(r) = 1] - \Pr_{x \in U_{c' \log n}}[C^A(G_f^{\text{IW97}}(x)) = 1]| < 1/n$.*

For x of size $c' \log n$, $G_f^{\text{IW97}}(x)$ is computable in time polynomial in n given access to f on inputs of length $c \log n$.

3.2. Nonuniform hardness results. Our first result illustrates our main technique. Recall that a language L has polynomial density if it contains at least $2^n/n^k$ strings of each length n , for some k . We use the notation $A \leq_{\text{tt}}^{\text{P/poly}} B$ to denote that there exists a truth-table (i.e., nonadaptive) reduction from A to B that is computable by a family of polynomial-size circuits.

THEOREM 31. *Let A be any PSPACE-robust set. Let L be a set of polynomial density such that for every $x \in L$, $\text{KT}^A(x) > |x|^\gamma$ for some constant $\gamma > 0$. Then A is reducible to L via $\leq_{\text{tt}}^{\text{P/poly}}$ reductions.*

Proof. Let f be the characteristic function of A . Consider the generator $G_f^{\text{BFNW}} : \{0, 1\}^{n^\epsilon} \mapsto \{0, 1\}^n$, where we choose ϵ as follows. We know that every bit of G_f^{BFNW} is computable in time $n^{c\epsilon}$ for some constant c independent of ϵ , given access to A . We may assume that $c > 1$, so we set $\epsilon = \gamma/2c$. We claim that any string in the range of G_f^{BFNW} has small KT^A complexity. Let $y = G_f^{\text{BFNW}}(x)$ for some $x \in \{0, 1\}^{n^\epsilon}$. On input x , every bit of $G_f^{\text{BFNW}}(x)$ is computable in time $n^{\gamma/2}$ with access to oracle A . Hence, $\text{KT}^A(y) \leq |x| + O(n^{\gamma/2} \log n) + O(1) \leq n^\gamma$. It follows that L distinguishes the output of G_f^{BFNW} from random, so by Theorem 28, f is $\leq_{\text{tt}}^{\text{P/poly}}$ reducible to L . \square

By Theorem 14 and Proposition 16, we can apply Theorem 31 to the following choices for the pair (A, L) :

- (i) $(A, L) = (\text{the set } A \text{ from Theorem 14, } R_{Kt}),$
- (ii) $(A, L) = (\text{the set } B \text{ from Theorem 14, } R_{KS}),$ and
- (iii) $(A, L) = (H, R_C).$

(In order to apply Theorem 31 we require that A is PSPACE-robust. By Theorem 27, H is PSPACE-robust, and the sets A and B from Theorem 14 are clearly PSPACE-robust, since they are complete for EXP and PSPACE, respectively.) Together with Proposition 20, this leads to the following results.

COROLLARY 32.

- (i) R_{Kt} is complete for EXP under $\leq_{tt}^{P/poly}$ reductions.
- (ii) R_{Kt} is complete for EXP under $\leq_{tt}^{P/poly}$ reductions for any constructible time bound t such that $2^{n^\epsilon} \leq t \leq 2^{n^{O(1)}}$ for some $\epsilon > 0$.
- (iii) R_{KS} is complete for PSPACE under $\leq_{tt}^{P/poly}$ reductions.
- (iv) $H \leq_{tt}^{P/poly} R_C.$

Proof. The results for R_{Kt} , R_{KS} , and R_C are immediate. The result for R_{Kt} follows from Proposition 19 and Theorem 31 (letting A be complete for E under linear-time reductions). \square

The last item in Corollary 32 appears to be the first “efficient” reduction from the halting problem to the Kolmogorov random strings. This should be contrasted with the uniform but very high-complexity truth-table reduction of [40].

A complete set for exponential space can be defined by considering a variant on KS complexity (which could naturally be denoted Ks), where the value to be minimized is $|d| + \log s$. Similarly, complete sets for doubly exponential time can be defined by minimizing $|d| + \log \log t$. This can be generalized to higher complexity classes in the straightforward manner.

It is natural to wonder how much nonuniform advice is needed for the reductions of Corollary 32. For instance, can the reductions be done with linear advice? For the case of deterministic nonadaptive reductions to R_{Kt} , Ronneburger shows in [52] that there is no fixed k such that advice of length n^k is sufficient, even if the reduction is not restricted to run in polynomial time, but instead can run for time 2^{n^k} . In contrast, in the next subsection we consider settings in which no nonuniform advice is needed at all.

3.3. Uniform hardness results. For the special cases of EXP and PSPACE, we are able to show hardness results under uniform notions of reducibility. First we state and prove a general uniform hardness result for PSPACE.

THEOREM 33. *Let L be a set of polynomial density such that for every $x \in L$, $KS(x) > |x|^\gamma$ for some constant $\gamma > 0$. Then $PSPACE \subseteq BPP^L$.*

Proof. We make use of the uniform derandomization technique of [34], together with the following theorem of [57].

THEOREM 34 (see [57]). *There exists a problem in $DSPACE(n)$ that is hard for PSPACE, random self-reducible, and downward self-reducible.*

Let $f \in DSPACE(n)$ be a function that is downward and random self-reducible and that is hard for PSPACE, as guaranteed by Theorem 34. Consider the generator $G_f^{IW98} : \{0, 1\}^{n^{\gamma/2}} \mapsto \{0, 1\}^n$. Since the function G_f^{IW98} is computable in space $O(n^{\gamma/2})$ with oracle access to f on inputs of length $O(n^{\gamma/2})$ and f is computable in linear space, we can compute $G_f^{IW98}(z)$ for $z \in \{0, 1\}^{n^{\gamma/2}}$ in space $O(n^{\gamma/2})$. It follows that every y in the range of G_f^{IW98} satisfies $KS(y) \leq O(|y|^{\gamma/2})$. Since L is a set of at

least polynomial density that contains only strings y of KS complexity at least $|y|^\gamma$, the set L distinguishes the output of G_f^{IW98} from random strings and by Theorem 29, there is a probabilistic procedure with oracle L that on input x outputs $f(x)$ with probability at least $2/3$. Hence, $PSPACE \subseteq BPP^L$. \square

For many sets L satisfying the hypothesis of Theorem 33 (including any such set that lies in $PSPACE/poly$, and all of the sets R_μ for which nonuniform hardness results were presented in the previous section), the BPP reduction of Theorem 33 can be improved to obtain a ZPP reduction. This is a consequence of the next lemma, which shows how probabilistic complexity classes can be derandomized using oracle access to strings of high Kolmogorov complexity. The proof makes use of the by now familiar fact that having access to the truth-table of a hard function can be used to derandomize BPP [49, 33].

LEMMA 35. *Let A be any oracle and L be a set such that $L \in P^A/poly$ and for every $x \in L$, $KT^A(x) > |x|^\gamma$ for some constant $\gamma > 0$.*

(i) $MA^L = NP^L$ if L contains at least one string of almost every length.

(ii) $BPP^L = ZPP^L$ if L is of at least polynomial density.

(iii) $BPP^L = P^L$ if there exists a polynomial time machine with oracle access to L that, on input 0^n , produces an element of L of length n .

All three statements hold even if the respective hypothesis on L holds only for infinitely many constants c and almost all lengths of the form n^c .

Proof. (i) The NP-machine M guesses a string $\chi_f \in L$ of length m , for $m = n^c$, and interprets it as the truth-table of a Boolean function f on inputs of size $\log m$. Since $\chi_f \in L$, $KT^A(\chi_f) \geq m^\gamma$. Thus by Theorem 11, f requires circuits of size at least $\Omega(m^{\gamma/3})$ even when the circuit has access to the oracle A . If, instead of A , the circuit has access to L , then (because of our assumption that L is reducible to A by circuits of size m^k for some $k \geq 1$), the size required to compute f is at least $\Omega(m^{\gamma/6k})$. The function f is of sufficient hardness to construct the generator G_f^{IW97} , as stated in Theorem 30, to stretch $O(\log n)$ random bits into n pseudorandom bits that are indistinguishable from random by any oracle circuit of size n with access to L . Thus we can fully derandomize the probabilistic part of the MA computation.

(ii) The proof is almost identical to the preceding argument. We have the additional assumption that L has polynomial density. Thus, instead of “guessing” the string χ_f as in the preceding argument, we can repeatedly pick strings at random. The expected running time until we find a $\chi_f \in L$ is polynomial. The result follows.

(iii) Instead of randomly choosing a candidate for χ_f as in the proof of statement (ii), we use the generating algorithm from the hypothesis to produce it. The rest of the argument is unchanged. \square

By Theorem 14 and Propositions 16 and 20, the common hypothesis of Lemma 35 holds for $L = R_{Kt}$ (using the set A from Theorem 14 as the set A), for $L = R_{KS}$ (using the set B from Theorem 14 as the set A), and for $L = R_C$ (using $A = H$). Thus one can obtain, e.g., $BPP^{R_{Kt}} = ZPP^{R_{Kt}}$, $BPP^{R_{KS}} = ZPP^{R_{KS}}$, $NP^{R_{Kt}} = MA^{R_{Kt}}$. Moreover, we have the following corollary.

COROLLARY 36. $PSPACE = ZPP^{R_{KS}} \subseteq ZPP^{R_{Kt}}$.

The techniques of Theorem 33 cannot be used to prove hardness results for classes larger than $PSPACE$. For EXP , however, we are able to use the theory of interactive proofs to obtain hardness results under NP-Turing reducibility. First, we mention a result that is implicit in [14].

THEOREM 37 (see [14]). *If $EXP \leq_T^{P/poly} L$, then $EXP \subseteq MA^L$.*

Proof. Let A be any language in EXP . Then A is accepted by a 2-prover interactive proof system with provers computable in EXP [13]. Thus these strategies are

computable in P^L/poly . The MA^L protocol is as follows. Merlin sends Arthur the polynomial-size circuits that, when given access to the oracle L , compute the answers given by the two provers for A . Arthur then executes the MIP protocol, simulating the provers' answers by executing the circuits and querying the oracle L . \square

COROLLARY 38. *Let L be a set of polynomial density in EXP such that for every $x \in L$, $\text{Kt}(x) > |x|^\gamma$ for some constant $\gamma > 0$. Then $\text{EXP} = \text{NP}^L$.*

Proof. The inclusion $\text{NP}^L \subseteq \text{EXP}$ is trivial. For the other inclusion, observe that Corollary 32 implies that the hypothesis to Theorem 37 is satisfied. The theorem now follows from the first item of Lemma 35. \square

COROLLARY 39. $\text{EXP} = \text{NP}^{R_{\text{Kt}}}$.

We also obtain the following curious corollary.

COROLLARY 40. $P^{R_{\text{Kt}}} \neq \text{NP}^{R_{\text{Kt}}} = \text{EXP}$ for any constructible monotone t such that $n^{O(1)}2^{nt}(n-1) \leq t(n) \leq 2^{n^{O(1)}}$, e.g., $t = 2^{n^2}$.

Proof. The equality follows from Corollary 38 by the third part of Proposition 17 and by Proposition 20. The inequality holds because the proof in [20] showing that R^t is not complete for EXP under \leq_{T}^P reductions carries over unchanged to R_{Kt}^t . We include a somewhat simplified argument.

Consider a \leq_{T}^P reduction from a unary language A to R_{Kt}^t . We claim that for inputs $x = 0^n$ of sufficiently large length, none of the queries of length n or more can be in R_{Kt}^t . Otherwise, we could describe the first such query q by n and the index i of the query. This yields a description of length $O(\log n) < n$. Moreover, we can generate q from this description in time $n^{O(1)}2^{nt}(n-1) \leq t(n)$ by simulating the polynomial-time reduction up to the moment it generates its i th query and answering all earlier queries by running the trivial exponential-time algorithm for R_{Kt}^t . This contradicts the hypothesis that q is in R_{Kt}^t . Thus, we can decide A as follows: Run the reduction by answering queries of length n or more negatively and running the trivial exponential-time algorithm for R_{Kt}^t on smaller queries. This yields a correct algorithm for A that runs in $\text{DTime}(2^{dn})$ for some fixed constant independent of A . However, the time hierarchy theorem implies that there are unary languages A in EXP that have higher complexity than this. \square

To the best of our knowledge, all prior examples of oracles for which $P \neq \text{NP}$ have been specifically constructed for that purpose. We know of no other “natural” examples of sets A for which $P^A \neq \text{NP}^A$.

We are unable to present any completeness or hardness results under deterministic polynomial-time reductions for any of the resource-bounded notions of Kolmogorov complexity that we have studied. It is interesting to observe, however, that we are able to do better when we consider the undecidable set R_C .

THEOREM 41. $\text{PSPACE} \subseteq P^{R_C}$.

Theorem 41 follows immediately from Theorem 33 and the following lemma, which implies that $\text{BPP}^{R_C} = P^{R_C}$ by the third item of Lemma 35 applied to $A = H$ and $L = R_C$. It is observed in [8] that very similar techniques suffice to show that $\text{NEXP} \subseteq \text{NP}^{R_C}$.

LEMMA 42 (see [19]). *There is a polynomial-time algorithm with oracle access to R_C that, on input 0^n , outputs a string of length n in R_C .*

We include a simple proof of Lemma 42 which works for our standard version of R_C , i.e., with a randomness threshold of $|x|/2$. Our proof also works for the smaller randomness thresholds we consider but does not work for a randomness threshold close to $|x|$. [19] gives a more complicated proof for the case where the oracle used is $\{x : C(x) \geq |x|\}$, i.e., for a randomness threshold of $|x|$; that proof works for any

reasonable randomness threshold between $|x|$ and $|x|^\epsilon$ for any positive ϵ (see Remark 2 after Theorem 10 in [19]).

Proof of Lemma 42. (We prove the lemma for the standard randomness threshold of $|x|/2$.) For any $m = n^{O(1)}$, we show how to construct a string z of length m such that $C(z) \geq |z|/2$ via a polynomial-time computation with access to oracle R_C . We will use the following property referred to as symmetry of information in [44, section 2.8]: There exists a constant c_1 such that for any strings z and y , $C(zy) \geq C(z) + C(y|z) - c_1 \log |zy|$.

We build z inductively. We start with z equal to the empty string. Assume (inductively) that $C(z) \geq |z|/2$. Try all strings y of length $2c_1 \log m$, and use the oracle R_C to see if $C(zy) \geq |zy|/2$. We are guaranteed to find such a y , since $C(y|z) \geq |y|$ holds for most y , and for any such y , $C(zy) \geq C(z) + C(y|z) - c_1 \log |zy| \geq |z|/2 + |y| - c_1 \log |zy| \geq |zy|/2$. Set z to be zy . \square

In a similar way, part 3 of Lemma 35 would allow us to obtain a *deterministic* polynomial-time reduction of PSPACE to R_{KS} in Corollary 36 if there was a deterministic method to construct a string of high KS complexity using R_{KS} as an oracle. We do not know if this is possible.

The question of whether or not long elements of R_{Kt} can be obtained in polynomial time relative to R_{Kt} turns out to be of critical importance in understanding the completeness properties of R_{Kt} . Let us formalize this as follows. Let Q denote the proposition “For all c there is a function f computable in polynomial time relative to R_{Kt} such that $f(0^n) \in R_{Kt} \cap \{0, 1\}^{n^c}$.” If Q is true, then Corollary 36 and the third item of Lemma 35 imply that $PSPACE \subseteq ZPP^{R_{Kt}} = P^{R_{Kt}}$; moreover, $R_{Kt} \notin P$ since otherwise Corollary 39 implies that $EXP = NP^{R_{Kt}} = NP \subseteq PSPACE \subseteq P^{R_{Kt}} = P$. On the other hand, if Q is false then $EXP \neq P^{R_{Kt}}$. This follows from an argument similar to one presented in the proof of Corollary 40: If there is some c for which no computation in $P^{R_{Kt}}$ on input 0^n can access a string in R_{Kt} of length greater than n^c , then it follows that every unary language in $P^{R_{Kt}}$ is in $DTime(2^{3n^c})$, which contradicts the time hierarchy theorem.

It should be noted in this regard that the property of symmetry of information, which was used in the proof of Lemma 42, provably does not hold for R_{Kt} [52].

Let us mention one other consequence of our PSPACE-completeness result. In [62] Watanabe and Tang showed that \leq_T^P and \leq_m^P reducibilities yield different classes of PSPACE-complete sets if and only if \leq_T^{BPP} and \leq_m^P reducibilities yield different PSPACE-complete sets. Using similar techniques, we are able to prove the following.

THEOREM 43. *There is a tally set T such that $PSPACE = P^{R_{KS} \cup T}$, where at least one of the following holds:*

- (i) R_{KS} is complete for PSPACE under \leq_{tt}^P reductions, but not under \leq_T^{\log} reductions, or
- (ii) $R_{KS} \cup T$ is complete for PSPACE under \leq_T^P reductions, but not under \leq_m^P reductions.

Proof. By Theorem 33 there is a probabilistic Turing machine M running in time n^k accepting QBF with oracle R_{KS} , with error probability less than 2^{-2n} . Let S be the set of all strings r such that r is the lexicographically first string of length n^k with the property that, for all strings x of length n , $M^{R_{KS}}(x, r)$ accepts if and only if $x \in QBF$. The set S is in PSPACE and, for almost all n , S contains exactly one string of length n^k . We encode the “good” coin flip sequences of S in the tally set $T = \{0^{2n^k+i} : \text{the } i\text{th bit of the unique string of length } n^k \text{ in } S \text{ is } 1\}$. The set R_{KS} contains only a finite number of strings in 0^* . It is immediate that $T \in PSPACE$ and that $QBF \in P^{R_{KS} \cup T}$.

If $R_{KS} \cup T$ is not complete for PSPACE under \leq_m^P reductions, then the second condition of the theorem holds.

On the other hand, if $QBF \leq_m^P R_{KS} \cup T$, then we can apply a standard argument of [17]. Berman showed that if a length-decreasing self-reducible set A is \leq_m^P -reducible to a tally set, then $A \in P$. A similar argument applied to the \leq_m^P reduction from $A = QBF$ to $R_{KS} \cup T$ yields a \leq_{tt}^P reduction from QBF to R_{KS} . We sketch the argument below for completeness. This, combined with Theorem 23, shows that the first condition of the theorem holds.

The modification of Berman's argument goes as follows. Let M denote the length-decreasing self-reduction of A , and f the reduction from A to $R_{KS} \cup T$. We build a reduction tree starting from the given input x as the single node. In the k th phase, we apply M to the active leaves of length $|x| + 1 - k$. Those nodes that map under f to a string outside of 0^* are made inactive. For each integer $m \geq 0$, we choose a representative among all nodes (if any) which f maps to 0^m . We keep the representative active and make all the other nodes which f maps to 0^m inactive. This process finishes after at most $|x|$ phases. Since the number of active nodes is polynomially bounded, each step involves only a polynomial amount of work. The leaves which f maps to strings outside of 0^* constitute the truth-table queries we make to R_{KS} . Once we know the answers to these queries, we can determine the answers to all remaining nodes in the reduction tree from bottom to top. \square

Note that in either case, we obtain a set that is \leq_T^P -complete but not \leq_m^{\log} -complete for PSPACE, namely, R_{KS} or $R_{KS} \cup T$. It was already known (using the techniques of [61]) that \leq_T^P and \leq_m^{\log} reducibilities provide different classes of PSPACE-complete sets, but the preceding theorem provides fairly "natural" examples of sets witnessing the difference.

4. Complexity of R_{KT} . The previous section paints an illuminating picture about the hardness of sets with high Kt, KS, and C complexity for PSPACE, EXP, and larger complexity classes. In this section, we explore what these techniques have to say about the hardness of R_{KT} , a set in coNP. We are not able to show completeness of R_{KT} for coNP, but we can show the hardness of R_{KT} under randomized polynomial-time reductions for problems that are thought to be NP-intermediate: Discrete Log, Factorization, and certain lattice problems.

We point out that the set R_{KT} seems closely related to the set MCSP defined in [36] as $\{(x, s) : \text{SIZE}(x) \leq s\}$. Although we do not know of efficient reductions between R_{KT} and MCSP in either direction, all our hardness results for R_{KT} also hold for MCSP. Based on a connection with natural proofs, [36] showed that if MCSP is in P, then, for any $\epsilon > 0$, there is a randomized algorithm running in time 2^{n^ϵ} that factors Blum integers well on the average. Our results imply that if MCSP is in P, then there is a randomized polynomial-time algorithm that factors arbitrary integers.

4.1. Tools. In order to prove hardness results for R_{KT} , we need to apply hardness versus randomness tradeoffs for pseudorandom generators G_f of lower computational complexity than in section 3. We will use the cryptographic pseudorandom generators that developed out of the seminal work by Blum and Micali [18], and by Yao [63]. In [30], it is shown how to construct such a pseudorandom generator $G_f^{\text{HILL}} : \{0, 1\}^n \mapsto \{0, 1\}^{2n}$ out of any function f . The pseudorandom generator G_f^{HILL} is computable in polynomial time given access to f and is secure provided f is one-way.

The known hardness versus randomness tradeoffs for G_f^{HILL} differ in two relevant respects from those used in section 3. First, breaking G_f^{HILL} only lets us invert f

on a nonnegligible fraction of the inputs, but not necessarily on all inputs. The implicit or explicit random self-reducibility of the problems considered in section 3 allowed us to make the transition from “nonnegligible fractions of the domain” to “the entire domain.” However, unlike for EXP and PSPACE, there are no NP-complete problems that are known to be random self-reducible. In fact, there provably are no nonadaptively random self-reducible NP-complete sets unless the polynomial-time hierarchy collapses [25].

Nevertheless, for some specific NP-intermediate problems h and polynomial-time computable functions f (where h may or may not coincide with f^{-1}), a worst-case to average-case connection is known. That is, inverting f on a nonnegligible fraction of the inputs allows one to compute h efficiently on any input. We are able to prove hardness of R_{KT} for such problems.

The second difference from section 3 is that the uniform hardness versus randomness tradeoffs in [30] are as strong as the nonuniform ones. Therefore, unlike in section 3, we need only to consider uniform reductions here.

We will apply G_f^{HILL} for functions f that take some additional parameters y besides the actual input x . In the case of the Discrete Log problem, for example, y will describe the prime p and the generator g of \mathbb{Z}_p^* defining the basis for the logarithm. More precisely, we will consider functions of the form $f(y, x)$ that are length-preserving for every fixed y , i.e., $f_y : \{0, 1\}^n \mapsto \{0, 1\}^n$, where $f_y(x) = f(y, x)$. The function $f(y, x)$ will be computable uniformly in time polynomial in $|x|$ (so without loss of generality, $|y|$ is polynomially bounded in $|x|$). The hardness versus randomness tradeoff in [30] can be stated as follows.

THEOREM 44 (see [30]). *Let $f(y, x)$ be computable uniformly in time polynomial in $|x|$. For any oracle L , polynomial-time probabilistic oracle Turing machine M , and polynomial p , there exists a polynomial-time probabilistic oracle Turing machine N and polynomial q such that the following holds for any n and y : If*

$$\left| \Pr_{|r|=2n,s} [M^L(y, r, s) = 1] - \Pr_{|x|=n,s} [M^L(y, G_{f_y}^{\text{HILL}}(x), s) = 1] \right| \geq 1/p(n),$$

then

$$\Pr_{|x|=n,s} [f(y, N^L(y, f(y, x), s)) = f(y, x)] \geq 1/q(n),$$

where r and x are chosen uniformly at random and s denotes the internal coin flips of M or N , respectively.

Theorem 44 states that if there exists a distinguisher with access to an oracle L that distinguishes the output of G_f^{HILL} from the uniform distribution, then oracle access to L suffices to invert f on a polynomial fraction of the inputs. We now argue that such a distinguisher exists in the case where L denotes R_{KT} or any set of polynomial density that contains no strings of small KT complexity.

THEOREM 45. *Let L be a language of polynomial density such that, for some $\epsilon > 0$, for every $x \in L$, $KT(x) \geq |x|^\epsilon$. Let $f(y, x)$ be computable uniformly in time polynomial in $|x|$. There exists a polynomial-time probabilistic oracle Turing machine N and polynomial q such that for any n and y*

$$\Pr_{|x|=n,s} [f(y, N^L(y, f(y, x), s)) = f(y, x)] \geq 1/q(n),$$

where x is chosen uniformly at random and s denotes the internal coin flips of N .

Proof. Let $G_y(x)$ denote $G_{f_y}^{\text{HILL}}(x)$. As in [51], we use the construction of [29] to modify G_y and obtain a pseudorandom generator G'_y producing longer output. Specifically, the proof of Theorem 4.1 of [51] constructs $G'_y : \{0, 1\}^n \mapsto \{0, 1\}^{2^k}$, and shows that if $z = G'_y(x)$, then $\text{SIZE}(z) = (n + k)^{O(1)}$. We can pick $k = O(\log n)$ such that for each x and polynomially bounded y , $\text{KT}(G'_y(x)) < |G'_y(x)|^\epsilon$. Thus L is a statistical test that accepts many random strings of length $|x|^{O(1)}$, but rejects all pseudorandom strings. As in [51], this gives us a probabilistic oracle machine M using L that distinguishes G_y from the uniform distribution. We then apply Theorem 44. \square

4.2. Hardness results. We now apply Theorem 45 to obtain our hardness results for R_{KT} . As will be clear from the proofs, R_{KT} can be replaced by any suitably dense language containing no strings of KT-complexity less than n^ϵ for some $\epsilon > 0$, such as R_{KT^t} for polynomial t . Other examples of such sets can be found in P^{MCSP} , and thus our hardness results carry over to MCSP as well. As observed in [11], the reductions in this section show that, under popular cryptographic assumptions, it is impossible even to approximate $\text{KT}(x)$ or $\text{SIZE}(x)$ within $|x|^{1-\epsilon}$.

We first consider the Discrete Log Problem, which takes as input a triple (p, g, z) , where p is a prime number, $0 < g < p$, and $0 < z < p$, and outputs a positive integer i such that $g^i \equiv z \pmod{p}$, or 0 if there is no such i . We have the following theorem.

THEOREM 46. *The Discrete Log Problem is computable in $\text{BPP}^{R_{\text{KT}}}$.*

Proof. On input (p, g, z) , we first check if p is prime [3]. Let n be the number of bits in p , and let y denote the pair (p, g) . Consider the function $f(y, x) = g^x \pmod{p}$. Theorem 45 with $L = R_{\text{KT}}$ gives us a polynomial-time probabilistic oracle Turing machine N such that for some polynomial q and all p and g , with probability at least $1/q(n)$ over randomly chosen x and s , $N^{R_{\text{KT}}}(p, g, g^x, s)$ produces an output i such that $g^i \equiv g^x \pmod{p}$.

Now we make use of the self-reducibility properties of the Discrete Log Problem. In particular, on our input (p, g, z) , we choose many more than $q(n)$ values v at random and run algorithm N on input $(p, g, zg^v \pmod{p})$. If z is in the orbit of g , then with high probability at least one of these trials will return a value u such that $g^u = zg^v \pmod{p}$, which means that we can pick $i = u - v$ and obtain $z \equiv g^i \pmod{p}$. On the other hand, if none of the trials is successful, then with high probability z is not in the orbit of g and the algorithm should return 0. \square

We are not able to improve our reduction from a BPP-reduction to a ZPP-reduction. That is, we know of no analogue of Lemma 35 for KT-complexity. We note that, for inputs (p, g, x) such that x is in the orbit of g , which is the usual class of inputs for which the discrete log is of interest, we do have ZPP-like behavior, since we can check whether the number i we obtain satisfies $g^i \equiv x \pmod{p}$. However, when x is not in the orbit of g , we obtain no *proof* of this fact—merely strong evidence.

The proof of Theorem 46 relies on the random self-reducibility of the Discrete Log Problem. In the terminology of section 4.1, this allows us to consider f^{-1} as the problem h that reduces to R_{KT} . The next problem we consider is a first example where h differs from f^{-1} .

THEOREM 47. *Factorization is computable in $\text{ZPP}^{R_{\text{KT}}}$.*

Proof. Consider Rabin's candidate one-way function $f(y, x) = x^2 \pmod{y}$, where $0 \leq x < y$. Theorem 45 with $L = R_{\text{KT}}$ gives us a probabilistic polynomial-time procedure with oracle access to R_{KT} that, for any fixed y , finds an inverse of $f(y, x)$ for a fraction at least $1/|y|^{O(1)}$ of the x 's with $0 \leq x < y$. Rabin [50] showed how

to use such a procedure and some randomness to efficiently find a nontrivial factor of y in case y is composite. This leads to a $\text{BPP}^{R_{\text{KT}}}$ algorithm for factoring. Since primality is in P [3], we can avoid errors and obtain the promised $\text{ZPP}^{R_{\text{KT}}}$ factoring algorithm. \square

Since Ajtai’s seminal paper [4, 5], several worst-case to average-case connections have been established for lattice problems. We will exploit these next.

We first review some lattice terminology. We refer to [22] for more background. Given a set B of n linearly independent vectors b_1, \dots, b_n over \mathbb{R}^n , the set $L(B) = \{ \sum_{i=1}^n z_i b_i \mid z_i \in \mathbb{Z} \}$ is called the lattice spanned by the basis B . We consider the usual notion of length of a vector v , $|v| = \sqrt{\sum v_i^2}$, and define the length of a set of vectors as the length of a longest vector in that set. For a lattice $L(B)$, $\lambda_i(B)$, $1 \leq i \leq n$, denotes the length of a shortest set of i linearly independent vectors from $L(B)$. The covering radius of $L(B)$, $\rho(B)$, is defined as the smallest ρ such that the union of all spheres of radius ρ centered at the points of $L(B)$ covers the entire space \mathbb{R}^n .

Applying our technique to Ajtai’s worst-case to average-case connections and their subsequent improvements and extensions [24, 47], we obtain the following hardness results for R_{KT} .

THEOREM 48. *For every $\epsilon > 0$, we can solve each of the following problems in $\text{BPP}^{R_{\text{KT}}}$. Given a basis $B \subseteq \mathbb{Z}^n$ (and a vector $t \in \mathbb{Z}^n$), find*

- (i) *(Shortest Independent Vector Problem (SIVP)) a set of n linearly independent vectors in $L(B)$ of length at most $n^{3+\epsilon} \cdot \lambda_n(B)$,*
- (ii) *(Shortest Basis Problem (SBP)) a basis for $L(B)$ of length at most $n^{3.5+\epsilon} \cdot \lambda_n(B)$,*
- (iii) *(Length of Shortest Vector Problem (LSVP)) a value $\tilde{\lambda}$, such that $\lambda_1(B) \leq \tilde{\lambda} \leq \omega(n^{3.5} \log n) \cdot \lambda_1(B)$,*
- (iv) *(Unique Shortest Vector Problem (Unique-SVP)) a shortest vector in $L(B)$ in case $\lambda_2(B) > n^{4+\epsilon} \cdot \lambda_1(B)$,*
- (v) *(Closest Vector Problem (CVP)) a vector $u \in L(B)$ such that $|u - t| \leq n^{3.5+\epsilon} \cdot \lambda_n(B)$,*
- (vi) *(Covering Radius Problem (CRP)) a value $\tilde{\rho}$, s.t. $\rho(B) \leq \tilde{\rho} \leq \omega(n^{2.5} \log n) \cdot \rho(B)$.*

The approximation factors in Theorem 48 represent the current state-of-the-art but are likely to be improved in the future.

In order to prove the statements above, we will use the following worst-case to average-case connection.

THEOREM 49 (see [5, 24]). *For any $\epsilon > 0$, there exist functions $q(n) = n^{O(1)}$ and $m(n) = n \log^2 q$ with q a power of 2 such that the following holds. For every $c > 0$, if there is probabilistic algorithm A , such that, with probability at least $1/n^c$ (over $M \in \mathbb{Z}_q^{n \times m}$ and over the random choices of A), $A(M)$ outputs a nonzero vector $u \in \mathbb{Z}^m$ such that $|u| \leq m$ and $Mu \equiv 0 \pmod q$, then there exists a BPP^A -algorithm A' that, given any basis $B \subseteq \mathbb{Z}^n$, outputs with high probability a set of n linearly independent vectors in $L(B)$ of length at most $n^{3+\epsilon} \cdot \lambda_n(B)$.*

Proof of Theorem 48. Let $q(n)$ and $m(n)$ be as in Theorem 49. Consider the collection of functions $f_{q,m} : \mathbb{Z}_q^{n \times m} \times \{0, 1\}^m \mapsto \mathbb{Z}_q^{n \times m} \times \mathbb{Z}_q^n$ defined by $f_{q,m}(M, v) = (M, Mv \pmod q)$. Letting $y = (q, m)$ and $x = (M, v)$, the function $f_y(x)$ is computable uniformly in time $|x|^{O(1)}$. By Theorem 45, there exists a polynomial-time probabilistic algorithm N with oracle access to R_{KT} that computes a preimage of $f_{q,m}(M, v)$ for at least a $1/n^{O(1)}$ fraction of the inputs (M, v) .

For any fixed M , f maps to at most q^n different values. Thus there can be at

most q^n vectors v , such that $f(M, v) \neq f(M, v')$ for all $v' \neq v$. In other words, for a fraction at least $1 - q^n/2^m > 1 - O(1/2^n)$ of the vectors v , there is a $v' \neq v$ with $f(M, v') = f(M, v)$. Therefore, if we pick M and v uniformly at random and run N to invert $f(M, Mv \bmod q)$, with probability at least $1/n^{O(1)}$ we obtain a vector $v' \in \mathbb{Z}^m$ such that $v' \neq v$ and $Mv \equiv Mv' \bmod q$.

Setting $u = v - v'$ yields a nonzero vector in \mathbb{Z}^m of length $|u| \leq m$ and satisfying $Mu \equiv 0 \bmod q$. This vector u is the output of the algorithm A on input M . Applying Theorem 49 to A yields the $\text{BPP}^{R_{\text{KT}}}$ algorithm for the SIVP.

The reductions for the SBP, the Unique-SVP, and the CVP follow from the one for the SIVP by arguments given in [24, 23]. The results for the LSVP and the CRP are obtained in a similar way based on the variants of the candidate one-way function f and the worst-case to average-case connection corresponding to Theorem 49 presented in [47]. \square

4.3. R_{KT} versus NP. Given our inability to prove that R_{KT} is coNP-complete, one may wonder whether R_{KT} is in NP. If it is, then this would provide a dense combinatorial property in NP that is useful against P/poly, contrary to a conjecture of Rudich [53]. We can also show the following.

THEOREM 50. *If R_{KT} is in NP, then $\text{MA} = \text{NP}$.*

Proof. It is shown in [32] that if an NP machine can, on input of length n , find the truth table of a function of size $n^{O(1)}$ with large circuit complexity, then $\text{MA} = \text{NP}$. Certainly this is easy if R_{KT} is in NP. \square

This observation (similar to ones in [32]) cannot be taken as evidence that $R_{\text{KT}} \notin \text{NP}$, since many conjecture that MA is equal to NP. However, it does show that proving R_{KT} in NP would require nonrelativizing proof techniques.

5. Open problems. In this paper, we present KT as a notion of time-bounded Kolmogorov complexity with close connections to circuit complexity. In so doing, we expose connections between circuit complexity and traditional Kolmogorov complexity and Levin's measure Kt. KT-complexity is also useful as a tool for summarizing some recent progress in the field of derandomization, and for describing the theory of natural proofs from the standpoint of Kolmogorov complexity. For an exposition along these lines, see [6].

The measures KT, KS, and Kt provide natural and interesting examples of apparently intractable problems in NP, PSPACE, and EXP that are not complete under the more familiar notions of reducibility and hence constitute a fundamentally new class of complete problems. It is worth pointing out that variants of these sets (such as $\{x : \text{Kt}(x) \geq |x|/3\}$) appear to be incomparable to our standard $R_{\text{Kt}} = \{x : \text{Kt}(x) \geq |x|/2\}$ under \leq_m^{P} reductions. As another example of this phenomenon, we are unable to present any reduction between $\{x : \text{KT}_U(x) \geq |x|/2\}$ and $\{x : \text{KT}_{U'}(x) \geq |x|/2\}$, where U and U' are two universal machines. This deserves further investigation.

Corollaries 39 and 36 combine to show that $\text{EXP} = \text{ZPP}$ if and only if $R_{\text{Kt}} \in \text{ZPP}$. This is because $R_{\text{Kt}} \in \text{EXP}$ and if $R_{\text{Kt}} \in \text{ZPP}$ then $\text{EXP} = \text{PSPACE} = \text{ZPP}^{R_{\text{Kt}}}$. This suggests that one might be able to show that R_{Kt} is complete under ZPP reductions, but we have not been able to show this.

Can one settle (one way or the other) the question of whether or not R_{Kt} is complete for EXP under $\leq_{\text{T}}^{\text{P}}$ reductions? For instance, is it possible to construct an element of R_{Kt} in $\text{P}^{R_{\text{Kt}}}$ (which would suffice to prove completeness, as in the proof of

Theorem 41)? Or is R_{Kt} more similar to the Buhrman–Mayordomo set R^t (which is provably *not* complete) in this regard?

Is there some sense in which KT complexity yields NP-complete sets? For instance, what can one say about $\{(x, y, i) : \text{KT}(x|y) \leq i\}$? The result of [58] is intriguing in this light; in [58] Vazirani and Vazirani presented a language in NP that is complete under probabilistic reductions that is not known to be complete under deterministic reductions. Their problem superficially seems to be related to time-bounded Kolmogorov complexity.

Other intriguing open questions are: Is $\text{PSPACE} \subseteq \text{P}^{R_{\text{KS}}}$? Is the EXP-complete set R_{Kt} in P? Is it in $\text{AC}^0[\oplus]$? We know of no fundamental obstacles that lie in the way of a direct proof that R_{Kt} is not in P, although it was pointed out to us by Rahul Santhanam that $\text{EXP} = \text{ZPP}$ if and only if there is a set in P of polynomial density containing only strings of Kt-complexity $\geq n^\epsilon$. The backward implication follows via the same argument that we used to show that $\text{EXP} = \text{ZPP}$ if and only if $R_{\text{Kt}} \in \text{ZPP}$. For the other direction, assume that $\text{EXP} = \text{ZPP}$, and let B be a set in EXP of polynomial density such that neither B nor its complement has an infinite subset in $\text{DTime}(2^n)$ [28]. Let A be the set in P consisting of (string, witness) pairs for the ZPP machine accepting B . If A contains infinitely many strings of low Kt complexity, then B contains infinitely many instances where membership can be decided in time 2^n , contrary to our choice of B .

The containment of PSPACE in $\text{P}^{R_{\text{C}}}$ raises the question of whether it might be possible to obtain characterizations of complexity classes in terms of efficient reductions to R_{C} . This is studied in more detail in [8] (where a nontrivial characterization of P having this flavor is presented).

Acknowledgments. We acknowledge illuminating discussions with Lance Fortnow, as well as helpful conversations of the first author with Paul Beame, Henry Cohn, Chris Umans, and Ramarathnam Venkatesan during a visit to Microsoft Research. We thank Jin-Yi Cai and Daniele Micciancio for clarifying some issues regarding lattice problems. We also acknowledge fruitful discussions with Steven Rudich, Valentin Kabanets, Manindra Agrawal, Troy Lee, Neil Jones, Rahul Santhanam, Kolya Vereshchagin, John Hitchcock, and Pavan Aduri. Finally, we thank the anonymous referees for their suggestions.

FULLY DYNAMIC ORTHOGONAL RANGE REPORTING ON RAM*

CHRISTIAN WORM MORTENSEN†

Abstract. We show that there exists a constant $\omega < 1$ such that the fully dynamic d -dimensional orthogonal range reporting problem for any constant $d \geq 2$ can be solved in time $O(\log^{\omega+d-2} n)$ for updates and time $O((\log n / \log \log n)^{d-1} + r)$ for queries. Here n is the number of points stored and r is the number of points reported. The space usage is $O(n \log^{\omega+d-2} n)$. For $d = 2$ our results are optimal in terms of time per operation, and this is the main contribution of this paper. Also for $d = 2$, we give a new improved fully dynamic structure supporting 3-sided queries. The model of computation is a unit cost RAM. We order the coordinates of points using *list order* as defined in the paper.

1. Introduction. Consider a database R of persons where each person has attributes such as an age, a weight, and a height. One of the most fundamental types of queries in the database is to ask for the set of persons in R who have an age between, say, 30 and 50 years, a weight between 80 and 90 kg, and a height between 160 and 170 cm. Data structures supporting these kinds of queries are called orthogonal range reporting structures and have been widely studied during the last 30 years. For surveys see Agarwal and Erickson [1] and Chiang and Tamassia [18]. In this paper we give new upper bounds for the fully dynamic variant of this problem where we in an online setting allow queries to be intermixed with updates which can insert a new person or delete an existing person. In case each person has exactly two attributes our upper bound is optimal in terms of time per operation by a lower bound of Alstrup, Husfeldt, and Rauhe [4].

1.1. Problem definition. In the d -dimensional fully dynamic orthogonal range reporting problem (henceforth the dynamic d -dimensional range reporting problem or just the d -dimensional range reporting problem) we must maintain a set R of at most $O(n)$ d -dimensional points under insertions and deletions. For each point $(x_1, \dots, x_d) \in R$ we must have $x_i \in L_i$ for $1 \leq i \leq d$, where L_i is an ordered set. Given a query $(x'_1, x''_1, \dots, x'_d, x''_d) \in L_1 \times L_1 \times \dots \times L_d \times L_d$ we must report the set $\{(x_1, \dots, x_d) \in R \mid x'_1 \leq x_1 \leq x''_1 \wedge \dots \wedge x'_d \leq x_d \leq x''_d\}$. We assume that if $(x_1, \dots, x_d) \in R$ and $(y_1, \dots, y_d) \in R$ are two different points, then $x_1 \neq y_1 \wedge \dots \wedge y_d \neq y_d$. Our model of computation is a unit cost RAM with word size at least $\log n$ bits. We define the *update time* to be the time it takes to insert a point into or delete a point from R . We consider only solutions to the problem where the time to answer a query has the form $Q + O(r)$, where r is the number of reported points and Q is independent of r , and we say such a solution has *query time* Q . Further, we call the maximum of the update time and the query time the *time per operation*.

*Received by the editors October 28, 2003; accepted for publication (in revised form) October 27, 2005; published electronically April 21, 2006. This paper is based on [31] and [30]. The result of [31] for the orthogonal segment intersection problem is not covered in this paper. Also, we use another method for extending into higher dimensions than in [30].

We get different problems depending on what we select as L_i . Traditionally, one is only allowed to compare the elements of L_i using a unit cost comparison operation. This is often specified as $L_i = \mathbb{R}$ and makes good sense on a pointer machine. We call this the *comparison order* variant of our problem. Another possibility is to take L_i to be the set of nonnegative integers smaller than m (we assume here $m \leq 2^w$, where w is the word size). We define this as the *m-order* variant. We define the *word order* variant to be the *m-order* variant with $m = 2^w$. All these variants have their shortcomings. In the comparison order variant, there is a trivial lower bound of $\Omega(\log n)$ on the time per operation because this is a lower bound for the dictionary problem on \mathbb{R} . In the *m-order* variant, it is not always possible to create a new attribute between two existing attributes when performing an insertion. For these reasons, we introduce in this paper what we define as the *list order* variant. For any linked list L we order the elements of L such that if $e, e' \in L$, then $e < e'$ if $e \neq e'$ and e appears before e' in L . In the list order variant, we then let L_i be a linked list and require each element of L_i to be the coordinate of exactly one point in R . When a point is inserted into (resp., deleted from) R a new element is then inserted into (resp., deleted from) each L_i for $1 \leq i \leq d$. Using a result by Dietz and Sleator [21] (cited as Theorem 8 in section 5.3) a structure for the comparison order variant can be turned into a structure for the list order variant with the same performance. Conversely, a structure for the list order variant can be turned into a structure for the comparison order variant if we add a term of $O(\log n)$ to the update and query time since such a term allows us to maintain a balanced search tree with the elements of each L_i . Finally, by the use of Theorem 6 cited in section 5.1, a structure for the list order variant can be turned into a structure for the word order variant if we add a term of $O(\sqrt{\log n / \log \log n})$ to the update and query time.

1.2. Our results. We show (Theorem 32) that there exists a constant $\omega < 1$ such that for any constant $d \geq 2$ the d -dimensional range reporting problem in the list order variant can be solved with update time $O(\log^{\omega+d-2} n)$, query time $O((\log n / \log \log n)^{d-1})$, and space $O(n \log^{\omega+d-2} n)$. The time bounds are worst case and the solution is deterministic. In the comparison order variant, the discussions of section 1.1 imply that the same result holds for $d \geq 3$ and that for $d = 2$ the time per operation becomes $\Theta(\log n)$.

For $d = 2$ we also consider queries of the restricted form $(x'_1, x''_1, x'_2, x''_2) \in L_1 \times L_1 \times L_2 \times L_2$, where x'_2 is the minimal element of L_2 . Such queries are called *3-sided*, whereas queries where x'_2 can take any value in L_2 are called *4-sided*. We show (Theorem 24) that the 2-dimensional range reporting problem in the list order variant with 3-sided queries only can be solved with update time $O(\log^\omega n)$, query time $O(\log n / \log \log n)$, and space $O(n)$. Here also, the time bounds are worst case and the solution is deterministic.

The data structures of this paper are too complicated and the constants involved too large to be useful in practice. However, some of the ideas of the paper may still have practical implications (see section 9 on open problems).

1.3. Relation to other work. The static 2-dimensional range reporting problem in the comparison order variant can be solved with query time $O(\log^2 n)$ and space $O(n \log n)$ using *range trees*. The range tree data structure was independently discovered by Bentley, Lee, Lueker, Shamos, Willard, and Wong (see [12, 9, 10, 25, 26, 40, 42]). It is commonly recognized that Bentley and Shamos were chronologically the first authors to publish their results [12, 9]. In a dynamic setting, their data structure was known to have an $O(\log^3 n)$ query time and an $O(\log^2 n)$ update time

using some version of the Logarithmic update method—sometimes called the static-to-dynamic transformation [11, 34, 36]. It was observed by Lueker and Willard (first independently and then in a joint paper [26, 40, 46]) that the query time of this dynamic method for range trees could be reduced to $O(\log^2 n)$ time (with no sacrifice in update time) using the $BB(\alpha)$ dynamic method. Willard [42] observed how to extend range trees with “downpointers” so that the query time could be further reduced to $O(\log n)$ time in the static case. The downpointer discovery by Willard [42] should not be confused with the $BB(\alpha)$ dynamic method (that was jointly coauthored by Lueker and Willard (see [26, 40, 46])). Because the two discoveries of the $BB(\alpha)$ dynamic method and the downpointer were made nearly simultaneously, several articles reviewing the prior literature have often inadvertently confused them.

Chazelle and Guibas [17] generalized downpointers as well as other ideas into a data structuring technique called fractional cascading. Mehlhorn and Näher [29] made fractional cascading dynamic with amortized time bounds on updates. They used this to develop a data structure for the 2-dimensional range reporting problem in the comparison order variant with update and query time $O(\log n \log \log n)$ on a pointer machine. Dietz and Raman [20] removed amortization from the results of [29] on a RAM. Using range trees the structure from [29] can be extended to $d > 2$ dimensions giving update and query time $O(\log^{d-1} n \log \log n)$ and space usage $O(n \log^{d-1} n)$. Until now, this was the fastest known solution in terms of time per operation (even in the n -order variant). Range trees with slack parameter [28, 37] can be used to get a structure with polylogarithmic update and query time and with space usage $O(n(\log n / \log \log n)^{d-1})$. Until now, no solution with space usage $o(n(\log n / \log \log n)^{d-1})$ and polylogarithmic time per operation was known (see end of paragraph for very recent work). For $d = 2$ a solution with linear space usage $O(n)$, update time $O(\log n)$, and query time $O(n^\epsilon)$ for a constant $\epsilon > 0$ is known [24]. Also, for $d = 2$, if only insertions or deletions (but not both) are supported Imai and Asano [23] described a solution using space $O(n \log n)$ and time $\Theta(\log n)$ per operation. Very recently, Nekrich [33] dynamized a structure by Alstrup, Brodal, and Rauhe [3] and obtained a structure for the d -dimensional dynamic range reporting problem with update time $O(\log^d n)$, query time $O(\log^{d-1} n)$, and space usage $O(n \log^{d-2+\epsilon})$ for any constant $\epsilon > 0$.

Let U be the update and Q be the query time of an orthogonal range reporting structure. For word size polylogarithmic in n Alstrup, Husfeldt, and Rauhe [4] showed that $Q = \Omega(\log n / \log(U \log n))$. This lower bound holds in the cell probe model of computation (which is stronger than the RAM model) for the amortized cost per operation, for 3-sided queries, and for the n -order variant. It follows that with polylogarithmic update time, the query time becomes $\Omega(\log n / \log \log n)$. Together with our new upper bound, this lower bound gives that the time per operation for the 4-sided 2-dimensional range reporting problem in the list order variant and the m -order variant is $\Theta(\log n / \log \log n)$ for $m \geq n$. As already mentioned our results also imply a bound of $\Theta(\log n)$ in the comparison order variant. The time per operation for the 2-dimensional range reporting problem in all the order variants of section 1.1 is thus now completely understood, and this is the major contribution of this paper.

McCreight [27] developed the priority search tree which solves the 2-dimensional range reporting problem in the comparison order variant with 3-sided queries only on a pointer machine. The update and query time of the priority search tree is $O(\log n)$ and it uses space $O(n)$. Willard [45] modified the priority search tree and obtained a structure using time $O(\log n / \log \log n)$ for updates and queries in the word order variant on a RAM. In this paper, we reduce the update time for this problem further

without increasing the query time or the space usage. Also, we generalize the result to the list order variant. As did Willard, we use a modified version of the priority search tree.

A longstanding open problem mentioned by McCreight [27] is whether it is harder to make a fully dynamic structure supporting 4-sided than it is for 3-sided queries. This paper together with the lower bound of [4] partly answers this question by showing that on the RAM the time per operation needed for the two problems is the same in all the order variants described in section 1.1. Whether the space usage for structures supporting 4-sided queries can be reduced to linear as for 3-sided queries is still open. This is even the case in the static case where the best known structures with polylogarithmic query time and constant time for each reported point use space $O(n \log^\epsilon n)$. The query time is $O(\log n)$ for the comparison order variant [15] and $O(\log \log n)$ for the n -order variant [3].

On the pointer machine in the comparison order variant, Chazelle [16] has shown that any static or dynamic structure for the 2-dimensional range reporting problem with polylogarithmic query time must use space $\Omega(n(\log n / \log \log n)^{d-1})$. For $d = 2$ this bound is matched by a static structure with query time $O(\log n)$ and space usage $O(n \log n / \log \log n)$ [14]. For $d > 2$ the best known upper bound with matching space usage has query time $O(\log^{d-1+\epsilon} n)$ for any constant $\epsilon > 0$ also in the static case [16].

In the input/output (I/O) model of computation with block size B and in 2 dimensions, a structure for 3-sided queries using space $O(n/B)$ disk blocks supporting updates in time $O(\log_B n)$ and queries in time $O(\log_B n + r/B)$ when r points are reported is described by Arge, Samoladas, and Vitter [6]. This is optimal in terms of time per operation in the comparison order variant. For 4-sided queries they describe a solution supporting updates in time $O((\log_B n) \log(n/B) / \log \log_B n)$ and queries in time $O(\log_B n + r/B)$ when r points are reported. The structure uses space $O((n/B) \log(n/B) / \log \log_B n)$ disk blocks.

1.4. Outline of paper. After this introduction we continue with preliminaries in section 2. In section 3 we give various definitions related to 2-dimensional range reporting. Also, we give an outline of how the results of this paper are obtained. In section 4 we give probably the most central construction of this paper, and this construction may be of independent interest. In section 5 we review various well-known data structures which we use in this paper. Also, we develop some new results on top of these structures. In section 6 we develop our solution to the 2-dimensional range reporting problem with 3-sided queries only. In section 7 we develop our solution to the 4-sided 2-dimensional range reporting problem. In section 8 we extend the solution of section 7 to higher dimensions. The paper concludes with open problems in section 9 and acknowledgments.

2. Preliminaries. For the rest of this paper we define $[i \dots j] = \{k \in \mathbb{Z} | i \leq k \leq j\}$ and we let \log denote the base-two logarithm. We will measure space in bits. We will use $\log^i \log n$ as an abbreviation for $(\log \log n)^i$. All time bounds are worst case and all structures are deterministic if not otherwise noted.

A linked list is a list where the elements are doubly linked with pointers. We make no assumptions about how the elements are laid out in memory. If the list supports insertions, we can insert a new element in it if we have a pointer to the existing element the new element should be inserted before or after. If the list supports deletions, we can delete an element if we have a pointer to it. We assume the elements of a linked list and the children of a node in a tree are ordered from left to right.

We will not distinguish between a data structure and the set of elements it contains. As a consequence, $|G|$ is the number of elements in the data structure G and $e \in G$ means that e is an element in G .

A function f is said to be *subadditive* if for integers $m, n \geq 0$ we have $f(m) + f(n) \leq f(m + n) + O(1)$. Suppose for each $n \geq 0$ we have a data structure G_n which uses space $f(n)$ bits and which can contain at most n elements. It follows (by induction on k) that if f is subadditive, then storing the elements of G_n in k different structures $G_{n(1)}, \dots, G_{n(k)}$ uses space at most $f(n) + O(k)$ bits, where $n = \sum_{i=1}^k n(i)$.

We will assume that the number of points which can be contained in the range reporting structures we ultimately design is bounded by $O(N)$. We note that N was called n in the introduction and that we have assumed a word size of at least $\log N$ bits. All the data structures we create in this paper are a part of one of our ultimate structures and can contain at most $O(N)$ elements. When constructing such a data structure, we often state that we can compute some function f from $[0 \dots O(N)]$ to $[0 \dots O(N)]$ in constant time using a *global lookup table*. What we mean by this is the following. As a part of the ultimate structure the data structure is a part of, we keep a table of size at most $O(N \log N)$ bits which is constructible in time $O(N)$. The function f can then be computed by performing a constant number of lookups in this table. We are allowed to assume the existence of such tables by using the global rebuilding of Overmars [34]. For brevity, we will omit the details in constructing and looking up in these tables.

3. Definitions and outline of constructions. The constructions of this paper involve many different kinds of range reporting structures. In section 3.1 we will define notation which captures almost all the kinds of 2-dimensional structures we look at. We will use this notation throughout the rest of the paper. Next, in section 3.2 we will give an outline of the constructions that lead to the results of section 1.2.

3.1. Definitions. We now define what it means for a range reporting structure R to have type $R^\tau(t_x : n_x, t_y : n_y)$, where n_x and n_y are integers, $\tau \in \{3, 4\}$, and $t_x, t_y \in \{d, s, s'\}$. R must have an *x-axis* $R.L_x$ and a *y-axis* $R.L_y$. The rest of this section is parametrized over a parameter $z \in \{x, y\}$. Each sentence of this section that contains a z should then be read twice: first with $z = x$ and then with $z = y$. So we can state which axes R must have as follows. R must have a *z-axis* $R.L_z$. R contains elements $e \in R$ which are also called points. A point $e \in R$ has a z -coordinate $e.z \in R.L_z$.

If $t_z = d$, we say the z -axis is *dynamic* and in this case, the z -axis is a linked list with $O(n_z)$ elements. Also, when $t_z = d$ we require that each element of $R.L_z$ is the z -coordinate of exactly one point. If $\tau = 4$, the structure supports 4-sided queries and if $\tau = 3$, the structure support 3-sided queries as defined in section 1.2. We will make this more precise in a moment. As an example, a structure with type $R^4(d : n, d : n)$ is a 4-sided 2 dimensional range reporting structure in the list order variant, and the structure can contain $O(n)$ points.

If $t_z = s$ or $t_z = s'$, we say the z -axis is *static* and in this case, $R.L_z$ is the set $[0 \dots \Theta(n_z)]$ (which is not required to be explicitly stored). If $t_z = s$, there can be at most one point in R with a given z -coordinate; if $t_z = s'$, we have no such restriction. We require that no two points share the same x - and y -coordinate. More precisely, we require that $e, e' \in M$ and $e.x = e'.x$ and $e.y = e'.y$ imply $e = e'$. As an example, a structure with type $R^4(s : n, s : n)$ can contain at most $O(n)$ points, and no two points can share an x - or y -coordinate. On the other hand, a structure with type

$R^4(s':n, s':n)$ can contain $O(n^2)$ points.

We support updates in the form of inserting a new point into R and deleting an existing point from R . From our requirements above it follows that if $t_z = d$, we will then also have to insert an element into and delete an element from $R.L_z$, respectively. For $x_1, x_2 \in R.L_x$ and $y_1, y_2 \in R.L_y$ we support a query (x_1, x_2, y_1, y_2) which must report the set $\{e \in R \mid x_1 \leq e.x \leq x_2 \wedge y_1 \leq e.y \leq y_2\}$. We say that the points in this set are in the *query region*. If $\tau = 3$, we require that y_1 in such a query can be assumed to be the minimal element of $R.L_y$. An implication of our definitions is that for $\tau = 4$ structures of type $R^\tau(s:n, d:n)$ and $R^\tau(d:n, s:n)$ are identical modulo renaming of axes, while this is not the case for $\tau = 3$.

Suppose R can contain at most n points for n small compared to N . In case R has static axes, we will sometimes allow updates to be performed in subconstant time per update by packing several updates into a single word. In this case, the user must assign to each point $e \in R$ a unique identifier or just *id* $e.id$ of size $O(\log n)$ bits. For each point e inserted into R the user must then in the words describing the update provide the triple $(e.x, e.y, e.id)$. For each point $e \in R$ deleted from R , the user must, again in the words describing the update, provide the tuple $(e.x, e.y)$. Finally, in connection with queries the id of the reported points are given to the user (using constant time per point reported).

We say R has *performance* (U, Q, S, t) if R supports $O(t)$ updates in time $O(U)$, has query time $O(Q)$, and has uses space $O(S)$ bits. S is allowed only to depend on the type of R and not on the number of points stored in R . It follows that if R can contain n points, we must have $S = \Omega(n \log n)$. We write (U, Q, S) as an abbreviation for $(U, Q, S, 1)$.

3.2. Outline of constructions. We now have the terminology to give an outline of the constructions leading to the results of section 1.2. Our construction consists of a number of steps which we will refer to during the paper. First, we give an outline of how we prove Theorem 24. This theorem gives our structure with type $R^3(d:N, d:N)$ proving the second result in section 1.2. All the steps O1 to O4 are performed in section 6.

- O1 First, we create a range reporting structure for the case we have only few points. For sufficiently small u compared to N (we have $u = 2^{\log^\epsilon N}$ for a constant $\epsilon > 0$) the structure has type $R^3(s:u, s:u)$, has subconstant update time, and small query time. The result of this step is in Lemma 20.
- O2 We then give the structure of step O1 a dynamic y-axis transforming it into a structure with type $R^3(s:u, d:u)$. What we lose is the subconstant update time; this structure has only constant update time. The query time is unchanged. The technique used is to assign a label of size $O(u)$ to each element on the y-axis and then to relabel elements on insertions. The result of this step is in Lemma 22.
- O3 By creating a fixed-shape tree (actually, a variant of a priority search tree) with a structure of step O2 in each internal node, we get a structure with type $R^3(s:n, d:n)$ for any $n \geq u$. The result of this step is in Lemma 23.
- O4 We then create our final structure with type $R^3(d:n, d:n)$. This is done by grouping points on the x-axis into blocks with a polylogarithmic number of points in each block. The blocks are then numbered respecting the order of the blocks, and then they are inserted into the structure of step O3 using these numbers. The result of this step is in Theorem 24.

Next, we give an outline of how we prove Theorem 32. This theorem gives a structure

with type $R^4(d : N, d : N)$ and a similar structure for higher dimensions. This is the first result from section 1.2. Steps O5 to O10 are performed in section 7, while step O11 is performed in section 8.

- O5 We extend the construction in step O1 to give a structure with type $R^4(s' : u, s : u)$. As in step O1 this structure has subconstant update time and small query time. The result of this step is in Lemma 25.
- O6 We use the same construction as in step O2 to get a dynamic x-axis. More precisely, we get a structure with type $R^4(d : u, s' : u)$. The result of this step is in Lemma 26.
- O7 By maintaining a predecessor structure, we transform this into a structure with a static but long x-axis. The structure we get has type $R^4(s' : n, s : u)$ for any $n, u \leq n \leq N$. The result of this step is in Lemma 27.
- O8 We then use the construction of section 4 to give the structure of step O7 type $R^4(s' : n, s' : u)$ almost without reducing its query time or increasing its update time. The result of this step is in Lemma 28.
- O9 We then give this structure a dynamic x-axis creating a structure R with type $R^4(d : n, s' : u / \log^3 n)$. This is done by grouping points into blocks of size $O(u)$ on the x-axis. In each block, we keep a structure of step O6. As in step O4 we maintain a numbering of the blocks and we insert each block into the structure of step O8 using the numbers as x-coordinate. The result of this step is in Lemma 29.
- O10 We then construct our structure with type $R^4(d : n, d : n)$. This is done by constructing a variant of a range tree using the structure of step O9 in some nodes and the structure of step O4 in some nodes of the tree. The result of this step is in Theorem 31.
- O11 Finally, we extend the structure of step O10 to higher dimensions. The result of this step is in Theorem 32.

4. From few to many points. In this section, we give the construction used in step O8 in section 3.2. As mentioned earlier, this is probably the most central construction of this paper. The construction allows us to create a 4-sided range reporting structure which can contain many points from one that can contain few points. The construction has applications besides the one in this paper [32, 31], and for this reason we will give a slightly more general form of the construction than we need here.

We now define what it means for a data structure G to have type (n, Y, \mathcal{Y}) , where n is an integer and \mathcal{Y} is a set of subsets of Y . G contains elements $e \in G$, where $e.x$, $0 \leq e.x < n$, is the *position* of e and $e.y \in Y$ is the *height* of e . Two different elements in G are not allowed to have both the same position and height implying $|G| \leq n|Y|$. We are allowed to update G by inserting a new element or by deleting an existing element. Further, for $0 \leq i, j < n$ and $q \in \mathcal{Y}$ we can ask the query $\text{report}(G, i, j, q)$ which must report the set $\{e \in G \mid i \leq e.x \leq j \wedge e.y \in q\}$. As in the rest of the paper, the query time is said to be $O(Q)$ if reporting this set takes time $O(Q)$ plus constant time for each reported point. We will then show the following theorem.

THEOREM 1. *Suppose we have a data structure G' with type (n, Y, \mathcal{Y}) and the restriction*

$$(1) \quad e, e' \in G' \wedge e.y = e'.y \implies e = e'.$$

Suppose further G' uses space $O(S)$ bits, has query time $O(Q)$, and update time $O(U)$. Then we can make a structure G with type (n, Y, \mathcal{Y}) without the restriction (1) which

uses space $O(Sn \log \log n)$ bits, has query time $O(Q \log \log n)$, and has update time $O(U \log \log n)$.

Observe that since G' can contain $|Y|$ elements we must have $S = \Omega(|Y| \log n)$. In this paper, we use only the following corollary to the theorem.

LEMMA 2. *Suppose there exists a structure with type $R^4(s' : n, s : u)$ and performance (U, Q, S) . Then there exists a structure with type $R^4(s' : n, s' : u)$ and performance $(U \log \log n, Q \log \log n, Sn \log \log n)$.*

Proof. The lemma is just another way of phrasing Theorem 1 if we select $Y = [0 \dots O(u)]$ and $\mathcal{Y} = \{[y_1 \dots y_2] \mid 0 \leq y_1, y_2 \leq O(u)\}$. \square

The rest of this section is devoted to the proof of Theorem 1. We need the following theorem which is shown by van Emde Boas et al. (see [39, 38]).

THEOREM 3. *Let w be the word size in bits. There exists a data structure called a VEB which can maintain a collection of $n \leq U \leq 2^w$ elements having keys in $[0 \dots U]$ which uses space $O(U \log U)$ bits and supports updates as well as predecessor and successor queries in time $O(\log \log U)$.*

We create a VEB of Theorem 3 for each element $y \in Y$. Each element $e \in G$ is inserted at position $e.x$ into the VEB for height $e.y$. Using these VEBs we link all elements with the same height together in order according to their positions. This will use space $O(n|Y| \log n) = O(Sn)$ and insertions and deletions can be performed in time $O(\log \log n)$.

We maintain a data structure S_n which we develop in the following. The data structure S_n contains triples $(e, x, y) \in S_n$, where e is an arbitrary pointer, x is an integer in $[0 \dots n - 1]$, and $y \in Y$ is the height of the triple. We maintain S_n such that $(e, e.x, e.y) \in S_n$ iff $e \in G$. We support a special `reportsub`(S_n, i, j, q) query which has the following properties:

1. `reportsub`(S_n, i, j, q) \subseteq `report`(G, i, j, q).¹
2. If for given y there exists an element $e \in$ `report`(G, i, j, q) with $i \leq e.x \leq j$ and $e.y = y$, then `reportsub`(S_n, i, j, q) contains at least one such e .
3. S_n has query time $O(Q)$.

A `report`(G, i, j, q) query can then be answered as follows. First, we perform a `reportsub`(S_n, i, j, q) query. Properties 1 and 3 ensure that we will not use too much time on this. For each height $y \in Y$ for which there exists an element $e \in$ `reportsub`(S_n, i, j, q) with height y we follow the pointers from e maintained by the VEB for height y to report the rest of the elements with this height. Property 2 ensures that this will report all elements.

We now describe the structure S_n . To avoid tedious details, we assume n has the form $n = 2^{2^m}$ for an integer $m \geq 0$. We observe that if $n > 2$ has this form, then \sqrt{n} has same form. The structure S_n is somewhat similar to a VEB, and we define it inductively on n . If $S_n = \emptyset$, the recursion stops. Otherwise, we keep an array $S_n.\text{min}$ (resp., $S_n.\text{max}$) indexed by Y . For each $y \in Y$ we store the triple $(e, x, y) \in S_n$ with minimal (resp., maximal) value of x in $S_n.\text{min}[y]$ (resp., $S_n.\text{max}[y]$) if any. We also keep an array $S_n.\text{bottom}$ indexed by $[0 \dots \sqrt{n} - 1]$ where in each entry we store a recursive structure with type $S_{\sqrt{n}}$. We store each triple $(e, i, y) \in S_n \setminus (S_n.\text{min} \cup S_n.\text{max})$ as $(e, i \bmod \sqrt{n}, y)$ in $S_n.\text{bottom}[i \text{ div } \sqrt{n}]$.² Finally, we keep a single recursive structure $S_n.\text{top}$ also with type $S_{\sqrt{n}}$. If for $y \in Y$ the structure $S_n.\text{bottom}[i]$ contains exactly one triple $(e, x, y) \in S_n$ with height y , we store (e, i, y) in $S_n.\text{top}$. We note that in

¹In section 4 we will not distinguish between a query and its answer.

²For integers i and d we define $i \bmod d$ and $i \text{ div } d$ to be the unique integers such that $0 \leq i \bmod d < d$ and $i = d(i \text{ div } d) + i \bmod d$.

this case e is stored in both $S_n.\text{bottom}$ and in $S_n.\text{top}$. If $S_n.\text{bottom}[i]$ contains more than one triple with height y , we store (e', i, y) in $S_n.\text{top}$, where e' is a pointer to the recursive structure in $S_n.\text{bottom}[i]$.

Inserting a triple (e, x, y) into S_n : If S_n contains at most one triple with height y , we just update $S_n.\text{min}[y]$ and $S_n.\text{max}[y]$ and we are done. Otherwise, we first check if (e, x, y) should go into $S_n.\text{min}[y]$ (resp., $S_n.\text{max}[y]$), and if this is the case we interchange (e, x, y) and the triple in $S_n.\text{min}[y]$ (resp., $S_n.\text{max}[y]$). Let T be the structure in $S_n.\text{bottom}[x \text{ div } \sqrt{n}]$. We then insert $(e, x \bmod \sqrt{n}, y)$ into T . Let m be the number of triples in T with height y after this insertion. If $m = 1$, we insert $(e, x \text{ div } \sqrt{n}, y)$ into $S_n.\text{top}$. If $m = 2$, there is a triple $(e', x \text{ div } \sqrt{n}, y)$ in $S_n.\text{top}$, and we replace (see next paragraph) this triple with the triple $(e'', x \text{ div } \sqrt{n}, y)$, where e'' is a pointer to T . We observe that when we update $S_n.\text{top}$ then T has at most two triples with height y and the update in T is performed by just accessing $T.\text{min}$ and $T.\text{max}$. It follows that we perform only a nonconstant number of updates in at most one recursive structure.

Replacing a triple $(e, x, y) \in S_n$ with the triple (e', x, y) : If $(e, x, y) = S_n.\text{min}[y]$ (resp., $(e, x, y) = S_n.\text{max}[y]$), we just update $S_n.\text{min}[y]$ (resp., $S_n.\text{max}[y]$) and we are done. Otherwise, let T be the structure in $S_n.\text{bottom}[x \text{ div } \sqrt{n}]$. First, we replace in T $(e, x \bmod \sqrt{n}, y)$ with $(e', x \bmod \sqrt{n}, y)$. Next, if T has exactly one triple with height y , we replace $(e, x \text{ div } \sqrt{n}, y)$ with $(e', x \text{ div } \sqrt{n}, y)$ in $S_n.\text{top}$. As with insertions we note that we need only to perform a nonconstant number of updates in at most one recursive structure.

Deleting a triple (e, x, y) from S_n : If S_n has at most two triples with height y , we just update $S_n.\text{min}[y]$ and $S_n.\text{max}[y]$ and we are done. Suppose therefore that S_n contains at least three triples with height y . We split into three cases: Case 1: In this case $(e, x, y) = S_n.\text{min}[y]$. Let $(e', t, y) = S_n.\text{top}.\text{min}[y]$, $(e'', l, y) = S_n.\text{bottom}[t].\text{min}[y]$ and $i = l + t\sqrt{n}$. Then (e'', i, y) is the triple in $S_n \setminus (S_n.\text{min} \cup S_n.\text{max})$ with height y which has the minimal value of i . Instead of deleting (e, x, y) from S_n we delete (e'', i, y) and afterwards we set $S_n.\text{min}[y]$ to (e'', i, y) . Case 2: In this case $(e, x, y) = S_n.\text{max}[y]$ and this case is handled in a symmetric way to Case 1. Case 3: In this case (e, x, y) is not equal to $S_n.\text{min}[y]$ or $S_n.\text{max}[y]$. The case is handled in a way similar to insertions: Let T be the structure in $S_n.\text{bottom}[x \text{ div } \sqrt{n}]$. We then delete $(e, x \bmod \sqrt{n}, y)$ from T . Let m be the number of triples in T with height y after this deletion. Suppose $m = 1$ and let (e', i, y) be the triple with height y in T . Then there is a triple $(e'', x \text{ div } \sqrt{n}, y)$ in $S_n.\text{top}$, where e'' is a pointer to T , and we replace this triple with the triple $(e', x \text{ div } \sqrt{n}, y)$. If $m = 0$, we delete $(e, x \text{ div } \sqrt{n}, y)$ from $S_n.\text{top}$. Again we observe that we need only to perform a nonconstant number of updates in at most one recursive structure.

What remains is to describe how to answer a `reportsub` query. In order to do this, we in addition to $S_n.\text{min}$ (resp., $S_n.\text{max}$) maintain a structure $S_n.\text{min}'$ (resp., $S_n.\text{max}'$) with the type of the structure given to Theorem 1. We maintain $S_n.\text{min}'$ (resp., $S_n.\text{max}'$) such that $S_n.\text{min}'$ (resp., $S_n.\text{max}'$) contains an element e with position x , height y , and a value $e.v = e'$ iff $S_n.\text{min}$ (resp., $S_n.\text{max}$) contains the triple (e', x, y) .

Answering a `reportsub`(S_n, i, j, q) query: If $i > j$ or $S_n = \emptyset$, we report nothing. Otherwise, let M be the set of pairs $\{(e.v, e.y) \mid e \in \text{report}(S_n.\text{min}', i, j, q) \cup \text{report}(S_n.\text{max}', i, j, q)\}$. We then iterate the following as long as possible: Take a pair $(e, y) \in M$, where e points to a recursive structure T in our induction on n , and replace the pair with (e', y) and (e'', y) assuming $T.\text{min}[y] = (e', x', y)$ and $T.\text{max}[y] = (e'', x'', y)$. We observe that the time we spend on performing these replacements is proportional to $|M|$. After this, report the elements $\{e \mid \exists y.(e, y) \in M\}$.

If $i = 0$ or $j = n - 1$, we stop. Otherwise, if $i \operatorname{div} \sqrt{n} = j \operatorname{div} \sqrt{n}$, we perform a `reportsub`($S_n.\text{bottom}[i \operatorname{div} \sqrt{n}], i \bmod \sqrt{n}, j \bmod \sqrt{n}, q$) query. Finally if $i \operatorname{div} \sqrt{n} \neq j \operatorname{div} \sqrt{n}$, we split the query into the three queries `reportsub`($S_n.\text{bottom}[i \operatorname{div} \sqrt{n}], i \bmod \sqrt{n}, \sqrt{n} - 1, q$), `reportsub`($S_n.\text{top}, i \operatorname{div} \sqrt{n} + 1, j \operatorname{div} \sqrt{n} - 1, q$), and `reportsub`($S_n.\text{bottom}[j \operatorname{div} \sqrt{n}], 0, j \bmod \sqrt{n}, q$). We note that the first and the last of these three queries are answered by just looking at the `min`, `min'`, `min`, and `max'` fields in the recursive structure. To analyze the space usage of S_n we need the following lemma.

LEMMA 4. *Suppose p is defined by $p(0) = 2$ and $p(h) = 2 + (1 + 2^{2^{h-1}})p(h - 1)$ for $h \geq 1$. Then $p(h) \leq (h + 1)2^{2^h}$.*

Proof. We show the lemma by induction on h . For $h = 0$ the lemma is trivially true. Suppose $h \geq 1$ and that the lemma is true for less h . Then we have $p(h) \leq 2 + (1 + 2^{2^{h-1}})h2^{2^{h-1}} = 2 + h2^{2^{h-1}} + h2^{2^h} \leq 2^{2^h} + h2^{2^h} = (h + 1)2^{2^h}$.

With p as in the lemma we observe that $p(\log \log n)$ is the number of `min`, `max`, `min'`, and `max'` structures we need and the lemma then bounds the space usage of S_n to $O(S_n \log \log n)$ bits as desired.

The running time of the update operations in S_n is $O(U \log \log n)$. This follows from the observation that when an update operation operates in more than one recursive structure, it does a nonconstant number of updates in at most one of these. A similar argument shows that the S_n has query time $O(Q \log \log n)$ concluding our proof of Theorem 1. \square

5. Lists, trees, and predecessor. In sections 5.1 to 5.5 we review various well-known data structures for lists, trees, and the predecessor problem. In sections 5.6 and 5.7 we develop some new results based on some of these well-known structures.

5.1. The predecessor problem. In this section we review various data structures for the predecessor problem. We have already cited one such structure, namely the VEB of Theorem 3. Combining the hashing scheme of [22] with Willard [41] we get the following structure.

LEMMA 5. *If we allow randomization, the space usage of Theorem 3 can be reduced to $O(n \log U)$ bits. The update time is then with probability $1 - n^{-c}$ for any desired constant $c > 0$.*

Building on Beame and Fich [8], Andersson and Thorup [5] have shown the following theorem.

THEOREM 6. *There exists a data structure called a BFAT which can maintain a collection of n elements having keys in $[0 \dots U]$. The structure uses space $O(n \log U)$ bits and supports updates as well as predecessor and successor queries in time $O(\min(\sqrt{\log n / \log \log n}, \log \log n \log \log U / \log \log \log U))$. U is called the universe size and we require $U = 2^{O(w)}$, where w is the word size in bits.*

We will take the time usage of Theorem 6 to be $O(\log^2 \log U)$ (recall that we write $\log^i \log U$ for $(\log \log U)^i$). This is possible since we will always have $n \leq U$ and thus $\log \log n \log \log U / \log \log \log U \leq \log^2 \log U$.

5.2. WBB trees. In this section we review WBB trees (weight balanced B-trees). Variants of these trees have been described by Willard [43], Dietz [19], and Arge and Vitter [7]. The description here is similar to the one in [7], where more details can be found.

Like an (a, b) -tree a WBB tree is a multibranching search tree where (1) elements are kept in the leaves, (2) keys to guide the search are kept in internal nodes, and (3) all leaves have the same depth (and height 0). We support updates to the tree in the form of insertions (not deletions) of elements. We define the weight of an internal

node as the number of elements in the leaves descendant to the node. The tree is parametrized over a *branching parameter* $d \geq 8$ and a *leaf parameter* $k \geq 1$. A leaf node must contain between k and $2k - 1$ elements. When an insertion makes a leaf node contain $2k$ elements it is split into two leaves, each with k elements. An internal node v at height h must have weight between kd^h and $4kd^h$, except if v is the root, in which case we require it only to have weight at most $4kd^h$. When an insertion gives v weight exactly $3kd^h$ a key in v is *marked* such that there is at least kd^h elements descendant to v both to the left and to the right of the marked key. Such a key exists because $(k3d^h - k4d^{h-1})/2 = kd^h(3 - 4/d)/2 \geq kd^h$. When v gets weight exactly $4kd^h$ it is split at the marked key. When a node w (leaf or internal) splits, a new child and a new key are inserted into the parent of w . If w is the root node, a parent of w is first created as new root. The following lemma gives central properties for WBB trees.

LEMMA 7. *Let T be a WBB tree with branching parameter d , leaf parameter k , and n elements. Then we have the following:*

1. *A leaf contains between k and $2k - 1$ elements.*
2. *Internal nodes have degree $O(d)$.*
3. *T has height at most $\min(\log n, O(\log n / \log d))$.*

Further, let $v \in T$ be an internal node at height $h \geq 1$. Then we have the following:

4. *At most one key in v is marked and when v splits it is at the marked key.*
5. *There are at most $4kd^h$ and at least kd^{h-1} elements descendant to v .*
6. *Exactly kd^h insertions are performed in leaves descendant to v from the time when a key in v is marked until the time when v splits.*

As observed in [7], in WBB trees we can maintain secondary structures in each internal node v containing all elements in leaves descendant to v and at the same time have worst case time performance on updates: When a key in v is marked, we can start to build the secondary structures for the two nodes v will eventually split into. Each time an update is performed in a leaf descendant to v we move a constant number of elements to the two new secondary structures. Items 5 and 6 in Lemma 7 ensure that we have sufficient time to do this and item 4 of the lemma ensures that we know which elements to put into which of the two new secondary structures. We finally remark that we can assume there are pointers between an internal node and its children.

5.3. The list order problem. The following theorem is shown by Dietz and Sleator [21]. This theorem was mentioned in the introduction as the theorem allowing us to transform a structure for the list order variant into a structure for the comparison order variant.

THEOREM 8. *There exists a linear sized data structure for a linked list supporting deletion and insertion of list elements in constant time such that we for given list elements e and e' in constant time can determine if $e < e'$.*

5.4. The online list labeling problem. We define the online list labeling problem as follows (other similar definitions are used in other papers; see, e.g., [47]). Let L be a linked list with at most n elements supporting insertions and deletions of elements. We must for each element $e \in L$ maintain an integer label $e.\text{label}$ of size $O(n)$ such that for $e, e' \in L$,

$$(2) \quad e < e' \implies e.\text{label} < e'.\text{label}.$$

An algorithm solving this problem is allowed to change the label of (relabel) elements when an element is inserted into or deleted from L . We require (2) to be maintained

during this relabeling. If the algorithm relabels at most m elements on each insertion into or deletion from L , we say that the algorithm has *relabeling cost* m . The following theorem is shown by Willard [44].

THEOREM 9. *There exists an algorithm for the online list labeling problem with relabeling cost $O(\log^2 n)$ and space usage $O(n \log n)$ bits, which uses time $O(\log^2 n)$ for insertions and deletions.*

5.5. List block balancing. The following theorem is proved by Dietz and Sleator [21, Theorem 5]. Recall that the Harmonic numbers $H_n = \sum_{i=1}^n 1/i$ satisfy $H_n = \Theta(\log n)$.

THEOREM 10. *Suppose x_1, \dots, x_n are variables which are initially zero. Iterate the following two steps. (1) Add a nonnegative value to each x_i such that $\sum_{i=1}^n x_i$ increases by at most one. (2) Set a largest x_i to zero. Then for all i , $1 \leq i \leq n$, we always have $x_i \leq 1 + H_{n-1}$.*

The next lemma follows directly from this theorem.

LEMMA 11. *Suppose $k \geq 1$ and that \mathcal{C} is a collection of at most n sets and that initially $\mathcal{C} = \{\emptyset\}$. Iterate the following two steps. (1) Add at most k elements to the sets of \mathcal{C} . (2) If $M \in \mathcal{C}$ is a largest set in \mathcal{C} and $|M| \geq 5k(1 + H_{n-1})$, then split M into two sets each of size at least $2k(1 + H_{n-1})$ and let these replace M in \mathcal{C} . Then for all $M \in \mathcal{C}$ we always have $|M| \leq 6k(1 + H_{n-1})$.*

We now describe a general technique used in [21] which we will call *list block balancing* with *block size* $s \geq \log^3 n$. We use this technique as a part of the steps O4 and O9 in section 3.2 where we group elements of an axis into numbered blocks and use this to convert a static axis to a dynamic axis.

Let L be an initially empty linked list in which at most $O(n)$ updates in the form of insertions and deletions can be performed. We want to maintain a grouping of the elements of L in blocks of size at most s respecting the order of the elements. Further, we want to maintain an integer label of size $O(n/s)$ for each block such that labels are always strictly increasing over the blocks.

Assume first that only insertions and not deletions can be performed in L . Define $k = s/(6(1 + H_{n-1}))$ and note that $k = \Theta(s/\log n)$. When a block contains $\lceil 4k(1 + H_{n-1}) \rceil$ elements, we *mark* the middle position of the block. For every k th insertion in L we take (in constant time) a block with most elements, and if it has $5k(1 + H_{n-1})$ elements or more, we split it into two at the marked position. Lemma 11 gives that no block becomes larger than s . We use Theorem 9 to assign labels to the blocks. Each block split requires $O(\log^2 n)$ relabelings and we distribute this work over the k insertions until the next split. It can be seen that we have to relabel a block for every $\Omega(k/\log^2 n) = \Omega(s/\log^3 n)$ insertion in L . We note that from the time a position in a block is marked until the block is split, $\Omega(s)$ insertions are performed in the block. This allows us to move all existing elements of the block into the two new blocks and possibly insert them into some data structure maintained in each block. This includes maintaining pointers between a block and the elements it contains. We finally describe how to handle deletions of elements in L . We maintain a list L' which has L as a sublist. We never delete elements from L' , but when we insert an element in L we also insert it in L' such that L remains a sublist of L' . We then use the algorithm just described to maintain a block division of L' which induces the wanted block division on L (some blocks in L may become empty). The following lemma gives central properties for the list block balancing technique.

LEMMA 12. *Let L be an initially empty linked list in which at most $O(n)$ updates in the form of insertions and deletions can be performed. If we use list block balancing*

with block size $s \geq \log^3 n$ on L , then we have the following:

1. Each block has size at most s .
2. Each block has a label of size $O(n/s)$. Further, $\Omega(s/\log^3 n)$ insertions are performed in L between each relabeling of a block.
3. At most one position in each block is marked, and when a block is split it is at the marked position.
4. At least $\Omega(s)$ insertions are performed in a block from the time it is marked until it is split.

5.6. A variant of the online list labeling problem. In this section we consider a variant of the online list labeling problem defined in section 5.4 where the elements are relabeled in subconstant time per element. This is the basis for the steps O2 and O6 in section 3.2 where we convert a static axis to a dynamic axis by relabeling coordinates. In the variant we consider, the user must assign to each element $e \in L$ a unique id of $O(\log n)$ bits when e is inserted into L , and this id cannot be changed as long as e remains in L . Further, we do not require the labels to be explicitly stored in the elements of L . Instead, we require that we can calculate the label of a given element in constant time. A similar approach was used by Dietz and Sleator [21] in their proof of Theorem 8. Finally, when an element is inserted into or deleted from L , the user must be given an array of triples describing the relabeling taking place because of the insertion or deletion. A triple (i, l, l') in this array means that the element with id i and current label l is given label l' . For technical reasons we allow only a total of $O(n)$ updates in the form of insertions and deletions to be performed in L .

When n is sufficiently small compared to N (that is, if we have a sufficiently large word size and can use a sufficiently large global lookup table), the following lemma gives a way to perform the relabeling caused by an insertion or deletion in constant time. In order to be able to do this, we pack the array describing the relabeling into a single word.

LEMMA 13. *If $\log^4 n \leq \log^{1-\epsilon} N$ for a constant $0 < \epsilon < 1$, the described variant of the online list labeling problem can be solved in constant time per insertion in and deletion from L , with a relabeling cost of $O(\log^3 n)$ and a space usage of $O(n \log n)$ bits.*

Proof. We use list block balancing with block size $\log^3 n$ on L . The label assigned to an element $e \in L$ in block b consists of the label of b multiplied with $\log^3 n$ plus the rank e has in b . This assignment of labels clearly fulfills (2) in section 5.4, and because blocks have labels of size $O(n/\log^3 n)$ the labels assigned to elements in L have size $O(n)$. Further, we need only to relabel $O(1)$ blocks for each insertion in L , and since blocks have size at most $\log^3 n$ we get a relabeling cost of $O(\log^3 n)$ as claimed.

For each block we maintain an array with the ids of the elements in the block in order. We store this array in a single word which is possible because it takes up only $O(\log^4 n)$ bits. These arrays can be used to find the label of a given element in constant time using a global lookup table. Also, using these arrays we can find the array of triples in constant time to return to the user because of an update. \square

5.7. The colored predecessor problem. In this section we consider the colored predecessor problem which we define as follows. Let L be a linked list with $O(n)$ elements into which new elements can be inserted and from which existing elements can be deleted. Further, the user must assign a color to an element when it is inserted into L , and the user can also change the color of an element in L . Given an element

$e \in L$ and a color c , we must be able to find the predecessor of e in L with color c . Dietz and Raman [20, Lemma 4.2] have shown the following theorem.

THEOREM 14. *With two colors the colored predecessor problem can be solved in time $O(\log \log n)$ for updates and queries and space $O(n \log n)$ bits.*

Using an extension of the techniques in [20] we show the following theorem, where we will use only the deterministic result. The theorem may be of independent interest, which is why we also provide the randomized result.

THEOREM 15. *The colored predecessor problem without restriction on the number of colors can be solved in space $O(n \log n)$ bits and in time $O(\log^2 \log n)$ for updates and queries. Alternatively, if we allow randomization, the time usage can be reduced to $O(\log \log n)$ and the update time is then with probability $1 - n^{-c}$ for any desired constant c .*

Proof. We first describe the randomized solution. The solution builds on ideas from the list block balancing technique. We first assume we can only update L by inserting a new element. Define $k = \log^2 n$. For each color c we divide the elements of L with color c into blocks with color c containing at most $6k(1 + H_{n-1})$ elements respecting the order of the elements. We store the elements of each block in a balanced binary search tree. We mark the first element of each block b with color c except if b is the first block in L with color c . We insert all elements of L into the structure of Theorem 14 using marked and not-marked as the two colors. We use Theorem 9 to assign a label $e.\text{label}$ to each marked element $e \in L$. We create a predecessor structure P_c of Lemma 5 for each color c , and each marked element $e \in L$ with color c is inserted into P_c at position $e.\text{label}$.

Answering queries: Suppose we want to find the predecessor of $e \in L$ with color c . We first use time $O(\log \log n)$ to find the marked predecessor e' of e in L . Assuming first that e' exists, we use $e'.\text{label}$ to perform a predecessor query in P_c which will identify a block b in time $O(\log \log n)$. If e' or b does not exist, we take b to be the first block in L with color c . The block b will contain the element we are looking for (provided it exists), and this element can then be found in time $O(\log \log n)$ using the binary search tree with the elements of b . We need to be able to compare two elements in L in constant time to do this, but this can be done using Theorem 8. We conclude that the total query time becomes $O(\log \log n)$.

Inserting an element e with color c in L : First, by performing a query as just described, we identify the strict predecessor e' of e with color c . We then insert e in the block containing e' . If e' does not exist, we insert e into the first block with color c . So far, we have used $O(\log \log n)$ time. We observe that e' will never become the first element of a nonfirst block with color c ; so far we do not need to remark elements in L because of the insertion. We now describe how to ensure that blocks do not become too big. Every time we have inserted k elements in L , we take (in constant time) a largest block, and if it has at least $5k(1 + H_{n-1})$ elements we split it in $O(\log \log n)$ time into two blocks, each with at least $2k(1 + H_{n-1})$ elements. Lemma 11 ensures that no block becomes too big. Splitting a block will mark a new element of L , and thus the structure of Theorem 9 requires us to change the label of $O(\log^2 n)$ marked elements. We distribute this work over the following $k = \log^2 n$ insertions in L performing $O(1)$ relabelings on each insertion. When relabeling a marked element with color c' we also update the structure $P_{c'}$ to reflect the new label of the element. Lemma 5 then gives that we get an update time of $O(\log \log n)$ with probability $1 - n^{-c}$ for any desired constant $c > 0$.

We now support that the user can *dot* an element $e \in L$ in time $O(\log \log n)$. When answering queries we must then ignore the dotted elements. We modify the

binary search tree in each block such that we can identify the predecessor of an element among the nondotted elements. This can be done by writing in each node if the subtree rooted in that node contains a nondotted element. Next, for each color c we modify the structure P_c such that we can perform a query among the blocks which contain at least one nondotted element. Using these modified structures we can answer queries as before with one remark. When we have searched in a block b we may discover that the predecessor e' of the query is contained in the predecessor block b' of b which contain at least one nondotted element. But we can find b' and then e' in time $O(\log \log n)$.

In order to make the data structure for L we do as in the list block balancing technique. We maintain a list L' using the data structure just described such that the nondotted elements of L' correspond to the elements of L in the same order. We can then answer queries in L by asking in L' . When we insert an element in L we also insert a corresponding element in L' . When we delete an element from L we dot the corresponding element in L' . When we change the color of an element in L we dot the corresponding element in L' and insert a new corresponding element with the new color in L' . Using global rebuilding [34] we can ensure that no more than $O(n)$ updates are performed in L' .

Finally, for the deterministic result, we just use a BFAT of Theorem 6 as P_c instead of the predecessor structure of Lemma 5. \square

For readers familiar with dynamic fractional cascading [17, 29, 20] we note that we will use Theorem 15 in situations where dynamic fractional cascading has traditionally been used. The reason for this is that if we use dynamic fractional cascading, the catalog graph will get high degree, leading to bad performance in the known data structures for dynamic fractional cascading.

6. Structures supporting 3-sided queries. The main purpose of this section is to perform the steps O1 to O4 in section 3.2, thus giving our final 3-sided range reporting structure. The data structure we develop will be based on the priority search tree of McCreight [27] and on extensions of the tree similar to the ones described by Willard [45] and Arge, Samoladas, and Vitter [6]. This is combined with the use of buffers in the style of Brodal [13].

This section is organized as follows. In section 6.1 we review priority search trees with the extensions of [45, 6]. In section 6.2 we describe a dictionary for points and in section 6.3 we describe how this dictionary can be transformed into a structure similar to the priority search tree of section 6.1. In section 6.4 we describe a way to implement the structure in section 6.3 for few points giving the structure of step O1. Also, we give this structure a dynamic y-axis performing step O2. In section 6.5 we look at 3-sided structures with many points first performing step O3 and finally step O4.

6.1. Priority search trees. The following theorem is essentially shown in [27].

THEOREM 16. *There exists a structure with type $R^3(d:n, d:n)$ and performance $(\log n, \log n, n \log n)$.*

The structure of the theorem is called a priority search tree. We will not show the theorem here. Instead, we will describe a way to make a structure R with type $R^3(s:n, s:n)$ or $R^3(s:n, d:n)$, and we will also refer to this structure as a priority search tree. The structure uses ideas from [27, 45, 6], where more details can be found. We defer the exact implementation details to later sections. We span a tree T with degree $d \geq 2$ and thus height $O(\log n / \log d)$ over $R.L_x$. For each node $v \in T$ we maintain a set $v.P$ such that the following invariants are fulfilled.

- j1. The sets $v.P$ for $v \in T$ are disjoint and their union are the points of R .
- j2. If $v \in T$ is a nonroot ancestor of $w \in T$ and $w.P$ is nonempty, then $v.P$ is nonempty.
- j3. If $v \in T$ is an ancestor of $w \in T$ and $p_w \in w.P$ and $p_v \in v.P$, then $p_v.y \leq p_w.y$.
- j4. If $v \in T$ and $p \in v.P$, then v is an ancestor of the leaf with $p.x$.

Observe that given the points of R and the values $|v.P|$ for all $v \in T$ there is at most one way to select $v.P$ for $v \in T$. We define for each internal node $v \in T$ the set $v.C$ as $\cup_{w \text{ child of } v} w.P$. Suppose we are given a query $(x_1, x_2, 0, y_2)$, where 0 is the first element in $R.L_y$. Let $M \subseteq T$ be the set of internal nodes which are an ancestor to a leaf with x_1 or x_2 and note that $|M| = O(\log n / \log d)$. The query is answered as follows:

- q1. For the root $v \in T$ report the points from $v.P$ inside the query region.
- q2. Set $M' = M$.
- q3. While M' is not empty, do the following:
 - q3.1. Remove a node v from M' .
 - q3.2. Report the points from $v.C$ which are inside the query region.
 - q3.3. Add to M' the internal nodes $u \in T \setminus M$ for which a point from $u.P$ was reported in item q3.2.

LEMMA 17. *We have the following:*

- 1. *All points of R inside the query region are reported.*
- 2. *All the descendant leaves to the nodes added to M' in item q3.3 are between x_1 and x_2 on $R.L_x$.*
- 3. *If item q1. and q3.2 can be handled in time $O(1 + r)$ when r points are reported, then the query time in R becomes $O(\log n / \log d)$.*

We now describe how to update R . We insert a point p into R by inserting it into $v.P$ for the root v of T . If this insertion breaks invariant j3 or if $v.P$ has become too big (according to some additional requirements we may have imposed), we take the point with the largest y-coordinate in $v.P$, remove it from $v.P$, and insert it recursively into $w.P$ for the child w of v such that invariant j4 is preserved. We delete a point by deleting it from the set $v.P$ in which it is located. If this deletion breaks invariant j2 or if $v.P$ becomes too small (again, according to some additional requirements), we take the point p' from $v.C$ with minimal y-coordinate, add p' to $v.P$, and recursively delete p' from the set $w.P$ in which it is located (w will be a child of v).

6.2. A dictionary for points. In this section we describe a dictionary for points. Besides supporting insertion of new points, it supports deletion and lookups of existing points given their x-coordinate. The dictionary uses ideas from [13]. In section 6.2 we modify the dictionary to support 3-sided queries in the style of section 6.1. We require updates to be performed such that two different points which are in the dictionary at the same time do not have the same x-coordinate. Further, it is not legal to perform a delete operation on a point which is not in the dictionary.

Our dictionary is parametrized over three parameters $d \geq 8$, g , and r , where $g \geq r$. We create a WBB tree T with branching parameter d and leaf parameter g . We keep pebbles in the nodes of T . Each pebble represents a point and there exists three kinds of pebbles: light pebbles, insert pebbles, and delete pebbles. Light pebbles are green, while insert and delete pebbles are red. We think of light pebbles as representing contained points and of red pebbles as representing updates which are not fully completed. The internal nodes can contain only red pebbles and leaf nodes can contain only green pebbles. It is important to distinguish between pebbles

and elements in the WBB tree—the former are used to describe which points the dictionary contains, while the latter are used to balance the tree and to maintain keys to guide the search in internal nodes. For $h \geq 1$ define

$$\begin{aligned} m_h &= r \left((d-2)/(d-1) + \sum_{n=h}^{\infty} 1/d^n \right) \\ &= r(d^h - 2d^{h-1} + 1)/(d^h - d^{h-1}). \end{aligned}$$

Because $h \geq 1$ we have $m_h \leq r$. The following procedure describes how to perform $r/3$ updates to the dictionary where pebbles describing the updates are added in item u3. In this section we do not add any pebbles in item u2 or item u4.1, but we allow it to be done to support our modifications in section 6.3.

- u1. Set v to the root of T and h to the height of v .
- u2. Add at most r/d^h red pebbles to v .
- u3. Add at most $r/3$ red pebbles to v representing the updates.
- u4. While v is not a leaf, do the following:
 - u4.1. Add at most r/d^h red pebbles to v .
 - u4.2. Take m_h red pebbles from v (or as many as there is if there is fewer) and move them (one at a time) to the children of v as determined by their x-coordinate and the keys to guide the search in v .
 - u4.3. Set v to the child of v which has most red pebbles and set $h = h - 1$.

Note that in case there is more than m_h red pebbles in v in item u4.2 we do not specify which pebbles to take. When a pebble enters a node $v \in T$ we apply the following items exhaustively:

- a1. If v contains a delete pebble p and an insert pebble p' such that p deletes p' , then remove both p and p' .
- a2. If v is a leaf and contains an insert pebble p , then (1) convert p to a light pebble and (2) if there is no element with the same x-coordinate as p in the WBB tree, insert such an element into v .
- a3. If v is a leaf and contains a delete pebble p , then remove the light pebble in v that p deletes (which we know is there).

When a node v is split the red and green pebbles are distributed to the two new nodes as determined by their x-coordinate and the marked key in v (if v is an internal node) or by their x-coordinate and the elements in v (if v is a leaf). Note that we can perform a lookup in the dictionary by looking at the pebbles in the nodes between a leaf and the root of T . We have the following lemma.

LEMMA 18. *At item u1, a maximal set of siblings at height $h \geq 1$ contains at most $(d-1)m_h$ red pebbles.*

Proof. First, observe that we can ignore splitting of nodes since they do not increase the number of pebbles in a maximal set of siblings. Further, there is no problem when a new root is created because it will contain no red pebbles. Consider the root node and assume it is not a leaf. Using $d \geq 8$ it is easy to show that $r/3 + 2r/d^h \leq m_h$, giving that all pebbles added to the root in items u2, u3, and u4.1 are removed again in item u4.2. Finally, consider a maximal set S of nonroot nonleaf siblings with height h . Assume by induction that the nodes in S contain at most $(d-1)m_h$ red pebbles. Assume further that they receive at most m_{h+1} pebbles from their common parent in item u4.2 and then receive additional, at most r/d^h , pebbles in item u4.1. The total number of red pebbles added to the nodes in S is then at most $m_{h+1} + r/d^h = m_h$. Let $s \leq dm_h$ be the total number of pebbles in the

nodes of S after this and let v be the node in S with most red pebbles selected in item u4.3. There must be at least s/d pebbles in v which are then removed in item u4.2. After this the nodes in S contain at most $s(1 - 1/d) \leq dm_h(1 - 1/d) = (d - 1)m_h$ red pebbles. \square

The following lemma gives central properties for the maintained structure.

LEMMA 19. *We have the following:*

1. *The execution of items u1 to u4 inserts at most r elements in T and this is done in a set of leaves which are siblings.*
2. *The space usage of T and its contained pebbles are linear in the number of insertions.*
3. *A leaf never contains more than $2g$ green pebbles.*
4. *A set of siblings never contains more than dr red pebbles.*

Proof. Items 1 and 2 are immediate. Item 3 follows from the fact that in each leaf there is an injective mapping from the green pebbles in the leaf to the elements of the WBB tree in the leaf. Finally, item 4 is true for leaf nodes since they contain no red pebbles. For internal nodes, item 4 is just a weak version of Lemma 18 because $m_h \leq r$. \square

6.3. A structure supporting 3-sided queries. We now make a number of modifications to the structure of section 6.2 in order to make it support 3-sided queries in the style of section 6.1. Initially, we will ignore marking of keys and splitting of nodes in T . As in section 6.2 two different points in the structure at the same time cannot have the same x-coordinate and in this section they cannot have the same y-coordinate either. We will still use insert and delete pebbles to represent updates which have not been fully completed. Also, the leaf nodes can still contain only light pebbles. However, we will now store both green and red pebbles in the internal nodes of T such that the green pebbles constitute a priority search tree of section 6.1. We will keep the following invariant which corresponds to invariant j3.

- i1. *The y-coordinate of a green pebble in a node v may not be larger than the y-coordinate of any pebble below v in T .*

For each internal node $v \in T$ we define a number $igreen(v)$ which we think of as the number of green pebbles we would like to be in v (there may be less but not more). If the root $v \in T$ is not a leaf, we require

$$(3) \quad 0 \leq igreen(v) \leq 2g$$

and for other internal nodes for $v \in T$ we require

$$(4) \quad g \leq igreen(v) \leq 2g.$$

As described below, a green pebble may be deleted by a red pebble, thus bringing the number of green pebbles in v down below $igreen(v)$. For this reason we introduce a new red pebble called a *poll* pebble which basically says that there should be a green pebble which is not there. Whenever a poll pebble is moved from a node v to one of its children w in step u4.2, we move a green pebble from w to v . This is made more precise below. We maintain the following invariant.

- i2. *Suppose v is an internal node and let v_o denote the number of poll pebbles and v_g the number of green pebbles in v . Then we require $igreen(v) = v_g + v_o$. It may happen that we have no light pebble to move from w to v because all light pebbles in that part of the tree have either been deleted or moved up higher in the tree. For this reason we also introduce a new green pebble which we call a *heavy**

pebble. A heavy pebble has no x-coordinate but has a y-coordinate larger than all nonheavy pebbles. According to invariant i1, a heavy pebble will never be above a light pebble in the tree; thus the names heavy and light pebble. When we consider splitting of nodes in T below, we relax invariant i1 such that this is not always true.

We now describe what happens when a red pebble enters a node $v \in T$ in item u4.2. We apply the following items exhaustively in addition to items a1 and a2 above (items a5 and a6 make item a3 superficial):

- a4. Let p be an insert pebble in v and let p' be a green pebble in v with the largest y-coordinate among the green pebbles in v . If p has a smaller y-coordinate than p' , then (1) convert p to a light pebble; (2) if p' is a light pebble, convert it to an insert pebble; and (3) if p' is a heavy pebble, remove it.
- a5. If v contains a delete pebble p and a light pebble p' such that p deletes p' , then remove p and p' and add a poll pebble to v .
- a6. If v is a leaf, remove any poll pebble from v .

The following item describes how a poll pebble p in a node v is moved to a child of v in item u4.2. This does not follow from the description so far because poll pebbles have no x-coordinate.

- m1. Let p' be the green pebble with the smallest y-coordinate among the green pebbles stored in the children of v if it exists. If p' exists, interchange p and p' . If p' does not exist, add a heavy pebble to v and remove p .

We note that items a4, a5, a6, and m1 never increase the number of red pebbles in a node. Thus, the described pebble game is indeed just a variant of the game of section 6.2 and all the lemmas of section 6.2 still hold. Also it can be checked that invariants i1 and i2 are never broken.

The described structure can answer 3-sided queries as in section 6.1 in the following sense. In items q1 and q3.2 we report the points represented by the insert and light pebbles in the node. However, we do not report a point which is deleted by a delete pebble above it. We can avoid this as follows. First, we implement M' as a stack so that T is traversed in depth-first order. Next, while we traverse T we maintain the set of delete pebbles contained in the nodes which are ancestors to the node we are currently visiting. We then report a point only if it is not in this set. In order for the algorithm to work, we must maintain some variant of invariant j2. Essentially this is done by ensuring that all internal nonroot nodes $v \in T$ contain at least one green pebble which is not deleted by a delete pebble above it. We handle this issue in detail in section 6.4.

We now describe how to handle marking of keys and splitting of nodes in T and how to select $igreen(v)$ for internal nodes $v \in T$. If v does not have a marked key, we select $igreen(v) = 0$ if v is the root and $igreen(v) = g$ otherwise. Assume for the rest of this paragraph that v is an internal node with a marked key. Each time we pass through v in item u2 or item u4.1 we increase the value of $igreen(v)$ with $\min(2g - igreen(v), r/d^h)$ and we add the same amount of poll pebbles to v to preserve invariant i2. Since each pass through v adds at most r elements to T below v (item 1 of Lemma 19) it follows from property 6 of Lemma 7 that when v is split into v' and v'' , we have $igreen(v) = 2g$. We then set $igreen(v') = igreen(v'') = g$. In the following we modify our structure such that invariant i2 and a relaxed version of invariant i1 are preserved in v' and v'' . We will say a child of v is a child of the left (resp., right) side of v if the keys of the child are all smaller (resp., larger) than the marked key in v . Similarly, we will say a pebble is in the left (resp., right) side of v if it has an x-coordinate and if this coordinate is smaller (resp., larger) than the marked key in v . We will put each heavy pebble in the left or right side of v , and this determines

where the pebble should go when v splits. We will replace invariant i1 with invariant i1' and i1". These variants are weaker than invariant i1. Also, we will introduce a new invariant, i3.

- i1'. The y -coordinates of the g green pebbles (or all of them if there are less than g green pebbles) in a nonroot node w with smallest y -coordinates may not be larger than the y -coordinate of any pebble below w in T .
- i1". If an internal node v has a marked key, the y -coordinate of a green pebble in the left (resp., right) side of v must not be larger than the y -coordinate of any pebble below the left (resp., right) side of v .
- i3. If an internal node v has a marked key, there can be at most g green pebbles in each side of v .

Invariant i1' is sufficient to ensure we can use the same query algorithm as outlined above. Further, it can be checked that invariants i1" and i3 allow us to preserve invariant i1' when we split a node. Inspired by invariant i3 we will say the left (resp., right) side of v is *full* if v has a marked key and the left (resp., right) side of v has g green pebbles.

We now modify the way we maintain our structure in order to preserve these modified invariants. First, we modify the way we select p' in item m1 as follows. If a side of v is full, we select p' to be the green pebble with the smallest y -coordinate among the green pebbles stored in the children of the nonfull side of v . Further, if we add a heavy pebble in item m1, we do it to a nonfull side. Next, we modify the way we select p' in item a4 as follows. If p is on a full side of v , we let p' be a green pebble in v with the largest y -coordinate among the green pebbles in v on the same side of v as p . With these modifications it can be checked that the modified invariants are preserved.

6.4. Few points. The proof of the following lemma gives a way to implement the structure from section 6.3 if there are few points. This is the structure from step O1 in section 3.2.

LEMMA 20. *Suppose $d \geq 8$ and that $1 \leq t \leq (\log^{1-\epsilon} N)/(d^2 \log^3 u)$ for a constant $0 < \epsilon < 1$. Then there exists a structure with type $R^3(s : u, s : u)$ and performance $(1, 1 + \log u / \log d, u \log u, t)$.*

Proof. As a basis for the structure we use the tree T from section 6.3 with the same value of d as in the lemma here.

We store as a part of each insert and light pebble the point it represents including x - and y -coordinates using $O(\log u)$ bits for each pebble. Next, we store as a part of each delete pebble the coordinates of the point it deletes, again using $O(\log u)$ bits. Poll and heavy pebbles do not have any associated information, so any pebble can be stored using $O(\log u)$ bits. Lemma 19 item 2 now gives that the space usage of T is linear in the number of insertions performed. Using global rebuilding of [34] we can get space usage $O(u \log u)$ bits and, further, Lemma 7 property 3 gives that we can keep the height of T on at most $\min(2 \log u, O(\log u / \log d))$ (we use $2 \log u$ instead of $\log u$ because we use global rebuilding on T).

In order to get constant update time, we modify the structure as follows. We maintain a set U of insert and delete pebbles. The user can then perform t updates by adding t pebbles to U (using a global lookup table to convert them to the appropriate format). Each time the user does this we execute a constant number of steps in item u4. In item u3 we take all pebbles in U and insert them into the root of T . Since T has height $O(\log u)$ there are not too many pebbles in U if

$$(5) \quad t \log u \leq r.$$

We will select g and r such that the following properties are fulfilled.

- k1. All pebbles in a maximal set of siblings of T can be stored in $O(\log^{1-\epsilon} N)$ bits in a single word.
- k2. The maximal size of U plus the maximal number of red pebbles on a root path is larger than the minimal number of green pebbles in an internal node fulfilling invariant i1'.

Property k1 together with a global lookup table of size $2^{\log^{1-\epsilon} N}$ allows us to perform item u4.2, item u4.3, and the corresponding updates in the involved nodes in constant time. Updating T will take constant time since we have just argued it consists of a constant number of steps, each taking constant time. Note that in order for this to work, it is central that we explicitly store the x - and y -coordinates as a part of the insert, delete, and light pebbles. Property k2 together with invariant i1' implies that any internal node v contains a green pebble p which is not deleted by a delete pebble above it and such that all green pebbles in nodes descendant to v have a y -coordinate not smaller than p (p may be a heavy pebble). This essentially ensures that invariant j2 is fulfilled. More precisely it ensures that the query algorithm outlined in section 6.3 reports all points inside the query region. Also, using a global lookup table with size $2^{\log^{1-\epsilon} N}$ we can execute items q1 and q3.2 in time $O(1+r)$ when r points are reported. Lemma 17 item 3 then gives that we get query time $O(\log u / \log d)$ in T .

We now discuss how to select g in order to fulfill property k1. Because $g \geq r$, Lemma 19 items 3 and 4 together with (3) and (4) implies that a set of siblings never contains more than $3dg$ pebbles. Since each pebble uses $O(\log u)$ bits, property k1 is fulfilled if $dg \log u \leq \log^{1-\epsilon} N$. So we select

$$(6) \quad g = (\log^{1-\epsilon} N) / (d \log u).$$

We then describe how to select r in order to fulfill property k2. Using Lemma 19 item 4 the number of green pebbles in an internal node is at least $g - dr$. If we also use the fact that T has height at most $3 \log u$ (it also has height at most $2 \log u$, but we use $3 \log u$ to support the modifications in the proof of Lemma 25), the number of red pebbles on a root path plus the number of pebbles in U is at most $r + 3dr \log u$. So we require $r + 3dr \log u < g - dr$ which is fulfilled if $4dr \log u \leq g$. So based on (6) we select

$$(7) \quad r = (\log^{1-\epsilon} N) / (4d^2 \log^2 u).$$

Equation (5) together with (7) now gives our requirement for t . \square

The reader may observe that a tree with fixed shape instead of the more complicated WBB tree appears to be sufficient in order to prove Lemma 20. The reason we use a WBB tree is the proof of Lemma 30.

In order to perform step O2 in section 3.2 we need to give the structure of Lemma 20 a dynamic y -axis. Since the same construction is needed in step O7 we prove the following general lemma which can do this transformation.

LEMMA 21. *Suppose $\log^4 u \leq \log^{1-\epsilon} N$ for a constant $0 < \epsilon < 1$ and there exists a structure with type $R^\tau(s : u, s : u)$ (resp., $R^\tau(s' : u, s : u)$) and performance $(U, Q, S, \log^3 u)$. Then there exists a structure with type $R^\tau(s : u, d : u)$ (resp., $R^\tau(s' : u, d : u)$) and performance (U, Q, S) .*

Proof. We describe a solution in which at most $O(u)$ updates can be performed. This restriction can be removed by the use of global rebuilding [34]. Let R be the structure with type $R^\tau(s : u, d : u)$ (resp., $R^\tau(s' : u, d : u)$) we want to design from the structure R' with type $R^\tau(s : u, s : u)$ (resp., $R^\tau(s' : u, s : u)$). We assume each

element $e \in R$ has a unique id $e.id$ of size $O(u)$ which we must report when reporting an element from a query in R . We maintain a labeling of the elements of $R.L_y$ using Lemma 13 getting the requirement $\log^4 u \leq \log^{1-\epsilon} N$. If $e \in R$, then as id for $e.y \in R.L_y$ we use the pair $(e.id, e.x)$. Lemma 13 then assigns a label $y.label$ of size at most $O(u)$ to each $y \in R.L_y$. For each element $y \in R.L_y$ with id (i, x) we keep an element in R' with y-coordinate $y.label$, x-coordinate x , and id i . This can be done by using a global lookup table to convert the array of triples provided by Lemma 13 into updates to give to R' . A query $(x_1, x_2, y_1, y_2) \in R$ is then answered by performing the query $(x_1, x_2, y_1.label, y_2.label)$ in R' . \square

We remark that we cannot use the same technique to give the structure two dynamic axes. We finally get the structure of step O2 in section 3.2.

LEMMA 22. *Suppose $d \geq 8$ and that $\log^6 u \leq (\log^{1-\epsilon} N)/d^2$ for a constant $0 < \epsilon < 1$. Then there exists a structure with type $R^3(s : u, d : u)$ and performance $(1, 1 + \log u / \log d, u \log u)$.*

Proof. Selecting $t = \log^3 u$ in Lemma 20 gives a structure with type $R^3(s : u, s : u)$ and performance $(1, \log u / \log d, u \log u, \log^3 u)$. Further, we get the requirement that $\log^3 u \leq (\log^{1-\epsilon} N)/(d^2 \log^3 u)$ or, equivalently, $\log^6 u \leq (\log^{1-\epsilon} N)/d^2$. Finally, inserting the obtained structure into Lemma 21 gives the desired result since the requirement $\log^4 u \leq \log^{1-\epsilon} N$ is fulfilled by our other requirement for u . \square

6.5. Many points. The following lemma gives our structure from step O4.

LEMMA 23. *For any sufficiently small constant $\epsilon > 0$ there exists a structure with type $R^3(s : n, d : n)$ and performance $(1 + \log n / \log^{1/6-\epsilon} N, 1 + \log n / \log \log N, n \log n)$.*

Proof. Define $u = \min(n, 2^{\log^{1/6-\epsilon/2} N})$. We let R' be the structure we get from Lemma 22 if we set d in the lemma to $\log^\epsilon N$. Then the maximal u we can use in the lemma is equal to the u we have just defined and R' gets type $R^3(s : u, d : u)$ and performance $(1, 1 + \log u / \log \log N, u \log u)$.

We assume for the rest of the proof that $n \geq u$ and thus $u = 2^{\log^{1/6-\epsilon/2} N}$ since otherwise R' is the structure we need to prove the theorem. We let the structure R with type $R^3(s : n, d : n)$ we want to design be a priority search tree of section 6.1. We give T degree u and require $|v.P| \leq 1$ for all $v \in T$. In each internal node $v \in T$ we keep a structure $v.R$ with the same type as R' . Let $v \in T$ be an internal node and assume $p \in w.P$ for a child w of v . We then store a point $p' \in v.R$ corresponding to p with $p'.y = p.y$ and with $p'.x$ set to the number of siblings w has to the left in T . Also, we link p and p' together with pointers. For each element $e \in R.L_y$ there is a unique node $v \in T$ and a unique element $e' \in v.R.L_y$ such that e and e' represent the same y-coordinate. We make a pointer from e to e' and color e with the color v . We maintain the colored predecessor structure of Theorem 15 on $R.L_y$ using the assigned colors.

We answer queries as in section 6.1 with the following remarks. Assume first a node $v \in M \cap M'$ is picked in item q3.1. In item q3.2 we then do as follows. For the (at most two) children $w \in M \cap M'$ of v we report the point in $w.P$ if it is in the query region. The remaining points to report can be found by a query in $v.R$. In order to find the y-coordinate to use in this query we make a query for the color of v in the structure of Theorem 15 maintained on $R.L_y$. We conclude that we must use a total time of $O(\log u / \log \log N + \log^2 \log n + r)$ to report r elements from v . This is also $O(\log u / \log \log N + r)$ since $u \leq n \leq N$. Assume next a node $v \in M' \setminus M$ is picked in item q3.1. Then Lemma 17 item 2 gives that we should report all the points in $v.C$ with a sufficiently low y-coordinate. These points can be found in constant time per point by walking through $v.R.L_y$ from the beginning stopping when the y-coordinate

becomes too big. Since $|M| = O(\log n / \log u)$ we conclude that the query time in R becomes $O((\log u / \log \log N) \log n / \log u) = O(\log n / \log \log N)$.

Updates can also be performed as in section 6.1 with remarks similar to the ones described for queries. For a total of $O(\log n / \log u)$ nodes $v \in T$ we need to update $v.R$ and to recolor an element of $R.L_y$. Updating $v.R$ takes constant time, while updating $R.L_y$ takes time $O(\log^2 \log n)$. The total update time thus becomes $O(\log^2 \log n \log n / \log u) = O(\log^2 \log n \log n / \log^{1/6-\epsilon/2} N) = O(\log n / \log^{1/6-\epsilon} N)$ as claimed. \square

Finally, the following theorem gives the structure of step O4 from section 3.2. For $n = N$ this gives the second result from the introduction.

THEOREM 24. *For any sufficiently small constant $\epsilon > 0$ there exists a structure with type $R^3(d : n, d : n)$ and performance $(\log \log n + \log n / \log^{1/6-\epsilon} N, \log \log n + \log n / \log \log N, n \log n)$.*

Proof. We describe a solution in which at most $O(n)$ updates can be performed. This restriction can be removed by the use of global rebuilding [34]. Let R be the structure with type $R^3(d : n, d : n)$ we want to design. We maintain a structure T of Lemma 23 with type $R^3(s : n / \log^3 n, d : n / \log^3 n)$ and performance $(1 + \log n / \log^{1/6-\epsilon} N, 1 + \log n / \log \log N, n / \log^2 n)$. We use list block balancing with block size $\log^3 n$ on $R.L_x$. We keep the points of a block b in a structure $b.R$ of Theorem 16. Let b be a block with assigned label x and let y be the first element of $b.R.L_y$. We then insert b in T with x -coordinate x and y -coordinate y . This is possible because labels of blocks have size $O(n / \log^3 n)$. If an element $e \in R.L_y$ represents the same y -coordinate as an element $e' \in T.L_y$ (resp., $e'' \in b.R.L_y$), we link e and e' (resp., e'') together with pointers.

We maintain the structure of Theorem 14 on $R.L_y$ giving elements which have a pointer to an element in $T.L_y$ one color and other elements another color. This allows us to identify the position in $T.L_y$ of any element in $R.L_y$ in time $O(\log \log n)$. For each block b we keep the elements of $b.R.L_y$ in a balanced binary search tree and we maintain a structure of Theorem 8 on $R.L_y$. This allows us to identify the position in $b.R.L_y$ of any element in $R.L_y$ also in time $O(\log \log n)$.

We need to relabel $O(1)$ blocks for each update in R , so we need to perform $O(1)$ updates in T for each update in R . Since updating $b.R$ for a block b and identifying elements in and updating $b.R.L_y$ and $T.L_y$ takes time $O(\log \log n)$ the total update time becomes $O(\log \log n + \log n / \log^{1/6-\epsilon} N)$.

We now describe how to answer a query $(x_1, x_2, 0, y_2)$, where 0 is the minimal element of $R.L_y$. Let b_1 be the block with x_1 and b_2 be the block with x_2 . We then answer the query by first making a local query in $b_1.R$ and then a local query in $b_2.R$ using time $O(\log \log n)$ (if $b_1 = b_2$, we need only to perform one local query in total). The remaining points can be found by performing a query in T . For each reported block b we identify the points from b to report by walking through $b.R.L_y$ from the beginning stopping when the y -coordinate becomes larger than y_2 (as in the proof of Lemma 23). Identifying the elements to query from in $b_1.R.L_y$, $b_2.R.L_y$, and $T.L_y$ requires time $O(\log \log n)$, so the total query time becomes $O(\log \log n + \log n / \log \log N)$. \square

7. Structures supporting 4-sided queries. The purpose of this section is to perform steps O5 to O10 in section 3.2, thus giving our final 4-sided range reporting structure for the 2-dimensional case. The section is organized as follows. In section 7.1 we describe a simple way to make a structure supporting 4-sided queries from one supporting 3-sided queries. In section 7.2 we use this to perform steps O5, O6,

and O7. We then apply the construction from section 4 to perform step O8 and then we perform step O9. Finally, in section 7.3 we perform step O10.

7.1. From 3-sided to 4-sided. In this section we describe a simple way to make a structure supporting 4-sided queries from one supporting 3-sided queries. Similar ideas have been used by Chazelle [14] and Overmars [35]. Suppose for any m , $m \leq n$, we have a structure with type $R^3(s' : n, s : m)$ and performance (U_m, Q_m, S_m) . We will now describe how to make a structure R with type $R^4(s' : n, s : n)$ and performance $(U_n \log n, Q_n, S_n \log n)$, provided U_m and Q_m are nondecreasing functions of m and provided S_m is a subadditive function of m . We span a complete binary tree T over $R.L_y$. Each node $v \in T$ spans a subinterval I of $R.L_y$, where $|I| \leq n$. We store in v two secondary structures $v.R_1$ and $v.R_2$ both with type $R^3(s' : n, s : |I|)$ and both containing all points of R with a y -coordinate in I . The structure $v.R_1$ (resp., $v.R_2$) should support queries of the form (x_1, x_2, y_1, y_2) , where y_1 (resp., y_2) is the leftmost (resp., rightmost) element in I . Inserting (resp., deleting) a point p into (resp., from) R requires inserting (resp., deleting) p into (resp., from) two secondary structures in each of the $O(\log n)$ ancestors of the leaf of T with $p.y$ using time $O(U \log n)$. Suppose we are given a query (x_1, x_2, y_1, y_2) . Let $v \in T$ be the nearest common ancestor of y_1 and y_2 and let v_l be the left and v_r the right child of v . The query can then be answered by performing a single query in $v_l.R_2$ and a single query in $v_r.R_1$ giving a query time $O(Q)$.

7.2. At least one short axis. The following lemma gives the structure from step O5 of section 3.2.

LEMMA 25. *Suppose $1 \leq t \leq (\log^{1-\epsilon} N)/\log^4 u$ for a constant $0 < \epsilon < 1$. Then there exists a structure with type $R^4(s' : u, s : u)$ and performance $(1, 1 + \log u, u \log^2 u, t)$.*

Proof. We will first how to construct a structure with type $R^4(s : u, s : u)$ and the claimed performance. We will do this by combining the proof of Lemma 20 with the construction in section 7.1. We keep all points in the dictionary of section 6.2. To avoid confusion we call the tree T' instead of T . Further, we make a number of modifications and simplifications described in the following. First, we use the y -instead of the x -coordinates of points. Second, we let T' be a complete binary tree with fixed shape, so nodes never split and keys are never marked. This implies that each leaf contains at most one green pebble. Third, we define $m_h = r/3$ for all h . Fourth, in our procedure for performing $r/3$ updates in T' we remove items u2 and u4.1. Lemma 18 can be shown to still hold with these modifications (a simpler proof carries through).

As in section 7.1 we have two secondary structures in each internal node of T' . Each time a pebble is moved from a node $v \in T'$ in item u4.2, a copy of the pebble is also given to the two secondary structures in v . For the secondary structures, we use structures similar to the one of Lemma 20 with $d = 8$. We select the same value for r in T' as in Lemma 20, namely the one given by (7) with $d = 8$. We can now answer queries as in section 7.1. We note that when reporting points from the secondary structures in T' we must also take the delete pebbles of the relevant nodes of T' into account. But this is not a problem because the height of T' plus the height of any secondary structure is at most $3 \log u$.

As in the proof of Lemma 20 we will add only t pebbles at a time to the root of T' (where t will be determined in a moment). We note that during the time $r/3$ pebbles are inserted into the root of T' we must go through items u1 to u4 as in the proof of Lemma 20. Further, each time we execute item u4.2 in T' we must also execute

the loop in items u1 to u4 in a constant number of secondary structures. Since the height of T' as well as the height of any secondary structure is at most $O(\log u)$ the following condition ensures that we do not add too many pebbles to the root of T' before we empty it again:

$$t \log^2 u \leq r.$$

Together with (7) this gives our requirement for t .

At most $O(\log u)$ pebbles are created for each insertion in T' , so using global rebuilding [34] we can get a space usage of $O(u \log^2 u)$ bits.

We give the structure type $R^4(s':u, s:u)$ using a standard trick: We insert each point e into the structure just described as a point e' with $e'.x = c \cdot u \cdot e.x + e.y$ and $e'.y = e.y$ for a constant c . Clearly, each point inserted will have unique x- and y-coordinates. However, it doubles the number of bits in each x-coordinate. It can be checked in our construction that this is not a problem. \square

As a corollary we get the following lemma, which gives the structure from step O6 of section 3.2.

LEMMA 26. *Suppose $\log^7 u \leq \log^{1-\epsilon} N$ for a constant $0 < \epsilon < 1$. Then there exists a structure with type $R^4(d:u, s':u)$ and performance $(1, \log u, u \log^2 u)$.*

Proof. Selecting $t = \log^3 u$ in Lemma 25 gives a structure with type $R^4(s':u, s:u)$ and performance $(1, \log u, u \log^2 u, \log^3 u)$. Further, we get the restriction on u that $\log^3 u \leq (\log^{1-\epsilon} N) / \log^4 u$ or, equivalently, $\log^7 u \leq \log^{1-\epsilon} N$. Finally, inserting the obtained structure into Lemma 21 and interchanging the two axes gives the desired result since the requirement $\log^4 u \leq \log^{1-\epsilon} N$ is fulfilled by our other requirement for u . \square

As a corollary, we get the structure from step O7 of section 3.2.

LEMMA 27. *Suppose $\log^7 u \leq \log^{1-\epsilon} N$ for a constant $0 < \epsilon < 1$. Then for any $n \leq N$ there exists a structure with type $R^4(s':n, s:u)$ and performance $(\log^2 \log n, \log u + \log^2 \log n, u(\log^2 u + \log n))$.*

Proof. Let R' be the structure of Lemma 26 restricted to having type $R^4(d:u, s:u)$. Let R be the structure with type $R^4(s':n, s:u)$ we want to design. We insert each element $e \in R$ into a BFAT of Theorem 6 with universe size $O((n+1)u)$ at position $u \cdot e.x + e.y$. We link all elements in R together according to this position. This list can be used as $R'.L_x$. Further, at most u elements will be stored in the BFAT and this concludes the proof of the lemma. \square

Plugging the structure of this lemma into Lemma 2 we get the structure of step O8 of section 3.2.

LEMMA 28. *Suppose $\log^7 u \leq \log^{1-\epsilon} N$ for a constant $0 < \epsilon < 1$. Then for any $n \leq N$ there exists a structure with type $R^4(s':n, s':u)$ and performance $(\log^3 \log n, \log u \log \log n + \log^3 \log n, nu \log n \log \log n(\log^2 u + \log n))$.*

The following lemma gives the structure from step O9 of section 3.2.

LEMMA 29. *For any $n \leq N$ and for any u where $\log^3 n \leq u$ and $\log^7 u \leq \log^{1-\epsilon} N$ for a constant $0 < \epsilon < 1$ there exists a structure with type $R^4(d:n, s':u/\log^3 n)$ and performance $(\log^3 \log n, (\log u + \log^2 \log n) \log \log n, n \log^2 u + n \log n)$.*

Proof. We describe a solution in which at most $O(n)$ updates can be performed. This restriction can be removed by the use of global rebuilding [34]. Let T be the structure of Lemma 28 where we select u in the lemma as $u/\log^3 n$ and n in the lemma as n/u . The structure T then gets type $R^4(s':n/u, s':u/\log^3 n)$ and performance $(\log^3 \log n, \log u \log \log n + \log^3 \log n, n \log n)$ (the space usage is actually smaller).

Let R be the structure with type $R^4(d : n, s' : u / \log^3 n)$ we want to design. We use list block balancing with block size u on $R.L_x$. If a block b with assigned label x contains one or more points with y -coordinate y , we insert b in T at x -coordinate x and y -coordinate y . This is possible because labels have size $O(n/u)$. Further, we need only to relabel a block for every $O(u / \log^3 n)$ update of R . Since this is also the length of $R.L_y$ we need only to perform $O(1)$ updates in T for each update in R . We maintain in each block b a structure $b.R$ of Lemma 26 with type $R^4(d : u, s' : u)$ and performance $(1, \log u, u \log^2 u)$. All points in b are stored in $b.R$ and the total space used by these structures is $O(n \log^2 u + n \log n)$ bits.

Suppose we are given a query (x_1, x_2, y_1, y_2) . Let b_1 be the block with x_1 and b_2 be the block with x_2 . We answer the query by first performing a local query in $b_1.R$ and then a local query in $b_2.R$ (if $b_1 = b_2$, we need only to perform one local query in total). The remaining points can be found by performing a query in T and then reporting relevant points from the reported blocks. This can be done in constant time per point if we for each block b and each y -coordinate $y \in R.L_y$ maintain a linked list with the points in b with y -coordinate y .

The space usage of the structure is dominated by the space used in the $b.R$ structures for the different blocks b . The update time is dominated by the time used in T and this concludes the proof of the lemma. \square

The following lemma gives the structure of Lemma 29 a somewhat dynamic y -axis.

LEMMA 30. *The structure of Lemma 29 can be given a dynamic y -axis in the following sense. The y -axis is a linked list where each element has a unique id of size $O(u)$. The id of an element is fixed when the element is inserted in the y -axis and we do not allow elements to be deleted from the y -axis. We allow many points to share a y -coordinate. We must provide a function f which, given (in a single word) an array with $O(\log^{1-\epsilon} N / \log u)$ ids, in constant time returns an array where the ids are sorted according to the order the elements with these ids have on the y -axis.*

Proof. Looking into the proofs of Lemma 27, Lemma 28, and Lemma 29 together with the construction of section 4 we see that it is sufficient to show that we can get a dynamic y -axis in the described way in the structure of Lemma 26. From the proof of this lemma it follows that it is sufficient that we can get a dynamic x -axis in the described way in Lemma 25. When inserting a point into this structure we will use the id of the x -coordinate as x -coordinate. Looking into the proof of Lemma 25 we see that the x -coordinates of points are not used in the maintenance of the tree T' . They are, however, used in the secondary structures which are the structures of Lemma 20. Here they are used as x -coordinates of pebbles and as keys of the WBB tree. However, the function f will give us all the information we need about the order of these coordinates. Further, it will do it fast enough because the construction in Lemma 20 never handles more than $O(\log^{1-\epsilon} N / \log u)$ pebbles at once. \square

7.3. Two long axes. We are now ready to prove the following theorem which for $n = N$ shows the first result from the introduction for $d = 2$.

THEOREM 31. *For any constant $\gamma > 0$ there exists a structure with type $R^4(d : n, d : n)$ and performance $(\log^{7/8+\gamma} N, \log N / \log \log N, \log^{1+7/8+\gamma} N)$.*

The structure we construct in the proof of the theorem is a kind of range tree (see section 1.3). Traditionally, range trees have degree 2. Our range trees are split into two parts. In the *top part*, nodes have degree u of Lemma 30 and we keep the points of an internal node in a structure of Lemma 30. In the *bottom part*, nodes have constant degree. The reason we need the bottom part is that the structure of Lemma 30 does not have a completely dynamic y -axis. The bottom part ensures that

nodes in the top part have sufficiently many points below them to allow the table to compute the function f of Lemma 30 to be built. Finally, to keep the query time low we keep in some levels of the tree the points in the structure of Theorem 24.

Proof of Theorem 31. Let R be the structure with type $R^4(d:n, d:n)$ we want to design. We store the elements of R in a WBB tree T with leaf parameter 1 and for $e \in R$ we use $e.y$ as key. We specify the degree of T in a moment. We let v_r denote the root of T . We first ignore splitting of nodes and marking of keys. We keep in each node $v \in T$ a linked list $v.L$ containing the points located in the leaves descendant to v sorted according to their x-coordinate. Let $v \in T$ be an internal node. We color the children of v such that no two different children of v have the same color. For each $e \in v.L$ there is exactly one child v' of v and one $e' \in v'.L$ such that e and e' represent the same point. We color e with the color of v' and we keep in e a pointer to e' (such a pointer is called a *downpointer* [42]). We keep the elements of $v.L$ in a colored predecessor structure of Theorem 15 using the assigned colors. The update and query time of this structure is $O(\log^2 \log |v.L|)$; we will take it to be $O(\log^2 \log N)$.

Suppose we are given a query (x_1, x_2, y_1, y_2) in R . We observe that $v_r.L$ contains all points of R sorted according to their x-coordinate. The coordinates x_1 and x_2 identify two elements in $v_r.L$ corresponding to the query interval on the x-axis. Further, using the pointers of the nodes of T to their parents we can identify the simple path in T between v_r and the leaf identified by y_1 . We proceed from v_r down along this path using the downpointers and the colored predecessor structures to maintain the query interval on $v.L$ for the nodes $v \in T$ we meet. Beginning in some node of T , we must report the elements in this interval that has a relevant set of colors. After this, we repeat the same process with y_2 instead y_1 and we are done.

Inserting a point p into R is performed in a way similar to the way a query is answered. $p.x$ identifies a position in $v_r.L$ where the point should be inserted. Also, $p.y$ identifies a simple path in T between the leaf with $p.y$ and v_r . We proceed from v_r down along this path inserting p into $v.L$ for the nodes v we meet and using the downpointers and the colored predecessor structures to maintain the position to insert into.

Deleting a point p from R is done as follows. $p.x$ determines the location of p in $v_r.L$. We then delete p from $v_r.L$ and use the downpointers to remove p from the other lists $v.L$ it is in. We do not delete p from T . Instead, we use global rebuilding [34] to ensure that at most half of the elements of T are deleted points.

Let $\epsilon > 0$ be a constant to be determined in a moment and suppose $v \in T$. If v has a height smaller than $\log^{1-\epsilon} N$, we say v is in the bottom part and otherwise we say v is in the top part of T . We will give v different degree parameters depending on whether it is in the bottom or top part. It is straightforward to modify WBB trees to support that. If a node w has a child v in the bottom part, we say that w is a leaf of the top part and that v is a root of the bottom part. Below we will analyze the time we need to use in the top and bottom part when performing an update or a query. Also, we will analyze how much space is used in the top and bottom part. Our results are summarized in Table 1.

TABLE 1

	Top part	Bottom part
Update time	$O(\log^{6/7+\epsilon/7} N \log^3 \log N)$	$O(\log^{1-\epsilon} N \log^2 \log N)$
Query time	$O(\log N / \log \log N)$	$O(\log^{1-\epsilon} N \log^2 \log N)$
Bits used	$O(n \log^{1+6/7+\epsilon/7} N)$	$O(n \log^{2+\epsilon} N)$

Ignoring $\log \log N$ factors the update time and space usage in the upper and lower part becomes identical if we select $\epsilon = 1/8$. The values here then become smaller than the ones claimed in the lemma.

Suppose $v \in T$ is a node in the bottom part. We then give v degree parameter 8 which is the minimal degree parameter we allow for WBB trees. We note that according to Lemma 7 property 5 a subtree rooted at a root in the bottom part of T has $\Theta(8^{\log^{1-\epsilon} N})$ leaves and according to property 3 has height $O(\log^{1-\epsilon} N)$. If we link the elements of $v.L$ with the same color together in order, we need only to spend time $O(\log^2 \log N)$ plus constant time for each point reported when we visit v during a query. Also, when visiting v during an update, we need to spend time $O(\log^2 \log N)$. We conclude that we get update and query time $O(\log^{1-\epsilon} N \log^2 \log N)$ in the bottom part of T . Since each point of R is stored in exactly one list $v.L$ for each level of T the total space usage for the bottom part becomes $O(n \log^{2-\epsilon} N)$ bits.

Suppose now $v \in T$ is a node in the top part. We store the elements of $v.L$ in the structure of Lemma 30 using the colors as ids of y-coordinates. For this reason we give v degree parameter $u = 2^{\log^{(1-\epsilon)/7} N}$ and note that with this selection the structure of Lemma 30 with an x-axis of length m gets performance $(\log^3 \log N, \log u \log \log N, m \log N)$. The maximal length of a simple path from the root of T to a leaf of the top part is $O(\log N / \log u) = O(\log^{6/7+\epsilon/7} N)$. We keep in v a table $v.G$ with length $8^{\log^{1-\epsilon} N}$. Such a table is large enough to allow f , needed by Lemma 30 to be computed in constant time. Also, it will not increase the space usage except for a constant factor. The update time in the top part becomes $O(\log^{6/7+\epsilon/7} N \log^3 \log N)$ and the space usage becomes $O((\log N / \log u) n \log N) = O(n \log^{1+6/7+\epsilon/7} N)$ bits again because each point of R is stored in exactly one list $v.L$ for each level of T .

The query time in the top part of T is $O((\log N / \log u) \log u \log \log N) = O(\log N \log \log N)$ and this is an $O(\log^2 \log N)$ factor too high. We fix this problem as follows. For each node v in the top part of T which is on a level divisible by $\log N / ((\log^2 \log N) \log u)$, we keep two structures of Theorem 24. In these structures we save the points of $v.L$ in the style of section 7.1. We then modify the way we answer queries as follows. When we in our proceeding down in T meet a node v in the top part of T on a level divisible by $\log N / ((\log^2 \log N) \log u)$ and when we have tried to report points from $w.L$ for the parent w of v , we stop. We then perform a query in one of the structures of Theorem 24 kept in v . After this, we do not need to proceed further down in T . This modification reduces the query time in the top part of T to $O(\log N / \log \log N)$. Further, since each point of R is stored in at most $O(\log^2 \log N)$ structures of Theorem 24, the time and space usage is not increased except for constant factors.

We now describe how to handle marking of keys and splitting of nodes in T . Consider the situation where a key k in a node v with parent w is marked (to simplify the discussion we assume that w exists or equivalently that v is not the root). Suppose v will eventually split into itself and a new node v' which will become the right sibling of v . We then select a color c' for v' such that no other current or coming child of w has color c' . During the time v is marked we move the points from $v.L$ with keys larger than k to $v'.L$. When a point p is moved we also color p with c' in $w.L$. Using the remark following Lemma 7 things can be adjusted such that we are finished when v split such that v can be split in constant time. We have to adjust queries such that they can handle partly split nodes. The details are tedious but standard and are thus omitted. If v contains a structure of Theorem 24, the splitting of this structure can

be handled in a way similar to the one just described. One problem remains. If v is in the top part of T we need to insert c' on the y-axis of the structure of Lemma 30 into w . This is done by updating $w.G$. Since w is in the top part of T it follows from Lemma 7 item 5 that $\Omega(2^{\log^{1-\epsilon} N})$ insertions of elements descendant to v will be performed before v splits, so we have time to rebuild $w.G$. We rebuild parts of $w.G$ during these insertions as follows (stating that all of $w.G$ should be rebuilt does not make sense because several children of w may be marked at the same time). When a key in v is marked there is a current set C of colors given to current or coming children of w . During the insertions of elements descendant to v before v splits we fill in all entries of $w.G$ which compare colors from $C \cup \{c'\}$. This will ensure that $w.G$ can always compare any set of colors of the children of w . In order to make queries work while v is splitting we actually need to update $w.G$ before we start building up $v'.L$, building up $v''.L$, and changing color of elements in $w.L$. \square

8. Higher dimensions. We will say a structure for the d -dimensional range reporting problem in the list order variant has type R_n^d if it can contain n points. Further, we will say such a structure has performance (U, Q, S) if it has update time $O(U)$, query time $O(Q)$, and space usage $O(S)$ bits. As in section 3.1 we allow U , Q , and S to depend on d and n but not on the number of points stored. This section is devoted to the proof of the following theorem which for $n = N$ shows the first result from the introduction.

THEOREM 32. *Let $d \geq 2$ and $\epsilon > 0$ be any constants and define $\omega = 7/8 + \epsilon$. Then for any $n \leq N$ there exists a structure for R_n^d with performance $(\log^{d-2+\omega} N, (\log N / \log \log N)^{d-1}, n \log^{d-1+\omega} N)$.*

Our proof of Theorem 32 is based on Lemma 33 below, which is a dynamization of a method proposed by Alstrup, Brodal, and Rauhe [3]. They described how to extend the dimension of a range reporting structure in a static setting where updates were not allowed.

LEMMA 33. *Suppose for any n we have a data structure with type R_n^d and performance (U_n, Q_n, S_n) , where U_n and Q_n are nondecreasing functions of n and S_n is a subadditive function of n . Then for any n and any constant $\epsilon > 0$ we can make a structure for R_n^{d+1} with performance $((U_n + \log^2 \log n) \log^{1+\epsilon} n, (Q_n + \log^2 \log n) \log n / \log \log n, S_n \log^{1+\epsilon} n)$.*

Proof. Let R be the structure with type R_n^{d+1} we want to make. For the proof we fix an axis of R , say, the x-axis. We store the elements of R in a WBB tree T with degree parameter $\log^{\epsilon/2} n$ and leaf parameter 1. For $e \in R$ we use $e.x$ as key, where $e.x$ is the x-coordinate of e . We first ignore deletion of points, splitting of nodes, and marking of keys.

Lemma 7 item 3 gives that T gets height $O(\log n / \log \log n)$. Let $v \in T$ be an internal node with height h and t children. For each pair (i, j) , where $1 \leq i \leq j \leq t$, we keep a secondary structure $v.R_{(i,j)}$ with the given type R_m^d , where $m = 4 \log^{h\epsilon/2} n$. Let v_1, \dots, v_t be the ordered children of v . We then in $v.R_{(i,j)}$ save all points which are in leaves descendant to v_k , where $i \leq k \leq j$ and where we ignore the x-coordinates when we store the points. Lemma 7 item 5 gives that there is room for these points in $v.R_{(i,j)}$.

We give each secondary structure of T a unique color. For any axis $R.L_y$ different from the x-axis let $v.R_{(i,j)}.L_y$ be the same axis of the secondary structure $v.R_{(i,j)}$. We then maintain pointers between the elements of $v.R_{(i,j)}.L_y$ and the corresponding elements of $R.L_y$. Each element in $R.L_y$ will contain a number of pointers and we use the BFAT of Theorem 6 (as a dictionary) to store these. Also, we maintain a structure

of Theorem 15 on $R.L_y$ where an element has the colors of the secondary structures it has pointers to (Theorem 15 can easily be generalized to allow an element to have any number of colors).

Assume we are given a query in R . By following pointers from nodes of T to their parents we can in linear time identify $O(\log n / \log \log n)$ secondary structures such that asking the query in these structures (ignoring the x-axis) gives the desired points. For each secondary structure the position on the axes in which we should perform the query can be found in time $O(\log^2 \log n)$ using the structure of Theorem 15 maintained on the axes of R . This shows that the query time becomes $O((Q_n + \log^2 \log n) \log n / \log \log n)$ as claimed (Q_n is a nondecreasing function of n).

Each point is stored in $O(\log^\epsilon n)$ secondary structures in $O(\log n / \log \log n)$ nodes of T . When inserting new points the updates to perform in the secondary structures can be found in a way similar to when answering queries and the update time becomes $O((U_n + \log^2 \log n) \log^{1+\epsilon} n / \log \log n)$ (U_n is a nondecreasing function of n). The space usage becomes $O(S_n \log^{1+\epsilon} n / \log \log n)$ bits (because S_n is a subadditive function of n).

Marking of keys and splitting of nodes can be handled as described after the remark of Lemma 7. The details are, as in the proof of Theorem 31, tedious but standard and are thus omitted. Finally, we delete a point by removing it from the axes of R and from the secondary structures in which it is located. We never delete elements from T . Instead, we use global rebuilding [34] to ensure that at most half of the elements of T are deleted points. \square

Finally, we have the following proof.

Proof of Theorem 32. If $d = 2$, Theorem 31 gives the desired result. Otherwise, we get the desired structure by applying Lemma 33 $d - 2$ times to Theorem 31 where we set $n = N$. \square

9. Open problems. We have given an optimal structure in terms of time per operation for the 2-dimensional range reporting on RAM. Also, we have given a new solution for the d -dimensional range reporting problem for any constant dimension $d \geq 3$. A very interesting open problem is to prove or disprove that our solution is optimal for any constant dimension $d \geq 3$. Showing a matching lower bound seems to be well beyond current lower-bound techniques.

The construction leading to our 2-dimensional range reporting structure (Theorem 31) is rather involved. Of course, it would be nice to have a simpler construction obtaining the same or a similar bound.

For query time $O(\log n / \log \log n)$, the update time of our 2-dimensional range reporting structures is $O(\log^\omega n)$ for a constant $\omega < 1$. However, the lower bound of [4] does not prevent even constant update time in this case. An open problem is to close or narrow the gap between these two update times.

The basic technique in the data structures of this paper has been to pack many points together in a single word. This has allowed us to process points in subconstant time per point. This idea is not new and is very similar to what is done in the I/O model of computation [2], where elements (or points) are packed together on disk blocks. For this reason, data structures for the I/O model and for the RAM model of computation have often inspired each other, and we have also used ideas from the I/O model in this paper. An open problem is to use ideas of this paper in the I/O model. In particular, it may be possible to reduce the update time of the structure of Arge, Samoladas, and Vitter [6] for dynamic range reporting in the I/O model of computation by using ideas from this paper. Such a solution may even be practical.

Acknowledgments. I am very grateful to my supervisors Stephen Alstrup and Theis Rauhe for introducing me to the range reporting problem, for bringing my attention to [13], and for helpful discussions in connection with this work. I would like to thank Dan Willard for clarifying the history of range trees. Finally, I would like to thank the anonymous referees for comments which have helped me to improve the presentation.
